The iodo complexes turned out to be even more configurationally labile than the chloro complexes. Their half-lives were found to be 62 min. at −15 °C and 15 min. at −4 °C in CD_2Cl_2.[49] Therefore, no conclusions regarding the stereochemistry of the substitution reaction $\boldsymbol{R_{Ru}S_C}$-**11**/$\boldsymbol{S_{Ru}S_C}$-**11** → $\boldsymbol{R_{Ru}S_C}$-**12**/$\boldsymbol{S_{Ru}S_C}$-**12** can be drawn, because the diastereomer ratios of the starting material (chloro complexes $\boldsymbol{R_{Ru}S_C}$-**11**/$\boldsymbol{S_{Ru}S_C}$-**11**) and the products (iodo complexes $\boldsymbol{R_{Ru}S_C}$-**12**/$\boldsymbol{S_{Ru}S_C}$-**12**) have nothing to do with it. The diastereoselectivities only reflect the different stabilities of the diastereomers in the respective diastereomer equilibria. Arguments such as those invoking total retention of configuration in the reaction of the major diastereomer $\boldsymbol{R_{Ru}S_C}$-**11** and partial retention and inversion in the reaction of the minor diastereomer $\boldsymbol{S_{Ru}S_C}$-**11** to account for the observed diastereoselectivities are inherently flawed.[50,51]

A single-crystal X-ray structure analysis had been carried out for the diastereomer $\boldsymbol{R_{Ru}S_C}$-**11**. It was assigned to the major diastereomer of the 87:13 pair $\boldsymbol{R_{Ru}S_C}$-**11**/$\boldsymbol{S_{Ru}S_C}$-**11** because "the crystals of this species have a higher chance of being isolated from a mixture" assuming "that each bulk-crystallized sample is a solid mixture of the two diastereomers in a ratio equal to that observed in their solutions" — a strange argument implying a 13% statistical chance of being wrong![48,51] The author's group dissolved the crystals obtained from the 87:13 mixture of $\boldsymbol{R_{Ru}S_C}$-**11**/$\boldsymbol{S_{Ru}S_C}$-**11** at −80 °C and showed by ^{1}H NMR spectroscopy that they consisted of the pure diastereomer $\boldsymbol{R_{Ru}S_C}$-**11**.[49] It was only in the temperature range around 0 °C that the minor dias-

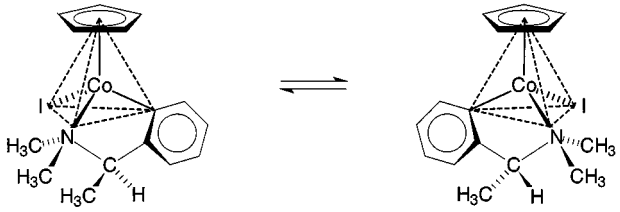
tereomer $S_{Ru}S_C$-**11** began to appear due to the onset of epimerization. Thus, from an 87:13 mixture of diastereomers under the aforementioned crystallization conditions, a single diastereomer crystallized exclusively and was removed from the equilibrium. Through re-establishment of the equilibrium, all the material was converted into a single pure diastereoisomer, a process referred to as an asymmetric transformation of the second kind.[54] If the Ru configuration were stable, the composition of the solid obtained on evaporation of the solvent would have been the same as that in solution (Nelson's conclusion).[48,51] However, after recognition of the configurational lability at the Ru center, the formation of a single pure isomer on crystallization can be understood. Consequently, there was no danger of picking a crystal of the minor diastereomer and of making a wrong configurational assignment.

In recent papers by Nelson's group,[52,53] further chiral-at-metal (η^6-arene)ruthenium complexes have been reported as being obtained through substitution of the chloride ligand in compounds of the type $R_{Ru}S_C$-**11**/$S_{Ru}S_C$-**11** by azide, nitrite, thiocyanate, cyanate, and other ligands. It will have to be checked whether these compounds really are "configurationally rigid in solution under mild conditions" and whether or not "these ligand substitution reactions proceed with predominant retention of configuration at ruthenium".

CpCo Complexes

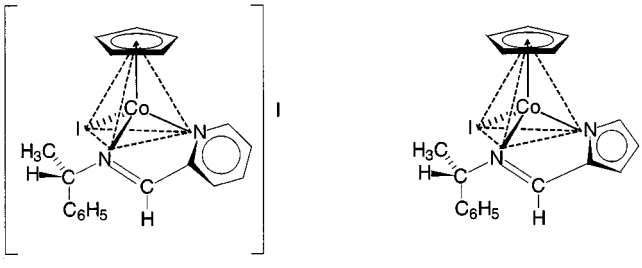
At the end of 1999, a paper was published by Pfeffer et al.[55] concerning a series of cobaltacyclic compounds of the type [(η^5-C_5H_5)Co(LL′)I] differing in the configuration at the metal. With the optically active ligands LL′H = (R_C)-(+)- and (S_C)-(−)-*N*,*N*-dimethyl-1-phenylethylamine, a mixture of the two diastereomers, $R_{Co}R_C$-**13**, $S_{Co}R_C$-**13** and $S_{Co}S_C$-**13**, $R_{Co}S_C$-**13**, respectively, in a 19:1 ratio (91% *de*) was obtained. This ratio "could not be improved by fractional crystallization or column chromatography" and "^{1}H NMR studies indicate that the compounds are configurationally stable at the cobalt center". Moreover, "no epimerization could be observed in solution, for instance, over a period of seven days at room temperature in either $CDCl_3$ or [D_6]acetone". Although the diastereomers "displayed comparable crystallization rates so that the bulk sample from which X-ray quality crystals were obtained contained the same ratio of both diastereomers as determined above", the crystal structure of $R_{Co}R_C$-**13** was assigned to the major diastereomer on the basis that "the crystals of this species have a higher statistical chance of being isolated from a mixture of diastereomers". Thus, the same (wrong) argumentation was used as for the (η^6-arene)ruthenium complexes discussed above.[48,50−53]

The author's group synthesized the complexes $R_{Co}R_C$-**13**/$S_{Co}R_C$-**13** according to the published procedure[55] using [(η^5-C_5H_5)CoI_2]$_2$ and *ortho*-lithiated (R_C)-(+)-*N*,*N*-dimethyl-1-phenylethylamine. Dark-green needles were obtained, the ^{1}H NMR spectrum of which in CD_2Cl_2 solution at room temperature exhibited signals due to both diastereomers $R_{Co}R_C$-**13** and $S_{Co}R_C$-**13** in a 96:4 ratio (92% *de*), in agreement with ref.[55] However, when a sample of crystals was dissolved in CD_2Cl_2 and the ^{1}H NMR spectrum was recorded at −40 °C, only the signals of the major diastereomer were seen.[49] Measurements at −20 °C, 0 °C, and +21 °C revealed that the minor diastereomer $S_{Co}R_C$-**13** was formed only at higher temperatures.



$R_{Co}R_C$-13 $S_{Co}R_C$-13

The half-life for the conversion of $R_{Co}R_C$-**13** into the equilibrium mixture $R_{Co}R_C$-**13** ⇆ $S_{Co}R_C$-**13** was estimated to be between 20 and 25 min. in CD_2Cl_2 solution at +1.4 °C. The accuracy of these measurements is limited by the fact that the equilibration of the major diastereomer involves only a small concentration change to give the equilibrium mixture major diastereomer/minor diastereomer = 96:4. Clearly, the major diastereomer $R_{Co}R_C$-**13** cannot be handled at room temperature without a rapid change in the metal configuration. The measurements leading to the postulation of configurational stability at the cobalt center[55] were thus most probably carried out with epimerized samples. Interestingly, it has been demonstrated previously that the configuration at cobalt is labile in compounds $R_{Co}S_C$-**14** and $R_{Co}S_C$-**15**.[56] However, the latter compounds, which are very similar to compounds $R_{Co}R_C$-**13**/$S_{Co}R_C$-**13** and are subject to the same stereochemical problem of the cobalt configuration, were not mentioned in ref.[55]

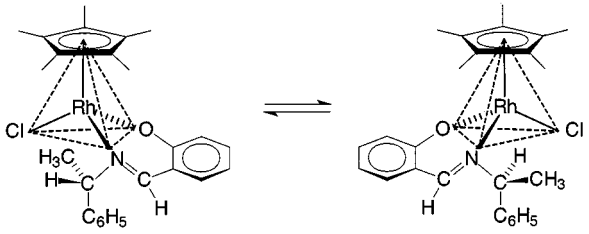


$R_{Co}S_C$-14 $R_{Co}S_C$-15

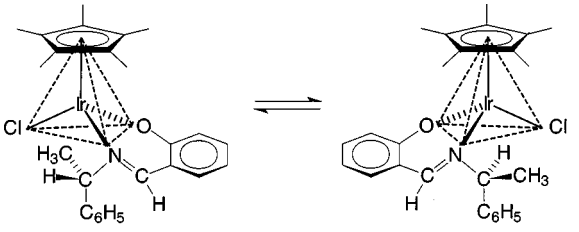
Cp*Rh and Cp*Ir Complexes

In 1997, Loza, Parr, and Slawin synthesized the compounds [Cp*M(ON)Cl] ($R_{Rh}S_C$-**16**/$S_{Rh}S_C$-**16** and $R_{Ir}S_C$-**17**/$S_{Ir}S_C$-**17**), where ON was the anion of (+)-*N*-[(*S*)-1-phenylethyl]salicylaldimine.[57] A high diastereomeric excess was claimed as, in the room-temperature ^{1}H NMR spectra, only one isomer was seen in each series. The compound $R_{Ir}S_C$-**17** was characterized by X-ray structure analysis, as a result

of which the (R_{Ir},S_C)-configuration was assigned to the only diastereomer observed in solution. These conclusions turned out to be wrong or unreliable because the authors had overlooked the configurational instability at the metal center in these complexes.[58]



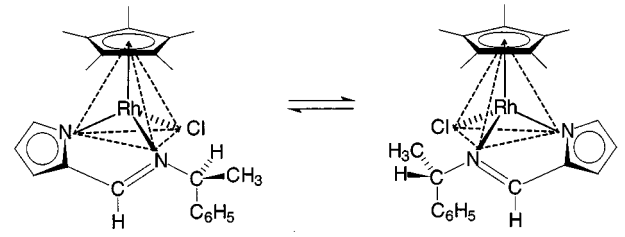
***R*$_{Rh}$*S*$_C$-16** **S*$_{Rh}$S$_C$-16**



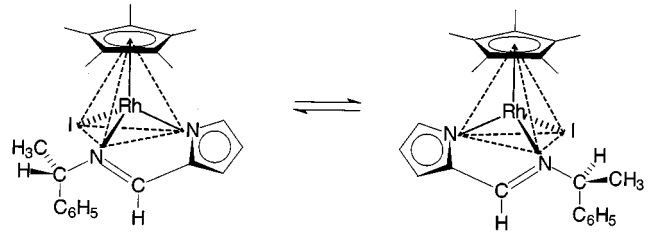
***R*$_{Ir}$*S*$_C$-17** **S*$_{Ir}$S$_C$-17**

The author's group confirmed that the ^{1}H NMR spectra of ***R***$_{Rh}$***S***$_C$**-16**/***S***$_{Rh}$***S***$_C$**-16** and ***R***$_{Ir}$***S***$_C$**-17**/***S***$_{Ir}$***S***$_C$**-17** featured only one set of signals. However, it was found that the room temperature ^{1}H NMR spectra were the averaged high temperature limiting spectra (fast-exchange regime of two diastereoisomers in their diastereomer equilibria). At low temperatures, interconversion of the two diastereomers of each pair became so slow that the diastereomers gave separate signals that could be integrated. The ratios were found to be 81:19 at −80 °C in CD_2Cl_2 in the rhodium series ***R***$_{Rh}$***S***$_C$**-16**/***S***$_{Rh}$***S***$_C$**-16** and 85:15 at −50 °C in $CDCl_3$ in the iridium series ***R***$_{Ir}$***S***$_C$**-17**/***S***$_{Ir}$***S***$_C$**-17**. As equilibration with respect to the metal center in these compounds is fast even at −80 °C, the transfer of the absolute configuration found in the solid state to the major isomer in solution, as assumed in ref.[57], does not have any sound basis.

It cannot be taken for granted that it is always the *major* isomer that crystallizes from a dynamic diastereomer equilibrium. In the series of chloro complexes ***R***$_{Rh}$***S***$_C$**-18**/***S***$_{Rh}$***S***$_C$**-18**, the diastereomer equilibrium distribution in CD_2Cl_2 was found to be ***R***$_{Rh}$***S***$_C$**-18**/***S***$_{Rh}$***S***$_C$**-18** = 87:13 at room temperature. In this case, it was definitely the *minor* diastereomer (13% content only!) that crystallized. This was proven by X-ray crystallography and low-temperature NMR spectroscopic analysis of the crystals dissolved at −80 °C. For the iodo system ***R***$_{Rh}$***S***$_C$**-19**/***S***$_{Rh}$***S***$_C$**-19**, the reverse was found to be true. From the 87:13 equilibrium mixture, the *major* isomer crystallized in a diastereomerically pure state. Due to the rapid isomerization of the compounds ***R***$_{Rh}$***S***$_C$**-16**/***S***$_{Rh}$***S***$_C$**-16** and ***R***$_{Ir}$***S***$_C$**-17**/***S***$_{Ir}$***S***$_C$**-17**, the NMR test at −80 °C is not available. Therefore, no unequivocal configurational assignment of the diastereomers in solution can be made.



***R*$_{Rh}$*S*$_C$-18** **S*$_{Rh}$S$_C$-18**



***R*$_{Rh}$*S*$_C$-19** **S*$_{Rh}$S$_C$-19**

Low Temperature NMR Spectra in Solution — A Solution for the Aforementioned Problems

Diastereomers differing only in the metal configuration may be formed under kinetic control or under thermodynamic control.[15] In both cases, the diastereomer ratios can be close to 1:1 or may reach high values.[15] Irrespective of the ratio, the isolation of diastereomerically pure samples or at least diastereomerically enriched samples (relative to the starting composition) should be possible by means of fractional crystallization or chromatography including zone cutting, provided that the diastereomers are configurationally stable at the metal center. If a diastereomer mixture resists separation or enrichment whatever its composition (as in refs.[48,55] etc.), the reason may be configurational instability at the metal atom. In such cases, the configurational stability/lability should be checked by all the available techniques, including the dissolution of samples crystallized at low temperatures and the measurement of low-temperature NMR spectra without prior warming. Provided that the equilibration between the two diastereoisomers is slow under the conditions of dissolution, this technique shows whether a crystallized sample consists of a pure diastereoisomer or a mixture of the two diastereomers. Depending on the crystallization conditions and the epimerization rate, both situations may be encountered.

In the previous paragraphs, several publications by different groups in good journals have been discussed, where the conclusions drawn were either partly or wholly wrong. At present, there are high standards as far as the publication of preparative work and X-ray structure analyses is concerned.

However, with respect to stereochemistry and mechanisms the quality standards are not so high, as demonstrated herein for the narrow field of half-sandwich ruthenium, cobalt, rhodium, and iridium complexes. Confusion results and corrections are required. In the worst case reinvestigations are necessary some time later to avoid contradictions. In most of the cases discussed, low temperature NMR experiments, easily available with modern equipment, would have proved or disproved the ideas, assumptions, and conclusions put forward. Why is this technique not used more frequently?

First Examples of a New Family of Redox-Functionalised Chelate Complexes Based on a 1,1′-Ferrocenediyl-Bridged Di(amido) Ligand

Ulrich Siemeling,*[a] Oliver Kuhnert,[b] Beate Neumann,[b] Anja Stammler,[b] Hans-Georg Stammler,[b] Benno Bildstein,[c] Michael Malaun,[c] and Piero Zanello[d]

Keywords: Amides / Sandwich compounds / Polymerisation / Titanium / Zirconium

Treatment of $Fe[(C_5H_4)NHPh]_2$ (**1**H_2) with $M(NMe_2)_4$ (**3a**: M = Ti, **3b**: M = Zr) in benzene afforded the chelates (**1**)$Ti(NMe_2)_2$ (**4**) and (**1**)$Zr(NMe_2)_2(HNMe_2)$ (**5**), respectively. Chelate **5** was cleanly oxidised by ferrocenium hexafluorophosphate in acetonitrile. Treatment of **5** with two equivalents of $[Me_2NH_2]Cl$ (**6**) in benzene afforded (**1**)$ZrCl_2(HNMe_2)$ (**7**). The chelates **5** and **7** were characterised by X-ray structure analyses. The new redox-active chelate complexes are precatalysts for the polymerisation of ethylene.

The search for new generation nonmetallocene catalysts for the polymerisation of α-olefins is of continuing interest.[1] Complexes of the Group 4 metals containing chelating di(amido) ligands represent a very promising class of (pre-)catalysts in this context. This has been demonstrated in recent years by the groups of Bochmann,[2] Eisen,[3] Gibson,[4] McConville,[5] Schrock,[6] and others,[7] building on earlier work by Bürger et al.[8] Ziegler and co-workers, using quantum-chemical methods, have rationalised the factors governing the ethylene polymerisation activity of such catalysts.[9]

We decided to utilise the novel 1,1′-ferrocenediyl-bridged ligand system $Fe[(C_5H_4)NPh]_2$ (**1**) in this context. This ligand is related to **2**, recently reported by Kempe and coworkers.[10] They found that, because of the high flexibility of **2**, complexes of the type **2**TiXY (X = Y = NMe_2; X = NMe_2, Y = Cl) are unstable. Not surprisingly, therefore, catalytically active complexes of **2** are unknown. In contrast, **1** would be expected to provide a fairly rigid ligand framework and should furthermore exhibit excellent π-donor qualities (beneficial for olefin insertion),[9] since the amido nitrogen atoms are directly connected to the electron-rich ferrocene moiety.[11]

We note that the electronic properties of our redox-active ligand system can be changed quite dramatically by oxidation. In fact, the development of redox-active ligands which allow the electrochemical control of stoichiometric and catalytic reactivities of transition metal centres is of great current interest.[12]

1 **2**

Metathesis of **1**H_2 [13] with one equivalent of $Ti(NMe_2)_4$ (**3a**) afforded (**1**)$Ti(NMe_2)_2$ (**4**). Analogously, treatment of **1**H_2 with $Zr(NMe_2)_4$ (**3b**) gave (**1**)$Zr(NMe_2)_2(HNMe_2)$ (**5**), and treatment of this with two equivalents of $[Me_2NH_2]Cl$ (**6**) furnished (**1**)$ZrCl_2(HNMe_2)$ (**7**) (Scheme 1). Di(amido)-zirconium(IV) complexes may be viewed as relatives of zirconocene derivatives[4] and hence ours are akin to the ferrocenediyl-bridged zirconocene dichloride $\{Fe[(C_5H_4)$-$C_5Me_4]_2\}ZrCl_2$ reported by Brintzinger and co-workers.[14]

Cyclic voltammetric studies have shown that the ligand precursor **1**H_2 undergoes a chemically reversible, one-electron oxidation at $E^{\circ\prime} = -0.06$ V (vs. SCE) in dichloromethane solution. Such an easy oxidation matches well the corresponding process exhibited by the related species $Fe[(C_5H_4)NMe_2]_2$ and $Fe[(C_5H_4)NPh_2]_2$.[15,16] Complexation of the metal-ligand fragment causes the ferrocenediyl-centred oxidation of the zirconaferrocenophane (**1**)$Zr(NMe_2)_2(HNMe_2)$ (**5**) to become slightly more difficult, by about 40 mV ($E^{\circ\prime} = -0.02$ V), indicating that the $Zr(NMe_2)_2(HNMe_2)$ fragment withdraws electron density from the ferrocene subunit. Chemical oxidation of **5** was cleanly achieved with one equivalent of ferrocenium hexafluorophosphate in acetonitrile.

Single crystal X-ray diffraction studies have been performed for both new zirconium compounds. The zirconium atom in **5** is coordinated by five nitrogen atoms in a distorted trigonal bipyramidal arrangement (Figure 1). The axial positions are occupied by the amino ligand and the

amido ligand *trans* to it, their ligating atoms forming an angle of 171.4(3)° with the Zr atom. The N(1)−Zr(1)−N(2) bite angle of the chelating ligand **1** is 132.9(3)°. The amino nitrogen−zirconium distance is 243.8(8) pm — consistent with a Zr−N(sp^3) single bond — while, thanks to their partial double-bond character, the four amido nitrogen−zirconium bonds are much shorter, ranging from 205.7(7) to 215.4(7) pm. These bond lengths are similar to those found for the related compound [Ph_2Si(N-Ar)$_2$]Zr(NMe_2)$_2$($HNMe_2$) (Ar = 2,6-$Me_2C_6H_3$).[4] The cyclopentadienyl rings of the ferrocene unit are in an eclipsed orientation. The parallel sandwich structure is slightly distorted and opens up towards the zirconium centre with a cyclopentadienyl ring tilt angle of 11.4°. The Fe−Zr distance of 333.9 pm precludes a significant bonding interaction between the two metal atoms.

The core geometry of **7** is also best described as distorted trigonal bipyramidal (Figure 2). Again, the amino ligand is in an axial position, the second axial position being occupied by a chloro ligand [N(3)−Zr(1)−Cl(1) 172.12(10)°]. In related systems containing linked amido-cyclopentadienyl ligands,[17] the amino ligand is positioned between the two chloro ligands. The N(1)−Zr(1)−N(2) bite angle is essentially identical to that in **5**, while the corresponding zirconium−nitrogen bond lengths are slightly shorter, resulting in a smaller cyclopentadienyl tilt angle of 9.4° and a shorter Fe−Zr distance of 331.0 pm. In both compounds, all amido nitrogen atoms are trigonal planar and the phenyl rings lie approximately in the plane defined by the zirconium atom and the amido nitrogen atoms of the chelating ligand **1**.

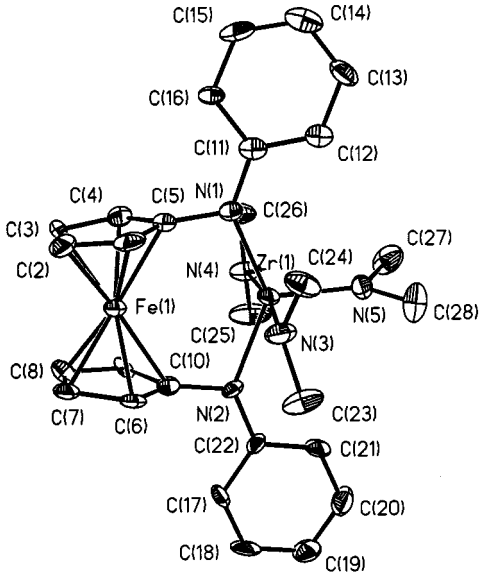

Figure 1. Molecular structure of **5** in the crystal; selected bond lengths (pm) and angles (°): Zr(1)−N(1) 212.8(7), Zr(1)−N(2) 215.3(7), Zr(1)−N(4) 215.4(7), Zr(1)−N(5) 205.7(7), N(1)−C(5) 142.3(11), N(1)−C(11) 139.5(10), N(2)−C(10) 141.3(10), N(2)−C(22) 138.9(9); N(3)−Zr(1)−N(5) 92.5(3), N(4)−Zr(1)−N(5) 96.0(3)

Preliminary investigations have shown that these new compounds are precatalysts for the polymerisation of ethylene.[18] The results of a detailed study, which also addresses the aspect of redox-tuning of catalyst activity, will be reported in due course.

Experimental Section

General: All manipulations were performed under an inert atmosphere (purified argon or dinitrogen), using standard Schlenk and cannula techniques or a conventional glovebox. Solvents and reagents were dried and purified by standard procedures. − NMR spectra were recorded at 300 K with a Bruker DRX 500 spectrometer operating at 500.13 MHz for ^{1}H; TMS was used as external reference. − The materials and apparatus used for the electrochemical investigations have been described elsewhere.[19] − Elemental analyses were performed by the Microanalytical Laboratory of Universität Bielefeld.

Complex 4: A solution of **1**H_2 (0.87 g, 2.35 mmol) and **3a** (0.53 g, 2.35 mmol) in benzene (1 mL) was kept at 70 °C for 2 h. The volatile components were then removed in vacuo. The residue was extracted with *n*-hexane (20 mL) and the extract filtered. The filtrate was reduced to dryness in vacuo, leaving the product as a brownish yellow solid. Yield 0.90 g (76%). − ^{1}H NMR ($CDCl_3$): δ = 3.24 (s, 12 H, NMe_2), 3.63 (s, 4 H, C_5H_4), 4.54 (s, 4 H, C_5H_4), 6.71 ("t", apparent J = 6.9 Hz, 2 H, Ph), 6.78 ("d", apparent J = 7.9 Hz, 4 H, Ph), 7.16 ("t", apparent J = 7.2 Hz, 4 H, Ph). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 45.1 (NMe_2), 68.9, 71.0, 87.3 (C_5H_4), 115.4, 118.1, 128.9, 154.5 (Ph). − $C_{26}H_{30}FeN_4Ti$ (502.3): calcd. C 62.17, H 6.02, N 11.15; found C 61.18, H 5.88, N 11.71.

Complex 5: Benzene (7 mL) was added to **1**H_2 (0.87 g, 2.35 mmol) and **3b** (0.60 g, 2.35 mmol), affording a light yellow precipitate. The mixture was stirred for 1 h at room temperature. Crystallisation from a minimal quantity of hot benzene afforded the product as light yellow crystals. Yield 0.99 g (71%). − ^{1}H NMR ($CDCl_3$): δ = 2.39 (br. s, 6 H, HNMe_2), 3.05 (s, 12 H, NMe_2), 3.70 (t, J = 1.9 Hz, 4 H, C_5H_4), 4.62 (t, J = 1.9 Hz, 4 H, C_5H_4), 6.66 ("t", apparent J = 7.2 Hz, 2 H, Ph), 6.74 ("d", apparent J = 7.8 Hz, 4 H, Ph), 7.17 ("t", apparent J = 7.7 Hz, 4 H, Ph). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 39.1 ($HNMe_2$), 43.2 (NMe_2), 68.5, 70.5, 89.9 (C_5H_4), 115.3, 117.0, 129.1, 153.9 (Ph). − $C_{28}H_{37}FeN_5Zr$ (590.7): calcd. C 56.93, H 6.31, N 11.86; found C 56.69, H 6.11, N 11.20.

Complex 5[PF_6]: A solution of **5** (59 mg, 0.10 mmol) and ferrocenium hexafluorophosphate (33 mg, 0.10 mmol) in acetonitrile (5 mL) was stirred at room temperature for 5 h. The volatile components (solvent and ferrocene) were then removed in vacuo, leaving the product as a brown solid. Yield 73 mg (99%). − $C_{28}H_{37}F_6FeN_5PZr$ (735.6): calcd. C 45.72, H 5.07, N 9.52; found C 45.69, H 5.02, N 8.87.

Complex 7: A solution of **5** (0.28 g, 0.47 mmol) and **6** (77 mg, 0.94 mmol) in benzene (10 mL) was stirred at room temperature for 15 h. The resulting yellow precipitate was then filtered off. Crystallisation from a minimal quantity of chloroform afforded the product as yellow needles. Yield 59 mg (22%). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 39.1 ($HNMe_2$), 43.2 (NMe_2), 68.9, 71.0, 87.3 (C_5H_4), 115.4, 118.1, 128.9, 154.5 (Ph). − $C_{24}H_{25}Cl_2FeN_3Zr{\cdot}2CHCl_3$ (812.2): calcd. C 38.45, H 3.35, N 5.17; found C 39.04, H 3.23, N 5.20.

Crystal Structure Determinations of 5 and 7:[20] A yellow single crystal of **5** (dimensions 0.5 × 0.5 × 0.25 mm) and **6** (dimensions 0.8 × 0.4 × 0.4 mm), respectively, was used for data collection at 173 K on a Siemens $P2_1$ four-circle diffractometer with graphite-mono-

chromated Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods. Programs used were Siemens SHELXTL PLUS[21] and SHELXL-97.[22] Full-matrix, least-squares refinement on F^2 was carried out anisotropically for the non-hydrogen atoms. Hydrogen atoms were included at calculated positions, using a riding model. Further X-ray structure analysis data are given in Table 1.

Palladium and Rhodium Complexes with Planar-Chiral Carborane Ligands[‡]

Henri Brunner,*[a] Andreas Apfelbacher,[a] and Manfred Zabel[a]

Dedicated to Professor Dr. Dieter Sellmann on the occasion of his 60th birthday

Keywords: Chirality / Carboranes / Palladium / Rhodium / Asymmetric catalysis

Base degradation of the prochiral 1-diphenylphosphanyl-2-phenyl-1,2-dicarba-*closo*-dodecaborane (**1**) affords the planar-chiral 7-diphenylphosphanyl-8-phenyl-7,8-dicarba-*nido*-undecaborate anion (**2**). Resolution of the racemic anion carried out using a well-established procedure, gave the internally diastereomeric palladium complexes **3*R*-*R*** and **3*R*-*S***. These complexes were separated by fractional crystallization. A single-crystal X-ray analysis of **3*R*-*R*** established the *exo*-*nido* bonding of the carborane ligand via the phosphorus atom and the adjacent BH group, and the (*R*) configuration of the carborane ligand. The enantiomerically pure anions of **2** were liberated from the diastereomerically pure palladium complexes **3*R*-*R*** and **3*R*-*S***, respectively, by subsequent addition of HCl and NaCN. The *exo*-*nido*-rhodium–carborane complexes **4**–**8** were prepared by heating **2e*R*** or **2e*S*** with $[Rh(COD)Cl]_2$ and/or a chiral chelating phosphane, such as DIOP and BINAP, under reflux. The chiral complexes were tested under enantioselective catalysis conditions such as hydrogenation of acetamidocinnamic acid, hydrogenation of ketopantolactone, and hydrosilylation of acetophenone.

Introduction

For the realization of planar chirality, the ferrocene system is the most suitable skeleton.[1] Two different substituents in the 1,2- or 1,3-positions of the same cyclopentadienyl ring are sufficient to make the systems chiral. In the cyclopentadienyl anions $[C_5H_3RR']^-$, the symmetry plane is removed on complexation with a metal fragment. In contrast, *nido*-carboranyl anions such as $[B_9C_2H_{10}RR']^-$ or $[B_9C_2H_9RR']^{2-}$, containing two different substituents in the open face, are chiral by themselves, because the cage side and the open face are different. Until recently, there have only been a few attempts to resolve *nido*-carboranyl anions, potential ligands in enantioselective catalysts. Early reports came from the groups of Zakharkin and Hawthorne.[2–5] Meanwhile, a series of optically active boron cage compounds was described, of which four were *nido*-C_2B_9 derivatives.[6] Last year a *nido*-carboranyl anion $[B_9C_2H_{10}RR']^-$ was resolved with a SPh and a CH_2OH substituent at the adjacent carbon atoms.[7]

In this paper we report on the resolution of the chiral carboranylphosphane anion $[B_9C_2H_{10}(PPh_2)(Ph)]^-$ [8] obtained as the racemate in the base degradation of the carborane $[B_{10}C_2H_{10}(PPh_2)(Ph)]$[9] (**1**), the phenyl substituent of which is introduced in the synthesis with phenylacetylene, and the diphenylphosphanyl group by metallation. The racemic anion is incorporated into a palladium complex containing enantiopure *ortho*-metallated *N,N*-dimethyl-(*S*)-1-phenylethylamine. After separation of the diastereomers, the resolved anions are cleaved from the palladium complex and introduced into rhodium complexes. In these metal complexes, the carboranylphosphane anion binds as a chelate ligand in an *exo*-*nido*-mode via the phosphorus atom and the adjacent B–H group. The enantiomers **4*R*** and **4*S***, and the enantiomers/diastereomers **5*RR*-*R***, **5*SS*-*S*** and **5*RR*-*S*** were used as catalysts in the enantioselective hydrogenation of acetamidocinnamic acid and ketopantolactone, and in the enantioselective hydrosilylation of acetophenone with diphenylsilane.[10]

The Planar-Chiral Anion 7-Diphenylphosphanyl-8-phenyl-7,8-dicarba-*nido*-undecaborate

The sequence of syntheses started with the addition of phenylacetylene to decaborane(14)[11] to give 1-phenyl-1,2-dicarba-*closo*-dodecaborane. Metallation of the acidic CH group with BuLi, and reaction with $ClPPh_2$ provided 1-diphenylphosphanyl-2-phenyl-1,2-dicarba-*closo*-dodecaborane[10] (**1**) (Scheme 1), on which a single-crystal X-ray analysis was performed, as shown in Scheme 1. Both carboranes are achiral molecules. Planar chirality only comes into play after the base degradation of **1** with piperidine to yield the salt piperidinium 7-diphenylphosphanyl-8-phenyl-7,8-dicarba-*nido*-undecaborate (**2a**) (Scheme 1).[9] Resolution of the racemic anion of **2a** was attempted by use of enantiomerically pure counter-cations, such as *N,N,N*-trimethyl-(*S*)-1-phenylethylammonium, *N*-methylbrucinium, or *N*-methylquininium as the resolving agents in ethanol. The exchange of the piperidinium ion in **2a** for the enantiomerically pure cations to give **2b**–**d** was carried out according to literature procedures.[9] In the three series **2b**–**d**, mixtures of two diastereomers in ratios of about 1:1 were isolated. It was not possible to separate the diastereomers of the series **2b**–**d** by crystallization. For example, after 15 recrystallizations of **2b** no change in the optical rotation of the diastereomer mixture was observed.

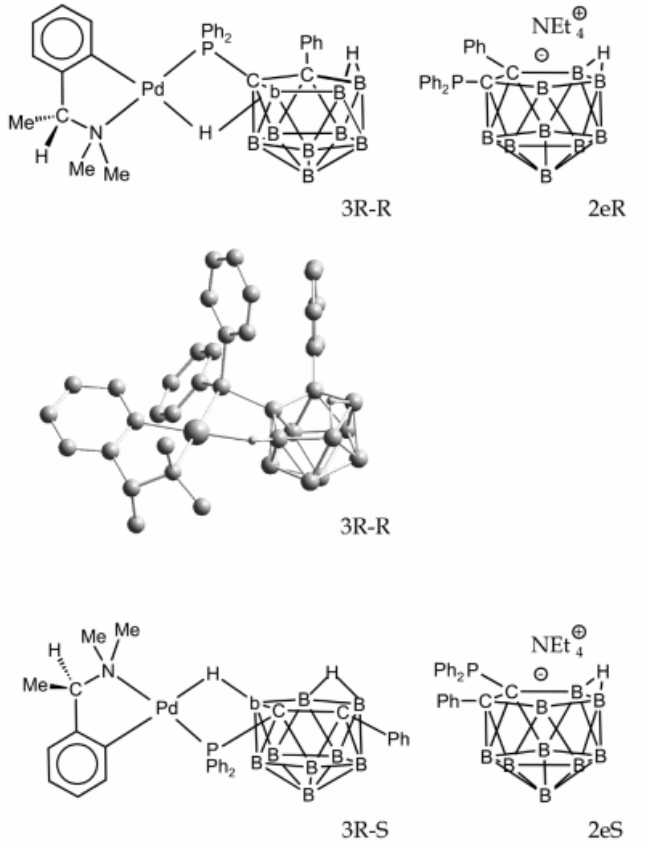
Resolution of the Anion *rac*-7-Diphenylphosphanyl-8-phenyl-7,8-dicarba-*nido*-undecaborate Via Internally Diastereomeric Palladium Complexes

Using the well-established procedure for the resolution of racemic bis(phosphanes) via internally diastereomeric palladium complexes,[12,13] it was possible to resolve the *rac*-7-diphenylphosphanyl-8-phenyl-7,8-dicarba-*nido*-undecaborate anion. The diastereomers **3*R*-*R*** and **3*R*-*S*** (Scheme 2) were synthesized from **2e** and di-μ-chlorobis{(*R*)-2-[1-(dimethylamino)ethyl]phenyl-*C,N*}palladium[14] in CH_2Cl_2 at 10 °C. To remove the by-product NEt_4Cl the solvent was exchanged for $CHCl_3$ and the solution was stirred for 3 h. During this time, the mixture of the diastereomers **3*R*-*R*** and **3*R*-*S*** precipitated as a yellow-green powder in a ratio 55:45. The NEt_4Cl remained in solution.

The IR spectrum of the mixture **3*R*-*R*/3*R*-*S*** shows an intense absorption at 2570 cm^{-1}, characteristic of the B−H stretching vibrations of *nido*-carboranes. The ^{31}P NMR spectrum of the mixture of the diastereomers exhibits singlets at δ = 28.64 for **3*R*-*R*** and 31.35 for **3*R*-*S***. The ^1H NMR spectrum displays a broad resonance centered at δ = −2.3 confirming the existence of a B−H−B bridge in **3*R*-*R*** and **3*R*-*S***. Two quadruplets at δ = −0.38 for **3*R*-*R*** and 0.35 for **3*R*-*S*** are assigned to the Pd−H−B bridges. The two diastereotopic methyl groups of the $N(CH_3)_2$ groups give two doublets at δ = 2.77 and 2.89 for **3*R*-*R***, and two doublets at δ = 2.61 and 3.08 for **3*R*-*S***. A doublet at δ = 1.83 for **3*R*-*R*** and a doublet at δ = 1.45 for **3*R*-*S*** results from the CCH_3 group, and a doublet of a quadruplet at δ = 3.62 for **3*R*-*R*** and a quadruplet at δ = 4.33 for **3*R*-*S*** from the CH group.

As **3*R*-*R*** and **3*R*-*S*** differ in the chemical shifts of their NMR spectra, the ratio **3*R*-*R*:3*R*-*S*** can be determined by integration of the methyl signals in the ^1H NMR spectrum, or the phosphorus signals in the ^{31}P NMR spectrum. Furthermore, the ^1H and ^{31}P NMR spectra indicate that **3*R*-*R*** and **3*R*-*S*** are the isomers in which PPh_2 and NMe_2 as well as BH and *ortho*-C are *trans* to each other. This is in agreement with the X-ray structure analysis for **3*R*-*R***, given below.



Scheme 2. The diastereomeric Pd complexes **3*R*-*R*** and **3*R*-*S***, and the resolved salts **2e*R*** and **2e*S*** (abbreviations: B = BH and b = B); ORTEP diagram of **3*R*-*R***

The separation of the diastereomers **3*R*-*R*** and **3*R*-*S*** was first attempted by fractional crystallization from toluene/petroleum ether at −20 °C. Yellow needles were isolated containing the diastereomers in a ratio of 1:1. However, in the separation of the diastereomers **3*R*-*R*/3*R*-*S*** from the by-product NEt_4Cl it had been noticed that in a mixture of toluene and pentane the **3*R*-*R*** isomer was enriched. Based on this observation a procedure to separate the diastereomers was developed. The 1:1 mixture **3*R*-*R*/3*R*-*S*** was dissolved in toluene. Dropwise addition of pentane precipitated a light brown powder enriched in **3*R*-*R*** (**3*R*-*R*/3*R*-*S*** = 90:10), whereas the filtrate was enriched in **3*R*-*S*** (**3*R*-*R*/3*R*-*S*** = 33:66). To get the pure diastereomers **3*R*-*R*** and **3*R*-*S***, both fractions were re-dissolved in toluene. Pentane was added and the solutions were crystallized to yield pure **3*R*-*R*** and **3*R*-*S***, respectively, as light brown, rhombic crystals. The separation of the diastereomers **3*R*-*R*** and **3*R*-*S*** can be monitored by ^1H and ^{31}P NMR spectroscopy.

A single-crystal X-ray analysis of **3*R*-*R*** established the (*R*) configuration (see below) of the *nido*-carborane ligand relative to the coordinated *ortho*-metallated *N,N*-dimethyl-(*R*)-1-phenylethylamine ligand (Scheme 2). It also

showed that the carborane ligand coordinated to the palladium atom with the phosphorus atom and the adjacent BH group in an *exo-nido* fashion. Furthermore, the X-ray analysis confirmed the *trans* position of PPh_2, NMe_2, and BH, *ortho*-C in **3*R*-*R***.

The configuration of planar-chiral carborane ligands was specified according to the Schlögl convention[1,2] for planar-chiral ferrocenes. The observer looks onto the open five-membered ring of the carborane. By considering the disposition of the substituents, ordered according to the Cahn−Ingold−Prelog rules, clockwise is assigned to the (*R*) configuration, counterclockwise to the (*S*) configuration. Thus, in complex **3*R*-*R*** (Scheme 2) the priority sequence is $PPh_2 > CPh > BH$, and the carborane ligand has an (*R*) configuration.

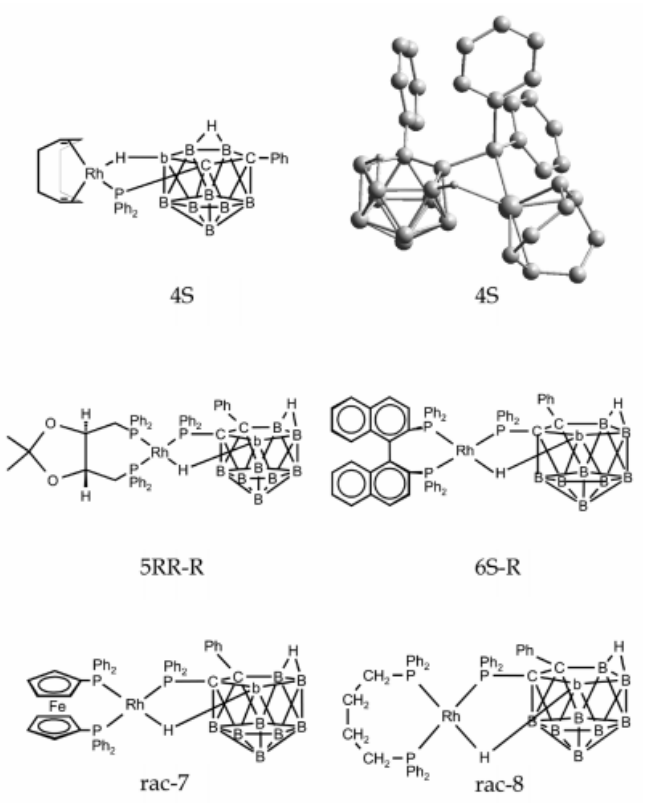
The liberation of the enantiomerically pure anions from the separated palladium complexes was performed in two steps. First, boiling solutions of the diastereomerically pure complexes **3*R*-*R*** and **3*R*-*S*** in acetone containing hydrochloric acid removed the *N*,*N*-dimethylamino-(*R*)-1-phenylethylamine ligand from the Pd complexes. Then, the carborane ligand was liberated from the palladium complex by dissolving in CH_2Cl_2 and stirring with an excess of NaCN and NEt_4Cl in water. Pure **2e*R*** and **2e*S*** (Scheme 2) were isolated from the organic phase as white powders, after discarding the water phase.

The IR spectra of **2e*R*** and **2e*S*** show an intense absorption at 2570 cm^{-1}, typical of the B−H stretching vibrations of *nido*-carboranes. The ^1H NMR spectra display a broad resonance at δ = −1.8 to −2.2, assigned to the B−H−B bridge, and a broad absorption at δ = −0.2 to −2.8 originating from the nine BH groups. The $^{31}P\{^1H\}$ NMR spectra exhibit one signal at δ = 9.45 for the PPh_2 group. The $^{11}B\{^1H\}$ NMR spectra show five peaks in a ratio of 1:1:5:1:1 at negative δ values. As expected, the optical rotations of **2e*R*** and **2e*S*** show an image/mirror image relationship. The enantiomeric purity of **2e*R*** seems to be a little higher than that of **2e*S***.

The Rhodium−Carborane Complexes 4−8

For the preparation of the Rh(COD)carborane complexes **4*R*** and **4*S*** (Scheme 3) enantiomerically pure **2e*R*** or **2e*S*** was refluxed with $[Rh(COD)Cl]_2$ in ethanol. The orange clear solution became a yellow suspension. After cooling to room temperature, the solvent was evaporated to a few mL, affording yellow **4*R*** and **4*S***, respectively. Solutions of these complexes in CH_2Cl_2 are air-sensitive. The $^{31}P\{^1H\}$ NMR spectra of **4*R*** and **4*S*** display a doublet centered at δ = 36.78 with a coupling constant $^1J_{Rh,P}$ = 114.6 Hz. Scheme 3 shows the ORTEP plot of the *exo-nido* structure of complex **4*S***.

For the syntheses of the rhodium−bis(phosphane)−carborane complexes **5**−**8** $[Rh(COD)Cl]_2$, **2e*R*** or **2e*S*** and the chelating bis(phosphane) were heated under reflux in ethanol. The rhodium complexes precipitated as orange powders in high purity. The bis(triphenylphosphane)rhodium complex containing the racemic anion 7-diphenylphosphanyl-8-phenyl-7,8-dicarba-*nido*-undecaborate had been described before.[15]



Scheme 3. The Rh(COD) complex **4*S*** and the ORTEP diagram of **4*S***; the [bis(phosphane)]Rh complexes **5**−**8** (abbreviations: B = BH and b = B)

With (*R*,*R*)- or (*S*,*S*)-DIOP as the chelating bis(phosphane), the enantiomers **5*RR*-*R*** and **5*SS*-*S***, as well as their diastereomer **5*RR*-*S*** were formed (Scheme 3). All the complexes were orange powders, slightly soluble, but air-stable in CH_2Cl_2 solution. The ^1H NMR spectra display the signals of the RhHB and BHB bridges at δ = −2.70 and −2.00 to −1.00 for **5*RR*-*R*** and **5*SS*-*S***, and at δ = −3.25 to −2.78 and −2.30 to −2.25 for **5*RR*-*S***, indicating the *exo-nido* structure of the complexes. The ^{31}P NMR spectra show ABX systems. The AB systems (8-line ddd structures for each P atom) are assigned to the two phosphorus atoms of the DIOP ligands, whereas the X parts of the spectra give doublets of a multiplet.

(*S*)-BINAP as the chelating bis(phosphane) afforded a 73% yield of a red-orange powder of **6*S*-*R*** (Scheme 3), for which the ^1H NMR spectrum indicates the *exo-nido* structure. The ^{31}P NMR spectrum shows an ABX system, in which the AB part is assigned to the two PPh_2 groups of BINAP (δ = 6.98 and 34.61) and the X part to the PPh_2 group of the carborane ligand (δ = 43.62).

Using racemic **2e** together with the chelating bis(phosphanes) bis(diphenylphosphanyl)ferrocene and 1,4-bis(diphenylphosphanyl)butane, racemates of the complexes **7** and **8** (Scheme 3) were formed in yields of 84% and 60%, respectively, as orange powders (*exo-nido* types). The $^{31}P\{^1H\}$ NMR spectra of both complexes exhibit ABX sys-

tems in which the AB parts are due to the two PPh_2 groups of the bis(phosphane) ligand (ddd structures) and the X parts, doublets of a multiplet, due to the carborane ligand.

Remarkably, attempts to coordinate bis(phosphanes), which form five-membered rings, such as CHIRAPHOS or NORPHOS, were not successful. Similarly, the chelating ligand (2*R*,3*R*)-1,4-dimercapto-2,3-butanediol and (*S*)-2,2′-diamino-1,1′-binaphthyl did not give the corresponding *exo-nido*-rhodium−carborane complexes. Thus, the preparation of rhodium−carborane complexes with another chelating ligand was confined to bis(phosphanes) forming seven-membered rings.

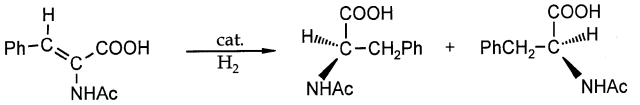
Enantioselective Catalysis

In order to explore the enantioselectivity of the new complexes **4**−**8** in asymmetric catalyses, the hydrogenation of acetamidocinnamic acid, the hydrogenation of ketopantolactone, and the hydrosilylation of acetophenone were selected for study. In all three systems it was found that only complexes **4** and **5** were catalytically active.

In a methanol solution of (*Z*)-α-*N*-acetamidocinnamic acid, containing the catalysts **4** and **5**, there was no hydrogenation while stirring under 1 atm of H_2 for 48 h at room temperature. However, complete hydrogenation resulted in an autoclave under 50 bar of H_2 at 65 °C in toluene/ethanol mixtures. The product *N*-acetylphenylalanine was converted into its methyl ester[16] in order to measure the *ee* by GC. After the hydrogenation with complexes **4*R*** and **4*S***, a black solution had formed indicating the decomposition of complexes **4*R*** and **4*S***, whereas with complexes **5*RR-R*** and **5*RR-S*** an orange solution resulted.

In 5 mL ethanol/10 mL toluene, **4*R*** gave 60−62% *ee* of *N*-acetyl-L-phenylalanine (Table 1, last column). The enantiomerically less pure **4*S*** afforded the D product in a somewhat reduced enantioselectivity. In **4*R*** and **4*S*** the planar-chiral carborane ligand is the only source of chirality, responsible for the chiral induction in the enantioselective hydrogenation reaction. Complex **5*RR-R***, containing (*R*,*R*)-DIOP in addition to the (*R*)-carborane ligand, produced 60−63% *ee* of *N*-acetyl-D-phenylalanine. Complex **5*RR-S***, containing (*R*,*R*)-DIOP in addition to the opposite (*S*)-carborane ligand, gave 50−57% *ee* with the same *N*-acetyl-D-phenylalanine in excess. Evidently, the configuration of *N*-acetylphenylalanine is controlled by the ligand (*R*,*R*)-DIOP. The small differences produced by the diastereomeric catalysts **5*RR-R*** and **5*RR-S*** could be due to the opposite configurations of the carborane ligand. Another explanation is the dissociation of the carborane ligand from the (*R*,*R*)-DIOP complexes **5*RR-R*** and **5*RR-S*** − a reasonable assumption, because empty coordination sites are needed for the binding of substrate and hydrogen during the catalysis.[17] However, the complete dissociation of the carborane ligands from the complexes **5*RR-R*** and **5*RR-S*** should give identical chiral inductions.

Table 1. Enantioselectivities (% *ee*) obtained with complexes **4** and **5** as catalysts in the hydrogenation of (*Z*)-α-*N*-acetamidocinnamic acid



Complex[a]	10 mL of ethanol 5 mL of toluene	5 mL of ethanol 5 mL of toluene	5 mL of ethanol 10 mL of toluene
4*R*	12.7, 12.0 L	48.1, (40.0), 50.1 L	61.9, 60.3, 61.7, 61.3, 62.3 L
4*S*	19.5 D	− −	55.8, 58.0, 54.8, 62.3 D
5*RR-R*	76.1, 79.6 D	(80.5) D	63.0, 60.2 D
5*RR-S*	62.6, 57.1 D	− −	56.6, 50.0, (40.4) D

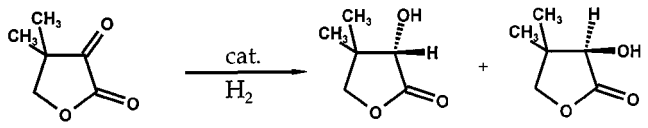
[a] Ratio catalyst/substrate = 1:100. Substrate quantity 200 mg (0.975 mmol). Reaction conditions: 50 bar H_2 pressure, 65 °C, 48 h. Quantitative hydrogenation according to ^1H NMR spectra. Enantiomeric excess determined by GC on a Chirasil-L-Val column.

It was interesting to investigate the dependence of the enantioselectivity on the composition of the solvent (Table 1, columns 2−4). The limiting factor was the solubility of acetamidocinnamic acid, which is insoluble in toluene and of the rhodium−carborane complexes, which are only sparingly soluble in ethanol. For complexes **4** with the COD/carborane ligand set, the enantioselectivity decreased appreciably with an increasing ethanol/toluene ratio. For complexes **5** the opposite trend was observed. The higher the ratio ethanol/toluene the higher was the chiral induction. For the complex **5*RR-R*** at a ratio ethanol/toluene = 10:5 the enantioselectivity was close to 80%. An *ee* of 80−81% is the value expected from the literature for the Rh(DIOP) catalyst.[18] The observed solvent dependence is therefore in agreement with a dissociation of the carborane ligand from complexes **5** during catalysis.

The hydrogenation of ketopantolactone, catalyzed by complexes **4** and **5**, was carried out in a stirred autoclave under 50 bar H_2 at 50 °C for 48 h in toluene, resulting in a complete reduction to (*R*)- and (*S*)-pantolactone.[19] The achieved enantioselectivities are given in Table 2. Complex **4*R***, consisting of the COD ligand and the enantiomerically pure (*R*)-carborane ligand, afforded (*R*)-pantolactone in 23% *ee*. The enantiomerically less pure enantiomer **4*S*** gave 16.4% *ee* of (*S*)-pantolactone. Again, the carborane ligand is the only chiral information in the complexes **4*R*** and **4*S***. Complexes **5*RR-R*** and **5*SS-S*** are enantiomers, containing the (*R*,*R*)-DIOP/(*R*)-carborane and the (*S*,*S*)-DIOP/(*S*)-carborane ligand set. These systems gave enantioselectivities of 59−66% for (*R*)- and (*S*)-pantolactone, respectively. For comparison, under the same conditions the catalyst [Rh(*R*,*R*)-DIOP-Cl]$_2$ afforded 54.4% of (*R*)-pantolac-

tone,[20] indicating a dissociation of the carborane ligand from the complexes **5*RR*-*R*** and **5*SS*-*S***.

Table 2. Complexes **4** and **5** as catalysts in the hydrogenation of ketopantolactone

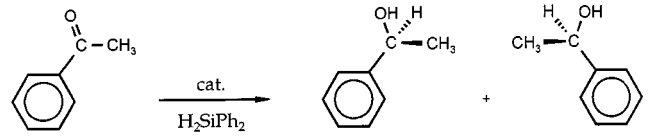


Complex[a]	*ee* [%]	Configuration
4*R*	22.5, 23.0	*R*
4*S*	(16.3)	*S*
5*RR*-*R*	63.6, 58.7, 63.4	*R*
5*SS*-*S*	58.9, 61.1, 66.6	*S*

[a] Ratio catalyst/substrate = 1:200. Ketopantolactone quantity 258 mg (2.01 mmol). Reaction conditions: 50 bar H_2 pressure, 50 °C, 48 h. Quantitative reduction and enantiomeric excess determined by GC on a Chirasil-DEX-CB column.

The hydrosilylation of acetophenone with diphenylsilane (room temperature, 48 h) was catalyzed by the complexes **4*R***, **5*RR*-*S*** and **5*SS*-*S*** to give (*R*)- or (*S*)-1-phenylethanol.[20,21] The enantioselectivities (and in addition the conversion and the enol ether content)[21] are summarized in Table 3. Complex **4*R*** induced an enantiomeric excess of 7−9% of (*R*)-1-phenylethanol, whereas the diastereomers **5*RR*-*S*** and **5*SS*-*S*** both gave 26−27% *ee* of (*R*)- and (*S*)-pantolactone, respectively. The enantioselectivity of [Rh(*R*,*R*)-DIOP-Cl]$_2$ as the chiral catalyst under the same conditions was 27% of (*R*)-1-phenylethanol,[18] compatible with a dissociation of the carborane ligand from **5*RR*-*S*** and **5*SS*-*S*** and a rhodium−DIOP species being the enantioselective catalyst.

Table 3. Complexes **4** and **5** as catalysts in the hydrosilylation of acetophenone with diphenylsilane



Complex[a]	Conversion [%]	Enol ether [%]	1-Phenylethanol Yield [%]	1-Phenylethanol *ee* [%]
4*R*	75, 83	0, 5	75, 79	8.9, 6.7 (*R*)
5*RR*-*S*	92, 92, 37	16, 9, 0	76, 83, 37	26.0, 26.3, 27.7 (*R*)
5*SS*-*S*	72, 80, 89	17, 45, 48	62, 59, 52	(20.7), 25.7, 27.5 (*S*)

[a] Ratio catalyst/acetophenone/diphenylsilane = 1:400:400. Acetophenone and diphenylsilane quantities 1.0 mL (8.5 mmol) and 1.6 mL (8.6 mmol). Reaction conditions: room temperature, 2 d. Conversion, content of enol ether and silyl ether measured by ^{1}H NMR spectroscopy. Enantiomeric excess determined by GC on a Chirasil-DEX-CB column.

In addition, the complexes **4*R*** and **4*S*** were used as catalysts in the diastereoselective hydrogenation of folic acid showing promising results.[22]

Experimental Section

General: All experiments were conducted under dry nitrogen using Schlenk techniques. Solvents were freshly distilled under nitrogen from appropriate drying agents before use. − NMR measurements: ^{1}H at 400 MHz and ^{13}C at 100.1 MHz referenced to $SiMe_4$, ^{11}B at 128 MHz referenced to external $BF_3{\cdot}OEt_3$, ^{31}P at 162 MHz referenced to external H_3PO_4 using a Bruker ARX 400 instrument (chemical shifts in units of parts per million downfield from $SiMe_4$, coupling constants in Hertz). − IR spectra: Beckman IR 4240. − Specific rotations: Perkin−Elmer polarimeter 241. Decaborane(14),[12] 1-phenylcarborane,[23] 1-diphenylphosphanyl-2-phenylcarborane[10] (**1**), tetraethylammonium 7-diphenylphosphanyl-8-phenyl-7,8-dicarba-*nido*-undecaborate[9] (**2e**), and DIOP[19,24] were synthesized according to literature procedures. BINAP, bis(diphenylphosphanyl)ferrocene, and 1,4-bis(diphenylphosphanyl)butane were commercially obtained.

Synthesis of the Mixture of Diastereomers (*R*)-{2-[1-(Dimethylamino)ethyl]phenyl-*C*,*N*}[*exo*-*nido*-(*R*)-(7-diphenylphosphanyl-8-phenyl-7,8-dicarbaundecaborato)]palladium (3*R*-*R*) and (*R*)-{2-[1-(Dimethylamino)ethyl]phenyl-*C*,*N*}[*exo*-*nido*-(*S*)-(7-diphenylphosphanyl-8-phenyl-7,8-dicarbaundecaborato)]palladium (3*R*-*S*): Compound **2** (7.66 g, 14.6 mmol) and (*R*)-di-μ-chlorobis{2-[1-(dimethylamino)ethyl]phenyl-*C*,*N*}palladium[15] (4.03 g, 7.03 mmol) were stirred in 200 mL of CH_2Cl_2 at −10 °C for 4 h. The solvent was evaporated and the yellow-green product was suspended in 20 mL of $CHCl_3$, while the NEt_4Cl remained in solution. After stirring for 3 h, the yellow-white diastereomers **3*R*-*R*/3*R*-*S*** were precipitated in a ratio of 55:45. The residue was filtered and washed with 3 × 5 mL of $CHCl_3$. Yield 5.48 g (58%). − $[\alpha]_\lambda$ (c = 1.0, CH_2Cl_2) = −6 (578 nm), −8 (546 nm), −24 (436 nm). − IR (KBr): $\tilde{\nu}$ = 2535 cm^{-1} vs (B−H). − MS (FAB-NI-LSIMS): *m*/*z* (%) = 647.7 (100) [M]$^+$, 498.3 (95) [M$^+$ − $C_{10}H_{14}N$]. − $C_{30}H_{39}B_9NPPd$ (647.7): calcd. C 55.44, H 6.06, N 2.15; found C 55.39, H 6.14, N 2.06.

Separation of the Diastereomers 3*R*-*R* and 3*R*-*S*: The diastereomeric mixture **3*R*-*R*/3*R*-*S*** (400 mg, 0.62 mmol) was dissolved in 50 mL of toluene and filtered. At 15−20 °C 150 mL of pentane was added through a dropping funnel within 5−6 h (1 drop per 3 s). 80−90 mg of a brown powder (**3$_{pow}$**) with a ratio **3*R*-*R*/3*R*-*S*** = 90:10 was precipitated and filtered off. The solvent of the filtrate was evaporated to yield 200 mg of a brown powder (**3$_{fil}$**) with a ratio **3*R*-*R*/3*R*-*S*** = 33:66. To obtain the pure diastereomers **3*R*-*R*** and **3*R*-*S***, 350 mg of **3$_{pow}$** or **3$_{fil}$** were dissolved in 50 mL of toluene. Pentane (35 mL) was added, and the solution filtered and crystallized at −20 °C to yield 200 mg (16%) of pure **3*R*-*R*** or 200 mg (23%) **3*R*-*S***.

3*R*-*R*: $[\alpha]_\lambda$ (c = 1.0, CH_2Cl_2) = 21 (578 nm), 30 (546 nm), 120 (436 nm). − ^{1}H NMR (CD_2Cl_2): δ = −2.4 to −2.1 (br., 1 H, BHB), −0.38 (q, $^1J_{H,B}$ = 34.1 Hz, 1 H, PdHB), 1.5−2.5 (br., 8 H, BH), 1.83 (d, $^3J_{H,H}$ = 6.6 Hz, 3 H, $CHCH_3$), 2.77 (d, $^4J_{H,P}$ = 2.0 Hz, 3 H, NCH_3), 2.89 (d, $^4J_{H,P}$ = 4.1 Hz, 3 H, NCH_3), 3.62 (dq, $^3J_{H,H}$ = 6.6 Hz, $^4J_{H,P}$ = 2.2 Hz, 1 H, CH), 6.16−6.25 (m, 1 H, Pd/CH_{ortho}), 6.45−6.55 (m, 1 H, H_{ar}), 6.69−6.91 (m, 9 H, H_{ar}), 6.94−7.09 (m, 1 H, H_{ar}), 7.11−7.19 (m, 2 H, H_{ar}), 7.39−7.63 (m, 3 H, H_{ar}), 7.81−7.92 (m, 2 H, H_{ortho} in PPh_2). − Signals different in ^{1}H{^{31}P} NMR (CD_2Cl_2): δ = 2.77 (s, 3 H, NCH_3), 2.89 (s, 3 H, NCH_3), 3.62 (q, $^3J_{H,H}$ = 6.6 Hz, 1 H, CH). − ^{11}B{^{1}H} NMR (CD_2Cl_2): δ = −34.15 (s, 1 B), −28.07 (s, 1 B), −23.31 (s, 2 B), −13.13 (s, 2 B), −10.91 (s, 1 B), −8.31 (s, 1 B), −2.70 (s, 1 B). − ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 23.41 (s, $CHCH_3$), 48.55 (s, NCH_3),

The Enantiomerically Pure Salts Tetraethylammonium (*R*)- and (*S*)-7-Diphenylphosphanyl-8-phenyl-7,8-dicarbaundecaborate (2e*R* and 2e*S*): A solution of **3*R*-*R*** or **3*R*-*S*** (1 g, 1.544 mmol) in 50 mL of acetone was heated under reflux for 8 h with 10 mL of conc. HCl. The solvent was removed and the residue was washed with water. The product was dissolved in CH_2Cl_2 (30 mL) and a solution of NaCN (1 g) and NEt_4Cl (1 g) in water (50 mL) was added. After stirring for 24 h, the organic layer was separated, washed with water and dried with $CaCl_2$. After filtering, the solvent was evaporated to yield 0.61 g (76%) of a white powder of **2e*R*** or **2e*S***, respectively.

2e*R*: $[\alpha]_\lambda$ (c = 1.0, CH_2Cl_2) = 149 (578 nm), 182 (546 nm), 513 (436 nm). − IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2530 vs (B−H). − MS (FAB-NI-LSIMS): m/z (%) = 410.3 (30) $[MO]^+$, 394.3 (50) $[M]^+$, 306.1 (100) [M^+ − CPh]. − ^1H NMR (CD_2Cl_2): δ = −1.8 to −2.2 (br., 1 H, BHB), −0.2 to 2.8 (br., 9 H, BH), 1.33 (t, $^3J_{H,H}$ = 6.9 Hz, 12 H, CH_3), 3.35 (q, $^3J_{H,H}$ = 6.9 Hz, 8 H, CH_2), 7.8−6.9 (m, 15 H, Ph). − $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = −34.66 (s, 1 B, BHB), −31.85 (s, 1 B, BHB), −22.55 to −12.65 (br., 5 B), −9.40 (s, 1 B), −6.62 (s, 1 B). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 9.45 (s). − $C_{28}H_{45}B_9NP$ (523.2): calcd. X-ray Crystal Structure Determination of 1, 3*R*-*R*, and 4*S*: Data collection was performed on a STOE Imaging Plate Diffraction System (IPDS) equipped with an Oxford Cryosystems Cryostream Cooler for low-temperature measurements (Table 4). All data were corrected for Lorentz and polarisation effects. Final unit cell parameters were obtained by a least-squares refinement on a set of either 2000 (**1**) or 8000 (**3*R*-*R***, **4*S***) reflections equally distributed in reciprocal space. The structures were solved by direct methods (SIR-97)[25] and subsequent difference Fourier methods. Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL97).[26] All non-H atoms were refined with anisotropic thermal parameters. H atoms were located from difference Fourier syntheses and refined with isotropic thermal parameters in three different ways: all free (**4*S***), some free, some as riding atoms (**3*R*-*R***), and all as riding atoms (**1**) with $U_{iso}(H) = 1.2U_{eq}$(C or B). The crystal structure of **3*R*-*R*** contains two toluene solvent molecules, one of them disordered between two orientations. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-147724 (**3*R*-*R***), CCDC-147725 (**4*S***) and CCDC-147726 (**1**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

New Chiral Cyclopentadienylrhenium Lewis Acids Featuring Fluorinated Triarylphosphanes and Enhanced Acceptor Abilities − An Unusual Carbon−Fluorine Bond Activation in a Metal Coordination Sphere

Wolfgang Mohr,[a] Gene A. Stark,[b] Haijun Jiao,[a] and J. A. Gladysz*[a]

Dedicated to Professor Dr. H.-J. Bestmann on the occasion of his 75th birthday

Keywords: Phosphanes / Chiral Lewis acids / Nucleophilic aromatic substitutions / Rhenium / Carbon−fluorine bond activation / DFT calculations

The acetonitrile complex $[(\eta^5\text{-}C_5H_5)Re(NO)(NCCH_3)(CO)]^+BF_4^-$ (**1**) and $P(4\text{-}C_6H_4CF_3)_3$ slowly react (2 d, room temperature) to give the substitution product $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(CO)]^+BF_4^-$ (**3**, 85%). The reaction of **1** and less nucleophilic $P(C_6F_5)_3$ must be conducted in a melt at 140 °C, but $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(C_6F_5)_3\}(CO)]^+BF_4^-$ (**11**) is isolated in 90% yield. Reduction of **3** by $NaBH_4$ gives the methyl complex $(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(CH_3)$, which is treated with TfOH and $H_3CN{=}C(H)C_6H_5$ to give the imine complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)\{N(CH_3){=}C(H)C_6H_5\}]^+TfO^-$ (**9**). Complex **9** was, like the non-fluorinated analog, unreactive towards allyltin nucleophiles. Complex **11** should lead to a more reactive imine complex, but $NaBH_4$ gave a methyl complex that was difficult to purify. However, $NaOCH_3$ or $NaSCH_3$/methanol gave easily purified $(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6F_4OCH_3)_3\}(CO_2CH_3)$ (85%) or $(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6F_4SCH_3)_3\}(CO_2CH_3)$ (51%), in which all *para*-fluorine atoms have undergone nucleophilic displacements, and the carbonyl ligands methoxide additions. This suggests that catalytic chemistry of the chiral Lewis acid $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(C_6F_5)_3\}]^+$ (**I**-F_{15}) will be complicated by nucleophilic degradation. Nonetheless, density functional calculations show that **I**-F_{15} is a much stronger σ acceptor and weaker π donor than less fluorinated analogs.

Introduction

Numerous modern catalytic methods for enantioselective organic synthesis make use of chiral transition metal Lewis acids.[1] The optimization of their steric and/or electronic properties is essential for many processes. For example, the fine tuning of donor/acceptor characteristics was critical to the development of chiral cyclopentadienyliron and -ruthenium catalysts for highly enantioselective Diels−Alder cycloadditions.[2] In the same vein, there are a variety of chiral titanium(IV) catalysts that activate aldehydes towards enantioselective additions of allylstannanes.[1] However, more electrophilic, fluorinated titanium(IV) catalysts are required to promote analogous reactions of less nucleophilic but cheaper and more readily available allylsilanes.[3]

We have undertaken extensive studies of adducts of the chiral rhenium Lewis acid $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ (**I**) and unsaturated organic ligands such as aldehydes,[4] ketones,[5] alkenes,[6] and imines.[7] These are readily available in enantiomerically pure form, and stoichiometric additions of strong carbon nucleophiles often proceed with high diastereoselectivities.[4−7] However, weaker nucleophiles such as allylstannanes do not give rapid additions. In fact, rate experiments show that **I**, unlike many other transition metal Lewis acids, does not strongly activate unsaturated ligands towards nucleophiles. This has hampered the development of transformations that would be catalytic in rhenium.

The lack of activation can be ascribed to electronic properties of **I**. Most transition metal Lewis acids are best regarded as amphoteres. Except for d^0 systems, they have occupied d orbitals that are usually capable of backbonding to the acceptor orbitals of Lewis bases. The Lewis acid **I** is a strong π base, with the high-lying d donor orbital shown in Figure 1. The importance of this orbital in bonding to unsaturated ligands is evidenced by numerous structural studies.[4a,5,8] These indicate that unsaturated ligands adopt conformations that allow high degrees of overlap of their acceptor orbitals, even in the presence of opposing steric factors.

Accordingly, we sought to prepare analogs of **I** with enhanced σ acidities and diminished π basicities. In principle, any of the three spectator ligands can be modified. However, the nitrosyl group is an outstanding π acceptor, and we know of no other three-electron donor that could further enhance the acidity of the rhenium ion. Cyclopentadienyl ligands can be extensively halogenated, or substituted with electron-withdrawing perfluoroalkyl groups.[9] These would represent viable modification strategies. However, we elected to investigate analogs with fluorinated triarylphosphanes, in part due to our independent interest in highly fluorinated phosphanes for use in fluorous phase catalysis.[10]

In this paper, we describe the synthesis and some surprising reactions of Lewis base adducts of the new chiral rhenium Lewis acids $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}]^+$ [**I**-

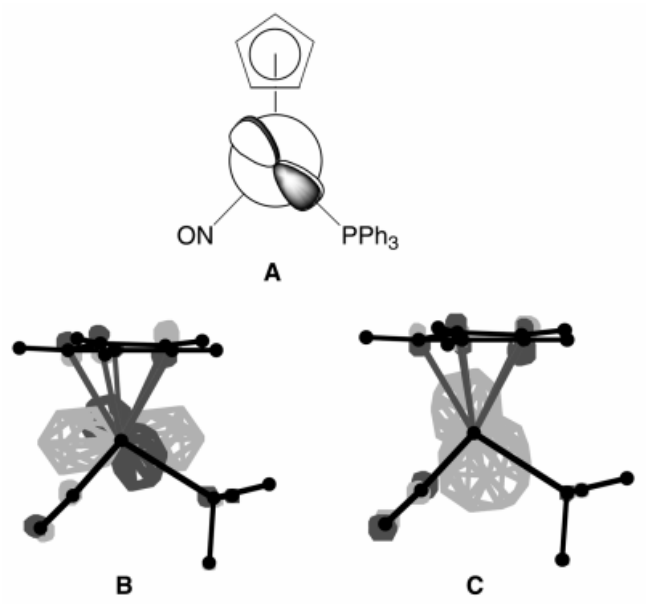

Figure 1. A: idealized d orbital HOMO of the chiral rhenium Lewis acid $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ (**I**); B: computed HOMO of the model Lewis acid $[(\eta^5\text{-}C_5H_5)Re(NO)(PH_3)]^+$ (ref.[25]); C: computed LUMO of the model Lewis acid $[(\eta^5\text{-}C_5H_5)Re(NO)(PH_3)]^+$ (ref.[25])

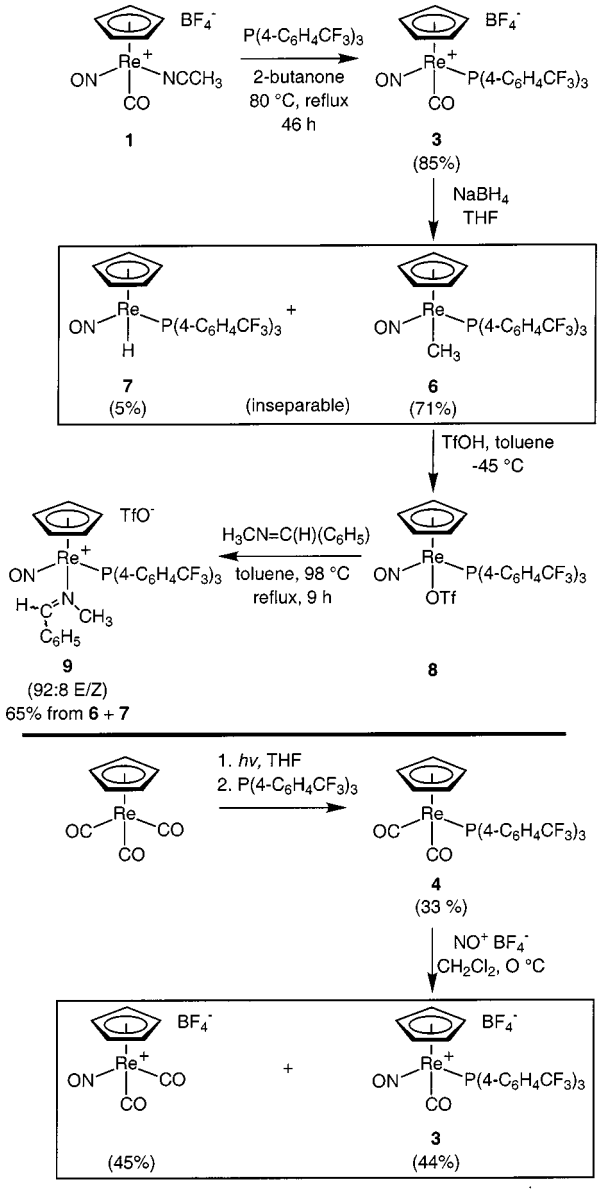
$(CF_3)_3]$ and $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(C_6F_5)_3\}]^+$ (**I**-F_{15}). In the former, the *para* positions of the aryl groups in **I** are substituted with trifluoromethyl groups. A slightly increased σ acidity, and a slightly decreased π basicity, was expected. In the latter, all aryl positions are fluorinated. A greatly enhanced Lewis acidity, and a greatly diminished π basicity, was expected. We also report high-level density functional calculations that allow more quantitative comparisons of the electronic properties of these compounds.

Results

The Nonafluorinated Lewis Acid I-$(CF_3)_3$

The substitution-labile acetonitrile complex $[(\eta^5\text{-}C_5H_5)Re(NO)(NCCH_3)(CO)]^+BF_4^-$ (**1**) and PPh_3 have previously been shown to react in refluxing ethyl methyl ketone to give the non-fluorinated phosphane complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CO)]^+BF_4^-$ (**2**).[11] As shown in Scheme 1, compound **1** and the commercially available phosphane $P(4\text{-}C_6H_4CF_3)_3$ were similarly allowed to react. Spectroscopic monitoring showed the need for a somewhat longer reaction time, presumably due to reduced nucleophilicity of the phosphane. After 46 h, workup gave the target complex $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(CO)]^+ BF_4^-$ (**3**) in 85% yield.

Complex **3** was characterized by NMR (^1H, ^{13}C, ^{31}P) and IR spectroscopy, as described in the Exp. Sect. As summarized in Table 1, the IR $\tilde{\nu}_{CO}$ and $\tilde{\nu}_{NO}$ values were 30−12 cm^{-1} greater than those of **2**,[11] consistent with decreased π basicity and increased σ acidity. The ^{13}C NMR CO signal was coupled to the phosphorus signal and upfield of that of **2** (Table 1). All aryl carbon atoms showed coupling to the phosphorus atom, and those *ipso* and *ortho*



Scheme 1. Syntheses and reactions of nonafluorinated complexes

to the trifluoromethyl group were further coupled to the fluorine atoms. Complex **3** could also be prepared by the reaction of dicarbonyl complex $(\eta^5\text{-}C_5H_5)Re(CO)_2\{P(4\text{-}C_6H_4CF_3)_3\}$ (**4**) and $NO^+BF_4^-$ (Scheme 1, bottom). However, due to a competing phosphane displacement to give $[(\eta^5\text{-}C_5H_5)Re(NO)(CO)_2]^+BF_4^-$,[11] the yield was only 44%. Complex **4** could in turn be prepared from $(\eta^5\text{-}C_5H_5)Re(CO)_3$[11] by a standard photolysis/substitution sequence in THF,[12] but our best yield was only 33%.

The reduction of non-fluorinated **2** by $NaBH_4$ in THF gives the methyl complex $(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CH_3)$ (**5**).[11] As shown in Scheme 1, compound **3** and $NaBH_4$ were analogously treated. Workup gave 97−93:3−7 mixtures of the expected methyl complex $(\eta^5\text{-}C_5H_5)\text{-}Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(CH_3)$ (**6**) and the unexpected hydride complex $(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(H)$ (**7**), as determined by integration of the cyclopentadienyl ^1H

NMR signals. The combined yield was 76%. Extensive attempts to separate hexane-soluble **6** and **7** by crystallization or TLC were unsuccessful. Hence, they were characterized as a mixture. Similar reductions have been effected with a variety of phosphane ligands,[13,14] but a hydride complex by-product has not been noted earlier. Both **6** and **7** exhibited diagnostic spectroscopic features,[11,15] such as $ReCH_3$ and ReH ^{1}H NMR signals (δ = 0.97 and −9.70) that were coupled to the phosphorus signal (J_{HP} = 6 and 29 Hz). The IR $\tilde{\nu}_{NO}$ value of **6** was greater than that of the non-fluorinated analog **5** (Table 1).[11]

The methyl complex **5** can be converted by various strong acid/solvent combinations into several functional equivalents of the chiral Lewis acid **I**. One of the most convenient is the corresponding triflate,[16] which can be isolated or treated directly with Lewis bases such as imines or thioethers to give adducts of the formula $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(L)]^+\ TfO^-$.[17,18] Based upon available data,[19] there would be a reasonable chance that related rhenium hydride complexes would behave similarly. Accordingly, the methyl complex **6** was used as a mixture with **7**.

As shown in Scheme 1, compound **6/7** and TfOH were combined in toluene at −45 °C to generate the new triflate complex $(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(OTf)$ (**8**). Complex **8** was not isolated, but directly treated with the imine $H_3CN{=}C(H)C_6H_5$. Since the analogous reaction of the non-fluorinated triflate is very slow at room temperature,[17] the sample was kept at 98 °C for 9 h. Workup gave the imine complex $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}\{N(CH_3){=}C(H)C_6H_5\}]^+TfO^-$ (**9**) as a 92:8 mixture of (*E*)/(*Z*) C=N isomers in 65% yield. Complex **9** was characterized analogously to **3** and **6/7**. The IR $\tilde{\nu}_{NO}$ value was greater than that of the non-fluorinated analog $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)\{N(CH_3){=}C(H)C_6H_5\}]^+TfO^-$ (**10**; Table 1),[17] which would logically correlate with an enhanced imine carbon electrophilicity. An (*E*) C=N isomer (larger phenyl and bulky rhenium substituents *trans*) also dominated with **10**.[17] These assignments were supported, among other factors, by the relative magnitudes of the $^4J_{HH}$ values of the $H_3CN{=}CH$ linkages (1.7 vs. 1.2 Hz).[20]

The imine complex **9** was combined with the allylstannane $H_2C{=}CHCH_2Sn(n\text{Bu})_3$ in CD_2Cl_2 and THF. The former sample was unchanged after 3 d at ambient temperature, as assayed by ^{1}H and ^{31}P NMR. The latter sample was unchanged after 1 d at 60 °C, as assayed by ^{31}P NMR. Carbon−carbon bond-forming reactions of imines and allylstannanes are readily catalyzed by titanium, palladium, and copper Lewis acids.[21] Hence, the modified rhenium Lewis acid **I**-$(CF_3)_3$ remained insufficiently activating, and a more reactive species was sought.

The Pentadecafluorinated Lewis Acid I-F_{15}

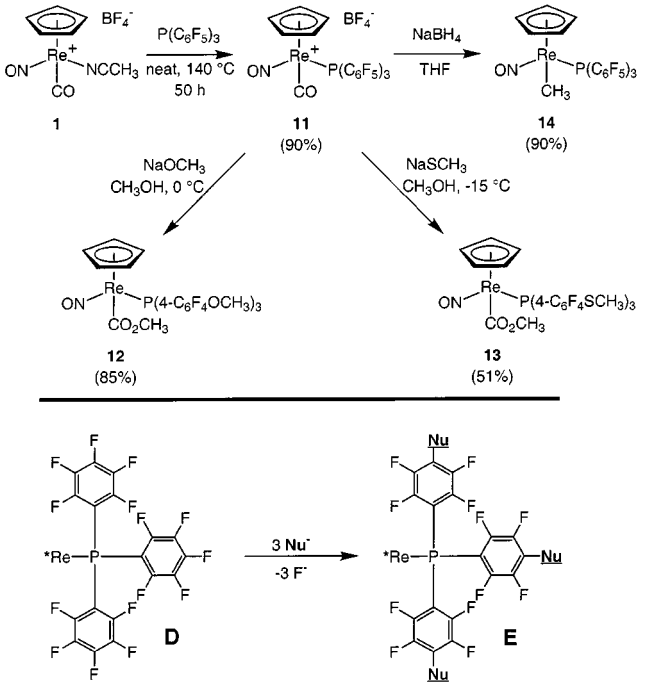
A $ClCH_2CH_2Cl$ solution of the acetonitrile complex **1** and the commercially available phosphane $P(C_6F_5)_3$ was kept at 88 °C for 11 h. No reaction occurred, as monitored by IR spectroscopy. A $Cl_2CHCHCl_2$ solution of **1** and $P(C_6F_5)_3$ was similarly kept at 129 °C for 14 h. An IR spectrum indicated that several products had formed. However, the ^{31}P NMR spectrum showed mainly $P(C_6F_5)_3$ (δ = −74.2; 73%), and one new signal that was assigned to the oxide $O{=}P(C_6F_5)_3$ (δ = −7.9; 27%) based upon the close agreement with the chemical shift in the literature (δ = −7.8).[22]

Reactions were attempted in the absence of solvent. Complex **1** and $P(C_6F_5)_3$ melt at 119 and 107 °C, respectively, and were kept at 140 °C (1.0:1.3 molar ratio) for 10 h. During this time, some of the $P(C_6F_5)_3$ sublimed to the top part of the flask not immersed in the oil bath. Thus, the reaction did not go to completion. Nevertheless, unchanged **1** could be separated from the desired substitution product $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(C_6F_5)_3\}(CO)]^+\ BF_4^-$ (**11**), which was isolated as a yellow powder in 32% yield. Modified reaction vessels were then assayed. The operationally most simple protocol involved starting with 1.5 equivalents of $P(C_6F_5)_3$, inserting some glass wool into the neck of the flask, immersing the flask *completely* in an oil bath (gas release bubbler protruding), and adding a second charge of $P(C_6F_5)_3$ (0.5 equiv.) halfway through the 50 h reaction. This gave **11** in 90% yield on a 3.5-g scale.

Complex **11** was characterized analogously to the other new compounds above. The IR $\tilde{\nu}_{CO}$ and $\tilde{\nu}_{NO}$ values were greater than the $P(4\text{-}C_6H_4CF_3)_3$ analog **3** (Table 1), indicating a further enhancement of σ acidity and diminution of backbonding into the NO and CO ligands. The ^{13}C NMR CO signal was upfield of that of **3** (Table 1). The ^{31}P NMR

signal was downfield of that of $P(C_6F_5)_3$ ($\delta = -48.0$ vs. -74.2 to -75.5).[22] However, only a broad singlet was observed ($w_{1/2} = 39-40$ Hz), as opposed to the fluorine-coupled pseudoquintuplet ($J_{PF} = 35$ Hz) of the free phosphane.

The enantiomers of the non-fluorinated carbonyl complex **2** are easily resolved.[11] The first step entails reaction with excess $NaOCH_3$ in methanol to generate the isolable methoxycarbonyl complex $(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CO_2CH_3)$.[11] Hence, **11** was similarly treated, as shown in Scheme 2. A product precipitated (**12**), but the ^1H NMR spectrum showed both the expected CO_2CH_3 signal ($\delta = 3.12$, s) and an unanticipated resonance ($\delta = 4.21$, t, $J_{HF} = 2$ Hz). These always appeared in concert, and integrated to a 3:9 ratio. The mass spectrum gave a parent ion consistent with the formula $(\eta^5\text{-}C_5H_5)Re(NO)\{P(C_6F_4OCH_3)_3\}(CO_2CH_3)$, in which a fluorine atom in each aryl ring has been substituted by a methoxy group. The ^{13}C NMR spectrum showed only four aryl signals, requiring a threefold *para* substitution, as well as two types of methoxy signals ($\delta = 62.9$, t, $J_{CF} = 4$ Hz and 48.9, s). Under optimized conditions, **12** could be obtained in 85% yield.



Scheme 2. Synthesis and reactions of pentadecafluorinated complexes

There is abundant precedent for nucleophilic aromatic substitutions of hexafluorobenzene, and the *para*-fluorine atoms of substituted pentafluorobenzenes.[23,24] However, the conversion of **11** to **12** represents one of the few times that this has been observed with a non-ligating arene in a metal coordination sphere.[24b] In a separate experiment, **11** and $NaOCH_3$ were combined in a 1:1 molar ratio in methanol, and the homogeneous reaction monitored by ^{31}P NMR. Several new signals appeared with chemical shifts close to that of **11** ($\delta = -50$ to -51), and several new signals appeared with chemical shifts close to that of **12** ($\delta = -33$ to -35). These were attributed to intermediate levels of *para* substitution. If methoxide addition to the carbonyl group of **11** were *ir*reversible, this would indicate that fluoride substitution occurs both before and after carbonyl addition.

In order to probe the generality of such threefold substitutions, **11** and the thiolate $NaSCH_3$ were allowed to react in methanol. As shown in Scheme 2, workup gave the sulfur-containing complex $(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6F_4SCH_3)_3\}(CO_2CH_3)$ (**13**) in 51% yield. Interestingly, a methoxy group selectively added to the carbonyl ligand of **11**, whereas thiomethoxy groups selectively displaced fluoride. This structure was supported by a molecular ion peak in the mass spectrum, a correct C/H/N/S microanalysis, and numerous IR and NMR features. For example, the IR $\tilde{\nu}_{CO}$ value of **13** was very similar to that of **12** (1613 vs. 1603 cm^{-1}). Also, the $ArSCH_3$ NMR signals of **13** were distinctly upfield of the $ArOCH_3$ signals of **12** [^1H: $\delta = 2.62$ (br s) vs. 4.21; $^{13}C\{^1H\}$: $\delta = 17.0$ (t, $J_{CF} = 5$ Hz) vs. 62.9].

Although the substitution reactions in Scheme 2 are of interest in their own right, they tempered our enthusiasm for the $P(C_6F_5)_3$ ligand as part of a second-generation chiral rhenium Lewis acid. Even if an enantiomer separation not requiring a methoxide addition could be effected, there would be a high probability that similar substitutions would compromise other target reactions or applications in catalysis. Accordingly, it was decided to pursue only one additional reaction in this series, that of **11** and $NaBH_4$. Under conditions comparable to those in Scheme 1, the methyl complex $(\eta^5\text{-}C_5H_5)Re(NO)\{P(C_6F_5)_3\}(CH_3)$ (**14**) could be isolated as a crude powder in 90% yield by benzene or toluene extraction of the reaction mixture.

Complex **14** exhibited a number of diagnostic spectroscopic features. These included (1) a ^1H NMR spectrum with methyl ($\delta = 0.76$, d, $J_{HP} = 10$ Hz) and cyclopentadienyl signals, both very similar to those of **6**, (2) corresponding ^{13}C NMR signals (Table 1), and (3) an intense molecular ion peak in the mass spectrum. However, NMR spectra showed residual benzene or toluene, even after prolonged periods under high vacuum that routinely removed these solvents from other complexes. Treatments with cold pentane improved the purities, but correct microanalyses could never be obtained. Finally, attempts to generate various functional equivalents of the Lewis acid **I**-F_{15} from **14** gave unusual results that would be difficult to interpret without further intensive study.

Computations

There would be obvious approaches to generating highly fluorinated but less substitution-prone triarylphosphanes. Hence, as a justification for possible continued work, we sought computational support for our intuitive estimation of the relative donor/acceptor properties of the fragments **I**, **I**-$(CF_3)_3$, and **I**-F_{15}. One starting point might be to compare model compounds with PH_3 ligands, several of which have been studied previously,[25] to those with PH_xF_{3-x} ligands. Although such systems would contain fewer atoms and electrons and could be investigated at a very high level of

rigor, they also constitute less satisfying models for triarylphosphanes.

Accordingly, the geometry of the trimethylphosphane complex (η^5-C_5H_5)Re(NO){$P(CH_3)_3$}(CH_3) was optimized at the level of density functional theory (B3LYP) with the LANL2DZ basis set and an additional set of polarization functions (LANL2DZp) as introduced by Hay and Wadt[26] and implemented in the GAUSSIAN98 program.[27] These results are fully described elsewhere.[26] Next, the phosphorus methyl groups were replaced by C_6H_5, 4-C_6H_4F, and C_6F_5 groups, keeping all geometric features of the (η^5-C_5H_5)Re(NO)(P)(CH_3) entity constant. Note that the second series features *para*-fluorine atoms, as opposed to the larger CF_3 groups of the compounds in Scheme 1.

The PPh_3, P(4-C_6H_4F)$_3$, and P(C_6F_5)$_3$ entities were partially optimized at the HF/LANL2DZ level. The rhenium−phosphorus conformations were allowed to vary, but the HCCC and FCCC torsion angles were fixed at 180.0° − in other words, planar arene rings. This approximation is justified by unpublished results with the hydride complex (η^5-C_5H_5)Re(NO)(PPh_3)(H), for which we have done a full structure optimization and find essentially planar phenyl rings. Next, the methyl groups were replaced by a positive charge, and the orbital energies of the resulting rhenium Lewis acids **I**, **I**-F_3 [roughly equivalent to **I**-$(CF_3)_3$], and **I**-F_{15} calculated**.**

Key data are summarized in Table 2. As would have been intuitively predicted, both the HOMO and LUMO energies decrease with increasing numbers of fluorine atoms. The HOMO energies decrease to a greater extent, indicating that major effect of the fluorine atoms is to diminish π basicity. However, the LUMO energy decrease is still significant, indicating a large enhancement of σ acidity. A mathematical consequence is that the HOMO/LUMO gap steadily *in*creases. Not surprisingly, the energies of other orbitals decrease with increasing fluorine substitution.

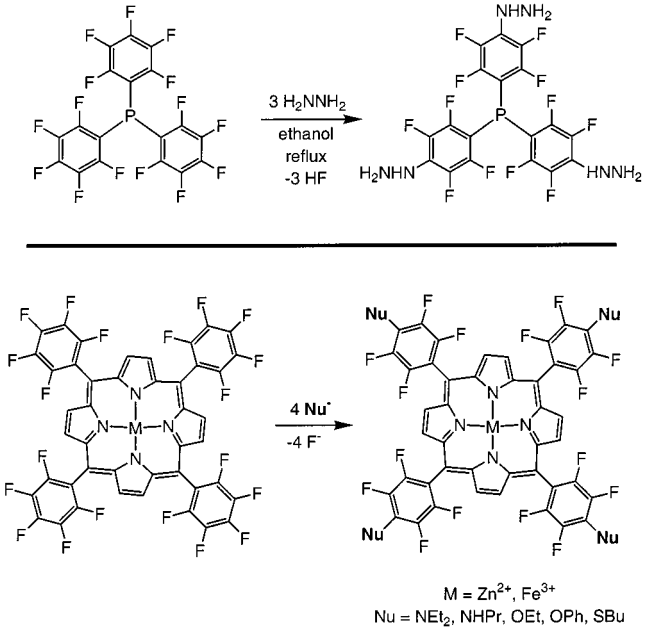
Table 2. Frontier orbital energies [eV] (HF/LANL2DZp) of the chiral Lewis acids

Orbital	Lewis acid		
	I	**I**−$(CF_3)_3$	**I**−F_{15}
LUMO+1	−1.15	−1.82	−2.19
LUMO	**−3.50**	**−4.09**	**−4.28**
HOMO	**−11.87**	**−12.67**	**−13.42**
HOMO−1	−11.93	−12.86	−13.53
HOMO−2	−12.21	−13.02	−13.80
Δ(LUMO − HOMO)	**8.37**	**8.58**	**9.14**

Discussion

A number of conclusions can be drawn from the above data. With regard to the original objective of this study, the chiral rhenium Lewis acid **I** will clearly require *more* than three highly electronegative aryl substituents in order to activate unsaturated ligands to a broader range of nucleophilic additions. The IR and computational data indicate that **I**-F_{15} should be much more activating than **I**-$(CF_3)_3$, where we had only negative results. However, Scheme 2 shows that this system is prone to nucleophilic displacement of the *para*-fluorine atoms in the aryl rings, a process with much precedent in the organofluorine literature.[23,24] One solution would be to seek substitution-resistant analogs, perhaps with *para*-CF_3 or -$C(CF_3)_3$ groups. The bulk of the latter might help to retard the possible nucleophilic displacement of fluorine atoms at other positions (*ortho*, *meta*).

Despite its markedly attenuated basicity, the perfluorinated phosphane P(C_6F_5)$_3$ has an extensive coordination chemistry.[28] However, to the best of our knowledge, none of these complexes has ever been observed to undergo nucleophilic aromatic substitution. Nonetheless, threefold substitutions do occur with the free ligand.[24a] As shown in Scheme 3, P(C_6F_5)$_3$ and hydrazine cleanly react in refluxing ethanol to give a tris(hydrazino) product. Under analogous conditions, substituted hydrazines gave only partial substitution. Reactions with alkoxides occur at room temperature, but are much more complex. In the case of $NaOCH_3$, the major products are derived from phosphorus−carbon bond cleavage, although the threefold substitution product P(4-$C_6F_4OCH_3$)$_3$ can be isolated in 20% yield.[24a] Thus, the rhenium Lewis acid **I**-F_{15} activates the *para*-fluorine atoms of P(C_6F_5)$_3$ towards substitution.



Scheme 3. Some relevant previously reported reactions

Metal-mediated carbon−fluorine bond activation is of particular current interest.[29] We are aware of only one other paper describing nucleophilic aromatic substitutions of σ-pentafluorophenyl groups in metal coordination spheres. The (porphyrin)zinc and -iron compounds illustrated in Scheme 3 (bottom) undergo clean fourfold substitutions with a variety of nucleophiles.[24b] The successful application of sulfur nucleophiles in both this system and ours suggests new ways by which metal complexes might be anchored to thiophilic gold surfaces.

If problems with nucleophilic aromatic substitution can be solved, there are potential advantages associated with perfluorinated triarylphosphanes in chiral transition metal Lewis acids. For instance, many examples of strongly attractive π-stacking interactions between perfluoroarenes and non-fluorinated analogs have recently been documented.[30] This might be a very effective control element for some types of enantioselective reactions. Indeed, Ojima has investigated transformations of various adducts the pentafluorinated iron Lewis acid $[(\eta^5\text{-}C_5H_5)Fe(CO)\{P(C_6H_5)_2C_6F_5\}]^+$.[31] This is approximately isostructural to our Lewis acids **I** and **I**-F_{15}, but with just one pentafluorophenyl ring. He often found improved stereoselectivities as compared to the non-fluorinated homolog $[(\eta^5\text{-}C_5H_5)Fe(CO)\{P(C_6H_5)_3\}]^+$. This was attributed to π interactions involving the fluorinated ring.

As noted in the introduction, the Lewis acid **I** might also be modified on the cyclopentadienyl ligand. Indeed, we have reported a number of more electron-rich alkylated derivatives.[32] From a synthesis standpoint, it would be relatively straight-forward to pursue a "tandem activation" strategy. Regardless, this paper concludes our investigations of new types of chiral rhenium Lewis acids that were begun in the USA. Future publications will describe new initiatives that were conceived and fully executed in our new laboratory in Franconia.

Experimental Section

General Data: All reactions were carried out under dry nitrogen using conventional Schlenk techniques. Analytical data were recorded with standard instruments, some of which were described in a previous paper.[17] Rather than enumerate the many small differences between the two locations in which this work was conducted, readers are referred to two dissertations.[33] − Solvents were treated as follows: acetone, distilled from P_2O_5; CH_3CN distilled from P_2O_5; CH_2Cl_2, distilled from Sicapent® (Fluka); ether, distilled from CaH_2; hexane, distilled from K; methanol, distilled from Mg; [D_6]acetone, stored over molecular sieves (4 Å). The imine $H_3CN{=}C(H)C_6H_5$ (Aldrich) was vacuum-distilled, $NaSCH_3$ was used as received (Fluka), and $P(4\text{-}C_6H_4CF_3)_3$ and $P(C_6F_5)_3$ were used as received (Strem) or prepared by literature procedures.[33b,34] Other solvents and reagents were used as received from common commercial sources.

$[(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(CO)]^+BF_4^-$ (3). − A: A Schlenk flask was charged with $[(\eta^5\text{-}C_5H_5)Re(NO)(NCCH_3)(CO)]^+BF_4^-$ (**1**;[11] 0.194 g, 0.429 mmol) and fitted with a condenser that was joined to an N_2 line/oil bubbler. Ethyl methyl ketone (20 mL) was added. The solution was refluxed (oil bath) with stirring for 46 h, and allowed to cool. Hexane (ca. 200 mL) was added. The yellow solid was collected by filtration, washed with pentane (20 mL), and dried by oil pump vacuum to give **3** (0.313 g, 0.363 mmol, 85%). − **B:** A Schlenk flask was charged with $(\eta^5\text{-}C_5H_5)Re(CO)_2\{P(4\text{-}C_6H_4CF_3)_3\}$ (preparation below; 1.121 g, 1.449 mmol) and CH_2Cl_2 (50 mL), and cooled to 0 °C. Solid $NO^+BF_4^-$ (0.204 g, 1.74 mmol; freshly washed with 20 mL of CH_2Cl_2) was added with stirring. The ice bath was allowed to warm. After 30 h, solvent was removed by rotary evaporation. THF (250 mL) was added. The bright yellow powder was collected on a frit to give $[(\eta^5\text{-}C_5H_5)Re(NO)(CO)_2]^+ BF_4^-$ (0.274 g, 0.647 mmol, 45%).[11] The filtrate was concentrated (ca. 2 mL), and hexane (50 mL) was added. The yellow solid was collected on a frit, washed with CH_2Cl_2/hexane (20 mL, 20:80 v/v) and pentane (20 mL), and dried by oil pump vacuum to give **3** (0.545 g, 0.632 mmol, 44%), m.p. 236−237 °C (dec.). − $C_{27}H_{17}BF_{13}NO_2PRe$ (862.4): calcd. C 37.60, H 1.99; found C 37.04, H 2.01. − IR (cm^{-1}, CH_2Cl_2/KBr): $\tilde{\nu}_{CO}$: 2027/2031 (s); $\tilde{\nu}_{NO}$: 1772/1772 (s). − NMR (δ, CD_3CN):[35] ^1H: 7.95−7.86 (m, 6 H of 3 C_6H_4), 7.63−7.52 (m, 6 H of 3 C_6H_4), 5.96 (s, C_5H_5); $^{13}C\{^1H\}$: 194.4 (d, $^2J_{CP}$ = 8.6, CO), 135.2 (d, $^2J_{CP}$ = 12.3, *o*-C_6H_4), 135.1 (d, $^1J_{CP}$ = 58.9, *i*-C_6H_4), 134.6 (qd, $^2J_{CF}$ = 33, $^4J_{CP}$ = 3, *p*-C_6H_4), 127.6 (qd, $^3J_{CF}$ = 3.9, $^3J_{CP}$ = 11.9, *m*-C_6H_4), 124.5 (q, $^1J_{CF}$ = 272, CF_3), 96.1 (s, C_5H_5); $^{31}P\{^1H\}$: 14.4 (s).

Reduction of 3: A Schlenk flask was charged with **3** (0.114 g, 0.132 mmol), THF (20 mL), and $NaBH_4$ (0.015 g, 0.40 mmol). The mixture was stirred for 2 h, and solvent was removed by oil pump vacuum. Benzene (100 mL) was added, and the sample was filtered through silica gel. Solvent was removed by rotary evaporation. The residue was dissolved in hexane (50 mL), and the solution was slowly concentrated by rotary evaporation. An orange powder formed, which was collected on a frit and dried under oil pump vacuum to give a 93:7 mixture (0.078 g) of $(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(CH_3)$ (**6**) (0.073 g, 0.093 mmol, 71%) and $(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}(H)$ (**7**) (0.005 g, 0.007 mmol, 5%), m.p. 165−166 °C. − IR (cm^{-1}, THF/hexane): $\tilde{\nu}_{NO}$: 1645/1663 (s). − MS:[36] 763 [**6**$^+$] (100%), 749 [**7**$^+$] (6%), 748 [**6**$^+$ − CH_3] (23%). − NMR (**6**; δ, $CDCl_3$):[35] ^1H: 7.77−7.67 (m, 6 H of 3 C_6H_4), 7.59−7.48 (m, 6 H of 3 C_6H_4), 5.00 (s, C_5H_5), 0.97 (d, $^3J_{CP}$ = 6.1, CH_3); $^{13}C\{^1H\}$: 139.9 (d, $^1J_{CP}$ = 48.6, *i*-C_6H_4), 133.8 (d, $^2J_{CP}$ = 11.1, *o*-C_6H_4), 132.4 (qd, $^2J_{CF}$ = 33, $^4J_{CP}$ = 2, *p*-C_6H_4), 125.5 (qd, $^3J_{CF}$ = 3.7, $^3J_{CP}$ = 10.1, *m*-C_6H_4), 123.5 (q, $^1J_{CF}$ = 273, CF_3), 90.0 (s, C_5H_5), −37.2 (d, $^2J_{CP}$ = 7.0, CH_3); $^{31}P\{^1H\}$: 28.9 (s). − NMR (**7**, partial; δ, $CDCl_3$): ^1H: 5.02 (s, C_5H_5), −9.70 (d, $^2J_{CP}$ = 29.3, ReH); $^{13}C\{^1H\}$: 85.8 (s, C_5H_5); $^{31}P\{^1H\}$: 31.6 (s).

$[(\eta^5\text{-}C_5H_5)Re(NO)\{P(4\text{-}C_6H_4CF_3)_3\}\{N(CH_3){=}C(H)C_6H_5\}]^+TfO^-$ (9): A Schlenk flask was charged with a **6/7** mixture (0.070 g, 0.092 mmol) and toluene (10 mL), and cooled to −45 °C (CH_3CN/CO_2). Then TfOH (0.008 mL, 0.09 mmol) was added dropwise with stirring. After 10 min, $H_3CN{=}C(H)C_6H_5$ (0.056 mL, 0.46 mmol) was added. The flask was placed in a 98 °C bath, and a precipitate began to form. After 9 h, the mixture was cooled to room temperature and hexane (50 mL) was added. The yellow-orange powder was collected by filtration, washed with hexane (10 mL), and dried by oil pump vacuum to give **9** as a 92:8 (*E*)/(*Z*) mixture (0.060 g, 0.059 mmol, 65%), m.p. 238−239 °C (dec.).[37] − $C_{35}H_{26}BF_{12}N_2O_4PReS$ (1026.6): calcd. The sample was stirred to dissolve all **11**, and then cooled to −15 °C (ice/NaCl bath). Then $NaSCH_3$ (0.1056 g, 1.507 mmol) was added with stirring. After 10 min, the yellow precipitate was collected on a glass frit (G3) and dried by oil pump vacuum to give **13** (0.1040 g, 0.108 mmol, 51%), m.p. 140−141 °C (dec.). − $C_{28}H_{17}F_{12}NO_3PReS_3$ (956.8): calcd. 35.15, H 1.79; N 1.46, S 10.05; found C 35.44, H 1.71, N 1.16, S 10.32. − IR (cm^{-1}, powder film): $\tilde{\nu}_{CO}$: 1603 (s); $\tilde{\nu}_{NO}$: 1718 (s). − MS:[36] 958 (2) [**13**$^+$ + H], 926 (100) [**13**$^+$ − OCH_3], 898 (20) [**12**$^+$ − CO_2CH_3], 616 (10) $[P(C_6F_4SCH_3)_3]^+$. − NMR (δ, $CDCl_3$):[35] ^1H: 5.40 (s, C_5H_5), 3.25 (s, OCH_3), 2.62 (br. s, $w_{1/2}$ = 4 Hz, 3 SCH_3); $^{13}C\{^1H\}$: 190.1 (d, $^2J_{CP}$ = 13, CO_2CH_3), 146.3 (dm, $^1J_{CF}$ = 254.2, *m*-C_6F_4), 146.1 (dm, $^1J_{CF}$ = 253.4, *o*-C_6F_4), 121.6 (t, $^2J_{CF}$ = 18.1, *p*-C_6F_4), 111.0 (m, *i*-C_6F_4), 94.0 (s, C_5H_5), 49.5 (s, OCH_3), 17.0 (t, $^4J_{CF}$ = 4.8, SCH_3); $^{31}P\{^1H\}$: −34.1 (br s, $w_{1/2}$ = 26 Hz).

(η^5-C_5H_5)Re(NO){P(C_6F_5)$_3$}(CH_3) (14): A Schlenk flask was charged with **11** (0.300 g, 0.323 mmol) and THF (15 mL) and (as an extra precaution) freeze-pump-thaw degassed (3 ×). Then $NaBH_4$ (0.026 g, 0.69 mmol) was added with stirring. After 10 min, the THF was removed by oil pump vacuum. Benzene (10 mL) was added, and the sample was filtered through a short silica gel plug on a glass frit (G3). Solvent was removed from the filtrate by rotary evaporation and oil pump vacuum to give **14** as an orange powder (0.241 g, 0.291 mmol, 90%) that still contained benzene (see text). The sample was suspended in cold pentane (10 mL), and analogously collected by filtration and dried. This gave **14** with less but still detectable residual solvent (0.225 g, 0.175 mmol, 84%), m.p. 141−143 °C (dec.). − $C_{24}H_8F_{15}NOPRe$ (828.5): calcd. C 34.79, H 0.97, N 1.69; found C 35.79, H 1.32, N 1.75. − IR (cm^{-1}, powder film): $\tilde{\nu}_{NO}$: 1687 (s). − MS:[36] 829 (100) [**14**$^+$], 297 (90) $[(C_5H_5)Re(NO)(CH_3)]^+$. − NMR (δ, [D$_6$]acetone):[35] ^1H: 5.28 (s, C_5H_5), 0.76 (d, $^3J_{HP}$ = 9.5, CH_3); $^{13}C\{^1H\}$: 147.9 (dm, $^1J_{CF}$ = 254.8, *m*-C_6F_5), 144.2 (dm, $^1J_{CF}$ = 250.3, *p*-C_6F_5), 138.6 (dm, $^1J_{CF}$ = 254.7, *o*-C_6F_5), 109.7 (m, *i*-C_6F_5),[39] 93.3 (s, C_5H_5), −33.1 (d, J_{CP} = 7.1, CH_3); $^{31}P\{^1H\}$: −26.5 (br s, $w_{1/2}$ = 16 Hz).

(η^5-C_5H_5)Re(CO)$_2${P(4-$C_6H_4CF_3$)$_3$} (4): A quartz tube was charged with (η^5-C_5H_5)$Re(CO)_3$ (0.584 g, 1.74 mmol)[11] and THF (250 mL), and placed in an ice/water bath. The solution was irradiated with a 450-W Hanovia high-pressure mercury-vapor lamp. The sample was continuously stirred and purged with N_2. The formation of (η^5-C_5H_5)$Re(CO)_2(THF)$[12a] was verified by IR ($\tilde{\nu}_{CO}$: 1908, 1836 cm^{-1}). After 3 h, the lamp was turned off and P(4-$C_6H_4CF_3$)$_3$ (1.01 g, 2.17 mmol) was added to the brown solution. After 72 h, solvent was removed by oil pump vacuum. Hexane (ca. 200 mL) was added, and the mixture was filtered through Celite. The filtrate was slowly concentrated by rotary evaporation. Off-white crystals formed, which were collected by filtration, washed with pentane, and dried by oil pump vacuum to give **4** (0.442 g, 0.580 mmol, 33%), m.p. 187−188 °C (dec.). − $C_{28}H_{17}F_9O_2PRe$ (773.6): calcd. C 43.47, H 2.21; found C 43.27, H 2.26. − IR (cm^{-1}, THF/CH_2Cl_2): $\tilde{\nu}_{CO}$: 1938/1937 (s), 1874/1869 (s). − NMR (δ, $CDCl_3$):[35] ^1H: 7.72−7.65 (m, 6 H of 3 C_6H_4), 7.58−7.47 (m, 6 H of 3 C_6H_4), 5.00 (s, C_5H_5); $^{13}C\{^1H\}$: 200.8 (d, $^2J_{CP}$ = 8.5, 2CO), 141.3 (d, $^1J_{CP}$ = 50.0, *i*-C_6H_4), 132.2 (d, $^2J_{CP}$ = 10.0, *o*-C_6H_4), 132.2 (qd, $^2J_{CF}$ = 33, $^4J_{CP}$ = 2, *p*-C_6H_4), 125.3 (qd, $^3J_{CF}$ = 3.7, $^3J_{CP}$ = 10.5, *m*-C_6H_4), 123.5 (q, $^1J_{CF}$ = 273, CF_3), 83.8 (s, C_5H_5); $^{31}P\{^1H\}$: 33.9 (s).

Vanadium(IV and V) Complexes Containing *SNO* (Dithiocarbonylhydrazone; Thiosemicarbazone) Donor Sets

Dongren Wang,[a] Martin Ebel,[a] Carola Schulzke,[a] Cerstin Grüning,[a] Saroj K. S. Hazari,[b] and Dieter Rehder*[a]

Keywords: Vanadium / Thiosemicarbazones / Thiohydrazones / Sulfur coordination / Biomimetic compounds

The VO^{2+} complexes [VOCl(*ONS*)] (**3**) and [VO(*ONS*)′] (**4**), and the VO^{3+} complexes [VO(OEt)(*ONS*)′] (**5**) {*ONS* = (*R*)-salicylaldehyde thiosemicarbazonate(1–) R = 5,6-C_4H_4 (**3a**) or 3-OMe (**3b**); (*ONS*)′ = (*R*)-salicylaldehyde[benzylmercaptothiocarbonylhydrazonate(2–)], R = H, (**4a/5a**) or 3-OMe (**4b/5b**)} have been prepared and characterised by IR, EPR, ^{1}H-, and ^{51}V-NMR spectroscopy. In (*S*)-*s*BuOH, **4a** converts to [VO{(*S*)-O*s*Bu}(*ONS*)′] (**5c**) and [VO(OH)(*ONS*)′] (or a condensation product thereof). Solutions of **5c** show three ^{51}V NMR signals, two of which are due to two diastereomers. The EPR spectra of **3** and **4** in THF reveal the presence of octahedral species in solution. The crystal and molecular structures of complexes **3a**·$OCMe_2$, **5a**, and **5b** have been obtained, revealing basically a tetragonal pyramid, and coordination of the sulfur function in the thiocarbonyl (**3**) or enethiolate mode (**5**). The relevance of the compounds to bioinorganic aspects is addressed.

Introduction

Vanadium coordination chemistry has attracted increasing interest during the last few years, due to the model character of many vanadium complexes for the biological function of vanadium,[1–5] the use of (oxo)vanadium complexes in oxidation and oxo transfer catalysis,[6,7] and potential medicinal applications such as the treatment of diabetes types I (insulin deficiency) and II (insulin resistance).[8,9] In its biogenic compounds, and in its interactions with biogenic ligand systems, vanadium coordinates to *O*, *N*, and *S* functions. Among the *O* functionalities are phenolate from tyrosine, as in the insulin-mimetic action of vanadium (possibly as a result of the inhibition of a protein tyrosine-phosphatase),[10] as well as dopa and hydroxy-dopa of tunichrome fragments in the vanadocytes of certain species of *Ascidiaceae* (sea squirts).[11] The imine nitrogen atom of histidine is coordinated to vanadate(V) (HVO_4^{2-}) in vanadate-dependent haloperoxidases from marine brown algae such as *Ascophyllum nodosum* (knobbed wrack),[12] and from the mould *Curvularia inaequalis*,[13,14] as well as to $V^{IV/II}$ in the VFe cofactor of the *M* cluster of vanadium-nitrogenase from *Azotobacter*.[15] In the latter case, the coordination sphere of vanadium is complemented by homocitrate and three bridging sulfides. Sulfur coordination, through cysteinate, has also been observed in vanadate-derivatised tyrosine phosphatase,[16] and is likely to be the initiating step in redox inhibition by V^V of enzymes containing cysteine in their active centre.[17] This process has been simulated by the in vitro oxidation of thiolates to disulfides.[18,19] As far as the use of vanadium-based catalyst systems in oxidation/oxygenation reactions is concerned, the conversion of sulfides (thioethers) RR′S to sulfoxides RR′S=O by peroxides is noteworthy, a process that is catalysed in vivo by vanadate-dependent peroxidases,[20,21] and in vitro by vanadium complexes containing *ONO* donor sets,[22–24] where *N* is an amine or imine function, and *O* a phenolic or alcoholic oxygen atom. The enantioselectivity of these reactions suggests an intermediate coordination of the sulfide to the vanadium centre, thus giving rise to an intermediate coordination sphere comprising *S*, *N*, and *O*.

Against this background, we are investigating vanadium complexes with *SNO* functional ligands such as thiosemicarbazones and mercaptothiocarbonylhydrazones with salicylaldehydes as the carbonyl component (Scheme 1). Sulfur coordination of these ligand systems occurs through the doubly bonded thio group in the case of the semicarbazones **1**, and through the thiolate group of the enthiol tautomer in the case of the hydrazones **2**, providing, in the latter case, rare examples[25–30] of redox-stable V^V complexes with thiolate coordination. The hydrazones **2** with a "masked" thiolate function are employed advantageously for coordination to vanadium(V), since they resist the otherwise common oxidation of thiolates to disulfides by V^V.

Thio coordination to vanadium is additionally of interest with respect to the insulin-mimetic potential of vanadyl dithiocarbamates.[31] More generally, metal complexes of thiosemicarbazones have also been discussed in the context of their antibacterial and antifungal properties.[32,33]

Results and Discussion

Preparation and Characteristics

The vanadium complexes were prepared as described by Equations (1) to (3) in THF [**3**; Equation (1)] and in eth-

anol/water [**4**, Equation (2), and **5**, Equation (3)], respectively, under either an inert gas (**3** and **4**) or under aerobic conditions (**5**). An acetate buffer was used to capture the protons generated in Equation (2).

$$[VOCl_2(thf)_2] + H\mathbf{1} \rightarrow \underset{\mathbf{3}}{[VOCl(\mathbf{1})]} + [Hthf]Cl \quad (1)$$

$$VO^{2+} + H_2\mathbf{2} \rightarrow \underset{\mathbf{4}}{[VO(\mathbf{2})]} + 2H^+ \quad (2)$$

$$2[VO(\mathbf{2})] + \tfrac{1}{2}O_2 + 2EtOH \rightarrow \underset{\mathbf{5a/b}}{2[VO(\mathbf{2})OEt]} + H_2O \quad (3)$$

The green complexes **3a** and **3b** were isolated as the THF and water adducts (**3a**·$^3/_4$THF and **3b**·$^1/_2H_2O$·$^1/_2$THF), respectively, the complexes **4a** and **4b** with varying amounts of solvent, viz. **4a**·EtOH, **4a**·$^1/_4H_2O$, and **4b**·H_2O. Crystals of **3a** were obtained as **3a**·$OCMe_2$ from acetone. Complexes **5a** and **5b** were free of coordinated solvent or solvent of crystallisation, and thus differ from the related hydrazone complex [VO(OMe)(*SNO*)′′(HOMe)], where (*SNO*)′′ is salicylaldehyde-thiobenzoylhydrazone.[34] Spectroscopic data are summarised in Table 1 and Table 2. All of the complexes show the IR bands characteristic of ν(−HC=N−) (around 1600 cm^{-1}) and ν(V=O) (998−962 cm^{-1}), with the latter usually doubled; cf. Table 1. An additional sharp and intense band observed for the crystals of **3a**·$OCMe_2$ at 1696 cm^{-1} is assigned to ν(C=O) of acetone of crystallisation. The bathochromic shift with respect to free acetone is due to the involvement of the carbonyl group in H bonding interaction with N−NH and C−NH_2 of the semicarbazone ligand, as identified by the X-ray structure analysis (see below). Complex **3a** still shows the ν(NH) (3276 and 3137 cm^{-1}) also present in the free ligand **1a** (3263 and 3165 cm^{-1}), indicating the coordination of the sulfur function in the thiocarbonyl form, a fact that is again corroborated by the structure determination. The corresponding ν(NH) for **1b** and **3b** are 3343 and 3167 cm^{-1}(**1b**), and 3291 and 3189 cm^{-1} (**3b**). The ν(C=S), 1192 in **1a** and 1185 cm^{-1} in **1b**, are slightly weakened on coordination, and thus experience a bathochromic shift to 1148 (**3a**) and 1162 cm^{-1} (**3b**). The complexes **4** and **5** show two resolved ν(C=N) bands, which we attribute to the presence of two C=N double bonds in the enthiolate framework of the hydrazone ligand (see the respective tautomeric form in Scheme 1).

The methine group is also clearly visible by its ^{1}H NMR feature (Table 2) of the diamagnetic complexes **5** (δ = 9.08); the methine proton resonances (δ = 7.98 in the free ligands **2**) are thus shifted to low (magnetic) field on coordination of the imine nitrogen atom. The protons of the methylene group of the benzyl substituent on the noncoordinating sulfur atom are only marginally affected. A feature of particular interest is the occurrence of two resonances, for the methylene and methyl protons of the ethyl group, in an intensity ratio of approximately 1:2 for uncoordinated ethanol and coordinated ethanolate, suggesting an equilibrium between ethoxide and hydroxo complex (or its condensation product) as depicted in Equation (4).

$$\begin{aligned} &[VO(OEt)\mathbf{2}] + H_2O \leftrightarrows [VO(OH)\mathbf{2}] + EtOH \\ &\quad\mathbf{5} \\ &2[VO(OH)\mathbf{2}] \leftrightarrows [\{VO(\mathbf{2})\}_2\mu\text{-}O] + H_2O \end{aligned} \quad (4)$$

This situation is also reflected in the ^{51}V NMR spectra, which show two resonances, separated by 51 ppm (**5a**) and 56 ppm (**5b**), with the less intense low-field signal corresponding to the hydroxo (or dimeric, μ-O-bridged) form. This assignment is carried out on the basis of the spectrum obtained after treatment of **4a** with (*S*)-*s*BuOH, which gives rise to the formation of [VO{(*S*)-O*s*Bu}**2a**] (**5c**) with two centres of chirality (V and C_α of the butoxide group) in equilibrium with [VO(OH)**2a**]. Of the two resonances, the less intense one at δ = −347 is a singlet belonging to the

[a] In $CDCl_3$. For the ligands **1a** and **1b**, see Exp. Sect. − [b] Intensity ratio ca.1:2; the first signal corresponds to free ethanol.

butoxide-free complex, while the more intense to higher field is doubled and belongs to **5c**. The separation between the two components of this signal, δ = −411.3 and −414.2, is within the range expected for the signal splitting for a vanadium compound being present as two diastereomeric pairs of enantiomers.[35,36] The ^{51}V chemical shifts are in the range expected for a donor set containing one sulfur function, i.e. to low field by about 150 to 200 ppm with respect to complexes with O_xN_y donor sets.[37]

The EPR spectrum of crystals of **3a**·$OCMe_2$ dissolved in THF exhibits the isotropic eight-line pattern typical of VO^{2+} complexes [$S = {}^1/_2$, $I(^{51}V) = {}^7/_2$]. Along with the main species in this spectrum, characterised by a hyper-fine coupling constant $A_0 = 93.7\cdot10^{-4}$ cm^{-1}, there is a second species with a rather high value ($A_0 = 101.0\cdot10^{-4}$ cm^{-1}). This situation is also revealed by the anisotropic spectrum in frozen THF solution (Figure 1), which is a superposition of the parallel (*z*) and perpendicular (*xy*) parts of the main (*1*) and the minor component (*2*). The A_z values are $A_z^{(1)} = 161\cdot10^{-4}$ and $A_z^{(2)} = 173\cdot10^{-4}$ cm^{-1}. Based on the additivity relationship $A_z = \Sigma n_i A_{zi}$ (n_i denotes the nature of the four equatorial ligand functions, and A_{zi} are the corresponding contributions to A_z),[38] a value of $161\cdot10^{-4}$ cm^{-1} is in agreement with an equatorial *ClONS* donor set in **3a**, while a value of $173\cdot10^{-4}$ cm^{-1} should indicate addition of an oxygen-functional ligand L in solution, such as THF, possibly accompanied by a rearrangement of the tridentate ligand so as to place the sulfur donor atom into an axial position.

Taking 45.7 and $33.9\cdot10^{-4}$ cm^{-1} as the contributions of a relatively weak *O* donor such as THF[39] and the thiocarbonyl function, respectively, a calculated value of $A_z^{(2)} = 172.8\cdot10^{-4}$ cm^{-1} is obtained, in very good agreement with the found coupling constant of $173\cdot10^{-4}$ cm^{-1}. We hence suggest an equilibrium as depicted in Equation (5), where species *1* is represented by **3a** and species *2* by *trans*-**3a(L)**, where *trans* denotes the position of S in the axial position (*trans* to the doubly bonded oxo ligand). In THF solutions, L would presumably be THF.

Since the same pattern arises in the isotropic spectrum of a solution of **3a**·$OCMe_2$ in CH_2Cl_2, where the compound is but sparingly soluble, L appears to be acetone in this solvent. In principal, the EPR of the vanillin derivative **3b** compares well with that of **3a**, in that there are two components *1* and *2* present in the spectrum. The ratio is, however inverse, i.e. compound *2* corresponding to the species with the larger coupling constant, **3b(L)**, is the major component. The A_0 and A_z values for **4a** and **4b** are somewhat larger (Table 1) than those for the tetragonal-pyramidal species *1* of **3a** and **3b**, in accord[40] with an octahedral coordination in solution and the equatorial plane dominated by strongly electronegative ligand functions in the case of **4**, which thus corresponds to **3(L)**. Again, the sixth position in the coordination polyhedron of THF solutions of **4** is supposed to be occupied by THF.

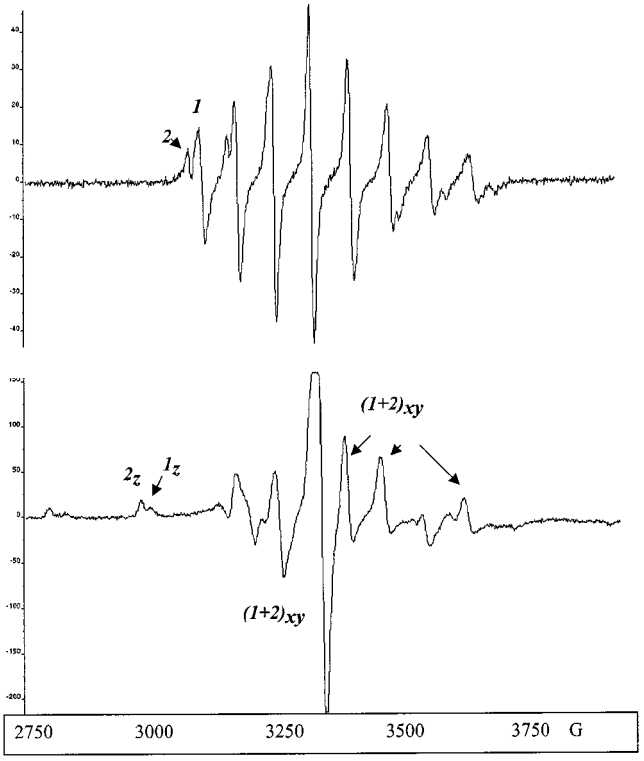

Figure 1. EPR spectrum of **3a** in THF solution at room temperature (top) and at 100 K; the *z* (parallel) and *xy* (perpendicular) components are indicated, as are the two species *1* and *2* present in solution; cf. Equation (4)

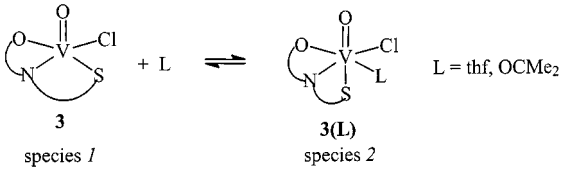

(5)

Structure Descriptions

Selected bond lengths and bond angles are given in Table 3. In the V^{IV} (VO^{2+}) thiosemicarbazone complex **3a**, vanadium is basically in a tetragonal-pyramidal environment (Figure 2) with the doubly bonded oxo group O1 of the vanadyl moiety in the apical position, and the chloro

ligand, O2, N1, and S3 of the tridentate thiosemicarbazone ligand in the plane. There is a sizeable distortion towards a trigonal bipyramid, quantified by a τ value of 0.28, where τ is defined by $\tau = [(O2-V-N1) - (O3-V-S2)]/60$; $\tau = 0$ for ideal tetragonal pyramids, and $\tau = 1$ in the case of an ideal trigonal bipyramid. The S3−C12 bond [1.708(3) Å] is significantly shorter than in most structurally characterised Ni and Cu complexes with comparable ligands (ca. 1.73−1.76 Å[39,41−44]), indicating coordination of the ligand through a thiocarbonyl rather than through an enthiolate in the case of **3a**, and is thus in agreement with thiosemicarbazones coordinated to early transition metals such as Cr[45] and Mo.[46] This view is corroborated by the localisation of the hydrogen atom on the nonbonding N2, which is linked by an intermolecular hydrogen bond to the carbonyl oxygen atom O3 of acetone of crystallisation; *d*(O3···H−N2) = 2.154 Å. Further intermolecular hydrogen bonds exist between the hydrogen atoms on the primary amine group (N3) and O3 [*d*(O3···H−N3) = 2.02] and the phenolate oxygen atom O2 [*d*(O2···H−N3) = 2.019 Å]. The hydrogen bonding network is shown in Figure 2 (bottom).

Other bonding parameters within the ligand system are comparable to those in thiosemicarbazone complexes of other metals.[38−46] The bond lengths between the vanadium centre and the three ligand functions also compare to those of the vanadium-*ONS* complex [V(nap-amtph)$_2$], where nap-amtph is the Schiff base formed between *o*-hydroxynaphthaldehyde and *o*-aminothiophenol,[47] and to [V(mpg)*o*-phen] [H_3mpg = *N*-(2-mercaptopropionyl)glycine]. In all these complexes [as in the hydrazone complexes **5** (see below)] the V−S bond lengths [**3a**: 2.358(1), [V(nap-amtph)$_2$]: 2.306(2) and 2.351(2), [V(mpg)*o*-phen]: 2.3820(14) Å] fall at the short end of the range for *d*(V−S);[47−49] they are also significantly shorter than in the complex [VO(H_2O)L], where H_2L is thiosemicarbazone-diacetate; [*d*(V−S) = 2.435, *d*(V−N) = 2.362 Å].[50] On the other hand, V−S bonds in V^V complexes containing the tetrafunctional trithiolate N($CH_2CH_2S^-$)$_3$ are still shorter (averaging around 2.25 Å[29,30]) than in the aforementioned complexes with *ONS* donor sets. The V−Cl bond in **3a** [2.341(1) Å] again compares to that in other chlorovanadium complexes.[35,51,52]

A tetragonal pyramid is also the basic structure for the V^V (VO^{3+}) thiohydrazone complexes **5a** and **5b** (Figure 3), in which the chloro ligand of the V^{IV} complex **3a** is replaced by an ethanolate moiety, and the tridentate *ONS* acts as a dianionic ligand. The vanadium ion is 0.49 (**5a**) and 0.52 Å (**5b**) above the plane spanned by S2, N1, O2, and O3 (i.e. the tridentate ligand and the ethoxy group). The distortion towards a trigonal bipyramid compares with that of **3a**, i.e. τ = 0.28 (**5a**) and 0.27 (**5b**). As expected for enthiolate (**5**) vs. thiocarbonyl coordination (**3**), the bond lengths *d*(S−C2) in **5** are substantially longer than *d*(S−C12) in **3a**, the *d*(N2−C2) in **5** substantially shorter than *d*(N2−C12) in **3a** (Table 3). In line with this view are the bond angles at N2: (N1−N2−C12) = 118.7(2)° in **3a** is close to the tet-

[a] Same numbering scheme as for **5a**.

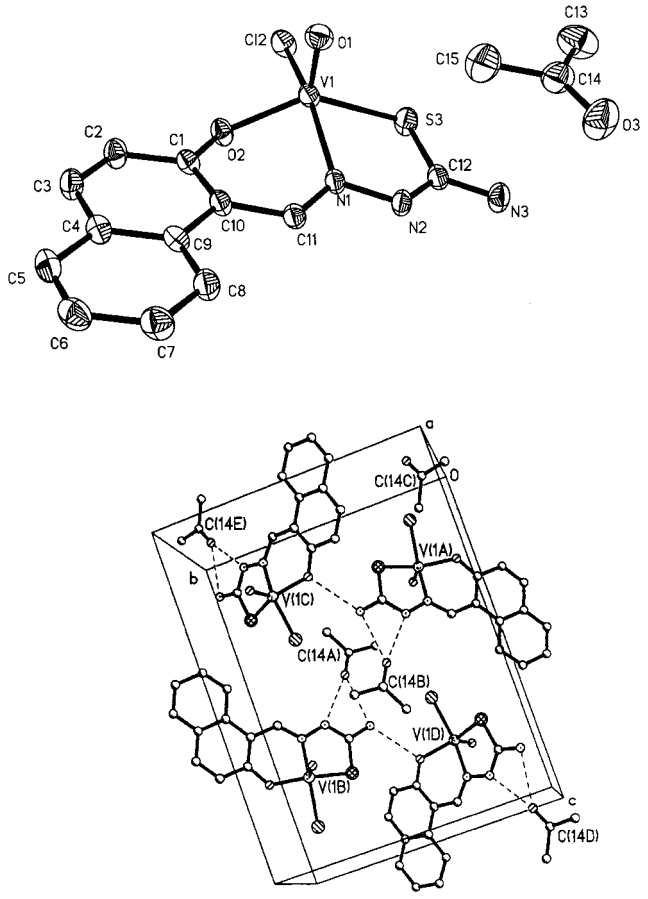

Figure 2. ORTEP plot (at the 50% probability level) and numbering scheme of **3a**·acetone (top), and a representation of the unit cell (bottom) showing the hydrogen bonding network (dashed lines)

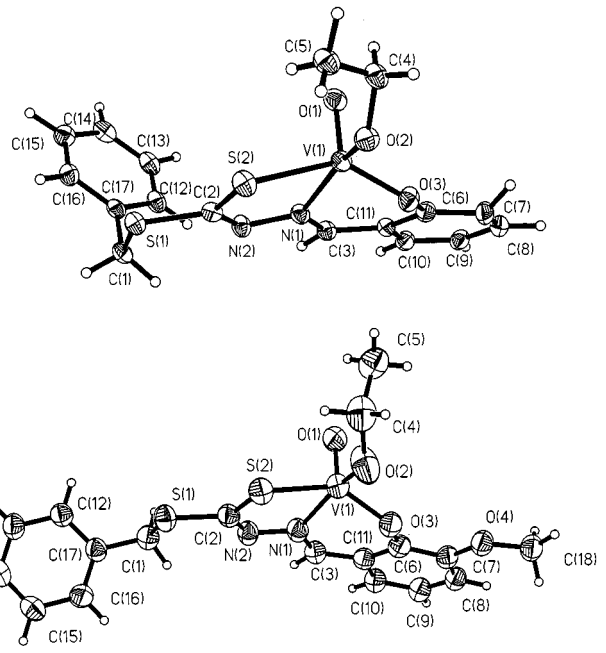

Figure 3. ORTEP plots (50% probability level) and numbering schemes for **5a** (top) and **5b** (bottom)

rahedral angle, while the angles (N1−N2−C2) = 112.5(3) (**5a**) and 112.2(5)° (**5b**) are close to that for trigonal planar geometry. The exchange of chloride in **3a** for ethanolate in **5** does not effect *d*(V−N1) *trans* to the negatively charged ligand, while the V−O(phenolate) bond is clearly shorter in **5** than in **3a**, and also shorter than in other structurally characterised early transition metal (Cr and Mo) complexes with a similar donor set,[45,46] or in Schiff base oxovanadium complexes with a salicylaldehyde moiety.[53] The reason for these unprecedentedly short V−O(phenolate) bonds, which approach the lengths otherwise observed with V−O(alcoholate) bonds [1.80 to 1.74 Å,[54] cf. also the respective data for *d*(V−O2) in Table 3], may be traced back to a strengthening of this bond as a result of comparatively weak bonding interaction between V^V and the soft thiolate opposite the hard phenolate oxygen.

The bicyclic system formed between the vanadium centre and the tridentate ligand is slightly folded along the V−N1 axis: The angles between the planes V−O3−C6−C11−C3−N1 and V−N1−N2−C2−S2 amount to 16.92(15) (**5a**) and 20.41(22)° (**5b**). The planes by themselves are not ideal, with the largest deviations encountered with V1 (−0.228) and O3 (0.252 Å) in the plane V−O3−C6−C11−C3−N1 of **5a**. Despite of the similarities between **5a** and **5b**, the only difference being the presence of a methoxy substituent on the aldehyde component in **5b**, the arrangement of the outer spheres of these complexes exhibits specific differences; Figure 3. While, in **5b**, the benzyl moiety stretches towards the periphery and the ethanolate is bent off the V=O group, the benzyl and ethoxide groups in **5a** are arranged so as to provide a large open cavity approximately 8.3 Å across.

Experimental Section

Starting materials were obtained from commercial sources [thiosemicarbazone, salicylaldehyde, 2-hydroxynaphthalenecarbaldehyde, *o*-vanillin, hydrazine hydrate (99−100%), and oxovanadium sulfate pentahydrate]. $[VOCl_2(thf)_2]$ was prepared according to a literature procedure.[55]

Physical Measurements: IR spectra were obtained as KBr pellets with a Perkin−Elmer spectrometer 1720 FT. − NMR spectra were recorded with a Bruker AM 360 or Varian Gemini 200 BB spectrometer with the usual spectrometer settings. All $\delta(^{51}V)$ values are referenced against $VOCl_3$. − EPR spectra were measured with a Bruker ESP 300E spectrometer at 9.74 GHz in 1−5 mM solutions. ^1H and ^{51}V NMR, EPR, and selected IR data for the complexes are collated in Table 1 and Table 2 in the Discussion. − X-ray structure analyses were carried out in the θ/2θ scan mode with an Enraf−Nonius CAD4 diffractometer with monochromated (graphite monochromator) Cu-K_α irradiation (λ = 1.54178 Å). The hydrogen atoms on N2 and N3 of **3a**·$OCMe_2$ were located; all other hydrogen atoms were placed into calculated positions and included with isotropic displacement factors in the last cycles of the structure refinements. The program packages SHELXS 86[56] and SHELXL 93[57] were used throughout. Absorption corrections (DIFABS) were carried out. Crystal data and data for the structure solutions and refinements are collated in Table 4. Crystallographic data (excluding structure factors) for the structures reported in this

2-Hydroxynaphthalene-1-carbaldehyde Thiosemicarbazone (H1a), and 6-Methoxysalicylaldehyde Thiosemicarbazone (H1b): These ligands were synthesised in analogy to the procedure of Poruhit et al.[58] For the preparation of H**1a**, a hot solution of thiosemicarbazone (2.25 g, 25 mmol) in 20 mL of ethanol was treated with 2-hydroxynaphthalenecarbaldehyde (4.31 g, 25 mmol) in 20 mL of ethanol, and the mixture was gently heated under reflux for 4 h. It was then cooled down to room temp., the precipitate collected by filtration, washed with ethanol and dried in vacuo. Yield 3.44 g (60%). − $C_{12}H_{12}N_3OS$ (246.31): calcd. C 58.76, H 4.52, N 17.14; found C 58.44, H 4.63, N 17.09. − H**1b** was obtained with a yield of 7.14 g (74%) in an analogous manner from thiosemicarbazone (4.50 g, 50 mL, dissolved in 20 mL of ethanol) and *o*-vanillin (7.60 g, 50 mmol, dissolved in 10 mL of ethanol) after 2 h of heating under reflux. − $C_9H_{11}N_3O_2S$ (225.27): calcd. C 47.99, H 4.90, N 18.66; found C 47.60, H 5.22, N 18.21. − ^{1}H NMR: δ (THF) [multiplicity, J Hz] = 10.71 and 10.57 (NH, NH$_2$); 9.03 (N=CH); 8.15 [d, 8.5], 7.807 [d, 9.0] and 7.79 [dd, 6.8], 7.51 [tt, 7.7 and 1.3], 7.37 [tt, 7.1], 7.14 [d, 9.0] (aromatic H).

Salicylaldehyde- and 6-Methoxysalicylaldehyde [(Benzylmercapto)-thiocarbonyl]hydrazone ($H_2$2a and $H_2$2b): The ligands were prepared by condensation of benzylmercaptothiocarbonylhydrazine (benzyl dithiacarbazate) and salicylaldehyde or *o*-vanillin.[59] Benzylmercaptothiocarbonylhydrazine (3.97 g, 20 mmol) and salicylaldehyde/vanillin (2.0 mL/3.05 g, 20 mmol), dissolved in 100/150 mL of ethanol, were heated under reflux for 90 min. The ligands separated in the form of pale yellow crystals on cooling the solution to room temp. Yield for H_2**2a**/H_2**2b** after recrystallisation from ethanol: 4.65/4.31 g (75/65%). The precursor benzylmercaptothiocarbonylhydrazine was prepared as follows: KOH (22.9 g) was dissolved in 140 mL of 90% ethanol and treated with 20 mL of hydrazine hydrate. The mixture was cooled in an ice bath to 8−10 °C, and 25 mL of CS_2 was added dropwise with stirring. The orange-yellow oil that formed was separated with a separating funnel and redissolved in 120 mL of precooled 40% ethanol, and the solution placed in an ice bath. Benzoyl chloride (50 mL) was then added with vigorous stirring. The ester separated as a white solid, which was filtered off and recrystallised from toluene and ethanol to yield 11.11 g of dry product. Additional 4.46 g of the compound was obtained by adding water to the filtrate and workup of the resulting precipitate. Overall yield 19%.

[VOCl(1a)] (3a) and [VOCl(1b)] (3b). − 3a: To a stirred solution of H**1a** (0.25 g, 1.0 mmol) in 20 mL of THF was added [$VOCl_2$(thf)$_2$] (0.28 g, 1.0 mmol) in 15 mL of THF. The resulting green solution was stirred at room temp. for 2 h. The green compound that separated was filtered off, washed with THF and then with *n*-pentane, and dried in vacuo. Yield 0.19 g (50%). − Analysis for **3a**·$^3/_4$THF: $C_{12}H_{10}ClN_3O_2SV\cdot{}^3/_4$THF (400.76): calcd. C 44.96, H 4.02, N 10.48, V, 12.71; found C 44.74, H 4.26, N 10.32, V 12.68. − IR (KBr): $\tilde{\nu}$/cm^{-1} = 3131, (NH), 1618 (C=N), 1541 (NH), 995 (V=O). −Crystals of **3a**·acetone suitable for the X-ray analysis were obtained by allowing an acetone solution of **3a** to slowly concentrate at room temperature. − **3b** was prepared in an analogous manner to **3a** from [$VOCl_2$(thf)$_2$] (0.28 g, 1.0 mmol) and H**1b** (0.23 g, 1.0 mmol) with a yield of 0.24 g (70%). − $C_9H_{10}ClN_3O_3SV\cdot{}^1/_2$THF·$^1/_2H_2O$ (371.70): calcd. C 35.53, H 4.07, N 11.30; found C 35.38, H 4.06, N 11.14. − IR (KBr): $\tilde{\nu}$/cm^{-1} = 3186 (NH), 1605 (C=N), ca. 980 (V=O).

[VO(2a)]·EtOH (4a·EtOH): The hydrazone H_2**2a** (0.79 g, 2.61 mmol), vanadyl sulfate (0.66 g, 2.61 mmol) and sodium acet-

ate trihydrate (0.71 g, 5.2 mmol) were dissolved in 60 mL of ethanol and stirred under N_2 over night. The green solution was then treated dropwise with 150 mL of N_2-saturated water. A green precipitate of **4a**·EtOH formed, which was filtered off, washed with water and pentane, and dried in vacuo. Yield 0.75 g (70%). − $C_{17}H_{18}N_2O_3S_2V$ (413.40): calcd. C 49.39, H 4.39, N 6.78; found C 49.43, H 4.59, N 6.74. − IR (KBr): $\tilde{\nu}/cm^{-1}$ = 3057/3026 (ArH), 2972 (CH_2), 1625, 1603/1588 (HC=N), 1546 (Ph−C=N), 1280, 1029, 985/967 (V=O), 823, 754, 698 [δ(CH)], 631, 567, 519, 459.

[VO(2a)]·$^1/_4H_2O$ (4a·$^1/_4H_2O$): To a suspension of H_2**2a** (0.76 g, 2.5 mmol) and sodium acetate trihydrate (0.68 g 5 mmol) in 60 mL of ethanol was added (under N_2) dropwise within 5 min a solution of oxovanadium sulfate pentahydrate (0.64 g (2.5 mmol) in 30 mL of water, and the mixture stirred at room temp. until all of the H_2**2a** had been taken up by the green solution (ca. 90 min). Water (90 mL) was added dropwise to precipitate **4a** as a microcrystalline product, which was filtered off, washed thoroughly with water followed by a few mL of pentane, and dried in vacuo. According to the elemental analysis, the green product contained $^1/_4$ mol percent of water. − $C_{15}H_{12}N_2O_2S_2V·^1/_4H_2O$ (371.84): calcd. C 48.45, H 3.39, N 7.53; found C 48.52, H 3.50, N 7.58. − The IR shows essentially the same features as that of **4a·EtOH**.

[VO(2b)]·H_2O (4b·H_2O): The hydrazone H_2**2b** (1.66 g, 5.0 mmol), vanadyl sulfate (1.28 g, 5 mmol), and sodium acetate trihydrate (1.37 g, 10.0 mmol) were dissolved in 50 mL of ethanol and stirred under N_2 overnight. The solution initially turned orange-brown, and a brown precipitate formed. (In more dilute solutions, the amount of precipitate that formed decreased, and the solution exhibited a brown-green colour.) To this suspension, 100 mL of water, degassed and saturated with N_2, was added dropwise and with stirring. The precipitate turned green; it was filtered off, washed with water and pentane, and dried in vacuo. Yield 1.40 g (69%). − $C_{16}H_{16}N_2O_4S_2V$ (415.38): calcd. C 46.27, H 3.88, N 6.74; found C 46.65, H 3.76, N 6.77. − IR (KBr): $\tilde{\nu}/cm^{-1}$ = 3084, 3061, 3030 (ArH), 2848 (OMe), 1602/1686 (HC=N), 1553 (Ph−C=N), 1299, 1255, 1110, 991/977 (V=O), 768, 735, 693, 606, 515.

[VO(OEt)2a] (5a), and [VO(OEt)2b] (5b): Complex **4a**·EtOH or **4b**·H_2O was heated under reflux in ethanol for 3−4 h (no inert gas). The brown to dusky brown products were separated and dried in vacuo. − **5a**: $C_{17}H_{18}N_2O_3S_2V$ (413.40): calcd. C 49.39, H 4.39, N 6.78; found C 49.43, H 4.59, N 6.74. − IR (KBr): $\tilde{\nu}/cm^{-1}$ = 3023 (ArH), 2974, 2922, 2860 (CH_2), 1602/1590 (HC=N), 1550 (Ph−C=N), 1275, 1028, 1004, 984/962 (V=O), 914, 909, 834, 765, 696 [δ(CH)], 645, 537, 519, 459. − **5b**: $C_{18}H_{19}N_2O_4S_2V$ (442.42): calcd. C 48.87, H 4.33, N 6.33; found C 45.99, H 4.14, N 6.45. − IR (KBr): $\tilde{\nu}/cm^{-1}$ = 3028 (ArH), 2983, 2934, 2832 (CH_2), 1600/1589 (HC=N), 1555 (Ph−C=N), 1285, 1257, 1227, 1108, 985/976 (V=O), 969, 776, 738, 699, 605, 447. − Black-brown rhombohedral crystals of **5a** and **5b** suitable for an X-ray diffraction analysis were obtained by allowing hot ethanol solutions to slowly cool down to room temperature.

The Complexation Behaviour of Crown Ethers with Some Divalent Transition Metal and Silver Ions in a 40%(v/v) Ethanol + Water Medium

Vijaykumar S. Ijeri[a] and Ashwini K. Srivastava*[a]

Keywords: Crown compounds / Transition metals / Electrochemistry / Stability constants / Silver

The stability constants in 40%(v/v) ethanol + water mixture were evaluated for complexes of Ni^{II}, Co^{II}, Cu^{II}, Zn^{II}, Mn^{II} and Ag^{I} with the macrocyclic polyethers 15-crown-5, benzo-15-crown-5, 18-crown-6 and dicyclohexano-18-crown-6 by conductometric titrations. In addition, a potentiometric study of the Cu^{II} and Ag^{I} complexes was undertaken to compare the results with those obtained by conductivity measurements. The complexation studies indicate 1:1 complex formation between the metal ion and crown ether and the log $K_{ML^{n+}}$ values are in the range 1.0–3.0. The limiting molar conductivities of the metal ions and their crown ether complexes were also determined.

Introduction

The complexation of alkali cations by neutral molecules was quite uncommon till the discovery of crown ethers by Pedersen,[1] who prepared and studied several crown ether complexes of alkali and alkaline earth metal ions.[2,3] Until now the complexation behaviour of alkali and alkaline earth metal ions with crown ethers has been extensively studied[4−8] in various solvents. The complexation of transition metal ions has been studied mainly with respect to aza and thia crown ethers,[4,8−12] as they are softer ligands. Little attention, however, has been given to the complexation behaviour of transition metal ions with oxygen-containing crown ethers.[7,13−16]

The object of the present work was to study the complexation behaviour of Ni^{II}, Co^{II}, Cu^{II}, Zn^{II}, Mn^{II} and Ag^{I} perchlorates with 15-crown-5 (15C5), benzo-15-crown-5 (B15C5), 18-crown-6 (18C6) and dicyclohexano-18-crown-6 (DCH18C6) in a 40%(v/v) ethanol + water medium by conductometry. The complexation of Cu^{II} and Ag^{I} has been studied by potentiometry as well in order to compare these results with those obtained by conductometric measurements. Aqueous alcohol is widely used as a physiological substrate. Also, as this particular composition ensured the solubility of B15C5 and DCH18C6, and, interestingly, lies on the maxima of the viscosity curve of ethanol + water mixtures, it was chosen for the present study.

Theory

The conductance data of the divalent metal perchlorates were treated by the Fuoss and Edelson method as used in previous studies.[6] The method consists of evaluating the limiting equivalent conductance (Λ_0) and the first step association constant (K_A) of an electrolyte MX_2 in 40% ethanol + water based on the following equilibrium:

$$M^{2+} + ClO_4^- \overset{K_A}{\rightleftharpoons} MClO_4^+ \quad (1)$$

where M = Ni, Co, Cu, Zn, Mn. The equilibrium leading to the neutral species $M(ClO_4)_2$ is neglected in this method.

The treatment of conductance data for silver perchlorate was done by using the Shedlovsky function.[17] The equations[6,7,18] used for the calculation of the stability constants are described briefly in the following sections.

Conductometric Study of Crown Ether Complexation with Metal Perchlorates

The complexation of a metal ion (M) with a crown ether (L) may be represented as:

$$\begin{array}{ccccc} M^{n+} & + & L & \rightleftharpoons & ML^{n+} \\ \alpha[M]_t & & [L]_t - (1-\alpha)[M]_t & & (1-\alpha)[M]_t \end{array} \quad (2)$$

where $[M]_t$, $[L]_t$ and α are the total concentration of cation, the total concentration of crown ether and the fraction of uncomplexed cation, respectively. Accordingly the thermodynamic stability constant $K'_{ML^{n+}}$ is given by:

$$K'_{ML^{n+}} = [ML]\cdot f_{ML^{n+}}/[M]\cdot f_{M^{n+}}[L]\cdot f_L \quad (3)$$

Where [ML], [M] and [L] are the concentrations of complexed cation, uncomplexed cation and uncomplexed crown ether, respectively, and $f_{ML^{n+}}$, $f_{M^{n+}}$ and f_L are the corresponding activity coefficients. The concentration stability constant $K_{ML^{n+}}$, which is reported, since $f_{ML^{n+}}$ and $f_{M^{n+}}$ are unknown, is given by:

$$K_{ML^{n+}} = K'_{ML^{n+}}\cdot f_{M^{n+}}/f_{ML^{n+}} = [ML]/[M][L] = (1-\alpha)/\alpha[L] \quad (4)$$

The conductivity (κ) of a solution containing metal perchlorate and crown ether is written as:

$$\kappa = \kappa_{MClO_4} + \kappa_{MClO_4} \quad (5)$$

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0404−0943 $ 17.50+.50/0

where κ_{MClO_4} and κ_{MClO_4} are the conductivities of metal perchlorate and metal crown ether perchlorate, respectively. The respective molar conductivities are given by:

$$\Lambda_{MClO_4} = \kappa_{MClO_4}/[M] = \kappa_{MLClO_4}/\alpha[M]_t \quad (6)$$

and

$$\Lambda_{MLClO_4} = \kappa_{MLClO_4}/[ML] = \kappa_{MLClO_4}/(1 - \alpha)[M]_t \quad (7)$$

Equation (5) may be written in terms of molar conductance (Λ) by considering the total concentration $[M]_t$ from Equation (6) and (7), to give:

$$\Lambda = \kappa/[M]_t = \alpha\Lambda_{MClO_4} + (1 - \alpha)\Lambda_{MLClO_4} \quad (8)$$

The correction for the viscosity changes is neglected, as the crown ether concentration was kept low. From Equation (4) and (8) one obtains:

$$K_{ML^{n+}} = (\Lambda_{MClO_4} - \Lambda)/(\{\Lambda - \Lambda_{MLClO_4}\}[L]) \quad (9)$$

where $[L] = [L]_t - \{[[M]_t \cdot (\Lambda_{MClO_4} - \Lambda)]/(\Lambda_{MClO_4} - \Lambda_{MLClO_4})\}$. The Λ_{MLClO_4} value is estimated from the Λ values at the point of a large $[L]_t$-to-$[M]_t$ ratio. With this value of Λ_{MLClO_4}, the $K_{ML^{n+}}$ value in Equation (9) can be calculated.

The procedure for obtaining the limiting ionic conductivity is as follows. From the principle of mass balance, the total concentration can be written as:

$$[M]_t = [M] + [ML] \quad (10)$$

$$[L]_t = [L] + [ML] \quad (11)$$

Combining Equation (4) with Equation (10) and (11), the following quadratic equation is obtained:

$$K_{ML^{n+}} \cdot [ML]^2 - \{1 - K_{ML^{n+}}([M]_t + [L]_t)\}[ML] + K_{ML^{n+}} \cdot [M]_t[L]_t = 0 \quad (12)$$

The [M] value is obtained from Equation (10) using the [ML] value calculated from Equation (12) at a particular concentration of metal perchlorate $[M]_t$ and crown ether $[L]_t$. The κ_{MClO_4} value in Equation (5) at this [M] point can be obtained from the Λ_{MClO_4} vs. $[MClO_4]^{1/2}$ plot. Then, the Λ_{MLClO_4} value at the corresponding [ML] point can be calculated from Equation (5) and (7) using this κ_{MClO_4} value and organised in the form of a Λ_{MLClO_4} vs. $[MClO_4]^{1/2}$ plot. The limiting molar conductance (Λ_0) of the metal−crown ether perchlorate is determined by extrapolation of the plot generated in the above manner. The limiting ionic conductance ($\lambda^0_{ML^{n+}}$) value of the metal−crown ether complex is obtained by using the value $\lambda^0_{ClO_4^-} = 26.8$ S cm^2 mol^{-1}. This value was obtained indirectly from the limiting molar conductivities of $AgClO_4$, $AgNO_3$, KCl and KNO_3.

Potentiometric Study of Crown Ether Complexation with Silver and Copper Perchlorates

The stability constant ($K_{ML^{n+}}$) for Ag^I with crown ether, from Equation (2) and (4), is given by:

$$K_{ML^{n+}} = (1 - \alpha)/(\alpha\{[L]_t - [M]_t(1 - \alpha)\}) \quad (13)$$

The determination of α is based on the measurement of the emf of the cell:

Ag/AgCl reference electrode // $AgClO_4$ + L /Ag in 40% ethanol + water

The conductance and potentiometric studies on $AgClO_4$ in 40% ethanol + water show that it is completely dissociated and the silver electrode behaves linearly over the range 1×10^{-1} M − 1×10^{-5} M. Therefore, the difference (ΔV) between the emf of the salt solution and that of the salt + crown ether solution can be taken to reflect the concentration ratios. The Nernst equation is used to give the following relation:

$$\alpha = 10^{-\Delta V/59.16mV} \quad (14)$$

Putting this value of α in Equation (13), $K_{ML^{n+}}$ is obtained.

Equation (15) was used to determine α for Cu^{II}:

$$\alpha = 10^{-\Delta V/29.58\ mV} \quad (15)$$

Results and Discussion

On treatment of the conductance data of the divalent metal perchlorates and silver perchlorate with the Fuoss−Edelsen and Shedlovsky equations, respectively, it was found that none of them showed any association in this solvent mixture. Similar observations were made by earlier workers[17,19] i.e. measurable association was found in cases where the ethanol percentage was greater than about 45% (v/v) for salts like potassium picrate, potassium chloride, cesium chloride, lithium chloride, etc. The values of the limiting molar conductivities, $\lambda^0_{M^{n+}}$ of the metal ions derived from the Fuoss−Edelson and Shedlovsky plots are given in Table 1 along with the limiting molar conductivities of the complexes.

Table 1. Limiting molar conductivities of M^{n+} and ML^{n+}

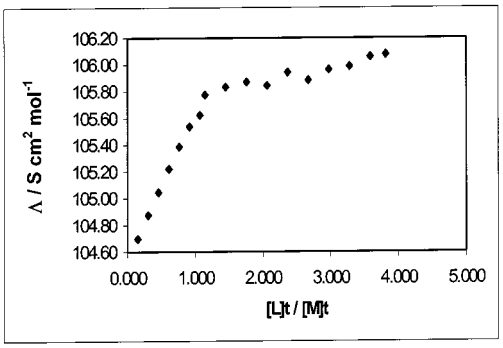

Figure 1. Plot of Λ vs. $[L]_t/[M]_t$ for 15C5−$Cu(ClO_4)_2$ system

Figure 1 and 2 show plots of Λ vs. $[L]_t/[M]_t$ for Cu^{II} and Ag^{I} with 15-crown-5, respectively, and they are representative of other metal ions and crown ethers.

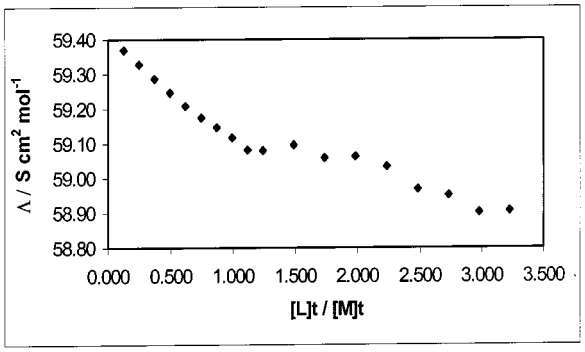

Figure 2. Plot of Λ vs. $[L]_t/[M]_t$ for 15C5−$AgClO_4$ system

It was observed that the Λ value increases with an increase in the $[L]_t/[M]_t$ ratio for all the systems involving the divalent transition metal ions, whereas a decrease in Λ values was observed in systems involving silver ions. This can be explained on the basis of the solvation sphere. The divalent transition metal ions have a high charge-to-radius ratio, on account of which they are highly solvated. On complexation, however, the crown ether molecule replaces the solvation sheath around the metal ion and, as a result, the moving entity becomes less bulky and more mobile. The silver ion, on the other hand, is relatively large and has a lower charge-to-radius ratio; hence it is solvated to a lesser extent. When complexed with crown ether it becomes bulkier causing a decrease in its mobility and also in the Λ values. The curves show a break point at $[L]_t/[M]_t \approx 1$, which indicates the formation of 1:1 complexes between the crown ethers and the metal ions. In the case of Ag-15C5 and Ag-B15C5 a slight break is also observed at $[L]_t/[M]_t \approx 2$, which hints at the formation of 2:1 sandwich complexes. However, in this paper we are confining our discussions to 1:1 complexes.

The values of the stability constants as log $K_{ML^{n+}}$ for the divalent metal ions (arranged in the order of increasing ionic radii) and silver complexes, obtained by conductometry and potentiometry, are given in Table 2 and 3, respectively.

Table 2. Stability constants (log $K_{ML^{n+}}$) for the metal ion−crown ether complexes by conductometry; figures in brackets indicate standard deviations ($6 \leq n \leq 9$)

Metal ion	15C5[a]	B15C5[a]	18C6[a]	DCH18C6[a]

Ag^{I}	1.37 (0.03)	1.15 (0.01)	2.07 (0.02)	1.87 (0.01)

[a] Log ($K_{ML^{n+}}$/mol dm^{-3}).

Among the divalent ions it is observed that copper happens to form more stable complexes, which may be explained on the basis of its larger size relative to the other ions. However, the lower stability of zinc complexes remains unexplained. Also, as there is not much difference in the ionic radii of the divalent metal ions studied, one cannot establish a clear relationship based on the cavity sizes and the ionic radii alone. Other factors such as extent of solvation, entropy changes, changes in the conformations, etc. also need to be considered. Among the crown ethers studied, it is observed that the substituent bearing crown ethers forms more stable complexes with the divalent ions. This may be due to the contraction of the cavity size, making it closer to the diameter of the ions. As a result, the most stable complexes are formed with B15C5, the order being B15C5 > 15C5 > DCH18C6 > 18C6. In the case of silver the opposite trend is observed, mainly because the diameter of the silver ion is much larger, the order being 18C6 > DCH18C6 > 15C5 > B15C5.

It is clear that the log $K_{ML^{n+}}$ values for copper and silver complexes in this medium are low relative to those in pure propylene carbonate (PC) and 20wt% propylene carbonate + ethylene carbonate (EC). For example, in PC log $K_{ML^{n+}}$ values for Ag−18C6 and Ag−DCH18C6 are 5.78 and 4.86, respectively,[6] and in 20wt% PC + EC they are 4.92 and 4.93, respectively.[7] The copper complexes in 20wt% PC + EC, with 15C5 and B15C5 show a log $K_{ML^{n+}}$ of 4.20 and 3.78, respectively.[7] This can be attributed to the strong solvating properties and hydrogen bonding capability of water and ethanol molecules. The hydrogen bonds of these molecules and the ether oxygen atoms decrease the complexing ability of crown ethers, whereas the log $K_{ML^{n+}}$ values for the divalent metal ions in 40% ethanol + water are nearly the same as those observed in methanol,[14] which has hydrogen bonds and a lower dielectric constant. The stability constants for Ag-B15C5 and Ag-18C6 complexes in a 90% (v/v) ethanol + water mixture[20] were found to be 3.47 and 3.58, respectively, whereas in pure ethanol[21] the values for Ag-15C5 and Ag-18C6 are 3.12 and 3.36, respectively. A comparison of these values shows the effect of hydrogen bonding. Water, being a strongly hydrogen bonding solvent, decreases the stability of the complexes, and as the percentage of water decreases, the stability increases. Similar observations were found in dioxane + water mixtures.[22] As the ratio of dioxane/water was increased from 2:8 (v/v) to 8:2 (v/v), the stability of the K-18C6 complex increased from 2.47 to 4.21. However, the transition metal complexes are less stable than the alkali metal complexes in

a similar medium (e.g. methanol)[8] and this can be explained on the basis of the "Hard and Soft, Acid-Base" (HSAB) concept.[12,23,24] The transition metal ions being soft acids would form stronger coordination bonds with sulfur/nitrogen-containing polyethers, which are softer bases than oxygen.

The limiting molar conductivities (Table 1) of the transition metal ion complexes do not show any particular trend, except that they are higher than those of the solvated ions, whereas in the case of silver complexes they are lower than those of the solvated ions.

Conclusion

The results obtained show that crown ethers form complexes with transition metal ions, although weak ones, in protic polar media and it is observed that the stabilities are not solely dependent on the ion/cavity sizes. The close agreement between the results obtained by conductometry and potentiometry is remarkable as it gives an accurate indication of the stabilities of the complexes.

Experimental Section

Solvents: Double distilled, deionised water was used for the preparation of all solutions. Triple distilled ethanol (over molecular sieves), containing less than 0.2% water (as determined by Karl Fischer titration), was used to prepare the ethanol-water mixtures. Both the solvents were stored in sealed containers to prevent atmospheric contamination. Appropriate volumes of ethanol and water were mixed to give the 40% (v/v) solvent mixture.

Reagents: Silver perchlorate was prepared as described in the literature[25] and standardized by titration against sodium chloride on a DL 53 autotitrator. The other metal perchlorates were prepared from their respective carbonates by the general methods described elsewhere[26] and were standardized by titration against EDTA on a DL 53 autotitrator. The crown ethers, 15-crown-5 (Fluka), benzo-15-crown-5 (Aldrich), 18-crown-6 (Aldrich) and dicyclohexano-18-crown-6 (Fluka) were used as received.

Apparatus: A Mettler Toledo DL53 autotitrator with automatic temperature compensation (ATC) was used for the standardization of metal salt solutions and potentiometric and conductivity measurements. The probes used were: silver electrode with Ag/AgCl reference electrode (DM 141-SC) and conductometric sensor (Inlab 710). An Elico, digital pH-mV meter (model LI-120) was used for emf measurements of cells involving Cu^{II}, in conjunction with a saturated calomel electrode (SCE).

Procedure for Conductometry: All measurements were done at 25 ± 0.1 °C, using a conductometric sensor Inlab 710 (with ATC), which was calibrated regularly with Mettler Toledo standard solutions. All molar conductivities were calculated after correcting for the solvent conductivity.

Method 1. Determination of K_A of the Transition Metal Perchlorates: Pure solvent mixture was placed in the cell and the conductance was measured. A step-by-step increase in the metal ion concentration was effected by means of the autotitrator. The conductivity was measured after each addition, followed by mixing, and the most stable reading over a span of 10 minutes was taken.

Method 2. Determination of $K_{ML^{n+}}$: The metal perchlorate solution ($\approx 1 \times 10^{-3}$ M) was placed in the cell and the conductivity was measured. The crown ether solution (≈0.02 M) was added to the cell in small increments until the total concentration of the crown ether was approximately 2−3 times as large as that of the metal perchlorate. The conductivity was measured after each addition as above.

Method 3. Determination of Λ_0 of $MLClO_4$: A crown ether solution ($\approx 2 \times 10^{-3}$ M) was placed in the cell and the conductance of the solution was measured. Then, a step-by-step increase in the concentration of metal perchlorate was effected as mentioned above until the concentration of metal perchlorate became approximately twice as large as that of the crown ether.

Procedure for Potentiometry: The silver indicator electrode (DM 141- SC) with an inbuilt Ag/AgCl reference element was used for all measurements involving Ag^{I} ions. As a general procedure, the emfs were recorded every 2 minutes. The potentials recorded were the average of the last two observations, which normally agreed to within ±0.1 mV; the measured cell potentials were reproducible to ±0.5 mV.

A pure copper wire (purity >99.95%) in conjunction with the SCE was used for measurement of emfs along with an Elico, digital pH-millivoltmeter. As a general procedure, the emfs were recorded every 2 minutes. The potentials recorded were the average of the last two observations, which normally agreed to within ±1 mV; the measured cell potentials were reproducible to ±3 mV.

Stock solutions of silver/copper perchlorates and crown ethers were prepared in a 40% ethanol + water mixture. The experimental solutions were prepared by appropriate dilution of the stock solutions to the required concentrations.

The dielectric constant and viscosity of 40%(v/v) ethanol + water were interpolated from previous data[17,27] using data fitting software (Numerical Methods Toolkit)[28] and were found to be 58.41 and 2.29 cP, respectively.

Synthesis and Coordination Chemistry of Chelate Ligands Containing Cyclopentadienyl, Indenyl and Fluorenyl Donors − Diastereoselectivity and NMR Structure Analysis

Joachim Vogelgesang,[a] Axel Frick,[a] Gottfried Huttner,*[a] and Peter Kircher[a]

Dedicated to Prof. Dr. Heinrich Vahrenkamp on the occasion of his 60th birthday

Keywords: Cyclopentadienes / Tripodal ligands / NMR spectroscopy / Distance geometry / Ruthenium / Phosphorus

The functionalised oxetane $O(CH_2)_2C(CH_2Br)(CH_2OMs)$ (**1**) is transformed into *tripod* ligands $ROCH_2C(CH_2PPh_2)(CH_2PR'_2)(CH_2Cp^{\#})$ (R = H, $SiMe_3$; R′ = Ph, Et; $Cp^{\#}$ = indenyl, fluorenyl) (**4**) in a few steps. Epichlorohydrin $O(CH_2)CH(CH_2Cl)$ (**5**) allows for diastereoselective one-pot syntheses of the Cp-functionalised chelate ligands $(Cp^{\#}CH_2)C(H)OH(CH_2PPh_2)$ ($Cp^{\#}$ = Cp, indenyl, fluorenyl) (**6**). The $SiMe_3$-protected derivatives of these ligands react with $RuCl_2(PPh_3)_3$ to produce $\{Me_3SiOCH(CH_2\text{-}\eta^1\text{-}PPh_2)(CH_2\text{-}\eta^5\text{-}Cp^{\#})Ru(PPh_3)(Cl)\}$ ($Cp^{\#}$ = Cp, indenyl) (**15**) with high diastereoselective preference. With the same starting material, *tripod* ligands **4** form $Me_3SiOCH_2C(CH_2\text{-}\eta^1\text{-}PPh_2)(CH_2\text{-}\eta^1\text{-}PR_2)(CH_2\text{-}\eta^5\text{-}Indenyl)RuCl$ (R = Ph, Et) (**16**). As shown by complete NMR spectroscopy based structure analyses (DG methods) of **16**, the formation of **16** (R = Et) is diastereoselective. The only diastereomer which is observed is the one in which the PEt_2 donor and the phenylene part of the indenyl ligand are juxtaposed. In addition to quantitative NMR spectroscopy structure analyses, traditional analytical techniques, including X-ray analyses, were used to confirm the results.

Introduction

Cyclopentadienyl ligands which are linked to additional donor groups by side-chains of appropriate lengths are a special class of chelate ligands and hold quite some promise in catalytic applications. Whereas the chemistry of *ansa* Cp ligands, so elegantly developed by H. Brintzinger and his group,[1] has boomed in recent years, the chemistry of Cp-based chelate ligands bearing functionalities other than Cp groups is only in its early state of development. This is especially surprising in the case of Cp derivatives containing additional phosphane donor groups, since the chemistry of $CpM(PR_3)_n$ metal templates is so well developed. The only possible reason for this fact appears to be the lack of suitable methods for the synthesis of the ligands. It has been shown that tripodal ligands $CH_3C(CH_2PR_2)(CH_2PR'_2)(CH_2Cp^{\#})$ ($Cp^{\#}$ = Cp, indenyl, fluorenyl) are accessible by different routes[2] and some coordination chemistry of such ligands has been reported.[3]

Since it has been shown that *tripod* ligands $H_3CC(CH_2X)(CH_2Y)(CH_2Z)$ (X, Y, Z = donor groups with at least one of them being a Cp derivative) are accessible via appropriately functionalised oxetanes in fair yields,[2] the development of the synthesis of hydroxy-functionalised *tripod* ligands $(HOCH_2)C(CH_2PR_2)(CH_2PR'_2)(CH_2Cp^{\#})$ via oxetane precursors appears to be worthwhile. In this paper ligands of this type ($Cp^{\#}$ = indenyl, fluorenyl; PR_2, PR'_2 = PPh_2, PEt_2) (**3**, **4**) as well as some of their coordination chemistry, are described.

Yet another way to hydroxy-functionalised chelate ligands containing phosphorus donor groups and $Cp^{\#}$ ligands linked by a three-carbon chain may be based on the use of epichlorohydrin as the starting material. It has been shown that the enantioselective synthesis of bidentate and tridentate chelate ligands containing up to three different phosphorus donors $HC(CH_2PR_2)(CH_2PR'_2)(OPR''_2)$ may be achieved in this way.[4] In this paper we show that $Cp^{\#}$ donor groups may also be introduced, leading to compounds $HC(CH_2Cp^{\#})(CH_2PPh_2)(OPPh_2)$ (**12**) and $ROCH(CH_2Cp^{\#})(CH_2PPh_2)$ (**6**, **9**). Some coordination compounds of these novel ligands are also described.

[a] For ease of comparison the sequence of entries in this table does not follow the numbering scheme; sequence of entries for each compound: ^1H NMR, $^{13}C\{^1H\}$ NMR, $^{31}P\{^1H\}$ NMR spectroscopic data are embedded in curly brackets; solvent: $CDCl_3$; $CH_{2a;b}$ designates CH_2 groups whose protons may be diastereotopic depending on the symmetry of the compound; lines adjacent to individual column entries indicate that signals referring to the columns to which these lines extend are within the range given in each case or are mapped to one and the same signal. − [b] This column refers to the composition of the individual compounds with reference to the graphical illustration (Footnote[c]). − [c] Designators of the individual groups as used in the header of the table: see graphics on top of the table.

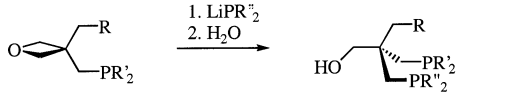
different PR_2 donors,[5] has also been shown to allow for the introduction of one phosphorus and one Cp donor.[6] The reaction of **1** with one equivalent of $LiPPh_2$ followed by the reaction with one equivalent of LiInd or LiFlu (Ind = indenyl, Flu = fluorenyl) yields compounds **2** after hydrolysis and chromatographic workup (Scheme 1).

Compounds **2a** (colourless oil) and **2c** (waxy solid) were produced in fair yields (74%/64%) while **2b** (oil) was obtained in a yield of only 10%. The yield of **2b** was lower than that of **2a** because $LiPEt_2$ is much more basic than $LiPPh_2$. Instead of replacing the OMs group, PEt_2^- deprotonated the methyl group of the mesylate function such that upon hydrolysis, the CH_2OMs function was transformed into the CH_2OH function from which the mesylate was prepared.[7] Similar problems have been observed with tosylate-activating groups where even the *p*-methyl group is acidic

enough to be deprotonated.[8] The use of phenylsulfonate might be an alternative solution, but has not yet been tested with the problem at hand. The sequence in which the nucleophiles are added in the synthesis of **2** from **1** is important, since selective monosubstitution, which results when $LiPR_2$ is added first, is not achieved when $LiCp^{\#}$ is added as the first reagent. Compounds **2** were fully characterised by their spectroscopic and analytical data (Table 1 and Table 10).

All the NMR (^1H, ^{13}C, ^{31}P) signals, except for those in the aromatic region, have been unambiguously assigned (Table 1). As had already been observed in the synthesis of indenyl-containing *tripod* ligands,[2a] the indenyl residue was selectively bonded at its 3-position.[9]

Compounds **2** reacted with $LiPR_2$ by the nucleophilic ring opening of the oxetane cycle to produce **3** after hydrolysis. After chromatographic workup, **3a** and **3c** were obtained as waxy solids, while **3b** formed an oil (Scheme 2).



2a R = Indenyl, R' = Ph
2b R = Indenyl, R' = Et
2c R = Fluorenyl, R' = Ph

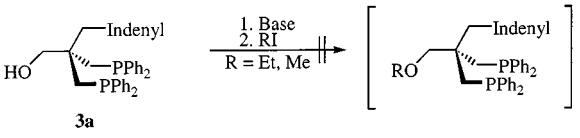
3a R = Indenyl, R' = R" = Ph
3b R = Indenyl, R' = Et, R" = Ph
3c R = Fluorenyl, R' = R" = Ph

Scheme 2

The transformation of **2** into **3** occurred in yields between 62% and 73%. Analytical (Table 10) and spectroscopic data (Table 1) of **3** are in full agreement with the assigned structure. An almost complete assignment of the NMR peaks (except for those in the aromatic regions) is reported in Table 1.

Preliminary experiments into the coordination chemistry of **3** indicated that the presence of the OH group might cause problems: Deprotonation of **3a** by one equivalent of *n*BuLi and subsequent reaction with $FeCl_2$ or $FeCl_2(PPh_3)_2$ [10] resulted in insoluble, brown products of unknown composition. The same protocol, however, yields $HOCH_2C(CH_2\text{-}\eta^1\text{-}PPh_2)_2(CH_2\text{-}\eta^5\text{-}Cp)FeCl$ when the Cp analogue of **3a** is used.[6] It appears that because the indenyl moiety is less acidic than the Cp moiety, deprotonation of the OH group of **3a** is a concomitant or even dominant reaction when **3a** is treated with *n*BuLi. The use of two equivalents of *n*BuLi did not improve the situation: Insoluble, brown products were again obtained. It was hoped to overcome this problem by protection of the hydroxy group as an ether derivative. It is known that transforming the CH_2OH groups of *neo*-pentane-based *tripod* ligands into ether functional groups is problematic.[11] Special protocols have been developed in specific cases which overcome these problems, one of these special protocols being based on rigid temperature control under Williamson conditions.[12]

Deprotonation of **3a** by *n*BuLi may be performed as a kind of titration, since a slight excess of *n*BuLi deprotonates the indenyl residue. The anion formed by deprotonation of the indenyl moiety is of an intense violet colour. The alkoxide which is obtained when **3a** is treated with one equivalent of *n*BuLi was allowed to react with methyl iodide or ethyl iodide in THF at temperatures from −15 °C up to 30 °C in different experiments (Scheme 3).



3a

Scheme 3

The selective formation of just one product was not observed in any of the experiments. TLC analyses as well as mass spectrometric and NMR spectroscopic analyses revealed the formation of a mixture of many products in each case. A tentative explanation for this observation may be a proton-transfer equilibrium activating the indenyl part of the ligand with the resulting indenyl anion being far more reactive towards alkyl iodides than the alkoxide function. Alkyl substitution may therefore occur at the indenyl group.

This hypothesis was not further investigated, since it was found that the protection of the alcohol group of **3** is easily achieved by its reaction with trimethylchlorosilane, leading to the siloxy derivatives **4** (Scheme 4), which are obtained as colourless oils of high viscosity. The analytical and spectroscopic data of compounds **4** (Table 10 and Table 1) are in full agreement with the assigned structures.

Scheme 4

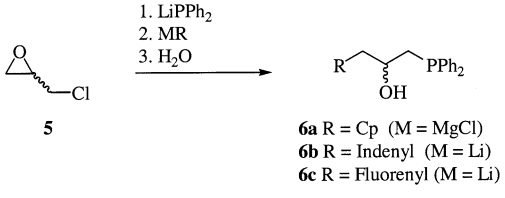
Starting from Epichlorohydrin

Epichlorohydrin (**5**) has been shown to be an efficient starting material for the synthesis of bidentate and tridentate chelate ligands.[4] The tandem-type process of ring-opening and ring-closing steps occurring upon treating epichlorohydrin with phosphorus nucleophiles has been analysed in detail.[4b,4c] An essential step in this synthetic approach is the nucleophilic opening of the oxirane ring by phosphide nucleophiles which has also been observed with some related oxirane starting materials.[13] In the case of epichlorohydrin as the ligand precursor, this ring-opening step has also been shown to work with nitrogen and sulfur nucleophiles.[4a] In view of this proven tolerance of the reaction, it appeared appealing to study the reactivity of **5** towards Cp nucleophiles.

It had already been shown by B. Rieger et al. that functionalised oxiranes may be attacked by Cp nucleophiles, with substitution at one of the oxirane carbon atoms and concomitant opening of the oxirane ring.[14] With respect to the nucleophilic ring-opening reaction of oxiranes, the Cp nucleophiles show the same type of reactivity as phosphorus, nitrogen and sulfur nucleophiles. This type of reaction works as well with **5** as the starting compound. When **5** was treated with one equivalent of $LiPPh_2$, attack occurred at the unsubstituted oxirane carbon atom. The phos-

phane-substituted alkoxide resulting from this reaction may be characterised as an intermediate at low temperatures.[4b,4c] At higher temperatures, the alkoxide oxygen atom attacks the CH_2Cl functional group with the formation of an oxirane, which may then be further attacked by nucleophiles at its unsubstituted carbon atom.[4]

This sequence of steps, when performed with CpMgCl as the second nucleophile, led to the formation of **6a** in which a Cp unit and a PPh_2 unit are connected by a 2-hydroxy-1,3-propanediyl chain (Scheme 5). Compound **6a** was obtained as a mixture of two double-bond isomers (Table 2, ^{13}C NMR). Its formation was always accompanied by the formation of some 1,3-bis(diphenylphosphanyl)-2-propanol, even when lower than stoichiometric quantities of $LiPPh_2$ were used. This by-product could not be separated from **6a** such that on first inspection, C,H analysis (Table 10) appeared to be inconsistent with the given formula. The relative content of this by-product was judged from the ^1H NMR spectrum of **6a** where the methine proton (at the 2-position of the C_3 chain) at the hydroxy-substituted carbon atom resonates at $\delta = 3.97$ (Table 2) while the $HOCH(CH_2PPh_2)_2$ proton gives rise to a signal at $\delta = 3.73$.[4b,4c] Chromatographic separation of the products was not possible. It was, however, possible to obtain an analytically pure derivative of **6a** (**9a**, see below). When LiInd or LiFlu were used as the nucleophiles in the second preparation step, minor quantities of the corresponding diphosphanes were also obtained, but could be separated by chromatography such that **6b**/**6c** were obtained as analytically pure substances. Compounds **6a** and **6b** are colourless oils, and **6c** is a colourless solid. The composition of **6** is evident from microanalytical and mass spectrometric data (Table 10). The structure is unequivocally clear from their NMR spectra (Table 2).

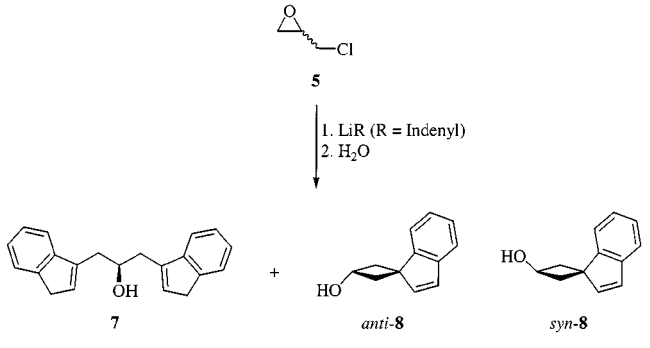


5

6a R = Cp (M = MgCl)
6b R = Indenyl (M = Li)
6c R = Fluorenyl (M = Li)

Scheme 5

The sequence in which the nucleophiles are added to **5** is important. It had already been observed that spiro cyclisation may occur when an electrophilically activating group is present at the 4-position relative to a Cp carbon atom.[2a] This type of reaction corresponds to the dominant reaction pathway when **5** is treated with Cp nucleophiles and this is apparent from the reaction of **5** with LiInd. When **5** was treated with five equivalents of LiInd, the disubstitution product **7** was obtained in only 4% yield while the spiro derivatives *syn*-**8**/*anti*-**8** were formed in 40% overall yield (Scheme 6).



7 *anti*-**8** *syn*-**8**

Scheme 6

The assignment of *syn* and *anti* configurations to the two components of the product mixture followed the arguments explicitly described for closely analogous cases which were observed during indenyl substitution of *neo*-pentane-derived *tripod* ligands and was based on ^1H NMR spectroscopic data (Table 3).[2a]

The isomers of **8** might in principle be separated by crystallisation as is demonstrated by the fact that upon crystallisation, single crystals of *anti*-**8** suitable for X-ray analysis were obtained. The structure of *anti*-**8** is shown in Figure 1 together with the structure of **7** from which single crystals could also be grown. There is nothing peculiar about the molecular structure of *anti*-**8**. Distances and angles are in the normal ranges (Table 4).

While the molecular symmetry of *anti*-**8** is C_s (Figure 1), the molecules aggregate in space group $P4_1$ to form a chiral crystal. The hydrophilic and hydrophobic parts of the molecule are embedded in specific compartments of the crystal with the hydroxy groups forming an infinite hydrogen-bonded spiral around a 4_1 axis of the $P4_1$-symmetric unit cell (Figure 2). The O···O distance between neighbouring oxygen atoms is only 265 pm. The position of the bridging hydrogen atoms has been determined by diffraction methods (H−O 83 pm, H···O 183pm). The O···H−O angle is 174°. The hydrogen bonds are hence almost linear. The H−O···H angle is approximately 110°. A view of this interesting arrangement in the direction of the 4_1 axis is shown in Figure 2, giving an impression of the infinite hydrophilic channels along the crystal.

The structure of **7** (Figure 1) shows no peculiarities in the bond lengths and angles (Table 5). The position of the indenyl substituents is such that they are as far apart as possible with respect to the three-carbon linker between them. This type of orientation of indenyl and fluorenyl substituents linked by a three-carbon chain had already been observed for *tripod* ligands containing these groups.[2a] The solid-state structure is again an interesting one. As already observed for *anti*-**8**, hydrophobic and hydrophilic compartments are well separated in the crystal. Compound **7** crystallises in the achiral space group $P2_1/n$. The hydroxy groups form hydrogen-bonded zigzag chains around the 2_1 axes of the unit cell. The O···O distances between the hydrogen-bonded oxygen atoms is only 274 pm. The H−O···H angle is 129°, the O−H distances were found to be 92 pm and 183 pm, with the O−H···O group being almost linear (168°).

It has been found that the transformation of enantiomerically pure epichlorohydrin into its disubstituted products $HOCH(CH_2PR_2)(CH_2PR'_2)$ follows a completely enantioselective pathway.[4] In order to find out if enantioselectiv-

anti-**8** **7**

Figure 1. Structures of **7** and *anti*-**8**

$[\alpha]_D^{20}$ = 17.28 ± 0.48. The optical rotations are thus opposite in sign but equal in size (within the limits of error). While this is no proof for complete enantioselectivity, it agrees with the observations that the reaction is completely enantioselective when using phosphorus nucleophiles.[4] It also agrees with the results of similar reactions with other types of oxiranes in which complete enantioselectivity is observed.[14]

Since the hydroxy groups in **6** might complicate the coordination of these ligands, protection of these groups was considered to be important. As already experienced with **3**, ether formation under Williamson conditions was not successful with **6**; only inseparable mixtures of compounds were obtained. In contrast, protection with chlorotrimethylsilane did not cause any problems and the siloxy derivatives **9** were prepared (Scheme 8).

Silylation of **6a** proceeded in close to quantitative yields and is also a good method to purify **6a**, since **9a** is easily separated from $Me_3SiOCH(CH_2PPh_2)_2$ by chromatography. Both compounds **9** were fully characterised by their analytical and spectroscopic data (Table 2 and Table 10).

In order to activate the hydroxy group of **6** it was not protected but instead the mesylate **11** was synthesised. For this purpose, the phosphane group had to be protected. Addition of BH_3·THF led to the formation of **10** (Scheme 9).

Compound **10** was obtained as an analytically pure, colourless oil after chromatographic workup (Table 10). In contrast to the other Cp derivatives containing phosphorus

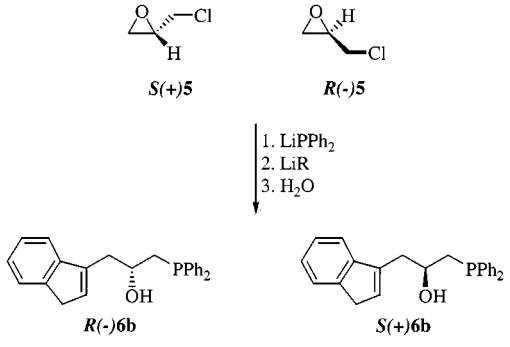
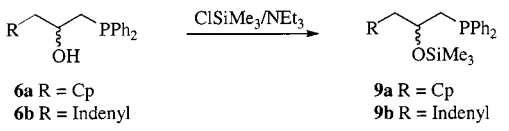
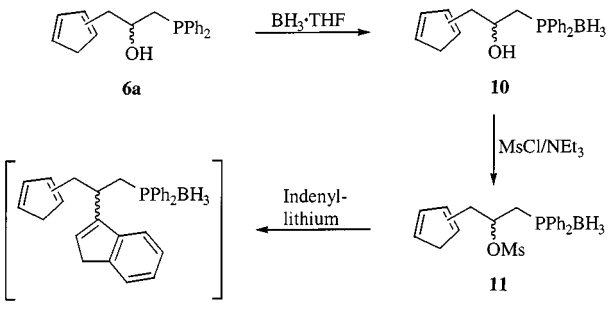


Scheme 7

donor groups described in this paper, the double bond isomers of **10** are resolved in its ^{31}P NMR spectrum (Table 2). This is consistent with earlier findings reported for some



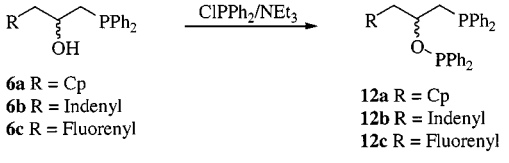
Scheme 8



Scheme 9

ligands containing Cp and PPh_2BH_3 substituents.[2b] Mesylation of **10** by standard methods led to **11**, which was obtained as a colourless oil after chromatography. Analytical and spectroscopic data (Table 10 and Table 2) confirmed its identity. To test the reactivity of the mesylate functional group in this compound, **11** was treated with two equivalents of indenyllithium. Hydrolysis and chromatographic workup gave only a mixture of products, among which the expected product was clearly present as shown by mass spectrometry (prominent signal at m/z = 420 [M^+]). Further purification was not possible.

Compounds **6** are also suitable starting materials for the synthesis of tripodal ligands. Their reaction with $ClPPh_2$ produced **12** containing one $CH_2Cp^{\#}$, one CH_2PPh_2 and one $OPPh_2$ group. Compounds **12a** and **12b** were obtained as colourless oils while **12c** was a waxy solid (Scheme 10).

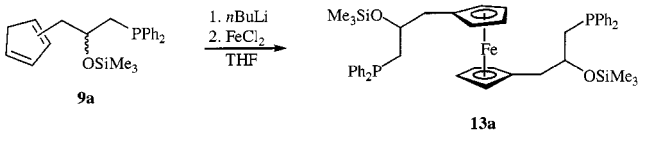


Scheme 10

Mass spectra, elemental analyses and NMR spectra are consistent with the given structures (Table 10 and Table 2). The double-bond isomers of **12a** give rise to separate peaks in the ^{31}P NMR spectrum (Table 2). The impurity of **6a** [$HOCH(CH_2PPh_2)_2$, see above] was transformed into its $OPPh_2$ derivative.[4] This derivative was present as an impurity in **12a** and could not be separated by chromatography (but compare **9a**, see above). Its elemental composition was determined by HRMS while **12b** and **12c** gave highly satisfying C,H analyses (Table 10). The NMR spectroscopic data (Table 2) were consistent with the given formulas; **12b** and **12c** also showed two separate peaks for their double-bond isomers in the ^{31}P NMR spectra (Table 2).

Coordination Chemistry

Tripodal ligands $RCH_2C(CH_2PR'_2)(CH_2PR_2'')(CH_2Cp)$ have been shown to form *tripod* metal templates $RCH_2C(CH_2\text{-}\eta^1\text{-}PR'_2)(CH_2\text{-}\eta^1\text{-}PR_2'')(CH_2\text{-}\eta^5\text{-}Cp)M$ with iron, manganese, molybdenum and ruthenium.[2,3,6,15] The procedures leading to manganese and molybdenum derivatives are complicated multi-step reactions and therefore were not suitable to test the coordination capabilities of Cp-containing *tripod* ligands.[2b,3a] In contrast, derivatives of the type $RCH_2C(CH_2\text{-}\eta^1\text{-}PR'_2)(CH_2\text{-}\eta^1\text{-}PR_2'')(CH_2\text{-}\eta^5\text{-}Cp)MCl$ have been obtained for M = Fe and Ru by convenient one-step procedures.[2a,3b,6,15] The different classes of ligands described in this paper were therefore initially tested for their reactions with $FeCl_2$ or $FeCl_2(PPh_3)_2$.[10] Compounds **4** did, after deprotonation with *n*BuLi, react with these reagents to yield deep-brown THF solutions from which no pure compounds could be isolated. In contrast, compounds **9** reacted with $FeCl_2(PPh_3)_2$ [10] under similar conditions to yield the ferrocene derivatives **13** instead of the corresponding $CpLFePPh_3Cl$ compounds. These ferrocene derivatives were obtained in good yields when $FeCl_2$ was used as the starting material (Scheme 11).



9a **13a**

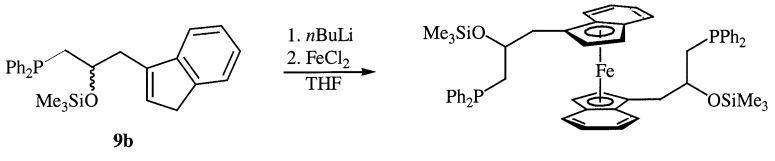
Scheme 11

Compound **13a** was obtained from **9a** as a yellow, waxy material in analytically pure form (Table 11). With two stereogenic centres, **13a** must exist as a mixture of *meso* and *racemic* forms. The interaction of the chiral groups is, however, too small to make this differentiation recognisable in its NMR spectra. Only one set of signals was observed for each group (see Experimental Section). One sharp ^{31}P NMR resonance is observed at $\delta = -23.6$. The Cp protons give rise to one unresolved signal at $\delta = 4.01$. Regarding the diastereotopic methylene protons, the pair at the CH_2Cp group gives rise to a well-resolved pattern at $\delta = 2.77$ with $^2J_{HH} = 14.0$ Hz and $^3J_{HH} = 6.0$ Hz (see Experimental Section) while those of the CH_2PPh_2 group appear as an unresolved multiplet at $\delta = 2.26$ (see Experimental Section). The ^{13}C NMR spectra show well-resolved peaks for the individual types of carbon atoms and allowed for the complete assignment of the Cp carbon atoms as well as of the carbon atoms of the side chains (see Experimental Section). As is characteristic for ferrocene and its derivatives **13a** shows a reversible oxidation in its cyclovoltammogram. The electronic influence of the side chains in **13a** is small, since oxidation occurs at $E_{1/2} = 325$ mV (vs. SCE), while ferrocene − under the same conditions − is oxidised at $E_{1/2} = 367$ mV.

The presence of free phosphane donors in **13a** is also apparent from its ^{31}P NMR signal at $\delta = -23.6$ (see Experimental Section). Additional evidence came from the reaction of **13a** with $Cr(CO)_5THF$ which resulted in a yellow, waxy substance. The mass spectrum of this yellow material shows a peak at $m/z = 1198$ [M^+, **13b**·2 $Cr(CO)_5$], which by consecutive loss of CO groups and one Cr atom, leads to a prominent signal at $m/z = 866$. Reaction of **9b** with $FeCl_2$ gave **13b** as a dark red, viscous oil (Scheme 12).

The number of stereoisomers is increased by a factor of two with respect to the number of isomers of **13a**, the reason being the loss of symmetry on going from the monosubstituted Cp ligand in **13a** to the monosubstituted indenyl ligand in **13b**. Nevertheless, only one sharp ^{31}P NMR signal is observed for **13b** at $\delta = -23.5$. The ^1H NMR spectrum of **13b**, on the other hand, clearly shows two different sets of signals with an intensity ratio of approximately 1:1. Thus, two signals are observed for the TMS protons, one at $\delta = -0.25$ and the other at $\delta = -0.20$. Two well-separated signals are also observed for the protons at the 3-position of the indenyl ligands, one at $\delta = 4.48$ and the other one at $\delta = 4.36$. The signals relating to the other protons partly overlap. COSY experiments,[16] nevertheless, allowed for their unambiguous assignment. It followed that there are two classes of isomers of **13b** which are discernible by ^1H NMR spectroscopic data. ^{13}C NMR spectroscopic data are in agreement with these findings (see Experimental Section). Since it had been shown with **13a** as the example that the chirality of the substituents does not lead to separate signals for the corresponding diastereomers, the two classes of isomers observed for **13b** must be due to the two sets of diastereomers which result by formally adding the R−IndFe entity to either of the two sides of the second R−Ind ligand. Compound **13b** shows a reversible oxidation, as one would expect for a ferrocene derivative with $E_{1/2} = 106$ mV (vs. SCE). It is more readily oxidised than ferrocene which shows its oxidation peak at 470 mV in the same experiment.

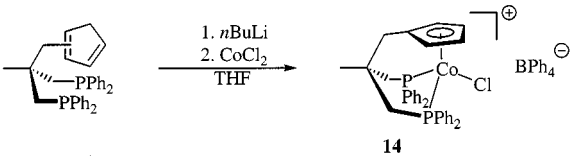
The reactions of **4** and **9** with $FeCl_2$ and $FeCl_2(PPh_3)_2$ [10] did not produce compounds in which the Cp-type donor and the phosphorus donors bind in a chelate mode. To test whether $CoCl_2$ might be an appropriate precursor for the formation of such chelate compounds, the prototype ligand



9b **13b**

Scheme 12

$CH_3C(CH_2PPh_2)_2(CH_2Cp)$[2b] was treated with $CoCl_2$·THF (Scheme 13).

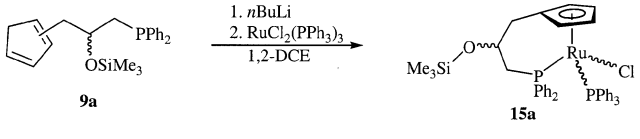


14

Scheme 13

From the dark brown reaction mixture, the violet chelate compound was separated by chromatography and isolated as its analytically pure BPh_4 salt **14**. The ^{31}P NMR resonance of **14** occurs at $\delta = 25.4$. The ^1H NMR spectrum, as well as the ^{13}C NMR spectrum, confirm the assigned structure (see Experimental Section). The isolation of **14** showed that $CoCl_2$ might be a suitable starting material to obtain the desired chelate compounds. Since the yield of **14** was lower than the yields of the corresponding iron compounds,[2a][3b,6] $RuCl_2(PPh_3)_3$ was tested as an alternative precursor. It had been found that its reaction with $CH_3C(CH_2PPh_2)_2(CH_2Cp)$ produces $CH_3C(CH_2$-η^1-$PPh_2)_2(CH_2$-η^5-Cp)RuCl in yields of up to 41% and it had also been observed that this compound, once formed, is quite stable.[15] Thus, the coordination capabilities of the ligands **9** were tested once again with $RuCl_2(PPh_3)_3$ as the starting coordination compound.

When **9a** was deprotonated by *n*BuLi in THF, a yellow, oily product remained after evaporation of the solvent. Addition of a solution of this residue in 1,2-dichloroethane to a solution of $RuCl_2(PPh_3)_3$ in 1,2-dichloroethane produced a slightly brown reaction mixture. Keeping this reaction mixture at 90 °C for 1 h resulted in the formation of **15a** as a yellow crystalline powder in yields of 50% after chromatographic workup (Scheme 14, Table 11). The chirality at the siloxy-substituted carbon atom and the metal-centred chirality result in **15a** existing as two diastereomers, each comprising of an enantiomeric pair. The ^{31}P NMR spectrum of **15a** shows two well-resolved doublets of high intensity and two equally well-resolved doublets with about $^1/_{10}$ of the intensity of the two major doublets (Experimental Section). The assumption that these two patterns arise from two diastereomers present in a ratio of 10:1 was justified by the ^1H NMR spectrum of **15a**. Four well-separated signals are observed for the Cp protons of the major isomer. Two of the four Cp protons of the minor isomer give rise to well-separated signals, while the other two are hidden under the signals of the methine protons and of one of the Cp protons of the major isomer (see Experimental Section). The diastereomeric ratio, as inferred from the corresponding integrals, was 13:1.



9a **15a**

Scheme 14

Diastereomeric discrimination has already been observed in the preparation of other similar compounds. B. Trost et al. have tested a series of chelate ligands which contain a Cp moiety covalently linked to a PPh_2 entity by a chiral spacer. When these ligands were used in the preparation of compounds of type **15a**, diastereomeric ratios of up to 5:1 were observed with $-(CH_2)_3-(H)(CH_2Ph)C-$ as the chiral linker, the stereogenic centre being bonded to the phosphorus atom.[17] Single crystals of **15a** were obtained in about 80% yield by slow evaporation of the solvent from saturated CH_2Cl_2/PE (boiling range 40−60 °C) solutions.

X-ray analysis showed them to contain the racemate of **15a** with two independent molecules **15a** in the asymmetric unit of the centrosymmetric unit cell (Table 6 and Figure 3). The configuration at the stereogenic centres of the analysed diastereomer was *R*,*R* and *S*,*S*. Based on the high yield with which single crystals were obtained, it was assumed that the major isomer was the diastereomer contained in the crystal. The chelate cycle formed by C4, C3, C2, C1, P1 and Ru1 adopts an approximate chair conformation (Figure 3; Table 6, torsion angles). The $OSiMe_3$ group is in an equatorial position (Figure 3 and Table 6) of this cycle. The PPh_3 ligand occupies an axial position, with the Cl ligand lying in an equatorial position with respect to this idealised description (Figure 3 and Table 6). The coordination around the ruthenium centre (Figure 3) is similar to that observed in other derivatives of the type $CpRuL_2Cl$.[15] The rotational position of the phenyl groups of the PPh_2 moiety of the chelate ligand corresponds to the generally observed position in *tripod* metal compounds $H_3CC(CH_2$-η^1-$PPh_2)_2(CH_2$-η^5-Cp)RuCl.[15] The phenyl groups of the PPh_3 ligand adopt the usual propeller-type arrangement (Figure 3). Bonding to the Cp ligand is symmetric, and all the $Ru-C^{Cp}$ distances are similar (Table 6). The Cp ligand is planar to within ± 1 pm. The carbon atom of the chelate chain which bonds to the Cp entity (Figure 3, C3) deviates from this plane by 16 pm (14 pm in the other independent molecule) in a direction opposite to the ruthenium centre.

[a] Atom identifiers refer to Figure 3; Z designates the centre of the Cp ligand. There are two independent molecules **15a** in the crystal; the data referring to the second molecule are given following the slash in each case.

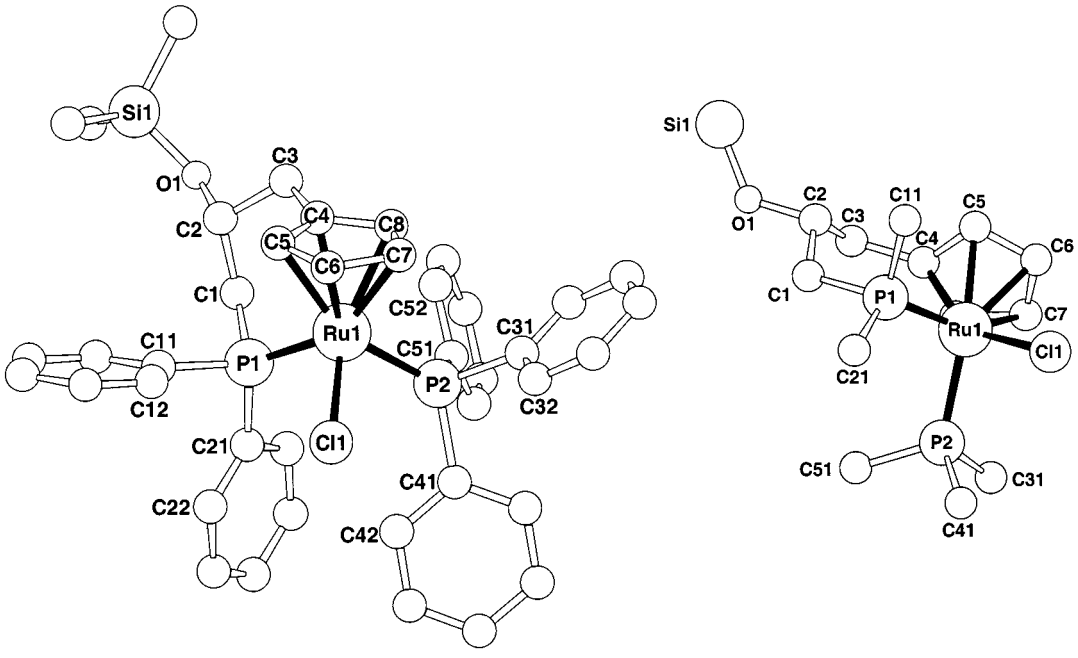

Figure 3. Structure of **15a**; left-hand side: general view and labelling scheme; right-hand side: view showing the chair conformation of the chelate cycle

The structure of the second diastereomer, which is formed in only 7% relative to the major isomer, must correspond to the one in which the positions of the PPh_3 and the Cl ligands are exchanged. Inspection of Figure 3 shows that steric crowding should increase by this exchange.

The number of possible isomers (four in the case of **15a**) occurring as two diastereomeric pairs will be increased by a factor of two when **9b** acts as a ligand in **15b**, due to the additional chirality introduced by anellating the Cp moiety.

The reaction of **9b** with $RuCl_2(PPh_3)_3$ under similar conditions used in the preparation of **15a** might thus, in principle, lead to the formation of four diastereomeric forms of **15b** (Scheme 15), each of them comprising of an enantiomeric pair, and the results of such a reaction might therefore be difficult to analyse. On the other hand, the diastereomeric discrimination already observed in the formation of **15a** might even be enhanced by the additional steric congestion introduced by the anellated benzene ring in the indenyl derivative compared to the Cp derivative. This is, in fact, found in the experimental results. Only two sharp and well-resolved doublets are observed for **15b** in its ^{31}P NMR spectrum. The ^{1}H NMR spectrum shows sets of signals which can unequivocally be assigned to only one diastereomer, with no indication of any contamination by other diastereomers. The signals for the methylene and the methine protons of the chelate cycle as well as the resonances of the two Cp protons are observed in the range between $\delta = 2.4$ and $\delta = 4.5$ (see Experimental Section). Assignment of the individual resonances was possible by analysis of the individual coupling constants, as well as by ^{31}P decoupling. In the ^{13}C NMR spectrum of **15b**, the corresponding resonances can unambiguously be assigned. The *ipso*-carbon atoms of the indenyl moiety were also identified by their corresponding signals. No attempt was made to assign the signals in the arene region.

All these NMR spectra show that only one diastereomer was formed by the reaction of **9b** with $RuCl_2(PPh_3)_3$. Based on the known structure of **15a**, it appears that anellation of the Cp moiety at the side of the chelate chain would lead to less steric crowding than anellation at the PPh_3 side. Replacing the Cp moiety in **15a** by the indenyl group, as in **15b**, resulted in an increase in diastereomeric differentiation and **15b** was formed exclusively in one diastereomeric form.

With *tripod* ligands such as **4b**, which have a stereogenic carbon centre by virtue of their two different phosphorus donors, diastereomeric differentiation might also be expected in their tripodal-coordinated derivatives. In order to test the coordination capabilities of **4**, the achiral ligand **4a** was deprotonated with *n*BuLi and treated with $RuCl_2(PPh_3)_3$. Chromatographic workup led to **16a** (Scheme 16). The yield of **16a** (42%) (Table 11) appeared sufficient to also test the less easily accessible ligand **4b** in this type of reaction. A modest yield of 16% of **16b** was obtained (Table 11, Scheme 17).

4b **16b**

Scheme 17

Both compounds **16** were obtained as red, microcrystalline powders. Two sharp doublets are observed in the ^{31}P NMR spectrum of **16a** (δ = 30.4, 54.0, $^{2}J_{PP}$ = 80.2 Hz, Table), as is expected owing to its lack of symmetry. One of the phosphorus atoms is close to the anellated benzene moiety of the indenyl ligand, while the other one is further away, on the less congested side of the compound. ^{1}H NMR spectroscopic data (Table 7) and ^{13}C NMR spectroscopic data (see Experimental Section) are in agreement with the given formula (Table 11). By an extensive series of NMR experiments, it was proved (see below) that the signal at δ = 30.4 can be assigned to the phosphorus nucleus which lies below the anellated benzene ring.

With **4b** as the ligand constituent of **16b**, two diastereomeric forms of **16b** could be expected: one with the anellated ring on the side of the PPh_2 group and a second with the PEt_2 group and the anellated ring close to each other. From the ^{31}P NMR spectroscopic data of **16b**, it appeared that only one of these isomers was formed (Table 7). In order to find out which of the two possible isomers was formed, since it was not possible to grow single crystals of **16**, the structures of **16a** and **16b** were elucidated by NMR experiments.

NMR Analysis

Compound **16a** shows a well-resolved ^{1}H NMR spectrum (Figure 4 and Table 7). Filtering this spectrum by means of long-range phosphorus coupling led to the lower traces shown in Figure 4. The signals of the methylene protons, as well as the signals of the aromatic protons are clearly differentiated by these traces. $^{2}J_{HP}$ coupling leads to prominent signals for the methylene groups which are directly bonded to the phosphorus nuclei. The protons of the methylene groups are diastereotopic owing to the lack of symmetry of the compound as a whole. This diastereotopicity is apparent from the characteristic doublet of doublets for each of the protons of the methylene groups linked to the phosphorus atom. The signals labelled H^{1A}/

H^{1B} (Figure 4 and Figure 6) are therefore assigned to the methylene group at P^1, the ones labelled H^{2A}/H^{2B} (Figure 4 and Figure 6) originate from the methylene group at P^2. The remaining signals H^{3A}/H^{3B} (Figure 4 and Figure 6) must therefore be due to the CH_2Cp group. The CH_2O-$SiMe_3$ group (Figure 4 and Figure 6) gives rise to signals at $\delta = 3.85$ and 0.36.

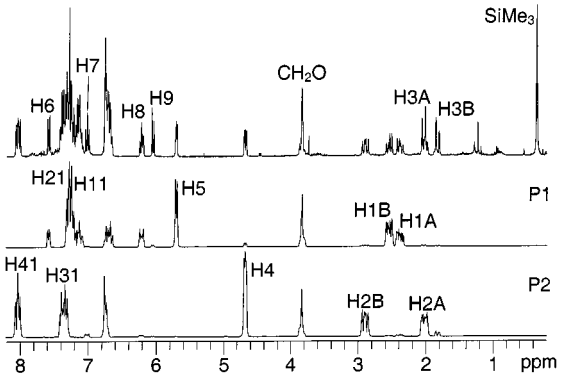

Figure 4. ^1H NMR spectrum (top) and cross-sections of the $\{^1H,^{31}P\}$-HMBC spectrum of **16a**; centre trace: filtering by long-range coupling to P^1; bottom trace: filtering by long-range coupling to P^2

The parts of the spectrum assigned to the protons of the Cp moiety are less conclusive: There are different pathways along which ^{31}P coupling to these protons may occur, while for the methylene protons $^2J_{HP}$ coupling is the dominant pathway. It is interesting to note that one of the Cp protons (H^5; Figure 4 and Figure 6) correlates strongly with P^1, while the other shows a strong correlation with P^2 (H^4; Figure 4 and Figure 6).

The aromatic protons are as well differentiated by their different correlations with P^1 and P^2 (Figure 4 and Figure 6). Unambiguous assignment was not possible from this experiment alone and the assignment given in Figure 4 was based on additional experimental grounds. A plausible argument for assigning the signal H^{41} (Figure 4 and Figure 6) comes from comparison with the NMR spectroscopic behaviour of other tripod metal compounds:[15,18] In the aryl region of the ^1H NMR spectra of such compounds, the signals with the greatest downfield shift have always been found to be due to the *ortho*-protons of phosphorus-bonded phenyl rings, wherever assignment was possible. The well-separated signal observed for H^{41} in the aromatic region (Figure 4 and Figure 6) together with its downfield shift allowed for its assignment to an *ortho*-proton of a phenyl

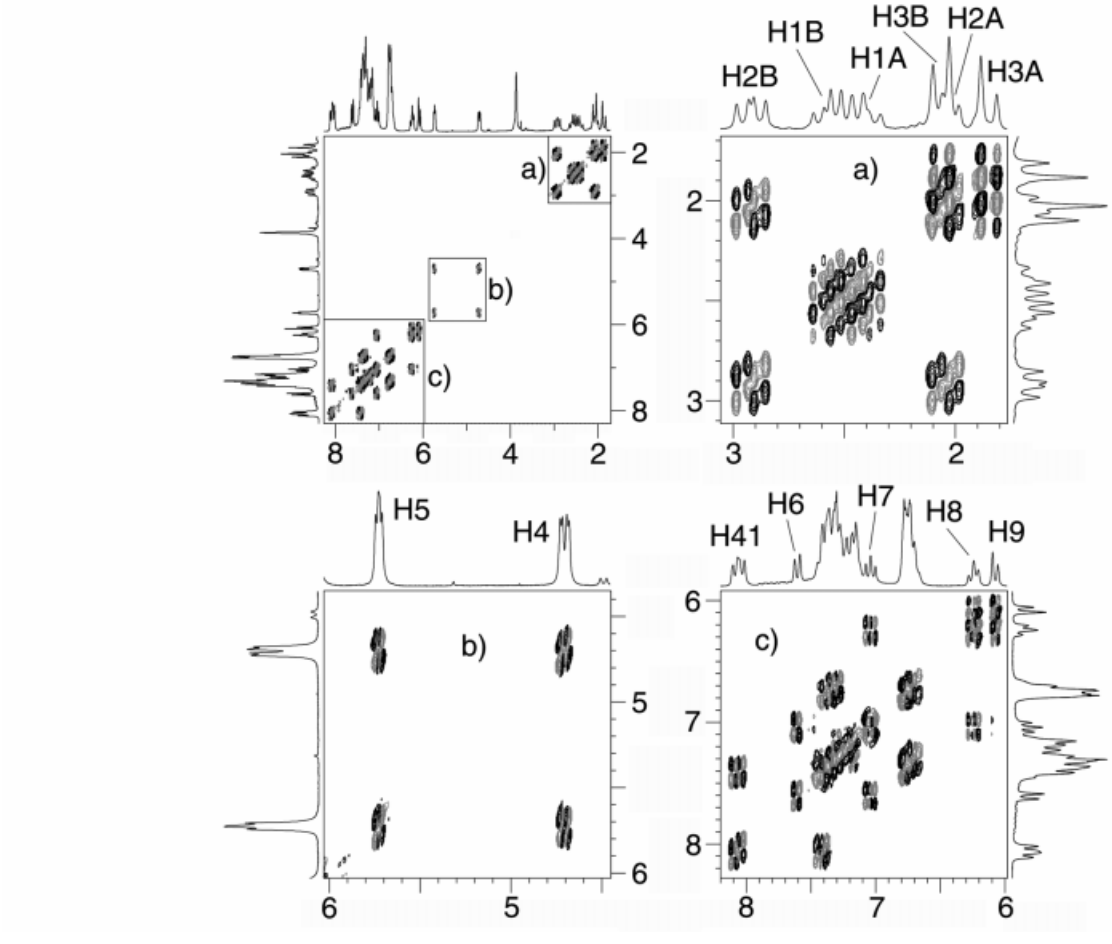

Figure 5. DQF-COSY spectrum of **16a**; the individual regions labelled a, b, and c in the complete spectrum (top left) are shown in magnified form under these labels

ring bonded to P^2. ^{31}P-decoupling reduced the doublet of doublet structure of this signal (Figure 4) to a well-resolved doublet, as expected.

The assignment of the individual signals in the methylene region was confirmed by COSY experiments. These experiments revealed the individual methylene groups by their $^2J_{HH}$ coupling (Figure 5a).

COSY data were important for the unambiguous assignment of resonances to the indenyl part of the molecule. While the Cp part of the indenyl ligand was clearly apparent even from 1D NMR experiments (Figure 4, see above), the signals of the protons H^6-H^9 (Figure 4, Figure 5 and Figure 6) in the anellated benzene ring of the indenyl fragment, while apparent as individual patterns, could not be assigned with respect to their mutual sequence. The COSY spectrum shown in Figure 5 (5c) enabled the sorting of the signals into a sequence of mutually neighbouring protons. The only ambiguity remaining was the question as to which of the protons, H^6 or H^9, was at the back or the front of the molecule (Figure 6). This ambiguity was resolved by NOE

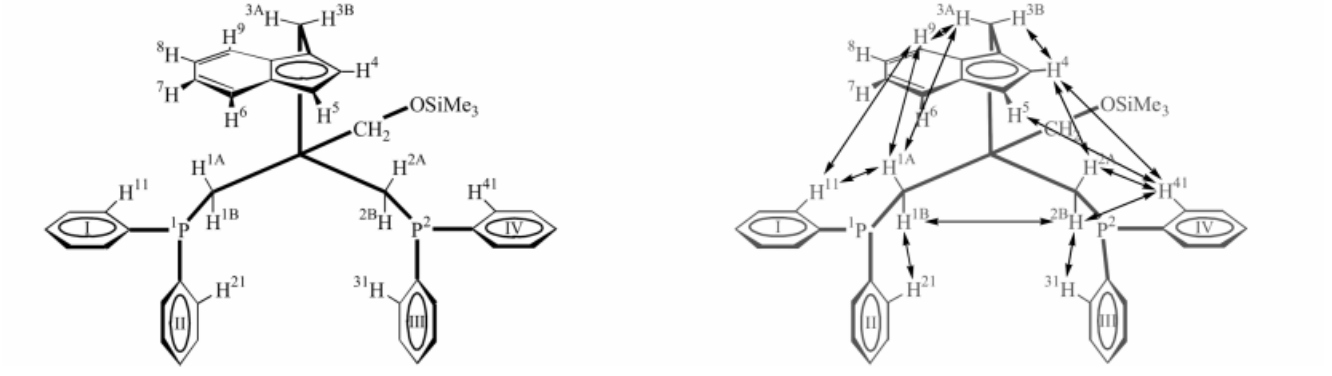

Figure 6. Numbering scheme used in the NMR analysis of **16a**; the right hand side shows the conformationally relevant and experimentally accessible NOE contacts as double-headed arrows

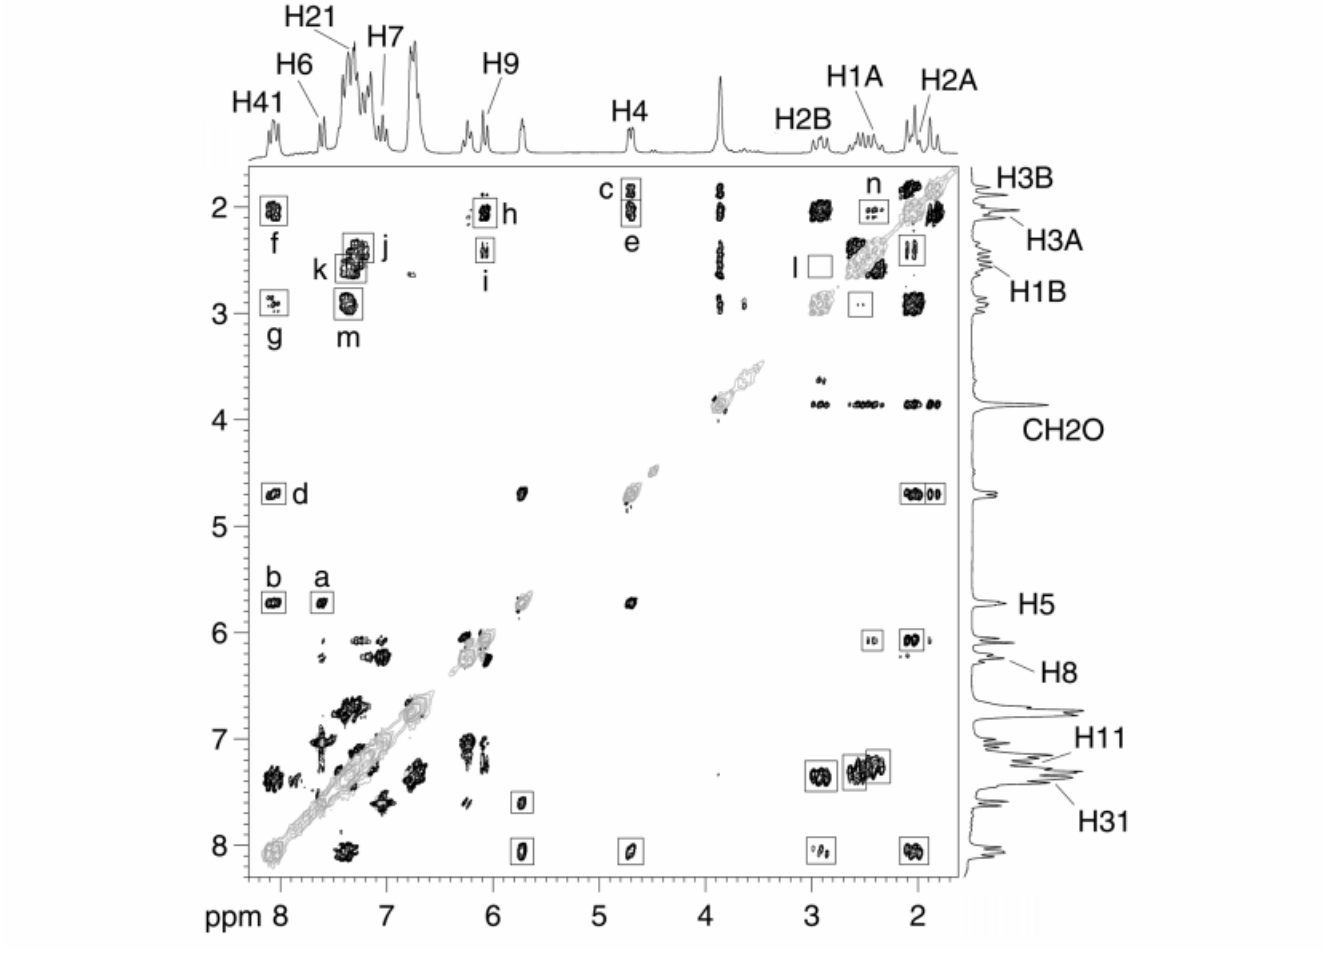

Figure 7. NOESY spectrum of **16a**; the labels designating individual conformationally relevant cross-peaks are used as an abbreviated reference in the text; the origin of the cross-peaks follows from the labelling of the spectral traces

experiments (Figure 7),[19] which finally allowed for the unambiguous assignment of all the conformationally relevant protons labelled in Figure 6. The ambiguity about the position of the protons H^6/H^9 was resolved by the observation of a strong cross-peak (Figure 7; labelled a) between one of the protons of the Cp part of the ligand (H^5) and one of the protons of the anellated benzene moiety (H^6). The position of both protons (referring to Figure 6) is clear from this observation.

H^5 shows a correlation with H^{41} (Figure 7; b) while H^4 shows correlations with H^{3b}, H^{41} and H^{2A} (Figure 7; c, d, e). H^{2A} itself correlates with H^{41} (Figure 7; f) and H^{41} shows a cross-peak with H^{2B} (Figure 7; g), which also correlates with H^{31} (Figure 7; m). These correlations built up a framework which unambiguously differentiated between the two sides of the compound and showed that the phosphorus atom labelled P^2 was at the side of the molecule opposite to that containing the anellated benzene ring (Figure 6).

The mutual orientation of the constituents at the other side of the molecule may be inferred from cross-peaks between H^9 and the methylene protons H^{3A} and H^{1A} (Figure 7; h, i). H^{1A} correlates with H^{11} and with H^{3A} (Figure 7; j, n). The second proton of this methylene group H^{1B}, shows a cross-peak with H^{21} as well as with H^{2b} (Figure 7; k, l). Some additional correlations involving *meta*-protons are also observed (Table 8). A scaffolding was thus apparent from the NOE experiments which qualitatively completely defined the conformation of **16a** (Figure 6, right-hand side).

A quantitative insight into the conformational manifold adopted by **16a** in solution was provided by a molecular modelling approach. To this end, a model representation was constructed. The basic geometry may be taken from the experimental structures of similar compounds such as $H_3CC(CH_2\text{-}\eta^1\text{-}PPh_2)_2(CH_2\text{-}\eta^5\text{-}Cp)RuCl$[15] with the anellated benzene moiety and the TMS group being added by modelling procedures.[20] The model thus generated was locally optimised with respect to energy as a template for any further calculations. Alternatively, the model may be constructed without explicit reference to similar molecules by using the parameters of the modelling package (Discover 3.0, ESFF force field) alone. Both these approaches led to basically the same conformations of the model template.

As was also observed in the structures of Cp derivatives $H_3CC(CH_2\text{-}\eta^1\text{-}PPh_2)_2(CH_2\text{-}\eta^5\text{-}Cp)RuCl$, the chelate cage itself is chiral.[15] The torsion angles $Ru-P-CH_2-C_{ipso}$ never conform to a mirror symmetric arrangement, even in the case of Cp derivatives.[2,3,6,15] With the indenyl ligand of **16a**, additional side differentiation was imposed on the molecules such that conformational diastereomers may exist. To cope with this problem, starting from the model compound, a second model was constructed leaving everything unchanged besides the orientation of the indenyl group which was rotated around its $C-CH_2$ axis by 180°. These two diastereomeric model templates, together with the quantitative information of the inter-proton distances were used for distance-geometry (DG) calculations.[21] From these procedures, a set of conformations resulted, which were in agreement with the restraints imposed by the distances pertaining to the model and by the inter-proton distances from the NOE data.

Contacts No.		1−9	1−30	10−30	15−30
RMS [pm]		35	36	36	38

[a] Atom labels refer to Figure 6 throughout. H42 (No. 27) and H12 (No. 29) designate protons in the *meta* position of the aryl rings IV and I, respectively. Contacts No. 1−9 refer to distances which are fixed by the covalent framework. In the final calculations, contacts No. 2 and 4 were used as reference distances to transform the NOE volume integrals into distances. Contacts No. 10−14 designate distances which are not fixed by the covalent framework but refer to CH_2 protons of the CH_2OSi fragment which are diastereotopically not differentiated in the spectra. The "dummy atom" approach was used to incorporate these contacts in the calculations.[29] Contacts No. 15−30 are also not fixed by the covalent framework and build up a tight scaffolding to which the conformation has to adopt. The *ortho* and *meta* protons of the aryl groups show no diastereotopic differentiation in the spectra. For the purpose of distance-geometry calculations, each pair of these protons was replaced by a dummy atom.[29] For the purpose of energy minimisation and rms calculation, the protons were assigned individually with respect to whichever one gave the shorter distance. The rms values given refer to inter-proton distances exclusively. The set of contacts to which they refer is indicated by the appropriate range in terms of their numeric labels. Since contacts No. 1−9 refer to distances which are fixed by covalent bonding, the respective rms value presents an expected value for the overall accuracy. The rms values referring to all contacts (No. 1−30) or only to conformationally relevant subsets (No. 10−30, No. 15−30) are well within the expected range.

Figure 8 shows the results obtained for **16a**. The ten conformations (grey) with the lowest distance violations (with the best overall agreement) are shown. While it is clear from the NMR observations that the phenyl groups are free to

RMS [pm]		34	32	30	34

[a] Atom labels refer to Figure 9 throughout. The meaning of columns and designations is analogous to the one explicitly described for **16a** in Table 8. Contacts No. 1, 2, 4, and 7 were used as the distance reference.

sis of energy minimisation. The resulting minimised conformation is shown in black in Figure 8.

With the best model from distance-geometry alone, the rms deviation between the observed and calculated distances is only approximately 3 pm. This traditional measure of quality of agreement between calculated conformations and NOE distances is quite biased, since the distances determined by the covalent framework and the distances referring to NOE contacts are measured by the same ruler. It appears more appropriate to consider the difference between NOE-derived distances and their computationally generated counterparts alone to derive a measure of quality. For the model generated by distance-geometry, this measure results in an rms of 48 pm. With the optimal conformation obtained after energy minimisation, this rms deviation is approximately 36 pm and thus corresponds to the error estimated for the accuracy of the NOE distances (Table 8).

The procedure as described for the NMR analysis of **16a** was also applied to **16b**. ^{1}H,^{31}P-HMBC[22] and ^{1}H,^{1}H-COSY experiments together with other 2D NMR spectroscopic data did allow for the complete assignment of an extensive subset of signals (Table 7, Figure 9 and Experimental Section).

The measured NOE contacts built up a tight scaffolding which the conformation of **16b** had to adopt (Figure 9, right-hand side). The NMR spectroscopic data also clearly showed that **16b** was diastereomerically pure. If there were another diastereomer present, its concentration must be below the NMR detectable limit (< 1%). It is clear from these experiments that the phosphorus nucleus of the PEt_2 group resonates upfield (P^1, δ = 33.8, Table 7) from that of the PPh_2 group (P^2, δ = 56.3, Table 7). It is also clear that the PEt_2 group is located on the same side as the anellated benzene ring. Refinement of the structure by the same procedures applied to **16a** led to the set of conformations shown in Figure 10.

The optimal single conformation is shown in black in Figure 10. The rms deviation between the calculated and experimental values of 18 conformationally relevant interproton distances (Figure 9) is only 30 pm (Table 9). This single conformation is therefore in optimal agreement with the NOE data. The most important result of this NMR analysis is that it proves that chiral indenyl-containing *tripod* ligands form their *tripod* metal derivatives under complete diastereoselective control.

Conclusion

Functionalised tripod ligands of the type $ROCH_2C(CH_2PPh_2)(CH_2PR'_2)(CH_2Cp^{\#})$ ($Cp^{\#}$ = indenyl, fluorenyl) are accessible from the oxetane precursor $O(CH_2)_2C(CH_2Br)(CH_2OMs)$ in a few steps. These tripod ligands form ruthenium complexes of the $CpRuL_2Cl$ type with the $Cp^{\#}$ group and the phosphorus donor groups linked by a *neo*-pentane scaffolding.

Epichlorohydrin is a suitable starting material to prepare chelate ligands $(Cp^{\#}CH_2)CHOH(CH_2PPh_2)$ in fully diastereoselective one-pot syntheses. These chelate ligands coordinate highly diastereoselectively to $Ru(PPh_3)(Cl)$.

The formation of the complex $Me_3SiOCH_2C(CH_2$-η^1-$PPh_2)(CH_2$-η^1-$PEt_2)(CH_2$-η^5-Indenyl)RuCl is completely diastereoselective, with the six-membered cycle of the indenyl constituent lying on the same side to which the PEt_2 group is coordinated.

A complete and unambiguous structure analysis of the *tripod* compounds $Me_3SiOCH_2C(CH_2$-η^1-$PPh_2)(CH_2$-η^1-$PR_2)(CH_2$-η^5-Indenyl)RuCl (R = Ph, Et) by a combination of NMR spectroscopy methods as well as distance-geometry modelling is reported, which documents the power of NMR methods for the quantitative analysis of structures of coordination compounds.

Experimental Section

General Remarks: All manipulations involving phosphanes were carried out under argon by means of standard Schlenk techniques and were monitored by TLC (Macherey−Nagel Co., Polygram SIL G/UV_{254}). All solvents were dried by standard methods[23] and distilled under argon. The solvents $CDCl_3$ and CD_2Cl_2 used for NMR spectroscopic measurements were degassed by three successive

"freeze-pump-thaw" cycles and dried over 4-Å molecular sieves. − MS: Finnigan MAT 8320; EI (70 eV); FAB (Xenon; matrix: 4-nitrobenzyl alcohol). − HR-MS(EI): Jeol JMS-700. − HR-MS(FAB): VG ZAB 2F − Melting points: Gallenkamp MFB-595 010; uncorrected values. − Optical rotations: Jasco DIP310, 10-cm cell, Na-D line (λ = 589 nm) − Cyclovoltammetry: EG&G Princeton Applied Research model 273; potentials in mV versus SCE at a glassy carbon electrode at 25 °C; solutions of compounds: 10^{-3} M in 0.1 M Bu_4NPF_6 in CH_2Cl_2. − Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg.

Materials: Silica gel (Kieselgel z. A. 0.06−0.2 mm, J. T. Baker Chemicals B. V.) used for chromatography was degassed at 1 mbar for 24 h and saturated with argon. A solution of *n*BuLi in hexane (2.5 M) was used for deprotonations. *S*-(+)- and *R*-(−)-epichlorohydrin (**5**) (97% *ee*) were degassed and checked for optical purity by measurement of their specific rotations ($|[\alpha]_D^{20}| = 34.3$[24]). $HPEt_2$,[25] $HPPh_2$,[26] 3-(bromomethyl)-3-(methanesulfonoxymethyl)oxetane (**1**),[5] 1,1-bis(diphenylphosphanylmethyl)-1-(cyclopentadienylmethyl)ethane,[2b] $(PPh_3)_2FeCl_2$ [10] and $(PPh_3)_3RuCl_2$ [27] were prepared according to or by adaptation of literature procedures. All other chemicals were obtained from commercial suppliers and used without further purification.

