Keywords: Enzyme models / Catalysis / Iron / Oxygen / N ligands

Three new complexes, $[Fe(LN_4H_2)Cl_2]^+$, $[Fe(LN_4H_2)(Cat)]^+$, and $[Fe(LN_4H_2)(DBC)]^+$, were synthesized by using the tetradentate macrocyclic ligand LN_4H_2 (where LN_4H_2, Cat, and DBC stand for 2,11-diaza[3,3](2,6) pyridinophane, catecholate, and 3,5-di-*tert*-butylcatecholate, respectively). The structure of $[Fe(LN_4H_2)Cl_2]^+$ was determined by X-ray diffraction. It crystallizes in the monoclinic space group *C*2/*c* with $a = 9.613(1)$, $b = 11.589(1)$, $c = 14.063(2)$ Å, β=110.20(2)°, $V = 1541.9(3)$ Å^3, and $Z = 4$. These complexes were found to catalyze the oxidation of catechol groups using O_2. This was performed in various organic solvents at 20 °C. The reaction rates were measured for the stoichiometric complexes $[Fe(LN_4H_2)(Cat)]^+$ and $[Fe(LN_4H_2)(DBC)]^+$. It was found that despite the relatively high energy of the ligand-to-metal charge transfer O(DBC or Cat)→Fe^{III}, their activity was comparable to that of the fast TPA systems [TPA indicates tris(2-pyridylmethyl)amine]. The oxidation products of $DBCH_2$ have been studied. It has then been shown that the LN_4H_2 systems catalyse by means of both intra- and extradiol cleavage of catechol groups. The existence of multiple reactive pathways can account for the fast reactivity observed.

Introduction

Catechol dioxygenases catalyze the ring cleavage of catechols using O_2 without coreductants. Two sub-classes of these enzymes can be distinguished. Intradiol ones contain a trigonal bipyramidal Fe^{III} ion and catalyze the insertion of both atoms of O_2 between the OH groups [C(1) and C(2)] of the catechol. Two different mechanisms have been proposed to account for their reactivity after the chelation of a doubly deprotonated catecholate. The first one proceeds by electrophilic attack of the catechol by O_2.[1] The alternative pathway implicates the Fe^{II}−semiquinonate character of the Fe^{III}−catecholate moiety generated by the charge transfer from the chelated ring to the metal center. The spin-forbidden rule for a reaction between an organic molecule and dioxygen is bypassed, so the oxidation occurs by the attack of the biradical O_2 on the spin density acquired by the substrate ring.[2] The following steps are the same for both pathways. The O_2 moiety binds to the iron center to yield a peroxo bridge between the metal ion and the substrate. The decomposition of this intermediate then leads to the release of the product and regeneration of the active site. Extradiol catechol dioxygenases contain a square-pyramidal Fe^{II} ion and catalyze the oxidative cleavage of catechols in a different fashion: Both atoms of the dioxygen molecule are inserted between C(1) and C(6) or C(2) and C(3). Que and Ho[2] proposed a mechanism for this subclass of enzymes. The first step of the catalytic cycle involves the chelation of a monoanionic substrate followed by the binding of O_2 to Fe^{II}. The Fe^{III}−superoxo species thus formed is proposed to have nucleophilic character on the distal oxygen atom.[2] The nucleophilic oxygen atom of the superoxo species then attacks the ring at the carbon atoms C(3) or C(6), and the product is released.

Among the models described in the literature,[2,3] the vast majority show intradiol catechol dioxygenase reactivity whereas a few behave as extradiol models.[4−9] Que and coworkers have suggested that the key step for the reactivity of intradiol models resides in the charge transfer from the catecholate to Fe^{III}.[10] Among the known models in the literature, the system based on TPA[11] presents the maximum Fe^{II}−semiquinone character and shows a fast ring cleavage of the catechols in stoichiometric conditions. Koch and Krüger[12] used the LN_4Me_2 macrocyclic ligand to achieve efficient catalysis although the rate was approximately 40 times slower than the stoichiometric TPA system.

Studies of extradiol dioxygenase models are scarce. However, basic requirements such as weak steric hindrance and a vacant coordination site for O_2 on the iron center seem essential.[7,8] An analysis of the structure of $[Fe(LN_4Me_2)cat]^+$ reported by Koch and Krüger[12] revealed that the steric hindrance provided by the methyl groups of the ligand could prevent the formation of the

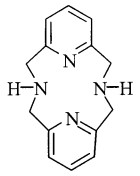
peroxo bridge between the Fe^{III} ion and the catecholate. Removing these groups appeared then a matter to favor the formation of the peroxo bridge and speed up the reaction. In the present paper, we investigate the effect of steric hindrance on the reactivity of Fe^{III}–catecholate complexes with O_2. We report the results obtained with the system based on the ligand 2,11-diaza[3,3](2,6) pyridinophane (LN_4H_2) (Scheme 1), the analog of the bulkier LN_4Me_2.



Scheme 1. Schematic representation of the ligand LN_4H_2

Results and Discussion

X-ray Crystal Structure Determination

The starting Fe^{III} complex is $[Fe(LN_4H_2)Cl_2]Cl$. Its structure has been determined. The complex cation is represented in Figure 1. Selected bond lengths and angles are listed in Table 1.

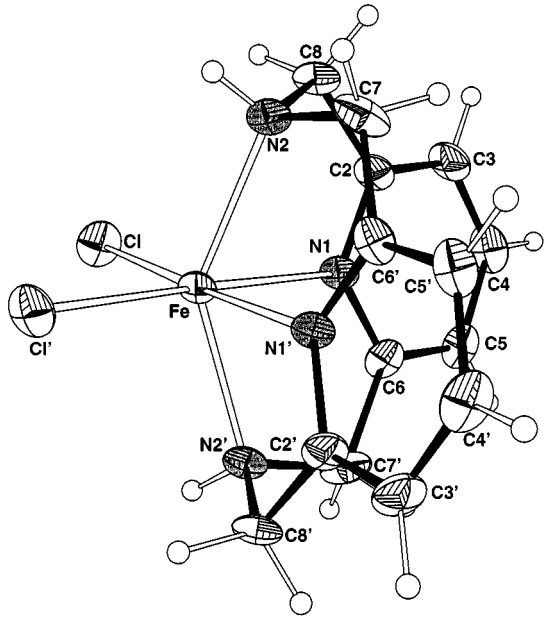


Figure 1. ORTEP plot showing the structure of $[Fe(LN_4H_2)(Cl)_2]^+$ with atom-labeling scheme; primed atoms are related to unprimed ones by symmetry elements of the molecule; displacement ellipsoids are drawn at the 50% probability level; H atoms are shown as small circles of arbitrary radii

It shows an internal C_{2v} symmetry with two mirror planes, one defined by the iron(III) and the *N*-pyridine atoms, and the other by the iron(III) and the *N*-amine atoms. As in previous studies with this macrocycle[13] or its analog LN_4Me_2,[12,14,15] the pseudo-octahedral iron ion is coordinated to the four nitrogen atoms of the ligand leaving two *cis* positions at the metal center that are occupied by two chloro groups in the present species. The ligand is folded along the $N_{amine}-N_{amine}$ axis, the pyridine moieties being nearly perpendicular to each other with a dihedral angle of 96.5(1)°. The $Fe-N_{py}$ distance of 2.09 Å and the $Fe-N_{amine}$ distance of 2.19 Å are slightly shorter than the same distances in the related high-spin $[Fe(LN_4Me_2)Cl_2]^+$ complex.[14] This surprising evolution, especially for the $Fe-N_{amine}$ distances, reflects without ambiguity the decreased steric hindrance at the metal center with LN_4H_2. The Fe–Cl distance of 2.29 Å agrees with the mean value of 2.283(4) Å calculated from other Fe^{III} complexes.[16]

UV/Vis Absorption Spectroscopy

The reaction of the yellow $[Fe(LN_4H_2)Cl_2]Cl$ in MeOH or CH_3CN with a catecholate immediately yielded a deep purple-blue solution. A purple-blue complex can be precipitated on addition of $NaBPh_4$. The UV/Vis spectrum of a solution of the resulting powder or of the solution obtained by mixing $[Fe(LN_4H_2)Cl_2]Cl$ and cat^{2-} shows two intense bands in the visible region. They are assigned as ligand-to-metal charge transfer (LMCT) bands from the doubly deprotonated chelating catecholate to the iron(III) ion.[10,17–19] This charge transfer generates some Fe^{II}–semiquinonate character[10] in the ground state, which is a key factor in the reactivity. The optical data of the catecholate (Cat) or 3,5-di-*tert*-butylcatecholate (DBC) complexes in MeOH or CH_3CN are given in Table 2.

As expected, the DBC species absorbs at a higher wavelength than the Cat species. This observation is consistent with the stronger electron-donating ability of the *tert*-butyl groups leading to an easier charge transfer from the DBC^{2-} to the iron ion.

The LMCT bands of these complexes can be considered as probes for the intradiol reactivity: the lower in energy the LMCT bands are, the faster the intradiol reactivity is. In comparison to other auxiliary ligands[11,20,21] or the close analog LN_4Me_2[12] the LMCT bands of our Fe^{III}–catecholate complexes lie at relatively high energies. However, other factors may be involved in the efficient oxidative cleavage of the catechols, in particular weak bulki-

ness of the auxiliary ligand[20,22] or spin equilibrium for the iron ion.[23]

Stoichiometric Kinetic Studies

The oxidative cleavage of catechols can be monitored by UV/Vis spectroscopy by following the decay of the LMCT bands with time. This procedure is characteristic of these kinds of studies.[20,21] The complexes $[Fe(LN_4H_2)(Cat)]BPh_4$ and $[Fe(LN_4H_2)(DBC)]BPh_4$ have been dissolved in CH_3CN or MeOH in order to obtain a final concentration in iron about 10 times lower than that of O_2 ($[O_2]$ = 1.62 mM in CH_3CN[24] and $[O_2]$ = 2 mM in MeOH,[25] at 20 °C under air). The kinetic analyses were then carried out by using a pseudo-first-order law. The second-order rate constants, at 20 °C, are tabulated in Table 2. A typical evolution of the LMCT bands during the oxygenation of the catecholate complex and the kinetic analysis are shown in Figure 2.

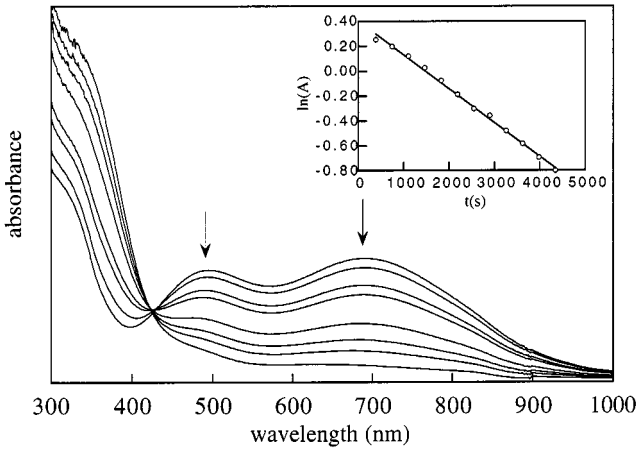

Figure 2. Evolution of the UV/Vis spectrum of $[Fe(LN_4H_2)(Cat)]^+$ in air-saturated MeOH at 20 °C; inset: plot of ln(A) vs. time

Compared to the LN_4Me_2 analog (k = 0.277 10^{-2} $M^{-1}s^{-1}$ for the substrate catecholate, and k = 0.377 $M^{-1}s^{-1}$ for the substrate di-*tert*-butylcatecholate in CH_3CN),[12] one can note a 160-fold increase and a 130-fold increase, respectively. These spectacular accelerations are certainly not attributable to electronic factors as deduced from UV/Vis spectra. Steric factors must be implicated as revealed by the structure analysis of $[Fe(LN_4H_2)Cl_2]^+$. The great accessibility of O_2 to the iron center appears then to be a very important parameter in order to perform a fast ring cleavage of the catechols. The rate constants can also be compared to that of the TPA system, the fastest intradiol catechol dioxygenase model reported so far[11]: in MeOH, the rate constants are very similar to those of TPA (10 vs. 8.6 $M^{-1}s^{-1}$).

Catalytic Catechol Dioxygenase Activity of $[Fe(LN_4H_2)Cl_2]Cl$

In a typical experiment, $[Fe(LN_4H_2)Cl_2]Cl$ was dissolved in CH_3CN, then 50 equiv. of $DBCH_2$ + 2 equiv. of NEt_3 in the same solvent were added. The reaction mixture was analyzed by Electrospray Ionization Mass Spectrometry (ESI-MS) at the end of the reaction, or by ^1H NMR spectroscopy during the course of the reaction, when the sample was prepared in CD_3CN, CD_3OD or $CDCl_3$.

Figure 3. shows the evolution, by NMR spectroscopy, of the reaction mixture in CD_3OD. The results are similar in other solvents. The excess of substrate is sufficient to avoid broadening of the peaks due to the paramagnetism of the Fe^{III} complex. The signals of the free substrate are observed at δ = 1.24, 1.37, 6.72 (d), and 6.73 (d). They disappear during the course of the reaction whereas other signals grow in intensity. The new signals correspond to three major products plus some other minor species that have not been further characterized by this technique. For the major products, the assignments have been made by comparing the spectra with those recorded in CD_3CN or in $CDCl_3$. We also referred to the complete work of Funabiki et al.[4] It appears then that muconic anhydride [the common intradiol cleavage product 3,5-di-*tert*-butyl-1-oxacyclohepta-3,5-diene-2,7-dione (**1**)] is detected at δ = 1.18, 1.27, 6.21 (d), and 6.61 (d). Two extradiol cleavage products are also detected: The first one is 3,5-di-*tert*-butyl-2-pyrone (**2**) (δ = 1.15, 1.24, 6.56, 6.58). The second one is detected at δ = 1.13, 1.16, 5.38, and 6.18. We propose that these signals correspond to the enol form of *cis*,*cis*-3,5-di-*tert*-butyl-2-hydroxymuconic semialdehyde (**3**). Indeed, its keto form has been detected unambiguously in $CDCl_3$ at δ = 1.10, 1.19, 5.28, and 9.75. These values are close to those reported by Funabiki et al.[4] It thus makes sense to propose that the more polar form of this product is stable in the more polar solvent whereas the less polar form is stabilized in the less polar solvent. The by-product 3,5-di-*tert*-butyl-1,2-benzoquinone (**6**) was not detected or only as trace amounts. Due to overlapping of the signals, the final spectrum has been

deconvoluted[26] in order to estimate intradiol versus extradiol cleavage. The results show that the oxygenation of 3,5-di-*tert*-butylcatechol by the LN_4H_2 system proceeds with an intradiol/extradiol ratio close to 1. Attempts to purify the reaction mixture by column chromatography have been unsuccessful due to the instability of the products. As a matter of fact, we cannot report a more quantitative attribution of the products.

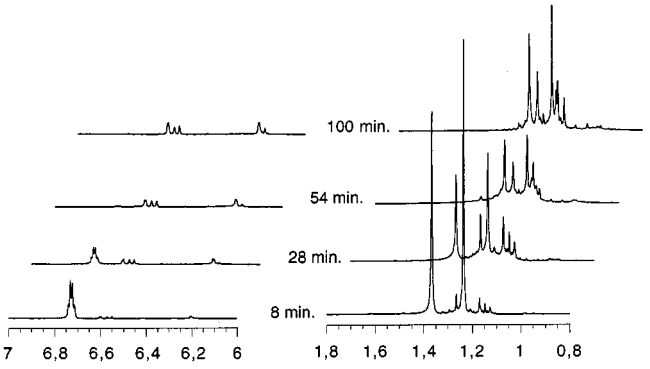

Figure 3. Progress of the reaction of $[Fe(LN_4H_2)(Cl)_2]^+$ + 50 $DBCH_2$ + 2 NEt_3 in air-saturated CD_3OD monitored by ^1H NMR spectroscopy; the peak at δ = 5.38 (see text) is omitted for clarity

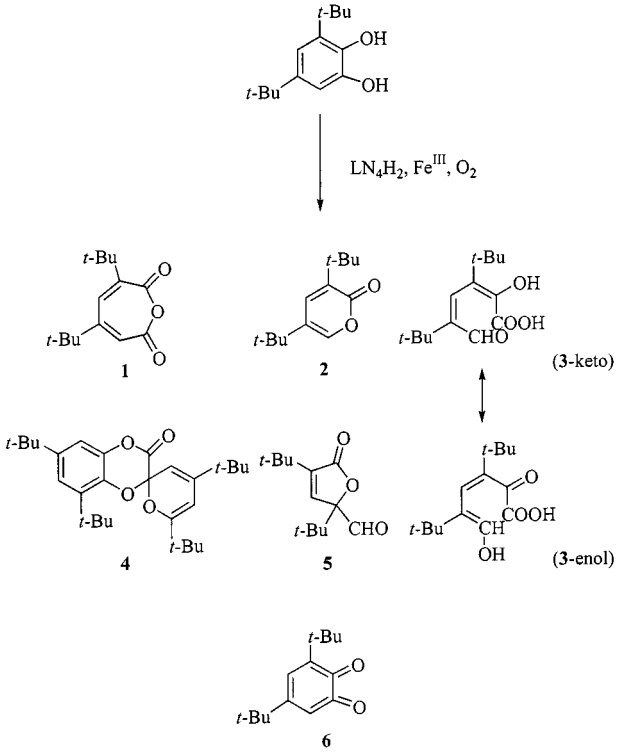
The oxygenation products have also been analyzed by ESI-MS from a reaction mixture in CH_3CN. An MeOH/H_2O (0.1% formic acid) mixture has been used for the detection of some species. The 3 major products are observed at *m*/*z* = 237.2 (**1**), *m*/*z* = 209.2 (**2**) and *m*/*z* = 255.4 (**3**). Other peaks are observed; some of them can be assigned as follows: *m*/*z* = 441.6 {4′,6,6′,8-tetrakis(1,1-dimethylethyl)spiro[1,4-benzodioxin-2(3*H*),2′-[2*H*]pyran]-3-one, **4**}, *m*/*z* = 225.3 (3,5-di-*tert*-butyl-5-formyl-2-furanone, **5**) and *m*/*z* = 221.2 (**6**). The results are summarized in Scheme 2.

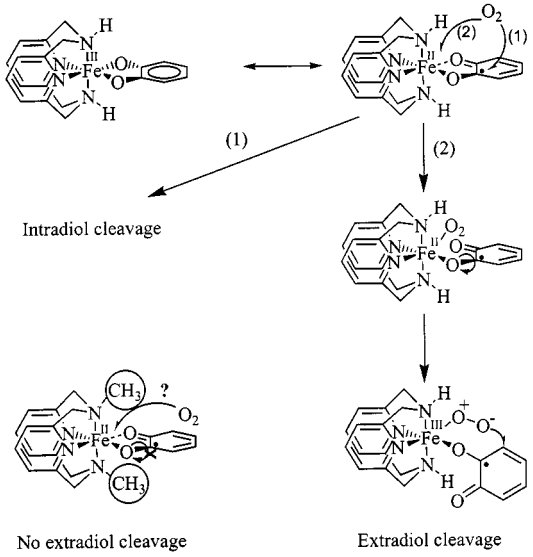


Scheme 2. Oxidation products of 3,5-di-*tert*-butylcatechol detected in this study

To the best of our knowledge, there are only two examples of structurally characterized synthetic iron complexes capable of carrying out extradiol cleavage. They are based on the tridentate ligands TACN (1,4,7-triazacyclononane)[5,7] or hydrotris(3,5-diisopropyl-1-pyrazolyl)-borate[8]. The authors evoke the necessity to dispose of several factors, namely a vacant site around the iron center for the coordination of O_2 and a moderate steric hindrance. Moreover Ito and Que[7] show that Lewis bases such as pyridines must be available in the reaction mixture. They propose that the Lewis base substitutes an oxygen atom of the substrate and thus converts it into a monodentate anion. The structure of the intermediate obtained allows the extradiol cleavage to occur.

Because of the rigidity of the 12-membered LN_4H_2 macrocycle, we never observed species with this ligand acting as tridentate. We therefore report here the first example of extradiol dioxygenase activity with a tetradentate ligand.

As revealed by UV/Vis, $[Fe(LN_4H_2)(DBC)]^+$ has some Fe^{II}–semiquinonate character which is believed to be at the origin of intradiol cleavage activity (pathway 1 in Scheme 3), as usually observed for complexes with tetradentate ligands.[10–12,20,21]



Scheme 3. Proposed mechanism for the reaction of $[Fe(LN_4H_2)(DBC)]^+$ with O_2

For the extradiol cleavage, we propose a mechanism inspired by Ito and Que[7] (see Scheme 3). In one, O_2 binds to the iron center to yield an Fe^{III}–superoxo species leading to the release of an oxygen atom of the enediolate moiety (pathway 2 in Scheme 3). The next sequence is then the ro-

tation of the substrate ring which is permitted due to the weak steric congestion on the amino groups. Finally, the oxygenation proceeds by the attack of the nucleophilic superoxide[2] at the carbon atom adjacent to the C−O group bound to the iron ion yielding extradiol cleavage of the aromatic ring.

The reason why the reactivity pattern of $[Fe(LN_4H_2)(DBC)]^+$ is clearly different from its analog LN_4Me_2 can only be related to the substituents of the macrocycles. The accessibility of the metal center is allowed with LN_4H_2 while the bulkiness of the methyl groups provides a crowded iron center in LN_4Me_2. The Fe^{III}−superoxo species responsible for the extradiol cleavage therefore cannot be obtained with the latter ligand. Moreover, the rotation of the ring catecholate should be forbidden due to the methyl groups. Consequently, the intermediate with the convenient stereospecificity for extradiol cleavage cannot be formed (see Scheme 3). Finally, we propose two reasons, related to the relative steric hindrance of the tetradentate macrocycles, to explain their different reactivity pattern.

The large rate constants observed for our catalyst may thus be due not only to the accessibility to the metal center but also to the existence of multiple reactive paths. To the best of our knowledge, no kinetic data for extradiol cleavage of catechols have been reported. At this stage we therefore cannot conclude whether one hypothesis is more valuable than the other one.

Conclusion

We isolated new Fe^{III} complexes based on the macrocyclic tetradentate ligand LN_4H_2. The structure of the chloro complex $[Fe(LN_4H_2)(Cl)_2]Cl$ has been determined. It reveals that the ligand adopts a bent conformation leaving two *cis* positions at the metal center that are occupied by two chloro ligands. The comparison of its bond lengths with the ones of the related $[Fe(LN_4Me_2)(Cl)_2]^+$ reported by Koch and Krüger bears evidence of the increased accessibility to the metal center in $[Fe(LN_4H_2)(Cl)_2]^+$.

Two other complexes with catecholate groups as exogeneous ligands have been prepared: $[Fe(LN_4H_2)(Cat)]^+$ and $[Fe(LN_4H_2)(DBC)]^+$. Their characterization by optical spectroscopy and ESI-MS are given. The reported complexes react with O_2 and the kinetics of the reaction has been measured. They show one of the fastest catechol dioxygenase reactivity ever reported for coordination compounds.

The catalysis of oxidative cleavage of $DBCH_2$ by $[Fe(LN_4H_2)(Cl)_2]Cl$ has been studied by ^1H NMR and ESI-MS. It indicates that this complex undergoes both intra- and extradiol dioxygenase activity, which is the first case reported with a tetradentate ligand, to date. The fast reactivity observed may thus be due to multiple reactive pathways. A mechanism based on the steric characteristics of the ligand is proposed to explain this tendency.

Experimental Section

General: Starting materials were purchased from Acros and were used as received. Solvents were purchased from Merck and used without purification except when indicated below. Syntheses of catecholate and 3,5-di-*tert*-butylcatecholate complexes were carried out in a glovebox equipped with an O_2/H_2O purifier (Jacomex BS531) − UV/Vis: Varian Cary 5E or Cary 300 Bio equipped with temperature controllers. − MS: VG Quattro II (Micromass, Manchester, UK) triple quadrupole electrospray mass spectrometer. Typical optimized values for the source parameters were: capillary 2.5 kV, counter electrode 0.4 kV, cone voltage 15−50 V, source temperature 80 °C. − NMR spectra were recorded with a Bruker AM250 at 20 °C, using the protonated impurity of the solvent as internal reference.

Synthesis of the Ligand: The ligand LN_4H_2 was prepared according to reported methods[27] and improved with slight modifications.

Syntheses of the Complexes

$[Fe(LN_4H_2)Cl_2]Cl$: A solution of $FeCl_3$ (54.1 mg; 0.33 mmol) in CH_3CN was added dropwise to a solution of LN_4H_2 (80 mg, 0.33 mmol) in CH_2Cl_2. The solution was refluxed for a few minutes and then allowed to cool down. A yellow powder was collected by filtration. Yield 70 mg (50%). Crystals for X-ray analysis were grown from an MeOH solution with aerial diffusion of CH_3CN. − ESI-MS m/z = 366.2 $[Fe(LN_4H_2)Cl_2]^+$. − $[Fe(LN_4H_2)Cl_2]Cl{\cdot}0.8H_2O$ $C_{14}H_{16}N_4Cl_3Fe{\cdot}0.8H_2O$ (416.9): calcd. C 40.33, H 4.25, Cl 25.51, N 13.44; found C 40.75, H 4.05, Cl 24.51, N 13.05.

$[Fe(LN_4H_2)(Cat)]BPh_4$: A solution of catechol (22 mg; 0.2 mmol) and NEt_3 (56 μL; 0.40 mmol) was added dropwise to a dry methanol solution of $[Fe(LN_4H_2)Cl_2]Cl$ prepared in the glovebox at room temperature with 48 mg of LN_4H_2 (0.2 mmol) and 32.4 mg of anhydrous $FeCl_3$ (0.2 mmol). The dark blue solution was stirred for 5 min, then 0.9 equiv. of $NaBPh_4$ (61.4 mg) in dry MeOH was added to give a dark blue microcrystalline powder. The solid was isolated by filtration, washed with MeOH and dried under vacuum. Yield 97 mg (60%). − EI-MS m/z = 404.2 $[Fe(LN_4H_2)(Cat)]^+$. − $[Fe(LN_4H_2)(Cat)]BPh_4{\cdot}1.4CH_3OH$ $C_{44}H_{40}N_4O_2BFe{\cdot}1.4CH_2OH$ (812.8): calcd. C 70.97, H 5.98, B 1.41, Fe 7.27, N 7.29; found C 70.90, H 5.53, B 1.33, Fe 7.1, N 7.43.

$[Fe(LN_4H_2)(DBC)]BPh_4$: The experimental procedure was similar to the one described for $[Fe(LN_4H_2)(Cat)]BPh_4$. Yield 120 mg (70%). − EI-MS m/z = 516.4 $[Fe(LN_4H_2)(DBC)]^+$. − $[Fe(LN_4H_2)(DBC)]BPh_4{\cdot}1.1CH_3OH$ $C_{52}H_{56}N_4O_2BFe{\cdot}1.1CH_3OH$ (869.4): calcd. C 73.23, H 6.99, B 1.24, Fe 6.41, N 6.43; found C 73.20, H 7.01, B 1.27, Fe 6.45, N 6.67.

Structure Determination: The crystal data of $[Fe(LN_4H_2)Cl_2]Cl$ and the parameters of data collection are summarized in Table 3. A flattened octahedron-shaped yellow crystal with the dimensions 0.65 × 0.40 × 0.30 mm of $[Fe(LN_4H_2)Cl_2]Cl$ was chosen for the X-ray diffraction experiment. The unit-cell and intensity data were measured with an Enraf−Nonius CAD-4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71070 Å). The cell constants were obtained by least-squares procedures based upon the 2Θ values of 25 reflections measured in the ranges $18.3° < 2\Theta < 25.2°$ at ambient temperature. During data collection three control reflections were measured every 3 h; the crystal was stable, and the check reflections showed a slight decay in intensity of only 7% during the X-ray data collection. A total of 2335 reflections were collected in the range $5.6° < 2\Theta < 59.9°$

within [$-13 \le h \le 13$, $0 \le k \le 16$, $0 \le l \le 19$]. From 2249 independent reflections, 2186 were considered as observed [$I > 2\sigma(I)$]. The structure was solved by direct methods with the program Shelxs86[28] and refined by using the Shelxl93 program.[29] The drawing was prepared with OrtepII.[30] The molecular cation was located in a special crystallographic position with the iron atom at the twofold rotation axis, along with the chloride anion. The structure was refined anisotropically (non-hydrogen atoms) by full-matrix least-squares approximation based on F^2. The hydrogen atom at the secondary nitrogen atom was localized in a difference Fourier synthesis and refined isotropically. Other hydrogen atom positions were calculated by assuming geometrical positions and were included in the structural model. Final weighting scheme was $w = 1/[\sigma^2(F_o^2) + (0.0411P)^2 + 2.0320P]$, where $P = (F_o^2 + 2F_c^2)/3$. The final refinement of this model was continued until convergence when $R1 = 0.0302$ for $F^2 > 2\sigma(F^2)$ and $R_w = 0.0806$ were reached. The final difference map showed the largest residual peaks which are 0.424 and -0.641 e·Å^{-3}. The two largest peaks were found at the Fe and Cl atoms. Complete crystallographic data (excluding structure factors) for the structure reported in this paper has been deposited at the Cambridge Crystallographic Data Centre with no. CCDC-148680. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk, World Wide Web: http://www.ccdc.cam.ac.uk].

Intramolecular Hydrogen-Bonding, Cation−π, and π-Stacking Interactions Affecting *cis*/*trans* Isomerization: Hexacarbonyltungsten Derivatives of Pyridyl-Substituted Arylphosphane Ligands

Leeni Hirsivaara,*[a] Matti Haukka,[b] and Jouni Pursiainen[a]

Keywords: *cis*/*trans* Isomerism / Hydrogen bonding / Intramolecular interactions / Phosphanes / Tungsten

A series of triphenylphosphane- and diphenyl(2-pyridyl)phosphane-substituted tetracarbonyltungsten derivatives has been prepared. Attractive intramolecular interactions between the phosphane ligands have been studied in both the neutral and protonated complexes; π-stacking, hydrogen-bonding, and cation–π bonding interactions were identified and were found to have an influence on the *cis*/*trans* isomerism of the complexes. It was found that the *cis*/*trans* isomerism could be switched by protonation or deprotonation of the diphenyl(2-pyridyl)phosphane derivatives. The complexes have been characterized by ^{31}P-, ^{1}H-, and ^{13}C NMR spectroscopy, X-ray crystallography, IR spectroscopy, and mass spectrometry.

Introduction

Supramolecular complexation through hydrogen-bonding, cation−π, or π-stacking interactions is an expanding area of research in chemistry, and is of enormous potential with regard to applications in several fields of chemistry and biology.[1] For example, enzyme catalysis is typically effected by attractive interactions between the enzyme and the substrate.

In organometallic chemistry, repulsive interactions between ligands are important parameters in determining the structures and reactivities of complexes. Supramolecular attractive interactions between ligands in the coordination sphere of a single transition metal complex have not attracted such attention. There are, however, examples of intramolecular π-stacking in transition metal complexes, both interligand[2,3] and intraligand.[4−6] There have also been studies concerning interligand hydrogen bonding in biochemically interesting purine and pyrimidine complexes,[7,8] theoretical studies of interligand hydrogen bonding between nitrogen donor ligands and small ligands such as H_2O, HF, or NH_3,[9,10] and some studies concerning interligand CH−π interactions.[11,12]

The full potential of attractive interactions between the ligands of organometallic complexes has not been evaluated: Attractive interactions between the ligands or between a ligand and a substrate offer a very promising approach to organometallic catalysis. In metalloenzymes, for instance, the interactions at the active site of an enzyme−substrate complex have been regarded as ligand−ligand interactions around the metal atom, playing a vital role in enzyme catalysis.[11]

In this work, attractive supramolecular interactions between phosphane ligands are used to modify *cis*/*trans* isomerization in complexes of the type $[W(CO)_4LL']$. Complexes $[W(CO)_4(PPh_3)_2]$ (**1**),[13] $[W(CO)_4(py)(PPh_3)]$ (**2**), $[W(CO)_4\{P(2\text{-py})Ph_2\}_2]$ (**3**), $[W(CO)_4\{P(2\text{-pyH})^+Ph_2\}\{P(2\text{-py})Ph_2\}](ClO_4^-)$ (**4**), $[W(CO)_4\{P(2\text{-py})Ph_2\}(PPh_3)]$ (**5**), and $[W(CO)_4\{P(2\text{-pyH})^+Ph_2\}(PPh_3)](ClO_4^-)$ (**6**)[13] have been used in this study.

Results

Synthesis of the Complexes

The aim of this study was to prepare and evaluate complexes in which phosphane ligands would be able to exhibit intramolecular attractions. These interactions could be π-stacking in neutral complexes, or cation−π or hydrogen-bonding interactions in cationic complexes. Sterically similar diphenyl(2-pyridyl)phosphane $[P(2\text{-py})Ph_2]$ and triphenylphosphane (PPh_3) were chosen as ligands.

Complexes $[W(CO)_4(PPh_3)_2]$ (**1**), $[W(CO)_4(py)(PPh_3)]$ (**2**), and $[W(CO)_4\{P(2\text{-py})Ph_2\}_2]$ (**3**) were synthesized by treating $[W(CO)_4(py)_2]$ with the appropriate phosphane ligand in benzene solution at 40−45 °C overnight.[14] When the reaction was performed using PPh_3 as the ligand, a mixture of complexes **1** and **2** was obtained. When $P(2\text{-py})Ph_2$ was used as the ligand, the only isolable product from the reaction was **3**, with no trace of a derivative analogous to **2**. The complex $[W(CO)_4\{P(2\text{-py})Ph_2\}(PPh_3)]$ (**5**) was prepared from **2** by the method described above. In the case of complexes **1**, **3**, and **5**, a mixture of *cis* and *trans* isomers was produced. When these complexes were purified by column chromatography, the *cis* isomer was eluted slightly faster than the *trans* isomer, but the bands could not be completely resolved. Complexes **3** and **5** were protonated with perchloric acid in chloroform solution to give the com-

pounds $[W(CO)_4\{P(2\text{-}pyH)^+Ph_2\}\{P(2\text{-}py)Ph_2\}](ClO_4^-)$ (**4**) and $[W(CO)_4\{P(2\text{-}pyH)^+Ph_2\}(PPh_3)](ClO_4^-)$ (**6**).

Solution Behavior of the Complexes

All the reported complexes were characterized by NMR spectroscopy. ^1H NMR spectroscopic data are reported in the Exp. Sect. $^{13}C\{^1H\}$ NMR data for complexes **1**−**6** are presented in Table 1. In the case of complexes forming a mixture of *cis* and *trans* isomers, where possible, the spectra of the individual isomers were measured starting from the pure isomer obtained by column chromatography. In the case of ^{13}C NMR spectroscopy, however, the time required for spectral acquisition was too long to keep the isomer

[a] Signals labeled dd appeared as triplets in the spectra.

pure during the measurements. In the case of complex **5** (Table 1), initial measurements were made on the mixture of *cis* and *trans* isomers as these could not be separated. The data obtained for the isomeric mixture were interpreted with the help of 2D HSQC spectra.

In the $^{13}C\{^1H\}$ NMR spectra of the symmetrically substituted complexes *trans*-**1**, *cis*-**3**, *trans*-**3**, and *cis*-**4**, the phosphane ligands are seen to be coupled,[15] causing the ^{13}C-^{31}P coupled resonance peaks to appear as pseudo triplets in the spectra (denoted as doublets of doublets in Table 1). In the case of unsymmetrical complexes, the spectra show normal doublets due to ^{13}C-^{31}P coupling.

$^{31}P\{^1H\}$NMR spectroscopic data for complexes **1** and **3**−**6** are presented in Table 2. The table also shows the relative amounts of the *cis* and *trans* isomers of the complexes. These equilibrium percentages were checked after the solutions had been left to stand for a week. It has been shown in previous studies that increased steric bulk of the phosphane favors the *trans* isomers, arylphosphanes showing only a very small proportion of the *cis* isomer.[14]

[a] d, $^2J_{pp}$ = 24 Hz, $^1J_{WP}$ not shown. − [b] d, $^2J_{pp}$ = 58 Hz. − [c] d, $^2J_{pp}$ = 23 Hz, $^1J_{WP}$ not shown. − [d] d, $^2J_{pp}$ = 61 Hz. − [e] Measured immediately after protonation, before disappearance of the signal.

In this study, complex $[W(CO)_4(PPh_3)_2]$ (**1**) behaved as expected, giving 32% of the *cis* isomer in $CDCl_3$ solution. On replacing one or two of the PPh_3 ligands by P(2-py)Ph_2, the amount of the *cis* isomer increased, even though the steric properties of the ligands were essentially unchanged. Thus, when one of the PPh_3 ligands was replaced by P(2-py)Ph_2 (complex **5**), the *cis* content increased to 41%, and when both of the PPh_3 ligands were replaced by P(2-py)Ph_2 (complex **3**), the *cis* content increased further to 56%. When complex **3** was protonated to give $[W(CO)_4\{P(2\text{-}pyH)^+Ph_2\}\{P(2\text{-}py)Ph_2\}](ClO_4^-)$ (**4**), the equilibrium changed entirely in favor of the *cis* form within a few hours. On protonation of complex **5** to give $[W(CO)_4\{P(2\text{-}pyH)^+Ph_2\}(PPh_3)](ClO_4^-)$ (**6**), the opposite occurred, and the equilibrium was shifted almost totally in favor of the *trans* form. These protonation reactions proved to be reversible: By adding base to a solution of **4** or **6**, the original *cis*/*trans* ratio was re-established within a few hours in the case of complex **4** or after standing overnight in the case of complex **6**.

X-ray Crystallography

Crystal structures were determined for complexes **2** and **3**. The structures of complexes **1** and **4** have been published in a preliminary communication.[13] Complex **5** did not crystallize adequately, while complex **6** decomposed upon attempted crystallization. Selected bond lengths and angles in all the structures are presented in Table 3 and Table 4. The determined crystal structures correspond to the major isomers in solution.

All the complexes were found to have a slightly distorted octahedral geometry, the angle between the ligands being widened in the *cis*-disubstituted derivatives: The angles between the phosphane ligands in diphosphane derivatives **3** and **4** were found to be 99.7 and 95.7°, respectively, while in the sterically less crowded triphenyl(2-pyridiyl)phosphane derivative **2** (Figure 1), the N−W−P angle was found to be 91.6°. Bond lengths around the metal centers reflect the relative *trans* effects of N, P and CO donors.

Complex $[W(CO)_4(PPh_3)_2]$ (**1**) crystallized in the *trans* form, as expected for a bulky phosphane ligand.[14] Complex $[W(CO)_4(py)(PPh_3)]$ (**2**, Figure 1) crystallized in the *cis* form, as found in solution. In the latter case, there is little

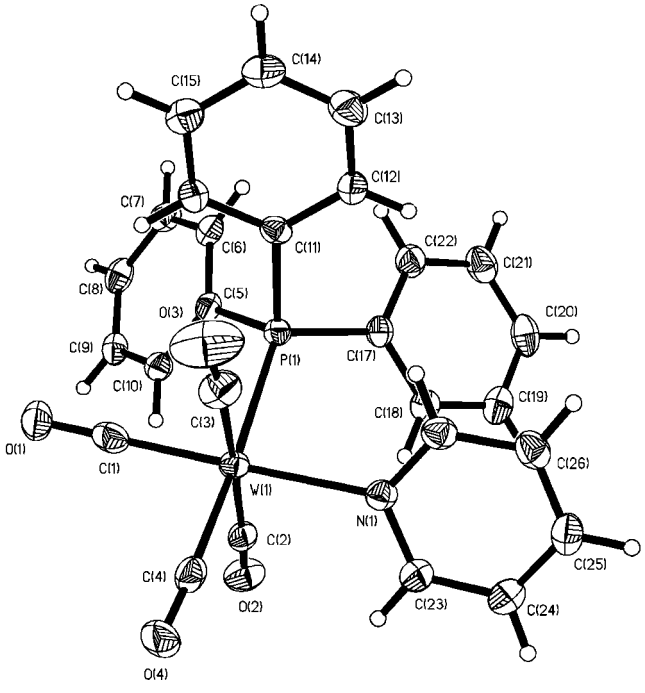

Figure 1. Crystal structure of complex $[W(CO)_4(py)(PPh_3)]$ (**2**)

steric stress to enforce adoption of the *trans* form. The complex $[W(CO)_4\{P(2\text{-py})Ph_2\}_2]$ (**3**, Figure 2) also crystallized in the *cis* form, despite being sterically similar to complex **1**. The structure of *cis*-**3** showed a face-to-face π-stacking interaction between the pyridyl rings, the distance between the centers of the rings being 3.902 Å, and the shortest distance between the atoms of the two rings being 3.527 Å, this being found between the carbon atoms directly attached to the P atom. The planes were found to be almost parallel, having a mutual angle of 7.18(7)°. This interaction is intramolecular rather than extending throughout the crystal system. The centroid–centroid distance between two π-stacked pyridine fragments is typically 3.3–3.8 Å, with contact angles usually falling between a parallel arrangement and a maximum of 40°.[16]

The protonated derivative of **3**, *cis*-$[W(CO)_4\{P(2\text{-pyH})^+Ph_2\}\{P(2\text{-py})Ph_2\}](ClO_4^-)$ (**4**, Figure 3) was found to have a structure in which the N atoms of the pyridyl rings are connected by a hydrogen bond, the distance between the two N atoms being 2.736(3) Å. Because of this hydrogen bond, the positive charge is delocalized over the two pyridine rings. Moreover, the structure of this complex also showed two cation–π bonds between the pyridinium cations and phenyl rings: One such interaction is found between the rings labeled R1 and R3, the centroid–centroid distance of the rings being 3.915 Å with an angle of 23.99°, while the other such interaction is found between the rings labeled R2 and R4, the distance between the centers of the rings being 3.918 Å with an angle of 19.17(15)°. In both cases, the closest distances between the atoms of the rings are found between the N atoms of the pyridyl rings and the C atoms of the phenyl rings directly attached to the P atom, the N1–C distance being 3.179 Å and the N2–C distance being 3.145 Å.

In addition to π-stacking, other weak interactions are also apparent in the solid state. Weak hydrogen bonding between the CO ligands and aryl hydrogen atoms is evident in all the studied complexes. This type of interaction has

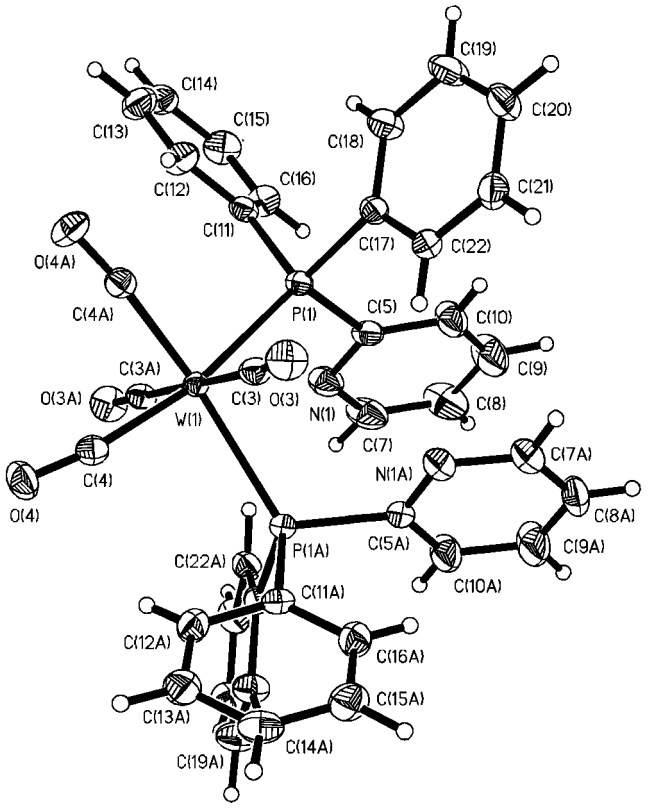

Figure 2. Crystal structure of complex *cis*-$[W(CO)_4\{P(2\text{-py})Ph_2\}_2]$ (**3**)

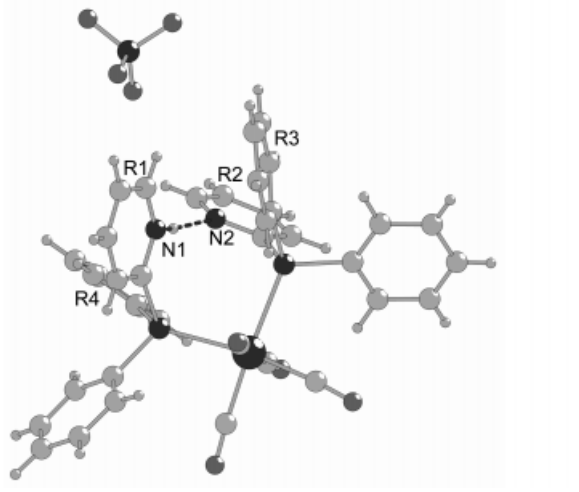

Figure 3. Structure of complex *cis*-$[W(CO)_4\{P(2\text{-pyH})^+Ph_2\}\{P(2\text{-py})Ph_2\}](ClO_4^-)$ (**4**)

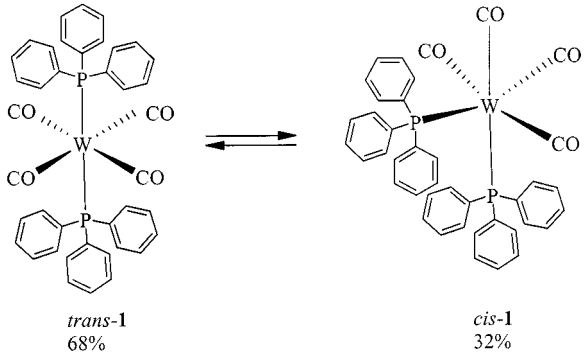
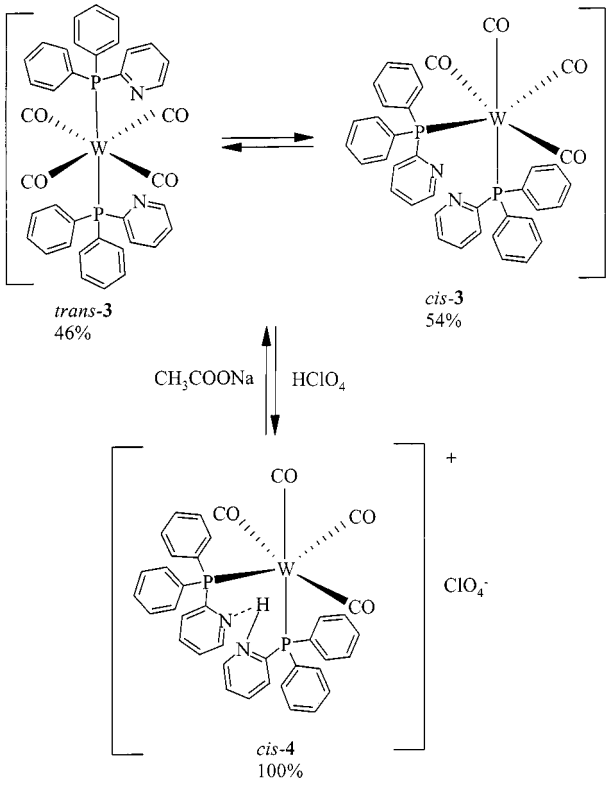
been reported for several carbonyl transition metal complexes.[17] As an example of weak hydrogen bonding in complex **1**, an intermolecular C−O···H distance of 2.529 Å with a C−O···H angle of 172.6° can be seen. Similarly, complex **2** shows an intermolecular C−O···H distance of 2.453 Å with an angle of 161.2°, while complex **3** shows a C−O···H distance of 2.58 Å with a C−O···H angle of 162.4°. Complex **4** shows two C−O···H distances of 2.52 Å with angles of 157.8° and 161.9°. In all of these complexes, this hydrogen-bonding interaction is mainly seen between neighboring molecules in the solid state. These interactions are thus expected to play no significant role in the *cis*/*trans* isomerism in solution.

Discussion

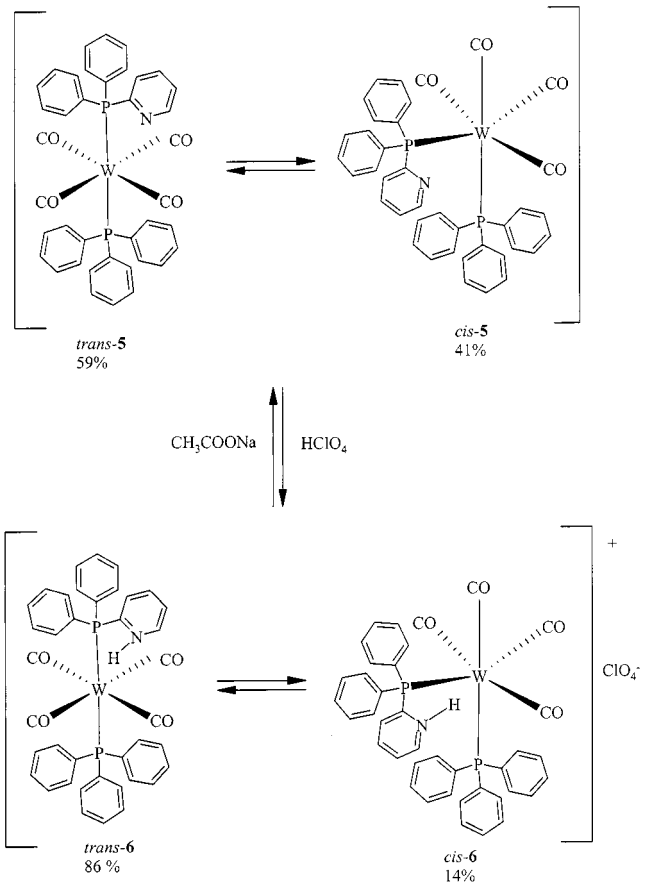
In solution, attractive or repulsive interactions between the ligands have an effect on the isomerization processes. Similar interactions also occur between the ligands and, for example, solvent molecules. The net effect of these interactions, in addition to the electronic properties of the coordination, determines the final structure. In this work, we have deliberately varied the attractions between phosphane ligands in order to cause changes in the relative amounts of the *cis* and *trans* isomers (Schemes 1, 2, and 3).



Scheme 1. Solution behavior of complex **1**



Scheme 2. Solution behavior of complexes **3** and **4**



Scheme 3. Solution behavior of complexes **5** and **6**

The differences in solution behavior of the neutral complexes $[W(CO)_4(PPh_3)_2]$ (**1**), $[W(CO)_4\{P(2\text{-py})Ph_2\}_2]$ (**3**), and $[W(CO)_4(PPh_3)\{P(2\text{-py})Ph_2\}]$ (**5**) can be explained in terms of reduced repulsion between the phosphane ligands due to attractive π−π interactions: Due to the heteroatom, the pyridyl ring is more polarized than the phenyl ring, making attractive π-stacking of pyridyl rings more favorable compared to that of phenyl rings.[18] In the *cis* isomer, showing π−π interactions, the steric repulsion between the ligands is minimized and evidently not much attraction is needed between the rings to favor the *cis* form.

In the case of complex **1**, the steric repulsion between the ligands clearly favors the *trans* isomer. Complex **6** has just one pyridyl ring, which could be involved in attractive π−π interactions with one of the phenyl rings, leading to a slight increase in the *cis* content compared to complex **1**, but the *trans* conformation is still slightly preferred. In complex **3**, the *cis* conformer is favored over the *trans* conformer. In this case, the π-stacking between the pyridyl rings has been confirmed by X-ray crystallography (Figure 2).

The solvent effects are difficult to estimate, but on the grounds of the enthalpies of adduct formation for pyridine (−22 kJ/mol) and benzene (−4.9 kJ/mol) with $CHCl_3$,[19,20] and the empirical solvent polarity parameters of $CHCl_3$ (E_T^N = 0.259), pyridine (E_T^N = 0.302), and benzene (E_T^N = 0.111),[21] pyridine can be expected to show a somewhat greater attraction towards chloroform than benzene. The solvent should actually favor a higher proportion of the *trans* arrangement for complexes **3** and **5** compared to complex **1**, because in the *trans* form the pyridyl groups would maximize their solvent interactions: In the structure of **3** (Figure 2) there are fewer possibilities for solvent interactions with the pyridyl groups. In view of this, the observed isomeric ratios necessitate attractive interactions that override both the steric repulsion of bulky ligands and the solvent interactions.

When complex **3** is protonated, the resulting complex **4** is 100% in the *cis* form. We have isolated the complex $[W(CO)_4\{P(2\text{-pyH})^+Ph_2\}\{P(2\text{-py})Ph_2\}](ClO_4^-)$ (**4**) with one protonated pyridyl ring. This structure offers the possibility of intramolecular N−H···N hydrogen bonding (Figure 3). This hydrogen bond, together with the two cation−π interactions observed, explains the preference for the *cis* isomer.

When complex **5** is protonated, the resulting complex $[W(CO)_4\{P(2\text{-pyH})^+Ph_2\}(PPh_3)](ClO_4^-)$ (**6**) is predominantly (86%) in the *trans* form. Here, there is only one pyridyl ring to bear the positive charge; the possibility still exists for intramolecular cation−π interactions between the pyridinium cation and the phenyl ring, but there is no possibility of intramolecular hydrogen bonding. In this case, the repulsion between the two phosphane ligands becomes important. Additionally, there is a possibility of intermolecular interactions, such as hydrogen bonding between the pyridinium hydrogen atom and the ClO_4^- anion, which may also increase the preference for the *trans* isomer (the *trans* form is even more clearly favored than in the case of the triphenylphosphane derivative **1**). Since the relative strengths of the solvent interactions in complexes **4** and **6** should be comparable, they do not provide an explanation for the structural differences between these two complexes.

The protonation reactions have been found to be reversible; the *cis*/*trans* isomer ratio can be tuned by adjusting the pH. Phosphane complexes are used in various catalytic reactions,[22] hence the ability to control *cis*/*trans* isomerism through attractive interligand interactions opens up possibilities for controlling the mechanisms of homogeneous catalytic reactions.

Experimental Section

General Remarks: All reactions were carried out under nitrogen using standard Schlenk techniques. Synthetic procedures were modified from the method described previously.[14] Benzene (Baker, 99%) was distilled from sodium and benzophenone ketyl under nitrogen. Hexacarbonyltungsten (Aldrich), triphenylphosphane (FF Chemicals), diphenyl(2-pyridyl)phosphane (Aldrich), dichloromethane (FF Chemicals, 99.8%), and hexane (Lab Scan, 95%) were used as received. Perchloric acid (Merck, 70%) was diluted to about 26%. The starting material $[W(CO)_4(py)_2]$ was prepared according to a literature method.[23] Crystals were grown by slow evaporation of the solvents from solutions in dichloromethane/hexane, and in the case of complex **4** from a solution in dichloromethane containing some perchloric acid.

Spectroscopy: ^{1}H NMR spectra (400 MHz; TMS), ^{13}C{^{1}H} NMR spectra (100 MHz; $CDCl_3$ at δ = 77.0), two-dimensional HSQC spectra, and ^{31}P{^{1}H} NMR spectra (162 MHz; ext. stand. 85% H_3PO_4) were recorded with a Bruker DPX 400 spectrometer with samples in $CDCl_3$ (CIL, 99.8% D, 0.03% TMS). IR spectra were recorded with a Bruker IFS 66 spectrometer with samples in dichloromethane. Exact masses were measured with a Micromass LCT mass spectrometer using the ESI+ method.

X-ray Crystallography. − Crystal Data for 2: $C_{27}H_{20}NO_4PW$, M_r = 637.26, monoclinic, a = 10.1507(2), b = 20.0282(3), c = 11.6940(3) Å, β = 97.6790(10)°, 2356.07(8) Å^3, T = 120 K, space group $P2_1/n$ (no. 14), Z = 4, D_{calcd} = 1.797 g cm^{-1}, μ(Mo-$K_α$) = 5.005 mm^{-1}, 25482 reflections collected, 4709 unique (R_{int} = 0.0474). The final R_1 was 0.0235 ($I > 2σ$) and $wR_2(F^2)$ = 0.0564 ($I > 2σ$). − **Crystal Data for 3:** $C_{38}H_{28}N_2O_4P_2W$, M_r = 822.41, monoclinic, a = 13.7402(2), b = 12.6068(2), c = 19.2044(3) Å, β = 96.4360(10)°, 3305.62(9) Å^3, T = 120 K, space group $C2/c$ (no. 15), Z = 4, D_{calcd} = 1.653 g cm^{-1}, μ(Mo-$K_α$) = 3.635 mm^{-1}, 19439 reflections collected, 3622 unique (R_{int} = 0.0238). The final R_1 was 0.0147 ($I > 2σ$) and $wR_2(F^2)$ = 0.0343 ($I > 2σ$). − Data were collected with a Nonius KappaCCD diffractometer using Mo-$K_α$ radiation (λ = 0.71073 Å). For compound **2**, hydrogen atoms were constrained to ride on their parent atom (C−H = 0.95 Å, U_{iso} = 1.2·C_{eq}). In the case of **3**, hydrogen atoms were located from the difference Fourier map and were refined isotropically. Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-153439 (**2**) and -153440 (**3**). Crystallographic data for the structures reported in a preliminary communication have also been deposited. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[W(CO)$_4$(PPh$_3$)$_2$] (1) and [W(CO)$_4$(py)(PPh$_3$)] (2): [W(CO)$_4$(py)$_2$] (242 mg, 0.533 mmol) was suspended in benzene (40 mL). Triphenylphosphane (151 mg, 0.577 mmol) was added and the mixture was stirred for 24 h at 40−45 °C. The solvent was then evaporated and the residue was purified by column chromatography using dichloromethane/hexane (1:1) as the eluent. Two products, [W(CO)$_4$(PPh$_3$)$_2$] (**1**) (132 mg, 40%) and [W(CO)$_4$(py)(PPh$_3$)] (**2**) (132 mg, 47%) were obtained. − **1**: $C_{40}H_{30}O_4P_2W$ (820.5), calcd. C 58.56, H 3.69; found C 58.32, H 3.20. − *trans*-**1**: ^{1}H NMR: δ = 7.26−7.56 (m). − IR (CH_2Cl_2): ν(CO) = 1886 cm^{-1}. − **2:** Exact mass: m/z = 638.0754 [M$^+$ − H] (calcd. for $C_{27}H_{21}NO_4PW$: 638.0718). − ^{1}H NMR (see Table 1 for numbering scheme): δ = 8.39 (d, 2-H), 7.49 (m, 4-H), 7.36 (m, 12-H), 7.31 (m, 14-H), 7.28 (m, 13-H), 6.82 (t, 3-H). − ^{31}P{^{1}H} NMR: δ = 33 ($^1J_{PW}$ = 238 Hz). − IR (CH_2Cl_2): ν(CO) = 2011 (s), 1884 (vs), 1846 (s) cm^{-1}.

[W(CO)$_4${P(2-py)Ph$_2$}$_2$] (3): [W(CO)$_4$(py)$_2$] (225 mg, 0.495 mmol) was suspended in benzene (40 mL). Diphenyl(2-pyridyl)phosphane (261 mg, 0.991 mmol) was added and the mixture was stirred for 24 h at 40−45 °C. After evaporation of the solvent, the residue was purified by column chromatography using dichloromethane as the eluent to afford [W(CO)$_4${P(2-py)Ph$_2$}$_2$] (225 mg, 55%). Exact mass: m/z = 823.1122 [M$^+$ − H] (calcd. for $C_{38}H_{29}N_2O_4P_2W$: 823.1112). − *cis*-**3:** ^{1}H NMR (see Table 1 for numbering scheme): δ = 8.51 (d, 3-H), 7.45 (m, 8-H), 7.41 (m, 5-H), 7.30 (m, 10-H), 7.26 (m, 9-H), 7.06 (m, 4-H), 7.02 (m, 6-H). − IR (CH_2Cl_2): ν(CO) = 2018 (m), 1911 (sh), 1898 (s), 1872 (sh) cm^{-1}. − *trans*-**3:** ^{1}H NMR (see Table 1 for numbering scheme): δ = 8.78 (d, 3-H), 7.65 (m, 8-H), 7.59 (td, 5-H), 7.36 (m, 9-,10-H), 7.29 (d, 6-H), 7.15 (t, 4-H). − IR (CH_2Cl_2): ν(CO) = 1890 cm^{-1}.

[W(CO)$_4${P(2-pyH)$^+$Ph$_2$}{P(2-py)Ph$_2$}](ClO$_4^-$) (4): Perchloric acid was added to a solution of complex **3** in $CDCl_3$. The product was deprotonated with CH_3COONa solution. − *cis*-**4:** Exact mass: m/z = 823.1109 [M$^+$ − H] (calcd. for $C_{38}H_{29}N_2O_4P_2W$ 823.1112); 98.9509 [ClO_4^-] (calcd. for ClO_4 98.9485). − ^{1}H NMR (see Table 1 for numbering scheme): δ = 8.18 (dd, 3-H), 7.89 (td, 5-H), 7.48 (m, 10-H), 7.47 (m, 9-H), 7.38 (m, 4-H), 7.34 (m, 8-H), 7.23 (dd, 6-H).

[W(CO)$_4${P(2-Py)Ph$_2$}(PPh$_3$)] (5): [W(CO)$_4$(py)(PPh$_3$)] (**2**, 110 mg, 0.173 mmol), obtained in the preparation of complex **1** as described above, was dissolved in benzene (20 mL) and diphenyl(2-pyridyl)-phosphane (55 mg, 0.209 mmol) was added. The resulting solution was stirred for 24 h at 40−50 °C and then the solvent was evaporated. The product was purified by column chromatography, first with dichloromethane/hexane (1:1) as eluent until the first fraction (starting material and traces of complex **1**) eluted, and thereafter with a 1:3 mixture until the product was eluted. Exact mass: m/z = 822.1194 [M$^+$ − H] (calcd. for $C_{39}H_{30}NO_4P_2W$: 822.1160). − *cis*-**5:** ^{1}H NMR (see Table 1 for numbering scheme): δ = 8.55 (dd, 3-H), 7.59 (m, 8-H), 7.45 (m, 5-H), 7.42−7.25 (m, 10-H), 7.30−7.20 (m, 9-H, 11- to 14-H), 7.08 (m, 4-H), 6.97 (m, 6-H). − *trans*-**5:** ^{1}H NMR (see Table 1 for numbering scheme): δ = 8.80 (dd, 3-H), 7.67 (m, 8-H, 11- to 14-H), 7.59 (m, 5-H), 7.45−7.35 (m, 9-H), 7.42−7.25 (m, 10-H), 7.29 (m, 6-H), 7.16 (m, 4-H). − IR (CH_2Cl_2): ν(CO) = 1888 cm^{-1}.

[W(CO)$_4${P(2-pyH)$^+$Ph$_2$}(PPh$_3$)](ClO$_4^-$) (6): Perchloric acid was added to a solution of complex **5** in $CDCl_3$. The product **6** was deprotonated with CH_3COONa solution. The protonated complex showed a tendency to decompose if the solution was left to stand over a period of days. − *trans*-**6:** Exact mass: m/z = 822.1164 [M$^+$ − H] (calcd. for $C_{39}H_{30}NO_4P_2W$: 822.1160); 98.9510 [ClO_4^-] (calcd. for ClO_4 98.9485). − ^{1}H NMR (see Table 1 for numbering scheme): δ = 9.16 (dd, 3-H), 7.90−7.20 (m, 4- to 14-H).

Acknowledgments

Financial support from the Neste foundation is gratefully acknowledged. We thank Mrs. Päivi Joensuu for recording the mass spectra, and Mrs. Päivi Pirilä for advice in the area of solution chemistry.

The Dioxoosmium(VI) Complex $[OsO_2(H_2biim)_2](NO_3)_2$ as Oxygen-Transfer Reagent − Synthesis and Solid-State Structure of Bis(2,2′-biimidazole)-bis(triphenylphosphane oxide)osmium(III) Nitrate

Andrei Maiboroda,[a] Gerd Rheinwald,[a] and Heinrich Lang*[a]

Dedicated to Prof. D. Sellmann on the occasion of his 60th birthday

Keywords: Coordination chemistry / Osmium / N ligands / Oxygen transfer / X-ray structure analysis

Treatment of OsO_4 (**1**) with 2,2′-biimidazole (H_2biim) (**2**) in a methanol/acetone mixture, and in the presence of nitric acid produces the novel dioxoosmium(VI) complex $[OsO_2(H_2biim)_2](NO_3)_2{\cdot}CH_3OH$ (**3**). Addition of 2 equiv. of PPh_3 (**4**) and 1 equiv. of nitric acid to **3** affords mononuclear $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**5**) by a redox reaction which involves the transfer of oxygen from osmium to PPh_3. The X-ray crystal structure of **5** reveals an octahedral coordination sphere around the osmium(III) centre. This occurs as a result of the two H_2biim chelating ligands in the equatorial positions and two datively bonded phosphane oxide groups $O{=}PPh_3$ in the axial positions. Hydrogen bonds are responsible for the formation of a polymeric structure in the solid state. The latter complex reacts with KOH to form monocationic $[Os(Hbiim)_2(O{=}PPh_3)_2]NO_3$ (**6**).

Introduction

Platinum metal containing complexes with, for example, five-membered nitrogen-containing heterocycles are of considerable interest since they can be used as starting materials for the synthesis of oligo- and polymetallic species, featuring at least two different metal centres.[1,2] Representative examples of such species are the pyrazolato-bridged homobimetallic rhodium and iridium complexes $[\{Rh_2(\mu\text{-}pz)_2(I)(C{\equiv}N\textit{t}Bu)_4\}_2(\mu\text{-}I)](CF_3SO_3)$,[1b] $[M(\mu\text{-}pz)(I)(C{\equiv}N\textit{t}Bu)_2]_2$,[1b] (M = Rh, Ir) and $Ir_2(\mu\text{-}H)(\mu\text{-}pz)(N{\equiv}CMe)(P\textit{i}Pr_3)_2$[2b] (pz = pyrazolate). In these complexes, the nitrogen-containing heterocyclic π-conjugated bridging units span the corresponding transition metal centres, giving rise to a bonding situation which allows the metal atoms to communicate with each other.[1] A further common feature of oligo- or polymetallic complexes is their significantly higher activity in many homogeneous catalytic processes, e.g. hydrogenation, hydroformylation, compared with their predecessors.[2] This catalytic enhancement can be explained in terms of an intramolecular electron transfer between the corresponding transition metal centres, via the π-conjugated organic building blocks.[3] Hence, the development of the chemistry of azolato-containing transition metal complexes of platinum metals is of interest, either in homogeneous catalysis, due to cooperative and synergetic effects, or in the study of intramolecular electronic communication.

For the synthesis of osmium complexes bearing 2,2′-biimidazole chelating ligands, the hydrido(phosphane) complexes $OsH_2Cl_2(P\textit{i}Pr_3)_2$[4a] or $OsH_6(P\textit{i}Pr_3)_2$[4b] were exclusively used as the synthetic tool. Nevertheless, all complexes prepared by this method contain only one 2,2′-biimidazole chelating group. Using the 2,2′-biimidazole as the bridging unit, also some heterobimetallic complexes, such as $(P\textit{i}Pr_3)_2H_2ClOs(\mu\text{-}Hbiim)MCl(cod)$ (M = Rh, Ir; cod = cyclooctadiene)[4a] or $(P\textit{i}Pr_3)_2H_3Os(\mu\text{-}biim)Ir(cod)$[4b] could also be prepared. Our aim in the present work was to synthesise different osmium complexes, containing at least two 2,2′-biimidazole chelating ligands, so as to use these species as effective starting materials for the preparation of oligonuclear transition metal complexes, based on the central osmium fragments $[Os(biim)_2(O{=}PPh_3)_2]^-$ or $[Os(Hbiim)_2(O{=}PPh_3)_2]^+$. We thus describe the reaction of OsO_4 with H_2biim in order to synthesise neutral and/or ionic osmium complexes, which feature two 2,2′-biimidazole ligands.

Results and Discussion

Synthesis and Spectroscopic Characterisation

In an attempt to synthesise osmium complexes with H_2biim chelating ligands (H_2biim = 2,2′-biimidazole) in the equatorial positions, we chose the dioxoosmium entity as the central building block. OsO_4 (**1**) was treated with two equivalents of H_2biim (**2**), in a 1:1 methanol/acetone mixture, and in the presence of nitric acid to afford the osmium(VI) complex $[OsO_2(H_2biim)_2](NO_3)_2{\cdot}CH_3OH$ (**3**) in a 60% yield (Scheme 1).

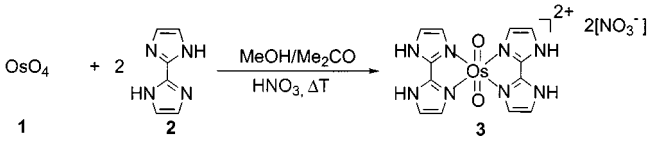


Scheme 1

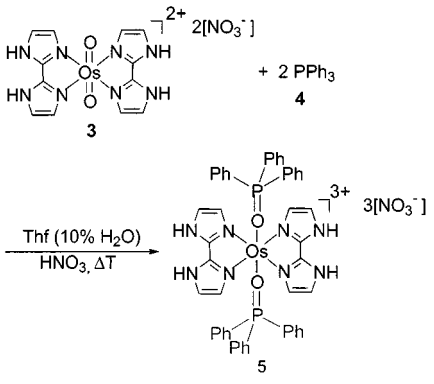
After appropriate workup, mononuclear **3** was obtained as an air-stable orange solid. However, it was found that **3** is poorly soluble in all well-known organic solvents, except dimethyl sulfoxide. The spectroscopic data (IR, ^{1}H, ^{13}C{^{1}H} NMR spectroscopy) of **3**, in which a planar Os(H$_2$biim)$_2$ arrangement is present, are consistent with the formulated structure (vide supra).

In the IR spectrum of **3** an intensive absorption band at 858 cm^{-1} is found, which can be assigned to the $\nu_{a(Os=O)}$ stretching vibration of the linear O=Os=O entity.[5] Additionally, a very sharp and narrow $\nu_{(NH)}$ absorption band is observed at 3140 cm^{-1}. As is typical for noncoordinated NO_3^- counter ions, only one band arises at 1488 cm^{-1} which is due to the asymmetric $\nu_{(NO)}$ stretching vibration.[6]

In the noncoordinated state the H$_2$biim ligand gives rise to only one ^{1}H NMR resonance signal at δ = 7.1 assigned to the CH protons, whereas in mononuclear **3**, two signals at δ = 7.81 (5-, 5′-H), as well as δ = 8.45 (4-, 4′-H) are observed in a 1:1 intensity ratio. This points to the fact that the H$_2$biim entity is bonded to the osmium(VI) centre as a chelate, via the two sp^2-hybridised nitrogen atoms; the NH functionalities are located on the opposite side.

Nevertheless, due to the low solubility of **3** in [D$_6$]dimethyl sulfoxide, only the resonance signals for the carbon atoms in the 4,4′- (δ = 128.7) and the 5,5′-position (δ = 123.4) could be detected in the ^{13}C{^{1}H} NMR spectrum, which also supports the symmetrical bonding of the H$_2$biim chelates to the osmium centre.

Dimethyl sulfoxide is the only suitable solvent for **3**, despite its high boiling point and its high coordination ability. It is for this reason that we wanted to prepare complexes with similar structures which are more soluble in common organic solvents, so that we could use these complexes as starting materials in the synthesis of oligometallic transition metal complexes. Therefore, we treated complex **3** with 2 equiv. of Ph$_3$P (**4**) and 1 equiv. of HNO$_3$ in boiling tetrahydrofuran containing 10% H$_2$O. During this reaction, the oxygen atoms bonded to the osmium centre transfer to the phosphorus atom of the added PPh$_3$. The resulting phosphane oxides Ph$_3$P=O selectively bond to the osmium centre of the Os(H$_2$biim)$_2$ segment, through their oxygen atoms in a dative fashion, to produce [Os(H$_2$biim)$_2$(O=PPh$_3$)$_2$]$^{2+}$ at first. The latter osmium(II) species is the most likely intermediate, which is then oxidised by nitric acid to produce [Os(H$_2$biim)$_2$(O=PPh$_3$)$_2$](NO$_3$)$_3$ (**5**) in a 76% yield based on **3** (Scheme 2).



Scheme 2

Complex **5**, when compared with **3**, is significantly more soluble in common organic solvents, such as dichloromethane, methanol, or acetone. However, similar oxygen transfer reactions producing osmium(II) complexes were established earlier for the reaction of the dioxo(porphyrino)osmium(VI) complex OsO$_2$(OEP) (OEP = *o*cta*e*thyl*p*orphyrine) with triphenylphosphane.[7]

One very noticeable feature in the preparation of **3** is that on treatment of **3** with PPh$_3$ in dry tetrahydrofuran or other organic solvents like acetone or toluene, no reaction takes place. This result leads to the conclusion that this reaction is catalysed by protic species. If this is true, complex **3** should react with PPh$_3$ in protic solvents, e.g. alcohols. Hence, **3** was treated with PPh$_3$ in a methanolic medium and **5** was indeed produced, however, with an isolated yield of only 15%. This can be explained by the fact that MeOH can act as σ-donating ligand to the osmium centre, which might reduce the selectivity of the reaction of **3** with PPh$_3$ (vide supra). The need for the protic solvent for the reaction of **3** with **4** to produce **5**, indicates that the mechanism for this reaction may also include the protonation of the central O=Os=O building block, thus the oxo atoms in **3** would exchange with H$_2$O by protonation. The IR- and NMR-spectroscopic data of **5** agree with the structure found by X-ray crystal structure analysis (see below).

In the IR spectrum of **3**, a strong N−H stretching vibration is found, whereas in the IR spectrum of **5**, a broad $\nu_{(NH)}$ absorption band centred at around 3100 cm^{-1} is characteristic. The strong $\nu_{a(NO3)}$ vibration found at 1488 cm^{-1} in **3** is significantly shifted to lower frequencies in **5**, and is observed at 1384 cm^{-1}. These observations point to the formation of hydrogen bonds between the NH groups of the 2,2′-biimidazole building blocks, the oxygen atoms of the NO_3^- counter ions, the MeOH and the H$_2$O molecules.

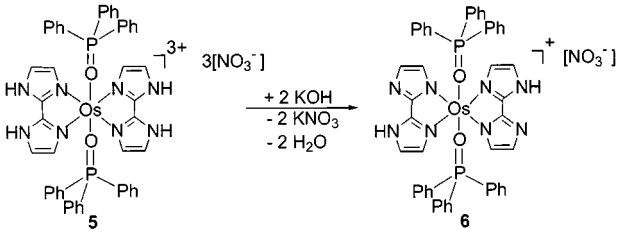
As result of the reduction of osmium(VI) in **3** by PPh$_3$, the linear O=Os=O group in **3** is transferred to a zigzag Ph$_3$P=O→Os←O=PPh$_3$ unit in **5**. As a result, the $\nu_{a(Os=O)}$ absorption band found in the IR spectrum of **3** at 858 cm^{-1} is not present in the spectrum of **5**. Nevertheless, the disappearance of $\nu_{(Os=O)}$ is accompanied with the appearance of the P=O stretching vibrations at 1131 cm^{-1} in the IR spectrum of **5**.

In the ^{1}H NMR spectrum of **5** a multiplet between δ = 7.0 and 8.2 is observed, resulting from the superimposition of the resonance signals of the protons of the phenyl groups, as well as the protons of the 2,2′-biimidazole chelating ligands. The ^{13}C{^{1}H} NMR spectrum of **5** shows the

four resonance signals expected for the sp^2-hybridised phenyl carbon atoms of the $Ph_3P{=}O$ entities, between δ = 129 and 133. The resonance signals of the H_2biim chelating ligands are shifted to a lower field, relative to **3**, and are observed at δ = 135.1 (5,5′-position), δ = 137.9 (4,4′-position) and δ = 139.9 (2,2′-position), respectively.

$^{31}P\{^1H\}$-NMR-spectroscopic studies carried out on **5** clearly demonstrate the appearance of one resonance signal for the phosphorus atom of the triphenylphosphane oxide at δ = 36.4. Relative to the noncoordinated $Ph_3P{=}O$, the signal is shifted to a lower field by 9.4 ppm, revealing the coordination to the osmium(III) centre through the oxygen atom. Similar observations were made for other complexes featuring the P=O group, e.g. $[(\eta^5\text{-}C_5H_5)Co\{O{=}P(OR)_3\}_3]^-$ (R = Me, Ph).[8] The absorbance bands at 360 nm (ε = $3.5{\cdot}10^3$ $mol^{-1}{\cdot}dm^3{\cdot}cm^{-1}$) and 388 nm (ε = $3.5{\cdot}10^3$ $mol^{-1}{\cdot}dm^3{\cdot}cm^{-1}$) in the UV/Vis spectrum of **5** can be attributed to ligand-to-metal charge-transfer transitions.[9]

Complex **5** possesses a total of four NH functionalities, which can be easily deprotonated using KOH as a suitable base. Thus, the reaction of **5** with KOH in a molar ratio of 1:2 leads, on loss of KNO_3 and H_2O to the formation of the monocationic complex $[Os(Hbiim)_2(O{=}PPh_3)_2]NO_3$ (**6**) (Scheme 3). This reaction is accompanied by a colour change from red (**5**) to violet (**6**). After appropriate workup, **6** can be isolated in a 85% yield.



Scheme 3

A very noticeable feature in the IR spectrum of **6**, when compared with those of **3** and **5**, is the significant decrease in the intensity of the absorption bands of the NH and NO_3^- groups relative to the other vibrations observed in the spectrum. These absorptions are found at 3095 (NH) and 1386 cm^{-1} (NO_3^-), respectively. This result gives the first hint that the NH units of the 2,2′-biimidazole ligands could be at least partly metallated. This deprotonation influences the donor/acceptor properties of the 2,2′-biimidazole ligands, resulting in a change of the electronic absorbance in the UV/Vis spectrum of **6**. In contrast to **5**, the UV/Vis spectrum of **6** contains two maxima at 344 and at 541 nm, respectively.

All other spectroscopic studies carried out on **6** (^1H, $^{13}C\{^1H\}$ NMR spectroscopy) do not show a significant influence on the chemical shifts of the organic ligands when compared with **5**. However, the $^{31}P\{^1H\}$-NMR-spectroscopic studies demonstrate that on extended measurements further resonance signals appear. This can be attributed to ligand exchange reactions obtained by substitution of O=PPh_3 by solvent molecules, e.g. CD_3OD. As a result, signals with lower intensity are observed at δ = 33.7 ($Ph_3P{=}O{\rightarrow}Os{\leftarrow}DOMe$) and δ = 22.3 (*non*coordinated $Ph_3P{=}O$), next to the resonance signal at δ = 37.1 which is typical for **6**.

Electrochemical Studies

Cyclic voltammetric studies were carried out on complex **5** in dichloromethane at 25 °C and at −5 °C. The obtained voltammograms are depicted in Figure 1. However, due to the low solubility of **3** (vide supra) no electrochemical studies could be carried out on this complex for comparison. Figure 1 shows cyclic voltammograms of $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**5**) in dichloromethane at 25 °C (top) and at −5 °C (bottom) (scan rate 60 mV s^{-1}).

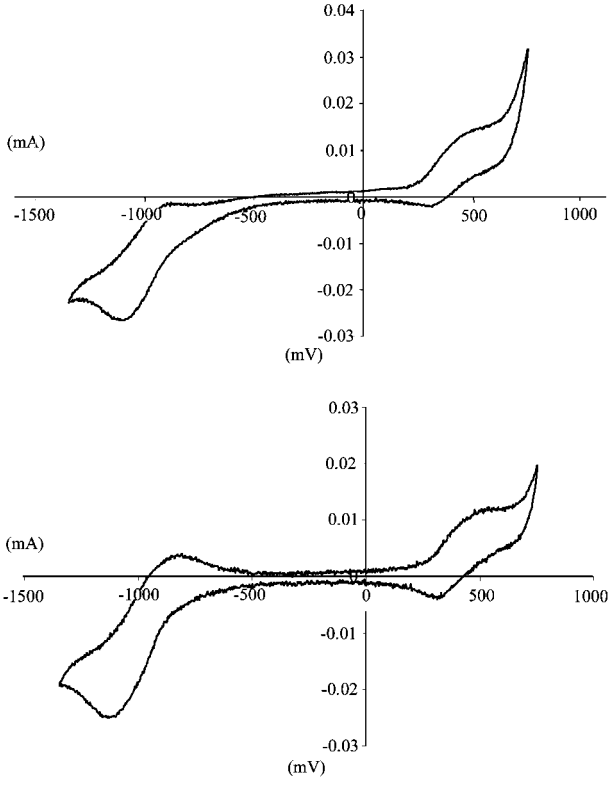


Figure 1. Cyclic voltammograms of $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3$ (**5**) in dichloromethane at 25 °C (top) and at −5 °C (bottom) (scan rate 60 mV s^{-1})

It was found that both the Os^{III}/Os^{II} reduction (E_{red} = −1.09 V) and the Os^{III}/Os^{IV} oxidation processes (E_{ox} = +0.52 V) are irreversible at 25 °C. However, on lowering the temperature to −5 °C these processes are quasi-reversible. Thus, the potentials of the redox couples Os^{IV}/Os^{III} ($E_{1/2}$ = −0.97 V, ΔE = 290 mV) and Os^{IV}/Os^{V} ($E_{1/2}$ = +0.42 V, ΔE = 210 mV) could be determined. Similar observations were made for the Os^{IV} complex anion $[OsCl_5(H_2O)]^-$,[10] thus indicating that a reversible redox behaviour is seen only at low temperatures. This is a characteristic feature for some osmium complexes.[11] This can be explained by the kinetic stabilisation of the reactive intermediates e.g. the dicationic Os^{II} complex $[Os(H_2biim)_2(O{=}$

$PPh_3)_2]^{2+}$ at low temperatures. This species is produced by the electrochemical reduction of **5** and can be chemically oxidised by the NO_3^- ion. Decreasing temperatures slow down this reaction and lead to the formation of the anodic peak in the cyclic voltammogram, due to the electrochemical oxidation of the corresponding Os^{II} species.

A characteristic feature of the electrochemical behaviour of complex **6** is a significant shift of the redox potentials of the Os^{III}/Os^{IV} and Os^{III}/Os^{II} couples to a more negative value, relative to **5**. This results from a partial deprotonation of the H_2biim chelating ligands, followed by an increase in the electronic density on the appropriate osmium centre in **6**. In contrast to **5**, the shape of the cyclic voltammogram of **6** is temperature independent. Both at 25 °C and at −5 °C, the half potential of the Os^{III}/Os^{IV} redox couple is observed at +0.29 V. However, the Os^{III}/Os^{II} redox process is irreversible with $E_{red} = -1.29$ V.

Solid-State Structure of 5

Single crystals of **5**, suitable for X-ray structure analysis, were obtained by slow evaporation of a 1:1 methanol/dichloromethane solution at 25 °C. Complex **5** crystallises with two molecules of the complex, one molecule of water and half a molecule of methanol per asymmetric unit in the triclinic space group $P\bar{1}$, with $a = 10.9098(13)$, $b = 10.9726(12)$, $c = 21.330(3)$, $\alpha = 78.280(2)$, $\beta = 87.315(2)$, $\gamma = 87.992(2)°$, $V = 2496.6(5)$ Å^3 and $Z = 1$. Each of the complex molecules possesses a centre of inversion located at the osmium atom (Figure 2); the symmetry-generated atoms are indicated with the suffixes a and b. The molecular structure of **5** is shown in Figure 2. Experimental crystal data are listed in Table 3 and geometric details are presented in Table 1. Figure 2 shows a ZORTEP drawing of one complex cation $[Os(H_2biim)_2(O{=}PPh_3)_2]^{3+}$ of **5** (50% probability level; the second cation, NO_3^-, H_2O, and MeOH are omitted for clarity).

Each individual complex cation $[Os(H_2biim)_2(O{=}PPh_3)_2]^{3+}$ (Figure 2) of **5** possesses an osmium(III) centre in an octahedral environment, with two datively bonded $O{=}PPh_3$ units in the axial positions and two H_2biim chelating ligands in the equatorial positions. Complex **5** is the first example of an osmium(III) complex with two axial $O{=}PPh_3$ ligands. Similar complexes are known for osmium(II) and osmium(IV) systems, e.g. $Os(OEP)(O{=}PPh_3)_2$ (OEP = octaethylporphyrine)[7a] and $K_2[\{Os(\eta^4\text{-chba-Et})(O{=}PPh_3)_2\}_2O]$ [chba-Et = 1,2′-bis(3,5-dichloro-2-hydroxybenzaimido)ethane].[12]

The H_2biim arrangement in **5** is thereby planar (r. m. s. deviation of the fitted atoms Os1, N1 to N4, and C1 to C6 = 0.072 Å, as well as Os2, N5 to N8, and C25 to C30 = 0.085 Å). The angles around the osmium centres in the latter entity deviate from an idealised square-planar geometry [N1−Os1−N4 = 77.14(8)°, N5−Os2−N8 = 77.70(8)°], due to the formation of a five-membered OsN_2C_2 cycle. This value is typical for transition metal biimidazole complexes in which bite angels of 75.3° {$[NEt_4]$-$[Ir(COD)(PPh_3)(tcbiim)]\cdot CH_2Cl_2$ (tcbiim = tetracyanobiimidazole)}[13] and 82.78° {$[Cu_2(Me_5dien)_2(biim)][BPh_4]_2$ (Me_5dien = pentamethyldiethylentriamine)}[14] are found. A similar bite angle as observed in **5** was experimentally observed in $Ir_2(COD)_2(CH_3C{\equiv}N)$(tcbiim) (78.214°).[14] Furthermore, this N−Os−N angle induces a distortion in the other angles of the equatorial square plane (Table 1).

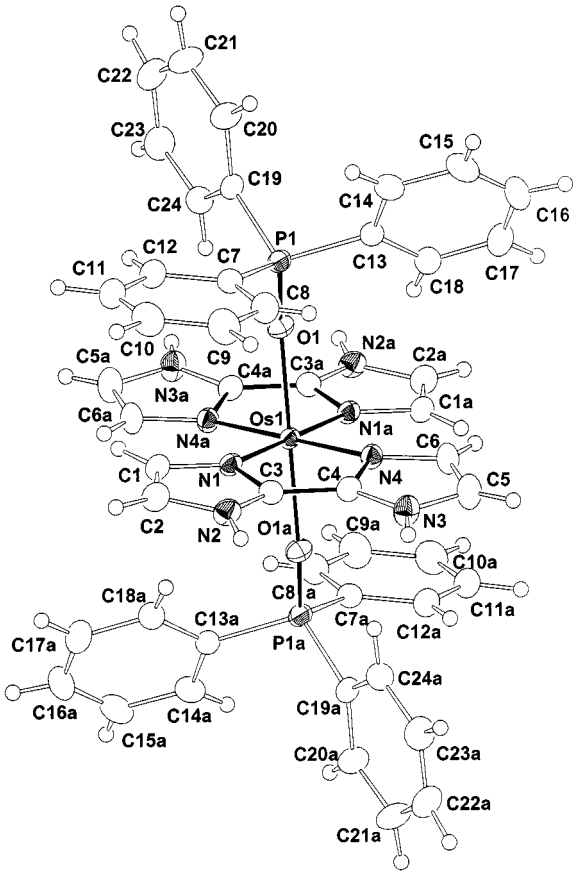

Figure 2. ZORTEP drawing of one complex cation $[Os(H_2biim)_2(O{=}PPh_3)_2]^{3+}$ of **5** (50% probability level; the second cation, NO_3^-, H_2O, and MeOH are omitted for clarity)

The two axially positioned $O{=}PPh_3$ ligands complete the octahedral coordination around the osmium atoms (for N−Os−O angles see Table 1). The Os−O−P angles of 146.53(11)° (Os1−O1−P1) and 140.16(11)° (Os2−O2−P2) are smaller than those found in $Os(OEP)(O{=}PPh_3)_2$ [154.2(5)°][7] and $K_2[\{Os(\eta^4\text{-chba-Et})(O{=}PPh_3)_2\}_2O]$ (153.0),[12] but still in the range typical for this type of arrangements. In general, M−O−P angles in $L_nM{-}O{=}PPh_3$ complexes (L_nM = transition metal fragment) range from 140 to about 180°, depending on the nature of the metal.[15]

The Os−O distances in **5** are 2.0129(16) Å (Os1−O1) and 2.0365(16) Å (Os2−O2), in between that found in $K_2[\{Os(\eta^4\text{-chba-Et})(O{=}PPh_3)_2\}_2O]$ (1.971 Å)[12] and $Os(OEP)(O{=}PPh_3)_2$ [2.036(7) Å].[7] This observation corresponds with the different ionic radii of Os^{II}, Os^{III}, and Os^{IV}.[5] The Os−N bonds, Os1−N1 [2.065(2) Å], Os1−N4 [2.072(2) Å], Os2−N5 [2.060(2) Å], and Os2−N8 [2.067(2) Å] are longer than the interatomic Os−N distances in the above-mentioned osmium complexes containing N ligands

Table 1. Selected geometrical details of $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3{\cdot}H_2O{\cdot}0.5CH_3OH$ (**5**)

and triphenylphosphane oxide, but significantly shorter than those found in osmium complexes featuring the H_2biim ligand and phosphanyl groups, e.g. $[OsCl(\eta^2\text{-}H_2)(H_2biim)(P{i}C_3H_7)_2]Cl$ (2.110−2.135 Å).[4a]

Figure 3 shows the SCHAKAL-99 drawing of **5** including the hydrogen-bonding scheme (phenyl groups of the $O{=}PPh_3$ ligands are omitted for clarity). As depicted in Figure 3, complex **5** possesses a polymeric zigzag chain in the solid state, due to hydrogen bonds between the complex cations $[Os(H_2biim)_2(O{=}PPh_3)_2]^{3+}$, NO_3^-, and the neutral solvent molecules H_2O and MeOH. The corresponding interatomic distances for all specified hydrogen bonds are presented in Table 2 and are in accordance with typical bond lengths between donor and acceptor atoms forming hydrogen bonds.[16] The complex cations in **5** (Figure 3) are spanned by two different linking units: (i) NO_3^- and (ii) NO_3^- and H_2O. However, the H_2O molecule of the latter building arrangement gives rise to a further hydrogen bond with the third NO_3^- ion, which itself is hydrogen-bonded to a terminal MeOH moiety (Figure 3).

Conclusions

In this study, it is shown that novel osmium complexes, featuring two 2,2′-biimidazole ligands are easily accessible. In addition, the novel dioxoosmium(VI) complex $[OsO_2(H_2biim)_2](NO_3)_2$ (**3**) is a very useful precursor for the preparation of an osmium(III) complex, $[Os(H_2bim)_2(O{=}PPh_3)_2](NO_3)_3$ (**5**), on reaction with PPh_3 in the presence of HNO_3. This reaction involves the transfer of an oxygen atom from osmium to phosphorus, and hence redox processes are typical. Furthermore, complex **5** can be deprotonated, with KOH as a suitable base, to afford monocationic $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3)$ (**6**). Complexes **5** and **6** both possess an osmium centre in an octahedral environment, as a result of the two 2,2′-biimidazole chelating ligands which are in the equatorial positions and two triphenylphosphane oxide groups in the axial positions *trans* to each other.

In future studies, the use of the latter complexes in the preparation of oligometallic complexes is of interest, since they bear with their 2,2′-biimidazole ligands coordination sites for the addition of further transition metal building blocks. These accessible complexes should provide very promising model systems for the study of electron transfer reactions and, in addition, they should be excellent catalysts in homogeneous catalysis due to the synergistic and cooperative effects of further transition metals being present.

Experimental Section

General Remarks: IR spectra were recorded with a Perkin−Elmer FT-IR spectrometer (Spectrum 1000) as KBr pellets. − UV/Vis spectra were recorded with a Perkin−Elmer Lambda 40 spectrophotometer in dichloromethane solutions and the concentrations were $8.0{\cdot}10^{-5}$ mol·dm^{-3}. − NMR spectra were recorded with a Bruker Avance 250 spectrometer, operating in the Fourier transform mode; NMR spectra were recorded at 250.131 MHz (^{1}H), 62.902 MHz (^{13}C{^{1}H}) or 101.249 MHz (^{31}P{^{1}H}, T = 303 K); chemical shifts (δ) are given in ppm with respect to $CDCl_3$ (^{1}H: δ = 7.29; ^{13}C{^{1}H}: δ = 77.5) as an internal standard. ^{31}P chemical shifts (δ) are given in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0) and $P(OMe)_3$ (δ = 139) as an external standard. − Melting (decomposition) points were determined with a Gallenkamp MFB 595 010 M melting point apparatus. − Electrochemical measurements were performed by cyclic voltammetry in dichloromethane solutions containing $[n\mathrm{Bu_4N}]PF_6$ (0.1 mol·dm^{-3}) at 25 °C and at −5 °C, using a standard three-electrode Pt−Pt−calomel cell and a Radiometer DEA 101 potentiostat. A scan rate of 60 mV·s^{-1} was used. All potentials were referenced to the ferrocene/ferrocenium FcH/Fc$^+$ couple ($E_{1/2}$ = 0.000 V). − Organic solvents (methanol, acetone, tetrahydrofuran, dichloromethane, CCl_4) were freshly distilled before use. Commercially available triphenylphosphane was used without further purification. 2,2′-Biimidazole was synthesised according to a literature procedure.[17] − Microanalyses were performed by the Laboratory of Elemental Analysis of the Technische Universität Bergakademie Freiberg.

Synthesis of $[OsO_2(H_2biim)_2](NO_3)_2{\cdot}CH_3OH$ (3): OsO_4 (**1**) (0.75 mmol, 5 mL of a 0.15 M solution), in CCl_4 was added to 40 mL of a 1:1 methanol/acetone mixture, containing H_2biim (**2**) (250 mg, 1.87 mmol) and HNO_3 (2.0 mmol) at 25 °C. The reaction mixture was heated to reflux for 4 h, and an orange product precipitated. After the reaction mixture was cooled to 25 °C, the orange precipitate was filtered, washed with 20 mL of acetone and dried in an oil-pump vacuum to afford **3**. Yield: 290 mg (0.45 mmol), 60% based on OsO_4. − M.p. gradual decomposition at T > 150 °C. − IR (KBr, cm^{-1}): $\nu_{a(Os=O)}$ 858, $\nu_{a(NO_3^-)}$ 1488, $\nu_{(NH)}$ 3140. − ^{1}H NMR ([D$_6$]DMSO): δ = 7.8 (br. s, 4 H, 5- ,5′-H/H_2biim), 8.5 (br. s, 4 H, 4- ,4′-H/H_2biim). − ^{13}C{^{1}H} NMR ([D$_6$]DMSO): δ = 123.4 (C-5, -5′/H_2bim), 128.7 (C-4, -4′/H_2biim). − Due to the low solubility of **3**, no further resonance signals could be detected. − $C_{13}H_{16}N_{10}O_9Os$ (646.54): calcd. C 24.15, H 2.50; N 21.67; found C 24.19, H 3.00, N 22.63.

Synthesis of $[Os(H_2biim)_2(O{=}PPh_3)_2](NO_3)_3{\cdot}H_2O{\cdot}0.5CH_3OH$ (5): $[OsO_2(H_2biim)_2](NO_3)_2{\cdot}CH_3OH$ (**3**) (200 mg, 0.31 mmol) was suspended in 50 mL of tetrahydrofuran (10% H_2O) containing PPh_3 (**4**) (175 mg, 0.665 mmol). The reaction mixture was heated to reflux for 3 h. HNO_3 (0.6 mL of a 0.5 M solution) was then added and the solution immediately turned from brown to red. The solution was cooled to 25 °C and filtered through a glass filter. All volatiles were then removed in an oil-pump vacuum. The remaining red residue was washed several times with 20 mL of toluene and 20 mL of dry tetrahydrofuran, and was then dried in vacuo to give a crude red product, which was crystallised from a dichloromethane/methanol mixture (4:1) at 25 °C to afford **5** as red crystals. Yield: 290 mg (0.23 mmol), 76% based on **3**. − M.p. 189 °C (dec.). − IR (KBr, cm^{-1}): $\nu_{a(NO_3)}$ 1385, $\nu_{(NH)}$ 3106, $\nu_{(P=O)}$ = 1131. − ^{1}H NMR ([D$_6$]DMSO): δ = 7.0−8.2 (m, C_6H_5, H_2biim). − ^{13}C{^{1}H} NMR ([D$_6$]DMSO): δ = 129.1 (C-*i*/C_6H_5), 130.2 (CH/C_6H_5), 131.8 (CH/C_6H_5), 133.0 (CH/C_6H_5), 135.1 (C-5, -5′/H_2biim), 137.9 (C-4, -4′/H_2biim), 139.9 (C-2, -2′/H_2bim). − ^{31}P{^{1}H} NMR ([D$_6$]DMSO): δ = 36.4. − UV/Vis (CH_2Cl_2): λ_{max} = 360 nm (ε = $3.5{\cdot}10^3$ mol^{-1}·dm^3·cm^{-1}), 388 nm (ε = $3.5{\cdot}10^3$ (mol^{-1}·dm^3·cm^{-1}). − CV (CH_2Cl_2, −5 °C): Os^{III}/Os^{II} redox couple, $E_{1/2}$ = −0.97 V (ΔE = 290 mV), Os^{III}/Os^{IV} redox couple, $E_{1/2}$ = +0.42 V (ΔE = 210 mV). − $C_{48}H_{48}N_{11}O_{12}OsP_2$ (1236.20): calcd. C 47.12, H 3.84, N 12.47; found C 47.36, H 4.19, N 12.11.

Synthesis of $[Os(Hbiim)_2(O{=}PPh_3)_2](NO_3){\cdot}2H_2O$ (6): Potassium hydroxide (30 mg, 0.53 mmol, dissolved in 5 mL of methanol) was added to a solution of $[Os(H_2bim)_2(O{=}PPh_3)_2](NO_3)_3{\cdot}H_2O{\cdot}0.5CH_3OH$ (**5**) (300 mg, 0.26 mmol) in a 4:1 dichloromethane/methanol mixture at 25 °C. The reaction mixture immediately turned from red to violet and KNO_3 subsequently precipitated. The reaction mixture was additionally stirred for 20 min and then filtered through a glass filter. From the filtrate all volatiles were removed in an oil-pump vacuum. The violet residue was washed with 10 mL of H_2O, 5 mL of acetone, and then dried in vacuo to afford **6** as a violet solid. Yield: 240 mg (0.22 mmol), 85% based on **5**. − M.p. 226 °C (dec.). − IR (KBr, cm^{-1}): $\nu_{a(NO_3)}$ 1386, $\nu_{(NH)}$ 3095, $\nu_{(P=O)}$ 1132. − ^{1}H NMR ([D$_4$]methanol): δ = 7.4−8.1 (m, C_6H_5, H_2biim). − ^{13}C{^{1}H} NMR ([D$_4$]methanol): δ = 130.5 (CH/C_6H_5), 133.4 (CH/C_6H_5), 133.6 (CH/C_6H_5), 134.6 (C-5, -5′/H_2biim), 138.6 (C-4, -4′/H_2biim), 141.3 (C-2, -2′/H_2bim). − Due to the low solubility of **6** the C-*i*/C_6H_5 resonance signal could not be detected. − ^{31}P{^{1}H} NMR ([D$_6$]DMSO): δ = 37.1. − UV/Vis (CH_2Cl_2): λ_{max} = 341 nm (ε = $4.5{\cdot}10^3$ mol^{-1}·dm^3·cm^{-1}), 541 nm (ε = $4.5{\cdot}10^2$ (mol^{-1}·dm^3·cm^{-1}). − CV (CH_2Cl_2, 25 °C): Os^{III}/Os^{II} redox couple, E_{red} = −1.29 V (irr.); Os^{III}/Os^{IV} redox couple, $E_{1/2}$ = +0.29 V (ΔE = 180 mV). − $C_{48}H_{44}N_9O_6OsP_2$ (1095.15): calcd. C 52.64, H 4.06, N 11.51; found C 52.82, H 3.89, N 12.11.

X-ray Crystallographic Study of 5: X-ray structure data (total/unique reflections: 20917/13900) were collected at 170 K with a

Bruker SMART CCD diffractometer for the red crystals of **5** (Table 3). The crystal was attached to a glass fiber with perfluoropolyalkyl ether (ABCR GmbH & Co KG, viscosity 1600 cSt.). The unit cell parameter was checked for the presence of higher lattice symmetry using PLATON.[18] Data were corrected for absorption using SADABS.[19] The structure was solved by direct methods (SHELXS-97).[20] Refinement was carried out by full-matrix least-squares techniques on F^2 (SHELXL-97/2).[20] Hydrogen atoms were located from the difference Fourier map. All hydrogen atoms were fully refined with the exception of H13, H49a, H49b, and H49c, which belong to the CH_3OH molecule and were included on their ideal positions, riding on their carrier atoms. All non-hydrogen atoms were refined anisotropically. The structural data (without structural factors) are deposited at the Cambridge Crystallographic Data Centre and can be acquired under the depositing number CCDC-152194 under the following address: CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$Mo^{V}_{2}O_{4}^{2+}$ Directs the Formation and Subsequent Linking of Potential Building Blocks under Different Boundary Conditions: A Related Set of Novel Cyclic Polyoxomolybdates

Achim Müller,*[a] Christoph Kuhlmann,[a] Hartmut Bögge,[a] Marc Schmidtmann,[a] Mario Baumann,[a] and Erich Krickemeyer[a]

Dedicated to Prof. Dieter Sellmann on the occasion of his 60th birthday

Keywords: Molybdenum / Polyoxometalates / Clusters / Ring structures

The synthesis and structural characterization of a novel series of deep-red mixed-valence (Mo^{VI}/Mo^{V}) compounds with nano-sized spherically shaped cluster anions containing 18, 40, or 54 Mo atoms, respectively, is reported: $Na_{10}[H_4Mo_{18}O_{56}(CH_3COO)_2] \times$ ca. 36 $H_2O \times 3$ CH_3COOH (**1**), $(NH_4)_{12}Na_{12}[Mo_{40}O_{128}] \times$ ca. 70 H_2O (**2**), $(NH_4)_{12}Na_{20}[H_4Mo_{54}O_{168}(CH_3COO)_4] \times$ ca. 64 H_2O (**3**), $Na_{32}[H_4Mo_{54}O_{168}(CH_3COO)_4] \times$ ca. 128 H_2O (**4**), and $Na_{32}[H_4Mo_{54}O_{168}(CH_3COO)_4] \times$ ca. 98 H_2O (**5**). Clusters **3**, **4**, and **5** differ in the packing of the rings in the lattice. The anions are easily formed by reduction of an acidified aqueous molybdate solution while the deliberately generated $Mo^{V}_{2}O_{4}^{2+}$ group – abundant in all clusters – has a directing influence on the formation of the preliminary building blocks. Furthermore, it is possible to control the ratio of the $\{Mo^{V}_{2}\}$ units to the Mo^{VI} centres by adjusting the specific concentration of the employed reducing agent.

Introduction

Obtaining a strategy for the formation of complex molecular systems with desired properties − constructed from simple building blocks by conservative self-assembly processes − is an ambitious endeavour in contemporary chemistry. In this context, the polyoxomolybdate system under consideration shows a variety of units (either as existing or virtual species), whose linking can be controlled by the deliberate generation of stable and transferable fragments.[1] An important step for us in this regard was, for example, the use of pentagonal $\{(Mo)Mo_5\}$-type units that allowed us not only to adjust the size of giant spherical species, but also to generate such types of molecules with practically 150 unpaired electrons at their periphery by linking these pentagonal units with Fe^{III} ($S = {}^5/_2$) centres.

A prominent feature of the chemistry of molybdenum is the formation of numerous polyoxomolybdate(VI) anions in aqueous solutions. Depending on the boundary conditions, the large number of species existing simultaneously in strongly overlapping equilibria can be considered − in this context − as an extensive library of building blocks, accessible on demand. The equilibria (the dynamics of aggregation reactions) are mostly characterized by the degree of acidity. On the other hand, the negative charge and therefore the nucleophilicity of intermediate cluster fragments can be increased by reduction, resulting in further attraction of electrophiles and thus in growth of the molecular systems.[2]

Reducing an acidified aqueous solution of ammonium heptamolybdate with sodium dithionite − under conditions that favour the generation of $Mo^{V}_{2}O_{4}^{2+}$ [= $Mo^{V}_{2}O_{4}(H_2O)_6^{2+} = \{Mo^{V}_{2}\}$] units (controlled pH and redox potential), led to the simultaneous precipitation of two compounds, $(NH_4)_{12}Na_{12}[Mo_{40}O_{128}] \times$ ca. 70 H_2O (**2**) and $(NH_4)_{12}Na_{20}[H_4Mo_{54}O_{168}(CH_3COO)_4] \times$ ca. 64 H_2O (**3**), which are easily distinguishable by their different crystal shapes.[3]

Since the ratio of the red lozenge-shaped crystals of **2** relative to the red needle-shaped ones of **3** depends upon the amount of reducing agent, our challenge was thus to find suitable conditions − based on our knowledge of the different Mo^{V}/Mo^{VI} ratios in **2a** and **3a** − for obtaining both compounds in a pure form. These experiments led to the discovery of a series of related new compounds.[4]

Results and Discussion

All mentioned cluster anions were formed by stepwise growth processes, initiated and directed by the in situ generated $Mo^{V}_{2}O_{4}^{2+}$ units. (During the last decade, several other compounds containing one, two, or more $\{Mo^{V}_{2}\}$ units have been reported.[5]) The important result, however, in the context of our a priori intention, is that all the clusters with $\{Mo^{V}_{2}\}$ groups reported here are distinguishable by their $\{Mo^{V}_{2}\}/Mo^{VI}$ ratios that result from the different redox equivalents of reducing agent used and from the proton concentration or acidity of the reaction medium. Table 1 summarizes these trends and includes clusters of the type $\{Mo_{48}\}$[6] and $\{Mo_{132}\}$[7] that also contain $\{Mo^{V}_{2}\}$ building

blocks. Notably, at *lower* pH values, molybdenum blue species like the ring-shaped $\{Mo_{154}\}$ cluster are formed where no $\{Mo_2^V\}$ units are present.[8]

All compounds were characterized by elemental analyses [including cerimetric titration for the determination of the (formal) number of reduced centres], thermogravimetry (to determine the amount of crystal water), spectroscopy (UV/Vis, IR, Raman), and single-crystal X-ray structure analyses [including bond valence sum (BVS) calculations for the determination of the position of the H_2O ligands, as well as for the distinction between Mo^{VI} and Mo^V centres]. The crystallographic data for the diamagnetic, mixed-valence compounds $Na_{10}[H_4Mo_{18}O_{56}(CH_3COO)_2] \times$ ca. 36 $H_2O \times$ 3 CH_3COOH (**1**), $(NH_4)_{12}Na_{12}[Mo_{40}O_{128}] \times$ ca. 70 H_2O (**2**), $(NH_4)_{12}Na_{20}[H_4Mo_{54}O_{168}(CH_3COO)_4] \times$ ca. 64 H_2O (**3**), $Na_{32}[H_4Mo_{54}O_{168}(CH_3COO)_4] \times$ ca. 128 H_2O (**4**), and $Na_{32}[H_4Mo_{54}O_{168}(CH_3COO)_4] \times$ ca. 98 H_2O (**5**) are given in Tables 2 and 3.

Detailed structural information can be obtained from Figures 1–4. Figure 1 illustrates the importance of the mentioned $Mo_2^VO_4^{2+}$ dumb-bell-type "linkers" (equivalent to the $\{Mo_2^VO_{10}\}$ structural building block in the solids, which of course does not exist in solution) for the $\{Mo_{18}\}$-, $\{Mo_{40}\}$-, and $\{Mo_{54}\}$-type clusters. These units have a high formation tendency in molybdate solutions in the presence of reducing agents at pH values relevant for the present investigations.

As an example, the $\{Mo_{18}\}$ cluster anion **1a**[9] (Figures 1 and 4) reflects the tendency of even small polyoxomolybdates to adopt ring-shaped structures. The anion itself has approximately C_{2h} symmetry, and consists of two identical building blocks – denoted as *cis*-$\{Mo_9^*\}$ – each containing five Mo^{VI} centres and two $\{Mo_2^V\}$ units (the asterisk * denotes the presence of reduced centres, i.e. of $\{Mo_2^VO_{10}\}$ groups, either as $\{Mo_2^*\}$ units or as part of the $\{Mo_8^*\}$ or $\{Mo_9^*\}$ framework). These four $\{Mo_2^V\}$ units

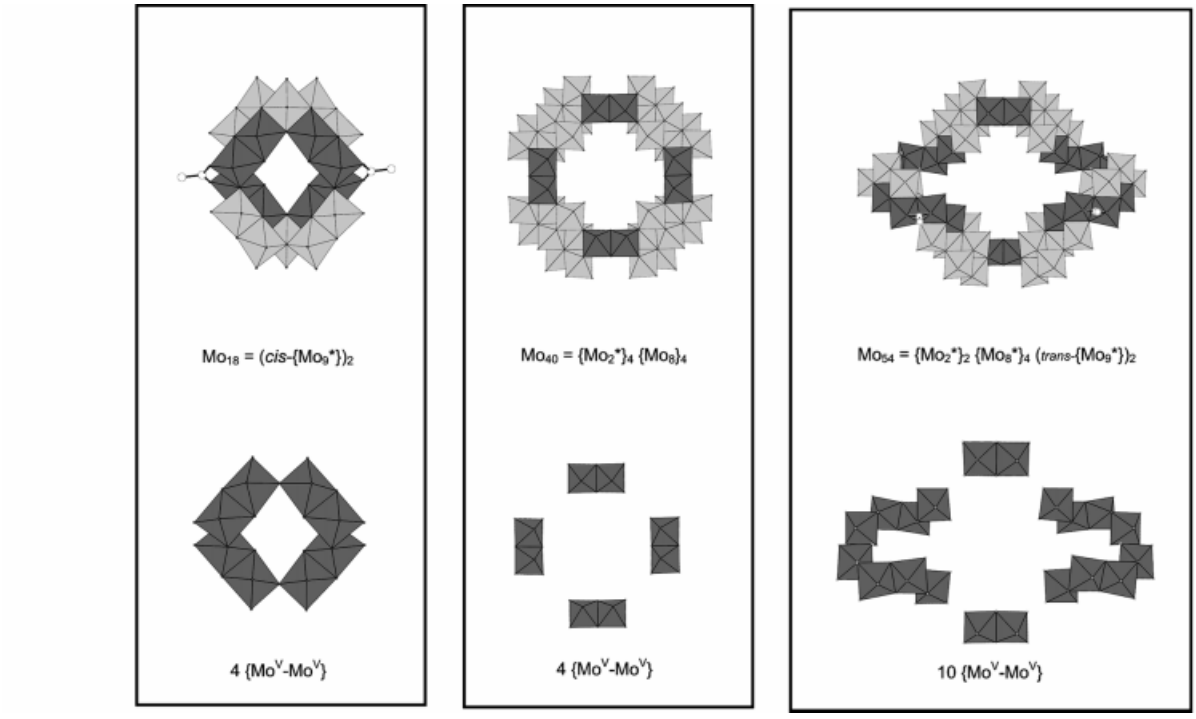

Figure 1. Polyhedral representations of the complete $\{Mo_{18}\}$ (**1a**) (left), $\{Mo_{40}\}$ (**2a**) (centre), and $\{Mo_{54}\}$ (**3a**–**5a**) (right) clusters based on the $\{Mo_2^*\}$ dumb-bells with Mo^V–Mo^V single bonds, highlighted in dark-grey (top); for clarity, the abundant $\{Mo_2^*\}$ groups are also shown separately (bottom)

form an oxomolybdenum(V) core fragment (see Figure 1, bottom) with a puckered cyclic framework comparable to that of the compound $Mo_8O_{16}(OMe)_8(PMe_3)_4$.[10] A more detailed view can be obtained from Figure 4, which also elucidates the notation *cis*- and *trans*-{Mo_9*} (occurring in the {Mo_{54}} cluster anion) regarding the different positions of the two molybdenum octahedra directed towards the central {Mo_7} moiety (note that the local symmetry of the *cis*-{Mo_9*} unit is C_s).

The polymorphic compound **2** crystallizes in two different space groups, $P2_1/m$ and *Pnma*. Its ring-shaped anions form layers that are separated by the cations. Depending on the orientation of the anions of two layers towards each other, either the monoclinic or the orthorhombic polymorph results.[11] The {Mo_{40}} anion **2a** (Figure 1) consists of 168 non-hydrogen atoms, i.e. 40 molybdenum centres (including eight Mo^V) and 128 oxygen atoms, and has approximately C_{4v} symmetry whereby eight {$Mo^{VI}O_6$ } and two {Mo^VO_6} octahedra form one {Mo_{10}} unit possessing a mirror plane. Cleaving two of the terminal octahedra of this {Mo_{10}} unit leads to an {Mo_8} framework resembling the γ-octamolybdate that was recently isolated as a main constituent of a nonamolybdate formed under a comparable proton concentration.[12] Here we prefer the alternative description: Four {Mo_2^V} groups link four {Mo_8} units (note that these units are not identical with the above-mentioned γ-octamolybdate), corresponding to the formula given above (Figure 1). Whereas in the case of **2** [containing the {Mo_{40}} (= {Mo_2*}$_4${Mo_8}$_4$) cluster anion **2a**] the {Mo_2^V} building units are not the dominating structural feature, this is actually the case for the {Mo_{54}} (= {Mo_9*}$_2$-{Mo_8*}$_4${Mo_2*}$_2$) cluster anion of **3**, **4**, and **5**, as well as for the {Mo_{18}} = {Mo_9*}$_2$ cluster anion of **1**, where all such units are directly connected (see Figures 1−4).

The crown-shaped (twisted) anion {Mo_{54}} (= {Mo_9*}$_2$ {Mo_8*}$_4${Mo_2*}$_2$, see Figure 2), abundant in compounds **3**, **4**, and **5**, consists of 238 non-hydrogen atoms, i.e. 54 molybdenum atoms (including 20 Mo^V), 176 oxygen, and eight carbon atoms, and has approximately C_{2v} symmetry (in the crystal lattice the site symmetry of the twisted anion is in all cases *i*). The formulation based on the three different building blocks ({Mo_2*}, {Mo_8*}, {Mo_9*}) − shown in Figure 2 − corresponds to the above-mentioned formula. Figures 3 and 4 show a comparison of the latter two building blocks with the two other related cluster anions **1a** and **2a**. The {Mo_8*} unit, containing six $Mo^{VI}O_6$ as well as two Mo^VO_6 octahedra, can be (formally) derived from the corresponding {Mo_8} unit of the {Mo_{40}} anion by a two-electron reduction step, i.e. by formation of an {Mo_2^V} group (Figure 3). The other building block (denoted *trans*-{Mo_9*}), present twice in the {Mo_{54}} cluster, consists of nine molybdenum−oxygen octahedra, and has approximately C_2 symmetry. Four Mo^V centres form two {Mo_2^V} units and point to opposite sites thereby enabling an interesting comparison with the *cis*-{Mo_9*} unit of the {Mo_{18}} cluster (Figure 4). Due to the different orientation of the {Mo_2^V} units towards each other (compared to the *cis*-{Mo_9*} units), the further linking of these structural building blocks is already fixed.

The {Mo_{54}} cluster anion can be "constructed" in the following way: Two of the {Mo_8*} units are linked by an {Mo_2^V} unit resulting in a super-unit of the type {Mo_8*}

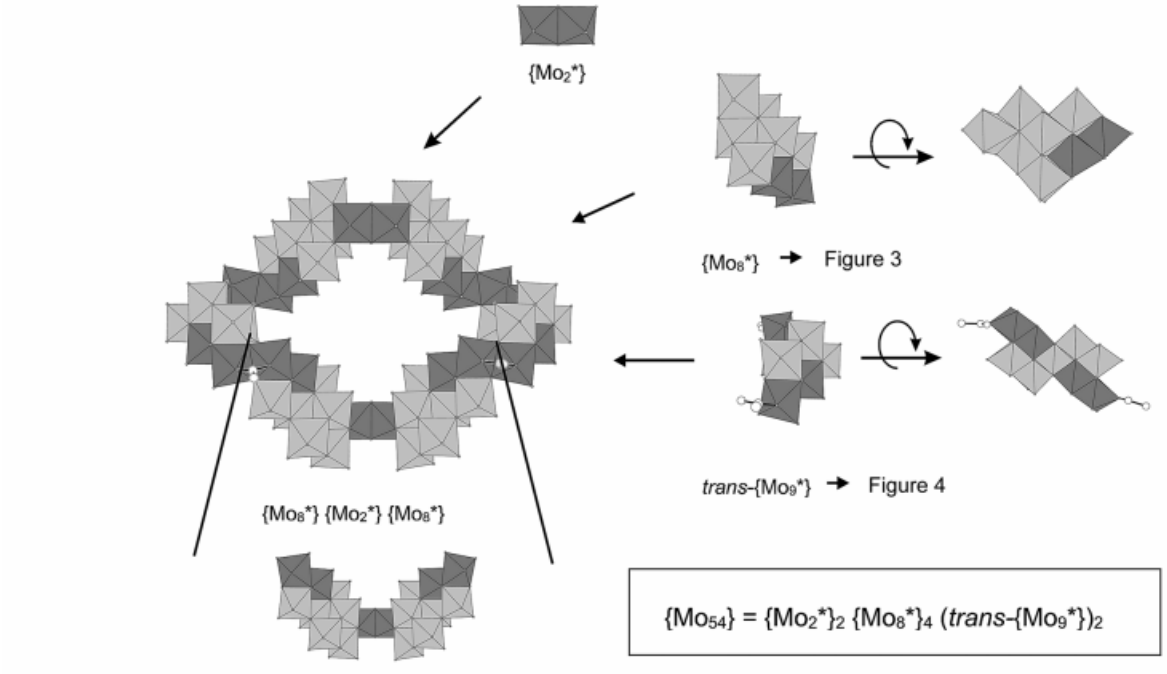

Figure 2. Polyhedral representation of the {Mo_{54}} cluster (left) and its three formal building blocks (right): {Mo_2*}, {Mo_8*}, and {Mo_9*} ({Mo_2*} = $[Mo_2^VO_4O_6]^{10-}$, {Mo_8*} = $[Mo_2^VMo_6^{VI}O_{28}]^{10-}$, and {$Mo_9$*} =$[(\mu_3\text{-}OH)_2Mo_4^VMo_5^{VI}O_{26}(CH_3COO)_2]^{10-}$); one super-unit of the type {Mo_8*}{Mo_2*}{Mo_8*} is also shown (bottom)

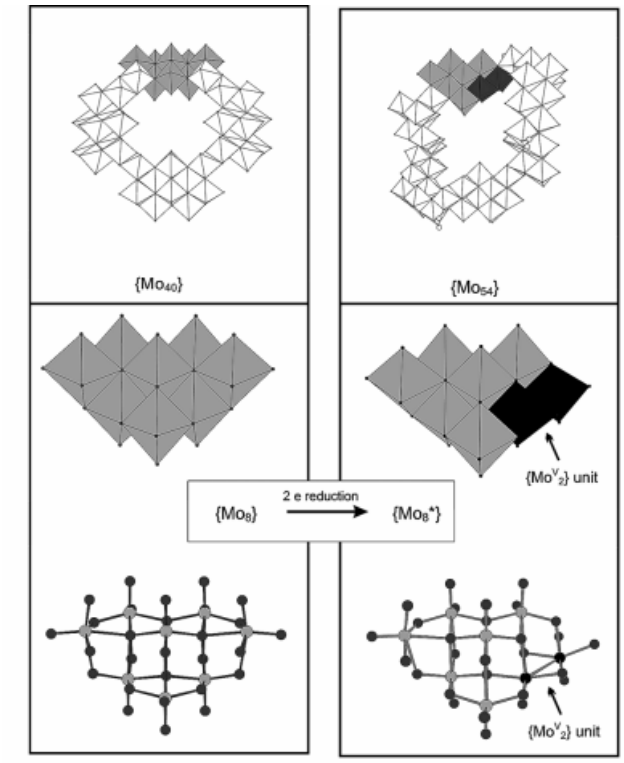

Figure 3. Structural comparison of an $\{Mo_8\}$ unit derived from $\{Mo_{40}\}$ (left) with the corresponding $\{Mo_8{*}\}$ unit (containing one $\{Mo^V{-}Mo^V\}$ type unit) of the $\{Mo_{54}\}$ (right) cluster in polyhedral representation (top) and as ball-and-stick model (bottom); ball-and-stick representation: Mo^V dark-grey, Mo^{VI} light-grey, O atoms medium grey; polyhedral representation: $\{Mo^V_2\}$ units dark-grey, $\{Mo^{VI}{}_mO_n\}$ moieties light-grey

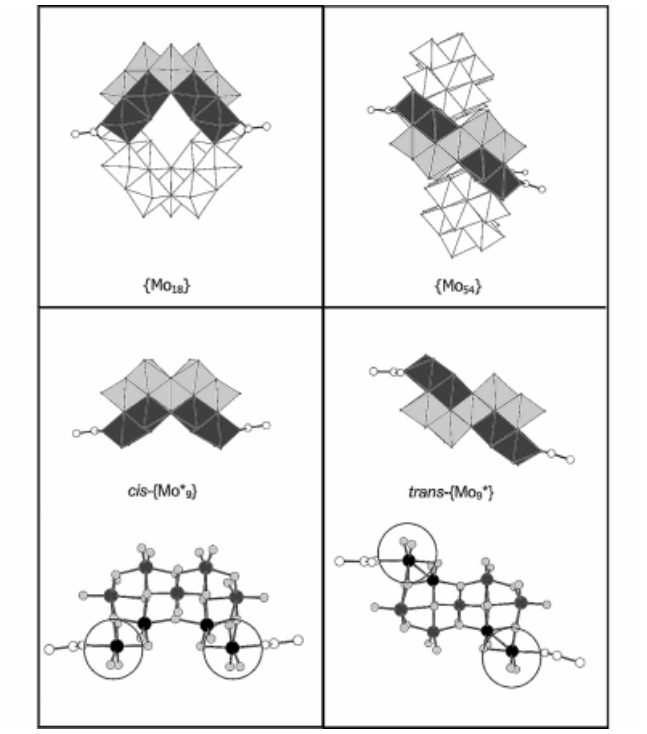

Figure 4. Structural comparison of $\{Mo_9{*}\}$ units − derived from the $\{Mo_{18}\}$ (top, left) and from the $\{Mo_{54}\}$ cluster (top, right) − in polyhedral and ball-and-stick representation; the classification of *cis* and *trans* corresponds to the position of the $\{Mo^V{-}Mo^V\}$ units relative to each other; ball-and-stick representation: Mo^V black, Mo^{VI} light-grey, O atoms medium grey; polyhedral representation: $\{Mo^V_2\}$ units dark-grey, $\{Mo^{VI}{}_mO_n\}$ moiety light-grey; the acetate ligands (carbon: open circle) are shown in both cases in ball-and-stick representation)

$\{Mo_2{*}\}\{Mo_8{*}\}$. Two of these are finally bridged at both ends through edge-sharing with the two *trans*-$\{Mo_9{*}\}$ building blocks and by an acetate ligand (Figures 2 and 4). Remarkably, the construction of the $\{Mo_{40}\}$ cluster can be described in the same way: Two super-units of the type $\{Mo_8\}\{Mo_2{*}\}\{Mo_8\}$ (i.e., the aforementioned non-reduced $\{Mo_8\}$ groups!) are linked by additional $\{Mo_2{*}\}$ groups resulting in the bowl-shaped anion.

Interestingly, it is possible to vary the packing of the cluster units by adding different reagents, e.g., acetylacetone or sodium chloride. Comparing the sodium salts of the $\{Mo_{54}\}$ compounds **4** and **5**, it is obvious that the crystal water content, and thus the unit cell volume, is reduced by ca. 1:7 through replacing sodium chloride by acetylacetone during the crystallization process. Adding other cations, e.g. ammonium leads to a further shrinking of the cell and relevant investigations are presently in progress.