NMR: Spectra were recorded at 298 K with a Bruker Avance DPX200 spectrometer at 200.13 MHz (^{1}H), 50.323 MHz (^{13}C), 81.014 MHz (^{31}P) and with a Bruker Avance DRX300 spectrometer at 300.13 MHz (^{1}H), 121.495 MHz (^{31}P); chemical shifts (δ) are reported in ppm with $CHCl_3$ (^{1}H: δ = 5.32; ^{13}C: δ = 53.5) as internal standard; ^{31}P chemical shifts (δ) are reported in ppm with 85% H_3PO_4 (^{31}P: δ = 0) as external standard. Acronyms of pulse programmes refer to pulse sequences supplied under these names for the BRUKER series of instruments; relaxation delays for 2D NMR experiments were set at around 1.5 s if not stated otherwise. ^{1}H-^{31}P-HMBC: pulse sequence inv4gslrnd; instruments DRX300 (**16a**), DPX200 (**16b**); spectral width F_2 = 2588 Hz, F_1 = 3888 Hz (**16a**), F_2 = 1717 Hz, F_1 = 2755 Hz (**16b**), mixing time 70 ms. ^{1}H,^{13}C-HMBC: pulse sequence inv4gslrnd; instrument DPX200; spectral width F_2 = 1380 Hz, F_1 = 6542 Hz (**16a**), F_2 = 1717 Hz, F_1 = 7348 Hz (**16b**), mixing time 70 ms. ^{1}H,^{13}C-HSQC: pulse sequence invieagssi; instrument DPX200; spectral width F_2 = 1380 Hz, F_1 = 6542 Hz (**16a**), F_2 = 1717 Hz, F_1 = 7046 Hz (**16b**). ^{1}H,^{1}H-DQFCOSY: pulse sequence cosygsmftp; instrument DPX200; spectral width 1380 Hz (**16a**), 1717 Hz (**16b**) in both dimensions. ^{1}H,^{1}H-NOESY: pulse sequence noesytp; instrument DPX200; spectral width 1380 Hz (**16a**), 1717 Hz (**16b**) in both dimensions; relaxation delay 2.0 s; mixing time 500 ms.

NOE Analysis: The NOE peaks were integrated by standard methods (volume integration, Felix software package from MSI).[20,28] The peak volumes were transformed to distances by assuming the initial rate approximation to be valid. For bringing the distances to an absolute scale, the known inter-proton distances of H^4/H^5 (265 pm) and H^{2A}/H^{2B} (178 pm) (**16a**) and H^{1A}/H^{1B}, H^{2A}/H^{2B}, H^{11A}/H^{11B} (178 pm) and H^4/H^5 (265 pm) (**16b**) were used. Other combinations of reference distances were also tested; different sets of references did not cause changes greater than 10%. Owing to the fact that only one mixing time was used, the overall accuracy of the NOE-derived distances will not be much better than 30 pm.

Distance-Geometry Calculations: The NOE-derived distances were used to build the distance matrix, together with the distance limits derived from covalent bonding. Upper and lower boundaries for NOE distances were set at 10%. The distance restraints derived from covalent bonding were defined by the DGII programme package (DGII package of NMR Refine module, InsightII, 98.0).[20b] Some of the protons, the *ortho*- and *meta*-protons of the phenyl groups and the protons of the CH_2OSiMe_3 group had to be replaced by dummy atoms since no diastereotopic differentiation was apparent for these protons. The upper boundary of the distance interval referring to these dummy protons was appropriately increased by 100 pm.[29] Distance-geometry calculations were used to produce a total of 200 conformations for each of the compounds **16a** and **16b**. The starting models were based on the structures obtained in each case by energy minimisation. In order to efficiently cope with the problem caused by the conformational chirality of the cage, the mirror image of this model with respect to the torsions within this cage was also incorporated as a starting point. Each of these two starting structures for each of the compounds **16a** and **16b** was allowed to adapt to the NOE restraints (DGII package of NMR Refine module, Insight98.0).[20b] The number of different conformations resulting from this procedure was limited to 100 for each starting geometry. It was observed that the minimisation procedure was able to converge from one sense of skew of the scaffolding to its opposite. Repetitive runs, however, showed that the degree of skewness of the chelate cage of the resulting structures was highly biased by the degree of skewness of the starting structure. This problem was overcome by the technique described above. With respect to the torsion angles $Ru-P-CH_2-C_{ipso}$, the DGII runs produce solutions which are close to being either symmetric with respect to the idealised mirror plane (bisecting the P−Ru−P angle and vertical to the P−Ru−P plane) or are antisymmetric with respect to this plane. With respect to energy minimisation calculations (see below) the best solutions for these torsional arrangements were used as a starting point. From the 200 conformations generated for both **16a** and **16b**, the 10 with the best overall agreement were selected to produce the superposition graphs shown in Figure 8 and Figure 10. In order to construct a model which best approximates the NOE distances and at the same time corresponds to a local minimum of the force field generated molecular hypersurface, the following procedure was adopted. Energy minimisation of the best structures generated by distance-geometry was done with the distances determined by NOE measurements constrained by corresponding high-force constants (harmonic potential force constants: 100 kcal·mol^{-1}·Å^{-2}). After reaching convergence, the NOE-derived constraints were removed and the conformation was allowed to relax on the basis of the molecular force field alone. The rms deviation between the model with NOE restraints and the one without was found to be 37 pm (**16a**) and 26 pm (**16b**) (based on all atoms). The resulting conformations are shown in black in Figure 8 and Figure 10. Generating an optimal model by the alternative procedure of taking the best solutions from the DGII runs as the starting points for the force-field refinement (no additional NOE restraints) led to similar results. The optimal solution derived by constrained refinement was again found. The minima derived by both methods were the same for **16a** (rms = 1.6 pm, based on all atoms) and **16b** (rms = 1.7 pm, based on all atoms). As a measure of agreement between the models and the experimental values, the rms deviation between the distance estimates from the model and from the experiment was calculated. Different subsets of inter-proton distances were included in these calculations. As is seen in Table 8 and Table 9, the individual error estimates were very similar to each other, independent of which subset was chosen for their calculation.

Synthetic Procedures: The analytical data are collected in Table 10 and 11. NMR spectroscopic data, if not explicitly given in the experimental protocols are presented in Table 1−3, and Table 7.

Table 10. Analytical data of compounds **2**−**12**

Ligand Syntheses

General Procedure for the Synthesis of Compounds 2: The corresponding phosphane R_2PH (10 mmol) for the generation of the nucleophile **I** was dissolved in THF (50 mL) and deprotonated by the dropwise addition of *n*BuLi (10 mmol) at 0 °C. This solution was stirred for 1 h at 25 °C. Meanwhile, nucleophile **II** (22 mmol, 2.2 equiv.) (indene or fluorene) was dissolved in THF (50 mL) and deprotonated in the same manner as nucleophile **I**. 3-(Bromomethyl)-3-(methanesulfonoxymethyl)oxetane (**1**) (10 mmol) was dissolved in THF (50 mL) and cooled to −10 °C. At this temperature, the previously prepared phosphide (nucleophile **I**) solution was added dropwise over a period of 2 h. After the addition was completed, the mixture was allowed to warm to 25 °C and stirring was continued for another 30 min. Meanwhile the solution of nucleophile **II** was heated to 60 °C and the oxetane solution was added dropwise over a period of 1 h. The mixture was then heated at reflux for 2 h. After cooling to 25 °C, the mixture was hydrolysed by the addition of water (30 mL). The organic phase was separated, and the aqueous layer was extracted with diethyl ether (3 × 30 mL). The combined organic phases were washed with saturated NaCl solution until a neutral pH was achieved, and then dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (silica gel; eluent, R_f, yields, and analytical data as given in Table 10).

General Procedure for the Synthesis of Compounds 3: Phosphane R_2PH (6 mmol, 1.2 equiv.) for the generation of the nucleophile was dissolved in THF (40 mL) and deprotonated by the dropwise addition of *n*BuLi (6 mmol) at 0 °C. This solution was stirred for 1 h at 25 °C. Meanwhile, oxetane **2** (5 mmol) was dissolved in THF (40 mL) and deprotonated in the same manner as the phosphane. The solution of the phosphide was added dropwise to the solution of the oxetane **2** over a period of 45 min at 25 °C. The resulting mixture was stirred for 3 h. The mixture was then heated at reflux for 2 h. After cooling to 25 °C the mixture was hydrolysed by the addition of water (30 mL). The organic phase was separated, and the aqueous layer was extracted with diethyl ether (3 × 30 mL). The combined organic phases were washed with saturated NaCl solution until a neutral pH was achieved, and then dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (silica gel; eluent, R_f, yields, and analytical data as given in Table 10).

General Procedure for the Synthesis of Compounds 4 and 9: The starting material (**3** or **6**) (4 mmol) was dissolved in CH_2Cl_2 (20 mL) and triethylamine (6 mmol, 1.5 equiv.) was added. The solution was cooled to 0 °C and trimethylsilyl chloride (5.2 mmol, 1.3 equiv.) was added dropwise. Stirring was continued for 1.5 h and then all volatiles were removed in vacuo. The remaining residue was further purified by column chromatography (silica gel; eluent, R_f, yields, and analytical data as given in Table 10).

General Procedure for the Synthesis of Compound 6a: Diphenylphosphane (10 mmol, 1 equiv.) was dissolved in THF (30 mL) and deprotonated by the dropwise addition of *n*BuLi (10 mmol) at 0 °C. This solution was stirred for 1 h at 25 °C. Meanwhile, epichlorohydrin (10 mmol) was dissolved in THF (30 mL) and cooled to −70 °C. At this temperature, the phosphide solution was added dropwise over a period of 45 min. After warming to 25 °C, the solution was stirred for 30 min and added dropwise over a period of 20 min to a solution of CpMgCl·2THF (23 mmol, 2.3 equiv.) in THF (40 mL). The resulting mixture was stirred for 15 h at 25 °C. The mixture was hydrolysed by the addition of an NH_4Cl solution (10%, 50 mL). The organic phase was separated, and the aqueous layer was extracted with diethyl ether (3 × 30 mL). The combined organic phases were washed with a saturated NaCl solution until a neutral pH was achieved and then dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (silica gel; eluent, R_f, yields, and analytical data as given in Table 10).

General Procedure for the Synthesis of Compounds 6b/6c: Diphenylphosphane (10 mmol, 1 equiv.) for the generation of the nucleophile **I** was dissolved in THF (30 mL) and deprotonated by the dropwise addition of *n*BuLi (10 mmol) at 0 °C. This solution was stirred for 1 h at 25 °C. Meanwhile, epichlorohydrin (10 mmol) was dissolved in THF (30 mL) and cooled to −70 °C. At this temperature, the solution of the phosphide was added dropwise over a period of 45 min. After warming to 25 °C, the solution was stirred for 30 min and added dropwise over a period of 20 min to a solution of nucleophile **II** (indenyllithium or fluorenyllithium, prepared in the same manner as nucleophile **I**) (23 mmol, 2.3 equiv.) in THF (40 mL). The resulting mixture was stirred for 15 h at 25 °C. The mixture was hydrolysed by the addition of water (30 mL). The organic phase was separated, and the aqueous layer was extracted with diethyl ether (3 × 30 mL). The combined organic phases were washed with a saturated NaCl solution until a neutral pH was achieved, and then dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (silica gel; eluent, R_f, yields, and analytical data as given in Table 10). The same procedure was used for the synthesis of *R*-(−)-**6b** from *S*-(+)-**5** and *S*-(+)-**6b** from *R*-(−)-**5**.

Procedure for the Synthesis of Compounds 7, 8: Indene (108 mmol) was dissolved in THF (40 mL). This solution was cooled to 0 °C and treated with *n*BuLi (108 mmol). The solution was allowed to warm to 20 °C and stirred for 1.5 h. Meanwhile, epichlorohydrin (2.16 mmol) was dissolved in THF (20 mL) at −40 °C. The freshly prepared solution of LiInd was added to this solution through a Teflon® capillary under a slight overpressure of Argon over 1 h. The resulting solution was stirred for 15 h at 20 °C. After hydrolysis with H_2O (30 mL), the organic phase was separated and the aqueous phase extracted with diethyl ether (3 × 30 mL). The combined organic phases were washed with a saturated NaCl solution until a neutral pH was achieved, and dried with $NaSO_4$. After evaporation of all volatiles in vacuo, the remaining material was dissolved in CH_2Cl_2 and separated by column chromatography (silica gel; eluent, R_f, yields, and analytical data as given in Table 10).

Procedure for the Synthesis of Compound 10: Compound **6a** (6.0 mmol) was dissolved in THF (40 mL). BH_3/THF (7.8 mL, 16.2 mmol) were added dropwise at 0 °C over 5 min. After stirring the solution for 1 h at 0 °C, the volatiles were removed in vacuo. The remaining colourless oil was dissolved in CH_2Cl_2 and purified by column chromatography (silica gel; eluent, R_f, yields, and analytical data as given in Table 10).

Procedure for the Synthesis of Compound 11: Compound **10** (6.0 mmol) was dissolved in CH_2Cl_2 (30 mL). After the addition of triethylamine (9 mmol), the solution was cooled to 0 °C. MsCl (7.8 mmol) was added over 2 min and the solution was stirred for 6 h at 20 °C. After hydrolysis with H_2O (10 mL), the organic phase was separated. The aqueous phase was extracted with CH_2Cl_2 (3 × 20 mL). The combined organic phases were washed with a saturated NaCl solution until a neutral pH was achieved, and dried with $NaSO_4$. After evaporation of the solvent, the viscous oily residue was dissolved in CH_2Cl_2 and purified by column chromatograph (silica gel; eluent, R_f, yields, and analytical data as given in Table 10).

General Procedure for the Synthesis of Compounds 12: Compound **6** (4 mmol) was dissolved in CH_2Cl_2 (20 mL) and triethylamine (5.6 mmol, 1.4 equiv.) was added. The solution was cooled to 0 °C and chlorodiphenylphosphane (4.8 mmol, 1.2 equiv.) was added dropwise. Stirring was continued for 2 h at 25 °C, and then all volatiles were removed in vacuo. The remaining residue was further purified by column chromatography (silica gel; eluent, R_f, yields, and analytical data as given in Table 10).

Syntheses of Coordination Compounds

General Procedure for the Synthesis of Compounds 13: Compound **9** (1 mmol) was dissolved in THF (20 mL) and deprotonated by the dropwise addition of *n*BuLi (1 mmol) at 0 °C. The solution was stirred for 1.5 h at 25 °C. Meanwhile, $FeCl_2$ (0.6 mmol) was suspended in THF (15 mL) and stirred for 30 min. This solution was added dropwise to the solution of the deprotonated ligand over a period of 10 min. The mixture was stirred for 1 h. After this time, the mixture was heated, in the case of **13a**, for 4 h at reflux, and in the case of **13b**, for 2 h at 50 °C. All volatiles were removed in vacuo and the remaining residue was further purified by column chromatography. In the case of **13a**, the remaining residue was taken up in diethyl ether and purified by chromatography on neutral Al_2O_3 (Brockmann activity grade III). On evaporation of the solvent from the eluate, the purified compound **13a** was obtained in oily form. Further purification could be achieved by washing with petroleum ether (boiling range 40−60 °C) and resulted in a microcrystalline solid (Table 11). In the case of **13b**, the remaining residue was purified by chromatography on neutral Al_2O_3 (Brockmann activity grade III). The contaminants were eluted with petroleum ether (boiling range 40−60 °C) and mixtures of petroleum ether/toluene. Subsequently, compound **13b** was eluted with toluene. On evaporation of the solvent from the eluate, the purified compound **13b** was obtained in microcrystalline form (Table 11).

$^{31}P\{^1H\}$ NMR: 13a ($CDCl_3$): δ = −23.6 (s). − **13b** ($CDCl_3$): δ = −23.5 (s).

General Procedure for the Synthesis of Compound 14: 1,1-Bis-(diphenylphosphanylmethyl)-1-(cyclopentadienylmethyl)ethane (1 mmol) was dissolved in THF (20 mL) and deprotonated by the dropwise addition of *n*BuLi (1 mmol) at 0 °C. The solution was stirred for 1.5 h at 25 °C. Meanwhile, $CoCl_2$ (1 mmol) was suspended in THF (20 mL) and cooled to −30 °C. The deprotonated ligand was added dropwise to this solution over a period of 5 min. After addition was completed, the mixture was allowed to warm to 20 °C and stirred for another 45 min. All volatiles were removed in vacuo. The remaining residue was dissolved in ethanol (20 mL) and $NaBPh_4$ (1 mmol) was added. After stirring for 2 h, all volatiles were removed in vacuo and the remaining residue was further purified by column chromatography. Compound **14** was eluted with THF/CH_2Cl_2 mixtures. On evaporation of the solvent from the eluate, the purified compound **14** was obtained in microcrystalline form (Table 11).

^1H NMR: 14 (CD_2Cl_2): δ = 1.26 (br. s, 2 H,CH_2Cp), 1.52 (br. s, 3 H, C_qCH_3), 2.29 (m, 2 H, CH_{2a}P, $^2J_{HH}$ = 15.7 Hz), 2.59 (m, 2 H, CH_{2b}P, $^2J_{HH}$ = 15.7 Hz), 4.68 (br. s, 2 H, Cp), 5.99 (br. s, 2 H, Cp), 6.75−7.95 (m, 60 H, aromatic C*H*).

$^{13}C\{^1H\}$ NMR: 14 (CD_2Cl_2): δ = 31.3 (m, *C*H_2P), 33.3 (t, C_qCH_3, $^3J_{CP}$ = 12.9 Hz), 35.1 (s, *C*H_2Cp), 47.3 (s, C_q), 76.7, 97.9, 100.5 (3 s, Cp), 121.6−135.8 and 162.3−165.3 (m, aromatic *C*H).

$^{31}P\{^1H\}$ NMR: 14 (CD_2Cl_2): δ = 23.3 (s).

General Procedure for the Synthesis of Compounds 15 and 16: The appropriate ligand (**4** or **9**) (1 mmol) was dissolved in THF (20 mL) and deprotonated by the dropwise addition of *n*BuLi (1 mmol) at 0 °C. This solution was stirred for 1.5 h at 25 °C. All volatiles were then removed in vacuo and the remaining residue was dissolved in 1,2-dichloroethane (1,2-DCE) (15 mL). This solution was added dropwise over a period of 10 min at 25 °C to a solution of $RuCl_2(PPh_3)_3$ (1 mmol) in 1,2-DCE (30 mL). The mixture was stirred for 30 min. After this time, the mixture was heated for 2 h (**16**)/1.5 h (**15**) at 90 °C. All volatiles were removed in vacuo and the remaining residue was further purified by column chromatography. − **16** [solid phase neutral Al_2O_3 (Brockmann activity grade III)]: The excess triphenylphosphane and other contaminants were eluted with diethyl ether and the compounds **16** were subsequently eluted with Et_2O/CH_2Cl_2 mixtures. − **15** (solid phase silica gel): The excess triphenylphosphane and other contaminants were eluted with petroleum ether (boiling range 40−60 °C) (PE) and PE/Et_2O mixtures. The compounds **15** were eluted with PE/Et_2O 1:1. − On evaporation of the solvent from the eluate, the purified compounds **15** and **16** were obtained in microcrystalline form (Table 11).

^1H NMR: 15a ($CDCl_3$): Major product: δ = −0.03 (s, 9 H, SiCH_3), 1.73 (dd, 1 H, CH_{2a}Cp, $^2J_{HH}$ = 12.0 Hz, $^3J_{HH}$ = 14.0 Hz), 2.05 (dd, 1 H, CH_{2b}Cp, $^2J_{HH}$ = 12.0 Hz, $^3J_{HH}$ = 12.0 Hz), 2.55 (m, 2 H, CH_2P), 3.68 (m, 1 H, C*H*OSi), 3.73 (br. s, 1 H, Cp), 3.88 (br. s, 1 H, Cp), 4.52 (br. s, 1 H, Cp), 5.40 (br. s, 1 H, Cp), aromatic C*H*: 6.55−6.70 (m, 2 H), 6.86−6.94 (m, 2 H), 6.95−7.50 (m, 19 H), 8.05−8.20 (m, 2 H). − Minor product: δ = 4.97 (s, 0.08 H, Cp), 5.18 (s, 0.08 H, Cp). − **15b** ($CDCl_3$): δ = 0.14 (s, 9 H, SiCH_3), 2.78 (m, 2 H, CH_2P), 3.23 (m, 1 H, Indenyl five-membered ring C*H*, $^3J_{HH}$ = 2.2 Hz), 3.28 (m, 1 H, CH_{2a}Indenyl), 3.70 (m, 1 H, CH_{2b}Indenyl, J_{HP} = 7.6 Hz), 4.08 (m, 1 H, C*H*OSi), 4.34 (m, 1 H, Indenyl five-membered ring C*H*, $^3J_{HH}$ = 2.2 Hz), 6.80−7.70 (m, 29 H, aromatic and olefinic C*H*).

For designation of protons see Figure 9.

^{31}P{^{1}H} NMR: 15a ($CDCl_3$): Main product: δ = 23.3 (d, $^2J_{PP}$ = 41.0 Hz), 43.2 (d, $^2J_{PP}$ = 41.0 Hz). − Minor product: 25.5 (d, $^2J_{PP}$ = 39.9 Hz), 40.4 (d, $^2J_{PP}$ = 39.9 Hz). − **15b** ($CDCl_3$): δ = 35.7 (d, $^2J_{PP}$ = 35.5 Hz), 40.0 (d, $^2J_{PP}$ = 35.5 Hz).

X-ray Crystallographic Study: Suitable crystals were taken directly out of the mother liquor, immersed in perfluorinated polyether oil and fixed to a glass capillary at 200 K. The measurements were carried out with a Nonius−Kappa CCD diffractometer (low-temperature unit, graphite-monochromated Mo-K_α radiation). The data was processed by the standard Nonius software.[30] All calculations were performed using the SHELX software package.[31] Structures were solved by direct methods with the SHELXS-97 programme[31a] and refined with the SHELXL-97 programme.[31b] Graphic handling of the structural data during solution and refinement was performed with XPMA.[32] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data for the structure determinations are compiled in Table 12. The figures of the structures (Figure 1−3) were made with WinRay-32.[33] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-140087 (**7**), -140086 (*anti*-**8**) and -140088 (**15a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are indebted to the German Science Foundation (DFG), SFB 247, the VW Foundation (Stiftung Volkswagenwerk) and the Fonds der Chemischen Industrie for financial support. A generous loan of ruthenium(III) chloride by the DEGUSSA AG is gratefully acknowledged. We wish to thank T. Jannack (mass spectrometry), the Microanalytical Laboratory and the Mass spectrometry department (high resolution mass spectra) of the Institute of Organic Chemistry.

Improved syntheses of the known clusters $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ (**1**) and $[\{(OC)_5Cr\}_6Sn_6]^{2-}$ (**4**) are reported. The new synthetic procedures also allow for the preparation of the molybdenum and tungsten derivatives $[\{(OC)_5M\}_6Ge_6]^{2-}$ (M = Mo: **2**; M = W: **3**) and $[\{(OC)_5M\}_6Sn_6]^{2-}$ (M = Mo: **5**; M = W: **6**). Compounds **1**–**6** were obtained as crystalline $[Ph_4P]$ salts, whose structures were determined for the whole series **1**–**6** by single-crystal X-ray analyses. All six $[Ph_4P]$ salts crystallise in tetragonal space groups, with the site group symmetries of the cluster core ranging from C_{4h} to D_{4h}. The average octahedral symmetry of the cluster core in solution is evident from ^{119}Sn NMR spectroscopic data. Reversible one-electron oxidation of the dianions is suggested by cyclovoltammograms, while reduction is irreversible throughout. Electronic transitions which could be due to the cluster core were not found in the experimentally accessible energy range above 300 nm (below 4 eV). These findings indicate a high intrinsic stability of the precise electron clusters $[Ge_6]^{2-}$ and $[Sn_6]^{2-}$.

Introduction

The main group clusters $[Sn_6]^{2-}$ and $[Ge_6]^{2-}$ have been characterised in the form of their organometallic derivatives $[\{(OC)_5Cr\}_6Sn_6]^{2-}$ (**4**) and $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ (**1**).[1,2] While octahedral aggregates are a common type of arrangement for transition-metal clusters and a common motif in the structural chemistry of boranes and carboranes, they are by no way the preferred motif for the aggregation of other main-group elements, either in molecular compounds or in solid-state phases.[3] Thus anionic aggregates of the heavier group-14 elements $[E_m]^{n-}$ of tetrahedral shape e.g. $[Ge_4]^{2-}$, of trigonal-bipyramidal shape $[E_5]^{n-}$ [4,5] or of a shape somewhere between a monocapped archimedian antiprism (*nido*) and a tricapped trigonal prism (*closo*) $[E_9]^{n-}$ [6−11] are well-characterised species known as components of solid-state structures.[3,12] They are also, to a lesser extent, known in molecular anions in solution or in salt-type molecular compounds. No aggregate of the type $[E_6]^{n-}$ [13,14] has ever been observed until now, and it is only in an organometallic environment that such species are persistent in molecular anions. The compounds $[\{(OC)_5Cr\}_6Sn_6]^{2-}$ (**4**)[1] and $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ (**1**)[2] are the only ones thus far characterised. Their octahedral structures are well documented,[1,2] but their chemical properties could not yet be studied in detail as they are difficult to prepare in large amounts. Analysing the properties of these prototype species would be interesting for the following reasons:

Simple MO models predict that the clusters $[E_6]^{2-}$ (E = Ge, Sn), which form the core of their organometallic derivatives $[(L_nM)_6E_6]^{2-}$ (L_nM = 16 electron transition metal template), should be especially stable in view of their large HOMO−LUMO gap. This is in agreement with the accepted electron-counting rules[15,16] which state that *closo* octahedral species are stable, with seven skeleton electron pairs which is just the number of such pairs in $[E_6]^{2-}$ (E = group-14 element). On the basis of this model, it can be deduced that oxidation as well as reduction of such species should be difficult, and reduction might well lead to rearrangements, producing more open forms of the clusters.[15,16] A large HOMO−LUMO gap, as expected on the basis of such models, would also mean that electronic absorptions arising from transitions within the cluster framework should have a relatively high energy. Furthermore, the structures of the $[E_6]^{2-}$ entities should be close to octahedral in each case, largely independent of the type of organometallic protecting group L_nM. This octahedral arrangement should also persist in solution.

With all these questions in mind, it appears necessary to search for better synthetic strategies to produce the compounds $[(L_nM)_6E_6]^{2-}$. It had recently been found that the digermanium derivative $[\{(OC)_5Cr\}_2Ge_2I_4]^{2-}$, which is itself obtained by the reduction of GeI_2 with $Na_2[Cr_2(CO)_{10}]$, is a suitable precursor from which $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ (**1**) is obtained in up to 40% yield by further reduction.[17] This result stimulated a more systematic screening of the reactions of $[M_2(CO)_{10}]^{2-}$ [18,19] (M = Cr, Mo, W) with $EHal_2$ (GeI_2, $SnCl_2$). In this way, feasible procedures for the syntheses of $[\{(OC)_5M\}_6E_6]^{2-}$ (E = Ge, Sn; M = Cr, Mo, W) have been developed such that the cyclovoltammetric and spectroscopic behaviour of these

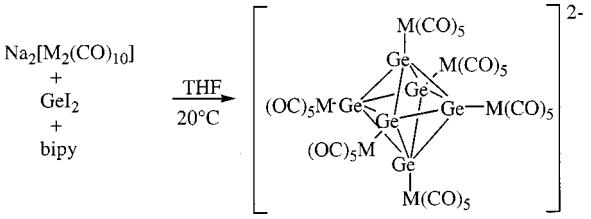
compounds, as well as their solid-state and solution structures, could now be studied in detail. The results of these preparative efforts and the spectroscopic, cyclovoltammetric, and structural studies are reported in this paper.

Results and Discussion

Preparation of Ge_6 Clusters

It had been shown that $K_2[Cr(CO)_5]$ reacts with $SnCl_2$ to produce $[\{(OC)_5Cr\}_6Sn_6]^{2-}$ (**4**) which could be isolated in the form of its $K(crypt)_2$ salt.[1] The straightforward transfer of this synthetic approach to the chemistry of germanium did, however, not result in an analogous $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ cluster. Only when $Na_2[Cr_2(CO)_{10}]$ was treated with GeI_2 in the presence of bipy (bipy = 2,2′-bipyridine), did the cluster $[\{(OC)_5Cr\}_6Ge_6]^{2-}$ (**1**) result (Scheme 1), which was isolated as its Ph_4P salt.[2]

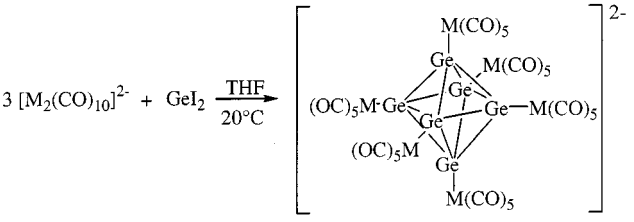


1 (M = Cr, yield: 11%)
2 (M = Mo, yield: 9%)
3 (M = W, yield: 9%)

Scheme 1. Syntheses and yields of **1**–**3** from a 1:1:1 mixture of the reagents

This type of procedure was now found to work with the decacarbonyldimetallates of molybdenum and tungsten as well, to produce **2** and **3**, respectively. The yields obtained in this route are modest throughout, with a maximum of 11% in the case of chromium and approximately 9% in the case of molybdenum and tungsten.

It has now been found that changing the stoichiometry of the reactants by increasing the amount of the dimetallate to a threefold molar excess with respect to GeI_2, produces the desired clusters in fair yields, without any addition of bipy (Scheme 2).

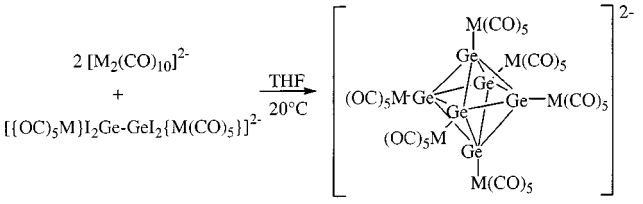


2 (M = Mo, yield: 47%)
3 (M = W, yield: 60%)

Scheme 2. Syntheses and yields of **2**, **3** from a 1:3 mixture of the reagents

It appears therefore that the only function of bipy in the reported synthesis of **1**[2] is to reduce the amount of GeI_2 by complexation, such that the stoichiometric excess of the dimetallate relative to the germanium iodide is appropriately increased.[20]

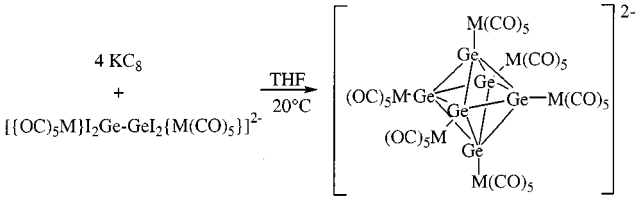
For the reaction of $[Cr_2(CO)_{10}]^{2-}$ with GeI_2, it has been shown that $[\{(OC)_5Cr\}I_2Ge-GeI_2\{Cr(CO)_5\}]^{2-}$ is obtained when the stoichiometric ratio of $[Cr_2(CO)_{10}]^{2-}$ and GeI_2 is 1:1.[17] This digermanium compound is an intermediate in the reductive pathway from GeI_2 to the $[Ge_6]^{2-}$ core of **1**: Further reduction of $[\{(OC)_5Cr\}I_2Ge-GeI_2\{Cr(CO)_5\}]^{2-}$ with 2 equiv. of $[Cr_2(CO)_{10}]^{2-}$ produces **1** in fair yields (Scheme 3).[17]



1 (M = Cr, yield: 40%)
3 (M = W, yield: 60%)

Scheme 3. Syntheses of **1** and **3** from tetraiododigermanate(2−)-precursors in a ratio 2:1

This type of reaction has been reported for compound **1**.[17] It has now been found that **3** can be obtained in good yields (60%) from $[\{(OC)_5W\}I_2Ge-GeI_2\{W(CO)_5\}]^{2-}$ [17] and 2 equiv. of $[W_2(CO)_{10}]^{2-}$. The decacarbonyldimetallates may be used as their sodium[18] or potassium salts,[19] without a significant change in reactivities and yields. The tetraiododigermanate derivatives $[\{(OC)_5M\}I_2Ge-GeI_2\{M(CO)_5\}]^{2-}$ are easily accessible for M = Cr, W, while for M = Mo the corresponding compound could not be isolated in a pure state. Its production is always accompanied by the formation of **2**, and it was not yet possible to separate the digermanate derivative from this cluster. For M = Cr and W, on the other hand, the compounds $[\{(OC)_5M\}I_2Ge-GeI_2\{M(CO)_5\}]^{2-}$ are ideal starting materials for the syntheses of **1** and **3**. Their reduction to these cluster compounds by KC_8 (Scheme 4) is a clean reaction from which the clusters are easily obtained in a pure state.



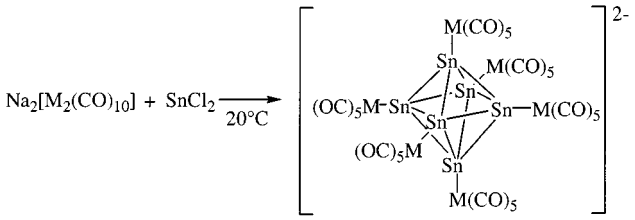
1 (M = Cr, yield: 42%)
3 (M = W, yield: 60%)

Scheme 4. Syntheses and yields of **1** and **3** by KC_8 reduction

Preparation of Sn_6 Clusters

The first compound of the series (**4**) was obtained from the reaction of $K_2[Cr(CO)_5]$ with $SnCl_2$.[1] It has now been found that the reaction of $Na_2[Cr_2(CO)_{10}]$ with $SnCl_2$ in a

1:1 molar ratio also leads to the formation of **4** (Scheme 5, Table 1).



4 (M = Cr, yield: 11%)
5 (M = Mo, yield: 36%)
6 (M = W, yield: 9%)

Scheme 5. Syntheses and yields of **4**–**6**

Table 1. Complexes of type **1**–**6**

	E	M	Cation
1	Ge	Cr	$[Ph_4P^+]$
2	Ge	Mo	$[Ph_4P^+]$
3	Ge	W	$[Ph_4P^+]$
4	Sn	Cr	$[Ph_4P^+]$
5	Sn	Mo	$[Ph_4P^+]$
6	Sn	W	$[Ph_4P^+]$

The reaction is sensitive to the molar ratio of the reactants: When $Na_2[Cr_2(CO)_{10}]$ and $SnCl_2$ are used in a 3:1 ratio, the star-type compound $[Sn\{Cr(CO)_5\}_3]^{2-}$ is the main product.[21] With $Na_2[Mo_2(CO)_{10}]$ or $Na_2[W_2(CO)_{10}]$ used in the same molar ratio, mixtures of products are obtained which do not contain any **5** or **6**, as judged from their IR absorptions. When a ratio of 1:1 is used, the isolated yield of **4** (as its Ph_4P salt) is approximately 10%, along with other products in the reaction mixture. $[\{(OC)_5Cr\}SnCl_3]^-$ and $[\{(OC)_5Cr\}_2SnCl_2]^{2-}$ (both isolated as their Ph_4P salts) were found to be formed in substantial amounts ($[Ph_4P][\{(OC)_5Cr\}SnCl_3]$, 26% and $[Ph_4P]_2[\{(OC)_5Cr\}_2SnCl_2]$, 42%). The same type of reaction has already been used to synthesise $[\{(OC)_5M\}_2SnCl_2]^{2-}$ (M = Cr, Mo, W).[22,23] These compounds were, in fact, the main products from which the clusters had to be separated by chromatography. In the case of **5**, the use of ethanol as the solvent instead of THF greatly improved the yield. In this solvent, **5** is precipitated by the addition of Ph_4PCl, while the $[Ph_4P]$ salts of the by-products remain in solution. Traces of $[Ph_4P]_2[\{(OC)_5Mo\}_2SnCl_2]$, which are precipitated together with $[Ph_4P^+]_2$·**5**, are easily washed out with ethanol such that analytically pure $[Ph_4P^+]_2$·**5** is obtained in 36% yield, without the necessity of chromatographic purification.

Structures and Properties

The structures of **1** and **4** have been reported for the phosphonium salt $[Ph_4P^+]_2$·**1**[2] and for the potassium salt $[K^+(crypt)]_2$·**4**.[1] In order to unequivocally prove the constitution of the phosphonium salts **2**–**6**, the structures were determined by X-ray analysis. Crystals of the tin compounds **4**–**6** were obtained by layering THF solutions of the salts with ethanol and the germanium compounds **2** and **3** were crystallised by layering DMA (*N*,*N*-dimethylacetamide) solutions of their salts with ethanol. From the crystals obtained this way, those of **4** contain 1 equiv. of THF per formula unit as a solvate, whereas the other compounds crystallise as such. The high symmetry of the phosphonium cation (S_4) and of the cluster anions are in agreement with tetragonal space groups, which are found for the phosphonium salts of all six compounds **1**–**6** (Table 6). The phosphorus centre of the phosphonium cation occupies a special position in each case such that its crystallographic point-group symmetry is S_4. The centres of the anionic clusters are also located at special positions. Owing to steric influence, the $M(CO)_5$ moieties have to be rotated around their Sn–M or Ge–M axes in such a way that they cannot conform to an arrangement which would be symmetric with respect to the idealised mirror planes of the "octahedron" formed by the main-group elements. The tilt imposed on these groups maximally allows for D_4 symmetry. This is the crystallographic symmetry apparent for the anions in $[Ph_4P^+]_2$·**1** and $[Ph_4P^+]_2$·**2** (space group *P*4/*nnc*). The phosphonium salts of **3**, **5**, and **6** crystallise in space group *I*4/*mmm*, which implies apparent D_{4h} symmetry of the anions. This apparent symmetry is fulfilled by a statistical 1:1 disorder of each $M(CO)_5$ group over two mirror-symmetric rotational positions. The $[Ph_4P]$ salt of **4** contains 1 equiv. of THF solvate per formula unit, its space-group symmetry is *I*4/*m*, with the crystallographic site-group symmetry of the cluster corresponding to C_{4h}. Again, this symmetry, which is exact for the Sn_6 core results from the superposition of two rotational positions of the $Cr(CO)_5$ units at the C_4 axis around their Cr–Sn bonds. The crystallographically determined symmetry of the "octahedron" formed by the main-group elements corresponds to the site-group symmetry in each case, and is, in fact, D_{4h} throughout. Therefore the main-group clusters have a tetragonally distorted octahedral symmetry. The observed distortion corresponds to a slight elongation of the octahedra along the C_4 axis (Table 2, Figure 1).

As the quantitative data (Table 2) show, there is a slight variation of the Ge–Ge distances from **1**–**3**, with **3** having $W(CO)_5$ groups showing the longest, and **1** having the $Cr(CO)_5$ groups showing the shortest distances. For the tin compounds **4**–**6**, no such variation is apparent (Table 2). The angles within and subtended by the main-group octahedra are fairly constant throughout and are in each case close to the values expected for an ideal octahedron (E–E–E: 60°, 90°; M–E–E: 135°; Table 2). The angles

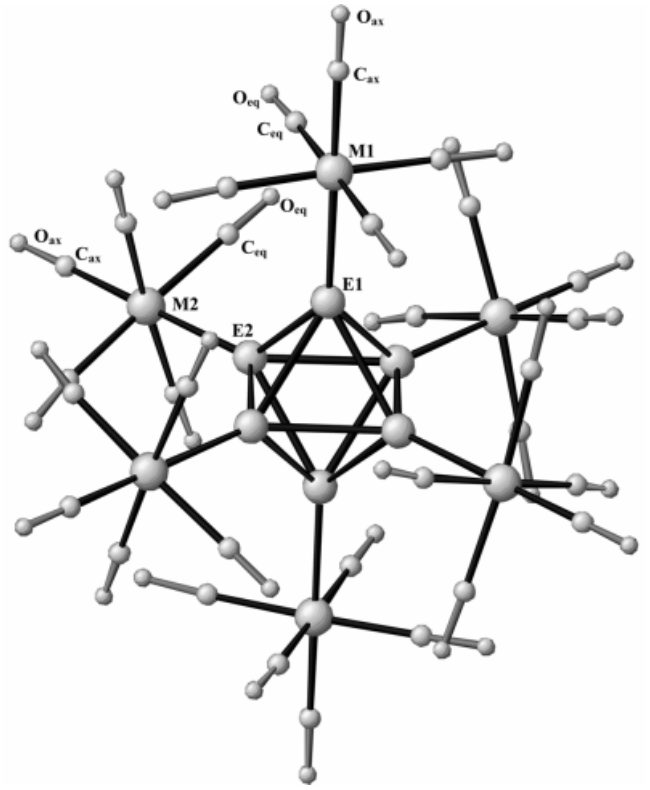

Figure 1. Structure of **2** as a representative of the architecture of **1**−**6**; labels refer to Table 2; the tetragonal axis is vertical in Figure 1, with E1 lying on this axis

describing the geometry of the $M(CO)_5$ fragments (Table 2) indicate a slight umbrella effect with the equatorial carbonyl groups bending towards the main-group centre. An overview of the geometric parameters characterising the $[E_6]^{2-}$ core of the clusters given in Table 2 makes it clear that neither the kind of the protective groups $M(CO)_5$ (M = Cr, Mo, W), nor the specific crystal environment, have a strong influence on the structure of the cluster core. It appears therefore that the observed geometry corresponds to a well-defined energy minimum on the corresponding hypersurface.

The idealised *closo* octahedral structure of the $[E_6]^{2-}$ core should therefore also characterise the structure of the compounds in solution. The pattern of $\tilde{\nu}$(CO) infrared bands observed for **1**−**6** (Table 3) is simple enough to substantiate this expectation. With two $M(CO)_5$ groups in slightly different chemical environments, a maximum of six absorptions should be expected. A maximum of five absorptions is observed (Table 3), and only four bands are apparent in most cases.

[a] DMA. − [b] THF.

This indicates that the high symmetry found in the anions in the solid state is also preserved in solution. A more direct indication of a cluster geometry that is octahedral on average, comes from NMR spectroscopy. The ^{119}Sn resonances of **4**−**6** (Table 4) show clear tin satellites in each case, with coupling constants of approximately 1800 Hz, characteristic of tin−tin contacts.[24] The integral ratio of the main signal to the satellites is as expected for an arrangement in which the observed tin nucleus is surrounded by four other nuclei, each of them in an abundance of 7.6% (calculated: 30.4%; observed 28%).[25] The ^{119}Sn NMR spectrum of $[Ph_4P^+]_2$·**6**

shows ^{183}W coupling with $^1J_{W-Sn} = 700$ Hz for the main signal, as well as for the satellites. In agreement with the overall octahedral geometry, there is only one ^{13}C resonance for the equatorial CO groups of compounds **1−6**, and one for the axial carbonyl groups, wherever these could be measured (solubility) (Table 4).

The $[E_6]^{2-}$ octahedra acting as the ligand core in compounds **1−6** are electron-precise *closo* clusters.[15,16] As a result of a low-lying HOMO and a high-energy LUMO, these clusters should be difficult to oxidise and reduce. Cyclic voltammetry reveals (Table 5) that despite the charge of −2 on these clusters, their oxidation occurs only at approximately +0.3 V (vs. SCE). This oxidation is reversible in some cases (Table 5). It thus follows that removing an electron from the filled t_{1u} HOMO does not induce a strong distortion of the cluster. Further irreversible oxidation of the cluster core is observed in the range up to approximately +0.8 V (vs. SCE) (Table 5). At higher potentials, the $M(CO)_5$ groups are oxidised. The peaks corresponding to an oxidation of the $M(CO)_5$ groups are roughly six times larger than the peaks that correspond to electron-transfer processes involving the cluster core. Polarograms also show an approximate 1:6 ratio of the corresponding step heights. This must mean that electron transfer involving the cluster core includes the whole $[E_6]^{2-}$ entity and not just one individual main-group centre, while electron transfer involving the $M(CO)_5$ entities involves each such group individually. Reduction of compounds **1−6** is irreversible throughout and occurs between −0.6 and −0.9 V (vs. SCE) (Table 5). Reduction of the $M(CO)_5$ entities is observed from approximately −1.4 V (vs. SCE) towards lower potentials and is also irreversible (Table 5).

The reversible oxidation of the cluster core documented by the cyclovoltammetric experiments would suggest that the cluster dianions could also be oxidised to the monoanions by chemical means. However, it was found that mild oxidants (sulfur, propylene sulfide, Fc^+), applied in solvents such as CS_2, DMA, THF, or mixtures of these, leave the dianions unchanged (IR control) for hours. Strong oxidants such as I_2 and tetrabromoorthoquinone lead to fragmentation of the clusters. The sodium salts of the cluster dianions are also stable against chemical reduction: Their THF solutions may be in contact with KC_8 without any sign of change, even after several days.

The cyclovoltammetric data indicate that the HOMO−LUMO separation within the clusters should be roughly 1.5 eV. Hence, if electronic HOMO−LUMO transitions were allowed, these would be expected to occur in the

[a] Potentials were measured vs. SCE with the exception of $[Ph_4P^+]_2$·**4** (see footnote[b]). The working electrode was a glassy-carbon electrode in each case, with a platinum wire used as the counter electrode. Redox processes were judged to be reversible if the separation of their anodic and cathodic peaks was similar to the one observed for the Fc/Fc^+ redox couple in the same experiment. A square-root dependence of peak height on scan speed was taken as the second criterion. The data given for the other electrode processes refer to peak potentials E_P^R or E_P^C throughout. − [b] The potentials refer to a platinum wire as the reference electrode and are thus on a deliberate absolute scale. Whenever an SCE electrode was immersed into the solution, the compound was found to disintegrate.

visible range. MO analysis of the cluster core on the other hand reveals that these transitions are symmetry-forbidden since the HOMO has t_{1u} symmetry and the LUMO has t_{2u} symmetry. The transition from the HOMO (t_{1u}) to the LUMO+1 (t_{1g}) would be symmetry-allowed. The energy difference between the corresponding orbitals is however quite large, and owing to the shape of the orbitals, the transition moment should be small. In agreement with this, UV/Vis spectra of the $[Ph_4P]$ salts **1**−**6** (Table 5) do not show a spectroscopic pattern that could be assigned to transitions within the cluster core. The high-energy absorptions above 350 nm are characteristic of $M(CO)_5$ derivatives as a whole (see for instance ref.[21]); the lower energy absorptions at approximately 400 nm are interpreted as LMCT absorptions. In agreement with germanium having a higher electronegativity than tin, these CT bands occur at higher energy for the germanium compounds than for the tin analogues (Table 5).

Experimental Section

General: All manipulations were carried out under argon by means of standard Schlenk techniques at 20 °C unless otherwise mentioned. All solvents were dried by standard methods, and distilled under argon. $[D_6]$DMSO and $[D_6]$acetone used for the NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried with 4 Å molecular sieves. Silica gel (Kieselgel z. A. 0.06−0.2 mm, J. T. Baker Chemicals B. V.) used for chromatography and Kieselgur (Kieselgur, gereinigt, geglüht, Erg. B.6, Riedel-de Haën AG) used for filtration were degassed at 1 mbar at 130 °C for 12 h and saturated with argon. − NMR: Bruker Avance DPX 200 at 200.13 MHz (^{1}H), 50.323 MHz (^{13}C{^{1}H}), 81.015 MHz (^{31}P{^{1}H}), 74.631 MHz (^{119}Sn{^{1}H}); chemical shifts (δ) in ppm relative to $[D_6]$DMSO (^{1}H: δ = 2.50; ^{13}C: δ = 39.4) and $[D_6]$acetone (^{1}H: δ = 2.05; ^{13}C: δ = 206.2) as internal standards and to 85% H_3PO_4 (^{31}P: δ = 0) and $(CH_3)_4Sn$ (^{119}Sn: δ = 0) as external standards, respectively. − IR: Bruker FT-IR IFS-66; CaF_2 cells. − UV/Vis/NIR: Perkin−Elmer Lambda 19; cells (0.2 cm; Hellma 110 suprasil). − Cyclic voltammetry: Methrom "Universal Meß- und Titriergefäß", Methrom GC electrode RDE 628, platinum electrode, SCE electrode, Princeton Applied Research Potentiostat Model 273, 10^{-3} M in 0.1 M nBu$_4$NPF$_6$/CH_3CN. − Elemental analysis: Microanalytical laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. − Melting points: Gallenkamp MFB-595 010; the values are not corrected.

Preparation of $[Ph_4P]_2[\{(OC)_5M\}_6Ge_6]$, $[Ph_4P^+]_2$·1, $[Ph_4P^+]_2$·2, $[Ph_4P^+]_2$·3 (M = Cr, Mo, W)

Method 1, the "bipy Method" (Suitable for the Preparation of $[Ph_4P^+]_2$·1−3): To a stirred orange solution of $Na_2[M_2(CO)_{10}]$[18] (M = Cr: 430 mg, 1 mmol; M = Mo: 518 mg, 1 mmol; M = W: 694 mg, 1 mmol) in THF (50 mL), solid GeI_2 (326 mg, 1 mmol) and solid 2,2′-bipyridine (156 mg, 1 mmol) were added in one portion. After stirring for 30 min, the deep red solution was filtered through Kieselgur (3 cm, Ø = 3 cm), concentrated in vacuo (3 mL) and purified by chromatography on silica gel (15 cm, Ø = 3 cm; THF). With THF as the eluent all by-products could be removed.[2,17,22] After elution with ethanol, the solutions of the sodium salts of **1**, **2**, and **3**, respectively, were obtained, which were reduced to 10 mL in vacuo. Addition of solid $[Ph_4P]Cl$ (750 mg, 2 mmol) led to the red-brown $[Ph_4P]$ salts of **1**, **2**, and **3**, which were separated from the mother liquor by filtration, washed with ethanol (2 × 5 mL) and diethyl ether (2 × 5 mL), and dried in vacuo. Yields: $[Ph_4P^+]_2$·**1**: 43 mg, 0.02 mmol, 11%; $[Ph_4P^+]_2$·**2**: 42 mg, 0.02 mmol, 9% $[Ph_4P^+]_2$·**3**: 50 mg, 0.02 mmol, 9% (with respect to GeI_2).

Method 2, Reduction with $K_2[M_2(CO)_{10}]$ (Suitable for the Preparation of $[Ph_4P^+]_2$·2, $[Ph_4P^+]_2$·3): KC_8 [811 mg, 6 mmol, freshly prepared by dry heating of graphite powder (577 mg, 48 mmol) with potassium (235 mg, 6 mmol) by a heat gun (650 °C) in a Schlenk tube under vacuum] and $M(CO)_6$ (M = Mo: 6 mmol = 1.58 g, M = W: 2.11 g, 6 mmol) in THF (50 mL) were stirred for 12 h at 20 °C, during which time CO evolution had ceased. After this period of time, solid GeI_2 (326 mg, 1 mmol) was added to the dark green heterogeneous mixture, causing a colour change to deep brown. After stirring for 1 h, the reaction mixture was filtered through Kieselgur (3 cm, Ø = 3 cm) and concentrated in vacuo (3 mL). Further workup was carried out as in Method 1. Yields: $[Ph_4P^+]_2$·**2**: 220 mg, 0.08 mmol, 47% $[Ph_4P^+]_2$·**3**: 320 mg, 0.10 mmol, 60% (with respect to GeI_2).

Method 3, Reduction of Tetraiododigermanates by Decacarbonyldimetallate (Suitable for the Preparation of $[Ph_4P^+]_2$·1, $[Ph_4P^+]_2$·3): To a solution of $Na_2[\{(OC)_5M\}I_2Ge-GeI_2\{M(CO)_5\}]$[17] (M = Cr, W) in THF (30 mL), a solution of $Na_2[M_2(CO)_{10}]$[18] in THF (30 mL) was added in 10-mL portions during a period of 3 h. The colour of the solution gradually turned to red-brown. Further workup was carried out as in Method 1. Yields: $[Ph_4P^+]_2$·**1**: 151 mg, 0.07 mmol, 40%; $[Ph_4P^+]_2$·**3**: 310 mg, 0.10 mmol, 60% (with respect to GeI_2).

Method 4, Reduction of Tetraiododigermanates with KC_8 (Suitable for the Preparation of $[Ph_4P^+]_2$·1, $[Ph_4P^+]_2$·3): To solid KC_8 [540 mg, 4 mmol; freshly prepared from graphite powder (384 mg, 32 mmol) and potassium (156 mg, 4 mmol) as above], a solution of $Na_2[\{(OC)_5M\}I_2Ge-GeI_2\{M(CO)_5\}]$[17] (M = Cr, W) in THF (50 mL) was added and stirred for 1 h. Further workup was carried out as in Method 1. Yields: $[Ph_4P^+]_2$·**1**: 164 mg, 0.07 mmol, 42%; $[Ph_4P^+]_2$·**3**: 306 mg, 0.10 mmol, 60% (with respect to GeI_2). Single crystals suitable for X-ray structure analysis were obtained by layering concentrated DMA solutions of $[Ph_4P^+]_2$·**1**, $[Ph_4P^+]_2$·**2**, and $[Ph_4P^+]_2$·**3** with ethanol.

Preparation of $[Ph_4P]_2[\{(OC)_5M\}_6Sn_6]$, $[Ph_4P^+]_2$·4 (M = Cr), $[Ph_4P^+]_2$·6 (M = W): To a stirred orange solution of $Na_2[M_2(CO)_{10}]$[18] (M = Cr: 430 mg, 1 mmol; M = W: 694 mg, 1 mmol) in THF (50 mL), solid $SnCl_2$ (190 mg, 1 mmol) was added in one portion. The orange solution turned deep red immediately. After stirring for 30 min, the reaction mixture was filtered through Kieselgur (3 cm, Ø = 3 cm). The resulting red solution was concentrated in vacuo (3 mL) and purified by chromatography on silica gel (15 cm, Ø = 3 cm; THF). A mixture of THF/ethanol (15:1) was used until the elute was colourless. A red band remained on top of the column and could be eluted with ethanol. $[Na^+]_2$·**4** and $[Na^+]_2$·**6** were obtained as deep red ethanolic solutions, which were concentrated to 10 mL in vacuo. Addition of solid $[Ph_4P]Cl$ (750 mg, 1 mmol) led to the corresponding deep red $[Ph_4P]$ salts of **4** and **6**, respectively, which precipitated immediately. The solids were separated from the mother liquor by filtration, washed with ethanol (2 × 5 mL), diethyl ether (2 × 10 mL), and dried in vacuo. Yields: $[Ph_4P^+]_2$·**4**: 46 mg, 0.02 mmol, 11%; $[Ph_4P^+]_2$·**6**: 50 mg, 0.02 mmol, 9% (with respect to $SnCl_2$). For growing single crystals of $[Ph_4P^+]_2$·**4** and $[Ph_4P^+]_2$·**6**, the deep-red solids were dissolved in

THF (5 mL) and layered with ethanol (20 mL). Within one week at 20 °C, deep-red crystals suitable for X-ray analysis were obtained.

Preparation of $[Ph_4P]_2[\{(OC)_5Mo\}_6Sn_6]$, $[Ph_4P^+]_2$·5: To a stirred ethanolic solution (50 mL) of $Na_2[Mo_2(CO)_{10}]$[18] (518 mg, 1 mmol), solid $SnCl_2$ (190 mg, 1 mmol) was added in one portion. After 30 min of stirring, the deep red solution was filtered through Kieselgur (3 cm, Ø = 3 cm), reduced to a volume of 10 mL in vacuo. Upon addition of solid $[Ph_4P]Cl$ (750 mg, 1 mmol), the red $[Ph_4P]$ salt of **5** precipitated immediately and was separated from the mother liquor by filtration. After washing the red solid with ethanol (2 × 5 mL) and diethyl ether (2 × 10 mL), the residue was dried in vacuo. Yield: $[Ph_4P^+]_2$·**5**: 171 mg, 0.06 mmol, 36% (with respect to $SnCl_2$). For growing single crystals of $[Ph_4P^+]_2$·**5**, the red solid was dissolved in THF (5 mL) and layered with ethanol (20 mL). Within one week at 20 °C, red crystals suitable for X-ray analysis were obtained.

X-ray Structure Determinations: The measurements for $[Ph_4P^+]_2$·**1**, **2**, **4**, **5**, **6** were carried out with a Siemens P4 four-circle diffractometer. Data for $[Ph_4P^+]_2$·**3** were collected with a Nonius Kappa CCD diffractometer, all using Mo-K_α radiation. In the case of the data collection with the Siemens P4 four-circle diffractometer, the intensities of three check reflections (measured every 100 reflections) remained constant throughout, thus indicating crystal and electronic stability. The data collected using a scintillation counter measuring device (Siemens P4) were corrected as usual including experimental absorption correction. The data from the CCD device (Nonius Kappa CCD) were processed by the standard Nonius software.[26] All calculations were performed using the SHELXT PLUS software package. Structures were solved by direct methods with the SHELXS-86 program and refined with the SHELXL-93 program.[27−29] The program XPMA[30] and WinRay32[31] were used for graphical handling of the data. The structures were refined in fully or partially anisotropic models by full-matrix least-squares calculations. Hydrogen atoms were introduced at calculated positions. The data for the structure determinations is presented in Table 6. Crystallographic data for the structures reported in this paper (except for $[Ph_4P^+]_2$·**1**: CSD-408093[2]) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-149568 ($[Ph_4P^+]_2$·**2**), -149565 ($[Ph_4P^+]_2$·**3**), -149564 ($[Ph_4P^+]_2$·**4**), -149566 ($[Ph_4P^+]_2$·**5**), and -149567 ($[Ph_4P^+]_2$·**6**). Monomer−Dimer Equilibria of Oxo/Imido Complexes of Heptavalent Rhenium: Theoretical and Spectroscopic Investigations

Philip Gisdakis,[a] Notker Rösch,*[a] Éva Bencze,[b,c] Janos Mink,[c,d] Isabel S. Gonçalves,[e] and Fritz E. Kühn*[b]

Keywords: Density-functional calculations / Imido ligands / Oxygen bridges / Rhenium / Transition states

Mixed oxo/imido derivatives of methyltrioxorhenium(VII) form dimers in the solid state at ambient temperature. Density-functional calculations show that the dimerization is exothermic. The most stable derivatives were calculated to display a pseudo trigonal-bipyramidal coordination with two bridging oxygen centers and the methyl groups in a *trans* arrangement. This configuration is energetically more favored than a *cis* arrangement of the methyl groups and a pseudo square-pyramidal structure at the metal centers. In the case of methyltrioxorhenium(VII), the dimerization is slightly endothermic, even for the optimal dimeric structure, so that dimers cannot be isolated. However, there is evidence for the transient existence of oxygen bridges between methyltrioxorhenium(VII) in solution. For mixed imido/oxo species, oxygen bridging is observed in all cases of dimerization; results of thermogravimetric/mass spectrometric studies demonstrate that these bridging dimers are weakly bound. From vibrational spectroscopic analysis, there is no evidence for nitrogen-bridged homologues. The density-functional calculations show that imido groups form bridges only in the case of sterically undemanding ligands. However, these complexes are too unstable to be isolated.

Introduction

Organorhenium(VII) oxides have been studied in great detail in recent years. The use of some derivatives, most prominently methyltrioxorhenium(VII), as catalysts in a broad range of reactions[1] triggered a significant amount of investigations,[2] among them several theoretical studies.[3] However, far less investigations have been devoted to organorhenium(VII)imido compounds. Very few studies concerning their synthesis, structures, and spectroscopic properties have been carried out in the last two decades.[2a,4] Recently, we discovered a temperature-dependent monomer−dimer equilibrium that occurs in solution in the case of mixed oxo/imido Re^{VII} complexes.[5] However, the ability of mixed oxo/imido complexes to form dimers may provide more insight into the propensity of methyltrioxorhenium(VII) to polymerize. It is important to remember that the first polymeric organometallic oxide ever described was formed from methyltrioxorhenium(VII).[6] To date, the manner in which the polymerization of methyltrioxorhenium(VII) starts or which intermediates are formed remain open to discussion since dimeric or oligomeric units have never been isolated or observed in situ. Therefore, it is of interest to compare methyltrioxorhenium(VII) with closely related complexes in which some or all of the oxygen ligands are replaced by imido groups, in order to examine conditions that would enable dimeric methylrhenium(VII) oxo complexes to be isolated. The energy differences between oxo/imido complexes and pure oxo complexes are of particular interest in this respect.

It is worth noting that isolated dimeric methylrhenium(VII) oxo/imido complexes have been observed to exhibit structural features[5] that differ from those predicted for hypothetical dimeric methyltrioxorhenium(VII) based on Hartree−Fock self-consistent field calculations using a relativistic effective core potential.[6c] In this context, a recent computational study focused on the thermochemistry of the Re−oxo bond cleavage in complexes of the type $LReO_3$, with L = Cp, Cp*, CH_3, C_6H_5, and others.[7] The Re−O bond-dissociation energy was found to depend quite strongly on the nature of the ligand L. A comparison of the calculated results with experimental data demonstrated the convincing accuracy of the applied computational method, a hybrid density-functional approach, and hence the opportunity for a computational study of organometallic thermochemistry.

Another point of interest in recent literature reports is the ability of methyltrioxorhenium(VII) and related complexes to easily exchange their terminal oxygen ligands. This has been shown by ^{17}O NMR spectroscopic studies[8] and it has been assumed that this process proceeds through oxy-

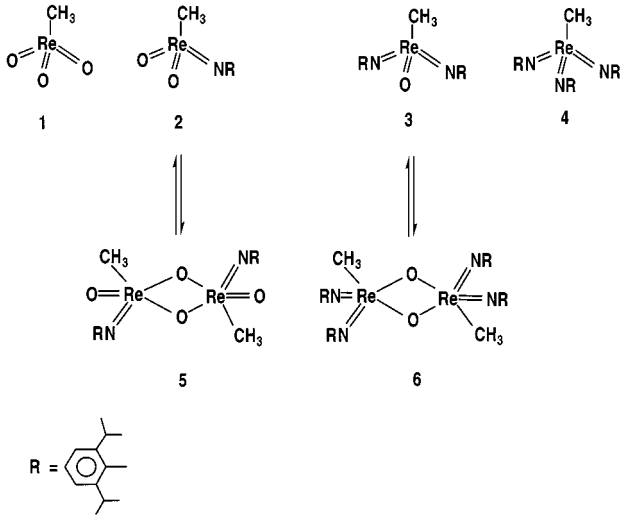
gen bridges. However, the existence of energetically accessible dimeric states that allow oxygen exchange through such bridges is still unclear.

In the present work, we perform a detailed theoretical study of the monomer−dimer equilibria that occur in the case of mixed methylrhenium(VII) oxo/imido species and we compare them to dimers of pure oxo and imido derivatives. The theoretical study is supplemented by thermogravimetric/mass spectrometric investigations of the sublimation behavior of selected complexes of this type and a detailed IR/Raman study of monomeric and dimeric oxo/imido methylrhenium(VII) complexes.

Results and Discussion

Dimer Systems

We start with an overview of the various monomers and dimers to be studied. From the monomeric compound CH_3ReO_3 (**1**) one can derive the monomers of interest if one successively substitutes oxo functions by imido groups to yield $CH_3ReO_2(NR)$ (**2**), $CH_3ReO(NR)_2$ (**3**), and $CH_3Re(NR)_3$ (**4**). In the computational investigation, we used two imido groups with R = H (**a**) and CH_3 (**b**), while for the experimental characterization we employed the (2,6-diisopropylphenyl)imido ligand (**c**) (see Scheme 1). Such a relatively bulky ligand is required to guarantee the sufficient stability of the product complexes. Accordingly, the hydrogen compound $CH_3ReO_2(NH)$ is referred to as **2a**, whereas **2b** designates the corresponding methylated compound $CH_3ReO_2(NCH_3)$. We proceeded in the same way with the bis- and tris(imido) complexes $CH_3ReO(NR)_2$ and $CH_3Re(NR)_3$. The experimentally characterized and therefore most stable dimer structures of the monomers **2c** and **3c** are denoted as **5c** and **6c**, respectively. We will begin by analyzing different isomeric structures of the analogous H- and CH_3-ligated systems **5a/b** and **6a/b** and later on will introduce a more detailed nomenclature for describing these different structures.



Scheme 1

In the computational study we focused on homogenous dimers, i.e. dimers that consist of two equal monomeric units of **1**, **2a/b**, and **3a/b**. We also studied two mixed dimers, composed of two different monomers. The complexes can only dimerize as two fundamental structural types: a pseudo trigonal-bipyramidal coordination [**A**, see Figure 1, (a) and (b)] and a pseudo square-pyramidal coordination of the rhenium center [**B**, see Figure 1, (c) and (d)]. In the latter case, two terminal and two bridging ligands form the basis of a square pyramid, while the methyl ligand defines its top. Structures **A** and **B** may each occur with a *cis* and *trans* orientation of the CH_3 ligand. Furthermore, we need

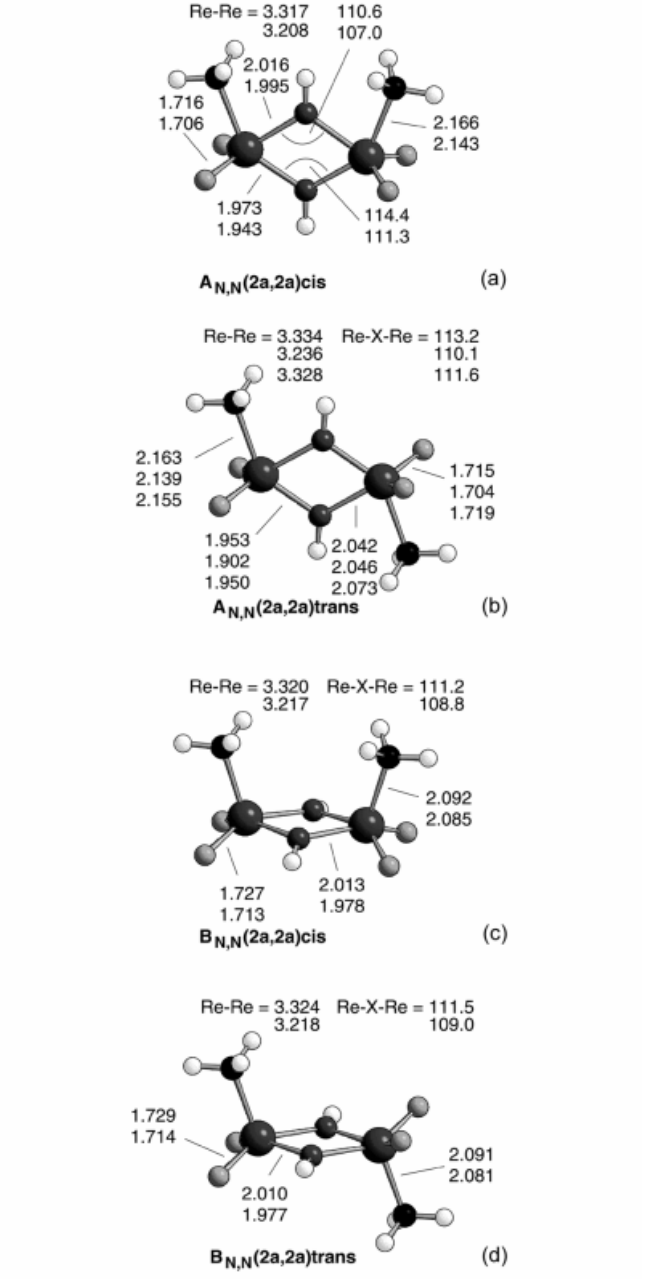


Figure 1. Calculated structures of homogeneous dimers of **2a** with bridging nitrogen centers; pertinent calculated structure parameters (bond lengths in Å, angles in °) of the corresponding dimers of **2a**, **1**, and **2b** listed in columns in that order

to indicate the bridging atoms X (O and/or N) of the imido complexes **2** and **3** and of the mixed dimers. For this purpose, we add the bridging atoms as subscripts. For instance,

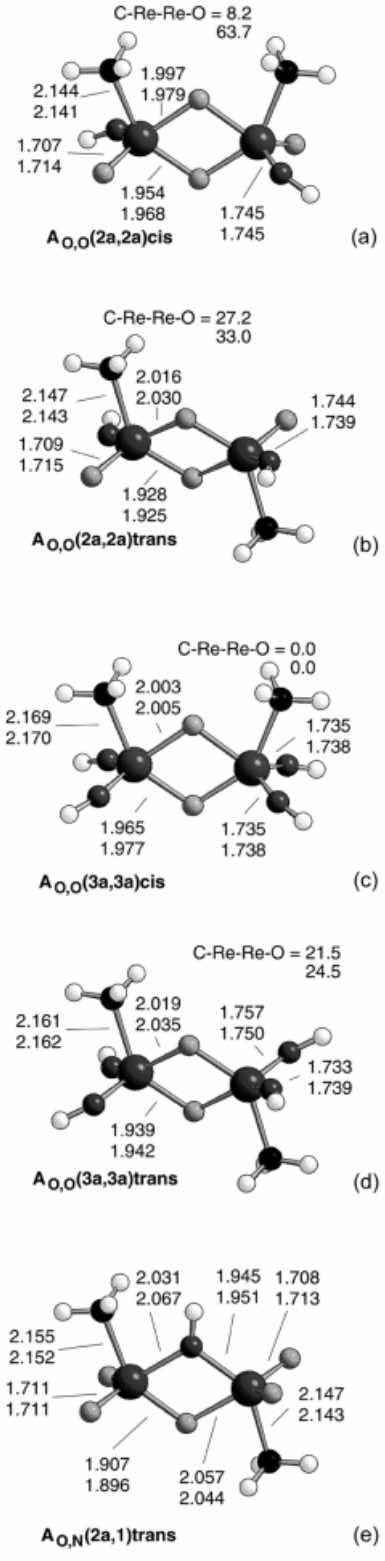

Figure 2. Calculated structures of homogeneous dimers of **2a** and **3a** with bridging oxygen centers and of the mixed O-bridged/N-bridged dimer (**2a**,**1**); pertinent calculated structure parameters (bond lengths in Å, angles in °) of the corresponding dimers of **2a** and **2b** or **3a** and **3b** in columns in that order

complex $\mathbf{A_{N,N}(2a-2a)cis}$ exhibits a trigonal-bipyramidal conformation (structure **A**) with two N atoms bridging two **2a** monomers in which the two methyl groups adopt a *cis* orientation.

In Figure 1 and Figure 2 we display various structures of dimers (**2a**,**2a**), (**3a**,**3a**), and (**2a**,**1**). Inspection of the calculated vibrational data reveals that, with one (partial) exception, all structures **A** correspond to local minima, whereas structures **B** represent transition structures (see below). The exceptional case $\mathbf{A_{N,N}(2b-2b)trans}$ features two vibrational modes with imaginary frequencies that correspond to rotational motions of the methyl substituents at the nitrogen centers; thus, even in this case, the remaining framework of the dimer represents a local-minimum structure.

Structural Properties

In Figure 1, featuring the homogeneous dimer of **2a** with bridging imido groups, we also present characteristic bond lengths and angles of dimers of **1** and **2b** in compact column form: values in the first line of each column refer to dimers with bridging NH groups (monomer **2a**). Values in the second line refer to dimers of the monomer **1**. Where present, values in the third line refer to dimers with bridging NCH_3 groups (monomer **2b**). To facilitate the calculations, symmetry constraints have been employed, resulting in idealized dimer structures (see below). The *cis* complexes [C_{2v} symmetry for **1** and **2a**; Figure 1, (a) and (c)] exhibit a mirror plane perpendicular to the carbon−rhenium plane, containing the bridging atoms, while the *trans* structures feature an inversion center [C_{2h} symmetry for **1** and **2a**; Figure 1, (b) and (d)]. In type **B** structures, the Re−X bonds are equivalent by symmetry, while type **A** structures exhibit two shorter and two longer Re−X bonds. Each bridging atom of complex $\mathbf{A_{X,X}(Y-Y)cis}$ is symmetrically located between the rhenium atoms and both Re−X bonds are of equal length. In complexes $\mathbf{A_{X,X}(Y-Y)trans}$ with two different Re−X bond lengths, each bridging atom X may be assigned to one of the two rhenium centers; the Re−X bond located closer to the methyl ligand is shorter.

Energetics

One goal of the computational study was to determine the most stable dimeric structures of MTO and of related imido complexes (Table 1). As models for the whole class of systems, we first calculated the formation energies of the dimers of MTO **1** and of the N-bridged dimers of the mono(imido) derivative **2a** of MTO, for both fundamental structure types **A** and **B** and different orientations of the methyl groups. In the next step, the most stable structures determined in this way were then also studied for the dimers of **2b**, **3a**, and **3b**. To assist in assessing the relative energies of the various configurations, the dimerization energies are compared in Figure 3. The formation of dimers $\mathbf{B_{O,O}(1-1)cis}$ and $\mathbf{B_{O,O}(1-1)trans}$, displaying a square-pyramidal coordination, from two MTO monomers is more endothermic (by 35.5 and 32.2 kcal/mol, respectively) than that of the corresponding type **A** dimers $\mathbf{A_{O,O}(1-1)cis}$ and

$A_{O,O}$(1−1)trans with a trigonal-bipyramidal coordination (by 5.8 and 1.7 kcal/mol, respectively). The *trans* configurations are more stable than the corresponding *cis* forms by 3−4 kcal/mol. It is worth noting that the differences in stability between the **A** and **B** forms are very similar for both *cis*/*trans* isomers. **$A_{O,O}$(1−1)cis** is more stable than **$B_{O,O}$(1−1)cis** by 29.7 kcal/mol; the corresponding energy difference of the *trans* complexes is 30.5 kcal/mol. For the most stable dimer **$A_{O,O}$(1−1)trans**, we also calculated that the enthalpy of formation (at T = 298.15 K) is larger than the dimerization energy by 1.7 kcal/mol (Table 1).

Table 1. Calculated results of dimerization energies ΔE and selected dimerization enthalpies ΔH (in kcal/mol)

	ΔE	ΔH
MTO dimers:		
$A_{O,O}$(1−1)cis	5.78	
$A_{O,O}$(1−1)trans	1.74	3.47
$B_{O,O}$(1−1)cis	35.54	
$B_{O,O}$(1−1)trans	32.21	
N-Bridged mono(imido) dimers:		
$A_{N,N}$(2a−2a)cis	−7.68	
$A_{N,N}$(2a−2a)trans	−9.34	−5.07
$B_{N,N}$(2a−2a)cis	17.97	
$B_{N,N}$(2a−2a)trans	20.08	
$A_{N,N}$(2b−2b)trans	12.38	13.39
Terminal mono(imido) dimers:		
$A_{O,O}$(2a−2a)cis	4.19	
$A_{O,O}$(2a−2a)trans	−1.15	4.10
$A_{O,O}$(2b−2b)cis	−0.33	
$A_{O,O}$(2b−2b)trans	−2.50	−1.04
Terminal bis(imido) dimers:		
$A_{O,O}$(3a−3a)cis	5.43	
$A_{O,O}$(3a−3a)trans	1.44	3.04
$A_{O,O}$(3b−3b)cis	0.68	
$A_{O,O}$(3b−3b)trans	−1.81	0.36
N-Bridged tris(imido) dimers:		
$A_{N,N}$(4a−4a)trans	−5.03	
$A_{N,N}$(4b−4b)trans	10.30	
Mixed dimers:		
$A_{O,N}$(1−2a)trans	−4.85	
$A_{O,N}$(1−2b)trans	4.23	

A similar stability trend was found for the N-bridged dimers of **2a**. Type **A** structures are more stable than type **B** structures. For **A**, the *trans* orientation of the methyl group is also more stable than the *cis* configuration: the dimerization energy was calculated to be −9.3 kcal/mol for **$A_{N,N}$(2a−2a)trans** and −7.7 kcal/mol for **$A_{N,N}$(2a−2a)cis.** However, the *cis*/*trans* energy difference, 1.6 kcal/mol, is only half as large as for the corresponding dimers of MTO. Note that for type **B** structures (square-pyramidal coordination of Re), the *cis*/*trans* preference is reversed. **$B_{N,N}$(2a−2a)cis** is less endothermic than **$B_{N,N}$(2a−2a)trans** with dimerization energies of 18.0 and 20.1 kcal/mol, respectively. This finding is a consequence of the symmetry constraints employed in the calculations. In the *trans* complex (C_{2h} symmetry), the imido H atom is unable to bend outside the Re−N−Re plane, as it can in the case of the *cis* orientation in which the H atom bends downwards (Figure 1). However, the **A**/**B** energy difference for the *trans* isomers (29.4 kcal/mol) is very similar to that of MTO dimers (29.7 kcal/mol for *cis* and 30.5 kcal/mol for *trans*). For the *cis* dimers of **2a**, the **A**/**B** energy difference is significantly reduced (25.7 kcal/mol) since **$B_{N,N}$(2a−2a)cis** is more stable than **$B_{N,N}$(2a−2a)trans**.

In contrast to the results obtained for the MTO dimers, the N-bridged dimers of **2a** feature exothermic dimerization energies for type **A** structures. For the most stable isomer **$A_{N,N}$(2a−2a)trans** we also calculated the enthalpy of dimerization (−5.1 kcal/mol, Table 1), which is less exothermic than the corresponding dimerization energy by 4.3 kcal/mol. Substitution of the bridging imido H atom by a methyl group in the most stable dimer **$A_{N,N}$(2a−2a)trans** leads to the congener **$A_{N,N}$(2b−2b)trans** and renders the dimerization endothermic (12.4 kcal/mol). This is due to steric hindrance, but electronic effects are also probably involved since the energy difference due to methylation (21.7 kcal/mol) seems to be too high to be caused by steric hindrance only. The dimerization enthalpy of **$A_{N,N}$(2b−2b)trans** is larger than the corresponding energy difference (1 kcal/mol, Table 1).

The fundamental structure type **A** (trigonal-bipyramidal coordination) with a *trans* orientation of the methyl groups yields the most stable structures of the O-bridged [**$A_{O,O}$(1−1)trans**] as well as of the N-bridged dimers [**$A_{N,N}$(2a−2a)trans**] of MTO and its imido derivatives. While the energy differences between corresponding complexes of structures **A** and **B** is about 30 kcal/mol, the *cis*/*trans* energy difference is approximately only 1−3 kcal/mol. Therefore, in the following we will focus on trigonal-bipyramidal complexes **A**, but we will continue to compare *cis* and *trans* isomers.

Substitution of two terminal oxo groups (one per monomer) in MTO dimers **$A_{O,O}$(1−1)cis/trans** by imido groups (NH in the case of monomer **2a** and NCH_3 in the case of monomer **2b**) leads to **$A_{O,O}$(2a−2a)cis/trans** and **$A_{O,O}$(2b−2b)cis/trans** (see Figure 2). The *cis* compounds were calculated with C_2 symmetry, while the *trans* configurations may be studied with a C_i-symmetry constraint. This substitution results in dimer formation becoming exothermic or at least less endothermic [**$A_{O,O}$(2a−2a)cis**]; in the case of the **2a** dimers, the dimerization energies change by −1.6 and −2.9 kcal/mol for *cis* and *trans* configurations, respectively, and even more so in the case of the **2b** dimers, by −6.1 and −4.2 kcal/mol for *cis* and *trans* configurations, respectively (Table 1). The energy preference between the more stable *trans* isomers is reversed at the enthalpy level: **$A_{O,O}$(2b−2b)trans** is estimated to be the only stable homogeneous dimer with terminal mono(imido) complexes.

Substitution of all four terminal oxo groups of **$A_{O,O}$(1−1)cis/trans** by imido ligands leads to the O-bridged dimers of the bis(imido) derivatives of MTO, **$A_{O,O}$(3a−3a)cis/trans** and **$A_{O,O}$(3b−3b)cis/trans**. The *cis* dimers were calculated with C_{2v} symmetry, while the *trans* compounds were calculated with C_i symmetry. Among these oxygen-bridged dimers with two terminal amido group, **$A_{O,O}$(3b−3b)trans** is estimated to exhibit the least endothermic enthalpy of formation (Table 1). In general, the formation energies of these dimers are larger than those of the corresponding mono(imido) compound dimers, but still lower than those of the corresponding dimers of MTO

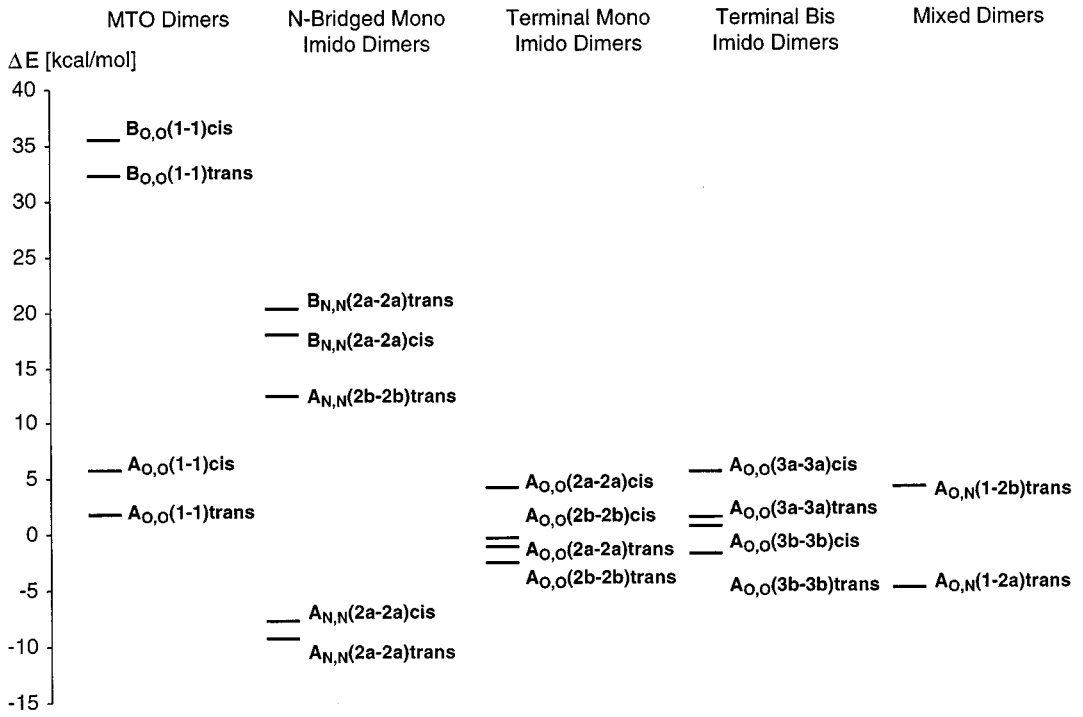

Figure 3. Calculated dimerization energies ΔE of various structures [MTO = methyltrioxorhenium(VII)]

(Figure 3). Just as in the case of the mono(imido) compounds, methyl substituents at the N atoms render dimer formation less endothermic. Substitution of the bridging oxygen centers of $\mathbf{A_{O,O}(3a-3a)trans}$ by NH groups leads to $\mathbf{A_{N,N}(4a-4a)trans}$; in this way, the dimerization energy is reduced by 6.5 kcal/mol, rendering the process exothermic (Table 1). On the other hand, the analogous substitution by NCH_3, resulting in the dimer $\mathbf{A_{N,N}(4b-4b)trans}$, changes the dimerization energy by 12.1 kcal/mol and renders the dimerization notably endothermic.

Mixed dimers provide more insight into the energy situation, since they feature one O and one NH bridge and are therefore intermediate between the dimeric structures of **1** and **2**. In these mixed dimers MTO, dimerizes with **2a** to form O,N-bridged $\mathbf{A_{O,N}(1-2a)trans}$ or with **2b** to form $\mathbf{A_{O,N}(1-2b)trans}$. Stated differently, if one substitutes one bridging oxygen center of the MTO dimer $\mathbf{A_{O,O}(1-1)trans}$ by NH, the dimerization energy changes by −6.6 kcal/mol and dimer formation becomes exothermic by −4.9 kcal/mol. Further substitution of the second bridging oxygen atom, leading to $\mathbf{A_{N,N}(2a-2a)trans}$ renders the formation even more exothermic with a change in the energy of dimer formation of −4.5 kcal/mol. In the case of NCH_3 the situation is reversed: substitution of the first imido renders dimer formation more endothermic by 2.5 kcal/mol and substitution of the second one even more so, by 8.2 kcal/mol.

In summary, substitution of one terminal oxo group of each monomer by an imido group renders dimer formation less endothermic or even exothermic. Substitution of the second terminal oxo group leads to a dimer stability in between that of MTO dimers and its mono(imido) derivatives. Compounds containing terminal NCH_3 groups always yield more stable dimers than NH imido complexes. Mixed O- and NH-bridged dimers exhibit dimer formation energies between those of purely O-bridged and purely NH-bridged complexes, while the mixed O- and NCH_3-bridged dimer forms more readily than the purely NCH_3-bridged dimer. These results suggest that NH groups in bridging positions render dimer formation more favorable, while NCH_3 imido complexes do so in terminal positions. In fact, imido groups with larger carbon substituents will not assume bridging positions.

Structurally, the dimerization reaction is an addition of two Re=O (Re=NR) bonds, resulting in a substitution of one Re=O (Re=NR) double bond by two Re−O (Re−NR) single bonds. One thus expects that the dimerization energy is controlled by the strength of the Re=O (Re=NR) bond.[7] To analyze this effect, we calculated the reaction energy for the monomeric compounds **1**, **2a/b**, and **3a/b**, when water is added to the rhenium−oxo bond, resulting in $Re(OH)_2$ moieties. In addition to model N-bridged dimerization, we calculated the energy of the addition of water to the Re=NR units of **2a/b**, which results in the formation of Re(OH)(NHR) moieties. Figure 4 demonstrates a linear correlation of these reaction energies of water addition with the most endothermic (or least exothermic) dimerization energies; only $\mathbf{A_{N,N}(2b-2b)trans}$ and $\mathbf{A_{N,N}(4b-4b)trans}$ give rise to exceptions. The more stable the product of water addition, the more exothermic is the dimerization. In $\mathbf{A_{N,N}(2b-2b)trans}$, the large endothermicity is due to the steric repulsion between the *N*-methyl groups and the methyl groups coordinated at the rhenium centers. As judged by the energy of water addition, the intrinsic dimerization energy should be comparable to that of MTO [$\mathbf{A_{O,O}(1-1)trans}$].

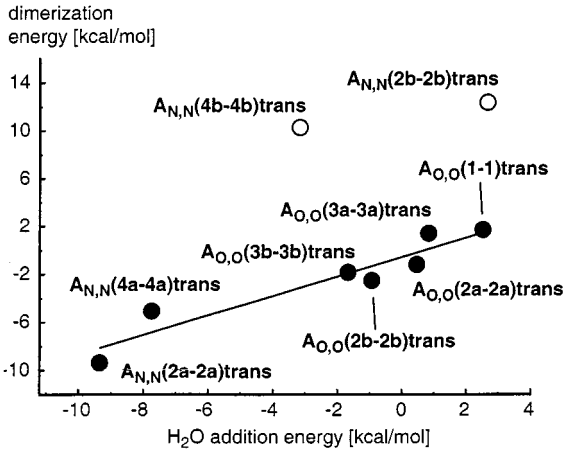

Figure 4. Calculated dimerization energies as function of the calculated energies of the addition of H_2O to an Re=X bond of the corresponding monomers

Thermogravimetry and Mass Spectrometry (TG-MS)

We now turn to a discussion of the dimerization process based on experimental information. We anticipated that two different features should influence the sublimation points of the complexes **1**−**4**: (i) the dimerization of compounds **2c** and **3c** by oxygen bridges (to yield **5c** and **6c**); and (ii) the increasing weight of the monomers due to successive replacement of terminal oxo ligands by bulky imido groups. The relative importance of these independent factors can be convincingly demonstrated by TG-MS examinations. The thermal behavior of CH_3ReO_3 (**1**) has already been reported.[9] This compound already begins to sublime below 50 °C; no decomposition is evident even after complete sublimation. These compounds are less volatile because of the weight increase due to the bulky imido ligands, and the dimerization to form compounds **5c** and **6c** at ambient temperatures. Therefore, they sublime at significantly higher temperatures than compound **1**. For **5c** and **6c**, sublimation is observed to start at 76.75 and 157.08 °C, respectively. The complexes sublime completely, and no residues remain. Mass spectrometry of the gas phase shows no traces of the dimeric species **5c** and **6c**, only the monomers **2c** and **3c** are observed. The sublimed compounds crystallize immediately on colder parts of the thermobalance. NMR and IR spectroscopy of the crystallized compounds clearly shows that dimers **5c** and **6c** have been reformed. The onset of the sublimation of complex **4c** is at 193.48 °C. As expected, no dimer is observed in the gas phase, whereas NMR and IR spectroscopy of the sublimed complex indicates the presence of the original dimer complex. No residue remains after the sublimation, confirming that decomposition does not take place. The changes in the temperature at which sublimation of complexes **1**, **4c**, **5c**, and **6c** starts evidently depends only on the molecular mass of the monomer and increases in accordance with the increasing number of the heavy imido ligands from < 50°C in **1** to nearly 200 °C in **4c**. These observations show that the energy which is necessary to monomerize complexes **5c** and **6c** must be relatively small and that the Re−O−Re bridges are weak. This is in good agreement with the computational results on the Re−O−Re bond strength described above and with observations made in solution.[5] Since all compounds examined display a dimerization energy of less then 5 kcal/mol, it is not surprising that Re−O−Re bonds break readily at the observed temperatures.

Vibrational Properties of the Dimers

The structures of the monomers under investigation belong to the C_{3v} (**1** and **4c**) and C_{2h} (**5c** and **6c**) symmetry groups or can be idealized such that these symmetry assignments hold. Characteristic vibrations are given in Table 2. Complex **4c** shows a strong analogy with compound **1**.[10] The only important difference in this context is observed for the $Re(=N)_3$ stretching vibrations which are assigned to the bands at 1333 cm^{-1} and 1290 cm^{-1} for the asymmetric and symmetric modes, respectively (calculated at 1268 cm^{-1} and 1311 cm^{-1} for **4b** and at 943 cm^{-1} and 971 cm^{-1} for **4a**, see below). The vibrations of the $[CH_3-Re]$ moiety are characteristic for all species examined. It is clear that the IR and Raman bands alternate, especially for the Re−O−Re and the $Re-CH_3$ skeletal stretching modes. This finding indicates the existence of an inversion center for the dimeric compounds. The mutual-exclusion rule is even more pronounced for low-frequency skeletal deformational modes (below 500 cm^{-1}, see Table 2).

There is no strong Raman band in the low-frequency region that can be assigned unambiguously to an Re−Re stretching mode. Accordingly, the dimeric compounds should have a bridging structure. The Re−Re bond lengths of **5c** and **6c** were determined experimentally to be 3.090(1) Å and 3.1190(3) Å, respectively;[5] the corresponding calculated values of the analogous methyl-ligated dimers of **2b** and **3b** [actually in configurations **$A_{O,O}$(2b−2b)trans** and **$A_{O,O}$(3b−3b)trans**, see below] are 3.18 Å and 3.20 Å, respectively. Therefore, the Re−Re interaction cannot be fully ignored, but the metal−metal interaction are probably very weak. For comparison, we mention that the Re−Re distance in the hypothetical dimer $(CH_3ReO)_2(\mu\text{-}O)_2$ of the Re^V species CH_3ReO_2 was calculated to be 2.59 Å. The metal−metal distance in the corresponding dimer $(CpReO)_2(\mu\text{-}O)_2$ of the species $CpReO_3$ was calculated to be 3.14 Å.[7] On the other hand, the Re−Re distance of the experimentally characterized dimer $[(CH_3)_2Re^{VI}O]_2(\mu\text{-}O)_2$ is 2.593(<1) Å[11] and that of $(Cp^*ReO)_2(\mu\text{-}O)_2$ is 3.143(<1) Å.[12]

On the basis of experimental IR and Raman spectroscopy, and the calculated dimerization energies, we conclude that there are no N-bridged dimers with bulky substituents on the nitrogen atom. All dimers are expected to feature bridging oxygen atoms. Experimental characterization of the vibrations of N-bridged dimers is thus not possible. For the oxygen-bridged dimers, two characteristic bands near 725 cm^{-1} and 695 cm^{-1} were assigned to Re−O−Re stretching modes. These Re−O−Re stretching vibrations have a lower intensity in solution spectra. There are no indications pointing to the formation of Re−N−Re bridges, neither in the solid state, nor in solution. However,

to allow for a systematic comparison, we have also calculated the vibrations of N-bridged dimers.

In Figure 5 we present the approximate normal modes ν_1 to ν_4 that involve a movement of the bridging atom; the corresponding calculated vibrational frequencies are collected in Table 3. The frequencies range from 470 to 750 cm^{-1}, and the largest occurs in the oxygen-bridged dimer $\mathbf{A_{O,O}(1-1)trans}$. An exception is vibration ν_4 which is similar for the dimers $\mathbf{A_{O,O}(2b-2b)trans}$, $\mathbf{A_{O,O}(3a-3a)trans}$, and $\mathbf{A_{O,O}(3b-3b)trans}$, but with slightly larger frequencies. N-Bridged dimers tend to exhibit higher frequencies than their O-bridged congeners. For $\mathbf{A_{N,N}(2a-2a)trans}$, ν_2 has a higher frequency than ν_1, in contrast to the other complexes. The frequencies ν_2 and ν_4 of $\mathbf{A_{N,N}(2a-2a)trans}$ couple to a N−CH_3 stretching mode, thus splitting into higher and lower frequency modes.

The experimental IR and Raman bands observed for compound **5c** at 950 cm^{-1} and 948 cm^{-1} demonstrate the presence of terminal oxygen atoms bonded to the rhenium center. It was not possible to assign a band to an Re−N−Re bridging structure of compounds **5c** and **6c**. Also for **4c** we were unable to identify a bridging NR unit, thus indicating the absence of such dimers. This is in agreement with the calculated results that the formation of N-

[a] See Figure 6 for sketches of the corresponding normal modes. − [b] Vibration couples to Re−C stretching vibration, and thus splits into symmetric and antisymmetric contributions. − [c] Vibration coupled to the N−CH_3 stretching vibration; the modes with higher frequencies exhibit a larger N−CH_3 contribution.

bridged dimers with bulky substituents is endothermic. In a nitrogen-bridging structure, compound **6c** should show strong stretching features for Re=O bonding. However, such features are completely missing from the vibrational spectra (Table 2).

We also did not observe a mixture of monomeric and dimeric molecules in the case of complexes **5c** and **6c** in the solid state. Only dimeric compounds seem to be present under these particular conditions. This question had remained unsettled since our first synthesis of these complexes and their identification as dimers by X-ray crystallography.[5] It had not been possible to exclude the simultaneous presence of both monomeric and dimeric forms in the solid state, but only dimers crystallize easily. Previously, we showed that a temperature-dependent monomer−dimer equilibrium can be observed by NMR spectroscopy in solution.[5]

Assignment of the spectral region below 500 cm^{-1} is rather complicated since a number of features are characteristic of 1,2,3-substituted aromatic ring vibrations. The imido ligand exhibits local C_{2v} symmetry, and therefore the polarized Raman bands have a_1 character. Consequently the polarized lines of compound **6c** at 439, 256, and 226 cm^{-1} can be assigned to modes *6a*, *9a*, and *10a*, respectively. This Wilson notation (italicized numbers) of the aromatic ring vibrations of the (2,6-diisopropylphenyl)imido ligand was chosen according to ref.[13]

It is interesting to compare the strengths of Re=O and Re−CH_3 bonds of different complexes[7] using the stretching frequencies as a probe for the bond strength. In CH_3ReO_3, the Re=O stretching frequencies ν(Re=O) are 997 cm^{-1} and 954 cm^{-1} for the symmetric and asymmetric vibrations, respectively. The Re=O bond length is 1.705 Å. For the dimeric compound **5c**, ν(Re=O) is 950 cm^{-1} and 948 cm^{-1} (for the symmetric and antisymmetric vibrations, respectively) and the Re=O bond length is 1.702 Å. According to these values, substitution of an oxo ligand of MTO by an imido group (or several such substitutions), and subsequent dimerization leads to a weakening of the Re=O bonds.

However, not only is the Re=O bond weakened owing to substitution of oxo groups by imido groups, but the Re−C bond also changes. Figure 6a shows how the Re−C stretching frequencies vary with the corresponding bond lengths based on experimental (filled symbols) and calculated data (open symbols). Calculated values differ from the corresponding experimental values (Table 4). For CH_3ReO_3 (**1**), *d*(Re−C) was measured to be 2.060 Å, while we calculated 2.090 Å. In accordance with this longer bond, the corresponding stretching frequency is lower (exp.: 574 cm^{-1}; calcd.: 550 cm^{-1}). For the other complexes investigated experimentally (**4c**, **5c**, and **6c**), we may compare the model systems **4b**, **$A_{O,O}$(2b−2b)trans** and **$A_{O,O}$(3b−3b)trans**. Here also, the calculated bonds tend to be weaker, as judged by an overestimation of the bond lengths [by 0.026 Å in **4b**, 0.008 Å in **$A_{O,O}$(2b−2b)trans**, and 0.021 Å in **$A_{O,O}$(3b−3b)trans**] and an underestimation of the corresponding stretching frequencies. These calculated data fit the same essentially linear relationship between bond lengths and frequencies as the experimental data (Figure 6a). The MTO dimer and the N-bridged imido dimer are the only exceptions (open diamonds, Figure 6a). Figure 6b shows the calculated stretching frequencies as a function of the natural atomic charge of the rhenium center. For the monomers **1**, **2a/b**, **3a/b**, and **4a/b**, we conclude that with increasing electron deficiency at the metal center, i.e. with higher positive charge *q*(Re) (Figure 6b), the Re−C bond becomes shorter and more rigid (higher vibrational frequency). The dimers do not fit that linear correlation. The effect of rehybridization on the metal center due to dimerization causes more complex changes in the electronic structure which, in turn, affects the Re−C bond.

Ligand Exchange between Monomers

Finally, we discuss the energies of group-exchange reactions between two monomers, which occur via a dimer structure. We will start by discussing a possible reaction coordinate. Symmetry is a key point for rationalizing this exchange problem. If we assume a synchronous process, the reaction pathway has to pass a structure where both M−X bonds of each bridging atom X are equivalent by symmetry.

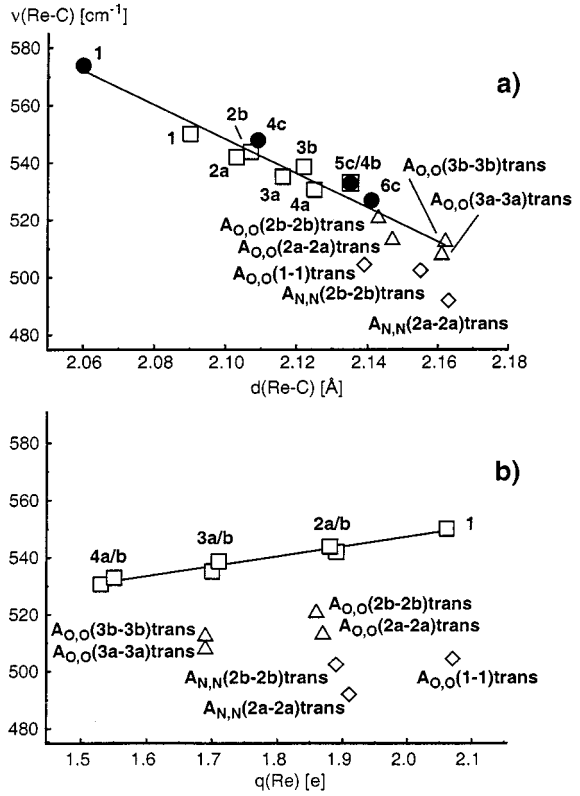

Figure 6. Experimental (filled circles) and calculated (open symbols) Re−C stretching frequencies ν(Re−C) as a function of (a) the Re−C bond length *d*(Re−C); and (b) the calculated natural atomic charges *q*(Re) of Re (in e); for the calculated data, the most stable conformers were used (monomers − open squares, O-bridged dimers − open triangles, MTO dimer and N-bridged dimers − open empty diamonds)

Table 4. Calculated and experimental Re−C bond lengths (in Å) and stretching frequencies (in cm^{-1}) for various monomers and dimers; also shown are the corresponding calculated natural atomic charge *q*(Re) (in e)

[a] Experimental values.

This structure can be a transition state, but it could also be a stable or metastable intermediate (see Figure 7). In the first case the reaction coordinate features one transition structure that interconnects two local equilibrium points of the potential-energy surface (PES). Each of the atoms can be assigned to a certain metal center. The final structure can either be two isolated molecules, or a dimer which has two bridging atoms X with two different M−X bond lengths. If the structure with the symmetry-equivalent M−X bonds is a (meta)stable intermediate, then the reaction path has two saddle points which lie between the symmetric local minimum structure and the structure where each atom X is uniquely assigned to only one metal center.

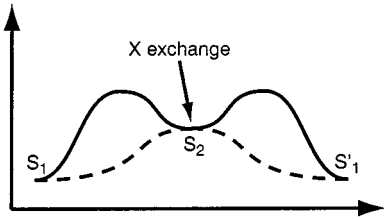

Figure 7. Sketch of the potential-energy surface for the exchange of group X in dimers at the stationary point S_2; the stationary points S_1 and S_1' indicate configurations in which the groups X can be assigned to one of the metal centers, either in the case of two monomers or in the case of a dimer with asymmetric bridges; the solid line represents an energy profile with S_2 as (meta)stable intermediate, the dashed line represents an energy profile with S_2 as transition state

In the following discussion of ligand-exchange reactions, we will restrict ourselves to the special case of oxygen-bridged dimers. For ligand-exchange reactions of MTO and related dimers, we can discriminate four pertinent structures which can be (meta)stable intermediate dimers or transitions states, or stable dimers in which each bridging atom X belongs to one metal center only.

Only structure $\mathbf{A_{O,O}(1-1)trans}$ exhibits two different M−X bonds, while the structures $\mathbf{A_{O,O}(1-1)cis}$, $\mathbf{B_{O,O}(1-1)cis}$ and $\mathbf{B_{O,O}(1-1)trans}$ can either be (meta)-stable intermediates, or transition states. From frequency calculations, one discovers that *cis* and *trans* structures **B** are both third-order saddle points, and thus not proper transition states. On the other hand, *cis* and *trans* configurations of structure **A** are both metastable.

The optimized transition state (see Figure 8) of the oxygen exchange reaction corresponds to a complex reaction coordinate. The barrier height $\Delta E^{\neq}$ is 23.8 kcal/mol ($\Delta H^{\neq}$ = 24.4 kcal/mol). It connects two isolated MTO complexes (lower-energy asymptote in Figure 7) with dimer structure $\mathbf{A_{O,O}(1-1)trans}$, which is thus identified as a metastable intermediate (Figure 7). The dimerization energy ΔE of this intermediate is 1.7 kcal/mol (ΔH = 3.5 kcal/mol, see Table 1). To facilitate the understanding of the three-dimensional structure of the transition state, we display two orientations of this structure in Figure 8. The arrows indicate the motion of the nuclei along the reaction coordinate in the direction in which the metastable intermediate $\mathbf{A_{O,O}(1-1)trans}$ is formed. Note that the order of the Re−O bond lengths in the bridging unit is reversed in comparison to the dimeric compound (see Figure 1). The shorter Re−O bond in the transition state (1.835 Å; Fig-

ure 8) is the one closer to the Re−C bond, which is 2.046 Å in the dimer [see Figure 1, (a)]. The longer bond in the transition structure (2.208 Å, Figure 8) is *trans* to the methyl group; it corresponds to the shorter bridging bond, 1.902 Å (Figure 1), of the dimer. These changes demonstrate the exchange of the two oxygen atoms through the formation of a dimer. In the transition state, the two carbon−rhenium bonds do not fall in one plane, in contrast to the dimer structure; the dihedral angle C−Re−Re−C is 115°. The nuclear motion along the reaction coordinate does not only comprise an exchange of oxygen centers, but also a rotation of each monomer around the shorter Re−O bridging bond in the transition state. However, the transition structure exhibits C_2 symmetry, with the rotation axis perpendicular to the plane that contains the Re−O bridging bonds.

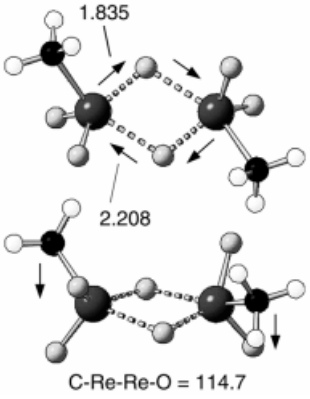

Figure 8. Calculated transition-state structure of oxygen exchange in the dimer $\mathbf{A_{O,O}(1-1)trans}$; top: view onto the Re−O−Re plane; bottom: Re−O−Re plane rotated around the Re−Re axis; arrows indicate motions of the nuclei along the reaction coordinate from the transition state to the metastable intermediate $\mathbf{A_{O,O}(1-1)trans}$; bond lengths in Å, angles in °

Conclusions

The most stable dimers of oxo, imido, and mixed imido/oxo alkylrhenium(VII) complexes display a trigonal-bipyramidal structure at the metal centers, with a *trans* arrangement of the methyl ligands. While the *cis* arrangement of the methyl ligands leads only to slightly higher energies (about 5 kcal/mol), pseudo square-pyramidal arrangements have a considerably higher energy (about 30 kcal/mol) than trigonal-bipyramidal structures. This is in good agreement with published structures, but contrasts with previously published HF calculations concerning the first step of the polymerization of methyltrioxorhenium(VII). In all cases examined, the stabilization gained by the dimerization process is rather small (usually < 5 kcal/mol), explaining the ease of the Re−O−Re bond cleavage and reformation during the sublimation process of the compounds **2** ⇄ **5** and **3** ⇄ **6**. In some cases, most notably for methyltrioxorhenium(VII), the dimerization process is (slightly) endothermic, according to our calculations. Therefore, dimers cannot be isolated but are likely to be present as short-lived species. This explains the ease of reversible oxygen-transfer reactions between O-labeled and -unlabeled organorhenium(VII) oxides which have often been observed,[8] even in water-free solvents. Based on the present results, we suggest that these processes proceed via (short-lived) oxygen bridges.

According to our calculations, N-bridged dimers of the compounds **2**−**4** should be stable. At first glance, this seems to contradict our vibrational spectroscopy results, which show no indication for N-bridged species whatsoever. However, our calculations were performed with N−H and $N-CH_3$ species as bridging groups and have already shown that dimer formation becomes more endothermic when N−H groups are substituted by $N-CH_3$ species. However, imido and mixed imido/oxo complexes with N−H or $N-CH_3$ groups are too unstable to be isolated.[4] The bulky ligands we used in an attempt to isolate imido or oxo/imido species evidently disfavor dimers significantly more than do CH_3 groups, thus resulting in monomers such as **4** becoming the energetically preferred species.

Experimental Section

All preparations and manipulations were performed with standard Schlenk techniques under oxygen- and water-free argon. Solvents were dried by standard procedures: THF, Et_2O, *n*-pentane, and *n*-hexane with Na/benzophenone ketyl. Acetonitrile and dichloromethane were distilled after heating at reflux for several hours over P_2O_5. Acetone was distilled from K_2CO_3 and kept over 4-Å molecular sieves. − The TG/MS studies were carried out with a Perkin−Elmer TGA 7 thermobalance coupled with a Balzers QMG 420 mass spectrometer. The thermolysis experiments were carried out in a dynamic helium environment (purity 5.0, 45 sccm) using a 50−600 °C temperature program at a rate of 10 °C/min. The temperature of the capillary interface was 280 °C. TG studies were additionally performed using a Shimadzu TGA-50 thermobalance. The experiments were carried out under nitrogen at 25−1000 °C, at a rate of 5 °C/min from room temperature to 1000 °C, using a platinum cell. − The Raman spectra were recorded with a Bio-Rad dedicated FT-Raman spectrometer using the near-infrared excitation 1064 nm of a Nd:YAG diode laser. − The infrared spectra in the 4000−200 cm^{-1} region were recorded using a Bio-Rad FTS-175 spectrometer equipped with CsI-based beam splitter, and the far-infrared (400−50 cm^{-1}) measurements were carried out with the same spectrometer, but using a 6-μm Mylar beam-splitter. − The compounds CH_3ReO_3 (**1**), $[CH_3ReO_2(NR)]_2$ (**5c**), $[CH_3ReO(NR)_2]$ (**6c**), and $CH_3Re(NR)_3$ (**4c**) (with R = 2,6-diisopropylphenyl) were prepared according to published procedures.[5,14]

Computational Details: All electronic structure calculations were performed with the hybrid B3-LYP[15] density-functional scheme,[16] using effective-core potentials for rhenium with a partly decontracted basis set for rhenium.[17] Geometry optimizations were carried out using a 6-311G(d,p) basis[18] on all centers (except Re). Enthalpies were calculated at this level following standard procedures.[19] Finally, two f exponents[3e,7] were added to the basis set of Re to evaluate energies in a single-point fashion. Details of this computational strategy have been discussed elsewhere.[7] Transition-state structures were verified to feature only one imaginary frequency in the vibrational spectrum. Additionally, by following

the transition vector, we verified that the reaction products and reactants are directly reached from the transition structure.[20]

Stereoselective Synthesis of Hexacoordinated Mononuclear Cyclometalated Rhodium(III) Complexes − Transfer of Chirality from the Metal Center to the Ligand

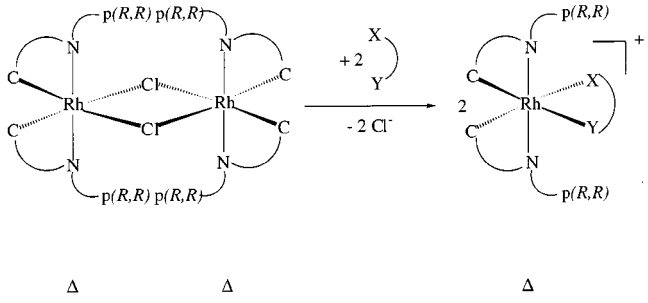
Liana Ghizdavu,[a] Alex von Zelewsky,*[a] and Helen Stoeckli-Evans[b]

Keywords: Rhodium / Chirality / Cyclometalations / Stereoselective synthesis / Mononuclear complexes

The cleavage of ΔΔ[Rh(th4,5ppy)$_2$(μ-Cl)]$_2$ [th4,5ppy is enantiomerically pure (8*R*,10*R*)-2-(2′-thienyl)-4,5-pinenopyridine(−)] by 5 different diimines and 11 diamines yields monomeric cations Δ[Rh(th4,5ppy)$_2$(*N*∩*N*)]$^+$. In all cases, the cleavage reaction preserves the original Δ configuration at the metal center. When *N*∩*N* is a chiral or a prochiral ligand, various degrees of stereoselectivity is observed, depending on where the stereogenic center is located in *N*∩*N*. The reported results open up a systematic method towards the synthesis of tris(bidentate)Rh^{III} complexes with a completely predetermined stereochemistry.

Introduction

The syntheses of coordination compounds in which the metal atom is a stereogenic center have not often been performed in a stereoselective manner.[1] This is in sharp contrast to the large number of examples known from organic chemistry in which stereoselectivity is the subject of intense study. Stereoselectivity in coordination compounds can be achieved through the use of enantiomerically pure chiral ligands in various ways. Here we describe the formation of mononuclear rhodium(III) complexes comprising of two cyclometalating bidentate ligands plus one bidentate diimine or diamine (Scheme 1).



Scheme 1

The reaction step that determines the configuration of the final product is the formation of a homochiral dimer.[2] The latter can be cleaved by achiral, prochiral or chiral bipyridine-type or diamine ligands (Table 1).[3]

This cleavage reaction takes place with the retention of the configuration at the metal centers in the dinuclear species.Thus, a generally applicable method is given for the stereoselective synthesis of compounds that are of high potential interest in various fields, such as enantioselective catalysis, and as intercalators in DNA.[4,5] Generally, the preparation of compounds that are isomerically pure is preferred over the often cumbersome and often inapplicable separation methods sometimes used in coordination chemistry.[6] This is certainly true for highly selective and efficient reactions such as those described in the present work.

Results and Discussion

The formation of the homochiral dinuclear precursor of the monomers, ΔΔ[Rh(th4,5ppy)$_2$(μ-Cl)]$_2$ (**I**) has been described before.[2] The configuration Δ at the two metal centers is induced by the natural product (−)-myrtenal, used for the synthesis of the thienyl-4,5-pinenepyridine ligand. Complex **I** can be prepared in high isomeric purity. It can be cleaved in a smooth reaction (CH_2Cl_2, 40 °C, ca. 60 min) producing the mononuclear species **I**−**XVII** in high yields (60−80%) as shown in Scheme 2, Scheme 3 and Scheme 4. We discuss the complexes according to the type of bidentate ligand used in the cleavage reaction.

Diimine Ligands

Three different types of diimine ligands can be distinguished: *Achiral* (bpy) → **II** (Scheme 2), *chiral with one pinene group* (4,5-pbpy, 5,6-pbpy) → **V**, **VI**, and *chiral with two pinene groups* (bis-4,5-pbpy, bis-5,6-pbpy) → **III** and **IV**. Complexes **II** and **III** were prepared as PF_6 salts.

The simplest of these species, **II**, has C_2 symmetry. The ^{1}H NMR spectrum clearly shows the equivalence of the corresponding protons in the two 2,2′-thienyl-4,5-pinenepyridine ligands and of those in the coordinated bpy in the complex. It also suggests the retention of configuration at the metal centers after the cleavage reaction, since two dia-

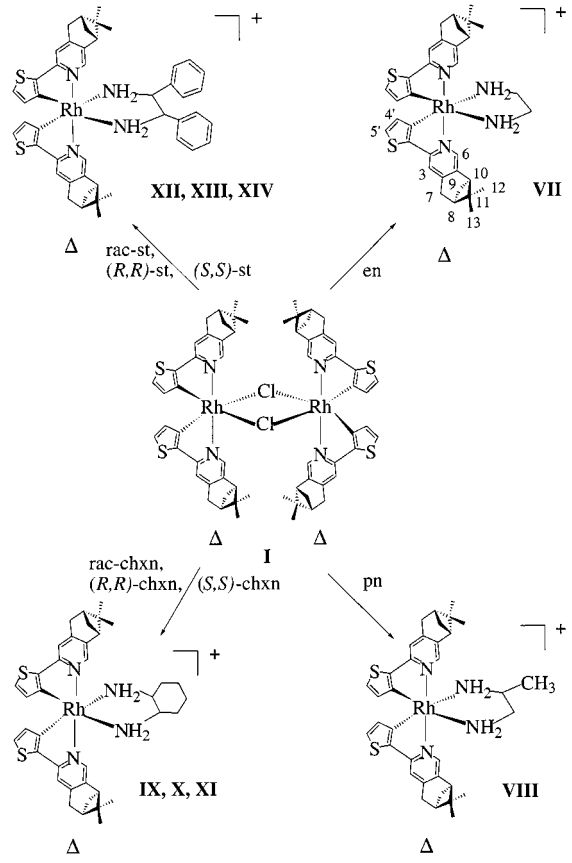
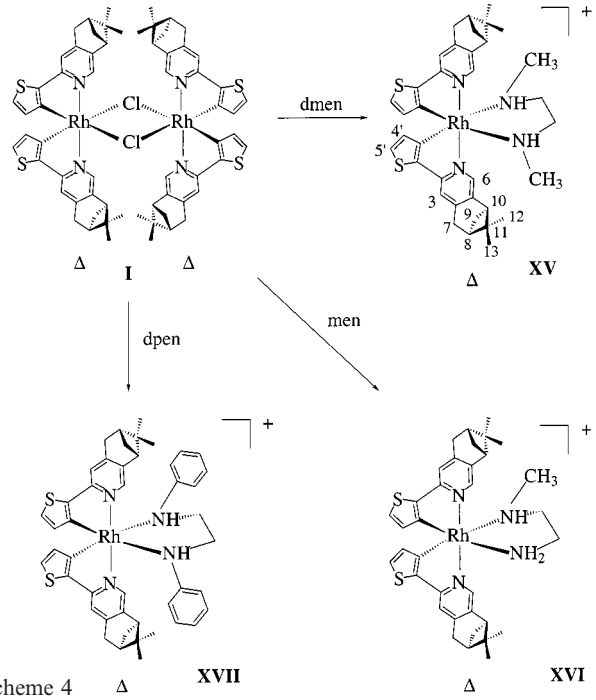


Scheme 3

stereomeric products [(*R*,*R*)Δ and (*R*,*R*)Λ, both C_2-symmetric] would result in two sets of protons. The Δ configuration follows from the CD spectrum (Figure 1), that gives clear indications for this isomer.[7] The strong peak of mass



Scheme 4

767 (**II**-PF_6) confirms the mononuclear nature of this complex.

The complexes **III** and **IV** also have C_2 symmetry, as demonstrated by ^{1}H NMR spectroscopy. The aromatic region of the ^{1}H NMR spectra is even more simple than that of **II** owing to the use of "dipineno"-fused 2,2′-bipyridines (bis-4,5-pbpy, bis-5,6-pbpy) ligands. Those spectra show one set of protons, which proves the isomeric purity of the complexes. The CD spectra are similar to those of **II**, again indicating the retention of the Δ configuration. The peaks (100%) at 955 (**III** − PF_6) and 956 (**IV** − Cl) correspond to mononuclear species.The complexes **V** and **VI** with the unsymmetrical ligands 4,5-pbpy and 5,6-pbpy are not C_2-symmetric. The ^{1}H NMR spectra are therefore more complicated. Nevertheless, only one complete set of signals is observed, again showing that the configuration of the metal center is retained. The assignment of the peaks was carried out using a combination of COSY and NOE techniques for **VI**, while **V** was characterised by COSY spectra. The CD spectra (Figure 1) are in agreement with the Δ configuration at the metal center and have the same shape as the spectra of the dinuclear ΔΔ precursor, and as the spectra of the complexes **II**, **III** and **IV**. The MS spectra show mass peaks 861 (**V**, **VI** − Cl), indicating that the complexes are mononuclear.

Diamine Ligands

Several 1,2-diamine-type ligands have been used: *Achiral diamines* (en) → **VII** (Scheme 3 and Scheme 4), *chiral and prochiral diamines with one stereogenic center* (pn and men) → **VIII**, **XVI** and *chiral and prochiral diamines with two stereogenic centers* (chxn, st, dmen, dpen) → **IX** → **XI**, **XII** → **XIV**, **XV**, **XVII**.

Δ[Rh(th4,5ppy)$_2$(en)]Cl

The cation **VII** shows all characteristic peaks of the th-4,5-pinenopyridine as well as the signals of the NH_2 and CH_2 groups of ethylenediamine in the ^{1}H NMR spectrum. No splitting of these peaks occurs, clearly indicating that only one configuration at the metal center is present. The CD spectrum of **VII** (Figure 2.) shows that the Δ configura-

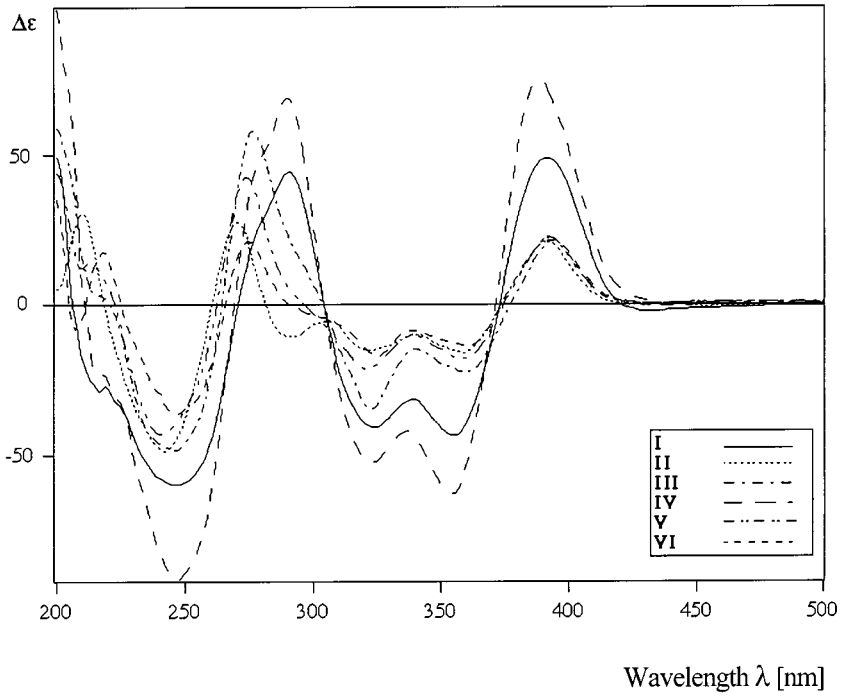


Figure 1. CD spectra of the complexes **I**, **II**, **III**, **IV**, **V** and **VI**

tion of the homochiral dinuclear precursor is preserved in the cleavage reaction.

Δ[Rh(th4,5ppy)$_2$(*rac*-pn)]Cl

The cation **VIII** occurs in two diastereomeric forms. The ^{1}H NMR spectrum shows a splitting of each signal of the th-4,5-pinenopyridine ligands in the aromatic region into four peaks (most easily seen e.g. in the signal of the 6′ proton at δ = 8.33 in the corresponding en complex). The small splitting (Δδ = 0.040 and 0.056, respectively, for 1:1 intensity lines for the 6′ proton) is due to the loss of the C_2 symmetry of the complex, whereas the larger splitting (Δδ = 0.27) is caused by the presence of two diastereoisomers Δ[Rh(th4,5ppy)$_2${(*R*)-pn}]Cl and Δ[Rh(th4,5ppy)$_2${(*S*)-pn}]Cl, respectively. These two diastereoisomers are formed in a ratio of 1:0.85, i.e. with a very low stereoselectivity. The CD spectra (Figure 2), which are mainly due to the disymmetry of the metal center and not to the ligands themselves, again clearly show the retention of the Δ configuration at the metal center.

Δ[Rh(th4,5ppy)$_2$(*rac*-chxn)]Cl (IX), Δ[Rh(th4,5ppy)$_2${(*R,R*)-chxn}]Cl (X), Δ[Rh(th4,5ppy)$_2${(*S,S*)-chxn}]Cl (XI)

Cleavage of the dinuclear complex **I** by *rac*-chxn (*rac*-trans-1,2-diaminocyclohexane) yields a product that shows a doubling of all peaks in the ^{1}H NMR spectrum (Figure 3, **IX**). The splitting is largest for proton 6 (Δδ = 0.32) and becomes smaller for proton 4 (Δδ = 0.038) and proton 3 (Δδ = 0.02), while the signals of protons 5 are superposed. The intensity ratio is nearly 1:1, indicating almost no stereoselectivity for this diamine ligand. An assignment of the two diastereomers is possible by using enantiomerically pure (*R*,*R*)-chxn and (*S*,*S*)-chxn. The two spectra in Figure 3 are obtained for **X** and **XI**.

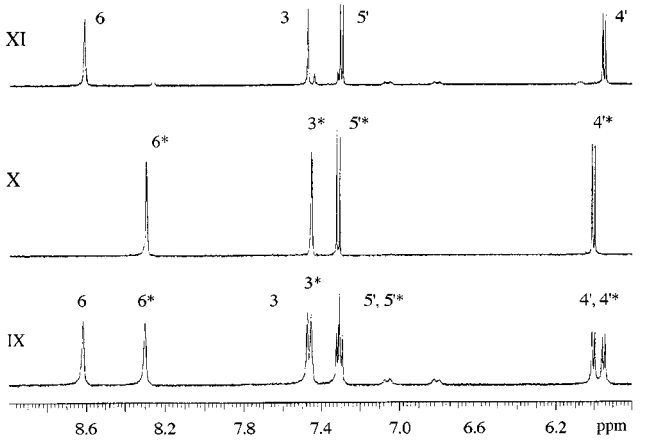

Figure 3. The aromatic region of the ^{1}H NMR spectra of complexes **IX**, **X** and **XI**

The CD spectra of all three complexes again show a retention of the Δ configuration upon cleavage of the dichloro bridge. Despite the fact that the ^{1}H NMR spectra show a relatively large splitting of the corresponding nuclei in the diastereomers, indicating an influence of the relative config-

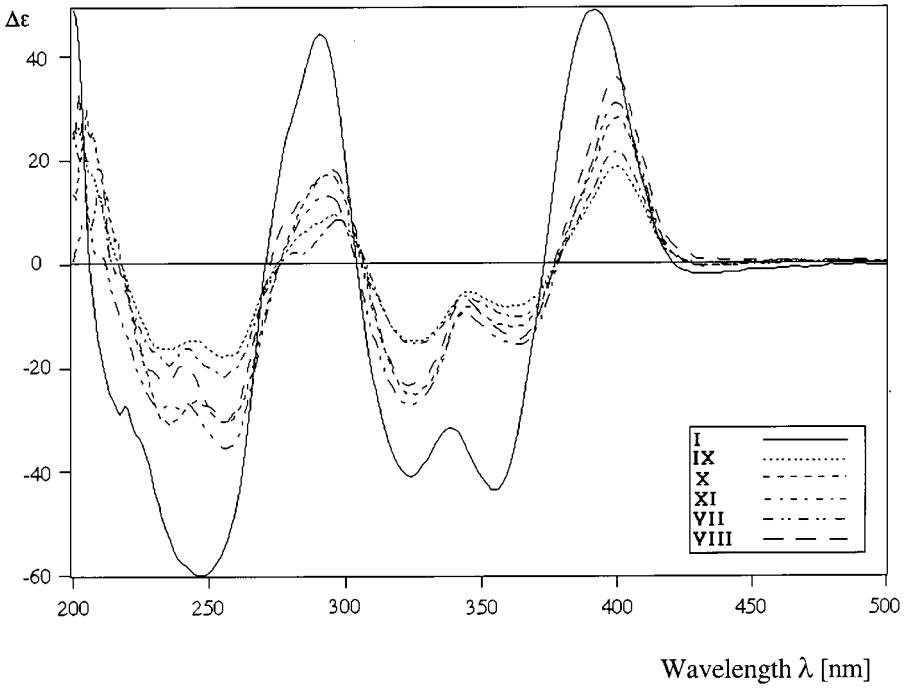

Figure 2. CD spectra of the complexes **I**, **VII**, **VIII**, **IX**, **X** and **XI**

urations of the chirality elements within the complex on the electronic structure, almost no chiral discrimination occurs in the cleavage reaction. Evidently, the differences in thermodynamic stability of the resulting diastereomers are too small to allow for significant stereoselectivity.

Δ[Rh(th4,5ppy)$_2$(*rac*-st)]Cl (XII), Δ[Rh(th4,5ppy)$_2${(*R*,*R*)-st}]Cl (XIII), Δ[Rh(th4,5ppy)$_2${(*S*,*S*)-st}]Cl (XIV)

The enantiomerically pure (*R*,*R*)- and (*S*,*S*)-stilbenediamines cleave the dinuclear complex **I** in a clean reaction, yielding isomerically pure mononuclear species (Figure 4). When the racemate of the ligand is used, both diastereomers, Δ[Rh(th4,5ppy)$_2${(*S*,*S*)-st}]Cl and Δ[Rh(th4,5ppy)$_2$-{(*R*,*R*)-st}]Cl, are observed in a 1:5.5 ratio by the ^{1}H NMR spectroscopy (Figure 4). The diastereomeric ratio was calculated from the signals for the protons at the 6 position in the ^{1}H NMR spectra. Since no separation step was applied to the reaction mixture after the cleavage reaction, this ratio represents the ''true'' stereoselectivity of this step.

In the case of Δ[Rh(th4,5ppy)$_2$[(*S*,*S*)-st}]Cl, crystals suitable for X-ray structure determination could be obtained.

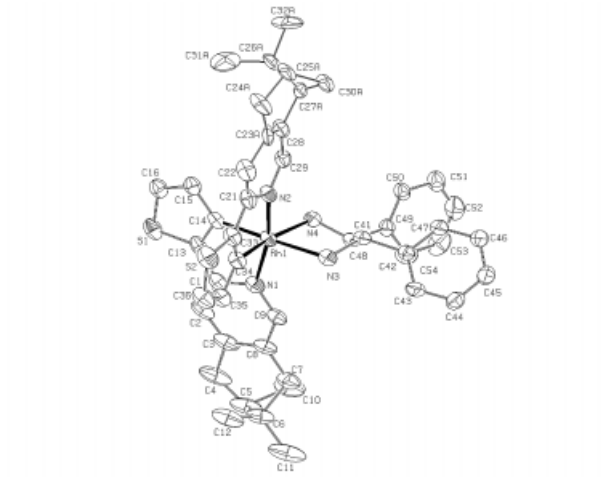

Figure 5. Numbered ORTEP[20] plot, with thermal ellipsoids drawn at the 30% probability level of the molecular structure of the cation Δ[Rh(th4,5ppy)$_2${(*S*,*S*)-st}]$^+$; the hydrogen atoms have been omitted for clarity

Structural Discussion

The X-ray structure (Table 2) of the Δ[Rh(th4,5ppy)$_2${(*S*,*S*)-st}]$^+$ cation (Figure 5) clearly reveals its absolute configuration. It is in agreement with all the other observations in this series of reactions, in which retention of the configuration at the metal center has always been observed. The enantiomerically pure diamine ligand with two (*S*)-configured stereogenic carbon centers adopts a δ conformation (ob) for the 5-membered chelate ring, putting the phenyl groups in equatorial positions.

This is to be expected from a consideration of interligand interactions, which would result in relatively large steric constraints in the axial orientation. The ^{1}H NMR spectrum reveals that this conformation is also strongly preferred in solution, since no broadening of the corresponding signals occur. The other features of the X-ray structure, such as bond lengths and angles, correspond to the expected values.

Δ[Rh{th4,5(*R*,*R*)ppy}$_2$(*N*,*N*′-dmen)]Cl (XV)

This compound is obtained from a smooth cleavage reaction of the dimer with *N*,*N*′-dimethylethylenediamine. Four diastereomers could be obtained, in principle, since the ligating nitrogen centers of the diamine are stereogenic after complexation. They can be designated as Δ[Rh-(th4,5(*R*,*R*)ppy)$_2$(*N*,*N*′-dm(*R*,*R*)en)]Cl (**A**), Δ[Rh{th4,5-(*R*,*R*)ppy}$_2${*N*,*N*′-dm(*S*,*S*)en}]Cl (**B**), Δ[Rh{th4,5-(*R*,*R*)ppy}$_2${*N*,*N*′-dm(*R*,*S*)en}]Cl (**C**), Δ[Rh{th4,5-

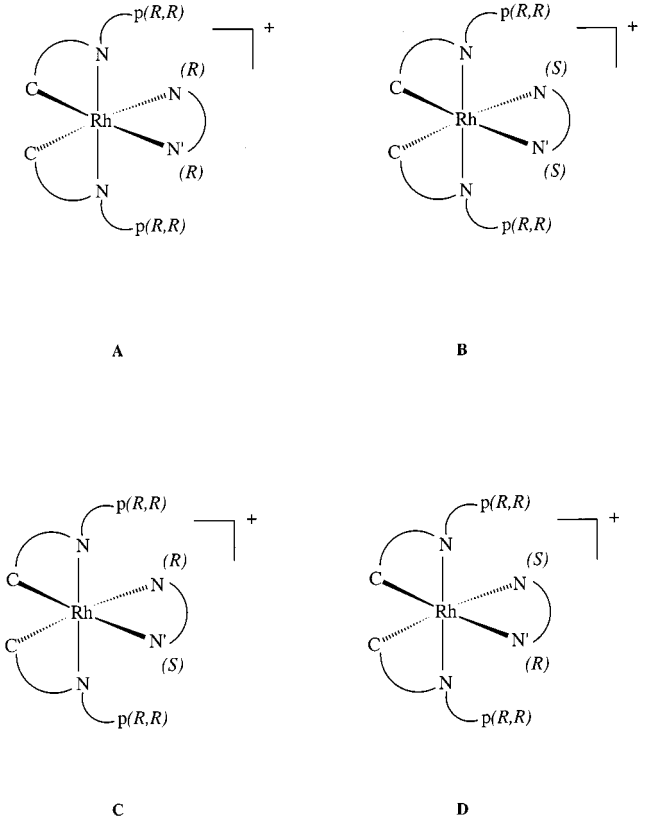

Figure 6. Isomers A, B, C, D

(*R*,*R*)ppy}$_2${*N*,*N*′-dm(*S*,*R*)en}] Cl (**D**). Compounds **A** and **B** are C_2-symmetric species, whereas **C** and **D** show no symmetry (Figure 6).

The ^{1}H NMR spectrum clearly indicates that only one C_2-symmetric complex is formed. Model considerations indicate that the species with a Δ,δ-(*R*,*R*) configuration should have the lowest energy. This corresponds to an axial configuration of the two methyl groups of the diamines.

Δ[Rh{th4,5(*R*,*R*)ppy}$_2$(*N*-men)]Cl (XVI), Δ[Rh{th4,5(*R*,*R*)ppy}$_2$(*N*,*N*′-dpen)]Cl (XVII)

Cleavage of the dinuclear precursor **I** with *N*-men and *N*,*N*′-dpen afforded the expected mononuclear species. These two ligands are prochiral in the sense that one or two ligating nitrogen centers are rendered stereogenic upon coordination to the metal center, as in the case of *N*,*N*′-dmen, described above. The unsymmetrical *N*-men ligand clearly forms one single isomer, within ^{1}H NMR detection limits. In analogy to the Δ[Rh{th4,5(*R*,*R*)ppy}$_2$(*N*,*N*′-dmen)]Cl, this isomer was assigned the configuration Δ-(*R*). The symmetrical *N*,*N*′-dpen again yields one single isomer, as in the case of *N*,*N*′-dmen.

Stereoselectivity

A stereoselective synthesis of coordination compounds has been known since the time of A. Werner.[8] However, it was not developed until recently in a systematic manner.[1] The contents of the present article are a contribution to the field of stereoselective synthesis of Rh^{III} complexes. The first point concerns the regioselectivity in the synthesis of the dinuclear complex from which the mononuclear species are obtained through cleavage reactions. It was shown earlier[9,10] that the cyclometalation is completely regioselective, yielding the *C*,*C*-*cis* isomer.

Owing to the chiral induction by the pinene groups p(*R*,*R*), the Δ diastereomer is strongly preferred over the corresponding Λ form.[2] The cleavage of the dimer always occurs with *complete retention* of configuration at the Rh^{III} centers. Of the 8 possible diastereomers Δ/Λ,A, Δ/Λ,B, Δ/Λ,C, Δ/Λ,D, one single compound, namely Δ,A is obtained from the Δ/Δ dimer, when an unsymmetrical diimine ligand *N*,*N*′ is used in the cleavage reaction. The same is observed for symmetric diimine ligands *N*,*N*′, in which a total of 6 diastereomers (C = D in this case) are possible (see Scheme 2). In cases where several isomers can be obtained by using racemic mixtures of chiral bidentate ligands (pn, chxn, and stilbenediamine), or where stereogenic centers are created at nitrogen donor atoms (*N*,*N*′-dmen, *N*-men, *N*,*N*′-dpen), various degrees of stereoselectivity have been ob-

Table 3. Diastereomeric ratios of complexes obtained by cleavage with racemic (**1**−**3**) or prochiral (**4**−**6**) diamines

Entry	Diastereomers	*de* (%)[a]
1	Δ[Rh(th4,5ppy)$_2${(*R*,*R*)-chxn}]Cl/Δ[Rh(th4,5ppy)$_2${(*S*,*S*)-chxn}]Cl	0
2	Δ[Rh(th4,5ppy)$_2${(*R*,*R*)-pn}]Cl/Δ[Rh(th4,5ppy)$_2${(*S*,*S*)-pn}]Cl	8

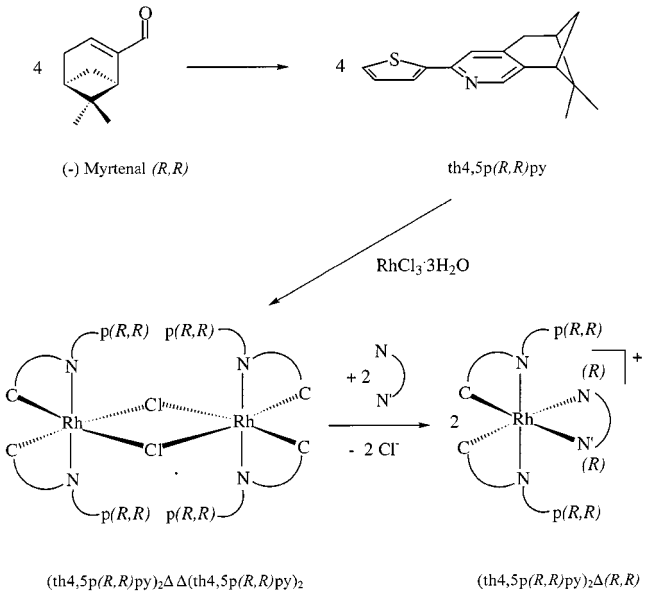
6	Δ[Rh(th4,5ppy)$_2${(*R*,*R*)-dpen}]Cl/Δ[Rh(th4,5ppy)$_2${(*S*,*S*)-dpen}]Cl	100

[a] Determined by ^{1}H NMR spectroscopy from the solution after completion of the reaction. This *de* value did not change appreciably during the course of the reaction.

served. The values of the diastereomeric excess (*de*) are given in Table 3.

In the three cases of chiral bidentate ligands pn, chxn, and stilbenediamine, the stereoselectivity is either absent (chxn), very low (pn) or relatively low (stilbenediamine). This is due to the fact that the stereogenic centers in these ligands are situated relatively far from the stereogenic centers located at the 4,5 positions of the pinene on the pyridine rings. In contrast, in all complexes in which the stereogenic center is created at a ligating nitrogen atom of the incoming diamine in the cleavage reaction, *complete* (within analytical accuracy) stereoselectivity is observed. The coordinating stereogenic nitrogen centers are formed with only one of two possible absolute configurations. Model studies show a strong preference for a Δ-(*R*,*R*) configuration, where (*R*,*R*) designates the absolute configuration of the coordinating nitrogen centers. We can safely assume that for *N*-men, and *N*,*N*′-dpen, the same configurations are present. This result shows that with these cyclometalated Rh^{III} complexes, a cascade of chirality can be realized (Scheme 5).



Scheme 5

The origin of the isomeric purity of the final mononuclear complexes, e.g. Δ[Rh{th4,5(*R*,*R*)ppy}$_2$(*N*,*N*′-dmen)]Cl, lies in the natural product (−)-myrtenal, which was synthesised biochemically in the plant myrtle (held sacred to Venus in ancient times).[11] All steps in the reaction scheme leading to the final product are stereoselective. Chirality is thus transferred from a relatively simple organic molecule to the bidentate ligand th4,5p(*R*,*R*)py, From there it is transferred to the metal center Rh^{III}, and then further to another ligand (*N*,*N*′-dmen, *N*-men, *N*,*N*′-dpen), in which two new stereogenic centers are created upon complexation.

Conclusions

The incorporation of a chiral natural compound, which is available in enantiomerically pure form, into a ligand by highly efficient synthetic procedures opens up new possibilities in coordination chemistry. In this contribution we showed that in this way, a family of chiral mononuclear Rh^{III} complexes with a predetermined absolute configuration is easily accessible. Starting with a cyclometalation reaction, the reaction sequence yields isomerically pure mononuclear products that consist of four stereogenic centers located on the ligands, and one on the metal ion. Chirality can be further transferred to prochiral ligands that form stereogenic centers upon complexation, increasing the number of chirality elements in the whole complex by one or two. The stereoselectivity of this last step strongly depends on the distance between the newly created stereogenic centers and the metal ion.

Experimental Section

Measurements and Materials: NMR spectra were obtained with a Varian Gemini-300 spectrometer (300 MHz for ^{1}H and 75.46 MHz for ^{13}C) using the solvent as internal standard relative to TMS; J values are reported in Hz, and δ in ppm. Definitive assignments of NMR spectra was achieved with a combination of NOE and COSY experiments, and APT techniques; qr = quaternary, te = tertiary, se = secondary, pr = primary carbon. − UV/Vis spectral data were recorded with Perkin−Elmer Lambda 5 and Perkin−Elmer Lambda 40 spectrometers; λ_{max} in nm, ε in M^{-1} cm^{-1}. − CD spectra were recorded with Jobin-Yvon and JASCO J-715 spectropolarimeters; λ_{max} (Δε) in nm. − IR spectral data were obtained with Perkin−Elmer 683 and Perkin−Elmer 16 PC FT-IR spectrometers; using samples (1%) in compressed KBr pellets; $\tilde{\nu}$ in cm^{-1}. − MS: VG-Instruments 7070E mass spectrometer equipped with an FAB inlet system. − Elemental analyses were carried out by CIBA Specialty Chemicals, Marly, Switzerland and in Ecole D'Ingineurs de Fribourg, Switzerland. − Unless otherwise stated, all chemicals and reagent-grade products were obtained from Fluka, Aldrich or Merck and used without further purification. (1*R*)-(−)-Myrtenal was obtained from Fluka, > 97%, [α] = 14.6. − The ligands (8*R*,10*R*)-2-(2′-thienyl)-4,5-pinenopyridine,[12] 4,5-pinenobipyridine,[3,13] 5,6-pinenobipyridine,[14] 4,5;4′,5′-pinenobipyridine,[15] 5,6;5′,6′-pinenobipyridine,[16] and 1,2-diphenylethylendiamine[17] were prepared according to literature methods.

X-ray Structure Determination of Δ[Rh(th4,5ppy)$_2${(*S*,*S*)-st}]Cl: Suitable crystals (yellow/orange cubes) of **XIV** were grown by the slow diffusion of diethyl ether into a solution of CH_2Cl_2. Intensity data were collected at 223 K with a Stoe Image Plate Diffraction system using Mo-K_α graphite-monochromated radiation. Image plate distance 70 mm, φ scans 0−200°, step Δφ = 1°, θ range 2.01−25.86°, $d_{max.}-d_{min.}$ = 12.45−0.81 Å. The structure was solved by direct methods using the program SHELXS-97.[18] The refinement and all further calculations were carried out using SHELXL-97.[19] The H atoms were included in calculated positions and treated as riding atoms using SHELXL-97 default parameters. The non-H atoms were refined anisotropically, using weighted full-matrix least squares on F^2. The Cl anion was disordered over two sites, one being situated on a twofold axis. The second was located at a general position and given an occupancy of 0.5. The coordinates correspond to the correct absolute structure of the molecule in the crystal. For one of the ligands, the pinene group was disordered over two sites (A, B); they were each given occupancies of 0.5. A region of electron density observed in a final difference map

was modeled satisfactorily as three partially occupied water molecules and the SWAT[19] parameter was also refined. The molecular structure and crystallographic numbering scheme are illustrated in the PLATON[20] drawing (Figure 5). The CIF files, including complete tables of bond lengths, bond angles and torsion angles have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 150465 {Δ[Rh(th4,5ppy)$_2$[(S,S)-st)]Cl}. Copies of the data can be obtained free of charge on applicaton to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Δ[Rh(th4,5ppy)$_2$(bpy)]PF$_6$ (II): A solution of ΔΔ[Rh(th4,5ppy)$_2$(μ-Cl)]$_2$ (64.73 mg, 0.05 mmol) and 2,2′-bipyridine (15.62 mg, 0.10 mmol) in CH_2Cl_2 (20 mL) was heated at reflux for 90 min under N_2 and protected from light. After cooling, addition of NH_4PF_6 (10% solution in MeOH, 3 mL) gave a white precipitate which was filtered off. Addition of a large excess of Et_2O to the filtrate yielded a yellow-orange precipitate of Δ[Rh(th4,5ppy)$_2$-(bpy)]PF$_6$, which was filtered off. The filtrate {still containing Δ[Rh(th4,5ppy)$_2$(bpy)]PF$_6$} was concentrated and diluted with CH_3CN (1 mL). Addition of H_2O (5 mL) gave the yellow-orange precipitate Δ[Rh(th4,5ppy)$_2$(bpy)]PF$_6$. The solid was filtered, added to the rest of the Δ[Rh(th4,5ppy)$_2$(bpy)]PF$_6$ powder and dried in vacuo. Yield: 57 mg (67%). − ^{1}H NMR (CD_3CN, 300 MHz): δ = 8.47 (d, 2 H, ^3J = 8.2 Hz, H−C(3′′)], 8.13 (dd, 2 H, ^3J = 8.12 Hz, ^3J = 7.69 Hz, ^4J = 1.65 Hz H−C(4′′)], 7.97 (ddd, 2 H, ^3J = 5.3 Hz, ^3J = 0.72 Hz H−C(6′′)], 7.54 (tdd, 2 H, ^3J = 7.6 Hz, ^3J = 5.38 Hz, ^4J = 1.15 Hz, H−C(5′′)], 7.45 (s, 2 H, H−C(6)] 7.43 (d, 2 H, ^3J = 4.8 Hz, H−C(5′)], 6.97 (s, 2 H, H−C(3)], 6.23 (d, 2 H, ^3J = 4.73 Hz, H−C(4′)], 3.04 (d, 4 H, ^3J = 3.02 Hz, H−C(7)], 2.567−2.63 (m, 4 H, H−C(10), H−C(9$_{exo}$)], 2.232 (tdd, 2 H, ^4J = 5.52 Hz, ^3J = 5.68 Hz, ^3J = 2.7 Hz, H−C(8)], 1.3 (s, 6 H, H−C(13)], 0.96 (d, 2 H, ^2J = 9.6 Hz, H−C(9$_{endo}$)], 0.68 (s, 6 H, H−C(12)]. − MS (FAB); *m/z* (%): 767 (100) [M − PF_6^-], 611 (43) [Rh(th4,5ppy)$_2$], 356 (5) [Rh(th4,5ppy]. − UV/Vis (CH_3CN): λ (ε) = 378 (10057), 307 (sh), 286 (34913), 270 (sh). − IR (KBr): ṽ = 3450 (w), 3055 (w), 2937 (m), 1619 (m), 1489 (s), 1469 (m), 1444 (m), 1427 (m), 1385 (w), 1242 (w), 1027 (w), 948 (w), 840 (s), 764 (m), 738 (w), 709 (w), 557 (m). − CD (CH_3CN): λ (Δε) = 391 (21), 358 (−16.1), 321 (−15.2), 270 (27.7), 242 (−49.5), 210 (30.5). − $C_{42}H_{40}F_6N_4PRhS_2\cdot 2H_2O$: calcd. Solid and Solution State NMR Spectra and the Structure of the Gallium Citrate Complex $(NH_4)_3[Ga(C_6H_5O_7)_2]\cdot 4H_2O$

Geoffrey E. Hawkes,*[a] Paul O'Brien,[b][+] Henryk Salacinski,[b] Majid Motevalli,[a] and Isaac Abrahams[a]

Keywords: Gallium / NMR spectroscopy / Structure elucidation / Citrate speciation

A gallium citrate complex $(NH_4)_3[Ga(C_6H_5O_7)_2]\cdot 4H_2O$ (**1**) has been isolated from an aqueous mixture of gallium nitrate and citric acid at pH = 9. In the solid state **1** is monomeric and includes the near centrosymmetric ion $[Ga(C_6H_5O_7)_2]^{3-}$ in the asymmetric unit, with each tridentate citrate coordinating to gallium through an alkoxide oxygen, an oxygen of the central carboxyl group and an oxygen of a terminal carboxyl group. The second terminal carboxyl group is not bound to the metal centre. The two alkoxide oxygen–gallium distances in the asymmetric unit are significantly shorter than the four carboxyl oxygen–gallium distances, indicating a stronger bond for the former. The number and intensities of the resolved resonances in the solid state ^{13}C MAS/NMR spectrum are consistent with the X-ray structure. In aqueous solution near neutral pH (5.5 to 6.4) the complex partially dissociates to give an equilibrium of the 1:1 and 1:2 gallium/citrate species together with free citrate. Two sets of resonances are observed in both the ^1H and ^{13}C NMR spectra of solutions of the complex and these correspond to bound and free citrate; there is no resolution of resonances for the 1:1 and 1:2 species. The relative strength of the alkoxide oxygen–gallium bond in the metal-bound citrate ligand leads to a slow intermolecular chemical exchange situation (rate < ca. 12 s^{-1}) between the bound and free ligand. The carboxylate oxygen–gallium bonds are quite labile and relatively rapid intramolecular chemical exchange occurs (rate > ca. 700 s^{-1}) between the metal-bound and pendant terminal carboxyl groups, averaging their ^1H and ^{13}C NMR signals. The diffusion coefficients for the free and complexed citrate measured from the ^1H NMR spectra do not appear to be complicated by chemical exchange effects and, as expected, the diffusion coefficient for the complexed ligand is smaller than for the free ligand. In solution in the intermediate pH range (4.8 to 6.4) a new ^{71}Ga signal is observed at ca. δ = 27 ($\Delta\nu_{1/2} \approx 10.6$ kHz) which is assigned to the gallium citrate complexed species.

Introduction

Citrate is a an important endogenous ligand which occurs in blood plasma[1] (ca. 10^{-4} mM) and ca. 0.3% w/w in teeth and bone.[2,3] Metal−citrate complexes are involved or implicated in a wide range of physiological functions; for example, ferrous citrate in the activation of catalytic activity of the enzyme aconitase (citrate isocitrate hydrolyase),[4] zinc citrate in the genetic disorder of zinc metabolism *acrodermatitis enteropathica*,[5,6] and aluminium citrate in neurotoxic conditions.[7] Bismuth−citrate complexes have been used[8,9] in the treatment of peptic ulcers; our interest focuses on gallium citrate complexes. Edwards and Hayes[10] reported that ^{67}Ga citrate accumulates in soft tissue tumours and, subsequently, hot gallium citrate has found wide use in a range of imaging systems for tumour localisation and in identifying inflammatory lesions.[11] In addition, Hart et al.[12] reported the use of cold gallium nitrate for the treatment of solid tumours and, more recently, Jonkhoff et al.[13] studied the therapeutic use of gallium citrate on leukaemic patients. Despite the widespread use of gallium citrate very little structural information is available. Banta et al.[14] reported the X-ray structural analysis of the trimethyl (and triethyl) ester complexes bis[(trimethylcitrato)dimethylgallium(III)] and we recently published the X-ray structure of the gallium(III) citrate complex $(NH_4)_3[Ga(C_6H_5O_7)_2]\cdot 4H_2O$ (**1**).[15] Here we present further discussion on the structure, together with a detailed NMR spectroscopic analysis of the structure both in the solid state and in solution around physiological pH.

Our preliminary report[15] showed that the complex anion is comprised of two tridentate citrate ligands giving rise to approximately octahedral coordination around the gallium. Citrate may act as both a chelating and a bridging ligand, and many X-ray structures have shown the metal complexes to be oligomeric with either the carboxyl groups or the hydroxy oxygens bridging more than one metal centre. However, monomeric 2:1 (citrate/metal) structures have been reported for the complex anions in ammonium bis(citrato)cuprate(II),[16] ammonium bis(citrato)zinc(II),[17] pyridinium bis(citrato)chromium(III),[18] and ammonium bis(monomethylcitrato)germanate(IV).[19] Citrate chelation in relation to enzymatic function has been the subject of an earlier review.[3]

Glickson et al.[20] measured the ^{71}Ga and ^1H NMR spectra of solutions of gallium nitrate with citric acid. They concluded that 1:1 citrate/metal complexes were formed in

strongly acidic media, whereas in near neutral solutions the stoichiometry of the complexation was more difficult to determine, although polymeric species were indicated. In a subsequent study of the aqueous gallium nitrate/citric acid system, Chang et al.[21] used both ^{1}H and ^{13}C NMR spectroscopy to show the existence of both 1:1 and 2:1 citrate/gallium complexes (Ga_nCit_n and Ga_nCit_{2n}), and for approximately neutral solutions concluded that n is a small integer. Apparent conditional (pH = 5.80) stability constants for the stepwise complexation were estimated as $K_1 = 48 \pm 1$ M^{-1} and $K_2 = 13 \pm 1$ M^{-1}.

Results and Discussion

The X-ray structure determination of (**1**) has been described in a preliminary communication.[15] As shown in Figure 1, two citrate ligands complex with each gallium to yield an approximately centrosymmetric molecule and the asymmetric unit is one molecule. The molecule is achiral with (*R*)-configuration at C3 and (*S*)-configuration at C9.

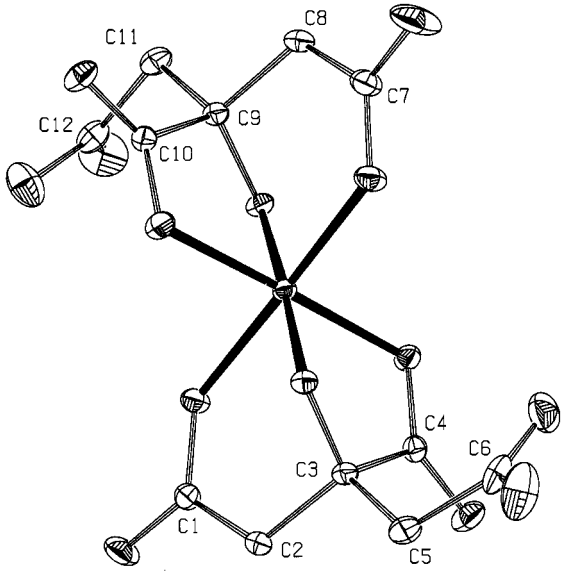

Figure 1. The structure of $[Ga^{III}(citrate)_2]^{3-}$

The high frequency region of the solid state 75.5 MHz ^{13}C magic angle spinning (MAS) NMR spectrum is shown in Figure 2 and summarised in Table 1. There are five well-resolved resonances at δ = 173.9, 179.4, 180.7, 185.6 and 189.9 due to the carboxyl groups, with the resonance at δ = 179.4 being approximately double the intensity of the other four. In addition there are two broader signals to lower frequency at δ = 76.0 due to the nonprotonated carbons C3,9, and at δ ≈ 48 due to the methylene carbons C2,5,8,11. The high frequency region is consistent with the X-ray structure, there being six inequivalent carboxyl groups with the shifts of two being accidentally the same at δ = 179.4. As described below we assign the two highest frequency signals

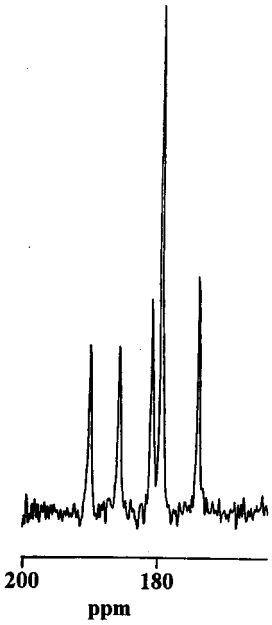

Figure 2. The high frequency region (carbonyl signals) of the 75.5 MHz ^{13}C solid state MAS NMR spectrum of $[Ga^{III}(citrate)_2]^{3-}$

Table 1. ^{13}C Chemical shifts for (**1**) in the solid and in solution

	Solid[a]	Solution[b] pH = 6.4	Solution[b] pH = 1.75
C1,6,7,12	173.9, 179.4,[c] 180.7	179.5	175.5
C4,10	185.6, 189.9	186.5	180.6
C3,9	76.0	74.6	74.7
C2,5,8,10	48	46.5	43.1

[a] Measured at 75.5 MHz. – [b] Measured at 100.6 MHz. – [c] This resonance has double intensity.

(δ = 185.6 and 189.9) to the central carboxyl carbons C4 and C10.

The solution state 122.0 MHz ^{71}Ga spectra of the gallium citrate complex, measured as a function of pH, are shown in Figure 3. The isotope ^{71}Ga has 39.6% natural abundance and the nucleus is quadrupolar with spin $I = {}^3/_2$, and as such it is to be expected that the NMR spectra are dominated by broad signals. The spectrum of the most acidic solution (pH = 1.75) is dominated by a relatively sharp signal at δ ≈ 0 with $\Delta\nu_{1/2}$ < ca. 500 Hz with evidence of a weaker broader ($\Delta\nu_{1/2} \approx$ 12 to 15 kHz) signal to slightly higher frequency (δ ≈ 30 to 40). Similarly, the spectrum of the most basic solution (pH = 9.4) has a sharper signal at δ = 222 with a suggestion of a very weak broad signal at δ ≈ 0. The spectra measured at intermediate pH values showed just a single broad signal: pH = 4.8, at δ ≈ 29 with $\Delta\nu_{1/2} \approx$ 7.7 kHz; pH = 5.5, at δ ≈ 30 with $\Delta\nu_{1/2} \approx$ 11.4 kHz; pH = 6.4, at δ ≈ 27 with $\Delta\nu_{1/2} \approx$ 10.6 kHz.

The ^{1}H and ^{13}C NMR spectra (400 and 100.6 MHz, respectively) show features in common with certain of the ^{1}H spectra reported by Glickson et al.[20] and the ^{13}C spectra reported by Chang et al.,[21] with the expected better resolution here resulting from the use of higher field spectro-

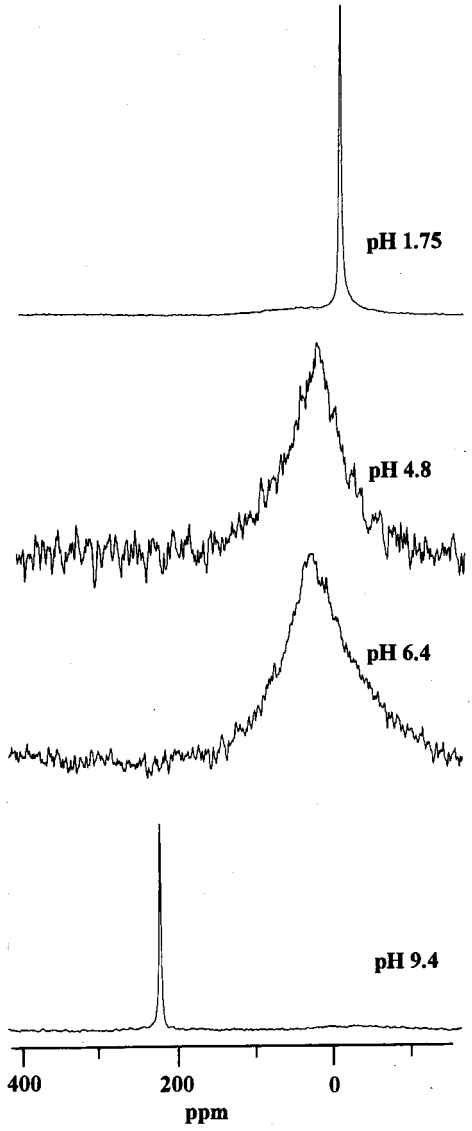

Figure 3. The 122.0 MHz solution state ^{71}Ga spectra of $[Ga^{III}(citrate)_2]^{3-}$ as a function of pH

meters. The ^{13}C spectrum of the complex at pH = 1.75 (Table 1) shows two sets of citrate resonances in an approximate ratio 45:55; the slightly weaker group signals occurring at δ = 43.1 ($-CH_2-$), 74.7 (>C<), 175.5 (terminal $-CH_2CO_2$), and 180.6 (central CO_2) are assigned to citrate in a Ga−citrate complex, whereas the slightly stronger signals at δ = 43.6, 73.7, 173.9 and 177.2 are assigned to free citrate. The assignment between free and complexed citrate for these two groups of signals is confirmed by the ^{13}C shift difference between the two carbonyl signals (3.3 ppm) from a solution of citric acid alone, measured at pH = 1.95. The ^1H spectrum at pH = 1.75 comprises two equally intense multiplets centred at δ = 2.91 and 2.76 due to overlapping signals from the free and complexed citrate methylene protons. At pH = 4.8 the ^{13}C resonances assigned to the complex are more intense than those due to free citrate (in the approximate ratio 65:35), whereas in the range pH = 5.5 to 6.4 the ratio is nearer 80:20. In basic solution at pH = 9.4 only one set of signals is observed due to free citrate. In the intermediate pH range (4.8 to 6.4) the appearance of the ^1H spectra are entirely consistent with the ^{13}C spectra, with two resolved *AB* type splitting patterns (e.g. at pH = 6.4, $\delta_A = 2.58$, $\delta_B = 2.44$, $J_{AB} = 16.9$ Hz for the complex, $\delta_A = 2.54$, $\delta_B = 2.41$, $J_{AB} = 15.2$ Hz for free citrate). The assignment of these *AB* signals between complexed and free citrate is confirmed by the values for J_{AB} across the pH range — Glickson et al.[20] reported J_{AB} values for free citrate in the range 16.2 to 15.4 Hz between pH = 0.75 and 8.71, and for gallium citrate in the range 16.7 (pH = 0.70) to 17.5 Hz (pH = 7.76). In the intermediate pH range many minor signals appeared in both the ^1H and ^{13}C spectra which are probably due to various oligomeric complex species.[20,21] These minor signals were not apparent in either ^1H or ^{13}C spectra measured at extremes of pH (1.75 and 9.4).

The ^{13}C shifts for the complex at pH = 6.4 (Table 1) were δ = 186.5, 179.5, 74.6 and 46.5, with the highest frequency signal due to the central carboxyl carbons C4,10 and the signal at δ = 179.5 due to the carboxyl carbons C1,6,7,12. The average shift for the two highest frequency ^{13}C signals in the solid state (vide supra) is δ = 187.8 and the average for the other carboxyl signals in the solid state is δ = 178.4. These two averages of solid state data compare favourably with the solution state shifts for the carboxyl signals and provide the assignment for the solid state signals.

The diffusion coefficients were measured for 30 mM and 10 mM samples by the ^1H NMR method (see Experimental section). As shown by Stejskal and Tanner,[22] the signal intensities vary according to Equation (1):

$$I_i = I_{0i} \exp(-K^2 \cdot D \cdot \Delta) \quad (1)$$

where $K = \gamma \cdot G_i \cdot \delta$ with γ the nuclear spin gyromagnetic ratio, and G_i and δ are the strength and duration of the field gradient, D is the diffusion coefficient for the molecular species and Δ is the diffusion period. The signal intensities I_i are measured as a function of the gradient strength G_i, and I_{0i} is the signal intensity in the absence of any field gradient. All plots of $\ln(I_i)/K^2$ were linear and the values for the diffusion coefficients obtained are given in Table 2. Deviation from linearity in these plots would have indicated the importance of chemical exchange between the various citrate species, occurring at an intermediate rate on the time-scale of the diffusion period (300 ms). For such complex behaviour a double-exponential dependence of I_i upon K^2 would be expected.[23]

Solid State Structure

Subsequent to our original interpretation[15] of the X-ray crystal structure, we have examined the possibility of alternative distributions of water and ammonium species in the structure refinement.[24] Bearing in mind the relative X-ray scattering of these species with that of the total crystal structure an unambiguous assignment is difficult. A mar-

Table 2. Diffusion coefficients, measured from ^{1}H spectra at 600 MHz, for free and complexed citrate in solutions of (**1**)

Sample[a]	30 mM	10 mM
Free citrate	5.64×10^{-10} m^2 s^{-1}	5.73×10^{-10} m^2 s^{-1}
Complexed citrate	4.34×10^{-10} m^2 s^{-1}	4.24×10^{-10} m^2 s^{-1}

[a] Samples at pH ca. 5.9

ginal improvement in *R* factors is seen with the two half-occupancy water sites changed to ammonium ions. This would suggest a molecular formula of $(NH_4)_4[Ga(C_6H_5O_7)(C_6H_4O_7)]\cdot 3H_2O$, wherein only one of the pendant carboxyl groups is protonated. However, this does not change the coordination geometry at gallium. For what it is worth the elemental analysis (see Experimental Section) supports our original interpretation of three ammonium ions and four water molecules in the molecular formula. An important feature of the previously reported[15] structure are the Ga−O distances. The Ga−O(2) and Ga−O(5) distances are 1.900 and 1.890 Å, and are notably shorter than the Ga−carboxyl oxygen distances which are in the range 1.976−2.054 Å. This feature must reflect the stronger bonding between the gallium and the alkoxide oxygens [O(2) and O(5)] than between gallium and the carboxyl oxygens. The crystal structures of other monomeric 2:1 citrate/metal complexes show the opposite situation, namely the metal−carboxyl bonds are shorter for the bis(citrato)-cuprate(II)[16] and bis(citrato)zinc(II)[17] anions, whereas for the bis(citrato)chromium(III)[18] anion the Cr−O bond lengths are all quite similar. In all three of these latter complexes the integrity of the hydroxyl group is maintained, i.e. it is not deprotonated. On the other hand, in the structure[19] of the bis(citrato)germanate(IV) anion the citrates do coordinate through alkoxide oxygens and the Ge−O(alkoxide) distance is 1.813 Å, with the Ge−O(carboxyl) distances at 1.908 and 1.930 Å. The shortening of the metal−alkoxide oxygen distance relative to the metal−carboxyl oxygen is maintained in other (polymeric) structures where the alkoxide is ligating a single metal, e.g. the complex anions[25] $[Bi_2(citrate)_2]$.

Glusker[3] has reported that the carbon backbone of the citrate ligand (the five carbon fragment including the two terminal carboxyl carbons) typically adopts one of two conformations in metal complexes. These are an extended conformation wherein the two torsion angles about the carbon−carbon bonds are both about 180°, or a folded conformation for which one of the angles is about 180° and the other is about 60°. The two distinct citrate ligands for **1** are both described by extended conformations with the torsion angles[26] for the first ligand C1−C2−C3−C5 and C2−C3−C5−C6 both equal to 176.6°, and for the second ligand C12−C11−C9−C8 equal to 165.2° and C11−C9−C8−C7 equal to −179.5°.

Solution State Structure

The earlier solution-state studies[20,21] used samples prepared by the equilibration of solutions of gallium nitrate and citric acid, in contrast to the samples used here which were prepared by direct dissolution of the crystalline gallium citrate complex **1**. However, it is clear that the main features of the solution structure are similar.

Glickson et al.[20] reported 27.5 MHz ^{71}Ga spectra of gallium nitrate in the presence of citrate in acidic solution. They concluded that the gallium citrate complex partially dissociates in acid medium to give $Ga(D_2O)_6^{3+}$, together with some undissociated complex; however, they did not obtain direct evidence for the presence of the gallium complex since they suggested that the signal due to the complex was broadened beyond detection by quadrupolar relaxation. In highly alkaline aqueous solution a signal due to $Ga(OD)_4^-$ was observed and it was concluded that little of the complex persisted. As indicated below, our analysis of the ^{1}H and ^{13}C NMR spectroscopic data indicate that the gallium citrate complex is the dominant species for a 100 mM solution at about neutral pH, and so our new ^{71}Ga data show the signal due to the complex to occur around $\delta = 27$ with a value for $\Delta\nu_{1/2} \approx 10$ to 12 kHz.

All solution state NMR spectroscopic data on the complex, both from this study and earlier work[20,21] show that in solution the terminal $-CH_2CO_2$ groups in the gallium complex are equivalent. The X-ray structure of the 1:2 complex indicates that in solution there should be at the very least two distinct environments for the $-CH_2CO_2$ groups — two of the groups are bound through oxygen to the gallium, and the other two are not directly bound. However, there are only single ^{13}C signals for the CH_2 and CO_2 groups and only one *AB*-type pattern in the ^{1}H spectrum for the complex. These observations are consistent with rapid intramolecular exchange between the two environments. While we cannot directly quantify the rate of this process, the full spread in ^{13}C shifts from the solid state for the CH_2CO_2 groups is 6.8 ppm (= 680 Hz), and therefore this exchange must occur with a rate greater than ca. 700 s^{-1}. This process cannot be intermolecular since in the intermediate pH range separate ^{13}C and ^{1}H signals are observed for both free and complexed citrate, and so any intermolecular exchange must be relatively very slow — the chemical shift separation for the *B* protons in the two environments is 0.03 ppm (at pH = 6.4), which is 12 Hz, and the rate of intermolecular exchange must be considerably slower than 12 s^{-1}. In solution we cannot specify unequivocally the nature of the gallium citrate complex as a 1:2 or as a 1:1 species. The ^{1}H and ^{13}C shifts for the citrate ligands in the two situations are likely to be very similar and could either be superimposed or coalesced by the intermolecular exchange which, although slow for the free ⇄ complexed citrate process, could be fast with respect to the 1:2 ⇄ 1:1 complexes with the smaller chemical shift difference.

Very slow intermolecular exchange results from the citrate ligands being anchored to the metal by the alkoxide oxygens [O(2) and O(5) in the structure]. The lengths of these metal−oxygen bonds are 1.90 and 1.89 Å, and are significantly shorter than the other four carboxyl oxygen−metal bonds (2.05, 1.98, 2.02 and 1.98 Å); these shorter bonds should also be the least labile.

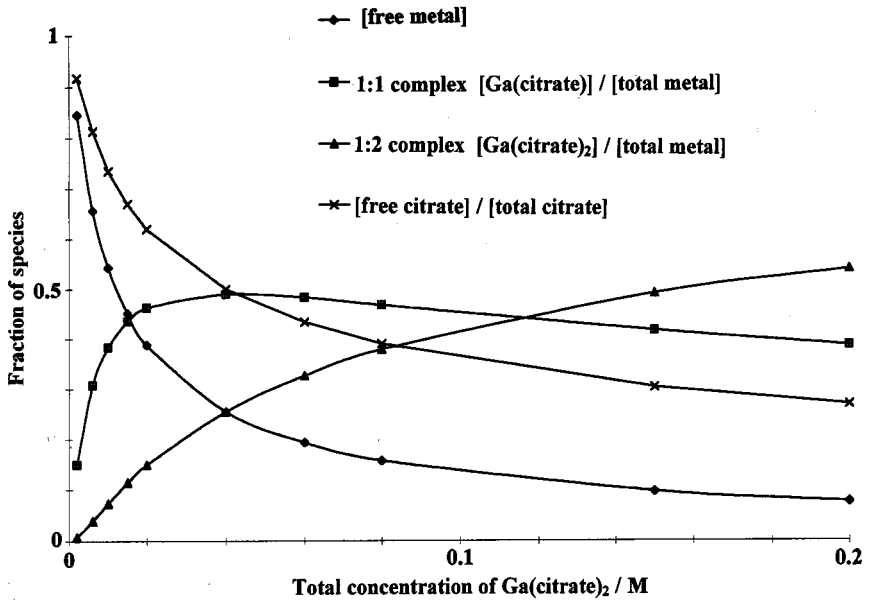

Figure 4. The relative proportions of the species present in a solution of $[Ga^{III}(citrate)_2]^{3-}$, calculated using the stability constants K_1 = 48 ± 1 M^{-1} and K_2 = 13 ± 1 M^{-1}

As indicated above, in the pH range 5.5 to 6.4 the ratio of complexed to free citrate is ca. 4:1, although we are unable to distinguish between complexed citrate in the 1:2 or 1:1 species. Chang et al.[21] were able to estimate conditional stability constants for the stepwise binding of citrate to gallium as K_1 = 48 ± 1 M^{-1} and K_2 = 13 ± 1 M^{-1} at pD = 5.40 (pH = 5.80). With these values we calculate the proportions of the various gallium species present at equilibrium as shown in Figure 4. For a total gallium concentration of 100 mM, as $Ga(citrate)_2$, the proportions of gallium present as the 1:2 complex and the 1:1 complex are 0.41 and 0.45 respectively. This distribution gives a total complexed-to-free citrate ratio as 1.8:1 which is similar to the ratio of 4:1 indicated by the ^{13}C and ^1H NMR spectroscopic data. To further substantiate this suggestion, the 600 MHz ^1H spectrum of a more dilute sample (ca. 30 mM

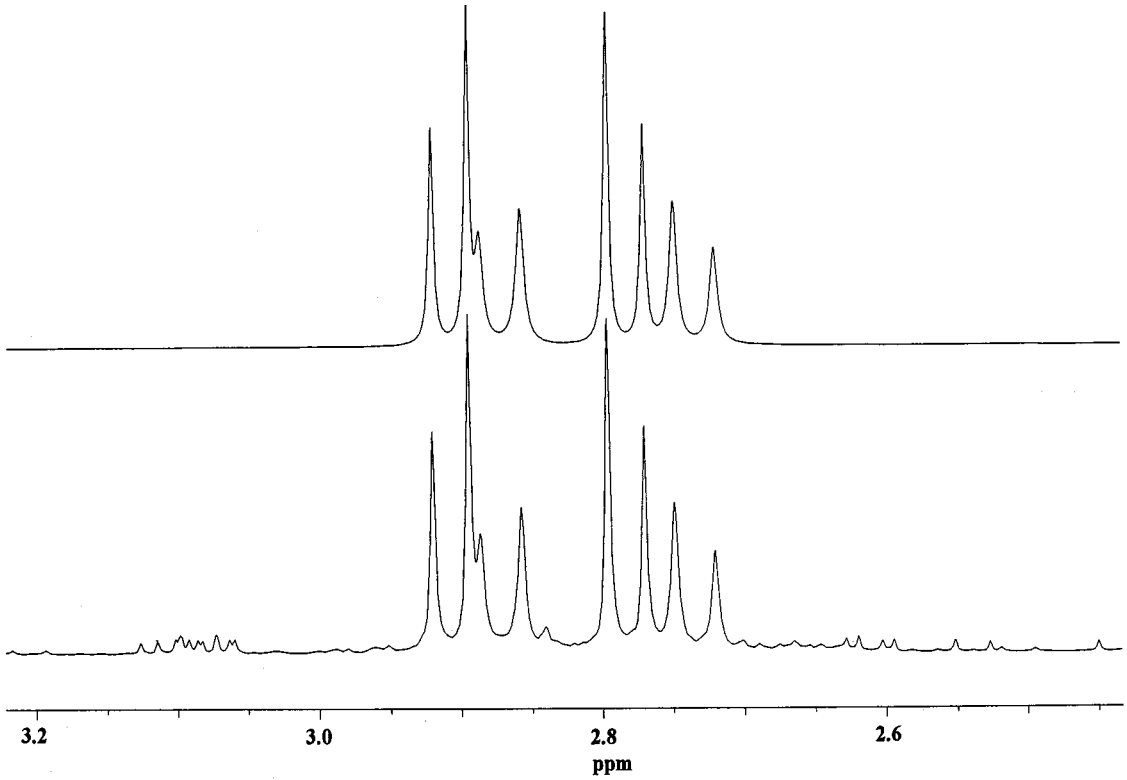

Figure 5. Experimental (lower) and simulated (upper) 600 MHz ^1H NMR spectra of the methylene region of 30 mM $[Ga^{III}(citrate)_2]^{3-}$ at pH 5.9

at pH 5.9) of Ga(citrate)$_2$ was measured (Figure 5) and integration gave a ratio for complexed to free citrate as 1.6:1. Inspection of Figure 5 gives the calculated complexed-to-free citrate ratio 0.8:1 at a total concentration of 30 mM. A third sample of ca. 10 mM gave an experimental ratio for complexed to free citrate as 0.5:1 compared with a calculated ratio (Figure 4) of 0.4:1. In principal our experimental data should allow the calculation of new values for the binding constants K_1 and K_2; however, since our samples were unbuffered solutions, and the concentrations used were approximate, such a calculation was not performed. It is sufficient to note that the complexed-to-free citrate ratios determined here experimentally are in reasonable agreement with those predicted from the conditional stability constant data of Chang et al.[21] in the same pH region.

The calculation for the spectrum shown in Figure 5 employed pure Lorentzian lineshapes and the average linewidth for the four lines of the *AB* pattern due to the complexed citrate was 0.5 greater than the average linewidth for the lines of the free citrate. This observation is fully consistent with the above argument that the ^{1}H NMR signals due to the complexed citrate are a composite of signals from both 1:2 and 1:1 complexes. In the lower field spectra (400 MHz) there was no direct evidence that the signals were due to a superposition of both 1:2 and 1:1 complexes, but at the higher field this additional broadening of the lines could be due to partial resolution of shifts from the two species, or to the higher field pushing the spectrum more towards the coalescence region for intermolecular exchange between the two species.

The diffusion coefficients measured (Table 2) for free citrate average to 5.7×10^{-10} m^2 s^{-1} over the two solutions (10 and 30 mM) and this is to be compared with the value 4.8×10^{-10} m^2 s^{-1} measured[27] for free citrate in human plasma, and 10.2×10^{-10} m^2 s^{-1} measured[28] for free citrate in a ranitidine bismuth citrate solution. It is reasonable that the plasma value should be somewhat lower since plasma is more viscous and contains a multitude of additional endogenous solutes. However, the origin of the larger discrepancy between the value for free citrate found here and that found by Parkinson et al.[28] is not obvious. The pH of the samples may be an important factor and further discussion should await the results of more detailed studies on the effect of the medium on the self diffusion coefficient of citric acid. The average value for the diffusion coefficient of the complexed citrate (Table 2) is 4.3×10^{-10} m^2 s^{-1} and again it is reasonable that this is lower than the free citrate value simply because of the increased molecular weight of the species. These values for the complexed citrate represent a composite of the values for the 1:1 and 1:2 gallium/citrate species which have different relative proportions in the two solutions (10 and 30 mM, vide supra), however the difference in the values for the complexed citrate between the two solutions is not significant (ca. 2%) and should not be interpreted further. The difference in the diffusion coefficients (free − complexed) although not great, is significant; that for the complexed citrate is ca. 25% smaller than that for the free ligand and this similarity helps to reinforce the conclusion that these major complexed species are not oligomeric. Therefore the earlier suggestion by Chang et al.[21] that the major complexed species are Ga_nCit_n and Ga_nCit_{2n} where n is a small integer can be refined to set $n = 1$.

Conclusion

The solid state structure of $(NH_4)_3[Ga(C_6H_5O_7)_2]\cdot 4H_2O$ (**1**) is monomeric and includes the near centrosymmetric ion $[Ga(C_6H_5O_7)_2]^{3-}$ in the asymmetric unit, with each tridentate citrate coordinating to gallium through the alkoxide oxygen, an oxygen of the central carboxyl group and an oxygen of a terminal carboxyl group. The second terminal carboxyl group is protonated and not bound to the metal centre. The two alkoxide oxygen−gallium distances in the asymmetric unit are significantly shorter than the four carboxyl oxygen−gallium distances, indicating a stronger bond for the former case. The number and intensities of resolved resonances in the solid state ^{13}C MAS/NMR spectrum are entirely consistent with the X-ray structure.

The pH-dependent ^{71}Ga NMR spectra of the complex in aqueous solution show a dominant peak due to $Ga(D_2O)_6^{3+}$ at pH = 1.75, and at pH = 9.4 a peak due to $Ga(OD)_4^-$, in agreement with the earlier work of Glickson et al.[20] In the intermediate pH range a new ^{71}Ga signal is observed at $\delta \approx 27$ ($\Delta\nu_{1/2} \approx 10.6$ kHz) which is assigned to the gallium citrate complexed species.

In aqueous solution nearer neutral pH (5.5 to 6.4) the complex partially dissociates to give an equilibrium of the 1:1 and 1:2 gallium/citrate species together with free citrate. For the solution species two sets of resonances are observed in both the ^{1}H and ^{13}C NMR spectra and these correspond to bound and free citrate, with no resolution of resonances for the 1:1 and 1:2 species. The relative strength of the alkoxide oxygen−gallium bond in the metal-bound citrate ligand leads to a slow chemical exchange situation between the metal-bound and free ligand. The carboxylate oxygen−gallium bonds are quite labile and relatively rapid chemical exchange results between the bound and pendant terminal carboxyl groups, thereby averaging their ^{1}H and ^{13}C NMR signals. The diffusion coefficients measured from the ^{1}H NMR spectra do not appear to be complicated by chemical exchange effects and, as expected, that for the complexed ligand is smaller than for the free ligand.

Experimental Section

The preparation of **1** has been previously reported.[15] Typical yields were in the range 60−70%. $C_{12}H_{30}GaN_3O_{18}$: calcd. C 25.11, H 5.27, N 7.32; found C 24.56, H 6.55, N 7.56; {$C_{12}H_{31}GaN_4O_{17}$, i.e. $(NH_4)_4[Ga(C_6H_5O_7)(C_6H_4O_7)]\cdot 3H_2O$: calcd. C 25.15, H 5.45, N 9.78}.

The solid state ^{13}C CP/MAS NMR spectrum was measured at 75.5 MHz using a Bruker MSL-300 spectrometer equipped with a standard Bruker MAS probe with double-bearing rotation mechanism. The sample was studied as a microcrystalline powder in a 4 mm o.d. zirconia rotor at an MAS frequency ca. 8.5 kHz. The spec-

trum was recorded at ambient probe temperature, and the chemical shifts are referenced to external liquid tetramethylsilane. The samples for solution state NMR were prepared by dissolution of the crystalline complex in D_2O at approximate concentrations of 100 mM, 30 mM and 10 mM, and the pH was adjusted by addition of NaOH or HCl solution. pD was measured using a Corning model 7 meter and pH is determined as pD (measured) + 0.40. ^{13}C, ^{71}Ga and ^{1}H solution state NMR spectra were measured at 100.6, 122.0 and 400 MHz, respectively, using a Bruker DRX-400 spectrometer, and additional ^{1}H spectra were obtained with a Bruker AMX-600. Chemical shifts are reported on the high frequency positive scale relative to external TSP (trimethylsilylpropionic acid) (^{1}H and ^{13}C) and a 1.0 M $Ga(NO_3)_3$ solution for ^{71}Ga spectra. The measurements of the diffusion coefficients used the AMX-600 instrument which is equipped with a Bruker B-AFPA30 gradient unit capable of providing gradients up to 2 T m^{-1} along the magnetic field direction (z axis). The diffusion data were acquired using a version of the LED delay pulse sequence[29] with the inclusion of the WATERGATE solvent peak suppression scheme[30] to eliminate the resonance of the water. A series of spectra were measured for values of the gradient strength in the range 1−30% maximum in random order using bipolar sine-shaped gradients (1 ms), a diffusion period of 300 ms and a gradient recovery time of 2 ms. The gradient strength was calibrated in a separate experiment on a water sample assuming a value[31] for the diffusion coefficient of water as 2.37×10^{-9} m^2 s^{-1}. Peak areas were measured by iterative simulation of the spectra using the Bruker WIN-1D and WIN-FIT programs, assuming pure Lorentzian lineshapes, and the intensities for each of the four lines of the *AB* patterns for the free and for the complexed citrate were summed for each value of the gradient strength used.

Acknowledgments

We thank the University of London Intercollegiate Research Service (ULIRS) for provision of the MSL-300 facility at University College, and for the AMX-600 spectrometer at QMW. We thank Mr. R.N Sheppard at IC for the measurement of the solution state spectra with the DRX-400 spectrometer, and the Microanalytical Service at IC for the elemental analysis. Finally we also thank one of the referees for pointing out the possibility that the pendant carboxyl groups might not be protonated.

Crystal Structures and ^{29}Si NMR Calculations of Amino-Functionalized Silyllithium Compounds

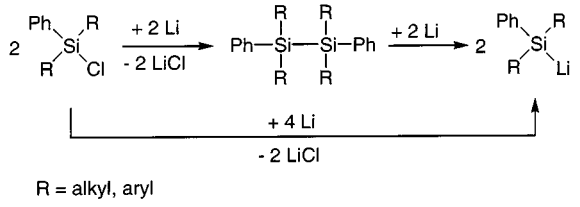
Carsten Strohmann,*[a] Oliver Ulbrich,[a] and Dominik Auer[a]

Keywords: Ab initio calculations / Lithium / NMR spectroscopy / Silanes / Si ligands

X-ray structural analysis of the amino-functionalized silyllithium compounds tris(tetrahydrofuran)[bis(diethylamino)phenylsilyl]lithium (**4**·3THF) and tris(tetrahydrofuran)[(diethylamino)bisphenylsilyl]lithium (**7**·3THF) are presented. Both compounds are monomeric in the solid state as well as in solution. Despite the formal negative charge at the silicon atom, the nitrogen centres are flattened. No Li–N interactions were observed, in contrast to the homologous (lithiomethyl)amines. RI-DFT calculations give an explanation for the variation of experimental Si–Li bond lengths of 2.627(4) Å (**4**·3THF), 2.682(8) Å (**7**·3THF) and 2.732(7) Å {tris(tetrahydrofuran)[bis(diphenylamino)phenylsilyl]lithium} (**1**·3THF). N–Si orbital interactions, influenced by the type of substituents located at the nitrogen centre, affect these structural parameters as well as the ^{29}Si NMR chemical shifts. The apparently unusual experimental values of the ^{29}Si NMR resonance signals at δ = 20.3 (for **7**·3THF) and δ = 28.4 (for **4**·3THF) can be explained by DFT-IGLO calculations and are a consequence of the combination of electronegative and electropositive substituents at the silicon centre.

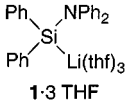
Introduction

Silyllithium compounds are useful and important reagents for silyl-group transfer reactions to organic molecules or organometallic systems.[1a,1b] Generally, silyllithiums can be prepared by reaction of a chlorosilane with lithium metal and cleavage of the disilane intermediate (Scheme 1),[2a−2c] although that method is limited to systems bearing at least one aryl group.[2c]



Scheme 1.

In contrast to alkyl- and arylsilyllithiums, functionalized silyllithium species have been studied less extensively. Some dialkylamino-functionalized silyllithium compounds with phenyl substituents at the central silicon atom have been developed by Tamao et al.[3a−3c] These compounds, especially **4** and **7**, can be prepared according to Scheme 1 and are stable in solution at room temperature. Nevertheless, structural information about these dialkylamino-functionalized silyllithium compounds is scarce.[4a,4b,5] Tamao and co-workers were able to prove that dialkylamino-functionalized silyllithiums are monomeric in solution by observation of ^{29}Si−^{7}Li coupling (quadruplet) in the ^{29}Si NMR spectra in the temperature range of −100 to −110 °C.[5] However, the nature of the unusual ^{29}Si NMR chemical shifts of such compounds is still not well understood. More structural information about dialkylamino-functionalized silyllithiums can be concluded from the solid state structure of tris(tetrahydrofuran)[(diphenylamino)bisphenylsilyl]-lithium (**1**·3THF) (Figure 1).[5]



1·3 THF

Figure 1. Structural formula of **1**·3THF

The crystal structure shows a monomeric silyllithium system with the lithium centre being coordinated by three THF molecules. A closer look at the structural parameters reveals a quite long Si−Li bond of 2.732(7) Å and a planar nitrogen centre. The phenyl substituents at the nitrogen centre enhance the planarisation of this centre, and therefore it is not clear if this system is comparable to the synthetically useful dialkylamino-functionalized silyllithiums. Elongation of the Si−Li and Si−N bonds in compound **1**·3THF should be caused by the additional interaction of the lone pair at the amino group with the phenyl substituents.

We attach importance to the clarification of the structural facts of dialkylamino-functionalized silyllithiums in order to study structure/reactivity patterns. The most important questions are: i) What are the structures of bis(diethylamino)phenylsilyllithium (**4**) or (diethylamino)bisphenylsilyllithium (**7**) in the solid state? and ii) How can we explain the unusual downfield shifts of the ^{29}Si NMR resonance signals?[3a,5]

Results and Discussion

The silyllithium compound **4** was prepared starting from chlorosilane **2** and lithium metal in THF, as described by

[a] Institut für Anorganische Chemie, Universität Würzburg

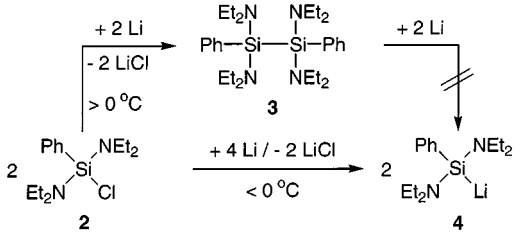
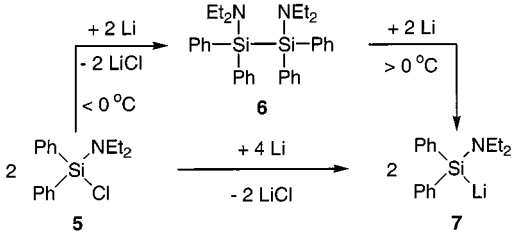
Tamao and co-workers (Scheme 2).[3c] In the ^{29}Si NMR spectrum of the reaction mixture of **2** with lithium metal at temperatures above 0 °C we observe a resonance signal for the disilane **3** (main product), as well as a signal for **4**. Furthermore we also found chlorosilane **2** at shorter reaction times, allowing us to conclude that the reaction of **2** with **4** to give **3** is slow. Disilane **3** is not cleaved by lithium to give the silyllithium compound **4**. We assume the following reaction pathway: the silyllithium compound **4** is the primary product of the reaction of chlorosilane **2** with lithium metal, compound **4** reacts to form the disilane **3** at temperatures above 0 °C and a cleavage of the disilane by lithium is not observed. Reaction of **2** at low temperatures (< 0 °C) leads to **4**, which is stable and does not react with chlorosilane **2** at that temperature.



Scheme 2.

The analogous synthesis of the silyllithium species **7**, also described by Tamao and co-workers,[3c] follows a different reaction path (Scheme 3). The primary product of the reaction of chlorosilane **5** with lithium metal at temperatures of −40 to −20 °C is the disilane **6**. Raising the temperature of the reaction mixture to 0 °C results in the cleavage of the Si−Si bond and the formation of the silyllithium species **7**. This can also be recognized by a change of colour during the reaction or from the analogous synthesis of **7** starting from **6**.



Scheme 3.

Compounds **4** and **7** were isolated as crystalline THF adducts. The amino-functionalized silyllithium compound **4**·3THF crystallized from *n*-pentane at −90 °C in the triclinic crystal system, space group $P\bar{1}$ (Figure 2 and Table 2). The crystals melt at temperatures above −20 °C. **4**·3THF is monomeric in the solid state with the lithium centre being surrounded by three THF molecules in a tetrahedral geometry. Neither an intramolecular coordination of the lithium centre by the nitrogen atoms nor a chelating effect could be observed. This is not unusual but *is* in contrast to (lithiomethyl)amines.[6] Nevertheless the Si−Li bond length is relatively short [2.627(4) Å] compared to other silyllithium species [2.732(7) Å in **1**·3THF;[5] 2.70 Å in $(Me_3SiLi)_2$·3 $(Me_2NCH_2CH_2NMe_2)_3$;[7] 2.66 Å in $(Me_3Si)_3SiLi$·3THF;[8] 2.67 Å in Ph_3SiLi·3THF;[9] 2.65 Å in $(Me_3SiLi)_6$].[10a,10b] The two nitrogen centres in **4**·3THF show an almost planar environment; the deviations from the plane are 0.057 and 0.088 Å. The total sum of the bond angles at the nitrogen centres are 354.9° and 358°, respectively (360° in **1**·3THF[5]). The Si−N bond lengths in **4**·3THF are relatively long [1.772(2) and 1.781(2) Å] compared to other aminosilanes [1.73 and 1.72 Å in $(Et_2N)_2PhSiSiPh(NEt_2)_2$],[11] but shorter than the corresponding bonds of 1.824(3) Å in **1**·3THF (see Table 1).

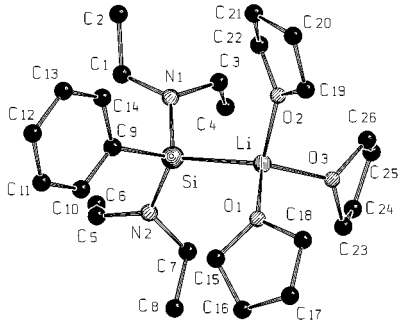


Figure 2. Molecular structure of tris(tetrahydrofuran)[bis(diethylamino)phenylsilyl]lithium (**4**·3THF) in the crystal; selected bond lengths [Å] and angles [°]: Si−Li 2.627(4), Si−N(1) 1.781(2), Si−N(2) 1.772(2), Si−C(9) 1.926(2), Li−O(1) 1.987(5), Li−O(2) 1.972(5), Li−O(3) 1.971(4); N(2)−Si−N(1) 112.66(11), N(2)−Si−C(9) 100.14(11), N(1)−Si−C(9) 100.01(11), N(2)−Si−Li 120.05(13), N(1)−Si−Li 110.26(13), C(9)−Si−Li 111.39(12), C(1)−N(1)−C(3) 113.4(2), C(1)−N(1)−Si 124.9(2), C(3)−N(1)−Si 116.6(2), C(7)−N(2)−C(5) 114.2(2), C(7)−N(2)−Si 119.0(2), C(5)−N(2)−Si 124.8(2)

Crystals from the amino-functionalized silyllithium compound **7**·3THF could be obtained by fast crystallization from a solution in *n*-pentane at −30 °C. The compound crystallises in the monoclinic crystal system, space group $P2_1/c$ with two molecules in the asymmetric unit (Figure 3 and 4, and Table 2). The structure analysis was performed at −10 °C, because single crystals of **7**·3THF are very sensitive to strong cooling, which results in a slow decomposition and bad quality of the collected reflection data. Like **4**·3THF the silyllithium species **7**·3THF is monomeric in the solid state and no intramolecular coordination of the lithium centre by the nitrogen atom was found. The lithium centres are surrounded by three THF molecules in a tetrahedral geometry. The Si−Li bond lengths [2.682(8) and 2.678(8) Å] are longer than in the comparable compound **4**·3THF. An elongation of the Si−N bond relative to other aminosilanes can also be observed. The nitrogen centre shows an almost planar environment, as in compound **4**·3THF, with deviations from the plane of 0.061 and 0.095 Å and a sum of angles of 357.6° and 354.1°, respectively.

The structure of **4**·3THF in [D_8]toluene solution is also monomeric, which is confirmed by an observed $^{29}Si-^{7}Li$ coupling [quadruplet for the resonance signal, $^{1}J(^{29}Si,^{7}Li)$= 56.8 Hz] in the ^{29}Si NMR spectrum at −40 °C. Further cooling causes an asymmetric spreading and a splitting of the signal set at −75 °C indicating a freezing of a dynamic process. Compound **7**·3THF also shows monomeric behavi-

Table 1. Selected data taken from crystal structure analysis and quantum chemical calculations

	Crystal structure analysis			Calculated values[a]		
	1·3THF[5]	**4**·3THF	**7**·3THF	**1**·3THF	**4**·3THF	**7**·3THF

our in [D_8]toluene solution. At −68 °C a $^{29}Si-^{7}Li$ coupling [quadruplet for the resonance signal, $^{1}J(^{29}Si,^{7}Li) = 50.6$ Hz] can be observed in the ^{29}Si NMR spectrum. Further cooling does not lead to an asymmetric spreading as in compound **4**·3THF. These $^{29}Si-^{7}Li$ couplings do not allow us to reach any definite conclusion about the nature of the Si−Li bond (contribution of covalency), although it is conspicuous that lithiated silanes with coordinating solvents show a directed Si−Li interaction[7−10b] in contrast to the alkyl homologues.[12]

Comparing the structures of the dialkylaminosilyllithium compounds **4**·3THF and **7**·3THF with other structural data from known silyllithium compounds shows, that the Si−Li bonds are among the shortest [2.627 (4) Å for **4**·3THF] and the longest [2.732(7) Å for **1**·3THF] of such systems. In order to distinguish between crystallographic (e.g. packing) and substituent effects at the silicon centre we performed quantum chemical calculations on compounds **1**·3THF, **4**·3THF and **7**·3THF. RI-DFT calculations at the BP86/TZVP level were used for structure optimization of these molecules. The relative values of important structural parameters, such as Si−Li and Si−N distances, are reproduced by these quantum chemical calculations (see Table 1). The performed DFT calculations overestimate the values of the bond lengths, as is common for such methods.[13a,13b]

NBO analyses show that the lone pair of the dialkyamino group interacts with an antibonding orbital located at the silicon centre, resulting in an increase in the charge at this centre compared to triorganosilyllithium compounds. These interactions cause a contraction of the polar Si−Li bond and therefore **4**·3THF has the shortest Si−Li distance of all three systems. Since **7**·3THF has only one dialkylamino group, the Si−Li bond length is longer than in **4**·3THF. The lone pair at the nitrogen centre in **1**·3THF is delocalized onto the phenyl groups; this results in a weaker interaction with the silicon centre and therefore the Si−N and Si−Li bonds are elongated.

Tamao and co-workers observed that the ^{29}Si NMR spectra of (aminosilyl)lithiums and (alkoxysilyl)lithiums show a downfield shift relative to the corresponding chlorosilanes, in contrast to (triorganosilyl)lithiums.[3a,5] In order to understand these downfield shifts and the observed structural parameters we optimized the energy of the simplified model compounds $Ph(Me_2N)_2SiLi$ and $Ph_2(Me_2N)SiLi$ by DFT methods [B3LYP/6−31+G(d)] and calculated the NMR resonance signals using the GIAO method [HF/6−311+G(2d,p)].[14a,14b] The geometrical parameters of the minimized model systems show similar structural characteristics as the molecular structures of **4**·3THF and **7**·3THF in the crystal, but with too short Si−Li bonds [2.476 Å for $Ph(Me_2N)_2SiLi$ and 2.490 Å for $Ph_2(Me_2N)SiLi$]. This effect can be explained by the absence of coordinating solvent molecules. The calculated values for the ^{29}Si NMR resonance signals of our model compounds are δ = 21.0

[$Ph(Me_2N)_2SiLi$] and δ = 18.9 [$Ph_2(Me_2N)SiLi$], close to the experimental values of δ = 28.4 for **4** and δ = 20.3 for **7**. These results confirm the trend of the downfield shift of functionalized silyllithiums compared to (triorgano)silyllithiums, and therefore coordinating solvent molecules can be omitted in model systems for ^{29}Si NMR calculations.

Calculations performed on the simplified model systems Me_3SiLi, $Me_2(H_2N)SiLi$ and $Me(H_2N)_2SiLi$ within the bounds of the DFT-IGLO method allow a thorough analysis of the shielding tensors concerning paramagnetic contributions of localised molecular orbitals (LMO).[15a,15b] The result is that, with the change from Me_3SiLi (calculated chemical shift: δ = −5.7) to $Me_2(H_2N)SiLi$ (calculated chemical shift: δ = 14.9), the significant contribution for the shielding tensors of the remaining two LMOs of the Si−C bond as well as the Si−Li LMO increase considerably. This is caused by the very large induced coupling of these LMOs with the σ*(Si−N) orbital, resulting in a decreased shielding [and increased chemical shift of $Me_2(H_2N)SiLi$]. At the same time the number of Si−C LMOs decreases (Si−N LMOs make a lower paramagnetic contribution than Si−C LMOs). The latter effect predominates with the addition of a second H_2N group [$Me(H_2N)_2SiLi$] causing, in total, an increase of the shielding compared to $Me_2(H_2N)SiLi$ [calculated chemical shift for $Me(H_2N)_2SiLi$: δ = 9.9]. A similar trend was observed for the gradual replacement of the methyl groups of Me_4Si with chloro substituents.[16] That effect can also be observed for other metallated silanes with R_2N or RO substituents and explained by NMR calculations. Further calculations on this topic are in progress.

Experimental Section

General: All preparations were performed using standard Schlenk techniques under an oxygen-free and water-free argon atmosphere. Tetrahydrofuran was dried over Na/benzophenone and freshly distilled under argon. ^{29}Si NMR spectra were recorded on a Bruker DRX-300 (59.6 MHz) spectrometer with an external standard of tetramethylsilane (δ = 0.0).

Synthesis of Tris(tetrahydrofuran)[bis(diethylamino)phenylsilyl]-lithium (4·3THF): The synthesis was performed as described by Tamao and co-workers[3c] but with a reaction temperature of −40 to −20 °C. − $^{29}Si\{^1H\}$ NMR (C_7D_8, 233 K): δ = 28.4 (q, $^1J_{SiLi}$ = 56.8 Hz).

Synthesis of Tris(tetrahydrofuran)[(diethylamino)bisphenylsilyl]-lithium (7·3THF): The synthesis was performed as described by Tamao and co-workers[3c]. − $^{29}Si\{^1H\}$ NMR (C_7D_8, 205 K): δ = 20.3 (q, $^1J_{SiLi}$ = 50.6 Hz).

Computational Methods: All calculations were carried out on gas-phase structures.[17] Structure optimizations of $Ph(Me_2N)_2SiLi$ and $Ph_2(Me_2N)SiLi$ at the B3LYP/6−31+G(d) level were performed using GAUSSIAN 98.[14b] Selected bond lengths [Å] and angles [°] for $Ph(Me_2N)_2SiLi$: Si−Li 2.481, Si−N(1) 1.788, Si−N(2) 1.788, Si−C(5) 1.922, C(5)−Si−N(1) 102.8, C(5)−Si−N(2) 102.8, N (sum over angles) 355.0; absolute SCF energy: −797.855415745 Hartree; − selected bond lengths [Å] and angles [°] for $Ph_2(Me_2N)SiLi$: Si−Li 2.490, Si−N 1.786, Si−C(3) 1.921, Si−C(9) 1.934, C(3)−Si−N 104.3, C(9)−Si−N 108.5, N (sum over angles) 352.4; absolute SCF energy: −894.925802514 Hartree.

The RI-DFT[18] calculations on compounds **1**·3THF, **4**·3THF and **7**·3THF were done with the TURBOMOLE[19] program at the BP86/TZVP level with starting coordinates taken from the crystal structure analyses. Selected bond lengths [Å] and angles [°] for **1**·3THF: Si−Li 2.770, Si−N 1.873, Si−C(1) 1.950, Si−C(7) 1.939, C(1)−Si−N 103.4, C(7)−Si−N 103.9, N (sum over angles) 360.0; absolute SCF energy: −1976.437591873 Hartree; − selected bond lengths [Å] and angles [°] for **4**·3THF: Si−Li 2.688, Si−N(1) 1.827, Si−N(2) 1.837, Si−C(9) 1.948, C(9)−Si−N(1) 100.8, C(9)−Si−N(2) 100.5, N (sum over angles) 357.9; absolute SCF energy: −1653.023345787 Hartree; − selected bond lengths [Å] and angles [°] for **7**·3THF: Si−Li 2.732, Si−N 1.824, Si−C(5) 1.964, Si−C(11) 1.947, C(5)−Si−N 105.8, C(11)−Si−N 101.4, N (sum over angles) 354.0; absolute SCF energy: −1671.469514876 Hartree. The criterion for convergence for these calculations was lowered to a change in absolute SCF energy of 5×10^{-5} Hartree, due to the size of these systems. Minimizing the energy starting from the second conformer of **7**·3THF in the crystal showed no significant differences in the results compared to the calculated values of the other conformer of **7**·3THF.

The GIAO method-based NMR calculations [HF/6−311+G(2d,p)] of $Ph(Me_2N)_2SiLi$ and $Ph_2(Me_2N)SiLi$ were performed with GAUSSIAN 98.[14a,14b] Calculated absolute shieldings σ were converted into relative shifts δ with σ calculated at the same level for TMS [$\sigma_{calcd}(Si)$ = 385.9]; calculated value of σ for $Ph(NMe_2)_2SiLi$: 364.83; calculated value of σ for $Ph_2(NMe_2)SiLi$: 367.18.

The structures of the model systems Me_3SiLi, $Me_2(H_2N)SiLi$ and $Me(H_2N)_2SiLi$ were optimized at the B3LYP/6−31+G(d) level using GAUSSIAN 98.[14b] Selected bond lengths [Å] and angles [°] for Me_3SiLi: Si−Li 2.516, Si−C 1.928, C−Si−C 104.2, C−Si−Li 114.4; absolute SCF energy: −416.770639118 Hartree; selected bond lengths [Å] and angles [°] for $Me_2(H_2N)SiLi$: Si−Li 2.509, Si−C(1) 1.921, Si−C(2) 1.930, Si−N 1.790, C(1)−Si−N 101.9, C(2)−Si−N 109.8; absolute SCF energy: −432.828715216 Hartree; selected bond lengths [Å] and angles [°] for $Me(H_2N)_2SiLi$: Si−Li 2.494, Si−C 1.915, Si−N(1) 1.788, Si−N(2) 1.788, C−Si−N(1) 100.5, C−Si−N(2) 100.6; absolute SCF energy: −448.891440368 Hartree. DFT-IGLO calculations of chemical shifts for Me_3SiLi, $Me_2(H_2N)SiLi$ and $Me(H_2N)_2SiLi$ have been done at the sum-over-states density-functional perturbation theory level (SOS-DFPT),[15b,20] varying the gradient-corrected PW91[21a−21c] exchange-correlation functional. A compromise strategy discussed earlier[15b,22a,22b] was applied to obtain accurate Kohn−Sham MOs with moderate effort, by adding an extra iteration with a larger integration grid and without fit of the exchange-correlation potential after SCF convergence had been reached. FINE[22a,22b] angular grids with 32 points of radial quadrature were used. All of the DFT-IGLO calculations were carried out using the deMon NMR code.[22a,22b,23] IGLO-II all-electron basis sets were used on all atoms with density and exchange-correlation potential fitting auxiliary basis sets of the sizes 5.1 (H), 5.2 (C, Li, N) and 5.4 (Si). Calculated absolute shieldings σ were converted into relative shifts δ with σ calculated at the same level for TMS [$\sigma_{calcd}(Si)$ = 368.1]. Absolute shielding σ and selected contributions of certain LMOs for Me_3SiLi: σ = 373.8, Si−C LMO −100.5, Si−Li LMO −103.7; absolute shielding σ and selected contributions of certain LMOs for $Me_2(H_2N)SiLi$: σ = 353.2, Si−C(1) LMO −116.0, Si−C(2) LMO −111.2, Si−N LMO −91.0, lone pair N LMO 7.4, Si−Li

X-ray Crystal Structure Analysis: Suitable crystals of **4**·3THF and **7**·3THF were obtained from *n*-pentane solutions at −30 °C (**7**·3THF) or −90 °C (**4**·3THF) as THF adducts. The crystals were mounted in inert oil on a glass fibre and transferred to the cold gas stream of the diffractometer [Stoe IPDS; graphite monochromated Mo-K_α radiation (λ = 0.71073 Å)]. The structures were solved using direct and Fourier methods (SHELXS-86[24a]); refinement by full-matrix least-squares methods (based on F_o^2, SHELXL-93[24b]); anisotropic thermal parameters for all non-H atoms in the final cycles; the H atoms were refined on a riding model in their ideal geometric positions. Crystal data and refinement details of structures **4**·3THF and **7**·3THF are reported in Table 2.

Crystallographic data (excluding structure factors) for the structures included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-139102 (**4**·3THF) and -151411 (**7**·3THF). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to the Deutsche Forschungsgemeinschaft (DFG), the Fonds der Chemischen Industrie and Chemetall GmbH for financial support and the donation of chemicals. We thank Prof. Dr. M. Kaupp, Universität Würzburg, for helpful discussions regarding the interpretations of the NMR calculations.

Covalently Linked Ruthenium(II)−Manganese(II) Complexes: Distance Dependence of Quenching and Electron Transfer

Katja E. Berg,[a] Anh Tran,[a] Mary Katherine Raymond,[b] Malin Abrahamsson,[b] Juliusz Wolny,[c] Sophie Redon,[a] Mikael Andersson,[b] Licheng Sun,[a] Stenbjörn Styring,[d] Leif Hammarström,*[b] Hans Toftlund,*[c] and Björn Åkermark*[a]

Keywords: Ruthenium / Manganese / N ligands / Electron transfer

Continuing our development of artificial models for photosystem II in green plants, a series of compounds have been prepared in which a $Ru(bpy)_3^{2+}$ photosensitizer is covalently linked to a manganese(II) electron donor. In addition to a trispicolylamine ligand, two other manganese ligands, dipicolylamine and aminodiacetic acid, have been introduced in order to study ligands that are appropriate for the construction of manganese dimers with open coordination sites for the binding of water. Coordination equilibria of the manganese ions were monitored by EPR. The interactions between the ruthenium and manganese moieties were probed by flash photolysis, cyclic voltammetry and steady-state and time-resolved emission measurements. The quenching of the Ru^{II} excited state by Mn^{II} was found to be rapid in complexes with short Ru–Mn distances. Nevertheless, each Ru^{II} species could be photo-oxidized by bimolecular quenching with methylviologen, and the subsequent electron transfer from Mn^{II} to Ru^{III} could be monitored.

Introduction

Considerable efforts have been made to create biomimetic systems for natural photosynthesis.[1] The search for alternative renewable energy sources often underlies this research, and there is a need to understand, at a fundamental level, how nature converts solar energy into chemical forms that can be stored. An important subject involves the structure and function of the manganese cluster in the oxygen-evolving complex (OEC) in photosystem II (PS II).[2−3]

To date, biomimetic systems have focused either on new polynuclear manganese model complexes, or on supramolecular assemblies based on porphyrins and transition metal complexes.[4−5] Our aim has been to use the principles of the natural PS II to construct supramolecular complexes in which a photosensitizer is covalently linked to one or several manganese ions. Ultimately, the idea in this project is to imitate Nature by photochemically oxidizing water to form oxygen, and to use the electrons released in this process to generate fuels, for example, H_2.

As an artificial replacement for the chlorophyll photosensitizer in PS II, we have used Ru^{II} trisbipyridyl complexes because they have favorable photochemical properties and are stable and relatively easy to synthesize. With complex **1b**, it was demonstrated that upon photo-oxidation of the Ru^{II} complex by an external acceptor, electron transfer occurred from Mn^{II} to Ru^{III}.[6] However, the rate of electron transfer in **1b** was rather low: $k_{ET} = 1.8 \cdot 10^5\ s^{-1}$. In an operating system, such a rate would probably be too low to compete with back electron transfer. It is therefore important to prepare complexes where the ET rate from the manganese is higher. An obvious way of increasing the rate relative to

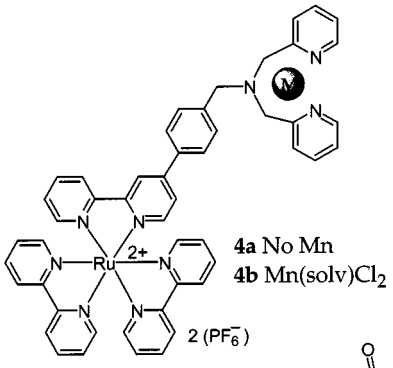
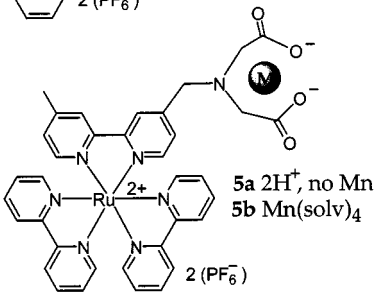
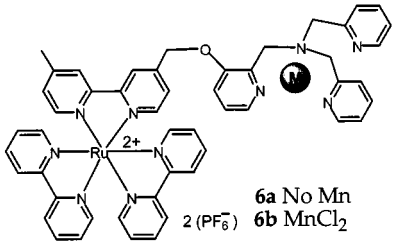
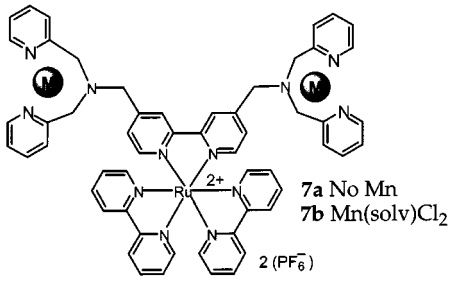
complex **1b** is to decrease the Ru−Mn distance. This was estimated to be ca. 13 Å by using Chem 3D.[6] The bispicene complex **2b**, which has an estimated Ru−Mn distance of ca. 9 Å, was therefore synthesized. However, because of quenching by the manganese, the lifetime of the excited state of this complex became so short, only 7 ns, that we were unable to observe electron transfer to the external acceptor, methylviologen.[6] The Ru−Mn distance thus seemed very important for the functioning of the Ru sensitizer.

A study of the influence of this distance on the lifetime of the excited state of the ruthenium moiety and also on the rate of electron transfer from Mn to the photogenerated Ru^{III} clearly seems interesting. We therefore decided to synthesize a few binuclear Ru−Mn complexes with different Ru−Mn distances. In this paper, we describe complexes **3b**−**7b**, where manganese is coordinated to dipicolylamine (dpa), trispicolylamine (tpa), and aminodiacetic acid (ada).







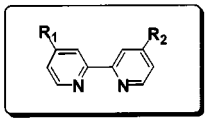


Dpa and tpa are known to bind manganese quite strongly.[7−8] In complex **4b**, a tolyl spacer was inserted between the Mn ligand and the Ru center, and in **6b** a longer link was used. The lifetimes of the excited states, the intramolecular electron transfer rates, as well as the coordinating ability and the stability in solution are discussed and compared to those previously reported for complexes **1b** and **2b**.

Results

Synthesis and Characterization

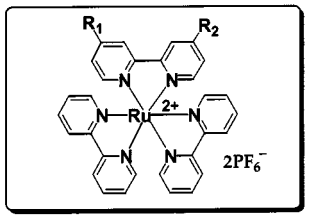
Two different strategies were used for the preparation of complexes **3b**−**7b**. In the synthesis of **5b**, ligand **8e** was obtained by the reaction of bromomethylbipyridine (**8b**) with iminodiacetic acid dimethyl ester.



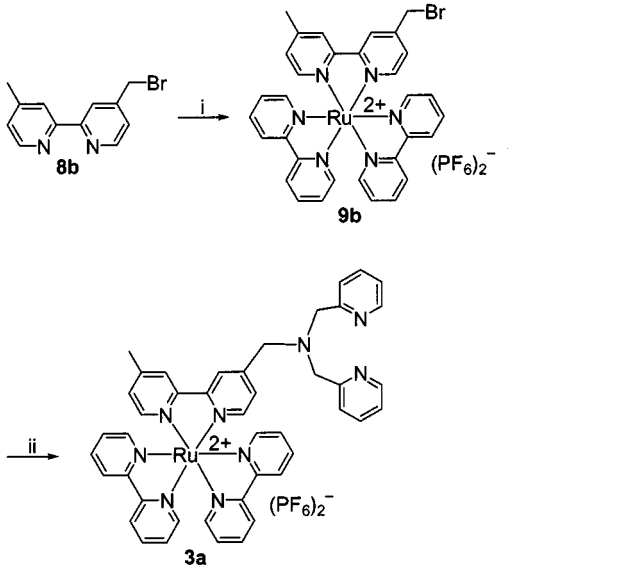
8a $R_1=CH_3$, $R_2=CH_2OH$
8b $R_1=CH_3$, $R_2=CH_2Br$
8c $R_1=R_2=CH_2OH$
8d $R_1=R_2=CH_2Br$
8e $R_1=CH_3$, $R_2=CH_2N(CH_2CO_2CH_3)_2$

The ruthenium part was then introduced to give **10a**, which was hydrolyzed to **5a** and reacted with manganese(II). Complex **5b** could not be obtained in a pure form. In the synthesis of the other complexes, the ruthenium part was introduced before the ligand for manganese. Thus complexes **3b** and **7b** were prepared by the reaction of the ruthenium complexes **9b** and **9c** with dipicolylamine to give **3a** and **7a**, respectively, which were then treated with manganese(II) (Scheme 1). Complex **6b** was prepared in a similar way by the reaction of complex **9b** with the phenolic trispicolylamine **16** (Scheme 2).

In the synthesis of complex **4b**, ligand **14** was first prepared by a classical polypyridine synthesis (Scheme 3). Tolualdehyde and pyruvate were condensed to give the ketoacid **11**, which after a second condensation with 2-pyridacyl pyridinium iodide and treatment with ammonia gave the

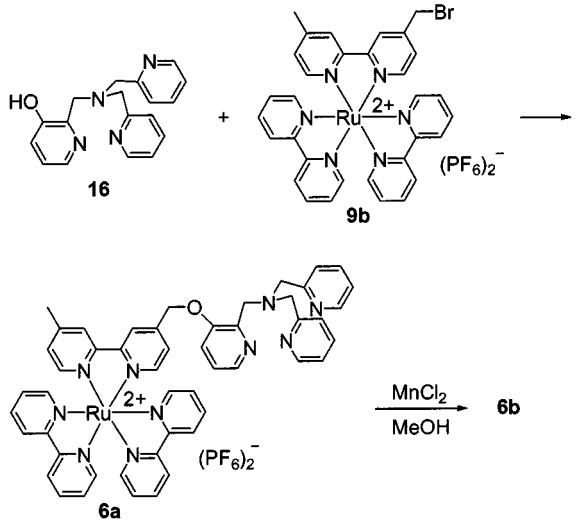


9a $R_1 = R_2 = H$
9b $R_1 = CH_3$, $R_2 = CH_2Br$
9c $R_1 = R_2 = CH_2Br$
10a $R_1 = CH_3$, $R_2 =$ 



(i) $Ru(bpy)_2Cl_2$, CF_3SO_3Ag, acetone; (ii) dipicolylamine, Et_3N, MeCN

Scheme 1



Scheme 2

ammonium carboxylate **12**. Decarboxylation by strong heating of the carboxylate in the absence of solvent gave the bipyridine **13**, which was brominated to give **14**. This was reacted with *cis*-$Ru(bpy)_2Cl_2$ to give the ruthenium complex **15**, then with dipicolylamine to give **4a**, which was converted into the dinuclear Ru−Mn complex **4b** by treatment with $MnCl_2$.

All new complexes in this paper, except **5b**, have been characterized using electrospray ionization mass spectroscopy (ESI-MS), ^1H NMR spectroscopy, and EPR spectroscopy. For manganese complexes, the NMR signals for the ruthenium moiety were generally observed as broadened peaks, whereas the signals for the manganese part could not be detected within a spectral width of 15 ppm.

Scheme 3

ESI-MS

In the ESI-MS spectra of complexes **3a**, **4a**, **5a**, **6a**, and **7a**, the singly-, doubly-, and/or triply charged species of the molecular ion were identified as the primary peaks of the spectra and are listed in the Experimental Section. Complexes **3b**, **4b**, **6b**, and **7b** gave rise to Mn-containing peaks, whereas **5b** gave a complicated pattern that could not be interpreted. The ESI-MS spectra of complexes **3b**, **4b**, **6b**, and **7b** in which Mn^{II} ions are incorporated into the ligands, contain numerous peaks from several species, differing by either the number of chlorides coordinated to manganese or by the presence of salt and/or solvent molecules held in the cavities. This apparent complexity clearly shows that manganese has been incorporated in the ligands.

EPR

The EPR spectra of solutions of the Ru−Mn complexes in MeOH/water (9:1) were recorded at 100 K. The very similar, jagged six-line spectra indicate that the coordination is very similar in the complexes **3b**, **4b**, **5b**, and **7b**. (Figure 1) The spectrum of **5b** is particularly interesting. Control experiments were conducted to exclude the possibility of Mn^{II} monomers or dimers bound to e.g. dissolved carbonate (CO_2 from the air). None of these control experiments showed spectra similar to those of the Ru−Mn complexes. In fact, when carbonate was added to a solution of $Mn^{II}Cl_2$, carbonate-bridging Mn^{II}−Mn^{II} dimers were

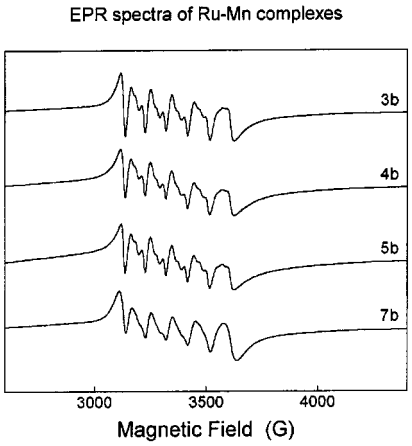

Figure 1. EPR spectrum showing the characteristic jagged 6-line trace for $Ru^{II}-Mn^{II}$ complexes (**3b**, **4b**, **5b**, and **7b**) in MeOH at 100 K

formed, yielding a broad spectrum with no hyperfine structure at 100 K.

Incorporation of manganese is rapid with bipyridyl and bispicen ligands,[6] and slow with the tpa, dpa, and ada ligands. It could be shown that this was partly due to complexation of CO_2 by the free ligands. When the solution was bubbled with nitrogen before the introduction of manganese, the rate of its incorporation was greatly increased. When excess $MnCl_2$ was added, and the solution was allowed to equilibrate for several days, the coordination of manganese into the ligands approached 100% in complexes **3b**, **4b**, **5b**, and **7b**.

UV/Vis Spectroscopy

The UV/Vis absorption spectra of all the ruthenium tris-bipyridyl complexes were similar to those of the parent $Ru(bpy)_3^{2+}$ complex (**9a**). Complexes **3a**, **4a**, **5a**, **6a**, and **7a** had the same absorption maxima (λ in nm): 245 (s), 253 (s), 287 (vs), and 453 (m) [for **9a**: 238, 259, 285, and 452 nm; for the dpa-ligand: 259 nm and a shoulder at 287 nm]. When manganese was coordinated into the ligand cavities of these complexes, thereby giving **3b**, **4b**, **5b**, **6b**, and **7b**, the absorption spectra were unchanged.

Emission Lifetimes and Quenching

The emission spectra of all complexes were typical of emission from the ^{3}MLCT state of $Ru(bpy)_3^{2+}$ complexes, with corrected emission maxima for the compounds without Mn listed in Table 1. Upon binding of Mn, emission was quenched, the curves were somewhat broadened, and the maxima underwent a red-shift. Since much emission comes from the unquenched, manganese-free complexes, the values for the Ru−Mn complexes are uncertain in some cases. All complexes without manganese had excited-state lifetimes of approximately 1000 ns (1300 for **4a**). The emission lifetimes of the complexes with coordinated manganese were very short for complexes **3b** and **7b** (2.2 and 0.8 ns, respectively). The bispicene complex **2b**, which has a similar Ru−Mn distance, also has a short lifetime.[6] The lifetime

Table 1. Photophysical data for complexes **1a**−**7a** and **10a**

Complex	Room temp. emission lifetime (fraction) τ [ns]	Room temp. corrected emission maximum λ [nm]	77 K corrected corrected emission maximum λ [nm]

2a	1050		
3a	880	640	585, 635, 697
4a	1300	629	588, 638, 699
5a	900	637	
6a		630	
7a	1090 (96%), 110 (4%)[a]	634	
10a	990		

[a] From reference [6]

of the ada complex **5b** was somewhat longer but because of poor coordination of manganese, the value is uncertain. For complexes **4b** and **6b**, which have approximately the same Ru−Mn distances as **1b**, it is interesting to note that the lifetime of **6b** was 120 ns, similar to that of **1b** (280 ns), but that of complex **4b** was only 23 ns (see Table 2).

The emission intensity of a 10 μM sample of **4b** in acetonitrile that was in a sealed, evacuated sample, remained constant over a period of 20 h. However, the emission of a second sample that was in a closed cuvette, but in acetonitrile saturated with air, increased to the level of the Mn-free complex **4a** with a half-life of 4 hours. Because the emission intensity is determined by the amount of bound manganese, this experiment demonstrated that atmospheric conditions promote manganese dissociation in this compound.

Flash Photolysis Studies

Electron-transfer reactions were studied by monitoring the transient absorptions of Ru^{II} species and the methylviologen radical ($MV^{+\cdot}$). The Ru^{III} species and $MV^{+\cdot}$ were generated by a laser flash which resulted in excitation of Ru^{II} followed by electron transfer to MV^{2+}, i.e. Equation (1).[5a,6]

$$Ru^{II}* + MV^{2+} \rightarrow Ru^{III} + MV^{+} \quad (1)$$

Since the formation of Ru^{III} occurred by means of a diffusion encounter of $Ru^{II}*$ with methylviologen, very high concentrations of MV^{2+} were necessary for compounds that have rapid intramolecular quenching of $Ru^{II}*$ by manganese (details in Experimental Section). This reaction was monitored by using the $MV^{+\cdot}$ absorption at approximately 600 nm, and the Ru^{II} ground-state bleaching at approximately 450 nm. In a subsequent reaction, the 450-nm absorption returned with a lifetime of the order of 1−10 μs, which we attributed to intramolecular electron transfer from the manganese [Equation (2)].

$$Ru^{III}-Mn^{II} \rightarrow Ru^{II}-Mn^{III} \quad (2)$$

In contrast, the $MV^{+\cdot}$ absorption at 600 nm remained for more than 100 μs. It decayed in a second-order reaction

Table 2. Emission and electron-transfer data for Ru−Mn complexes and calculated Ru−Mn distances

Complex	Emission lifetime (fraction) τ [ns]	Ru−Mn complex[a] [%]	Electron transfer rate[b] [s^{-1}]	Calculated Ru−Mn distance[c] [A]
1b[d]	260	80	$1.8\cdot10^5$	13
2b[e]	7	93	−	9
3b	2.2	65	$1.3\cdot10^6$	9
4b	23	68	$1.6\cdot10^6$	14
5b	19[f]	8	[g]	9
6b	120	97	$1.3\cdot10^5$	14
7b	0.8 (76%), 2.9 (24%)[h]	94	[g]	9
10b	−	0	[g]	9

[a] These percentages are from the fitting of the fluorescence decay curves of the Ru−Mn complexes. Each curve was fitted by a sum of two exponentials (three for **7b**), one exponential corresponding to the bound complex, and the other to the dissociated complex. Approximately 30 μM solutions of the 1:1 Ru−Mn complexes in acetonitrile were used. The percentages of bound complex are probably all concentration dependent. − [b] This is the half-life of the fastest component of the 450 nm Ru^{II} recovery. − [c] These are maximum Ru−Mn distances estimated by molecular mechanics starting from the most extended conformations using constrained metal−ligand distances. − [d] **1b** in acetonitrile (39μM). From reference [6a]. − [e] **2b** in acetonitrile (67 μM). From reference [6a]. − [f] Determined with a twofold excess of $MnCl_2$ in acetonitrile, in order to obtain a larger fraction of attached Mn and thus a more reliable value. − [g] Not measured due to a low degree of Mn association or inability to quench the very short-lived excited state with methylviologen (see text). − [h] The fluorescence decay curve was fitted by a sum of two exponentials. This may be due to the presence of an impurity.

with $k_{ET} = 5\cdot10^9$ $M^{-1}s^{-1}$, which we attributed to a diffusion-controlled recombination with the Mn^{III} species and some recombination with Ru^{III}.

When manganese was not present e.g. in **4a**, the 450 nm absorption and the 600 nm decay were mirror images, showing that the oxidized Ru^{III} regained an electron from the $MV^{+\cdot}$ in a recombination reaction that reformed the ground-state reactants [Equation (3)].

$$Ru^{III} + MV^{+\cdot} \rightarrow Ru^{II} + MV^{2+} \quad (3)$$

For **3a**, the Ru^{II} recovery at 450 nm was somewhat faster (first-order rate constant $k_{ET} \approx 1\cdot10^5$ s^{-1}) owing to irreversible electron transfer from the dpa ligand, which leads to a build-up of $MV^{+\cdot}$. For **6a**, an even faster recovery was observed, $k_{ET} \geq 1\cdot10^7$ s^{-1}, accompanied again by a build-up of $MV^{+\cdot}$. However, the ligands were stabilized against oxidation when Mn^{II} was coordinated. Thus, in **3b**, **4b**, and **6b** it was the Mn^{II} that was oxidized, and the $MV^{+\cdot}$ did not accumulate, presumably because it recombined with the Mn^{III} species (Figure 2). Complexes **3b** and **4b** displayed much faster Ru^{II} recovery then their Mn-free counterparts. In contrast, the recovery was much slower for **6b** (Figure 1) than for the manganese-free complex **6a**. The electron-transfer rate constants are summarized in Table 2.

Owing to partial dissociation of the Mn, the Ru^{II} recovery traces for **3b** and **4b** were fitted to a sum of two exponential processes, with a dominating fast recovery followed by a much slower one with smaller amplitude. The slower recovery rates agreed with measurements made with the Mn-free complexes. Only a small part of the slow recovery phase was seen on the timescale of the fast ET process [Equation (1)]. Therefore it could be represented by an exponential function in the fit, even though it was a second- or mixed first/second-order process.

For complex **6b**, a clean single-exponential first-order recovery of Ru^{II} was observed upon flash excitation in the presence of MV^{2+}. The rate constant ($1\cdot10^5$ s^{-1}) was much lower than for complexes **3b** ($1.3\cdot10^6$ s^{-1}) and **4b** ($1.6\cdot10^6$ s^{-1}).

Cyclic Voltammetry

The half-wave potential ($E_{1/2}$) of the complexes **3a**, **3b**, **4a**, **4b**, **6a**, **6b**, and **9a** were determined by cyclic voltammetry (Table 3). For all the measured complexes, the peak split, ΔE_p, between the anodic (E_{pa}) and the cathodic (E_{pc}) peak potentials is less than 134 mV for the $Mn^{III/II}$ peak and less than 84 mV for the $Ru^{III/II}$ and the first reduction peak. The cyclic voltammograms of **4a** and **4b** are shown in Figure 3.

The reversible oxidation peak at approximately 1.30 V vs. SCE and the three reversible reduction peaks are typical of $Ru^{III/II}$ oxidation and ligand reduction in $Ru(bpy)_3^{2+}$ complexes. The irreversible oxidative peak for **4a** at approximately +1.1 V vs. SCE, also present for **3a**, was assigned to oxidation of the dpa ligand. When Mn^{II} was coordinated (**4b**), a reversible peak, which was assigned to the $Mn^{III/II}$ couple, appeared at +0.90 V vs. SCE. Complexes **6a** and **6b** gave similar values for the corresponding peaks. Thus, the free energy changes ($\Delta G°$) of electron transfer from Mn^{II} to Ru^{III} were −0.39 eV and −0.49 eV (ignoring work term corrections) for **4b** and **6b**, respectively. The $Ru^{III/II}$ and the first ligand reduction potentials were very similar for **4a** and **4b**, and for **6a** and **6b**, showing that insertion of the neutral Mn^{II} complex only has a small coulombic effect on the ruthenium complex.

Discussion

Synthesis and Characterization

In the synthesis of complex **1b**, the bridging bipyridyl ligand was treated with *cis*-$Ru(bpy)_2Cl_2$ to give a mixture of mono- and diruthenium complexes, from which the mono-

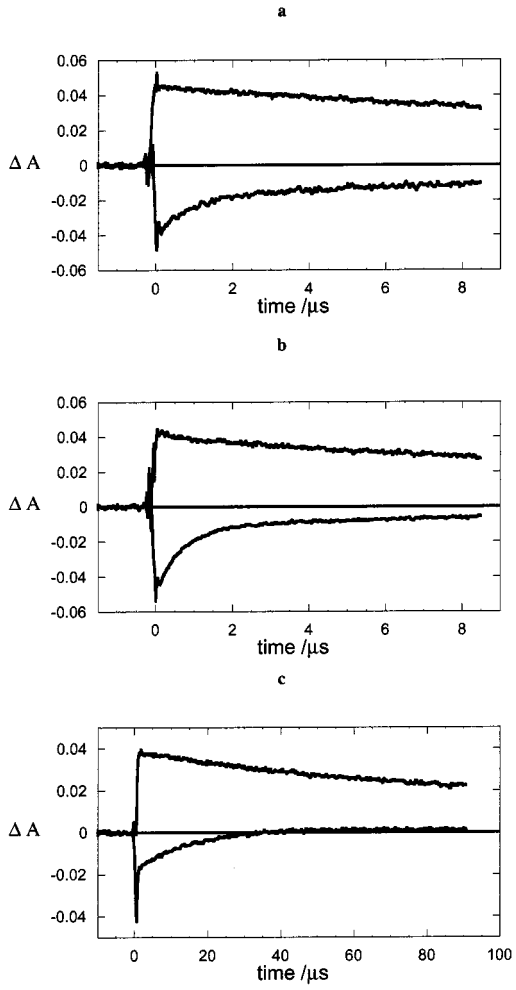

Figure 2. Transient absorption curves of Ru−Mn complexes (ca. $4\cdot10^{-5}$ M) with $MV(PF_6)_2$ in deoxygenated acetonitrile at room temperature: (a) **3b** with 0.30 M $MV(PF_6)_2$, (b) **4b** with 0.11 M $MV(PF_6)_2$, and (c) **6b** with 10 mM $MV(PF_6)_2$. It is worth noting that the relative contribution from the manganese-free fraction decreases regularly when going from (a) to (c). This is both due to an increasing degree in manganese binding, and to an increase in the excited-state lifetime for the Ru−Mn complex. Even with 0.30 M methyl viologen in (a), only a small part of the short-lived excited state of **3b** reacts, while the long-lived fraction of manganese-free complex present reacts quantitatively.

Table 3. Redox potentials determined by cyclic voltammetry in 0.1 M $TBA\cdot BF_4/CH_3CN$ at a glassy-carbon electrode (scan rate 100 mV/s). $E_{1/2}$ = redox half-way potential, $(E_{pa} + E_{pc})/2$

complex could be isolated by chromatography. However, the substituted bipyridyl ligand in **2b** is unsymmetrical, and this strategy was therefore less attractive for the preparation

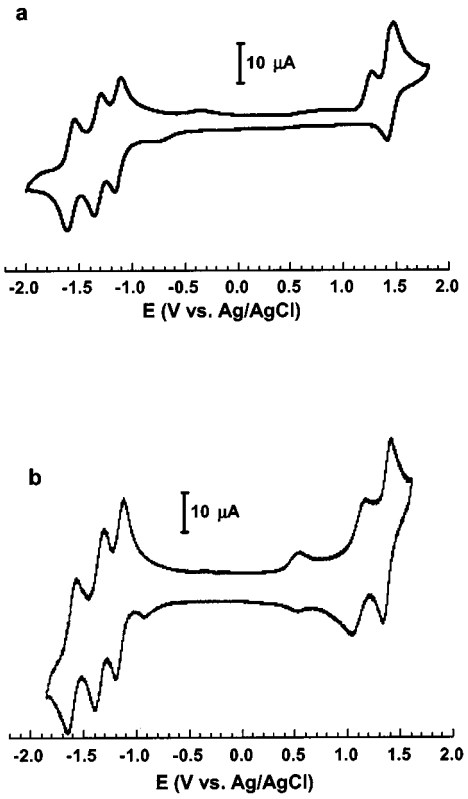

Figure 3. Cyclic voltammogram of (a) **4a** (0.92 mM) (b) **4b** (1.02 mM) in 0.1 M $TBA\cdot BF_4$/MeCN at a glassy-carbon electrode. The small peak at ≈0.5 V vs. Ag/AgCl is due to an impurity present in the electrolyte which is adsorbed onto the electrode. The scan rate used is 100 mV/s

of this complex. Instead, the Ru^{II} trisbipyridyl moiety was prepared before introducing the ligand for manganese.[6] Both strategies have been applied for the preparation of the complexes reported here. In the synthesis of **5b**, the ligand **8e** was first prepared and ruthenium could then be introduced selectively. Manganese could then be added after hydrolysis of the ester groups. In the synthetic routes to complexes **3b**, **4b**, **6b**, and **7b**, in which the final ligand could coordinate both ruthenium and manganese quite strongly, the intermediate ruthenium complexes **9b**, **9c**, and **15** were prepared first. As in the synthesis of **2b**, the ligand for manganese was then introduced, followed by manganese(II), to give the dinuclear complexes **3b**, **4b**, **6b**, and **7b**.

The EPR spectra of the Ru−Mn complexes all show essentially the same pattern (Figure 1). It can be concluded that the coordination geometry around manganese in the complexes is similar. Furthermore, the EPR spectra are identical whether the Mn^{II} is coordinated to an N- or to an O-donor; the patterns of the EPR spectra are mainly dependent on the coordination geometry around manganese.

With the exception of **5b**, the bipyridine ligand in **1b** is the weakest chelator for manganese of all the complexes described in this paper. The lifetime measurements show that in a dilute acetonitrile solution (ca. 30 μM), approximately 30% of the manganese is dissociated in complexes **3b**, **4b**, and **7b**. This indicates stability similar to that of com-

plex **2b**. In contrast, only ca. 3% dissociation was observed with the tpa-complex **6b**. In aqueous solution, however, the coordinated manganese is rapidly lost from all the complexes **3b**−**7b**.

The bis-manganese complex **7b** gave a similar EPR spectrum as complex **3b**, suggesting the presence in **7b** of two nonbridging manganese(II) ions which do not interact. The molecular model of complex **7b** suggests that the two dpa moieties stretch away from each other in space owing to steric restriction, thus minimizing the likelihood of bridge formation between the two dpa units. An increase in the spacer length between the bipyridine and the dpa unit, or an uncoordinated bipyridine with free rotation about the bond between the pyridine rings would most probably allow for the formation of a Mn-oxo or Mn-acetato bridge.

The low rate of incorporation of manganese into the dpa cavity, as observed by EPR, could be due to the need to displace a molecule of CO_2, solvent, or ions already coordinated in the cavity. However, the introduction of a phenyl group to act as a rigid spacer between the Mn-coordinating ligand and the ruthenium entity did not change the coordination affinity for manganese: **3b** and **4b** have approximately the same amount of Mn dissociation (Table 2). Furthermore, the redox potential of Ru^{II} is the same in **4a**, in which manganese is absent, and in **4b**. This indicates that the weak coordination of manganese is mainly due to the nature of the ligand. The steady-state emission yield experiments (see Results section) demonstrated that Mn^{II} dissociated completely within hours in air-equilibrated solution, but that it remained bound in evacuated samples. This suggests that manganese is displaced either directly, for example by CO_2 in air, or indirectly as a result of oxidation of the dpa ligand.

Quenching of the Ru^{II}-Excited State by Manganese

Before coordination of manganese, the ruthenium complexes **1a**−**7a** have lifetimes of approximately 1000 ns, very similar to the lifetime of the parent bipyridine complex **9a**. On coordination of manganese, the lifetime is decreased, probably due to energy transfer by an exchange mechanism[6b] involving the low-lying d−d states of the Mn^{II}. It would be expected that a short intermetallic distance would lead to more rapid quenching of the ruthenium excited state. The Ru−Mn distances determined by Chem 3D are summarized in Table 2. In general, complexes with shorter Ru−Mn distances (**3b**, **5b**, and **7b**) indeed have shorter emission lifetimes (Table 2). An exception is complex **4b**, which has an estimated Ru−Mn distance of ca. 14 Å but a lifetime of only 23 ns. This may be due to significant electron delocalization over the phenyl group.[9] This would lead to a MLCT state that would be located more on the phenyl-substituted bipyridine. In contrast, complexes **1b** and **6b**, which have comparable Ru−Mn distances (13−14 Å), have much longer lifetimes: 260 ns and 120 ns, respectively.

The Ru^{II}* quenching rate constant in **7b** is almost double that of **3b**, which supports the suggestion that the two manganese units in **7b** act as independent moieties. The fact that an additional exponent with a lifetime of 2.9 ns is needed to describe the decay in **7b** indicates that there may be a small fraction present where only one manganese atom is coordinated. The Mn-free complex **7a** also exhibits emission decay with a major ($\tau \approx 1000$ ns) and a very minor component (4% with $\tau \approx 100$ ns). Complex **6b** displays a distinct mono-exponential decay, in sharp contrast to the results obtained with complexes **3b**−**5b**.

Electron Transfer

The regeneration of the Ru^{II} sensitizer after photo-oxidation by methylviologen was very fast for **3b** and **4b** (Table 2). The reduction potentials show that electron transfer from Mn^{II} to Ru^{III} is energetically favorable, e.g. for **4b** $\Delta G^\circ = -0.39$ eV. Furthermore, the Ru^{II} recovery rates for **3b** and **4b** are much higher than those for the Mn-free complexes **3a** and **4a**. The measured Ru^{II} recovery rates are too high to be explained by a bimolecular reaction between Ru^{III} and Mn^{II} at the low concentrations (0.04 mM) employed. In addition, it could be shown that the rate constant for electron transfer was independent of the concentration for **4b**. We therefore attributed the Ru^{II} recovery in **3b** and **4b** to an intramolecular electron transfer from the Mn^{II} to the photogenerated Ru^{III}, in agreement with our previous reports on Ru−Mn complexes.[6]

Similarly, intramolecular electron transfer is observed for complex **6b**. In this case, the rate constant is lower than for the manganese-free complex **6a**. However, in **6a** the ligand is the electron donor, but in **6b** it is the manganese ion, because the ligand is stabilized against oxidation after binding the metal. As a consequence, the electron transfer in **6b** is reversible, and the methylviologen radical is not accumulated. A possible reason for the rapid reaction of the amine in **6a** relative to **3a** could be that the longer link in the former could fold back towards the ruthenium. When the manganese atom is coordinated, the ligand is probably less flexible.

The electron-transfer rates for **3b** and **4b** are both nearly an order of magnitude faster than those observed for complexes **1b**[6] and **6b**. The faster rate in **3b** is not surprising considering its shorter Ru−Mn distance. The rapid Mn^{II} to Ru^{III} electron transfer rate in **4b** however, was unexpected. Although the rate constant for electron transfer through phenylene spacers may decrease relatively slowly with distance,[10] the fact that the Ru−Mn distance is 5 Å longer was expected to result in a much lower rate for **4b**. The high rate observed could be due to either a folding of the dpa unit or to conjugation through the phenylene spacer. The latter effect is perhaps the most probable since the spacer in **4a**, which has no manganese, has an influence both on the wavelength of the emission from the excited state of ruthenium (red shift of ca. 5 nm relative to **3a**) and on the lifetime of this state (1300 ns vs. 950 ns for **3a**).

Conclusions

A series of supramolecular complexes with a $Ru(bpy)_3^{2+}$ core covalently linked to Mn-binding ligands have been pre-

pared and characterized. The coordinated manganese(II) was found to act as a strong quencher for the excited state of ruthenium, probably by energy transfer. In the absence of manganese, the excited-state lifetime of the $Ru(bpy)_3^{2+}$-type complexes was typically approximately 1000 ns. When the manganese ions were coordinated, the lifetimes were much shorter and there appeared to be a close relationship between the Ru−Mn distance and the emission lifetime. Thus the lifetimes of complexes **1b** and **6b**, in which the Ru−Mn distances were estimated to be 13−14 Å (by Chem 3D), were decreased to 255 and 120 ns, respectively. As the Ru−Mn distances were further shortened to ca. 9 Å, as in complexes **2b**, **3b**, and **7b**, the lifetimes became dramatically short: 7, 1.6, and 0.8 ns, respectively. The short lifetime of **4b**, (23 ns) in which the Ru−Mn distance is ca. 14 Å, is an exception which can be rationalized by delocalization of the excited state over the conjugated phenyl spacer.

Although we still have a fairly limited number of examples, the results so far seem to indicate that the rates of intramolecular electron transfer from manganese(II) to photo-generated ruthenium(III) also show some correlation with the Ru−Mn distances, increasing from ca. $1\cdot10^5$ s^{-1} for complexes **1b** and **6b** to $1.3\cdot10^6$ s^{-1} for complex **3b**.

In an artificial system, the electron transfer from manganese to the photo-generated ruthenium(III) must probably be fast in order to compete efficiently with back electron transfer from the acceptor. Our results suggest that this will be difficult with systems in which the manganese and ruthenium atoms are sufficiently close for rapid electron transfer because of the efficient quenching caused by the manganese atom. This problem presumably also exists in the natural PS II, where it has been solved by the insertion of a tyrosine unit (TyrosineZ) between the photosensitizer, chlorophyll P_{680} and the manganese cluster. This tyrosine unit then acts as an electron transfer relay. We have recently shown that a tyrosine group does not quench the excited state of Ru^{II} [11] and also that it can transfer an electron to the photo-oxidized ruthenium and recover it in an intramolecular reaction with a manganese(II)/(II) dimer.[12] In our future work we will therefore try to prepare supramolecular complexes in which a ruthenium(II) and a manganese(II) ion are linked by a tyrosine type unit.

Experimental Section

NMR, MS, and EPR: The ^1H NMR spectra were recorded on a Bruker AM400 MHz spectrometer or on a Bruker DMX500 MHz spectrometer, using TMS as internal standard. The electrospray ionization mass spectrometry (ESI-MS) experiments were performed on a TSQ700 (nanoES ion source) with acetonitrile or acetone as solvent. The EPR spectra were measured on a Bruker EMX spectrophotometer at 100 K using a 9:1 mixture of MeOH/H_2O as solvent.

Absorption and Emission Measurements: Spectroscopic grade acetonitrile was used for all measurements. The UV spectra were measured on a Varian Cary 5E UV/Vis-NIR spectrophotometer. Emission spectra were recorded using a SPEX fluorolog II system. Emission lifetimes were determined by using time-correlated single photon counting. The samples were purged with nitrogen gas and excited either at 327 nm by the frequency-doubled output from a YAG-pumped DCM dye laser, or at 400 nm by the frequency-doubled fundamental from a Ti-sapphire laser. A monochromator or interference filter centered at 610 nm was used to select the emission wavelength, which was detected with a microchannel plate. The two systems gave identical lifetimes within experimental error. The instrumental responses corresponded to four points or less out of 512 of the experimental decay curves and were not considered in the curve fitting.

Transient absorption studies were done by using an excimer laser pumping a Coumarin 47-dye laser to produce excitation pulses at 460 nm with a 15 ns width and an energy of 1 mJ/pulse at the sample. A pulsed Xe lamp provided analyzing light and the detection wavelengths were selected with a monochromator. All solutions were bubbled with nitrogen gas. The concentrations of the complexes were approximately 30 μM and that of methylviologen bis(hexafluorophosphate), $(MV(PF_6)_2$, was 0.15−0.30 M in the studies of complexes **3b** and **4b**, and 10−20 mM for all other samples. The transient absorption curves were fitted to single- or double-exponential functions.

Cyclic Voltammetry: The electrolyte was a 0.1 M solution of tetrabutylammonium tetrafluoroborate (TBA·BF_4, Aldrich) in acetonitrile. The TBA·BF_4 was vacuum dried at 140 °C for 48 hours before use, and acetonitrile (Aldrich, 99.8%) was used as received. The glassware was cleaned, oven-dried, and transferred while hot to an argon filled glove box in which the experiments were performed.

A three-electrode system connected to an Eco Chemie model Autolab/GPES electrochemical interface was used. The working electrode was a freshly polished glassy-carbon disc (diameter 3 mm) and the counter electrode consisted of glassy carbon. The reference electrode was Ag/AgCl in LiCl saturated acetonitrile. Both the reference and the counter electrodes were separated from the solution by a salt bridge in contact with the working electrode.

The $E_{1/2}$ for **3a**, **3b**, **4a**, **4b**, **6b**, and $Ru(bpy)_3(Cl)_2$ (**9a**) were measured relative to a ferrocenium/ferrocene internal reference. The $E_{1/2}$ values are reported relative to SCE. The conversion was made by setting the $Ru^{III/II}$ value obtained for $Ru(bpy)_3(Cl)_2$ equal to 1.324 V relative to SCE.[13]

Materials: Azobis(isobutyronitrile) was recrystallized from EtOH. All other commercial reagents were used as obtained without further purification. Carbon tetrachloride was distilled from P_2O_5 prior to use. All other solvents were of HPLC grade (>99.7%) for synthesis or spectroscopic grade for optical measurements and were used as received. Silica gel 60 (230−400 mesh, Merck, Darmstadt, Germany) and neutral aluminum oxide gel (Aldrich) were used for column chromatography. The $MV(PF_6)_2$ was prepared by reacting 4,4′-bipyridine with MeI, then adding aqueous NH_4PF_6 to precipitate the PF_6 salt. The product was purified by recrystallization from EtOH.

4-Hydroxymethyl-4′-methyl-2,2′-bipyridine (8a): To a stirred suspension of 4,4′-dimethyl-2,2′-bipyridine (2.0 g, 11 mmol) in 1,4-dioxane (100 mL) was added SeO_2 (2.0 g, 18 mmol). The mixture was heated at reflux for 24 h. After cooling to room temperature, the mixture was filtered, and the solvent was removed under reduced pressure. The resulting pink solid was redissolved in chloroform, and the suspension was filtered to remove selenium by-products. After three successive dissolution and filtration treatments, crude product (1.4 g) was obtained. The resulting solid was suspended in methanol (15 mL), and sodium borohydride (0.3 g) in NaOH (0.2

M, 2.5 mL) was added dropwise to the stirred mixture cooled on ice. The mixture was stirred at room temperature for an additional hour and the methanol was then removed under reduced pressure. The remaining aqueous suspension was diluted with saturated Na_2CO_3 solution (6 mL) and extracted with chloroform. The organic phase was dried and the solvent evaporated. The crude product was purified by column chromatography (MPLC)[14] to give 4-hydroxymetyl-4′-methyl-2,2′-bipyridine (1.2 g, 83%). All analytical data were in agreement with those reported by Geren et al.[15]

4-Bromomethyl-4′-methyl-2,2′-bipyridine (8b): 8a (1.0 g, 5.0 mmol) was dissolved in HBr (48%, 50 mL), and H_2SO_4 (conc., 2 mL) was added to the solution. The red solution was heated at reflux until all the starting material had been consumed as monitored by TLC (Al_2O_3, hexane/EtOAc, 10:90). After the reaction had gone to completion (5−6 h), H_2O (13 mL) and CH_2Cl_2 (13 mL) were added. The aqueous layer was brought to pH 8 by adding saturated sodium carbonate solution and extracted with 10 mL portions of CH_2Cl_2 until the organic layer was colorless. The combined organic layers were dried with $MgSO_4$ and the CH_2Cl_2 removed in vacuo to yield 4-bromomethyl-4′-methyl-2,2′-bipyridine (**8b**) (1.3 g, 98% yield). All analytical data were in agreement with those previously reported.[6]

Ru(bpy)$_2$(4-bromomethyl-4′-methylbipyridine)(PF$_6$)$_2$ (9b): Complex **9b** was isolated and characterized as reported earlier by Sun et al.[6]

Ru(bpy)$_2$[4-(dpa-CH$_2$)-4′-methylbipyridine](PF$_6$)$_2$ (3a): Dipicolylamine[16] (0.015 g, 0.073 mmol) and Et_3N (1 equiv.) were dissolved in acetonitrile and added dropwise to a solution of Ru(bpy)$_2$(4-bromomethyl-4′-methylbipyridine)(PF$_6$)$_2$ (**9b**) (0.071 g, 0.073 mmol) in acetonitrile. The reaction mixture was heated at reflux under argon for 3 h, then cooled and filtered. The filtrate was evaporated in vacuo and the product was purified by chromatography (MPLC)[14] (silica gel, MeCN/water/KNO_3(sat.), 28:1:2). The desired product eluted as the second band and excess KNO_3 was removed by filtration after dissolving the product in acetone. Water and NH_4PF_6 were added to a MeOH solution of the product to afford a red−orange product which was collected by filtration, washed and dried to yield Ru(bpy)$_2$[4-(dpa-CH$_2$)-4′-methylbipyridine](PF$_6$)$_2$ (**3a**) (0.042 g, 53%). − ^{1}H NMR ([D$_6$]acetone): δ = 2.58 (s, 3 H, MebpyCH_3), 4.37 (s, 2 H, MebpyCH_2N−), 4.49 (s, 4 H, dpaCH_2N−), 7.37−7.42 (m, ^1J = 6 Hz, 1 H, MebpyPy′−*H*), 7.50−7.55 (m, 3 H, bpyPy−*H*), 7.52−7.58 (m, ^1J = 6 Hz, 1 H, MebpyPy−*H*), 7.64−7.68 (m, 1 H, bpyPy−*H*), 7.67−7.72 (m, 4 H, dpaPy−*H*), 7.77 (d, ^1J = 6 Hz, 1 H, MebpyPy−*H*), 7.83 (d, ^1J = 6 Hz, 1 H, MebpyPy′−*H*), 7.85 (ddd, 1 H, bpyPy−*H*), 7.99 (d, ^1J = 5 Hz, 2 H, bpyPy−*H*), 8.02 (ddd, 1 H, bpyPy−*H*), 8.14 (dd, 2 H, dpaPy−*H*), 8.18 (ddd, 1 H, bpyPy−*H*), 8.19 (ddd, 2 H, bpyPy−*H*), 8.26 (ddd, 1 H, bpyPy−*H*), 8.58 (s, 1 H, MebpyPy′−*H*), 8.75 (s, 1 H, MebpyPy−*H*), 8.79 (d, ^1J = 8 Hz, 3 H, bpyPy−*H*), 8.83 (d, ^1J = 8 Hz, 1 H, bpyPy−*H*), 9.02 (d, ^1J = 5 Hz, 2 H, dpaPy−*H*). − ESI-MS (*m/z*): 1086.2 [M + H$^+$], 940.2 [M − PF$_6^-$], 398.0 [M − 2 PF$_6^-$].

2-Oxo-4-(tolyl)but-3-enoic Acid (11): This compound was prepared by a method described by Baba et al.[17] To a solution of sodium pyruvate (8.3 g, 0.075 mol) in water (15 mL) cooled in an ice bath, was added tolualdehyde (6.0 g, 0.050 mol) dissolved in EtOH (85 mL). To this rapidly stirred mixture was added NaOH (10% w/w, 30 mL). After stirring for an additional 15 min, the mixture was acidified with HCl (2 M), and stirred for 5 min. The yellow precipitate was filtered and washed with water and EtOH, and dried to give the acid **11** (4.9 g, 52%). − ^{1}H NMR ([D$_6$]DMSO): δ = 2.33 (s, 3 H, −phenylCH_3), 6.70 (d, 1 H, −HC=C*H*CO−), 7.23 (d, 2 H, phenyl−*H*), 7.40 (d, 1 H, −*H*C=CHCO−), 7.53 (d, 2 H, phenyl−*H*).

4-(*p*-Tolyl)-2,2′-bipyridine (13): This compound was prepared by a modification of the method described by Baba et al.[17] A suspension of the acid **11** (4.0 g, 0.021 mol), 2-pyridacylpyridinium iodide[18] (9.7 g, 0.030 mol) and ammonium acetate (16 g, 0.21 mol) in water (150 mL) was heated at reflux for 3 h. The resulting precipitate was filtered from the hot solution and washed with water and dried to yield the ammonium salt of -4-(*p*-tolyl)-2,2′-bipyridine-6-carboxylic acid (**12**) (3.5 g, 53%). Mp: 181 °C (uncorr.). − ^{1}H NMR ([D$_6$]DMSO): δ = 2.39 (s, 3 H, −phenylCH_3), 7.37 (d, ^1J = 8 Hz, 2 H, phenyl−*H*), 7.48 (dd, ^1J = 8 Hz, 5 Hz, 1 H, Py′−*H*), 7.76 (d, ^1J = 8 Hz, 2 H, phenyl−*H*), 7.98 (t, ^1J = 8 Hz, 1 H, Py′−*H*), 8.14 (s, 1 H, Py−*H*), 8.50 (d, ^1J = 8 Hz, 1 H, Py′−*H*), 8.58 (s, 1 H, Py−*H*), 8.72 (d, ^1J = 5 Hz, 1 H, Py′−*H*).

The ammonium salt **12** (2.0 g, 6.5 mmol) was gently heated over a Bunsen flame until evolution of CO_2 had ceased. The solution was cooled, suspended in Et_2O, and stirred in the presence of activated charcoal for 15 min. Filtration and evaporation of the solvent gave a brown solid (1.2 g). Column chromatography (Al_2O_3, CH_2Cl_2/EtOH, 9:1) gave 4-(*p*-tolyl)-2,2′-bipyridine (tolbpy) (1.0 g, 38%) as a pale yellow powder. Mp: 112 °C (uncorr.). − ^{1}H NMR ([D$_6$]DMSO): δ = 2.39 (s, 3 H, −phenylCH_3), 7.38 (d, 2 H, phenyl−*H*, *J* = 8 Hz), 7.49 (dd, 1 H, Py′−*H*, *J* = 8 Hz, 5 Hz), 7.75 (d, 1 H, Py′−*H*, *J* = 5 Hz), 7.78 (d, 2 H, phenyl−*H*, *J* = 8 Hz), 7.98 (t, 1 H, Py′−*H*, *J* = 8 Hz), 8.45 (d, 1 H, Py′−*H*, *J* = 8 Hz), 8.66 (s, 1 H, Py−*H*), 8.73 (d, 2 H, Py−*H* and Py′−*H*, *J* = 5 Hz). MS (EI) (*m/z*): 246.2 [M$^+$].

{4-[*p*-(Bromomethyl)phenyl]}-2,2′-bipyridine (14): A solution of *p*-tolbpy (**13**) (0.5 g, 2.0 mmol), *N*-bromosuccinimide (0.4 g, 2.0 mmol), and azobis(isobutyronitrile) (0.010 g, 0.065 mmol) in dry CCl_4 (20 mL) was heated at reflux for 19 h under argon. The cooled reaction mixture was filtered. On removal of the solvent, a yellow oil was obtained which soon crystallized to give a yellow solid (0.58 g, 88% yield). This crude product was used in the next reaction without further purification. A peak at δ = 4.6 ($CDCl_3$) in the NMR spectrum was identified as the methylene protons between the bromine and the phenyl group.

Ru(bpy)$_2${[4-(*p*-bromomethyl)phenyl]-2,2′-bipyridine}(PF$_6$)$_2$ (15): A solution of *cis*-Ru(bpy)$_2$Cl$_2$ · 2 H$_2$O[19] (0.89 g, 1.7 mmol) and silver triflate (0.89 g, 3.5 mmol) in anhydrous acetone (65 mL) was stirred for 15 h at room temperature under argon and protected from light. The precipitated AgCl was removed by filtration, and compound **14** (0.55 g, 1.7 mmol) was added to the red filtrate. This reaction mixture was stirred in the dark at room temperature for 6 h under an argon atmosphere. The acetone was evaporated and the red residue was dissolved in a mixture of MeOH (15 mL) and water (25 mL). The ruthenium complex was precipitated from the solution by addition of concentrated NH_4PF_6. The red−brown precipitate was collected by suction filtration and washed with water. Purification by column chromatography (MPLC)[14] (Al_2O_3, CH_2Cl_2/EtOH, 95:5) afforded the red complex (0.50 g, 29% yield). − ^{1}H NMR ([D$_6$]acetone): δ = 4.76 (s, 2 H, −phenylCH_2Br), 7.59−7.64 (m, 5 H, Py′−*H* and Py′′−*H*), 7.71 (d, ^1J = 8 Hz, 2 H, phenyl−*H*), 7.91 (dd, ^1J = 7 Hz, 2 Hz, 1 H, Py−*H*), 7.99 (d, ^1J = 8 Hz, 2 H, phenyl−*H*), 8.10−8.12 (m, 5 H, Py−*H* and Py′′−*H*), 8.19 (d, ^1J = 5 Hz, 1 H, Py′−*H*), 8.24−8.28 (m, 5 H, Py′−*H* and Py′′−*H*), 8.88 (d, ^1J = 6 Hz, 4 H, Py′′−*H*), 9.13 (d, ^1J = 8 Hz, 1 H, Py′−*H*), 9.18 (d, ^1J = 2 Hz, 1 H, Py−*H*).

Ru(bpy)$_2$[{4′-[4-bis(2-methylpyridine)aminomethyl]phenyl}bipyridine](PF$_6$)$_2$ (4a): Compound **15** (0.084 g, 0.082 mmol) and dipicolylamine[16] (0.021 g, 0.11 mmol) were dissolved in acetonitrile (2 mL). After the addition of 3 drops of Et_3N, the solution was

heated at reflux for 7 h. The solvent was evaporated and the resulting residue was purified by column chromatography on silica gel using MeCN/water/KNO_3(sat.) (28:1:2) as eluent to afford the pure product (0.019 g, 20%). − ^{1}H NMR ([D$_6$]acetone): δ = 3.89 (s, 2 H, phenylCH_2N−), 3.91 (s, 4 H, dpaCH_2N−), 7.30 (dd, ^1J = 5 Hz, 2 H, dpaPy−*H*), 7.56−7.62 (m, 5 H, bpyPy−*H* (4 H) and tolbpyPy′−*H* (1 H)), 7.68 (d, ^1J = 7 Hz, 2 H, dpaPy−*H*), 7.71 (d, ^1J = 9 Hz, 2 H, phenyl−*H*), 7.82 (dt, ^1J = 7 Hz, 2 Hz, 2 H, dpaPy−*H*), 7.87 (dd, ^1J = 6 Hz, 2 Hz, 1 H, tolbpyPy−*H*), 7.96 (d, ^1J = 9 Hz, 2 H, phenyl−*H*), 8.06 (d, ^1J = 6 Hz, 1 H, tolbpyPy−*H*), 8.07−8.11 (m, 4 H, bpyPy−*H*), 8.15 (d, ^1J = 6 Hz, 1 H, tolbpyPy′−*H*), 8.19−8.25 (m, 5H; bpyPy−*H* (4 H) and tolbpyPy′−*H* (1 H)), 8.57 (d, ^1J = 5 Hz, 2 H, dpaPy−*H*), 8.85 (d, ^1J = 8 Hz, 4 H, bpyPy−*H*), 9.12 (d, ^1J = 9 Hz, 1 H, tolbpyPy′−*H*), 9.13 (s, 1 H, tolbpyPy−*H*). − ESI-MS (*m*/*z*): 1002.3 [M − PF_6^-], 501.3 [M − PF_6^- + H^+], 428.3 [M − 2 PF_6^-].

4-[Bis(methyl acet-2-yl)aminomethyl]-4′-methyl-2,2′-bipyridine (8e): The hydrochloride salt of iminodiacetic acid dimethyl ester (0.44 g, 2.4 mmol) and anhydrous sodium carbonate (1.0 g) were dissolved in acetonitrile (150 mL). 4-Bromomethyl-4′-methyl-2,2′-bipyridine (**8b**) (0.63 g, 2.4 mmol) was added and the reaction was stirred for 10 h at 4 °C. After heating at reflux overnight, the reaction mixture was cooled and filtered. The solid was washed with ethyl acetate and the solvent evaporated under reduced pressure. The crude dark red product was purified on silica gel using ethyl acetate as eluent. The desired product was obtained as an uncolored oil (0.57 g, 76%). − ^{1}H NMR ($CDCl_3$): δ = 2.43 (s, 3 H, bpyCH_3), 3.59 (s, 4 H, CH_2COO), 3.70 (s, 6 H, ester OCH_3), 4.04 (s, 2 H, bpyCH_2), 7.12 (d, 1 H, bpyPy−*H*), 7.48 (d, 1 H, bpyPy−*H*), 8.22 (s, 1 H, bpyPy−*H*), 8.33 (s, 1 H, bpyPy−*H*), 8.54 (d, ^1J = 5 Hz, 1 H, bpyPy−*H*), 8.64 (d, ^1J = 5 Hz, 1 H, bpyPy−*H*).

Ru(bpy)$_2${4-[CH$_2$N(CH$_2$COOH)$_2$]-4′-methylbipyridine}(PF$_6$)$_2$ (5a): Hydrolysis of ester **10a** in a NaOH/H_2O solution overnight gave the desired diacid **5a** in quantitative yield. − ^{1}H NMR (D_2O): δ = 2.50 (s, 3 H, MebpyCH_3), 3.21 (s, 4 H, −NCH_2COOH), 3.90 (s, 2 H, MebpyCH_2N−), 7.24 (d, 1 H, MebpyPy′−*H*), 7.32−7.43 (m, 4 H, bpyPy−*H*), 7.46 (d, 1 H, MebpyPy−*H*), 7.63 (d, 1 H, MebpyPy′−*H*), 8.00−8.06 (m, 4 H, bpyPy−*H*), 8.43 (s, 1 H, MebpyPy′−*H*), 8.51 (d, 4 H, bpyPy−*H*), 8.60 (s, 1 H, MebpyPy−*H*). − ESI-MS (*m*/*z*): 874.3 [M − PF_6^-], 364.2 [M − 2 PF_6^-].

{2-[(Dipicolyl)aminomethyl]}-3-hydroxypyridine (16): 2-Bromomethyl-3-hydroxypyridine hydrobromide (3.8 g, 0.014 mol), obtained according to a literature procedure[20] was added over a period of 3 h, to a refluxing solution of dipicolylamine[16] (2.8 g, 0.014 mol) in MeCN (400 mL), containing sodium carbonate (10 g). The mixture was heated at reflux overnight, cooled, and purified by column chromatography on silica gel, using CH_2Cl_2/MeOH (94:6) as eluent, to give compound **16** (HO-tpa) in 78% yield. ^{1}H NMR ($CDCl_3$): δ = 7.16 (d, ^1J = 2.6 Hz, 2 H), 7.25 (m, 2 H), 7.37 (d, ^1J = 8.6 Hz, 2 H), 7.72 (td, ^1J = 8.6 Hz, 1.2 Hz, 2 H), 7.92 (m, 1 H), 8.47 (d, ^1J = 4.8 Hz, 2 H). − ^{13}C NMR ($CDCl_3$): δ = 123.0, 123.3, 123.5, 124.4, 137.5, 139.7, 144.6, 149.0, 153.6, 158.3. − ESI-MS (*m*/*z*): 306 [M^+].

Ru(bpy)$_2$[4-(CH$_2$O-tpa)-4′-methylbipyridine](PF$_6$)$_2$ (6a): Metallic sodium (3.1 mg) was dissolved in dry MeOH (5 mL), and **16** (HO-tpa) (0.041 g, 1.35 mmol) was added followed by DMSO (4 mL). MeOH was evaporated under reduced pressure. Ru(bpy)$_2$(4-bromomethyl-4′-methylbipyridine)(PF$_6$)$_2$ (**9b**, 0.13 mg) was added and the mixture was heated at 80 °C for 4 d in the dark. DMSO was removed under vacuum and the resulting product was purified by chromatography (silica gel, MeCN/water/KNO_3(sat.), 7:1:1). The compound was precipitated by the addition of saturated NH_4PF_6 (aq.) and purified further by MPLC[14] on aluminum oxide using CH_2Cl_2/MeOH (95:5) to give compound **6a** in 46% yield. − ^{1}H NMR ([D$_6$]acetone): δ = 2.53 (s, 3 H, bpyCH_3), 3.96 (s, 4 H, pyCH_2N−), 4.07 (s, 2 H, pyCH_2N−), 5.42 (s, 2 H, bpyOCH_2−), 7.06 (m, 2 H, py−*H*), 7.24 (m, 1 H, py−*H*), 7.43 (m, 2 H, py−*H*), 7.56−7.65 (m, 9 H, py−*H*), 7.87 (d, ^1J = 5.8 Hz, 1 H, Mebpy−*H*), 7.98−8.10 (m, 6 H, py−*H*), 8.18−8.24 (m, 5 H, py−*H*), 8.33 (d, ^1J = 6.0 Hz, 1 H, Mebpy−*H*), 8.69 (s, 1 H, Mebpy−*H*), 8.82 (m, 4 H, bpy−*H*), 8.94 (s, 1 H, Mebpy−*H*). − ESI-MS (*m*/*z*): 1046 [M − PF_6^-], 450 [M − 2 PF_6^-].

[4,4′-Bis(bromomethyl)]-2,2′-bipyridine (8d): Compound **8d** was prepared via the diol **8c** in the same manner as **8b**, but with a large excess of SeO_2 to oxidize the dimethylbipyridine and 2 mol equivalents of $NaBH_4$ to reduce the dialdehyde. Due to problems with hydrolysis during attempted purification of this ligand, the crude product was used directly in the following step.

Ru(bpy)$_2$[4,4′-bis(CH$_2$Br)bpy](PF$_6$)$_2$ (9c): *cis*-Ru(bpy)$_2$Cl$_2$·2 H_2O[19] (0.10 g, 0.20 mmol) and silver triflate (2 equiv.) were dissolved in anhydrous acetone. The mixture was stirred for 7 h at room temperature under argon. The AgCl that formed during the reaction was removed by filtration. [4,4′-Bis(bromomethyl)]-2,2′-bipyridine (**8d**) (0.068 g, 0.20 mmol) was added to the filtrate and the reaction mixture was allowed to stir at room temperature under argon. After 1.5 h, the solvent was evaporated under reduced pressure and the red product was redissolved in MeOH. The product was precipitated by the addition of concentrated aqueous NH_4PF_6. The resulting product was purified by column chromatography (MPLC)[14] on neutral Al_2O_3, gradient elution, EtOH/CH_2Cl_2, 0:100 to 10:90, to afford Ru(bpy)$_2$[4,4′-bis(CH_2Br)-bpy](PF$_6$)$_2$ (**9c**) (0.072 g, 35% yield).

Ru(bpy)$_2$[4,4′-bis(CH$_2$-dpa)bpy](PF$_6$)$_2$ (7a): A solution of dipicolylamine[16] (0.028 g, 0.14 mmol) and Et_3N (slight excess) was added dropwise to a solution of **9c** (0.072 g, 0.069 mmol) in MeCN. The reaction was allowed to stir for 7 h under argon. The solvent was removed under reduced pressure and the product was purified by column chromatography (silica gel, MeCN/water/KNO_3(sat.), 28:1:2). The desired product was eluted as the second band and excess KNO_3 was removed by filtration after dissolving the product in acetone. The product was then precipitated from a MeOH/water solution by adding concentrated aqueous NH_4PF_6 to yield **7a** (0.070 g, 79%). − ^{1}H NMR ($CDCl_3$): δ = 3.94 (s, 8 H, dpaCH_2N−), 4.08 (s, 4 H, bpyCH_2N−), 7.19−7.22 (ddd, 4 H, dpaPy−*H*), 7.50 (dd, 4 H, dpaPy−*H*), 7.52−7.55 (m, 4 H, bpyPy−*H*), 7.65 (d, 2 H, bpyPy′−*H*), 7.66 (d, 2 H, bpyPy′−*H*), 7.66−7.71 (ddd, 4 H, dpaPy−*H*), 7.74−7.76 (dd, 4 H, bpyPy−*H*), 8.14−8.17 (m, 4 H, bpyPy−*H*), 8.58 (dd, 4 H, dpaPy−*H*), 8.91 (s, 2 H, bpyPy′−*H*), 9.11−9.14 (dd, 4 H, bpyPy−*H*). − ESI-MS (*m*/*z*): 495.8 [M − 2 PF_6^-], 331.1 [M − 2 PF_6^- + H^+].

Ru(bpy)$_2${4-[CH$_2$N(CH$_2$CO$_2$CH$_3$)$_2$]-4′-methylbipyridine}(PF$_6$)$_2$ (10a): *cis*-Ru(bpy)$_2$Cl$_2$ · 2 H_2O[19] (0.89 g, 1.8 mmol) and **8e** (0.60 mg, 1.8 mmol) were dissolved in MeOH (200 mL) and heated at reflux overnight. The solvent was removed and water (80 mL) was added. After filtration of the red solution, a large excess of NH_4PF_6 (1.0 g) was added to the filtrate and the orange precipitate was collected by filtration, washed with water and dried to yield **10a**. The product was purified by column chromatography (MPLC)[14] (Al_2O_3, CH_2Cl_2/EtOH, 97:3) and obtained in 65% yield. − ^{1}H NMR ([D$_6$]-acetone): δ = 2.64 (s, 3 H, MebpyCH_3), 3.67 (s, 6 H, −COOCH_3), 3.72 (s, 4 H, −NCH_2COOCH$_3$), 4.25 (s, 2 H, MebpyCH_2), 7.48 (d, 1 H, MebpyPy′−*H*), 7.61−7.67 (m, 4 H, bpyPy−*H*), 7.71 (d, 1 H,

MebpyPy−*H*), 7.92 (d, 1 H, MebpyPy′−*H*), 8.00 (d, 1 H, MebpyPy−*H*), 8.06−8.15 (m, 4 H, bpyPy−*H*), 8.23−8.29 (m, 4 H, bpyPy−*H*), 8.46 (s, 1 H, MebpyPy′−*H*), 8.88 (d, 4 H, bpyPy−*H*), 8.92 (s, 1 H, MebpyPy−*H*). − ESI-MS (*m/z*): 902.3 [M − PF_6^-], 378.1 [M − 2 PF_6^-].

Ru(bpy)$_2$[4-(CH$_2$-O-tpa-Mn)-4′-methylbipyridine](PF$_6$)$_2$ (6b): $MnCl_2 \cdot 4\,H_2O$ (0.030 g, 0.15 mmol) was added to compound **6a** (0.12 g, 0.10 mmol) dissolved in MeOH (10 mL). After 10 min, a concentrated aqueous solution of NH_4PF_6 was added and a red precipitate was formed after 5 min of stirring at room temperature. Filtration and washing with cold MeOH and Et_2O, followed by drying gave **6b** as a red solid (0.11 g, 83% yield). − ^{1}H NMR ([D$_6$]acetone): proton signals from the ligands in the ruthenium moiety were broadened, and proton signals for the manganese ligands were not seen when using a spectral width of 15 ppm. − ESI-MS (*m/z*): 1175 [M − PF_6^-], 567 [M − PF_6^- − Cl^-], 514 [M − 2 PF_6^-], 331 [M − 2 PF_6^- − Cl^-].

The Mn complexes **3b**, **4b**, **5b**, and **7b** were prepared in a similar way as **6b**, except that the reaction times with $MnCl_2$ varied from a few hours to two days. After the addition of NH_4PF_6, filtration and drying, the complexes **3b**, **4b**, **5b**, and **7b** were obtained as fine powders. Complex **5b** was only obtained in an impure state and was not fully characterized.

Ru(bpy)$_2$(bpy-dpaMn)(PF$_6$)$_2$Cl$_2$ (3b): ESI-MS (*m/z*): 569.8 [M − 2 Cl^-], 533.3 [M − PF_6^- + H^+], 514.5 [M − PF_6^- − Cl^-], 460.3 [M − 2 PF_6^-].

Ru(bpy)$_2$(bpy-tolyl-dpaMn)(PF$_6$)$_2$Cl$_2$ (4b): ESI-MS (*m/z*): 1127.2 [M − PF_6^-], 600.7 [M − 2 Cl^-], 545.7 [M − PF_6^- − Cl^-], 315.5 [M − 2 PF_6^- − Cl^-].

Ru(bpy)$_2$(bpy-bisdpaMn$_2$)(PF$_6$)$_2$Cl$_4$ (7b): ESI-MS (*m/z*): 749.3 [M − Cl^- + H^+], 731.2 [M − 2 Cl^-], 676.9 [M − PF_6^- − Cl^-].

Acknowledgments

The financial support for this work was provided by the Nordic Energy Research Council, the Knut and Alice Wallenberg Foundation, the Swedish Research Council for Engineering Sciences, the Swedish Natural Science Research Council, and the European TMR Program (TMR Network CT 96-0031). We are also very thankful to Jens Z. Pedersen for recording the EPR spectra, Tina Esbech for measuring the ESI-MS spectra, and Daniel Czermac for contributions to the synthesis.

Chlorination of Platinum-Bound Salicylaldoxime. The First Example of a Structurally Characterized Monodentate Salicylaldoxime-Type Ligand

Savelii F. Kaplan,[a] Vadim Yu. Kukushkin,*[a] Sergiu Shova,[b] Kinga Suwinska,[c] Gabriele Wagner,[d] and Armando J. L. Pombeiro*[d]

Keywords: Salicylaldoxime complexes / Platinum / Ligand reactivity / Metal-mediated synthesis / Chlorination

The reaction of $K_2[PtCl_4]$ and salicylaldoxime in an approximate 1:2 molar ratio in water resulted in the isolation of a mixture of four compounds from which [Pt(*o*-OC_6H_4CH=NOH)$_2$] (**1**) and [PtCl(OC_6H_4CH=NOH)(HOC_6H_4CH=NOH)] (**2**) were isolated, whereas the other two were shown to be unstable and decomposed both in solution and on SiO_2 during chromatography. Chlorination of **1** and **2** with Cl_2 resulted in the oxidative addition of chlorine to the platinum(II) center and in the chlorination of the benzene ring, giving the platinum(IV) complexes [$PtCl_2$(3,5,2-Cl,Cl,OC_6H_2CH=NOH)$_2$] (**3**) and [$PtCl_3$(3,5,2-Cl,Cl,OC_6H_2CH=NOH)(3,5,2-Cl,Cl,HOC_6H_2CH=NOH)] (**5**), respectively, containing commercially unavailable 3,5-dichloro-2-hydroxybenzaldehye oxime. Alternatively, treatment of **1** with NOCl resulted only in the oxidation of the platinum(II) center to furnish [$PtCl_2$(*o*-OC_6H_4CH=NOH)$_2$] (**4**), whereas the benzene rings of salicylaldoximato ligands remained intact. All complexes were characterized by C, H, N, Cl and Pt elemental analyses, FAB^+ mass spectrometry, IR and ^1H, $^{13}C\{^1H\}$ and ^{195}Pt NMR spectroscopy. Compounds **1**, **3** and **5** were analyzed by X-ray crystallography. In **1**, the salicylaldoximato ligands adopt a *trans* configuration and the hydrogen atoms of the OH groups are involved in intramolecular hydrogen bonding, forming five-membered rings. In **3**, every molecule of the complex forms the repeating unit for a self-assembly that produces infinite one-dimensional polymeric chains directed along the z axis held by hydrogen bonds. The complex **5** represents the first example of a structurally characterized metal complex with a monodentate salicylaldoxime-type ligand, although the conventional bidentate *N,O*-coordination mode is a classical topic in coordination chemistry.

Introduction

Although oximes (RR′C=NOH) display one of the most versatile modes of reactivity in metal-mediated processes, their conversions at a metal center have attracted attention only in the last decade.[1,2] Being involved in these studies for the last five years, we have been investigating some aspects of oxime ligand reactivity, in particular with respect to (*i*) the OH group, e.g. their facile deprotonation and the self-assembly of the oxime-oximato species formed,[3] addition to nitriles bound to Pt^{IV},[4,5] Re^{IV} [6] and Rh^{III} [7] ions, addition to ketones in a Pt^{IV} complex,[8] formation of metallacycles accompanied by the OH addition;[9] (*ii*) the N−OH group, e.g. its oxidative addition to an electron-rich rhenium(I) center,[10] (*iii*) the oxime N atom, e.g. its oxidation to give (nitrosoalkane)Pt complexes[11,12] or its reduction in a strongly acidic solution,[13] (*iv*) the C=N group, e.g. its metal-mediated hydrolysis[14] and the conversion into the nitrile group upon Ru-assisted dehydration of aldoximes.[15] Following these studies, we turned our attention to the reactions of *peripheral* R/R′ groups and have recently reported the chlorination, by molecular chlorine, of the platinum(II) salicylaldoxime, *trans*-(*S,N*)-[$PtCl_2$(*o*-HOC_6H_4-CH=NOH)(Me_2SO)]·H_2O, and the salicylaldoximato(1$^-$), *trans*-(*S,N*)-[PtCl(*o*-OC_6H_4CH=NOH)(Me_2SO)], complexes.[16] Instead of the Piloty reaction, which in the case of aldoximes leads to chloro oximes, RC(Cl)=NOH (*via* RCH(Cl)−N=O),[17] or to the formation of platinum(III) derivatives previously detected upon the chlorination of (*vic*-dioximato)platinum(II) compounds,[18] we observed both the chlorination of the salicylaldoxime benzene ring and the oxidative addition of Cl_2 to the platinum(II) center. Conclusions that can be derived from the latter work indicate that platinum acts as a protecting center for the oxime functionality and this allows for the formation of the chlorinated species, which cannot be synthesized by direct chlorination of the corresponding salicylaldoxime.

Our interest in the continuation of the chlorination experiments lied in at least three areas. Firstly, we wondered if the protection of the NOH group and the concomitant chlorination of the benzene ring was peculiar for the complexes being investigated or if the reaction could be extended to other salicylaldoxime platinum compounds. Secondly, it was expected to contribute to the almost unexplored chemistry of salicylaldoxime coordinated to plat-

inum. Thirdly, our own observations[16] and also some earlier studies[19] indicated the possibility of *N-monodentate* coordination of classical *bidentate chelating* ligands such as salicylaldoxime and its derivatives. We therefore focused our efforts on the structural determination of previously uncharacterized monodentate species. In this paper we present the revisited synthesis (previously reported by Cox et al.[19]) of two salicylaldoxime complexes of platinum(II). We report the X-ray structure of one of the compounds, as well as the isolation of a new product, chlorination studies of the two platinum(II) compounds with Cl_2 and NOCl giving, in one case, a Pt^{IV}-based *monodentate* chlorinated salicylaldoxime that was successfully characterized by X-ray single-crystal diffraction. Furthermore, an unusual intermolecular hydrogen bonding was shown by an X-ray study of one of the Pt^{IV} products. This hydrogen bonding results in a self-assembly, forming infinite one-dimensional polymeric chains, and is significant in the developing field of self-assembly of metal complexes by hydrogen bonding, which has applications in crystal engineering and materials science.[3]

Results and Discussion

Synthesis of Platinum(II) Compounds with Salicylaldoxime(ato) Ligands

Cox and co-authors[19] reported the reaction of $K_2[PtCl_4]$ and salicylaldoxime in a molar ratio of approximately 1:2 in water, resulting in the isolation of a mixture of the *bis*-chelate [Pt(*o*-$OC_6H_4CH{=}NOH)_2$] and the complex [$PtCl_2$(*o*-$HOC_6H_4CH{=}NOH)_2$] that contains, as had been suggested,[19] monodentate salicylaldoxime ligands. It was pointed out[19] that the latter complex is unstable in solutions and decomposes on standing.

The ^{195}Pt NMR spectrum of the crude mixture, prepared according to a known procedure,[19] showed four signals of similar intensities, and TLC showed four well-defined spots. The signal at $\delta = -1611$ (480 Hz) in the spectrum was assigned to [Pt(*o*-$OC_6H_4CH{=}NOH)_2$] (**1**) and the peak at $\delta = -1842$ (360 Hz) was ascribed to [$PtCl(OC_6H_4CH{=}NOH)(HOC_6H_4CH{=}NOH)$] (**2**) (both are depicted in Scheme 1). The former was isolated by following the method of Cox,[19] and the latter was separated from the mixture by chromatography, and both were characterized by C, H, N, Cl and Pt elemental analyses, FAB^+ mass spectrometry, IR and ^1H, $^{13}C\{^1H\}$ and ^{195}Pt NMR spectroscopy. Compound **1** was analyzed by X-ray crystallography. Our attempts to isolate two other compounds [^{195}Pt NMR: $\delta = -1999$ (500 Hz) and $\delta = -2064$ (250 Hz)] failed because of their decomposition both in solution and on SiO_2 during chromatography. Although the values of the chemical shifts for these yet unidentified species seem to be reasonable for *cis* and *trans* isomers of **1**, no further evidence in favor of these complexes was obtained.

Complex **1** was characterized by X-ray single-crystal diffractometry. The coordination polyhedron of the centrosymmetric compound is a slightly distorted square plane (Figure 1).

The salicylaldoximato ligands in the structure adopt a *trans* configuration and the hydrogen atoms of the OH groups are involved in intramolecular hydrogen bonding, forming a five-membered ring. Interestingly, these H atoms, found from the difference synthesis, are disordered by two positions with a 50% population at each one, i.e. at the oxime =NOH group and at the phenol OH group, thus indicating the existence of two solid tautomers. However, careful comparison of bond lengths in the chelated ring of **1** with (*i*) typical bond lengths in oxime/oximato compounds; (*ii*)

distances within both the chelated salicylaldoximato ring and the monodentate salicylaldoxime ligand in the two platinum(IV) complexes from both the current (see Table 1) and previous work;[16] and (*iii*) bond lengths in some other salicylaldoximato complexes,[20] does not give any further evidence in favor of the phenol tautomeric structure.

Chlorination of [Pt(*o*-$OC_6H_4CH{=}NOH)_2$] (1)

Passage of excess Cl_2 through a chloroform solution of **1** for 20 min at room temperature resulted in the oxidative addition of chlorine to the platinum(II) center and in the chlorination of the benzene ring (Scheme 1). As a result of the overall process, the platinum(IV) complex [$PtCl_2$(3,5,2-Cl,Cl,$OC_6H_2CH{=}NOH)_2$] (**3**) (Scheme 1), containing commercially unavailable 2-hydroxy-3,5-dichlorobenzaldehyde oxime was isolated in 85% yield. The oxime 3,5,2-Cl,Cl,$HOC_6H_2CH{=}NOH$ was prepared earlier by the chlorination of salicylaldehyde to give 3,5,2-Cl,Cl,$HOC_6H_3CH{=}O$ and its subsequent condensation with hydroxylamine.[21] We have also observed that when nitrosyl chloride is used instead of molecular chlorine, only oxidation of the central ion is observed, to give [$PtCl_2$(*o*-$OC_6H_4CH{=}NOH)_2$] (**4**), and the benzene rings remain intact.

As already indicated,[16] chlorination of *free* salicylaldoxime under the same conditions as for the platinum(II) complexes gave a variety of products due to oxidative deoximation[1,2] and chlorination, with no dominant compound. The latter fact suggests that coordination affects the reaction by blocking and thus protecting the oxime N atom from oxidation, thus also making the chlorination selective.

The structure of **3** was determined by X-ray crystallography. In the centrosymmetric complex, the coordination polyhedron of platinum is a slightly distorted octahedron with the ligands in a *trans* configuration (Figure 2). All bonds around the Pt center have normal values. The chelate ring is in the envelope-like conformation where the Pt atom deviates from the organic unit by 0.256 Å.

The oxime group is involved in an unusual hydrogen bonding (Figure 3), e.g. the *intermolecular* − rather than *intramolecular* as in the case of [Pt(*o*-$OC_6H_4CH{=}NOH)_2$] (**1**) − O(2)−H···Cl(3) hydrogen bond [O(2)···Cl(3)(*x,y,z* − 1) = 3.155, H···Cl(3) 2.34 Å, angle O(2)−H···Cl(3) 161°]. According to Wells,[22] O···Cl^- distances in the range 2.95−3.4 Å are found for O−H···Cl^- hydrogen bonds (for Cl^-···H_3O^+ the distance is 2.95[22]). Every molecule of the complex forms the repeating unit for a self-assembly that produces infinite one-dimensional polymeric chains directed along the *z* axis held by H-bonds. It is worth noting that the study of self-assembly of metal complexes, in particular by hydrogen bonding, is a rapidly developing field

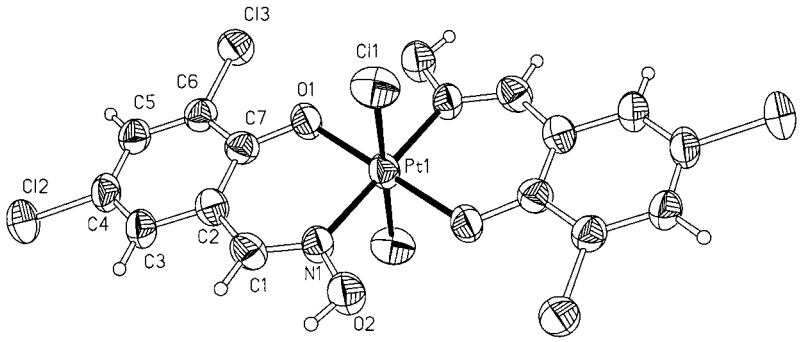

Figure 2. View of *trans-(N,N)*-[$PtCl_2$(3,5,2-Cl,Cl,$OC_6H_2CH{=}NOH)_2$] (**3**) with atomic numbering

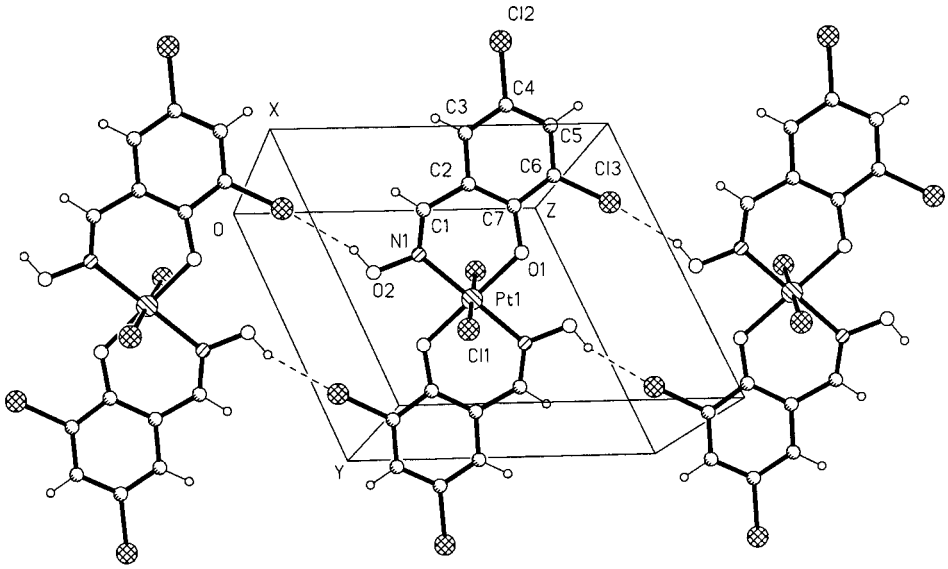

Figure 3. Packing diagram for *trans-(N,N)*-[$PtCl_2$(3,5,2-Cl,Cl,$OC_6H_2CH{=}NOH)_2$] (**3**) showing the hydrogen-bonding scheme

that is intrinsic for crystal engineering and materials science,[3] and from that point of view, it is likely that the observation of hydrogen bonding in the (salicylaldoximato)-Pt^{IV} compound deserves further investigation.

Chlorination of [PtCl($OC_6H_4CH{=}NOH$)($HOC_6H_4CH{=}NOH$)] (2) and Crystal Structure of *trans-(N,N)*-[$PtCl_3$(3,5,2-Cl,Cl,$OC_6H_2CH{=}NOH$)(3,5,2-Cl,Cl,$HOC_6H_2CH{=}NOH$)] (5)

The chlorination of **2** with molecular chlorine proceeded similarly to that described above for **1** (Scheme 1), but the reaction with NOCl gave a variety of products, which were not separated. In the former case, both monodentate and chelating ligands are chlorinated selectively at the 3- and 5-positions of the aromatic ring rather than at the oxime CH=N group, indicating that coordination of the phenolic oxygen has no influence on the course of the chlorination. However, the most interesting result from this part of the work is that the salicylaldoxime ligand maintains its monodentate coordination, which was unambiguously confirmed by X-ray study. In *trans-(N,N)*-[$PtCl_3$(3,5,2-Cl,Cl,$OC_6H_2CH{=}NOH$)(3,5,2-Cl,Cl,$HOC_6H_2CH{=}NOH$)] (**5**), the platinum exhibits a slightly distorted octahedral geometry with three meridian Cl ligands (Figure 4).

The values of the Pt−Cl bond lengths (Table 2) agree well with those of previously characterized platinum(IV) chloride compounds,[4,5] although the Pt−Cl(2) bond [2.316(4) Å] is slightly shorter that the other two [2.338(4) and 2.336(4) Å]. The most interesting feature of the structure is the presence of two different salicylaldoxime species, i.e. one is an unusual monodentate ligand and the other is the conventional *N,O*-salicylaldoximato chelate. Surprisingly, the corresponding bond lengths in the two types of salicylaldoximato ligands are the same within 3σ. Although the hydrogen atoms at the =NOH moieties were not found, the bond lengths indicated in Table 1 favor the oxime tautomeric structure in both cases.

IR and NMR Spectroscopic Characterization of 5

In IR spectra, only one band of ν(C=N) stretching vibrations appears for the *bis*-chelated species **1** and **3**, whereas complexes **2** and **5**, containing both chelating and monodentate ligands, display two ν(C=N) bands. ^1H and $^{13}C\{^1H\}$ NMR spectra of **1** and **3** show only one set of signals for

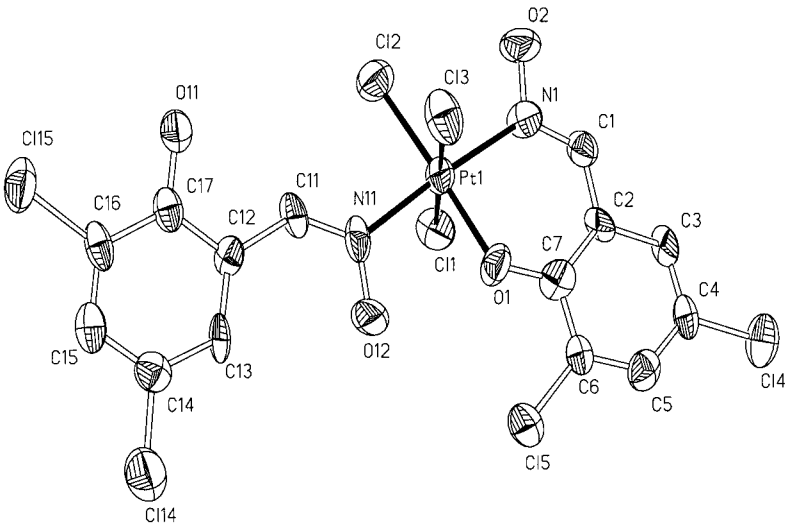

Figure 4. View of *trans-(N,N)*-[$PtCl_3$(3,5,2-Cl,Cl,$OC_6H_2CH{=}NOH$)(3,5,2-Cl,Cl,$HOC_6H_2CH{=}NOH$)] (**5**) with atomic numbering

the salicylaldoximato-type ligands, while two sets are observed for **2** and **5**. Full assignment of the ^{1}H NMR peaks for **1**−**3** and **5** was made by means of one-dimensional homodecoupling and NOE experiments. By measuring NOE interactions between the oxime CH=N proton and the proton at the 6-position of the aromatic ring, one might distinguish between signals arising from the chelating and the monodentate ligands. In the chelate, in which the conformation of the ligand is fixed, the CH=N and 6-H protons are held at a distance of approximately 2.47 Å, as confirmed by the X-ray analysis of **5** (see above). This distance is sufficiently short to give rise to a NOE signal, and indeed this peak was observed for the *bis*-chelated complex [Pt(*o*-$OC_6H_4CH{=}NOH)_2$] (**1**) (δ = 8.51 to 7.50). The monodentate ligand, however, has more conformational freedom and, consequently, the average distance between the corresponding protons is much larger than in the chelated ligand. Therefore, one would expect a much weaker or even no observable NOE signal for the monodentate ligand. In agreement with this hypothesis, in both compounds **2** and **5**, only one CH=N proton revealed a strong NOE interaction with the 6-H proton (δ = 8.44 to 7.53 for **2**, δ = 8.64 to 7.76 for **5**), whereas irradiation of the second CH=N proton (δ = 8.84 for **2** and δ = 9.03 for **5**) did not show any NOE interaction. Furthermore, a comparison of the chemical shift and the coupling constants $^3J_{PtH}$ of the CH=N protons of the two ligands shows that, for the monodentate ligand, the δ value is higher (δ = 8.84−9.03 vs. δ = 8.44−8.77 for the chelate), while the $^3J_{PtH}$ value is smaller (23−30 Hz vs. 35−45 Hz for the chelate).

^{1}H NMR spectroscopic experiments with **2** or **5** also showed that the monodentate ligands do not interconvert into chelating ligands. For **2**, slow decomposition occurs upon prolonged storage (3 weeks at 20−25 °C) or on heating (3 d at 56 °C) to give a mixture of unidentified products. In contrast, **5** is stable and even after storage at room temperature for two months or on heating at 56 °C for 4 d in the presence of pyridine, neither transformation into the corresponding *bis*-chelated complex **3**, substitution of the monodentate ligand for pyridine, or decomposition were observed.

It is also worth mentioning that chlorination of the mixture of (salicylaldoxime)Pt^{II} complexes, prepared according to the method of Cox and co-authors,[19] gave, besides [$PtCl_2$(3,5,2-Cl,Cl,$OC_6H_2CH{=}NOH)_2$] (**3**) and [$PtCl_3$-(3,5,2-Cl,Cl,$OC_6H_2CH{=}NOH$)(3,5,2-Cl,Cl,HOC_6H_2-$CH{=}NOH$)] (**5**), a purely organic material, i.e. 3,5,2-Cl,Cl,$HOC_6H_2C(Cl){=}NOH$. The latter is, at least formally, derived from both the Piloty reaction and the chlorination of the benzene ring. Since this compound was not observed in the course of the chlorination of salicylaldoxime itself,[16] and furthermore, chlorination of the individual platinum(II) complexes does not give 3,5,2-

Cl,Cl,$HOC_6H_2C(Cl)$=NOH, we anticipate that the chlorination occurs in the benzene ring of coordinated ligand followed by liberation of the chlorinated species. An investigation of this reaction is underway in our group.

Experimental Section

Materials and Apparatus: Salicylaldoxime (Aldrich) and solvents were obtained from commercial sources and used as received. Cl_2 for chlorination was obtained from the reaction of $KMnO_4$ and HCl by a standard procedure.[23] Traces of HCl were removed by bubbling through water and dried over H_2SO_4. Nitrosyl chloride was obtained by the reaction of an aqueous solution of $NaNO_2$ with concentrated HCl. Residues of HCl were removed over $NaNO_2$, and NO_2 was removed by treatment with moist KCl. The nitrosyl chloride was finally dried over $CaCl_2$.[24] − Melting points were determined on a Kofler table. For TLC, Silufol UV 254 SiO_2-plates were used. − Positive-ion FAB mass spectra were obtained on a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (NBA) matrices of the samples with 8 keV (ca. 1.28×10^{15} J) Xe atoms. Mass calibration for the data-system acquisition was achieved using CsI. EI-MS of 3,5,2-Cl,Cl,$HOC_6H_2C(Cl)$=NOH was measured on the same mass spectrometer. − Infrared spectra (4000−400 cm^{-1}) were recorded on a BIO-RAD FTS 3000MX instrument in KBr pellets, while spectra in the range 400−140 cm^{-1} were measured on a Hitachi FYS-3 spectrometer in polyethylene pellets. − ^1H, $^{13}C\{^1H\}$ and ^{195}Pt NMR spectra were obtained on a Varian UNITY 300 spectrometer at ambient temperature. ^{195}Pt chemical shifts are reported relative to aqueous $K_2[PtCl_4]$ = −1630 ppm, half-height line widths are given in parenthesis.

Synthetic Work and Characterization

Preparation of (Salicylaldoximato)Pt^{II} Complexes: The complexes were prepared by treatment of $K_2[PtCl_4]$ with salicylaldoxime as described by Cox et al.[19] Complex [PtCl(OC_6H_4CH=NOH)(HOC_6H_4CH=NOH)] (**2**) was separated from the other species by TLC on SiO_2 (Silica gel L 5/40 μ, CHEMAPOL) with $CHCl_3$ as eluent (R_f [Pt(*o*-OC_6H_4CH=NOH)$_2$] (**1**) = 0.62, R_f [PtCl(OC_6H_4CH=NOH)(HOC_6H_4CH=NOH)] (**2**) = 0.29, while other species remain on the baseline). [PtCl(OC_6H_4CH=NOH)(HOC_6H_4CH=NOH)] (**2**) was then desorbed with acetone, and the solvent was removed in vacuo at room temperature. The residue was crystallized over a layer of cold water (5−10 °C). The *bis*-chelate [Pt(*o*-OC_6H_4CH=NOH)$_2$] (**1**) was obtained in according to a published method[19] and recrystallized from acetone.

Chlorination of [Pt(*o*-OC_6H_4CH=NOH)$_2$] (1) by Cl_2: Molecular chlorine was passed through a lemon-yellow solution of **1** (0.136 g, 0.29 mmol) in $CHCl_3$ (80 mL) for 20 min at 20−25 °C. A cherry-brown solution formed, and was left to evaporate at 14−18 °C in an open 100-mL beaker to ca. 10 mL. Transparent, glittering rhombic-like brownish crystals of *trans-(N,N)*-[$PtCl_2$(3,5,2-Cl,Cl,OC_6H_2CH=NOH)$_2$] (**3**) were separated by filtration, washed with a Me_2CO/CCl_4 mixture (1:2, v/v, 3 × 3 mL), diethyl ether (3 × 3 mL) and dried in a vacuum-desiccator at room temperature over $CaCl_2$. Yield: 0.167 g, 85%.

***trans-(N,N)*-[$PtCl_2$(3,5,2-Cl,Cl,OC_6H_2CH=NOH)$_2$] (3):** − $C_{14}H_8N_2Cl_6O_4Pt$: calcd. C 24.85, H 1.18, N 4.14, Cl 31.46, Pt 28.85; found C 24.60, H 1.26, N 3.94, Cl 32.00, Pt 28.52. − FAB^+-MS, *m/z*: 606 $[M - 2Cl]^+$, 588 $[M - 2Cl - OH]^+$, 571 $[M - 2HCl - 2OH]^+$. − M.p. 238 °C. − TLC, R_f = 0.48 (eluent $CHCl_3$). − IR (KBr, selected bands): $\tilde{\nu}$ = 1645 mw ν(C=N), 1596 s ν(C=C), 1422 s, br. δ(O−H), 1189 ms ν(C−O), 912 s ν(N−O), 358 ms ν(Pt−Cl) cm^{-1}. − ^1H NMR ([D_6]acetone): δ = 7.82 and 7.84 (two d, 2.2 Hz, 1*H* each, phenyl H), 8.91 [s + d, $^3J_{PtH}$ = 37.9 Hz, 1 *H*, =C(H)−], 11.00 (s, 1 *H*, NOH). − $^{13}C\{^1H\}$ and ^{195}Pt NMR spectra were not measured even at high acquisition time owing to the low solubility of the complex in common deuterated solvents.

Chlorination of [PtCl(OC_6H_4CH=NOH)(HOC_6H_4CH=NOH)] (2) by Cl_2: Complex **2** (0.034 g, 0.068 mmol) was dissolved in $CHCl_3$ (10 mL) and molecular chlorine was passed through this solution for 20 min at 18−20 °C. The color of the reaction mixture turned from lemon-yellow to dark red during the chlorination. The reaction mixture was transferred to a long narrow tube, the solvent was evaporated at room temperature and cherry-red crystals of *trans-(N,N)*-[$PtCl_3$(3,5,2-Cl,Cl,OC_6H_2CH=NOH)(3,5,2-Cl,Cl,HOC_6H_2CH=NOH)] (**5**) were collected from the bottom part of the tube (0.015 g, 29%). A brownish material was collected from the upper part of the tube. Stirring this brownish material in heptane gave an additional amount of less pure **5** (0.021 g, 41%).

***trans-(N,N)*-[$PtCl_3$(3,5,2-Cl,Cl,OC_6H_2CH=NOH)(3,5,2-Cl,Cl,HO-C_6H_2CH=NOH)] (5):** − $C_{14}H_9N_2Cl_7O_4Pt$: calcd. C 23.58, H 1.26, N 3.93, Cl 34.83, Pt 27.38; found C 23.85, H 1.28, N 3.87, Cl 35.00, Pt 27.52. − FAB^+-MS, *m/z*: 643 $[M - 2Cl + H]^+$, 603 $[M - 3HCl]^+$. − M.p. 211 °C (dec.). − TLC, R_f = 0.62 (eluent acetone/ chloroform 1:2, v/v). − IR spectrum (KBr, selected bands): $\tilde{\nu}$ = 1655 w and 1635 w ν(C=N) and ν(C=C), 1187 m

ν(C−O), 357 m and 347 m ν(Pt−Cl) cm^{-1}. − ^1H NMR ([D$_6$]acetone): δ = 7.83 (d, J_{HH} = 2.7 Hz, 1 *H*, phenyl H), 8.47(d, J_{HH} = 2.7 Hz, 1 *H*, phenyl H), 9.03 [s + d, $^3J_{PtH}$ = 23.4 Hz, 1 *H*, = C(H)−, monodentate ligand], 7.76 (d, J_{HH} = 2.7 Hz, 1 *H*, phenyl H), 7.79 (d, J_{HH} = 2.7 Hz, 1 *H*, phenyl H), 8.64 [s + d, $^3J_{PtH}$ = 35.7 Hz, 1 H strong NOE to the signal at δ = 7.76, =C(H)−, bidentate ligand], 10.94 (br., OH). − $^{13}C\{^1H\}$ NMR ([D$_6$]acetone): δ = 131.0, 132.7, 135.8 and 136.0 (aromatic CH's), 149.1 (J_{PtC} = 28 Hz) and 151.4 (J_{PtC} not observed)(N=CH), 118.7 (J_{PtC} = 22 Hz), 119.8 (J_{PtC} = 25 Hz), 122.0, 123.5, 124.8, 125.6, 132.0 and 136.7 (quaternary C's). − ^{195}Pt NMR ([D$_6$]acetone): δ = +252 (440 Hz).

3,5,2-Cl,Cl,HOC$_6$H$_2$C(Cl)=NOH: This purely organic material was formed by the chlorination of a mixture of salicylaldoxime complexes, prepared in agreement with Cox et al.,[19] and was separated mechanically upon fractional crystallization of the products of the reaction from an acetone/toluene (3:1, v/v) mixture. Colorless needles. − $C_7H_4NCl_3O_2$: calcd. C 34.94, H 1.66, N 5.83, Cl 44.29; found C 34.45, H 2.10, N 5.65, Cl 45.10. − EI-MS, *m/z:* 241 $[M]^+$, 203 $[M - HCl]^+$. − M.p. 141 °C [vs. *ref.* m.p. 194−195 °C for 3,5-Cl,Cl-C$_6$H$_3$CH=NOH[21]). − TLC, R_f = 0.67 (eluent: chloroform). − IR (KBr, selected bands): $\tilde{\nu}$ = 3423 vs ν(O−H), 1651 mw and 1605 mw ν(C=N) and ν(C=C), 1180 m ν(C−O) cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 7.48 (d, 1 *H*, J_{HH} = 2.2 Hz), 7.76 (d, 1 *H*, J_{HH} = 2.6 Hz), 9.02 (s, 1 *H*, C−OH), 10.64 (s, 1 *H*, oximic OH). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 132.01 (CH), 127.34 (CH) quaternary carbons were not observed owing to the low solubility of the compound.

Chlorination of [Pt(*o*-OC$_6$H$_4$CH=NOH)$_2$] (1) by NOCl: Nitrosyl chloride was passed through a lemon-yellow solution of **1** (0.13 g, 0.28 mmol) in a mixture of CCl_4 (10 mL) and $CHCl_3$ (50 mL) for 20 min at 5 °C. A cherry-brown solution was formed and left to evaporate at 14−18 °C in an open 100-mL beaker to ca. 10 mL. Transparent, glittering rhombic-like brownish crystals of **4** were separated by filtration, washed with a Me_2CO/CCl_4 mixture (1:2, v/v, 3 × 3 mL), diethyl ether (3 × 3 mL), and dried at room temperature in a vacuum-desiccator over $CaCl_2$. Yield: 0.11 g, 73%.

***trans-(N,N)*-[PtCl$_2$(*o*-OC$_6$H$_4$CH=NOH)$_2$] (4):** − $C_{14}H_{12}N_2Cl_2O_4Pt$: calcd. C 31.24, H 2.25, N 5.20, Cl 13.17, Pt 36.24; found C 30.99, H 2.30, N 5.11, Cl 13.69, Pt 35.8. − FAB$^+$-MS, *m/z*: 538 $[M]^+$. − M.p. 149−152 °C (dec.). − IR (KBr, selected bands): $\tilde{\nu}$ = 1652 m ν(C=N), 1597 s ν(C=C), 912 s ν(N−O) cm^{-1}. − ^1H NMR ([D$_6$]DMSO): δ = 6.82 (t, J_{HH} = 7.7 Hz, 1 *H*), 7.29 (d, J_{HH} = 9.2 Hz, 1 *H*), 7.45 (t, J_{HH} = 7.2 Hz, 1 *H*), 7.56 (d, J_{HH} = 7.2 Hz, 1 *H* each *o*-phenyl H), 8.77 [s + d, $^3J_{PtH}$ = 34.8 Hz, 1 *H*, =C(H)−], 11.78 (s, br, 1 *H*, NOH). Solubility of the complex in [D$_6$]DMSO was insufficient to allow for the accumulation of either $^{13}C\{^1H\}$ or ^{195}Pt NMR spectra, even with long acquisition times.

X-ray Crystal Structure Determinations

(*i*) Dark yellow prismatic crystals of **1** were grown by the slow evaporation of a solution in CCl_4 at room temperature. Diffraction data were collected on an Enraf−Nonius CAD 4 diffractometer. Diffractometer data were processed by the program PROFIT,[25] with profile analysis of reflections. The structures were solved by means of Fourier synthesis based on the Pt-atom coordinates obtained from the Patterson synthesis using SHELXTL package.[26] All non-hydrogen atoms were treated anisotropically. H atoms were located in a difference Fourier map and refined isotropically. An extinction correction was applied. Lorentz, polarization and absorption corrections were made.[27]

(*ii*) Transparent, glittering rhombic-like brownish crystals of **3** were obtained directly from the reaction mixture. The crystallographic measurements were performed on an Enraf−Nonius CAD-4 CCD diffractometer using the technique described in ref.[28] The structure was solved by direct methods and refined anisotropically for non-hydrogen atoms and isotropically for H atoms using SHELXL-97.[29] Positions of hydrogen atoms bonded to carbons were calculated based on known atom geometry. These hydrogen atoms were allowed to ride on their neighboring carbons during the refinement.

Their thermal parameters were assigned the value of 1.2 times the initial equivalent isotropic thermal parameters of their neighboring carbons and were not refined. The oxime H atom was located by difference Fourier synthesis and refined with restraints to maintain the geometry derived from the difference map. Its thermal parameter was assigned the value of 1.5 times the initial equivalent isotropic thermal parameter of its neighboring oxygen and was not refined. The final *R*-value was 0.0389 for 1779 reflections with $I = 2\sigma(I)$.

(*iii*) Dark cherry-red prismatic crystals of **5** were obtained after the slow evaporation of a solution in acetone/toluene (3:1, v/v) in a long (150 mm) narrow (5 mm) tube. Diffraction data were collected on a Syntex $P2_1$ diffractometer. An extinction correction was not made. Before anisotropic refinement, an absorption correction was made using DIFABS[30] program. The contributions of hydrogen atoms were included at fixed calculated positions, based on geometrical requirements. All experimental data processing, solving and refinement were performed using the CSD[27] program. Crystal data for **1**, **3** and **5** are given in Table 3.

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-144573 (**1**), CCDC-144575 (**3**) and CCDC-144574 (**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Europium "Second Generation" Precursors for Metal-Organic Chemical Vapor Deposition: Characterization and Optical Spectroscopy

Graziella Malandrino,*[a] Marco Bettinelli,*[b] Adolfo Speghini,[b] and Ignazio Luciano Fragalà[a]

Keywords: Luminescence / Chemical vapor deposition / Europium / Polyether adducts

The novel complex precursor $Eu(hfa)_3$·monoglyme and the analogous $Eu(hfa)_3$·diglyme [Hhfa = 1,1,1,5,5,5-hexafluoroacetylacetone, monoglyme = $CH_3OCH_2CH_2OCH_3$, diglyme = $CH_3O(CH_2CH_2O)_2CH_3$] have been synthesized in a single step reaction and characterized by elemental analysis, mass spectrometry, and IR and Raman spectroscopy. Thermogravimetric data and the linear evaporation behavior have shown that both complexes are thermally stable and can be evaporated to leave less than 4% residue. Luminescence spectra in the visible region provided evidence of a remarkable covalent character of the metal-ligand bonding in both complexes with the distortion of the coordination sphere around the europium(III) ion in $Eu(hfa)_3$·monoglyme greater than that in $Eu(hfa)_3$·diglyme. DSC measurements and variable temperature luminescence spectra have shown the presence of a structural transition at 71.4 °C from a solid to a plastic phase for $Eu(hfa)_3$·diglyme.

Introduction

Several efforts have recently been devoted to the design of novel lanthanide complexes with suitable mass transport properties for metal-organic chemical vapor deposition (MOCVD) applications.[1−4] This is due to the severe drawbacks of first generation MOCVD precursor complexes, i.e. their thermal instability, reactivity with oxygen, low volatility, and high residues left upon sublimation. In addition, their use as precursors for MOCVD deposition of LnF_3 and LnOF requires the use of an additional fluorine source.[5]

Conversely, the polyether adducts of lanthanide fluorinated β-diketonates[6−14] exhibit improved properties in terms of thermal stability and volatility, thus representing a class of novel second-generation precursors that has been successfully applied to the MOCVD fabrication of various materials.[7,8,14−17] These adducts represent single-source precursors for the MOCVD fabrication of LnF_3 and LnOF (Ln = La, Gd) phases[7,8,17] which are challenging host matrices for different applications such as X-ray storage phosphors, laser materials, and optical waveguides.

In this context, MOCVD techniques offer several advantages[18] over classical physical techniques and are well suited for depositing good quality films even for those applications where high performances are required as, for example, the deposition of epitaxial Pr-doped BaF_2 on a CaF_2 substrate for optical waveguide applications.[19]

Herein, we report the synthesis, physicochemical characterization, and mass transport properties of the novel europium MOCVD precursor $Eu(hfa)_3$·monoglyme [Hhfa = 1,1,1,5,5,5-hexafluoroacetylacetone, monoglyme = $CH_3OCH_2CH_2OCH_3$]. We also report a viable and safer route (than that already proposed[20]) to the analogue $Eu(hfa)_3$·diglyme [diglyme = $CH_3O(CH_2CH_2O)_2CH_3$]. The europium(III) ion has been chosen among the trivalent lanthanide ions due to its intense luminescence in the visible region that opens up several opportunities for technological applications and represents an important tool to study both the coordination geometry and the coupling with the surrounding vibrations.[21] In addition, the laser-excited and vibrational Raman spectroscopy of these adducts are discussed and compared with the Gd analogues.[7]

Results and Discussion

Synthesis

The $Eu(hfa)_3$·L adducts have been prepared through a one-pot reaction from europium oxide, hexafluoroacetylacetone and the polyether in hexane [Equation (1)]:

$$1/2Eu_2O_3 + 3Hhfa + L \rightarrow Eu(hfa)_3\cdot L + 3/2H_2O \quad (1)$$

The slight excess of europium oxide favors the isolation of the product since the insoluble unreacted Eu_2O_3 may be easily filtered off. In contrast with the previously reported procedures for the analogous lanthanum precursors[6] as well as for $Eu(hfa)_3$·diglyme,[20] the present methodology avoids the use of carcinogenic benzene. It is worth noting that the present $Eu(hfa)_3$·monoglyme adduct, at variance with the $La(hfa)_3$·monoglyme·H_2O homologue, is water-free. This is clearly due to the smaller ionic radius of the europium(III) ion, which enables the monoglyme ligand to saturate the coordination sphere, thus preventing any water coordination.

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0404−1039 $ 17.50+.50/0

The present adducts are very soluble in common organic solvents such as ethanol, chloroform, acetone, pentane, toluene and slightly soluble in cyclohexane. Both adducts have low melting points and sublime quantitatively at low temperature under vacuum. They are nonhygroscopic and can be handled in air.

Infrared Spectra

The IR spectra of the crude and sublimed $Eu(hfa)_3$·polyether adducts show identical features. The absence of any bands around 3600 cm^{-1} in the spectra of **1** and **2** is indicative of H_2O-free species. All the spectra show singular absorption bands around 1650 cm^{-1}, due to C=O stretching vibrations, and at 1520 cm^{-1}, due to the C=C stretching vibrations. The other bands, observed at 1100−1300 cm^{-1}, represent C−O bending and/or stretching of the polyether ligand overlapping with the C−F stretching frequencies. Peaks around 860 and 1050 cm^{-1} are indicative of glyme coordination to the europium hexafluoroacetylacetonate moiety.[8]

Raman Spectra

The room temperature vibrational Raman spectra of pelletized powders of **1** and **2** and of the corresponding gadolinium analogues are virtually identical for wavenumbers lower than 1500 cm^{-1}. As a representative example, we show in Figure 1 the Raman spectrum of **2**.

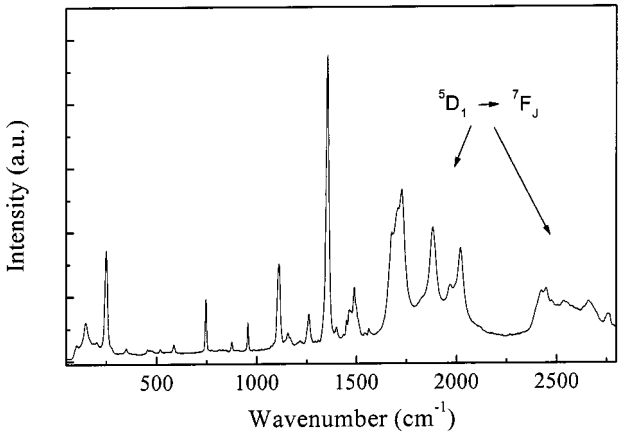

Figure 1. Room temperature Raman spectrum of **2** (λ_{EXC} = 488.0 nm)

The prominent peak at about 1350 cm^{-1} is assigned to vibrations involving the -CF_3 grouping, whilst the bands close to 1500 cm^{-1} are assigned to modes involving -CH_2- deformations.[22] The sharp peak at 250 cm^{-1} is due to a metal-oxygen vibration.[23] In the case of the spectra of the europium(III) compounds **1** and **2**, additional peaks are present in the 1500−3000 cm^{-1} spectral region which are missing in the corresponding spectra of the gadolinium analogues. These features are assigned to electronic emission transitions from the $^5D_1$ excited state to the ^7F_J ground multiplet of europium(III), as they are not observed in the Raman spectrum of the isostructural gadolinium complex, and on the basis of the energy level structure of europium(III) ion, as already observed for different hosts.[24]

Thermogravimetric and Calorimetric Data

The thermal behavior of the raw adducts **1** and **2** has been studied by thermal gravimetric analysis (TG), and differential scanning calorimetry (DSC) under N_2. The TG curves of **1** and **2** show singular sublimation steps (Figure 2) in the 100−246 °C (residue = 3% to 290 °C) and 113−255 °C (residue = 2% to 260 °C) temperature ranges, respectively.

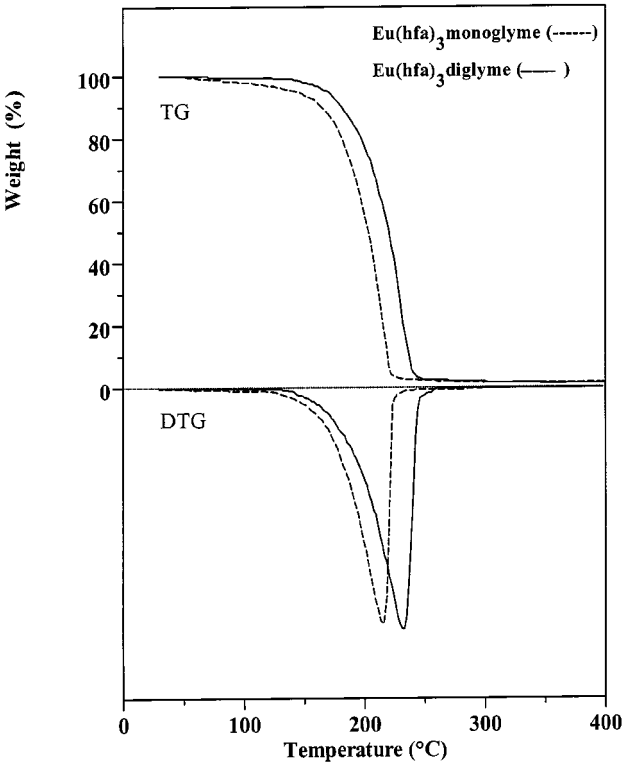

Figure 2. TG-DTG curves of adducts **1** and **2**

The linear behavior of the TG atmospheric pressure vaporization rates (Figure 3) of adducts **1** and **2** indicate that both adducts are thermally stable and, therefore, represent interesting precursors for MOCVD applications.

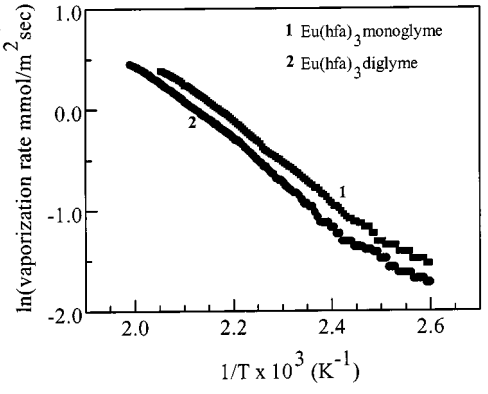

Figure 3. DSC curves of adducts **1** and **2**

The DSC curves of $Eu(hfa)_3$·L adducts are reported in Figure 4. Adduct **1** shows a sharp melting point at 81.2 °C (9.14 cal/g), in good agreement with that observed with a Koffler Microscope (80−82 °C). Evaporation from the melt occurs afterwards. The DSC curve of the diglyme adduct **2** shows some interesting features. Two sharp endothermic peaks are observed at 71.4 °C (9.26 cal/g) and 122.0 °C (1.04 cal/g). Several consecutive heating and cooling DSC experiments in the 30−150 °C temperature range have shown the disappearance of the first peak after the first cycle. The second peak, in contrast, remains unchanged in terms of both the temperature and the ΔH associated with the process. The peak at 71.4 °C again becomes evident after standing for several hours at room temperature. This endothermic process represents a "thermal anomaly"[25] and may be associated with a transition from the solid to a plastic phase.[9] The second peak is associated with the complete melting. This conclusion agrees well with the optical microscopy observations upon heating, which show the disappearance of the crystal color at 73−76 °C and complete melting at 123−126 °C.

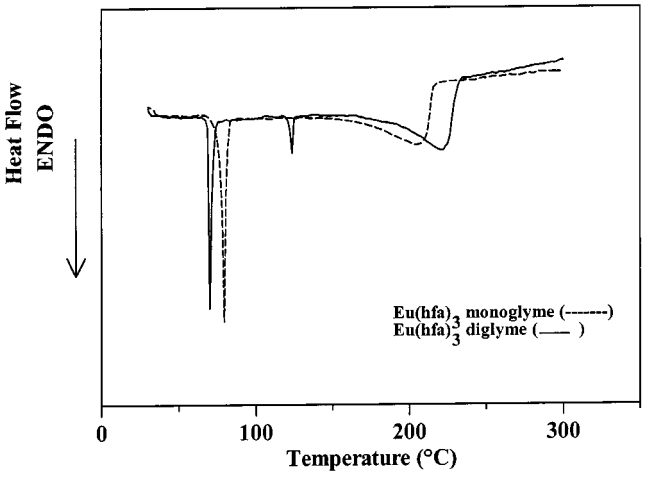

Figure 4. Atmospheric pressure TG vaporization rate data of adducts **1** and **2** as a function of the temperature

Finally, it is interesting to remark that the DSC features of **1** and **2** are almost identical to those of the Gd homologues. Note that both the Eu[20] and Gd[7] diglyme adducts, in fact, have identical crystal structures within the same space group and almost identical unit-cell dimensions (0.01 Å difference between corresponding cell parameters).

Mass Spectra

The FAB spectra of adducts **1** and **2** show peaks due to the loss of both the hfa ligand and the polyether (see Table 1).

Peaks arising from the characteristic fluorine transfer process, already found in the spectra of the alkaline earth[26] and analogous lanthanide[7,8] β-diketonate polyether adducts, are also observed. The observed MS peaks are associated with $[Eu(hfa)_2$·polyether$]^+$, $[Eu(hfa)$·polyether + $F]^+$, $[Eu(hfa)_2]^+$, $[Eu(hfa) + F]^+$, $[Eu$·polyether + $2F]^+$ and $[EuF_2]^+$ fragments. No molecular ion peaks or peaks at higher mass have been observed, in agreement with the monomeric nature of the complexes.

Table 1. Major peaks in the mass spectra of adducts **1** and **2**; the given *m*/*z* ratios are related to the isotope ^{153}Eu

Assignment	$Eu(hfa)_3$·monoglyme	$Eu(hfa)_3$·diglyme
$[Eu(hfa)_2$·L$]^+$	657 (100%)	701 (100%)
$[Eu(hfa)$·L + F$]^+$	469 (28%)	513 (19%)
$[Eu(hfa)$·L$]^+$	450 (15%)	494 (36%)
$[Eu(hfa)$ + F$]^+$	379 (11%)	379 (<5%)
$[Eu(hfa)]^+$	360 (75%)	360 (21%)
$[Eu$·L + 2F$]^+$	281 (12%)	325 (11%)
$[Eu$·L + F$]^+$	262 (<5%)	306 (9%)

Luminescence Spectra

The room-temperature, laser-excited luminescence spectra of powders of **1** and **2**, measured with an excitation wavelength of 488.0 nm, consist of $f \rightarrow f$ emission transitions from the $^5D_0$ excited state to the ^7F_J multiplet of the europium(III) ion. The $^5D_0 \rightarrow {}^7F_0$ transition cannot be split by the crystal field and its profile gives information on the number of different coordination sites accommodating the europium(III) ion. The presence of a single band in the high resolution luminescence spectra of both **1** and **2** indicates that the europium(III) ion occupies a single site in both compounds. In the case of **2**, this observation agrees well with the X-ray single-crystal structure reported by Kang et al.,[20] in which only one europium(III) site is present, as well as with the crystal structure of the isostructural gadolinium(III) compound.[7]

The peak position of the $^5D_0 \rightarrow {}^7F_0$ transition is related to the nephelauxetic effect and to the covalency of the europium(III)−ligand bond.[27] In both **1** and **2** the $^5D_0 \rightarrow {}^7F_0$ maxima are located in the "covalent" region of the nephelauxetic scale,[27,28] but in the case of **1** the $^5D_0 \rightarrow {}^7F_0$ peak occurs at a longer wavelength than in **2** (see Table 2). This is indicative of a greater europium(III)-ligand covalency in the former.

The ratio of the integrated intensities of the $^5D_0 \rightarrow {}^7F_2$ and $^5D_0 \rightarrow {}^7F_1$ transitions [Equation (2)] can be considered indicative of the asymmetry of the coordination polyhedron of the europium(III) ion[29] and can thus be used to compare the degree of distortion in complexes having similar ligand arrays. The rather high R value (6.6) of **2** points to a distorted first coordination sphere around the europium(III) ion (point symmetry C_1), as found in the crystal structure determination.[20] In the case of **1**, whose crystal structure is not known, the even higher R value (11.0) is indication of a very asymmetric europium(III) site.

$$R = \frac{I(^5D_0 \rightarrow {}^7F_2)}{I(^5D_0 \rightarrow {}^7F_1)}$$

The overall crystal field (CF) splitting values associated with the $^7F_1$ state are reported in Table 2. The smaller crystal field splitting observed in **1** can be correlated to a smaller (than in **2**) europium(III) coordination number. In fact, the crystal data of $Eu(hfa)_3$·diglyme[20] point to a coor-

Table 2. Measured intensity ratios R, peak luminescence wavelengths λ_{max} of the $^5D_0 \rightarrow {}^7F_0$ transition, crystal field splittings of the $^7F_1$ state and lifetimes τ of the $^5D_0$ excited state of europium(III) for the two compounds under investigation

Compound	R	$\lambda_{max}(^5D_0 \rightarrow {}^7F_0)$/nm	CF splitting ($^7F_1$)/cm^{-1}	$\tau(^5D_0)$/ms
Eu(hfa)$_3$·monoglyme	11.0	579.9	251	0.93
Eu(hfa)$_3$·diglyme	6.6	579.4	292	0.96

dination number of nine for the europium(III) ion, while an eight-coordinate environment can be assumed for **1**, with both hfa and monoglyme acting as bidentate ligands, since no water molecules are coordinated to the metal ion.

The luminescence excitation spectra of both **1** and **2**, associated with the $^5D_0 \rightarrow {}^7F_2$ transition, consist of sharp $f \rightarrow f$ transitions for wavelengths higher than 450 nm, and of a broad band peaking at about 400 nm (Figure 5). The latter feature is assigned to an Eu−O ligand-to-metal charge transfer transition[30] since both polyether and hfa ligands do not show absorption bands in this spectral region.

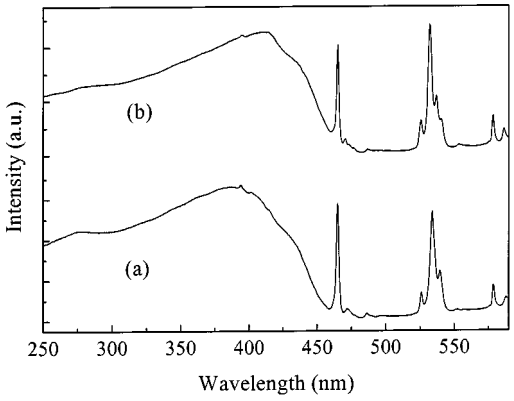

Figure 5. Room temperature excitation spectra of adducts **1** (a) and **2** (b)

Inspection of the high resolution, room-temperature luminescence spectrum (Figure 6) shows that a weak structure is located in both the high- and low-energy sides of the $^5D_0 \rightarrow {}^7F_0$ pure electronic transition. These features are assigned to vibronic sidebands due to coupling between the $^5D_0 \rightarrow {}^7F_0$ electronic transition and the vibrational modes involving the europium(III) ion.[31,32] Vibronic sidebands have often been observed in the luminescence and excitation spectra of europium(III)-doped crystalline and noncrystalline solids.[33,34] Less frequently they have also been observed in the spectra of europium(III) coordination compounds.[35] In general, vibronic sidebands mainly relative to the $^5D_0 \rightleftarrows {}^7F_2$ transition have usually been studied.[36]

The maxima in the vibronic sideband at lower energy are located about 80, 150 and 250 cm^{-1} from the pure electronic line in the case of **1,** and 80, 140, 185 and 250 cm^{-1} in the case of **2**. These differences are assigned to the wavenumbers of vibrational modes coupled to the europium(III) electronic transitions and, therefore, localized close to the metal ion. The vibrations are assigned to Eu−O modes, due to their small wavenumber values. In particular, the maximum at 250 cm^{-1} agrees with the presently proposed assignment of the Raman band at the same frequency to the

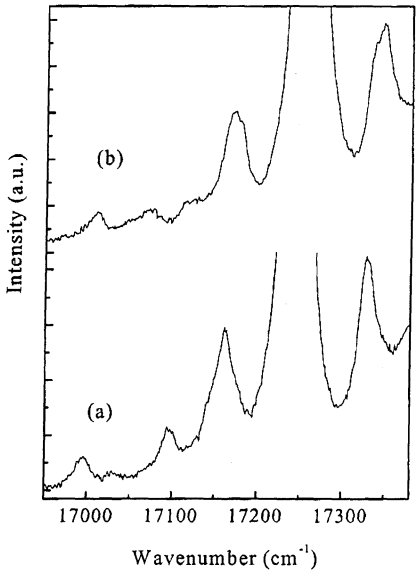

Figure 6. Room temperature luminescence spectra of adducts **1** (a) and **2** (b)

Eu−O stretching mode (vide supra). The other modes observed in the vibronic sideband probably represent other stretching and bending modes at the europium(III) center.

The luminescence decay curves from the europium(III) $^5D_0$ state in **1** and **2**, measured at room temperature, with excitation and observation wavelengths of 395.0 and 613.0 nm, respectively, are perfectly exponential for about three decades. The associated lifetimes of the $^5D_0$ state [$\tau(^5D_0)$, Table 2] are relatively short for europium(III) compounds (<1 ms), but compatible with both the high intensity of the hypersensitive $^5D_0 \rightarrow {}^7F_2$ emission transition and the presence of high frequency vibrations in the complexes. The exponential decays, in addition, are indicative that energy transfer and migration processes are probably inefficient in these compounds due to the rather long distance [8.047 Å in the gadolinium(III) homologue of **2**][37] between neighboring metal centers in the crystals.

The nature of the "thermal anomaly" observed at 71.4 °C in the DSC curves of **2** has been also investigated by low resolution luminescence spectra in the temperature range 20−90 °C. The experimental data show that the spectra do not change significantly for temperatures up to about 80 °C. Beyond this temperature, the intensities of the $^5D_0 \rightarrow {}^7F_2$ and $^5D_0 \rightarrow {}^7F_0$ emission transitions increase abruptly, compared to the magnetic dipole $^5D_0 \rightarrow {}^7F_1$ transition, so that the asymmetry ratio *R* approaches the value of 12 at 90° C. This clearly indicates that beyond 80 °C the first coordination sphere of the europium(III) ion undergoes a marked distortion, possibly due to the transition to a plastic phase.

We note that the *R* value associated with **2** in the plastic phase lies close to that found for **1** in the solid phase. Therefore, it is possible that packing constraints force the coordination geometry of europium(III) in the solid phase of **2** to be more symmetrical than in the plastic phase.

MOCVD Depositions

Preliminary MOCVD experiments indicate that both adducts are well suited for the deposition of europium-containing films. In particular, the diglyme adduct has been successfully applied to Eu−O−F film deposition. A typical X-ray glancing incidence diffraction (GID) pattern of an Eu−O−F film deposited at 700 °C on quartz substrate is shown in Figure 7. Reflections point to the formation of two different polycrystalline oxyfluoride phases, the orthorhombic $Eu_6O_5F_8$ [38] and the rhombohedral EuOF.[39] The observed intensities are different from those reported for a polycrystalline powder, thus suggesting that some texturing occurs upon growth. An SEM micrograph of an Eu−O−F film deposited at 700 °C is reported in Figure 8. The image shows a very homogeneous surface with ≈1 μm diameter grains uniformly distributed.

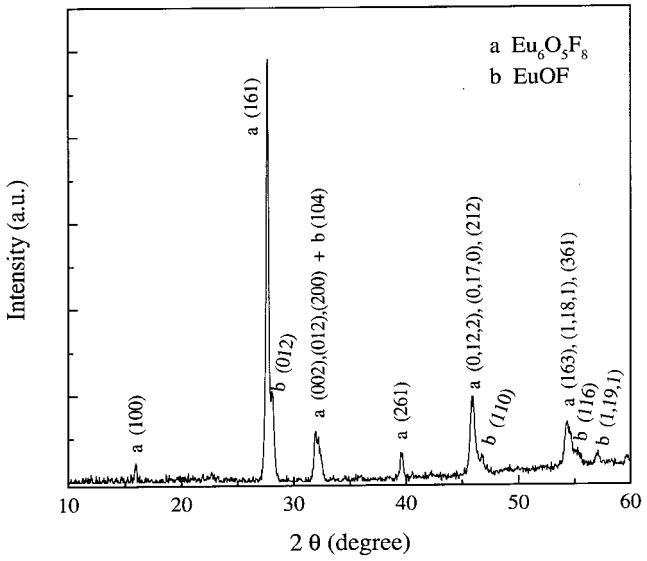

Figure 7. X-ray GID pattern of an MOCVD grown Eu−O−F film on a quartz substrate using the $Eu(hfa)_3$·diglyme precursor

Conclusions

The optical spectroscopy of the two $Eu(hfa)_3$·monoglyme and $Eu(hfa)_3$·diglyme adducts has been studied. The experimental results have provided information on the distortion of the coordination sphere around the lanthanide ion, on the covalence of the metal-ligand bond and on the coupling between electronic transitions and vibrational modes involving the europium(III) ion. Luminescence spectroscopy data have also been used to complement the DSC data of $Eu(hfa)_3$·diglyme in order to understand the nature of the phase transition at 71.4 °C.

There is evidence that the present $Eu(hfa)_3$·monoglyme and $Eu(hfa)_3$·diglyme adducts are thermally stable, highly volatile compounds that can be used even in atmospheric-pressure MOCVD deposition at temperatures lower than 200 °C. Low melting points allow their use as thermally stable precursors in the liquid phase, hence under constant vaporization and mass transport rates. Finally, both adducts **1** and **2**, analogously to the $La(hfa)_3$·diglyme precursor,[16] could act as liquid solvents for a large variety of metal precursors of relevance for MOCVD applicability, thus providing liquid multi-element single-sources for simultaneous delivery of different metal components in the required stoichiometries.

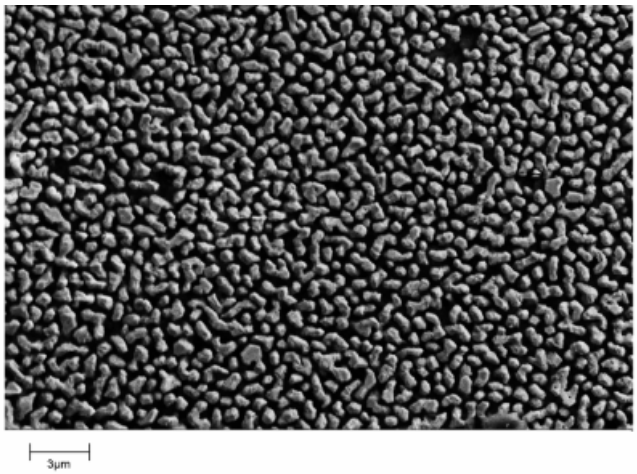

Figure 8. SEM micrograph of an MOCVD grown Eu−O−F film on a quartz substrate using the $Eu(hfa)_3$·diglyme precursor

Their vapor-phase transport characteristics at low- and atmospheric pressure make them attractive candidates not only for laboratory MOCVD processes but also for industrial applications.

Experimental Section

Reagents: Commercial Eu_2O_3, Hhfa, monoglyme, and diglyme (Aldrich) were used without any further purification.

General Procedures: Elemental microanalyses were performed in the Analytical Laboratories of the University of Catania. Infrared data were collected on a 684 Perkin−Elmer spectrometer either as nujol or hexachlorobutadiene mulls between KBr plates. Thermal measurements were made using a Mettler 3000 system equipped with a TG 50 thermobalance, a TC 10 processor and DSC 30 calorimeter. Weights of the samples were between 15−20 mg (TGA) and 4−10 mg (DSC). Analyses were made under prepurified nitrogen using a 5 °C/min heating rate. FAB mass spectra were obtained with a Kratos MS 50 spectrometer. The 488.0 nm line of a Spectra-Physics 2017 Argon laser was used to excite room temperature luminescence and Raman spectra. A fiber optic probe coupled to a Dilor Superhead, equipped with a suitable notch filter, was employed. The scattered signal was analyzed by a Jobin-Yvon HR460 monochromator and a Spectrum One CCD detector. A 1200 lines/mm grating was used to collect Raman and high resolution (≈2 cm^{-1}) luminescence spectra in the region of the $^5D_0 \rightarrow {}^7F_0$ transition of europium(III), whilst the other laser-excited luminescence spectra were measured using a 150 lines/mm grating. Low resolution emission and excitation spectra in the visible and UV regions were measured in the temperature range 20−90 °C using a JASCO FP-

777 spectrofluorimeter (bandwidths of 1.5 nm for both excitation and emission) and a conventional circulation thermostat. The decay curves of the luminescence were measured at room temperature using a Perkin−Elmer LS50 pulsed lamp spectrofluorimeter.

Synthesis of $Eu(hfa)_3$·monoglyme (1): The adduct was synthesized adopting a synthetic strategy analogous to that previously reported for the Gd analogue.[7] Eu_2O_3 (2.035 g, 5.78 mmol) was first suspended in hexane (200 mL) and then monoglyme (1.040 g, 11.56 mmol) was added to the suspension. Hhfa (7.217 g, 34.69 mmol) was added under vigorous stirring after 10 min. and the mixture was refluxed under stirring for 1 hour. The excess of europium oxide was then filtered off. Pale yellow crystals precipitated after partial evaporation of the solvent. The crystals were collected by filtration and dried under vacuum. The yield was 8.589 g (86%). The melting point of the crude product was 80−84 °C. − $C_{19}H_{13}EuF_{18}O_8$ (863.23): calcd. C 26.41, H 1.52; found C 26.52, H 1.47. The adduct quantitatively sublimes at 75−80 °C/10^{-3} Torr. − IR (nujol or hexachlorobutadiene): $\tilde{\nu}$ = 3620 (w), 3540 (w), 2930 (vs), 1660 (vs), 1610 (w), 1570 (m), 1540 (m), 1495 (s), 1455 (s), 1380 (m), 1350 (vw), 1260 (s), 1200 (s), 1150 (s), 1100 (m), 1060 (s), 1030 (w), 1010 (vw), 950 (w), 860 (m), 805 (m), 770 (w), 740 (w), 660 (s) cm^{-1}. The MS and IR data of the raw[40] and sublimed adduct are identical.

Synthesis of $Eu(hfa)_3$·diglyme (2): Prepared as described for the monoglyme adduct from Eu_2O_3 (1.956 g, 5.56 mmol), Hhfa (6.939 g, 33.36 mmol) and diglyme (1.489 g, 11.11 mmol). Yield 9.180 g (91%). The "apparent" melting point of the crude product was 72−74 °C (vide infra the DSC data). − $C_{21}H_{17}EuF_{18}O_9$ (907.28): calcd. C 27.77, H 1.89; found C 27.94, H 1.92. The adduct quantitatively sublimes at 85−90 °C/10^{-3} Torr. − IR (nujol or hexachlorobutadiene): $\tilde{\nu}$ = 2930 (s), 1650 (vs), 1605 (w), 1555 (m), 1530 (m), 1495 (s), 1460 (s), 1380 (m), 1350 (w), 1260 (s), 1205 (s), 1140 (s), 1090 (s), 1065 (m), 1045 (s), 1010 (m), 945 (m), 870 (m), 835 (vw), 800 (m), 770 (w), 740 (m), 650 (s) cm^{-1}. The MS and IR data of the raw and sublimed adduct are identical.

MOCVD Experiments: Low-pressure MOCVD depositions of Eu−O−F films were carried out under O_2 (500 sccm) flow as carrier and reaction gas, using a horizontal hot-wall reactor. The $Eu(hfa)_3$·diglyme source temperature was maintained at 120 °C. Quartz slides were used as substrates in the 600−700 °C temperature range. Scanning Electron Microscopy (SEM) micrographs were recorded using a LEO IRIDIUM 1450 Electron Microscope. X-ray glancing incidence diffraction (GID) patterns were recorded on a Bruker-AXS D5005 θ-θ X-ray diffractometer equipped with a Goebel mirror and a thin film attachment using Cu-K_α radiation operating at 40KV/ 30 mA.

Synthesis and Magnetic Properties of a Polymeric Nitridochromium(V) Complex with a Tetradentate Schiff Base Ligand

Masanobu Tsuchimoto,*[a] Naoki Yoshioka,*[b] and Shigeru Ohba[a]

Keywords: Nitrides / Chromium / Polymers / Schiff bases / Magnetic properties

A novel polymeric nitridochromium(V) complex with a Schiff base ligand [CrN(salpn)] [H_2(salpn) = *N,N′*-disalicylidene-1,3-propanediamine] was prepared by photolysis of an azidochromium(III) complex in acetonitrile. X-ray crystal structure analyses of the starting material $\{(CH_3)_2NH_2\}_2[CrCl_2(salpn)]Cl$ (**1**) and the polymeric complex [CrN(salpn)] (**3**) were carried out. The orange complex **3** has a linear ···Cr≡N···Cr≡N··· chain structure with the N···Cr distance being 2.508(2) Å. Magnetic data show that **3** has a ferromagnetic intermolecular interaction in the chains (J = +8.4 cm^{-1}).

Introduction

The synthesis of new linear-chain polynuclear metal complexes is important because of their physical properties (e.g. magnetism and electric conductivity) and structural characteristics. Several oxovanadium(IV) complexes with tetradentate Schiff base ligands, such as [VO(salpn)] (H_2salpn = *N,N′*-disalicylidene-1,3-propanediamine), have linear-chain structures (···V=O···V=O···) in the solid state.[1] It has been reported that these polymeric oxovanadium(IV) complexes with a $(d_{xy})^1$ electron configuration (z axis oriented along the V=O bond) have an intermolecular ferromagnetic interaction in the chains with an exchange coupling parameter, $J \approx +5$ cm^{-1}.[2,3] The occurrence of a ferromagnetic interaction for these complexes has been explained in terms of McConnell's spin polarization theorem.[2]

Recently, the preparation of a polymeric nitridomanganese(V) complex [MnN(salpn)], by photoirradiation of an azidomanganese(III) complex has been reported.[4] The diamagnetic polymeric nitridomanganese(V) complex with a $(d_{xy})^2$ electron configuration has ···Mn≡N···Mn≡N··· chains in the crystal. This result led us to prepare a polymeric nitridochromium(V) complex with a $(d_{xy})^1$ electron configuration. All the polymeric nitridometal complexes (···M≡N···M≡N···) reported so far are diamagnetic with a d^0 (V^V,[5,6] Mo^{VI},[7] W^{VI},[8] Re^{VII} [9]) or a d^2 (Mn^V [4]) electron configuration. This paper reports the first preparation and crystal structure of a polymeric nitridochromium(V) complex [CrN(salpn)]. The temperature dependence of magnetic susceptibilities and low-temperature magnetization experiments are also reported.

Results and Discussion

Synthesis

The starting chromium(III) complex $\{(CH_3)_2NH_2\}_2$-$[CrCl_2(salpn)]Cl$ (**1**) was prepared by the reaction of the Schiff base ligand with anhydrous chromium(III) chloride in DMF.[10] The dimethylammonium cation in **1** originates from the decomposition of DMF. The azidochromium(III) complex $(CH_3)_2NH_2[Cr(N_3)_2(salpn)]$ (**2**) was prepared by the reaction of **1** with sodium azide in acetone. The nitridochromium(V) complex [CrN(salpn)] (**3**) was prepared by photoirradiation of **2** in acetonitrile. The orange complex **3** is stable in air at ambient temperature. The IR spectrum of **3** shows the Cr≡N stretching bands at 956 and 961 cm^{-1}, which are significantly shifted to lower energy than that of monomeric [CrN(salen)] (1012 cm^{-1}).[11] The electronic spectrum of **3** in acetonitrile shows a d−d transition band around 569 nm as a shoulder. This d−d band is assigned to the $3d_{yz,zx} \leftarrow 3d_{xy}$ transition, which is observed at 535 nm in the spectrum of [CrN(salen)].[12]

X-ray Crystal Structures

X-ray structure analyses of **1** and **3** were carried out. The molecular structures of **1** and **3** are shown in Figure 1 and 2, respectively. Selected bond lengths and angles are listed in Table 1 and 2, respectively.

Complex **1** has an octahedral structure with the chloro ligands in the *trans* position. The dimethylammonium cations are hydrogen bonded to the oxygen atoms of the ligand and the chloride ion [Figure 1(b)]. The distances N26···O4, N26···O5, N27···O4, N27···O5 are in the range 2.972(2)−3.151(2) Å, and the distances N26···Cl25 and N27···Cl25 are 3.140(2) Å and 3.151(2) Å, respectively. Prismatic crystals of **1** show dichroism; the (1 −1 0), (−1 1 0),

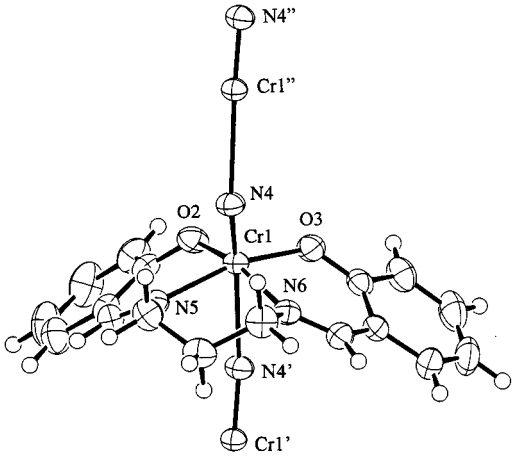

Figure 2. ORTEP drawing of **3** with 50% probability ellipsoids

(−1 0 1), (1 0 −1) planes are green, and the (1 1 0), (−1 −1 0) planes are brown.

Complex **3** has a polymeric structure with a distorted octahedral coordination geometry. The linear ···Cr≡N···Cr≡N··· chains run along the 2_1 screw axes parallel to the *c* axis. The Cr≡N and Cr···N distances are 1.559(2) Å and 2.508(2) Å, respectively. The Cr≡N···Cr angle is 153.7(1)°. The Cr1 atom is displaced by 0.321(1) Å from the N_2O_2 coordination plane. The six-membered N−N chelate ring shows a chair conformation. The crystal

structure of **3** is isostructural with that of polymeric [MnN(salpn)], whose Mn≡N and Mn···N distances are 1.520(3) Å and 2.528(3) Å, respectively.[4] On the other hand, the V···O distance in polymeric [VO(salpn)] [2.213(9) Å][1] is shorter than the Cr···N distance in **3**. The V=O units in [VO(salpn)] are more strongly bonded to each other than the Cr≡N units in **3**.

Magnetic Properties

The ESR spectrum of **3** in benzene at room temperature is shown in Figure 3. The spectrum shows a strong isotropic ESR signal due to the chromium isotope with $I = 0$ at $g_{iso} = 1.978$, with a satellite quartet pattern ascribed to the less-abundant (9.5%) ^{53}Cr isotope with $I = 3/2$. The central strong signal and low-field satellite signals show a well-resolved septet superhyperfine structure [$A(N) = 0.26$ mT] with an intensity ratio of 1:3:6:7:6:3:1 due to three equivalent nitrogen nuclei, two from the salpn ligand and one

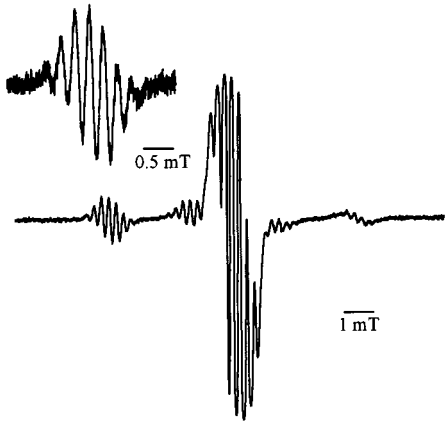

Figure 3. ESR spectrum of **3** in benzene at room temperature

from the apical nitrido atom. A similar extent of the Fermi-contact interaction occurs for the three nitrogen nuclei, despite their chemical nonequivalence. The equivalent isotropic superhyperfine coupling constants for the apical nitrido atom and the basal nitrogen atom are observed for [CrN(salen)][12] and other nitridochromium(V) complexes with tetradentate ligands.[13–15] The superhyperfine coupling constant (0.26 mT) in the spectrum of [CrN(salpn)] corresponds to a spin density of 0.005 on each nitrogen, based on the value of an isolated nitrogen atom (55.7 mT).[16]

The magnetic susceptibility data for **3**, plotted as the thermal variation of reciprocal molar susceptibility χ_m^{-1}, and $\chi_m T$, are shown in Figure 4 and 5, respectively. The behavior of the χ_m^{-1} vs. T plots in Figure 4 is well described by the Curie-Weiss law, $\chi_m = C/(T - \theta)$, with $C = 0.367$ emu K/mol and $\theta = +5.9$ K above 14 K. The positive θ value indicates the ferromagnetic interaction between the nitridochromium(V) spin centers. The overall appearance of the $\chi_m T$ vs. T plots in Figure 5 also indicates a ferromagnetic interaction. Although the $\chi_m T$ plots at 5000 G (represented as circles) show saturation below 5 K, the $\chi_m T$ value at 200 G (represented as triangles) increases even near $T =$ 1.8 K. The magnetic susceptibility data can be analyzed using the Heisenberg model with the exchange interaction between the nitridochromium(V) ion on a chain [Equation (1)].

$$H = -J\sum_{i=1}^{n-1} S_i \cdot S_{i+1} \tag{1}$$

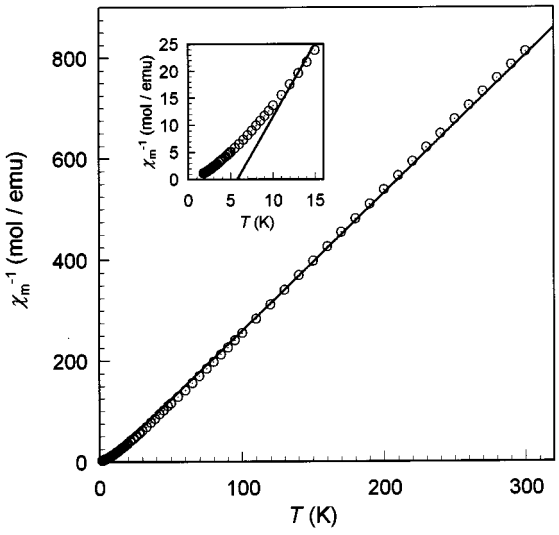

Figure 4. χ_m^{-1} vs. T (○) plot of **3**; the inset shows the χ_m^{-1} vs. T plot in the low-temperature region; the solid lines were calculated from the Curie-Weiss law

The thermal variation of magnetic susceptibility of a magnetic chain can be described by the empirical function introduced by Baker et al. [Equation (2)].[17]

$$\chi_m = \frac{N_A g^2 \beta^2}{kT} F(J,T)$$

with

$$F(J,T) = \frac{1}{4}[(1 + 5.7979916x + 16.902653x^2 + 29.376885x^3 + 29.832959x^4 + 14.036918x^5)/(1 + 2.7979916x + 7.0086780x^2 + 8.6538644x^3 + 4.5743114x^4)]^{2/3} \tag{2}$$

and

$$x = \frac{J}{2kT}$$

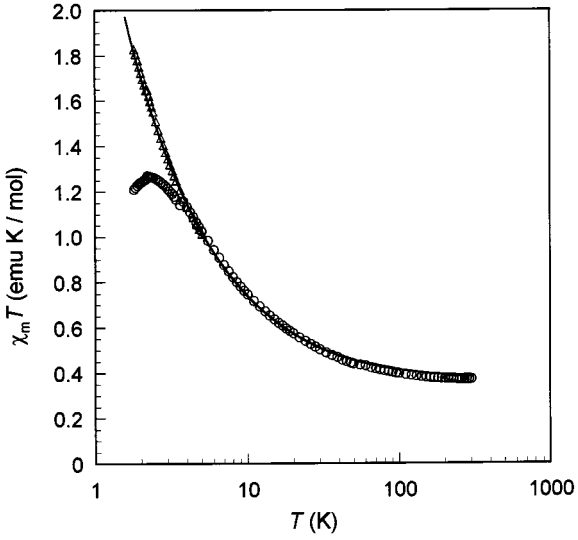

Figure 5. $\chi_m T$ vs. T plots of **3** under an applied field of 0.02 T (△) and 0.50 T (○)

The best-fit curve using Equation (2) is shown as a solid line in Figure 5, corresponding to $J = +8.4$ cm^{-1}. To clarify the intermolecular coupling, the magnetization of **3** was measured at 1.8 K (Figure 6). The magnetization curve of **3** exceeds the Brillouin function with $S = 1/2$ and nearly coincides with that of $S = 12/2$ at 1.8 K, indicating the formation of a high-spin cluster with $S = 12/2$ on average.

According to the McConnell theorem,[18] the exchange interaction between two aromatic radicals A and B can be described by the sum of the two-center exchange integrals in the form

$$H^{AB} = -S^A \cdot S^B \sum_{ij} J_{ij}^{AB} \rho_i^A \rho_j^B \tag{3}$$

where S^A and S^B are the total spin operators for molecules A and B, respectively, and ρ_i^A and ρ_j^B are the π-spin densities on atoms i and j of A and B, respectively. If we apply Equation (3) to a dimer of nitridochromium(V) units (each is denoted as A and B) in **3**, and consider that i and j correspond to the chromium(V) ion and the nitrido ion, respectively, Equation (3) can be written in the form

$$H^{AB} = -S^A \cdot S^B J_{Cr\cdots N}^{AB} \rho_{Cr}^A \rho_N^B \tag{4}$$

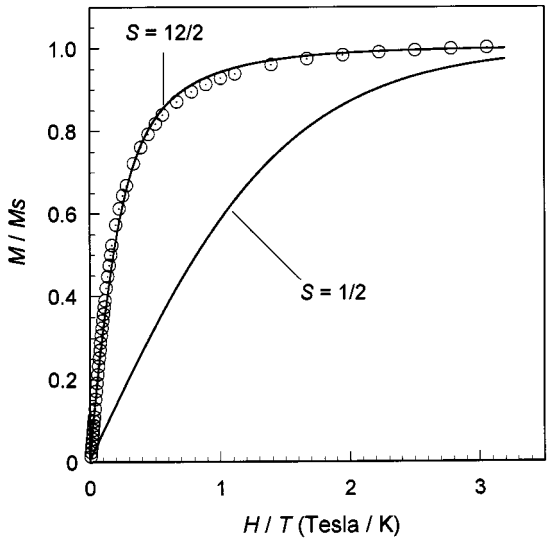

Figure 6. Magnetization isotherm of **3** at 1.8 K; the solid lines were calculated with the Brillouin function

When a ferromagnetic intermolecular coupling is observed between molecules A and B, $J^{AB}_{Cr\cdots N}$ is negative and ρ^{A}_{Cr} and ρ^{B}_{N} are positive and negative, respectively. Spin polarization on the nitrido ion was observed in the ESR spectrum of **3**, although the sign of the polarized spin is uncertain. A negative spin density is expected for the polarized spin on the nitrido ion.

In the present study, a ferromagnetic intermolecular interaction between the nitridochromium(V) spin centers is observed for **3**. A similar ferromagnetic intermolecular interaction is observed for polymeric [VO(salpn)] with the same $(d_{xy})^1$ electronic configuration. However, the magnetic interaction in **3** ($J = +8.4$ cm^{-1}) is larger than that in [VO(salpn)] ($J = +5.2$ cm^{-1}),[2] while the distance between the Cr≡N units in **3** is longer than that between the V=O units in [VO(salpn)] (vide supra). Further investigations are necessary to elucidate the intermolecular ferromagnetic coupling in the Cr≡N and V=O polymeric systems.

Experimental Section

{(CH$_3$)$_2$NH$_2$}$_2$[CrCl$_2$(salpn)]Cl (1): The ligand H$_2$salpn was prepared by the reaction of 1,3-propanediamine with two equivalent amounts of salicylaldehyde in ethanol. The solvent was evaporated from the reaction mixture to yield an oily product, which was used for the following reaction without purification. To a DMF solution (300 mL) of the ligand (50 mmol), was added anhydrous chromium(III) chloride (7.92 g, 50 mmol). The reaction mixture was refluxed for 4 h. After cooling, unreacted chromium(III) chloride was removed by filtration, and the filtrate was evaporated to dryness. The residue was suspended in ethanol, and the precipitate was collected by filtration. The light green powder was washed with ethanol and ether, and dried. Yield: 18.1 g (68%). − $C_{21}H_{32}Cl_3Cr_1N_4O_2$ (530.86): calcd. C 47.51, H 6.08, N 10.55; found C 47.56, H 6.10, N 10.54.

(CH$_3$)$_2$NH$_2$[Cr(N$_3$)$_2$(salpn)] (2): To a suspension of {(CH$_3$)$_2$NH$_2$}$_2$[CrCl$_2$(salpn)]Cl (8.0 g, 15 mmol) in acetone (1 L), was added sodium azide (2.6 g, 40 mmol). The mixture was refluxed for 3 h, and filtered. The green precipitate was dissolved in hot acetone (2 L), and insoluble salts were removed by filtration. The combined filtrate was evaporated to dryness, and the residue was suspended in diethyl ether. A green crude product was collected by filtration and dried. Yield: 6.6 g (96%). IR (KBr): $\tilde{\nu}$ = 2058 cm^{-1} ν(N$_3$). The complex was used for the following reaction without purification.

[CrN(salpn)] (3): Although no problems were encountered in this study, azide complexes are explosive and photolysis of the complex was carried out with caution. (CH$_3$)$_2$NH$_2$ [Cr(N$_3$)$_2$(salpn)] (1.39 g, 3 mmol) was suspended in acetonitrile (1 L), and the mixture was irradiated with a 400 W high-pressure mercury lamp below 20 °C under an argon atmosphere, with stirring. After 2 h, another 3 mmol of the azido complex was added to the reaction mixture, and the mixture was irradiated for 24 h. The color of the mixture gradually turned to red during the irradiation. After irradiation, the mixture was filtered, and the filtrate was evaporated to ca. 5 mL. The resulting orange precipitate was collected by filtration, and dried. This crude product was dissolved in dichloromethane, and applied to a silica gel column (∅ 3.5 cm × 20 cm). The product was eluted with dichloromethane/ethyl acetate (10:1 v/v). A main orange band was collected and evaporated to dryness to yield orange needle crystals. Yield: 1.12 g (54%). − $C_{17}H_{16}Cr_1N_3O_2$ (346.33): calcd. C 58.96, H 4.66, N 12.13; found C 58.83, H 4.66, N 12.09. − IR (KBr): $\tilde{\nu}$ = 956 cm^{-1}, 961 ν(Cr≡N). − UV/Vis {CH$_3$CN, $\sigma/10^3$ cm^{-1} (log ε/M^{-1}cm^{-1})}: λ = 17.6 (1.70, sh), 21.7 (sh), 27.0(3.87), 36.0 (4.37), 41.2 (4.69).

X-ray Crystallographic Study: Dichroic (green and brown) prismatic crystals of {(CH$_3$)$_2$NH$_2$}$_2$[CrCl$_2$(salpn)]Cl (**1**) were obtained by slow diffusion of diethyl ether vapor into a DMF solution of the complex. Orange needle crystals of [CrN(salpn)] (**3**) were grown from a dichloromethane solution. The intensity data were collected at 25 °C on a Rigaku four-circle AFC-7R diffractometer with graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) up to 2θ = 55° by $\theta-2\theta$ scans. Three standard reflections were measured at every 150 reflections. Absorption corrections were made by the numerical integration method for **1**,[19] and the Ψ scans method for **3**.[20] The structures were solved by direct methods on a Silicon Graphics O^2 workstation with the program system TEXSAN.[21] Non-hydrogen atoms were treated anisotropically, and hydrogen atoms were introduced at ideal positions. Refinement was based on F^2 against all the 5837 reflections for **1**, and against 2062 reflections for **3**. The R value was 0.031 for the 4912 reflections with $I > 2\sigma(I)$ for **1**, and 0.029 for 1780 reflections with $I > 2\sigma(I)$ for **3**. The absolute structure of **3** was determined with the Flack parameter $x = -0.05(3)$.[22] The crystal data and experimental details are listed in Table 3.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-148481 (**1**) and -148482 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Magnetic Measurements: The magnetic susceptibility measurements were carried out with a SQUID magnetometer (Quantum Design MPMS-5) in the temperature range 1.8−300 K using a magnetic field of 0.5 and 0.02 T. The susceptibilities of **3** have been corrected for the diamagnetic contribution of $\chi_{dia} = -166 \times 10^{-6}$ emu mol^{-1}, calculated by Pascal's method. Magnetization experiments up to 5.5 T were carried out at 1.8 K.

Chiral Chloro-Bridged η^6-Phenylglycine Ruthenium(II) Complexes Formed by Dehydrogenation of (*R*)-2,5-Dihydrophenylglycine[‡]

Harald Dialer,[a] Peter Mayer,[a][‡‡] Kurt Polborn,[a][‡‡] and Wolfgang Beck*[a]

Dedicated to Professor Kurt Dialer on the occasion of his 80th birthday

Keywords: Ruthenium / Iridium / Palladium / Amino acids

The reaction of N- or C-terminal protected (*R*)-2,5-dihydrophenylglycines with ruthenium(III) chloride gives the chloro-bridged η^6-phenylglycine complexes **1**–**3** without racemization. Dehydrogenation also occurs with (*R*)-2,5-dihydrophenylglycine and $[(n\mathrm{Bu}_3\mathrm{P})\mathrm{PdCl}_2]_2$ on exposure to air to yield the phenylglycinate chelate complex **6**. The structures of a pyridine complex from **2** $[\mathrm{Cl}_2(\mathrm{pyridine})\mathrm{Ru}\{\eta^6\text{-}\mathrm{C}_6\mathrm{H}_5\mathrm{CH}(\mathrm{CO}_2\mathrm{Et})\mathrm{NHCOCF}_3\}]$ **(4)** and of $[\mathrm{Cp}^*(\mathrm{Cl})\mathrm{Ir}(N,O\text{-dihydrophenylglycinate})]$ (**5**) were determined by X-ray diffraction.

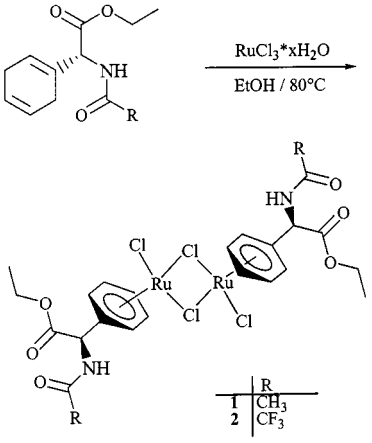
Introduction

The broad scope of the chemistry and application of organometallic complexes of transition metals with α-amino acids and peptides was recently reviewed.[2] Various η^6-arene complexes of aromatic amino acids formed with CpRu and (*p*-cymene)Ru fragments may be useful for the labelling of peptides and proteins.[3−11] Recently, much attention has focused on the development of chiral (arene)ruthenium complexes for the catalytic transfer hydrogenation of ketones[12−19] and for asymmetric Diels−Alder reactions.[20] In addition, there is great interest in the coordination behaviour of ruthenium(II) complexes with ligands tethered to the η^6-arene donor.[21,22] (Arene)ruthenium complexes with functional substituents at the η^6-arene moiety could give rise to homogeneous catalysts which display special solubility properties or can be immobilized on resins.

Our synthetic approach is based on the dehydrogenation of functional cyclohexadienes with ruthenium(III) trichloride in ethanol, a method established by Bennett et al.[23,24] Here we report the synthesis of novel chloro-bridged η^6-phenylglycine ruthenium(II) complexes starting from the synthetic amino acid (*R*)-2,5-dihydrophenylglycine,[25] which is easily accessible by Birch reduction from D-phenylglycine[26] and which is applied as a β-lactam antibiotic side chain.

Results and Discussion

In order to avoid side reactions N- and C-terminal protection of the substrate (*R*)-2,5-dihydrophenylglycine is necessary. Due to the strongly acidic conditions during the dehydrogenation reaction, acid-stable protecting groups (acetyl and trifluoroacetyl) are favourable for the amino terminus. Subsequent reaction of these protected cyclohexadienyl amino acids with ruthenium(III) chloride hydrate in refluxing ethanol produces the novel chloro-bridged η^6-phenylglycine ruthenium(II) complexes **1** and **2** which can be isolated in good yields as orange powders (Scheme 1).



Scheme 1

Protection of the cyclohexadienyl amino acid can also be achieved by protonation with HCl/ethyl acetate to yield the amino acid hydrochloride as an intermediate. During the dehydrogenation reaction, esterification of the carboxylate moiety is observed giving rise to the chloro-bridged η^6-phenylglycine ruthenium(II) complex **3** (Scheme 2).

In the IR spectra of the η^6-phenylglycine ruthenium(II) complexes **1**−**3** the absorptions of the ester function can be observed at about 1740 cm^{-1}. For the amide-protected derivatives **1** and **2** the amide absorptions appear in the typical range. There is no evidence for racemization under the

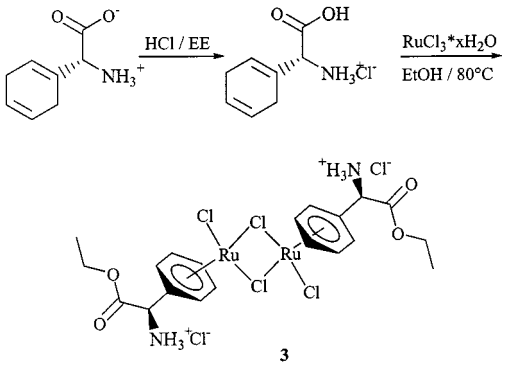


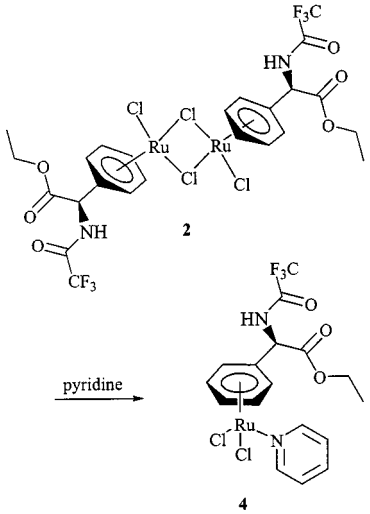
Scheme 2

acidic reaction conditions; this is confirmed by NMR spectroscopy. The ^{1}H NMR spectra of the complexes **1**−**3** display only a single set of signals appearing in the region δ = 5.5−6.1 for the aromatic protons. In the ^{13}C NMR spectra of the compounds **1**−**3** the signals of the aromatic carbon atoms can be observed in the area δ = 80−90 thus confirming an η^6-coordination of phenylglycine to the ruthenium centre.

Compared to the known chloro-bridged arene ruthenium complexes (e.g. arene = benzene, cymene)[23,24] the complexes **1**−**3** exhibit strongly enhanced solubility in polar solvents and even in water, which could make them useful for the labelling of peptides or proteins. Unfortunately, all η^6-phenylglycine ruthenium(II) complexes are sensitive to light in the solid state and in solution leading to greenish decomposition products. This could be due to coordination of the side chain and to a change of the arene coordination mode.

Saponification of the ester group in **3** should lead to deprotection which could allow coordination of the amino acid side chain.

Cleavage of the chloro bridges in complex **2** with pyridine produces the monomeric pyridine adduct **4** (Scheme 3) which was characterized by X-ray diffraction.



Scheme 3

The structure of complex **4** is shown in Figure 1. Relevant bond lengths and angles for complex **4** are collected in Table 1 and the crystallographic data in Table 2.

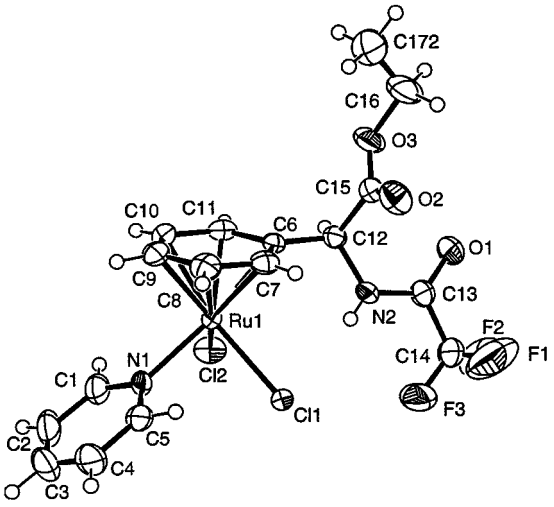


Figure 1. ORTEP projection of the ruthenium complex **4** with the atom numbering scheme

X-ray crystallography confirms the η^6-coordination of phenylglycine, but reveals racemisation at the α-carbon leading to a 1:1 mixture of enantiomers in the crystal. This racemisation occurs due to the basicity of pyridine which is also a typical feature of free phenylglycine.[27]

(*R*)-2,5-dihydrophenylglycine reacts with base and the chloro-bridged complex [Cp*IrCl$_2$]$_2$ to give the *N*,*O*-chelate **5** (Scheme 4).

As confirmed by NMR spectroscopy, complex **5** is produced as a 1:1 mixture of the diastereomers R_CR_{Ir} and R_CS_{Ir}. Two sets of signals in the ^{1}H NMR spectrum of **5** reveal the typical pattern of a monosubstituted cyclohexadiene moiety with a multiplet in the area δ = 2.61−2.79 for the aliphatic protons and a multiplet in the range δ = 5.62−5.84 for the olefinic protons.

Only one diastereomer crystallises from dichloromethane (confirmed by NMR spectroscopy) which was assigned to the R_CS_{Ir} configuration by X-ray diffraction. The structure of complex **5** (shown in Figure 2) is analogous to that of half-sandwich complexes (arene)(Cl)M(α-aminocarboxylate) with other α-amino acids.[2,28,29] Due to the rather high standard deviations a closer discussion of the bonding parameters is not appropriate.[40]

The cyclohexadiene moiety in 2,5-dihydrophenylglycine shows a strong tendency towards rearomatisation to a phenyl group when exposed to air. This was demonstrated by the synthesis of complex **6** from (*R*)-2,5-dihydrophenylglycine and [(*n*Bu$_3$P)PdCl$_2$]$_2$ in nondegassed methanol (Scheme 5).

The ^{1}H NMR spectrum of complex **6** does not show any signals of a cyclohexadiene moiety. In contrast the typical pattern of a monosubstituted benzene is observed in the area δ = 7.33−7.69. As confirmed by an ^{31}P NMR experi-

ment, complex **6** is produced as a mixture of the *cis* and *trans* isomers **6a** and **6b** in the ratio 2:3. For several other Pd and Pt complexes with P and N donors[30−36] the *trans* P−M−N configuration is favoured.

Conclusion

The chiral chloro-bridged η^6-phenylglycine ruthenium complexes **1**−**3** can be synthesized by a dehydrogenation reaction of derivatives of (*R*)-2,5-dihydrophenylglycine without racemization. The reaction provides an easy access to organometallic complexes with π-coordinated optically active amino acids, and further ligands can be introduced into the chloro-bridged compounds. Cleavage of the chloro bridges in **2** with pyridine to form the monomeric complex **4** leads to a 1:1 mixture of enantiomers. In the reaction of (*R*)-2,5-dihydrophenylglycine with the complex $[Cp^*IrCl_2]_2$ the *N,O*-chelate **5** is produced. The strong tendency of 2,5-dihydrophenylglycine towards rearomatisation in air was demonstrated with the synthesis of complex **6** from (*R*)-2,5-dihydrophenylglycine and $[(nBu_3P)PdCl_2]_2$ in nondegassed methanol.

Experimental Section

General Remarks: All reactions were performed under an atmosphere of argon in Schlenk tubes. Ethanol was degassed prior to use. NMR measurements were recorded on Jeol GSX 270 and Jeol EX 400 spectrometers. IR analyses were obtained on a Nicolet 520 FT-IR spectrometer. Derivatives of (*R*)-2,5-dihydrophenylglycine were prepared according to literature procedures .[25,37]

1: $RuCl_3 \cdot 3H_2O$ (347 mg, 1.32 mmol) was added to *N*-acetyl-(*R*)-2,5-dihydrophenylglycine ethyl ester[25] (1.221 g, 5.47 mmol) in 100 mL of ethanol and the mixture heated under reflux. The dark solution turned green after approximately 1 h. After an additional 4 h the reaction was complete, resulting in a clear red solution which was reduced in vacuo to half of the volume. Upon cooling to −30 °C for 16 h orange microcrystals of **1** precipitated which were filtered off, washed with cold ethanol and dried in vacuo. Yield: 851 mg (82%). − IR (KBr): $\tilde{\nu}$ = 3304 m, 3077 w, 2960 w, 1740 vs (CO_2), 1664 vs, 1531 s (NCO), 1447 m, 1371 m, 1296 m, 1209 m, 1023 m, 857 m cm^{-1}. − ^1H NMR (270 MHz, CD_2Cl_2): δ = 1.23 (t, ^3J = 7.1 Hz, 6 H, CH_2CH_3), 2.13 (s, 6 H, CH_3), 4.17 (q, ^3J = 7.1 Hz, 2 H, OCH_2), 4.18 (q, ^3J = 7.1 Hz, 2 H, OCH'_2), 5.14 (d, ^3J = 6.5 Hz, 2 H, α-H), 5.52−5.83 (m, 10 H, H_{arom}), 7.90 (d, *J* = 6.4 Hz, 2 H, NH). − ^{13}C NMR (100.5 MHz, CD_2Cl_2): δ = 13.88 (CH_2CH_3), 22.57 (CH_3), 54.82 (α-C), 62.34 (CH_2CH_3), 80.20, 80.29, 81.58, 83.13, 92.89 (C_{arom}), 167.76 (CO_2), 170.81 (CON). − $C_{24}H_{30}Cl_4N_2O_6Ru_2$ (786.46): calcd. C 36.65, H 3.84, N 3.56; found C 36.22, H 3.93, N 3.42.

2: $RuCl_3 \cdot 3H_2O$ (347 mg, 1.32 mmol) was added to 825 mg (2.98 mmol) of *N*-trifluoroacetyl-(*R*)-2,5-dihydrophenylglycine ethyl ester (prepared according to references [37] and [25]) in 20 mL of ethanol and the mixture heated under reflux. The dark solution turned greenish-brown after approximately 1 h. After an additional 4 hours the reaction was complete, resulting in a clear red solution which was reduced in vacuo to half of the volume. Upon cooling to −30 °C orange microcrystals of **2** precipitated which were filtered off, washed with cold ethanol and dried in vacuo. Yield 351 mg (71%). − IR (KBr): $\tilde{\nu}$ = 3077 m, 2989 m, 2601 w, 1744 vs (CO_2), 1635 w, 1544 m, 1467 w, 1371 w, 1285 m, 1236 s, 1182 m, 1021 m, 860 w cm^{-1}. − ^1H NMR (270 MHz, CD_2Cl_2): δ = 1.25 (t, ^3J = 7.1 Hz, 6 H, CH_2CH_3), 4.21 (q, ^3J = 7.0 Hz, 2 H, OCH_2), 4.24 (q, ^3J = 7.0 Hz, 2 H, OCH'_2), 5.37 (d, ^3J = 7.0 Hz, 2 H, α-H), 5.53 (q, *J* = 5.4 Hz, 2 H, H_{arom}), 5.60 (q, *J* = 5.9 Hz, 2 H, H_{arom}), 5.69 (d, *J* = 5.8 Hz, 4 H, H_{arom}), 5.98 (t, *J* = 5.4 Hz, 2 H, H_{arom}), 9.03 (s, br, NH). − ^{13}C NMR (100.5 MHz, CD_2Cl_2): δ = 13.54 (CH_2CH_3), 54.87 (α-C), 63.02 (CH_2CH_3), 78.55, 79.03, 82.55, 84.97, 87.51, 89.43 (C_{arom}), n.o. (CF_3), 156.98 (CON), 166.23 (CO_2). − $C_{24}H_{24}Cl_4F_6N_2O_6Ru_2 \cdot 2EtOH$ (986.54): calcd. C 34.09, H 3.67, N 2.84; found C 34.45, H 3.37, N 2.95.

3: (*R*)-2,5-dihydrophenylglycine (600 mg, 3.92 mmol) was stirred with 10 mL of a solution of HCl in ethyl acetate (approx. 2 M) for 1 h. To this suspension $RuCl_3 \cdot 3H_2O$ (205 mg, 0.78 mmol) and 35 mL of ethanol were added and the resulting mixture heated under reflux for 16 h. The orange precipitate was filtered off, washed with cold ethanol and dried in vacuo. Yield 472 mg (78%). − IR (KBr): $\tilde{\nu}$ = 3063 m, 2990 w, 2601 w, 1746 vs (CO_2), 1637 w, 1472 s, 1374 m, 1294 m, 1240 s, 1185 m, 1098 m, 1008 m, 857 m cm^{-1}. − ^1H NMR (270 MHz, CD_3OD): δ = 1.25 (t, ^3J = 7.2 Hz, 6 H, CH_2CH_3), 4.29 (q, ^3J = 7.2 Hz, 2 H, OCH_2), 4.31 (q, ^3J = 7.2 Hz, 2 H, OCH'_2), 5.17 (s, 2 H, α-H), 5.85−6.14 (m, 10 H, H_{arom}), 7.48 (s, NH_3). − ^{13}C NMR (67.9 MHz, CD_3OD): δ = 13.24 (CH_2CH_3), 55.48 (α-C), 63.96 (CH_2CH_3), 83.12, 83.27, 85.03 (C_{arom}), 165.94 (CO_2). − $C_{20}H_{28}Cl_6N_2O_4Ru_2$ (775.31): calcd. C 30.98, H 3.64, N 3.61; found C 30.09, H 3.77, N 3.27.

4: A solution of the ruthenium complex **2** (99 mg, 0.12 mmol) in 10 mL of pyridine was stirred for 12 h. The solvent was then removed under reduced pressure and the residue dried in vacuo. Recrystallisation from dichloromethane/hexane afforded orange crystals suitable for X-ray diffraction. Yield 128 mg (91%). − IR (KBr): $\tilde{\nu}$ = 3201 m, 3062 m, 2981 w, 1748 vs (C=O), 1725 vs, 1636 m, 1604 m, 1545 s, 1447 s, 1216 s, 1181 s, 1164 s, 1069 m, 1017 m, 860 w, 761 s, 695 s cm^{-1}. − ^1H NMR (270 MHz, CD_2Cl_2): δ = 1.27 (t, ^3J = 7.0 Hz, 3 H, CH_2CH_3), 4.28 (pt, ^3J = 7.1 Hz, 2 H, OCH_2), 5.44 (d, ^3J = 6.9 Hz, 1 H, α-H), 5.53−5.72 (m, 3 H, H_{arom}), 5.95 (m, 1 H, H_{arom}), 6.09 (m, 1 H, H_{arom}), 7.48 (m, 3 H, H_{py}), 8.98 (m, 2 H, H_{py}), 9.01(s, br, NH). − ^{13}C NMR (100.5 MHz, CD_2Cl_2): δ = 13.84 (CH_2CH_3), 55.73 (α-C), 63.01 (CH_2CH_3), 81.48, 81.65, 86.47, 87.11, 88.67, 88.93 (C_{arom}), 125.11, 129.16, 138.48 (py), 155.12 (CON), 166.80 (CO_2). − $C_{17}H_{17}Cl_2F_3N_2O_3Ru \cdot 1/2py$ (565.85): calcd. C 41.39, H 3.48, N 6.19; found C 41.43, H 3.66, N 6.34.

5: A suspension of (*R*)-2,5-dihydrophenylglycine (58 mg, 0.38 mmol) in 10 mL of methanol was stirred with a 1.3 M solution of NaOMe in methanol (290 μL, 0.38 mmol). After 30 min. $[Cp^*IrCl_2]_2$ [38] (150 mg, 0.19 mmol) was added and the mixture stirred for an additional 2 h. The solvent was then removed at reduced pressure and the residue dissolved in 5 mL of dichloromethane. After filtration through Celite the clear yellow solution was set aside. Within 12 h yellow crystals of **5** precipitated. Yield 181 mg (86%). − IR (KBr): $\tilde{\nu}$ = 3223 m, 3223 m (NH), 2917 w, 1637 vs (C=O), 1455 m, 1361 s, 1256 m, 1163 m, 1034 m, 960 m cm^{-1}. − ^1H NMR (270 MHz, CD_3OD): δ = 1.70 (s, 15 H, CH_3), 2.61−2.79 (m, 4 H, CH_2), 3.87 (d, *J* = 14.9 Hz, 1 H, α-H), 5.62−5.84 (m, 3 H, CH). − ^{13}C NMR (100.5 MHz, CD_2Cl_2): δ = 8.70 ($C_5(CH_3)_5$), 24.75, 26.63 (CH_2), 59.90 (α-C), 84.24 ($C_5(CH_3)_5$), 123.60, 124.87, 126.22, 126.48 (CH), 177.98 (CO_2). − $C_{18}H_{25}ClIrNO_2 \cdot 1/2CH_2Cl_2$ (557.54): calcd. C 39.86, H 4.88, N 2.51; found C 40.10, H 5.13, N 2.40.

6: A suspension of (*R*)-2,5-dihydrophenylglycine (61 mg, 0.40 mmol) in 7 mL of nondegassed methanol was stirred with a 1.3 M solution of NaOMe in methanol (304 μL, 0.40 mmol). After 30 min. $[(nBu_3P)PdCl_2]_2$ [39] (150 mg, 0.20 mmol) was added and the mixture stirred for an additional 12 h. The yellow precipitate was then removed by centrifugation, dried in vacuo and redissolved in dichloromethane. After filtration through Celite the solvent was removed under reduced pressure. The residue was recrystallized from dichloromethane/*n*-hexane. Yield 169 mg (83%). − IR (KBr): $\tilde{\nu}$ = 3216 s (NH), 3121 m, 2930 vs, 2872 s, 1634 vs (C=O), 1597 m, 1465 m, 1455 m, 1377 s, 1210 m, 1093 m, 907 m, 804 w, 787 w, 762 m, 725 m, 699 s cm^{-1}. − ^1H NMR (270 MHz, CD_2Cl_2): δ = 0.86−0.98 (m, 9 H, CH_3, *n*Bu), 1.39−1.84 (m, 18 H, CH_2, *n*Bu), 3.59 (m, br, NH_2), 4.61 (m, 1 H, α-H), 7.33−7.45 (m, 3 H- and *p*-C_6H_5), 7.61−7.69 (m, 2 H, *o*-C_6H_5). − ^{13}C NMR (100.5 MHz, CD_2Cl_2): δ = 13.54 ($PCH_2CH_2CH_2CH_3$, A+B), 25.92 ($PCH_2CH_2CH_2CH_3$, A), 25.94 ($PCH_2CH_2CH_2CH_3$, B), 24.15 (d, *J* = 14.5 Hz, $PCH_2CH_2CH_2CH_3$, A), 24.24 (d, *J* = 14.0 Hz, $PCH_2CH_2CH_2CH_3$, B), 21.78 (d, *J* = 30.0 Hz, $PCH_2CH_2CH_2CH_3$, A), 22.82 (d, *J* = 31.0 Hz, $PCH_2CH_2CH_2CH_3$, B), 61.41 (α-C, A), 64.12 (α-C, B), 127.20, 128.28, 128.66, 129.09 (Ph, A+B), 181.29 (CO_2, A+B). − 31P NMR (109.4 MHz, CD_2Cl_2): δ = 27.55 (s, A), 28.80 (s, B); (1.5:1). − $C_{20}H_{35}ClNO_2PPd \cdot H_2O$ (512.34): calcd. C 46.88, H 7.28, N 2.73; found C 46.83, H 7.50, N 2.64.

Synthesis, Structure and Characterization of the New Complex $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1]^{4+}$ [L_1 = *N,N′*-Bis(1-methylimidazolyl-2-methyl)-*N,N′*-Bismethyl-1,2-ethanediamine] − Formation of the $(\mu\text{-}O)(\mu\text{-}H_3O_2)$ Complex upon Deprotonation

Sandrine Poussereau,[a] Geneviève Blondin,*[a] Geneviève Chottard,[b] Jean Guilhem,[c] Luba Tchertanov,[c] Eric Rivière,[a] and Jean-Jacques Girerd[a]

Keywords: Iron / Oxo complexes / Methane monooxygenase / UV/Vis spectroscopy / Raman spectroscopy

The compound $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1](ClO_4)_4\cdot 2H_2O$ [**1**$(ClO_4)_4\cdot 2H_2O$] [L_1 = *N,N′*-bis(1-methylimidazolyl-2-methyl)-*N,N′*-bismethyl-1,2-ethanediamine] was synthesized. It is characterized by a linear Fe–(μ-O)–Fe motif with an Fe···Fe distance of 3.584(1) Å. The measurement of the magnetic susceptibility as a function of temperature indicated a strong antiferromagnetic coupling between the two high-spin Fe^{III} ions ($J = -223\ cm^{-1}$ with $H = -J\cdot S_1\cdot S_2$). In the solid state, the symmetric stretching vibration mode of the Fe–(μ-O)–Fe core unit was detected at 347 cm^{-1}, in agreement with a straight Fe–(μ-O)–Fe angle. Upon addition of up to one equivalent of triethylamine to an acetonitrile solution of **1**, conversion to the $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH)L_1]^{3+}$ complex **2** was observed. This last species was isolated as a perchlorate salt [**2**$(ClO_4)_3\cdot H_2O$]. Susceptibility measurements and Raman and UV/Vis investigations on the powder and/or an acetonitrile solution confirmed the presence of an intramolecular hydrogen bond between the coordinated water molecule and the hydroxide group leading to a bent $[Fe(\mu\text{-}O)Fe]^{4+}$ core structure.

Introduction

The oxidation of methane to methanol with dioxygen catalyzed by soluble methane monooxygenase (MMO) has elicited much interest during recent years. This reaction takes place in the hydroxylase component of MMO (MMOH),[1,2] the structure of which has been determined by X-ray diffraction studies in the native ($MMOH_{ox}$) and reduced ($MMOH_{red}$) forms for *Methylococcus capsulatus*,[3,4] and in the native form only for *Methylosinus trichosporium*.[5] The catalytic site determined in the two forms is constituted by two iron atoms bridged by the carboxylato group of a glutamate residue (E144). Both iron sites are in the +III oxidation state in $MMOH_{ox}$ and connected by two extra bridges: one water molecule and one hydroxide group.[4,5] In the reduced state, both metallic centers have the +II oxidation degree, a single oxygen atom of the carboxylate side function of the glutamate residue E243 being present as a second bridge.[4] The only exogeneous ligand is a water molecule that is coordinated to one Fe^{II} site and that recent investigations in the catalytic cycle of the enzyme have brought to the fore. It has been suggested that one of its protons is transferred to one oxygen atom of the O−O bridge in the peroxo form of MMOH (compound P)[6,7] formed by reaction of $MMOH_{red}$ with dioxygen.[8−11] This would leave a hydroxo group ligated to one Fe^{III} site or bridging the two metallic centers.[6,7] Compound P spontaneously converts to compound Q, which has been shown by Mössbauer and X-ray absorption studies to present a di-Fe^{III}-di-μ-oxo core unit.[12] It has been proposed that upon this evolution, a second proton is transferred from the hydroxide molecule to the hydrogenated peroxo bridge, allowing the release of a water molecule.[6,7] The two bridging oxygen atoms of the $[Fe_2(\mu\text{-}O)_2]^{4+}$ unit would thus have different origins, one coming from the dioxygen molecule and the other one being the doubly deprotonated coordinated water molecule present in $MMOH_{red}$. Compound Q is the active catalytic species that interacts with the alkane substrate.[6,8,9,13]

Many efforts have been made to synthesize dinuclear iron complexes presenting the diamond core structure. For this purpose, tetradentate ligands are used.[14−18] Starting with a $[(H_2O)Fe(\mu\text{-}O)Fe(OH)]^{3+}$ core unit, we have shown recently the possibility to obtain the double-bridged structure $[Fe(\mu\text{-}O)(\mu\text{-}OH)Fe]^{3+}$.[14] The protonated form of the diamond core structure is thus formed in the same way as would be the di-iron-di-μ-oxo unit of compound Q, an oxygenated group converting from a η^1- to a μ-type coordination. This behavior seems to be common to several systems.[14,16,19] In our effort to model the active site of MMOH, the synthesis of two new iron-oxo complexes with

the tetradentate ligand containing imidazole groups *N,N′*-bis(1-methylimidazolyl-2-methyl)-*N,N′*-bismethyl-1,2-ethanediamine (L_1, see Scheme 1) are presented. Complex **1**$(ClO_4)_4{\cdot}2H_2O$ has a $[(H_2O)Fe(\mu\text{-}O)Fe(OH_2)]^{4+}$ core unit and we show here the possibility to abstract one proton from one water molecule and to isolate the $[(H_2O)Fe(\mu\text{-}O)Fe(OH)]^{3+}$ system (**2**). This second complex is shown to be stable in solution and insensitive to further deprotonation.

Results and Discussion

X-ray Crystal Structure of $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1](ClO_4)_4{\cdot}2H_2O$

The structure consists of one $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1]^{4+}$ complex cation, four perchlorate anions and two water molecules. An ORTEP view of the cation is presented in Figure 1, and selected bond lengths and angles are listed in Table 1.

The cation possesses a crystallographicaly imposed symmetry, with the two iron atoms bridged by an oxygen atom which lies on an inversion center. The iron atom shows a pseudo-octahedral coordination with the two nonmethylated nitrogen atoms of the imidazole rings in axial positions and the two nitrogen amine atoms in equatorial positions

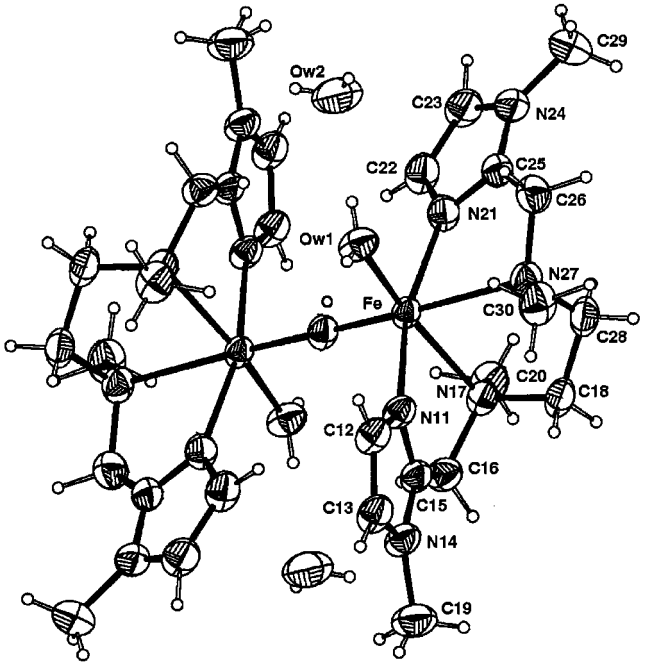

Figure 1. ORTEP view of the $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1]^{4+}$ cation in the crystal of compound **1**$(ClO_4)_4{\cdot}2H_2O$, showing the 50% probability thermal ellipsoids

[a] Symmetry transformations used to generate equivalent atoms: #1−x,−y,−z+1.

providing the *cis*-α conformation. This conformation is also adopted by tetradentate ligands derived from the *N,N′*-bis(2-pyridylmethyl)ethane-1,2-diamine (bispicen)[14,16−20] or the very similar ligand to L_1 *N,N′*-bis(imidazol-4-ylmethyl)ethane-1,2-diamine in a di-Mn-di-μ-oxo complex.[21] A water molecule occupies the sixth coordination site of each iron. The two coordinated water molecules are in *trans* positions with respect to one another due to the inversion center at the bridging oxygen atom.

The coordination at the Fe atom indicates an important deviation from octahedral geometry. The Fe atom and the four equatorial atoms form an approximate plane with a mean deviation from the respective least-squares planes of 0.2 Å. The axial nitrogen atoms N17 and N27 lie above and below the equatorial plane by 2.082(2) and −2.054(2) Å, respectively. The imidazole moieties are oriented nearly perpendicularly relative to the equatorial plane with dihedral angles 87.91(9)° and 84.7(1)°. The dihedral angle between the imidazole ring planes of 62.8(1)° indicates a significant rotation of the five-membered rings around the coordination bonds.

The two $Fe-N_{amine}$ distances as well as the two $Fe-N_{imidazole}$ distances in the $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1]^{4+}$ cation are not identical. Thus, Fe−N11 [2.125(2) Å] is longer than Fe−N21 [2.084(2) Å] and Fe−N27 [2.337(2) Å] is longer than Fe−N17 [2.210(2) Å]. Such an important difference between the chemically identical bonds, especially for the pair of $Fe-N_{amine}$ bond lengths (δ = 0.23 Å) can be attributed to a *trans* effect. Indeed, the disposition of the atoms N27, the metallic centre and bridging oxygen is nearly linear with a bond angle of 169.08(6)°.

The $[(H_2O)Fe(\mu\text{-}O)Fe(OH_2)]^{4+}$ core structure has been previously obtained using the bidentate 1,10-phenanthroline (phen) ligand[22] or tetradentate ones like 2,2′:6′,2′′:6′′,2′′′-quaterpyridine (qpy),[23] tris(2-pyridylmethyl)amine (tpa),[24,25] tris[(1-methylimidazol-2-yl)methyl]amine (tmima),[26] 3-[bis(2-pyridylmethyl)amino]propionate (bpp^-),[27] or nitrilotriacetate (nta^{3-}).[28] The Fe−(μ-O) distance [1.7918(5) Å] observed here is very similar to the ones observed in the other complexes [from 1.771(5) to 1.83(1) Å]. The complex with the ligand qpy has a linear Fe−(μ-O)−Fe core structure as observed in **1**, the other

cores having a bent geometry with bridging angles ranging from 153.2(6) to 177.5(5)°. The Fe···Fe separation [3.584(1) Å] in **1** is the longest among the seven complexes mentioned here.

The bond length Fe−Ow of 2.052(2) Å is in the range of those previously reported value for Fe^{III} complexes coordinated by water [2.021(5)−2.19(1) Å]. The main difference lies in the torsion angle Ow−Fe···Fe−Ow which is equal, in increasing order, to 7.7° in $[(nta)(H_2O)Fe(\mu\text{-}O)Fe(H_2O)(nta)]^{2-}$, 8.8° in $[(bpp)(H_2O)Fe(\mu\text{-}O)Fe(H_2O)(bpp)]^{2+}$, 81.9° in $[(phen)_2(H_2O)Fe(\mu\text{-}O)Fe(OH_2)(phen)_2]^{4+}$, 123.0° in $[(tpa)(H_2O)Fe(\mu\text{-}O)Fe(OH_2)(tpa)]^{4+}$, 131.7° in $[(tmima)(H_2O)Fe(\mu\text{-}O)Fe(OH_2)(tmima)]^{4+}$ and 180° in **1** (not defined for $[(qpy)(H_2O)Fe(\mu\text{-}O)Fe(OH_2)(qpy)]^{4+}$ since the four atoms are aligned). The intramolecular π-π stacking of the phenanthroline rings in $[(phen)_2(H_2O)Fe(\mu\text{-}O)Fe(OH_2)(phen)_2]^{4+}$ may impose such a disposition. In the mentioned complexes, the coordinated water molecules are involved in the hydrogen bond network that may be at the origin of the variety of torsion angles observed.

As mentioned above, the studied complex crystallizes as a hydrate salt. The water molecule coordinated to the iron is involved in a strong hydrogen bond Ow1−H2w1···Ow2 with one solvent molecule [the distances Ow1···Ow2 and H2w1···Ow2 are 2.594(4) and 1.81(2) Å, respectively, and the angle at H is 174(4)°]. The other hydrogen atoms of both water molecules participate in hydrogen bonding with the perchlorate anions.

Magnetic Susceptibility Measurements

The molar magnetic susceptibilities χ_M of a powder sample of $\mathbf{1}(ClO_4)_4\cdot 2H_2O$ and $\mathbf{2}(ClO_4)_3\cdot H_2O$ were measured as functions of the temperature. For **1**, $\chi_M T$ decreases from 0.74 $cm^3\cdot mol^{-1}\cdot K$ at 300 K to a plateau at 0 below 55 K, indicating a strong antiferromagnetic coupling interaction between the two high spin Fe^{III} ions ($S_1 = S_2 = 5/2$).

The same behavior was detected for **2**: at 300 K, $\chi_M T$ equals 1.40 $cm^3\cdot mol^{-1}\cdot K$ and diminishes to reach a plateau at 0 below 35 K. The decrease of $\chi_M T$ is again characteristic of an antiferromagnetic exchange interaction between the two high spin Fe^{III} sites, but the higher value of $\chi_M T$ detected at 300 K for **2** reveals a weaker coupling than in **1**.

The best fits were obtained by setting the *g* factor to 2: $J = -223$ cm^{-1} for **1** and $J = -133$ cm^{-1} for **2**. The *J* value calculated for **1** is of the same magnitude as the one measured for the other di-aquo-di-iron-μ-oxo complexes: −210 cm^{-1} in $[(tpa)(H_2O)Fe(\mu\text{-}O)Fe(H_2O)(tpa)]^{4+}$,[24] −220 cm^{-1} in $[(phen)_2(H_2O)Fe(\mu\text{-}O)Fe(OH_2)(phen)_2]^{4+}$ [22] and −228 cm^{-1} in $[(bpp)(H_2O)Fe(\mu\text{-}O)Fe(OH_2)(bpp)]^{2+}$.[27]

However, the value determined for **2** is significantly less negative than the ones measured for $[(H_2O)Fe(\mu\text{-}O)Fe(OH)]^{3+}$ core complexes: −194 cm^{-1} with TPA,[24] −196 cm^{-1} with 5-Et_3-TPA[15] and −184 cm^{-1} with bispicMe_2en.[14] This weaker coupling interaction reveals a less efficient superexchange pathway. As previously mentioned in the literature, the latter is essentially governed by the Fe−(μ-O) distances for bridging angles ranging from 120 to 180°.[29,30] It has been established that the coupling constant *J* is correlated to half of the shortest superexchange pathway between the two Fe^{III} ions, designated as P according to Equation (1):

$$J = A\cdot\exp[B(P - 2)] \quad (1)$$

with $A = -17.52$ cm^{-1} and $B = -12.663$ $Å^{-1}$ if *P* is expressed in Å and *J* in cm^{-1}.[29,31,32] For **1**, *P* equals 1.791 Å, which gives a coupling constant of −247 cm^{-1}, in agreement with the value of −223 cm^{-1} observed experimentally. For compound **2** it is possible to evaluate from the *J* value an average Fe−(μ-O) distance of 1.84 Å, a value slightly greater than the ones measured by X-ray diffraction studies on the three $[(H_2O)Fe(\mu\text{-}O)Fe(OH)]^{3+}$ core structures for which the *P* parameter ranges from 1.80 to 1.82 Å.[14,15,24]

One can argue that the exchange coupling constant calculated here for compound **2** is closer to the values determined for the double-bridged $[LFe(\mu\text{-}O)(\mu\text{-}OH)FeL]^{3+}$ systems {−113 cm^{-1} for L = 6-Me_3-TPA,[19] −106 cm^{-1} for L = bispicEt_2en,[19] −84 cm^{-1} for L = bispicMe_2en[16] (see also remark 42 in ref. [19])}, a formulation that cannot be rejected on the basis of the elementary analysis alone. Nevertheless, as will be shown in the next section, the Raman studies support the hypothesis of a single μ-oxo bridge.

Raman Spectra

We will focus on the frequency domain (330 to 650 cm^{-1}) where the symmetric stretching vibration mode of the Fe−(μ-O)−Fe core unit is expected to be detected. This vibration mode has been shown to be strongly dependent on the bridging angle,[33] and is thus indicative of the core unit geometry. In the solid state, the Raman spectrum of compound $\mathbf{1}(ClO_4)_4\cdot 2H_2O$ exhibits a band centered at 347 cm^{-1}, while it is detected at 455 cm^{-1} for complex $\mathbf{2}(ClO_4)_3\cdot H_2O$. Only the acetonitrile solution of **2** was investigated and the recorded spectrum is very similar to that obtained in the solid state. The band detected at 455 cm^{-1} in the solid state is shifted to 458 cm^{-1} in solution. From the published correlation of the ν_s frequency as a function of the Fe−(μ-O)−Fe angle, 347 cm^{-1} would correspond to a straight angle and is in good agreement with the X-ray diffraction results.

The higher frequency observed for **2** indicates a bent core structure. The double-bridged $[Fe(\mu\text{-}O)(\mu\text{-}OH)Fe]^{3+}$ cores are characterized by an even higher frequency for the symmetric vibration, around 600 cm^{-1}.[14,16,19] The μ-oxo-μ-hydroxo core can thus be dismissed since no signature is detected at such a high frequency. The approximate 150° bridging angle value deduced from the correlation mentioned above is slightly too high to be compatible with the presence of $H_3O_2^-$ as a second bridge, since the X-ray diffraction studies performed on such complexes lead to the determination of Fe−(μ-O)−Fe angles in the range 136−139°.[14,15,24] The likelihood of the presence of a $H_3O_2^-$ bridge is enforced, however, by the fact that the correlation we are referring to has been established for clusters presenting shorter Fe−(μ-O) distances than the one ex-

pected from the magnetic measurements. As the separation between the iron and the oxygen atoms increases, one can expect the ν_s frequency to decrease.[34] The bridging angle value of 150° may hence be an overestimation.

Both the magnetic and the Raman studies performed in the solid state support the existence in **2** of an intramolecular hydrogen bond between the coordinated water and hydroxide molecules, this interaction persisting in solution (Scheme 2).

Scheme 2

UV/Vis Absorption Spectra

The spectra of **1** [spectrum (a)] and **2** [spectrum (e)] recorded on acetonitrile solutions are shown in Figure 2.

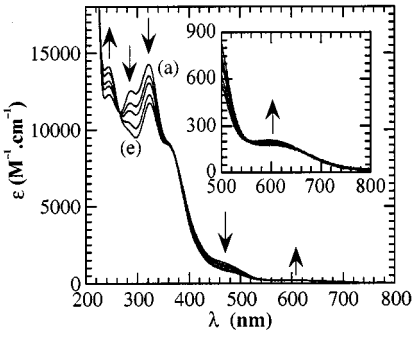

Figure 2. UV/Vis spectra of complexes $\mathbf{1}(ClO_4)_4{\cdot}2H_2O$ [spectrum (a)] and $\mathbf{2}(ClO_4)_3{\cdot}H_2O$ [spectrum (e)] dissolved in dry acetonitrile; spectra (b) to (e) correspond respectively to the addition of 0.3, 0.5, 0.8 and 1 equivalent of Et_3N to a solution of **1**; the inset shows an amplification of the 500 to 800 nm region

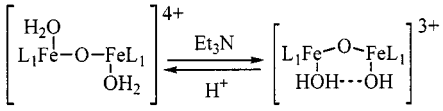
Similar features between those two spectra may be noted. The bands at 245 nm (ε = 12300 $M^{-1}{\cdot}cm^{-1}$ for **1** and ε = 14100 $M^{-1}{\cdot}cm^{-1}$ for **2**) can be assigned to $\pi\rightarrow\pi^*$ transitions in the aromatic groups of the ligand. Other bands are observed at 287 nm (ε = 12500 $M^{-1}{\cdot}cm^{-1}$ for **1**, ε = 9800 $M^{-1}{\cdot}cm^{-1}$ sh for **2**), 323 nm (ε = 14250 $M^{-1}{\cdot}cm^{-1}$ for **1** and ε = 11750 $M^{-1}{\cdot}cm^{-1}$ for **2**), 365 nm (ε = 8900 $M^{-1}{\cdot}cm^{-1}$ for **1** and **2**) and 472 nm (ε = 1300 $M^{-1}{\cdot}cm^{-1}$ for **1** and ε = 830 $M^{-1}{\cdot}cm^{-1}$ for **2**). The last two originate from weak oxo-to-iron LMCT transitions and, more specifically, the transition at 472 nm is assigned to the $^6A_1 \rightarrow (^4A_1, {}^4E)$ transition and is the signature of the Fe−(μ-O)−Fe motif, independent of the bridging angle value.[16,35] Another important characteristic of the μ-oxo core is expected in the 550−700 nm region, the response being strongly dependent on the Fe−(μ-O)−Fe angle: the more bent, the less energetic and/or the more intense.[36] Magnifying the 550−800 nm region reveals the existence of a low-intensity band centered around 600 nm with a molar extinction coefficient larger for **2** (ε = 205 $M^{-1}{\cdot}cm^{-1}$) than for **1** (ε = 175 $M^{-1}{\cdot}cm^{-1}$). A similar increase in the intensity of the absorption has been observed for the tpa complexes[16]: the band at 572 nm (ε = 125 $M^{-1}{\cdot}cm^{-1}$) for $[tpa(H_2O)Fe(\mu\text{-}O)Fe(OH_2)tpa]^{4+}$ is shifted to 608 nm (ε = 165 $M^{-1}{\cdot}cm^{-1}$) in $[tpa(H_2O)Fe(\mu\text{-}O)Fe(OH)tpa]^{3+}$. Such a behavior indicates that **2** presents a bent structure in contrast to the linear arrangement in **1**. The molar extinction coefficient value measured for **2** is in agreement with a mono-μ-oxo core unit, the protonated diamond core $[Fe(\mu\text{-}O)(\mu\text{-}OH)Fe]^{3+}$ being characterized by an epsilon value greater by at least a factor of three. Results from UV/Vis absorption spectroscopy thus corroborate the conclusion formulated from Raman analysis, i.e. the persistence in solution of the internal hydrogen bond in **2**.

The conversion between **1** and **2** may be achieved in solution by addition of one equivalent of triethylamine to a solution of **1**, or by addition of one equivalent of perchloric acid to a solution of **2**. Figure 2 reproduces the changes in the UV/Vis spectrum of **1** upon the addition of Et_3N. Three isosbestic points are detected at 260, 555 and 680 nm, supporting the existence in solution of two chromophores. Spectra (b) to (d) can indeed be reproduced by assuming a linear combination of spectra (a) and (e), the coefficient for (e) being the number x of equivalents of base added and the one for (a) being $(1 - x)$. This indicates that the reaction is quantitative. The same holds if $HClO_4$ is added to **2** (see Scheme 3). A parallel control of the acido-basic conversions have been performed by X-band EPR and no signal has been detected, supporting the persistence in solution of dinuclear complexes.



Scheme 3

It was not possible to further deprotonate compound **1** with Et_3N contrary to what has been reported for the analogous phenanthroline complex.[37] This suggests that even in acetonitrile solution, the coordinated water molecule in **2** is engaged in a hydrogen bond interaction, which is in agreement with the postulated $H_3O_2^-$ bridge.

Conclusion

We have studied here the $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1](ClO_4)_4{\cdot}2H_2O$ [$\mathbf{1}(ClO_4)_4{\cdot}2H_2O$] species and the

associated monodeprotonated form $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH)L_1](ClO_4)_3\cdot H_2O$ [**2**$(ClO_4)_3\cdot H_2O$]. The two complexes have been characterized by different spectroscopic techniques such as UV/Vis and Raman. Compound **1**$(ClO_4)_4\cdot 2H_2O$ has, moreover, been characterized by an X-ray diffraction study. The interconversion between **1** and **2** by addition of one equivalent of base or acid has been followed by UV/Vis absorption spectroscopy. No evolution towards a di-bridged system in a dry acetonitrile solution has been noted for **2** contrary to what has been observed for other $[(H_2O)Fe(\mu\text{-}O)Fe(OH)]^{3+}$ systems containing coordinated pyridine groups.[14,15] The generation of the diamond core structure seems to be related to the lability of the coordinated water molecule and the nature of the polydentate ligand. Imidazole is a stronger σ-donor and weaker π-acceptor ligand than pyridine. This could be the origin of the elongation of the Fe−(μ-O) bond that is suggested from magnetic susceptibility and Raman data. The Fe^{III} ions could thus be less electrophilic when coordinated to imidazoles instead of pyridines, and less sensitive to a nucleophilic attack of the coordinated hydroxide ion, preventing the formation of the protonated diamond core structure.

Experimental Section

General Remarks: Reagents and solvents were purchased commercially and used as received. Acetonitrile used for solution studies was distilled before use and dried on an alumina column. The synthesis of *N,N′*-dimethyl-*N,N′*-bis(1-methylimidazol-2-ylmethyl)-ethane-1,2-diamine (L_1) has been described previously.[38]

Caution! *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small quantities of these compounds should be prepared and handle behind suitable protective shields.*

$[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1](ClO_4)_4\cdot X$ [X = $2H_2O$, **1$(ClO_4)_4\cdot 2H_2O$; X = C_2H_5OH, **3**$(ClO_4)_4\cdot C_2H_5OH\cdot H_2O$]:** An ethanol/water solution (1:1, 5 mL) containing L_1 (138 mg, 0.5 mmol) was mixed with one equivalent of sodium hydroxide (0.1 mL of a 5 M solution). $Fe(ClO_4)_3\cdot 6H_2O$ (232 mg, 0.5 mmol) dissolved in 2 mL of water was then added. An orange precipitate appeared that was then filtered and washed with water to give138 mg of product (48% yield versus Fe). When $Fe(ClO_4)_3\cdot 6H_2O$ was added as an ethanolic solution, an orange precipitate was also formed. In both cases orange crystals were obtained by slow evaporation of an acetonitrile solution differing only in the nature of the solvation molecules. − $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1](ClO_4)_4\cdot C_2H_5OH\cdot H_2O$ ($C_{30}H_{60}Cl_4Fe_2N_{12}O_{21}$, 1178.38): calcd. C 30.58, H 5.13, N 14.26, Cl 12.03; found C 30.47, H 5.05, N 14.06, Cl 12.00.

$[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH)L_1](ClO_4)_3\cdot H_2O$ (2**$(ClO_4)_3\cdot H_2O$):** To 10 mL of a methanolic degassed solution containing L_1 (138 mg, 0.5 mmol) and triethylamine (0.139 mL, 1.0 mmol) was added, under an argon atmosphere, 5 mL of a degassed methanolic solution of $Fe(ClO_4)_3\cdot 6H_2O$ (232 mg, 0.5 mmol). A small argon gas current was maintained overnight and tiny brownish green crystals were obtained (95 mg, 37% yield versus Fe). They were too small to allow an X-ray diffraction measurement. − $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH)L_1](ClO_4)_3\cdot H_2O$ ($C_{28}H_{53}Cl_3Fe_2N_{12}O_{16}$, 1031.85): calcd. C 32.59, H 5.17, N 16.29; Cl, 10.31; found C 32.64, H 5.11, N 16.01; Cl, 10.62.

Raman Spectroscopy: Raman spectra were recorded on a Jobin-Yvon double monochromator U_{1000} equipped with an As/Ga photomultiplier and photocounting detection. The excitation wavelength line was the 413.1 nm line of a Kr^+ laser at 10−15 mW incident power level. Solid samples of compounds **1**$(ClO_4)_4\cdot 2H_2O$ and **2**$(ClO_4)_3\cdot H_2O$ were mounted on a disk rotating at about 1000 rpm. The spectral width was 4 cm^{-1}. The solution sample of **2** was transferred in a degassed rotating cell. The spectral resolution was 6 cm^{-1}.

Magnetic Susceptibility Measurements: Magnetic susceptibility data were recorded on a MPMS5 magnetometer (Quantum Design Inc.). The calibration was made at 298 K using a palladium reference sample furnished by Quantum Design Inc. The data were collected over a temperature range of 10−300 K at a magnetic field of 1.0 T and were corrected for diamagnetism. The $\chi_M T$ vs. T curves were fitted using the van Vleck formula where the same g factor was assumed for each spin state S. The energies appearing in the exponential arguments are derived from the Heisenberg-van Vleck-Dirac Hamiltonian $-J\boldsymbol{S_1}\cdot\boldsymbol{S_2}$. The total spin S runs from $|S_1 - S_2|$ to $S_1 + S_2$ by unit steps.

EPR Spectroscopy: EPR spectra were recorded on Bruker ER 200 D and 300 spectrometers at X-band. For low temperature studies, an Oxford Instrument continuous-flow liquid helium cryostat and a temperature control system were used.

UV/Vis Spectroscopy: UV/Vis spectra were recorded on a Varian Cary 5E spectrophotometer.

X-ray Crystallographic Study: **1**$(ClO_4)_4\cdot 2H_2O$ ($C_{28}H_{56}Cl_4Fe_2N_{12}O_{21}$; M = 1150.33 g·mol^{-1}) crystallizes in the orthorhombic space group P_{bca} with a = 17.101(2) Å, b = 13.824(3) Å, c = 20.922(6) Å and α = β = γ = 90°, Z = 8, d = 1.545 g·cm^{-3}. The unit-cell and intensity data were measured with an Enraf−Nonius CAD-4 diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). A prismatic orange crystal of $[L_1(H_2O)Fe(\mu\text{-}O)Fe(OH_2)L_1](ClO_4)_4\cdot 2H_2O$ with the dimensions 0.53 × 0.33 × 0.25 mm was chosen for the X-ray diffraction measurement. The cell constants were obtained by least-squares procedures based upon the 2Θ values of 25 reflections measured in the range 22.0 < 2Θ < 23.7° at ambient temperature. During data collection, three control reflections were measured every three hours. The crystal was stable and the check reflections showed a negligible decay in intensity of 0.45% during all the X-ray data collection. A total of 8682 reflections were collected in the range 4.26 < 2Θ < 50.0° within [−20 ≤ h ≤20, 0 ≤ k ≤ 16, 0 ≤ l ≤ 24]. From 4348 independent reflections, 2867 were considered as observed [$I > 2\sigma(I)$]. The structure was solved by direct methods with the program SHELXS-86[39] and refined by using the SHELXL-93[40] program. The molecular cation was located in a special crystallographic position with the oxygen atom at an inversion center (0,0,0.5). The perchlorate anions were located in a general crystallographic position. The observed disorder in the structure involved the anions; both perchlorates were disordered over two sites with nonidentical occupations (0.74 and 0.26; 0.70 and 0.30). The structure was refined anisotropically (non-hydrogen atoms) by full-matrix least-squares approximation based on F^2. The hydrogen atoms at the oxygen atoms of water molecules were localized in a difference Fourier synthesis and refined isotropically. Other hydrogen atom positions were calculated by assuming geometrical positions and were included in the structural model. The final weighting scheme was $w = 1/[\sigma^2(F_o^2) + (0.0568\ P)^2 + 0.001\ P]$, where $P = (F_o^2 + 2F_c^2)/3$. The final refinement of this model was continued until convergence when $R1$ = 0.0360 for $F^2 > 2\sigma(F^2)$ and R_w =

0.0840 were reached. The final difference map showed the largest residual peaks of 0.398 and −0.169 e·Å^{-3}. The two largest peaks were found at the Fe atoms.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-143394. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Syntheses and Luminescent Properties of Eu^{III} and Tb^{III} Cryptates in Solution

Qiu-Yun Chen,[a] Chang-Jian Feng,[a] Qin-Hui Luo,*[a] Chun-Ying Duan,[a] Xin-Sheng Yu,[a] and De-Jun Liu[a]

Keywords: Europium / Lanthanides / Cryptands / Luminescence / Mass spectrometry

The syntheses, characterization and luminescent properties of europium(III) and terbium(III) cryptates synthesized by [2+3] condensation of tris(2-aminoethyl)amine with 2,6-diformyl-4-R-phenol (R = Cl, F, *t*Bu) in the presence of Eu^{3+} or Tb^{3+} have been reported. The crystal structure of the europium cryptate (R = Cl) shows that the coordination number of the Eu^{III} ion is nine and that a guest water molecule is encapsulated in the cavity. The cryptates have a high stability which confers good fluorescence properties in solution.

Introduction

Studies on the syntheses and properties of lanthanide macrocyclic complexes are a fascinating area.[1,2] Their novel structures and interesting properties make macrocyclic lanthanide complexes valuable for technological applications.[3−5] Europium(III) complexes, for instance, can be used as luminescence probes in biology,[6−9] as luminescence labels in medical diagnostics,[10,11] and as contrast agents for magnetic resonance imaging.[12,13] Recent research has demonstrated that cryptands are useful as potential ligands for encapsulating lanthanide(III) ions and are able to shield metal ions from interaction with solvents to avoid radiationless deactivation processes in luminescence emission. Cryptates have high thermodynamic and kinetic stability and metal ion dissociation is negligible at high dilution.

Lanthanide cryptates with valuable luminescence properties can be obtained by a suitable choice of ligands with antenna chromophores.[1] Recently, the syntheses and metal luminescence properties of some cryptates have been reported, such as the cryptates based on oxamacrocycles,[14,15] azamacrocycles,[16,17] macrocycles with bipyridyl[18,19] and phenanthroline groups,[20] and macrocycles with functionalized calixarenes.[21,22] However, the number and type of cryptates are still quite limited.[23] A new kind of lanthanide cryptate (Gd^{III}, Tb^{III}, Eu^{III} and Dy^{III} etc.) derived from tris(2-aminoethyl)amine (tren) and 2,6-diformylphenol (dfp) was reported previously by Nelson,[24] Fenton[25] and our group,[26] although their luminescence properties were hardly mentioned. Recently, Plates et al.[27] made a detailed study on the solid fluorescence of phenolic cryptates of Eu, Dy, Yb; in solution; their fluorescence, however, is quenched completely by nonradiative deactivation. Herein we report some europium(III) and terbium(III) cryptates derived from the reaction of tren with 2,6-diformyl-4-R-phenol [R = Cl (dcp), F (dfp), *t*Bu (dbp)] (Figure 1). Their compositions and structures are slightly different from those previously reported[24,25] due to different reaction conditions. They possess a high coordination number (nine), a water molecule encapsulated in the inner sphere of the complex as a guest (not coordinated to the metal ion), and a high stability. These features result in their good fluorescence properties in solutions.

Results and Discussion

Characterization of the Cryptates

According to the elemental analyses and molar conductivities (Table 1), the cryptates can be divided into three kinds: (a) 1:1 electrolytes $[Ln(H_2L^1)(NO_3)(H_2O)]NO_3$ [Ln = Eu^{III} **2**; Tb^{III} **3**]; (b) 2:1 electrolytes $[Eu(H_3L^1)(NO_3)(H_2O)](NO_3)_2$ **1**; (c) double salts (1:1 electrolytes) $[Ln(H_2L^{2,3})(NO_3)(H_2O)][Ln(NO_3)_4]$ (Ln = Eu^{III}, Tb^{III}, **4**−**7**]. The type of complex obtained was determined chiefly by the reaction conditions. For example, when using excess tren (i.e. a molar ratio tren:dfp (or dcp):Ln^{III} of 2:2:1), the phenolic protons were neutralized because of the slight basicity of the solution and the 1:1 electrolytes were obtained; when the molar ratio of the three materials is 2:3:1, the

Table 1. Elemental analysis and molar conductance data for the cryptates

No.	Cryptate (Formula)[a]	Yield (%)	Analysis(%) C, H, N[b]	Λ_m (298 K) scm^2mol (DMF)
1	$[Eu(H_3L^1)(NO_3)(H_2O)](NO_3)_2$ $(C_{36}H_{41}Cl_3EuN_{11}O_{13})$	65	39.30, 4.01, 13.45 (39.90), (3.87), (13.86)	125
2	$[Eu(H_2L^1)(NO_3)(H_2O)](NO_3)\cdot 4H_2O$ $(C_{36}H_{48}Cl_3EuN_{10}O_{14})$	73	38.78, 4.35, 12.34 (39.18), (4.35), (12.70)	88
3	$[Tb(H_2L^1)(NO_3)(H_2O)](NO_3)\cdot 9H_2O$ $(C_{36}H_{58}Cl_3N_{10}O_{19}Tb)$	68	35.80, 4.79, 11.77 (36.03), (4.87), (11.67)	81
4	$[Eu(H_2L^2)(NO_3)(H_2O)][Eu(NO_3)_4]\cdot 2H_2O$ $(C_{36}H_{44}Eu_2F_3N_{13}O_{21})$	58	31.72, 3.62, 13.30 (31.86), (3.30), (13.40)	65
5	$[Tb(H_2L^2)(NO_3)(H_2O)][Eu(NO_3)_4]\cdot 3H_2O$ $(C_{36}H_{46}F_3N_{13}O_{22}Tb_2)$	52	30.72, 3.32, 13.51 (31.14), (3.34), (13.12)	84
6	$[Eu(H_2L^3)(NO_3)(H_2O)][Eu(NO_3)_4]\cdot 3H_2O$ $(C_{48}H_{73}Eu_2N_{13}O_{21})$	48	38.84, 4.77, 12.68 (39.16), (4.94), (12.37)	84
7	$[Tb(H_2L^3)(NO_3)(H_2O)][Tb(NO_3)_4]\cdot 4H_2O$ $(C_{48}H_{75}N_{13}O_{22}Tb_2)$	47	38.40, 5.32, 12.46 (38.37), (5.02), (12.13)	81

[a] H_3L^1, H_2L^2, H_2L^3 denote the cryptand; the subscripts of H denote the number of protons on the phenoxy group in the cryptand. – [b] Calculated values for the formula of cryptates are given in parentheses.

2:1 electrolyte was produced; when excessive lanthanide(III) nitrate was added the double salts were obtained. Our one-step synthesis is quite different from the two-step procedure which includes the preparation of sodium complexes and a subsequent transmetallation reaction. In our cryptates, the coordination entities are also quite different from those of other authors[24,25,38] (see below).

The IR spectra of the cryptates (Table 2) show a band at ca. 1650 cm^{-1} attributable to ν(C=N). The bands at 1478 cm^{-1} and 1296 cm^{-1} are due to ν(N=O) (ν_1) and $\nu_{aym}(NO_2)$ (ν_5), respectively, of the coordinated nitrate. The $\nu_{sym}(NO_2)$ vibration (ν_2) at 1051 cm^{-1} is characteristic of a bidentate nitrate group. The strong sharp band at 1384 cm^{-1} is characteristic of an ionic nitrate.[36] The IR spectra show that there are both coordinated and ionic nitrates in the complexes.

The electronic spectra of the cryptates display three strong absorption bands. The band centered around 400 nm is assigned to the C=N chromophores, whereas the other two bands at ca. 270 nm and 230 nm are assigned to the π–π* transition of the K band of the benzene rings.

Thermogravimetric analysis of $[Eu(H_3L^1)(NO_3)(H_2O)](NO_3)_2$ shows that there are three weight-loss processes. The cryptate begins to lose 1.55% of its weight below 120 °C, corresponding to the loss of one water molecule (calcd. 1.65%), indicating that the water molecule in the cavity is only weakly bound. The second step occurs at 210–310 °C, where 11.1% of the total weight was lost, corresponding to the loss of the two nitrate ions in the outer sphere (calcd. 11.34%). In the range 311–340 °C, a weight loss of 5.8% is observed due to loss of the coordinated nitrate ion (calcd. 5.67%).

Electrospray Mass Spectrum

The positive-ion ES mass spectrum of $[Eu(H_2L^1)(NO_3)(H_2O)]^+$ is shown in Figure 2. The base peak at m/z = 887.5 corresponds to $[Eu(HL^1)]^+$ ($C_{36}H_{37}Cl_3EuN_8O_3$) whose isotopic distribution is shown in Figure 3a. From the numbers and natural isotopic abundances of the atoms in $[Eu(HL^1)]^+$, a revised program[37] was used to calculate the isotopic distribution at m/z = 887.5. The calculated pattern (Figure 3b) agrees well with the experimental one. The other peaks in Figure 2 can be assigned to the species formed by solvation, loss of protons and loss of the chlorine atoms from the benzene ring of the cryptate. The ES-MS peaks of the representative cryptates are shown

Table 2. IR and UV spectroscopic data for the cryptates **1**–**7**

Cryptate	IR ν_{max} (cm^{-1})						UV(MeCN) λ_{max} (nm) ($\varepsilon/dm^3mol^{-1}cm^{-1}$)		
	O–H	C=N	N=O	NO_3^-	NO_2 (asymm)	NO_2 (sym)			
1	3380	1650s 1640s	1478s	1384s	1296s	1051s	230 (83000)	264 (30000)	406 (16000)
2	3381	1653s	1478s	1384s	1297s	1050s	226 (86000)	269 (31000)	412 (13000)
3	3400	1645s	1475s	1384s	1292s	1060s	228 (96000)	268 (37000)	412 (18000)
4	3380	1655s	1478s	1384s	1290s	1040s	229 (79000)	272 (39000)	408 (25000)
5	3384	1645s	1475s	1384s	1292s	1040s	225 (58000)	272 (45000)	412 (33000)
6	3410	1642s	1478s	1384s	1296s	1042s	228 (73000)	267 (42000)	410 (10000)
7	3402	1640s	1478s	1384s	1296s	1041s	228 (94000)	251 (33000)	410 (12000)

in Table 3. The base peaks of the three cryptates formed by losing the encapsulated water molecule and the coordinated nitrate anion, namely $[Ln(H_nL)]^{n+}$, are different from those of the Nd^{III} cryptates,[26] with a base peak corresponding to $[Nd(HL^1)(NO_3)(H_3O)]^+$, indicating that under similar ES-MS conditions, the encapsulated water molecule and the coordinated nitrate anion in $[Eu(H_3L^1)(NO_3)(H_2O)]^{2+}$ can be lost easier than those in $[Nd(HL^1)(NO_3)(H_3O)]^+$. This may be due to the different distances between the water molecule and the metal atom in the cavity. In the cryptate **1** the distance for Eu−O(1w) is 3.070 Å, which is longer than the Nd−O(oxonium) bond (3.027 Å), as shown by X-ray structural analysis.

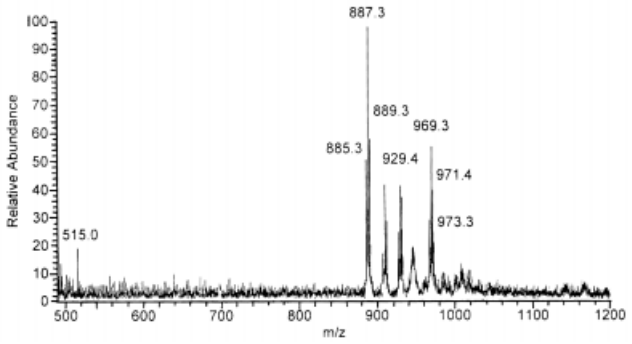

Figure 2. The ES-MS spectrum of the $[Eu(H_2L^1)(NO_3)(H_2O)]^+$ in MeOH

Crystal Structure

The structure of the cryptate cation $[Eu(H_3L^1)(NO_3)(H_2O)]^{2+}$ is shown in Figure 4. The crystal structure data are listed in Table 4 and 5. In the complex, Eu^{III} is located asymmetrically at one end of the cavity and is nine-coordinated, by three imino nitrogen atoms N(3), N(6), N(8), three phenolic oxygens O(1), O(2), O(3), two oxygens of the bidentate nitrate O(4), O(5) and one of the bridgehead nitrogen atoms, and forms a distorted monocapped square antiprism. The coordination distances are 2.491 and 2.532 Å, respectively, for two oxygens of the bidentate nitrate, in the range 2.288−2.416 Å for the phenolic oxygens, 2.492−2.562 Å for the imino nitrogens, and the Eu^{III}−N(4) distance is 2.761 Å, showing a weak interaction between Eu^{III} and the bridgehead nitrogen atom. Except for the coordination distance of Eu^{III}−N(4), the other bond distances are shorter than those of the Nd^{III} cryptate containing the same ligand.[26] This may be because the Eu^{3+} ion has a smaller radius than Nd^{3+}. In the distorted, capped, square antiprism, N(4) is the capped atom and the four oxygen atoms O(1), O(2), O(3), O(4) form the distorted basal plane (mean deviation 0.1862 Å); the distance between Eu^{III} and the basal plane is 1.3602 Å. The upper plane is composed of N(3), N(6), N(8) and O(5) (mean deviation 0.0776 Å), and the distance between the upper plane and Eu^{III} is 0.9551 Å. The biplanar angle between the two planes is 5.2°. The distance between the two bridgehead nitrogens N(1) and N(4) is 8.407 Å.

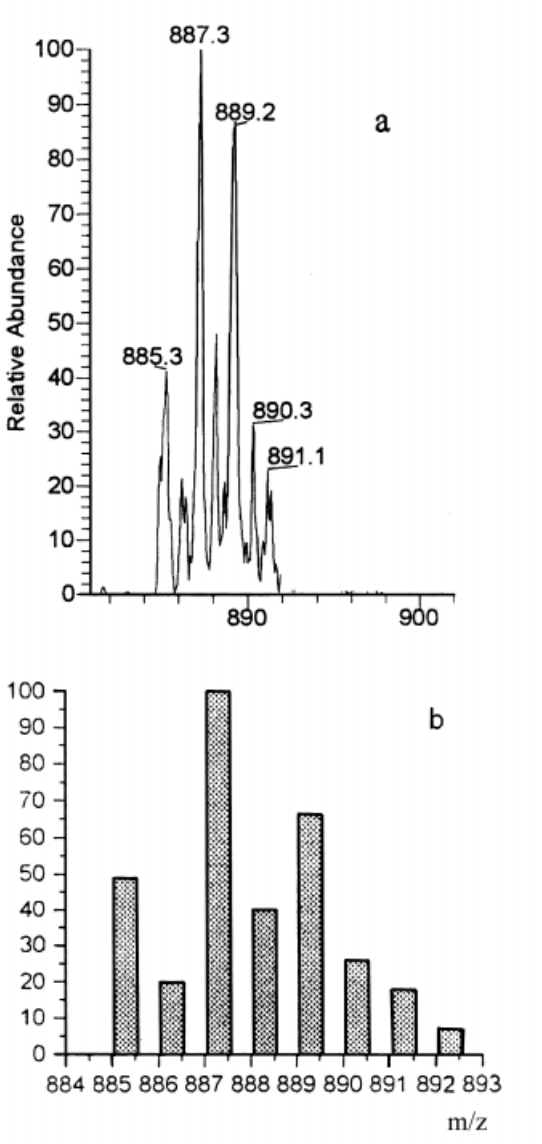

Figure 3. The isotopic distribution of the peak cluster at m/z = 887.5 for $[Eu(H_2L^1)(NO_3)(H_2O)]^+$: (a) experimental pattern, (b) calculated pattern

At one end of the cavity, a water molecule is encapsulated in the host macrocycle as a guest; the distance between O(1w) of the water molecule and Eu^{III} is 3.070 Å, and is longer than that of reported analogous cryptates whose distances are in the range 2.304−2.437 Å.[24,38] This confirms that the water molecule in our cryptate is not coordinated to the Eu^{III} atom.

Luminescence Properties of the Cryptates

Excitation of the Eu^{III} cryptates in MeCN solution with light at 400 nm gives rise to the characteristic emission of the Eu^{3+} ion and all four cryptates have similar emission spectra. Comparing the excitation band with the absorption band of the cryptate **2** at ca. 400 nm, the similarity between the absorption and excitation spectra indicates energy transfers from the excited state of the ligand to the Eu^{III} vibration level.[6] The emission spectrum of the cryptate **2**

Table 3. ES-MS spectroscopic data for the cryptates **2**, **6** and **7** in methanol solution

	Cryptate	Peak (*m*/*z*)	Assignment
2	$[Eu(H_2L^1)(NO_3)(H_2O)]^+$	969.5 (60)	$[Eu(H_2L^1)(NO_3)(H_2O)]^+$
		947.5 (25)	$[Eu(H_2L^1-2Cl)(NO_3)(H_2O)_2+MeOH]^+$
		929.5 (55)	$[Eu(H_2L^1-2Cl)(NO_3)(H_2O)+MeOH]^+$
		887.5 (100)	$[Eu(HL^1)]^+$
		515.0 (20)	$[Eu(H_3L^1\text{-}Cl)(NO_3)(H_2O)+3MeOH]^{2+}$
6	$[Eu(H_2L^3)(NO_3)(H_2O)]^+$	975.4 (45)	$[Eu(HL^3\text{-}C(CH_3)_3](NO_3)(H_2O)]^+$
		952.5 (100)	$[Eu(HL^3)]^+$
		476.8 (30)	$[Eu(H_2L^3)]^{2+}$
7	$[Tb(H_2L^3)(NO_3)(H_2O)]^+$	1022.2 (24)	$[Tb(H_2L^3)(NO_3)]^+$
		959.4 (48)	$[Tb(HL^3)]^+$
		511.7 (14)	$[Tb(H_3L^3)(NO_3)]^{2+}$
		480.2 (100)	$[Tb(H_2L^3)]^{2+}$

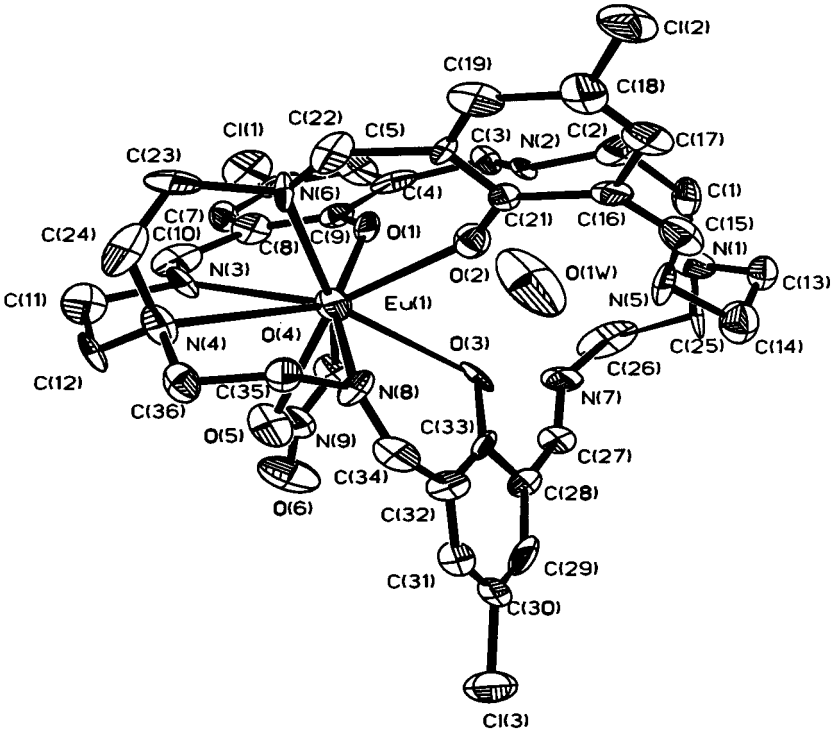

Figure 4. Crystal structure of $[Eu(H_3L)(NO_3)(H_2O)]^{2+}$ ion

is shown in Figure 5. All emissions arise from the $^5D_0$ level corresponding to the $^5D_0 \rightarrow {}^7F_1$ ($\Delta J = 0, 1-4$) transition. The weak band at 580 nm arises from the $^5D_0 \rightarrow {}^7F_0$ transition. The band around 593 nm for $^5D_0 \rightarrow {}^7F_1$, which is magnetic-dipole allowed, is hardly affected by a change of the coordination environment. The intense band around 613 nm for $^5D_0 \rightarrow {}^7F_2$ is an electric-dipole allowed transition and its emission intensity is sensitive to the coordination environment of Eu^{III}. The intensity for the $^5D_0 \rightarrow {}^7F_2$ transition is much higher than that for $^5D_0 \rightarrow {}^7F_1$, showing that the complex has no inversion center. All the ratios of the intensities of the $^5D_0 \rightarrow {}^7F_2$ to the $^5D_0 \rightarrow {}^7F_1$ transition are about 4.5:1 for the three cryptates (**2**, **4** and **6**) with different substituents, implying a similar symmetry.[23] The bands around 655 nm and the bands around 700 nm are produced from the transitions $^5D_0 \rightarrow {}^7F_3$ and $^5D_0 \rightarrow {}^7F_4$, respectively. A wide band around 480 nm is observed corresponding to the ligand emission whose quantum yield is 8.8×10^{-2} (MeCN).

Under the same experimental conditions, the Tb^{III} cryptate **7** displays a weak band at 542 nm, due to the $^5D_4 \rightarrow {}^7F_5$ transition, which is overlapped partly by a strong emission band of the ligand. For cryptates **3** and **5**, only a ligand-centered band is observed, implying a poor energy transfer between the ligand triplet state and the $^5D_4$ state of Tb^{III}.

The luminescent quantum yields and the life times at 613 nm of some Eu^{III} cryptates in MeCN are shown in Table 6. From this table it can be seen that the quantum yield and lifetime of the cryptate **2** with a chlorine substituent are higher than those of **3** and **6**. The reason for this is not clear yet as there are very few of these cryptates with which to make a good comparison.

The fluorescence properties of the europium(III) cryptates derived from 2,6-diformylphenol have attracted much attention. These studies have focused on the cryptates with CH_3, OCH_3 and phenyl substituents,[27,38] although they do not display fluorescent emission in solution. The luminescence difference between our cryptates and other authors' ones results from the different structures. As shown by the crystal structure, the coordination number of Eu^{III} in cryptate **1** is nine, and in **2**−**7** it is also nine. Coordinative saturation of Eu^{III} blocks the coordination of solvent molecules to the metal centre. It is of interest to note that, for **1**, the water molecule does not coordinate to Eu^{III} even though it is located within the cryptate cavity. This is not the case for the Eu^{III} phenolic cryptates reported by other authors,[24,25,38] in which coordination numbers of seven or eight, and a water molecule or monodentate ligand, which can dissociate easily (SCN^-,NO_3^-, etc.), are found coordinated to the metal ion. In these cases, in solution, the interaction between the Eu^{III} and water or solvent molecules results in nonradiative deactivation which quenches the fluorescence.

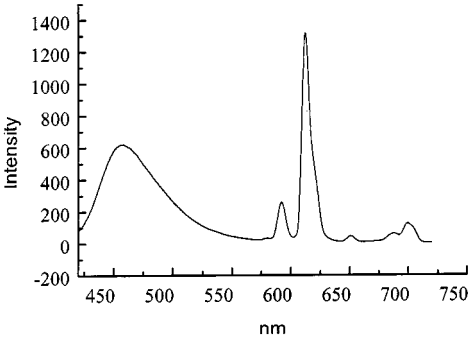

Figure 5. Emission spectra for the cryptate **2** in MeCN at an excitation wavelength of 400 nm

Experimental Section

Materials: $Ln(NO_3)_3 6H_2O$ (Ln = Eu, Tb) was prepared by dissolving Ln_2O_3 (99.99%) in an excess of nitric acid; 2,6-diformyl-4-R-phenol (R = Cl, F, *t*Bu)[28] and tris(2-aminoethyl)amine (tren) were prepared by literature methods.[29] Their physical constants and spectroscopic data are in agreement with literature values. The acetonitrile for the fluorescence study was dried by treatment with CaH_2 and distillation over P_2O_5. The $[Ru(bipy)_3]Cl_2$ used as a standard material in the quantum yield measurement was synthesized according to a literature procedure[30] and recrystallized twice from doubly distilled water. Its spectroscopic data were in agreement with literature values; its quantum yield value was checked against rhodamine B[31] and was also in accordance with the literature value.

Physical Measurements: Elemental analysis was performed on a Perkin−Elmer 240c analytical instrument. The molar electrical conductivitives in DMF solution containing ≈10^{-4} mol dm^{-3} com-

plexes were measured at 25 °C ± 0.1 °C using a BSD-A conductometer. The IR spectra were measured as a KBr disc using a Nicolet 5 DX FT-IR spectrophotometer. Electronic spectra were recorded on a UV-3100 spectrophotometer. Thermoanalysis of the complexes was performed on a SDT 2960C TA thermoanalyser under an argon atmosphere at a rate of 10 °C min^{-1}. The electrospray mass spectra (ES-MS) were determined on a Finnigan LCQ mass spectrometer; the concentrations of the samples were about 1.0 μmol dm^{-3}. The diluted solutions were electrosprayed at a flow rate of 5×10^{-6} dm^{-3} min^{-1} with a needle voltage of +4.5 kV. The mobile phase was an aqueous solution of methanol (v/v, 1:1). The samples were run in the positive-ion mode.

Luminescence Measurement: The luminescence spectra were measured with a Hiachi Model F4500 spectrofluorometer. In measurements of emission and excitation spectra the bandpass was 5.0 nm. The quantum yield of the Eu^{III} complexes was measured using a relative method with $[Ru(bipy)_3]Cl_2$ as the standard. Its quantum yield is 0.042 in aqueous solution at 20 °C.[35] The quantum yields of the Eu^{III} complexes were calculated from Equation (1):

$$\Phi_x/\Phi_s = [A_s/A_x]\,[n_x^2/n_s^2][D_x/D_s] \quad (1)$$

where Φ is the quantum yield, subscript s stands for the reference and x for the sample, A is the absorbance at the excitation wavelength, n is the refractive index (1.343 for MeCN solution and 1.344 for aqueous solution),[31] and D is the emission integrated area. The sample absorbances at excitation wavelength were kept as low as possible to avoid fluorescence errors (A_{exc} = 0.09−0.11). Solutions containing complexes of about 1.0×10^{-6} mol dm^{-3} were deoxygenated with a stream of super-pure nitrogen for 15 minutes.

The fluorescence lifetimes of the complexes were measured on a SPEX-FL2T2 spectrofluorimeter equipped with a flash lamp. The signals were recorded by photomultiplier using single-photon counting. Because in each solution only a single light-emitting species is present and there is no quenching of the emissive state by other excited state molecules, the fluorescence intensities decay exponentially over time t, obeying Equation (2):[34]

$$I_t = I_0 \exp(-t/\tau) \quad (2)$$

where I_0 and I_t are the fluorescence intensities at the time t = 0 and time t, respectively. The emission lifetime of fluorescence, τ, was obtained by fitting the fluorescence-decay curve into Equation (2).

Crystal Structure Determination: A summary of the crystal data, intensity collection and structure refinement is given in Table 4. Intensity data were measured on a Siemens P4 four-circle diffractometer with monochromatic Mo-K_α (λ = 0.71073) radiation in the ω-scan mode with a variable scan speed of 4.0−60.0° $min.^{-1}$ in ω. All data were corrected for Lorentz and polarization effects during data reduction using XSCANS.[32]

The structure was solved by direct methods. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares. The hydrogen atoms of the ligands were placed in their calculated positions with C−H = 0.93 Å. The hydrogen atoms of the water molecules in the cryptate **1** were found in the difference Fourier map. All the hydrogen atoms were assigned fixed isotropic thermal parameters (1.2 times that of the atoms to which they are attached) and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were included in the structure-factor calculations. One of the two nitrate anions was found to be disordered. The s.o.f.′s were 0.54 and 0.46 for the disordered parts containing nitrogen atoms N(11) and N(11′), respectively. All computations were carried out using the SHELXTL-PC program package.[33]

Syntheses of the Cryptates

$[Eu(H_3L^1)(NO_3)(H_2O)](NO_3)_2$ (1): A methanol solution (10 cm^3) containing tren (0.058 g, 0.40 mmol) was added dropwise to a stirred methanol solution (15 cm^3) containing dcp (0.111 g, 0.6 mmol) and $Eu(NO_3)_3{\cdot}6H_2O$ (0.112 g, 0.25 mmol). The reaction mixture was refluxed for 4 hours. Concentration of the solution resulted in the yellowish product $[Eu(H_3L^1)(NO_3)(H_2O)](NO_3)_2$ which was filtered off, washed with methanol and diethyl ether, and dried in a vacuum desiccator.

The cryptates **2**−**7** were prepared by a similar procedure except that the molar ratios were changed. For **2** and **3**: tren:dcp:Eu^{3+} = 1:1.2:0.5; for **4**−**7**: tren:dfp (or dbp):Eu^{3+} = 1:1.2:1.

First Dioxomolybdenum(VI) Complexes Containing Chiral Oxazoline Ligands: Synthesis, Characterization and Catalytic Activity

Montserrat Gómez,*[a] Susanna Jansat,[a] Guillermo Muller,[a] Gladys Noguera,[b] Helena Teruel,*[b] Vicent Moliner,[c] Elena Cerrada,[d,e] and Michael Hursthouse[e]

Keywords: Molybdenum / Oxo ligands / Oxidation / Catalysis / N ligands / Density functional calculations

The *cis*-[$MoO_2(N,O)_2$] complexes containing chiral oxazoline ligands (*N,O*) [**1**: *N,O* = **A**, (4′*R*)-2-(4′-ethyl-3′,4′-dihydroxazol-2′-yl)phenolato; **2**: *N,O* = **B**, (4′*S*)-2-(4′-isopropyl-3′,4′-dihydroxazol-2′-yl)phenolato] were synthesised and characterised, both in solution and in the solid state. These pseudo-octahedral neutral complexes were obtained as mixtures of diastereomers due to the chirality of the ligand and at the metal centre (Δ or Λ). Theoretical DFT calculations corroborate the isomer distribution. For complex **1**, the two major diastereomers, **Δ-*N*-*cis*-1** and **Λ-*N*-*trans*-1**, crystallised independently and the molecular structures were determined by single-crystal X-ray diffraction. NMR experiments at 800 MHz for **2** allowed the determination of the isomeric composition in solution. The product distribution depends on the coordinating nature of the solvent. Complexes **1** and **2** catalyse the oxidation of triphenylphosphane and styrene.

Introduction

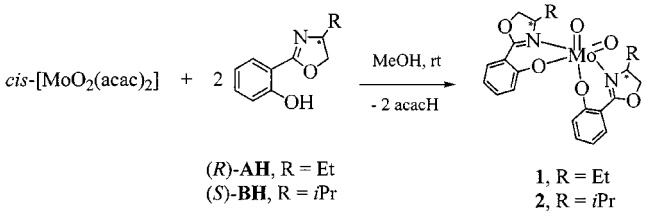
Transition metal oxo compounds are involved in oxygen transfer chemistry in both biological[1] and industrial processes.[2] Molybdenum complexes have been extensively studied, especially as models for heterogeneous oxidation catalysts and as the active site of oxo-transfer, molybdenum-containing enzymes.[3] Until recently, most oxo compounds used as oxidation catalysts contained sterically demanding sulfur ligands, since they were believed to be suitable models.[4] Indeed, the nature of the ligands around the molybdenum centre is critical for the success of the catalytic reaction.[5]

To understand oxo-transfer properties, numerous dioxomolybdenum complexes involving a wide range of ligands have been prepared and characterized.[6] Bidentate *S,S*-, *N,N*-, *O,O*- or *N,O*-donor ligands are common in monometallic complexes with the $[MoO_2]^{2+}$ core.[7] Among them, *N*-donor ligands[8] are of interest because they are robust in oxygen transfer reactions. In particular, chiral oxazoline ligands are especially useful in many organic transformations.[9] However, to the best of our knowledge, this kind of ligand has not been studied with molybdenum systems.

Therefore, we decided to synthesise neutral, monometallic complexes containing anionic ligands with oxazoline moieties. Here we describe the synthesis and characterization, both in solution and in the solid state, of new chiral oxomolybdenum complexes containing phenolatooxazoline ligands of the general formula *cis*-[$MoO_2(N,O)_2$] (where *N,O* = **A** or **B**). Moreover, we report on the ability of these complexes to act as oxo transfer reagents in oxidation processes.

Results and Discussion

A one-pot reaction of [$MoO_2(acac)_2$] and the optically pure oxazoline ligands [(*R*)-**AH**, (*S*)-**BH**] in methanol afforded the neutral dioxomolybdenum (VI) complexes **1** and **2**, respectively (Scheme 1), in a similar manner to that reported for Mo[10] and other metals (Ni, Pd, Mn).[11] All the compounds were obtained in high yields and are stable both in the solid state and in solution, although after several days in chloroform some oxazoline decoordination was detected by ^{1}H NMR spectroscopy.



Scheme 1

A relevant feature of these hexacoordinate complexes is the relative position of the bidentate anionic *N,O* oxazoline ligands, which leads to the formation of several geometrical isomers. According to the relative position of the iminic nitrogen atoms and the oxo groups, three arrangements are expected: a) the two oxazoline nitrogen atoms *cis* to both oxo groups (*N-cis*); b) each nitrogen atom *trans* to one oxo group (*N-trans*) and c) one nitrogen atom *cis* to the oxo groups and one *trans* to one oxo group (*N-cis,trans*) (Scheme 2). Owing to the asymmetrical environment

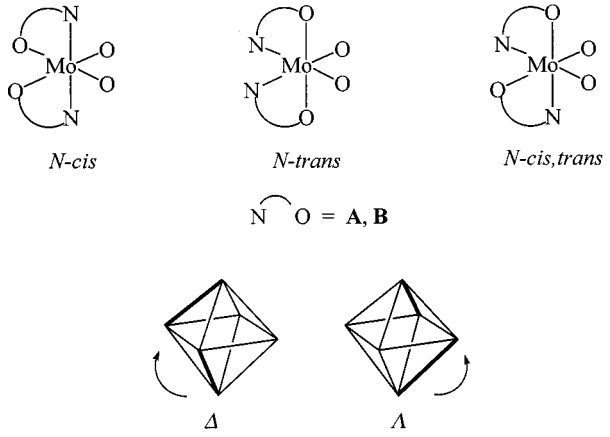
around the metal atom, each of these possibilities has a pair of isomers, Δ and Λ. Therefore, for each complex, six diastereomers are possible.



Scheme 2

Solid State Structures

The IR spectra for these Mo complexes exhibit two very strong absorption bands at ca. 920 and 890 cm^{-1}, which were assigned to the *cis*-[MoO_2] fragment. In addition, a strong signal at ca. 1620 cm^{-1} corresponds to the stretching of the C=N imine bond.

For complex **1**, monocrystals corresponding to two isomers were isolated from a dichloromethane/diethyl ether solution upon recrystallization. The crystal structures of complexes **Δ-*N-cis*-1** and **Λ-*N-trans*-1** determined by single-crystal X-ray diffraction analysis are shown in Figure 1 and 2, respectively.

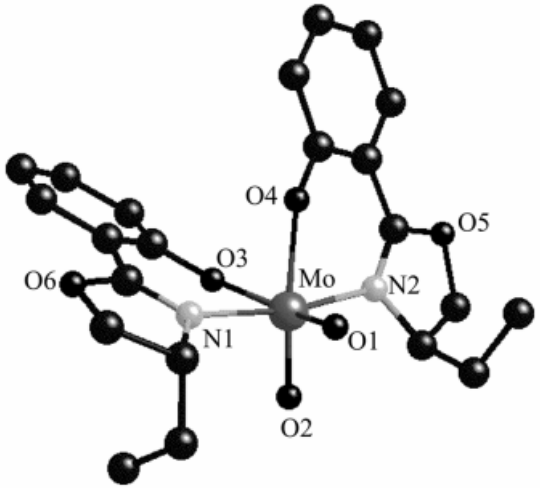


Figure 1. View of the molecular structure of complex **Δ-*N-cis*-1**; hydrogen atoms have been omitted for clarity

In both structures, the molecules show a distorted octahedral geometry around the molybdenum atom (Table 1). An expansion of the dioxo fragment O(1)−Mo−O(2) from 90° to 100.7° and 105.4° was observed for **Δ-*N-cis*-1** and **Λ-*N-trans*-1**, respectively, as reported for similar complexes.[10b,12] Furthermore, the N(1)−Mo−N(2) angle showed a contraction from 180° to 168.8° for **Δ-*N-cis*-1**, and from 90° to 75.4° for **Λ-*N-trans*-1**. A similar trend was observed for the O(3)−Mo−O(4) angle, from 90° to 80.5° and from 180° to 158.8° for **Δ-*N-cis*-1** and **Λ-*N-trans*-1**, respectively. The bite angles O(3)−Mo−N(1) and O(4)−Mo−N(2) were ca. 79° in both cases, an observation which is consistent with other dioxomolybdenum six-membered *N,O*-coordinated complexes.[10a,13]

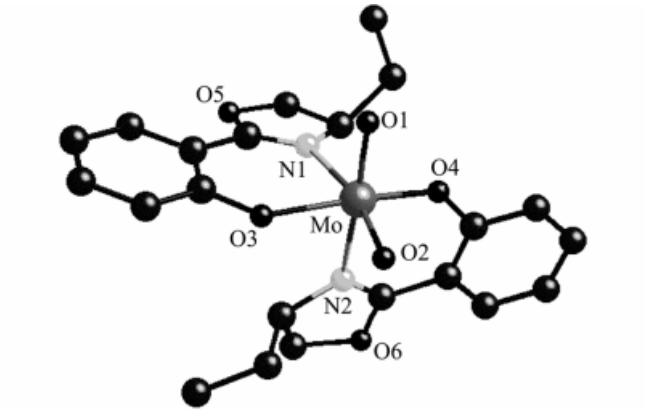

Figure 2. View of the molecular structure of complex **Λ-*N-trans*-1**; hydrogen atoms have been omitted for clarity

Table 1. Selected bond lengths (Å) and bond angles (°) for **Δ-*N-cis*-1** and **Λ-*N-trans*-1** (with esd's in parentheses)

	Δ-*N-cis*-1	**Λ-*N-trans*-1**
Mo−O(1)	1.700(2)	1.6991(14)
Mo−O(2)	1.708(2)	1.704(2)
Mo−O(3)	2.056(2)	1.964(2)
Mo−O(4)	2.045(2)	1.9541(14)
Mo−N(1)	2.149(3)	2.334(2)
Mo−N(2)	2.151(3)	2.312(2)
O(1)−Mo−O(2)	100.73(13)	105.37(8)
O(3)−Mo−N(1)	79.18(9)	78.91(6)
O(4)−Mo−N(2)	79.39(9)	78.15(6)
O(3)−Mo−O(4)	80.49(9)	158.81(7)
N(1)−Mo−N(2)	168.80(10)	75.37(6)

The Mo−O bond lengths for the dioxo group were ca. 1.7 Å in both structures, as reported previously.[14] The distances Mo−N for **Λ-*N-trans*-1** [Mo−N(1) = 2.31 Å and Mo−N(2) = 2.33 Å] were longer than for **Δ-*N-cis*-1** (Mo−N ≈ 2.15 Å) due to the oxo *trans* influence. However, the molybdenum phenolic oxygen lengths either in **Δ-*N-cis*-1** or **Λ-*N-trans*-1** showed a negligible influence of the geometrical arrangement.

To date, no *N-cis* dioxo bis(bidentate-*N,O*) molybdenum complexes have been described in the solid state in the literature. As this arrangement is only observed for complexes containing polydentate ligands, and is constrained by coordination requirements,[15] we carried out theoretical studies. DFT calculations for complex **1** showed that **Δ-*N-cis*-1** was the most stable conformer and that **Λ-*N-trans*-1** and **Λ-*N-**

***cis,trans*-1** were higher in energy by 2.6 and 10.9 kcal·mol^{-1}, respectively. Removal of the substituent at the stereocentre showed the same energy trend, but values were similar for Λ-*N-trans* and Λ-*N-cis,trans* (1.85 and 2.32 kcal·mol^{-1}, respectively). Therefore, the relative stability of Δ-*N-cis* and Λ-*N-trans* was independent of the substituent, while Λ-*N-cis,trans* was not.

NMR Spectroscopic Studies

NMR spectroscopy allowed us to detect the presence of several species for these molybdenum complexes in solution. To assign accurately the signals, the monocrystals obtained for complex **1**, ***N-cis*-1** and ***N-trans*-1**, were independently dissolved in deuterated chloroform at 233 K. Under these conditions, the spectra showed mainly the presence of the isomer found in the crystal. Remarkable differences in the chemical shifts for H_b were observed. Compared to the free oxazoline [$\delta(H_b) = 4.10$], for ***N-cis*-1**, the signal shifted downfield ($\delta = 4.68$), but upfield for ***N-trans*-1** ($\delta = 3.72$; Table 2). This behaviour can be attributed to interactions with the oxo groups, as shown by the average interatomic distances H···O=Mo from the crystallographic data (for ***N-cis*-1**, ca. 3.2 Å and for ***N-trans*-1**, ca. 4.6 Å).

For complex **2**, we distinguished four compounds in deuterated chloroform solution, with a ratio of 42:11:5:1. For complex **1**, the signals of the different species were less split, but in addition to the signals corresponding to the two major isomers (in a relative ratio of 17:8), other less-intense signals were also observed. No isomeric composition change was observed in either compound in the temperature range studied (from 233 K to 323 K).

The ^{1}H NMR spectra (monodimensional and 2D NOESY experiments) revealed that the two anionic *N,O* ligands (**A** and **B** fragments) are equivalent for the two major isomers, *N-cis* and *N-trans* (Table 2), for both complexes **1** and **2**. This observation suggests that, in solution, the pseudo-octahedral environment around the metal atom is more symmetric than in the solid state, where the two oxazoline ligands are inequivalent. However, the anionic ligands in the *N-cis,trans* isomer are not equivalent, as observed in the 800 MHz ^{1}H NMR spectrum for complex **2**

Table 2. Selected ^{1}H NMR spectroscopic data[a] (δ) for **1** ($CDCl_3$, 500 MHz, 298 K), **2** ($CDCl_3$, 800 MHz, 298 K) and **I** (CD_3COCD_3, 250 MHz, 200 K)

[a] Multiplicity (d, doublet; dd, doublet of doublets; m, multiplet; p, pseudo; t, triplet; td, triplet of doublets), relative integration, and coupling constants (in Hz) in parentheses. – [b] For atom labelling, see figure above table. – [c] Two overlapped multiplets for the ***N-trans*-2** and ***N-cis,trans*-2** isomers. – [d] One proton under $\delta = 4.66$ signal of ***N-cis*-2** isomer.