Looking at the charge per Mo atom and the value $R = \Sigma O/\Sigma Mo$ for all aggregates shows values that are practically constant, except for the charge per Mo atom in case of the $\{Mo_{132}\}$ ball-type species and its derivative. A value of $R \approx 3$ is observed in many cases, and even for large aggregates like the big wheel $[(MoO_3)_{154}H_{14}]^{14-}$.

Conclusions

Our synthetic route has as its aim the deliberate synthesis of clusters based on the use of $\{Mo^V_2\}$ units under different boundary conditions. In this context, it is interesting to note that the $\{Mo^{VI}_8\}$ building block, which is important for the present preparation conditions,[13] can at least formally be reduced to the actual $\{Mo_8{*}\}$ building block containing one $\{Mo^V_2\}$ dumb-bell unit (Figure 4) and, in the presence of additional molybdenum and reducing agent, to the $\{Mo_9{*}\}$ building block. The general strategic approach to control molecular growth by conservative self-organization processes offers, in principle, a wide variety of new species that can be constructed from simple building blocks.

Experimental Section

General Techniques: All reactions were performed using 100-mL Erlenmeyer flasks where no attempts were made to exclude oxygen. All chemicals except sodium dithionite were at least of reagent grade, and were used as supplied. Note, that sodium dithionite (85% iodometrically) should be fresh and powdered prior to use. The use of aged charges, which contain more water and might be

partly decomposed, will result in lower yields and gives less crystalline materials. − Elemental analyses (C,H,N) were performed using a LECO CHN 920 analyzer. The nitrogen values were determined by the Kjeldahl method, the sodium content by flame photometry. (The error limits for the determination of the sodium and ammonium cations in **2** and **3** restrict somewhat the reliability of their quantity in the formula unit by ±1.) − Vibrational spectroscopy was carried out with a Bruker IFS66/FRA106. − The amounts of crystal water were determined thermogravimetrically with a Shimadzu TA-60WSI thermo-balance under argon. − The UV/Vis spectra were measured using either a Shimadzu UV-160A or a Beckman Acta M IV instrument (solid with cellulose as reference). The compounds are stable in dry air but decompose easily while dissolving in water.

Preparation of 1: To a solution of 7.70 g of sodium molybdate dihydrate (31.8 mmol), 50.0 g of sodium acetate trihydrate (367.4 mmol), and 5.0 g of sodium chloride (85.6 mmol) in 300 mL of H_2O, an aqueous hydrazine sulfate solution (0.1 M, 61 mL) and afterwards 75 mL of acetic acid (100%) were added. The reaction medium was heated whilst stirring for 4 d at 35 °C (slow colour change from green to brownish-green) while the volume of the solution was kept constant by adding water. The solution was subsequently cooled to room temperature and filtered. The filtrate was kept in an open beaker and the volume of the solution was reduced by slow evaporation (up to 130 mL). Crystalline **1** was filtered off after 1 week and dried with $CaCl_2$. Yield 2.0 g (30% based on Mo). − IR (KBr pellet): $\tilde{\nu}$ = 3440 (s), 3162 (s), 1636 (m) [$\delta(H_2O)$], 1541 (m), 1443 (m), 1394 (sh), 1330 (m), 1028 (w), 960 (sh), 935 (s), 898 (m), 712, 636, 565, 498, 411. − Raman (λ_e = 1064 nm, undiluted powder): $\tilde{\nu}$ = 966, 930 [ν(Mo=O)], 747, 774, 662, 574, 507, 358, 330, 286, 200, 157 cm^{-1}. − UV/Vis (cellulose): λ_{max} = ca. 260, ca. 340, ca. 395, ca. 535, ca. 1040 nm. − $C_{10}H_{94}Mo_{18}Na_{10}O_{102}$ (3803.6): calcd. C 3.16, H 2.49, Na 6.04, H_2O 17.0; found C 3.3, H 2.4, Na 8.2, H_2O 14. − Cerimetric titration: 8±1 e.

Preparation of 2. − (a) After a solution of 3.00 g of ammonium heptamolybdate tetrahydrate (2.4 mmol) in 25 mL of water was acidified with 0.8 mL of acetic acid (100%), 0.20 g of sodium dithionite (1.1 mmol) were added (colour change to deep-green). After stirring the solution for 5 min, 3.00 g of sodium chloride was dissolved and the resulting solution was allowed to stand for 4.5 h for crystallization. The precipitated red lozenge-shaped crystals were filtered off, washed with aqueous acetone (50 vol-%) and finally dried in air. Yield 0.28 g (9% based on Mo). ***Note:*** After 5 h, crystals of **3** also start to precipitate. Pure crystalline **2**, i.e. an {Mo_{54}}-free product, can be obtained by replacing acetic acid by hydrochloric acid (**2** does not contain acetate ligands!). − **(b)** After a solution of 3.00 g of ammonium heptamolybdate tetrahydrate (2.4 mmol) in 25 mL of water was acidified with 3.0 mL of hydrochloric acid (1 M), 0.20 g of sodium dithionite (1.1 mmol) was added (colour change to deep-green). After stirring the solution for 5 min, 3.00 g of sodium chloride was dissolved and the resulting solution was allowed to stand for 4.5 h for crystallization. The precipitated red lozenge-shaped crystals were filtered off, washed with aqueous acetone (50-vol%) and finally dried in air. − Yield 0.58 g (18% based on Mo). ***Note:*** Comparing the two preparation methods the total yield was higher when hydrochloric acid was used, but the crystals were less suitable for single-crystal X-ray structure analysis. − IR (KBr pellet): $\tilde{\nu}$ = 3440 (s), 3162 (s), 1617 (m) [$\delta(H_2O)$], 1400 (s) [$\delta_{as}(NH_4^+)$], 946 (s) [ν(Mo=O)], 903 (sh), 869 (s), 765 (m), 724 (s), 652 (s), 486 (m) cm^{-1}. − Raman (λ_e = 1064 nm, undiluted powder): $\tilde{\nu}$ = 965, 937 [ν(Mo=O)], 909, 989, 842, 774, 723, 489, 375, 347, 276, 203, 143 cm^{-1}. − UV/Vis (cellulose): λ_{max} = ca. 285, ca. 380 nm. − $H_{188}Mo_{40}N_{12}Na_{12}O_{198}$ (7638.9): calcd. H 2.46, N 2.20, Na 3.61, H_2O 16.5; found H 2.08, N 2.22, Na 3.8, H_2O 14 (calcd. for compound containing 70 H_2O). − Cerimetric titration: 8±1 e.

Preparation of 3. − (a) After acidifying a solution of 3.00 g of ammonium heptamolybdate tetrahydrate (2.4 mmol) and 0.5 g of sodium acetate trihydrate in 25 mL of water with 3.0 mL of hydrochloric acid (1 M), 0.30 g of sodium dithionite (1.7 mmol) was added (colour change to deep-green). After stirring for 5 min, 3.00 g of sodium chloride was added and the resulting solution was allowed to stand for crystallization for 15−18 h. The precipitated red needle-shaped crystals were filtered off, washed with acetone and finally dried in air. Yield 0.67 g (20% based on Mo). − **(b)** After a solution of 3.00 g of ammonium heptamolybdate tetrahydrate (2.4 mmol) in 25 mL of water was acidified with 0.8 mL of acetic acid (100%), 0.30 g of sodium dithionite (1.7 mmol) was added (colour change to deep-green). After stirring the solution for 5 min, 3.00 g of sodium chloride was dissolved and the resulting solution was allowed to stand for 12−15 h for crystallization. The precipitated red needle-shaped crystals were filtered off, washed with aqueous acetone (50-Vol%), and finally dried in air. − Yield 0.3 g (8% based on Mo). ***Note:*** Comparing the two preparation methods, the total yield is higher when hydrochloric acid is used (similar to compound **2**), but the crystals are less suitable for single-crystal X-ray structure analysis. − IR (KBr pellet): $\tilde{\nu}$ = 3459 (s), 1624 (m) [$\delta(H_2O)$], 1540 (m) [$\nu_{as}(COO^-)$], 1436 (sh), 1402 (s), 962 (m), 944 (m) [ν (Mo=O)], 899 (m), 860 (m), 716 (m), 660 (m), 624 (m), 490 (m) cm^{-1}. − Raman (λ_e = 1064 nm, undiluted powder): $\tilde{\nu}$ = 969, 945, 936 [ν(Mo=O)], 765, 660, 491, 380, 357, 280, 242, 204 cm^{-1}. − UV/Vis (cellulose): λ_{max} = ca. 270, ca. 325, ca. 360 nm. − $C_8H_{192}Mo_{54}N_{12}Na_{20}O_{240}$ (9938.3): calcd. C 0.97, H 1.93, N 1.68, Na 4.63, H_2O 11.6; found C 0.94, H 2.38, N 1.68, Na 4.3, H_2O 11. − Cerimetric titration: 20±1 e.

Preparation of 4: To a solution of 4.50 g of sodium molybdate dihydrate (18.6 mmol) and 1.00 g of sodium acetate trihydrate in 25 mL of water, 1.00 g of sodium dithionite (5.75 mmol) was added (colour change to deep-brown). After stirring for 5 min, the solution was acidified with 3.00 mL of hydrochloric acid (1 M), stirred for an additional 15 min and finally allowed to stand for crystallization. The red needle-shaped crystals were filtered off after 7 d, washed with acetone and subsequently dried in air. − Yield 0.37 g (10% based on Mo). − IR (KBr pellet): $\tilde{\nu}$ = 3459 (s), 1635 (m) [$\delta(H_2O)$], 1541 (m) [$\nu_{as}(COO^-)$], 1445 (m), 961 (m), 944 (m) [ν(Mo=O)], 900 (m), 861 (m), 718 (m), 667 (m), 620 (m), 491 (m) cm^{-1}. − Raman (λ_e = 1064 nm, undiluted powder): $\tilde{\nu}$ = 975, 947, 936 [ν(Mo=O)], 838, 762, 663, 509, 478, 358, 284, 243, 205 cm^{-1}. − UV/Vis (cellulose): λ_{max} = ca. 280, 320, 360 nm. − $C_8H_{272}Mo_{54}Na_{32}O_{304}$ (11150.7): calcd. C 0.86, H 2.44, Na 6.60, H_2O 20.6; found C 0.88, H 2.10, Na 6.8, H_2O 18. − Cerimetric titration: 20±1 e.

Preparation of 5: To a solution of 4.50 g of sodium molybdate dihydrate (18.6 mmol) in 25 mL of water, 2.0 mL of acetylacetone was added dropwise (colour change to yellow) followed by 1.00 g of sodium dithionite (5.75 mmol) (colour change to deep-brown). After stirring for 5 min, the reaction medium was acidified with 2.0 mL of acetic acid (100%) and stirred for an additional 15 min. After 3 d, the red needle-shaped crystals were filtered off, washed with aqueous acetone (70 vol-%) and finally dried in air. − Yield 0.33 g (10% based on Mo). − IR (KBr): $\tilde{\nu}$ = 3459 (s), 1635 (m) [$\delta(H_2O)$], 1541 (m) [$\nu_{as}(COO^-)$], 1445 (m), 961 (m), 944 (m) [ν(Mo=O)], 900 (m), 861 (m), 718 (m), 667 (m), 620 (m), 491 (m) cm^{-1}. − Raman (λ_e = 1064 nm, undiluted powder): $\tilde{\nu}$ = 974, 952,

X-ray Crystallography: Crystals were taken directly from the mother liquor and mounted on a glass fibre at 183 K. In case of **3**, the crystals were first dried and then mounted for X-ray investigations. Diffraction data were collected with a Bruker AXS three-circle diffractometer with a 1 K-CCD detector. The structures were solved by direct methods using SHELXS-97 and refined by full-matrix least squares with SHELXL-93/97. All non-hydrogen atoms were refined anisotropically. The assignment of Mo^V and Mo^{VI} centres, as well as the protonation, clearly follows from bond valence sum calculations[14] and is in agreement with the charge on the cluster anions and the fact that all the Mo^V centres form dumbbell-type $\{Mo_2^V\}$ units with covalent Mo–Mo single bonds. Due to disorder, not all cations could be localized. The crystallographic data for **1** and **2** are given in Table 2, for **3**, **4**, and **5** in Table 3. Further details on the crystal structure investigation of **2** may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany [Fax: (internat.) + 49-(0)7247/808-666; E-mail: crysdata@fiz-karlsruhe.de] on quoting the depository numbers CSD-411693 and 411694. Crystallographic data (excluding structure factors) for compounds **1** and **3–5** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-156640 (**1**), -156641 (**3**), -156642 (**4**), and -156643 (**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Tellurium / Chalcogens / Metallacycles / Imidodiphosphinates / Crystal structure

The synthesis of the following organotellurium(IV) compounds $[C_4H_8TeI\{Ph_2(Se)PNP(Se)Ph_2\}]$ (**2**), $[C_4H_8TeI\{Ph_2(S)PNP(S)Ph_2\}]$ (**3**), $[C_8H_8TeI\{Ph_2(S)PNP(S)Ph_2\}]$ (**4**), $[C_4H_8Te\{Ph_2(S)PNP(S)Ph_2\}_2]$ (**5**), and $[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}]_2[I, I_3]$ (**6**) was achieved. These compounds have been characterized by microanalysis, multielement NMR and IR spectroscopy, positive ion FAB mass spectrometry and single-crystal X-ray diffraction analysis. The solid-state structures show that the coordination geometry at the tellurium center in every derivative can be described as a distorted pseudo-trigonal bipyramid, in which the lone-pair of electrons is supposed to occupy an equatorial position. The selenium and sulfur ligands exhibit an aniso-bidentate chelating coordination mode on interaction with the tellurium center. When the aniso-bonded donor atoms are included in the coordination sphere, the environment about Te becomes distorted square-pyramidal for the monochelate derivatives **2**–**4** and distorted octahedral for the bis(chelate) compound **5**. In compound **6**, two oxygen ligands act as bridges between two $C_4H_8Te–O–TeC_4H_8$ units, forming a 16-membered cationic ring. The anions, I^- and I_3^-, are located above and below the twisted ring with Te···I interactions ranging from 3.532(2) to 3.902(3) Å.

Introduction

We became interested in the chemistry of organotellurium(IV) in conjunction with our studies on the coordination chemistry of heavy main group elements with tetraphenyldichalcogenoimidodiphosphinate ligands. It became apparent that the $[Ph_2(Q)PNP(Q')Ph_2]^-$ [Q/Q′ = O/O (**1a**), S/S (**1b**), Se/Se (**1c**), O/S (**1d**), S/Se(**1e**)] ligands are ideal for studying the influence of distinct donor-atom sets and the stereochemical influence of the electron lone-pair on the geometry of main group metal complexes.[1−5] This is because they offer the opportunity to vary both the donor atoms and because of the large degree of conformational freedom observed in the variable M−Q−P angle and P−N−P conjugated systems. Some interesting and unusual examples of compounds containing these ligands are certain lanthanide complexes,[1] the quasi-ideal *trans*-octahedral organotin compounds,[2] the true square-planar $[Sn\{Ph_2(Se)PNP(Se)Ph_2\}_2]$,[3] $[Te\{Ph_2(Q)PNP(Q)Ph_2\}_2]$ (Q= S[6] and Se[7]), $[Se\{Ph_2(Q)PNP(Q)Ph_2\}_2]$ (Q= S[8] and Se[9]) complexes, and the tellurium-containing 12-membered ring, $[4\text{-}MeOC_6H_4Te\{Ph_2(S)PNP(S)Ph_2\}]_2$.[7]

We decided to synthesize new 2,2-dihydrobenzotellurophene and 1,1-tetrahydrotellurophene derivatives employing the symmetrical imidodichalcogenidephosphinates **1a**−**c** in order to study the effect of the donor atom strength on the tellurium geometry and the comparison with analogous organotellurium(IV) derivatives containing oxygen- sulfur- and selenium-based ligands such as dithio-[10−12] and monothiocarbamates,[13] dithiophosphinates,[12] dithiophosphates,[14] carboxylates,[15] $R_2(Q)PNP(Q')R_2$,[6,7,16,17] and $R_2(S)P(CH_2)_2P(S)R_2$,[17] etc.

Here we report five new organotellurium(IV) compounds, $[C_4H_8TeI\{Ph_2(Se)PNP(Se)Ph_2\}]$ (**2**), $[C_4H_8TeI\{Ph_2(S)PNP(S)Ph_2\}]$ (**3**), $[C_8H_8TeI\{Ph_2(S)PNP(S)Ph_2\}]$ (**4**), $[C_4H_8Te\{Ph_2(S)PNP(S)Ph_2\}_2]$ (**5**), and the ionic ring $[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}]_2[I, I_3]$ (**6**). They have been characterized by microanalysis, multielement NMR and IR spectroscopy, positive ion FAB mass spectrometry and single-crystal X-ray diffraction analysis.

Results and Discussion

The reported compounds were obtained by the reaction of $C_4H_8TeI_2$ or $C_8H_8TeI_2$ with the appropriate sodium or potassium salt of the ligands in either a twofold excess or in equimolecular amounts. The mono- or disubstituted derivatives were isolated from the selenium and sulfur ligands [RTeIL] [R = C_4H_8, C_8H_8 (**2**−**4**)] and $[C_4H_8TeL_2]$ (**5**).

As byproducts the known Te^{II} bis(chelates), $[Te\{Ph_2(Q)PNP(Q)Ph_2\}_2]$ (Q= S[6] and Se[7]), were also obtained. By using the oxygen ligand, only the unexpected 16-membered ionic ring $[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}]_2^{2+}$ (**6**) was isolated. This compound is probably formed from a 1,1-oxydiiodine ditellurium compound ($[C_4H_8TeI]_2O$) in the reaction mixture as the analogous 1,1-oxydibromide[18] was isolated previously from aqueous alkali solution. The formation of **6** may be explained by the fact that the $C_4H_8TeI_2$ was added to the non-anhydrous alkali solution in which the ligand salt was synthesized. Two of the oxygen ligands could then react with the $[C_4H_8TeI]_2O$ to form the ring system. All the compounds are soluble in common organic solvents (CH_2Cl_2, $CHCl_3$, C_6H_6). However, in solution they undergo rapid exchange and reductive elimination, such as has been observed previously in many chalcogen-bonded organotellurium(IV) derivatives.[12−14,16b,16c,17] Due to the difficulty of relying on the characterization in solution, every effort was made to obtain X-ray quality crystals of each compound.

The NMR spectroscopic data presented in the Exp. Sect. were assigned based on the spectra recorded immediately after dissolution in $CDCl_3$ solution. The ^1H and ^{13}C NMR spectra show the expected methylene (and also aromatic for **4**) protons and carbon atoms from the organoyltellurium moiety, as well as the phenyl resonance from the ligands. The signal of the CH_2 group attached to the tellurium center experiences a small upfield shift relative to that of the starting materials $C_4H_8TeI_2$ and $C_8H_8TeI_2$. The peaks of the 16-membered ring are the most upfield-shifted. The peaks in the phenyl region of the spectra are similar to those found for other derivatives containing imidophosphinates, but are poorly resolved so that the phosphorus-carbon coupling was ill-defined in some cases and the *ipso*-carbon resonances are not observed in others. In all cases the spectra recorded after one day, in the case of the selenium compound after a few hours, show more signals than those of the initially dissolved compound. According to the observed chemical shifts, some of these peaks may be attributable to the $[Te\{Ph_2(Q)PNP(Q)Ph_2\}_2]$ (Q= S[6] and Se[7]) species and the free acid ligands. The ^{31}P resonances are upfield-shifted by about 15 ppm relative to the corresponding free-acid ligand for all the compounds. The signals are closer to the chemical shift of the corresponding deprotonated ligands. The ^{125}Te resonance of C_4H_8TeIL and $C_4H_8TeL_2$ are shifted downfield compared to that of $C_4H_8TeI_2$ (δ = 782 ppm). This is in contrast to the upfield shift observed for the related $C_4H_8TeI(S_2PR_2)$ (R = Me, Et)[12] and some R_2TeL_2 and R_2TeXL (L = $SOCNR_2$,[10b][10e] S_2CNR_2 [13]) species. Some other analogous derivatives also exhibit deshielded ^{125}Te resonances relative to R_2TeI_2, such as R_2TeIL (R = Me and L = S_2COR,[10c] S_2POGO[10a] with G = alkylene moieties) and R_2TeL_2 (R = *p*-$MeOC_6H_4$ and L = dimethyl- and diethyldithiocarbamates).[10d] The ^{125}Te resonance of the 16-membered ionic compound is shifted upfield compared to that of $C_4H_8TeI_2$.

The positive ion FAB mass spectra recorded immediately after dissolving the compounds in CH_2Cl_2 show low-intensity signals for the corresponding molecular ions, but rather intense peaks of fragments containing tellurium, i.e. *m*/*z* = 186 $[C_4H_8Te]^+$, 313 $[C_4H_8TeI]^+$, $[C_4H_8Te\ L]^+$ with L = **1a** (*m*/*z* = 416), **1b** (*m*/*z* = 448), and **1c** (*m*/*z* = 544). All of the observed signals exhibit the expected isotopic distribution patterns.

The infrared spectra of **2** to **6** exhibit strong absorption bands in the range of 1259 to 1219 cm^{-1} for the $\nu(P_2N)$ vibrations and two characteristic bands for phosphorus−donor atom stretching vibrations {1122 and 1095 cm^{-1} [ν(PO)] for **6**, two ν(PS) bands in the range 554−517 for **3**−**5**, and 437 [ν(PSe)] for **2**}.

Structural Description

Figure 1 shows the molecular structures and atomic labeling scheme for derivative **2**, while those of **3** and **4** are illustrated in Figure 2. The molecular structure of **5** is given in Figure 3, and that of $[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}][I, I_3]$ (**6**) is shown in Figure 4. Selected bond lengths and angles are summarized in Table 1.

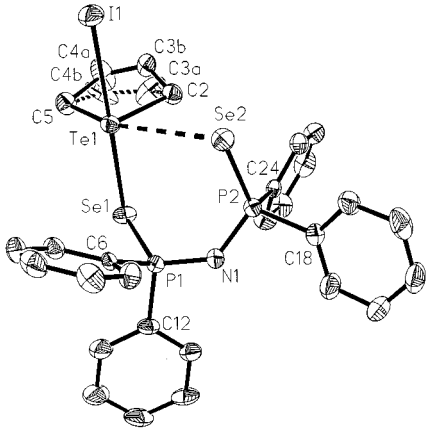

Figure 1. Molecular structure of $[C_4H_8TeI\{Ph_2(Se)PNP(Se)Ph_2\}]$ (**2**); the ellipsoids enclose a 30% probability

The coordination geometry at the tellurium center in every compound can be described as the sawhorse structure typical of tellurium(IV) compounds in which the lone-pair of electrons is supposed to occupy an equatorial position in a distorted trigonal bipyramid.[10−16c] The carbon atoms occupy the remaining equatorial positions with an average C−Te−C angle of 84.8°. The average Te−C bond length (2.135 Å) is within the range of the values observed in related organotellurium(IV) derivatives with chalcogen-containing ligands.[10−18]

In compounds containing sulfur and selenium donor atoms (**2**−**5**), the ligands display an asymmetrical chelating coordination mode on interaction with the tellurium center. This results in two sets of Te−donor atom bond lengths. The short Te−S bond lengths cover the range 2.61−2.67 Å, comparable with the values reported for related R_2TeXL structures containing analogous $R_2(Q)PNP(Q')R_2$,[6,7,16,17]

Figure 2. Molecular structures of $[C_4H_8TeI\{Ph_2(S)PNP(S)Ph_2\}]$ (**3**) and $[C_8H_8TeI\{Ph_2(S)PNP(S)Ph_2\}]$ (**4**); the ellipsoids enclose a 30% probability

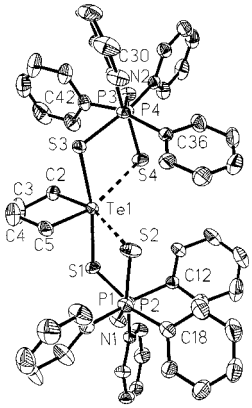

Figure 3. Molecular structures of the bis(chelate) compound $[C_4H_8Te\{Ph_2(S)PNP(S)Ph_2\}_2]$ (**5**); the ellipsoids enclose a 30% probability

and $R_2(S)P(CH_2)_2P(S)R_2$ [17] ligands. The short Te−Se bond length [2.721(1) Å] is slightly shorter than the values observed in $[Te\{R_2(Se)PNP(Se)R_2\}_2]$ [R = Ph (av.

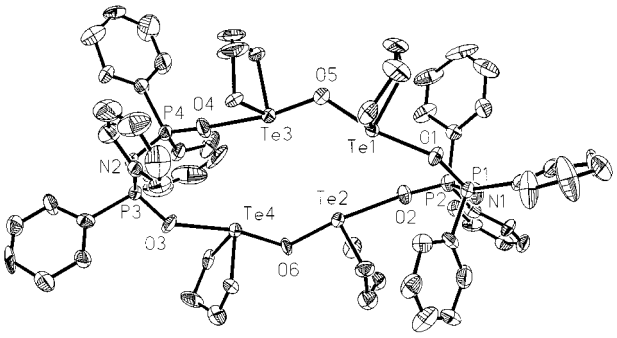

Figure 4. Molecular structure of the cation $[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}]_2^{2+}$; the ellipsoids enclose a 30% probability

2.797 Å)[6] and R = *i*Pr (av. 2.804 Å)[16d]]. The weakly bonded donor atoms are attached to the tellurium atom at larger Te···S distances ranging from 3.282(2) to 3.451(2) Å and at a Te···Se length of 3.4650(12) Å. The normalized Pauling partial bond orders[16c] of these longer Te···S/Se bonds are within the range of 0.16 to 0.27, that of Te···Se being 0.19. Thus, they are still compatible with their being part of the coordination sphere, and hence aniso-bonded. The S−Te−S bite angles in complexes **3**−**5** are similar to those found in the analogous $[Me_2Te\{Ph_2(S)PNP(S)Ph_2\}_2]$ and $[Me_2TeI\{Ph_2(S)PNP(S)Ph_2\}]$.[16c]

In the bis(chelate) derivative **5**, the two strongly bonded sulfur atoms occupy the axial positions, while in the mono-substituted compounds the axial sites are occupied by the iodine atom and the strongly bonded donor atom. The I−Te−Se axial angle [177.51(3)°] is considerably larger than the I−Te−S angle [171.8(1)°], while the S−Te−S axial angle is smaller [170.59(5)°]. When the aniso-bonded donor atoms are included in the coordination sphere, the environment about Te becomes distorted square-pyramidal in the mono derivatives **2**−**4** and distorted octahedral in the bis-(chelate) compound **5**.

The Te−I bond lengths of RTeIL (**2** and **4**) are similar to those in $C_4H_8TeI_2$,[12] $C_8H_8TeI_2$ [19] and related R_2TeI_x species.[20] This and the generally longer Te−S bond in compounds containing imidodiphosphinates suggest a lower *trans* influence than in analogous halodithiocarbamates, -monothiocarbamates and dithiocarbonates.[10−13,15] However, the most remarkable difference with these 1,1-dithiolate compounds is that the imidophosphinate compounds do not exhibit any intermolecular interactions.

The TeS_2P_2N chelate rings of **3** and **4** are arranged in a distorted boat conformation with the tellurium and nitrogen atoms at the apices.[21] However, the $TeSe_2P_2N$ and TeS_2P_2N rings of the remaining chelate compounds **2** and **5** exhibit a folded geometry with one phosphorus atom lying essentially within the coordination plane and with the P−N−P−Se/S plane folded by 120.2° out of the coordination plane Te1−Se1−Se2−P2 for **2**, and by 40.7° and 129.9° out of the planes Te1−S1−S2−P1 and Te1−S3−S4−P4 for **5**. The ring bond lengths are consistent with some localization of the bonding, i.e. the short

[a] In molecule **4**, the C2 and C5 labels correspond to the C1a and C3a atoms, respectively.

and long bonds alternate through the six-membered ring (see Table 1).

The molecular structure of $[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}]_2[I, I_3]$ (**6**) is shown in Figure 4. In the 16-membered cationic ring two oxygen ligands behave as bridges between two $C_4H_8Te-O-TeC_4H_8$ units. The Te−O(ligand) bond lengths cover the range 2.273(17) to 2.453(17) Å. These bonds are slightly longer than the sum of the covalent radii,[22] and are also longer than the corresponding distances found in chelates like $[Me_2TeCl\{Ph_2(O)PNP(S)Ph_2\}]$,[16c] $[Ph_2Te(O_2CR)_2]$ (R = CH_3, CCl_3),[15b,15c] and $[C_4H_8Te(O_2CPh)_2]$.[15a] The average Te−O bond length in the $C_4H_8Te-O-TeC_4H_8$ moiety is 1.988 Å. The Te−O−P angles (av. 154.5°) are notably larger than the observed Te−S−P angles (av. 104.84°) in the complexes containing the sulfur-bridge ligand, i.e. $[4\text{-}MeOC_6H_4Te\{Ph_2(S)PNP(S)Ph_2\}]_2$ [7] and $[(4\text{-}MeOC_6H_4TeCl_3)_2\{\mu\text{-}Ph_2(S)PCH_2CH_2P(S)Ph_2\}]$.[17] The average of the axial O−Te−O angles is 168.9°, comparable with the values observed in related tellurium(IV) sawhorse structures.[10−18] The 16-membered ring adopts a twisted conformation. The two anions I^- and I_3^- are located above and below the 16-membered ring $[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}]_2^{2+}$ with Te···I1 and Te···I2 distances ranging from 3.532(2) to 3.902(3) Å, within the sum of the van der Waals radii (4.35 Å).[23]

Conclusion

The isolation and spectroscopic characterization of mono- and disubstituted tetrahydro- and benzodihydrotelluropheno-containing symmetric $[Ph_2(Q)PNP(Q)Ph_2]^-$ ligands was achieved despite the propensity for such species to undergo disproportionation and reductive elimination in solution. The selenium and sulfur ligands act as anisobidentate chelate ligands such as was observed previously in related organotellurium derivatives containing 1,1-dithio- or monothio ligands, carboxylates, and asymmetric $R_2(Q)PNP(Q')R_2$.[10−16] The bite angles and Te−Q bond lengths are larger than those in compounds with 1,1-ligands, so that the angles about Te are less distorted. No

intermolecular interactions involving iodine or donor atoms were observed. The employment of the oxygen ligand leads to the formation of a novel 16-membered cationic ring $[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}]_2^{2+}$ (**6**) in which the ligand acts as a bridge. This compound may be formed from the two ligands and the $[C_4H_8TeI]_2O$ formed in the reaction mixture.

Experimental Section

General Remarks: Chemicals of commercial grade were purchased from Aldrich and were used as supplied. The compounds $C_4H_8TeI_2$ and $C_8H_8TeI_2$ were prepared according to the methods described by Al-Rubaie et al.[24] and by Ziolo et al.[19b] The ligand salts were prepared by treatment of the free ligands with potassium ethoxide or sodium hydroxide. The FAB mass spectra were measured using a 3-nitrobenzyl alcohol support in the positive ion mode with a Jeol JMS-SX102A instrument. The ^1H (300 MHz), ^{13}C (75 MHz), ^{31}P (121 MHz), ^{77}Se (57 MHz) and ^{125}Te (94 MHz) NMR spectra were recorded in $CDCl_3$ with a Jeol Eclipse+ 300 spectrometer at room temperature using as external references TMS, 85% H_3PO_4, $TeCl_4$, and Ph_2Se_2. The IR spectra (KBr discs) were recorded with a Nicolet FT-IR Magna 750 spectrometer. Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, TN.

$[C_4H_8TeI\{Ph_2(Se)PNP(Se)Ph_2\}]$ (2): A solution of $C_4H_8TeI_2$ (0.25 g, 0.57 mmol) in dichloromethane was added to freshly prepared $K[Ph_2(Se)PNP(Se)Ph_2]$ (0.33 g, 0.57 mmol). The mixture was stirred and elemental Te precipitated almost immediately from the solution. The mixture was filtered after 10 min of stirring and the filtrate was concentrated by pumping off the solvent. A layer of *n*-hexane was allowed to diffuse slowly into the concentrated solution leading to yellow crystals of $[C_4H_8TeI\{Ph_2(Se)PNP(Se)Ph_2\}]$ (**2**) and orange-yellow crystals of $[Te\{Ph_2(Se)PNP(Se)Ph_2\}_2]$[7] [m.p. 266 °C, ref.[7] 275 °C; ^{31}P NMR ($CDCl_3$): δ = 23.6 (s) (ref.[7] δ = 24.4)]. − **2**: Yield: 0.31 g (64.6%); m.p. (dec.) 153−154 °C. −IR (KBr): $\tilde{\nu}$ =1220 cm^{-1} s [ν(PN)], 437 m [ν(PSe)]. − MS (FAB^+, $CHCl_3$): *m*/*z* = 186 [$C_4H_8{}^{130}Te^+$], 313 [$C_4H_8{}^{130}TeI^+$], 544 [$(^{80}SePPh_2)_2N^+$], 672 [$^{130}Te(^{80}SePPh_2)_2N^+$], 728 [$C_4H_8{}^{130}Te(^{80}SePPh_2)_2N^+$], 854 [$C_4H_8{}^{130}TeI(^{80}SePPh_2)_2N^+$]. − ^1H NMR ($CDCl_3$): δ = 2.16−3.0 (m, 4 H, $TeCH_2CH_2$), 3.3−3.8 (m, 4 H, $TeCH_2$) 7.37 (m, 12 H, Ph-H_{m+p}), 7.9 (m, 8 H, Ph-H_o). − ^{13}C NMR ($CDCl_3$): δ = 33.9 ($TeCH_2CH_2$), 45.34 ($TeCH_2$), 128.3 (Ph-C_m), 130.68 (Ph-C_p), 131.4−131.1 (Ph-C_o). − ^{31}P NMR ($CDCl_3$): δ = 35.5 (br. s). − ^{77}Se NMR ($CDCl_3$): δ = −146.64 (d). − ^{125}Te NMR ($CDCl_3$): δ = 797 (t). − $C_{28}H_{28}INP_2Se_2Te$ (852.9): calcd. C 39.43, H 3.31; found C39.17, H 3.19. − A similar procedure was attempted starting from $C_8H_8TeI_2$ and the ligand, however only the tellurium(II) derivative $[Te\{Ph_2(Se)PNP(Se)Ph_2\}_2]$,[7] was isolated.

$[C_4H_8TeI\{Ph_2(S)PNP(S)Ph_2\}]$ (3): This compound was synthesized by placing $C_4H_8TeI_2$ (0.5 g, 1.14 mmol), $K[Ph_2(S)PNP(S)Ph_2]$ (0.55 g, 1.14 mmol), and approximately 25 mL of dichloromethane in a flask, and stirring this mixture was stirred at room temperature for 30 min. It was then filtered and the filtrate was concentrated by pumping off all the solvent. The compounds were crystallized by allowing a layer of *n*-hexane to diffuse slowly into a concentrated solution of the remaining solid in CH_2Cl_2. Yield: 0.72 g (82.9%); m.p. (dec.) 146−147 °C. − IR (KBr): $\tilde{\nu}$ = 1216 cm^{-1} vs [ν(PN)], 544 s, 517 m [ν(PS)]. − MS (FAB^+, $CHCl_3$): *m*/*z* = 186 [$C_4H_8{}^{130}Te^+$], 448 [$(SPPh_2)_2N^+$], 578 [$^{130}Te(SPPh_2)_2N^+$], 634 [$C_4H_8{}^{130}Te(SPPh_2)_2N^+$]. −$^1H$ NMR ($CDCl_3$): δ = 2.56−2.78 (m, 4 H, $TeCH_2CH_2$), 3.3−3.6 (m, 4 H, $TeCH_2$) 7.36 (m, 12 H, Ph-$CH_{m,p}$), 7.88 (m, 8 H, Ph-CH_o). − ^{13}C NMR ($CDCl_3$): δ = 33.6 ($TeCH_2CH_2$), 46.06 ($TeCH_2$), 128.08 (Ph-C_m), 130.4 (Ph-C_p), 131.0 (Ph-C_o). − ^{31}P NMR ($CDCl_3$): δ = 45 (br. s). −^{125}Te NMR ($CDCl_3$): δ = 834.2 (t). − $C_{28}H_{28}INP_2S_2Te$ (759.11): calcd. C 44.30, H 3.72; found C43.99, H 3.60.

$[C_8H_8TeI\{Ph_2(S)PNP(S)Ph_2\}]$ (4): This compound was obtained according to the procedure described for **3** from $C_8H_8TeI_2$ (0.5 g, 1.03 mmol) and $K[Ph_2(S)PNP(S)Ph_2]$ (0.49 g, 1.03 mmol). Yield: 0.51 g (61.3%); m.p. (dec.) 127−129 °C. − IR (KBr): $\tilde{\nu}$ = 1226 cm^{-1} s [ν(PN)], 546 m, 525 s [ν(PS)]. − MS (FAB^+, $CHCl_3$): *m*/*z* = 234 [$C_8H_8{}^{130}Te^+$], 361[$C_8H_8{}^{130}TeI^+$], 448 [$(SPPh_2)_2N^+$], 682 [$C_8H_8{}^{130}Te(SPPh_2)_2N^+$]. − ^1H NMR ($CDCl_3$): δ = 4.99 (m, 4 H, $TeCH_2$), 7.14 (m, 4 H, C_6H_4), 7.35 (m, 12 H, Ph-$CH_{m,p}$), 7.9 (m, 8 H, Ph-CH_o). −^{13}C NMR ($CDCl_3$): δ = 49.92 ($TeCH_2$), 127.7 ($C_{4,7}$) 128.27 (Ph-C_m), 129.8 ($C_{5,6}$), 130.9 (Ph-C_p), 131.2 (Ph-C_o), 139.2 ($C_{3a,7a}$). −^{31}P NMR ($CDCl_3$): δ = 42.3 (br. s). − ^{125}Te NMR ($CDCl_3$): δ = 760 (m). − $C_{38}H_{28}INP_2S_2Te$ (807.16): calcd. C 47.62, H 3.50; found C47.36, H 3.37

$[C_4H_8Te\{Ph_2(S)PNP(S)Ph_2\}_2]$ (5): This compound was prepared as described for **3** from $C_4H_8TeI_2$ (0.5 g, 1.14 mmol) and $K[Ph_2(S)PNP(S)Ph_2]$ (1.10 g, 2.28 mmol). Yield: 0.86 g (69.6%); m.p. (dec.) 135−137 °C. − IR (KBr): $\tilde{\nu}$ = 1219 cm^{-1} s [ν(PN)], 554 s, 508 m [ν(PS)]. −MS (FAB^+, $CHCl_3$): *m*/*z* = 186 [$C_4H_8Te^+$], 448 [$(SPPh_2)_2N^+$], 578 [$^{130}Te(SPPh_2)_2N^+$], 634 [$C_4H_8{}^{130}Te(SPPh_2)_2N^+$]. − ^1H NMR ($CDCl_3$): δ = 2.30 (br. s, 4 H, $TeCH_2CH_2$), 3.18 (br. s, 4 H, $TeCH_2$), 7.27 (m, 12 H, P-$CH_{m,p}$), 7.88 (m, 8 H, P-CH_o). −^{13}C NMR ($CDCl_3$): δ = 33.21 ($TeCH_2CH_2$), 47.46 ($TeCH_2$), 128.2 (Ph-C_m), 130.12 (Ph-C_p), 131.3 (Ph-C_o). − ^{31}P NMR ($CDCl_3$): δ = 44.2 (br. s). − ^{125}Te NMR ($CDCl_3$): δ = 856 (m). − $C_{52}H_{48}N_2P_4S_4Te$ (1080.71): calcd. C 57.79, H 4.8; found C57.51, H 4.71

$[O(TeC_4H_8)_2\{Ph_2(O)PNP(O)Ph_2\}]_2[I, I_3]$ (6): This compound was prepared as described for **3** from $C_4H_8TeI_2$ (0.8 g, 1.83 mmol), freshly prepared $Na[Ph_2(O)PNP(O)Ph_2]$ (0.8 g, 1.83 mmol), and approximately 25 mL of ethanol. $[O(TeC_4H_8)_2\{Ph_2(O)PNP(SO)Ph_2\}]_2$ (**6**) was isolated as dark brown crystals from the bottom of the crystallization flask. Yield 0.79 g (20.5%); m.p. (dec.) 137 °C. − IR (KBr): $\tilde{\nu}$ = 1259 cm^{-1}s [ν(PN)], 1122 vs, 1095 s [ν(PO)]. − MS (FAB^+, $CHCl_3$): *m*/*z* = 416 [$(OPPh_2)_2N^+$], 602 [$C_4H_8{}^{130}Te(OPPh_2)_2N^+$], 760 [$^{130}Te_4O_6P_4N_2^+$]. − ^1H NMR ($CDCl_3$): δ = 2.21 (m, 4 H, $TeCH_2CH_2$), 2.97 (m, 4 H,$TeCH_2$), 7.26 (m, 12 H, P-$CH_{m,p}$), 7.73 (m, 8 H, P-CH_o). − ^{13}C NMR ($CDCl_3$): δ = 29.8 ($TeCH_2CH_2$), 31.27 ($TeCH_2$), 127.96 (Ph-C_m), 130.33 (Ph-C_p), 131.39 (Ph-C_o). − ^{31}P NMR ($CDCl_3$): δ = 14.3 (s). − ^{125}Te NMR ($CDCl_3$): δ = 777.2 (br. s). − $C_{64}H_{72}I_4N_2O_6P_4Te_4$ (2107.18): calcd. C 36.48, H 3.44; found C36.11, H 3.25.

X-ray Crystallographic Study: Suitable crystals were mounted on glass fibers and sealed with epoxy glue. Data were collected at room temperature on a Siemens P4/PC diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073). Details of the data collections and refinements are summarized in Table 2. Data were collected using the ω-scan mode (3° ≤ 2θ ≤ 50°). The intensity data (except those for **5**) were corrected for absorption (Ψ-scan). The structures were solved by direct methods using SHELXS-97[25] (for **2**, **5** and **6**) and SIR-97[26] (for **3** and **4**). They were all refined by full-matrix least-squares calculations using the program system SHELXL-97.[27] Non-hydrogen atoms were refined anisotropically. In the case of **2**, there was disorder involving atoms

Keywords: Siderophores / Iron / Chelation / Drug targeting / Fast kinetics

This report deals with a kinetic and thermodynamic study of complex formation between Fe^{III} and a new series of synthetic chelators, 2,3- (FR401) and 3,4-dicatecholspermidine (FR295). For the following data, the first value concerns FR295 and the second FR401. Each ligand undergoes five acid-base dissociations, four of which involve the hydroxy groups of the catechol moieties and the final one the central ammonium group. They occur with average at pK_{2a} = 8.40 and 7.95 for the first two hydroxy groups, pK_{3a} = 12.6 and 12.20 for the two remaining hydroxy groups and pK_{1a} = 5.50 and 4.90 for the ammonium group. Complex formation with both chelators occurs rapidly in acidic media (pH < 2), resulting in the second-order complex formation rate constants k_1 = 450 M^{-1} s^{-1} and 500 M^{-1} s^{-1} and first-order complex dissociation rate constants k_{-1} = 0.82 s^{-1} and 0.28 s^{-1}. From these two elementary rates, the complex dissociation constant is determined in acidic media: $K_1 = 1.82 \cdot 10^{-3}$ M and $5.6 \cdot 10^{-4}$ M. The Fe^{III} complexes also undergo five proton dissociations with marked decreases in the catechol pK_a value: ΔpK_{1a} = 1.25 and 1.25, ΔpK_{2a} = 6.60 and 6.50, ΔpK_{3a} = 6.55 and 6.95. From ΔpK_a and K_1, the affinity of both FR295 and FR401 for Fe^{III} is determined: log β = 29 and 31 with pFe = 22 and 25. This new series of chelators is aimed for antibiotic targeting. It proved efficient in inhibiting *Plasmodium falciparum* growth and delivered iron ions to Gram-negative bacteria.

Introduction

Iron is one of the most essential elements for practically all life forms. In its most common state of oxidation, Fe^{III} is insoluble in neutral media. It is, therefore, directly unavailable for the living species.[1] Consequently, this element is solubilised and regulated in physiological media by several iron transport and acquisition systems. In microorganisms, one of the most important is constituted by siderophores.[2] Siderophores are very efficient low molecular mass iron chelators used and or synthesized when iron is required. Once in the chelate form these iron transport systems are recognized by the cell, where they are admitted across the membranes by specific paths, and iron is delivered.[3]

Synthetic chelators can be siderophore-like and, therefore, used by some cells for the acquisition of iron.[3] Considerable effort to synthesize siderophore-like and other high-efficiency iron chelators has been made in the last twenty years. Most of these molecules were synthesised for the therapy of iron-overload which can be partially eliminated by chelation.[4,5] Other approaches were investigated to use the siderophore for drug delivery inside pathogenic microorganisms.[6] Siderophores can also be effective against malaria.[7]

Most of the iron ligands in siderophores are catechols and/or hydroxamates.[1,2] A series of synthetic chelators based on a spermidine skeleton bearing catechols behaved as siderophores and as iron scavengers. They inhibited *Plasmodium falciparum* proliferation in vitro and delivered iron to several Gram-negative bacteria, thereby, promoting their growth.[8,10]

This inhibition of *Plasmodium falciparum* is of interest as malaria is still the major cause of human mortality in the tropics where an increasing prevalence of strains of *Plasmodium falciparum* resistant to chloroquine and other antimalarial drugs.[7,11] As for the siderophore activity, it opens up ideas of using these molecules for drug delivery. Indeed, with the emergence of AIDS, and the consequent increase in the number of immunodepressive patients, opportunistic diseases such as tuberculosis with new forms of resistance to antibiotics have appeared.[12] Some of these forms of resistance are mostly related to impermeability of the microorganism's membrane to the drug than to a the classical deactivating enzymes.[12] This impermeability can be overcome by delivering the drug as an antibiotic−siderophore adduct using the microorganism's iron acquisition pathway.[3,8,12,13] Macrolide antibiotics linked to catecholspermidines proved to be effective against antibiotic-resistant mycobacteria.[8,13] These promising results may lead to a new series of antibiotic carriers and antimalarial drugs based on the catecholspermidine series.

Fe^{III} is insoluble in neutral media. It can be complexed to other chelators, in physiological media in the so-called low molecular mass iron pool.[2] However, in vertebrates and some invertebrates, it is regulated by the transferrins, which possess very high affinities for the metal (> 10^{20}

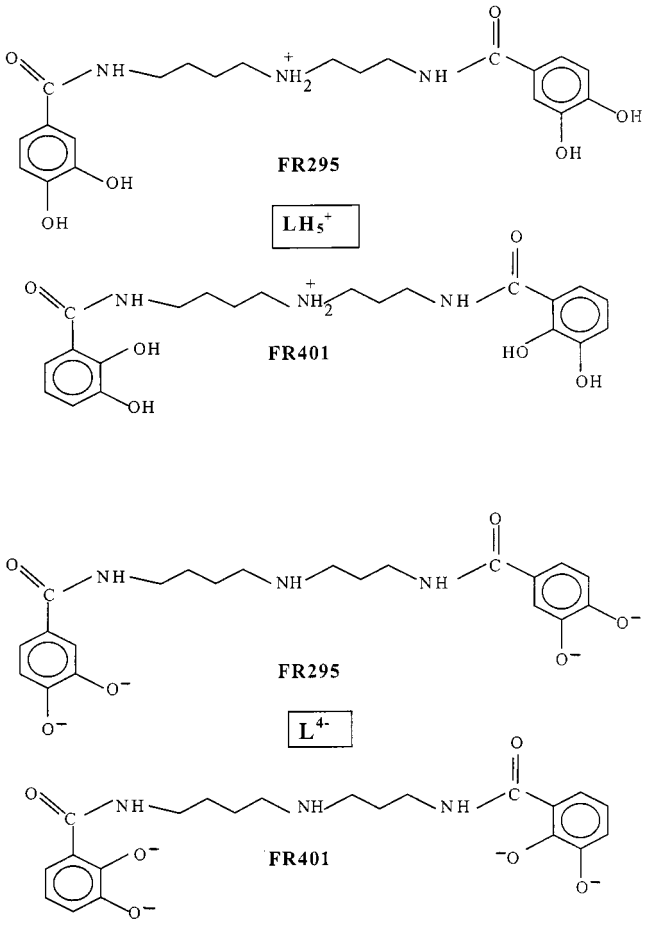
M^{-1}).[14] Therefore, in order to be competitive and to keep their iron charge, synthetic siderophores must possess extremely high affinities for Fe^{III}.[15−18] The affinity constants of natural or synthetic siderophores for iron range from 10^{20} M^{-1} to $> 10^{40}$ M^{-1}.[15−18] These extremely high affinities render any thermodynamic or kinetic analysis of complex formation with Fe^{III} difficult.[18] In this article we analyse, by the chemical relaxation approach and analytical chemistry,[14,19−21] the kinetic and thermodynamic behaviour of the siderophore-like 2,3 (FR401) and 3,4-dicatecholspermidines (FR295, Scheme 1) during complex formation with Fe^{III}.



Scheme 1

Results and Discussion

All our experiments were performed at an ionic strength of μ = 0.2 in the presence of Cl^-. At pH = 2−4, the absorption spectra of both FR295 and FR401 are independent of acidity, which indicates the presence of a single prototropic species for each of them. From pH = 4 to 7, the absorption spectra vary to attain a first plateau at pH = 7−8. They vary again to attain a second plateau at pH = 9−10. From pH = 10−13, the spectra vary again to reach a third plateau in very basic media (Figures 1, 2, and 3).

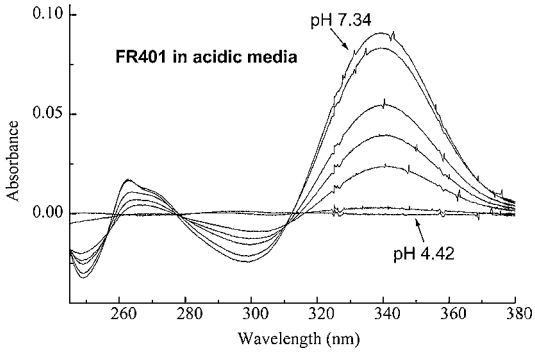


Figure 1. Differential absorption spectra of FR401 between pH = 4.42 and 7.34 with $c_0 = 4.5 \cdot 10^{-5}$ M and μ = 0.2 at 25±0.5 °C

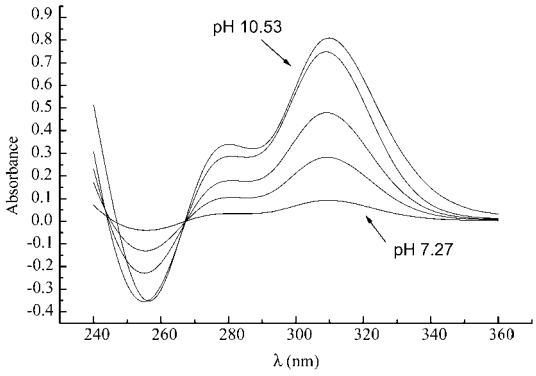

Figure 2. Differential absorption spectra of FR295 between pH = 7.27 and pH 10.53 with $c_0 = 4.5 \cdot 10^{-5}$ M and μ = 0.2 at 25±0.5 °C

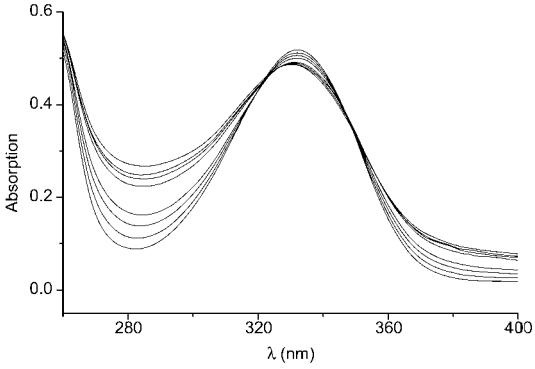

Figure 3. Absorption spectra of FR401 between pH = 10.56 and 13.15 with $c_0 = 5.0 \cdot 10^{-5}$ M and μ = 0.2 at 25 °C

When $FeCl_3$ is added to an acidic solution (pH ≈ 2) of FR295 or FR401, marked modifications in the absorption spectra of both ligands occur (Figure 4). This implies the formation of an iron(III) complex with FR295 and FR401.

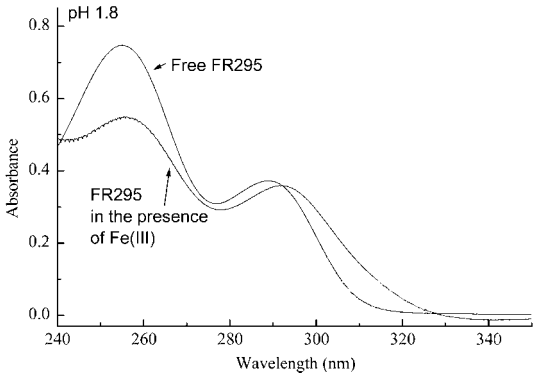

Figure 4. Absorption spectra of FR295 at pH = 1.80 in the absence and presence of 1 equiv. of $FeCl_3$ with $c_0 = c_1 = 4.5 \cdot 10^{-5}$ M and $\mu = 0.2$ at 25±0.5 °C

When the pH of solutions of FR295 and FR401 containing 1 equiv. of $FeCl_3$ are varied from acidic to basic ($2 < pH < 10$), modifications in the absorption spectra occur (Figure 5). Adding another equivalent of Fe^{III} does not have any effect on these absorption spectra and leads to the precipitation of iron hydroxide at $pH > 2.5$. All these experiments were performed under argon in order to avoid catechol oxidation and all the processes observed were reversible.

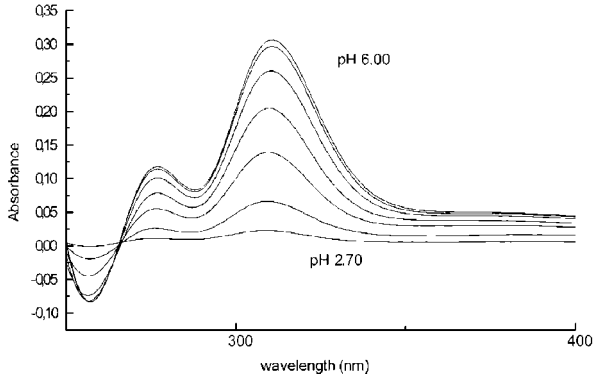

Figure 5. Differential absorption spectra of FR295 in the presence of 1 equiv. of $FeCl_3$ between pH = 2.70 and 6.00 with $c_0 = c_1$ and $\mu = 0.2$ at 25±0.5 °C

Free Ligand Proton Dissociations

The two dicatecholspermidine ligands FR401 and FR295 can exist as several prototropic species (Scheme 1).[22] When the pH of FR401 and FR295 solutions is increased, the variations in the absorption spectra of the ligands indicate the presence of one or more prototropic species in each of the 3−7, 7−9.5 and 9.5−13 pH ranges (Figures 1, 2, 3). To a first approximation, we assume that in each pH range, a ligand species can deprotonate according to Equation (1) where ion charges are not written.

$$LH_{(m-n)} + n\,H^+ \rightleftarrows LH_m \quad (1)$$

The Beer−Lambert law can be expressed in each of the pH ranges as in Equation (2) where A is the absorbance at a given wavelength, with $l = 1$ cm for all of the experiments, m is 5 in acidic media, n is the number of the protons involved in the acid-base reactions, $\varepsilon_{(m-n)}$ is the molecular extinction coefficient of the $LH_{(m-n)}$ species and ε_m is the molecular extinction coefficient of the of the LH_m species.

$$A = \{\varepsilon_{(m-n)}[LH_{(m-n)}] + \varepsilon_m[LH_m]\}l \quad (2)$$

Equation (2) can also be expressed as Equation (3)[23,24] where $\Delta A = A - A_0$, $\Delta\varepsilon = \varepsilon_{(m-n)} - \varepsilon_m$ and c_0 is the ligand concentration, with A_0 the absorbance due to the LH_m species and $\boldsymbol{K}_a = [LH_m][H^+]^n/[LH_{(m-n)}]$.

$$\Delta\varepsilon/\Delta A = 1/c_0 + [H^+]^n/(K_a c_0) \quad (3)$$

The best linear regression of the experimental $\Delta\varepsilon/\Delta A$ against $[H^+]^n$ is obtained for $n = 1$ in all of the pH ranges (Figures 6, 7, and 8 and Table 1).

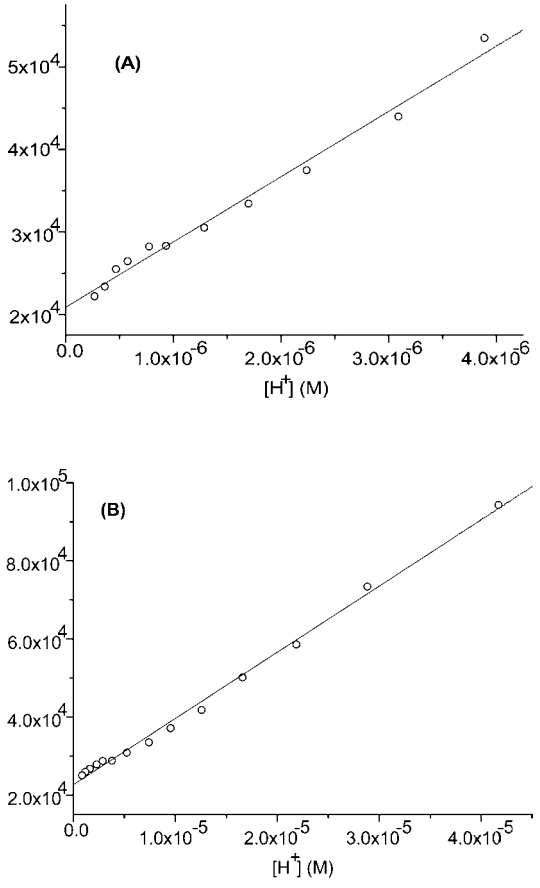

Figure 6. Plot of $\Delta\varepsilon/\Delta A$ against $[H^+]$ at pH ≤ 7: A) FR295, intercept, $(2\pm0.05)\cdot10^4$ M^{-1}; slope $(7.90\pm0.50)\cdot10^9$ M^{-2}; $r = 0.99357$; B) FR401, intercept, $(2.25\pm0.05)\cdot10^4$ M^{-1}; slope, $(1.70\pm0.05)\cdot10^9$ M^{-1}

In both ligands, there are five deprotonation sites; four proton losses can occur from the two dicatechol moieties of FR295 and FR401 and another proton loss from the central quaternary ammonium group. However, we only detected three proton dissociations, each of which seems to

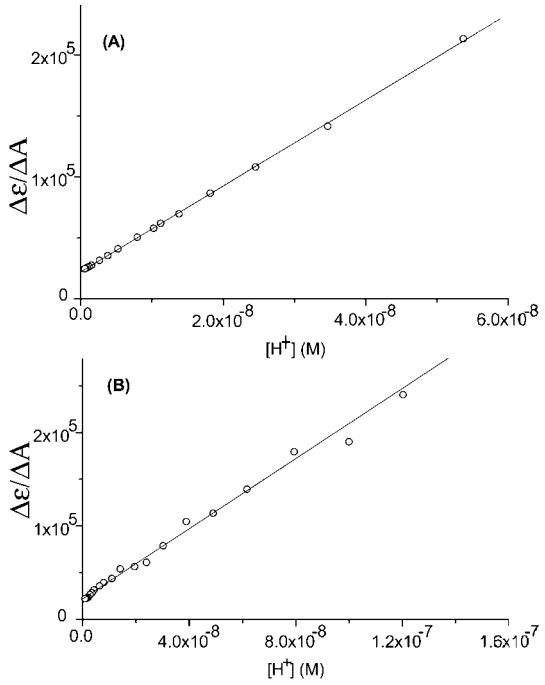

Figure 7. Plot of $\Delta\varepsilon/\Delta A$ against $[H^+]$ at 10. 50 ≥ pH ≥ 7: A) FR295, intercept, $(2.20\pm0.5)\cdot10^4$ M^{-1}; slope, $(3.50\pm0.05)\cdot10^{12}$ M^{-1}; r = 0.99983; B) FR401, intercept, $(2.20\pm0.05)\cdot10^4$ M^{-1}; slope, $(1.90\pm0.05)\cdot10^{12}$ M^{-1}

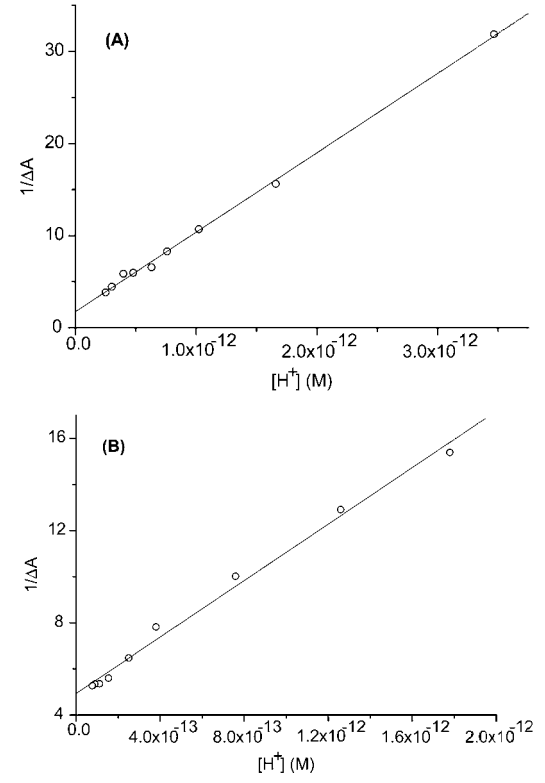

Figure 8. Plot of $1/\Delta A$ against $[H^+]$ at pH ≥ 10.50: A) FR295, intercept, 1.80±0.2; slope, $(8.60\pm0.15)\cdot10^{12}$ M^{-1}; r = 0.99912; B) FR401, intercept, 4.90±0.30; slope, $(6.20\pm0.30)\cdot10^{12}$ M^{-1}; r = 0.99569

Table 1. An approximation of the overall proton dissociation constants involved in the acid-base equilibria of FR295 and FR401

Ligand	3 < pH < 6 pK_{1a}	6 < pH <9 pK_{2a}	9 < pH < 13 pK_{3a}
FR295	5.50 ± 0.02	8.40 ± 0.02	12.60 ± 0.02
FR401	4.90 ± 0.02	7.95 ± 0.02	12.10 ± 0.02

involve a single proton transfer. Although the two dicatecholspermidine ligands are not symmetrical, in each of the ligands, the catechol moieties have the same environment and are practically identical. Therefore, these dicatechols should behave in the same way towards proton dissociation that can explain the presence of what seems to be isosbestic points in Figures 1 to 3 and 5. An isosbestic point may imply the presence of two species in the medium. Nonetheless, it cannot constitute as evidence for this presence.[25] Subsequently, we can assume that the three measured pK_a values of Table 1 can describe five proton dissociations. We can, therefore, write Equations (4) to (8) with L^{4-}, the completely deprotonated species, $K_{1a} = [LH_4][H^+]/[(LH_5)^+]$, $K_{2a} = [(LH_3)^-][H^+]/[LH_4]$, $K_{3a} = [(LH_2)^{2-}][H^+]/[(LH_3)^-]$, $K_{4a} = [(LH)^{3-}][H^+]/[(LH_2)^{2-}]$ and $K_{5a} = [L^{4-}][H^+]/[(LH)^{3-}]$.

$$LH_4 + H^+ \rightleftarrows (LH_5)^+ \quad (4)$$

$$(LH_3)^- + H^+ \rightleftarrows LH_4 \quad (5)$$

$$(LH_2)^{2-} + H^+ \rightleftarrows (LH_3)^- \quad (6)$$

$$(LH)^{3-} + H^+ \rightleftarrows (LH_2)^{2-} \quad (7)$$

$$L^{4-} + H^+ \rightleftarrows (LH)^{3-} \quad (8)$$

At pH < 9.5, three protons are involved in acid-base reactions with both ligands (Table 1) In this case the Beer−Lambert law can be expressed as in Equation (9).

$$A = \varepsilon_1[LH_5] + \varepsilon_2[LH_4] + \varepsilon_3[LH_3] + \varepsilon_4[LH_2] + \varepsilon_5[LH^{3-}] + \varepsilon_6[L^{4-}] \quad (9)$$

At 6 < pH < 9.5 $[LH_5^+]$, $[LH_4]$, $[LH_3^-]$ >> $[LH_2^{2-}]$, $[LH^{3-}]$, $[L^{4-}]$ and at pH > 9.5 $[LH_5^+]$, $[LH_4]$, $[LH_3^-]$ << $[LH_2^{2-}]$, $[LH^{3-}]$, $[L^{4-}]$. In this case, with K_{1a}, K_{2a}, K_{3a}, K_{4a}, and K_{5a} and the conservation of mass, we can write Equations (10) and (11) at 6 < pH <9.5 and pH > 9.5, respectively.

$$A = \frac{\{\varepsilon_1[H]^3 + \varepsilon_2[H]^2K_{1a} + \varepsilon_3[H]K_{1a}K_{2a} + \varepsilon_4K_{1a}K_{2a}K_{3a}\}c_0}{([H]^3 + [H]^2K_{1a} + [H]K_{1a}K_{2a} + K_{1a}K_{2a}K_{3a})} \quad (10)$$

$$A = \frac{c_0\{\varepsilon_4[H^+]^2 + \varepsilon_5[H^+]K_{4a} + \varepsilon_6 K_{4a}K_{5a}\}}{[H^+]^2 + [H^+]K_{4a} + K_{4a}K_{5a}} \quad (11)$$

Two non-linear least-squares regressions were obtained for each of the two ligands. The first two were for the data collected at pH < 9.5 [Equation (10)] and the other two for the data collected at pH > 9.5 [Equation (11)]. They gave very close $K_{2a} \approx K_{3a}$ and $K_{4a} \approx K_{5a}$ values. This implies that the values reported in Table 1 can be expressed as $pK_{2a} \approx (pK_{2a} + pK_{3a})/2$ and $pK_{3a} \approx (pK_{4a} + pK_{5a})/2$. All these pK_a values are in agreement with those reported for catechol proton dissociations. These occur in the vicinity of neutrality for one hydroxy group and at pH > 10 for the second.[22] As for the ammonium group of the spermidine, the values of the proton dissociation constant are highly dependent on the nature of the associated moieties and can vary from about 2 to more than 10.[26]

Complex Proton Dissociation

If a monocomplex is formed between Fe^{III} and FR295 or FR401, as Figure 4 seems to imply, it can also deprotonate at the catechol moieties and the central ammonium group. The variation of the absorption spectra of the two complexes seems to indicate the presence of at least three prototropic species in the pH = 3−6 area (Figure 5).

As in the case of the free ligands, we assume to a first approximation that in each pH range when at least one species deprotonates to yield the other, we can write Equation (12).

$$FeLH_{(m-n)} + nH^+ \leftrightarrows FeLH_m \quad (12)$$

As m is unknown, ion charges are not written. The Beer−Lambert law can be expressed in each of the pH ranges as Equation (13) [where A is absorbance at a given wavelength, with l = 1 cm for all our experiments; $\varepsilon'_{(m-n)}$ is the molecular extinction coefficient of the $FeLH_{(m-n)}$ species and ε''_m is the molecular extinction coefficient of the of $FeLH_m$] and Equation (14) {where $\Delta A = A - A_0$ and $\Delta\varepsilon' = \varepsilon'_{(m-n)} - \varepsilon''_m$, with A_0 the absorbance due to the LH_m species and $K_n = [FeLH_{(m-n)}][H^+]^n/[FeLH_m]$}.

$$A = \{\varepsilon'_{(m-n)}[LH_{(m-n)}] + \varepsilon''_m[LH_m]\}l \quad (13)$$

$$\Delta\varepsilon'/\Delta A = 1/c_0 + [H^+]^n/(K_n c_0) \quad (14)$$

Equation (14) is never obeyed by our experimental data. However, the plot of $1/\Delta A$ against $[H^+]$ can be roughly simulated by three lines, each of which obeys Equation (15) with $K'_{na} = [FeLH_{(m-1)}][H^+]/[FeLH_m]$, where ΔA_{n0} is the experimental differential absorption determined from the intercept of each of the three regression lines.

$$1/\Delta A = 1/\Delta A n_0 + [H^+]/\Delta A_0 K'_{na} \quad (15)$$

We, therefore, assumed that the Fe^{III} complex undergoes at least three proton losses when the pH range is ca. 2 to ca. 8 [Equations (16) to (18)].

$$FeLH_{(m-3)} + H^+ \leftrightarrows FeLH_{(m-2)} \quad (16)$$

$$FeLH_{(m-2)} + H^+ \leftrightarrows FeLH_{(m-1)} \quad (17)$$

$$FeLH_{(m-1)} + H^+ \leftrightarrows FeLH_m \quad (18)$$

In this case the Beer−Lambert relation can be expressed as Equation (19) in which, ε'_3, ε'_2, ε'_1, and ε' are the molecular extinction coefficients of species $FeLH_{(m-3)}$, $FeLH_{(m-2)}$, $FeLH_{(m-1)}$, and $FeLH_m$, respectively.

$$A = \varepsilon'_3[FeLH_{(m-3)}] + \varepsilon'_2[FeLH_{(m-2)}] + \varepsilon'_1[FeLH_{(m-1)}] + \varepsilon'[FeLH_m] \quad (19)$$

Equation (19) can be expressed as a function of c_0, $K'_{1a} = [FeLH_{(m-1)}][H^+]/[FeLH_m]$, $K'_{2a} = [FeLH_{(m-2)}][H^+]/[FeLH_{(m-1)}]$ and $K'_{3a} = [FeLH_{(m-3)}][H^+]/[FeLH_{(m-2)}]$ as in Equation (20).

$$\Delta A = \frac{(\varepsilon'_3 - \varepsilon')K_{1a}K'_{2a}K'_{3a} + (\varepsilon'_2 - \varepsilon')K'_{1a}K'_{2a}[H^+] + (\varepsilon'_1 - \varepsilon')K'_{1a}[H^+]^2}{K'_{1a}K'_{2a}K'_{3a} + K'_{1a}K'_{2a}[H^+] + K'_{1a}[H^+]^2} \times c_0 \quad (20)$$

A non-linear least-squares regression of the data against Equation (20), where $(\varepsilon'_3 - \varepsilon')$ is determined experimentally and the equilibrium constants are roughly estimated from the three lines related to Equation (15) in the three different pH ranges, gave the K'_{1a}, K'_{2a}, and K'_{3a} values with about 10 to 15% of uncertainty (Figure 9, Table 2).

Therefore, the proton dissociation constants of the FR295 and FR401 ligands are shifted from basic to acidic when the ligands are complexed by Fe^{III}. As for the free ligand, we will assume that the apparent pK_a values reported in Table 2 concern the deprotonation of the ligands engaged in the complex. Complex formation can be accompanied by the deprotonation of the ligands involved which stabilises the complex.[27−29] Catechols are very good chelators for Fe^{III} whereas amines are not.[27,29] Since the affinity of a ligand for a metal increases upon proton loss,[28] we assume that pK'_{1a} and pK'_{3a} are related to catechol deprotonation. Consequently, each of pK'_{1a} or pK'_{3a} involves two proton dissociations, whereas pK'_{2a} involves the amine single proton dissociation.

Kinetics of Complex Formation

When acidic solutions of FR295 or FR401 are mixed rapidly with a solution of $FeCl_3$, a single kinetic process is observed. It appears as an exponential increase of absorption at λ = 290 nm for each of the ligands (Figures 10 and 11). The rate of this process depends on the $FeCl_3$ concentration and the pH value for 1.5 ≤ pH ≤ 2.2. At pH > 2.2 iron hydroxides start appearing.[30]

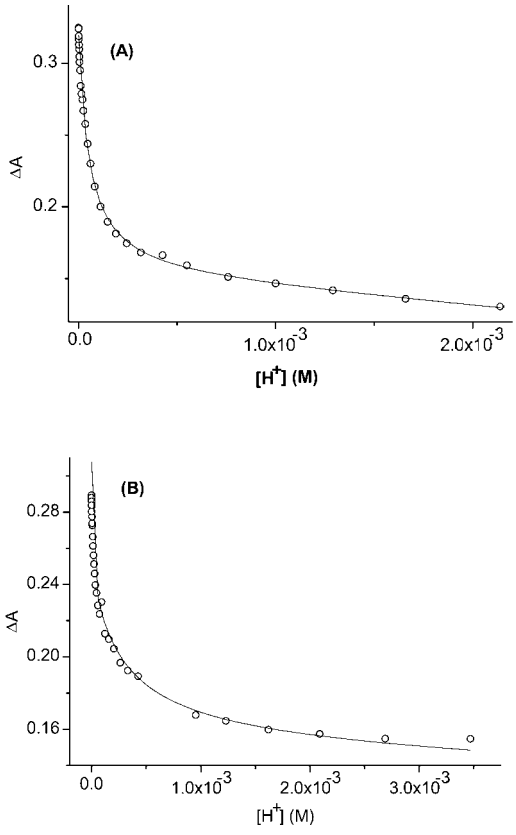

Figure 9. Plot of ΔA against $[H^+]$ at 25±0.5 °C for $c_1 = 4.5\cdot10^{-5}$ M and $\mu = 0.2$, and the non-linear least-squares regression fit according to Equation (20): A) FR295 with $K'_{1a} = (9.0\pm1.0)\cdot10^{-7}$ M, $K'_{2a} = (5.0\pm0.3)\cdot10^{-5}$ M and $K'_{3a} = (1.60\pm0.15)\cdot10^{-2}$ M; B) FR401 with $K'_{1a} = (7\pm1)\cdot10^{-6}$ M, $K'_{2a} = (2.30\pm0.30)\cdot10^{-4}$ M and $K'_{3a} = (3.5\pm0.3)\cdot10^{-2}$ M

Table 2. An approximation of the overall proton dissociation constants involved in the acid-base equilibria of the Fe^{III} monocomplexes of FR295 and FR401

Ligands	pK'_{2a} ammonium	pK'_{1a} catechol	pK'_{3a} catechol
FR295	4.25 ± 0.05	1.80 ± 0.05	6.05 ± 0.05
FR401	3.65 ± 0.05	1.50 ± 0.05	5.15 ± 0.05

In FR295 and FR401, the pK_a values of the catechol and central ammonium groups are both higher than 3 (Table 1). Subsequently, under our experimental conditions (pH ≤ 2), both chelators are in the protonated form $(LH_5)^+$ (Scheme 1). In this case, the chemical relaxation approximation will only be relevant for $c_1 \geq 2c_0$,[21] where c_1 is the analytical $FeCl_3$ concentration. The kinetic processes of Figures 10 and 11 always appear as a single exponential phenomenon that may imply the formation of a single complex. All this suggests that, because the two kinetic phenomena are pH-dependent, and because there is an excess of iron along with the detection of a single relaxation mode,[19–21,23,24,27] $(LH_5)^+$ may react with one Fe^{III} with

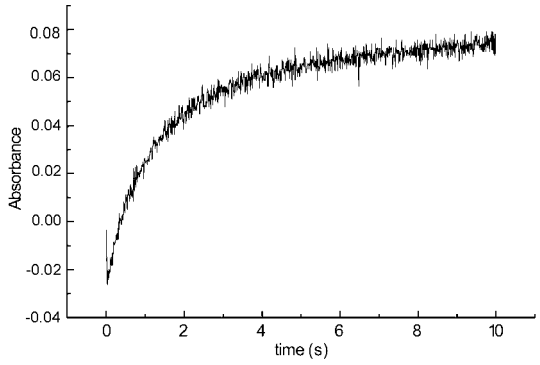

Figure 10. Exponential increase of the absorption with time at λ = 290 nm when an FR295 solution is rapidly mixed with a $FeCl_3$ solution with $c_0 = 4\cdot10^{-4}$ M, $c_1 = 5\cdot10^{-3}$ M and $\mu = 0.2$ at pH = 1.90 and 25±0.5 °C

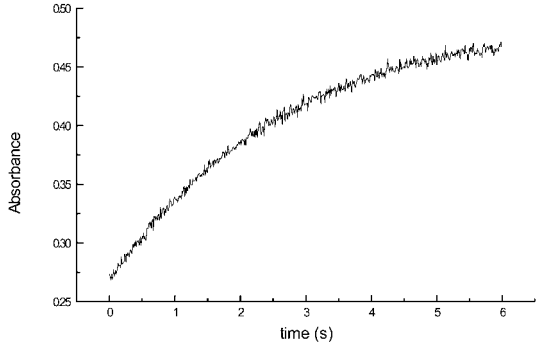

Figure 11. Exponential increase of the absorption with time at λ = 290 nm when a FR401 solution is rapidly mixed with a $FeCl_3$ solution with $c_0 = 4\cdot10^{-4}$ M, $c_1 = 3.6\cdot10^{-3}$ M and $\mu = 0.2$ at pH = 1.47 and 25±0.5 °C

the involvement of a proton transfer process. This can occur according to three possible mechanisms in which $FeLH_3^{2+}$ is the iron complex with each of the catechol moieties deprotonated on one hydroxy group and LH_3^- is the ligand species, also deprotonated on one hydroxy group.[27]

Mechanism I

$$Fe^{3+} + LH_5^+ \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} FeLH_5^{4+} \text{ (rate-limiting)} \quad (21)$$

$$Fe\,LH_{(5-n)}^{(n+2)+} + nH^+ \leftrightarrows FeLH_5^{4+} \quad (22)$$

Mechanism II

$$LH_{(5-n)}^{(n-1)-} + nH^+ \leftrightarrows LH_5^+ \quad (23)$$

$$Fe^{3+} + LH_{(5-n)}^{(n-1)-} \underset{k_{-1}}{\overset{k_2}{\rightleftarrows}} FeLH_{(5-n)}^{(n+2)+} \text{ (rate-limiting)} \quad (24)$$

Mechanism III

$$Fe^{3+} + LH_5^+ \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} FeLH_{(5-n)}^{(n+2)+} + nH^+ \quad (25)$$

A proton dissociation is usually diffusion-controlled and occurs in the μs range.[19,20,23,24] Therefore the phenomena of Figures 10 and 11 must involve rate-limiting complex formation. The reciprocal relaxation time equations associated with rate-limiting Equation (21) and Equation (24) and with Equation (25) are expressed as Equations (26) to (28) where $\boldsymbol{K}^2_{2a} = [LH_{(5-n)}{}^{(n-1)-}][H^+]^n/[LH_5{}^+]$ and $\boldsymbol{K}'^2_{1a} = [Fe LH_{(5-n)}{}^{(n+2)+}][H^+]^n/[FeLH_5{}^{4+}]$.[19,20,27]

$$\tau_1^{-1} = k_{-1}[H^+]^n/([H^+]^n + \boldsymbol{K}'_{1a}) + k_1([LH_5{}^+] + [Fe^{3+}]) \quad (26)$$

$$\tau_2^{-1} = k_{-2} + k_2([LH_5{}^+] + [Fe^{3+}])\boldsymbol{K}^2_{2a}/[H^+]^2 \quad (27)$$

$$\tau_3^{-1} = k_3([Fe^{3+}] + [LH_5{}^+]) + k_{-3}[H^+]^n \quad (28)$$

Under our experimental conditions where $c_1 \geq 2c_0$, and where $\boldsymbol{K}'_{1a}$, $[H^+] >> c_1$, c_0 and $\boldsymbol{K}_{2a}$, Equations (26), (27), and (28) can be simplified into Equations (29), (30), and (31), respectively.

$$\tau_1^{-1}(1 + \boldsymbol{K}'^2_{1a}/[H^+]^n) \approx k_{-1} + k_1(c_1 - c_0)(1 + \boldsymbol{K}'^2_{1a}/[H^+]^n) \quad (29)$$

$$\tau_2^{-1} \approx k_{-2} + k_2(c_1 - c_0)\boldsymbol{K}_{2a}{}^n/[H^+]^n \quad (30)$$

$$\tau_3^{-1} \approx k_3(c_1 - c_0) + k_{-3}[H^+]^n \quad (31)$$

Equations (30) and (31) are not obeyed by the experimental data. This eliminates Mechanisms II and III. Two good linear least-squares regressions of the experimental relaxation times against Equation (29) are obtained for FR295 and FR401 when $n = 2$ (Figures 12 and 13). From the slope and intercept of these two regression lines k_1, k_{-1} and $\boldsymbol{K}_1 = k_{-1}/k_1 = [Fe^{3+}][LH_5{}^+]/[FeLH_5{}^{4+}]$ are determined (Table 3).These rate constants are of the same order of magnitude as those reported for complex formation with Fe^{3+}.[18,27,32,33]

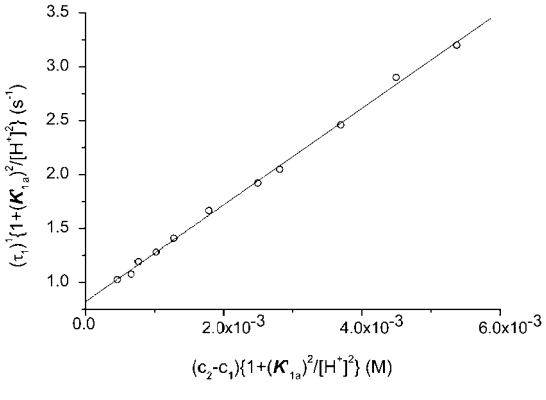

Figure 12. Plot of $\tau^{-1}(1 + \boldsymbol{K}'^2_{1a}/[H^+]^2)$ against $(c_1 - c_0)(1 + \boldsymbol{K}'^2_{1a}/[H^+]^2)$ in acidic media ($1.47 \leq pH \leq 2.20$): intercept, 0.82 ± 0.04 s^{-1}; slope, 450 ± 20 M^{-1} s^{-1}; $r = 0.99905$

If the fast formation of another complex following that of $FeLH_3{}^{2+}$ is involved in Mechanism I, to a first approximation, we can write at a fixed pH value reactions in Equations (32) and (33).

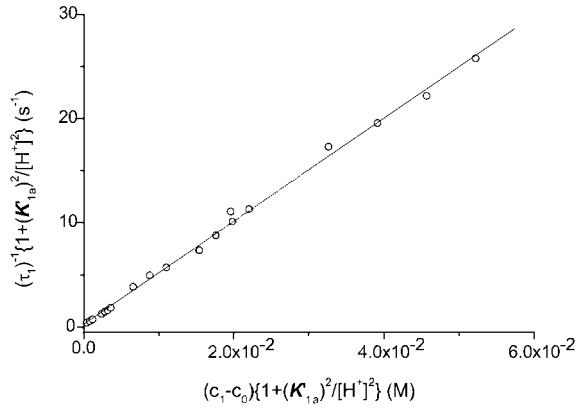

Figure 13. Plot of $\tau^{-1}(1 + \boldsymbol{K}'^2_{1a}/[H^+]^2)$ against $(c_1 - c_0)(1 + \boldsymbol{K}'^2_{1a}/[H^+]^2)$ in acidic media ($1.50 \leq pH \leq 2.20$) for FR401: intercept, 0.28 ± 0.03 s^{-1}; slope, 500 ± 20 $M^{-1} \cdot s^{-1}$; $r = 0.99849$

Table 3. The rate and equilibrium constants involved in complex formation between FR295 and FR401 with Fe ^{III} in acidic media

Ligand	k_1 [$M^{-1}s^{-1}$]	k_{-1} [s^{-1}]	$K_1 \times 10^4$ [M]	$K_1^{-1} \times 10^{-3}$ [M^{-1}]
FR295	450 ± 20	0.82 ± 0.04	18.2	0.55
FR401	500 ± 20	0.28 ± 0.03	5.6	1.80

$$Fe^{3+} + \mathcal{L} \underset{k_{-(obs)}}{\overset{k_{(obs)}}{\rightleftharpoons}} Fe\mathcal{L} \text{ (rate-limiting)} \quad (32)$$

$$Fe\mathcal{L} + L \leftrightarrows Fe\mathcal{L}_2 \quad (33)$$

In these reactions, the state of protonation of the ligand L and the complexes $Fe\mathcal{L}$ and $Fe\mathcal{L}_2$ are not known. Under our experimental conditions ($c_1 >> c_0$) with a fixed pH, the expression of the reciprocal relaxation time associated with rate limiting Equation (32) can be estimated by Equation (34) where the apparent equilibrium constant $K = [L][Fe\mathcal{L}]/[Fe\mathcal{L}_2]$.[20]

$$\tau_1^{-1} = k_{-obs}(K/[L]) + k_{obs}(c_1 - c_0) \quad (34)$$

This last equation is not obeyed by our experimental data. Furthermore, in acidic media, at $pH \approx 2$, Fe^{III} starts being present in the $FeOH^{2+}$ form [Equation (35)][31] with an equilibrium constant $K_{(FeOH)} = [H^+][FeOH^{2+}]/[Fe^{3+}] \approx 2 \cdot 10^{-3}$ M.[31]

$$FeOH^{2+} + H^+ \leftrightarrows Fe^{3+} + H_2O \quad (35)$$

If complex formation occurs between $FeOH^{2+}$, and FR401or FR295 the reciprocal relaxation time equation associated with Equation (36) will be expressed as Equation (37).[24]

$$LH_5^+ + FeOH^{2+} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} FeOHLH_5^{3+} \quad (36)$$

$$\tau_3^{-1} = k_{-4} + k_4\{c_1 K_{FeOH}/(K_{FeOH} + [H^+]) - c_0\} \quad (37)$$

Equation (37) is not obeyed by our experimental data. In contrast, if we take into account the presence of $FeOH^{2+}$ in the experimental medium, the reciprocal relaxation equation associated with the reaction in Equation (21) of Mechanism I will be expressed as Equation (38).

$$\tau^{-1} = k_1\{c_1[H^+]/([H^+] + K_{FeOH}) - c_0\} + k_{-1}[H^+]^n/([H^+]^n + K'_{1a}) \quad (38)$$

Under our experimental conditions ($1.4 < pH < 2$, $[FeOH^{2+}]$) Equation (38) simplifies into Equation (29). In this case, the presence of $FeOH^{2+}$ will not affect our kinetic analysis.

With dicatechols in non-hexadentate chelators such as amonabactins, more than one chelator can be engaged in complex formation with Fe^{III}.[22] Under our experimental conditions, we only detected a single 1:1 complex. This, however, does not exclude the formation of complexes with different stoichiometries (Fe_2L_3) under other experimental conditions where for instance $c_0 \leq c_1$. Moreover, as in the case of enterobactin, in FR401, the protonation of the oxygen ligand at position 2 may lead to a monosalicylate-type coordination with Fe^{III}.[34] Nevertheless, this coordination cannot occur with FR295 because it does not have a hydroxy group at position 2. Furthermore, the fact that the behaviours of both the FR401 and FR295 ligands towards complex formation are identical tends to exclude the salicylate-type coordination with FR401. In acidic media, for both FR295 and FR401, a complex is formed between Fe^{3+} and $L(H_5)^+$. This complex loses five protons from pH = 2 to 9. If we assume that, as in the case of the free ligands, the proton dissociation constants reported in Table 3 refer to two proton losses from the equivalent hydroxy groups in each of the two catechol moieties and from the central ammonium group, as shown for the free ligands, then $p\boldsymbol{K}'_{1a} = (pK_{2a} + pK'_{3a})/2$, $p\boldsymbol{K}'_{3a} = (pK'_{4a} + pK'_{5a})/2$ and $p\boldsymbol{K}'_{2a} = pK'_{1a}$ with $K'_{1a} = [(FeLH_4)^{3+}][H^+]/[(FeLH_5)^{4+}]$, $K'_{2a} = [(FeLH_3)^{2+}][H^+]/[(FeLH_4)^{3+}]$, $K'_{3a} = [(FeLH_2)^+][H^+]/[(FeLH_3)^{2+}]$, $K'_{4a} = [FeLH][H^+][(FeLH_2)^+]$ and $K'_{5a} = [(FeL)^-][H^+][FeLH]$.

$$(FeLH_4)^{3+} + H^+ \leftrightarrows (FeLH_5)^{4+} \quad (39)$$

$$(FeLH_3)^{2+} + H^+ \leftrightarrows (FeLH_4)^{3+} \quad (40)$$

$$(FeLH_2)^+ + H^+ \leftrightarrows (FeLH_3)^{2+} \quad (41)$$

$$FeLH + H^+ \leftrightarrows (FeLH_2)^+ \quad (42)$$

$$(FeL)^- + H^+ \leftrightarrows FeLH \quad (43)$$

The affinities of catechols for iron are extremely high.[16,18,22,28,29,31] We may, therefore, assume that with the analytical Fe^{III} concentration $c_1 \approx c_0$, the complexes of FR295 and FR401 are the predominant species from mildly acidic to basic media. This is always required with Fe^{III} complexes in order to avoid ferric hydroxide precipitation.

The Affinities of FR295 and FR401 for Fe^{III}

The affinity of a ligand for a metal increases upon proton loss.[28] This is manifested by the so-called chelation effect in which the apparent pK_a of the ligand engaged in the coordination with the metal decreases upon complex formation.[29]. The greater the pK_a difference (ΔpK_a) is between the free ligand proton dissociation and that of the same ligand engaged in the complex media, the higher is the affinity for the metal.[14,23,27] In Mechanism I, upon complex formation [Equation (20)], $FeLH_5^{4+}$ readily deprotonates by a diffusion-controlled acid-base dissociation to produce $FeLH_3^{2+}$ [Equation (21)]. The proton loss increases the affinities of both FR401 and FR295 for the metal by more than 12 orders of magnitude ($[Fe^{3+}][LH_3^-]/[FeLH_3^{2+}] = K_1K'_{1a}K'_{2a}/K_{1a}K_{2a}$). $FeLH_5^{4+}$ is, therefore, practically inexistent in the experimental medium. $FeLH_3^{2+}$ in turn deprotonates to finally yield FeL^- with another increase in the affinity of several orders of magnitude (Table 4). This is deduced from Equation (1) and the proton dissociation constants of the free ligand and of the complex [Equations (44) and (45)]. This yields $\log\beta$ ($-\log K$) values of Equations (29) and (31) for FR295 and FR401, respectively.

$$Fe^{3+} + L^{4-} \leftrightarrows FeL^- \quad (44)$$

$$1/\beta = K = [L^{4-}][Fe^{3+}]/[FeL^-] = K_1(K'_{1a}K'_{2a}K'_{3a}K'_{4a}K'_{5a})/(K_{1a}K_{2a}K_{3a}K_{4a}K_{5a}) \quad (45)$$

Table 4. The affinity constants and the pFe involved in complex formation between Fe^{III} and FR295 and FR401

Ligand	log β	pFe
FR295	29	22
FR401	31	25

These values are high and place both ligands in the classical range of affinities expected for dicatechols. Indeed, with monocatechols, the affinities for iron are about 37 ($\log\beta_3$) and for a tricatechol they are about 40.[16,18,22] The pH increase stabilises the complex by the consequent deprotonation of the hydroxy groups and allows it to achieve the $\log\beta$ value of 30 with the completely deprotonated ligands. An amine is not a particularly good ligand for Fe^{III}.[30] However, the pK_a we ascribed to the deprotonation of the ammonium group in the free ligand is shifted by more than 1 pK_a unit in the complex. This implies that the central

amine is also engaged in complex formation. This engagement is not, however, as strong as that observed for the catechol moieties where the ΔpK_a value exceeds 6 pK_a units implying, as expected, a very strong coordination to the metal centre.[28,29] Fe^{III} can then be considered to be coordinated to two catechol moieties and one amine group with the sixth coordination site probably occupied by water. Although we succeeded in synthesising the Fe^{III} and Ga^{III} complexes of FR401 and FR295 (Exp. Sect.), we do not yet have direct evidence to confirm such a structure. All that we can say is, that under our experimental conditions, with $c_1 \geq c_0$ a monoferric complex is formed between Fe^{III} and one FR295 or FR401 ligand and that in both cases five donor atoms seem to be engaged in the formation of this complex.

The affinities of FR295 and FR401 for iron are reported for complex formation with the fully ionised ligand L^{4-} [Equation (46)]. The FeL^- form is not the only one present in the vicinity of neutrality. Therefore, in order to have a scale of efficiency for iron chelators, Raymond et al. defined the pFe ($-\log[Fe^{3+}]$) scale. The pFe is determined for an analytical ligand concentration of 10^{-4} M and an analytical Fe^{III} concentration of 10^{-6} M at pH = 7.4, which is equivalent to that of physiological media.[15] From the different proton dissociation constants of Tables 2 and 3 and from mass conservation [Equations (46) and (47)] we can determine the analytical expression of $[Fe^{3+}]$ [Equation (48)] with $c_0 << [L] \approx c_1$.

$$c_1 = [FeL^-] + [FeLH_2^+] + [FeLH_4^+] + [Fe] \quad (46)$$

$$c_0 = [L] + [FeL^-] + [FeLH_2^+] + [FeLH_4^+] \quad (47)$$

$$[Fe^{3+}] = \frac{K\{[H^+]^5 + (K_{2a})^2[H^+]^3 + (K_{2a}K_{3a})^2[H^+] + (K_{2a}K_{3a})^2K_{1a}\}c_1}{\{[H^+]^5 + (K'_{1a})^2[H^+]^3 + (K'_{1a}K'_{3a})^2[H^+] + (K'_{1a}K'_{3a})^2K_{2a}\}c_0} \quad (48)$$

Table 4 represents the affinities of both ligands for iron and the relevant pFe. These values indicate that FR295 and FR401 can be considered as very good ligands for Fe^{III}.[15–18,22,34] This can explain their siderophore-like role with mycobacteria and their capacity to inhibit the growth of *Plasmodium falciparum* in vitro, where they probably act as iron sequestering agents depriving the medium of this element essential for the development of the microorganism.

Experimental Section

KCl (Merck Suprapur), NaOH, and HCl (Merck Titrisol), EDTA (Merck Titriplex), $FeCl_3$, sodium hydrogen carbonate (Normapur), EtOH, acetic acid (100%), DMSO, sodium acetate, sodium formate and sodium citrate (Merck), gallium nitrate (ACROS), and Hepes (Aldrich) were used without further purification. Water and glassware were prepared as described previously.[14] FR295 and FR401 were synthesized and purified according to published procedures and were kept under vacuum at −20 °C.[8,10,13]

Stock Solutions: All stock solutions were used fresh. Because of the chelator's slight solubility in aqueous media ($< 10^{-3}$ M), FR295 and FR401 were first dissolved in ethanol at 10^{-2} M. These solutions were later diluted to the 10^{-4} to 10^{-5} M range in the final buffers. The solutions at pH < 2.5 were not buffered; those at 2.5 < pH < 3.5 were buffered with formate, those at 3.5 < pH < 6 with acetate, those at 6 < pH < 8.5 with Hepes and those at pH > 8.5 with carbonate. Buffer salt concentration was $5 \cdot 10^{-2}$ M and the final pH was attained by microinjections of concentrated HCl, NaOH, or AcOH. $FeCl_3$ solutions were prepared in acidic media at pH < 2. The Fe^{III} complexes of FR401 and FR295 were prepared in acidic media by adding the required amount of $FeCl_3$ to the ligands. The pH was then gently raised to final values by microinjections of concentrated NaOH. The final ionic strength of all solutions was adjusted to 0.2 with KCl. For pH > 5, all solutions were prepared under argon in a glove bag.

pH Measurements: The pH values were measured at 25±0.5 °C with a Jenco pH-meter equipped with an "Ingold" combined microelectrode calomel/glass. Buffers used for pH standardization were of pH = 4.00, 7.00, and 10.01 (Sigma).

Spectrophotometric Measurements: Spectrophotometric measurements were performed in anaerobic conditions under argon at 25±0.5 °C with a Cary C210 or a Perkin–Elmer Lambda 2 spectrophotometer equipped with a magnetic stirring device and thermostatted cell carrier. For each set of experiments, the spectra were recorded under different pH values. The reversibility of the observed processes with $[H^+]$ was checked at the end of each series of measurements by lowering the final pH to the initial values and by comparing the final to the initial absorption spectra. Values were discarded throughout the series where there was a difference of > 3% between the spectra of identical pH values. This was done in order to avoid the risk of catechol oxidation mainly in basic media.

Stopped-Flow Measurements: Kinetic measurements were performed by mixing acidic solutions of FR401 or FR295 with solutions of $FeCl_3$ under argon in an SF 3 L Hi-Tech stopped-flow spectrophotometer equipped with a thermostatted bath (25±0.5) °C.

Mathematical Formalism and Signal Analysis: The experimental conditions were set so as to permit the use of chemical relaxation formalism.[21] All experimental signals were analysed as described elsewhere.[14] They were all pure exponentials and were dealt with as relaxation modes.[14,19–21]

Solubility of the Ligands and Synthesis of the Fe^{III} and Ga^{III} Complexes with the FR295 and FR401 Ligands: Saturated ethanol solutions of FR401 and FR295 were added to solutions of $FeCl_3$ in 50% water and ethanol. The colour of the mixture immediately turned dark and a precipitate appeared. The pH was then gently raised to neutrality, and the precipitate filtered, washed, and dried under vacuum. It was slightly soluble in DMSO, ethanol, and methanol. Electrospray mass spectrometry experiments performed on the methanolic solutions of the precipitate showed only the presence of FR401 and FR295 ligands and iron. The same experiments were repeated by mixing the same alcoholic solutions of FR295 and FR401 with solutions of gallium nitrate. The solubility of the dark precipitate was too low to allow any NMR spectroscopic measurements. Both FR295 and FR401 are scarcely soluble in purely aqueous media. Under our experimental conditions the highest concentration attained was $< 10^{-3}$ M. This concentration did not allow the use of other measurement techniques such as potentiometric p***K*** determination.

Concerted Development of Chiral Conformations in [(Alkyloxycarbonyl)methyl]tricarbonyl(triphenylphosphane)cobalt Complexes

Claudia Zucchi,[a] Roland Boese,[b] Kathy Alberts,[a][‡] Thomas Herbrich,[a][‡] Gergely Tóth,[c] Lajos Bencze,[c] and Gyula Pályi*[a]

Keywords: Cobalt / Carbonyl ligands / Chirality / Phosphanes

The *trans*-[(alkyloxycarbonyl)methyl]tricarbonyl(triphenylphosphane)cobalt complexes $[ROC(O)CH_2]Co(CO)_3PPh_3$ (R = Me, *n*Pr, *i*Pr, *t*Bu, and *c*Hex) have been prepared and characterized by IR, ^1H, ^{13}C, and ^{31}P NMR spectroscopy. Crystal and molecular structure determination by X-ray diffraction analysis revealed the following phases: $P\bar{1}$ (R = Me), $P2_1/n$ (R = *n*Pr), $P\bar{1}$ (R = *i*Pr), $P2_1/c$ (R = *t*Bu), $P\bar{1}$ and $P2_1/c$ (R = *c*Hex). The results show concerted development of chiral conformations (both enantiomers) in all cases.

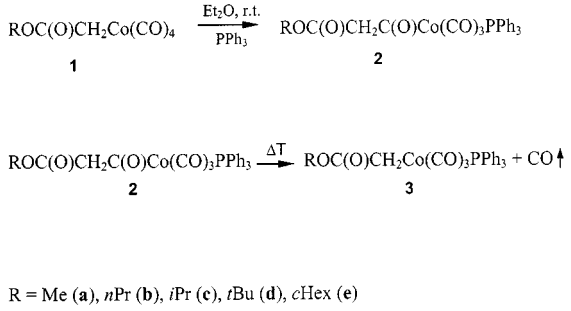
Introduction

The generation of molecular chirality presents an attractive challenge, both from an intellectual and a preparative point of view.[1] The mechanisms for the transfer of chiral information from one reacting group or molecule to the product are of the utmost importance for the design of more efficient systems.[2] In transition metal catalysed or assisted reactions, this transfer is usually an intramolecular process.[3] Since a number of the most efficient chiral ligands used in asymmetric catalysis (e.g., BINAP) exhibit conformational chirality,[4] the development of chiral conformations[5] in transition metal complexes acting as catalysts in these reactions represents an important research goal.

As part of a program aimed at learning more about the mechanisms of intramolecular transfer of chiral information in mono-[6] and dinuclear[7] organocobalt complexes, we have undertaken a systematic preparative and structural study of the [(alkyloxycarbonyl)methyl]tricarbonyl(triphenylphosphane)cobalt complexes, $[ROC(O)CH_2]Co(CO)_3PPh_3$ (R = Me, *n*Pr, *i*Pr, *t*Bu, and *c*Hex).[8] The results obtained with these complexes are reported herein.

Results and Discussion

trans-[(Alkyloxycarbonyl)methyl]tricarbonyl(triphenylphosphane)cobalt complexes (**3**) with achiral alkyl groups in the ester fragment (Me: **a**; *n*Pr: **b**; *i*Pr: **c**; *t*Bu: **d**; *c*Hex: **e**) were prepared in three steps. These steps (Scheme 1) consisted of ion metathesis, ligand-promoted carbonylation, and subsequent thermal decarbonylation.



Scheme 1

The constitutions and structures of complexes **3** were established by elemental analyses, by IR and NMR spectroscopy (spectroscopic data were compared with those of previously characterized compounds of similar structure[6b,6c,8–10]), and by determination of the crystal and molecular structures of the crystalline products by X-ray diffraction analysis (Figures 1–3; Tables 1–6 in the Exp. Sect.).

The crystal structures belong to centrosymmetric space groups with two or four molecules per unit cell, respectively. The *c*Hex ester complex **3e** was obtained in two different crystal forms ($P\bar{1}$ and $P2_1/c$ phases), highlighting the fact that the conformational effects are not critically dependent on intermolecular forces but rather on intramolecular interactions. Complex **3a** contains one diethyl ether solvate

molecule for every two molecules of the complex in the lattice of the $P\bar{1}$ phase; crystalline phases of the complexes **3b**−**e** were found to be solvate-free.

The X-ray diffraction results show that the overall molecular structure of complexes **3** (Figures 1−3) can be described in terms of approximate trigonal-bipyramidal geometry, with the two non-carbonyl ligands in the axial positions, which is a common feature of all alkyl-type [RCo-$(CO)_3$L][6b,6c,8a,9b,9c,11,12] and acyl-type [RC(O)Co$(CO)_3$L] (L = tertiary phosphane, I^-)[9b,9c,12,13] monosubstituted carbonylcobalt complexes. The molecules of complexes **3** may be regarded as being composed of three main moieties: (i) the (alkyloxycarbonyl)methyl fragment, (ii) the central (equatorial) $Co(CO)_3$ group, and (iii) the triphenylphosphane ligand (Scheme 2).

These moieties are linked by two single bonds, Co−C(H_2) and Co−P, about which rotation can occur. The C(H_2)−C(O) and P−C_{ar} bonds, rotations about which are directly related to the chiral inversions, are far away from each other with the cobalt atom and the Co−C(H_2) and Co−P bonds in between. The plane of the five heavy atoms of the ester group C−C(O)OC is oriented quasi-parallel to the plane of the $Co(CO)_3$ group (interplanar angle less than 25°). Other possible conformations of this group allowed by the rotation around the C_{sp^2}−C_{sp^3} bond are not populated. The slightly bent carbonylcobalt "plane" (consisting of seven atoms) has its concave face directed towards the ester fragment.

The σ-bond system that extends along the molecular axis is composed of two- and threefold conformational axes and adopts a highly relaxed staggered conformation throughout the molecule. The substituents at the sp^3-carbon atom (adjacent to Co), i.e. two H atoms and the ester group, are positioned above the OC−Co−CO forks (Scheme 3).

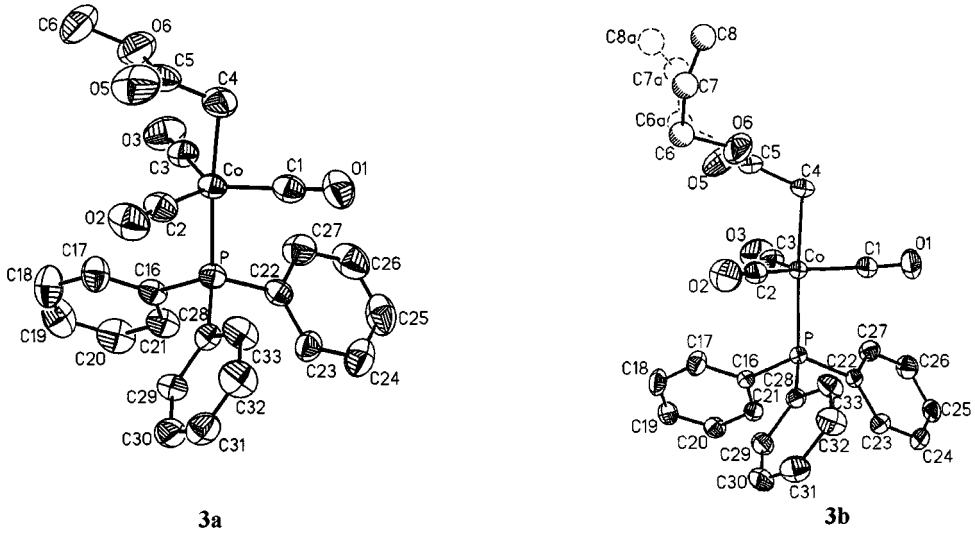

Figure 1. ORTEP drawing of the X-ray molecular structure of the complexes **3a** and **3b**, perpendicular view to the Co−P axis (one structure each)

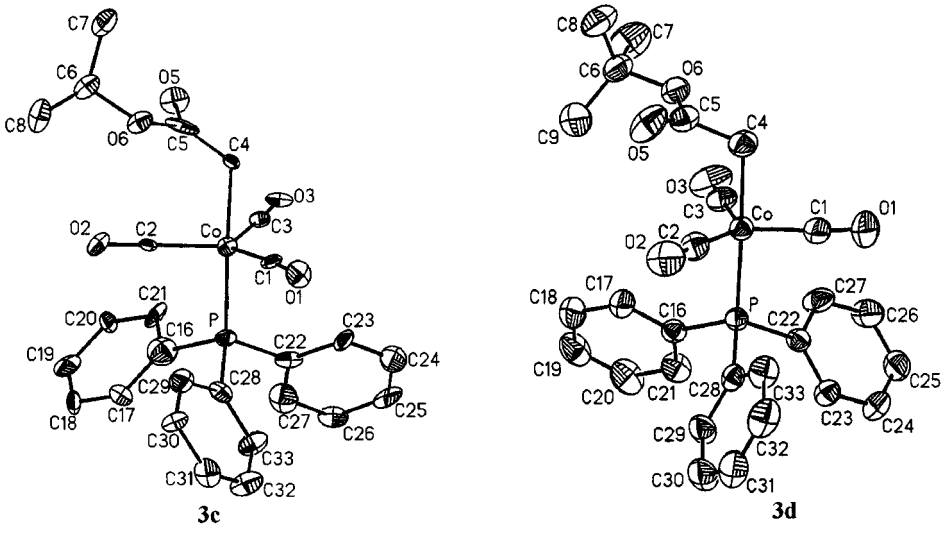

Figure 2. ORTEP drawing of the X-ray molecular structure of complexes **3c** and **3d**, perpendicular view to the Co−P axis (one structure each)

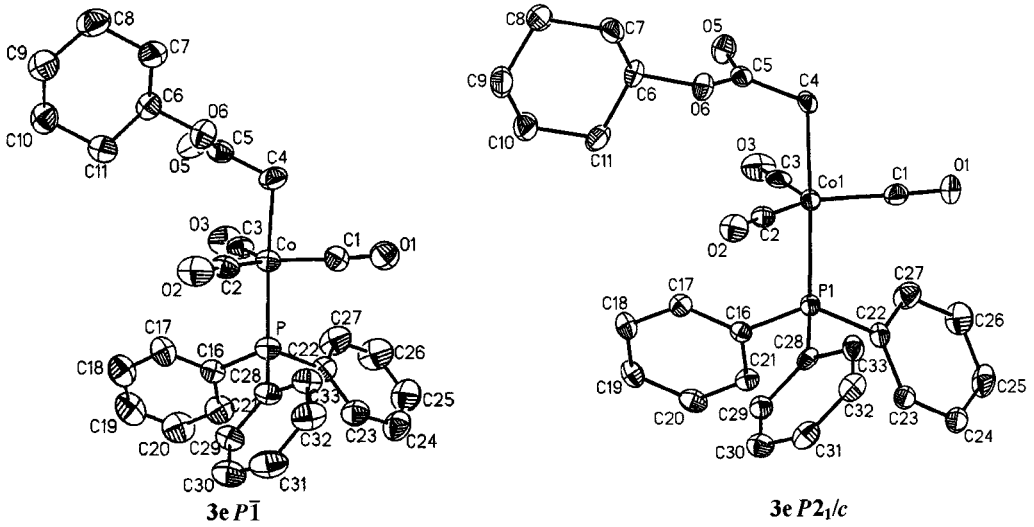

Figure 3. ORTEP alrawing of the X-ray molecular structure of complex **3a** ($P\bar{1}$ and $P2_1/c$ phases), perpendicular view to the Co−P axis (one structure each)

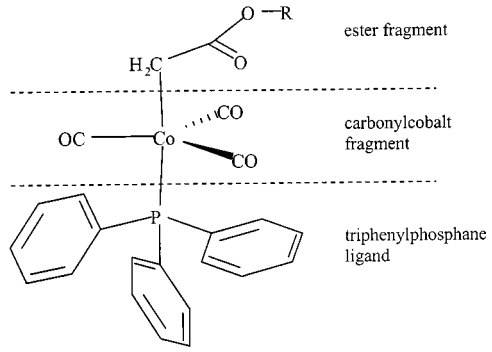
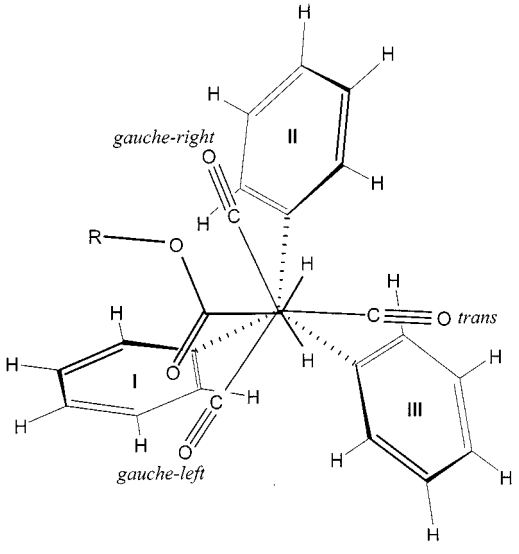


Scheme 2. Main fragments of the complexes **3**



Scheme 3. Complexes **3**, view in the Co−P axis

Due to the bulkiness of the ester group, the adjacent OC−Co−CO angle is widened to release the strain, with a concomitant compression of the other angles at Co. The staggered conformation of the $Co(CO)_3-PPh_3$ rotor is manifested in the orientation of the *ortho*-H atoms of the aromatic rings towards the equatorial plane rather than in the orientations of the $P-C_{ar}$ bonds. The "natural" (as in the free ligand) propeller shape of the triphenylphosphane ligand is preserved, but the positions ($Co-P-C_{ar}-C_{ar}$ angles) of the individual phenyl rings are not identical in complexes **3a**−**e** due to the perturbation, which seems to be most pronounced at the Ph group denoted by **I** in Scheme 3. This perturbation is clearly less pronounced in the methyl ester (**3a**) and the *n*-propyl ester (**3b**) and reaches a maximum in the isopropyl derivative (**3c**). It is not so great in the *tert*-butyl ester (**3d**), for reasons which will be discussed later.

An interesting feature seen in all but one (**d**) of the complexes **3** is a relatively short intramolecular contact between an α-H atom of the ester group and the ester carbonyl oxygen atom, as illustrated for the cyclohexyl derivative **3e** in Figure 4. The distance of this intramolecular interaction is certainly within the limits for H-bonding[14,15] (2.9−3.3[14a] or even 3.6 Å[14b] between two bridged heavy atoms). The five atoms (O−C−O−C−H) define a somewhat distorted ring. The formation of such a ring cannot be observed in the case of the *t*Bu derivative (**3d**), which lacks an α-H atom on the ester group. The charge transfer to the ester carbonyl group is also reflected in a shift to higher wavenumbers of its ν(C−O) band in the solution IR spectra; complex **3d** shows the lowest-energy absorption in this series. This systematic change in the solution spectra also indicates that the ring-forming H-bond interaction remains intact in *n*-hexane solution. The formation of this H-bonded ring obviously contributes to the rigidity of the ester group.

Where the ester has two α-H atoms, the >C=O···H−C(H)R interaction leads to a differentiation of the hydrogen atoms of this $>CH_2$ group. This generates a centre of chirality at the ester α-C_{sp^3} atom of complex **3b** as well as at the corresponding position in the Et derivative

	OH (Å)	O-C(sp^3) (Å)	O-C-O-C (deg.)	C-O-C-H (deg.)

(discussed elsewhere[8a,16]), as shown in Scheme 4. We were, however, unable to detect this effect in the solution phase by low-temperature ^1H NMR spectroscopy down to −80 °C in CD_2Cl_2 or to −50 °C in [D_6]acetone.

An additional "through-space" interaction could be identified between the Co atom and the ester $C_{sp}{}^2$ atom in complexes **3a**−**e**. These atoms are separated by only 292−298 pm (Table 6), which is significantly shorter than the sum of the van der Waals radii (Co−C 385 pm[17]), indicating a kind of coordinative interaction (termed "auto-solvation"[18]) between these atoms. As a result of this interaction, the carboxyl $C_{sp}{}^2$ atom becomes tetracoordinated; since it then bears four different substituents, it can adopt (*R*) and (*S*) enantiomeric configurations, as shown in Scheme 5.

Scheme 5

The overall approximate trigonal-bipyramidal geometry of complexes **3** is very important with regard to the main viewpoint of the present study: The *trans*-axial distribution of the (generally) flexible alkyl (or acyl) and phosphane ligands provides an ideal situation for the investigation of concertedness in the development of certain conformations in these ligands on the "opposite" sides of the molecule. In fact, a quantitative concertedness can be observed for the conformations of the ester fragment, with respect to the $Co(CO)_3$ moiety, and the triphenylphosphane ligand in all derivatives **3** described herein (the schematic representation

and the notation used for these conformations is shown in Scheme 6).

The following two important points emerged:

(i) In the solid phase, the molecules invariably show 100% concertedness in the sense that for each conformer of the ester group, there is *only one* corresponding conformer of the triphenylphosphane fragment.

(ii) The above mechanism excludes 50% of the statistically possible combinations, allowing only *re*,**M** and *si*,**P** for **3a**, **3c**, and **3d**, and only *re*,**P** and *si*,**M** for **3b** and for the two phases of **3e**.

This selection rule appears to be independent of (a) the number of molecules in the unit cell ($Z = 2$ or 4 for complexes **3**), and (b) the point group (as demonstrated by the behaviour of the two different phases of complexes **3e**). Recently, we performed an exhaustive molecular mechanical and quantum chemical analysis of the ethyl ester derivative[8a,16] $EtOC(O)CH_2Co(CO)_3PPh_3$. In this study, we found that the concerted conformational changes in this complex are controlled by a clockwork-analogous mechanism, where the displacements in the ester ligand are "felt" by the phosphane by transmission through the cogwheel-like $Co(CO)_3$ moiety.[16] This mechanism is responsible for the marked reduction in the number of statistically possible isomers to the number observed experimentally. The main goal of the present study has been to explore whether this concerted development of conformations is operative for other ester derivatives, with configurationally achiral groups in the ester fragment. The six structures reported in the present paper indicate a fairly general validity of this rule.

Beyond the correlations in the development of chiral conformations in molecules **3**, a strict correlation of these chiral conformations with the "secondary" centres of chirality, identified in the crystalline phases, has been observed. The (*R*) and (*S*) enantiomers (formed by H-bonding) of the ester alkyl α-C_{sp}^3 atoms (Scheme 4) in the Et and *n*Pr derivatives are 100% correlated to the corresponding *re*,**P** and *si*,**M** conformations, respectively.

These findings will hopefully aid detailed understanding of the mechanism of the intramolecular transfer of chiral information, which is of particular importance with regard to the design of third-generation (conformational) chiral catalysts and auxiliaries. We are extending our investigations to ester derivatives containing one or more configurational chiral centre(s) in the ester group or the phosphane ligand. The findings of these studies will be reported in subsequent papers.

Experimental Section

General Remarks: Starting materials were of commercial origin, with the exception of cyclohexyl bromoacetate[19] and octacarbonyldicobalt,[20] which were prepared by published procedures. − All

operations were performed using standard Schlenk techniques.[21] − IR spectra were recorded with a Bruker FT-IR IFS 113V spectrometer. − ^{1}H, ^{13}C, and ^{31}P NMR spectra were recorded with a Bruker AMX-400 instrument. − X-ray diffraction measurements were made with a Nicolet R3m/V four-circle diffractometer with Mo-K_α radiation at 298 K. Calculations were performed using the Bruker-AXS SHELXTL Vers. 5.10. Atomic scattering factors were taken from SHELXTL and ref.[22] Corrections for anomalous dispersion were made according to ref.[23] − For the preparation of the alkylcobalt complexes $[ROC(O)CH_2]Co(CO)_3PPh_3$, the procedures followed were essentially those described in ref.[8b] (Scheme 1).

Preparation of *c*HexOC(O)CH$_2$Co(CO)$_3$PPh$_3$ (3e): $Co_2(CO)_8$ (171 mg, 0.5 mmol) in Et_2O (15 mL) was reduced to $Na[Co(CO)_4]$ with Na/Hg. The resulting solution, containing 1 mmol of $Na[Co(CO)_4]$, was filtered into a Schlenk vessel under Ar and then cooled to −20 °C. Under stirring, cyclohexyl bromoacetate (221 mg, 1 mmol) was added in a single portion, which led to the immediate precipitation of white NaBr. Stirring was continued at this temperature for 4 h, in the course of which the colour of the solution gradually became more yellow and eventually turned brown. Thereafter, the solution was allowed to warm to room temperature and stirred for a further 1 h. A sample was taken (1 mL), which was analysed by IR spectroscopy in the 1600−2200 cm^{-1} range. This analysis showed the disappearance of the strong band due to $[Co(CO)_4]^-$ (at ca. 1900 cm^{-1}) and the emergence of a band system corresponding to an $RCo(CO)_4$-type complex,[9] further accompanied by an "organic" ν(C−O) absorption at ca. 1720−1710 cm^{-1}. This result indicated *c*HexOC(O)CH$_2$Co(CO)$_4$ (**1e**) to be the only carbonylcobalt species present in the reaction mixture. The solution was then filtered and to the filtrate, containing 1 mmol of complex **1e**, triphenylphosphane [P(C$_6$H$_5$)$_3$; 262 mg, 1 mmol] was added in a single portion at room temp. The resulting mixture was stirred for 3 h, in the course of which a gradual colour change from brown to light-yellow was observed. At this point, a sample (1 mL) was withdrawn and analysed by IR spectroscopy in the C−O stretching range (1600−2200 cm^{-1}); complete disappearance of the band system attributed to complex **1e** was observed, and two new band systems had emerged with an approximate intensity ratio of 1:9. The stronger band system, showing absorptions at higher wavenumbers, was attributed to the acylcobalt-type complex *c*HexOC(O)CH$_2$C(O)Co(CO)$_3$(PPh$_3$) (**2e**)[9] based on the fact that two acyl ν(C−O) bands were observed for this system. The weaker band pattern was assigned to *c*HexOC(O)CH$_2$Co(CO)$_3$(PPh$_3$) (**3e**) on the basis of comparisons with the spectra of previously characterized $ROC(O)CH_2Co(CO)_3PPh_3$ complexes.[6,8] The reaction mixture was subsequently warmed to 32 °C and stirred for a further 8 h at this temperature. After this treatment, a further sample was analysed by IR spectroscopy. This analysis showed the quantitative transformation of the acyl-type complex **2e** to the alkyl-type complex **3e**. The solvent was then evaporated at room temp. under reduced pressure. The crude product was recrystallized from Et_2O/*n*-hexane (ca. 6:1) to yield a yellow crystalline product (178 mg, 32.6%). This was characterized by elemental analyses, IR and NMR spectroscopy, and X-ray diffraction analysis. − $C_{29}H_{28}CoO_5P$ (546.445): calcd. C 63.74, H 5.16, Co 10.78, P 5.67; found C 63.9, H 5.4, Co 10.8, P 5.7. − X-ray diffraction analysis of this product revealed a $P\bar{1}$ phase (see later). The crude product obtained from an identical experiment was recrystallized from *n*-hexane. This operation yielded 168 mg (30.8%) of a yellow crystalline product, which was subsequently identified as belonging to the $P2_1/c$ phase. − Found C 63.8, H 5.3, Co 11.0, P 5.5.

Complexes 3a, 3b, 3c, and 3d: These were prepared by essentially the same procedure as described above. IR, ^{1}H, ^{13}C, and ^{31}P NMR spectroscopic data are listed in Tables 1, 2, 3, and 4. Experimental parameters relating to the X-ray diffraction measurements are shown in Table 5. Selected bond lengths and angles are collected in Table 6. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-163127 (**3a**) -163128 (**3b**), -163129 (**3c**), -163130 (**3d**), -163131 (**3e** monoclinic), -163132 (**3e** triclinic). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

3a: $C_{26}H_{22}CoO_{5.5}P$ [**3a**·$^1/_2(C_2H_5)_2O$] (515.387): calcd. C 60.95, H 4.33; found C 61.1, H 4.7.

3b: $C_{26}H_{24}CoO_5P$ (506.380): calcd. C 61.67, H 4.78; found C 62.1, H 5.0.

Ruthenium-Capping of Di- and Tetraethynylbiphenyls

Berta Gómez-Lor,[a] Amelia Santos,*[a] Marta Ruiz,[a] and Antonio M. Echavarren*[b]

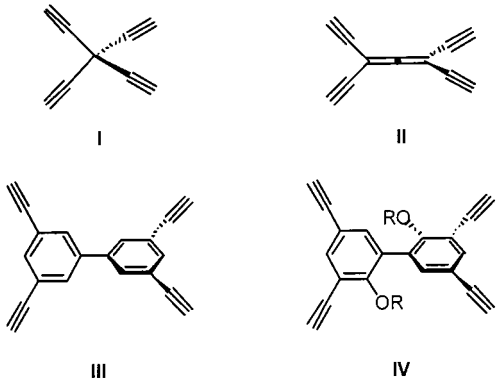
Keywords: Ruthenium / Vinylidene complexes / Hydrido complexes / Alkynes

The di- and tetraalkynyl biphenyls **3** and **5** have been synthesized from the tetrabromo derivative **1** by using Pd-catalyzed cross-coupling reactions. The reaction of **3** or **5** with *cis*-[$RuCl_2(dppe)_2$] (**8**) affords vinylidene ruthenium complexes, which were deprotonated with Et_3N to give the terminal σ-alkynylruthenium derivatives **9**–**12**. The reaction of **3** or **5** with [$Ru(CO)ClH(PPh_3)_3$] (**13**) gave the corresponding di-σ-alkenyl ruthenium complexes **14** and **15**.

Introduction

Carbon-rich organometallics containing rigid conjugated branches have attracted great attention, since they are potentially useful for building carbon-rich networks,[1] organometallic polymers[2] and π-conjugated polymetallic systems,[3] which can all find applications in material science. Of special interest are the σ-alkynyl complexes, since they allow electronic communication between coordinated metal centers through the C≡C bonds in the π-conjugated systems. Indeed, a number of alkynyl complexes have been designed for use in nonlinear optics[4] and as liquid crystals.[5] Polyethynylated complexes may form organometallic polymers in which the metal binds two ethynyl groups.[4b,5c,6] Polymetallic compounds with -$(C{\equiv}C)_n$- or polyethynylbenzene bridges have also been studied.[3,4b,4c,5c,7] Other di- or trimetallic alkynyl complexes have been prepared from ethynyl ferrocene.[8] Additionally, alkynyl derivatives have given rise to mixed-valence systems,[9] and organometallic macrocycles[10] have also been prepared.