(Table 2). For this compound, the 2D NOESY spectra did not show exchange signals (at various mixing times: 250, 500 and 600 ms at 800 MHz) among the three isomers (***N-cis*-2**, ***N-trans*-2** and ***N-cis,trans*-2**). In addition, a fourth species (**I**) was observed, which showed broader signals and exchange signals with ***N-cis*-2** and ***N-trans*-2**.

Nevertheless, in deuterated acetone at 200 K, a mixture of two compounds (6:1) was observed, where **I** can be assigned to the more abundant species and the minor species seems to be ***N-cis*-2**. At higher temperatures, other signals associated with ***N-cis,trans*-2** appear and those belonging to **I** became less intense. A similar behaviour was observed for a solution of complex **2** in $CDCl_3/CD_3CN$ (1:1). These data indicate that acetone or acetonitrile compete with the oxazoline nitrogen for coordination to the metal. Therefore, the observed exchange process described above could be associated to the rupture of one Mo−N bond of one of the two major isomers (*N-cis* or *N-trans*) and subsequent nitrogen coordination to the metal, giving the other isomer (*N-trans* or *N-cis*).

Oxo-Transfer Reactions

The stoichiometric oxidation of PPh_3 by **1** or **2** was carried out in $CDCl_3$ at room temperature, and the solution was analysed by ^{31}P NMR spectroscopy. Total conversion of PPh_3 to $OPPh_3$ occurred in less than an hour and in 80 minutes with complex **2** and **1**, respectively, as shown in Figure 3.

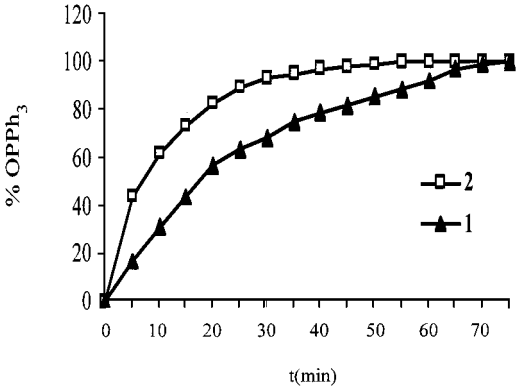

Figure 3. Plot of percent of triphenylphosphane formed against time for **1** or **2**

When complexes **1** and **2** reacted with an excess of PR_3 and DMSO, a fast reaction was observed, transforming the substrate into the corresponding oxide in a catalytic manner [Equation (1)].

$$PPh_3 + (CH_3)_2SO \xrightarrow{[Mo]} OPPh_3 + (CH_3)_2S \quad (1)$$

[Mo] = **1**, **2**

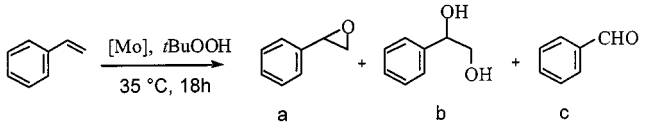
After three days, no phosphane was detected in either case. The colour of the reaction mixtures changed from yellow to yellow-green for complex **2**, and from yellow to yellow-orange for **1**. These reactions contrast with other disubstituted dioxomolybdenum compounds such as $[MoO_2(S_2CNR_2)_2]$,[16] which immediately turns purple (Mo^V), thus our results indicate that the oxo transfer process with complex **1** or **2** does not involve a Mo^V-oxo intermediate.

Styrene Epoxidation

Complexes **1** and **2** were also tested as catalytic precursors in styrene epoxidation, using several oxidants: DMSO, hydrogen peroxide and *t*BuOOH. Conversion of the substrate was only observed with the organic peroxide. No epoxide was obtained in the absence of the molybdenum complex.

The activity obtained with complexes **1** and **2** (25−29% conversion of the olefin) was relatively low when compared, under identical experimental conditions, with other dioxomolybdenum systems such as $[MoO_2(S_2CNEt_2)_2]$ and $[MoO_2(NCS)_2(bipy)]$, but was similar to $[MoO_2(acac)_2]$ (Table 3). However, **1** and **2** showed a better selectivity towards styrene oxide and its diol than the other complexes tested, while benzaldehyde, the cleavage product, was produced in a small amount (10.4−11.5%). The asymmetric induction for **1** and **2** was practically negligible (ca. 2% *ee*).

Table 3. Mo-catalyzed styrene epoxidation[a] with *t*BuOOH as oxidant



[Mo]	Conv. (%)[b]	**a** (%)[c]	**b** (%)[c]	**c** (%)[c]
1	29.0	12.8	5.8	10.4
2	25.0	8.8	4.7	11.5
$[MoO_2(acac)_2]$	26.0	2.8	6.4	17.0
$[MoO_2(S_2CNEt)_2]$	42.0	6.1	10.6	25.4
$[MoO_2(NCS)_2(bipy)]$	66.5	13.0	4.6	48.8

[a] Reaction conditions: 0.05 mmol of catalyst, 2 mmol of olefin, 3 mmol of *t*BuOOH and 2 cm^3 of toluene at 35 °C for 18 h. − [b] Yield based on amount of oxygenated products as determined by GC chromatography. − [c] Yield based on reacted styrene determined by GC chromatography.

Conclusions

We conclude that the oxazoline ligands [(*R*)-**AH** and (*S*)-**BH**] allow the stabilisation of molybdenum(VI) complexes of general formula *cis*-$[MoO_2(N,O)_2]$ (**1** and **2**), which are obtained as mixtures of three diastereomers due to the ligand and metal chirality. The structural elucidation of these mixtures was performed by means of NMR spectroscopy and X ray diffraction. Theoretical studies (DFT) have allowed us to corroborate that the Δ-*N-cis* coordination is the most stable arrangement. Moreover, a fourth species, **I**, is present in solution. In chloroform, the major compound is Δ-*N-cis*, an arrangement which until now has only been observed for polydentate ligands. In contrast, in coordinating solvents (acetone and acetonitrile), **I** becomes the major

species. Although the catalytic activity of complexes **1** and **2** in styrene oxidation is relatively low, the selectivity towards styrene oxide and its diol is important under the mild experimental conditions tested.

Experimental Section

General: All compounds were prepared under a purified nitrogen atmosphere using standard Schlenk and vacuum line techniques. The solvents were purified by standard procedures and distilled under nitrogen.[17] *cis*-$[MoO_2(acac)_2]$[18] and the ligands (*R*)-**AH** and (*S*)-**BH**[19] were prepared as described previously. NMR spectra were recorded on Bruker Avance 600, Bruker Avance 800, Varian XL-500, Varian Gemini or Bruker DRX 250 spectrometers. Chemical shifts are reported downfield from standards (TMS for ^1H NMR spectra and H_3PO_4 for ^3P NMR spectra). IR spectra were recorded on a Nicolet 520 FT-IR and Bruker IFS 55 FTIR spectrometer. FAB mass spectra were obtained on a Fisons V6-Quattro instrument. The GC-MS analyses were performed on a Hewlett-Packard 5890 Series II gas chromatograph (50 m Ultra 2 capillary column) interfaced to a Hewlett-Packard 5971 mass selective detector. Enantiomeric excesses were determined by GC on a FS-cyclodex-β-I/P column. Elemental analyses were carried out by the Serveis Cientifico-Tècnics de la Universitat de Barcelona in an Eager 1108 microanalyzer.

Dioxo-bis[(4′*R*)-2-(4′-ethyl-3′,4′-dihydroxazol-2′-yl)phenolato-*N,O*]molybdenum(VI) (1): A solution of (+)-(4′*R*)-2-(4′-ethyl-3′,4′-dihydrooxazol-2′-yl)phenol (0.258 g, 1.350 mmol) in CH_3OH (5 cm^3) at room temperature was added to a solution of $[MoO_2(acac)_2]$ (0.200 g, 0.617 mmol) in CH_3OH (20 cm^3). The reaction mixture was stirred for 4 h and the light orange precipitate was filtered and recrystallised from CH_2Cl_2/diethyl ether (2:1). Yield: 0.251 g (80%). − $C_{22}H_{24}MoN_2O_6$ (508.38): calcd. C 51.98, H 4.76, N 5.51; found C 50.90, H 4.86, N 5.40. − MS (FAB positive): *m*/*z* = 508 [M^+]. − IR(KBr): $\tilde{\nu}$ = 1648 (st, C=N), 910, 882 (Mo=O) cm^{-1}.

Dioxo-bis[(4′*S*)-2-(4′-isopropyl-3′,4′-dihydroxazol-2′-yl)phenolato-*N,O*]molybdenum(VI) (2): A solution of (−)-(4′*S*)-2-(4′-isopropyl-3′,4′-dihydrooxazol-2′-yl)phenol (0.277 g, 1.350 mmol) in CH_3OH (5 cm^3) at room temperature was added to a solution of $[MoO_2(acac)_2]$ (0.200 g, 0.617 mmol) in CH_3OH (20 cm^3). The reaction mixture was stirred for 4 h and the yellow precipitate was filtered and recrystallised from CH_2Cl_2/diethyl ether (2:1). Yield: 0.288 g (87%). − $C_{24}H_{28}MoN_2O_6$ (536.43): calcd. C 53.74, H 5.26, N 5.22; found C 53.50, H 5.29, N 5.25. − MS (FAB positive): *m*/*z* = 537 [M^+]. − IR (KBr): $\tilde{\nu}$ = 1650 (st, C=N), 919, 885 (Mo=O) cm^{-1}.

Oxidation of PPh_3 by Complex 1 or 2: A solution of PPh_3 (30 mg, 0.115 mmol) in $CDCl_3$ (0.6 cm^3) was added to **1** (20 mg, 0.039 mmol) or **2** (20 mg, 0.037 mmol) in an NMR tube and the solution was monitored immediately by $^{31}P\{^1H\}$ NMR spectroscopy at 25 °C. The first kinetic point was taken at *t* = 5 min. The reaction was followed by integrating the signals corresponding to triphenylphosphane and triphenylphosphane oxide.

Oxidation of PPh_3 by DMSO in the Presence of Complex 1 or 2: DMSO (0.5 cm^3) was added to a mixture of **1** (20 mg, 0.039 mmol) or **2** (20 mg, 0.037 mmol) and an excess of PPh_3 (30 mg, 0.115 mmol) in $CDCl_3$ (0.6 cm^3). An aliquot of this solution was transferred to an NMR tube and the solution was monitored immediately by $^{31}P\{^1H\}$ NMR at 25 °C. The first kinetic point was taken at *t* = 5 min. The reaction was followed by integrating the signals corresponding to triphenylphosphane and triphenylphosphane oxide.

Molybdenum-Catalysed Styrene Epoxidation: The precursor (0.05 mmol of complex: 25.7 mg for **1**; 27.1 mg for **2**) was dissolved in

2 cm^3 of toluene. Styrene (208 mg, 2 mmol) was added, followed by an aqueous solution of *tert*-butyl hydroperoxide (*t*BuOOH/H_2O: 3:2; 0.19 cm^3, 3 mmol). The mixture was stirred for 18 h at 35 °C, until no conversion of styrene was observed (monitored by gas chromatography). After removing the solvent under reduced pressure, the oil was purified by column chromatography (SiO_2; ethyl acetate). The conversion of styrene was determined by gas chromatography. The enantiomeric excesses were determined by gas chromatography.

Crystallography: The crystallographic data for **Δ-*N-cis*-1** and **Λ-*N-trans*-1** are summarized in Table 4. Single crystals were grown by diffusing diethyl ether into a dichloromethane solution of the isomer mixture, thereby obtaining orange (**Δ-*N-cis*-1**) and yellow (**Λ-*N-trans*-1**) crystals.

The crystal data for both isomers were collected using a Delf Instrument FAST TV area-detector diffractometer positioned at the window of a rotating-anode. Intensities were collected with graphite monochromated Mo-K_α radiation (λ = 0.71069 Å), using the $\omega/2\theta$ scan technique. Structures were solved by direct methods using the SHELXS-97 program and refined by full-matrix least-squares on F_o^2 using SHELXL-97.[20] Data were corrected using the SORTAV program.[21] All hydrogen atoms were included in idealised positions.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-153158 (**Λ-*N-trans*-1**) and -153159 (**Δ-*N-cis*-1**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Calculations: The geometry of the isomers ***N-cis***, ***N-trans*** and ***N-cis,trans*** was optimized[22] in vacuo by means of the GAUSSIAN98 package of programs.[23] Ab initio molecular orbital calculations were carried out at the Hartree−Fock (HF) level with methods based on Density Functional Theory (DFT), and using the standard 3−21G basis set. We used Becke′s three-parameter functional (B3)[24] which includes the Slater exchange along with corrections involving the gradient of electron density, and the correlation functional of Lee, Yang and Parr, which includes both local and nonlocal terms (LYP).[25,26] The parameters are those determined by Becke by fitting to the G1 molecule set.[24b,27]

Keywords: Macrocycles / N ligands / Copper / Structure elucidation / Electrochemistry

We report the first direct synthesis of a *trans*-III copper(II) complex of tetramethylcyclam. This new derivative is hexacoordinate in the solid state and square planar in solution. Reduction of this latter leads to a complex voltammetry pattern which could be explained considering an isomerization process.

Introduction

N-substituted polyazamacrocycles have several potential applications: *N*-substituted cyclams, which represent the most widely studied series of tertiary amine macrocycles can be used for medical purposes,[1,2] treatment of water wastes containing heavy metals,[3] or catalysis.[4] Therefore the understanding of the influence of *N*-substitution of the ligand on the coordination mode still remains an important field of interest.

The *N,N′,N″,N‴*-tetramethylcyclam derivative (tmc) was first obtained by Barefield and co-workers in the early 70′s.[5,6] A recently described alternative to this seminal synthesis involves the reduction of a bisammonium salt of the bisaminal 1,4,8,11-tetraazatricyclo[9,3,1,1^{4,8}]hexadecane and allows the preparation of tmc without further purification with an overall yield of ca. 80% starting from cyclam.[7]

Metallation of tmc by transition metal ions systematically led to five-coordinate type-I isomers[8] with all substituents (methyl groups and metal axial ligand) pointing in the same direction. This geometry, first suggested by UV/Vis spectroscopy, has since been confirmed by X-ray diffraction studies of numerous tmc complexes of Ni^{II},[9,10] Cu^{II},[11] Fe^{II},[12] Zn^{II},[13] and Co^{II}.[14] Although different conformations were reported for the macrocycle, the isomers were all characterized by the pentacoordination of a metal ion located above the macrocyclic cavity, and bearing one axial ligand, either an anion or a neutral coordinating solvent molecule. Type-III isomers could, until now, only be obtained by tetramethylation of the easily available cyclam type-III homologues;[15,16] clean isomerisation of type-I to type-III isomers could not be achieved, although an interconversion process restricted to nickel species in strongly coordinating solvent has been reported.[9,10,17,18]

Results and Discussion

We report here the first direct synthesis of a type-III [tmcCu]$^{2+}$ starting from the free ligand and the metallic salt: indeed, when tmc was dissolved in a refluxing solution of sodium hydroxide in water followed by addition of copper bis(tetrafluoroborate), only the type-III [(tmc)Cu](BF$_4$)$_2$ isomer was isolated (See Experimental Section). UV/Vis spectroscopic data correspond to a type-III square-planar (N$_4$) structure in solution, whereas a *trans*-III configuration with two BF_4^- counterions coordinated to the copper ion could be established in the solid state by X-ray crystallography (see below). Since complexation in water at room temperature affords the pentacoordinated I isomer, it appears that the temperature and basicity of the reaction medium are the key parameters responsible for the stereochemistry of the complexation; a very similar observation has been reported in the case of *N,N′*-difunctionalised derivatives.[19]

The visible spectrum of (tmc)Cu^{2+} is rather insensitive to the nature of the solvent; shifting from coordinating (water) to noncoordinating (nitromethane) solvents led to a shift of λ_{max} from 558 to 530 nm and ε from 193 to 142. This fact suggests that the solvent does not take place in the first coordination sphere and leads us to propose a square-planar (N$_4$) coordination scheme for [(tmc)Cu](BF$_4$)$_2$ in solution. These data are close to those observed for related copper complexes known for their square-planar geometry. For example, Elias et al. and Delgado et al. reported absorption maxima (epsilon values) of 520−600 nm (131−139), and 580 nm (192), respectively.[20−22] Moreover, these values differ significantly from those obtained for pen-

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0404−1077 $ 17.50+.50/0

tacoordinate tmc copper complexes ($\lambda_{max} \approx 690$ nm, $\varepsilon \approx 260$)[23] and hexacoordinate cyclam copper complexes ($\lambda_{max} = 586-620$ nm, $\varepsilon \approx 50$).[19]

Conversely, in the solid state, the complex exhibits a hexacoordinate *trans*-III geometry. The asymmetric unit (see ORTEP[24] view in Figure 1) is composed of one half of the complex (with the Cu^{2+} cation lying on an inversion centre) and a BF_4^- anion. The complex presents a distorted octahedral geometry with the copper atom located in the N_4 plane and a fluorine atom coordinating the latter in an axial position on both sides of the macrocycle.

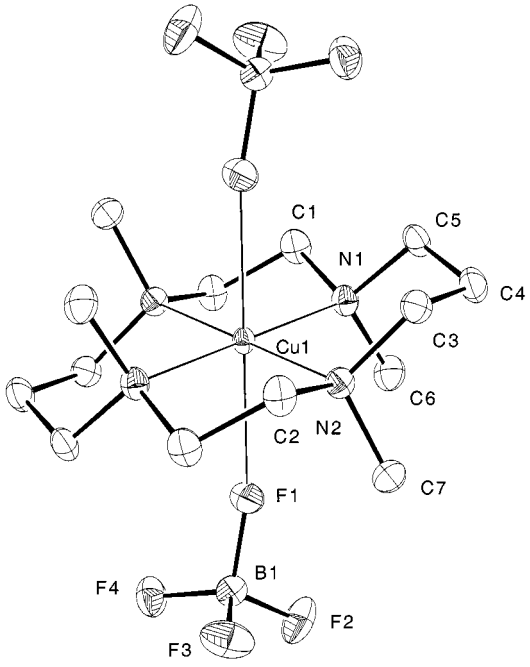

Figure 1. ORTEP drawing of *trans*-III $[(tmc)Cu](BF_4)_2$; the thermal ellipsoids are at the 50% probability level

The anion coordination is evidenced by the distance F1−Cu (2.529 Å), the almost four right angles F1−Cu−N ($89.30 < \alpha < 90.70°$) and the longer distance B−F1 (1.421 Å) when compared to the other three B−F bond lengths (1.376−1.386 Å). The equatorial Cu−N distances are almost equivalent [2.074(1) and 2.077(1) Å] and the N−Cu−N angles are close to right angle values [86.89(5) and 93.11(5)°]. The N−C and C−C distances range from 1.489 to 1.497 Å and from 1.513 to 1.526 Å, respectively, indicating a very small dispersion around their respective mean values 1.493(5) and 1.519(5) Å. All bond lengths and angles are comparable to typical values found in the literature for this kind of complex.[25] The six- and five-membered rings building the complex have chair and envelope conformations, respectively.

Electrochemical reduction of this type-III $[(tmc)Cu](BF_4)_2$ dissolved in acetonitrile leads to a complex voltammetry pattern. The reduction happens at a rather high potential (−0.41 V vs. SCE, 2 V/s), in agreement with the general trend of tmc ligands stabilising lower oxidation states than unsubstituted cyclam; however, the reduction wave remains chemically irreversible even at potential scan rates as high as 2000 V s^{-1} and a new redox couple appears at $E^0 = -0.28$ V as shown in Figure 2. This clearly establishes that the initially formed type III $[(tmc)Cu]^+$ has a lifetime shorter than 50 μs and very rapidly evolves to another copper(I) species that is fairly stable on the cyclic voltammetry time scale, as evidenced by its chemically reversible oxidation wave (Figure 2A). At longer time scales, corresponding to slow cyclic voltammetry, this new Cu^I species also undergoes a rearrangement to yield a third form of $[(tmc)Cu]^+$, the reversible oxidation of which now takes place around $E^0 = +0.07$ V (Figure 2B).

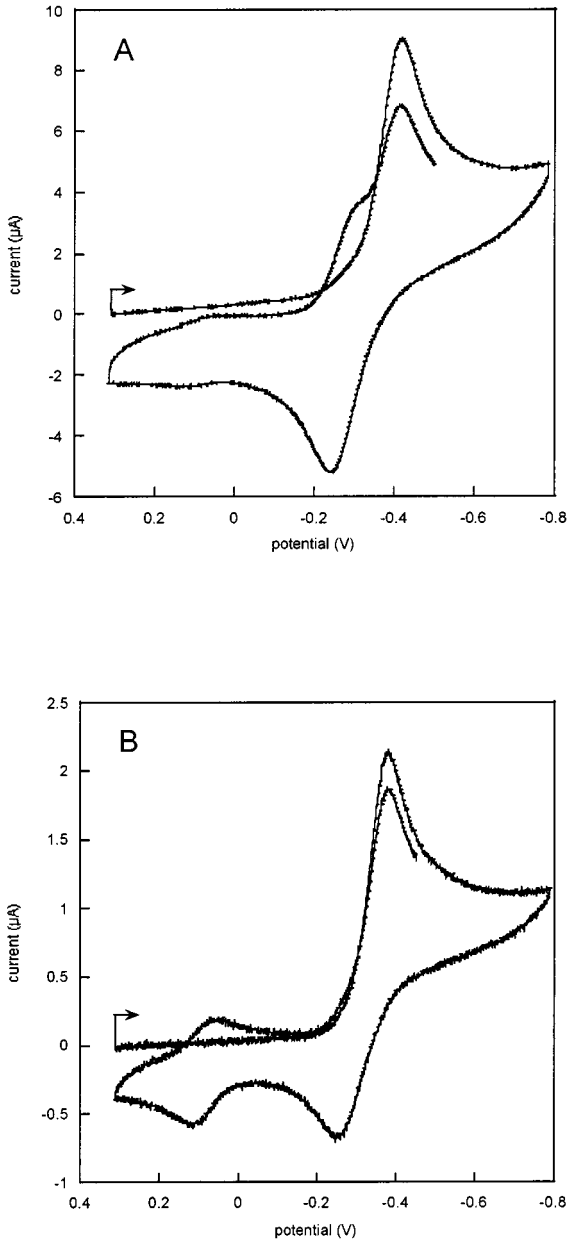

Figure 2. Cyclic voltammograms of a 2 mm solution of type-III $[(tmc)Cu](BF_4)_2$ in acetonitrile 0.1 M $nBu_4N(BF_4)$ recorded at a platinum disc electrode (0.5 mm diameter) at room temperature; potential scan rate 10 V/s (A) and 0.5 V/s (B)

This general pattern is reminiscent of what has been observed and described for a related *trans*-III derivative of copper(II) coordinated to a hexadentate tetra-*N*-substituted

cyclam derivative.[19] In the latter case, the observation of two subsequent isomerisations of the initial copper(I) complex has been attributed to partial decoordination associated with a modification from a type-III to a type-I configuration. Further investigations concerning the assignment of the structure of the electrogenerated (tmc)Cu^+ derivatives are required to confirm the analogy and establish the occurrence of a related type-III to type-I transformation process taking place at the level of the tmc copper(I) derivative.

Work is in progress to clearly establish the influence of the experimental conditions (pH, temperature, ...) on the stereochemistry of tetra-*N*-substituted cyclam complexes.

Experimental Section

General: UV/Vis spectroscopic data were collected on a Varian Cary 5 spectrophotometer. Mass spectra were recorded on a Bruker ProFlex III MALDI/TOF mass spectrometer using dithranol as matrix. X-ray diffraction data were collected on an Enraf−Nonius Kappa-CCD diffractometer equipped with an Oxford Cryostream low temperature device.

All the electrochemical experiments were run under argon. $n$$Bu_4NBF_4$ was used as the supporting electrolyte; it was obtained from $n$$Bu_4N(HSO_4)$ and $NaBF_4$, recrystallized from ethyl acetate/hexane and dried at 60 °C under vacuum.

Cyclic voltammetry experiments were performed in an air-tight, three-electrode cell connected to a vacuum line. The reference electrode was SCE (Tacussel) separated from the solution by a bridge compartment filled with the same solvent supporting electrolyte solution as that used in the cell. The counter electrode was a platinum spiral wire with ca. 1 cm^2 apparent surface area. The working electrodes were disks obtained from cross sections of gold wires (diameters 25 to 500 μm). An EG & G PAR-175 signal generator was used; the potentiostat was home-made, with a positive feedback loop for ohmic drop compensation. The currents and potentials were recorded on a Nicolet 310 oscilloscope.

[(tmc)Cu](BF$_4$)$_2$: Tetramethylcyclam (0.64 g, 2.5 mmol) and NaOH (0.3 g, 7.5 mmol) in 20 mL of water were heated under stirring at 90 °C. $Cu(BF_4)_2{\cdot}H_2O$ (0.64 g, 2.5 mmol) was then added. The mixture was stirred at 90 °C for one hour. After filtration and slow evaporation of the solvent, purple crystals of *trans*-III [(tmc)Cu]$(BF_4)_2$ suitable for an X-ray study were collected (0.62 g, 50%). − MS (MALDI/TOF): m/z = 319 [(tmc)Cu]$^+$. − $C_{14}H_{32}B_2CuF_8N_4$ (493.58): calcd. C 34.07, H 6.53, N 11.35; found C 34.48, H 6.22, N 11.33.

X-ray Crystallographic Study: Crystal data for $[C_{14}H_{32}N_4Cu][2(BF_4)]$, dark blue prismatic crystal of dimension 0.42 × 0.20 × 0.14 mm, M = 493.60, monoclinic, space group $P2_1/n$, Z = 2, a = 8.9279(3) Å, b = 9.2302(2) Å, c = 12.6028(4) Å, β = 91.55(1)°, U = 1038.17(5) Å^3, D_c = 1.579 g cm^{-3}, T = 130(2) K, F(000) = 510, Mo-K_α radiation (λ = 0.71073 Å), μ = 1.130 mm^{-1}, 16925 reflections measured in the range 2.74° ≤ θ ≤ 30.02°, with 3016 being unique (R_{int} = 0.0752) which were used in all calculations. The structure was solved by direct methods and refined using full-matrix least-squares on F^2 to $R1$ = 0.0330, S = 1.009, for 2548 reflections with $I > 2\sigma(I)$ and 133 refined parameters, $wR2$ (all data) = 0.0805. Programs used: SHELXS-97 for structure determination and SHELXL-97 for refinement (G. M. Sheldrick, University of Göttingen).

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-150973. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Electrochemical Strategies for the Strengthening of Polymer−Metal Interfaces

Noëlle Baute,[a] Christine Jérôme,[a] Lucien Martinot,[b] Marc Mertens,[a] Viktor M. Geskin,[c] Roberto Lazzaroni,[c] Jean-Luc Brédas,[c] and Robert Jérôme*[a]

Keywords: Electrochemistry / Polymers / Surface chemistry

Polymers have been widely used for the protection of metals against corrosion and for improving the performance of structural adhesive joints. In this contribution, the weakness and short-term durability of these polymer–metal interactions and some common approaches for alleviating this problem are briefly reviewed. Among the existing techniques, electrochemical processes offer the advantage of controlled interfacial reactions. Promising results have been reported by Stratmann et al. and Lécayon et al., who have emphasized the interest and opportunity to create strong chemical bonds between the organic coating and the metallic substrate. Their work is discussed in this review, along with results recently obtained in our group.

1. Polymer−Metal Associations

Suitable combinations of metals and organic polymers play an increasingly important role in modern technology. One of the most direct examples is the use of polymers as glue for metal objects. The adhesive bonding for structural joint formation has several distinct advantages over more conventional joining techniques: (i) the lack of local stress concentration, in contrast to riveted joints; (ii) the limitation of electrolytic corrosion when different metals are joined; and (iii) easy design and construction techniques.[1] Furthermore, polymer coatings have the potential to protect metals from chemical corrosion by acting as barriers.[2,3] Generally, only permanent polymer−metal interactions can delay delamination when the environment contains very aggressive species (e.g. ions, oxygen, water), prone to electrochemical and chemical attack.[4−8] As a rule, as long as the coating adheres strongly to its substrate, the metal is efficiently protected from any corrosion processes. Conversely, any defect or discontinuity in the coating (e.g., as a consequence of mechanical stress), makes the metal accessible to the electrolyte, thereby forming an aqueous corrosion cell between this defect and the delamination front. It is generally accepted that corrosion does not play a decisive role in the loss of adhesion in metal−polymer joints, but that this problem is rather a post-failure phenomenon.[9−11]

Noëlle Baute was born in Verviers (Belgium) in 1972, and studied chemistry at the University of Liège where she obtained her degree in 1994. In 1995, she joined the group of Professor R. Jérôme at the "Center for Education and Research on Macromolecules", where she studied the electrochemical grafting of polymers onto metals and contributed to the extension of this process to various acrylic and methacrylic monomers. She received a PhD for this research work in 1999. She is currently working at AEROFLEET (Liège, Belgium), in the section for high technology composite materials.

Christine Jérôme was born in Belgium in 1971, and studied chemistry at the University of Liège. In 1995 she joined the group of Professor R. Jérôme at the "Center for Education and Research on Macromolecules" where she studied conducting polymers as ion-exchange resins for radioactive waste treatment. She received a PhD for this research work in 1999. She currently holds a Postdoctoral Researcher Position from the "National Foundation for Scientific Research" (FNRS) and is working in the field of electropolymerization.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Figure 1 schematically shows the primary corrosion reactions that occur in the case of delamination of an epoxy coating from a steel substrate. The anodic reaction is the dissolution of iron, which is expected to occur in any location where an aqueous medium is available to accept ferrous ions, for example, within a defect of the polymer coating. The primary cathodic reaction is the formation of hydroxide ions by the reduction of oxygen at the metal−polymer interface. Five components are required for this reaction to occur: water, oxygen, electrons flowing from the local anode to the local cathode, positive counterions (e.g., Na^+) for the generated OH^- anions, and metal oxide, which is an active catalyst in the reduction reaction. All these components are commonly present beneath the coating at the boundary of the defect. In the case of weak metal−coating interactions (hydrogen bonding between an hydrated metal oxide and the epoxy resin in Figure 1), the cathodic reaction is responsible for the detachment of the polymer from the metal. As delamination proceeds, the cathodic site moves, remaining just in front of the debonding region.

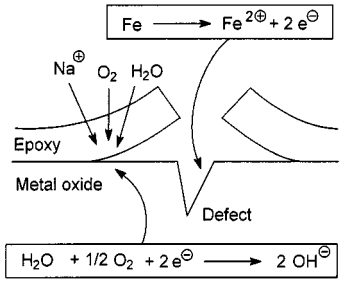

Figure 1. Schematic diagram of the delamination mechanism initiated by corrosion in a steel/epoxy coating system[11]

Numerous methods have been proposed to limit the extent of this loss of adhesion initiated by corrosion,[11] the general principle being to prevent at least one of the required components from being present at the metal−polymer interface. Although the fundamentals that govern the corrosion processes under protective coatings are generally well understood, little progress has been made to successfully prevent their occurrence. Nevertheless, these methods rely upon simple chemical and physical concepts that are easily implemented by adding at most one step in the coating process. As representative examples of these techniques, let us mention (i) the use of fluorinated polymers that limit the extent of water permeation usually occurring through most organic coatings;[3−11] (ii) the addition of fillers in order to reduce both the oxygen permeation rate[12] and internal stresses through the polymer layer; or (iii) metal pre-treatments by corrosion inhibitors, which is the most commonly used method. A thorough review of inhibitors, together with their corrosion-retarding mechanism, has been published by Trabanelli and Carasitti.[13]

Although corrosion of the metal substrate plays an important role in the delamination process, it must be stressed that joint delamination is essentially initiated by weak polymer−metal interactions.[11,14] To solve this problem in many technological applications, stable and porous oxide layers are prepared on top of the metal by adequate pre-treatment (chromic acid etching, phosphoric acid anodizing, etc.)[11,15] before coating with the polymer. This technique can impart a reasonable durability upon exposure to environmental attacks. The origin of the good adhesion between this inorganic conversion coating and the polymer is not well understood. It is probably due to mechanical interlocking between the polymer and the porous surface oxide of the substrate. However, the formation of strong chemical bonds between the substrate and the polymer, instead of weak secondary interaction forces, is expected to be more efficient in inhibiting any electrochemical reaction at the interface. Although physical treatments, such as plasma polymerization,[16,17] are of great interest, this review will mainly focus on electrochemical techniques. Their advantage over surface plasma modification is essentially that controllable reactions are involved. Furthermore, electrochemistry is a valuable technique for the polymerization of various monomers at metal surfaces, which allows for the broadening of the search for improved polymer−metal interactions. In this respect, two main electrochemical strategies have been proposed to create strong chemical bonds between organic polymers and metals.

The first strategy devised by Stratmann[18] consists of three main steps (Figure 2). The metal surface is first cleaned carefully (step 1) in order to make reactive centers (A) available. A monolayer of specially designed (A−B) molecules is then chemisorbed onto this surface (step 2), and finally a polymer is covalently bonded to these immobilized molecules (step 3).

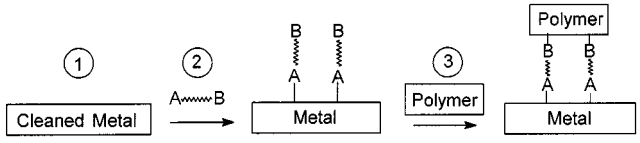

Figure 2. Reaction scheme proposed by Stratmann,[18] in which "cleaned metal" refers to the surface covered by a monolayer of sites A after electrochemical reduction

The second strategy is based on the pioneering work by Lécayon et al.,[19] who proposed that direct "grafting" of a polymer onto a metal can be achieved by controlled cathodic electropolymerization of the parent monomer (Figure 3).

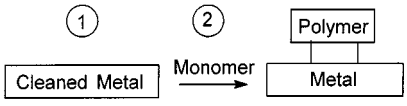

Figure 3. Reaction scheme proposed by Lécayon et al.[19]

2. Organic Molecules as Anchors for Further Polymerization

2.1. Chemical Approach

During the last decades, chemical modification of the surface of metals and carbon has been widely investigated.[20−22] It is well known that metal surfaces can be pre-treated, for example, by chromic acid etching, in order to remove old oxide layers and to generate new ones

that exhibit well-defined microdepressions acting as efficient mechanical interlocking sites.[11,15] This renewed surface is favorable not only to physisorption, but also to chemisorption as a result of secondary interactions (e.g. hydrogen bonding) between polar groups on the polymer and hydroxy groups on the metal oxide surface. These hydroxy groups have been widely exploited in order to anchor "chemical coupling agents," which are most often low molecular weight multifunctional molecules (organosilanes) able to anchor the polymer coating to the metal substrate through water-resistant covalent bonds.[11,23] It is, however, a delicate task to generate a perfect monolayer of the coupling agent attached to the substrate surface. Usually, several layers of physisorbed coupling agents are deposited on the surface from the cast solution. Since these layers are cohesively weak, fracture is generally observed in this region, as confirmed by Auger and X-ray photoelectron spectroscopy (XPS).[24]

2.2. Electrochemical Approach

The approach proposed by Stratmann[18] is an improvement of the aforementioned concept. As a model system, this author used polycrystalline iron (cleaned of any organic impurities) as substrate and thiols (e.g., *n*-decanethiol: *n*-$C_{10}H_{21}SH$) as model coupling agents. Thiols are indeed reported to strongly chemisorb onto the clean iron surface by formation of Fe−S bonds as result of S−H bond cleavage. It has been shown that OH groups present on the metal oxide surface cannot be displaced by the thiol groups, whereas stable bonds are formed between clean metals and thiols, as confirmed by X-ray photoelectron spectroscopy.[18,25−26] The first step of the process is thus the careful removal of the metal oxide layer from the surface under electrochemically controlled conditions. Figure 4 shows the cell used for the preparation of the iron surface and the binding of the thiol onto this surface. The iron surface, free from any oxide layer, is prepared by polarization in perchloric acid (1 M, $HClO_4$) at a potential of −0.72V vs. the standard hydrogen electrode (SHE). Under these conditions, the metallic state of the iron surface is thermodynamically stable.[25] In the next step, the thiol is poured onto the surface of the aqueous electrolyte and the iron electrode is slowly pulled out of the electrolyte through this organic layer, under controlled potential (Figure 4). The hydrophilic thiol groups (SH), which are preferentially oriented towards the polar electrolyte, are transferred to the new iron/thiol phase boundary.

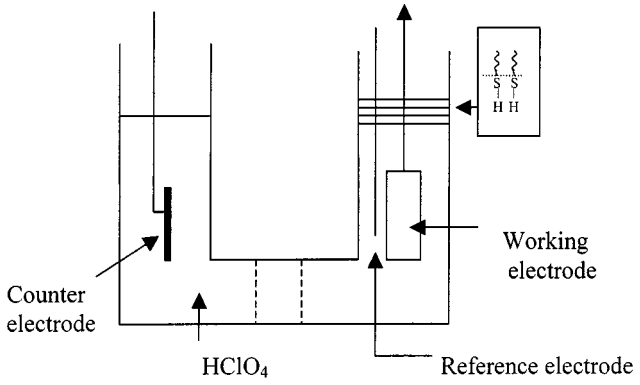

Figure 4. Electrochemical cell used by Stratmann[18]

As result of the formation of a well-ordered thiol monolayer, water does not wet this surface anymore. It has been also observed by Auger Electron Spectroscopy (AES) that an appropriate electrochemical post-treatment of the samples in neutral aqueous electrolytes significantly increases the packing density of the thiol on the iron substrate, while keeping the bond between the thiol and the metal surface intact.[26]

In view of the high reactivity of the clean iron surface either in air or in aqueous electrolytes, the high stability of this surface after modification by thiols is quite remarkable. Since this organic layer is very thin, this stability does not result from a barrier effect blocking the diffusion of oxygen and/or water. Rather, the change in the chemical and electrochemical reactivity of iron is the direct consequence of the chemisorption that saturates the clean metal surface.[27] All these results are very promising and point to the key importance of creating stable bonds between the metal and the coupling agents. These studies were, however, conducted with monofunctional molecules in order to avoid any competitive reactions of two different reactive groups of the organic molecules with the metal surface. The structure of bifunctional organic molecules now has to be optimized in order to strongly bridge metals and polymers. In this respect, the work by Itoh et al.[28] dealing with the modification of copper surfaces by bifunctional thiols is worth mentioning.

3. Electropolymerization

3.1. Brief Overview

Among the techniques suitable for the coating of metals by polymer films, electropolymerization has the advantage of proceeding through controlled reactions initiated by electron transfer to/from the monomer dissolved in the electrolytic medium. The combination of electrochemistry and polymer chemistry is far from being new and has been extensively reviewed in the last decades.[29−32] This paper does not aim at duplicating the survey of earlier works on electropolymerization, but rather at emphasizing the possible contribution of electropolymerization to the coating of metal surfaces by polymers formed in situ. Before focusing on the most relevant results obtained by Lécayon et al.[19] and our group, we will rapidly review the other contributions reported in the literature.

Wilson et al. were the first to report the electrochemical initiation of the polymerization of vinyl monomers.[33] Early works[29−33] dealt with electropolymerization occurring in solution. The formation of the initiating species results from indirect electron transfer at the electrode, i.e., by reaction of the electrolyte, followed by interaction with the monomer. These reactions are either cathodic or anodic. While free radicals are generated by the discharge of protons, per-

oxides or easily reducible compounds at the cathode,[33] Kolbe's reaction is the process at the anode reported most often[34] (Figure 5).

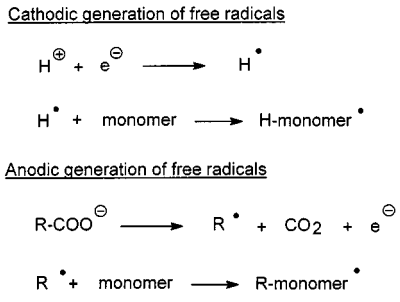

Figure 5. Polymerization initiated by free radicals[30]

Direct electron transfer from the cathode to the monomer was first suggested by Yang et al.[35] in 1957 and supported later by Funt et al.[36] Radical anions can, however, be formed by both direct and indirect processes (Figure 6).

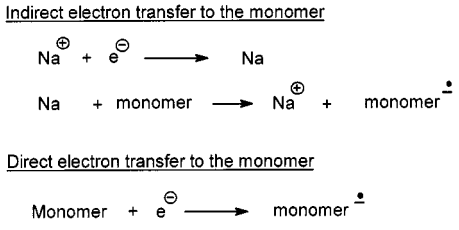

Figure 6. Polymerization initiated by radical anions[30]

According to Yamazaki et al.,[37] indirect initiation better accounts for the results reported by Funt et al. These authors proposed that direct initiation is only possible when the electrolysis is conducted under specific conditions: (i) the reduction potential of the conducting salt has to be more negative than that of the monomer, in order to avoid any indirect transfer, (ii) the electrical conductivity of the electrolytic solution must be high, and (iii) aprotic solvents have to be used in order to avoid indirect initiation by free radicals.

The deposition of polymer on the metal has been long considered as an unexpected and undesirable side-reaction, because the rapid formation of an insulating film makes the control of the process or the study of the reaction mechanism very difficult. Attempts to overcome this problem include the use of a solvent for the polymer formed, more efficient stirring and reduced electrode surface area. Lately, nevertheless, increasing attention has been paid to polymer deposition as an interesting method to protect metals against corrosion.[38−42] This coating approach is significantly different from conventional electrocoating methods that require the electrophoretic deposition of a preformed ionizable polymer from solution or suspension onto the substrate.[43−45]

Because of the high cost and potential environmental drawbacks of organic solvents, aqueous media have been extensively studied.[39] Nevertheless, Mengoli and Tidswell have investigated the cathodic electropolymerization on steel of several acrylic and methacrylic monomers in dimethylformamide and dimethyl sulfoxide.[46] The use of an organic solvent has the advantage of dissolving most organic conducting salts and of swelling most polymers of interest. Obviously, the monomer/solvent pair has to be selected in terms of poor solubility of the polymer, thus leading to film formation either by polymer precipitation or by polymer cross-linking.[47−49] The main difficulties and drawbacks met in these studies are the partial covering of the electrode, poor adhesion and poor chemical stability.

Since 1980, an increasing number of interesting papers have been published on this topic,[50] particularly on the synthesis of polymer composites containing carbon fibers[51] and on the coating of metal surfaces for aerospatial or electronic applications.[52] Undoubtedly as soon as new techniques dedicated to the design of stable polymer−metal associations are available, new application fields will develop rapidly. In this respect, the contribution of Lécayon et al., reviewed in ref.[19], is of major importance.

3.2. Electrografting of Organic Polymers onto Common Metals

Lécayon et al. have demonstrated that electrochemistry is well suited to the building up of an adherent insulating polyacrylonitrile (PAN) film onto the surface of common metals.[19,53,54] They have studied the cathodic electropolymerization of acrylonitrile (AN) in rigorously anhydrous acetonitrile (ACN), containing tetraethylammonium perchlorate (TEAP) as a conducting salt. In the case of the acrylonitrile (AN)/nickel system, the mechanism proposed for the surface modification is sketched in Figure 7. The negative polarization of the nickel electrode has three major effects: (i) the formation of the cathode double layer, (ii) the reduction of the metal oxide layer, and (iii) the formation of an electron-rich metal surface, which can act as a base. As a result of the electric field at the cathode and the strong dipole moment of AN (3.9 D[55]), the acidic vinyl β-carbon atom of acrylonitrile is orientated towards the metal. A Lewis acid−base reaction can then occur, leading to strong bonding between AN and Ni (chemisorption). According to the authors, the π electron doublet referring to the original vinyl bond of AN is transferred to the substituted carbon atom (CH), so that the basic character originally located at the surface of the electrode is displaced to the end of the first attached AN molecule. Monomer addition can then be repeated many times, which leads to the formation of a strongly bonded PAN film. The PAN film and the PAN/metal interface have been investigated by a number of spectroscopic techniques:[56−60] XPS, IR, ellipsometry, ultraviolet photoemission spectroscopy (UPS), electron-induced X-ray emission spectroscopy (EXES). Electrochemical impedance data[60] show that the metal surface is more efficiently blocked by electrodeposited PAN than by PAN merely cast from solution. The direct observation of C−Ni bonds formed at the interface has also been reported.[59]

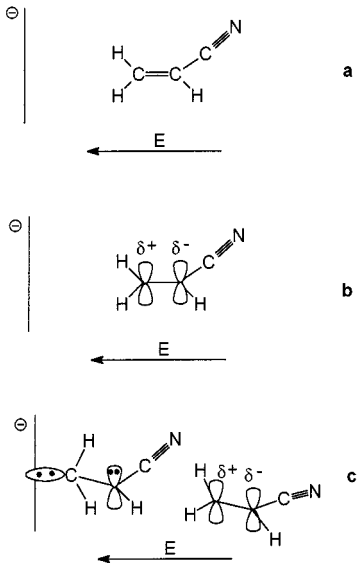

Figure 7. Molecular model for the acrylonitrile/metal interaction in the cathode double layer according to Lécayon et al.:[54] a) the molecule is oriented; b) the molecule is polarized; c) a chemisorbed radical anion is formed, which can interact with another molecule; polymerization then propagates by means of an anionic mechanism

The "grafting" reaction reported by Lécayon et al. differs from previous studies [61−63] that showed the formation of AN radical anions, followed by rapid dimerization and anionic polymerization initiated in solution by both anionic ends of the species. It is worth noting that the two peaks in the voltammogram recorded during AN reduction (Figure 8) were never observed before. According to Viel,[64] the two reduction peaks stem from surface passivation (less cathodic peak, referred to as peak I) and from a diffusion-controlled process (peak II), respectively.

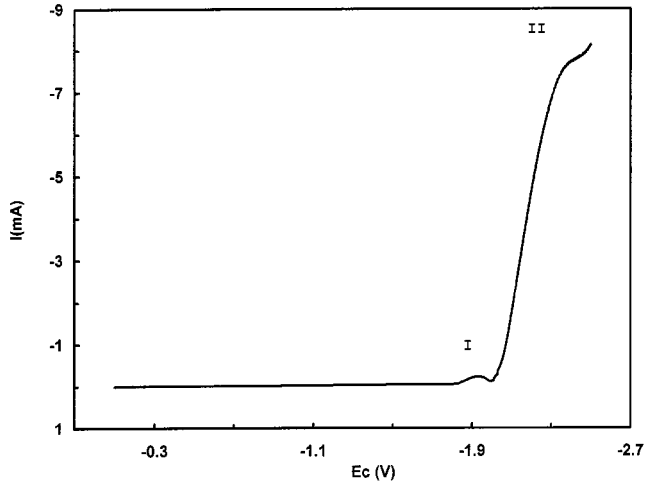

Figure 8. Cathodic response of a 0.1 M AN solution in acetonitrile; [TEAP] = $5\cdot10^{-2}$ M, v = 20 mV·s^{-1}

In addition to the so-called grafted polymer, this author also mentions the formation of non-grafted chains[64] which are easily removed by rinsing the electrode with a solvent for PAN, such as dimethylformamide (DMF). It is also proposed that the "grafting reaction" is likely to occur at potentials less cathodic than peak II, but no clear experimental information is provided about the formation of non-grafted chains. Originally, the grafting reaction, i.e., the chemisorption of AN radical anions, was described as a "secondary electrode reaction",[65] when compared to dimerization and polymerization occurring in solution.[63] In fact, the grafting reaction has been observed thanks to the rigorous experimental conditions used by Lécayon et al.[66]

3.2.1. Experimental Requirements

Contamination of the metal surface by oxide and any organic impurities is detrimental to strong monomer chemisorption. Thus, careful cleaning of the electrode substrate is a prerequisite to impart stability to the interface between the metal and the organic molecule, as confirmed by Stratmann et al.[18] The whole grafting reaction must thus be conducted in a glove box under dry and inert conditions. The nickel oxide is reduced in the electrochemical cell filled with a solution of the monomer and the conducting salt at potentials less cathodic than the potential required for the AN reduction (Figure 9).

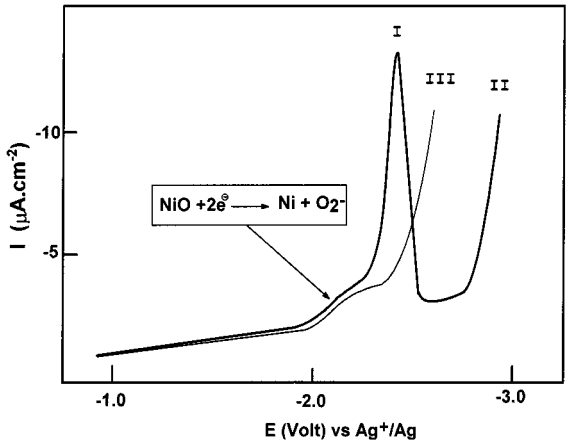

Figure 9. Voltammograms in ACN/TEAP solutions: I and II are the inhibition peak and the diffusion peak, respectively, when the solution contains AN; III in absence of AN[54]

Ellipsometric measurements have been carried out in situ during the first step of the cathodic electropolymerization of acrylonitrile on nickel, and they have confirmed that the grafting reaction is initiated at the electrode sites released by the reduction of the native oxide.[58] This observation explains why grafting is usually observed on metals such as Ni, Fe, or Cu, whereas it does not occur on metals for which the oxide cannot be reduced electrochemically (e.g. Al, Zn).[67−69]

The use of a conducting salt which is inert in the potential range in which the electrochemical signature of the AN electroreduction is observed has to be pointed out. Indeed, according to Yamazaki et al.,[37] inorganic conducting salts such as $NaNO_3$, are commonly reduced at potentials less cathodic than the monomer, leading to the indirect initiation of the polymerization in solution (Figure 6). In a patent,[66] Lécayon et al. recommend the use of tetraethyl-

ammonium perchlorate (TEAP), which is known for its electrochemical stability up to high cathodic potentials.[70]

The purity of solvents and monomer has also a critical importance for the grafting reaction to be successfully achieved. According to Lécayon et al.,[67] impurities, such as H_2O and O_2, can slow down or inhibit the polymer deposition. Their content in the electrochemical solution has to be lower than 5−10 ppm. These features have been confirmed by Mertens[68] who deliberately contaminated the electrochemical solution by increasing amounts of water or oxygen. The main effect of small quantities of water added to the ACN/TEAP solution is to shift the upper limit of the cathodic window (current rise attributed to the solvent reduction) towards less cathodic values and to increase the intensity of peak I (Ip_1, Table 1).[68]

Table 1. Peak *I* intensity [μA] with increasing water amount, [AN] = 1 M; ACN/TEAP; $v = 20\ mV \cdot s^{-1}$

Water content [ppm]	Ip_1 on Ni [μA]	Ip_1 on steel [μA]
10	30	30
100	125	80
400	200	−

According to Viel,[64] the intensity of peak I is strongly dependent on the polymerization kinetics, the inhibition time being controlled by the rate of formation of the insulating polymer film.

The increase in the intensity of peak I thus indicates a slower inhibition of the cathode. An explanation might be the earlier termination of the grafted chains by water, consistent with formation of thinner films as measured by ellipsometry (ex situ measurements).[71] When the water content is increased further, non-bonded chains are predominantly formed as a result of indirect initiation by hydrogen radicals (Figure 5). The film adhesion is rapidly lost, since it is composed mainly of non-bonded polymer chains embedded in a few grafted ones.

In contrast to water, the reduction of oxygen ($O_2 + e^- \rightarrow O_2^-$) dissolved in the electrochemical medium gives rise to a well-defined voltammetric wave at potentials less cathodic than the AN reduction. In that case, according to Mertens, the indirect initiation of the AN polymerization by the reduction by-product is the predominant process, at the expense of the grafting reaction.[68]

3.2.2. Recent Advances

Owing to the interest and potential of this unusual electrografting reaction, Mertens et al. recently reinvestigated[68,72−73] the cathodic reduction of acrylonitrile (AN). In the opinion of those authors, the intimate mechanism of the AN electropolymerization was still unclear. This is the reason why they studied this electrochemical reaction in acetonitrile (ACN), a poor solvent for PAN commonly used by Lécayon et al., as well as in dimethylformamide (DMF), a good solvent for the polymer.

Mertens et al. used mechanically polished metal plates as working electrodes, instead of polycrystalline substrates prepared by sputtering a thin layer of pure Ni onto polished metal plates under high vacuum.[67] The surface oxide of the electrode was electrochemically reduced in an ACN/TEAP solution in a glove box just prior to polymer deposition from a fresh solution of monomer. This two-step process prevents O_2^- species from being formed in the monomer solution, thus avoiding possible cross-linking of PAN.[68]

Mertens et al.[72][73] pointed out the critical role of the applied potential, showing that PAN is strongly bonded to the nickel cathode only at the potential of peak I (Figure 8). In this potential range, a thin homogeneous and colorless polymer film is formed, even when the reaction is conducted in a good solvent for PAN, such as dry DMF. This observation confirms the strong adhesion of the PAN film onto the cathode, consistently with the grafting claimed by Lécayon et al.[53] In sharp contrast, a PAN film spin-coated onto nickel is rapidly dissolved in this solvent. When the potential is further increased (Figure 8, peak II), no grafting is observed anymore; the polymerization then proceeds in solution. These non-grafted chains are rapidly dissolved in DMF, while they are merely precipitated on the cathode as a thick yellowish non-adherent film in ACN. Although PAN films formed at the potential of peak I are generally too thin and too smooth to be visible by scanning electron microscopy (SEM), Figure 10 shows the nucleation of the PAN chains formed at the potential of peak II in ACN, leading to a cauliflower-like morphology.

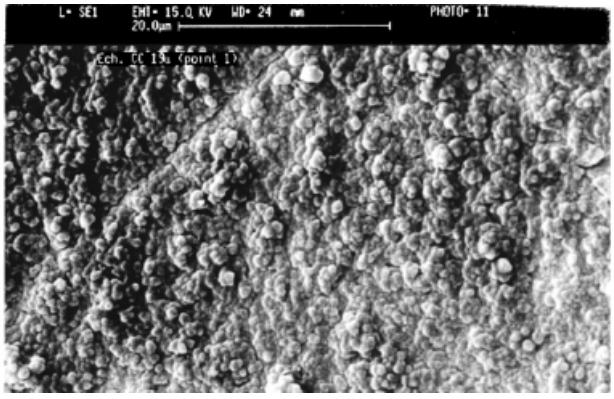

Figure 10. Scanning electron micrograph of PAN film deposited on Ni in a 0.05 M TEAP solution in ACN at the potential of peak II[68]

Mertens et al.[74] investigated the identification of the species responsible for the polymer propagation and tentatively proposed two different mechanisms for the AN electropolymerization in relation to the applied potential. The reaction that occurs at the potential of peak I does not fit classical electrochemical models since the intensity of peak I decreases when the monomer concentration increases; the process seems to be neither fully faradaic nor fully capacitive in nature. In order to identify the species active at the two reduction potentials, agents able to react selectively with radicals or anions and inert in the potential range of interest were added to the electrolyte solution. The addition of either diphenylpicrylhydrazyl (DPPH), radical scavenger

or ε-caprolactone (probe for anionic polymerization) led to evidence for the formation of a radical species that initiates and propagates the PAN firmly attached to the Ni cathode (Figure 11).

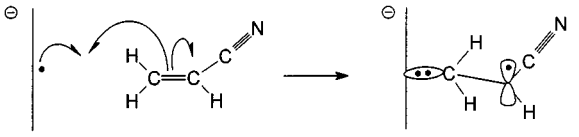

Figure 11. Mechanism proposed by Mertens et al. for the AN grafting reaction at peak I[74]

At the more cathodic potential (peak II), reduction of AN is a faradic process based on the transfer of one electron to the monomer, and on the formation of a radical-anion that rapidly dimerizes and initiates the AN polymerization in solution, in agreement with previous work by Bhadani et al.[63] In addition to this dual mechanism, a possible bond-breaking of the originally "grafted" PAN chains has to be considered when the potential becomes more cathodic than that of peak I.[74] In ACN, an increasingly more cathodic potential is also responsible for the strain of the originally grafted film, so that the conductivity of the cathode is restored locally, allowing the anionic polymerization of AN to occur and to lead to PAN films with a cauliflower aspect (Figure 10).

The model proposed by Mertens et al. (Figure 11) differs markedly from that of Lécayon et al. (Figure 7), who proposed an anionic mechanism for the grafted growing chains. Nowadays, the electrografting mechanism is still a matter of controversy.[75] Whatever the structure of the propagating species, the most important result is the clear identification of the potential range in which the formation of an adherent polymer film can be controlled. In this respect, dynamic mechanical thermal (DMTA) and infrared spectroscopic analyses[76] have recently shown that the structure of the PAN film depends on the potential at which it is formed. Indeed PAN "grafted" at the potential of peak I is mainly isotactic and the film is amorphous, in contrast to ungrafted PAN formed at more cathodic potentials, which is mainly atactic and forms a paracrystalline film in ACN.

In order to control the film thickness and roughness, these features have been studied in relation to the solvent used and the monomer concentration. The thickness of dried films prepared in the potential range of peak I was measured by ellipsometry; it clearly depends on these experimental parameters[72] (Figure 12). The film was thicker in DMF than in ACN and this can be rationalized on the basis of the precipitation of the growing PAN chains in the latter case and the solvation of the chains in the former case. Indeed, as soon as the PAN chains reach some critical length in ACN, they precipitate on the electrode, which is detrimental to their propagation. The situation is completely different in DMF, since the growing chains are solvated during the whole polymerization.

This qualitative explanation is supported by Atomic Force Microscopy (AFM) data which show that PAN films deposited in DMF at high monomer concentration are thick enough to mask the morphological features of the

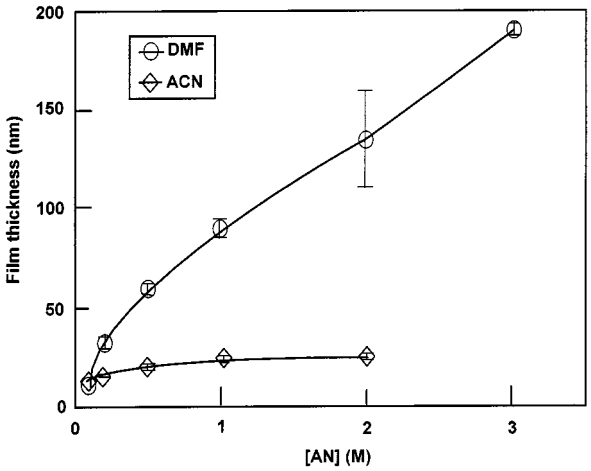

Figure 12. Dependence of the PAN film thickness on the monomer concentration in ACN and DMF[72]

substrate. Figure 13 is a typical image of the bare nickel surface which is used as a reference for the observation of the coated electrodes. Generally, the morphology of thin PAN films, grafted in ACN or DMF at low AN concentration (0.1−0.2 M), appears to consist of small polymer grains deposited on the electrode (Figure 14, A and 14, B). The average size of the grains is in the 40−60 nm range over the whole surface. The polymer deposit is not thick enough to mask the largest defects of the nickel surface (as ridges present on Figure 13 are still visible on Figure 14, A and B). At higher AN concentrations (1−2 M), clear morphological differences are observed depending on the solvent used (Figure 15, A and B). Films prepared in ACN show the same granular morphology as in dilute solution, with characteristic sizes of approximately 50 nm (Figure 15, A). However, the ridges of the original metal surface are less visible, in agreement with the formation of thicker films. Details reminiscent of the metal surface are no longer ob-

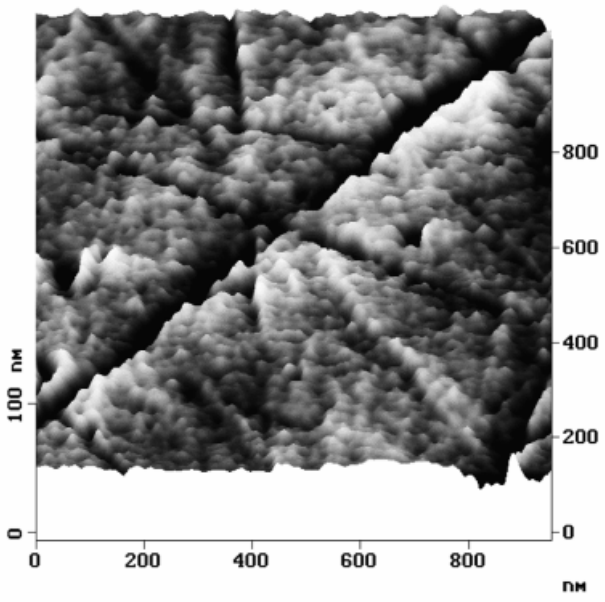

Figure 13. Atomic force micrograph of bare nickel

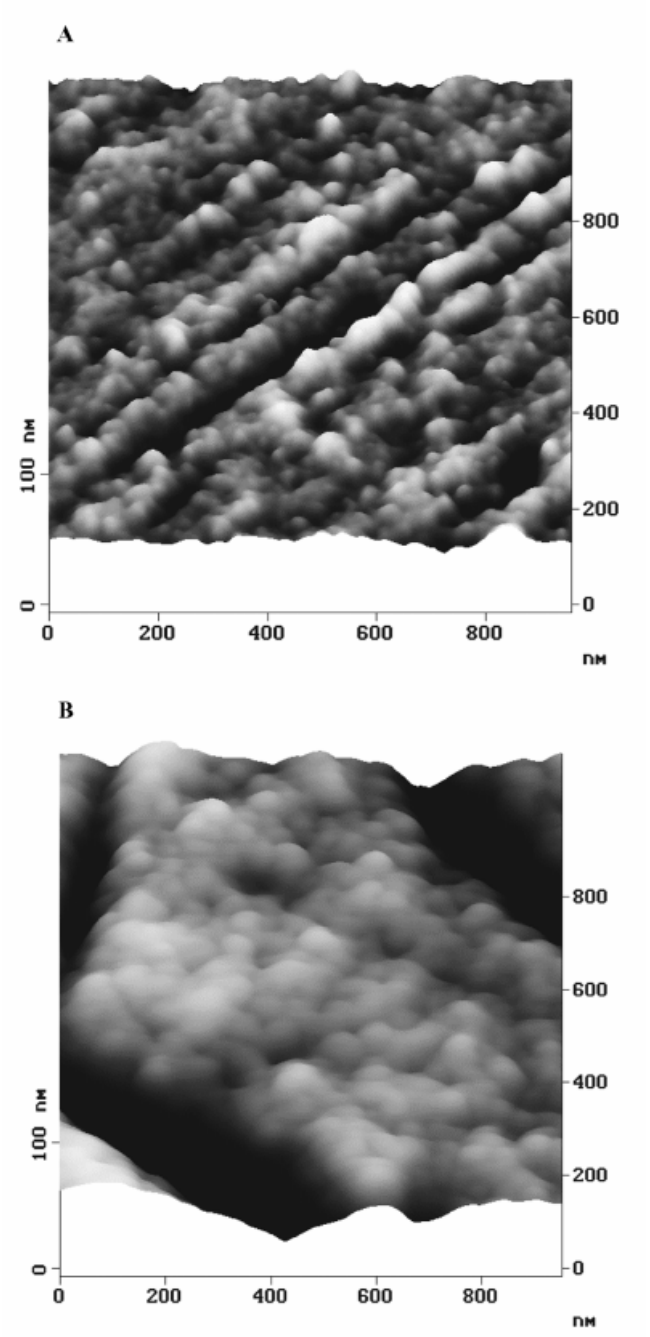

Figure 14. Atomic force micrographs of PAN films deposited on Ni in the potential range of peak I: A) AN 0.1 M in ACN; B) AN 0.2 M in DMF

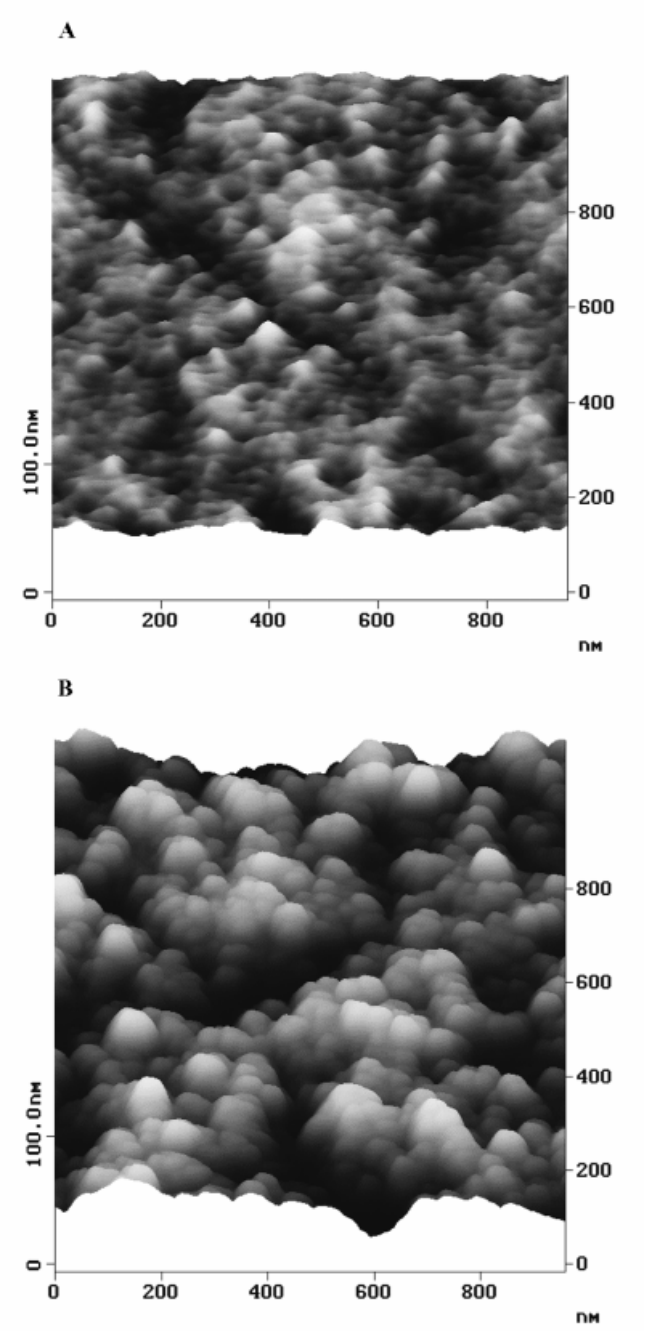

Figure 15. Atomic force micrographs of PAN films deposited on Ni in the potential range of peak I: A) AN 1 M in ACN; B) AN 2 M in DMF

served in films grafted in DMF (Figure 15, B). In this case, the PAN deposit is clearly thicker and the film consists of nodules much larger in size (100 to 150 nm) than the grains observed in ACN.

As direct applications of the fine control of the AN electrografting, specific achievements have been reported, for example, preparation of thin α-emitting sources by simultaneous electroreduction of AN and uranium salts,[77] preparation of electrical connectors by an adequate thermal post-treatment of electrografted PAN thin films[78] and protection of art pieces.[68,79]

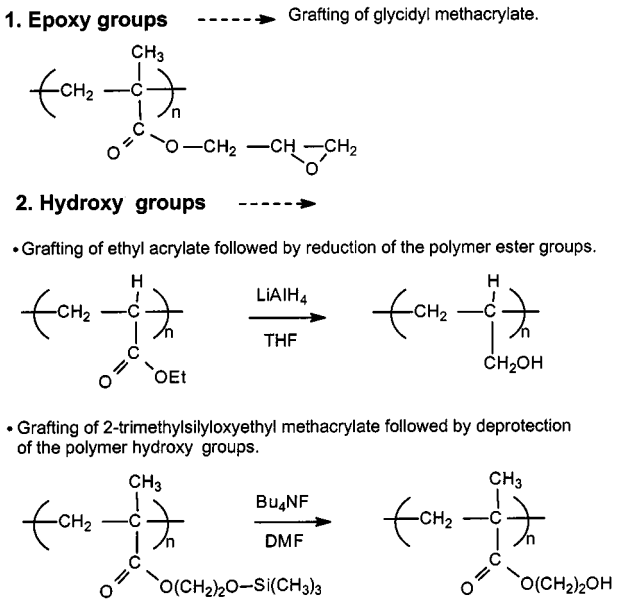
Very recently, efforts have been devoted to improve the understanding of the electrografting reaction and to functionalize the very adherent thin films formed. The unusual electrografting reaction has been shown to strongly depend on the ability of the monomer to be adsorbed onto the clean cathode. Therefore, the monomer has to compete efficiently with the solvent and with the conducting salt[80] to be adsorbed and react at the cathode surface rather than in solution. ^{13}C NMR spectroscopic data and theoretical calculations[81] have shown that AN is particularly prone to interact strongly with the cathode. Nevertheless, paying

special attention to the competitive adsorption of monomer and solvent (or conducting salt), (meth)acrylic monomers have been successfully grafted.[80,82]

Furthermore, the use of coupled quartz crystal microbalance and cyclic voltammetry has confirmed that the inhibition peak is the actual signature of the strong monomer chemisorption and growth of grafted chains.[82] At more cathodic potentials, polymerization occurs in solution, while previously bonded chains are detached from the electrode. In this respect, a major difference has been pointed out in the behavior of acrylic and methacrylic monomers. Indeed, in the latter case, bonded and non-bonded chains are simultaneously formed in the potential range of peak I. Acrylic polymers are thus better candidates for the efficient coating and long-term protection of metals.

The possibility of electrografting acrylonitrile-containing copolymers has also been investigated.[83] As a rule, the composition of the grafted chains depends on the local concentration of the comonomer. If the comonomer has no tendency to accumulate in the close vicinity of the cathode (e.g. vinyl acetate), then only homopolyacrylonitrile is grafted. In the reverse case (e.g. ethyl acrylate), copolymer chains are grafted, and the composition of the film depends mainly on the capability of each comonomer to compete with the solvent for adsorption. However, the capacity of the films to cover the electrode seems limited, possibly as consequence of the extra competition of the two monomers to adsorb onto the cathode. In order to alleviate this disappointing situation, the sequential electrografting of each monomer in two different cells has been proposed.[84] Mixed films, combining the properties of two polymers, are formed when the monomer less prone to compete with the solvent molecules is electrografted first at a more cathodic potential than the second monomer. Since the grafting density is expected to depend on the adsorption of the monomer, this result supports the general idea of the competitive monomer/solvent adsorption onto the cathode in the very first step of the grafting process. In the same way, the full electrochemical synthesis of insulating/conducting composites has also been investigated.[85] An unexpected application has also been found by using electrografted substrates as templates for the synthesis of conducting polymers leading to formation of polypyrrole wires.[86]

The electrografting technique thus allows for the control not only of the adherence of organic coatings on metals, but also of their nature and composition. For example, it is now possible to prepare electrografted films containing epoxy groups in one step, and films containing hydroxy groups in two steps (Scheme 1).[87] In this respect, it is worth noting that the electrografting of 2-hydroxyethyl methacrylate (Scheme 1) could pave the way for biomedical applications (e.g., catheters).



Scheme 1. Functionalization of electrografted films

4. Conclusions and Challenges

The electrochemical strategies proposed by Stratmann et al.[18] and Lécayon et al.[19] have brought valuable answers to the problems caused by the weakness and short lifetimes of polymer−metal associations. From an economic point of view, the approach by Stratmann et al. is more advantageous, since it can be carried out under mild conditions in water, in contrast to the electrografting proposed by Lécayon et al. Extension of the model systems studied by Stratmann et al. to real systems consisting of the adsorption of bifunctional organic molecules and the reaction of the modified surface with film-forming monomers in the next turning point to pass.

Despite some stringent experimental conditions, electrografting appears to have a promising future for the preparation and protection of small-size and high-value devices.[77−79] One pending problem is the small thickness of the grafted films. Indeed, a polymer coating usually imparts corrosion resistance to a substrate when the thickness is greater than 50μm.[88] At present, the electrografted films do not provide this beneficial effect since the number of deposition cycles and the deposition techniques (voltamperometry, chronoamperometry, chronopotentiometry) do not allow for an increase in the final thickness of the film.[72]

The use of the grafted coating as a primer also becomes more promising with the ability to graft a larger number of monomers.[80−82,87,89−92] In this field, the controlled chemical modification of grafted films remains a challenging issue. The copolymerization of AN with "functional" monomers such as acrylate, and the electrografting of blends could be an interesting way to combine various interesting properties at the surface. Recent developments resulting in the diversification of the grafted substrate allow for the preparation of primers able to interact strongly with a top-coat.

The search for new monomers prone to electrografting remains the best way to simultaneously overcome the two main drawbacks of the polymer−metal association; i.e., the

weakness of both the substrate/polymer and polymer/surrounding medium interfaces.

The Control of Nanostructured Solids: A Challenge for Molecular Chemistry

Robert J. P. Corriu[a]

Keywords: Silicates / Organic-inorganic hybrid composites / Materials science / Sol-gel processes / Nanostructures

Nanostructured hybrid organic-inorganic solids are a class of materials of growing interest because of their great potential in synthesis and possible applications. All organic molecules containing at least two $-Si(OR)_3$ groups can be transformed by hydrolytic polycondensation at silicon into materials in which the $-Si(OR)_3$ groups are changed into $-SiO_{1.5}$. Moreover, the physical properties of the organic units included in the silica matrix are maintained in the solid. This sol-gel-type transformation leads initially to a viscous sol that allows devices to be made (films, matrices and even fibres in some cases). Finally, these materials exhibit both short-range and long-range organisation in the solid when the organic units have a rigid geometry.

I. Introduction

The concept of "Chimie Douce" has been introduced recently in the field of Materials Science.[1,2] This method of obtaining solids represents a breaking down of the preparation of materials and this concept, which is based on inorganic polymerisation, has opened the field of Materials Science to molecular chemistry.

The methodology used in classical solid state chemistry is based on the thermodynamic evolution of the reaction. Whatever the experimental conditions, success is based on the self arrangement of the system leading to stable (or metastable) materials. This approach to the elaboration of materials includes the high temperature methodologies leading to crystals, glasses or ceramics, as well as to other techniques that require lower temperatures such as the synthesis of crystalline aggregates, the preparation of polyanions from solutions, or the hydrothermal synthesis of zeolites.

[a] Laboratoire de Chimie Moléculaire et Organisation du Solide, UMR 5637, Université Montpellier II,
Place E. Bataillon, 34095 Montpellier Cedex 5, France

The properties of the solid materials obtained by these methods are always governed by the general thermodynamic laws represented by the phase diagram.

In contrast, the methodologies encompassed by the phrase "Chimie Douce" are based on kinetic control of the solid synthesis. The solids obtained are not the most thermodynamically stable, but they are the result of a multiparametric chemistry based on mechanistic control of the chemical reactions. One commonly used approach of "Chimie Douce" chemistry is the sol-gel methodology,[3,4] which corresponds to an inorganic polymerisation (Scheme 1). Scheme 2 illustrates the complexity of the hydrolytic polycondensation of $Si(OR)_4$ by showing the possible competitive reactions occurring at the same time.

The preparation of SiO_2 by this route is controlled by the kinetics of the hydrolytic polycondensation that occurs around the silicon atom through nucleophilic substitution at silicon. In this process H_2O acts as a nucleophile and displaces ROH in the first step. The condensation leading to Si−O−Si bonds occurs by hetero or homo condensation (see Scheme 2). This mechanism is a highly complex one because of the four functionalities, the possibility of redistribution, and the formation of chains or rings leading to a

Robert Corriu, born in 1934 in Port-Vendres, France, obtained his Docteur des Sciences Physiques in 1961 from the Université de Montpellier. He became Assistant Professor at the Université de Perpignan in 1963, Associate Professor at the Université de Poitiers in 1964, and Professor at the Université de Montpellier in 1969. His research interests in organometallic chemistry have been focused on organosilicon, organogermanium, and organophosphorus compounds, transition metal complexes, and hypercoordinated silicon and phosphorus compounds. More recently, he has concentrated his research efforts on the elaboration of solids from molecular precursors. His main interest is now connected with hybrid organic-inorganic materials and molecular chemistry permitting solid organisation. He has obtained awards from the French Chemical Society (Prix Sue in 1969 and Prix Lebel in 1985), from the CNRS (silver medal in 1982), and from the American Chemical Society (Kipping Award in 1984). He was elected to the French Academy of Sciences in 1991 and Polish Academy in 1997. He obtained the Alexander Von Humboldt Research Award in 1992, the Max Planck Research Award in 1993, and the Wacker Silicon Award in 1998.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

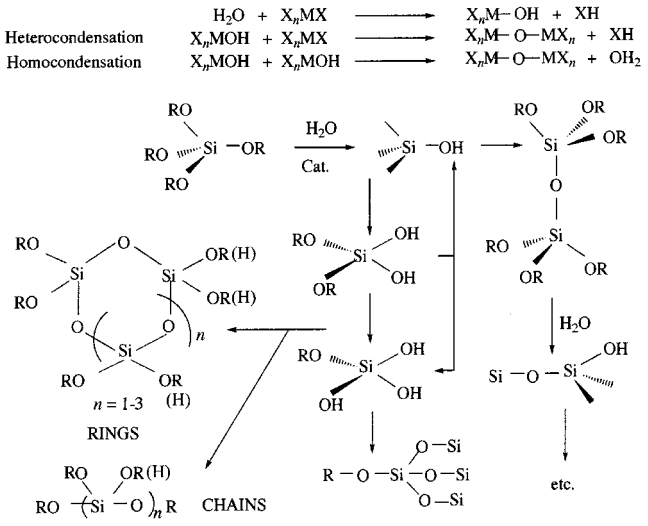


Scheme 2. Sol-gel hydrolytic polycondensation of metal alkoxides

highly crosslinked solid. The detailed mechanism for this process is unknown. However, several attempts to elucidate this aspect of the reaction have been made, leading to isolated but interesting results.[5−7]

The use of this chemistry for solid preparation is nowadays strongly connected to polymer science. The physical properties of the highly crosslinked polymers obtained are controlled by the mechanism of the reaction used to build the chains of the resulting macromolecules.[8] In the same manner, the synthesis of the inorganic materials performed by sol-gel corresponds to a kinetically controlled process. The texture of the solid obtained, described in terms of macroscopic properties (specific surface area, porosity, density etc.), is highly dependent on the experimental conditions, a fact that strongly suggests kinetic control of the solid.[9−12] Thus, although it is not possible to predict the texture of the solid, the method is highly flexible because of the great number of parameters that can be manipulated (temperature, concentrations, solvent, catalyst, nature of leaving group etc.) to give experimental control over the texture obtained. It is also important to point out the flexible processability inherent in the formation of the sol. The sol is a viscous liquid that allows devices to be obtained: e.g. films by coating and fibres by spinning, as well as matrices with the possibility of inclusions.

In materials science the gels are described as unstable solids.[4] They cannot be classified as metastable since their stability can be dependent on experimental conditions. This fact has led to difficulties as far as reproducibility is concerned. However, after extensive studies performed on silsesquioxanes and nanostructured hybrid organic-inorganic materials, we have shown that *reproducibility is attained when the experiments are carefully performed with the precision that is necessary for physical chemistry experiments or analytical measurements.*[8−11] Moreover, the stability of these solids is very good when they are stored under very strictly controlled conditions that exclude the presence of reagents such as air humidity.[13]

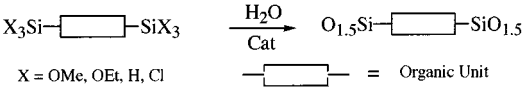
The sol-gel methodology is an alternative to the classical thermodynamic routes for the synthesis of solids. It allows materials to be obtained by "step-by-step" chemistry starting from molecular precursors at low temperatures. The preparation of the solids through "Chimie Douce" processes is the natural bridge between molecular and solid state chemistry. There is a wonderful way to obtain, in one step, new materials in which organic, inorganic, organometallic molecules or polymers can been included or chemically bound to inorganic matrices. A wide field of research is now open to chemists, including the possibility of designing the organisation of the porosity of the inorganic matrix using templates or micellar media.[14−27]

This paper focuses on the organic-inorganic hybrid materials obtained from molecular precursors. However, it is important to make the distinction between nanocomposites and the nanostructured hybrid materials[28−40] that are the topic of this paper.

The polycomponent solids corresponding to nanocomposites are obtained by hydrolytic polymerisation of a metal alkoxide previously mixed with organic molecules (or polymers). These solids can be separated into two phases by washing with an organic solvent. However, it is important to point out that this approach to the synthesis of materials is the simplest and most efficient. The method allows interesting devices to be obtained very quickly in order that their properties can be studied. The method also provides a very flexible way to obtain new materials and to include organic units, with desirable physical properties, within inorganic matrices. Silica is currently the most useful oxide matrix because of its physical and chemical properties and also due to its ease of preparation and processability by the sol-gel methodology. The number of possibilities open is vast and includes, amongst others, the preparation of controlled me-

soporous materials, molecular imprinting and foot printing, and optical devices. etc. Indeed, in this area a large number of papers[21−31] have been published that describe numerous very interesting materials.

In contrast, the nanostructured hybrid materials that form the topic of this paper are obtained by hydrolytic polycondensation of a molecular precursor in which trifunctional silicon atoms SiX_3 are covalently bound to the organic moiety (Scheme 3).



Scheme 3. Elaboration of organic-inorganic hybrid solids from bis-silylated precursors

The hydrolytic polycondensation allows the $SiO_{1.5}$ groups to be crosslinked around the organic unit to give to monophasic solids. These solids correspond to nanostructured materials. This aspect will be developed in more detail later in the paper.

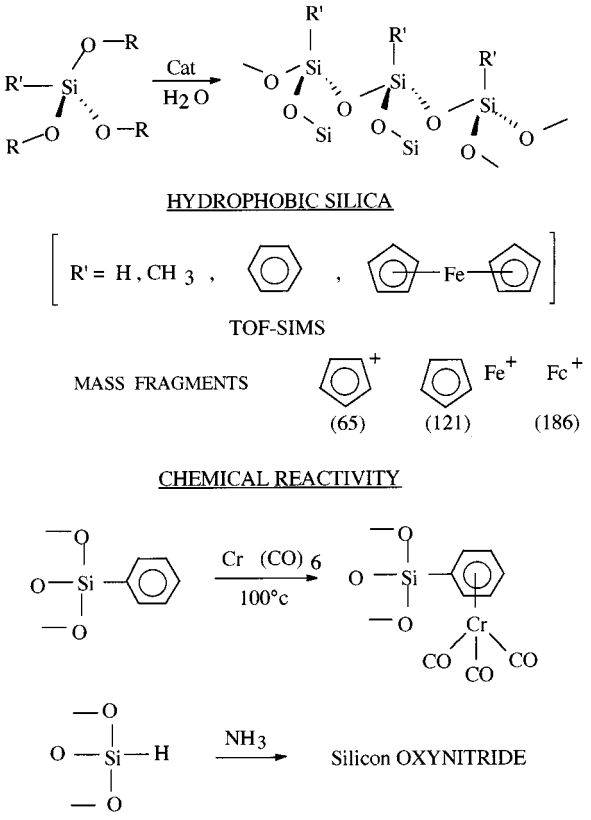
II. Monophasic Hybrid Organic-Inorganic Materials: Scope and Limitations

Scheme 3 outlines the principle used in the synthesis of these materials. It is important to summarise the main results obtained in this field to date and to point out the main features of this class of materials.

The main prerequisite is the presence of non-hydrolysable and non-oxidisable bonds between the organic unit and the oxide matrix. The second requirement is the presence of groups that permit the formation of the oxide matrix by a hydrolytic polycondensation (''Chimie Douce'' process). Trifunctional silicon groups (SiX_3) are very convenient for this purpose and trialkoxysilyl groups [$-Si(OR)_3$ (R = Me, Et, *i*Pr)] are commonly used.[32−40] However, $-SiCl_3$ [41] and $-SiH_3$ [42] groups can also lead to silica matrices. Moreover, Si−C bonds are highly stable towards hydrolysis and oxidation and many routes have been found for the introduction of a silicon group into an organic molecule.

II.a. Materials Obtained from Mono-silylated Precursors

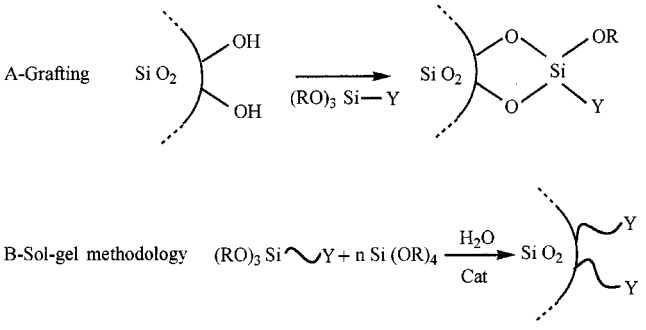
The focus of this paper is on nanostructured materials obtained from precursors containing at least two Si−C bonds.[34−40] The case of monocomponent hybrids with only one Si−C bond has been reviewed recently.[32,33] Monocomponent systems are particularly interesting since they open the way to functionalised surfaces. It has been demonstrated that the hydrolytic polycondensation of $R-SiX_3$ leads to solids in which the organic part is mainly located at the surface of the material, as evidenced by TOF-SIMS (Time of Flight Secondary Ion Mass Spectrometry),[43] by the hydrophobicity of the material obtained, and by the reactivity of the functionalities attached to the organic group R[44,45] (Scheme 4).



Scheme 4. Hybrid materials obtained from mono-silylated precursors

The characteristics of the materials obtained for catalysis, separation, its physical properties or other purposes are related to the accessibility of the functional groups in the solid.

The location of the functionalities at the surface is a very important feature and two routes are used for the preparation of these materials: grafting of an oxide surface (generally SiO_2) (route A) or preparation by the sol-gel methodology (route B) (Scheme 5).



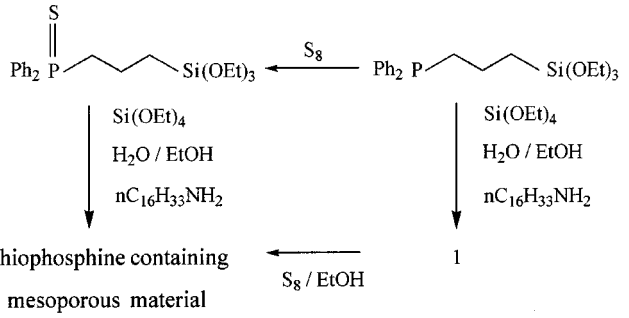
Scheme 5. Functionalisation in hybrid solids

Although grafted silica with interesting applications has been prepared by route A, route B is generally a more efficient way to obtain materials than route A. A similar trend is observed in the case of the mesoporous materials prepared using a micellar medium.[46,47] The sol-gel polycond-

ensation of $Si(OR)_4$ in the presence of a surfactant solution in H_2O leads to a hybrid material with a regular hexagonal distribution of the surfactant. After elimination of the surfactant it is possible to obtain a mesoporous SiO_2 in which the pores are regularly distributed within the material.[22]

Functionalisation of mesopores can be achieved by grafting (route A) using the reactive groups located inside the mesopores.[21,48−52] However, it is possible to obtain directly a mesoporous silica that has a narrow and organised porosity and contains chemical functionalities located inside the pores. The methodology used is similar to that shown in route B, but is performed in presence of surfactant. The lipophilicity of the precursor permits its inclusion in the surfactant. Thus, during the formation of SiO_2, the polar Si−OH head is at the surface and the lipophilic and functional tail is included in the micelle.[21,47,53−56]

Scheme 6 illustrates the synthesis of thiophosphane-containing materials either by direct preparation using method B in presence of a micellar medium, or by reaction of S_8 on the phosphane-containing material prepared by the same method.[53] The materials obtained by the two methods exhibit the same characteristic features in terms of ^{31}P, ^{13}C, ^{29}Si NMR, porosity etc.



Scheme 6. A phosphane-containing material elaborated in micellar media

II.b. Bis-Silylated Precursors

The main features of these systems are summarised by four key points, which will be discussed in greater depth in the following sections.

(1) Processability. (2) Wide range of synthetic possibilities. (3) Inclusion in the oxide matrix of the desired physical properties using appropriate organic moieties. (4) Inclusion of the desired chemical properties.

II.b.1. Processability

In all cases the sol-gel methodology allows processable materials to be obtained since the inorganic polymerisation occurs with formation of a highly viscous sol. Thus, it is always possible to obtain films (by coating), matrices, and also fibres (by spinning).

II.b.2. Wide Range of Possibilities

The wide range of possibilities for the synthesis of materials is exemplified by the fact that, in all cases studied to date, the organic unit is included within the silica matrix without any transformations. The hydrolytic polycondensation occurs under mild conditions and it does not induce any rearrangement or bond breaking in the organic compound: the ^{13}C NMR spectra of the organic units are almost identical in solution and in the oxide matrix. ^{29}Si NMR spectroscopy, which is sensitive to the first and second nearest neighbours, allows easy discrimination between the T ($C-SiO_3$) and the Q (SiO_4) units.[57][58] The cleavage of the Si−C bonds corresponds to the formation of Q units whose signals are located in the range $\delta = -90$ to -110, and are shifted to higher field in comparison to the T units ($\delta = -40$ to -80) depending on the nature of the organic group. The only exception is the case of the Si−C≡C bond, which can be cleaved by H_2O when fluoride ions are used as the catalyst.[17−20,59−73] Scheme 7 shows, as an example, the ^{29}Si NMR and IR spectra observed before and after cleavage of Si−C bonds in the case of the tetraethynylbenzene hybrid material.[61] The solid (I) is obtained from the corresponding precursor by hydrolysis. Treatment with NH_4F/H_2O in MeOH leads to Si−C≡C cleavage. However, the tetraethynylbenzene formed (II) cannot be separated from SiO_2. It is possible to show by spectroscopic analysis that the reaction is complete, as illustrated in Scheme 7.

Any organic molecule containing at least two SiX_3 units can be transformed into a nanostructured hybrid material by hydrolytic polycondensation (Scheme 8). Thus, this very flexible synthetic route does not suffer from any limitation in terms of access to materials. In this way chemists have the opportunity to include in a solid material any organic molecule that has a desirable physical property in solution. It also offers an alternative to the thermodynamic approach to the preparation of materials since is allows all the possibilities available by molecular chemistry to be combined in the design of new kinds of materials (Scheme 8).

II.b.3. Physical Properties in the Hybrid Materials

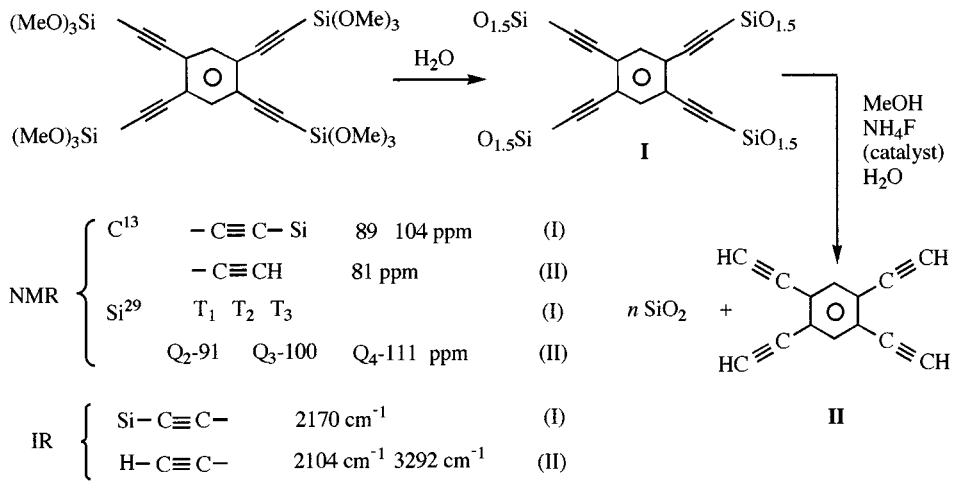
Generally speaking the physical properties of the organic part are maintained in the hybrid solid. However, these properties can be different depending on whether the location of the organic part is at the surface or in the core of the material. Moreover, possible strains induced by the rigidity of the solid can lead to some distortion of the physical properties of the organic compound. A few examples are given below.

(i) Electrochemistry

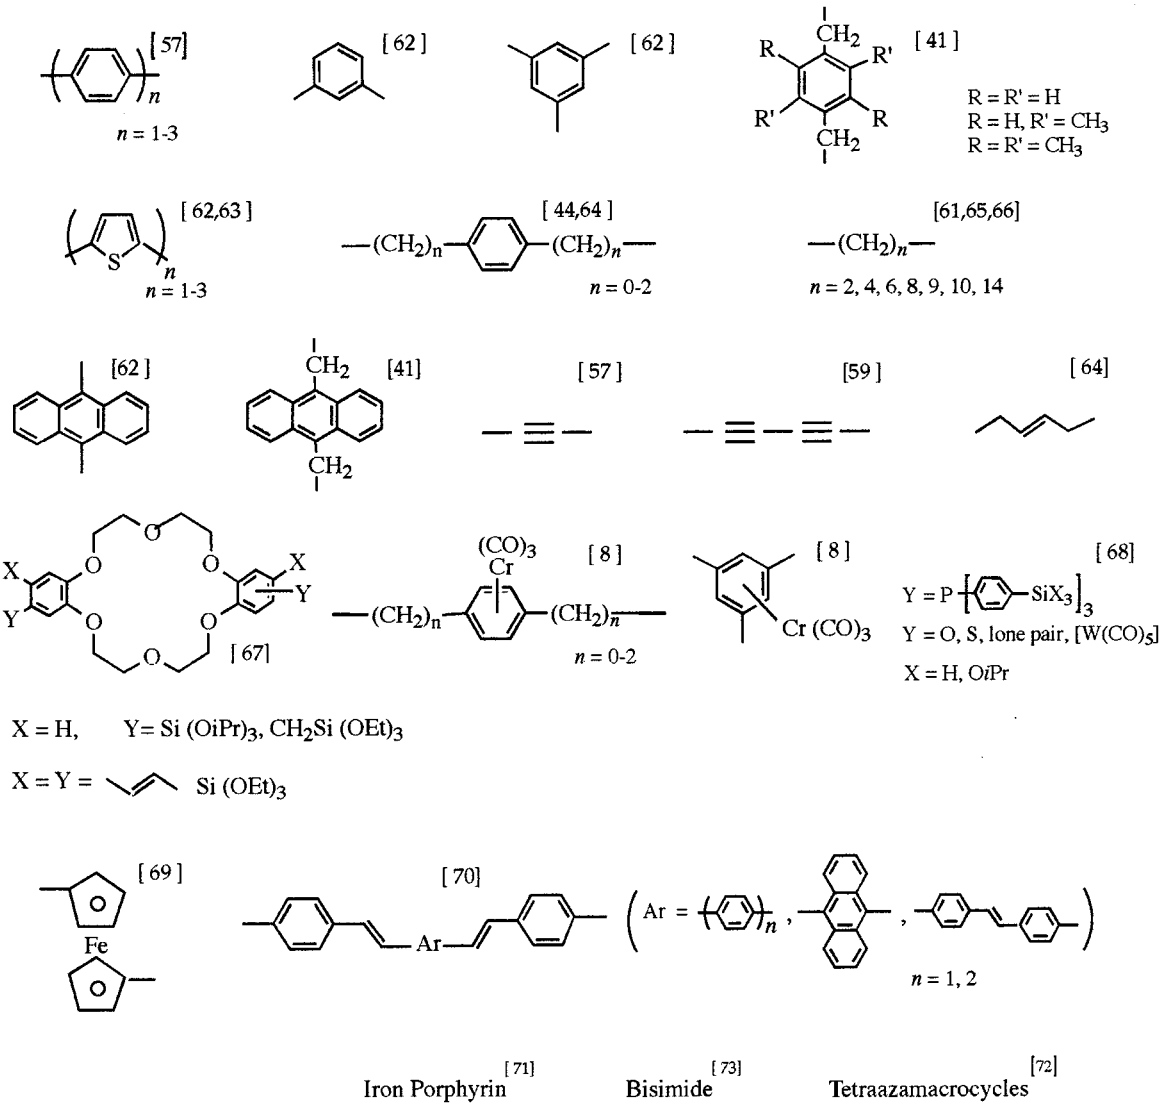
Ferrocene is a good example because of its high stability and precise electrochemical behaviour.[74] The electrochemistry observed is very different in the cases of mono- and bis-silylated ferrocene.[75]

Gels III and IV, respectively formed from trimethoxysilylferrocene and 1,1′-bis(trimethoxysilyl)ferrocene copolymerized with tetramethoxysilane and deposited onto platinum, allow modified electrodes to be built and these systems have interesting electrochemical properties (Scheme 9).[75]

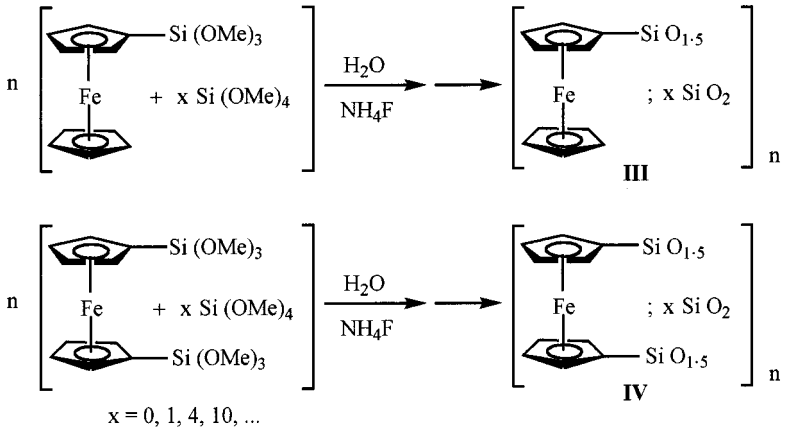
Solid IV, obtained from the bis-silylated ferrocene, displays a Cottrelian diffusion of charge transfer and exhibits



Scheme 7. Cleavage of the Si−C≡C bond catalysed by fluoride ions; spectroscopic characterisation



Scheme 8. Examples of organic units included in nanostructured materials



Scheme 9. Gels obtained from mono and bis-silylated ferrocene

classical reversible cyclic voltammograms: the peak current scales in a linear way with the square root of the scan rate (Figure 1).

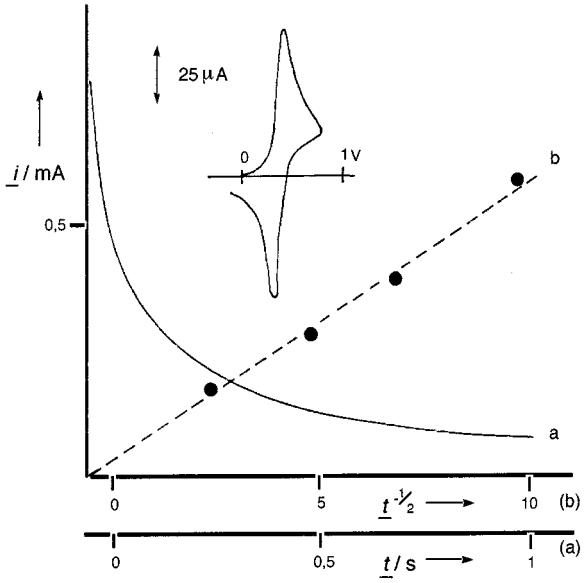


Figure 1. Typical chronoamperometric and linear Cottrell curves of a gel prepared from a bis-silylated ferrocene precursor: (a) plot of current i versus time t, (b) plot of current i versus $t^{-1/2}$

Furthermore, it proved impossible to perform complete oxidation of Fe^{II} into Fe^{III} in a macroelectrolysis carried out on a suspension of IV.[76] The process is, however, reversible (Figure 2). Such behaviour is due to the fact that some ferrocenyl units are embedded in the core of the solid and do not participate to the electrochemical process.

In the gels III (Scheme 9), derived from the mono-silylated ferrocene, the charge transfer follows a law with a fractional exponent. This unique behaviour is indicative of a particular substructure in the gels. Moreover in this case, complete and reversible oxidation of Fe^{II} into Fe^{III} is observed in macroelectrolysis, as evidenced by Mössbauer spectroscopy[76] (Figure 2).

(ii) Optical Properties

Molecular precursors containing 1−4 phenylene vinylene units have been prepared.[70] These organic units are known for their photoluminescence properties.[77]

Solid materials containing these organic fragments have been easily prepared by sol-gel from the appropriate precursors. These materials provide examples of the inclusion of chromophores into silica frameworks (Scheme 10).

The absorption and fluorescence spectra of the gels exhibit maxima at 495−496 nm, which are similar to the values observed with the corresponding precursors in the solid state. However, the high energy emission of the precursor at 466 nm is absent (Figure 3). The optical properties of the chromophores are retained in the solid and they lead to materials with potential optical and electro-optical applications. Moreover, it was observed that upon formation of the solid the position and form of the photoluminescence spectra changes. The modifications observed are different depending on the nature of the aromatic fragment Y.

II.b.4. Chemical Properties of the Hybrid Materials

The chemistry in the solid state is essentially the same as the chemistry occurring in homogeneous phases (liquid or gas). However, working with the solid does cause some very important changes, the first one being due to the highly restricted mobility of the compound in question. At room or moderate temperatures the motions of the atoms are limited to vibration and to a very low conformational flexibility. This restricted mobility is connected with a large decrease of the entropy. The second change in the chemistry involves the location of the organic part either at the surface or in the core of the solid. Thus, the accessibility of the reactive sites towards a particular reagent will be different depending on the texture (mainly specific surface area and porosity) and the structure of the solid: the structure corresponds to the relative arrangements of the organic units within the material.

A few examples are given in order to illustrate the chemical reactivity of such solids.

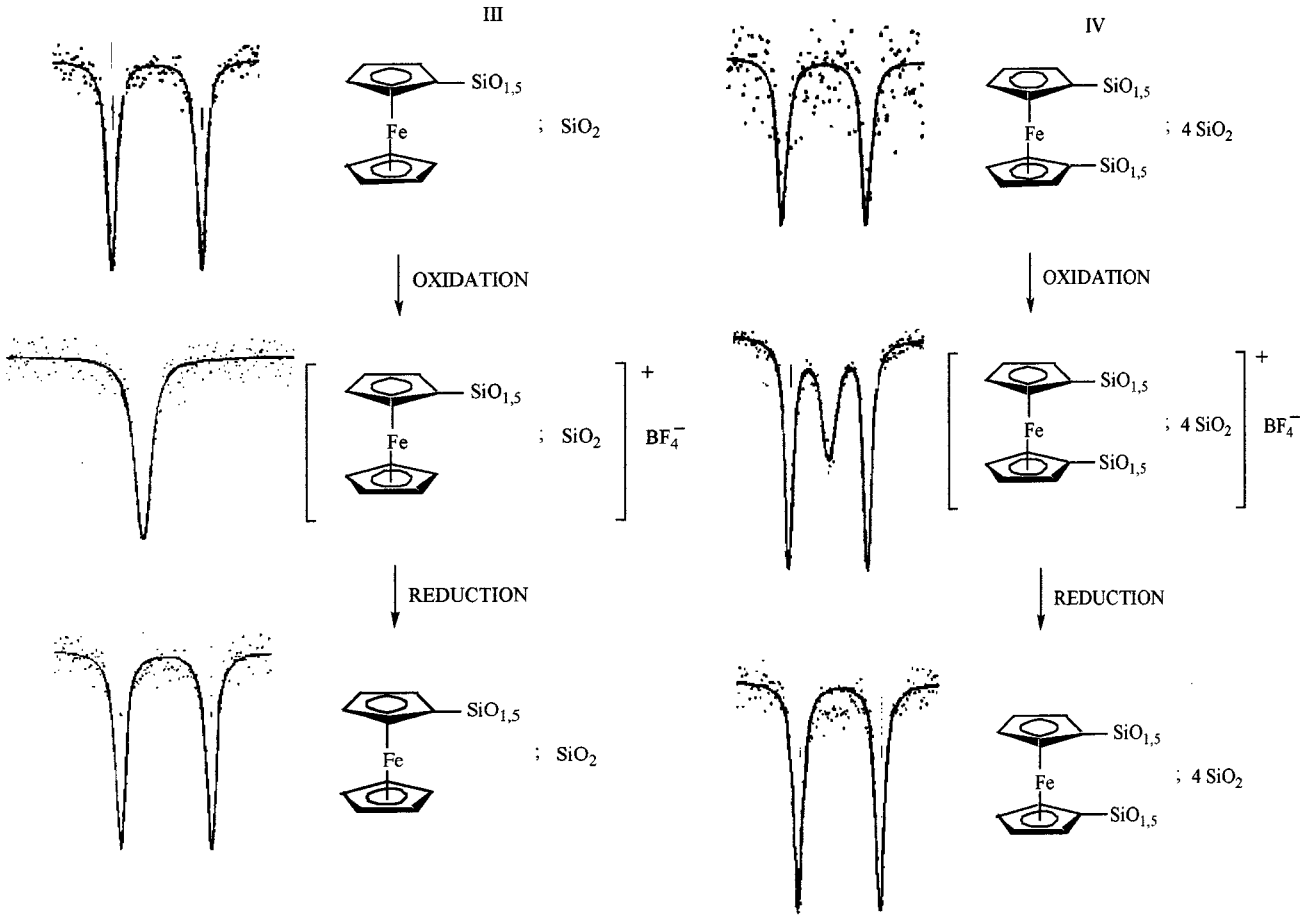

Figure 2. Mössbauer spectra of hybrid solids with ferrocenyl units

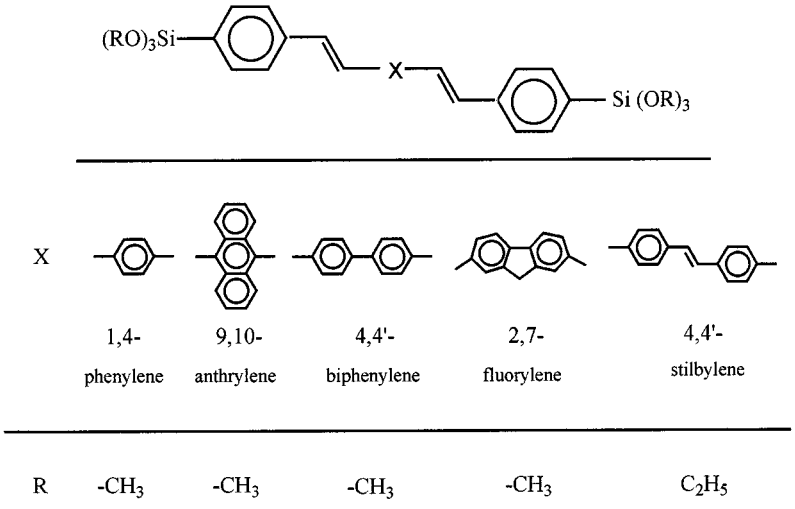

Scheme 10. Precursors with oligo-1,4-phenylene vinylene precursors

(i) Chemical Accessibility at Phosphorus and Crosslinking Ratio

The phosphorus atom is a good probe for the study of the chemical accessibility due to the fact that it has a wide range of reactivity towards both uncrowded (O_2, S_8, CH_3I etc.) and more crowded reagents (alkyl halides or transition metals). Moreover, its very high NMR sensitivity (^{31}P) permits a very reliable measurement of chemical changes at phosphorus.[78]

We have considered the reactivity on the solids V to VII, which were obtained by hydrolytic polycondensation from the corresponding $Si(OiPr)_3$ precursors. The reagents H_2O_2, S_8, CH_3I, φCH_2Br, $THF/W(CO)_5$, and BH_3 were used (Scheme 11).[79]

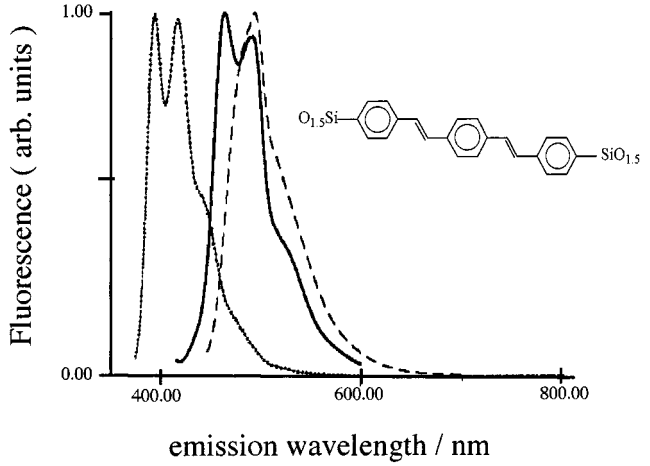

Figure 3. Photoluminescence spectra of gels with 1,4-phenylene vinylene units (precursor in THF (····) and KBr (−−) and the corresponding gel (---)

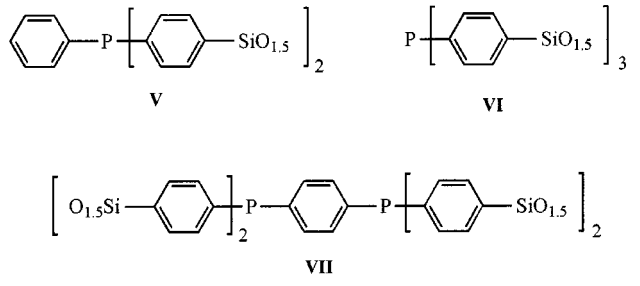
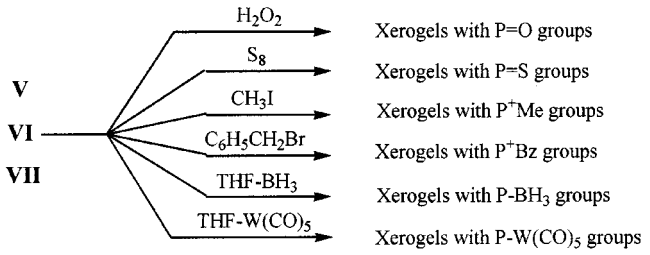




Scheme 11. Chemical accessibility of phosphorus atoms in hybrid solids incorporating phosphane units

Table 1 shows that all the phosphorus atoms are accessible to uncrowded reagents (H_2O_2, S_8, CH_3I), regardless of the specific surface area and the degree of crosslinking of the solid measured by the number of functionalities. (The degree of polycondensation at silicon has a similar magnitude for all the solids prepared.)

Table 1

Solid	S[a]	f	H_2O_2 or S_8[b]	CH_3I[b]	THF/$W(CO)_5$ [b]
V	<10	6	100	100	100
VI[c]	30	9	100	95	5
VI[d]	400	9	100	100	80
VII	460	12	100	100	20

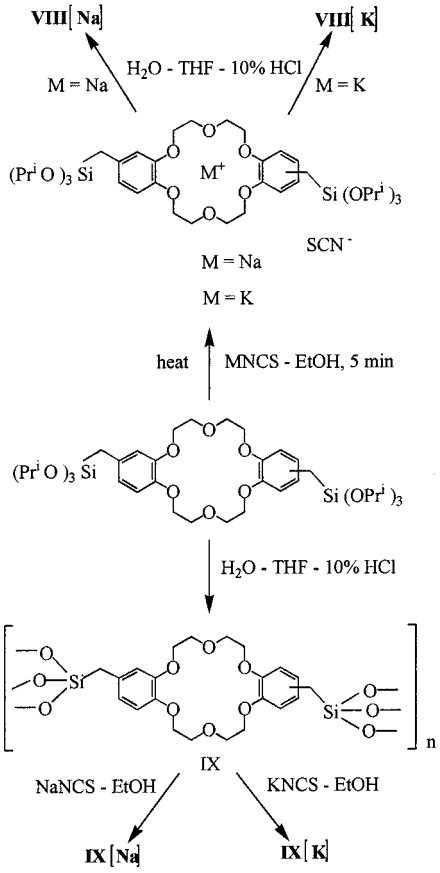
[a] Specific surface area (BET) [$m^2\ g^{-1}$]. − [b] Reaction yield obtained from NMR spectroscopy on solids; f = number of functionalities at silicon. − [c] Solids obtained with *p*-toluene sulfonic acid (1%) as catalyst. − [d] Solids obtained with HCl (10%) as catalyst.

In contrast, the reactivity of the crowded reagent THF/$W(CO)_5$ is highly dependent on the crosslinking of the solid, which appears to be the dominant parameter. The specific surface area also plays a role, but to a lesser extent.

The steric hindrance of the reagent involves drastic requirements and the most rigid materials are not mobile enough to allow access to phosphorus. Thus, solid VII, which has twelve condensation directions, exhibits poor reactivity.[79]

(ii) Influence of the Solid on Crown-Ether Properties

Hybrid materials incorporating crown ethers have been prepared as shown in Scheme 12.[67]

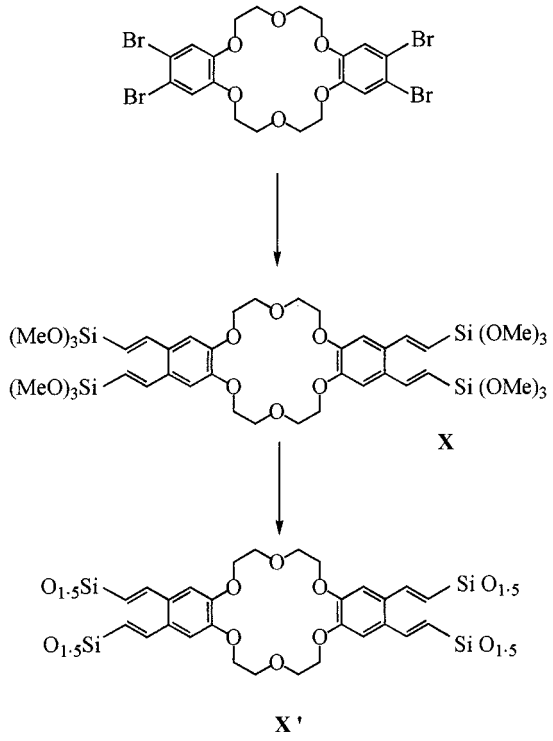


Scheme 12. Hybrid materials incorporating crown ether units from bis-silylated precursors

We prepared the gels VIII [Na] and VIII [K] by hydrolysis of the complexes of crown ethers with Na^+ and K^+. These solids were compared to the materials obtained by treatment of the solids IX with Na^+ and K^+, which gave IX [Na] and IX [K]. The degree of complexation of VIII [Na] and VIII [K] is high (95%), suggesting that the polycondensation at silicon does not induce a strong distortion of the geometry of the crown ether, a situation that could lead to the elimination of complexed salts. In contrast, IX [Na] and IX [K], obtained by direct complexation of the solids, are totally different: only 45% of the sites are complexed by Na^+ (IX [Na]) and 73% by K^+ (IX [K]). These observations

suggest that during the polycondensation of the non-complexed precursor, a distortion occurs that restricts the conformational aptitude of the crown ether ring for complexation of Na^+ and K^+. In this case, the use of complexed and non-complexed crown ethers as precursors leads to different materials. In order to verify this hypothesis we prepared the precursor X, which can lead to more crosslinked solids by increasing the number of functionalities.

In this case the possibility of direct complexation of the solid X′, obtained after hydrolytic polycondensation, is very low: 12% for Na^+ and 37% for K^+ (Scheme 13) and, in addition, ≈ 40% of the crown ether units do not exhibit the appropriate geometry for complexation with Na^+ or K^+. The rigidity of the crown ether in the solid prevents the conformational mobility necessary for complexation.



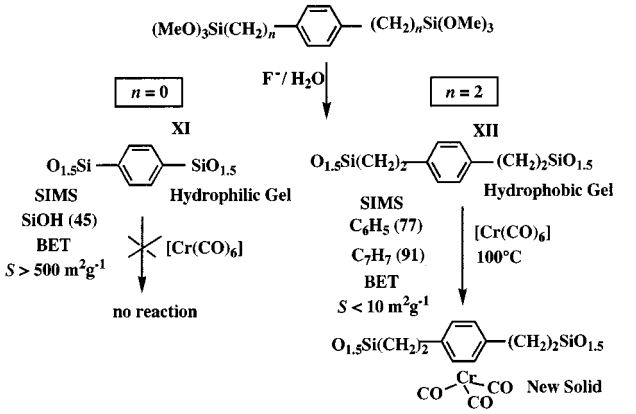
Scheme 13. Hybrid material incorporating crown ether units from tetra-silylated precursors

(iii) Chemical Reactivity Connected with Solid Organisation

A number of previous observations have shown that the molecular geometry is a very important parameter in controlling solid organisation. The example presented here illustrates the drastically different behaviours observed between the solids obtained from two similar precursors.[8,44]

Despite the fact that the two precursors are very similar, materials XI and XII, obtained using the same experimental conditions, exhibit completely different chemical and physical properties (Scheme 14).

XI is a hydrophilic solid with a high specific surface area (550 $m^2\ g^{-1}$) for which the TOF-SIMS does not exhibit any fragment arising from C_6H_4. Indeed, only Si−OH fragments can be detected. Interestingly, XI does not react with



Scheme 14. Influence of the molecular geometry of the precursor on chemical and physical properties of the solid

$Cr(CO)_6$, which is consistent with the fact that the organic groups are embedded in the core of the solid.

In contrast, XII is a hydrophobic resin that has a very low specific surface area and the TOF-SIMS mass fragments exhibit phenyl (m/z = 77) and tropylium (m/z = 91) units. Moreover, Si−OH fragments cannot be detected.[43] These results suggest strongly that the organic groups are located at the surface of the solid. This fact is evidenced by the good yield observed in the reaction with $Cr(CO)_6$ (about 80%).

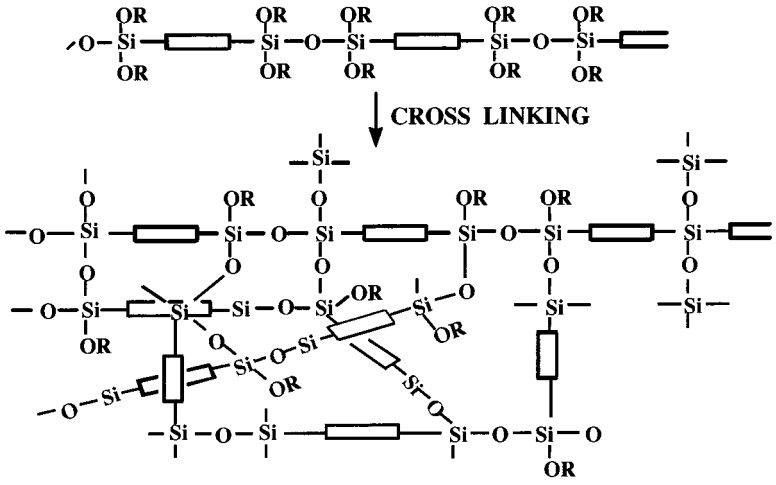
These two examples illustrate very well the significance of the organic unit in controlling the solid arrangement under identical experimental conditions. The rigid precursor leads to a solid with a completely different chemical reactivity to that of the solid obtained by polycondensation of a more flexible precursor.

III. Organisation of Hybrid Materials

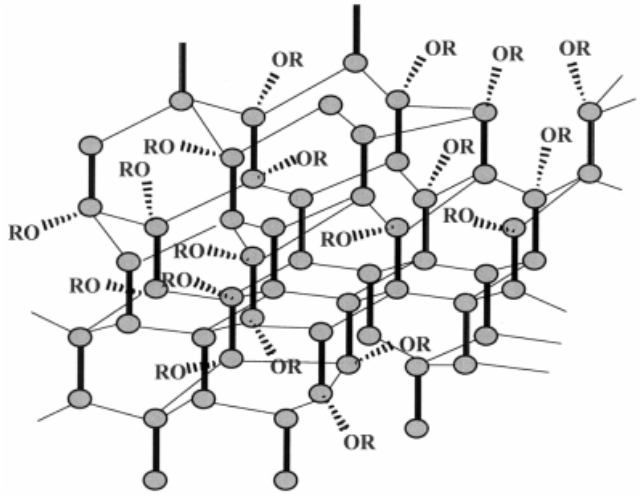
All the hybrid materials reported in the literature to date are described as amorphous materials. Their XRD patterns are generally similar to those of amorphous silica. However, it is known that the XRD patterns can only be observed in solids with a long-range organisation. Moreover, at the moment a physical method that permits the study of short-range organisation in the solids is not available, with the exception of SAXS (Small Angle XR Scattering).[77]

(i) Preliminary Reports: Local Order in the Solid

The possibility and the nature of organisation were chemically assessed chemically. In section II.b.4(iii), we discussed the results obtained with XI and XII, which suggest that the arrangements of their organic units in the solid are completely different.[9,44] The hydrophobic material XII, in which the aromatic groups are at least partly located at the surface (detection by SIMS) and are also chemically accessible with good yield, can be more or less described as a solid in which molecular chains are crosslinked. Thus, $Cr(CO)_6$ dissolved in an organic solvent is able to pass through the material and react with the aromatic groups (Schemes 15 and 16).



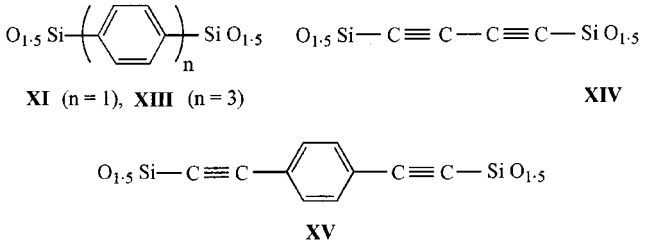
Scheme 15. Short-range organisation in the solid



Scheme 16. Short-range organisation in the solid

In the hydrophilic material, XII, the aromatic groups are not detected by TOF-SIMS and they are not chemically accessible.

Moreover, a local order in the material is evidenced by the presence of a broad XR diffraction signal in SAXS.[80] Besides XII, this kind of XR diffraction signal has been observed in the case of three hybrids (XIII, XIV, XV), which were synthesized from precursors that also have a rigid geometry[81] (Scheme 17).



XI (n = 1), **XIII** (n = 3) **XIV** **XV**

Scheme 17. Hybrid solids from precursors with a rigid geometry

We propose the formation of local order (Scheme 16) in which the organic units are regularly alternated. The representation proposed here allows us to explain the presence of OCH_3 and OH fragments in TOF-SIMS and the absence of aromatic units since only one Si−C bond is located at the surface. This model also explains the hydrophilicity. The lack of flexibility accounts for the very poor reactivity towards $Cr(CO)_6$ and the regularity of the arrangements is in agreement with the SAXS results, which show a diffraction peak for a distance close to the size of the organic spacer.

In the case of XIII, a diffraction signal was observed at 15 Å.[82]

These values are estimated from the q values using the Bragg law as a first approximation. They provide evidence for the existence of a short-range order in the solid. However, the distance is only indicative, since the Bragg law is valid only for narrow diffraction signals. In the case of the two other materials, we reported the scattering peaks at 8.1 Å for XIV[59] and two signals at 11.4 Å and 5.5 Å for XV.[81] In this case, it was observed that the order demonstrated by the XR diffraction signal is independent of experimental parameters like the solvent, concentration, or catalyst. Moreover, the study of the copolymerisation between the precursor XV and TMOS shows a unidimensional swelling. The q values vary in a linear manner with the volumic fraction of added silica:

$q_{1,n} = q_{1,0}\ (1 - 0.48\ \ SiO_2)$ (n = mol number of TMOS, = volumic fraction), indicating the unidimensional swelling of a short-range organised solid.[83]

All these facts are in agreement with a local order in the solid that arises during its formation.

(ii) Physical Evidence of Long Range Organisation

We have obtained some physical evidence of long-range organisation in the solid by birefringence experiments performed with the solid derived from the precursor XV.[83]

A homogeneous solution of XV in THF with an equimolecular amount of H_2O was introduced into a confined cell made of glass plates treated with oriented Teflon. In the sealed cell the isotropic solution always appeared dark regardless of the angle of the crossed polarizers. After a few minutes bright domains appeared in different places due to

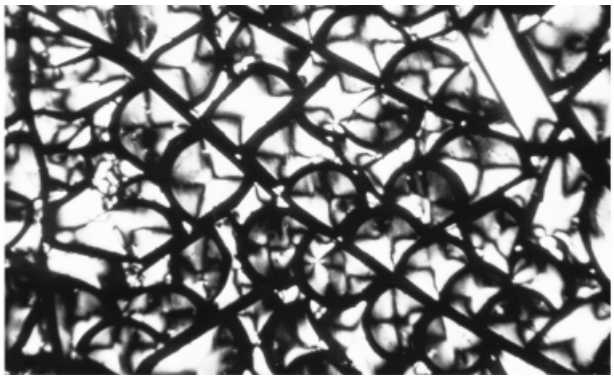


Figure 4. Physical evidence for long-range organisation by birefringence experiments

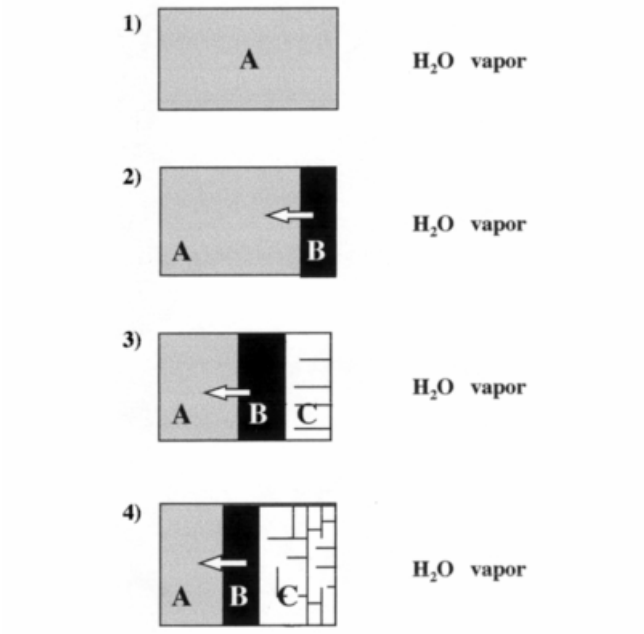

Scheme 18. Birefringence experiments: evolution of a part of a cell during the polycondensation process: A = precursor; B = liquid-to-gel isotropic medium; C = anisotropic gel and xerogel (dark lines: cracks)

birefringence. A few hours later the whole field of view the cell was birefringent and some cracks appeared (Figure 4).

Another set of experiments was performed with a controlled partial pressure of water using open cells containing the pure crystalline precursor. The results are represented in Scheme 18.

The microcrystalline precursor XV is birefringent and was converted into an isotropic liquid from which a birefringent solid formed. The birefringence subsequently increases upon ageing the gel and birefringent cracks were observed. This experimental procedure allows the history of the xerogel formation to be traced through the successive states: precursor, oligomers, polymers, sol, gel and cracks.

Thus, birefringence that corresponds to a micrometric scale organisation is observed when the polycondensation at silicon occurs to give crosslinked solids. Interestingly, the driving force for the organisation in the material during the polycondensation appears to be the rigidity of the organic unit included in the silica matrix.

IV. Conclusion

This short review has briefly covered only a few aspects of the wide possibilities opened up by the combination of Molecular Chemistry and "Chimie Douce" for the preparation of new kinds of materials.

Both approaches are based on kinetic control of the synthesis and their wedding has opened the way to materials that combine organic, inorganic and also macromolecular chemistry with inorganic polymerisation.

These new avenues are made accesible by the flexibility of "Chimie Douce", which permits the elaboration of oxides by a hydrolytic polycondensation mechanism. This low temperature polymerisation is compatible with the existence of covalent bonds between the oxide and organic, inorganic or macromolecular units. These hybrid materials combine the properties of the oxide matrix and the physical and chemical properties of the units included in the solid material. In the case of silica, the physical properties are restricted. However, this matrix has the great advantage of having a very wide chemical flexibility, good stability and excellent processability in the viscous sol state. The matrix allows the organic or organometallic partner to jump from its molecular state to the solid material. In this state the molecule becomes a part of the whole and the properties cannot be described in terms of isolated systems but as the properties of the material. For instance, the possible organisation of the organic or organometallic groups may enhance the physical properties in comparison to the isolated units. It is also possible to modify the chemical properties. A good example is the case of mesoporous materials obtained by the MCM-type route. These materials, called catalytic materials, have interesting possibilities in polyfunctional catalysis as well as for selective separation and purification.

The new horizons provided by hybrid organic-inorganic materials appear very wide and the future offers the prospect of many developments as chemists explore new routes to other oxides and to other kinds of matrices.

Acknowledgments

The author wishes to thank his co-workers who were involved in this research area − Professors G. Cerveau and C. Reyé, Doctors J. P. Bezombes, B. Boury, C. Chuit, G. Dubois, E. Framery, C. Lepeytre, V. Le Strat, A. Mehdi − for their cooperation, fruitful discussions and great efficiency. Professor Delord and Doctors Combarieu and Nobili are also acknowledged for their cooperation.

On the Crystal Engineering of Organogallium Alkoxides Derived from Primary-Amine Alcohols − Relationships between Hydrogen Bonding and Donor−Acceptor Bonds

Janusz Lewiński,*[a] Janusz Zachara,[a] Tomasz Kopeć,[a] Kazimierz B. Starowieyski,[a] Janusz Lipkowski,[b] Iwona Justyniak,[a,b] and Edyta Kołodziejczyk[b]

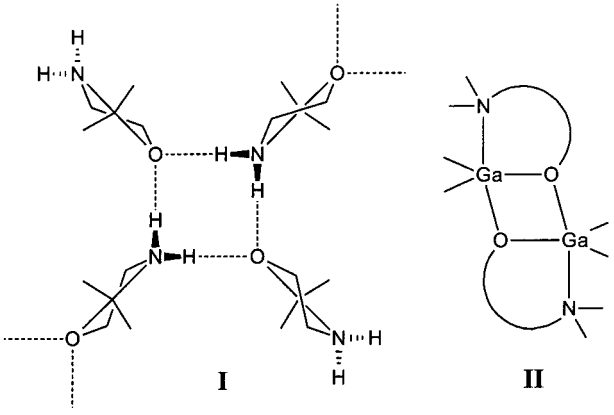
Keywords: Gallium / Alkoxides / Crystal engineering / Donor-acceptor systems / Hydrogen bonds

The crystal structure analysis of model organogallium amine-alkoxides $Me_2Ga(OCH_2CH_2CH_2NH_2)$ (**2**) and $[Me_2Ga\{\mu\text{-}OCH_2CH(CH_3)NH_2\}]_2$ (**3**), demonstrate how hydrogen bonding can effectively compete with metal–ligand coordination preferences in determining the molecular and crystal structure and how conformational changes in a ligand and increased steric bulk on the carbon atom adjacent to the amine group can impart on a network morphology and molecular aggregations.

Introduction

In the last two decades, a detailed analysis of intermolecular interactions in crystals and the design of supramolecular architecture have become a rapidly expanding area.[1] Investigations of the self-assembly of organic molecules through intermolecular interactions have lead to the identification of a number of useful tools for supramolecular design, the most efficient being hydrogen bonding.[2] In spite of the large number of contributions and advances in the self-assembly of organic molecules based on noncovalent interactions, the area of organometallic compounds in this context remains largely unexplored.[3] Here we report preliminary results in aiding our understanding of relationships between intra- and intermolecular forces resulting from donor-acceptor and hydrogen bonding interactions using gallium alkoxides with primary-amine termini as model complexes.

Starting with pioneering work on the ligative possibilities of gallium alkoxides derived from amine alcohols,[4] considerable research has been devoted to the determination and understanding of the structure of this class of compounds.[5−15] Over twenty years ago Chong et al. reported the structural characterization of the dimethylgallium derivative of amine ethanol, $Me_2Ga(OCH_2CH_2NH_2)$ (**1**), and demonstrated that the latter compound exists as discrete four-coordinate monomers linked by an extensive network of N−H···O hydrogen bonds in the solid state.[6] Although the authors have not discussed in detail the hydrogen bond network, our analysis revealed a symmetrical three-dimensional architecture (structure **I**, Scheme 1). Surprisingly, to the best of our knowledge, competition between the four-coordinate complexes with an extended hydrogen bond network and the metal-ligand coordination preferences, for example the formation of the five-coordinate $[R_2Ga(O,N)]_2$-type adduct **II**, have not been studied. In order to test how the molecularity and network architecture of gallium alkoxides may be controlled by an appropriate choice of primary-amine-terminated alcohols, dimethylgallium derivatives of 3-amino-1-propanol, $Me_2Ga(\mu\text{-}OCH_2CH_2CH_2NH_2)$ (**2**), and 2-amino-1-propanol, $\{Me_2Ga[\mu\text{-}OCH_2CH(CH_3)NH_2]\}_2$ (**3**), were synthesized and structurally characterized, and the structural features were compared with those of the previously reported 2-amino-1-ethanol analogue.



Scheme 1

Results and Discussion

The interaction of Me_3Ga with an equimolar amount of the corresponding amino alcohol in CH_2Cl_2 at −78 °C results in methane evolution and the quantitative formation of the dialkylgallium *O,N*-chelate complexes **2** and **3**. Single crystals suitable for an X-ray analysis were obtained from the concentrated solution at −20 °C.

The crystal structure of **2** contains four crystallographically independent monomeric molecules with essentially the same geometry, in which each Me_2Ga moiety is chelated in a tetrahedral geometry by the amine alkoxide ligand (average Ga−O and Ga−N distances are 1.879 Å and 2.037 Å, respectively) (Figure1). The alkoxide oxygen and amine nitrogen atoms act as complementary hydrogen donors and acceptors leading to a fully hydrogen-bonded network. The molecules in the ribbon assemble with pairs of strongly hydrogen-bonded chains (average NH···O distance is 1.90 Å; the N−H···O angles range from 170 to 176°). The chains are then cross-linked by very weak N−H···O interactions (average H···O distance is 2.45 Å and mean N−H···O angle 170°), forming the hydrogen bond network shielded by hydrophobic groups.

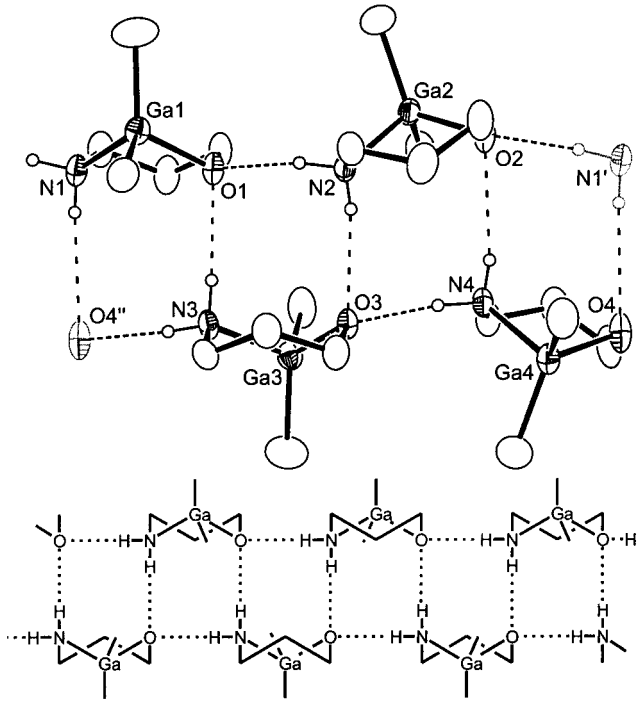

Figure 1. The hydrogen bonding observed in crystalline $Me_2Ga(OCH_2CH_2CH_2NH_2)$ (**2**) showing molecular chains parallel to [010], linked together by hydrogen bonds formed by the axial amine hydrogens and alkoxide oxygens; top: the arrangement of four independent molecules; bottom: schematic representation of the hydrogen bonding network; selected bond lengths (Å) and angles (°): Ga(2)−O(2) 1.874(3), Ga(3)−O(3) 1.885(3), Ga(4)−O(4) 1.870(3), Ga(1)−N(1) 2.043(4), Ga(2)−N(2) 2.039(4), Ga(3)−N(3) 2.026(4), Ga(4)−N(4) 2.041(4), Ga(1)−O(1) 1.887(3); O(1)−Ga(1)−N(1) 91.48(15), O(2)−Ga(2)−N(2) 92.94(15), O(3)−Ga(3)−N(3) 91.65(14), O(4)−Ga(4)−N(4) 92.26(15)

The monomeric moieties in the idealized chains are related by the glide plane passing through the oxygen and nitrogen atoms. Thus, the elongation of the backbone in 3-amino-1-propanol relative to 2-amino-1-ethanol enforces the crystal structure of gallium alkoxides. An explanation of this different supramolecular behavior of **1** and **2** in the crystal is provided by an analysis of the heterocycle conformation in both compounds. The six-membered GaOCCCN rings in **2** adopt a chair-like conformation. As a consequence of this geometry both the amine hydrogens and oxygen lone-pairs become nonequivalent and situated in axial and equatorial positions. Inspection of the space-filling representation of the crystal structure of **2** undoubtedly shows that steric requirements favor interactions between the equatorial hydrogen and equatorial lone-pair. However, in the crystal structure involving the gallium alkoxide derived from 2-amino-1-ethanol, the five- membered GaOCCN chelate rings are slightly twisted around the C−C bond giving rise to spatial equivalency of the amine hydrogens and oxygen lone-pairs. The bisectionally positioned hydrogens and lone pairs form a symmetrical, three-dimensional, hydrogen bond network (**I**, Scheme 1).

In contrast to the four-coordinate hydrogen bonded polymeric structures of **1** and **2**, compound **3** is dimeric, being bridged by the oxygens of the chelating alkoxide ligand (Figure 2). The crystal structure of **3** comprises individual five-coordinate dimeric molecules with no unusually short intermolecular contacts. The general structural features of the molecules are consistent with those observed for related gallium alkoxides (average $Ga-O_{equatorial}$, $Ga-O_{axial}$ and Ga−N distances are 1.923 Å, 2.113 Å and 2.348 Å, respectively).[5,13] It is worth noting that the crystal structure exhibits disorder indicating the presence of the (*R**,*R**)-$[Me_2Ga(O,N)]_2$ and (*R*,*S*)-$[Me_2Ga(O,N)]_2$ diastereomers (Figure 2). These diastereomers result from the association of monomeric moieties of the same or opposite configuration as the chiral center in the *O*,*N*-chelating ligand. Thus, the formation of the dialkylgallium alkoxide adducts derived from chiral amine-functionalized alcohols is not a stereoselective reaction, contrary to the highly stereoselective association of dialkylaluminum alkoxides derived from chiral carbonyl-functionalized alcohols recently reported by our group.[16]

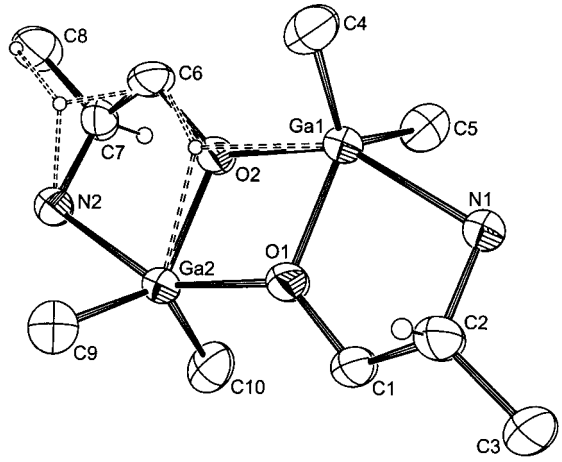

Figure 2. ORTEP view of the molecular structure of $\{Me_2Ga[\mu\text{-}OCH_2CH(CH_3)NH_2]\}_2$ (**3**) showing the disordered 2-amino-1-propanolato ligands of opposite configuration as the chiral center; thermal ellipsoids are drawn at 30% probability level; selected bond lengths (Å) and angles (°): Ga(1)−O(1) 1.916(3), Ga(1)−O(2) 2.127(15), Ga(1)−N(1) 2.349(4), Ga(2)−O(2) 1.929(14), Ga(2)−O(1) 2.106(4), Ga(2)−N(2) 2.347(4); O(1)−Ga(1)−N(1) 76.57(14), O(2)−Ga(1)−N(1) 149.8(4), O(2)−Ga(2)−N(2) 75.9(4), O(1)−Ga(2)−N(2) 150.14(14)

A question arises why compounds **1** and **2** crystallize as discrete four-coordinate monomers linked by an extensive network of N−H···O hydrogen bonds and **3** occurs as a five-coordinate dimer in the solid state. It is apparent that the relative stability of the five-coordinate dimer vs. the four-coordinate, hydrogen-bonded polymer depends on the balance between the energy of coordinate bonds and hydrogen bonds; however, energy-related questions are difficult to answer at present. The reported results show that for **1** and **2** cooperative hydrogen bond interactions effectively compete with the metal ligand coordination preferences in determining the molecular and crystal structure. On the other hand, the substitution of a hydrogen by a methyl group on the carbon atom adjacent to the hydrogen donor presumably results in a weakening of the intermolecular hydrogen bond interactions and enforces the structural changes.

Conclusion

In conclusion, metal alkoxides with a primary-amine functionalized side chain provide the means to study intra- and intermolecular forces resulting from donor-acceptor and hydrogen bonding interactions. Further studies on the effects of conformational and steric changes in a subunit structure on the molecular and crystal structure of metal alkoxides are in progress.

Experimental Section

General Remarks: All reactions were carried out under dry nitrogen using standard Schlenk techniques. Solvents were dried and distilled prior to use. NMR spectra were recorded on a Varian 300 VXL spectrometer.

(3-Aminopropanolato)dimethylgallium (2): A solution of 3-amino-1-propanol (0.60 g, 8.0 mmol) in CH_2Cl_2 (10 cm^3) was cooled to −78 °C and Me_3Ga (0.92 g, 8.0 mmol) was added dropwise. After the addition was completed, the reaction mixture was warmed to room temperature and stirred for 0.5 h. Concentration of the mother solution followed by crystallization at −20 °C gave a colorless solid. Yield: 80%. − ^{1}H NMR (C_6D_6, 300 MHz): δ = −0.14 (s, 6 H, Ga−CH_3), 0.82−1.35 (2 H, NH_2), (br. m, 2 H, CH_2), 2.27 (br. t, 2 H, CH_2), 3.81 (br. t, 2 H, OCH_2). − $C_5H_{14}GaNO$ (173.89): calcd. C 34.53, H 8.11, N 8.05; found C 34.46, H 8.18, N 8.06.

Bis(μ-2-aminopropanolato-*N*,*O*)tetramethyldigallium (3): A solution of 2-amino-1-propanol (0.60 g, 8.0 mmol) in CH_2Cl_2 (10 cm^3) was cooled to −78 °C and Me_3Ga (0.92 g, 8.0 mmol) was added dropwise. After the addition was completed, the reaction mixture was warmed to room temperature and stirred for 0.5 h. Complex **3** was isolated at −20 °C as colorless crystals. Yield: 90%. − ^{1}H NMR (C_6D_6, 300 MHz): δ = −0.07 (s, 12 H, Ga−CH_3), 0.42 (br, 4 H, NH_2), 0.50 (d, 6 H, CH_3), 2.38 (br. m, 2 H, CH) 2.97 and 3.51 (dd, 4 H, OCH_2). − $C_{10}H_{28}Ga_2N_2O_2$ (347.78): calcd. C 34.53, H 8.11, N 8.05; found C 34.48, H 8.15, N 8.03.

X-ray Crystal Structure Analysis: Single crystals of **2** and **3** suitable for X-ray diffraction studies were placed in a thin-walled capillary tube (Lindemann glass 0.5 mm) in an inert atmosphere. The tube was plugged with grease, then flame-sealed and mounted on a goniometer head. Selected crystallographic data, the parameters for data collection and refinement procedures are presented in Table 1.

Compound 2: Unit cell parameters and intensity data for compound **2** were collected with a P3 Siemens diffractometer employing graphite monochromated Mo-K_α radiation. The crystal classes and the orientation matrices were obtained by the least-squares refinement of 30 well-centered reflections randomly selected in the 2θ range 16−29°. The intensities were collected in the ω−2θ mode

and corrected for Lorentz-polarization effects and crystal decomposition (3.8%). A Gaussian absorption correction based on the crystal shape was applied, which resulted in transmission factors ranging from 0.531 to 0.634. The structure was solved by direct methods using the SHELXS-86 program.[17] The distribution of the peaks showed that compound **2** crystallizes with four independent molecules in the asymmetric unit. The structure of **2** was refined by full-matrix least-squares on F^2 using the program SHELXL-97.[18] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms of the methyl groups C(25) and C(35) were refined as disordered groups with two positions rotated by 60° about the C−C bond. The remaining hydrogen atoms were located from the Fourier-difference map and isotropically refined.

Compound 3: Diffraction data were collected at room temperature on a Nonius Kappa diffractometer equipped with a CCD area detector. The structure was solved by direct methods (SHELXS-86 program[17]). Compound **3** crystallizes with one independent dimeric molecule in the asymmetric unit. Full-matrix least-squares refinement was carried out on F^2 (SHELXL-97[18]). All non-hydrogen atoms were refined anisotropically. The O(2)C(6)C(7)C(8)N(2) ligand revealed substantial disorder, which was modeled in terms of two sets of $OCH_2CH(CH_3)NH_2$ atoms (two moieties of opposite configuration as the chiral center) with adjusted occupancy factors of 0.61(1) and 0.39(1), respectively. Both disordered moieties were refined anisotropically using similarity restraints for the chemically equivalent C−C, C−O and C−N distances. Hydrogen atoms were added to the structure model at geometrically idealized coordinates with fixed isotropic temperature factors.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-151158 (**2**) and CCDC-151159 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation and Structural Characterization of the First Germylaluminate

Tassilo Habereder,[a] Klaus Knabel,[a] and Heinrich Nöth*[a]

Keywords: Lithium / Germanium / Aluminum / Anions / Structure elucidation

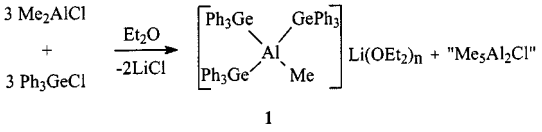
The reaction of $LiGePh_3$ with Me_2AlCl in ether yields the trisgermylaluminate $Li(OEt_2)_n[(Ph_3Ge)_3AlMe]$. The Ge–Al bond length is 2.520 Å and the geometry around the Al center almost tetrahedral.

Introduction

The chemistry of compounds with direct bonds between boron atoms and group 14 elements has found increased interest in recent years. Silylboranes and stannylboranes have proved to be versatile reagents in organic synthesis[1] and they are particularly useful for transition metal-catalyzed addition reactions to unsaturated organic compounds.[2] More recently, compounds containing Si–Al[3] or Si–Ga[4] bonds moved into focus because the $(Me_3Si)_3Si$ or $(Me_3C)_3Si$ groups stabilize polyhedral aluminum, gallium and indium clusters;[5] silylalanes and silylaluminates are also known. The molecular structures of the adducts $(Me_3Si)_3Al{\cdot}L$[6] [L = THF, NMe_3, $P(SiMe_3)_3$] and $Ph_2Al-Si(SiMe_3)_3{\cdot}THF$[7] have been described, as well as those of $(Me_3Si)_3Si-Al(tmp)_2$ (tmp = 2,2,6,6-tetramethylpiperidino),[8] $(t\mathrm{Bu}_3Si)_2Al-Al(Si t\mathrm{Bu}_3)_2$,[9] $Si(AlCl_2{\cdot}OEt_2)_4$,[10] $[Ph_2PAl(SiMe_3)_2]_2$ [11] and silylaluminates such as $Li(THF)_4[Cl_3AlSi(SiMe_3)_3]$ and $Na(THF)_2[Al(SiMe_3)_4]$.[12] As far as we are aware no molecular compound containing an Al–Ge bond has been structurally characterized. Dufaut et al.[13] reported that the reduction of digermanes with $LiAlH_4$ yields various germylaluminates amongst which only $Li(Ph_3GeAlH_3){\cdot}THF$ was identified by microanalysis; all other compounds were identified from the products of their controlled hydrolysis. Rösch et al.[14] succeeded in the preparation of $Al(GeMe_3)_3{\cdot}THF$ by reacting $Hg(GeMe_3)_2$ with elemental aluminum. A structural characterization by X-ray methods was, at the time, not standard. Here we report the synthesis and molecular structure of a novel germylaluminate.

Because salt elimination is the most straightforward pathway to synthesize B–Ge bonds[15] we also utilized this method for the synthesis of new molecules with Al–Ge bonds. To this end a solution of triphenylgermyllithium[16] in Et_2O was allowed to react with an equimolar amount of dimethylaluminum chloride [Equation (1)]. The reaction mixture was monitored by ^{27}Al NMR spectroscopy. The spectrum showed two signals at δ = 189 and 62.

These data indicate the formation of methylalanes as well as possibly a pentacoordinated aluminum species.[17] On layering a concentrated toluene solution with hexane single



1 (1)

crystals separated which were suitable for an X-ray structure analysis. The crystalline product was unambiguously identified as lithium{methyltris(triphenylgermyl)aluminate} (**1**). Its elemental analysis indicated that five molecules of ether are coordinated but the crystal structure analysis showed only three ether molecules. Compound **1** is responsible for the high field Al NMR signal and is similar to the ^{27}Al NMR signal for $Li[Al(SiMe_3)_4]$.[17] The filtrate contained no other germanium compound, although its ^{27}Al NMR spectrum showed the presence of an aluminum species with $\delta^{27}Al$ = 189. We assigned this broad signal to Me_5Al_2Cl as we found a ^{27}Al NMR signal for Me_2AlCl at δ = 165 in ether solution, and at δ = 179 in hexane solution. That only a single signal is observed for "Me_5Al_2Cl" can be explained by substituent exchange, which is common in the chemistry of aluminum alkyls.[18] Compound **1** crystallizes in the space group $P2_1/c$ with four formula units in the unit cell. The unit cell contains methyltris(triphenylgermyl)aluminate anions and ether-solvated lithium cations. The ether molecules are highly disordered. No accurate coordination geometry was found. Much more interesting is the anionic part of compound **1** (see Figure 1). It shows three Al–Ge bonds of almost equal lengths with an average of 2.520(2) Å. This value is slightly longer than the sum of the covalent radii of these two atoms [Al = 1.25, Ge = 1.22; Σ = 2.47 Å].[10] This complies with the presence of a tetracoordinated Al center. As far as we are aware this is the first Al–Ge bond length determined in a molecular unit. The Al atom in **1** shows only a minor distortion from a tetrahedral environment. The Ge–Al–Ge angles were determined to be on average 110.2(3)°, whereas the average Ge–Al–C bond angle is 108.6(2)°. This indicates that the methyl group almost demands as much space as a Ph_3Ge group.

The unexpected formation of **1** described in Equation (1) can be explained on the basis that Me_2AlCl was added to Ph_3GeLi. Thus at the beginning of the reaction there is a

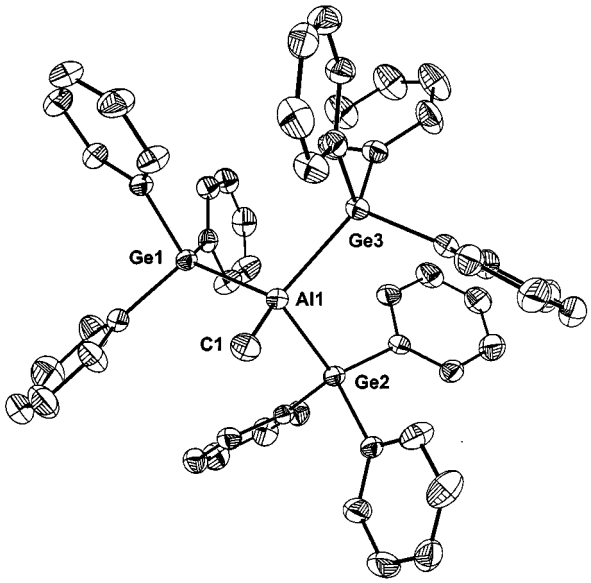

Figure 1. View of the anionic part of the molecular structure of **1**; thermal ellipsoids are shown at a 25% probability level and hydrogen atoms are omitted for clarity; selected interatomic distances [Å] and angles [°]: Ge1−Al1 2.526(2), Ge2−Al1 2.511(2), Ge3−Al1 2.523(2), C1−Al1 1.982(6); C1−Al1−Ge1 110.1(2), C1−Al1−Ge2 107.0(2), C1−Al1−Ge3 108.9(2), Ge1−Al1−Ge2 109.8(1), Ge1−Al1−Ge3 113.3(1), Ge2−Al1−Ge3 107.5(1)

large excess of the germyllithium compound. In the first step an aluminate $[(Ph_3Ge)AlMe_2Cl]^-$ is expected to be formed. This anion will lose a chloride, with formation of insoluble LiCl, producing $Ph_3GeAlMe_2$. This latter, on reaction with a second equivalent of Ph_3GeLi, will generate $Li[(Ph_3Ge)_2AlMe_2]$ as an intermediate which may either directly react with Me_2AlCl to form $(Ph_3Ge)_2AlMe$ and LiCl or methylate Me_2AlCl with formation of $AlMe_3$. This and Me_2AlCl will produce "Me_5Al_2Cl". Substituent exchange reactions are well-known in alkyl aluminum chemistry.[18] Further investigations of the chemistry of Al−Ge compounds are in progress.

Experimental Section

The experiments were performed under anhydrous conditions under an argon atmosphere using Schlenk techniques. $LiGePh_3$ was prepared according to a literature procedure.[16] NMR spectra were recorded with a JEOL 400 instrument. For X-ray work a Siemens P4 diffractometer (graphite monochromator, Mo-K_α radiation) equipped with an area detector and a low temperature device LT2 was employed. Data collection was performed with the program SMART,[20] data reduction with the program SAINT,[20] and absorption correction with the program SADABS.[21] For all other calculations the program package SHELXTL was used.[22] The Li atom and the non-hydrogen atoms of the anion were refined anisotropically. The hydrogen atoms of the Ph and Me groups were placed in calculated positions and included in the final refinement isotropically. The O and C atoms of the ether molecules were included isotropically with free SOF values.

Lithium{methyltris(triphenylgermyl)aluminate}·$(Et_2O)_5$ (1): A solution of Ph_3GeLi (1.5 mmol) in approximately 40 mL of Et_2O was cooled to −78 °C and slowly treated with a hexane solution containing of Me_2AlCl (1.45 mmol). After stirring for 1 h at ambient temperature all volatile components were removed in vacuo. The solid residue was dissolved in 50 mL of toluene, the solution filtered and layered with 20 mL of hexane. This afforded 0.60 g of **1** (yield 90% based on Ph_3GeLi), as colorless prisms; m.p. 152 °C. − ^{1}H NMR (270 MHz, C_7D_8): δ = 0.49 (s, 3 H $AlCH_3$), 1.30 (t, $^3J_{HH}$ = 8.2 Hz, 16 H, OCH_2CH_2), 1.65 (br. s, 14 H, OCH_2CH_2), 3.46 (q, $^3J_{HH}$ = 8.2 Hz, 11 H, OCH_2), 3.77 (br. m, 9 H, OCH_2), 7.35 (m, 27 H, *p*-Ph-*H* and *m*-Ph-*H*), 7.76 (m, 18 H, *o*-Ph-*H*). − ^{27}Al NMR (104 MHz, C_7D_8): δ = 62 ($h_{1/2}$ = 5850 Hz).

Metallic Palladium in the Heck Reaction: Active Catalyst or Convenient Precursor?

Andrea Biffis,*[a] Marco Zecca,[a] and Marino Basato[a]

Keywords: Palladium / Heterogeneous catalysis / Heck reaction

Novel experimental evidence is presented pointing out that "heterogeneous" palladium metal catalysts employed in Heck-type reactions mainly act as sources of soluble palladium(II) complexes, which are the true catalytically active species.

The Heck reaction has been the subject of thorough investigation for several years. This reaction is usually homogeneously catalyzed by palladium(II) complexes with ligands such as phosphanes, amines or heterocyclic carbenes.[1] However, Heck-type reactions can also be efficiently catalyzed by palladium metal dispersed onto a number of supports including carbon, silica, magnesium oxide or zeolites;[2−15] for example, palladium on carbon is reported to be currently employed in some small-scale industrial processes.[16,17] Palladium metal colloids appear to be active catalysts as well,[18−23] and there is speculation that metal colloids formed in situ are involved also in ligandless homogeneous Heck reactions with simple palladium salts.[22]

In spite of many claims that with all these catalysts the reaction takes place on the metal surface, more sound evidence that the catalysis is truly heterogeneous would be desirable. In fact, whereas some authors reported that the reaction stops after separating the catalyst,[8,12] this did not occur in other cases.[10,15] Indeed, a significant palladium leaching into the solution after just one catalytic cycle was often observed.[12,13]

In this communication, we wish to report that: (i) under Heck conditions heterogeneous palladium metal catalysts undergo significant metal leaching, caused primarily by the presence of aryl halides (bromides and even chlorides); (ii) the presence of a coordinating base such as sodium acetate promotes metal leaching with relatively less reactive aryl halides; (iii) the released soluble metal species are active catalysts for the Heck reaction.

We have tested a 1% w/w Pd/Al_2O_3 catalyst (from Alfa, serial 89112, lot 1969000), hereafter coded AO-Pd, and a 1% w/w Pd catalyst supported on a tailor-made ion-exchange resin (0.38 meq./g sulfonate groups, sodium form), hereafter coded PS-Pd (see Experimental Section). The catalysts were first employed in the Heck reaction of 4-bromo- and 4-chloroacetophenone (BA and CA, respectively) with *n*-butylacrylate (NBA) in *N*,*N*-dimethylacetamide (DMA) (Table 1). Both catalysts were active with BA, AO-Pd being slightly superior. In contrast, the yields with CA were low and did not increase even after 24 h. Remarkably, the catalysts invariably lost palladium: leaching from PS-Pd was virtually complete after the reaction with BA!

Table 1. Heck reactions[a] with supported Pd metal

Catalyst	Aryl halide	Yield (%)	Pd leached (%)
AO-Pd	BA	97	79
PS-Pd	BA	82	100
AO-Pd	CA	5	22
PS-Pd	CA	6	92

[a] Reaction conditions: 10 mmol aryl halide, 10 mmol NaOAc, 17 mmol NBA, 0.1 g catalyst (0.1% mol/mol), 25 mL DMA; inert atmosphere (N_2), 120 °C, 3 h. Selectivity for the Heck product was 100% in all cases.

In order to ascertain which agent caused the metal leaching, both catalysts were allowed to react separately with different components of the reaction mixture under the same conditions of the previous tests. The results are summarized in Table 2. No metal leaching occurred upon treatment with DMA alone or after addition of NaOAc and/or the acrylate. PS-Pd underwent extensive metal leaching when treated with a solution of BA in DMA. The combination of the aryl bromide with NaOAc caused an even higher leaching from PS-Pd and a noticeable leaching from AO-Pd. CA alone was ineffective; significant palladium dissolution took place only when it was combined with NaOAc. We did not observe palladium leaching with chlorobenzene, either alone or in combination with NaOAc (entries 8−9, Table 2).

After the leaching tests, we checked for the presence of active species in solution. The suspensions were filtered hot under an inert gas atmosphere, then NaOAc and NBA were added to the filtrate, which already contained the aryl halide. The resulting mixture was stirred for 3 h at 120 °C and then analyzed for the reaction products (Table 3). Yields were fully comparable to those reported in Table 1. This findings suggest that released palladium is actually also responsible for catalysis in the presence of the "heterogen-

eous'' catalyst. The Pd species released by CA (entry 7, Table 2) are almost as active as the species released by BA (entry 5, Table 3). The observed reactivity was quite comparable to that of $Pd(OAc)_2$ (last entry in Table 3). After the coupling, the solutions usually exhibited the typical orange color of palladium(II) species; tiny amounts of Pd black were observed only occasionally. It was even possible to perform a second reaction cycle by adding fresh reagents to the solution, although the residual catalytic activity was slightly lower. In one of the filtrates from AO-Pd (entry 4, Table 2) the second Heck coupling of BA occurred with 96% yield after 24 h.

Table 3. Homogeneous Heck reactions promoted by leached palladium species

Entry	Palladium source	Dissolved Pd (mmol)	Coupled aryl halide	Yield (%)[a]
1	PS-Pd (entry 5, Table 2)	0.088	BA[b]	100

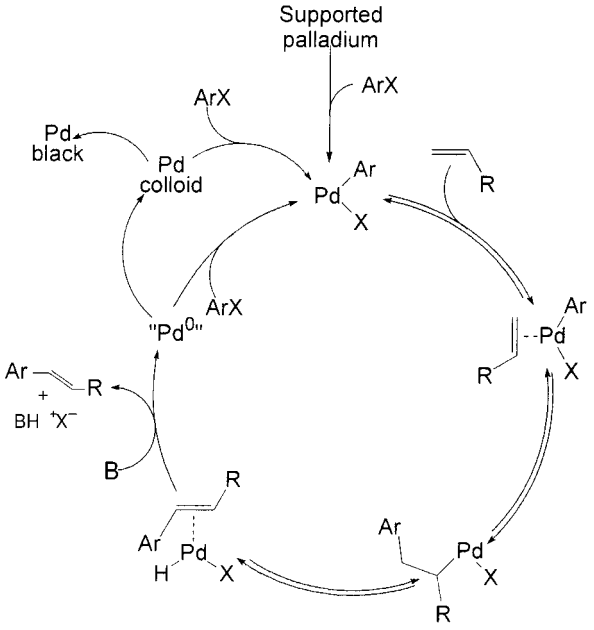
3	AO-Pd (entry 5, Table 2)	0.011	BA[b]	83
4	AO-Pd (entry 7, Table 2)	0.020	CA[b]	8
5	PS-Pd (entry 7, Table 2)	0.092	CA[b] + BA[c]	95[d]
6	$Pd(OAc)_2$	0.050	BA	80

[a] Reaction conditions: 10 mmol aryl halide, 10 mmol NaOAc, 17 mmol NBA, 25 mL DMA; inert atmosphere (N_2), 120 °C, 3 h. – [b] Residue from leaching tests. – [c] Added to the filtrate. – [d] The yield is referred to BA.

As palladium leaching occurs only in the presence of an aryl halide, it should be the direct consequence of the oxidative addition of the halide to surface atoms of the metal particles. Hence, the palladium should be released in the +II oxidation state, and good coordinating agents towards palladium(II) should enhance the extent of metal leaching. The data of Table 2 show that NaOAc helps the solubilization of palladium in particular when the supposed oxidant is CA, which is less prone to oxidative addition than the analogous bromide. As acetate ions are much better ligands for palladium(II) than for palladium(0), this observation supports our hypothesis that the metal is released into solution in an oxidized form. Accordingly, we argue that the soluble palladium(II) species directly enter the catalytic cycle just after being generated from the supported metal (Scheme 1). Virtually the same cycle was originally proposed by Heck to account for the observed catalytic action of palladium black.[3]



Scheme 1. A possible catalytic cycle for the Heck reaction with Pd metal catalysts

It may be argued that the released palladium(II) species can in principle be reduced just after leaching to form soluble palladium colloids. This was proposed in order to explain "ligandless'' catalysis of the Heck reaction by simple palladium(II) salts. Indeed, very recently Reetz has shown that the formation of Pd colloids parallels the onset of the Heck reaction catalyzed by bis(benzonitrile)dichloropalladium(II).[22] However, he also gave experimental evidence that Pd colloids are readily and quantitatively oxidized to palladium(II) species by a *stoichiometric* quantity of an activated aryl halide (iodobenzene). As we employed a 1000:1 excess of aryl halide to the metal, the presence of colloidal palladium under our conditions is very unlikely.

We did not measure the leaching rate in our experiments, but qualitative observations suggest that the accumulation of active palladium(II) species in the solution is a relatively slow process under the conditions employed in this work. This could explain why some authors did not observe significant catalytic activity in the filtrate after removal of the "heterogeneous'' catalyst shortly after the onset of the reaction. Furthermore, this hypothesis can also explain the observations of other authors on the influence of the support[15] and of the structure of the Pd particles[21] on catalyst activity. Indeed, if the leaching process is slow, the overall reaction rate can become limited by the leaching process. Since leaching is truly a surface reaction, structure-activity relationships may be expected.

We believe that our results represent strong evidence that "heterogeneous'' palladium metal catalysts employed for the Heck reaction are mainly sources of soluble palladium(II) complexes, which are the actual catalytic species (Scheme 1). We have investigated for the first time the mechanism of metal leaching and we have demonstrated

that leaching is critically dependent on the presence of the aryl halide; the presence of a coordinating base may have a promoting effect. We have shown that metal leaching takes place not only with the more activated aryl halides such as iodobenzene, but also with bromo- and even chloroarenes, and that the leached species are active catalysts for the Heck reaction.

In conclusion, it seems that the only way to have a catalytic system for this reaction which could be properly defined "heterogeneous" is to devise a support able to coordinate and therefore to heterogenize the palladium(II) and palladium(0) species which occur in the different stages of the reaction cycle. In this area, Arai and co-workers recently reported that some inorganic supports are able to rebind leached Pd species after the end of the reaction.[13] We are currently engaged in the development of novel resin supports for this purpose.

Experimental Section

Preparation of Catalyst PS-Pd: Styrene (8.63 g) and technical grade divinylbenzene (0.65 g) (55% of crosslinking monomers) were dissolved in dimethyl sulfoxide (4 g). After addition of sulfoethyl methacrylate (0.76 g) the solution was exposed to γ-rays (^{60}Co) at 0.5 Gy s^{-1} and at a distance of 21 cm for 72 h at room temp. The obtained resin rod was crushed, extensively washed with methanol, acetone and diethyl ether, vacuum dried and sieved to a particle size of <0.18 mm. Palladium was incorporated by treating 2 g of the resin overnight with a solution of $Pd(OAc)_2$ (43.7 mg) in 40 mL THF, followed by reduction with 10 equivalents $NaBH_4$ in ethanol/THF (4:1). Pd was quantitatively incorporated into the resin as metal nanoparticles with an average size of 3−4 nm (TEM).

General Procedure for the Catalytic Tests: Aryl halide (10 mmol), NaOAc (0.84 g, 10 mmol), catalyst (0.1 g, 0.01 mmol Pd) and *N*,*N*-dimethylacrylamide (25 mL) were mixed at room temperature in a three-necked, round-bottomed flask equipped with a reflux condenser. The resulting mixture was degassed and put under an inert atmosphere (N_2). *n*-Butylacrylate (17 mmol) was added and the flask was put into an oil bath at 120 °C and stirred for 3 h. Yields were determined by GC.

General Procedure for the Leaching Tests: The catalyst (0.1 g) was suspended in *N*,*N*-dimethylacrylamide (25 mL) in a three-necked, round-bottomed flask equipped with a reflux condenser. One or more of the other reaction components was then added (Table 2); the quantity of each component was the same as in the catalytic experiments described above. The resulting mixture was degassed, put under an inert atmosphere (N_2) in an oil bath at 120 °C and stirred for 18 h. The resulting mixture was filtered hot under an inert atmosphere; the missing reaction components were immediately added to the liquid phase, after which the reaction mixture was put again in the oil bath at 120 °C and stirred for the desired reaction time. Yields were determined by GC. The filtered solids were extensively washed with water and acetone and dried under vacuum. The Pd content in the residual solid catalyst was determined, after mineralization, by ICP-AES spectroscopy.

Keywords: Carboxylate ligands / Crystal engineering / Iron / N ligands / X-ray diffraction / Polymers

A metal-ligand complex $[Fe(phen)(\mu_6\text{-bta})_{1/2}]_n$ (phen = 1,10-phelanthroline; bta = benzene-1,2,4,5-tetracarboxylate ligand) has been hydrothermally synthesized and structurally characterized by single crystal X-ray crystallography, showing that it possesses a novel, two-dimensional polymeric structure.

Introduction

The recent interest in the crystal engineering of special geometrical and topological coordination polymers arises from their potential application in catalysis, chemical absorption, magnetism and electrical conductivity.[1] Due to their widespread utility, the ability to modify the structures of such materials or design of new materials is of the utmost importance. A synthetic strategy widely used in this area is by coordination of metal ions to polydentate ligands that function as connectors. In this context, multi-connecting ligands which provide two or more bidentate metal-binding sites are appealing as building blocks for coordination polymers because they promise robust networks with good electronic communication between the metal centers.[2] They also offer new network architectures, many of which do not exist in natural solids. "Clay mimics" or "zeolite mimics" have the gross analogues but are based upon very different chemical components, and, most importantly, they are inherently modular and therefore fine-tunable.[3] Presently, there are considerable efforts devoted to the formation of metal-polycarboxylate assemblies.[4] A particular case in this area is the assembly of benzenetricarboxylate-based supramolecules. Interesting two-dimensional structures such as $[Cu_3(tma)_2(H_2O)]_n$,[4a] $[Ni(C_{12}H_3ON_6O_2)]_3(tma)_2\cdot 18H_2O$,[4e] and $[M_3(tma)_2]\cdot 12H_2O$[4b] (M = Co, Ni, Zn, tma = benzenetricarboxylate) etc., are all reported to be based on this bridging ligand and transition metal ions.

The benzene-1,2,4,5-teracarboxylate ligand (= bta) as a multi-connecting ligand is also an excellent candidate for the planning of coordination polymers; comparatively few examples have been reported to date in relation to applying it to the building of coordination polymers. The use of a system of one kind of metal ion and two kinds of organic ligands that contain such a ligand for the assembly of coordination polymers has also never been described. We have therefore conducted an investigation of such a system $FeCl_2$-Na_4bta-phen-H_2O by a hydrothermal method. The obtained compound $[Fe(\mu_6\text{-bta})(phen)]_n$ (**1**) is unprecedented, exhibiting a two-dimensional polymeric structure, linking the metal ions with bta bridging units. We report here the synthesis and structural characterization of this novel compound.

Results and Discussion

Crystal analysis reveals the details for the structure of compound **1**. It consists of two-dimensional polymeric layers $[Fe(phen)(\mu_6\text{-bta})_{1/2}]_n$ formed by bta units bridging [Fe(phen)] groups. As illustrated in Figure 1, each Fe^{II} ion is six coordinated by one phen and three bta ligands. Eight oxygen atoms from four deprotonated carboxyl groups of each bta unit are all used as coordinating atoms, and bind to six metal ions. Four oxygen atoms from two neighboring carboxyl groups of one bta unit coordinate to three metal atoms, two of which bind to one Fe^{II} ion with the other two binding to two Fe^{II} ions; the remaining four oxygen atoms of the bta unit coordinate to a further three metal atoms with the same mode. The layer grids consist of two kinds of holes, one is an eight-membered-ring hole consisting of two carboxyl groups and two metal atoms, and the other is a 14-membered-ring hole, around which are two bta units and two Fe^{II} ions. The local geometry around each Fe^{II} center can be described as a slightly distorted octahedron. The Fe^{II} center coordinates to six ligating atoms with four Fe−O distances of 2.083(2), 2.091(2), 2.166(2), 2.199(2) Å and two Fe−N distances of 2.232(3) and 2.182(3) Å.

Figure 2 is a view of the packing diagram for compound **1**. It shows that along the crystallographic *b* axis, all the two-dimensional polymeric layers are arranged in an ABAB fashion. Between two neighboring layers, the phen rings from different layers interdigitate. The alternate A···A or B···B interlayer distance is 18.504 Å, and the average interlayer distance is 9.252 Å.

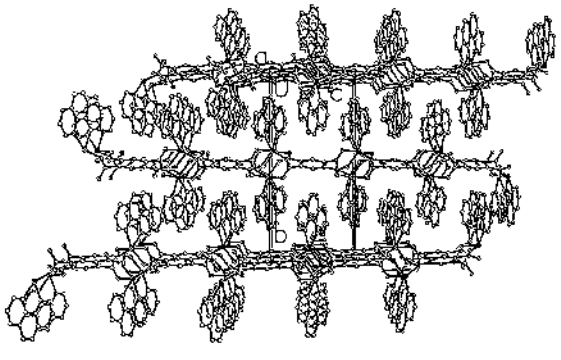

Figure 2. Crystal packing of the compound [Fe(phen) (μ_6-bta)$_{1/2}$]$_n$

Figure 3 shows that between two neighboring layers the interdigitated phen rings are parallel groups such as CQA/CQQ, CFF/CFA, CJJ/CJA, or CHH/CHA (here, the eight groups of three letters such as CQA represent 1,10-phenanthroline planes). The average distance between two adjacent parallel phen planes is small (3.2 Å), indicating that there are weak spatial π-π interactions between these phen rings. This type of π-π packing may be of high interest for the design of advanced materials.

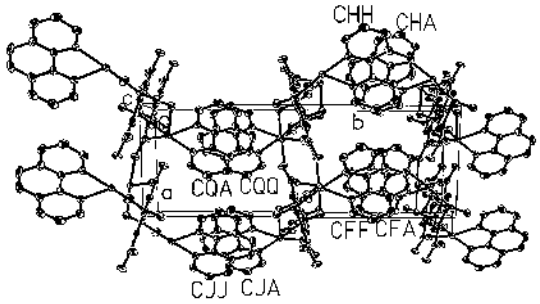

Figure 3. The parallel π-π packing of 1,10-phenanthroline plane between neighbouring polymeric layers in the crystal; the 1,10-phenanthroline planes CQA/CQQ, CFF/CFA, CJJ/CJA and CHH/CHA are parallel groups, but they are each bonded to different polymeric layers

In the chemical realization of multi-dimensional metal and polycarboxylate solids, a major challenge may come from the control of dimensionality. There are at least four problems in this respect. Firstly, since H_2O molecules are also excellent ligands for hard metal ions such as Fe^{II}, ancillary ligation of metal ions by water may result in low dimensionality such as discrete $Co(H_2bta)$[5] or $\{[Mn(H_2O)_5]_2(bta)\}\cdot H_2O$ units.[6] Secondly, in a system with a metal ion and two kinds of organic ligands, low dimensionality may come from the coordinating competition between the two kinds of organic ligands, such as full occupation of six sites per metal ion by three phen ligands, forming discrete metal complex cations $[Fe(phen)_3]^{2+}$. Thirdly, the low dimensionality may be caused by competition from polycarboxylate itself, due to its facile formation of hydrogen-bonded dimers or polymers.[7] Finally, in basic and even neutral aqueous solutions, the formation of Fe^{II}−ligand complexes will compete with the process of forming hydroxo- and oxo-bridged metal networks,[8] and result in much lower yields of the target coordination polymer.

During our exploration of the above-mentioned system, we maintained the molar ratio of phen:Fe^{II} at less than 0.7:1, thus favoring the formation of compound **1**. As the ratio gets larger, $Fe(phen)_3^{2+}$ cations form more easily, resulting in the formation of low dimensional products. The pH value of the reaction system is also an important factor: it must be maintained higher than 9.5 in order to obtain the target complex.

For entropic reasons, synthesis at higher temperature can promote the formation of polymer frameworks of higher dimensionality through the loss of terminal ancillary ligands. This may be justified by the following analysis. From the viewpoint of thermodynamics, self-assembled structures represent thermodynamic minima. For compound **1**, a possible formatting reaction may be described as follows:

$$\tfrac{1}{2}n\ [bta]^{4-} + n\ [Fe(H_2O)_6]^{2+} + n\ Phen \rightarrow [Fe(phen)](bta)_{1/2}]_n + 6n\ H_2O$$

$$\tfrac{1}{2}n \qquad n \qquad n \qquad 1 \qquad 6n$$

The variation of molecular number in this reaction is $1/2n + n + n \rightarrow 1 + 6n$ (mol) and the entropy of the system increases ($\Delta S > 0$). The replacement of six water molecules with the stronger ligand phen and with carboxyl O-atoms may favor lowering the enthalpy of the system ($\Delta H < 0$). Thus giving $\Delta G = \Delta H - T\Delta S$ to be less than 0. Synthesis at higher temperature can make $T\Delta S$ greater, and thus contribute more to the variation of the free energy, facilitating the production of the target complex. This kind of consideration is easy to confirm in the crystal engineering of target complexes by self-assembly methods.[9]

This compound appears to provide a matrix for the generation of a particular metal-benzene-tetracarboxylate sheet. As a natural extension of the structural chemistry of such a network, the replacement of phen with other similar ligands, such as bipyridine, is possible, and this work is currently under way. The experimental verification of compound **1** may help us to understand more about polycarboxylate ligands, and to engineer new supramolecular architectures.

Experimental Section

Synthesis: We prepared the compound with a mixture of $FeCl_2{\cdot}4H_2O$ (1.00 g), 1,10-phenanthroline (0.33 g), sodium benzenetetracarboxylate [Na_4(bta), 1.70 g] and H_2O (24 mL) in a 30cm^3 Teflon-lined reactor (pH = 10). The reactor was sealed and heated to 160 °C for 72 hours under autogenous pressure. The obtained deep red crystals were isolated by filtration and washed with distilled water (yield 36% based on phen). IR spectra were recorded on a Perkin−Elmer 783 spectrometer as KBr pellets: $\tilde{\nu}$ = 2358(s). 1602(vs), 1510(s), 1478(s), 1423(s), 1410(s), 1370(vs), 1285(m), 1140(s),1103(s), 918(s), 852(vs), 814(s), 780(s), 740(s), 732(s), 662(m), 640(m), 600(s), 510(s), 420(m) cm^{-1}. − $C_{17}H_9FeN_2O_5$ (377.11): calcd. C 56.54, H 2.51, N 7.76, Fe 15.47; found C 56.50, H 2.55, N 7.550, Fe 15.40.

X-ray Crystal Structure Determination: Crystal data and structure refinement for the title compound are listed in the Table 1. A single crystal of compound **1** was studied on a Siemens P4 four-circle diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073Å) and ω-2θ scans. The structure was solved by the heavy-atom method and successive Fourier syntheses [SHELXS and SHELXL (Version 5.03, 1993)]. The refinement was performed by full-matrix least-squares refinement.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-151718. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Lithium Insertion and XPS Study in $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$

María-Luisa Martínez-Sarrión,*[a] Lourdes Mestres,[a] Rosa Palacín,[b] and Marta Herráiz[a]

Keywords: Lithium / Insertions / Electrochemistry / Photoelectron spectroscopy

The stoichiometry and lithium insertion reactions with *n*BuLi and by electrochemical techniques of solid solutions $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$ with a perovskite-type structure have been studied. Stoichiometry data are given in the form of a solid solution triangle. In general, the amount of lithium inserted is consistent with the number of vacancies. The results of the chemical and electrochemical lithium insertion are similar: upon lithium insertion Cr^{VI} is reduced to Cr^{III}.

Introduction

Materials with structures derived from the high temperature phase γ-Li_3PO_4 comprise an extensive family of lithium-ion-conducting solid electrolytes known as LISICONS or γ-structures. Recently, a new group of lithium-ion conductors and mixed conductors in the LISICON family have been found that contain $Cr^{[5+]}$ as a framework cation.[1,2] The electrochemical intercalation of lithium into chromium(V)-containing oxides isostructural with β- and γ-Li_3PO_4 has been studied. β-Li_3CrO_4 can reversibly intercalate around one mol of Li per formula unit to give $Li_{3+x}CrO_4$ ($0 < x < 1$) with a discharge capacity of 196 $mAhg^{-1}$. Electrochemical data indicate that there may be a region with two phases in the approximate range $0.3 < x < 0.8$. Essentially, these materials are dimensionally stable to intercalation and de-intercalation.[3]

The X-ray photoelectron spectra of the different compounds of Cr^{III} were measured and from these data the chemical shifts of the core electrons were determined and related to a calculated charge based on Pauling's electronegativities.[4] A few years ago the binding energies of the chromium(III) 2p electrons was proposed to be dependent primarily on the oxidation number, although perturbations result from changes in the structure and in the Madelung potential. Multiplet splitting in chromium(III) compounds contributes to peak widths and the chemisorption of water and oxygen has a marked effect on the peak profiles and the accuracy of binding energy measurements.[5]

The electronic structures of the perovskite system $La_{1-x}(M^{2+})_xCrO_3$ (M = Mg, Sr) has been more widely studied than Cr_2O_3 and La_2O_3 by X-ray photoelectron spectroscopy. The main peaks and satellites of inner and outer electrons were properly assigned.[6]

Spinel solid solutions of general formula $ZnCr_xGa_{2-x}O_4$ have been studied by X-ray photoelectron spectroscopy. These XPS spectra indicated that in the spinel solid solutions no significant change in the electronic structure of Cr^{3+} ions occur, and a similar covalency in all the $ZnCr_xGa_{2-x}O_4$ solid solutions, irrespective of their composition, has been reported.[7]

In a previous paper[8] we studied the $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Mn_{3y}O_3$ system, and the bulk conductivity data from the impedance complex plane plots were plotted in an Arrhenius format. The plots are linear and the conductivity decreases as the amount of lithium decreases. The variation in ionic conductivity with the lithium composition is quite large, although the ionic and electronic conductivity remain similar for $y = 0.01$.

The $Pr_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$ system showed similar behavior.[9] AC/DC measurements indicated that these compounds are mixed conductors. The Li^+ conductivity decreases as the amount of lithium decreases, while electronic conductivity increases with the amount of chromium. Similar measurements indicate that $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$ compounds are mixed conductors. The lithium ion conductivity decreases as the amount of lithium decreases, meanwhile electronic conductivity increases with the amount of chromium.[10]

Here we examine the chemical and electrochemical insertion and de-insertion of lithium in $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$ mixed conductors.

Results and Discussion

Chemical lithium intercalation was carried out on different compositions of the region of perovskite-like solid solutions on the phase diagram.[10] Along join 1 ($La_{0.583}Li_{0.25}TiO_3-LaCrO_3$), the lithium and lanthanum composition and the number of vacancies changes, along join 2 ($La_{0.60}Li_{0.20}TiO_3-La_{0.80}Li_{0.20}Ti_{0.40}Cr_{0.60}O_3$) the amount of lithium was constant, along join 3 ($La_{0.567}Li_{0.30}TiO_3-La_{0.86}Ti_{0.40}Cr_{0.60}O_3$), the number of vacancies was constant, along join 4 ($La_{0.583}Li_{0.25}TiO_3-La_{0.75}Li_{0.25}Ti_{0.50}Cr_{0.50}O_3$), the amount of lithium was constant, and along join 5

($La_{0.86}Ti_{0.40}Cr_{0.60}O_3-La_{0.80}Li_{0.20}Ti_{0.40}Cr_{0.60}O_3$) the chromium amount was constant (Figure 1).

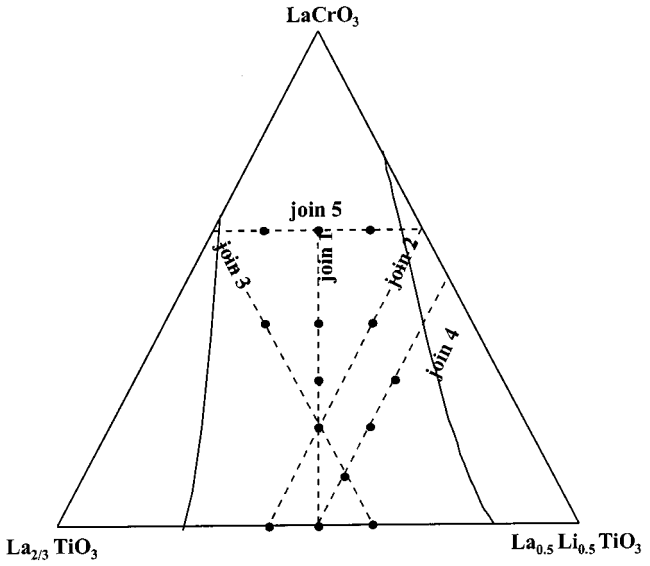

Figure 1. Composition triangle and joins of chemical lithium intercalation

ICP analyses were then carried out and these results are shown in Table 1, with the (Cr + Ti) amount set to unity and the remaining values re-normalised in the formula $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$. In general, the amount of lithium inserted is consistent with the number of vacancies. For all compositions the Li:La:Ti:Cr ratios were in good agreement with the values expected from the starting compositions.

The compositions along join 1 were measured by EPMA. The experimental values of oxygen contents have larger uncertainties than the values for La, Ti and Cr due to the difficulty in separating the O-K_α signal from that emitted by the carbon coating and partial absorption of the O-K_α signal by the carbon. $SrTiO_3$, which was the standard for oxygen, and some samples were coated together to improve the oxygen measurements. The results obtained in join 1,[10] allowed us to establish that the oxygen content varies between 2.95 and 3.01. For this reason we assume that the oxygen content in all the samples is nearly to 3.

Figures 2–5 show the amount of lithium inserted versus amount of lanthanum for joins 1, 3, 4 and 5, respectively. In join 1 (where the lithium and lanthanum composition and the number of vacancies changes), when the lanthanum and chromium amount increases, the number of vacancies decreases, therefore the amount of lithium inserted must also decrease. In Figure 2 we can see this behavior, except for the sample $La_{0.71}Li_{0.19}Ti_{0.69}Cr_{0.31}O_3$ in which 0.16 mol of lithium is inserted. This behaviour can be attributed to the cubic structure of the $La_{0.58}Li_{0.25}TiO_3$ and $La_{0.70}Li_{0.21}Ti_{0.79}Cr_{0.21}O_3$ compounds and the orthorhombic structure of $La_{0.71}Li_{0.19}Ti_{0.69}Cr_{0.31}O_3$, $La_{0.76}Li_{0.17}Ti_{0.59}Cr_{0.41}O_3$, and $La_{0.83}Li_{0.07}Ti_{0.39}Cr_{0.61}O_3$.[10] In join 3 (the number of vacancies was constant), the substitution of chromium for titanium increases the amount of lithium inserted, which decreases with an increase in the amount of lanthanum. In join 4 (the lithium amount was constant), when lanthanum and chromium increase, the number of vacancies decreases, and, consequently, the amount of lithium inserted is reduced. In join 5 (the chromium amount was constant) the lithium insertion increases as the number of vacancies increases.

[a] (calculated A-site vacancy) = 1 − (La content + Li content).

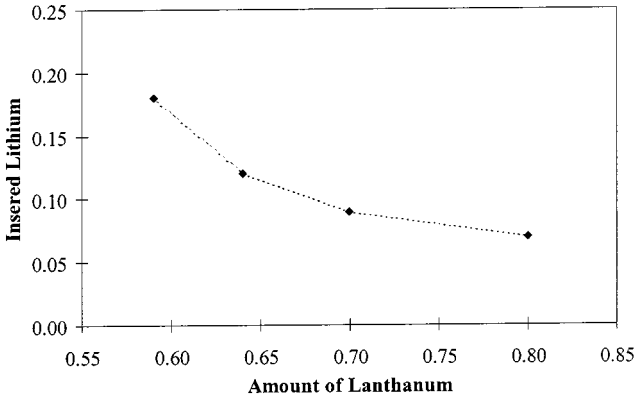

Figure 3. Plot of amount of lithium inserted vs. amount of lanthanum in join 3

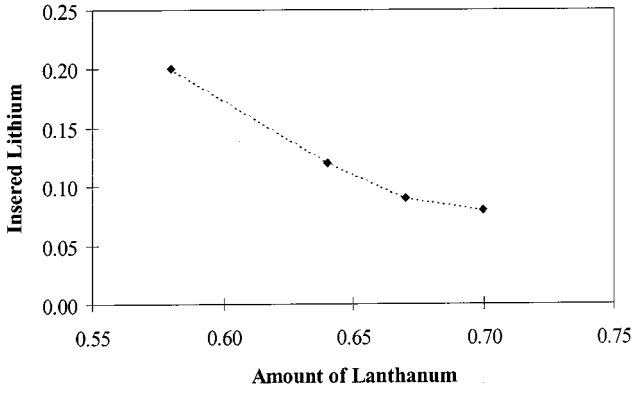

Figure 4. Plot of amount of lithium inserted vs. amount of lanthanum in join 4

The cell parameters of the lithium inserted phases show no differences with the non-lithium inserted phases (Table 2).

De-lithiation reactions were performed by treating some compositions of the lithiated compounds with iodine in dry acetonitrile. The results are shown in Table 3. The process of lithium insertion-delithiation is reversible.

The degrees of lithium uptake observed in electrochemical experiments down to 1.5 V vs. Li^0-Li^+ were approximately consistent with those obtained after chemical lithiation. Some typical composition-voltage profiles are shown in Figure 6, corresponding to samples along join 4 containing both titanium and chromium. Contrary to what has been reported for pure La−Li−Ti−O perovskites,[11,12] the degree of lithium intercalation in chromium-containing samples is never higher, within the experimental errors, than the number of A-type vacancies. On the other hand, the increase in the chromium content seems to be associated with an electrochemical step appearing at about 2.3 V vs. Li^0-Li^+ upon reduction of the samples. The electrochemical de-intercalation (i.e. oxidation) is difficult to achieve and only takes place at ≈4V, (Figure 6) for sample $La_{0.69}Li_{0.24}Ti_{0.69}Cr_{0.31}O_3$.

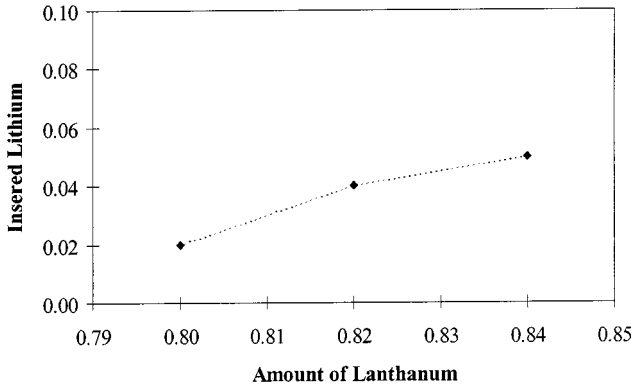

Figure 5. Plot of amount of lithium inserted vs. amount of lanthanum in join 5

The X-ray photoelectron spectroscopy of different compositions were compared with the values from Table 4. Figure 7 shows the Cr (2p) spectrum for the composition $La_{0.92}Li_{0.05}Ti_{0.21}Cr_{0.79}O_3$ (c in Figure 7), and we compared this with the patterns of Cr_2O_3 (a) and CrO_3 (b) from 565 to 605 eV. The main peaks of this sample, located at 576.2 eV ($Cr2p_{3/2}$) and 585.9 eV ($Cr2p_{1/2}$), correspond to Cr^{3+}. The shake-up satellite of $Cr2p_{3/2}$ is seen at ≈582 eV and, for $Cr(2p_{1/2})$, the satellite appears at ≈597 eV. The main peaks of chromium show a shoulder that indicates the presence of chromium in another number state, probably Cr^{6+} (Fig-

ure 7). These shoulders appear at 578.9 eV and 585.5 eV. The presence of chromium in two different number states is the origin of the electronic conductivity in these compounds.[6]

In an attempt to study the variation in the number state of chromium caused by lithium insertion, the X-ray photoelectron spectrum of $La_{0.71}Li_{0.19}Ti_{0.69}Cr_{0.31}O_3$ before and after lithiation was recorded. In this sample the amount of inserted lithium was highest. Figure 8a shows the Cr2p spectrum of this sample. In the lithium-inserted sample (Figure 8b), the ratio between the peak areas Cr^{6+}/Cr^{3+} decreases as a result of the reduction of Cr^{6+} to Cr^{3+} with the introduction of positive charges (Li^+) in the structure.

The same study was performed for titanium (Figure 9). In both samples the titanium is present mostly as Ti^{4+}, and no change is produced in its number state during the insertion.

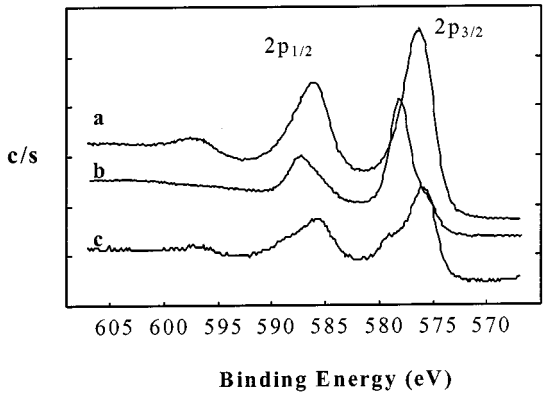

Figure 7. X-ray photoelectron spectra of Cr 2p region of: a) Cr_2O_3, b) CrO_3 and c) $La_{0.92}Li_{0.05}Ti_{0.21}Cr_{0.79}O_3$

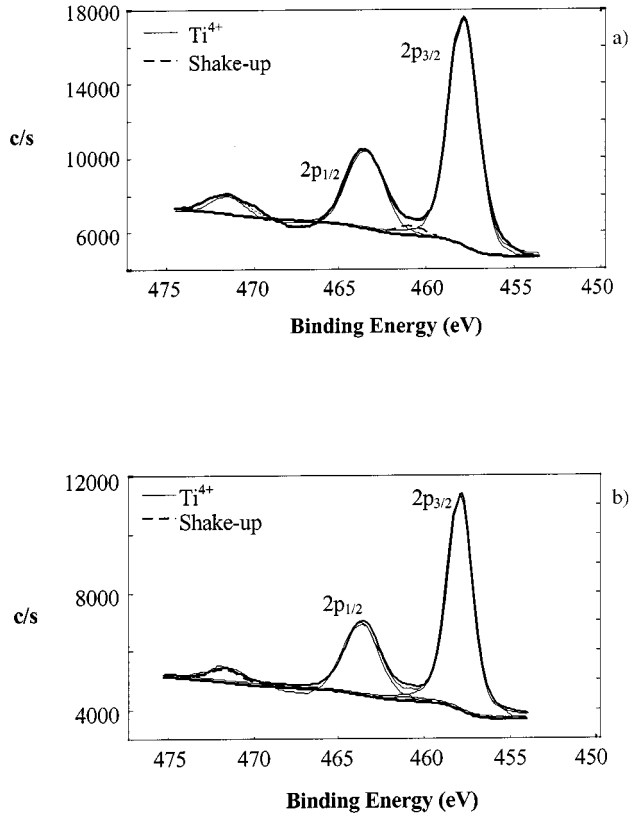

Figure 9. X-ray photoelectron spectra of Ti 2p region of: a)$La_{0.71}Li_{0.19}Ti_{0.69}Cr_{0.31}O_3$ and b) $La_{0.71}Li_{0.35}Ti_{0.69}Cr_{0.31}O_3$

Conclusion

A large range of single-phase solid solutions have been synthesized in the triangle $La_{2/3}TiO_3-LaCrO_3-La_{0.5}Li_{0.5}TiO_3$. The phase diagram in the single-phase region showed two polymorphs with a perovskite-like structure. The polymorph with the lowest chromium content has a cubic perovskite structure, and that with the highest chromium content shows an orthorhombic distortion. The cell parameters of the lithium-inserted phases show no differences with the non-lithium inserted phases. The presence of chromium in two different number states is the origin of the electronic conductivity in $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$.

Experimental Section

Syntheses: La_2O_3 (99.9% Fluka), TiO_2 (Aldrich 99 +%), Cr_2O_3 (>99%, Fluka) and Li_2O_3 (>99% Aldrich) were used as starting materials. La_2O_3, and TiO_2 were dried overnight at 900 °C prior to weighing. These chemicals were weighed, mixed in an agate mortar with acetone, dried and heated at 650 °C for 2 h to drive off CO_2. After grinding, samples were pressed into pellets and covered with powder of the same composition to avoid loss of lithium during the thermal treatment. The pellets were fired at 1100 °C for 8 h giving green products which were reground, repelleted, and fired at 1200 °C and at 1250 °C for 12 h, and again at 1300 °C for 4 h.

X-ray Diffraction: The crystalline phase identification and lattice parameters were obtained by powder X-ray diffraction with a Siemens D-500 diffractometer in reflection mode using Cu-K_α radiation. Lattice parameters were obtained using a silicon internal standard.

Chemical Lithium Intercalation: Chemical lithium intercalation was carried out by reacting the ground sample with *n*BuLi (1.6 M) in a hexane solution in a dried glove box filled with N_2 gas at 50 °C for 3 days with shaking. The X-ray diffraction pattern of the intercalate products was recorded after washing in hexane. After the chemical lithium intercalation, the samples were analysed by ICP, using a Jobin Ybon analyzer.

Electrochemical Lithium Intercalation: Electrochemical intercalation experiments were performed in Swagelok™ cells.[13] The positive electrode consisted of a ground powder mixture of the precursor and SuperP Carbon (kindly supplied by MMM, Belgium). Two sheets of Whattmand GF/D borosilicate glass fiber soaked with 1 M $LiPF_6$ in 1:1 EC/DMC electrolyte (Merck) were used as a separator, and the negative electrode consisted of lithium foil (0.38 mm thick). The cells were monitored with an Arbin BT2042 cycler operating in galvanostatic low current mode at 1Li/200 h.

X-ray Photoelectron Spectra: XPS spectra were recorded on a Perkin Elmer PHI 5500-ESCA SYSTEM with Al-K_α radiation (1486.6 eV). The energy calibration, including sample charging, was made against C(1s) peaks from the usual contamination. With a value of 83.8 eV for Au (4f 7/2), the energy is 284.8 eV. The pressure of the sample chamber was maintained below 10^{-9} Torr. The peaks were fitted by the Multipak computer program.[14]

Electron Probe Microanalysis: Some samples were studied by EPMA, to verify homogeneity, with a CAMECA SX50 EPMA instrument.

The Intramolecular Ligand-Exchange Reaction of (*SP*-4-2)-Dichlorobis-(2-hydroxyethylamine)platinum(II) and (*OC*-6-22)-Tetrachlorobis-(2-hydroxyethylamine)platinum(IV), a ^{1}H and $^{15}N,^{1}H$-HMQC NMR Study

Markus Galanski,[a] Wolfgang Zimmermann,[a] Christian Baumgartner,[a] and Bernhard Klaus Keppler*[a]

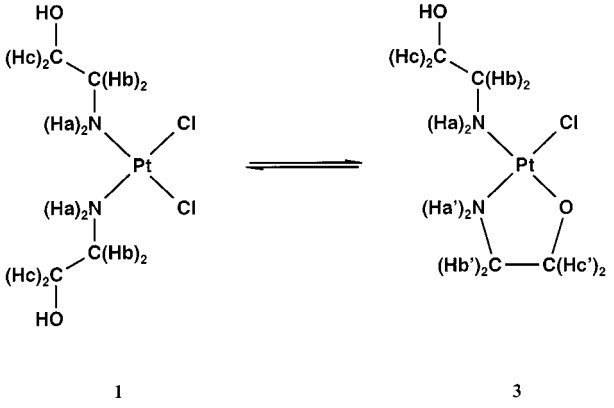
Keywords: Platinum / Ligand exchange / X-ray diffraction / NMR spectroscopy / N ligands

The bis(ethanolamine)platinum complexes (*SP*-4-2)-dichlorobis(2-hydroxyethylamine)platinum(II) (**1**) and (*OC*-6-22)-tetrachlororbis(2-hydroxyethylamine)platinum(IV) (**2**) have been synthesized and their chemistry in aqueous solution has been investigated due to the fact that **1** forms very stable monoadducts with 5′-GMP. In water **1** and **2** are converted into (*SP*-4-3)-chloro(2-ethanolatoamine-κ^2N,O)(2-hydroxyethylamine)platinum(II) (**3**) and (*OC*-6-31)-trichloro(2-ethanolatoamine-κ^2N,O)(2-hydroxyethylamine)platinum(IV) (**4**) with a chelating ethanolatoamine ligand by a intramolecular ligand exchange reaction, which was confirmed by ^{1}H and 2D $^{15}N,^{1}H$-HMQC NMR experiments and the crystal structure determination of **4**.

Introduction

Cisplatin,[1,2] *cis*-$[PtCl_2(NH_3)_2]$, is commonly used for the treatment of testicular and ovarian cancer as well as cervical, bladder and head and neck tumors.[3] The application of cisplatin in therapy is limited by the dose-dependent nephrotoxicity, among a variety of other side effects.[4] There are different strategies for the development of new platinum-based anticancer compounds. Great efforts are undertaken to reduce toxicity and side effects of the platinum compounds, to increase their activity spectrum and to circumvent acquired resistance of cells to cisplatin.[5−8]

A key objective of our research in this subject is to achieve a selective accumulation of antitumor platinum complexes in specific tissues of the organism and to investigate the mode of action of tumor-inhibiting platinum compounds. Therefore, the bis(ethanolamine) platinum(II) and (IV) complexes (*SP*-4-2)-dichlorobis(2-hydroxyethylamine)-platinum(II) (**1**, Scheme 1) and (*OC*-6-22)-tetrachlorobis(2-hydroxyethylamine)platinum(IV) (**2**, Scheme 2) have been synthesised. These compounds can, on the one hand, be used for further derivatisation at the OH group with carrier molecules due to the concept of drug targeting,[9] and on the other hand the bis(ethanolamine) complexes themselves are very interesting because their hydroxy groups can act as acceptors or donors for hydrogen bonds, which could play an important role in the binding of platinum complexes to DNA, the major target of platinum-based chemotherapy.[10,11] Furthermore, it has been shown previously that the formation of bisadducts between **1** and 5′-GMP is very slow and that **1** forms extremely stable 5′-GMP monoadducts, which can be detected in solution by capillary electrophoresis over a period of more than 10 days in the presence of 5′-GMP (1:2).[12]



Scheme 1. Equilibrium of complexes **1** and **3** in water

This unexpected observation has led us to focus on the chemistry of **1** and its kinetically more inert tetrachloro analogue **2** in aqueous solution.

Results and Discussion

Whenever (*SP*-4-2)-dichlorobis(2-hydroxyethylamine)-platinum(II) or (*OC*-6-22)-tetrachlorobis(2-hydroxyethylamine)platinum(IV) are dissolved in water intramolecular ligand exchange reactions can be observed: One of the chloro ligands is released and a ethanolatoamine chelate is formed resulting in the complexes (*SP*-4-3)-chloro(2-ethanolatoamine-κ^2N,O)(2-hydroxyethylamine)platinum(II) (**3**) and (*OC*-6-31)-trichloro(2-ethanolatoamine-κ^2N,O)(2-hydroxyethylamine)platinum(IV) (**4**) (Scheme 1 and 2).

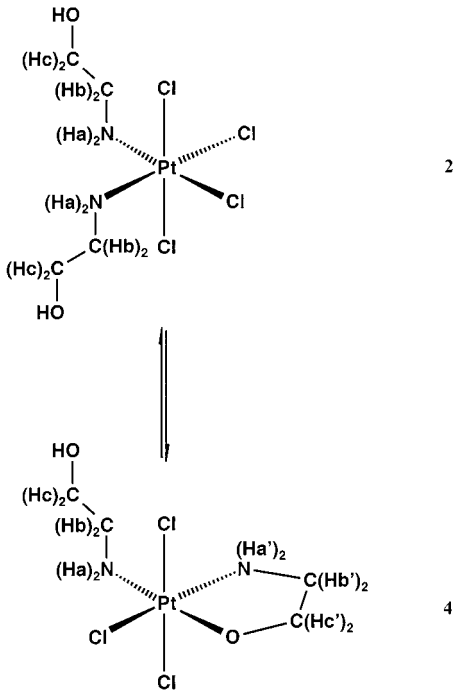

Scheme 2. Equilibrium of complexes **2** and **4** in water

Intramolecular Ligand Exchange Reaction of Compound 1

When dissolving **1** in aqueous solution one should expect three ^{1}H resonances, two multiplets for the CH_2 protons and a broad multiplet for the NH_2 group. However, five minutes after dissolution of **1** in water four additional ^{1}H signals of methylene protons and two additional NH_2 resonances can already be detected; these increase with time (Figure 1). After one day 75% of the bis(ethanolamine) complex **1** and 25% of the ethanolatoamine chelate **3** are present in solution.

The mixture of **1** and **3** shows two sets of three multiplets in the region of the methylene protons, whereas three broad signals for the NH_2 protons can be found. The three methylene protons in the neighborhood of the coordinated amine resonate in the region δ = 2.9 to 2.4. They are broad and not clearly resolved due to coupling with the amine protons and the quadrupolar moment of the ^{14}N nucleus. The before-mentioned signals are separated from the three CH_2 triplets of the methylene protons in the neighborhood of the oxygen atom, which can be found between δ = 3.8 and 3.4.

The amine protons of **1** and **3** are detected between δ = 4.8 and 5.6 and can be assigned to the three different NH_2 groups by 2D ^{15}N,^{1}H-HMQC spectroscopy (Figure 2). The NH_2 protons of complex **1** (trans to Cl) resonate at δ = 4.92 with a ^{15}N chemical shift of δ = −50.02. The cross signal of the coordinated amine ligand of **3** within the chelate ring was found at δ = 5.49/−31.46 whereas the signal of the NH_2 group *trans* to oxygen was detected at δ = 5.11 and −69.98, respectively. With this information the signal assignment of the CH_2 protons to the different ligands [complex **1**: δ = 3.75 (H_c), 2.78 (H_b); complex **2**: δ = 3.71 (H_c), 3.49 ($H_{c'}$), 2.63 (H_b), 2.49 ($H_{b'}$)] was performed by ^{1}H,^{1}H-DQF shift correlation spectroscopy.

As expected, the intramolecular ligand exchange reaction can be suppressed by dissolving complex **1** in DCl solution. Under these conditions only two ^{1}H signals in the CH_2 region at δ = 3.63 (H_c) and 2.95 (H_b) are observed which indicates that the equilibrium is shifted towards complex **1**.

Intramolecular Ligand Exchange Reaction of Compound 2

In case of the kinetically more inert tetrachloroplatinum-(IV) complex **2** the intramolecular ligand exchange reaction can also be observed in water but it is slowed down in com-

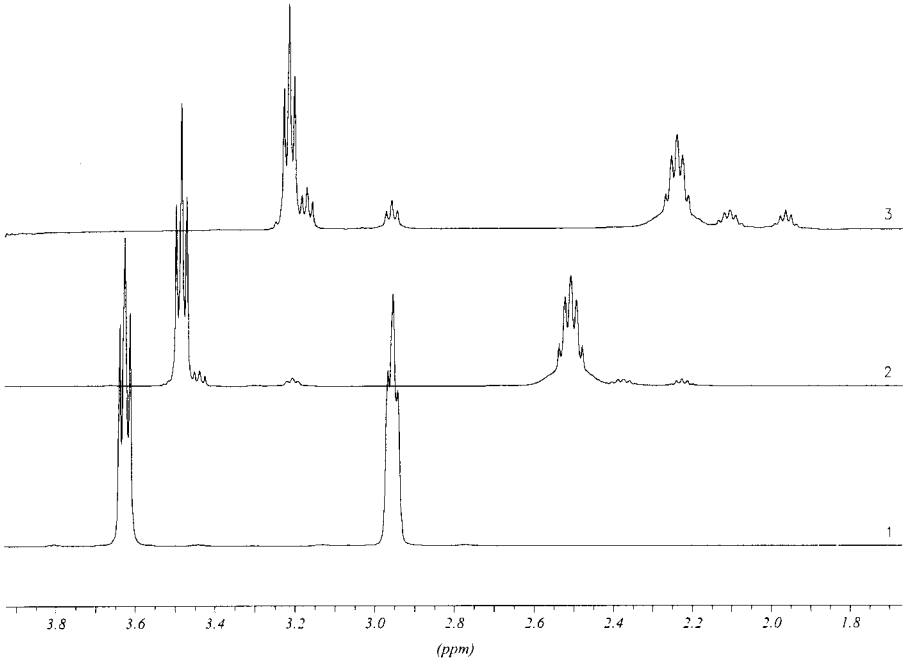

Figure 1. ^{1}H NMR spectra of **1** in DCl solution (1) and after one (2) and 24 hours (3) in H_2O/D_2O (9:1)

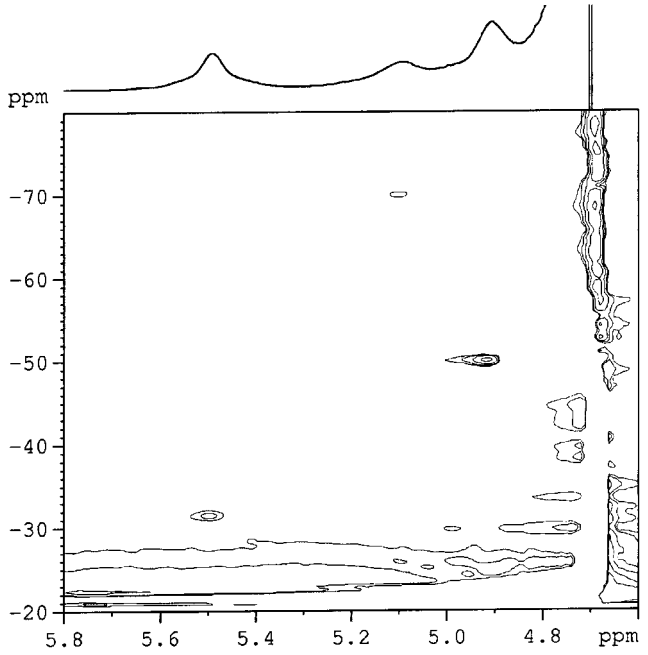

Figure 2. $^{15}N,^{1}H$-HMQC NMR spectrum of **1** after three hours

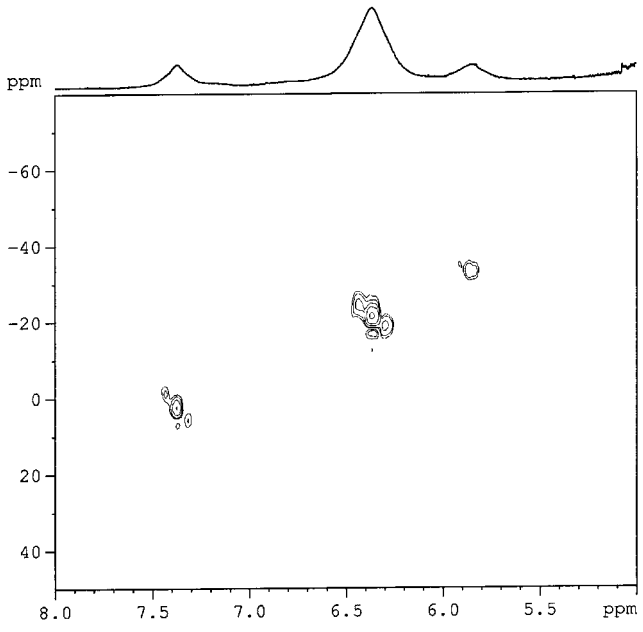

Figure 3. $^{15}N,^{1}H$-HMQC NMR spectrum of **2** after seven days

parison to the platinum(II) analogue **1**. After 12 days a nearly equimolar mixture of **2** and **4** (Scheme 2) is present in solution, whereas after 23 days 20% of **2** and 80% of **4** can be detected. Analogous to the mixture of compounds **1** and **3** there are two sets of CH_2 protons found in the ^{1}H NMR spectrum: three triplets for the methylene protons in the neighborhood of oxygen [**2**: $\delta = 3.70$ (H_c); **4**: 3.65 (H_c), 3.19 ($H_{c'}$)] and two broad multiplets at $\delta = 2.98$ (H_b of **2** and **4**) and 2.60 ($H_{b'}$) for the CH_2 protons in the neighborhood of the coordinated amine.

The NH_2 protons of compound **2** (*trans* to Cl) resonate at $\delta = 6.36$ with a ^{15}N chemical shift of $\delta = -21.78$ (Figure 3). The protons of the coordinated amine of **4** *trans* to the chloro ligand are found at $\delta = 7.31$; the ^{15}N chemical shift is observed at $\delta = 2.52$. The $^{1}H,^{15}N$ cross peak of the amine ligand *trans* to oxygen was detected at $\delta = 5.87$ and -33.02, respectively.

The assignment of the signals was done in this case by 2D $^{15}N,^{1}H$-HMQC, 2D $^{1}H,^{1}H$-COSY and 2D HMQC-TOCSY where the latter experiment combines both the heteronuclear and the homonuclear shift correlation in one experiment.

It was possible to isolate crystals of complex **4** after dissolution of **2** in water for nine days.

The crystal structure of (*OC*-6-31)-trichloro(2-ethanolatoamine-κ^2N,O)(2-hydroxyethylamine)platinum(IV) is shown in Figure 4. The atoms around the platinum center are arranged octahedrally. The two N atoms as well as Cl3 and O1 show a square-planar arrangement around the platinum atom. The angular sum of the equatorial atoms is 360.1° [N1−Pt−N2 = 91.9(2)°, N1−Pt−O1 = 85.3(2)°, N2−Pt−Cl3 = 93.22(17)° and O1−Pt−Cl3 = 89.59(18)°]. The Pt−N [Pt−N1 = 2.059(6) Å, Pt−N2 = 2.066(6) Å] and Pt−Cl [Pt−Cl1 = 2.319(18) Å, Pt−Cl2 = 2.315(19) Å, Pt−Cl3 = 2.331(18) Å] distances are similar to those in (*OC*-6-22)-tetrachlorobis(2-hydroxyethylamine)-platinum(IV).[13] The Cl1 and Cl2 atoms are axial to the equatorial plane and the Cl1−Pt−Cl2 axis is nearly linear [Cl1−Pt−Cl2 = 177.46(7)°]. Four intermolecular hydrogen bonds of each complex are found [N1−H1A···O2 = 2.955 Å (N1−O2); N1−H1B···O1 = 2.895 Å (N1−O1); N2−H2A···O2 2.772 Å (N2−O2); N2−H2B···O1 = 2.791 Å (N2−O1)].

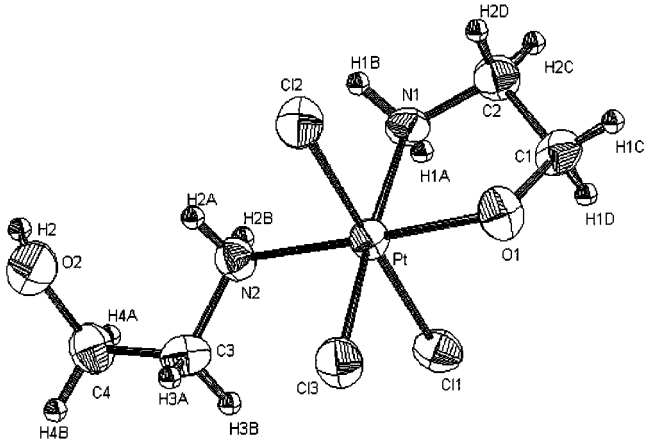

Figure 4. Molecular structure of **4** in the crystal

^{1}H, 2D-$^{1}H,^{1}H$ and 2D $^{15}N,^{1}H$ NMR studies were also carried out with the crystals of compound **4**. In aqueous solution, four ^{1}H signals are observed for the methylene protons at $\delta = 3.66$ (H_c), 3.19 ($H_{c'}$), 2.97 (H_b) and 2.61

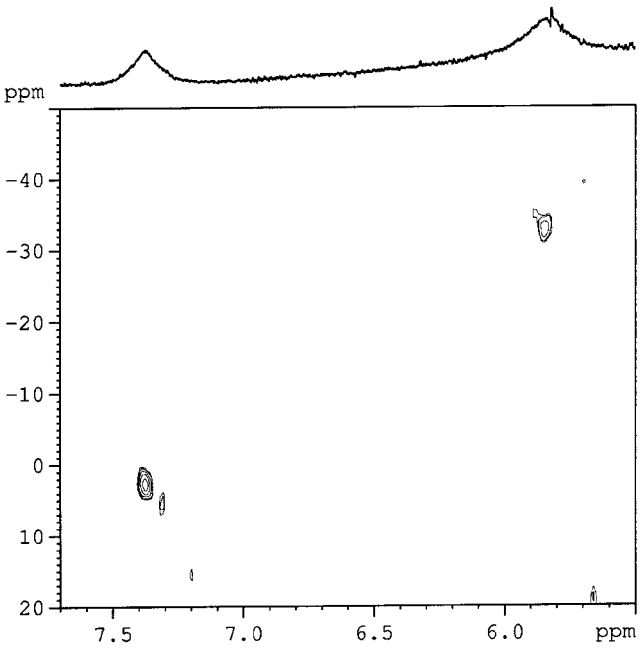

Figure 5. $^{15}N,^{1}H$-HMQC NMR spectrum of the crystals of compound **4**

($H_{b'}$), whereas the protons of the coordinated amine resonate at δ = 7.38 and 5.83. In the $^{15}N,^{1}H$ correlated spectrum of **4** two $^{1}H,^{15}N$ cross peaks (δ = 7.38/2.57 and 5.83/−32.29) are found (Figure 5) in accordance with the signals of compound **2** in solution.

Conclusion

In conclusion, it has been shown that the bis(ethanolamine)platinum complexes **1** and **2** undergo intramolecular ligand exchange reactions in water resulting in platinum compounds **3** and **4** with a chelating ethanolatoamine ligand. This conversion was confirmed by ^{1}H and $^{15}N,^{1}H$-HMQC spectroscopy. The structure of compound **4** in the crystal was also determined. These results clearly indicate that the formation of monoadducts between **1** and 5′-GMP which are very stable over a period of more than 10 days can be explained by the presence of the ethanolatoamine chelate **3** in solution.

Experimental Section

General Remarks: ^{1}H, $^{1}H,^{1}H$-DQF-COSY, $^{15}N,^{1}H$-HMQC and $^{15}N,^{1}H$-HMQC-TOCSY spectra were recorded in H_2O/D_2O (9:1) or DCl at 301 K in a gradient-enhanced mode using a Bruker Avance DPX 400 instrument (UltraShield™ Magnet) and standard pulse programmes at 400.13 (^{1}H) and 40.55 MHz (^{15}N). Chemical shifts were measured relative to the solvent or to external aqueous $^{15}NH_4Cl$ (δ = 0). The X-ray data were collected on a Nonius Kappa CCD diffractometer at room temperature. Elemental analyses were performed by the microanalytical laboratory at the University of Vienna.

(*SP*-4-2)-Dichlorobis(2-hydroxyethylamine)platinum(II) (1) and (*SP*-4-3)-chloro(2-ethanolatoamine-κ²*N,O*)(2-hydroxyethylamine)-platinum(II) (3): The preparation of **1** has been described previously.[13] Compound **1** was dissolved in H_2O/D_2O or D_2O/DCl for NMR spectroscopic studies. Dissolution of **1** in DCl (0.4 mL D_2O and 0.2 mL DCl [20% in D_2O]):
1: ^{1}H NMR (D_2O/DCl): δ = 3.63 [t, ($^{3}J(H_c,H_b)$ = 5.3 Hz), 4 H, H_c], 2.95 [t, ($^{3}J(H_b,H_c)$ = 5.0 Hz), 4 H, H_b].

Upon dissolving **1** in water two products are observed (75% of **1** and 25% of **3** after 24 hours):
1: ^{1}H NMR (H_2O/D_2O, 9:1): δ = 4.92 [m, 4 H, H_a], 3.75 [t, $^{3}J(H_c,H_b)$ = 5.1 Hz, 4 H, H_c], 2.78 [m, $^{3}J(H_b,H_c)$ = 5.1 Hz, 4 H, H_b]. − ^{15}N NMR (H_2O/D_2O, 9:1): δ = −50.02 (N_a).

3: ^{1}H NMR (H_2O/D_2O, 9:1): δ = 5.49 [m, 2 H, $H_{a'}$], 5.11 [m, 2 H, H_a], 3.71 [t, $^{3}J(H_c,H_b)$ = 4.9 Hz, 2 H, H_c], 3.49 [t, $^{3}J(H_{c'},H_{b'})$ = 5.2 Hz, 2 H, $H_{c'}$], 2.63 [m, $^{3}J(H_b,H_c)$ = 4.9 Hz, 2 H, H_b], 2.49 [m, $^{3}J(H_{b'},H_{c'})$ = 5.2 Hz, 2 H, $H_{b'}$]. − ^{15}N NMR (H_2O/D_2O, 9:1): δ = −69.98 (N_a), −31.46 ($N_{a'}$).

(*OC*-6-22)-Tetrachlorobis(2-hydroxyethylamine)platinum(IV) (2) and (*OC*-6−31)-trichloro(2-ethanolatoamine-κ²-*N,O*)(2-hydroxyethylamine)platinum(IV) (4): The preparation of **2** has been described previously.[13] For the preparation of **4** compound **2** (21 mg) was dissolved in 3 mL of water at 50 °C. The solution was stored in an open flask for nine days and orange crystals of **4** were obtained. − $C_4H_{13}Cl_3N_2O_2Pt$ (422.60): calcd. C 11.37, H 3.10, Cl 25.17, N 6.63, Pt 46.16; found C 11.44, H 3.07, Cl 25.03, N 6.44, Pt 45.86. By dissolving **2** in water two products are observed (50% of **2** and **4** after 12 days):
2: ^{1}H NMR (H_2O/D_2O, 9:1): δ = 6.36 (m, 4 H, H_a), 3.70 [t, $^{3}J(H_c,H_b)$ = 5.23 Hz, 4 H, H_c], 2.98 (m, 4 H, H_b). − ^{15}N NMR (H_2O/D_2O, 9:1): δ = −21.78 [^{1}J(N,Pt) = 228 Hz, ^{2}J(H,Pt) = 60 Hz, N_a].

4: ^{1}H NMR (H_2O/D_2O, 9:1): δ = 7.31 (m, 2 H, $H_{a'}$), 5.87 (m, 2 H, H_a), 3.65 [t, $^{3}J(H_c,H_b)$ = 5.2 Hz, 2 H, H_c], 3.19 [t, $^{3}J(H_{c'},H_{b'})$ = 5.5 Hz, 2 H, $H_{c'}$], 2.98 (m, 2 H, H_b), 2.60 (m, 2 H, $H_{b'}$). − ^{15}N NMR (H_2O/D_2O, 9:1): δ = 2.52 [^{1}J(N,Pt) = 282 Hz, ^{2}J(H,Pt) = 48 Hz, $N_{a'}$], −33.02 (N_a).

Upon dissolving **4** in water only one product is observed and the spectrum is equivalent to that of **4** in the mixture of **2** and **4**.

4: ^{1}H NMR (H_2O/D_2O, 9:1): δ = 7.38 (m, 2 H, $H_{a'}$), 5.83 (m, 2 H, H_a), 3.66 [t, $^{3}J(H_c,H_b)$ = 5.3 Hz, 2 H, H_c], 3.19 [t, $^{3}J(H_{c'},H_{b'})$ = 5.5 Hz, 2 H, $H_{c'}$], 2.97 (m, 2 H, H_b), 2.61 (m, 2 H, $H_{b'}$). − ^{15}N NMR (H_2O/D_2O, 9:1): δ = 2.57 [^{1}J(N,Pt) = 251 Hz, ^{2}J(H,Pt) = 52 Hz, $N_{a'}$], −32.29 (N_a).

X-ray Crystallographic Study:[14] The single crystal data were collected on a Nonius Kappa CCD diffractometer at room temperature. The measured intensities were corrected for Lorentz and polarisation effects. The crystal structure was determined by direct methods (SHELXS-97, Sheldrick, 1997a)[15] and subsequent Fourier and difference-Fourier syntheses. Final structure parameters of all three substances were obtained by full-matrix least squares techniques on F^2 (SHELXL-97, Sheldrick, 1997b).[16] Further X-ray structure analysis data are given in Table 1.

Synthesis and X-ray Structure of $[\{(Cp'_2Nb)_2WTe_4\}W(CO)_4]\cdot 1.5C_7H_8$, the First Organometallic Derivative of the WTe_4^{2-} Anion, and of $[Cp'_4Nb_2Te_2]$ ($Cp' = \eta^5$-tBuC$_5$H$_4$)

Henri Brunner,[a] Joachim Wachter,*[a] Robert Wanninger,[a] and Manfred Zabel[a]

Keywords: Niobium / Metallocenes / Tungsten / Tellurium / Carbonyl complexes / Anions

Reaction of $[Cp'_2NbTe_2H]$ (**1**) ($Cp' = \eta^5$-tBuC$_5$H$_4$) with $[W(CO)_6]$ in decane at 140 °C gives red $[\{(Cp'_2Nb)_2WTe_4\}W(CO)_4]$ (**2**), whereas in the reaction of **1** with $[Cr(CO)_6]$ green-black $[Cp'_4Nb_2Te_2]$ (**3**) is formed. The crystal structures of **2** and **3** have been determined. The structure of **2** contains a slightly distorted WTe_4 tetrahedron to which two niobocene fragments and one $W(CO)_4$ group are coordinated. The crystal structure determination of **3** reveals the presence of two Cp'_2Nb units bridged by two Te atoms. Complex **2** represents the first example of an organometallic derivative of the unknown WTe_4^{2-} anion.

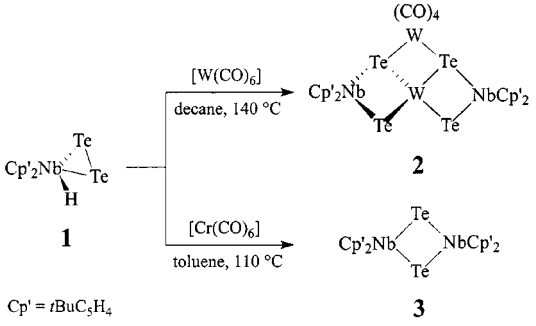
Introduction

Tetrathiometalates exhibit a rich structural chemistry upon coordination to inorganic and organometallic fragments.[1] The resulting heterometallic complexes possess more or less extended structures and they often show interesting electronic and optical properties.[1,2] Whereas an extension of this chemistry to MSe_4 compounds has been realized only very recently,[1,3] the corresponding tetratellurometalates are still unknown. This fact seems rather surprising if one takes into account the very varied coordination chemistry of Te-derived ligands.[4]

Recently, we have developed a synthetic method for the preparation of bimetallic tetrathio- and tetraselenometalates of the type $[(Cp^*_2Nb)_2ME_4]$ ($Cp^* = C_5Me_5$; M = Cr, Mo; E = S, Se). In these compounds the central "inorganic" core derives from a binary transition metal carbonyl, e.g. $[M(CO)_6]$, whereas the two peripheral niobocene units and the four chalcogen bridges are provided by $[Cp^*_2Nb(\eta^2\text{-}E_2)H]$, a niobocene(V) complex bearing a hydrido and a chalcogenido ligand.[5] In an extension of this work we now wish to report the synthesis of the first organometallic derivative of the still unknown WTe_4^{2-} salt from $[Cp'_2Nb(\eta^2\text{-}Te_2)H]$ (**1**; $Cp' = t$BuC$_5$H$_4$) and $[W(CO)_6]$. Complex **1** has been prepared from Cp'_2NbH_3 and elemental tellurium, and there is sufficient evidence that it bears an η^2-Te_2 ligand along with a hydride atom.[6]

Results and Discussion

The reaction of **1** with one equivalent of $[W(CO)_6]$ in decane (140 °C, 15 h) gives the red complex $[\{(Cp'_2Nb)_2WTe_4\}W(CO)_4]$ (**2**) in 54% yield [Equation (1)]. The composition of complex **2** follows from X-ray crystallography and elemental analyses. As a by-product, a dark green compound of composition $[Cp'_4Nb_2Te_2]$ (**3**) is formed in 6% yield. Compound **3** is formed in much better yield (64%) from the reaction of **1** with $[Cr(CO)_6]$ in boiling toluene along with traces of a red as-yet-unidentified compound [Equation (1)]. Complex **3** has been characterized by means of FD mass spectra and X-ray crystallography; the C value of elemental analyses of **3** differs by 1% for unknown reasons.



(1)

Complex **2** shows in the IR spectrum (toluene) three strong CO absorptions at 2005, 1972, and 1904 cm^{-1}. This is one less than would be expected from the crystal structure (see below) so we presume that two of the bands are accidentally degenerate. The UV/Vis spectrum reveals one absorption band at $\lambda = 477$ nm. The ^{1}H NMR spectrum contains two singlets for the tBu groups and eight multiplets of equal intensity between $\delta = 3.24$ and 6.05 for the C_5H_4 hydrogen atoms. Thus, the NMR pattern of **2** reflects two orientations of the Cp′ ligands with respect to the $W(CO)_4$ moiety as, due to the solid state structure, both W atoms are lying on a C_2 axis. The ^{1}H NMR spectrum of **3** shows two multiplets at 24 °C for the aromatic hydrogen atoms and one singlet for the tBu groups.

The crystal structure of **2** reveals the presence of four independent molecules in the asymmetric unit, which are practically identical. The central feature of the structure of **2** is a WTe_4 tetrahedron to which two niobocene units are

coordinated (Figure 1), giving rise to a nearly linear Nb−W−Nb arrangement. A $W(CO)_4$ fragment is inserted between two of the Te bridges of the central WTe_4 tetrahedron. The W−Te distances within the WTe_4 unit range from 2.540(2) to 2.604(2) Å, the μ_2-Te−W(1) distances being slightly shorter than those of μ_3-Te−W(1). Similar values have been found in $W(PMe_3)_4(Te)_2$ [2.596(1) Å][7] and in $[WOTe_3]^{2-}$ [2.530(1)−2.544(2) Å],[8] which have been attributed to W−Te double bonds. By contrast, the distances Te(2)−W(2) and Te(3)−W(2) [2.848(2) and 2.845(2) Å, respectively] are much longer, thus reflecting a formally lower oxidation state of the W(2) center.[9] In the central WTe_4 tetrahedron there is a slight distortion of the angle Te(3)−W(1)−Te(2), which is 119.30(6)°. Whereas the distances between opposite Te ligands seem to be far beyond direct bonding interactions, the Nb−W distances (3.333 Å mean) may be a borderline case for direct interactions between both metals.