The assembly of carbon-rich two- or three dimensional nanomaterials from ethynylated scaffolds has also attracted great attention.[11,12] Major achievements in this field are the preparation of tetraethynylmethane (**I**),[13] tetraethynylethene,[14] hexaethynylbenzene,[15] and π-metal complexes of tetraethynylcyclobutadiene,[16] and pentaethynylcyclopentadiene.[17] Tetraethynylallene (**II**), topologically related to the tetraalkyne **I**, still remains an elusive target. The biphenyls **III**[18] and **IV**, which display the four alkynes in a flexible elongated tetrahedral arrangement, could offer a potential alternative to **I** and **II** (Scheme 1).



Scheme 1

Herein we report the synthesis of alkynes **3** and **5** as new potential building blocks for the construction of carbon-rich networks,[19] and their reactions with the ruthenium complexes *cis*-[$RuCl_2(dppe)_2$] (**8**) [dppe = 1,2-bis(diphenyl)-phosphanylethane] and [$Ru(CO)ClH(PPh_3)_3$] (**13**), which afford mono- and di-alkynyl and di-alkenyl ruthenium complexes, respectively, in good yields.[20]

Results and Discussion

Synthesis of Di- and Tetraalkynylbiphenyls

The synthesis of alkynes **3** and **5** was based on palladium-catalyzed transformations as the key steps. The tetrabromo diester **1** was readily obtained from 2,2′-biphenol by bromination with excess bromine in methanol at 23 °C,[21] followed by acylation with pivalic anhydride (95% overall yield). Thus, Sonogashira coupling[22] of tetrabromo dipivalate ester (**1**) with excess trimethylsilylacetylene {[$PdCl_2(PPh_3)_2$] and CuI catalysts (20 mol % each), Et_3N, 70 °C, 48 h] led to **2** (89% yield). No further coupling between **2** and trimethylsilylacetylene took place through the more hindered *o*-bromides by using this coupling procedure, even under severe conditions (Scheme 2).

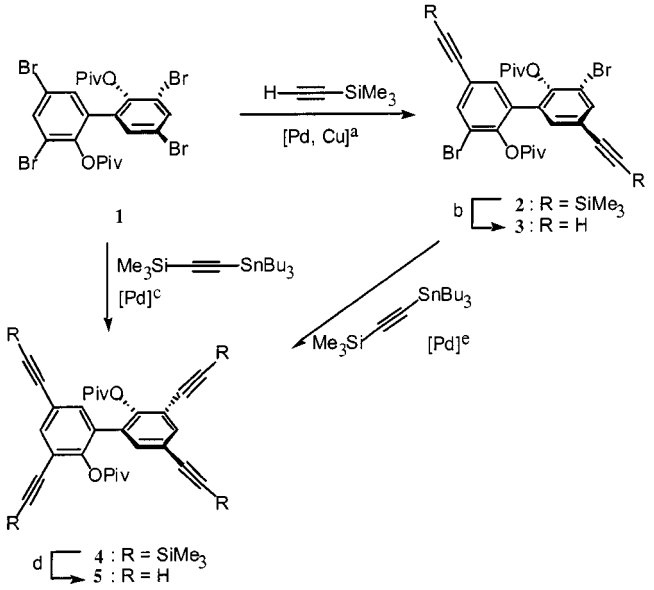
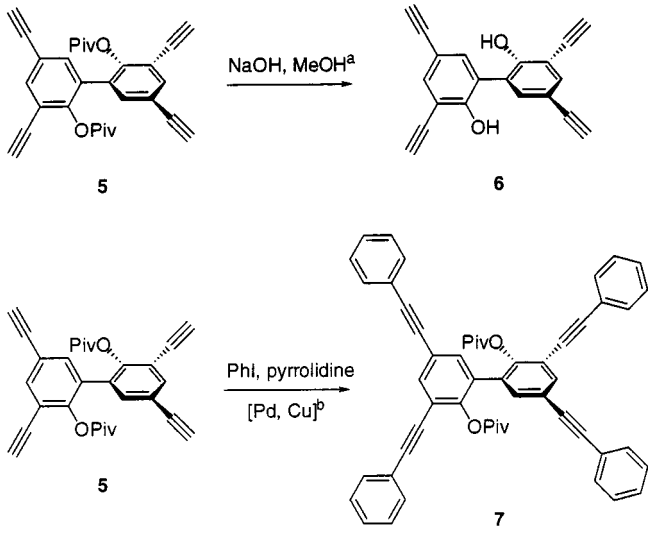


Scheme 2. a: $[PdCl_2(PPh_3)_2]$ (20 mol %), CuI (20 mol %), Et_3N, 70 °C, 48 h (89%); b: K_2CO_3, MeOH, 23 °C, 30 min. (90%); c: $[Pd(PPh_3)_4]$ (20 mol %), toluene, reflux, 4 h (90%); d: K_2CO_3, MeOH, 23 °C, 30 min. (95%); e: $[Pd(PPh_3)_4]$ (20 mol %), toluene, reflux, 4 h (92%)



Scheme 3. a: NaOH, MeOH, 23 °C, 18 h (80%); b: $[Pd(PPh_3)_4]$ (20 mol %), CuI (20 mol %), pyrrolidine, 23 °C, 3 h (83%)

However, by using the Stille coupling[23] the four bromides could be efficiently replaced by alkynyl substituents in a single step. Thus, coupling of **1** with (trimethylsilylethynyl)-tributylstannane[24] in the presence of $[Pd(PPh_3)_4]$ as catalyst gave the tetraalkynyl derivative **4** (90% yield) as a stable colorless oil. The biphenyl **4** was also obtained by the coupling of dibromide **2** with (trimethylsilylethynyl)tributylstannane under the same conditions (92% yield). The terminal alkynes **3** and **5** could be obtained by standard deprotection of the TMS groups with K_2CO_3 in MeOH in 90 and 95% yields, respectively. The pivaloyl groups of **5** could be efficiently removed under stronger basic conditions [NaOH, MeOH, 23 °C, 18 h, 80%] to yield the biphenol **6**. This compound could undergo self-condensation by copper- or palladium-catalyzed alkyne−alkyne coupling to furnish three dimensional polymers bearing hydrophilic cavities.

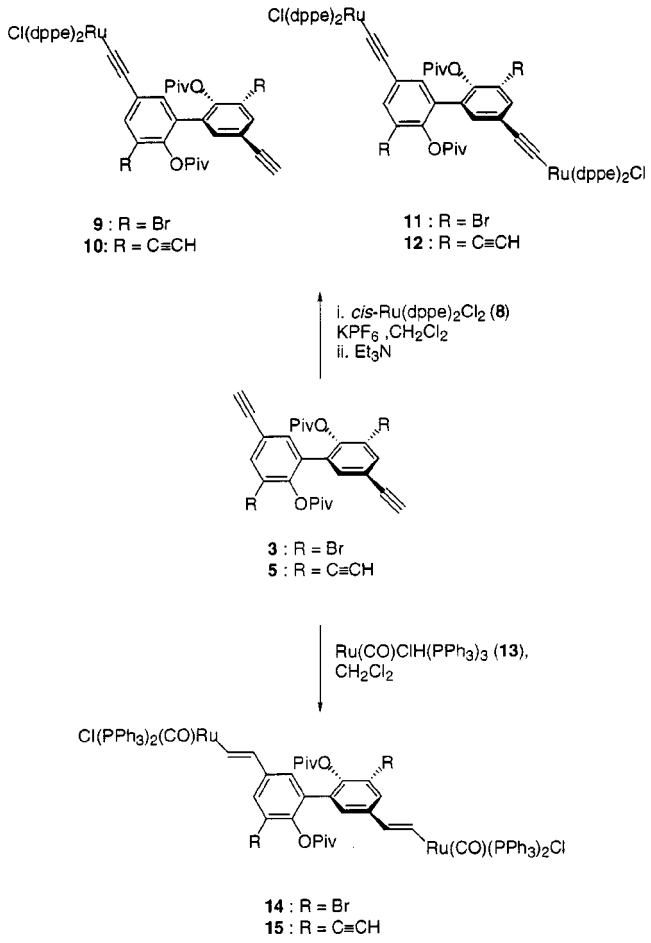
While alkynes **3** and **5** are stable compounds that can be stored under ordinary conditions, alkyne **6** undergoes slow decomposition as a solid. However, it can be easily manipulated and stored in the dark without significant decomposition. The potential utility of these tetraethynylbiphenyls as tectons for the building of more complex structures relies upon their ability to couple with appropriate electrophiles. Thus, the coupling of **5** with iodobenzene (4 equiv.) afforded **7** [$Pd(PPh_3)_4$ and CuI (20 mol % each), pyrrolidine, 23 °C, 3 h, 83%; Scheme 3].

Synthesis of Ruthenium Alkynyl Complexes

The reactions of alkynes **3** and **5** with one equivalent of *cis*-$[RuCl_2(dppe)_2]$ (**8**) and two equivalents of KPF_6 in CH_2Cl_2 at room temperature for four days led to the conversion of the starting alkynes into a mixture of two ruthenium complexes. On the basis of the spectroscopic data and literature precedent,[25−27] these products were tentatively assigned as the monovinylidene and η^2-alkyne ruthenium complexes. Thus, the IR spectra show relatively intense bands in the range 1625−1630 cm^{-1}, characteristic of the vinylidene ruthenium complexes. However, the ^1H NMR spectra were complex, suggesting that isomeric (η^2-alkyne)ruthenium complexes were also present in solution. These complexes decompose readily in the presence of dissolved oxygen or water to furnish the carbonyl complex $[Ru(CO)Cl(dppe)_2]PF_6$ almost quantitatively. This ruthenium(II) complex was characterized by IR and ^1H NMR spectroscopy and by the determination of the crystal structure.[28,29] Similar transformations of vinylidene- or allenylidene complexes into their carbonyl derivatives have been reported previously.[30]

The crude mixtures containing the monovinylidene and η^2-alkyne isomers were readily deprotonated with Et_3N in CH_2Cl_2 at room temperature to give the corresponding monoalkynyl complexes **9** (72%) and **10** (74%), respectively. Similarly, reaction of **3** and **5** with two equivalents of *cis*-$[RuCl_2(dppe)_2]$ (**8**) and four equivalents of KPF_6 for seven days at room temperature, followed by deprotonation, furnished the dialkynyl ruthenium complexes **11** (72%) and **12** (85%) (Scheme 4).

Crystals of complexes **11** and **12** could be obtained, although the crystal structure determination could not be performed due to their decomposition by the X-rays. The IR spectra of all these alkynyl complexes are very similar and show very strong ν(C≡C) bands around 2050 cm^{-1}. In the ^{13}C NMR spectrum of **12** the quintet at δ = 127.9 ($^2J_{PC}$ = 16 Hz) was assigned to the alkynyl carbon which is α to Ru, thus demonstrating a *trans*-configuration of the chloro- and ethynyl ligands.



Scheme 4

A cyclic voltammetric study of complex **12** showed a single quasi-reversible redox wave for both ruthenium systems [$E_{1/2}$ versus Cp_2Fe^+/Cp_2Fe: + 0.72 V (ΔE_p = 63 mV)]. This unique oxidation wave shows that the dialkynyl complex **12** is capable of providing two electrons at the same potential and that the bridge between the ethynylated phenyl rings of the biphenyl system does not allow significant communication between the ruthenium centers.

Synthesis of Ruthenium Alkenyl Complexes

The reaction of alkynes **3** and **5** with two equivalents of [Ru(CO)HCl(PPh_3)$_3$] (**13**) in CH_2Cl_2 at room temperature gave rise to the red dialkenyl complexes **14** (92%) and **15** (91%). As expected,[31] the hydroruthenation proceeds in a cis fashion, as demonstrated by a trans $^3J(^1H\text{-}^1H)$ coupling of 13.7−14 Hz. Although the pentacoordinated Ru centers of these complexes are less sterically hindered than those of **9**−**12**, a tetrametallated derivative could not be obtained by reaction of alkyne **5** with four equivalents of hydride **13**.

Conclusions

We have described the synthesis of the di- and tetraalkynyl biphenyls **3** and **5** from the tetrabromo derivative **1** by using Pd-catalyzed cross-coupling reactions as well as their derivatization with ruthenium complexes to afford stable alkynyl and alkenyl complexes. The reaction of the terminal −C≡CH groups of **3** and **5** with *cis*-[$RuCl_2$(dppe)$_2$] (**8**), followed by deprotonation of these mixtures with Et_3N, leads to the terminal σ-alkynylruthenium derivatives. Reaction of **3** and **5** with the ruthenium hydride [Ru(CO)ClH(PPh_3)$_2$] (**13**) gave the corresponding di-σ-alkenyl complexes. The diruthenium complexes **12** and **15** bear two free terminal alkyne groups, which could be further metallated to form heterometallic complexes. Further work in this area is in progress.

Experimental Section

General: Infrared spectra were recorded at the ICMM on a Nicolet 20 SXC FT-IR spectrophotometer, using KBr disks. The NMR determinations were carried out on a Bruker AC-200 (or a Bruker AMX-300) apparatus at 23 °C. Mass spectra were performed at the SIdI (UAM), using the fast cesium-ion bombardment (liquid secondary ion mass spectrometry, LSIMS) or EI-MS techniques. Only the most significant IR frequencies and MS fragmentations are given. Elemental analyses were performed at the ICMM or SIdI (UAM). Differential thermal analysis (DTA) curves were obtained at the ICMM, using a Stanton STA 781 analyzer. All reactions were performed under a nitrogen atmosphere, using Schlenk techniques and the solvents were deoxygenated and dried by standard methods.

Cyclic voltammetric measurements were carried out at the Universidad Complutense de Madrid (Departamento de Química Inorgánica I, Facultad de Ciencias Químicas) on an Autolab apparatus equipped with a PSTA 10 potentiostat, using a three-electrode cell with platinum wire as working and auxiliary electrodes and Ag/AgCl electrode as a reference with a solution of the complex (10^{-3} mol/dm^3) in dichloromethane containing [Nbu_4][BF_4] (0.2 mol/dm^3) as the base electrolyte, at a scan rate of 200 mV s^{-1}. Values are referred to an Ag/AgCl electrode and ferrocene was used as internal standard.

The complexes [$PdCl_2(PPh_3)_2$], [$Pd(PPh_3)_4$],[32] *cis*-[$RuCl_2$(dppe)$_2$] (**8**),[33] and [RuHCl(CO)(PPh_3)$_3$] (**13**)[34] were prepared by known procedures.

3,5,3′,5′-Tetrabromobiphenyl-2,2′-diyl Dipivalate (1): A solution of 3,3′,5,5′-tetrabromo-2,2′-dihydroxybiphenyl (2.00 g, 4.0 mmol) in pyridine (50 mL) and pivalic anhydride (4.0 mL, 19.7 mmol) was heated under refluxing conditions for 2 h. After being cooled to room temperature, the mixture was diluted with water and extracted with EtOAc. The organic layer was washed with aqueous HCl (10%), dried (Na_2SO_4) and the solvent was evaporated to yield **1** (2.60 g, 97%) as a beige solid: m.p. 115 °C. − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.13 (s, 18 H), 7.34 (s, 2 H), 7.78 (s, 1 H), 7.79 (s, 1 H). − ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ = 26.7, 39.1, 118.2, 119.00, 132.5, 132.6, 135.8, 145.5, 174.9. − EI-MS: *m*/*z* (%) = 666 (0.5) [M$^+$], 582 (5), 498 (8), 417 (4), 339 (1), 311 (3), 85 (43), 57 (100). − $C_{22}H_{22}Br_4O_4$ (670.03): calcd. C 39.44, H 3.31; found C 39.40, H 3.15.

3,3′-Dibromo-5,5′-bis(trimethylsilylethynyl)biphenyl-2,2′-diyl Dipivalate (2): A mixture of **1** (500 mg, 0.74 mmol), trimethylsilylacetylene (0.42 mL, 3 mmol), [$PdCl_2(PPh_3)_2$] (103 mg, 0.148 mmol), and CuI (56 mg, 0.30 mmol) in Et_3N (25 mL) was stirred at 23 °C

for 12 h. The mixture was diluted with CH_2Cl_2, washed with H_2O, dried and the solvents evaporated. The residue was chromatographed (hexane/EtOAc, 4:1) to give **2** as a colorless oil (466 mg, 89%). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 0.23 (s, 9 H), 0.25 (s, 9 H), 1.12 (s, 18 H), 7.30 (s, 1 H), 7.31 (s, 1 H), 7.70 (s, 1 H), 7.71 (s, 1 H). − ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ = −0.2, 26.7, 39.1, 96. 6, 102.0, 116.9, 122.4, 133.4, 131.61, 136.2, 146.2, 175.2. − EI-MS: *m*/*z* (%) = 702 (2) [M^+], 618 (14), 534 (13), 519 (5), 439 (8), 179 (7), 85 (11), 73 (12) 57 (100). − $C_{32}H_{40}Br_2O_4Si_2$ (704.64): calcd. C 54.54, H 5.72; found C 54.88, H 6.11.

3,3′-Dibromo-5,5′-diethynylbiphenyl-2,2′-diyl Dipivalate (3): A mixture of **2** (466 mg, 0.66 mmol) and K_2CO_3 (182 mg, 1.3 mmol) in a mixture of CH_2Cl_2 (2 mL), MeOH (10 mL), and H_2O (0.5 mL) was stirred at 23 °C for 30 min. The mixture was diluted with CH_2Cl_2, washed with H_2O, aqueous HCl (10%), dried (Na_2SO_4) and the solvents evaporated to yield **3** as a colorless oil (332 mg, 90%). Recrystallization (Et_2O/hexane, 1:1) gave **3** as a white solid, m.p. 121−123 °C. − IR (KBr): ṽ = 3262 s ν(≡CH), 2104 w ν(C≡C), 1748 vs ν(C=O). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.11 (s, 18 H), 3.12 (s, 2 H), 7.33 (s, 1 H), 7.73 (s, 1 H), 7.74 (s, 1 H), 7.75 (s, 1 H). − ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ = 26.7, 39.0, 79.2, 80.8, 117.1, 121.3, 131.6, 133.5, 136.5, 146.6, 174.7. − EI-MS: *m*/*z* (%) = 558 (0.1) [M^+], 474 (80), 389 (0.1), 309 (0.2), 231 (2), 85 (21), 57 (100). − $C_{26}H_{24}Br_2O_4$ (560.28): calcd. C 55.74, H 4.32; found C 56.58, H 4.77.

3,3′,5,5′-Tetrakis(trimethylsilylethynyl)biphenyl-2,2′-diyl Dipivalate (4): A mixture of **1** (134 mg, 0.2 mmol), [$Pd(PPh_3)_4$] (46 mg, 0.04 mmol) and (trimethylsilyl)ethynyltributylstannane (470 mg, 1.2 mmol) in toluene (10 mL) was heated under refluxing conditions for 4 h. After being cooled to room temperature, the mixture was diluted with CH_2Cl_2, washed with water and a saturated solution of KF, dried (Na_2SO_4) and the solvents evaporated. The residue was chromatographed (hexane/EtOAc, 9:1) to give **4** as a colorless oil (133 mg, 90%). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 0.21 (s, 18 H), 0.23 (s, 18 H), 1.13 (s, 18 H), 7.30 (s, 1 H), 7.31 (s, 1 H), 7.61 (s, 1 H), 7.62 (s, 1 H). − ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ = −0.2, 26.8, 38.9, 95.4, 98.7, 99.8, 102.8, 118.5, 120.9, 130.3, 134.3, 136.7, 149.2, 175.2. − EI-MS: *m*/*z* (%) = 738 (36) [M^+], 654 (100), 570 (28), 481 (4), 467 (13), 57 (25). − $C_{42}H_{58}O_4Si_4 \cdot 0.5H_2O$ (748.26): calcd. C 67.42, H 7.95; found C 67.41; 8.18.

3,3′,5,5′-Tetraethynylbiphenyl-2,2′-diyl Dipivalate (5): A mixture of **4** (139 mg, 0.118 mmol) and K_2CO_3 (33 mg, 0.24 mmol) in a mixture of CH_2Cl_2 (1 mL), MeOH (5 mL), and H_2O (0.3 mL) was stirred at 23 °C for 30 min. The mixture was diluted with CH_2Cl_2, washed with H_2O and aqueous HCl (10%), dried (Na_2SO_4) and the solvents evaporated to give **5** (77 mg, 95%) as a white solid: m.p. 125 °C. − IR (KBr): ṽ = 3306 ms, 3279 sh ν(≡CH), 2165 w, 2135 w ν(C≡C), 1750 vs ν(C=O). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.11 (s, 18 H), 3.08 (s, 2 H), 3.21 (s, 2 H), 7.37 (d, *J* = 2.0 Hz, 2 H), 7.66 (d, *J* = 2.0 Hz, 2 H). − ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ = 26.7, 38.9, 77.6, 78.5, 81.4, 82.6, 117.7, 120.1, 130.4, 134.8, 136.9, 150.1, 175.3. − FAB-MS: *m*/*z* (%) = 450 (15) [M^+], 366 (47), 282 (87), 253 (11), 224 (15), 85 (9), 57 (100). − $C_{30}H_{26}O_4 \cdot 0.5H_2O$ (459.53): calcd. C 78.41, H 5.92; found C 78.87, H 5.97.

2,2′-Dihydroxy-3,3′,5,5′-tetra(ethynyl)biphenyl (6): A mixture of **5** (10 mg, 0.022 mmol) and NaOH (6 mg, 0.15 mmol) in a mixture of MeOH (2 mL), and H_2O (0.1 mL) was stirred at 23 °C for 18 hours. The mixture was diluted with CH_2Cl_2, washed with H_2O and aqueous HCl (10%), dried (Na_2SO_4) and the solvents evaporated to give **6** (5 mg, 80%) as a white solid: (decomposes without melting; the DTA curve shows two exothermic peaks at 115 °C and 196 °C). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.01 (s, 2 H), 3.49 (2 H), 7.43 (d, *J* = 2.0 Hz, 2 H), 7.59 (d, *J* = 2.0 Hz, 2 H). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 76.7, 77.4, 82.1, 84.8, 109.9, 114.7, 123.5, 136.0, 136.2, 154.7. − EI-MS: *m*/*z* (%) = 282 (100) [M^+], 253 (23), 224 (32).

3,3′,5,5′-Tetra(phenylethynyl)biphenyl-2,2′-diyl Dipivalate (7): A mixture of **5** (41 mg, 0.1 mmol), [$Pd(PPh_3)_4$] (23 mg, 0.02 mmol), iodobenzene (60 μL, 0.53 mmol), and CuI (4 mg, 0.02 mmol) in pyrrolidine (5 mL) was stirred at 23 °C for 3 h. The mixture was diluted with CH_2Cl_2, washed with H_2O, dried and the solvents evaporated. The residue was chromatographed (hexane/EtOAc, 9:1) to give **7** as a colorless oil (62 mg, 83%). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.17 (s, 18 H), 7.78 (d, *J* = 2.1 Hz, 2 H), 7.39−7.27 (m, 12 H), 7.55−7.45 (m, 10 H). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 26.9, 39.1, 83.7, 87.5, 90.4, 94.2, 118.8, 121.3, 122.7, 122.8, 128.4, 128.5, 128.7, 130.8, 131.6, 131.7, 133.8, 135.9, 148.9, 175.6. − EI-MS: *m*/*z* (%) = 754 (8) [M^+], 670 (25), 586 (62), 57 (100). − HRMS calcd. for $C_{54}H_{42}O_4$: 754.3083; found 754.3054.

Synthesis of the Monosubstituted Alkynyl Complex 9: A solution of alkyne **3** (29 mg, 0.052 mmol), *cis*-[$RuCl_2$(dppe)$_2$] (**8**) (50 mg, 0.052 mmol), and KPF_6 (18.96 mg, 0.103 mmol) in CH_2Cl_2 (5 mL) was stirred for 4 days at room temperature. The intermediate vinylidene complex could be isolated by trituration with hexane as a brown-beige powder (75 mg, 88%). − IR (KBr): ṽ = 3274 w ν(≡CH), 1750 ms ν(C=O), 2110 vw ν(C≡CH), 1620 ms ν(=C=C), 836 vs ν(PF_6). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.07, (s, 9 H), 1.17 (s, 9 H), 2.60−3.05 (m, 8 H), 3.11 (s, 1 H), 3.12 (br. s, 1 H), 6.85−7.55 (m, 43 H), 7.68 (br. s, 1 H) (minor signals of an η^2-alkyne complex were also observed); − $C_{78}H_{72}Br_2ClF_6O_4P_5Ru$ (1638.61): calcd. C 57.17, H 4.43; found C 57.11, H 4.48. An excess of Et_3N (0.05 mL, 0.35 mmol) was added to the brownish-yellow solution containing the vinylidene complex and the resulting solution was stirred for 1 h at 23 °C. After addition of CH_2Cl_2 (15 mL), this yellow solution was washed with water (3 ×). After the usual extractive workup, the solvent was partially evaporated. Addition of hexane led to a yellow precipitate, which was filtered off to give **9** (55 mg, 72%). − IR (KBr): ṽ = 3298 w ν(≡CH), 2110 vw ν(C≡CH), 2054 s ν(C≡C), ν(C=O). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.14 (s, 9 H), 1.16 (s, 9 H), 2.66 (br. s, 8 H), 3.17 (s, 1 H), 6.22 (br. s, 1 H), 6.64 (br. s, 1 H), 6.84−7.49 (m, 33 H), 7.51 (br. s, 8 H), 7.75 (s, 1 H). − ^{31}P{^{1}H} NMR (121.5 MHz, $CDCl_3$): δ = 49.55 (s). − $C_{78}H_{71}Br_2ClO_4P_4Ru \cdot 0.5H_2O$ (1501.63): calcd. C 62.39, H 4.83; found C 62.44, H 4.89.

Formation of *trans*-[Ru(CO)Cl(dppe)$_2$]PF_6 from Biphenyl 3 and Ruthenium Complex 8: A solution of alkyne **3** (26 mg, 0.05 mmol), *cis*-[$RuCl_2$(dppe)$_2$] (**8**) (89 mg, 0.10 mmol), and KPF_6 (34 mg, 0.20 mmol) in CH_2Cl_2 (5 mL) was stirred for 7 days at 23 °C until no free alkyne was detectable by TLC. The mixture was filtered and the filtrate was partially evaporated. Addition of hexane led to precipitation of a solid, which was filtered off and washed with hexane to give a beige powder (140 mg, quantitative yield). This solid was suspended in CH_2Cl_2 (2 mL) and hexane (10 mL), and was then stirred in air at 23 °C for 3 h. The solvents were evaporated and the greenish-brown solid was triturated with Et_2O and filtered off to give a greenish-beige powder. To eliminate residual vinylidene, the crude product was dissolved in CH_2Cl_2 (5 mL) and treated with Et_3N (0.1 mL) at 23 °C. The solution was washed with water (3 ×) and, after the usual extractive workup, the residue was filtered through basic alumina. Partial evaporation of the solvent and addition of hexane gave *trans*-[Ru(CO)Cl(dppe)$_2$]PF_6 as gray-white crystals (98 mg, 59%) and the dialkynyl complex **9** (20 mg,

11%) as yellow crystals, which were separated by fractional crystallization.

***trans*-[Ru(CO)Cl(dppe)$_2$]PF$_6$:** IR (KBr): $\tilde{\nu}$ = 1946 vs ν(C=O), 837 vs ν(PF_6). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 2.66 (m, 4 H), 2.92 (m, 4 H), 6.95−7.50 (m). − $C_{53}H_{48}ClF_6OP_5Ru$ (1106.3): calcd. C 57.54, H 4.37; found C 57.51, H 4.40.

Synthesis of the Monosubstituted Alkynyl Complex 10: Alkyne **5** (23 mg, 0.052 mmol) was treated as above to give **10** as a yellow powder (52 mg, 74%). − IR (KBr): $\tilde{\nu}$ = 3282 ms ν(≡CH), 2110 vw ν(C≡CH), 2049 s ν(C≡C), 1748 s ν(C=O). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.13 (s, 9 H), 1.15 (s, 9 H), 2.67 (br. s, 8 H), 3.13 (s, 2 H), 3.21 (s, H), 6.22 (br. s, 1 H), 6.60 (br. s, 1 H), 6.89−7.10 (2m, 16 H), 7.10−7.32 (2m, 16 H), 7.37 (br. s, 1 H), 7.46 (br. s, 8 H), 7.67 (s, 1 H). − ^{31}P{^{1}H} NMR (121.5 MHz, $CDCl_3$): δ = 49.45(s). − $C_{82}H_{73}ClO_4P_4Ru{\cdot}H_2O$ (1400.89): C 70.30, H 5.40; found C 70.40, H 5.34. The intermediate vinylidene complex could be isolated as above to give a brown-beige powder: IR (KBr): $\tilde{\nu}$ = 3273 ms ν(≡CH), 2110 w ν(C≡CH), 1751 ms ν(C=O), 1628 ms ν(=C=C), 843 vs ν(PF_6). − $C_{82}H_{74}ClF_6O_4P_5Ru$ (1528.9): calcd. C 64.42, H 5.18; found C 64.75, H 5.52.

Synthesis of the Disubstituted Alkynyl Complex 11: A solution of alkyne **3** (29 mg, 0.052 mmol), *cis*-[$RuCl_2$(dppe)$_2$] (**8**) (100 mg, 0.10 mmol), and KPF_6 (38 mg, 0.21 mmol) in CH_2Cl_2 (5 mL) was stirred for 7 days at 23 °C. The mixture was filtered and the filtrate was partially evaporated. Addition of hexane led to precipitation of a solid, which was filtered off and washed with hexane to give the divinylidene complex. − IR (KBr): $\tilde{\nu}$ = 1750 ms ν (C=O), 1626 s ν (=C=C), 836 vs ν (PF_6). − $C_{130}H_{120}Br_2Cl_2F_{12}O_4P_{10}Ru_2$ (2716.9): calcd. C 57.47, H 4.45; found C 57.41, H 4.46. An excess of Et_3N (0.71 mmol, 0.1 mL) was added to the solution containing the vinylidene complex, and the resulting solution was stirred for 1 h at 23 °C. The yellow solution, after addition of CH_2Cl_2 (15 mL), was washed with water (3 ×). After the usual workup the solvent was partially evaporated. Addition of hexane led to the formation of a yellow microcrystalline powder, which was filtered off to give **11** (89 mg, 72%). − IR (KBr): $\tilde{\nu}$ = 2050 s ν(C≡C), 1750 s ν(C=O). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.19 (s, 18 H), 2.66 (br. s, 16 H), 6.48 (br. s, 2 H), 6.54 (br. s, 2 H), 6.92 (m, 16 H), 7.02 (m, 20 H), 7.18 (m, 12 H), 7.29 (m, 16 H), 7.40 (m, 16 H). − ^{13}C NMR ($CDCl_3$, 50.32 MHz): δ = 26.9, 30.6 (m), 39.0, 110.7, 115.4 (br. s, Ru−C≡*C*), 127.0, 127.3 (br. s), 128.1 (quint, $^2J_{PC}$ = 16 Hz, C≡*C*−Ru), 128.9 (br. s), 131.7, 132.6, 133.9, 134.5 (br. s), 134.7, 135.8 (m), 141.5, 175.3. − ^{31}P{^{1}H} NMR (121.5 MHz, $CDCl_3$): δ = 49.90 (s). − FAB-MS: *m*/*z* (%) = 2421 (8) [M^+], 2386 (3), 2026 (59), 897 (59), 685 (6), 499 (42), 316 (56), 185 (95), 57 (100). − $C_{130}H_{122}Br_2Cl_2O_6P_8Ru_2{\cdot}2H_2O$ (2461.00): calcd. C 63.45, H 5.00; found C 63.26, H 5.17.

Synthesis of the Disubstituted Alkynyl Complex 12: An excess of Et_3N (0.1 mL, 0.71 mmol) was added to the brownish-yellow solution containing the divinylidene complex prepared from **5** (23 mg, 0.052 mmol), and the resulting solution was stirred for 1 h at 23 °C. The yellow solution, after addition of CH_2Cl_2 (15 mL), was washed with water (3 ×). After the usual extractive workup, the solvent was partially evaporated. Addition of hexane led to a yellow microcrystalline powder of the dialkynyl complex **12** (101 mg, 85%) as a yellow powder. This compound contained traces of the monoalkynyl complex **10**. A pure product was obtained by crystallization from CH_2Cl_2/hexane to yield yellow crystals, which decompose on exposure to X-ray radiation. IR (KBr): $\tilde{\nu}$ = 3282 m ν(≡CH), 2110 w ν(C≡CH), 2049 s ν(C≡C), 1748 s ν(C=O). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 1.18 (s, 18 H), 2.66 (br. s, 16 H), 3.15 (s, 2 H), 6.48 (br. s, 2 H), 6.58 (br. s, 2 H), 6.88−7.10 (m, 34 H), 7.10−7.22 (m, 16 H), 7.36 (br. s, 32 H). − ^{13}C NMR ($CDCl_3$, 75.5 MHz): δ = 26.8, 30.6, 38.8, 79.4 (s, *C*≡CH), 80.0 (s, C≡*C*H, 111.2, 115.5 (s, Ru−C≡*C*), 126.9 (br. s), 127.3 (br. s), 127.9 (quint., $^2J_{PC}$ = 16 Hz, C≡*C*−Ru), 128.4, 128.9 (br. s), 130.5, 131.8, 133.9, 134.5 (br. s), 135.2, 135.8 (q, *J* = 22.7 Hz, dppe), 145.2, 175.5. − ^{31}P{^{1}H} NMR (121.5 MHz, $CDCl_3$): δ = 49.89 (s). − FAB-MS: *m*/*z* (%) = 2315.1 (6) [M^+], 1917 (4), 1381 (2), 957 (9), 933 (19), 897 (100), 685 (16.). − $C_{134}H_{120}Cl_2O_4P_8Ru_2{\cdot}1.5H_2O$ (2342.25): calcd. C 68.71, H 5.28; found C 68.69, H 5.30. The intermediate divinylidene could be isolated as above as a beige powder: IR (KBr): $\tilde{\nu}$ = 3285 m ν(≡CH), 2110 vw ν(C≡CH), 1757 ms ν(C=O), 1628 s ν(=C=C), 843 vs ν(PF_6). − $C_{134}H_{122}Cl_2F_{12}O_4P_{10}Ru$ (2607.2): 61.73, H 4.72; found C 62.61, H 5.15.

Synthesis of the Disubstituted Alkenyl Complex 14: A solution of [$RuHCl(CO)(PPh_3)_3$] (**13**; 80 mg, 0.084 mmol) and alkyne **3** (23.5 mg, 0.042 mmol) was stirred at 23 °C in CH_2Cl_2 (10 mL) for 30 min. The orange-red solution was concentrated and hexane was added. after cooling to 0 °C, the mixture was filtered and the filtrate was evaporated. The residue was taken up in CH_2Cl_2/Et_2O and filtered. Hexane was added to the filtrate to give a precipitate, which was filtered off to give **14** (78 mg, 92%) as an orange solid. − IR (KBr): $\tilde{\nu}$ = 1924 vs ν(C≡O), 1736 s ν(C=O). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 0.93 (s, 18 H), 5.49 (d, $^3J_{HP}$= 13.7 Hz, 2 H), 6.35 (s, 2 H), 6.89 (s, 2 H), 7.20−7.42 (m, 36 H, Ph), 7.45−7.70 (m, 24 H, Ph), 8.38 (d, $^3J_{HP}$ = 13.7 Hz, 2 H). − $C_{100}H_{86}Br_2Cl_2O_6P_4Ru_2{\cdot}CH_2Cl_2$ (2025.43): calcd. C 59.89, H 4.38; found C 59.83, H 4.27.

Synthesis of the Disubstituted Alkenyl Complex 15: Similarly, a solution of [$RuHCl(CO)(PPh_3)_3$] (**13**; 50 mg, 0.0525 mmol) and the alkyne **5** (11.83 mg, 0.0263 mmol) was stirred at 23 °C in CH_2Cl_2 (5 mL) for 1.5 h. After partial evaporation of solvent, addition of Et_2O led to a precipitate, which was filtered off to give **15** (44 mg, 91%). − IR (KBr): $\tilde{\nu}$ = 3288 w ν(≡CH), 2110 vw ν(C≡CH), 1922 vs ν(C≡O), 1740 ν(C=O). − ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 0.93 (s, 18 H), 3.11 (s, 2 H), 5.53 (d, $^3J_{HP}$ = 14.0 Hz, 2 H), 6.41 (d, *J* = 2.0 Hz, 2 H), 6.84 (d, *J* = 2.0 Hz, 2 H), 7.42−7.20 (m, 36 H), 7.70−7.45 (m, 24 H, Ph), 8.33 (dm, $^3J_{HP}$ = 14.0 Hz, 2 H); − $C_{104}H_{88}Cl_2O_6P_4Ru_2{\cdot}0.75H_2O$ (1844.26): calcd. C 67.73, H 4.89; found C 67.80, H 4.80.

Acknowledgments

We are grateful to the DGES (Projects PB97-0002-C2-01 and 02) for support of this research. We also thank the MEC for a predoctoral fellowship to M. R. and to the CAM for a postdoctoral fellowship to B. G.-L. We acknowledge Johnson Matthey PLC for a generous loan of $PdCl_2$ and $RuCl_3$.

Molecular Features of Co^{III} Tetra- and Pentammines Affect Their Influence on DNA Structure

Alison Rodger,*[a] Andrew Parkinson,[a] and Stephen Best[b]

Keywords: Bioinorganic chemistry / Non-covalent interactions / Coordination chemistry / Circular dichroism / UV/Vis spectroscopy

The polyamines spermine and spermidine cause a range of structural effects on DNA. $[Co(NH_3)_6]^{3+}$ is known to mimic many of these effects and we have shown previously that (+)-$[Co(en)_3]^{3+}$ and (–)-$[Co(en)_3]^{3+}$ (en = ethylenediamine) do so as well. In this paper the effects of mono- and disubstitution of the Co^{III} ammines by aqua, halo and nitro groups is explored. The overall effectiveness of the amines in conferring thermal stability on the ct-DNA proceeds in the order: spermine > (+)-$[Co(en)_3]^{3+}$ ≈ (–)-$[Co(en)_3]^{3+}$ ≈ $[Co(NH_3)_6]^{3+}$ ≈ spermidine > $[Pt(NH_3)_4]^{2+}$ > $[Co(NH_3)_5H_2O]^{3+}$ ≈ $[Co(NH_3)_5Cl]^{2+}$ ≈ $[Co(NH_3)_5Br]^{2+}$ > *cis*-$[Co(en)_2NH_3Cl]^{2+}$ > $[Co(NH_3)_5(NO_2)]^{2+}$ ≈ *trans*-$[Co(NH_3)_4(H_2O)_2]^{3+}$; whereas the B→Z transition-induction ordering is: spermine ≈ $[Co(NH_3)_6]^{3+}$ > (+)-$[Co(en)_3]^{3+}$ ≈ $[Co(NH_3)_5(H_2O)]^{3+}$ > (–)-$[Co(en)_3]^{3+}$ > $[Co(NH_3)_5Br]^{2+}$ > $[Co(NH_3)_5Cl]^{2+}$, with the other amines failing to cause the transition under the 11 mM salt concentration and temperature ramp conditions used; the DNA bending ranking is: spermine > $[Co(NH_3)_6]^{3+}$ > (+)-$[Co(en)_3]^{3+}$ > (–)-$[Co(en)_3]^{3+}$ > $[Co(NH_3)_5(H_2O)]^{3+}$ > *trans*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ > spermidine, with the other 2+ amines (the aquo complexes will be 2+ at neutral pH), especially the bromo and nitro compounds, having comparatively little effect. While the presentation of NNN triangular faces is found to be important in the B→Z transition, the fact that the halo ligands are probably substituted by the DNA phosphates plays a role, especially in the DNA bending, where deep penetration of the major groove is concluded to be required. A favourable interaction between the backbone and the aquo ligands may enhance the B→Z transition.

Introduction

The two DNA-binding polycations spermidine $[H_3N(CH_2)_3NH_2(CH_2)_4NH_3]^{3+}$ and spermine $[H_3N(CH_2)_3NH_2(CH_2)_4NH_2(CH_2)_3NH_3]^{4+}$ are present in all cells.[1] The precise cellular functions of polyamines are unclear but they are known to neutralise over 40% of chromosomal DNA and to inhibit damage by reactive oxygen species,[2] radiation,[3,4] and alkylating agents.[5] Furthermore, polyamines stabilise DNA to heat and induce and stabilise A, B, Z (usually observed with alternating G-C sequences) and collapsed DNA structures.[6–8] We have recently shown that the cobalt(III) ammine complexes $[Co(NH_3)_6]^{3+}$, (+)-$[Co(en)_3]^{3+}$, and (−)-$[Co(en)_3]^{3+}$ (en = ethylenediamine) mimic different aspects of the DNA interaction of the small polyamine molecules spermidine and spermine.[8,9]

Our molecular modelling study[9] of $[Co(NH_3)_6]^{3+}$, (+)-$[Co(en)_3]^{3+}$, and (−)-$[Co(en)_3]^{3+}$ with DNA shows that these cobalt ammines do not bind in the minor groove of any sequence, and their residence times in the major groove decrease in the order spermine > $[Co(NH_3)_6]^{3+}$ > (+)-$[Co(en)_3]^{3+}$ > (−)-$[Co(en)_3]^{3+}$. In addition, while the spermine binding was found by Yuki et al. to be cooperative,[11] in analogous simulations[9] the others were found not to be. These amines all reduce the linear dichroism (LD) signal of DNA by bending calf thymus (ct) and micrococcus lysodeikticus (ml) DNAs. Since the molecules are major groove binders, we concluded that their behaviour supports the amine-major-groove bending model.[12] The comparative effectiveness of the cobalt ammines at bending DNA suggests that the presentation of a triangular NNN face to the DNA optimises the bend-causing interaction — $[Co(NH_3)^{3+}]$ has a high number of pre-formed NNN triangles, whereas spermine does not. The ethylenediamine complexes are somewhat less effective as they have fewer such faces. A similar geometric argument is required for the induction of the B→Z transition. Crystal structure data are consistent with the formation of five hydrogen bonds between $[Co(NH_3)_6]^{3+}$ and the major-groove convex surface of Z-DNA, specifically to guanine O6 and N7 and the phosphate oxygens.[13]

In order to probe the role of NNN triangular faces further, we have investigated the interaction of a set of cobalt(III) tetra- and pentaamines with DNA. In this work we have used temperature-dependent normal absorption to probe the stabilising effect of the ammines on duplex DNA; circular dichroism (CD), which depends on the asymmetric character of an absorbing chromophore, to probe ligand binding; and linear dichroism (LD) to probe the effect of the ammines on DNA length and flexibility.

Results and Discussion

ct-DNA Absorbance Temperature Dependence

The absorbance spectra of a set of substituted cobalt ammines are illustrated in Figure 1. A wavelength of 280 nm, rather than the usual 260 nm, was chosen to follow the temperature dependence of ct-DNA absorbance in the presence of these ammines (Figure 2) to minimise the ligand contribution to the changes. The DNA melting curves show unusual pre- and post-melting transitions, most of which are consistent with the temperature dependence of the free ligand (data not shown), although the negative pre-melting transitions are all enhanced in the presence of the DNA. There was no evidence of light scattering above 300 nm in either temperature-dependent absorbance (data not shown) or CD spectra (Figure 4). The ligand effects were largest for the bromine-substituted compound (a 40 μM solution had a change of −0.02 absorbance units from baseline at 60 °C), so it is likely, at least in this case, that a substitution reaction removes a ligand-to-metal charge-transfer transition and that the DNA influences the kinetics of such reactions. Whether the ligands end up covalently bound to the DNA or their aquation is catalysed is not clear from these data.

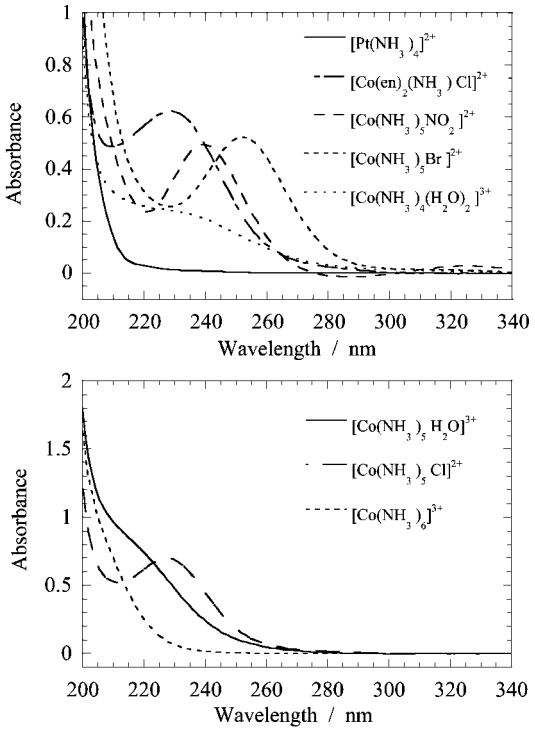

Figure 1. Normal absorption spectra of DNA binding ammines (40 μM in 10 mM NaCl and 1 mM cacodylate); $[Co(NH_3)_4(H_2O)_2]^{3+}$ is the *trans* isomer and $[Co(en)_2NH_3Cl]^{2+}$ (en = ethylenediamine) the *cis* isomer

Taking derivatives of the main hyperchromic denaturing transitions, thus assuming that the pre- and post-melting transitions could be ignored, the stabilization conferred upon the DNA by the amines is summarized in Figure 3. Substituting an amine group in $[Co(NH_3)_6]^{3+}$ by a Cl, Br, NO_2 or H_2O ligand, seriously impedes the metal complex's ability to stabilize DNA. The post-melting transition of $[Co(en)_2NH_3Cl]^{2+}$ makes it impossible to determine T_m for this system accurately after the first few ammine concentrations. The values would lie below the other halo species.

Effect of Ammines on poly[d(G-C)$_2$] Structure

The pentammine $[Co(NH_3)_5(H_2O)]^{3+}$ induces Z-form DNA as effectively as (+)-$[Co(en)_3]^{3+}$ (data not shown). $[Co(NH_3)_5Br]^{2+}$ and $[Co(NH_3)_5Cl]^{2+}$ also induce the Z-form DNA of poly[d(G-C)]$_2$ (Figure 4) to some extent. Concentrations of 20 μM spermidine,[9] *cis*-$[Co(en)_2NH_3Cl]^{2+}$, $[Pt(NH_3)_4]^{2+}$, $[Co(NH_3)_5(NO_2)]^{2+}$, and *trans*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ do not promote the B→Z transition in poly[d(G-C)]$_2$ (60 μM in 10 mM NaCl) (Figure 4). The CD changes observed with these ligands, with the exception of *trans*-$[Co(NH_3)_4(H_2O)_2]^{3+}$, are the same as those induced by increasing the temperature of poly[d(G-C)$_2$].[9] $[Co(NH_3)_5(NO_2)]^{2+}$ does, however, promote the B→Z transition at 0 mM NaCl, 1 mM cacodylate buffer which is the behaviour previously observed for spermidine.[9]

LD of ct-DNA with Cobalt Tetra- and Pentaammines

Figure 5 summarises the LD of ct-DNA at 260 nm with added cobalt ammine. The initial addition of each ammine results in a small decrease in DNA orientation. We previously found that ≈20 μM spermine, ≈60 μM $[Co(NH_3)_6]^{3+}$, ≈80 μM $[Co(en)_3]^{3+}$, and 240 μM of spermidine are required to cause the LD signal to be sharply reduced. The monoaquo complex requires ≈140 μM and the diaquo complex begins to bend the DNA at ≈ 200 μM, and requires ≈400 μM to complete it.

Comparison of the Amines

The overall effectiveness of the amines in conferring thermal stability on the ct-DNA proceeds in the order:

spermine > (+)-$[Co(en)_3]^{3+}$ ≈ (−)-$[Co(en)_3]^{3+}$ ≈ $[Co(NH_3)_6]^{3+}$ ≈ spermidine > $[Pt(NH_3)_4]^{2+}$ > $[Co(NH_3)_5H_2O]^{3+}$ ≈ $[Co(NH_3)_5Cl]^{2+}$ ≈ $[Co(NH_3)_5Br]^{2+}$ > *cis*-$[Co(en)_2NH_3Cl]^{2+}$ > $[Co(NH_3)_5(NO_2)]^{2+}$ ≈ *trans*-$[Co(NH_3)_4(H_2O)_2]^{3+}$

whereas the B→Z transition induction ordering is:

spermine ≈ $[Co(NH_3)_6]^{3+}$ > (+)-$[Co(en)_3]^{3+}$ ≈ $[Co(NH_3)_5(H_2O)]^{3+}$ > (−)-$[Co(en)_3]^{3+}$ > $[Co(NH_3)_5Br]^{2+}$ > $[Co(NH_3)_5Cl]^{2+}$

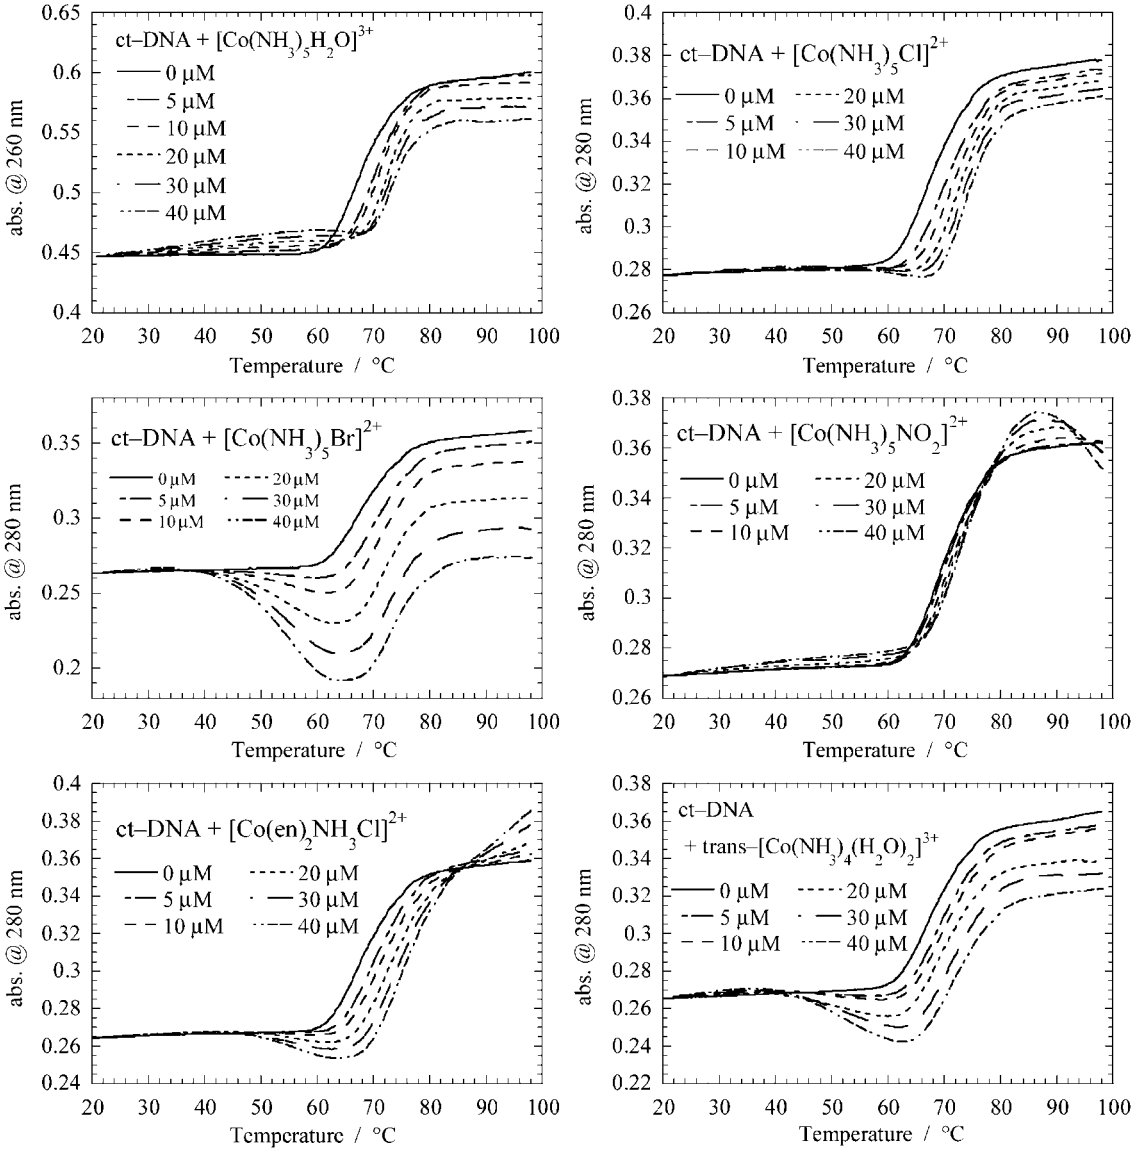

Figure 2. Absorbance versus temperature plot for ct-DNA (60 μM, 10 mM NaCl, 1 mM cacodylate) with addition of cobalt ammines at various concentrations as indicated in the figure

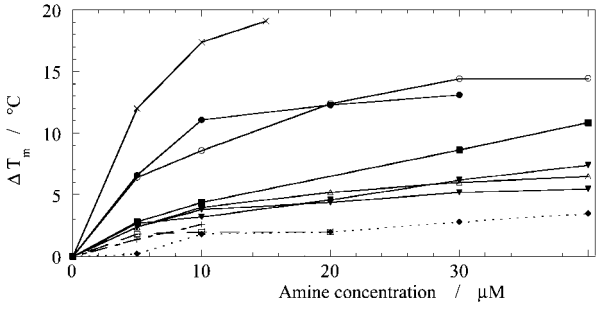

Figure 3. Summary of the change in T_m of ct-DNA (60 μM, 10 mM NaCl, 1 mM cacodylate) as a function of the amine concentration (concentrations are indicated in the figure); spermine, spermidine and $[Co(NH_3)_6]^{3+}$ data are taken from ref.[9]; the order of the melting temperature plots is, from top to bottom at 10 μM: spermine > $[Co(NH_3)_6]^{3+}$ > spermidine > $[Pt(NH_3)_4]^{2+}$ > $[Co(NH_3)_5Cl]^{2+}$ > $[Co(NH_3)_5Br]^{2+}$ > $[Co(NH_3)_5H_2O]^{3+}$ > *cis*-$[Co(en)_2NH_3Cl]^{2+}$ > $[Co(NH_3)_5(NO_2)]^{2+}$

with the other amines failing to cause the transition under the 11 mM salt concentration and temperature ramp conditions used; the DNA bending ranking is:

spermine > $[Co(NH_3)_6]^{3+}$ > (+)-$[Co(en)_3]^{3+}$ > (−)-$[Co(en)_3]^{3+}$ > $[Co(NH_3)_5(H_2O)]^{3+}$ > *trans*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ > spermidine

with the other ammines having comparatively little effect. The most notable things about the above lists is that, with the exception of spermine, the ranking of the molecules varies. There is a general trend of reducing efficacy with reducing charge (the aquo complexes will be deprotonated at pH = 6.8[16]). The two enantiomers of $[Co(en)_3]^{3+}$ behave in a similar fashion, but with the possible exception of the thermal stability, where they have a very similar effect, the (−)-enantiomer affects the DNA structure less than the (+)-enantiomer. This correlates with the previous simula-

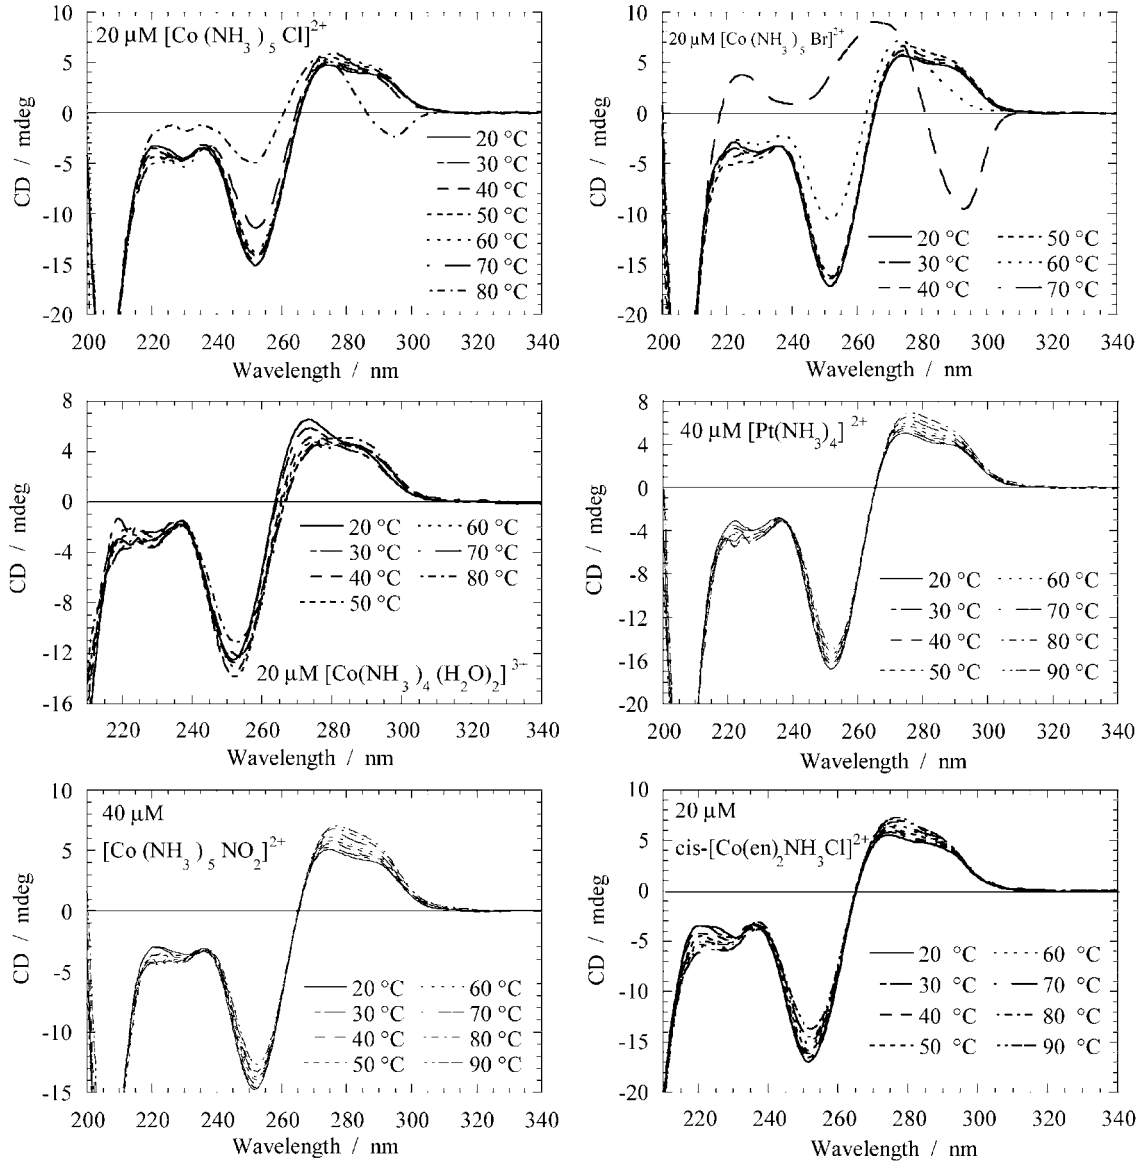

Figure 4. CD spectra of poly[d(G-C)]$_2$ (100 μM in 10 mM NaCl and 1 mM cacodylate buffer) in the presence of a fixed concentration of various amines as the temperature is raised at 4 °C/minute; amine concentration and temperatures are indicated in each figure

tion studies[8] that showed the (+)-enantiomer spending more time localised on the DNA than the (−)-enantiomer.

The DNA thermal stability gives an indication of binding strength, assuming the binding site size and binding modes are similar,[17] so we can conclude that water, halo and especially nitro substitution reduces the DNA affinity of a molecule or significantly changes the binding mode.

The changes in the absorbance of the cobalt tetra- and pentammines observed at elevated temperatures suggest that substitution reactions may be occurring (the change is not reversed upon temperature reduction). The halo-substituted complexes all lose absorbance intensity consistent with the loss of ligand (in this case the halogen ligand)-to-metal charge-transfer transitions. Strong direct cobalt−phosphate interactions have previously been observed by FTIR spectroscopy between $[Co(NH_3)_5Cl]^{2+}$ and the phosphates in ct-DNA with H-bonding interactions observed with the bases.[18] In contrast, no direct bonding was evident with $[Co(NH_3)_6]^{3+}$.[18] This was interpreted to mean that the chloro group was displaced, facilitating the direct bonding of the cobalt to the DNA backbone. Direct cobalt phosphate binding has also been observed between $[Co(NH_3)_5Cl]^{2+}$ and purine nucleotides.[19] From a DNA-charge neutralisation viewpoint these 2+ cobalt ammines thus effectively become 3+ when they loose the Cl^-; in addition they cannot be located particularly deeply in the major groove. It is reasonable to suppose that *cis*-$[Co(en)_2NH_3Cl]^{2+}$ behaves analogously but with lower affinity due to the steric hindrance of the ethylenediamines. The lower thermal stability of DNA in the presence of the

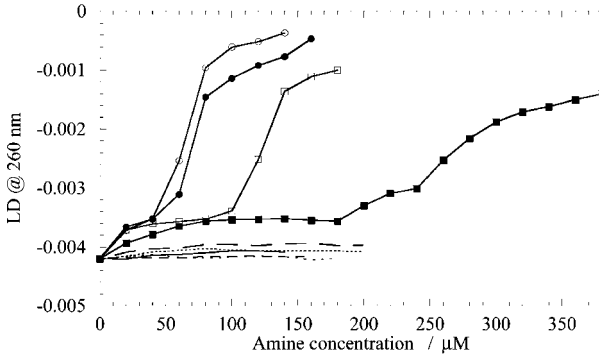

Figure 5. Summary of the LD signals of ct-DNA (60 μM in 10 mM NaCl, 1 mM cacodylate buffer) in the presence of ammines (concentration are indicated in the figure); experiment performed with the same rotation speed; order of LD plots is, from top to bottom at 50 μM: (+)-$[Co(en)_3]^{3+}$ > (−)-$[Co(en)_3]^{3+}$ > $[Co(NH_3)_5H_2O]^{3+}$ > $[Co(NH_3)_4(H_2O)_2]^{3+}$ > *cis*-$[Co(en)_2NH_3Cl]^{2+}$ > $[Pt(NH_3)_4]^{2+}$ > $[Co(NH_3)_5Cl]^{2+}$ > $[Co(NH_3)_5Br]^{2+}$ > $[Co(NH_3)_5(NO_2)]^{2+}$

halo compounds compared with $[Co(NH_3)_6]^{3+}$ may thus be deduced to correlate with a different binding site and a smaller binding affinity.

By way of contrast, the bulky negatively charged NO_2^- ligand will not have a good affinity for the backbone. Its groove binding preferences will also differ from those of an NH_3 ligand since its hydrogen bonding requirements are as an acceptor not a donor.

Conclusion

The inability of the nitro and halo compounds to bend the DNA significantly thus leads us to the conclusion that the bend-inducing binding mode requires deep penetration of the groove by hydrogen-bonding donors. In this context the low hydrogen bonding energy of $[Co(NH_3)_6]^{3+}$ compared with, for example, Mg^{2+} determined by Black and Cowan[20] is not necessarily significant — the hydrogen bonding energy just has to be large enough to position and orient the metal complex in the mode that favours DNA bending once the dominant electrostatic binding energy has assured DNA−metal complex binding.

The halo compounds creep up the ranking order for the B→Z transition, suggesting that the induction of this transition is favoured by some backbone interaction as well as groove binding. It has previously been concluded[9,10] that a triangular face of amines facing the DNA that could interact with the N7/O6 sites of intrastrand guanine bases is required to induce the B→Z transition. In agreement with this hypothesis, *trans*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ and $[Pt(NH_3)_4]^{2+}$,[21] which have no triangular arrangements of amine groups, are incapable of inducing the B→Z transition (even in the absence of NaCl). Substitution of one amine on the $[Co(NH_3)_6]^{3+}$ reduces the transition induction and also reduces the number of triangular faces from 8 to 4. This is consistent with there being fewer effective binding modes to promote the B→Z transition. Neither spermidine nor the weaker binding NO_2 induces a transition in the presence of NaCl, however, they do so at 0 mM NaCl. This presumably relates to the need to reduce the competition for DNA sites from any other positively charged species. In the case of the ethylenediamine ligands, their bulk requires that an effective NNN face must not include the backbone of the ethylenediamine, so the number of NNN faces is reduced again resulting in the slip down the ranking order of the tris-ethylenediamine complexes, with the enantiomer that fits better into the major groove, according to our molecular modelling studies,[9] being able to optimise its interaction. The halo-ethylenediamine complex cannot present a triangular face to the groove while binding to the phosphates, and therefore cannot induce the transition. The mono-aquo complex ends up between the two tris-ethylenediamine enantiomers in its effectiveness, showing a balance of the number of NNN faces (which is higher for the mono-aquo complex) and DNA binding strengths (which is lower for the mono-aquo complex).

Experimental Section

Materials: Ultra pure water (18.2 MΩ) was used in all experiments. ct-DNA was purchased from Sigma/Aldrich Chemical Co. Ltd. Poly[d(G-C)]$_2$ was obtained from Pharmacia Biochemicals. All polynucleotides were dissolved in water without further purification (this required overnight stirring for ct-DNA) and kept frozen until the day of the experiment. DNA solutions were prepared by diluting in 1 mM cacodylate buffer (made up from the sodium salt of cacodylic acid, $C_2H_6AsO_2Na$, 98% purchased from Sigma/Aldrich buffered with hydrochloric acid to a pH of 6.8) with the required NaCl (>99.5% purity, Sigma/Aldrich). The concentration of DNA was determined spectroscopically using ε_{247nm} = 8400 $M^{-1}cm^{-1}$ for poly[d(G-C)]$_2$ and ε_{258nm} = 6600 $M^{-1}cm^{-1}$ for ct-DNA, expressed as the molarity of the phosphate groups.

Methods

Absorbance: Normal absorption spectra were obtained using a Cary 1E spectrometer equipped with a multicell cell changer and Peltier heating unit accessories. Rectangular quartz cuvettes with a reduced volume (4 mm width) and 1 cm path length were used for the absorbance versus temperature melting curves. The cuvettes were filled almost completely (approximately 1300 μL) and the top of the cuvette was sealed with PTFE thread seal tape to ensure no leakage occurred during heating. Samples were heated from 20−98 °C with a ramp rate of 0.1 °C/minute to eliminate any lag between the temperature of the solution and the heating block. Melting temperatures were determined by the derivative method in the Cary software with a data interval equal to the data collection interval (0.2 °C).

CD: Circular dichroism (CD), the difference in absorption of left and right circularly polarised light, was used to follow the transition of poly[d(G-C)]$_2$ into the Z-form in the presence of the ammines. Spectra were collected in 1 cm rectangular path length cuvettes using a Jasco J-715 spectropolarimeter equipped with a Peltier temperature-control device. The samples were heated from 20 °C at a ramp rate of 40 °C/hour and a CD spectrum collected every 10 °C. No equilibration time was allowed prior to the collection of the first spectrum. Since CD is uniquely sensitive to the symmetry of a system, even the achiral transition metal complexes will gain an induced signal at wavelengths where they absorb light. This be-

comes a particular issue for the brominated complex, which has significant absorbance at 260 nm (see Figure 1).

Flow LD: Linear dichroism (LD) is the difference in absorption of light linearly polarised parallel, $A_{\parallel}$, and perpendicular, $A_{\perp}$, to an orientation axis:

$$LD = A_{\parallel} - A_{\perp}$$

In this work, DNA was oriented by shear flow of the DNA sample between a fixed outer cylinder and a rotating solid quartz inner cylinder separated by a 0.5 mm wide gap.[14,15] The linearly polarised light was incident radial to the flow cell. A Jasco J-715 spectropolarimeter adapted for LD measurements was used. The LD of DNA is dominated by the $\pi-\pi^*$ transitions of the DNA bases. Thus, DNA LD probes the average orientation of the DNA bases. On a qualitative level, the LD of DNA can indicate changes in length and variations in the conformation of DNA induced by a binding drug. If the DNA is made more flexible or shortened then it will orient less effectively and the LD signal will be reduced.

Ligand Effects on the Kinetics of the Reversible Binding of NO to Selected Aminocarboxylato Complexes of Iron(II) in Aqueous Solution

Thorsten Schneppensieper,[a] Alicja Wanat,[a,b] Grazyna Stochel,*[a] Sara Goldstein,[c] Dan Meyerstein,[d] and Rudi van Eldik*[a]

Keywords: Catalysts / Chelates / Iron / Kinetics / Nitrogen oxides

Rate constants for the formation and dissociation of Fe^{II}(L)NO (L = aminocarboxylato) have been determined using stopped-flow, temperature jump, flash photolysis, and pulse radiolysis techniques. For a series of ligands the formation rate constants vary between 1.6×10^6 and 2.4×10^8 M^{-1} s^{-1}, whereas the dissociation rate constants vary between 0.11 and 3.2×10^3 s^{-1} at 25 °C. These rate constants result in stability constants ($K_{NO} = k_f/k_d$) ranging from 5.0×10^2 to 1.1×10^7 M^{-1}, which are in good agreement with values of K_{NO} determined by a combined spectrophotometric and potentiometric technique. The results are discussed with reference to available literature data, and interpreted in terms of a generalized reaction mechanism.

Introduction

It has been our interest in recent years to find metal chelates for the selective and efficient binding of NO in aqueous solution, to be employed in alternative denitrification processes.[1] Metal ions can catalyse such processes and can also increase the degree of absorption of NO by direct coordination to the metal center.[2,3] The fundamental coordination chemistry involves the reversible or partially reversible binding of NO by inexpensive and highly soluble metal complexes. Aminocarboxylato complexes of iron(II) are known for their ability to bind NO rapidly,[4–7] and are therefore used to enhance the solubility of NO in aqueous solution in industrial applications, in order to remove NO from exhaust gases. Little mechanistic information is presently available on these reactions, although some scattered rate constants for these reactions and stability constants are reported in the literature.[8–20]

In a recent systematic study[1] we reported the extent to which the reversible binding of NO to aminocarboxylato complexes of iron(II) can be tuned by the selected chelate. In general, a good correlation between the oxygen sensitivity of the chelated iron(II) complex and the formation constant for the Fe^{II}(L)NO complex, i.e. the ability of chelated iron(II) to bind NO was found. This trend correlated with a decreasing reversibility of the reaction, i.e. the ability of Fe^{II}(L)NO to release NO, and an increasing tendency of Fe^{II}(L)NO to exist as Fe^{III}(L)NO^- in solution. The latter complex underwent subsequent slow decomposition, during which Fe^{III}(L) and N_2O were formed.

We have now performed systematic kinetic studies on the reaction of NO with selected Fe^{II} complexes, based on their rather unique behaviour as observed in our more general and qualitative investigation referred to above.[1] These include Fe^{II} complexes of edta, hedtra, nta, dtpa, ttha, and mida (see Table 1 for selected abbreviations). Of this series, the Fe^{II}mida and Fe^{II}edta complexes behave totally differently with respect to the binding of NO. The Fe^{II}mida complex shows almost no oxygen sensitivity, exhibits a low binding affinity for NO, and releases NO almost completely when an inert gas was passed through the solution. In contrast, Fe^{II}edta is extremely oxygen-sensitive, shows a very high binding affinity for NO, and releases NO slowly and incomplete when treated with an inert gas. Kinetic studies on the formation and dissociation reactions were performed using complementary stopped-flow, temperature jump, flash photolysis, and pulse radiolysis techniques. The results are compared to available data for some of these systems reported in the literature. Our studies provide a quantitative basis for the earlier observed trends and reveal important mechanistic information.

Results and Discussion

Employed Kinetic Techniques

It was the purpose of this study to clarify the basic kinetics of the binding of NO to a series of aminocarboxylato complexes of iron(II). Table 2 summarizes the available kinetic and thermodynamic data on such reactions using a variety of techniques.[4] In many cases the reported rate constants were determined in an indirect manner, which re-

 Hydroxyethylenediaminetriacetic acid (Hedtra)
 Nitrilotriacetic acid (nta)
 Triethylenetetraminehexaacetic acid (ttha)
 Methyliminodiacetic acid (mida)
 Diethylenetriaminepentaacetic acid (dtpa)

sulted in large variations in the reported data. In order to verify the earlier data and obtain data on new systems, we employed different complementary kinetic techniques (for more details see Exp. Sect.).

The binding of NO to $Fe^{II}(L)$ can be expressed by the overall reaction shown in Equation (1). Different kinetic techniques can be used to measure k_f and k_d.

$$Fe^{II}(L)(H_2O)_n + NO \underset{k_d}{\overset{k_f}{\rightleftharpoons}} Fe^{II}(L)(H_2O)_{n-1}NO + H_2O \quad (1)$$

Stopped-flow techniques can be employed to rapidly mix solutions containing the reactants if the reactions occur on the millisecond time scale. The observed rate constant in the presence of excess of $Fe^{II}(L)$ can be expressed as shown in Equation (2), from which k_f and k_d can be extracted by measuring k_{obs} as a function of $[Fe^{II}(L)]$. The ratio k_f/k_d equals the overall equilibrium constant K_{NO}, and should be in agreement with values for K_{NO} determined in other non-kinetic ways. A combination of UV/Vis spectroscopy and electrochemical detection of NO was used to determine K_{NO}, which was found to range from $(1.0 \pm 0.1) \times 10^3$ to $(1.5 \pm 0.2) \times 10^7$ M^{-1} at 25 °C for the series of complexes investigated.[1]

$$k_{obs} = k_f[Fe^{II}(L)] + k_d \quad (2)$$

In principle it is also possible to measure k_d directly, and not by the determination of an intercept according to Equation (2), by using an NO-trapping technique with the stopped-flow method. In this case $Fe^{II}(L)NO$ is treated with another complex that binds NO more strongly and rapidly than the system under investigation. Under such condition, release of NO can become the rate-limiting step, which means that k_d can be determined directly from the observed kinetic trace. Two suitable complexes for determining k_d for the release of NO from $Fe^{II}(L)NO$ are $Fe^{II}(edta)(H_2O)^{2-}$ (excluding L = edta) and $Ru^{III}(edta)H_2O^-$, both of which react rapidly (k_f is ca. 1×10^8 M^{-1} s^{-1} at pH = 5 and 25 °C)[4,21] with NO to form the corresponding nitrosyl complexes (see Scheme 1). When an excess of either of these complexes is employed, such that the release of NO, i.e. k_d, becomes the rate-limiting step, the observed rate constant becomes independent of the excess concentration employed and equals k_d.

Flash photolysis can be employed to study the kinetics of Equation (1) on a significantly faster time scale. Irradiation at 532 nm induces the release of NO, followed by relaxation kinetics to the original equilibrium position (see Scheme 2), for which the rate expression of Equation (2) applies.

A third kinetic technique employed in this study is temperature jump. This technique can be used to perturb changes in the equilibrium position for systems that exhibit a significant temperature dependence. For the observed relaxation kinetics, the first-order rate constant is given by

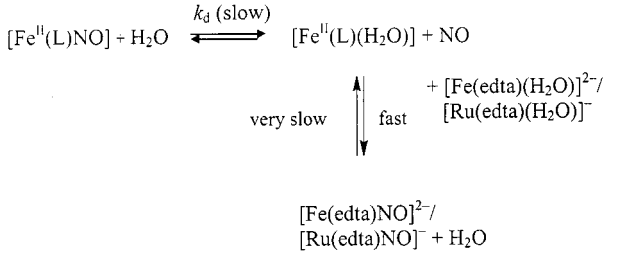
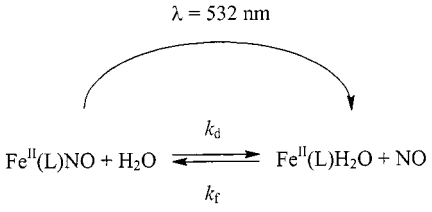


Scheme 1. Determination of k_d with the scavenger complexes $Fe^{II}(edta)(H_2O)^{2-}$ or $Ru^{III}(edta)(H_2O)^-$ for complexes of the type $Fe^{II}(L)NO$



Scheme 2. NO release following irradiation at 532 nm during flash photolysis experiments

Equation (3), where $[Fe^{II}(L)H_2O]_e$ and $[NO]_e$ represent the equilibrium concentrations. According to rate law of Equation (3), measurements of k_{obs} as a function of the sum of the equilibrium concentrations should enable the determination of k_f and k_d.

$$k_{obs} = 1/\tau = k_f\{[Fe^{II}(L)(H_2O)]_e + [NO]_e\} + k_d \quad (3)$$

A fourth kinetic technique employed in this study is pulse radiolysis. The reaction of $Fe^{II}(L)$ with NO was studied by pulse-irradiation of aqueous solutions containing 2 mM $Fe^{III}(L)$, 58−170 μM NO, 1 M methanol, and either 2 mM acetate or phosphate buffer. Under these conditions, e^-_{aq} reduces $Fe^{III}(L)$ to $Fe^{II}(L)$ and $^{\cdot}OH$ is scavenged by CH_3OH to produce $^{\cdot}CH_2OH$ as shown in Equations (4) to (6). (The numbers in parenthesis are G values, which represent the

number of molecules formed per 100 eV energy absorbed by pure water.[22])

$$H_2O \xrightarrow{\gamma,\ e^-} e^-_{aq}\ (2.6),\ {}^{\cdot}OH\ (2.7),\ {}^{\cdot}H\ (0.6),\ H_2\ (0.45),\ H_2O_2\ (0.7),\ H_3O^+\ (2.6) \quad (4)$$

$$e^-_{aq} + Fe^{III}L \rightarrow Fe^{II}L \quad (5)$$

$$CH_3OH + {}^{\cdot}OH \rightarrow {}^{\cdot}CH_2OH + H_2O \quad (6)$$

The ·H radicals are only a small fraction (ca. 10%) of the total radicals formed by the radiation, and most of them are scavenged by CH_3OH to produce $^{\cdot}CH_2OH$, while the rest react with NO.[22] The reaction rate of NO with $^{\cdot}CH_2OH$ is expected to be similar to that with ethanol radical, i.e. 3×10^9 M^{-1} s^{-1},[22] most probably forming O=N−CH_2OH as the primary product, which might further react to form HO−N=CH_2. The rate constant for the reaction of $Fe^{II}L$ with NO was determined by monitoring the formation of the absorbance at 440 or 450 nm under pseudo-first-order conditions, where $[Fe^{II}L] = \text{dose} \times G_e \approx 5$ μM and $[NO] \approx [NO]_0 - \text{dose} \times G_{OH} \approx 53-165$ μM.

Data Measured for k_f and k_d

Stopped-Flow Measurements

Recently,[23] k_f was measured directly using the stopped-flow technique, in the case of $Ru^{III}(edta)H_2O^-$ to be 1×10^7 M^{-1} s^{-1} in phosphate buffer at pH = 7.4 and 7.3 °C. In order to measure such high rate constants, second-order reaction conditions and low concentrations of both reactants were selected to obtain conditions where the reaction is slower than the dead time (2−4 ms) of the stopped-flow instrument. We repeated the measurements on the $Ru^{III}(edta)H_2O^-$ system in acetate buffer at pH = 5.0 and 8 °C,[21] but surprisingly found $k_f = 1 \times 10^5$ M^{-1} s^{-1}, which is ca. 100 times slower than the literature value.[23] This apparent discrepancy could be resolved by considering that the buffer should not be present in the Ru^{III} solution, but only in the NO-containing solution prior to mixing in the stopped-flow instrument. The buffer can substitute the labile water molecule in $Ru^{III}(edta)H_2O^-$ and cause a much slower substitution reaction with NO in producing the final product $Ru^{II}(edta)(NO^+)^-$. It follows from these measurements that the literature value is valid at 8 °C, and a reasonable extrapolation to 25 °C results in $k_f \approx 1 \times 10^8$ M^{-1} s^{-1}. Similar experiments with Fe^{II}(edta) and Fe^{II}(hedtra) at low temperature and low reactant concentrations revealed that k_f for these complexes is on the limit or faster than 5×10^7 M^{-1} s^{-1} at pH = 5 and 25 °C, i.e. very similar to that reported for $Ru^{III}(edta)H_2O^-$, and could not be resolved using this kinetic technique. The high k_f values make these complexes ideal candidates for studying the reverse release of NO on complexes that bind NO less rapidly, using the trapping technique referred to above. Alternatively, an excess of such a complex can be used to study the release of NO from a complex that exhibits a similar reactivity towards NO, since the concentration ratio then determines the nature of the final product and the extent to which the rate-determining release of NO will be observed.

For the systems under the current investigation, k_f could not be determined using stopped-flow techniques, even under low temperature and concentration conditions, and therefore flash photolysis, pulse radiolysis, and temperature jump techniques were employed. However, for all the investigated systems, k_d could be measured directly using either $Ru^{III}(edta)H_2O^-$ and/or $Fe^{II}(edta)H_2O^{2-}$ to trap NO as described below.

With $Fe^{II}(edta)H_2O^{2-}$ as the NO scavenger during the release of NO from Fe^{II}(mida)NO, the absorption maximum at 444 nm, which is characteristic for Fe^{II}(mida)NO,

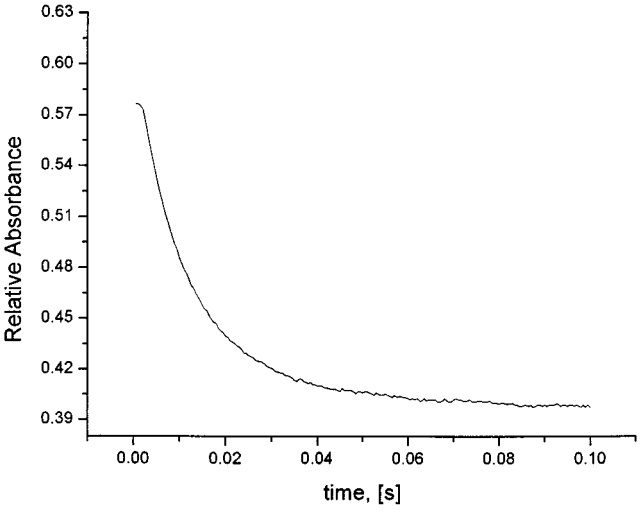


Figure 1. Typical absorbance-time plot for the release of NO from 0.25 mM $Fe^{II}(edta)NO^{2-}$, recorded with the stopped-flow instrument using 7.5 mM $Ru^{III}(edta)H_2O^-$ as a scavenger at pH = 5.0 (0.05 M NaAc), λ = 436 nm, T = 24.4 °C

Table 3. Dependence of k_d on $[Fe^{II}(edta)H_2O^{2-}]$ and $[Ru^{III}(edta)H_2O^-]$ in the presence of 0.2 M acetate buffer [pH = 5.0; I = 0.5 M ($NaClO_4$), T = 25 °C] for the release of NO from $Fe^{II}(mida)_2NO^{2-}$

1.5×10^{-3} M $Fe^{II}(mida)_2NO^{2-}$ + x M $Fe^{II}(edta)H_2O^{2-}$		2.5×10^{-3} M $Fe^{II}(mida)_2NO^{2-}$ + x M $Ru^{III}(edta)H_2O^-$	
$[Fe^{II}(edta)(H_2O)^{2-}]$ [M]	k_d [s^{-1}]	$[Ru^{III}(edta)(H_2O)^-]$ [M]	k_d [s^{-1}]
1.0×10^{-3}	55.0 ± 0.4	5.0×10^{-3}	53.0 ± 0.5
1.5×10^{-3}	60.0 ± 0.5	7.5×10^{-3}	54.0 ± 0.3
2.5×10^{-3}	57.3 ± 0.4	1.0×10^{-2}	52.5 ± 0.3

decreased in intensity while a new band at 435 nm appeared, indicating the formation of $Fe^{II}(edta)NO^{2-}$. The rate constant for NO release from $Fe^{II}(mida)NO$ was found to be 57.3 ± 0.4 s^{-1} in the presence of excess of $Fe^{II}(edta)H_2O^{2-}$ and 52.5 ± 0.3 s^{-1} in the presence of excess of $Ru^{III}(edta)H_2O^{-}$ at 25 °C. Thus, there is a good agreement between the values of k_d determined using the two different NO scavengers. In both cases the rate-limiting step is the release of NO from the nitrosyl complex.

Table 4. Dependence of k_d for the release of NO from $Fe^{II}(edta)NO^{2-}$ on $[Ru^{III}(edta)H_2O^{-}]$ in the presence of 0.2 M acetate buffer [pH = 5.0; I = 0.5 M ($NaClO_4$), T = 25 °C]

2.5×10^{-4} M $Fe(edta)^{-2}$ + x M $Ru(edta)H_2O^{-}$ $[Ru(edta)(H_2O)^{-}]$ [M]	k_d [s^{-1}]
2.5×10^{-3}	91.0 ± 0.4
5.0×10^{-3}	90.4 ± 0.6
7.5×10^{-3}	91.8 ± 0.6

The release of NO from $Fe^{II}(edta)NO^{2-}$ with $Ru^{III}(edta)H_2O^{-}$ as a scavenger was complete within 100 ms, and k_d was calculated to be 91.0 ± 0.4 s^{-1} at 25 °C. A typical stopped-flow trace for this reaction is shown in Figure 1. The decrease in the absorption at 436 nm is consistent with the reaction equilibrium presented in Scheme 1. The observed rate constants were found to be independent of the concentration of the trapping complex as shown in

Table 5. Summary of kinetic data determined during this study for the reaction of NO with aminocarboxylato complexes of iron(II) at 25 °C

Complex	pH	k_f [$M^{-1}s^{-1}$]	k_d [s^{-1}]	K_{NO} (= k_f/k_d)[a][b] [M^{-1}]	K_{NO} [M^{-1}]	Method
$Fe^{II}(edta)$	4.9	$(1.5 \pm 0.2) \times 10^8$				pulse radiolysis

[a] The stability constants were calculated from k_f/k_d, which were obtained kinetically. – [b] Stability constants for nitrosyl complexes are based on the equilibrium between $Fe^{II}(L)_x$ and $Fe^{II}(L)_x(NO)$ complexes; the complex concentrations were measured using UV/Vis spectroscopy and the concentration of free NO in solution was determined directly with an NO electrode, from which K_{NO} was calculated.[1]

Tables 3 and 4, and therefore represent values for k_d. The results of these measurements are summarized in Table 5. The lowest k_d values were found for $Fe^{II}(ttha)NO^{4-}$ and $Fe_2^{II}(ttha)NO^{2-}$ with $k_d = 0.39 \pm 0.01$ and 0.11 ± 0.01 s^{-1} at 25 °C, respectively. The release of NO was found to be slightly faster for $Fe^{II}(hedtra)NO^-$ ($k_d = 4.2 \pm 0.1$ s^{-1}), $Fe^{II}(dtpa)NO^{3-}$ ($k_d = 5.5 \pm 0.4$ s^{-1}), and $Fe^{II}(nta)NO^-$ ($k_d = 9.3 \pm 0.2$ s^{-1}). Significantly higher rate constants were obtained for $Fe^{II}(mida)NO$ ($k_d = 57.3 \pm 0.4$ s^{-1}) and $Fe^{II}(mida)_2NO^{2-}$ ($k_d = 62.2 \pm 0.6$ s^{-1}), while the highest value was found for $Fe^{II}(edta)NO^{2-}$ ($k_d = 91.0 \pm 0.4$ s^{-1}). Kinetic data for the NO release in the case of edta, nta, and dtpa are available from the literature (see Table 2).[2,5,17] In the case of Fe^{II}(edta) the predicted literature value of $k_d > 60$ s^{-1} could be confirmed, whereas significantly lower rates were measured in the present study for nta and dtpa. The trapping technique employed enables a direct measurement of the dissociation rate constant, and in principle must give more accurate values than those obtained using indirect methods. By way of comparison, k_d for aquated iron(II) was found to be 788 ± 100 s^{-1} (at 5 °C), i.e. aquated iron(II) binds NO very weakly and releases it rapidly. Extrapolated to 25 °C, the latter value is in good agreement with the value obtained from flash photolysis experiments (see further Discussion).

Flash Photolysis Measurements

The procedure outlined in Scheme 2 was employed for all investigated systems. A typical kinetic trace is shown in Figure 2. The concentration dependence of k_{obs} resulted in linear plots, as predicted by Equation (2), for which typical examples are shown in Figures 3 and 4 for $Fe^{II}(nta)NO^-$ and $Fe^{II}(H_2O)_5NO^{2+}$, respectively. The Fe^{II}(edta) complex is the species with the highest formation rate constant, i.e. $k_f = (2.4 \pm 0.1) \times 10^8$ M^{-1} s^{-1} at 25 °C (pH = 5). This result agrees well with literature data (see Table 2), where rate constants around 1.3×10^8 M^{-1} s^{-1} at different pH values and temperatures were found. For Fe^{II}(nta), Fe^{II}(hedtra), and Fe^{II}(dtpa), k_f was found to be $(2.1 \pm 0.1) \times 10^7$, $(6.1 \pm 0.1) \times 10^7$ and $(1.1 \pm 0.1) \times 10^7$ M^{-1} s^{-1} at 25 °C, respectively. While the value for the nta system is in good agreement with data reported in the literature,[12] the obtained rate constant for the dtpa system is significantly higher than that obtained before with the temperature jump technique.[5] We believe, however, that the value measured in the present study is more reliable, since the stability constants (K_{NO}) obtained from kinetic and thermodynamic measurements are in perfect agreement with these data (see Table 5). The Fe^{II}(hedtra) complex reacts only half as fast as the edta complex, but the stability constant is more than five times higher, as a result of the NO release kinetics reported above. The k_f values for Fe_2^{II}(ttha) and Fe^{II}(ttha) are $(3.5 \pm 0.1) \times 10^6$ and $(1.0 \pm 0.1) \times 10^6$ $M^{-1}s^{-1}$ at 25 °C, respectively. The lowest k_f values were found for $Fe^{II}(mida)$ (1.9×10^6 M^{-1} s^{-1}), $Fe^{II}(mida)_2$ (1.8×10^6 M^{-1} s^{-1}) and $Fe^{II}(H_2O)_6$ (1.6×10^6 M^{-1} s^{-1}), respectively.

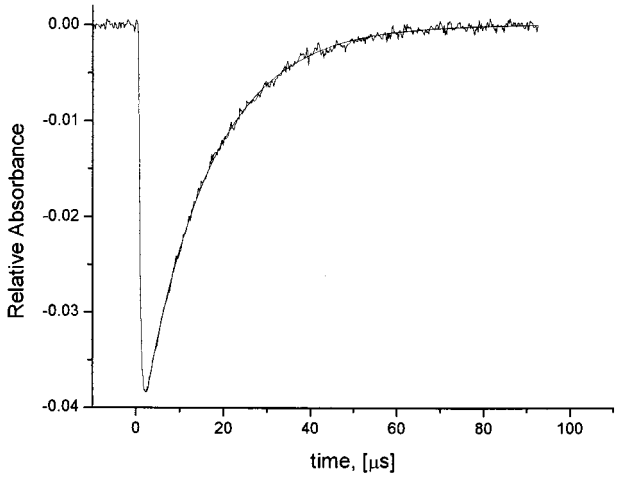

Figure 2. Typical absorbance-time plot for the reaction of Fe^{II}(nta) with NO at pH = 5.0 (0.1 M NaAc), $I = 0.5$ M ($NaClO_4$) and $T = 25$ °C; photolysis wavelength = 532 nm, detection wavelength = 439 nm

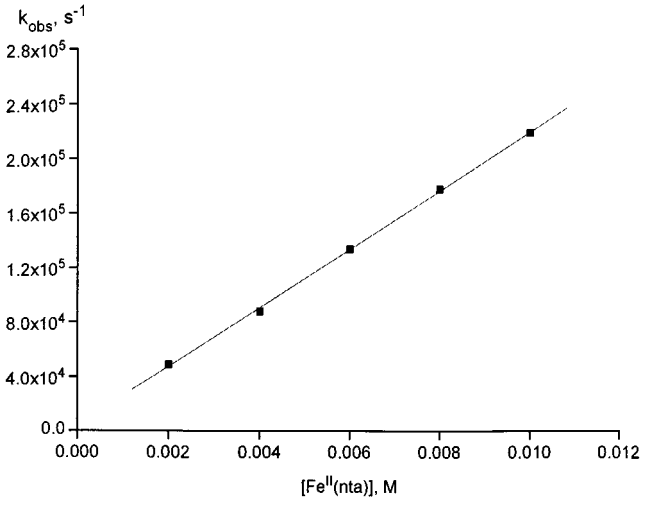

Figure 3. Plot of k_{obs} as a function of [Fe^{II}(nta)], measured at pH = 5.0 (0.2 M NaAc) and $T = 25$ °C; photolysis wavelength = 532 nm, detection wavelength = 439 nm

Pulse Radiolysis Measurements

Figure 5 presents a typical absorbance-time trace recorded for the reaction of Fe^{II}(edta) with NO using the pulse radiolysis procedure described above. Values of k_f determined with this method were slightly lower in comparison with the results obtained from the flash photolysis experiments, viz. 1.5×10^8 M^{-1} s^{-1} at pH = 4.9 for Fe^{II}(edta), 3.4×10^7 M^{-1} s^{-1} at pH = 5.6 for Fe^{II}(hedtra), and 1.3×10^7 M^{-1} s^{-1} at pH = 5.4 for Fe^{II}(nta). This difference can probably be accounted for in terms of the different temperatures at which the experiments were performed, viz. ca. 20 °C in the pulse radiolysis experiments compared to 25 °C in the flash photolysis experiments. However, in the case of

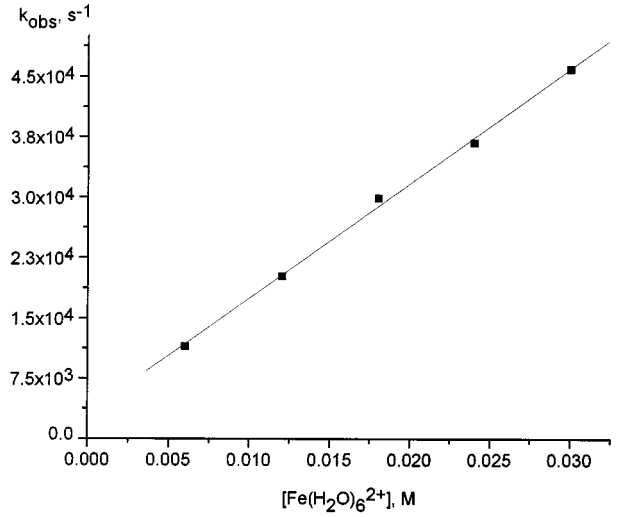

Figure 4. Plot of k_{obs} as a function of $[Fe(H_2O)_6^{2+}]$, measured at pH = 5.0 (0.2 M NaAc) and T = 25 °C; photolysis wavelength = 532 nm, detection wavelength = 451 nm

dtpa and ttha complexes (see Table 5), the values of k_f are much lower than those obtained in the flash photolysis experiments. For these systems it was not possible to perform a concentration dependence study due to the high absorbance of the 2 mM $Fe^{III}(L)$ solution. The second-order rate constant had to be calculated from a single point measured in the presence of 0.104 mM NO at 500 and 470 nm for the dtpa and ttha complexes, respectively. The absorbance changes at these wavelengths are extremely small, which further adds to the uncertainty in the rate constants. In addition, the calculated value of K_{NO} based on the rate constants from the flash photolysis experiments is in good agreement with the directly determined value. These facts lead us to conclude that the flash photolysis data probably represent the more realistic rate constants for the studied systems.

Temperature Jump Measurements

Measurements of k_f for the Fe^{II}(mida) complexes failed using pulse radiolysis. This led us to probe the temperature jump method to establish the accuracy of the data measured with the flash photolysis technique. Equilibrium mixtures of Fe^{II}(mida) and Fe^{II}(mida)NO were studied, and a typical absorbance-time trace is reported in Figure 6. A systematic concentration-dependence study according to Equation (3) (shown in Figure 7) resulted in $k_f = (8.6 \pm 0.8) \times 10^5$ M^{-1} s^{-1}, which agrees within experimental errors with the data from the flash photolysis experiments. The intercept of the line represents k_d for the release of NO, and was found to be 69 ± 50 s^{-1}. Considering the large error limits (up to 15%) usually encountered in temperature jump

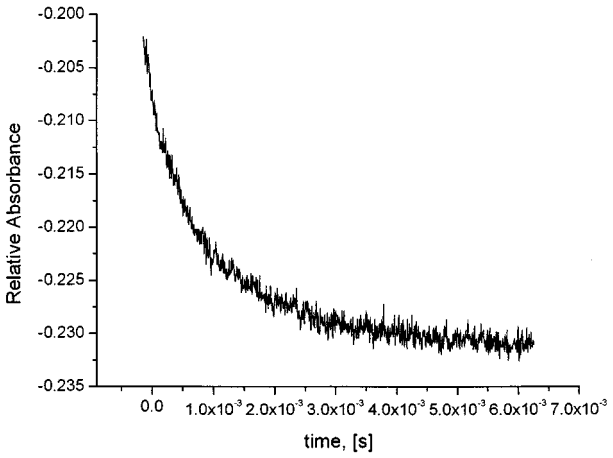

Figure 6. Typical absorbance-time trace for the reaction of Fe^{II}(mida) with NO using the temperature jump techniques; $k_{obs} = 1.08 \times 10^3$ M^{-1} s^{-1}; experimental conditions: $\lambda_{det.}$ = 444 nm, T = 25 °C, $[Fe^{II}(mida)NO] = 7.9 \times 10^{-4}$ M, $[Fe^{II}(mida)] = 1.2 \times 10^{-3}$ M, $[NO] = 5.5 \times 10^{-5}$ M, pH = 5.0 (0.1 M NaAc), I = 0.5 ($NaClO_4$)

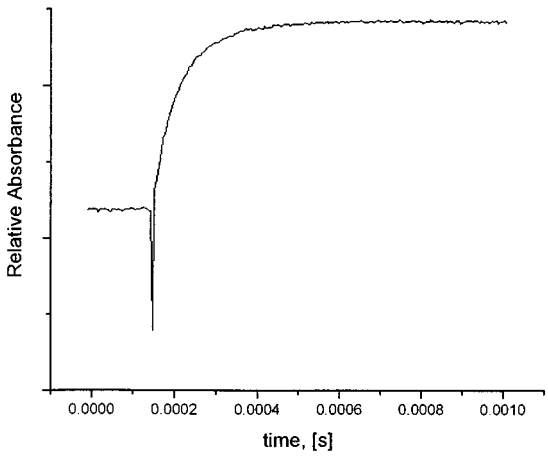

Figure 5. Typical absorbance-time trace for the reaction of $Fe^{II}(edta)H_2O^{2-}$ with NO using pulse radiolysis; the solution contained 2 mM $Fe^{III}(edta)H_2O^-$, 1 M CH_3OH, and 0.115 mM NO at pH = 7.2 (4 mM phosphate buffer), 1.5 μs pulse duration, λ = 440 nm, T = 20 °C

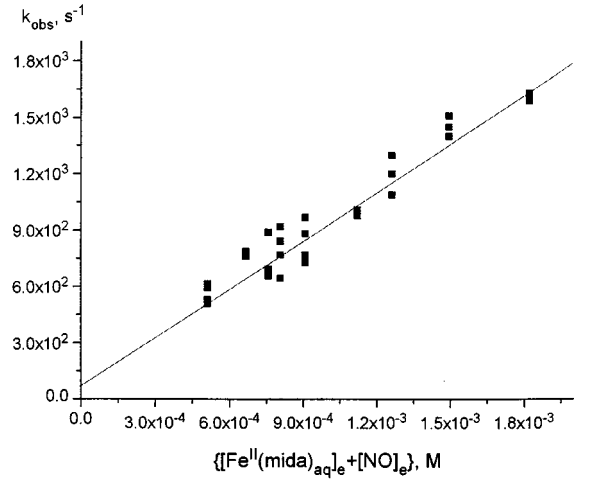

Figure 7. Plot of k_{obs} as a function of $\{[Fe^{II}(mida)_{aq}]_e + [NO]_e\}$ for the reaction of Fe^{II}(mida) with NO obtained using the temperature jump technique; experimental conditions: $\lambda_{det.}$ = 444 nm, T = 25 °C, pH = 5.0 (0.1 M NaAc), I = 0.5 ($NaClO_4$)

experiments, this value is in reasonable agreement with the more accurate one determined via stopped-flow measurements using the trapping technique.

Conclusion

Four different kinetic techniques were employed to study the binding reaction of NO to a series of aminocarboxylato complexes of iron(II). Depending on the selected system, one or more techniques could be used to determine k_f. The rate constant for the dissociation of NO could be measured successfully in all cases using the stopped-flow technique and $Fe^{II}(edta)H_2O^{2-}$ or $Ru^{III}(edta)H_2O^{-}$ as NO scavengers. As a result of its higher stability and much less oxygen sensitivity, $Ru^{III}(edta)H_2O^{-}$ appears to be more promising for practical applications as an NO scavenger than $Fe^{II}(edta)H_2O^{2-}$, although they both bind NO at approximately the same rate.

The fastest rate constant for the binding of NO was found in the case of edta, which is ca. 4 times faster than the reaction of $Fe^{II}(hedtra)H_2O$ with NO. Taking into account the 22 times faster NO release from the edta complex, the nitrosyl adduct of the hedta complex is around 5 times more stable than the edta complex at 25 °C. On this basis, we can account for the reported difference in the stability constants for these two complexes. The $Fe^{II}(nta)NO^{-}$ complex has approximately the same stability constant as the edta complex, where in this case both k_f and k_d are smaller. All other complexes have significantly lower stability constants due to their lower k_f values. On comparing the iron(II) complexes of mida and edta in terms of their application as catalysts for the exhaust gas denitrification, the reaction of $Fe^{II}(mida)$ with NO is approximately 100 times slower than the corresponding reaction with $Fe^{II}(edta)H_2O^{2-}$, which accounts for almost the same difference in the value of K_{NO}. This apparent disadvantage of the mida complex could for example be partially compensated for by longer contact time between the exhaust gas and the catalyst. In addition, the mida complex is almost oxygen-insensitive, which prevents unwanted oxidation of the chelate and allows the effective regeneration of the catalyst.

In general, a good agreement between the values of K_{NO} calculated from the kinetic data and those determined directly with the aid of the NO electrode was observed (see Table 5). The thermodynamic value furthermore assisted the selection of appropriate kinetic data in those cases where differing k_f values were found. The results in Table 5 demonstrate the large influence of the aminocarboxylato chelates on the values of the rate constant and the overall equilibrium constant. There seems to be no simple correlation between these constants and the selected donor groups or charge on the iron(II) complexes. The formation reaction must to some degree be controlled by the lability of the coordinated water molecules on the iron(II) centre, whereas the dissociation reaction is largely affected by the oxidation state of the metal centre, viz. $Fe^{II}-NO$ or $Fe^{III}-NO^{-}$ or $Fe^{I}-NO^{+}$. The distribution of charge density in the Fe−NO bond should depend on the donor properties of the selected chelate. Solomon et al.[24] have clearly shown that in the case of $Fe^{II}(edta)NO$, the Fe−NO centre has an $Fe^{III}-NO^{-}$ character.

Details on the intimate mechanism of these reactions cannot be obtained from rate constant measurements only. With the kinetic methods now well worked out to investigate these reactions, it has become possible to go a step further and to study the temperature and pressure dependence of the formation and dissociation reactions reported here. From these dependencies the activation parameters ($\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta V^{\neq}$) can be obtained and used to gain further insight into the intimate nature of the underlying reaction mechanisms. In addition, since it is reasonable to expect that k_f is controlled by the lability of coordinated water, the rate and activation parameters for the solvent exchange reactions on the selected iron(II) complexes should also be studied. These results and their mechanistic interpretation will be reported in a forthcoming paper.

Experimental Section

Materials and Methods

Chemicals: All chemicals were of analytical grade and were used as received. Solutions were prepared with distilled and purified water using a Milli-Q water purification system. The ligands mida and nta were supplied by Akzo Nobel. All other ligands and chemicals were purchased from Arcos Chimica, Fluka, Lancaster Synthesis, or Sigma-Aldrich with the highest available purity (at least 97%). NO gas, purchased from Messer Griesheim or Rießner Gase in a purity of at least 99.5 vol-%, was cleaned from trace amounts of higher nitrogen oxides like N_2O_3 and NO_2 by passing it through an Ascarite II column (NaOH on silica gel, Sigma-Aldrich). NO from a gas tank should not be used after six months following the date of its industrial preparation, since decomposition causes a drastic decrease in the purity of the gas. The decomposition is pressure-dependent, which led us to only use bottles filled with a maximum pressure of 20 bar, and resulted in a longer lifetime of the NO gas. All experiments were performed under strict exclusion of air oxygen. Buffer solutions were deaerated for extended periods (in general 1 min per mL solution) with pure N_2 or Ar, or in some cases using freeze-thaw cycles under vacuum, in order to completely remove the dissolved dioxygen in solution, before they were brought in contact with Fe^{II} salts or nitric oxide.

Measurements: The pH was measured using a Mettler Delta 340 pH-meter. The reference electrode was filled with NaCl instead of KCl to prevent precipitation of $KClO_4$. UV/Vis spectra were recorded with a Cary 1G UV/Vis spectrophotometer from Varian using a 1-cm quartz cuvette directly attached to a round flask with a side gas connection. The determination of the stability constants was performed as described elsewhere.[1] The concentration of free NO was determined with an ISO-NOP electrode connected to an ISO-NO Mark II nitric oxide sensor from World Precision Instruments. The NO electrode consists of a membrane-covered anode that selectively oxidizes NO to NO_3^{-} ions. The resulting current is proportional to the concentration of NO in solution. The NO electrode was calibrated daily with fresh solutions of sodium nitrite and potassium iodide according to the method suggested by the manufacturers. The calibration factor nA/μM was determined with a linear fit program.

Kinetic Measurements

Laser Flash Photolysis: Laser flash photolysis kinetic studies were carried out with the use of the LKS.60 Spectrometer from Applied Photophysics for detection and a Nd:YAG laser (SURLITE I − 10 Continuum) pump source operating in the second ($\lambda_{exc.}$ = 532 nm) harmonic (245 mJ pulses with ca. 7-ns pulse widths). Spectral changes at appropriate wavelength were monitored using a 100-W Xenon arc lamp, monochromator, and photomultiplier tube PMT − 1P22. The absorbance reading was balanced to zero before the flash, and data were recorded with a digital storage oscilloscope DSO HP 54522A and then transferred to a computer for sequential analysis. Gas-tight quartz cuvettes were used throughout this study. The rate constant for the NO uptake reaction was detected around 435 nm, where a maximum in the UV/Vis spectrum is present. A stock solution of NO was prepared in a gas-tight syringe by degassing a 0.2 M acetate buffer solution (pH = 5.0), followed by saturation with NO. Dilutions of known concentration were prepared from this saturated solution by the use of the syringe technique. Oxygen-free solutions of iron(II) complexes were synthesized and diluted to appropriate concentrations in the vacuum line.

Pulse Radiolysis: Pulse radiolysis experiments were carried out with the Varian 7715 linear accelerator with 5-MeV electrons pulses of 0.5 μs and 200 mA current. The dose per pulse was determined with the hexacyanoferrate(II) dosimeter [5 mM $K_4Fe(CN)_6$ in N_2O-saturated water] using $G\varepsilon[Fe(CN)_6^{3-}] = 6.7 \times 10^3\ M^{-1}\ cm^{-1}$ at 420 nm[25] to be 13.8 Gy. A 150-W Xe lamp produced the analysing light. Appropriate filters were used to minimize photochemistry. Irradiation was carried out in a 4-cm Spectrosil cell using three light passes. Nitric oxide solutions were prepared in gas-tight syringes by purging first the water with He to remove O_2, followed by bubbling for 30 min with NO. NO-saturated solutions (1.8 mM at 21 °C and 690 Torr)[26] were stored in syringes and subsequently diluted with He-saturated solutions to the desired concentrations by the syringe technique.

Temperature Jump: The complex formation reactions were studied using the earlier described joule-heating temperature jump apparatus (rise time ≈ 10 μs) (Messanlagen, Göttingen)[27] A temperature jump of 3 °C was applied to solutions thermostatically maintained at 22 °C during an electric discharge of ca. 20 kV. Kinetic traces for relaxation were monitored mostly at 444 nm, with at least 5, and up to 10, replicate traces being processed as reported earlier,[28,29] by emulating a transient recorder with a 486 PC equipped with a TR-PC 25-8 card from Dr. Strauss System Elektronik GmbH. After the jump, a single relaxation process was observed in each trace. The rate constant for the relaxation curve was fitted with the OLIS KINFIT program.[30]

Stopped-Flow: The kinetics of NO release from $Fe^{II}(L)NO$ were studied with a thermostated (±0.1 °C) stopped-flow spectrometer (SX-18 MV, Applied Photophysics) coupled to an online data acquisition system. At least five kinetic runs were recorded under all conditions, and the reported rate constants represent the mean values. The kinetic data were analysed with the OLIS KINFIT program.

Keywords: Amides / Carbonylations / Carbonyl complexes / Rhodium

Dimethyl formamide (DMF) can be a convenient source of the carbonyl ligand in the coordination chemistry of rhodium, ruthenium, iridium, and platinum. We have undertaken a thorough study concerning the course of this reaction. In a first step, DMF-containing complexes are produced, which is usually accompanied by chloride redistribution. Then, upon refluxing, carbonyl species in the same oxidation state are obtained, presumably as a result of HCl-mediated DMF decomposition. Provided that water levels are kept low, reduction can occur to provide the complexes $[NH_2(CH_3)_2][RhCl_2(CO)_2]$, $[NH_2(CH_3)_2][RuCl_3(CO)_2(DMF)]$, $[RuCl_2(CO)_2(DMF)_2]$, and $[NH_2(CH_3)_2][IrCl_2(CO)_2]$. In the case of platinum, reduction is not effective and $[NH_2(CH_3)_2][PtCl_3(CO)]$ is obtained. No carbonylpalladium species can be synthesized in this way, the reaction producing copious amounts of colloidal metal. Adding phosphanes to these chlorocarbonyl-containing solutions allows easy, one-step syntheses of a variety of complexes.

Introduction

Because of its properties (stable, aprotic, polar, and high boiling point), DMF has been employed as a solvent in a wide variety of catalytic reactions including hydrogenations, hydroformylations, carbonylations, and syn-gas reactions.[1−17] Nevertheless, in some cases, its implication as a reactant has been observed and solvent effects that do not seem to be directly linked with its polarity have been noticed, particularly when the catalytic reaction involves carbon monoxide or further reactions with carbonyl compounds. Thus, in the course of an investigation of the ruthenium-catalyzed hydroesterification of ethylene, the results of which have been reported previously,[1,2] a strong solvent effect was noted. In this reaction, the solvent could be involved in the formation of the active species; in particular, the complex $[PPN][RuCl_3(CO)_2(DMF)]$ has been isolated after reaction of the precatalyst $[PPN][RuCl_3(CO)_3]$ with boiling DMF.[1] In the hydroformylation of formaldehyde using a rhodium catalyst of the general formula $[RhCl(CO)L_2]$ (L: tertiary phosphane ligand), a dramatic effect has been noticed when using DMF as the solvent.[3] This represents an unusual solvent dependence, particularly as the hydroformylation of alkenes can normally be carried out in almost any solvent. The authors postulated that coordination by the solvent could affect the catalyst reactivity. Recently, DMF has been shown to be a ligand of palladium and copper in the course of the oxidation of an alkene to the corresponding ketone.[4] Finally, Mitsudo et al. have developed the direct hydroamidation of alkenes by formamides using ruthenium catalysts.[5] A C−H formyl activation step is invoked in the catalytic cycle.

In the transfer hydrogenation of D-glucose carried out in DMF with $[RuCl_2(PPh_3)_3]$ as a catalyst, a deactivation of the catalyst has been observed.[6,7] At 123 °C, the starting complex was transformed into the catalytically inactive species $[RuCl_2(CO)(DMF)(PPh_3)_2]$, for which the authors assumed that a decarbonylation of the solvent had occurred to generate the carbonyl ligand. In the case of ethylene hydroesterification starting from $RuCl_3{\cdot}xH_2O$, Petit et al.[8] proposed a partial decomposition of DMF to explain the production of $[NMe_4]I$, which involves iodomethane, used to promote the reaction, and dimethylamine produced by DMF decomposition. For the decarbonylation of alkyl formates in the presence of chloride salts of osmium,[9] a positive effect of the solvent has also been noticed. In this case, a catalytic decomposition of DMF to give CO and dimethylamine was proposed; the production of the amine, which can catalyze the decarbonylation of alkyl formates, would seem to provide a good explanation of this effect since formates are usually decomposed in basic media. In this latter study, no information was given regarding the osmium species present at the end of the reaction.

Apart from the aforementioned catalytic reactions, a careful examination of the literature shows that the use of DMF as a carbonylating agent for the synthesis of organometallic compounds has not yet been systematically examined. Even though it has long been known that transition metal salts can give well-characterized carbonyl complexes,

or in some cases carbonylhydrido complexes, upon treatment with alcohols, acyl halides, aldehydes, or formic acid, little is known about the decarbonylation of DMF. Rusina and Vlćek were the first to report such a reaction,[18] studying the formation of carbonyl complexes of the platinum group metals and using DMF as the CO source. Thus, the complex $[RhCl(CO)(PPh_3)_2]$ was prepared by refluxing a solution of $RhCl_3$ in DMF in the presence of triphenylphosphane. Later, Varshavskii and Cherkasova[19] prepared the acetylacetonato complex $[Rh(acac)(CO)_2]$ by two different routes. The first was similar to that employed by Rusina and Vlćek, involving a one-pot reaction of the salt and acetylacetone in boiling DMF (procedure A). The second route (procedure B) required the prior formation of carbonyl-containing rhodium intermediates obtained by heating $RhCl_3$ in DMF, which were then treated with acetylacetone to give $[Rh(acac)(CO)_2]$. The same group has proposed that in the case of $RhCl_3{\cdot}3H_2O$ and H_2PtCl_6, the $[RhCl_2(CO)_2]^-$ and $[PtCl_3(CO)]^-$ anions, respectively, are produced by DMF decarbonylation.[20] Nevertheless, no explanation was given concerning the course of the reaction.

Since these first synthetic results, other β-diketonato complexes of rhodium have been prepared according to procedure A.[21−24] Vaska's compound $[IrCl(CO)(PPh_3)_2]$ has also been prepared by this procedure.[25] The same method was used to prepare other carbonylphosphane-containing iridium complexes.[26,27] Decarbonylation of DMF has also been used for the preparation of ruthenium species containing bipyridyl ligands of the general formula $[Ru(CO)L(bipy)_2]^{n+}$ starting from $RuCl_3{\cdot}3H_2O$.[28−33] In most of these cases, procedure A is employed and very long reaction times are required. Recently, Forster et al.[34] have reported a 1-h synthesis of the complex $[RuCl(CO)(L{-}L')_2]^+$ (L−L′: pyridyltriazole) using procedure B. The 2-methylimidazole-containing complex *trans*-$[Ru(CO)(DMF)(2\text{-}MeIm)_4][CF_3SO_3]_3$ was synthesized from $[Ru(DMF)_6][CF_3SO_3]_3$ by a reaction involving abstraction of CO from DMF,[35] the required dimethylamine co-product having been detected. The decarbonylation of DMF has also been investigated with the molybdenum complex *trans*-$[Mo(N_2)_2(dppe)_2]$ [dppe: bis(diphenylphosphanyl)ethane] in refluxing benzene.[36] The products of this reaction are the complex $[Mo(CO)(DMF)(dppe)_2]$ and dimethylamine, which was detected by GLC. The authors proposed a mechanism that is exactly the reverse process of the carbonylation of amines by noble metals. The complex $[Mo(CO)(HCONEt_2)(dppe)_2]$ has been similarly prepared starting from diethylformamide. Carbon monoxide and dimethylamine have also been found as the sole products of the decomposition of DMF photocatalyzed by a ruthenium compound containing a porphyrin ligand.[37]

In the course of our investigations on noble metal catalyzed carbonylation reactions, we have undertaken a comprehensive study of the reactions of $RhCl_3{\cdot}3H_2O$, $IrCl_3{\cdot}3H_2O$, $RuCl_3{\cdot}3H_2O$, K_2PtCl_4, $PdCl_2$, and Na_2PdCl_6 with DMF and other amides. Preliminary results of our investigations of the reactions of $RhCl_3{\cdot}3H_2O$ and $IrCl_3{\cdot}3H_2O$ with DMF have already been reported.[38]

Results and Discussion

A. Reaction of $RhCl_3{\cdot}3H_2O$ with DMF

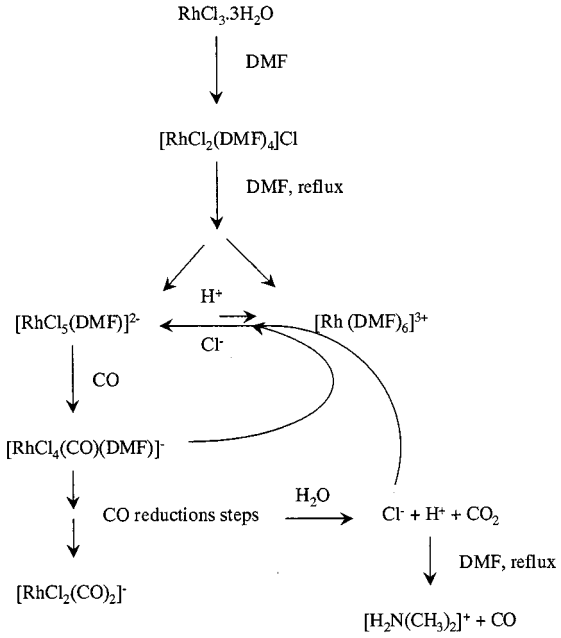
Infrared Monitoring of the Reduction and Identification of Several Intermediate Species

When $RhCl_3{\cdot}3H_2O$ is refluxed in commercially available *N*,*N*-dimethylformamide, the color of the solution changes from dark red to orange within 30 min. If the heating is continued, some metallic rhodium begins to precipitate, indicating a complete reduction of the salt. IR monitoring of the reaction shows that, after 2 min, the dark-red solution contains a carbonyl species at low concentration since a weak carbonyl band is detected at 2092 cm^{-1}. After 5 min, as the solution lightens, two new bands with the same intensity appear beside the band at 2092 cm^{-1}, one at 2063 cm^{-1} and the other at 1984 cm^{-1}. After 15 min, the band at 2092 cm^{-1} has disappeared and only the two strong bands at 2063 and 1984 cm^{-1}, characteristic of the $[RhCl_2(CO)_2]^-$ anion, are present; their intensity remains constant after 30 min of reaction.

Direct evaporation of the solvent from the final orange solution leads to the deposition of large amounts of black insoluble rhodium species along with the complex $[NH_2(CH_3)_2][RhCl_2(CO)_2]$ and the salt $[NH_2(CH_3)_2]Cl$. Alternatively, addition of one molar equivalent of $[AsPh_4]Cl$ affords $[AsPh_4][RhCl_2(CO)_2]$ in 70% yield after recrystallization of the crude product from dichloromethane/*n*-heptane (see Table 1).

In order to identify the first carbonyl intermediate species giving a ν_{CO} band at 2092 cm^{-1}, several experiments were performed that showed this compound to be $[RhCl_4(CO)(DMF)]^-$, as detailed below. A precedent for this anion is the related complex $[RhCl_4(CO)(CH_3OH)]^-$, which gives a ν_{CO} band at 2103 cm^{-1}.[39] This rhodium(III) intermediate is depicted in Scheme 1, together with all the isolated intermediates that can be proposed as being involved in the formation of $[RhCl_2(CO)_2]^-$ from $RhCl_3{\cdot}3H_2O$ through DMF decarbonylation.

In the first of the aforementioned experiments, direct FAB^- mass-spectrometric analysis of the dark-red DMF solution obtained after 2 min revealed only the presence of two main fragments, one at m/z = 245 corresponding to $[RhCl_4]^-$ and the other at m/z = 210 due to $[RhCl_3]^-$. To intercept this first intermediate, 1 mol-equiv. of $[AsPh_4]Cl$ was added to this solution, the solvent was evaporated, and the product was precipitated by adding acetone/*n*-heptane. A reddish powder was obtained, which did not show any carbonyl−rhodium band in its IR spectrum, but rather a broad CO band at 1641 cm^{-1} characteristic of coordinated DMF (free DMF: 1673 cm^{-1}). As mass-spectrometric analysis suggested that chloro-rich species were produced at an early stage of the reaction and that direct isolation of the first carbonyl compound was not possible, probably due to its low concentration and the lability of the CO ligand under our experimental conditions, we investigated the effect of an excess of chloride with regard to the stabilization of



Scheme 1. General reaction pathway for the generation of $[RhCl_2(CO)_2]^-$ from $RhCl_3{\cdot}3H_2O$ and DMF

intermediate species. In the presence of 5−10 mol-equiv. of KCl, rapid precipitation of the violet complex $[NH_2(CH_3)_2]_2[RhCl_5(DMF)]$ was observed upon refluxing $RhCl_3{\cdot}3H_2O$ solutions in DMF. Further heating of the reaction mixture led to the quick re-dissolution of this species, and pure $[AsPh_4][RhCl_2(CO)_2]$ was obtained from the orange solution by adding $[AsPh_4]Cl$ after 25 min of reaction. Therefore, the presence of excess of Cl^- in the medium does not change the outcome of the reaction but allows trapping of $[NH_2(CH_3)_2]_2[RhCl_5(DMF)]$. The corresponding aqua anion $[RhCl_5(H_2O)]^{2-}$ has been reported to be the predominant chlororhodium(III) complex present in hydrochloric acid solutions of $RhCl_3{\cdot}3H_2O$.[26]

In a separate experiment, we carbonylated $[NH_2(CH_3)_2]_2[RhCl_5(DMF)]$ by bubbling CO through a solution in DMF for 15 min at 50 °C. After the addition of $[AsPh_4]Cl$ and evaporation of the solvent, an orange powder was recovered, which analyzed as $[AsPh_4]_2[RhCl_5(CO)]$ and gave a ν_{CO} band at 2081 cm^{-1} (see Table 1). The $[RhCl_5(CO)]^{2-}$ anion has previously been reported by Colton et al. as an intermediate species when $RhCl_3{\cdot}3H_2O$ is treated with hydrochloric and formic acid mixtures to produce $[RhCl_2(CO)_2]^-$.[40] Thus, upon monitoring of the reaction in the absence of CO bubbling, $[RhCl_5(CO)]^{2-}$ is not detected.

We have discovered that reaction of $[AsPh_4]_2[RhCl_5(CO)]$ with 5 equiv. of DMF in boiling chloroform allows isolation of the reddish complex $[AsPh_4][RhCl_4(CO)(DMF)]$ in good yields. This compound shows a ν_{CO} band at 2092 cm^{-1} in DMF.

As these latter anionic species contain more chlorine (five and four Cl ligands, respectively) than the starting rhodium salt, further attempts were made to identify the corresponding cationic complexes, which should presumably have a lower chlorine content. After treating $RhCl_3{\cdot}3H_2O$ with DMF at room temperature for 16 h, we isolated a cationic species that could clearly be formulated as $[RhCl_2(DMF)_4]Cl$. This complex shows one ν_{CO} band at 1639 cm^{-1} (m, broad) in its IR spectrum, which is consistent with a D_{4h} group symmetry, the four coordinated DMF ligands lying in the equatorial plane.