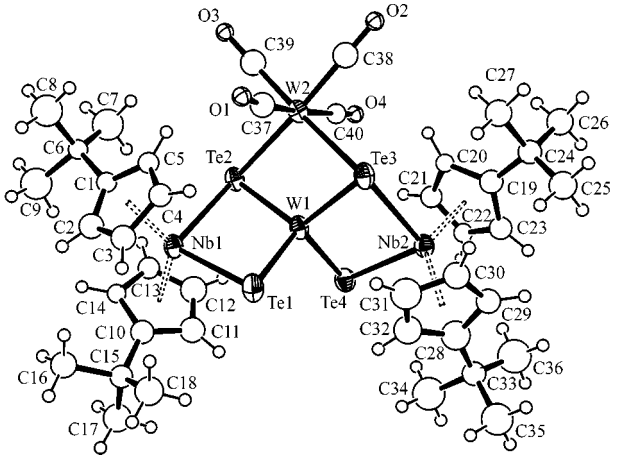

Figure 1. Molecular structure of $[\{(Cp'_2Nb)_2WTe_4\}W(CO)_4]$ (**2**); selected distances [Å] and angles [°]: W(1)−Te(1) 2.539(2), W(1)−Te(2) 2.600(2), W(1)−Te(3) 2.604(2), W(1)−Te(4) 2.553(2), W(2)−Te(2) 2.845(2), W(2)−Te(3) 2.841(2), Nb(1)−Te(1) 2.823(3), Nb(1)−Te(2) 2.827(2), Nb(2)−Te(3) 2.844(3), Nb(2)−Te(4) 2.834(3), Te(1)···Te(2) 4.22(3), Te(3)···Te(4) 4.25(2), Nb(1)···W(1) 3.35(1), Nb(2)···W(1) 3.33(2); Te(1)−W(1)−Te(2) 109.9(1), Te(1)−W(1)−Te(3) 103.5(1), Te(1)−W(1)−Te(4) 108.4(1), Te(2)−W(1)−Te(3) 119.3(1), Te(2)−W(1)−Te(4) 104.8(1), Te(3)−W(1)−Te(4) 110.6(1), Te(2)−W(2)−Te(3) 104.2(1), Nb(1)−Te(1)−W(1) 77.2(1), Nb(1)−Te(2)−W(1) 76.2(1), Nb(2)−Te(3)−W(1) 75.3(1), Nb(2)−Te(4)−W(1) 76.3(1), Te(1)−Nb(1)−Te(2) 96.2(1), Te(3)−Nb(2)−Te(4) 96.6(1), W(1)−Te(2)−W(2) 68.3(1), W(1)−Te(3)−W(2) 68.1(1), Nb(1)−W(1)−Nb(2) 163.8(1)

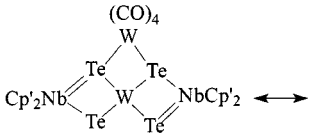
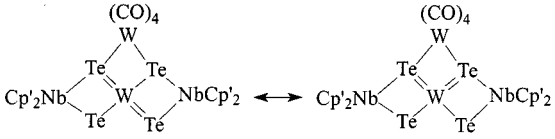
On the basis of these results a formal description of the bonding system in **2** either includes a W^{II} center, which is chelated by two $[Cp'_2NbTe_2]^-$ anions (structure type **A**), or a derivative of a tetratellurotungstate(VI) with two coordinated niobocene(III) ligands (structure type **B**). Taking into account the relatively short W−Te bonds in the central WTe_4 unit, it seems likely that the canonical forms **B** contribute more to the overall bonding system than **A**. In this sense **2** may be assumed to be the missing link in the series of bis(niobocene)tetrachalcogenido metalates $[(Cp^*_2Nb)_2ME_4]$ (M = Cr, Mo, W; E = S, Se, Te). These compounds are characterized by a delocalized bonding system including the whole metal-ligand system, as has been established by means of spectroscopic and theoretical investigations.[5]



A



B

The crystal structure of **3** contains a planar rhombohedral Nb_2Te_2 core to which four Cp′ ligands are coordinated. Additionally, the molecule has a crystallographic inversion center and the conformation of the Cp′ ligands corresponds to that of the *meso* diastereomer (Figure 2). A similar conformation has been found in the related compound $[Cp'_4Zr_2(\mu\text{-}Te)_2]$.[10] From the distances (>3.6 Å) one can exclude direct bonding interactions between opposite atoms of the core. The Nb−Te distances (2.80 Å) are only slightly shorter than those in **2** and they are in the range of Nb−Te single bonds.[11] As a consequence, compound **3** should formally contain two Nb^{IV} centers which is in obvious contrast to the observed diamagnetism of the molecule. For these reasons considerable through-space metal−metal coupling must be considered, as has been recently established for $[(C_5H_5)_4Zr_2(\mu\text{-}I)_2$.[12] This point, as well as studies of the chemical behavior, are currently under investigation.

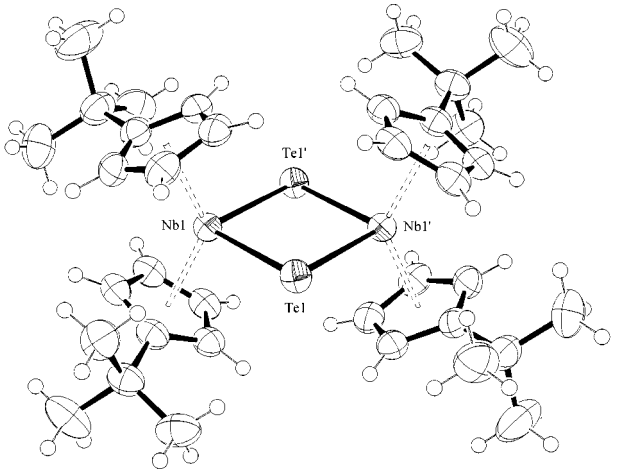


Figure 2. Molecular structure of $[Cp'_4Nb_2Te_2]$ (**3**); selected distances [Å] and angles [°]: Nb(1)−Te(1) 2.7969(4), Nb(1′)−Te(1) 2.8127(4), Nb(1)···Nb(1′) 3.647(1), Te(1)···Te(1′) 4.262(1); Nb(1)−Te(1)−Nb(1′) 81.12(1), Te(1)−Nb(1)−Te(1′) 98.88(1)

In conclusion the reaction of $[Cp'_2NbTe_2H]$ with $[Cr(CO)_6]$ or $[W(CO)_6]$ provides access to new polymetallic telluride complexes. Complex **2** is the first organometallic

derivative of the still unknown WTe_4^{2-} anion, whereas the analogous $CrTe_4$ derivative does not form under comparable conditions. Instead, formation of the dinuclear chromium-free complex **3** has been observed.

Experimental Section

General Methods. Experimental and spectroscopic techniques are reported in ref.[13] [Cp′$_2$Nb(Te$_2$)H] (**1**) was prepared from [Cp′$_2$NbH$_3$] and Te powder in THF.[6]

Synthesis of 2: A solution of [Cp′$_2$NbTe$_2$H] (**1**) (560 mg, 0.946 mmol) and [W(CO)$_6$] (330 mg, 0.938 mmol) in 140 mL of decane was stirred for 12 h at 140 °C in the dark. The color turned from dark orange to red during the reaction. After evaporation of the solvent the residue was dissolved in 12 mL of toluene and transferred to a column containing SiO_2 (15 × 3 cm). A red band was eluted with toluene containing [{(Cp′$_2$Nb)$_2$WTe$_4$}W(CO)$_4$] (**2**) (420 mg, 0.252 mmol, 54%). A following dark green band contained [Cp′$_4$Nb$_2$Te$_2$] (**3**) (25 mg, 0.027 mmol, 6%). Recrystallization of **2** from toluene gave red needles. − IR (toluene): ν(CO) = 2005 (s), 1972 (vs), 1904 (s) cm^{-1}. − ^{1}H NMR (400 MHz, CD_2Cl_2, 24 °C): δ = 6.05 (m, 2 H, C_5H_4), 5.87 (m, 2 H, C_5H_4), 5.59 (m, 2 H, C_5H_4), 5.56 (m, 2 H, C_5H_4), 5.48 (m, 2 H, C_5H_4), 4.78 (m, 2 H, C_5H_4), 4.01 (m, 2 H, C_5H_4), 3.24 (m, 2 H, C_5H_4), 1.53 (s, 18 H, *t*Bu), 1.43 (s, 18 H, *t*Bu). − UV/Vis (THF): λ (ε) (Lmol^{-1}cm^{-1}) = 477 nm (3208). − $C_{40}H_{52}Nb_2O_4Te_4W_2C_7H_8$ (1752.87): calcd. C 32.20, H 3.45; found C 32.38, H 3.49.

Synthesis of 3: Compound **1** (560 mg, 0.946 mmol) and [Cr(CO)$_6$] (200 mg, 0.909 mmol) were dissolved in 140 mL of toluene and stirred for 12 h at 110 °C in the dark. The color turned from dark orange to green-black during the reaction. The mixture was cooled to room temperature and the solvent evaporated. The residue was dissolved in 12 mL of toluene and chromatographed on SiO_2 (column 15 × 3 cm). Elution with toluene first gave a red band containing 20 mg of a still unidentified compound and then a green-black band containing [Cp′$_4$Nb$_2$Te$_2$] (**3**) (280 mg, 0.302 mmol, 64%). Complex **3** was recrystallized from toluene/pentane (1:2). − ^{1}H NMR (400 MHz, CD_2Cl_2, 24 °C): δ = 5.05 (m, 8 H, C_5H_4), 4.46 (m, 8 H, C_5H_4), 1.44 (s, 36 H, *t*Bu). − FD-MS (toluene): *m*/*z* = 925.6 [M$^+$]. − $C_{36}H_{52}Nb_2Te_2$ (925.81): calcd. C 46.70, H 5.66; found C 45.78, H 5.69.

X-ray Structure Determination: For the crystals of both compounds **2** and **3** the shape and the size were determined for numerical absorption correction. The structures of **2** and **3** were solved by direct methods (Table 1). For **3**, subsequent difference Fourier syntheses revealed the position of the non-hydrogen atoms and all these atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included on idealized positions and refined using a riding model.

The structure refinement of **2** was handicapped by two problems: i) For data collection only thin needles were available giving rise to very weak intensities mainly at higher reflection angles. Only one third of the measured reflections were observed with an intensity greater than 2σ(*I*). This causes some peculiarities concerning the results of the refinement. Internal *R* values, especially *R*(σ) = 0.3451, are high and are mainly influenced by the large number of weak reflections. The same is true for the low value of GOF. The unexpectedly high *R*1 for all data can be explained by the fact that too many very weak or even negative intensities are setting a wrong bias, when transformed to *F* values. The "normal" behavior of *R*1 and *wR*2 for the observed data [$I > 2\sigma(I)$] supports this point of view. Also, due to the large number of weak reflections no weighting factor could be refined and so unit weights were applied. Finally, only the heavy atoms could be refined with anisotropic thermal parameters. ii) Five toluene solvent molecules could be located by difference Fourier syntheses but there was still a solvent accessible void present. Since from the remaining difference Fourier peaks no reasonable molecule could be built all these maxima were erased and the size and electron content of this void was determined by the program SQUEEZE.[14] The center of the void was located at (0.5, 0, 0.5), the size and electron content was refined to 766 Å^3 with 65 e$^-$. For one more toluene molecule, the size of the void and the electron number are too high. The possibility that one decane molecule (reaction medium) was still present after chromatography and recrystallisation seemed unlikely. Nevertheless, for the calculation of molecular weight, *F*(000) and density one more toluene molecule was included, because no chance was seen to find the proper molecule from a data set with so many weak reflections at high reflection angles. The final refinement, leading to the given results, was carried out after back-Fourier transformation of all density found in the disordered solvent area.

The unusual result that four symmetry independent molecules were found in the elementary cell was checked and proved to be right by programs implemented in the PLATON package: a) No different cell choice was suggested by LEPAGE, therefore only an anorthic cell and space group is possible. The highest possible, $P\bar{1}$ was chosen; b) Even if only the heavy atoms were included in the file for calculations, PLATON could not find additional symmetry elements nor did it suggest a higher symmetry than applied. Obviously a denser packing of **2** with higher symmetry of cell and structure is not possible.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication

nos. CCDC-148287 (**2**) and -148288 (**3**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

New Sterically Encumbered 2,9-Diarylphenanthrolines for the Selective Formation of Heteroleptic Bis(phenanthroline)copper(I) Complexes

Michael Schmittel,*[a] Christoph Michel,[a] Shi-Xia Liu,[a] Daniel Schildbach,[b] and Dieter Fenske[c]

Dedicated to Prof. Dr. Dr. h. c. mult. Siegfried Hünig on the occasion of his 80th birthday

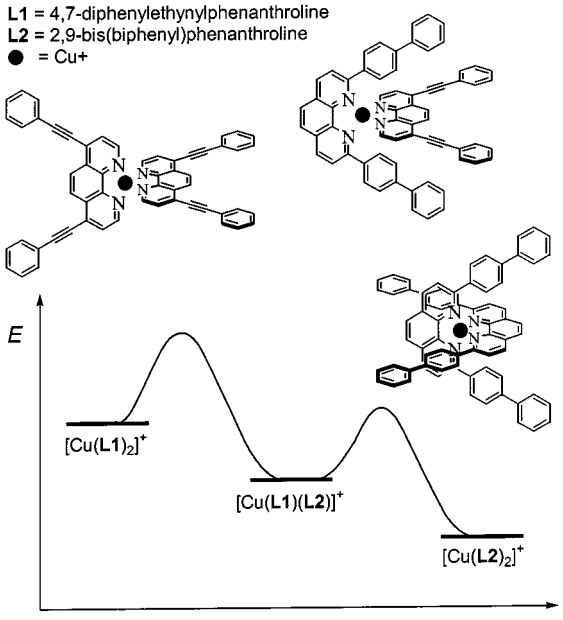
Keywords: Copper / Phenanthroline / Coordination chemistry / Semiempirical calculations / Fluorescence

The synthesis and characterization of several 2,9-diarylphenanthrolines with anthracenyl substituents in the 2-position is described. These compounds were used to prepare a series of homoleptic and heteroleptic bis(phenanthroline)copper(I) complexes, whose cyclic voltammetry, UV/Vis and fluorescence data are investigated. From PM3 semiempirical calculations it becomes clear that two different strategies can be applied to prepare clean heteroleptic complexes.

Introduction

We have recently introduced a new concept to prepare heteroleptic bis(phenanthroline)copper(I)[1] and -silver(I)[2] complexes $[M(\mathbf{L1})(\mathbf{L2})]^+$ in a clean and well-defined manner using a ligand with bulky groups in the 2- and 9-positions. In metallosupramolecular chemistry, control of the clean formation of heteroleptic complexes is extremely valuable for highly selective self-assembly processes with two different ligands **L1** and **L2**, e.g. of linear and macrocyclic oligophenanthrolines,[3] as the number of potential aggregates is markedly reduced. Consequently, we have used this protocol for the synthesis of supramolecular boxes[3] of nanometer dimensions with appropriately spaced internal functional groups.

As bis(phenanthroline)copper(I) complexes are kinetically labile,[4] a thermodynamically controlled setup has to be found that favors the heteroleptic complex over the two alternative homoleptic complexes. In our concept,[1,2] 2,9-diaryl substitution at one phenanthroline (**L2**) plays a critical role. In combination with a second phenanthroline, which does not bear 2,9-aryl substituents (**L1**), the stability sequence of the resulting copper(I) complexes becomes predictable (Scheme 1); the corresponding homoleptic bis-2,9-diarylphenanthroline copper(I) complex $[Cu(\mathbf{L2})_2]^+$ is always the most stable because of the interplay of increased σ-basicity of **L2** and π-π interactions between the 2,9-aryl groups and the second phenanthroline core. The latter stabilization is present in $[Cu(\mathbf{L2})_2]^+$ four times, but only twice in $[Cu(\mathbf{L1})(\mathbf{L2})]^+$ and is absent in $[Cu(\mathbf{L1})_2]^+$.



Scheme 1

The straightforward concept to prepare $[Cu(\mathbf{L1})(\mathbf{L2})]^+$ is consequently based on the fact that we have to prevent the formation of the most stable complex $[Cu(\mathbf{L2})_2]^+$ through steric blocking, so that of the remaining complexes it is the heteroleptic $[Cu(\mathbf{L1})(\mathbf{L2})]^+$ that is the thermodynamically favored option. In earlier investigations[1,2] we successfully used **L2** = **1** and would like now to assess whether other aryl substituents, such as naphthyl and anthracenyl, at the phenanthroline would also be suited for the preparation of heteroleptic copper(I) complexes. In the present paper[5] we describe the preparation of ligands **2**–**5** (Scheme 2) and their potential in the selective heteroleptic copper(I) complex formation.

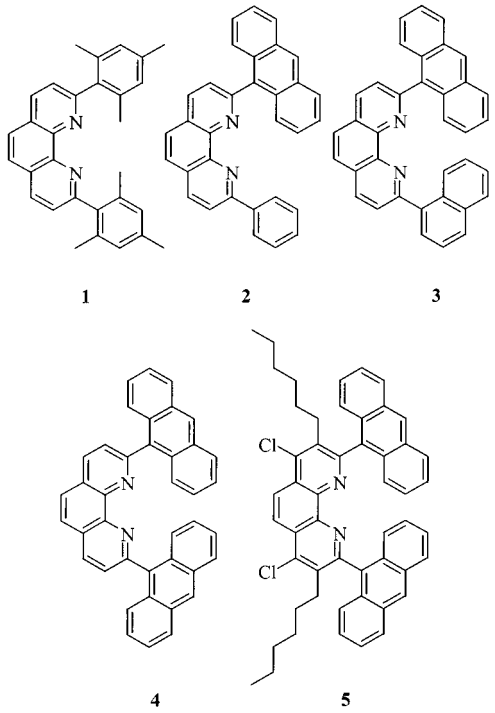


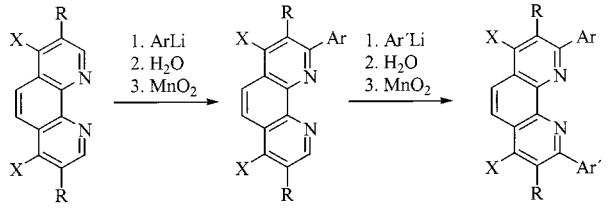
Scheme 2

Moreover, ligands **2**−**5** seemed to be promising candidates because a number of sensing supramolecules contain anthracene as a fluorescent subunit (or fluorophor) given its strong and well-characterized emission and its chemical stability.[6] For example, De Silva has developed many anthracene-based sensors for metal ions.[7] Additionally, compound **5** was prepared because the two hexyl groups at the 3- and 8-positions should increase the solubility of the system.[8]

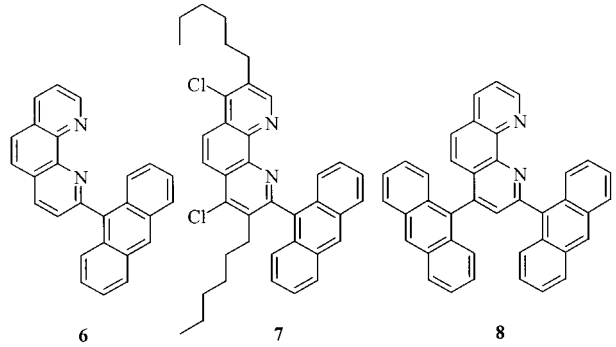
Results

Phenanthroline Ligands

Synthesis: For the preparation of the 2,9-substituted phenanthrolines, the two-step synthesis shown in Scheme 3 proved to be the method of choice and this is based on a strategy established earlier by Sauvage.[9] Simultaneous arylation of both the 2- and 9-positions of 1,10-phenanthroline either failed completely or proceeded with low yields. In order to overcome this problem, 1,10-phenanthroline was first reacted with a slight excess of the aryllithium reagent at room temperature, followed by hydrolysis and rearomatization of the intermediate with activated MnO_2. Subsequently, the procedure was repeated once again using the monoarylated phenanthrolines **6** and **7** (Scheme 4). The crude product could be purified either by recrystallization or by column chromatography on silica gel and subsequent recrystallization.



Scheme 3. 2,9-Diaryl-1,10-phenanthrolines from 1,10-phenanthroline by nucleophilic aromatic substitution followed by rearomatization



Scheme 4

Yields for the first arylation ranged from 37%−67% (for **7** and **6**, respectively), while the yield of the second step was heavily dependent on the steric bulk of the new substituents [with phenyl: 64%; with naphthyl: 25%, and anthracenyl: 21% (**4**)]. In contrast, the yield for the second arylation **7** → **5** was 59%. The structures of all new phenanthrolines were proved using ^1H and ^{13}C NMR spectroscopy and elemental analysis.

The yields of the nucleophilic aromatic substitution reactions are sometimes lower due to by-product formation. In the reaction of **6** with anthracenyllithium we actually isolated the 2,4-substituted phenanthroline **8** as the main product (39%). It is clear that steric shielding hampers the formation of **4** (21%) and directs arylation to the 4-position, a reaction that is not possible with **5**. An analogous regioselectivity has been reported for nucleophilic substitutions at pyridine, although this is a rare case.[10] However, to the best of our knowledge[11] this is the first time that a nucleophilic arylation has led preferentially to a 2,4-diarylphenanthroline.

Structural Characterization of the Ligands

X-ray Structure of 5: Because of its good solubility and the presence of two large anthracenyl rings, we investigated **5** in greater detail. Ligand **5** could readily be crystallized from dichloromethane and hence was investigated by X-ray crystallography. Figure 1 depicts the structure of **5** in the solid state from a top and a side view.

From Figure 1 one can clearly see the steric demand of the two large anthracenyl groups. To avoid repulsions between the two anthracenyl rings or between the anthracenyl ring and the hexyl groups the two anthracenyl moieties assume an almost orthogonal arrangement with regard to the phenanthroline plane (dihedral angle = 96°). The structure of ligand **5** is well described by the PM3 calculation, as demonstrated by the selected data provided in Table 1.

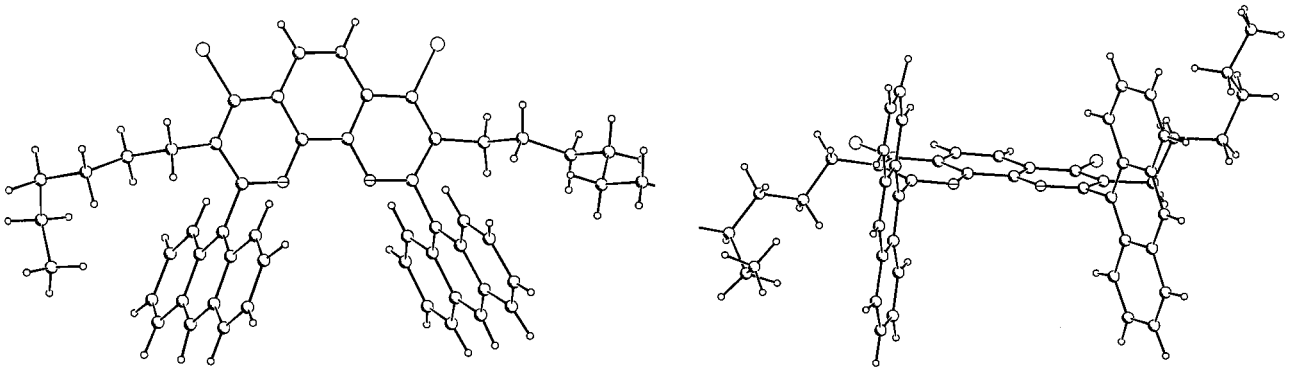


Figure 1. Schakal plot of 2,9-dianthracenyl-4,7-dichloro-3,8-dihexyl-1,10-phenanthroline (**5**)

NMR Investigations: As one would anticipate, given the extended aromatic residues, the proton NMR spectra of **5** show a solvent dependence; i.e. the shifts vary with the solvent ($CDCl_3$ or [D_6]benzene). While the 5,6-H phenanthroline signal is not shifted, the signal of the 10-H at the anthracene substituents experiences a high-field shift from $\delta = 8.4$ ($CDCl_3$) to $\delta = 8.1$ ([D_6]benzene). After adding trifluoroacetic acid to the NMR solution in $CDCl_3$ the phenanthroline 5,6-H′s experience the expected down-field shift (by 0.2 ppm), but the doublet for 1-H and 8-H at the anthracene rings is shifted towards high field by about 0.3 ppm.

Luminescence Properties: The emission spectra of the ligands **2**−**7** in dichloromethane were recorded (Figure 2) at room temperature upon excitation at 346 nm. The emission maxima appear between 439−472 nm.

Preparation of the Copper Complexes

Homoleptic Copper Complexes: To assess the feasibility of the various ligands **2**−**7** with regard to our concept (see Introduction) we checked whether they would easily form homoleptic complexes in the presence of copper(I). For ligands **2**, **3**, **6** and **7** the reaction with 0.5 equiv. of [Cu(MeCN)$_4$]BF_4 or [Cu(MeCN)$_4$]PF_6 in dichloromethane

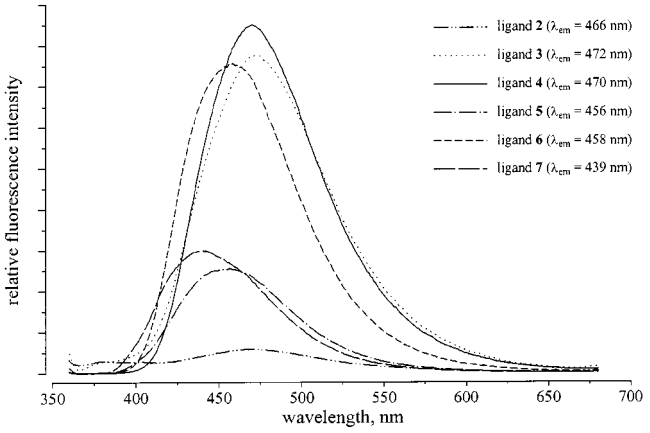

Figure 2. Luminescence spectra of various phenanthrolines at room temperature in CH_2Cl_2 solution (excitation at 346 nm where the absorbance of all the compounds is 1.11)

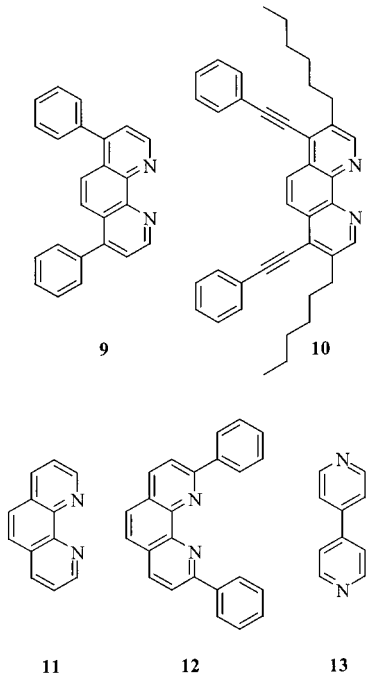
readily afforded the intensely red-colored homoleptic complexes $[Cu(\mathbf{2})_2]^+$, $[Cu(\mathbf{3})_2]^+$, $[Cu(\mathbf{6})_2]^+$, and $[Cu(\mathbf{7})_2]^+$ in good yields (50−85%) at room temperature.

By using the conditions described above, phenanthrolines **4** and **5** − with bulky anthracenyl groups at the 2- and 9-positions − only afforded yellow complexes, which were assigned as the monophenanthroline complexes $[Cu(\mathbf{4})(MeCN)_2]BF_4$ or $[Cu(\mathbf{5})(MeCN)_2]BF_4$. Additionally, the ^1H NMR spectra of the reaction mixtures showed signals for uncoordinated phenanthroline **4** or **5**. Even when the complexation was performed at 80 °C (in C_6D_6) for three hours the color of the solution did not turn red, indicating that a bis(phenanthroline)copper(I) complex had not been formed. The ESI mass spectrum shows a large ion peak at m/z = 874, which is indicative of the complex $[Cu(\mathbf{5})(MeCN)]^+$, and m/z = 833 for the ion $[Cu(\mathbf{5})]^+$. $[Cu(\mathbf{4})(MeCN)_2]BF_4$ was purified by recrystallization and characterized by elemental analysis.

Heteroleptic Copper Complexes: To test the suitability of the anthracenyl-substituted phenanthrolines **4** and **5** for the clean preparation of heteroleptic complexes, we treated them with 1 equiv. of 4,7-substituted ligands **9** or **10** (Scheme 5) in the presence of 1 equiv. of $[Cu(MeCN)_4]^+$ at room temperature. Evaporation of the solvent led to the precipitation of a red solid, yielding the heteroleptic complexes $[Cu(\mathbf{4})(\mathbf{9})]^+$, $[Cu(\mathbf{5})(\mathbf{9})]^+$, and $[Cu(\mathbf{5})(\mathbf{10})]^+$ in good yields.



Scheme 5

Characterization of the Copper Complexes

The identities of the copper(I) complexes could be established through elemental analysis, ESI mass spectrometry, IR and NMR spectroscopy.

^1H NMR Spectroscopy: The spectra exhibit well-resolved signals for the homoleptic as well as the heteroleptic complexes in CD_2Cl_2 or $CDCl_3$, which is true even for the sterically loaded complex $[Cu(\mathbf{3})_2]PF_6$. A 2D ROESY ^1H NMR experiment clearly confirms its highly shielded structure. Rotation about the anthracene-phenanthroline axes is no longer possible, as shown by the fact that the inner and the outer ring of the anthracenes can be differentiated. From the literature it is known that aryl substituents with a lower steric demand lead to broadening of the Ar−H signals,[12] and in the absence of *ortho* substituents the aryl rings are free to rotate relative to the phenanthroline on the NMR time scale.[13]

The formation of the heteroleptic complexes is indicated by characteristic ^1H NMR shifts. Coordination of the 2,9-

Table 2. Characteristic ^1H NMR chemical shifts of the 2,9-substituted-1,10-phenanthrolines in heteroleptic complexes

[a] In $CDCl_3$. − [b] In CD_2Cl_2.

substituted ligands to the positively charged metal center results in typical downfield shifts for all protons at the phenanthroline core (Table 2). In contrast, the 2,9-H′s at the 4,7-substituted phenanthroline experience a strong high-field shift (Table 3). This is due to the shielding effect of the anthracenyl (and other aryl) groups placed below and above the aromatic plane of the second phenanthroline, i.e. the one with 4,7-substituents, in the tetrahedral copper complex.

Table 3. Characteristic ^{1}H NMR chemical shifts of the 4,7-substituted-1,10-phenanthrolines in heteroleptic complexes

Electrochemical Data: The oxidation behavior of the homoleptic and heteroleptic copper(I) complexes was studied by cyclic voltammetry. All compounds undergo a reversible one-electron oxidation process, which can be attributed to the $Cu^I \rightarrow Cu^{II}$ couple.[14] The redox potentials (Table 4) range from 0.0−0.3 V for the homoleptic complexes [Cu(**6**)$_2$](BF$_4$), [Cu(**7**)$_2$](PF$_6$), and the heteroleptic complexes [Cu(**4**)(**9**)](PF$_6$), [Cu(**5**)(**9**)](PF$_6$) and [Cu(**5**)(**10**)](PF$_6$). For the complexes whose copper center is shielded efficiently the redox potential is somewhat higher.

Table 4. Electrochemical data of various copper(I) complexes

Compound	$E_{1/2}$ [a]	ΔE_p
[Cu(**6**)$_2$](BF$_4$)	−0.05	107
[Cu(**7**)$_2$](PF$_6$)	0.22	130
[Cu(**2**)$_2$](PF$_6$)	0.50	74
[Cu(**3**)$_2$](PF$_6$)	0.56	68
[Cu(**4**)(CH$_3$CN)$_2$](BF$_4$)	0.53	193
[Cu(**4**)(**9**)](PF$_6$)	0.16	103
[Cu(**5**)(**9**)](PF$_6$)	0.23	156
[Cu(**5**)(**10**)](PF$_6$)	0.28	134

[a] Half-wave potentials $E_{1/2}$ (V vs. ferrocene/ferrocenium) of copper(I) complexes determined by cyclic voltammetry in dichloromethane at $\nu = 100$ mVs^{-1} (electrolyte: 0.1 M Bu_4NPF_6).

Photophysical Data: Absorption data for the homoleptic and heteroleptic complexes in dichlormethane are shown in Table 5. All complexes absorb in a broad region of the UV and visible spectrum. They show very intense ligand-centered (LC) bands in the UV region and much weaker metal-ligand charge-transfer (MLCT) bands in the visible region. The MLCT bands are very broad because the copper(II) complex involved in the electronic transition has an equilibrium geometry very different from that of the ground state copper(I) system.[13]

Table 5. Room temperature absorption data of various copper(I) complexes in dichloromethane at room temperature

Complex	λ_{max} [nm] (ε) [M^{-1}cm^{-1}]
[Cu(**6**)$_2$](BF$_4$)	457 470 (4090)
[Cu(**7**)$_2$](PF$_6$)	470 (6130)
[Cu(**2**)$_2$](PF$_6$)	457 (2640)
[Cu(**3**)$_2$](PF$_6$)	456 (3830)
[Cu(**4**)(**9**)](BF$_4$)	474 (6900)
[Cu(**5**)(**9**)](PF$_6$)	499 (9400)
[Cu(**5**)(**10**)](PF$_6$)	496 (13400)

The homoleptic complexes with the more sterically demanding ligands **2** and **3** exhibit lower absorption wavelengths than the complexes with the 2-substituted phenanthrolines **6** and **7**. This fact is equally clear in the solid state, as the former complexes appear orange whereas the latter complexes are deep red. Moreover, a low-energy shoulder is observed for [Cu(**2**)$_2$]$^+$ and [Cu(**3**)$_2$]$^+$, which can be attributed to distortion of the complexes from D_{2d} symmetry.[15] Such distortion is not possible for complexes [Cu(**2**)$_2$]$^+$ and [Cu(**3**)$_2$]$^+$ because of the steric bulk of the four 2,9-substituents (see also calculated structures).

The room-temperature emission spectrum of [Cu(**3**)$_2$]$^+$ was investigated in dichloromethane. The complex shows an almost complete quenching of fluorescence (at 472 nm).

Quantum Chemical Calculations: To gain a better understanding of the thermodynamics we decided to study the complex equilibria using PM3[16] semi-empirical calculations with parameters for copper (Table 6). Systematic deviations caused by the parametrization should be small due to error cancelation in the calculation of equilibria (or isodesmic reactions).

As the PM3 calculations gave a good prediction about the structure of ligand **5** we also evaluated some of the structural characteristics of the complexes. Of particular interest are the structures of compounds [Cu(**2**)$_2$]$^+$, [Cu(**3**)$_2$]$^+$, [Cu(**4**)$_2$]$^+$, and [Cu(**4**)(**9**)]$^+$ (see Discussion).

*Reaction of **5** with 4,4′-Bipyridine (**13**):* As the large anthracenyl moieties preclude formation of the homoleptic complex [Cu(**5**)$_2$]$^+$, we expected that **5** would also form well-defined Cu^I complexes with ligands binding less strongly than phenanthrolines. The shielded environment about copper in [Cu(**5**)]$^+$ should also bring about some kinetic stabilization. When we treated **5** with 4,4′-bipyridine (**13**) in the presence of copper(I) (molar ratio 2:1:2), only one species was found in solution according to the ^{1}H NMR spectrum, which was indicative of the bisheteroleptic complex [Cu$_2$(**5**)$_2$(**13**)](PF$_6$)$_2$. The protons of the bipyridine moiety exhibit a strong high-field shift ($\Delta\delta = 2.1$ ppm for 2-,2′-H and 1.5 ppm for 3-,3′-H protons), a situation clearly indicative of a heteroleptic complex in which **13** is symmetrically buried in the cavity of two ligands **5**. Unfortunately, crystals of this compound could not be obtained for X-ray analysis, presumably due to the fact that the copper(I) centers weakly bind acetonitrile and dichloromethane, as evidenced by elemental analysis and ES mass spectrometry. For

Table 6. PM3 calculated (see ref.[16]) heats of formation of the ligands and the corresponding homoleptic and heteroleptic complexes

Ligand	ΔH_f [kcal mol^{-1}]	Homoleptic complex	ΔH_f [kcal mol^{-1}]	Heteroleptic complex	ΔH_f [kcal mol^{-1}]
1	73.3	$[Cu(\mathbf{1})_2]^+$	161.2	$[Cu(\mathbf{4})(\mathbf{9})]^+$	327.3
2	164.2	$[Cu(\mathbf{2})_2]^+$	329.8	$[Cu(\mathbf{4})(\mathbf{11})]^+$	275.8

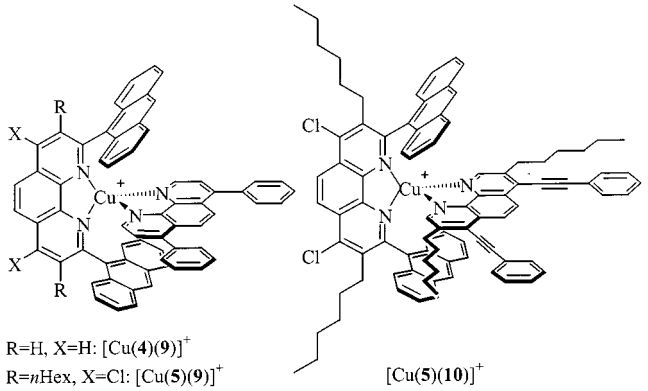
11	71.6	$[Cu(\mathbf{11})_2]^+$	144.0	$[Cu(\mathbf{11})(\mathbf{12})]^+$	193.8
12	122.3	$[Cu(\mathbf{12})_2]^+$	242.4	$[Cu(\mathbf{2})(\mathbf{9})]^+$	286.2

example, mass analysis showed a peak for $[Cu_2(\mathbf{5})_2(\mathbf{13})(CH_3CN)]^{2+}$ at $m/z = 932.0$. In a collisionally activated dissociation (CAD)[17] experiment, complex $[Cu_2(\mathbf{5})_2(\mathbf{13})(CH_3CN)]^{2+}$ readily fragments to form the ion $[Cu(\mathbf{5})]^+$ at $m/z = 833.2$.

Discussion

Formation of the Complexes

The present investigation has disclosed phenanthrolines **4** and **5** as suitable new ligands for controlling the clean preparation of heteroleptic bis(phenanthroline)copper(I) complexes. It is important to state that the heteroleptic complexes $[Cu(\mathbf{4})(\mathbf{9})]^+$, $[Cu(\mathbf{5})(\mathbf{9})]^+$, and $[Cu(\mathbf{5})(\mathbf{10})]^+$ (Scheme 6) were formed without the need for external control from reaction conditions, such as sequence of addition, reaction temperature etc.



R=H, X=H: $[Cu(\mathbf{4})(\mathbf{9})]^+$
R=*n*Hex, X=Cl: $[Cu(\mathbf{5})(\mathbf{9})]^+$

$[Cu(\mathbf{5})(\mathbf{10})]^+$

Scheme 6

It is well-known that copper(I) phenanthroline complexes with sterically unimpeded ligands are kinetically labile at room temperature (rates $> 6.2 \times 10^4$),[4] and so we have to assume that in the reactions

$$[Cu(CH_3CN)_4]^+ + \mathbf{4} + \mathbf{9} \rightarrow [Cu(\mathbf{4})(\mathbf{9})]^+$$
(no formation of $[Cu(\mathbf{4})_2]^+$ and of $[Cu(\mathbf{9})_2]^+$)

$$[Cu(CH_3CN)_4]^+ + \mathbf{5} + \mathbf{9} \rightarrow [Cu(\mathbf{5})(\mathbf{9})]^+$$
(no formation of $[Cu(\mathbf{5})_2]^+$ and of $[Cu(\mathbf{9})_2]^+$)

the formation of the homoleptic complexes is suppressed by thermodynamic and/or kinetic factors. Indeed, all heteroleptic complexes in Scheme 6 are characterized by a phenanthroline having two large anthracenyl rings in the 2- and 9-positions. In independent experiments we could verify that even under harsh conditions the formation of $[Cu(\mathbf{4})_2]^+$ and $[Cu(\mathbf{5})_2]^+$ does not occur. In contrast, homoleptic complexes were afforded readily with ligands whose 2- and 9-positions were less shielded, e.g. **2**, **3**, **6**, and **7**. However, the question remains as to whether the formation of $[Cu(\mathbf{4})_2]^+$ and $[Cu(\mathbf{5})_2]^+$ is impeded thermodynamically or kinetically.

To answer this question we employed PM3 calculations, although this method does entail a major restriction as, strictly speaking, such calculations are only relevant for the gas phase. Neglecting this constraint, it becomes clear from the calculations that all complexes, even the sterically loaded ones, are thermodynamic minimum structures (for heats of formation, see Table 6). To probe the PM3 calculations we investigated the equilibrium $[Cu(\mathbf{L1})_2]^+ + [Cu(\mathbf{L2})_2]^+ \rightarrow 2\,[Cu(\mathbf{L1})(\mathbf{L2})]^+$ (see Scheme 1). Accordingly, $[Cu(\mathbf{L2})_2]^+$ is favored over $[Cu(\mathbf{L1})(\mathbf{L2})]^+$ by 1.4 kcal mol^{-1}, while experimentally it is favored by roughly 1 kcal mol^{-1}.[18]

Next, we tried to understand the stability of the complexes by evaluating different factors, such as σ-basicity, π-π stacking and steric strain. The critical assessment of the two subsequent equilibria,

$$[Cu(\mathbf{11})_2]^+ + 2 \times \mathbf{12} \rightleftarrows [Cu(\mathbf{12})_2]^+ + 2 \times \mathbf{11} \qquad \Delta H_{rxn} = -3.0 \text{ kcal mol}^{-1},$$

$$[Cu(\mathbf{9})_2]^+ + 2 \times \mathbf{12} \rightleftarrows [Cu(\mathbf{12})_2]^+ + 2 \times \mathbf{9} \qquad \Delta H_{rxn} = 0 \text{ kcal mol}^{-1}$$

indicates that, according to PM3, ligand **12** (with its 2,9-diaryl substituents) forms a more stable homoleptic complex than the parent compound **11**, but this must be due to an increase of the σ-basicity brought about by the 2,9-phenyl groups, and not by π-π stacking. π-π Stacking between the 2,9-aryls and the second phenanthroline is not recognized by PM3 as a stabilizing motif due to the fact that $[Cu(\mathbf{9})_2]^+$ and $[Cu(\mathbf{12})_2]^+$ exhibit the same stability. This is definitely a shortcoming of PM3, since we[18] and others[19] have seen clear structural indications for π-π stacking in phenanthroline copper(I) complexes. Despite this deficiency, PM3 should be useful to evaluate the steric strain encountered in the complex formation with large ligands. To establish a reference point we have defined arbitrarily that the σ-basicity of ligand **12** matches the σ-basicity of 2,9-diaryl-substituted ligands **2**–**4**. As a consequence,

the equilibrium between homoleptic complexes of **12** and **2**−**4** should reflect the steric crowding in the complex.

$$[Cu(\mathbf{12})_2]^+ + 2 \times \mathbf{2} \rightleftarrows [Cu(\mathbf{2})_2]^+ + 2 \times \mathbf{12}$$
$$H_{strain} = \Delta H_{rxn} = +3.6 \text{ kcal mol}^{-1}$$
$$[Cu(\mathbf{12})_2]^+ + 2 \times \mathbf{3} \rightleftarrows [Cu(\mathbf{3})_2]^+ + 2 \times \mathbf{12}$$
$$H_{strain} = \Delta H_{rxn} = +7.4 \text{ kcal mol}^{-1}$$
$$[Cu(\mathbf{12})_2]^+ + 2 \times \mathbf{4} \rightleftarrows [Cu(\mathbf{4})_2]^+ + 2 \times \mathbf{12}$$
$$H_{strain} = \Delta H_{rxn} = +20.0 \text{ kcal mol}^{-1}$$

The strain enthalpy (H_{strain}) in the homoleptic complexes indeed increases with the size of the 2,9-diaryl substituents. In particular, a substantial strain increase is observed when we compare ligand **4** (the same should apply for ligand **5**) with **2** or **3**.

A look at the thermodynamics of the equilibria involving heteroleptic complexes $[Cu(\mathbf{L})(\mathbf{11})]^+$ is also very informative. With ligands **L** = **9** and **12** there is no clear predisposition for the heteroleptic complex. However, the bulky ligands (**L** = **2**−**4**) exhibit an increasing preference for the heteroleptic complex with increasing demand in the series: **4** > **3** > **2** (measured in $[Cu(\mathbf{L})(\mathbf{9})]^+$).

$$[Cu(\mathbf{9})_2]^+ + [Cu(\mathbf{11})_2]^+ \rightleftarrows 2\,[Cu(\mathbf{9})(\mathbf{11})]^+$$
$$\Delta H_{rxn} = -0.2 \text{ kcal mol}^{-1}$$
$$[Cu(\mathbf{11})_2]^+ + [Cu(\mathbf{12})_2]^+ \rightleftarrows 2\,[Cu(\mathbf{11})(\mathbf{12})]^+$$
$$\Delta H_{rxn} = +1.2 \text{ kcal mol}^{-1}$$
$$[Cu(\mathbf{2})_2]^+ + [Cu(\mathbf{9})_2]^+ \rightleftarrows 2\,[Cu(\mathbf{2})(\mathbf{9})]^+$$
$$\Delta H_{rxn} = -3.8 \text{ kcal mol}^{-1}$$
$$[Cu(\mathbf{3})_2]^+ + [Cu(\mathbf{9})_2]^+ \rightleftarrows 2\,[Cu(\mathbf{3})(\mathbf{9})]^+$$
$$\Delta H_{rxn} = -10.0 \text{ kcal mol}^{-1}$$
$$[Cu(\mathbf{4})_2]^+ + [Cu(\mathbf{9})_2]^+ \rightleftarrows 2\,[Cu(\mathbf{4})(\mathbf{9})]^+$$
$$\Delta H_{rxn} = -23.6 \text{ kcal mol}^{-1}$$
$$[Cu(\mathbf{4})_2]^+ + [Cu(\mathbf{11})_2]^+ \rightleftarrows 2\,[Cu(\mathbf{4})(\mathbf{11})]^+$$
$$\Delta H_{rxn} = -24.2 \text{ kcal mol}^{-1}$$

The obvious conclusion from these calculations is that the clean formation of heteroleptic complexes can be brought about by purely thermochemical factors that are controlled by the 2,9-substituents. The thermodynamic preference for heteroleptic complexes with ligands **2**−**4** is apparently due to strain in the homoleptic complexes $[Cu(\mathbf{2}-\mathbf{4})_2]^+$, which is liberated when the heteroleptic complex is formed.

Inspired by our calculations we now wanted to test experimentally whether formation of the heteroleptic complex $[Cu(\mathbf{3})(\mathbf{9})]^+$ is possible despite the fact that a stable complex $[Cu(\mathbf{3})_2]^+$ is known. Indeed, the reaction of ligands **3** and **9** in presence of 1 equiv. of $[Cu(MeCN)_4]BF_4$ at room temperature yielded the heteroleptic complex $[Cu(\mathbf{3})(\mathbf{9})]^+$ in quantitative yield, as evidenced by ^{1}H NMR and ESI mass spectrometry. This is clear evidence for a new way to control heteroleptic bis(phenanthroline)copper(I) complexes just on the basis of their thermodynamic preference. Steric blocking of the formation of the most stable homoleptic complex is no longer needed.

While thermodynamic control of heteroleptic complex formation is certainly the exclusive element to guide the formation of $[Cu(\mathbf{3})(\mathbf{9})]^+$, this is most likely not the case with $[Cu(\mathbf{4})(\mathbf{9})]^+$. While we have not been able to calculate the transition state (TS) for the reaction $[Cu(CH_3CN)_4]^+ + 2 \times \mathbf{4} \rightarrow [Cu(\mathbf{4})_2]^+$, the analysis of structural models clearly indicates that there will be enormous strain in the TS. As such, we suggest that the formation of $[Cu(\mathbf{4})_2]^+$ is precluded by its high TS energy.

Ligands **4** and **5** do not undergo homoleptic complex formation and so they are ideal candidates to react with weaker ligands, such as 4,4′-bipyridine (**13**). This ligand is of particular interest as palladium-4,4′-bipyridine complexes play an important role in molecular triangles and squares.[20] Compound **13** is also often used in the field of *crystal engineering* to prepare coordination polymers.[21,22] In our case, however, only formation of $[Cu_2(\mathbf{5})_2(\mathbf{13})](PF_6)_2$ was observed. The complex carries two additional ligands at copper(I), such as acetonitrile. Because a solid state structure is not available, we present here the PM3 calculated structure that rationalizes the strong NMR shift effects observed in the proton spectrum (Figure 3).

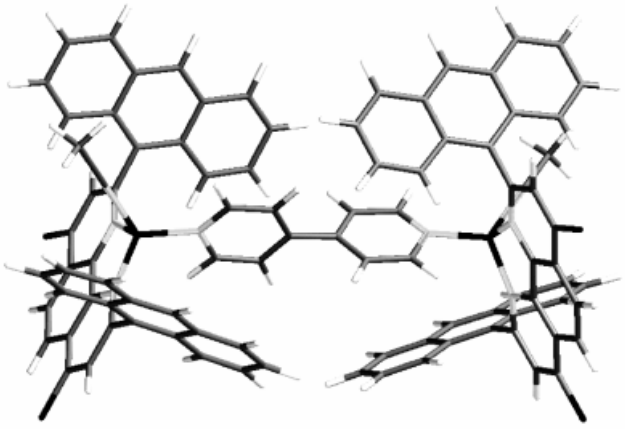


Figure 3. PM3 calculated structure of complex $[Cu_2(\mathbf{5})_2(\mathbf{13})](PF_6)_2$ including two bound acetonitrile ligands

Structure and Properties of the Complexes

Structure: To date there are no crystal structures available for the complexes and for this reason we have used the PM3 calculated structures (Figure 4) to obtain an idea about the arrangement of the phenanthroline and aryl residues. We noted above that the PM3 structure of **5** is in good agreement with the X-ray structure. One has to bear in mind, however, that the PM3 calculations failed to reproduce the weak π-π interaction between the 2,9-aryl groups and the phenanthroline. As this may lead to some distortion in the complex we only want to discuss a few key elements. For example, the angle between the two phenanthrolines is 90° (for $[Cu(\mathbf{4})(\mathbf{9})]^+$) and 87° (for $[Cu(\mathbf{2})]^+$ and $[Cu(\mathbf{3})]^+$), but 80° for $[Cu(\mathbf{4})]^+$. Accordingly, with increased bulk there are deviations from ideal tetrahedral coordination. In complex $[Cu(\mathbf{4})(\mathbf{9})]^+$ the arrangement of the ligands is hardly impeded by strain, but heavy distortions at the metal center and the phenanthroline and the 2,9-aryl substituents do show up in the strained homoleptic complexes. For example, the anthracenyl rings (10° to 14°) and the phenanthroline units (6° to 13°) are severely distorted from

planarity on going from $[Cu(\mathbf{2})]^+$ to $[Cu(\mathbf{4})]^+$, but are planar in the unstrained complex $[Cu(\mathbf{4})(\mathbf{9})]^+$.

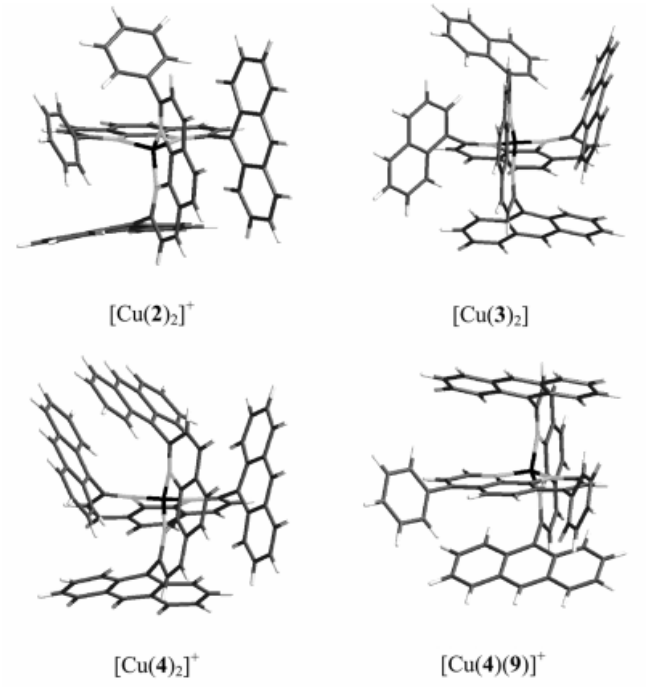

Figure 4. PM3 calculated structures of a few copper complexes

Electrochemical Measurements: The values for the oxidation potential are in the expected range for phenanthroline-type complexes.[23,24] It has been reported that these values depend on the nature of the substituents at the phenanthroline and that the redox potential becomes more positive when the metal ion is subjected to steric constraints that prevent rearrangement in the coordination sphere upon oxidation.[25] Comparison of the homoleptic and heteroleptic complexes shows that the oxidation potentials for the homoleptic complexes are higher than those for the heteroleptic ones because of the rigidity at the metal center. Moreover, the small ΔE_p values for $[Cu(\mathbf{2})_2](PF_6)$ and $[Cu(\mathbf{3})_2](PF_6)$ indicate that their reorganization is rather small on going from Cu^I to Cu^{II}, a situation in contrast to that observed with the other complexes. The results are in agreement with those found in earlier investigations.[12]

On going from $[Cu(\mathbf{4})(\mathbf{9})](PF_6)$ to $[Cu(\mathbf{5})(\mathbf{9})](PF_6)$, phenanthroline **4** is replaced by **5**, a ligand with additional alkyl groups in the 3,8-positions, and thus a small decrease of the oxidation potential is expected as alkyl groups are better σ-donors.[25] However, the reverse is found. Presumably, the back strain effect of the alkyl groups leads to a tighter arrangement at the metal center in $[Cu(\mathbf{5})(\mathbf{9})](PF_6)$.

Luminescence of Ligands and Complexes: Upon excitation at 346 nm all phenanthrolines **2**−**7** exhibit a fluorescence at 439−472 nm that is broadened due to interactions with the solvent. In agreement with textbook knowledge[26] we assign this emission to the $S_1 \rightarrow S_0 + h\nu$ radiative transition of the excited anthracenyl group attached to the 2- (and 9-) position of the phenanthroline core. Apparently, the sp^2-nitrogen donor atoms of the phenanthroline cannot quench the fluorescence, while efficient quenching is usually observed with appended tertiary amines.[27] In the series **2**−**4** (Figure 2), the emission maximum stays roughly the same, but the fluorescence intensity decreases in the order **4** > **3** >> **2**. Such behavior is to be expected from the well-known free rotor effect,[26] as in this series the twisting motion about the phenanthroline and 2,9-diaryl axis is clearly facilitated. When we compare **4** with **5** and **6** with **7** a strong decrease in the fluorescence intensity is registered, which could be due to the presence of 4- and 7-chloro substituents.[28]

Fluorescence at 472 nm is not observed upon complexation of **3** with copper(I). As the absorption maximum of $[Cu(\mathbf{3})_2]^+$ is located at 456 nm, the photoexcited anthracene is quenched by the MLCT process.[29] As a consequence, recognition of the uncomplexed ligand **3** by copper(I) is indicated through fluorescence quenching and, in principle, ligand **3** could be used as a quenchofluorimetric detector[30] towards Cu^I ions.

Conclusion

A series of homoleptic and heteroleptic bis(phenanthroline)copper(I) complexes is presented that is based on ligands carrying sterically bulky groups at the 2- and 9-positions. For the clean preparation of heteroleptic complexes two concepts are elaborated. The first one is based on the fact that steric blocking kinetically prevents the formation of the homoleptic complex having 2,9-diaryl substituents at the phenanthroline. The second one relies on the thermodynamic destabilization of the homoleptic complex having 2,9-diaryl substituents.

Experimental Section

General Remarks: $[Cu(MeCN)_4]BF_4$ [31] and $[Cu(MeCN)_4]PF_6$ [32] were prepared according to literature procedures. All other chemicals were commercially available and used without further purification. The solvents were distilled before use and dried with appropriate desiccants (CH_2Cl_2 from P_2O_5, MeCN from P_2O_5 and NaH, DMSO from calcium sulfate under reduced pressure). − ^1H NMR spectra were recorded on either Bruker AC 200 (200 MHz) or Bruker AC 250 (250 MHz) spectrometers (using the deuterated solvent as the lock and residual solvent as the internal reference). − IR spectra were recorded on a Perkin−Elmer 1605 FT-IR spectrophotometer. − Microanalyses were carried out with a Carlo Erba 1106 Elemental Analyzer. − Electrospray mass spectra (ES-MS) were recorded with a ThermoQuest LCQ Deca Finnigan. − Electrochemical measurements were performed with a Potentiostat Modell 362, Princeton Applied Research.

The solvent used for photophysical studies was CH_2Cl_2 (Merck, Uvasol). UV/Vis spectra were recorded on a J&M TIDAS II absorption spectrometer, while the emission spectra were obtained with a Spex Fluorolog 2 spectrofluorometer. To make comparisons possible in the emission measurements, the absorbance A for all ligands was the same (A = 1.11) at the excitation wavelength λ_{exc} = 346 nm.

The calculations were performed using *Spartan Pro* with the parameter set PM3(tm) for transition metals.[33] The geometries were

optimized using the Merck molecular force field (MMFF) and refined using the semiempirical method PM3(tm).

4,7-Dichloro-3,8-dihexyl-1,10-phenanthroline and 4,7-diethynylphenyl-3,8-dihexyl-1,10-phenanthroline were synthesized as reported previously.[8]

2-(9-Anthracenyl)-1,10-phenanthroline (6): A 1.5 M solution of *n*-butyllithium in pentane (6.60 mL, 9.90 mmol) was slowly added to a solution of 9-bromoanthracene (2.40 g, 9.32 mmol) in 100 mL of diethyl ether at 0 °C. The solution was allowed to stir for 60 min at 0 °C. A suspension of 1,10-phenanthroline (1.00 g, 5.48 mmol) in 40 mL of toluene was added. The solution first became yellow and then turned dark violet. The mixture was stirred for 48 h at room temperature. After the addition of water (60 mL) the layers were separated and the aqueous layer was extracted three times with dichloromethane (3 × 10 mL). The combined organic extracts were stirred with 20 g of activated MnO_2 for 2 h. The mixture was dried with $MgSO_4$ and filtered. After evaporation of the filtrate the resulting solid was separated by column chromatography (SiO_2, trichloromethane, R_f = 0.62). The second fraction contained the pale yellow product (1.30 g, 67% yield). − M.p. > 300 °C. − ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 7.29−7.34 (m, 2 H, 2′-H, 7′-H), 7.40−7.48 (m, 2 H, 3′-H, 6′-H), 7.58 (d, *J* = 8.9 Hz, 2 H, 1′-H, 8′-H), 7.60 (dd, *J* = 8.1 Hz, *J* = 1.7 Hz, 1 H, 8-H), 7.83 (d, *J* = 8.2 Hz, 1 H, 3-H), 7.88 (d, *J* = 8.9 Hz, 1 H, 6-H), 7.95 (d, *J* = 8.9 Hz, 1 H, 5-H), 8.07 (d, *J* = 8.4 Hz, 2 H, 4′-H, 5′-H), 8.28 (dd, *J* = 8.1 Hz, *J* = 1.7 Hz, 1 H, 7-H), 8.44 (d, *J* = 8.2 Hz, 1 H, 4-H), 8.57 (s, 1 H, 10′-H), 9.15 (dd, *J* = 4.4 Hz, *J* = 1.7 Hz, 1 H, 9-H). − ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 122.9 (C-8), 125.0 (C-3), 125.3, 125.6, 126.4, 126.5, 126.8, 127.4, 128.3, 129.0, 130.5, 131.3, 135.8, 135.9, 136.0, 137.8, 146.4 (C-10a), 146.5 (C-1a), 150.5 (C-9), 158.9 (C-2). − IR (KBr): $\tilde{\nu}$ = 3049 cm^{-1}, 1617, 1586, 1504, 1482, 1387, 1192, 844, 731, 668. − $C_{26}H_{16}N_2$: calcd. C 87.62, H 4.52, N 7.86; found C 87.39, H 4.76, N 7.59.

2-(9-Anthracenyl)-4,7-dichloro-3,8-di-*n*-hexyl-1,10-phenanthroline (7): To a solution of 9-bromoanthracene (4.98 g, 19.0 mmol) in dry diethyl ether (150 mL) was added dropwise 1.5 M *n*-butyllithium (13 mL) and the mixture was stirred for 9 h at 0 °C. After the addition of 4,7-dichloro-3,8-hexyl-1,10-phenanthroline (2.43 g, 6.42 mmol) the mixture was stirred for 3 d at room temperature. After hydrolysis with water (50 mL) and separation of the phases, the aqueous layer was extracted with dichloromethane (3 × 20 mL). The combined organic layers were stirred with activated MnO_2 (30.0 g, 343 mmol) for 1 h. The mixture was dried over magnesium sulfate and then filtered. After removing the solvent in vacuo, the residue was purified by column chromatography (SiO_2, trichloromethane, R_f = 0.76) and recrystallized from cyclohexane/*n*-hexane (1:1) to yield a yellow solid (1.40 g, 37%). − M.p. 161 °C. − ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 0.58 (t, *J* = 7.0 Hz, 3 H, CH_3), 0.79−0.90 (m, 2 H, CH_2), 0.87 (t, *J* = 7.0 Hz, 3 H, CH_3), 1.22−1.44 (m, 10 H, CH_2), 1.61−1.70 (m, 4 H, CH_2), 2.54 (t, *J* = 7.8 Hz, 2 H, CH_2), 2.98 (t, *J* = 7.8 Hz, 2 H, CH_2), 7.23−7.47 (m, 6 H, anthracenyl), 8.06 (d, *J* = 8.9 Hz, 2 H), 8.48 (d, *J* = 9.5 Hz, 1 H, 6-H), 8.55 (d, *J* = 9.5 Hz, 1 H, 5-H), 8.57 (s, 1 H, 10′-H), 8.92 (s, 1 H, 9-H). − ^{13}C NMR ($CDCl_3$, 63 MHz): δ = 13.7, 14.0, 21.9, 22.5, 28.4, 28.9, 29.0, 29.6, 30.5, 31.4, 31.5, 31.6, 107.8, 123.5, 123.6, 125.0, 125.8, 125.9, 126.2, 126.5, 127.5, 128.4, 130.5, 131.4, 134.3, 135.4, 137.0, 137.2, 141.0, 142.5, 152.1 (C-9), 159.7 (C-2). − IR (KBr): $\tilde{\nu}$ = 3050 cm^{-1} (m, Ar−H), 2953, 2926, 2855 (s, C−H), 1605 (m), 1570 (s), 1534 (s, arom. C=C), 1464 (s, C−H), 1391 (s), 1347 (m), 1316 (m), 1233 (m), 1040 (m, Ar−Cl). − $C_{38}H_{38}Cl_2N_2$: calcd. C 77.00, H 6.47, N 4.73; found C 76.71, H 6.51, N 4.62.

Synthesis of 2,9-Substituted Phenanthrolines: A typical procedure is shown here for compound **2**.

2-(9-Anthracenyl)-9-phenyl-1,10-phenanthroline (2): Under an inert atmosphere a 1.5 M solution of *tert*-butyllithium in pentane (1.40 mL, 2.10 mmol) was added to bromobenzene (298 mg, 1.86 mmol) in 5 mL of anhydrous diethyl ether at 0 °C. After 1 h stirring at 0 °C the solution was added dropwise to a suspension of **6** (178 mg, 500 μmol) in 10 mL of anhydrous toluene. The resulting deep-red solution was stirred overnight at room temperature. Water (10 mL) was then added. The layers were separated and the aqueous phase was extracted with dichloromethane (3 × 10 mL). The combined extracts were stirred with activated MnO_2 (2.00 g, 23.0 mmol) for 2 h, by which time the intense yellow color had disappeared. The mixture was dried over magnesium sulfate, filtered, and evaporated to give a solid. The crude product was recrystallized from cyclohexane to yield 138 mg (64%) of yellow crystals. − M.p. > 315 °C (decomp.). − ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 7.30−7.70 (m, 9 H), 7.86 (d, *J* = 8.3 Hz, 1 H, 3-H), 7.86−7.90 (m, 3 H, 8-H, 5-H, 6-H), 8.09 (d, 2 H), 8.18−8.22 (m, 2 H, 2′′-H, 6′′-H), 8.34 (d, *J* = 8.6 Hz, 1 H, 7-H), 8.43 (d, *J* = 8.3 Hz, 1 H, 4-H), 8.59 (s, 1 H, 10′-H). − ^{13}C NMR ($CDCl_3$, 63 MHz): δ = 120.4, 123.2, 125.1, 125.7, 125.8, 126.1, 126.6, 126.9, 127.8, 128.4, 128.6, 128.8, 129.1, 129.9, 130.4, 131.4, 135.9, 136.8, 139.6, 140.9, 146.3 (C-10a), 146.6 (C-1a), 157.3 (C-9), 158.3 (C-2). − IR (KBr): $\tilde{\nu}$ = 3042 cm^{-1} (m, C−H), 2923, (s, =C−H), 2845 (m), 1663 (w, C=C), 1587, 1542, 1483 (s, C=C), 1449 (w), 1356 (m), 1314, 1101, 1022, 886, 852 (s), 765, 732, 693 (vs), 615. − $C_{32}H_{20}N_2 \cdot 1H_2O$: calcd. C 85.31, H 4.92, N 6.37; found C 85.49, H 4.43, N 6.37.

Other examples of 2,9-substituted compounds were prepared by following the above procedure.

2-(9-Anthracenyl)-9-(1-naphthyl)-1,10-phenanthroline (3): Yield 25% of a yellow solid. − M.p. > 300 °C. − ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 7.23−7.53 (m, 8 H), 7.64 (d, *J* = 8.6 Hz, 2 H), 7.72 (d, *J* = 7.0 Hz, 1 H), 7.84−7.88 (br. s, 2 H, 5-H, 6-H), 7.86 (d, *J* = 8.3 Hz, 1 H, 3-H), 7.95 (d, *J* = 8.3 Hz, 1 H, 8-H), 8.05 (s, 1 H), 8.09 (d, *J* = 8.4 Hz, 2 H), 8.22 (d, *J* = 8.6 Hz, 1 H), 8.46 (d, *J* = 8.3 Hz, 1 H, 7-H), 8.53 (d, *J* = 8.3 Hz, 1 H, 4-H), 8.59 (s, 1 H, 10′-H). − ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 123.0, 124.8, 124.9, 125.2, 125.6, 125.9, 126.3, 126.4, 126.5, 126.9, 127.3, 127.5, 127.6, 127.7, 127.8, 128.0, 128.1, 128.4, 128.5, 129.3, 130.3, 131.4, 133.9, 135.6, 135.9, 136.4, 138.1, 140.6, 154.5, 158.4. − IR (KBr): $\tilde{\nu}$ = 3048 cm^{-1} (w, =C−H), 1621 (m, C=C), 1577, 1550, 1499, 1442, 1402, 1351, 1136, 1015, 888 (s), 850 (s), 788 (w), 732 (s), 630. − $C_{36}H_{26}N_2 \cdot 0.5H_2O$: calcd. 2,4-Bis(9-anthracenyl)-1,10-phenanthroline (8): Yield 39% of yellow crystals. − M.p.: > 300 °C. − ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 7.27 (d, J = 8.6 Hz, 1 H, 5-H), 7.35−7.56 (m, 8 H), 7.62 (d, J = 8.6 Hz, 1 H, 6-H), 7.57−7.64 (m, 2 H), 7.64 (dd, J = 7.7 Hz, J = 4.3 Hz, 8-H), 7.87−7.92 (m, 2 H), 7.94 (s, 1 H, 3-H), 8.04−8.16 (m, 4 H), 8.23 (dd, J = 7.7 Hz, J = 1.8 Hz, 1 H, 7-H), 8.56 (s, 1 H, 10′-H), 8.65 (s, 1 H, 10′′-H), 9.23 (dd, J = 4.3 Hz, J = 1.8 Hz, 1 H, 9-H). − ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 124.6, 125.0, 125.4, 125.9, 126.0 (2 ×), 126.4 (2 ×), 127.0, 127.7, 127.9, 128.0, 128.2, 128.5, 128.7, 129.0, 129.5, 130.3, 130.6, 131.5, 135.6, 135.9, 145.9, 146.0, 146.8 (C-10a), 147.1 (C-1a), 150.7 (C-9), 158.6 (C-2). − IR (KBr): $\tilde{\nu}$ = 3045 cm^{-1} (m, =C−H), 1617 (m), 1577 (m), 1541 (s), 1480 (s), 1442 (m), 1375 (w), 1342 (w), 1013 (m), 888 (s), 832 (s), 788 (s), 730 (vs), 652 (m), 614 (m). − $C_{40}H_{24}N_2 \cdot 0.75H_2O$: calcd. C 87.82, H 4.72, N 5.12; found C 87.94, H 4.72, N 4.99.

Data for Homoleptic Complexes. − General Procedure for the Synthesis of the Homoleptic Cu^I Complexes

[Cu(6)$_2$]BF$_4$: $[Cu(MeCN)_4]BF_4$ (42.0 mg, 134 μmol) was dissolved in anhydrous acetonitrile (5 mL) under an inert atmosphere at room temperature. Upon addition of **6** (80.0 mg, 268 μmol) in anhydrous dichloromethane (5 mL) the solution immediately turned to a deep red hue. After 30 min of stirring at room temperature, the solvent was removed in vacuo. The solid was purified by recrystallization from CH_2Cl_2/cyclohexane to yield [Cu(**6**)$_2$]BF_4 as orange needles (84 mg, 84%). − M.p. > 300 °C. − ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 6.81 (d, J = 8.9 Hz, 2 H), 7.02−7.24 (m, 6 H), 7.07 (dd, J = 8.1 Hz, J = 4.6 Hz, 2 H, 8-H), 7.38−7.44 (m, 4 H), 7.57 (d, J = 8.5 Hz, 2 H), 7.65 (dd, J = 4.6 Hz, J = 1.5 Hz, 2 H, 9-H), 7.69 (d, J = 8.0 Hz, 2 H, 3-H), 7.78 (d, J = 8.5 Hz, 2 H), 7.80 (d, J = 9.2 Hz, 2 H, 5-H), 7.83 (s, 2 H), 7.90 (d, J = 9.2 Hz, 2 H, 6-H), 8.25 (dd, J = 8.1 Hz, J = 1.5 Hz, 2 H, 7-H), 8.33 (d, J = 8.0 Hz, 2 H, 4-H). − ^{13}C NMR (50 MHz, CD_2Cl_2): δ = 125.3, 125.7, 125.9, 126.1 (2 ×), 126.3, 127.4, 127.5, 127.6, 128.2, 128.4, 129.1, 129.2, 129.3, 129.7, 130.1, 130.5, 131.0, 131.3, 132.6, 136.4, 137.9, 143.2, 144.2, 147.9 (C-9), 157.5 (C-2). − IR (KBr): $\tilde{\nu}$ = 3049 cm^{-1}, 1705, 1654, 1618, 1560, 1508, 1489, 1444, 1408, 1383, 1357, 1356, 1221, 1198, 1142, 1054, 883, 844, 734, 662. − $C_{52}H_{32}N_4CuBF_4 \cdot 0.5H_2O$: calcd. General Procedure for the Synthesis of Heteroleptic Cu^I Complexes: One equivalent of $[Cu(MeCN)_4]PF_6$ or $[Cu(MeCN)_4]BF_4$ was dis-

solved in dry dichloromethane under an inert atmosphere. One equivalent of the sterically hindered 2,9-substituted phenanthroline **4** or **5** was added, resulting in a yellowish solution. After 5 min stirring at room temperature one equivalent of 4,7-substituted phenanthroline was added and a deep red solution formed immediately. The mixture was stirred for another 30 min, and the solvent was removed in vacuo. The red solids were purified by column chromatography (silica gel, dichloromethane/methanol = 10:1) to remove traces of additional ligands and copper salts.

Data for Heteroleptic Cu^{I} Complexes

[Cu(4)(9)]BF$_4$: [Cu(MeCN)$_4$]BF$_4$ (34.5 mg, 110 μmol) was allowed to react with **4** (34.5 mg, 110 μmol) and **9** (58.5 mg, 110 μmol) to yield, after filtration and recrystallization from dichloromethane/cyclohexane, [Cu(**4**)(**9**)]BF$_4$ (99.0 mg, 88%) as orange crystals. − M.p. > 300 °C. − ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 6.59 (d, J = 5.0 Hz, 2 H, 3′′-H, 8′′-H), 6.92−7.13 (m, 8 H, anthracenyl), 7.14 (d, J = 5.0 Hz, 2 H, 2′′-H, 9′′-H), 7.23 (bd, J = 8.4 Hz, 4 H, anthracenyl), 7.31 (bd, J = 7.7 Hz, 4 H, anthracenyl), 7.41 (s, 2 H, 10′-H), 7.45 (s, 2 H, 5′′-H, 6′′-H), 7.57−7.68 (m, 10 H, phenyl), 8.27 (d, J = 8.0 Hz, 2 H, 3-H, 8-H), 8.46 (s, 2 H, 5-H, 6-H), 8.97 (d, J = 8.0 Hz, 2 H, 4-H, 7-H). − ^{13}C NMR (50 MHz, CD_2Cl_2): δ = 125.3, 125.9, 126.6 (2 ×), 127.0, 128.0, 128.7, 129.1, 129.5, 129.8, 130.4, 130.8, 131.0, 131.2, 131.4, 132.0, 136.0, 138.6, 139.0, 143.5, 146.1, 148.0, 148.9, 158.7. − IR (KBr): $\tilde{\nu}$ = 3055 cm^{-1}, 1654, 1618, 1560, 1492, 1421, 1354, 1059, 875, 845, 767, 734, 703, 628. − ESI-MS: calcd. for $C_{64}H_{40}N_4Cu^+$: m/z = 927.3, found m/z = 927.4. − $C_{64}H_{40}N_4CuBF_4 \cdot H_2O$: calcd. C 74.38, H 4.10, N 5.42; found C 74.21, H 4.15, N 5.12.

[Cu$_2$(5)$_2$(13)](BF$_4$)$_2$: [Cu(MeCN)$_4$]BF$_4$ (26.5 mg, 84.4 μmol) was allowed to react with **5** (64.9 mg, 84.8 μmol) and 4,4′-bipyridine (**13**) (6.50 mg, 42.0 μmol) in dichloromethane. After stirring for 2 h the product was precipitated by adding pentane. After filtration and washing with pentane the product was obtained as red crystals (34.1 mg, 49%). − M.p. > 120−135 °C. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 0.55 (t, J = 7.5 Hz, 12 H, CH_3), 0.65−0.95 (m, 12 H, CH_2), 1.25−1.43 (m, 12 H, CH_2), 2.60−2.75 (m, 8 H, CH_2), 3.65 (m, 8 H, CH_2), 5.96−6.10 (m, 4 H, 3′′-H, 5′′-H), 6.60−6.75 (m, 4 H, 2′′-H, 6′′-H), 7.10−7.20 (m, 12 H, anthracenyl), 7.20−7.35 (m, 12 H, anthracenyl), 7.85−7.95 (m, 8 H, anthracenyl), 8.43 (s, 4 H, 10′-H), 8.77 (s, 4 H, 5-H, 6-H). − ^{13}C NMR (63 MHz, $CDCl_3$): δ = 15.3, 23.7, 30.2, 30.7, 32.4, 33.8, 114.2, 126.7, 126.9, 127.2, 128.6, 129.3, 130.6, 130.7, 131.5, 132.7, 133.9, 142.4, 144.6, 146.6, 159.8, 159.9, 160.7. − IR (KBr): $\tilde{\nu}$ = 3051 cm^{-1} (m, Ar−H), 2955 (s), 2927 (s), 2856 (s, C−H), 1604 (s), 1534 (w, arom. C=C), 1458 (m, C−H), 1410 (w), 1084 (vs, B−F), 819 (m), 800 (m), 738 (s). − ESI-MS: calcd. for $C_{114}H_{100}N_6Cl_4Cu_2 \cdot CH_3CN^{2+}$: m/z = 931.8, found m/z = 932.0. − $C_{114}H_{100}N_6Cl_4Cu_2B_2F_8 \cdot 1CH_3CN \cdot 1CH_2Cl_2$: calcd. C 66.21, H 4.99, N 4.62; found C 66.31, H 5.26, N 4.98.

[Cu(5)(9)]PF$_6$: Reaction of [Cu(MeCN)$_4$]PF$_6$ (18.6 mg, 50.0 μmol) with **5** (38.5 mg, 50.0 μmol) and **9** (16.6 mg, 50.0 μmol) yielded [Cu(**5**)(**9**)]PF$_6$ (58.0 mg, 88%) as a red powder. − M.p. > 170 °C (decomp.). − ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 0.51 (t, J = 6.9 Hz, 6 H, CH_3), 0.73−0.96 (m, 12 H, CH_2), 1.36−1.42 (m, 4 H, CH_2), 2.73−2.77 (m, 4 H, CH_2), 6.60 (d, J = 4.9 Hz, 2 H, 3′-H, 8′-H), 6.91−6.95 (m, 4 H, anthracenyl), 7.03 (d, J = 4.9 Hz, 2 H, 2′-H, 9′-H), 7.08−7.17 (m, 12 H, anthracenyl), 7.43 (s, 2 H, 10′-H), 7.44 (s, 2 H, 5′-H, 6′-H), 7.58−7.66 (m, 10 H, phenyl), 8.78 (s, 2 H, 5-H, 6-H). − ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 13.6, 21.8, 28.7, 28.9, 30.6, 31.2, 123.3, 124.3, 124.5, 124.6, 124.9 (2 ×), 125.7, 126.6 (2 ×), 127.1, 127.5, 129.0, 129.2 (2 ×), 129.9, 133.2, 136.7, 139.8, 141.3, 142.8, 143.0, 146.4, 146.6, 157.5. − IR (KBr): $\tilde{\nu}$ = 3442 cm^{-1}, 2956, 2927, 2866, 2856, 1622, 1560, 1457, 840, 738, 557. − ESI-MS: calcd. for $C_{76}H_{62}N_4Cl_2Cu^+$: m/z = 1165.8, found m/z = 1165.9. − $C_{76}H_{62}N_4Cl_2CuPF_6 \cdot 1.5H_2O$: calcd. C 68.24, H 4.90, N 4.19; found C 68.18, H 4.40, N 4.20.

[Cu(5)(10)]PF$_6$: [Cu(MeCN)$_4$]PF$_6$ (18.6 mg, 50.0 μmol) was allowed to react with **5** (38.5 mg, 50.0 μmol) and 4,7-diethynylphenyl-3,8-di-*n*-hexyl-1,10-phenanthroline (**10**) (27.4 mg, 50.0 μmol) to afford [Cu(**5**)(**10**)]PF$_6$ (37.8 mg, 49%) as a dark red powder. − M.p. 146−148 °C. − ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 0.49 (t, J = 6.9 Hz, 6 H, CH_3), 0.76−0.83 (m, 8 H, CH_2), 0.95 (t, J = 6.9 Hz, 6 H, CH_3), 1.29−1.56 (m, 24 H, CH_2), 2.44 (m, 4 H, CH_2), 2.63 (m, 4 H, CH_2), 6.98−7.03 (m, 4 H, anthracenyl), 7.10−7.24 (m, 12 H, anthracenyl), 7.36 (s, 2 H, 10′-H), 7.41 (s, 2 H, 2′-H, 9′-H), 7.60−7.71 (m, 6 H, phenyl), 7.75 (m, 4 H, phenyl), 8.08 (s, 2 H, 5′-H, 6′-H), 8.79 (s, 2 H, 5-H, 6-H). − ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 13.6, 14.0, 21.7, 22.6, 28.4, 28.7, 29.7, 30.0, 30.4, 31.6, 31.7, 32.8, 83.0, 104.1, 121.8, 124.1, 124.5, 124.6, 124.8, 126.1, 126.3, 127.0, 127.1 (2 ×), 127.8, 128.8 (2 ×), 129.7, 129.9, 131.9, 132.7, 139.2, 139.4, 139.7, 142.7, 143.2, 147.1, 157.4. − IR (KBr): $\tilde{\nu}$ = 3449 cm^{-1}, 2953, 2924, 2854, 2208, 1620, 1558, 1539, 1506, 1457, 840, 756, 737, 557. − ESI-MS: calcd. for $C_{92}H_{86}N_4Cl_2Cu^+$: m/z = 1382.2, found m/z = 1382.0. − $C_{92}H_{86}N_4Cl_2CuPF_6$: calcd. Synthesis and Characterization of Epitaxial FAU-on-EMT Zeolite Overgrowth Materials

Ann M. Goossens,[a] Bart H. Wouters,[a] Piet J. Grobet,[a] Veronique Buschmann,[b] Lucien Fiermans,[c] and Johan A. Martens*[a]

Keywords: Crystal engineering / Epitaxial intergrowth / Overgrowth / Faujasite type Zeolites / Two-step synthesis

Epitaxial FAU zeolite films were achieved on micrometer-sized EMT support crystals using a two-step synthetic procedure, in which EMT support crystals with hexagonal-platelet morphology, were added to a synthesis gel for the crystallization of an FAU phase. Identification of the appropriate synthesis parameters made it possible to suppress homogeneous nucleation and initial breeding, and to promote the secondary nucleation of the FAU crystallites on the surface of the EMT support crystals. The presence of both an FAU and an EMT phase was verified with powder X-ray diffraction (XRD). Scanning electron microscopy (SEM) was used to confirm the formation of a layer of FAU crystallites on the EMT support crystals. The growth of the FAU phase was found to start at the corners and edges of the EMT support. An FAU crystallization front progressed from the edges towards the center of the hexagon until the EMT support crystals became completely covered by an FAU zeolite film with a thickness of ca. 300 nm. The compositional difference between the EMT support and the FAU film was investigated with ^{29}Si magic angle spinning (MAS) nuclear magnetic resonance (NMR) spectroscopy, X-ray photoelectron spectroscopy (XPS) and energy-dispersive analysis of X-rays (nano-EDAX). The continuous nature of the film was confirmed by the absence of intracrystalline mesopores, which was evidenced by nitrogen physisorption.

Introduction

The phase-pure zeolite samples used in a diversity of industrial applications are exceptions in the field of zeolite crystallization. Indeed, the majority of zeolite crystallization conditions used result in the formation of physical mixtures of zeolite phases and intergrowth materials. A pure zeolite phase is obtained only when the synthesis parameters are finely tuned. An overview of the different types of intergrowths relevant to zeolites, building on the classification proposed by Rao and Thomas,[1] is provided in Figure 1. Basically, there are two types of intergrowths. Polytypism can be pictured as a regular stacking, without mismatch of bonds, of different structurally uniform domains in each individual zeolite crystal. Epitaxy involves the oriented overgrowth of a zeolite crystal with a compositionally or structurally different zeolite phase. These epitaxial intergrowths, also called overgrowths, can be isotactic. This means that every atom of the interface belongs to both flanking structures constituting that interface.

Polytypical intergrowths of FAU/EMT,[2,3] ERI/OFF,[4,5] MFI/MEL,[6,7] MAZ/MOR,[8,9] and the ABC 6-membered ring structures[10,11] have been described in literature. In these layered materials, the individual domains are all externally accessible. Epitaxial intergrowths are the preferred type of intergrowths for obtaining a controlled microscopic separation, as well as the organization of catalytic, molecular sieving and/or adsorptive functions. Only a few examples of epitaxy have been given in literature so far. Wise et al.[12,13] observed an OFF/LEV overgrowth. De Vos Burchart et al.[14] reported the structural overgrowth of zeolite X onto zeolite A crystals. This was realized by a one-step synthesis in which the gel composition giving rise to zeolite A gradually changed to favor the crystallization of zeolite X. An analogous overgrowth of zeolite P on zeolite A was discussed by Breck[15] in terms of partial conversion of zeolite A into zeolite P. In the proposed molecular model for the oriented growth of zeolite X onto zeolite A, the binding efficiency, defined as the percentage of tetrahedrally coordinated T-atoms, is only 67%,[14] thus classifying this overgrowth amongst the nonisotactic systems.

It is common practice to add seed crystals of the desired zeolite phase to a synthesis batch to ensure product purity and/or to increase the rate of crystallization. The presence of seeds can result in a more rapid crystal growth on the surface of the seed crystals or can provoke secondary nucleation. Several mechanisms of secondary nucleation are known, such as micro-attrition, fluid shear, needle breeding and initial breeding, all resulting in the formation of a new population of crystals which eventually remain attached to the surface of the seed crystals.[16] In this work, we investigated the possibility of synthesizing epitaxial intergrowths of FAU-on-EMT by a two-step synthetic procedure, similar to seeding, in which a zeolite layer is grown over support crystals by a conventional crystallization method. Structural overgrowths of zeolite X onto zeolite A, and vice-versa,

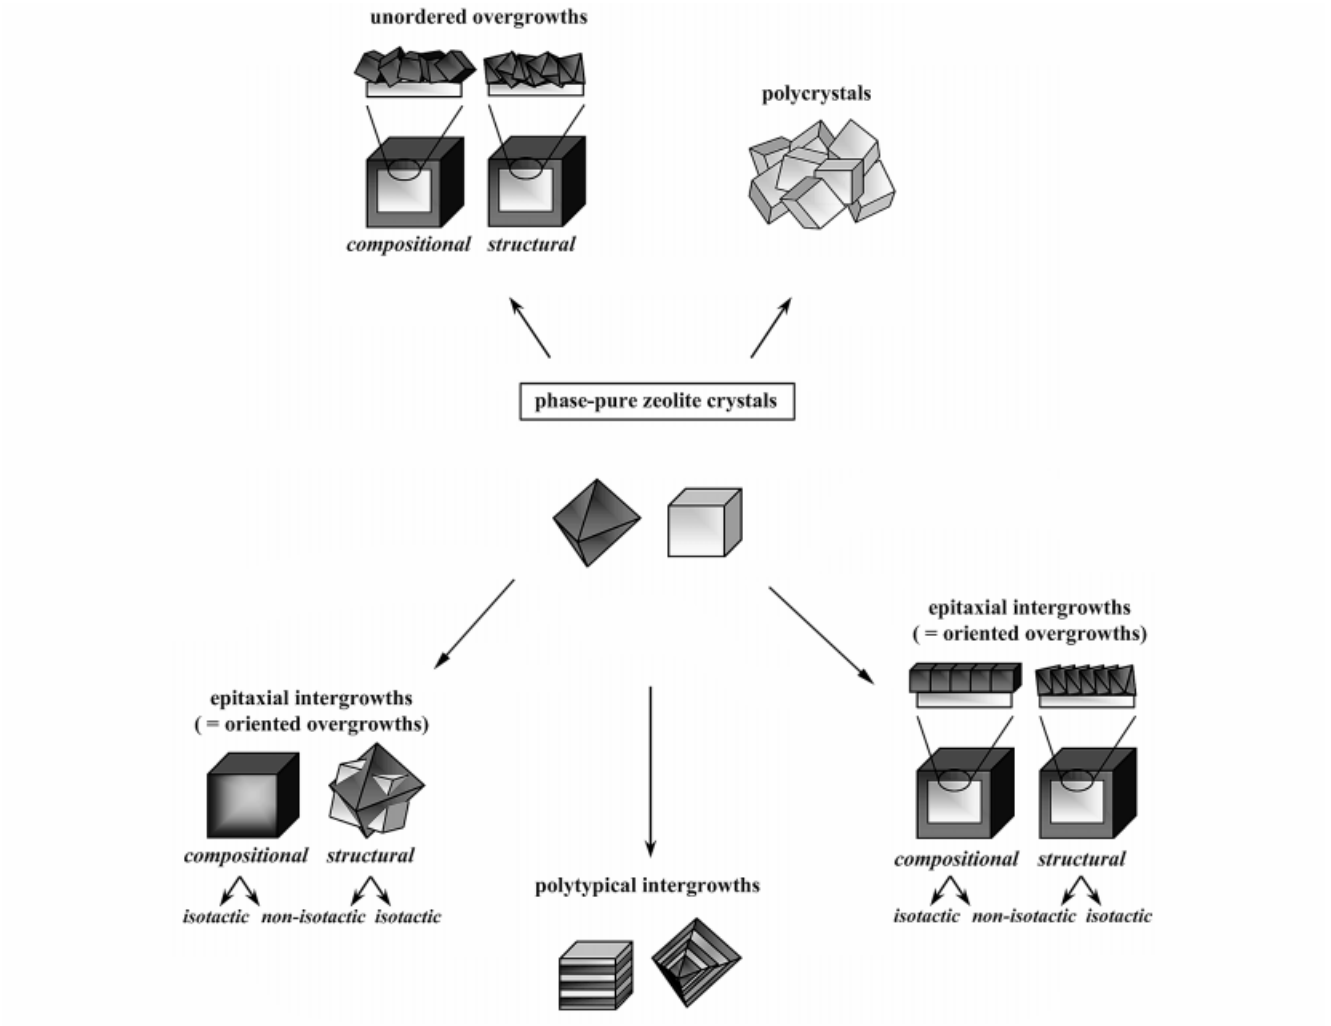

Figure 1. Zeolites and their intergrowths

were previously obtained by using this technique.[14] Compositional overgrowths of ZSM-5 and silicalite were also prepared using such a two-step synthesis.[17–19]

Two structure types with the mnemonic codes FAU and EMT belong to the family of faujasite type zeolites. The FAU and EMT zeolite topologies are structurally related. These zeolite frameworks can be constructed by linking hexagonal prisms into so-called faujasite sheets. Three different relative positions (*a*, *b*, and *c*) exist for these sheets, allowing linkage in the third crystallographic direction. Cubic stacking of faujasite sheets (*abc*) generates the FAU topology, whereas the hexagonal sequence (*ab*) gives rise to the EMT structure. Changes in the stacking sequence from *abc* to *ab* in one crystal produce an FAU/EMT polytypical material. A number of aluminosilicate zeolites have already been identified as polytypical intergrowths of FAU and EMT, ranging from intimately intergrown FAU and EMT layers to segregated FAU and EMT blocks.[3] In previous work, an epitaxial FAU-on-EMT overgrowth material consisting of micrometer-sized hexagonal-platelet EMT support crystals coated with a continuous layer of FAU crystallites was achieved. This was done by introducing the synthesized EMT crystals into a hydrogel for the crystallization of a FAU phase.[20] High-resolution transmission electron microscopy (HRTEM) in combination with selected-area electron diffraction (SAED) revealed the epitaxial relation between the EMT support crystals and the FAU crystallites. The epitaxial relations were: $\{0001\}_{\mathrm{EMTsupport}}$ // $\{111\}_{\mathrm{FAUlayer}}$ and $[11\bar{2}0]_{\mathrm{EMTsupport}}$ // $[\bar{1}10]_{\mathrm{FAUlayer}}$. Furthermore, HREM images of the interface suggested that the overgrowth was isotactic.

The purpose of the present study was to explore the synthesis conditions for the systematic overgrowth of EMT support crystals with an epitaxial and continuous film of FAU crystallites. The synthesis parameters investigated included the molar composition of the synthesis gel, the amount of support crystals added, the pretreatment of the support crystals, the aging and the crystallization time. The

products obtained were identified using X-ray diffraction (XRD) and scanning electron microscopy (SEM). Information about the silicon and aluminum incorporation in the overgrowth materials was obtained from ^{29}Si magic angle spinning (MAS) nuclear magnetic resonance (NMR). The possible presence of compositional heterogeneity in the overgrowing FAU crystallites was investigated using X-ray photoelectron spectroscopy (XPS) and electron nanoprobe analysis of X-rays (nano-EDAX). The crown-ether incorporation was monitored with thermogravimetric-differential thermal analysis (TG-DTA). The continuity of the micropores was verified using nitrogen physisorption.

Results and Discussion

Synthesis of Epitaxial FAU-on-EMT Overgrowth Materials

FAU-on-EMT overgrowth materials were synthesized in two steps. For each experiment, fresh EMT support crystals were prepared using the conventional recipe.[21] According to XRD (Figure 2, a), the EMT support crystals were of excellent crystallinity. The micropore volume of the calcined EMT samples was 0.31 mL/g, confirming the high crystallinity.[21] SEM pictures (Figure 3, a) show the typical hexagonal-platelet morphology. The diagonal dimension of the hexagonal prisms was between 2 and 3 μm, whereas the height varied from 0.5 to 1 μm. The different EMT samples used as supports were not phase-pure, but contained up to 30 wt-% of the FAU structure type. The FAU impurity was detected by XRD as explained in the FAU/EMT quantification section (vide infra). In the SEM pictures, some isolated octahedras were detected next to the abundant hexagonal prisms assigned to the EMT phase. These octahedrally shaped crystals are typical for FAU zeolites. However, their number was too small relative to the amount of FAU estimated by XRD. Most likely, part of the FAU impurity was present as a polytypical intergrowth with EMT. The presence of ca. 10 wt-% of polytypical FAU in EMT samples is not unusual and was also found by other workers.[2,22]

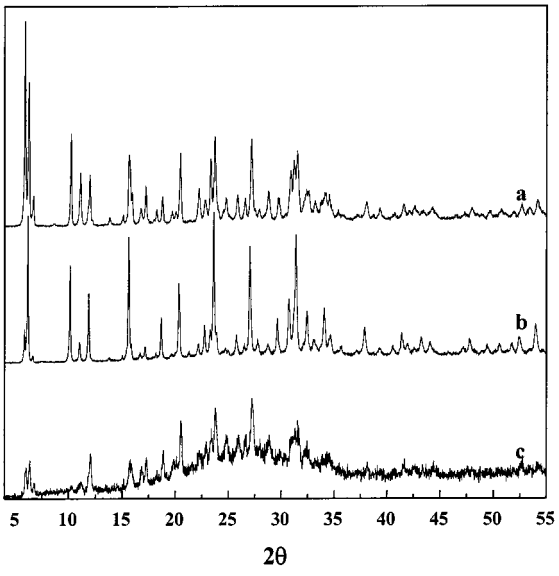

Figure 2. Powder X-ray diffraction patterns of calcined (a) EMT support crystals, (b) sample FauEmt-1a and (c) sample FauEmt-3a

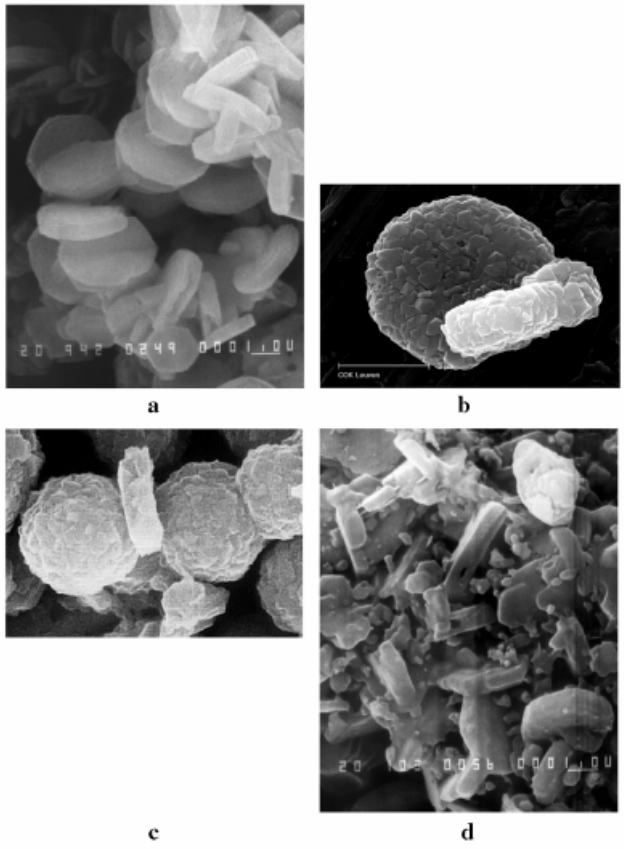

Figure 3. SEM pictures of (a) EMT support crystals, (b, c) sample FauEmt-1a, and (d) sample FauEmt-3a

In the second step, the EMT support crystals were added to a synthesis gel for the crystallization of a FAU phase, which optionally contained crown-ether molecules. Different experiments were conducted in order to explore the influence of the molar composition of the synthesis gel, the amount of EMT support crystals added, the pretreatment of the support crystals, the aging and the crystallization time (Table 1). The products obtained were characterized using powder X-ray diffraction (XRD) and scanning electron microscopy (SEM) (Table 1). The sample notation refers to the crystallographic nature of both phases (Fau for cubic and Emt for hexagonal faujasite). The Arabic number following the hyphen refers to a specific synthesis gel composition, whereas the final letter points to a specific set of synthesis parameters.

Influence of the Molar Composition of the FAU Synthesis Gel

In the first set of experiments (No. 1−5, Table 1), an amount of the synthesized EMT support crystals, typically 0.20 g per g of gel, was added to a freshly prepared FAU synthesis gel which optionally contained crown-ether molecules. The mixtures of gel and support crystals were immediately heated to the crystallization temperature of 373 K. Crystallization took 3 d.

In the literature, several aluminosilicate hydrogel compositions and inorganic bases have been proposed to pro-

duce FAU phases under hydrothermal conditions.[15] It is recognized that the alkalinity of the hydrogel, expressed as the OH^-/SiO_2 ratio, is a crucial parameter. Low alkalinities substantially decrease the nucleation, as well as the crystallization rate, yielding poorly crystalline FAU materials. A very alkaline inorganic gel with a Na_2O/SiO_2 ratio of 0.375 was used in experiment No. 1 (sample FauEmt-1a, Table 1). According to XRD (Figure 2, b), the product contained a considerable amount of FAU, as well as EMT. Since the diffraction lines of the cubic FAU phase coincide with the lines of the hexagonal EMT phase, the detection of FAU was based on the relative intensities of lines belonging to the hexagonal phase alone and of common reflections of the cubic and the hexagonal phase. SEM pictures (Figure 3, b) revealed that a layer consisting of small crystals, some of which had an octahedral shape, covered all faces of the hexagonal platelets. This morphology indicates that the FAU zeolite has nucleated and grown on all faces of the original hexagonal-platelet EMT support crystals, thus yielding a polycrystalline film. As the support crystals were no longer visible, the FAU film was considered to be continuous. The morphology of the overgrowth material further suggests that all FAU crystallites are oriented with one of their {111} planes parallel to the {0001} planes of the EMT support, classifying this FAU-on-EMT overgrowth material as an epitaxial intergrowth. Besides the EMT support crystals being coated with an oriented layer of FAU crystallites, a small number of roughly spherical particles with irregular surfaces were also observed (Figure 3, c). This particular EMT support originally contained 19 wt-% of FAU, part of it being present as isolated FAU crystals with octahedral morphology. Octahedral particles were no longer present in the overgrowth sample, indicating that the octahedral FAU crystals also became overgrown by a layer of FAU crystallites, resulting in these roughly spherical particles. The absence of octahedral crystals also indicated that homogeneous nucleation and initial breeding, both yielding an undesirable population of isolated FAU crystals, were suppressed.

The EMT-type zeolite can be synthesized from aluminosilicate hydrogels doped with 18-crown-6 ether and characterized by an Na_2O/SiO_2 ratio of 0.24.[23] An FAU phase can be obtained from a similar gel provided the sodium content is increased.[21] Inoculation of an 18-crown-6 ether containing FAU synthesis gel characterized by a high Na_2O/SiO_2 ratio of 0.375 with EMT support crystals (sample FauEmt-2a, Table 1), resulted in the formation of an epitaxial FAU-on-EMT overgrowth material.[20]

According to the original synthesis recipe of Delprato et al.,[23] the FAU structure type can crystallize from an aluminosilicate hydrogel containing 15-crown-5-ether, with an Na_2O/SiO_2 ratio of 0.24. The XRD pattern of the crystallization product obtained from such a gel inoculated with the synthesized EMT support crystals (sample FauEmt-3a, Table 1) is characterized by the presence of a broad amorphous background with maximum intensity around a 2θ value of 25° (Figure 2, c). The sharp diffraction lines correspond to those of the EMT support crystals added. SEM pictures (Figure 3, d) show intact support crystals embedded in an amorphous gel matrix. It is concluded that the overgrowth process did not take place in this system. An attempt was made to favor the overgrowth formation by increasing the Na_2O/SiO_2 ratio of the FAU synthesis gel from 0.24 to 0.375 (sample FauEmt-4a, Table 1). The crys-

tallization of FAU during the second step of the synthetic procedure was confirmed by XRD and SEM. Morphologically, sample FauEmt-4a was similar to sample FauEmt-1a and consisted of hexagonal-platelet EMT support crystals coated with a continuous layer of FAU crystallites. However, by increasing the amount of NaOH in the gel, both the sodium content, as well as the alkalinity were increased. In order to find out whether overgrowth formation was dependent on the sodium content or on the alkalinity, another experiment (No. 5) was performed in which the Na^+ content was increased at a constant OH^-/SiO_2 ratio (sample FauEmt-5a, Table 1). This was done by introducing part of the sodium as sodium aluminate. The product crystallized from such a gel was a FAU-on-EMT overgrowth material, similar to sample FauEmt-4a. Therefore, it is concluded that the sodium content of the gel, rather than the alkalinity, is the crucial parameter.

From experiments No. 1−5 (Table 1), it can be concluded that the synthesized EMT support crystals can be overgrown by a continuous, epitaxial layer of FAU crystallites using sodium aluminosilicate hydrogels, which optionally contained crown-ether molecules, provided the Na_2O/SiO_2 ratio of the gel is higher than or equal to 3.40. The crown-ether seemed to have no influence on the overgrowth morphology.

Influence of the Amount of Support Crystals Added

In the next set of experiments (No. 6−10, Table 1) different amounts of EMT support crystals were added in order to obtain samples with different degrees of overgrowth formation. The weight ratio of gel to support crystals was varied between 1.7:1 and 10:1, while keeping the other synthesis parameters constant, i.e. no aging of the synthesis gel and a crystallization time of 3 d.

The use of different amounts of support crystals allowed us to observe discrete stages in the process of overgrowth formation. Figure 4 (a−d) shows SEM pictures of samples for which decreasing quantities of EMT support crystals were used and illustrate the progress of the overgrowth formation. These pictures suggest that the secondary nucleation preference of the FAU phase decreases in the order, corners = edges > faces. This preference for corners and edges, representing the largest concentration of anchoring points, is observed both in the presence (sample FauEmt-2c, Figure 4, a), as well as in the absence of 18-crown-6 ether molecules (sample FauEmt-1c). At intermediate gel/support ratios, it can be seen that a rim of FAU crystallites progresses towards the center of the hexagonal faces (samples FauEmt-1b, Figure 4, b, and FauEmt-2b). When the weight ratio of the synthesized support crystals per gram of FAU synthesis gel is about 0.20, the EMT support crystals become completely covered with FAU crystallites. All of the FAU crystallites were oriented in the same way with respect to the support (samples FauEmt-2a, Figure 4, c, and FauEmt-1a). Further reduction of the amount of EMT support crystals (sample FauEmt-1d, Figure 4, d) resulted in the formation of roughly spherical FAU(18) crystals with an irregular surface, in addition to completely covering the hexagonal prisms. This indicates that, in this instance, the surface offered by the EMT support crystals is not large enough to suppress homogeneous nucleation from the FAU synthesis gel.

Influence of the Pretreatment of the Support Crystals

Thompson and co-workers[24,25] reported that handling seed crystals (washing, drying or calcining) prior to their addition to a synthesis gel always results in so-called initial breeding, hence yielding a new population of isolated crystals. The degree to which initial breeding occurs is dependent on the manner in which the seed crystals are pretreated. Since the two-step synthetic procedure, applied in this work, to produce overgrowth materials is similar to seeding, pretreatment of the support crystals was expected to be detrimental for the process of overgrowth formation.

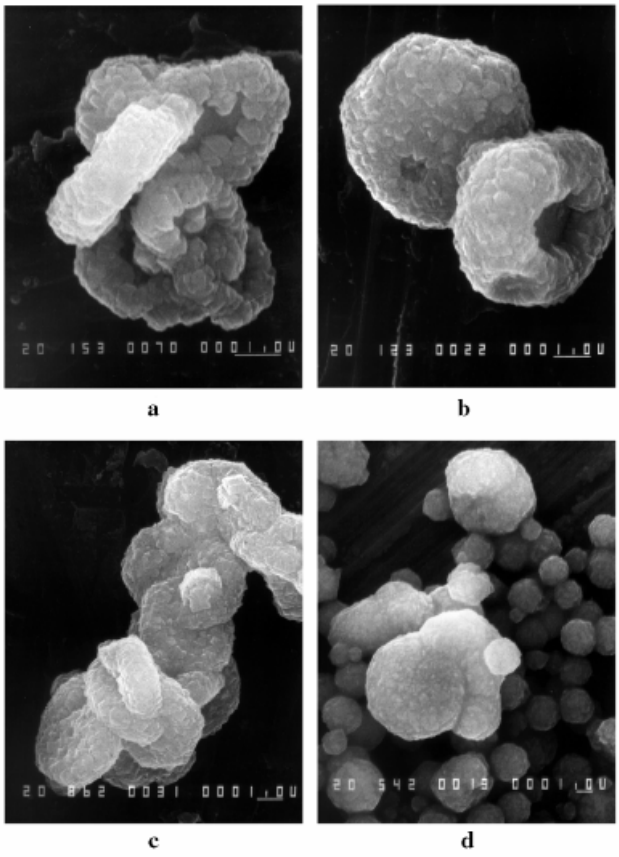

Figure 4. SEM pictures of samples (a) FauEmt-2c, (b) FauEmt-1b, (c) FauEmt-2a, and (d) FauEmt-1d

Two experiments (No. 11 and 12, Table 1) were conducted in which the EMT support crystals were first washed with deionized water until the pH value of the wash water reached 9 (sample FauEmt-2d, Table 1) or washed, dried, and calcined (sample FauEmt-2e, Table 1) before they were added to an FAU gel containing sodium and 18-crown-6 ether. In both cases, there was partial overgrowth with FAU crystallites (Figure 5, a−b). However, overgrowth formation was much less pronounced than in experiments without pretreatment of the support but with the same gel/support

ratio (sample FauEmt-2a, Figure 4, c). An undesirable population of isolated, roughly spherical FAU crystals with diameters of 1 to 2 μm, exhibiting irregular surfaces was also observed. This was most pronounced for sample FauEmt-2e (Figure 5, b). The initial breeding mechanism, favored by the drying and calcination, could have been responsible for the formation of these isolated FAU crystals.

Influence of the Aging and Crystallization Time

In all previous experiments the crystallization time was kept constant at 3 d. This length of time was long enough to obtain overgrowth materials from hydrogels with an Na_2O/SiO_2 ratio of 0.34 or 0.375. On the other hand, no crystallization took place from hydrogels with a reduced sodium content. Therefore, a new set of experiments (No. 13−24, Table 1) was conducted in order to investigate the influence of the aging and the crystallization time on the overgrowth process.

Ten overgrowth experiments (No. 13−22, Table 1), in which the synthesized EMT support crystals were added to an FAU synthesis gel containing sodium and 18-crown-6 ether, were performed using crystallization times from 4−120 h (samples FauEmt-2f to FauEmt-2o, Table 1). In the first 16 h of crystallization (samples FauEmt-2f to FauEmt-2i, Table 1), no FAU phase could be observed with XRD (Figure 6, a; sample FauEmt-2i). SEM pictures (Figure 7, a) show EMT support crystals embedded in an amorphous gel matrix. After 20 h of crystallization (sample FauEmt-2j, Table 1), some EMT support crystals were decorated at their edges with small FAU crystallites. A residual amorphous phase was also observed (Figure 7, b). Four hours later (sample FauEmt-2k, Table 1), the amorphous material was no longer present and all EMT support crystals were partially coated with small FAU crystallites (Figure 6, b and Figure 7, c). The use of longer crystallization times did not alter the morphology of the overgrowth product. In this series of experiments (No. 13−22, Table 1), it was clearly shown that the growth of the FAU phase starts at the corners and edges of the hexagonal-platelet EMT support crystals. An FAU crystallization front progresses subsequently from the edges towards the center of the hexagon. The same sequence was encountered in the set of experiments in which the amount of support crystals added was varied, while the crystallization time was kept constant (No. 6−10, Figure 4, a−d).

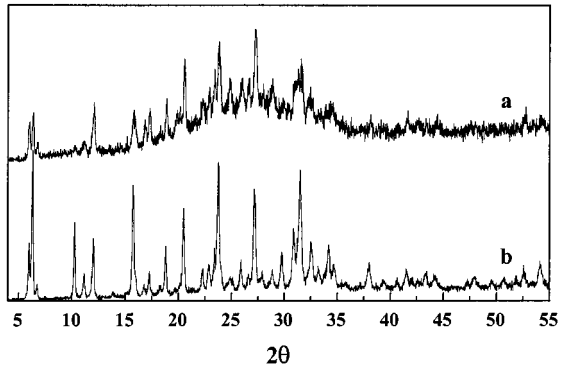

Figure 6. Powder X-ray diffraction patterns of calcined samples (a) FauEmt-2i and (b) FauEmt-2k

In order to evaluate whether a longer crystallization time would be necessary for overgrowth formation in the systems of the present study with a low sodium content, the crystallization time of experiment FauEmt-3a (Table 1) was prolonged from 3 to 6 d (sample FauEmt-3b, Table 1). This did not result in the transformation of the amorphous synthesis gel into a crystalline product, thereby indicating that crystallization of an FAU phase in the presence of support crystals is not possible from freshly prepared synthesis gels characterized by an Na_2O/SiO_2 ratio of 0.24.

Aging the low alkaline FAU synthesis gel containing 15-crown-5 ether for 3 d at room temperature before the EMT support crystals were added to it (sample FauEmt-3c,

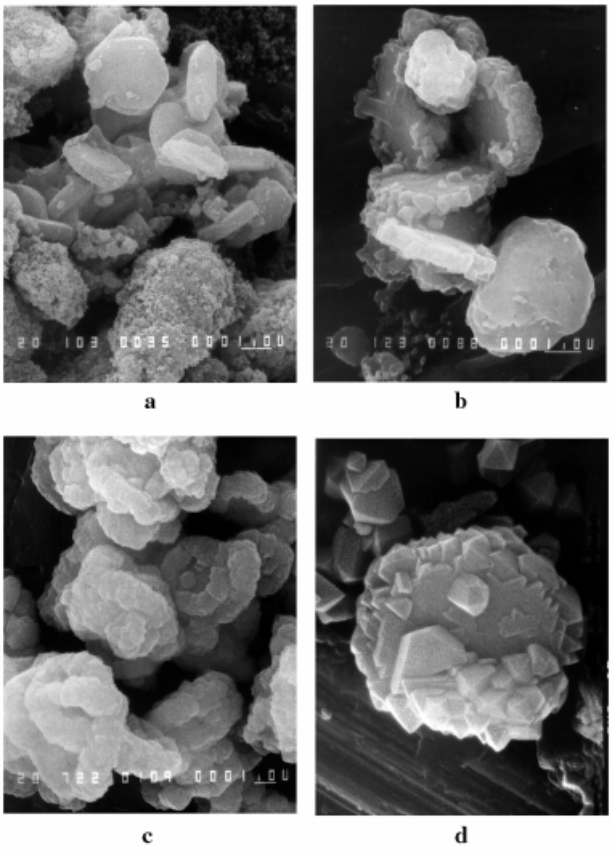

Figure 7. SEM pictures of samples (a) FauEmt-2i, (b) FauEmt-2j, (c) FauEmt-2k, and (d) FauEmt-3c

Table 1), resulted in the formation of an epitaxial FAU-on-EMT overgrowth material. However, the EMT support crystals were not completely covered by FAU crystallites, and a new population of isolated FAU crystals with octahedral morphology was also obtained (Figure 7, d). In this case, the hydrogel was supersaturated, giving rise to homogeneous nucleation of an FAU phase along with secondary nucleation of FAU crystallites on the surface of the EMT support crystals.

FAU/EMT Quantification

The amount of FAU and EMT in the FAU-on-EMT overgrowth materials was estimated with XRD by using a calibration curve. For this purpose, two calcined overgrowth samples were quantified using the Rietveld refinement technique.[26] These reference samples, FauEmt-2a and FauEmt-2c, contained 80 and 51 wt-% of the FAU phase, respectively (Table 2). Most of the FAU-on-EMT overgrowth materials obtained in this study have FAU contents in this range. The reference zeolite powders were physically mixed in five different proportions and the XRD patterns of these mixtures were recorded. The peak intensities of four selected diffraction lines belonging to the EMT phase alone (Table 3) and of five common reflections of the FAU and the EMT phase (Table 3), were obtained by integration and summation. The EMT content (in wt-%) was correlated to the intensity ratio of these sums ($I_{EMT}/I_{EMT+FAU}$). The experimental data points were fitted with the parabolic relation given in Equation (1).

$$\text{EMT (wt-\%)} = 68 \times (I_{EMT}/I_{EMT+FAU})^2 + 108 \times I_{EMT}/I_{EMT+FAU} + 1 \quad (1)$$

The FAU and EMT contents of some selected overgrowth samples and of the EMT support crystals were derived from XRD using Equation (1), and reported as absolute weights in Table 2. It is clear from this table that the weight of EMT in the overgrowth product was systematically lower than the weight of the EMT phase in the support crystals added. This suggests that part of the EMT phase dissolved during the overgrowth process. The dissolution behavior of the EMT crystals was therefore studied in more detail.

Dissolution of the Support Crystals

It is known that in strong mineral bases, siliceous frameworks are more soluble than aluminosilicate frameworks. The reason for this is the more facile base-catalyzed hydrolysis of silyloxy bridges, whereas the tetrahedral aluminum centers in an aluminosilicate lattice are relatively inert to hydroxide attack due to the negative framework charge associated with these centers.[27−29]

In order to obtain some information about the dissolution behavior of the EMT support crystals in basic environments, such as in the gels used for the formation of FAU-on-EMT overgrowth materials, two experiments were conducted. In the first experiment (EMT-A), a FAU synthesis gel containing sodium and 18-crown-6 ether was aged for 3 d at room temperature. The solid phase was separated from the liquid phase by ultra-centrifugation at 17 000 rpm for 2 h. A mass of 5 g of the synthesized EMT crystals was added to 25 mL of this liquid. This particular batch of EMT crystals did not contain any FAU, according to XRD. In the EMT-B experiment, 5 g of the same EMT crystals was suspended in 25 mL of a 2.5 M NaOH solution. The resulting slurries were transferred into PTFE-lined stainless-steel autoclaves, which were kept at 373 K for 3 d. The products were recovered by vacuum filtration, washed with deionized water and dried at 333 K. Calcination was done in a muffle furnace at 823 K for 20 h.

By comparing the weight of the product with that of the EMT crystals added (on a calcined basis), it was found that 52 and 68 wt-% of EMT had dissolved in experiments A and B, respectively. The XRD pattern of EMT-A (Figure 8, a) corresponded to that of EMT. The diffraction lines belonging to the EMT structure type were somewhat less intense than in the original EMT sample (Figure 2, a). In sample EMT-B, XRD confirmed the formation of zeolite P, as well as residual EMT (Figure 8, b). The formation of zeolite P is often observed in Ostwald successive phase transformations of faujasite type zeolites which are left in their mother liquor for some time.[30,31]

The EMT-A and EMT-B samples were examined using SEM (Figure 9, a−b) and HRTEM (Figure 10, a−c). All EMT-A crystals showed dissolution to a similar extent. The dissolution caused the formation of pits over the entire sur-

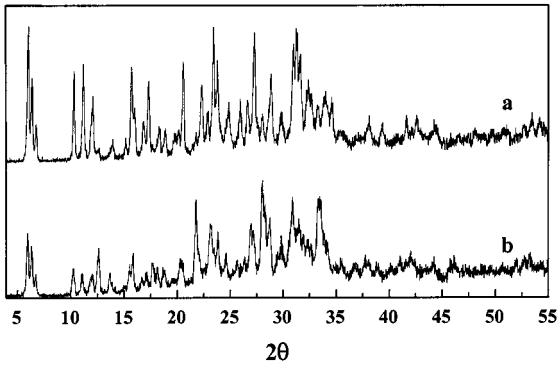

Figure 8. Powder X-ray diffraction patterns of calcined samples (a) EMT-A and (b) EMT-B

face of the crystals (Figure 9, a, and Figure 10, a). The higher degree of dissolution of sample EMT-B relative to that of EMT-A was seen in the SEM and HRTEM pictures (Figure 9, b, and Figure 10, b–c). Many EMT-B crystals had decomposed into smaller fragments. Some particles retained their initial hexagonal-platelet morphology and were more strongly dissolved at the center than at the outer rim. The larger particles with smooth surfaces, which could be observed in sample EMT-B with the SEM (Figure 10, b), are most likely zeolite P crystals. It is known from the literature that the Si and Al positioning in the EMT crystals synthesized with 18-crown-6 ether is not uniform.[32] The 12-MRs circumscribing the hyperchannels running in the direction perpendicular to the hexagonal faces are more siliceous (Si/Al ratio of 5.7) than the 12-MRs delineating the channels running parallel to the hexagonal faces and connecting the hypocages with the hyperchannels. This could explain why the dissolution was more pronounced in the direction of the hyperchannels and why the outer rim, exposing more Al-rich 12-MRs, is more resistant to dissolution by the base.

The Si/Al ratios of the partially dissolved EMT crystals of samples EMT-A and EMT-B, as determined with nano-EDAX, varied between 2.2 and 1.3, depending on the degree of dissolution. These low values indicate that EMT samples recovered after base-treatment are significantly enriched with aluminum, confirming the selective removal of SiO_2 in the alkaline solutions. Phase-pure EMT crystals with such low Si/Al ratios have not been reported previously. The low Si/Al ratios imply that silicon has been substituted by aluminum in the residual EMT framework. Reinsertion of aluminum into faujasite type zeolites is possible provided a concentrated solution of a strong base is present.[33]

The parent EMT sample, and the EMT-A and EMT-B samples were characterized with nitrogen physisorption. The external surface area, the micropore volume and the micropore diameter calculated from the adsorption branch of the isotherms are given in Table 4. All isotherms are of type I revealing the presence of a microporous solid. The micropore volumes of EMT-A and EMT-B were 0.26 and 0.14 mL/g (Table 4), respectively. In both samples, there was very little nitrogen uptake in the P/P_0 range of 0.1 to 0.8, indicating the absence of capillary condensation in small mesopores. The nitrogen uptake at P/P_0 values exceeding 0.8 is indicative of the presence of large mesopores, typically present in the interstitial voids between particles. The generation of 28 and 37 m^2/g of external surface area in EMT-A and EMT-B, respectively, compared with 4 m^2/g in the original EMT sample, can be explained by an increase of the surface roughness (sample EMT-A) and a decrease in the particle size (sample EMT-B). It is concluded that the dissolution process did not generate mesopores in the crystals, suggesting that the dissolution occurred through the removal of framework fragments in a block-wise manner. The micropore diameter determined using the Horvath–Kawazoe approach increased from 0.64 to

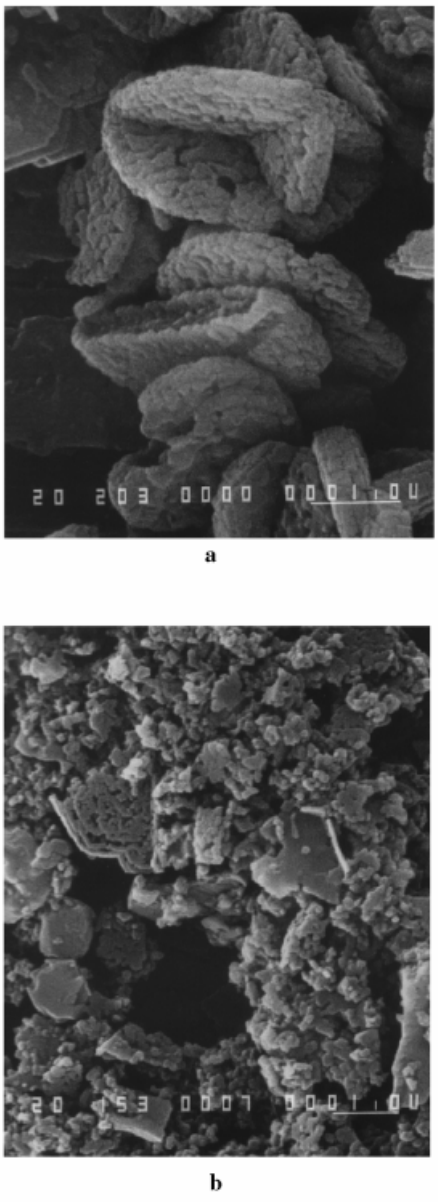

Figure 9. SEM pictures of samples (a) EMT-A and (b) EMT-B

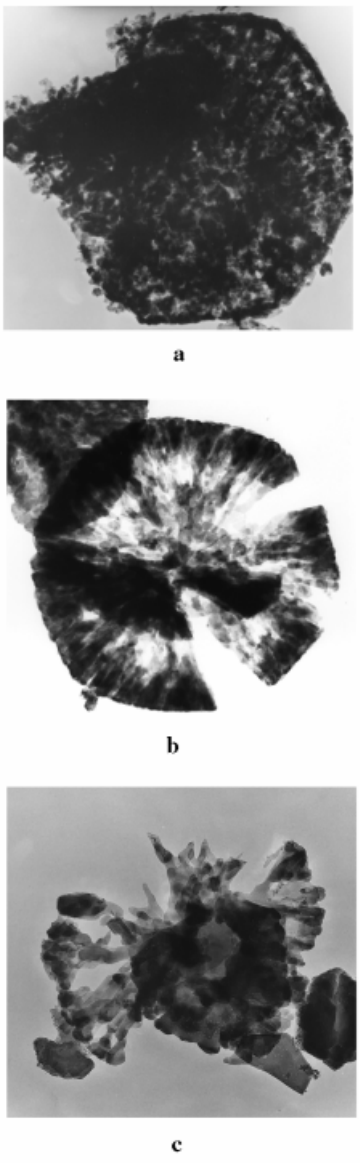

Figure 10. HRTEM pictures of samples (a) EMT-A and (b, c) EMT-B

0.65 nm for sample EMT-A. Such an increase is in agreement with the enrichment of the framework with aluminum.

Characterization of Both the FAU and the EMT Phase

In the previous section, it was shown how EMT crystals partially dissolve in the alkaline conditions of synthesis gels. In the two-step synthetic procedure for overgrowth formation, the material balance suggested that a significant part of the EMT crystals dissolved (Table 2). In this section, the FAU-on-EMT overgrowth materials were characterized in more detail in order to find out the extent to which the EMT support crystals were altered during the overgrowth process.

FAU-on-EMT overgrowth samples synthesized with three types of FAU gels and with different degrees of overgrowth formation were characterized using nitrogen physisorption (Table 5). The adsorption isotherms of the FAU-on-EMT overgrowth materials were similar to those of the EMT support crystals. The absence of nitrogen uptake in the P/P_0 range of 0.1 to 0.8 was indicative of the absence of mesopores inside the particles, and thus for the continuous nature of the FAU film. The micropore volume of all samples was between 0.29 and 0.32 mL/g (Table 5), as is expected for FAU and EMT phases of high quality.[21] The high micropore volume also indicated that the micropores of both the FAU layer, as well as the EMT support were accessible to nitrogen. For all overgrowth samples investigated, the specific external surface area was below 10 m^2/g (Table 5), this value being only a little higher than the specific external surface area of the support crystals (4 m^2/g). The external surface area increased proportionally with the

Table 4. External surface area, micropore volume and micropore diameter of calcined EMT samples, before and after base-treatment, as determined from their N_2 adsorption isotherms

Sample	External surface area [m^2/g]	Micropore volume [mL/g]	Micropore diameter [nm]
EMT	4	0.31	0.64
EMT-A	28	0.26	0.65
EMT-B	37	0.14	–[a]

[a] Determination not reliable.

Table 5. External surface area, micropore volume and micropore diameter of selected overgrowth samples (calcined), as determined from their N_2 adsorption isotherms

Sample	FAU (wt-%)	External surface area [m^2/g]	Micropore volume [mL/g]	Micropore diameter [nm]
FauEmt-1a	74	9	0.29	0.67
FauEmt-2a	80	8	0.30	0.68
FauEmt-4a	76	9	0.29	0.65
FauEmt-1b	61	7	0.29	0.66
FauEmt-1c	45	5	0.30	0.65
FauEmt-2b	51	4	0.32	0.65
FauEmt-2c	62	7	0.31	0.67

FAU content of the overgrowth samples (Table 5). Therefore, the specific external surface area could be attributed to the FAU crystallites exposing more external surface area than the EMT support crystals, owing to their smaller size. The micropore diameters derived from the nitrogen adsorption isotherms using the Horvath–Kawazoe approach were in the range of 0.65 to 0.68 nm, and in agreement with the presence of 12-MRs. The micropore diameters showed a systematic increase with increasing FAU content (Table 5). Nitrogen physisorption showed that the EMT core of the FAU-on-EMT overgrowth materials was rather intact. Furthermore, it showed that the significant alterations, observed in the base-treated EMT-A and EMT-B samples, did not take place in the EMT crystals, which were overgrown by a layer of FAU crystallites. It seems that of all the EMT support crystals added, a fraction became overgrown, whereas the rest dissolved completely. The absence of particles resembling the partially dissolved EMT-A and EMT-B samples in the SEM images of all FAU-on-EMT overgrowth materials supports this hypothesis.

The distribution of Si(*n*Al) environments in the EMT support crystals and in some selected FAU-on-EMT overgrowth samples was determined with ^{29}Si MAS NMR. The ^{29}Si MAS NMR spectrum of the EMT support crystals is shown in Figure 11, a. This spectrum can be simulated by five Gaussian peaks with the maxima positioned at chemical shift values of $\delta = -105.80$, assigned to Si(0Al); at $\delta = -101.21$ and -99.69, both assigned to Si(1Al); at $\delta = -94.06$, assigned to Si(2Al); and at $\delta = -89.13$, assigned to Si(3Al). A signal for Si(4Al) environments expected at $\delta \approx -84$ could not be distinguished from the background. From this simulation, the framework Si/Al ratio of the support crystals was calculated to be 3.4. The ^{29}Si MAS NMR spectra of FAU-on-EMT overgrowth samples with FAU content between 74 and 80 wt-%, and prepared using three types of FAU synthesis gels (samples FauEmt-1a, FauEmt-2a, and FauEmt-4a) are shown in Figure 11 (b–d). The spectra were simulated with Gaussian curves, as explained for the support crystals. An additional small line at $\delta = -84$, representing Si(4Al) environments, was present. The Si(*n*Al) distributions and the framework Si/Al ratios of the support crystals and the overgrowth samples are presented in Table 6. The Si(*n*Al) distributions are similar amongst the selected overgrowth materials, but significantly different from that of the support crystals. The population of silicon in the Si(0Al) and Si(1Al) sites is lower, and that in the Si(2Al) and Si(3Al) sites is higher than in the support (Table 6). The framework Si/Al ratio of the overgrowth sample prepared from an inorganic aluminosilicate hydrogel was 2.7 (sample FauEmt-1a, Table 6). In the presence of crown-ether molecules, a slightly higher Si/Al ratio of 2.9 was obtained (samples FauEmt-2a and FauEmt-4a, Table 6).

In another series of samples, the degree of overgrowth formation was varied between 51 and 80 wt-% by decreasing the amount of support crystals added to an FAU synthesis gel containing sodium and 18-crown-6 ether (samples FauEmt-2c to FauEmt-2a). The Si(*n*Al) distributions of these overgrowth samples are also given in Table 6. It was observed that when the FAU content increased, the concentration of Si(4Al), Si(3Al), and Si(2Al) environments increased, whereas the population of silicon in the Si(1Al) and the Si(0Al) sites decreased. This resulted in a decreasing framework Si/Al ratio with increasing FAU content from 3.1 for an FAU content of 51 wt-% to 2.9 for an FAU content of 80 wt-% (Table 6). The increase in the micropore diameter with increasing FAU content of the FAU-on-EMT overgrowth materials (Table 5) can be explained by the en-

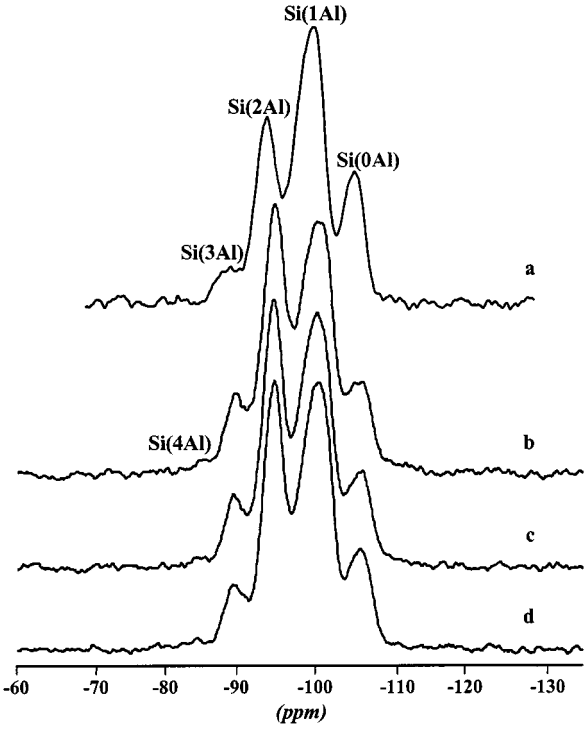

Figure 11. ^{29}Si MAS NMR spectra of: (a) calcined EMT support crystals, and calcined overgrowth samples (b) FauEmt-1a, (c) FauEmt-2a, and (d) FauEmt-4a

represent the weight fractions of support and FAU layer in the FAU-on-EMT overgrowth products, respectively.

$$Si/Al_{FAUlayer} = [Si/Al_{overgrowth} - Si/Al_{support} \times fraction_{support}]/fraction_{FAUlayer} \quad (2)$$

The $Si/Al_{FAUlayer}$ ratios of samples prepared using different FAU gel compositions (samples FauEmt-1a, FauEmt-2a and FauEmt-4a) are listed in Table 6. The FAU layer grown in the presence of crown-ether molecules was characterized by a Si/Al ratio of 2.7 (samples FauEmt-2a and FauEmt-4a). This value is in good agreement with the Si/Al ratio of FAU crystallized homogeneously from such gels in the absence of support crystals.[21] In the absence of crown-ether molecules, a value of 2.3 was obtained (sample FauEmt-1a). This Si/Al ratio is in the expected range for NaY zeolites synthesized from such inorganic gels. The series of samples with different degree of overgrowth formation (samples FauEmt-2c to FauEmt-2a, Table 6) displayed $Si/Al_{FAUlayer}$ ratios from 2.5 for FAU crystallites growing only at the corners and edges of the support crystals (sample FauEmt-2c), to 2.7 for a continuous film of FAU crystallites (sample FauEmt-2a).

In the sample FauEmt-2a, the EMT support crystals were completely covered by FAU crystallites. Therefore, the Si/Al ratio of the FAU layer could also be determined by X-ray photoelectron spectroscopy. The Si/Al ratio according to XPS, and representative of the external surface of the FAU crystallites was 2.8. The agreement with the NMR spectroscopic data which showed a Si/Al ratio of 2.7 was excellent. This provides a strong argument for the validity of the assumptions made in the exploitation of the NMR spectroscopic data with Equation (2), in general, and of the assumed intactness of the EMT support crystals, in particular. According to XPS, the Na/Al stoichiometry was close to unity (Na/Al = 0.97), confirming that the charges originating from the incorporation of Al atoms in the framework were balanced by Na cations.

Table 6. Framework Si/Al ratios and percentage distribution of the different Si(*n*Al) environments as determined by ^{29}Si MAS NMR spectroscopy

Sample	FAU (wt-%)	Si(4Al)	Si(3Al)	Si(2Al)	Si(1Al)	Si(0Al)	Si/Al overgrowth	Si/Al FAU layer
Support	0−19	0	5	25	52	18	3.4	–
FauEmt-1a	74	2	9	34	43	12	2.7	2.4
FauEmt-2a	80	1	9	32	44	14	2.9	2.7
FauEmt-4a	76	1	8	31	47	13	2.9	2.7

FauEmt-2c	51	0	7	28	49	16	3.1	2.5

richment of the sample with aluminum through the FAU phase. Indeed, aluminum enrichment is known to give rise to an expansion of the unit cell.

For the calculation of the Si/Al ratio of the FAU layer based on the ^{29}Si MAS NMR spectroscopic data, the following assumptions were made. It was assumed that a number of EMT support crystals added did not become covered with FAU crystallites, but dissolved completely. Furthermore, it was assumed that there was neither dissolution, nor alteration of the Si/Al ratio of the EMT support crystals, which became overgrown by FAU crystallites. An additional complication in the calculation was the presence of FAU in the EMT support. Part of the FAU impurity was present as a polytypical intergrowth with EMT, the rest as isolated crystals with octahedral shapes. It was assumed that the FAU impurity had the same Si/Al ratio as the EMT phase, and that it dissolved or became overgrown in the same proportion as the EMT support crystals. These assumptions led to the expression of Equation (2) for the Si/Al ratio of the FAU layer, in which $fraction_{support}$ and $fraction_{FAUlayer}$

It was possible to determine the Si/Al ratio of individual FAU crystallites of sample FauEmt-2a by using electron nanoprobe analysis (nano-EDAX). It was found that the FAU crystallites grown at the corners and edges of the EMT support crystals had a Si/Al ratio of 2.5, whereas the FAU crystallites grown in the center of the basal $\{0001\}_{EMT}$ planes had an Si/Al ratio of 2.8. There were many more crystallites at faces than at corners and edges, thus explaining why the overall Si/Al ratio of the FAU layer, deter-

mined by NMR spectroscopy and XPS, corresponded to that on the $\{0001\}_{EMT}$ planes. The FAU crystallites start growing at the corners and edges of the EMT support crystals and hence the first FAU crystallites formed are richer in aluminum than the crystallites formed at a later stage. In a sample in which overgrowth formation was limited to the corners and edges of the support by increasing the amount of support crystals added, the Si/Al ratio was indeed 2.5 (sample FauEmt-2c, Table 6). The increase in the Si/Al ratio of the FAU crystallites during the overgrowth process may be explained by the decrease in the pH during the crystallization of the faujasite type zeolite in the presence of crown ethers.[23] Depletion of aluminum in the synthesis gel might be another reason for this behavior.

The EMT support crystals were prepared in the presence of 18-crown-6 ether, whereas the synthesis gel for the FAU layer optionally contained crown-ether molecules. The incorporation of crown-ether molecules in the support crystals and some selected overgrowth materials was studied with thermogravimetric-differential thermal analysis (TG-DTA). Typical TGA/DTA profiles of the EMT support crystals and a representative FAU-on-EMT overgrowth material, recorded under He/O_2 are given in Figure 12. The weight-losses observed during heating can be attributed to the endothermic desorption of water, followed by a multiple-step exothermic decomposition of crown-ether molecules.[34] On the basis of this last weight-loss, the crown-ether content of the support crystals, as well as of some selected overgrowth materials were calculated and expressed as the number of crown-ether molecules per 192 T-atoms, representing 8 large cages in both the FAU and the EMT structure (Table 7). The number of crown-ether molecules in the EMT support crystals corresponded to approximately 9.5 molecules per 8 cages (Table 7). The presence of an excess of crown-ether molecules relative to the number of cages is in agreement with previous data.[21] Assuming that the crown-ether content of the support crystals did not change during the overgrowth process, the amount of crown-ether molecules per 192 T-atoms in the FAU layer ($CE_{FAUlayer}$) could be related to the crown-ether content of the overgrowth ($CE_{overgrowth}$) according to Equation (3).

$$CE_{FAUlayer} = [CE_{overgrowth} - CE_{support} \times fraction_{support}]/fraction_{FAUlayer} \quad (3)$$

These numbers are given in Table 7. The FAU crystallites synthesized in the presence of crown-ether molecules (samples FauEmt-2a to FauEmt-5a) contain approximately one crown-ether molecule per cage, or eight per 192 T-atoms. Even without intentional addition of crown-ether molecules to the FAU synthesis gel, the FAU layer occluded some crown-ether molecules (samples FauEmt-1a to FauEmt-1c, Table 7). Comparison of the amount of crown-ether molecules in the inorganic FAU layer with the amount liberated by partial dissolution of the EMT support crystals showed that the dissolution process alone could not account for all crown-ether molecules incorporated in the FAU layer. Additional crown-ether molecules could be provided by the mother liquor surrounding the support crystals, or as molecules that are physisorbed on the external surface of the support crystals. These phenomena were more pronounced when more support crystals were used, thus resulting in an enhanced incorporation of crown-ether molecules in the FAU layer (Table 7).

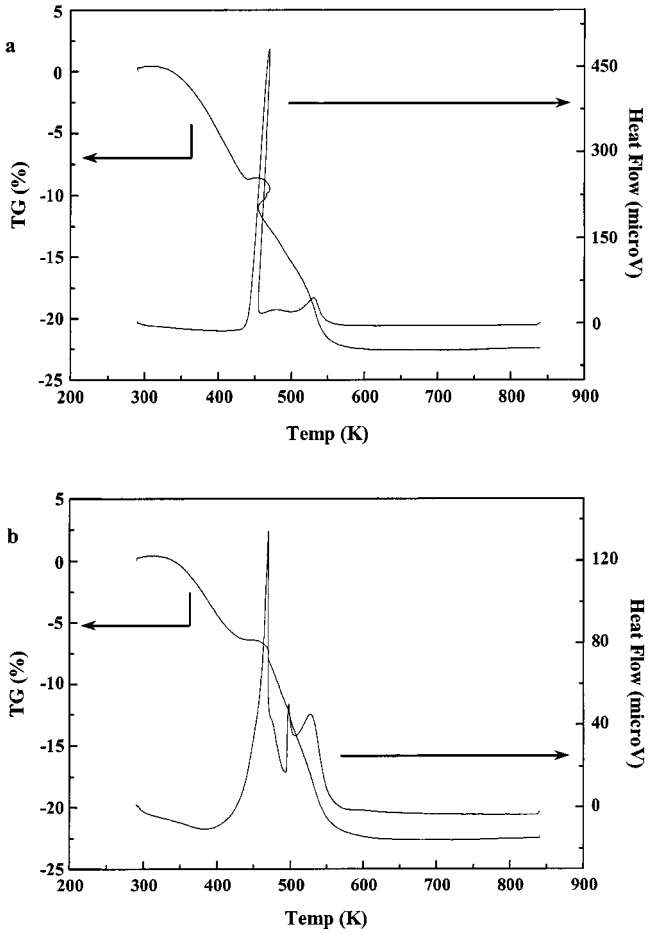

Figure 12. TGA/DTA profiles recorded under He/O_2 of (a) EMT support crystals and (b) sample FauEmt-2a; the oblique nature of the largest heat flow peak and the concomitant bump in the TG curve are due to the higher temperatures caused by the exothermic crown-ether decomposition[34]

Table 7. Crown-ether content of the support crystals, some FAU-on-EMT overgrowth materials and the FAU layer, as determined with TG-DTA

Sample	CE/192 T-atoms		
	support	overgrowth	FAU layer
FauEmt-2a	10.0	8.6	8.2
FauEmt-2b	10.0	8.9	7.9
FauEmt-2c	10.0	9.1	7.9
FauEmt-4a	9.1	8.3[a]–9.9[b]	8.0[a]–10.2[b]
FauEmt-5a	9.5	9.1[a]–10.9[b]	8.9[a]–11.4[b]

Overgrowth Synthesis Efficiency

In this section, two aspects of synthesis efficiency are discussed, namely the FAU yield with respect to the gel and

the EMT losses due to partial dissolution of the support crystals. Comparison of the weight of EMT in the overgrowth product with the weight of EMT support crystals added, showed that part of the EMT phase dissolved (Table 2). In the calculations in the previous section, it was assumed that the FAU impurity phase of the EMT support crystals dissolved in the same proportion as the EMT phase. This assumption led to reasonable interpretations of the FAU and EMT contents of the FAU-on-EMT overgrowth materials and of the framework Si/Al ratios of the respective phases.

The assumed weights of FAU impurities dissolved during the overgrowth process are given in Table 2. The FAU yield with respect to the gel was obtained by subtracting the weight of the FAU impurity phase which did not dissolve from the weight of FAU in the final product, and dividing this value by the weight of synthesis gel (Table 2). In the experiments with three different FAU gel compositions (samples FauEmt-1a, FauEmt-2a and FauEmt-4a), the amount of FAU crystallites formed per gram of gel was about the same. Approximately 0.14 g (calcined amount) of the FAU structure type crystallized per gram of synthesis gel (Table 2). This value corresponds to a yield of ca. 55 wt-%, in terms of silicon, whereas the yield in terms of aluminum is approximately 100 wt-%, thus suggesting that the maximal possible conversion of the FAU gel was achieved. However, comparison of the EMT yield in the overgrowth product with the weight of EMT support crystals added (Table 2), showed that 24−47% of the support crystals did dissolve. The dissolution was most pronounced in hydrogels containing crown-ether with an OH^-/SiO_2 ratio of 0.75 (samples FauEmt-2a and FauEmt-4a, Table 2). Dissolution of a number of the support crystals enriched the synthesis gel with silicon and aluminum. Assuming that the aluminosilicate species generated through dissolution were consumed during the growth of the FAU phase, the yields of the FAU layer in terms of silicon and aluminum could be recalculated as ca. 45 and 80 wt-%, respectively. Aluminum remains the limiting factor with respect to the yields, as generally encountered with Y type zeolites.

Variation of the crystallization time between 1 and 5 d (samples FauEmt-2k to FauEmt-2o) only had a small effect on the amount of FAU formed per gram of FAU synthesis gel. On the other hand, the amount of support crystals dissolved during the overgrowth process remained constant until a crystallization time of 3 d, after which it increased substantially (Table 2). This observation provides additional evidence for the assumed intactness of the EMT core of the FAU-on-EMT overgrowth materials obtained in the three-day synthetic experiments. As long as there is gel and the overgrowth process is taking place, the EMT support crystals which are covered with FAU crystallites do not dissolve. When the overgrowth process is terminated, the mother liquor becomes depleted and the most siliceous part of the overgrowth, i.e. the EMT core, starts to dissolve. Synthesis time is, therefore, a critical synthesis parameter. Prolongation of the crystallization time might be used for the preparation of hollow particles with a shell composed of Al-rich FAU crystallites, by dissolving the Si-rich EMT core. Hollow crystals are expected to have favorable mass- and heat-transfer properties, and may be advantageous, for example, in rapid-pressure-swing adsorptive separations.

Quantification of the FAU-on-EMT overgrowth materials obtained using different amounts of support crystals (samples FauEmt-1a to FauEmt-1c and FauEmt-2a to FauEmt-2c) showed that the yield of FAU formed per gram of FAU synthesis gel decreased with an increasing amount of EMT crystals added, especially in presence of 18-crown-6 ether molecules (Table 2). A possible explanation for this decrease is that, although the percentage of dissolved support crystals diminishes when more support crystals are used, the absolute amount of support crystals dissolved per gram of FAU synthesis gel increases, thus perturbing the original optimized FAU gel composition to a larger extent.

Conclusions

In this paper, the potential of the two-step synthetic procedure for synthesizing systematic FAU-on-EMT overgrowth materials has been investigated. Inoculation of a FAU synthesis gel with a high sodium content (Na_2O/SiO_2 = 0.34 or 0.375) and which optionally contained crown-ether molecules, with EMT support crystals, resulted in the formation of a continuous film of FAU crystallites on the original micrometer-sized hexagonal-platelet EMT support crystals. The overgrowth was achieved at 373 K within 1 d. On the other hand, no crystallization took place from an FAU synthesis gel containing 15-crown-5 ether and with a low sodium content (Na_2O/SiO_2 = 0.24), unless this gel was aged for 3 d at room temperature prior to the addition of EMT support crystals. However, in this case the support crystals were not completely covered with FAU crystallites and a new population of isolated FAU crystals with octahedral morphology was obtained. Washing or washing, drying and calcining the support crystals before they were added to the FAU synthesis gel was detrimental and resulted in the formation of an undesirable population of isolated FAU crystals. Variation of the amount of support crystals added or the synthesis time showed that the FAU crystallites preferentially nucleate and grow on the corners and edges of the EMT support crystals. Only when the amount of the synthesized EMT support crystals per gram of synthesis gel is approximately 0.20 g, do the support crystals become completely coated with FAU crystallites.

The FAU-on-EMT overgrowth materials obtained were characterized in detail using a variety of physico-chemical characterization techniques. Quantification of the overgrowth materials with XRD revealed that the yield of FAU with respect to the gel was similar for the three types of gel compositions used. After 3 d at 373 K, the overgrowth process was complete and the supply of nutrients from the gel exhausted. The yield of FAU layer in terms of the gel decreased with an increasing amount of support crystals added. Of the EMT support crystals added, a fraction dis-

solved completely, whereas the rest became overgrown. The overgrown support crystals were not damaged and maintained their Si/Al ratio and their original micropore volume.

The dissolution behavior of the synthesized EMT crystals in basic solutions was investigated. The dissolution was found to cause the formation of pits over the entire surface. Extensive dissolution resulted in the formation of particles, which were more strongly dissolved at the center than at the outer rim. The EMT crystals dissolved in a block-wise manner and finally were decomposed into smaller fragments with Si/Al ratios as low as 1.3. Such debris from EMT dissolution were not observed in the overgrowth formation experiments.

The Si/Al ratio of the FAU crystallites was found to be dependent on the gel composition and on the position of the crystallites with respect to the surface of the EMT support. The first crystallites formed, which were positioned at the corners and edges of the EMT support crystals, were richer in aluminum than the crystallites formed at a later stage and present in the center of the basal $\{0001\}_{EMT}$ planes. FAU-on-EMT overgrowth materials synthesized in the presence of crown-ether molecules contain approximately one crown-ether per cage. Even in the absence of crown-ether molecules during the second synthetic step, the FAU phase occluded some crown-ether molecules, which were introduced with the synthesized EMT support crystals. This amount was more pronounced when more EMT support crystals were added to the inorganic FAU synthesis gel. Nitrogen physisorption measurements indicated that all pores were accessible to nitrogen. The low external surface areas of the FAU-on-EMT overgrowth materials were in agreement with the absence of mesopores and a tight fitting of the support and the overgrowing layer.

Experimental Section

Two-Step Synthesis: Hydrogels for the synthesis of FAU type zeolites were obtained following the procedure described by Feijen et al.,[21] and using Ludox HS-40 (DuPont), NaOH pellets (Merck), gibbsite (Fluka), 15-crown-5 ether (1,4,7,10,13-pentaoxacyclopentadecane, Acros) or 18-crown-6 ether (1,4,7,10,13,16-hexaoxacyclooctadecane, Acros) and distilled water. A given amount of the synthesized EMT support crystals was added to these gels, which were optionally aged for 3 d at room temperature. The resulting mixtures were stirred for 15 min and subsequently transferred into PTFE-lined stainless-steel autoclaves. These autoclaves were heated to the crystallization temperature of 373 K under quiescent conditions without aging. After the crystallization time had elapsed, the solid products were recovered by vacuum filtration, washed with deionised water until the pH value of the wash water was below 10 and dried at 333 K. Calcination was done in a muffle furnace at 823 K for 20 h. − EMT support crystals were prepared in a similar way to the hydrogels with the following molar oxide ratios: 10 SiO_2/1 Al_2O_3/2.4 Na_2O/0.97 18-crown-6/135 H_2O. − These gels were aged in PTFE-lined stainless-steel autoclaves for 3 d at room temperature and subsequently heated to the crystallization temperature of 373 K at autogenous pressure without stirring. After 11 d, the autoclaves were cooled in water and a wet cake of the EMT support crystals was recovered by vacuum filtration.

Powder X-ray Diffraction (XRD): XRD patterns were collected with an automated Siemens D-5000matic diffractometer using Cu-K_α radiation. XRD profiles were recorded in the range of 2θ values between 4 and 55°, with steps of 0.02° and counting times of 1.2 s.

Scanning Electron Microscopy (SEM): SEM pictures were taken with a Jeol superprobe 733 and of a Philips XL30 FEG apparatus. A gold film was sputtered onto the samples supported on alumina disks prior to their observation.

High-Resolution Transmission Electron Microscopy (HRTEM): HRTEM investigations were carried out with a 200-kV Philips CM200 Ultra Twin apparatus with a point-to-point resolution of 0.19 nm. The zeolite powder was deposited onto a carbon support and remained stable under the electron beam irradiation for at least several minutes. Nano-EDAX (energy-dispersive analysis of X-rays) was performed with the same apparatus equipped with a Noran EDX-detector having an ultra-thin window. The TEM was operated in the nanoprobe-mode, which implies that the electron beam diameter was reduced to 5 nm or even smaller.

NMR Spectroscopy: ^{29}Si magic angle spinning (MAS) NMR spectroscopy was performed with a Bruker MSL400 (9.4 T) spectrometer at 79.5 MHz, with a pulse length of 4 μs, a repetition time of 5 s, a spinning rate of 4 kHz and 11 000 scans. The ^{29}Si chemical shifts were reported relative to Me_4Si.

X-ray Photoelectron Spectroscopy (XPS): XPS was carried out with a Perkin−Elmer PHI 5500 ESCA system using monochromatic Al-K_α radiation. The binding energies were referred to C(1s) = 286.4 eV. The evaluation of the surface composition was performed using the intensities of the Na(1s), O(1s), Si(2p), and Al(2p) lines.

Nitrogen Physisorption: Nitrogen physisorption isotherms at 77 K were recorded with an Omnisorp-100 analyzer from Coulter, operating in the continuous flow mode. Before recording the isotherms, calcined samples were outgassed at 673 K under high vacuum (10^{-6} kPa) for at least 12 h. Micropore volumes and specific external surface areas were derived from the isotherms using the t-plot method of Lippens and de Boer.[35] The Horvath−Kawazoe method[36] was applied to determine the micropore diameter.

Thermogravimetric and Differential Thermal Analysis (TG-DTA): TG-DT analyses were performed simultaneously with a Setaram TGA92 thermobalance under oxygen/helium (25:75 vol-%) using typically 30 mg of sample and a flow of 35 mL/min. The temperature was increased at a rate of 5 K/min from room temperature to 823 K.

Sterically Fixed Dithiolate Ligands and Their Zinc Complexes: Derivatives of 1,8-Dimercaptonaphthalene

Markus Tesmer[a] and Heinrich Vahrenkamp*[a]

Keywords: S ligands / Alcohols / Zinc / Structure elucidation / Enzyme models

The synthesis of two new dithiols, 1,8-dimercapto-2,7-di(*tert*-butyl)naphthalene (H_2L^1) and 1,8-dimercaptonaphthoic anhydride (H_2L^2), is described. They react with diethylzinc to yield the polymeric complexes L^1Zn and L^2Zn. L^1Zn dissolves in the presence of pyridine to form $[L^1Zn{\cdot}py]_x$, which is presumed to be dimeric. Both L^1Zn and L^2Zn react with neocuproin. Structure determinations have confirmed the tetrahedral ZnN_2S_2 coordination in the resulting LZn·neo complexes.

Introduction

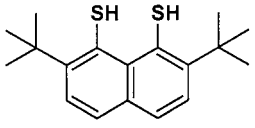
The chemistry of transition metal thiolates is a world of thiolate-bridged oligomers and polymers.[1,2] This extends into biology with the ubiquitous presence of the $Fe_4S_4(SR)_4$ redox unit and the accumulation of copper, zinc or cadmium in the metallothioneins. Yet Nature is able to prevent thiolate bridging and metal aggregation by isolating the cysteine-thiolate donors and limiting the space available to the metals, thereby making the cysteine sulfur one of the prominent monodentate ligands for metals in biology.

Model studies of sulfur-rich metal environments in metalloenzymes invariably suffer from this problem of complex aggregation.[3,4] As a result, far-reaching advances have often only been made in the exceptional situations where thiolate bridging is not preferred, typical examples being the bioinorganic chemistry of octahedral iron[5] or the ZnN_2S_2 coordination motif of the zinc finger proteins.[6]

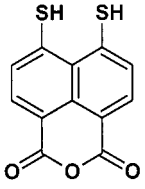
In the bioinorganic chemistry of zinc, model studies of the alcohol dehydrogenases have met with this problem.[7,8] The attachment of the metal to the protein by an NS_2 (histidine, cysteine, cysteine) ligation[9] calls for amine bis-thiolates as model ligands. But to date no such thiolate[10,11] has been found to produce mononuclear $(NS_2)Zn-X$ complexes that are free from thiolate bridging and that bear a ligand X as a substitute for the substrate of the enzyme. The best approximation has been achieved by NS_2 ligands in which the sulfur donors are not of the thiolate type.[12]

The standard procedures for reducing the bridging tendency of thiolate ligands (steric hindrance or increased electronegativity) have been applied successfully to zinc complexes: tris(*tert*-butyl)benzene thiolate has been used to produce a tricoordinate $Zn(SR)_2$·pyridine complex,[13] and we have used pentafluorobenzene thiolate to model the $ZnNS_2O$ ligation pattern of the alcohol dehydrogenase enzyme−substrate complexes.[14]

We are not aware that these principles have been applied to chelating bis-thiolate ligands, and our attempts to do so are reported in this paper. We wanted to synthesize a ligand in which the two thiolate donors have fixed positions in space. This should serve the purpose of preorganization (i.e. good chelating properties) while at the same time the lack of conformational freedom would reduce the oligonucleating tendency. We chose the 1,8-dimercaptonaphthalene framework for our purposes. It strictly defines the locations of the two sulfur atoms, while allowing the attachment of bulky substituents at the 2- and 7-positions or the attachment of electron-withdrawing substituents anywhere on the naphthalene skeleton. The target ligands were H_2L^1 and H_2L^2. This paper describes their synthesis and some preliminary chemistry of their zinc complexes.



H_2L^1



H_2L^2

Results and Discussion

The Ligands

1,8-Dimercaptonaphthalene[15] and 1,8-dimercaptohexachloronaphthalene[16] have been described in the literature, but not investigated extensively as ligands.[16,17] Our approach of generating the 1,8-dithiol functionality in H_2L^1 and H_2L^2 followed the established procedure of introducing sulfur as the naphthalene-1,8-disulfide and then reducing it. Scheme 1 describes this for H_2L^1, using the literature method to prepare naphthalene-1,8-disulfide.[18] The overall yield of H_2L^1 starting from bromonaphthalene was 8%. H_2L^1 is a yellow crystalline solid which is soluble in weakly polar organic solvents. It is easily identified by its simple

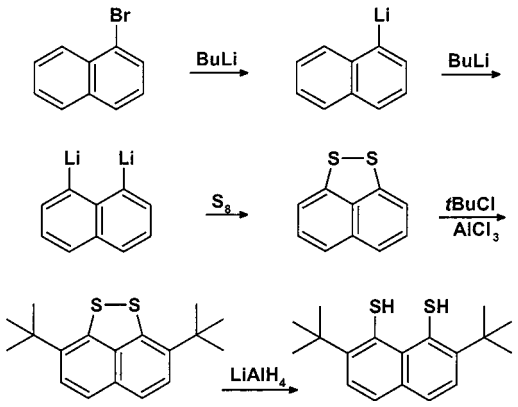
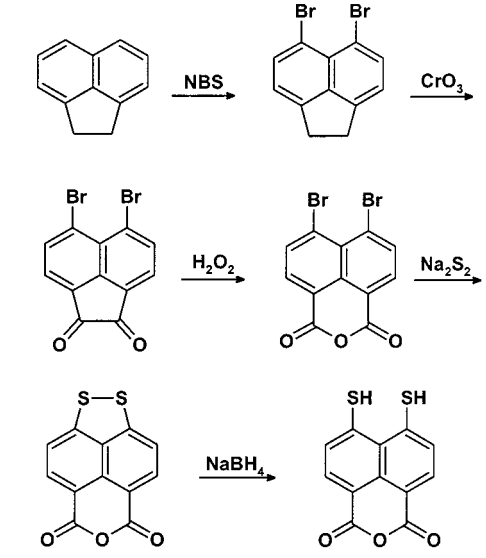
^{1}H NMR spectrum (see Experimental Section). Upon exposure to air, it is oxidized to the disulfide. Upon deprotonation, its colour in solution becomes a deeper yellow.



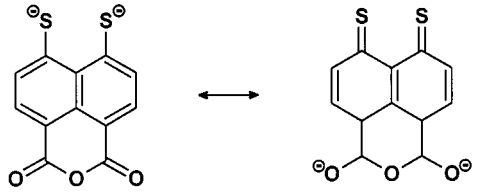
Scheme 1

The synthesis of H_2L^2 was performed according to Scheme 2 starting from acenaphthene, using the literature procedure[19] to generate its 1,8-dibromide. The overall yield of H_2L^2 starting from acenaphthene was again 8%.



Scheme 2

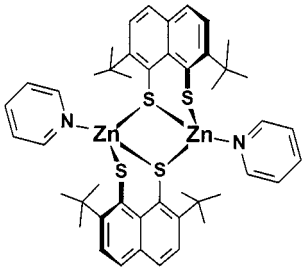
H_2L^2 is a yellow solid of low solubility which again has a simple ^{1}H NMR spectrum (see Experimental Section). Its air sensitivity is similar to that of H_2L^1. Deprotonation greatly enhances its solubility in polar solvents. Its solutions are deep red, indicating the delocalized nature of the anion according to the following valence structures.



Zinc Complexes

Diethyl zinc was found to be the best reagent to convert H_2L^1 and H_2L^2 into the binary zinc complexes ZnL^1 (**1**) and ZnL^2 (**2**), respectively, by hydrolytic cleavage in aprotic media. The resulting compounds **1** and **2** were obtained in very good yields. They dissolve only in very good donor solvents, in agreement with the assumption that they are oligomeric or polymeric. It is likely that they contain zinc in a ZnS_4 environment, i.e. each thiolate sulfur bridges two zinc ions.

Some attempts were made to isolate adducts of ZnL with monodentate donors. They were successful for the combination ZnL^1/pyridine. Upon addition of equimolar amounts of pyridine to a suspension of ZnL^1 in chloroform, the complex dissolved. However, a new precipitate of composition ZnL^1·pyridine (**3**) formed immediately; again, this complex was of rather low solubility. This reaction did not occur with ZnL^2. Assuming the likely $ZnNS_3$ coordination in this species, it follows that one of the two thiolate functions acts as a bridge. Thus a dimeric structure can be proposed for **3**, in analogy with the one described by Kellogg for the zinc complex of a sterically hindered pyridine-bis(thiolate) ligand.[10]



As expected, the highly preferred ZnN_2S_2 coordination with **1** and **2** was readily found in the form of mononuclear complexes. We chose neocuproin (2,9-dimethylphenanthroline, neo) as the bidentate nitrogen co-ligand, as we had previously found it to be most suitable for this purpose.[20] Compounds **1** and **2** dissolve in its presence, and cleanly form the 1:1 complexes (neo)Zn(L^1) (**4**) and (neo)Zn(L^2) (**5**), which are orange crystalline solids suitable for X-ray analysis (see below). In complex **5**, the electron-withdrawing properties of ligand L^2 can be confirmed by the positions of its ν(CO-carboxylate) IR bands: these are shifted by approximately 20 cm^{-1} to lower wavenumbers than those of H_2L^2.

Structures

The structure determinations of **4** and **5** (see Figure 1 and 2) confirmed the identities and compositions of the species described here, and gave some information about the ligating properties of L^1 and L^2. The crystalline structure of compound **4** has an asymmetric unit with two molecules that are quite similar. The overall coordination geometries in **4** and **5** are as expected, with Zn−N and Zn−S distances

in the normal range and with relatively small N−Zn−N and relatively large S−Zn−S angles.

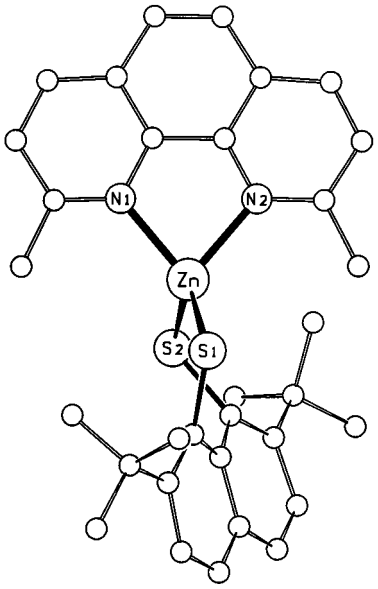


Figure 1. Molecular structure of **4** (one of the two independent molecules); bond lengths [Å]: Zn−S1 2.227(1)/2.222(1), Zn−S2 2.229(1)/2.226(1), Zn−N1 2.086(3)/2.085(3), Zn−N2 2.091(3)/2.092(3); bond angles [°]: S1−Zn−S2 103.06(4)/103.51(4), N1−Zn−N2 80.1(1)/80.5(1), S1−Zn−N1 126.1(1)/126.6(1), S1−Zn−N2 114.5(1)/115.7(1), S2−Zn−N1 113.0(1)/109.0(1), S2−Zn−N2 120.4(1)/122.0(1)

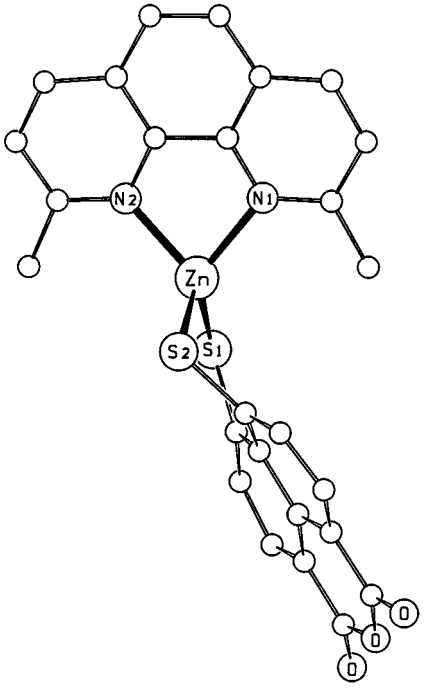

Figure 2. Molecular structure of **5**; bond lengths [Å]: Zn−S1 2.230(2), Zn−S2 2.260(2), Zn−N1 2.058(5),Zn−N2 2.050(4); bond angles [°]: S1−Zn−S2 103.04(7),N1−Zn−N2 81.6(2), S1−Zn−N1 125.1(1), S1−Zn−N2 122.7(1), S2−Zn−N1 111.8(1), S2−Zn−N2 112.0(1)

However, both complexes are severely distorted from their ideal C_{2v} symmetry. The reason for this lies in the conformational requirements of the sulfur atoms which do not allow for the zinc ions to reside together with them in the planes of the naphthalene rings. The necessity for small Zn−S−C angles (101−108°) together with the given Zn−S bond lengths enforces an out-of-plane motion of the zinc ions and/or both sulfur atoms. This geometry is highlighted in Figure 1 and 2. In these figures, the bisector of the S−Zn−S angle is in the plane of the paper with a viewing direction normal to the plane of the neocuproin ligand. The naphthalene rings are bent away from the bisector, and partly rotated with respect to their expected orientation perpendicular to the plane of the paper. This relieves the torsional strain at the sulfur atoms and the intramolecular repulsive forces.

More specifically, in both independent molecules of **4**, the sulfur atoms are bent away in opposite directions from the naphthalene plane by approximately 1.0 and 1.2 Å. The carbon atoms attached to them follow this movement to a lesser degree. The out-of-plane displacement of the sulfur atoms is reversed for the zinc ion which is roughly in the naphthalene plane again. Concomitantly, the naphthalene plane is tilted by only 8° with respect to the bisector of the S−Zn−S angle. In **5**, the sulfur atoms are also bent away from the naphthalene plane in opposite directions, but this time by only 0.75 Å on average. Contrary to the case in compound **4**, both S−Zn bonds in **5** are tilted in the same direction, thereby causing the observed tilt of 30° of the naphthalene ring with respect to the bisector of the S−Zn−S angle. The reason for this difference between **4** and **5** may lie in the *tert*-butyl substituents of **4**, which prevent the pronounced tilting owing to their van der Waals interactions with the methyl groups of the neocuproin ligand. Generally, the observed asymmetry of **4** and **5** seems to effect the necessary relief from the inherent steric strain, thereby making ligand L^1 and L^2 suitable for their intended purpose.

The ZnN_2S_2 ligation in complexes **4** and **5** is also the most common one in zinc finger motifs.[6] The geometric features of the ZnN_2S_2 units in these complexes and in the zinc fingers compare reasonably well but, as was discussed in detail for zinc-neocuproin complexes of bis(cysteinyl)-peptides,[20] the geometric constraints induced by the small bite angle of the neocuproin ligand make the N−Zn−N angles smaller and concomitantly the S−Zn−S angles larger than the situation in the proteins.

Conclusions

The ligands H_2L^1 and H_2L^2 were accessible. They are two new members of a hitherto unexplored group of sterically fixed dithiolate ligands that are geometrically similar to the dithiolene ligands. The ligand H_2L^1 is sterically crowded owing to the favourable positioning of its *tert*-butyl substituents, whereas the Ligand H_2L^2 is electron poor. At the same time, the dianion L^2 should have ligating properties for hard metal ions at its carboxylate oxygen atoms, as in-

dicated by its resonance structures and the IR spectroscopic data of its zinc complex **5**.

The preliminary complexation reactions with zinc have outlined the coordinating potential of both ligands. While the binary ZnL compounds **1** and **2** could be expected to be polymeric, addition of one pyridine ligand to **1** is sufficient to break up its polymeric structure. The excellent coligand neocuproin ensured the formation of the 1:1:1 complexes **4** and **5**, with a ZnN_2S_2 coordination. Their structure determinations have revealed the basic ligation properties of the naphthalene-1,8-dithiolates. The conformational requirements of the sulfur atoms do not allow for a planar arrangement of the naphthalene rings, the sulfur atoms and the zinc ion. However, the two complex geometries that were observed show that a strain-free and strong metal-dithiolate coordination is present.

Experimental Section

For general preparative and measuring procedures, see ref.[21] All reactions were carried out under a nitrogen atmosphere. Starting materials were obtained commercially or prepared according to the references given.

Ligand H_2L^1: a) 2,7-Di(*tert*-butyl)naphthalene-1,8-disulfide: Naphthalene-1,8-disulfide[18] (3.00 g, 15.8 mmol) was dissolved at 50 °C in a mixture of nitromethane (37 mL) and *tert*-butyl chloride (4.38 g, 47.3 mmol). Anhydrous $AlCl_3$ (400 mg, 3.00 mmol) was added and the mixture was stirred at 50 °C for 20 min. After cooling to room temp. the product precipitated. Washing with nitromethane and recrystallization from acetone yielded 2,7-di(*tert*-butyl)-naphthalene-1,8-disulfide (1.82 g, 38%) as orange crystals, m.p. 129 °C. − $C_{18}H_{22}S_2$ (302.5): calcd. C 71.47, H 7.33; found C 71.55, H 7.37. − ^{1}H NMR ($CDCl_3$): δ = 1.50 (s, 18 H, *t*Bu), 7.36 (d, *J* = 8.0 Hz, 2 H, $H^{5,6}$), 7.42 (d, *J* = 8.0 Hz, 2 H, $H^{4,7}$).

b) H_2L^1: A solution of 2,7-di(*tert*-butyl)naphthalene-1,8-disulfide (5.43 g, 28.5 mmol) in THF (50 mL) was treated with $LiAlH_4$ (1.08 g, 28.5 mmol) and heated at reflux for 1 h. After cooling to room temp., water (1 mL) and 10 M HCl (15 mL) were added dropwise to the stirred solution. After extraction with dichloromethane (100 mL), the organic layer was separated, washed with water (3 × 30 mL) and dried over Na_2SO_4. The solvent was removed in vacuo and the residue was recrystallized from cyclohexane/THF (5:1). H_2L^1 was obtained as a yellow powder (8.25 g, 95%), m.p. 137 °C. − $C_{18}H_{24}S_2{\cdot}C_6H_{12}$ (304.5 + 84.2): calcd. C 74.16, H 9.34; found C 75.40, H 9.31. − IR (KBr): $\tilde{\nu}$ = 2544 (SH) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 1.50 (s, 12 H, C_6H_{12}), 1.64 (s, 18 H, *t*Bu), 4.41 (s, 2 H, SH), 7.48 (d, *J* = 8.6 Hz, 2 H, $H^{4,5}$), 7.50 (d, *J* = 8.6 Hz, 2 H, $H^{3,6}$).

Ligand H_2L^2: a) 1,8-Dibromoacenaphthenedione: 1,8-Dibromoacenaphthene[19] (8.51 g, 27.3 mmol) was dissolved in acetic anhydride (1 L) at 110 °C. CrO_3 (21.1 g, 211 mmol) was added carefully to the stirred solution over a period of 2 h. The resulting green suspension was stirred at 160 °C for 30 min., and then poured while hot onto crushed ice (1 kg). Conc. HCl (20 mL) was added and the mixture was filtered. The brownish precipitate was washed with water, dried in vacuo and recrystallized from acetic anhydride (2 L). 1,8-Dibromoacenaphthenedione (6.23 g, 67%) was obtained as a light brown solid, m.p. 239 °C. − $C_{12}H_4Br_2O_2$ (340.0): calcd. C 42.40, H 1.19; found C 42.22, H 1.19. − ^{1}H NMR ($CDCl_3$): δ = 7.93 (d, *J* = 7.6 Hz, 2 H, $H^{4,7}$), 8.27 (d, *J* = 7.6 Hz, 2 H, $H^{3,8}$).

b) 1,8-Dibromonaphthoic Anhydride: 1,8-Dibromoacenaphthenedione (6.23 g, 18.3 mmol) was dissolved in a mixture of 1,4-dioxane (400 mL) and NaOH (2 M, 400 mL) and heated to 100 °C. A solution of H_2O_2 (10%, 400 mL) was added slowly to the stirred solution. After stirring for a further 30 min. at 100 °C, the mixture was cooled to room temp. and filtered. The filtrate was acidified with conc. HCl producing a voluminous precipitate. This was separated by centrifugation, washed twice with water and dried in vacuo. Recrystallization from acetic anhydride (2.5 L) yielded 1,8-dibromonaphthoic anhydride (4.84 g, 74%) as a light brown powder, m.p. 260 °C. − $C_{12}H_4Br_2O_3$ (356.0): calcd. C 40.49, H 1,13; found C 40.45, H 1.11. − ^{1}H NMR ([D_6]acetone): δ = 7.95 (d, *J* = 7.5 Hz, 2 H, $H^{5,8}$), 8.17 (d, *J* = 7.5 Hz, 2 H, $H^{4,9}$).

c) Naphthoic Anhydride-1,8-disulfide: Na (1.56 g, 67.9 mmol) and sulfur (2.18 g, 68.0 mmol) were suspended in DMF (40 mL). The mixture was stirred at 100 °C until the vigorous reaction had produced a voluminous precipitate. A suspension of 1,8-dibromonaphthoic anhydride in DMF (20 mL) was quickly added, upon which the mixture turned deep purple. After heating at 140 °C for 10 min, it was poured while hot into water (300 mL). The resulting orange suspension was acidified with conc. HCl, and the precipitate was isolated by centrifugation, washed twice with water and dried in vacuo. Recrystallization from 1,4-dioxane (1.6 L) in the presence of activated charcoal (1 g) yielded naphthoic anhydride-1,8-disulfide (2.41 g, 68%) as a red solid, m.p. 330 °C (dec.). − $C_{12}H_4O_3S_2$ (356.0): calcd. C 55.37, H 1.55; found C 55.32, H 1.59. − ^{1}H NMR ([D_6]acetone): δ = 7.83 (d, *J* = 8.0 Hz, 2 H, $H^{3,9}$), 8.37 (d, *J* = 8.0 Hz, 2 H, $H^{4,8}$).

d) HL^2: Naphthoic anhydride-1,8-disulfide (0.32 g, 1.20 mmol) was suspended in methanol (10 mL). After the addition of $NaBH_4$ (94 mg, 2.50 mmol) the mixture turned purple. After stirring for 2 h, the mixture was filtered and the filtrate treated with conc. HCl (1 mL) and stirred for 1 h. The resulting yellow precipitate was washed with water and methanol and dried in vacuo to afford H_2L^2 as a yellow powder (0.23 g, 73%), m.p. 280 °C (dec.). − $C_{12}H_6O_3S_2$ (262.3): calcd. C 54.95, H 2.31; found C 54.18, H 2.59. − IR (KBr): $\tilde{\nu}$ = 2537 (SH) cm^{-1}. − ^{1}H NMR ([D_6]acetone): δ = 5.51 (s, 2 H, SH), 7.80 (d, *J* = 8.2 Hz, 2 H, $H^{5,8}$), 8.42 (d, *J* = 8.2 Hz, 2 H, $H^{4,9}$).

Compound 1: A solution of H_2L^1 (0.20 g, 0.66 mmol) in chloroform (10 mL) was treated dropwise with a solution of diethyl zinc (81 mg, 0.66 mmol) in *n*-hexane (2.0 mL). The resulting precipitate was filtered off, washed with chloroform and dried in vacuo, leaving behind compound **1** (0.23 g, 95%) as a yellow powder, m.p. 160 °C (dec.). − $C_{18}H_{22}S_2Zn$ (367.9): calcd. C 58.77, H 6.03, Zn 17.77; found C 57.38, H 5.97, Zn 17.32. − ^{1}H NMR ([D_6]DMSO): δ = 1.68 (s, 18 H, *t*Bu), 7.06 (d, *J* = 8.5 Hz, 2 H, $H^{4,5}$), 7.25 (d, *J* = 8.5 Hz, 2 H, $H^{3,6}$).

Compound 2: Prepared in the same manner as **1** from H_2L^2 (0.10 g, 0.38 mmol) in toluene (15 mL) and diethyl zinc (47 mg, 0.38 mmol). Compound **2** was obtained as a pale orange powder (0.12 g, 97%), m.p. 175 °C (dec.). − $C_{12}H_4O_3S_2Zn$ (325.7): calcd. C 44.26, H 1.24, Zn 20.08; found C 44.07, H 1.16, Zn 19.89. − ^{1}H NMR ([D_6]DMSO): δ = 7.84 (d, *J* = 8.2 Hz, 2 H, $H^{5,8}$), 8.37 (d, *J* = 8.2 Hz, 2 H, $H^{4,9}$).

Compound 3: A suspension of **1** (0.20 g, 0.54 mmol) in chloroform (10 mL) was treated with a solution of pyridine (44 mg, 0.55 mmol) in chloroform (2 mL). A clear solution was formed from which a yellow solid precipitated after a few seconds. The precipitate was

filtered off, washed with chloroform and dried in vacuo, leaving behind compound **3** as a yellow powder (0.21 g, 85%), m.p. 105 °C (dec.). − $C_{23}H_{27}NS_2Zn$ (447.0): calcd. C 61.80, H 6.09, N 3.13, Zn 14.63; found C 59.48, H 5.97, N 3.05, Zn 14.50. − IR (KBr): $\tilde{\nu}$ = 1609 (C=N) cm^{-1}. − ^1H NMR ([D$_6$]DMSO): δ = 1.68 (s, 18 H, *t*Bu), 7.06 (d, *J* = 8.5 Hz, 2 H, H^{4,5}), 7.25 (d, *J* = 8.5 Hz, 2 H, H^{3,6}), 7.41 (m, 2 H, py), 7.82 (m, 1 H, py), 8.58 (m, 2 H, py).

Compound 4: A solution of H_2L^1 (0.20 g, 0.66 mmol) and neocuproin hydrate (0.14 g, 0.67 mmol) in chloroform (10 mL) was treated with diethyl zinc (81 mg, 0.66 mmol) in *n*-hexane (2.0 mL). After stirring for 20 min. the volume was reduced to 2 mL in vacuo. Addition of petroleum ether (4 mL) produced a precipitate which was filtered off and washed with petroleum ether. Recrystallization from dichloromethane/hexane (1:1) yielded **4** as orange crystals (0.36 g, 95%), m.p. 115 °C (dec.). − $C_{32}H_{34}N_2S_2Zn{\cdot}CH_2Cl_2$ (576.2 + 84.9): calcd. C 59.96, H 5.49, N 4.24, Zn 9.89; found C 59.82, H 5.54, N 3.98, Zn 10.03. − IR (KBr): $\tilde{\nu}$ = 1621 and 1591 (C=N) cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 1.77 (s, 18 H, *t*Bu), 3.19 (s, 6 H, CH_3), 5.35 (s, 2 H, CH_2Cl_2), 7.27 (d, *J* = 8.6 Hz, 2 H, H^{4,5}), 7.45 (d, *J* = 8.6 Hz, 2 H, H^{3,6}), 7.74 (d, *J* = 8.4 Hz, 2 H, neo-H^{3,8}), 7.94 (s, 2 H, neo-H^{5,6}), 8.44 (d, *J* = 8.4 Hz, 2 H, neo-H^{4,7}).

Compound 5: A suspension of **2** (0.10 g, 0.31 mmol) in chloroform (3 mL) was treated with neocuproin hydrate (70 mg, 0.31 mmol). The resulting clear solution formed a precipitate upon addition of hexane (6 mL), which was filtered off, washed with hexane and dried in vacuo, leaving behind compound **5** as orange crystals (0.13 g, 77%), m.p. 140 °C (dec.). − $C_{26}H_{16}N_2O_3S_2Zn{\cdot}C_6H_{14}$ (533.9 + 86.2): calcd. C 61.98, H 4.88, N 4.52, Zn 10.54; found C 62.52, H 5.55, N 4.33, Zn 10.11. − IR (KBr): $\tilde{\nu}$ = 1734 and 1700 (C=O), 1617 and 1590 (C=N) cm^{-1}. − ^1H NMR ([D$_6$]acetone): δ = 0.88 (m, 6 H, hexane-CH_3), 1.27 (m, 8 H, hexane-CH_2), 2.76 (s, 6 H, CH_3), 7.99 (d, *J* = 8.2 Hz, 2 H, H^{5,8}), 8.09 (d, *J* = 8.2 Hz, 2 H, H^{4,9}), 8.11 (d, *J* = 8.3 Hz, 2 H, neo-H^{3,8}), 8.27 (s, 2 H, neo-H^{5,6}), 8.90 (d, *J* = 8.3 Hz, 2 H, neo-H^{4,7}).

Structure Determinations:[22] Crystals of **4** were obtained by layering a dichloromethane solution with hexane, and crystals of **5** were obtained by layering a chloroform solution with hexane. Diffraction data were recorded with the ω/2θ technique on a Nonius CAD4 diffractometer fitted with a molybdenum tube (Mo-K_α, λ = 0.7107 Å) and a graphite monochromator. No absorption corrections were applied. The structures were solved by direct methods and refined anisotropically with the SHELX program suite.[23] Hydrogen atoms were included with fixed distances and isotropic temperature factors which were 1.5 times the value of those of their attached atoms. Parameters were refined against F^2. The *R* values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]]^{1/2}$. Drawings were produced with SCHAKAL.[24] Table 1 lists the crystallographic data.

Preparation and Crystal Structure of $Na_7Ba_{14}CaN_6$: A New Subnitride in the $Na_xBa_{14}CaN_6$ Series

Grigori V. Vajenine[a] and Arndt Simon*[a]

Dedicated to Professor Kurt Dehnicke on the occasion of his 70th birthday

Keywords: Barium / Calcium / Sodium / Nitrides / Cluster compounds / Subvalent compounds / Structure elucidation

The crystal structure of a new subnitride, $Na_7Ba_{14}CaN_6$, could be solved and refined based on single crystal and powder X-ray diffraction data. The compound contains $Ba_{14}CaN_6$ clusters, which are arranged in a Na matrix as in the other subnitrides of the $Na_xBa_{14}CaN_6$ (x = 8, 14, 17, 21, 22) series. The $Ba_{14}CaN_6$ clusters form a slightly distorted ccp arrangement, with octahedral holes filled by Na_7 units and with tetrahedral holes remaining empty. Details of the crystal structure, such as packing and occurrence of voids, are compared to these in closely related $Na_8Ba_{14}CaN_6$. Preparations of samples composed mostly of $Na_7Ba_{14}CaN_6$ and intergrown crystals of $Na_7Ba_{14}CaN_6$ and $Na_8Ba_{14}CaN_6$ are described.

Introduction

In a recent publication[1] the crystal structure and preparation of a new member of the $Na_xBa_{14}CaN_6$ series with x = 8 was reported. This compound joined the family of the previously known $Na_{14}Ba_{14}CaN_6$,[2,3] $Na_{17}Ba_{14}CaN_6$,[3] $Na_{21}Ba_{14}CaN_6$,[3] and $Na_{22}Ba_{14}CaN_6$.[3,4] All of these compounds feature $Ba_{14}CaN_6$ clusters, which are bonded ionically in their interior and bonded metallically to Na atoms between the clusters.

While probing various synthetic routes leading to $Na_8Ba_{14}CaN_6$, X-ray powder diffraction patterns, presumably belonging to further phases in the $Na_xBa_{14}CaN_6$ series, were observed.[1] One of these phases could be identified as $Na_7Ba_{14}CaN_6$. Below we report the preparation and crystal structure of this new subnitride.

Results and Discussion

The crystal structure of the new phase $Na_7Ba_{14}CaN_6$ is closely related to that of the recently reported $Na_8Ba_{14}CaN_6$.[1] Both structures are built from nearly identical hexagonal layers of $Ba_{14}CaN_6$ clusters separated by sodium atoms, as shown in Figure 1 and 2. This specific type of cluster is a condensate of six face-sharing Ba_5CaN octahedra, as described earlier.[2,3] While in the case of $Na_8Ba_{14}CaN_6$ these clusters stack on top of each other (Figure 2), rhombohedral stacking, a distorted variant of ccp arrangement, is observed in $Na_7Ba_{14}CaN_6$ (Figure 1); because of this, the sodium chains filling the available channels between the clusters in $Na_8Ba_{14}CaN_6$ are interrupted with a formal loss of one sodium atom per cluster. The sodium atoms in $Na_7Ba_{14}CaN_6$ can be viewed as clustered in Na_7 units (Figure 3), although this viewpoint is purely formal. This provides, however, a different approach to describe the structure of the subnitride. If one considers the centers of mass of the Na_7 and $Ba_{14}CaN_6$ blocks in $Na_7Ba_{14}CaN_6$, the trigonally distorted NaCl structure type emerges: while the $Ba_{14}CaN_6$ clusters are arranged in a

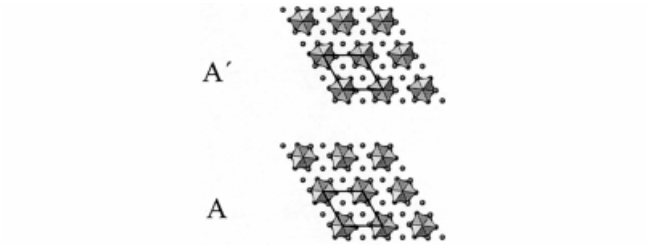

Figure 2. Two layers of $Ba_{14}CaN_6$ clusters with sodium atoms in between comprising a repeat unit of $Na_8Ba_{14}CaN_6$ in the [001] direction viewed along the *c*-axis; the unit cell is outlined; the simple hexagonal packing of the clusters is indicated by the AA′ labelling, where the primed and unprimed layers differ in the cluster orientation (using the same symbols A and A′ in Figures 1 and 2 ignores the slightly different cluster orientation: while the A′ layers are practically identical in both figures, the A layers differ)

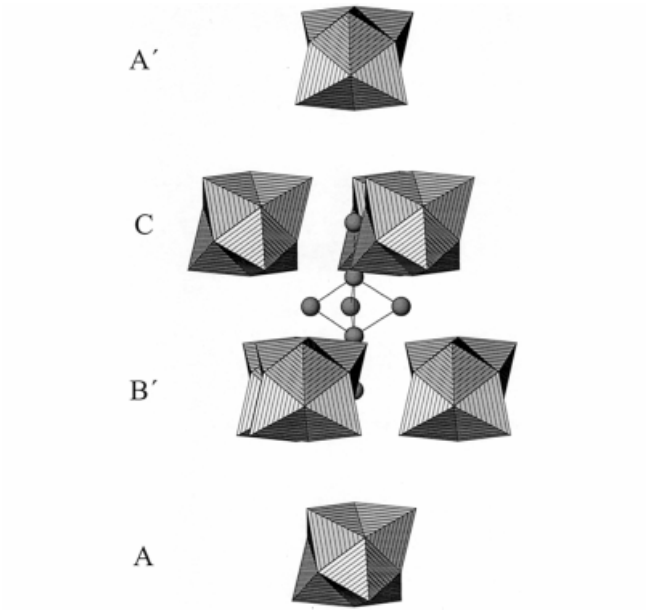

Figure 3. An Na_7 unit in an octahedral hole of the nearly ccp arrangement of $Ba_{14}CaN_6$ clusters in $Na_7Ba_{14}CaN_6$ (the *c*-axis is vertical); the labelling of the cluster layers is the same as in Figure 1

nearly ccp fashion as mentioned above, with the effective *c*/*a* ratio only 13% greater than that of the ideal cubic lattice, the Na_7 units occupy all octahedral holes.

Details of the crystallographic data for $Na_7Ba_{14}CaN_6$ can be found in Table 1. All interatomic distances (see Table 2) in $Na_7Ba_{14}CaN_6$ are similar to these in the other $Na_xBa_{14}CaN_6$ compounds. The intracluster distances are compared to those of $Na_8Ba_{14}CaN_6$ in Table 2; these are characteristic of ionic bonding.[2] The Na−Na (3.44, 3.77, and 3.80 Å) and Na−Ba (4.01−4.51 Å) distances are also in the range of the values observed in the other subnitrides of the series and are indicative of metallic bonding.[2] The intercluster Ba−Ba (4.767 and 4.781 Å) contacts are almost identical to those in $Na_8Ba_{14}CaN_6$.

The displacement factors for the sodium atoms (Table 3 and 4) are relatively large, which also has been linked to the metallic nature of the Na−Na and Na−Ba bonding.[1] In addition, two sodium positions feature strongly elongated thermal ellipsoids (split position refinement was unsuccessful). This, however, could be due to the chemical environment of these sodium atoms: thermal motion along the *c*-direction is much easier, as for the similar positions in $Na_8Ba_{14}CaN_6$, where thermal ellipsoids elongated parallel to the *c*-axis are also observed for the sodium atoms in the channels between $Ba_{14}CaN_6$ clusters.

A strong anisotropy of the Na thermal ellipsoids could also be caused by the presence of voids in the crystal structure of $Na_7Ba_{14}CaN_6$, which are similar to those found in the other compounds of the $Na_xBa_{14}CaN_6$ series. In an earlier investigation[3] it was definitely ruled out that these voids are due to the presence of contaminants, in particular hydrogen. We therefore anticipate that the voids in the structure of $Na_7Ba_{14}CaN_6$ are empty, too, in spite of the presence of hydrogen in the investigated sample as indicated by the contamination by Ba_2NH. The largest void in $Na_7Ba_{14}CaN_6$, located at (0,0,0.1106), is surrounded by a distorted cube of four Na and four Ba atoms (Figure 4). The distances from these atoms to the center of the void are 3.16 Å [Ba(3), 3×], 3.47 Å [Na(1), 1×], 3.66 Å [Ba(1), 1×], and 4.40 Å [Na(3),

Table 1. Details of the single crystal and powder diffraction investigations on $Na_7Ba_{14}CaN_6$

	Single crystal data	Powder data
Radiation, wavelength	Mo-K_α, 0.71073 Å	Cu-$K_{\alpha1}$, 1.54051 Å
Crystal system, space group	Rhombohedral, $R\bar{3}c$ (No. 167), $Z = 6$

N(1)	0.027(13)	0.035(14)	0.032(13)	−0.006(11)	0.000(10)	0.015(12)

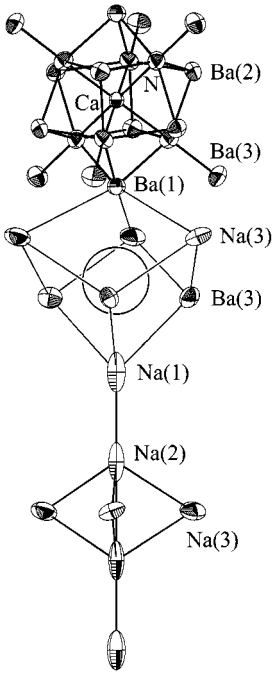

Figure 4. A fragment of the $Na_7Ba_{14}CaN_6$ structure with a $Ba_{14}CaN_6$ cluster (top), a Na_7 fragment (bottom), and the largest void (middle); the rather cube-like surrounding of the void is emphasized; the thermal ellipsoids are drawn for all atoms, the c-axis is vertical

3×]. The strongly anisotropic thermal ellipsoids of the sodium atoms may be considered a consequence of the preferred thermal motion in the direction of the void. We also note that these voids represent the tetrahedral holes in the ccp arrangement of the $Ba_{14}CaN_6$ clusters.

Experimental Section

Preparations: Due to the extreme sensitivity to air and moisture of all substances involved, these were handled either under high vacuum (10^{-6}−10^{-5} mbar) or under purified argon. Preparation of distilled metallic Ba, filtered metallic K, Na−K alloy, and the mixed subnitride $Ba_{1.83}Ca_{0.17}N$ have been described in detail previously. All syntheses mentioned below were carried out, unless stated otherwise, in cleaned Ta containers sealed under argon; these containers were themselves also sealed under argon in Duran glass ampoules. For details of these procedures refer to ref.[1]

$Na_{14}Ba_{14}CaN_6$ was prepared from metallic Ba (291.4 mg, 2.12 mmol), $Ba_{1.83}Ca_{0.17}N$ (1156 mg, 4.24 mmol), and Na-rich Na−K alloy (1300 mg; 31 mmol Na and 15 mmol K). The reagents with the overall stoichiometry $K_{21}Na_{45}Ba_{14}CaN_6$ were mixed and heated to 120 °C, then held at this temperature for a year. During the course of the reaction the ampoule was taken out four times for a short time and gently shaken. The solid reaction product was separated from excess alloy in a press. The product is $Na_{14}Ba_{14}CaN_6$ (the observed reflections matched the expected pattern of the cubic structure with a = 17.895 Å as reported in ref.[2]) with about 10 wt.% of a $NaBa_3N$ impurity (hexagonal with a = 8.4414 Å and c = 6.9817 Å[5]) according to X-ray diffraction. NaBa

was prepared as described in ref.[6] Equimolar amounts of Na and Ba were mixed in a Duran glass container and heated under argon at 140°C for two days. The resulting diffraction pattern matched that of the cubic structure with a = 17.027 Å.[7]

Single crystals of $Na_7Ba_{14}CaN_6$ were obtained in the following way. In sample A, $Ba_{1.83}Ca_{0.17}N$ (687.9 mg, 2.50 mmol), NaBa (203.4 mg, 1.27 mmol), and Na (49.4 mg, 2.2 mmol) with an approximate $Na_8Ba_{14}CaN_6$ overall stoichiometry were mixed, pressed into a pellet, and heated to 192 °C for 10 days, then held at 220 °C for 52 days and at 250 °C for 42 days with intermediate grindings of the pellet. This product (635.4 mg, 0.285 mmol "$Na_8Ba_{14}CaN_6$") was then mixed with K-rich Na−K alloy (206.0 mg; 0.96 mmol Na and 4.7 mmol K), yielding a $K_{17}Na_{11}Ba_{14}CaN_6$ overall stoichiometry. The mixture was heated to 350 °C and held at this temperature for 20 days, then cooled at 0.5°C/hour to 220 °C, held at 220 °C for 24 days, and finally cooled to room temperature by switching off the furnace. Crystals were manually selected from the resulting alloy-solid mixture and sealed under argon in glass capillaries.

A sample composed mostly of $Na_7Ba_{14}CaN_6$ was obtained by extracting sodium from $Na_{14}Ba_{14}CaN_6$ with metallic potassium. In sample B, $Na_{14}Ba_{14}CaN_6$ (217.8 mg, 0.091 mmol) was mixed with potassium (109.2 mg, 2.80 mmol), the resulting molar ratio being K:$Na_{14}Ba_{14}CaN_6$ = 31:1. The mixture was heated to 250 °C for 10 days, cooled at 0.2 °C/hour to 150 °C, and then finally cooled at 0.5 °C/hour to room temperature. Na−K alloy formed in the course of the reaction; the solid residue was separated from the alloy in a press. A portion of the solid product was ground together with glass powder and sealed in a 0.3 mm glass capillary for powder X-ray diffraction analysis.

Crystal Structure Investigations: Crystals obtained from sample A were first tested on a precession camera. Already at this stage it was apparent that most crystals were either pure $Na_8Ba_{14}CaN_6$ (hexagonal with a = 11.419 Å and c = 21.543 Å[1]) or intergrown with crystals of another phase, which is rhombohedral with the a-axis being practically the same as that of the $Na_8Ba_{14}CaN_6$ phase and the c-axis approximately three times that of the $Na_8Ba_{14}CaN_6$ phase, suggesting a structural similarity between the two phases. Two crystals featuring the largest fraction of the new phase (about 50%) were further investigated on a STOE image-plate diffractometer (IPDS). It was possible to separate the reflections belonging to the new phase from those belonging to $Na_8Ba_{14}CaN_6$; the poor quality of the obtained reflection data also introduced some ambiguity in finding the correct space group (see above). The initial measurement of the lattice parameters for the crystals yielded a = 11.35(1) Å and c = 62.85(5) Å (see footnote to Table 1). Using the linear V/Z vs. x correlation in the $Na_xBa_{14}CaN_6$ series,[1] the approximate x value of 6.7 could be obtained, suggesting that the new phase might have the stoichiometry $Na_7Ba_{14}CaN_6$.

Crystal structure solution was attempted based on the data collected at room temperature on one of the two crystals using direct methods (SHELXS-97), followed by full-matrix least-squares structure refinement (SHELXL-97).[8] The structure could be solved in space groups $R\bar{3}$ (No.148), $R32$ (No. 155), and $R3c$ (No. 161); their common subgroup $R3$ (No. 146) could, of course, also be used. A closer inspection of the structures obtained in these space groups revealed their mutual similarity, hence a refinement in the common supergroup $R\bar{3}c$ (No. 167) was attempted. All atoms could be refined anisotropically yielding indeed the stoichiometry $Na_7Ba_{14}CaN_6$ and chemically reasonable distances and displacement factors. The final R value of 13.1% was, however, a cause for concern. Closer inspection of the data set revealed that this relatively high value was mainly due to the inconsistency of equivalent reflections as indicated by the $R_{internal}$ value of 8.6%. This could have been caused by incomplete separation of reflections of $Na_7Ba_{14}CaN_6$ and $Na_8Ba_{14}CaN_6$. The large final R value is also manifested by substantial peaks in the Fourier difference map, the largest of which lie within 1.2 Å of the Ba(3) position.

In order to support the structural solution obtained from the single crystal diffraction data, a Rietveld refinement of the powder diffraction data, which were collected with sample B on a STADI-P STOE diffractometer with Cu-$K_{\alpha 1}$ radiation at room temperature, was attempted using the CSD package.[9] Before the refinement, the impurity reflections belonging to Ba_2NH (≈10 wt.%), $Na_8Ba_{14}CaN_6$ (≈5 wt.%), and $NaBa_3N$ (≈5 wt.%) were removed from the pattern (Figure 5). The refinement was carried out in the 2θ range from 7° to 35°. While the isotropic displacement factors for the barium atoms could be refined, those for all other atoms had to be fixed at the values obtained in the refinement of the single crystal diffraction data. The positions of the atoms obtained in the Rietveld refinement were less accurate than those deduced from the single crystal diffraction data, though both sets were within error bars from each other. The Rietveld refinement resulted in more accurate unit cell parameters: a = 11.360(1) Å and c = 63.061(7) Å. The corresponding unit cell volume leads to the improved x value of 6.9 in $Na_xBa_{14}CaN_6$, if the linear V/Z vs. x correlation[1] is employed.

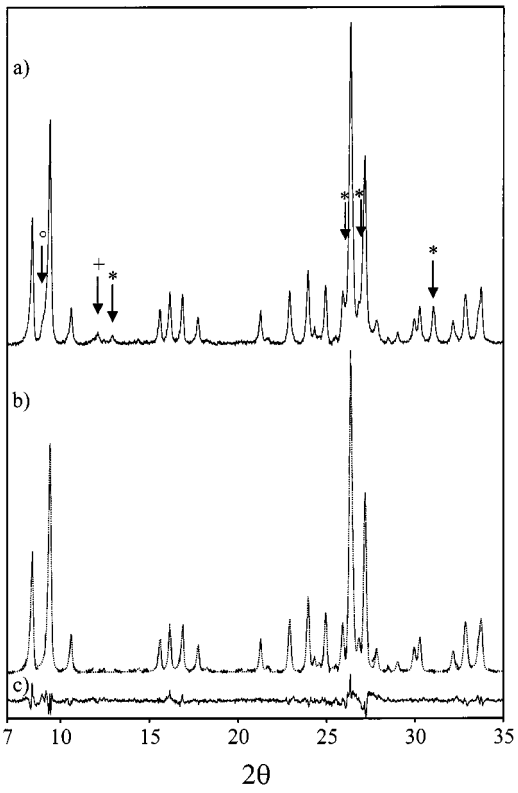

Figure 5. Measured X-ray diffraction pattern of $Na_7Ba_{14}CaN_6$: (a) strong reflections of impurity phases are indicated with arrows: $Na_8Ba_{14}CaN_6$ (°), $NaBa_3N$ (+), and Ba_2NH (*); these impurity reflections were removed from the pattern before Rietveld refinement was carried out; (b) the solid line represents the measured data and the dotted line shows the calculated curve; the difference between the two lines is plotted below (c)

Refinement of Guinier diffraction data (23 reflections) leads to similar lattice constants: a = 11.368(4) Å and c = 63.094(14) Å. In

addition, decomposition of $Na_7Ba_{14}CaN_6$ at ≈272 °C could be observed in a temperature-dependent Guinier measurement. The strongest reflections of the resulting diffraction pattern belong to $Na_8Ba_{14}CaN_6$.

The results of the single crystal and powder diffraction investigations are combined as follows. The unit cell parameters are taken from the Rietveld refinement (see Table 1 for refinement details), but the atomic positions (Table 3) and the anisotropic displacement factors (Table 4) are taken from the refinement of the single crystal diffraction data (see also Table 1 for details).

Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-411488.

Acknowledgments

The authors thank Dr. O. Oeckler for collecting and help with analyzing the single crystal diffraction data, Dr. J. Köhler for providing programs to analyze crystal structures for voids and for help with Rietveld refinement, and W. Röthenbach for temperature-dependent Guinier measurements. Thanks are also due to the Max Planck Society and the Alexander von Humboldt Foundation for providing G.V.V. with financial support during this study.

Dedicated to Prof. Dr. Dr. h. c. Gerhard Fritz on the occasion of his 80th birthday

Keywords: Lithium / Borates / Coordination chemistry

Several solvates of $LiBH_4$ with amines have been prepared and characterized by X-ray structure determinations. $LiBH_4{\cdot}3H_2NPh$ (**1**) is monomeric with a triply bridging BH_4 group. $LiBH_4{\cdot}2en$ (**3**) is shown to be an ionic compound containing chains of cationic $[Li(en)_2)]^+$ units. In contrast, the BH_4 group of $LiBH_4{\cdot}$triene (**4**) forms triple hydride bridges to the Li centers of a Li(triene) chain, making the Li atoms hexacoordinated by 3 × N and 3 × H atoms. Reaction of $LiBH_4$ with *tert*-butylamine generates the compound $3LiBH_4{\cdot}4H_2NtBu$ (**2**). The structure of **2** consists of an infinite chain of $LiBH_4$ units having three different kinds of Li centers, two of which have an environment of 2 × N and 4 × H atoms, whereas the third type is surrounded by five hydrogen atoms. Pyrrolidine reacts with $LiBH_4$ to give $LiBH_4{\cdot}HNC_4H_8$ (**5**), the structure of which in the solid state shows an infinite chain with heptacoordinated Li centers (N and 6 × H). In contrast, dibenzylamine gives the compound $LiBH_4{\cdot}2HN(CH_2Ph)_2$ (**6**), which is dimeric with hexacoordinated Li centers (2 × N and 4 × H) in the crystal, and a similar structure was found for $LiBH_4{\cdot}(i\text{PrNCH}_2)_3$ (**7**) but with heptacoordinated Li ions (3 × N and 4 × H). Addition of $(MeNCH_2)_3$ to $LiBH_4$ in toluene leads to $4LiBH_4{\cdot}2(MeNCH_2)_3$ (**8**), in which the two amine ligands bind to two Li ions, Li1 being hexacoordinated by (4 + 2) N atoms, Li2 by 2 × N atoms and 4 × H atoms from two different BH_4 groups. Li2 is part of a layer structure composed of $Li_3(BH_4)_4^-$ units. In contrast, a chain structure is evident in $3LiBH_4{\cdot}2(PhCH_2NCH_2)_3$ (**9**), as shown by the presence of separate $Li[(PhCH_2NCH_2)_3]_2$ cations and $Li_2(BH_4)_3$ anionic building blocks.

Introduction

Alkali metal tetrahydridoborates, particularly $NaBH_4$, are commercially produced.[2] Large quantities of $NaBH_4$ are used for the bleaching of pulp[3] and it is also useful for depositing heavy metals in waste water.[4] $LiBH_4$, on the other hand, is a very useful reducing agent of wide applicability.[5] Its reducing power is superior to that of $NaBH_4$ and its solubility is generally greater than that of $NaBH_4$. The solubility of $LiBH_4$ depends on the solvation of this compound by the solvent and a number of ether and amine solvates have been described in the literature.[4,6] However, in most cases, information about their structures in the crystal has not been available until recently.[6]

The structures of solvates of $LiBH_4{\cdot}n$L depend on the type and number (n) of ligand molecules (L). This results in a large variety of structures that range from mononuclear species through a preference for dinuclear molecules to extended chains and double chains to three-dimensional arrays. We report here new information on amine solvates of $LiBH_4$ that adds to the diversity of structures in the crystalline state but also shows that the BH_4 group is a particularly versatile ligand.[7]

Syntheses

It is well known that the alkali metal tetrahydridoborates, particularly $LiBH_4$ and $NaBH_4$, dissolve well in liquid ammonia or primary amines. Extraction of $NaBH_4$ from the solid mixture of $NaOMe/NaBH_4$ by isopropylamine is a known technical process.[8] An even better solvent is liquid ammonia, which dissolves 104 g of $NaBH_4$ in 100 mL,[9] while only 20 g of KBH_4 is soluble in the same amount of solvent.[10] Nevertheless, the composition of the solvates, particularly with primary amines, has yet to be well established in most cases.[11]

In the present work two routes have been used to obtain and isolate amine solvates of $LiBH_4$. The first method involves treatment of $LiBH_4$ with an excess of an amine in the presence of a nonpolar solvent such as toluene. In the second route, $LiBH_4$ is simply dissolved in the amine and the solvate isolated from the resulting solution. The ligand displacement reaction as depicted in Equation (2) was less successful. Reactions according to Equation (1) have been used to prepare compounds **1**–**9**.

$$LiBH_4 + n\text{L} \rightarrow LiBH_4 \cdot n\text{ L} \quad (1)$$

$$LiBH_4 \cdot OEt_2 + n\text{ L} \rightarrow LiBH_4 \cdot n\text{ L} + OEt_2 \quad (2)$$

We report here only on those amine solvates that were obtained in the form of single crystals. Our attempts to pre-

A B

pare single crystals of isopropylamine and ethylamine have so far failed. Even the solid products that we isolated were difficult to analyze due to rapid loss of amine. Therefore, their composition could not be reliably determined.

It should be noted that, according to ^{11}B NMR spectroscopic data, the amine not only solvates $LiBH_4$ but also removes a BH_3 group to form amine−borane adducts $L{\cdot}BH_3$ that are readily identified by the typical 1:3:3:1 quadruplet in the ^{11}B NMR spectra.[12] This kind of behavior is more pronounced for toluene solutions than for hexane solutions. In the case of the formation of **8**, a substantial amount of $(\text{MeNCH}_2)_3{\cdot}BH_3$ was formed; the compound was isolated and subjected to a crystal structure determination.[13]

NMR and IR Spectra

Although the structures of the $LiBH_4$ solvates in the solid state are of special interest, their state in solution is at least of the same importance because reactions, for instance the reduction of functional groups of organic compounds, are performed in solvents. However, knowledge about the structure in the solid state may be helpful in the assignment of IR data.

Table 1 summarizes the ^{11}B and ^{7}Li NMR spectroscopic data. It should be noted that there is only one ^{7}Li signal for each of the compounds investigated. This is, at first glance, a rather surprising observation. If the solid and solution state for the dimeric molecules $[LiBH_4{\cdot}(\text{MeNCH}_2)_3]_2$[6b] and $[LiBH_4{\cdot}(i\text{PrNCH}_2)_3]_2$ (**7**) were the same, one would expect only a single signal. However, the shielding should be different because in the former compound only two of the three ring nitrogen atoms coordinate to Li (in the solid state) while all three nitrogen atoms of the $(i\text{PrNCH}_2)_3$ ligand bind to the Li center. Indeed, the ^{7}Li NMR signal for the latter compound is better shielded. On the other hand, if the solid-state structure of compound **9** was retained in solution then one would expect at least two signals, one of them being highly shielded due to the coordination of one of the three Li centers (vide infra) to six nitrogen atoms. However, only a single signal is observed. Therefore, the ^{7}Li NMR spectrum is not compatible with the structure found in the crystal indicating dynamic behaviour in solution.

Table 1. $\delta^{7}Li$ and $\delta^{11}B$ data and coupling constants $^{1}J(^{11}B^{1}H)$ (1:4:6:4:1 quintuplets) for lithium tetrahydridoborate amine solvates

Compound	$\delta^{7}Li$	$\delta^{11}B$	$^{1}J(^{11}B^{1}H)$ [Hz]	Solvent
1	0.1	−38.0	81	aniline
2	1.07	−38.3	81	C_6D_6
3	2.0	−38.3	81	pyridine
4	1.7	−38.1	81	pyridine
5	1.32	−41.1	87	C_6D_6
6	–	−38.2	81	MeC_6H_{11}
7	0.097	−38.5	81	toluene
8	0.74	−38.6	96	toluene
9	0.347	−39.4	unresolved	C_6D_6

A considerable degree of deshielding occurs for compounds with an $LiBH_4$/N ratio close to 1:1. However, it is unlikely that the chain structure of $3LiBH_4{\cdot}4H_2NtBu$ is retained in solution. The chains are expected to break down into smaller units, possibly into units such as those suggested in formulas **A** (for **2**) or **B** (for **5**). A tetrameric unit is not unfeasible because such a unit has been found for

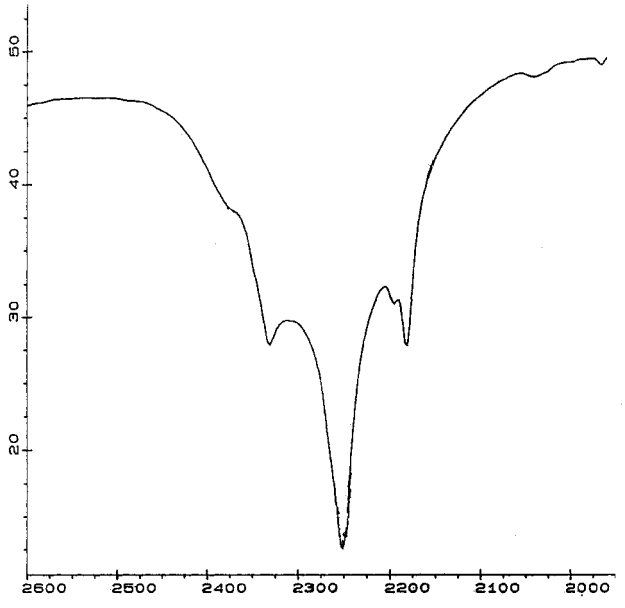

Figure 1. IR spectrum of $LiBH_4{\cdot}3H_2NPh$ (**1**) in Nujol; only the B−H stretching region is depicted

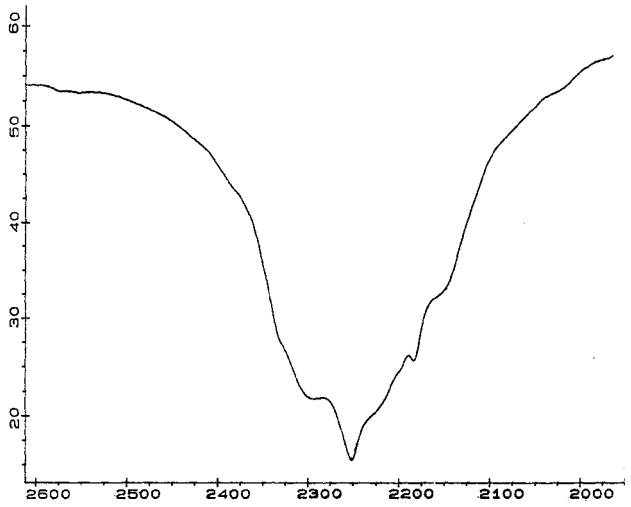

Figure 2. IR spectrum of $LiBH_4 \cdot 2en$ (**3**) in Nujol; only the B−H stretching region is shown

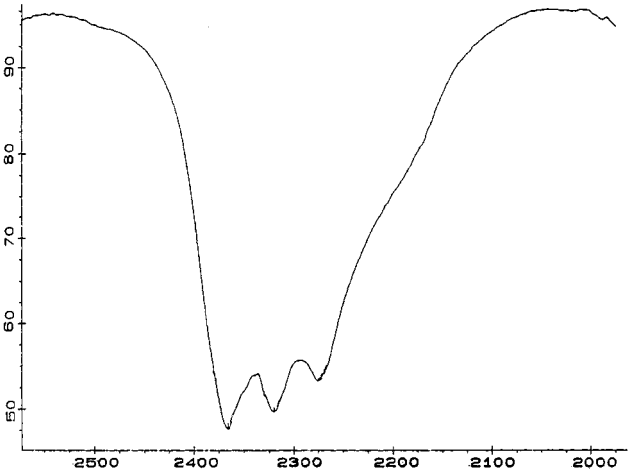

Figure 3. IR spectrum of $3LiBH_4 \cdot 4tBuNH_2$ (**2**) in Nujol showing the B−H stretching region

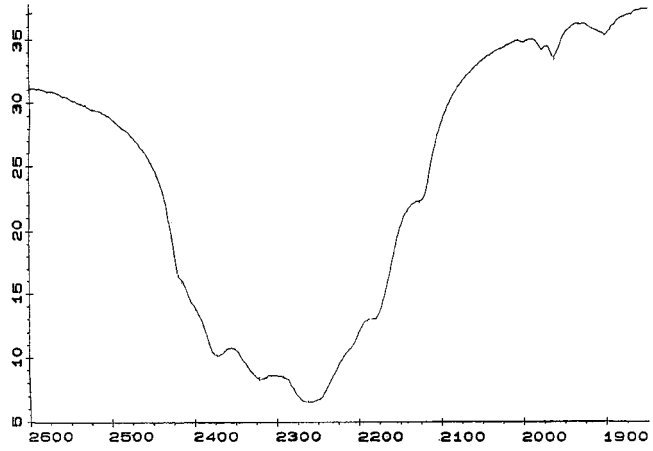

Figure 4. IR spectrum of $\{Li[(PhCH_2NCH_2)_3]_2\}Li_2(BH_4)_3$ (**9**) in Nujol showing the B−H stretching region

$[NaBH_4 \cdot L]_4$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane).[6b]

All compounds show only one 1:4:6:4:1 quintuplet for the BH_4 anion in the proton-coupled ^{11}B NMR spectrum except for compound **9**, which gave rise to a broad signal without fine structure due to B,H coupling. The $\delta^{11}B$ values span a narrow range from $\delta = -38.3$ to -41.1. Therefore, irrespective of the composition of the compounds, all BH_4 groups are chemically equivalent in solution, as are their H atoms. In addition, $^1J(BH)$ does not allow a structural distinction of the various Li···H−B interactions observed in the crystal structures.

Figure 1 (compound **1**), Figure 2 (**3**), Figure 3 (**2**), and Figure 4 (**9**) show some IR spectra measured from Nujol mulls and the values of the B−H stretching bands observed for compounds **1**−**9** are given in the Exp. Sect.

One might expect that the B−H stretching bands for $[LiBH_4(MeNCH_2)_3]_2$[6b] and **7** should be rather similar because both show the same type of bonding for the BH_4 group (vide infra). Nevertheless, noticeable differences do exist. Even if we neglect the shoulder at 2154 cm^{-1} for $[LiBH_4(MeNCH_2)_3]_2$, the wave numbers are sufficiently different for the two species, as exemplified by the strong bands at 2272 and 2366 cm^{-1} for the former and 2185 and 2378 cm^{-1} for the latter compound. The IR spectrum of compound **9**, with its $Li_2(BH_4)_3$ chain, shows four strong B−H stretching bands with two shoulders, all of which are rather broad. This spectrum is indicative of the presence of different BH_4 groups, and its features are similar to those of the IR spectrum in the B−H stretching region of compound **8** with its sheet-like arrangement of the $Li_3(BH_4)_4$ anionic lattice. In any case, the IR spectra of compounds

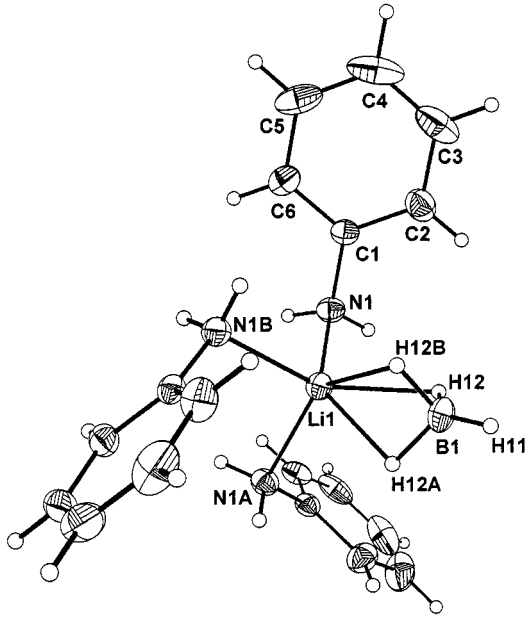

Figure 5. Molecular structure of $LiBH_4 \cdot 3NH_2Ph$ (**1**); only one of the two independent molecules is depicted; thermal ellipsoids represent a 25% probability; selected atom distances (in Å): molecule 1: Li1−N1 2.135(2), Li1···B1 2.279(6), N1−C1 1.416(2), B1−H11(term.) 0.86(5), B1−H12(bridge) 1.10(4); molecule 2: Li2−N2 2.137(2), Li2···B2 2.363(6), N2−C7 1.418(2), B2−H21(bridge) 0.89(5), B2−H22(term.) 0.94(4); selected bond angles (in °): molecule 1; N1−Li1−B1 116.1(1), C1−N1−Li1 113.6(1), N1−Li1−N1A 102.1(1), B1−H12−Li1 92(2), H11−B1−H12 120.9(2); molecule 2: N2−Li2−B2 112.5(1), C7−N2−Li2 113.3 (1), N7−Li2−N(7A) 106.3 (1), B2−H21−Li2 106(2), H21−B2−H22 126(3)

1−**9** do not allow unequivocal assignment to a specific bonding pattern of the BH_4 groups to the Li centers.

Structures of the Amine Solvates of $LiBH_4$

The most simple structure amongst the solvates of primary amines with $LiBH_4$ is the aniline solvate $LiBH_4 \cdot 3H_2NPh$, (**1**, see Figure 5). Compound **1** crystallizes trigonally in the space group $R3$ with $Z = 6$, i.e. there are two independent molecules in the unit cell. Both molecules have C_3 symmetry, with the threefold axis running through the Li and B atoms and the terminal hydrogen atom of a μ_3^1-BH_4 group. The Li−B distances in the two molecules are significantly different [Li1−B1 2.279(6), Li2−B2 2.363(6) Å]. This is due to different N−Li−B bond angles. At atom Li1 the angle is larger [116.1(1)°] than at atom Li2 [112.5(1)°]. However, the bond angles Li−N−C are identical for both molecules.

The crystals that separated from a toluene solution of $LiBH_4$ after addition of tBuNH$_2$ had the (unexpected) composition $3LiBH_4 \cdot 4t$BuNH$_2$ (**2**). This compound crystallizes monoclinically in the space group $C2/c$. Figure 6 represents the contents of the asymmetric unit.

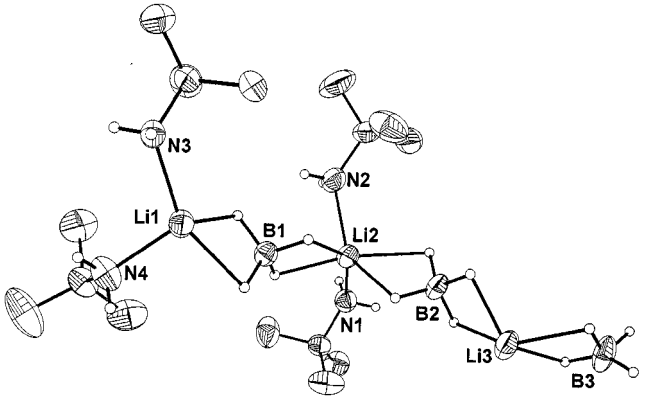

Figure 6. Molecular structure of $3LiBH_4 \cdot 4NH_2t$Bu (**2**) in the asymmetric unit; thermal ellipsoids are presented on a 25% probability scale; selected bond lengths (in Å): Li1−N4 2.076(5), Li1−N3 2.089(5), Li1···B1 2.476(5), B1···Li2 2.609(5), Li2−N1 2.086(5), Li2−N2 2.092(5), Li2···B2 2.500 (5), B2···Li3 2.404(6), Li3···B3 2.382(6); selected bond angles (in °): N3−Li1−N4 108.5(2), N4−Li1−3.1 112.6(2), N3−Li1−B1 127.8(2), B1−Li2−N1 121.9(2), B1−Li2−N2 90.2(2), B2−Li2−B1 116.1(2), N2−Li2−B2 122.1(2), B2−Li3−B3 125.2(2)

It should be noted that there are *three* different Li centers, and it is clear that only atom Li2 is coordinatively saturated (e.g. hexacoordinated) while atoms Li1 and Li3 are not. Only two of the three Li centers bind to two amine molecules each, while atom Li3 does not bear an amine ligand. The N−Li−N bond angles at Li1 and Li2 are close to tetrahedral [N3−Li1−N4, N1−Li2−N2 110.4(2)°]. If we consider the BH_4 group to be a pseudohalide − considering the boron atom as the center of a pseudofluoride − then we can assume that atom Li2 sits in a distorted tetrahedral environment, with bond angles Li−B−Li ranging from 98.1(2) to 122.1(2)°. However, the bridging hydrogen atoms are, of course, closer to the Li center than the boron atoms and are normally taken as the coordination partner. In this case it is clear that the H−Li−H bond angles must be rather sharp as a consequence of the tetrahedral BH_4 group. The typical feature of compound **2** is that, as far as the *asymmetric* unit is concerned, each BH_4 group acts as a $2\mu_2^1$ group. This is shown by the fact that we note two LiH_2B bridges from each BH_4 group to two *different* Li centers (see Figure 6). Inspection of the structure of **2** in the lattice shows that the molecular part of the asymmetric unit is the subunit of an extended chain (see Figure 7). We see that atom Li3 is surrounded by three BH_4 groups that supply, in total, five hydrogen atoms for coordination. For this $Li(BH_4)_3$ unit, two BH_4 groups retain one B−H bond in a terminal position and the other three H atoms form a double hydride bridge and a single bridge to atoms Li3 and Li3A, respectively. The third BH_4 group (B2) interacts with atom Li3 through two hydride bridges. Atom Li1 is hexacoordinated: There are two hydrogen atoms each from two different BH_4 groups (Figure 7). However, the group $B(1)H_4$ is exceptional because all four H atoms coordinate to Li centers (Li1, Li2). The bonding mode in this case is $2\mu_1^2,2\mu_1^1$.[6b] Li2 is also hexacoordinated, but in a different way to Li1 because the two adjacent BH_4 groups supply double hydride bridges. In summary, two Li atoms of **2** are hexacoordinated and one is pentacoordinated.

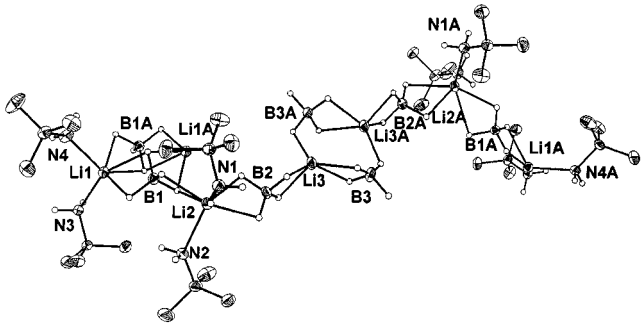

Figure 7. Chain arrangement of $3LiBH_4 \cdot 4NH_2t$Bu (**2**) in the lattice; note the pentacoordination at atom Li3

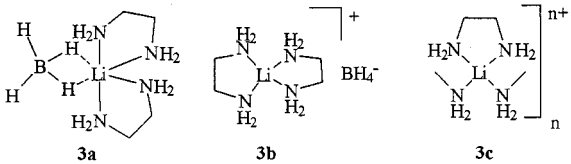
Ethylenediamine (en) is the simplest primary diamine. It forms the solvate $LiBH_4 \cdot 2$en (**3**) which by X-ray structure determination is shown to be the ionic compound $[Li(en)_2]BH_4$ in the solid state. The cationic part does *not* have the simple structure, as shown by formula **3b**. Rather the $Li(en)_2$ unit forms an extended chain (Figure 8) because every Li center is part of only one LiN_2C_2 five-membered ring. The second en molecule bridges the Li atoms as indicated in formula **3c**. The BH_4 groups do not coordinate with Li atoms. Figure 9 shows a view of the contents of **3** in the unit cell down the b axis.



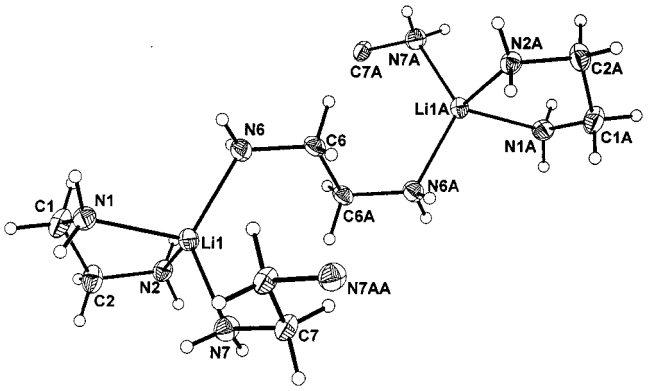


Figure 8. The $Li(en)_2$ chain in the lattice of $LiBH_4$·2en (**3**); only part of one of the two independent chains is presented but data are given for both cations; selected bond lengths (in Å): cation of molecule 1: N1−C1 1.468(3), N2−C2 1.466(2), N1−Li1 2.059(3), N2−Li1 2.052(3), N6−Li1 2.059(4), N7−Li1 2.071(4), B1−H 1.09(6)−1.16(3); cation of molecule 2: N3−C4 1.465(3), N4−Li3 1.464(3), N3−Li2 2.061(3), N4−Li2 2.059(4), N5−Li2 2.060(4), N8−Li2 2.065(4), B2−H 1.05(3)−1.16(3); selected bond angles (in °): C1−N1−Li1 102.5(2), C2−N2−Li1 102.8(1), N7−Li1−N6 123.7(2), N1−Li1−N6 108.8(2), N2−Li1−N7 100.6(2), N1−Li1−N7 113.6(2), N2−Li1−N6 111.0(2), N2−Li1−N1 88.3(1); for molecule 2: N4−Li2−N5 110.2(2), N5−Li2−N3 109.0(2), N5−Li2−N8 124.0(2), N4−Li2−N3 88.2(1), N4−Li3−N8 106.0(2), N3−Li2−N8 113.5(2)

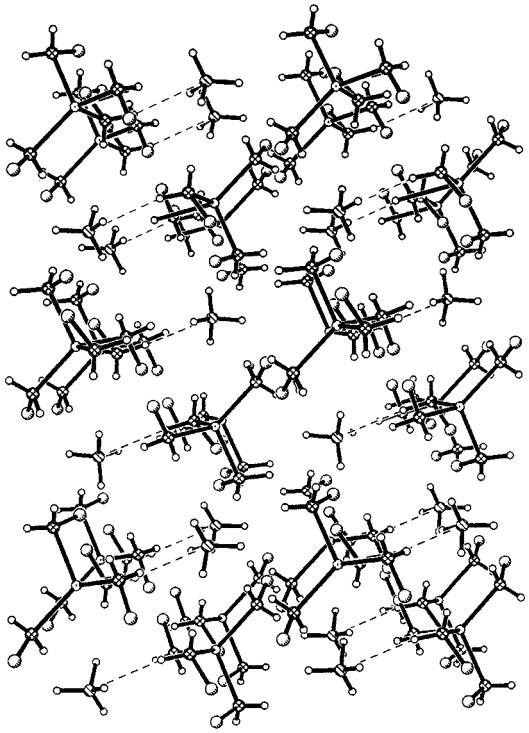

Figure 9. Plot of the structure of compound **3** in the crystal in a view down the *b* axis

The solvate of lithium tetrahydridoborate with diethylenetriamine has the composition $LiBH_4$·$(H_2N-CH_2-CH_2)_2NH$ (**4**). Figure 10 describes the structure of two formula units of **4** in the crystal which form part of an extended chain. Each Li atom is hexacoordinated by three nitrogen and three hydrogen atoms. Each BH_4 group supplies three hydrogen atoms through three Li···H−B bridges (μ_3^1-mode). Consequently, the Li···B atom distance is fairly short at 2.336(4) Å. The Li···N distances range from 2.085(3) to 2.161(3) Å, the longest bond being formed with the secondary nitrogen atom of the triamine. It is interesting that the amine does not act as a tridentate ligand in forming complex **4a**. Rather a chain structure results with a *syn* orientation of the BH_4 groups. Li···H distances span a small range, the shortest distance being 2.13 Å and the longest 2.29 Å, while the B···H distances to the terminal hydrogen atom H [1.17(3) Å] seem to be longer than the three bridge B−H bonds [1.03(3), 1.10(3), and 1.15(3) Å]. Inspection of the geometry of the BH_4 group reveals the presence of a distorted *tetrahedron* whose H−B−H bond angles can be quite narrow (103°) or quite open (122°). As expected, the N2−Li1−N3 bond angle of the LiN_2C_2 five-membered ring is small [85.8(1)°] while the bond angle N(1B)−Li1−N2 is tetrahedral [109.8(1)°]. Astonishingly, the N−C−C bond angles also vary significantly, the smallest one being 109.2(2)° and the largest 116.0(2)°.

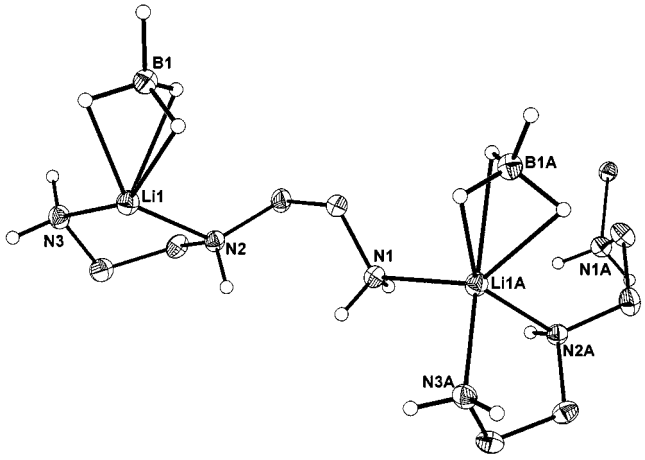

Figure 10. Structure of $LiBH_4$·triene (**4**); two molecular units that are part of a chain are depicted; thermal ellipsoids are drawn on a 25% probability scale; selected atom distances (in Å): Li1−N2 2.161(3), Li1−N3 2.085(3), Li1···B1 2.336(4), N1−Li1A 2.698(3), B−H (term.) 1.17, B−H (bridge) 1.03−1.15; selected bond angles (in °): Li1−N3−C4 101.5(1), Li1−N2−C3 102.8(1), Li1A−N1−C1 117.3(1), H13−B1−Li1 164.2(2), N3−Li1−N2 85.8(1), N1B−Li1−B1 113.3(1), N3−Li1−H13(term.) 151.4(2), N3−Li1−N1B 100.0(1), N2−Li1−N18 109.8(1), N3−Li1−B1 124.4(1), N2−Li1−B1 119.5(1); note that N1B binds to Li1

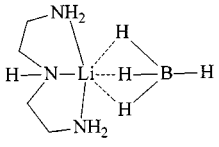

4a

Lithium tetrahydridoborate−pyrrolidine, $LiBH_4$·HNC_4H_8 (**5**), was not expected to have a simple structure because there is only one amine ligand available for coordination to the Li center. Moreover, the crystal contains toluene, its composition being $2LiBH_4$·$2NHC_4H_8$·$C_6H_5CH_3$.