A second cationic complex was isolated as a blue by-product from the $RhCl_3{\cdot}3H_2O$ solution in DMF after heating with an excess of KCl. After 15 min, $[NH_2(CH_3)_2]_2[RhCl_5(DMF)]$ precipitated; after this had been filtered off, the blue species was obtained by slow crystallization from the filtrate. Positive-mode electrospray MS data of the blue material showed that no chloro ligands were present, although the assignment of the more intense peaks at m/z = 280.9, 340.8, 415.0, and 502.8 remains uncertain due to rather facile loss of the coordinated DMF. The presence of one ν_{CO} band at 1655 cm^{-1} in the IR spectrum due to the DMF ligands, and of peaks corresponding to coordinated DMF {in D_2O solution: δ = 7.80 [s, 1 H, $HCON(CH_3)_2$], 2.88 and 2.73 [s, 3 H, $HCON(CH_3)_2$]} in the ^1H NMR spectrum, leads us to propose an $[Rh(DMF)_6]^{3+}$ structure for this complex. The analogous ruthenium complex $[Ru(DMF)_6]^{n+}$ (n = 2, 3) has recently been characterized.[41] This $[Rh(DMF)_6]^{3+}$ complex, for which the counterions are light, as shown by FAB-MS (negative mode), can be formulated as $[Rh(DMF)_6]Cl_3$ and can be expected to react with an excess of Cl^- anions to afford the anionic species $[RhCl_5(DMF)]^{2-}$. The various intermediate cationic rhodium species that have been isolated are reported in Table 1.

It can be concluded from IR monitoring of the reaction and from the isolation or trapping of some of the intermediate species, that the reaction of DMF with the starting rhodium(III) salt involves a complex series of equilibria. The presence of Cl^- ions strongly affects the balance between the identified anionic and cationic species. Both the CO ligand and the $[NH_2(CH_3)_2]^+$ cation arising from DMF have been identified, but no evidence of DMF activation at the metal centre can be given.

Water- and/or HCl-Assisted DMF Activation

A further series of experiments was carried out in order to gain better insight into the parameters that affect the course of the reaction, in particular the role of Cl^- ions. Firstly, the use of commercial DMF, containing around 0.1% of water, produced $[RhCl_2(CO)_2]^-$ in 30 min as an orange solution containing a small amount of black rhodium (Table 2, Figure 1). In each experiment, $[AsPh_4]Cl$ was added and the yield of isolated $[AsPh_4][RhCl_2(CO)_2]$ was determined. In run 1 of Table 2, the yield achieved was 70%.

The addition of chloride (KCl) to the reaction medium stabilizes the system, as shown by the absence of any metallic rhodium, but no significant promoting effect on the reduction was observed (runs 2 and 3 in Table 2). Such an

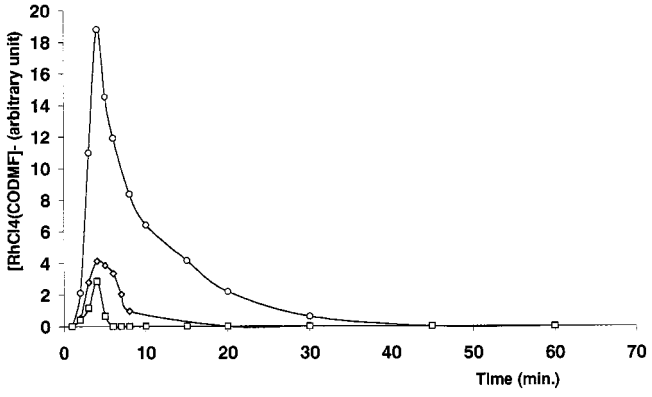

Figure 2. Intensity of the ν_{CO} band of $[RhCl_4(CO)DMF]^-$ at 2092 cm^{-1} during the reaction of $RhCl_3·3H_2O$ with: (○) DMF; (□) DMF + 10 mol-equiv. of dry HCl per $RhCl_3·3H_2O$; (◇) DMF + 5 molar equivalents of H_2O per $RhCl_3·3H_2O$

excess of chloride improved the precipitation of $[NH_2(CH_3)_2]_2[RhCl_5(DMF)]$.

The addition of 5–10 equiv. of dry HCl (5 M HCl in diethyl ether or dioxane) to the $RhCl_3·3H_2O$/DMF mixture was found to have a different and pronounced effect (runs 4 and 5 in Table 2). With 10 equiv., even after reaction for 45 min, the solution remained dark-orange with precipitation of black rhodium. Moreover, the carbonyl band at 2092 cm^{-1} persisted in the IR spectrum (Figures 1 and 2), beside the two bands due to $[RhCl_2(CO)_2]^-$, indicating that the reaction was incomplete. Precipitation of $[NH_2(CH_3)_2]Cl$, arising from DMF decomposition, was also noted. In this case, it is clear from Figure 2 that the production of $[RhCl_4(CO)(DMF)]^-$ was greatly enhanced compared to run 1, suggesting that larger quantities of CO were provided by the acid-catalyzed DMF decomposition. As the yield of $[RhCl_2(CO)_2]^-$ was lower when the concentration of $[RhCl_4(CO)(DMF)]^-$ was significant, we suggest that anhydrous HCl is rapidly neutralized by $NH(CH_3)_2$ arising from the DMF. Thus, no more carbon monoxide can be generated in the medium to maintain the reaction and more particularly the reduction. This experiment further shows that rhodium is unlikely to directly promote the DMF decomposition.

On the contrary, when aqueous solutions of HCl were used (37% in water), another phenomenon was observed; with 5–10 equiv. of acid (runs 6 and 7 in Table 2), the reaction was complete within 12 min and the solution became lemon-yellow, giving the highest yield achieved in this study

(88%). The change in color, i.e. from orange for runs 1 to 5 to lemon-yellow for runs 6 and 7, might be taken to indicate a more complete reaction, as evidenced by the higher yields of the isolated product achieved in the latter cases.

Finally, the role of water itself was examined. We have observed that by adding 5 equiv. of water per mol of rhodium, the reduction can be achieved within 12 min (Table 2, Figure 1 and Figure 2) and the yield of $[RhCl_2(CO)_2]^-$ reaches 85% with no black rhodium formation. We propose that the presence of water assists the reduction step from $[RhCl_4(CO)(DMF)]^-$ to $[RhCl_2(CO)_2]^-$ and that the addition of HCl accelerates the production of CO from DMF, as evidenced by the significant amounts of ammonium chloride detected in the medium. Formally, $COCl_2$ is eliminated in the reduction step and is rapidly hydrolyzed, but we prefer to consider the water-gas shift reaction, which produces CO_2 and H_2 from CO and H_2O. The reduction step is, in fact, the reductive elimination of HCl from the coordination sphere of the rhodium(III) species. Equation (1) shows the overall stoichiometry of several reactions. The complex $[RhI_2(CO)_2]^-$ has previously been shown to be a good catalyst of the water-gas shift reaction.[42]

$$[RhCl_4(CO)(DMF)]^- + 2\,CO + H_2O \rightarrow [RhCl_2(CO)_2]^- + 2\,HCl + CO_2 + DMF \quad (1)$$

To sum up this section on the rhodium activity, we have shown that DMF coordinates to the rhodium salt to give $[RhCl_2(DMF)_4]Cl$, disproportionation of which affords $[RhCl_5(DMF)_2]^{2-}$ and $[Rh(DMF)_6]^{3+}$. The latter species gives the former dianionic one in the presence of chloro ligands. Isolation of $[RhCl_5(DMF)]^{2-}$ with $[NH_2(CH_3)_2]^+$ as the counterion shows that, at this stage of the rhodium(III) chemistry, significant amounts of DMF have been decomposed, thus indicating the presence of an acidic medium. As commercial $RhCl_3{\cdot}3H_2O$ is obtained by evaporation of acidic aqueous solutions of rhodium trichloride, traces of HCl can be present at the beginning of the reaction. However, as no carbonyl species have been detected in the early stages, we conclude that the formation of $[RhCl_2(CO)_2]^-$ resembles an autocatalytic process, which does not involve the activation of DMF at the rhodium center.

Use of Other Amides

In order to test the generality of the reaction, we investigated the behavior of various formamides in this reductive carbonylation. At 180 °C, *N*-methylformamide gave yellow solutions containing a small amount of black material in around 1 min. In their IR spectra, such solutions showed only the two ν_{CO} bands of $[RhCl_2(CO)_2]^-$ at 2073 and 1997 cm^{-1}. The yield of $[AsPh_4][RhCl_2(CO)_2]$ was 72%. When the same reaction was performed at 140 °C, the expected product was obtained in less than 10 min without any precipitation of metallic rhodium. When a solution of $RhCl_3{\cdot}3H_2O$ in formamide was gently heated from room temperature to 120 °C (i.e., well below its boiling point of 210 °C), the ν_{CO} bands of $[NH_4][RhCl_2(CO)_2]$ were detected at 2079 and 2005 cm^{-1} above 100 °C, but the solution was dark and large quantities of black material were deposited. Using diethylformamide at 160 °C produced $[H_2NEt_2][RhCl_2(CO)_2]$ (ν_{CO} = 2060, 1981 cm^{-1}) in 30 min without any metallic precipitate. Although this reaction appeared to be quantitative on the basis of IR measurements, on a small preparative scale the yield of isolated product, usually $[AsPh_4][RhCl_2(CO)_2]$, was ca. 70%. Yields of around 85% were achieved when small quantities of water were introduced to promote the reductive carbonylation. Finally, using *N*-methylacetamide ($CH_3CONHCH_3$; m.p. 28 °C) at 180 °C, a black solution with copious precipitation of a black material was obtained in less than 5 min, and no CO stretching band could be detected in the IR spectrum of the solution.

Direct Preparation of Several Rhodium Complexes

Starting from DMF solutions containing the $[NH_2(CH_3)_2][RhCl_2(CO)_2]$ complex, we added various ligands at room temperature to produce the corresponding rhodium(I) complexes (procedure B). Direct addition of 2 equiv. of PPh_3, as reported by Varshavskii et al.,[19] $P(OPh)_3$, or tris(*m*-sulfonatophenyl)phosphane (TPPTS) furnished the corresponding $[RhCl(CO)L_2]$ square-planar complexes in high yields. Addition of 3 mol of $P(OPh)_3$ resulted in the generation of $[RhCl\{P(OPh)_3\}_3]$. The use of bis(diphenylphosphanyl)propane gave $[Rh(CO)(dppp)_2]Cl$ in 75% yield.

Substitution of the chloro ligand can also be performed. As in the case of $[Rh(acac)(CO)_2]$,[19] addition of 1,1-dimethylethanethiol afforded the corresponding bridged dinuclear complex $[Rh_2(\mu\text{-}S\textit{t}Bu)_2(CO)_4]$ in 80−85% yield. After stirring for 5 min, IR monitoring showed that the tetracarbonyl complex had been formed, and the subsequent addition of 2 equiv. of PPh_3 or TPPTS resulted in the formation of $[Rh_2(\mu\text{-}S\textit{t}Bu)_2(CO)_2(PPh_3)_2]$ or $[Rh_2(\mu\text{-}S\textit{t}Bu)_2(CO)_2(TPPTS)_2]$, respectively.

We have observed that for phosphane ligands, procedure A, in which all the reactants are introduced at the beginning, gives the same results but with much longer reaction times (2−5 h). However, no clean reaction could be achieved by adding HS*t*Bu according to procedure A. Hence, the present method allows the high-yielding preparation in a one-pot procedure of various carbonylrhodium complexes without the use of carbon monoxide gas.

B. Reaction of $IrCl_3{\cdot}3H_2O$ with DMF

An identical study has been carried out on $IrCl_3{\cdot}3H_2O$ in DMF. It is known from the literature[43] that $[IrCl_2(CO)_2]^-$ can be generated using carbon monoxide by refluxing in a high boiling point alcohol such as 2-methoxyethanol. This is presumably due to the higher stability or inertness of iridium(III) compared to rhodium(III).

In the present case, refluxing of a solution of $IrCl_3{\cdot}3H_2O$ in DMF resulted in a beige precipitate after 5 min, which rapidly redissolved on further heating. This species was isol-

ated by stopping the reaction and, after cooling, analyzed as $[NH_2(CH_3)_2]_2[IrCl_5(DMF)]$. As for rhodium, the formation of this species was favored in the presence of an excess of Cl^- ions, for instance in aqueous HCl. After reaction for 10 min, the IR spectrum of the solution showed a ν_{CO} band at 2048 cm^{-1}. The intensity of this band increased, while the color of the solution became progressively more orange. After 30 min, addition of $[AsPh_4]Cl$ to trap this intermediate species resulted in the production of $[AsPh_4][IrCl_4(CO)(DMF)]$, which was isolated as an orange precipitate in 69% yield following the addition of water. On further heating of the initial solution, the two ν_{CO} bands at 2045 and 1965 cm^{-1} intensified, which was accompanied by a concomitant decrease in the band at 2048 cm^{-1}. Heating for 15 h was required to completely transform the starting complex into $[IrCl_2(CO)_2]^-$, albeit with a large amount of black metal. Addition of $[AsPh_4]Cl$ allowed the isolation of $[AsPh_4][IrCl_2(CO)_2]$ in 10% yield.

In order to improve the reduction step from $[IrCl_4(CO)(DMF)]^-$ to $[IrCl_2(CO)_2]^-$, 5 equiv. of water were added. The reaction indeed became faster, but large amounts of the black precipitate were still present. Addition of 5 equiv. of aqueous HCl (37% in water) and heating for 60 min resulted in the clean production of $[IrCl_2(CO)_2]^-$ in 70% yield. Anhydrous HCl or larger amounts of aqueous HCl were found to have a negative effect.

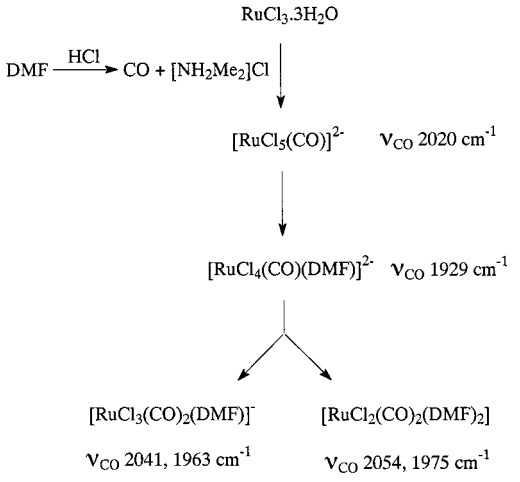
This reaction was thus slower than that for rhodium. The direct isolation of $[IrCl_5(DMF)]^{2-}$ and $[IrCl_4(CO)(DMF)]^-$ indicates that the same mechanism should be operative for both metals. As for rhodium, both the CO ligand and the $[NH_2(CH_3)_2]^+$ cation arising from DMF decomposition could be identified, but again no evidence was found for DMF activation at the metal center.

Addition of 2 equiv. of PPh_3 to the solution containing $[IrCl_2(CO)_2]^-$ was found to result in the immediate formation of $[IrCl(CO)(PPh_3)_2]$. Thus, it appears that procedure B, which involves addition of the ligand after generation of the carbonylchloro anion, is faster than procedure A for generating the desired compound.

C. Reaction of $RuCl_3 \cdot 3H_2O$ with DMF

In the case of ruthenium, the reaction was found to be slower and more complex than that for rhodium. Scheme 2 depicts the various complexes detected during this study.

On heating a solution of $RuCl_3 \cdot 3H_2O$ in DMF, a ν_{CO} band was seen at 2020 cm^{-1} in the IR spectrum after 15 min, corresponding to the red species $[PPN]_2[RuCl_5(CO)]$, which was isolated following the addition of [PPN]Cl. After further heating for 25 min, five more ν_{CO} bands appeared at 2054, 2041, 1975, 1963, and 1929 cm^{-1}. The band at 2020 cm^{-1} rapidly disappeared, whereas that at 1929 cm^{-1} persisted for up to 2 h. The other four bands showed no evolution on heating for longer times. No ruthenium black was observed in the course of the reaction. In a separate experiment, reaction of $RuCl_3 \cdot 3H_2O$ with DMF in the presence of 5 equiv. of aqueous HCl allowed isolation of the green ruthenium(II) product



Scheme 2. General reaction pathway for the generation of $[RuCl_3(CO)_2(DMF)]^-$ and $[RuCl_2(CO)_2(DMF)_2]$ from $RuCl_3 \cdot 3H_2O$ and DMF

$[PPN]_2[RuCl_4(CO)(DMF)]$, showing ν_{CO} bands at 1929 cm^{-1} and 1638 cm^{-1} due to coordinated DMF.

We found that by adding 2.5 equiv. of dry HCl to a solution of $RuCl_3 \cdot 3H_2O$ in DMF, a single complex showing two ν_{CO} bands at 2041 and 1963 cm^{-1} was obtained after reaction for 60 min. In the course of the reaction, the two intermediates giving rise to the bands at 2020 and 1929 cm^{-1} (here shifted to 1919 cm^{-1} due to medium effect) were also transiently observed, but disappeared more quickly. The two final ν_{CO} bands at 2041 and 1963 cm^{-1} are attributable to $[RuCl_3(CO)_2(DMF)]^-$,[1] which was isolated as the PPN salt in 65% yield. Addition of larger amounts of dry HCl resulted in the production of small amounts of $[RuCl_3(CO)_3]^-$ (ν_{CO} bands at 2124, 2008 cm^{-1}), together with $[RuCl_3(CO)_2(DMF)]^-$; this can be attributed to a higher concentration of CO in the solution.

A second complex, showing ν_{CO} bands at 2054 and 1975 cm^{-1}, was isolated following the addition of [PPN]Cl to the yellow solution exhibiting the four ν_{CO} bands at 2054, 2041, 1975, and 1963 cm^{-1} (after refluxing a solution of $RuCl_3 \cdot 3H_2O$ in DMF for 2 h). The products were isolated by precipitation with water. The yellow precipitate was found to contain $[PPN][RuCl_3(CO)_2(DMF)]$ and the unknown complex. Column chromatographic separation on silica allowed isolation of the latter species as pure $[RuCl_2(CO)_2(DMF)_2]$. Scheme 2 summarizes the reaction pathway for the reductive carbonylation of $RuCl_3 \cdot 3H_2O$; it does not involve any DMF activation at the metal center.

As for rhodium and iridium, the solution containing the carbonylchloro species could be used to prepare various complexes. The complex *cis,cis,trans*-$[RuCl_2(CO)_2(PPh_3)_2]$ could be selectively obtained by adding PPh_3 to the solution containing the $[RuCl_3(CO)_2(DMF)]^-$ anion (obtained from a DMF/dry HCl mixture) at 140 °C.

D. Reactions of K_2PtCl_4, $PdCl_2$, and Na_2PdCl_6 with DMF

The reactivities of palladium and platinum salts were found to differ markedly from those of rhodium, iridium,

and ruthenium. Indeed, on refluxing $PdCl_2$ or Na_2PdCl_6 in DMF, the rapid formation of colloidal palladium suspensions was observed within 10 min. Attempts to stabilize possible carbonyl species by adding anhydrous or aqueous HCl, KCl, or even [PPN]Cl, were unsuccessful. Heating a solution of $PdCl_2$ in DMF at 100 °C for 2 h resulted in the formation of a dark solid, which was identified as $[PdCl_2(DMF)_2]$. This compound has already been prepared[44] by treating $PdCl_2$ with DMF at room temperature. However, upon dissolution in another solvent, this complex dissociates with loss of its two DMF ligands. Thus, we did not succeed in finding conditions under which a carbonylpalladium complex could be directly produced from a palladium salt through DMF decarbonylation.

As regards platinum, the refluxing of K_2PtCl_4 in DMF produced copious amounts of black metal. Neither HCl (anhydrous or aqueous) nor KCl prevented this precipitation. Nevertheless, the IR spectrum of the solution showed the presence of a weak ν_{CO} band at 2087 cm^{-1}. Thus, we added 1 equiv. of [PPN]Cl at the beginning of the reaction. Under these conditions, the carbonylplatinum(II) complex [PPN][$PtCl_3(CO)$] could be cleanly obtained without any black precipitate, albeit in a yield of just 52%.

Conclusion

Dimethylformamide, as well as diethylformamide and methylformamide, can act as convenient sources of carbon monoxide. This study has shown that, mainly for rhodium, iridium, and ruthenium, it is possible to produce carbonylhalo complexes in high yields. The presence of small amounts of water clearly assists the reduction of the commercial salts into rhodium(I), $[RhCl_2(CO)_2]^-$, iridium(I) $[IrCl_2(CO)_2]^-$, and ruthenium(II) $[RuCl_4(CO)(DMF)]^{2-}$. Presumably, the reduction proceeds through the water-gas shift reaction. As no evidence has been found for DMF activation at the metal center, an HCl-mediated decomposition of the solvent is proposed to explain the formation of CO and $[NH_2(CH_3)_2]^+$.

The good yields obtained for these carbonyl complexes show that the methodology used in this work is either an attractive one-step route for preparation of the complexes, or a means of directly obtaining the catalytic precursors in DMF solution. Such a procedure is not applicable in the case of palladium, since it leads only to deposition of the black metal, and appears to be limited for platinum, for which $[PtCl_3(CO)]^-$ is obtained in modest yield. Finally, by the direct addition of various ligands to the carbonylhalo-containing DMF solutions, as described here with a few examples, the corresponding classical complexes may be obtained in high yields according to a simplified procedure.

Experimental Section

General Remarks: All synthetic manipulations were carried out under nitrogen using standard Schlenk techniques. Dimethylformamide and the other reagents were used as received (Aldrich). − Elemental analyses were performed with a Carlo Erba EA-1110 instrument. − Infrared spectra were recorded with a Perkin−Elmer 225 spectrophotometer using a 0.1-mm cell equipped with CaF_2 windows. − NMR spectra were recorded with a Bruker AC 200 MHz instrument (^1H, ^{31}P, and ^{13}C). ^1H and ^{13}C NMR spectroscopic data were referenced to the solvent peaks, while ^{31}P NMR spectra were referenced to 85% H_3PO_4 as an external standard. Chemical shifts are expressed in ppm and coupling constants in Hz. − Mass spectrometry (FAB, Xe 100 eV, NBA matrix) was performed with a Nermag R10-10 apparatus. − Procedure B was used for all the syntheses.

Rhodium Complexes

$[NH_2(CH_3)_2]_2[RhCl_5(DMF)]$: The complex was prepared from $RhCl_3{\cdot}3H_2O$ (1.0 g, 3.8 mmol) and KCl (1.41 g, 19 mmol) in DMF (15 mL). On heating the solution under reflux (160 °C) for 15 min, it turned progressively from deep-red to dark-orange and the product precipitated as a violet powder. After cooling to room temperature, the product was collected by filtration using a Büchner funnel, washed with acetone, and dried in vacuo to give 0.255 g (15% based on $RhCl_3{\cdot}3H_2O$). − IR (KBr pellets): ν_{CO} = 1636 cm^{-1} (coordinated DMF). − ^1H NMR (D_2O): δ = 7.81 [s, 1 H, $HCON(CH_3)_2$], 2.88 and 2.73 [2 s, 2 × 3 H, $HCON(CH_3)_2$], 2.60 [s, 6 H, $NH_2(CH_3)_2$]. − $^{13}C\{^1H\}$ NMR (D_2O): δ = 165.2 [d, $HCON(CH_3)_2$, J_{Rh-C} = 17 Hz], 31.4 and 36.9 [s, $HCON(CH_3)_2$], 34.6 [s, $NH_2(CH_3)_2$]. − MS (FAB^-, H_2O): *m/z* (%) = 418 (100) $[\{NH_2(CH_3)_2\}_2\{RhCl_5[HN(CH_3)_2]\}]^-$, 383 (19) $[\{NH_2(CH_3)_2\}_2\{RhCl_4[HN(CH_3)_2]\}]^-$, 326 (26) $[RhCl_5\{HN(CH_3)_2\}]^-$, 244 (31) $[RhCl_4]^-$. − $C_7H_{23}Cl_5N_3ORh$ (445.45): calcd. C 18.87, H 5.20, N 9.43, O 3.59; found C 18.53, H 5.20, N 9.39, O 3.32.

$[AsPh_4][RhCl_4(CO)(DMF)]$: The complex was prepared from $[AsPh_4]_2[RhCl_5(CO)]$ (0.18 g, 0.179 mmol) and DMF (0.065 g, 0.895 mmol) in $CHCl_3$ (10 mL). The solution was heated under reflux for 15 min, allowed to cool, filtered, and the product was precipitated by adding *n*-heptane. It was collected by filtration using a Büchner funnel, washed with *n*-heptane, and dried in vacuo to give 0.11 g {88% based on $[AsPh_4]_2[RhCl_5(CO)]$}. − IR (KBr pellets): ν_{CO} = 2085, 1637 cm^{-1} (coordinated DMF). − ^1H NMR ($CDCl_3$): δ = 7.88 [s, 1 H, $HCON(CH_3)_2$], 2.89 and 2.75 [2 s, 2 × 3 H, $HCON(CH_3)_2$]. − MS (FAB^-, CH_3CN): *m/z* (%) = 362 (10) $[RhCl_4(DMF)]^-$, 289 (100) $[RhCl_4]^-$. − $C_{28}H_{27}AsCl_4NO_2Rh$ (729.17): calcd. C 46.12, H 3.73, N 1.92, O 4.39; found C 45.53, H 3.40, N 1.79, O 4.32.

$[RhCl_2(DMF)_4]Cl$: The complex was prepared from $RhCl_3{\cdot}3H_2O$ (0.5 g, 1.9 mmol) in DMF (15 mL). The solution was stirred at room temperature for 48 h, then filtered, and the solvent was evaporated in vacuo at 50 °C. The resulting oil was treated at room temperature with acetone to yield a brown precipitate. The final product was washed several times with acetone and dried in vacuo to give 0.105 g (11% based on $RhCl_3{\cdot}3H_2O$). − IR (KBr pellets): ν_{CO} = 1639 cm^{-1} (coordinated DMF). − ^1H NMR (D_2O): δ = 8.04 [s, 1 H, $HCON(CH_3)_2$], 2.96 and 2.78 [2 s, 2 × 3 H, $HCON(CH_3)_2$]. − $^{13}C\{^1H\}$ NMR (D_2O): δ = 168.8 [d, $HCON(CH_3)_2$, J_{Rh-C} = 19 Hz], 41.4 and 36.1 [s, $HCON(CH_3)_2$]. − MS (FAB^+, H_2O): *m/z* (%) = 465 (6) $[RhCl_2(DMF)_4]^+$, 392 (5) $[RhCl_2(DMF)_3]^+$, 356 (11.8) $[RhCl(DMF)_3]^+$, 319 (3) $[RhCl_2(DMF)_2]^+$, 248 (100) $[RhCl_2(DMF)]^+$. − $C_{12}H_{28}Cl_3N_4O_4Rh$ (501.64): calcd. C 28.73, H 5.63, N 11.17, O 12.76; found C 28.43, H 5.29, N 10.39, O 11.32.

$[AsPh_4][RhCl_2(CO)_2]$: The complex was prepared from $RhCl_3{\cdot}3H_2O$ (1.0 g, 3.8 mmol) and H_2O (0.35 mL, 19.5 mmol) in

DMF (15 mL). On heating the solution under reflux (160 °C), it turned progressively from deep-red to yellow. IR monitoring indicated the formation of the carbonylchloro anion. After 15 min, $[AsPh_4]Cl$ (1.58 g, 3.8 mmol) was added and the mixture was concentrated to a volume of 3 mL in vacuo at 100 °C. It was then allowed to cool to room temperature and ca. 6 N aq. HCl (20 mL) was added dropwise to precipitate the complex as a yellow powder. The product was collected by filtration using a Büchner funnel, washed with ca. 6 N aq. HCl (100 mL), and dried in vacuo to give 1.98 g (85% based on $RhCl_3 \cdot 3H_2O$). – IR (KBr pellets): ν_{CO} = 2054, 1975 cm^{-1}. – MS (FAB$^-$, CH_3CN): *m/z* (%) = 229 (8) $[RhCl_2(CO)_2]^-$, 201 (16) $[RhCl_2(CO)]^-$, 173 (100) $[RhCl_2]^-$. – $C_{26}H_{20}AsCl_2O_2Rh$ (613.18): calcd. C 50.93, H 3.29; found C 50.62, H 3.27.

[RhCl(CO)L$_2$] Complexes [L = PPh$_3$, P(OPh)$_3$, or TPPTS]: These three compounds were prepared from $RhCl_3 \cdot 3H_2O$ (0.3 g, 1.14 mmol) and H_2O (0.11 mmL, 6.11 mmol) in DMF (10 mL) in a closed Schlenk tube without any reflux condenser system. On heating the solution under reflux, it turned progressively from deep-red to yellow. IR monitoring of the reaction indicated the formation of the carbonylchloro anion $[RhCl_2(CO)_2]^-$. After 15 min, the mixture was cooled to room temperature and 1.95 equiv. of the appropriate phosphane was added [0.58 g of PPh_3, 0.69 g of $P(OPh)_3$ or 1.45 mg of TPPTS]. The reaction was immediate, giving a significant evolution of CO. An IR spectrum of the solution showed a single ν_{CO} band at 1977 cm^{-1} (PPh_3 complex), 2012 cm^{-1} [$P(OPh)_3$ complex], or 1982 cm^{-1} (TPPTS complex). The yellow complexes were precipitated by the addition of cold water (50 mL) [PPh_3 and $P(OPh)_3$ complexes] or ethanol (50 mL) (TPPTS complex). Collection of the products by filtration using a Büchner funnel and washing with water (150 mL) [PPh_3 and $P(OPh)_3$ complexes] or ethanol (150 mL) (TPPTS complex) afforded clean products in reproducible yields of around 80%.

[RhCl(CO)(PPh$_3$)$_2$]: IR (KBr pellets): ν_{CO} = 1960 cm^{-1} (vs). – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 32.5 (d, J_{Rh-P} = 125 Hz). – $C_{37}H_{30}ClOP_2Rh$ (690.95): calcd. C 64.32, H 4.38, O 2.32; found C 64.36, H 4.57, O 3.08.

[RhCl(CO){P(OPh)$_3$}$_2$]: IR (KBr pellets): ν_{CO} = 1998 cm^{-1} (vs). – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 113.6 (d, J_{Rh-P} = 214 Hz). – $C_{37}H_{30}ClO_7P_2Rh$ (786.95): calcd. C 56.47, H 3.84, O 14.23; found C 56.24, H 4.07, O 14.34.

[RhCl(CO)(TPPTS)$_2$]: IR (KBr pellets): ν_{CO} = 1968 cm^{-1} (vs). – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 34.2 (d, J_{Rh-P} = 126 Hz). – $C_{37}H_{36}ClNa_6O_{25}P_2S_6Rh$ (1411.32): calcd. C 31.49, H 2.57, O 28.34; found C 32.12, H 2.63, O 29.68.

[RhCl{P(OPh)$_3$}$_3$]: This compound was prepared by adding 3 equiv. of $P(OPh)_3$ (1.05 g, 3.42 mmol) to the aforementioned $[NH_2(CH_3)_2][RhCl_2(CO)_2]$ solution [prepared from $RhCl_3 \cdot 3H_2O$ (0.3 g, 1.14 mmol) and H_2O (0.35 mL, 19.5 mmol) in DMF (15 mL)] at room temperature. The reaction was immediate, giving a significant evolution of CO. The complex was precipitated by adding cold water (50 mL). Collection of the product by filtration using a Büchner funnel and washing with water (150 mL) afforded a clean product in reproducible yields of around 80%. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 112.5 (dd, J_{Rh-PA} = 222 Hz, J_{PA-PB} = 55 Hz), 118.9 (td, J_{Rh-PB} = 281 Hz, J_{PA-PB} = 55 Hz). – $C_{54}H_{45}ClO_9P_3Rh$ (1069.23): calcd. C 60.66, H 4.24, O 13.47; found C 60.29, H 4.43, O 13.08.

[Rh(CO)(dppp)$_2$]Cl (dppp = 1,3-diphenylphosphanylpropane): This compound was prepared by adding 2 equiv. of dppp (0.94 g, 2.28 mmol) to the aforementioned $[NH_2(CH_3)_2][RhCl_2(CO)_2]$ solution [prepared from $RhCl_3 \cdot 3H_2O$ (0.3 g, 1.14 mmol) and H_2O (0.35 mL, 19.5 mmol) in DMF (15 mL)] at room temperature. The reaction was immediate, giving a significant evolution of CO. The complex was precipitated by adding cold water (50 mL). Collection of the product by filtration using a Büchner funnel and washing with water (150 mL) afforded a clean product in yields of around 70%. – IR (KBr pellets): ν_{CO} = 1930 cm^{-1}. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = –11.8 (td, P_{eq}, J_{Rh-Peq} = 122 Hz, $J_{Peq-Pax}$ = 30 Hz), 16.1 (td, P_{ax}, J_{Rh-Pax} = 85 Hz, $J_{Peq-Pax}$ = 30 Hz) [A_2B_2X]. – ^{31}P-^{103}Rh COSY ($CDCl_3$): δ_{Rh} = 1255. – $C_{55}H_{52}ClOP_4Rh$ (991.27): calcd. C 66.64, H 5.29, O 1.61; found C 66.42, H 4.87, O 1.84.

[Rh$_2$(μ-S*t*Bu)$_2$(CO)$_4$]: This compound was prepared by adding 10 equiv. of 1,1-dimethylethanethiol (900 μL, 11 mmol) to the aforementioned $[NH_2(CH_3)_2][RhCl_2(CO)_2]$ solution [prepared from $RhCl_3 \cdot 3H_2O$ (0.3 g, 1.14 mmol) and H_2O (0.35 mL, 19.5 mmol) in DMF (15 mL)] at room temperature. After 5 min, the IR spectrum of the solution showed four ν_{CO} bands at 2062, 2050, 1999, and 1984 cm^{-1}. The complex was precipitated by the dropwise addition of cold water (50 mL). Collection of the product by filtration using a Büchner funnel and washing with water (150 mL) afforded a clean product in 80–85% yield. – IR (KBr pellets): ν_{CO} = 2060, 2044, 2003, 1990, 1983 cm^{-1}. – $C_{12}H_{18}O_4Rh_2S_2$ (496.22): calcd. C 29.05, H 3.66, O 12.92, S 12.90; found C 28.87, H 3.77, O 12.45, S 12.56.

[Rh$_2$(μ-S*t*Bu)$_2$(CO)$_2$L$_2$] Complexes (L = PPh$_3$ or TPPTS): To the aforementioned solution of $[Rh_2(\mu\text{-}StBu)_2(CO)_4]$ in DMF (see previous synthesis), which exhibited four ν_{CO} bands at 2062, 2050, 1999, and 1984 cm^{-1}, 1 equiv. of the appropriate phosphane per mol of rhodium was added (0.3 g of PPh_3 or 0.73 g of TPPTS). An immediate evolution of CO was noticed and the reaction was complete within 5 min. The IR spectrum of the solution showed a ν_{CO} band at 1977 cm^{-1} (PPh_3 complex) or 1982 cm^{-1} (TPPTS complex). The complex was precipitated by adding cold water (50 mL) (PPh_3 complex) or ethanol (50 mL) (TPPTS complex). Collection of the product by filtration using a Büchner funnel and washing with water (150 mL) (PPh_3 complex) or ethanol (150 mL) (TPPTS complex) afforded clean products in reproducible yields of around 80%.

[Rh$_2$(μ-S*t*Bu)$_2$(CO)$_2$(PPh$_3$)$_2$]: IR (KBr pellets): ν_{CO} = 1964, 1948 cm^{-1}. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 37.5 (d, J_{Rh-P} = 151 Hz). – $C_{26}H_{20}O_2P_2Rh_2S_2$ (964): calcd. C 56.91, H 5.57, O 3.30, S 6.60; found C 56.81, H 5.51, O 3.20, S 6.38.

[Rh$_2$(μ-S*t*Bu)$_2$(CO)$_2$(TPPTS·3H$_2$O)$_2$]: IR (KBr pellets): ν_{CO} = 1967 cm^{-1}. – $^{31}P\{^1H\}$ NMR (D_2O): δ = 39.7 (d, J_{Rh-P} = 152 Hz). – $C_{46}H_{54}O_{26}Na_6P_2Rh_2S_8$ (1685.14): calcd. C 32.79, H 3.23, O 24.69; found C 33.24, H 3.25, O 25.41.

Iridium Complexes

[NH$_2$(CH$_3$)$_2$]$_2$[IrCl$_5$(DMF)]: The complex was prepared from $IrCl_3 \cdot 3H_2O$ (0.5 g, 1.42 mmol) and aqueous HCl (37%, 250 μL) in DMF (5 mL). On heating the solution under reflux (160 °C), it turned progressively from deep-red to dark-orange and the product precipitated as a beige powder. After 6 min, the mixture was allowed to cool to room temperature and the product was collected by filtration using a Büchner funnel, washed with acetone, and dried in vacuo to give 0.155 g (20% based on $IrCl_3 \cdot 3H_2O$). – IR (KBr pellets): ν_{CO} = 1645 cm^{-1} (coordinated DMF). – ^1H NMR (D_2O): δ = 7.99 [s, 1 H, *H*CON(CH_3)$_2$], 3.07 and 2.98 [2 s, 2 × 3 H, HCON(C*H*$_3$)$_2$], 2.63 [s, 6 H, NH_2(C*H*$_3$)$_2$]. – $^{13}C\{^1H\}$ NMR (D_2O): δ = 174.4 [d, H*C*ON(CH_3)$_2$, J_{Rh-C} = 16 Hz], 35.8 and 40.8

[s, $HCON(CH_3)_2$], 37.4 [s, $NH_2(CH_3)_2$]. − $C_7H_{23}Cl_5IrN_3O$ (534.76): calcd. C 15.72, H 4.34, N 7.86, O 2.99; found C 15.77, H 4.23, N 7.63, O 3.60.

[AsPh$_4$][IrCl$_4$(CO)(DMF)]: The complex was prepared from $IrCl_3 \cdot 3H_2O$ (0.5 g, 1.42 mmol) in DMF (5 mL). On heating the solution under reflux (160 °C), it turned progressively from deep-red to orange. After 30 min, the heating was stopped and [AsPh$_4$]Cl (0.6 g, 1.43 mmol) was added. The mixture was concentrated to a volume of 2 mL and the pale-yellow complex was precipitated by the addition of cold water (25 mL), washed with water (50 mL), and dried in vacuo to give 302 mg (26% based on $IrCl_3 \cdot 3H_2O$). − IR (KBr pellets): ν_{CO} = 2060, 1645 cm^{-1} (coordinated DMF). − ^{1}H NMR ($CDCl_3$): δ = 8.53 [s, 1 H, $HCON(CH_3)_2$], 3.02 and 2.98 [2 s, 2 × 3 H, $HCON(CH_3)_2$]. − MS (FAB$^-$, CH_3CN): *m*/*z* (%) = 405 (100) [$IrCl_4(DMF)]^-$, 362 (12) [$IrCl_4(CO)]^-$, 337 (25) [$IrCl_4]^-$. − $C_{28}H_{27}AsCl_4IrNO_2$ (818.48): calcd. C 41.09, H 3.32, N 1.71, O 3.91; found C 40.86, H 3.33, N 1.78, O 2.75.

[AsPh$_4$][IrCl$_2$(CO)$_2$]: The complex was prepared from $IrCl_3 \cdot 3H_2O$ (0.3 g, 0.85 mmol) and HCl (0.15 mL, 37% in water) in DMF (10 mL). On heating the solution under reflux, it turned from red to orange. After 50 min, HCl (0.10 mL, 37% in water) was added and refluxing was maintained for a further 10 min. Thereafter, the solution was allowed to cool to room temperature and [AsPh$_4$]Cl (0.355 g, 0.85 mmol) was added. After evaporation of the solvent, the complex was washed with acetone/diethyl ether (1:9) to furnish 0.42 g of yellow crystals (71% based on $IrCl_3 \cdot 3H_2O$). − IR (KBr pellets): ν_{CO} = 2036, 1967 cm^{-1}. − MS (FAB$^-$, CH_3CN): *m*/*z* (%) = 319 (19) [$IrCl_2(CO)_2]^-$, 291 (100) [$IrCl_2(CO)]^-$. − $C_{26}H_{20}AsCl_2IrO_2$ (702.49): calcd. C 44.45, H 2.87, O 4.56; found C 44.62, H 2.98, O 4.34.

[IrCl(CO)(PPh$_3$)$_2$]: The complex was prepared by adding 2 equiv. of PPh_3 (0.89 g, 3.4 mmol) to the aforementioned $[NH_2(CH_3)_2][IrCl_2(CO)_2]$ solution in DMF [prepared from $IrCl_3 \cdot 3H_2O$ (0.6 g, 3.8 mmol) and HCl (0.35 mL, 37% in water) in DMF (15 mL)] at room temperature. The reaction was immediate and the IR spectrum of the solution showed a single ν_{CO} band at 1965 cm^{-1}. The lemon-yellow complex was then precipitated by adding cold water (100 mL), collected by filtration using a Büchner funnel, and washed with cold methanol (100 mL). After drying in vacuo, 1.59 g of [IrCl(CO)(PPh$_3$)$_2$] was collected (60% based on $IrCl_3 \cdot 3H_2O$). − IR (KBr pellets): ν_{CO} = 1957 cm^{-1}. − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 24.1 (s). − $C_{37}H_{30}ClIrOP_2$ (780.27): calcd. C 56.96, H 3.88, O 2.05; found C 56.62, H 4.27, O 3.34.

Ruthenium Complexes

[PPN]$_2$[RuCl$_5$(CO)]: The complex was prepared from $RuCl_3 \cdot 3H_2O$ (0.4 g, 1.53 mmol) in DMF (15 mL) in a closed Schlenk tube without any reflux condenser system. The solution was heated under reflux and IR monitoring of the reaction showed the formation of the carbonylchloro anion (ν_{CO} = 2020 cm^{-1}). After 10 min, the solution was allowed to cool and [PPN]Cl (0.88 g, 1.53 mmol) was added. After concentration of the solution in vacuo at 100 °C to a volume of 5 mL, cold water (10 mL) was added dropwise to precipitate the complex as a dark-red powder. After collection of the product by filtration using a Büchner funnel and washing with water (100 mL), the product was dried in vacuo to give 0.15 g (7% based on $RuCl_3 \cdot 3H_2O$). − IR (KBr pellets): ν_{CO} = 2008 cm^{-1}. − $C_{73}H_{60}Cl_5N_2OP_4Ru$ (1383.52): calcd. C 63.37, H 4.37, N 2.02, O 1.16; found C 63.22, H 4.33, N 2.18, O 1.55.

[PPN]$_2$[RuCl$_4$(CO)(DMF)]: The complex was prepared from $RuCl_3 \cdot 3H_2O$ (0.3 g, 1.15 mmol) and HCl (250 μL, 37% in water) in DMF (8 mL) in a closed Schlenk tube without any reflux condenser system. On heating the solution under reflux (160 °C), it turned progressively from deep-red to dark-green. After 30 min, the heating was stopped and [PPN]Cl (0.4 g, 0.7 mmol) was added. The green complex was precipitated by adding cold water (25 mL), washed with further water (50 mL), and dried in vacuo to give 0.138 g (26% based on $RuCl_3 \cdot 3H_2O$). − IR (KBr pellets): ν_{CO} = 1918, 1644 cm^{-1} (coordinated DMF). − ^{1}H NMR (CD_2Cl_2): δ = 8.61 [s, 1 H, $HCON(CH_3)_2$], 2.98 and 2.95 [2 s, 2 × 3 H, $HCON(CH_3)_2$]. − $C_{76}H_{67}Cl_4N_3O_2P_4Ru$ (1421.16): calcd. C 64.23, H 4.75, N 2.96, O 2.25; found C 64.32, H 4.52, N 2.38, O 1.86.

[PPN][RuCl$_3$(CO)$_2$(DMF)]: The complex was prepared from $RuCl_3 \cdot 3H_2O$ (0.4 g, 1.53 mmol) and anhydrous 4 M HCl in dioxane (1 mL, 4 mmol) in DMF (15 mL) in a closed Schlenk tube without any reflux condenser system. On refluxing the solution, it turned progressively from red to orange. IR monitoring indicated the formation of the carbonylchloro anion (ν_{CO} = 2042 and 1964 cm^{-1}). After 1 h, the solution was allowed to cool and [PPN]Cl (0.88 g, 1.53 mmol) was added. After concentration of the mixture in vacuo at 100 °C to a volume of 5 mL, cold water (10 mL) was added dropwise to precipitate the complex as a yellow powder. The product was collected by filtration using a Büchner funnel, washed with water (100 mL), dried in vacuo, and recrystallized from acetone/heptane to give 0.85 g of yellow crystals (64% based on $RuCl_3 \cdot 3H_2O$). − IR (KBr pellets): ν_{CO} = 2045, 1970, 1636 cm^{-1} (coordinated DMF). − ^{1}H NMR ($CDCl_3$): δ = 8.52 [s, 1 H, $HCON(CH_3)_2$], 2.91 [s, 6 H, $HCON(CH_3)_2$]. − MS (FAB$^-$, CH_3CN): *m*/*z* (%) = 300 (100) [$RuCl_3(CO)(DMF)]^-$, 280.5 (19) [$RuCl_3(DMF)]^-$, 264.8 (7) [$RuCl_3(CO)_2]^-$, 208 (31) [$RuCl_3]^-$. − $C_{41}H_{37}Cl_3N_2O_3P_2Ru$ (875.13): calcd. C 56.27, H 4.26, N 3.20, O 5.48; found C 56.62, H 4.27, N 3.05, O 5.34.

[RuCl$_2$(CO)$_2$(DMF)$_2$]: The complex was prepared from $RuCl_3 \cdot 3H_2O$ (0.4 g, 1.53 mmol) in DMF (15 mL) in a closed Schlenk tube without any reflux condenser system. On refluxing the solution, it turned progressively from red to orange. After 2 h, it was allowed to cool and [PPN]Cl (0.88 g, 1.53 mmol) was added. After concentration of the mixture in vacuo at 100 °C to a volume of 5 mL, cold water (10 mL) was added dropwise to precipitate a yellow powder. The product was collected by filtration using a Büchner funnel, washed with water (100 mL), and dried in vacuo. Chromatographic separation on a column of silica [Degussa Sipernat 22; eluent: acetone/2-propanol (20:80, v/v)] furnished the pure complex in the first fraction; yield 0.17 g (30% based on $RuCl_3 \cdot 3H_2O$). − IR ($CHCl_3$): ν_{CO} = 2073, 2009, 1652, 1645 cm^{-1} (coordinated DMF). − ^{1}H NMR ($CDCl_3$): δ = 8.28 [s, 1 H, $HCON(CH_3)_2$], 8.37 [s, 1 H, $HCON(CH_3)_2$], 3.18 [s, 3 H, $HCON(CH_3)_2$], 3.16 [s, 3 H, $HCON(CH_3)_2$], 3.06 [s, 3 H, $HCON(CH_3)_2$], 3.00 [s, 3 H, $HCON(CH_3)_2$]. − $C_8H_{14}Cl_2N_2O_4Ru$ (374.19): calcd. C 25.68, H 3.77, N 7.49, O 17.10; found C 25.58, H 3.11, N 6.92, O 16.45.

***cis*,*cis*,*trans*-[RuCl$_2$(CO)$_2$(PPh$_3$)$_2$]:** The complex was prepared by adding 2 equiv. of PPh_3 (0.8 g, 3.05 mmol) to the aforementioned $[NH_2(CH_3)_2][RuCl_3(CO)_2(DMF)]$ solution in DMF [prepared from $RuCl_3 \cdot 3H_2O$ (0.4 g, 1.53 mmol) and anhydrous HCl (1 mL, 4 mmol, 4 M in dioxane) in DMF (15 mL)] at 140 °C. The solution was maintained at this temperature until its IR spectrum showed the ν_{CO} bands at 2058 and 1994 cm^{-1} characteristic of *cis*,*cis*,*trans*-$[RuCl_2(CO)_2(PPh_3)_2]$ (1 h). The yellow solution was then allowed to cool to room temperature, and the pale-yellow complex was precipitated by adding cold water. It was collected by filtration using a Büchner funnel, washed with water (100 mL), and dried in vacuo to give 0.7 g of the title compound (64% based on $RuCl_3 \cdot 3H_2O$).

− IR (KBr pellets): ν_{CO} = 2054, 1992 cm^{-1}. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 17.2 (s). − $C_{38}H_{30}Cl_2O_2P_2Ru$ (752.58): calcd. C 60.65, H 4.02, O 4.25; found C 60.85, H 4.15, O 4.94.

Palladium and Platinum Complexes

[$PdCl_2(DMF)_2$]: The complex was prepared from $PdCl_2$ (0.2 g, 1.13 mmol) in DMF (15 mL). The solution was heated for 120 min at 100 °C and then concentrated to dryness in vacuo at 50 °C. The complex (0.091 g, 25% based on $PdCl_2$) was recovered as a black powder. − IR (KBr pellets): ν_{CO} = 1656 cm^{-1} (coordinated DMF). − $C_6H_{14}Cl_2N_2O_2Pd$ (323.52): calcd. C 22.28, H 4.36, N 8.66; found C 22.50, H 3.91, N 7.90.

[PPN][$PtCl_3(CO)$]: The complex was prepared from K_2PtCl_4 (0.4 g, 0.96 mmol) and [PPN]Cl (0.554 g, 0.97 mmol) in DMF (15 mL). The solution was refluxed for 120 min and then allowed to cool to room temperature. The complex (0.438 g, 53% based on K_2PtCl_4) was recovered by precipitation with cold water and washed with further water (100 mL). − IR (KBr pellets): ν_{CO} = 2072 cm^{-1}. − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 150.2 (s). − $C_{37}H_{30}Cl_3NOP_2Pt$ (868.04): calcd. C 51.20, H 3.48, N 1.61; found C 51.89, H 3.77, N 2.14.

Acknowledgments

The authors are grateful to Engelhard CLAL for a generous loan of rhodium and palladium salts.

Synthesis, Characterization and Ethylene Polymerization Activity of Zirconium Complexes Containing Nonsymmetric Diamido Ligands Derived from 2-Aminobenzylamine

Régis M. Gauvin,[a] Christian Lorber,*[b] Robert Choukroun,[b] Bruno Donnadieu,[b] and Jacky Kress*[a]

Keywords: Amines / Zirconium / Fluxionality / Catalysis / Olefin polymerizations

Several *N*,*N*′-bis(trialkylsilyl)-substituted diamines of the general formula [$(SiR_3)_2$-ABA]H_2 [ABA = 2-amidobenzylamido, SiR_3 = $SiMe_3$ (**1a**), $SiMePh_2$ (**1b**), $SiMe_2t$Bu (**1c**) or Si*i*Pr_3 (**1d**)], together with related compounds in which the substituents of the two nitrogen atoms are different, e.g. [($SiMePh_2$)($SiMe_3$)-ABA]H_2 (**1g**), have been synthesized. Their reaction with 2 equiv. of *n*BuLi afforded the dilithiated derivatives, which reacted with $ZrCl_4$ to yield metallaspirocyclic complexes of the type Zr[$(SiR_3)_2$-ABA]$_2$. Protonolysis of $Zr(NMe_2)_4$ with 1 equiv. of the parent diamines led to the monosubstituted complexes Zr[$(SiR_3)_2$-ABA]$(NMe_2)_2$ [SiR_3 = $SiMe_3$ (**4a**), $SiMePh_2$ (**4b**) or $SiMe_2t$Bu (**4c**)] and Zr[($SiMePh_2$)($SiMe_3$)-ABA]$(NMe_2)_2$ (**4g**) in high yield, and subsequent reaction with excess $SiMe_3Cl$ afforded the dichlorides Zr[$(SiMe_3)_2$-ABA]Cl_2 (**5a**), Zr[$(SiMe_2t$Bu$)_2$-ABA]Cl_2 (**5c**), and Zr[($SiMePh_2$)($SiMe_3$)-ABA]Cl_2 (**5g**). The X-ray crystal structure of **5c** shows that it forms dimers via two Zr–Cl bridges; moreover, a bonding interaction between the zirconium centre and the aryl *ipso*-carbon atom linked to the anilinic nitrogen atom is evident. A hydrochlorinated derivative of **5c**, Zr[$(SiMe_2t$Bu$)_2$(H)-ABA]Cl_3 (**6c**), was also analysed by X-ray diffraction and shown to exhibit analogous structural characteristics. Low-temperature NMR studies revealed all these complexes to be fluxional and permitted an insight into the molecular structures in solution. The ABA framework undergoes a rocking motion about the corresponding ZrN_2 plane, whose activation energy is between 37 and 43 kJ mol^{-1}. Compounds **3** and **5** exist as several stereoisomers that interconvert by this process. On activation with MAO, the dichloride complexes of type **5** polymerize ethylene at both room temperature and pressure to yield linear high molecular mass polyethylenes with a broad molecular mass distribution.

Introduction

The search for new olefin polymerization catalysts based on chelating diamido ligands has concentrated mostly on Group 4 transition metal complexes of symmetric ligands containing two identical amide functions.[1] However, attempts to design catalysts for the stereoselective polymerization of α-olefins with the help of such ligands has met with limited success.[2] Nonsymmetric diamido ligands containing two different amido functions are potentially of great interest in this regard, particularly if the nitrogen substituents of each amido function can be modified independently. This would help us, if polymerization of α-olefins could be obtained, to better understand the influence of electronic and steric effects of the ligands on the stereoselectivity results.

Herein, we wish to describe the synthesis of several *N*,*N*′-disubstituted 2-aminobenzylamines. This fragment affords a suitable framework for the purpose outlined. Its application resulted in the generation of a series of bis(dimethylamido)- and dichlorozirconium complexes. The fluxional behaviour ot these new complexes and their ability to catalyse the polymerization of olefins have been analysed. One of these ligands has been reported recently, together with three titanium and two zirconium complexes containing the ligand.[3]

Results and Discussion

Ligands Precursors

The *N*,*N*′-bis(trialkylsilyl)-substituted diamines [$(SiR_3)_2$-ABA]H_2 (**1a**−**1d**) were synthesized as reported for **1a**[3] by treating the dilithio salt of 2-aminobenzylamine with 2

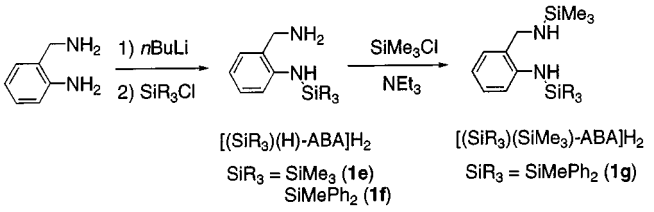
equiv. of trialkylchorosilanes in diethyl ether (or THF for **1d**)/hexane (Scheme 1), and isolated as viscous oils (or a cream solid for **1c**) in 80−90% yield. For **1d**, 18 h of heating in THF to reflux was necessary to complete the reaction. Compound **1a**, but not the others, could also be obtained by the reaction of 2-aminobenzylamine with 2 equiv. of Me_3SiCl in the presence of triethylamine (96% yield).

Initial attempts to synthesize $[(SiR_3)(SiR'_3)$-ABA$]H_2$ derivatives possessing two different nitrogen substituents led to the diamines $[(SiMe_3)$(H)-ABA$]H_2$ (**1e**) and $[(SiMePh_2)$(H)-ABA$]H_2$ (**1f**) being obtained as yellow-orange oils (93−95% yield, Scheme 2), which contain silyl substituents located solely on the anilino nitrogen atom. These compounds tend to disproportionate into **1a**−**b** and 2-aminobenzylamine. Compound **1e** was hence contaminated (7% total amount) with **1a**, and also with $[(H)(SiMe_3)$-ABA$]H_2$, of which neither could be properly separated. On the other hand, treatment of 2-aminobenzylamine with 1 equiv. of Me_3SiCl in the presence of triethylamine preferentially introduces the substituent on the benzylamino nitrogen atom, affording $[(H)(SiMe_3)$-ABA$]H_2$, but this reaction is also unselective and leads to the formation of **1a** in almost equal proportions. Only compound $[(SiMePh_2)(SiMe_3)$-ABA$]H_2$ (**1g**) could be generated as a viscous oil from **1f** (87% isolated yield, Scheme 2). The diamines were characterized by ^1H and ^{13}C NMR spectroscopy. It is of interest to note that the benzylic protons give rise to a doublet or a triplet, whether the adjacent nitrogen atom is substituted or not. This indicates that hydrogen exchange in the benzylamino groups is slower in these compounds than in the 2-aminobenzylamine precursor, for which the corresponding coupling is not observed.

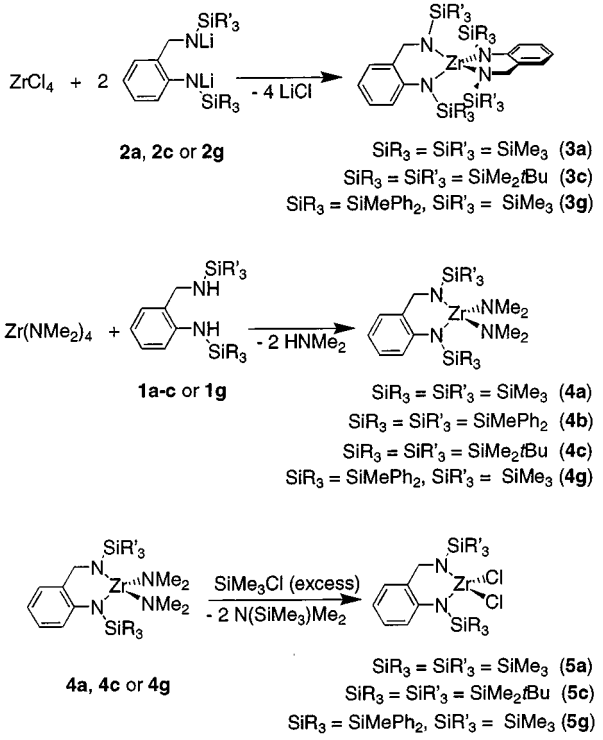


Scheme 2

The dilithiated derivatives $[(SiR_3)_2$-ABA$]Li_2$ [SiR_3 = $SiMe_3$ (**2a**), $SiMePh_2$ (**2b**), $SiMe_2tBu$ (**2c**)] or $SiiPr_3$ (**2d**)] and $[(SiMePh_2)(SiMe_3)$-ABA$]Li_2$ (**2g**) were obtained as white solids or a brown paste (**2d**) (34−95% yield) by double deprotonation of **1a**−**d** or **1g** with *n*BuLi in hexane. The observation of an AX pattern for the room-temperature ^1H NMR signal of the CH_2 groups of **2a** and **2g**, and of a broad singlet for the corresponding protons of **2b**−**d**, suggests that these compounds possess a disymmetrical aggregated structure in solution. This is confirmed by the dimeric ladder structure of **2a** in the solid state, established by X-ray diffraction.[4] The fluxional nature of these lithiated compounds was further characterized by the coalescence of the AX spectrum of **2a** into a singlet at 41 °C ($\Delta G^{\neq}$ = 61.6 kJ·mol^{-1}),[5] and by the splittting of the broad singlet of **2b** into a doublet of doublets at δ = 4.56 and 3.53 at −33 °C in $[D_8]$toluene.

Zirconium Complexes

Even when only low proportions of the dilithio reactants were used, transmetallation reactions between **2a**, **2c** or **2g** and $ZrCl_4$ led to the metallaspirocyclic complexes $Zr[(SiMe_3)_2$-ABA$]_2$ (**3a**), $Zr[(SiMe_2tBu)_2$-ABA$]_2$ (**3c**), and $Zr[(SiMePh_2)(SiMe_3)$-ABA$]_2$ (**3g**) (Scheme 3), as reported earlier for **3a**.[3] However, compounds **2b** and **2d** gave only mixtures that could not be separated. In particular, using 2 equiv. of **2g**, compound **3g** was synthesized in good yield in hot toluene and isolated as a yellow solid. Its ^1H NMR spectrum at room temperature is analogous to that of **3a**,[3] displaying an AX pattern at δ = 4.89 and 3.93 (CD_2Cl_2, ^2J = 13.4 Hz) for the two CH_2 groups, which is consistent with a tetrahedral structure of C_2 symmetry, of the type of that determined for **3a** by X-ray diffraction.[3]



Scheme 3

The dichloride derivatives were prepared from the bis(dimethylamido) precursors. These were synthesized by protonolysis of $Zr(NMe_2)_4$ [6] with 1 equiv. of the diamines **1** (Scheme 3). Complexes $Zr[(SiMe_3)_2$-ABA$](NMe_2)_2$ (**4a**), $Zr[(SiMePh_2)_2$-ABA$](NMe_2)_2$ (**4b**), $Zr[(SiMe_2tBu)_2$-ABA$](NMe_2)_2$ (**4c**), and $Zr[(SiMePh_2)(SiMe_3)$-ABA$](NMe_2)_2$ (**4g**) were obtained in high yield (96−99%) as pale yellow to orange, viscous oils. The diamine **1d**, however, did not react with $Zr(NMe_2)_4$. The ^1H and ^{13}C NMR spectra of the four complexes, at room temperature, reveal the presence of two apparently equivalent and symmetrical NMe_2 ligands for one coordinated ABA group, the two benzylic protons

of which give rise to a singlet. The fluxional behaviour that lies at the root of these unexpected observations is specified below.

Complexes **4a**, **4c** and **4g** react with an excess of trimethylsilyl chloride to give the respective dichloride derivatives Zr[$(SiMe_3)_2$-ABA]Cl_2 (**5a**),[7] Zr[$(SiMe_2tBu)_2$-ABA]Cl_2 (**5c**), and Zr[$(SiMePh_2)(SiMe_3)$-ABA]Cl_2 (**5g**) in good yield (Scheme 3). However, the analogous reaction involving **4b** was unsuccessful. The solid pale yellow products are poorly soluble in hydrocarbons, and the singlets observed at δ = 4.72, 4.59 and 4.87 in their ^1H NMR spectra (C_6D_6, room temperature), which are assigned to their methylene groups, are indicative of a high apparent symmetry similar to that found for the amido complexes of type **4**.

Single crystals of **5c** were grown by cooling a saturated toluene/pentane solution to −20 °C and were analysed by X-ray diffraction. The molecular structure of **5c** is shown in Figure 1, and selected bond lengths and angles are listed in Table 1. The structure consists of discrete dimers that reside on an inversion centre of the space group, the association between the two monomeric units being realised via two weak zirconium−chlorine bridging interactions [Zr−Cl(2)′ = 2.706 Å]. Hence, each zirconium atom is pentacoordinate and possesses a distorted trigonal-bipyramidal coordination geometry. The benzylamido nitrogen atom and the bridging chloride ion occupy the axial sites [N(1)−Zr−Cl(2)′ = 163.7°]. The main distortion results from the acute Cl(2)−Zr−Cl(2)′ angle in the planar bridging Zr_2Cl_2 unit (75.5°), while the diamide ligand chelate angle [N(1)−Zr−N(2) = 93.1°], as well as the other bond angles around the zirconium centre, are within the usual ranges. Short Zr−N bond lengths [Zr−N(1) = 2.016 Å, Zr−N(2) = 2.012 Å] and sp^2-hybridized nitrogen atoms [the summation of bond angles is 359.0° at both N(1) and N(2)] indicate strong π-donation from the two nitrogen atoms to the electron-deficient zirconium centre. As expected, the zirconium−chlorine bond length of the bridging halide ion [Zr−Cl(2) = 2.554 Å] is longer than that of the terminal one [Zr−Cl(1) = 2.386 Å].

Zr−Cl(2)−Zr′	104.49(3)		

The ligand chelate ring is severely puckered. Of particular relevance is its significant folding along the C(1)−N(2) axis (70.7°), and the correspondingly very short Zr−C(2) distance (2.537 Å). This effect, which is more pronounced than in compound **3a**,[3] and certainly contributes to an even shorter Zr−N(2) bond along with reduction of the C(2)−N(2)−Zr angle to 93.3°, is similar to that discussed for several *o*-phenylenediamido complexes.[8] It is ascribed to a bonding interaction between the zirconium centre and the aryl *ipso*-carbon atom linked to the anilinic nitrogen atom. This way of compensating electronic unsaturation at the metal centre is distinct from that found in the analogous titanium complex Ti[$(SiMe_3)_2$-ABA]Cl_2. In the latter case, an interaction between the metal centre and the benzylic methylene group, that gives rise to a significantly different ligand geometry, has been shown to occur.[3] It is similar, however, to that found in the lithium derivative **2a**.[4] The infrared spectra suggest that **5a** is also dimeric in the solid state, as revealed by the broad absorption observed at 254 cm^{-1}, assigned to zirconium−chloride bridges, but not **5g** for which an analogous band is totally absent.

By following the same crystallization procedure but, apparently, under slightly different and uncontrolled conditions, a further zirconium complex was unexpectedly crystallized in low yield from solutions of **5c**. An X-ray analysis of this compound revealed it to be Zr[$(SiMe_2tBu)_2$(H)-ABA]Cl_3 (**6c**) (i.e. the hydrochlorinated derivative of **5c**), in which the benzylamido nitrogen atom of **5c** has been protonated to afford a coordinated benzylamino function. This results in the sp^3 hybridization of this nitrogen atom [sum of angles formed by non-H atoms around N(2) = 343.2°] and in the substantial lengthening of the corresponding zirconium−nitrogen bond [Zr−N(2) = 2.388 Å]. The other structural characteristics of **6c** are similar to those of **5c**. Compound **6c** crystallizes in the same space group, and also consists of discrete centrosymmetric dimers that are associated via two chloride bridges (Figure 2, Table 2). The geometry of each monomeric unit is now a distorted octahedron, leading to somewhat different bond angles around the zirconium centre. However, the distinctive configuration of the ABA chelate ring is retained in this complex. The interaction between the zirconium centre and the anilinic *ipso*-carbon atom of the aryl ring is strengthened, as revealed by

the shorter corresponding distance [Zr−C(1) = 2.513 Å] and the more acute C(1)−N(1)−Zr angle (91.2°), suggesting that the metal centre is slightly more electron-deficient than in **5c**. It may also be noted that the chloride bridges are *trans* to the anilido function and not to the benzylamido nitrogen atom as in **5c**. As a consequence, the aryl rings are perpendicular to the Zr_2Cl_2 plane, instead of overhanging it as in **5c**.

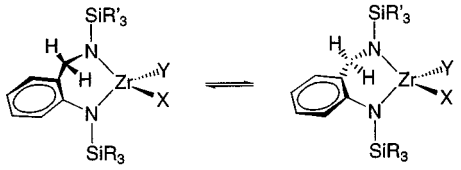
Fluxionality

The apparent discrepancy between the twisted, nonplanar geometry of the ABA ligands in complexes **5c** and **6c** and the room-temperature NMR spectra of complexes **4**−**5** prompted us to examine the low-temperature ^{1}H NMR spectra of compounds **3**−**5**. Thus, it was possible to verify that the two benzylic hydrogen atoms are actually diastereotopic in all cases, but equilibrate rapidly at higher temperatures in **4**−**5** by a dynamic process that seems common to all members of the series. We suggest this process consists of the rocking motion of each ABA framework about the corresponding ZrN_2 plane, as illustrated in Scheme 4 for a monomeric tetrahedral structure. This process will interconvert the two enantiomeric configurations of the complexes if X = Y (complexes **4** and **5**, if monomeric), but not if X ≠ Y (complexes **3**).



Scheme 4

Figure 3 illustrates the coalescence of the broad AB quadruplet observed at 205 K for the benzylic protons of **4a** in [D_8]toluene (δ = 4.51/4.25, ^2J = 15.4 Hz) into the singlet already mentioned above. However, the two NMe_2 ligands give rise to a lone singlet over the whole temperature range, although up to four singlets may be expected in the limiting spectrum of this complex. Compound **4b** behaves similarly, revealing a doublet of doublets at δ = 4.30/4.08 at 185 K (CD_2Cl_2, ^2J = 15.1 Hz) that coalesce into a singlet at 202 K. Moreover, two distinct NMe_2 signals are observed, in this case, at 185 K (δ = 2.73 and 1.99), as well as two resonances at δ = 7.63 and 7.55 assigned to the *ortho*-protons of the $SiMePh_2$ substituent of the anilinic nitrogen atom, and these two pairs coalesce at 211 K and 194 K, respectively. This is in agreement with the proposed monomeric structure of this molecule and the fluxionality represented on Scheme 4. Compound **4g** affords less clear-cut observations because the limiting spectrum is not reached, even at 180 K in CD_2Cl_2. However, two broad $SiMePh_2$ resonances are distinguished again at δ = 7.60 and 7.49, that coalesce at 183 K. The activation energies determined[5] for these three complexes are reported in Table 3. Clearly, they depend on both the electronic and steric properties of the trialkylsilyl substituents of the two ABA nitrogen atoms, and on the strength of the Zr−aryl interaction discussed above for **5c** and **6c**.

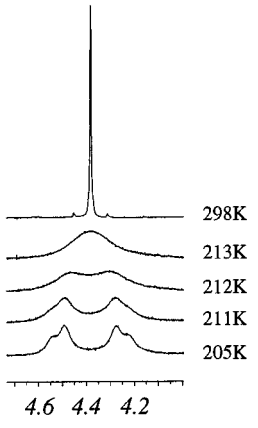


Figure 3. Variable-temperature ^{1}H NMR spectra of complex **4a** in the benzylic region ([D_8]toluene, 300 MHz)

Spirocyclic complexes of type **3** contain two ABA ligands and may therefore exist as three isomers differing in the respective configuration of these ligands. One of the isomers

Table 3. Activation energy for the ABA rocking process in complexes **4**

	4a ([D$_8$]toluene)	**4b** (CD_2Cl_2)	**4g** (CD_2Cl_2)
$\Delta G^{\neq}$ [kJ mol^{-1}]	42.4 (± 0.2)	40.3 (± 0.4)	37.5 (± 0.4)

would be nonsymmetric and the others ideally C_2-symmetric, so that the resonances of up to four nonequivalent ligands may be expected in the ^{1}H NMR limiting spectrum of each of the compounds. In full agreement with this assumption, complex **3g** at 185 K in CD_2Cl_2 exhibits four $SiMe_3$ singlets (δ = 0.06, −0.01, −0.09 and −0.20) and four Si*Me*Ph$_2$ singlets (δ = 1.03, 0.64, 0.46 and 0.22) of unequal intensity (Figure 4). The three isomers are therefore present in comparable amounts. The other regions of the spectrum are less well resolved but follow the same trend. On raising the temperature, all sets of resonances coalesce to yield the simple spectrum observed at room temperature. The complexity of the spectral changes makes the determination of the corresponding activation energies unsafe. Notwithstanding, these appear to be close to the values obtained for compounds **4** and it seems reasonable to conclude that the interconversion of the three stereoisomers occurs by the ligand rocking process of Scheme 4.

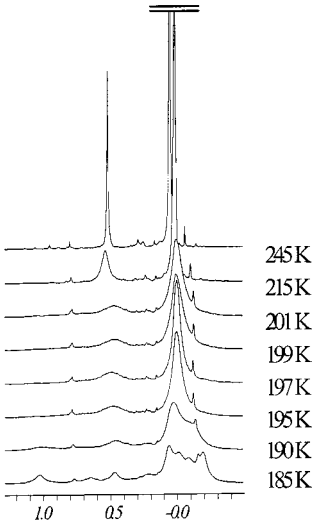

Figure 4. Variable-temperature ^{1}H NMR spectra of complex **3g** in the Si−Me region (CD_2Cl_2, 300 MHz)

Complex **3a** has been described as a single isomer in the solid state as well as in solution.[3] However, its ^{1}H NMR spectrum at 185 K in CD_2Cl_2 shows two broad singlets at δ = 0.42 and 0.07 for the $SiMe_3$ substituent of the anilinic nitrogen atom. The relative intensities of these signals, that coalesce at 195 K ($\Delta G^{\neq}$ = 38.2 ± 0.4 kJ mol^{-1}), are in the approximate ratio 3:1. Despite the fact that an analogous observation was not made for the benzylamido $SiMe_3$ substituent, nor for the benzylic protons (whose signals overlap at 185 K), this indicates that at least two of the three possible stereoisomers are present in solution, and that they interconvert at a rate which is close to that of **3g**.

The dichloride complexes **5** may remain dimeric in solution, as are **5a** and **5c** in the solid state, or they may dissociate into tetrahedral monomers. An ^{1}H NMR spectroscopic analysis of [D$_8$]toluene solutions of 5**a** and **5g** clearly favors the former, since very complicated spectra were obtained at 200 K (Figure 5). These coalesce again at a higher temperature. As for compounds **3**, the existence of the three stereoisomers expected for these dimers, and their interconversion by the ABA rocking process, are thus indicated. However, chemical exchange between the monomeric constituents of the dimers is also implied in this case, resulting in the singlet observed above 275 K for the benzylic protons, instead of the AB spin system shown by compounds **3**. The monomeric form could even be present in substantial amounts and be the origin of some of the resonances detected at 200 K. As illustrated in Figure 5, the coalescence phenomenon indeed seems to occur in two or three successive steps with slightly different rates.

On the other hand, the spectrum of **5a** in CD_2Cl_2 at 180 K is simpler and reveals only one doublet of doublets for the benzylic protons (δ = 5.42/4.33, ^2J = 16.2 Hz), that coalesces into a singlet on raising the temperature. This is analogous to the behavior of the bis(dimethylamido) derivatives **4** and may indicate the monomeric nature of **5a** in this solvent. However, it may also result from faster intermolecular exchange between the monomeric units of dimeric species, both assumptions are consistent with the more polar nature of dichloromethane with respect to toluene. From the temperature of coalescence (213 K), the activation energy of the ABA rocking motion that corresponds to this observation was calculated to be $\Delta G^{\neq}$ = 39.9 ± 0.4 kJ mol^{-1}, which is close to the values obtained for **3a** and **4a**, but markedly higher than that of the analogous titanium complex Ti[(SiMe$_3$)$_2$-ABA]Cl$_2$, for which the signal for the benzylic protons remains as a singlet at 183 K.[3] This latter observation may be correlated with the absence of any M−C$_{ipso}$ contact in the titanium complex. The importance of such interactions on the activation energies is further emphasized by the substantially higher value ($\Delta G^{\neq}$ = 51 kJ mol^{-1}) reported for a similar process involving compound [*o*-C$_6$H$_4$(NSi*i*Pr$_3$)$_2$Zr(O*t*Bu)$_2$], in which the Zr−aryl interaction in the 5-membered chelate ring is on the contrary stronger.[8]

Ethylene Polymerization

In the presence of MAO as cocatalyst, the dichloride complexes of type **5** polymerize ethylene at both room temperature and pressure, but remain inactive against α-olefins such as propylene and 1-hexene. As appears from Table 4, the ethylene polymerization activity of all compounds is low[1] and of a short life time. It is considerably inhibited at 0 °C for **5g**, but only slightly affected at 50 °C for **5a**. The resulting polyethylenes, which were separated by conventional methods, are linear (by ^{1}H NMR spectroscopy) and show a very broad molecular mass distribution, characteristic of multisite catalysts. Activation of the catalytic precursors with MAO thus appears more complicated than envisaged.[9] The molecular masses obtained with **5a** are high,

[a] The reactions were run in toluene (10 mL) under constant ethylene pressure, using 1000 equiv. of MAO as cocatalyst (except for Entry 4: 500 equiv.). − [b] By SEC (140 °C, 1,2,4-trichlorobenzene) vs. polystyrene standards.

whereas **5g** leads to much lower values. If this difference does not result from the difference in ethylene pressure between experiments 1 and 5, it would indicate a ligand effect showing that ABA-based ligands remain bound to the zirconium centre in the catalytically active species. These catalytic systems were not further optimized.

Conclusion

We have shown that various trialkylsilyl substituents can be linked to the two nitrogen atoms of 2-aminobenzylamine, and that the chelating diamido ligands derived from these diamines can serve to stabilize a series of zirconium complexes and to modulate their properties. Structural investigations have shown that the chloride compounds form dimers, and that zirconium−aryl interactions are probably responsible for the restrained flexibility of the ligands. As expected from their low coordination numbers and high electron deficiency, these complexes catalyse the polymerization of ethylene, but unfortunately the activities remain low in all cases.

Experimental Section

General Procedures: All experiments were performed in a high-vacuum line using standard Schlenk techniques or in a dry box under N_2. Solvents were dried with Na/benzophenone ketyl (pentane, toluene, hexane, THF, ether) or P_2O_5 (dichloromethane) and distilled prior to use under nitrogen. Deuterated solvents were dried with activated 4-Å molecular sieves. Known compounds that were not commercial were prepared according to literature procedures. Methylaluminoxane (MAO) was purchased as a 10% toluene solution from Schering or Aldrich. − NMR spectra were recorded with a Bruker AC-300, AC-250 or SY-200 spectrometer at ambient probe temperature unless otherwise indicated. ^{1}H and ^{13}C chemical shifts are reported in ppm versus $SiMe_4$ and were determined by reference to the residual solvent peaks. − Elemental analyses were performed by the Service Central d'Analyse du CNRS (Vernaison), the Service Commun de Microanalyse de l'ULP (Strasbourg), or the Service d'Analyse du LCC (Toulouse). − Infrared spectra were recorded with a Perkin−Elmer 1600 FT-IR spectrometer in the 4000−200 cm^{-1} range using KBr or CsI disks. − Size Exclusion Chromatography (SEC) analyses were carried out at BP−Grangemouth with a AT7 GPC Waters 150-CV instrument in 1,2,4-trichlorobenzene at 140 °C relative to polystyrene standards. − Activation energies were calculated using the Eyring equation.[5]

[(SiMe$_3$)$_2$-ABA]H$_2$ (1a): The synthesis of this compound has been reported in the literature.[3] In an alternative method, 13.8 mL of triethylamine (99.0 mmol) was added to a vigorously stirred solution of 2-aminobenzylamine (3 g, 24.6 mmol) in 130 mL of diethyl ether at 0 °C, and 6.90 mL of chlorotrimethylsilane (54.4 mmol) was then added dropwise. The reaction mixture containing a voluminous white precipitate was stirred for 48 h at room temperature and filtered, and the filtrate was concentrated to dryness. Extraction of the residue with 20 mL of pentane and removal of the volatiles in vacuo yielded the product as a yellow oil which could be used without further purification. Short-path distillation under high vacuum, however, led to an analytically pure colorless oil (6.281 g, 96%). − ^{1}H NMR (C$_6$D$_6$, 300 MHz): δ = 7.17 (dt, 1 H, H^4 or H^5), 7.02, 6.92 (dd, 1 H, H^3 and H^6), 6.76 (dt, 1 H, H^4 or H^5), 5.30 (s, broad, 1 H, ArN*H*), 3.73 (d, ^3J = 6.8 Hz, 2 H, CH$_2$), 0.27 (s, 9 H, ArNHSi*Me*$_3$), 0.12 (t, broad, 1 H, CH$_2$N*H*), 0.00 (s, 9 H, CH$_2$NHSi*Me*$_3$). − ^{13}C NMR (C$_6$D$_6$, 75 MHz): δ = 147.83 (C^2), 129.98, 128.52, 117.66, 116.43 (C^3−C^6), 45.95 (CH$_2$), 0.43 (SiMe$_3$), −0.44 (SiMe$_3$). The C^1 signal could not be detected. − IR (neat): $\tilde{\nu}$ = 3342 (sh) and 3298 cm^{-1}, (ν_{N-H}). − C$_{13}$H$_{26}$N$_2$Si$_2$ (266.5): calcd. C 58.58, H 9.83, N 10.51; found C 58.24, H 9.68, N 10.37.

[(SiMePh$_2$)$_2$-ABA]H$_2$ (1b): 10.2 mL of a 1.6 M solution of *n*BuLi in hexane (16.4 mmol) was slowly added whilst stirring at −78 °C to a solution of 2-aminobenzylamine (1 g, 8.2 mmol) in 60 mL of diethyl ether. The yellow solution was allowed to warm to room temperature, stirred for 3 h, and cooled again to −20 °C; 3.81 g of chloro(methyl)diphenylsilane (16.4 mmol) in 20 mL of diethyl ether was then added dropwise. After stirring overnight at room temperature, the brown reaction mixture was centrifuged and the resulting orange solution was concentrated to dryness to yield 3.629 g of a yellow oil (86%) which can be recrystallized from cold pentane. − ^{1}H NMR (C$_6$D$_6$, 300 MHz): δ = 7.72 (m, 4 H, H$_o$ ArNHSiMe*Ph*$_2$), 7.43 (m, 4 H, H$_o$ CH$_2$NHSiMe*Ph*$_2$), 7.18 (m, 12 H, H$_m$ + H$_p$ SiMe*Ph*$_2$), 6.92 (m, 3 H, Ar), 6.64 (m, 1 H, Ar), 5.70 (s, broad, 1 H, ArN*H*), 3.88 (d, ^3J = 6.4 Hz, 2 H, CH$_2$), 0.80 (t, broad, 1 H, CH$_2$N*H*), 0.78 (s, 3 H, ArNHSi*Me*Ph$_2$), 0.37 (s, 3 H, CH$_2$NHSi*Me*Ph$_2$). − ^{13}C NMR (C$_6$D$_6$, 75 MHz): δ = 146.67 (C^2), 137.10, 136.86 (C$_{ipso}$ SiMe*Ph*$_2$), 135.03, 134.88 (C$_{o/m}$ SiMe*Ph*$_2$), 130.13 (Ar), 130.08, 129.74 (C$_p$ SiMe*Ph*$_2$), 128.56 (Ar), 128.43, 128.18 (C$_{o/m}$ SiMe*Ph*$_2$), 118.31, 117.52 (Ar), 46.12 (CH$_2$), −2.22 (ArNHSi*Me*Ph$_2$), −3.39 (CH$_2$NHSi*Me*Ph$_2$). The C^1 signal could not be detected. − IR (nujol mull): $\tilde{\nu}$ = 3336 and 3256 cm^{-1}, (ν_{N-H}). − C$_{33}$H$_{34}$N$_2$Si$_2$ (514.8): calcd. C 76.99, H 6.66; found C 76.34, H 6.37.

[(SiMe$_2$*t*Bu)$_2$-ABA]H$_2$ (1c): This compound was prepared in THF according to the procedure described for **1b**. After removal of the volatiles under vacuum, the reaction residue was extracted with pentane. Concentration to dryness gave the product as a cream solid which was used without further purification (85% yield). − ^{1}H NMR (C$_6$D$_6$, 250 MHz): δ = 7.15 (t, 1 H, H^4 or H^5), 7.02, 6.98 (d, 1 H, H^3 and H^6), 6.79 (t, 1 H, H^4 or H^5), 5.21 (s, broad, 1 H, ArN*H*), 3.84 (d, 2 H, CH$_2$), 1.03 (s, 9 H, *t*Bu), 0.85 (s, 9 H, *t*Bu), 0.29 (s, 6 H, ArNHSi*Me*$_2$*t*Bu), 0.01 (s, 6 H, CH$_2$NHSi*Me*$_2$*t*Bu). The CH$_2$N*H* signal was not detected, but was found at δ = 1.44 in [D$_8$]THF. − C$_{19}$H$_{38}$N$_2$Si$_2$ (322.6): calcd. C 65.07, H 10.92, N 7.99; found C 64.9, H 10.8, N 7.9.

[(Si*i*Pr$_3$)$_2$-ABA]H$_2$ (1d): This compound was prepared in THF according to the procedure described for **1b**. The chlorotriisopropylsilane was added at room temperature, and the solution was refluxed for 18 h. After concentration to dryness, the product was extracted as a brown oil with pentane (82% yield). − ^{1}H NMR (C$_6$D$_6$, 300 MHz): δ = 7.18 (dd, 1 H, H^3 or H^6), 7.12 (dt, 1 H, H^4 or H^5), 6.89 (dd, 1 H, H^3 or H^6), 6.77 (dt, 1 H, H^4 or H^5), 4.44 (s, broad, 1 H, ArN*H*), 3.92 (d, ^3J = 6.1 Hz, 2 H, CH$_2$), 1.15 (m, 42 H, Si*iPr*$_3$), 0.35 (t, broad, 1 H, CH$_2$N*H*). − ^{13}C NMR (C$_6$D$_6$, 75 MHz): δ = 147.04 (C^2), 129.47 (C^1), 129.58, 128.38, 118.10, 116.88 (C^3−C^6), 46.02 (CH$_2$), 18.72 (SiCH*Me*$_2$), 11.99 (SiC*H*Me$_2$), 11.64 (SiC*H*Me$_2$). − IR (neat): $\tilde{\nu}$ = 3361 (sh) and 3331 cm^{-1}, (ν_{N-H}). − C$_{25}$H$_{50}$N$_2$Si$_2$ (434.9): calcd. C 69.05, H 11.59, N 6.44; found C 68.66, H 11.47, N 6.35.

[(SiMe$_3$)(H)-ABA]H$_2$ (1e): To a solution of 250 mg of 2-aminobenzylamine (2.05 mmol) in 25 mL of diethyl ether at −80 °C, 1.3 mL of a 1.6 M solution of *n*BuLi in hexane (2.05 mmol) was added. A white precipitate built up rapidly. After 2 h at room temperature, the reaction mixture was cooled to −80 °C and 0.26 mL of chorotrimethylsilane (2.05 mmol) was added. The temperature was left to reach room temperature. After 12 h, filtration through Celite and concentration to dryness yielded an orange oil containing 93% of **1e** (by ^{1}H NMR). − ^{1}H NMR (C$_6$D$_6$, 300 MHz): δ = 7.17 (dt, 1 H, H^4 or H^5), 6.92 (m, 2 H, H^3 and H^6), 6.75 (dt, 1 H, H^4 or H^5), 6.10 (s, broad, 1 H, ArN*H*), 3.51 (t, ^3J = 5.8 Hz, 2 H, CH$_2$), 0.45 (t, broad, 1 H, CH$_2$N*H*$_2$), 0.28 (s, 9 H, ArNHSi*Me*$_3$).

[(SiMePh$_2$)(H)-ABA]H$_2$ (1f): This compound was prepared as a yellow viscous oil according to the procedure described for **1e** (95% yield). − ^{1}H NMR (C$_6$D$_6$, 300 MHz): δ = 7.76 (m, 4 H, H$_o$ SiMe*Ph*$_2$), 7.19 (m, 6 H, H$_m$ + H$_p$ SiMe*Ph*$_2$), 6.89 (m, 3 H, Ar), 6.83 (s, broad, 1 H, ArN*H*), 6.65 (m, 1 H, Ar), 3.53 (t, ^3J = 5.8 Hz, 2 H, CH$_2$), 0.80 (s, 3 H, ArNHSi*Me*Ph$_2$), 0.45 (t, broad, 2 H, CH$_2$N*H*$_2$). − ^{13}C NMR (C$_6$D$_6$, 75 MHz): δ = 147.97 (C^2), 137.39 (C$_{ipso}$ SiMe*Ph*$_2$), 134.96 (C$_{o/m}$ SiMe*Ph*$_2$), 129.93 (C$_p$ SiMe*Ph*$_2$), 129.82, 128.57 (Ar), 128.38 (C$_{o/m}$ SiMe*Ph*$_2$), 118.01, 117.82 (Ar), 46.73 (CH$_2$), −2.22 (ArNHSi*Me*Ph$_2$). The C^1 signal could not be detected. − C$_{20}$H$_{22}$N$_2$Si$_2$ (346.6): calcd. C 75.42, H 6.96; found C 75.77, H 7.07.

[(SiMePh$_2$)(SiMe$_3$)-ABA]H$_2$ (1g): 2.480 g of **1f** (7.8 mmol) was dissolved in 30 mL of diethyl ether at 0 °C; 1.26 mL of triethylamine (9 mmol) and 1.04 mL of chlorotrimethylsilane (9 mmol) were added successively, and the reaction mixture was left to reach room temperature. After 3 h, the white precipitate of triethylammonium chloride was filtered and the resulting solution was concentrated to dryness to yield 2.640 g of a pale yellow oil (87%). This can be used without further purification. − ^{1}H NMR (C$_6$D$_6$, 300 MHz): δ = 7.72 (m, 4 H, H$_o$ SiMe*Ph*$_2$), 7.19 (m, 6 H, H$_m$ + H$_p$ SiMe*Ph*$_2$), 7.00 (dd, 1 H, H^3 or H^6), 6.91 (m, 2 H, H^4 or H^5 and H^3 or H^6), 6.69 (dt, 1 H, H^4 or H^5), 5.98 (s, broad, 1 H, ArN*H*), 3.79 (d, ^3J = 6.6 Hz, 2 H, CH$_2$), 0.78 (s, 3 H, ArNHSi*Me*Ph$_2$), 0.18 (t, broad, 1 H, CH$_2$N*H*), −0.12 (s, 9 H, CH$_2$NHSi*Me*$_3$). − ^{13}C NMR (C$_6$D$_6$, 75 MHz): δ = 147.45 (C^2), 137.00, (C$_{ipso}$ SiMe*Ph*$_2$), 135.00, (C$_{o/m}$ SiMe*Ph*$_2$), 130.04 (C$_p$ SiMe*Ph*$_2$), 129.89, 128.52 (Ar), 128.39 (C$_{o/m}$ SiMe*Ph*$_2$), 118.14, 117.53 (Ar), 46.21 (CH$_2$), −0.73 (CH$_2$NHSi*Me*$_3$), −2.47 (ArNHSi*Me*Ph$_2$). The C^1 signal could not be detected. − IR (neat): $\tilde{\nu}$ = 3372 (sh) and 3264 cm^{-1}, (ν_{N-H}).

[(SiMe$_3$)$_2$-ABA]Li$_2$ (2a): To a solution of 1.7 g of **1a** (6.38 mmol) in 50 mL of pentane at −70 °C, 8.4 mL of a 1.6 M solution of *n*BuLi in hexane (13.4 mmol) was slowly added. After leaving overnight at room temperature, the yellow solution was concentrated to ca. 15 mL and placed at −20 °C. Large crystals could be separated after one night, and a second crop was obtained on concentrating further (1.025 g, 58%). − ^{1}H NMR (C$_6$D$_6$, 300 MHz): δ = 6.94 (dt, 1 H, H^4 or H^5), 6.84 (dd, 1 H, H^3 or H^6), 6.58 (dt, 1 H, H^4 or H^5), 6.27 (d, 1 H, H^3 or H^6), 4.39 (d, ^2J = 10.3 Hz, 1 H, C*H*H′), 3.68 (d, ^2J = 10.3 Hz, 1 H, CH*H*′), 0.22 (s, 9 H, ArNSi*Me*$_3$), 0.05 (s, 9 H, CH$_2$NSi*Me*$_3$). On heating to 330 K, the two doublets at

δ = 4.39 and 3.68 coalesce into a broad singlet at δ = 3.96 (2 H); T_c = 314 K. − ^{13}C NMR (C_6D_6, 75 MHz): δ = 157.26 (C^2), 136.53 (C^1), 131.60, 129.62, 125.83, 119.11 (C^3−C^6), 48.78 (CH_2), 2.96 ($SiMe_3$), 0.60 ($SiMe_3$). − IR (nujol mull): No absorptions above 3000 cm^{-1}.

[(SiMePh$_2$)$_2$-ABA]Li$_2$ (2b): This compound was prepared from **1b** according to the procedure described for **2a**. After 48 h of stirring at room temperature, the product was directly filtered as a white powder that was dried in vacuo (34% yield). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.46 (m, broad, 20 H, SiMe*Ph*$_2$), 6.70 (m, 2 H, Ar), 6.67, 6.17 (m, 1 H, Ar), 4.02 (s, broad, 2 H, CH_2), 0.40 (s, 3 H, ArNSi*Me*Ph$_2$), 0.13 (s, 3 H, CH_2NSi*Me*Ph$_2$). − IR (nujol mull): No absorptions above 3000 cm^{-1}.

[(SiMe$_2$*t*Bu)$_2$-ABA]Li$_2$ (2c): This compound was prepared from **1c** according to the procedure described for **2a**. After 24 h of stirring at room temperature, the product was obtained as a thick brown oil after concentration to dryness, that eventually solidified as an off-white solid (80% yield). − ^{1}H NMR (C_6D_6, 200 MHz): δ = 7.20 (s, 1 H, H^4 or H^5), 7.05 (m, 2 H, H^3 and H^6), 6.56 (t, 1 H, H^4 or H^5), 4.37 (s, 2 H, CH_2), 1.16 (s, 9 H, *t*Bu), 1.15 (s, 9 H, *t*Bu), 0.33 (s, 6 H, ArNSi*Me*$_2$*t*Bu), 0.19 (s, 6 H, CH_2NSi*Me*$_2$*t*Bu).

[(Si*i*Pr$_3$)$_2$-ABA]Li$_2$ (2d): This compound was prepared as a viscous brown oil from **1d** according to the procedure described for **2c** (95% yield). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.10 (m, 2 H, Ar), 6.97 (d, 1 H, H^3 or H^6), 6.70 (t, 1 H, H^4 or H^5), 4.23 (s, broad, 2 H, CH_2), 1.15 (m, 42 H, Si-*i*Pr$_3$).

[(SiMePh$_2$)(SiMe$_3$)-ABA]Li$_2$ (2g): This compound was obtained as a white powder from **1g** according to the procedure described for **2b** (45% yield). − ^{1}H NMR (C_6D_6, 300 MHz, 286 K): δ = 7.69 (d, 2 H, H_o SiMe*Ph*Ph′), 7.48 (d, 2 H, H_o SiMePh*Ph*′), 7.23 (m, 6 H, H_m + H_p SiMe*Ph*$_2$), 6.77 (dt, 1 H, H^4 or H^5), 6.60 (dd, 1 H, H^3 or H^6), 6.50 (dt, 1 H, H^4 or H^5), 6.12 (d, 1 H, H^3 or H^6), 4.56 (d, ^2J = 11.9 Hz, 1 H, C*H*H′), 3.60 (d, ^2J = 11.9 Hz, 1 H, CH*H*′), 0.48 (s, 3 H, ArNSi*Me*Ph$_2$), 0.01 (s, 9 H, CH_2NSi*Me*$_3$). − IR (nujol mull): No absorptions above 3000 cm^{-1}.

Zr[(SiMe$_2$*t*Bu)$_2$-ABA]$_2$ (3c): This compound was obtained from **2c** according to the procedure described for **3g** (52% yield). − ^{1}H NMR (C_6D_6, 200 MHz): δ = 7.16−7.00 (m, 6 H, Ar), 6.88 (d, 2 H, H^3 or H^6), 4.80 (s, broad, 2 H, C*H*H′), 4.05 (s, broad, 2 H, CH*H*′), 1.08 (s, 18 H, *t*Bu), 0.82 (s, 18 H, *t*Bu), 0.44 (s, 12 H, ArNSi*Me*$_2$*t*Bu), 0.15 (s, 12 H, CH_2NSi*Me*$_2$*t*Bu).

Zr[(SiMePh$_2$)(SiMe$_3$)-ABA]$_2$ (3g): A mixture of 25 mg of $ZrCl_4$ (0.11 mmol) and 86 mg of **2g** (0.22 mmol) in 15 mL of toluene was stirred at 80 °C for 48 h. After cooling to room temperature, the mixture was centrifuged and the clear yellow solution was concentrated to dryness to yield 71 mg of a yellow solid (76%). − ^{1}H NMR (CD_2Cl_2, 300 MHz): δ = 7.25 (m, 22 H, SiMe*Ph*$_2$ + Ar), 6.99 (m, 4 H, Ar), 6.55 (m, 2 H, Ar), 4.89 (d, ^2J = 13.4 Hz, 2 H, C*H*H′), 3.93 (d, ^2J = 13.4 Hz, 2 H, CH*H*′), 0.53 (s, 6 H, ArNSi*Me*Ph$_2$), 0.09 (s, 18 H, CH_2NSi*Me*$_3$).

Zr[(SiMe$_3$)$_2$-ABA](NMe$_2$)$_2$ (4a): To a solution of 497 mg of $Zr(NMe_2)_4$ (1.86 mmol) in 25 mL of pentane at −70 °C, a solution of 497 mg of **1a** (1.86 mmol) in 10 mL of pentane was added. After room temperature had been reached, the reaction mixture was stirred for one night. After evaporation of all volatiles under primary, and then secondary vacuum, 798 mg of a pale yellow oil (96%) was obtained. − ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.14 (m, 2 H, Ar), 6.99 (d, 1 H, H^3 or H^6), 6.79 (dt, 2 H, H^4 or H^5), 4.42 (s, 2 H, CH_2), 2.84 (s, 12 H, NMe_2), 0.32 (s, 9 H, ArNSi*Me*$_3$), 0.13 (s, 9 H, CH_2NSi*Me*$_3$). − ^{13}C NMR (C_6D_6, 75 MHz): δ = 151.23 (C^2), 137.8 (C^1), 129.10, 128.23, 123.53, 120.38 (C^3−C^6), 49.71 (CH_2), 41.92 (NMe_2), 1.43 ($SiMe_3$), 0.95 ($SiMe_3$).

Zr[(SiMePh$_2$)$_2$-ABA](NMe$_2$)$_2$ (4b): This compound was prepared from **1b** according to the procedure described for **4a**. It consists of a very viscous orange oil (96% yield). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.70 (m, 4 H, H_o SiMe*Ph*$_2$), 7.62 (m, 4 H, H_o SiMe*Ph*$_2$), 7.20 (m, 12 H, H_m + H_p SiMe*Ph*$_2$), 7.08, 6.97 (d, 1 H, H^3 and H^6), 6.95, (t, 1 H, H^4 or H^5), 6.70 (t, 1 H, H^4 or H^5), 4.61 (s, 2 H, CH_2), 2.45 (s, 12 H, NMe_2), 0.74 (s, 3 H, Si*Me*Ph$_2$), 0.65 (s, 3 H, Si*Me*Ph$_2$). − ^{13}C NMR (CD_2Cl_2, 75 MHz): δ = 151.56 (C^2), 139.13, 137.16, 136.67 (C^2 and C_{ipso} SiMe*Ph*$_2$), 135.77, 135.13 (C_o SiMe*Ph*$_2$), 130.30, 129.46 (C_p SiMe*Ph*$_2$), 128.96 (Ar), 128.20, 128.04 (C_m SiMe*Ph*$_2$), 127.79, 124.01, 119.88 (Ar), 50.42 (CH_2), 41.60 (NMe_2), −1.12 (Si*Me*Ph$_2$), −1.61 (Si*Me*Ph$_2$). The C^1 signal could not be detected.

Zr[(SiMe$_2$*t*Bu)$_2$-ABA](NMe$_2$)$_2$ (4c): This compound was prepared from **1c** according to the procedure described for **4a**, along with 5 d of stirring at room temperature in pentane, or 4 h in refluxing toluene. The product was further purified by extraction with pentane (orange oil, 99% yield). − ^{1}H NMR (C_6D_6, 250 MHz): δ = 7.20−7.09 (m, 3 H, Ar), 6.82 (t, 1 H, H^4 or H^5), 4.60 (s, broad, 2 H, CH_2), 2.80 (s, 12 H, NMe_2), 1.04 (s, 9 H, *t*Bu), 1.03 (s, 9 H, *t*Bu), 0.29 (s, 6 H, ArNSi*Me*$_2$*t*Bu), 0.16 (s, 6 H, CH_2NSi*Me*$_2$*t*Bu). − $C_{23}H_{48}N_4Si_2Zr$ (436.8): calcd. C 52.32, H 9.16, N 10.61; found C 52.29, H 9.77, N 10.73.

Zr[(SiMePh$_2$)(SiMe$_3$)-ABA](NMe$_2$)$_2$ (4g): This compound was prepared from **1g** according to the procedure described for **4a**. It consists of a yellow oil (98% yield). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.65 (m, 4 H, H_o SiMe*Ph*$_2$), 7.14 (m, 7 H, H_m + H_p SiMe*Ph*$_2$ and H^3 or H^6), 7.06 (d, 1 H, H^3 or H^6), 6.89, 6.73 (dt, 1 H, H^4 and H^5), 4.52 (s, 2 H, CH_2), 2.63 (s, 12 H, NMe_2), 0.79 (s, 3 H, ArNSi*Me*Ph$_2$), 0.14 (s, 9 H, CH_2NSi*Me*$_3$). − ^{13}C NMR (C_6D_6, 75 MHz): δ = 152.18 (C^2), 136.96 (C_{ipso} SiMe*Ph*$_2$), 136.10, 135.96 (C^1 and C_o SiMe*Ph*$_2$), 130.27 (C_p SiMe*Ph*$_2$), 128.61 (Ar), 128.14 (C_m SiMe*Ph*$_2$), 127.85, 122.90, 119.74 (Ar), 49.14 (CH_2), 41.88 (NMe_2), 1.22 (CH_2NSi*Me*$_3$), −1.21 (ArNSi*Me*Ph$_2$). − ^{13}C NMR (CD_2Cl_2, 75 MHz): δ = 152.80 (C^2), 136.59, 136.38 (C^1 and C_{ipso} SiMe*Ph*$_2$), 135.91 (C_o SiMe*Ph*$_2$), 130.48 (C_p SiMe*Ph*$_2$), 128.32 (Ar), 128.25 (C_m SiMe*Ph*$_2$), 127.30, 122.23, 119.98 (Ar), 48.67 (CH_2), 41.95 (NMe_2), 1.04 (CH_2NSi*Me*$_3$), −1.36 (ArNSi*Me*Ph$_2$).

Zr[(SiMe$_3$)$_2$-ABA]Cl$_2$ (5a): To a solution of 830 mg of **4a** (1.9 mmol) in 40 mL of pentane at −50 °C, 2.4 mL of chlorotrimethylsilane (19 mmol) was added. After room temperature had been reached, the reaction mixture was vigorously stirred overnight. After filtration, washing of the precipitate with cold pentane (20 mL) and drying in vacuo, one obtained 622 mg of a pale yellow solid (78%). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.00 (m, 2 H, Ar), 6.77 (m, 2 H, Ar), 4.72 (s, 2 H, CH_2), 0.43 (s, 9 H, ArNSi*Me*$_3$), 0.15 (s, 9 H, CH_2NSi*Me*$_3$). − ^{13}C NMR (C_6D_6, 75 MHz): δ = 149.81 (C^2), 132.22 (C^1), 128.72, 128.72, 122.47, 120.24 (C^3−C^6), 49.50 (CH_2), 0.56 ($SiMe_3$), 0.45 ($SiMe_3$). − IR (nujol mull): $\tilde{\nu}$ = 313 (f), 289 (m) and 254 (F, broad) cm^{-1}, (ν_{Zr-Cl}).

Zr[(SiMe$_2$*t*Bu)$_2$-ABA]Cl$_2$ (5c): This compound was prepared from **4c** according to the procedure described for **5a** and a slightly different workup. The reaction mixture was first concentrated to dryness and the solid residue extracted with small amounts of toluene. Removal of toluene and other volatiles under vacuum afforded a solid that was washed again with 2×1 mL of cold pentane and dried under vacuum (55% yield). − ^{1}H NMR (C_6D_6, 250 MHz): δ = 7.20 (m, 2 H, Ar), 7.00−6.96 (m, 2 H, Ar), 4.59 (s, 2 H, CH_2), 1.02

(s, 9 H, *t*Bu), 0.95 (s, 9 H, *t*Bu), 0.40 (s, 6 H, ArNSi*Me*$_2$*t*Bu), 0.31 (s, 6 H, CH_2NSiMe_2tBu). – $C_{19}H_{36}Cl_2N_2Si_2Zr$ (475.4): calcd. C 44.68, H 7.10, N 5.48; found C 44.45, H 6.71, N 5.24.

Zr[(SiMePh$_2$)(SiMe$_3$)-ABA]Cl$_2$ (5g): This compound was prepared from **4g** according to the procedure described for **5a**. It consists of a pale yellow solid (81% yield). – ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.79 (m, 4 H, H$_o$ SiMe*Ph*$_2$), 7.15 (m, 6 H, H$_m$ + H$_p$ SiMe*Ph*$_2$), 6.93 (d, 2 H, H^3 and H^6), 6.75, 6.67 (dt, 1 H, H^4 and H^5), 4.87 (s, 2 H, CH_2), 0.92 (s, 3 H, ArNSi*Me*Ph$_2$), 0.19 (s, 9 H, CH_2NSiMe_3). – ^{13}C NMR (C_6D_6, 75 MHz): δ = 151.36 (C^2), 137.21 (C$_o$ SiMe*Ph*$_2$), 132.79 (C$_{ipso}$ SiMe*Ph*$_2$), 131.53 (C$_p$ SiMe*Ph*$_2$), 131.40 (C^1), 129.00 (C$_m$ SiMe*Ph*$_2$), 128.24, 121.87, 120.36 (Ar), 48.60 (CH_2), 0.89 (CH_2NSiMe_3), −1.52 (ArNSi*Me*Ph$_2$). – IR (nujol mull): 339 (m) and 294 (m) cm^{-1}, (ν_{Zr-Cl}).

X-ray Crystallographic Structure Determination and Refinements of 5c and 6c: Data for **5c** (and **6c**) were collected at low temperature (T = 160 K) with a Stoe Imaging Plate Diffraction System (IPDS), equipped with an Oxford Cryosystems Cryostream Cooler Device and using graphite-monochromated Mo-K_α radiation (λ = 0.71073Å). The crystal-to-detector distance was 70 (80) mm, 179 (147) exposures were obtained with 0° < φ < 250° and with the crystal rotated through 1.4° (1.7°) in φ. The final unit cell parameters were obtained by means of a least-squares refinement of a set of 5000 well-measured reflections, and a crystal decay was monitored in the course of data collection by measuring 200 reflections by image. No significant fluctuations of intensities have been observed during measurements. Structures have been solved by direct methods using SIR92,[10] and refined by least-squares procedures on F^2 with the aid of SHELXL97.[11] The atomic scattering factors were taken from International Tables for X-ray Crystallography.[12] All non-hydrogen atoms were anisotropically refined and the last cycles of refinement weighting schemes[12] were applied. All hydrogen atoms were located on a difference Fourier map and refined with a riding model, except the hydrogen atom H(2) connected to the amine group of **6c** which has been isotropically refined. For **5c** a molecule of solvent (toluene) has been located, this molecule seems to be disordered around an inversion center and has been anisotropically refined with restraints on distances and angles. Drawings of molecules are performed with the program ZORTEP[13] with 50% probability displacement ellipsoids for non-hydrogen atoms. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-155993 (CCDC-155994). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. Main data for **5c** and **6c** are reported in Table 5.

Ethylene Polymerization Procedures: Polymerization experiments were performed in a 50-mL glass reactor equipped with a mechanical stirrer or in standard Schlenk-type glassware with magnetic stirring, whether ethylene pressure was 6 bar or 1 bar, respectively. The catalyst precursor was first introduced into the reactor as a toluene solution of controlled volume and concentration. The MAO solution was added at the desired temperature, before the reactor was pressurized as rapidly as possible with ethylene and the pressure, as well as vigorous stirring, maintained constant during the polymerization time. The polymerization was then quenched by pouring the reaction mixture into a 10% solution of aqueous HCl in methanol. The polymer was collected by filtration, washed several times with methanol and then acetone, dried in vacuo at 80 °C, and weighed. ^{1}H NMR and SEC analyses were carried out at 140 °C in $C_2D_2Cl_4$ or 1,2,4-trichlorobenzene respectively.

New Octahedral $RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] Complexes Containing One Hemilabile Ketophosphane Ligand

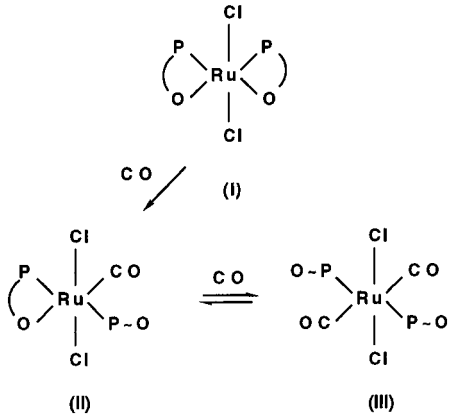
Bernard Demerseman[a]

Keywords: Ruthenium / Phosphanes / O ligands / Carbonyl ligands / Isomerizations

The reaction of the ketophosphanes $Ph_2PCH_2C(=O)t$Bu (**1**), $Ph_2PCMe_2C(=O)i$Pr (**1′**), or $Ph_2PCMe_2CH_2C(=O)$Me (**1′′**) with a precursor complex $RuCl_2(L)(\eta^6$-*p*-cymene) [L = PMe_3 (**a**), $PMePh_2$ (**b**), P*i*PrPh$_2$ (**c**), PPh_3 (**d**), $P(OMe)Ph_2$ (**e**), $P(OMe)_3$ (**f**)] in methanol and under carbon monoxide, provides an access to a novel family of complexes (*ttt*)-$RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] (**2a–e**, **2′a**,**e**,**f**, and **2′′a**) with *trans*-chlorine and *trans*-phosphorus atoms. Further reaction with carbon monoxide or acetonitrile under thermal activation yields the *cis*,*cis*,*trans* derivatives (*cct*)-$RuCl_2(CO)_2(L)[\eta^1$-(*P*)-ketophosphane] **4a**,**b** and **4′a**, and (*cct*)-$RuCl_2(CO)(MeCN)(L)[\eta^1$-(*P*)-ketophosphane] **5a**,**b**,**d**. Complexes **2a**,**b** and **2′a** rearrange under thermal activation, or after exposure to sunlight, into the (*ctc* and *ccc*)-$RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] isomers, with *cis*-chlorine and *cis*-phosphorus atoms, **6a**,**b** and **6′a**, respectively. Complexes **6a**,**b** reversibly add one molecule of carbon monoxide when forming the all-*cis* derivatives (*ccc*)-$RuCl_2(CO)_2(L)[\eta^1$-(*P*)-ketophosphane] **7a**,**b**, respectively. The removal of one chloride ligand in complexes **4a**, **4′a**, or **5a** with silver tetrafluoroborate affords the stable cationic derivatives $\{RuCl(CO)(L')(PMe_3)[\eta^2$-(*P*,*O*)-ketophosphane]$\}[BF_4]$, **8a** and **8′a** (L′ = CO) and **9a** (L′ = MeCN), respectively. Mild basic conditions are sufficient to allow the synthesis of the enolatophosphane derivatives (*ttt*)-$RuCl(CO)_2(L)[\eta^2$-(*P*,*O*)-$Ph_2PCH{=}C(t$Bu)O], **10a**,**c**,**e**, and of the analogous (*ccc*) and (*cct*) isomers, **11a**,**b** and **12a**, respectively.

Introduction

The discovery of the hemilabile behaviour of an ether−phosphane ligand,[1] in which the ether functionality coordinates at a ruthenium centre, has undoubtedly stimulated the interest of organometallic chemists with regard to functional phosphanes. The complexation of such ligands is of interest since the oxygen−metal bond is weak, thus providing facile access to coordinative unsaturation.[2,3] The series of $RuCl_2[\eta^2$-(*P*,*O*)-functional phosphane]$_2$ complexes, in which the organic function consists of an ether,[1,4−8] an ester,[9−11] or a keto group, have been largely studied.[12,13] Interestingly, their geometry is of type **I** (see Scheme 1), consisting of *trans*-chlorine, *cis* phosphorus, and *cis*-oxygen atoms, respectively. The preferred *cis* arrangement of the phosphorus atoms is unusual, as emphasised by the ability of complexes **I** to trap carbon monoxide through an irreversible process involving a *cis*-to-*trans* rearrangement of the phosphorus atoms (Scheme 1). The resulting complexes **II** exhibit a noteworthy fluxional behaviour through easy exchange between the coordinating modes of the oxygen atoms (not depicted in Scheme 1) and are able to interconvert with type-**III** complexes by reversible addition of carbon monoxide. We report herein a convenient route to new hybrid (*ttt*)-$RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] complexes with *trans*-chlorine and *trans*-phosphorus atoms. They are analogous of both type-**II** and all-*trans* $RuCl_2(CO)_2L_2$ complexes, and their study will allow further comparison. Furthermore, under basic conditions they are suspected of generating coordinatively unsaturated η^2-(*P*,*O*)-enolatophosphane derivatives by a formal HCl abstraction.



Scheme 1

Results

Synthesis of (*ttt*)-$RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] Complexes 2−2′′

An equimolar mixture consisting of a precursor complex $RuCl_2(L)(\eta^6$-*p*-cymene) [L = PMe_3 (**a**), $PMePh_2$ (**b**), P*i*PrPh$_2$ (**c**), PPh_3 (**d**), $P(OMe)Ph_2$ (**e**), $P(OMe)_3$ (**f**)] and a ketophosphane [$Ph_2PCH_2C(=O)t$Bu (**1**), $Ph_2PCMe_2C(=O)i$Pr (**1′**), $Ph_2PCMe_2CH_2C(=O)$Me (**1′′**)] in methanol was stirred at ambient temperature under carbon monoxide. Subsequent workup allowed all-*trans* (based on two *trans*-

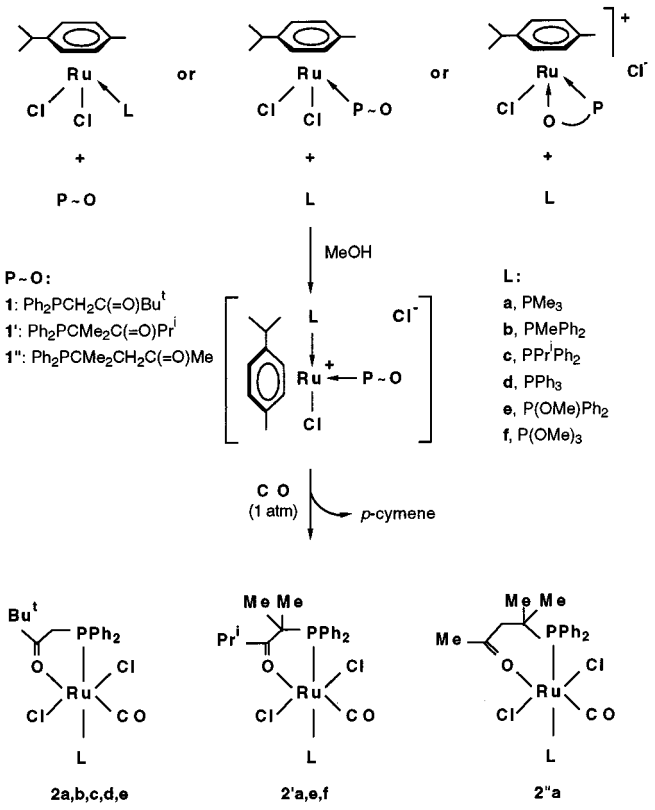
chlorine and two *trans*-phosphorus atoms, respectively) complexes (*ttt*)-$RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] **2a**−**e**, **2′a**,**e**,**f**, and **2′′a**, to be isolated in moderate to high yields (49−84%) as orange air-stable crystals (except for **2d**) (Scheme 2). The reaction formally consists of the substitution of a 6e-donor ligand (*p*-cymene) by one molecule of carbon monoxide and one molecule of ketophosphane acting as a 4e-donor. The generality of the reaction is not only shown by the involvement of a β- (**1**, **1′**) or a γ-ketophosphane (**1′′**), but also by the ability of the precursor complex $RuCl_2(\eta^6$-*p*-cymene)$[\eta^1$-(*P*)-$Ph_2PCH_2C(=O)t$Bu][14] in providing an alternative route to complexes of type **2**, when reacting with a ligand L such as $P(OMe)Ph_2$ and with carbon monoxide, to afford the expected derivative **2e** (see Scheme 2). The permethylated β-ketophosphane **1′** is unable to form a similar $RuCl_2(\eta^6$-*p*-cymene)$[\eta^1$-(*P*)-$Ph_2PCMe_2C(=O)i$Pr] derivative, but reacts with dimeric $[RuCl_2(\eta^6$-*p*-cymene)$]_2$ in methanol to generate a cationic species $\{RuCl(\eta^6$-*p*-cymene)$[\eta^2$-(*P*,*O*)-$Ph_2PCMe_2C(i$Pr)=O]$\}^+$, which has previously been characterised as its PF_6 salt.[14] Such solutions of $\{RuCl(\eta^6$-*p*-cymene)$[\eta^2$-(*P*,*O*)-$Ph_2PCMe_2C(i$Pr)=O]$\}$Cl in methanol may also be used to synthesise complexes **2′**. As summarised in Scheme 2, these distinct pathways leading to complexes **2**−**2′′** may be rationalised in terms of the formation of a transient cationic species $\{RuCl(\eta^6$-*p*-cymene)(L)$[\eta^1$-(*P*)-ketophosphane]$\}^+$ that will further react with carbon monoxide. Such a mechanism accounts for the requirement of methanol as the solvent, which allows a transient cleavage of one Ru−Cl bond. The reaction does not work in a solvent such as CH_2Cl_2. This strongly suggests the key role of methanol in the labilisation of the Ru−Cl bond.

The structures of complexes **2**−**2′′** were determined from a combination of elemental analysis, IR spectroscopy and ^{1}H, $^{31}P\{^1H\}$, $^{13}C\{^1H\}$, and ^{13}C NMR spectroscopy. Elemental analysis indicates the retention of two chlorine atoms per Ru atom. The IR spectra (Table 1) exhibit a very strong absorption close to 1940 cm^{-1} assigned to the carbon monoxide ligand, as well as a strong absorption close to 1640 cm^{-1} (1673 cm^{-1} for **2′′a**) indicating the coordination of the oxygen atom of the ketophosphane.[14] The $^{31}P\{^1H\}$ NMR spectra (Table 1) consist of an AB spin system and the large coupling constant values (> 300 Hz) indicate a mutual *trans* arrangement of the two phosphorus nuclei.[15] The ^{1}H and $^{13}C\{^1H\}$ NMR spectra both indicate a plane of symmetry requiring a relative *trans* arrangement of the two chloride ligands. Accordingly, the PCH_2 protons in complexes **2** and the $PCMe_2$ methyl groups in complexes **2′** and **2′′** are found to be equivalent by ^{1}H NMR spectroscopy. Furthermore, the two phenyl groups of the Ph_2P fragment are found to be equivalent by $^{13}C\{^1H\}$ NMR spectroscopy. The ^{13}C NMR resonances assigned to the C=O and C≡O carbon nuclei are close, but a simple comparison between the $^{13}C\{^1H\}$ and ^{13}C NMR spectra allows an unambiguous determination, since only the keto resonance is affected by far ^1H-^{13}C coupling.

The thermal stability of complexes **2**−**2′′** depends on the nature of the ancillary ligand L. The most stable complexes



Scheme 2

are **2a**, **2′a**, and **2′′a** (in which L = PMe_3). They were unaffected when thermally treated under reflux in methanol for several hours. In contrast, **2e** [in which L = $P(OMe)Ph_2$] decomposed in hot methanol as indicated by the formation of $RuCl_2(CO)[\eta^1$-(*P*)-$Ph_2PCH_2C(=O)t$Bu][η^2-(*P*,*O*)-$Ph_2PCH_2C(t$Bu)=O].[12] This latter complex was detected by $^{31}P\{^1H\}$ NMR spectroscopy.

Reversible and Irreversible Carbon Monoxide Binding by Complexes 2−2′

The $^{31}P\{^1H\}$ NMR spectrum of a solution of **2a** (or **2b**) in CD_2Cl_2 that was kept under carbon monoxide disclosed a new species, besides the minor presence of **2a** (or **2b**). After removal of the carbon monoxide, recovery of pure **2a** (or **2b**) is indicated by the corresponding NMR spectrum. The set of $^{31}P\{^1H\}$ NMR resonances corresponding to the new species still consists of an AB spin system and large coupling constant values (> 300 Hz), thus indicating a mutual *trans* arrangement of the two phosphorus nuclei. Attempts to isolate the species failed, but such reversible carbon monoxide binding by **2a** (or **2b**) is very similar to the reversible formation of complexes **III** from complexes **II**, as depicted in Scheme 1. Therefore, the reversible formation of the all-*trans* derivatives (*ttt*)-$RuCl_2(CO)_2(L)[\eta^1$-(*P*)-$Ph_2PCH_2C(=O)t$Bu] (**3a**,**b**) may be reasonably assumed (Scheme 3). In contrast, an irreversible binding of carbon monoxide by toluene solutions of complexes **2a**,**b** and **2′a** occurs upon thermal activation (≥ 80 °C), yielding the colourless *cis*,*cis*,*trans* derivatives (*cct*)-$RuCl_2(CO)_2(L)[\eta^1$-(*P*)-

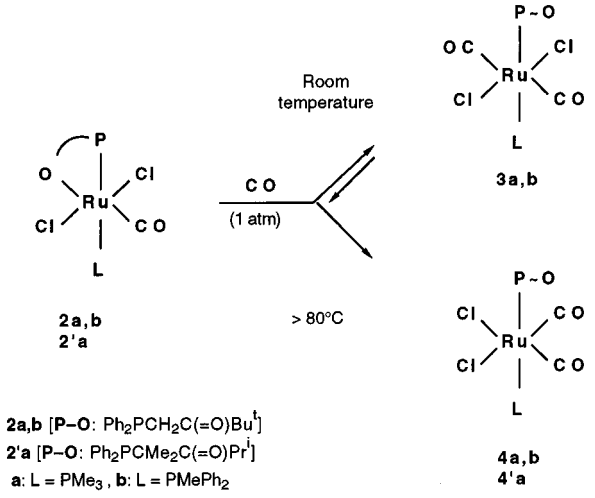
ketophosphane] (**4a**,**b** and **4′a**) (Scheme 3). The formation of **4a**,**b** and **4′a** involves an additional *trans*-to-*cis* rearrangement of the chloride ligands, relative to the $\eta^2\text{-}(P,O) \rightarrow \eta^1\text{-}(P)$ transformation of the coordination of the ketophosphane, therefore allowing the entrance of one carbon monoxide molecule.

The $^{31}P\{^1H\}$ NMR spectra of **4a**,**b** still consist of an AB spin system and the large coupling constant values ($^2J_{PP} >$ 300 Hz, Table 1) indicate the retention of the mutual *trans* arrangement of the two phosphorus nuclei. Both the ^1H and $^{13}C\{^1H\}$ NMR spectra of **4a**,**b** and **4′a** indicate a plane of symmetry. Their IR spectra exhibit two strong absorptions (close to 2055 and 1990 cm^{-1}) as expected for a relative *cis* arrangement of two carbonyl ligands, as well as an absorption close to 1700 cm^{-1} assigned to the uncoordinated keto functionality. A relative *cis* arrangement of the two carbonyl ligands obviously requires a relative *cis* arrangement of the two chlorine atoms.