Figure 11 represents the contents of the asymmetric unit of **5** in the triclinic cell. This arrangement is reminiscent of the structure of $[LiBH_4$·tmen$]$[14] because the two BH_4 groups are of the $2\mu_1^1,\mu_1^2$ type, i.e. there are two single Li−H−B bridges to two different Li centers while a third

hydrogen atom bridges two Li atoms. In addition, another BH_4 group supplies two H atoms through LiH_2B bridges. This situation means that the Li centers are heptacoordinated.

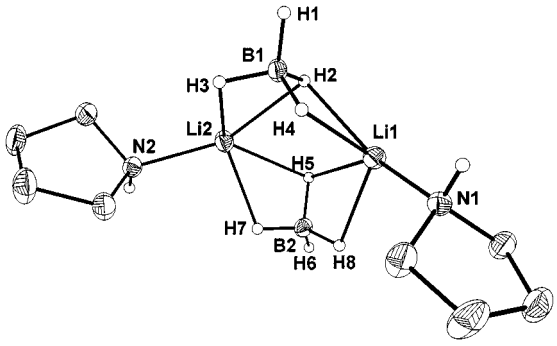

Figure 11. Structure of $LiBH_4 \cdot HNC_4H_8$ (**5**) in the crystal; the contents of the asymmetric unit are depicted; the C atoms of the disordered toluene molecule are not included; thermal ellipsoids are drawn on a 25% probability scale; selected atom distances (in Å): N1−Li1 2.022(6), N2−Li2 2.205(5), Li1−B1 2.561(6), Li1−B2 2.530(6), Li2−B1 2.527(6), Li2−B2 2.569(6), Li1−H 2.08−2.23, Li2−H 2.03−2.09, B1−H 1.08(3)−1.15(3), B2−H 1.05(4)−1.14(4); selected bond angles (in °): N1−Li1−B1 116.5(2), N1−Li1−B2 118.6(2), N2−Li2−B1 118.0(2), N2−Li2−B2 116.7(2), N1−Li1−H8 95(1), N1−Li1−H5 145.0(9), N1−Li1−H2 141.0(9), N1−Li1−H4 93(1), N2−Li2−H7 94(1), N2 − Li2−H5 140.9(9), N2−Li2−H3 92.4(9)

The structure of **5** shows short Li−N bonds [2.024(6) Å] and rather uniform Li···H distances [2.09(3) Å], and this is also true for the B−H bond lengths [1.10(4)−1.15(4) Å]. The H−B−H bond angles are close to tetrahedral, meaning that the asymmetry induced at the BH_4 groups by the different interactions of its hydrogen atoms with the Li centers is not reflected in different bond angles.

Figure 12 shows how the smallest unit forms an infinite chain in the lattice by the action of inversion center. For the sake of clarity several pyrrolidine units are not depicted. The result of this symmetry operation is also depicted in Figure 13, which shows a view down the *b* axis. In the chain each Li center is not only coordinated to an N atom but also to three different BH_4 groups, all of which are of the $2\mu_1^1,\mu_1^2$ type.

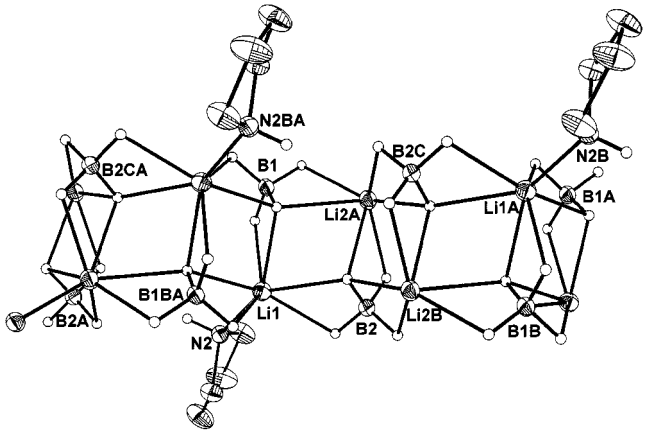

Figure 12. View of the chain of compound **5** in the lattice; only part of the pyrrolidine ligands is depicted in the interest of clarity

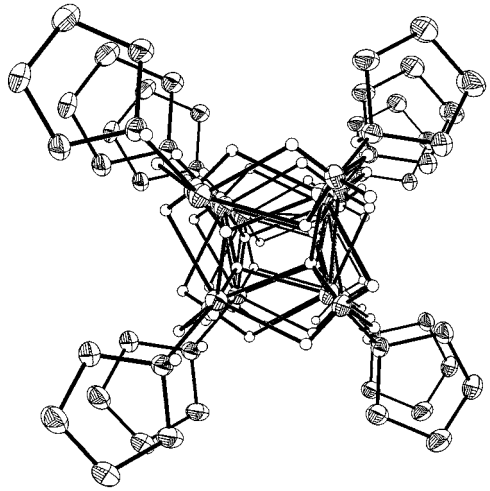

Figure 13. View of the chain down the *b* axis

It is amazing that $LiBH_4$ adds only one pyrrolidine molecule but two dibenzylamines in spite of the fact that the dibenzylamine is sterically more demanding. Compound **6**, $LiBH_4 \cdot 2HN(CH_2Ph)_2$, crystallizes in the monoclinic system and the unit cell contains dimeric units. Figure 14 depicts the molecular structure of this system, which has a center of symmetry.

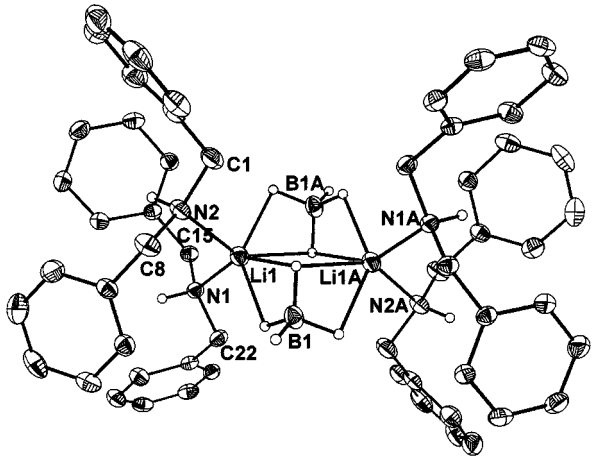

Figure 14. Molecular structure of dimeric $LiBH_4 \cdot 2NH(CH_2Ph)_2$ (**6**); thermal ellipsoids are drawn on a 25% probability scale; selected atom distances (in Å): Li1−N1 2.126(3), Li1−N2 2.131(4), Li1···B1 2.516(4), Li−H 1.9−2.2, B−H 1.1−1.2; selected bond angles (in °): N1−Li1−N2 107.5(1), N1−Li1−B1 122.0(1), N2−Li1−B1 101.9(2), Li1−B1−Li1A 80.3(1), B1−Li1−B1A 99.7(1)

The structure of **6** is analogous to the structure of $(LiBH_4 \cdot tmen)_2$.[14] As expected the N1−Li1−N2 bond angle is wider (107.5°) than for $[LiBH_4 \cdot tmen]_2$ (74.6°) because the nitrogen atoms are not constrained in a five-membered ring. A second consequence is that the Li−N bond lengths are shorter.

We have already reported that $[LiBH_4(MeNCH_2)_3]_2$[6b] has a structure closely related to the structure of $[LiBH_4 \cdot tmen]_2$,[14] because only *two* of the *three* nitrogen atoms of $(MeNCH_2)_3$ coordinate to a Li center.[6b] A structure related but different to $[LiBH_4(MeNCH_2)_3]_2$ is displayed by dimeric $LiBH_4(i\text{PrNCH}_2)_3$ (**7**). As Figure 15 re-

veals, all three nitrogen atoms of the amine ligand are now bonded to the Li ion, and two monomeric units are joined through two $\mu_1^2,2\mu_1^1$-BH_4 units. Nevertheless, the triazacyclohexane ligand is not symmetrically bonded to the Li center; Li−N bond lengths are 2.10(1), 2.20(1), and 2.38(1) Å; Li−H distances range from 1.93 to 2.17 Å.

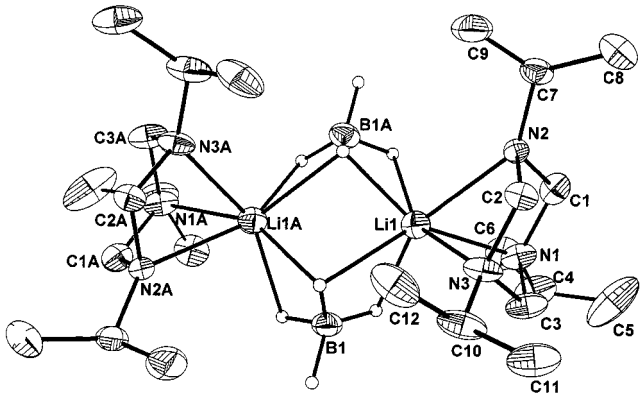

Figure 15. ORTEP plot of dimeric $LiBH_4$·(*i*PrNCH$_2$)$_3$ (**7**); hydrogen atoms bonded to carbon atoms are omitted; thermal ellipsoids represent a 25% probability; selected atom distances (in Å): Li1−N1 2.10(1), Li1−N2 2.38(1), Li1−N3 2.20(1), Li1···B1 2.53(1), Li1−H2 (Li1A) 1.93(6), Li1−H1 2.00(1), B−H (term.) 1.14(6), B−H (bridges) 1.12−1.14(5); selected bond angles (in °): N1−Li1−N3 65.5(4), N1−Li1−N2 62.9(4), N3−Li1−N2 60.8(4), B1−H1−Li1 (μ_1^1) 103.8(9), B1−H2−Li1 (μ_1^2) 100.7(6), B1−H2−Li1A (μ_1^2) 94.4(6), Li1A−H3−B1 (μ_1^1) 94.4(1), Li1−H2−Li1A 97.8(1)

If the reaction of $LiBH_4$ with (MeNCH$_2$)$_3$ is performed in toluene instead of in boiling xylene,[6b] then the product formed does not have a 1:1 composition but is 2$LiBH_4$·(MeNCH$_2$)$_3$ (**8**). The crystals of this compound are orthorhombic with space group *Pcca* but the structure could also be solved in the monoclinic space group $P2_1/c$. Figure 16 shows the contents of the asymmetric unit, which formally consists of a dimeric unit of **8**.

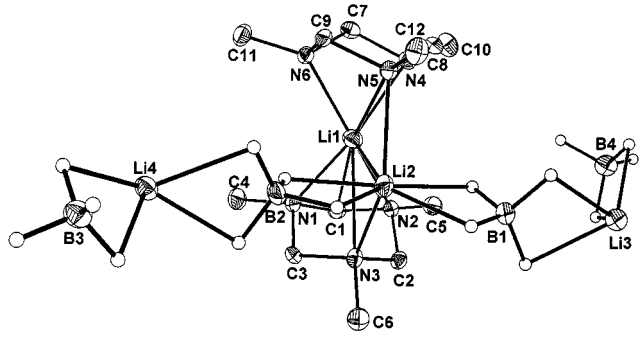

Figure 16. ORTEP plot for the contents in the asymmetric unit of 4$LiBH_4$·2(MeNCH$_2$)$_3$ (**8**); CH hydrogen atoms are omitted; thermal ellipsoids are depicted on a 25% probability scale; selected atom distances (in Å): Li1−N1 2.674(3), Li1−N2 2.141(1), Li1−N3 2.115(2), Li1···Li2 2.770(5), Li2−N1 2.297(2), Li2−B1 2.429(2), Li3···B1 2.376(3), Li3···B2 2.349(3), B3···Li3 2.319(3); selected bond angles (in °): N3−Li1−N1 58.48(6), N2−Li1−N1 57.83(6), N2−Li1−N3 66.28(5), N1−Li−N1A 99.75(1), N2−Li1−N2A 166.8(2), N3−Li1−N3A 157.4(2), N1−Li2−N1A 125.8(2), Li2−B1−Li3 161.2(2), B1−Li3−B2 126.2(1), Li3−B2−Li3B 167.8(2), B3−Li3−B1 126.2(1), B2−Li3−B3 125.4(1)

At first glance the unusual structural feature of compound **8** is that one Li center is "centrally" coordinated to two (MeNCH$_2$)$_3$ molecules while a second Li ion coordinates to two N atoms of the "sandwiched" Li1 atom. A closer look reveals that Li1 is asymmetrically coordinated to the N donor atoms and resides on a crystallographic twofold axis. There are four short Li1−N distances [2.115(2) to 2.142(1) Å] and two long ones [2.674(3) Å]. These latter distances are longer than the Li−C distances of Li1 to atoms C1 and C1A [2.467(2) Å]. The orientation of the two rings with respect to one another represents an "eclipsed" position. Atom Li2 coordinates with atoms N1 and N1A and the Li2−N bond lengths are 2.297(2) Å. One of the reasons for this asymmetry in coordination is the rather short Li1···Li2 distance of 2.770(5) Å.

The second feature is the presence of a layer structure of composition $[Li_3(BH_4)_4]^-$. Each Li center in this layer is hexacoordinated by six hydrogen atoms stemming from three BH_4 groups, each one corresponding to two Li(H$_2$)B units. This kind of $2\mu_2^1$ coordination finally leads to the two-dimensional array of $LiBH_4$ units as depicted in Figure 17. Thus, compound **8** can be given the formula $[Li\{(MeNCH_2)_3\}_2][Li_3(BH_4)_4]$ where the chain atom Li2 "shares" the nitrogen atoms N1 and N1A with Li1.

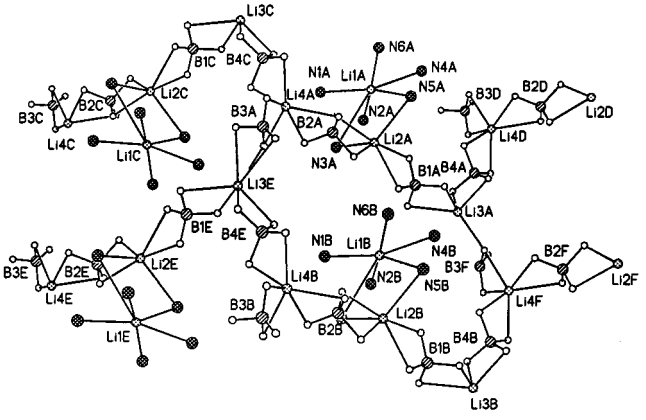

Figure 17. Part of the layer structure of compound **8** in the crystal; extension to the layer is through the B3- and Li3-type atoms; C and H atoms of the amine ligand have been removed for the sake of clarity; here, the structure is shown for the refinement in space group $P2_1/c$; in this space group the atoms on B3 and Li3 could be located and refined. However, it is more likely that the orthorhombic space group *Pcca* is correct; in this case atom B3 resides on a mirror plane and only three hydrogen atoms could be located but not the fourth; the action of the mirror plane leads, of course, to disorder of the H atoms of this BH_4 group

However, when 1,3,5-tribenzyl-1,3,5-triazacyclohexane is employed as a ligand for $LiBH_4$ then compound **9** is formed and this, by X-ray structure determination, can best be described as $\{Li[(PhCH_2NCH_2)_3]_2\}\{Li_2(BH_4)_3]$. The high steric demand of the ligand $(PhCH_2NCH_2)_3$ leads to a separation of one Li cation, out of three $LiBH_4$ units, from its anion with formation of the cation $Li[(PhCH_2NCH_2)_3]_2^+$, as shown in Figure 18. The Li center occupies a special position.

It should be noted that the six Li−N distances of the cations Li1 and Li4 are rather similar, spanning the range from 2.223(2) to 2.293(3) Å. Atoms Li1 and Li4 are located on a crystallographic inversion center and, consequently, three N−Li−N bond angles within each cation are 180°.

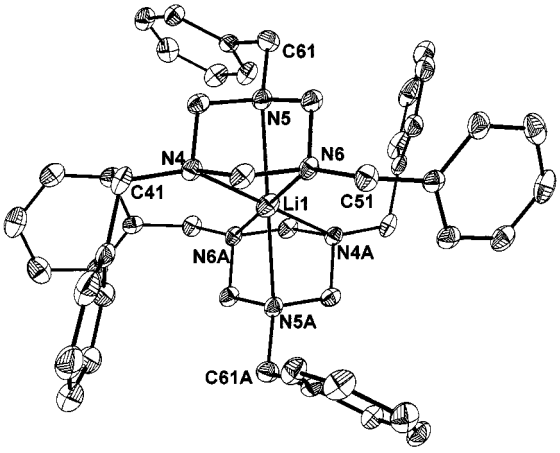

Figure 18. One of the two independent centrosymmetric $[Li(PhCH_2NCH_2)_3]$ cations of compound **9**; hydrogen atoms omitted; selected atom distances (in Å): Li1−N4 2.339(3), Li1−N5 2.285(3), Li1−N6 2.315(3); selected bond angles (in °): N4−Li1−N5 60.9(1), N4−Li1−N6 60.9(1), N5−Li1−N6 61.3(1); N4−Li1−N4A 180

For each heterocycle all N−Li−N bond angles are close to 63°.

The plot shown in Figure 19 demonstrates that the cations $Li[(PhCH_2NCH_2)_3]_2^+$ separate the chain structure of the anionic part of **9**. There are two different kinds of BH_4 units. The BH_4 groups of atoms B1 and B3 are typical $2\mu_1^1,\mu_1^2$ ligands, each having one terminal B−H bond. However, the BH_4 group of atom B3 uses all of its four hydrogen atoms for bridging to three Li atoms in a $3\mu_1^1,\mu_1^2$ function. However, there were non-negligible residuals around atom B2, and particularly at the adjacent Li3 atom. Moreover, the thermal motion of atom B2 was suspect and the tricoordinated H atom shows a somewhat longer Li−H distance [2.17(5) Å] than the dicoordinated H atoms. Indeed, refinement of the H atom positions of this exceptional BH_4 group was best for a disorder involving two sites, one with one Li−H bond (2.1 Å) and an almost planar BH_3 group, and a second site with a distorted BH_4 group. This disorder refined well with SOF = 0.5 (see Figure 20). Indeed, the thermal ellipsoid for B3 is compatible with this kind of disorder. It seems, therefore, that a BH_3 group is stabilized by the lattice. We have noticed this kind of structure in two out of three crystal structure determinations of compound **9**. Consequently, we found an electron density for a hydrogen atom bonded to Li3 (2.1 Å). The plot in Figure 19 demonstrates the packing of the cations and anion in the lattice.

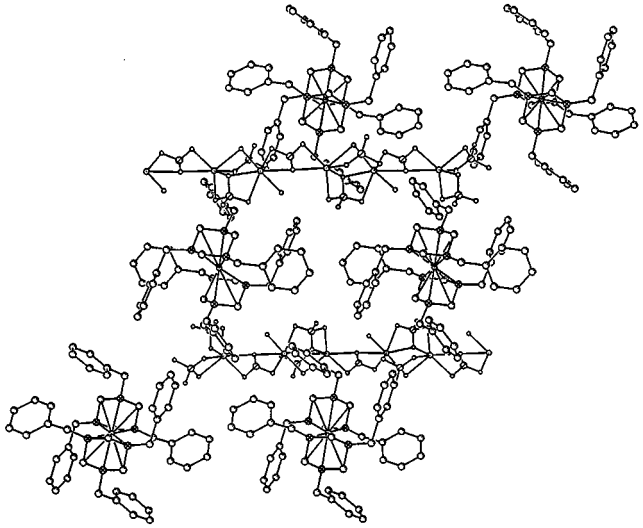

Figure 19. Arrangements of atoms in compound **9** in the crystal separated into $Li[(PhCH_2NCH_2)_3]_2$ cations and anionic $[Li_2(BH_4)_3]$ chains; these are depicted for the BH_3/LiH disorder in the chain

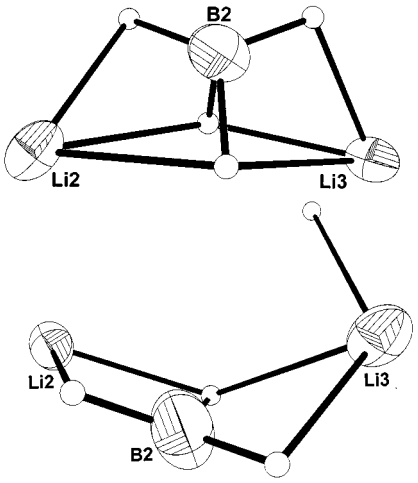

Figure 20. Disordered arrangement of the $B2(H)_4$ group between atoms Li2 and Li3; the tetrahedral BH_4 group (top) and the BH_3 (LiH) group (bottom)

Discussion

It has previously been noted that the bonding mode of the BH_4 group in mononuclear $LiBH_4{\cdot}n$L species depends on the number of ligands L and their steric demand. For $n = 3$ and L = pyridine[6b] or aniline the anion BH_4^- uses three of its hydrogen atoms to form Li−H−B bridges. However, if the ligand is sterically more demanding, e.g. collidine with $n = 2$, only a bidentate μ_2^1-BH_4 group is present.[6b]

On the other hand, if the ratio Li/N is 1:2, as found for $LiBH_4{\cdot}2HN(CH_2Ph)_2$ (**6**), dimers are formed. The structure and bonding of **6** correspond with the prototype of this pattern, $[LiBH_4{\cdot}tmen]_2$,[14] where the BH_4 group functions as a $2\mu_1^1,\mu_1^2$-ligand, i.e. one hydrogen atom binds to two Li centers with the other two forming single Li−H−B bridges. This structural feature is also realized in $[LiBH_4{\cdot}(MeNCH_2)_3]_2$ even if the Li/N ratio is 1:3. However, the effective Li/N ratio is 1:2 because only two out of the three nitrogen atoms of the ligand coordinate strongly to the Li center.[6b] In compound **2**, $3LiBH_4{\cdot}4H_2NtBu$, the Li/N ratio is only 1:1.33. Thus, the Li ions cannot all be coordinated by two nitrogen atoms. The possible structures $(LiBH_4{\cdot}2H_2NtBu){\cdot}2(LiBH_4{\cdot}H_2NtBu)$ or $[Li(H_2NtBu)_4]$-$[Li_2(BH_4)_3]$ are not formed but rather

$2(LiBH_4 \cdot 2H_2NtBu) \cdot (LiBH_4)$. The "$LiBH_4$" part is, of course, coordinatively unsaturated and shares BH_4 groups with the amine carrying $LiBH_4 \cdot 2H_2NtBu$ units, as depicted in Figure 7.

This feature becomes even more apparent for $LiBH_4 \cdot HNC_4H_8$ (**5**) with a ratio Li/N = 1:1. Formation of a chain structure through BH_4 sharing leads to hexacoordinated, coordinatively saturated Li centers. In this case, the BH_4 group joins two Li ions through $2\mu_2^1$ bridges and all four hydrogen atoms are used for coordination through double hydrogen bonds $Li(H)_2B$.

Unexpectedly, $LiBH_4 \cdot (i\text{PrNCH}_2)_3$ (**7**) also forms dimers like $LiBH_4 \cdot$tmen, and $LiBH_4 \cdot (\text{MeNCH}_2)_3$, in spite of the fact that in **7** all three N atoms of the heterocycle coordinate to Li while in the other two compounds the Li centers carry only two N atoms. However, the coordination in **7** is asymmetric: There are two short Li−N distances (2.10, 2.20 Å) and a significantly longer one (2.38 Å). This situation is in contrast to that in $LiBH_4 \cdot$PMDTA,[6b] which is mononuclear in spite of the fact that the three nitrogen atoms of the pentamethyldiethylenetriamine ligand are also asymmetrically bonded. Clearly, PMDTA is sterically more demanding than $(i\text{PrNCH}_2)_3$, and this may be the reason why **7** is dimeric in the crystal.

An Li/N ratio of 1:1.5 is present in the compound $2LiBH_4 \cdot (\text{MeNCH}_2)_3$ (**8**) and a 1:2 ratio in $3LiBH_4 \cdot 2(\text{PhCH}_2\text{NCH}_2)_3$ (**9**). In both cases, extended structures are formed but there are significant differences between the two compounds. Due to the large steric effect of the ligand tribenzyl-1,3,5-triazacyclohexane, one Li center is "sandwiched" between two amine ligands, which surround the cation centrosymmetrically. Thus, compound **9** contains tris(tetrahydridoborato)dilithiate anionic units, which form a chain structure in the crystal. In the case of compound **8** the nitrogen ligand also sandwiches a Li center by four short and two longer Li−N bonds, but two of the six nitrogen atoms bind a second Li atom, which is additionally coordinated to two BH_4 groups. The resulting unit, which finally leads to a layer structure, therefore has the composition $Li_3(BH_4)_4^-$, where one of the three Li centers coordinates with the amine ligand.

Since the BH_4 group can be regarded as a "pseudofluoride" one may expect that amine complexes of lithium halides form similar structures. However, structural analogs of the amine complexes of $LiBH_4$ have not been reported to date. The only compound having an extended chain is LiCl−15-crown-5.[15] All others are either dimeric, trimeric, or tetrameric.[16] In these cases pyridines, tmen, or PMDTA were used as ligands and comparisons are limited. Thus, at the present time, the anion BH_4^- proves to be a most versatile ligand. In addition, it is demonstrated for the first time that certain amine solvates of $LiBH_4$ form polymeric anionic units $[Li_n(BH_4)_{n+1}]^-$. However, the solid-state structures do not seem to be retained in solution because only one type of BH_4 ion is detected by ^{11}B NMR spectroscopy as well as single ^7Li resonances, irrespective of the various kinds of structures found for the solid state.

Experimental Section

All experiments were performed under dry nitrogen with strict exclusion of moisture. Consequently, all solvents were dried and stored under nitrogen. $LiBH_4$ was of commercial grade (Chemetall GmbH), as were the amines, which were dried by treatment with CaH_2 followed by distillation, in the case of liquids, or by recrystallization of the vacuum-dried solids. − NMR: Bruker AC 200 (^{11}B), Jeol 270 (^1H, ^{13}C), Jeol EX400 (^7Li); Standards: $BF_3 \cdot OEt_2$ external; 1 M aq. LiCl solution, external; C_6D_6 and $SiMe_4$ internal. − IR: Nicolet-FT spectrophotometer. − Elemental analyses: Microanalytical Laboratory of the Department of Chemistry, University of Munich.

Lithium Tetrahydridoborate−Aniline(1:3) (1): $LiBH_4$ (231 mg, 10.6 mmol) was suspended in aniline (20 mL). After stirring for 20 min, the turbid solution was filtered and the filtrate stored at 8 °C. Clear needles of **1** suitable for X-ray structure analysis separated within a few days. Yield: 257 mg of **1** (8%), m.p. 58−62 °C (dec.). On removing aniline from the filtrate a larger amount of **1** was isolated (yield not determined). − NMR (in aniline): ^7Li NMR: δ = 0.1(3). − ^{11}B NMR: δ = −38.0 [quint, $^1J(^{11}B^1H)$ = 81 Hz]. − IR (Nujol, B−H stretching region): $\tilde{\nu}$ = 2377 cm^{-1} w, 2331 m, 2252 vst, 2196 m, 2183 m. − $C_{18}H_{25}BLiN_3$ (301.23): calcd. C 71.79, H 8.37, N 13.95; found C 69.77, H 8.52, N 13.53.

Lithium Tetrahydridoborate−*tert*-Butylamine(3:4) (2): $LiBH_4$ powder (250 mg, 11 mmol) was suspended in toluene (10 mL) with stirring and *tert*-butylamine (1.2 mL, 11.3 mmol) was added. The suspension was heated at reflux for 30 min. The insoluble material was removed by filtration (G3 frit) and the solution cooled to −20 °C in a refrigerator. Clear needles separated from the solution within one week. Yield: 190 mg (18%), m.p. ca. 10 °C. A further quantity of compound **2** was isolated from the concentrated filtrate. − NMR (C_6D_6 + TMS): ^7Li NMR: δ = 1.07. − ^{11}B NMR: δ = −38.3 [quint, $^1J(^{11}B^1H)$ = 81 Hz]. − IR (B−H stretching region): $\tilde{\nu}$ = 2366 cm^{-1} st, 2320 st, 2275 st. − $C_{16}H_{56}B_3Li_3N_4$ (357.90): calcd. C 53.69, H 15.77, B 9.06, Li 5.82, N 15.65; found C 51.96, H 15.92, B 8.9, Li 5.9, N 16.62.

Lithium Tetrahydridoborate−Ethylenediamine(1:2) (3): $LiBH_4$ (58.5 mg, 2.69 mmol) was suspended in a mixture of ethylenediamine (171 mg, 2.85 mmol) and pyridine (5 mL). After addition of methylcyclohexane (1 mL) the slightly turbid solution was subjected to filtration and the filtrate kept at 8 °C. Crystals of **3** separated in a few hours. These crystals deteriorated quickly in a stream of nitrogen. Yield: 35 mg of **3** (9%), m.p. 91 °C. From the filtrate a further quantity of **3** could be obtained by reducing the volume of the solution. − NMR (pyridine): ^7Li NMR: δ = 2.0. − ^{11}B NMR: δ = −38.3 [quint, $^1J(^{11}B^1H)$ = 81 Hz]. − IR (Nujol, B−H stretching region): $\tilde{\nu}$ = 2300 cm^{-1} sh, 2252 st, 2220 sh, 2183 m, 2147 m. − A satisfactory elemental analysis could not be obtained.

Lithium Tetrahydridoborate−Diethylenetriamine (4): $LiBH_4$ (190 mg, 8.71 mmol) was dissolved in a mixture of diethylenetriamine (895 mg, 8.67 mmol) and pyridine (10 mL). After stirring for 15 min, toluene (1 mL) was added and insoluble material was removed by filtration. After keeping the solution at 8 °C, colorless prisms separated. Yield: 121 mg (11%), m.p. 110−118 °C (dec.). − NMR (pyridine): ^7Li NMR: δ = 1.7 (s). − ^{11}B NMR: δ = −38.1 [quint, $^1J(^{11}B^1H)$ = 81 Hz]. − IR (Nujol, B−H stretching region): $\tilde{\nu}$ = 2326 cm^{-1} sh, 2251 st br, 2219 sh, 2182 sh. − $C_4H_{17}BLiN_3$ (125.17): calcd. C 38.45, H 13.71, N 33.63; found C 38.68, H 13.39, N 32.14.

Lithium Tetrahydridoborate−Pyrrolidine (5): A suspension of $LiBH_4$ (410 mg, 19 mmol) in toluene (45 mL) and pyrrolidine (1.56 mL, 18.9 mmol) was heated to reflux for 10 min. Most of the solid dissolved and the insoluble material was removed from the hot solution. The filtrate was cooled to −20 °C. Colorless needles separated within 12 h. The needles were isolated by filtration using a cooled frit. Single crystals for X-ray determination were removed directly from the suspension. Yield: 106 mg (54%), m.p. ca. 0 °C. − NMR (C_6D_6 + TMS): ^{7}Li NMR: δ = 1.32. − ^{11}B NMR: δ = −41.1 [quint, $^1J(^{11}B^1H)$ = 87 Hz]. − IR (B−H stretching region): $\tilde{\nu}$ = 2252 cm^{-1} st, 2279 st, 2355 sh. − $C_4H_{13}BLiN$ (92.90): calcd. C 48.05, H 14.87, B 11.64, Li 7.47, N 15.08; found C 48.79, H 14.00, B 11.0, Li 7.4, N 15.47.

Lithium Tetrahydridoborate−Dibenzylamine(1:2) (6): Dibenzylamine (50 mL) was saturated with $LiBH_4$ and excess $LiBH_4$ was removed by filtration. The clear solution was layered with cyclohexane (20 mL). A precipitate formed and was filtered off. ^{11}B NMR of the solution showed the presence of a BH_4 unit and a BH_3 group in a 3:7 ratio. The filtrate was cooled to 8 °C. Crystals of **6** separated as colorless prisms, m.p. 81−83 °C (dec.). − ^{11}B NMR: δ = −38.2 [quint, $^1J(^{11}B^1H)$ = 81 Hz], −14.0 (broad). − ^{1}H NMR (C_6D_6): δ = 0.6 [1:1:1:1 q, $^1J(^{11}B^1H)$ = 81 Hz]. − IR (B−H stretching region): $\tilde{\nu}$ = 2370 cm^{-1} st, 2332 st, 2305 st, 2272 st, 2238 st. − $C_{28}H_{34}BLiN_2$ (416.30): calcd. C 80.78, H 8.23, N 6.73, B 2.60, Li 1.67; found C 76.91, H 7.91, N 6.42, B 2.95, Li 1.97.

Lithium Tetrahydridoborate−1,3,5-Triisopropyl-1,3,5-triazacyclohexane (7): To a stirred suspension of $LiBH_4$ (440 mg, 20 mmol) in toluene (36 mL) was added the ligand (4.84 mL, 20.2 mmol). Most of the $LiBH_4$ dissolved on heating the suspension at reflux for 30 min. Insoluble material had to be rapidly removed from the suspension because crystals settled quite quickly from the solution on cooling to room temperature. Yield: 1.9 g (40%), m.p. 98−102 °C (dec.). − ^{7}Li NMR (toluene): δ = 0.097. − ^{11}B NMR (C_6D_6 + TMS): δ = −15.9 [q, $^1J(^{11}B^1H)$ = 60 Hz], −38.5 [quint, $^1J(^{11}B^1H)$ = 81 Hz], ratio ca. 1:8. − IR (B−H stretching region): $\tilde{\nu}$ = 2185 cm^{-1} st, 2250 m, 2283 m, 2316 w, 2334, w, 2378 st. − $C_{12}H_{31}BLiN_3$ (235.14): calcd. C 61.29, H 13.29, B 4.60, N 17.87; found C 59.92, H 12.96, B 4.30, N 18.52.

Lithium Tetrahydridoborate−(1,3,5-Trimethyl-1,3,5-triazacyclohexane)(4:2) (8): Lithium tetrahydridoborate (1.03 g, 47.4 mmol) was suspended in toluene (40 mL). The amine (6.65 mL, 47.4 mmol) was added to the stirred suspension and stirring was continued for 2 h. The suspension was quickly heated to reflux and kept at this temperature for 10 min. Insoluble materials were removed from the hot solution and the filtrate cooled to −20 °C. Prismatic crystals separated within 12 h. Yield: 2.97 g (73.4%), m.p. 78 °C. − ^{7}Li NMR (toluene): δ = 0.74. − ^{11}B NMR (toluene): δ = −38.6 [quint, $^1J(^{11}B^1H)$ = 86 Hz]. − IR (B−H stretching region): $\tilde{\nu}$ = 2184 cm^{-1} sh, 2253 st, 2319 m, 2328 m, 2373 st. − $C_{12}H_{42}B_4Li_4N_6$ (341.48): calcd. C 42.20, H 12.40, B 12.66, N 24.61; found C 42.10, H 12.05, B 12.10, N 24.62.

Lithium Tetrahydridoborate−(1,3,5-Tribenzyl-1,3,5-triazacyclohexane)(3:2) (9): To a stirred suspension of $LiBH_4$ (220 mg, 10 mmol) in toluene (20 mL) was added the amine ligand (3.57 g, 10.1 mmol). After keeping the mixture at reflux for 1 h, the hot suspension was filtered. Crystals separated within 4 h from the filtrate, which was kept at −20 °C. Yield: 720 mg (28%), m.p. 134−136 °C. A second crop was isolated on reducing the volume of the filtrate under vacuum. The yield of the second crop was not determined. − ^{7}Li NMR (C_6D_6 + TMS): δ = 0.347. − ^{11}B NMR ([D_8]toluene): δ =

X-ray Structure Determinations: X-ray structure determinations were performed with a Siemens P4 diffractometer, using Mo-K_α radiation and a graphite monochromator. Data were collected with a CCD area counter at 193 K (Siemens LT2 device). Several drops of a suspension containing the single crystals were transferred to precooled perfluoro polyether oil and kept at −40 °C. The selected single crystal was mounted on a glass fiber. The dimensions of the unit cell were calculated from the reflections of a total of 75 frames recorded for five different settings of the crystal using the program SMART.[17] Data collection was performed in the hemisphere mode by recording 1200 frames with $\Delta = 0.3°$ at two different χ settings. The program SAINT[18] was used for data reduction. Structure solution and refinement was carried out with the programs SHELX93[19] by applying direct methods. Non-hydrogen atoms were refined with anisotropic thermal parameters. Positions of hydrogen atoms attached to boron atoms were taken from the difference Fourier map. Their positions and isotropic thermal parameters were refined. All other H atoms were placed in calculated positions and included in the refinement with a riding model. − Compound **5** was obtained from toluene solution. There were five peaks that we assigned to C atoms of a disordered toluene but the C−C distances were rather irregular. One of these C atoms could not be refined anisotropically. − The structure of compound **8** was solved and refined in two space groups, monoclinic $P2_1/c$ and orthorhombic *Pcca*. The β angle was very close to 90° and, in the first runs, a solution was only obtained for the $P2_1/c$. In this solution all four H atoms could be located at B3. Refinement in *Pcca* led to more favorable *R* values, although the H atoms at B3 refined to give a disordered arrangement at B3 due to its position on a mirror plane. − A disorder was also found for the $B(3)H_4$ group in compound **9**, which indicates a disordered tetrahedral BH_4 group and a BH_3 and LiH group. These were included in the refinement with SOF = 0.5, a value indicated by a previous refinement without constraints. − A summary of crystallographic data and information referring to data collection and refinement is given in Table 2. Additional material (without structure factor tables) are deposited with the Cambridge Crystallographic Data Centre as supplementary publications CCDC-143680 (**1**), -143681 (**2**), -143682 (**3**), -143683 (**4**), -143684 (**5**), -143685 (**6**), -143686 (**7**), -143687 (**8**), -143688 (**9**). Copies of the data can be obtained on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.uk].

Platinum(II) Compounds with Enantiomerically Pure Bis(pinene)-Fused Bipyridine Ligands − Diimine-Dichloro Complexes and Their Substitution Reactions

Brunhilde Kolp,[a] Dirk Abeln,[b] Helen Stoeckli-Evans,[c] and Alexander von Zelewsky*[a]

Keywords: Chirality / Platinum / Substitution reactions / Diastereoselectivity / N ligands

The synthesis of chiral square-planar Pt^{II} complexes using symmetrical and unsymmetrical bis(pinene)-fused 2,2′-bipyridine is described. The neutral diimine dichloro complexes show a strong deviation of the coordination sphere from planarity if the pinene groups are attached at the 5- and 6-positions of the pyridine rings. However, this distortion does not occur in parallel with the chiral configuration at the diimine ligands. The substitution of the two *cis*-chloro ligands with diamines to form five-membered chelate rings shows little diastereoselectivity when racemic mixtures of chiral diamines are used. Also, ligands that are prochiral at the ligating centers show little selectivity upon coordination.

Introduction

Square-planar coordination geometry, the most frequent coordination mode of diamagnetic d^8-metals do not generally exhibit chirality, since genuinely planar structures cannot be chiral in three-dimensional space. Deviations from planarity can, however, lead to chiral configurations. An early example of this type was the platinum(II) complex containing one molecule of *meso*-stilbenediamine and one molecule of isobutylenediamine occuring as a pair of enantiomers.[1] Complexes in which a distortion from planarity occurs in a way that permits chirality have recently been found in the class of bis-cyclometallated compounds. These compounds have a very strong tendency to form *cis*-complexes, leading to helical configurations of ligands that interact strongly, thereby avoiding coplanarity.[2] The advent of nonracemic pyridine and bipyridine ligands derived from naturally occurring terpene compounds[3] has prompted us to investigate the possibility of a stereoselective synthesis of coordination species that show chiral elements within the ligand and around the metal center. It has been shown that metal chirality can be predetermined in "square-planar" complexes (SP-4-complexes) by using this type of ligand in *diastereoselective syntheses.*[4]

Here we present the preparation and characterization of a series of enantiomerically pure Pt^{II} complexes, in which the chirality is located in the "chiralized" bipyridine ligands. The investigations focus on the question whether the ligands **L1**−**L5** induce chiral distortions from planarity in the complex and whether chirality can be transferred in stereoselective reactions to ligands that occupy the coordination sites around the central metal (Scheme 1).

Results and Discussion

Chiral Bipyridine Ligands

For the synthesis of the substituted bipyridine ligands **L1**−**L5**, the method described by F. Kröhnke[5] was modified. The synthesis of the compounds **L1**, **L2**, and **L5** has already been described.[6,7] The preparation of ligand **L3** was similar to that of **L2** except that for one of the two 'Kröhnke cyclizations', (+)-α-pinene was used as starting material and for the second one (−)-α-pinene was used, which gave the *meso* ligand **L3**.

The preparation of compound **L4** is shown in Scheme 2. Chirality was introduced by using enantiomerically pure (−)-β-pinene (**1**) as starting material. Compound **1** was oxidized to the (+)-nopinone (**2**) following a 'one-pot' method described by Brown.[8] The nopinone was treated with $NaNH_2$ which resulted in the formation of enolate **3**. Treatment of **3** with formaldehyde in a Na_2CO_3 solution gave the α,β-methylene ketone **4**, which was used for the condensation with the 'Kröhnke salt' **5** in the same way as already described by von Zelewsky et al.[7] for **L2**.

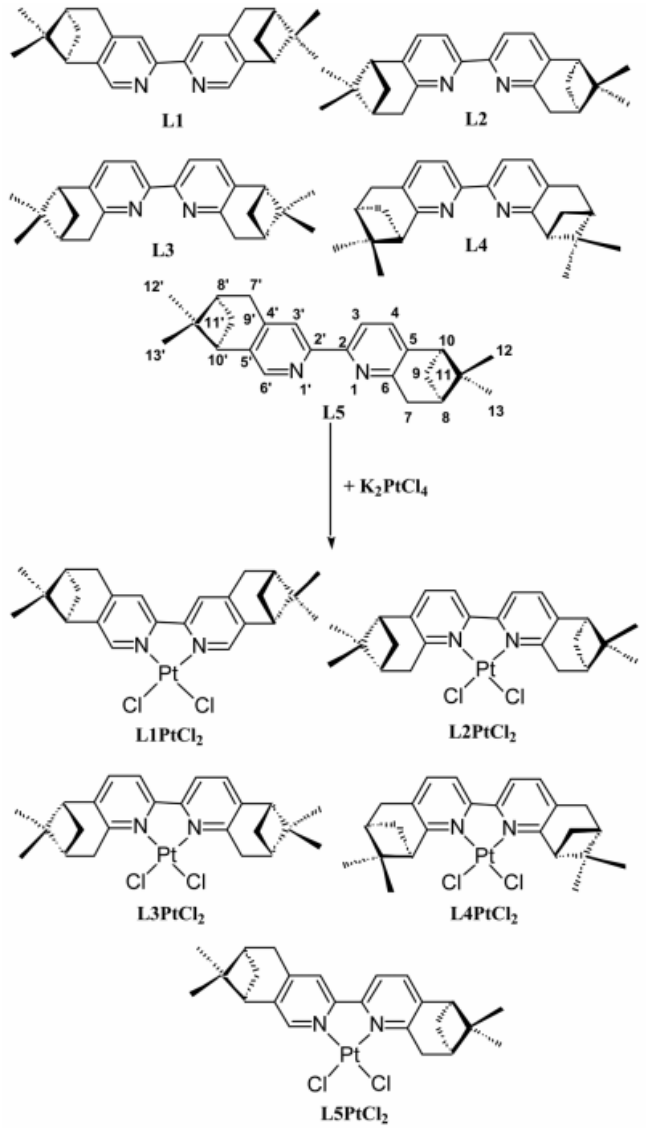
Complex Formation and Characterization in Solution

The complexation of **L1**, **L2**, **L3**, **L4**, and **L5** with Pt^{II} was carried out in aqueous hydrochloric acid solution using K_2PtCl_4 as starting material (Scheme 1). The yellow, uncharged dichloro complexes precipitated out of the aqueous solution and were isolated and purified. As expected, the formation of bis-diimine complexes was not observed, since the ligands are sterically bulky.

^1H NMR Spectroscopy

All compounds prepared were fully characterized by ^1H-, ^{13}C-, and ^{195}Pt NMR spectroscopy. Figure 1 shows the

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0505−1207 $ 17.50+.50/0



Scheme 1

^{1}H NMR spectra of **L1** and **L2**, and of their Pt-complexes. The pairs of diastereotopic protons H^7 (H^{7endo} and H^{7exo}) are isochronous in free **L1** and **L2**, as well as in **L3**, **L4**, and **L5**. However, a strong downfield shift with a concomitant splitting and a large geminal coupling occurs in the complexes **L2PtCl$_2$**, as well as in **L3PtCl$_2$** and **L5PtCl$_2$**, whereas **L1PtCl$_2$** and **L4PtCl$_2$** still show the same behavior as the free ligand. In **L1PtCl$_2$**, the complex formation strongly influences the aromatic proton H^6, whereas in the case of **L4PtCl$_2$**, the aliphatic proton H^{10} is shifted strongly downfield. The aliphatic protons, except for H^7 in **L2**, **L3**, and **L5**, H^{10} in **L4**, and the aromatic protons H^3 and H^4 are only very slightly influenced by complexation.

Ligands **L1**−**L4** and their Pt complexes all show equivalent halves in the ^{1}H NMR spectra (Figure 1). This equivalence is due to a C_2 axis in **L1**, **L2**, and **L4**, whereas **L3** has a mirror plane. These symmetry elements are no longer present in the solid state, as will be discussed later. In the unsymmetrical ligand **L5**, all the protons of the two halves are nonequivalent, as expected.

^{13}C NMR

In all cases, the ^{13}C NMR spectra show the expected features. Contrary to the ^{1}H NMR spectra, the ^{13}C NMR spectra of the diastereomeric ligands **L2** and **L3** exhibit differences in the chemical shift values of C^5. However the complexes **L2PtCl$_2$** and **L3PtCl$_2$** don't show any differences in the ^{1}H NMR or in the ^{13}C NMR spectra.

^{195}Pt NMR

More information about the isomeric purity of the complexes can be obtained by ^{195}Pt NMR spectroscopy, since chemical shifts are usually very large for this nucleus. All compounds show a single Pt-signal. The values in Table 1 show a small influence ($\Delta\delta$ = 14 ppm) of the pinene groups at the 4- and 5-positions when compared to the complex with unsubstituted 2,2′-bipyiridine. The shift values for the complexes with the 5,6-pinene-bipyridine ligands are much larger, in the order of $\Delta\delta \approx 400$ ppm. The diastereomeric complexes **L2PtCl$_2$** and **L3PtCl$_2$** are not distinguishable.

Electronic and CD Spectra

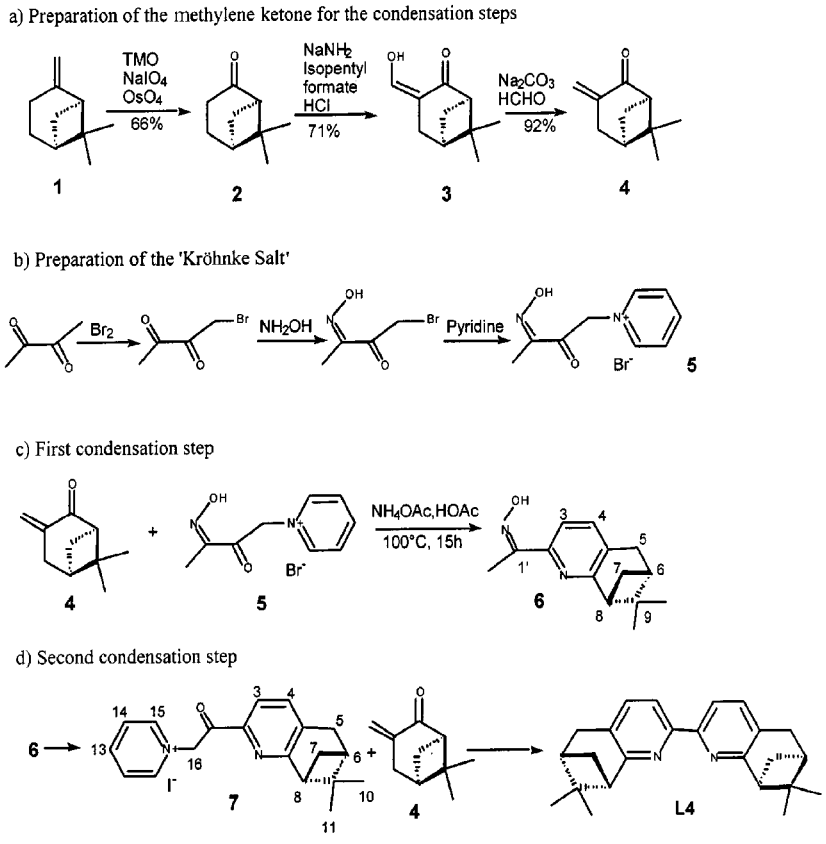
Neither the UV or the CD spectra are very strongly influenced by complex formation. All free ligands show two absorption maxima in the UV region. Complexation with $PtCl_4^-$ leads to a red shift of these ligand transitions as well as to two additional bands above 300 nm (Table 2). The CD activity, which is very small in the accessible spectral range (250 nm−700 nm) is hardly enhanced through complex formation. This is in marked contrast to complexes where two or three chiral bipyridine ligands coordinate to one metal center.[9]

X-ray Structure Determination

One of the ligands, **L2** gave suitable crystals for structure determination. Tables 3, 6, and 8 contain the relevant crystallographic data. Figure 2 reveals an approximately C_2-symmetric structure with a *transoid* conformation of the two pyridine rings. The values of all the internal coordinates (bond lengths and bond angles) are as expected. A feature that is worth noting is the banana-like deformation of the bpy moiety, which can be expressed in terms of the angle γ, as defined in Scheme 3 and given in Table 6. Although, the ligand changes its conformation from *transoid* to *cisoid*, this type of distortion is preserved and even significantly enhanced (vide infra) upon coordination.

The X-ray structures of the complexes **L2PtCl$_2$**, **L3PtCl$_2$**, and **L4PtCl$_2$** (no suitable crystals of **L1PtCl$_2$** and **L5PTCL$_2$** could be obtained), allow for an investigation of the question as to whether the metal itself assumes a chiral configuration induced by the chiral ligands. Figures 3, 4, and 5 show representations of these molecules in a projection that stresses the out-of-plane position of the ligand atoms. Selected bond lengths and angles are listed in Tables 3, 4, and 5.

L2PtCl$_2$ and **L4PtCl$_2$** crystallize in the triclinic space group *P*1. In the former case, there are two independent complex molecules per asymmetric unit, whereas the latter contains four independent molecules. Compound **L3PtCl$_2$**



Scheme 2. Synthesis overview for **L4**

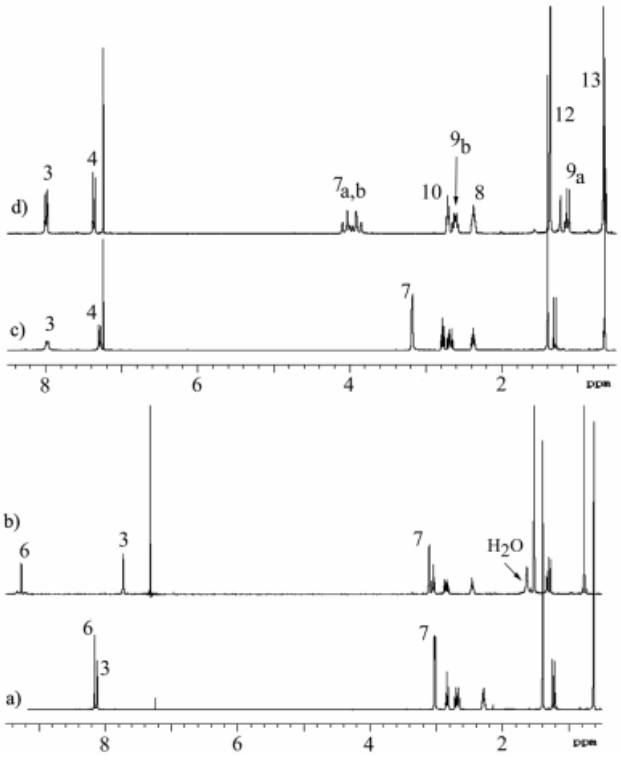


Figure 1. ^{1}H NMR spectra of the ligands **L1** and **L2**, and their platinum complexes: a) free ligand **L1**, b) **$L1PtCl_2$**, c) free ligand **L2**, d) **$L2PtCl_2$**

Table 1. ^{195}Pt NMR spectroscopic data [referenced to $NaPtCl_6$ ($\delta = 0.0$)]

$[Pt(2,2'\text{-bpy})Cl_2]$	−2315
$L1PtCl_2$	−2329
$L2PtCl_2$	−1884
$L3PtCl_2$	−1887
$L4PtCl_2$	−1939
$L5PtCl_2$	−2066

crystallizes in the triclinic, centrosymmetric space group $P\bar{1}$ with one independent molecule per asymmetric unit.

The independent molecules in the lattice of **$L2PtCl_2$** and **$L4PtCl_2$** do not show strong variations in their structural parameters (Tables 3, 4, and 8). In both cases, the molecules designated as I (Tables 3 and 4), serve as a basis for further discussion.

All three complexes **$L2PtCl_2$**, **$L3PtCl_2$**, and **$L4PtCl_2$** show strong deviation from planarity. Table 6 lists bond angles and distances that characterize these deviations, as given in Scheme 3. In the complex with the *meso*-form ligand **L3**, a strong out-of-plane distortion is observed, whereby both chlorine ligands are displaced to the same side of the coordination plane defined by the five-membered chelate ring. Figure 3 shows how the two chloride ligands are located on the same side as the methyl groups of the pinene moieties of the bent pinene-bpy-ligand. Most surprisingly, exactly the same type of deformation is ad-

opted by the C_2-symmetric (in the uncoordinated form) ligands in their complexes **L2PtCl$_2$** and **L4PtCl$_2$**. Again, both chlorine ligands are displaced towards the same side of the coordination plane. Even the crystal packing is very similar in all three cases. These three complexes are all strongly distorted from square-planar geometry, yet it seems that the stereogenic centers are not decisive for the type of distortion. In addition, the distortions occur in a counter-intuitive way. We would have expected that both chloride ligands lie on the opposite side of the plane to the methyl groups of the pinene moieties in the *meso*-form complex, and that the complex with the enantiomerically pure ligand would adopt approximately C_2 symmetry.

A similar phenomenon (mismatched symmetry) was observed by Newkome et al.[10] for palladium complexes with bipyridine ligands substituted at the 6- and 6,6′-positions. The parameters **d1** and **d2** in Table 6 are defined in the same way as in literature[10] (Scheme 3). In addition, we introduce the distances **d1*** and **d2***, respectively (Scheme 3), which we consider to be a more reliable measure of the distortion from a square-planar arrangement. It is difficult to know whether these distortions are due to packing effects (e.g.

π-stacking) or whether they are properties of the isolated molecules. In solution, all complexes show the expected symmetrical behavior of the two ligand halves on the NMR time scale.

Substitution Reactions

In order to determine the influence of a chiral ligand on the substitution reactions of the two *cis*-chloride ligands, a series of diamine ligands were treated with the [Pt(pinene-bpy)]Cl$_2$ complexes, as shown in Scheme 4. Table 7 shows the diamines that were treated with the complexes of Scheme 1. The products are numbered according to their position in this 'matrix'. The main point of interest is the stereoselectivity in these cases, where the incoming ligands can adopt a chiral configuration. Coordinated ethylenediamine adopts a chiral conformation.[11] In the complex [Pt(bpy)(en)]$^{2+}$, which was also synthesized for reference purposes[12], the CH$_2$-protons of 'en' appear as a singlet at δ = 2.82. Two satellites due to ^{1}H-^{195}Pt coupling are clearly resolved (Figure 6, a). Here, the λ- and δ- conformers of the five-membered chelate ring of ethylenediamine are enantiomers. The achiral time average between the two conformers has a C_{2v} symmetry, which results in one signal for the four CH$_2$ protons of 'en' (Scheme 5). In the case of the complex **13**, with the *meso*-form of the ligand, two signals for the methylene protons are expected, since the time-averaged symmetry is reduced to C_S, rendering the two protons 'above' and 'below' the coordination plane nonequivalent. With complex **12**, the two conformers are the (*RR*δ)- and (*RR*λ)-diastereomers. Again, two signals for the CH$_2$ protons are expected. Figure 6, b and c, show the relevant parts of the ^{1}H NMR spectra of these compounds. In both cases, the four protons (assigned as '15' in Figure 6) appear as one broad signal. Complexes **11**, **14**, and **15** behave in a very similar way as **12** and **13**, except that the lack of C_2 symmetry in **15** is clearly discernible in its NMR spectrum.

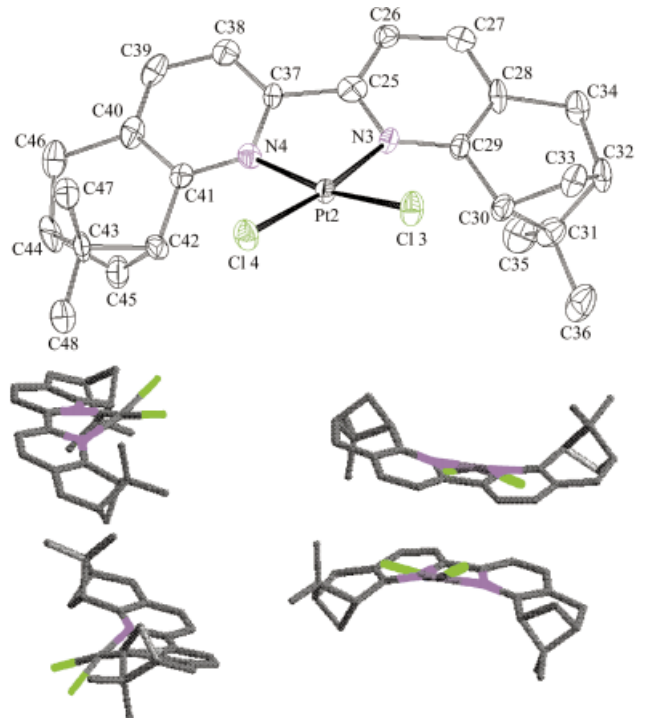

Figure 5. ORTEP[16] plot and Cerius2[17] packing representation of the crystal structure of **L4PtCl$_2$**

The substitution reactions with 'dmen', 'men', piperazine, and homopiperazine were successfully carried out only with **L1PtCl$_2$**. Complexation by replacing the two chlorine atoms with the achiral bidentate ligand 'dmen' with this compound creates stereogenic centers at the nitrogen atoms. The formation of four different diastereomers is possible, as represented in Scheme 6. In addition, the two conformers of the chelate ring, δ and λ, will now probably differ more in energy relative to 'en'. In the NMR spectrum of **51** (Fig-

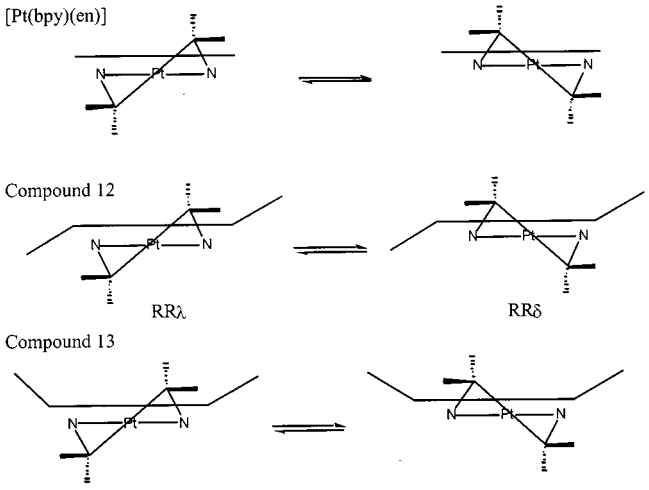

Scheme 5

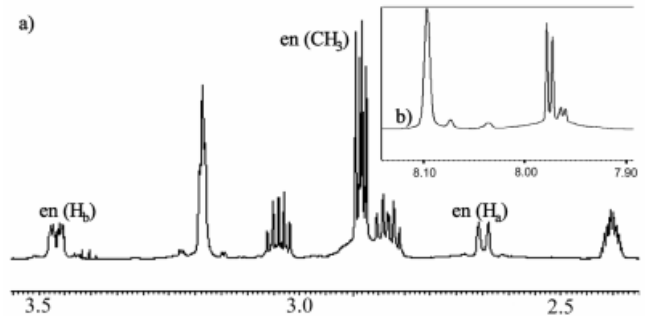

Figure 7. ^{1}H NMR spectrum (500 MHz) of compound **51**; a) aliphatic region, b) aromatic region

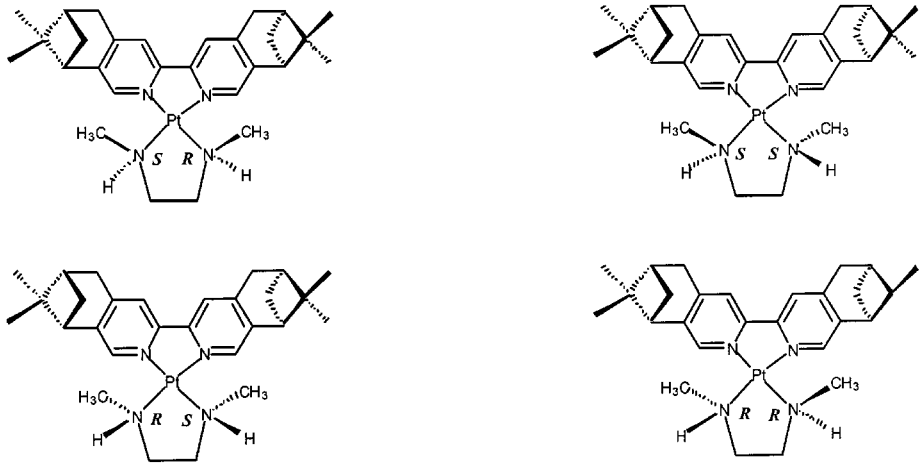
ure 7, a and b) most of the signals appear twice, with a ratio of 1:1. Small additional signals are observed in the region of the aromatic protons, as well as for the NH signal and the C(13)-methyl protons in an approximate ratio of 1:0.15. This indicates the formation of two main diastereomers, which are probably the two less constraining (*R,R*)- and (*S,S*)- forms. Furthermore, in this case we observed the expected nonequivalence (as discussed above) of the 'en'-methylene protons, which appear separated by 0.82 ppm as doublets with a coupling constant of 8.8 Hz. The diastereotopicity is much more pronounced owing to the new stereogenic centers located at the neighboring N-atoms.

In the case of 'men', the number of possible diastereomers is reduced to two since only one nitrogen atom becomes stereogenic and in addition a complete loss of symmetry occurs upon complexation with this unsymmetrical ligand. The NMR spectrum of compound **61** shows that both diastereomers, those with (*R*)- and (*S*)- configurations at the methylated N-atom, are formed in an approximate ratio of 1:1. Most of the signals of the ligands are quadrupled. Furthermore, the $H_2-C(15)$ ethylene protons appear as two separate doublets, whereas the $H_2-C(15')$ protons, which are not influenced by a close stereogenic center, gave rise to a singlet (the methyl-bearing nitrogen atom was assigned arbitrarily as N(14)]. The substitution of **L1PtCl$_2$** with piperazine yields only one possible isomer. Compound **71** shows the expected NMR pattern. The diastereotopic protons of the CH_2 groups of the piperazine ring are separated by 0.78 ppm, with a geminal coupling constant of 8.2 Hz.

In the case of homopiperazine, also only one isomer is possible, but the substitution results in a complete loss of symmetry owing to the absence of a C_2 axis of symmetry in the ligand. However, the influence of the unsymmetrical homopiperazine on the proton signals of the pinene group is small. The loss of symmetry could only be observed in the 500 MHz NMR spectra of compound **81**. All the proton signals of the pinene group show the same pattern as in the case of the symmetrical complexes, except that a doubling of the *exo*-oriented CH_3 groups and the *endo*-oriented $H-C(9)$ protons is also evident. Furthermore, two separate signals for the aromatic protons at the 6- and 6′-positions were observed. The signals for the protons of the CH_2 groups 15 and 15′, as well as 16 and 16′ are separated by 0.25 ppm and 0.51 ppm, respectively, in the latter case because of their diastereotopicity. The two protons at the C(17)-position do not show this phenomenon.

The ligand *trans*-1,2-diaminocyclohexane (DACH) is of special interest because of its configurations that are fixed by the six-membered ring. Substitution reactions were carried out with the pure (*S,S*) and (*R,R*)-forms, as well as with the racemic mixture (*S,S*)/(*R,R*) = 1:1. In the case of ligand **L1**, all the spectra of the substitution products **21**,



Scheme 6. The four possible diastereoisomers after the substitution reaction of **L1PtCl$_2$** with 'dmen'

31, and **41** are indistinguishable. Although this does not exclude a diastereoselective reaction, it is highly improbable that such selectivity occurs. In the case of the much bulkier ligand **L2**, complexes **22** and **32** can be distinguished by a difference in chemical shifts of one of the methyl groups and of one of the protons of the CH_2-group in the pinene part. From this, a diastereomeric ratio of (*RR*)/(*SS*) = 1:1.3 is calculated. The corresponding analysis for ligand **L4** yields a slightly higher diastereoselectivity for the (*R,R*)-form [(*R,R*)/(*S,S*) = 1.5:1].

Conclusions

Chiral bipyridine ligands induce significant distortions in square-planar platinum complexes if the 'substituents' of the pyridine are at the 6- and 6′-positions. However, C_2-symmetric, homochiral ligands yield molecules of low symmetry if the two other ligand positions are occupied by Cl^-. The distortions are not determined by the chiral nature of these ligands, since an overall achiral *meso*-form behaves in a very similar way. Consequently, substitution of these chlorides by amines proceeds in a nonstereoselective manner.

Experimental Section

Products: Solvents and reagents were purchased from Fluka and Aldrich. Iodine was sublimed before use. Pyridine was dried with KOH and freshly distilled prior to use. Ammonium acetate was dried for 5−6 h before use in a vacuum oven at 40 °C. Diethyl ether was distilled from sodium/benzophenone prior to use. The precursor platinum complex $K_2[PtCl_4]$ was prepared following procedures described by Livingstone.[13]

Measurements: NMR spectra were recorded on a 'Varian Gemini 300' (300.075 MHz) or on a 'Bruker Avance DRX500' (500.13 MHz) spectrometer. Chemical shifts are given in ppm using TMS or the solvent itself as internal standard, and coupling constants *J* are given in Hz. Assignment of the ^1H and ^{13}C NMR signals was performed by COSY, DEPT and HETCOR techniques. Diastereotopic protons are labeled as H_a for the *endo*-oriented protons and H_b for the *exo*-oriented protons. The *exo* methyl groups of the pinene moieties are assigned as 12 and 12′, the *exo*-oriented ones as 13 and 13′. The ^{195}Pt NMR spectra were recorded on the Varian Gemini 300 at 64.376 MHz. The signals were referenced to Na_2PtCl_6[14] (δ = 0.0). − UV/Vis spectra were measured on a Perkin−Elmer Lambda 40 spectrometer. − Mass spectral data were acquired on 'VG Instrument 7070E' equipped with a FAB inlet system. − Elemental analysis were obtained from CIBA Specialties, Marly (Switzerland) and 'Ecole d'ingéneurs de Fribourg' (Switzerland).

General: Compounds **3** and **4** (Scheme 2) were synthesized following a method described by M.Gianini.[7] The preparation of the appropriate Kröhnke salt **5** (Scheme 2) for condensation with **4** was described by Rupprecht.[7] The preparation of ligand **L5** was first described by Philippe Lainé in a private communication.[6]

L3: [2-{(−)-α-Pineno[2,3-*e*]pyridin-2-yl}acetyl]pyridinium iodide (2.27 g, 5.4 mmol, prepared as described in ref.[7]), pinocarvone (0.81 g, 5.40 mmol) prepared from (+)-α-pinene[7], and dry ammonium acetate (3.6 g) were dissolved in glacial acetic acid (7 mL) and stirred at 100 °C for 15 h. After cooling the dark brown reaction mixture to room temperature, water (100 mL) was added, followed by extraction of the water phase with hexane (at least 7 × 50 mL). The collected organic phases were washed with water (100 mL), dried with $MgSO_4$ and filtered. Evaporation of the solvent yielded **L3** (780 mg, 42%). The product was recrystallized from acetone. − ^1H NMR (300 MHz, $CDCl_3$): δ = 8.02 [d, ^3J = 7.9 Hz, 2 H, H−C(3,3′)], 7.30 [d, ^3J = 7.9 Hz, 2 H, H−C(4,4′)], 3.19 [d, ^3J = 2.6 Hz,4 H, H_2−C(7)], 2.78 [dd, ^3J = 5.6, 5.6 Hz, 2 H, H-(10,10′)], 2.68 [ddd, ^2J = 9.6 Hz, ^3J = 5.6, 5.6 Hz, 2 H, H_b−C(9,9′)], 2.37 [m, 2 H, H−C(8,8′)], 1.40 [s, 6 H, H_3−C(12,12′)], 1.28 [d, ^2J = 9.6 Hz, 2 H, H_a−C(9,9′)], 0.65 [s, 6 H, H_3−C(13,13′)]. − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 156.2 [C(2,2′)], 141.8 [C(4,4′)], 133.9 [C(3,3′)], 117.9 [C(2,2′)], 112.8 [C(5,5′)], 46.5 [C(10,10′)], 40.3 [C(8,8′)], 39.5 [C(11,11′)], 36.6 [C(7,7′)], 31.9 [C(9,9′)], 26.1 [C(12,12′)], 21.3 (13,13′)]. − EI-MS: *m/z* (%) = 344 (100) [M^+], 329 (58) [$M^+ - CH_3$], 303 (59), 271 (22), 257 (42), 154 (10). − $C_{24}H_{28}N_2$ (344.5): calcd. C 83.68, H 8.19, N 8.13, found C 82.92, H 8.40, N 7.94.

(6*R*,8*R*)-2-(1′-Ethyloxime)-5,6,7,8-tetrahydro-9,9-dimethyl-6,8-metaquinoline (6): The Kröhnke salt **5** (6.90 g, 26.6 mmol), NH_4 acetate (17.7 g), glacial acetic acid (28 mL), and **4** (4.0 g, 26.6 mmol) were heated at reflux for 15 h. The reaction mixture was cooled to room temperature, diluted with water (100 mL) and extracted with hexane [7 × 50 mL). The combined organic phases were washed with water (100 mL), dried with $MgSO_4$ with active charcoal, and filtered. After evaporating the solvent a brown viscous liquid (3.84 g, 63%) was obtained. − ^1H NMR (300 MHz, $CDCl_3$): δ = 7.51 [d, ^3J = 7.7 Hz, 1 H, H−C(3)], 7.40 [d, ^3J = 7.7 Hz, 1 H, H−C(4)], 3.09 [dd, ^3J = 5.8, 5.8 Hz, 1 H, H−C(8)], 2.93 [d, ^3J = 2.9 Hz, 2 H, H-(5)], 2.72 [ddd, ^2J = 9.8 Hz, ^3J = 5.8, 5.8 Hz, 1 H, H_a−C(7)], 2.35 [s, 3 H, H_3−C(11)], 1.28 [d, ^2J = 9.8 Hz, 1 H, H_b−C(7)], 0.65 [s, 3 H, H_3−C(10)].

1-{2-(Pineno[2,3-*e*]pyridin-2-yl)acetyl}pyridinium Iodide (7): Product **6** (3.80 g, 15 mmol) was reacted with HCl (70 mL, 25%) and heated at reflux for 8 h. After cooling the reaction mixture to room temperature, the black solution was brought to pH = 3 by the addition of NaOH (30%), and then carefully adjusted to pH = 7−8 with Na_2CO_3. This mixture was then extracted with hexane (7 × 50 mL). The organic phases were washed with water (100 mL), dried with $MgSO_4$ and filtered. Evaporation of the solvent gave a brown−yellow, viscous liquid (2.96 g). A portion of this product (2.70 g) was dissolved in pyridine (4 mL) in a 250-mL flask. Iodine (3.20 g, 12.5 mmol) dissolved in pyridine (10 mL) was added, and the mixture was heated at reflux for 3 h. After removing excess pyridine by vacuum distillation, dry diethyl ether (180 mL) was added to the black residue and kept at 4 °C overnight. The brown powder was filtered off, washed twice with diethyl ether and dried under high vacuum for 2 d. In order to obtain a good precipitate, it was essential to carry out this reaction with the exclusion of water, resulting in an hygroscopic product (7.05 g, 90%). The product was a mixture of the desired product **7** and pyridinium iodide. The ratio was determined to be 1:1. − ^1H NMR (300 MHz, [D_6]DMSO): (numbering see Scheme 2) δ = 9.00 [d, ^3J = 6.8 Hz, 2 H, H−C(15)], 8.70 [t, ^3J = 7.8 Hz, 1 H, H−C(13)], 8.25 [dd, ^3J = 7.8, 6.7 Hz, 2 H, H−C(14)], 7.89 [d, ^3J = 7.7 Hz, 1 H, H−C(3)], 7.86 [d, ^3J = 7.7 Hz, 1 H, H−C(4)], 6.48 [s, 2 H, H−C(16)], 3.05 [m, 3 H, H−C(8), H−C(5)], 2.80 [dd, ^2J = 9.8 Hz, ^3J = 5.8 Hz, 1 H, H_a−C(7)], 2.38 [m, 1 H, H−C(6)], 1.44 [s, 3 H, H_3−C(11)], 1.21 [d, ^2J = 9.8 Hz, 1 H, H_b−C(7)], 0.65 [s, 3 H, H_3−C(10)]. −

Pyridinium iodide: δ = 8.91 [d, ^3J = 6.5 Hz, 2 H, H−C(15)], 8.55 [t, ^3J = 7.8 Hz, 1 H, H−C(13)], 8.03 [dd, ^3J = 7.7, 6.6 Hz, 2 H, H−C(14)].

L4: Compound **7** (3.0 g, 4.78 mmol), ammonium acetate (3.1 g) and **4** (0.72 g, 4.78 mmol) were dissolved in glacial acetic acid (6 mL) and stirred at reflux for 15 h. The reaction temperature was gradually raised over a period of 4 h starting at 50 °C. After cooling the reaction mixture to ambient temperature, water (80 mL) was added. The mixture was extracted with hexane [7 × 50 mL). Washing, drying and evaporation of the solvent yielded a yellow powder (0.94 g, 57%). Recrystallization from hexane gave white crystals of **L4**. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.08 [d, ^3J = 7.7 Hz, 2 H, H−C(3,3′)], 7.49 [d, ^3J = 7.7 Hz, 2 H, H−C(4,4′)], 3.09 [dd, ^3J = 5.8, 5.8 Hz, 2 H, H−C(10,10′)], 2.94 [d, ^3J = 2.9 Hz, 4 H, H_2−C(7,7′)], 2.71 [ddd, ^2J = 9.8 Hz, ^3J = 5.8, 5.8 Hz, 2 H, H_b−C(9,9′)], 2.31 [m, 2 H, H−C(8,8′)], 1.40 [s, 6 H, H_3−C(12,12′)], 1.32 [d, ^2J = 9.8 Hz, 2 H, H_a−C(9,9′)], 0.65 [s, 6 H, H_3−C(13,13′)]. − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 165.8 [C(2,2′)], 152.6 [C(6,6′)], 136.0 [C(4,4′)], 130.0 [C(5,5′)], 118.9 [C(3,3′)], 50.5 [C(10,10′)], 40.3 [C(8,8′)], 39.9 [C(11,11′)], 31.2 (C7,7′)], 30.9 [C(9,9′)], 26.0 [C(12,12′)], 21.5 [C(13,13′′)]. − EI-MS: *m*/*z* (%) = 344 (25) [M^+], 329 (10) [$M^+ - CH_3$], 315 (7) [$M^+ - 2\ CH_3$], 301 (100) [$M^+ - 3\ CH_3$]. − $C_{24}H_{28}N_2$ (344.5): calcd. C 83.7, H 8.2, N 8.1; found C 83.6, H 8.2, N 7.9.

L5: [2-{(−)-α-Pineno[2,3-*e*]pyridin-2-yl}acetyl]pyridinium iodide (5.46 g, 13.0 mmol, prepared as described in ref.[7]) was suspended in formamide (50 mL). (1*R*)-(−)-Myrtenal (1.96 g, 13.0 mmol) and dry ammonium acetate (2.51 g) were added to this suspension and the reaction mixture was stirred at reflux for 15 h. After cooling the mixture to 0 °C, water (80 mL) was added and the mixture was stirred for 30 min. The black solution was extracted with diethyl ether (at least 8 × 70 mL). The collected organic phases were washed twice with water (80 mL), dried with $MgSO_4$ and filtered. Evaporation of the solvent yielded a brown powder (3.2 g). Recrystallization from acetone gave pure **L5** (2.50 g, 56%). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.17 [s, 1 H, H−C(6′)], 8.14 [s, 1 H, H−C(3′)], 7.99 [d, ^3J = 7.8 Hz, 1 H, H−C(3)], 7.30 [d, ^3J = 7.8 Hz, 1 H, H−C(4)], 3.18 [d, ^3J = 2.6 Hz, 2 H, H_2−C(7)], 3.03 [d, ^3J = 2.7 Hz, 2 H, H_2−C(7′)], 2.84 [dd, ^3J = 5.5 Hz, 1 H, H−C(10′)], 2.78 [dd, ^3J = 5.7 Hz, 1 H, H−C(10)], 2.68 [m, 2 H, H_b−C(9,9′)], 2.38 [m, 1 H, H−C(8)], 2.28 [m, 1 H, H−C(8′)], 1.40 [s, 6 H, H_3−C(12,12′)], 1.30 [d, ^2J = 9.6 Hz, 1 H, H_a−C(9)], 1.22 [d, ^2J = 9.6 Hz, 1 H, H_a−C(9′)], 0.66 [s, 3 H, H_3−C(13)], 0.62 [s, 3 H, H_3−C(13′)]. − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 156.3 [C(2)], 154.8 [C(4′)], 154.2 [C(6)], 145.5 [C(2′)], 145.2 [C(6′)], 142.6 [C(5′)], 141.4 [C(5)], 133.8 [C(4)], 120.3 [C(3′)], 117.6 [C(3)], 46.4 [C(10)], 44.4 [C(10′)], 40.2 [C(8)], 40.1 [C(8′)], 39.5 [C(11)], 39.3 [C(11′)], 36.7 [C(7)], 32.9 [C(7′)], 31.9 [C(9)], 31.8 [C(9′)], 26.0 [C(12,12′)], 21.3 [C(13,13′)]. − EI-MS: *m*/*z* (%) = 345 (100) [M^+], 330 (44) [$M^+ - CH_3$], 301 (78), 271 (26), 257 (44), 154 (9).

L1PtCl$_2$: Compound **L1** (600 mg, 1.7 mmol) was added to a solution of K_2PtCl_4 (723 mg, 1.7 mmol) dissolved in HCl (0.2 M, 80 mL). After stirring for 3 h at reflux, the yellow precipitate was filtered off and washed with water. The crude product was dried at 50 °C in a vacuum oven. Recrystallization from chloroform/heptane gave bright yellow **L1PtCl$_2$** (1.02 g, 1.6 mmol, 96%). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 9.20 [s, 2 H, H−C(6,6′)], 7.66 [s, 2 H, H−C(3,3′)]; 3.02 [d, ^3J = 2.5 Hz, 4 H, H_2−C(7,7′)], 2.95 [dd, ^3J = 5.4, 5.4 Hz, 2 H, H−C(10,10′)], 2.77 [m, 2 H, H_b−C(9,9′)], 2.36 [m, 2 H, H−C(8,8′)], 1.42 [s, 6 H, H_3−C(12,12′)], 1.19 [d, ^2J = 10.2 Hz, 2 H, H_a−C(9,9′)], 0.66 [s, 6 H, H_3−C(13,13′)]. − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 181.7 [C(2,2′)], 148.8 [C(4,4′)], 146.4 [C(5,5′)], 145.2 [C(6,6′)], 121.2 [C(3,3′)], 44.8 [C(10,10′)], 39.5 [C(8,8′)], 33.5 [C(11,11′)], 31.3 [C(7,7′)], 29.7 [C(9,9′)], 25.6 [C(12,12′)], 21.5 [C(13,13′)]. − ^{195}Pt NMR (64.376 MHz, $CDCl_3$): see Table 1. − FAB-MS: *m*/*z* (%) = 610 (25) [M^+]; 575 (86) [$M^+ - Cl$]; 537 (18) [$M^+ - 2\ Cl$]; 460 (20), 391 (43), 345 (98) [L1], − $C_{24}H_{28}Cl_2N_2Pt$ (610.5): calcd. C 47.20, H 4.62, N 4.59, found C 47.40, H 4.69, N 5.07.

[{Bis[(−)-pineno]−2,2′-bipyridine}(ethylenediamine)Pt^{II}](PF$_6$)$_3$ (11): To a suspension of **L1PtCl$_2$** (100 mg, 0.16 mmol) in water/acetone (1:1, 25 mL), ethylenediamine (10 μL) was added. After heating the reaction mixture at reflux for 8 h, the solution was cooled to room temperature and unreacted starting material was filtered off. The acetone was evaporated from the filtrate and solid NH_4PF_6 was added to the aqueous solution. The mixture was kept for 1 h at 4 °C. The white precipitate was filtered off, washed with water, and dried in vacuum. Purification by recrystallization from ethanol/diethyl ether gave **11** (90 mg, 62%). − ^{1}H NMR (300 MHz, [D_3]ACN): δ = 8.07 [s, 2 H, H−C(3,3′)], 7.97 [s, $J_{Pt\text{-}H}$ = 29.8 Hz, 2 H, H−C(6,6′)], 5.11 [b, 4 H, H_2−N(14,14′)], 3.17 [d, ^3J = 2.3 Hz, 4 H, H_2−C(7,7′)], 2.96 [dd, ^3J = 5.4, 5.4 Hz, 2 H, H−C(10,10′)], 2.80 [m, 6 H, H_b−C(9,9′), H_2−C(15,15′)], 2.40 [m, 2 H, H−C(8,8′)], 1.45 [s, 6 H, H_3−C(12,12′)], 1.23 [d, ^2J = 9.9 Hz, 2 H, H_a−C(9,9′)], 0.66 [s, 6 H, H_3−C(13,13′)]. − ^{13}C NMR (MHz, [D_3]ACN): δ = 147.0 [C(6,6′)], 124.3 [C(3,3′)], 47.9 (C15,15′)], 45.4 [C(10,10′)], 40.2 [C(8,8′)], 33.9 [C(7,7′)], 31.3 [C(9,9′)], 25.2 [C(12,12′)], 21.3[C(13,13′)], (the quaternary carbon atoms could not be detected). − FAB-MS: *m*/*z* (%) = 744 (12) [$M^+ - PF_6$], 598 (69) [$M^+ - 2\ PF_6$], 537 (13) [M^+ − en], 307 (29), 171 (57), 154 (100).

[{Bis[(−)-pineno]−2,2′-bipyridine}(R,R-DACH)Pt^{II}](PF$_6$)$_2$ (21): Compound **L1PtCl$_2$** (100 mg, 16 mmol) was suspended in water/acetone (1:1, 25 mL). (*R*,*R*)-diaminocyclohexane (30 mg, 26 mmol) was added. After the reaction mixture was heated at reflux for 10 h, unreacted starting materials were filtered off and the acetone was evaporated from the filtrate. To this solution, solid NH_4PF_6 was added and the solution was allowed to stand for 4 h at 4 °C. The white product was filtered off and washed with water. The product (95 mg, 61%), was recrystallized from ethanol/diethyl ether. − ^{1}H NMR (300 MHz, [D_3]acetonitrile): δ = 8.07 [s, 2 H, H−C(3,3′)], 8.00 [s, 2 H, H−C(6,6′)], 5.38 [b, 2 H, H_b−N(14,14′)], 4.77 [b, 2 H, H_a−N(14,14′)], 3.17 [d, ^3J = 3.4 Hz, 4 H, H_2−C(7,7′)], 2.96 [dd, ^3J = 5.3, 5.3 Hz, 2 H, H−C(10,10′)], 2.83 [ddd, ^2J = 10.0 Hz, ^3J = 5.8, 5.8 Hz, 2 H, Hb−C(9,9′)], 2.63 [m, 2 H, H−C(15,15′)], 2.40 [m, 2 H, H−C(8,8′)], 2.15 [d, ^2J = 12.0 Hz, 2 H, H_a−C(16,16′)], 1.65 [d, ^2J = 8.9 Hz, 2 H, H_a−C(17,17′)], 1.45 [s, 8 H, H_3−C(12,12′), H_b−C(16,16′)], 1.25 [d, ^2J = 8.9 Hz, 2 H, H_b−C(17,17′)], 1.24 [d, ^2J = 10.0 Hz, 2 H, H_a−C(9,9′)], 0.67 [s, 6 H, H_3−C(13,13′)]. − ^{13}C NMR (75 MHz, [D_3]acetonitrile): δ = 155.8; 154.5; 153.3; 148.9 [C(4,4′)], 146.9 [C(6,6′)], 124.2 [C(3,3′)], 62.5 [C(15,15′)], 45.3 [C(10,10′)], 40.4 [C(8,8′)], 36.7 [C(11,11′)], 34.2 [C(7,7′)], 33.2 (16,16′)], 31.6 [C(9,9′)], 25.8 [C(12,12′)], 24.8 [C(17,17′)], 21.5 [C(13,13′)]. − FAB-MS: *m*/*z* (%) = 799 (18) [$M^+ - PF_6$], 653 (11) [$M^+ - 2\ PF_6$], 327 (100).

Crystallographic Measurements and Structure Solution:[13] Suitable crystals of **L2** were grown from acetone as pale yellow rods. Intensity data were collected at room temperature on a Stoe AED2 4-circle diffractometer using Mo-K_α graphite-monochromated radiation (λ = 0.71073 Å) with ω/2Θ scans in the 2Θ range 5−51°. The structure was solved by direct methods using the program SHELXS-97[14]. The refinement and all further calculations were carried out using SHELXL-97[15]. H-atoms were located from difference Fourier maps and refined isotropically. The non-H atoms were refined anisotropically, using weighted full-matrix least-squares method on F^2. The absolute structure was assigned with reference to the absolute structure of the ligand.

Crystallographic details are given in Table 8 and significant bond lengths and bond angles are listed in Table 3.

Suitable crystals for the platinum complexes were grown by diffusion of heptane into a chloroform solution. The data for **L2PtCl$_2$** and **L4PtCl$_2$** were collected on a 'Siemens SMART CCD′ System, whereas a 'STOE Image Plate Diffraction System′ was used to collect data for **L3PtCl$_2$**. Determinations of the crystal class, orientation matrix, and unit-cell dimensions were performed in a standard fashion. The data were collected using monochromated Mo-K_α

ATP Recognition Through a Fluorescence Change in a Multicomponent Dinuclear System Containing a $Ru(Tpy)_2^{2+}$ Fluorescent Core and a Cyclam−Cu^{2+} Complex

Miguel E. Padilla-Tosta,[a] José Manuel Lloris,[a] Ramón Martínez-Máñez,*[a] Teresa Pardo,[a] Felix Sancenón,[a] Juan Soto,[a] and M. Dolores Marcos[a]

Keywords: Ruthenium / N ligands / Molecular recognition / Fluorescence / Sensors

The Cu^{2+} complex of the ligand L^1 (L^1 = [Ru(tpycyclam)-(mtpy)]$^{2+}$, tpycyclam = 1-[4′-*p*-tolyl-(2,2′:6′,2′′-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane and mtpy = 4′-methyl-2,2′:6′,2′′-terpyridine) is able to display a selective sensing response against anions such as ATP. The L^1–Cu^{2+} system contains a $Ru(tpy)_2^{2+}$ fluorescent core and a cyclam–Cu^{2+} subunit. The fluorescent response of the $Ru(tpy)_2^{2+}$ core in an aqueous environment (acetonitrile/water, 70:30) is governed by the quenching produced by the Cu^{2+} cation. In the presence of anions the L^1–Cu^{2+} system shows a rich emission fluorescent response. Electrochemical studies on the $Cu(cyclam)^{2+}$ complex in propylene carbonate in the presence of certain anions allowed us to conclude that the interaction with the anions sulfate, phosphate, ATP, ADP and GMP is mainly electrostatic whereas chloride and bromide form axial covalent bonds with the copper atom in the $Cu(cyclam)^{2+}$ complex. The addition of anions that coordinate at the axial positions of the square-planar Cu^{2+}–cyclam subunit (such as Cl^-, Br^- and OH^-) produced an enhancement of the emission intensity. This enhancement is attributed to the occupation of the apical positions of copper in the Cu^{2+}–L^1 complex that might reduce the probability of an interaction between the Cu^{2+} ions and the $Ru(tpy)_2^{2+}$ groups reducing the quenching process and, consequently, resulting in an enhancement of the fluorescence. A prediction of the fluorescent behaviour with the anions sulfate, phosphate, ATP, ADP and GMP that give electrostatic interactions with the positively charged cyclam–Cu^{2+} and/or $Ru(tpy)_2^{2+}$ centres is rather difficult. Potentiometric studies on the L^1–Cu^{2+}–H^+–ATP system suggested that the [$Cu(L^1)$(ATP)] complex is responsible for the quenching observed at basic pH in the presence of ATP. It is noticeable that the quenching of the intensity of the fluorescence due to ATP in the pH range 9 to 10 is selective and no other anion studied is able to quench the emission of the $Ru(tpy)_2^{2+}$ core in this pH range.

Introduction

The development of new sensing molecules based on the application of supramolecular chemistry concepts is an area of current interest.[1,2] It involves the functionalisation of suitable coordination sites with appropriate groups that can switch their state upon guest binding. When the switching process is followed by a change in a macroscopically observable parameter such as redox potential, absorption or emission spectrum etc., then it is simple to get information in relation to molecular events (the presence or not of a certain guest).[3−5] In general, some factors can be straightforwardly controlled to procure selectivity against a target guest: (i) the nature of the binding sites; (ii) the nature of the signalling subunit; and (iii) the solvent in which the receptor−guest interaction takes place. Such is the number of combinations that the search for new, selective signalling receptors seems to be wide open.[6]

Although anion recognition and fluorescent sensing methods are both fields of interest there are very few examples dealing with the use of fluorescent receptors for anion sensing.[7−9] The development of such new receptors involves the linkage of fluorescent groups to anion coordination sites. In this sense, we have recently been involved in the study of $Ru(tpy)_2^{2+}$ as a fluorescent signalling subunit.[10] Additionally, several types of anion coordination sites have been tested, among them polyammonium units have been some of the most widely used. In contrast, transition metal ions have been much less studied as potential binding sites in receptors based on the "binding site-signalling subunit" concept.[11] When metal ions are used as centres for metal−ligand interactions it is possible to construct structurally defined complexes with appropriate metal cations that might impose high barriers for anion discrimination.[11] We report here the fluorescent behaviour of a multicomponent dinuclear system containing $Ru(tpy)_2^{2+}$ as the fluorescent signalling subunit and a cyclam−Cu^{2+} complex in the presence of anions such as chloride, sulfate, phosphate, ATP, ADP and GMP.

Results

Quenching Studies

The complex L^1 (see below) contains a ruthenium(II) bisterpyridine core covalently anchored to a polyamine unit. We have recently reported studies on the fluorescence beha-

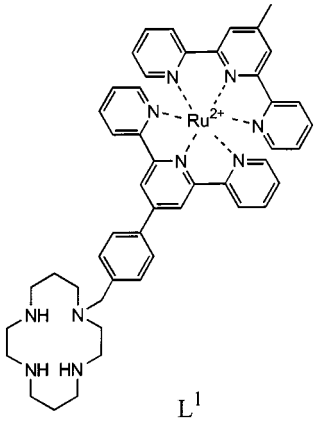
viour of the $Ru(tpy)_2^{2+}$ centre in L^1 in the presence of transition metal ions in acetonitrile/water solutions. It was found that in the presence of stoichiometric amounts of Cu^{2+}, the fluorescence of the $Ru(tpy)_2^{2+}$ core in L^1 diminished in the pH range of 4−7 (λ_{ex} = 484 nm, λ_{em} = 650 nm). This behaviour is clearly observed in Figure 1, which plots the relative emission intensity for L^1 in the presence of Cu^{2+} at certain pH values ($L^1-Cu^{2+}-H^+$ system). The figure also shows the emission intensity found for L^1 as a function of the pH (L^1-H^+ system). The emission intensity of L^1 is pH-independent: the presence of Cu^{2+} reduces the emission intensity at neutral and acidic pH. Additional solution studies (potentiometric experiments) allowed us to determine that the fall of the fluorescent emission intensity is observed when the complex $[Cu(L^1)]^{4+}$ exists in solution, whereas the protonation of the ligand (to give $[Cu(HL^1)]^{5+}$) at acidic pH, or the formation of hydroxo complexes ($[Cu(L^1)(OH)]^{3+}$ and $[Cu(L^1)(OH)_2]^{2+}$) at basic pH, hinders the quenching mechanism (see below). The $[Cu(L^1)]^{4+}$ complex more likely contains the Cu^{2+} cation coordinated by the cyclam unit in a square-planar environment.[10]



L^1

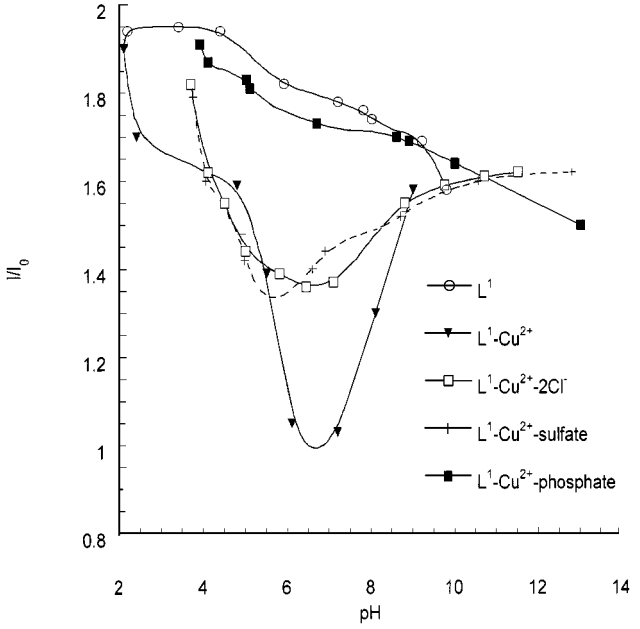


Figure 1. Relative intensity vs. pH for the $L^1-Cu^{2+}-A-H^+$ system, with A = phosphate, sulfate and chloride

We complete now these preliminary fluorescent results with new studies on the effect that the presence of certain anions has on the emission behaviour of the $L^1-Cu^{2+}-H^+$ system. In the first step we studied the fluorescent emission behaviour of the $Ru(tpy)_2^{2+}$ core as a function of the pH when one equivalent of chloride is added to a solution containing L^1 and Cu^{2+}. It was found that the *I* vs. pH profile of this system ($Cu^{2+}-L^1-H^+-Cl^-$) is very close to that found for the $Cu^{2+}-L^1-H^+$ system (without chloride). However, addition of a second equivalent of chloride induces an enhancement of the fluorescence (decrease of quenching) and an additional excess results in an *I* vs. pH profile close to that found for the L^1-H^+ system (deactivation of the quenching process; see Figure 1). A similar effect to that found for chloride (not shown in Figure 1) is observed when Br^- is added to the $Cu^{2+}-L^1$ system.

The fluorescent behaviour of the $Cu^{2+}-L^1-H^+$ system has also been tested against other anions such as sulfate and phosphate (see Figure 1). Whereas sulfate gave a response between that observed for L^1-H^+ and that of the $Cu^{2+}-L^1-H^+$ system, the presence of phosphate resulted in a similar *I* vs. pH profile to that found for the L^1-H^+ system (see Figure 1).

Of special interest is the study of the effect produced by biological anions such as ATP, ADP and GMP on the fluorescence behaviour of the $Cu^{2+}-L^1-H^+$ system (see Figure 2). The AMP anion is insoluble in acetonitrile/water (70:30 v/v) and could not be studied. It was found that the *I* vs. pH curve of the $L^1-Cu^{2+}-H^+-ATP$ system was quite different to that of $Cu^{2+}-L^1-H^+$. This time the quenching effect is still fully effective but it operates for different pH values, from 6 to 11 (see Figure 2) with a minimum for the fluorescent emission intensity at pH 9.2. GMP also modifies the emission intensity vs. pH curve of the $L^1-Cu^{2+}-H^+$ system and shows a minimum at a pH of

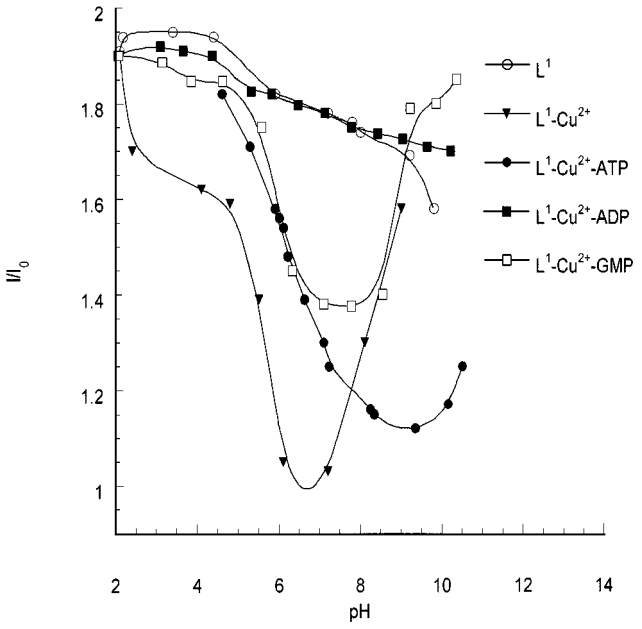

Figure 2. Relative intensity vs. pH for the $L^1-Cu^{2+}-A-H^+$ system, with A = ATP, ADP and GMP

ca. 7.5. In contrast, the ADP anion shows a similar *I* vs. pH profile to that found for the L^1-H^+ system.

In summary, the system containing Cu^{2+} and the ligand L^1 shows a rich fluorescent response in the presence of anions. The most significant feature is that ATP is able to induce quenching of the fluorescent $Ru(tpy)_2^{2+}$ subunit at pH 9.2, a pH at which none of the other anions studied (such as phosphate, sulfate, chloride, bromide, ADP or GMP) are able to produce any significant effect on the fluorescent behaviour of the $Cu^{2+}-L^1$ complex. It is also interesting to note that, in general, L^1 is a poor fluorescent chemosensor for anions, whereas it is the presence of Cu^{2+}, as we show in this work, that induces the mentioned changes in the fluorescence behaviour of the Ru-tpy subunit when anions are also present. In order to rationalise the emission fluorescent behaviour described above we have carried out additional electrochemical and potentiometric studies in an attempt to characterise the nature of the species existing in solution in the presence of certain anions.

Electrochemical Studies

Electrochemical studies on the $Cu(cyclam)^{2+}$ complex in the presence of anions can give information about the kind of interaction between the anion and the Cu^{2+}-cyclam centre. For instance, the axial coordination of anions to Cu^{2+} in a cyclam environment could be studied electrochemically and it is expected that strong axial coordination would reduce significantly the oxidation potential of the process $Cu^{2+} \rightarrow Cu^{3+} + 1e^-$. Electrochemical studies on $Cu(cyclam)^{2+}$ in the presence of phosphate, sulfate, ADP, chloride and bromide in propylene carbonate as solvent (0.1 mol dm^{-3} tetrabutylammonium perchlorate) have been carried out. Other solvents such as acetonitrile/water were discarded because the oxidation potential of Cu^{2+} in $Cu(cyclam)^{2+}$ is poorly defined probably due to the oxidation of water. Attempts to carry out studies in acetonitrile were also unsuccessful as phosphate and sulfate gave insoluble precipitates with the $Cu(cyclam)^{2+}$ complex.

In propylene carbonate, the $Cu(cyclam)^{2+}$ complex gave an irreversible oxidation process at 1.3 V vs. SCE. In the presence of chloride there is a cathodic oxidation potential shift up to 170 mV, whereas in the presence of sulfate and phosphate the electrochemical shift is only of 50 and 90 mV, respectively. The presence of ADP does not induce any significant oxidation potential shift of the Cu^{2+}/Cu^{3+} couple (less than 20 mV). Additionally, the presence of chloride produces a change of colour in the complex $Cu(cyclam)^{2+}$ that is not observed upon addition of sulfate, phosphate, or ADP anions. All these results appear to suggest that the interaction of the anions sulfate, phosphate, ADP and also probably ATP and GMP with the $Cu(cyclam)^{2+}$ unit is mainly electrostatic whereas chloride and also probably bromide and OH^- form covalent bonds with $Cu(cyclam)^{2+}$ in axial positions.

Stability Constants

Taking into account the difficulty of characterising the $L^1-Cu^{2+}-H^+-$anion systems at a molecular level we have accomplished potentiometric studies in an attempt to characterise some of these systems thermodynamically. Bearing in mind the selectivity found for ATP at basic pH (see Figure 2) we have carried out titration experiments in the presence of this biologically important anion in acetonitrile/water (70:30 v/v) solutions. Figure 3 shows the distribution diagram of the $L^1-Cu^{2+}-H^+-$ATP system.

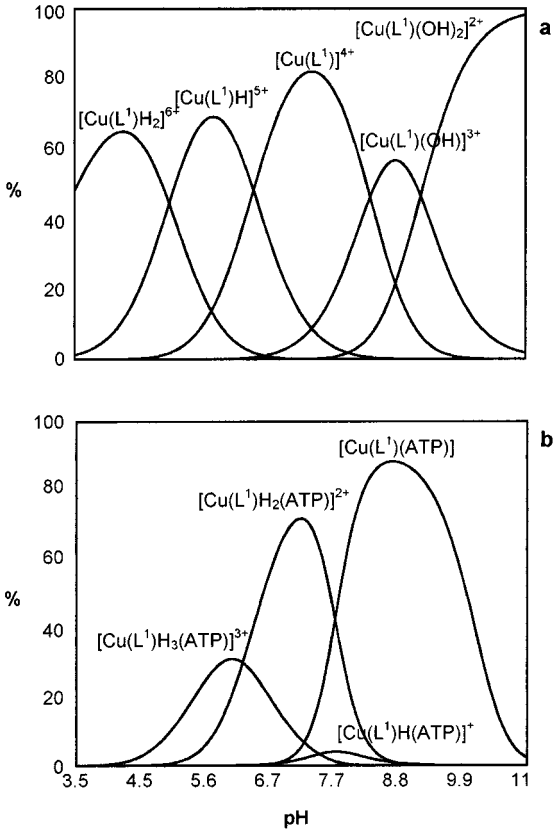

Figure 3. Distribution diagrams for the systems: a) $L^1-Cu^{2+}-H^+$; b) $L^1-Cu^{2+}-ATP-H^+$; in the presence of anions only the ligand−copper−anion species have been plotted

Table 1 shows the formation stability constants for the $L^1-Cu^{2+}-H^+-$ATP system. In the presence of ATP the complexes $[Cu(L^1)H_3(ATP)]^{3+}$, $[Cu(L^1)H_2(ATP)]^{2+}$, $[Cu(L^1)H(ATP)]^+$ and $[Cu(L^1)(ATP)]$ have been detected. Whereas the nature of protonated complexes is not easy to determine bearing in mind that both the ATP anion and the $[Cu(L^1)]^{4+}$ cation can be protonated, we can probably ascribe the formation of the $[Cu(L^1)(ATP)]$ complex to the interaction between the cation $[Cu(L^1)]^{4+}$ and the anion ATP^{4-}. Thus, the logarithm of the stability constant for the equilibrium $[Cu(L^1)]^{4+} + ATP^{4-} \rightleftarrows [Cu(L^1)(ATP)]$ is 6.10. The most interesting feature arises when comparing the distribution diagrams in Figure 3 and the plot of the emission intensity vs. pH for the $L^1-Cu^{2+}-H^+-$ ATP system in Figure 2: the agreement between the pH range where the quenching is observed and the pH range of existence of the $[Cu(L^1)(ATP)]$ complex is noticeable.

Table 1. Logarithms of the stability constants for the $L^1-Cu^{2+}-ATP-H^+$ systems in acetonitrile/water (70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) at 25 °C

Reaction	log*K*[a][b]
$L^1 + Cu^{2+} + ATP + 3H^+ \rightleftarrows [Cu(L^1)H_3(ATP)]$[c]	41.26(4)[d]
$L^1 + Cu^{2+} + ATP + 2H^+ \rightleftarrows [Cu(L^1)H_2(ATP)]$	35·00(4)
$L^1 + Cu^{2+} + ATP + H^+ \rightleftarrows [Cu(L^1)H(ATP)]$	26.18(4)
$L^1 + Cu^{2+} + ATP \rightleftarrows [Cu(L^1)(ATP)]$	19.40(5)

[a] Stability constants for the $L^1-Cu^{2+}-H^+$ system from ref.[10] are the following: $(L^1)^{2+} + Cu^{2+} + 2H^+ \rightleftarrows [Cu(H_2L^1)]^{6+}$, log*K* = 24.84(5); $(L^1)^{2+} + Cu^{2+} + H^+ \rightleftarrows [Cu(HL^1)]^{5+}$, log*K* = 19.77(8); $(L^1)^{2+} + Cu^{2+} \rightleftarrows [Cu(L^1)]^{4+}$, log*K* = 13.30(7); $(L^1)^{2+} + Cu^{2+} + H_2O \rightleftarrows [Cu(L^1)(OH)]^{3+} + H^+$, log*K* = 4.89(10); $(L^1)^{2+} + Cu^{2+} + 2H_2O \rightleftarrows [Cu(L^1)(OH)_2]^{2+} + 2H^+$, log*K* = −4.36(9). – [b] The formation stability constants for the $L^1-ATP-H^+$ system from ref.[13] are the following: $(L^1)^{2+} + ATP^{4-} + 2H^+ \rightleftarrows [L^1H_2ATP]$, log*K* = 27.82(6); $(L^1)^{2+} + ATP^{4-} + 3H^+ \rightleftarrows [L^1H_3ATP]^+$, log*K* = 36.75(6); $(L^1)^{2+} + ATP^{4-} + 4H^+ \rightleftarrows [L^1H_4ATP]^{2+}$, log*K* = 43.75(6); $(L^1)^{2+} + ATP^{4-} + 5H^+ \rightleftarrows [L^1H_5ATP]^{3+}$, log*K* = 48.02(10); $(L^1)^{2+} + ATP^{4-} + 6H^+ \rightleftarrows [L^1H_6ATP]^{4+}$, log*K* = 52.10(6). – [c] Charges have been omitted for clarity. – [d] Values in parentheses are standard deviations on the last significant figure.

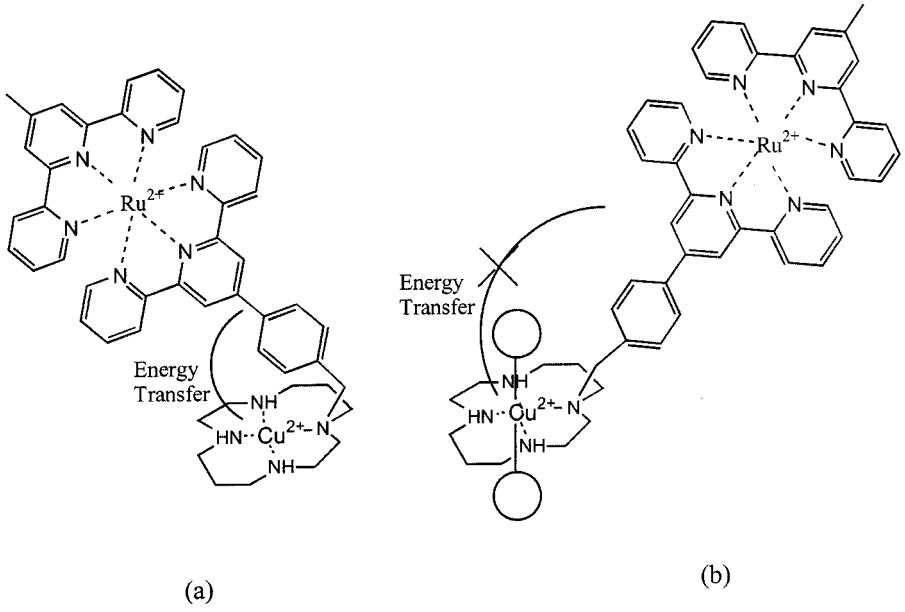
Discussion

Coordinating vs. Noncoordinating Anions

The $[Cu(L^1)]^{4+}$ cation can interact with anions in two different manners: (i) by covalent bonds when anions are able to coordinate the axial positions of the square-planar cyclam−Cu^{2+} unit, or (ii) through electrostatic interactions when anions interact by coulombic forces with the positively charged cyclam−Cu^{2+} and/or $Ru(tpy)_2^{2+}$ centres. As the electrochemical experiments suggest, the anions ATP, ADP, GMP sulfate and phosphate give electrostatic interactions with the $Cu^{2+}-L^1$ species, whereas chloride, bromide and OH^- give axial covalent coordination with the copper centre of the cyclam−Cu^{2+} subunit.

We have recently reported that the quenching of the fluorescence observed for the $[Cu(L^1)]^{4+}$ complex most likely occurs by means of an energy-transfer mechanism.[10] Such a mechanism requires a close proximity between the fluorophore and the copper metal ion, as occurs when copper is in a square planar coordination inside the cyclam polyamine (see Scheme 1a). In the presence of chloride, the occupation of the apical positions might significantly reduce the probability of interaction between Cu^{2+} ions and $Ru(tpy)_2^{2+}$ groups, thus reducing the quenching process (see Scheme 1b) and, consequently, resulting in an enhancement of the fluorescence upon chloride binding. A similar effect is observed when Br^- is added to a $Cu^{2+}-L^1$ system and, in general, the same effect would be expected with anions able to give strong interactions with Cu^{2+} ions through the axial positions (in fact, the OH^- anions also eliminate the Cu^{2+} quenching effect).

Prediction of the fluorescence response of the $L^1-Cu^{2+}-H^+$ system in the presence of anions able to give mainly coulombic interactions (sulfate, phosphate, ATP, ADP and GMP) is rather difficult. The quenching mechanism in Scheme 1 is operative for chloride (and also for bromide and OH^-) but is not valid for sulfate, phosphate, ATP, ADP or GMP. One would expect that the anions able to give mainly coulombic interactions with the $Cu^{2+}-L^1$ complex may impose geometrical constraints that could modulate the distance between the Cu^{2+} and the $Ru(tpy)_2^{2+}$ core and therefore induce changes in the emission behaviour of the $Cu^{2+}-L^1$ system. However, whether the interaction would enhance or reduce the emission intensity is not easy to specify. Nevertheless, the interaction of the $Cu^{2+}-L^1$ complexes with those anions has proved



Scheme 1

to produce a rich fluorescent response, as shown in Figure 1 and 2.

Suggested Mechanism for ATP Quenching

For the $L^1-Cu^{2+}-H^+$ and $L^1-Cu^{2+}-H^+-ATP$ systems we have carried out both potentiometric titrations and fluorescent emission studies. Potentiometry allowed us to characterise the nature of the complexes existing in solution (see Figure 3 for the distribution diagrams), whereas fluorescent studies permitted us to determine the emission response as a function of the pH (see Figure 2). By a combination of both techniques it might be possible to determine which species are responsible for a particular change in the emission fluorescence intensity at a certain pH. Thus, for the $L^1-Cu^{2+}-H^+$ system the quenching of the emission behaviour is observed when the $[Cu(L^1)]^{4+}$ complex exists. In fact, there is a close relation between the intensity vs. pH curve for the $L^1-Cu^{2+}-H^+$ system in Figure 1 and the pH range of existence of the $[Cu(L^1)]^{4+}$ complex (see Figure 3). This quenching is related to the existence of Cu^{2+} in a square-planar environment. In a similar manner, the quenching for the $L^1-Cu^{2+}-ATP-H^+$ system in the 6−11 pH range appears to be directly related to the presence in solution of the $[Cu(L^1)(ATP)]$ complex. As stated above this anion-cation complex is probably formed by electrostatic interaction between the species $[Cu(L^1)]^{4+}$ and ATP^{4-}. Additionally, as the presence of ATP probably doesn't induce any change in the coordination mode of the Cu^{2+} inside the cyclam unit, it might be concluded that in the 6−11 pH range the quenching is related to the presence of the "$[Cu(L^1)]^{4+}$" unit (in the $[Cu(L^1)(ATP)]$ complex) which contains Cu^{2+} in a square-planar environment. In this case ATP seems to be able to modulate the pH zone where the $Cu^{2+}-$cyclam square-planar unit responsible for the quenching exists by binding to the $L^1-Cu^{2+}-H^+$ system. In other words, ATP is able to modify the pK_a value for complex protonation and/or formation of hydroxo derivatives. However, it cannot be completely ruled out that the quenching observed could be produced by the nucleotide moiety rather than by the Cu^{2+} cation. It is noticeable that the quenching of the intensity of the fluorescence due to ATP in the pH range 9 to 10 is selective and no other anion studied is able to quench the emission of the $Ru(tpy)_2^{2+}$ core at this pH range. Thus, coordination of ATP with the L^1-Cu^{2+} system results in a selective sensing of the anion through a fluorescent-signalling event.

Conclusions

In conclusion, we have studied a multicomponent system able to display a selective sensing response against target anions such as ATP. The receptor L^1 contains a $Ru(tpy)_2^{2+}$ fluorescent core and a covalently attached cyclam unit. This receptor was reported to show a poor fluorescence response in the presence of anions. In contrast, the formation of the Cu^{2+} complex of L^1 produces a very rich fluorescence response. The $Cu^{2+}-L^1$ fluorescence emission in an aqueous environment is governed by the quenching produced between the $Cu^{2+}-$cyclam subunit and the $Ru(tpy)_2^{2+}$ fluorescent core. The maximum effectiveness for the quenching process takes place when the complex $[Cu(L^1)]^{2+}$ is present. Addition of anions that could coordinate axial positions of the square-planar cyclam$-Cu^{2+}$ unit produces an enhancement of the fluorescence. ATP is selectively recognised through a selective quenching by the $Cu^{2+}-L^1$ system.

Experimental Section

Synthesis: The L^1 complex was prepared following published methods[12] by reaction of $[Ru(mtpy)Cl_3]$ (mtpy = 4′-methyl-2,2′:6′,2′′-terpyridine) and 1-[4′-*p*-tolyl-(2,2′:6′,2′′-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane in the presence of *N*-ethylmorpholine as a mild reductant. The Cu^{2+} complex of L^1 was prepared in situ by addition of stoichiometric amounts of copper(II) perchlorate to an acetonitrile/water (70:30 v/v) solution of L^1. This solution was used for the fluorescent and potentiometric studies in the presence of anions.

Physical Measurement and Instrumentation: Photochemical data were obtained with a FS900CDT steady state T-Geometry Fluorometer, Edinburgh Analytical Instruments. All solutions for photophysical studies were degassed. The concentration of the $Cu^{2+}-L^1$ complex and the concentration of the anions was ca. 1.0×10^{-3} mol dm^{-3}. Potentiometric titrations were carried out in acetonitrile/water (70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) using a reaction vessel water-thermostatted at 25.0 ± 0.1 °C under nitrogen. The titrant was added with a Crison microburette 2031. Experimental potentiometric details have been published previously.[13] The computer program SUPERQUAD[14] was used to calculate the protonation and stability constants. The titration curves for each system (ca. 250 experimental points corresponding to at least three titration curves, pH range investigated 2.0−10.5, concentration of the ligand and anion was ca. 1.0×10^{-3} mol dm^{-3}) were treated either as a single set or as separate entities without significant variations in the values of the stability constants. Finally the sets of data were merged together and treated simultaneously to give the stability constants.

Co^{2+} Translocation in a Terpyridine−Cyclam Ditopic Receptor

Miguel E. Padilla-Tosta,[a] José M. Lloris,[a] Ramón Martínez-Máñez,*[a] Teresa Pardo,[a] Felix Sancenón,[a] Juan Soto,[a] and M. Dolores Marcos[b]

Keywords: Translocation / Ditopic receptors / Electrochemistry / Cobalt complexes

The coordination behaviour of the ditopic receptor of 1-[*p*-(2,2′:6′,2′′-terpyrid-4′-yl)tolyl]-1,4,8,11-tetraazacyclotetradecane (L^1) towards Co^{2+} in acetonitrile/water (70:30, v/v) has been investigated. At acidic pH values, the L^1–H^+–Co^{2+} system shows an oxidation wave at 150 mV vs. SCE, characteristic of Co^{2+} in a bis(terpyridine) environment. Upon addition of OH^-, a reduction in the intensity of the wave at 150 mV is observed and a new oxidation wave appears at 1.30 V. This new wave is close to that found for $[Co(cyclam)]^{2+}$ under similar working conditions. The electrochemical data thus suggest that there is a pH-controlled translocation of the Co^{2+} ion from the bis(terpyridine) to the cyclam environment. A similar inference can be made from the results of UV/Vis studies. A thermodynamic characterization of the L^1–H^+–Co^{2+} system has also been carried out. Stability constants have been determined in acetonitrile/water (70:30, v/v, containing 0.1 mol dm^{-3} nBu_4NClO_4 at 25 °C) using potentiometric techniques. The following species were found: $[Co(L^1)_2H_4]^{6+}$, $[Co(L^1)_2H_3]^{5+}$, $[Co(L^1)H]^{3+}$, $[Co(L^1)]^{2+}$, and $[Co(L^1)(OH)]^+$. The 2:1 ligand-to-metal species $[Co(L^1)_2H_4]^{6+}$ and $[Co(L^1)_2H_3]^{5+}$ are assigned to complexes where Co^{2+} is coordinated by two terpyridine units. The $[Co(L^1)H]^{3+}$, $[Co(L^1)]^{2+}$, and $[Co(L^1)(OH)]^+$ species are assigned to complexes where the Co^{2+} cation is in the cyclam binding domain. The pH-induced Co^{2+} jumping between coordination sites is discussed in terms of the different basicities of cyclam and terpyridine. Co^{2+} jumping between coordination sites has also been studied by the sequential acidification of basic mixtures of L^1 and Co^{2+}. Under these conditions, the translocation was observed at a different pH value than when an acid-to-basic path was followed. The effect of anions such as phosphate and chloride on the translocation process has also been studied. In the presence of phosphate, translocation occurs at pH = 11 rather than at pH ≈ 8. The phosphate–L^1 and phosphate–L^1–Co^{2+} systems have been characterized by potentiometry and a remarkably good agreement has been found between the electrochemical and potentiometric data.

Introduction

The appropriate arrangement of suitably predisposed individual molecular elements has recently resulted in the development of systems such as sensors, switches, molecular devices, etc.[1] This has led to the exploration of interesting new effects arising from particular molecular organisations or specific assemblies of individual components with the aim of mimicking the more complex functions observed in biological systems.[2] Among known molecular functions is that of translocation.[3] It has been argued that the translocation process (positional changes of atoms in a molecule) resembles mechanical processes at the macroscopic level but is operative on the molecular scale.[4] Compounds used for such studies generally have in common the property of bi- or multistability. Thus, mechanical microscopically based translocation processes involve interconversion between two structurally different states in bi- or multistable systems. To construct such systems, several suitable components have to be coupled in a specific manner. The prerequisites of the final device are a molecule containing multiple binding sites (a polytopic ligand), a guest (organic or inorganic) capable of being bound by the binding domains, and a suitable switching mechanism to induce jumping of the guest between sites on the polytopic receptor. For instance, several examples have been reported where bound cations shift from one site to another in ditopic receptors as a result of redox triggering.[5] In these systems, the shift arises as a result of the dependence of the binding preference of the metal ion on its oxidation state. Besides redox triggering, ionically controlled translocation is also possible. We describe herein a translocation process found in the interaction of Co^{2+} with the ditopic ligand 1-[*p*-(2,2′:6′,2′′-terpyrid-4′-yl)tolyl]-1,4,8,11-tetraazacyclotetradecane (L^1) possessing 2,2′:6′,2′′-terpyridine and 1,4,8,11-tetraazacyclotetradecane (cyclam) coordination domains. We have found the metal ion jumping between these two coordination sites to be ionically governed by protons. This pH-induced jumping is discussed in terms of the basicities of the cyclam and terpyridine units and the values of the formation stability constants. The effect of certain anions on the translocation process has also been studied.

Results and Discussion

The design of artificial systems for studying translocation processes requires careful choice of each individual component. We have assembled two coordination sites (terpyri-

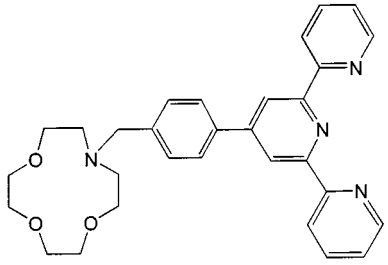
L^1



L^2

Scheme 1

dine and cyclam), both of which are capable of coordinating transition metal ions.[6] The use of an appropriate mediator (i.e. protons) makes it possible to control the relative affinity of each binding domain towards a certain metal cation. Terpyridine and cyclam components were chosen in view of the large difference in basicity between their nitrogen atoms. Besides this difference, the terpyridine-cyclam couple also has to meet an important thermodynamic requirement; the stability constants of each binding domain with a certain metal ion must be adequately complemented by the basicities of the binding atoms in order to observe, when the pH value is modulated, jumping between coordination sites (see below).

Terpyridine and cyclam were covalently linked by reaction of 4′-[4-(bromomethyl)phenyl]-2,2′:6′,2′′-terpyridine with an excess of 1,4,8,11-tetraazacyclooctadecane (cyclam) in dichloromethane in the presence of triethylamine as a base, to give the ditopic receptor L^1 (see Scheme 1). Details of the synthesis have been published elsewhere.[7] L^1 is insoluble in water and therefore the coordination studies were carried out in acetonitrile/water (70:30, v/v) mixtures. The use of other solvent mixtures such as dioxane/water or DMSO/water was also precluded by inadequate solubility.

Once the ditopic ligand had been synthesized, the next step was the choice of a suitable metal ion. Co^{2+} was selected in view of the fact that its coordination environment, in both the cyclam and terpyridine moieties, can easily be monitored by electrochemical techniques. Co^{2+} in a bis(terpyridine) coordination environment displays a very characteristic oxidation process at ca. 200 mV vs. SCE, whereas when coordinated by cyclam the oxidation to Co^{3+} becomes much more difficult.

Acidified solutions of Co^{2+} and L^1 (molar ratio L^1/Co^{2+} = 2:1) show a reversible oxidation wave at 150 mV with a ratio between the cathodic and anodic peak intensities, i_{pc}/i_{pa}, of ca. 1. This value is very close to the oxidation potential found for the complex $[Co(MePhtpy)_2]^{2+}$ [MePhtpy = 4′-(4-methylphenyl)-2,2′:6′,2′′-terpyridine] under similar working conditions. However, whereas the oxidation wave of the $[Co(MePhtpy)_2]^{2+}$ complex does not change as a function of the pH value, the addition of OH^- to the $Co^{2+}-L^1$ system leads to a decrease in the intensity of the wave at 150 mV and the appearance of an oxidation process at higher anodic potential (1.35 V). The new wave is similar to that found for the $[Co(cyclam)]^{2+}$ complex in acetonitrile/water. Figure 1 shows the electrochemical behaviour of the $Co^{2+}-L^1$ system at certain pH values. The data suggest that a translocation occurs,[8] which is schematically represented in Scheme 2. Figure 2 shows a plot of the intensity of the oxidation wave of the Co^{2+}−bis(terpyridine) core as a function of the pH value for the L^1-Co^{2+} system.

The large difference in intensity between the 150 mV and 1.35 V waves merits comment. This is not an unexpected behaviour and can be attributed to the low diffusion coefficient of the bis(terpyridine) complex and to adsorption processes observed for the oxidation of the cyclam$-Co^{2+}$ species. Moreover, the oxidation wave at 1.35 V is cathodically shifted when the pH value is very basic, probably due to the formation of hydroxo complexes.

The jumping of Co^{2+} between the terpyridine and cyclam environments can also be observed by UV/Vis spectrophotometry. The visible spectrum of $Co^{2+}-L^1$ is pH-dependent. At acidic pH values, a poorly defined band with a maximum centred at 515 nm is found. When the solution is basified, a dramatic decrease in its intensity is observed. The spectra of the $Co^{2+}-L^1$ system under acidic and basic conditions closely resemble those found for the complexes $[Co(MePhtpy)_2]^{2+}$ and $[Co(cyclam)]^{2+}$, respectively.

The electrochemical and UV/Vis experiments thus suggest that there is a proton-induced jumping of the cobalt cation between the two different sites on the ditopic receptor L^1. In addition, we have completed the study with a thermodynamic characterization of the system. The thermodynamic behaviour of polyamines such as cyclam can be adequately studied by potentiometry. However, this technique is not generally suitable for solution studies on polypyridines. Potentiometry, as a technique for deducing stability constants in polyamines, is based on the competition between the metal ion and protons to bind to the N donor atoms. The nitrogen atoms in polyamines are sufficiently basic to react with protons even in the presence of metal ions to give the protonated free receptors. Thus, a requirement for the deduction of stability constants by means of potentiometry is that both the free receptor and the complex must be observable in the pH range studied (usually 2−10). This is generally the case with polyamines, but not with terpyridines due to their lower basicities. However, although simple titrations of terpyridine in the presence of a metal ion would not lead to accurate determinations of

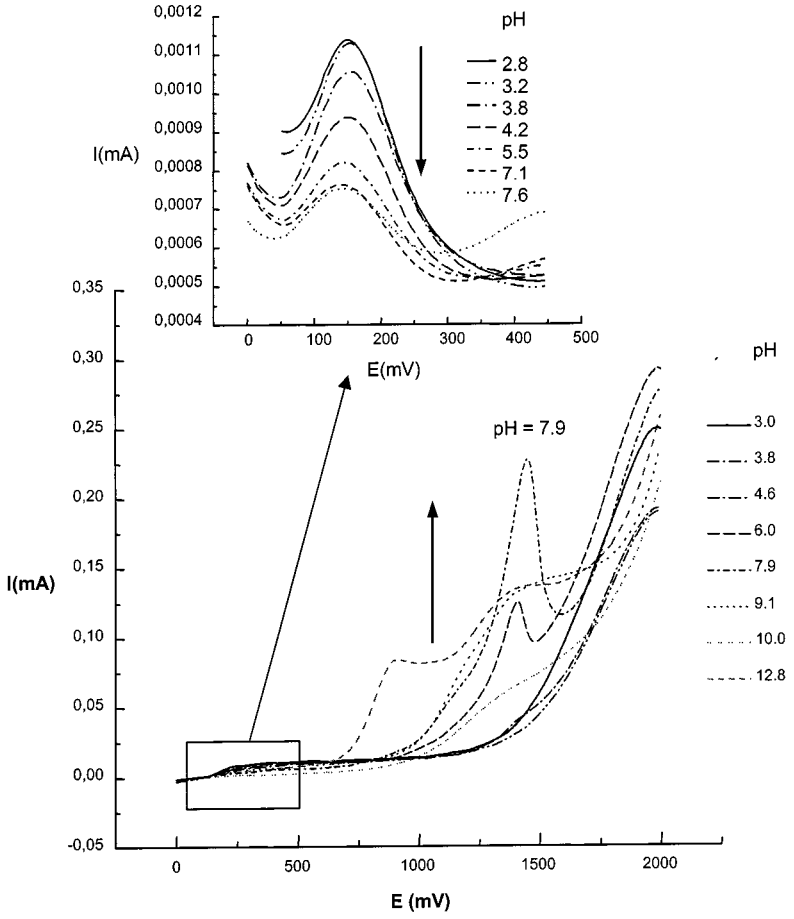


Figure 1. Electrochemical behaviour of the L^1-Co^{2+} system at various pH values using rde and differential pulse voltammetry

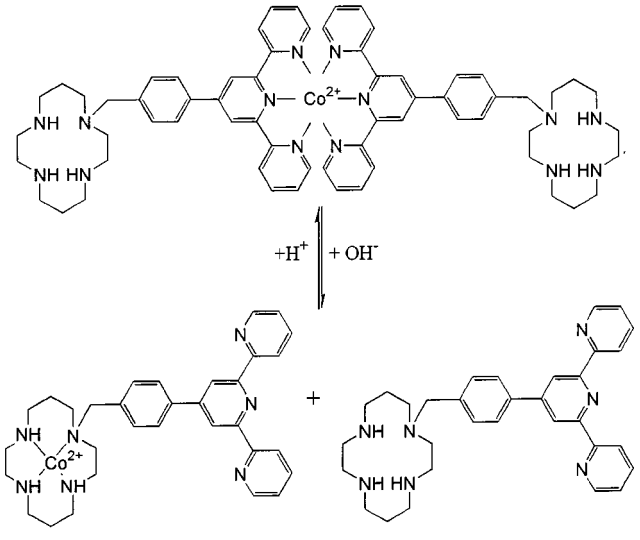

Scheme 2

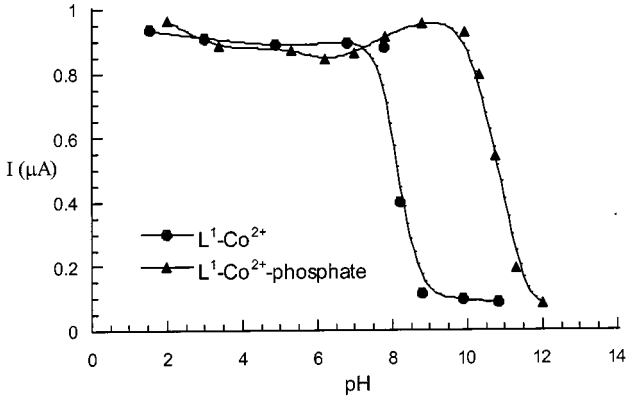

Figure 2. Intensity of the oxidation potential of the Co^{2+}−bis(terpyridine) core at 150 mV vs. SCE as a function of the pH value and in the presence of phosphate for the L^1-Co^{2+} system

the stability constants, more complex experiments can be designed for the thermodynamic characterization of terpyridine−metal mixtures. Thus, a terpyridine−metal solution might be treated with a ligand (appropriate for potentiometric study) that strongly competes with terpyridine in binding the metal cation. At this point, it is important to state that receptor L^1 does indeed meet the requirement outlined above; terpyridine is covalently coupled to a polyamine that, as suggested by the electrochemical experiments, strongly reduces the affinity of the Co^{2+} for the coordination environment of the former. Therefore, one should be able to carry out standard potentiometric experiments to thermodynamically characterize the $L^1-H^+-Co^{2+}$ system.

The first step involved the determination of the protonation constants of L^1 by titrating previously acidified solutions of the ligand in acetonitrile/water (70:30, v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) with KOH.

Although L^1 has seven possible protonation sites, only five constants could be measured, indicating that two protonation processes are too acidic to be determined (see Table 1).

Table 1. Protonation constants (log*K*) of L^1, mftpy, and cyclam [mftpy = 4′-(4-methylphenyl)-2,2′:6′,2′′-terpyridine; cyclam = 1,4,8,11-tetraazacyclooctadecane] in acetonitrile/water (70:30, v/v) containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate at 25 °C

Reaction	L^1 log*K*	mftpy log*K*	cyclam log*K*
$L + H^+ \rightleftarrows (HL)^+$ [a]	9.75(4)[b]	4.35(2)	11.62(2)
$L + 2\,H^+ \rightleftarrows (H_2L)^{2+}$	15.40(4)	6.80(2)	21.85(3)

$(H_2L)^{2+} + H^+ \rightleftarrows (H_3L)^{3+}$	4.31	1.25	1.37
$(H_3L)^{3+} + H^+ \rightleftarrows (H_4L)^{4+}$	3.62		
$(H_4L)^{4+} + H^+ \rightleftarrows (H_5L)^{5+}$	2.88		

[a] Charges have been omitted for the sake of clarity. — [b] Values in parentheses are standard deviations in the last significant figure.

In order to compare the protonation behaviour of the ditopic receptor with those of the individual components, the stepwise protonation constants of the cyclam as well as those of 4′-[(4-methyl)phenyl]-2,2′:6′,2′′-terpyridine were also determined in acetonitrile/water (70:30, v/v) mixtures (see Table 1). Three and two protonation processes were observed for the cyclam and terpyridine units, respectively. The protonation constants obtained in acetonitrile/water (70:30, v/v) solutions are in good agreement with the analogous constants reported in water.[9] Cyclam displays two very basic protonation processes in water with log*K* values for the processes cyclam + $H^+ \rightleftarrows$ Hcyclam$^+$ and Hcyclam$^+$ + $H^+ \rightleftarrows$ H_2cyclam^{2+} of 11.5 and 10.5, respectively. In contrast, the third and fourth protonation processes are much less basic with log*K* values of 1.5 and 0.9. Terpyridine shows less basic character in water. Only two protonation constants could be determined, with log*K* values for the processes H^+ + tpy $\rightleftarrows$ Htpy$^+$ and Htpy$^+$ + $H^+ \rightleftarrows$ H_2tpy^{2+} of 4.65 and 3.5. It can be concluded that the difference in basicity found between the terpyridine and the cyclam in water is retained in acetonitrile/water and probably also in the ditopic ligand L^1. Comparison of the basicity constants of L^1 with those of the individual components (see Table 1) suggests that the first two protonation processes occur at the cyclam core, the third and fourth protonations at the terpyridine, whereas the final protonation process relates to the attack of a proton at the cyclic polyamine.

Potentiometric studies aimed at determining the nature of the L^1–Co^{2+} complexes in solution have also been carried out in acetonitrile/water (70:30, v/v) by titrating previously acidified solutions containing the ligand and the metal ion in a 2:1 molar ratio with KOH. The potentiometric data were fitted with a model where the following complexes were found: $[Co(L^1)_2H_4]^{6+}$, $[Co(L^1)_2H_3]^{5+}$, $[Co(L^1)H]^{3+}$, $[Co(L^1)]^{2+}$, and $[Co(L^1)(OH)]^+$. Table 2 shows the formation stability constants for these complexes.

Table 2. Stability constants (log*K*) for the formation of Co^{2+} complexes of L^1 in acetonitrile/water (70:30, v/v) containing 0.1 mol dm^{-3} nBu_4NClO_4 at 25 °C

Reaction	log*K*
$Co^{2+} + 2\,L^1 + 4\,H^+ \rightleftarrows [Co(L^1)_2H_4]^{6+}$	47.20(5)[a]
$Co^{2+} + 2\,L^1 + 3\,H^+ \rightleftarrows [Co(L^1)_2H_3]^{5+}$	42.81(4)
$Co^{2+} + L^1 + H^+ \rightleftarrows [Co(L^1)H]^{3+}$	18.82(4)
$Co^{2+} + L^1 \rightleftarrows [Co(L^1)]^{2+}$	12.76(3)
$Co^{2+} + L^1 + H_2O \rightleftarrows [Co(L^1)(OH)]^+ + H^+$	0.83(5)

[a] Values in parentheses are standard deviations in the last significant figure.

The 2:1 ligand-to-metal species $[Co(L^1)_2H_4]^{6+}$ and $[Co(L^1)_2H_3]^{5+}$ are attributed to complexes where the cobalt(II) is coordinated by two terpyridine units. The additional presence of protons in these complexes indicates that the peripheral cyclam groups are protonated.

The 1:1 ligand-to-metal complexes $[Co(L^1)H]^{3+}$, $[Co(L^1)]^{2+}$, and $[Co(L^1)(OH)]^+$ are attributed to species where the cobalt ion is coordinated by the cyclam binding unit. Scheme 3 shows the assignments of the various com-

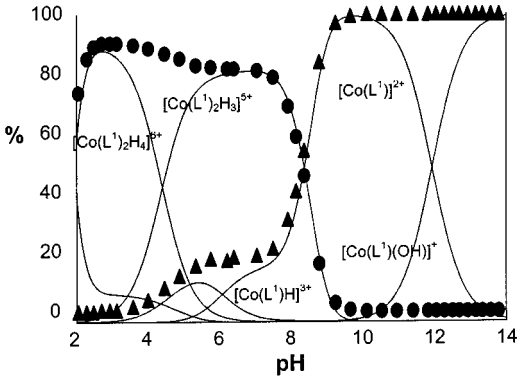

Figure 3. Distribution diagram of the various species derived from the $L^1-H^+-Co^{2+}$ system and a plot of the overall percentages of the Co^{2+}−cyclam (s) and Co^{2+}−bis(terpyridine) complexes (•) as a function of the pH value

plexes existing in solution. Figure 3 shows the distribution diagram for the $L^1-H^+-Co^{2+}$ system. The Co^{2+}−cyclam complexes have formation stability constants very similar to those reported for the Co^{2+}−cyclam−H^+ system. For instance, the stability constant for the formation of the complex $[Co(cyclam)]^{2+}$ is $\log K = 12.71$,[9] which is very close to the value found for the process $Co^{2+} + L^1 \rightleftarrows [Co(L^1)]^{2+}$, i.e. $\log K = 12.76$. This indicates that the presence of a bulky terpyridylphenyl group attached to the cyclam core and the use of acetonitrile/water solutions instead of pure water does not significantly modify the coordination behaviour of the cyclic tetraamine. The $\log K$ value for the formation of the bis(terpyridine)−cobalt(II) complex, $Co^{2+} + 2\,tpy \rightleftarrows [Co(tpy)_2]^{2+}$, is 18.6.[9] The analogous stability constant for $Co^{2+} + 2\,L^1 \rightleftarrows [Co(L^1)_2]^{2+}$ cannot be obtained from the potentiometric titrations of the $Co^{2+}-H^+-L^1$ system. However, it can be approximately deduced from the stability constant for the process $Co^{2+} + 2\,L^1 + 4\,H^+ \rightleftarrows [Co(L^1)_2H_4]^{6+}$, assuming that the process $[Co(L^1)_2]^{2+} + 4\,H^+ \rightleftarrows [Co(L^1)_2H_4]^{4+}$ would have an approximate value of 30.80 [$\log K = 30.80$ is calculated as twice $\log K = 15.40$ corresponding to the $L^1 + 2\,H^+ = (H_2L^1)^{2+}$ process]. This gives a stability constant for the process $Co^{2+} + 2\,L^1 \rightleftarrows [Co(L^1)_2]^{2+}$ of ca. 16.40, which suggests that $\log K$ for the formation of the Co^{2+}−bis(terpyridine) complex of L^1 in acetonitrile/water is of the same order of magnitude as that reported for the formation of the $[Co(tpy)_2]^{2+}$ complex.

Figure 3 also shows a plot of the overall percentages of the Co^{2+}−cyclam and Co^{2+}−bis(terpyridine) species as a function of the pH value. A pH-dependent coordination pattern can be seen, with cyclam complexes as the main species at basic pH values and bis(terpyridine) complexes being present at a level of 80% or more at pH < ca. 8. Remarkably, the translocation process represented in Figure 3 is in good agreement with the electrochemical data presented in Figure 2.

To fully understand how translocation operates one should be aware of the relationship between stability constants and ion jumping. The easiest system one can picture is a receptor containing two coordination sites (A and B), both of which can either be protonated or form a complex with a certain metal ion M. Let us assume that the stability constant for the A + M ⇄ AM process is larger than that for B + M ⇄ BM. Under these circumstances, only when the protonation constant for A + H ⇄ AH is larger than that for B + H ⇄ BH can a complete pH-controlled translocation be observed. Therefore, to observe ionically governed pH-induced jumping of the metal ion between coordination sites, a requirement that has to be fulfilled is a difference in basicity and binding strength towards the metal ion in favour to the more basic binding sites. The translocation process then works as follows: When the proton concentration is low (basic pH values), the metal ion is coordinated by the more basic centre (stronger complex); when the proton concentration is increased, the more basic centre becomes protonated, inducing the jumping of the metal ion to the less basic binding domain. The $Co-L^1-H^+$ system is similar to that described above, the only difference being the presence of 2:1 ligand-to-metal complexes. To observe translocation in this case, the formation stability constant for complexation of the metal ion at the less basic centre (terpyridine) has to be less than twice that for complexation at the more basic coordination environment (cyclam). Bearing in mind that this requirement is fulfilled in the $Co^{2+}-L^1$ system, one would expect pH-induced jumping between coordination sites, as is indeed observed {$Co^{2+} + L^1 \rightleftarrows [Co(L^1)]^{2+}$; $\log K = 12.71$ for Co^{2+} in the cyclam environment, and $Co^{2+} + 2\,L^1 \rightleftarrows [Co(L^1)_2]^{2+}$; $\log K \approx 16.4$ for Co^{2+} in the bis(terpyridine) environment}. At basic pH values, Co^{2+} jumping occurs from the bis(terpyridine) environment to the more basic cyclam binding domain. This process can be represented by the chemical reaction $[Co(L^1)_2H_3]^{5+} \rightleftarrows [Co(L^1)]^{2+} + L^1 + 3\,H^+$; $\log K = -30.05$. As can be seen, the $[Co(L^1)]^{2+}/[Co(L^1)_2H_3]^{2+}$ ratio is controlled by the proton concentration. The more basic the solution, the greater the proportion of Co^{2+} in the cyclam.

We also synthesized the receptor L^2 by reaction of 4′-[(4-bromomethyl)phenyl]-2,2′:6′,2″-terpyridine and 4,7,10-trioxa-1-azacyclododecane. L^2 is similar to L^1 in the sense that it also contains two coordination sites of different basicities. Although we have not carried out potentiometric studies on L^2 in acetonitrile/water, we have found in the literature that cobalt forms 1:1 complexes with the ligand 1,7-dioxa-4,10-diazacyclododecane (L^3) with a stability constant for the process $Co^{2+} + L^3 \rightleftarrows [Co(L^3)]^{2+}$ of $\log K = 6.01$.[10] A similar order of magnitude is presumed for the process $Co^{2+} + L^2 \rightleftarrows [Co(L^2)]^{2+}$. Therefore, as the value of the stability constant of the bis(terpyridine) complex ($\log K \approx 16$) is greater than twice the formation stability constant of Co^{2+} with the oxa-aza ligand, for the $Co^{2+}-L^2-H^+$ system one would expect the bis(terpyridine) species to be predominant over the entire pH range. Indeed, the electrochemical data reveal a unique oxidation process at ca. 150 mV attributable to the presence of Co^{2+} in a bis(terpyridine) coordination environment and the intensity of the electrochemical wave does not change over the pH range studied. There is no evidence for any translocation process. This highlights the importance of a careful

choice of each element in the design of systems displaying pH-modulated translocations.

Ionically controlled metal ion jumping has been demonstrated for the interaction a terpyridine−cyclam ditopic receptor with Co^{2+}. In addition, we have studied some factors that might have an effect on the translocation.

The first effect concerns the fact that demetallation from cyclam is slower than the process of metal incorporation into the macrocycle. This is a well-known effect and is generally operative in cyclic polyamines. The influence of this effect on the Co^{2+} jumping between coordination sites has been studied by monitoring the electrochemical behaviour of basic mixtures of L^1 and Co^{2+} upon their stepwise acidification. Under these conditions, the Co^{2+} ion remains in the cyclam core until pH ≈ 6. Further acidification induces translocation to give bis(terpyridine) species. At neutral pH value, the most stable complex is that involving the bis(terpyridine) and Co^{2+}−cyclam species are transformed to this thermodynamically favoured arrangement. However, this process is very slow; at pH = 7, only after two weeks was a partial translocation of the Co^{2+} from the cyclam to the bis(terpyridine) observed.

The operation of this kinetic process gives a hysteresis loop. Hysteresis phenomena in the solid state are well documented.[11] In contrast, studies of hysteresis loops in solution are, to the best of our knowledge, scarce.[12] This hysteresis phenomenon arises as a consequence of the existence of a bistable system coupled with a large kinetic activation barrier. Although the system is far from comparable with other well-known systems and is far too simple to be of any application, it complies with the very basic requirements for information storage: the existence of two metastable states (Co^{2+} in cyclam and Co^{2+} in terpyridine) for a given environmental condition (neutral solutions) that can be readily interconverted by the variation of an external parameter (pH).

A different approach that might affect the pH value at which translocation occurs involves the addition of anions. If the relative affinities of a certain anionic guest towards Co^{2+}−cyclam and Co^{2+}−terpyridine complexes are different, then a modulation of the translocation might be achieved. To examine this attractive possibility, we studied the Co^{2+} jumping between coordination sites in the presence of phosphate and chloride anions. A plot of the intensity of the Co^{2+}/Co^{3+} oxidation wave in the bis(terpyridine) environment as a function of the pH value in the presence of phosphate is shown in Figure 2. Translocation from the terpyridine to the cyclam environment in the presence of phosphate occurs at pH ≈ 11, quite different from the pH value (8) at which ion jumping is observed in the absence of this anion. In contrast, chloride does not affect the pH value of translocation. It is noteworthy that although some molecular systems have been described where a translocation effect is induced by redox triggering or by the pH value, there have been very few examples reported in the literature where ion jumping is modulated by the presence of anions.[13]

Table 3. Stability constants (log*K*) for the formation of phosphate complexes of L^1 in acetonitrile/water (70:30, v/v) containing 0.1 mol dm^{-3} nBu_4NClO_4 at 25 °C

Reaction	log*K*
$L^1 + PO_4^{3-} + 2\,H^+ \rightleftarrows [L^1H_2PO_4]^-$	26.37(4)[a]
$L^1 + PO_4^{3-} + 3\,H^+ \rightleftarrows [L^1H_3PO_4]$	35.63(3)
$L^1 + PO_4^{3-} + 4\,H^+ \rightleftarrows [L^1H_4PO_4]^+$	43.21(3)
$L^1 + PO_4^{3-} + 5\,H^+ \rightleftarrows [L^1H_5PO_4]^{2+}$	47.25(3)

[a] Values in parentheses are standard deviations in the last significant figure.

We also carried out potentiometric studies to thermodynamically characterize the L^1−phosphate−H^+ and L^1−Co^{2+}−phosphate−H^+ systems. Table 3 shows the stability constants for the formation of the phosphate complexes of L^1 in acetonitrile/water (70:30, v/v). Potentiometric techniques give information about the stoichiometries of the formed complexes, but do not give direct information concerning the nature of the species. Therefore, it is not straightforward to deduce whether the protons in the complexes are bonded to the phosphate or to L^1. Nevertheless, bearing in mind the pH ranges of existence of the various phosphate species and the pH ranges of existence of the protonated $(H_jL^1)^{j+}$ species, we can tentatively assign the complex $[(L^1)H_2(PO_4)]^-$ to the interaction of $(L^1H)^+$ with HPO_4^{2-}, and the complexes $[(L^1)H_3(PO_4)]$, $[(L^1)H_4(PO_4)]^+$, and $[(L^1)H_5(PO_4)]^{2+}$ to the interaction of the anion $H_2PO_4^-$ with $(L^1H)^+$, $(L^1H_2)^{2+}$, and $(L^1H_3)^{3+}$, respectively.

Table 4 shows the stability constants for the formation of the complexes of the L^1−Co^{2+}−phosphate−H^+ system. The following complexes were found: $[Co(L^1)_2H_5(PO_4)]^{4+}$, $[Co(L^1)_2H_4(PO_4)]^{3+}$, $[Co(L^1)_2H_3(PO_4)]^{2+}$, $[Co(L^1)_2H_2(PO_4)]^+$, and $[Co(L^1)(OH)(PO_4)]^{2-}$. Taking into account the pH ranges of existence of the PO_4^{3-}, HPO_4^{2-}, and $H_2PO_4^-$ species and the distribution diagram of the L^1−Co^{2+}−phosphate−H^+ system in Figure 4, we tentat-

Table 4. Stability constants (log*K*) for the formation of complexes of L^1 with Co^{2+} and phosphate in acetonitrile/water (70:30, v/v) containing 0.1 mol dm^{-3} nBu_4NClO_4 at 25 °C

Reaction	log*K*
$2\,L^1 + Co^{2+} + PO_4^{3-} + 5\,H^+ \rightleftarrows [Co(L^1)_2H_5(PO_4)]^{4+}$	68.12(5)[a]
$2\,L^1 + Co^{2+} + PO_4^{3-} + 4\,H^+ \rightleftarrows [Co(L^1)_2H_4(PO_4)]^{3+}$	62.22(4)
$2\,L^1 + Co^{2+} + PO_4^{3-} + 3\,H^+ \rightleftarrows [Co(L^1)_2H_3(PO_4)]^{2+}$	54.65(4)
$2\,L^1 + Co^{2+} + PO_4^{3-} + 2\,H^+ \rightleftarrows [Co(L^1)_2H_2(PO_4)]^+$	46.00(4)
$L^1 + Co^{2+} + PO_4^{3-} + H_2O \rightleftarrows [Co(L^1)(OH)(PO_4)]^{2-} + H^+$	9.30(4)

[a] Values in parentheses are standard deviations in the last significant figure.

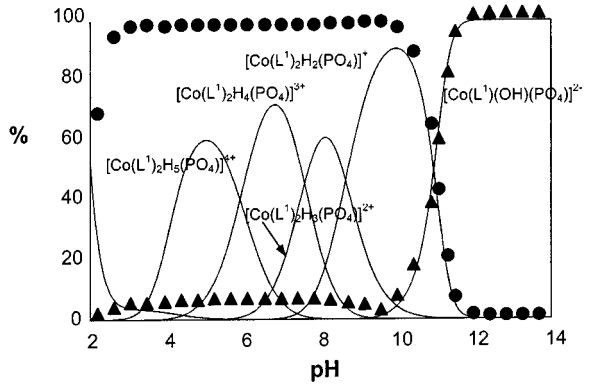

Figure 4. Distribution diagram of the various species derived from the $L^1-H^+-Co^{2+}$−phosphate system and a plot of the overall percentages of the Co^{2+}−cyclam (▲) and Co^{2+}−bis(terpyridine) complexes (•) as a function of the pH value

ively assign the complex $[Co(L^1)_2H_2(PO_4)]^+$ to the interaction of HPO_4^{2-} with $[Co(L^1)_2H]^{3+}$, and the complexes $[Co(L^1)_2H_5(PO_4)]^{4+}$, $[Co(L^1)_2H_4(PO_4)]^{3+}$, and $[Co(L^1)_2H_3(PO_4)]^{2+}$ to the interactions of $H_2PO_4^-$ with $[Co(L^1)_2H_3]^{5+}$, $[Co(L^1)_2H_2]^{4+}$, and $[Co(L^1)_2H]^{3+}$, respectively. On this basis, the stability constant for the process $[Co(L^1)_2H_3]^{5+} + H_2PO_4^- \rightleftarrows [Co(L^1)_2H_5(PO_4)]^{4+}$ is, for instance, $\log K = 3.79$.

The 2:1 ligand-to-metal species $[Co(L^1)_2H_5(PO_4)]^{4+}$, $[Co(L^1)_2H_4(PO_4)]^{3+}$, $[Co(L^1)_2H_3(PO_4)]^{2+}$, and $[Co(L^1)_2H_2(PO_4)]^+$ are attributed to complexes where the cobalt(II) is in a bis(terpyridine) environment, whereas in the complex $[Co(L^1)(OH)(PO_4)]^{2-}$ the Co^{2+} cation is coordinated by the cyclam domain. Figure 4 also shows a plot of the overall percentages of the Co^{2+}−cyclam and Co^{2+}−terpyridine species as a function of the pH value. There is a remarkable agreement between this plot and the electrochemical data presented in Figure 2. The modulation induced in the translocation process by the presence of phosphate suggests that this anion has a greater affinity for Co^{2+}−terpyridine than for Co^{2+}−cyclam complexes. The net result is that translocation occurs at higher pH values than in the absence of phosphate.

Conclusions

In conclusion, we have studied the ionically induced translocation of Co^{2+} in the ditopic receptor L^1, which contains two binding sites, cyclam and terpyridine, of different basicities. The solution mixture L^1-Co^{2+} has been thermodynamically characterized using potentiometric techniques. The pH value at which the translocation takes place can be modified by following a basic-to-acidic path or by the addition of suitable anions. In the latter case, the different affinities of the phosphate anion for the species existing in solution produces a remarkable shift in the pH value at which ion jumping is observed.

Experimental Section

The ditopic ligand L^1 was prepared according to a published method;[7] L^2 was synthesized according to ref.[14]; all other reagents were commercially available and were used as received. − Potentiometric titrations were carried out in acetonitrile/water (70:30, v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) under nitrogen in a water-thermostatted (25.0 ± 0.1 °C) reaction vessel. The titrant was added by means of a Crison 2031 microburette. The potentiometric measurements were made using a Crison 2002 pH meter and a combined glass electrode. The titration system was automatically controlled by a PC using a program that monitors the e.m.f. values and the volume of titrant added. The electrode was calibrated as a hydrogen ion concentration probe by titration of precise amounts of HCl with CO_2-free KOH solution and determining the equivalent point by Gran's method,[15] which gives the standard potential $E'°$ and the ionic product of water ($K'_w = [H^+][OH^-]$). The concentrations of the metal ion solutions were determined using standard methods. The computer program SUPERQUAD[16] was used to calculate the protonation and stability constants. The titration curves for each system (ca. 250 experimental points corresponding to at least three titration curves; $pH = -\log[H^+]$ range investigated 2−10; concentration of the ligand and metal ion ca. $1.2 \cdot 10^{-3}$ mol dm^{-3}) could be treated either as a single set or as separate entities without significant variations in the values of the stability constants. Finally, the data set was merged and treated as one to give the stability constants. Electrochemical experiments were carried out in acetonitrile/water (70:30, v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) using a Tacussel IMT-1 programmable function generator connected to a Tacussel PJT 120-1 potentiostat. The working electrode was platinum with a saturated calomel reference electrode separated from the solution under study by a salt bridge containing the solvent/supporting electrolyte. The auxiliary electrode was a platinum wire.

Characterisation and Properties of Amorphous Nonstoichiometric $Ge_{1-x}C_x$:H Compounds Obtained from X-Ray Radiolysis of Germane/Ethylene Mixtures

Paola Benzi,*[a] Mario Castiglioni,[a] and Paolo Volpe[b]

Keywords: Semiconductors / Germanium / Carbides / Radiochemistry / Alloys / Gas-phase reactions

Compounds of amorphous hydrogenated nonstoichiometric germanium carbide were obtained from the radiolysis of GeH_4/C_2H_4 mixtures containing 3–30% ethylene. The composition of the materials varied depending on the ethylene percentage in the irradiated mixture. The bonding and the structure of the compounds so obtained were investigated by infrared spectroscopy, and their optical gap values determined by the Tauc procedure. The variation of optical gap values as a function of carbon content is discussed.

Introduction

In the past two decades, there has been a growth in interest in amorphous alloys (i.e. SiC, SiGe, GeC) due to their possible electronic and photovoltaic applications. A variety of different techniques are used to obtain these materials, some of which involve the decomposition of gaseous reactants.[1−9] Heat or electromagnetic quanta can provide the energy for the decomposition of the reactants. In particular, the use of high-energy quanta (i.e. X or γ) allows one to overcome the problem related with the differential activation of compounds having very different bond energies.

In our laboratory, high-energy radiation has been used to decompose gaseous mixtures with the aim of obtaining amorphous materials, particularly α-GeC:H. In fact, although the properties of germanium carbide are not well known, probably due to a lack of a simple preparation method, the theoretical conversion-yield values obtained from the plot proposed by Prince[10] using the optical gaps calculated from the Davis and Mott equation[11] suggest that the amorphous Ge−C alloys can have good photovoltaic properties depending on the Ge/C ratio.[12]

In previous work, the solids obtained from the radiolysis of mixtures of GeH_4 and saturated hydrocarbons have been studied,[15−18] but the carbon content of the solid is generally low, even when a mixture that is rich in hydrocarbons is used.

The materials prepared from mixtures of GeH_4 and unsaturated hydrocarbons are now under examination, with the aim of increasing the carbon content. In fact, mass spectrometry studies[13,14] have also suggested that the presence of the more reactive unsaturated bond can lead to an increase of carbon content in the solid. In this work we report on the characterisation of materials obtained by radiolysis of GeH_4/C_2H_4 mixtures at room temperature.

Results and Discussion

From the irradiation of germane/ethylene mixtures both volatile and condensed products are obtained, which were analysed using different techniques. The analysis of the residual gas phase (after irradiation) was performed by gas chromatography/mass spectrometry: besides unchanged ethylene and germane, di- and trigermane were revealed; traces of volatile hydrocarbons formed by condensation of two or three ethylene molecules were seldom observed. Several more interesting mixed compounds, containing from one to three germanium atoms and from one to six carbon atoms, were also detected.

In Figure 1 (**a**, **b**) variations in yields of gaseous products as a function of the ethylene percentage in the reaction mixture are shown.

The liquid or solid products obtained from radiolysis were deposited on the bottom of the irradiated vials. The colour, consistency, and physical state of these compounds depend on the ethylene percentage in the mixtures. A brown-orange dusty solid is obtained from the mixture containing 3% ethylene. If the ethylene percentage is increased the solid becomes clearer, and at around 15% ethylene content it becomes waxy. When the ethylene percentage exceeds 15% an orange liquid is formed, but when the ethylene amount reaches 30% the liquid becomes colourless.

In Table 1 the quantity, the average empirical formula and other properties of the condensed phases obtained from irradiation of germane/ethylene mixtures with ethylene ranging from 3 to 30% are reported.

The presence of hydrocarbons in the condensed phase has been excluded by solvent extraction of the products followed by gas chromatography/mass spectrometry analysis. This result is in agreement with the finding of only trace amounts of gaseous hydrocarbons in the residual gas mixture after irradiation. Moreover, the prevailing presence of

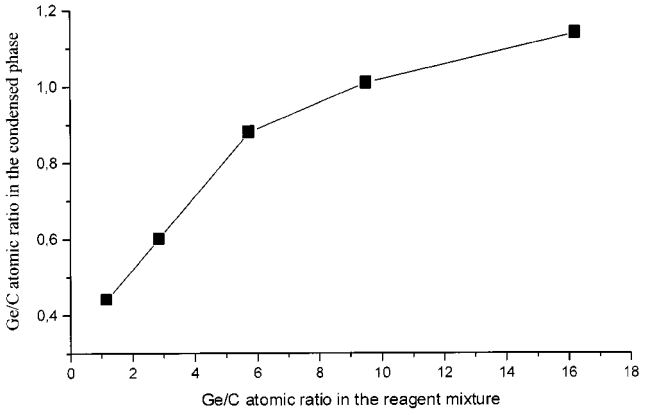

Figure 2. Ge/C atomic ratio in the condensed products obtained from irradiation as a function of Ge/C atomic ratio in the reacting gas mixture (the solid line are to guide the eye)

species containing both germanium and carbon in the gas phase and the results of elemental analysis suggest that the materials obtained from irradiation of GeH_4/C_2H_4 consist of polymeric chains containing Ge−C bonds. The X-ray diffraction spectra of the compounds do not show any crystallinity i.e. the materials are in the amorphous state.

All the species formed from the various mixtures are insoluble in common organic and inorganic solvents, but are rapidly oxidised by strong oxidising agents (such hydrogen peroxide or nitric acid). They are not very stable to the air and when exposed for a few days to the laboratory atmosphere they slowly undergo oxidation and become white. For this reason all the analyses on condensed phases were performed soon after opening the vials.

Figure 2 shows the variation of the Ge/C atomic ratio in the condensed phase obtained from irradiation as a function of the Ge/C ratio in the initial gas mixture.

As the ethylene concentration was increased in the reacting mixture, both the carbon content and the total amount of the condensed phase increased (Table 1). On the contrary, using saturated hydrocarbons,[15−18] the carbon content in the solid products increased, although the total solid yield decreased as the hydrocarbon content in the starting mixture was increased. These findings indicate that in the presence of saturated hydrocarbons, the initiation and propagation process of the polymerisation reaction leading to the solid is due to GeH_x ($n = 1-3$) species, whereas in the present experiment the ethylene molecules start and sustain the polymerisation process.

During irradiation both ionic and radical species may be involved in the formation of volatile and condensed products. From Fourier transform and high pressure mass spectrometric experiments[13] the main ionic reactions are:

$GeH_3^+ + GeH_4 \rightarrow Ge_2H_3^+ + 2H_2$

$GeH_3^+ + GeH_4 \rightarrow Ge_2H_5^+ + H_2$

$GeH_3^+ + C_2H_4 \rightarrow Ge_2H_5^+ + H_2$

Nevertheless, as reported in a previous paper,[19] the radical reactions should give the major contribution to the

Table 1. Composition, weight, and characteristics of the condensed products obtained from irradiation of GeH_4/C_2H_4 mixtures

[a] Percentage of carbon atoms in the condensed phase. − [b] Percentage of hydrogen atoms in the condensed phase.

products formation. In the same paper, from experimental data and ab initio theoretical calculations, we have hypothesised the germane radicals with one or no hydrogen atoms to be the most probable initiators of the polymeric chain:

$GeH_n + C_2H_4 \rightarrow GeC_2H_{n+4}$ $(n = 0, 1)$

$GeH_n + GeH_4 \rightarrow Ge_2H_{n+4}$ $(n = 0, 1)$

The species produced from the above reactions are still reactive and may react further with ethylene or germane molecules, leading to chain propagation up to solid products. Alternatively, they may also react with light radicals (mostly hydrogen) terminating the chain propagation and leading to volatile products.

Figure 3 shows the fraction of decomposed germane as a function of the amount of ethylene in the mixture. It increases from around 0.5 to 2% of germane when the ethylene percentage ranges from 3 to 30%.

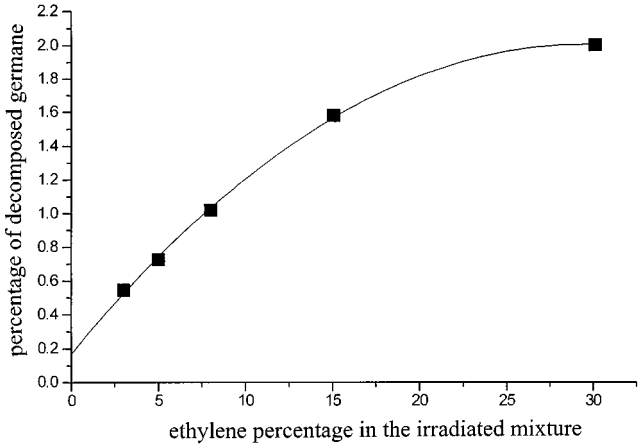

Figure 3. Percentage of decomposed germane (gaseous and condensed products are considered) with respect to the amount initially present in the mixture as a function of ethylene percentage in the irradiated mixture (the solid line is the fit of the experimental data)

This behaviour indicates that the ethylene competes effectively with hydrogen radicals in the reactions with primary and secondary radical species, promoting the chain propagation and inhibiting the radical recombination reactions. This hypothesis is also supported by the decreasing yield of di- and trigermane together with the general increase of Ge−C containing gaseous species observed when the ethylene percentage is increased. Furthermore, the ratio between the yields of condensed and gaseous products is much higher than in the GeH_4/saturated hydrocarbons system (Figure 1 and Table 1).

Bonding and Structure

IR spectroscopy was used to study the bonding configuration and structure of the α-GeC:H materials obtained. In fact the IR spectra can detect the presence and the relative abundance of CH_n, GeH_n, and GeC groups. A typical IR absorption spectrum in the 3200 to 400 cm^{-1} wave-number region, for a sample obtained from the irradiation of a 15:85 mixture of ethylene/germane, is shown in Figure 4a.

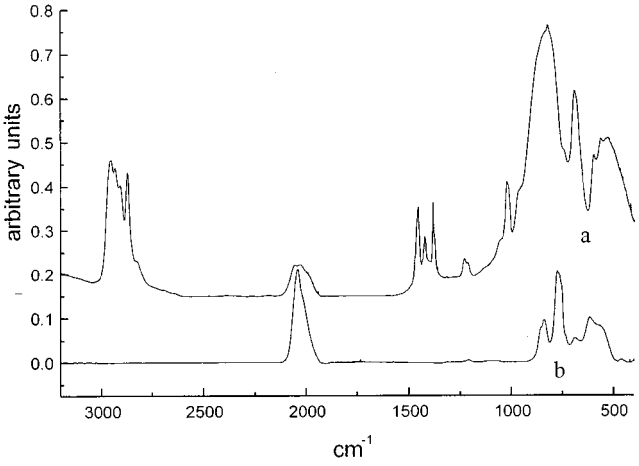

Figure 4. Infrared absorption spectrum in the 3300 to 400 cm^{-1} wave-number region of (a) a sample obtained from irradiation of the mixture with 15% ethylene, and (b) a sample obtained from irradiation of pure monogermane; the former is shifted on the *y* axis

In Figure 4b the spectrum of the solid obtained from irradiation of pure monogermane is shown for comparison.

The IR spectra of samples prepared from gas mixtures containing 3%, 15%, and 30% ethylene have been superimposed and divided into three regions, as depicted in Figure 5.

In the 3050 to 2800 cm^{-1} range (Figure 5a) the absorption of the CH_m ($m = 1-3$) stretching modes take place. Considering the position of the stretching bands of the CH_m ($m = 1-3$) grouping in hydrocarbons and the results reported about analogous bands in α-GeC:H and α-SiC:H,[20−24] we can assign the signals around 2955 and 2872 cm^{-1} to CH_3 groups, the signals around 2934 and 2824 cm^{-1} to CH_2 groups, and the band at 2905 cm^{-1} can be attributed to CH groups. Figure 5a shows that the intensity of the above signals increases with ethylene percentage in the reaction mixture. In particular, the normalised integrated absorption I of deconvoluted signals, defined by[21,25]

$$I = \int \alpha(\omega)\omega / d\omega$$

where α(ω) is the absorption coefficient at wave-number ω], indicates that the peak around 2955 cm^{-1}, attributed to the stretching of CH_3 groups, increases sevenfold, whereas the carbon content of the sample increases only 2.5 times (Table 1). This finding indicates that, as observed for α-SiC:H alloys,[23,24] the increase of carbon content causes the solid to incorporate a larger number of CH_3 groups. The CH_3 bonding configuration leads to a less dense material with inner surfaces or voids,[24] which allows oxygen penetration into the sample if exposed to air. This is in agreement with the above-mentioned oxidation process undergone by our samples, which becomes faster as the carbon content is higher.

Figure 5b shows the IR spectrum between 2125 and 1925 cm^{-1}. The signal is an envelope of bands whose deconvolution exhibits two partially overlapped bands at 2013 and

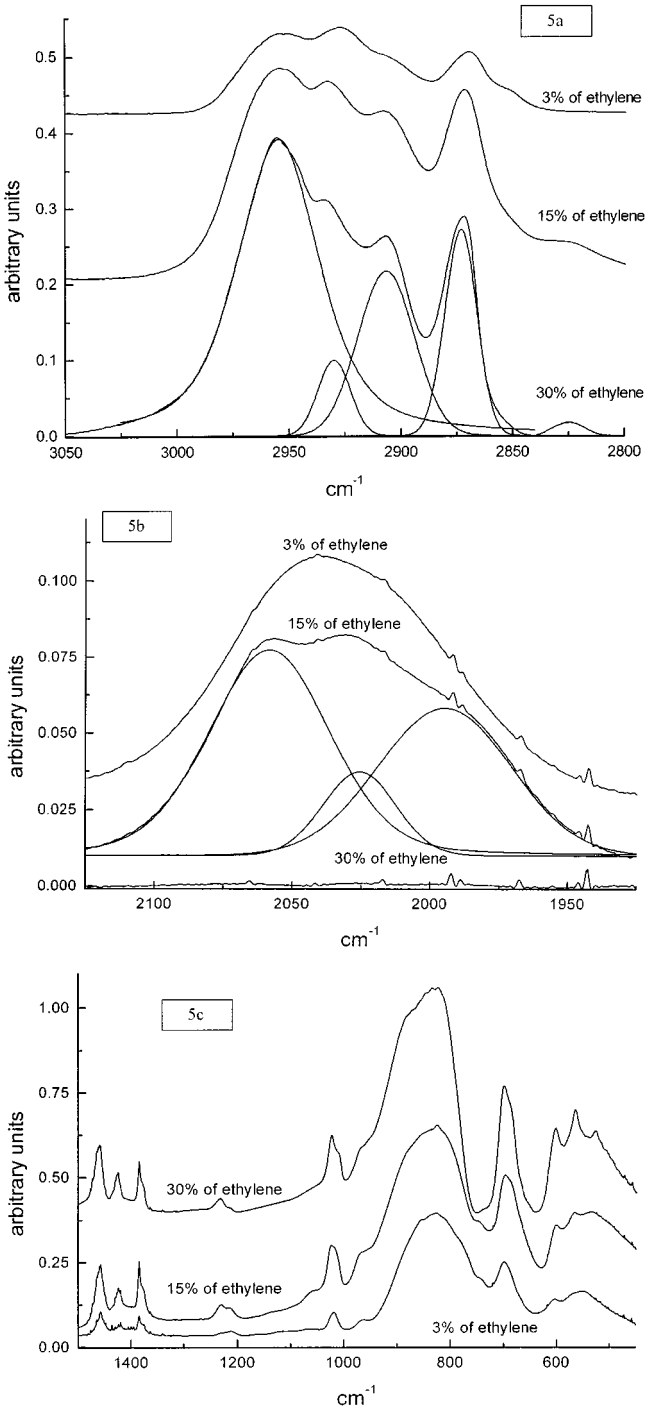

Figure 5. The IR absorption bands of samples obtained from irradiation of mixtures with 3%, 15%, and 30% ethylene: **a**: (3050−2800 cm^{-1}), **b**: (2125−1925 cm^{-1}), **c**: (1500−400 cm^{-1}); in parts **a** and **b** the spectra of the samples obtained from mixtures with 3 and 15% of ethylene are shifted on the *y* axis; in part **c** the spectra of the samples obtained from mixtures with 15 and 30% ethylene are shifted on the *y* axis; the deconvoluted signals for the sample obtained from mixtures with 30 and 15% of ethylene, respectively, are also depicted in parts **a** and **b**

2051 cm^{-1} (the deconvoluted signals are not reported in Figure 5b for clarity) and three bands at 1994, 2025, and 2058 cm^{-1} for the samples obtained from mixtures with 3 and 15% ethylene, respectively. The sample obtained from the mixture containing 30% ethylene does not exhibit any signals in this range. The observed bands can be assigned unambiguously to the Ge−H stretching mode, but the interpretation of the substructure of these bands involves various degrees of uncertainty.[22−28] In α-Ge:H compounds, a band at 1970 cm^{-1} was observed and attributed both to the stretching of GeH groups inside cavities much larger than that corresponding to a monovacancy,[25,26] or to GeH_2 group stretching. Bands at 2000 and 2060 cm^{-1} were attributed to $(GeH_2)_n$ polygermane and GeH_3 groups, respectively. On the other hand, as observed in α-SiC:H for the bands of Si−H bond stretching,[23,26] in α-GeC:H the bands due to Ge−H bond stretching can shift as the environment of the oscillatory species changes due to the presence of carbon atoms bound to germanium atoms.[21] In fact, the stretching bonds are strengthened by attaching carbon atoms to Si or Ge atoms due to the higher electronegativity of carbon with respect to Si or Ge.

In order to estimate the influence of neighbouring atoms on the frequencies of GeH and GeH_2 attached to one, two, or three carbon atoms, we have plotted, as proposed by Lukovsky for SiH and SiH_2,[29] the molecular GeH and GeH_2 vibrational frequencies (obtained from literature data[30−35]) as a function of $\Sigma SR(R_j)$, where $\Sigma SR(R_j)$ is the group-stability-ratio sum for substituting groups. The results are shown in Figures 6a and 6b.

The fits of the points give the following Equations for GeH and GeH_2 frequencies, respectively:

$$\nu(\mathrm{GeH}) = 1740 + 27.0 \sum_{j=1}^{3} SR(Rj) \pm 13$$

$$\nu(\mathrm{GeH_2}) = 1800 + 34.0 \sum_{j=1}^{2} SR(Rj) \pm 11$$

The frequencies for GeH and GeH_2 attached to one, two, or three carbon atoms calculated with Equation (1) and Equation (2), respectively, are summarised in Table 2.

With these indications, the band at 2013 cm^{-1} from the sample obtained in the presence of 3% ethylene could be attributed to GeH or GeH_2 attached to two or one carbon atoms, respectively, whereas the band at 2053 cm^{-1} could be assigned to GeH or GeH_2 bound to three or two carbon atoms, respectively. Considering the Ge/C ratio (see Table 1) we suggest that these bands are more probably due to GeH and GeH_2 modes, respectively.

Analogous considerations suggest that the three bands at 1995, 2025, and 2059 cm^{-1} of the sample with 15% ethylene must be attributed to GeH connected to one carbon atom and to GeH_2 attached to one or two carbon atoms, respectively. However it must be considered that the band position can also be affected by the presence of internal surfaces analogously to α:Ge−H,[25,26] therefore the suggested band attribution suffers from some extent of uncertainty.

It is noteworthy that as the carbon content of the sample increases, the band's intensity in the 1950−2150 cm^{-1} range decreases and no band is present for a sample obtained from a 30% ethylene mixture. This behaviour seems to indicate that hydrogen bound to germanium is substituted by

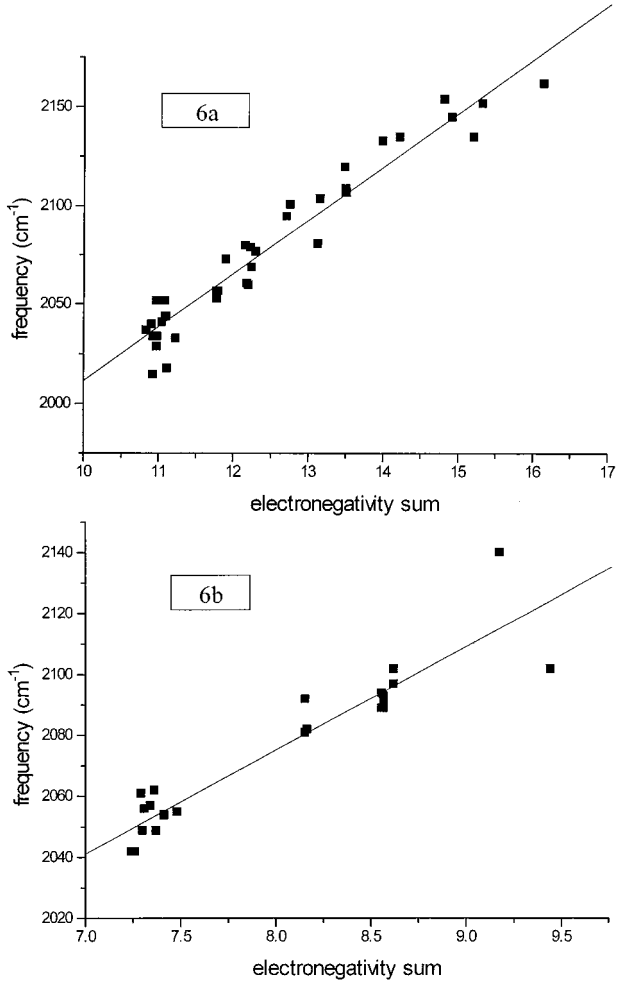

Figure 6. Frequency of GeH (**a**) and GeH_2 (**b**) stretching versus electronegativity for substituted germane molecules; the points are the experimental frequencies and the solid lines are the fits to the molecular data for the di- and trisubstituted molecules

Table 2. Stretching frequencies calculated for GeH and GeH_2 groups

GeH		GeH_2	
Ge_3GeH	1952 cm^{-1}	Ge_2GeH_2	1978 cm^{-1}
Ge_2CGeH	1983 cm^{-1}	$GeCGeH_2$	2018 cm^{-1}
GeC_2GeH	2014 cm^{-1}	C_2GeH_2	2058 cm^{-1}
C_3GeH	2047 cm^{-1}		

carbon even if overall the hydrogen content in the condensed products increases. In fact, it must be considered that $E_{bond}(C-H) > E_{bond}(Ge-H)$[36] and, as observed in the α-SiC:H system,[24] the more probable bonding sites for hydrogen atoms are those having the largest bond energy. This is in agreement with both the above-mentioned increase of the band intensity attributable to CH_3 groups and the observed increase (calculated from the integral of deconvoluted signals) of the CH_3/CH_2 ratio.

Figure 5c shows the spectra in the 1500 and 400 cm^{-1} wavenumber region. In this range many bands are present, and the interpretation is difficult due to the presence of broad bands (which are envelopes of modes) and by the overlapping of Ge−C stretching with Ge−H wagging modes or with $Ge-CH_n$ and GeH_2 bending modes.[21,22,25] Moreover, in this region the deformation modes of $(CH_m)_nC/Ge$ ($m = 1-3$; $n = 1-3$) groups are expected.[21,24]

The signals at 1385 cm^{-1} and 1458 cm^{-1} are attributable to the symmetrical and asymmetrical deformation modes of the $(CH_3)_nC$ groups ($n = 1-3$).[20,24,37] The weak band around 1424 cm^{-1}, whose intensity increases with increasing carbon and hydrogen content in the condensed phase, is probably due to the deformation mode of the CH_3Ge groups.[24,37] Two signals around 1210 and 1225 cm^{-1} are also present. Considering (i) that the intensity of the band at 1225 cm^{-1} increases while that of the band at 1210 cm^{-1} decreases with the carbon and hydrogen content, and (ii) - that Rubel et al.[24] attribute the two bands around 1230 and 1245 cm^{-1} to a bending mode of $(CH_m)_nC/Si$ ($m, n = 1-3$) and to a symmetric deformation mode of the CH_3Si group, respectively, the bands at 1210 and 1225 cm^{-1} have been assigned to analogous vibrational modes of CH_3Ge and $(CH_m)_nC/Ge$ groups. The signal around 1024 cm^{-1} and the shoulder at 965 cm^{-1} are attributable to CH_n rocking and/or wagging modes[38,39] and to C−C stretching modes, respectively. The broad band between 950 and 750 cm^{-1} can be due to both GeH_2 and to GeH_3 bending modes and to $Ge-CH_n$ wagging mode.[21,25] The above attribution of the signal between 2150 and 1950 cm^{-1} and the presence of a strong signal around 850 cm^{-1} for the sample from 30% ethylene (which exhibits no signal attributable to Ge−H stretching modes) support this hypothesis. The peak at 700 cm^{-1}, which exhibits an increasing intensity with ethylene percentage in the gaseous mixture, can be attributed to a rocking vibration of the CH_2 groups in the $-(CH_2)_n-$ chains with $n > 4$.[40] In the 500−650 cm^{-1} region three peaks are observed in the spectra, although other authors refer to one, two, or even four peaks, attributable both to Ge−C stretching and GeH wagging modes.[21,27,36,41] The observation of these signals even for the sample obtained from the mixture with 30% ethylene indicates that the bands between 500 and 650 cm^{-1} can be attributed to a Ge−C bond even if a contribution from the GeH group (if present) cannot be excluded.

To sum up, all the results indicate that the materials obtained from irradiation of GeH_4/C_2H_4 mixtures are amorphous nonstoichiometric $Ge_{1-x}C_x$:H compounds with chains forming a network in which the Ge atoms are less hydrogenated than the C atoms, which present many network-terminating configurations.

Optical Properties

The light absorption measurements of the samples were performed at photon energies between 0.5 and 6.25 eV. The optical gap values (E_{opt}) have been obtained from the intercept with the x axis of the extrapolated linear part of the curves calculated following the usual Tauc procedure.[42] It

consists of plotting $(\alpha h\nu)^{1/2}$ vs. the photon energy, $h\nu$, according to:

$$(\alpha h\nu)^{1/2} = B(h\nu - E_{opt})$$

where α is the absorption coefficient from spectrophotometric measurements, h Planck's constant, ν the photon frequency, B a constant, and E_{opt} the optical band gap.

The values of E_{opt} as a function of carbon molar fraction in the condensed phase are shown in Figure 7a.

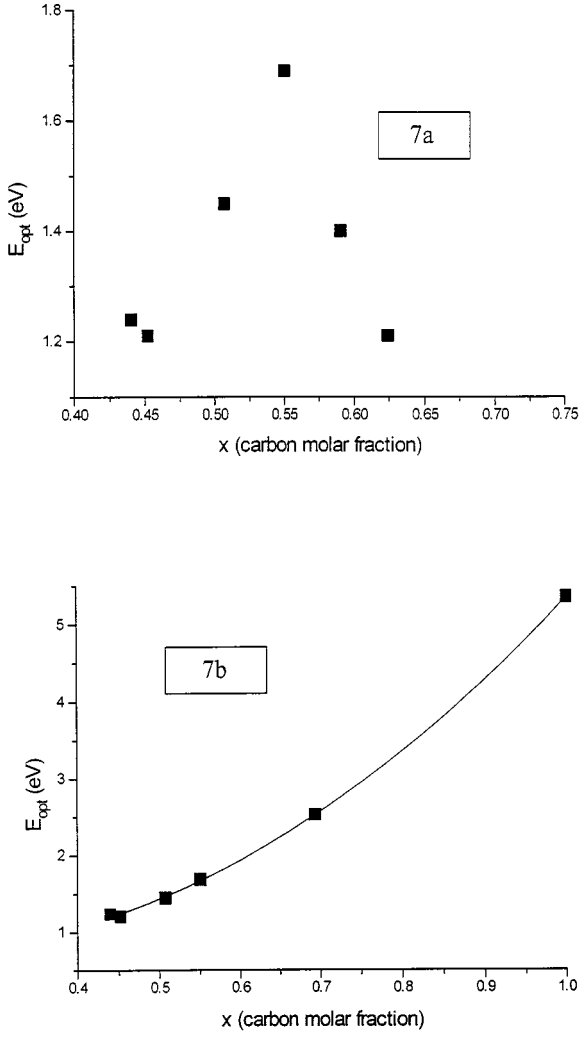

Figure 7. (**a**) Values of E_{opt} as a function of carbon molar fraction in the condensed phase of a few samples with different composition; (**b**) increasing data of part **a** and 2.53 eV are used to extrapolate to $x = 1$

The E_{opt} values are between 1.2 and 1.7 eV, which is in good agreement with previously reported data.[7,17,21,22] In particular, the sample with composition $Ge_{0.49}C_{0.51}$:H shows an E_{opt} of 1.49 eV, which is very close to the value (1.45 eV) reported by Shinar[22] for a sample with a very similar composition. Figure 7a shows that E_{opt} increases with increasing carbon content, reaching a maximum for a sample with composition $Ge_{0.45}C_{0.55}$:H, and then decreases, as reported for α-SiC:H alloys.[7] The variation of optical properties depending on film composition is related to the local bonding. In a binary alloy, such as germanium carbide, Ge−Ge, Ge−C, and C−C bonds are possible, and their relative proportions may change with increasing carbon content. If sp^3-bonded alloys are hypothesised, E_{opt} should continuously increase with the carbon content because Ge−Ge bonds are replaced by stronger Ge−C[36] bonds. When the carbon molar fraction, x, is higher than 0.5, Ge−C bonds are replaced by even stronger C−C bonds.[36,44] Nevertheless, we observe a maximum in the plot of E_{opt} vs. carbon content at around $x = 0.55$. To explain this trend, a C sp^2-bonding configuration must be considered.[7,44,45] It is reasonable to suppose that in our Ge−C alloys with $x > 0.5$ the carbon atoms exceeding the stoichiometric composition show a tendency to form zones in which several carbon atoms are bonded together, forming a threefold coordinated graphite-type local environment, as proposed for Si−C alloys.[7] The occurrence probability of these regions is enhanced if the carbon content increases. The decrease of E_{opt} observed when the carbon content increases over a critical value both in α-GeC:H and α-SiC:H,[7,44,45] is attributed to the presence of this graphit-type carbon. This is in agreement with the approach of conduction and valence band edges shown by Robertson[44] for α-SiC:H alloys when the amount of sp^2-bonded carbon increases. Therefore, we think that the observed trend of E_{opt} for our α-$Ge_{1-x}C_x$:H sample, in which a maximum is present, is related to gap narrowing in carbon rich compounds due to the considerable presence of C sp^2 bonding.

An E_{opt} value of 2.53 eV has also been obtained for a sample with composition $GeC_{2.26}H_{5.92}$ (Figure 7b). This high value, which is in apparent contradiction with the above trend, is attributable to the high hydrogen content of the sample. In fact, hydrogen is found to broaden the band gap both for sp^3- and sp^2-bonded alloys.[44,45] Moreover, hydrogen promotes formation of sp^3-hybridised C atoms over sp^2, terminating any dangling bonds and thus reducing the size of the graphite-type cluster and increasing the gap. This is in agreement with the IR results that indicate that if the carbon and hydrogen content of the samples is increased, the CH_3-groups increase is considerably higher than the relative increase of carbon content. Moreover, it is interesting to note that if only the increasing E_{opt} values of Figure 7a and 2.53 eV are considered, the extrapolation for $x = 1$ of the line in Figure 7b, gives a value close to that of diamond (5.45 eV).[45]

Conclusions

The results obtained above indicate that amorphous non-stoichiometric Ge_{1-x}−C_x:H compounds can be obtained from X-ray radiolysis of germane/ethylene mixtures over a wide range of compositions by varying the ethylene percentage in the mixture. When the ethylene percentage is increased, the carbon and hydrogen content also increases. In the IR spectra, the vibrational modes of CH_n ($n = 1-3$) and GeH_n ($n = 1-2$) groups are evident. Vibrational modes of $GeCH_n$ ($n = 1-3$) groups and Ge−C bonds are also

present. The hydrogen atoms bond preferably to carbon atoms; in fact, when the carbon and hydrogen content increases the carbon hydrogenation degree increases, whereas the hydrogenation of germanium decreases indicating that the Ge−H bonds are substituted by Ge−C bonds.

The optical gaps of the compounds depend on the carbon content: values between 1.2 and 1.7 eV have been found. The E_{opt} increases with increasing carbon molar fraction until it reaches a critical value around 0.55, and then decreases giving a maximum in E_{opt}. This trend is attributed to the presence of sp^2-hybridised C atoms forming π-bonded clusters when the carbon molar fraction exceeds 0.55.

Experimental Section

Monogermane was prepared according to a literature procedure,[46] and purified by bulb-to-bulb distillation. Ethylene was high purity SIAD (Società Italiana Acetilene e Derivati) gas and was used without further purification.

Samples of GeH_4/C_2H_4 mixtures of different composition were irradiated with 250 keV X-rays in 365-mL Pyrex vessels at a total pressure of 700 Torr. During irradiation, performed under static conditions, the irradiated mixture composition did not vary markedly. Moreover, as the condensed products were deposited on the bottom of the vials, out of the main X-ray trajectory, the dose absorbed by the products was negligible.

Standard vacuum techniques were used to handle both reactants and gaseous products.

The X-ray source was a CPXT-320 tube (Gilardoni) with a maximum output of 320 keV. The dose absorbed by each sample was 5.0×10^4 Gy at a rate of 1.0×10^4 Gy/h. During the irradiation the temperature did not exceed 320 K.

Gas phase products were analysed by gas chromatography-mass spectrometry (GC-MS) on a Varian 3400-Finnigan ITD instrument equipped with an Alltech AT-1 chromatographic column (polydimethylsiloxane, length 30 m, I.D. 0.25 mm, film thickness 1.0 μm). The temperature ranged from 243 K to 523 K at 10 K/min. A He carrier head pressure of 10 psi was used. Ionisation in the trap was achieved by 70 eV EI and ion acquisition was recorded in the 20−650 u mass range. Quantitative determination of volatile compounds was accomplished calibrating the gas chromatograph with GeH_4. The values reported are the average of at least four experiments.

The composition of the solids was determined by elemental (C and H) analysis.

The X-ray powder-analyses were performed on a Siemens D 500 diffractometer, using Cu-K_α radiation (graphite monochromator on the secondary beam).

The condensed phases were examined by IR spectroscopy (KBr pellets) with an FTIR Bruker Equinox 55 instrument equipped with a program for the deconvolution of overlapped peaks. The resolution was 2 cm^{-1}. All spectra were gathered at room temperature.

The UV/Vis spectrum was obtained with a Perkin−Elmer Lambda 15 spectrophotometer from the material deposited on the quartz disk, using a clean quartz disk irradiated at the same dose as a reference.

Cobalt/Mercury Carbide Clusters Based on Trigonal-Prismatic or Octahedral Co_6C Skeletons − X-ray Crystal Structure of $(NEt_4)_2[Co_6C(CO)_{12}\{HgW(CO)_3Cp\}_2]$

Keywords: Carbonyl complexes / Cluster compounds / Cobalt / Mercury / Rearrangements

The anionic transition metal clusters $(NEt_4)[Co_6C(CO)_x\{HgM\}]$ [M = $W(CO)_3Cp$, $Mo(CO)_3Cp$, $Fe(CO)_2Cp$, $Co(CO)_4$, $Mn(CO)_5$] (x = 13 or 15) have been obtained by reaction of the corresponding octahedral (x = 13) or trigonal-prismatic (x = 15) cobalt carbido carbonyl clusters with the mercury derivatives ClHgM. Metal skeleton rearrangements and some redox processes have been found to be induced by varying both the temperature and the solvent, resulting in new compounds containing tetra- or hexacoordinated mercury atoms.

Introduction

The fact that the mercury units HgM^+ [M = a metal fragment such as $Mo(CO)_3Cp$] can readily be attached to a wide variety of transition metal cluster anions has stimulated their use as general building blocks in the systematic synthesis of heterometallic clusters. In general, *typical* μ_2- and μ_3-HgM modes are found for a large number of polynuclear metal carbonyl clusters, where the mercury fragments bridge metal-metal edges or cap triangular faces of cluster cores.[1] Two-centre two-electron bonding is found only for the simplest bi- and trimetallic compounds.[2]

In comparison with other transition metals, only very few cobalt/mercury systems have been reported to date. This is surprising because cobalt and rhodium, for example, are unique in forming two hexanuclear anions with different metal frameworks, the octahedral $[M_6C(CO)_{13}]^{2-}$ (86 EC) and the trigonal-prismatic $[M_6C(CO)_{15}]^{2-}$ (90 EC), which can be interconverted through the uptake and release of carbon monoxide.[3−5] This process can be rationalized in terms of a trigonal-twist mechanism, which involves the mutual rotation of the two triangles of metal atoms.

These considerations prompted us to explore the possibility of incorporating HgM^+ units into both of the aforementioned hexacobalt frameworks and to identify skeletal isomers. We were also interested in extending our studies to the investigation of potential skeletal rearrangements involving the new mercury/cobalt systems thus synthesized.

Results and Discussion

The selected ClHgM species [M = $W(CO)_3Cp$, $Mo(CO)_3Cp$, $Fe(CO)_2Cp$, $Co(CO)_4$, $Mn(CO)_5$] were reacted separately with the NEt_4^+ salts of the anions $[Co_6C(CO)_{15}]^{2-}$ (**1**) and $[Co_6C(CO)_{13}]^{2-}$ (**2**) (see Scheme 1).

Reactions with the Trigonal-Prismatic $[Co_6C(CO)_{15}]^{2-}$ Anion (1)

Treatment of $(NEt_4)_2[Co_6C(CO)_{15}]$ (**1**) with ClHgM in CH_2Cl_2 at −12 °C in the presence of a thallium salt as a halide abstractor gave the brown cluster complexes $(NEt_4)[Co_6C(CO)_{15}\{HgM\}]$ [M = $W(CO)_3Cp$ (**3a**), $Mo(CO)_3Cp$ (**3b**), $Fe(CO)_2Cp$ (**3c**), $Co(CO)_4$ (**3d**), $Mn(CO)_5$ (**3e**)]. Only compound **3a** could be isolated as a crystalline solid; the other mercury derivatives were recovered as oily materials. The ν(CO) patterns in the IR spectra of **3a−e** were found to be almost superimposable if the bands due to the M part were ignored. The ν(CO) bands are shifted to higher wavenumbers (by 30 cm^{-1}), indicating a decrease in electron density at the cobalt atoms. The observation of the ^{13}C NMR signal due to the carbide carbon atom at δ = 357 confirmed that the incorporation of the mercury fragment does not induce a dramatic rearrangement of the metal framework. Mass spectrometry showed that the trigonal-prismatic Co_6C skeleton was preserved following the attachment of the mercury units. Thus, the parent molecular peak $[M^-]$ was observed for all the compounds, except in the case of the mercury/cobalt complex **3d**, where the most intense peak corresponded to [M − 2CO].

In light of these data, we propose a molecular structure for type **3** complexes consisting of a triangular prism of cobalt atoms where one of the triangular faces, corresponding to the most basic sites on the prism surface,[6] is capped by the mercury atom. In fact, this is the structure found for the analogous cluster anion of rhodium

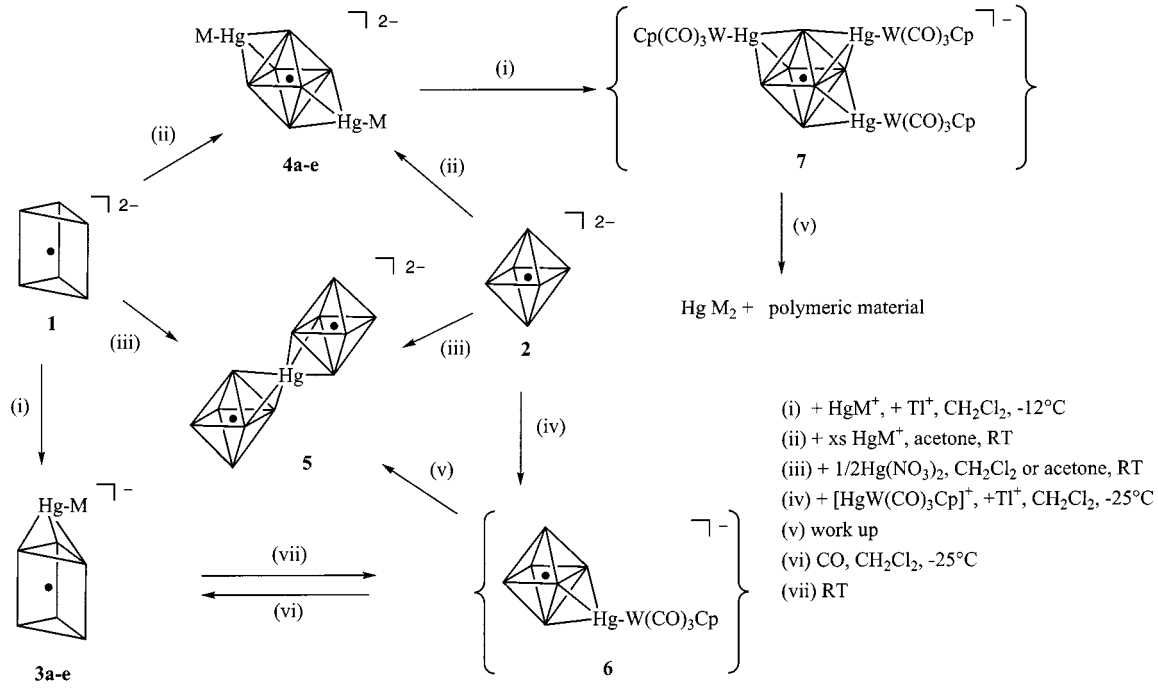

Scheme 1

$[Rh_6C(CO)_{15}\{AuPR_3\}]^-$ (R = Ph, Et),[7,8] which is not surprising in view of the well-known isolobal relationship between the fragments $AuPPh_3$ and HgM.[9] This implies, albeit with some exceptions, that both units occupy the same sites of a given cluster.[10] The remaining negative charge suggested the possibility of introducing another mercury unit into these type **3** complexes. In fact, the reaction of **3** with ClHgM in a 1:1 molar ratio yielded a highly insoluble material that could not be characterized, along with the trimetallic species HgM_2. The formation of these two products can be rationalized in terms of a rapid ligand-redistribution process of the initially formed $[Co_6C(CO)_{15}(HgM)_2]$. This result is in agreement with our predictions that the neutral mercury/transition metal clusters should be unstable with regard to the symmetrization process, while the negatively charged species should be reasonably stable and hence isolable in most cases.[11]

In order to avoid the formation of oily materials and to determine whether the solvent plays an important role in our reactions, we allowed the $[Co_6C(CO)_{15}]^{2-}$ anion (**1**) to react with ClHgM in acetone at room temperature. Surprisingly, under these conditions, we were able to isolate brown crystals of $(NEt_4)_2[Co_6C(CO)_{12}\{HgM\}_2]$ [M = $W(CO)_3Cp$ (**4a**), $Mo(CO)_3Cp$ (**4b**), $Fe(CO)_2Cp$ (**4c**), $Co(CO)_4$ (**4d**), $Mn(CO)_5$ (**4e**)] in moderate yields, accompanied by Co^{II} salts. These complexes were characterized by elemental analyses, spectroscopic data, and mass spectrometry. Their ν(CO) bands were found to be shifted to lower frequencies by around 20 cm^{-1}, which is consistent with an increase in the electron density at the cobalt atoms. Their ^{13}C NMR spectra featured signals corresponding to the CO and Cp ligands, but the carbide signal was not observed. For all the clusters of type **4**, FABMS showed the $[M + H]^-$ peak in accordance with the formula $[Co_6C(CO)_{12}\{HgM\}_2]^{2-}$.

The structure of **4a** was confirmed by X-ray analysis. The geometry of the anion is shown in Figure 1, together with the atom numbering scheme. Selected bond lengths and angles are listed in Table 1.

The structure of this complex is based on that of the parent $[Co_6C(CO)_{13}]^{2-}$ anion and has the two $HgW(CO)_3Cp$ groups capping opposite faces of the distorted Co_6 octahedron. All the other edges are bridged by CO ligands to give a symmetrical structure with the central carbon atom at a crystallographic centre of symmetry. Each cobalt atom bears a terminal carbonyl ligand. As expected, the mercury coordination to the Co_3 faces causes an appreciable lengthening of the distances between these cobalt atoms (average 2.806 Å). The Hg atom resides in a strongly distorted tetrahedral arrangement involving the three Co atoms and the W atom. The $HgW(CO)_3Cp$ moiety shows the usual four-legged piano stool arrangement with a W−Hg distance of 2.781(2) Å.

The coordination of this unit does not lead to any appreciable expansion of the Co_6C octahedron, and the distances between the carbido carbon atom and the cobalt atoms (average 1.873 Å) remain similar to those observed in the $[Co_6C(CO)_{13}]^{2-}$ anion [average 1.87(1) Å].

The Co−Hg distances (average 2.717 Å) are shorter than those observed in other $Co_3(\mu_3\text{-}HgR)$ systems, e.g. $[FeCo_3(CO)_{12}\{\mu_3\text{-}HgMo(CO)_3Cp\}]$ (average 2.816 Å) and $[RuCo_3(CO)_{12}\{\mu_3\text{-}HgCo(CO)_4\}]$ (average 2.756 Å).[12] The Co_6Hg_2 metal framework found for **4a** has no precedent in the chemistry of the Group 9 elements. Its formation re-

quires the loss of three carbonyl ligands from the starting anion in order to permit both the skeletal rearrangement from the prism to the octahedron and the redox process that gives the double negative charge on the cluster. Considering that each HgM fragment contributes 12 electrons to the polyhedral electron count of the cluster, compound **4** conforms to the number of electrons (110) expected for a bicapped octahedron according to the condensation rules given by polyhedral skeletal electron-pair theory.[13] It is noteworthy that the formation of **4**, possessing a Co_6 octahedral core, proceeds through a skeletal rearrangement of the trigonal prism $[Co_6C(CO)_{15}]^{2-}$ resulting from the incorporation of two mercury units. This structural feature has not previously been observed in the chemistry of rhodium. For example, the reaction of $[Rh_6C(CO)_{15}]^{2-}$ with two equivalents of $ClAuPPh_3$ affords $[Rh_6C(CO)_{15}\{AuPPh_3\}_2]$,[7] which displays a trigonal-prismatic framework of Rh atoms capped on both triangular faces by a gold atom. It is clear that in the present case the driving force for the skeletal rearrangement is the energy involved in the formation of the three new Co−Co bonds as well as three extra Co−Hg bonds and the entropic contribution from the liberation of the three CO ligands required in the transformation of the trigonal prism to the octahedral core. On the other hand, steric interactions between the terminal and in-plane edge-bridging carbonyl ligands and the incoming mercury fragments should not be ruled out as an influence on the skeletal rearrangement process.

In an attempt to obtain other cobalt clusters possessing trigonal-prismatic skeletons, we tried to synthesize $[Hg\{Co_6C(CO)_{15}\}_2]^{2-}$ by reacting the starting cobalt anion $[Co_6C(CO)_{15}]^{2-}$ (**1**) with $Hg(NO_3)_2$ in a 2:1 molar ratio in CH_2Cl_2 or acetone at room temperature (see Scheme 1). However, the spectroscopic data of the brown crystals thus obtained indicated that the new compound was actually $[Hg\{Co_6C(CO)_{13}\}_2]^{2-}$ (**5**). ^{13}C NMR spectroscopy proved to be an excellent tool for determining the geometry of the cobalt core: the carbide carbon atom gives rise to a signal at $\delta \approx 460$ when it is at the centre of the octahedron or at $\delta \approx 350$ when it resides within the trigonal prism. In the case of **5**, the ^{13}C NMR spectrum features a signal at $\delta = 466$, suggesting a metal framework based on a six-coordinate mercury atom capping one triangular face of two octahedra. Consequently, the coordination about mercury can be described as octahedral, which is rather unusual in the organometallic chemistry of this element.[14]

Reactions with the Octahedral $[Co_6C(CO)_{13}]^{2-}$ Anion (2)

When a solution of $(NEt_4)_2[Co_6C(CO)_{13}]$ **(2)** in CH_2Cl_2 was treated with $ClHgW(CO)_3Cp$ (1:1 molar ratio) at −25 °C in the presence of a thallium salt, the IR spectrum of the solution showed a shift of the carbonyl bands to higher wavenumbers (by around 40 cm^{-1}), indicating the attachment of the mercury fragment to the skeleton of the cobalt anion. Efforts to isolate the expected product $(NEt_4)[Co_6C(CO)_{13}\{HgW(CO)_3Cp\}]$ **(6)** were unsuccessful; after workup of the solution we could only separate HgM_2 along with crystals of $(NEt_4)_2[Hg\{Co_6C(CO)_{13}\}_2]$ **(5)**, the identity of which was established by comparison with an authentic sample obtained from the reaction of $[Co_6C(CO)_{13}]^{2-}$ **(2)** with $Hg(NO_3)_2$ (see Scheme 1). In view of the fact that it proved impossible to isolate compound **6**, we submitted a fresh reaction solution in CH_2Cl_2 to mass spectrometric analysis in order to confirm the formation of the desired complex. We thus observed the parent molecular peak, $[M^-]$, corresponding to the formula $[Co_6C(CO)_{13}\{HgW(CO)_3Cp\}]^-$.

The question that arises is the mechanism by which **5** is formed in the above reaction. The simultaneous formation of the symmetrical species in the course of the reaction suggests that **5** is formed from the nonisolated species **6** by slow ligand redistribution. Despite the fact that $[Co_6C(CO)_{13}\{HgW(CO)_3Cp\}]^-$ bears one negative charge and, consequently, is relatively inert to symmetrization processes, with high nuclearity clusters a spontaneous albeit slow symmetrization occasionally takes place.[15,16] The failure to isolate **6** precluded its spectroscopic characterization. However, it was thought that the addition of four electrons to its polyhedral skeleton, by reaction with carbon monoxide, would facilitate skeletal arrangement to the trigonal-prismatic $[Co_6C(CO)_{15}\{HgW(CO)_3Cp\}]^-$ **(3a)**, which has been characterized previously. Indeed, compound **6** was found to react with a smooth stream of CO at −25 °C to give **3a**, thus confirming our expectations. Interestingly, when the reaction mixture was allowed to warm to room temperature, reversion to **6** was noted. Bearing in mind the isolobal relationship between HgM and $AuPPh_3$, and the fact that the crystal structure of the anion $[Co_6C(CO)_{13}\{AuPPh_3\}]^-$ has recently been determined,[17] we propose a similar metal core for **6** consisting of a cobalt octahedron capped at a triangular face by the mercury atom.

The importance of the nature of the solvent as well as the temperature was again evidenced in the reaction of $[Co_6C(CO)_{13}]^{2-}$ (**2**) with HgM^+. When the reaction was carried out in acetone at room temperature, moderate yields of type **4** complexes were obtained. Their formation from the octahedral cobalt anion involves the loss of one carbonyl ligand according to an as-yet-unclear mechanism. Taking into account the dianionic character of type **4** compounds and their relative stability, we decided to test their reactivity further. When **4a** was reacted with another equivalent of $ClHgW(CO)_3Cp$ in CH_2Cl_2 at −12 °C in the presence of a thallium salt, the expected monoanionic $[Co_6C(CO)_{12}\{HgW(CO)_3Cp\}_3]^-$ species **7** could be detected in solution by IR spectroscopy as well as by mass spectrometry (ESMS), where the parent molecular peak was observed. Unfortunately, however, after workup the isolated products were $Hg[W(CO)_3Cp]_2$ and a highly insoluble, intractable material. This behaviour would suggest that the incoming third metal fragment promotes a spontaneous symmetrization reaction.

In conclusion, we have shown that both hexanuclear cobalt clusters react with mercury halide complexes to give mono- and di-capped trigonal prisms or octahedral skeletons. The tendency of the more open trigonal-prismatic cores to rearrange into an octahedral geometry would seem to indicate that the latter metal framework is the most stable for mixed mercury/cobalt clusters.

Electrochemical Studies

The electrochemical properties of these compounds were studied in the electroactivity range of the solvent (CH_2Cl_2) to compare the electrochemical behaviour of the octahedral and prismatic geometry complexes, as well as to allow comparison with related compounds.

The Co_6-based prismatic complex **3a** showed a one-electron irreversible reduction step at $E_{p,c} = -0.80$ V and a one-electron reversible oxidation step at $E^{o\prime} = 0.66$ V (see Table 2), but the instability of the compound did not permit a mechanistic study of its electrochemical processes.

Owing to the rapid decomposition of the cluster **4c** in solution, no electrochemical study could be carried out. The other dianionic octahedral clusters with different mercury fragments showed a reversible reduction at around −1.2 V, except for the cobalt derivative **4d**, for which the reduction step was irreversible. These species were also seen to undergo an irreversible oxidation at around 0.2 V when the scan rate was 0.1 Vs^{-1}, but it became a quasi-reversible process at a scan rate of 0.5 Vs^{-1} (Table 2). The oxidation was a one-electron step, as shown by comparison with the height of the reduction wave (due to passivation phenomena, reliable coulometry could not be performed). When the oxidation was carried out in an EPR tube with $[FeCp_2][PF_6]$

Table 2. Cyclic voltammetry data

5	−0.55	88	0.80	1	0.26[c]			1
	−0.88	123	1.15	1				

[a] Scan rate: 0.1 Vs^{-1} vs. SCE in 0.1 M Bu_4NBF_4 in CH_2Cl_2 or acetone at −15 °C. − [b] $E_{p,c}$ (irreversible reduction). − [c] $E_{p,a}$ (irreversible oxidation).

in CH_2Cl_2 at −78 °C, the radical species $[Co_6C(CO)_{12}\{HgM\}_2]^{\cdot -}$ was detected. The X-band EPR spectrum consists of a single strong resonance centred at ca. 3373 G (g = 2.0028). The identities of the decomposition products were verified by IR spectroscopy.

Compound **5** shows a one-electron irreversible oxidation step at $E_{p,a}$ = 0.26 V (controlled potential coulometry at 0.3 V). Moreover, this cluster was seen to undergo two well-defined one-electron reversible reductions at $E^{o\prime}$ = −0.55 V and $E^{o\prime}$ = −0.88 V by comparison of the wave heights with that for the oxidation step (Table 2). The instability of this compound in solution and the passivation phenomena at the electrode surface precluded a supplementary electrochemical study.

In summary, we have observed that those compounds which adopt an octahedral geometry exhibit reversible reduction steps, while the prismatic cluster shows an irreversible reduction wave. This behaviour compares well with the irreversible reduction steps found for the prismatic $[Co_6C(CO)_{15}]^{2-}$ starting dianion.[19]

Conclusions

Reaction of the $[Co_6C(CO)_{15}]^{2-}$ and $[Co_6C(CO)_{13}]^{2-}$ anions with one mol of HgM^+ gives the octanuclear species $[Co_6C(CO)_{15}\{HgM\}]^-$ and $[Co_6C(CO)_{13}\{HgM\}]^-$, having spiked Co_6C trigonal-prismatic and spiked octahedral skeletons, respectively. These species can be interconverted through the addition or elimination of CO. On the other hand, the use of an excess of HgM^+ has been found to lead invariably to the cluster $[Co_6C(CO)_{12}\{HgM\}_2]^{2-}$, in which the Co_6C octahedron is doubly-capped by HgM^+ moieties. Finally, electrochemical studies on the dimercury complexes have revealed that their oxidation leads to radical species $[Co_6C(CO)_{12}\{HgM\}_2]^{\bullet -}$, which could be detected by EPR.

Experimental Section

General: All manipulations were performed under an atmosphere of purified N_2 using standard Schlenk techniques. All solvents were distilled from appropriate drying agents. − Infrared spectra were recorded from samples in CH_2Cl_2 or acetone solution on a Nicolet FT-IR 520 spectrophotometer. − ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded on Bruker DRX 250 and Varian XL-500 spectrometers and were referenced to TMS (δ_H, δ_C = 0.0) and 85% H_3PO_4 (δ_P = 0.0). − FAB and ES mass spectra were recorded on a Fisons VG Quattro spectrometer with samples injected as CH_2Cl_2, methanol, or acetone solutions. − EPR spectra were obtained on a Bruker ESP 300 E spectrometer operating in the X-band mode at 100 K, as maintained by a standard Bruker VT 1000 cryostat. − The compounds ClHgM[20] [M = $Mo(CO)_3Cp$, $W(CO)_3Cp$, $Fe(CO)_2Cp$, $Co(CO)_4$, $Mn(CO)_5$], $(NEt_4)_2[Co_6C(CO)_{15}]$,[6] and $(NEt_4)_2[Co_6C(CO)_{13}]$[3] were synthesized as described previously. The synthetic methodology detailed in this section corresponds to the reactions described in Scheme 1 that afforded better yields and pure final products. The elemental analyses for compounds **3b−e** are not reported because they did not burn properly in the analyser.

Synthesis of $(NEt_4)[Co_6C(CO)_{15}\{\mu\text{-}HgM\}]$ [M = $W(CO)_3Cp$ (3a), $Mo(CO)_3Cp$ (3b), $Fe(CO)_2Cp$ (3c), $Co(CO)_4$ (3d), $Mn(CO)_5$ (3e)]: Details of the synthesis of **3a** also apply to **3b−e**, although the latter were obtained as oily materials. To a precooled solution of $(NEt_4)_2[Co_6C(CO)_{15}]$ (**1**) (0.30 g, 0.28 mmol) in CH_2Cl_2 (15 mL) at −12 °C were added solid $ClHgW(CO)_3Cp$ (0.16 g, 0.28 mmol) and $TlBF_4$ (0.09 g, 0.28 mmol). After stirring for 10 min, the starting material had been consumed and the mixture was filtered to remove the salts. The filtrate was layered with pentane (5 mL). Storage at −30 °C for 8 h resulted in the deposition of **3a** as a brown crystalline solid (0.15 g, 37% yield). − IR (CH_2Cl_2): $\tilde{\nu}$ (ν_{CO} stretch) = 2053 cm^{-1} m, 2011 vs, 1963 s, 1889 m, 1856 m. − ^1H NMR (295 K, CD_2Cl_2): δ = 1.3 (tt, 12 H, CH_3), 3.2 (q, 8 H, CH_2), 5.5 (s, 5 H, C_5H_5). − ^{13}C NMR (295 K, CD_2Cl_2): δ = 7.3 (s, CH_3), 53.0 (s, CH_2), 86.9 (s, C_5H_5), 357.0 (s, C). − FABMS: m/z = 1318 [M^-]. − $C_{32}H_{26}Co_6HgNO_{16}W$ (1449.58): C 26.51, H 1.74, N 0.97; found C 26.59, H 1.72, N 1.00.

3b: IR (CH_2Cl_2): $\tilde{\nu}$ (ν_{CO} stretch) = 2053 cm^{-1} m, 2007 vs, 1963 s, 1882 m, 1852 m. − ^1H NMR (295 K, CD_2Cl_2): δ = 1.3 (tt, 12 H, CH_3), 3.2 (q, 8 H, CH_2), 5.4 (s, 5 H, C_5H_5). − FABMS: m/z = 1233 [M^-].

3c: IR (CH_2Cl_2): $\tilde{\nu}$ (ν_{CO} stretch) = 2069 cm^{-1} w, 2049 m, 2008 vs, 1925 w, 1857 m. − ^1H NMR (295 K, CD_2Cl_2): δ = 1.32 (tt, 12 H, CH_3), 3.2 (q, 8 H, CH_2), 4.7 (s, 5 H, C_5H_5). − FABMS: m/z = 1164 [M^-].

3d: IR (CH_2Cl_2): $\tilde{\nu}$ (ν_{CO} stretch) = 2063 cm^{-1} m, 2049 m, 2011 vs, 1849 m. − FABMS: m/z = 1103 [M^- − 2CO].

3e: IR (CH_2Cl_2): $\tilde{\nu}$ (ν_{CO} stretch) = 2070 cm^{-1} w, 2047 m, 2010 vs, 1860 w. − ESMS: m/z = 1182 [M^-].

Synthesis of $(NEt_4)_2[Co_6C(CO)_{12}\{\mu_3\text{-}HgM\}_2]$ [M = $W(CO)_3Cp$ (4a), $Mo(CO)_3Cp$ (4b), $Fe(CO)_2Cp$ (4c), $Co(CO)_4$ (4d), $Mn(CO)_5$ (4e)]: The general procedure is described for the case of **4a**. To a solution of $(NEt_4)_2[Co_6C(CO)_{15}]$ (**1**) (0.30 g, 0.28 mmol) in acetone (20 mL) at room temperature was added solid $[ClHgW(CO)_3Cp]$ (0.16 g, 0.28 mmol). After the mixture had been stirred for 2 h, addition of a 30% excess of $[ClHgW(CO)_3Cp]$ (0.05 g) was found to be necessary to complete the reaction. The reaction mixture was stirred for a further 2 h and then hexane (20 mL) was added in order to precipitate the salts. After filtration, the slow addition of further hexane (10 mL) under vigorous stirring led to the deposition of red-brown crystals of **4a** (0.18 g, 30% yield). − IR (acetone): $\tilde{\nu}$ (ν_{CO} stretch) = 2001 cm^{-1} w, 1962 vs, 1875 m, 1863 m, 1814 m. − ^1H NMR (295 K, [D_6]acetone): δ = 1.4 (tt, 24 H, CH_3), 3.5 (q, 16 H, CH_2), 5.3 (s, 10 H, C_5H_5). − ^{13}C NMR (295 K, [D_6]acetone): δ = 7.5 (s, CH_3), 52.8 (s, CH_2), 88.6 (s, C_5H_5), 218.0 (m, CO), 237.5 (m, CO). − FABMS: m/z = 1768 [M + H]$^-$. − $C_{45}H_{50}Co_6Hg_2N_2O_{18}W_2$ (2029.37): C 26.61, H 2.48, N 1.37; found C 26.69, H 2.51, N 1.40.

For compounds **4b−e**, the addition of diethyl ether (20 mL) caused the precipitation of the salts. Indeed, all the crystalline solids were obtained with diethyl ether, although varying excesses of ClHgM, different reaction times, and modified final workup conditions were needed.

4b: 40% excess $ClHgMo(CO)_3Cp$; 2 h reaction time; the final precipitation was achieved by the addition of diethyl ether (20 mL) in aliquots of 5 mL. 0.14 g, 27% yield. − IR (acetone): $\tilde{\nu}$ (ν_{CO} stretch) = 2002 cm^{-1} w, 1964 vs, 1882 m, 1868 m, 1814 m. − ^1H NMR (295 K, [D$_6$]acetone): δ = 1.4 (tt, 24 H, CH_3), 3.5 (q, 16 H, CH_2), 5.2 (s, 10 H, C_5H_5). − ^{13}C NMR (295 K, [D$_6$]acetone): δ = 7.5 (s, CH_3), 52.8 (s, CH_2), 89.9 (s, C_5H_5), 235.7−229.7 (m, CO). − FABMS: *m/z* = 1594 $[M + H]^-$. − $C_{45}H_{50}Co_6Hg_2N_2O_{18}Mo_2$ (1853.55): C 29.16, H 2.72, N 1.51; found C 29.19, H 2.75, N 1.52.

4c: 25% excess $ClHgFe(CO)_2Cp$; 6 h reaction time; precipitation occurred after 8 h at −30 °C. 0.12 g, 25% yield. − IR (acetone): $\tilde{\nu}$ (ν_{CO} stretch) = 2053 cm^{-1} m, 1994 m, 1969 vs, 1908 w, 1891 w, 1816 m. − ^1H NMR (295 K, [D$_6$]acetone): δ = 1.4 (tt, 24 H, CH_3), 3.5 (q, 16 H, CH_2), 4.6 (s, 10 H, C_5H_5). − ^{13}C NMR (295 K, [D$_6$]acetone): δ = 7.5 (s, CH_3), 52.8 (s, CH_2), 81.1 (s, C_5H_5), 214.2 (s, CO). − FABMS: *m/z* = 1458 $[M + H]^-$. − $C_{43}H_{50}Co_6Fe_2Hg_2N_2O_{16}$ (1717.34): C 30.07, H 2.93, N 1.63; found C 30.11, H 2.95, N 1.65.

4d: 30% excess $ClHgCo(CO)_4$; 2 h reaction time; the final precipitation was accomplished by the addition of diethyl ether (20 mL) in aliquots of 5 mL. 0.12 g, 25% yield. − IR (acetone): $\tilde{\nu}$ (ν_{CO} stretch) = 2052 cm^{-1} m, 1977 vs, 1963 s, 1890 w, 1825 m. − ^{13}C NMR (295 K, [D$_6$]acetone): δ = 7.5 (s, CH_3), 52.8 (s, CH_2), 209.7 (s, CO), 233.2 (m, CO). − FABMS: *m/z* = 1445 $[M + H]^-$. − $C_{37}H_{40}Co_8Hg_2N_2O_{20}$ (1705.37): C 26.06, H 2.36, N 1.64; found C 26.09, H 2.37, N 1.66.

4e: 25% excess $ClHgMn(CO)_5$; 6 h reaction time; precipitation occurred after 8 h at −30 °C. 0.14 g, 28% yield. − IR (acetone): $\tilde{\nu}$ (ν_{CO} stretch) = 2062 cm^{-1} m, 1981 vs, 1954 s,sh, 1891 w, 1820 m. − ^{13}C NMR (295 K, [D$_6$]acetone): δ = 7.5 (s, CH_3), 52.8 (s, CH_2), 218.1 (m, CO). − FABMS: *m/z* = 1493 $[M + H]^-$. − $C_{39}H_{40}Co_6Hg_2Mn_2N_2O_{22}$ (1753.40): C 26.71, H 2.29, N 1.60; found C 26.73, H 2.32, N 1.62.

$(NEt_4)_2[Hg\{Co_6C(CO)_{13}\}_2]$ (5): Solid $Hg(NO_3)_2$ (0.05 g, 0.15 mmol) was added to a solution of $(NEt_4)_2[Co_6C(CO)_{13}]$ (**2**) (0.30 g, 0.30 mmol) in CH_2Cl_2 (20 mL). The mixture was stirred at room temperature for 5 h and then filtered. The resulting solution was layered with hexane (10 mL) and cooled overnight at −30 °C to give 0.16 g (30% yield) of a dark-brown crystalline solid. − IR (CH_2Cl_2): $\tilde{\nu}$ (ν_{CO} stretch) = 2037 cm^{-1} w, 2007 vs, 1844 w. − ^{13}C NMR (295 K, CD_2Cl_2): δ = 7.8 (s, CH_3), 53.0 (s, CH_2), 219.5 (s, CO), 225.1 (s, CO), 466.0 (s, C). − FABMS: *m/z* = 1633 $[M - CO]^-$. − ESMS: *m/z* = 830 $[M/2]^{2-}$. − $C_{44}H_{40}Co_{12}HgN_2O_{26}$ (1922): C 25.14, H 0.95, N 1.33; found C 25.19, H 0.99, N 1.34.

Reaction of $(NEt_4)_2[Co_6C(CO)_{13}]$ with $ClHgW(CO)_3Cp$ − Formation of $(NEt_4)[Co_6C(CO)_{13}\{\mu_3\text{-}HgW(CO)_3Cp\}]$ (6): To a solution of $(NEt_4)_2[Co_6C(CO)_{13}]$ (**2**) (0.30 g, 0.30 mmol) in CH_2Cl_2 (15 mL) at −25 °C were added solid $ClHgW(CO)_3Cp$ (0.17 g, 0.30 mmol) and $TlBF_4$ (0.09 g, 0.30 mmol). The resulting mixture was stirred for 1 h. Subsequent addition of hexane (5 mL) caused the precipitation of the salts, which were filtered off. The IR and ES mass spectra of the resulting solution confirmed the formation of $[Co_6C(CO)_{13}\{\mu_3\text{-}HgW(CO)_3Cp\}]^-$ (**6**). − IR (CH_2Cl_2): $\tilde{\nu}$ (ν_{CO} stretch) = 2053 cm^{-1} m, 2004 vs, 1870 m, 1845 m. − ESMS: *m/z* = 1263 $[M]^-$.

Reaction of $(NEt_4)_2[Co_6C(CO)_{12}\{\mu\text{-}HgW(CO)_3Cp\}_2]$ with $ClHgW(CO)_3Cp$ − Formation of $(NEt_4)[Co_6C(CO)_{12}\{HgW(CO)_3Cp\}_3]$ (7): To a solution of $(NEt_4)_2[Co_6C(CO)_{12}\{\mu\text{-}HgW(CO)_3Cp\}_2]$ (**4a**) (0.25 g, 0.12 mmol) in CH_2Cl_2 (15 mL) at −12 °C were added solid $[ClHgW(CO)_3Cp]$ (0.07 g, 0.12 mmol) and $TlBF_4$ (0.04 g, 0.12 mmol). The resulting mixture was stirred for 1 h. Subsequent addition of hexane (5 mL) caused the precipitation of the salts, which were filtered off. The IR and ES mass spectra of the resulting solution confirmed the formation of $[Co_6C(CO)_{12}\{\mu\text{-}HgW(CO)_3Cp\}_3]^-$ (**7**). − IR (CH_2Cl_2): $\tilde{\nu}$ (ν_{CO} stretch) = 1993 cm^{-1} vs, 1962 s, 1878 m. − ESMS: *m/z* = 2303 $[M]^-$.

Electrochemical Measurements: Electrochemical measurements were carried out using an Electrokemat potentiostat.[21] Electrochemical experiments were performed at −15 °C with CH_2Cl_2 as a solvent, except in the case of compounds **4a−e**, in an airtight three-electrode cell connected to an argon line. The reference electrode consisted of a saturated calomel electrode (SCE), separated from the nonaqueous solutions by a bridge compartment. The counterelectrode was a spiral of platinum wire 8 cm in length and 0.5 cm in diameter with an apparent surface area of ca. 1 cm^2. The working electrode was an Au wire (0.125 mm diameter). For electrolysis, a gold wire (1 mm in diameter, 10 cm in length) or a platinum foil was used. $E^{o\prime}$ values were determined as the average of the cathodic and anodic peak potentials, i.e. $(E_{p,c} + E_{p,a})/2$. The supporting electrolyte $(n\text{Bu}_4\text{N})[BF_4]$ (Fluka, electrochemical grade) was used as received. Dichloromethane and acetone were freshly distilled prior to use. The solutions used for the electrochemical studies were typically 4×10^{-4} M in the cluster complex and 0.1 M in $(n\text{Bu}_4\text{N})[BF_4]$. Under the same conditions, ferrocene was found to be oxidized at $E^{o\prime}$ = 0.42 V vs. SCE and the peak potential separation ΔE was 60 mV. Cyclic voltammetry experiments were run at a scan rate of 0.1 Vs^{-1}.

X-ray Structure Determination of 4a: A prismatic crystal (0.1 × 0.1 × 0.2 mm) was selected and mounted on an Enraf−Nonius CAD4 four-circle diffractometer. Crystallographic and experimental details are summarized in Table 3. Unit cell parameters were determined from the automatic centring of 25 reflections ($12 < \Theta < 21°$) and refined by least-squares methods. Intensities were collected with graphite-monochromated Mo-K_α radiation using the ω/

Table 3. Crystal data and structure refinement for **4a**

Empirical formula	$C_{45}H_{48}Co_6Hg_2N_2O_{18}W_2$
Formula weight	2027.31
Temperature	293(2) K
Wavelength	0.71069 Å
Crystal system, space group	monoclinic, $P2_1/n$
Unit cell dimensions	a = 13.283(9) Å, α = 90°
	b = 13.544(10) Å, β = 101.75(5)°
	c = 15.409(10) Å, γ = 90°
Volume	2714(3) $Å^3$
Z	2
Calculated density	2.481 Mg/m^3
Absorption coefficient	11.704 mm^{-1}
F(000)	1892
Crystal size	0.1 × 0.1 × 0.2 mm
Θ range for data collection	2.02 to 29.96°
Index ranges	$-18 \le h \le 18$
	$0 \le k \le 19$
	$0 \le l \le 21$
Reflections collected/unique	8354/7845 [R(int) = 0.0220]
Refinement method	Full-matrix least-squares on F^2
Data/parameters	7845/331
Goodness-of-fit on F^2	0.985
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0279, $wR2$ = 0.0449
R indices (all data)	$R1$ = 0.1091, $wR2$ = 0.0732
Largest diff. peak and hole	0.616 and −0.597 e.$Å^{-3}$

2Θ scan technique. 8354 reflections were measured in the range $2.02 \leq \Theta \leq 29.96$, 7845 of which were nonequivalent by symmetry [R_{int} (on I) = 0.022]. 6478 reflections were considered as observed, applying the condition $I > 2\sigma(I)$. Three reflections were measured every two hours as an orientation and intensity control; no significant intensity decay was observed. Lorentz polarization but no absorption corrections were made.

The structure was solved by direct methods using SHELXS and refined by full-matrix least-squares methods with SHELX-97,[22] using all 7845 nonequivalent reflections. Very negative intensities were discarded. The function minimized was $\Sigma w||Fo|^2 - |Fc|^2|^2$, where $w = [\sigma^2(I) + (0.0102P)^2]^{-1}$, and $P = (|F_o|^2 + 2|F_c|^2)/3$; f, f', and f'' were taken from the International Tables of X-ray Crystallography.[23]

The cyclopentadiene unit was refined with the C−C bond length and the C−C−C bond angle constrained to 1.420 Å and 108.0°. The final R (on F) factor was 0.027, wR (on $|F|^2$) = 0.044, and goodness of fit = 0.479 for all observed reflections. The number of refined parameters was 331. Max. shift/e.s.d. = 0.00, mean shift/e.s.d. = 0.00. Max. and min. peaks in final difference synthesis: 0.616 and −0.597 eÅ^{-3}, respectively.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-145260. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Novel Electron-Rich Hydrophilic Phosphanes with Carboxylated Cyclohexyl Substituents[‡]

David J. Brauer,[a] Konstantin W. Kottsieper,[a] Thomas Nickel,[a] Othmar Stelzer,*[a] and William S. Sheldrick[b]

Dedicated to Professor Dr. M. Schmidt on the occasion of his 75th birthday

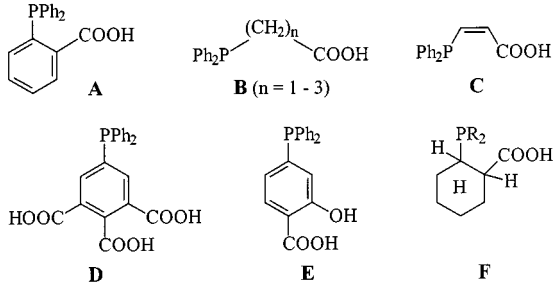
Keywords: Phosphanes / NMR spectroscopy / Carboxylic acids / Chelates / Palladium

Addition of diphenylphosphane or phenylphosphane to methyl 1-cyclohexenecarboxylate (**1**) under base catalysis, yields the novel tertiary or secondary phosphanes **2a**, **3**, or **4a** containing cyclohexyl backbones with the carboxylic groups in the 2-position. The carboxylated derivative of the borane adduct of tricyclohexylphosphane **5a** is accessible by a related reaction using $Cy_2P(BH_3)Li$ instead of Ph_2PH or $PhPH_2$. The complete analysis of the ^1H NMR spectrum of **2a** using 2D NMR spectroscopy (H,H-, C,H-COSY NMR spectra, ^{13}C-INADEQUATE) reveals the bis(equatorial) position of the Ph_2P and COOMe substituents. This is supported by the results of the X-ray structural analysis of **2b** (space group $P2_1/c$). On addition of $Cy_2P(BH_3)Li$ to **1** and subsequent hydrolysis, **5a**, the first functionalized derivative of tricyclohexylphosphane is obtained. In contrast to **2b**, the COOMe substituent in **5a** occupies the axial position, the bulky phosphanyl group being equatorial as indicated by the X-ray structural analysis (space group $P2_1$). Molybdenum(0) and palladium(II) complexes of **2a** and **2b** have been synthesized. The influence of the carboxylated cyclohexyl substituent on the electronic and steric parameters of **2a** and **2b** is discussed.