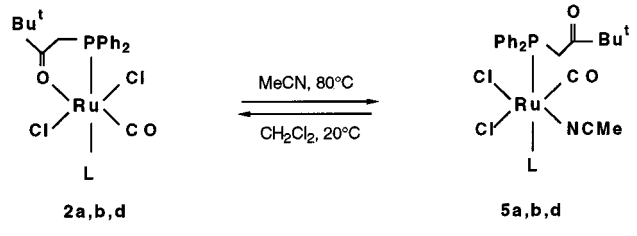
Reversible Acetonitrile Binding by Complexes 2

A *trans*-to-*cis* rearrangement of the chloride ligands is also involved when complexes **2a**,**b**,**d** are heated under reflux in acetonitrile, yielding the lemon-yellow *cis*,*cis*,*trans* complexes (*cct*)-$RuCl_2(CO)(N{\equiv}CMe)(L)[\eta^1\text{-}(P)$-ketophos-



Scheme 3

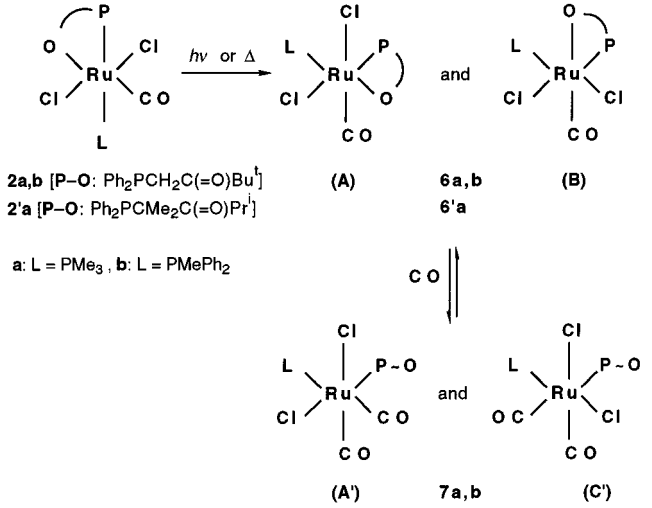
phane] (**5a**,**b**,**d**) (Scheme 4). The η^2-(*P*,*O*) → η^1-(*P*) modification of the coordination of the ketophosphane allows one acetonitrile ligand to enter. The $^{31}P\{^1H\}$ NMR spectra of complexes **5a**,**b**,**d** exhibit large $^2J_{PP}$ coupling constant values, indicating a retention of the relative *trans* arrangement of the phosphorus atoms. However, their ^1H NMR spectra show the two PCH_2 protons of the ketophosphane to be diastereotopic. Their $^{13}C\{^1H\}$ NMR spectra also indicate a loss of symmetry. This lack of a plane of symmetry suggests a relative *cis* arrangement of the two chloride ligands. Complexes **5a**,**b**,**d** were found to be stable in the solid state but not in dichloromethane solutions, as monitored by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy. Thus, after standing for 1 d at room temperature, an NMR-spectroscopic sample of pure **5a** in CD_2Cl_2 shows a substantial presence of free acetonitrile, as well as the recovery of **2a**. The reaction of acetonitrile with crude **2d** (L = PPh_3), that was obtained as an insoluble precipitate which retained several impurities, allows the preparation of **5d** as analytically pure yellow crystals. Furthermore, a concentrated solution of **5d** in dichloromethane deposited orange crystals of pure **2d**, merely by standing for several days. A simple substitution of the weakly bonded acetonitrile ligand by carbon monoxide (instead of the formation of **2a** or **2d**) was not observed when a solution of **5a** or **5d** in dichloromethane was kept under carbon monoxide. This result is likely to be related to the kinetically favoured formation of *trans* derivatives in such processes.[16]



Scheme 4

Isomerisation of Complexes 2−2′

A slow reaction occurred when an orange solution of **2a** in toluene was heated at 80 °C under an inert gas, as indicated by the formation of a pale-yellow precipitate. After heating for 2 d and subsequent removal of the volatiles, the ^1H and $^{31}P\{^1H\}$ NMR analysis of the resulting material revealed a mixture consisting of a new species, **6a**, as well as unreacted **2a**, in a 2:1 ratio (Scheme 5). It is worth noting the thermal stability of complex **6a** which was successfully isolated in a 75% yield as an analytically pure precipitate after a solution of **2a** in toluene was heated under reflux. Thus, this procedure was used to synthesize **6b** starting from **2b**, while **6′a** was conveniently obtained after heating **2′a** in ethanol under reflux. The isomerisation of complexes **2a**,**b** and **2′a** into complexes **6a**,**b** and **6′a** also occurred when solutions of **2a**,**b** and **2′a** in dichloromethane were exposed to sunlight. Similar treatment of a solution of **2a** or alternatively **6a**, both led to mixtures of **2a** and **6a** in a 15:85 ratio, indicating a reversible process. This was determined by ^1H NMR spectroscopy. From the ratio it can be seen that **6a** is highly favoured. Irradiation from sunlight proved useful in synthesising **6a** and **6′a**, as detailed in the Exp. Sect. Complexes **6a**,**b** and **6′a** were characterised by elemental analysis and spectroscopic studies. The $^{31}P\{^1H\}$ NMR spectrum of **6′a** exhibits a small $^2J_{PP}$ coupling constant value (Table 1), indicating a relative *cis* arrangement of the phosphorus atoms.[15] The ^1H NMR spectrum shows two inequivalent $PCMe_2$ methyl groups. IR spectroscopy indicates the coordination of the keto functionality, and this η^2-(*P*,*O*) coordination of the ketophosphane obviously requires a relative *cis* arrangement of the corresponding oxygen and phosphorus coordinating atoms. Furthermore, the $^{13}C\{^1H\}$ NMR resonance assigned to the carbon monoxide ligand in **6′a** discloses two small $^2J_{PC}$ coupling constant values ($^2J_{PC}$ = 19.8 and 12.6 Hz), indicating a *cis* position of the carbon monoxide ligand relative to both phosphorus atoms. Therefore, only two octahedral structures, namely **A** and **B** as depicted in Scheme 5, remain conceivable. The NMR- and IR-spectroscopic study of **6a** leads to the same conclusion when some additional weak resonances are omitted. These resonances are too weak to allow further characterisation of the corresponding species; however, $^{31}P\{^1H\}$ NMR spectroscopy does show a small $^2J_{PP}$ coupling constant value. The NMR-spectroscopic study of **6b** was more informative and shows the presence of two isomers in a 3:2 ratio. These two isomers involve both a mutual *cis* arrangement of the phosphorus atoms and a *cis* arrangement of the carbon monoxide ligand relative to the phosphorus atoms, as expected for a mixture of **A** and **B**. To summarise these results, complex **6′a**, which involves the bulkiest ketophosphane **1′** and a small ligand L = PMe_3, shows only one isomer in solution, **A** or **B**. Complex **6b**, which involves the smaller ketophosphane **1** but a bulkier ligand L = $PMePh_2$, shows a mixture of **A** and **B** isomers in solution. Complex **6a**, which involves the ketophosphane **1** and L = PMe_3, will also show a mixture of **A** and **B** isomers, but one is highly favoured.



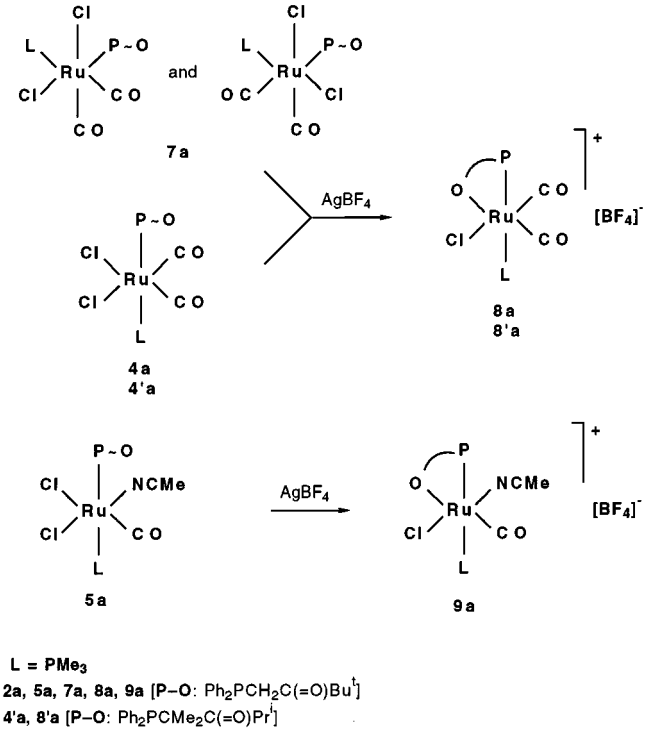
Scheme 5

Binding of Carbon Monoxide by Complexes 6−6′

Dichloromethane solutions of **6a** and **6b** were found to bind carbon monoxide (1 atm, ambient temperature) affording **7a** and **7b**, respectively (Scheme 5). Complexes **6a** and **6b** were recovered in the absence of carbon monoxide, indicating a reversible reaction. It should be noted that this process does not affect the **A/B** ratio (in **6a** and **6b**). In contrast, **6′a** irreversibly adds carbon monoxide affording the *cct* derivative **4′a**. This involves a *cis*-to-*trans* rearrangement of the phosphorus atoms. The NMR spectra of both **7a** and **7b** show a mixture of two isomers, namely **A′** and **C′** (Scheme 5). The small $^2J_{PP}$ coupling constant values (Table 1) clearly indicate the retention of the *cis* arrangement of the phosphorus atoms. The ^1H NMR spectrum shows the PCH_2 protons of the ketophosphane **1** to be inequivalent and rules out a *trans* mutual arrangement of the two chlorine atoms. The $^{13}C\{^1H\}$ NMR spectra indicate, for each molecule **A′** and **C′** that one carbon monoxide ligand is located in a *cis* position relative to the two phosphorus atoms and the second one in a *trans* P−Ru−CO arrangement.[15] Thus, only the two octahedral structures **A′** and **C′** remain conceivable. The isomeric structures **A′** and **C′** both show *cis* mutual arrangements of the two chlorine atoms and of the two carbonyl ligands, respectively, and are thus the two conceivable structures for an all-*cis*-$RuX_2(CO)_2(L)(L')$ complex. It is interesting to note that a simple substitution of the coordinated oxygen atom in **A** by an entering carbon monoxide molecule will lead to **A′**. However, a similar exchange of the coordinated oxygen atom in **B** by carbon monoxide will result in the formation of a symmetrical structure with *trans* carbon monoxide ligands, rather than **C′**. This is not experimentally detected. The stability of complexes **7a**,**b** is related to the nature of the ancillary ligand L. Complex **7a** (L = PMe_3) was found to be stable in a dichloromethane solution, or alternatively in a methanol solution, at ambient temperature and under carbon monoxide, but is converted into **4a** in hot methanol (see Exp. Sect.). In contrast, **7b** (L = $PMePh_2$) is stable in a dichloromethane solution, but is converted into **4b** on dissolution in methanol, even at ambient temperature. The straightforward formation of **4′a** on treatment of **6′a** with carbon monoxide, is indicative of the steric effect of the bulky ketophosphane **1′**, favouring a *cis*-to-*trans* rearrangement of phosphorus atoms.

Formation of Cationic Derivatives

Halide abstraction from **7a** using silver tetrafluoroborate creates an unsaturated centre that was found to trigger a *cis*-to-*trans* rearrangement of phosphorus atoms. This produces the cationic derivative **8a** in which the oxygen atom from the ketophosphane ligand completes the coordination at the ruthenium centre (Scheme 6). Complexes **4a** and **4′a** are also convenient precursors for the synthesis of such cationic derivatives, and afford the expected derivatives **8a** and **8′a**, respectively, through the removal of a chloride ligand (Scheme 6). In contrast, attempts to obtain cationic derivatives starting from a complex **2**, such as **2a**, invariably failed, even under carbon monoxide.



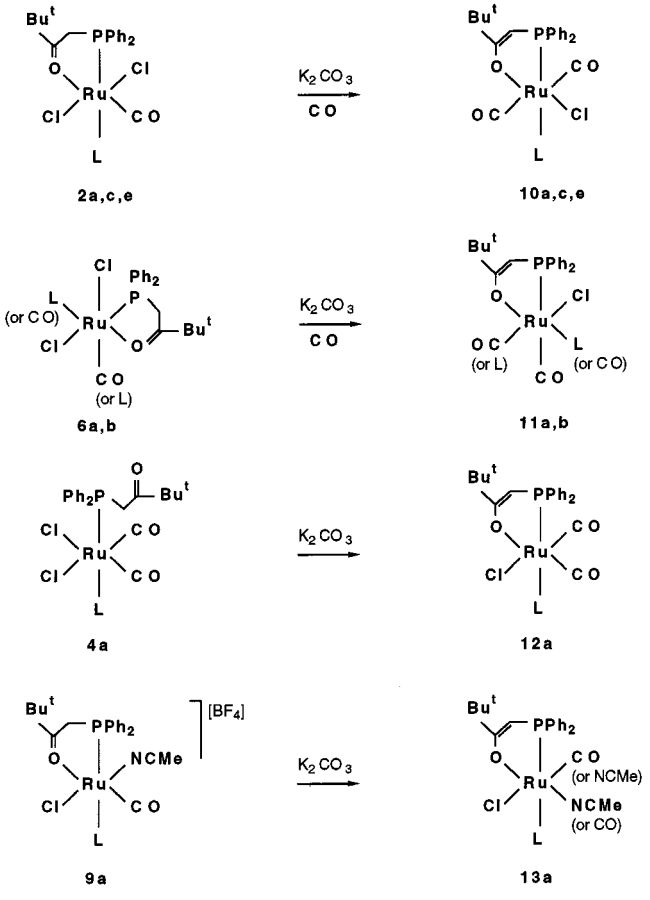
Scheme 6

The structures of complexes **8a** and **8′a** are unambiguously deduced from their $^{31}P\{^1H\}$ NMR spectra, which exhibit large $^2J_{PP}$ coupling constant values (Table 1) indicating a *trans* arrangement of the phosphorus atoms, and from their IR spectra which indicate a *cis* arrangement of the carbonyl ligands and the coordination of the keto functionality. The observation of two inequivalent PCH_2 protons by ^1H NMR spectroscopy also suggests a relative *cis* arrangement of the two carbonyl ligands. The substitution of one chloride ligand by the oxygen atom from the ketophosphane was also achieved starting from the fragile (pre-

sumably owing to its labile acetonitrile ligand) complex **5a**, which reacts with silver tetrafluoroborate to yield the more stable cationic derivative **9a** (Scheme 6).

Stereoselective Synthesis of Enolatophosphane Derivatives

Complexes **2a**,**c**,**e** were found to be rather robust under basic conditions (K_2CO_3 in dichloromethane or KOH in methanol). However, the consumption of the starting material was detected by $^{31}P\{^1H\}$ NMR spectroscopy after prolonged reaction times (several days at ambient temperature), but the observation of very numerous new resonances indicated an intractable mixture. Under such basic conditions and under carbon monoxide, a fast and selective process occurred, resulting in the formation of the enolatophosphane complexes **10a**,**c**,**e**. It is worth noting that the complexes **10a**,**c**,**e** retain an all-*trans* structure based on two *trans*-coordinating phosphorus atoms, two *trans*-carbonyl ligands and two *trans*-X-type coordinating atoms (Scheme 7). The process formally consists of the removal of one HCl molecule and the coordination of one molecule of carbon monoxide. Derivatives **6a**,**b** reacted in a similar manner and afforded the enolatophosphane derivatives **11a**,**b**, respectively, which retain a relative *cis* arrangement of the phosphorus atoms. The NMR-spectroscopic study of **11a**,**b** discloses one isomer for **11a**, but a mixture of two isomers for **11b**. These isomers involve both a relative *cis* arrangement of the phosphorus atoms and of the carbon monoxide ligands, respectively. For each structure, one carbon monoxide ligand is located in a *cis* position relative to the two phosphorus atoms, whereas the second carbon monoxide ligand is located in a *trans* position relative to a phosphorus atom, but three structures remain conceivable (vide infra). The formation of the enolatophosphane derivatives **12a** and **13a**, starting from the neutral *cct* isomer **4a** and from the cationic derivative **9a**, respectively, formally consists solely of the removal of one molecule of HCl or $H[PF_6]$ (Scheme 7), and was also found to be very stereoselective. This was monitored by $^{31}P\{^1H\}$ NMR spectroscopy.

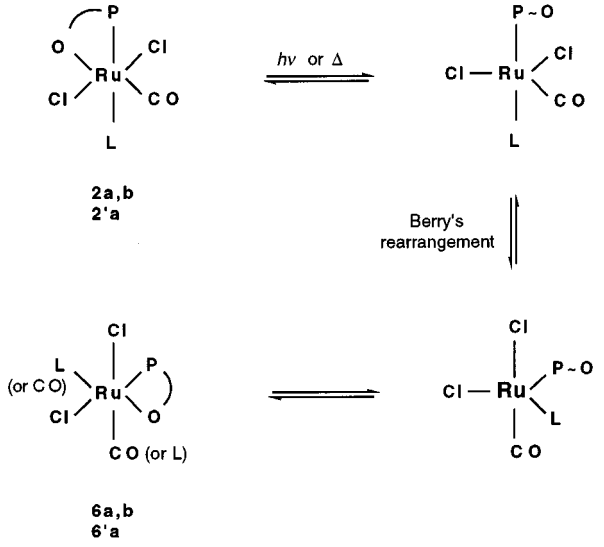


a, L = PMe_3; **b**, L = $PMePh_2$; **c**, L = PPr^iPh_2; **e**, L = $P(OMe)Ph_2$

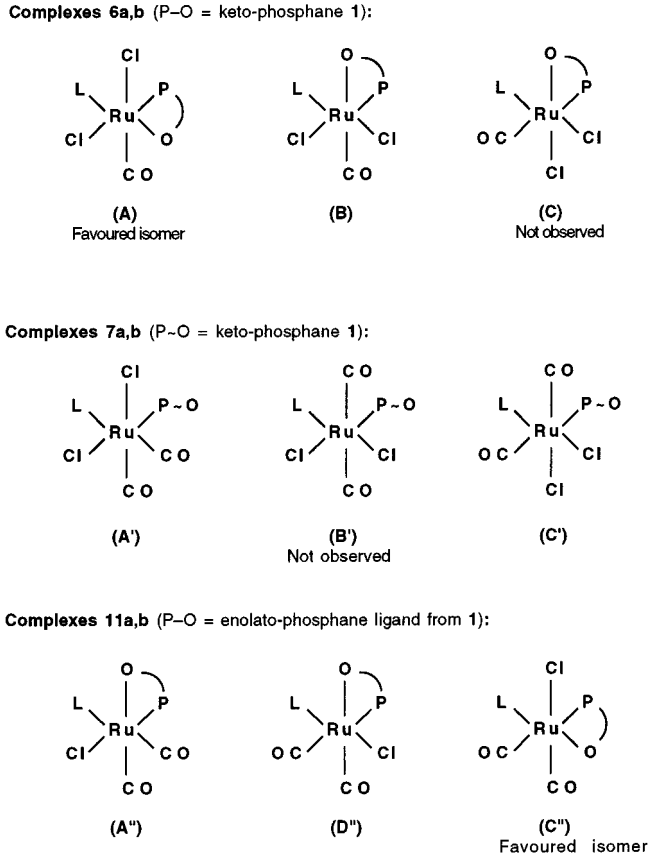
Scheme 7

Discussion

The removal of the arene ligand from $RuCl_2(L)(\eta^6$-*p*-cymene) complexes allows the coordination of a ketophosphane along with a CO ligand, thus providing access to a new family of octahedral Ru complexes bearing two distinct phosphorus-containing ligands. The process selectively leads to all-*trans* complexes based on of two *trans*-chlorine and *trans*-phosphorus atoms. The hemilabile character of the ketophosphane ligand allows the reversible formation of new all-*trans*-$RuX_2(CO)_2L_2$-type complexes (but with distinct L ligands) by reversible uptake of carbon monoxide. Previous studies concerning $RuX_2(CO)_2L_2$ complexes have proved that all-*trans* complexes easily rearrange under thermal activation into their thermodynamically favoured *cct* isomers through a preliminary cleavage of one Ru−CO bond. The mechanism of this transformation has been thoroughly elucidated.[16] Therefore, the formation of complexes of type **4** and **5** under thermal activation and in the presence of an entering ligand such as carbon monoxide or acetonitrile might be expected, and this accounts for the recovery of complexes of type **2** from **5** by loss of acetonitrile. The behaviour of complexes **2** under thermal activation and in the absence of an entering ligand was less predictable. Whereas all-*trans*-$RuX_2(CO)_2L_2$ complexes rearrange into their *cct* isomers, complexes of type **2** selectively afford the corresponding all-*cis* isomers **6**. This observation suggests that the formation of *cct* isomers of **2** (with *cis*-chlorine and *trans*-phosphorus atoms) is disfavoured due to the requirement of a (C=)O→Ru−Cl *trans* arrangement (only O→Ru−Cl *cis* arrangements are observed in complexes **2** and **6**). In contrast, the coordination of carbon monoxide is stabilised through the *trans* effect of a chloride ligand in (*cct*)-$RuX_2(CO)_2L_2$ complexes. As depicted in Scheme 8, the transformation of complexes **2** into complexes **6** may be assumed to involve a pentacoordinated intermediate arising from the cleavage of the oxygen−ruthenium bond. Such a Berry rearrangement[17] through a dissociative pathway already accounts for the isomerisation of all-*trans*-$RuX_2(CO)_2L_2$ complexes into their all-*cis* isomers.[16]



Scheme 8. Rationale accounting for the reversible isomerisation of complexes **2a**,**b** and **2′a** into complexes **6a**,**b** and **6′a**

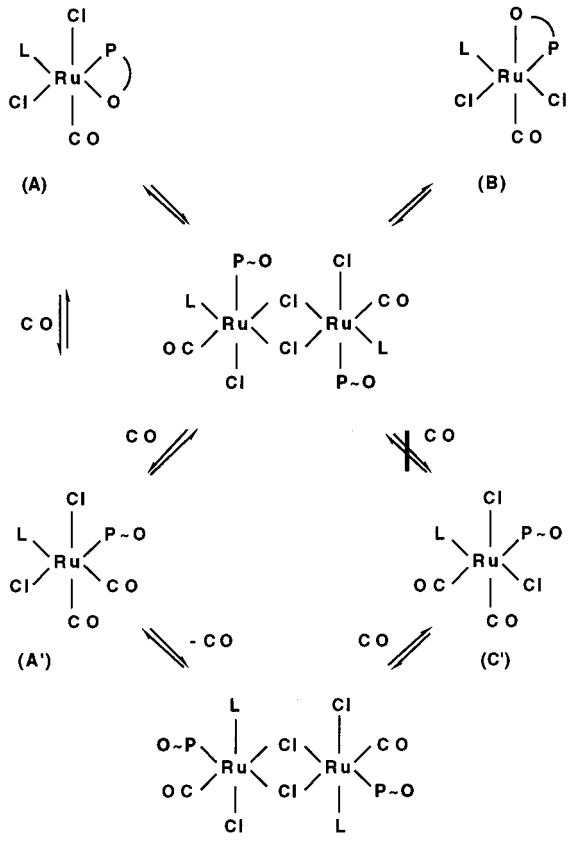


Scheme 9. Comparison between the distinct structures of complexes **6a**,**b**, **7a**,**b**, and **11a**,**b**

The formation of complexes **6** preserves the hemilabile property of the ketophosphane ligand as emphasised by the reactivity of complexes **6** towards carbon monoxide. Complexes **6a** and **6b** reversibly bind carbon monoxide to afford **7a** and **7b**, respectively. Solutions of **7a** and **7b** in dichloromethane both reveal a mixture of two all-*cis* isomers. As depicted in Scheme 9, a comparison of the structures of type **6** and **7** complexes excludes a mechanism based on the CO displacement of the weakly bound oxygen atom in complexes **6**, despite the fact that the structure **A′** of **7** may arise from **A** of **6**. The structure **C′** which is also observed in complexes **7**, is unexpected when compared with **A** and **B** of complexes **6**. The expected structure **B′** (Scheme 9) was not detected experimentally.

Moreover, the **A′**/**C′** ratio in a complex of **7** is unambiguously distinctly related to the **A**/**B** ratio in the parent complex **6**. Thus, the complete reversibility of the transformation of **6** to **7** provides further evidence for a dynamic equilibrium between **A** and **B**, and between **A′** and **C′**. The facile recovery of **6a** (or **6b**) from **7a** (or **7b**) illustrates the easy loss of carbon monoxide by **7**. However, preliminary cleavage of one Ru−CO bond in **7** (dissociative mechanism) will transiently generate a coordinatively unsaturated intermediate favouring a *cis*-to-*trans* rearrangement of the phosphorus atoms.[16] Therefore, an associative mechanism will more likely account for the retention of the all-*cis* geometry. The reversible **A** ⇄ **B** and **A′** ⇄ **C′** transformations are also easy. They may formally involve the exchange of the positions of the chlorine atom and the oxygen atom for the **A** ⇄ **B** isomerisation, and of the chlorine atom and the carbon monoxide ligand for the **A′** ⇄ **C′** isomerisation. As depicted in Scheme 10, all these reversible transformations may be achieved without any involvement of coordinatively unsaturated species. Associative pathways consisting of the transient formation of halogen-bridged dinuclear species easily account for the experimental observations. The formation of analogous dinuclear compounds by halogen-bridge formation from $RuX_2(CO)_2L_2$ complexes, which has been previously reported,[15,16] further supports such a mechanism.

The formation of the enolatophosphane derivatives **10a**,**c**,**e**, **11a**,**b**, and **12a** (Scheme 7) was found to be highly stereoselective. Preliminary coordination of the entering ligand, subsequent deprotonation of the η^1-(P)-coordinated ketophosphane and substitution of one chloride ligand by an anionic oxygen atom are the steps of a simple mechanism which account for the stereoselective formation of **10a**,**c**,**e** and **11a**,**b**. The formation of **12a** starting from **4a**, in which the ketophosphane is already η^1-(P)-coordinated, clearly provides the experimental support to such a mechanism. The formation of **13a** starting from the cationic complex **4a**, involves the simple deprotonation of the ketophosphane ligand. The NMR-spectroscopic study of **10a**,**c**,**e** allows an unambiguous structural determination. The structural determination is less accurate in the case of **11a**,**b**, but only *cis*-phosphorus and *cis*-carbonyl arrangements are observed. Thus, three structures, namely **A″**, **D″**, and **C″** (Scheme 9), remain conceivable after the examination of the NMR-spectroscopic data. Only one of them is involved in the case of **11a**, but two in the case of **11b** which reveals a mixture of two isomers. The **A″** and **D″** structures show an O−Ru−CO *trans* arrangement which may arise from **A′** and **C′** in the corresponding parent compound **7**.



Scheme 10. Simple rationale accounting for the easy isomerisation of complexes **6a**,**b** and **7a**,**b**

Only **C**′ may lead to the third structure **C**′′, which shows a Cl−Ru−CO *trans* arrangement. It should be noted that a chloride ligand is more labile when *trans* to a phosphorus atom. Therefore, the **C**′ → **C**′′ transformation will be a favoured pathway and the observation of only one isomer when starting from **7a** will thus suggest the structure **C**′′ for **11a**. The precursor **7b** involves a bulkier ancillary ligand L = $PMePh_2$ than L = PMe_3 in **7a**. For steric reasons, a slower **C**′ → **C**′′ transformation may result and a **C**′ → **D**′′ remains highly disfavoured, however, the **A**′ → **A**′′ transformation may become more competitive. This will result in a mixture of the two isomers **C**′′ and **A**′′ in the case of **11b**. This behaviour emphasises the high stability of the Cl−Ru−CO *trans* arrangement, and therefore also suggests that the favoured isomer in complexes **6a**,**b** and **6**′**a** is **A**. The observation of isomer **B** is related to steric hindrance.

Conclusion

This study of the new family of complexes *trans*-$RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] (**2**) emphasises the stability of the O→Ru bond in a *trans*-(C)=O→-Ru←(C≡O) arrangement, and the inability of the oxygen atom of the ketophosphane to coordinate *trans* to the chloride ligand. Due to this inability, the *cct* isomers of complexes **2** remain the speculative species. From this point of view, $RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] complexes remarkably differ from $RuX_2(CO)_2L_2$ compounds in which the *cct* isomers are thermodynamically favoured. The cleavage of the O→Ru bond in complexes **2**, that occurs under thermal activation or sunlight irradiation, results in a true coordinatively unsaturated species which allows the formation of stable *cis*-$RuCl_2(CO)(L)[\eta^2$-(*P*,*O*)-ketophosphane] derivatives according to a Berry rearrangement. Under less drastic conditions, the substitution of the coordinated oxygen atom by an entering ligand such as carbon monoxide probably occurs through an associative mechanism, allowing the geometry to be retained. The easy deprotonation of the ketophosphane $Ph_2PCH_2C(=O)t$Bu allows the generation of $RuCl(CO)_2(L)[\eta^2$-(*P*,*O*)-enolatophosphane] derivatives, and this transformation also preserves the geometry of the corresponding precursor complexes.

Experimental Section

General: The reactions were performed using Schlenk-type techniques, but only the handling of ketophosphanes required a rigorous exclusion of oxygen. Solvents were distilled under an inert gas after drying according to conventional methods. − Elemental analyses were performed by the Service de Microanalyse du CNRS, Vernaison, France. − Infrared spectra were recorded with a Nicolet 205 FT infrared spectrometer as Nujol mulls. − NMR spectra were recorded at 297 K with an AC 300 FT Bruker instrument (^{1}H: 300.13; ^{13}C: 75.47; ^{31}P: 121.50 MHz; absolute values of coupling constants in Hz) and referenced internally to the solvent peak. The following abbreviations are used: s: singlet; d: doublet; t: triplet; t_a: apparent triplet; q_4: quadruplet; m, unresolved multiplet. − The precursor complexes $RuCl_2(L)(\eta^6$-*p*-cymene) were obtained by treating $[RuCl_2(\eta^6$-*p*-cymene)]$_2$ with a stoichiometric amount of the corresponding phosphorus derivative L.[18] The ketophosphanes $Ph_2PCH_2C(=O)t$Bu (**1**), $Ph_2PCMe_2C(=O)i$Pr (**1**′), and $Ph_2PCMe_2CH_2C(=O)$Me (**1**′′), were prepared as previously reported.[12,14]

Synthesis of Complexes 2−2′′

(*ttt*)-$RuCl_2(CO)(PMe_3)[Ph_2PCH_2C(t$Bu)=O] (2a): $RuCl_2(PMe_3)$(*p*-cymene) (13.3 g, 34.8 mmol) was added to a solution of ketophosphane **1** (9.90 g, 34.8 mmol) in methanol (200 mL). As for the preparation of the other complexes **2−2**′′, the Schlenk tube was protected from light with aluminium foil and the mixture was then stirred under carbon monoxide at room temperature. After 2 d, the resulting slurry was heated and then filtered to obtain an orange solution that deposited orange crystals on cooling. Yield 13.6 g, 70%. − ^{1}H NMR ($CDCl_3$): δ = 7.60−7.39 (m, 10 H, Ph), 4.04 (dd, 2 H, $^2J_{PH}$ = 10.1, $^4J_{PH}$ = 1.4, PCH_2), 1.70 (dd, 9 H, $^2J_{PH}$ = 10.3, $^4J_{PH}$ = 2.3, PMe_3), 1.33 (s, 9 H, *t*Bu). − ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 229.5 (dd, $^2J_{PC}$ = 8.6, $^3J_{PC}$ = 4.9, C=O), 205.8 (dd, $^2J_{PC}$ = 17.1 and 11.0, C≡O), 133.6 (d, $^3J_{PC}$ = 11.0, Ph_2P, *meta*), 131.2 (dd, $^1J_{PC}$ = 42.1, $^3J_{PC}$ = 7.3, Ph_2P, *ipso*), 131.0 (d, $^4J_{PC}$ = 2.4, Ph_2P, *para*), 128.9 (d, $^2J_{PC}$ = 9.8, Ph_2P, *ortho*), 46.3 (d, $^3J_{PC}$ = 3.5, CMe_3), 43.0 (d, $^1J_{PC}$ = 23.8, PCH_2), 27.1 (s, CMe_3), 13.8 (d, $^1J_{PC}$ = 28.9, PMe_3). − ^{13}C NMR (CD_2Cl_2, selected values): δ = 229.5 (broad, C=O), 205.8 (dd, $^2J_{PC}$ = 17.1 and 11.0, C≡O), 43.0 (td, $^1J_{HC}$ = 131, $^1J_{PC}$ = 23.8, PCH_2), 13.8 (q_4d, $^1J_{HC}$ = 130, $^1J_{PC}$ = 28.9, PMe_3). − $C_{22}H_{30}Cl_2O_2P_2Ru$ (560.4): calcd. C 47.15, H 5.40, Cl 12.65, P 11.05; found C 47.48, H 5.49, Cl 12.60, P 11.00. − Probably due to a solid-state effect, the IR absorptions (Table 1)

assigned to the carbon monoxide ligand and to the keto functionality are split.

(*ttt*)-$RuCl_2(CO)(PMePh_2)[Ph_2PCH_2C(tBu)=O]$ (2b): A mixture consisting of $RuCl_2(PMePh_2)$(*p*-cymene) (7.00 g, 13.8 mmol) and ketophosphane **1** (4.00 g, 14.1 mmol) was dissolved in dichloromethane (30 mL), and methanol (70 mL) was then added. The mixture was stirred for 3 d (under carbon monoxide) and the resulting yellow slurry was concentrated under vacuum and diethyl ether was then added. The yellow precipitate was collected by filtration and then dissolved in dichloromethane (50 mL). The solution was filtered and the orange filtrate was covered with ethanol (250 mL) in an open flask allowing natural evaporation. Orange crystals were obtained. Yield 6.40 g, 68%. – ^{1}H NMR ($CDCl_3$): δ = 7.82–7.36 (m, 20 H, Ph), 4.06 (dd, 2 H, $^2J_{PH}$ = 10.5, $^4J_{PH}$ = 1.3, PCH_2), 2.23 (dd, 3 H, $^2J_{PH}$ = 9.2, $^4J_{PH}$ = 1.9, PMe), 1.08 (s, 9 H, *t*Bu). – $C_{32}H_{34}Cl_2O_2P_2Ru$ (684.5): calcd. C 56.15, H 5.01, Cl 10.36, P 9.05; found C 56.18, H 4.92, Cl 10.31, P 9.06.

(*ttt*)-$RuCl_2(CO)(PiPrPh_2)[Ph_2PCH_2C(tBu)=O]\cdot CH_2Cl_2$ (2c): Complex **2c** was similarly obtained in a 49% yield starting from $RuCl_2(PiPrPh_2)$(*p*-cymene) and ketophosphane **1**. – ^{1}H NMR (CD_2Cl_2): δ = 7.69–7.30 (m, 20 H, Ph), 3.97 (dd, 2 H, $^2J_{PH}$ = 10.2, $^4J_{PH}$ = 0.7, PCH_2), 3.46 (m, 1 H, C*H*Me$_2$), 1.04 (dd, 6 H, $^3J_{HH}$ = 7.0, $^3J_{PH}$ = 14.8, CH*Me*$_2$), 0.87 (s, 9 H, *t*Bu). – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 228.0 (dd, $^2J_{PC}$ = 7.1, $^4J_{PC}$ = 4.6, C=O), 206.8 (t_a, $^2J_{PC} \approx {}^2J_{P'C} \approx$ 13.4, C≡O), 135.2 (d, $^3J_{PC}$ = 8.2, Ph_2P, *meta*), 133.6 (dd, $^3J_{PC}$ = 9.9, $^5J_{PC}$ = 1.5, Ph_2P, *meta*), 131.1 (d, $^4J_{PC}$ = 2.1, Ph_2P, *para*), 130.9 (dd, $^1J_{PC}$ = 44.0, $^3J_{PC}$ = 4.4, Ph_2P, *ipso*), 130.2 (d, $^4J_{PC}$ = 1.7, Ph_2P, *para*), 130.1 (dd, $^1J_{PC}$ = 35.6, $^3J_{PC}$ = 3.3, Ph_2P, *ipso*), 128.8 (d, $^2J_{PC}$ = 9.8, Ph_2P, *ortho*), 128.1 (d, $^2J_{PC}$ = 8.8, Ph_2P, *ortho*), 45.9 (d, $^3J_{PC}$ = 2.9, *C*Me$_3$), 43.1 (d, $^1J_{PC}$ = 24.2, PCH_2), 26.8 (s, C*Me*$_3$), 22.6 (dd, $^1J_{PC}$ = 23.9, $^3J_{PC}$ = 1.8, *C*HMe$_2$), 18.1 (s, CH*Me*$_2$). – Easy loss of dichloromethane from the crystals occurs as seen by the elemental analysis results, which indicated the retention of only 0.8 CH_2Cl_2 per Ru; $C_{34}H_{38}Cl_2O_2P_2Ru\cdot$(0.8 CH_2Cl_2) (712.6 + 67.9 = 780.5): calcd. C 53.55, H 5.11, Cl 16.35, P 7.94; found C 53.56, H 5.15, Cl 16.47, P 7.95. – Probably due to a solid-state effect, the IR absorptions (Table 1) assigned to the carbon monoxide ligand and to the keto functionality are split.

(*ttt*)-$RuCl_2(CO)(PPh_3)[Ph_2PCH_2C(tBu)=O]\cdot{}^2/_3CH_2Cl_2$ (2d): A mixture was prepared starting from $RuCl_2(PPh_3)$(*p*-cymene) (9.50 g, 16.7 mmol), ketophosphane **1** (4.84 g, 17.0 mmol), dichloromethane (25 mL), and methanol (130 mL). It was stirred for 3 d. The resulting yellow precipitate was collected by filtration and washed with diethyl ether (100 mL). Yield 9.70 g, 72%. The low solubility of the compound precludes further purification.

Recovery of 2d from 5d: A solution of **5d** (4.00 g, 5.08 mmol) in dichloromethane (50 mL) was kept in the dark at room temperature. Orange crystals were collected after 10 d. Yield 1.58 g, 39%. – ^{1}H NMR (CD_2Cl_2): δ = 7.75–7.35 (m, 25 H, Ph), 4.12 (dd, 2 H, $^2J_{PH}$ = 10.7, $^4J_{PH}$ = 1.4, PCH_2), 1.11 (s, 9 H, *t*Bu). – $C_{37}H_{36}Cl_2O_2P_2Ru\cdot({}^2/_3\ CH_2Cl_2)$ (746.6 + 56.6 = 803.2): calcd. C 56.32, H 4.69, Cl 14.71, P 7.71; found C 56.06, H 4.69, Cl 15.12, P 7.33.

(*ttt*)-$RuCl_2(CO)[P(OMe)Ph_2][Ph_2PCH_2C(tBu)=O]$ (2e): Methanol (120 mL) was added to a solution consisting of $RuCl_2[Ph_2PCH_2C(=O)tBu]$(*p*-cymene)[14] (5.47 g, 9.26 mmol) and $P(OMe)Ph_2$ (3.20 mL, 16.0 mmol) in dichloromethane (60 mL). This mixture was stirred for 3 d. The resulting yellow slurry was concentrated under vacuum and diethyl ether was added. The yellow precipitate was collected by filtration and washed with diethyl ether. Yield 3.40 g, 52%. This crude product was found pure by NMR-spectroscopic analysis. Fractional crystallisation from a dichloromethane/ethanol mixture allowed the formation of orange-yellow crystals of analytical quality. – ^{1}H NMR (CD_2Cl_2): δ = 7.93–7.40 (m, 20 H, Ph), 4.07 (dd, 2 H, $^2J_{PH}$ = 10.5, $^4J_{PH}$ = 1.5, PCH_2), 3.65 (d, 3 H, $^3J_{PH}$ = 13.0, OMe), 0.99 (s, 9 H, *t*Bu). – $C_{32}H_{34}Cl_2O_3P_2Ru$ (700.5): calcd. C 54.86, H 4.89, Cl 10.12, P 8.84; found C 54.59, H 4.87, Cl 10.30, P 8.50.

(*ttt*)-$RuCl_2(CO)(PMe_3)[Ph_2PCMe_2C(iPr)=O]$ (2′a): A mixture consisting of $RuCl_2(PMe_3)$(*p*-cymene) (2.37 g, 6.20 mmol), ketophosphane **1′** (1.85 g, 6.20 mmol) and methanol (40 mL), was stirred for 2 d. The resulting yellow slurry was cooled to –20 °C and the yellow crystalline precipitate was then collected by filtration and washed with cold methanol (20 mL). Yield 3.00 g, 84%. Orange-yellow crystals were obtained by recrystallisation from hot methanol. – ^{1}H NMR (CD_2Cl_2): δ = 7.61–7.40 (m, 10 H, Ph), 3.33 (m, 1 H, C*H*Me$_2$), 1.67 (dd, 9 H, $^2J_{PH}$ = 10.4, $^4J_{PH}$ = 2.2, PMe_3), 1.54 (d, 6 H, $^3J_{PH}$ = 9.9, $PCMe_2$), 1.27 (d, 6 H, $^3J_{HH}$ = 6.6, CH*Me*$_2$). – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 229.8 (dd, $^2J_{PC}$ = 13.2, $^3J_{PC}$ = 3.9, C=O), 205.2 (dd, $^2J_{PC}$ = 16.4 and 10.0, C≡O), 136.1 (dd, $^3J_{PC}$ = 10.3, $^5J_{PC}$ = 1.1, Ph_2P, *meta*), 131.1 (d, $^4J_{PC}$ = 2.3, Ph_2P, *para*), 128.4 (dd, $^1J_{PC}$ = 38.6, $^3J_{PC}$ = 1.7, Ph_2P, *ipso*), 128.1 (d, $^2J_{PC}$ = 9.7, Ph_2P, *ortho*), 55.3 (d, $^1J_{PC}$ = 17.2, P*C*Me$_2$), 36.9 (d, $^3J_{PC}$ = 2.9, *C*HMe$_2$), 24.4 (s, PC*Me*$_2$), 20.9 (s, CH*Me*$_2$), 13.7 (dd, $^1J_{PC}$ = 29.8, $^3J_{PC}$ = 1.5, PMe_3). – $C_{23}H_{32}Cl_2O_2P_2Ru$ (574.4): calcd. C 48.09, H 5.62, Cl 12.34, P 10.78; found C 48.10, H 5.63, Cl 12.11, P 10.93.

(*ttt*)-$RuCl_2(CO)[P(OMe)Ph_2][Ph_2PCMe_2C(iPr)=O]$ (2′e): A mixture consisting of $RuCl_2[P(OMe)Ph_2]$(*p*-cymene) (5.20 g, 9.95 mmol), ketophosphane **1′** (3.08 g, 10.3 mmol), dichloromethane (15 mL), and methanol (90 mL), was stirred for 4 d. The resulting mixture was concentrated under vacuum and diethyl ether was then added. A yellow precipitate (6.20 g) was collected by filtration and washed with diethyl ether. This solid was dissolved in dichloromethane (40 mL) and the orange solution was covered with methanol (40 mL) and diethyl ether (100 mL) to obtain orange crystals. Yield 5.15 g, 72%. – ^{1}H NMR ($CDCl_3$): δ = 7.98–7.39 (m, 20 H, Ph), 3.63 (d, 3 H, $^3J_{PH}$ = 12.9, OMe), 3.09 (m, 1 H, C*H*Me$_2$), 1.52 (d, 6 H, $^3J_{PH}$ = 9.9, $PCMe_2$), 0.80 (d, 6 H, $^3J_{HH}$ = 6.7, CH*Me*$_2$). – $C_{33}H_{36}Cl_2O_3P_2Ru$ (714.6): calcd. C 55.47, H 5.08, Cl 9.92, P 8.67; found C 55.38, H 5.06, Cl 10.12, P 8.47.

(*ttt*)-$RuCl_2(CO)[P(OMe)_3][Ph_2PCMe_2C(iPr)=O]$ (2′f): A solution obtained from $RuCl_2[P(OMe)_3]$(*p*-cymene) (4.66 g, 10.8 mmol), ketophosphane **1′** (3.23 g (10.8 mmol) and methanol (60 mL), was stirred for 7 d. The resulting orange-yellow slurry was heated to obtain an orange solution that was filtered. The filtrate was slowly cooled to –20 °C to afford orange crystals. Yield 4.10 g, 61%. – ^{1}H NMR (CD_2Cl_2): δ = 7.59–7.38 (m, 10 H, Ph), 3.86 (d, 9 H, $^3J_{PH}$ = 11.1, OMe), 3.34 (m, 1 H, C*H*Me$_2$), 1.56 (d, 6 H, $^3J_{PH}$ = 10.1, $PCMe_2$), 1.28 (d, 6 H, $^3J_{HH}$ = 6.7, CH*Me*$_2$). – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 234.6 (dd, $^2J_{PC}$ = 12.9, $^3J_{PC}$ = 4.5, C=O), 204.0 (dd, $^2J_{PC}$ = 23.1 and 10.6, C≡O), 136.2 (dd, $^3J_{PC}$ = 9.8, $^5J_{PC}$ = 1.7, Ph_2P, *meta*), 131.3 (d, $^4J_{PC}$ = 1.9, Ph_2P, *para*), 128.1 (d, $^2J_{PC}$ = 9.9, Ph_2P, *ortho*), 127.4 (dd, $^1J_{PC}$ = 41.6, $^3J_{PC}$ = 3.2, Ph_2P, *ipso*), 54.6 (d, $^1J_{PC}$ = 18.0, P*C*Me$_2$), 53.2 [d, $^2J_{PC}$ = 3.8, $P(OMe)_3$], 36.9 (d, $^3J_{PC}$ = 2.7, *C*HMe$_2$), 24.5 (s, PC*Me*$_2$), 20.8 (s, CH*Me*$_2$). – $C_{23}H_{32}Cl_2O_5P_2Ru$ (622.4): calcd. C 44.38, H 5.18, Cl 11.39, P 9.95; found C 44.48, H 5.21, Cl 11.43, P 9.90.

(*ttt*)-$RuCl_2(CO)(PMe_3)[Ph_2PCMe_2CH_2C(Me)=O]$ (2′′a): Methanol (80 mL) was added to a mixture of $RuCl_2(PMe_3)$(*p*-cymene) (2.70 g, 7.06 mmol) and ketophosphane **1′′** (2.65 g, 9.32 mmol),

and this mixture was stirred for 2 d. The volatiles were evaporated under vacuum. The resulting solid was dissolved in dichloromethane (30 mL). The solution was filtered and methanol (50 mL) was added to the orange filtrate. The slow concentration of this solution afforded orange crystals. Yield 2.35 g, 59%. − ^{1}H NMR (CD_2Cl_2): δ = 7.84−7.30 (m, 10 H, Ph), 3.50 (d, 2 H, $^3J_{PH}$ = 20.3, CH_2), 2.50 (s, 3 H, MeCO), 1.57 (dd, 9 H, $^2J_{PH}$ = 10.2, $^4J_{PH}$ = 2.1, PMe_3), 1.30 (d, 6 H, $^3J_{PH}$ = 11.3, $PCMe_2$). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 221.7 (s, C=O), 205.7 (dd, $^2J_{PC}$ = 16.5 and 13.0, C≡O), 135.8 (d, $^3J_{PC}$ = 9.0, Ph_2P, *meta*), 133.4 (d, $^1J_{PC}$ = 38.8, Ph_2P, *ipso*), 130.1 (d, $^4J_{PC}$ = 2.2, Ph_2P, *para*), 127.7 (d, $^2J_{PC}$ = 9.3, Ph_2P, *ortho*), 52.8 (d, $^2J_{PC}$ = 6.4, CH_2), 36.2 (s, MeCO), 30.3 (dd, $^1J_{PC}$ = 12.6, $^3J_{PC}$ = 1.7, P*C*Me_2), 25.6 (s, PC*Me*$_2$), 13.2 (d, $^1J_{PC}$ = 28.8, PMe_3). − $C_{22}H_{30}Cl_2O_2P_2Ru$ (560.4): calcd. C 47.15, H 5.40, Cl 12.65, P 11.05; found C 47.35, H 5.38, Cl 12.84, P 11.00.

Reactivity of Complexes 2 towards Carbon Monoxide

(*ttt*)-$RuCl_2(CO)_2(PMe_3)[Ph_2PCH_2C(=O)tBu]$ (3a): A solution of **2a** (0.15 g) in $CDCl_3$ (2.0 mL) was stirred for 2 h under carbon monoxide. The ^{1}H NMR spectrum of the resulting solution shows a 1:4 mixture of **2a** and **3a**, but the addition of hexane to such a solution selectively led to the recovery of **2a**. − ^{1}H NMR ($CDCl_3$, available values for **3a** from such a mixture of **2a** and **3a**): δ = 4.04 (dd, 2 H, $^2J_{PH}$ = 9.4, $^4J_{PH}$ = 1.4, PCH_2), 1.69 (dd, 9 H, $^2J_{PH}$ = 10.1, $^4J_{PH}$ = 2.1, PMe_3), 1.05 (s, 9 H, *t*Bu).

(*ttt*)-$RuCl_2(CO)_2(PMePh_2)[Ph_2PCH_2C(=O)tBu]$ (3b): A solution of **2b** (0.15 g) in $CDCl_3$ (2.0 mL) was treated similarly, and the ^{1}H NMR spectrum of the resulting solution shows a ca. 1:1 mixture of **2b** and **3b**. − ^{1}H NMR ($CDCl_3$, mixture of the two complexes): δ = 7.82−7.36 (m, 20 H, Ph), ca. 4.10 (2 H, PCH_2), ca. 2.20 (m, 3 H, PMe), 1.08 and 1.05 (2 s, 9 H, *t*Bu).

(*cct*)-$RuCl_2(CO)_2(PMe_3)[Ph_2PCH_2C(=O)tBu]$ (4a): An orange solution of **2a** (1.00 g, 1.78 mmol) in hot toluene (80 °C, 40 mL) was stirred for 2 d under carbon monoxide and the resulting colourless solution was concentrated under vacuum to leave the crude product. Recrystallisation from hot methanol afforded colourless crystals of **4a**. Yield 0.79 g, 75%. − ^{1}H NMR (CD_2Cl_2): δ = 7.78−7.34 (m, 10 H, Ph), 4.28 (d, 2 H, $^2J_{PH}$ = 7.6, PCH_2), 1.60 (dd, 9 H, $^2J_{PH}$ = 10.8, $^4J_{PH}$ = 2.4, PMe_3), 0.76 (s, 9 H, *t*Bu). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 210.0 (dd, $^2J_{PC}$ = 10.0, $^4J_{PC}$ = 1.9, C=O), 193.4 (dd, $^2J_{PC}$ = 11.5 and 10.0, C≡O), 133.6 (d, $^3J_{PC}$ = 9.8, Ph_2P, *meta*), 131.2 (dd, $^1J_{PC}$ = 44.9, $^3J_{PC}$ = 1.4, Ph_2P, *ipso*), 131.1 (d, $^4J_{PC}$ = 2.3, Ph_2P, *para*), 128.5 (d, $^2J_{PC}$ = 10.0, Ph_2P, *ortho*), 46.0 (s, *C*Me_3), 31.8 (d, $^1J_{PC}$ = 25.0, PCH_2), 26.0 (s, C*Me*$_3$), 15.3 (dd, $^1J_{PC}$ = 33.3, $^3J_{PC}$ = 1.2, PMe_3). − ^{13}C NMR (CD_2Cl_2, selected values): δ = 31.8 (td, $^1J_{HC}$ = 130, $^1J_{PC}$ = 25.0, PCH_2). − $C_{23}H_{30}Cl_2O_3P_2Ru$ (588.4): calcd. C 46.95, H 5.14, Cl 12.05, P 10.53; found C 46.63, H 5.33, Cl 11.83, P 10.16.

(*cct*)-$RuCl_2(CO)_2(PMePh_2)[Ph_2PCH_2C(=O)tBu]\cdot CH_2Cl_2$ (4b): Complex **4b** was similarly obtained as colourless crystals in a 70% yield starting from **2b**. − ^{1}H NMR ($CDCl_3$): δ = 7.90−7.37 (m, 20 H, Ph), 4.50 (d, 2 H, $^2J_{PH}$ = 8.0, PCH_2), 2.30 (dd, 3 H, $^2J_{PH}$ = 10.6, $^4J_{PH}$ = 1.6, PMe), 0.79 (s, 9 H, *t*Bu). − $C_{33}H_{34}Cl_2O_3P_2Ru\cdot CH_2Cl_2$ (712.6 + 84.9 = 797.5): calcd. C 51.21, H 4.55, Cl 17.78, P 7.77; found C 51.21, H 4.64, Cl 16.98, P 7.71; the low chlorine value is attributed to an easy partial loss of CH_2Cl_2.

(*cct*)-$RuCl_2(CO)_2(PMe_3)[Ph_2PCMe_2C(=O)iPr]\cdot MeOH$ (4′a): A solution of **2′a** (3.00 g, 5.22 mmol) in hot toluene (85 °C, 60 mL) was stirred for 20 h under carbon monoxide, and the resulting colourless solution was concentrated to dryness under vacuum. Recrystallisation from hot methanol afforded colourless crystals. Yield 2.86 g, 86%. − ^{1}H NMR (CD_2Cl_2): δ = 7.87−7.28 (m, 10 H, Ph), 3.38 (s, 3 H, MeOH), 3.26 (m, 1 H, C*H*Me_2), 1.66 (dd, 9 H, $^2J_{PH}$ = 10.9, $^4J_{PH}$ = 2.4, PMe_3), 1.47 (d, 6 H, $^3J_{PH}$ = 12.9, $PCMe_2$), 1.19 (d, 6 H, $^3J_{HH}$ = 6.7, CH*Me*$_2$). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 218.0 (s, C=O), 193.9 (t_a, $^2J_{PC} \approx {}^2J_{P'C} \approx$11.3, C≡O), 136.4 (d, $^3J_{PC}$ = 7.9, Ph_2P, *meta*), 132.8 (d, $^1J_{PC}$ = 35.8, Ph_2P, *ipso*), 130.5 (d, $^4J_{PC}$ = 2.2, Ph_2P, *para*), 127.8 (d, $^2J_{PC}$ = 9.4, Ph_2P, *ortho*), 53.2 (dd, $^1J_{PC}$ = 17.2, $^3J_{PC}$ = 2.3, P*C*Me_2), 50.8 (s, MeOH), 35.7 (s, *C*HMe_2), 22.0 (s, PC*Me*$_2$), 20.7 (s, CH*Me*$_2$), 15.3 (d, $^1J_{PC}$ = 35.4, PMe_3). − $C_{24}H_{32}Cl_2O_3P_2Ru\cdot MeOH$ (602.4 + 32.0 = 634.5): calcd. C 47.33, H 5.72, Cl 11.18, P 9.76; found C 47.26, H 5.85, Cl 10.93, P 9.54.

Reactivity of Complexes 2 towards Acetonitrile

(*cct*)-$RuCl_2(CO)(MeCN)(PMe_3)[Ph_2PCH_2C(=O)tBu]$ (5a): **2a** (1.96 g, 3.50 mmol) was heated in acetonitrile (25 mL) to obtain a pale-yellow solution. On standing overnight at room temperature, lemon-yellow crystals formed. They were collected and then washed with acetonitrile (10 mL). Yield 1.75 g, 83%. − ^{1}H NMR (CD_2Cl_2): δ = 7.97−7.36 (m, 10 H, Ph), 4.40 (dd, 1 H, $^2J_{HH}$ = 17.1, $^2J_{PH}$ = 8.6, PCH_2, H_a), 4.25 (dd, 1 H, $^2J_{HH}$ = 17.0, $^2J_{PH}$ = 5.0, PCH_2, H_b), 1.64 (s, 3 H, MeCN), 1.54 (dd, 9 H, $^2J_{PH}$ = 10.3, $^4J_{PH}$ = 2.3, PMe_3), 0.74 (s, 9 H, *t*Bu). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 211.0 (dd, $^2J_{PC}$ = 10.7, $^4J_{PC}$ = 2.5, C=O), 199.5 (dd, $^2J_{PC}$ = 13.6 and 11.5, C≡O), 135.2 (d, $^3J_{PC}$ = 10.8, Ph, *meta*), 133.2 (d, $^3J_{PC}$ = 9.0, Ph, *meta*), 131.5 (d, $^1J_{PC}$ = 38.6, Ph, *ipso*), 130.9 (d, $^4J_{PC}$ = 2.7, Ph, *para*), 130.7 (d, $^1J_{PC}$ = 38.6, Ph, *ipso*), 129.6 (d, $^4J_{PC}$ = 1.8, Ph, *para*), 128.2 (d, $^2J_{PC}$ = 9.9, Ph, *ortho*), 128.0 (d, $^2J_{PC}$ = 9.0, Ph, *ortho*), 122.7 (s, Me*C*N), 45.9 (s, *C*Me_3), 31.4 (d, $^1J_{PC}$ = 19.9, PCH_2), 25.8 (s, C*Me*$_3$), 14.1 (d, $^1J_{PC}$ = 30.5, PMe_3), 3.6 (s, *Me*CN). − $C_{24}H_{33}Cl_2NO_2P_2Ru$ (601.5): calcd. C 47.93, H 5.53, Cl 11.79, N 2.33, P 10.30; found C 48.20, H 5.69, Cl 11.69, N 2.45, P 10.33.

(*cct*)-$RuCl_2(CO)(MeCN)(PMePh_2)[Ph_2PCH_2C(=O)tBu]$ (5b): Similarly, **2b** (2.12 g, 3.10 mmol) was heated in acetonitrile (30 mL) to obtain a pale-yellow solution that deposited lemon-yellow crystals. Yield 1.83 g, 81%. − ^{1}H NMR (CD_2Cl_2): δ = 8.00−7.32 (m, 20 H, Ph), 4.48 (dd, 1 H, $^2J_{HH}$ = 17.1, $^2J_{PH}$ = 8.9, PCH_2, H_a), 4.40 (dd, 1 H, $^2J_{HH}$ = 17.1, $^2J_{PH}$ = 5.8, PCH_2, H_b), 2.21 (dd, 3 H, $^2J_{PH}$ = 9.9, $^4J_{PH}$ = 1.7, PMe), 1.05 (s, 3 H, MeCN), 0.75 (s, 9 H, *t*Bu). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 210.9 (dd, $^2J_{PC}$ = 10.6, $^4J_{PC}$ = 1.7, C=O), 199.8 (t_a, $^2J_{PC} \approx {}^2J_{P'C} \approx$ 12.5, C≡O), 135.6−127.8 (m, 4 Ph groups), 122.0 (s, Me*C*N), 46.0 (s, *C*Me_3), 31.3 (d, $^1J_{PC}$ = 21.3, PCH_2), 25.8 (s, C*Me*$_3$), 12.5 (dd, $^1J_{PC}$ = 30.4, $^3J_{PC}$ = 1.4, PMe), 2.7 (s, *Me*CN). − $C_{34}H_{37}Cl_2NO_2P_2Ru$ (725.6): calcd. Isomerisation of Complexes 2−2′

(*ccc*/*ctc*)-RuCl$_2$(CO)(PMe$_3$)[Ph$_2$PCH$_2$C(*t*Bu)=O] (6a). − Photo-Isomerisation of 2a: In a typical experiment, **2a** (2.00 g, 3.57 mmol) was dissolved in dichloromethane (50 mL) in a Schlenk flask. The flask was closed and placed behind a window where it was exposed to sunlight. After standing for two weeks (corresponding to ca. 50 h of exposure to sunlight), the solvent was removed under vacuum. The resulting solid was analysed by ^{1}H NMR spectroscopy, which indicated a 85% formation of **6a**. The solid was then dissolved in hot ethanol (60 mL) to obtain a solution that deposited pale-yellow crystals of **6a** on cooling. Yield 1.35 g, 68%. − **Thermally Induced Isomerisation of 2a:** A mixture of **2a** (2.00 g, 3.57 mmol) and toluene (30 mL) was heated under reflux for 20 h. The resulting cream-coloured precipitate was collected by filtration and dried under vacuum. Yield 1.54 g, 77%. − ^{1}H NMR (CD_2Cl_2): δ = 7.92−7.29 (m, 10 H, Ph), 4.26 (dd, 1 H, $^2J_{HH}$ = 17.9, $^2J_{PH}$ = 11.4, PCH_2, H_a), 4.09 (dd, 1 H, $^2J_{HH}$ = 17.9, $^2J_{PH}$ = 10.8, PCH_2, H_b), 1.51 (d, 9 H, $^2J_{PH}$ = 11.2, PMe_3), 1.29 (s, 9 H, *t*Bu). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 227.2 (t_a, $^2J_{PC} \approx {}^3J_{PC} \approx$ 2.0, C=O), 197.5 (dd, $^2J_{PC}$ = 19.5 and 12.8, C≡O), 134.4 (d, $^3J_{PC}$ = 10.4, Ph, *meta*), 133.9 (d, $^1J_{PC}$ = 50.1, Ph, *ipso*), 132.2 (d, $^4J_{PC}$ = 2.4, Ph, *para*), 131.7 (d, $^4J_{PC}$ = 2.4, Ph, *para*), 131.2 (d, $^2J_{PC}$ = 10.4, Ph, *ortho*), 130.2 (d, $^1J_{PC}$ = 24.4, Ph, *ipso*), 129.7 (d, $^3J_{PC}$ = 9.8, Ph, *meta*), 129.2 (d, $^2J_{PC}$ = 11.0, Ph, *ortho*), 47.2 (d, $^1J_{PC}$ = 30.5, PCH_2), 46.0 (t_a, $^3J_{PC} \approx {}^4J_{PC} \approx$ 3.0, *C*Me_3), 27.1 (s, C*Me*$_3$), 19.2 (d, $^1J_{PC}$ = 37.3, PMe_3). The second but very minor isomer was only detected by $^{31}P\{^1H\}$ NMR spectroscopy (Table 1). − $C_{22}H_{30}Cl_2O_2P_2Ru$ (560.4): calcd. C 47.15, H 5.40, Cl 12.65, P 11.05; found C 47.41, H 5.43, Cl 12.21, P 10.77.

(*ccc*/*ctc*)-RuCl$_2$(CO)(PMePh$_2$)[Ph$_2$PCH$_2$C(*t*Bu)=O] (6b). − Photo-Isomerisation of 2b: A solution of **2b** (11.3 g, 16.5 mmol) in dichloromethane (150 mL) was treated as above. After 3 weeks of exposure to sunlight, the solvents were evaporated and the remaining solid was dissolved in methanol (100 mL) to obtain a solution that slowly deposited pale-yellow crystals of **6b**. Yield 5.95 g, 53%. The mother liquor was stirred under carbon monoxide for 20 h to afford a colourless precipitate of **4b** (3.08 g, overall yield 79%, with respect to the recovery of ruthenium). − **Thermally Induced Isomerisation of 2b:** A mixture of **2b** (3.54 g, 5.17 mmol) and toluene (50 mL) was heated as above to obtain a cream-coloured precipitate. Yield 2.60 g, 73%. − ^{1}H NMR (CD_2Cl_2, asterisk-marked values for the major ca. 3:2 isomer): δ = 7.90−7.60 (m, 20 H, Ph), 4.24* and 4.32 (2 dd, 1 H, $^2J_{HH}$ = 17.9* and 18.0, $^2J_{PH}$ = 10.8* and 10.9, PCH_2, H_a), 4.15 and 4.11* (2 dd, 1 H, partially overlapped, $^2J_{PH}$ = 10.8*, PCH_2, H_b), 2.19* and 1.15 (2 d, 3 H, $^2J_{PH}$ = 10.9* and 9.5, PMe), 1.30* and 1.12 (2 s, 9 H, *t*Bu). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, asterisk-marked values for the major isomer): δ = 227.4* (t_a, $^2J_{PC} \approx {}^3J_{P'C} \approx$ 1.7, C=O), 227.2 (d, $^2J_{PC}$ = 2.9, C=O), 203.9 (dd, $^2J_{PC}$ = 19.1 and 14.5, C≡O), 197.4* (dd, $^2J_{PC}$ = 19.0 and 12.9, C≡O), 137.8−127.6 (m, Ph resonances for both isomers), 48.7* (d, $^1J_{PC}$ = 31.5, PCH_2), 48.5 (d, $^1J_{PC}$ = 33.9, PCH_2), 45.6* (d, $^3J_{PC}$ = 3.4, *C*Me_3), 45.6 (d, $^3J_{PC}$ = 2.9, *C*Me_3), 27.0* (s, C*Me*$_3$), 26.7 (s, C*Me*$_3$), 17.9* (d, $^1J_{PC}$ = 36.1, PMe), 16.6 (d, $^1J_{PC}$ = 37.0, PMe). − $C_{32}H_{34}Cl_2O_2P_2Ru$ (684.5): calcd. C 56.15, H 5.01, Cl 10.36, P 9.05; found C 55.86, H 5.10, Cl 10.40, P 9.29.

(*ccc*/*ctc*)-RuCl$_2$(CO)(PMe$_3$)[Ph$_2$PCMe$_2$C(*i*Pr)=O] (6′a). − Photo-Isomerisation of 2′a: Exposure to sunlight of a solution of **2′a** (3.00 g, 5.22 mmol) in dichloromethane (50 mL) resulted in a pale-yellow solution. Toluene (150 mL) was then added and partial slow evaporation of the solvents afforded pale-yellow crystals of **6′a·toluene**. Yield 2.36 g, 68%. − **Thermally Induced Isomerisation of 2′a:** A mixture of **2′a** (4.00 g, 6.96 mmol) and ethanol (60 mL) was heated under reflux for 3 d. The resulting solution was concentrated to dryness to leave a pale-yellow solid that was identified as pure **6′a** by NMR spectroscopy and elemental analysis. − ^{1}H NMR ($CDCl_3$): δ = 8.16−7.20 (m, 10 H, Ph), 3.28 (m, 1 H, C*H*Me_2), 1.52 (d, 9 H, $^2J_{PH}$ = 11.0, PMe_3), 1.49 (d, 3 H, $^3J_{PH}$ = 9.5, PC*Me*), 1.39 (d, 3 H, $^3J_{PH}$ = 12.8, PC*Me*), 1.39 (d, 3 H, $^3J_{HH}$ = 6.8, CH*Me*), 1.32 (d, 3 H, $^3J_{HH}$ = 6.6, CH*Me*). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 232.4 (dd, $^2J_{PC}$ = 7.2, $^3J_{PC}$ = 1.8, C=O), 197.6 (dd, $^2J_{PC}$ = 19.8 and 12.6, C≡O), 136.4 (d, $^2J_{PC}$ = 9.0, Ph, *ortho*), 133.0 (d, $^1J_{PC}$ = 46.7, Ph, *ipso*), 133.0 (d, $^3J_{PC}$ = 9.0, Ph, *meta*), 132.7 (s, Ph, *para*), 131.5 (s, Ph, *para*), 129.1 (d, $^3J_{PC}$ = 10.8, Ph, *meta*), 128.7 (d, $^2J_{PC}$ = 10.8, Ph, *ortho*), 125.9 (d, $^1J_{PC}$ = 43.1, Ph, *ipso*), 58.6 (d, $^1J_{PC}$ = 25.1, P*C*Me_2), 37.1 (d, $^3J_{PC}$ = 3.6, *C*HMe_2), 24.4 (s, CH*Me*), 23.0 (s, CH*Me*), 20.7 (s, PC*Me*), 20.5 (s, PC*Me*), 18.8 (d, $^1J_{PC}$ = 37.7, PMe_3). − $C_{23}H_{32}Cl_2O_2P_2Ru$: calcd. C 48.09, H 5.62, Cl 12.34, P 10.78; found C 48.10, H 5.70, Cl 12.26, P 10.67. − $C_{23}H_{32}Cl_2O_2P_2Ru$·toluene (574.4 + 92.1 = 666.5): calcd. C 54.06, H 6.05, Cl 10.64, P 9.29; found C 53.93, H 6.13, Cl 10.67, P 9.23.

Reactivity of Complexes 6−6′ towards Carbon Monoxide

(*ccc*)-RuCl$_2$(CO)$_2$(PMe$_3$)[Ph$_2$PCH$_2$C(=O)*t*Bu] (7a): A pale-yellow solution of **6a** (2.50 g, 4.46 mmol) in dichloromethane (30 mL) was stirred for 20 h under carbon monoxide, and the resulting clear solution was covered with hexane (100 mL) under the carbon monoxide, to obtain **7a** as colourless crystals. Yield 2.28 g, 87%. Alternatively, a solution of **6a** (2.00 g, 3.57 mmol) in methanol (40 mL) was stirred for 20 h under carbon monoxide to afford **7a** (as determined by NMR and IR spectroscopy) as a white precipitate that was collected by filtration and dried. Yield 1.73 g, 82%. Attempts to recrystallise from hot methanol afforded colourless crystals, but of the *cct* isomer **4a**. − ^{1}H NMR (CD_2Cl_2, asterisk-marked values for the major 3:1 isomer): δ = 7.86−7.41 (m, 10 H, Ph), 4.72* and 4.33 (2 dd, 1 H, $^2J_{HH}$ = 17.8* and 17.3, $^2J_{PH}$ = 7.5* and 6.8, PCH_2, H_a), 4.39* and 4.02 (2 dd, 1 H, $^2J_{PH}$ = 7.5* and 9.9, PCH_2, H_b), 1.24* and 1.23 (2 d, 9 H, $^2J_{PH}$ = 10.6* and 10.3, PMe_3), 1.06 and 0.81* (2 s, 9 H, *t*Bu). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2, asterisk-marked values for the major isomer): δ = 209.9* (d, $^2J_{PC}$ = 10.4, C=O), 208.7 (d, $^2J_{PC}$ = 6.1, C=O), 194.9 (dd, $^2J_{PC}$ = 15.9 and 12.2, C≡O), 194.0* (t_a, $^2J_{PC} \approx {}^2J_{P'C} \approx$ 13.4, C≡O), 190.1* (dd, $^2J_{PC}$ = 115.4 and 11.6, C≡O), 189.7 (dd, $^2J_{PC}$ = 118.4 and 11.0, C≡O), 134.3−128.5 (m, Ph resonances for both isomers), 46.1* (d, $^3J_{PC}$ = 1.8, *C*Me_3), 45.8 (d, $^3J_{PC}$ = 2.4, *C*Me_3), 36.4 (d, $^1J_{PC}$ = 35.5, PCH_2), 32.0* (d, $^1J_{PC}$ = 28.5, PCH_2), 26.7* (s, C*Me*$_3$), 26.0 (s, C*Me*$_3$), 18.9* (d, $^1J_{PC}$ = 36.0, PMe_3), 14.3 (d, $^1J_{PC}$ = 33.0, PMe_3). − $C_{23}H_{30}Cl_2O_3P_2Ru$ (588.4): calcd. C 46.95, H 5.14, Cl 12.05, P 10.53; found C 46.80, H 5.12, Cl 11.91, P 10.73.

(*ccc*)-RuCl$_2$(CO)$_2$(PMePh$_2$)[Ph$_2$PCH$_2$C(=O)*t*Bu] (7b): Complex **7b** was studied by NMR spectroscopy after a solution of **6b** in $CDCl_3$ (or CD_2Cl_2) was stirred overnight under carbon monoxide. − ^{1}H NMR ($CDCl_3$, asterisk-marked values for the major 4:1 isomer): δ = 7.80−7.13 (m, 20 H, Ph), 4.88* and 4.47 (2 dd, 1 H, $^2J_{HH}$ = 18.0* and 17.4, $^2J_{PH}$ = 6.2* and 4.8, PCH_2, H_a), 4.35* and 1.98 (2 dd, 1 H, $^2J_{PH}$ = 7.9* and 10.2, PCH_2, H_b), 2.36 and 1.35* (2 d, 3 H, $^2J_{PH}$ = 10.9 and 10.5*, PMe), 0.82* and 0.71 (2 s, 9 H, *t*Bu). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, asterisk-marked values for the major isomer): δ = 209.9* (d, $^2J_{PC}$ = 10.6, C=O), 208.2 (d, $^2J_{PC}$ = 9.9, C=O), 194.4* (t_a, $^2J_{PC} \approx {}^2J_{P'C} \approx$ 12.4, C≡O), 193.6 (dd, $^2J_{PC}$ = 13.4 and 11.1, C≡O), 188.8 (dd, $^2J_{PC}$ = 117.4 and 10.8, C≡O), 187.7* (dd, $^2J_{PC}$ = 116.0 and 10.3, C≡O), 139.5−127.8 (m, Ph resonances for both isomers), 45.8* (d, $^3J_{PC}$ = 1.6, *C*Me_3), 45.6 (d, $^3J_{PC}$ = 1.3, *C*Me_3), 32.3* (d, $^1J_{PC}$ = 28.9, PCH_2), 31.3 (d, $^1J_{PC}$ = 26.8, PCH_2), 26.0 (s, C*Me*$_3$), 25.8* (s, C*Me*$_3$), 11.9 (d, $^1J_{PC}$ = 35.9,

PMe), 11.6* (d, $^1J_{PC}$ = 33.8, PMe). − The removal of the solvent from such solutions left a white solid consisting of a mixture of **7b** and **6b**, but allowing the determination of the main IR absorptions of **7b** in the solid state (Table 1).

Formation of 4b in Methanol: See synthesis of **6b**.

Reaction of 6′a with Carbon Monoxide: A solution of **6′a** in dichloromethane was stirred for 20 h under carbon monoxide and then examined by $^{31}P\{^1H\}$ NMR spectroscopy which indicated a complete conversion of **6′a** into **4′a**.

Cationic Derivatives

(*cct*)-{RuCl(CO)$_2$(PMe$_3$)[Ph$_2$PCH$_2$C(*t*Bu)=O]}(BF$_4$)·$^1/_2$CH$_2$Cl$_2$ (8a): A mixture consisting of **4a** (3.50 g, 5.95 mmol) and $AgBF_4$ (1.16 g, 5.95 mmol) in dichloromethane (60 mL) was stirred overnight. The resulting solution was decanted, then filtered and the filtrate was covered with diethyl ether (150 mL) to afford colourless crystals. Yield 3.15 g, 78%. Complex **8a** was obtained in a similar manner when starting from **6a** instead of **4a**. − ^1H NMR (CD_2Cl_2): δ = 7.84−7.33 (m, 10 H, Ph), 4.79 (ddd, 1 H, $^2J_{HH}$ = 18.7, $^2J_{PH}$ = 11.2, $^4J_{PH}$ = 2.9, PCH$_2$, H$_a$), 4.11 (dd, 1 H, $^2J_{HH}$ = 18.7, $^2J_{PH}$ = 10.9, PCH$_2$, H$_b$), 1.84 (dd, 9 H, $^2J_{PH}$ = 11.3, $^4J_{PH}$ = 2.6, PMe$_3$), 1.36 (s, 9 H, *t*Bu). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 238.0 (t$_a$, $^2J_{PC} \approx {}^3J_{P'C} \approx$ 4.9, C=O), 195.5 (dd, $^2J_{PC}$ = 13.3 and 9.0, C≡O), 190.0 (dd, $^2J_{PC}$ = 11.6 and 9.2, C≡O), 134.4 (dd, $^3J_{PC}$ = 11.7, $^5J_{PC}$ = 1.5, PhP, *meta*), 133.3 (d, $^4J_{PC}$ = 2.6, PhP, *para*), 132.7 (d, $^4J_{PC}$ = 2.3, PhP, *para*), 131.6 (d, $^1J_{PC}$ = 47.7, PhP, *ipso*), 130.9 (d, $^3J_{PC}$ = 11.4, PhP, *meta*), 130.4 (d, $^2J_{PC}$ = 10.7, PhP, *ortho*), 130.0 (d, $^2J_{PC}$ = 11.6, PhP, *ortho*), 125.2 (dd, $^1J_{PC}$ = 53.5, $^3J_{PC}$ = 2.6, PhP, *ipso*), 47.9 (d, $^3J_{PC}$ = 3.5, *C*Me$_3$), 44.0 (d, $^1J_{PC}$ = 30.5, PCH$_2$), 27.0 (s, C*Me*$_3$), 14.9 (dd, $^1J_{PC}$ = 33.9, $^3J_{PC}$ = 1.4, PMe$_3$). − $C_{23}H_{30}BClF_4O_3P_2Ru\cdot{}^1/_2CH_2Cl_2$ (639.7 + 42.6 = 682.2): calcd. Synthesis and Structure of an Asymmetric Binuclear Phenylhydrazonato Anionic Complex of Palladium Containing a Pd−C(aryl) Bond *cis* to a Pd−N(amido) Bond

Arancha Carbayo,[a] José V. Cuevas,[a] Gabriel García-Herbosa,*[a] Santiago García-Granda,[b] and Daniel Miguel[c]

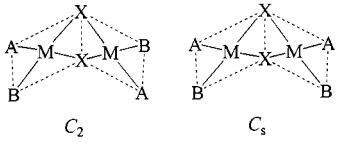
Dedicated to Professor D. Rafael Uson on the occasion of his 75th birthday

Keywords: Palladium / Hydrazones / Cyclopalladatation / Amido compounds

The synthesis and structure of a unique asymmetric folded binuclear anionic complex of palladium containing two different hydrazonato ligands and showing a Pd–N(amido) bond *cis* to a Pd–C(aryl) bond is described.

Introduction

Organometallic complexes of the platinum-group metals containing M−N(amido) bonds arranged *cis* to the M−C bond are of interest for their role as catalysts in important reactions that involve C−N bond formation, such as alkene hydroamination[1,2] and the synthesis of arylamines from aryl halides,[3] or in other processes such as hydrogenation of imines.[4,5] Non-planar binuclear complexes formed by two equivalent square-planar halves can exhibit C_2 or C_s symmetry (see Scheme 1 where M means any metal with square-planar geometry, X any atom or group of atoms bridging the two equivalent sides and A and B are different ligands). The most commonly found C_2 isomers are chiral even when formed by two equivalent moieties.



Scheme 1

Arylhydrazones are versatile ligands that provide both C−H and N−H bonds to activate. Binuclear orthopalladated phenylhydrazonato C_2 palladium(II) complexes containing Pd−C(aryl) bonds arranged *trans* to terminal Pd−N(amido) bonds have been reported, thus proving that, although rare, it is possible to obtain palladium compounds containing both bonds.[6,7] Mononuclear complexes of general formula $[PdAr(NHPh)(PMe_3)_2]$ with these two bonds in *trans* array have also been reported.[8] They were stabilized against the natural tendency of terminal Pd−N(amido) bonds to make bridges, by using P-donor ligands *cis* to the amido bond.

The stabilization of palladium compounds containing Pd−C and Pd−N(amido) bonds in a *cis* disposition has been achieved introducing the P-donor nonlabile chelating ancillary ligand DPPF [1,1′-bis(diphenylphosphanyl)ferrocene].[3] An interesting example is the recently reported mononuclear palladium hydrazonato complex $[Pd(DPPF)(Ar)(NH-N=CPh_2)]$ (Ar = *p*-tolyl); it undergoes C−N reductive elimination and plays and active role in the catalytic arylation of diphenylhydrazones.[9]

Results and Discussion

Here we report the synthesis and structural characterization of $[Bu_4N][Pd\{C_6H_4C(CH_3)=N-NHPh\}\{\mu\text{-}N(Ph)-N=C(CH_3)C_6H_4\}(\mu\text{-}Cl)PdCl]$ (**1**), an asymmetric C_1 binuclear phenylhydrazonato palladium(II) complex containing a Pd−C(aryl) bond *cis* to a Pd−N(amido) bond. It is a remarkable structure since binuclear complexes have commonly two equivalent halves and also because the *cis* arrangement of amido and aryl bonds around the palladium center is achieved without the use of P-donor ligands.

The reaction of the dimeric orthopalladated complex $[Pd\{C_6H_4C(CH_3)=N-NHPh\}(\mu\text{-}Cl)]_2$[10] with Bu_4NOH (molar ratio 1:1) in MeOH cleanly affords **1** in 79% yield. The use of an excess of Bu_4NOH (molar ratio 1:2) led to the same result indicating that the second N−H bond is difficult to deprotonate. The ^1H NMR spectrum of **1** shows two sharp singlets at δ = 2.18 and 2.24 corresponding to two methyl groups, demonstrating the presence of two nonequivalent hydrazonato ligands. A multiplet at δ = 6.28 is

assigned to the proton attached to C(14) and involved in a weak agostic Pd(2)−H−C(14) interaction.[11] The IR spectrum of **1** shows two C=N bands at $\tilde{\nu}$ = 1574 and 1587 cm^{-1}.

An ORTEP drawing of **1** is provided in Figure 1. The two previous examples of binuclear palladium hydrazonato complexes found in the Cambridge Crystallographic Database correspond to species with two equivalent halves and the Pd−C(aryl) bond *trans* to the Pd−N(amido) bond.[6,7] No previous examples of binuclear palladium(II) complexes containing a Pd−C bond *cis* to a Pd−N(amido) bond were found. Complex **1** consists of two square-planar units in a folded (C_1) array bridged by one chlorine atom and one hydrazonato ligand. The folding angle between the two coordination planes is 133.72(1)°. While both phenylhydrazonato ligands present in **1** are orthometallated to each palladium atom in a five-membered well-known fashion, only one phenylhydrazonato ligand is *N*-deprotonated. Thus, one of the phenylhydrazonato ligands is doubly deprotonated, at the C−H bond of the phenyl group and at the N−H bond. The other phenylhydrazonato ligand is singly deprotonated at a C−H bond of the phenyl group keeping the NH group protonated and uncoordinated. Attention has recently been paid to metal complexes containing a pendant NH group that can be considered as being in the intermediate coordination sphere, as they are neither directly bound to the metal center nor being in the outer sphere.[12] It allows selective two-point binding of other ligands such as ketones that may bond normally to the metal center and through hydrogen bond interaction to the NH group.

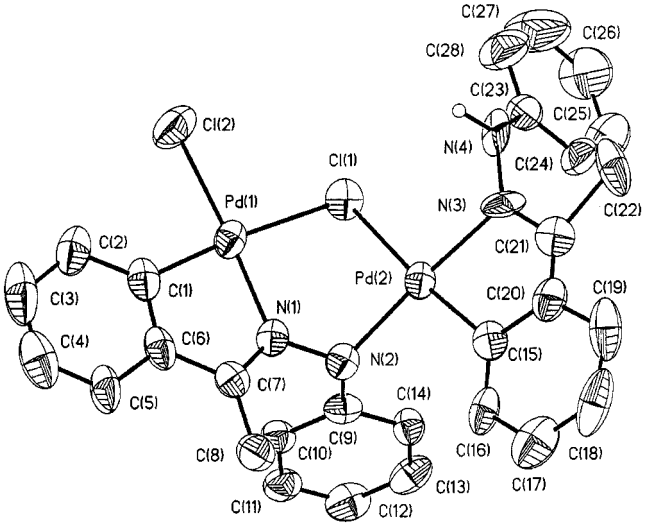

Figure 1. ORTEP drawing of **1**; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Pd1−Pd2 3.533(1), Pd1−C1 2.008(17), Pd1−N1 2.084(12), Pd1−Cl1 2.434(5), Pd1−Cl2 2.310(6), Pd2−C15 1.99(2), Pd2−N2 2.021(16), Pd2−N3 2.052(17), Pd2−Cl1 2.412(5), N1−N2 1.42(2), N3−N4 1.36(3); Cl2−Pd1−C1 94.0(9), C1−Pd1−N1 81.6(9), N1−Pd1−Cl1 92.8(5), Cl1−Pd1−Cl2 91.5(2), Cl1−Pd2−N2 89.3(5), N2−Pd2−C15 95.9(9), C15−Pd2−N3 79.0(9), N3−Pd2−Cl 95.9(5)

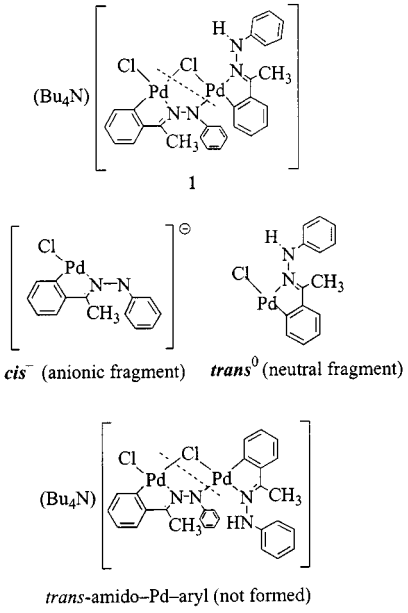
The sum of the four angles is 359.9° for Pd(1) and 360° for Pd(2). The Pd(2)−N(2) amido distance is 2.021(16) Å, similar to 2.035(9) Å which is the distance found in $[Pd(DPPF)(Ar)(NH-N=CPh_2)]$[9], a complex containing also a Pd−C(aryl) bond *cis* to a Pd−N(amido) bond. The N−N distance is noticeably different in both hydrazonato ligands. In the bridging one the N(1)−N(2) bond length is 1.42(2) Å, whereas in the other one the corresponding N(3)−N(4) distance is 1.36(3) Å. They are extreme examples of the typical N−N bond-length range in hydrazones (1.38−1.41 Å).[13]

A detailed discussion of the mechanism leading to **1** is not possible at this stage. In any case, it is clear that complex **1** is the result of the coupling of two monometallic fragments through the dashed line as shown in Scheme 2.



Scheme 2

The final geometry requires that the fragment containing the deprotonated nitrogen atom has a *cis* configuration of C and Cl atoms, whereas the fragment with the protonated nitrogen must bear a *trans* arrangement of Cl and C. It is likely that the reaction involves the cleavage of the symmetric parent dimer, probably by incorporation of solvent molecules (methanol) as labile ligands. Quantum chemical calculations using the PM3 model implemented in Mac-Spartan Pro indicate that for the neutral fragment the *trans* "C−Pd−Cl" array is more stable than the *cis* one by 4.174 $kcal \cdot mol^{-1}$. On the contrary, for the anionic fragment the *cis* arrangement is more stable than the *trans* one by 5.635 $kcal \cdot mol^{-1}$, this being consistent with the formation of the resulting geometry. Additionally, calculations carried out on both **1** and its *trans* amido−Pd−aryl isomer (see Scheme 2) indicate that the *cis* isomer **1** is more stable than the alternative *trans* isomer by ca. 18 $kcal \cdot mol^{-1}$. Aryl-palladium complexes tend to coordinate hard ligands in a position *trans* to the Pd−C(aryl) bond and to avoid

coordination of soft ligands. This fact has been reported as transphobia,[14,15] and is followed in *trans*-[PdAr(NHPh)(PMe_3)$_2$].[8] In complex **1** the hard N(amido) ligand arranges *cis* to the Pd−C(aryl) bond, leaving the softer ligand chloro in *trans* position to the Pd−C(aryl) bond. The alternative *trans* isomer of **1** would contain a Pd−C(aryl) bond with the harder amido ligand in *trans* position, obeing transphobia arguments, but this isomer is not formed. Further, but elusive at the moment, examples of amido−palladium−aryl complexes seems to be required to be able to say more about the factors that control the arrangement of these C and N donor ligands around the palladium center.

Interestingly, in spite of the adequate (and unusual) *cis* arrangement of the aryl and amido ligands to undergo reductive elimination reaction, complex **1** showed to be very stable when heated under reflux in acetone. Even in excess of PPh_3 the products of the reaction do not contain Pd^0 but Pd^{II} derivatives whose characterization is currently being carried out.

Experimental Section

General: ^{1}H (80 MHz) and ^{13}C (200 MHz) NMR data were collected in $CDCl_3$ solutions (298 K) using TMS as standard reference with a Bruker AC 80 and with a Varian VXR 200 spectrometer, respectively. Elemental analyses were performed by the Servicio Central de Apoyo a la Investigación of the University of Burgos (Spain).

Preparation of [Bu_4N][Pd{$C_6H_4C(CH_3)$=N−NHPh}{μ-N(Ph)−N=$C(CH_3)C_6H_4$}(μ-Cl)PdCl] (1): 200 mg (0.28 mmol) of [Pd{$C_6H_4C(CH_3)$=N−NHPh}(μ-Cl)]$_2$[10] were suspended in 50 mL of dichloromethane, and then 0.28 mL (0.28 mmol) of Bu_4NOH (1 M solution in methanol) was added. After stirring for 30 min at room temperature, the complex was completely dissolved to afford a red solution. The solution was stirred for 6 h and then it was filtered through kieselgur in order to remove any traces of solid. The filtrate was concentrated in vacuo and layering with hexane afforded a red precipitate which was collected and washed with hexane. The product was recrystallised from dichloromethane/hexane to yield 206 mg (79%) of the complex **1**. − $C_{44}H_{61}Cl_2N_5Pd_2$: calcd. C 55.99, H 6.52, N 7.42; found C 55.62, H 6.42, N 7.15. − ^{1}H NMR: δ = 0.91 [m, 12 H, ($^{\delta}CH_3)_4$N−], 1.32 [m, 16 H, (−$^{\gamma}CH_2$−$^{\beta}CH_2)_4$N−], 2.18 [s, 3 H, −C(CH_3)=N−N−Ph], 2.24 [s, 3 H, −C(CH_3)=N−N(H)−Ph], 3.13 [m, 8 H, (−$^{\alpha}CH_2)_4$N], 6.28 (m, 1 H, agostic), 6.99 (m, 14 H, aromatic), 7.65 (m, 2 H, aromatic), 7.91 (m, 1 H aromatic), 8.98 (s, 1 H, −NH−). − ^{13}C{^{1}H} NMR: δ = 13.8, 14.1, 14.2, 19.8, 24.0, 58.5, 113.0, 114.6, 115.6, 121.7, 123.0, 123.6, 124.5, 125.2, 125.6, 126.4, 127.7, 128.4, 128.6, 129.0, 130.2, 135.1, 135.7, 136.4, 144.7, 146.9, 154.8, 156.0, 157.3, 158.0, 176.5, 177.2.

X-ray Crystallographic Study: Crystals of **1** were grown from dichloromethane/hexane. Data were collected with an Enraf−Nonius CAD4 diffractometer. The structure was solved by Patterson methods, phase expansion, and subsequent Fourier maps with DIRDIF.[16] Full-matrix least-squares refinement was made with SHELX-93.[17] Perspective drawing in Figure 1 was made with PLATON.[18] $C_{44}H_{61}Cl_2N_5Pd_2$, M = 944.69, monoclinic, space group $P2_1/c$, a = 21.514(4) Å, b = 20.353(4) Å, c = 20.709(4) Å, β = 86.14(3)°, V = 9048(3) Å^3, Z = 8, D_c = 1.387 Mg/m^3, crystal size 0.26 × 0.20 × 0.17 mm, F(000) = 3896, T = 293(2) K, Mo-K_α radiation, λ = 0.71073 Å. 16378 reflections were measured, giving 8196 independent reflections after merging (R_{int} = 0.0564), with 4469 reflections having $I > 2\sigma(I)$. Two chemically equivalent but crystallographically independent anion/cation pairs were found in the asymmetric unit. The final indices [$I > 2\sigma(I)$] were $R1$ = 0.0808, $wR2$ = 0.2074. Crystallographic data (excluding structure factors) for the structure reported in this paper has been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-156983.Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structure−Property Dependence of the First Hyperpolarisabilities of Organometallic Merocyanines Based on the μ-Vinylcarbynediiron Acceptor and Ferrocene Donor

Tony Farrell,*[a] Anthony R. Manning,*[a] Timothy C. Murphy,[a] Timo Meyer-Friedrichsen,[b] Jürgen Heck,[b] Inge Asselberghs,[c] and André Persoons[c]

Keywords: Nonlinear optical materials / Ferrocene / Merocyanine / Hyper Rayleigh scattering / Solvatochromism / Bond-length alternation

In order to investigate the structure–property relationship of nonlinear optical materials, a series of organometallic chromophores were synthesised utilising the $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C\text{–})]^+$ electron-accepting moiety and the ferrocenyl group, Fc, as the electron donor. The π-linker between these two termini was systematically modified and the mutual electronic communication between them was determined using IR, NMR, and electronic absorption spectroscopy. An X-ray structure determination of $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C\text{–}CH{=}CH\text{–}CH{=}C(Cl)\text{–}Fc)][BF_4]$ confirmed the strong electronic interaction between the donor and the acceptor with reduced π-bridge bond-length alternation. The nonlinear optical properties of these complexes were examined using the hyper Rayleigh scattering technique. The experimental first hyperpolarisabilities are some of the highest obtained for ferrocenyl chromophores and, significantly, no enhancement was found due to two-photon absorption fluorescence. When polyene linkers $-(CH{=}CH)_n-$ are used, the values for β_0 increase with a ca. $n^{1.5}$ dependence with no sign of saturation up to $n = 4$. However, the highest values for β and β_o were obtained for linkers which contained an aromatic ring as opposed to pure polyenes and in this respect a benzene ring was more effective than a thiophene or furan. Consequently, the higher β and β_0 are not exhibited by those merocyanines with the highest values for λ_{max}. It is concluded for these compounds that a low excitation energy E_{eg} and a large transition moment M for the electronic excitation are less important than a large change in the dipole moment $\Delta\mu_{eg}$. Furthermore, a chloro substituent on the olefinic double bond proximate to the ferrocenyl group has a dramatic effect on the β and β_0 values.

Introduction

Molecular electronics is an emerging and intriguing area of research. Understanding the structure−property relationship of NLO-active chromophores is of fundamental importance if molecular architecture is to be tailored to achieve specific NLO responses. The strategy requires sequential variation of molecular parameters, full evaluation of the effects which these variations have on the ground and excited states, and then analysing the outcome on the NLO response. Organic systems have been subject to extensive studies whereby the effects of modulating such variables as spacer aromaticity, bond-length alternation, and end-group donor and acceptor strengths have been quantified.[1−7] Less work has been carried out on organometallic chromophores despite the fact that organometallic complexes are often particularly appealing because their redox states may be changed easily. However, there are now increasing numbers of ferrocenyl complexes which display interesting molecular electronic functions such as nonlinear optical (NLO) properties (including frequency doubling and tripling of incident light),[8−13] and metallocenes have been used in amperometric sensory devices[14] and liquid crystals.[15,16]

One of our approaches has been to synthesise complexes which utilise the cationic diiron moiety $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C-)]^+$ moiety, as an electron acceptor in molecular systems which are candidates for second harmonic generation (SHG). This end-group is particularly attractive because theoretical[17] and experimental[18−22] research has indicated that conjugation between the $Fe_2(\mu\text{-}C)$ unit and the substituted vinyl system is maintained throughout rotation about the μ-C-vinyl bond.

Hyper Rayleigh scattering (HRS) studies using 1064 nm incident light on the stilbenyldiiron series $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C{-}CH{=}CH{-}C_6H_4{-}CH{=}CH{-}C_6H_4{-}R)][BF_4]$ (where R = NO_2, H, OMe, NMe_2), were promising.[22] Based on these findings the objective of this work was to prepare a comparable series of merocyanines utilising the diiron cationic electron acceptor and ferrocene as the donor. It was proposed that modifications of the π-bridge between these termini by incorporating olefins and aryl or heteroaryl units as well as more subtle changes, i.e. replacing an H atom on an olefinic unit by a Cl atom along

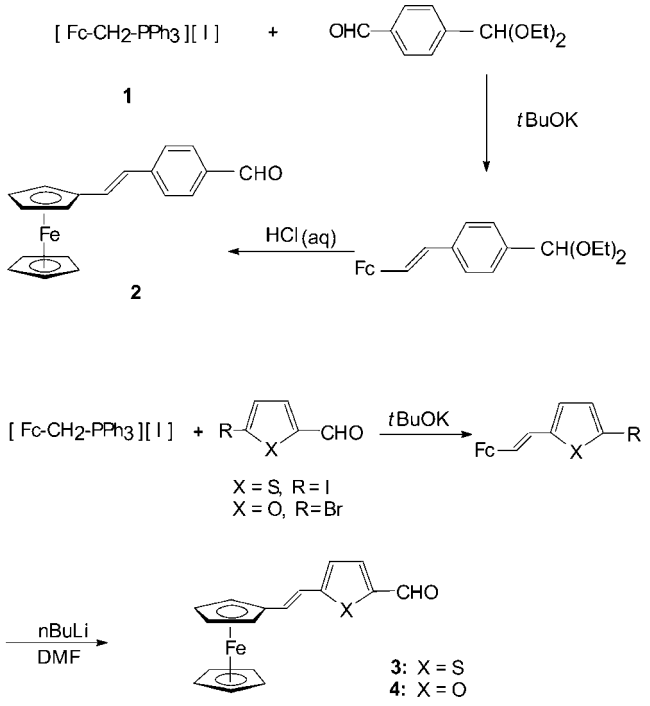
the π-linker, could give systems which exhibit large second-order NLO effects and would help to clarify the criteria necessary to achieve this.[23−26]

Results and Discussion

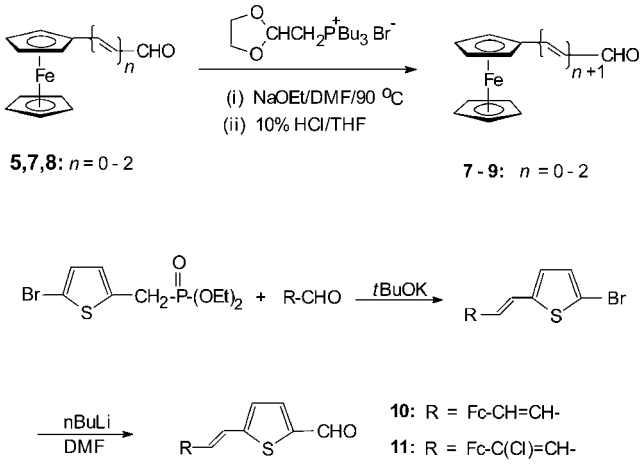
Synthesis

Wittig condensation of terephthalaldehyde mono(diethyl acetal) with an equimolar amount of the phosphonium salt [Fc−CH_2−PPh_3][I] (**1**)[27,28] and *t*BuOK, provided the acetal Fc−CH=CH−C_6H_4−$CH(OEt)_2$ which was not isolated but immediately converted into the aldehyde Fc−CH=CH−C_6H_4−CHO (**2**) by treating with aqueous HCl (Scheme 1). Wittig condensation of **1** with 5-iodothiophene-2-carboxaldehyde[29−31] and 5-bromofuryl-2-carboxaldehyde[29,32,33] followed by lithium/halogen exchange and DMF quenching gave the heteroarylferrocenyl aldehydes Fc−CH=CH−C_4H_2S−CHO (**3**) and Fc−CH=CH−C_4H_2O−CHO (**4**).



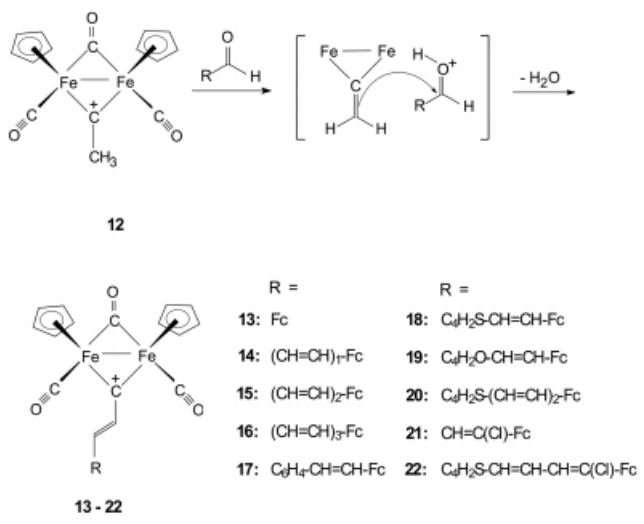
Scheme 1. Synthesis of ferrocenyl aldehydes **2−4**

Ferrocene aldehyde[34] **5** and (chlorovinyl)ferrocene aldehyde[35] **6** were prepared by known procedures while the extended [formyl(vinyl)$_n$]ferrocenes **7−9** were obtained by the method of Spangler and McCoy (Scheme 2).[36] The extended vinylthienyl aldehydes Fc−CH=CH−CH=CH−C_4H_2S−CHO (**10**) and Fc−C(Cl)=CH−CH=CH−C_4H_2S−CHO (**11**) were prepared by a Wittig−Horner−Wadsworth−Emmons procedure using diethyl [(2-bromothienyl)methyl]phosphonate[22] (Scheme 2). As before, lithium/halogen exchange followed by DMF quenching afforded **10** and **11** in high yields. All ferrocenyl aldehydes were characterised by ^{1}H NMR spectroscopy and exhibited signals, which were consistent with all-(*E*) geometries.



Scheme 2. Synthesis of ferrocenyl aldehydes **7−11**

When the aldehydes **2−11** were condensed with [Fe_2(η-C_5H_5)$_2$(CO)$_2$(μ-CO)(μ-C−CH_3)][BF_4][37] (**12**) in CH_2Cl_2 at 35 °C for 12 h, they gave intensely coloured reaction mixtures. The air-stable merocyanine salts [Fe_2(η-C_5H_5)$_2$(CO)$_2$(μ-CO)(μ-C−{π-linker}−Fc)][BF_4], **13−22**, were isolated by filtering the reaction mixture and layering the filtrate with diethyl ether (Scheme 3). The complexes **13−22** were fully characterized by spectroscopic and elemental analysis. However, some of the products contained solvent of crystallization that could not be removed by vacuum drying. This was confirmed by NMR spectroscopy that revealed varying amounts of CH_2Cl_2, diethyl ether and/or water. No attempt was made to quantify this solvent of crystallisation and the microanalytical data are given as found. However, the spectroscopic data are in agreement with the proposed formulae and we are confident of them.



Scheme 3. Reactions of **12** with ferrocenyl aldehydes **2−11**

Crystal Structure of $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C{-}CH{=}CH{-}CH{=}C(Cl){-}Fc)][BF_4]$ (21)

Suitable crystals of **21** were grown from a CH_2Cl_2/OEt_2 solution and subjected to an X-ray diffraction study. Crystal data and structure refinement are given in Table 5. A perspective view of the molecule and its atom numbering is depicted in Figure 1. Selected bond lengths and angles are listed in Table 1. The $Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C)$ moiety has a *cis* structure with dimensions similar to those found in other μ-vinylcarbyne cations.[22,38,39] The −CH=CH−CH=C(Cl)− π-bridge linker displays all-(*E*) geometry with C15−C16 and C17−C18 bond lengths of 1.359(5) and 1.356(5) Å respectively, which are rather long for $C_{sp^2}-C_{sp^2}$ double bonds. Furthermore, there is a shortening of the $C_{sp^2}-C_{sp^2}$ single bonds towards the diiron terminus [C14−C15 = 1.414(5), C16−C17 = 1.424(9), and C18−C19 = 1.447(9) Å], which is evidence for the delocalisation of the positive charge into the vinylcarbyne system and particularly through the first double bond in the solid state.[19−21] This is particularly important because bond-length alternation (BLA, the difference between the average lengths of carbon−carbon single and double bonds in a merocyanine) has been established as a useful parameter in relation to NLO response.[23,40,41] A good correlation between theory and experiment led to the conclusion that optimal NLO activity is achieved when BLA = 0.03−0.05 Å. The BLA across the π-bridge of **21** is 0.07 Å, which indicates a potentially high first hyperpolarisability.

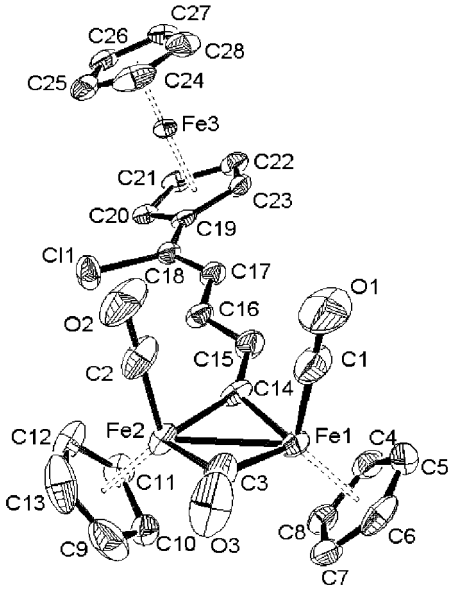


Figure 1. Molecular structure and atom labelling of $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C{-}CH{=}CH{-}CH{=}C(Cl){-}Fc)][BF_4]$ (**21**); 30% ellipsoids; hydrogen atoms and $[BF_4]^-$ anion omitted for clarit)

Further evidence for the π-interaction between the diiron moiety and the first double bond is the planarity of the $Fe_2(\mu\text{-}C)$ and C14−C16 units with the dihedral angle between the their best planes being only 1.5(6)°. The entire π-linker (C14−C19) is also quite planar with C17 and C14 displaying greatest deviations [+10.4(3) and −10.1(2)°, respectively] and a dihedral angle of 9.2(7)° between the best planes through C14−C16 and C17−C19. Nonetheless, the dihedral angle of 24.3(2)° between the C19−C23 (ferrocenyl $\eta\text{-}C_5H_4$) and the $Fe_2(\mu\text{-}C)$ planes suggests that the ground state (GS) electronic delocalisation within the cation is effected mainly via the π-bridge with only a limited contribution from the ferrocenyl end group.

Spectroscopy

The solution IR spectra of complexes **13−22** contain three absorption bands in the ν(CO) region (Table 2). Their relative intensities are consistent with the presence of a *cis*-$Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C)$ moiety similar to those found in other $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C{-}R)]^+$ complexes.[19−22,38,39] The frequencies of these bands are a good indication of the electronic coupling between the $Fe_2(\mu\text{-}C)$ electron accepting moiety and the vinylferrocenyl complex donor system. Increased electron density at the diiron terminus results in increased M→CO back donation with a concomitant shift of the ν(CO) bands to lower frequencies. The ν(CO) vibrations of the vinylcarbyne complexes **13−22** are found at lower frequencies than those of $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)\{\mu\text{-}C{-}CH{=}CHC(CH_3)_3\}][BF_4]$[19] (**23**) (2036, 2003, 1853 cm^{-1}) and at very much lower frequencies than those of $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C{-}CH_3)][BF_4]$[19] (**12**) (2047, 2016, 1853 cm^{-1}). They demonstrate that in the ground state (GS), (i) extension of the π-linker with polarisable olefinic units increases the positive charge at the $Fe_2(\mu\text{-}C)$ core, (ii) when aromatic groups are included in the spacer, the delocalisation of this positive charge decreases with increasing aromaticity of that group, and (iii) the CH=C(Cl)−Fc unit is a weaker donor than CH=CH−Fc.

The spectra also display the expected absorption bands due to the BF_4^- ion and some unexpectedly strong bands lying between 1450 and 1600 cm^{-1}. The intensities of the latter are comparable to those of the ν(CO) modes e.g. for **21** they are found at 1553 (4.6) and 1521 (13.1) cm^{-1} [relative intensities with ν(CO) set to 10]. As they are not present in the IR spectrum of **12**, they are attributed to the ν(C=C) and other internal vibrations of the vinylferrocenyl ligand. Their enhanced intensities is a consequence of the high degree of polarisation within the π-system of the molecule.

The ^1H NMR spectra of **13−22** are consistent with the proposed structures. In particular, the ^1H-^1H coupling constants across all the olefinic CH=CH units ($J > 13.5$ Hz), confirm an (*E*) configuration in all cases. Although the two C_5H_5 ligands of the diiron unit are formally in different environments, a single resonance is observed in the ^1H NMR spectra of all the complexes. This suggests that in all cases there is facile rotation about the μ-C−CH bond which has a low bond order and is close to a single bond. This is consistent with the X-ray data discussed above. The protons of the ferrocenyl C_5H_4 ring appear as two broad resonances downfield from the singlet due to its C_5H_5 group. The

chemical shift of these signals depends on the interaction between the ferrocenyl electron donor and the cationic di-iron terminus and is related to both the length and the ease of polarisation of the bridge. For example, as the π-linker in the $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)\{\mu\text{-}C-(CH=CH)_n-Fc\}]^+$ cations is extended from $n = 1$ to $n = 4$, the C_5H_4 ^1H NMR signals are shifted 0.71 ppm upfield.

The ^{13}C NMR spectra of **13**−**22** exhibit all the anticipated resonances, but the most informative are those due to the μ-C atom (δ = 408−432, Table 2). They are highly shielded relative to the μ-C signal of **12** (δ = 499), but deshielded compared with the μ-C signal of alkenylidenediiron complexes $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C=CH-R)]$ (δ = 270−340).[18,21,22,42−45] The greater the degree of charge delocalisation within the μ-carbyne moiety of the cation, the more pronounced is the upfield shift of this signal which will therefore depend on the length and ease of polarisation of the π-linker. The effect of π-bridge modification on the chemical shift of the μ-C resonance can be summarised as follows: (i) increasing conjugation by adding olefinic units results in a slight downfield shift, (ii) replacing a heteroaryl π-spacer by the more aromatic benzenoid unit also results in a downfield shift and (iii) replacing the CH=CH proximate to the ferrocene by a CH=C(Cl) unit produces an upfield shift. Thus the electron donating effect of the ferrocenyl group in the GS decreases with donor−acceptor separation, the presence of aromatic π-spacers and the increasing electronegativity of the bridge carbon atom α to it.

The UV/Vis spectra of **13**−**22**, like those of most ferrocenyl derivatives, exhibit two intense absorption bands in the visible region (Table 3).[8−12,46−49] Figure 2 demonstrates the effect of π-bridge extension on the absorption spectra of $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)\{\mu\text{-}C-(CH=CH)_n-Fc\}]^+$. Both bands are red-shifted with increasing polyenic chain length but this is more pronounced for the

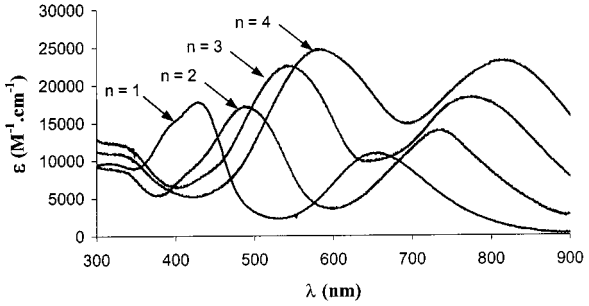

Figure 2. Effect of π-bridge extension on the absorption spectra of the $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C-(CH=CH)_n-Fc)][BF_4]$ salts **13−16**

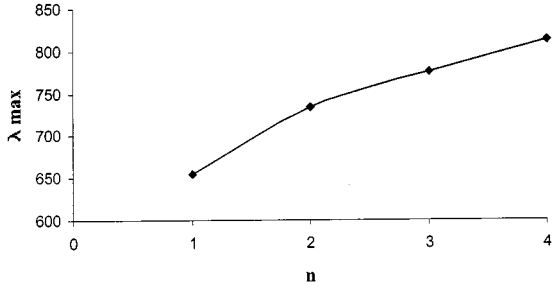

Figure 3. The variation of λ_{max} of the DA−CT absorption band of the $[Fe_2(\eta\text{-}C_5H_5)(CO)_2(\mu\text{-}CO)(\mu\text{-}C-(CH=CH)_n-Fc)][BF_4]$ salts **13−16**, with increasing *n*

higher energy band. In the case of organic donor−acceptor dyes, extending the π-linker results in the CT band moving to a limiting value known as the merocyanine limit (Figure 3).[50] Therefore we suggest that the low-energy band is probably due to a donor−acceptor transition (DA−CT) and the higher energy band to an intraligand π−π* transition (LL−CT). Many contrasting theoretical models have attempted to describe the electronic origin of these bands and their contribution to the second-order response.[51−53] Our assignments are in agreement with the most recent of these.[53]

The wavelengths of both absorption bands in the electronic spectra of **13−22** are solvent-dependent (Table 3). This is important because theoretical and experimental results suggest that the performance of NLO chromophores is optimised when there is a large difference between the dipole moments of the ground state (GS) and the excited state (ES) of the system.[54,55] and solvatochromism of the CT bands of chromophores is considered a manifestation of this change in dipole moment upon excitation.[50] In the case of **13−22** both bands are significantly blue-shifted with increasing solvent polarity (Figure 4 and Table 3). This indicates a large change in dipole moment upon excitation from a more charge-localised GS with a high dipole moment to an excited state where the positive charge is more delocalised throughout the entire molecule and the dipole moment is lower. In **13−16** the distance between donor and acceptor is increased by inserting more CH=CH units into the linker. Consequently it is not surprising that the solvatochromic shifts $\Delta\tilde{\nu}$ also increase along the same series as dipole moments are a function of charge and distance. Furthermore, when the benzene spacer in **17** is replaced by a thiophene in **18** or a furan in **19**, the charge delocalisation in the GS is increased, the dipole moment change on excitation is reduced, and so is the solvatochromic shift (Table 3). At the same time, one would expect a decrease in solvatochromism upon incorporation of heterocycles into the π-linker because of their ability to act as auxiliary donors within the bridge.[3−6,22]

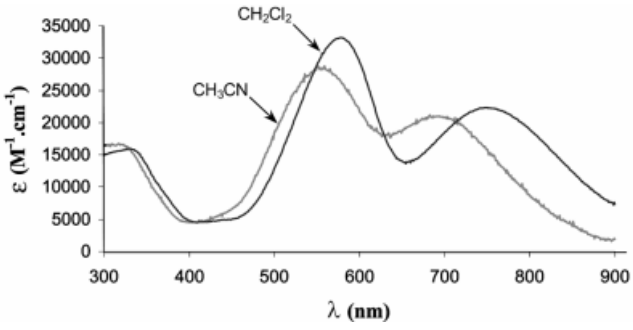

Figure 4. Solvatochromic behaviour of $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C-CH=CH-C_4H_2O-CH=CH-Fc)][BF_4]$ (**19**)

Another notable feature is the effect of replacing the −CH=CH− double bond proximate to the metallocene by a −CH=C(Cl)− unit. This increases the electronegativity of the ferrocenyl α-carbon atom and reduces the electron-donating capability of the ferrocenyl unit. If we consider that mesomers **A** and **B**, and to a lesser extent **C**, are the principal contributors to the GS of the diene π-bridged complexes **14** and **21** (Figure 5), then replacing X = H by X = Cl significantly reduces the stability of **C** and its contribution to the overall GS structure. Reduced charge delocalisation has the effect of raising the HOMO and we can presume that it also raises the energy of the LUMO, as mesomer **C** contributes substantially to the ES. Inspection of the spectra shows that on going from **14** to **21** there is (i) a downfield shift of the μ-C signal in the ^{13}C NMR spectrum, (ii) an increase of the frequencies of the ν(CO) modes, (iii) a red-shift of the λ_{max} of the DA−CT band, and (iv) a decrease of its solvatochromism. These observations show that the second olefinic unit contributes significantly to charge delocalisation in the GS and that perturbing it has a significant effect on the HOMO.

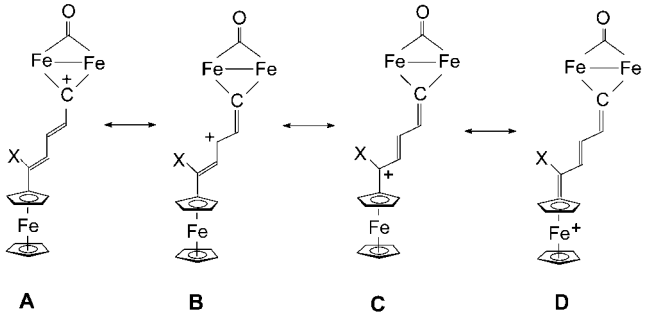

Figure 5. Four mesomeric forms of **14** and **21** (C_5H_5 and CO ligands omitted for clarity)

The same structural modification but in the extended π-bridged complexes incorporating a thienyl group, i.e. **20** and **22**, has a different effect. The IR and NMR spectroscopic data suggest that electronic communication between the termini is reduced upon incorporation of the aromatic heterocycle but that there are only minor changes in the degree to which positive charge is delocalised away from the $Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C^+)$ group. However, the electronic absorption spectra suggest that introduction of the chloro substituent affects the LUMO on going from **20** to **22** and brings about a blue-shift of the DA−CT band.

Hyperpolarisability Measurements

The NLO properties of **13−22** were evaluated by the hyper Rayleigh scattering (HRS) technique to determine their first hyperpolarisability β.[56] This technique involves detecting the incoherently scattered frequency-doubled light $I(2\omega)$ generated from a solution of the sample. Several different concentrations of solute are taken so as to eliminate possible solvent contributions, which are generally linear. The dependence of the ratio $I(2\omega)/I(\omega)^2$ from the concentration of the NLO chromophore referred against a standard leads to the β(HRS) value.

There are certainly pitfalls associated with the technique which, if unchecked, lead to overestimation of the β values. Nonetheless, it remains the easiest means of assessing the first hyperpolarisability of ionic and octupolar molecules.[57] The most common source of unreliable results is from two-photon fluorescence absorption (TPAF).[58−61] However, there are now several methods which may be used to discriminate between a true SHG signal and a TPAF-enhanced one, e.g. the use of bandpass filters[12,22] or a scanning monochromator.[62] Also, numerous techniques have been developed to avoid or abstract the TPAF contribution to β: long wavelength measurement,[63−65] time-resolved HRS,[66] high-frequency demodulation[67] and the measurement of the TPAF spectrum to abstract the fluorescence contribution to the HRS signal.[68,69]

The HRS experiments were carried out in CH_2Cl_2 solution at 1064 nm fundamental wavelength using *p*-nitroaniline (*p*NA) as an external reference. The calculated β values of the complexes **13−22** are presented in Table 3. These values are resonance-enhanced and therefore the static first hyperpolarisabilities (β_o) have been calculated using the two-level model [TLM, Equation (1)].[54,55] We have reservations about using the TLM to calculate β_o as (i) strictly speaking, it is not applicable in situations where there is significant absorption near the SHG signal (532 nm) and (ii) the relative contributions of the two transitions in metallocene chromophores are still uncertain with the latest study reporting that both transitions contribute significantly to the optical nonlinearity.[53] Nonetheless, to allow comparisons to be drawn between these complexes and the rest of the body of work on ferrocenyl systems we calculate the β_o values using the lower energy CT transition (Table 4).

$$\beta_{CT}(-2\omega,\omega,\omega) = \frac{3\Delta\mu_{eg}M^2}{(\hbar\omega)^2}\cdot\frac{\omega_{eg}^2}{\left(1-4\omega^2/\omega_{eg}^2\right)\cdot\left(\omega_{eg}^2-\omega^2\right)} \qquad (1)$$

$$\beta_0 = \frac{3\Delta\mu_{eg}M^2}{(E_{eg})^2}\cdot$$

To ensure that the calculated values are real, a check for multiphoton-induced fluorescence enhancement was undertaken using bandpass filters at λ = 400, 450, 500, 532, 560, 650, and 700 nm with a bandwidth of 10 nm as reported earlier.[22] A fluorescence signal should have a considerably broader line than the sharp HRS signal (Figure 6) and the maximum of the emission band occurs infrequently at λ/2.[62,68,69] Overall the β values obtained for this series of cationic ferrocenyl chromophores are exceptionally high, but they have been rigorously checked for TPAF and show no enhancement.

There are two points of general interest in the values of β and β_0 (Table 3). Firstly, those of the $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)\{\mu\text{-}C-(CH=CH)_n-Fc\}][BF_4]$ (**13−16**) complexes increase on lengthening the π-system with olefinic units, and a plot of log *n* against log β_o (Figure 7)

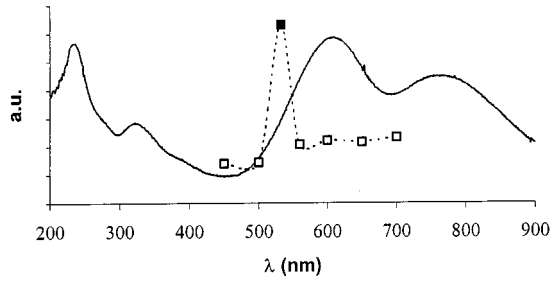

Figure 6. Absorption (full) and emission (dotted) spectra of the $[Fe_2(\eta\text{-}C_5H_5)(CO)_2(\mu\text{-}CO)\{\mu\text{-}C{-}CH{=}CH{-}C_4H_2S{-}(CH{=}CH)_2{-}Fc\}][BF_4]$ (**20**) in CH_2Cl_2; filled square is λ = 532 nm signal

shows that $\beta_o \propto n^{1.5}$. This confirms that the static first hyperpolarisability of donor−acceptor polyene systems rise sharply with the length of the conjugated path. Furthermore, there is no evidence for the "saturation" of the β_o enhancement with n increasing to 4, unlike λ_{max}, which is levelling off (Figure 3). In view of our results coupled with the linear optical data it would appear that the enhancement of β_o for these cationic merocyanines could be largely attributed to $\Delta\mu_{eg}$, and M and less on the energy of the transition E_{eg}.

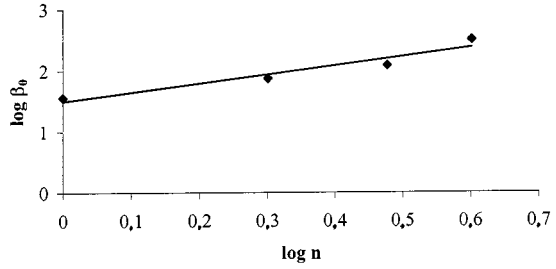

Figure 7. Conjugation length dependence of β_0 for the $[Fe_2(\eta\text{-}C_5H_5)(CO)_2(\mu\text{-}CO)\{\mu\text{-}C\text{-}(CH{=}CH)_n{-}Fc\}][BF_4]$ salts **13−16**

The second point of interest is that for the aromatically bridged $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C{-}CH{=}CH{-}(ring){-}CH{=}CH{-}Fc)][BF_4]$ salts the order of molecular nonlinearity decreases when the bridging aromatic ring is based on benzene (**17**) > thiophene (**18**) > furan (**19**). This result differs from those of recent studies of the second-order NLO effects in organic materials which have led to the conclusion that heterocyclic aromatic units provide better conjugation with increased first hyperpolarisabilities than do benzenoid moieties.[5−7] Albert et al. have demonstrated that the position of aromatic spacers within the conjugated system is important, and that in neutral molecules optimal NLO response is achieved by appending strong donors to electron-excessive spacers and strong acceptors to electron-deficient ones.[4] Consequently it is possible that in cationic molecules the combination of the acceptor with π-deficient aromatic groups may optimise the NLO response.

However, we are not convinced that this is the whole answer, and in seeking to explain our results we note that the TLM predicts that large, frequency-independent first hyperpolarisabilities are obtained for compounds exhibiting

− a low-energy CT transition (energy E_{eg}),

− a large transition moment M which is directly correlated to the oscillator strength i.e. the extinction coefficient ε should be large,

− a large change in dipole moment $\Delta\mu_{eg}$, which is indicated by a pronounced solvatochromism of the CT transition.

The optical data for **17−19** show that absorption band wavelengths ($1/E_{eg}$) and intensities decrease along the series **19** > **18** > **17**, whilst the solvatochromic effect $\Delta\tilde{\nu}$ and β/β_0 increase. This is consistent with the proposal that the most important factor in determining the values of β and β_0 for these compounds is the dipole moment change during the electronic transition, $\Delta\mu_{eg}$, and that a low transition energy E_{eg} and a high transition moment M is much less important. We suggest that for these compounds increasing the ring aromaticity reduces the delocalisation of the positive charge onto the ferrocenyl group and limits it to the μ-C−CH=CH moiety in the GS but not in the ES, and therebye enhances the change in dipole moment $\Delta\mu_{eg}$ on excitation. Further support is lent to this suggestion by comparing the β_o values of complexes **14** and **21**. The spectroscopic and X-ray data show that the CH=C(Cl) unit also reduces the delocalisation of the ferrocenyl electrons in the GS and as a consequence the β_0 value of **21** is very much larger than that of **14**. However, the same modification has a much reduced effect in the extended π-bridged complexes **20** and **22**, where the donor and acceptor are further apart and the conjugated linker includes a heterocyclic aromatic group.

There have been a number of studies of NLO-active organometallic complexes utilising the ferrocene fragment as an electron donor[71−77] and the $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C-)]^+$ electron-accepting moiety.[22,45] However, problems arise when comparing NLO values obtained from different techniques and solvents.[57][58] Meaningful comparisons can only be made between our complexes and others characterised using the HRS technique at 1064 nm incident radiation (Table 4). The second-order hyperpolarisabilities presented in Table 4 confirm that the combination of ferrocenyl donor with the $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C-)]^+$ acceptor is very effective as **13−22** have some of the highest β and β_0 values so far observed for organometallic compounds.

Conclusion

In summary, we have systematically modified the conjugation pathway of the cationic organometallic merocyanine system $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C-CH=CH-\{\pi\text{-linker}\}-Fc)][BF_4]$ and examined the effects on the linear and nonlinear optical properties. The results agree with some previously held tenets in that extending the π-linker with olefinic units result in a bathochromic shift of the λ_{max} and concomitantly increase the second-order NLO response. However, they do not agree with others. When aromatic spacers are included, the results suggest that the first hyperpolarisabilities are optimised when the ground state delocalisation of the ferrocenyl electrons is reduced. Better results are achieved when the more aromatic benzene unit replaces thiophene or furan moieties. It appears that for our cationic merocyanines (**13−22**) a low excitation energy E_{eg} for the electronic excitation is less important than a large change in the dipole moment $\Delta\mu_{eg}$ and a large transition moment *M*. Furthermore, the observation that the substituent on the olefinic double bond proximate to the ferrocenyl group has a dramatic effect on the β and β_0 values (cf. **14−21**) emphasises the necessity for further rigorous and systematic research to elucidate the structure−property relationship, which is so vital for the advancement of this field.

Experimental Section

Solvent Purification and Instrumentation: Dichloromethane and THF were dried by refluxing in the presence of calcium hydride and distilled prior to use. THF was further distilled from sodium/benzophenone. Acetonitrile was dried by refluxing in the presence of calcium sulfate and distilled prior to use. − Infrared spectra were recorded with a Perkin−Elmer Paragon 1000 spectrometer. Peak positions are in cm^{-1} with relative peak heights in parentheses. − UV/Vis spectra were recorded with a Perkin−Elmer Lambda 6 spectrometer. Band positions are in nm with band intensities in parentheses. − NMR spectra were recorded with a JEOL JNM-GX 270 FT spectrometer. Chemical shifts are in ppm downfield from TMS as an internal standard and in parentheses are (multiplicity, integration, coupling constants *J* in Hz) where appropriate. − Elemental analyses were carried out in the Microanalytical Laboratory, University College, Dublin.

General Procedure for the Condensation of Ferrocenyl Aldehydes 9−11 with $[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C-CH_3)][BF_4]$ (12): Complex **12**[37] (0.25 g, 0.57 mmol) and an excess of aldehyde (1.2 equiv.) was stirred in CH_2Cl_2 (50 mL) at 35 °C for twelve hours. The reaction mixture was filtered and the product precipitated from the filtrate by carefully adding diethyl ether (25 mL) and cooling overnight.

$[Fe_2(\eta\text{-}C_5H_5)_2(CO)_2(\mu\text{-}CO)(\mu\text{-}C-CH=CH-Fc)][BF_4]$ (13): Yield 0.20 g (54%). − ^{1}H NMR [$(CD_3)_2CO$]: δ = 9.64 (d, 1 H, *J* = 14.1 Hz, μ-C−CH), 8.46 (d, 1 H, *J* = 14.1 Hz, μ-C−CH=CH), 5.55 (s, 10 H, C_5H_5), 5.42, 5.36 (C_5H_4, Fc), 4.43 (C_5H_5, Fc). − ^{13}C NMR [$(CD_3)_2CO$]: δ = 408.0 (μ-C), 257.7 (μ-CO), 209.8 (CO), 162.3, 150.9 (μ-C−CH=CH), 92.1 (C_5H_5), 80.7, 80.3, 74.5, 74.0 (Fc). − IR (CH_2Cl_2): ν(CO) 2024 (10.0), 1993 (2.7); ν(μ-CO) 1837 (5.4); ν(C=C) 1605 (2.8), 1525 (13.2), 1461 (2.3). − UV/Vis: (CH_2Cl_2): λ_{max} (ε) = 655 nm (10,953 $M^{-1}\cdot cm^{-1}$), 428 nm (17,736 $M^{-1}\cdot cm^{-1}$); (CH_3CN): λ_{max} (ε) = 634 (9,390 $M^{-1}\cdot cm^{-1}$), 421 (15,245 $M^{-1}\cdot cm^{-1}$). − $C_{26}H_{21}BF_4Fe_3O_3$ (635.8): calcd: C 49.07, H 3.30; found C 48.70, H 3.31.

X-ray Structure Determination of 21: Crystals suitable for an X-ray structure analysis were obtained by diffusion of Et_2O into a CH_2Cl_2 solution of **21**. The data were collected with a four-circle Hilger & Watts diffractometer, Mo-K_α, λ = 0.71073 Å. The structure was resolved by direct methods (SHELXL-86).[78] Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-93).[79] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined with a fixed isotropic thermal parameter related by a factor of 1.2 to the value of the equivalent isotropic thermal parameter of their carrier atoms. Weights were optimised in the final refinement cycles. Crystal data and structure refinement are given Table 5, whilst selected bond lengths [pm] and angles [°] are listed in Table 1. Crystallographic data (excluding structure factors) for the reported structure have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149412. Copies of the data can be obtained free of charge on application

to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44 1223/336-033; E-mail: deposit@ccdc.cam.ac-uk].

HRS Measurements of the First Hyperpolarisabilities: Experimental setup details can be found in ref.[56] An Nd:YAG laser with a wavelength of 1064 nm was used as incident light source. All measurements were carried out in dry CH_2Cl_2 with sample concentrations of 10^{-6} to 10^{-4} M using *p*-NA as the external reference [$\beta(CH_2Cl_2) = 21.6\cdot10^{-30}$ esu[56]]. The compounds were checked for flourescence using the bandpass filter method described in ref.[22]

Interaction of Some Methylenediphosphanes with Hexafluoroacetone and Hexafluorothioacetone Dimer

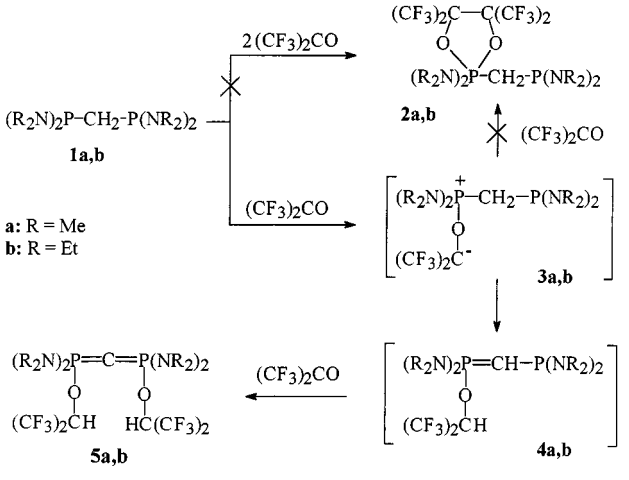
Igor V. Shevchenko,*[a] Rostislav N. Mikolenko,[a] Enno Lork,[b] and Gerd-Volker Röschenthaler*[b]

Keywords: Phosphanes / Hexafluoroacetone / Hexafluorothioacetone / Ylides / Wittig reactions

The reactions of methylenediphosphanes **1a–c** with hexafluoroacetone (HFA) and hexafluorothioacetone dimer (HFTA) gave the respective carbodiphosphoranes **5a**, **5b**, **6**, **15**, and **19**. The carbodiphosphoranes **6** and **19**, with phenyl groups at phosphorus, were able to react further with C=O or C=S functions. Compound **6** added one equivalent of HFA across one of the ylidic P=C bonds to give compound **9**, a stable intermediate of the Wittig reaction. The addition of HFTA to **19** gave, unexpectedly, the isomeric compound **21**. The molecular structures of **9**, **15**, and **21** were confirmed by X-ray investigations.

Introduction

It is well-known that the reaction of hexafluoroacetone (HFA) with phosphorus(III) derivatives can lead to the formation of 1,3,2- or 1,4,2-dioxaphospholanes.[1–4] Recently we found that the interaction of HFA with the methylenediphosphanes **1a** and **1b** proceeds in a different way to yield quantitatively the carbodiphosphoranes **5a** and **5b**,[5,6] but not the expected 1,3,2-dioxaphospholanes **2a** and **2b** (Scheme 1).



Scheme 1

The mechanism probably involves the intermediate formation of the unstable betaines **3a** and **3b**, which do not add a second molecule of hexafluoroacetone to give **2a** and **2b**, but undergo a proton migration from the $P-CH_2-P$ unit to the secondary carbon of the hexafluoroisopropoxy group forming the monoylides **4a** and **4b**. It is difficult to detect these products by NMR spectroscopy at room temperature since they react quickly with HFA to give the final products **5a** and **5b**. Thus, the presence of the methylene group with labile protons in the α-position to the phosphorus atoms is a necessary condition for this reaction.

Results and Discussion

In order to answer the question as to whether this reaction is an exception or it has more common character, we decided to use the *P*-phenyl-substituted starting material **1c** (Scheme 2).

Like compounds **1a** and **1b**, the bis(diphenylphosphanyl-methane) **1c** reacts with HFA to give the respective carbodiphosphorane **6**. After slow bubbling of gaseous HFA through a solution of **1c** in benzene at 20 °C, the ^{31}P NMR spectrum of the reaction mixture showed the presence of only compound **6** as a singlet at $\delta = 35.3$. The ^{19}F NMR spectrum displays only a doublet at $\delta = -72.45$ ($^3J_{HF} = 6.6$ Hz) confirming the equivalence of the all fluorine atoms and the presence of one proton in each $HC(CF_3)_2$ unit.

The carbodiphosphorane **6** is stable in solution at room temperature for several hours and quickly decomposes in the absence of the solvent. The decomposition of the molecule proceeds analogously to that of **5a** or **5b**, and gives methylene bis(difluorophosphorane) **7**[6] and methylenediphosphane oxide **8**. It is interesting that the formation of the dioxide **8** is not accounted for by the hydrolysis of the bisdifluorophosphorane **7**, as the reaction was carried out under anaerobic conditions. The formation of the analogous dioxide was also observed for **5a** and **5b**.[6]

Unlike compounds **5a** and **5b**, the carbodiphosphorane **6** is able to add one more equivalent of HFA across one of the ylidic P=C bonds with the formation of the cyclic product **9**, which is poorly soluble and crystallizes from the reaction mixture in good yield. It can be considered as a Wittig reaction intermediate, which are usually unstable at room temperature and cannot be isolated. Only a few compounds of this type are known. For example, an analogous addition has been observed for some other carbodiphosphoranes.[7–9] The proposed structure of compound **9** is in accordance with ^{31}P and ^1H NMR spectroscopy; the two different $HC(CF_3)_2$ groups display two characteristic multiplets at $\delta = 3.21$ and 4.36 in the ^1H NMR spectrum. However, the ^{19}F NMR spectrum displays an interesting peculiarity that may reflect the molecular structure of **9**. The two CF_3 groups connected to the four-membered ring are equivalent and display a common signal rather than the two quadruplets that we observed earlier for an analogous compound.[6] The equivalence of these CF_3 groups could be a result of the appropriate symmetry of the molecule: for example, if the plane of symmetry were to coincide with the four-membered cycle. However, the appearance of such symmetry in this molecule is very unlikely. Another explanation is that the four-membered cycle is open in solution, making the rotation of the $(CF_3)_2C$ unit possible. Looking for an answer to this question, we investigated this compound by X-ray analysis (Figure 1).

This analysis showed that the molecule does not have a plane of symmetry, which is why the equivalence of the CF_3 groups in solution can be only explained by the cleavage of one of the bonds of the four-membered ring. The ring is strained, as the C(1)−P(2)−O(1) angle is only 76° (in crystalline form), which should promote its opening. Although the C(1)−C(2) bond (152 pm) is somewhat longer then the normal $C_{sp^2}-C_{sp^3}$ bond, and is closer to normal $C_{sp^3}-C_{sp^3}$ bond lengths, its cleavage is unlikely, as this would result in the formation of the carbene structure, which, according to our previous results, should be unstable. We have already tried to obtain phosphonium-substituted carbenes, however they were very unstable and we could isolate only the products of their decomposition.[6]

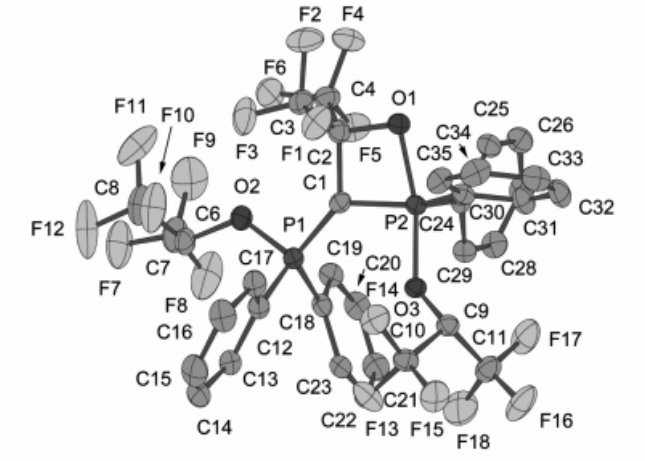

Figure 1. Perspective view and labeling scheme for the molecule **9**; selected bond lengths [pm] and angles [°]: P(1)−O(2) 162.16(19), P(1)−C(1) 170.3(3), P(1)−C(12) 179.2(3), C(1)−P(2) 175.1(3), C(1)−C(2) 151.5(4), C(2)−O(1) 141.0(3), P(2)−O(1) 178.38(19), P(2)−O(3) 177.80(18), P(2)−C(24) 182.4(3); P(1)−C(1)−P(2) 130.10(15), C(1)−P(2)−O(1) 76.00(11), C(1)−C(2)−O(1) 96.1(2), C(2)−O(1)−P(2) 94.96(15), C(2)−C(1)−P(2) 92.63(17), C(2)−C(1)−P(2)−O(1) 3.97(14)

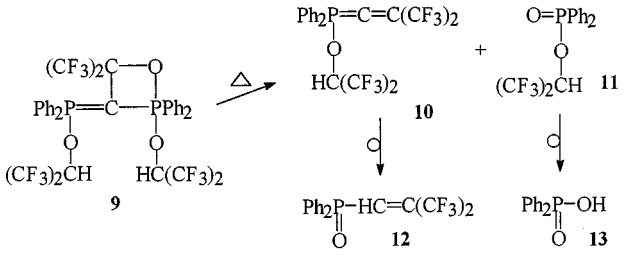
We think that cleavage of the C(2)−O(1) bond [141.0(3) pm] is less preferable than that of the P(2)−O(1) bond, as in the latter case it would form the more stable zwitterionic structure **9a**. The reversible cleavage of the P−O bond of the intermediate oxaphosphetanes has also been postulated by other authors for the Wittig reaction mechanism.[10]

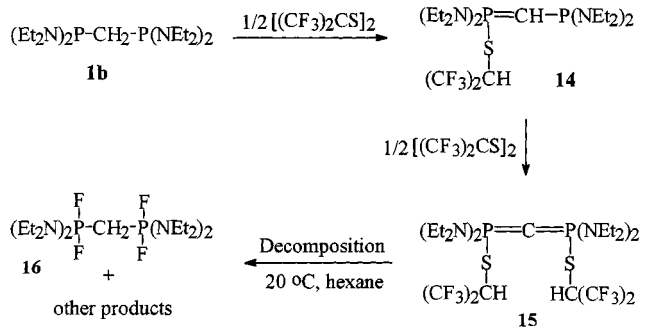
Indeed, heating compound **9** in chloroform or toluene solution at 60−100 °C led to the completion of the Wittig reaction, and gave a mixture of compounds **10**−**13** (Scheme 3), their relative amounts depending on the temperature and the solvent used. Compound **10** was not stable during the decomposition and was only detected by ^{31}P NMR spectroscopy as a singlet at $\delta = 36$. Compound **11** was isolated in low yield as a pure crystalline product. The formation of two other products **12** and **13** can be accounted for by the decomposition of the compounds **10** and **11**, in accordance with our above-mentioned conclusion about the formation of the dioxide **8**. Compound **12** showed two characteristic quadruplets for the two inequivalent CF_3 groups in the ^{19}F NMR spectra. Compound **13** was identified by comparison with a sample obtained independently.



Scheme 3

Thus, the substitution of the dialkylamino groups at phosphorus in methylenediphosphanes **1a** and **1b** by phenyl groups did not change the course of the reaction with HFA.

Our further interest was directed to the reaction of methylenediphosphanes **1a**−**c** with HFTA, whose properties are somewhat different from that of HFA (e.g. it easily dimerizes, and exists as a dimer at room temperature).[11] Therefore, one could expect that the softer sulfur atom might change the course of reaction (Scheme 1). However, compound **1b** and HFTA in hexane gave the carbodiphosphorane **15** quantitatively at −40 °C (Scheme 4). The ^{31}P NMR spectrum of the reaction mixture, taken immediately after the addition of HFTA to **1b**, displayed only one intense singlet at δ = 41.22 (similar to the chemical shift value found for **5b**), indicating two magnetically equivalent phosphorus nuclei of **15**. A two-step reaction is proposed with the intermediate formation of the mono ylide **14**, which was detected in the reaction mixture by ^{31}P NMR spectroscopy as two doublets at δ = 67.4 and 74.7 ($^2J_{PP}$ = 61 Hz) when only one equivalent of HFTA was added to the starting material.



Scheme 4

The carbodiphosphorane **15** turned out to be less stable than its oxygen analog **5b**. It decomposed in hexane solution at room temperature after several hours, whereas carbodiphosphorane **5b** was stable for two days under the same conditions. The choice of hexane as a solvent is very important for this reaction as in other solvents compound **15** is not stable or its synthesis may be accompanied by the formation of by-products. The decomposition of **15** gave a complex mixture with the predominant product being methylenebis(difluorophosphorane) **16**. This product was previously isolated after the decomposition of **5b** and showed the same signal in the ^{31}P NMR spectrum of a triplet at δ = −52.2 ($^1J_{FP}$ = 728 Hz).[6]

Despite the reduced stability of carbodiphosphorane **15**, it was possible to isolate it in a crystalline form, although all our efforts to obtain crystals of the more stable oxygen derivative **5b** failed. Colorless crystals of compound **15** can be stored at −25 °C, however they turn yellow and slowly decompose at room temperature. The X-ray analysis of **15** showed the following molecular structure (Figure 2).

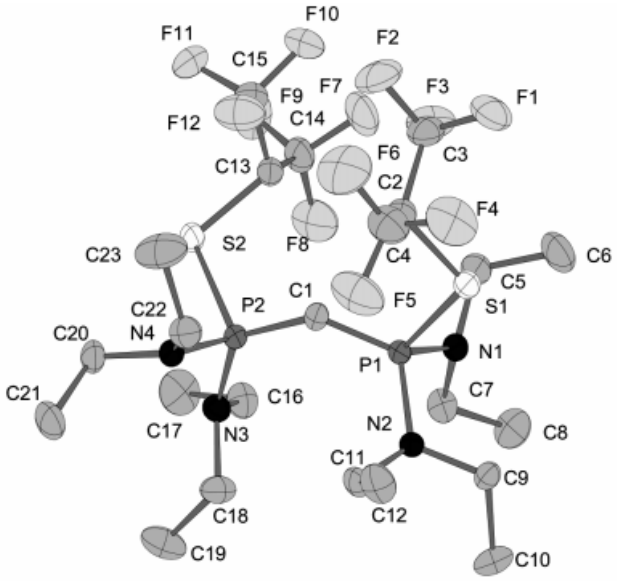


Figure 2. Perspective view and labeling scheme for the molecule **15** (H atoms are omitted for clarity); selected bond lengths [pm] and angles [°]: P(1)−N(1) 167.32(12), P(1)−C(1) 162.57(15), C(1) −P(2) 162.60(15), P(1)−S(1) 217.60(5), S(1)−C(2) 180.40(16), N(1)−C(5) 147.81(19), C(2)−C(3) 152.1(2); C(1)−P(1)−N(1) 122.84(7), C(1)−P(1)−S(1) 108.73(5), N(1)−P(1)−N(2) 101.47(6), N(1)−P(1)−S(1) 98.12(5), P(1)−C(1)−P(2) 139.52(9), P(1)−S(1)−C(2) 101.81(5)

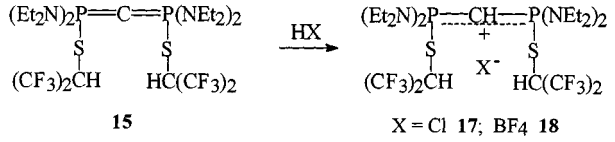
Unlike allenes[12] and heteroallenes, in which the angle between the two double bonds is about 180°, the P=C=P angle in carbodiphosphoranes lies in the range 117−150°, depending on the structure and packing effects.[13−17] The only exception is hexa(dimethylamino)carbodiphosphorane, which has a linear structure and D_{3d} symmetry.[18] Here, the P=C=P angle of carbodiphosphorane **15** is 139.5° with a P=C bond length of 162.57 pm. Both phosphorus atoms of compound **15** have significantly distorted tetrahedral symmetry, with the largest deviation from the ideal angle being 13.3°. It is interesting that because of the low symmetry of the molecule in the solid state the ethyl groups of the diethyl substituents and CF_3 groups of the hexafluoroisopropoxy units are not equivalent. In solution, however, these groups are equivalent and have equal spectral characteristics. For example, all fluorine nuclei display a doublet at δ = −67.7 ($^3J_{HF}$ = 8.14 Hz) in the ^{19}F NMR spectra, which means that in a solution of **15** there is either a rotation or a rapid flip-flop movement around the P−C−P bonds.

The carbodiphosphorane **15**, as a strong base, reacts with acids: for example, with HCl or HBF_4 it gives the corresponding colorless salts **17** and **18** (Scheme 5). As was to be expected, the positive charge of the cation is delocalized over the P−C−P triad, resulting in the magnetic equivalence of the phosphorus nuclei. The ^{31}P NMR spectra of compounds **17** and **18** show only one singlet at δ = 62 and 68, respectively. The analogous salts have been obtained earlier for carbodiphosphoranes **5a** and **5b**, and showed the same spectroscopic data.[5] The chloride **17**, however, differs

from its oxygen derivative. After the addition of HCl to a solution of **15** in hexane compound **17** immediately precipitates from the reaction mixture as a colorless crystalline product that is insoluble in non-polar solvents. This product is stable at room temperature in the solid state. However, the dissolution of this compound leads to its transformation (slowly in [D_8]toluene and rapidly in $CDCl_3$) into another product, which shows two doublets at $\delta = 62.7$ and 71.1 ($^2J_{PP} = 42.6$ Hz) in the ^{31}P NMR spectrum. Since the analogous oxygen derivatives are stable in symmetrical form,[5] the decomposition of **17** can only be explained by the presence of sulfur atoms and by the nucleophilicity of the chlorine anion. Although the appearance of substantial amounts of by-products was not observed in the ^{31}P NMR spectra, we could not isolate the unknown product in a crystalline form and investigate it more thoroughly.



Scheme 5

In contrast to the chloride anion, the tetrafluoroborate is less nucleophilic and the corresponding salt **18** was stable and did not decompose even in boiling $CDCl_3$ solution. This compound crystallized easily allowing us to establish its structure by X-ray analysis (Figure 3).

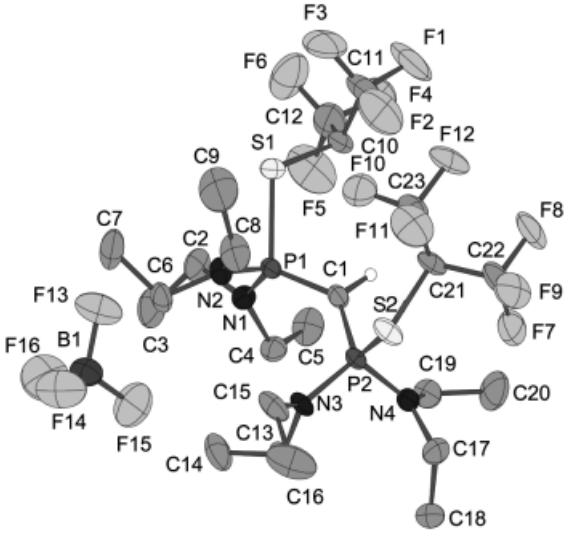


Figure 3. Perspective view and labeling scheme for the molecule **18**; selected bond lengths [pm] and angles [°]: P(1)−N(1) 163.6(3), P(1)−C(1) 169.6(4), C(1) −P(2) 169.7(4), P(1)−S(1) 212.72(14), S(1)−C(10) 182.5(4), N(1)−C(2) 148.2(5), C(10)−C(11) 152.2(6); C(1)−P(1)−N(2) 116.21(19), C(1)−P(1)−S(1) 111.42(14), N(1)−P(1)−S(1) 107.61(13), N(1)−P(1)−N(2) 108.99(17), P(1)−C(1)−P(2) 129.2(2), P(1)−S(1)−C(10) 111.86(15)

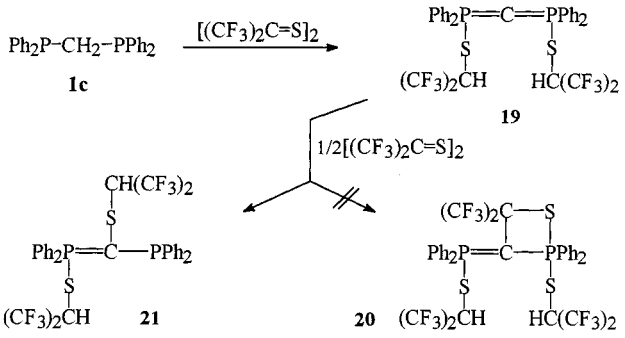
The addition of one proton to the P=C=P carbon atom of **15** leads to certain changes in the geometry of the product. As one would expect, the P−C−P angle in **18** becomes significantly narrower (129.2° versus 139.5°). The angles between the phosphorus atoms bonds become closer to those for a tetrahedral geometry. The P−C−P bond lengths of **18** are larger than those of **15** [169.6(4) versus 162.57(15) pm]. However, the other bonds at the phosphorus atoms are shorter in **18** than in **15**. The largest difference (4.9 pm) was found for the P−S bonds, which may indicate the possible participation of the sulfur atoms in delocalization of the positive charge.

The interaction of the dimer of HFTA with methylenebis(diphenylphosphane) **1c** turned out to be quite unusual. The first phase of this reaction, the addition of the two HFTA units to **1c**, does not differ from the analogous reaction with HFA and gives carbodiphosphorane **19** (Scheme 6). Unlike carbodiphosphoranes **5**, **6**, and **15**, which are relatively stable in solution at room temperature, compound **19** exists in diethyl ether solution only at −70 °C and can be detected spectroscopically only at this temperature. There is no doubt about the symmetrical structure of this compound as the ^{31}P NMR spectrum at this temperature shows only one intense singlet at $\delta = 22.5$. The oxygen derivative **6** displays similar spectroscopic data. At −40 °C the carbodiphosphorane **19** decomposes completely in solution within 30−40 min.



Scheme 6

In contrast to carbodiphosphorane **6**, which reacts further with HFA very slowly at room temperature, carbodiphosphorane **19** is very active and easily reacts even at low temperature (−70 °C) with HFTA. However, the character of this interaction is not quite clear. If 1.5 equivalents of the dimer of HFTA were added to the methylenediphosphane **1c** the reaction mixture only showed two doublets in the ^{31}P NMR spectrum at $\delta = 65.2$ and −4.5, with a coupling constant of 185.3 Hz. The same spectroscopic data were found for the colourless crystalline product that was isolated from the reaction mixture in good yield. We were sure that this was the cyclic product **20**, which is analogous to compound **9**. However, the ^{19}F NMR spectrum showed the presence of only two fragments of HFTA in the molecule. Beside this, the mass spectrum together with the analytical data pointed to a molecular weight of 748.56, the same as in carbodiphosphorane **19**. The X-ray analysis solved

this puzzle and gave structure **21** (Figure 4) which is the constitutional isomer of compound **19**.

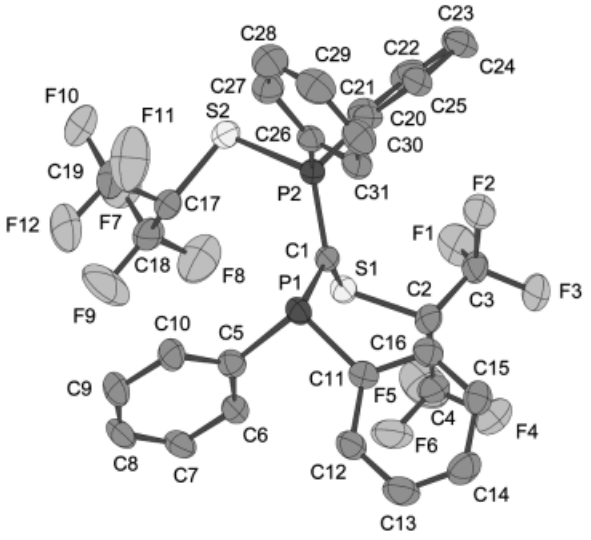


Figure 4. Perspective view and labeling scheme for the molecule **21**; selected bond lengths [pm] and angles [°]: P(1)−C(1) 181.4(5), C(1)−P(2) 170.4(5), P(2)−S(2) 215.55(19), C(1)−S(1) 176.8(5), P(1)−C(5) 183.1(5), P(2)−C(20) 181.3(5); P(1)−C(1)−P(2) 117.6(3), C(1)−P(1)−C(5) 106.2(2), P(1)−C(1)−S(1) 125.5(3), P(2)−C(1)−S(1) 113.4(3), C(1)−P(2)−S(2) 117.22(18), C(1)−P(2)−C(20) 116.0(2)

These two isomers exist independently from each other and do not interconvert. Carbodiphosphorane **19** is unstable and decomposes with the formation of a mixture of compounds that does not contain signals of the other isomer. Thus, in order to transform the symmetric carbodiphosphorane **19** into its asymmetrical isomer **21** the presence of HFTA is necessary. HFTA most likely plays a catalytic role in this process. However in this case it is not clear why the same yield of **21** cannot be obtained with only a small excess of HFTA.

It is interesting to note that the value of the $^2J_{PP}$ coupling constant of compounds containing the P−C−P system may vary in the range from less then 1 Hz to over 100 Hz. The $^2J_{PP}$ coupling constant of the compound **21** was unusually large 185 Hz. However, the largest value of this constant has been recently reported for $1\sigma^4,3\sigma^2$-diphosphaallene.[19]

Although, to the best of our knowledge, this unusual isomerization does not have direct analogies in the literature, it may be related to other migration processes observed for phosphorus compounds.[19,20]

Experimental Section

All operations were performed under nitrogen in a glove box. The solvents were dried by standard procedures. − The NMR spectra were measured with a JEOL FX-90Q, Bruker DPX 200 or Bruker AMX 360 spectrometer. The ^{1}H and ^{13}C chemical shifts are referenced to tetramethylsilane (TMS). The ^{31}P chemical shifts were measured using 85% aqueous orthophosphoric acid as an external standard. As usual, high frequency shifts are given positive signs. The digital resolutions were 0.25 Hz, 0.5 Hz, and 1.25 Hz for ^{1}H, ^{13}C, and ^{31}P NMR spectra, respectively.

Synthesis of Compound 6: A solution of methylenebis(diphenylphosphane) **1c** (30 mg, 0.078 mmol) in [D_6]benzene (0.5 mL) was placed in a tube with diameter 4−5 mm (a 5 mm NMR tube can be used) and 3.8 mL (0.172 mmol) of gaseous HFA were slowly bubbled through it at room temperature using a syringe with a thin needle. The end of the needle was placed at the bottom of the tube. The reaction mixture showed the following spectral parameters: ^{1}H NMR (89.56 MHz, C_6D_6): δ = 6.27 [br. sept., $^3J_{HF}$ = 6.58 Hz, 2 H, *H*C(CF_3)$_2$], 6.95 (m, 12 H, Ph), 7.70 (m, 8 H, Ph). − ^{19}F NMR (84.26 MHz, C_6D_6): δ = −72.46 (d, $^3J_{HF}$ = 6.58 Hz, 12 F, C*F*$_3$). − ^{31}P NMR (36.2 MHz, C_6D_6): δ = 35.3 (s, 2P).

Synthesis of Compound 9: Gaseous hexafluoroacetone (19 mL, 0.832 mmol) was condensed into a solution of methylenebis(diphenylphosphane) **1c** (100 mg, 0.260 mmol) in benzene (1 mL) in a glass tube. The tube was sealed and kept at room temperature for 3 days. According to the NMR spectroscopic data the reaction was complete in 30 h, and the rest of the time was needed for the crystallization of the product as a colorless crystals. The crystals were filtered off, washed with 0.4 mL of dichloromethane and dried in vacuo 0.05 mm. Yield 145 mg (63%), m.p. 121−124 °C. − ^{1}H NMR (89.56 MHz, $CDCl_3$): δ = 3.57 [d. sept., $^3J_{PH}$ = 10.6 Hz, $^3J_{FH}$ = 6.6 Hz, 1 H, C*H*(CF_3)$_2$], 4.72 [d. sept., $^3J_{PH}$ = 13.2 Hz, $^3J_{FH}$ = 5.6 Hz, 1 H, C*H*(CF_3)$_2$], 7.25−8.12 (m, 20 H, Ph). − ^{19}F NMR (84.26 MHz, $CDCl_3$): δ = −70.98 (d, $^3J_{FH}$ = 6.6 Hz, 6 F, CF_3), −72.26 (s, 6 F, CF_3), −74.39 (s, 6 F, CF_3). − ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = −32.5 (d, $^2J_{PP}$ = 56.0 Hz), 58.8 (d, $^2J_{PP}$ = 56.0 Hz). − $C_{34}H_{22}F_{18}O_3P_2$ (882.46): calcd. C 46.28, H 2.51; found C 46.26, H 2.53.

Synthesis of Compound 11: A solution of compound **9** (100 mg, 0.113 mmol) in toluene (1 mL) was heated at 100 °C for 5 h. The solvent was removed in vacuo (0.05 mm), the remaining oil was dissolved in boiling hexane and the solution was left at 20 °C overnight. A mixture of compounds **11**−**13** with predominant content of **11** was separated, and the mother liquid was kept for two weeks at 20 °C followed by two weeks at −20 °C. Colourless crystals of **11** (7 mg, 16%) were separated from the precipitated oil and dried in vacuo. − ^{1}H NMR (89.56 MHz, $CDCl_3$): δ = 5.41 [d. sept., $^3J_{PH}$ = 12.29 Hz, $^3J_{FH}$ = 5.86 Hz, 1 H, C*H*(CF_3)$_2$], 7.35−7.95 (m, 10 H, Ph). − ^{19}F NMR (84.26 MHz, $CDCl_3$): δ = −73.96 (d, $^3J_{FH}$ = 5.86 Hz, 6 F, CF_3). − ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 68.33 [d. sept., $^2J_{PC}$ = 4.8 Hz, $^2J_{FC}$ = 35.1 Hz, 1 C, *C*H(CF_3)$_2$], 120.4 (d, $^1J_{PC}$ = 274.9 Hz, 2 C, Ph), 128.5 (d, $^2J_{PC}$ = 14.7 Hz, 4 C, Ph), 131.2 (d, $^3J_{PC}$ = 11.7 Hz, 4 C, Ph), 132.95 (d, $^4J_{PC}$ = 2.9 Hz, 2 C, Ph),. − ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 39.85 (s, 2 P). − $C_{15}H_{11}F_6OP_2$ (368.22): calcd. C 48.93, H 3.01; found C 48.21, H 3.13.

Synthesis of Compounds 12 and 13: A solution of compound **9** (150 mg, 0.170 mmol) in chloroform (1.5 mL) was heated to 60 °C for 48 h and then the solvent was removed in vacuo (0.05 mm). Crystallization of the residue from dichloromethane/hexane gave a mixture of two types of crystals for compounds **12** and **13** (24 mg), which were mechanically separated.

12: − ^{1}H NMR (89.56 MHz, $CDCl_3$): δ = 7.37 (d, $^2J_{PH}$ = 11.6 Hz, 1 H), 7.44−7.92 (m, 10 H, Ph). − ^{19}F NMR (84.26 MHz, $CDCl_3$): δ = −65.7 (q, $^4J_{FF}$ = 7.33 Hz, 3 F, CF_3), −59.1 (q, $^4J_{FF}$ = 7.33 Hz, 3 F, CF_3). − ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 17.1 (s, 2 P).

13: − ^{1}H NMR (89.56 MHz, $CDCl_3$): δ = 7.28−7.90 (m, 10 H, Ph), 8.81 (br. s, 1 H) − ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 26.5 (s, 2 P).

Synthesis of Compound 15: A solution of HFTA (50 mg, 0.137 mmol) in hexane (1.2 mL), cooled to −40 °C, was quickly added to a solution of methylenebis[bis(diethylamino)phosphane] **1b** (50 mg, 0.137 mmol) in hexane (1.2 mL) at the same temperature. The reaction mixture was stirred at −20 °C for 5 min. and then kept at this temperature for 20 min. The colorless crystalline product **16** was filtered off and dried in vacuo. Yield of the crystals 48 mg (48%). According to the ^{31}P NMR spectrum the mother liquor contained compound **15** only. − ^{1}H NMR (360.13 MHz, C_6H_{14}): δ = 1.33 (t, $^{1}J_{HH}$ = 7.1 Hz, 24 H, CH_2CH_3), 3.33 (m, 16 H, CH_2CH_3), 5.02 [sept, 2 H, $CH(CF_3)_2$]. − ^{19}F NMR (188.31 MHz, C_6H_{14}): δ = −67.7 (d, $^{3}J_{HF}$ = 8.14 Hz, 12 F, CF_3). − ^{31}P NMR (145.78 MHz, C_6H_{14}): δ = 41.4 (s, 2 P). − $C_{23}H_{42}F_{12}N_4P_2S_2$ (728.67): calcd. C 37.91, H 5.81; found C 37.57, H 5.79.

Synthesis of Compound 18: The reaction mixture of the carbodiphosphorane **15** obtained as described above was diluted with hexane (2 mL) and warmed to 20 °C. At this temperature the crystals of **15** dissolved completely. The solution was then quickly cooled to −20 °C and the equivalent amount of HBF_4 (solution in ether) was added to it. The colourless crystalline product that precipitated immediately was filtered off and dried in vacuo. Yield 98 mg (88%); after crystallization from CH_2Cl_2/diethyl ether at −25 °C the yield is 61% (68 mg). − ^{1}H NMR (360.13 MHz, $CDCl_3$): δ = 1.20 (t, $^{3}J_{HH}$ = 7.06 Hz, 24 H, NCH_2CH_3), 1.91 (t, $^{2}J_{PH}$ = 4.9 Hz, 1 H, P−CH−P), 3.27 (m, 16 H, NCH_2CH_3), 4.25 [br. sept., $^{3}J_{FH}$ = 7.1 Hz, 2 H, $HC(CF_3)_2$]. − ^{19}F NMR (188.31 MHz, $CDCl_3$): δ = −69.5 (d, $^{3}J_{HF}$ = 7.1 Hz, 12 F, CF_3), −151.2 (s, BF_4). − ^{31}P NMR (145.78 MHz, $CDCl_3$): δ = 68.2 (s, 2 P). − $C_{23}H_{43}BF_{16}N_4P_2S_2$ (816.48): calcd. C 33.83, H 5.31; found C 33.71, H 5.02.

Synthesis of Compound 21: A solution of thiohexafluoroacetone (72 mg, 0.198 mmol) in ether (2 mL) was cooled to −70 °C and quickly added to a solution of methylenebis(diphenylphosphane) **1c** (50 mg, 0.130 mmol) in ether (3 mL) at the same temperature. The reaction mixture was stirred at −70 °C for 10 min. The reaction solution was then concentrated to a volume of about 0.6 mL. Hexane (1 mL) was added and solution was kept at −25 °C for 3 days. The colourless crystalline product formed over this time was filtered off and dried in vacuo. Yield of the crystals 50 mg (50%). According to the ^{31}P NMR spectrum the mother liquid contained compound **21** only. − ^{1}H NMR (360.13 MHz, $CDCl_3$): δ = 3.20 [sept., $^{3}J_{FH}$ = 8.07 Hz, 1 H, $CH(CF_3)_2$], 4.36 [d. sept., $^{3}J_{FH}$ = 7.34 Hz, $^{3}J_{PH}$ = 1.98 Hz, 1 H, $CH(CF_3)_2$], 6.85−7.18 (m, 12 H, Ph), 7.78−8.08 (m, 8 H, Ph). − ^{19}F NMR (188.31 MHz, $CDCl_3$): δ = −66.15 (dd, $^{3}J_{HF}$ = 7.4 Hz, J_{PF} = 2.6 Hz, 6 F, CF_3), −65.75 (d, $^{3}J_{HF}$ = 7.4 Hz, 6 H, CF_3) − ^{31}P NMR (145.78 MHz, $CDCl_3$): δ = −4.5 (d, $^{2}J_{PP}$ = 185 Hz, 1 P, P−C−P), 65.2 (d, $^{2}J_{PP}$ = 185 Hz,

X-ray Crystal Structure Determination of Compounds 9, 15, 18, and 21: All crystallographic measurements were performed at 173(2) K on a Siemens P4 diffractometer, using graphite monochromated Mo-K_α radiation (λ = 71.073 pm) and an LT2 low temperature device. The structures were solved by direct methods and refined by full-matrix least-squares on F^2 using SHELX-97 (Sheldrick, 1997). All non-hydrogen atoms were refined anisotropically and the position of the hydrogen atoms were calculated using a riding model. Crystal data, data collection and processing parameters are given in Table 1.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication nos. CCDC-150573 (**9**), CCDC-150574 (**15**), CCDC-150575 (**18**), and CCDC-150576 (**21**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the Deutsche Forschungsgemeinschaft for financial support (436 UKR 17/15/99) We are thankful to Dr. Th. Dülcks for the MS measurements and Peter Brackmann for his assistance in the X-ray structure analyses.

Keywords: Chirality / Biphosphole / Rhodium / Iridium / Catalysis / Hydrogenations / Hydroformylations

A convenient method for the synthesis of new racemic Rh^I and Ir^I complexes $[M(BIPHOS)(COD)]BF_4$ have been developed from the BIPHOS ligand and $[M(COD)Cl]_2$ precursors. These complexes have been tested as catalysts for hydrogenation and hydroformylation reactions. Excellent regioselectivities in branched aldehyde (98%) have been obtained in hydroformylation with the rhodium $[Rh(BIPHOS)(COD)]BF_4$ complex. The application of this convenient method to the synthesis of enantiomerically pure $[M(BIPHOS)(COD)]BF_4$ complexes has been investigated.

Introduction

Chiral diphosphane ligands, in particular those with C_2 symmetry,[1] have proved to be powerful auxiliaries in catalytic asymmetric processes.[2] We were interested in the possibilities offered by the 1,1′-diphenyl-3,3′,4,4′-tetramethyl-2,2′-biphosphole (BIPHOS, **1**), first synthesized by Mathey et al. in 1986.[3] This diphosphane combines the axial chirality generated by the biphosphole framework with the central chirality of the phosphorus atoms. This implies the existence of six stereoisomers corresponding to three pairs of enantiomers (Figure 1). In a previous report,[4] we have shown that BIPHOS exists in solution as an equilibrium mixture of two diastereoisomers, **1a** and **1b**, because of the configurational instability of the central chirality of the phosphorus atoms and probably also because of the axial chirality. This stereolability does not exist in the solid state and the three diastereoisomers have been fully characterized by X-ray diffraction.[4] In solution in the presence of a transition metal, the equilibrium shifts to the most favorable configurations for chelating the metal $\{[a]^S_{RR}$ and $[a]^R_{SS}\}$. In this way, we have obtained numerous chiral complexes of Ni, Pd, Pt, Rh[5] and Ru,[6] as racemic mixtures. Recently, the enantiomerically pure palladium complex $[PdCl_2(BIPHOS)]$ was synthesized from the enantiomerically pure BIPHOS ligand **1** $\{[a]^S_{RR}$ or $[a]^R_{SS}\}$ obtained by spontaneous resolution upon crystallization. It proved to be active in catalytic asymmetric allylic substitution.[7]

Here, we report a convenient method for synthesizing new racemic rhodium(I) and iridium(I) complexes $[M(BIPHOS)(COD)]^+$, and their use in the catalytic hydrogenation and hydroformylation reactions. We have also investigated the synthesis of enantiomerically pure complexes $[M(BIPHOS)(COD)]^+$ from the enantiomerically pure BIPHOS ligand **1**.

Results and Discussion

Synthesis of $[M(BIPHOS)(COD)]BF_4$ Complexes in Racemic Form

In our previous work on 2,2′-biphosphole (BIPHOS), we have shown that this diphosphane is a rather good ligand for transition metals, as evidenced by the formation of bis-biphosphole complexes.[8] For example, under the conditions used with classical diphosphanes,[9] BIPHOS (1 equiv. per rhodium atom) reacted rapidly with $[Rh(COD)Cl]_2$ or $[Rh(COD)_2]BF_4$ at ambient temperature by displacement of the two labile COD ligands to afford $[Rh(BIPHOS)_2]^+$ (**2**)[5] instead of $[Rh(BIPHOS)(COD)]^+$ (**3**) (Scheme 1).

In order to prepare the monosubstituted biphosphole complex **3**, which could be an interesting catalyst precursor for hydrogenation[10] and hydroformylation,[10] we attempted to reduce the reactivity of BIPHOS towards the rhodium precursors by working at low temperature. At −78 °C with the $[Rh(COD)_2]BF_4$ precursor, the reaction proceeded rapidly in a dichloromethane solution and afforded a mixture of two complexes, **3** and **2′′**, in the ratio 75:25, which could not be separated.

When the $[Rh(COD)Cl]_2$ precursor was used under the same conditions, a new rhodium complex **4** was observed by ^{31}P NMR spectroscopy (δ = 40.65, $^1J_{P-Rh}$ = 137 Hz) at −78 °C, along with the minor complex **2′** (δ = 46.10, $^1J_{P-Rh}$ = 122 Hz). This new complex slowly disappeared when the temperature increased, leading quantitatively to complex **2′** at room temperature. Complex **4**, which appears as an intermediate in the formation of complex **2′**, might

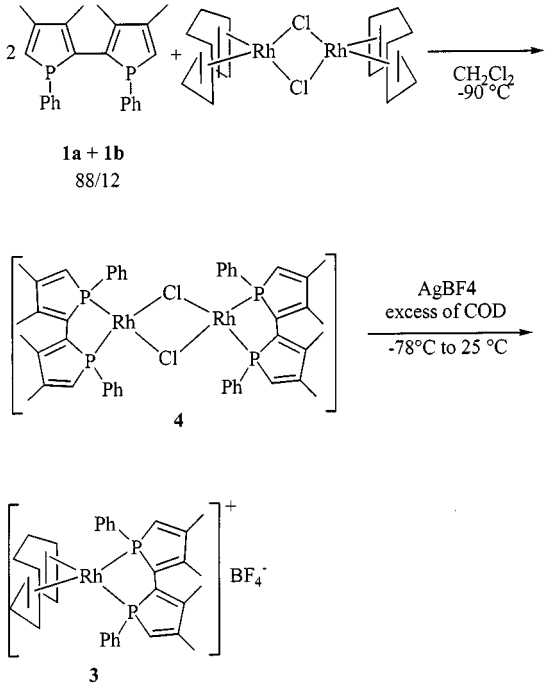
be the dinuclear complex $[Rh(BIPHOS)Cl]_2$.[11] Such an intermediate might allow the preparation of the desired complex $[Rh(BIPHOS)(COD)]BF_4$ by cleavage of the μ-Rh−Cl bonds and subsequent coordination of COD at the vacant rhodium site. Indeed, $[Rh(BIPHOS)Cl]_2$, quantitatively obtained by addition of two equivalents of a dichloromethane



Scheme 2

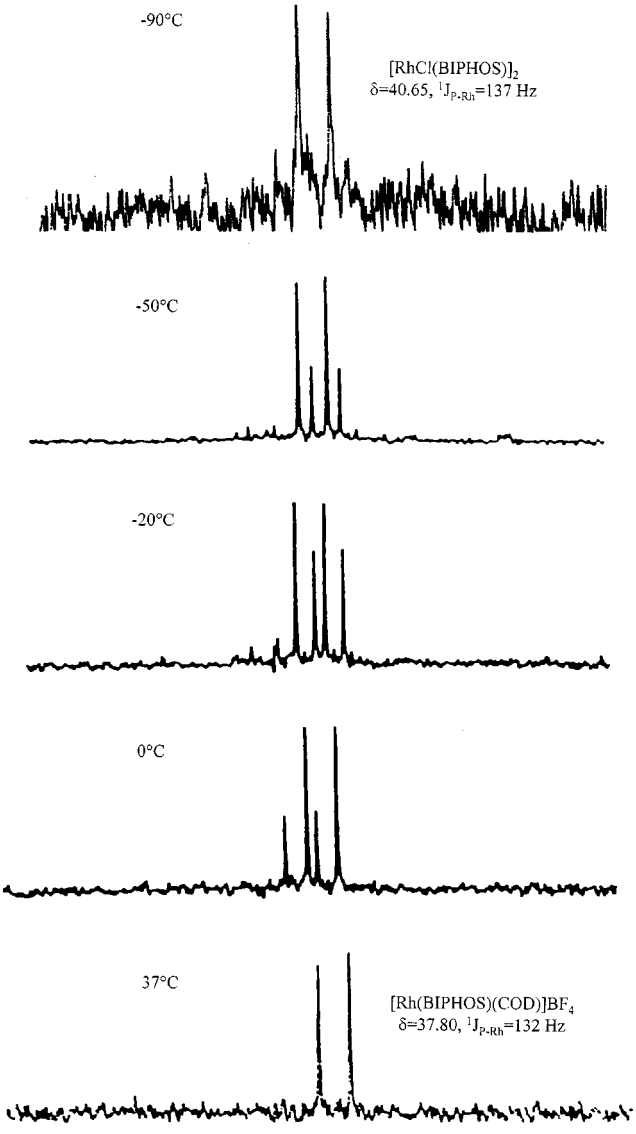


Figure 2. ^{31}P NMR studies from −90 °C to ambient temperature for the reaction of BIPHOS with $[Rh(COD)Cl]_2$

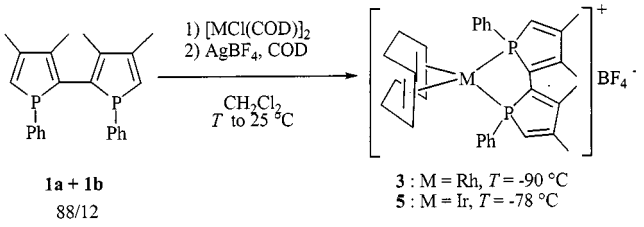
solution of BIPHOS to a dichloromethane solution of $[Rh(COD)Cl]_2$ precursor cooled to −90 °C, led to $[Rh(BIPHOS)(COD)]BF_4$ (**3**) after addition of four equivalents of $AgBF_4$ and an excess of cyclooctadiene at −78 °C (Scheme 2). This reaction was monitored by ^{31}P NMR spectroscopy from −78 °C to ambient temperature (Figure 2) showing the disappearance of complex **4** and the concomitant appearance of complex **3** (δ = 37.80, $^1J_{P-Rh}$ = 132 Hz). Complex **3** was isolated in 95% yield and characterized by multinuclear NMR spectroscopy, mass spectrometry and elemental analysis.

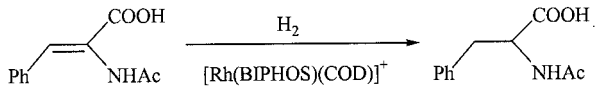
This method was then applied to the synthesis of an analogous iridium complex. Starting from $[Ir(COD)Cl]_2$ under similar conditions (Scheme 3), the ^{31}P NMR studies from −78 °C to ambient temperature revealed that the reaction was more complicated, since various intermediates were detected during the course of the reaction. However, the $[Ir(BIPHOS)(COD)]BF_4$ complex **5** was obtained quantitatively at room temperature, and was isolated in a pure form as a red solid, which was characterized by NMR spectroscopy, mass spectrometry and elemental analysis.



Scheme 3

Catalysis

As a preliminary evaluation of the catalytic properties, these new rhodium and iridium complexes $[M(BIPHOS)(COD)]BF_4$ were tested in hydrogenation and hydroformylation reactions. Initial hydrogenation experiments were performed with the complexes **3** and **5** as precursor catalysts in the hydrogenation of α-acetoamidocinnamic acid. The rhodium complex $[Rh(BIPHOS)(COD)]BF_4$ (**3**) shows moderate activity for this hydrogenation in MeOH, THF or CH_2Cl_2 giving complete conversion over 20 h at 25 °C under 15 atm. of H_2 (Scheme 4, Table 1). Under the same conditions, the iridium complex $[Ir(BIPHOS)(COD)]BF_4$ (**5**) proved to be inactive. At higher pressure (150 atm.), very weak conversions, in the range 6−10%, were recorded (Table 1).



Scheme 4

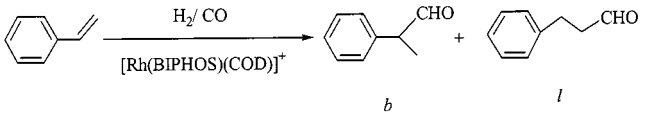
8	**5**	CH_2Cl_2	150	7

[a]Reaction conditions: T = 25 °C, t = 20 h, [cat]/[substrat] = 2:100.

To extend the utility of the $[Rh(BIPHOS)(COD)]BF_4$ catalyst precursor the hydroformylation of styrene was examined. The reaction was carried out at a temperature of 25 °C and a pressure of 150 atm. of CO/H_2 (1:1) (Scheme 5). High conversions of styrene were recorded, giving predominantly aldehydes with branched selectivities in CH_2Cl_2 (97%) or MeCN (98%) (Table 2). In MeOH, the regioselectivity towards the branched aldehyde regioisomer was lower, and the linear alcohol resulting from hydrogenation of the corresponding aldehyde was also formed in addition to the formyl regioisomer. Complex **4** proved to be a very regioselective catalyst in the hydroformylation of styrene.[12]



Scheme 5

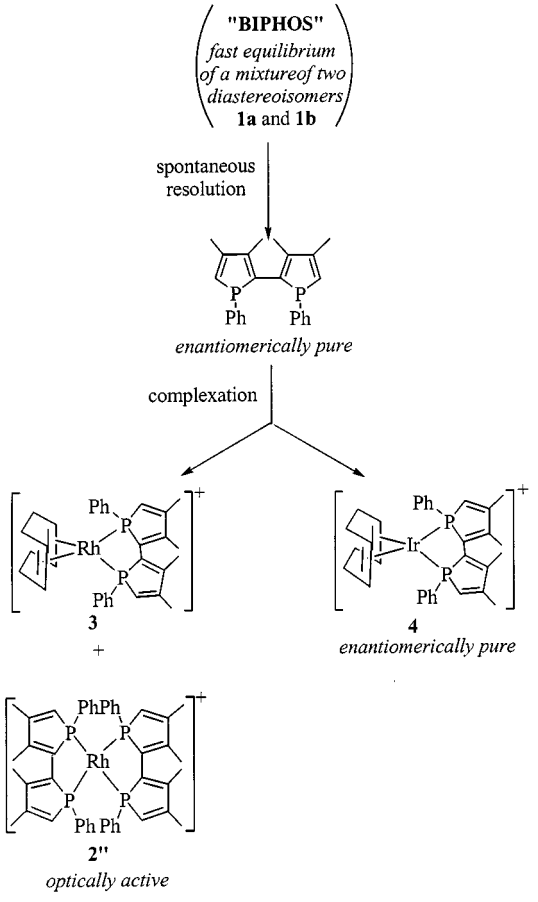
Synthesis of $[M(BIPHOS)(COD)]BF_4$ Complexes in Optically Active Form

In order to get an insight into asymmetric catalysis, we attempted to synthesize optically pure $[M(BIPHOS)(COD)]BF_4$ complexes. The present methods developed for the synthesis of racemic $[M(BIPHOS)(COD)]BF_4$ complexes, which require low temperature conditions, should be a convenient method for the synthesis of the optically pure

complexes. Indeed, enantiomerically pure BIPHOS ligand **1** {$[a]^{S}_{RR}$ or $[a]^{R}_{SS}$} was obtained by spontaneous resolution upon crystallization;[4] it racemizes in solution above −60 °C.[4] We investigated these syntheses with large single crystals (typically 50 to 150 mg) and the purity of each crystal was checked with polarized light before being used in the reaction. Using a slightly modified procedure that involved the addition of a single crystal of BIPHOS instead of a solution of BIPHOS, the reaction did not lead to complex **3** but quantitatively afforded complex **2′′**. Upon reverse addition, two problems arose. The first problem was to obtain a complete dissolution of the crystal at low temperature before addition of the metal precursor. For that, the solubilisation of one single crystal of **1** was carried out by stirring for 16 hours at −78 °C. Then, the solution was cooled to −90 °C before adding the solution of $[M(COD)Cl]_2$ precursor. However, this caused the second problem. During the addition, the ligand was always kept in excess with respect to the metal, and the formation of $[Rh(BIPHOS)_2]^+$ (**2**) could not be avoided, hence we obtained a mixture of complexes **2′′** and **3** in a 1:1 ratio at low temperature (Scheme 6). These two complexes could not be separated, as reported above for the racemic version. However, the optical rotation observed, $[\alpha]_D$ = 172, proved that optically active complexes $[Rh(BIPHOS)_2]BF_4$ and/or $[Rh(BIPHOS)(COD)]BF_4$ had been obtained.



Scheme 6

In contrast to the rhodium case, we were easily able to obtain the iridium complex **5** in an optically active form. In this case, the reaction was carried out by addition of one pure single crystal of BIPHOS to a dichloromethane solution of $[Ir(COD)Cl]_2$ cooled to −78 °C, followed by treatment with $AgBF_4$ in the presence of an excess of cyclooctadiene (Scheme 6). This complex was isolated as a red solid in 95% yield with $[\alpha]_{578}$ = −95 (c = 0.02, CH_2Cl_2). The enantiomeric purity of complex **5** has not been evaluated; however, starting from different single crystals of BIPHOS, the same absolute value of [α] was obtained for complex **5**. Therefore, as in the case of the palladium complex,[7] we can consider that in dichloromethane at −78 °C, a single crystal of enantiomerically pure BIPHOS ligand reacts with $[Ir(COD)Cl]_2$ to give the enantiomerically pure complex [Ir(BIPHOS)(COD)]BF_4.

Conclusions

We have developed a convenient route for the preparation of new racemic Rh^I and Ir^I complexes [M(BIPHOS)(COD)]BF_4, and we have evaluated their catalytic properties in the hydrogenation and hydroformylation reactions. The efficiency of the rhodium complex was demonstrated in particular in hydroformylation, in which excellent regioselectivities (98%) in the branched aldehyde were obtained. In contrast, no specific efficiency was observed for the iridium complex.

This convenient synthetic method, when applied to the enantiomerically pure BIPHOS ligand, allows the synthesis of an enantiomerically pure iridium complex and an optically active mixture of the rhodium complexes **2′′** and **3**. Were are currently studying a method for the isolation of the rhodium complex in an optically pure form and hence carrying out studies of its use in asymmetric catalysis.

Experimental Section

Instrumentation: All reactions were carried under an inert atmosphere of dry argon using Schlenk glassware and vacuum line techniques. The experiments requiring H_2 or H_2/CO pressure were carried out into a stainless steel high pressure reactor by "TOP-industrie". Floodgates for gas introduction and evacuation were fixed on the lid. A glass ampoule containing the reaction mixture was inserted into the reactor and stirring and heating were external.

^{1}H, ^{13}C{^{1}H, ^{31}P} and ^{31}P {^{1}H} NMR spectra were recorded on a Bruker WMX 400 instrument operating at 400, 100 or 162 MHz, respectively, or on a Bruker AM 250 instrument operating at 250, 63 or 101 MHz, respectively. Chemical shifts are reported in parts per million (ppm) relative to Me_4Si (^{1}H and ^{13}C) or 85% H_3PO_4 (^{31}P). Mass spectra were obtained on a Mermag R10−10 instrument. Elemental analyses were performed by the "Service d′Analyse du Laboratoire de Chimie de Coordination" at Toulouse, France. Optical rotations were measured on a Perkin−Elmer 241 polarimeter.

Chemicals: BIPHOS **1**[3] and the complexes **2′**[5] and **2′′**[5] were synthesised as previously described. $[Rh(COD)Cl]_2$ precursor was purchased from Aldrich Chemical Co. $[Ir(COD)Cl]_2$ precursor was purchased from Fluka. Solvents were freshly distilled from standard drying agents.

Preparation of Complex 3. Racemic Form: BIPHOS (**1**; 82 mg, 0.22 mmol) in dichloromethane (1.5 mL) at −90 °C was quickly added to a solution of (1,5-cyclooctadiene)rhodium(I) chloride dimer (54 mg, 0.11 mmol) in dichloromethane (4 mL) at −90 °C. The mixture was stirred for 20 min. and was then rapidly warmed to −78 °C. 1,5-Cyclooctadiene (0.107 mL, 0.88 mmol) was then slowly added followed by addition of silver tetrafluoroborate (42 mg, 0.22 mmol). The reaction mixture was warmed to 25 °C within 2 hours and filtered. The solvent was removed in vacuo and the resulting red solid was washed four times with diethyl ether (5 mL). The residue was dried in vacuo giving a brown solid (139 mg, 95%). − ^{1}H NMR (CD_2Cl_2): δ = 1.70 (s, 6 H, CH_3), 2.21 (s, 6 H, CH_3), 2.12−2.54 [m, 8 H, CH_2 (COD)], 5.17 [m, 2 H, CH (COD)], 5.89 [m, 2 H, CH (COD)], 6.60 (d, $^2J_{H-P}$ = 32.6 Hz, 2 H, CH-P), 7.37−7.63 (m, 10 H, Ph). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 159.8 (s, *C*−CH_3), 145.6 (t, J_{C-P} = 14.6 Hz, *C*−CH_3), 136.8 (t, J_{C-P} = 39.3 Hz, *C*=C−CH_3), 132.9 (t, J_{C-P} = 6.2 Hz, Ph), 131.8 (s, Ph), 129.7 (t, J_{C-P} = 5.1 Hz, Ph), 120.0 (m, CH-P), 99.2 [m, CH (COD)], 98.5 [m, CH (COD)], 30.2 [s, CH_2 (COD)], 30.0 [s, CH_2 (COD)], 18.9 (t, J_{C-P} = 5.5 Hz, CH_3), 15.2 (t, J_{C-P} = 4.2 Hz, CH_3). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 37.80 (d, $^1J_{P-Rh}$ = 132.2 Hz). − FAB-MS (MNBA, CH_2Cl_2): *m/z* (%) = 585 (100) [M − BF_4]$^+$. − $C_{32}H_{36}BF_4P_2Rh$ (672.30): calcd. C 57.17, H 5.39; found C 56.82, H 5.09.

Optically Active Form: A single crystal of BIPHOS was added to dichloromethane at −78 °C and the mixture was stirred overnight. After cooling to −90 °C, a dichloromethane solution of (1,5-cyclooctadiene)rhodium(I) chloride dimer was then added to the BIPHOS solution and the resulting mixture was stirred for only 5 min. The procedure is then the same as described above. The final product was a 1:1 mixture of $[Rh(BIPHOS)_2]BF_4$ (**2′′**) and $[Rh(BIPHOS)(COD)]BF_4$ (**3**). $[\alpha]_D$ = 172 (*c* = 0.3, CH_2Cl_2).

Preparation of Complex 5. Racemic Form: BIPHOS (97 mg, 0.26 mmol) in dichloromethane (1.5 mL) at −78 °C was quickly added to a solution of(1,5-cyclooctadiene)iridium(I) chloride dimer (87 mg, 0.13 mmol) in dichloromethane (4 mL) at −78 °C. The mixture was stirred for 1 h at −78 °C. 1,5-Cyclooctadiene (0.130 mL, 1.03 mmol) was then slowly added followed by the addition of silver tetrafluoroborate (44 mg, 0.26 mmol). The reaction mixture was warmed to 25 °C within 2 hours and filtered. The solvent was removed in vacuo and the resulting purple solid was washed four times with *n*-pentane (5 mL). The residue was dried in vacuo giving a dark red solid (140 mg, 95%). − ^{1}H NMR (CD_2Cl_2): δ = 1.72 (d, $^4J_{H-H}$ = 1 Hz, 6 H, CH_3), 2.25 (s, 6 H, CH_3), 2.06−2.04 [m, 8 H, CH_2 (COD)], 4.73 [m, 2 H, CH (COD)], 5.43 [m, 2 H, CH (COD)], 6.67 (d, $^2J_{H-P}$ = 32.8 Hz, 2 H, CH-P), 7.37−7.56 (10 H, m, Ph). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 159.7 (s, *C*−CH_3), 145.8 (t, J_{C-P} = 14.6 Hz, *C*−CH_3), 136.5 (dd, J_{C-P} = 55.1 Hz, J_{C-P} = 25.8 Hz, *C*=C−CH_3), 132.4 (d, J_{C-P} = 9.7 Hz, Ph), 131.7 (s, Ph), 129.5 (d, J_{C-P} = 10.2 Hz, Ph), 120.4 (d, J_{C-P} = 44.4 Hz, CH-P), 83.2 [m, CH (COD)], 32.8 [s, CH_2 (COD)], 31.3 [s, CH_2 (COD)], 18.9 (d, J_{C-P} = 11.7 Hz, CH_3), 15.9 (t, J_{C-P} = 9.5 Hz, CH_3). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 32.78. − FAB-MS (MNBA, CH_2Cl_2): *m/z* (%) = 675 (100) [M − BF_4]$^+$. − $C_{32}H_{36}BF_4IrP_2$ (761.61): calcd. C 50.46, H 4.76; found C 49.90, H 4.66.

Optically Active Form: A single crystal of BIPHOS was added directly to a dichloromethane solution of(1,5-cyclooctadiene)iridium(I) chloride dimer at −78 °C and the resulting mixture was stirred overnight at −78 °C. The procedure was the same as described above. $[\alpha]_{578}$ = 95 (*c* = 0.02, CH_2Cl_2).

Hydrogenation Experiments: In a typical experiment, a solution of 2×10^{-2} mmol of catalyst and substrate (50 equiv.) in 2 mL of the desired solvent was transferred under argon into a 3 mL glass ampoule. It was then placed into a stainless steel autoclave and stirred for 3 h with α-acetamidocinnamic acid. The reaction vessel was then pressurized to the required H_2 pressure and stirred for the desired time. After slow venting of the reactor, the mixture containing *N*-acetylphenylalanine was filtered through silica with ethyl acetate as eluent. The conversion was measured directly by integration of the CH_3 signals in the ^{1}H NMR spectrum.

Hydroformylation Experiments: The procedure was the same as described for hydrogenation. The mixture was stirred for 1 h before the autoclave was pressurized (CO/H_2 = 1:1). The conversion rate was measured directly by integration of the C*H*O and PhC*H*CH_2 signals in the ^{1}H NMR spectrum and the branched/linear value was given by integration of the C*H*O signals (branched: δ = 9.1, linear: δ = 9.2).

Hydrido(3-hydroxyalkynyl) Complexes as Intermediates in the Activation of Propargyl Alcohol Derivatives by [Cp*RuCl(dippe)] [Cp* = C_5Me_5, dippe = 1,2-bis(diisopropylphosphanyl)ethane]

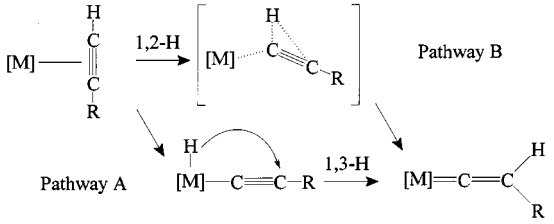
Keywords: Sandwich complexes / Ruthenium / Isomerizations / Hydrido ligands / Allenylidene ligands

The reaction of propargyl alcohol derivatives with the complex [Cp*RuCl(dippe)] [dippe = 1,2-bis(diisopropylphosphane)ethane] and $NaBPh_4$ in MeOH yields hydrido(3-hydroxyalkynyl) compounds [Cp*Ru(H){C≡CC(OH)RR′}(dippe)][BPh_4] [R, R′ = Ph, Ph (**1a**); H, Ph (**1b**); H, Me (**1c**)]. These represent intermediates in the formation of 3-hydroxyvinylidene species [Cp*Ru{=C=CHC(OH)RR′}(dippe)][BPh_4] [R, R′ = Ph, Ph (**2a**); H, Ph (**2b**); H, Me (**2c**)], into which they irreversibly rearrange both in solution and in the solid state. Solution kinetic studies have been carried out on this isomerization process. Ulterior dehydration processes are feasible, resulting in the formation of allenylidene [Cp*Ru(=C=C=CRR′)(dippe)][BPh_4] [R, R′ = Ph, Ph (**3a**); H, Ph (**3b**)] or vinylvinylidene [Cp*Ru{=C=CHCH(=CH_2)}(dippe)][BPh_4] (**4**) species. The X-ray crystal structure of the novel secondary allenylidene complex [Cp*Ru(=C=C=CHPh)(dippe)][BPh_4] is presented.

Introduction

It is well known that coordination of terminal alkynes to metal complexes reverses the relative stabilities of acetylene and vinylidene, this being a general procedure used for the synthesis of a wide range of vinylidene complexes.[1] In the case of propargyl alcohols HC≡CC(OH)R_2, subsequent dehydration of the resulting 3-hydroxyvinylidene complex may eventually lead to allenylidene compounds.[2,3] By analogous methods, complexes containing even longer unsaturated carbon chains have been obtained.[2,4] Interest in vinylidene complexes has been partly focussed on their utility in stoichiometric or catalytic transformations of alkenes and alkynes.[5] On the other hand, how the alkyne to vinylidene tautomerization takes place is still subject of research.

As a first reasonable approach to the isomerization mechanism, one may envisage oxidative addition of the alkyne to the metal centre thereby furnishing an alkynyl(hydrido)-metal complex.[6] (Scheme 1, Pathway A). Several cases of this are known in the chemistry of Co, Rh, and Ir,[7] and it is supported by ab initio MO calculations.[8] In the case of d^6 systems (Ru^{II}, Os^{II}, Mn^{I}), however, a pathway involving oxidative addition would seem to be a thermodynamically unfavourable process,[9] and a direct 1,2-hydrogen shift in the initially formed alkyne complex would be the most plausible pathway to a vinylidene[10] (Scheme 1, Pathway B). Actually, reactions of $[CpM(PR_3)_2]^+$ (M = Fe, Ru, Os) fragments with 1-alkynes normally lead directly to vinylidene complexes $[CpM(=C=CHR)(PR_3)_2]^+$ without any observable intermediates.[1,11] In the case of the complex [CpOsCl(P*i*Pr_3)$_2$], the isomerization of the π-alkyne complex [CpOsCl(P*i*Pr_3)(η^2-HC≡CPh)] into the vinylidene derivative takes place without any evidence of the intermediacy of alkynyl(hydrido) species.[12] Its reaction with alkynes and alkynols to afford the first examples of alkynyl(hydrido)osmium(IV) complexes that do not rearrange to their vinylidene isomers has only recently been reported.[13] In the case of ruthenium, there are several examples of direct isomerization to vinylidene,[14] vinylidene/π-alkyne equilibria,[15] and vinylidene to π-alkyne isomerization,[16] for which alkynyl(hydrido) species have never been detected. The relatively recent use of basic ruthenium fragments containing η^5-C_5Me_5 and their application in the activation of terminal alkynes[17] has allowed new insights into this matter.



Scheme 1

Thus, study of the interaction of [Cp*RuCl(dippe)] with 1-alkynes allowed for the first time the isolation and characterization of metastable alkynyl(hydrido)ruthenium(IV) species as intermediates in the formation of the more stable vinylidene isomers.[18] These studies showed that the mechanism of this isomerization involves hydrido ligand dissociation as a proton and subsequent protonation on the β-carbon atom of the alkynyl ligand (Scheme 2).[19] It was also found that the isolation of these metastable intermediates is strongly dependent on the preparative method

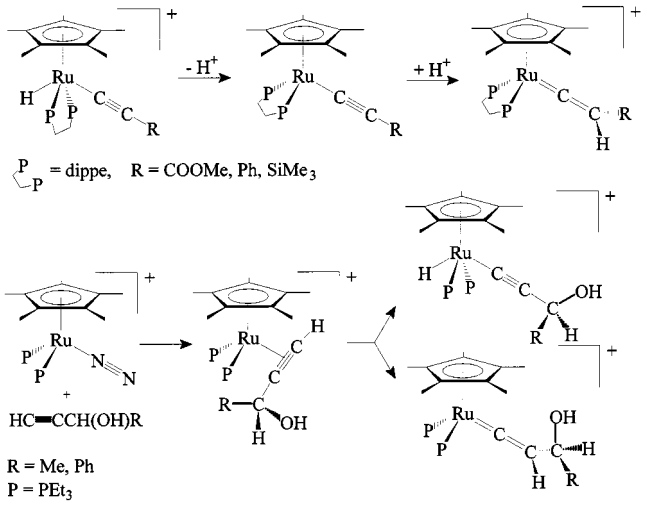
used. In the case of propargyl alcohols, which form complexes that are more soluble in the methanol used as solvent, this dependence proved to be crucial in that only 3-hydroxyvinylidene or dehydration products were isolated in the course of our earlier studies on [Cp*RuCl(dippe)].[20] A similar study has recently been carried out on the system [Cp*RuCl(PEt_3)$_2$], which contains a monodentate and sterically less demanding phosphane as a co-ligand. In this case, it was possible to detect η^2-alkynol derivatives and to monitor by $^{31}P\{^1H\}$ NMR their isomerization by two alternative pathways that are simultaneously operative at low temperature, namely direct 1,2-H shift and oxidative addition.[21] Furthermore, following an appropriate strategy, hydrido(3-hydroxyalkynyl) derivatives of the type [Cp*Ru(H){C≡CC(OH)R_2}(PEt_3)$_2$][BPh_4] were isolated and fully characterized. In view of these results, we have now re-examined the reactivity of [Cp*RuCl(dippe)] towards alkynols. As a result, we have been able to isolate new hydrido(3-hydroxyalkynyl) complexes, which have allowed us to perform further kinetic studies of the isomerization process into 3-hydroxyvinylidene species. Dehydration reactions of these compounds have led to new allenylidene and vinylvinylidene complexes, which have been fully characterized.



Scheme 2

Results and Discussion

The metastable complexes [Cp*Ru(H){C≡CC(OH)RR′}(dippe)][BPh_4] [R, R′ = Ph, Ph (**1a**); H, Ph (**1b**); H, Me (**1c**)] were isolated by precipitation following addition of the solid chloro complex [Cp*RuCl(dippe)] to a solution of $NaBPh_4$ and the alkyne in the minimum volume of MeOH at 0 °C. With an alkyne such as HC≡CCOOEt, the complex [Cp*Ru(H)(C≡CCOOEt)(dippe)][BPh_4] (**1d**) is easily obtained by adding $NaBPh_4$ prior to the alkyne. However, alkynols form more alcohol-soluble complexes owing to the presence of the hydroxy group. As a consequence, hydrido(3-hydroxyalkynyl) compounds can remain unnoticed due to the fact that isomerization to the vinylidene may occur to a greater or lesser extent prior to precipitation. This could only be avoided by adhering strictly to the aforementioned procedure and accounts for the fact that species analogous to compounds **1a**−**1c** were not detected in our previous work on this system. Furthermore, the reaction with HC≡C−CH_2OH yields the alkynyl(hydrido) complex only as a minor product even under these experimental conditions. Only in the case of HC≡CC(OH)Ph_2 was it possible to isolate the complex [Cp*Ru(H){C≡CC(OH)Ph_2}(dippe)][BPh_4] as a solid in pure form, uncontaminated by any of the 3-hydroxyvinylidene isomer. In the IR spectrum of compound **1a**, the ν(OH), ν(C≡C), and ν(Ru−H) bands are seen at 3578, 2100, and 2045 cm^{-1}, respectively. The $^{31}P\{^1H\}$ NMR spectrum recorded in $CDCl_3$ at 0 °C consists of a singlet at δ = 73.1, whereas in the ^1H NMR spectrum the terminal hydride ligand appears as a triplet at δ = −9.17 with a coupling constant of 30.5 Hz. Since this compound does not isomerize at 0 °C, it was possible to record the $^{13}C\{^1H\}$ NMR spectrum, which features a triplet at δ = 103.7 and a singlet at δ = 116.4, in good accord with the expected resonances for the α- and β-carbon atoms of the alkynyl ligand. In the case of the alkynols HC≡CCH(OH)R (R = Me, Ph), the corresponding hydrido(3-hydroxyalkynyl) complexes **1b** and **1c** could also be obtained in good yields, but were invariably accompanied by minor amounts of their 3-hydroxyvinylidene isomers.

The spectral properties of these complexes closely resemble those of complex **1a**. The main difference is observed in the $^{31}P\{^1H\}$ NMR spectrum of **1b** (Figure 1), where the presence of a chiral centre at the γ-carbon atom induces a magnetic nonequivalence of the phosphorus atoms, giving rise to an AB spin system at low temperatures ($^3J_{PP'}$ = 18 Hz). This pattern has also been observed in some analogous complexes such as [Cp*Ru(H){C≡CC(OH)RR′}(PEt_3)$_2$][BPh_4] (R, R′ = H, Ph; Me, Ph) ($^3J_{PP'}$ = 20−21 Hz)[21] and [CpOs(H){C≡CC(OH)MePh}(P*i*Pr_3)$_2$][PF_6] ($^3J_{PP'}$ = 23.5 Hz).[13] The pattern is

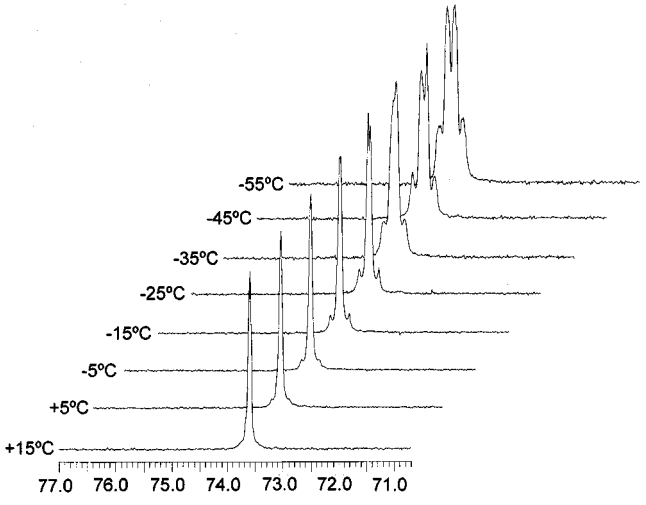


Figure 1. Stacked $^{31}P\{^1H\}$ NMR spectra illustrating the evolution of the [Cp*Ru(H){C≡CCH(OH)Ph}(dippe)][BPh_4] (**1b**) signal with temperature

temperature-dependent and the doublets coalesce to a singlet above +15 °C, most likely due to an averaging of the anisotropy of the phosphorus atom environments through rotation of the CH(OH)Ph group about the C−C bond.

Compounds **1a−1c** isomerize into the vinylidene species [Cp*Ru{=C=CHC(OH)RR′}(dippe)][BPh_4] [R, R′ = Ph, Ph (**2a**); H, Ph (**2b**); H, Me (**2c**)] both in solution and in the solid state at room temperature (see Scheme 3), as has also been reported elsewhere.[6,18,21] However, as for [Cp*RuH(C≡CCOOMe)(dippe)][BPh_4],[19] the tautomerization of **1d** into the vinylidene complex [Cp*Ru(=C=CHCOOEt)(dippe)][BPh_4] (**2d**) only occurs in solution, and not in the solid state. Orange crystalline products, identified as vinylidene complexes by IR and NMR spectroscopy, were obtained when samples of **2a−2c** were heated in the solid state for several hours at 40 °C. In contrast to the other complexes, a clean preparation of [Cp*Ru{=C=CHC(OH)Ph_2}(dippe)][BPh_4] (**2a**) by isomerization of **1a** in solution is not possible due to the fact that spontaneous dehydration ensues. The vinylidene protons of **2a** and **2d** appear as broad singlets at δ = 4.37 and 4.52 in the respective ^{1}H NMR spectra, while in the ^{13}C{^{1}H} NMR spectra, the vinylidene α-carbon atoms give triplets at δ = 338.8 and 338.7 with coupling constants of 16.1 and 14.3 Hz, respectively. In the ^{1}H NMR spectra of **2b** and **2c**, the vinylidene protons appear as doublets at δ = 4.33 and 3.98, while the protons on the γ-carbon atoms give signals at δ = 5.40 (doublet) and 4.51 (doublet of quadruplets), respectively. The ^{31}P{^{1}H} NMR spectra of **2b** (Figure 2) and **2c** at 25 °C each consist of an AB spin pattern with a coupling constant of 17.1 Hz. In these cases, the doublets are more clearly separated from each other. This suggests an increased anisotropy in the chemical environments of the phosphorus atoms of **2b** and **2c** as compared to **1b** and **1c** due to the effect of the chiral centre on the γ-carbon atom. This can be attributed to the change in hybridization from sp to sp^2 at the β-carbon atom. The doublets move closer to each other as the temperature is increased, indicating chemical shift averaging, but do not coalesce even at 45 °C. In fact, the phosphorus atoms are expected to remain magnetically nonequivalent even at the fast-exchange limit due to the presence of the chiral substituent. This is consistent with the observed pattern, which has also been reported for related compounds such as [Cp*Ru{=C=CHCH(OMe)-Me}(PMe_2Ph)$_2$][PF_6] [17a] and [(η^5-C_9H_7)Ru{=C=CHCH(OMe)Ph}(PPh_3)$_2$][PF_6].[22]

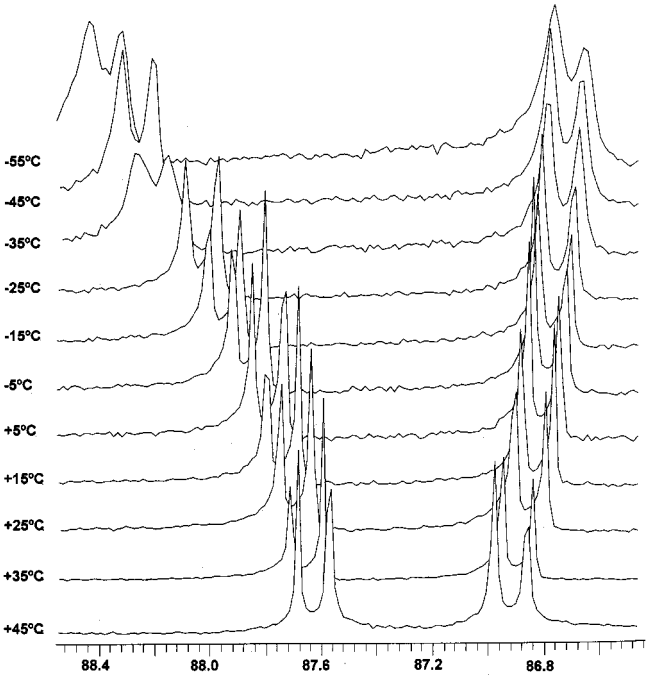

Figure 2. Stacked ^{31}P{^{1}H} NMR spectra illustrating the evolution of the [Cp*Ru{=C=CHCH(OH)Ph}(dippe)][BPh_4] (**2b**) signal with temperature

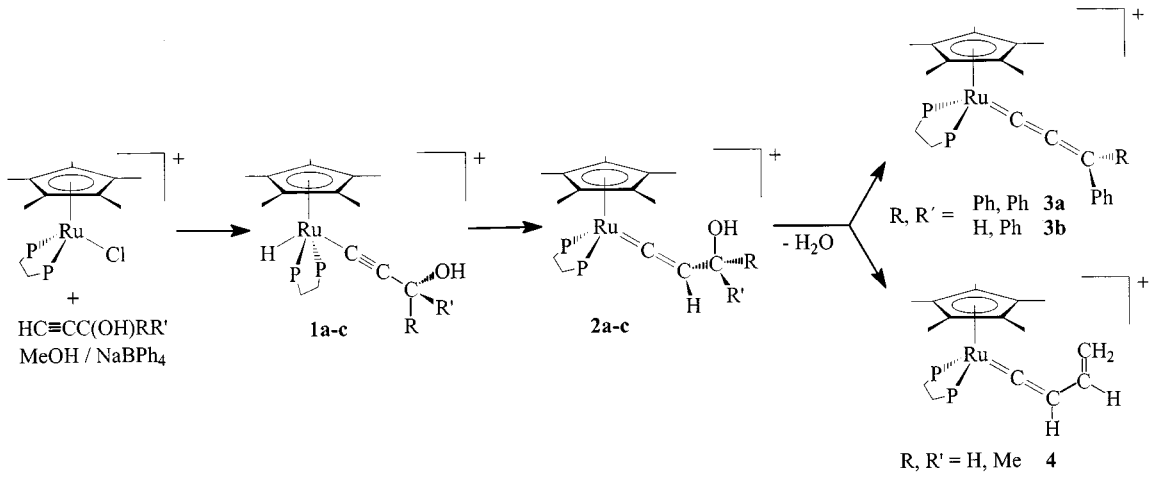
In order to establish the sequence of intermediates in the activation of alkynes and alkynols by the moiety {[Cp*Ru(dippe)]$^+$}, we first attempted to detect the intermediacy of π-alkyne complexes in the first step of the overall process. While an equilibrium between the π-alkyne and alkynyl(hydrido) species was found for the previously described [Cp*Ru(η^2-HC≡CH)(dippe)][BPh_4],[19] in the case of substituted alkynes these adducts are expected to be thermodyn-



Scheme 3

amically less favourable. The substituent on the alkyne makes steric interactions with the phosphane and Cp* methyl groups much stronger when this ligand is bound to the metal centre in an η^2-fashion as compared to those in an η^1-alkynyl or -vinylidene complex.

At variance with our latest results on the system containing the moiety $\{[Cp^*Ru(PEt_3)_2]^+\}$, the reaction of alkynes with labile cationic adducts of the type $[Cp^*Ru(L)(dippe)]^+$ (L = C_2H_4, N_2)[23] at low temperature did not provide any supporting evidence for the formation of π-alkyne intermediates. Upon addition of an excess of the appropriate alkynol (or HC≡CCOOEt) to a precooled $CDCl_3$ solution of the ethylene complex $[Cp^*Ru(C_2H_4)(dippe)][BPh_4]$[23] at −40 °C, the initial resonance in the $^{31}P\{^1H\}$ NMR spectrum (one singlet at δ = 77.9) remained unchanged below −20 °C. Above this temperature, this signal irreversibly disappeared, being replaced by a single resonance attributable to the corresponding alkynyl(hydrido) species **1a−1d**. The metallic fragments $\{[Cp^*Ru(PEt_3)_2]^+\}$ and $\{[Cp^*Ru(dippe)]^+\}$ are able to activate C−H bonds in alkynes by virtue of their high basicities. This ability is enhanced for the $\{[Cp^*Ru(dippe)]^+\}$ moiety: While complexes containing PEt_3 give mixtures of alkynyl(hydrido) and vinylidene species, formed through the intermediacy of π-alkyne adducts, the analogous compounds containing dippe only form vinylidene species, according to a pathway involving the intermediacy of the alkynyl(hydrido) species. Prior coordination of the alkyne seems to favour the formation of the vinylidene isomer by a direct pathway involving a 1,2-hydrogen shift, as has been observed for $[Cp^*Ru(\eta^2\text{-}HC{\equiv}CH)(dippe)]^+$,[19] $[Cp^*Ru\{\eta^2\text{-}HC{\equiv}CCH(OH)R\}(PEt_3)_2]^+$,[21] and $[CpOsCl(\eta^2\text{-}HC{\equiv}CPh)(P\mathit{i}Pr_3)]$.[13]

The kinetics of the isomerization of complexes **1a−1d** into **2a−2d** has been studied. The temperature range in which the process takes place at measurable rates is clearly determined by the substituent on the γ-carbon atom (see Table 1). Thus, the isomerization of **1a** proceeds at measurable rates in the range 25−45 °C, whereas for **1d** it can only be observed at 10−30 °C. The stepwise substitution of the phenyl groups on the γ-carbon atom decreases the temperature range by ca. 10 °C. In all cases, the rate is first order with respect to the alkynyl(hydrido) complex. From Eyring plots, the activation parameter was determined (Table 1) to be $\Delta G^{\ddagger}_{298} \approx 21$ kcal mol^{-1} in each case. These results can be compared with those reported for cobalt complexes, i.e. $\Delta G^{\ddagger}_{298} \approx 31$ kcal mol^{-1} for $[Co(H)(C{\equiv}CPh)PP_3]^+$ [PP_3 = $P(CH_2CH_2PPh_2)_3$],[7a] and with our earlier kinetic studies on the isomerization of $[Cp^*Ru(H)(C{\equiv}CR)(dippe)]^+$ [19] (R = COOMe, Ph, $SiMe_3$), in which $\Delta G^{\ddagger}_{298}$ was estimated to be ca. 20 kcal mol^{-1}. Migration of the hydrido ligand as a proton following dissociation and subsequent protonation of the β-carbon atom has previously been proposed as the mechanism for this transformation in solution, and it is supported by sound experimental evidence.[7a,19] It is further supported in the present case by the observed solvent effect on the isomerization rate. The formation of the vinylidene complex **2d** from **1d** is subject to a strong solvent dependence: the process takes place more rapidly in acetone, in which the constant at 5 °C is $(3.16 \pm 0.16) \times 10^{-3}$ s^{-1}, whereas a comparable constant of $(3.74 \pm 0.21) \times 10^{-3}$ s^{-1} is only found at 25 °C in $CDCl_3$. The slower rate in $CDCl_3$ made this the solvent of choice for our kinetic NMR studies. In acetone, the time scale of the faster isomerization overlaps with that of the process of ethylene substitution used to obtain the alkynyl(hydrido) species in situ. Chloroform invariably contains trace amounts of HCl (DCl), which may hamper the dissociation of the hydride as a proton during the course of isomerization. Given the small quantities of acid present, it merely slows down the process, but it is known that strong acids such as HBF_4 can completely inhibit the isomerization. On the other hand, the Lewis base character of acetone possibly has the reverse effect (i.e. base catalysis), accelerating the proton transfer from the metal centre to the β-carbon atom.

As a consequence of the steric hindrance and electron-releasing ability of the $\{[Cp^*Ru(dippe)]^+\}$ moiety, its vinylidene complexes are less electrophilic and more stable towards the addition of an alcohol to the α-carbon atom, but dehydration should also be disfavoured in electron-rich complexes.[4] However, complex **2a** undergoes spontaneous

dehydration in solution, yielding the allenylidene complex [Cp*Ru(=C=C=CPh_2)(dippe)][BPh_4] (**3a**) as a dark-red solid after workup. In the case of 3-hydroxyvinylidene complexes bearing one H on the γ-carbon atom (**2b** and **2c**), complete dehydration can only be achieved by passing a solution in CH_2Cl_2 through an acidic alumina column. In the first case, the *secondary* allenylidene [Cp*Ru(=C=C=CHPh)(dippe)][BPh_4] (**3b**) is obtained as a dark-green solid (see Scheme 3). The IR absorption due to the cumulated C=C=C in **3a** and **3b** appears at 1890 and 1915 cm^{-1}, respectively, i.e. at the lower end of the usual range (1800−2100 cm^{-1}).[2] Other monosubstituted allenylidenes have been obtained by activation of secondary propargyl alcohols with the fragments $[(\eta^5\text{-}C_9H_7)Ru(PPh_3)_2]^+$ [22] and $[Ru(Ph_2PCH_2PPh_2)_2Cl]^+$.[25] In both cases, the infrared absorption is seen at higher $\tilde{\nu}$ [cm^{-1}] for monosubstituted than for disubstituted systems. Monosubstituted allenylidenes are very scarce due to their higher reactivity, and are only known in electron-rich complexes. Ongoing studies on allenylidene reactivity have confirmed that **3b** is indeed more reactive than **3a**.

In the $^{13}C\{^1H\}$ NMR spectra of compounds **3a** and **3b**, the metal-bound carbon atoms show characteristic low-field resonances (δ = 287.2 and 294.3), and the order $\delta(C^\alpha) > \delta(C^\beta) > \delta(C^\gamma)$ is found in both cases. The ^1H NMR spectrum of the allenylidene compound **3b** shows a broad singlet at δ = 9.20 due to the proton on the γ-carbon atom as the only notable feature. Slow recrystallization of **3b** from acetone/ethanol (1:2) afforded green crystals suitable for X-ray diffraction analysis, and its X-ray crystal structure was determined. An ORTEP[24] view of the cationic complex is shown in Figure 3.

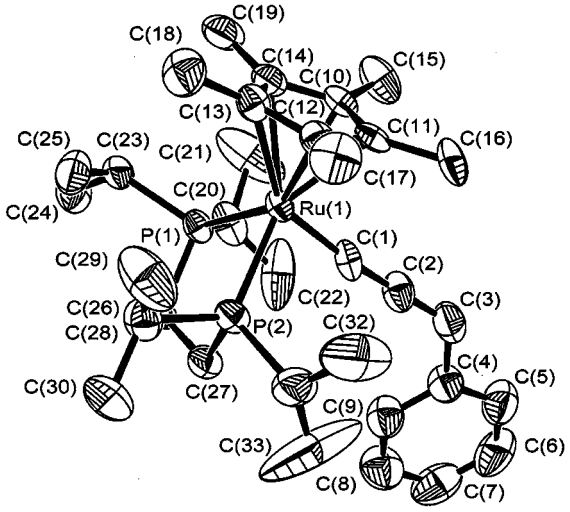

Figure 3. ORTEP view of the cation [Cp*Ru(=C=C=CHPh)(dippe)]$^+$ in compound **3b** showing the atom labelling scheme; hydrogen atoms have been omitted for clarity; selected bond lengths [Å] and angles [°]: Ru1−C10 2.266(7), Ru1−C11 2.258(6), Ru1−C12 2.294(7), Ru1−C13 2.337(7), Ru1−C14 2.329(7), Ru1−C1 1.865(8), Ru1−P1 2.3479(19), Ru1−P2 2.336(2), C1−C2 1.249(10), C2−C3 1.320(12); P1−Ru1−P2 81.99(7), Ru1−C1−C2 172.8(7), C1−C2−C3 177.5(9), C2−C3−C4 128.1(8)

The allenylidene ligand appears to be almost linearly assembled on the ruthenium centre. The bond lengths Ru(1)−C(1) = 1.865(8) Å, C(1)−C(2) = 1.249(10) Å, and C(2)−C(3) = 1.320(12) Å are consistent with a substantial contribution from the alkynyl mesomer, as is usually the case for compounds of this type. In a recent review, the normal ranges of such distances for a variety of allenylidene complexes were quoted as $Ru-C^\alpha$ = 1.84−2.00 Å, $C^\alpha-C^\beta$ = 1.18−1.27 Å, and $C^\beta-C_\gamma$ = 1.35−1.41 Å, respectively.[2] From a rapid overview, it can be concluded that electron-rich allenylidenes of this type more closely resemble the mesomeric form A, which is the usual way of representing them.

The atoms of the allenylidene ligand define a least-squares plane that forms a dihedral angle of 3.51° with the plane defined by C(1), Ru(1), and the centroid of the Cp*. This disposition has been commonly observed in other half-sandwich (allenylidene)Ru derivatives, since it appears to maximize the effectiveness of the metal−ligand π-overlap.[26] It is interesting to note that in this structure the phenyl substituent of the allenylidene ligand is oriented in an *endo* fashion, being directed away from the methyl substituents of the Cp* ring in order to minimize steric interactions. This is in contrast to the structure of the closely related derivative [CpRu(=C=C=CMePh)(dippe)][BPh_4],[20] in which the phenyl group is *exo*-oriented with respect to the Cp ligand and points away from the phosphane isopropyl groups. This example once again illustrates the effect of the differences in the steric properties of the Cp and Cp* ligands on the stereochemistry of their complexes.

Finally, dehydration of compound **2c** leads to the vinylvinylidene complex [Cp*Ru(=C=CH−CH=CH_2)(dippe)][BPh_4] (**4**) rather than to the corresponding allenylidene derivative (see Scheme 3). This is expected for 3-hydroxyvinylidene compounds bearing labile protons on their δ-carbon atoms, as a consequence of the reduced stabilization of the partial positive charge generated on the γ-carbon atom in allenylidene ligands (Scheme 4, canonical form B). The ^1H NMR spectrum of **4** exhibits four signals in the range δ = 4.4−6.2, which were assigned by two-dimensional correlation (COSY) and show an appropriate coupling pattern. The vinylidene carbon atom gives rise to a low-field triplet at δ = 347.7 in the $^{13}C\{^1H\}$ NMR spectrum.

$$[Ru]^+{=}C{=}C{=}CRR' \longleftrightarrow [Ru]{-}C{\equiv}C{-}\overset{+}{C}RR'$$

A B

Scheme 4

Our current interest is centred on the reactivity of the allenylidene complexes described in this work. Despite their electron-rich character, they are able to undergo nucleophilic attack by a series of donor molecules. The resulting species will be described in detail in a forthcoming paper.

Conclusion

It has been demonstrated that previously overlooked hydrido(3-hydroxyalkynyl)Ru^{IV} complexes of the type [Cp*

Ru(H){C≡CC(OH)RR′}(dippe)][BPh_4] are the only observable intermediates in the activation of propargyl alcohols by [Cp*RuCl(dippe)], and that they can be isolated in high yields by careful control of the reaction conditions. These species rearrange into their vinylidene tautomers according to a dissociative mechanism. The thus generated 3-hydroxyvinylidene complexes undergo dehydration yielding either allenylidene or vinylvinylidene species depending upon the substituents present at the γ-carbon atom.

Experimental Section

General Remarks: All synthetic operations were performed under dry dinitrogen or argon using conventional Schlenk techniques. Tetrahydrofuran, diethyl ether, and petroleum ether (boiling point range 40−60 °C) were distilled from the appropriate drying agents. All solvents were deoxygenated immediately prior to use. [Cp*RuCl(dippe)][27] and [Cp*Ru(η²-CH_2=CH_2)(dippe)][BPh_4][23] were prepared according to reported procedures. − IR spectra were recorded from Nujol mulls of the samples with a Perkin−Elmer FT-IR Spectrum 1000 spectrophotometer. − NMR spectra were recorded with a Varian Unity 400 MHz or a Varian Gemini 200 MHz instrument. Chemical shifts are given in parts per million relative to $SiMe_4$ (^1H and $^{13}C\{^1H\}$) or 85% H_3PO_4 ($^{31}P\{^1H\}$). In the NMR spectra, the tetraphenylborate protons and carbon atoms of all cationic compounds showed signals in the appropriate shift ranges, while in the IR spectra a band was seen at 1580 cm^{-1}. − Microanalyses were performed by the Serveis Científico-Tècnics, Universitat of Barcelona.

Preparation of Alkynyl(hydrido) Derivatives [Cp*RuH(C≡CR)(dippe)][BPh_4] [R = C(OH)Ph_2 (1a), CH(OH)Ph (1b), CH(OH)Me (1c), COOEt (1d)]: [Cp*RuCl(dippe)] (133 mg, 0.25 mmol) was added to a solution of the appropriate alkyne or alkynol (0.30 mmol) and $NaBPh_4$ (81 mg, 0.50 mmol) in MeOH (5 mL) at 0 °C (ice bath). The mixture was allowed to warm until a white microcrystalline solid precipitated, which was collected by filtration, washed with cold EtOH and petroleum ether, and stored at −20 °C. As expected for isomeric compounds, microanalytical data were identical to those for 3-hydroxyvinylidenes **2a**−**2d**. Selected spectroscopic data are as follows.

1a: Yield 226 mg (88%). − $C_{63}H_{79}BOP_2Ru$ (1026.1): calcd. C 73.7, H 7.76; found C 73.8, H 7.74. − IR (Nujol): $\tilde{\nu}$ = 3578 ν(OH), 2100 ν(C≡C), 2045 cm^{-1} ν(RuH). − ^1H NMR (400 MHz, $CDCl_3$, 273 K): δ = −9.17 (t, $^2J_{HP}$ = 30.5 Hz, 1 H, Ru−H), 1.84 [s, 15 H, $C_5(CH_3)_5$], 2.52 (br. s, 1 H, OH), 0.99−1.14 [m, 24 H, PCH(CH_3)$_2$], 1.37 and 1.63 (m, 2 H each, PCH_2), 2.12 and 3.12 (m, 2 H each, PCH), 7.30−7.36 (m, 6 H, C_6H_5), 7.47 (m, 4 H, C_6H_5). − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 273 K): δ = 73.1 (s). − $^{13}C\{^1H\}$ NMR (100.58 MHz, $CDCl_3$, 273 K): δ = 10.97 [s, $C_5(CH_3)_5$], 18.17, 18.77, 19.11, and 20.69 [s, PCH(CH_3)$_2$], 21.43 (m, PCH_2), 24.89 and 27.93 (m, PCH), 75.34 (s, C^γ), 101.3 [s, $C_5(CH_3)_5$], 103.7 (t, $^2J_{CP}$ = 25.2 Hz, C^α), 116.4 (s, C^β), 126.0, 127.6, 128.2, and 145.7 (s, C_6H_5).

1b: Yield 195 mg (82%). − $C_{57}H_{75}BOP_2Ru$ (950.0): calcd. C 72.1, H 7.96; found C 72.1, H 7.90. − IR (Nujol): $\tilde{\nu}$ = 3563 ν(OH), 2106 ν(C≡C), 2062 cm^{-1} ν(RuH). − ^1H NMR (400 MHz, $CDCl_3$, 273 K): δ = −9.11 (t, $^2J_{HP}$ = 30.5 Hz, 1 H, Ru−H), 1.04−1.17 and 1.26−1.36 [m, 24 H, PCH(CH_3)$_2$], 1.82 [s, 15 H, $C_5(CH_3)_5$], 2.08 (m, 4 H, PCH_2), 2.88 and 3.01 (m, 2 H each, PCH), 3.10 (br. s, 1 H, OH), 5.45 [s, 1 H, Ru−C≡CC*H*(OH)Ph], 7.40 and 7.56 (m, 5 H, C_6H_5). − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 273 K): δ = 73.7 (s).

1c: Yield 189 mg (85%). − $C_{52}H_{73}BOP_2Ru$ (888.0): calcd. C 70.3, H 8.29; found C 70.1, H 8.29. − IR (Nujol): $\tilde{\nu}$ = 3532 ν(OH), 2115 ν(C≡C), 2050 cm^{-1} ν(RuH). − ^1H NMR (400 MHz, $CDCl_3$, 273 K): δ = −9.10 (t, $^2J_{HP}$ = 31.0 Hz, 1 H, Ru−H), 0.96−1.11 and 1.16−1.21 [m, 24 H, PCH(CH_3)$_2$], 1.35 [d, $^3J_{HH}$ = 6.0 Hz, 3 H, Ru−C≡C−CH(OH)CH_3], 1.84 [s, 15 H, $C_5(CH_3)_5$], 2.08 (m, 4 H, PCH_2), 3.09 (m, 4 H, PCH), 3.43 (br. s, 1 H, OH), 4.50 [q, $^3J_{HH}$ = 6.0 Hz, 1 H, Ru−C≡C−C*H*(OH)CH_3]. − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 233 K): δ = 73.20 (s).

1d: Yield 211 mg (92%). − $C_{53}H_{73}BO_2P_2Ru$ (916.0): calcd. C 69.5, H 8.03; found C 69.4, H 7.89. − IR (Nujol): $\tilde{\nu}$ = 2099 ν(C≡C), 2062 ν(RuH), 1681 cm^{-1} ν(C=O). − ^1H NMR (400 MHz, $CDCl_3$, 273 K): δ = −8.78 (t, $^2J_{HP}$ = 28.2 Hz, 1 H, Ru−H), 0.98−1.27 [m, 24 H, PCH(CH_3)$_2$], 1.19 (t, $^3J_{HH}$ = 6.8 Hz, 3 H, $COOCH_2CH_3$), 1.84 [s, 15 H, $C_5(CH_3)_5$], 1.98 and 2.07 (m, 2 H each, PCH_2), 2.90 (m, 4 H, PCH), 4.12 (q, $^3J_{HH}$ = 6.8 Hz, 2 H, $COOCH_2CH_3$). − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 273 K): δ = 72.3 (s). − $^{13}C\{^1H\}$ NMR (100.58 MHz, $CDCl_3$, 273 K): δ = 10.89 [s, $C_5(CH_3)_5$], 14.37 (s, $COOCH_2CH_3$), 18.24, 18.30, 19.45, and 19.88 [s, PCH(CH_3)$_2$], 21.74 (m, PCH_2), 25.94 and 25.60 (m, PCH), 60.52 (s, $COOCH_2CH_3$), 102.0 (t, $^2J_{CP}$ = 23.0 Hz, C^α), 104.2 [s, $C_5(CH_3)_5$], 109.4 (s, C^β), 164.1 (s, *C*OOEt).

Preparation of Vinylidene Derivatives [Cp*Ru(=C=CHR)(dippe)][BPh_4] [R = C(OH)Ph_2 (2a), CH(OH)Ph (2b), CH(OH)Me (2c), COOEt (2d)]: The solid complexes **1a**−**1c** (1 mmol) were heated at 35 °C for 3 h under an inert gas, in the course of which they gradually underwent a colour change from white/yellow to orange. This corresponded to a quantitative and clean isomerization process to give the respective vinylidene isomers. Complex **2d** was obtained after stirring a solution of **1d** (916 mg, 1 mmol) in acetone for 2 h at room temperature, followed by removal of the solvent. Selected IR and NMR spectroscopic data are as follows.

2a: Yield 1026 mg (100%). − $C_{63}H_{79}BOP_2Ru$ (1026.1): calcd. C 73.7, H 7.76; found C 73.8, H 7.72. − IR (Nujol): $\tilde{\nu}$ = 3558 ν(OH), 1633 cm^{-1} ν(C=C). − ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 0.94−1.18 [m, 24 H, PCH(CH_3)$_2$], 1.81 [s, 15 H, $C_5(CH_3)_5$], 1.73 and 1.86 (m, 2 H each, PCH_2), 2.02 and 2.23 (m, 2 H each, PCH), 2.32 (br. s, 1 H, OH), 4.37 (br. s, 1 H, Ru=C=CHR), 7.27−7.34 (m, 10 H, C_6H_5). − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 298 K): δ = 83.7 (s). − $^{13}C\{^1H\}$ NMR (50.29 MHz, $CDCl_3$, 298 K): δ = 11.04 [s, $C_5(CH_3)_5$], 18.46, 18.67, 19.58, and 20.27 [s, PCH(CH_3)$_2$], 21.44 (vt, $^{1,3}J_{CP}$ = 21.5 Hz, PCH_2), 25.50 and 33.39 (m, PCH), 102.8 [s, $C_5(CH_3)_5$], 121.3 (s, C^β), 95.63 (s, C^γ), 125.4, 127.9, 128.6, and 145.5 (s, C_6H_5), 338.7 (t, $^2J_{CP}$ = 16.1 Hz, C^α).

2b: Yield 950 mg (100%). − $C_{57}H_{75}BOP_2Ru$ (950.0): calcd. C 72.1, H 7.96; found C 72.1, H 7.90. − IR (Nujol): $\tilde{\nu}$ = ν(OH) not obsd., 1643 cm^{-1} ν(C=C). − ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 0.94−1.20 [m, 24 H, PCH(CH_3)$_2$], 1.83 [s, 15 H, $C_5(CH_3)_5$], 2.00 (m, 4 H, PCH_2), 2.11 and 2.30 (m, 2 H each, PCH), 2.57 (br. s, 1 H, OH), 4.33 [d, $^3J_{H^aH^b}$ = 9.0 Hz, 1 H, Ru=C=C*H*^{a}CH^b(OH)Ph], 5.40 [d, $^3J_{H^aH^b}$ = 9.0 Hz, 1 H, Ru=C=CH^{a}C*H*^{b}(OH)Ph], 7.28, 7.36, and 7.39 (m, 5 H, C_6H_5). − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 298 K): δ = 87.7 and 86.9 (d, $^2J_{PP'}$ = 17.1 Hz). − $^{13}C\{^1H\}$ NMR (50.29 MHz, $CDCl_3$, 298 K): δ = 10.88 [s, $C_5(CH_3)_5$], 18.14, 19.18, 19.42, and 19.69 [m, PCH(CH_3)$_2$], 21.13, 25.23, and 31.74 (m, PCH and PCH_2), 66.97 (s, C^γ), 102.6 [s, $C_5(CH_3)_5$], 116.0 (s, C^β), 128.3, 128.5, 128.8, and 143.1 (s, C_6H_5), 337.4 (t, $^2J_{CP}$ = 14.3 Hz, C^α).

2c: Yield 888 mg (100%). − $C_{52}H_{73}BOP_2Ru$ (888.0): calcd. 2d: Yield 916 mg (100%). − $C_{53}H_{73}BO_2P_2Ru$ (916.0): calcd. C 69.5, H 8.03; found C 69.2, H 8.00. − IR (Nujol): $\tilde{\nu}$ = 1693 ν(C=C), 1680 cm^{-1} ν(C=O). − ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 0.88−1.00 and 1.08−1.30 [m, 24 H, PCH(CH_3)$_2$], 1.18 (t, $^3J_{HH}$ = 7.0 Hz, 3 H, $COOCH_2CH_3$), 1.84 [s, 15 H, $C_5(CH_3)_5$], 1.96 (m, 4 H, PCH_2), 2.28 and 2.85 (m, 2 H each, PCH), 4.13 (q, $^3J_{HH}$ = 7.0 Hz, 2 H, $COOCH_2CH_3$), 4.52 (br. s, 1 H, Ru=C=CH−). − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 298 K): δ = 84.6 (s). − $^{13}C\{^1H\}$ NMR (50.29 MHz, $CDCl_3$, 298 K): δ = 10.85 [s, $C_5(CH_3)_5$], 14.37 (s, $COOCH_2CH_3$), 18.32, 19.50, and 19.90 [s, PCH(CH_3)$_2$], 21.89 (vt, $^{1,3}J_{CP}$ = 20.2 Hz, PCH_2), 25.20 and 32.25 (m, PCH), 60.46 (s, $COOCH_2CH_3$), 104.3 [s, $C_5(CH_3)_5$], 109.5 (s, C^β), 164.0 (s, *C*OOEt), 338.8 (t, $^2J_{CP}$ = 14.3 Hz, C^α).

Preparation of Allenylidene Complexes [Cp*Ru(=C=C=CRPh)(dippe)][BPh$_4$] [R = Ph (3a), H (3b)] and Vinylvinylidene Complex [Cp*Ru(=C=CHCH=CH$_2$)(dippe)][BPh$_4$] (4): Complex **3a** was obtained by adding the alkynol (0.30 mmol) to a solution of [Cp*RuCl(dippe)] (133 mg, 0.25 mmol) in MeOH (15 mL). After stirring the mixture for 6 h under reflux, the addition of $NaBPh_4$ (81 mg, 0.50 mmol) caused the precipitation of a dark-red solid, which was collected by filtration, washed with EtOH and petroleum ether, and dried in vacuo. The solid was recrystallized from acetone/ethanol (1:2) to give dark-red needles. Complexes **3b** and **4** were obtained by passing a solution of the corresponding 3-hydroxyvinylidene complex (0.25 mmol) in CH_2Cl_2 (1 mL) through a column of Al_2O_3 (acidic, activity grade I, height of column 10 cm) and collecting a dark-green band of **3b** and a brown band of **4**. Removal of the solvent from these fractions left solids, which were dried in vacuo and recrystallized from acetone/ethanol (1:2). Slow crystallization gave dark-green crystals of **3b**. Selected spectroscopic data are as follows:

3a: Yield 238 mg (94%). − $C_{63}H_{77}BP_2Ru$ (1008.1): calcd. C 75.1, H 7.70; found C 75.0, H 7.67. − IR (Nujol): $\tilde{\nu}$ = 1890 cm^{-1} ν(C=C=C). − ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 0.88−0.96, 1.00−1.06, and 1.13−1.18 [m, 24 H, PCH(CH_3)$_2$], 1.84 [s, 15 H, $C_5(CH_3)_5$], 1.89 (m, 4 H, PCH_2), 1.99 and 2.17 (m, 2 H each, PCH), 7.36 (t, $^3J_{HH}$ = 8.3 Hz, 2 H, *p*-C_6H_5), 7.57 (d, $^3J_{HH}$ = 8.3 Hz, 4 H, *o*-C_6H_5), 7.59 (t, $^3J_{HH}$ = 8.3 Hz, 4 H, *m*-C_6H_5). − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 298 K): δ = 87.9 (s). − $^{13}C\{^1H\}$ NMR (50.29 MHz, $CDCl_3$, 298 K): δ = 11.27 [s, $C_5(CH_3)_5$], 18.15, 19.80, and 19.43 [s, PCH(CH_3)$_3$], 21.29 (vt, $^{1,3}J_{CP}$ = 18.8 Hz, PCH_2), 25.83 and 30.79 (m, PCH), 102.7 [s, $C_5(CH_3)_5$], 128.5, 129.0, 130.5, and 144.2 (s, C_6H_5), 150.1 (s, C^γ), 214.7 (s, C^β), 287.2 (t, $^2J_{CP}$ = 17.2 Hz, C^α).

3b: Yield 170 mg (73%). − $C_{57}H_{73}BP_2Ru$ (932.0): calcd. C 73.5, H 7.89; found C 73.6, H 7.85. − IR (Nujol): $\tilde{\nu}$ = 1915 cm^{-1} ν(C=C=C). − ^1H NMR (400 MHz, CD_2Cl_2, 298 K): δ = 0.84−0.95, 1.01−1.09, and 1.13−1.18 [m, 24 H, PCH(CH_3)$_2$], 1.89 [s, 15 H, $C_5(CH_3)_5$], 1.97 (m, 4 H, PCH_2), 2.21 (m, 4 H, PCH), 7.36 (t, $^3J_{HH}$ = 8.3 Hz, 1 H, *p*-C_6H_5), 7.66 and 7.69 (m, 4 H, C_6H_5), 9.20 (br. s, 1 H, Ru=C=C=C*H*Ph). − $^{31}P\{^1H\}$ NMR (161.89 MHz, CD_2Cl_2, 298 K): δ = 88.3 (s). − $^{13}C\{^1H\}$ NMR (50.29 MHz, CD_2Cl_2, 298 K): δ = 11.36 [s, $C_5(CH_3)_5$], 18.41, 19.47, and 19.90 [s, PCH(CH_3)$_3$], 21.87 (vt, $^{1,3}J_{CP}$ = 20.1 Hz, PCH_2), 26.14 and 30.57 (m, PCH), 103.5 [s, $C_5(CH_3)_5$], 129.9, 130.4, 131.6, and 142.8 (s, C_6H_5), 139.3 (s, C^γ), 219.8 (s, C^β), 294.3 (t, $^2J_{CP}$ = 17.6 Hz, C^α).

4: Yield 163 mg (75%). − $C_{52}H_{71}BP_2Ru$ (870.0): calcd. C 71.8, H 8.23; found C 71.6, H 8.21. − IR (Nujol): $\tilde{\nu}$ = 1633 cm^{-1} ν(C=C). − ^1H NMR (400 MHz, $CDCl_3$, 298 K): δ = 0.93−1.19 [m, 24 H, PCH(CH_3)$_2$], 1.62 and 1.79 (m, 2 H each, PCH_2), 1.81 [s, 15 H, $C_5(CH_3)_5$], 1.99 and 2.16 (m, 2 H each, PCH), 4.88 (d, $^3J_{H^aH^b}$ = 17.0 Hz, 1 H, Ru=C=CH^a−CH^b = CH$^c_2$), 4.46 and 4.91 (d, $^3J_{H^bH^c}$ = 10.0 Hz, 1 H each, Ru=C=CH^a−CH^b = CH^c_2), 6.19 (dt, $^3J_{H^aH^b}$ = 17.0 Hz, $^3J_{HbHc}$ = 10.0 Hz, 1 H, Ru=C=CH^a−CH^b = CH$^c_2$). − $^{31}P\{^1H\}$ NMR (161.89 MHz, $CDCl_3$, 298 K): δ = 87.3 (s). − $^{13}C\{^1H\}$ NMR (50.29 MHz, $CDCl_3$, 298 K): δ = 11.00 [s, $C_5(CH_3)_5$], 18.35, 19.31, and 19.79 [s, PCH(CH_3)$_3$], 21.61 (vt, $^{1,3}J_{CP}$ = 18.8 Hz, PCH_2), 25.45 and 31.42 (m, PCH), 111.1 (s, C^β), 103.3 [s, $C_5(CH_3)_5$], 117.2 (s, Cδ), 121.4 (s, C^γ), 347.7 (t, $^2J_{CP}$ = 14.8 Hz, C^α).

Kinetics Studies of Alkynyl−Hydride to Vinylidene Isomerization: Solutions of the complex [Cp*Ru(η^2-H_2C=CH_2)(dippe)][BPh_4] were prepared in $CDCl_3$ under an inert gas in NMR tubes and were cooled to −80 °C in a liquid N_2/ethanol bath. An excess of the appropriate alkyne or alkynol was added and the tubes were kept at this temperature to arrest the isomerization process during transport and handling. A tube was then removed from the cooling bath and inserted into the precooled probe head of a Varian UNITY 400 spectrometer at 243 K. Once shims had been adjusted, the probe was warmed to 263 K to allow the in situ formation of the corresponding alkynyl(hydrido) complexes. After completion of this reaction, the temperature was raised to the desired level for study. The NMR temperature controller was previously calibrated against a methanol sample, the reproducibility being ± 0.5 °C. $^{31}P\{^1H\}$ NMR spectra were recorded at regular intervals for at least three half-lives using the spectrometer software for accurate time control. Peak intensities were analysed from stacked plots of the $^{31}P\{^1H\}$ NMR spectra. First-order rate constants were derived from the least-squares best-fit lines of the ln(intensity) versus time plots. The uncertainty in the isomerization rate constants represents one standard deviation (± σ) derived from the slope of the best-fit line. Uncertainties in the activation enthalpies and entropies were calculated from the uncertainties in the slope and intercept of the best-fit lines of the Eyring plots.

X-ray Structure Determination of [Cp*Ru(=C=C=CHPh)(dippe)][BPh$_4$] (3b): Empirical formula $C_{57}H_{73}BP_2Ru$, molecular mass 931.97, crystal size 0.30 × 0.30 × 0.14 mm, monoclinic, space group $P2_1/c$ (no. 14), a = 14.763(3) Å, b = 18.320(3) Å, c = 18.433(3) Å, β = 92.44(2) °, V = 4980(15) Å^3, Z = 4, $\rho_{calcd.}$ = 1.243 g cm^{-3}, T = 290(2) K, λ(Mo-$K_α$) = 0.71069 Å, graphite monochromator, μ(Mo-$K_α$) = 4.15 cm^{-1}, F(000) = 1976, transmission factor interval 0.76−1.00, scan speed (ω) 4° min^{-1}, 5.64° < 2θ < 50.12°, 7720 measured reflections, 7305 unique reflections, 4693 observed reflections [$I > 2\sigma(I)$], 550 parameters, reflection/parameter ratio 13.3. X-ray diffraction measurements were made on crystals of the appropriate size, which were mounted on a glass fibre and transferred to a Rigaku AFC6S automatic diffractometer. In each case, accurate unit cell parameters and an orientation matrix were determined by least-squares fitting from the settings of 25

high-angle reflections. Data were collected by the ω/2θ scan method. Decay was monitored by measuring three standard reflections every 100 measurements. Lorentz and polarization corrections were applied. Decay and semiempirical absorption corrections (ψ method) were also applied. The structure was solved by the Patterson method and subsequent expansion of the model using DIRDIF.[28] All calculations for data reduction and structure solution were carried out with a VAX 3520 computer at the Servicio Central de Ciencia y Tecnología de la Universidad de Cádiz, using the TEXSAN[29] software system. All hydrogen atoms were included at idealized positions and were allowed to ride on the parent carbon atoms. Full-matrix least-squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with SHELXL-97,[30] concluding with the values $R1 = 0.0678$ and $wR2 = 0.1810$ for data having $I > 2\sigma(I)$. ORTEP[24] was used for plotting. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-157842. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We wish to thank the Ministerio de Educación y Cultura of Spain (DGICYT, Project PB97-1357) and the Junta de Andalucía (PAI − FQM 0188) for financial support. We also thank Johnson Matthey plc for including us in their precious metal loan scheme, and the Royal Society of Chemistry for the award of a grant for International Authors (to M. J. T.).

Chemistry at the Sterically Shielded Mercury Centre of the [(η^4-pp3)PtHg] Fragment

Walter Schuh,[a] Holger Kopacka,[a] Klaus Wurst,[a] and Paul Peringer*[a]

Keywords: Mercury / Platinum / Cluster compounds / Phosphanes / NMR spectroscopy

Treatment of [(η^4-pp3)PtH]OTf (pp3 = tris[2-(diphenylphosphanyl)ethyl]phosphane) with PhHgCl gave [(η^4-pp3)PtHgCl]OTf (**1a**) in good yield. The reaction of **1a** with the carbonylmetallates $[Mn(CO)_5]^-$ or $[Co(CO)_4]^-$ and TlOTf produced the linear trinuclear clusters [(η^4-pp3)PtHgMn(CO)$_5$]OTf (**2**) or [(η^4-pp3)PtHgCo(CO)$_4$]OTf (**3**), respectively. The reaction of **1a** with PR_3 and TlOTf gave [(η^4-pp3)PtHg(PR_3)](OTf)$_2$ (**4**: R = *n*Bu; **5**: R = Ph), with $Ph_2P(CH_2)_nPPh_2$ (*n* = 1, 2) or dppmSe [dppmSe = bis(diphenylphosphanyl)methane monoselenide] adducts in which the diphosphane/diphosphane monoselenide adopts a monodentate, bridging or chelating bonding mode depending on the ligand and the stoichiometry. The mercury-bound phosphane complexes extrude elemental Hg within hours or days. The new compounds were characterised by multinuclear NMR spectroscopy and, in part, by single-crystal X-ray diffraction. The NMR investigations yielded unprecedented parameters, e.g. very large ^{31}P coordination chemical shift for a monodentate phosphane or ^2J(Hg–Pt–P) couplings that were two to three times larger than Hg–P one-bond couplings within the same complex.

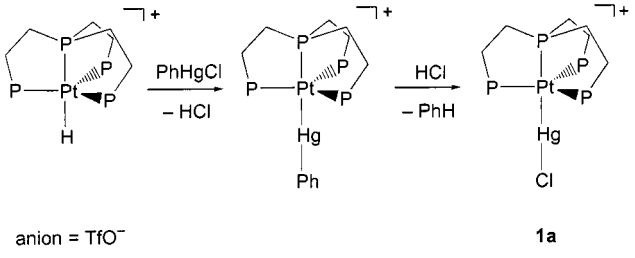
Introduction

Clusters containing an unsupported mercury−platinum bond tend to extrude elemental mercury.[1] The noticeable stability of the Pt−Hg bond in [(η^4-pp3)PtHgPh]OTf[2] and the closely related compound [(η^4-np3)PtHgMe](BPh$_4$)[3] (np3 = tris[2-(diphenylphosphanyl)ethyl]amine) has been attributed to the shield of the six phenyl groups of the pp3 or np3 ligand. This stimulated an investigation of the chemistry of the [(η^4-pp3)PtHg] fragment. We report here on a comfortable and high-yielding access to [(η^4-pp3)PtHgCl]OTf (**1a**), which is an appropriate compound for substitution reactions with carbonylmetallates, mono- and bidentate phosphanes, or phosphane selenides at the mercury site.

2. Results and Discussion

2.1. Syntheses and Reactions

We observed that [(η^4-pp3)PtHgPh]OTf slowly degrades in chloroform solution to give [(η^4-pp3)PtHgCl]OTf (**1a**), attributable to the presence of trace amounts of HCl in $CHCl_3$, which cleave the mercury−carbon bond and leads to the substitution of the phenyl group by chloride. This was exploited in a comfortable high-yield synthesis of **1a** by treatment of [(η^4-pp3)PtH]OTf with PhHgCl according to Scheme 1: The reaction is thought to proceed by intermediate formation of [(η^4-pp3)PtHgPh]$^+$, which is in turn acidolysed by HCl formed in stoichiometric amounts.



Scheme 1. Proposed synthetic pathway for **1a**

In the presence of excess chloride, **1a** slowly degrades by extrusion of elemental mercury to [(η^4-pp3)PtCl]Cl.[4] Compound **1a** is air-stable in solution and in the solid state, readily soluble in CH_2Cl_2, slightly soluble in MeOH, and was isolated as a yellow microcrystalline powder from CH_2Cl_2/toluene. Compound **1a** was characterised by ^{31}P, ^{195}Pt and ^{199}Hg NMR spectroscopy. Yellow crystals of [(η^4-pp3)PtHgCl](PF$_6$)·CH_2Cl_2 (**1b**·CH_2Cl_2), which were suitable for single-crystal X-ray diffraction, were obtained by slow diffusion of a methanolic solution of NH_4PF_6 into a CH_2Cl_2 solution of **1a**. The reaction of **1a** with the carbonylmetallates $[Mn(CO)_5]^-$ or $[Co(CO)_4]^-$ in THF and subsequent treatment with TlOTf gave the linear heterotrinuclear clusters [(η^4-pp3)PtHgMn(CO)$_5$]OTf (**2**) and [(η^4-pp3)PtHgCo(CO)$_4$]OTf (**3**) (Scheme 2). Both were characterised by multinuclear NMR and elemental analysis, **2** in addition by single-crystal X-ray diffraction. There are only three reports on complexes with a Pt−Hg−Mn or Pt−Hg−Co bond sequence in the literature,[5] the compounds were characterised by spectroscopic methods, no single crystal structure determinations had been performed.