Introduction

Phosphanylcarboxylic acids play an important role as bifunctional P,O chelating ligands in important catalytic processes like the Shell higher olefin process (SHOP).[2,3] In catalytic and stoichiometric reactions, the weakly coordinated oxygen donor can be replaced reversibly, thus providing a coordination site for an incoming ligand or a substrate molecule. Some of these "hemilabile" ligands,[4] e.g. **A**−**C**, have been known for a long time[5] and efficient synthetic routes have been developed recently.[2c,6] These employ either nucleophilic phosphanylation reactions or Pd-catalyzed P−C coupling reactions between aromatic bromides or iodides and primary or secondary phosphanes.[7] Using the latter synthetic strategy, multiply functionalized aromatic phosphanylcarboxylic acids, e.g. **D** and **E**, have been obtained.

Phosphanylcarboxylic acids containing a cyclohexane backbone (**F**) have not been reported so far, however. In contrast to aromatic phosphanes, e.g. **A**−**E**, with carboxylated phenyl substituents, the coordination chemistry of ligands of type **F** should show novel aspects connected with the cyclohexane backbone. Due to the substitution pattern at the phosphorus atom, these ligands have a bulky and electron-rich P donor group capable of forming P,O chelates with transition metal ions. The mutual *cis* or *trans* position of the R_2P and carboxylic groups will be determined by the bulkiness of the substituents R, thus controlling the tendency of these ligands to form stable P,O chelates with chirogenic bridging carbon atoms C(1) and C(2).



Results

Synthesis of 1-(Diphenylphosphanyl)cyclohexane-2-carboxylic Acid and Derivatives (2a, 2b)

For the syntheses of phosphanylcarboxylic acids and their derivatives containing a 1,2-cyclohexanediyl backbone, methyl 1-cyclohexenecarboxylate (**1**) was used in all cases as a starting material. Base-catalyzed addition of

[‡] Water-Soluble Phosphanes, 16. − Part 15: Ref.[1]

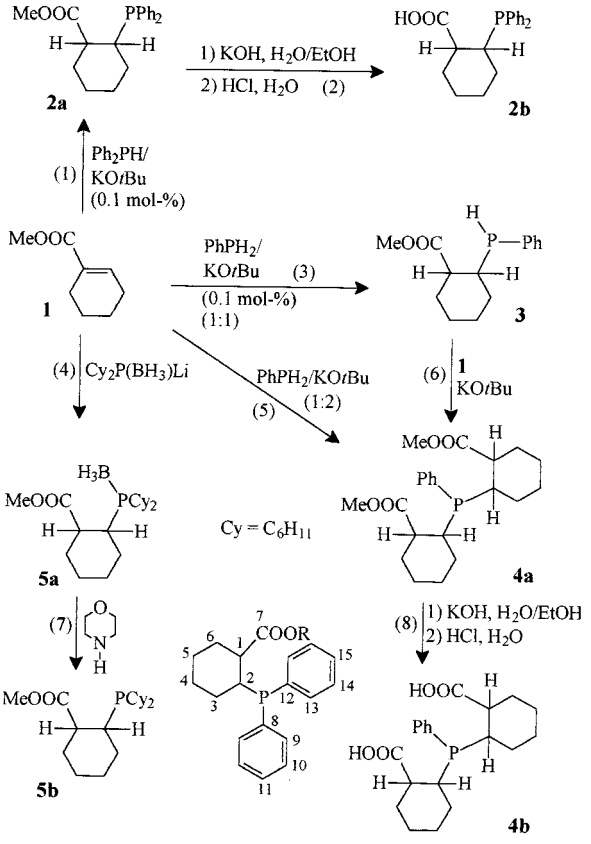
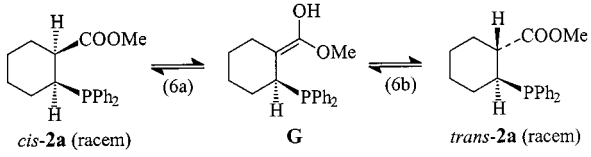
Ph_2PH to **1** using 0.1 mol-% of KO*t*Bu gave **2a** in 71% yield (Scheme 1). Derivative **2a**, with two centers of chirality (α- and β-C), may be formed as a mixture of two pairs of diastereoisomers (*cis*-**2a**, *trans*-**2a**). The regioselectivity of base-catalyzed addition of secondary phosphanes to activated olefins has been discussed elsewhere,[8] the reactions are assumed to take place by Michael addition, the *anti*-Markownikow products being formed exclusively.



Scheme 1

Immediately after completion of the reaction of Ph_2PH with **1** the $^{31}P\{^1H\}$ NMR spectrum of the reaction mixture shows two resonances at $\delta_P = -1.86$ and -9.47 in a 1:2 intensity ratio. On extending the time of reaction the intensity of the signal at $\delta_P = -1.86$ increases at the expense of that at $\delta_P = -9.47$, which after 24 h had disappeared almost completely. The product **2a** obtained after workup of the reaction mixture shows only one signal in the $^{31}P\{^1H\}$ NMR spectrum at $\delta_P = -1.86$. These observations may be explained by an epimerization process by formation of an enol-type intermediate **G**[9] (Scheme 2).



Scheme 2

Initially, the *cis* isomer of **2a** (racemate) is formed preferably under kinetic control of the addition reaction, which is rearranged then to the thermodynamically more stable *trans*-**2a** (racemate).

The solution structure of *trans*-**2a** was obtained by analysis of the 400 MHz ^1H and $^1H\{^{31}P\}$ NMR spectrum (Figure 1a, 1b) in the range between $\delta_H = 0.8-2.95$. The ten nonequivalent protons H(1a)−H(6a) (A, B, C, D, E, F, G, H, M, and N) of the 1,2-disubstituted cyclohexane backbone and the ^{31}P nucleus, give rise to a complicated pattern in the ^1H and $^1H\{^{31}P\}$ NMR spectra by H,H and P,H coupling (Figure 1c). The multiplets in the ^1H NMR spectrum of **2a** at $\delta_H = 2.47$ (N) and 2.81 (M) with the appearance of a doublet of doublets of triplets or a doublet of triplets, respectively, may be assigned to the hydrogen atoms at C(1) ($\delta_C = 46.42$) and C(2) ($\delta_C = 36.18$) by analysis of the C,H-COSY NMR spectrum.[10] In a first approximation they may be considered as the MN part of an MNADEFX spin system [M, N = H(1a), H(2a); A = H(3a); D = H(6a); E = H(3e); F = H(6e); X = ^{31}P] with the P−H coupling being very small (0.64 Hz) for H(2a). Comparison of the ^1H NMR and $^1H\{^{31}P\}$ NMR spectrum reveals $^1H-^{31}P$ coupling fine structure of the resonances at $\delta_H = 1.01$, 1.45, 1.82, 1.92, and 2.47. As indicated by the H,H-COSY-45 NMR spectrum the protons with $\delta_H = 2.81$ (M) and 2.47 (N) are coupled to those with $\delta_H = 2.47$, 1.82, and 1.01 or $\delta_H = 2.81$, 1.92, and 1.74, respectively. The carbon atoms connected with the hydrogen atoms ($\delta_H = 1.82$ and 1.01 or $\delta_H = 1.92$ and 1.74) may be assigned to C(3) and C(6). A value of 9.6 Hz was determined for the coupling constant ^3J(HH) between the protons N and M. The resonances of H(N) and H(M) show a large (ca. 10 Hz) and a small (ca. 3.5−4.0 Hz) additional splitting due to vicinal H,H coupling with the hydrogen atoms of the respective neighbouring CH_2 groups. This pattern of ^3J(HH) is consistent with a bis(axial) position of the hydrogen atoms at C(1) and C(2) and a *trans* arrangement of the COOMe and PPh_2 substituents.

In derivatives of cyclohexane, vicinal H,H coupling constants are typically in the range between 7 and 9 Hz for hydrogen atoms in bis(axial) and 2−5 Hz in axial-equatorial or bis(equatorial) positions.[11] Due to overlapping of correlation peaks in the δ_H range between 0.8 and 2.0, a complete analysis of the H,H-COSY-45 NMR spectrum was not possible. In order to obtain an assignment of the $^{13}C\{^1H\}$ NMR signals for all carbon atoms of the cyclohexane backbone of **2a** an INADEQUATE spectrum[12] in the δ_C range between 12 and 50 was obtained. Making use of these results, the H,H-COSY-45 spectrum of **2a** could further be analyzed, thus allowing us to assign the hydrogen atoms in axial and equatorial positions of the cyclohexane backbone. Employing typical values for the geminal and vicinal H,H coupling constants,[11] the $^1H\{^{31}P\}$ NMR spectrum of **2a** was simulated using the program g NMR.[13] The result is shown in Figure 1b, the values obtained for the various coupling constants ^nJ(HH) ($n = 2-4$) and ^nJ(PH) ($n = 2-5$) are collected in Table 1. In agreement with results reported in the literature for 1,2-substituted derivatives of cyclohexane,[14] geminal H,H coupling constants are in a very narrow range between −13.81 and

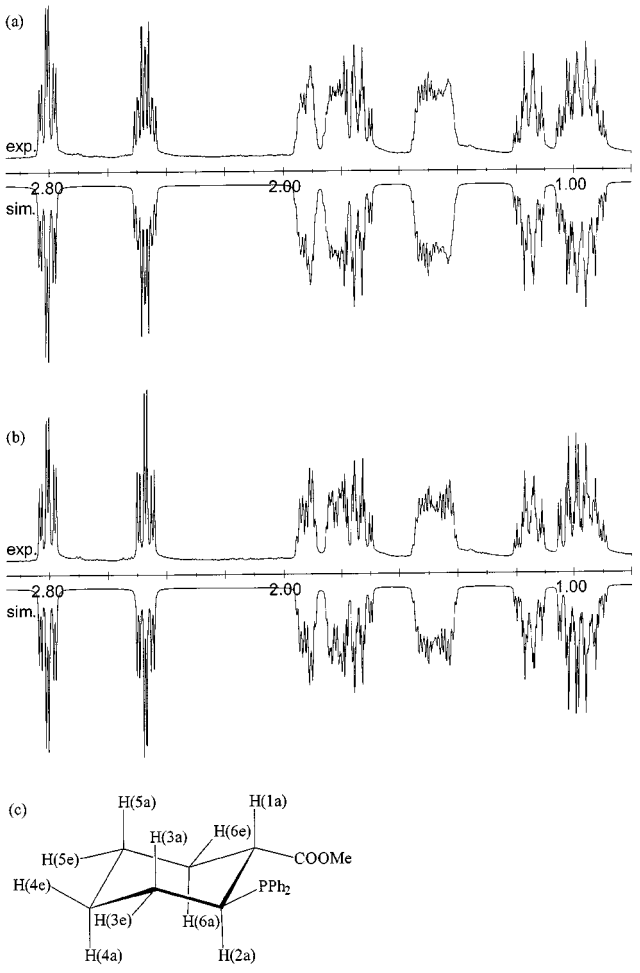


Figure 1. (a) ^{1}H NMR spectrum of **2a** (experimental, simulated); (b) ^{1}H{^{31}P} NMR spectrum of **2a** (experimental, simulated); (c) numbering scheme for the carbon and hydrogen atoms of the cyclohexyl backbones

−13.27 Hz. For axial protons ^3J(HH) is about 10 Hz, with significantly smaller values (ca. 4 or 5 Hz) being observed for protons in axial-equatorial or equatorial-equatorial positions.

The configurational analysis of **2a** was completed by the iterative simulation of the ^{1}H NMR spectrum (Figure 1a). To the best of our knowledge, this is the first complete analysis of a disubstituted derivative of cyclohexane with phosphorus as substituent. Consistent with the results obtained above, the vicinal coupling constants ^3J(PH) (4−7 Hz) obtained are typical for an H−C−C−P arrangement with dihedral angles of about 60°.[15a][15b] The small geminal coupling ^2J(PH) (0.64 Hz) (Table 1) indicates that in the most preferred conformation with respect to the P−C axis the lone pair at the phosphorus atom is in *trans* position to the hydrogen atom.[15c,15d]

Due to the asymmetric substitution at the α- and β-carbon atoms the phenyl groups of the Ph_2P substituent are chemically nonequivalent, as indicated by the doubling of the corresponding resonances in the ^{13}C{^{1}H} NMR spectrum. The assignment of the signals is based on comparison with pertinent data,[16] and ^{13}C{^{1}H}-DEPT NMR spectra.

Ester hydrolysis of **2a** with KOH in an ethanol/water mixture gave the potassium salt of the carboxylic acid **2b**. After concentration of the reaction mixture to dryness, the free acid was precipitated by acidification of the aqueous solution of the residue. The ^{31}P{^{1}H} NMR spectrum of **2b** shows a singlet at $\delta_P = -3.36$. A complete assignment of the 15 signals in the ^{13}C{^{1}H} NMR spectrum of **2b** could be achieved using the ^{13}C{^{1}H}-DEPT NMR spectrum, and by comparison with the results obtained for **2a** (see above). Making use of a C,H-COSY NMR and H,H-COSY-45 NMR spectrum all resonances in the ^{1}H NMR and the ^{1}H{^{31}P} NMR spectrum of **2b** could be assigned to the hydrogen atoms at C(1)−C(6), and their position in axial or equatorial sites of the cyclohexane ring system established. Although the lines are somewhat broadened compared with those of **2a**, the multiplet fine structure of the resonances corresponding to the protons on C(1) and C(2) ($\delta_H = 2.47$ and 2.86) are well resolved. By analysis of this part of the ^{1}H NMR and the ^{1}H{^{31}P} NMR spectrum, the vicinal H,H and H,P coupling constants ^3J(HH) and ^3J(PH) could be obtained. The pattern of the values of these coupling constants compares very well with that in **2a**, indicating a similar stereochemistry in both compounds.

Molecular Structure of 1-(Diphenylphosphanyl)cyclohexane-2-carboxylic Acid (2b)

In order to confirm the stereochemistry of **2b** as derived from the analysis of the NMR spectra, a crystal structure

Table 1. ^{1}H NMR spectroscopic data of **2a**; for the numbering of the hydrogen atoms see Figure 1c

δ_H values [ppm]			
H(1a)	2.47	H(2a)	2.81

analysis was performed. Recrystallization of **2b** from methanol afforded crystals suitable for X-ray structural analysis. Carboxylic acid **2b** crystallizes in the space group $P2_1/c$ with four molecules in the asymmetric unit showing an (*RS*)

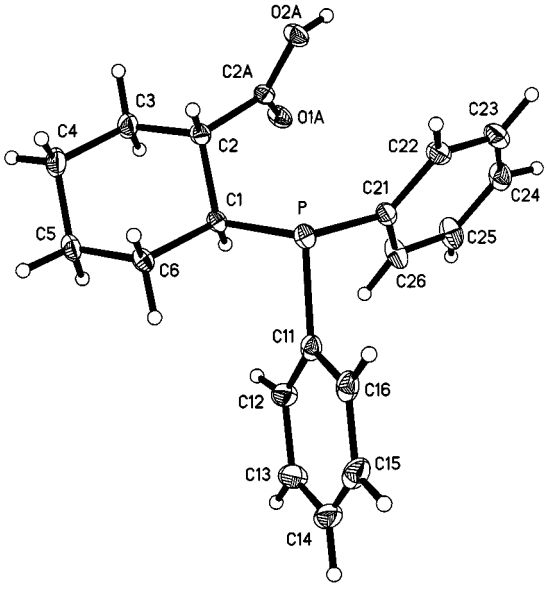

Figure 2. Molecular structure of **2b**; selected bond lengths [Å] and angles [°]: P−C(1) 1.859(3), P−C(11) 1.833(3), P−C(21) 1.832(3), C(1)−C(2) 1.540(3), C(2)−C(3) 1.538(4), C(1)−C(6) 1.533(3), C(5)−C(6) 1.518(4), C(3)−C(4) 1.510(4), C(4)−C(5) 1.504(4), C(2)−C(2A) 1.504(3), C(2A)−O(2A) 1.280(3), C(2A)−O(1A) 1.235(3); C(1)−P−C(11) 101.59(12), C(1)−P−C(21) 103.30(11), C(11)−P−C(21) 99.94(12), P−C(1)−C(2) 111.64(18), C(1)−C(2)−C(2A) 113.45(21), H(1)−C(1)−C(2)−H(2) −178.74, P−C(1)−C(2)−C(2A) 63.96(26)

and (*SR*) configuration. The structure (Figure 2) reveals the bis(equatorial) arrangement of the Ph_2P and COOH substituents with values for the H(1)−C(1)−C(2)−H(2) or P−C(1)−C(2)−C(2A) torsion angles of −178.7 or 63.96(26)°, respectively, in agreement with the solution structure of **2b** obtained by configurational analysis by means of NMR spectroscopy (see above). The carbon−phosphorus distances C(11)−P [1.833(3) Å], C(21)−P [1.832(3) Å], and C(1)−P [1.859(3) Å] (see caption to Figure 2) are in the typical range.[17] Due to the steric effect of the COOH group, the bond angle C(21)−P−C(1) [103.30(11)°] is somewhat enlarged compared with C(11)−P−C(1) [101.59(12)°] and C(21)−P−C(11) [99.94(12)°]. As a result the bond angle C(2A)−C(2)−C(3) [107.56(22)°] is compressed as compared with C(1)−C(2)−C(2A) [113.45(21)°].

Addition of $PhPH_2$ to Methyl 1-Cyclohexenecarboxylate (1)

The base-catalyzed 1:1 addition of $PhPH_2$ to **1** using 0.1 mol-% of KO*t*Bu proceeds stepwise with the secondary phosphane **3** being formed initially. Immediately after the completion of the addition reaction, four signals are observed in the $^{31}P\{^1H\}$ NMR spectrum of the reaction mixture δ_P = −30.02, −36.89, −37.95, and −49.67, of which after 24 h only two signals remain (δ_P = −30.02 and −37.95). As a result of the asymmetric substitution at the phosphorus atom, **3** may exist as four pairs of diastereoisomers [*SSS*/*RRR* (*cis*), *SSR*/*RRS* (*cis*), *RSS*/*SRR* (*trans*), *RSR*/*SRS* (*trans*), the sequence of the stereogenic centers being C,C,P], which have been observed initially in the $^{31}P\{^1H\}$ NMR spectrum. Epimerization processes at the β-carbon and phosphorus atoms yield the thermodynamically most stable two *trans* diastereoisomers (see above). The $^{13}C\{^1H\}$ NMR spectrum of **3** shows 24 signals, 16 of them showing doublet fine structure due to C−P coupling. Assignment of all resonances was achieved by comparison with the corresponding data of **2a** and with the aid of a $^{13}C\{^1H\}$-DEPT NMR spectrum. The resonances at δ_C = 175.1 and 175.2 (CO) or 51.07 and 51.09 (OMe), respectively, may be assigned to the COOMe group. The complex ^1H NMR spectrum of the cyclohexane part of **3** could not be analyzed completely as described for **2a** (see above). The signals in the δ_H range 2.0−2.4 correspond to the hydrogen atoms on C(1) and C(2). For the two diastereoisomers of **3** two doublets at δ_H = 3.98 and 4.18 with a large ^1J(PH) splitting (208 and 210 Hz) are observed. Additional fine structure is due to ^3J(HH) coupling between the hydrogen atoms on P and C(2) (ca. 5.6 and 3.6 Hz, respectively).

If $PhPH_2$ is added to **1** in a 1:2 molar ratio using 0.1 mol-% of KO*t*Bu as catalyst, the tertiary phosphane **4a** is formed in high yield. The four diastereoisomers (*cis* and *trans* isomers) of the secondary phosphane **3** are formed initially. During this time, rearrangement of the *cis*/*trans* isomeric mixture of the intermediate **3** occurred to yield the *trans* isomer only. For a completion of the addition reaction with formation of the tertiary phosphane **4a** the reaction mixture had to be heated under reflux for 8 h.

The tertiary phosphane **4a** has a maximum of five stereogenic centers (four carbon atoms and one phosphorus atom), thus forming six pairs of enantiomers and four *meso* compounds. In all *meso* isomers the phosphorus atom (P) is pseudo-asymmetric,[18] while the molecule as a whole is achiral. The phosphorus atom in two of the racemic pairs [e.g. $S_CS_C(P)S_CS_C$] is achiral. In agreement with these considerations the $^{31}P\{^1H\}$ NMR spectrum of **4a** shows ten signals in a δ_P range typical for tertiary phosphanes,[19] five of them [δ_P = −2.23 (28%), −2.96 (11%), −5.17 (46%), −7.26 (8%), and −10.32 (5%)] having intensities higher than ca. 5%. Due to overlapping of the $^{13}C\{^1H\}$ and ^1H NMR resonances of the numerous diastereoisomers, signal assignments for **4a** were only possible for some groups.

Addition of Cy_2PH to Methyl 1-Cyclohexenecarboxylate (1)

Addition of Cy_2PH to methyl 1-cyclohexenecarboxylate (**1**) under the conditions employed for the synthesis of **2a**, **3**, and **4a** did not succeed due to its lower acidity compared with Ph_2PH and $PhPH_2$.[20] If the lithium phosphanide Cy_2PLi,[21] obtained by metallation of Cy_2PH with methyllithium, was employed in this addition reaction, a mixture of compounds was obtained. The BH_3 adduct of the tertiary phosphane **5a** was formed, however, in high yields if the borane complex $Cy_2P(BH_3)Li$ was used instead of the free phosphide. Phosphane−borane complexes[22] have recently

been used as valuable intermediates in the syntheses of phosphane derivatives not accessible by other methods.[23]

Due to the coupling of the phosphorus with the boron nucleus, the $^{31}P\{^1H\}$ NMR spectrum of **5a** shows a broadened signal at $\delta_P = 32.73$. In the ^{11}B NMR spectrum a doublet [^1J(BP) = 47 Hz] with additional fine structure is observed. In the $^{13}C\{^1H\}$ NMR spectrum of **5a**, 16 of the 20 resonances show $^{31}P-^{13}C$ coupling fine structure. The signal at $\delta_C = 41.0$ corresponds to C(1), while the resonances at 34.9 [^1J(PC) = 28 Hz], 32.09 [^1J(PC) = 9 Hz], and 31.6 [^1J(PC) = 11 Hz] may be assigned to the *ipso*-carbon atoms C(2), C(8), and C(9) using $^{13}C\{^1H\}$-DEPT NMR spectra. The assignments for C(2) and C(6) were proven to be correct by the combination of the results of the C,H-COSY- and H,H-COSY-45 NMR spectra. The ^1H NMR spectrum of **5a** could not be analyzed due to extensive signal overlapping.

Deprotection of **5a** with a large excess of morpholine gave the borane-free tertiary phosphane **5b** in high yield as indicated by $^{31}P\{^1H\}$ NMR spectrum ($\delta_P = 8.52$). This deprotection procedure has been used extensively by Imamoto and others.[24] After evaporation of morpholine and the morpholine−borane complex in vacuo, the free phosphane **5b** was obtained as a colorless oil. The $^{31}P\{^1H\}$ NMR spectrum of **5b** shows a singlet at $\delta_P = 8.52$. In the 100.6 MHz $^{13}C\{^1H\}$ NMR spectra of **5b** eleven of the 20 resonances show a $^{31}P-^{13}C$ coupling fine structure. Due to signal overlapping four resonances in the range of $\delta_C = 28.03-28.19$ could not be assigned. The signal at $\delta_C = 44.02$ [^2J(PC) = 20.3 Hz] corresponds to C(1), while the resonances at 33.35 [^1J(PC) = 22.4 Hz], 33.10 [^1J(PC) = 19.3 Hz], and 32.11 [^1J(PC) = 20.3 Hz] may be assigned to the *ipso*-carbon atoms C(2), C(8), and C(9) as indicated by the $^{13}C\{^1H\}$-DEPT NMR spectrum.

Molecular Structure of 5a

In order to elucidate the structure of **5a**, an X-ray crystallographic study was undertaken. The crystals used in the investigation were grown from a solution in methanol. A view of the molecular structure is given in Figure 3. It shows that the phosphorus atom occupies an equatorial position of each cyclohexyl ring while the COOMe substituent is in an axial position. Since the latter is directed towards the perimeter of the molecule, steric interactions involving this substituent are minimal. In fact, the smallest C−P−B bond angle [108(5)°] involves the cyclohexyl group bearing the ester, the others being on the average 4(1)° larger. The P−B and average P−C bond lengths of 1.920(6) and 1.841(9) Å, respectively, are normal.

The atoms P, B, and C(15) define a pseudo-mirror plane for the molecule which is violated mainly by the methoxycarbonyl group. Since this pseudo-asymmetry element lies perpendicular to the monoclinic axis of the noncentrosymmetric space group $P2_1$, a considerable proportion of the structure is distributed centrosymmetrically in the crystal. This coincidence, along with the large atomic displacements of the cyclohexyl groups are probably responsible for the large variation of the C−C bond lengths, 1.32(1)−1.61(1) Å, which should not be taken seriously.

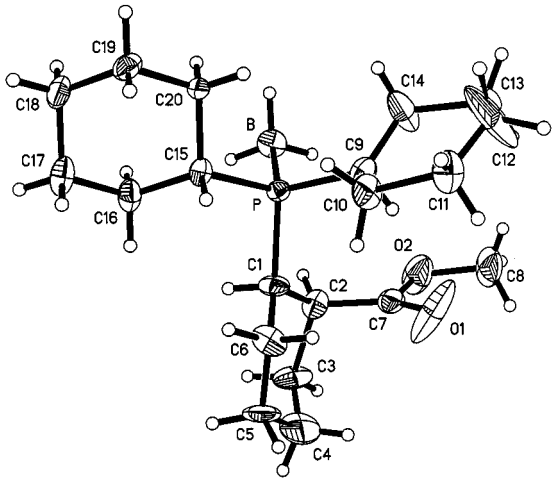

Figure 3. Molecular structure of **5a**; selected bond lengths [Å] and angles [°]: P−C(1) 1.835(6), P−C(9) 1.851(8), P−C(15) 1.837(4), P−B 1.920(6), C(2)−C(7) 1.505(11), C(7)−O(1) 1.267(11), C(7)−O(2) 1.378(9); C(1)−P−C(9) 107.9(3), C(1)−P−C(15) 104.9(4), C(9)−P−C(15) 107.8(3), C(1)−P−B 108.9(5), C(9)−P−B 114.4(5), C(15)−P−B 112.4(3), H(1)−C(1)−C(2)−H(2) 55.3(2)

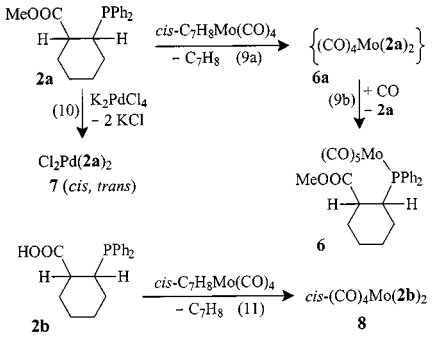
Transition Metal Complexes of 2a and 2b

In order to obtain some information about the influence of the bulky cyclohexyl substituent on the ligand properties of the phosphanes **2a** and **2b**, molybdenum(0) and palladium(II) complexes were synthesized. Phosphane **2b** reacted with *cis*-$C_7H_8Mo(CO)_4$ in a straightforward manner to give the disubstituted complex **8** (Scheme 3), which is insoluble in most solvents. The corresponding reaction of **2a** proceeded very slowly. Initially, the $^{31}P\{^1H\}$ NMR spectrum of the reaction mixture showed in addition to the signal of **2a** two resonances at $\delta_P = 46.81, 46.24$, which may be assigned to the disubstituted complex **6a** formed as a mixture of diastereoisomers. If the reaction was run for a further couple of hours in order to complete the consumption of **2a** a third resonance at $\delta_P = 47.05$ appeared in the $^{31}P\{^1H\}$ NMR spectrum. This signal increased at the expense of those at $\delta_P = 46.81$ and 46.24 that disappear completely after ca 90 h. The resonance at $\delta_P = 47.05$ could be assigned to the monosubstituted complex **6** being formed by decomposition of **6a** with liberation of **2a**. Compound **6** was isolated from the reaction mixture by thin layer chromatography. Obviously, **2a** is too bulky to form a stable *cis*-disubstituted $Mo(CO)_4$ complex. Decomposition of **8** is not observed since it is precipitated from the reaction mixture during its formation.

The electronic parameter χ_i^{Ni} derived from the $\nu(CO)(A_1)$ stretching frequencies of the complexes $(CO)_3Ni(PR^1R^2R^3)$ may be taken as a measure for the electronic donor−acceptor properties of the phosphane ligands $PR^1R^2R^3$ as proposed by Tolman.[25a] As shown by us and others,[25b,25c] the analogous values χ_i^{Mo} obtained from the *cis*-$(CO)_4Mo(PR^1R^2R^3)_2$ complexes may be used instead of those obtained from the nickel complexes (χ_i^{Ni}). By compar-



Scheme 3

ison of the χ_i^{Mo} values obtained for **2b** (2020 cm^{-1}) with those of Ph_2PH (2028 cm^{-1}), Ph_3P (2023 cm^{-1}), Me_3P (2016 cm^{-1}), and Cy_3P (2010 cm^{-1}), phosphane **2b** may be placed in between Ph_3P and Me_3P.

On reaction of **2a** with K_2PdCl_4 the palladium(II) complexes of type **7** are formed. The ^{31}P NMR spectrum of the reaction mixture shows two intense signals at $\delta_P = 29.02$ and 28.84, and two weak resonances at $\delta_P = 28.05$ and 27.85. The low-field signals at $\delta_P \approx 29$ may be assigned to the *meso* (*SR*, *RS*) and *rac* forms (*SR*, *SR*) of the *trans* isomer, while the resonances at $\delta_P \approx 28$ correspond to the *cis* isomer. Since the difference in δ_P of the *cis* and *trans* isomers of **7** is much smaller than the typical range (10−15)[26] observed for $Cl_2Pd(PR_3)_2$ complexes it is of no diagnostic value. The assignment of the intense signals at $\delta_P = 29.02$ and 28.84 to the *trans* structure of **7** is based upon the triplet fine structure of some of the resonances in the $^{13}C\{^1H\}$ NMR spectrum of **7** (see Exp. Sect.). The carbon atoms in **7** represent the X part of an ABX spin system (A, B = ^{31}P, X = ^{13}C),[27a] which for a large value of $^2J(PP)$ as in *trans*-$Cl_2Pd(PR_3)_2$ complexes appears as a triplet.[27b][27c]

It has been shown that the ^{31}P NMR chemical shift of *trans*-$(PR_3)_2PdCl_2$ complexes correlates well with the steric parameters θ_{Tol} [28] or θ[29] of the ligands PR_3, derived from X-ray data. For the ligand **2a** a value of ca. 150° may be derived for θ_{Tol}.

Experimental Section

General: For experimental details, see Part 15 of this series.[1] − Phenylphosphane, diphenylphosphane,[30a,30b] dicyclohexylphosphane,[30c] and $C_7H_8Mo(CO)_4$ [31] were synthesized by known methods. Methyl 1-cyclohexenecarboxylate (**1**) was purchased from Aldrich GmbH. ^1H-, ^{31}P-, ^{13}C-, and ^{11}B NMR spectra were recorded with a Bruker AC 400 or AM 250 and a JEOL FX90 Q Fourier transform spectrometer. Mass spectra were obtained with a Varian MAT 311 A.

Synthesis of 2a: Diphenylphosphane (5.21 g, 28 mmol) and KO*t*Bu (0.34 g, 3 mmol) were dissolved in 50 mL of toluene. To this solution methyl 1-cyclohexenecarboxylate (4.21 g, 30 mmol) was added. After stirring for 12 h, 10 mL of water was added and the reaction mixture was neutralized with 6 mL of 0.5 M hydrochloric acid. The organic phase was separated and dried with Na_2SO_4. The product (8.44 g, 92%) obtained after evaporation of the solvent was recrystallized from methanol. Yield 6.49 g (71%). − **2a:** $C_{20}H_{23}O_2P$ (326.4): calcd. C 73.60, H 7.10; found C 73.69, H 6.95. − MS; *m/z:* 326 [M^+]. − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 46.42 (C1, *J* = 19.3 Hz), 36.18 (C2, *J* = 16.3 Hz), 27.28 (C3, *J* = 4.1 Hz), 25.59 (C4, *J* = 4.1 Hz), 24.94 (C5), 30.05 (C6, *J* = 9.2 Hz), 175.13 (C7, *J* = 3.0 Hz), 137.28, 136.42 (C8, C12, *J* = 14.2, 17.3 Hz), 135.21, 133.03 (C9, C13, *J* = 21.0, 17.2 Hz), 128.60, 128.46 (C10, C14, *J* = 5.7, 7.6 Hz), 129.21, 128.19 (C11, C15), 51.04 (Me, *J* = 2.0 Hz). − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −1.86.

Synthesis of 3: The synthesis was performed as reported for **2a** using 3.08 g (28 mmol) of $PhPH_2$, 4.21 g (30 mmol) of methyl 1-cyclohexenecarboxylate, and 0.34 g (3 mmol) of KO*t*Bu as the catalyst. The product obtained was purified by distillation in vacuo (113−120 °C, < 0.01 mbar). Yield 4.64 g (66%). − **3:** $C_{14}H_{19}O_2P$ (250.3): calcd. C 67.19, H 7.65; found C 67.05, H 7.51. − MS; *m/z*: 250 [M^+]. − ^1H NMR (C_6D_6): δ = 2.32, 2.37 (H1, m), 2.12, 2.28 (H2, m), 0.78−1.90 (H3, m, H6, m), 1.03, 1.43 (H4, m), 0.94, 1.46 (H5, m), 3.39, 3.40 (Me, s), 7.00−7.60 (arom. H), 3.98, 4.18 [PH, *J*(PH) = 208, *J*(HH) = 5.6, *J*(PH) = 210, *J*(HH) = 3.6 Hz]. − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 48.4, 47.6 (C1, *J* = 12.2, 12.2 Hz), 36.1, 35.9 (C2, *J* = 14.2, 11.1 Hz), 31.5, 30.8, 30.6, 30.4 (C3, C6, *J* = 2.0, 8.1, 11.2, 8.1 Hz), 26.4, 25.9 (C4, *J* = 6.1, 7.1 Hz), 24.9, 24.8 (C5), 175.2, 175.1 (C7), 134.1, 133.6 (C8, *J* = 13.2, 13.2 Hz), 135.8, 135.0 (C9, *J* = 16.3, 15.3 Hz), 128.53, 128.51 (C10, *J* = 6.1, 5.6 Hz), 128.7, 128.4 (C11), 51.09, 51.07 (Me). − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −30.02, −37.95 (*J* = 208, 210 Hz).

Synthesis of 4a: The synthesis of **4a** was performed as reported for **3** using 2.20 g (20 mmol) of $PhPH_2$, 7.01 g (50 mmol) of methyl 1-cyclohexenecarboxylate, and 0.22 g (2 mmol) of KO*t*Bu. The oily residue obtained after evaporation of the solvent could not, however, be purified by recrystallization from different solvents. Yield 6.95 g (89%). − **4a:** $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −0.6, −2.23, −2.96, −3.0, −3.12, −4.38, −5.17, −7.26, −7.31, −10.32.

Hydrolysis of 2a and 4a: Compounds **2a** (1.96 g, 6 mmol) or **4a** (6.95 g, 18 mmol) were added to a solution of 0.69 g (11 mmol) or 4.91 g (74 mmol) of KOH (85%) in a water/ethanol mixture (15:50 or 10:30 mL) with gentle warming. The reaction mixtures were heated under reflux for 4 h. Thereafter the solvents were distilled off in vacuo, and the residues were dissolved in 40 mL of water. Insoluble material was removed by filtration and the clear filtrate was acidified with hydrochloric acid (0.5 or 3 M). Colorless precipitates were formed, which were collected by filtration, washed with two aliquots of water (5 mL) and dried in vacuo. Yields 1.51 g (81%) for **2b**, 5.62 g (87%) for **4b**. − **2b**: $C_{19}H_{21}O_2P$ (312.3): calcd. C 73.06, H 6.78; found C 73.18, H 6.97. − ^1H NMR (C_6D_6): δ = 2.47 (H1a, m), 2.86 (H2a, m), 1.02 (H3a, m) 1.80 (H3e, m), 1.14 (H4a, m), 1.55 (H4e, m), 0.98 (H5a, m), 1.44 (H5e, m), 1.72 (H6a, m), 1.95 (H6e, m), 7.00−7.65 (arom. H), 11.9 (COOH, br.). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 45.7 (C1, *J* = 19.3 Hz), 35.5 (C2, *J* = 15.3 Hz), 26.7 (C3, *J* = 5.1 Hz), 25.0 (C4, *J* = 4.1 Hz), 24.6 (C5), 29.2 (C6, *J* = 9.2 Hz), 182.4 (C7, *J* = 5.1 Hz), 137.1, 136.3 (C8, C12, *J* = 14.2, 17.3 Hz), 135.2, 133.1 (C9, C13, *J* = 21.4, 18.3 Hz), 128.7, 128.5 (C10, C14, *J* = 6.1, 7.1 Hz), 129.2, 128.4 (C11, C15). − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −3.36. − **4b:** $C_{20}H_{27}O_4P{\cdot}0.5\ H_2O$ (371.4): calcd. C 64.68, H 7.60; found C 64.05, H 7.19. − MS; *m/z*: 362 [M^+]. − ^1H NMR (C_6D_6): δ = 0.80−3.00 (H1−H6, m), 7.00−7.90 (arom. H), 12.0 (COOH, br.). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 45.8−48.6 (C1), 32.2−33.7 (C2), 24.6−30.8 (C3−C6), 133.9, 134.3 (C8, *J* = 21, 16 Hz), 134.8, 135.3, 136.0, 136.4 (C9, *J* = 20, 15, 16, 21 Hz), 127−131 (C10, C11), 181−182 (COOH). − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 3.10, 2.02, −1.25, −4.45, −6.26.

Synthesis of 5a: To a solution of $Cy_2PH{\cdot}BH_3$ (5.74 g, 27 mmol) in 90 mL of THF was added *n*BuLi (15% in *n*-hexane) (11.79 g, 28 mmol) at −78 °C within a period of 30 min. The reaction mixture was stirred for 10 min at −76 °C and then allowed to warm up to ambient temperature. Thereafter the solution was again cooled down to −45 °C and 3.68 g (26 mmol) of methyl 1-cyclohexenecarboxylate was added. The reaction mixture was warmed to ambient temperature and stirred for 1 h. Water (35 mL) was added, and the reaction mixture was neutralized with 1 M hydrochloric acid. The organic phase was separated and dried with Na_2SO_4. The colorless residue left after removal of the solvent in vacuo was recrystallized from methanol. Yield 6.09 g (66%). − **5a:** $C_{20}H_{38}BO_2P$ (352.3): calcd. C 68.19, H 10.87; found C 67.56, H 10.87. − MS; *m*/*z*: 351 [M^+ − H]. − ^{1}H NMR (C_6D_6): δ = 3.30 (H1, m), 1.86 (H2, m), 1.33, 1.94 (H6, m), 2.19 (H8, m), 1.84 (H9, m), 3.41 (Me, s), 0.6−2.8 (overlapping multiplets). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 41.03 (C1), 34.91 (C2, *J* = 27.9 Hz), 32.02 (C6, *J* = 9.4 Hz), 175.35 (C7, *J* = 1.3 Hz), 32.09 (C8, *J* = 9.0 Hz), 31.62 (C9, *J* = 11.2 Hz), 51.94 (Me), 29.94, 29.17 (*J* = 3.9 Hz), 28.80, 28.62 (*J* = 12.2 Hz), 28.23 (*J* = 9.2 Hz), 28.19 (*J* = 8.0 Hz), 27.86 (*J* = 9.8 Hz), 27.77 (*J* = 8.6 Hz), 27.70 (*J* = 4.4 Hz), 27.15 (*J* = 1.3 Hz), 26.98 (*J* = 1.2 Hz), 24.02 (*J* = 4.0 Hz), 22.50 (*J* = 1.1 Hz). − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 32.73 [$^1J(^{11}B-^{31}P)$ = 47 Hz].

Deprotection of 5a: Compound **5a** (0.27 g, 0.8 mmol) was dissolved in 15 mL of morpholine. The solution was stirred for 2 h at 90 °C. Thereafter the solvent and the morpholine−borane complex were removed in vacuo (100 °C, < 0.01 mbar). The crude **5b** was obtained as a colorless oil. Purification was achieved by recrystallization from methanol. Yield 0.25 g (98%). − **5b:** $C_{20}H_{35}O_2P$ (338.5): calcd. C 70.97, H 10.42; found C 70.14, H 10.35. − MS; *m*/*z*: 338 [M^+ − H]. − ^{1}H NMR (C_6D_6): δ = 2.85 (m, H1), 3.48 (s, Me), 1.00−2.35 (aliph. H). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 44.02 (C1, *J* = 20.3 Hz), 33.35 (C2, *J* = 22.4 Hz), 33.10 (C8, *J* = 10.3 Hz), 32.11 (C9, *J* = 20.3 Hz), 50.60 (Me), 174.52 (C7), 32.51 (*J* = 17.3 Hz), 31.75 (*J* = 14.2 Hz), 31.02 (*J* = 9.2 Hz), 30.23 (*J* = 10.2 Hz), 30.22 (*J* = 8.1 Hz), 28.19−28.03 (4 C atoms), 27.43 (*J* = 5.1 Hz), 26.97−26.94 (2 C atoms), 25.16 (*J* = 6.1 Hz), 21.95. − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 8.52.

Synthesis of 6: $C_7H_8Mo(CO)_4$ (0.15 g, 0.5 mmol) and **2a** (0.33 g, 1 mmol) were dissolved in 10 mL of dichloromethane. The reaction mixture was stirred at ambient temperature for 96 h. Thereafter the solvent was removed in vacuo (20 °C, 0.01 mbar) and the remaining solid was purified by thin layer chromatography (SiO_2 PSC plates, Merck). The yellow zone containing **6** was extracted with CH_2Cl_2 and the solvent removed in vacuo. Yield: 0.11 g (38%). − **6:** $C_{25}H_{23}MoO_7P$ (562.4): calcd. C 53.34, H 4.12; found C 53.25, H 4.40. − MS; *m*/*z*: 533 [M^+ (^{95}Mo) − CO − 4 H]. − ^{1}H NMR (C_6D_6): δ = 2.80 (m, H1), 3.08 (m, H2), 0.8−1.8, 2.2 (m, H3−H6), 2.88 (s, Me), 6.95−7.93 (arom. H). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 45.2 (C1), 38.5 (C2, *J* = 14 Hz), 26.0 (C3, *J* = 12 Hz), 28.6 (C4, *J* = 8 Hz), 24.7 (C5), 31.0 (C6, *J* = 6 Hz), 174.8 (C7, *J* = 3 Hz), 137.3, 133.3 (C8, C12, *J* = 32, 30 Hz), 135.4, 132.8 (C9, C13, *J* = 12, 11 Hz), 129.3, 129.1 (C10, C14, *J* = 8, 10 Hz), 131.2, 130.3 (C11, C15, *J* = 2, 2 Hz), 51.5 (Me), 207.2 (CO_{eq}, *J* = 9 Hz), 211.1 (CO_{ax}, *J* = 23 Hz). − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 47.05. − IR (KBr disc, cm^{-1}): $\tilde{\nu}$ = 2072, 1961, 1930, 1915.

Synthesis of 7: Dichloromethane (30 mL) and methanol (10 mL) were added to a mixture of **2a** (0.65 g, 2 mmol) and potassium tetrachloropalladate (K_2PdCl_4) (0.33 g, 1 mmol). The mixture was stirred at ambient temperature for 5 d and the solid material was removed by filtration through a suction funnel. After removal of all volatiles from the filtrate in vacuo (20 °C, < 0.01 mbar) **7** was obtained as a yellow solid. Yield 0.77 g (93%). − **7:** $C_{40}H_{36}Cl_2O_4P_2Pd$ (830.1): calcd. C 57.88, H 5.59; found C 57.52, H 5.6. − ^{1}H NMR (CD_2Cl_2): δ = 2.40 (m, H1), 3.45 (m, H2), 0.97, 1.62 (m, H5), 3.03, 3.08 (s, Me), 7.96 (m, H9), 7.71 (m, H13), 1.72, 1.59, 2.42, 0.86, 1.64, 1.43 (aliph. H), 7.25−7.65 (arom. H). −

$^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 44.49, 44.37 (C1), 33.93, 33.94 (C2, *N* = 24.0, 22.4 Hz), 24.80, 24.72 (C5), 31.28, 31.22, 28.62, 28.49, 26.00, 25.93 (C3, C4, C6, *N* = 7.6, 7.6, 5.0, 5.0, 14.8, 15.2 Hz), 174.49, 174.39 (C7), 51.28, 51.24 (Me), 128.87, 128.85, 125.45, 125.35 (C8, C12, *N* = 39.2, 39.2, 45.8, 46.2 Hz), 136.74, 136.70 133.69, 133.64 (C9, C13, *N* = 12.8, 12.8, 11.6, 11.2 Hz), 127.98, 127.96, 127.91, 127.88 (C10, C14, *N* = 9.6, 10.2, 10.6, 10.6 Hz), 131.06, 131.06, 130.18, 130.10 (C11, C15). – $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 28.84, 29.01.

Synthesis of 8: To a solution of $C_7H_8Mo(CO)_4$ (0.15 g, 0.5 mmol) in 10 mL of dichloromethane was added **2b** (0.31 g, 1 mmol), and the reaction mixture was stirred at ambient temperature for 12 h. The crystals precipitated were collected by filtration using a suction funnel, washed with three aliquots of 2 mL of dichloromethane and dried in vacuo (20 °C, 0.01 mbar). Yield 0.33 g (78%). – **8:** $C_{42}H_{42}MoO_8P_2$ (832.7): calcd. C 60.58, H 5.08; found C 59.80, H 4.96. – HPLC ESI(–) MS; *m/z*: 749 [M^- – 3 CO – H]. – IR (KBr disc): $\tilde{\nu}$ = 2020, 1915, 1901, 1859 cm^{-1}.

X-ray Structure of 2b: A crystal (0.30 × 0.36 × 0.60 mm) was sealed in a glass capillary. X-ray data were measured with a Siemens P4 diffractometer equipped with a graphite monochromator and employing Mo-K_α radiation. The structure was solved by direct methods using the SHELXTL program package. Selected crystallographic details are listed in the caption to Figure 2. Experimental data are collected in Table 2.

X-ray Structure of 5a: A crystal (0.15 × 0.24 × 0.44 mm) was glued to a glass fiber. X-ray data were collected with a Siemens P3 diffractometer equipped with a graphite monochromator and employing Mo-K_α radiation. A complete set of intensities including Friedel opposites were measured, and they were corrected empirically for absorption. Systematic absences suggested that the space group was either $P2_1$ or $P2_1/m$ and since the latter would impose mirror symmetry on **5a**, the chirality of **5a** suggested that the former would be correct. Direct methods assuming $P2_1$ yield the positions of the P, B, and cyclohexyl-C atoms, but the arrangement of these atoms obeyed the mirror symmetry required by $P2_1/m$. A subsequent difference Fourier synthesis contained a mirror-related pair of COOC fragments, and the pseudo-mirror plane was broken by incorporating only the entity bonded to the C(2) atom. The structure was refined anisotropically with isotropic hydrogen atoms added in idealized positions by various riding models, and the discussion is based on this model. Unfortunately, the Flack absolute structure parameter, 0.4(2), has been determined imprecisely, so the crystal under investigation may have contained molecules exhibiting the (*R*,*R*) configuration shown in Figure 3, the mirror-related (*S*,*S*) configuration or a mixture of both. Because of the poor convergence encountered in the refinement of the structure in the noncentrosymmetric space group, an attempt was made to develop the structure in $P2_1/m$. This effort led to satisfactory coordinates for the cyclohexyl group divided by the mirror plane and the P and B atoms, but other atoms were poorly defined, the C(8) atom residing on the mirror plane, therefore this model was discarded. Experimental data are collected in Table 2.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-147247 (**2b**) and -146877 (**5a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2, 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

X-ray Powder Diffraction and Solid-State NMR Investigations in Cadmium−Lead Hydroxyapatites

Béchir Badraoui,[a] Adriana Bigi,*[b] Mongi Debbabi,[a] Massimo Gazzano,[c] Norberto Roveri,[b] and René Thouvenot[d]

Dedicated to Professor Alberto Ripamonti on the occasion of his 70th birthday

Keywords: Hydroxyapatite / Rietveld method / ^{31}P MAS NMR spectroscopy / Ionic substitution / X-ray diffraction

In the proposed experiment, the maximum amount of cadmium substitution in lead hydroxyapatite accounts for about 30 atom-%. The crystal structures of PbHA at different degrees of cadmium substitution for lead (4.9, 10.0, 22.4 and 29.0% Cd atoms) have been investigated by X-ray powder pattern fitting and ^{31}P MAS NMR. The site-occupancy factors of metal atoms clearly indicate a preference of cadmium for site **1** of the apatite structure, which is more selective at low cadmium content. A progressive shift of the OH group towards the center of the triangles formed by the site **2** metals has been observed with increasing cadmium content. The different environments of the phosphate group demonstrated by ^{31}P NMR spectroscopic data are discussed in relation to structural data.

Introduction

Hydroxyapatite (CaHA), $Ca_{10}(PO_4)_6(OH)_2$, is a member of a large family of isomorphous substances, and the study of its physico-chemical properties represents an area of intensive interdisciplinary research activity. CaHA is of great interest in the design of biomaterials, in chromatography, in catalysis and in water treatment.[1,2] The CaHA structure can easily host a variety of substituents, both cationic and anionic, whose presence affects the physico-chemical properties of the compound.[3−7] Ionic substitutions can be involved in several applications: dental and bone pathologies, pollution due to phosphate fertilizers, ion-exchange properties for water treatment, radioactive waste confinement, bioceramics for bone implants, catalysis, luminescence, phosphorescence, etc. The most frequently encountered form of CaHA crystallizes in the hexagonal $P6_3/m$ space group, with lattice constants a = 9.42 Å and c = 6.88 Å.[2] The unit cell contains ten cations arranged in two nonequivalent sites: four at site **1** and six at site **2**, as shown in Figure 1. At site **1**, Ca ions are aligned in columns and surrounded by nine oxygen atoms. Ca ions at site **2** are arranged in equilateral triangles centered on the screw axes and surrounded by seven oxygen atoms, one of which belongs to the OH^- groups and the others to the PO_4^{3-} tetrahedra. The OH^- groups occur in columns parallel to the c axis and pass through the centers of the calcium triangles. Among the divalent cations which can be incorporated into the CaHA structure, cadmium, strontium and lead are known to replace calcium in the whole range of composition, while barium−calcium hydroxyapatite exhibits a zone of immiscibility.[8−12] The lattice parameters of these mixed apatites vary linearly with the composition, with the exception of the c axis of lead−calcium hydroxyapatite that displays a discontinuity at about 50 atom-% of lead. The peculiar variation of the c-axis dimension has been ascribed to an inhomogeneous lead distribution at the two nonequivalent cation sites, on the basis of the results of powder pattern structure refinements of Pb−Ca apatites, which indicate a clear preference of lead for site **2** of the hydroxyapatite structure.[9]

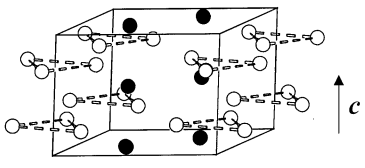

Figure 1. Perspective view of the metal ion in site **1** (black circles) and site **2** (white circles) of HA structure

We now report the results of an X-ray powder pattern fitting study and of a ^{31}P NMR investigation carried out on Cd−Pb mixed hydroxyapatite samples prepared from solutions containing 5 (Cd5), 10 (Cd10), 20 (Cd20) and 30

(Cd30) atom-% Cd. The results give important details of the structural modifications induced by cadmium on the lead hydroxyapatite structure.

Results

The results of the structural refinements indicate that the maximum amount of cadmium substitution in lead hydroxyapatite (PbHA; hereafter MHA = metal apatite) accounts for about 30 atom-%. In other words, the upper limit of the solid solutions is $Cd_3Pb_7(PO_4)_6(OH)_2$. In spite of the limited range of Cd incorporation, the decrease in cell parameters is quite regular when the amount of Cd increases, indicating true solid solutions and a behavior according to Vegard's law, where x = Cd × 100/(Cd + Pb) and σ values are the standard deviation:

$a = (9.8765 - 0.0062\ x)$, $\sigma(a) = 1.3 \times 10^{-4}$ Å
$c = (7.4148 - 0.0080\ x)$, $\sigma(c) = 2.4 \times 10^{-4}$ Å

Increasing amounts of CdO are present in the preparations obtained at greater Cd concentrations, up to 60%. At even greater concentrations [i.e. Cd/(Cd + Pb) > 60%], the products display nonapatitic powder X-ray diffraction patterns, characteristic of lead-substituted tricadmium phosphate.

[a] a = 9.861(1) Å, c = 7.3604(1) Å, R_p = 7.8, R_{wp} = 10.1. − [b] a = 9.810(1) Å, c = 7.3315(6) Å, R_p = 5.5, R_{wp} = 7.3. − [c] a = 9.741(1) Å, c = 7.2522(7) Å, R_p = 6.5, R_{wp} = 8.3. − [d] a = 9.692(1) Å, c = 7.174(1) Å, R_p = 10.5, R_{wp} = 13.5.
The pattern R factor R_p is defined as $R_p = 100\{\Sigma|Y_{oi} - Y_{ci}|/\Sigma Y_{oi}\}$. The weighted pattern R factor R_{wp} is defined as $R_{wp} = 100\{\Sigma w_i(Y_{oi} - Y_{ci})^2/\Sigma w_i(Y_{oi})^2\}^{1/2}$.

X-ray Data

The refined structural parameters of the samples Cd5, Cd10, Cd20 and Cd30 are reported in Table 1, and the data about cationic distribution are reported in Table 2. Figure 2 displays the final plot for Cd10 sample as a typical comparison between the observed and calculated profiles. The final agreement indices, R_{wp}, are 10.1, 7.3, 8.3 and 13.5 for Cd5, Cd10, Cd20 and Cd30, respectively. The bond lengths and angles for the two metal environments are reported in Table 3.

The refinement of the four samples of Cd−PbHA indicates that the cadmium content in the crystalline phase of these samples is 8.4, 10.0, 22.4 and 29.0 for Cd5, Cd10, Cd20 and Cd30, respectively. These values are very close to those expected on the basis of the stoichiometry of the reagents and on chemical analysis (4.9, 10.6, 21.0 and 30.6, respectively), with the exception of Cd5, which exhibits an appreciably greater Cd incorporation.

^{31}P NMR Spectroscopic Data

The 162 MHz ^{31}P MAS spectra of Cd5 and Cd30 are presented in Figure 3 and the relevant data are reported on Table 4. Two distinct isotropic signals can be detected for the two low cadmium containing apatites but only a relatively broad band occurs for Cd20 and Cd30.

Discussion

Structural Analysis

Cadmium can replace lead in the hydroxyapatite structure by up to about 30 atom-%, inducing a linear contraction of the lattice constants in agreement with its smaller size. The partial miscibility found for Cd−Pb apatites is in contrast with the behaviour observed for Cd−Ca and Pb−Ca apatites.[6,13] The complete miscibility of Ca and Cd hydroxyapatites is not surprising in view of their similar size, which is not the case for Ca and Pb ions. The miscibility of the Ca−Pb hydroxyapatites can be justified on the basis of the large difference in the polarizabilities of calcium and lead ions: Ca^{2+} is a hard acid, giving mainly ionic interactions with oxygen, whereas Pb^{2+} is a soft acid, displaying a considerable tendency towards polarization and covalent interactions. In the Cd−Pb case, we have two soft acids. Their significant tendency towards covalent interactions and directional bonding, which is most likely the origin of the large distortions of the PO_4 tetrahedra, probably limits the possibility of mutual substitution. In particular, the precipitation of nonapatitic phases at high cadmium concentrations suggests that the presence of lead, even in small amounts, inhibits the formation of CdHA.

The results of the powder fitting structure refinements indicate a clear preference of cadmium for site **1** of the apat-

Table 2. Cadmium substitution (atom-%) in Cd−Pb hydroxyapatites, e.s.d. in parentheses

	Cd1/(Cd1 + Pb1)	Cd1/(Cd1 + Cd2)	Cd2/(Cd1 + Cd2)	Cd2/(Cd2 + Pb2)	Cd/(Cd + Pb)[a]

ite structure. At low concentrations, Cd occupies almost exclusively site **1**, whereas at a higher degree of substitution, the selectivity is smaller, although the preference is maintained. As is clearly shown in Table 2, most of the Cd ions in Cd5 (99%) are at site **1**. The occupancy of site **1** by Cd decreases to 92% in Cd10, to 79% in Cd20 and to 67% in Cd30, in which about 50% of the metal atoms at site **1** are Cd. This result could be expected on the basis of the shorter metal−metal distances at site **1** (M−M = 3.62 Å in PbHA) which is more suitable for the smaller Cd ion, than at site **2** (M−M = 4.22 Å in PbHA). Furthermore, this is in agreement with the preference of Pb for site **2**, where the arrangement of the "staggered" equilateral triangles allows for the optimization of the packing of larger ions, in contrast to site **1** where the strict alignment of the columns causes a stronger repulsion.

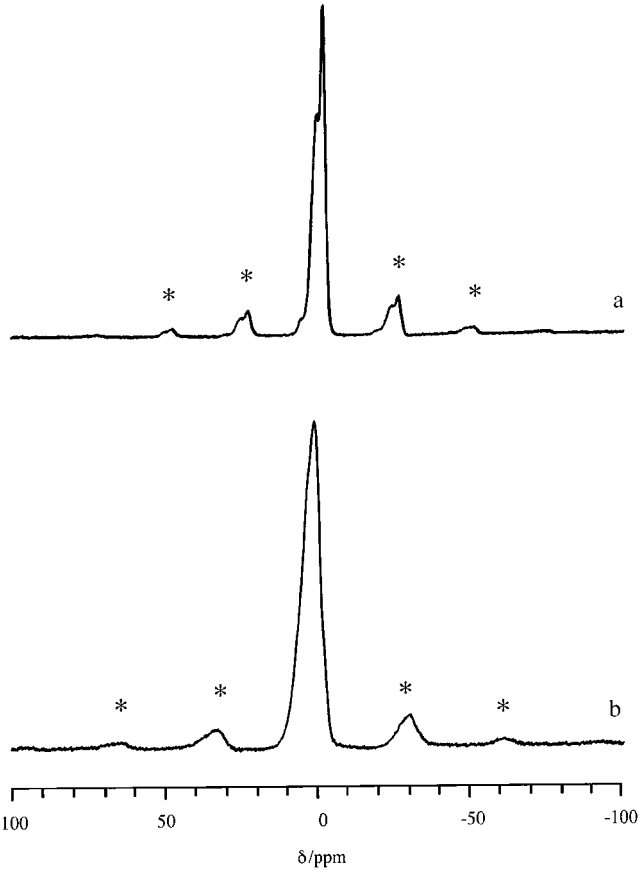

Figure 3. 162 MHz ^{31}P MAS NMR spectra of (a) Cd5 (spinning rate 4 kHz) and (b) Cd30 (spinning rate 5 kHz); asterisks mark spinning side bands

Table 4. ^{31}P MAS solid-state NMR spectroscopic data

Sample	δ_{iso} (ppm)	$\Delta\nu_{1/2}$ [a]	Relative amount[b] (%)
Cd5	−1.1	1.9 (310)[b]	47
	+0.9	3.1 (500)[b]	53
Cd10	−1.0	1.6 (260)[b]	27
	+1.1	4.3 (700)[b]	73
Cd20	+1.8	5.3 (860)	−
Cd30	+1.9	7.0 (1130)	−

[a] In ppm, with the values in Hz in parentheses. − [b] From line-fitting analysis.

For the sample Cd5, the discrepancy between the value of the cadmium content obtained from the Rietveld refinement and the value measured by chemical analysis, can be ascribed to the slight modification of the diffraction pattern induced by cadmium incorporation: 5% of lead substituted by cadmium corresponds to only a 1.5% intensity variation in the region of the most intense peaks (ca. 30° − 2θ). Furthermore, the value of the Cd5 unit-cell volume is an indirect confirmation that cadmium substitution amounts to approximately 5%, since it fits very well with those of the other samples in the plot of volume against Cd%.

The insertion of cadmium into the PbHA lattice appreciably affects the position of the OH group in the channel formed by the metals of site **2**, as can be seen in Figure 3. In CdHA, as well as in CaHA, the OH ion is just a little bit out of the plane of the triangles formed by the site **2** metals; on the other hand, the OH ion in PbHA is approximately halfway between two successive planes of lead triangles, because of the presence of the larger metal ions. The substitution of cadmium for lead causes a shift of the group along the channel toward the center of the plane (see Figure 4) with a behaviour very similar to that previously verified for Pb−Ca hydroxyapatite.[9] The shift is also appreciable when a very small amount of cadmium is inserted at site **2**, as reported in Table 3 for Cd5 and Cd10.

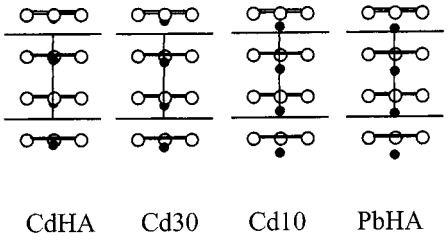

Figure 4. A view of the OH oxygen position (black circles) along the *z* axis in CdHA, PbHA and mixed Cd−Pb hydroxyapatites

The distortion indices of the phosphate group of the solid solutions (data are reported in the Supporting Information) are greater than those of the end members, indicating that the cationic substitution also induces deformations in the phosphate tetrahedra. In any case, the observed distorsions are consistent with the data reviewed by Baur.[14]

Cd−PbHA ^{31}P MAS NMR

The pure phases, $Cd_{10}(PO_4)_6(OH)_2$ and $Pb_{10}(PO_4)_6(OH)_2$, each present a unique isotropic signal at $\delta = +12.2$ and -0.7, respectively, according to the presence of a unique crystallographic site for the phosphate group in the apatitic cell. The chemical shift variation between CdHA and PbHA can be correlated to the increase in the lattice parameters.[15]

It should be noted that the chemical shift difference between these two phases is relatively large ($\Delta\delta \approx 13$), because the signal for CdHA is the most deshielded of the known hydroxyapatites for which δ_{iso} is in the range -0.7 to $+2.9$.[16−18] When considering the partial substitution of Cd for Pb at the metallic sites, one has to consider the cationic environment of the phosphate group. The phosphorous atom displays 9 (O−M) contacts, as shown in Figure 5.

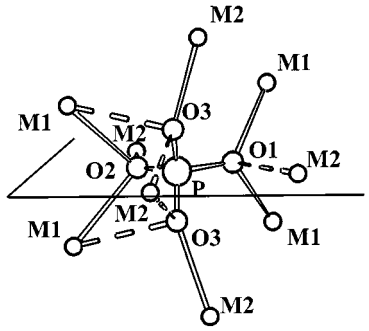

Figure 5. The cationic environment of the phosphate group; the bonds longer than 2.7 Å are dotted; the mirror plane is enhanced

If we assume a statistical distribution of the cadmium atoms over the different sites, one would expect, through progressive replacement of Pb by Cd, various cationic environments, ranging from zero cadmium, nine lead atoms (abbreviated as PPb_9) to nine cadmium, zero lead atoms (abbreviated as PCd_9). In the frame of this assumption, the relative proportion of a $PCd_xPb_{(9-x)}$ environment (x = integer) is given by the statistical formula

$$p_{[PCd_xPb_{9-x}]} = C_9^x\, p_{Cd}^x\, p_{Pb}^{9-x}$$

where C_9^x is the binomial coefficient

$$\left(\frac{9!}{x!(9-x)!}\right)$$

and p_{Cd} and p_{Pb} represent the atomic fractions of Cd and Pb, respectively. Assuming that the first metallic neighbours primarily determine the shielding of the phosphorus nucleus, one therefore expects essentially ten different ^{31}P chemical shifts.

With the oversimplified assumption of regular ^{31}P deshielding by increasing the number x of Cd atoms in the immediate environment of the phosphorus nucleus, the ^{31}P NMR MAS spectrum should present a maximum of ten isotropic signals with an interline separation of approximately (12.2 + 0.7)/9 ppm, i.e. 1.4 ppm (240 Hz at 9.4 T). The relative intensity of each signal is proportional to the probability of each environment. Actually, as shown in Figure 5 where it is evident that P, O1, O2, and three M2 atoms lie in the mirror plane, six types of metal atoms have to be considered and this can affect the shielding of the P nucleus in different ways, that is:

− in the mirror plane, $M_2(O_1)$, $M_2(O_2)$ and $M_2(O_3, O_3)$

− out of the mirror plane, $M_1(O_1)$, $M_1(O_2)$ and $M_2(O_3)$

Furthermore, for a given $[PCd_xPb_{(9-x)}]$ group, the ^{31}P chemical shift is also slightly affected by more remote metallic substituents.

Both these effects, which act as a perturbation of the dominant "nearest-neighbour effect" should, at best, lead to some broadening of the isotropic signal of the $[PCd_xPb_{(9-x)}]$ group with respect to those of the "pure" $[PPb_9]$ and $[PCd_9]$ groups (maximum broadening for the

most disordered cases [PCd_5Pb_4] and [PCd_4Pb_5]). The spectrum of a mixed lead−cadmium hydroxyapatite should therefore appear as a succession of nearly regularly spaced signals between $\delta = -0.7$ and $+12.2$, the most intense signal shifting progressively to higher frequencies by progressive replacement of lead by cadmium. Such types of solid-state MAS spectra were recently observed by ^{207}Pb NMR spectroscopy for solid solutions of lead−strontium nitrates.[19]

If the line width of the individual lines exceeds the chemical shift difference (due to both homogeneous and heterogeneous line broadening), the different signals are no longer resolved and the isotropic resonances should appear as a unique band, eventually with shoulders. The position of this band should shift to higher frequencies when increasing the cadmium content and its width should reach a maximum for an equal content of cadmium and lead. It is what is actually observed with the samples Cd20 and Cd30, for which the isotropic signal ($\Delta\nu_{1/2} \approx 1$ kHz) moves slightly from $\delta = 1.8$ to 1.9, but the spectra for the samples with lower Cd content cannot be explained in the frame of these assumptions.

Actually, the spectra of these mixed phases consist of two isotropic resonances at approximately the same positions [$\delta \approx -1.0$ (narrow) and $\delta \approx +1.0$ (broad)]. The relative intensity of both signals, obtained from line-fitting analysis, amounts to approximately 1:1 for Cd5 and approximately 1:3 for the Cd10 sample (Table 4). Although the overall line width is significantly larger for the latter ($\Delta\nu_{1/2} \approx 800$ Hz) than for the former ($\Delta\nu_{1/2} \approx 600$ Hz), no additional signal could be detected on the high frequency part of the isotropic band for the Cd10 sample. Therefore one must assume that identical $PPb_{(9-x)}Cd_x$ groups are present in both mixed phases, but with different concentrations. Let us return to the results of the Rietveld calculation: it has been demonstrated that cadmium atoms are preferentially located at site **1**. At low cadmium contents, Cd is almost exclusively at site **1**, as confirmed by crystallographic analysis (Table 2).

Furthermore, in manganese-substituted fluorapatites, Suitch et al.[20] showed that one Mn^{2+} ion at site **1** per unit cell distorts the phosphate tetrahedron in such a way that it hinders the fixation of another Mn^{2+} at both sites **1** and **2**, leading to the partial segregation of the Mn^{2+} ions in one of the four channels of the apatitic cell. This situation can also be anticipated in the present case of Pb−Cd apatites.

For an amount of 5% Cd, only one out of eight sites **1** are occupied by a Cd^{2+} ion: That means that only one out of every two unit cells contains a Cd^{2+} ion. Then two different environments for the phosphate group are equally probable, that is PPb_9 and $PCdPb_8$; or when considering only sites **1** in the unit cell (labelled as $_{S1}$): **A** = $[P(Pb_4)_{S1}]$ and **B** = $[P(CdPb_3)_{S1}]$ (see Figure 6), where **A** would give the narrow isotropic signal at $\delta = -1.0$ and **B** the relatively broad signal at $\delta = +1.0$. Distortion of the groups **B** with respect to **A** is apparent from the higher chemical-shift anisotropy of the corresponding NMR signal, leading to a relatively higher intensity of their spinning side bands at either rotor speeds (see Figure 3a).

For the manganese-substituted fluroapatites containing 5 atom-% Mn, Suitch et al.[20] observed two distinct IR stretching $\nu_1(PO_4)$ bands, which they assigned similarly to the two kinds of phosphate, with or without an interaction with a Mn^{2+} cation. For higher manganese content, Suitch et al.[20] observed the progressive disappearance of the IR band assigned to the phosphate group not interacting with an Mn^{2+} cation: they suggested that for the composition [$MnCa_9(PO_4)_6F_2$], there is strictly one Mn atom per unit cell, that is a regular arrangement of Mn^{2+} alternated with Ca^{2+} cations at one site **1** channel or, considering the P environment, there is one unique group $P(Ca_3Mn)_{S1}$.

A similar situation in Cd10 would lead to an NMR spectrum with a unique isotropic resonance at approximately $\delta = +1.0$ (due to group **B**). Actually, the NMR spectrum exhibits two resonances at $\delta = -1.0$ and $+1.0$. In agreement with the results obtained for Cd5, the two resonances could be assigned to a group **A** and to a group **B**. However, taking into account the stoichiometry of the sample, it is necessary to postulate the presence of a third group **C** containing two cadmium atoms at site **1,** with an **A/B/C** ratio of 0.25:0.5:0.25. This hypothesis would also justify the relative amounts of the two NMR signals, provided that the shielding for the **C** group is almost the same as that for the **B** group (that is, the chemical shift increment when substituting the second Cd^{2+} ion is smaller than that due to the first Cd^{2+} cation). The presence of **C** groups, with partial clustering of cadmium atoms in Cd_2 pairs, would explain

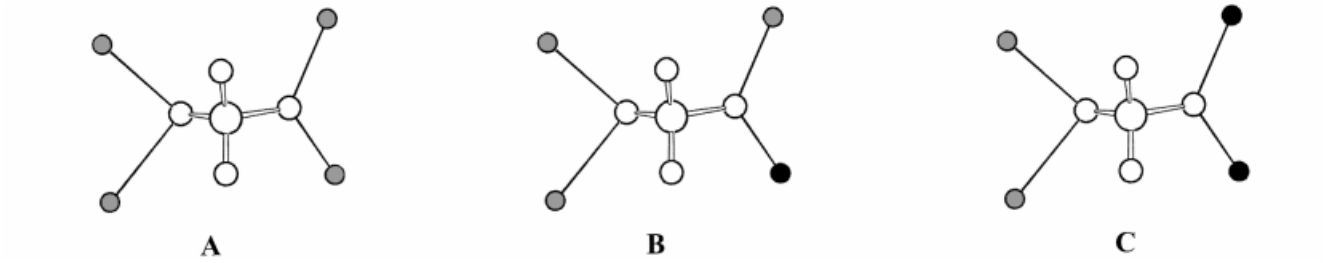

Figure 6. Phosphate group environments displaying three possible distributions of Pb (grey circles) and Cd (black circles) in site **1**

the pronounced phosphate distortion of the samples at low Cd content.

Conclusions

The results of this paper indicate that CdHA and PbHA exhibit only a limited range of solubility: cadmium can substitute lead up to 30 atom-%, whereas lead seems to avoid the incorporation into CdHA. Cadmium ions display a clear preference for site **1** of the apatite structure, in agreement with the shorter metal−metal distances at this site than at site **2**. When the cadmium content is increased, part of the substituent cations begin to fill site **2**, so that at the maximum degree of substitution, two of the four metal ions at site **1** are Cd, whereas only one of the six metal ions in the equilateral triangles characteristic of site **2** is Cd. The preference of cadmium for site **1** is responsible for the observed significant shift of the OH group towards the plane of the site **2** metals, as shown by its increase when the cadmium content at site **1** is increased. Furthermore, the presence of a relatively low amount of cadmium at site **1** induces a limited, but appreciable distortion of the phosphate tetrahedra that might be due to the presence of two different environments for the phosphate group, in agreement with the results of NMR spectroscopic analysis.

Experimental Section

General: Cadmium−lead hydroxyapatites were synthesized in aqueous systems by a double decomposition method,[6,7] starting from solutions containing 5, 10, 20, 30, 40, 50, 60 atom-% Cd, where atom-% = [Cd/Cd + Pb] × 100. The samples obtained are labeled as Cd%, where % is the amount of Cd^{2+} ions in the solution. − Stoichiometric quantities of cadmium nitrate and lead acetate (0.05 M solution A) and disodium hydrogen phosphate (0.03 M, solution B) were prepared separately in distilled water. The (Cd + Pb)/P molar ratio was adjusted to be the stoichiometric one (1.67); each solution was stirred under nitrogen. Solution A was added to solution B, maintained at 100 °C under nitrogen to improve the homogeneity of the precipitate, and to prevent the formation of carbonated apatites. The precipitate was allowed to be in contact with the mother solution for 2 h, then filtered and washed with hot distilled water. An aqueous solution of ammonia was then added in order to maintain the pH value at about 11 during the maturation (3 h) at 100 °C. The precipitate was then filtered and dried at 110 °C for 24 h. − The XRD data were collected with a Philips PW 1710 diffractometer using a graphite monochromator. The step range was from 5 to 95°(2θ), with a counting time of 10 s for each step and a step width of 0.03°. − ^{31}P MAS NMR spectra were obtained at room temperature with a Bruker MSL400 spectrometer (9.4 T) operating at 162 MHz, using a 4-mm MAS Doty probe. − Magic angle spinning (MAS) spectra were obtained with spinning rates up to 5 kHz, using single-pulse excitation. Chemical shifts are reported relative to 85% aqueous orthophosphoric acid H_3PO_4 (δ= 0).

Structural Analysis: The full pattern refinements were carried out by means of the Rietveld method using the DBWS-9411 program.[21,22] − The space group ($P6_3/m$, no. 176) and the atomic positions of the lead hydroxyapatite structure[12] were used as the starting set in the refinement procedure. The X-ray scattering factors for Cd^{2+}, Pb^{2+}, O^- ions and for the P atom were used. A third-order polynomial was employed to assimilate the background while the peaks were fitted by using a pseudo-Voigt function. The halfwidth of the diffraction peaks as a function of 2θ was evaluated by the Caglioti equation.[23] In the first cycles, the scale factor and the background coefficients were refined. Successively, the profile parameters (peak widths and their dependence on 2θ, true 2θ zero, Lorentzian fraction) and the lattice parameters were allowed to vary too. Finally, the occupancy factors (O.F.) were refined and the cation substitution was tested. − No constraint was imposed on the overall cadmium content. The two metal sites were imposed to be fully and complementarily occupied by lead and cadmium. The occupancy factors of O and P were assumed as constant, in agreement with the apatite stoichiometry. The fractional atomic coordinates were refined, starting from the atomic positions of the two metals. No attempt was made to distinguish the position of Pb atoms from that of the substituting Cd atoms. The same thermal factors (t.f.) were used for Cd and Pb atoms; the individual t.f. values were kept constant but an overall thermal parameter was refined. In the last refinement cycles, optimizing 28 variables (structural and nonstructural parameters) simultaneously tested the possible preferred orientations of the 001 reflections. All the nonstructural refined parameters are reported as Supporting Information and are available on the WWW under http://www.wiley-vch.de/home/eurjic or from the author. − Further details of the crystal-structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-411418 to -411421.

EXAFS Data Analysis of Vitamin B_{12} Model Compounds − A Methodological Study

Emiliano Fonda,[a,b,c] Alain Michalowicz,[c] Lucio Randaccio,*[a] Giovanni Tauzher,[a] and Gilberto Vlaic[a,b,d]

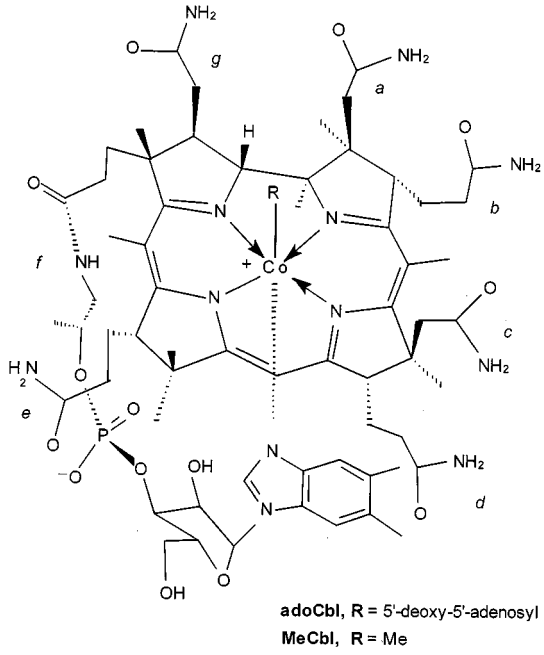
Keywords: EXAFS spectroscopy / Cobaloxime / Vitamins

In view of several controversial EXAFS results on cobalamins and B_{12} model compounds published in the last ten years, a methodological study is presented to explain the origin of these controversial results and to propose how to improve EXAFS structural-parameter refinement. The advantages and limitations of first-shell filtering, constrained refinement, and the importance of the mapping technique are described in order to suggest and encourage improvement of data-analysis codes. The conclusions can be generalized and applied to the EXAFS analysis of the majority of metal complexes

Introduction

The B_{12}-based enzymes are among the few cofactors known so far that contain a metal−carbon bond. These coenzymes belong to the alkylcobalamin series (RCbl). They consist of a cobalt corrinoid with a pendant nucleotide, which occupies five coordination sites of a pseudo-octahedral Co^{III}, the sixth position being occupied by an R alkyl group or by a CN ligand in vitamin B_{12} itself (Scheme 1).[1,2] All the currently known B_{12} enzymatic reactions involve the making and breaking of the Co−C bond. In order to better understand the structure and reactivity of cobalamins, simple models have been proposed and investigated. The cobaloximes $LCo(DH)_2R$ (L = Lewis base, $(DH)_2$ = bis(dimethylglioximate)] represent the most widely studied class of models.[3] Such model studies have complemented those on cobalamins well,[1,2] thereby providing clues into the elusive mechanisms of B_{12}-dependent enzymatic processes, particularly those involving the homolytic Co−C cleavage.[3] One of the problems was the knowledge of the accurate structure of cobalamins. Up to a few years ago, for reasons previously reported,[4] the available structural determinations, based on conventional X-ray sources, were of poor accuracy, in contrast with the very accurate structures of the simple models.[3] Only recently[4,5,6] have the first accurate determinations based on synchrotron diffraction data appeared.

However, the interest in the structure of these systems has also prompted several Extended X-ray Absorption Fine Structure (EXAFS) studies, principally on cobalamins,[7,8,9] but also on models[10] and more recently on the B_{12} coenzyme bound in methylmalonyl-coenzyme A mutase.[11,12]



Scheme 1

The main advantage of EXAFS with respect to X-ray Diffraction (XRD) is that it does not require crystalline samples and can be used in solution. Although EXAFS is expected to be an order of magnitude less accurate than XRD for small molecules,[13] EXAFS can be exploited in the structural studies of metallo-proteins when XRD is not available and, more importantly, to follow the variations in the coordination about the metal centres within the active site.[14] In recent years, as the number of EXAFS results on B_{12} derivatives[7,8,9] and related model compounds[10] has increased, the discussion of these results, when compared to crystal structures, has become controversial.

In almost all EXAFS works, the Co−ligand distances have been deduced from fits of the first shell Fourier-filtered spectrum. This method, largely used since the pioneering

works in EXAFS,[15] has been criticized[16,17] in the case of B_{12} for two reasons: i) Fourier filtering may lose a part of the actual signal. In fact, the contribution of the axial ligands from between the first and second coordination spheres may overlap; ii) The information contained in the first shell Fourier-filtered signal is insufficient to allow for any reliable determinations of the coordination distances of the equatorial Co−N distances and of the two axial ligands. For instance, Chance used this method to determine the local structure of Co in cobalamins and enzyme-bound cobalamins.[7−9] However, in the case of $(H_2OCbl)[ClO_4]$, there were dramatic discrepancies between the accurate XRD structure and that obtained by EXAFS.[8] In fact, the EXAFS value of the Co−N axial distances in H_2OCbl^+ [2.14(3) Å] and in $Co^{II}Cbl$ [1.99(3) Å] appear to be reversed with respect to those determined by XRD [1.925(2) and 2.13(2) Å, respectively]. Furthermore, the *trans* influence of H_2O, CN and SO_3-Cbl appeared to be very similar from EXAFS analysis, the *trans* axial Co−N distances varying in the range 2.14(3)−2.16(4) Å.[9] On the contrary, XRD results indicate a dramatic lengthening of the axial Co−N bond in SO_3^{2-} [2.149(5) Å][5a] and CN^- [2.041(3) Å] derivatives,[5b] with respect to the value of 1.925(2) Å found in the aqua derivative.[6]

Recently, more reliable methods than Fourier filtering of the first shell were employed. Giorgetti et al.[10] worked on a series of Costa-type models $(H_2O)Co(DO)(DOH)R$, in which R = CH_2CF_3, CH_2CO_2Me Me, CH_2Ph, *i*Pr, and (DO)(DOH)=*N*,*N*′-propanediylbis(2,3-butanedione-2-imine-3-oxime). These authors studied the variation of the distances between cobalt and its first neighbours, while the rest of the structure was kept constant. Multiple-scattering (MS) calculations and unfiltered data had been employed. Nevertheless, analogous large discrepancies (0.15−0.2 Å) in the axial coordination bond lengths, also including opposite trends of the R *trans* influence, were detected in a subsequent XRD study.[18] Scheuring et al.[11] employed the so-called "global-mapping technique" to study B_{12} in the glutamate mutase enzyme. Unfiltered data sets and MS calculations were employed. This technique consists of mapping the value of the χ^2 versus the variation of the distances of two ligands, while the rest of the structure is kept fixed. The minima in the map correspond to possible distances. Two possible Co−N axial distances were found. Between the short (2.17 Å) and the long (2.6 Å) distances, they chose the latter, because an XRD structure[19] of the B_{12}-enzyme indicated a long distance. Champloy et al.[12] worked on methylcobalamin bound to the enzymes, glutamate mutase and 2-methylene glutarate mutase. They found identical EXAFS spectra for the free and enzyme-bound MeCbl and two minima at the same distances as those of Scheuring et al.[11] In the free Me-Cbl, the Co−N axial distance is "short" and a recent X-ray structural determination of MeCbl furnished an axial Co−N distance of 2.162(4) Å.[5b] On this basis, they define the long distance found by Scheuring et al.[11] as implausible. However, the reason for the appearance of the other minimum in the EXAFS modelling was not clearly established.

In view of the various approaches adopted so far to examine EXAFS data,[8,10−12,20] it is highly desirable to study and discuss the fundamental aspects of EXAFS data analysis of this kind of compound, in order to find a way to standardize analysis of EXAFS results. In fact, despite the fact that it is becoming a common technique, EXAFS may risk losing its credibility among biochemists and chemists because of the above controversy. Therefore, it is essential to better understand what kind of structural information can actually be obtained by EXAFS. We present here an EXAFS methodological study carried out on several cobaloximes, $RCo(DH)_2py$ with R = Cl, N_3, Me, CH_2Ph, adamantyl (adam)[21] (see Figure 1). These cobaloximes were chosen since their structures have been determined with great accuracy.[22] Furthermore, they are stable under measurement conditions and can be handled without the main problems associated with cobalamins, namely their sensitivity to visible light or X-rays.[23] Finally, their axial fragments exhibit as wide a range of bond lengths as possible. These characteristics are essential to carry out an intensive and reliable methodological study. Using B_{12} compounds would have made this work much more complicated, while leaving much room for ambiguity. However, we plan to carry out a similar analysis on B_{12} complexes in the near future. Such a study would have added significance in view of the recent finding that the lengthening due to the trans influence of R in cobalamins is about twice that in cobaloximes.

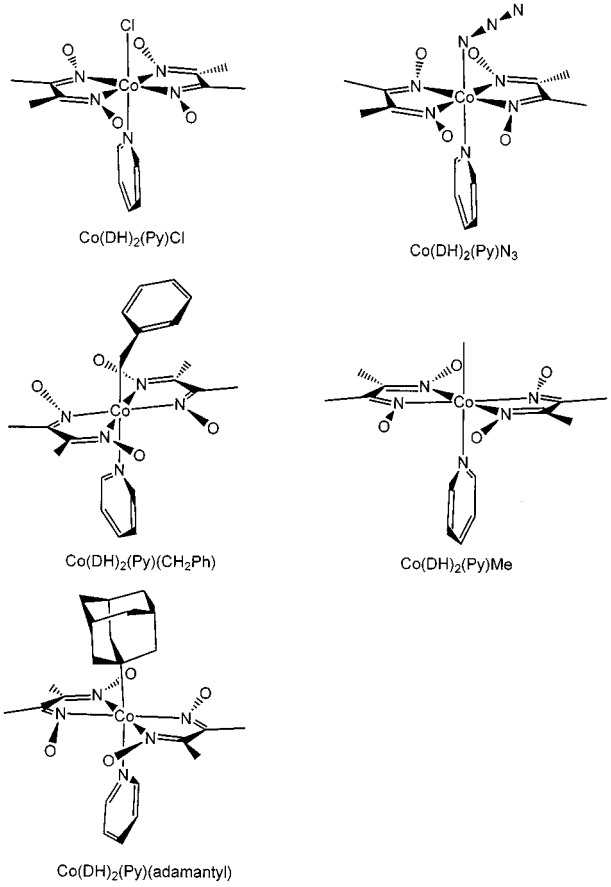

Figure 1. Schemes of the studied complexes, the upper ligand is the only one that changes through the series

Results and Discussion

Limits of the "First-Shell Analysis"

The most common method used to analyze EXAFS data consists of isolating the nearest-neighbours (NN) contributions by Fourier filtering the EXAFS signal. This method has been applied successfully in many cases since the beginning of EXAFS analysis,[24] and its description can be found in a large number of reviews and books.[13,25−27] Although this method is easy to apply because it drastically reduces the complexity of the calculations, it suffers from the limitations discussed in the introduction section. Furthermore, when applying the back-Fourier filtering window, the choice of the limits is not always easy and is always arbitrary. It is a trial and error procedure, while it is often presented as a simple one-way procedure. An example of this and similar problems is given later for R = adam (Figure 2). Finally, if the resolution of EXAFS is expressed as $\Delta r = \pi/(2\Delta k)$, in present case this translates to approximately 0.08−0.10 Å. If the distances do not differ by more than Δr, EXAFS will not resolve them. For the molecules considered in this work, ligands are at distances that differ by approximately 0.1 Å (see Table 2, crystallographic distances) so we are near the limits of the technique.

"First-Shell Analysis" Applied to Cobaloximes

In Table 1, the results of r-space refinements of the first-coordination shell are shown and r-space intervals are shown in Figure 3. When the experimental signal is approximated with a variable number of N atoms at the same distance (Table 1.i), almost 6 neighbours were found only if R = N_3. This should not be surprising: if R = N_3, the Co−R, Co−py, and Co−N(DH)$_2$ distances are quite close (see Table 2, crystal ref.), and this simple model can be used to obtain an acceptable coordination number (CN) and average distance. A lower CN indicates that interference between various contributions reduces the total signal. Therefore, another approach to obtain the actual coordination numbers and distances is to take into account that NN are at two or three different distances. In this case, it has been assumed that 4 N donors are at the same distance (corresponding to the four N donors of (DH)$_2$]. A variable number of N (or Cl or C when indicated in brackets) has been refined as a second contribution to the signal (results are shown in Table 1.ii). In this way, although axial distances are within ±0.05 Å of XRD values (see Table 2, Crystal. ref.), for R = adam, CH_2Ph, and Me, a ligand is apparently missing. For R = Cl, the Cl position is easily determined, but only 4.3 nitrogen atoms are detected in the first shell. Finally, in the case of R = N_3, the coordination number (CN) is correct (5.7 ± 0.4, i.e., 6 NN), but the distance of the first four N donors is 0.05 Å longer, and that of the axial ones is 0.1 Å shorter than the corresponding XRD values. This can be explained in terms of the correlation between the parameters, since the three actual distances are 4 × 1.895, 1 × 1.950, and 1 × 1.973, and it is difficult to resolve them by EXAFS. Finally, a three-distance model, with three free distances and fixed coordination numbers, was employed (the results are reported in Table 1.iii). For R = adam and R = CH_2Ph, the results are acceptable (differences with respect to XRD values are less than ±0.07 Å) and χ^2_v of model ii) and iii) are comparable. On the contrary, for R = Cl, Me, and N_3, errors exceeding 0.1 Å have been found and χ^2_v of model iii) is bigger than that of more

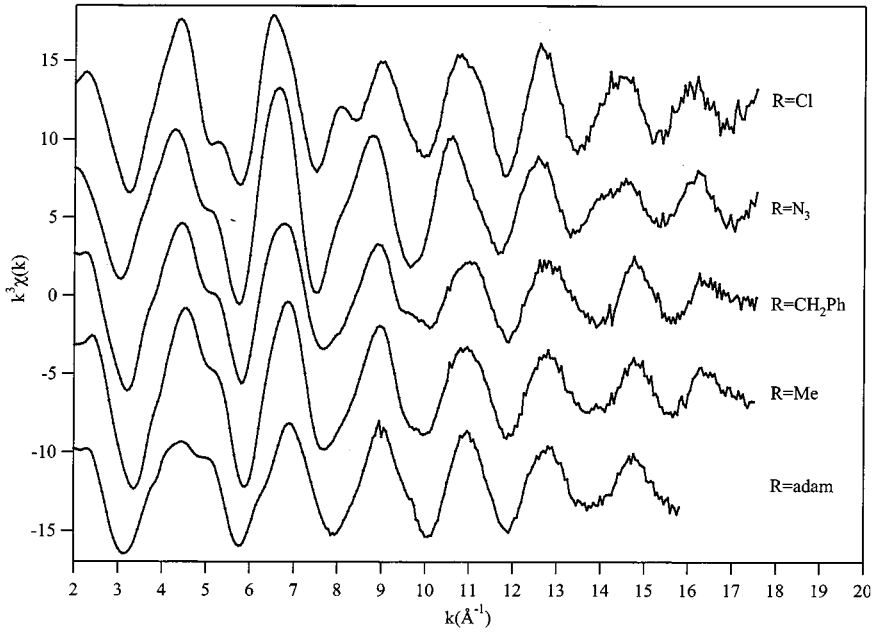

Figure 2. Raw k^3-weighted EXAFS spectra are shown; spectra have been extracted and interpolated on a grid with Δk = 0.02 Å^{-1}; no filtering or smoothing has been applied; spectra are shifted for clarity

Table 1. Results of refinements limited to the first shell; data were obtained with refinements in *r*-space (intervals are shown in Figure 3) assuming i) a model with a variable number of N atoms at the same distance; ii) a model with 4 N at one distance and a variable number of N at another distance (except for R = Cl and Me); iii) a model with 4 N at one distance and the actual atoms of R and Py (N) at a second and third distance, respectively. The refinement degree of freedom is labelled ν

simple models. In the case of R = Me the position of Me is undetermined (1.9±0.3 Å). Therefore, unacceptable results are obtained in at least 50% of the cases. The Co−Cl distance and the average distance between cobalt and the four $N(DH)_2$ are accurately determined, because their contributions are dominant.

An Approach to a Complete Simulation

Another way to analyze EXAFS data is to consider the unfiltered spectrum in *k*-space, or an *r*-space interval large enough to cover all relevant peaks (in the studied cobaloximes almost all relevant contributions are below 4 Å). Thus, information from a large number of contributions is included in the analyzed region. On the other hand, the number of independent points is limited (in our case to approximately 25) and is not sufficiently larger than the number of fitted parameters. For this reason, the set of parameters should be carefully chosen before performing a refinement. Care must be taken in choosing the relevant parameters and in linking related quantities, thereby avoiding redundancies. Constraints are based on the knowledge that we have of similar structures. It will be demonstrated that the use of such constraints, whenever possible, is of primary importance. If the system is completely unknown, EXAFS analysis is restricted to a comparison with known systems or first-shell analysis. In most cases, the challenge is to determine which of the several models reproduces the actual structure. In B_{12} model compounds (cobaloximes, in this work) the main problem is to determine the distances of the ligands from cobalt. Schematically a cobaloxime (see Figure 1) may be represented by two coplanar chelate ligands (two DH units referred by a mirror). Thus, the system may be defined by considering ligands as rigid bodies and only specifying the Co−N(DH)$_2$, Co−N(py), and Co−(R) distances and, in the case of R = Ch_2Ph and R = N_3, the angles Co−C_1−C_2 and Co−N_1−N_2 respectively. Actually, such angles are in the range 110°−120° [121.8(1)° for R = N_3[22b] and 116.7(2)° for R = CH_2Ph[22c]]. With regard to the results presented here and in the following discussion, the angles have been fixed at these values. This has been done in order to simplify the calculations and to focus the discussion on the problem of determining distances. However, it has been verified that refinements that include these angles give correct results (within EXAFS accuracy), that is, 127 ± 2° in the case of R = N_3 and 116 ± 3° in the case of R = CH_2Ph. It is worth noting that the use of the structures of rigid bodies directly taken from crystallographic databases suffers from some limitations. Sometimes small

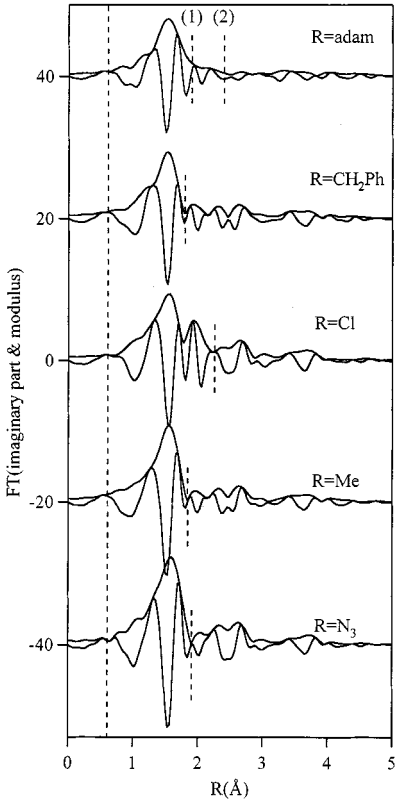

Figure 3. Fourier transform (not phase corrected, imaginary part and modulus plots) of the EXAFS spectra shown in Figure 2; two vertical dashed lines show approximate filtering intervals used to obtain the results in Table 1; for R = adam, two limits (1) and (2) are possible; limit (2) was chosen to obtain the results shown in Table 1; spectra are shifted for clarity

changes (±0.02 Å) to the internal distances can significantly improve the fit of EXAFS data. This happens when two significant contributions interfere, for example, Co−C(DH)$_2$ and Co−O(DH)$_2$ interfere destructively, (see Figures 4 and 5) and their relative distances are critical in determining the signal amplitude. However, it is easy to apply a correction because their contributions are strong and nearly in perfect opposition. Most likely, the best way to do this is a *restrained refinement* as described by Binsted et al.[28] The method used in the present work is a *constrained refinement*,[28] since the former was not possible with the codes in our possession. The remaining relevant parameters are: E_0 to match experiment and theory edge position, S_0^2 (amplitude reduction factor) and a series of Debye−Waller factors (σ_i^2). S_0^2 has been fixed to 1 as suggested by Roy and Gurman[29] (this assumption was tested on $Co(NH_3)_6Cl_3$). The σ_{SS}^2 (single-scattering Debye−Waller factors) values are expected to be very close to each other, and they have been fixed at the same value for similar atoms at similar distances. Only the Co−Cl pair requires its own $\sigma_{Cl,SS}^2$, which is slightly smaller. The MS paths have different σ_i^2, but two relations have been employed to reduce the number of parameters. The σ^2 of triple-scattering paths involving the same couple of atoms in co-linear arrangements is double the single scattering σ_{SS}^2. For example, when the single-scattering (SS) path of Co−N_1−Co has its σ_{SS}^2, the MS path Co−N_1−Co−N_1−Co has $\sigma_{MS}^2 = 2\sigma_{SS}^2$; this was also assumed for paths such as Co−N_1−Co−N_2−Co when N_1 and N_2 are on opposite sides of Co. For triple-scattering paths with angles of approximately 120−160°, instead of using complex relations[20] and due to the homogeneity of the atoms and bonds involved, an average value of three times σ_{SS}^2 has been used. This empirical assumption worked satisfactorily in all five cobaloximes, speeded up calculations while performing contour plots, and did not affect the reliability of the results. Another approach is to calculate Debye−Waller factors using semi-empirical methods.[30] This procedure is flexible and more rigorous, but computationally too heavy for this work. On the other hand, the use of the simple and fast Debye-correlated model is unjustified, even if it was used by other authors for cobalamins.[11] Thanks to the above assumptions the simulation of the entire spectrum required only approximately 6−7 parameters.

Constrained Refinement of Cobaloximes and the Mapping Technique

Numerical results obtained with the assumptions described above are compared with crystallographic distances and listed in Table 2. Distances are determined with some accuracy, but it is evident that discrepancies between XRD and EXAFS are still present. Our EXAFS data were collected at liquid-nitrogen temperature (LNT), while XRD data were collected at room temperature (room temp.). Thus, some small discrepancy is expected, but not as large as 0.05 Å. However, the average accuracy in determining the axial distances with this method can be estimated to be about 0.05 Å. An explanation as to why filtering of the first peak is a risky technique for such molecules can be suggested. The contributions to the EXAFS signal for R = adam (worse simulation) and R = N_3 (better simulation) have been drawn separately in Figure 4 and Figure 5, respectively. In the case of R = adam, the filtering limit used to obtain the results in Table 1 is marked as (2). It is apparent that an important contribution from all NNN (next nearest neighbours) is present well below this limit (see Figure 4). This contribution is not negligible with respect to that of the axial donors. If a narrow filter, as limit (1) in Figure 4, is chosen, almost 50% of the axial contribution is lost (Co−N(Py) and Co−C(adam)]. A different situation is shown in Figure 5 for R = N_3: the first three contributions [Co−N(DH)$_2$, Co−N(Py) and Co−N(N_3)] are in phase and the amplitude of the signal is almost the sum of their amplitudes. This means that the majority of the contributions are included in the filter, and at the same time, the relative importance of the other contributions in the filter is negligible. In fact, for R = N_3, acceptable results have been obtained (see Table 1, a). It is interesting to observe that the Co−C(DH)$_3$ and Co−O(DH)$_2$ contributions (in Figures 4 and 5) have similar amplitudes, and opposite phases giving a very small signal. For this reason, in the region above 2 Å only small features appear, even if several NNN contributions are in that region.

Table 2. Results of fits performed with refinement *c* (see text); crystallographic values are reported for comparison; EXAFS data were recorded at liquid nitrogen temperature, and crystallographic data at room temperature; in the case of R = adam, the crystallographic values are referred to a similar structure where Py is replaced by 4-Me_2N-Py; the refinement degree of freedom is labelled ν

The finding of multiple solutions, the difference between constrained and unconstrained refinements and the importance of extending the simulation as far as possible should be discussed. For this purpose, χ^2 maps have been calculated. In fact, although constrained refinement dramatically reduces correlation between variables,[28] it does not guarantee that a single solution is found. Some χ^2 maps have been obtained by varying the distances of the axial ligands [Co−N(py), Co−R] and plotting the χ^2, after the other parameters have been refined. Therefore, each point of the grid is the result of an independent refinement. Scattering paths have not been recalculated at each point. Nonetheless, phase and amplitude functions can be regarded as quite accurate in an interval of ±0.2 Å around the contour plot centre. Each minimum of the χ^2 surface is a possible solution to our problem. Contour plots reported in Figures 6, 7, and 8 have been calculated by three different refinement procedures: a) Without constraints; b) With constraints, but limiting the refinement up to 3 Å and thus excluding an isolated large peak between 3 and 4 Å; c) With a constrained refinement up to 4 Å (no contribution is present above 4 Å). Contour plots are presented only for R = adam, CH_2Ph, and Me (Figures 6, 7, and 8, respectively), since they are more representative. Inspection of these plots shows that most contain several minima. For R = adam (Figure 6, a, b, and c), there are always two close minima. They correspond to the interchange of the axial distances (adam at r_1 and py at r_2 or vice versa). The same happens for R = CH_2Ph and Me, as will be discussed later in detail. Looking at Figure 6 (a), two equivalent minima are present. Since C and N are very similar species for EXAFS, swapping the two atoms gives the same solution. If it is important to know at which distance py and adam are, a differentiation between ligands is essential. Constrained refinement is the best tool to differentiate the ligands, but it works only if the interval chosen to make the fit contains significant different contributions from the two ligands. Thus, by refinement b (Figure 6, b) two equivalent minima were found, since the most significant differences between adam and py are above 3 Å. Between 3 and 4 Å, MS is dominant and different geometries can play a significant role. In fact, in plot c, two minima are present, but one is significantly lower than the other. On a statistical basis, it is possible to determine without ambiguity the distance from the metal of each ligand. This means that we can truly distinguish between adam and py. Considering R = CH_2Ph (Figure 7), the maps are more difficult to analyze. At least four minima are present in the centre of map *a*. They can be grouped as follows [Co−C(CH_2Ph); Co−N(py)] ≈ (2.03; 2.08), (2.1; 2.02) and ≈ (1.85; 2.05), (2.05; 1.78). The first two minima correspond approximately to the exchange of the two ligands, as already described for R = adam. The other two

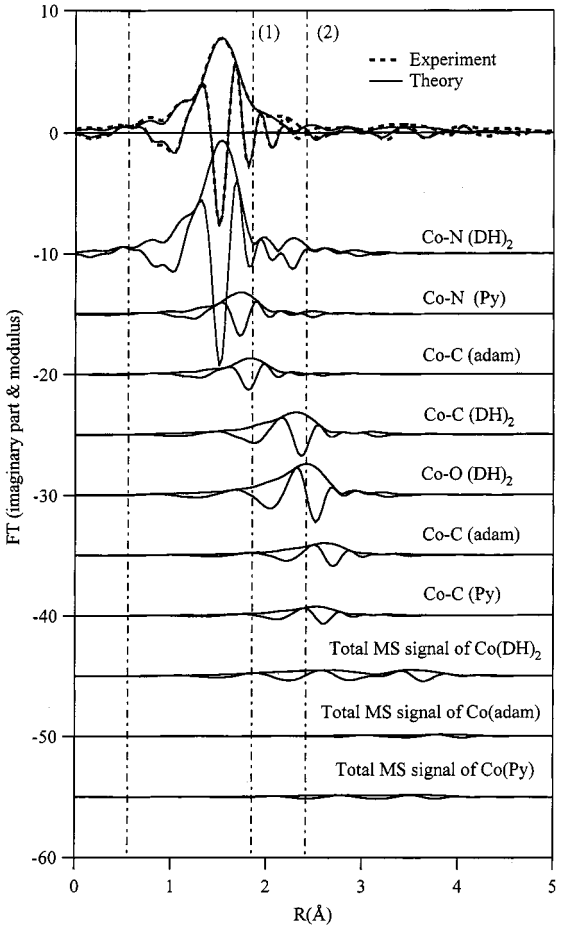

Figure 4. R = adam: comparison of FT (not phase corrected) of experimental and theoretical spectra; all contributions to the total theoretical signal are presented below, ranked for increasing frequency. MS contributions are grouped; spectra are shifted for clarity

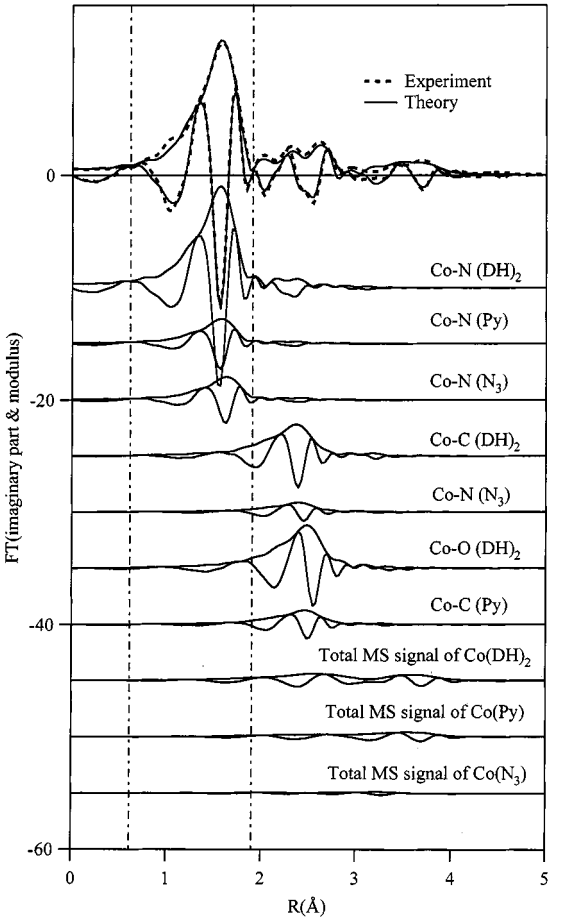

Figure 5. R = N_3: comparison of FT (not phase corrected) of experimental and theoretical spectra; all contributions to the total theoretical signal are presented below, ranked for increasing frequency; MS contributions are grouped; spectra are shifted for clarity

minima correspond to an almost correct position for one of the two axial ligands, while the other is "pushed" into the contribution of the four $N(DH_2)$ donors. Actually, this distance is even shorter than that of $Co-N(DH_2)$. The reasons for the existence of such minima can easily be explained. They are due to the fact that, while fitting the contributions of each atom independently, the $Co-C(CH_2Ph)$ contribution can be masked by the four $Co-N(DH_2)$. A small displacement of the latter and of the Co−N(py) distance then compensates for this error. If the displacement of the atoms in the first shell is linked with that of the bonded atoms and the contributions of the latter are not negligible, this rearrangement is no longer possible. Minima are then better defined, and false minima tend to disappear. For instance, compare plot a with plot b and plot c of Figure 7. Refinement c leads to a marginal improvement, and removes the minimum at $[Co-C(CH_2Ph); Co-N(py)] \approx (1.78; 2.03)$ that can be still obtained by refinement b, but it is possible to discard this solution by the *F*-test. It is worth noting that these "low-distance minima" are also present in Figure 6. These minima are at the lower limits of the map and at a high χ^2 value. In fact, Co−L and Co−R distances for R = adam are longer than for R = CH_2Ph. Thus, they are easier to distinguish and exhibit a poorer correlation with $Co-N(DH_2)$. When R = Me, it is difficult to distinguish py and Me (see minima in Figure 8, a and b) and only with refinement c (when all MS involving the atoms of py are included), can a precise minimum close to XRD results be obtained (see Figure 8, c). Note that in the contour plots for all R (Me, py, CH_2Ph) minima appear at higher distances too. They are always at map upper limits and not perfectly distinguishable, but most likely they correspond to those reported by Champloy et al.[12] The analysis of such far minima is beyond the scope of this paper, since a more complex procedure involving recalculation of scattering paths during refinements should be employed. Work will be carried out in this direction in the future to produce a more flexible and rigorous EXAFS analysis code. However, these far minima appear to be close to the NNN positions. Thus, the explanation is similar to that suggested for the lower distance minima visible in Figure 7 (a).

The approximation of keeping the distance of one axial ligand fixed to an average value obtained from similar structures, while mapping the other, has been reported in

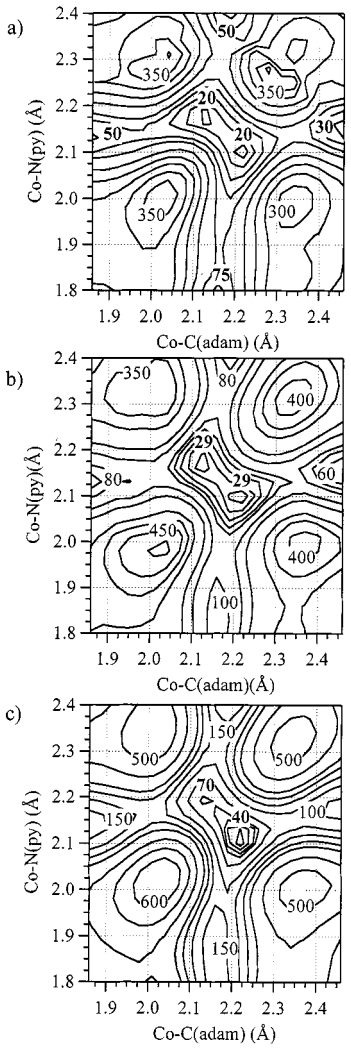

Figure 6. R = adam: contour plots obtained with refinements a, b, and c (see text for details); in case (c) one of the two local minima can be discarded and the axial ligands are distinguishable

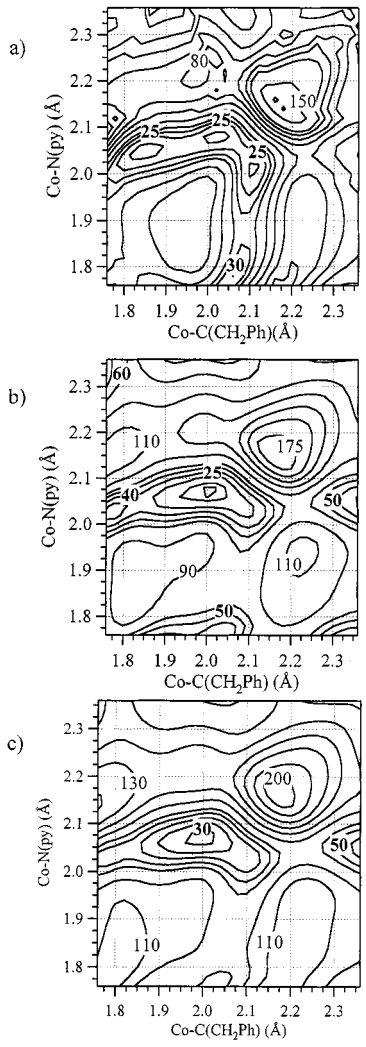

Figure 7. R = CH_2Ph: contour plots obtained with refinements a, b, and c; refinements b and c are almost equivalent (see text for details)

literature.[12] Without questioning the chemical validity of such an assumption, it must be pointed out that in many cases this is risky. In fact, the position of a ligand directly influences the position found for the others. The χ^2 curves obtained by varying the Co−C(Ch_2Ph) distance for different values of the Co−N(py) distance are shown in Figure 9. Co−N(py) values are only 0.02 Å apart, but different χ^2 profiles are obtained. It is apparent that the choice of the "best" minimum for Co−C(Ch_2Ph) distance depends on the value chosen for the Co−N(py) distance (unconstrained refinement).

Finally, with refinement c, answers can be found to such questions as: Is py bonded to Co for R = Cl? Is Me bonded to Co for R = Me? Limiting the analysis to the first shell, the probability of obtaining the presence or absence of the axial ligand (Me, when R = Me; py, when R = Cl) is about 50%. With refinement *c*, the probability that py and Me are bonded (at the correct distance) is at least 75%.

Conclusion

Although the constrained refinement gives an accuracy of about 0.05 Å on the axial distances and an overall correct picture of the actual structure, multiple solutions have been found in some cases. Accordingly to Scheuring et al.,[11] the mapping technique provides a valuable tool to rationalize discrepancies between EXAFS and XRD. It has been shown that multiple minima can be eliminated or discriminated in most cases. The mapping technique plays an essential role in indicating a correct solution and this option should be included in all advanced EXAFS data-analysis codes, together with an advanced constrained/restrained refinement. The principal challenge in fitting EXAFS data of complex systems will be to determine the relevant degrees of freedom of the studied structures and to relate them to as many EXAFS parameters as possible. Thus, the task now is to write codes to integrate ab initio EXAFS calculations,

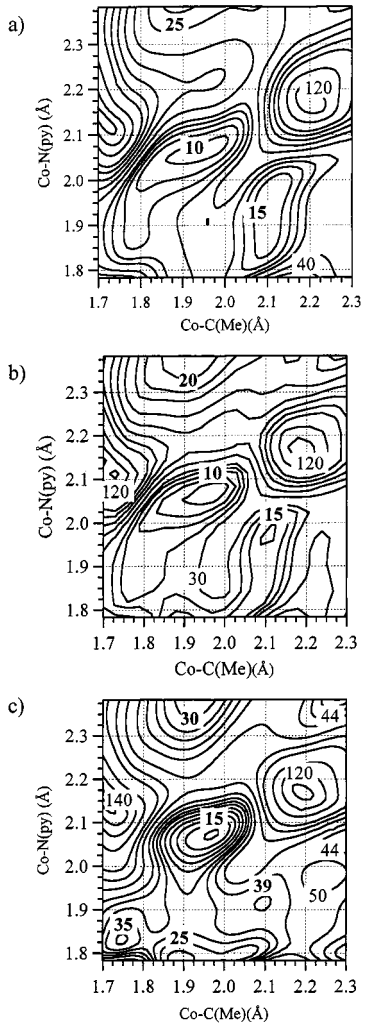

Figure 8. R = Me: contour plots obtained with refinements a, b, and c are shown (see text for details); refinement c is necessary to make the ligands distinguishable

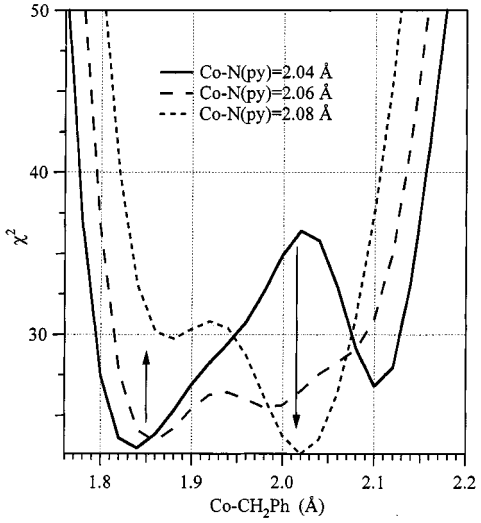

Figure 9. R = CH_2Ph: The χ^2 profile was obtained by varying the Co−CH_2Ph distance for three Co−N(py) values; for very similar values of the latter distance, different values for the Co−CH_2Ph distance were obtained (see position of the minima); arrows indicate minima modifications when the Co−N(py) distance is varied

refinement, and molecular modelling tools, and to make them accessible to the community.

Experimental Section

All reagents and chemicals were commercial products and were used as received. $Co(DH)_2(Py)Cl$,[31] $Co(DH)_2(Py)N_3$,[32] $Co(DH)_2(Py)Me$[32], and $Co(DH)_2(Py)(CH_2Ph)$[33] were synthesized according to reported methods. All these complexes were recrystallized from methanol/H_2O and their purity confirmed by elemental analysis. $Co(DH)_2(Py)$(adamantyl) was obtained by a modification of the synthetic procedure previously reported for the analogous compounds having aniline or 4-dimethylpyridine as axial bases.[22e] Aqueous NaOH solution (2 pellets in 5 mL) was added, with stirring, to dissolve a suspension of $Co(DH)_2(Py)Cl$ (0.8 g, 2 mmol) in methanol (200 mL). While flushing with nitrogen, a suspension of $NaBH_4$ (0.11 g, 3.0 mmol) in water (1 mL) was added, followed by solid 1-iodoadamantane (Aldrich, 1.05 g, 4 mmol). After the solution was vigorously stirred for 40 min, the stream of nitrogen was stopped. The volume of the solution was reduced to ca. 20 mL on a rotary evaporator and the unchanged 1-iodoadamantane was removed by filtration. H_2O (50 mL) was added to the remaining solution, and the red−brown crystals of the desired compound precipitated. The solid was collected by filtration, air dried, and washed with diethyl ether (3 × 10 mL), to remove the residual 1-iodoadamantane. The product was recrystallized by the addition of water to a methanolic solution. Yield 40%. − $C_{23}H_{34}CoN_5O_4$ (503.5): calcd. C 54.9, H 6.81, N 13.9; found C 54.5, H 6.55, N 13.7. − EXAFS data were recorded in the transmission mode at the LURE laboratory (Orsay, France) on beam-line EXAFS-IV in 1999, except for the sample R = adamantyl, which was recorded on EXAFS-1 (now EXAFS-13) in 1994. On beam-line EXAFS-IV, ion chambers were filled with a He/Ne mixture and harmonics were rejected by detuning the two crystals of the Si(331) monochromator. On EXAFS-1, where a Si(331) channel-cut monochromator was the only choice, and no mirrors were available, ion chambers were filled with air to reduce harmonic contamination to a negligible extent. All data were collected at liquid nitrogen temperature. During data analysis, the EXAFS signal $\chi(k)$[34] was multiplied by the cube of the wave-vector modulus $[k^3\chi(k)]$ to balance the decay of the signal due to thermal disorder. Best results were obtained using this weighting, which in some way extends the effective signal range when the signal-to-noise ratio is sufficiently high. Excellent data sets were obtained (see Figure 2). Using a k^0 or k^1 weighting, the signal decayed so quickly that the last part had a small influence on χ^2, and information was partially lost.[16] EXAFS spectra were multiplied by a Hanning window with k_{min} = 3.65 Å^{-1}, k_{max} about 17 Å^{-1} (from 16.5 to 17.5 depending on sample), Δk_{sills} = 2 (except for R = adam: k_{min} = 3.65 Å^{-1}, k_{max} = 14 Å^{-1} Δk_{sills} = 1 Å^{-1}). Fits were performed in *r*-space. We also checked that *k*-space and *r*-space fits did not give results that differed by more than the estimated error bar. Data analysis was carried out on a Red Hat Linux 6.0 powered PC with the UWXAFS suite[35] (Autobk 2.61 and Feffit 2.52 h, version 2.54 for *k*-space fitting) and theoretical standards were obtained using FEFF 7.0.[36] Molecular-modelling structures were obtained from the CSD database, and analyzed with the help of ChemOffice by CambridgeSoft on an iMac. To interface the CSD database and ChemOffice with FEFF 7.0, the Crystalff code was used.[37] The χ^2 maps were obtained using a Perl script to run Feffit on the desired grid points and to archive the results. Contour plots were drawn using Igor Pro 3.0 by WaveMetrics Inc.

Acknowledgments

We thank the Ministero della Ricerca Scientifica e Tecnologica (Roma) (PRIN9803184222) and Consiglio Nazionale delle Ricerche (CNR) for financial support. We are grateful to Dr. K. Provost for code Crystallf, Dr. M. Newville for providing latest improved versions of his Feffit code (2.52 h and 2.54). We acknowledge Dr. F. Champloy for helpful discussions, and the teams of beam-lines EXAFS-13 and EXAFS-IV of LURE for assistance during measurements.

cis-Octahedral Nickel(II) Complexes with Symmetric and Unsymmetric Tripodal Tetraamine Ligands

Christian Ochs,[a] F. Ekkehardt Hahn,*[b] and Thomas Lügger[b]

Keywords: Tripodal ligands / Nickel / Structure elucidation / UV/Vis spectroscopy

Nickel(II) complexes with the aliphatic tripodal tetraamine ligands $N(CH_2CH_2NH_2)_3$ (tren, **1**), $N[(CH_2CH_2CH_2NH_2)(CH_2CH_2NH_2)_2]$ (baep, **2**), $N[(CH_2CH_2CH_2NH_2)_2(CH_2CH_2NH_2)]$ (abap, **3**), and $N(CH_2CH_2CH_2NH_2)_3$ (trpn, **4**) are reported. The tripodal tetradentate N_4 ligands **1**–**4** react with $Ni(NO_3)_2{\cdot}6H_2O$ in acetonitrile or methanol to give the blue nickel(II) complexes $[Ni(\mathbf{1})(\eta^1\text{-}NO_3)_2]$ (**5a**), $[Ni(\mathbf{2})(\eta^1\text{-}NO_3)_2]$ (**5b**), $[Ni(\mathbf{3})(\eta^2\text{-}NO_3)]NO_3{\cdot}CH_3CN$ (**5c**·CH_3CN), and $[Ni(\mathbf{4})(\eta^2\text{-}NO_3)]NO_3{\cdot}CH_3OH$ (**5d**·CH_3OH). With $NiCl_2{\cdot}6H_2O$, the complexes $[Ni(\mathbf{1})Cl(H_2O)]Cl{\cdot}H_2O$ (**6a**), $[Ni(\mathbf{2})(\mu\text{-}Cl)_2Ni(\mathbf{2})]Cl_2{\cdot}2CH_3OH$ (**6b**·$2CH_3OH$), $[Ni(\mathbf{3})Cl(H_2O)]Cl$ (**6c**), and $[Ni(\mathbf{4})(H_2O)_2]Cl_2{\cdot}H_2O$ (**6d**·H_2O) are obtained. The molecular structures of complexes **5a**–**d** and **6b**–**d** have been determined by X-ray diffraction analysis and they are compared with the molecular structure of the previously characterized complex **6a**. Complexes **5a**–**d** and **6b**–**d** exhibit octahedrally coordinated nickel atoms. The tripodal ligands occupy four of the six coordination sites in a *pseudo-facial* manner. Complexes of the unsymmetrical ligands **2** and **3** possess both five- and six-membered chelate rings. The extension of the ligand arms in **1**–**4** leads to a systematic variation in the geometric and UV/Vis spectroscopic properties of the complexes depending on the size of the chelate rings formed by the ligands.

Introduction

The sterically unhindered tripodal tetraamine ligand tren (**1**) is known to form a large number of coordination compounds with different metal ions. Comparatively little is known about the coordination chemistry of the unsymmetric higher tren homologues, e.g. bis(2-aminoethyl)(3-aminopropyl)amine (baep, **2**), (2-aminoethyl)bis(3-aminopropyl)amine (abap, **3**), and the symmetric tris(3-aminopropyl)amine (trpn, **4**) (Figure 1).

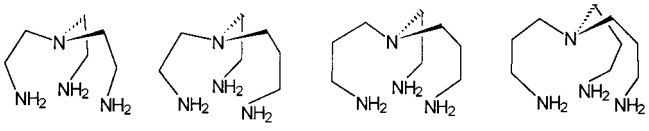

Figure 1. Topology of the tripodal tetraamine ligands studied

Complexes of Ni^{II} with **1** were first described in 1926.[1] Since then, various monomeric octahedral,[2–5] trigonal-bipyramidal,[6–9] and dinuclear coligand-bridged octahedral[10–12] Ni^{II} complexes of **1** or its hexamethylated analogue Me_6tren have been reported. Thermochemical and spectroscopic studies of aqueous solutions of Ni^{II} complexes of **4** have indicated that these complexes are octahedral.[13,14] However, the precise molecular structures of the (trpn)Ni^{II} complexes remain unknown. Nickel complexes of the unsymmetric ligands **2** and **3** have not hitherto been described.

The stepwise insertion of a CH_2 group into each of the ligand arms in **1** leads to the ligands **2**–**4**.[15–17] Compared to **1**, these ligands possess an unchanged set of donor groups with expanded linkers between them. This slight topological variation has profound consequences. Ligands **2**–**4** are more basic than **1**,[17] since the ammonium groups formed upon protonation are further apart in these ligands than they would be in tren. The geometric parameters of the five- and six-membered chelate rings that could be formed by **2**–**4** have been analyzed and it was concluded that for complexes with both macrocyclic and non-macrocyclic ligands, an increase of the chelate ring size from five-membered to six-membered will increase the stability of complexes of smaller relative to larger metal ions.[18]

A systematic study of these contradicting effects was carried out with a complete series of Cu^{II} complexes with the ligands **1**–**4**.[16a,17,19] Depending on the ligand topology, these complexes adopt either a trigonal-bipyramidal or a distorted square-pyramidal geometry.[16,17]

The stability constants of the copper complexes were found to decrease systematically over five orders of magnitude depending on the number of six-membered chelate rings present.[17] Studies on the octahedral Co^{III} complexes with **1**,[20] **2**,[16b] **3**,[15] and **4**[20] revealed differences in the catalytic activities of these complexes in the hydrolysis of phosphate esters. It would appear that the stability and reactivity of complexes with tripodal tetraamine ligands may be controlled and significantly manipulated by the ligand topology if the governing principles are fully understood. This might ultimately prove useful for the modelling of nitrogen-rich active sites in metalloproteins. To study the con-

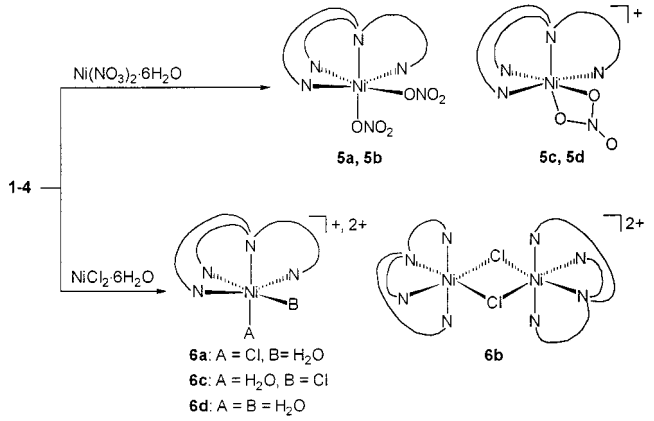
sequences of a variation of the ligand topology of tripodal tetraamines with respect to the properties of octahedral metal complexes, we have prepared the Ni^{II} complexes of **1−4**. It was assumed that octahedral complexes with two monodentate coligands in *cis* positions would be formed. Furthermore, we have studied the effects of the counterions by preparing two series of complexes starting from $NiCl_2{\cdot}6H_2O$ and $Ni(NO_3)_2{\cdot}6H_2O$. The molecular structures and spectroscopic properties of the nickel complexes obtained are compared with the data for the previously characterized nickel complex with the ligand tren $[Ni(\mathbf{1})Cl(H_2O)]Cl{\cdot}H_2O$ (**6a**).[2]

Results and Discussion

Seven new octahedral Ni^{II} complexes with the symmetric and unsymmetric tripodal tetraamine ligands **1−4** have been synthesized and structurally characterized. Depending on the ligand topology, complexes of type **5** (Scheme 1) contain either two η^1-coordinated nitrate ions or an η^2-coordinated nitrate ion and a nitrate counterion. A second series of complexes **6** has been synthesized from ligands **1−4** and nickel dichloride in water. In this series, the complex **6a** with the ligand **1** has been described previously.[2] In both series, the ligand topology is systematically varied by the stepwise insertion of methylene groups into the ligand arms. The structural and spectroscopic trends observed in the two series are discussed below.



Scheme 1. Preparation of Ni^{II} complexes of ligands **1−4**

Improved Synthesis of Bis(2-aminoethyl)(3-aminopropyl)-amine (2)

The previously described preparation of **2**,[16a] by addition of 1 equiv. of acrylonitrile to ammonia followed by Strecker synthesis, reaction of the resulting dinitrile with glyconitrile ($HOCH_2CN$),[21] and finally reduction of the trinitrile with AlH_3, has not always given satisfactory results. The critical step has proved to be the condensation reaction of the dinitrile with $HOCH_2CN$ for the introduction of the third ligand arm at the central nitrogen atom. Under the conditions described, the reaction often yields polymeric products with the desired trinitrile present only in trace amounts. We assume that this is due to the low basicity of the central nitrogen atom of the dinitrile precursor. It is known that α-cyanomethyl and β-cyanoethyl groups at a nitrogen atom markedly lower its basicity.[22] Under such conditions, decomposition and self-condensation reactions of the glyconitrile are favored over the condensation reaction with the amine. Consequently, the only possible means of enhancing the condensation reaction is through activation of the glyconitrile. This is best achieved by tosylation and tosylated glyconitrile can easily be prepared from glyconitrile and *p*-toluenesulfonyl chloride.[23] The condensation reaction of $TsOCH_2CN$ with $HN(CH_2CN)(CH_2CH_2CN)$ proceeds at 50 °C in DMF within 5 d. The resulting ammonium salt was converted into the free amine with aqueous sodium carbonate. The crude product could be recrystallized from hot chloroform. As reported previously,[16] ligand **2** is obtained from the trinitrile by hydrogenation with AlH_3.

Preparation of Nickel Complexes

Addition of stoichiometric amounts of the tripodal ligands **1−4** to solutions of $Ni(NO_3)_2{\cdot}6H_2O$ in methanol or acetonitrile gives deep-blue solutions, from which the complexes $[Ni(N_4)(\eta^1\text{-}NO_3)_2]$ (**5a**: N_4 = **1**; **5b**: N_4 = **2**) and $[Ni(N_4)(\eta^2\text{-}NO_3)_2]NO_3{\cdot}X$ (**5c**: N_4 = **3**, X = CH_3CN; **5d**: N_4 = **4**, X = CH_3OH) can be crystallized by slow diffusion of gaseous diethyl ether into them. Reactions of **1−4** with

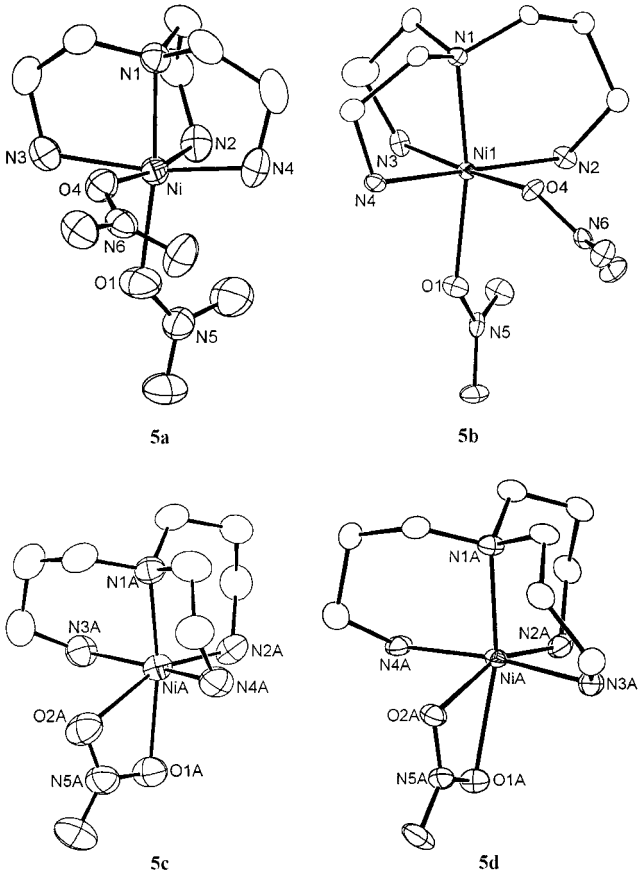


Figure 2. ORTEP plots of complexes **5a** and **5b** and of the cations in complexes **5c** and **5d**; solvent molecules and counterions in **5c** and **5d** have been omitted for clarity

$NiCl_2 \cdot 6H_2O$ in acetonitrile or methanol yield complexes $[Ni(N_4)Cl(H_2O)]Cl$ (**6a**: N_4 = **1**;[2] **6c**: N_4 = **3**), $[Ni(N_4)(\mu\text{-}Cl)_2(N_4)Ni]Cl_2 \cdot 2CH_3OH$ (**6b**: N_4 = **2**), and $[Ni(N_4)(H_2O)_2]Cl_2$ (**6d**: N_4 = **4**). Crystallization of the complexes was achieved in the same manner as described for **5a**−**d**, or by slowly concentrating a methanolic solution. With acetonitrile as the solvent, all the complexes were found to be air-stable and soluble in water. A schematic representation of complexes of types **5** and **6** is presented in Scheme 1.

Molecular Structures of the Nitrate Salts

The molecular structures of complexes **5a**−**d** have been determined by X-ray diffraction methods. In all cases, *cis*-octahedral complexes were formed. As can be seen from Figure 2, the main difference between the complexes lies in the coordination mode of the nitrate anions. In **5a** and **5b**, the *cis*-octahedral coordination is completed by two η^1-coordinated nitrate anions, while in both **5c** and **5d** only one η^2-coordinated nitrate anion is found.

This difference arises from differences in the steric bulk and demand of the coordinated tripodal tetraamines. The relationship between steric demand of the coordinated tetraamine and the coordination mode of the nitrate anions is best reflected in the $N_{tert}-Ni-NH_2$ angles. Complex **5a** contains only five-membered chelate rings and all the $N_{tert}-Ni-NH_2$ angles are smaller than 90° (Table 1). The larger six-membered chelate rings in **5d** lead to $N_{tert}-Ni-NH_2$ angles that are all larger than 90°. Complexes **5b** and **5c**, containing both five- and six-membered chelate rings, are intermediate between these limiting cases with $N_{tert}-Ni-NH_2$ angles larger than 90° for the six-membered rings and smaller than 90° for the five-membered ones. A similar relationship between the $N_{tert}-Cu-NH_2$ angles and the different chelate ring sizes has been described for trigonal-bipyramidal[16a] and tetragonal-pyramidal[17] copper complexes. As a consequence of this geometrical situation, the size of the cavity left for coligands decreases on going from **5a** to **5d**. In **5a** and **5b**, it is still large enough to accommodate two monodentate nitrate anions, while in **5c** and **5d** only one bidentate nitrate anion can fit into the cavity and the second nitrate anion is left uncoordinated as a counterion. Not only the number of coordinated nitrate anions, but also the Ni−O distances are at least partially determined by the topology of the tripodal tetraamine. The shortest Ni−O distance [2.075(3) Å] is observed for **5a** and, as expected, the largest values [2.224(4) Å and 2.195(4) Å] are found in **5d**. It would appear that this is not exclusively due to steric effects. In complexes **5a**, **5b**, and **5c**, the shorter of the two Ni−O distances is found *trans* to the tertiary nitrogen atom of the tripod, while the longer one is found *trans* to a primary amine group [2.075(3) Å vs. 2.280(2) Å for **5a**, 2.087(3) Å vs. 2.171(3) Å for **5b**, 2.139(4) Å vs. 2.280(4) Å and 2.147(4) Å vs. 2.216(4) Å for **5c**; Table 1]. This trend is reversed in **5d**, where the shorter Ni−O distance in each of the two independent molecules in the asymmetric unit lies *trans* to a primary amine group [2.174(4) Å vs. 2.224(4) Å and 2.168(4) Å vs. 2.195(4) Å]. Moreover, the differences in the Ni−O distances (Ni−O *trans* to N_{tert} vs. Ni−O *trans* to NH_2) diminish in the series of complexes on going from **5a** (0.205 Å) to **5c** (0.141 Å and 0.069 Å) and are finally reversed in **5d** (0.05 Å and 0.027 Å). We explain this observation in terms of an increase in the basicity of the central nitrogen atom of the tripodal ligands. The basicity of N_{tert} increases from $pK_a < 2$ for **1** to $pK_a = 5.8$ for **4**, while the basicity of the primary amine groups remains essentially unchanged.[17] The diminishing difference in the basicities of the primary and tertiary amine functions in **1** to **4** leads to a less pronounced difference in the Ni−O distances *trans* to N_{tert} and *trans* to the NH_2 groups. While the Ni−O bond *trans* to the tertiary amine becomes longer on going from **5a** to **5d**, the Ni−O bond length *trans* to a primary amine group changes less and ultimately becomes shorter than the Ni−O bond *trans* to N_{tert} in the case of **5d**. From this, it can be concluded that the ligand topology in complexes **5a**−**d** determines both the steric and, to a lesser extent, the electronic situation at the metal center.

Molecular Structures of the Chloride Salts

The molecular structures of complexes **6b**−**d** are depicted in Figure 3. Again, *cis*-octahedral complexes with chloride or water coligands were formed. It would appear that the distribution of the coligands among the two free coordination sites at the nickel atom is random and seemingly depends on the conditions used for crystallization of the complexes. Complex **6b**, which was obtained by slow concentration of a methanolic solution, crystallizes as a dinuclear species where two bridging chloride atoms complete the octahedral coordination environments at the nickel atoms. On the other hand, **6c** and **6d** were crystallized by diffusion of diethyl ether into acetonitrile solutions and are mononuclear complexes. In complex **6c**, a water molecule occupies the *trans* position and a chloride ion the *cis* position relative to N_{tert}, while in **6d** two coordination sites at nickel are occupied by water molecules. The series is completed by compound $[Ni(\mathbf{1})Cl(H_2O)]Cl \cdot H_2O$ (**6a**).[2] Its molecular structure was first investigated by Jørgensen in 1956.[24] On the basis of its electronic spectra in aqueous solution, it was suggested that **6a** should be formulated as $[Ni(\mathbf{1})(H_2O)_2]Cl_2$. Some years later, it was shown that it is $[Ni(\mathbf{1})Cl(H_2O)]Cl \cdot H_2O$ in the solid state,[2] while $[Ni(\mathbf{1})(H_2O)_2]^{2+}$ cations exist in water. Interestingly, in the solid state, the coordination of the monodentate ligands in **6a** (Cl *trans* to N_{tert}) is exactly opposite to that found in **6c** (Cl *cis* to N_{tert}).

As for the nitrate salts **5**, certain bonding parameters of the tripodal tetraamine in complexes **6** (Table 2) are strongly dependent on the topology of the ligand. The $N_{tert}-Ni-L_{trans}$ axis is essentially linear for all complexes of type **6**. As for the nitrate complexes, the $N_{tert}-Ni-N_{cis}$ angles are smaller than 90° for five-membered chelate rings and larger than 90° for six-membered rings.

In contrast to the nitrate complexes of type **5**, the monodentate ligands in complexes **6** are sterically non-demanding. The distances between the nickel atoms and these ligands allow an evaluation of the dependence of the *trans*

[a] Data from ref.[2]

effect of the different amine groups of the tripodal tetraamine on the ligand topology. For two identical monodentate ligands, as found in **6b** (Cl^-) and **6d** (H_2O), the following trends were found. In **6b**, containing the ligand **2**, the bond to the monodentate ligand *trans* to N_{tert} [Ni−Cl1 2.4449(6) Å] is shorter than that to the ligand *cis* to N_{tert} [Ni−Cl1* 2.4840(6) Å]. This situation is reversed in **6d**, containing ligand **4** with an increased basicity of the central nitrogen atom.[17] In **6d**, the distance to the ligand *cis* to N_{tert} [Ni−O2 2.165(3) Å] is shorter than that to the ligand *trans* to N_{tert} [Ni−O1 2.174(3) Å]. However, even the increase in the basicity of the tertiary nitrogen atom on going from **1** to **4** does not lead to a shortening of the N_{tert}−Ni distance in either series of complexes due to the concomitant increase in the number of sterically less favored six-membered chelate rings.

UV/Vis Spectra

A d^8 ion like Ni^{II} in an octahedral ligand field gives rise to four absorption bands.[25] The three strongest ones are caused by the spin-allowed transitions from the ground state $^3A_{2g}$ to the excited triplet states $^3T_{2g}$, $^3T_{1g(F)}$, and $^3T_{1g(P)}$. A weaker band of low intensity can be attributed to the spin-forbidden transition to the singlet state ^1E_g. In practice, it is seldom observed as a discrete band, but more often as a shoulder of the $^3A_{2g} \rightarrow {}^3T_{2g}$ transition band at about 800 nm.[26,27]

For complexes of types **5** and **6**, three distinct absorption bands are observed. The transitions from $^3A_{2g}$ to the $^3T_{1g(P)}$ and $^3T_{1g(F)}$ excited states appear as sharp bands of high

intensity in the regions 350−380 nm and 560−620 nm, respectively, whereas the absorption band at about 950−1100 nm, due to the $^3A_{2g} \rightarrow {}^3T_{2g}$ transition, is broad and of low intensity. A shoulder at about 800 nm is found for complexes **5a**,**b** and **6a**,**b**, while for the rest of the complexes this feature seems to be superimposed by the long-wavelength $^3A_{2g} \rightarrow {}^3T_{2g}$ transition. The exact values for the absorption maxima and the molar extinction coefficients are listed in Table 3.

[a] Data from ref.[2] − [b] Complex **6a** synthesized for this study.

One of the most notable results is the observation of a bathochromic shift with increasing number of six-membered chelate rings. This can be ascribed to the weaker ligand field generated by the six-membered chelate rings, which are known to be less stable than five-membered chelate rings.[17,28] Thus, the distance between the energy sublevels is decreased and the transitions are seen to be shifted to longer wavelengths.

Conclusion

With complexes **5a**−**d** and **6b**−**d** we present seven new complexes forming two series of octahedral Ni^{II} complexes with aliphatic tripodal tertraamine ligands. The series **6b**−**d** is completed by compound **6a**, which has previously been characterized by Marzotto et al.[2] The variation of the lengths of the ligand arms leads to complexes with different size chelate rings. This causes a distortion of the octahedral coordination environment, a variation in the space available for binding and in the strengths of the bonds to monodentate coligands, and a slight shift of the absorption maxima in the UV/Vis spectra. These effects will allow, at least in part, control over the binding of monodentate ligands depending on the topology of the tripodal tetraamine without a change in the nature of the donor groups. Ligands **1**−**4** might therefore prove useful for the introduction of minute changes in the modelling of amine-rich reaction centers in metalloproteins.

Experimental Section

Materials and Methods: All manipulations were carried out under air. Solvents were purified by standard methods and freshly distilled prior to use. − Infrared spectra were recorded from samples in KBr with a Perkin−Elmer IR 983 instrument. − Elemental analyses (C, H, N) were performed with a Vario EL Elemental Analyzer. − FAB mass spectra were recorded with Finnigan MAT 112 or Finnigan MAT 711 instruments. − UV/Vis spectra were recorded in methanol with a Perkin−Elmer Lambda 9 UV/Vis NIR spectrophotometer.

Ligand Syntheses: Tris(2-aminoethyl)amine (**1**) was purchased from Aldrich and was used without further purification. Ligands **2**, **3**, and **4** were synthesized according to the method of Dittler-Klingemann and Hahn.[16a] Alternatively, ligand **3** can be prepared by the method of Fanshawe and Blackman.[15] We preferred the preparation outlined in ref.[16] since the free ligand and not the hydrochloride is initially obtained in this preparation. For the present study, the synthesis of **2** was slightly modified compared to the published procedure.[16a]

Modified Preparation of Bis(2-aminoethyl)(3-aminopropyl)amine (2): Ligand **2** has previously been obtained by Michael addition of acrylonitrile to ammonia followed by a Strecker synthesis to yield the dinitrile $HN(CH_2CN)(CH_2CH_2CN)$. The addition of a second $-CH_2CN$ group to the central nitrogen atom using glyconitrile ($HOCH_2CN$) proved more difficult and very often failed due to reasons not yet fully understood. However, reaction of the dinitrile $HN(CH_2CN)(CH_2CH_2CN)$ with $TsOCH_2CN$[23] in DMF at 50 °C over a period of 5 d yielded the salt of the desired trinitrile, $[HN(CH_2CN)_2(CH_2CH_2CN)]OTs$. On addition of an excess of aqueous sodium carbonate and cooling the resulting mixture to 5 °C, colorless crystals of $N(CH_2CN)_2(CH_2CH_2CN)$ separated within a few days. The crude product could be recrystallized from hot chloroform. Reduction of the trinitrile with AlH_3 as described previously[16a] gave bis(2-aminoethyl)(3-aminopropyl)amine (**2**) in 64% yield.

Preparation of Nickel Complexes from $Ni(NO_3)_2$·6H_2O: The preparation of **5a** is described as an example. $Ni(NO_3)_2$·6H_2O (290 mg, 1 mmol) was dissolved in acetonitrile (5 mL) and then ligand **1** (146 mg, 1 mmol) was added dropwise by means of a syringe. The blue solution thus obtained was stirred at room temperature for 30 min, filtered, and concentrated to a volume of 3 mL. Slow diffusion of diethyl ether into the flask led to the deposition of dark-blue crystals of **5a**, which proved to be suitable for X-ray crystallography without the need for recrystallization. The air-stable crystals were collected by filtration, washed with diethyl ether, and carefully dried. This procedure could also be carried out in methanol.

5a: Yield 263 mg [80% based on $Ni(NO_3)_2$·6H_2O]. − $C_6H_{18}N_6NiO_6$ (329.0): calcd. C 21.91, H 5.52, N 25.55; found C 22.18, H 5.40, N 24.93. − MS (FAB, positive ions, DMSO/glycerol): *m*/*z* (%) = 266 (83) $[Ni(\mathbf{1})(NO_3)]^+$, 203 (100) $[Ni(\mathbf{1}) - H]^+$, 58 (6), 44 (53).

5b: Yield 255 mg [74% based on $Ni(NO_3)_2$·6H_2O]. − $C_7H_{20}N_6NiO_6$ (343.0): calcd. C 24.51, H 5.88, N 24.50; found C 24.31, H 5.80, N 24.38. − MS (FAB, positive ions, DMSO/glycerol): *m*/*z* (%) = 280 (100) $[Ni(\mathbf{2})(NO_3)]^+$, 217 (90) $[Ni(\mathbf{2}) - H]^+$, 58 (13), 44 (60).

5c·CH_3CN: Yield 278 mg [78% based on $Ni(NO_3)_2$·6H_2O] of slightly air-sensitive (loss of solvent) crystals. − $C_{10}H_{25}N_7NiO_6$ (398.1): calcd. C 30.18, H 6.33, N 24.63; found C 30.25, H 6.37, N 24.39. − MS (FAB, positive ions, DMSO/glycerol): *m*/*z* (%) = 294 (84) $[Ni(\mathbf{3})(NO_3)]^+$, 232 (100) $[Ni(\mathbf{3}) - H]^+$, 174 (48), 143 (30), 58 (37), 44 (48).

5d·CH_3OH: Yield 269 mg [72% based on $Ni(NO_3)_2$·6H_2O] of slightly air-sensitive (loss of solvent) crystals. − $C_{10}H_{28}N_6NiO_7$ (403.1): calcd. C 29.80, H 7.00, N 20.85; found C 29.77, H 6.94, N

20.70. − MS (FAB, positive ions, DMSO/glycerol): *m/z* (%) = 308 (38) [Ni(**4**)(NO_3)]$^+$, 245 (56) [Ni(**4**) − H]$^+$, 143 (26), 58 (75), 44 (38).

Preparation of Nickel Complexes from $NiCl_2$·$6H_2O$: The preparation of the previously synthesized[2] **6a** is described as an example. To a solution of $NiCl_2$·$6H_2O$ (236 mg, 1 mmol) in methanol (5 mL) was added **1** (146 mg, 1 mmol). After stirring for 30 min at room temperature, the mixture was concentrated to a volume of 3 mL. To initiate crystallization, 1 mL of acetonitrile and a few drops of diethyl ether were added to the concentrated mixture and the resulting purple-blue solution was cooled to 5 °C. After a few hours, needle-shaped crystals had formed, which were collected by filtration and washed with diethyl ether. Recrystallization from methanol by slowly concentrating the solution gave blue, plate-shaped crystals suitable for X-ray analysis.

6a: Yield 132 mg (45% based on $NiCl_2$·$6H_2O$). − $C_6H_{20}Cl_2N_4NiO$ (only directly coordinated water was left after drying, 293.9): calcd. C 24.53, H 6.86, N 19.07; found C 24.68, H 6.79, N 18.91. − MS (FAB, positive ions, DMSO/glycerol): *m/z* (%) = 239 (75) [Ni(**1**)Cl]$^+$, 203 (24) [Ni(**1**) − H]$^+$.

6b·2CH_3OH: Yield 309 mg (48% based on $NiCl_2$·$6H_2O$). − $C_{16}H_{48}Cl_4N_8Ni_2O_2$ (643.8): calcd. C 29.85, H 7.51, N 17.40; found C 29.76, H 7.49, N 17.32. − MS (FAB, positive ions, DMSO/glycerol): *m/z* (%) = 253 (70.2) [{Ni(**2**)Cl}$_2$]$^{2+}$, 217 (17.53) [Ni(**2**) − H]$^+$.

6c: Yield 132 mg (41% based on $NiCl_2$·$6H_2O$). − $C_8H_{24}Cl_2N_4NiO$ (321.9): calcd. C 29.85, H 7.51, N 17.40; found C 29.95, H 7.37, N 17.32. − MS (FAB, positive ions, DMSO/glycerol): *m/z* (%) = 267 (89) [Ni(**3**)Cl]$^+$, 232 (47) [Ni(**3**)]$^+$, 174 (36).

6d·H_2O: Yield 176 mg (50% based on $NiCl_2$·$6H_2O$). − $C_9H_{28}Cl_2N_4NiO_2$ (only directly coordinated water was left after drying, 353.9): calcd. C 30.54, H 7.97, N 15.83; found C 30.60, H 7.84, N 15.71. − MS (FAB, positive ions, DMSO/glycerol): *m/z* (%) = 281 (53) [Ni(**4**)$(H_2O)(OH)$]$^+$, 246 (34) [Ni(**4**)]$^+$, 188 (28).

Crystal Structure Analyses: Crystals of **5a−d** and **6b−d** obtained by crystallization from methanol were found to slowly decompose in air, most probably due to loss of solvent of crystallization. However, those obtained by crystallization from acetonitrile proved to be more stable. Complexes **5c**, **5d**, **6b**, and **6d** were crystallized as solvates **5c**·CH_3CN, **5d**·CH_3OH, **6b**·$2CH_3OH$, and **6d**·H_2O. Suitable crystals were mounted on an Enraf−Nonius CAD-4 diffractometer at low temperature (**5b**, **5d**·CH_3OH, **6b**·$2CH_3OH$) or at room temperature. Salient crystal and data collection details are listed in Table 4. Routine search and autoindexing procedures yielded the dimensions of the unit cell for all seven compounds. Diffraction data were collected using ω−2θ scans. Raw data were reduced to structure factors[29] (and their e.s.d. values) by correcting for scan speed, Lorentz and polarization effects. No decay corrections were necessary. Empirical absorption corrections (based on Ψ scans) were applied to the raw data for **5b**, **5d**·CH_3OH, and **6b**·$2CH_3OH$. The structure solutions were found by standard Patterson methods. The positional parameters for all non-hydrogen atoms were refined by using first isotropic and then anisotropic thermal parameters. Difference Fourier maps calculated at this stage showed the positional parameters of the hydrogen atoms. However, hydrogen atoms were added to the structure models in calculated positions and were refined as riding atoms. No hydrogen positions were calculated for non-coordinated solvent molecules. Calculations were carried out with SHELXL-93[30] (refinement on F^2). ORTEP[31] was used for all molecular drawings. The asymmetric unit for **5c**·CH_3CN and **5d**·CH_3OH contains two independent molecules, while **6b**·$2CH_3OH$ possesses a crystallographic inversion center and the asymmetric unit contains 1/2 of the complex. Table 1 and Table 2 list selected bond lengths and angles for complexes **5** and **6**, respectively. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-149397 (**5a**), -149398 (**5b**), -149399 (**5c**·CH_3CN), -149400 (**5d**·CH_3OH), -140401 (**6b**·$2CH_3OH$), -149402 (**6c**), and -149403 (**6d**·H_2O). Copies of the data may be obtained free of charge from the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax (internat.) + 44-1223/360-033; E-mail: deposit@ccdc.cam.ac.uk].

UV/Vis Spectra: The UV/Vis spectra of all the complexes were recorded from 250 nm (40000 cm^{-1}) to 1400 nm (7100 cm^{-1}) at room temperature in methanol solution. The

wavelengths of the absorption maxima and the molar extinction coefficients of the absorption bands are listed in Table 3.

Structure, Magnetic Properties and Magnetic Phase Diagram of a Layered, Bimetallic, Cyanide-Bridged Cr^{III}-Ni^{II} Metamagnet

Arnaud Marvilliers,[a] Simon Parsons,[b] Eric Rivière,[a] Jean-Paul Audière,[a] Mohamedally Kurmoo,[c] and Talal Mallah*[a]

To the memory of Olivier Kahn to whom we owe a great deal

Keywords: Chromium / Cyanides / Magnetic properties / Nickel

The reaction of hexacyanochromate(III) with $Ni(tmc)^{2+}$ (tmc = tetramethylcyclam) leads to the formation of the layered compound $[Ni(tmc)]_3[Cr(CN)_6]_2{\cdot}18H_2O$ displaying a corrugated sheet structure. Within each layer, the Ni(tmc) units are surrounded by two $Cr(CN)_6$ complexes in a *trans* fashion while the $Cr(CN)_6$ units are linked to three Ni(tmc) molecules in facial positions. The magnetic studies show ferromagnetic interaction for a $Ni^{II}(d^8, t_{2g}^6e_g^2)$–CN–$Cr^{III}(d^3, t_{2g}^3)$ system within the layers. Below a critical temperature (T_N = 14 K), a bulk antiferromagnetic order is observed due to a small interlayer antiferromagnetic interaction. An antiferromagnetic → ferromagnetic phase transition occurs for an applied field H_C of 1200 Oe expressing the metamagnetic behavior of the compound. The phase diagram of the compound was constructed and the antiferromagnetic interlayer magnetic energy was estimated to be equal to 0.1 cm^{-1}.

Introduction

Over the last ten years, bimetallic, cyanide-bridged systems built from hexacyanometallates have provided new materials possessing three,[1−9] two,[10−16] one[17−21] and zero[22−27] dimensionality.[28] Room temperature molecular-based magnets as well as photoinduced magnets have been synthesized and characterized.[4,29−32] Kahn and coworkers opened new perspectives in the field by preparing a $Mo^{III}-Mn^{II}$ cyanide-bridged, three-dimensional ferromagnet (T_C = 51 K) possessing large magnetic anisotropy.[33,34]

The magnetic properties are intimately related to the dimensionality of the systems. When the cyanide bridges spread in the three directions of space, long-range magnetic ordering occurs. On the other hand, if the cyanide bridges are restricted in zero dimensions, leading to high-spin discrete species,[22,23,26,27] new phenomena like the blocking and the quantum tunneling of the magnetization may be observed.[35,36]

We report here the preparation, crystal structure, magnetic properties and magnetic phase diagram of a new compound $[Cr(CN)_6]_2[Ni(tmc)]_3{\cdot}18H_2O$ obtained from the reaction of $[Ni(tmc)](ClO_4)_2$ (tmc = tetramethylcyclam, a tetradentate ligand) and $K_3[Cr(CN)_6]{\cdot}2H_2O$.

Results and Discussion

Synthesis and Characterization

The reaction of $[Ni(tmc)](ClO_4)_2$ and $K_3[Cr(CN)_6]{\cdot}2H_2O$ in water leads to the formation of an insoluble pale pink powder. The IR spectrum of the powder shows the presence of all the features expected for the organic tmc ligand in addition to two bands at 2154 and 2129 cm^{-1} assigned to the asymmetric vibrations of bridging and nonbridging cyanides. Elemental analysis is consistent with the following formula $[Cr(CN)_6]_2[Ni(tmc)]_3{\cdot}18H_2O$. In order to estimate accurately the number of water molecules and to study the effect of dehydration, thermogravimetry was carried out in

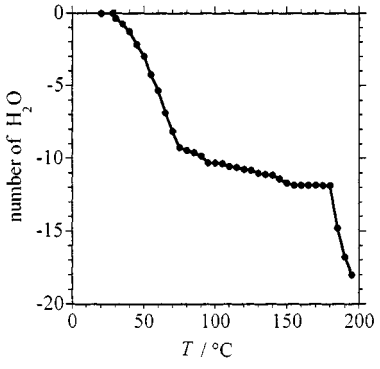

Figure 1. Thermogravimetric analysis in the form of loss of water molecules per unit formula versus temperature

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0505−1287 $ 17.50+.50/0

the temperature range 20−190 °C. Upon heating, nine water molecules are lost between room temperature and 75°C (Figure 1).

A further three water molecules are lost between 75 and 185 °C, where decomposition occurs. A total loss of 12 water molecules per unit formula is thus observed, although chemical analysis gave a total of 18 water molecules per unit formula. The remaining six water molecules are possibly more strongly bound through hydrogen bonds. The IR spectrum of a powder heated up to 180 °C and that of a nonheated sample are identical. The IR spectrum of the powder heated above 185 °C shows the absence of many bands belonging to the organic ligand.

Single crystals were obtained by a slow diffusion of aqueous solutions of the two precursors in an H tube. The IR spectrum of a few crystals was found to be identical to that of the powder.

Structure

X-ray diffraction studies reveal a layered structure with corrugated sheets as depicted in Figure 2 and 3. Within each layer, each Ni(tmc) unit is surrounded by two hexacyanochromate complexes in a *trans* position, as expected, while the $Cr(CN)_6$ units are linked to three Ni(tmc) disposed in a facial manner. The observed honeycomb-like corrugated layers are the result of: (i) the facial and not the meridional disposition of the three nickel complexes around the chromium anion, and (ii) the presence of an inversion center located on the nickel atoms. The same spatial arrangement has already been found in a related compound reported earlier where the tetradentate ligand cyclam were used instead of tetramethylcyclam.[12]

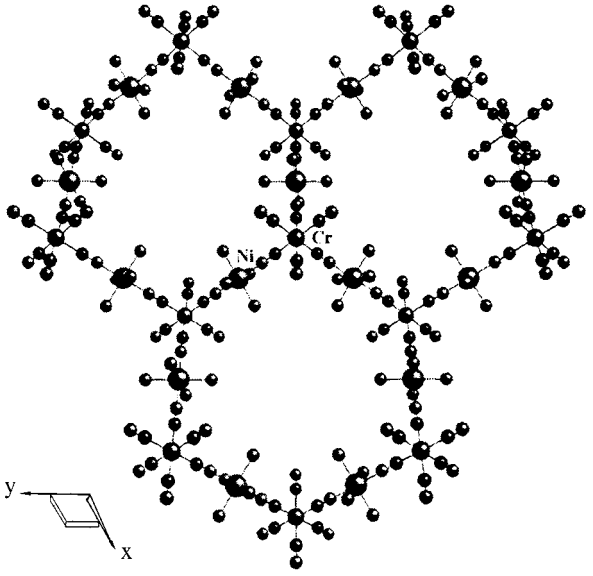

Figure 2. View along the *z* axis showing the honeycomb-like structure of the layers

All chromium atoms are crystallographically equivalent within the structure. The geometry around Cr can be considered as being isotropic. Around the nickel, the shortest distance [Ni(1)−N(10) = 2.089(10)Å] is that with the cyanides′ nitrogen atoms. The Ni−N bonds to the tmc′s nitrogen atoms are 2.185(18) and 2.306(14) Å for Ni(1)−N(1) and Ni(1)−N(4) respectively (Figure 4).

Despite the high *R* factor (14%), there is a clear tendency to have longer Ni−N bonds within the macrocycle than with the apical cyanides′ nitrogen atoms. This lengthening has already been noted for cyclam derivatives.[37] It has been attributed to the nonbonded repulsion between the hydrogen atoms of the alkyl substituents and those of adjacent carbon atoms. This bond lengthening within the macrocycle results in a shortening of the apical Ni−N bond lengths when axial ligands are present. Indeed, the apical Ni−N bond lengths are shorter for *trans*-[Ni(tetrapropylcyclam)$(NCS)_2$] than for *trans*-[Ni(cylam)(NCS).[38,39] The same tendency is observed when comparing the data of the present compound to those of the previously reported cyclam analogue. The shortest Ni−N bond length is found for nitrogen atoms belonging to the organic macrocycle [Ni−N = 2.06(2) Å] for the cyclam analogue, while for the present compound the apical Ni−N bond length is found to be the shortest. Another important difference between the two compounds is the value of the Ni(1)−N(10)−C(10) angle [173.4(1)°] which is closer to linearity in the present compound than when cyclam is used [171.6(1)°].

Magnetic Properties

All the magnetic studies were performed on a powdered sample and it was checked that the properties of a few single crystals were the same as that of the powder. The $\chi_M T = f(T)$ curve (Figure 5, recorded in an applied field of 3000 Oe) shows that $\chi_M T$ increases smoothly between 300 and 50 K upon cooling and then sharply below 50 K. A maximum is observed at $T = 14$ K. The $\chi_M T$ value at $T = 300$ K (8.18 cm^3 K mol^{-1}) is well above what is expected for two noninteracting Cr^{III} and three noninteracting Ni^{II} ions i.e. 7.03 cm^3 K mol^{-1}, obtained by fitting the high temperature part of the $1/\chi_M = f(T)$ curve.[40]

The increase of $\chi_M T$ upon cooling is the signature of a ferromagnetic-exchange coupling between nearest neighbor metal ions through the cyanide bridge. This has already been observed in related systems and has been ascribed to the orthogonality of the Cr^{III} and Ni^{II} magnetic orbitals.[2,22,26] The abrupt increase of $\chi_M T$ below 50 K to a maximum value as large as 156 cm^3 K mol^{-1} indicates the occurrence of a large correlation between the magnetic ions within the layers which is the origin of the magnetic anisotropy within the compound.[41]

In order to investigate the low temperature behavior, the temperature dependence of the magnetization was first measured in the presence of a weak applied field (30 Oe) and then at higher fields ranging from 400 to 1400 Oe.[42] The susceptibility (*M*/*H*) vs. temperature curve performed at $H = 30$ Oe (Figure 6) reveals the presence of a maximum at $T = 14$ K. The presence of such a maximum rules out the possibility of a 3D ferromagnetic order, where a saturation of the susceptibility is expected.

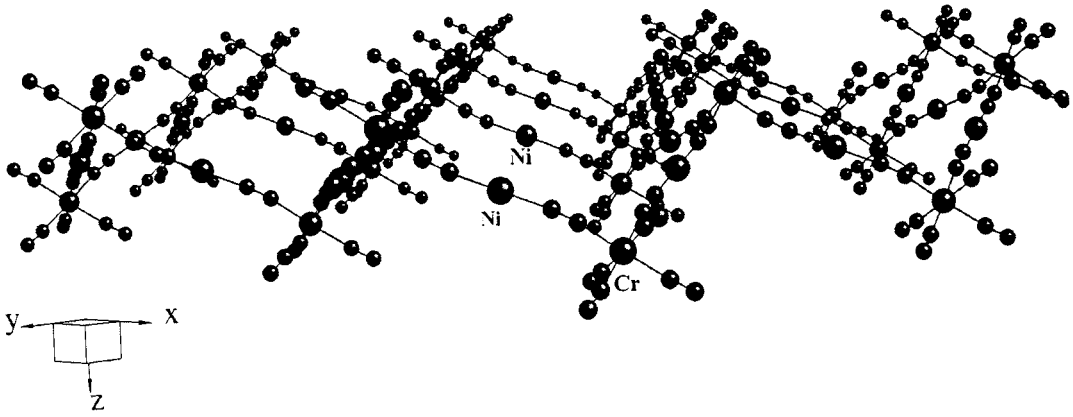

Figure 3. View along the *xy* plane revealing the corrugated sheets (tmc has been removed for clarity)

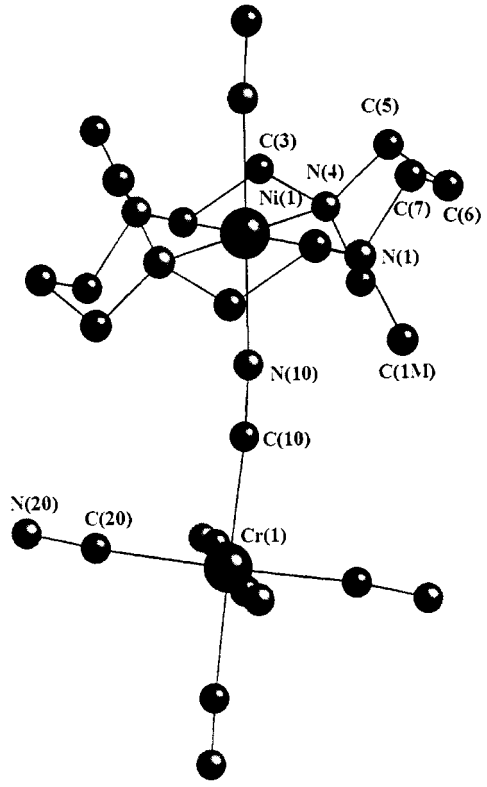

Figure 4. View of a dinuclear unit with atom-numbering scheme (hydrogen atoms are omitted for clarity); selected bond lengths [Å] and angles [°] with standard variations in parentheses: Ni(1)−N(1) 2.185(18), Ni(1)−N(4) 2.306(14), Ni(1)−N(10) 2.089(10), C(10)−N(10) 1.141(14), C(20)−N(20) 1.075(13), Cr(1)−C(10) 2.067(9), Cr(1)−C(20) 2.103(9); C(10)−N(10)−Ni(1) 173.4(10), N(10)−C(10)−Cr(1) 173.6(10), N(10)−C(20)−Cr(1) 174.7(11)

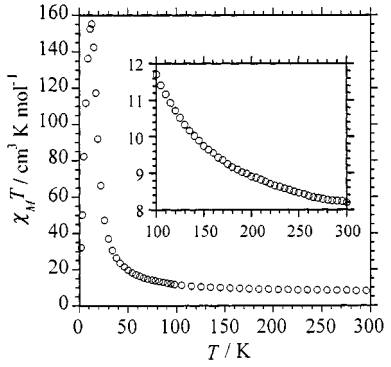

Figure 5. Thermal variation of the product of susceptibility and temperature of $[Cr(CN)_6]_2[Ni(tmc)]_3 \cdot 18H_2O$ ($\chi_M T$ versus T) in an applied field H = 3 kOe; inset: the increase of $\chi_M T$ between 300 and 100 K

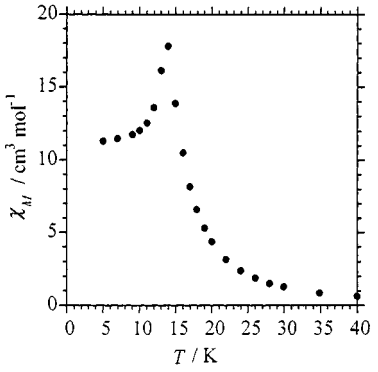

Figure 6. Thermal variation of the susceptibility in a field of 30 Oe

On the other hand, the fact that at low temperature (5 K) the susceptibility value (11.3 cm^3 mol^{-1}) is about two thirds that at the maximum (17.8 cm^3 mol^{-1}) is the signature of the occurrence of antiferromagnetic ordering in a randomly nonoriented sample.[43] For antiferromagnets in noncubic symmetry and within the framework of the mean field approximation, the perpendicular and the parallel components of the susceptibility measured on a single crystal have the same value at the ordering temperature. Below T_N, the perpendicular component remains constant in order to minimize the magnetic energy while the value of the parallel component decreases and vanishes at low temperature. Since the susceptibility of a powder is given by $\chi = (\chi_{\parallel} + 2\chi_{\perp})/3$, its value expected at low temperature corresponds to two thirds that of the maximum, as observed experimentally in the present compound.

Upon increasing the strength of the applied magnetic field, the maximum of the $M = f(H)$ curves (Figure 7) shifts

towards low temperature and disappears beyond $H = 1400$ Oe, showing a saturation of the magnetization.

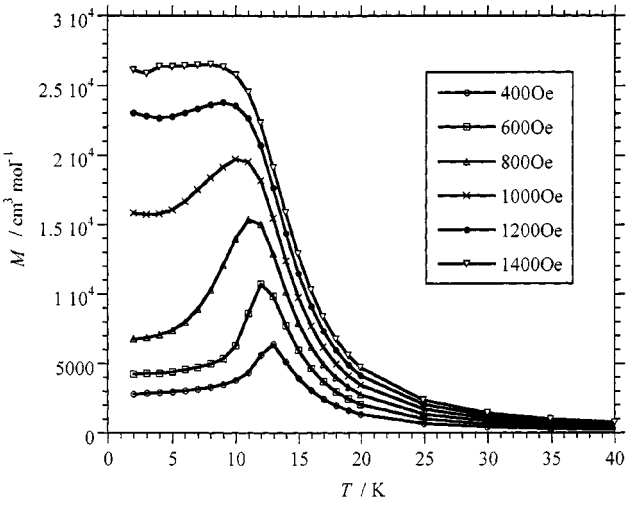

Figure 7. Thermal variation of the magnetization of a polycrystalline sample for different applied magnetic fields

This is the signature of the appearance of a ferromagnetic phase induced by the external applied magnetic field. On the other hand, the magnetization vs. field measurements performed at $T = 2$ K (Figure 8) present a sigmoidal shape. Upon increasing the applied field from zero, the magnetization increases first linearly and then abruptly and reaches saturation around 7 kOe. The sigmoidal shape of the $M = f(H)$ curve is characteristic of a metamagnetic behavior. This is the result of the transition from an antiferromagnetic to a field-induced ferromagnetic phase without going through an intermediate spin-flop phase. Such an abrupt transition is observed only if magnetic anisotropy is of the same order of magnitude or larger than the antiferromagnetic interaction so that the antiparallel magnetic moments remain in the same direction as the increasing applied magnetic field. In the case where the anisotropy energy is weaker than the antiferromagnetic energy, beyond a given magnetic field (which is usually very small) the system goes through an intermediate phase with canted magnetic moments (the spin-flop phase) before reaching the ferromagnetic phase. In such a situation, upon increasing the applied magnetic field a linear increase of the magnetization that extrapolates to zero for $H = 0$ should be observed before saturation is reached.[44,45] Such metamagnetic behavior has been already observed in layered compounds with strong ferromagnetic intralayer interactions and relatively weak interlayer antiferromagnetic interactions so that the magnetic anisotropy energy need not be very strong. The critical field needed to overcome the antiparallel alignment of the magnetic moments is found to be equal to 1170 Oe at $T = 2$K.

In summary, we can conclude that within the layers a ferromagnetic interaction operates leading to a relatively large correlation between the magnetic ions, while between the layers a weak antiferromagnetic interaction occurs leading to an overall antiferromagnetic order at $T_N = 14$ K. This antiferromagnetic order is overcome by an external applied field of 1170 Oe at $T = 2$ K.

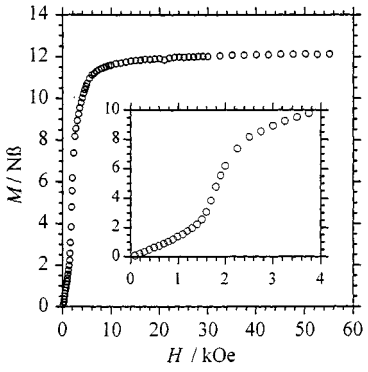

Figure 8. Variation of the magnetization as a function of the applied magnetic field at $T = 2$ K; inset: the sigmoidal shape at low values of the field

Magnetization vs. field isotherms performed at temperatures ranging from 2 to 14 K (not shown here) demonstrate that the critical field value decreases upon increasing the temperature and vanishes at $T = 14$ K. The critical field is estimated at the intersection of two linear slopes before and after the transition. Plotting the critical field H_C(T) as a function of the temperature at which the magnetization isotherms are measured leads to the phase diagram of the metamagnet (Figure 9). This phase diagram (which is partial as explained below) presents two regions delimited by the H_C(T) = f(T) curve. The region below the curve corresponds to the domain of stability of the antiferromagnetic phase while the upper region corresponds to the domains where the field-induced ferromagetic and the paramagnetic phases are stable. These two phases are, of course, well separated but a frontier line is difficult to determine experimentally.

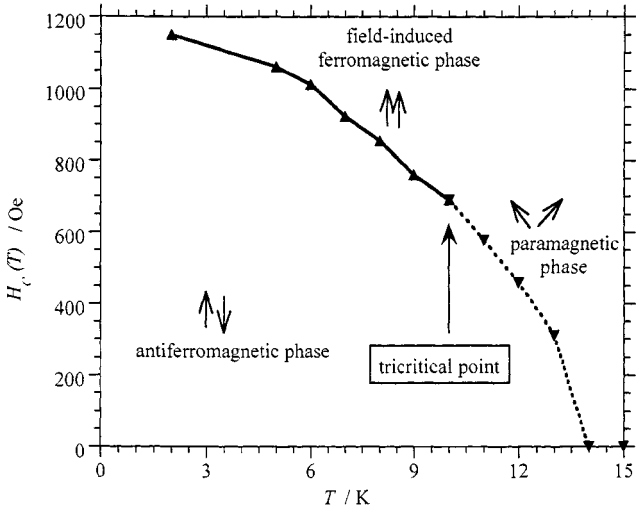

Figure 9. Phase diagram of the metamagnet; the dashed curve represents the range of second order magnetization and the continuous curve represents first order hysteresis magnetization; the tricritical point separates the two regions

However, a metamagnet has a tricritical point (T_{TCP} in the following discussion) where the three phases coexist; this tricritical point belongs to the H_C(T) = f(T) curve.[45] At temperatures below T_{TCP} the antiferromagnetic−ferromagnetic transition is a first order trans-

ition and a hysteresis loop should be observed in the $M = f(H)$ curves, while at temperatures above that of the tricritical point (but below T_N), the antiferromagnetic−paramagnetic phase transition is a second order transition and no hysteresis loop can be present. So, in order to determine the temperature of the tricritical point, we measured the magnetization as a function of the applied field for temperatures ranging from 2 to 12 K. Figure 10 shows the presence of a hysteresis loop in the $M = f(H)$ curve performed at $T = 2$ K.

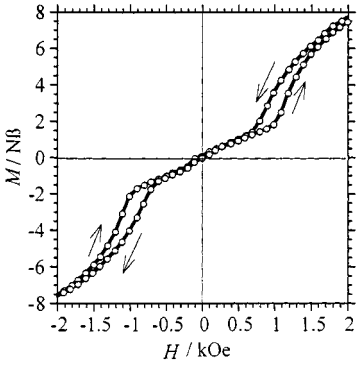

Figure 10. Hysteresis curve recorded between −2 and +2 kOe at $T = 2$ K

The maximum width of the loop is found to be equal to 244 Oe. When the temperature is increased, the width of the hysteresis loop decreases to 70 Oe at $T = 9$ K and almost vanishes at 10 K (Figure 11). Between 10 and 13 K, the $M = f(H)$ curves still have the sigmoidal shape (less pronounced than at lower temperatures) but no hysteresis could be detected anymore. This allows us to place the tricritical point at $T_{TCP} = 10$ K.

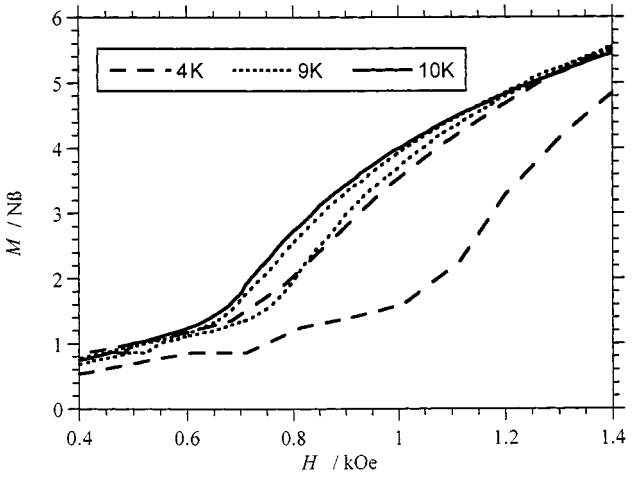

Figure 11. Isothermal magnetization curves measured at $T = 4$ K (-----), 9 K (·····) and 10 K (—); note the hysteresis behavior at 9 and 4 K

The value of the critical field H_C of the metamagnet may be obtained by extrapolating the $H_C(T) = f(T)$ curve to $T = 0$ K; it is found to be equal to 1200 Oe. This corresponds to the magnetic field needed to overcome the antiparallel alignment of the spins. The corresponding magnetic energy is given by $g\beta H_C$ and is found to be equal to 0.1 cm^{-1} when assuming a g value of 2.

Concluding Remarks

The quality of the crystal structure of this compound is not high enough to allow a thorough discussion of the origin of the bulk magnetic properties reported. For instance, the position of the water molecules that occupy the interlayer space (18 per unit formula) could not be refined and there was no possibility of knowing whether a hydrogen-bonded network exists within the compound. However, TGA studies show that six water molecules (per unit formula) cannot be removed before decomposition (which occurs at a rather high temperature). This suggests that these water molecules belong to a hydrogen-bonded network spreading all over the compound and linking the layers together. On the other hand, the magnetic properties of a sample heated at 180 °C under vacuum for 24 hours are the same as those of a nonheated sample. This is in line with the hypothesis of the presence of water molecules linking the layers through hydrogen bonds and thus forming a pathway for the interlayer antiferromagnetic interaction responsible for the antiferromagnetic order. The magnitude of the magnetic energy corresponding to the interlayer antiferromagnetic interaction (0.1 cm^{-1}) is weak but reasonable for a separation of 9.25 Å between the layers. This is still in a distance range where exchange through bonds may be more important than through space (dipolar).

The metamagnetic behavior observed is the result of the presence of a magnetic anisotropy with an energy at least as large as the energy responsible for the antiferromagnetic interaction between the layers. A quantitative determination of the magnetic anisotropy energy may be obtained from single crystal magnetic studies. Unfortunately, such studies could not be carried out because of a lack of crystals of suitable size and shape. However, the large correlation between the magnetic moment evidenced by the rather large value of the susceptibility at the Néel temperature is responsible for the presence of the magnetic anisotropy that leads to the metamagnetic behavior. The large correlation is the result of a relatively large ferromagnetic exchange interaction through the cyanide bridge. The lack of such a correlation in the previously reported cyclam analogue indicates that the magnitude of the $Cr^{III}-Ni^{II}$ ferromagnetic interaction is larger in the present tmc-based compound.[12,46] This may be related to the local structure around the Ni atoms; shorter apical Ni−N bond lengths and Ni−N−C angles (NC being the cyanide bridges) closer to linearity in the present compound may be the origin of the larger ferromagnetic short-range interaction and thus responsible for the bulk magnetic properties observed in the present compound and absent in the cyclam analogue.

Experimental Section

Hazards: Perchlorate salts should be handled with care and used in small quantities.

Syntheses: The $[Ni(tmc)](ClO_4)_2$ salt was prepared as previously reported.[47] The powder samples of the reported compound were obtained as follows: an aqueous solution (50 mL) containing 10^{-3} mol of $[Ni(tmc)](ClO_4)_2$ was added dropwise to 50 mL of an aqueous solution containing an equimolar amount of $K_3[Cr(CN)_6]\cdot 2H_2O$. A pale pink powder immediately formed, which was filtered, thoroughly washed with water and then dried under vacuum. – $C_{54}H_{132}Cr_2N_{24}Ni_3O_{18}$ (1685.9): calcd. C 37.67, H 7.67, N 19.53, Ni 10.24, Cr 6.05; found C 37.61, H 7.70, N 19.49, Ni 10.13, Cr 5.93.

General Remarks: Thermogravimetric studies were carried out in argon atmosphere at a heating rate of 1 °C per minute. The magnetic measurements were performed using a SQUID magnetometer operating in the 300–2 K temperature range and the 0–55 kOe magnetic field range. The drawings were carried out with the CRYSTAL MAKER program.[48]

Crystal Data for 1: $C_{54}H_{132}Cr_2N_{24}Ni_3O_{18}$, M = 1685.97, trigonal, a = 16.055(4), c = 9.248(7) Å, U = 2064.4(17) Å^3, T = 220 K, space group $P\bar{3}m1$, Z = 1, Cu-$K_{\alpha 1}$ = 3.461 mm^{-1}, 3503 reflections measured, of which 1161 were unique (R_{int} = 0.0745). The structure was solved by direct methods (SIR92) and refined with Shelxl-97;[49,50] solvent water was treated in the manner described by van der Sluis and Spek.[51] The final conventional R factor [based on F and 788 data with $F > 4(F)$] was 0.1465. The high R factor reflects complete disorder of the macrocycle about the crystallographic 2/m site occupied by the Ni. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 147292. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

[40] The $\chi_M T$ value of 7.03 for noninteracting metal ions allows us to compute the g value for Ni^{II} which is found to be equal to 2.10 assuming a g value of 1.99 for Cr^{III}.
[41] The value of $\chi_M T$ has no real meaning because at this temperature the magnetization is field dependent, nevertheless the high value indicates the presence of a large correlation within the layers.
[42] It was checked that ac susceptibility vs. temperature plots performed at 0 and 50 Oe static applied field are identical to those of Figure 6 which indicate that saturation effects are nonexistent at such low fields. On the other hand, such measurements made at different frequencies of the oscillating field and with zero static field confirm the presence of a magnetic ordering at T = 14 K.

[44] We must be cautious at this stage because our measurements

were carried out on a powder and not on an oriented single crystal with the applied field parallel to the easy axis, but the shape of the $M = f(H)$ curve, which is the sum of the parallel and the perpendicular components of the magnetization, presents a too sharp transition to be that of a spin-flop phase.

Methacrylate-Substituted Mixed-Metal Clusters Derived from Zigzag Chains of $[ZrO_8]/[ZrO_7]$ and $[TiO_6]$ Polyhedra

Bogdan Moraru,[a] Guido Kickelbick,[a] and Ulrich Schubert*[a]

Keywords: Zirconium / Titanium / Alkoxides / Oxo ligands / Cluster compounds / Organic-inorganic hybrid composites

Reaction of titanium butoxide and zirconium butoxide with methacrylic acid in different molar ratios results in the formation of the mixed-metal clusters $Ti_4Zr_4O_6(OBu)_4(OMc)_{16}$, $Ti_2Zr_4O_4(OBu)_2(OMc)_{14}$, $Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$, and $Ti_2Zr_6O_6(OMc)_{20}$ (OMc = methacrylate). The molecular structures of these clusters have been determined by single-crystal X-ray diffraction analysis. They are based on a common structural motif, namely a zigzag chain comprising two terminal $[TiO_6]$ octahedra and two or four central $[ZrO_8]$ dodecahedra or $[ZrO_7]$ pentagonal bipyramids sharing common edges. Two additional $[TiO_6]$ octahedra or $[ZrO_8]$ dodecahedra are condensed at the flank of the main chain.

Introduction

The so-called POSS-reinforced polymers (POSS = polyhedral oligomeric silsesquioxanes) have recently attracted much interest as a new class of inorganic-organic hybrid materials. They are prepared by the copolymerization of organic monomers with oligomeric $(RSiO_{1.5})_x$ species, mainly the cubic $R_8Si_8O_{12}$ clusters, in which one or (less often) more than one of the organic substituents R incorporates a polymerizable group.[1] The POSS-reinforced polymers show interesting improvements in their thermal and mechanical properties relative to those of the parent polymers.

Additional property modifications can be expected upon reinforcement of organic polymers with metal oxide clusters, especially those of transition metals. Thus, changes in the optical properties may result, or polymers with particular magnetic or catalytic properties may be generated.

However, only a few oxometallate clusters substituted with polymerizable organic ligands are available and, to the best of our knowledge, only $Bu_{12}Sn_{12}O_{14}(OH)_6(OMc)_2$ (OMc = methacrylate),[2] $Ti_3O_2(O\mathit{i}Pr)_5(OCMe{=}CH_2)_3(\mathit{i}PrOH)$,[3] and $[SiW_{10}O_{36}(Si_2R_2O)]^{4-}$ or $[SiW_{11}O_{39}(OSi_2R_2)]^{4-}$ (R = unsaturated organic groups)[4] have hitherto been used as co-monomers in polymerization reactions.[5]

We have recently prepared and structurally characterized several acrylate- or methacrylate-substituted oxotitanium and oxozirconium clusters of differing sizes and shapes, such as $Zr_6O_4(OH)_4(OMc)_{12}$,[6] $Zr_4O_2(OMc)_{12}$,[6,7] $[Zr_6O_4(OH)_4(OAcr)_{12}]_2$ (OAcr = acrylate), $Zr_6O_4(OH)_4(OMc)_{12}(PrOH)$,[8] $Ti_6O_4(OEt)_8(OMc)_8$,[9] $Ti_9O_8(OPr)_4(OMc)_{16}$,[10] and $Ti_4O_2(O\mathit{i}Pr)_6(OAcr)_6$.[11] These crystalline clusters are reproducibly obtained in very high yields by treating $Zr(OR)_4$ or $Ti(OR)_4$ with a defined excess of (meth)acrylic acid. In the first step of this reaction, one or more alkoxide ligands are substituted by carboxylate groups. The alcohol thus liberated then undergoes an esterification reaction. The water produced along with the ester serves to hydrolyze the remaining alkoxide groups and acts as the source of the oxide or hydroxide groups in the clusters. The very slow production of water allows a very controlled growth of the carboxylate-substituted oxometallate clusters.

Small amounts of the clusters $Zr_6O_4(OH)_4(OMc)_{12}$, $Zr_4O_2(OMc)_{12}$, $Ti_4O_2(O\mathit{i}Pr)_6(OAcr)_6$, and $Ti_6O_4(OEt)_8(OMc)_8$, which can be considered as structurally well-defined nanosized building blocks, were then used as co-monomers in radical polymerizations with methyl methacrylate and methacrylic acid. Even small proportions of the clusters (typically 0.5−2 mol-%) were found to efficiently crosslink the organic polymer chains. This results, inter alia, in a controllable swelling behavior, a higher thermal stability, and modified dielectric properties of the resulting inorganic-organic hybrid polymers.[7,12,13] Our initial results indicated that not only the proportion of the cluster, but also its size and shape and the number of polymerizable groups around its core, influence the material properties of the hybrid polymers to some extent. For this reason, our aim was to prepare methacrylate-substituted clusters of different sizes and shapes. In this paper, we report the synthesis and structural characterization of four oblong-shaped mixed-metal oxo clusters of Ti and Zr. Surprisingly, the structures of the clusters turned out to be based on a straightforward common construction principle.

Results and Discussion

Reaction of $Ti(OBu)_4$, $Zr(OBu)_4$, and methacrylic acid in a 1:1:8.5 ratio resulted in the formation of crystalline $Ti_4Zr_4O_6(OBu)_4(OMc)_{16}$ (**1**) in almost quantitative yield. The same cluster was obtained when $Ti(OEt)_4$ was employed instead of $Ti(OBu)_4$. The formation of butyl methacrylate could be monitored spectroscopically, which suggested the mass balance given in Equation (1).

$$4\,Ti(OBu)_4 + 4\,Zr(OBu)_4 + 22\,CH_2{=}C(Me)COOH \rightarrow Ti_4Zr_4O_6(OBu)_4(OMc)_{16}\,(\mathbf{1}) + 6\,CH_2{=}C(Me)COOBu + 22\,BuOH \quad (1)$$

When the $Ti(OBu)_4/Zr(OBu)_4$ ratio was changed from 1:1 to about 1:2, while keeping the total proportion of methacrylic acid constant (4.2 mol methacrylic acid per mol metal alkoxide), the cluster $Ti_2Zr_4O_4(OBu)_2(OMc)_{14}$ (**2**) was formed. The compositions of **1** and **2** were verified by X-ray structure analyses (see below). The spectroscopic data, elemental analyses, and powder diffractograms confirmed that **1** and **2** were formed as the sole products of the respective reactions. Assignment of the signals in the ^1H and ^{13}C NMR spectra to individual ligands proved difficult because they occupy a number of stereochemically different coordination sites. However, the spectra gave a good "fingerprint" of each particular cluster.

Increasing the $Ti(OBu)_4/Zr(OBu)_4$ ratio to 1:3 resulted in a mixture of clusters. In addition to the previously obtained cluster **2**, the clusters $Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$ (**3**) and $Ti_2Zr_6O_6(OMc)_{20}$ (**4**) were also formed. The composition of the mixture was verified by comparison of the powder diffraction patterns calculated from the individual crystal structure analyses with the powder XRD of the product mixture. Cluster **3** was obtained as the sole product when $Ti(OBu)_4$, $Zr(OPr)_4$ (instead of the butoxide), and methacrylic acid were reacted in a 1:1:8.2 molar ratio.

The latter result is remarkable in that it shows that seemingly minor changes in the reaction conditions may result in different clusters (although they are structurally related − see below): The only difference in the reaction conditions leading to **1** and **3**, respectively, is that zirconium *butoxide* is used in the former case, while zirconium *propoxide* is used in the latter. However, as mentioned above, replacing $Ti(OBu)_4$ by $Ti(OEt)_4$ did not result in a different cluster. These observations show that the relative reaction rates of the two alkoxides play an important role, and that the reactivity of the zirconium alkoxide evidently dominates the formation of the cluster nucleus, eventually leading to a particular cluster geometry. This is consistent with the higher reactivity of zirconium alkoxides relative to titanium alkoxides.

Clusters **1** and **4** have the general composition $M_8O_6X_{20}$ ($M = Ti^{IV}$ or Zr^{IV}; X = singly negatively charged ligand). The $M_6O_4X_{16}$ composition of **2** and **3** corresponds to a higher degree of condensation. Thus, increasing the $Zr(OBu)_4/Ti(OBu)_4$ ratio in the starting mixture from 1:1 to 3:1 not only favors the formation of the clusters with a higher Zr/Ti ratio, but also the formation of more highly condensed clusters ($M_6O_4X_{16}$ as opposed to $M_8O_6X_{20}$). It should be noted at this point that the previously obtained cluster $Zr_6O_4(OH)_4(OMc)_{12}$, obtained by reacting only $Zr(OPr)_4$ with a 3.8-fold excess of methacrylic acid,[6] also has the $M_6O_4X_{16}$ composition.

The molecular structures of clusters **1**−**4** are based on a common structural motif. This can best be visualized by comparing the cluster cores built up from connected polyhedra (Figure 1). In this representation the carbon atoms have been omitted, i.e. the corners of the polyhedra represent the oxygen atoms (from any ligand).

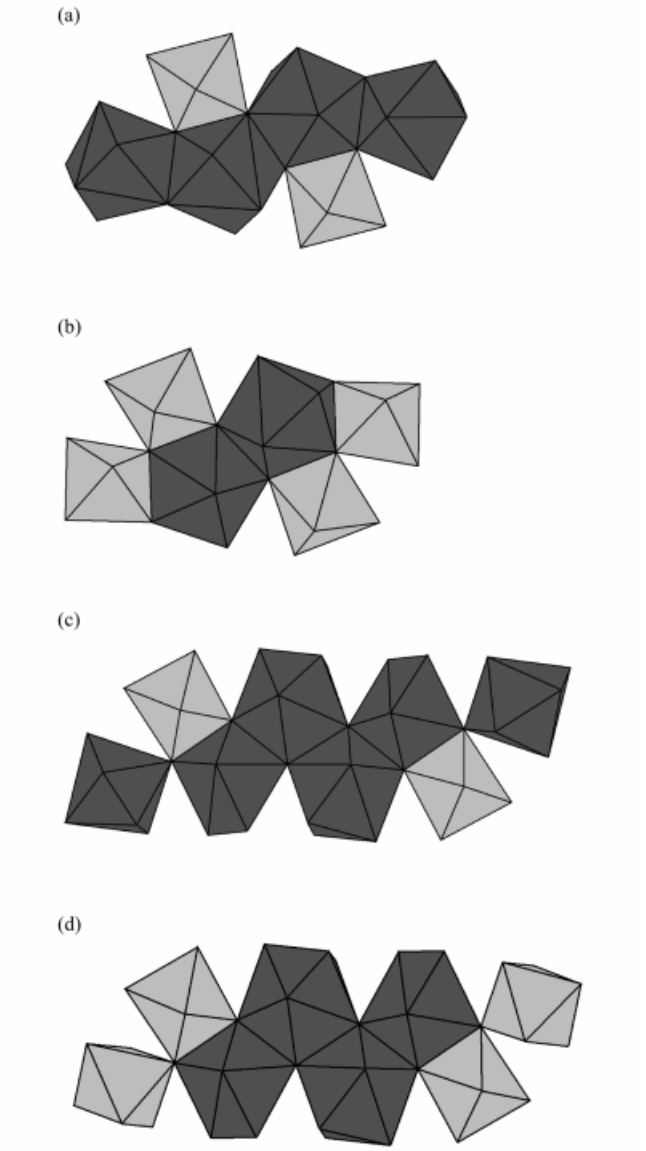

Figure 1. Cores of connected polyhedra present in the clusters **1**−**4**: (a) $Ti_2Zr_4O_4(OBu)_2(OMc)_{14}$ (**2**), (b) $Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$ (**3**), (c) $Ti_2Zr_6O_6(OMc)_{20}$ (**4**), (d) $Ti_4Zr_4O_6(OBu)_4(OMc)_{16}$ (**1**); the central Zr polyhedra in **1** and **4** are 8-coordinate, while the Zr polyhedra bonded to the $[TiO_6]$ octahedra are 7-coordinate

The structural motif common to both six-atom clusters **2** and **3** is a zigzag chain of two $[ZrO_8]$ dodecahedra and two $[TiO_6]$ octahedra, which share common edges. The $[TiO_6]$ octahedra terminate the main chain. The zigzag arrangement is adopted because the central $[ZrO_8]$ dodecahedra share *cis* edges with the neighboring polyhedra (i.e. two $[ZrO_8]$ dodecahedra and one $[TiO_6]$ octahedron are connected by a μ_3-oxygen atom). The main difference between **2** and **3** is the presence of two additional polyhedra condensed onto the $[ZrO_8]$ dodecahedra of the zigzag chain at edges *cis* to the chain-terminating $[TiO_6]$ octahedra. The "extra" polyhedra are $[ZrO_8]$ dodecahedra in **2** and $[TiO_6]$ octahedra in **3**.

In **1** and **4**, the zigzag chain is extended by two oxozirconium polyhedra, but the connectivity is the same. Again, edge-sharing [TiO_6] octahedra terminate the main chain, and there are also additional [ZrO_8] dodecahedra (in **4**) or [TiO_6] octahedra (in **1**) at the flank of the main chain. Contrary to **2** and **3**, the additional polyhedra are condensed onto the main chain through a common corner rather than a common edge. The two polyhedra in **1** and **4** that extend the zigzag chain are distorted [ZrO_7] pentagonal bipyramids, located between the terminal [TiO_6] octahedra and the central [ZrO_8] dodecahedra.

Although both clusters **2** and **3** (composition $M_6O_4X_{16}$) need 16 negatively charged ligands for charge compensation of the M_6O_4 core, the 16 ligands have to occupy a different number of coordination sites due to the different coordination numbers of Ti and Zr. Thus, the $Ti_2Zr_4(\mu_3\text{-}O)_4$ core in **2** has 32 coordination sites (6 per Ti, 8 per Zr, minus the coordination sites occupied by the μ_3-O), while the $Ti_4Zr_2(\mu_3\text{-}O)_4$ core in **3** has only 28. Since each of the methacrylate ligands is bidentate (bridging or chelating), both butoxy groups in **2** need to be bridging (μ_2) (Figure 2). The same calculation shows that two of the butoxy groups in **3** must be bridging, while the remaining four are terminal. The latter are located at the titanium atoms (Figure 3). In both cases, the bridging butoxy groups connect the "extra" polyhedra to the zirconium dodecahedron of the zigzag chain [O(4) bridging Zr(1) and Zr(2) in **2**; O(28) bridging Zr and Ti(2) in **3**]. As previously observed for single-metal oxide clusters of Ti or Zr, methacrylate ligands are invariably coordinated to titanium in a bridging mode, but can either bridge or chelate zirconium atoms.

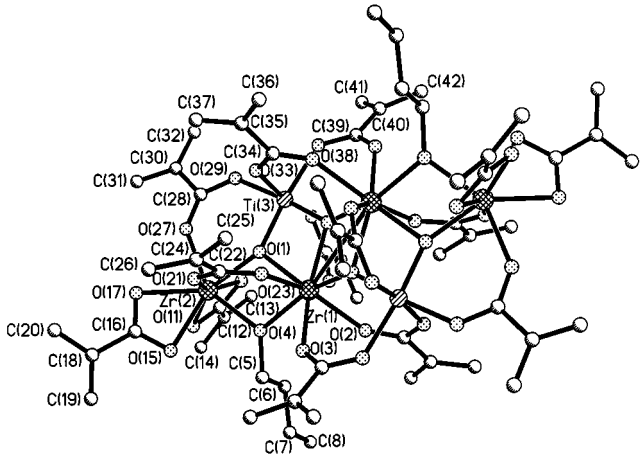

Figure 2. Molecular structure of $Ti_2Zr_4O_4(OBu)_2(OMc)_{14}$ (**2**); hydrogen atoms are omitted for clarity

The 20 ligands of the clusters **1** and **4** (composition $M_8O_6X_{20}$) have to occupy 36 coordination sites in **1** and 40 sites in **4** (in both compounds, two zirconium atoms are only 7-coordinate!). Thus, the four butoxy groups in **1** (Figure 4) must be terminal. They are located at the "extra" titanium atoms. In **4** (Figure 5), the methacrylate ligands occupy all the coordination sites, hence no ligands have to coordinate in a monodentate fashion. This calculation also

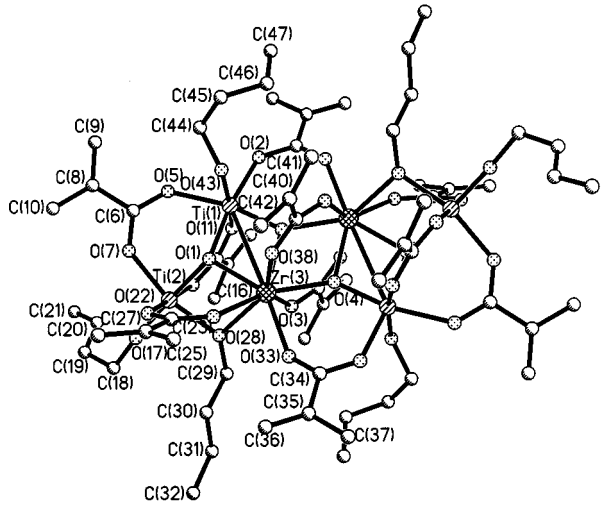

Figure 3. Molecular structure of $Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$ (**3**); hydrogen atoms are omitted for clarity

explains why one of the zirconium atoms in **4** must be 7-coordinate rather than 8-coordinate: the two additional ligands required for 8-coordination could not be compensated by the charge of the cluster core.

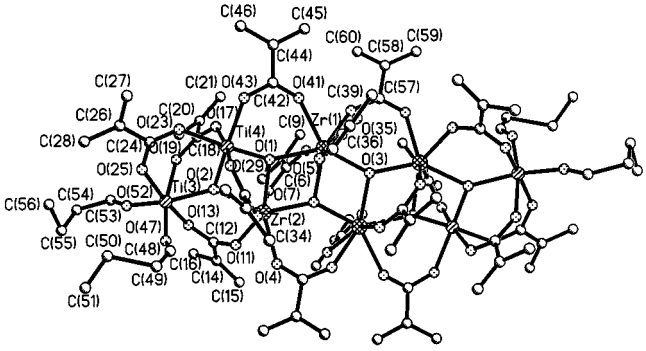

Figure 4. Molecular structure of $Ti_4Zr_4O_6(OBu)_4(OMc)_{16}$ (**1**); hydrogen atoms are omitted for clarity

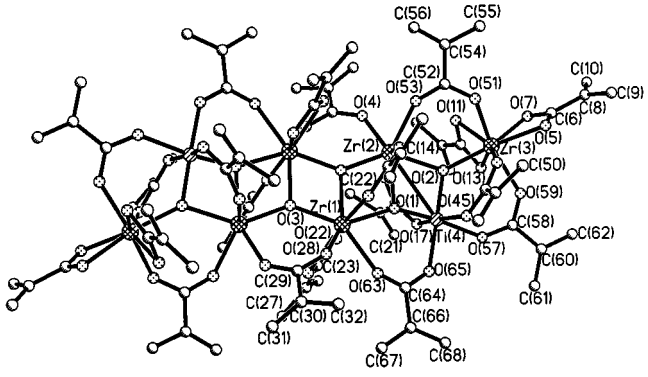

Figure 5. Molecular structure of $Ti_2Zr_6O_6(OMc)_{20}$ (**4**); hydrogen atoms are omitted for clarity

The question arises as to whether it is possible to further extend the zigzag chain observed in the clusters **1** and **4** by the insertion of two additional [ZrO_7] or [ZrO_8] polyhedra. The composition of the resulting clusters would then be $M_{10}O_8X_{24}$ (i.e. $Ti_2Zr_8O_8X_{24}$ or $Ti_4Zr_6O_8X_{24}$). The 24 singly

negatively charged ligands X would then have to occupy 52 coordination sites in a hypothetical $Ti_2Zr_8O_8X_{24}$ species or 48 coordination sites in $Ti_4Zr_6O_8X_{24}$ (for 8-coordinate Zr). Even if some of the zirconium atoms were to be only 7-coordinate and all of the ligands X were bidentate carboxylate ligands, such a $Ti_2Zr_8O_8X_{24}$ cluster would not be possible because the number of ligands X (a consequence of the charge balance) would be insufficient to occupy the existing coordination sites. A zigzag-shaped cluster of the composition $Ti_4Zr_6O_8X_{24}$ would only be possible if some of the carboxylate ligands coordinated to Ti were to be chelating (which is not the case in the known structures). Therefore, clusters with longer zigzag chains based on the same construction principle as that seen in **1**−**4** cannot be expected.

Conclusions

We have shown in this paper that a number of clusters with Ti/Zr ratios ranging from 2:1 to 1:3 can be prepared by reacting the metal alkoxides with methacrylic acid. The clusters **1**−**3** can be obtained in high yields without the need for laborious separation procedures. The formation of the clusters is probably due to the slow generation of water by simultaneous ester formation as outlined in the Introduction. The clusters **1**−**4** fill the gap between the single-metal oxotitanium and oxozirconium clusters that we have isolated previously. Using these new methacrylate-substituted clusters as co-monomers in polymerization reactions, we should be able to tune the properties of the resulting hybrid polymers (e.g., refractive index) by varying the inorganic building blocks. The shape and size of the clusters − as inorganic nanoparticles − may also be important with regard to the modification of the polymer properties. SAXS measurements on poly(methyl methacrylate) crosslinked by the clusters $Zr_6O_4(OH)_4(OMc)_{12}$, $Zr_4O_2(OMc)_{12}$, and $Ti_6O_4(OEt)_8(OMc)_8$ have shown that the scattering objects can be approximated by spheres (Zr_4 clusters) or discs with diameters of about 1 nm,[12] which corresponds to the crystallographically determined cluster sizes. The clusters described herein are rod-shaped, with lengths between 1.2 (**3**) and 1.8 nm (**1**) (distance between the most distant oxygen atoms) and diameters of about 0.65 nm.

The clusters described in this paper also serve to improve the understanding of the structure evolution in multi-component sol-gel systems, especially those modified by carboxylic acids. Although, as discussed above, the kind of cluster obtained to some extent reflects the reactivity differences of the alkoxides, the formation of the mixed-metal clusters also shows that the organic additives may serve to achieve a homogeneous distribution of the two metals through the formation of carboxylate-bridged extended structures. The only Ti/Zr mixed-metal alkoxide derivatives hitherto reported are the pinacolate derivatives $TiZr_2(OCMe_2CMe_2O)_4(OCMe_2CMe_2OH)_2(OiPr)_2$ and $Ti_2Zr_2(OCMe_2CMe_2O)_6(OiPr)_4$.[14]

Experimental Section

All operations were carried out in Schlenk tubes under argon. The alkoxides and methacrylic acid were used as received (Aldrich).

$Ti_4Zr_4O_6(OBu)_4(OMc)_{16}$ (1): A 99% solution of $Ti(OBu)_4$ (1.901 g, 5.53 mmol) in butyl alcohol was mixed with an 80% solution of $Zr(OBu)_4$ (2.681 g, 5.59 mmol) in the same solvent. After the addition of 99% methacrylic acid (4.095 g, 47.1 mmol), the mixture was stored in a closed vessel at room temperature. After 7 d, colorless crystals of **1** had been produced, which were isolated by decanting the mother liquor and drying. Yield 4.23 g (85%); m.p. 124 °C. − ^{1}H NMR ($CDCl_3$): δ = 0.88−0.93 (m, 25 H, $OCH_2CH_2CH_2CH_3$), 1.34−1.39 (m, 16 H, $OCH_2CH_2CH_2CH_3$), 1.51−1.56 (m, 16 H, $OCH_2CH_2CH_2CH_3$), 1.83−1.89 [m, 48 H, $=C(CH_3)COO$], 3.61−3.66 (t, 16 H, $OCH_2CH_2CH_2CH_3$), 5.52−5.56 [m, 16 H, *cis*-$CH_2=C(CH_3)COO$], 6.07−6.17 [m, 16 H, *trans*-$CH_2C(CH_3)COO$]. The higher relative intensity of the OBu group signals in the ^{1}H NMR spectra indicates the presence of four residual butyl alcohol

ules per cluster. – ^{13}C NMR ($CDCl_3$): δ = 13.7 ($OCH_2CH_2CH_2CH_3$), 18.4 [$CH_2C(CH_3)COO$], 30.6 ($OCH_2CH_2CH_2CH_3$), 34.8 ($OCH_2CH_2CH_2CH_3$), 62.7 ($OCH_2CH_2CH_2CH_3$), 125.1–127.1 [$CH_2C(CH_3)COO$], 136.5–137.7 [$CH_2C(CH_3)COO$], 173.7–176.5 (COO). – $C_{64}H_{88}O_{34}Ti_2Zr_4$10 BuOH (2603.3): calcd. C 49.2, H 7.1; found C 50.4, H 7.3. – TiO_2/ZrO_2 from TGA: calcd. for **2**·10 BuOH 25.0%, found 23.6%.

$Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$ (3) and $Ti_2Zr_6O_6(OMc)_{20}$ (4): A 99% solution of $Ti(OBu)_4$ (1.303 g, 3.79 mmol) in butyl alcohol was mixed with an 80% solution of $Zr(OBu)_4$ (5.352 g, 11.25 mmol) in the same solvent. After the addition of 99% methacrylic acid (5.259 g, 60.5 mmol), the mixture was stored in a closed vessel at room temperature. After 7 d, a mixture of colorless crystals of **2**–**4** had been produced, which was recovered by decanting the mother liquor and drying. Yield 7.54 g. Crystals of **4** were manually separated from the mixture for a crystal structure determination.

$Ti_4Zr_2O_4(OBu)_6(OMc)_{10}$ (3): A 99% solution of $Ti(OBu)_4$ (1.650 g, 4.80 mmol) in butyl alcohol was mixed with a 70% solution of $Zr(OPr)_4$ (2.144 g, 4.58 mmol) in propanol. After the addition of methacrylic acid (3.363 g, 38.7 mmol), the mixture was stored in a closed vessel at room temperature. After 7 d, colorless crystals of **3** had formed, which were isolated by decanting the mother liquor and drying. Yield 2.361 g (87%); m.p. 133 °C. – ^1H NMR ($CDCl_3$): δ = 0.91 (m, 35 H, $OCH_2CH_2CH_2CH_3$), 1.34–1.40 (m, 12 H, $OCH_2CH_2CH_2CH_3$), 1.54–1.58 (m, 12 H, $OCH_2CH_2CH_2CH_3$), 1.91 [m, 30 H, $CH_2C(CH_3)COO$], 3.59–3.63 (m, 6 H, $OCH_2CH_2CH_2CH_3$), 5.52–5.59 [m, 10 H, *cis*-$CH_2C(CH_3)COO$], 6.07–6.17 [m, 10 H, *trans*-$CH_2C(CH_3)COO$]. – $C_{64}H_{86}O_{30}Ti_4Zr_2$ (1709.4): calcd. C 44.5, H 6.1; found C 42.7, H 5.1. – TiO_2/ZrO_2 from TGA: calcd. 32.8%, found 31.9%.

X-ray Structure Analyses of 1–4: Selected crystals were mounted on a Siemens SMART diffractometer with a CCD area detector. Graphite-monochromated Mo-K_α radiation (λ = 71.073 pm) was used for all measurements. The crystal-to-detector distance was 4.40 cm. A hemisphere of data was collected by a combination of three sets of exposures at 213 K. Each set had a different φ angle for the crystal; each exposure was of duration 20 s and covered 0.3° in ω. The data were corrected for polarization and Lorentz effects and an empirical absorption correction (SADABS) was applied. The cell dimensions were refined using all unique reflections. The structure was solved by direct methods (SHELXS-86). Refinement was carried out by the full-matrix least-squares method based on F^2 (SHELXL-93) with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were inserted in calculated positions and refined as riding on the corresponding atom. The asymmetric unit of **3** contains a disordered molecule of methacrylic acid. Only the carbon atoms could be located; they were refined anisotropically without hydrogen atoms attached to them. Crystallographic data (excluding structure factors) for the structures of **1**–**4** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-149355 (**1**), -149356 (**2**), -149357 (**3**), and -149358 (**4**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. Synthesis, Characterisation and Antiviral Activity of Platinum(II) Complexes with 1,10-Phenanthrolines and the Antiviral Agents Acyclovir and Penciclovir

Nicola Margiotta,[a] Francesco P. Fanizzi,[b,c] Joze Kobe,[d] and Giovanni Natile*[a]

Keywords: Acyclovir / Penciclovir / Platinum / Atropisomerism / Antiviral agents / Drug research

Four novel hybrid drugs $[Pt(acy)_2(Me_2phen)]I_2$ (**1**), $[Pt(pen)_2(Me_2phen)](NO_3)_2$ (**2**), $[Pt(acy)_2(phen)](NO_3)_2$ (**3**), and $[Pt(pen)_2(phen)](NO_3)_2$ (**4**) have been prepared by reaction of the antiviral guanine derivatives acyclovir (acy) and penciclovir (pen) with platinum complexes having 2,9-Me_2-1,10-phenanthroline (Me_2phen) and 1,10-phenanthroline (phen) as carrier ligands. Both the Me_2phen and phen carrier ligands are able to hinder rotation of the guanine bases about the Pt–N(7) bonds rendering the interconversion among rotamers very slow on the NMR time scale. A favourable dipole–dipole interaction between the *cis*-coordinated purine bases stabilises the *HT* rotamers, which are the only species detected in solution. The stability in a physiological medium and the anti-HIV properties in vitro of the complexes have been evaluated. In a 0.1 M solution of NaCl, the compounds with Me_2phen (**1** and **2**) were found to be very stable while the compounds with phen (**3** and **4**) underwent displacement of one purine base by a chloride ion. This rather unexpected result may have some relevance in connection with the stability of major DNA adducts of cisplatin in which two guanines are cross-linked by a $Pt(NH_3)_2$ moiety. Although none of the complexes showed anti-HIV activity, complexes **1** and **2**, bearing methyl substituents in the *ortho* positions of the phenanthroline, were much more cytotoxic than **3** and **4**. This is probably due to a greater stability of the former complexes in biological media caused by the presence of the two methyl groups wrapping the metal centre and inhibiting the nucleophilic attack of an incoming ligand at the platinum centre.

Introduction

The discovery of acyclovir [9-(2-hydroxyethoxymethyl)-guanine, acy] in 1977, the first drug with high selectivity, was the starting point of antiviral chemotherapy.[1] Acyclovir is a synthetic analogue of guanosine with a linear chain in place of the ring sugar, it inhibits selectively the replication of Herpes Simplex Virus (HSV) by interfering with DNA synthesis. After entering into the infected cell, acyclovir is phosphorylated by the virus-induced thymidine kinase (TK) to acyclovir-monophosphate (acyclo-GMP).[2] The rate of phosphorylation by mammalian TK is negligible and this makes acyclovir highly selective towards HSV. The drug is further phosphorylated by cellular enzymes to produce first acyclo-GDP and then acyclo-GTP. The latter is a selective inhibitor of the viral DNA polymerase because it competes with dGTP for incorporation into the growing DNA strand. The inclusion of acyclovir, containing a single hydroxyl group, stops the duplication process.

Acyclovir is the drug of choice for the treatment of HSV and Varicella Zoster Virus (VZV) infections. It is commonly used in the treatment of primary and recurrent genital herpes and mucocutaneous HSV and VZV infections in immunosuppressed patients.

Hundreds of synthetic analogues of acy have been synthesised, among these analogues are ganciclovir and penciclovir (pen). Ganciclovir shows higher activity towards cytomegalovirus (CMV) than acyclovir, while penciclovir shows a similar spectrum of activity as acyclovir, as well as activity against human hepatitis B virus.[3]

The coordination ability of acyclovir and its analogues has attracted the interest of many researchers in view of the fact that DNA polymerases contain Zn^{2+} and/or are activated by metal ions such as Mg^{2+}, Mn^{2+}, and Co^{2+}. Complexes of acyclovir with Cd^{II}, Co^{II}, and Cu^{II} have been synthesised and characterised and,[4] in some instances, their antiviral properties were also investigated.[5,6] The structural analogies of acyclovir with purine nucleotides have inspired the synthesis of complexes with platinum(II).[7–10] Anticancer platinum(II) drugs are known to crosslink DNA at adjacent purine bases, and bifunctional adducts of this type are believed to be responsible for anticancer activity.[11,12]

Amines have usually been used as carrier ligands for platinum drugs;[13] however, polycyclic aromatic amines, such as phenanthroline, in addition to being bidentate N-donor ligands, also have an intercalating ability towards double-helix DNA.[14] The binding to Calf Thymus DNA has been investigated for some phenanthroline complexes.[15]

A special case is that of the *ortho* disubstituted phenanthroline 2,9-Me_2-1,10-phenanthroline (Me_2phen, neocup-

roine) which has long been investigated for its ability to increase the chemical reactivity of platinum(II) substrates of formula $[PtX_2(Me_2phen)]$ (X = halogen ligand).[16,17] Because of the steric interaction between the *ortho* substituents of the phenanthroline and the *cis* halogen ligands, $[PtX_2(Me_2phen)]$ substrates react readily with an extra ligand (L) to give the corresponding addition product $[PtX_2(L)(Me_2phen)]$. For L = a π-acceptor ligand (such as alkene, alkyne, and carbon monoxide) the addition product has a five-coordinate geometry; in contrast, for L = a σ-donor ligand (such as amine, phosphane, etc.) the platinum remains four-coordinate and the neocuproine acts as a monodentate ligand. With longer reaction times the displacement of one X and back chelation of Me_2phen is also observed.

Pursuing our interest in the synthesis of hybrid drugs combining in one molecule the features of *cis*-amine platinum antitumor drugs and antiviral nucleotide analogues,[7−10] we have carried out the synthesis of platinum complexes containing a bidentate phenanthroline and two antiviral purine bases in the coordination sphere. The stereochemistry of the new compounds, as well as preliminary data on their antiviral activity, are reported in the present work.

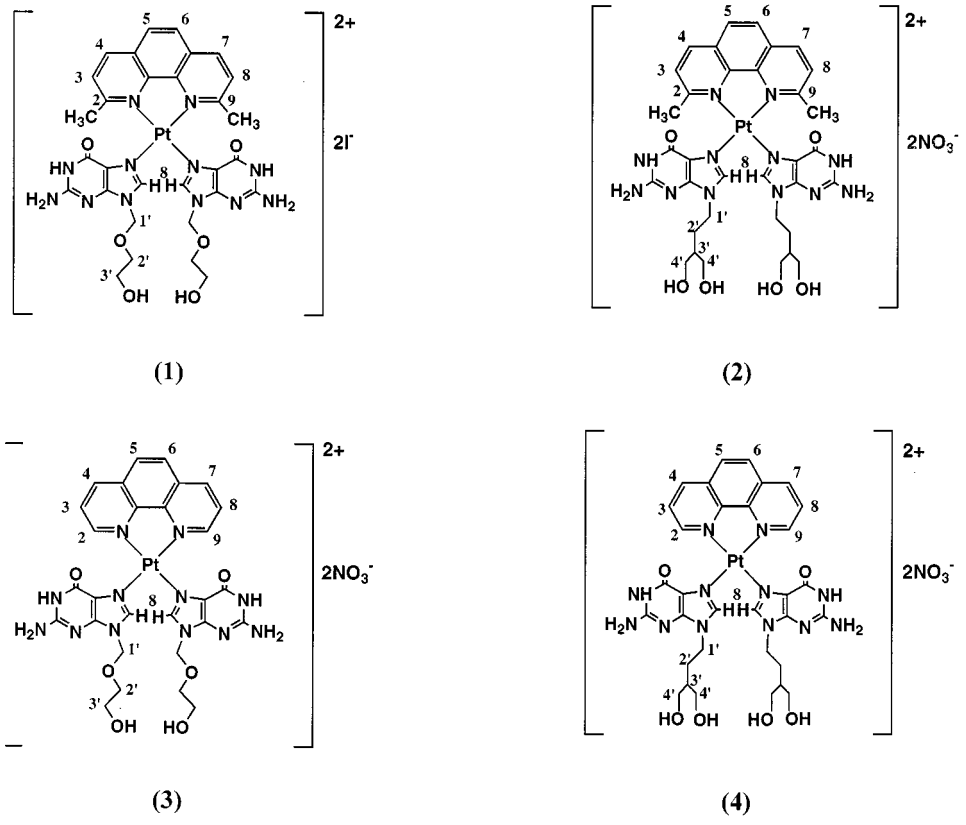
Results and Discussion

In a recent paper[8] we investigated the antiviral and anticancer properties of *cis*-$[PtCl(acy)(NH_3)_2](NO_3)$ in comparison to those of acyclovir and cisplatin. The platinum-acyclovir complex maintained the antiviral activity of acyclovir, although it showed a minor efficacy on a molar basis (ID_{50}= 7.85 and 1.02 μM for *cis*-$[PtCl(acy)(NH_3)_2](NO_3)$ and acyclovir, respectively). However, the novel hybrid drug, although less toxic towards tumour cells than cisplatin, showed similar activity when equitoxic doses were administered in vivo to P388 leukaemia-bearing mice (% T/C = 209 and 211 for *cis*-$[PtCl(acy)(NH_3)_2](NO_3)$ and cisplatin, respectively). *cis*-$[PtCl(acy)(NH_3)_2](NO_3)$ was also active against a cisplatin-resistant subline of the P388 leukaemia, thus indicating that the mechanism of action could be different from that of cisplatin.

On this basis we directed our attention to the synthesis of platinum compounds containing antiviral purinic bases and a phenanthroline as ligands (Scheme 1), with the aim of improving the antitumoral and/or the antiviral properties by taking advantage of the intercalating ability of phenanthrolines.

Synthesis of the Compounds

The preparation of the complexes was straightforward. The diiodoplatinum complex $[PtI_2(Me_2phen)]$ is a rather reactive substrate due to the steric clash between the *ortho* methyl substituents of the phenanthroline and the *cis* iodo ligands, which strongly destabilises the square-planar geometry.[16,17] It reacts smoothly with acyclovir (solvent CH_2Cl_2/CH_3OH, 1:1 v/v) to give substitution of the iodo ligands and formation of the cationic species



Scheme 1. Schematic drawing of compounds **1**−**4**

$[PtI(acy)(Me_2phen)]^+$ and $[Pt(acy)_2(Me_2phen)]^{2+}$. The separation of the two reaction products was accomplished by taking advantage of their different solubilities in water. The divalent salt $[Pt(acy)_2(Me_2phen)]I_2$ (**1**) is very soluble in water while the monovalent salt $[PtI(acy)(Me_2phen)]I$ (**5**) is sparingly soluble in water but rather soluble in methanol.

The synthesis of $[Pt(pen)_2(Me_2phen)](NO_3)_2$ (**2**) was carried out using DMF as solvent because of the insolubility of penciclovir in more common solvents. The starting $[PtI_2(Me_2phen)]$ substrate was first converted into the solvato species $[Pt(DMF)_2(Me_2phen)]^{2+}$ by reaction with a stoichiometric amount of $AgNO_3$. The solvato species reacts smoothly with a stoichiometric amount of penciclovir (ratio 1:2) to give complex **2**.

The preparation of $[Pt(acy)_2(phen)](NO_3)_2$ (**3**) and $[Pt(pen)_2(phen)](NO_3)_2$ (**4**) was carried out using the same procedure as described for **2**. The use of DMF as solvent was caused by the insolubility of the starting $[PtI_2(phen)]$ complex in common solvents.

Stereochemical Investigations

Complex 1

All complexes were characterised by elemental analysis, IR and NMR spectroscopy. A bathochromic shift of the stretching frequency of the C=O group in position 6 of the purine ring (1697 cm^{-1} in complex **1** and 1717 cm^{-1} in free acyclovir) is indicative of coordination of the guanine base to platinum through N(7).[18,19]

The ^1H NMR spectrum of **1** in D_2O shows a single set of signals (Figure 1, Table 1) which is in agreement with a symmetrical complex. The phenanthroline is symmetrical with chemical shifts at $\delta = 2.35$ for the methyls in positions 2 and 9 and at $\delta = 8.69$ ($J_{H\text{-}H} = 8.4$ Hz), 8.11, and 7.71 ($J_{H\text{-}H} = 8.4$ Hz) for protons 4/7, 5/6, and 3/8, respectively. Also, the two acyclovir ligands give a single set of resonances. The chemical shift of the H(8) protons at $\delta = 8.53$ is also indicative of N(7) coordination of the purine bases to platinum ($\delta = 7.91$ for free acyclovir).[13,20]

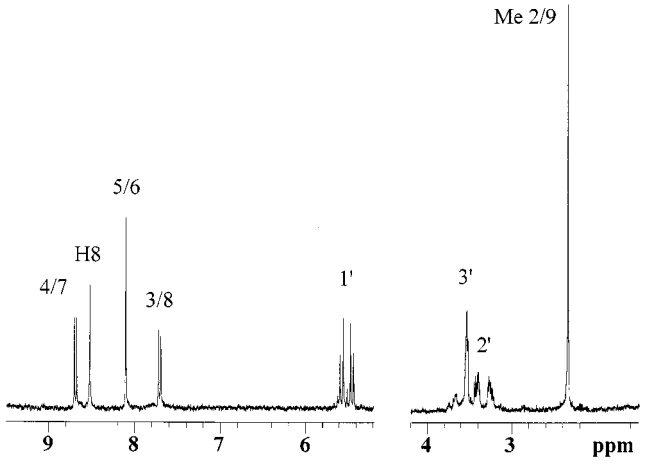


Figure 1. Sections of the ^1H NMR spectrum in D_2O of complex **1**

For $Pt(A)G_2$ complexes (where A is a C_2-symmetrical bidentate ligand and G a guanine derivative) different rotamers are possible: one *HH* conformer (Head-to-Head) with the H(8) of the two G's on the same side of the platinum coordination plane, and two *HT* conformers (Head-to-Tail) with the H(8) on opposite sides of the coordination plane (Scheme 2).[21,22] The two *HT* conformers differ in their chirality (Λ or Δ). The relation between the trace of the helix [a line connecting the O(6) atoms of the two guanines] and the axis of the helix (the perpendicular to the coordination plane passing through the platinum centre) is described by the index and thumb of the left hand in the Λ conformer and of the right hand in the Δ conformer. In the case of nonchiral G ligands all rotamers will be symmetrical (C_s and C_2 symmetry for the *HH* and *HT* rotamers, respectively); moreover the two *HT* rotamers will constitute a couple of enantiomers and will be identical from an NMR point of view.

From previous work[23–27] it is well-known that in $Pt(A)G_2$ complexes the rate of interconversion between rotamers [which requires rotation of the nucleobases around the Pt–N(7) bonds] depends upon the steric bulk of the carrier ligand (A). This interconversion is always fast, with respect to the NMR time scale, for primary amines, but can become very slow (half-lives of hours) for secondary and tertiary amines with a rigid structure. Me_2phen is to be ascribed to this second class of ligands since the steric bulk created by the methyls in positions 2 and 9 of the phenanthroline is expected to hinder the rotation of the two acyclovir molecules about the Pt–N(7) bonds, therefore the observation of only one set of signals was quite surprising. A single set of signals would mean either a free rotation about the Pt–N(7) bonds or slow rotation and a predominance of either the *HH* or the *HT* conformers. To answer this question a similar complex containing guanosine, instead of acyclovir, was prepared.[28] The ribose rings present in the guanosine ligands are chiral and thus render the two *HT* rotamers inequivalent (although they remain C_2-symmetrical) and the *HH* rotamer nonsymmetrical (C_1 symmetry). Assuming a slow interconversion different signals should be observed for the different rotamers. The ^1H NMR spectrum of $[Pt(guo)_2(Me_2phen)]Cl_2$ in D_2O showed, in the region of H(8), two very strong and rather shielded signals (at $\delta = 8.38$ and 8.35), and two very weak and rather deshielded signals (at $\delta = 8.86$ and 8.88). Literature data indicate that the *HT* orientation is stabilised with respect to the *HH* orientation by a better dipole–dipole interaction between the two guanine bases; this must be the case also for the $[Pt(guo)_2(Me_2phen)]Cl_2$ complex. Therefore the two strong signals can be assigned to the H(8) protons of the two *HT* rotamers (ΔHT and ΛHT), while the two very weak signals can be assigned to the single, nonsymmetrical, *HH* conformer. Big changes in the isomer distribution are not expected for substitution of the ribose ring of guanosine by the 2-hydroxyethoxymethyl chain of acyclovir, therefore we can expect that the preferred isomer for **1** has an *HT* conformation. The value of the H(8) chemical shift (at rather high field) supports the above conclusion.

Additional information about the conformational rigidity of complex **1** could be gained from examination of the

NMR signals belonging to the 2-hydroxyethoxymethyl chains. The assignment of the multiplet centred at δ = 5.52 to the C(1′)H$_2$ protons was straightforward. Quite more difficult was the assignment of the multiplets at δ = 3.36 and 3.55 to the C(2′)H$_2$ and C(3′)H$_2$ protons, respectively. These two methylenes give coincident signals (δ = 3.67) in free acyclovir. A two dimensional ^{13}C,^{1}H HETCOR experiment was diagnostic for their assignment (an expansion of the aliphatic region of the two dimensional ^{13}C,^{1}H spectrum is shown in Figure 2).

On the basis of characteristic values of ^{13}C chemical shifts for similar organic chains (e.g. diethylene glycol), the cross peak A (at δ = 61 on the ^{13}C axis) is assigned to C(3′)H$_2$ and the two cross peaks B (at δ = 72 on the ^{13}C axis) are assigned to C(2′)H$_2$. It is worth noting that both methylene groups bound to the ether oxygen, C(1′)H$_2$ and C(2′)H$_2$, exhibit a marked diastereotopic splitting of the CH$_2$ protons. Such a splitting is absent in the uncoordinated acyclovir and is indicative of the formation of a chiral centre in the complex. The platinum becomes a chiral centre only in the *HT* rotamers, therefore the observation of such a diastereotopic splitting also lends support to the *HT* conformation being by far the most abundant for compound **1**. Furthermore, the large value of the diastereotopic splitting indicates that the rate of interconversion between *HT* enantiomers is rather slow.

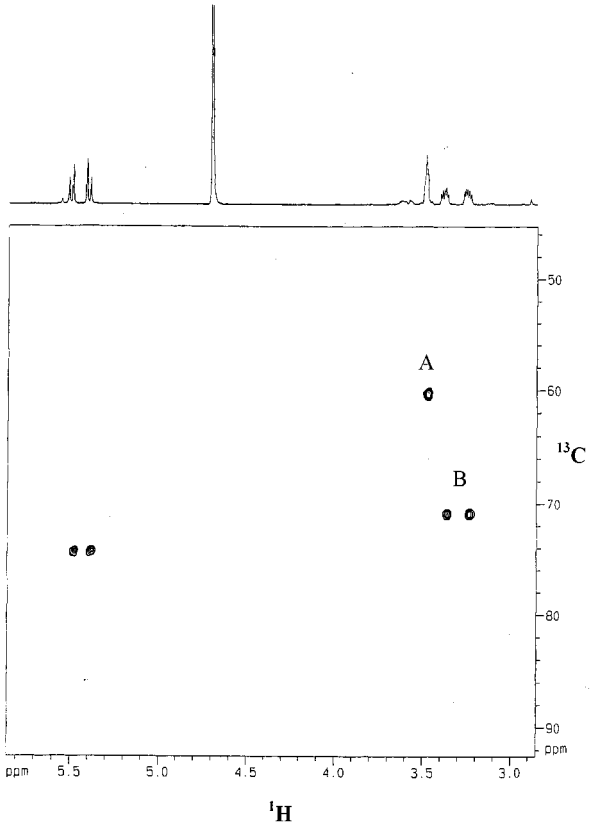

Figure 2. ^{1}H,^{13}C two dimensional (HETCOR) spectrum in D_2O of complex **1** in the region of the aliphatic protons; A = C(3′)H$_2$, B = C(2′)H$_2$

Ligand Exchange in Complex 1

Complex **1** is the only compound of the series which has been isolated with iodide as counterions. In CD_3OD (Figure 3, Table 1) compound **1** is in equilibrium with two new species: one of the new species is easily recognised as free acyclovir, the second species is characterised by having two singlets (at δ = 3.34 and 2.25) in the methyl region of the spectrum indicating that the two methyls of Me_2phen are inequivalent. Furthermore, integration of the signals indicates that the new complex contains only one molecule of

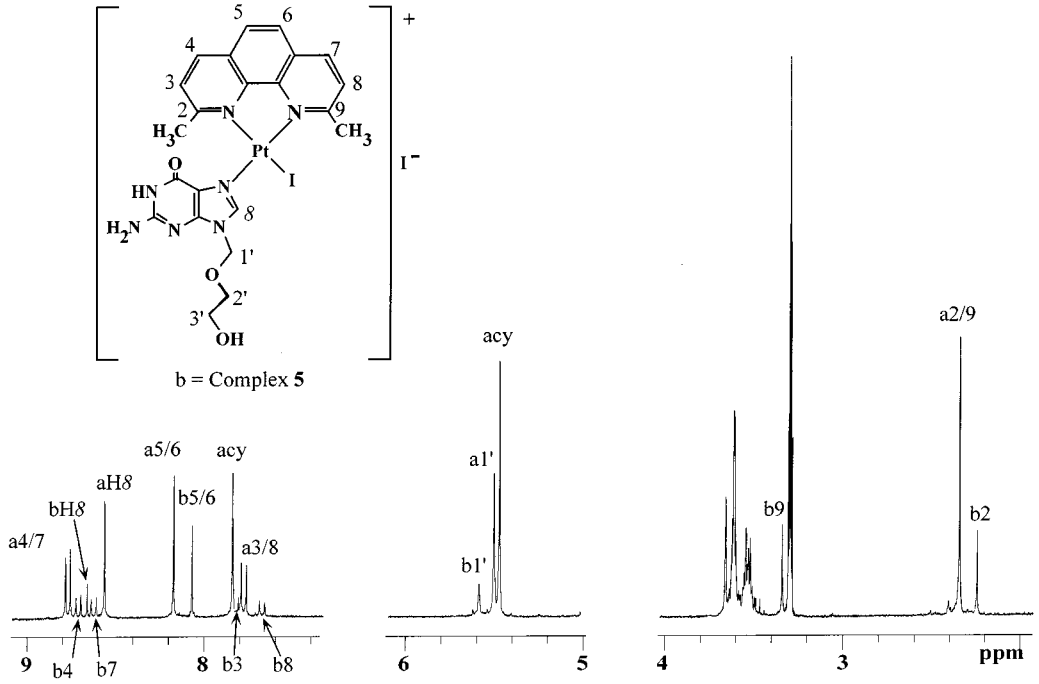

Figure 3. ^{1}H NMR spectrum in CD_3OD of complex **1**; a = complex **1**, b = complex **5**, acy = free acyclovir

acyclovir per phenanthroline and therefore must be formulated as [PtI(acy)(Me_2phen)]I (**5**) with a bidentate Me_2phen, one iodide, and one acyclovir residue in the coordination sphere of platinum.