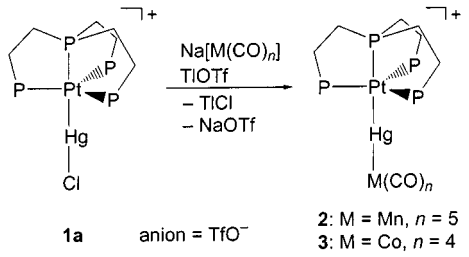
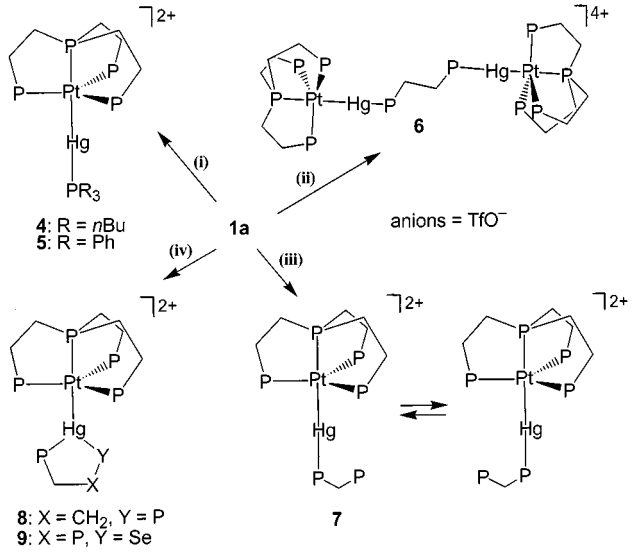


Scheme 2. Synthesis of **2** and **3**

Treatment of **1a** with the monodentate phosphanes P*n*Bu$_3$ and PPh$_3$ in the presence of TlOTf led quantitatively (according to ^{31}P NMR) to the complexes [(η^4-pp3)PtHg(PR$_3$)](OTf)$_2$ (**4**: R = *n*Bu; **5**: R = Ph) as depicted in Scheme 3.



Scheme 3. (i) TlOTf/PR$_3$; (ii) TlOTf/0.5 dppe; (iii) TlOTf/dppm; (iv) TlOTf/dppe (**8**) or TlOTf/dppmSe (**9**)

Since the complexes decompose very rapidly in the presence of halides, TlOTf was used as a chloride scavenger. In the absence of phosphanes, TlOTf is not able to abstract the chloride ligand from **1a**. This was, however, accomplished by AgOTf, but the presumptive product [(η^4-pp3)PtHg](OTf)$_2$ immediately extruded elemental mercury. The phosphane complexes **4** and **5** decomposed within 1 d − in the presence of chloride or excess phosphane within hours − into elemental mercury and [(η^4-pp3)-Pt(PR$_3$)](OTf)$_2$, which were identified according to their ^{31}P NMR spectroscopic data.[6,7] Hence, **4** and **5** as well as the other phosphane derivatives described below could not be isolated in the solid state. The use of P(OMe)$_3$ or P(H)Ph$_2$ instead of PR$_3$ according to Scheme 3 immediately produced elemental mercury and the mononuclear platinum complexes [(η^4-pp3)Pt{P(H)Ph$_2$}](OTf)$_2$ or [(η^4-pp3)Pt{P(OMe)$_3$}](OTf)$_2$, respectively, identified by their ^{31}P NMR spectroscopic data.[8,9]

The products of the reaction of **1a** with 0.5 equiv. of Ph$_2$P(CH$_2$)$_n$PPh$_2$ in the presence of TlOTf depends on *n*: Whereas dppe (*n* = 2) gives the phosphane-bridged tetranuclear complex [(η^4-pp3)PtHg(μ-dppe)HgPt(η^4-pp3)]-(OTf)$_4$ (**6**) shown in Scheme 3, dppm (*n* = 1) reacts, presumably because of steric reasons, with only 0.5 equiv. of **1a** to give the complex [(η^4-pp3)PtHg(η^1-dppm)](OTf)$_2$ (**7**) containing monodentate dppm. Complex **7** shows a fluxional behaviour in solution, monitored by variable-temperature ^{31}P NMR spectroscopy (see below), which can be interpreted as an intramolecular end-over-end exchange between the mercury-bound and the free-dppm phosphorus atom. Compound **7** can be synthetised quantitatively (according to ^{31}P NMR spectroscopy) by treating **1a** with dppm in a molar ratio of 1:1 (Scheme 3).

The potential for mercury to increase its coordination number in the fragment [(η^4-pp3)PtHg] can be seen from the reaction of **1a** with dppe or dppmSe in a molar ratio of 1:1. As indicated in Scheme 3, we propose a chelate bonding mode of dppe and dppmSe (according to ^{31}P NMR spectroscopic results) in the complexes [(η^4-pp3)PtHg(η^2-dppe)](OTf)$_2$ (**8**) and [(η^4-pp3)PtHg(η^2-dppmSe)](OTf)$_2$ (**9**), resulting in a tricoordinate mercury centrer that is part of a five-membered ring system.

2.2. NMR Spectroscopy

The NMR parameters of compounds **1**−**9** are collected in Tables 1 and 2. In the Tables and the subsequent discussion, the axial phosphorus atom of the platinum-bound pp3 ligand is designated as P^a, while P^e denotes the equatorial pp3 phosphorus atoms. P^3 denotes the mercury-bound phosphorus atom(s), and all other phosphorus atoms are designated as P^4.

Table 1. NMR parameters of the compounds **1a**, **2** and **3** in CH_2Cl_2

	1a	**2**	**3**
δ(P^a)	142.5	162.9	146.6
J(P^{a}P^e)	2	5	not resolved

J(HgP^e)	412	251	299
δ(Pt)	−5577	−5188	−5292
J(HgPt)	11010	6200	8035
δ(Hg)	910	2017	1370

The one-bond Hg−Pt coupling of the linear bond sequence Pt−Hg−X is thought to give an estimate of the *trans* influence of the group X, as has been extensively exploited for linear P−Pt−X or P−Hg−X arrangements.[10] According to Table 1 this reveals a greater *trans* influence of the Mn(CO)$_5$ fragment compared with Co(CO)$_4$, the smallest *trans* influence in the present series is exerted by the chloride ligand. One-bond Hg−Pt couplings reported in the literature range between 37610 and 2783 Hz.[2,3,11] The size of ^{1}*J*(PtP^a) and ^{2}*J*(HgP^a) couplings of **1a**−**3** show a similar dependence on the ligand attached to the mercury centre. The diagonal P^a−Pt−Hg geometry effects very large two-bond Hg−P^a couplings. This is also true for compounds **4**−**9** (see below), and has been previously noted for

Table 2. NMR parameters of the compounds **4**−**9** in CH_2Cl_2/MeOH (4:1)

	4 (T = 0 °C)	**5** (T = −40 °C)	**6** (T = −60 °C)	**7** (T = −30 °C)	**8** (T = −40 °C)	**9**[a] (T = 20 °C)

δ(P^4)	−	−	−	−	−	34.0

[a] **9**: δ(Se) = −203, J(HgSe) = 842, $J(SeP^4)$ = 672; δ(Pt) = −5526, δ(Hg) = 1598.

[(η⁴-pp3)PtHgPh]OTf.[2] Even larger ^2J(HgP) coupling constants have been observed in Hg−Ir clusters (3879−3822 Hz).[12]

The tetranuclear complex **6** displays an $[AM_3P]_2$ spin system, the ^{199}Hg and ^{195}Pt satellites show an $AA'M_3M'_3PP'X$ pattern. This reflects the dppe-bridged structure of **6**. The values of $^1J(HgP^3)$ are 1484−902 Hz, revealing a strong *trans* influence of the [(η⁴-pp3)Pt] moiety. There are only few reports on compounds exhibiting a M−Hg−P bond sequence (M = transition metal),[11c,13] and the ^1J(HgP) couplings in these clusters are comparatively small as well (2483−170 Hz).

Compounds **7** and **8** exhibit an AM_3P_2 spin system flanked by ^{199}Hg and ^{195}Pt satellites at temperatures given in Table 2. The bonding modes of the bidentate phosphanes dppm and dppe in these complexes are monodentate and chelating, respectively.

The dppm ligand in **7** is involved in an end-over-end exchange that is fast on the NMR time scale at −30 °C. End-over-end fluxionality is also present in other mercury−dppm complexes.[14] The slow exchange limit is not reached at −100 °C, the lowest temperature attained. However, significant broadening of the P^3 signal in comparison with the other ^{31}P resonances of **7** is observed at this temperature. All couplings involving P^3 as well as its chemical shift given in Table 2 may be considered as mean values of the parameters for the mercury-bound and the free-dppm phosphorus atom. The fluxionality at −30 °C is responsible for the relatively small values of these parameters compared with compounds **4**−**6**. The preference of the monodentate bonding mode of dppm in **7** over a chelate structure is attributed to considerable strain in four-membered Hg−dppm rings.

The structure of **8** is based on the value of the one-bond Hg−P^3 coupling of 1265 Hz, which is comparable to the couplings observed for compounds **4**−**6**. No significant broadening of the P^3 signal in comparison with the other ^{31}P resonances could be observed down to −100 °C. The relatively small values of δ(P^3), $^2J(PtP^3)$, and $^3J(P^aP^3)$ are attributed to a nonlinear Pt−Hg−P^3 geometry as a consequence of the increased coordination number at the Hg atom. This is in keeping with the data of **9**.

Compound **9** involving the potentially bidentate ligand dppmSe shows an AM_3PX spin system in the $^{31}P\{^1H\}$ NMR spectrum flanked by ^{199}Hg, ^{195}Pt, and ^{77}Se satellites. The value for Hg−P^3 coupling approximately coincides with that found for **8**, revealing an Hg−P^3 bond. The coordination of the selenium atom to the mercury centre is inferred by an Hg−Se coupling of 842 Hz compared with a range for ^1J(HgSe) couplings of 960−750 Hz.[15] The reduced value of $^1J(SeP^4)$ with respect to the free ligand is also indicative for the coordination of Se.[15] Due to the value of $^2J(PtP^3)$ (494 Hz) ranging between that found in **6**, with an essentially linear Pt−Hg−P geometry, and **8**, with a symmetrically bent Pt−Hg−P arrangement, we suppose an asymmetric coordination geometry around the Hg atom in **9**, where P^3 is shifted towards the Pt−Hg vector and Se is consequently shifted away. The magnitude of $^3J(P^aP^3)$ (165 Hz) is in agreement with this presumption. A related angular dependence for two-bond P−Hg−P coupling constants has been pointed out by Dakternieks.[16] The asymmetric bonding of P^3 and Se in **9** is thought to be caused by steric demands.

The most exciting feature of compounds **4**−**6**, **8**, and **9** is that the Hg−P^a coupling constants over two bonds are larger by a factor of two to three than the corresponding $^1J(HgP^3)$ couplings within the same molecule (compound **7** has not been considered in this context, because Hg−P one-bond couplings are not accessible due to chemical exchange). This observation implies that care should be taken for the assignment of connectivities in mercury-containing clusters on the basis of the magnitudes of Hg−P coupling constants.

Complexes **4**−**6**, for which an essentially linear Pt−Hg−P^3 arrangement is anticipated, are characterised by very large ^{31}P shifts of the mercury-coordinated phosphorus atom. The corresponding coordination shifts (Δδ) amount up to +120 ppm in compound **4**. Slightly lower

values were found for the mercury-bound phosphanes in the compounds $[L'HgMo(CO)_2L(\eta^5\text{-}C_5H_5)](BF_4)$ (L' = PPh_3, PCy_3; L = CO, diverse phosphane ligands),[13a] where the mercury atom is dicoordinated by Mo and P.

2.3. Crystallography

Yellow crystals of $[(\eta^4\text{-pp3})PtHgCl](PF_6)\cdot CH_2Cl_2$ (**1b**·CH_2Cl_2) were grown by slow diffusion of a methanolic solution of NH_4PF_6 into a CH_2Cl_2 solution of $[(\eta^4\text{-pp3})PtHgCl]OTf$. The molecular structure of the complex cation of **1b** is shown in Figure 1, selected bond lengths and angles are collected in Table 3.

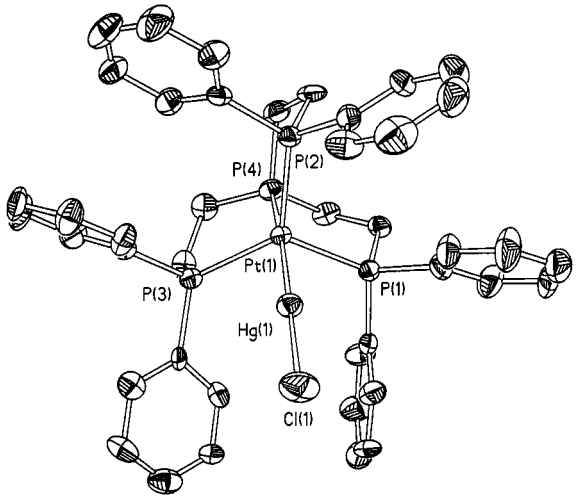

Figure 1. Molecular structure of the complex cation of **1b**·CH_2Cl_2

Table 3. Selected bond lengths [pm] and angles [°] in **1b**·CH_2Cl_2

Hg(1)−Cl(1)	237.7(2)	Cl(1)−Hg(1)−Pt(1)	174.63(7)
Hg(1)−Pt(1)	255.11(9)	P(4)−Pt(1)−Hg(1)	172.96(6)
Pt(1)−P(4)	224.3(2)	P(3)−Pt(1)−Hg(1)	89.11(6)
Pt(1)−P(3)	230.9(2)	P(1)−Pt(1)−Hg(1)	90.80(6)
Pt(1)−P(1)	233.4(2)	P(2)−Pt(1)−Hg(1)	100.98(6)
Pt(1)−P(2)	235.1(2)		

The platinum atom of the complex cation of **1b** exhibits a quasi-trigonal-bipyramidal coordination sphere with the central pp3 phosphorus atom and the mercury centre in axial positions and the three terminal pp3 phosphorus ligands in equatorial positions. The mercury atom is dicoordinated by Pt and Cl in an approximately linear manner. The Pt−Hg distance is very similar to that found in $[(\eta^4\text{-np3})PtHgMe](BPh_4)$ (253.1 pm),[3] the Hg−Cl bond length is slightly increased compared to that in $HgCl_2$ (225 pm).[17]

The Pt−Hg−Cl angle amounts to 174.63(7)° in keeping with the absence of any Hg···Cl interactions with chloride ions of other cations. This is most likely the result of the steric shielding of the phenyl groups of the pp3 ligand and/or the poor acceptor qualities of the mercury centre.

Yellow crystals of $[(\eta^4\text{-pp3})PtHgMn(CO)_5]OTf\cdot 1.5\ CH_2Cl_2$ (**2**·1.5 CH_2Cl_2) were obtained at −19 °C from a solution of **2** in MeOH/CH_2Cl_2 (1:1) saturated at room temperature. The crystals contain two crystallographically independent $[(\eta^4\text{-pp3})PtHgMn(CO)_5]OTf$ entities per asymmetric unit both possessing very similar geometries. The molecular structure of one of the crystallographically independent complex cations of **2** is shown in Figure 2, selected bond lengths and angles are collected in Table 4.

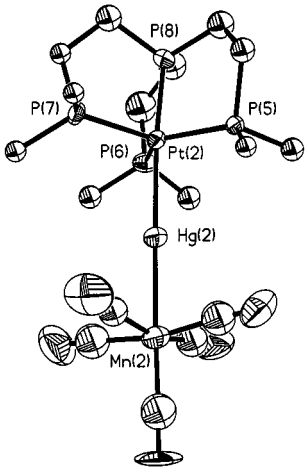

Figure 2. Molecular structure of one of the crystallographically independent complex cations in **2**·1.5 CH_2Cl_2; for clarity only the *ipso*-carbon atoms of the phenyl groups attached to the pp3 phosphorus atoms are shown

Table 4. Selected bond lengths [pm] and angles [°] in **2**·1.5CH_2Cl_2

Hg(1)−Pt(1)	260.5(2)	P(3)−Pt(1)−Hg(1)	95.0(2)
Hg(1)−Mn(1)	264.7(5)	P(1)−Pt(1)−Hg(1)	93.1(2)
Hg(2)−Pt(2)	259.0(2)	P(8)−Pt(2)−Hg(2)	175.1(2)

Pt(1)−P(4)	223.6(7)	P(5)−Pt(2)−Hg(2)	89.1(2)
Pt(1)−P(2)	231.5(7)	P(7)−Pt(2)−Hg(2)	97.3(2)
Pt(1)−P(3)	233.3(7)	C(4)−Mn(1)−Hg(1)	84(2)
Pt(1)−P(1)	233.5(7)	C(1)−Mn(1)−Hg(1)	84.4(13)
Pt(2)−P(8)	224.4(7)	C(5)−Mn(1)−Hg(1)	176.4(11)
Pt(2)−P(6)	229.7(7)	C(2)−Mn(1)−Hg(1)	83.7(13)
Pt(2)−P(5)	230.5(7)	C(3)−Mn(1)−Hg(1)	84(2)
Pt(2)−P(7)	232.5(6)	C(7)−Mn(2)−Hg(2)	79.5(10)
Pt(1)−Hg(1)−Mn(1)	178.96(14)	C(8)−Mn(2)−Hg(2)	84.4(11)
Pt(2)−Hg(2)−Mn(2)	176.12(12)	C(9)−Mn(2)−Hg(2)	82.7(9)
P(4)−Pt(1)−Hg(1)	177.7(2)	C(10)−Mn(2)−Hg(2)	178.2(11)
P(2)−Pt(1)−Hg(1)	91.7(2)	C(6)−Mn(2)−Hg(2)	84.4(11)

The platinum atom of the complex cation of **2** exhibits a quasi-trigonal-bipyramidal coordination sphere, with the central pp3 phosphorus atom and Hg in axial positions and the three terminal pp3 phosphorus ligands in equatorial positions. The mercury atom is dicoordinated by Pt and Mn in an approximately linear manner, Mn showing a slightly distorted octahedral environment. The Pt−Hg distances are slightly longer than in **1b**, the Hg−Mn bond lengths are increased in comparison with the compounds $[\{\eta^2\text{-}(2\text{-}ClC_6H_4)_2N_3\}HgMn(CO)_5]$ (255.7 pm)[18] and $[Hg\{Mn(CO)_5\}_2]$ (260.8, 261.0 pm).[19]

Experimental Section

Elemental analyses were performed by the Institut für Physikalische Chemie, Universität Wien. − $^{31}P\{^1H\}$ NMR spectra were re-

corded at variable temperatures (if not otherwise stated at 20 °C) with a Bruker DPX 300 spectrometer, and were referenced against external 85% H_3PO_4. $^{199}Hg\{^1H\}$, $^{195}Pt\{^1H\}$, and $^{77}Se\{^1H\}$ NMR spectra were recorded at 20 °C with the same instrument and referenced against external 2 mmol HgO in 1 mL of 60% $HClO_4$, 1 mol/l Na_2PtCl_6 and neat $SeMe_2$, respectively. Compound [(η⁴-pp3)PtCl]Cl[4] and solutions of $Na[Mn(CO)_5]$ and $Na[Co(CO)_4]$ in THF[20] were prepared according to literature procedures, all other compounds were purchased from commercial suppliers and used without further purification. If not stated otherwise, all reactions were carried out under an inert gas in absolute solvents purified by standard procedures.

[(η⁴-pp3)PtHgCl]OTf (1a): A suspension of [(η⁴-pp3)PtCl]Cl (936.7 mg, 1 mmol) in CH_2Cl_2/MeOH 4:1 (25 mL) was treated with $NaBH_4$ (113.4 mg, 3 mmol), which was added under vigorous stirring in small portions over a period of 10 min. The resulting pale yellow solution was stirred for 1 h. The organic phase was washed four times with water (10 mL). This represents a slightly modified synthesis of [(η⁴-pp3)PtH]Cl to that reported by Brüggeller.[21] [(η⁴-pp3)PtH]Cl was then treated with a solution of TlOTf (353.4 mg, 1 mmol) in MeOH (2 mL), and [(η⁴-pp3)PtH]OTf formed by anion metathesis and precipitation of TlCl. The precipitate was separated by centrifugation, the pale yellow solution was concentrated to dryness in vacuo. The residue was redissolved in 20 mL of CH_2Cl_2, then treated with PhHgCl (313.2 mg, 1 mmol) and stirred for 24 h. After filtration, the clear yellow solution was concentrated to a volume of ca. 2 mL, then [(η⁴-pp3)PtHgCl]OTf (**1a**) was precipitated by addition of toluene (20 mL). The product was separated by centrifugation and dried in vacuo. Yield: 1.08 g (89%).

[(η⁴-pp3)PtHgCl](PF₆)·CH₂Cl₂ (1b): Yellow crystals were grown by slow diffusion of a methanolic solution of NH_4PF_6 into a CH_2Cl_2 solution of [(η⁴-pp3)PtHgCl]OTf. − $C_{43}H_{42}ClF_6HgP_5Pt{\cdot}CH_2Cl_2$ (1258.8): calcd. C 39.33, H 3.30; found C 39.05, H 3.25.

[(η⁴-pp3)PtHgMn(CO)₅]OTf (2): A solution of $Na[Mn(CO)_5]$ (0.05 mmol) in THF (0.25 mL) was added to **1a** (62.5 mg, 0.05 mmol) and stirred for 5 min. After evaporation of the solvent, the residue was redissolved in CH_2Cl_2 (0.5 mL) and treated with a solution of TlOTf (17.7 mg, 0.05 mmol) in MeOH (0.2 mL). The resulting precipitate of TlCl was removed by centrifugation and the clear orange solution was concentrated until precipitation of [(η⁴-pp3)PtHgMn(CO)₅]OTf (**2**) began. A small amount of CH_2Cl_2 was added to redissolve the precipitate and the solution left for crystallisation at −19° C for 2 d. Yield: 30 mg (43%). − $C_{48}H_{42}F_3HgMnO_8P_4PtS$ (1410.4): calcd. C 40.88, H 3.00; found C 40.47, H 2.87.

[(η⁴-pp3)PtHgCo(CO)₄]OTf (3): A solution of $Na[Co(CO)_4]$ (0.05 mmol) in THF (0.25 mL) was added to **1a** (62.5 mg, 0.05 mmol) and stirred for 5 min. After evaporation of the solvent, the residue was redissolved in CH_2Cl_2 (0.5 mL) and treated with a solution of TlOTf (17.7 mg, 0.05 mmol) in MeOH (0.2 mL). The resulting precipitate of TlCl was removed by centrifugation and the clear yellow solution washed two times with 1 mL of water. The solvent was then evaporated, the residue dissolved in CH_2Cl_2 (0.2 mL) and the product precipitated by addition of petroleum ether (60−70 °C) (2 mL). The yellow precipitate was collected by centrifugation and dried in vacuo. Yield: 52 mg (76%). − $C_{47}H_{42}CoF_3HgO_7P_4PtS$ (1386.4): calcd. C 40.72, H 3.05; found C 40.78, H 2.95.

Weighting scheme	calcd. $w = 1/[\sigma^2(F_o^2) + (0.0417{\cdot}P)^2 + 7.0681{\cdot}P]$, where $P = (F_o^2 + 2{\cdot}F_c^2)/3$	calcd. $w = 1/[\sigma^2(F_o^2) + (0.0437{\cdot}P)^2 + 175.1567{\cdot}P]$, where $P = (F_o^2 + 2{\cdot}F_c^2)/3$

[(η^4-pp3)PtHgL](OTf)$_2$ (4: L = P*n*Bu$_3$; 5: L = PPh$_3$; 7: L = dppm; 8: L = dppe; 9: L = dppmSe): TlOTf (17.7 mg, 0.05 mmol) was dissolved in MeOH (0.1 mL) and **1a** (62.5 mg, 0.05 mmol) added with stirring to give a yellow suspension. The ligand (0.05 mmol) and CH_2Cl_2 (0.4 mL) were added and the suspension stirred for 5 min. After this, the precipitate of TlCl was separated from the yellow solution by centrifugation. All compounds rapidly decompose by extrusion of elemental mercury and could not be obtained analytically pure in the solid state.

[(η^4-pp3)PtHg(μ-dppe)HgPt(η^4-pp3)](OTf)$_4$ (6): TlOTf (17.7 mg, 0.05 mmol) was dissolved in MeOH (0.1 mL) and **1a** (62.5 mg, 0.05 mmol) added with stirring to give a yellow suspension. The ligand (0.05 mmol) and CH_2Cl_2 (0.4 mL) were added and the suspension stirred for 5 min. After this, the precipitate of TlCl was separated from the yellow solution by centrifugation. Compound **6** rapidly decomposed by extrusion of elemental mercury and could not be obtained analytically pure in the solid state.

X-ray Structure Determinations: Crystals of **1b**·CH_2Cl_2 and **2**·1.5CH_2Cl_2 were examined by similar procedures. Crystals were mounted on a glass fibre, X-ray data were collected with a Siemens P4 diffractometer using Mo-K_α radiation (λ = 71.073 pm, monochromator: highly oriented graphite crystal, ω scan). Unit cell parameters were determined from 30−41 randomly selected reflections in the range θ = 5.3−12.5°, obtained by P4 automatic routine. Every 97 reflections 3 standard reflections were measured. Data were corrected for Lorentz polarisation and absorption effects (ψ scans). The structures were solved by direct methods and subsequent difference Fourier techniques (SHELXS-86).[22] Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-93).[23] All non-hydrogen atoms in the structure of **1b** as well as all non-hydrogen and non-carbon atoms in the structure of **2** were refined anisotropically, the carbon atoms in structure of **2** were refined isotropically. All hydrogen atoms were placed at calculated ideal positions (riding model). Crystal data and details of structure determinations and refinements are collected in Table 5. Crystallographic data (excluding structure factors) for the structure of **1b**·CH_2Cl_2 and **2**·1.5CH_2Cl_2 have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication numbers CCDC-157011 and -157010. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Formation and Structure of Thulium(III) Cyclopentadienides as Products of Reactions Directed Towards the Synthesis of Thulium(II) Cyclopentadienides

Igor L. Fedushkin,*[a] Frank Girgsdies,[b] Herbert Schumann,*[b] and Mikhail N. Bochkarev[a]

Keywords: Cyclopentadienyl ligands / Ether splitting / Redox reactions / Thulium / X-ray structures

$TmI_2(THF)_2$ and $[C_5Me_5]K$ react in THF to yield the Tm^{III} complex $(C_5Me_5)_2TmI(THF)$ (**1**). The reaction of **1** with excess sodium in 1,2-dimethoxyethane (DME) leads, through Tm^{II} intermediates and a reductive splitting of DME solvent molecules, to the trisodium dithulium(III) complex $[(DME)_2Na(\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_5Me_5)Tm(\eta^5\text{-}C_5Me_5)(\mu_2\text{-}OMe)_2(Na\text{-}\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_5Me_5)\text{-}Na(\mu\text{-}OMe)_2Tm(\eta^5\text{-}C_5Me_5)_2]$ (**2**). Treatment of $TmI_2(THF)_2$ with $[(Me_3Si)_2C_5H_3]MgCl$ (**3**) in THF yields the dimeric Tm^{III} complex $[\{1,3\text{-}(Me_3Si)_2C_5H_3\}_2TmCl]_2$ (**4**), while $TmI_3(THF)_3$ reacts with $[C_5H_4CH_2CH_2NMe_2]K(THF)$ (**5**) to yield solvent-free $(C_5H_4CH_2CH_2NMe_2)_2TmI$ (**6**). The new Tm^{III} compounds have been characterized by elemental analysis, IR spectroscopy, and mass spectrometry. The molecular structures of **2**, **4**, **5**, and **6** have been determined by single-crystal X-ray diffraction analysis.

Introduction

We recently reported on the first molecular thulium(II) complex, $TmI_2(DME)_3$, which was prepared by reduction of TmI_3 with metallic thulium in DME.[1] Analogous organic solvent adducts of neodymium and dysprosium diiodide were obtained by high-temperature reactions (> 200 °C) of the respective metal powders with iodine in sealed glass ampoules followed by treatment of the reaction products with DME or THF.[2] The molecular lanthanide(II) diiodides characterized to date include those of samarium, europium, ytterbium, thulium, neodymium, and dysprosium. According to their standard potentials, the stability of the divalent oxidation state decreases in the order $Eu^{II} > Yb^{II} > Sm^{II} > Tm^{II} > Dy^{II} > Nd^{II}$.[3] Whereas organometallic complexes of divalent europium, ytterbium, and samarium are well known and syntheses of the first organolanthanum(II) complex, $[K(18\text{-crown-}6)(C_6H_6)_2][(Cp^{tt}{}_2La)_2(C_6H_6)]_2\text{-}C_6H_6$ (Cp^{tt} = 1,3-tBu$_2$C$_5$H$_3$),[4a] and of the first organoscandium(II) complex, $[\{(P_3C_2tBu_2)Sc\}_2(P_3C_3tBu_3)]$,[4b] have recently been reported, organometallic derivatives of divalent thulium, dysprosium, and neodymium are still unknown. Therefore, we have tried to synthesize organothulium(II) complexes, in the knowledge that they would be very reactive towards organic substrates.[5] Thulium(II) iodide promised to be a suitable starting material. However, as demonstrated by the experiments described below, we were not successful in isolating organothulium(II) complexes, but isolated some interesting new thulium(III) complexes instead. Their formation and structures are reported herein.

Results and Discussion

Malachite-green $TmI_2(THF)_2$ reacts with $[C_5Me_5]K$ (molar ratio 1:2) in THF at −30 to +20 °C; the color of the reaction mixture changes first to brownish-green and finally to light-brown. After removal of the solvent, extraction of the remaining solid with toluene, and concentration of the toluene extract, yellow needle-shaped crystals precipitate. These were found to be composed of the thulium(III) complex $(C_5Me_5)_2TmI(THF)$ (**1**) rather than the expected $(C_5Me_5)_2Tm^{II}$ compound (Scheme 1). Compound **1** melts at 285 °C without decomposition; the high relative intensities of the molecular fragment ions $[(C_5Me_5)_2TmI]^+$ (49.86%), $[(C_5Me_5)TmI]^+$ (50.27%), and $[(C_5Me_5)_2Tm]^+$ (100%) in the EI mass spectrum at 241 °C confirm its remarkable thermal stability. The IR spectrum of **1** is rather uninformative, allowing only a clear assignment of the

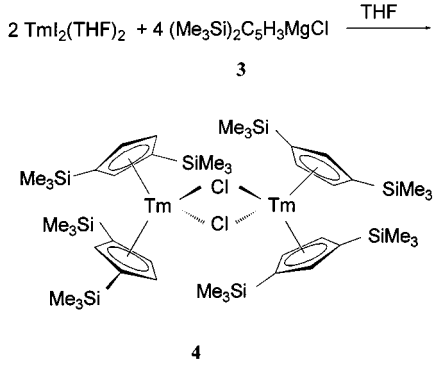
strong THF absorptions at 1010 and 860 cm^{-1}. We have previously observed a similar oxidation of Tm^{II} to Tm^{III} in the reaction of $TmI_2(DME)_3$ with $[Me_2Si(3\text{-}t\text{Bu-5-Me-}C_5H_3)(C_9H_6CH_2CH_2NMe_2)]Na_2$, which afforded the thulium(III) complex *ansa*-$[Me_2Si(3\text{-}t\text{Bu-5-Me-}C_5H_3)(C_9H_6CH_2CH_2NMe_2)]TmI$.[6]

In a subsequent experiment, we tried to obtain the bis(pentamethylcyclopentadienyl)thulium(II) complex by reducing compound **1** with sodium. At the start of the reaction of **1** with excess sodium in DME at 20 °C, a green coating appeared on parts of the metal surface indicating the formation of a thulium(II) species. However, this green coating disappeared very quickly and after stirring for 1 h, a light-yellow reaction mixture was obtained. Filtration and concentration of the solution afforded an oily residue, which partly redissolved in diethyl ether. From the concentrated clear ethereal solution, colorless crystals precipitated, which were found to contain thulium, but were free of iodine and melted at 68−72 °C with decomposition. The IR spectrum of these crystals shows an absorption band attributable to coordinated DME, together with a very strong, broad band at 1100 cm^{-1} indicating the presence of methoxide groups, these arising from cleavage of the DME solvent molecules. Such C−O activation has previously been observed by Lappert et al.,[7] who studied the reactions of $[1,3\text{-}(SiMe_3)_2C_5H_3]_3Nd$ and $(1,3\text{-}t\text{Bu}_2C_5H_3)_3Ce$ with lithium in DME yielding the corresponding methoxide complexes $[1,3\text{-}(Me_3Si)_2C_5H_3]_2Nd(\mu\text{-}OMe)_2Li(DME)$ and $[(1,3\text{-}t\text{Bu}_2C_5H_3)_2Ce(\mu\text{-}OMe)]_2$, respectively. The isolated crystals were characterized by single-crystal X-ray diffraction analysis. Whereas the data from a first diffraction experiment[8] implied some intrinsic contradictions, a second X-ray analysis of a crystal of the same crop afforded precise structural data, from which the formula of the compound formed in the reaction of **1** with sodium in DME could be assigned as $[(DME)_2Na(\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_5Me_5)Tm(\eta^5\text{-}C_5Me_5)(\mu_2\text{-}OMe)_2(Na\text{-}\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_5Me_5)Na(\mu\text{-}OMe)_2Tm(\eta^5\text{-}C_5Me_5)]$ (**2**), i.e. one containing only thulium(III) ions. The first step in the reaction is the expected reduction of **1** with the formation of green Tm^{II} species, which, because of their high reduction potential and high oxophilicity, attack DME solvent molecules with reductive splitting of MeO−C bonds and the formation of thulium(III) methoxide units. The generation of the four methoxide groups of **2** requires four electrons. Since two of the intermediately formed thulium(II) species provide only two electrons, the sodium metal must also take part in the reductive cleavage of DME. At this point, it should be noted that sodium metal does not react with DME in the absence of lanthanide compounds, not even on prolonged reflux. The organic products formed in the DME splitting process could not be identified.

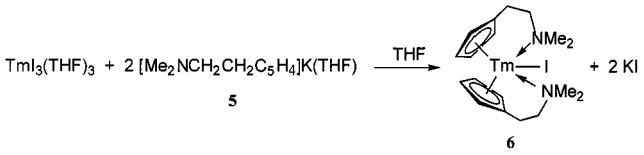
From the results reported above, we conclude that the possibility of synthesizing a stable organothulium(II) compound will probably arise by the use of space-demanding substituted cyclopentadienyl ligands or of cyclopentadienyl ligands containing nitrogen as a strong donor atom in the side chain, thus stabilizing the complex by additional intramolecular metal coordination. Lappert et al.[4a] have previously demonstrated that bulky cyclopentadienyl ligands are effective in stabilizing Ln^{II} ions. Therefore, we studied the interactions of $TmI_2(THF)_2$ with $[1,3\text{-}(Me_3Si)_2C_5H_3]M$ [M = K[9] or MgCl (**3**)]. Since only intractable product mixtures were obtained using the potassium cyclopentadienide, which can only be recovered from organic media in an impure state, we turned our attention to the corresponding cyclopentadienylmagnesium chloride, $[1,3\text{-}(Me_3Si)_2C_5H_3]MgCl$ (**3**), which can be obtained from $[1,3\text{-}(Me_3Si)_2C_5H_3]K$ and $MgCl_2$ (1:1 molar ratio) in diethyl ether as a pure crystalline solid. Addition of **3** to a solution of $TmI_2(THF)_2$ in THF (2:1 molar ratio) led to the immediate formation of a highly dispersed dark-grey solid, which reacted readily with water and was found to consist of metallic magnesium formed by reduction of MgICl by intermediately formed organothulium(II) species. As a consequence, workup of the reaction mixture again afforded only an organothulium(III) derivative, the dimeric compound $[\{1,3\text{-}(Me_3Si)_2C_5H_3\}_2TmCl]_2$ (**4**) (Scheme 2). Compound **4** was isolated in 67% yield and did not melt below 280 °C. Its mass spectrum shows ion peaks of a fragment of the dimer, $[M - 2\ CH_3 - (CH_3)_3Si]_2^+$ (0.5%), of the monomeric unit $[Cp^{\#}{}_2TmCl]^+$ (8%), and of fragments predominantly formed by cleavage of Si−C bonds. The MS data indicate that the metallocene structure of **4** is thermodynamically rather stable.



Scheme 2

The [2-(dimethylamino)ethyl]cyclopentadienyl ligand, which has already been used successfully for the synthesis of the ytterbium(II) complex $(Me_2NCH_2CH_2C_5H_4)Yb$,[10] should offer another possible means of obtaining a stable organothulium(II) complex. The corresponding potassium salt, $[Me_2NCH_2CH_2C_5H_4]K(THF)$ (**5**), was prepared from $Me_2NCH_2CH_2C_5H_5$ [11] and KH in THF according to literature methods (Scheme 3).[12] It forms long needle-shaped crystals, the structure of which we determined by X-ray diffraction analysis (Figure 3). Once again, compound **5** and $TmI_2(THF)_2$ did not react to form a Tm^{II} derivative. Indeed, in this case, workup of the reaction mixture did not even allow the isolation of a Tm^{III} complex, which we expected to be formed by oxidation of a Tm^{II} intermediate. However, the expected thulium(III) complex $(Me_2NCH_2CH_2C_5H_4)_2TmI$ (**6**) could be isolated as solvent-free colorless needles in 74% yield by treating **5** with

$TmI_3(THF)_3$ (2:1 molar ratio) in THF at 20 °C (Scheme 3). The crystals melt at 109−111 °C without decomposition. The EI mass spectrum of **6** shows no molecular ion peak at temperatures up to 220 °C. The most intense molecular fragments, $[(DoCp)_2Tm]^+$ (9%) and $[(DoCp)TmI]^+$ (4%), were detected at 158 °C (DoCp = $C_5H_4CH_2CH_2NMe_2$).



5 6

Scheme 3

Again, at the initial stage of the reaction of **6** with excess sodium in diethyl ether, the intermediate formation of a Tm^{II} compound was indicated by a light-green color of the mixture. However, this coloration disappeared within a few minutes and workup of the reaction mixture did not afford any well-defined products. This is in accordance with previously reported attempts[13] to synthesize cyclopentadienylthulium(II) complexes by reduction of the corresponding Tm^{III} compounds with alkali metals.

Molecular Structures of 2, 4, 5, and 6

Crystals suitable for single-crystal X-ray diffraction studies were obtained from diethyl ether (**2**), hexane (**4**), or THF (**5** and **6**). The crystal and structure refinement data for **2**, **4**, **5**, and **6** are listed in Table 1.

The molecule of **2** (Figure 1) contains two regions of disorder, both located around centers of symmetry. In the center of the molecule, a pentamethylcyclopentadienyl unit is statistically distributed between two symmetry-related alternative orientations. Since the centroid positions of the two orientations are different, the adjacent sodium position is split. At the ends of the molecule, the fragment $[Na(DME)_2]$ has a statistical occupancy of 50%. Due to overlap of the DME regions of neighboring molecules, at first glance the structure seems to be polymeric. However, two different DME molecules may not occupy the same space simultaneously, hence only one orientation can be realized between a given pair of molecules. Consequently, the structure consists of discrete isolated units. The picture given in Figure 1 (top) can be viewed in two ways. The open ellipsoids, together with their filled counterparts, represent the disordered parts of the structure. These atoms have crystallographic occupancies of 50%, resulting in an averaged structure corresponding to $[(DME)_2Na]_{1/2}$(μ-

The X-ray crystal structure of $[\{1,3\text{-}(Me_3Si)_2C_5H_3\}_2TmCl]_2$ (**4**) shows this complex to be a centrosymmetric, chloro-bridged dimer (Figure 2). Compound **4** crystallizes in the monoclinic space group $P2_1/c$ with two dimers in the unit cell. The bond lengths and bond angles estimated for **4** are in the characteristic ranges for the various fragments.[13,14]

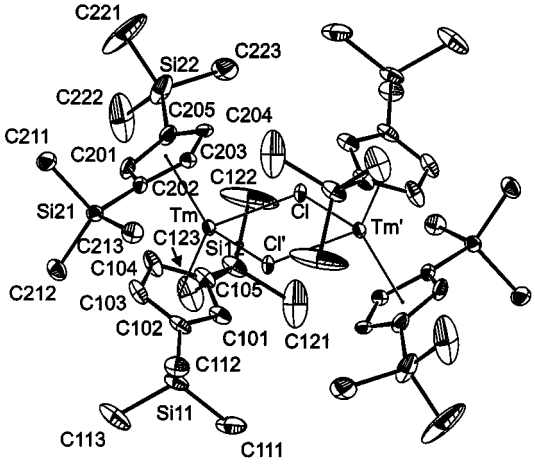

Figure 2. Molecular structure of **4** showing the atom numbering scheme (30% probability thermal ellipsoids); all hydrogen atoms have been omitted for clarity; selected bond lengths [A] and angles [°]: Tm−Cp(1) 2.314(3) [Tm−C 2.582(6)−2.642(5)], Tm−Cp(2) 2.316(3) [Tm−C 2.604(6)−2.618(5)], Tm−Cl 2.6829(15), Tm−Cl′ 2.6883(13); Cp(1)−Tm−Cp(2) 130.08(10), Cp(1)−Tm−Cl 110.60(7), Cp(1)−Tm−Cl′ 111.03(8), Cp(2)−Tm−Cl 106.82(8), Cp(2)−Tm−Cl′ 106.46(8), Cl−Tm−Cl′ 80.85(4), Tm−Cl−Tm′ 99.15(4); Cp(1) and Cp(2) represent the centroid positions of the rings C(101)−C(105) and C(201)−C(205), respectively; symmetry operation (′) used to generate equivalent atoms: $1-x$, $1-y$, $1-z$

$[Me_2NCH_2CH_2C_5H_4]K(THF)$ (**5**) (Figure 3) is polymeric and crystallizes in the chiral orthorhombic space group $P2_12_12_1$ with four formula units per unit cell. The structure consists of infinite one-dimensional chains extending parallel to the *b* axis. Each potassium atom is coordinated by one THF molecule, the C_5H_4 aromatic ring system, the nitrogen atom of the 2-(dimethylamino)ethyl side chain, and, additionally, by the C_5H_4 ring system of a neighbouring molecule. The $\mu_2\text{-}\eta^5\text{:}\eta^5$ coordination of the cyclopentadienyl moi-

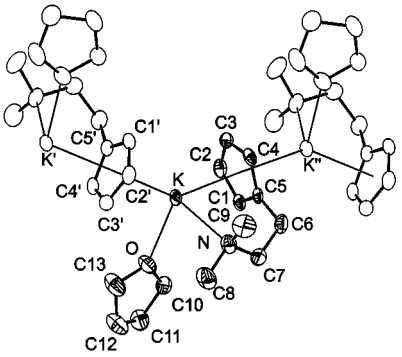

Figure 3. Section of the polymeric structure of **5** showing the atom numbering scheme (30% probability thermal ellipsoids); symmetry-equivalent atoms are represented by open ellipsoids to emphasize the asymmetric unit; all hydrogen atoms have been omitted for clarity; selected bond lengths [A] and angles [°]: K−Cp 2.8082(16) [K−C 3.007(3)−3.097(3)], K−Cp′ 2.8183(16) [K−C 3.007(3)−3.119(3)], K−N 2.867(3), K−O 2.734(3); Cp−K−Cp′ 143.23(5), O−K−N 88.01(10), Cp−K−N 85.38(7), Cp−K−O 109.43(6), Cp′−K−N 115.23(8), Cp′−K−O 101.76(6), K−Cp−K′′ 174.56(6); Cp represents the centroid position of the ring C(1)−C(5); symmetry transformations used to generate equivalent atoms: (′) $1-x$, $1/2+y$, $1/2-z$; (′′) $1-x$, $-1/2+y$, $1/2-z$

ety is characterized by only small differences in the K−C bond lengths (3.007−3.119 Å) and an almost linear K−Cp−K arrangement (174.56°).

The complex $(Me_2NCH_2CH_2C_5H_4)_2TmI$ (**6**) crystallizes in the orthorhombic space group *Pcnb*. The molecules possess a twofold rotational axis containing the thulium and iodine atoms (Figure 4). Consequently, the asymmetric unit comprises half a molecule for a total of two formula units per unit cell. In **6**, both donor atoms are intramolecularly coordinated to the thulium atom. As for other donor-functionalized bis(cyclopentadienyl)lanthanide(III) halides having a formal coordination number of 9,[15] the coordination geometry around the thulium atom is that of a distorted trigonal bipyramid with the two cyclopentadienyl rings and the iodine atom occupying the equatorial positions and the two nitrogen atoms of the cyclopentadienyl side chains in the axial positions forming an N−Tm−N angle of 157.9°. The distance from the thulium atom to the ring centers is 2.352 Å and the Tm−I and Tm−N distances of 3.014 and 2.789 Å, respectively, are within the ranges found for other thulium(III) complexes.[13,14]

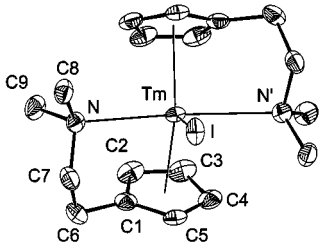

Figure 4. Molecular structure of **6** showing the atom numbering scheme (50% probability thermal ellipsoids); all hydrogen atoms have been omitted for clarity; selected bond lengths [Å] and angles [°]: Tm−Cp 2.352(2) [Tm−C 2.627(5)−2.650(4)], Tm−I 3.0145(4), Tm−N 2.789(4); I−Tm−Cp 114.27(6), I−Tm−N 78.97(8), Cp−Tm−Cp′ 131.46(8), Cp−Tm−N 90.91(11), Cp−Tm−N′ 98.12(11), N−Tm−N′ 157.94(16); Cp represents the centroid position of the ring C(1)−C(5); symmetry transformation (′) used to generate equivalent atoms: $1 - x$, $1/2 - y$, z

Conclusion

Reactions of thulium(II) iodide with cyclopentadienylpotassium or -magnesium derivatives do not yield stable cyclopentadienylthulium(II) complexes. Under the conditions used, only thulium(III) derivatives are formed. Neither the C_5Me_5 ligand nor the donor-functionalized $Me_2NCH_2CH_2C_5H_4$ or the bulky 1,3-$(Me_3Si)_2C_5H_3$ ligand are able to stabilize organothulium(II) complexes in coordinating ether solvents.

Experimental Section

General Remarks: All manipulations were carried out either in vacuo or under nitrogen using standard Schlenk techniques. The solvents used were dried with sodium/benzophenone and were condensed in vacuo prior to use. − Melting points and decomposition temperatures were determined for samples sealed in capillaries in vacuo. − Elemental analyses were performed on a Perkin−Elmer Series II CHNS/O Analyser 2400. − IR spectra were recorded with a Specord M-80 spectrometer. The samples were prepared as mulls in Nujol. − Mass spectra (EI, 70 eV) were recorded with a Varian MAT 311A spectrometer. Only characteristic fragments and highest-abundance isotope peaks are listed. Relative intensities (%) are given in parentheses. − Informative NMR spectra of the thulium(III) complexes could not be obtained due to the strong paramagnetism of thulium(III) (μ_{eff} = 7.0−7.5 B.M.). $TmI_2(THF)_5$ formed in the reaction of $TmI_3(THF)_3$ with metallic thulium in THF changes into $TmI_2(THF)_2$ upon drying at 90 °C. The detailed experimental procedure will be published elsewhere. Literature methods were used for the synthesis of $[Me_2NCH_2CH_2C_5H_4]K(THF)$ (**5**),[12] and [1,3-$(Me_3Si)_2C_5H_3$]K.[9]

$(C_5Me_5)_2TmI(THF)$ (1): To a stirred suspension of $(C_5Me_5)K$ (1.12 g, 6.42 mmol) in THF (25 mL), precooled to −30 °C, was added $TmI_2(THF)_2$ (1.84 g, 3.24 mmol). The brownish-green mixture was allowed to warm to ambient temperature over a period of 2 h and then stirred for a further 1 h. The solvent was then removed in vacuo and the remaining solid was extracted with toluene (3 × 15 mL). Concentration of the combined toluene extracts to a volume of 8−10 mL led to the deposition of **1** (0.69 g, 34%) as yellow needle-shaped crystals; m.p. 285 °C. − IR (Nujol): $\tilde{\nu}$ = 1230 (w), 1190 (m), 1010 (vs), 965 (w), 920 (m), 860 (vs), 670 cm^{-1} (w). − MS (241 °C, ^{169}Tm): *m*/*z* (%) = 565.8 (49.86) $[M - THF]^+$, 439.0 (100) $[M - THF - I]^+$, 430.8 (50.27) $[M - THF - C_5Me_5]^+$, 295.8 (43.39) $[M - THF - 2\ C_5Me_5]^+$. − μ_{eff} (295 K) = 7.7 B.M. − $C_{24}H_{38}IOTm$ (638.40): calcd. I 19.88, Tm 26.46; found I 21.02, Tm 26.54.

$[(DME)_2Na][(C_5Me_5)_2Tm(OMe)_2\{Na(C_5Me_5)Na\}(OMe)_2Tm(C_5Me_5)_2]$ (2): A mixture of $(C_5Me_5)_2TmI(THF)$ (1.61 g, 2.52 mmol) and sodium (0.3 g, 13.04 mg-atom) in DME (10 mL) was stirred for 1 h at ambient temperature. The light-yellow solution was then decanted from the excess sodium, the solvent was removed under reduced pressure, and the oily residue was dried in vacuo. Treatment of this residue with diethyl ether (15 mL) led to the precipitation of NaI. The ether solution was centrifuged and decanted from the precipitate. Within 1 d, colorless crystals of **2** had precipitated from the concentrated (5 mL) ether solution. Yield 0.51 g (29%); m.p. 68−72 °C (decomp). − IR (Nujol): $\tilde{\nu}$ = 1300 (m), 1250 (m), 1160 (m), 1100 (vs), 1030 (s), 980 (m), 920 (w), 870 cm^{-1} (s). − μ_{eff} (295 K) = 7.4 B.M. − $C_{62}H_{107}Na_3O_8Tm_2$ (1387.36): calcd. C 53.68, H 7.77, Tm 24.35; found C 53.87, H 6.41, Tm 24.77.

[1,3-$(Me_3Si)_2C_5H_3$]MgCl (3): To a stirred suspension of $MgCl_2$ (0.77 g, 8.08 mmol) in diethyl ether (50 mL), [1,3-$(Me_3Si)_2C_5H_3$]K (1.95 g, 7.84 mmol) was added. After 2 h, the mixture was filtered. The ether solution was concentrated in vacuo and the remaining waxy solid was washed with hexane (20 mL). Recrystallization of the solid from diethyl ether gave **3** (1.12 g, 53%). − MS (73 °C, ^{24}Mg): *m*/*z* (%) = 442.2 (78.31) $[Cp^{\#}{}_2Mg]^+$, 427.3 (84.16) $[Cp^{\#}{}_2Mg - CH_3]^+$, 339.1 (16.14) $[Cp^{\#}{}_2Mg - 2\ CH_3 - TMS]^+$, 268.1 (1.02) $[Cp^{\#}MgCl]^+$, 251.0 (9.76) $[Cp^{\#}{}_2Mg - 3\ CH_3 - 2\ TMS]^+$, 233.2 (9.95) $[Cp^{\#}Mg]^+$, 210.2 (5.84) $[Cp^{\#}]^+$, 195.2 (8.91) $[Cp^{\#} - CH_3]^+$, 73.0 (100) $[TMS]^+$, 59.0 (5.07) $[MgCl]^+$. − $C_{11}H_{21}ClMgSi_2$ (269.22): calcd. C 49.08, H 7.86; found C 49.44, H 8.27.

$[\{1,3\text{-}(Me_3Si)_2C_5H_3\}_2TmCl]_2$ (4): Addition of [1,3-$(Me_3Si)_2C_5H_3$]MgCl (0.84 g, 3.13 mmol) to a solution of $TmI_2(THF)_2$ (0.95 g, 1.67 mmol) in THF (40 mL) led to an immediate darkening of the reaction mixture. The solvent was removed in vacuo and the residual solid was extracted with hexane at 50 °C. The colorless

compound **4** (0.65 g, 67%) crystallized on cooling of the hexane extract; m.p. > 280 °C. − IR (Nujol): $\tilde{\nu}$ = 1440 (s), 1400 (m), 1320 (m), 1250 (vs), 1095 (vs), 985 (w), 930 (s), 845 (vs), 800 (s), 765 (s), 700 (m), 640 (m), 620 cm^{-1} (m). − MS [$Cp^{\#}$ = 1,3-$(Me_3Si)_2C_5H_3$, 207 °C, ^{169}Tm]: *m/z* (%) = 622.4 (8.22) $[M]^+$, 607.4 (100) $[M - CH_3]^+$, 587.1 (10.99) $[M - Cl]^+$, 518.9 (15.92) $[M - 2\ CH_3 - TMS]^+$, 499.2 (24.31) $[M - CH_3 - (CH_3)_3Si - Cl]^+$, 413.0 (6.45) $[M - Cp^{\#}]^+$, 397.0 (9.83) $[M - Cp^{\#} - CH_3]^+$, 210.2 (8.20) $[Cp^{\#}]^+$, 195.2 (10.92) $[Cp^{\#}\ CH_3]^+$, 73.0 (97.51) $[TMS]^+$. − μ_{eff} (295 K) = 7.2 B.M. − $C_{22}H_{42}ClSi_4Tm$ (623.30): calcd. C 42.38, H 6.79, Tm 27.19; found C 41.11, H 6.55, Tm 27.95.

$(C_5H_4CH_2CH_2NMe_2)_2TmI$ (6): To a suspension of $TmI_3(THF)_3$ (1.9 g, 2.48 mmol) in THF (35 mL) was added $(C_5H_4CH_2CH_2NMe_2)K(THF)$ (1.25 g, 5.06 mmol). The mixture was stirred for 1 h at room temperature. Evaporation of the solvent and extraction of the residual solid with toluene (3 × 10 mL) gave **6** (1.05 g, 74%) as colorless crystals; m.p. 109−111 °C. − MS (DoCp = $C_5H_4CH_2CH_2NMe_2$, 158 °C, ^{169}Tm): *m/z* (%) = 440.9 (9.09) $[M - I]^+$, 431.8 (4) $[M - DoCp]^+$, 295.7 (1.71) $[M - 2\ DoCp]^+$, 58.2 (100) $[CH_2NMe_2]^+$. − $C_{18}H_{28}IN_2Tm$ (568.27): calcd. C 38.02, H 4.97, N 4.93; found C 37.53, H 4.33, N 5.14.

Crystal Structure Determinations: Data were collected with a Siemens SMART CCD area detector diffractometer (ω scans, *T* = 173 K) for **2**, **5**, **6** or with an Enraf−Nonius CAD4 diffractometer (ω−2θ scans, *T* = 163 K) for **4**. Both diffractometers were equipped with low-temperature devices and were operated with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods using SHELXS-97[16] (**2**, **5**, **6**) or SHELXS-86[17] (**4**) and were refined against F^2 using SHELXL-97[18] (**2**, **5**, **6**) or SHELXL-93[19] (**4**). In the case of **2**, **5**, and **6**, an empirical absorption correction was applied using the program SADABS.[20] All non-hydrogen atoms were refined with anisotropic thermal parameters, except for the ring atoms of the disordered C_5Me_5 ligand in **2**. Hydrogen atoms were placed in idealized positions with fixed isotropic temperature factors (U_{iso} = 0.08 $Å^2$). Crystal and structure refinement data are given in Table 1. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-158695 (**2**), -158696 (**4**), -158697 (**5**), and -158698 (**6**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Trifunctional Phosphane Ligands and Their Application in the Synthesis of Novel Cage-Structured Platinacyclophanes and Trinuclear Chain-Like Platinacycles by Self-Assembly[‡]

Ekkehard Lindner,*[a] Monther Khanfar,[a] and Manfred Steimann[a]

Dedicated to Professor Dieter Sellmann on the occasion of his 60th birthday

Keywords: Cyclophanes / Platinum / P ligands / Supramolecular chemistry / Self assembly

The synthesis of the 1,3,5-tris[(diphenylphosphoryl)alkyl]-benzenes **7**–**10** succeeds by reaction of the corresponding 1,3,5-tris(bromoalkyl)benzenes **3**–**6** with ethyl diphenylphosphinite in an Arbusov-type reaction. Reduction of these phosphane oxides leads to the trifunctional phosphane ligands **11**–**14**. Their potency of self-assembly was examined by the employment of platinum(II) complex fragments. A five-component self-assembly consisting of 3 equiv. of the platinum complex $Cl_2Pt(NCPh)_2$ and 2 equiv. of the ligands **11**–**14** under high-dilution conditions led to the formation of the nanoscaled triplatinacyclophanes **1** and **15**–**17**. Polymers were formed as by-products from the reactions between **11**–**13** and $Cl_2Pt(NCPh)_2$, whereas in the case of **14** three other platinacyles **18**–**20** with a chain-like structure were formed. The structures of the metallacycles **1** and **15**–**17** as well as **18**–**20** were elucidated by $^{31}P\{^1H\}$, $^{13}C\{^1H\}$, and $^{195}Pt\{^1H\}$ NMR spectroscopic investigations.

Introduction

Supramolecular chemistry, which may be regarded as a result of modern coordination chemistry,[1] is at the frontier of molecular sciences as is shown by the fast growth of publications in this area in the last decade.[2] Cyclophanes and in particular metallacyclophanes are part of this chemistry.[3,4] They contain cavities that have the capacity to include guest molecules of different kinds.[4] The synthesis of these fascinating compounds was troublesome. However, studies in self-organization have provided a lot of interesting molecular architectures capable of being used for host−guest chemistry, such as "cyclophane boxes",[5] squares and polygons,[6] cylinders,[7] rods[8] and many others.[9] Unlike two-dimensional metallacyclophane boxes, three-dimensional multicyclic species are still rare today.[5,10]

Mono- and multidentate phosphanes are attractive ligands for the generation of complexes with a great variety of transition metal fragments.[11] Recently, van Koten et al.[12] synthesized a tetradentate ligand in which the phosphane arms are attached via methylene groups to a benzene ring in the 1,2,4,5-positions. The introduction of a symmetrically 1,3,5-trisubstituted benzene ring with at least C_3 symmetry into phosphane chemistry has advantages for the synthetic design[13] of self-assembled supramolecular molecules[14] and for chemical selectivity.[15] As it was demonstrated recently such tridentate phosphanes are suitable for assembly via three platinum atoms to give an elastic, three-dimensional molecular cage. By virtue of its size it was possible to reversibly encapsulate 1,2-dichloroethane into the triplatinacyclophane **1** (Figure 1).[16] In continuation of this work several triplatinacyclophanes were generated with different cage sizes in order to study the dependence of the number of methylene groups in the ligand system on the type of self-assembly. Due to this novel tridentate phosphane ligands are introduced in this investigation. They are based on a central benzene ring which is provided with three flexible aliphatic spacer units, each carrying a phosphane group at their ends. Such ligands can be employed in catalysis and supramolecular chemistry.

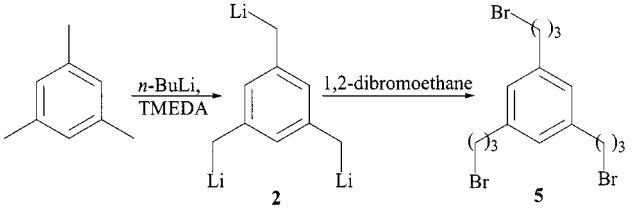
Results and Discussion

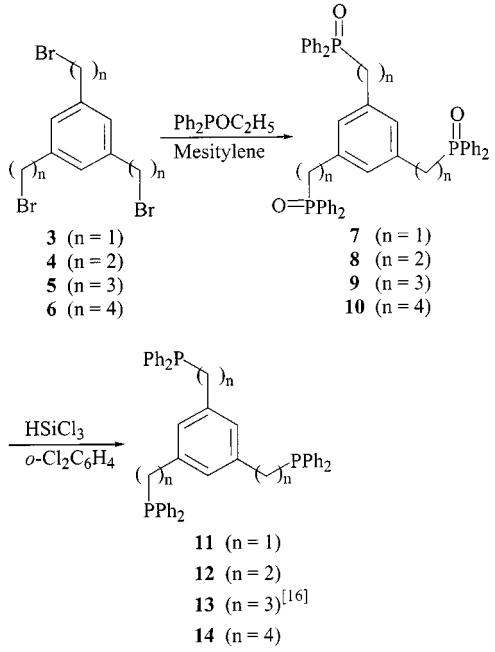
Ligand Synthesis

For the synthesis of the target ligands **11**−**14** the 1,3,5-tris(bromoalkyl)benzenes **3**−**6** are used as starting materials. However, according to the literature 1,3,5-tris(bromopropyl)benzene (**5**) is only available in a complicated eight-step reaction sequence.[17] Therefore a much simpler access to **5** was developed. Lithiation of mesitylene with *n*BuLi/TMEDA in *n*-hexane afforded the trilithium derivative **2**. Subsequent addition of a suspension of **2** in *n*-pentane to a solution of 1,2-dibromoethane in *n*-pentane at −85 °C resulted in the formation of **5** in about 20% yield (Scheme 1).



Scheme 1

Reactions of the trifunctionalized chloro- or bromoalkylbenzenes **3**−**6** with $MPPh_2$ (M = Li, Na) or $LiCH_2PPh_2$ were not successful. Also treatment of **2** with $ClPPh_2$ or $ClCH_2PPh_2$ did not result in the isolation of a defined product. Therefore a method of van Koten et al. was applied which was recently published.[12,18] According to this procedure an Arbusov reaction was carried out between **3**−**6** and $Ph_2POC_2H_5$ yielding quantitatively the phosphane oxides **7**−**10** (Scheme 2). In *o*-dichlorobenzene these phosphane oxides can easily be reduced with $HSiCl_3$ to the corresponding trifunctionalized phosphanes **11**−**14** (Scheme 2). Whereas the phosphane oxides **7**−**10** represent colorless solids with rather high melting points, which are soluble in all organic solvents of high and medium polarity, the colorless phosphanes are obtained as waxy (**11**), crystalline (**12**), or gummy products (**13**,**14**). In contrast to **7**−**10** they are not soluble in polar solvents. The composition of **7**−**14** was confirmed by FAB and EI mass spectra, showing in each case the molecular peak. The IR spectra (in KBr) of **7**−**10** display a sharp absorption between 1197 and 1225 cm^{-1} which is assigned to the P=O stretching vibration. Expectedly, in the $^{31}P\{^1H\}$ NMR spectra (in $CDCl_3$) of the phosphane oxides **7**−**10** one singlet is observed for each of them (δ = 31 to 34) which is shifted to higher fields (δ = −9 to −15) on going from **7**−**10** to the phosphanes **11**−**14**.



Scheme 2

Crystal Structures of 9 and 12

To obtain more detailed structural information about the trifunctional phosphane oxides and their oxygen-free analogues, X-ray structural analyses were performed on compounds **9** and **12** (Scheme 2). ORTEP drawings of their molecular structures with atom labeling are depicted in Figures 2 and 3. Although the crystal structure of **9** is of restricted quality, it can be used for a brief discussion. Because **9** has a C_3 axis of symmetry which is passing through the center of the benzene ring all three phosphane arms are equivalent. This fact gives rise to several structural implications. All distances between the phosphorus and carbon atoms of the central benzene ring are equal [5.307(5) Å] and the P1−C2, P1A−C2A, and P1B−C2B axes are bent towards the plane of the central benzene ring by an angle of 144.2(6)°. A further consequence is that the phosphorus atoms are located at the vertices of an equilateral triangle that is parallel to the benzene ring. The distance between the phosphorus atoms is 10.179(6) Å (Figure 2).

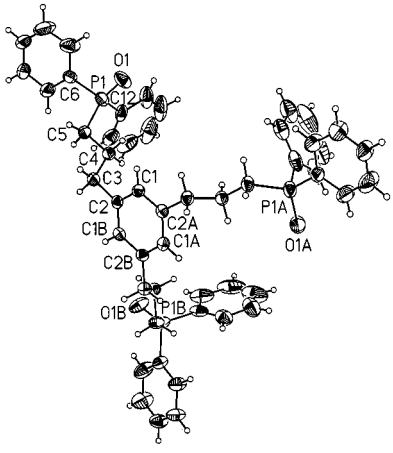


Figure 2. Molecular structure of **9** in the crystal; ORTEP plot with thermal ellipsoids at 20% probability; selected distances [Å] and angles [°]: P1−O1 1.487(4), P1−C6 1.800(5), P1−C5 1.809(4), P1−C12 1.809(8), P1−C2 5.307(5), P1−P1A = P1A−P1B = P1−P1B 10.179; C1A−C2−P1 = C1B−C2A−P1A = C1−C2B−P1B 144.2(6)

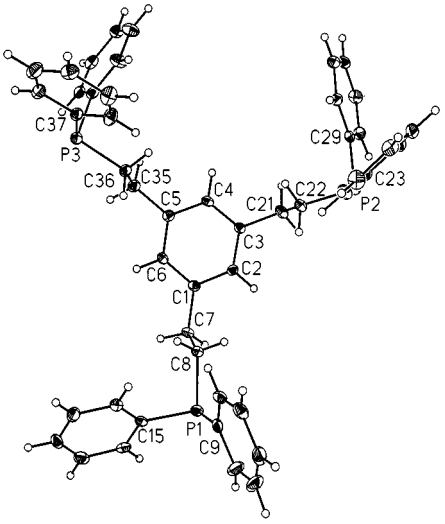

Figure 3. Molecular structure of **12** in the crystal; ORTEP plot with thermal ellipsoids at 20% probability; selected distances [Å] and angles [°]: P1−C9 1.831(7), P1−C8 1.834(5), P1−C15 1.849(5), P2−C23 1.809(6), P2−C29 1.833(5), P2−C22 1.847(5), P3−C36 1.854(5), P3−C37 1.811(7), P3−C43 1.839(5) P1−C1 4.180(3), P2−C3 4.166(3), P3−C5 4.169, P1−P2 8.672, P2−P3 9.292(4), P1−P3 9.329; C4−C1−P1 154.9(3), C6−C3−P2 157.9(4), C2−C5−P3 157.7(4)

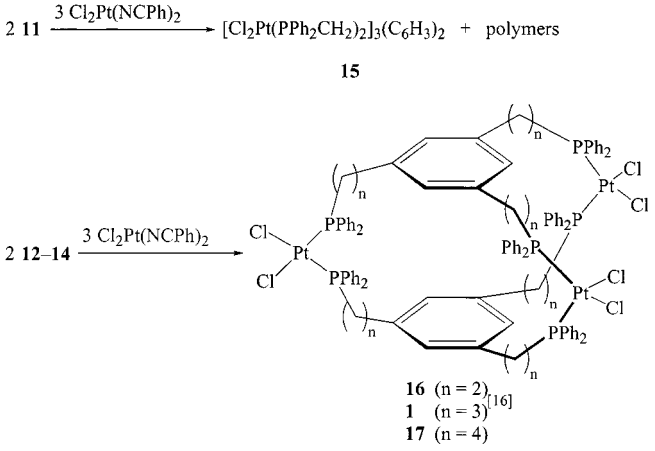
In the structure of the phosphane **12** such a C_3 axis of symmetry is not existent. Therefore the different distances between the phosphorus atoms as well as between these and the carbon atoms of the central benzene ring are not equal (Figure 3) and the nonsymmetric triangle constituted by phosphorus atoms is not parallel to the benzene ring. The P1−C1, P2−C3 and P3−C5 axes are bent towards the plane of the benzene ring by angles of 154.9(3), 157.9(4), and 157.7(4)°, respectively.

Motifs Generated by Self-Assembly

To obtain self-assembled cyclophane structures a pre-organization of the components is a necessary prerequisite. Trifunctionalized phosphane ligands of the type **11**−**14** provide the necessary rigidity that is important for this pre-organization. For the generation of the three-dimensional platinacyclophanes **15**, **16**, and **17** the ligands **11**, **12**, and **14** were treated with $Cl_2Pt(NCPh)_2$ in dichloromethane according to the high-dilution method (Scheme 3).[19] In contrast to the platinacyclophane **1**, which was recently described,[16] the smaller cages **15** and **16** were obtained in lower yields. In particular the platinacyclophane **15** could not be isolated in pure form, since polymers and oligomers were formed as by-products, an observation which was also made by Fujita et al. with comparable nitrogen ligands.[10c] The solubility of **15** as well as these by-products is too low for separation. This property also led to the prevention of a template synthesis being performed in order to enhance the yield of **15**. Because of its better solubility **16** could be obtained as a pure compound by chromatography.

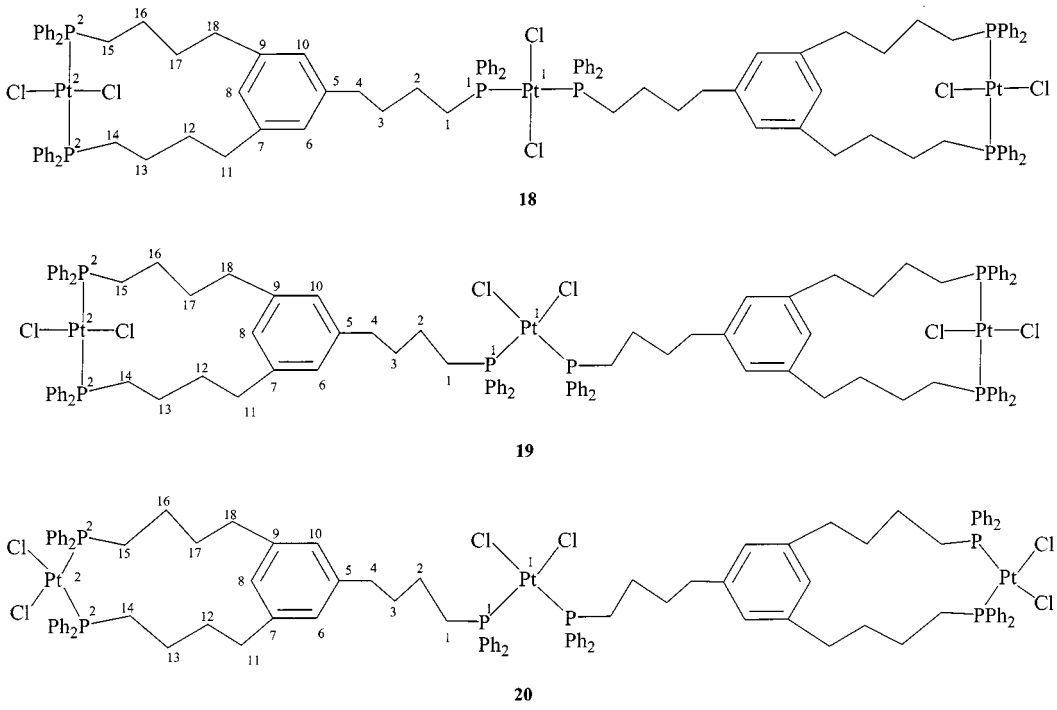


Scheme 3

Compared to **11** and **12** the behavior of ligand **14,** with four methylene units towards $Cl_2Pt(NCPh)_2$, was different. No oligomers or polymers were detected. In addition to the occurrence of the triplatinacyclophane **17** three other species **18**−**20** were isolated with increasing yields in the sequence **18** > **19** > **20** (Scheme 4). The separation of **17**−**20** was performed by column chromatography. However, **17** always contained impurities of **20**. According to their FAB mass spectra these compounds show the same molecular mass and it turned out that they are structural isomers. To optimize the yield of the triplatinacyclophane **17** the reaction between **14** and $Cl_2Pt(NCPh)_2$ was carried out at different temperatures (−70 to +40 °C) in dichloromethane. At low temperatures the yields were around 10% and decreased with increasing temperature. At 40° C the structural isomer **18** is predominant (86%) and the formation of **17** is thermodynamically unfavorable.[20] Benzene is the best solvent for the generation of **17**; it is superior to CCl_4 or $CHCl_3$.

The triplatinacyclophanes **1**, **15**−**17** and trinuclear platinacycles **18**−**20** represent colorless to pale yellow compounds that show similar solubility behavior to their corresponding ligands **11**−**14**. However, **15** is nearly insoluble in all organic solvents. The *all-trans* complex **18** transforms slowly to the *trans-cis-trans* complex **19**.

Structural information about the motifs and geometry of the platinacyles **16**−**20** is available by $^{31}P\{^1H\}$ NMR spectroscopic investigations. ^{31}P chemical shifts and $^{195}Pt-^{31}P$ coupling constants allow an unambiguous distinction between the architecture of the molecules and their stereoisomerism. Complexes with *cis* geometry show coupling constants of about 3500 Hz, whereas those with a *trans* environment reveal values of about 2500 Hz.[21] It is also well known that ^{31}P signals of *trans* isomers are shifted upfield compared to those of *cis* isomers.[21] The $^{31}P\{^1H\}$ NMR spectra of **16** and **17** each show a singlet for the six chemical equivalent phosphorus atoms at δ = 7.1 and 9.6, respectively, and a doublet for the ^{195}Pt satellites, which is typical for *cis*-PtP_2 fragments. This assignment is confirmed by $^{195}Pt\{^1H\}$ NMR spectra, which each display a triplet at δ = −4423 and −4413 with coupling constants of $^1J_{PtP}$ = 3600 and 3668 Hz, respectively. Moreover, the structure of **1** was recently confirmed by an X-ray structural analysis.[16] Because **15** was impurified by polymers and because of its low



Scheme 4

solubility in all organic solvents, no exact NMR spectroscopic data were available.

In contrast to **16**, **17** (and **1**[16]) the $^{31}P\{^{1}H\}$ NMR spectra of the trinuclear platinacycles **18**−**20** show two ^{31}P singlets in a ratio of 2:1. This is a clear indication that two different ^{31}P nuclei are present. Each singlet is accompanied by a doublet as satellites that is traced back by the $^{195}Pt-^{31}P$ coupling (see Exp. Sect.). According to the chemical shifts and the size of the coupling constants, **18** is characterized by an *all-trans* structure. In the case of the metallacycle **19** the central platinum atom (Pt^1, Scheme 4) has a *cis* geometry, whereas both terminal platinum atoms (Pt^2) have a *trans* configuration. In compound **20** an *all-cis* structure was established. The fact that the terminal platinum atoms in **18**−**20** are incorporated in a cycle was confirmed by the value of the $^{195}Pt-^{31}P$ coupling constants which is higher than that of the noncyclized central platinum atom. Moreover the terminal cyclized P_2Pt moieties show higher chemical shifts than the central *trans*-P_2Pt unit. A reverse observation was made in the case of **20**.

A short discussion of the ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra of the cycles **16**−**20** is with regards to the central benzene rings and the adjacent methylene groups. Only one ^{1}H signal is observed in the spectra of **16** (δ = 6.42) and **17** (δ = 6.86) for the aromatic protons. A different situation was found in the cases of **18**−**20**. Two singlets in a 2:1 ratio are assigned to H^6/H^{10} and H^8, which is in agreement with the proposed structure (Scheme 4). The methylene protons only give rise to broad unresolved signals. Two different ^{13}C resonances occur in the spectra of the cages **16** and **17** and they are ascribed to the methine (δ = 126.1) and quaternary carbon atoms [δ = 129.6 (**16**), 132.4 (**17**)] of the benzene rings. In the case of **16** the second one is split into a doublet, because of the $^{31}P-^{13}C$ coupling ($^{3}J_{PC}$ = 7 Hz). The corresponding signals for the aromatic methine and quaternary carbon atoms in the spectra of **18**−**20** are split into two peaks with an intensity of 2:1 (see Exp. Sect.). A doublet at δ = 28.6 ($^{2}J_{PC}$ = 47 Hz) in the spectrum of **16** and a singlet at δ = 35.8 in that of **17** are assigned to the methylene carbon atoms which are adjacent to the benzene rings. These resonances are split into two signals with an intensity of 2:1 in the spectra of **18**−**20**.

Conclusion

In contrast to metallacyclophanes, the chemistry of organic cyclophanes is much more developed.[3] However, within the last five to ten years several new architectures of metallacyclophanes with interesting properties have been described in the literature.[1−3,5,6] This new variant of cyclophanes is available by self-assembly of multifunctional ligands with suitable metal fragments. In the present investigation a simple strategy was introduced that allows a convenient access to trifunctional phosphanes. They are provided with a central benzene ring with three phosphane arms in a symmetrical 1,3,5-position. The distance of these phosphanes from the benzene ring is controlled by methylene functions of different length. Ligands of this type cannot be used only for the generation of metallocyclophanes, but also as the first generation of dendrimers[10b,22] and for the synthesis of catalytically active transition metal complexes.[14a] It was demonstrated that these trifunctional phosphane ligands are capable of undergoing self-assembly

with adequate platinum complex fragments. Three items are observed that affect the formation of three-dimensional platinacyclophanes: 1) the rigidity of the ligand system, 2) steric factors, and 3) intramolecular chelation. The first point is predominant in the formation of cages with a trisphosphane that contains no methylene groups between the central benzene ring and the phosphorus donors. Therefore, the system appears to be rigid and it is not possible for the phosphanes to avoid contact between each other to reduce the steric congestion caused by the phenyl substituents. Also the P-donors are too far away from a metal center to give intramolecular chelation.[10b] By the introduction of methylene groups and by increasing their number, the ligand system becomes more flexible and the phosphane moieties are able to move away from each other to minimize the interactions and hence the steric demand. This was clearly observed in the crystallization patterns of these systems from triclinic (**7**, one phosphane group is in the opposite direction of the other two[23]), via monoclinic (**12**, this report) to cubic (**9**, this report) for trifunctional phosphanes with one, two, and three methylene groups, respectively, as was shown from X-ray crystal structural analyses. However, the introduction of only one methylene group is not enough to reduce the steric hindrance, which means intermolecular chelation results in the favored formation of polymers. The flexibility of a phosphane system with four methylene bridges is accompanied by a release of the steric factor and thus enables intramolecular chelation. This is the reason that the formation of the chain-like platinacycles **18**−**20** are favored compared with that of the cage **17**. The optimum for self-assembly is obtained if the ligand contains three methylene groups.

Experimental Section

General: All synthetic reactions and manipulations were performed under dry argon using standard Schlenk techniques. *n*-Pentane and TMEDA were freshly distilled from $LiAlH_4$, dichloromethane from calcium hydride, benzene from sodium benzophenone ketyl, and mesitylene and *o*-dichlorobenzene from molecular sieves (5 Å). − Column chromatography: Activated silica gel, 0.063−0.200 mm or 0.04−0.063 (Merck); column dimensions are reported in the specific sections describing the synthesis of the compounds. − Purifications by thin layer chromatography were carried out on preparative TLC glass plates (20 × 20 cm) using silica gel 60 F254, 0.5 mm (Merck). − Elemental analysis: Elementar Vario EL analyzer. − Mass spectra: EI-MS: Finnigan TSQ 70 eV (200 °C); FD and FAB-MS: Finnigan 711A (8 kV), modified by AMD. − IR: Bruker IFS 48 FT-IR. − ^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$, and $^{195}Pt\{^1H\}$ NMR: Bruker DRX-250 spectrometer operating at 250.13, 62.90, 101.26, and 53.55 MHz, respectively. ^1H NMR chemical shifts were referenced with TMS as the internal standard. $^{13}C\{^1H\}$ NMR chemical shifts were calibrated against the deuterated solvent multiplet and referenced to TMS. $^{31}P\{^1H\}$ NMR chemical shifts were measured relative to external 85% H_3PO_4 with downfield values being taken as positive. $^{195}Pt\{^1H\}$ NMR chemical shifts were measured relative to external 37.5% $Na_2[PtCl_6]\cdot 6\,H_2O$. − Compounds **3**,[24] **4**,[25] **2**,[26] ethyl diphenylphosphinite,[27] $Cl_2Pt(NCPh)_2$,[28] and **14**[29] were synthesized according to the literature methods.

1,3,5-Tris(3′-bromopropyl)benzene (5): Pyrophoric **2**, prepared from *n*-butyllithium (500 mL, 15% in *n*-hexane), TMEDA (92.97 g, 800 mmol) and mesitylene (16.4 g, 136 mmol), was suspended in *n*-pentane (250 mL) and added in portions to a solution of 1,2-dibromoethane (150 g, 800 mmol) in *n*-pentane (200 mL) at −85 °C. After stirring for 2 h, the resulting mixture was allowed to warm slowly to room temperature. After neutralization, the organic phase was separated and the aqueous phase was extracted twice with CH_2Cl_2. The combined organic extracts were dried (Na_2SO_4) and the volatile materials were distilled. The residual material was subjected to column chromatography (30 × 7 cm, *n*-hexane) to afford a colorless oil. Yield 12.0 g, 20%. − ^1H NMR ($CDCl_3$): δ = 1.36 (quint, $^3J_{HH}$ = 7.0 Hz, 6 H, CH_2CH$_2$Br), 2.73 (t, $^3J_{HH}$ = 7.4 Hz, 6 H, CH_2CH$_2$CH$_2$Br), 3.40 (t, $^3J_{HH}$ = 6.6 Hz, 6 H, CH$_2$CH_2Br), 6.88 (s, 3 H, aromatic H). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 33.4 (CH_2Br), 34.0 (*C*H$_2$CH$_2$Br), 34.3 (*C*H$_2$CH$_2$CH$_2$Br), 126.8 (aromatic CH), 141.2 (aromatic C). − MS (70 eV, EI, 200 °C): *m*/*z* (%) = 438 (27), 440 (92), 442 (100), 444 (27) [M^+], 363 (4), 361 (8), 359 (5) [M^+ − Br], 331 (41), 333 (69), 335 (40) [M^+ − CH_2CH_2Br].

1,3,5-Tris(diphenylphosphorylmethyl)benzene (7): A modification to the literature procedure was applied.[30] To a suspension of **3** (4.25 g, 12 mmol) in mesitylene (20 mL), Ph_2POEt (15.37 g, 67 mmol) was added. Heating of the reaction mixture to 110 °C afforded a colorless solution. After heating of the reaction mixture to 150 °C for 2 h, a white precipitate was formed. The solid was collected and crystallized from hot benzene, to afford a colorless solid. Yield 8.0 g, 93%, m.p. 210−211 °C (m.p.[30] 205−206 °C). − ^1H NMR ($CDCl_3$): δ = 3.44 (d, $^3J_{PH}$ = 13.8 Hz, 6 H, CH_2P), 6.96 (d, $^4J_{PH}$ = 1.9 Hz, 3 H, aromatic C_6H_3), 7.47−7.50 (m, 18 H, *ortho*- and *para*-P−C_6H_5), 7.59 (m, 12 H, *meta*-P−C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 37.7 (d, $^1J_{PC}$ = 66.9, *C*H$_2$P), 123.6 (s, *tert*-C_6H_3), 128.6 (d, $^3J_{PC}$ = 12.1 Hz, *meta*-C_6H_5), 130.6 (m, *quat*-C_6H_3), 131.1 (d, $^2J_{PC}$ = 9.3 Hz, *ortho*-C_6H_5), 131.8 (s, *para*-C_6H_3), 137.4 (d, $^1J_{PC}$ = 99.6 Hz, *ipso*-C_6H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 30.9. − IR (KBr): $\tilde{\nu}$ = 3053, 3024 (aromatic CH), 2950, 2893 (CH_2), 1437 (P−Ph), 1198 (P=O) cm^{-1}. − MS (70 eV, EI, 200 °C): *m*/*z* (%) = 720 (1) [M^+], 596 (9) [M^+ − P(O)Ph], 519 (5) [M^+ − $P(O)Ph_2$], 201 (100) [$P(O)Ph_2^+$].

1,3,5-Tris(2′-diphenylphosphorylethyl)benzene (8): To a suspension of **4** (3.99 g, 10 mmol) in mesitylene (20 mL), Ph_2POEt (14.0 g, 61 mmol) was added. Heating of the reaction mixture to 90 °C afforded a colorless solution. The procedure continued as outlined for **7** to afford a colorless solid. Yield 7.0 g, 98%, m.p. 234−235 °C. − ^1H NMR ($CDCl_3$): δ = 2.49 (m, 6 H, CH_2P), 2.82 (m, 6 H, CH_2CH$_2$P), 6.79 (s, 3 H, C_6H_3), 7.42−7.55 (m, 18 H, *ortho*- and *para*-P−C_6H_5), 7.75 (m, 12 H, *meta*-P−C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 27.5 (d, $^3J_{PC}$ = 2.14 Hz, *C*H$_2$CH$_2$P), 32.0 (d, $^1J_{PC}$ = 69.0, *C*H$_2$P), 126.1 (s, *tert*-C_6H_3), 128.9 (d, $^3J_{PC}$ = 11.4 Hz, *meta*-C_6H_5), 130.9 (d, $^2J_{PC}$ = 9.3 Hz, *ortho*-C_6H_5), 132.0 (d, $^4J_{PC}$ = 2.14 Hz, *para*-C_6H_5), 132.8 (d, $^1J_{PC}$ = 99.6 Hz, *ipso*-C_6H_5), 142.1 (d, $^3J_{PC}$ = 14.9 Hz, *quat*-C_6H_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 32.7. − IR (KBr): $\tilde{\nu}$ = 3052, 3022 (aromatic CH), 2935 (CH_2), 1438 (P−Ph), 1188 (P=O) cm^{-1}. − MS (70 eV, EI, 200 °C): *m*/*z* (%) = 560 (37) [M^+ − $P(O)Ph_2$], 359 (100) [M^+ − 2P(O)Ph_2], 201 (56) [$P(O)Ph_2^+$]. − MS (FD, CH_2Cl_2, 30 °C): *m*/*z* (%) = 763 (100) [M^+]. − $C_{48}H_{45}O_3P_3$ (762.8): MS (HR, pos. FAB, NBA, 50 °C): *m*/*z* = 763.25960 [M^+]; calcd. 763.26599. − $C_{48}H_{45}O_3P_3$ (762.8): calcd. C 75.58, H 5.95; found C 75.36, H 5.82.

1,3,5-Tris[3′-(diphenylphosphoryl)propyl]benzene (9): Ph_2POEt (4.70 g, 20.4 mmol) was added to a suspension of **4** (1.50 g, 3.4 mmol) in mesitylene (20 mL). Heating of the reaction mixture

to 70 °C afforded a colorless solution. After heating of the reaction mixture to 150 °C for 4 h, the volatile materials were removed under vacuum at 90 °C. The residue was solidified after cooling. A colorless solid product was obtained upon crystallization from benzene/*n*-hexane. Yield 2.54 gm, 93%, m.p. 115 °C. – ^{1}H NMR ($CDCl_3$): δ = 1.90 (m, 6 H, CH_2P), 2.24 (m, 6 H, CH_2CH$_2$P), 2.61 (t, $^3J_{HH}$ = 7.4 Hz, 6 H, CH_2CH$_2$CH$_2$P), 6.70 (s, 3 H, C_6H_3), 7.39–7.51 (m, 18 H, *ortho*- and *para*-P–C_6H_5), 7.68 (m, 12 H, *meta*-P–C_6H_5). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 23.0 (d, $^2J_{PC}$ = 3.4, CH$_2$*C*H$_2$CH$_2$P), 29.2 (d, $^1J_{PC}$ = 71.4 Hz, *C*H$_2$P), 37.1 (d, $^3J_{PC}$ = 14.8 Hz, *C*H$_2$CH$_2$CH$_2$P), 126.5 (s, *tert*-C_6H_3), 129.1 (d, $^3J_{PC}$ = 12.1 Hz, *meta*-C_6H_5), 130.7 (d, $^2J_{PC}$ = 8.8 Hz, *ortho*-C_6H_5), 131.8 (d, $^4J_{PC}$ = 2.7 Hz, *para*-C_6H_5), 133.0 (d, $^1J_{PC}$ = 98.4 Hz, *ipso*-C_6H_5), 141.2 (s, *quat*-C_6H_3). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 33.8. – IR (KBr): ṽ = 3054, 3055 (CH_2), 2960, 2934 (aromatic CH), 1184 (P=O) cm^{-1}. – MS (pos. FAB, NBA, 50 °C): *m*/*z* (%) = 805 (37) [M$^+$ + H], 603 (9) [M$^+$ – P(O)Ph$_2$], 589 (15) [M$^+$ – CH$_2$P(O)Ph$_2$], 576 (2) [M$^+$ – CH$_2$CH$_2$P(O)Ph$_2$], 229 (16) [CH$_2$CH$_2$P(O)Ph$_2^+$], 215 (100) [CH$_2$P(O)Ph$_2^+$], 201 (55) [P(O)Ph$_2^+$]. – $C_{51}H_{51}O_3P_3$ (804.9). – MS (HR, pos. FAB, NBA, 50 °C): *m*/*z* = 805.31829 [M$^+$]; calcd. 805.31294. – $C_{51}H_{51}O_3P_3$ (804.9): calcd. C 76.11, H 6.39; found C 76.39, H 6.40.

1,3,5-Tris(diphenylphosphanylmethyl)benzene (11): A suspension of **3** (1.23 g, 1.7 mmol) in *o*-dichlorobenzene (10 mL) was heated in a three-necked 100-mL round-bottom flask, equipped with reflux condenser. The suspension became a clear solution at about 90 °C. The reaction mixture was further heated to 120 °C. At this temperature trichlorosilane (2.10 g, 15.5 mmol) was added dropwise through a septum. After 2 h, the reaction mixture was allowed to cool slowly to room temperature. The reaction mixture was neutralized by degassed sodium hydroxide (20%, 40 mL) which was added through a dropping funnel at –10 °C (ice/salt bath). The organic layer was separated and the aqueous layer was extracted with dichloromethane (3 × 30 mL). The combined organic extracts were dried (Na_2SO_4) filtered (P3) and dried in vacuum to give a colorless solid. Yield 1.1 g, 96%, m.p. 58 °C. – ^{1}H NMR ($CDCl_3$): δ = 3.08 (s, 6 H, CH_2P), 6.50 (s, 3 H, C_6H_3), 7.18 (s, 30 H, P–C_6H_5). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 35.9 (d, $^1J_{PC}$ = 15.7 Hz, *C*H$_2$P), 128.4 (d, $^3J_{PC}$ = 6.4 Hz, *meta*-C_6H_5), 128.7 (s, *para*-C_6H_3), 130.7 (s, *tert*-C_6H_3), 133.0 (d, $^2J_{PC}$ = 18.5 Hz, *ortho*-C_6H_5), 137.4 (dt, $^2J_{PC}$ = 8.5 Hz, $^4J_{PC}$ = 1.4 Hz, *quat*-C_6H_3), 138.6 (d, $^1J_{PC}$ = 15.7 Hz, *quat*-C_6H_5). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = –9.4. – IR (KBr): ṽ = 3070, 3050 (aromatic CH), 2925, 2904 (CH_2), 1432 (P–Ph) cm^{-1}. – MS (70 eV, EI, 200 °C): *m*/*z* (%) = 672 (37) [M$^+$], 595 (3) [M$^+$ – Ph], 487 (37) [M$^+$ – Ph$_2$], 301 (25) [M$^+$ – 2PPh$_2$]. – $C_{45}H_{39}P_3$ (672.7): MS (HR, 70 eV, EI, 210 °C): *m*/*z* = 672.230597 [M$^+$]; calcd. 672.226445. – $C_{45}H_{39}P_3$ (672.7): calcd. C 80.35, H 5.84; found C 80.04, H 5.85.

1,3,5-Tris[(2′-diphenylphosphanyl)ethyl]benzene (12): The same procedure outlined for **11** was applied for the synthesis of **12**. A suspension of compound **8** (3.05 g, 4.0 mmol) in *o*-dichlorobenzene (10 mL) became a colorless solution at 110 °C. After reduction with trichlorosilane (4.94 g, 36.5 mmol) and work-up, a white solid was obtained. Yield 2.80 g, 98%, m.p. 108–109 °C. – ^{1}H NMR ($CDCl_3$): δ = 2.32 (m, 6 H, CH_2P), 2.66 (m, 6 H, CH_2CH$_2$P), 6.78 (s, 3 H, C_6H_3), 7.33–7.35 (m, 18 H, *ortho*- and *para*-P–C_6H_5), 7.45 (m, 12 H, *meta*-P–C_6H_5). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 30.3 (d, $^2J_{PC}$ = 12.8 Hz, *C*H$_2$CH$_2$P), 32.3 (d, $^1J_{PC}$ = 18.5 Hz, CH$_2$P), 125.9 (s, *tert*-C_6H_3), 128.6 (d, $^3J_{PC}$ = 7.1 Hz, *meta*-C_6H_5), 128.8 (s, *para*-C_6H_5), 132.9 (d, $^2J_{PC}$ = 18.5 Hz, *ortho*-C_6H_5), 138.7 (d, $^1J_{PC}$ = 12.8 Hz, *ipso*-C_6H_5), 143.1 (d, $^3J_{PC}$ = 12.8 Hz, *quat*-C_6H_3). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = –14.3. – IR (KBr): ṽ = 3068, 3051 (aromatic CH), 2940, 2924 (CH_2), 1479 (P–Ph) cm^{-1}. – MS (70 eV, EI, 200 °C): *m*/*z* (%) = 714 (13) [M$^+$], 637 (7) [M$^+$ – Ph], 529 (27) [M$^+$ – Ph$_2$]. – $C_{48}H_{45}P_3$ (714.8): MS (HR, pos. FAB, NBA, 50 °C): *m*/*z* = 715.26919; found 715.26919. – $C_{48}H_{45}P_3$ (714.8): calcd. C 80.66, H 6.35; found C 80.56, H 6.15.

1,3,5-Tris[(3′-diphenylphosphanyl)propyl]benzene (13): The same procedure outlined for **11** was applied for the synthesis of **13**. A suspension of compound **9** (1.29 g, 1.6 mmol) in *o*-dichlorobenzene (10 mL) became a colorless solution at 80 °C. After reduction with trichlorosilane (2.0 g, 14.8 mmol) and work-up, a colorless oil was obtained. Yield 1.10 g, 91%. – ^{1}H NMR ($CDCl_3$): δ = 1.74 (m, 6 H, CH_2CH$_2$P), 2.08 (m, 6 H, CH$_2$CH_2P), 2.66 (t, $^3J_{HH}$ = 7.4 Hz, 6 H, CH_2CH$_2$CH$_2$P), 6.73 (s, 3 H, *tert*-C_6H_3), 7.33 (m, 18 H, *ortho*- and *para*-P–C_6H_5), 7.41 (m, 12 H, *meta*-P–C_6H_5). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 27.6 (d, $^2J_{PC}$ = 6.1 Hz, *C*H$_2$CH$_2$P), 27.7 (d, $^1J_{PC}$ = 20.9 Hz, CH$_2$P), 37.2 (d, $^3J_{PC}$ = 14.2 Hz, *C*H$_2$CH$_2$CH$_2$P), 126.4 (s, *tert*-C_6H_3), 128.6 (d, $^3J_{PC}$ = 6.7 Hz, *meta*-C_6H_5), 128.9 (s, *para*-C_6H_5), 132.9 (d, $^2J_{PC}$ = 17.5 Hz, *ortho*-C_6H_5), 138.3 (d, $^1J_{PC}$ = 10.1 Hz, *ipso*-C_6H_5), 141.9 (s, *quat*-C_6H_3). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = –14.8. – MS (70 eV, EI, 200 °C): *m*/*z* (%) = 756 (53) [M$^+$], 571 (28) [M$^+$ – PPh$_2$], 557 (29) [M$^+$ – CH$_2$PPh$_2$], 543 (35) [M$^+$ – CH$_2$CH$_2$PPh$_2$], 199 (100) [CH$_2$PPh$_2$]$^+$. – MS (pos. FAB, NBA, 50 °C): *m*/*z* (%) = 757 (16) [M$^+$ + H], 571 (7) [M$^+$ – PPh$_2$], 557 (7) [M$^+$ – CH$_2$PPh$_2$], 543 (5) [M$^+$ – CH$_2$CH$_2$PPh$_2$], 199 (100) [CH$_2$PPh$_2^+$].

Preparation of the Triplatinacyclophanes 15–17 and the Trinuclear Platinacycles 18–20: Solutions of Cl_2Pt(NCPh)$_2$ (708 mg, 1.5 mmol) and the corresponding ligand (1.0 mmol) in dichloromethane (250 mL each) were simultaneously added dropwise during 36 h into stirred dichloromethane (600 mL). After the addition was complete, the reaction mixture was stirred for 24 h at room temperature. The solvent was then removed under vacuum and the resulting residue was subjected to column chromatography.

3,3,14,14,25,25-Hexachloro-2,2,4,4,13,13,15,15,24,24,26,26-dodecaphenyl-2,4,13,15,24,26-hexaphospha-3,14,25-triplatina[5$_3$]-(1,3,5)-cyclophane (15): Yield 54 mg, 5%, white solid, m.p. 273–275 °C. – ^{1}H NMR ($CDCl_3$): δ = 3.9 (br. s, CH_2P), 6.68 (s, C_6H_3), 7.31–7.65 (m, C_6H_5). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 15.8 (t, $^1J_{PtP}$ = 2548 Hz). – IR (KBr): ṽ = 3050 (aromatic CH), 2928 (CH_2), 1435 cm^{-1} (P–Ph). – MS (neg. FAB, NBA, 50 °C): *m*/*z* = 2180 [M$^-$ + Cl]. – $C_{90}H_{78}Cl_6P_6Pt_3$ (2143.3): calcd. C 50.43, H 3.67; found C 49.98, H 3.40.

4,4,17,17,30,30-Hexachloro-3,3,5,5,16,16,18,18,29,29,31,31-dodecaphenyl-3,5,16,18,29,31-hexaphospha-4,17,30-triplatina[7$_3$]-(1,3,5)-cyclophane (16): Yield 56 mg, 15%, white solid, m.p. 241–242 °C. – ^{1}H NMR ($CDCl_3$): δ = 2.64, 2.36 (br. s, 24 H, CH_2P, CH_2CH$_2$P), 6.42 (s, 6 H, C_6H_3), 7.11–7.49 (m, 60 H, C_6H_5). – ^{13}C{^{1}H} NMR (62.90 MHz, $CDCl_3$, 25 °C): δ = 22.2 (d, $^1J_{PC}$ = 90 Hz, *C*H$_2$P), 28.6 (d, $^2J_{PC}$ = 47 Hz, *C*H$_2$CH$_2$P), 126.1(s, *tert*-C_6H_3), 128.1 (d, $^3J_{PC}$ = 20 Hz, *meta*-C_6H_5), 129.6 (m, *ipso*-C_6H_5), 129.9 (s, *para*-C_6H_5), 131.6 (d, $^2J_{PC}$ = 23 Hz, *ortho*-C_6H_5), 140.3 (m, *quat*-C_6H_3). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 7.14 (sd, $^1J_{PtP}$ = 3600 Hz). – ^{195}Pt NMR ($CDCl_3$): δ = –4423 (t, $^1J_{PtP}$ = 3600 Hz). – IR (KBr): ṽ = 3051 (aromatic CH), 2923 (CH_2), 1434 (P–Ph) cm^{-1}. – MS (neg. FAB, NBA, 50 °C): *m*/*z* = 2262 [M$^-$ + Cl]. – $C_{96}H_{90}Cl_6P_6Pt_3$ (2227.5): calcd. C 51.76, H 4.07; found C 51.53, H 4.10.

6,6,29,29,40,40-Hexachloro-5,5,7,7,22,22,24,24,39,39,41,41-dodecaphenyl-5,7,22,24,39,41-hexaphospha-6,23,40-triplatina[11$_3$]-(1,3,5)-cyclophane (17): Yield 108 mg, 9%, colorless amorphous solid, m.p. 230 °C. – ^{1}H NMR ($CDCl_3$): δ = 1.65 (br. s, 24 H,

$CH_2CH_2CH_2P$), 2.37 (s, 12 H, CH_2P), 2.55 (s, 12 H, $CH_2CH_2CH_2CH_2P$), 6.86 (s, 6 H, *tert*-C_6H_3), 7.1−7.7 (m, 60 H, P−C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 24.4 (s, $CH_2CH_2CH_2CH_2P$), 25.9 (d, $^2J_{PC}$ = 45 Hz, CH_2CH_2P), 32.9 (d, $^1J_{PC}$ = 16 Hz, CH_2P), 35.8 (s, $CH_2CH_2CH_2CH_2P$), 126.1 (s, *tert*-C_6H_3), 128.3 (t, $^3J_{PC}$ = 5.7 Hz, *meta*-P−C_6H_5), 131.1 (s, *para*-P−C_6H_5), 132.4 (m, *ipso*-P−C_6H_5), 133.5 (t, $^2J_{PC}$ = 6.3 Hz, *ortho*-P−C_6H_5), 143.4 (s, *quat*-C_6H_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 9.6 (sd, $^1J_{PtP}$ = 3668 Hz). − ^{195}Pt NMR ($CDCl_3$): δ = − 4413 (t, $^1J_{PtP}$ = 3668 Hz). − IR (KBr): $\tilde{\nu}$ = 3051 (aromatic CH), 2925, 2853 (CH_2), 1435 (P−Ph) cm^{-1}. − MS (neg. FAB, NBA, 50 °C): *m/z* = 2395 [M^-]. − (pos. FAB, NBA, 50 °C): *m/z*: 2359 [M^+ − Cl]. − $C_{108}H_{114}Cl_6P_6Pt_3$ (2395.9): calcd. C 54.14, H 4.80; found C 54.40, H 4.71.1

Compound 18: Yield 60 mg, 5%, colorless amorphous solid, m.p. 158 °C. − ^1H NMR ($CDCl_3$): δ = 1.51, 1.71 (br. s, 24 H, H2,3,12,13,16,17, for labeling see Scheme 4), 2.23 (m, 4 H, H-1), 2.37 (m, 12 H, H-4,-11,-18), 2.51 (br. s, 8 H, H-14,-15), 6.65 (s, 4 H, H-6, -10), 6.98 (s, 2 H, H-8), 7.2−7.7 (m, 60 H, P−C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 21.7 (s, C12,17), 22.0 (s, C3), 22.8 (d, $^2J_{PC}$ = 41 Hz, C2), 23.1 (d, $^2J_{PC}$ = 46 Hz, C13,16), 30.9 (t, $^1J_{PC}$ = 16 Hz, C14,15), 32.0 (t, $^1J_{PC}$ = 13 Hz, C1), 33.7 (s, C11,18), 34.4 (s, C4), 125.5 (s, C6,10), 126.0 (s, C8), 127.1 (t, $^3J_{PC}$ = 5 Hz, *meta*-P−C_6H_5), 129.3 (s, *para*-P−C_6H_5), 129.7 (m, *ipso*-P^2−C_6H_5), 129.9 (m, *ipso*-P^1−C_6H_5), 132.4 (t, $^2J_{PC}$ = 6 Hz, *ortho*-P^2−C_6H_5), 132.7 (t, $^2J_{PC}$ = 6 Hz, *ortho*-P^1−C_6H_5), 140.3 (s, C7,9), 141.2 (s, C5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 13.6 (sd, $^1J_{PtP}$ = 2534 Hz, 2P, P^1), 14.8 (sd, $^1J_{PtP}$ = 2566 Hz, 4P, P^2). − $^{195}Pt\{^1H\}$ NMR ($CDCl_3$): δ = −3973 (t, $^1J_{PtP}$ = 2566 Hz, 2Pt, Pt^2), −3960 (t, $^1J_{PtP}$ = 2534 Hz, 1Pt, Pt^1). − IR (KBr): $\tilde{\nu}$ = 3053, 3006 (aromatic CH), 2926, 2854 (CH_2), 1434 (P−Ph) cm^{-1}. − MS (neg. FAB, NBA, 50 °C): *m/z* = 2395 [M^-]. − $C_{108}H_{114}Cl_6P_6Pt_3$ (2395.9): calcd. C 54.14, H 4.80, found C 54.32, H 4.81.

Compound 19: Yield 240 mg, 20%, pale yellow amorphous solid, m.p. 171 °C. − ^1H NMR ($CDCl_3$): δ = 1.50, 1.70 (br. s, 24 H, H-2,3,12,13,16,17), 2.23 (m, 4 H, H-1), 2.37 (m,12 H, H-4,-11,-18), 2.54 (br. s, 8 H, H-14,-15), 6.60 (s, 4 H, H-6,-10), 6.98 (s, 2 H, H-8), 7.1−7.6 (m, 60 H, P−C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 22.0 (s, C3,12,17), 23.4 (s, $^2J_{PC}$ = 37 Hz, C13,16), 23.8 (d, $^2J_{PC}$ = 38 Hz, C2), 30.9 (t, $^1J_{PC}$ = 17 Hz, C14,15), 31.6 (t, $^1J_{PC}$ = 16 Hz, C1), 33.7 (s, C11,18), 34.2 (s, C4), 125.4 (s, C6,10), 126.1 (s, C8), 127.0 (t, $^3J_{PC}$ = 5 Hz, *meta*-P−C_6H_5), 129.3 (s, *para*-P−C_6H_5), 129.7 (m, *ipso*-P^1−C_6H_5), 129.9 (m, *ipso*-P^2−C_6H_5), 132.4(t, $^2J_{PC}$ = 6 Hz, *ortho*-P−C_6H_5), 140.4 (s, C7,9), 140.9 (s, C5). −

Compound 20: Yield 720 mg, 60%, pale yellow amorphous solid, m.p. 191−193 °C. − ^1H NMR ($CDCl_3$): δ = 1.47, 1.85 (br. s, 24 H, H-2,-3,-12,-13,-16,-17), 2.13 (m, 8 H, H-14,-15), 2.37 (m, 4 H, H-1), 2.55 (br. s, 12 H, H-4,-11,-18), 6.82 (s, 4 H, H-6,-10), 6.92 (s, 2 H, H-8), 7.1−7.7 (m, 60 H, P−C_6H_5). − $^{13}C\{^1H\}$ NMR (62.90 MHz, $CDCl_3$, 25 °C): δ = 24.4 (s, C3), 24.6 (s, C12,17), 25.9 (d, $^2J_{PC}$ = 45 Hz, C2), 27.5 (d, $^2J_{PC}$ = 48 Hz, C13,16), 32.9 (t, $^1J_{PC}$ = 16 Hz, C14,15), 33.6 (t, $^1J_{PC}$ = 13 Hz, C1), 35.5 (s, C11,18), 36.0 (s, C4), 126.1 (s, C8), 126.6 (s, C6,10), 128.1 (t, $^3J_{PC}$ = 5 Hz, *meta*-P^2−C_6H_5), 128.3 (s, $^3J_{PC}$ = 5 Hz, *meta*-P^1−C_6H_5), 130.9 (s, *para*-P^2−C_6H_5), 131.1 (s, *para*-P^1−C_6H_5), 131.2 (m, *ipso*-P−C_6H_5), 133.1(t, $^2J_{PC}$ = 5 Hz, *ortho*-P^2−C_6H_5), 133.5 (t, $^2J_{PC}$= 5 Hz, *ortho*-P^1−C_6H_5), 141.8 (s, C7,9), 142.3 (s, C5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 6.7 (sd, $^1J_{PtP}$ = 3610 Hz, 4 P, P^2), 8.7 (sd, $^1J_{PtP}$ = 3635 Hz, 2 P, P^1). − ^{195}Pt NMR ($CDCl_3$): δ = − 4431 (t, $^1J_{PtP}$ = 3610 Hz, 2 Pt, Pt^2), − 4413 (t, $^1J_{PtP}$ = 3635 Hz, 1 Pt, Pt^1). − IR (KBr): $\tilde{\nu}$ = 3051 (aromatic CH), 2925, 2853 (CH_2), 1435 (P−Ph) cm^{-1}. − MS (neg. FAB, NBA, 50 °C): *m/z* = 2395 [M^-]. − $C_{108}H_{114}Cl_6P_6Pt_3$ (2395.9): calcd. C 54.14, H 4.80; found C 54.50, H 4.91.

X-ray Structure Determination of 9 and 12: Crystallographic data for both compounds are summarized in Table 1. Colorless single crystals were obtained from slow cooling of a benzene/*n*-hexane solution of **9** and slow diffusion of *n*-pentane into a solution of **12**, respectively. Each crystal was mounted on a glass fiber with the aid of perfluoropolyether RS 3000 and transferred to a Siemens P4 diffractometer (Mo-K_α radiation, graphite monochromator). The lattice constants for both compounds were determined by 25 precisely centered high-angle reflections and refined by least-square methods. Accurate unit cell parameters and orientation matrices were formed by least-squares refinement of setting angles of a set of well-centered reflections, which were found by a random search. Intensities were collected by the ω-scan technique. No absorption correction was made. While **12** crystallized in the monoclinic space group $P2_1/n$ (Z = 4), **9** crystallized in the cubic space group $Pa\bar{3}$ (Z = 8), and no solvent molecules were detected in the crystal lattice. The structures were solved by direct methods with ShelXTL V5.1 (NT version)[31] and refined by least squares using the same program with anisotropic thermal parameters for all non-hydrogen atoms. All hydrogen atoms were located in calculated positions (riding mode). Maximum and minimum peaks in the final difference synthesis were 1.076 and −0.275 (**9**), and 0.907 and −0.867 (**12**) e $Å^{-3}$, respectively. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-158457 (**9**) and -158456 (**12**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Dipyridylamine Ligands − Synthesis, Coordination Chemistry of the Group 10 Metals and Application of Nickel Complexes in Ethylene Oligomerization

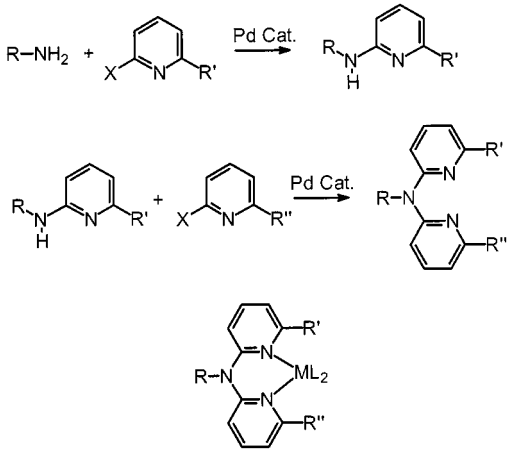
Thomas Schareina,[a] Gerhard Hillebrand,[a] Hans Fuhrmann,[a] and Rhett Kempe*[a]

Keywords: N ligands / Nickel / Palladium / Polymerization / Catalysis

A great variety of 2,2′-bipyridylamines can be synthesized starting from primary amines or 2-aminopyridines (for instance, symmetrically and unsymmetrically substituted as well as chiral ligands) by palladium-catalyzed aryl amination. The reaction of such ligands with [$PdCl_2$(COD)] or [$NiBr_2$(DME)] (COD = cycloocta-1,5-diene; DME = 1,2-dimethoxyethane) led to the corresponding dichloro or dibromo complexes. The results of X-ray crystal structure analyses of selected compounds show that the ligands coordinate through the two pyridine N-atoms. Their palladium complexes have a slightly distorted planar coordination (in the case of nickel a distorted tetrahedral coordination), with N–M–N angles of 96.0(2)° (M = Ni) and 85.7° (averaged, M = Pd). The nickel complexes are highly active ethylene oligomerization catalysts if activated with $Et_3Al_2Cl_3$.

Introduction

2,2′-Bipyridylamines are accessible by sequential palladium-catalyzed aryl amination reactions starting from a primary amine[1,2] (Scheme 1, above). Such compounds have three sites where coordination to a transition metal may occur: the two pyridine moieties and the amine function. Since the amine N-atom can only bind in a strained fashion together with one or two pyridyl units, such ligands act as bidentate chelates with binding only to the pyridyls. In contrast to the classical 2,2′-bipyridine type ligand, which was described recently as the most widely used ligand,[3] six-membered rings are formed (Scheme 1, below). Recently N-ligands have received much attention,[4] as bipyridylamines might be an interesting alternative to diphosphane or diimine ligands, the latter of which has recently attracted considerable interest in regard to its combination with the group 10 metals as olefin polymerisation catalysts.[5,6] Due to the great variety of substitution patterns which can be easily established for the bipyridylamines (variation of R, R′ and R′′, Scheme 1) it may be possible to fine-tune transition metal complex reactivity. To the best of our knowledge, work on applications of bipyridylamine ligand complexes in olefin polymerization has not been published yet.[6] The coordination chemistry of the simplest member of the bipyridylamine group, the 2,2′-dipyridylamine (commercially available), has been described in detail for copper.[7] However, compounds of other transition metals such as complexes of the chromium triad,[8] of rhodium,[9] cobalt,[10] nickel,[11] palladium,[12] ruthenium,[13] and cadmium[14] are much rarer. In this article we report on the ligand synthesis and coordination chemical studies of novel bipyridylamines, as well as some applications of the synthesized nickel complexes in ethylene oligomerization.



Scheme 1. Synthesis of bipyridylamines and the coordination mode of these ligands in transition metal complexes (R, R′, R′′ = alkyl, aryl substituents; X = Cl, Br; L = additional ligands)

Results and Discussion

Ligand Syntheses

Palladium-catalyzed aryl−X activation (X = I, Br or Cl) reactions are an efficient tool for the synthesis of bi- and triarylamines by C−N bond formation.[1] If 2-X-pyridines are used X can be Cl as the systems are activated, although the formation of catalyst-deactivating palladium pyridine complexes has to be avoided. In order to prevent this the palladium catalyst has to be stabilized by chelating bisphosphane ligands.[1a] Reactions of 2-aminopyridines with one or two equivalents of the corresponding 2-halopyridines and 1.25 or 2.5 equiv. of sodium-*tert*-butoxide in the presence of 1 mol % 1,3-bis(diphenylphosphanyl)propane and 0.5 mol % Pd_2dba_3 in toluene at 80 °C leads, usually after less than one hour, to a color change to yellow. After stirring for an additional 12 hours, work up with dichlorome-

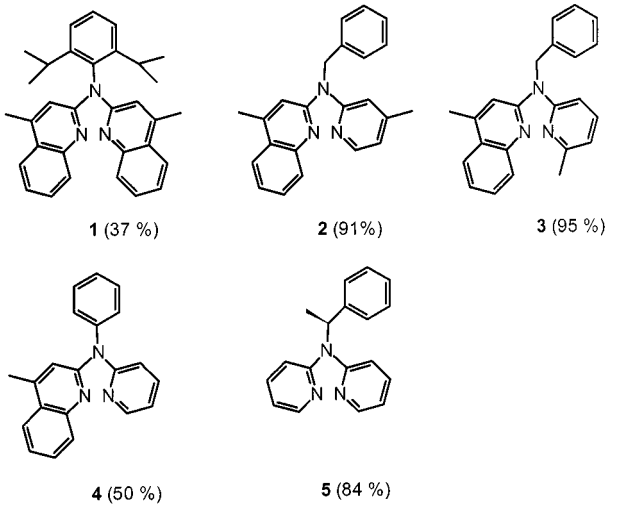
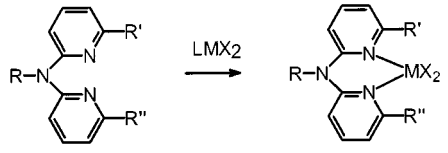
thane, or ether, and water followed. The compounds were purified by chromatography, distillation or crystallization. Compound **1** was prepared from 2,6-diisopropylaniline, compound **2** from 2-(benzylamino)-4-methylpyridine, compound **3** from 2-(benzylamino)-6-methylpyridine, compound **4** from 2-pyridylaniline and compound **5** from (*S*)-1-phenylethylamine (Scheme 2).



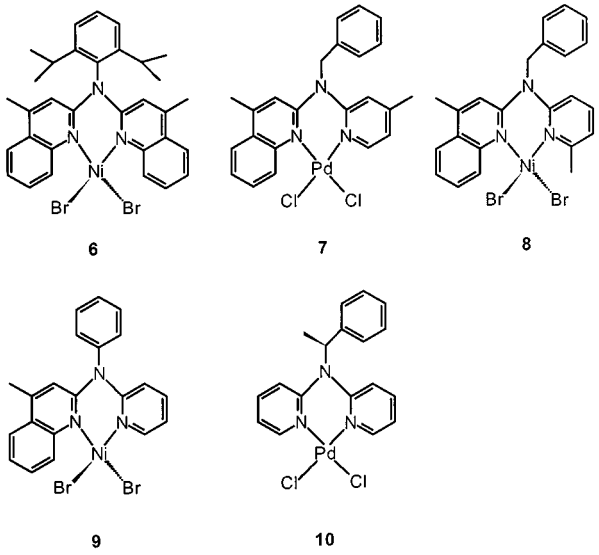
Scheme 2. The bipyridylamine ligands used, including numbering

Group 10 Metal Complex Syntheses and Structures

The reaction of **1**, **3** and **4** with [$NiBr_2$(DME)] (DME = dimethoxyethane) gave rise to blue- or purple-colored crystalline materials (Scheme 3). The structures of all the synthesized group 10 metal complexes are summarized in Scheme 4. NMR investigation of **6**, **8** and **9** gave rather broad signals indicating the existence of d^8 high-spin complexes. EPR spectra in dilute CH_2Cl_2 solutions could not be recorded either at room or at lower temperatures. Single crystals of **8** suitable for an X-ray crystal structure analysis (Figure 1) could be grown from a CH_2Cl_2 solution; crystallographic details are listed in Table 1. The coordination of the nickel center is best described as tetrahedral as observed for dibromodipyridylnickel(II) complexes[15] {dibromodipyridylnickel(II) = [$NiBr_2$(dipy)]}. The $Ni-N_{pyridine}$ bond lengths of **8** (mean = 1.99 Å) are well in accordance with those observed for (dipy)$NiBr_2$ complexes (mean = 2.00 Å). The N−Ni−N angle in **8** [96.0(2)°] is significant larger than that observed in [$NiBr_2$(dipy)] complexes (mean = 82.8°). Thus it can be concluded that the bipyridylamine-type ligands may favor tetrahedral coordination, similar to bipyridyl ligands, since the six-membered chelate is closer to the ideal tetrahedral angle, although still far from the ideal value.



Scheme 3. Synthesis of the group 10 metal complexes (R, R′, R′′ = alkyl, aryl substituents; X = Cl, Br; L = additional ligands)



Scheme 4. Synthesized Ni and Pd complexes, including numbering

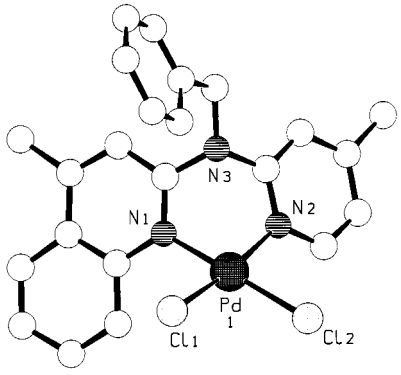


Figure 1. Molecular structure of **7**; selected bond lengths [Å] and angles [°]: N1−Pd1 2.032(3), N2−Pd1 2.012(3), Cl1−Pd1 2.3033(11), Cl2−Pd1 2.2980(10), N2−Pd1−N1 84.82(11), N2−Pd1−Cl2 91.80(8), N1−Pd1−Cl2 173.83(8), N2−Pd1−Cl1 170.54(8), N1−Pd1−Cl1 92.79(8), Cl2−Pd1−Cl1 91.36(4)

The reaction of **2** and **5** with [$PdCl_2$(COD)] (COD = cycloocta-1,5-diene) gave rise to yellow crystalline materials (Scheme 3). NMR investigation of **2** and **5** revealed a sharp single signal set suggesting the existence of monomeric diamagnetic species in solution. The X-ray crystal structure analyses of both compounds confirm these complexes to be mononuclear in the solid state as well; crystallographic details are listed in Table 1. The coordination of the palladium centers is best described as square planar, in contrast to the nickel compounds but well in agreement with what was observed previously for dipyridyldichloropalladium(II) complexes {dichlorodipyridylpalladium(II) = [$PdCl_2$(dipy)]}. A CSD[16] search for [$PdCl_2$(dipy)] complexes revealed ten hits with a mean of the Pd−N bond length of 2.029(18) and a mean of the N−Pd−N bond angle of 80.1(7)°. Similar Pd−N distances (mean = 2.02 Å) have been found in **7** and **10** (Figure 2 and 3) The N−Pd−N

bond angle (mean = 85.7°) differs by more than 5° and is even 4.5° larger than the highest value observed in known [$PdCl_2$(dipy)] complexes.

Ethylene Oligomerization Studies

Recently, considerable effort has been devoted to the synthesis of hyperbranched oligomers from inexpensive monomers such as ethylene and propene.[17] Such materials are useful in the lubricant industry as base stocks and as precursors to lubricant additives, especially since the demand for synthetic lubricants is rising.[18]

Complexes **6**, **8** and **9** were investigated with regard to catalytic applications in ethylene oligomerization after activation with chloroaluminum alkyls. The results of the oligomerization experiments are summarized in Table 2. Remarkably high activities are observed for all Ni complexes when using $Et_3Al_2Cl_3$ as a co-catalyst and CH_2Cl_2 as the solvent. All nickel complexes show a high tendency towards the formation of C4–C6 fraction products. Highly branched oligomers with a ratio of methyl protons (at δ = 0.87)/total alkyl protons (by ^{1}H NMR integration) of 0.61 were obtained for the higher boiling fraction. An important quantity of these oligomeric products were saturated, as found by GC-IR studies. A low temperature and low ethylene pressure were used due to the high activity of the systems under the described conditions.

Table 2. Oligomerization of ethylene with Ni complexes (5×10^{-6} mol_{Ni}, Al/Ni = 600, activator $Et_3Al_2Cl_3$, 200 mL of dichloromethane)

[a] TON = turnover number [$mol_{ethene}/mol_{catalyst}$]. − [b] Thereafter no gas uptake. − [c] Thereafter only marginal gas uptake. − [d] >90% butenes.

Conclusion

Several conclusions can be drawn from this study. Firstly, palladium-catalyzed aryl amination is an efficient tool in the preparation of a great variety of 2,2′-bipyridylamine ligands. Secondly, these compounds act as bidentate ligands to stabilize group 10 metal complexes. Thirdly, the nickel complexes are highly active ethylene oligomerization catalysts if activated with $Et_3Al_2Cl_3$.

Experimental Section

Materials and Procedures: All reagents were obtained commercially and used as supplied. Column chromatography was performed on silica gel 60 (0.063−0.200 mm) from Merck. All manipulations of air-sensitive materials were performed with rigorous exclusion of oxygen and moisture in dried Schlenk-type glassware on a dual manifold Schlenk line, interfaced to a high-vacuum line, or in an argon-filled glovebox (mBraun labmaster 130) with a high-capacity recirculator (<1.5 ppm O_2). Solvents (Aldrich) and NMR solvents (Cambridge Isotope Laboratories all 99 atom% D) were freshly distilled from sodium tetraethylaluminate.

Physical Measurements: NMR spectra were recorded on a BRUKER ARX 400 instrument with a variable temperature unit. ^1H and ^{13}C chemical shifts were referenced to the solvent resonances and reported relative to TMS. Elemental analysis were performed with a Leco CHNS-932 elemental analyzer. X-ray diffraction data were collected on a STOE-IPDS diffractometer using graphite monochromated Mo-K_α radiation. The crystals were mounted in a cold nitrogen stream. The structure was solved by direct methods (SHELXS-86)[19] and refined by full-matrix least-squares techniques against F^2 (SHELXL-93).[20] SCHAKAL was used for structure representations.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-159116 (**7**), CCDC-159117 (**8**) and CCDC-159118 (**10**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of the Ligands

Synthesis of 1: 2,6-Diisopropylaniline (0.89 g, 5.0 mmol), 2-chlorolepidine (1.78 g, 10.0 mmol), 1,3-bis(diphenylphosphanyl)propane (25 mg, 6×10^{-5} mol), dipalladiumtris(benzylideneacetone) (28 mg, 3×10^{-5} mol) and sodium *tert*-butoxide (1.20 g, 12.5 mmol) were combined in a Schlenk vessel under argon. Toluene (20 mL) was then added and the mixture stirred at 80 °C for 120 h. After cooling, the resulting mixture was taken up with diethyl ether and washed twice with a saturated aqueous sodium chloride solution. The organic solution was dried over sodium sulfate and the solvent removed in a rotary evaporator. The resulting dark red oil was subjected to fast column chromatography over silica gel (eluent: petroleum ether/ethyl acetate, 10:1 v/v) to remove polar by-products. Recrystallization of the resulting semi-solid oil from *n*-hexane yielded 0.82 g (37%) of colorless needles. − ^1H (C_6D_6): δ = 7.95 (d, 2 H), 7.62 (d, 2 H), 7.45 (s, 2 H), 7.36 (m, 3 H), 7.29 (m, 2 H), 7.17 (m, 2 H), 3.57 (hept, J = 6.7 Hz, 2 H), 2.19 (s, 6 H), 1.11 (d, J = 6.7 Hz, 12 H). − ^{13}C NMR(C_6D_6): δ = 156.4, 148.7, 147.9, 144.5, 139.0, 129.3, 129.0, 125.9, 124.8, 124.2, 123.8, 116.9, 29.1, 24.1, 18.7. − $C_{32}H_{33}N_3$ (459.62): calcd. C 83.62, H 7.24, N 9.14; found C 82.98, H 7.54, N 9.26.