To check this hypothesis complex **5** was prepared independently by using the same experimental conditions as for the preparation of complex **1** but adding only one equivalent of acyclovir per molecule of platinum substrate. The isolated complex **5**, fully characterised by elemental analysis and IR spectroscopy, exhibits a ^{1}H NMR spectrum in CD_3OD that is identical to that observed for the newly formed complex in the NMR spectrum of **1** in CD_3OD. Therefore we can conclude that in methanol the following equilibrium is established:

$$[Pt(Acy)_2(Me_2phen)]^{2+} + I^- \rightleftharpoons [PtI(Acy)(Me_2Phen)]^+ + Acy$$

The presence of the above equilibrium was also confirmed by addition of KI (five times the stoichiometric amount) to a solution of **1** in CD_3OD. The molar ratio **1**:**5** which was 1.75 before the addition of KI became 0.5 after the addition of KI clearly supporting the involvement of the iodide ion in the equilibrium of displacement of one acyclovir ligand from **1**.

A question to be answered before concluding this section is why the above equilibrium is observed in methanol but not in water. A reasonable explanation for this is that methanol is less efficient than water in solvating charged species and keeping them well separated. A parameter directly related to this property is the dielectric constant, which is far bigger for water (78.5) than for methanol (32.6).

Complex 2

Significant IR data for complex **2** are the C=O stretching vibration at 1691 cm^{-1} and the NO_3^- stretching vibration at 1389 cm^{-1}. A complete assignment of the ^{1}H NMR spectroscopic data is given in Table 1. The discussion given for **1** applies entirely also to **2**.

Complex 3

Significant IR data for complex **3** are the C=O stretching vibration at 1693 cm^{-1} and the NO_3^- stretching vibration at 1384 cm^{-1}.

The ^{1}H NMR spectrum of complex **3** in D_2O is shown in Figure 4 and the chemical shift values are reported in Table 1.

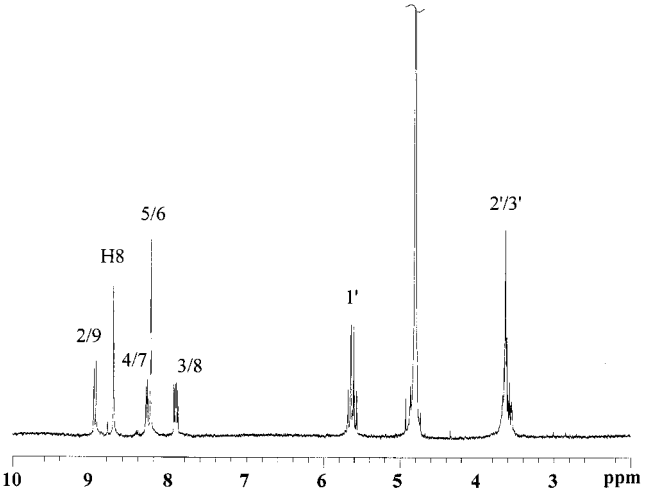

Figure 4. ^{1}H NMR spectrum in D_2O of complex **3**

As with **1**, a single set of signals was also observed for **3**. However, since the phen ligand does not contain bulky substituents in the *ortho* positions, the observation of a single set of resonances could stem from a fast interconversion (on the NMR time scale) of different rotamers (both *HH* and *HT*) and not from the presence of only the enantiomeric *HT* rotamers (as was the case for **1**). To answer this question the analogous compound containing guanosine instead of acyclovir ($[Pt(guo)_2(phen)](NO_3)_2$) was synthesised.[28] The presence of the chiral ribose renders the *HH* rotamer no longer C_s-symmetrical and causes the two *HT* rotamers, although still C_2-symmetrical, to be different from one another. The observation of two major sets of signals (belonging to the two *HT* rotamers) is clearly indicative of slow interconversion among rotamers, therefore we can conclude that the rate of interconversion among the rotamers of **3** is also slow on the NMR time scale and the single set of signals is assignable to the most favoured *HT* enantiomers. Also, the observation of a diastereotopic splitting for the $C(1')H_2$ protons, similar to that seen for complex **1**, supports the idea of a slow interconversion between the *HT* enantiomers of complex **3** in D_2O.

The steric bulk of phen is much smaller than that of Me_2phen (the deviations from the planar geometry caused by the steric interaction between the *cis* ligands is very large in platinum complexes with Me_2phen but is undetectable in platinum complexes with phen); however, the rigidity of the phen ligand does not permit any relief of the steric interaction which builds up when the rotating G comes across the *ortho* hydrogens of the phenanthroline.

Complex 4

Significant IR data for complex **4** are the C=O stretching vibration at 1692 cm^{-1}, and the NO_3^- stretching vibration at 1384 cm^{-1}. The complete assignment of the ^1H NMR spectroscopic data for **4** is given in Table 1. The discussion given for **3** applies also to **4**.

Stability of the Complexes in Physiological Medium

The observation that the iodide counter ion is capable of displacing the coordinated acyclovir from **1** prompted us to investigate the chemical stability of these compounds in physiological medium. Therefore **1**, **2**, **3**, and **4** were each dissolved in D_2O containing 0.1 M NaCl and ^1H NMR spectra were measured over a period of time.

Complexes **1** and **2** were found to be very stable over a period of two weeks. On the other hand, complexes **3** and **4** underwent ligand dissociation equilibria similar to that observed for **1** in methanol (entering of a chloro ligand and displacement of one purine base). After ten days the concentration of **3** and **4** was slightly less than 80% of the initial concentration.

This unexpected result (greater stability of the more sterically hindered compounds **1** and **2**) is probably a consequence of the *ortho* substituents of neocuproine shielding the metal centre and inhibiting the nucleophilic attack of an entering chloride upon the platinum atom.[29]

The displacement of a purine base by a chloride ion in saline solution may have some relevance in relation to the stability of the major DNA adduct of cisplatin in which two purines are cross-linked by a $Pt(NH_3)_2$ moiety.

Biological Activity of Compounds 1−4

While the cytostatic activity of compounds **1**−**4** is still under investigation, preliminary results on their antiviral activity have already been obtained. So far the antiviral activity of the four hybrid drugs has been tested against the Human Immunodeficiency Virus (HIV) and more precisely against HIV-1(IIIB) and HIV-2(ROD) viruses in MT_4 cells. An automated in vitro tetrazolium-based colorimetric assay was used to screen the inhibitory activity of the drugs.[30] The results are reported in Table 2.

Table 2. Anti-HIV-1(IIIB) and HIV-2(ROD) activity and cytotoxicity properties of compounds **1**−**4**, free acyclovir, and penciclovir in MT_4 cells

Compound	HIV Strain	EC_{50} [a]	IC_{50}[b]	SI[c]
1	IIIB	>1.81	1.81	<1
	ROD	>2.47	2.47	<1
2	IIIB	>6.02	6.02	<1
	ROD	>11.8	11.8	<1
3	IIIB	>132	>132	–
	ROD	>132	>132	–
4	IIIB	>124	>124	–
	ROD	>124	>124	–
Acyclovir	IIIB	>555	>555	–
	ROD	>555	>555	–
Penciclovir	IIIB	>493	>493	–
	ROD	>493	>493	–

[a] EC_{50} is defined as the concentration of compound (μM) which inhibits 50% of the viral replication. – [b] IC_{50} is defined as the concentration of compound (μM) which reduces the viability of the treated cells to 50% of that of untreated cells. – [c] SI (Selective Index) = IC_{50}/EC_{50}.

In general, a drug is considered to be active against HIV-1 and HIV-2 viruses if the EC_{50} is ≤1 μM.[3,30,31] None of the tested compounds exhibited anti-HIV activity at subtoxic concentrations. It should be noted, however, that the free acyclovir and penciclovir are also deprived of anti-HIV activity. Therefore a better indication of a synergistic effect, if any, stemming from the coupling of antiviral nucleotides with cisplatin-like substrates will come from anti-HSV and antitumor assays which are in progress.

However, an interesting result stemming from these preliminary experiments is the cytotoxic activity against MT_4 cells, which is far greater for compounds **1** and **2** than for compounds **3** and **4**. The two couples of compounds have a similar charge (+2) and, presumably, similar cell permeability. Therefore, their different behaviour is to be ascribed to a different reactivity in the biological medium determined by the presence in **1** and **2** of two methyl substituents in the *ortho* positions of the phenanthroline.

Conclusions

Platinum(II) complexes containing a bidentate phenanthroline and the antiviral agents acyclovir and penciclovir

have been synthesised and characterised. Both the Me_2phen and the phen carrier ligands are able to hinder rotation of the guanine bases about the Pt−N(7) bond with the consequence that the interconversion between rotamers is very slow on the NMR time scale. This was expected for Me_2phen but was rather unexpected for phen and is a clear demonstration that in addition to the steric bulk the rigidity of the carrier ligand can also deeply influence the rate of interconversion among rotamers in $Pt(A)G_2$ complexes. The rigidity of the phen ligand does not allow any relief of the steric interaction that builds up when the rotating G comes across the *ortho* protons of phen.

The different behaviour in water and methanol of **1** indicates that the solvating ability and the dielectric constant of the solvent play an important role in the stabilisation of cationic platinum species in the presence of coordinating anions such as Cl^- or I^-. In this context, an unexpected result was the greater stability in water solution and in the presence of 0.1 M NaCl of complexes with neocuproine (**1** and **2**) with respect to those with phenanthroline (**3** and **4**). The higher stability of the former complexes is probably favoured by the shielding of the metal centre by the methyl substituents in positions 2 and 9 of the phenanthroline which prevents the chloride ions from entering into the coordination sphere of the metal.

Although complexes **1**−**4** are not active against HIV-1(IIIB) and HIV-2(ROD) viruses; nevertheless there are two important observations: i) the use of neocuproine (a phenanthroline with methyl substituents in positions 2 and 9) instead of unsubstituted phenanthroline can increase the cytotoxicity of the compounds by two order of magnitude, ii) the increase in cytotoxicity appears to be in relation to the greater stability in the biological medium of the neocuproine derivatives.

Experimental Section

Physical Measurements: Elemental analyses were performed on a Elemental Analyzer mod. 1106 Carlo Erba Instrument. IR Spectra were recorded on a spectrophotometer Perkin−Elmer Spectrum One using KBr as solid support for pellets. ^{1}H NMR spectra were recorded on a Bruker AM-WB 300 MHz instrument. Chemical shifts were referred to TMS by using the residual protic solvent peaks as internal references (δ = 4.80 for D_2O and δ = 3.30 for CD_3OD). ^{13}C,^{1}H HETCOR two dimensional experiments were performed on a DRX 500 MHz WB Avance Bruker Instrument with D_2O as solvent and internal CH_3OH as reference for ^{13}C (δ = 50.2).

Starting Materials: Commercial reagent grade chemicals, 2,9-Me_2-1,10-phenanthroline (Me_2phen, neocuproine), 1,10-phenanthroline (phen), guanosine (guo), DMSO and DMF, were used without further purification.

$[PtCl_2(DMSO)_2]$,[32] $[PtX_2(Me_2phen)]$ (X = Cl, I),[33] $[Pt(guo)_2(Me_2phen)]Cl_2$, $[Pt(guo)_2(phen)](NO_3)_2$,[28] acyclovir (acy) and penciclovir (pen)[34] were prepared by previously reported procedures.

Preparation of $[PtI_2(phen)]$: A suspension of $[PtCl_2(DMSO)_2]$ (300 mg, 0.71 mmol) in methanol was treated with a large excess of KI (581 mg, 3.5 mmol). After stirring for one day, the initially yellow suspension became an orange solution containing the dimeric complex $[Pt_2I_4(DMSO)_2]$. This solution was treated with phen (140 mg, 0.71 mmol) and left stirring for one hour during which time a yellow-orange precipitate was formed. The precipitate was collected by filtration of the mother solution, the filtrate was concentrated to half its volume by evaporation of the solvent under reduced pressure and kept at room temperature for a few days during which time another yellow precipitate was formed. The collected solid fractions were washed with methanol and dried under vacuum. Yield 424 mg (95%) based on the starting platinum complex. − $C_{12}H_8I_2N_2Pt$ (629.10): calcd. C 22.9, H 1.3, N 4.5; found C 22.6, H 1.3, N 4.4.

Preparation of $[Pt(acy)_2(Me_2phen)]I_2$ (1): A solution containing $[PtI_2(Me_2phen)]$ (102 mg, 0.155 mmol) dissolved in CH_2Cl_2/CH_3OH (200 mL; 1:1, v/v) was treated with acyclovir (70 mg, 0.31 mmol). After stirring for 2 hours, the initially orange solution became yellow. The solvent was evaporated under vacuum and the yellow residue was suspended in 100 mL of water and stirred overnight. The water solution was then filtered and taken to dryness by evaporation of the solvent under vacuum. The yellow residue proved to be the salt $[Pt(Me_2phen)(acy)_2]I_2$. Yield 178 mg (90%). − $C_{31}H_{36}Cl_2I_2N_{12}O_6Pt$ (**1**·CH_2Cl_2) (1192.5): calcd. C 30.1, H 3.0, N 13.2; found C 30.8, H 2.9, N 13.7.

Preparation of $[PtI(acy)(Me_2phen)]I$ (5): $[PtI_2(Me_2phen)]$ (82 mg, 0.125 mmol) was dissolved in CH_2Cl_2 (70 mL) and treated with a stoichiometric amount of acyclovir (28.4 mg, 0.126 mmol) previously dissolved in 70 mL of CH_3OH. The yellow solution was left stirring for one day and then concentrated to 50 mL by evaporation of the solvent under vacuum. Addition of diethyl ether (300 mL) caused the precipitation of a yellow solid, which was separated by filtration of the solution, carefully washed with ether, and dried under vacuum. Yield 109 mg (90%). − $C_{23}H_{25}Cl_2I_2N_7O_3Pt$ (**5**·CH_2Cl_2) (967.29): calcd. C 28.6, H 2.6, N 10.1; found C 28.1, H 2.4, N 10.2.

Preparation of $[Pt(pen)_2(Me_2phen)](NO_3)_2$ (2): A solution of $[PtCl_2(Me_2phen)]$ (149 mg, 0.31 mmol) in DMF (75 mL) was treated with $AgNO_3$ (109 mg, 0.628 mmol) previously dissolved in a minimum amount of water (1 mL). After stirring in the dark for 12 h at room temperature, the solution was filtered through celite to remove AgCl. The filtered yellow solution was treated with penciclovir (157 mg, 0.62 mmol) and stirred for 4 h. Addition of diethyl ether (300 mL) caused the formation of a creamy precipitate. The precipitate was collected by filtration of the solution, washed with acetone and ether, and dried under vacuum. The crude product was extracted with 100 mL of water, the solution was filtered and taken to dryness by evaporation of the solvent under vacuum. Yield 249 mg (75%). − $C_{34}H_{46}N_{14}O_{14}Pt$ (**2**·$2H_2O$) (1069.9): calcd. C 38.2, H 4.3, N 18.4; found C 38.1, H 4.3, N 18.4.

Preparation of $[Pt(acy)_2(phen)](NO_3)_2$ (3) and $[Pt(pen)_2(phen)](NO_3)_2$ (4): $[PtI_2(phen)]$ (150 mg, 0.24 mmol) was dissolved in DMF (80 mL) at 50 °C and treated with $AgNO_3$ (81.3 mg, 0.48 mmol). The solution was cooled to room temperature and stirred in the dark overnight. The solution was filtered through celite to remove the yellow AgI precipitate and treated with a stoichiometric amount of acyclovir (107 mg, 0.48 mmol) for complex **3** and penciclovir (120 mg, 0.48 mmol) for complex **4**. The solution was left stirring for 4 h and then treated with diethyl ether to induce the precipitation of the platinum complex. The solid was collected by filtration of the solution, washed with acetone and ether, and finally dried under vacuum. The crude product was extracted with

water (40 mL), the solution was filtered and taken to dryness under vacuum to give pure compounds **3** and **4**, respectively. Yields 189 mg (80%) and 200 mg (80%) for complex **3** and **4**, respectively. − $C_{28}H_{36}N_{14}O_{15}Pt$ (**3**·3H_2O) (1003.8): calcd. C 33.5, H 3.6, N 19.5; found C 33.2, H 3.2, N 18.9. − $C_{32}H_{44}N_{14}O_{15}Pt$ (**4**·3H_2O) (1059.3): calcd. C 36.3, H 4.2, N 18.5; found C 35.6, H 3.7, N 18.3.

Biological Tests: The antiviral assays were carried out according to the method reported in ref.[35]

Acknowledgments

Thanks are expressed to Dr. Sandra A. De Pascali for the help in the preparation of the platinum complexes. We are also grateful to Prof. Erik De Clercq and Drs. Christophe Pannecouque and Myriam Witvrouw (Katholieke Universiteit, Rega Instituut, Leuven, Belgium), who carried out the antiviral assays. The authors also thanks the University of Bari (Contribution ex 60%), the Ministero dell'Università e della Ricerca Scientifica e Tecnologica, MURST (Cofin. 1988 no. 9803021072) and the EC (COST Chemistry projects D8/0009/97 and D8/0012/97).

Small Platinum−Thallium Clusters Stabilized by Ethylenediamine, $[(NC)_5Pt-Tl(en)_{n-1}]$ ($n = 1-3$) − Characterization in Solution and in the Solid State

Guibin Ma,[a][‡] Mikael Kritikos,[b] and Julius Glaser*[a]

Keywords: Metal−metal interactions / Platinum / Thallium / N ligands / NMR spectroscopy

Three neutral binuclear platinum–thallium compounds containing a direct and "naked" (unsupported by ligands) metal–metal bond have been prepared in dimethyl sulfoxide (DMSO). The compounds have the formula $[(NC)_5Pt–Tl(en)_{n-1}]$ (n = 1–3, for compounds **1**, **2** and **3**, respectively) and were found to exist in solution by means of multinuclear NMR (^{195}Pt, ^{205}Tl, ^{13}C and ^{1}H) and Raman spectroscopy. The compounds exhibit very large single bond $^{195}Pt–^{205}Tl$ spin-spin coupling constants of 48–66 kHz. In addition, the solid state analogues of **1** and **3**, $[(NC)_5Pt–Tl(DMSO)_4](DMSO)$ and $[(NC)_5Pt–Tl(en)_2](DMSO)_2$, were synthesized and their structures determined by single crystal X-ray diffraction. The metal–metal bond lengths of Pt–Tl are 2.6131(4) Å and 2.6348(5) Å in compounds **1** and **3**, respectively. Crystal data for compound **1:** monoclinic, space group *Cc* (No. 9), $Z = 4$, $a = 17.2367(14)$, $b = 9.5560(11)$, $c = 17.7941(15)$ Å, $\beta = 100.551(10)°$, $V = 2881.4(5)$ Å^3, $T = 110(1)$ K; and for compound **3:** monoclinic, space group $P2_1$ (No. 4), $Z = 2$, $a = 9.3167(14)$, $b = 12.3007(13)$, $c = 11.4586(16)$ Å, $\beta = 112.318(16)°$, $V = 1214.8(3)$ Å^3, $T = 110(1)$ K.

Introduction

A direct metal−metal bond between platinum and thallium atoms in the solid state was first described by Nagle et al.[1] Later, the binuclear compound $[Pt(CN)_2Tl(crown\text{-}P_2)](NO_3)$ {Crown-P_2: 1,10-bis[(diphenylphosphanyl)methyl]-1,10-diaza-4,7,13,16-tetraoxaoctadecane, formula: $C_{38}H_{48}N_2O_4P_2$}[2] and trinuclear Pt−Tl−Pt compounds, e.g. *cis*-$[Tl\{(1\text{-methylthyminato})_2Pt(NH_3)_2\}_2](NO_3)\cdot 7H_2O$[3] and $(NBu_4)_2[Tl\{Pt(C_6F_5)_4\}_2]$,[4] with Pt−Tl metal−metal bonds, have been synthesized. Three compounds containing a slightly larger Pt−Tl cluster unit have also been prepared, namely $[TlPt_3(CO)_3(PCy_3)_3][Rh(\eta\text{-}C_8H_{12})Cl_2]$ (Cy = cyclohexyl),[5] $[TlPt_6(\mu\text{-}CO)_6(\mu\text{-}dppp)_3]^+$ [dppp = $(C_6H_5)_2P(CH_2)_3P(C_6H_5)_2$],[6] and $[Pt_3\{\mu_3\text{-}Tl(acac)\}(ReO_3)(\mu\text{-}dppm)_3]^+$ [dppm = $(C_6H_5)_2PCH_2P(C_6H_5)_2$].[7] Hao et al.[8] have prepared hexaplatinum clusters with carbonyl and diphosphane ligands, e.g. $[Pt_6(\mu\text{-}CO)_6(\mu\text{-}dppp)_2(dppp)_2]$, and were able to trap Hg^0 and Tl^I in $[Pt_6(\mu_6\text{-}Hg)(\mu\text{-}CO)_6(\mu\text{-}dppp)_3]$ and $[Pt_6(\mu_6\text{-}Tl)(\mu\text{-}CO)_6(\mu\text{-}dppp)_3]^+$, respectively. In the latter compound, the Pt−Tl bond lengths are in the range of 2.860(3)−2.992(3) Å.

Recently, a new family of four binuclear platinum-thallium cyano compounds with the formula $[(NC)_5Pt-Tl(CN)_{n-1}]^{(1-n)}$ ($n = 1-4$ for compounds **I**, **II**, **III** and **IV,** respectively), which contain a direct metal−metal bond unsupported by the ligands, have been synthesized from $Tl(ClO_4)_3$, $K_2Pt(CN)_4$ and NaCN in aqueous solution.[9−11] The compounds possess long-term stability but undergo photochemically induced two-electron transfer between the metal ions when exposed to daylight. Thus, possible applications in photovoltaic devices, for example in a "wet" solar cell of the Grätzel type[12] can be envisaged. However, several chemico-physical parameters of the compounds, such as stability, electrochemical properties or light absorption characteristics, have to be tuned in order to fit the demands of the cell. Therefore, we have initiated a study of possible modifications of these compounds, including both preparative efforts and experimental and theoretical characterization in solution and in the solid state.

The binuclear compounds **I**−**IV** can be viewed as consisting of two units, $Pt(CN)_5$ and $Tl(CN)_n$. The platinum unit is stable and relatively inert in all four compounds whereas the geometry of the thallium entity changes depending on the number of cyanide ligands;[9,10] these cyanide ligands have been found to be kinetically labile. Hence, there is a possibility to replace the cyanides by other ligands, for example amines or organic solvent molecules. Here, the bidentate ethylenediamine ligand was deemed suitable for further study due to its "robustness" and to the fact that Tl^{III} can form strong complexes with N-donor ligands.[13−15] Recently, it was found in this laboratory that, although Tl^{III} ethylenediamine complexes are difficult to

prepare in aqueous solution, very stable complexes are formed in organic solvents.[16]

In the present paper, complexes of $[(NC)_5Pt-Tl(en)_{n-1}]$ ($n = 1-3$) with a direct Pt−Tl bond have been studied both in DMSO solution and in the solid state.

Results and Discussion

Characterization in Solution by Multinuclear NMR Spectroscopy

The binuclear complexes $[(NC)_5Pt-Tl(DMSO)_4]$ (**1**), $[(NC)_5Pt-Tl(en)(DMSO)_x]$ (**2**) and $[(NC)_5Pt-Tl(en)_2]$ (**3**) were prepared in DMSO solvent according to the following reactions:

$$[Tl(dmso)_6]^{3+} + [Pt(CN)_4]^{2-} + CN^- \rightleftharpoons \underset{\mathbf{1}}{[(NC)_5Pt{-}Tl(dmso)_4]} + 2\ DMSO \quad (1)$$

$$[Tl(dmso)_6]^{3+} + en \rightleftharpoons [Tl(en)(dmso)_x]^{3+} + (6{-}x)\ DMSO \quad (2)$$

$$[Tl(en)(dmso)_x]^{3+} + [Pt(CN)_4]^{2-} + CN^- \rightleftharpoons \underset{\mathbf{2}}{[(NC)_5Pt{-}Tl(en)(dmso)_x]} \quad (3)$$

$$[Tl(en)_3]^{3+} + [Pt(CN)_4]^{2-} + CN^- \rightleftharpoons \underset{\mathbf{3}}{[(NC)_5Pt{-}Tl(en)_2]} + en \quad (4)$$

The compounds **1**, **2** and **3** were prepared, according to the reactions in Equation (1) to (4), in solutions in which the composition was varied in order to achieve different en/Pt−Tl ratios. The content and the concentration of the compounds in each solution were determined by means of ^{205}Tl and ^{195}Pt NMR spectroscopy. Since the chemical shifts of the three compounds fall in different regions (see Table 1), and the spin−spin coupling patterns represent "fingerprints" of each compound, the composition of the solutions could be easily determined.

$[(NC)_5Pt-Tl(en)_2]$ (3)

Reaction of $[Tl(en)_3](ClO_4)_3$, $K_2Pt(CN)_4$ and NaCN [Equation (4)] in DMSO yielded a colorless solution. The ^{195}Pt and ^{205}Tl NMR spectra of this solution showed the existence of only one Pt−Tl bonded complex (Figure 1 a, b). The ^{205}Tl NMR spectrum (Figure 1a) of the resulting solution shows one triplet signal (with the intensity ratio 1:3.9:1) centered at $\delta = 1885$. Two small symmetrical peaks at both sides (with a very large spin-spin coupling constant, ≈48 kHz) arise from spin-spin coupling between the ^{205}Tl and ^{195}Pt nuclei (^{195}Pt: $I = 1/2$, natural abundance 33.8%); together with the central uncoupled peak they give the intensity ratio of 1:3.9:1 as expected for one thallium coupled to one platinum atom. Another peak at $\delta = 2900$ was detected in the ^{205}Tl NMR spectrum of this solution and was assigned to the unreacted $[Tl(en)_3]^{3+}$ complex. The ^{195}Pt NMR spectrum of the Pt−Tl compound (Figure 1b) consists of a 1:1 doublet centered at $\delta = 370$ due to the coupling between ^{195}Pt and ^{205}Tl (^{205}Tl: $I = 1/2$, natural abundance 70.5%) with the same Pt−Tl coupling constant ≈48 kHz to ^{205}Tl as observed in the ^{205}Tl NMR spectrum. In addition, there is another barely resolved doublet due to the coupling of ^{195}Pt to the other thallium isotope, ^{203}Tl, with $I = 1/2$ and natural abundance 29.5%. The huge spin-spin coupling constant of $^1J(^{205}Tl-^{195}Pt)$ ≈48 kHz indicates formation of a direct Pt−Tl bond.

A ^{13}C NMR spectrum of the 99% ^{13}CN enriched complex showed that two types of coordinated cyanides exist in $[(NC^{13})_5Pt-Tl(en)_2]$ (Figure 2). One signal appears at $\delta = 97.3$ with spin-spin coupling constants $^2J(^{13}C^A-^{205}Tl) = 9150$ Hz and $^1J(^{13}C^A-^{195}Pt) = 834$ Hz and is assigned to the axial cyanide, labeled as CN^A. The other signal, at $\delta = 85.9$, with spin-spin coupling constants $^2J(^{13}C^C-^{205}Tl) = 391$ Hz and $^1J(^{13}C^C-^{195}Pt) = 818$ Hz, belongs to the cyanides (CN^C) in the square-planar $Pt(CN)_4$ unit. The ^{13}C NMR signal of the coordinated ethylenediamine ligand overlaps with the signal of deuterated $[D_6]$DMSO at $\delta = 39$. Considering the composition of the solution and the available information on the previously described Pt−Tl complexes **I**−**IV**,[9,10] these findings indicate that the composition of the complex is $[(NC)_5Pt-Tl(en)_2]$.

Table 1. Selected NMR parameters for the complexes $[(NC)_5Pt-Tl(en)_{n-1}]$ ($n = 1-3$) and for some related dimeric (Pt−Tl) and monomeric platinum and thallium species in solution; for the notation of the carbon/cyanide sites in the platinum-thallium cyano complexes, see Figure 6;

[a] The ^{205}Tl NMR chemical shift is given in ppm toward higher frequency with respect to an aqueous solution of $TlClO_4$ extrapolated to infinite dilution at 25 °C; the ^{195}Pt NMR chemical shift is given in ppm toward higher frequency from $\chi(^{195}Pt) = 21.4$ MHz; $\delta[PtCl_6]^{2-} = 4533$ at 25 °C in aqueous solution. − [b] DMSO solution. − [c] Aqueous solution, ref.[9,10].

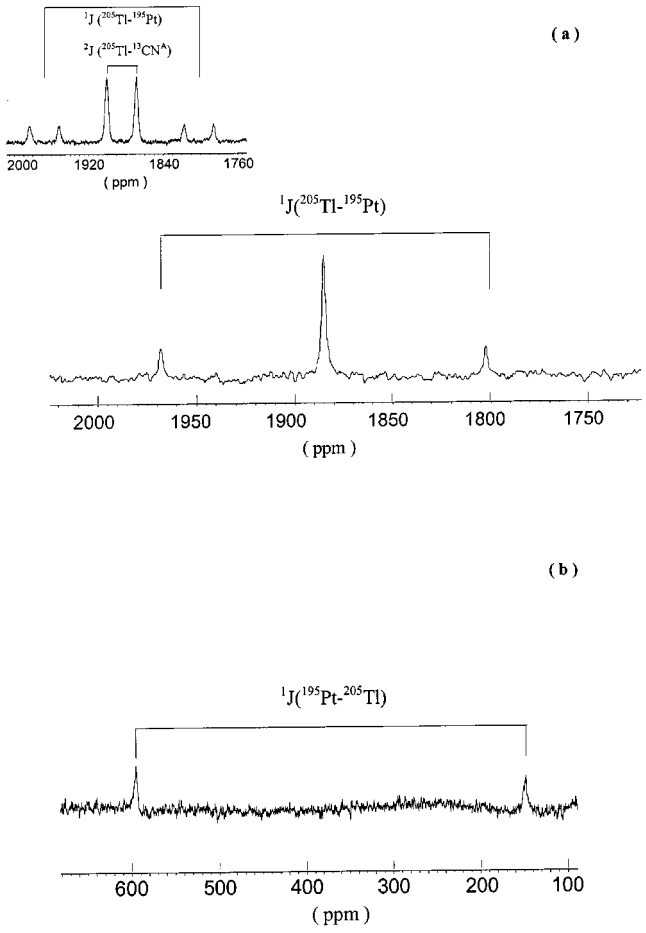

Figure 1. (a) 288.5 MHz ^{205}Tl NMR spectrum of $[(NC)_5Pt-Tl(en)_2]$ in DMSO; the concentrations of $[Tl(en)_3](ClO_4)_3$, $K_2Pt(CN)_4$ and NaCN are all 50 mmol/L (the inset shows the spectrum for a solution of the same compound with all cyanide enriched in ^{13}C, 99%); (b) 107.5 MHz ^{195}Pt NMR spectrum of $[(NC)_5Pt-Tl(en)_2]$ in the same solution, 298 K

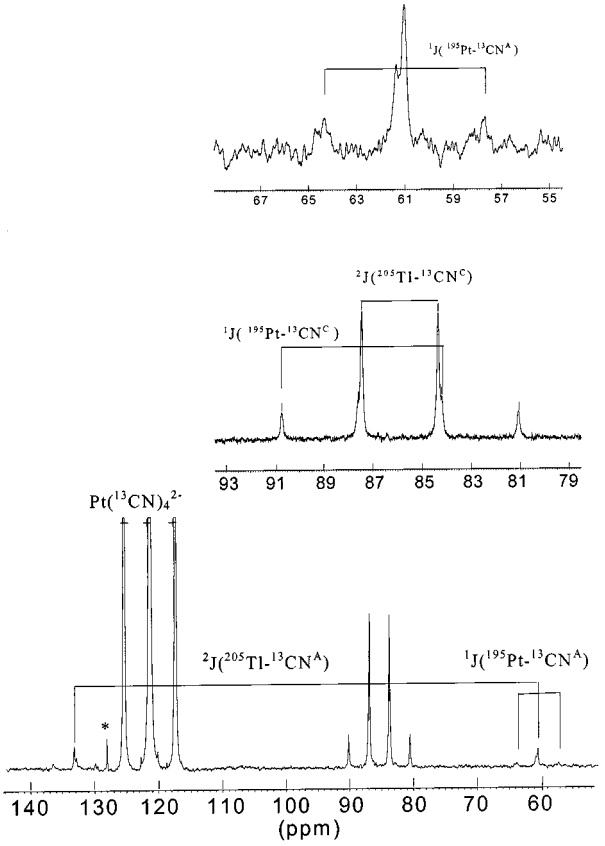

Figure 2. 125.7 MHz ^{13}C NMR of $[(NC^{13})_5Pt-Tl(en)_2]$ in $[D_6]$DMSO solution, 298 K; the composition of the solution is 50 mmol/L $[Tl(en)_3](ClO_4)_3$, 50 mmol/L $NaPt(^{13}CN)_4$ and 50 mmol/L $Na^{13}CN$ (the ^{13}C signal of en at δ = 39 — not shown in the spectrum — overlaps with the ^{13}C signals of the deuterated $[D_6]$DMSO solvent); * impurity; + signals of unreacted $[Pt(^{13}CN)_4]^{2-}$

$[(NC)_5Pt-Tl(DMSO)_4]$ (1) and $[(NC)_5Pt-Tl(en)(DMSO)_x]$ (2)

In a similar way, the two remaining compounds were characterized. The ^{205}Tl NMR spectrum of compound **2** in DMSO solution is a triplet centered at δ = 1448 with the spin-spin coupling constant between ^{205}Tl and ^{195}Pt equal to ≈55 kHz. The ^{195}Pt NMR spectrum of this species is a 1:1 doublet centered at δ = 494 with the same spin-spin coupling constant of about 55 kHz.

For compound **1** in DMSO, the ^{205}Tl NMR chemical shift is δ = 887 and the ^{195}Pt NMR shift is δ = 574 with $^1J(^{205}Tl-^{195}Pt)$ = 65.8 kHz. Selected ^{205}Tl, ^{195}Pt and ^{13}C NMR spectroscopic data of the three compounds are listed in Table 1. (^{205}Tl and ^{195}Pt NMR spectra for compounds **1** and **2** are shown in the Supporting Information).

In the ^{1}H NMR spectra, the signal of the free ethylenediamine CH_2 groups appears at δ = 2.82. For compounds **2** and **3**, signals appear at δ = 3.47 and 3.65, respectively, and are assigned to the protons of the coordinated ethylenediamine ligand.

No metal−metal bonded species were detected when only $[Pt(CN)_4]^{2-}$ and $[Tl(en)_3]^{3+}$ were present in solution. However, with additional cyanide Pt−Tl compounds are formed. This is proved by NMR spectrosocopy (for **1**, **2** and **3)** and X-ray diffraction analysis (for **1** and **3**). Thus, it is apparent that the extra cyanide is necessary for the formation of the Pt−Tl bond.

An important experimental observation should be mentioned in this context: the spin-spin coupling constant $^2J(^{205}Tl-^{13}C)$ for the linear entity ^{A}NC−Pt−Tl (axial cyanide) is more than one order of magnitude larger than that of ^{C}NC−Pt−Tl (equatorial cyanides, i.e. C−N^C is perpendicular to the Pt−Tl bond), cf. Table 1. This indicates that the fifth cyano ligand plays a key role in stabilization of the Pt−Tl bond. It can be explained by an overlap of the Tl s orbital, the Pt d_z^2 orbital and the CN p_z orbital to form a molecular orbital ^{A}NC−Pt−Tl along the *z* axis: thus, the linear ^{A}NC−Pt−Tl- unit is stabilized.

Raman Spectra of 1 and 3 in the Solid State

A characteristic feature of the Raman spectra of the Pt−Tl compounds in aqueous solution is the presence of a strong and sharp band in the low frequency region,[10] which is due to the metal−metal (M−M) bond stretch-

ing.[17] In general, bimetallic compounds with unsupported single metal−metal bonds display M−M stretching bands at wave numbers lower than 200 cm^{-1}, while multiple bonding or ligand bridging in conjunction with an M−M single bond leads to higher wavenumbers.[18] The Raman spectra of the solid compounds **1** and **3** exhibit metal−metal vibrations at 154 cm^{-1} and 156 cm^{-1}, respectively.

The C≡N stretching region of the binuclear species is also informative and can provide an additional support for the structure of the compounds. We assign the two sharp bands at 2174 cm^{-1}, 2161 cm^{-1} for **1** and at 2168 cm^{-1}, 2151 cm^{-1} for **3** to the symmetric (A_{1g}) and antisymmetric (B_{1g}) stretching vibrations of the four equivalent cyanides ($C{\equiv}N^C$) of the $Pt(CN)_4$ unit in D_{4h} symmetry[19] in the compounds $[(^CNC)_4(^ANC)Pt-Tl(en)_{n-1}]$ ($n = 1-3$). These bands shift to high frequency and are very close to the stretching bands at 2153 cm^{-1}(s) and 2137 cm^{-1}(m) for the $[Pt(CN)_4]^{2-}$ complex in the solid state. The higher frequency bands at 2184 cm^{-1} and 2179 cm^{-1} are assigned to the $C{\equiv}N^A$ ligand in compounds **1** and **3**, respectively.

Crystal Structures of $[(NC)_5Pt-Tl(DMSO)_4](DMSO)$ (1) and $[(NC)_5Pt-Tl{\cdot}(en)_2](DMSO)_2$ (3)

The structures of **1** and **3** in the solid state were determined by single crystal X-ray crystallography and are shown in Figure 3 and 4, respectively. Selected bond lengths and angles of **1** and **3** are given in Table 2 and 3, respectively.

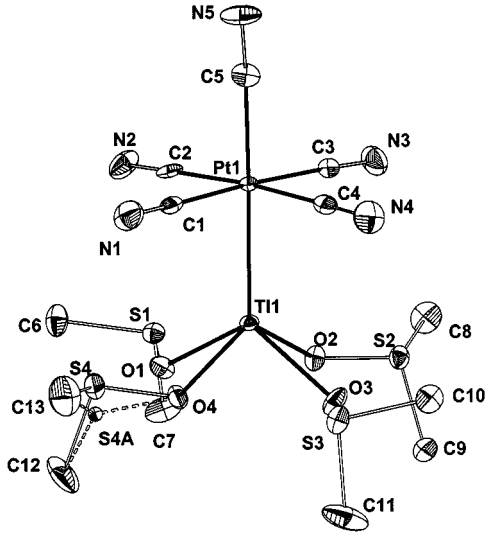

Figure 3. ORTEP view of the binuclear complex $[(NC)_5Pt-Tl(DMSO)_4]$ in the crystal structure of $[(NC)_5Pt-Tl(DMSO)_4](DMSO)$ (ellipsoids at 50% probability level)

In the structure of **1**, a $Pt(CN)_5$ unit is bonded to a $Tl(DMSO)_4$ unit with a Pt−Tl bond length of 2.6131(4) Å. The difference in bond length between the axial and equatorial cyanide groups is less pronounced than in complex **3**. In **1**, the equatorial Pt−C bond lengths are around 2.01(1) Å while the axial Pt−C bond length is 2.037(7) Å. Four crystallographically different DMSO groups are coordinated to thallium with Tl−O bond lengths in the range 2.287(5) to 2.311(4) Å. The Tl atom is coordinated in a square pyramidal fashion, and is located 1.08 (1) Å from the basal plane defined by the four O atoms. In the same way as in **3** (see below), the two en groups and the four cyano ligands are arranged in an eclipsed geometry.

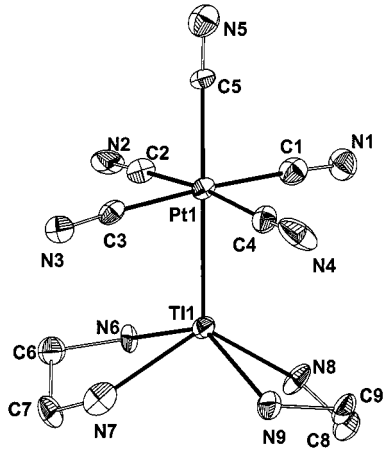

Figure 4. ORTEP view of the binuclear complex $[(NC)_5Pt-Tl(en)_2]$ in the crystal structure of $[(NC)_5Pt-Tl(en)_2](DMSO)_2$ (ellipsoids at 50% probability level)

The structure of **3** is closely related to that of **1**. The $Pt(CN)_5$ unit is bonded to the $Tl(en)_2$ group with a Pt−Tl bond length of 2.6348(5) Å. The coordination around Pt consists of two kinds of cyanide groups. The axial cyanide has a Pt−C bond length of 2.082(6) Å, whereas the four cyanide groups located in a square around the metal ion have considerably shorter Pt−C bond lengths of 2.01(1) Å.

Thallium has a distorted square pyramidal coordination geometry and is located 1.00 (1) Å from the basal plane defined by the four N atoms. The two en ligands and the four cyanide groups form an eclipsed conformation to each other.

The Pt−Tl bond lengths in compounds **1** and **3** are significantly shorter than the Pt−Tl bond lengths in $[Tl(crown\text{-}P_2)Pt(CN)_2]^+$ [2.911(2) and 2.958(2) Å] [2] and in $[Pt_6(\mu_6\text{-}Tl)(\mu\text{-}CO)_6(\mu\text{-}dppp)_3]^+$ [2.860(3) − 2.992(3) Å],[8] in which the oxidation states of the metal ions are Pt^{2+} and Tl^+, but very similar to the Pt−Tl bond lengths in $[(NC)_5Pt-Tl(bipy)(DMSO)_3]$ [2.6187(7) Å] and $[(NC)_5Pt-Tl(bipy)_2]$ [2.6117(5) Å] in which the sum of the oxidation states is +5.[20] In the Pt−Tl cyano complexes, $[(NC)_5Pt-Tl(CN)_{n-1}]^{(1-n)}$ (n = 2−4), studied in aqueous solution by the EXAFS technique,[21] the Pt−Tl bond lengths are in the range 2.598−2.638 Å. The Pt−Tl bond length increases with increasing number of cyano ligands attached to the thallium. The X-ray diffraction data show that the Pt−Tl bond lengths in compounds **1** and **3** in the solid state are of the same order of magnitude as those in the Pt−Tl cyano complexes in solution. The Tl−N bond lengths (average 2.376 Å) in **3** are very close to those in $[Tl(en)_3](ClO_4)_3$ (average 2.370 Å),[16] where thallium is hexacoordinated by three en ligands, which is probably due to the lower actual charge on thallium in $[(NC)_5Pt-Tl(en)_2]$ than in $[Tl(en)_3](ClO_4)_3$. The $Tl-O_n$ (n = 1−4) bond lengths in compound **1** (2.287−2.311 Å) are shorter than the Tl−O bond lengths in $[Tl(bipy)_3(DMSO)](ClO_4)_3$ [2.333(10) Å] [20] and in $[TlCl_5(DMSO)]^{2-}$ [2.42(2) Å],[22] but are longer than the Tl−O bond length in $[Tl(DMSO)_6]^{3+}$ [2.224(3) Å].[23]

Discussion

Chemical Shifts

The ^{205}Tl NMR chemical shifts of Tl^{III} complexes are very sensitive to a change in the coordination sphere of the metal ion. In the series of Pt−Tl-en complexes, a linear dependence between δ_{Tl}/δ_{Pt} and the number of coordinated en ligands is observed (Figure 5). A similar behavior was also observed for Tl^{III} ethylenediamine complexes $[Tl(en)_n]^{3+}$ (n = 0−3),[16] where the individual chemical shifts, δ_{Tl}, for the different species were linearly shifted to higher frequency upon an increase of the coordination number.

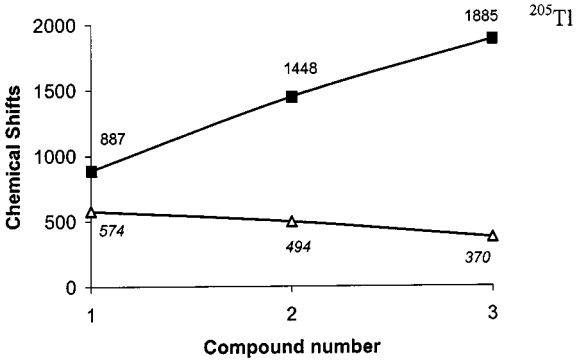

Figure 5. ^{195}Pt and ^{205}Tl NMR chemical shifts for the compounds **1, 2, 3** $[(NC)_5Pt-Tl(en)_{n-1}]$ (n = 1-3, respectively) in DMSO, 298 K; ■ ^{205}Tl NMR; Δ ^{195}Pt NMR

Several earlier studies of Cd^{2+} complexes, which similarly to Tl^{3+} has a d^{10} configuration, indicate the direction and the magnitude of the expected chemical shift change for the complex formation with different ligands, e.g. N-donors to high frequency, O-donors to low frequency.[24−28] A linear correlation between the ^{113}Cd NMR chemical shift and the number of coordinated ligands, very similar to the results of the present work, has also been observed for the Cd-glycine complexes $[Cd(Gly)_n]^{2-n}$ (n = 0−3).[29]

NMR chemical shifts are due to nuclear shielding, which includes the diamagnetic and paramagnetic terms of the Ramsey equation.[30] A theoretical study of metal NMR chemical shifts in metal ion complexes by the ab initio finite perturbation SCF method showed that the paramagnetic term is 10−100 times larger than the diamagnetic contribution.[31] Closed p and d subshells give no contribution to the paramagnetic term, which is caused by the donation of the electrons from the ligands to the metal's outer p orbitals and by the back-donation of electrons from the metal d orbitals to the ligands. Highly electronegative ligands withdraw more σ electrons from the fully occupied d_σ orbitals of the metal. This σ interaction produces holes in the (n − 1)d shell of the metal.[31]

This theoretical description can be used to explain the experimental results observed here for the Tl^{III} complexes.

The coordinated nitrogen (NH_2) is highly electronegative and attracts electrons from Tl d_σ orbitals. The electron cloud density of the thallium atom in its *N*-bonded complexes is lower than without ligands: the higher the ligand coordination number, the lower the electron cloud density around the thallium ion. This effect leads to a deshielding of the thallium nucleus; thus, its chemical shift increases. A similar trend between ^{205}Tl NMR chemical shift and the coordination number was observed in Tl^{III}-cyano complexes, $[Tl(CN)_n]^{3-n}$.[32a]

The ^{195}Pt NMR chemical shift decreases with an increasing number of the Tl-coordinated ethylenediamine ligands in the compounds $[(NC)_5Pt-Tl(en)_{n-1}]$ (n = 1−3). This trend has also been observed in the compounds $[(NC)_5Pt-Tl(CN)_{n-1}]^{(1-n)}$ (n = 1−4)[10] and in $[(NC)_5Pt-Tl(bipy)_{n-1}]$ (n = 2−3).[20] Also for the ^{195}Pt NMR chemical shifts a linear correlation to the number of coordinated ethylenediamine ligands was observed (see Figure 5).

Usually, NMR chemical shifts for heavy metal ions exhibiting a very large chemical shift range are very sensitive to the oxidation state of the metal.[32b,32c] ^{205}Tl NMR chemical shifts of Tl^{I} species are normally in the range from δ = −200 to 200 and those of Tl^{III} species are usually between δ = 2000 and 3000. The ^{195}Pt NMR chemical shifts of $[Pt^{IV}(CN)_6]^{2-}$ and $[Pt^{II}(CN)_4]^{2-}$ are δ = 655 and −213, respectively.[10] In the currently studied compounds, $[(NC)_5Pt-Tl(en)_{n-1}]$ (n = 1−3), the ^{205}Tl NMR chemical shifts fall in the region between Tl^{I} and Tl^{III}, and ^{195}Pt NMR chemical shifts between Pt^{II} and Pt^{IV} (see Table 1). Consequently, the oxidation states of the metal ions in these compounds are close to Pt^{III} and Tl^{II}: this implies that the transfer of two electrons from the substrate $[Pt^{II}(CN)_4]^{2-}$ to Tl^{III} has been partially accomplished. The studied Pt−Tl complexes can thus be treated as intermediates in an overall two-electron transfer process eventually leading to thermodynamically stable products in the stable oxidation states Pt^{IV} and Tl^{I}.[9,10]

Another indication of the changed oxidation states of the metals in these compounds is provided by the bond lengths Tl−O and Tl−N. The bond lengths Tl−O (average 2.295 Å) in **1** and Tl−N (average 2.376 Å) in **3** are somewhat longer than those in $[Tl(DMSO)_6]^{3+}$ [2.227(3) Å][23] and $[Tl(en)_3]^{3+}$ (average 2.370 Å).[16] The slight increase of the bond lengths, despite the lower coordination number in the studied Pt−Tl compounds, is compatible with the change of the oxidation states of the metal ions upon formation of the Pt−Tl bond.

A detailed discussion of the oxidation states of the metal ions is outside the scope of the present work and will be discussed in a forthcoming paper.

Spin-Spin Coupling Constants

The very large values of the spin-spin coupling constants are the most striking feature of the bimetallic Pt−Tl complexes. For the en complexes, they are of the same order as for the Pt−Tl complexes with cyanide (cf. Table 1).[10] It is clear that all the spin-spin coupling constants (except $Pt-C^{C}$) decrease upon coordination of additional ligands L (L = cyanide, bipyridine and ethylenediamine) to the thallium side of the metal−metal entity $[(NC)_5Pt-TlL_n]$. The probable origin for the large coupling constants is the fact that the relativistic contraction of the 6s shell of thallium leads to an increase of 6s electron density on the Tl nucleus. This in turn contributes to the dominant Fermi contact term for the spin-spin coupling which is reflected in large values of $J(^{205}Tl-X)$. A similar situation occurs in the species Hg_3^{2+} where the enormous isotropic spin-spin coupling constant, $^{1}J(^{199}Hg-^{199}Hg)$ = 139600 Hz, is due to the large 6s contribution to the Hg−Hg bond and the large 6s electron density at the mercury nucleus caused by relativistic effects on this heavy atom.[33]

Conclusions

A new series of small Pt−Tl bonded clusters $[(NC)_5Pt-Tl(en)_{n-1}]$ (n = 1−3, for **1**, **2** and **3** respectively) was obtained in DMSO solution from reactions between $[Pt(CN)_4]^{2-}$, $[Tl(en)_n]^{3+}$ (n = 1, 3) and CN^-. The existence of a metal−metal bond in the three complexes was proved in solution by multinuclear NMR spectroscopy [spin-spin coupling constants $^{1}J(^{205}Tl-^{195}Pt)$ in the range 48000−66000 Hz], and in the solid by single crystal X-ray diffraction [Pt−Tl bond length = 2.6131(4) and 2.6348(5) Å, in the solid compounds **1** and **3,** respectively]. Additional support for the Pt−Tl bond was obtained from the metal−metal vibration in the FT Raman spectra of the solids. These solids comprise the shortest Pt−Tl metal−metal bonds among the hitherto structurally known solid compounds[1−8] and constitute the first single crystal structure information of the growing family of "naked" Pt−Tl bond clusters.

The new family of metal−metal bonded, photosensitive compounds synthesized during the last few years, $[(NC)_5Pt-Tl(CN)_{n-1}]^{(1-n)}$ (n = 2−4), has now been enlarged by three new members containing a nitrogen-coordinated thallium (Figure 6). If, as suggested previously,[9,10] these metal−metal bonded compounds are to be used in photovoltaic solar cells,[12] or to serve as a model for such a photovoltaic system, then their structure should be tuned to have properties appropriate for this type of cell, e.g. light absorption in a large part of the visible spectrum, reversible light-induced electron transfer, suitable redox potential and ion diffusion properties in solution. The presently studied Pt−Tl compounds with ethylenediamine can be seen in this

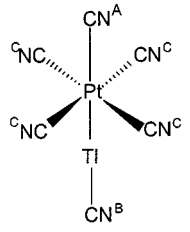

Figure 6. Sketch of the Pt−Tl compound **II** showing the notation for the cyanide sites

context as a first modification showing that tuning of the properties by means of nitrogen coordinating ligands is feasible.

Experimental Section

The solid compounds thallium(III) trifluoroacetate [Aldrich, $Tl(CF_3CO_2)_3$], potassium tetracyanoplatinate(II) [Aldrich, $K_2Pt(CN)_4$], sodium cyanide (Merck, Germany, NaCN), platinum(II) chloride (Aldrich, $PtCl_2$, 98%), sodium cyanide-^{13}C (Cambridge Isotope Laboratories, $Na^{13}CN$, ^{13}C 99%), thallium(I) carbonate (Aldrich, Tl_2CO_3, 99.95%) and liquid ethylenediamine (Merck, 99%) were all analytical grade and were used without further purification. DMSO was dried over molecular sieves (4 Å). During all experimental work the Pt−Tl compounds were protected from light.

$Tl(ClO_4)_3$ Stock Solution: Solid $TlClO_4$ was prepared from Tl_2CO_3 and an equivalent amount of $HClO_4$ and recrystallized from water. An acidic stock solution of $Tl(ClO_4)_3$ (1.2 M) was prepared by anodic oxidation of $TlClO_4$.[34a][34b] The Tl^{III} and acid concentrations were determined by titration with 0.1 M standard NaOH and $KBrO_3$ solutions after adding an excess of solid NaCl to the analyzed solution and using methyl orange as indicator.[34c]

Solid $[Tl(en)_3](ClO_4)_3$: Liquid ethylenediamine (0.08 mL, 1 mmol) was dissolved in 2 mL water. Then, a portion of the acidic aqueous solution of $Tl(ClO_4)_3$ (1.2 M; 0.21 mL 0.25 mmol) was added slowly under stirring. A black precipitate formed instantaneously, but dissolved soon thereafter. After addition of all the thallium (en/Tl ratio 3:1) the solution turned black again. Then, an approximate 10-fold excess of ethylenediamine was added and after half an hour of stirring the solution became colorless. The solution (at pH ≈ 10) was kept in a refrigerator; white round crystals formed at the bottom of the flask. The solution was filtered off and the crystals were dried in vacuum. The thallium content of the crystal compound $[Tl(en)_3](ClO_4)_3$ was determined by ICP (Inductively Coupled Plasma Atomic Emission Spectroscopy): calcd. 29.9%; found 30.1%.

The Raman spectra of $[Tl(en)_3](ClO_4)_3$ were recorded with a Renishaw System 1000 spectrometer equipped with a microscope (Leica DMLM). The band positions and assignment are as follows: 2976s, 2961s, 2897s (NH_2 and CH_2 str.); 1468m, 1278m (CH_2 and NH_2 bend); 1143m, 1021m (CN and CC str.); 936vs, 622s (ClO_4^- str.); 443vs, 302s (TlN str.). Abbreviations: vs: very strong; s: strong; m: medium.

Solid $[Tl(DMSO)_6](ClO_4)_3$: A portion of the acidic aqueous solution of $Tl(ClO_4)_3$ (1.2 M; 80 μL 0.1 mmol) was slowly added to freshly distilled DMSO (1 mL) under stirring. After addition of each drop of the concentrated $Tl(ClO_4)_3$ solution a white precipitate appeared but dissolved quickly. The colorless solution, kept in the dark, was degassed for 10 minutes with a water pump in a vacuum desiccator, and then degassed for 10 minutes again after three days. White cube-shaped crystals were obtained at the bottom of the flask. The composition of $[Tl(DMSO)_6](ClO_4)_3$ was proved by solving the crystal structure by single crystal X-ray diffraction and by Raman and infrared spectroscopic data.[23]

Preparation of Pt−Tl Compounds in Solution: For the synthesis of compound **1** (reaction 1) the solid compounds $[Tl(DMSO)_6](ClO_4)_3$ and $K_2Pt(CN)_4$ (0.05 mmol each) were dissolved in 1 mL DMSO. Then, a DMSO solution containing NaCN (0.05 mmol) was added.

Synthesis of compound **2** (reactions 2 and 3): $[Tl(en)](CF_3COO)_3$ was prepared in 1 mL DMSO by mixing $Tl(CF_3COO)_3$ (0.05 mmol) and liquid en (0.06 mmol). Then, solid $K_2Pt(CN)_4$ (0.05 mmol) was added, followed by addition of a DMSO solution containing NaCN (0.05 mmol).

Compound **3** (reaction 4): Crystalline powder samples of $[Tl(en)_3](ClO_4)_3$ and $K_2Pt(CN)_4$ (0.05 mmol each) were dissolved in 1 mL DMSO. Then, NaCN (0.05 mmol) in DMSO solution was added slowly with stirring. The reaction was slow; after two/three days a high concentration of the product was achieved. For the synthesis of ^{13}C enriched compounds **1, 2** and **3**, totally enriched compounds $Na_2Pt(^{13}CN)_4$ and $Na^{13}CN$(s) were used. $Na_2Pt(^{13}CN)_4$ was prepared in DMSO solution by the reaction between $PtCl_2$(s) and $Na^{13}CN$(s) in 1:4 molar ratio.

Preparation of Crystals: Crystals suitable for Raman and X-ray diffraction experiments were crystallized from solutions used in the NMR measurements. **1·(DMSO)**: 1 mL DMSO solution containing 0.05 mmol $[Tl(DMSO)_6](ClO_4)_3$, $K_2Pt(CN)_4$ and NaCN in a 1:1:1 molar ratio was kept in a vacuum desiccator in the dark. White small round crystals formed at the bottom of the flask after several days. **3·(2DMSO)**: A DMSO solution containing $[(NC)_5Pt-Tl(en)_2]$ (as proved by ^{205}Tl NMRspectroscopy) was degassed for 10 minutes with a water pump in a vacuum desiccator, and after three days degassed again for 10 minutes. After slow evaporation of DMSO under vacuum, rod-shaped white crystals appeared after several days. The crystals used for X-ray structural analysis were collected by filtration and recrystallized from DMSO using the same procedure as described above. Raman spectra of the solid compounds **1** and **3** were recorded with a Renishaw System 1000 spectrometer equipped with a microscope (Leica DMLM). The band positions and assignments are as follows: **1:** 3003m, 2919s (CH_3 str.); 2184s ($C{\equiv}N^A$ str.); 2174m, 2161m ($C{\equiv}N^C$ str.), 1419m, 1318w, 986m, 923m (CH_3 bend), 720s, 684s (CS str.), 453s (TlO str.), 389m, 334m (CSC or OSC bend), 154vs (Pt−Tl str.). **3:** 2950m, 2917s, 2889m (NH_2 and CH_2 str.), 2179s ($C{\equiv}N^A$ str.), 2168m, 2151m ($C{\equiv}N^C$ str.), 1452w, 1416w (CH_2 and NH_2 bend), 1094w, 1012m (CN and CC str.), 430s, 366s (TlN str.), 156vs (Pt−Tl str.). Abbreviations: vs: very strong; s: strong; m: medium; w: weak.

NMR Measurements: All NMR measurements were performed with a Bruker DMX500 spectrometer at a probe temperature of 25 ± 0.5 °C. DMSO was used as solvent for ^{205}Tl and ^{195}Pt NMR measurements and [D$_6$]DMSO for ^{13}C and ^1H NMR spectra.

^{205}Tl NMR spectra were recorded at SF = 288.49 MHz; typical NMR parameters: flip angle ≈30°; spectral window = 86 kHz; pulse repetition time = 0.5 s for Tl^{III} and 1s for Tl^I. The chemical shifts are reported in ppm toward higher frequency with respect to an external aqueous solution of $TlClO_4$ extrapolated to infinite dilution.

^{195}Pt NMR spectra were recorded at SF = 107.49 MHz with typical NMR parameters: flip angle ≈45°; spectral window = 91.4 kHz, pulse repetition time 2.5 s. The chemical shifts are given in ppm toward higher frequency from $\chi(^{195}Pt)$ = 21.4 MHz; $\delta[PtCl_6]^{2-}$ = 4533 at 25 °C in aqueous solution.

^{13}C NMR spectra were recorded at SF = 125.7 MHz with typical NMR parameters: flip angle ≈30°; spectral window = 25.1 kHz; pulse repetition time = 1.5 s; proton decoupled. The chemical shifts are reported in ppm with respect to the DMSO signal at δ = 39.5 from TMS.

^1H NMR spectra were recorded at SF = 500.1 MHz; flip angle ≈ 30°; pulse repetition time = 2 s. Chemical shifts are given in ppm with respect to the DMSO signal δ = 2.49 from TMS.

X-ray Crystal Structure Determination

Data Collection and Refinement: Suitable crystals of **1·(DMSO)** and **3·(2DMSO)** were selected under a polarizing microscope and mounted on a glass fiber. The data were collected on a Stoe image-plate diffractometer and were corrected for Lorentz, polarization and absorption effects using the X-SHAPE program package.[35] The structures were solved by direct methods (SHELXS-97)[36] and refined by full matrix least-squares on F^2 (SHELXL-97).[37] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were added at their ideal positions and refined using a riding model. Compound **3·(2DMSO)** was refined as a racemic twin [Flack parameter = 0.436(14)] since refinement in the centrosymmetric space group $P2_1/m$ introduced severe disorder in the DMSO molecules and unrealistically short C−C bonds in the en groups. In molecule **1**, the S4 atom of the DMSO ligand was treated as being disordered with occupancy factors of 0.78(1) and 0.22(1) for S4 and S4a, respectively. Selected crystal data for compound **1** and **3** are listed in Table 4.

Table 4. Selected crystal data for $[(NC)_5Pt-Tl(DMSO)_4]$-(DMSO)(**1**) and $[(NC)_5Pt-Tl(en)_2](DMSO)_2$ (**3**)

Ruthenium−Cobalt Mixed-Metal Nitrido and Nitrene Carbonyl Clusters: Structure, Reactivity, and ^{15}N NMR Spectroscopy

Emmie Ngai-Man Ho,[a] Zhenyang Lin,[b] and Wing-Tak Wong*[a]

Keywords: Electrochemistry / NMR spectroscopy / Nitrides / Nitrenes / Ruthenium / Cobalt / Cluster compounds

The reaction of $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (**1**) with $[Cp^*Co(CO)_2]$ ($Cp^* = \eta^5\text{-}C_5Me_5$) in refluxing THF afforded the new clusters $[Ru_3Co(\mu\text{-}H)(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$ (**2**), $[Ru_2Co(CO)_6(\mu_3\text{-}CO)(\eta^5\text{-}C_5Me_5)(\mu_3\text{-}NH)]$ (**3**), $[Ru_5(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_3(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)]$ (**4**), and $[Ru_6Co(\mu_3\text{-}H)(CO)_8(\mu\text{-}CO)_3(\mu_4\text{-}\eta^2\text{-}CO)(\eta^5\text{-}C_5Me_5)_3(\mu_4\text{-}N)]$ (**5**). Clusters **2** and **3** have typical butterfly nitrido and triangular nitrene structures, whilst compound **4** is a novel square-pyramidal pentaruthenium μ_4-NH carbonyl cluster with a Cp* ligand transferred from the external mononuclear Co complex. Cluster **4** can also be obtained by the reaction of **1** with pentamethylcyclopentadiene in the presence of 1,3-cyclohexadiene, albeit in low yield. Compound **5** consists of a rare Ru_6Co metal framework where a basal Ru–Ru edge of the central Ru_4 tetrahedron is capped by a Cp*Co fragment and another edge is bridged by a diruthenium unit. Complex **2** was found to be converted into **3** upon deprotonation with 1,8-diazabicyclo[5.4.0]undec-7-ene, on refluxing with $[Cp^*Co(CO)_2]$, or on exhaustive electrolysis. Upon thermolysis of **2** with PhC_2Ph in *n*-octane, $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**6**) and $[Ru_3Co(CO)_5(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)\{\mu_4\text{-}\eta^3\text{-}NC(O)C_2(C_4H_4)CHCH(Ph)\}(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**7**) were obtained in moderate yields. The structures of **6** and **7** both consist of a slightly twisted Ru_3Co square base with a quadruply bridging PhC_2Ph ligand. Cluster **6** is capped by a μ_4-NH moiety on the opposite side, while in **7** a CO ligand and an *ortho*-carbon atom of a Ph group from another PhC_2Ph ligand interact with the μ_4-N nitrido atom. Molecular orbital calculations have been carried out in order to gain further insight into the electronic structures of these interesting square-planar Ru_3Co and Ru_4 clusters. The butterfly Ru_2Co_2 nitrido complex $[Ru_2Co_2(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$ (**8**) was isolated from the reaction of $[Ru_3Co(CO)_{12}(\mu_4\text{-}N)]$ with $[Cp^*Co(CO)_2]$ in refluxing THF as a result of metal exchange of an $Ru(CO)_3$ fragment by a Cp*Co moiety. The redox properties of the compounds described herein have been investigated by means of cyclic voltammetry and controlled potential coulometry. Cluster **6** was shown to be able to tolerate both the addition of two electrons and the removal of one electron without significant structural change. The chemical environments of the nitrogen atoms of these clusters have been investigated by analysis of their ^{15}N NMR chemical shifts.

Introduction

Nitrido and nitrene clusters are members of a potentially vast class of mixed transition metal−main group compounds. Such molecules are currently of structural and chemical interest[1−9] since they offer opportunities to evaluate the validity of current models of bonding for mixed polynuclear systems and to improve on the degradative instability of homonuclear metal compounds. Metal surface-bound nitrido and nitrene species are believed to be central to a number of heterogeneously catalysed chemical processes such as nitrogen oxide reduction, the Haber process, and hydrazine decomposition.[10] In several surface reactions involving NO or N_2, adsorbed nitrogen atoms are known to be key intermediates. In the case of the Haber process, the mechanism is believed to involve formation of the metal nitride followed by successive additions of hydrogen atoms to the nitrogen giving ammonia.[11] In view of the metal cluster−metal surface analogy,[12] chemical reactivity studies of low-valent nitrido and nitrene are of considerable interest.

The chemistry of the triruthenium carbonyl methoxynitrido clusters $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$ and $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (**1**) has been described in previous papers by ourselves and others.[13−19] These two methoxynitrido clusters were reported to be synthetic precursors for nitrido and nitrene species such as $[Ru_4(CO)_{12}(\mu_4\text{-}N)(\mu\text{-}OMe)]$, $[Ru_6(CO)_{13}(\mu\text{-}CO)(\mu_5\text{-}N)(\mu_3\text{-}NH)(\mu_3\text{-}OMe)\{\mu\text{-}\eta^2\text{-}C(O)OMe\}_2]$, and $[Ru_6(CO)_{16}(\mu\text{-}CO)_2(\mu_4\text{-}NH)(\mu\text{-}OMe)(\mu\text{-}R)]$ (where R = H, OMe, or NCO),[15−17] albeit giving only low yields (≈ 5%). A series of nitrene clusters containing alkyne ligands, $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NR)(\mu_4\text{-}\eta^2\text{-}PhC_2R')]$ [R = H, OMe, or C(O)OMe; R′ = H or Ph], was obtained in more acceptable yields from reactions of $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$ with alkynes.[13,14] It is suspected that the formation of nitrido ligands, and hence of nitrene ligands as well, involves initial N−O bond scission of the methoxynitrido ligand. In the formation of these polynuclear μ_4-nitrido or μ_4-NR species, coupling reactions of the methoxynitrido clusters such as $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$ or **1** with other organometallic moieties (another molecule of a methoxynitrido cluster or some degraded

ruthenium carbonyl fragments) is invariably accompanied by N−O bond cleavage. In order to generate some nitrido or nitrene clusters and to study the underlying mechanisms of their formation, methods allowing the incorporation of different external organometallic fragments would be desirable.

Mixed-metal clusters are potential precursors to supported bimetallic catalysts. Moreover, the different metals provide effective labels for ligand fluxionality studies, and varying the metals of the cluster core offers the possibility of metallo- and bond-selectivity and thus of directing reactivity for a range of reagents. Mixed ruthenium−cobalt systems are especially attractive because of the significance of these metals in CO chemistry, e.g. in the catalysis of CO hydrogenation,[20,21] and in the homologation of alcohols[22−24] and esters.[25,26] More recently, Ru/Co mixed-metal clusters have been used as precursors to generate nanoparticles with unusual magnetic properties.[27] The reactions of $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$ with $[(\eta^5\text{-}C_5H_5)Mo(CO)_3H]$/$[\{(\eta^5\text{-}C_5H_5)Mo(CO)_3\}_2Hg]$ have been studied.[28] However, neither the nitrene nor the nitrido species were isolated. In this paper, we report on an initial study of the syntheses, characterization, electrochemical properties, and structures of a series of ruthenium−cobalt mixed-metal nitrido and nitrene carbonyl clusters obtained by addition of Co mononuclear complexes to clusters **1** and $[Ru_3Co(CO)_{12}(\mu_4\text{-}N)]$, as well as on ^{15}N NMR spectroscopic studies of the nitrido/nitrene ligands in these clusters.

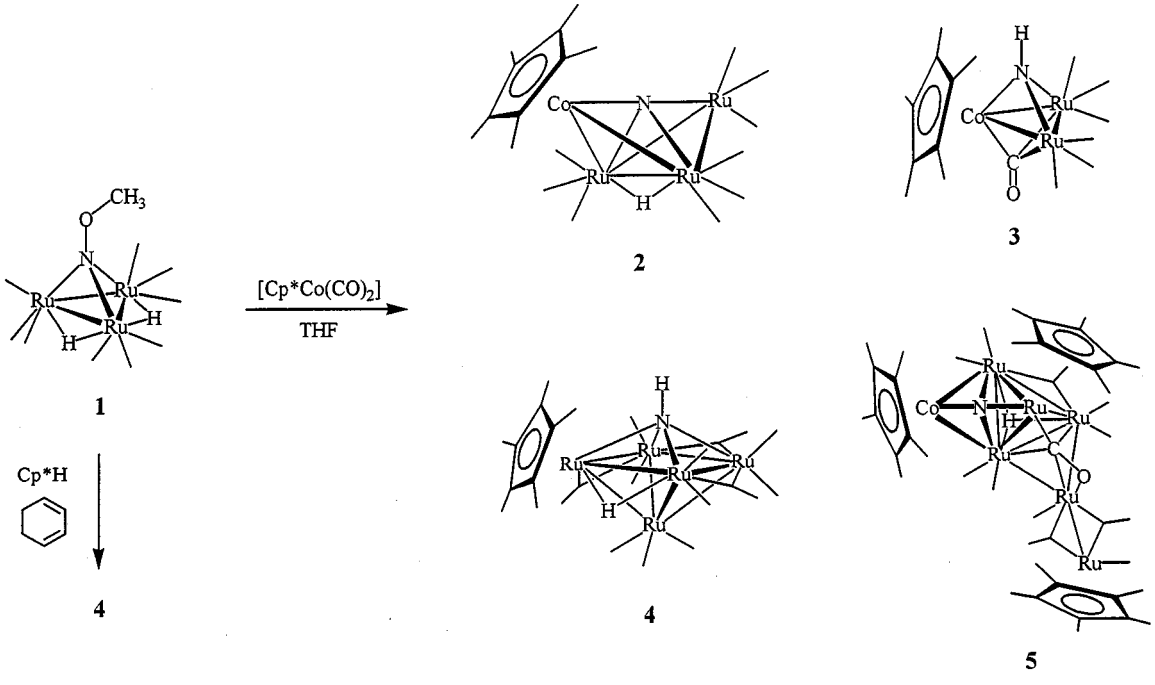
Results and Discussion

Synthesis and Characterization

Reaction of $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (1) with $[Cp^*Co(CO)_2]$

A solution of $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (**1**) and $[Cp^*Co(CO)_2]$ in THF becomes almost black upon refluxing over a period of 10 h. Subsequent chromatographic separation of the product mixture gives, in order of elution, brown $[Ru_3Co(\mu\text{-}H)(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$ (**2**, 55%), trace amounts of starting material $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (**1**) and the known compound $[Ru_3(\mu\text{-}H)(CO)_9(\mu\text{-}NH_2)]$,[15,29] purple $[Ru_2Co(CO)_6(\mu_3\text{-}CO)(\eta^5\text{-}C_5Me_5)(\mu_3\text{-}NH)]$ (**3**, 20%), red $[Ru_5(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_3(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)]$ (**4**, 3%), and green $[Ru_6Co(\mu_3\text{-}H)(CO)_8(\mu\text{-}CO)_3(\mu_4\text{-}\eta^2\text{-}CO)(\eta^5\text{-}C_5Me_5)_3(\mu_4\text{-}N)]$ (**5**, 2%) (Scheme 1). The structures of clusters **2**−**5** were unambiguously established by single-crystal X-ray crystallography and were supported by ^1H and ^{15}N NMR, IR, and UV/vis spectroscopic data, as well as by FAB mass spectrometry (Table 1). These compounds are essentially air-stable in the solid state, have varying degrees of stability in solution, and are all soluble in *n*-hexane.

Cluster **2** readily crystallizes from a rich brown-coloured band over a period of a few days. The presence of the Cp* and metal hydride groups in this compound is apparent from its ^1H NMR spectrum (singlets at δ = 1.98 and −24.40), while the integrals of these resonances reveal a



Scheme 1. Treatment of dihydrido cluster **1** with 2 equiv. of $[Cp^*Co(CO)_2]$ led to the formation of the $[Ru_3Co(\mu\text{-}H)(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$ (**2**), $[Ru_2Co(CO)_6(\mu_3\text{-}CO)(\eta^5\text{-}C_5Me_5)(\mu_3\text{-}NH)]$ (**3**), $[Ru_5(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_3(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)]$ (**4**), and $[Ru_6Co(\mu_3\text{-}H)(CO)_8(\mu\text{-}CO)_3(\mu_4\text{-}\eta^2\text{-}CO)(\eta^5\text{-}C_5Me_5)_3(\mu_4\text{-}N)]$ (**5**) in yields of 55%, 20%, 3%, and 2%, respectively; cluster **4** could be directly synthesized by the reaction of **1** with pentamethylcyclopentadiene and 1,3-cyclohexadiene, albeit in low yield (4%)

[a] Cp*(c) denotes the centroid of the C_5Me_5 rings.

Cluster **2**, $[Ru_3Co(\mu\text{-}H)(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$, consists of a tetranuclear metal core exhibiting a butterfly geometry. The Cp*Co fragment occupies a wing-tip position, and the Ru atoms bear three terminal carbonyl ligands each. The centroid of the η^5-C_5Me_5 ligand is 1.660 Å from the Co(1) atom, which is similar to the typical distance in Cp*Co clusters [Co−$Cp^*_{ave.}$ 1.695 Å].[5,30] The nitrido N(1) is semi-encapsulated within the butterfly and is displaced towards Co(1) at a distance of 1.714(3) Å. The hydride ligand revealed by ^1H NMR spectroscopy was located by Fourier-difference synthesis and was found to bridge the Ru(1)−Ru(3) hinge. Thus, the bond angles Ru(3)−Ru(1)−C(1)/C(3) and Ru(1)−Ru(3)−C(7)/C(9) are larger (average 107.4°) than the corresponding values along the other wings (average 97.1°). The dihedral angle between the butterfly wings in **2** measures 78.6°

The molecular structure of $[Ru_2Co(CO)_6(\mu_3\text{-}CO)(\eta^5\text{-}C_5Me_5)(\mu_3\text{-}NH)]$ (**3**) is depicted in Figure 2, while key bond lengths and angles are listed in Table 3. Cluster **3** contains a heterometallic Ru_2Co triangular metal core, triply-capped in an asymmetric fashion by a μ_3-NH ligand through the coordination of the nitrogen atom [Ru(1)−N(1) 2.017(4) Å, Ru(2)−N(1) 2.019(5) Å, and Co(1)−N(1) 1.862(4) Å] on one side and a μ_3-CO ligand on the other. The nitrene hydrogen and nitrogen atoms give rise to a triplet ($\delta = 7.46$, $J_{NH} = 54.80$ Hz) and a doublet [$\delta = 131.4$, $J(^{15}NH) = 76.95$ Hz] in the ^1H and ^{15}N NMR spectra, respectively. Both signals are downfield shifted compared with those of $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NH)]$ {^1H: $\delta = 6.33$ (t, $J_{NH} = 55.0$ Hz); ^{15}N: $\delta = 82.5$ [d, $J(^{15}NH) = 77.5$ Hz]},[18] which suggests that the Cp*Co moiety is more electron-withdrawing than the isolobal $Ru(CO)_3$ group. The μ_3-capping ligand C(7)−O(7) is found to be displaced towards Co(1) at a distance of 1.821(6) Å [Co(1)−C(7)], while the Ru(1)−C(7) and Ru(2)−C(7) distances amount to 2.399(6) and 2.402(6) Å, respectively. The isolation of **3** was unexpected, since one of the ruthenium vertices had to be replaced by an isoelectronic (η^5-C_5Me_5)Co(CO) fragment through a "metal-exchange" reaction.[31] Such metal-exchange reactions are known, but are not common in cluster chemistry.[31−33]

[a] Cp*(c) denotes the centroid of the C_5Me_5 rings.

Besides these heterometallic complexes, a pentaruthenium μ_4-nitrene cluster **4** was also isolated from this reaction. Its IR spectrum features vibrational absorptions due to both the terminal and bridging carbonyl ligands. Its ^{1}H NMR spectrum displays a triplet centred at $\delta = 6.28$ with a coupling constant of 48.82 Hz, which may be attributed to the NH proton. Resonances at $\delta = 2.20$ and -14.92 are assigned to the Cp* and hydride ligands, respectively. The presence of a quadruply-bridging nitrene ligand is evident from the ^{15}N NMR spectrum, which shows a doublet at $\delta = 145.4$ [$J(^{15}NH) = 68.26$ Hz] relative to liquid NH_3. Four absorption bands at 330, 345, 405, and 466 nm are seen in the UV/vis spectrum of **4** (Table 1).

Red crystals of **4**, suitable for X-ray diffraction studies, were grown from a saturated solution in $CHCl_3$/*n*-hexane at −20 °C. The molecular structure of **4** is depicted in Figure 3 and the relevant structural parameters are summarized in Table 4. Cluster **4** consists of a square-pyramidal cluster of five ruthenium atoms, with a quadruply-capping NH ligand spanning the square base. A η^5-coordinated C_5Me_5 ligand, transferred from the external [Cp*Co(CO)$_2$] complex, is coordinated to one basal Ru atom at a distance of 1.856 Å. To the best of our knowledge, [Cp*Co(CO)$_2$] acting as a source of Cp* in an intermolecular ligand-transfer reaction is very rare in cluster chemistry. A ligand-transfer process of Cp in a comparable ruthenium cluster was observed in [$Ru_6(\mu_3$-H)(CO)$_{12}(\mu$-CO)$(\mu_4$-η^2-CO)$_2(\eta^5$-$C_5Me_5)$].[34] Three of the basal Ru−Ru edges are bridged by carbonyl ligands, while the fourth is bridged by a hydride ligand. The bridging carbonyl and hydride ligands involving the Cp*-coordinated Ru(1) are found to be slightly disordered among these sites. These two ligands reside in semi-triply-bridging positions, while the other two cap the equatorial sites of the square base. The nonbonding lengths Ru(5)···C(1) and Ru(5)···H are 2.59 Å and 2.33 Å, respectively [cf. Ru(1)−C(1) 2.00(2), Ru(2)−C(1) 2.15(2), Ru(1)−H 1.95, and Ru(4)−H 2.17 Å]. The μ_4-NH moiety caps the Ru_4 base in a symmetrical fashion, with an average Ru−N distance of 2.145 Å. The mean deviation from the plane defined by Ru(1), Ru(2), Ru(3), and Ru(4) is 0.0067 Å and the nitrene N atom lies 0.91 Å above this mean plane. Cluster **4** might be viewed as an N-protonated product of a ruthenium μ_5-nitrido cluster anion.[3,35] For comparison, in the $[Ru_5(CO)_{14}(\mu_5\text{-N})]^-$ anion, the nitrido atom resides 0.21(2) Å below the basal plane of the ruthenium atoms and acts as a five-electron donor. By Fourier-difference synthesis using low-angle data, the H atom was found to be located 0.88 Å from the nitrene N atom. In **4**, the μ_4-NH moiety is assigned as a four-electron donor, giving a cluster valence electron (CVE) count of 74. This is the same as that for the cluster anion $[Ru_5(CO)_{14}(\mu_5\text{-N})]^-$.[3,35]

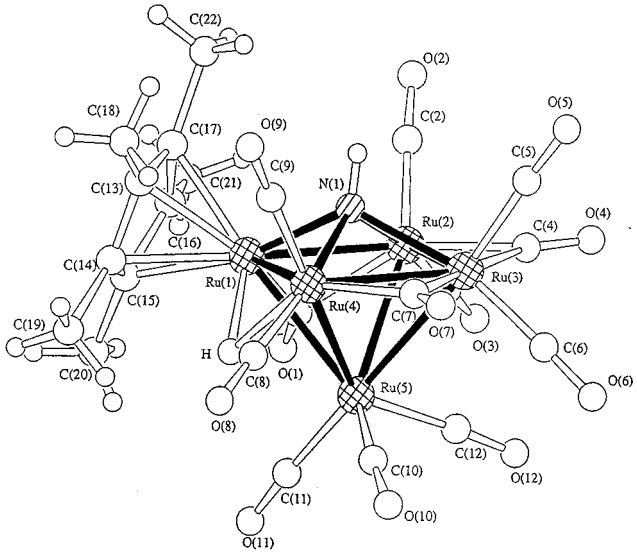

Figure 3. The molecular structure of $[Ru_5(\mu\text{-H})(CO)_9(\mu\text{-CO})_3(\eta^5\text{-}C_5Me_5)(\mu_4\text{-NH})]$ (**4**) showing the atom numbering scheme

[a] Cp*(c) denotes the centroid of the C_5Me_5 rings.

In our previous reports,[13−15] all the tetraruthenium μ_4-NH nitrene ligands have been stabilized by bridging $Ru(CO)_4$ or μ_4-η^2-alkyne fragments. However, in the present case, this ligand is stabilized by a quadruply-bridging $Ru(CO)_3$ moiety. This pseudo-octahedral skeletal framework $[Ru_5(\mu_4\text{-ER})]$ (R = alkyl or aryl group, etc.) has been seen with phosphorus,[36−40] sulfur,[41−43] and even carbon.[44] This is the first time that a μ_4-NH fragment has been observed in this type of structure. The square Ru_4 fragment provides a

model for chemical transformations at the (100) face of metallic ruthenium.[45,46] Although ruthenium is a very important catalytic metal, models for the interaction of nitrogen fragments with this (100) array are rare.[13−15]

It is believed that cluster **4** is formed by enlargement of the starting triruthenium cluster, with coordination of a Cp* ligand transferred from the external mononuclear complex. When **1** is heated in THF in the presence of an excess of pentamethylcyclopentadiene and 1,3-cyclohexadiene, **4** is obtained in 4% yield (Scheme 1). In the absence of 1,3-cyclohexadiene, there is no observable reaction under similar conditions, hence the diene must be important is removing a proton from the free Cp*H ligand. In both synthetic methods {involving $[Cp^*Co(CO)_2]$ or Cp*H}, the pentamethylcyclopentadiene is transferred as a Cp^{*-} anion.

The last eluted product is $[Ru_6Co(\mu_3\text{-}H)(CO)_8(\mu\text{-}CO)_3(\mu_4\text{-}\eta^2\text{-}CO)(\eta^5\text{-}C_5Me_5)_3(\mu_4\text{-}N)]$ **5**. Its IR spectrum shows the presence of both terminal and bridging carbonyl ligands (Table 1). The four singlet resonances in its ^1H NMR spectrum, with integrals in the ratio 15:15:15:1, correspond to the three Cp* ligands and one triply-bridging hydride. With reference to clusters **2**−**4**, the relatively upfield signal at $\delta = 1.76$ could be assigned to the Cp* ligand on the Co(1) atom. A downfield singlet at $\delta = 548.8$ is observed in the ^{15}N NMR spectrum. In the electronic absorption spectrum of **5**, three bands are seen at 360, 390 and 579 nm. X-ray quality crystals of cluster **5** were grown from a $CHCl_3$/*n*-hexane solution at −20 °C. A perspective view of the molecular structure is depicted in Figure 4. Selected interatomic distances and angles are listed in Table 5.

The metal framework of **5** consists of a central Ru_4 tetrahedron with an Ru−Ru edge bridged by a Cp*Co fragment and the other edges bridged by a further two Ru atoms. A structurally related Ru_6 cluster, $[Ru_6(\mu_3\text{-}H)(CO)_{12}(\mu\text{-}CO)(\mu_4\text{-}\eta^2\text{-}CO)_2(\eta^5\text{-}C_5Me_5)]$,[34] has been reported. The difference between cluster **5** and this Ru_6 cluster is that one μ_4-η^2-CO of the latter is replaced by a μ_4-nitrido ligand, which is bound to the Cp*Co moiety. Therefore, in **5**, a five-electron μ_4-N and a four-electron μ_4-η^2-CO donor ligand are situated in the two butterfly arrays created by the bridging Co and Ru atoms and the faces of the Ru_4 tetrahedron, respectively. The dihedral angles between the wings of the butterflies are 77.2° and 121.2°. The C−O bond length in the μ_4-η^2-carbonyl ligand is considerably longer than the terminal C−O bonds [1.25(2) vs. ave. 1.17(1) Å], which may be attributed to electron donation from the C−O π-bond and a significant reduction in bond order due to the $d_\pi-p_\pi$ bonding of the three Ru atoms. Besides the η^5-C_5Me_5 ligand on the Co atom, the other two must be transferred from other $[Cp^*Co(CO)_2]$ complexes. One is bound to the apical Ru atom of the central tetrahedron, while the other is coordinated to the spiked-edge Ru(6) atom. The interactions between the Cp^{*-} ligands and Co [Co(1)−Cp*(c) 1.671 Å] are stronger than those involving the Ru atoms [Ru(2)/Ru(6)−Cp*(c) 1.890 and 1.907 Å]. A positive charge is considered to be localized on the Co atom, whereas the charges associated with the Ru atoms are delocalized throughout the cluster. This is also consistent

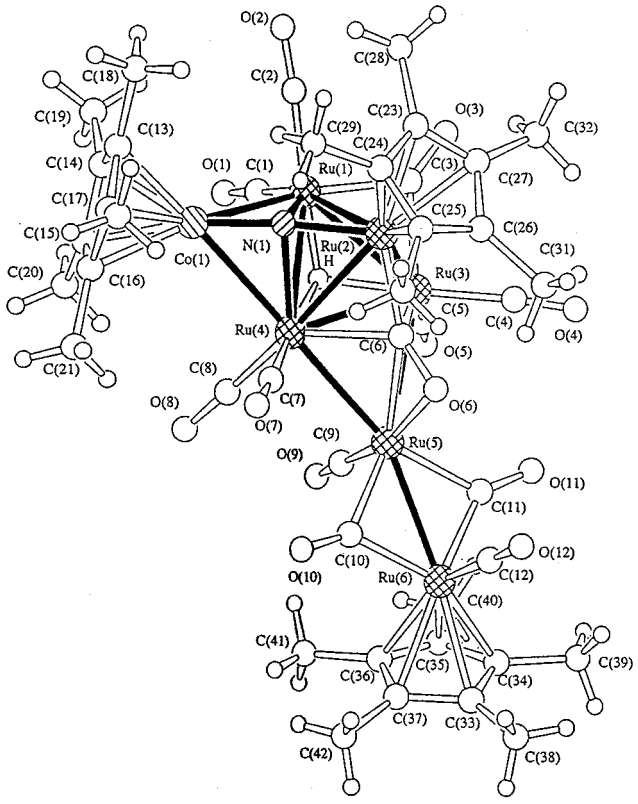

Figure 4. The molecular structure of $[Ru_6Co(\mu_3\text{-}H)(CO)_8(\mu\text{-}CO)_3(\mu_4\text{-}\eta^2\text{-}CO)(\eta^5\text{-}C_5Me_5)_3(\mu_4\text{-}N)]$ (**5**) showing the atom numbering scheme

[a] Cp*(c) denotes the centroid of the C_5Me_5 rings.

with the observation of short Ru(2)−Ru(4) and Ru(5)−Ru(6) bond lengths. A further supporting argument provided by the ^{1}H NMR resonances of the relevant Cp* ligands. This Ru_6Co metal skeleton is seldom found in either homo- or heterometallic cluster chemistry. The hydride ligand, which gives rise to a signal at $\delta = -26.46$ in the ^{1}H NMR spectrum, was located by Fourier-difference synthesis and was found to cap beneath the basal plane, Ru(1)−Ru(3)−Ru(4), of the central Ru_4 tetrahedron. The formation of **4** and **5** is clearly a complex transformation involving the scavenging of additional ruthenium atoms and the incorporation of Cp* ligands from the mononuclear complexes. The overall yields of **4** and **5** are accordingly modest and lower than those of clusters **2** and **3**.

Conversion between 2 and 3

(a) Reaction of 2 with DBU

The reaction of cluster **2** with 1 equivalent of DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) was monitored by ^{1}H NMR spectroscopy. The sterically hindered base DBU is commonly used as a deprotonating agent for metal clusters and a mechanism for this type of reaction has been proposed.[47] The hinge-bridged hydride was found to undergo dissociation within a few minutes (Scheme 2). This reaction proved to be irreversible; deprotonated **2** was not converted back to **2** upon addition of a slight excess of CF_3COOH. Instead of re-protonation, the deprotonated cluster **2** underwent degradation to give **3** along with significant decomposition products.

(b) Reaction of 2 with [Cp*Co(CO)$_2$]

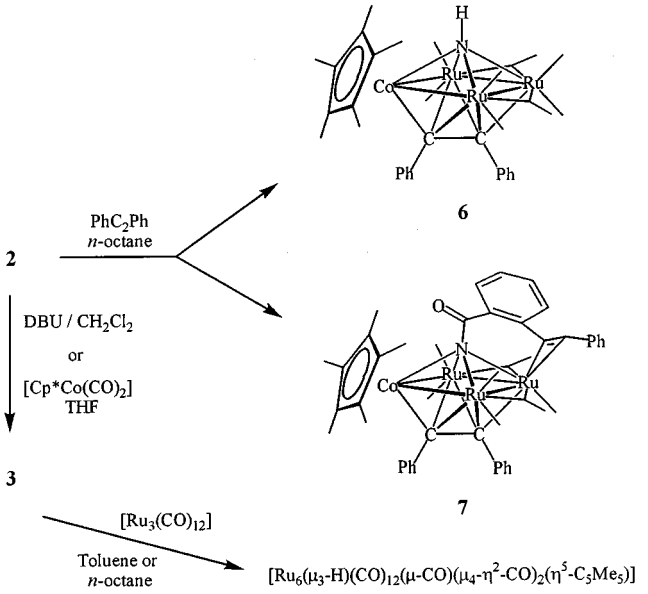
Compound **2** was allowed to react with excess [Cp*Co(CO)$_2$] in refluxing THF for 10 h (Scheme 2). After removing the solvent in vacuo, chromatographic separation of the residue gave a moderate yield of cluster **3** as the only isolable product.

(c) Reaction of 3 with [Ru$_3$(CO)$_{12}$]

In an attempt to convert **3** to **2**, compound **3** was allowed to react with a slight excess of [$Ru_3(CO)_{12}$] in a high boiling point solvent such as toluene or *n*-octane. After refluxing for 4 h, the known [$Ru_6(\mu_3\text{-H})(CO)_{12}(\mu\text{-CO})(\mu_4\text{-}\eta^2\text{-CO})_2(\eta^5\text{-}C_5Me_5)$][34] cluster had been produced in 10% yield, accompanied by starting material **3** and decomposition products (see Scheme 2). Cluster **3** was thus largely unreactive under these conditions and no significant change was observed over a period of 12 h. A high energy barrier preventing the desired reaction probably led instead to the degradation of the [$Ru_3(CO)_{12}$] cluster to give mononuclear fragments, thereby accounting for the observed reaction.

Thermolysis of 2 with PhC$_2$Ph

It has been shown previously that protonation of [PPN][$Ru_4(CO)_{12}(\mu_4\text{-N})$] in the presence of diphenylacetylene gives a μ_4-NH containing species, [$Ru_4(CO)_9(\mu\text{-CO})_2(\mu_4\text{-NH})(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$].[48] Moreover, treatment of



Scheme 2. Deprotonation of cluster **2** in CH_2Cl_2 with DBU afforded only **3**; treatment of **2** with [Cp*Co(CO)$_2$] in refluxing THF also gave **3**; thermolysis of **2** in *n*-octane with a slight excess of PhC_2Ph resulted in the isolation of [$Ru_3Co(CO)_6(\mu\text{-CO})_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-NH})(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$] (**6**) and [$Ru_3Co(CO)_5(\mu\text{-CO})_2(\eta^5\text{-}C_5Me_5)\{\mu_4\text{-}\eta^3\text{-NC(O)}C_2(C_4H_4)CHCH(Ph)\}(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$] (**7**) in yields of 18% and 6%, respectively; attempted preparation of cluster **2** from cluster **3** with [$Ru_3(CO)_{12}$] led only to the known [$Ru_6(\mu_3\text{-H})(CO)_{12}(\mu\text{-CO})(\mu_4\text{-}\eta^2\text{-CO})_2(\eta^5\text{-}C_5Me_5)$][34]

[$Ru_3(\mu\text{-H})_2(CO)_9(\mu_3\text{-NPh})$] with diphenylacetylene was found to afford a μ_4-nitrene cluster [$Ru_4(CO)_9(\mu\text{-CO})_2(\mu_4\text{-NPh})(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$].[49] Therefore, alkynes are thought to have an important structural stabilizing effect, facilitating the formation and isolation of μ_4-nitrene-containing clusters. Cluster **2**, a molecule with a μ_4-nitrido group coordinated between the wings of an Ru_3Co butterfly, was thus submitted to skeletal expansion reactions with diphenylacetylene in *n*-octane, which led to the incorporation of a two-carbon fragment into the cluster framework (Scheme 2). Separation by preparative TLC gave two major products, [$Ru_3Co(CO)_6(\mu\text{-CO})_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-NH})(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$] (**6**) and [$Ru_3Co(CO)_5(\mu\text{-CO})_2(\eta^5\text{-}C_5Me_5)\{\mu_4\text{-}\eta^3\text{-NC(O)}C_2(C_4H_4)CHCH(Ph)\}(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$] (**7**) in yields of 18% and 6%, respectively. Their spectroscopic data are presented in Table 1. The IR spectra show the presence of both terminal and bridging carbonyl ligands. In the UV/vis spectrum of **6**, absorption bands are seen at 296, 330, 420, and 505 nm. The ^{1}H NMR signals due to the organic moieties of **6** and **7** are fully consistent with the proposed structures. Detailed assignments of the protons of the diphenylacetylene ligands were made with the aid of a 2D HH-COSY experiment (see Table 1). In both **6** and **7**, the protons of the phenyl group on the acetylenic carbon σ-bonded to the Ru atom are seen to have similar chemical shifts as those in [$Ru_4(CO)_9(\mu\text{-CO})_2(\mu_4\text{-NH})(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$].[48] The signals of the protons of the other phenyl group are subject to a downfield shift due to the effect of the Cp*Co moiety. The resonances of the protons of these two phenyl groups in both **6** and **7** can be easily assigned with the aid of a 2D HH-COSY experiment. The five protons of the phenyl

group on the acetylenic carbon σ-bonded to Ru in **7** have a significantly different environment. This may be due to some extent to the restriction of rotation in this phenyl ring. The ^{15}N NMR spectrum of the ^{15}N-enriched sample of **6** features a doublet at δ = 70.2 [$J(^{15}NH)$ = 69.26 Hz]. The ^{15}N NMR study of **7** was hindered due to the low yield of this cluster. Nevertheless, the structures of both complexes have been established by X-ray crystallographic studies.

Brown crystals of clusters **6** and **7**, suitable for X-ray diffraction studies, were grown from saturated CH_2Cl_2/*n*-hexane solutions at −20 °C. The molecular structures of **6** and **7** are shown in Figure 5 and Figure 6, respectively, and relevant structural parameters are listed in Table 6. The molecular geometries of clusters **6** and **7** are similar in that the three Ru atoms and one Co atom are arranged in a slightly twisted square base. One face of the square is capped by a μ_4-nitrene ligand, while the other is spanned by a quadruply-bridging PhC_2Ph ligand. Species analogous to **6**, with $Ru(CO)_3$ in place of the Cp*Co moiety, have previously been obtained in this laboratory by the reaction of PhC_2R (R = H, Ph) with the triruthenium methoxynitrido cluster $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$.[13,14] The Cp* ligands are coordinated to the Co atoms at distances of 1.687 and 1.722 Å in **6** and **7**, respectively. The quadruply-bridging diphenylacetylene ligands in **6** and **7** are bound to the metal square through C(19)−C(20), with σ interactions to Ru(2) and Co(1) and longer η^2 interactions to Ru(1) and Ru(3). The cluster may also be viewed as a pentagonal bipyramid, the basal plane being defined by Ru(2), C(20), C(19), Co(1), and N(1). The mean deviations from the plane defined by the four metal atoms are 0.200 Å in **6** and 0.198 Å in **7**. In both cases, it is the Co(1) atoms that show the greatest deviations from these mean planes, by 0.365 Å in **6** and 0.380 Å in **7**. To the best of our knowledge, these compounds represent the first examples of the coordination of μ_4-nitrene fragments to a square Ru_3Co metal cluster. The nitrene N atoms asymmetrically cap the square bases, being tilted towards Co(1). The nitrene N atom lies above the basal plane, with a distance to the mean plane of 1.019 Å and 1.102 Å in clusters **6** and **7**, respectively. In cluster **6**, the hydrogen atom was located by Fourier-difference synthesis using low-angle data at 0.75 Å from the μ_4-NH nitrogen atom. A novel coupling reaction is observed in **7**, which involves a carbonyl group, an *ortho*-carbon of a Ph group of the PhC_2Ph ligand, and the μ_4-N atom. The activated acetylenic ligand is also found to be coordinated to Ru(2). The carbonyl group coupled between the Ph group and the μ_4-N ligand has a C−O bond length of 1.22(1) Å, which is typical for a ketone C=O group. The C(39)−C(40) bond length is significantly lengthened to 1.41(1) Å upon coordination to an Ru centre as the alkyne is reduced to a *trans* alkene.

If the μ_4-nitrene and quadruply-bridging diphenylacetylene groups are both assigned as being four-electron donors, the electron count for these metal clusters is 62, which is two electrons less than the expected electron count (64) for a square-planar transition metal cluster.[50] Within the formalism of the 18-electron rule, the 62-electron square

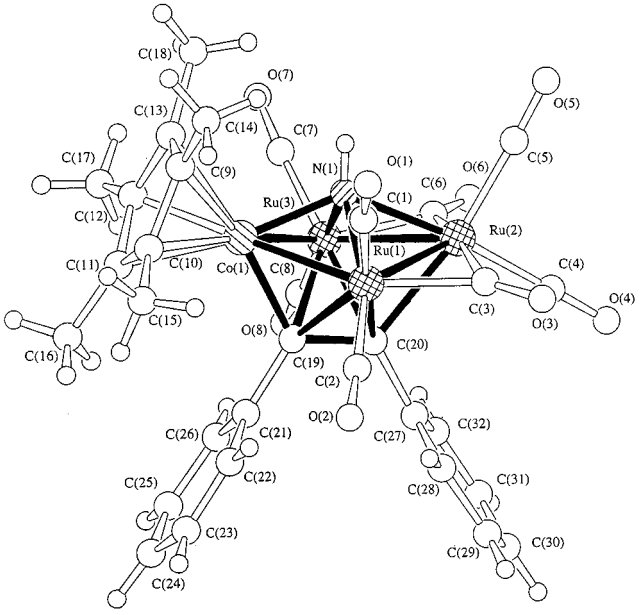


Figure 5. The molecular structure of $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**6**) showing the atom numbering scheme

clusters **6** and **7** are electronically unsaturated, and a 2 electron-3 centre bond has been proposed as being delocalized between the two 17-electron centres and one 16-electron centre bridged by two μ-CO groups. Clusters **6** and **7** can be described as pentagonal-bipyramidal structures if the N and C atoms in both the μ_4-NH and the PhC_2Ph units are also considered as skeletal atoms. The electron count for the cluster in such a consideration is 70, conforming to the $14n + 4m + 2$ rule,[50] where *n* represents the number of transition metal atoms and *m* denotes the number of main group atoms. To further understand the electronic structure of cluster **6**, we carried out molecular orbital calculations on the model cluster $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5H_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}HC_2H)]$.[51] The NBO analysis[52] shows that the Wiberg bond orders[53] of the metal−metal bonds are all appreciably positive (0.14 for Co−Ru, 0.07 for Ru−Ru), indicating the existence of metal−metal bonding. Lesser bond orders for the Ru−Ru bonds are due to of the bridging carbonyls in these bonds. The bond orders for Ru−N and Ru−C (HC_2H) are 0.20 and 0.30, respectively. Those for Co−N and Co−C (HC_2H) are 0.45 and 0.60, respectively, making them greater than those of the corresponding Ru−N and Ru−C bonds. These results suggest that the interactions between the metal and the bridging main group atoms are crucial with regard to the stabilities of the clusters. Figure 7 shows spatial plots[54] of the highest occupied [Figure 7(a)] and the lowest unoccupied [Figure 7(b)] molecular orbitals. The HOMO is mainly localized on the Ru centres, with a slight Co(d)−Ru(d) antibonding interaction. However, the LUMO is mainly localized on the CpCo fragment, again with a slight Co(d)−Ru(d) antibonding interaction. In the LUMO, the antibonding character between Co and the Cp ligand is also noticeable.

In order to investigate this new class of square-planar μ_4-nitrene clusters in detail, molecular orbital calculations

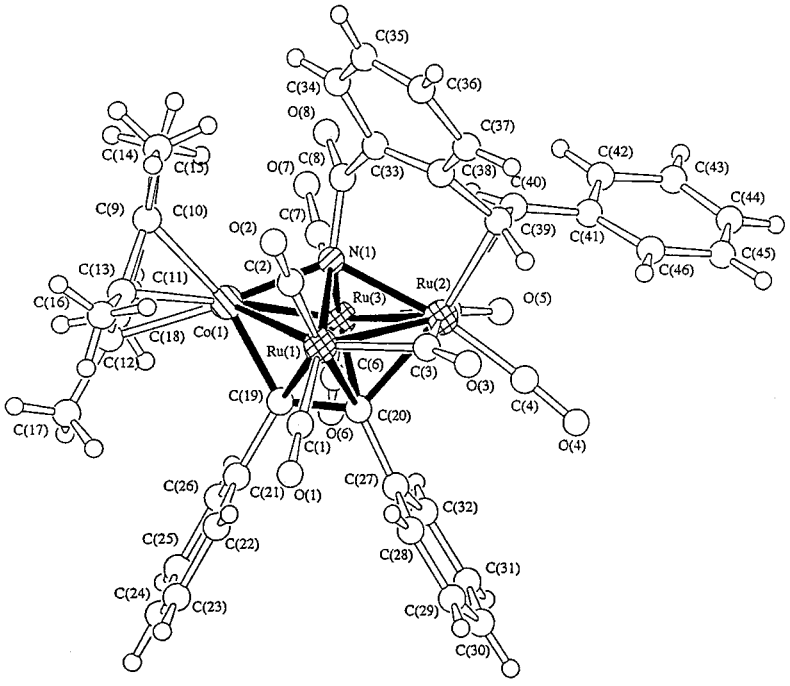

Figure 6. The molecular structure of $[Ru_3Co(CO)_5(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)\{\mu_4\text{-}\eta^3\text{-}NC(O)C_2(C_4H_4)CHCH(Ph)\}(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**7**) showing the atom numbering scheme

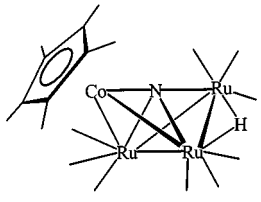
were also performed on the analogous tetraruthenium $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NOMe)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ cluster.[13] The electron count of this metal cluster is also thought be 62, which is two electrons less than expected.[50] Therefore, a delocalized picture should better describe the electronic structure of the cluster. If the N and C atoms in both the μ_4-NOMe and PhC_2Ph units are also considered as skeletal atoms, the cluster can actually be described as pentagonal-bipyramidal. In this case, the total electron count is 70, again conforming to the $14n + 4m + 2$ rule.[50] In other words, the cluster obeys Wade's $n + 1$ rule.[55] We have also carried out molecular orbital calculations on the model cluster $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NOH)(\mu_4\text{-}\eta^2\text{-}HC_2H)]$.[56] The NBO analysis[52] shows that the Wiberg bond orders[53] of the four Ru−Ru bonds are all appreciably positive (ca. 0.1), indicating the existence of metal−metal bonding. The corresponding bond orders for Ru−N, Ru−C (HC_2H), and Ru−CO (bridging) range from 0.15 to 0.55. These results suggest that the metal−ligand interactions are crucial with regard to the stability of the cluster. Figure 8 shows spatial plots[54] of the highest occupied molecular orbital (HOMO) [Figure 8(a)] and the lowest unoccupied molecular orbital (LUMO) [Figure 8(b)]. Both the HOMO and LUMO contain the metal(d)−metal(d) antibonding interaction. On careful examination of these orbitals, one can see that the HOMO can be considered as the antibonding combination among the so-called "t_{2g}"-like orbitals derived from the relevant metal fragments. These "t_{2g}"-like orbitals are approximately nonbonding with respect to the coordinated ligands. However, the LUMO can be described as the skeletal antibonding molecular orbital. The corresponding fragment orbitals in the LUMO involve more metal−ligand antibonding character.

The electronic structures of **6** and $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NOMe)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ show that both are unsaturated square-planar clusters, which may account for the observed NMR anisotropy. Diamagnetic effects had previously been observed in the ^1H and ^{15}N chemical shifts of the μ_4-NH groups in **6** and $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$.[13,48] In comparison with the electron-precise cluster **4**, the chemical shifts of **6** and the tetraruthenium μ_4-NH clusters appear further upfield. The ^1H chemical shift of the μ_4-NH proton in the saturated compound **4** is $\delta = 6.28$, whereas for the unsaturated compound **6** and the Ru_4 analogue, the corresponding shifts are $\delta = 2.76$ and 1.87, respectively. In fact, the ^1H NMR resonance of the μ_4-NH moiety is a sensitive probe for delineating the bonding type in all these new clusters. The ^{15}N chemical shifts of the μ_4-NH groups follow the same trend; thus, for the unsaturated clusters **6** and $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$[13,48] the NH signals are seen at $\delta = 70.2$ and 47.6, while for the saturated **4** it is found at $\delta = 145.4$. The nature of the NMR anisotropy leads to a weaker effective magnetic field above the centre of the Ru_3Co/Ru_4 ring in the unsaturated compounds.[57]

Migration of a hydride ligand to the nitrido atom is an essential step in the formation of **6** and **7**. This probably involves a hydride shift to give structure I, as shown below.



I

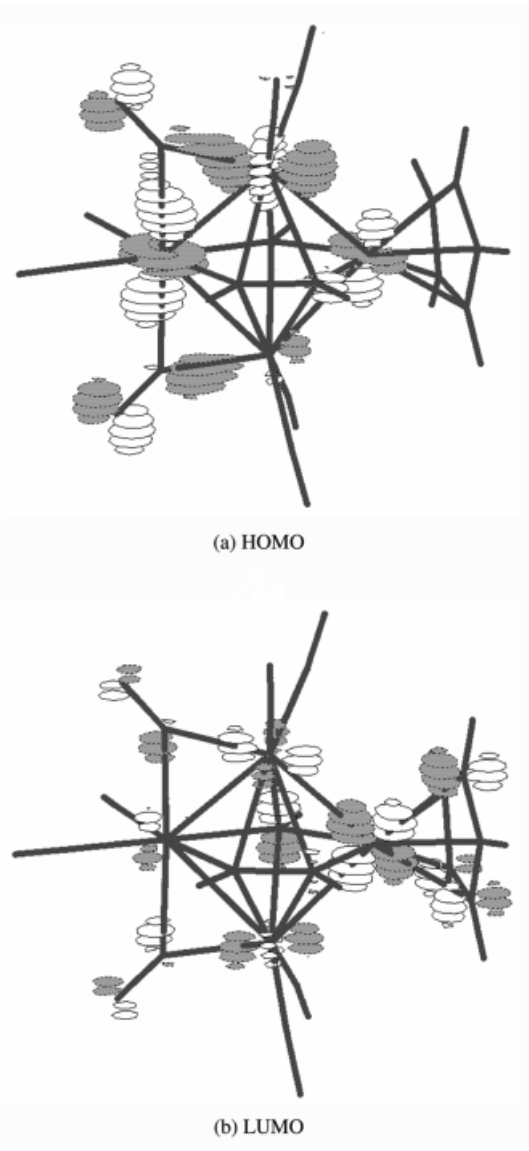

Figure 7. Spatial plots of the highest occupied (a) and the lowest unoccupied (b) molecular orbitals for $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5H_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}HC_2H)]$

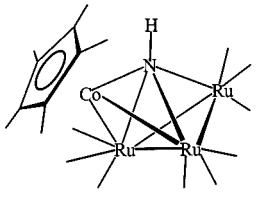
This type of skeleton has been structurally established in another system.[58] The hydrogen atom shows a preference for the ruthenium sites as opposed to those involving the Co(1) atom.[59] The hydride ligand eventually migrates to the nitrogen atom to give structure II in the case of **6**.



II

Conceptually, the addition of an acetylene group to II can easily be described as an insertion of the C≡C unit into the hinge M−M bond of the cluster. Concomitant unfolding of the wings of the butterfly allows stabilization of the acetylene through direct interaction with all four metal centres. A further coupling of a carbonyl ligand and a PhC_2Ph ligand to the nitrene N atom is observed in cluster **7**. The metal-bonded H atom and the H on the *ortho*-carbon atom are transferred to the acetylenic carbons in a *trans* configuration and give rise to doublet resonances at δ = 5.75 and 2.72 with a mutual coupling of 12.26 Hz. Heating of **6** with PhC_2Ph under similar reaction conditions does not give any observable amount of **7**, indicating that the H atom is not easily detached from the nitrene N atom. The shortcomings of bridging or capping main group atoms as cluster stabilizing entities have long been established.[49,60−70] However, in the present case, the main-group N-atom is shown to be valuable not only for its influence on incoming ligands, but also for its capacity to participate in skeletal rearrangements while maintaining cluster nuclearity.

Reaction of $[Ru_3Co(CO)_{12}(\mu_4\text{-}N)]$ with $[Cp^*Co(CO)_2]$

In order to prepare some Co-rich mixed-metal clusters by a stepwise reaction, the cluster $[Ru_3Co(CO)_{12}(\mu_4\text{-}N)]$[1]

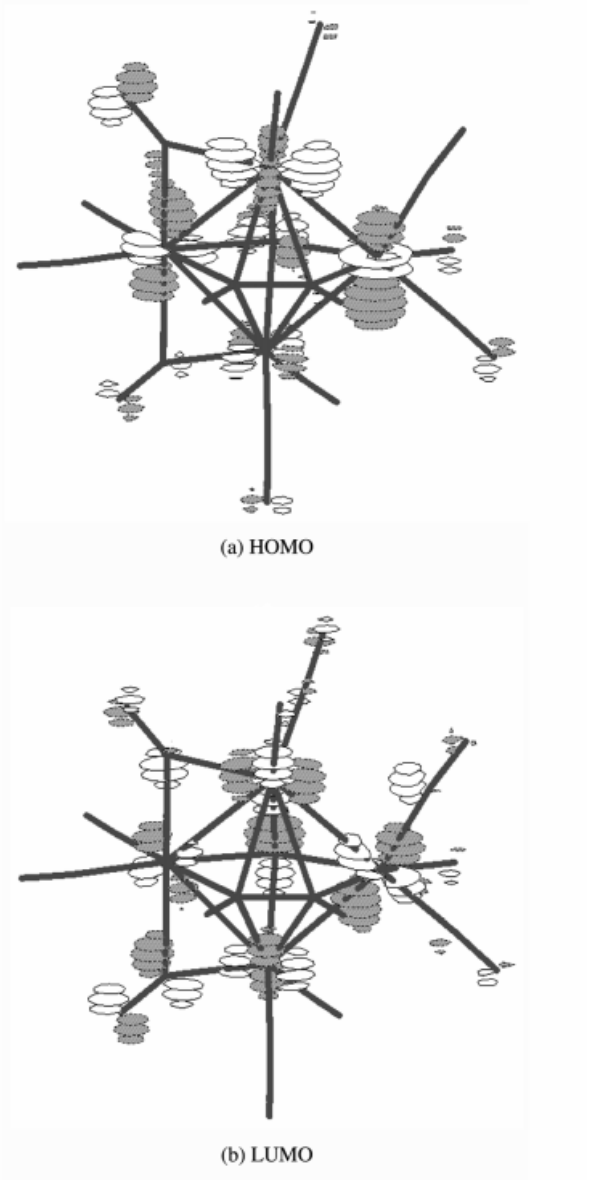


Figure 8. Spatial plots of the highest occupied (a) and the lowest unoccupied (b) molecular orbitals for $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NOH)(\mu_4\text{-}\eta^2\text{-}HC_2H)]$

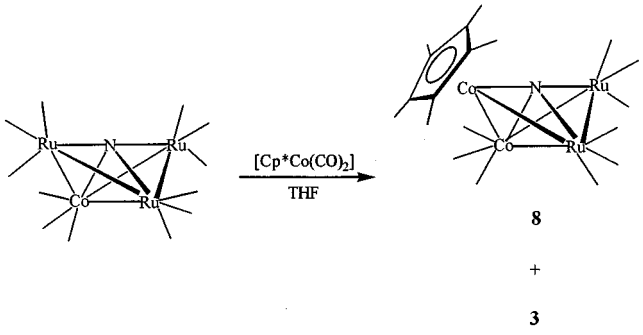

Scheme 3. Treatment of $[Ru_3Co(CO)_{12}(\mu_4\text{-}N)]$ with 2 equiv. of $[Cp^*Co(CO)_2]$ in refluxing THF resulted in the formation of $[Ru_2Co_2(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$ (**8**) and cluster **3** in yields of 32% and 41%, respectively

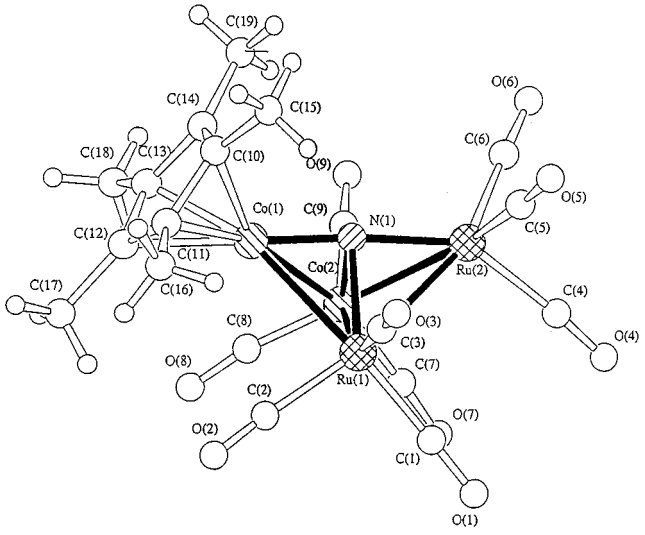

Figure 9. The molecular structure of $[Ru_2Co_2(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$ (**8**) showing the atom numbering scheme

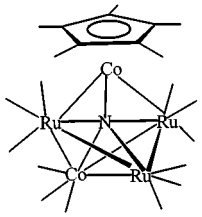
was allowed to react with $[Cp^*Co(CO)_2]$ in refluxing THF for 4 h (Scheme 3). Dark-brown crystals of $[Ru_2Co_2(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$ (**8**) were obtained in high yield, accompanied by some **3**. Cluster **8** was fully characterized by conventional spectroscopic techniques and elemental analysis (Table 1). The ^1H and ^{15}N NMR spectra of **8** feature singlet resonances at $\delta = 1.89$ and $\delta = 524.7$, respectively. The electronic absorption spectrum of cluster **8** is virtually identical to that of **2**, consisting of four bands at 315, 360, 435, and 520 nm. A single-crystal X-ray analysis was carried out; the structure of **8** is depicted in Figure 9, while selected bond parameters are collected in Table 2.

The two ruthenium and two cobalt atoms of cluster **8** define a butterfly metal core, with a nitrogen atom bridging the wing-tip positions of the cluster. The Cp* ligand is coordinated to the wing-tip Co atom at a distance of 1.656 Å. The same butterfly core was also observed in cluster **2**. Thus, the structure of **8** is related to that of **2**, with a $Co(CO)_3$ fragment replacing the hinge $HRu(CO)_3$ moiety. Thus, the Cp*Co moiety in molecule **8** occupies a wing-tip position and the other Co atom is placed at a hinge site. The Co(1)−Co(2) bond in **8** [2.545(1) Å] is significantly longer than that in $[Co_3(\mu_3\text{-}CO)(\eta^5\text{-}C_5Me_5)_3(\mu_3\text{-}NH)]$.[5] The M−N bond lengths involving the wing-tip metals [Ru(2)−N(1) 1.926(5) Å and Co(1)−N(1) 1.723(5) Å] are shorter than those involving the hinge metal atoms [Ru(1)−N(1) 2.039(5) Å and Co(2)−N(1) 1.950(5) Å]. The Ru(1)−N(1)−Co(2) and Ru(2)−N(1)−Co(1) angles are 80.2(2)° and 174.3(3)°, respectively. The dihedral angle between the butterfly wings in **8** measures 103.39°, which is very different from that in **2** (78.59°). The formation of cluster **8** is believed to result from a metal-exchange[31,32] reaction, accomplished by an addition−elimination sequence. The first step should be the incorporation of the Cp*Co fragment into the "butterfly" $[Ru_3Co(CO)_{12}(\mu_4\text{-}N)]$ core to give intermediate III.



III

Although structure III is an electron-precise species, this kind of wing-tip-bridged butterfly metal skeleton involving a μ_5-nitrido ligand is rarely observed. The only other known example occurs in $[Ru_6(CO)_{13}(\mu\text{-H})(\mu_5\text{-N})(\mu_3\text{-}\eta^2\text{-}PhC_2Ph)_2]$.[13] Thus, an $Ru(CO)_3$ or an $RuCo(CO)_5$ fragment is eliminated to give a more favourable metal framework, i.e. butterfly [**8**] or triangular [**3**] clusters. The source of the nitrene hydrogen in the formation of cluster **3** is uncertain; it may come from the degradation of solvent molecules or from a trace amount of moisture in the solvent.

Electrochemistry

The electrochemistry of clusters **1**−**3**, **6**, and **8** has been examined in CH_2Cl_2 by means of cyclic voltammetry and controlled-potential coulometry, using *n*-tetrabutylammonium hexafluorophosphate (TBAHFP) as the supporting electrolyte. The redox potential values obtained are summarized in Table 7; for comparison, those of compounds $[Ru_4(CO)_9(\mu\text{-CO})_2(\mu_4\text{-NOMe})(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**9**), $[Ru_4(CO)_9(\mu\text{-CO})_2(\mu_4\text{-NH})(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**10**), and $[Ru_4(CO)_9(\mu\text{-CO})_2\{\mu_4\text{-NC(O)OMe}\}(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**11**) are also listed.[13]

Table 7. Electrochemical data for compounds **1**−**3**, **6**, **8**, and $[Ru_4(CO)_9(\mu\text{-CO})_2(\mu_4\text{-NR})(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ [**9**, R = OMe; **10**, R = H, and **11**, R = C(O)OMe][13]

11	–	−1.29	–

[a] Ca. 10^{-3} M cluster in 0.1 M TBAHFP in dichloromethane at 298 K, the working electrode was made of glassy carbon, the auxiliary electrode and the reference electrode were a platinum wire and $Ag/AgNO_3$, respectively. Scan rate 100 mVs^{-1}. The potentials are referenced to $Ag/AgNO_3$ (0 V) under the same conditions, calibrated with ferrocene. − [b] E_{pa} and E_{pc} are the anodic and cathodic potentials, respectively. − [c] Values in parentheses are half-wave potential values, $E_{1/2}$.

The cluster $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$ exhibits an irreversible cathodic wave (E_{pc}) at −1.66 V vs. $Ag/AgNO_3$, along with a weak oxidation wave at −0.63 V. The region where the weak oxidation wave appears was initially empty, with the wave appearing after the cathodic wave was traversed. The ΔE_p values remained virtually unchanged on varying the scan rates from 50 to 1000 mVs^{-1}. For $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$, an additional irreversible anodic wave is observed at E_{pa} = 1.11 V. Controlled-potential coulometry at the oxidation step (E_w = 1.25 V) indicates that this anodic process consumes 1 faraday/mol of $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$. On the basis of the relative peak currents of the cathodic and anodic waves, the reduction process could be assigned as a one-electron step. The addition of one electron to the cluster $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$ is believed to afford the 49e cluster $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]^-$, which is unstable and loses a CO ligand to give the 47e species $[Ru_3(CO)_9(\mu_3\text{-NOMe})]^-$ [71] according to an EC mechanism. Cyclic voltammograms of cluster **1** show the same features as those seen for $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$, with a pair of cathodic and anodic waves at E_{pc} = −2.13 V and E_{pa} = 0.83 V vs. $Ag/AgNO_3$. A small return oxidation wave at −0.68 V is seen for the transient 47e $[Ru_3(\mu\text{-H})_2(CO)_8(\mu_3\text{-NOMe})]^-$, similar to that seen for $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$. A salient feature of the electrochemical behaviour of the cluster $[Ru_3(\mu\text{-H})_2(CO)_9(\mu_3\text{-NOMe})]$ (**1**) is that this dihydrido derivative of $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$ is both harder to reduce and easier to oxidize than the corresponding μ_3-CO-capped cluster $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$. The greater difficulty in reducing dihydrido cluster **1** in CH_2Cl_2 is shown by the fact that the E_{pc} value for the 0/−1 couple is 470 mV more negative than that for $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$. Likewise, the +1/0 oxidation couple of **1** is less positive than that for $[Ru_3(CO)_9(\mu_3\text{-CO})(\mu_3\text{-NOMe})]$ by 280 mV. These data are consistent with the premise that the hydrido ligands effectively function as stronger σ-electron donors and as weaker π-acceptors than μ_3-CO ligands.

Although clusters **2** and **8** are obtained from different reactions, they have similar metal architectures and ligand dispositions, with an Ru atom and a hinge μ-H in **2** being replaced by a Co atom in **8**. Both exhibit similar electrochemical behaviour in their cyclic voltammograms. Two electrode processes are evident from their voltammograms: (i) a reversible reduction wave at −1.26 V for **2** and at −1.13 V for **8**, and (ii) an irreversible oxidation wave at around 0.55 V. The species with the higher cobalt-content, cluster **8**, is easier to reduce to the corresponding monoanionic derivative. Controlled-potential electrolyses at E_w = −1.4 V for **2** and −1.3 V for **8** showed that the reduction processes involve one faraday/mol of cluster molecule. Cyclic voltammetric tests run after exhaustive electrolyses showed that the 0/−1 cathodic steps are chemically reversible. On the other hand, controlled-potential coulometry run at 0.7 V for both **2** and **8** showed that two electrons are removed for each molecule. Cluster **8** was found to decompose further, while cluster **2** was stoichiometrically converted into cluster **3**. Analysis of the cyclic voltammetric responses relating to the cathodic peaks of **2** and **8**, with scan rates υ varying from 50 mVs^{-1} to 1000 mVs^{-1}, indicated that: (i) the peak current ratio i_{pa}/i_{pc} remains close to unity, (ii) the current function (proportional to $i_{pc}/\upsilon^{1/2}$) is essentially constant, and (iii) the peak-to-peak separation is between 80 and 100 mV. This trend in peak-to-peak separation parallels that obtained for ferrocene under the same

experimental conditions. Thus, we can assume that the reduction steps of both **2** and **8** proceed by an essentially reversible electron-transfer process. Upon one-electron addition, no gross structural variation should occur in these Ru−Co mixed-metal nitrido complexes. The irreversible two-electron oxidations in **2** and **8** can be assigned as following ECEC or EEC processes. After controlled-potential electrolysis of cluster **2** at 0.7 V for 180 min, the current had decayed to background levels and the experiment was halted. Two faradays of charge were required for each mol of **2**, which was found to be almost completely converted into cluster **3**. In order to verify this oxidation process chemically, attempts were made to react **2** with $Ag[BF_4]$ and $[NO][PF_6]$, since the oxidation of **2** occurred at a potential well within the range of these common oxidizing agents. Although vigorous reactions took place when $Ag[BF_4]$ or $[NO][PF_6]$ was added to the cluster in CH_2Cl_2, no cluster **3** could be detected and only decomposition products were obtained. This may possibly be due to Ag^+ and NO^+ reacting with the cluster rather than merely oxidizing it.[71] A cyclic voltammetric study of compound **3** in CH_2Cl_2 revealed an irreversible one-electron reduction at −1.68 V. With a good π-acceptor μ_3-CO ligand, cluster **3** was found to be reduced at a similar potential as the cluster $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$.

The redox behaviour of $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**6**) is shown in Figure 10. It displays one oxidation and two separated reduction processes, all of which are reversible. Controlled-potential coulometry corresponding to the first cathodic step ($E_w = -1.5$ V) consumes one electron per molecule. Analyses of the cyclic voltammograms exhibited by $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]^{1+/0}$ and $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]^{1-/2-}$ lead to the same diagnostic results. Thus, the square Cp* $Ru_3Co(\mu_4\text{-}NH)$ core exhibits remarkably flexible redox behaviour and, within the short timescale of cyclic voltammetry, is able to accommodate both the addition of two electrons and the removal of one electron without significant molecular strain. Among the clusters discussed so far, only **2**, **6**, and **8** exhibit reversible one-electron transfers, and one common feature of these clusters should be noted: all three have strongly π-bonding η^5-C_5Me_5 ligands. A correlation of this behaviour may be drawn by comparison with the mononuclear analogues such as ferrocene[72] and dibenzenechromium,[73] which are also reversibly oxidized. Clusters **2**, **6**, and **8** are derived from the chemistry of metallocenes, where the metallic core is "shielded" from destruction by π-ligands. The same conclusion was reached from bonding calculations on cluster **6**. It is expected that reduction of the cluster leads to break-up of the CpCo fragment {in the model cluster $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5H_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}HC_2H)]$} or dissociation of the Cp ligand [see Figure 7(b)]. In view of the weak Co(d)−Ru(d) antibonding character of the LUMO for **6**, one may expect this to be more reversible. While oxidation is predicted to enhance the Ru−Co interaction, it would also significantly weaken the Ru−CO (bridging) interactions because the HOMO contains appreciable Ru(d)→bridging CO(π*) back-donation [see Figure 7(a)]. The square-planar μ_4-nitrene complex **6** is also found to be unsaturated, having 62 CVE's. Electrochemically, it would be expected to take up two electrons to achieve a stable 64-CVE configuration, which is indeed observed; cluster **6** undergoes two sequential, chemically reversible, one-electron additions.

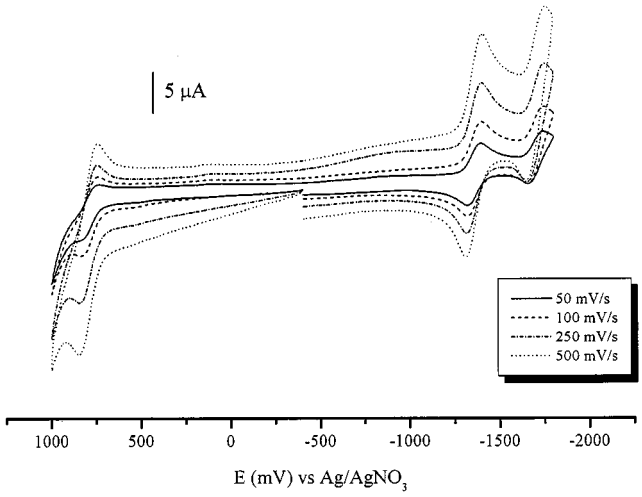

Figure 10. Cyclic voltammogram of **6** in CH_2Cl_2 with 0.1 M TBAHFP as supporting electrolyte using glassy carbon working electrode at 298 K; the increasing current arises from scans at 50, 100, 250, and 500 mV/s, respectively; the voltammograms were recorded against an $Ag/AgNO_3$ reference electrode

We also examined the electrochemical behaviour of the clusters $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NR)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ [**9**, R = OMe; **10**, R = H, and **11**, R = C(O)OMe]. In view of the close similarities in ligation and structure for these three 62-electron bicapped tetraruthenium clusters containing a diphenylacetylene ligand and a μ_4-capped nitrene moiety, it is not surprising that they show similar redox characteristics. Clusters **9**, **10**, and **11** exhibit only irreversible reductions within the solvent limits. The value of the cathodic peak potential (E_{pc}) is about −1.3 V. Weak oxidation waves are observed at −0.99 V and −0.38 V for **9**, at −0.68 V for **10**, and at −0.78 V for **11** upon scan reversal. Increased scan rates did not lead to any noticeable reversibility of the redox couple. Exhaustive electrolyses on all three clusters **9**, **10**, and **11** at $E_w = -1.45$ V showed that the cathodic step involves the addition of one electron per molecule. The absence of a re-oxidation wave for this 0/−1 redox couple indicates the existence of a fast chemical follow-up step that extricates the mono-reduced clusters from solution before they can be oxidized back to the neutral clusters. In accordance with the electronic structure of **9** outlined above, we expect reduction of the cluster to destabilize the metal−metal interactions and to lead to fragmentation, while oxidation can be expected to enhance the interaction. With respect to the reduction scan, these results are consistent with the electrochemical behaviour of **9**; however, no oxidation wave is observed within the potential range of the solvent, thus the comment regarding the oxidation scan cannot be verified. Cluster **6** has a similar structure to cluster **10**, except that the Cp*Co moiety is replaced by an

$Ru(CO)_3$ moiety. The redox behaviour of **10** has been shown to be different from that of **6**. Apart from enhancing the reversibility of the electrochemical processes, the Cp* Co moiety also makes both reduction and oxidation more feasible within the potential range of CH_2Cl_2 as the solvent. The behaviour of heterometallic carbonyl clusters is still uncertain.

^{15}N NMR Spectroscopy

^{15}N NMR spectroscopy is a sensitive and informative tool in characterizing cluster nitridos and nitrenes. In our previous report,[13] we presented nitrogen-15 magnetic resonance spectroscopic data for a series of μ_4-nitrene [μ_4-NH, NOMe, or NC(O)OMe] clusters. A μ_5-nitrido atom in a bridged-butterfly metal skeleton was found to exhibit an unusually high-frequency signal (δ = 549.8). In order to investigate the environments of the various nitrogen atoms of the homo- or heterometallic compounds in this study, all the clusters except **7** were examined by ^{15}N NMR. Table 1 summarizes the ^{15}N chemical shifts obtained.

The cluster $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$, formed by the reaction of $[PPN][Ru_3(CO)_{10}(\mu\text{-}NO)]$ with $CF_3SO_3CH_3$, shows a resonance at δ = 287.3 (reference: liq. NH_3) in its ^{15}N NMR spectrum when the compound is 90% enriched with ^{15}N. Hydrogenation of $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$ gave cluster $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (**1**), which showed a ^{15}N chemical shift of δ = 301.0.[29] Clusters **2** and **3** are the major products of the reaction between **1** and $[Cp^*Co(CO)_2]$, and exhibit signals at δ = 481.1 (s) and 131.4 [d, $J(^{15}NH)$ = 76.95 Hz], respectively. The ^{15}N NMR signal of **2** lies in the typical range for butterfly species. The ^{15}N chemical shift of the μ_3-NH N atom of **3** appears 48.9 ppm further downfield compared to that of the corresponding triruthenium μ_3-NH cluster $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NH)]$.[29] The ^{15}N NMR spectrum of $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NH)]$ features a doublet at δ = 82.5 downfield from liquid NH_3 [$J(^{15}NH)$ = 77.5 Hz], which is characteristic of a direct NH bond. Cluster **4** can be viewed as the *N*-protonated analogue of $[Ru_5(CO)_{14}(\mu_5\text{-}N)]^-$, which gives a ^{15}N resonance at δ = 464.9.[3] Cluster **4** gives a doublet at δ = 145.4 [$J(^{15}NH)$ = 68.26 Hz], which is significantly upfield (319.5 ppm) from the resonance of $[Ru_5(CO)_{14}(\mu_5\text{-}N)]^-$. The ^{15}N resonance of **4** is significantly downfield shifted (by 97.8 ppm) compared to that of $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$,[13] in which the square-planar Ru_4 skeleton is stabilized by a quadruply-bridging acetylene ligand to give an electron-precise cluster according to the EAN rule. By comparison with the saturated clusters $[Ru_3(CO)_{10}(\mu_2\text{-}NH_2)]$ (δ = −33.5) and $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NH)]$ (δ = 82.5), the resonance of **4** is seen to conform to a smooth trend of increasing magnitude with increasing nuclearity around the hydrogen-bonded nitrogen. Thus, the greater the number of ruthenium atoms bonded to the nitrogen moiety, the more deshielded is the nitrogen resonance. The observed $J(^{15}NH)$ coupling constants are fully consistent with calculated values based on the $J(^{14}NH)$ coupling constants [76.86 Hz for **3** and 68.47 Hz for **4**]. Cluster **5** resembles **2**, but with cluster expansion on the Ru_3 wing face with a triruthenium chain. The further coordination of the triruthenium chain leads to a downfield shift of ca. 68 ppm. $[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ (**6**) is an analogous complex to $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$,[13] with an $Ru(CO)_3$ moiety being replaced by a $Co(\eta^5\text{-}C_5Me_5)$ group. This exchange leads to a downfield shift in the nitrogen resonance by 22.6 ppm relative to the corresponding Ru_4 cluster [δ = 47.6, $J(^{15}NH)$ = 70.54 Hz]. The higher field shifts of the unsaturated $[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ and **6** relative to the saturated cluster **4** can be attributed to diamagnetic anisotropy effects. In the formation of cluster **6** from **2**, migration of a hydride ligand to the nitrido is involved, hence cluster **6** could be viewed as the "protonation" product of **2** to give the μ_4-NH cluster. The large increase in shielding arising from this direct "protonation" of a butterfly interstitial highlights the large contribution to the deshielding of the interstitial by low-energy circulations of quasi-lone-pair electrons. Similar examples of this have been observed in the protonation of $[FeRu_3N(CO)_{10}\{P(OMe)_3\}_2]^-$, both at the hinge and at the nitrogen, to give the μ_4-NH intermediate, where the nitrogen shielding is increased by 231 ppm.[74] Protonation of the hinge-protonated carbide $[HFe_4C(CO)_{12}]^{2-}$ to give the μ_4-η^2-CH compound increases the carbon shielding by a correspondingly large amount, i.e. 129 ppm.[75] The measurements made in this study on cluster **6** are the first to be

Table 8. Coupling constants of selected μ_3-NH and μ_4-NH ligands

μ_3-NH complexes	$J(^{14}NH)$	$J(^{15}NH)$

μ_4-NH complexes	**$J(^{14}NH)$**	**$J(^{15}NH)$**
$[Ru_5(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_3(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)]$ **4**	48.82	68.26
$[Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$ **6**	49.08	69.26
$[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)]$[13]	50.71	70.54
$[Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}HC_2Tol)]$[13]	49.30	70.64

reported for a square Ru_3Co complex having an exclusively quadruply-bridging nitrene ligand. One interesting aspect worth mentioning is that the coupling constants for direct ^{15}N-^{1}H interaction in the μ_4-NH moieties are smaller than those for the μ_3-NH groups. Table 8 lists coupling constants for the μ_3-NH and μ_4-NH ligands. The ^{15}N-^{1}H coupling constants can be converted into ^{14}N-^{1}H coupling constants by the equation $J(^{14}NH) = -0.713 \times J(^{15}NH)$, where -0.713 comes from γ_{14}/γ_{15}.[76] Thus, these characteristic values provide useful information in ascertaining whether the nitrene is bound to three or four metal centres.

Cluster **8** is another butterfly cluster analogous to **2** with a hinge $HRu(CO)_3$ fragment replaced by an isolobal $Co(CO)_3$ moiety. The ^{15}N resonance signal is seen at δ = 524.7 with a downfield shift of 43.6 ppm. In conjunction with the results in our previous report,[13] the close relationship between cluster structure and the chemical shift of the cluster nitrogen atom in the ^{15}N NMR spectra has turned out to be a useful tool for the analysis of the products in this system.

Conclusion

Triruthenium methoxynitrido carbonyl clusters $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}NOMe)]$ and **1** have been extensively studied with regard to deoxygenation to give the coordinated nitrido or nitrene ligands by thermolysis, pyrolysis, or nucleophilic reaction with alkynes. On the basis of various reactivities of the starting clusters, we have demonstrated some new rational high-yielding synthetic routes to the heterometallic tetranuclear nitrido cluster **2**. The formation of this cluster can be simply described as an addition of a mononuclear organometallic complex to the methoxynitrido cluster species with the elimination of two carbonyl ligands and a methanol molecule. The pseudo-octahedral Ru_5N framework arrangement makes cluster **4** a particularly attractive model for surface processes; thus the square Ru_4 fragment generated constitutes an interesting model for a ruthenium (100) surface. The rather unusual Cp* transfer process has also been observed in this study. Decarbonylation of cluster **2** with an alkyne initiates a hydride migration from a hinge to a nitrido nitrogen atom. This leads to a skeletal rearrangement, where the hinge of the butterfly cluster is ruptured through the insertion of the alkyne ligand. This square Ru_3Co face skeleton presents an opportunity to evaluate nitrene chemistry on a mixed transition metal surface. The incorporation of a Cp*Co moiety in a μ_4-nitrene cluster has been shown to enhance the reversibility of electrochemical processes and make both reduction and oxidation more feasible. Thus, the chemistry of this cluster differs significantly from that observed for homometallic analogues. Both the ^{15}N NMR and electrochemistry studies of these clusters have provided valuable information regarding the environment of the nitrene/nitrido nitrogen atoms and their redox properties.

Experimental Section

General Procedures: All reactions and manipulations were carried out under argon using standard Schlenk techniques, except for the chromatographic separations. Solvents were purified by standard procedures and distilled prior to use. Unless otherwise stated, all chemicals were purchased commercially and were used as received. $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$,[29] [PPN][$^{15}NO_2$],[78] and [Cp*$Co(CO)_2$][79] were prepared according to literature methods. − Reactions were monitored by analytical thin-layer chromatography (Merck Kieselgel 60 F_{254}) and the products were separated by thin-layer chromatography on plates coated with silica (Merck Kieselgel 60 GF_{254}). − Infrared spectra were recorded on a Bio-Rad FTS-7 IR spectrometer with samples in 0.5 mm calcium fluoride solution cells. − ^{1}H NMR spectra were recorded on a Bruker DPX300 NMR spectrometer with samples in CD_2Cl_2 solution and were referenced to $SiMe_4$ (δ = 0). − ^{15}N NMR spectra were recorded on a Bruker DPX500 NMR spectrometer with samples in $CDCl_3$ solution using liq. NH_3 as a reference. − Positive and negative ionization fast atom bombardment (FAB) mass spectra were recorded on a Finnigan MAT 95 mass spectrometer using *m*-nitrobenzyl alcohol or α-thioglycerol as matrices. − Electronic absorption spectra were measured at room temperature on a Hewlett−Packard 8453 diode-array UV/vis spectrophotometer with samples in quartz cells with 1 cm path length. − Microanalyses were performed by Butterworth Laboratories, U.K.

Reaction of $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (1) with [Cp*$Co(CO)_2$]: A solution of $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (**1**, 100 mg, 0.17 mmol) in THF (50 mL) was heated with 2 equivalents of [Cp*$Co(CO)_2$] (83.1 mg, 0.33 mmol) under argon atmosphere. After refluxing for 10 h, the colour of the solution had changed to dark brown. The solvent was then removed under reduced pressure. The residue was redissolved in a small amount of CH_2Cl_2 and separated by preparative TLC eluting with *n*-hexane/dichloromethane (6:1, *v*/*v*). Four new products were isolated, in the following order of elution: brown $[Ru_3Co(\mu\text{-}H)(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)]$ (**2**, R_f = 0.80, 69.8 mg, 0.091 mmol, 55%), trace amounts of starting $[Ru_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}NOMe)]$ (**1**, R_f = 0.75) and known $[Ru_3(\mu\text{-}H)(CO)_9(\mu\text{-}NH_2)]$[15,29] ($R_f$ = 0.70), purple $[Ru_2Co(CO)_6(\mu_3\text{-}CO)(\eta^5\text{-}C_5Me_5)(\mu_3\text{-}NH)]$ (**3**, R_f = 0.55, 30.3 mg, 0.050 mmol, 20%), red $[Ru_5(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_3(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)]$ (**4**, R_f = 0.10, 3.0 mg, 0.003 mmol, 3%), and green $[Ru_6Co(\mu_3\text{-}H)(CO)_8(\mu\text{-}CO)_3(\mu_4\text{-}\eta^2\text{-}CO)(\eta^5\text{-}C_5Me_5)_3(\mu_4\text{-}N)]$ (**5**, R_f = 0.07, 2.4 mg, 0.0017 mmol, 2%). − $C_{19}H_{16}NO_9CoRu_3$ (**2**, 764.5): calcd. C 29.84, H 2.09, N 1.83; found C 29.7, H 2.3, N 1.9. − $C_{17}H_{16}NO_7CoRu_2$ (**3**, 607.4): calcd. C 33.61, H 2.64, N 2.31; found C 33.7, H 2.4, N 2.4. − $C_{22}H_{17}NO_{12}Ru_5$ (**4**, 992.7): calcd. C 26.61, H 1.71, N 1.41; found C 26.8, H 1.8, N 1.6. − $C_{42}H_{46}NO_{12}CoRu_6$ (**5**, 1422.2): calcd. C 35.47, H 3.24, N 0.99; found C 35.6, H 3.1, N 1.0.

Reaction of Complex 1 with Pentamethylcyclopentadiene and 1,3-Cyclohexadiene: A solution of complex **1** (30 mg, 0.050 mmol) in THF (30 mL) has heated with 1 drop each of pentamethylcyclopentadiene and 1,3-cyclohexadiene under argon atmosphere. The initially yellow solution turned brown upon refluxing. After 10 h, the reaction mixture was concentrated to dryness under reduced pressure. The residue was redissolved in CH_2Cl_2 (2 mL) and separated by preparative TLC eluting with *n*-hexane/CH_2Cl_2 (2:1, *v*/*v*) to afford one red band containing **4** (R_f = 0.40) corresponding to a 4% yield (1.2 mg, 0.0012 mmol). The reaction of complex **1** with a drop of pentamethylcyclopentadiene was also attempted in the absence of 1,3-cyclohexadiene under otherwise similar conditions. The refluxing mixture was monitored by IR and spot TLC, but no reac-

tion was observed. About 80% of the starting material was recovered by TLC work-up on preparative silica plates.

Reaction of Complex 2 with DBU: Compound **2** (20 mg, 0.026 mmol) was stirred in basified dichloromethane (20 mL) [prepared by the addition of DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) (0.2 mL of 0.13 M solution in CH_2Cl_2) to distilled dichloromethane (20 mL)]. The reaction was monitored by spot TLC and ^1H NMR spectroscopy until all the starting material had been consumed (about 10 min). The solvent was then removed under reduced pressure and the residue was chromatographed on silica using *n*-hexane/dichloromethane (6:1, *v*/*v*) as eluent. The only isolable product was cluster **3** (R_f = 0.55; 3.6 mg, 0.0059 mmol, 15%).

Reaction of Complex 2 with [Cp*Co(CO)$_2$]: A solution of cluster **2** (20 mg, 0.026 mmol) and [Cp*Co(CO)$_2$] (9.8 mg, 0.039 mmol) in THF was refluxed for 10 h. The solvent was then removed in vacuo and the residue was subjected to TLC using *n*-hexane/CH_2Cl_2 (6:1, *v*/*v*) as the eluent. Cluster **3** was obtained in 35% yield (R_f = 0.55, 8.4 mg, 0.014 mmol), accompanied by a small amount of unchanged **2** (R_f = 0.80, 1.0 mg, 0.0013 mmol, 5%).

Reaction of Complex 3 with [Ru$_3$(CO)$_{12}$]: Compound **3** (20 mg, 0.033 mmol) and a slight excess of [$Ru_3(CO)_{12}$] (15.4 mg, 0.024 mmol) were dissolved in *n*-octane or toluene (30 mL). The purple solution was heated to reflux for 4 h. The solvent was then removed under reduced pressure and the residue was subjected to TLC using *n*-hexane/CH_2Cl_2 (6:1, *v*/*v*) as eluent. The first band contained [$Ru_3(CO)_{12}$] (R_f = 0.95, 8.9 mg, 0.014 mmol). Two complexes were isolated in the following order of elution: [$Ru_6(\mu_3\text{-}H)(CO)_{12}(\mu\text{-}CO)(\mu_4\text{-}\eta^2\text{-}CO)_2(\eta^5\text{-}C_5Me_5)$][34] ($R_f$ = 0.60, 3.8 mg, 0.0033 mmol, 10%) and cluster **3** (R_f = 0.55, 6 mg, 0.0099 mmol, 30%).

Thermolysis of 2 with PhC$_2$Ph: A solution of compound **2** (20 mg, 0.026 mmol) and diphenylacetylene (9.3 mg, 0.052 mmol) in *n*-octane (30 mL) was refluxed under argon atmosphere for 5 h. The complete consumption of **2** was indicated by spot TLC monitoring. After cooling, the solvent was evaporated in vacuo. Chromatography of the residue on silica eluting with *n*-hexane/dichloromethane (2:1, *v*/*v*) afforded two major bands. Two consecutive bands were then eluted, containing [$Ru_3Co(CO)_6(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}NH)(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$] (**6**, R_f = 0.40, 4.3 mg, 0.0047 mmol, 18%) and [$Ru_3Co(CO)_5(\mu\text{-}CO)_2(\eta^5\text{-}C_5Me_5)\{\mu_4\text{-}\eta^3\text{-}NC(O)C_2(C_4H_4)CHCH(Ph)\}(\mu_4\text{-}\eta^2\text{-}PhC_2Ph)$] (**7**, R_f = 0.15, 1.7 mg, 0.0016 mmol, 6%). − $C_{32}H_{26}NO_8CoRu_3$ (**6**, 914.7): calcd. C 42.01, H 2.84, N 1.53; found C 42.2, H 2.8, N 1.5. − $C_{46}H_{36}NO_8CoRu_3$ (**7**, 1092.9): calcd. C 50.55, H 3.30, N 1.28; found C 50.7, H 3.2, N 1.4.

Reaction of [Ru$_3$Co(CO)$_{12}$(μ$_4$-N)] with [Cp*Co(CO)$_2$]: A suspension of [$Ru_3Co(CO)_{12}(\mu_4\text{-}N)$] (100 mg, 0.14 mmol) and two equivalents of [Cp*Co(CO)$_2$] (70.2 mg, 0.28 mmol) in THF was refluxed. The resulting solution gradually changed from orange to dark-brown. Thermolysis was continued until no starting materials remained (about 4 h, as confirmed by IR spectroscopy). The mixture was then concentrated to dryness in vacuo. The dark-brown residue was redissolved in CH_2Cl_2 (2 mL) and TLC separation (*n*-hexane/dichloromethane, 9:1, *v*/*v*) afforded [$Ru_2Co_2(CO)_9(\eta^5\text{-}C_5Me_5)(\mu_4\text{-}N)$] **8** ($R_f$ = 0.80, 32.4 mg, 0.045 mmol, 32%) and cluster **3** (R_f = 0.48, 35.0 mg, 0.058 mmol, 41%). − $C_{19}H_{15}NO_9Co_2Ru_2$ (**8**, 721.3): calcd. C 31.62, H 2.08, N 1.94; found C 31.8, H 2.2, N 1.8.

Electrochemical Studies

Electrochemical measurements were carried out using an EG & G Princeton Applied Research (PAR) Model 273A potentiostat/galvanostat connected to an interfaced computer employing PAR 270 electrochemical software. Cyclic voltammograms were obtained using a gas (argon) sealed two-compartment cell equipped with a glassy carbon working electrode (Bioanalytical), a platinum wire auxiliary electrode (Aldrich), and an Ag/$AgNO_3$ reference electrode (Bioanalytical) at room temperature; 0.1 mol dm^{-3} *n*-tetrabutylammonium hexafluorophosphate (TBAHFP) in anhydrous deoxygenated CH_2Cl_2 was used as a supporting electrolyte. Ferrocene was added at the end of each experiment as an internal standard.[80] Potential data (vs. Ag/$AgNO_3$) were checked against the ferrocene (0/+1) couple; under the actual experimental conditions the ferrocene/ferrocenium couple is located at +0.18 V. Bulk electrolyses

were carried out in a gas-tight cell consisting of three chambers separated at the bottom by fine frits, with a carbon cloth (80 mm^2) working electrode in the middle, and $Ag/AgNO_3$ reference and Pt gauze auxiliary electrodes in the lateral chambers. The working potentials (E_w) for reduction and oxidation processes were ca. 0.15 V more negative and more positive than the corresponding electrode potentials (E_p), respectively; all coulometric experiments were performed in duplicate.

Crystallography

Crystals suitable for X-ray analyses were glued onto glass fibres with epoxy resin or sealed in 0.3 mm glass capillaries. Intensity data were collected at ambient temperature on either a Rigaku-AFC7R diffractometer (complex **2**) or a MAR research image plate scanner (complexes **3−8**) using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) in the ω − 2θ and ω scan modes, respectively. Details of the intensity data collection and crystal data are given in Table 9 and Table 10. The diffracted intensities were corrected for Lorentz and polarization effects. The Ψ scan method was employed for semiempirical absorption corrections in the case of **2**,[81] while an approximate absorption correction based on inter-image scaling was applied in the case of **3−8**. Scattering factors were taken from ref.[82] and anomalous dispersion effects[83] were included in F_c. The structures were solved by direct methods (SIR-92[84] for **6−8**; SHELX-86[85] for **2−5**) and expanded by Fourier-difference techniques. Atomic coordinates and thermal parameters were refined by full-matrix least-squares analysis on F, with the ruthenium atoms and non-hydrogen atoms being refined anisotropically whenever possible. The nitrene and metal hydride hydrogens were located by Fourier-difference synthesis, while those of the organic moieties were generated in their ideal positions (C−H 0.95 Å). Calculations were performed on a Silicon Graphics computer, using the program package TEXSAN.[86]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre (CCDC) as supplementary publication nos. CCDC 149061−149067. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Effect of Halide Contaminant Ions in the Hydrothermal Treatment of Amorphous Titania on the Phase Change from Anatase to Rutile During Calcination

James Ovenstone*[a] and Kin-Chau Chan[a]

Keywords: Hydrothermal treatment / Titania / Anatase / Rutile / Phase change

Hydrothermal treatment in salt solutions has been used to crystallise and stabilise the anatase phase of titania. Halide contaminants have been shown to accelerate crystallisation of anatase when compared to reactions in pure water, but as anion size increases, the crystallisation improvement is less. The crystallised anatase has then been calcined to form rutile. The impurity ions appear to adsorb to the titania surface and have been shown to have a strong influence on the anatase/rutile transition, reducing the rutile formation during calcination due to the steric hindrance of the rutile nucleation sites on the titania surface. The adsorption sites for the anions affecting anatase crystallisation and rutile formation are different.

1. Introduction

Many factors which influence the phase change from anatase to rutile in titania have been investigated,[1,2,3] and in particular, the influence of doping ions. It has been proposed that the presence of Co^{2+}, Cu^{2+}, K^+, Na^+, Fe^{3+}, Li^+, and Mn^{4+}, all accelerate the transformation of anatase to rutile by increasing the oxygen ion vacancy concentration, while the presence of W^{6+}, NO_3^-, Cl^-, F^-, SO_4^{2-}, PO_4^{2-}, and Nb^{5+} all hinder the transformation by reducing the oxygen ion vacancy concentration.[4,5,6,7] Most of these studies have only been concerned with the final phase change during calcination, however, and very little work has considered the effects of the synthesis method of the anatase itself.

Previous results have shown that the control over the hydrothermal conditions, as well as over the contaminant ions present after the amorphous titania production are vital to controlling the crystallisation properties of the anatase powder.[8,9] In addition, the preparation route for the amorphous precursor has been shown to be vital for controlling the properties of the hydrothermally crystallised anatase. In recent work we have shown that the presence of a small amount of brookite contaminant in the anatase phase can strongly enhance the phase change to rutile. The preparation route for the amorphous titania, as well as the hydrothermal conditions can be used to control how much brookite is present in the anatase powder.[10]

Criado and Real showed how the presence of the phosphate ion inhibited the formation of rutile during calcination, by adsorption to the titania surface, rather than by lattice ion substitution.[11] In the current work, particular attention has been paid to the hydrothermal systems including the halide ions, since these are common contaminants in titania powders, but also to the influence of the preparation route of the amorphous precursor, as this can also be an important factor.

2. Results and Discussion

2.1 Crystallisation of the Ethoxide Derived Powder

Hydrothermal reactions in 0.5 M sodium halide salt solutions were studied to see their effect on the phase change to rutile. The hydrothermal products were all anatase, except for the reaction in NaF, which formed a different phase, which has been noted before.[9] This phase could not be identified from the JCPDS database files and will be the subject of further work at a later date. Figure 1 shows the X-ray powder diffraction (XRD) traces for the products after hydrothermal treatment. Anatase has formed in all cases (except for the fluoride reaction).

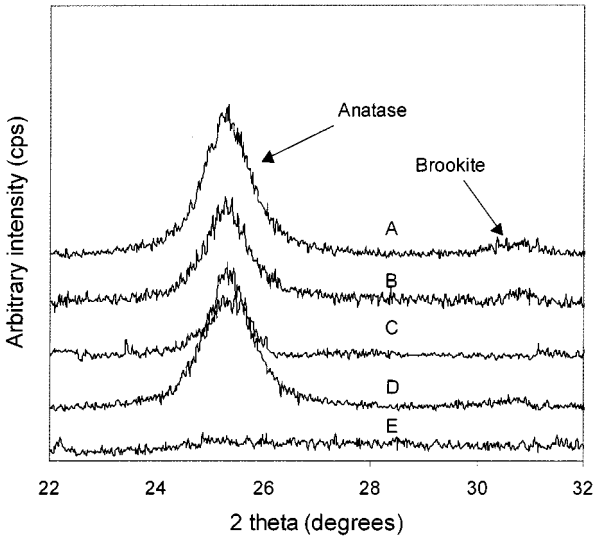

Figure 1. XRD traces of products from hydrothermal treatments in 0.5 M sodium halide salt solutions. A) H_2O, B) NaI, C) NaBr, D) NaCl, E) NaF

The extent of crystallisation was estimated from the loss in specific surface area from the original high surface area amorphous material (Figure 2).[8] Ion coupled plasma mass spectrometry (ICPMS) results showed that the concentration of adsorbed contaminant ions after hydrothermal treatment remained constant at around 15 wt% ±5%. Therefore, the number of mol of contaminate ions per mol of titania fell as the molecular weight of the contaminate ion increased. This would suggest that the adsorption of the salts to the surface of the titania powder is controlled by the anion rather than the cation. Clearly, the presence of the halide salts increased the rate of crystallisation (since in all cases the surface area was lower, indicating less amorphous material present). It can also be seen that the rate of crystallisation was enhanced most by the presence of the chloride ion and least by the iodide ion, indicating that the larger ions have the least effect. Furthermore, as the halide ion size increases, so the crystallite size of the anatase formed, decreases. The mechanism by which the ions accelerate the crystallisation is considered to be a surface reaction, where the halide ion can adsorb to the surface, distorting the lattice due to its large size, and thus enabling the rearrangement of the titanium and oxygen ions. Due to the large size difference between the halide contaminant ions and the oxide ions (compare 1.4 Å for O^{2-} with 1.81 Å for Cl^{-}) it would be extremely unlikely that the halides could enter the lattice under the relatively mild conditions of the crystallisation (120 °C). As the anion size increases, its growth accelerating effect decreases, since the ions fluctuate too rapidly between the solvated and surface bound states in the autoclave. This limits the time for anatase crystallite growth, and gives smaller anatase crystallite sizes (Figure 2). As a result, after hydrothermal treatment, the powders treated in salt solutions with larger anions, still have a considerable amount of high surface area amorphous material remaining (measured using the Brunauer, Emmett, and Teller isotherm (BET), Figure 2).[9]

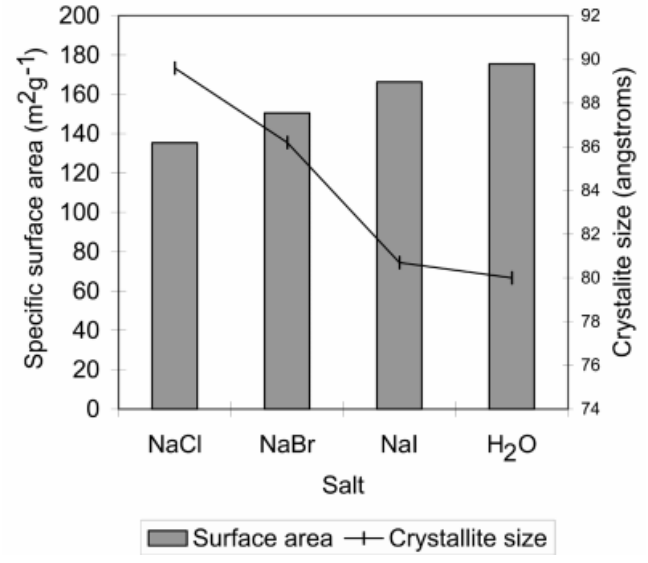

Figure 2. Chart showing the variation in specific surface area (SSA) and crystallite size with salt for hydrothermal reactions carried out at 120 °C for 90 minutes

2.2 Calcination to Form Rutile

The powders treated hydrothermally, produced mostly rutile after calcination, as can be seen from Figure 3, although when sodium fluoride was used, again other phases were formed. Although absolute intensities of peaks in XRD spectra are not quantitatively comparable there is still a very obvious difference in the amount of rutile formed between the samples with different contaminants, with the largest contaminant ions producing the least amount of rutile. Crystallite size data (calculated from the XRD data) showed that the rutile produced from each reaction had a very similar particle size (around 65 nm). This is surprising, since usually, the larger the crystallite size in the anatase product after hydrothermal treatment, then the lower the crystallinity of the rutile after calcination (i.e. the anatase is stabilised). Therefore, the remaining adsorbed salts must have a strong influence over the phase change during calcination.

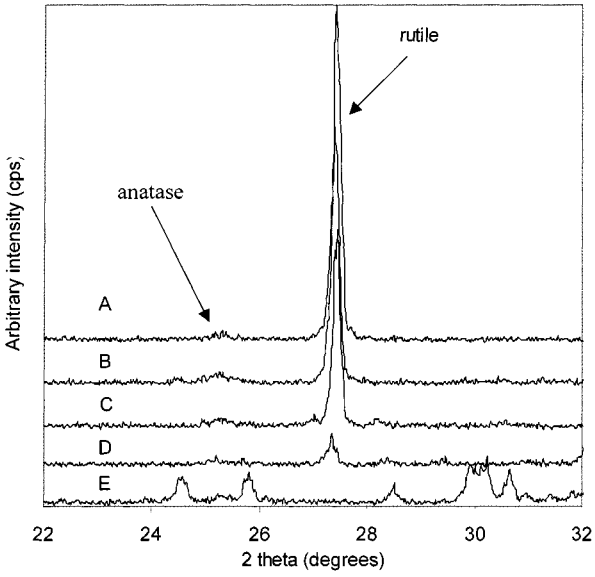

Figure 3. XRD traces for C3 powders hydrothermally treated in 0.5 M sodium halide salt solutions then heated in a DTA apparatus at 20 °C per min to 1000 °C and cooled. A) H_2O, B) NaCl, C) NaBr, D) NaI, E) NaF

This can be explained in terms of the initial reaction in the autoclave, where the anions bind to the surface of the amorphous titania, accelerating the growth of anatase as described previously.[9] The crystallised material has a considerably smaller surface area, and therefore less halide material bound to the surface. The remaining amorphous titania, however, still has a considerable amount of contaminating ions adsorbed to its high surface area material after hydrothermal treatment and these ions (the halide contaminants), reduce the rate of crystallisation by a different mechanism under the dry, ion immobilising, calcination conditions. The literature explanation for the slowing of the phase change of rutile by monovalent anions is the replacement of O^{2-} ions by the cations which would result in the reduction of O^{2-} ion vacancies in the lattice to compensate for the change in charge.[4–7] However, this seems unlikely

due to the difference in size between the monovalent anions used and the oxide ions (ionic radius = 1.4 Å), and particularly doubtful in the case of the large iodide ion (ionic radius = 2.20 Å). In addition, replacement of the small O^{2-} ions in the lattice by the larger halide ions, would doubtless cause a detectable shift in the lattice parameters of the titania, and a noticable shift in the XRD peaks. This is not the case. Therefore, a surface chemistry solution is more likely. Since the halide ions clearly exert a larger stabilising effect than the difference in crystallite size of the hydrothermal anatase product, it would then seem logical that the halide ions in some way block the rutile nucleation site on the titania surface. Since the binding site for the iodide and other halide ions should be the same, and the other halide ions have a far smaller inhibiting effect on the phase change, the binding site may not be the actual rutile nucleation site (which is also on the surface).[1] Instead, a site, which is close to the rutile nucleation site, may be the adsorption point for the halide ions, so that only an ion as large as the iodide ion could sterically inhibit its rearrangement to the rutile phase.

Further evidence for the phase stabilisation as a surface effect rather than an ion exchange is in the products for the reactions carried out in sodium fluoride solutions. Only the hydrothermal treatment in sodium fluoride resulted in phases other than anatase during the hydrothermal stage, and these phases changed to completely new phases during calcination. This implies that only the fluoride ion (1.33 Å) is small enough to either replace the oxide ions in the titania lattice, or enter other sites within the lattice, and that such an incorporation results in the formation of various new phases depending on the reaction conditions. In addition, the incorporation of the cation (sodium) also seems to be controlled by the size of the anion, as only the sodium fluoride formed new phases. If the cation was the controlling agent, the sodium would be expected to enter the lattice in all cases, forming new phases.

2.3 Effect of Changing Amorphous Precursors

As the preparation route to the amorphous titania precursor has been shown to have a strong influence on the anatase product after hydrothermal treatment,[8] and upon the subsequent phase change to rutile,[10] the effect on the phase change of the use of different precursors has been investigated after treatment in different salt solutions. Comparative studies of the effects of the halide ion solutions have been made on two other anatase powders precipitated by different methods. Powder A3 was precipitated from $TiCl_4$ under predominantly acidic conditions, resulting in a powder which retained some adsorbed chloride contamination. This powder was also shown by Raman spectroscopy to have some anatase like short range order, despite being X-ray amorphous. Powder B3 was also precipitated from $TiCl_4$, but under strongly basic conditions, thus eliminating any chloride contamination, but leaving the powder with some ammonium ions adsorbed to the surface. Raman spectroscopy showed this powder to be truly amorphous, as was the C3 powder.[8]

The A3 powder gave products similar to those for the C3 powder after hydrothermal treatment, both in the extent of the reaction when compared to pure water, and in the order of crystallinity of product between the salts. The B3 powder produced much less crystalline powders after hydrothermal treatment, and the relative effects of the different salts on the crystallisation of the anatase was much less clear. After calcination, however, both the A3 and the B3 powders showed a similar trend in rutile formation to the original experiments with the C3 powder.

These results indicate that there may be two types of surface adsorption site on the titania. The first is an acidic site on the amorphous powder and, in the presence of a halide contaminant, allows the rapid growth of the anatase phase after its nucleation by the water. Hence the B3 powder exhibited almost no anatase crystallite growth due to its high surface basicity. The second is probably a less acidic site, on the anatase itself, and so the surface basicity of the B3 powder did not hinder the adsorption of the halide, nor the subsequent effect on the phase change to rutile of the halide ion. The A3 and C3 powders are both effectively neutral, and so would also be expected to exhibit this behaviour during calcination.

To summarise, in terms of contaminant ions, it can be seen that the ion size is crucial in determining its influence on the phase change. Anions can strongly influence the anatase crystallisation, increasing the rate of crystallisation. It has been shown that as their size increases, the strength of surface adsorption decreases in hydrothermal solution, producing less crystalline anatase. The expected surface adsorption site for the halide ions causing this effect is basic in nature. The halide ions also hinder the nucleation of the rutile phase during calcination, however, by means of a steric hindrance effect. The larger halide ions have a larger stabilising effect on the anatase, as they can block the rutile nucleation site more effectively. The ions causing this effect are expected to adsorb to neutral or basic surface sites. The effects of surface adsorbed salts are controlled predominantly by the cations, since the anion (sodium) is capable of entering the lattice (as demonstrated by the NaF reactions), but did not unless the anion was sufficiently small.

Experimental Section

$TiCl_4$ (30 mL, 0.273 mol) was diluted with ice cold water (300 mL). A 1.5 M NH_3 solution was added dropwise to the clear $TiCl_4$ solution until the pH was raised from 0.5 to 3.0 (appox.740 mL). The white precipitate formed was aged for 24 hours before washing with water until the pH reached 7. The amorphous powder (A3) was then dried for 24 hours at room temperature.

$TiCl_4$ (20 mL, 0.182 mol) was diluted with ice cold water (200 mL), and added dropwise to a 7.5 M ammonia solution (1000 mL). The pH fell from 12.5 to 10.9 as the white precipitate formed. Again the amorphous precipitate was aged for 24 hours before washing until the pH reached 9.2. The amorphous powder (B3) was then dried for 24 hours at room temperature.

$Ti(OC_2H_5)_4$ (25 g, 0.108 mol) was added to 550 mL of dry ethanol, and mixed thoroughly before being added to a 0.6 M solution of

water in ethanol [5.94 mL (0.330 mol) of water in 550 mL of ethanol]. After ageing for 25 minutes, the reaction mixture was centrifuged and washed twice with ethanol before drying in a vacuum dessicator.[12]

Hydrothermal crystallisation was carried out by dispersing 60 mg of amorphous titania powder in 10 mL of distilled water in an autoclave (internal volume 20 mL), and then heating the autoclave to 120 °C for 90 minutes. 1 M salt solutions (sodium fluoride, sodium chloride, sodium bromide, and sodium iodide) were sometimes used in place of water.

After treatment in the autoclaves, the powders were washed with water and dried at room temperature under vacuum. Samples of the powders were dissolved, and their halide ion contents and titanium contents measured by ICPMS. The phase was determined by XRD (Rigaku Rotaflex), using a 2θ range of 10−70°, a step size of 0.02°, and a scan speed of 4°/min. A Cu-K_α source with a wavelength of 1.5406 Å, and equipped with a nickel filter to remove the K_β lines. The crystallite size was estimated by Scherrer's method. The formula used for calculation of the particle size was $p_m = k\lambda/\beta_{1/2}\cos\theta°$. In this case, p_m is the mean particle diameter (in nanometres), k is a constant (0.89), λ is the wavelength of the X-ray radiation, and θ is the diffraction angle of the peak. $\beta_{1/2}$ is the pure diffraction breadth at half the maximum value of the peak. This is calculated as $\beta = B - b$, where B is the experimentally observed width, and b is the breadth of a highly crystalline material (particle size >> 1000 Å). In this case silicon powder was used. The XRD step size was reduced to 0.006° at a rate of 0.5°/min. For anatase, the peak with the Miller indices 101 (100%) was used, while for rutile the 110 (100%) peak was used. Although it is not possible to accurately estimate the particle sizes using this method, it is extremely sensitive to the trends in particle size for the same material. In addition, TEM was used to confirm that the particle sizes were in a suitable region. The specific surface area was measured using the 3 point BET method using a Yuasa Ionics NOVA 1000 instrument. Differential thermogravimetric analysis (TG/DTA) was carried out on a Seiko SSC5200H system. The TG/DTA apparatus was used to calcine samples by heating at a ramp of 20 °Cmin^{-1} to 1000 °C before allowing to cool. The phase of these samples was then checked again by XRD, and the anatase/rutile composition estimated by the method outlined by Spurr and Myers.[13] The anatase/rutile proportions using the equation $f = 1/[1+1.26(I_R/I_A)]$. Here f is the weight fraction of anatase, I_R is the intensity of the main rutile XRD peak (Miller indices = 110), and I_A is the intensity of the main anatase XRD peak (Miller indices = 101). They estimated the error in this measurement to be within 1%. Raman spectroscopy was carried out using a Kaiser Optical Systems Holoprobe rpt. System. Salt concentrations in hydrothermal products were obtained using atomic absorption spectroscopy.

Acknowledgments

Synthesis, Spectral Characterisation and Crystal Structure of (1,24-Bicyclophthalocyaninato)bismuth(III)

Karim Benihya,[a] Mireille Mossoyan-Déneux,*[a] and Michel Giorgi[b]

Keywords: Bismuth / Phthalocyanines / Bicyclic / Molecular structure / IR spectroscopy / UV/Vis spectroscopy

A new orange bicyclophthalocyanine complex of bismuth(III), [Bi($C_{48}H_{24}N_{13}$)], has been synthesised by means of the template reaction of bismuth(III) acetate with phthalodinitrile. The ligand consists of the phthalocyanine skeleton, which is bridged by two additional isoindole units. The conjugation of the phthalocyanine ring is interrupted by the two bridgehead sp^3-hybridised carbon atoms. The main difference between this new bicyclophthalocyanine and those previously reported in the literature lies in the position of the bridgehead carbon atoms. In order to differentiate between these bicyclophthalocyaninato complexes, we propose a nomenclature: [Bi($C_{48}H_{24}N_{13}$)] is named Bi(1,24-Pcc), and the other bicyclic ligands already reported in the literature are named (1,16-Pcc) and (1,17-Pcc). The molecular structure of Bi(1,24-Pcc) shows the coordination polyhedron around the bismuth atom, made up of the six isoindole nitrogen atoms of the macrocycle, as a strongly distorted trigonal prism. The two Bi–N_{iso} bonds of the bridge and two of the four Bi–N_{iso} bonds of the (Pc) ring have bond lengths between 2.40 and 2.47 Å. One of the remaining bonds is longer (2.55 Å), and the sixth has a very short length of 2.20 Å. This new complex was fully characterised by UV/Vis and IR spectroscopy, also reported here.

Introduction

We recently reported the synthesis and characterisation of a new phase of the triple-decker compound, $Bi_2(Pc)_3$.[1] During the preparation of $Bi_2(Pc)_3$, if reaction mixture was heated to approximately 240 °C and allowed to cool to room temperature, we obtained many bright, orange−red crystals. This compound, **1**, was characterised by X-ray diffraction as a complex containing six units of phthalonitrile organised in three cycles per bismuth atom. The ligand consists of a phthalocyanine skeleton bridged by two additional isoindole moieties (Figure 1). The conjugation of the phthalocyanine ring is interrupted by the two bridgehead pyrrole C_α atoms, which are sp^3 hybridised. Similar phthalocyanine complex precursors were reported by Baumann et al.,[2] and by Perkins and Whelen[3] with cobalt and copper as the central metal atoms, and by Barnhart and Skiles with copper and nickel as the central metal atoms.[4] Although the molecular structure had not yet been elucidated, these authors proposed a structure similar to the one that we obtained. The complete resolution of the molecular structure of a neighbouring yellow−green complex, the bicyclophthalocyaninatochloroniobium(IV), [Nb($C_{48}H_{24}N_{13}$)Cl] (**2**) was reported for the first time by Gingl and Strähle.[5] Janczac and Kubiak obtained other green bicyclophthalocyanine complexes, $M^{III}(C_{48}H_{24}N_{13})$ **3**, with indium(III), gadolinium(III), thallium(III), and cerium(III),[6] and reported the molecular structure of the Gd,[7] In,[6] and Tl[8] complexes. All these complexes contain a ligand with the same overall formula ($C_{48}H_{24}N_{13}$), but these ligands have different structures and point symmetries. The main difference between these macrocyclic ligands lies in the bridgehead carbon atoms.

In **3**, the bridgehead atoms are the pyrrole C_α atoms (C1 and C17 in our numbering scheme, proposed in Figure 1) which belong to the two opposite isoindole rings of the phthalocyanine skeleton, and are on both sides of the metal(III). In **2**, the bridgehead atoms are the pyrrole C_α atoms (C1 and C16) that belong to the two neighbouring isoindole rings of the phthalocyanine skeleton. In **1**, the bridgehead atoms are the pyrrole C_α atoms (C1 and C24) belonging to the two opposite isoindole rings as is the case in **3**, but they are on the same side of the bismuth atom. Thus this bicyclophthalocyanine ligand has an original structure.

Results and Discussion

Proposal for Nomenclature

In the literature, the names of these bicyclophthalocyanines are confusing. The empirical formula of the ligand ($C_{48}H_{24}N_{13}$) does not indicate either the nature of the ligand related to phthalocyanine or the different positions of the bridgehead carbons. The substitutive nomenclature of IUPAC is not easy to use. For example, compound **3** in which the trivalent metal is substituted by three hydrogen atoms, is named 29*H*,31*H*,35*H*-19,5-(nitrilo[1,3]isoindolediylidenenitrilo[1]isoindolyl[3]ylidenenitrilo)phthalocyan-

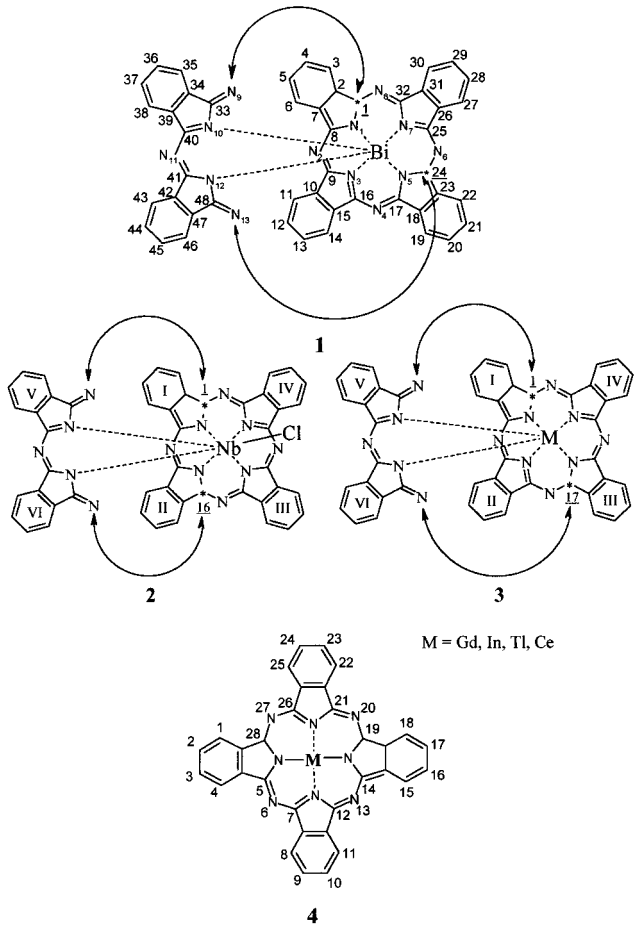

Figure 1. Structure of **1**, Bi(1,24-Pcc), compared to bicyclophthalocyanine complexes **2**, NbCl (1,16-Pcc), and **3**, M(1,17-Pcc) (M = Gd, In, Tl); reported in the literature. Our numbering scheme is used for all structures rather than that adopted for substituted phthalocyanine macrocycles **4**

ine.[9] For simplification, in reference[7] and subsequent papers, Janczak et al. named the bicyclic macrocycle in compound **3** as Pcc, and this name is now an accepted abbreviation of this hexapyrrole ligand.[9] Since three different hexapyrrole ligands of this kind have now been synthesised, we propose to indicate the numbering of the bridgehead carbons as prefixes in the letter code. For phthalocyanine compounds, the numbering scheme generally used in the literature[9,10] is shown in Figures 1−4. It was selected by the authors to indicate the position of the substituted groups at the periphery of the phthalocyanine macrocycle. The IUPAC name mentioned above follows this numbering scheme, but in the clockwise sequence, the numbering prefixes being as small as possible. We think that this numbering scheme is not suitable for that kind of complex. Bicyclophthalocyanines are not substituted phthalocyanines: the colour is different, the visible spectrum does not show the intense Q-band characteristic of phthalocyanine systems, and finally, bicyclophthalocyanines are chemically more reactive than the usual phthalocyanines. All these differences are explained by the interruption of the π-conjugation of the phthalocyanine ring. Furthermore, the differences in the colours of the three different bicyclophthalocyanine ligands reported in the literature are probably due to the different number of benzopyrrole moieties involved in the π-electron delocalisation between the two bridgehead carbon atoms. So it seems to us that the positional indices of the bridgehead atoms have priority over the indices of possible substituents at the periphery of the benzene rings. In the same way as R. Kubiak and J. Janczak,[8,11−13] and some other authors[14−16] did for crystallographic purposes, we started the numbering of the carbons from one pyrrole carbon C_α so that the carbon atoms of the first isoindole ring (I) are numbered from 1 to 8, those of the second (II) from 9 to 16, those of the third (III) from 17 to 24 and those of the fourth (IV) from 25 to 32, nitrogen atoms being numbered separately. In order to have the substitution prefixes as small as possible, we started the numbering of the carbon atoms from a bridgehead carbon. With this numbering scheme, compounds **2** and **3** are named NbCl(1,16-Pcc) and M(1,17-Pcc) (M = Gd, In, Tl), respectively, and **1** is named Bi(1,24-Pcc). There are some advantages in this numbering scheme: a) The indices are independent of the clockwise or anticlockwise sequence and of the bridgehead carbon atom chosen as number one; b) The second index directly indicates the number of benzopyrrole moieties between the two bridgehead carbon atoms, each benzopyrrole moiety being made up of eight carbon atoms.

Synthesis and Properties

It is not surprising that the structure of the bicyclophthalocyanine with niobium(IV), in which the metal is bonded to a chlorine atom, is different to that of bicyclophthalocyanines with trivalent metals, but it is unexpected that **1** has a structure different from those of all the metal(III) bicyclophthalocyanines prepared by Janczak et al. These authors had stated that the chemical composition of the metallophthalocyanines with trivalent metals was strongly dependent on their preparation method.[17] Effectively, **1** and **3** were prepared differently, with a change in the metallation agents, the weight proportions, the pressure and the nature of the atmosphere, the temperature and the reaction time. But we think that the formation of Bi(1,24-Pcc) can also be explained by the properties of the bismuth atom, which are different from those of indium(III), gadolinium(III), and thallium(III) ones. Compound **1** was first obtained using the method employed in the preparation of $Bi_2(Pc)_3$,[1] and the heating was interrupted at approximately 230−240 °C. However, the evolution of the reaction mixture to the triple-decker compound was very fast, and hence, the formation of a larger amount of orange crystals was easier when the ratio of phthalodinitrile/bismuth acetate was reduced to 7.

Compound **1** has been synthesised from the template reaction of phthalodinitrile around the bismuth(III) acetate following the reaction:

$$6\,[C_6H_4(CN)_2] + {}^1/_2\,N_2 + 3\,e^- + Bi^{3+} \rightarrow [C_{48}H_{24}N_{13}]Bi$$

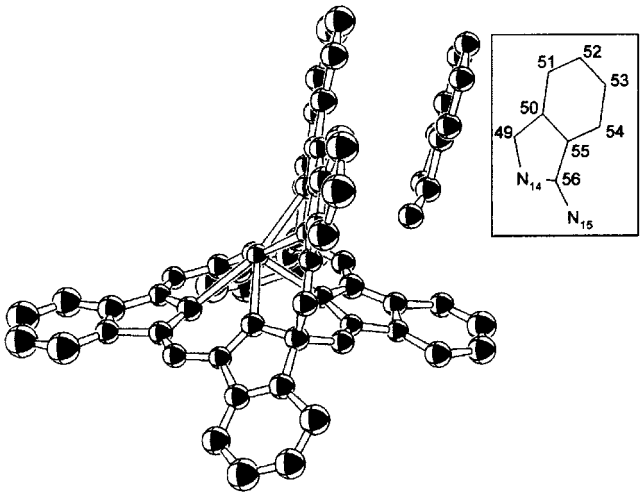
That reaction was performed in air. The phthalodinitrile was involved in an hexamerisation reaction, but was also partly sublimed, and partly involved in secondary polymerisation reactions and in decomposition reactions.[10,18] We believe that the additional nitrogen atom, as well as the three electrons that allow for the formation of the trianionic ligand $[C_{48}H_{24}N_{13}]^{3-}$, arise from these secondary reactions.

Like Tl^{III}(1,17-Pcc), **1** was not soluble in conventional organic solvents: acetone, DMF, DMSO, benzene, toluene, chloronaphthalene. Washing with these solvents allowed us to separate **1** from other by-products of the reaction. A mixture of orange crystals and a light grey powder was retained by the filter. Crystals of **1** are very hydrophobic and, in spite of a very high density (1.48), floated at the interface of a water/acetone/pentane (1/1/1) mixture, while the light grey powder fell to the bottom of the vessel. The crystals were large and very crumbly, and their quality was not good enough for a diffraction study. When dissolved in concentrated acids, the triple-decker compound $Bi_2(Pc)_3$, and **1** decomposed, giving bismuth salts, but the former was converted into free phthalocyanine $H_2(Pc)$ while the latter was converted into phthalimide, the hydrolysis product of phthalonitrile. This experimental result showed that the $(Pcc)^{3-}$ ligand is effectively less stable than the $(Pc)^{2-}$ ligand, as assumed by Gingl and Strähle,[5] because of the interruption of the π-conjugation along the inner 16-membered ring.

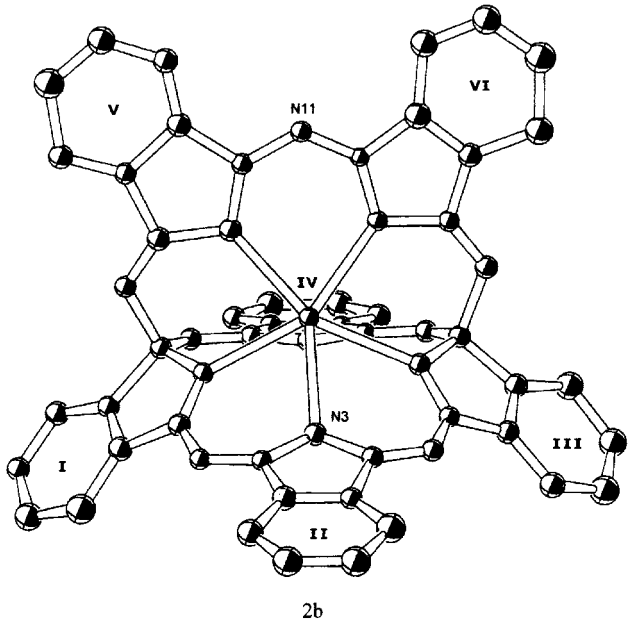
Kasuga and Tsutsui reported that the bicyclophthalocyanine complexes have bright colors.[19] Superphthalocyanines are dark blue,[20] metallophthalocyanines with a rigorously planar phthalocyanine ligand, such as Cu(Pc) or Co(Pc), are dark blue−violet and metallophthalocyanines, such as Pb(Pc), in which the ligand is saucer-shaped, are dark green. Janczak and Kubiak assumed that this interruption of the π-conjugation undoubtedly accounts for the specific green colour of metallobicyclophthalocyanines. They suggested that the blue−violet colour was characteristic of all phthalocyanines in which there is full delocalisation of π-electrons along the inner 16-membered ring, and that green was the characteristic colour of bicyclophthalocyanines in which the π-electron delocalisation is interrupted.[7,8] Effectively, all reported bicyclophthalocyanines complexes with the (1,17-Pcc) ligand are green. As proved by X-ray analysis, **1** and **2** are also bicyclophthalocyanines in which the π-electron delocalisation is interrupted: **2** is yellow−green, **1** is not green, but bright orange, closer to red than to yellow. We believe that the color of the complex depends on the length of the π-electron delocalisation and particularly on the number of benzopyrrole moieties involved in the delocalisation. In **2** and **3**, the interruption of the π-conjugation divides the macrocycle (Pc) into two parts, each containing two benzopyrrole moieties, while in **1** there are three benzopyrrole moieties in one part and only one in the other part. Note that boron subphthalocyanines (SubPc)B, which contain only three benzopyrrole moieties, are characterised by their bright color.[21] (SubPc)BPh, which has a phenyl group on the boron atom, is a golden brown solid,[21] and finally, a boron subphthalocyanine substituted with *tert*-butyl groups at the periphery of the macrocycle is magenta-coloured.[22] The bright orange colour of the crystals of Bi(1,24-Pcc) is probably due to the extension of the π-delocalisation along three benzopyrrole moieties.

Crystal Structure of Bi(1,24-Pcc)

Figure 2 shows two ORTEP views of **1**. Part (a) shows a co-crystallised molecule of VII behind the bridging cycle. The molecular structure of **1** was determined unambiguously by the X-ray diffraction study, and a last series of Fourier difference cycles revealed some electronic densities, all lying in the same plane. Among these electronic densities, the most identifiable scheme was a five-membered cycle. They were attributed to a strongly disordered co-crystallised molecule.



2a



2b

Figure 2. ORTEP drawings of **1** with the co-crystallised molecule (with the atoms numbered in the inset) (2a), and facially viewed with the numbering of all benzopyrrole moieties (2b)

Compound **1** was formed in molten phthalonitrile, and during several attempts to purify it by sublimation, the orange crystals broke up and gave a yellow−orange powder and some sublimed light yellow powder, the IR spectrum of which suggested the presence of a large amount of phthalonitrile. Furthermore, the formation of $Bi_2(Pc)_3$ by heating only washed orange crystals is impossible, but the heating of orange crystals in molten phthalonitrile up to 310 °C always produced the triple-decker compound. On the basis of these experimental observations, we attributed these residual densities to a cyclised phthalonitrile, probably an intermediate in the synthesis of $Bi_2(Pc)_3$, stabilised by the interaction with Bi(1,24-Pcc) in the crystal. This additional benzopyrrole moiety was fixed as $C_8H_4N_2H_2$, numbered as indicated in Figure 2(a) and named VII.

Gingl and Strähle have described their bicyclic complex as two phthalocyaninato anions having a common half. Effectively, in **2**, the macrocycle formed by the benzopyrrole rings I, II, III, and IV on the one hand and that formed by the benzopyrrole rings I, II,VI, and V on the other, make up a ring similar to a phthalocyanine with eight pyrrole α carbons and four N_{aza} bridges, but it is not really a phthalocyanine system owing to the interruption of the π-conjugation. In **3** there is only one phthalocyanine-like ring formed by benzopyrrole rings I, II, III, and IV. The macrocycle formed by I, II,VI, and V rings on the one hand and that formed by the III, IV,VI, and V rings on the other, both have eight pyrrole α carbons but five N_{aza} bridges, and not four. Compound **1** is a molecule that contains a ring similar to a superphthalocyanine formed by the five benzopyrrole moieties I, II, III, V, and VI, and a phthalocyanine-like ring formed by the four benzopyrrole moieties I, II, III, and IV. These two macrocycles have three common isoindole rings (I, II, and III).

While **2** has a twofold axis passing through the Cl and Nb atoms, and through the (N2) N_{aza} atom of the common half (Pc) ring, **1** and **3** have no crystallographic symmetry element. In Figure 2(b) it seems that there is a molecular pseudo symmetry plane passing through N3, N7, and N11, and through the bismuth atom, but the angle values and the bond lengths around the two sp^3 carbons, reported in Table 1, show that some pseudo-symmetrical distances are not equal in the estimated standard deviation limits (e.g., compare C1−N8 and C24−N6 bond lengths). This disymmetry is probably due to the co-crystallised molecule. The observed values are typical for normal sp^3 carbon atoms that are σ-bonded to an sp^2 nitrogen atom or to another sp^2 carbon atom. Furthermore, all bond lengths of the macrocyclic skeleton of **1** are comparable to the corresponding lengths reported for **2**[5] and **3**.[6−8] Because of the interruption of the π-conjugation, the (Pc)-like ring is not planar and it is difficult to find reference planes, as is the case in **3**, in which there are three similar planes, each containing two benzopyrrole units. We choose two reference planes for **1**. The first, P1 is the mean-plane formed by the isoindole nitrogens N1, N3, N5, and N7 and is the reference for the phthalocyanine ring atoms. N1 and N5 are above P1, while N3 and N7 are under P1. The second reference plane P2, formed by C1, N10, N12, and C24, is taken as a reference for the atoms belonging to the bridging cycle. The deviation from P2 of these four atoms is very small (below $2\cdot10^{-3}$ Å). P3 is the mean plane of the co-crystallised molecule. As shown in Figure 3, the dihedral angle between P1 and P2 is 101.70° (±2.96°) and the bismuth atom lies at a distance of 1.259 Å from P1 and 1.212 Å from P2.

Table 1. Characteristic values (bond lengths and angles) around the two sp^3-hybridised carbon atoms

C1 Atom		C24 Atom

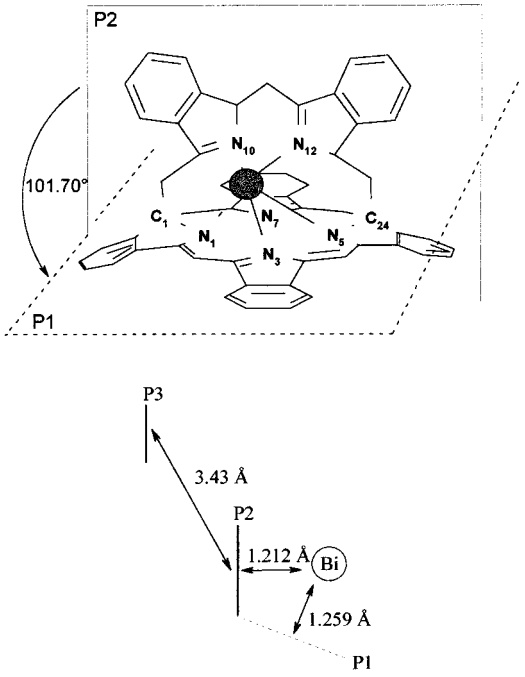

Figure 3. (Above) Dihedral angles [deg.] between mean planes P1 and P2. (Below) Distances [Å] between: 1) the bismuth(III) atom and these planes; 2) mean planes P2 and P3

All benzopyrrole units are planar, and the dihedral angles between the pyrrole and the benzene rings are smaller than the estimated standard deviation. Figure 2 clearly shows that the benzopyrrole II is nearly in P1, but that the other three benzopyrrole groups deviate strongly from P1. The dihedral angles of the benzopyrrole mean planes I, II, III, and IV with P1 are 38.1, 2.9, 38.6, and 22.0° respectively, and the estimated standard deviation is equal to 3.6°. In the bridging moiety, the dihedral angles between mean planes VI and V, and P2 are 7.4° and 170.7°, respectively. P3 was

calculated in order to determine its position relative to the bridging ring, and particularly to unit VI. The dihedral angle between mean plane VI and P3 is 7.9°, with an estimated standard deviation of 4.7° so that the co-crystallised molecule may be considered as nearly parallel to the benzopyrrole VI. The two mean planes are separated by 3.43 Å, but the N15 atom lies only 2.97 Å from mean plane VI: there is some interaction between the co-crystallised molecule and the benzopyrrole VI, and we believe that this interaction allows for the immediate stabilisation of the crystal and a cyclised form of the benzonitrile, an intermediate in the synthesis of the triple-decker compound.

The coordination polyhedron, made up of the six isoindole nitrogen atoms is a strongly distorted trigonal prism. Related distances are reported in Table 2 and compared with other bond lengths for bicyclophthalocyanine compounds reported in the literature. In both phases of $Bi_2(Pc)_3$,[24,1] the bismuth is bonded to the internal (Pc) ring by long $Bi-N_{iso}$ distances (mean value: 2.734 Å) and to the external (Pc) rings by short $Bi-N_{iso}$ distances (mean value: 2.334 Å). In **1** we note that four $Bi-N_{iso}$ bonds (N1, N5, N10, and N12) have bond lengths between 2.40 and 2.47 Å, but that the Bi−N3 bond is longer [2.554(1) Å] and the Bi−N7 bond has a very short length of 2.200(1) Å. The first result is comparable with that found in $Bi(Pc)_2(CH_2Cl_2)$ (2.47 Å) described by Homborg,[23] and slightly larger than that found for $Bi-N_{iso}$ bonds of the external macrocycles in the triple-decker compounds. The second value is intermediate between the two different values obtained in the triple-decker compounds. The Bi−N7 bond length is shorter than the $Bi-N_{iso}$ distances reported by Janczak and Kubiak for $[Bi(Pc)]_4(Bi_4I_{16})$ as the smallest known among the bismuth phthalocyanine complexes[25] [between 2.260(11) and 2.283(10) Å]. The $Bi(Pc)^+$ moiety in $[Bi(Pc)]_4(Bi_4I_{16})$ is the only bismuth monophthalocyanine with an elucidated structure. In the other known phthalocyanine complexes, the metal is sandwiched between two phthalocyanine rings and it is reasonable that the $Bi-N_{iso}$ distances are longer.

We now compare the coordination polyhedron with those of the other bicyclophthalocyanines (Table 2). Except for Bi−N7, all the $Bi-N_{iso}$ bond lengths are longer than those of the $M-N_{iso}$ bonds reported in the literature for bicyclophthalocyanine compounds with M = Gd, Nb, Tl, and In. This is consistent with the fact that the Bi^{3+} cation has the largest ionic radius in the series, as reported by Shannon[26] for a coordination number of six. In **2** and **3**, the shortest $M-N_{iso}$ bond lengths are those in which the pyrrole nitrogen atoms are directly bonded to the sp^3 carbon atoms. Furthermore, in compounds **3** and except for M−N5 in (1,17-Pcc)Tl, the longest $M-N_{iso}$ bonds are those related to the pyrrole nitrogen atom of the bridging cycle. In **1**, the bridge divides the macrocycle (Pc) so that there are three benzopyrrole moieties in the one section and only one in the other section. This disymmetry displaces the bismuth atom on the same side as the lone benzopyrrole so that Bi−N7 is the smallest known $Bi-N_{iso}$ bond among bismuth phthalocyanine complexes and, on the opposite side, Bi−N3 is then the longest $Bi-N_{iso}$ bond in **1**. Among the four remaining $Bi-N_{iso}$ bonds, as observed in the compounds **2** and **3**, the shortest $Bi-N_{iso}$ bond lengths are those in which the nitrogen atoms of the pyrrole moiety are directly bonded to the sp^3 carbon atom and the longest $Bi-N_{iso}$ bonds are those related to the pyrrole nitrogen atoms of the bridge. Compound **1** has six $M^{III}-N_{iso}$ σ-bonds, like compound **3**, but the cation Bi^{3+} has two valence electrons more than thallium or indium. That electron pair is not necessary for the formation of the six bonds and may be located as a non-bonding electron pair on the bis-

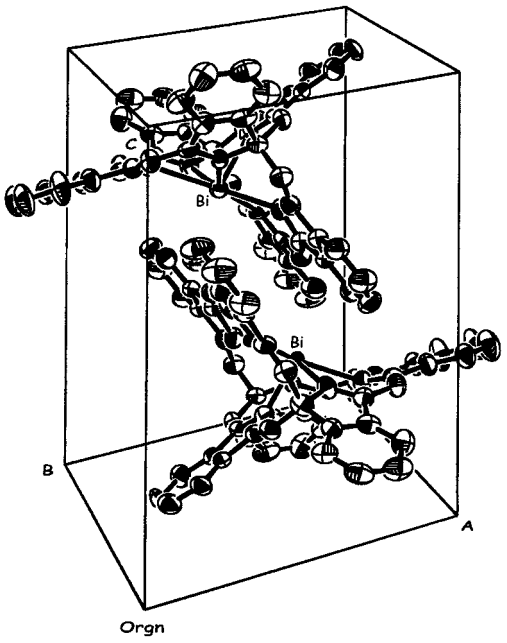

Figure 4. Relative position of two molecules of **1** in the crystal cell

muth atom, inducing the distortion of the coordination polyhedron.

Figure 4 shows the relative position of two molecules of **1** in the crystal cell. Compound **1** is first formed during the synthesis of $Bi_2(Pc)_3$ and its stoichiometry is exactly half that of $Bi_2(Pc)_3$. One can easily deduce that the relative position of these two molecules of **1** in the crystal cell determines the first stage of the dimerisation of **1** to give the triple-decker bismuth phthalocyanine.

The shortest interatomic distances between two successive bicyclophthalocyanine molecules are N3···C29 (3.42 Å) and C28···C8 (3.47 Å). These distances indicate a very weak interaction between the π-electron delocalisation systems of the related benzopyrrole rings. Nevertheless, interactions concerning carbon atoms at the periphery of the phenyl rings cannot participate in the formation of $Bi_2(Pc)_3$. More interesting are the distances between the aza-nitrogen of the first molecule and the α-carbons of the pyrrole ring of the second molecule. These distances can be considered as too long to allow for a dimerisation through these atoms (N9···C48 = 5.66 Å and N13···C33 = 5.64 Å). It is remarkable that two successive bicyclic molecules are closer in **3** than in **1**. These distances are 3.25, 3.36, and 3.36 Å for the indium, gadolinium, and thallium complexes, respectively.

UV/Vis Spectroscopy

Figure 5 shows the UV/Vis spectrum of **1**. We distinguish a very small Q band at λ = 630 nm and a very large and intense B band at 302 nm with two shoulders at 392 nm and at approximately 455 nm. The spectrum of **1** is very different from that of the monophthalocyanine Bi(Pc)Cl reported by Isago and Kagaya.[27] All the bands of **1** are blue-shifted, and the most striking difference is the almost complete disappearance of the Q band.

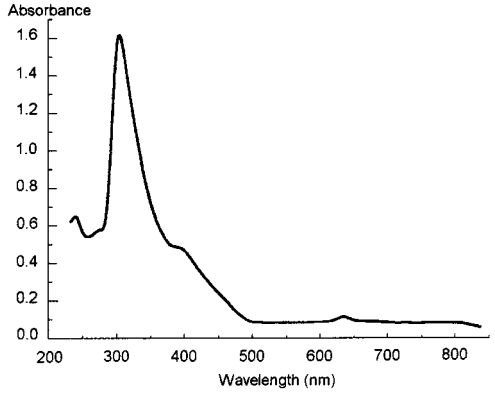

Figure 5. UV/Vis spectrum of **1** recorded using a KBr pellet medium (0.5%)

The appearance of an intense Q band generally characterises the phthalocyanine group and is assigned in the literature to a π → π* transition delocalised over the (Pc) ring.[28] It is then understandable that the interruption of the π-conjugation in the (Pc) ring in **1** involves the important decrease in the Q band. The shoulder between 380 and 480 nm contains at least two bands. Such a shoulder in the visible/near-UV region was reported by Gouterman et al.[28] in the spectrum of Pb(Pc), and was attributed to the presence of an allowed $6p_z$ (metal)→π* (Pc) charge-transfer transition (MLCT: Metal-to-Ligand Charge Transfer), by analogy with the (porphyrinato)lead(II) complex. Following this conclusion, Isago et al.[27] have assigned the extra 415 nm band in the visible spectrum of Bi(Pc)Cl to an hyper MLCT band, an excitation from an $a_{2u}(6p_z)$ orbital of bismuth(III) to an eg(π*) (Pc) orbital. In the same way, Lever et al.[29] and Stillman et al.[30] assigned the transitions at approximately 450 nm to metal-to-ligand (MLCT) or ligand-to-metal (LMCT) charge-transfer transitions, depending on the oxidation state of the transition metal. Other authors have assigned this broad band as evidence for the existence of a free radical (Pc) ring, which is not inconsistent with the proposal of a charge-transfer transition. In the lithium phthalocyanine radical, Li(Pc), a doublet at 427 and 473 nm has been attributed to the free radical monophthalocyanine[31−33] while a similar broad band centred at approximately 450−470 nm has also been attributed to a free-radical phthalocyanine ring in $Ln(Pc)_2$[34−36] and in $In(Pc)_2$.[37] It is difficult to use the interpretation of monophthalocyanine or diphthalocyanine spectra for the interpretation of the spectrum of the compound **1** because Bi(Pc)Cl and other phthalocyanine compounds have a C_{4v} or D_{4h} symmetry, while **1** has no symmetry element, the allowed transitions are different and the molecular orbitals should have different energies and a different electron-density distribution. Nevertheless the shape and the energy of the transition at approximately 390−480 nm is very similar to those reported for Pb(Pc),[28] Bi(Pc)Cl,[27] or $In(Pc)_2$,[37] so we propose to assign that transition to a charge transfer from bismuth to the bicyclophthalocyaninato ligand. The B band, which is mostly an $a_{2u}\rightarrow e_g$ transition, has the same shape as the B band of Bi(Pc)Cl and is very intense, with an ε value of $0.6\cdot10^5$ $M^{-1}cm^{-1}$, close to that measured in porphyrin compounds. In the phthalocyanine compounds, the B band has an ε value much smaller than 10^5 $M^{-1}cm^{-1}$.[28] In addition to the B band, some authors[38−40] described two other bands at lower wavelengths: the N band resulting mainly from a $b_{2u}(\pi) \rightarrow e_g(\pi^*)$ transition, and the L band resulting from a combination of $a_{2u}(\pi)\rightarrow e_g(\pi^*)$ and $b_{2u}(\pi)\rightarrow e_g(\pi^*)$ transitions.[38] The bands appearing in the spectrum of **1** at 275 nm, as a shoulder of the B band, and at 238 nm may be assigned to the N and L transitions, respectively.

Infra-Red Spectroscopy

Figure 6 shows the FTIR spectrum of **1** between 500 and 2000 cm^{-1} (Figure 6a) and between 50 and 650 cm^{-1} (Figure 6b). Our assignments were made based on literature reports[37,41−51] and by comparison with those made for Pb(Pc).[1,27] Some very intense and fairly intense bands characteristic of Pb(Pc) are evident in the spectrum of Bi(1,24-Pcc), with only a slight modification. These are for Pb(Pc)/Bi(1,24-Pcc), respectively: bands at 725/720 cm^{-1} [out-of-plane C−H deformations γ(C−H)[27]], 772/774

cm^{-1} [C−N stretching vibration in pyrrole skeleton, ν(C−N)], 950/953 cm^{-1} and that at 1003/997 cm^{-1}, the band at 1080/1065 cm^{-1} and that at 1161/1162 cm^{-1} both assigned to C−N stretching vibration, and the bands at 1282/1299 and 1479/1482 cm^{-1}, all in the range of the C−C stretching vibration frequencies in the isoindole skeleton, ν(C−C).

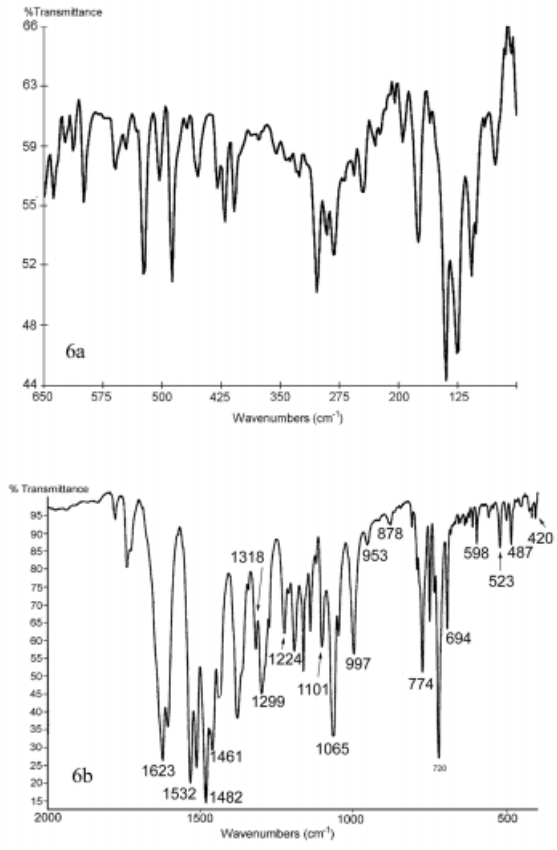

Figure 6. Far (6a) and middle (6b) infra-red spectra of **1**, recorded using 10% polyethylene and 0.5−1% KBr pellets, respectively

Other very intense or fairly intense bands in the spectrum of Pb(Pc) became smaller in the spectrum of Bi(1,24-Pcc): the band at 742/750 cm^{-1}, [out-of-plane C−H deformations γ(C−H)[27]], the bands at 1059/1047 cm^{-1} and 1113/1101 cm^{-1} [both in-plane C−H deformations, β(C−H)], and the band at 1313/1318 cm^{-1} in the range of the C−C stretching vibrations frequencies in the isoindole skeleton, ν(C−C). The band at 882 cm^{-1}, described as a metal-dependent vibration of the macrocycle,[46] is very sharp and intense in Pb(Pc) and becomes very small and broad at 878 cm^{-1} in **1**. That modification is probably due to important differences in the coordination polyhedra of the two complexes. In the range of the ν(C−C) or ν(C−N) stretching vibration frequencies, the bands at 1329 and 1404 cm^{-1} disappear and many new bands appear at 1139, 1192, 1224, 1461, 1512, 1532, and 1623 cm^{-1}. A medium band at 1606 cm^{-1} in the Pb(Pc) spectrum becomes very intense. The complexity of the Bi(1,24-Pcc) spectrum and the large number of new bands in the range of aromatic ν(C−C) or ν(C−N) stretching vibration frequencies is due to the lack of symmetry elements and to the large range of bond lengths observed in the different isoindole rings constituting the Bi(1,24-Pcc) molecule, particularly for the bonds around the sp^3 carbon atoms which are longer than normal $C_\alpha-N_{iso}$ or $C_\alpha-C_\beta$ bonds.

Owing to the presence of a sharp band at 1745 cm^{-1}, we first assumed that the co-crystallised molecule should be a phthalimide, which has an intense C=O vibration at 1746 cm^{-1} and a medium band for the N−H vibration at 3203 cm^{-1}. However, the position and the intensities of the residual electronic densities detected around the identified five-membered cycle in the X-ray diffraction study are not consistent with oxygen atoms. In the IR spectrum, we did not find any band between 2000 and 4000 cm^{-1} which would allow for the unambiguous characterisation of the co-crystallised molecule. This is probably due to the non-stoichiometric ratio of this cyclised phthalonitrile, compared to the six benzopyrrole units in the Bi(1,24-Pcc). Between 3000 and 3200 cm^{-1}, we observed a broad group of small bands that is evident in all phthalocyanine spectra, including that of $Bi_2(Pc)_3$, characteristic of the aromatic C−H vibrations. At approximately 2240 cm^{-1}, a very small band was observed, which we assigned to −CN groups of residual phthalonitrile in the crystal, or to a co-crystallised molecule, intermediate in the synthesis of $Bi_2(Pc)_3$. Janczac and Kubiak studied the formation of the phthalocyaninato (2-) ring from o-dicyanobenzene molecules and observed that, depending on the reaction conditions, only one of the cyano groups of *o*-dicyanobenzene undergoes a transformation, with a change from sp to sp^2 hybridisation.[18]

Below 700 cm^{-1} the spectrum of **1** is not a typical spectrum of phthalocyanine compounds. There is a very sharp and fairly intense band at 694 cm^{-1}, which is not present in usual phthalocyanine spectra. In Pb(Pc) and other common metallophthalocyanines, only four or five bands, characteristic of phthalocyanine ring deformations, are evident between 700 and 360cm^{-1}. For Pb(Pc),[1] they lie at 627, 560, 497, and 436 cm^{-1}. In the spectrum 6b, we observe 13 bands between 360 and 650 cm^{-1}. The ligand of **1** is not a phthalocyanine but, as shown in the structural part, a macrocycle made up of a superphthalocyanine-like ring and a phthalocyanine-like ring having three common isoindole moieties. This fact and the absence of symmetry elements explain the large number of allowed vibrations. The band at 353 cm^{-1} appears with the same shape and intensity in the spectra of Pb(Pc) and $Bi_2(Pc)_3$,[1] at 351 cm^{-1}. It has been described as metal dependant and due to the isoindole ring out-of-plane deformations.[34,44] Between 200 and 350 cm^{-1} in the spectrum of Pb(Pc), only two bands were observed at 231 and 271 cm^{-1}, assigned in the literature to the metal−nitrogen vibrations.[1,37,49] In the same wavenumber range, spectrum 6b shows many bands that we assign to the $Bi-N_{iso}$ stretching vibrations of the different $Bi-N_{iso}$ bonds. Below 200 cm^{-1}, we observe two new bands at 194 and 174 cm^{-1}. The two intense bands at 146 and 125 cm^{-1} in the spectrum of Pb(Pc) are at 140 and 126 cm^{-1} in the spectrum of **1**, in which we note two supplementary new bands at 107 and 101 cm^{-1}. The spectrum of lattice vibra-

tions between 50 and 100 cm^{-1} shows few differences between Pb(Pc) and **1**.

Conclusion

We have prepared a new orange bismuth(III) bicyclophthalocyanine complex. It is a new member of the family of the hexapyrrole ligand complexes in which a $N(C_8H_4N)N(C_8H_4N)N$ bridge is extended between two Cα pyrrole carbon atoms of a phthalocyanine ring, interrupting the π-conjugation of the macrocycle. These hexapyrrole complexes can be now classified into three groups of ligands, differing by the position of the bridgehead carbon atoms. In this paper, we have proposed a numbering scheme in order to differentiate each group of this class of compounds by their names. The positional indices of the bridgehead carbons are indicated as a prefix in front of the letter code (Pcc) of the hexapyrrole ligand. With this numbering scheme indicating the number of benzopyrrole units over which the π-delocalisation is extended, NbCl(1,16-Pcc)[5] is the only reported member of the first group, M(1,17-Pcc) (with M = Gd, In, Tl, and Ce)[6−8] describes the second group, and Bi(1,24-Pcc) is the first member of a new group. This new complex was fully characterised by UV/Vis and IR spectroscopy. The most striking feature of the UV/Vis spectrum is the almost complete disappearance of the Q band, explained by the interruption of the π-conjugation through the (Pc) ring. The IR spectrum from 50 cm^{-1} to 2000 cm^{-1} was reported and compared to usual IR phthalocyanine spectra. The large number of new bands can be explained by the lack of symmetry elements and by the large range of bond lengths observed in the different isoindole rings making up the Bi(1,24-Pcc) molecule, particularly for the bonds around the sp^3 carbon atoms and in the coordination polyhedron. The molecular structure of **1** was established and shows the smallest known $Bi-N_{iso}$ bond among bismuth phthalocyanine complexes. The relative position of the molecules of Bi(1,24-Pcc) in the crystal cell, and the distances between the atoms of two neighbouring molecules indicate a very weak interaction between the two π-electron systems. The distances between the aza-nitrogen atom of the first molecule, and the α-carbons of the pyrrole ring of the second molecule are too long to explain the formation of $Bi_2(Pc)_3$ by a direct dimerisation of two molecules of Bi(1,24-Pcc). This is confirmed by the fact that the isolation of $Bi_2(Pc)_3$ by heating only washed orange crystals is impossible while the heating of orange crystals in molten phthalonitrile up to 310 °C always produced the triple-decker compound. We observed a co-crystallised molecule VII, nearly parallel to one of the two benzopyrrole units of the bridge, and 3.43 Å apart. This strongly disordered molecule was not fully characterised. The IR spectroscopy and X-ray diffraction results suggest that it is a cyclised phthalonitrile molecule. Some experiments are currently underway to identify it, and to understand its importance in the reaction mechanism of the synthesis of $Bi_2(Pc)_3$.

Experimental Section

General Remarks: FT-IR: Nicolet 20 SXB spectrometer with 2 cm^{-1} resolution. Perkin−Elmer Spectrum 1000 with 1 cm^{-1} resolution. KBr pellets (1%) and polyethylene pellets (10%) were used within the range of 4000−400 cm^{-1} and 400−50 cm^{-1}, respectively. Pellets were prepared with some clean crystals, picked out under a microscope. − UV/Vis: Unicam UV 4 spectrometer.

Synthesis and Purification: The synthesis of **1** was performed using the method for the synthesis of $Bi_2(Pc)_3$, in the same vessel and apparatus.[1] Bismuth acetate (1.6 g, 4 mmol), and phthalonitrile (3.64 g, 28 mmol, puriss. 99% Fluka) were ground and placed in an open-reaction vessel which was put in the oven, pre-heated to 180 °C. The temperature probe was placed between the wall of the oven and that of the reaction vessel. The temperature was raised slowly (2°/min) to 230−240° C. The mixture was then slowly cooled to room temperature. The crude product was a mixture of orange crystals with some remaining reactants and by-products. Using a Soxhlet apparatus, the crystals were washed with acetone, DMF, toluene, and then ethanol. The isolated dry powder was a mixture of orange crystals and a light-grey powder, and was shaken in a mixture of acetone/water/pentane (1:1:1). Crystals of **1** were floating at the interface of the phases, (water + acetone/pentane) while the light-grey powder was deposited at the bottom of the vessel. The interface of the solvents was sucked up with a Pasteur pipette connected to a water aspirator pump, and orange crystals were isolated (440 mg, 0.392 mmol, 9.8%). It was impossible to get reliable elemental analytical data: the yield is low (<10%) and the calculations are not precise because of the disordered co-crystallised molecule, in a non-stoichiometric ratio. In spite of these unreliable analyses, the molecular structure of Bi(1,24-Pcc) was determined unambiguously by the X-ray diffraction study.

X-Ray Crystallographic Study: A suitable orange crystal of small size (0.1 × 0.1 × 0.05 mm) was mounted on an Enraf−Nonius Kappa CCD[52] diffractometer. Despite its well-defined shape, the crystal gave a diffraction pattern of medium quality, showing some light rings of diffusion, probably due to the precipitate that could be observed on the surface of the sample. A 180° (through 2°-steps of 240 seconds each) φ scan measurement was performed at room temperature using the Mo-K_α wavelength. The cell parameters were refined (Denzo[53]) with the use of 7053 reflections and are reported in Table 3 with the crystallographic parameters. The data were first corrected for absorption effects with Sortav.[54] The bismuth atom and some cycles of the organic ligand could then easily be located with SIR92.[55] As some remaining undefined fragments could not be assigned in the first steps of the calculations, we performed a series of anisotropic refinements (MaXus[56]), only on the well-defined bicyclophthalocyanine moiety, adding the hydrogen atoms at idealised positions, until the R factor reached a reasonable value. A last Fourier difference gave some peaks of density (all rigorously lying in the same plane) that could be attributed to a cyclised phthalonitrile solvate. The most identifiable scheme among these electron densities was a five-membered cycle. These atoms were finally introduced (with isotropic displacement parameters) in the calculations as $C_8H_4N_2H_2$ and refined as a rigid block fragment to the final R indices: R_1 [$F^2 > 3\sigma(F^2)$] = 0.059, wR_1 [$w = 1/\sigma^2 (F^2) + 0.03F^2$] = 0.093. The residual positive Fourier peak is equal to 1.58 eÅ^3 and is located near the bismuth atom. This density cannot be unambiguously attributed to a free electron pair on the bismuth atom as it can also be due to an absorption problem. This point could not be clarified either by the empirical correction used, or by a numerical one that we also tested. Crystallographic data (ex-

A Versatile Approach to the Intramolecular Organization of Two Bipyridine-Like Chelating Units in a Polytopic Ligand

Larissa Kovbasyuk,[a][‡] Markus Hoppe,[a] Hans Pritzkow,[a] and Roland Krämer*[a]

Dedicated to Prof. Dr. Dieter Sellmann on the occasion of his 60th birthday

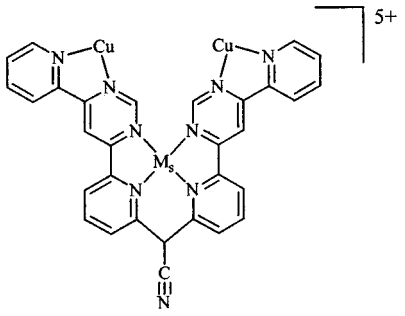
Keywords: Bioinorganic chemistry / Copper / Enzyme mimics / Ligand design / Catalysis

The synthesis of four novel polypyridyl ligands, in which two 4,6-[bis(2-pyridyl)]pyrimidine units are covalently linked by spacer groups –S– (**1**), –S–S– (**2**), –Se– (**7**), and –Se–Se– (**6**), is reported. A new unsymmetrical dinucleating ligand **4** was isolated as a by-product in the synthesis of **2** and has been characterized by X-ray crystallography. Copper(II) complexes $[(\mathbf{1})Cu](NO_3)_2{\cdot}5H_2O$ and $[(\mathbf{7})Cu](ClO_4)_2{\cdot}6H_2O$ have been isolated, spectroscopic data for which are consistent with tetradentate N_4 coordination by the ligands. In situ prepared polynuclear copper(II) complexes of **1** and **7** show different catalytic activities in the cleavage of the phosphodiester 2-hydroxypropyl *p*-nitrophenyl phosphate. This might be a consequence of the influence of the covalent spacer (S or Se) on the preorganization of two bipyridine-like chelating units in $[LCu]^{2+}$, which bind two catalytic Cu^{2+} ions.

Introduction

In many enzymes, chemical transformations are mediated by the cooperation of two active site metal ions. This functional motif is particularly prominent in phosphoryl transfer enzymes including phosphodiesterases, nucleases, phosphatases, and DNA/RNA-polymerases.[1] During the last 15 years, many dinuclear model complexes have been designed to improve the understanding of metal−metal cooperation in such enzymes.[2] Preorganization, i.e. intermetal distance and relative orientation of coordination polyhedra, is a parameter that is of fundamental importance with regard to reactivity. In practice, it is difficult to design a model system that allows systematic variation of the preorganization while other factors that influence the reactivity are kept constant. Breslow has described dinuclear zinc(II) complexes in which two (chelator) Zn subunits are covalently linked by spacer groups of varying size. This approach requires laborious synthesis of a set of appropriate ligands and allows only rough tuning of metal−metal separation.[3] We have recently described trinuclear complexes $(L)M_sCu_2$, in which a "structural" metal ion M_s is coordinated to the tetradentate site and two "functional" Cu^{2+} ions bind to the bipyridine-like chelating groups of the ligand[4] (Scheme 1). The catalytic activity of this complex in the cleavage of a phosphodiester was shown to be strongly dependent on the nature of the structural metal ion M_s.

This was interpreted in terms of different catalyst conformations, i.e. fine-tuning of the preorganization of the two functional Cu^{2+} ions, depending on the ionic radius of M_s and on its tendency to distort the N_4-M_s coordination plane.



Scheme 1. Trinuclear complex $(\mathbf{L})M_sCu_2$

$(L)M_sCu_2$ constituted the first example of an abiotic allosteric catalyst; M_s is a noncovalent modifier of the reactivity, but is not directly involved in the reaction. In this context, we report herein on the synthesis of related polypyridyl ligands and their metal complexes.

Variation of the spacer group that covalently links the dipyridylpyrimidine subunits (Scheme 2) is tested as an additional possible means of controlling organization of the bipyridine-like chelating groups and of tuning the reactivity of the polynuclear complexes.

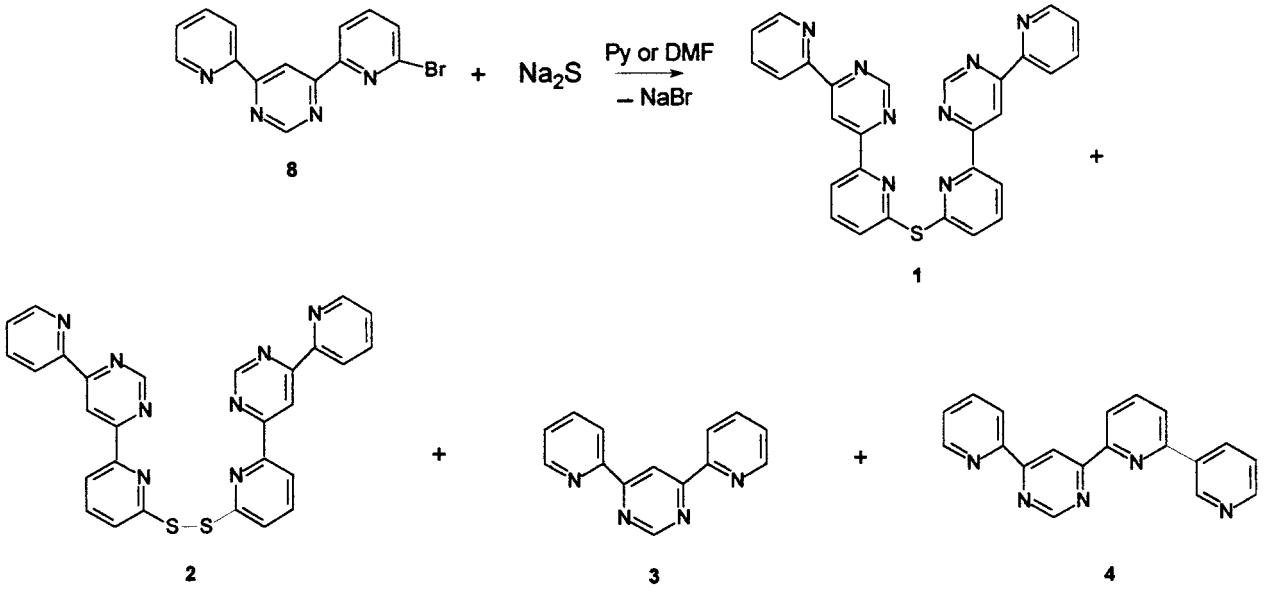
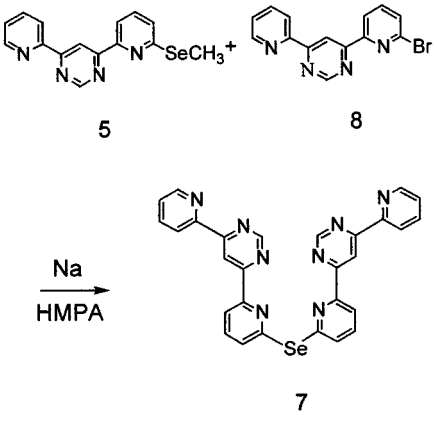


Scheme 3. Synthesis of **1**, **2**, and **4**

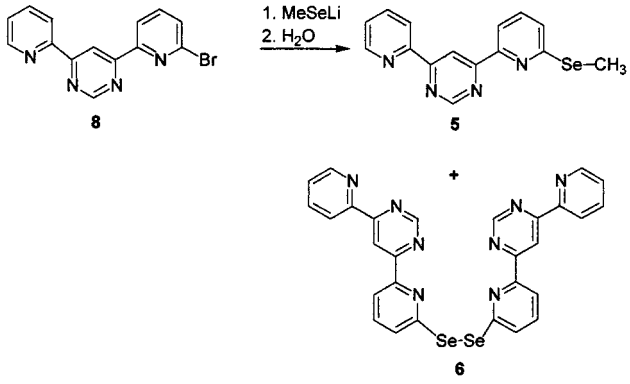
Results and Discussion

Preparation of the novel polypyridyl ligands **1**, **2**, **6**, and **7** is outlined in Scheme 3, Scheme 4, and Scheme 5. The synthesis of the precursor 4-(6-bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine (**8**) is described elsewhere.[5]



Scheme 4. Synthesis of **7**

The synthesis of compounds with a py−S−py moiety by reaction of pyridyl bromides and thiols has been described previously. In particular, bis(2-pyridyl) sulfide has been isolated following reaction of 2-mercaptopyridine with 2-bromopyridine and K_2CO_3 in DMF.[6] In the present case, the thiol was not isolated but is involved as an intermediate in the formation of **1** from the bromo compound and Na_2S. Oxidation of the thiol intermediate by oxygen during workup gives the disulfide compound **2**. The yields of compounds **1** and **2** were found to be dependent on the ratio of **8** to Na_2S. For optimal yields of **1** and **2**, the requisite **8**/Na_2S ratios proved to be 1:1.5 and 1:5, respectively.



Scheme 5. Synthesis of **5** and **6**

As a side product, 4-[6-(2-pyridyl)-2-pyridyl]-6-(2-pyridyl)pyrimidine (**4**) was isolated when the reaction described in Scheme 3 was conducted in pyridine. The mechanism of its formation is unclear. Ligand **7** was obtained in analogy to a reported method for the synthesis of bis(2-pyridyl) selenide[12] from halopyridines and $LiSeCH_3$. In the first step, methyl 6-[6-(2-pyridyl)-4-pyrimidinyl]-2-pyridyl selenide (**5**) was synthesized by reaction of CH_3Li, selenium, and **8**.

Cleavage of the Se−CH_3 bond was achieved in the second step by treatment with metallic sodium, resulting in the formation of a selenolate intermediate, which displaced the bromine in **8** to give **7** (Scheme 4). **6** was unexpectedly obtained as a side product in the synthesis of **5** (Scheme 5), and its yields could be optimized using a higher ratio of CH_3Li/Se to **8**. Presumably, a selenol(ate) intermediate is involved and the Se−Se bond is formed by air oxidation. Ligands **1** and **2** were obtained as pale-yellow powders, **6** and **7** as yellow powders, and were characterized by mass spectrometry, NMR spectroscopy, and C,H,N analysis. The crystal structure of **4** (white needles) was elucidated by X-ray analysis.

Compound **4** was formed as a by-product when the reaction outlined in Scheme 4 was performed in pyridine, but not when DMF was used as solvent. Thus, the reaction is rationalized in terms of a C−C coupling of **8** with the pyridine solvent. The mechanism of this process is not clear, but activation of pyridine for a C−C coupling reaction at its C-2 position under relatively mild conditions (90−100 °C, 7 h, Na_2S) is, to the best of our knowledge, quite unusual. Thus, for unambiguous determination of the structure of **4**, it was subjected to X-ray crystallographic analysis. Suitable crystals of **4** were obtained by isothermal crystallization from acetone. The molecular structure of **4**, showing the numbering scheme used, is presented in Figure 1. Selected bond lengths and angles are given in Table 1.

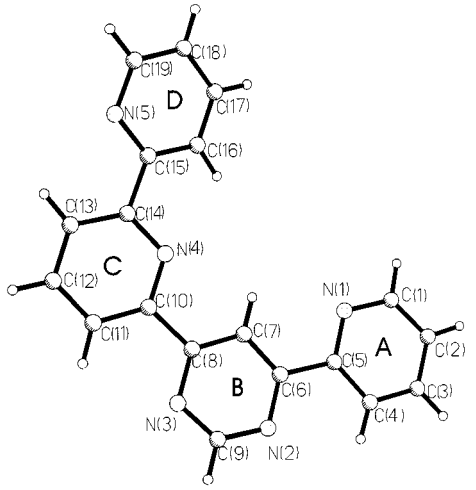


Figure 1. Molecular structure of **4** showing numbering scheme

The unit cell is monoclinic and contains four molecules of **4**. The rings A, B, and C are coplanar, whereas the plane of ring D forms an angle of 30° with the A, B, and C planes. The bond lengths and angles in **4** are typical for pyridine and pyrimidine heterocycles.[7]

Mononuclear copper(II) complexes of **1** and **7** were prepared by mixing the ligands and suitable metal salts in organic solvents and were isolated as green powders. Attempts to crystallize these complexes failed. C,H,N analyses of the solids were consistent with hydrated 1:1 complexes with the formulae [Cu(**1**)]$(NO_3)_2\cdot 5H_2O$ and [Cu(**7**)]$(ClO_4)_2\cdot 6H_2O$. Copper(II) complexes of **2** and **6** could not be isolated, although mass spectrometry indicated the formation of 1:1 complexes. Evidence of the decomposition of the complexes by redox processes was noted. Thus, solutions show the gradual appearance of new bands at around 450 nm in their UV/Vis spectra, similar to $[(bpy)_2Cu^{I}]^+$.