Synthesis of 2: 2-(Benzylamino)-4-methylpyridine (2.77 g, 14 mmol), 2-chloro-4-methyl-quinoline (2.5 g, 14.1 mmol), 1,3-bis(diphenylphosphanyl)propane (0.23 g, 0.56 mmol), dipalladiumtris(benzylideneacetone) (0.26 g, 0.28 mmol) and sodium *tert*-butoxide (4.06 g, 42.2 mmol) were combined in a Schlenk vessel under argon. Toluene (40 mL) was then added and the resulting brown mixture stirred at 70 °C for 40 h. After cooling to room temperature the solvent was evaporated in vacuo into a dry-ice-cooled trap. The resulting slurry was taken up with diethyl ether and the solution washed three times with a saturated aqueous sodium chloride solution. The organic solution was dried over magnesium sulfate, and the solvent removed on a rotary evaporator. The resulting brown oil was purified by column chromatography over silica gel (eluent: petroleum ether/ethyl acetate, 4:1 v/v). Yield: 4.38 g (91%) of a yellow oil, which didn′t solidify even after drying in vacuum and prolonged standing. − ^1H NMR (C_6D_6): δ = 8.41 (d, 1 H), 8.24 (d, 1 H), 7.83 (d, 2 H), 7.70 (dd, 1 H), 7.56 (td, 1 H), 7.31 (s, 2 H), 7.29 (s, 1 H), 7.08 (s, 1 H), 6.50 (d, 1 H), 6.06 (s, 2 H, benzyl. CH_2), 2.21 (d, J = 7.0 Hz, 3 H, Lp-CH_3), 1.91 (s, 3 H, py-CH_3). − ^{13}C NMR (C_6D_6): δ = 157.63, 155.72, 148.13, 147.90, 147.69, 143.93, 140.13, 135.64, 128.93, 128.38, 127.44, 126.37, 125.16, 123.38, 123.25, 118.83, 115.75, 115.43, 51.31, 20.29, 18.12. − $C_{23}H_{21}N_3$ (339.43): calcd. C 81.38, H 6.24, N 12.38; found C 81.32, H 6.21, N 12.15.

Synthesis of 3: 2-(Benzylamino)-6-methylpyridine (1.49 g, 7.5 mmol), 2-chloro-4-methyl-quinoline (1.33 g, 7.5 mmol), 1,3-bis(diphenylphosphanyl)propane (0.124 g, 0.30 mmol), dipalladiumtris(benzylideneacetone) (0.140 g, 0.153 mmol) and sodium *tert*-butoxide (0.96 g, 10 mmol) were combined in a Schlenk vessel under argon. Dry toluene (25 mL) was then added and the resulting brown mixture stirred at 70 °C for 40 h. After cooling, the solvent was removed on a rotary evaporator, the resulting slurry taken up with diethyl ether and the solution washed three times with a saturated aqueous sodium chloride solution. The organic solution was dried over magnesium sulfate and the solvents evaporated. The resulting brown oil was purified by fast column chromatography over silica gel (eluent: petroleum ether/ethyl acetate, 5:1 v/v). Yield: 2.42 g (7.13 mmol, 95%) of a yellow highly viscous oil, which didn′t solidify even after drying in vacuum and prolonged standing. − ^1H NMR (C_6D_6): δ = 2.00 (s, 3 H), 2.30 (s, 3 H), 5.53 (s, 2 H, benzyl. CH_2), 6.34 (d, 1 H), 6.79 (d, 1 H), 6.9 (t, 1 H), 6.95 (t, 1 H), 7.05 (m, 1 H), 7.07 (m, 1 H), 7.10 (m, 4 H), 7.33 (dt, 1 H), 7.48 (dd, 1 H), 7.59 (m, 2 H), 8.01 (m, 1 H). − ^{13}C NMR (C_6D_6): δ = 157.9, 157.4, 156.4, 148.6, 144.5, 140.9, 137.7, 129.6, 129.1, 128.2, 127.1, 125.8, 124.1, 124.0, 117.3, 116.1, 112.9, 51.8, 24.7, 18.8. −

$C_{23}H_{21}N_3$ (339.43): calcd. C 81.38, H 6.24, N 12.38; found C 81.05, H 6.00, N 12.31.

Synthesis of 4: 2-Pyridylaniline (1.702 g, 10 mmol), 2-chloro-4-methylquinoline (1.78 g, 10 mmol), 1,3-bis(diphenylphosphanyl)-propane (0.165 g, 0.40 mmol), dipalladiumtris(benzylideneacetone) (0.18 g, 0.20 mmol) and sodium *tert*-butoxide (1.35 g, 14 mmol) were combined in a Schlenk vessel under argon. Toluene (30 mL) was then added and the dark green mixture stirred at 70 °C for 54 h. Workup as for **3**, but with dichloromethane solvent. The raw product was isolated as a dark brown solid, which was recrystallized from absolute ethanol. Yield: 1.57 g (5.04 mmol, 50%) of yellow crystalline needles. – ^{1}H (C_6D_6): δ = 1.98 (d, 3 H, CH_3), 6.64 (m, 1 H), 6.93 (m, 2 H), 7.0–7.1 (m, 6 H), 7.18 (m, 2 H), 7.24 (ddd, 1 H), 7.48 (dd, 1 H), 7.89 (dd, 1 H), 8.15 (m, 1 H). – ^{13}C (C_6D_6): δ = 157.7, 156.1, 147.6, 147.2, 144.7, 143.8, 135.9, 128.7, 128.4, 128.2, 127.7, 125.1, 124.8, 123.4, 122.7, 117.2, 116.9, 116.8, 17.5. – $C_{21}H_{17}N_3$ (311.38): calcd. C 81.00, H 5.50, N 13.49, found C 81.00, H 5.74, N 13.27.

Synthesis of 5: 2-Bromopyridine (2.53 g, 16.0 mmol), (*S*)-1-phenylethylamine (0.97 g, 8.00 mmol), $Pd_2(DBA)_3$ (0.18 g, 0.20 mmol, 4 mol % Pd), 1,3-bis(diphenylphosphanyl)propane (0.16 g, 0.39 mmol), sodium *tert*-butoxide (1.34 g, 13.9 mmol) and 50 mL of toluene were combined in a Schlenk vessel. The mixture was stirred at 70 °C for 36 h. After cooling to room temperature the solvent was evaporated in vacuo into a dry-ice-cooled trap. Ether (50 mL) and water (50 mL) were added to the reaction mixture and, after separation, the organic phase was extracted twice with a saturated aqueous sodium chloride solution. The solution was dried over magnesium sulfate and the solvent removed on the rotary evaporator. Vacuum distillation at 150 °C/0.1 mbar yielded 1.85 g (84%) of a colorless oil. – ^{1}H NMR (C_6D_6): δ = 1.47 (d, *J* = 6.7 Hz, 3 H, CH_3), 4.64 (quint, *J* = 6.7 Hz, 1 H, CH), 6.08–6.12 (m, 2 H), 6.43–6.47 (m, 2 H), 7.13–7.17 (m, 2 H), 7.20–7.31 (m, 5 H), 7.80–8.00 (m, 2 H). – ^{13}C NMR (C_6D_6): δ = 24.3 (CH_3), 54.6 (CH), 107.2, 117.3, 117.9, 127.8, 128.7, 137.9, 145.2, 148.8, 156.2. – $C_{18}H_{17}N_3$ (275.35): calcd. C 78.52, H 6.22, N 15.26; found C 78.37, H 6.45, N 15.31.

Synthesis of the Metal Complexes

Synthesis of 6: [$NiBr_2$(DME)] (0.23 g, 0.74 mmol) was suspended in 5 mL dichloromethane. A solution of **1** (0.34 g, 0.76 mmol) in 5 mL dichloromethane was then added, the color of the solution changing to a deep purple. After standing overnight the solution was filtered and the grey residue washed with 10 mL of dichloromethane. 10 mL of toluene was then added to the solution and the solvents were evaporated until about 8 mL of toluene remained. After some days of standing crops of purple crystals precipitated, and these were separated and washed with 5 mL of toluene. Yield: 0.31 g (54%). – ^{1}H NMR ($CDCl_3$): δ = 12.70 (br. s), 7.25–7.40 (m), 7.13–7.22 (m), 2.98 (s), 2.37 (s), 1.46 (s), 1.16 (d). – ^{13}C NMR ($CDCl_3$): δ = 142.9, 133.6, 129.5, 128.7, 125.8, 123.4, 121.9, 116.8, 24.7. The NMR spectra obtained were rather broad due to the paramagnetism of the Ni. – $C_{39}H_{41}Br_2N_3Ni$ (**5**·toluene: 770.26): calcd. C 60.81, H 5.37, N 5.46; found C 61.17, H 5.21, N 5.42.

Synthesis of 7: Compound **2** (0.125 g, 0.37 mmol) was dissolved in 3 mL of dichloromethane and added to [$PdCl_2$(COD)] (0.105 g, 0.37 mmol, 1 equiv.) in a Schlenk vessel. After a week orange crystals separated from the solution, and these were used directly for an X-ray analysis. In a separate run, the solvent was removed with a syringe under argon, the crystals were washed twice with 1 mL portions of diethyl ether and dried in vacuum to yield 0.11 g (49%) of product. The crystals appeared to lose dichloromethane on vacuum treatment: the X-ray analysis showed dichloromethane, whereas the elemental analysis of the material from the second run showed none. – ^{1}H (CD_2Cl_2): δ = 9.37 (d, *J* = 8.4 Hz, 1 H), 8.60 (d, *J* = 7.4 Hz, 1 H), 7.90 (d, 2 H), 7.81 (m, 2 H), 7.57 (dt, *J* = 1.5, *J* = 8.4 Hz, 1 H), 7.43 (t, *J* = 7.4 Hz, 2 H), 7.31 (br. t, *J* = 7.5 Hz, 1 H), 7.16 (s, 1 H), 7.03 (m, 2 H), 5.45 (m, 2 H, N–CH_2), 2.66 (s, 3 H), 2.36 (s, 3 H). – $C_{23}H_{21}Cl_2N_3Pd$ (516.76): calcd. C 49.51, H 3.79, N 7.53; found C 49.50, H 3.81, N 7.59. – ^{13}C NMR (CD_2Cl_2): δ = 151.8, 150.3, 149.8, 144.5, 133.1, 130.1, 129.7, 128.5, 127.5, 126.8, 126.0, 125.6, 122.2, 121.8, 114.9, 113.0, 53.9, 28.7, 18.5.

Synthesis of 8: A solution of **3** (0.34 g, 1 mmol) in 10 mL of dichloromethane was added to [$NiBr_2$(DME)] (0.31 g, 1 mmol) in a Schlenk vessel, resulting in a purple solution. After 4 days at room temperature the solution was filtered and the remaining solid washed with three 5 mL portions of dichloromethane. The washings were added to the filtrate. The combined solution was layered with 15 mL of diethyl ether and kept for one week at room temperature. The solvent was then removed from the resulting purple prismatic crystals, which were washed with two 10 mL portions of diethyl ether. Yield: 0.32 g (0.57 mmol, 57%). – ^{1}H ($CDCl_3$): δ = (all broad singlets due to the paramagnetism of the Ni) 11.16 (0.3 H), 10.50 (0.8 H), 7.17 (3 H), 7.02 (1 H), 6.88 (2 H), 6.17/6.02 (4 H), 2.59 (1 H), 1.40 (1 H), 0.00 (12 H). – $C_{23}H_{21}Br_2N_3Ni$ (557.93): calcd. C 49.51, H 3.79, Br 28.64, N 7.53; found C 49.50, H 3.81, Br 28.45, N 7.59.

Synthesis of 9: [$NiBr_2$(DME)] (0.30 g, 0.9 mmol) was suspended in 5 mL of THF and a warm solution of **4** (0.28 g, 0.9 mmol) in 5 mL of THF was added in four portions with a syringe. A purple solid precipitated after 5 min. The next day, filtration yielded a purple, microcrystalline solid, which was dried in vacuo. The yield was not determined. For recrystallisation, a small amount was dissolved in 5 mL hot dichloromethane, cooled to room temperature and layered with 3 mL of diethyl ether. Again, only a microcrystalline powder was obtained.^{1}H ($CDCl_3$): δ = (all broad due to the paramagnetism of the Ni) 12.4 (br. s, 2 H), 8.8 (s, 1 H), 8.35 (d, 1 H), 7.97 (m, 2 H), 7.7 (m, 7 H), 7.54 (m, 1 H), 6.83 (br. s, 2 H), 6.65 (br. s, 5 H), 6.53 (s, 1 H), 2.67 (s, 3 H). – $C_{21}H_{17}Br_2N_3Ni$ (M_w = 529.88 g/mol): calcd. C 47.60, H 3.23, Br 30.16, N 7.93; found C 47.45, H 3.21, Br 29.39, N 7.74.

Synthesis of 10: [$PdCl_2$(COD)] (0.13 g, 0.47 mmol) was added to a solution of **5** (0.14 g, 0.50 mmol) in 30 mL of dichloromethane. The mixture was stored at –78 °C for crystallization. Filtration yielded 0.13 g (61%) of orange crystals. – ^{1}H NMR (C_6D_6): δ = 1.73 (d, *J* = 6.4 Hz, 3 H, CH_3), 5.44 (q, *J* = 6.4 Hz, 1 H, CH), 6.88–6.94 (m, 2 H), 7.15–7.19 (m, 2 H), 7.25–7.29 (m, 3 H), 7.43–7.49 (m, 1 H), 7.53–7.58 (m, 2 H), 7.78–7.85 (m, 1 H), 8.64–8.85 (m, 2 H). – ^{13}C NMR (C_6D_6): δ = 22.6 (CH_3), 59.7 (CH), 118.3, 119.0, 120.2, 120.8, 126.5, 127.3, 128.5, 138.7, 139.7, 140.2, 150.3, 151.2, 151.6, 152.5. – $C_{18}H_{17}Cl_2N_3Pd$ (452.68): calcd. C 62.14, H 5.05, N 7.51; found C 62.08, H 5.21, N 7.33.

Polymerization Studies: The oligomerization of ethylene (99.95%) was carried out in a batch process using a 1-L glass autoclave fitted with a gas inlet, dosing device, pressure gauge, and a magnetically driven and continuously regulated paddle stirrer with a hollow shaft (0 to 800 rpm). The solvent, dichloromethane, was dried by standard methods and distilled under argon. $Et_3Al_2Cl_3$ was used as supplied (Aldrich). 5×10^{-3} mmol of the Ni complexes were dissolved in 200 mL of dichloromethane and introduced under inert conditions into the autoclave. After the temperature of the mixture had been adjusted and $Et_3Al_2Cl_3$ had been added as a cocata-

lyst the oligomerization reaction started at an internal pressure as described in Table 2. After a reaction time of 1 hour the contents of the autoclave were decomposed by addition of methanolic HCl. The oligomers were analyzed by GC, GC-IR and NMR spectroscopy.

Coordination Chemistry of Unsymmetrical Tripodal Ligands with an NNO_2 Donor Set

Christian Ochs,[a] F. Ekkehardt Hahn,*[b] and Roland Fröhlich[c]

Keywords: Tripodal ligands / Copper / Radicals / N ligands / O ligands

The synthesis of two new tripodal ligands $N(CH_2CH_2NH_2)(CH_2CH_2CH_2OH)_2$ (H_4-**1**) and N[2,3,5-C_6H_2-(OH)(SCH_3)(CH_3)]($CH_2CH_2CH_2NH_2$)($CH_2CH_2CH_2OH$) (H_4-**2**) is reported. Both tetradentate ligands contain a central tertiary nitrogen atom, as well as two OH and one NH_2 functionalized ligand arm. The tripods do not only exhibit an unsymmetrical N_2O_2 donor set, but also possess two C_3 and one C_2 chains between the central nitrogen atom and the terminal donors. On coordination of the central tertiary nitrogen atom, the ligands are capable of forming both six- and five-membered chelate rings in their metal complexes. Both ligands react with $[Cu(OAc)_2{\cdot}H_2O]_2$ to give the dinuclear copper(II) complexes $[Cu(\eta^4\text{-}\mu\text{-}O\text{-}H_3\text{-}\mathbf{1})_2Cu](PF_6)_2$ (**3**) and $[(\eta^3\text{-}H_3\text{-}\mathbf{2})Cu(\mu\text{-}OAc)_2Cu(\eta^3\text{-}H_3\text{-}\mathbf{2})]{\cdot}2CH_3CN$ (**4**·$2CH_3CN$). The molecular structures of **3** and **4**·$2CH_3CN$ have been determined by X-ray diffraction. Complex **3** contains two slightly distorted square-pyramidal ($\tau = 0.181$) copper atoms, with O-donors in the apical positions. The dinuclear complex **4**, which was synthesized to model the copper site in galactose oxidase, also shows a distorted square-pyramidal coordination geometry ($\tau = 0.205$ and $\tau = 0.101$) around both copper(II) atoms. Complex **4** contains two uncoordinated primary alcohol functionalities of the ligands. In addition, both the ligand H_4-**2** and its dinuclear copper complex $[(\eta^3\text{-}H_3\text{-}\mathbf{2})Cu(\mu\text{-}OAc)_2(\eta^3\text{-}H_3\text{-}\mathbf{2})]{\cdot}2CH_3CN$ can easily be oxidized to yield free or coordinated phenoxyl radicals, which are stable on the time scale of cyclic voltammetry.

Introduction

Redox reactions involving a transition metal ion and a redox-active amino acid side chain, e.g. tyrosine, play a key role in many biochemical processes.[1] Some years ago, Ito et al.[2] have shown that the reactive site in galactose oxidase (E.C. 1.1.3.9) GO, a copper enzyme that was isolated from the parasitic fungus *Fusarium dendroides*, contains a tyrosyl radical which is coordinated to a copper(II) center. Galactose oxidase catalyzes the stereospecific oxidation of D-galactose and various primary alcohols to the corresponding aldehydes, coupled to the simultaneous reduction of O_2 to H_2O_2 [Equation (1)].

$$RCH_2OH + O_2 \rightarrow RCH{=}O + H_2O_2 \quad (1)$$

The X-ray crystal structure analysis of the inactive form of galactose oxidase at a 1.7 Å resolution showed a mononuclear copper(II) center that is surrounded by a square-pyramidal N_2O_3 coordination environment.[2] As depicted in Figure 1, two histidine residues (His-496, His-581), one tyrosinate (Tyr-272) and one water or acetate molecule reside in the equatorial plane, while the remaining apical position is occupied by the oxygen atom of another tyrosinate ligand (Tyr-495). A unique characteristic of the copper site in galactose oxidase is that the equatorial tyrosinate residue Tyr-272 is covalently linked to a sulfur atom of the neighboring cysteine Cys-228. This leads to a lowering of the oxidation potential and significantly facilitates the formation of a tyrosyl radical from Tyr-272.[3] Furthermore, in the oxidized form of GO, antiferromagnetic coupling of the single electron in the copper(II) $d_{x^2-y^2}$ orbital with the tyrosyl radical is observed, giving a diamagnetic and EPR silent ($S = 0$) ground state of oxidized, active galactose oxidase.[4]

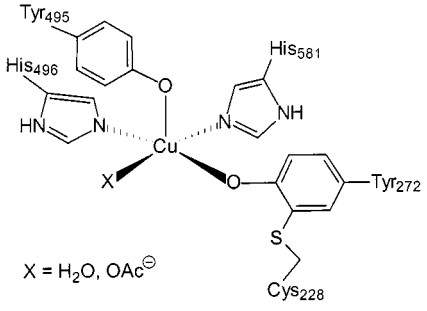

Figure 1. The active site in galactose oxidase

Several attempts have been made in the last years to mimic the geometric, spectroscopic and catalytic properties of native galactose oxidase. Functional model complexes have been presented by Tolman[5] and by Stack and coworkers.[6] Recently, Wieghardt et al.[7] described a functional model of galactose oxidase derived from a

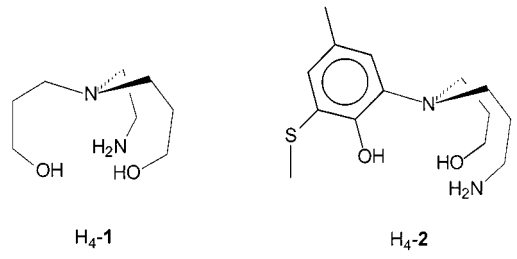
Cu^{II}−iminosemiquinone with a square-planar $[Cu(O-N-O)(NEt_3)]$ (O−N−O = dianionic ligand with one imine and two two phenolate donors) reaction center, which showed a high catalytic activity despite the lack of most structural features found at the active center of native galactose oxidase.

Various Cu^{II} complexes have been prepared in order to model the structural features of the reactive center in galactose oxidase. Mostly tripodal tetradentate ligands that contain one or two phenol and pyrazole or pyridine donor groups were used, providing an N_3O[3a,8,9] or N_2O_2[10,11] coordination environment for the copper center. Pentacoordination is normally achieved by coordination of a counterion or a solvent molecule. Unfortunately, all of the model compounds lack significant features found in the reactive site of native galactose oxidase. These features include a Cu^{II} atom coordinated in a square-pyramidal fashion which exhibits a thioether-functionalized phenoxyl donor in the equatorial plane and another O-donor in the apical position. Two more N-donors and one labile (possibly solvent molecule) O-donor in the equatorial plane should complete the overall N_2O_3 coordination environment.

If a GO model is to be built from a tetradentate tripodal ligand, certain restrictions apply. Such ligands, together with a monodentate coligand, form trigonal-bipyramidal or square-pyramidal complexes with Cu^{II}. For example $[Cu(tren)(NH_3)]^{2+}$ in the solid state is an almost perfect trigonal bipyramid.[12] A systematic study with higher homologues of tren, e.g. with ligands where methylene groups were added stepwise to the three ligand arms, revealed that the tripod with one ethyl and two propyl ligand arms $N(CH_2CH_2CH_2NH_2)_2(CH_2CH_2NH_2)$ forms a square-pyramidal Cu^{II} complex where the apical position is occupied by a donor linked to the central nitrogen atom by a propyl chain.[13] Thus, the topology of the tetradentate tripod determines both the overall geometry of the Cu^{II} complex (sqp vs. tbp), as well as the position of the donors in the complex (donor group at the end of a propyl chain in the apical position). Studies with unsymmetrical tetradentate tripods providing an N_3O donor set for Cu^{II} [8,9] gave similar results. Again, it was found that the formation of square-pyramidal Cu^{II} complexes is preferred when the ligand is capable of forming a 5,6,6-membered chelate ring sequence.[8]

These observations can be used to design ligands for the preparation of GO model compounds. Any tetradentate tripod with a central nitrogen atom capable of forming a 5,6,6-membered chelate ring sequence should give a more or less perfectly coordinated square-pyramidal Cu^{II} complex with a donor at the end of a propyl chain in the apical position.

The aliphatic tripodal ligand H_4-**1** (Figure 2) was synthesized to investigate the extent to which the above mentioned results for N_4 and N_3O ligands (control of complex geometry vs. ligand topology) are transferable to a N_2O_2 donor set. Ligand H_4-**1** should form a square-pyramidal Cu^{II} complex with one of the oxygen donors in the apical and the other in an equatorial position.



H_4-**1** H_4-**2**

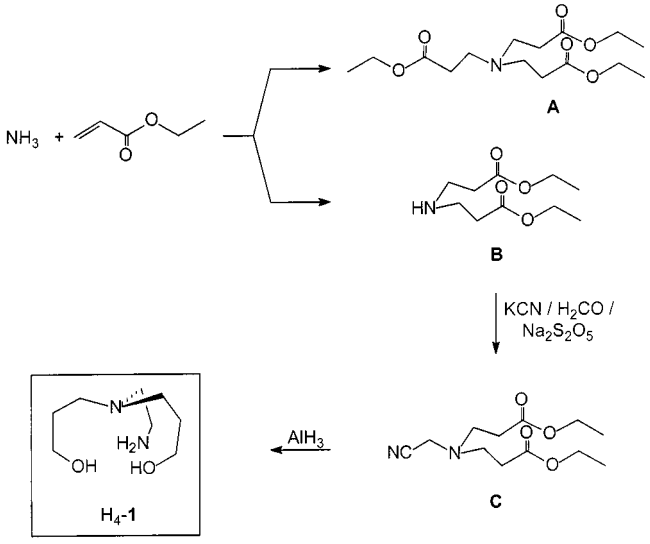
Figure 2. Topology of the tripodal N_2O_2 ligands H_4-**1** and H_4-**2**

The second ligand H_4-**2** (Figure 2), providing an N_2O_2 donor set, was designed for a more accurate structural modeling of the reactive site in GO. This ligand is expected to form a square-pyramidal Cu^{II} complex with a 5,6,6-membered chelate ring sequence. The phenolate oxygen donor, linked by a C_2 chain to the central nitrogen atom, is expected to occupy an equatorial coordination site. In addition, the aromatic ring is functionalized with an *o*-(methylthio) group which in native GO is essential for the formation of a tyrosyl radical on oxidation. The mode of coordination of the two donors linked by C_3 chains to the central nitrogen atom can be elucidated by X-ray crystallography. One of them is expected to occupy an apical coordination site in a Cu^{II} complex. Overall, ligand H_2-**2** possesses an N_2O_2 donor set. It differs from N_2O_2 ligands previously reported[10,11] by possessing aliphatic amine and alcohol donor groups in the presence of an *o*-(methylthio)-functionalized phenol.

Results and Discussion

Ligand Syntheses

Our strategy for the preparation of the unsymmetrical N_2O_2 ligand H_4-**1** involves three reaction steps as depicted in Scheme 1. For the condensation of the C_3 chains to



Scheme 1. Preparation of ligand H_4-**1**

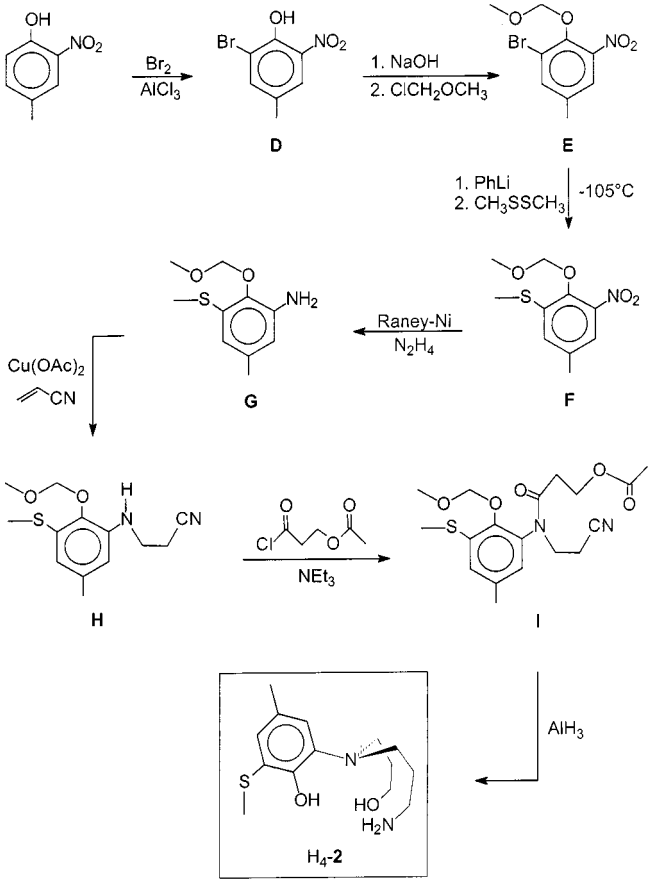
ammonia, the Michael addition of ethyl acrylate had previously proved useful.[14] However, this reaction leads to a mixture of the tertiary (**A**) and secondary amines (**B**), which can be separated by distillation.[14a] Cyanomethylation of the secondary amine **B** by the Strecker synthesis according to the modification of Knoevenagel,[15] yielded the α-nitrilamine **C**. Finally, all protected donor groups were simultaneously liberated by reduction with AlH_3, which led directly to the free ligand H_4-**1**.

Ligand H_4-**1** contains one NH_2- and two OH-substituted ligand arms in addition to the central tertiary nitrogen atom. Furthermore, the ligand possesses an unsymmetrical topology with regard to the three alkyl chains, containing one C_2 and two C_3 arms. This allows for the formation of both five- and six-membered chelate rings yielding a 5,6,6 ring sequence on complex formation. Due to the flexibility and lengths of the alkyl arms, the ligand should be capable of providing an N_2O_2 coordination environment for a copper(II) ion without any steric strain.

Ligand H_4-**2** (Figure 2) was developed on the basis of simple force field calculations and molecular modeling experiments. It was assumed that a tripod, which could form a 5,6,6-chelate ring sequence, would form a square-pyramidal Cu^{II} complex with one of the C_3-linked donors in the apical position. Linking the phenol group directly to the central nitrogen atom should force the oxygen atom of this group in the equatorial position of the expected square-pyramidal complex. Taking into account the significance of the equatorial (*RS*)-substituted Tyr-272 for galactose oxidase activity, an *o*-(methylthio)phenol group was selected. In addition, the *para* position relative to the phenolic OH group was blocked by a methyl group in order to prevent dimerization when a radical intermediate is formed after one-electron oxidation. A similar N_2O_2 ligand capable of forming a 5,6,6-chelate ring sequence and possessing an *o*-(methylthio)phenol group was presented by Whittaker.[10] However, this ligand like all other tripods providing an N_2O_2 donor set and a 5,6,6-chelate ring sequence,[11] contains a phenol group connected to the central nitrogen atom in a way that the phenolic oxygen atom will be part of a six-membered chelate ring.

For the synthesis of H_4-**2**, *o*-nitro-*p*-cresol was selected as a suitable starting material. This molecule contains, at least in the protected form, all three of the desired functional groups for the construction of the aromatic part of H_4-**2**. The complete reaction sequence for the preparation of H_4-**2** is depicted in Scheme 2.

In a first reaction, the aromatic core of *o*-nitro-*p*-cresol was brominated by treatment with bromine in the presence of the Lewis acid catalyst $AlCl_3$.[16] The position *ortho* to the OH group is exclusively brominated, yielding compound **D**, due to the *ortho*- and *meta*-directing effect of the OH and the NO_2 substituents, respectively. Subsequently, **D** was deprotonated with NaOH, and the resulting phenolate was treated with (chloromethoxy)methane to give the MOM-protected derivative **E**.[17] Halogen/metal exchange of the bromine substituent, by use of phenyllithium at −105 °C resulted in the formation of a reactive aryllithium species that was not isolated.[18] This *ortho*-lithiated intermediate was quenched with dimethyl disulfide.[19] The *o*-(methylthio)-substituted compound **F** was isolated in good yield. According to a literature procedure,[20] the nitro group in **F** can be reduced quantitatively to the amine by an excess of hydrazine in the presence of Raney nickel to yield the aniline derivative **G**. Subsequently, a β-cyanoethyl group which will serve as the synthon for the 3-aminopropyl arm, was introduced by a copper(II) acetate catalyzed Michael addition of acrylonitrile to **G**. This resulted in the formation of compound **H**.[21] Finally, a C_3 chain (the precursor for the 3-hydroxypropyl arm) was added to the central nitrogen atom by acylation of **H** with β-acetoxypropionyl chloride, which was synthesized as described.[22] After chromatographic purification, amide **I** was obtained as a crystalline white solid. Reduction of **I** with AlH_3 yielded the ligand H_4-**2**. Under these conditions even the MOM-protected phenolic OH group is liberated. This is quite surprising since MOM ethers are known to be stable in basic media and are normally cleaved under acidic conditions. Ligand H_4-**2** is a sticky white solid which is slightly air-sensitive.



Scheme 2. Preparation of ligand H_4-**2**

Ligand H_4-**2**, like H_4-**1**, possesses an N_2O_2 donor set and an unsymmetrical topology. It is capable of forming a 5,6,6-membered chelate ring sequence and should be suitable for the preparation of square-pyramidal Cu^{II} complexes. H_4-**2** contains an *o*-(methylthio)-substituted phenol which is

directly connected to the central nitrogen atom of the ligand backbone. This is in contrast with tripodal N_2O_2 ligands published to date with regard to the modeling of the copper site in galactose oxidase. The electron-donating *o*-(methylthio) and the *p*-methyl substituents and the direct linkage of the aromatic ring to the central nitrogen atom should significantly lower the redox potential for the oxidation of this phenol group, while the substituents in the *ortho* and *para* positions relative to the OH group will prevent the formed phenoxyl radical from dimerizing.

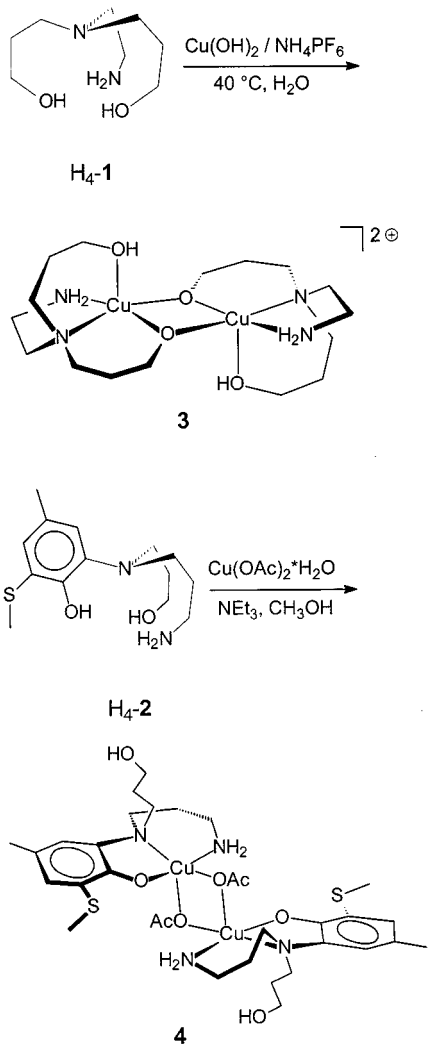
Preparation of Copper Complexes

Freshly prepared $Cu(OH)_2$, suspended in water, reacted at 40 °C with a stoichiometric amount of ligand H_4-**1** to give a blue suspension which contained unidentified copper species (probably hydroxides). Addition of 2 equiv. of NH_4PF_6 to such a suspension yielded a deep blue solution. From this solution complex **3** crystallized over a period of 6 h (Scheme 3). The complex is air-stable and can be recrystallized from water as deep blue prisms. The reaction of $[HNEt_3]^+[H_3$-**2**$]^-$ with an equimolar amount of $[Cu(OAc)_2{\cdot}H_2O]_2$ in methanol at room temperature yielded a dark green solution. On addition of a mixture of acetonitrile and *tert*-butyl methyl ether, and on cooling to −30 °C, air-sensitive blue plates crystallized, which were identified as **4**·2CH_3CN by X-ray crystallography (Scheme 3).

Molecular Structures of 3

The X-ray crystal structure analysis shows the formation of the dinuclear complex $[Cu(\eta^4\text{-}\mu\text{-O-}H_3\text{-}\mathbf{1})_2Cu](PF_6)_2$ (**3**) from $Cu(OH)_2$ and the ligand H_4-**1**. The dication of complex **3** resides on a crystallographic inversion center in the unit cell. Each copper(II) ion is coordinated by two nitrogen atoms, one terminal propyloxy group (O1) and two μ^2-propyloxo groups (O2) (Figure 3). The bridging oxygen atom O2 is deprotonated while the monodentate oxygen atom O1 remains protonated in the complex. The charge distribution was assigned based on the presence of only two PF_6^- anions which make the complex a dication with two monodeprotonated ligands H_3-**1**$^-$. The most acidic functions of the ligand are the alcohol groups. We concluded that O2 is the deprotonated alcohol group, based on the difference in the Cu−O distances [Cu−O1 2.339(3) Å, Cu−O2 1.920(3) Å].

The coordination geometry around the copper centers is best described by the use of the τ-criterion,[23] which indicates that the coordination geometry in **3** is only slightly distorted (τ = 0.181) from square-pyramidal. Atom O1 occupies the apical position. The Cu_2O_2 core shows a significant rhombic distortion. The angle O2−Cu−O2* is 78.10(13)°, while for Cu−O2−Cu* an angle of 101.90(13)° is observed. The Cu and Cu* distance is 3.001(1) Å. The Cu−N and $Cu-O_{eq}$ bond lengths are only slightly different [Cu−N1 2.033(3), Cu−N2 1.992(4) and Cu−O2 1.920(3), Cu−O2* 1.944(3) Å], leading to an almost symmetrical bridge between the copper atoms.



Scheme 3. Preparation of complexes **3** and **4**

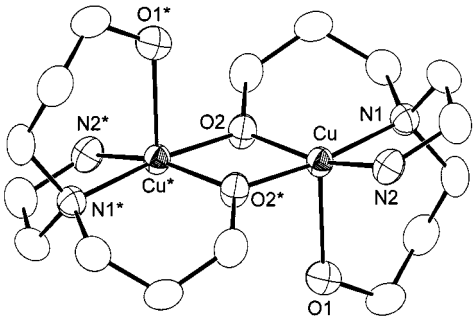


Figure 3. ORTEP plot of one complex dication of **3** (hexafluorophosphate anions are not shown); selected bond lengths [Å] and angles [°]: Cu···Cu 3.001(1), Cu−O1 2.339(3), Cu−O2 1.920(3), Cu−O2* 1.944(3), Cu−N1 2.033(3), Cu−N2 1.992(4); O1−Cu−O2 90.91(14), O1−Cu−O2* 91.77(13), O1−Cu−N1 94.74(14), O1−Cu−N2 106.3(2), O2−Cu−O2* 78.10(13), O2−Cu−N1 98.66(13), O2−Cu−N2 161.9(2), O2*−Cu−N1 172.79(14), O2*−Cu−N2 95.43(15), N1−Cu−N2 85.7(2), Cu−O2−Cu* 101.90(13)

A 5,6,6-chelate ring sequence is observed in the dication of **3**. This should and does lead to a square-pyramidal coordination geometry, with a donor atom of a six-membered

chelate ring (O1) in the apical position. In this regard, the molecular structure of **3** meets our expectations and experiences gained from related aliphatic tripodal N_4 ligand systems.[13] However, complex **3** cannot serve as a GO model compound since GO contains a mononuclear square-pyramidal copper center and not a binuclear one.

To the best of our knowledge **3** is one of two examples of a clearly square-pyramidal copper complex with an apical O-donor derived from a tripodal N_2O_2 ligand. Previously described tripodal N_2O_2 ligands with pyridyl and phenolate donors gave dinuclear copper complexes which deviate significantly from the square-pyramidal geometry, towards a trigonal-bipyramidal geometry.[10][11b] However, one tripodal N_2O_2 ligand with bulky substituents at its pyridyl and phenolate donors[11c] forms a distorted square-pyramidal mononuclear copper complex ($\tau = 0.273$) with a 5,6,6-chelate ring sequence and with an oxygen donor at the end of a C_3 chain in the apical position. These results together with the molecular structure of **3** indicate again, that the coordination geometry of copper complexes with tripodal ligands can at least partly be controlled and manipulated by the ligand topology.

Molecular Structures of 4·2CH_3CN

The X-ray structure analysis of **4**·2CH_3CN revealed that the oxygen-bridged, inversion-symmetric, dinuclear complex [(η^3-H_3-**2**)Cu(μ-OAc)$_2$Cu(η^3-H_3-**2**)]·2CH_3CN had formed (Scheme 3, Figure 4). The asymmetric unit contains two halves of the complex, which are not related by crystallographic symmetry.

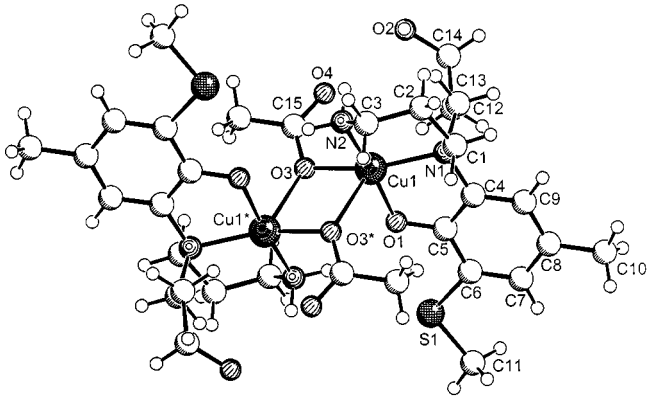

Figure 4. SCHAKAL plot of one molecule of complex **4** (the asymmetric unit contains two nearly identical halves of a molecule); selected bond lengths [A] and angles [°] for molecule A [molecule B]: Cu1···Cu1 3.2729(11) [3.2375(12)], Cu1−O1 1.916(3) [1.909(3)], Cu1−O3 1.999(3) [1.993(3)], Cu1−O3* 2.374(3) [2.529(3)], Cu1−N1 2.056(3) [2.056(4)], Cu1−N2 1.980(4) [1.970(3)]; O1−Cu1−O3 92.15(12) [92.21(12)], O1−Cu1−O3* 88.18(12) [85.33(12)], O1−Cu1−N1 86.09(13) [86.21(14)], O1−Cu1−N2 171.36(14) [169.21(14)], O3−Cu1−O3* 83.47(12) [89.36(12)], O3−Cu1−N1 159.04(14) [163.13(14)], O3−Cu1−N2 88.95(13) [88.74(14)], O3*−Cu1−N1 117.30(12) [107.23(12)], O3*−Cu1−N2 83.42(13) [83.93(13)], N1−Cu1−N2 95.91(15) [95.92(15)], Cu1−O3−Cu1* 96.53(12) [90.64(12)]

In complex **4** both copper(II) ions reside in a square-pyramidal ($\tau = 0.205$ and $\tau = 0.101$) N_2O_3 coordination environment, but in contrast to the situation in **3**, the μ^2-oxy bridges in **4** result from the bridging coordination of acetate oxygen atoms. The two acetate oxygen atoms occupy equatorial (O3) and apical (O3*) positions at the copper atom. Each Cu^{II} ion is coordinated by two nitrogen and three oxygen donors (one phenolate and two acetate oxygen atoms), while the hydroxypropyl arm (O2) of the ligand remains uncoordinated. Like in **3**, both copper atoms are coordinated in a square-pyramidal fashion, but again a dinuclear complex was obtained and hence it cannot act as an acceptable GO model compound.

The apical Cu−O bond is not exactly perpendicular to the equatorial plane which also leads to a rhombic distortion of the Cu_2O_2 core [O3−Cu−O3* 83.47(12)° and 89.36(12)°, Cu−O3−Cu* 96.53(12)° and 90.64(12)°]. For the same reason all O3*−Cu−L_{eq} angles significantly deviate from the ideal value of 90° expected for a perfect tetragonal pyramid.

The Cu−N bond lengths are almost equal, as found in **3** [Cu1−N1 2.056(3) Å and 2.056(4) Å, Cu1−N2 1.980(4) Å and 1.970(3) Å]. The Cu−O_{eq} distances [Cu−O1 1.916(3) Å and 1.909(3) Å, Cu−O3 1.999(3) Å and 1.993(3) Å] are similar. However, the separation Cu−O_{apical} is much more pronounced [Cu−O3* 2.374(3) Å and 2.529(3) Å], a behavior observed in all square-pyramidal copper complexes with an O-donor in the apical position.

Due to reasons we do not exactly know yet, and in contrast with the coordinated ligand (H_3-**1**)$^-$ in **3**, each (H_3-**2**)$^-$ ligand anion in complex **4** uses only three of the four donor groups for binding to the copper atom, while the hydroxypropyl arm is not coordinated and remains protonated. We believe that this is not exclusively due to the steric situation in **4**, but also to the low stability of the six-membered chelate ring which would have formed with the hydroxypropyl ligand arm. A similar behavior of related aliphatic tripodal ligands has been reported recently.[24] In addition it has been shown that the stability of the copper complex with the ligand trpn, which exclusively forms six-membered chelate rings is about 10^5 times lower than the stability of the corresponding tren complex that contains only five-membered chelate rings.[13b] The acetate oxygen atoms are apparently better donors than the hydroxypropyl group when competing for the coordination site at the copper center. Similar behavior has been reported for copper complexes with a tripodal ligand capable of forming a 5,6,6-chelate ring sequence, where the presence of chloride ions prevents the formation of the chelate complex, and a copper complex with chloride ligands was obtained.[11c] Table 1 lists some structural parameters for **3** and **4**.

Cyclic Voltammetry

The cyclic voltammogram of complex **3** recorded in an acetonitrile solution exhibits an irreversible oxidation potential at $E_{pa} = +1375$ mV vs. Ag/AgCl. Complex **3** is quite stable relative to to the corresponding Cu^{III} species which is highly reactive and rapidly decomposes to non-identified

Table 1. Comparison of selected structural details in complexes **3** and **4**·2CH_3CN

Complex	Cu−N_{eq} [Å]	Cu−O_{eq} [Å]	Cu−O_{ap} [Å]	τ
3	1.992(4), 2.033(3)	1.920(3), 1.944(3)	2.339(3)	0.179
4·2CH_3CN	1.980(4), 2.056(3)	1.916(3), 1.999(3)	2.374(3)	0.205, 0.101

products. Upon application of a negative potential an irreversible reduction is observed at $E_{pc} = -725$ mV vs. Ag/AgCl in acetonitrile. This corresponds to the process $Cu^{II} + e^- \rightarrow Cu^{I}$, which is followed by the dissociation of the Cu^{I} complex and disproportionation of Cu^{I} to Cu^{II} and Cu^0.

The results of the cyclic voltammetric analysis of the redox potentials of ligand H_4-**2** and complex **4** are shown in Figure 5. In the cathodic region, the free ligand H_4-**2** displays one quasireversible oxidation peak at $E = +130$ mV vs. Ag/AgCl in acetonitrile (top, solid line).

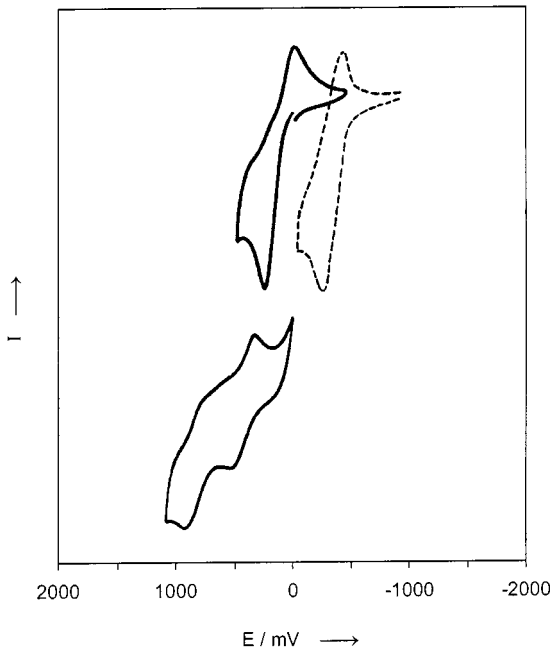

Figure 5. Cyclic voltammograms of H_4-**2** (top, solid line), $(H_3$-**2**$)^-$ (top, dashed line) and of complex **4** (bottom); *E* vs. Ag/AgCl in acetonitrile

This process corresponds to the oxidation of the phenolic moiety, leading to a phenoxyl radical which is prevented from dimerizing. The same process is observed when the phenolic OH group is deprotonated in the presence of $(n\text{Bu})_4N^+OH^-$. The oxidation potential of the phenol group is then shifted towards a more negative potential by about 440 mV than reported previously,[10,11] and is now observed as a quasireversible voltammetric response at $E = -310$ mV vs. Ag/AgCl in acetonitrile (top, dashed line). This low-potential redox step arises from the relatively facile oxidation of the electron-rich thioether and amino-substituted phenol. Recently, such stable, free phenoxyl radicals have also been shown to be essential for enzymes other than galactose oxidase, e.g. glyoxal oxidase[25] and ribonucleotide reductase[1b].

Although the oxidation of the blue dimeric copper complex **4** takes place at a somewhat higher potential than the protonated ligand H_4-**2**, **4** is also easily oxidized. A broad peak, which seems to be the result of the overlapping of two independent redox processes, is observed between 0 and +1000 mV vs. Ag/AgCl in acetonitrile (Figure 5, bottom). The oxidation of the phenolate takes place at a potential of $E^1 = +430$ mV vs. Ag/AgCl, while a second oxidation process occurs at $E^2 = +870$ mV vs. Ag/AgCl. The superimposing cyclic voltammetric responses suggest a quasireversible electron transition, which indicates that in **4** a stable phenoxyl radical is formed on oxidation. In addition, the ligand stabilizes the copper(II) state, since reduction of the complex is observed at a very low potential ($E = -1320$ mV vs. Ag/AgCl in acetonitrile; not shown in Figure 5). This reduction process is irreversible and leads to a deposit of copper(0) on the electrode surface, as concluded from a sharp anodic oxidation peak at $E_{pc} = -60$ mV during the reverse scan with the typical features of a redissolution process.[10]

Conclusion

We have prepared two novel nonsymmetric tripodal ligands which provide an N_2O_2 donor set. Both ligands are capable of coordinating to Cu^{II} to give a 5,6,6-chelate ring sequence. For this chelate ring sequence, square-pyramidal complexes with a donor linked by a C_3 chain in the apical position are expected. Ligand H_4-**1** indeed forms such a complex. However, this complex is dinuclear. With ligand H_2-**2**, we present a tripod with an *o*-amino-*o*-(methylthio)-substituted phenolate donor. This ligand also forms a square-pyramidal Cu^{II} complex, which is also dinuclear. While the dinuclear nature of complexes **3** and **4**·2CH_3CN excludes them from the acceptable mononuclear GO models, they still provide information about the ligand design for the preparation of structural GO models. Among the dinuclear complexes with an N_2O_2 donor set, **3** and **4**·2CH_3CN contain copper atoms which deviate least from the required square-pyramidal coordination geometry, as judged by the τ values of 0.181 for **3** and 0.205 and 0.101 for **4**·2CH_3CN. Thus, the 5,6,6-chelate ring sequence indeed leads to the desired square-pyramidal complexes. Finally, the unique *o*-amino-*o*-(methylthio)-substitution of the phenol donor in ligand H_4-**2** leads to a significant reduction of the redox potential for the oxidation of the free or coor-

dinated phenolate group to the corresponding phenoxyl radical, which is stabilized against dimerization by *p*-methyl substitution of the aromatic ring. Based on these observations we propose that substitution of the aliphatic OH and NH_2 donors in H_4-**2** by aromatic ones (phenol and pyridine) and sterically more bulky substituents at the phenol groups could lead to a square-planar, mononuclear Cu^{II} complex, which would serve as a satisfactory structural GO model.

Experimental Section

General Remarks: All manipulations were carried out under argon. Solvents were purified by standard methods, freshly distilled and degassed prior to use. − Infrared spectra were recorded in KBr using a Perkin−Elmer IR 983 spectrometer. − NMR spectra were recorded with a Bruker AM 250 spectrometer. − Elemental analyses (C,H,N,S) were performed with a Vario EL Elemental Analyzer. − EI and +FAB mass spectra were recorded with Finnigan MAT 112 or Finnigan MAT 711 instruments. − UV/Vis spectra were recorded with a Perkin−Elmer Lambda 9 UV/Vis/NIR spectrophotometer. − Cyclic voltammetric experiments were carried out with a Bank High Power Potentiostat Wenking HP 72 and a Bank Scan Generator Wenking Model VSG 83, using a three-electrode cell configuration (working electrode: Pt; auxiliary electrode: Pt; reference electrode: Ag/AgCl/3 M KCl; $E_{Fc/Fc+}$ = 435 mV). The experiments were performed in acetonitrile with 0.1 M tBu_4NPF_6 as the supporting electrolyte with scan rates of 100 mV/s.

Ligand Syntheses

B: 3,3′-Iminobis(ethyl propionate) **B** was prepared according to a procedure published previously.[14] − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 4.12 (q, 4 H, $-OCH_2$), 2.92 (t, 4 H, NCH_2), 2.49 (t, 4 H, CH_2COO), 1.84 (s, 1 H, NH), 1.24 (t, 6 H, CH_3). − $^{13}C\{^1H\}$ NMR (62.90 MHz, $CDCl_3$): δ = 172.38 (COO), 60.15 (CH_2O), 44.68 (NCH_2), 34.52 (CH_2COO), 13.97 (CH_3).

C: Formaldehyde (2.027 g, 0.025 mol, 37% in water) was added to a solution of sodium pyrosulfite $Na_2S_2O_5$ (2.376 g, 0.0125 mol) in 10 mL of water. The reaction mixture was heated to 50 °C for a period of 45 min and then cooled to 0 °C. **B** (5.431 g, 0.025 mol) was added slowly while maintaining the temperature below 5 °C. Subsequently, the flask was allowed to warm to room temperature and the reaction mixture was stirred for 2 h. The mixture was again cooled to 0 °C and a solution of KCN (5.431 g, 0.025 mol) in 8 mL of water was added. The resulting solution was stirred overnight at room temperature. During this period an oil had separated, which was extracted with chloroform (3 × 50 mL). The organic phases were combined and dried with anhydrous $MgSO_4$. All solvents were removed in vacuo, and the residue was distilled at 115 °C ($2\cdot10^{-2}$ mbar). Yield: 5.070 g (79.1% relative to **B**) of a colorless oil. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 4.12 (q, 4 H, OCH_2), 3.64 (s, 2 H, CH_2CN), 2.90 (t, 4 H, NCH_2), 2.48 (t, 4 H, CH_2COO), 1.24 (t, 6 H, CH_3). − $^{13}C\{^1H\}$ NMR (62.90 MHz, $CDCl_3$): δ = 171.39 (COO), 114.84 (CN), 60.41 (OCH_2), 49.37 (NCH_2), 41.96 (CH_2CN), 32.85 (CH_2COO), 13.99 (CH_3).

H_4-1: All protected donor groups in **C** were liberated simultaneously by reduction with AlH_3. The AlH_3 was prepared from lithium aluminium hydride (LAH) (5.40 g, 0.143 mol) and H_2SO_4 (6.183 g, 60 mmol, 96%) in 150 mL of dry THF as described.[13a] Compound **C** (5.07 g, 19.8 mmol), dissolved in 30 mL of THF, was added dropwise to the vigorously stirred AlH_3 suspension, at room temperature. The reaction mixture was stirred for 24 h at ambient temperature, and residual AlH_3 was carefully hydrolyzed with water (8.2 mL, 0.46 mol). All solids were removed by filtration and repeatedly washed with methanol (6 × 50 mL). The organic layers were combined, all solvents removed in vacuo, and the residue was distilled at 135 °C ($2\cdot10^{-3}$ mbar). Ligand H_4-**1** was obtained as a colorless oil. Yield 2.234 g (64% relative to **C**). − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 3.67 (s + t, 6 H, OH + CH_2O), 2.80 (t, 2 H, $NCH_2CH_2NH_2$), 2.58 (t, 4 H, $NCH_2CH_2CH_2$), 2.50 (t, 2 H, CH_2NH_2), 1.70 (m + s, 6 H, $CH_2CH_2CH_2$ + NH_2). − $^{13}C\{^1H\}$ NMR (62.90 MHz, $CDCl_3$): δ = 61.27 (CH_2O), 56.45 ($NCH_2CH_2NH_2$), 52.27 ($NCH_2CH_2CH_2$), 39.29 (CH_2NH_2), 28.97 ($CH_2CH_2CH_2$). − MS (EI): *m*/*z* (%) = 176 (2.55, $[M]^+$), 146 (100, $[M - H_2O]^+$), 102 (57.38), 58 (70.21). − IR (KBr): $\tilde{\nu}$ = 3343 (br. s, N−H + O−H), 2939, 2869 (s, C−H), 1593 (m, N−H), 1373 (m, O−H), 1464 (s, C−H), 1216 (m, C−N), 1063 (s, C−O).

D: Anhydrous $AlCl_3$ (18.0 g, 0.12 mol) was suspended in 50 mL of dry dichloromethane of. This mixture was treated with a solution of *o*-nitro-*p*-cresol (15.314 g, 0.1 mol) in 20 mL of dichloromethane. When the evolution of HCl had ceased, bromine (17.5 g, 0.11 mol) was added dropwise and the dark green suspension was stirred overnight at room temperature. The mixture was hydrolyzed with 10 g of ice under vigorous evolution of HCl. Subsequently, 50 mL of water and 30 mL of dichloromethane were added and the resulting suspension was mixed with 30 mL of aqueous HCl (32%). The clear orange organic layer was separated, washed twice with acidic water and dried with anhydrous $MgSO_4$. The solvent was stripped in vacuo to give 21.33 g (91%) of a yellow powder. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 11.0 (s, 1 H, OH), 7.92, 7.74 (s, 2 H, Ar-H), 2.38 (s, 3 H, CH_3). − $^{13}C\{^1H\}$ NMR (62.90 MHz, $CDCl_3$): δ = 150.09, 141.76, 132.70, 124.04, 118.94, 112.81 (Ar−C), 20.19 (CH_3).

E: The sodium salt of **D** was obtained by deprotonation of the phenolic OH group with aqueous NaOH. To achieve this **D** (11.6 g, 0.05 mol), dissolved in 24 mL of hot (70 °C) ethanol, was added to a warm solution of NaOH (2.04 g, 0.051mol) in a mixture of 24 mL of ethanol and 3.5 mL of water. Immediately a red precipitate separated, which was collected by filtration and dried in vacuo for several hours. A sample of the sodium salt of **D** (12.7 g, 0.05 mol) was suspended in 70 mL of dry THF. (Chloromethoxy)methane (MOMCl) (4.026 g, 0.05 mol) was then added dropwise to this suspension. ***Warning: (Chloromethoxy)methane (MOMCl) is known to be extremely carcinogenic!*** The mixture was refluxed for 4 h. During this period the color of the suspension changed from red to white. The reaction mixture was extracted three times with a saturated K_2CO_3 solution, and the combined organic layers were dried with anhydrous $MgSO_4$. Removal of the solvent yielded 11.95 g (86.6%) of a pale yellow powder, that was purified by recrystallization from a mixture of hexane/ether (3:1, v:v). − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.66, 7.54 (s, 2 H, Ar-H), 5.12 (s, 2 H, OCH_2O), 3.54 (s, 3 H, OCH_3), 2.34 (s, 3 H, CH_3). − $^{13}C\{^1H\}$ NMR (62.90 MHz, $CDCl_3$): δ = 137.89, 136.05, 124.36, 119.13 (Ar−C, only 4 resonances were observed), 100.68 (OCH_2O), 58.01 (OCH_3), 20.36 (CH_3).

F: Compound **E** (16.565 g, 0.06 mol) was dissolved in 250 mL of dry THF and cooled to −105 °C with a mixture of diethyl ether/liquid nitrogen as described previously.[18b] Over a period of 30 min phenyllithium (37 mL, 0.066 mol, 1.8 M solution in hexane/ether, 70:30) was slowly added via a syringe maintaining the temperature below −100 °C. When all the phenyllithium had been added, the

red suspension was stirred for 1 h at −105 °C and subsequently quenched with dry, degassed dimethyl disulfide (11.3 mL, 0.12 mol). After 15 min, the mixture was allowed to warm to −78 °C. After stirring at this temperature for an additional 30 min, the orange suspension was carefully hydrolyzed with 15 mL of degassed water and slowly brought to 0 °C. Toluene (150 mL) was added and the total volume of the solution was reduced to 100 mL in vacuo. Ether (150 mL) was then added. The resulting organic phase was repeatedly extracted with water until the aqueous layer remained colorless. After drying with anhydrous $MgSO_4$ and removal of the solvents in vacuo, a brown oily residue was obtained. Column-chromatographic purification (SiO_2, hexane/ethyl acetate, 4:1, R_f = 0.29) yielded 10.05 g (72.3%) of an intense orange oil. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 7.30, 7.10 (s, 2 H, Ar-H), 5.02 (s, 2 H, OCH_2O), 3.50 (s, 3 H, OCH_3), 2.42 (s, 3 H, SCH_3), 2.32 (s, 3 H, CH_3). − ^{13}C{^{1}H} NMR (62.90 MHz, $CDCl_3$): δ = 144.82, 144.18, 136.14, 135.03, 130.12, 121.11 (Ar-C), 100.06 (OCH_2O), 57.88 (OCH_3), 20.80 (CH_3), 14.89 (SCH_3).

G: A solution of **F** (7.298 g, 0.03 mol) in 100 mL of methanol was cooled to 0 °C and mixed with hydrazine (6 g, 0.12 mol, 100%). After addition of three small portions of Raney nickel, it was stirred until the evolution of gas had ceased and the mixture decolorized. In order to decompose the excess hydrazine an additional portion of Raney nickel was added and the suspension was heated to reflux for 90 min. The solid metal was separated by filtration under argon, and all solvents were removed in vacuo. The oily residue obtained was dissolved in 50 mL of degassed dichloromethane and the solution was dried with anhydrous $MgSO_4$. Removal of the solvent in vacuo yielded 5.77 g (90.2%) of **G** as a yellow oil. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 6.37, 6.34 (s, 2 H, Ar-H), 5.04 (s, 2 H, OCH_2O), 3.94 (br. s, 2 H, NH_2), 3.62 (s, 3 H, OCH_3), 2.40 (s, 3 H, SCH_3), 2.24 (s, 3 H, CH_3). − ^{13}C{^{1}H} NMR (62.90 MHz, $CDCl_3$): δ = 139.80, 139.51, 135.04, 132.04, 115.88, 113.95 (Ar-C), 99.11 (OCH_2O), 57.58 (OCH_3), 21.07 (CH_3), 14.71 (SCH_3).

H: Acrylonitrile (3.188 g, 0.06 mol) and **G** (8.535 g, 0.04 mol) were mixed with the catalyst $Cu(OAc)_2 \cdot H_2O$ (0.839 g) and the polymerization inhibitor quinone (0.17 g). The mixture was heated to 110 °C and the reaction was monitored by chromatography (SiO_2, hexane/ethyl acetate, 4:1, $R_f^{\mathbf{G}}$ = 0.18, $R_f^{\mathbf{H}}$ = 0.13). The reaction was complete after 4 h, otherwise additional portions of acrylonitrile and copper catalyst had to be added. The resulting brown residue was purified by column chromatography (SiO_2, hexane/ethyl acetate). Yield 7.55 g (70.9%) of a brown crystalline solid. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 6.36, 6.25 (s, 2 H, Ar-H), 5.02 (s, 2 H, OCH_2O), 4.88 (br. s, 1 H, NH), 3.62 (s, 3 H, OCH_3), 3.50 (q, 2 H, NHC*H*$_2$), 2.62 (t, 2 H, CH_2CN), 2.40 (s, 3 H, SCH_3), 2.24 (s, 3 H, CH_3). − ^{13}C{^{1}H} NMR (62.90 MHz, $CDCl_3$): δ = 139.74, 135.36, 132.00, 118.05, 115.31 (Ar-C, only 5 resonances were observed), 108.87 (CN), 99.32 (OCH_2O), 57.71 (OCH_3), 39.56 ($NHCH_2$), 21.56 (CH_3), 18.04 (CH_2CN), 14.68 (SCH_3).

I: H (5.332 g, 20 mmol) was dissolved in a mixture of dry diethyl ether (25 mL) and chloroform (5 mL) and treated with acetoxypropionyl chloride (3.09 g, 20.5 mmol) which was synthesized according to a published procedure.[22] On reaction the mixture slightly warmed and became darker in color. After 30 min, triethylamine (2.086 g, 20.6 mmol) was added, and the solution was stirred for one additional hour at room temperature. Washing of the reaction solution with water, drying of the organic phase with anhydrous $MgSO_4$ and removal of the solvents in vacuo yielded a brown oil that was purified chromatographically (SiO_2, hexane/ethyl acetate, 1:1, $R_f^{\mathbf{I}}$ = 0.15). The product crystallized as colorless needles. Yield: 4.95 g (65%). − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 6.99, 6.86 (s, 2 H, Ar-H), 5.01 (q, 2 H, OCH_2O), 4.52 + 4.41 (dd, 2 H, $NC(O)CH_2$), 4.37 + 4.30 (dd, 2 H, $NC(O)CH_2CH_2$), 3.48 (s, 3 H, OCH_3), 2.77 (q, 2 H, NCH_2), 2.60 (t, 2 H, CH_2CN), 2.46 (s, 3 H, SCH_3), 2.36 (s, 3 H, CH_3), 2.02 (s, 3 H, $C(O)CH_3$). − ^{13}C{^{1}H} NMR (62.90 MHz, $CDCl_3$): δ = 170.78 [C(O)O + C(O)N], 147.24, 135.69, 134.93, 134.24, 126.74, 126.70 (Ar-C), 117.89 (CN), 99.35 (OCH_2O), 60.32 (OCH_3), 47.51 [$NC(O)CH_2CH_2O$], 44.42 [$NC(O)CH_2$], 33.26 (NCH_2), 21.00 (Ar-CH_3), 20.88 [$C(O)CH_3$], 16.41 (CH_2CN), 14.70 (SCH_3).

H_4-2: All protected donor groups in **I** were liberated simultaneously by use of AlH_3. The AlH_3 was prepared from lithium aluminium hydride (LAH) (2.73 g, 72 mmol) and H_2SO_4 (3.065 g, 30 mmol, 96%) in 70 mL of dry THF as described.[13a] Ligand precursor **I** (3.75 g, 10 mmol), dissolved in 30 mL of THF, was added dropwise to the vigorously stirred AlH_3 suspension. The reaction mixture was stirred for 24 h at ambient temperature, residual AlH_3 was carefully hydrolyzed with water (5.4 mL, 0.3 mmol), and all solids were removed by filtration. The solid residue was repeatedly extracted with methanol under argon. All organic phases were combined and all solvents were removed in vacuo. The oily residue obtained was dissolved in a small portion of dichloromethane and this solution was filtered and dried with anhydrous $MgSO_4$. Removal of the solvent in vacuo yielded a yellow sticky oil that crystallized at −30 °C. Alternatively, addition of diethyl ether to oily H_4-**2** gave a white powder. Yield: 1.51 g (84.8%). − $C_{14}H_{24}N_2O_2S$ (284.42): calcd. C 59.12, H 8.51, N 9.85, S 11.27; found C 58.24, H 8.49, N 9.58, S 11.37. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 6.66 (s, 2 H, Ar-H), 5.64 (br. s, 4 H, Ar-OH, CH_2-OH, NH_2), 3.58 (t, 2 H, CH_2OH), 2.98 (t + t, 4 H, NCH_2), 2.84 (t, 2 H, CH_2NH_2), 2.36 (s, 3 H, SCH_3), 2.22 (s, 3 H, Ar-CH_3), 1.60 (m + m, 4 H, $CH_2CH_2CH_2$). − ^{13}C{^{1}H} NMR (62.90 MHz, $CDCl_3$): δ = 152.96, 136.99, 125.52, 124.34, 120.77, 118.36 (Ar-C), 60.95 (CH_2OH), 52.99 ($NCH_2CH_2CH_2OH$), 48.41 ($NCH_2CH_2CH_2NH_2$), 38.69 (CH_2NH_2), 29.06, 26.35 ($CH_2CH_2CH_2$), 20.95 (Ar-CH_3), 14.94 (SCH_3). − MS (EI), *m*/*z* (%) = 284 (38.79) $[M]^+$, 240 (20.22) $[M - CH_2CH_2NH_2]^+$, 196 (100), 182 (21.11), 134 (6.95). − IR (KBr): ṽ: 3504 (s, N−H), 3337 (s, O−H), 2950, 2918, 2848, 2799 (s, C−H), 1547 (m, N−H), 1448 (m, O−H), 1265 (m, C−N), 1077 (s, C−O), 830, 871 (m, C−H of a 1,2,3,5-substituted aromatic ring).

Preparation of Copper Complexes

3: For the preparation of **3** freshly precipitated $Cu(OH)_2$ (195 mg, 2 mmol) was suspended in water (10 mL) and ligand H_4-**1** (370 mg, 2.1 mmol) was added dropwise with a syringe. The blue suspension was stirred at 40 °C for 60 min, and then solid NH_4PF_6 (652 mg, 4 mmol) was added, resulting in a deep blue solution. The solution was reduced to a volume of 5 mL and cooled to 5 °C. After 24 h, deep blue crystals had formed. The crystals were collected by filtration and recrystallized from warm acetonitrile/diethyl ether. Yield 596 mg (68.9%). − $C_{16}H_{38}Cu_2F_{12}N_4O_4P_2$ (767.52): calcd. C 25.04, H 4.99, N 7.30; found C 25.09, H 5.17, N 7.46. − MS (FAB, positive ions, 3-nitrobenzyl alcohol/DMSO), *m*/*z* (%) = 475 (18.95, $[M - H]^+$), 301 (37.67, $[Cu(H_3$-**1**$) + Cu]^+$), 239 (33.19, $[$**3** $+ H]^{2+}$). − IR (KBr): ṽ: 3549, 3378, 3330 (w, O−H + N−H), 2970, 2875, 2833 (m, C−H), 1596 (m, NH_2), 1473, 1459, 1433 (m, C−H), 1065, 1046 (s, C−O); 833, 558 (s, PF_6). − UV/Vis (CH_3OH): λ_{max} [nm] (ε) = 270 (4900), 366 (2000), 585 (120).

4: H_4-**2** (62.6 mg, 0.22 mmol) was mixed with triethylamine (44.4 mg, 0.44 mmol). The mixture was added dropwise to a solution of $Cu(OAc)_2 \cdot H_2O$ (43.9 mg, 0.22 mmol) in 10 mL of methanol, resulting in the formation of a green solution. After stirring for 30 min, the solvent was removed in vacuo and the residue suspended

in acetonitrile and filtered. To the clear, deep green solution was added *tert*-butyl methyl ether. Cooling the solution to −30 °C yielded blue plate-shaped crystals. Yield 8.3 mg (4.6%) of **4**·2CH_3CN. − $C_{36}H_{58}Cu_2N_6O_8S_2$ (894.08): calcd. C 47.33, H 6.45, N 6.90, S 7.89; found C 47.48, H 6.53, N 7.09, S 8.13. − MS (FAB, positive ions, 3-nitrobenzyl alcohol/DMSO), *m/z* (%) = 409 (11.34) $[Cu_2(H_3\text{-}\mathbf{2})]^+$, 346 (18.20) $[Cu(H_3\text{-}\mathbf{2})]^+$. − UV/Vis ($CH_3OH$): λ_{max} [nm] (ε) = 310 nm (15360), 400 (sh, 220), 650 (140).

Crystal Structure Analyses: Crystallographic data for complexes **3** and **4**·2CH_3CN are presented in Table 2. Crystals of **3** are air-stable. Diffraction data were collected at room temperature with an Enraf−Nonius CAD-4 diffractometer. No absorption correction was applied. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were added at geometrically idealized positions and were refined using a riding model. Complex **4**·2CH_3CN rapidly degenerates in air under loss of co-crystallized solvent. Suitable specimens were mounted at 198 K on a Nonius Kappa CCD diffractometer with a rotating anode generator. Diffraction data were collected at 198 K. An absorption correction via SORTAV was applied to the raw data ($0.85 \leq T \leq 0.99$). All other non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were added at geometrically idealized positions and were refined using a riding model. The following programs were used: Data collection EXPRESS and COLLECT, data reduction MolEN and DENZO-SMN, absorption correction for CCD data SORTAV, structure solution SHELXS-86 and SHELXS-97, structure refinement SHELXL-97, graphical presentation ZORTEP and SCHAKAL-92. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-150423 and -150424 for **3** and **4**·2CH_3CN, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Dinucleotide Hydrolysis Promoted by Dinuclear Zn Complexes − The Effect of the Distance between Zn Ions in the Complexes on the Hydrolysis Rate

Shun-ichi Kawahara[a] and Tadafumi Uchimaru*[a]

Keywords: Hydrolysis / Ligand effects / RNA recognition / Zinc

The rate of hydrolysis of an RNA dimer, uridylyl(3′→5′)uridine (UpU), promoted by dinuclear Zn complexes resulting from a series of ligands with differently spaced Zn ion binding sites, was examined. Although the ligands in the present study have in common two di-2-pyridylmethylamino moieties as the Zn binding sites, the activities of these ligands toward the hydrolysis were quite different. Our results suggest that the distance between metal ion coordination sites is an essential factor for the intrinsic activities of the dinuclear complexes.

Introduction

Biomimetic chemistry[1] involves the imitation of functional biomolecules, usually enzymes, by simple artificial molecules. Many studies have been carried out in this field, not only because investigations on the actions of simple artificial molecules are helpful for understanding the reaction mechanism of biomolecules, but also because biomimetic compounds have wide potential scope for medicinal and pharmaceutical applications. In particular, the design of an artificial molecule that promotes the hydrolysis of phosphodiester linkages in RNA under neutral conditions has attracted much attention, since such a molecule will provide a basic structure of anti-cancer and anti-viral drugs.

Many natural ribonucleases and ribozymes that catalyze the hydrolysis of phosphodiester bonds in RNA have metal ions in their active sites.[2] Recently, the double metal-ion mechanism has been widely accepted: the catalytic efficiency of natural nucleases is considered attributable to cooperative action of the two (or more) metal cations in the active sites.[2] Vallee et al. reported that cocatalytic motifs in the enzymes contain two or more ions, and that the distances between the ions range between 3 and 5 Å, based on the X-ray structure analyses.[2c] Our previous theoretical study supported the double metal-ion mechanism.[3] Inspired by this mechanism, several research groups have developed various dinuclear metal-ion complexes possessing high catalytic efficiency toward the hydrolysis of phosphodiester linkages.[4] The efficiency of the catalytic activity of the dinuclear complex can often be related to the distance between the two metal ions in the complex. However, very few systematic studies have been reported from this point of view. Only one exception was reported by Chapman et al.; namely, that the distance between the metals determines the selectivity of the catalysts.[4d]

We examined the rate of hydrolysis of an RNA dimer, uridylyl(3′→5′)uridine (UpU), promoted by dinuclear Zn complexes resulting from a series of ligands. Because of the lack of basicity of the uracil ring, the reaction of UpU is the simplest model of nucleotide hydrolysis. Di-2-pyridylmethylamine has a high affinity for the Zn ions: log of the binding constant (log k_{bind}) is 7.57 in 0.10 M KNO_3.[5] Our ligands have two differently distanced di-2-pyridylmethylamino groups at the benzylic positions as Zn coordination sites. Herein, we show that the efficiency of the hydrolytic activity of the Zn complexes is highly sensitive to the distance between the two Zn ions in the complexes.

Results and Discussion

Figure 1 shows the structures of the ligands used in this study. Ligands **1**−**5** have two di-2-pyridylmethylamino groups as Zn coordination sites, while ligand **6** has only one coordination site. In all the ligands, di-2-pyridylmethylamino groups are attached to the benzylic carbon atoms.

Semiempirical AM1[6] calculations suggested that the shortest distance between the two nitrogen atoms would be 4.4, 5.2, 7.7, 7.2, and 11.3 Å in **1a**, **2a**, **3a**, **4a**, and **5a**, respectively. The conformational analysis using Monte Carlo (MC) simulations was studied for bis(hydrogen dimethylammonium)dications (**1**−**5b**) as the models to confirm the distribution of the distance between the two intramolecular cations. Figure 2 shows the relationship between the distance of the two protons (horizontal axis, Å) and the energy (vertical axis, kcal/mol). The results of the conformers, which had energies within 20 kcal/mol for their most stable conformers, are shown. The order of the proton−proton distance was **1b** < **2b** < **4b** ≤ **3b** << **5b**. However, a widely spread distribution was observed in the case of **1b**, and the energy of the conformer of **1**, which has the minimum distance, was very high.

Next, the affinity of the ligands toward Zn ions was studied through competitive titration with 2-(5-bromo-2-

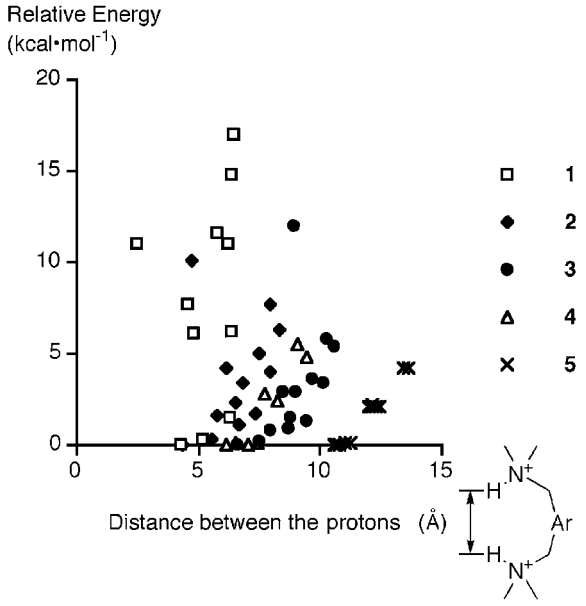

Figure 2. Relationship between the distance of the two protons (horizontal axis, Å) and the energy (vertical axis, kcal/mol)

pyridylazo)-5-[*N*-2-propyl-*N*-(3-sulfopropyl)amino]phenol (5Br-PAPS, see Supporting Information, Section 2). The titration results suggest that at least 95% of the ligands **2**−**5** in solution form a dinuclear complex under the experimental conditions in this report (typically, [Ligand] = 0.1 mM, [Zn] = 0.05 mM, see Figure 3 and Exp. Sect.). Hereafter, we refer to the dinuclear and mononuclear complexes as **L**-Zn_2 and **L**-Zn_1, respectively. We also carried out titration experiments by using Cu^{II} ion solution (see Supporting Information, Section 3). The Cu^{II} ion titration curves indicate that ligands **2**−**5** form the dinuclear Cu^{II} ion complexes and only **1** does not form a dinuclear complex. The binding affinity of the Zn ion with di-2-pyridylmethylamine is much less than that of the Cu^{II} ion (log k_{bind} = 9.31 in 0.10 M KNO_3 [5]). Additionally, from the result of the kinetics described below, it can be suggested that ligand **1** cannot form the dinuclear complex **1**-Zn_2 otherwise the amount of the dinuclear Zn ion complex of ligand **1** under the experimental conditions in this report would be considerably smaller than that of the dinuclear complex resulting from the other ligands.

We examined the rate of hydrolysis of UpU at pH 7.0 and 60 °C in the presence of the ligands. The ligands **1**−**6** showed no ability to hydrolyze UpU without Zn ions. We kept the concentration of Zn ions at 0.1 mM and measured the pseudo-first order rate constant k_{obs} under different ligand concentrations (from 0 to 0.4 mM). The values of k_{obs} are plotted against ligand concentration in Figure 3-I.[7]

The value of k_{obs} in the presence of a 0.1 mM amount of the Zn ion without any ligand was $4.0 \times 10^{-4}\ h^{-1}$. For ligands **2**, **3**, and **4**, the value of k_{obs} increased with increase of the ligand concentration, and the largest values of k_{obs} for these ligands were observed under the conditions of a concentration ratio of [Zn]/[ligand] of 2:1. Hereafter, we refer to this condition as condition A. Further increase of the concentration of these ligands resulted in a decrease of k_{obs}. These results suggest that ligands **2**, **3**, and **4** should form a considerable amount of dinuclear Zn complexes under condition A and that, compared to the Zn ion itself and the mononuclear complexes, the resulting dinuclear complexes should be more active toward the hydrolysis. The enhancement of the rate of hydrolysis for ligand **2** under condition A was the most striking: the k_{obs} found for the condition A was $1.6 \times 10^{-2}\ h^{-1}$, which was around 40 times and 4 times as large as k_{obs} measured in the absence of the ligand and that observed for the condition of [Zn]/[**2**] = 1:1 (condition B), respectively. For ligand **5**, k_{obs} gradually increased with an increase of the ligand concentration, but the enhancement of the hydrolysis rate was much less significant than for ligands **2**, **3**, and **4**. The values of k_{obs} for ligands **1** and **6** were insensitive to the ligand concentration: these ligands did not substantially affect the rate of hydrolysis.

Figure 3-II shows the difference in k_{obs} from ligand to ligand under conditions A and B. The difference in k_{obs} under condition A was much more striking than those observed under condition B. Although ligands **1**−**5** commonly have two di-2-pyridylmethylamine moieties, ligand **2** showed substantially higher activity than the other ligands.

Next, the values of k_{obs} were measured under different concentrations of the Zn ion (from 0.1 to 1.0 mM) with a constant concentration (0.1 mM) of the ligands. The values of k_{obs} are plotted against the concentration of the Zn ion ([Zn]) in Figure 3-III. Figure 3-III clearly shows again that ligand **2** enhances the rate of hydrolysis under the condition of [Zn]/[**2**] = 2:1 (condition A). We also measured k_{obs} without the ligand under the same conditions. In the absence of the ligand, although the value of k_{obs} tends to increase slightly upon increasing [Zn], the value of k_{obs} is found to be relatively insensitive to [Zn] (see Figure 3-III). For ligand **2**, however, k_{obs} increased from 1.4×10^{-3} to $1.6 \times 10^{-2}\ h^{-1}$ on going from the condition of [Zn]/[ligand] = 1:1

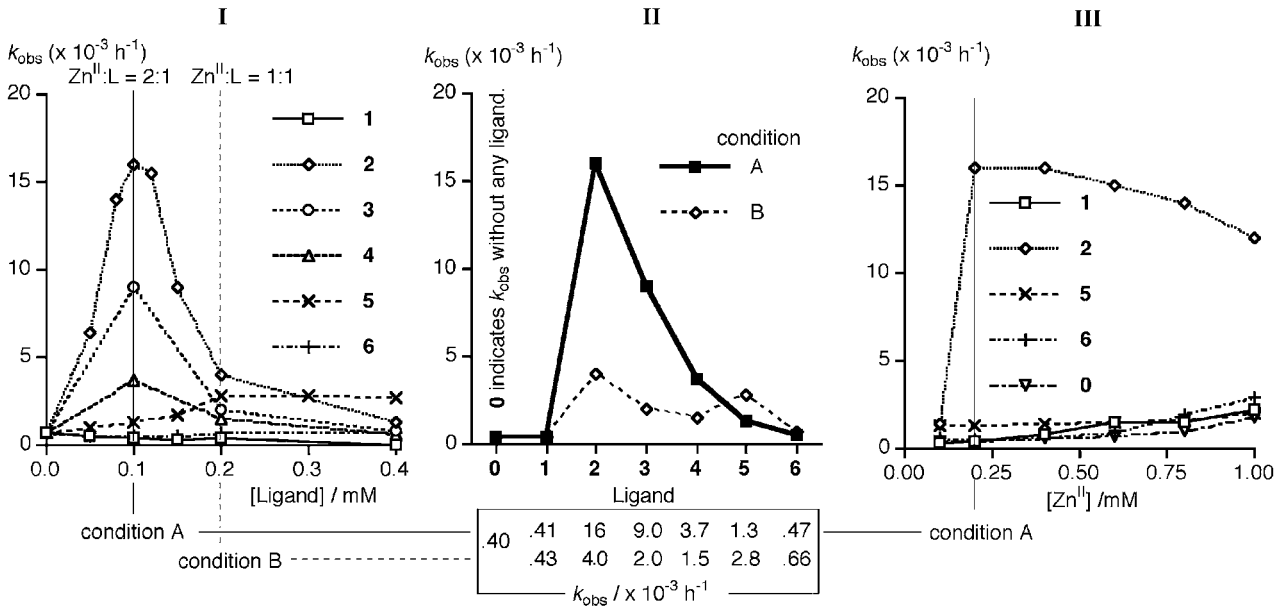

Figure 3. I) k_{obs} with various concentrations of **L** at a constant Zn ion concentration (0.2 mM); II) Relationship between k_{obs} and the backbone structure of the complexes under the conditions A and B; III) k_{obs} at a constant concentration of **L** (0.1 mM) with various Zn ion concentrations

to that of [Zn]/[ligand] = 2:1 (condition A). For ligand **2**, the value of k_{obs} decreased gradually in the presence of an excess amount of Zn ions. This finding can be interpreted as follows: Zn ions without the ligands, which have a much lower catalytic activity than that of **2**-Zn_2, interact with the substrate, and this interaction will inhibit electrostatically the approach of the dinuclear complex to the substrate. As expected from the results given in Figure 3-I, the k_{obs} values for ligands **5** and **6** were insensitive to [Zn] and these ligands showed no substantial enhancement of the rate of hydrolysis.

The binding constants of the ligands toward Zn ions and the structure of the ligands should both be related to the difference in k_{obs} values under condition A (Figure 3-II). As described above, at least 95% of the ligands form dinuclear Zn complexes under this condition. The k_{obs} values increased almost linearly with increase of [Zn] and [ligand] for both ligands **2** and **4**. This trend was observed regardless of the concentration of the dinuclear Zn complexes. We measured the rate of the hydrolysis under different concentrations of the Zn ion and ligands with the concentration ratio of [Zn]/[ligand] being kept at 2:1. As shown in Figure 4,[8] the k_{obs} value for ligand **2** was always greater than that for ligand **4**.

These results suggest that the differences in k_{obs} in Figure 3-II are attributable mainly to the difference in the structure of the ligands, and more specifically, the difference in the distance between the two metal coordination sites. The k_{obs} values under condition A in Figure 3-II are likely to be almost proportional to the intrinsic activities of the dinuclear complexes toward the hydrolysis. Ligands **2**, **3**, and **4** enhanced the hydrolysis rate under condition A and, thus, the two Zn ions in the dinuclear complexes of these

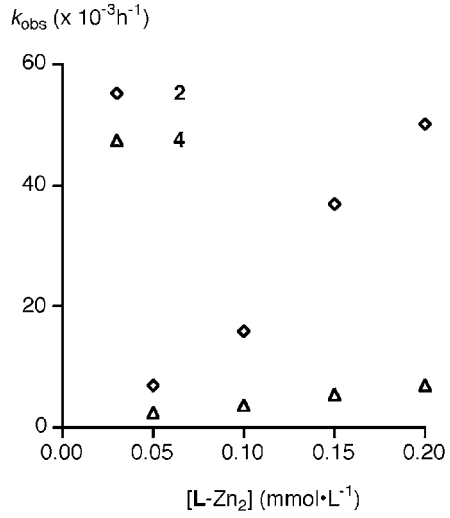

Figure 4. The k_{obs} values of **2**-Zn_2 and **4**-Zn_2 at various concentrations

ligands will act in a cooperative manner to promote the hydrolysis. According to the k_{obs} values in Figure 3-II, the intrinsic activity of the **2**-Zn_2 would be around 1.8 times and 4.3 times as large as those of **3**-Zn_2 and **4**-Zn_2, respectively. Meanwhile, ligands **1** and **5** did not enhance the hydrolysis under condition A. Formation of the dinuclear complex **1**-Zn_2 might be difficult (see above). Indeed, ligand **1** did not show enhancement of the rate of hydrolysis even under condition A. On the other hand, the two Zn ions in **5**-Zn_2 cannot act in a cooperative manner, probably because the distance between the two Zn ions is too large.

Previously, Chapman et al. examined systematically the activities of dinuclear Zn complexes toward the hydrolysis

of phosphodiesters.[4d] Their study covered a series of dinuclear complexes, with distances between the two metal ions in the binding sites similar to those for ligands **1**−**5**. They found that the dinuclear complex with a relatively large distance between the coordination sites, in which the distance between two bound metal ions would be comparable to that for ligand **5**, has the highest activity for the hydrolysis of phosphodiester, while the dinuclear complex with a short distance between the coordination sites has a higher activity for the hydrolysis of phosphomonoesters. They point out that a phosphodiester is sterically more hindered than a phosphomonoester, and that the phosphomonoester dianion is more basic than the phosphodiester monoanion. They then concluded that the phosphomonoester hydrolysis needs the two metal ions to be close, while the phosphodiester hydrolysis needs a larger separation between the two metal ions. In contrast, in the present study, ligand **2** was found to have the highest activity toward the phosphodiester hydrolysis. Obviously, a shorter distance between the two metals was preferred for the hydrolysis of phosphodiester, considering the fact that ligand **1** cannot bind two metal ions. The findings of Chapman et al. and ourselves may not seem to be in agreement with each other at first sight. However, a cyclic amine/imine structure, whose behavior of metal-ion binding will be quite different from that of the di-2-pyridylmethylamino group, was employed for the metal binding sites in their study. Consequently, their results and ours cannot be compared directly.[9] These findings show that dinuclear complexes, which have a different metal-ion binding site structure, react with the substrates in a different manner. We would like to point out that a ligand whose structure corresponds to **2** has been successfully applied as a metal coordination site for the sequence-selective hydrolysis of RNA:[4i,10] Matsuda et al. introduced the Zn ion binding site at the 5′-end of a DNA oligomer that recognizes the targeted sequence of RNA. They found that the ligand structure of **2** hydrolyzes the phosphodiester bonds in RNA at the targeted position in highly efficient manner.[4i] Xu et al. reported the X-ray structure of the phosphodiesterase (PDE4) active site.[11] They pointed out that the distance between the two ions in the active site is around 3.9 Å, and suggested that the two metal ions constitute a dinuclear motif similar to that found in other enzymes that catalyze the hydrolysis or formation of a phosphate bond. Meanwhile, our MC simulations suggested that the distance between the two ions in the dinuclear complexes resulting from ligands **1**−**5** would increase in the order **1** < **2** < **4** ≤ **3** < < **5**. For all ligands, the two metal ions would be more than 4 Å apart. However, the titration experiments showed that ligand **1** cannot form the dinuclear complex. Considering these findings, the metal complex resulting from ligand **2** (**2**-Zn_2) is likely to bear the closest resemblance to the dinuclear motif observed in enzymes: the distance between the two metal ions in **2**-Zn_2 will probably be similar to that in the dinuclear motif in PDE4. Thus, it is reasonable that **2**-Zn_2 was found to be the most efficient catalyst for the hydrolysis of UpU among the metal complexes studied in the present work.

Conclusion

We examined the activities of the ligands **1**−**6** toward the hydrolysis of UpU in the presence of Zn ions. In agreement with the double metal-ion mechanism, ligands **2**, **3**, and **4** showed the highest activity under dinuclear complex forming conditions. Interestingly, although ligands **1**−**5** have two di-2-pyridylmethylamino moieties as Zn ion binding sites in common, the activities of these ligands toward the hydrolysis are quite different. Our results suggest that the difference in the k_{obs} value for ligands **2**−**5** under the dinuclear complex forming condition (condition A) should be almost proportional to the intrinsic activity of the dinuclear complexes toward the hydrolysis, which implies that the distance between the metal ion coordination sites will be an essential factor for the intrinsic activities of the dinuclear complexes.

Experimental Section

General: Silica gel TLC and column chromatography were performed using Merck Kieselgel 60F-254 and Wakogel C-200, respectively. All NMR spectra were recorded with a Varian Gemini-300BB spectrometer. ^1H spectra were referenced to the TMS peak, and ^{13}C spectra were referenced to the $CDCl_3$ peak. IR spectra were recorded with a Jasco FT/IR-5300 instrument. Mass spectra were recorded with a Hitachi N80E instrument. HPLC purity analysis of the ligands was carried out using Luna-Si column (Phenomenex, 4.6 × 150 mm, 3 μm) using $CHCl_3$/MeOH (1:1, v/v) as an eluent. Figure 5-I in the Supporting Information shows the HPLC profiles of the free ligands. Over 99% purity was guaranteed for all ligands in the analysis.

Preparation of the Ligands: Ligand **1** was prepared by *N*-alkylation of *o*-xylylenediamine dihydrochloride,[12] in a modification of the procedure reported by Sato et al.[13] A solution of 2-(chloromethyl)-pyridinium hydrochloride (3.30 g, 20.12 mmol) and *o*-xylylenediamine dihydrochloride (1.05 g, 5.02 mmol) in water (12 mL) was added to aqueous NaOH solution (5.0 M, 12 mL). Then, hexadecyltrimethylammonium chloride (0.16 g, 0.50 mmol) and $CHCl_3$ (10 mL) were added successively to the solution. The resulting mixture was heated to reflux in $CHCl_3$ for 12 h with vigorous stirring. The precipitate was separated by filtration and the filtrate was extracted three times with $CHCl_3$ (20 mL portions). The organic layer was collected and dried over Na_2SO_4. After evaporation of the solvent, the residue was chromatographed on silica gel by elution with $CHCl_3$/MeOH (the content of MeOH was increased from 0 to 2%). The yield of the product was 44% (1.1 g).

***N*,*N*,*N*′,*N*′-Tetra-(2-pyridylmethyl)-*o*-xylylenediamine (1a):** IR(KBr): $\tilde{\nu}$ = 1591, 1570, 1473, 1433 (C=C, C=N), 1047 cm^{-1} (C−N). − ^1H NMR ($CDCl_3$): δ = 3.67 (s, 4 H, PhCH_2 × 2), 3.70 (s, 8 H, PyCH_2 × 4), 7.12−7.16 (m, 4 H, Ph), 7.18−7.65 (m, 12 H, Py^{3-5} × 4), 8.50−8.52 (m, 4 H, Py^6 × 4). − ^{13}C NMR ($CDCl_3$): δ = 55.87 (PhCH_2), 60.28 (PyCH_2), 121.97 (Py^3), 122.87 (Py^5), 126.96 ($Ph^{3\ or\ 4}$), 129.49 ($Ph^{4\ or\ 3}$), 136.52 (Py^4), 137.79 (Ph^1), 148.97 (Py^6), 159.77 (Py^2). − HRMS for $C_{32}H_{33}N_6$ $[M]^+$: calcd. 501.2767; found 501.2754.

Ligands **2**−**6** were prepared in yields of 80−95% by *N*-alkylation of 2,2′-dipyridylmethylamine with the corresponding arylmethyl-(di)bromides. A typical procedure is given for preparation of ligand

2: *m*-Xylylenedibromide (1.32 g, 5.00 mmol), di-2-pyridylmethylamine (2.00 g, 9.63 mmol), and *N*,*N*-diisopropylethylamine (1.30 g, 10.06 mmol) were dissolved in $CHCl_3$ (50 mL). After 4 h of stirring at room temperature, the resulting solution was washed once with water (25 mL) and dried over Na_2SO_4. The product was purified by silica gel chromatography with $CHCl_3$/MeOH (the content of MeOH was increased from 0 to 2%) as the eluent. The yield of the product was 95% (2.37 g).

Computational Methods: All MO calculations were carried out using SPARTAN 5.11.[14] The most stable conformers of **1**−**5b** were studied in a systematic conformer search: The dihedral angle in freely rotatable bonds (two Ar−CH_2 and two CH_2−NH_2) was varied in 120° steps in the initial structures. The structures of **1**−**5b** were then optimized in an AM1 Hamiltonian. Monte Carlo simulations were carried out using Macro Model 6.0.[15] Each structure in the simulation was optimized using the Amber* force field.[16] The effect of solvation was included in the simulations by implicit treatment of solvent water with the GB/SA model.[17]

Kinetic Analysis of the UpU Hydrolysis: Reaction conditions of the UpU hydrolysis: $[UpU]_0$ = 0.02 mM in 100 mM HEPES buffer (pH = 7.0), reaction temperature = 60 °C. The reaction was monitored by reverse-phase HPLC (Phenomenex, Luna 3μ C8(2), 4.6 × 150 mm, 3 μm. Conditions: a linear gradient of 1−9% MeCN in 0.1 M aqueous $AcONH_4$ (pH = 7.0) in 8 min. at a flow of 1.0 mL·min^{-1} at 50 °C). The eluent was monitored at 258 nm by a SOMA S-310A UV/Vis detector. The pseudo-first order reaction rate constants (k_{obs}) were obtained as slopes of ln($[UpU]_0$/[UpU]) vs. time, where $[UpU]_0$ is the initial concentration of the substrate. The pseudo-first order reaction profile and its reproducibility are shown in the Supporting Information (Section 4).

Nanoscopic Metal Particles − Synthetic Methods and Potential Applications

Helmut Bönnemann*[a] and Ryan M. Richards[a]

Keywords: Nanoparticles / Catalysis / Colloids / Fuel cells

Mono- and bimetallic colloidal particles have gained increasing attention in science and application throughout the last several years. In this contribution, we present a synopsis of the wet chemical syntheses of these materials and survey potential applications in catalysis and materials science. Methods for the characterization of these particles and their surfaces are not reviewed here.

Introduction

Colloidal metals − originally called gold sols − first generated interest because of their intense colors, which enabled them to be used as pigments for glass or ceramics. Nanoparticulate metal colloids are generally defined as isolable particles between 1 and 50 nm in size that are prevented from agglomerating by protecting shells. They can be redispersed in water ("hydrosols") or organic solvents ("organosols"). The number of potential applications of these colloidal particles is growing rapidly because of the unique electronic structure of the nanosized metal particles and their extremely large surface areas. A considerable body of knowledge has been accumulated on these materials over the last few decades.[1−12] Highly dispersed mono- and bimetallic colloids can be used as precursors for a new type of catalyst that is applicable both in the homogeneous and heterogeneous phases.[13−16] Besides the obvious applications in chemical catalysis, recent studies have examined the potential of nanostructured metal colloids as fuel cell catalysts.[17−20]

Wet Chemical Preparations

Nanostructured metal colloids have been obtained by so-called "top-down methods", e.g. by the mechanical grinding of bulk metals and subsequent stabilization of the resulting nanosized metal particles by the addition of colloidal protecting agents.[21−22] Metal vapor techniques have provided chemists with a very versatile route for the production of a wide range of nanostructured metal colloids on a preparative laboratory scale.[23−28] The use of metal vapor techniques is, however, limited because the operation of the apparatus is demanding and it is difficult to obtain narrow particle size distributions. The "bottom-up methods" of wet chemical nanoparticle preparation rely on the chemical reduction of metal salts, electrochemical pathways, or the controlled decomposition of metastable organometallic compounds. A large variety of stabilizers, e.g. donor ligands, polymers, and surfactants, are used to control the growth of the initially formed nanoclusters and to

Prof. Dr. H. Bönnemann was born in 1939. He studied chemistry at the RWTH Aachen and began his graduate work in Mülheim in 1964 under the supervision of Nobel Laureate Prof. Karl Ziegler. He obtained his doctorate in 1967 in Aachen. In 1974, he was appointed lecturer at Aachen and obtained his Habilitation in Industrial Chemistry in 1976. After two years of industrial experience in the central research laboratories of Degussa (1978/79), he became Professor of Industrial Chemistry at the RWTH Aachen in 1981. He is currently the leader of a research group at the Max-Planck-Institute for Coal Research (Department of Heterogeneous Catalysis) in Mülheim an der Ruhr, Germany. His research fields include novel nanostructured materials, fuel cell catalysts, and organized nanometal−organic hybrid structures.

Ryan M. Richards obtained his B.Sc. degree from Michigan State University in 1994. He then obtained a Master's degree from Central Michigan University working with organometallic compounds in the laboratory of Bob Howell. From 1996 to 2000, he worked in the laboratory of Kenneth Klabunde at Kansas State University, where he conducted research on metal oxide nanoparticles. During his Ph.D. research, he spent six months as an invited scientist at the Boreskov Institute of Catalysis in Novosibirsk, Russia. After completing his Ph.D. work, he joined the research group of Helmut Bönnemann as a postdoctoral researcher at the Max-Planck-Institute für Kohlenforschung in Mülheim an der Ruhr, Germany. His research interests are nanostructured materials, fuel cell catalysts, nanoparticle−polymer hybrids.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

prevent them from agglomeration. The chemical reduction of transition metal salts in the presence of stabilizing agents to generate zerovalent metal colloids in aqueous or organic media was first published in 1857 by Faraday[29] and this approach has become one of the most common and powerful synthetic methods in this field.[10,11,30] The first reproducible standard protocols for the preparation of metal colloids (e.g., for 20 nm gold by reduction of $[AuCl_4]^-$ with sodium citrate) were established by Turkevich.[1−3] He also proposed a mechanism for the stepwise formation of nanoclusters based on nucleation, growth, and agglomeration, which in essence is still valid. Data from modern analytical techniques and more recent thermodynamic and kinetic results have been used to refine this model, as illustrated in Figure 1.[31−36]

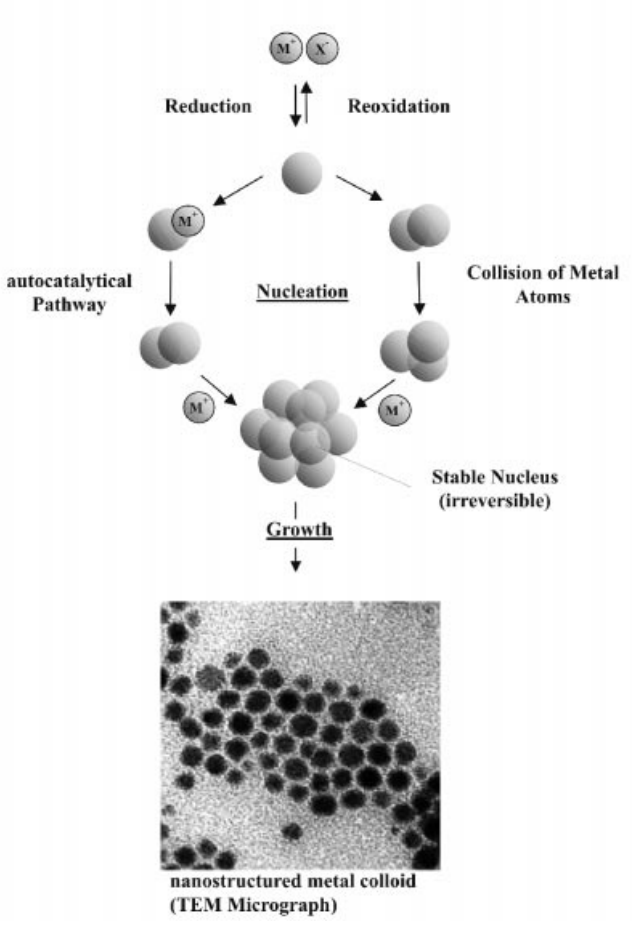

Figure 1. Formation of nanostructured metal colloids by the "salt reduction" method (adapted with permission from ref.[135])

In the embryonic stage of the nucleation, the metal salt is reduced to give zerovalent metal atoms.[31] These can collide in solution with further metal ions, metal atoms, or clusters to form an irreversible "seed" of stable metal nuclei. The diameter of the "seed" nuclei can be well below 1 nm depending on the strength of the metal−metal bonds and the difference between the redox potentials of the metal salt and the reducing agent applied.

Protective agents are necessary to stabilize nanostructured colloidal metals and to prevent agglomeration. Two basic modes of stabilization have been distinguished (Figure 2).[30]

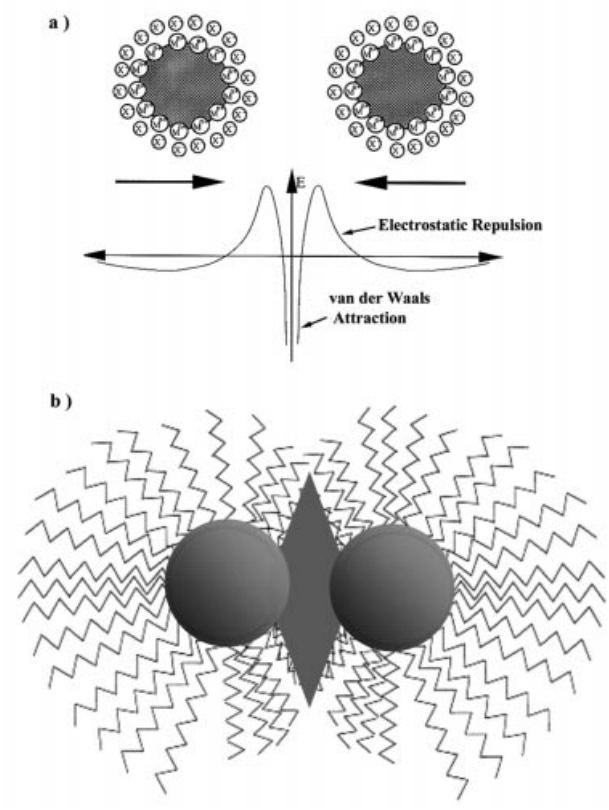

Figure 2. a) Electrostatic stabilization of nanostructured metal colloids (scheme adapted with permission from ref.[30]); b) steric stabilization of nanostructured metal colloids (scheme adapted with permission from ref.[30])

Electrostatic stabilization [see Figure 2, a)] is based on the Coulombic repulsion between the particles caused by the electrical double layer formed by ions adsorbed at the particle surface (e.g. sodium citrate) and the corresponding counterions. This is exemplified by the gold sols prepared by the reduction of $[AuCl_4]^-$ with sodium citrate.[1−3]

Steric stabilization [Figure 2, b)] is achieved by the coordination of sterically demanding organic molecules that act as protective shields on the metallic surface. In this way, nanometallic cores are separated from each other and agglomeration is prevented. The main classes of protective groups selected from the literature are: polymers[37−40] and block copolymers; P, N, and S donors (e.g. phosphanes, amines, thioethers);[6,57−82] solvents such as THF,[6,83] THF/MeOH,[84] and propylene carbonate;[85] long-chain alcohols;[41−56,86] surfactants;[6,7,9,15,16,85,87−98] and organometallics.[99−102] In general, lipophilic protective agents give metal colloids that are soluble in organic media ("organosols"), while hydrophilic agents yield water-soluble colloids ("hydrosols"). In Pd organosols, stabilized by tetra-

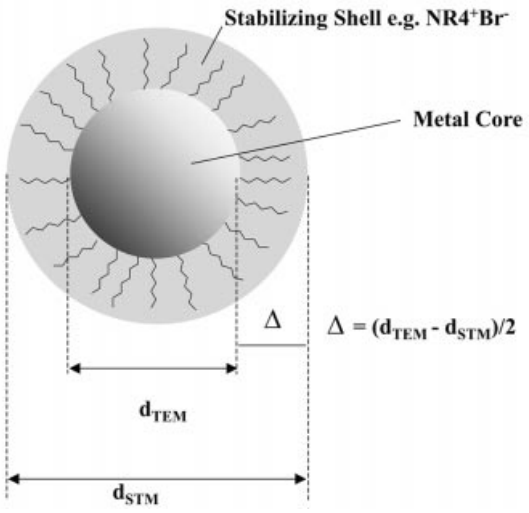

Figure 3. Differential TEM/STEM study of a Pd organosol showing that the metal core (size = d_{TEM}) is surrounded by a monolayer of the surfactant [thickness $\Delta = (d_{TEM} - d_{STM})_2$] (adapted with permission from ref.[103])

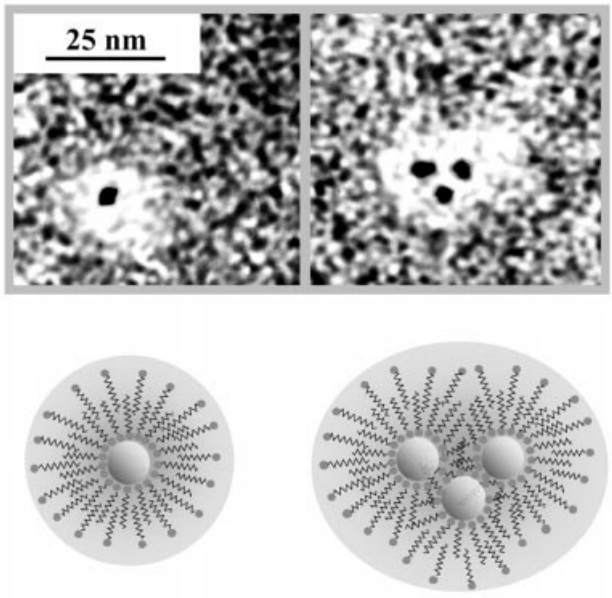

Figure 4. Top: TEM micrographs of colloidal Pt particles (single and aggregated; average core size = 2.8 nm) stabilized by carboxybetaine 12 (3−5 nm, contrasted with uranyl acetate against the carbon substrate); bottom: schematic model of the hydrosol stabilization by a double layer of the zwitterionic carboxybetaine 12 (ΛΛΛ = lipophilic alkyl chain; −o = hydrophilic, zwitterionic head group) (adapted from ref.[104])

alkylammonium halides, the metal core is protected by a monolayer of the surfactant coating (Figure 3).[103]

In contrast, metal hydrosols that are stabilized by zwitterionic surfactants capable of self-aggregation are enclosed in organic double layers. After the application of uranyl acetate as a contrasting agent, TEM micrographs show that the colloidal Pt particles (average size 2.8 nm) are surrounded by a double layer zone of the zwitterionic carboxybetaine (3−5 nm). The hydrophilic head group of the betaine interacts with the charged metal surface and the lipophilic tail is associated with the tail of a second surfactant molecule resulting in the formation a hydrophilic outer sphere (see Figure 4).[104] Pt or Pt/Au particles have been hosted in the hydrophobic holes of non-ionic surfactants, e.g. polyethylene monolaurate.[105,106]

Reducing Agents

It has been experimentally verified in the case of silver[31] that stronger reducing agents produce smaller nuclei in the "seed". These nuclei grow during the "ripening" process to yield colloidal metal particles in the size range 1−50 nm, which have a narrow size distribution. The mechanism of particle formation was assumed to involve an agglomeration of zerovalent nuclei in the "seed" or, alternatively, collisions of already formed nuclei with reduced metal atoms. Henglein[32] has monitored the stepwise reductive formation of Ag_3^+ and Ag_4^+ clusters by spectroscopic methods. His results strongly suggest that an autocatalytic pathway is involved, in which metal ions are adsorbed and successively reduced at the zerovalent cluster surface. The formation of colloidal Cu protected by cationic surfactants (NR_4^+) was investigated by in situ X-ray absorption spectroscopy, which revealed the formation of an intermediate Cu^+ state prior to nucleation of the particles.[35] It is now generally accepted that the size of the resulting metal colloid is determined by the relative rates of nucleation and particle growth, although the processes involved in nucleation and particle growth cannot be analyzed separately.

The main advantages of the salt reduction method in the liquid phase are that it is reproducible and allows colloidal nanoparticles with a narrow size distribution to be prepared on a multigram scale. The classical Faraday route, as in the reduction of $[AuCl_4]^-$ with sodium citrate for example, is still used to prepare standard 20 nm gold sols for histological staining applications.[1,107] Wet chemical reduction procedures have been applied in the last decades to successfully combine practically all transition metals with the different types of stabilizers and the whole range of chemical reducing agents. In 1981, Schmid et al. established the "diborane-as-reductant route" for the synthesis of $Au_{55}(PPh_3)_{12}Cl_6$ (1.4 nm), a full shell ("magic number") nanocluster stabilized by phosphane ligands.[57−71] Clusters of Au_{55} are uniformly formed when a stream of B_2H_6 is carefully introduced into an Au^{III} ion solution. The "diborane route" for $M_{55}L_{12}Cl_n$ nanoclusters was recently reviewed by Finke et al.[11] Bimetallic nanoclusters made accessible by this method[57−71] have been thoroughly characterized. Using silsesquioxanes, the phosphane ligands may be quantitatively exchanged in the Au_{55} nanoclusters, which causes marked changes in the physical and chemical behavior of these clusters.[71] The synthesis and general chemistry of nanosized silica-coated metal particles has been elaborated by Mulvaney.[72] The "alcohol reduction process" of Hirai and Toshima[10,37−40,323,324] is widely applicable for the preparation of colloidal precious metals stabilized by organic polymers such as poly(vinylpyrrolidone) (PVP), poly(vinyl alcohol) (PVA), and poly(methylvinyl

ether). Alcohols having α-hydrogen atoms are oxidized to the corresponding carbonyl compound (e.g. methanol to formaldehyde) during the salt reduction. The method for preparing bimetallic nanoparticles by the co-reduction of mixed ions has been evaluated in a recent review.[10] Hydrogen is an efficient reducing agent for the preparation of electrostatically stabilized metal sols and of polymer-stabilized hydrosols of Pd, Pt, Rh, and Ir.[108−112] Moiseev's "giant" palladium cluster [Figure 5, a)][73−78] and Finke's polyoxoanion- and tetrabutylammonium-stabilized transition metal nanoclusters [Figure 5, b)][11,34,113−117] were also prepared by the hydrogen reduction pathway.

The characterization of Moiseev's giant cationic palladium clusters[73−78] [Figure 5, a)] [idealized formula $Pd_{\approx 561}L_{\approx 60}(OAc)_{\approx 180}$ (L = phenanthroline, bipyridine)] and their catalytic properties have recently been reviewed by Finke et al.[11] The results of a combination of modern instrumental analysis methods applied to Finke's nanoclusters were discussed in detail in the same review.[11]

Colloidal Pt in water[2,118] was obtained using CO, formic acid, sodium formate, formaldehyde, and benzaldehyde as reductants.[119] Silanes have been found to be effective for the reductive preparation of Pt sols.[120,121] Duff, Johnson, and Baiker have successfully introduced tetrakis(hydroxymethyl)phosphonium chloride (THPC) as a reducing agent that allows the size- and morphology-selective synthesis of Ag, Cu, Pt, and Au nanoparticles from the corresponding metal salts.[122−127] Furthermore, hydrazine,[128] hydroxylamine,[129] and electrons trapped in, for example, $K^+[(crown)_2K]^-$,[130] have been applied as reductants. In addition, BH_4^- is a powerful and valuable reagent for the salt reduction method. However, a disadvantage is that transition metal borides are often found alongside the nanometallic particles.[131,132] Tetraalkylammonium hydrotriorganoborates[6,7,9,15,87−89] offer a wide range of applications in the wet chemical reduction of transition metal salts. In this case, the reductant $[BEt_3H]^-$ is combined with the stabilizing agent (e.g. NR_4^+). The surface-active NR_4^+ salts are formed immediately at the reduction center in high local concentration and prevent particle aggregation. Trialkylboron is recovered unchanged from the reaction mixture and no borides contaminate the products.

$$MX_\nu + NR_4(BEt_3H) \longrightarrow M_{colloid} + \nu\ NR_4X + \nu\ BEt_3 + \nu/2\ H_2\uparrow \quad (1)$$

M = metals of groups 6–11; X = Cl, Br; ν = 1–3; R = alkyl, C_6–C_{20}

As synthesized, the NR_4^+-stabilized "raw" metal colloids typically contain 6−12 wt-% of metal. "Purified" transition metal colloids containing ca. 70−85 wt-% of metal are obtained by work-up with ethanol or diethyl ether and subsequent reprecipitation from a solvent of different polarity (see Table 9 in ref.[6]). The pre-preparation of $[NR_4]^+[BEt_3H]^-$ can be avoided if NR_4X is coupled to the metal salt prior to the reduction step. Transition metal nanoparticles stabilized by NR_4^+ can also be obtained from NR_4X/transition metal double salts. A number of conventional reducing agents may be applied since the local concentration of the protecting group is sufficiently high for Equation (2) to hold.[7,15]

Table 1. THF-stabilized organosols of early transition metals

Product	Starting material	Reducing agent	T [°C]	t [h]	Metal content [%]	Size [nm]
[Ti·0.5THF]	$TiBr_4$·2THF	$K[BEt_3H]$	room temp.	6	43.5	(< 0.8)
[Zr·0.4THF]	$ZrBr_4$·2THF	$K[BEt_3H]$	room temp.	6	42	–
[V·0.3THF]	VBr_3·3THF	$K[BEt_3H]$	room temp.	2	51	–
[Nb·0.3THF]	$NbCl_4$·2THF	$K[BEt_3H]$	room temp.	4	48	–
[Mn·0.3THF]	$MnBr_2$·2THF	$K[BEt_3H]$	50	3	70	1–2.5

In a recent review,[11] the scope and limitations of this method were evaluated. Isolable colloids of the zerovalent early transition metals stabilized only by THF have been prepared by $[BEt_3H]^-$ reduction of the preformed THF adducts of $TiBr_4$ [Equation (3)], $ZrBr_4$, VBr_3, $NbCl_4$, and $MnBr_2$. Table 1 summarizes the results. Detailed studies of [Ti·0.5 THF][83] have shown that it consists of Ti_{13} clusters in the zerovalent state, stabilized by six intact THF molecules (Figure 6).

$$x\,[TiBr_4 \cdot 2\,THF + x{\cdot}4\,K[BEt_3H] \xrightarrow{THF,\ 2\ h,\ 20\ °C} [Ti \cdot 0.5\,THF]_x + x{\cdot}4\,BEt_3 + x{\cdot}4\,KBr\downarrow + x{\cdot}4\,H_2\uparrow \quad (3)$$

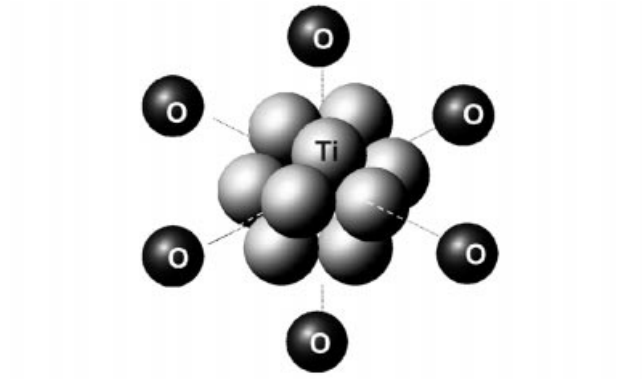

Figure 6. Ti_{13} cluster stabilized by six THF O atoms in an octahedral configuration

By analogy, [Mn·0.3THF] particles (1–2.5 nm) have been prepared[133] and their physical properties have been studied.[134] The THF in Equation (3) has been successfully replaced by tetrahydrothiophene (THT) in the case of Mn, Pd, and Pt organosols, but attempts to stabilize Ti and V in this way led to decomposition (Figure 7).[15] Figure 8 gives a survey of the $[BEt_3H]^-$ method.

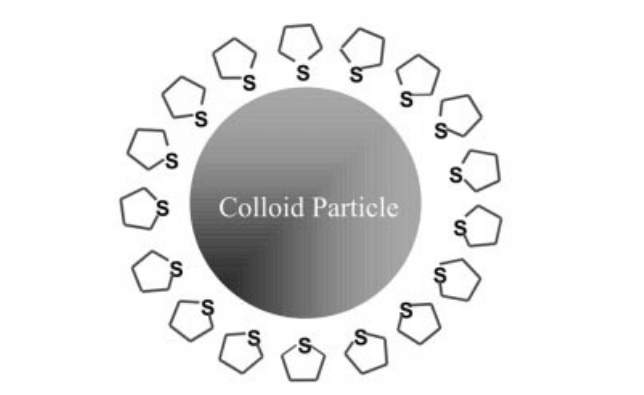

Figure 7. Organosols stabilized by tetrahydrothiophene; M = Ti, V (decomposition); M = Mn, Pd, Pt; stable colloids

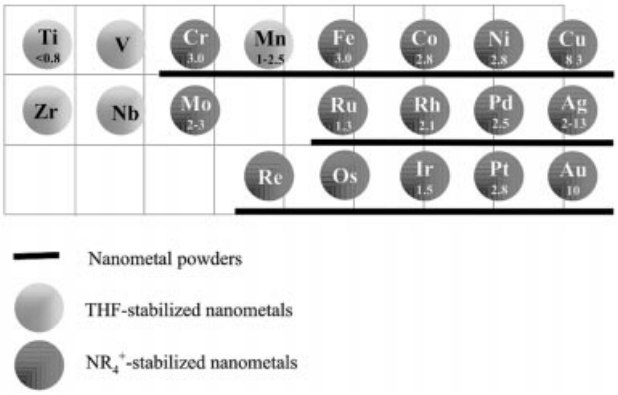

Figure 8. Nanopowders and nanostructured metal colloids accessible by the $[BEt_3H]^-$ reduction method (including the mean particle sizes obtained) (adapted with permission from ref.[7])

The advantages of the method (Figure 8) may be summarized as follows:

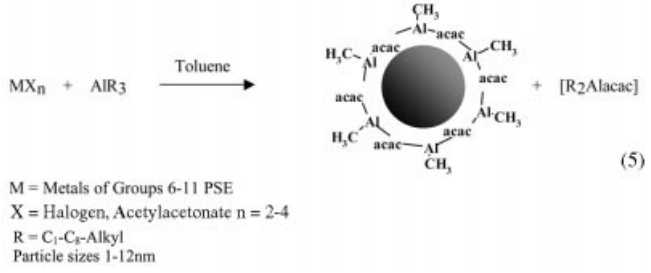
– The method is generally applicable to salts of metals of Groups 4–11 in the Periodic Table.
– It yields extraordinarily stable metal colloids that are easy to isolate as dry powders.
– The particle size distribution is nearly monodisperse.
– Bimetallic colloids are easily accessible by co-reduction of two different metal salts.
– The synthesis is suitable for multigram preparations and is easy to scale up.

One of the drawbacks of this method is that the particle size of the resulting sols cannot be varied by altering the reaction conditions. Highly water-soluble hydrosols, particularly those of zerovalent precious metals, were made accessible by using betaines instead of NR_4^+ salts as the protecting group in Equation (1). A wide variety of hydrophilic surfactants may be used in Equation (2).[7,15,88] Reetz and Maase have reported a new method for the size- and morphology-selective preparation of metal colloids using tetraalkylammonium carboxylates of the type $NR_4^+R'CO_2^-$ (R = octyl; R′ = alkyl, aryl, H) as both the reducing agent and the stabilizer [Equation (4)].[135–137,325]

$$M^+ + R_4N^+\ R'CO_2^- \xrightarrow{50\text{–}90\ ^\circ C} M^0(R_4NR'CO_2)_x + CO_2 + R'\text{–}R' \quad (4)$$

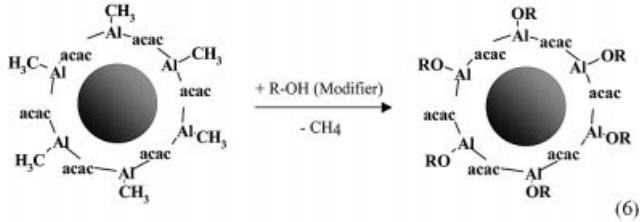
R = octyl, R' = alkyl, aryl, H

The resulting particle sizes were found to correlate with the electronic nature of the R′ group in the carboxylate. Electron donors produced small nanoclusters, whereas electron-withdrawing substituents R′ yielded larger particles. For example, Pd particles of size 2.2 nm were formed when $Pd(NO_3)_2$ was treated with an excess of tetra(*n*-octyl)ammonium carboxylate bearing R′ = $(CH_3)_3CCO_2^-$ (an electron-donating group) as the substituent. With R′ = $Cl_2CHCO_2^-$ (an electron-withdrawing substituent), the particle size was found to be 5.4 nm. Bimetallic colloids of the following were obtained with tetra(*n*-octyl)ammonium formate as the reductant: Pd/Pt (2.2 nm), Pd/Sn (4.4 nm), Pd/Au (3.3 nm), Pd/Rh (1.8 nm), Pt/Ru (1.7 nm), and Pd/Cu (2.2 nm). The shape of the particles was also found to depend on the reductant: With tetra(*n*-octyl)ammonium glycolate and $Pd(NO_3)_2$, a significant amount of trigonal particles was detected in the resulting Pd colloid. Organoaluminum compounds have been used for the "reductive stabilization" of mono- and bimetallic nanoparticles [see Equation (5) and Table 2].[99,100]



According to Equation (5), colloids of zerovalent elements of Groups 6−11 of the Periodic Table (and also of tin) may be prepared in the form of stable, isolable organosols. Available analytical data suggest that a layer of condensed organoaluminum species protects the transition metal core against aggregation, as depicted in Equation (5). However, the exact "backbone" of the colloidal organoaluminum protecting agent has not yet been completely established.

Unreacted organoaluminum groups (e.g. $Al-CH_3$, $Al-C_2H_5$) from the starting material are still present in the stabilizer and have been detected by quantitative protonolysis experiments. These active Al−C bonds have been used for a controlled protonolysis by long-chain alcohols or organic acids ("modifiers") to give Al−alkoxide groups in the stabilizer [Equation (6)].



Modifiers: alcohols, carbonic acids, silanols, sugars, polyalcohols, polyvinylpyrrolidone, surfactants, silica, alumina, etc. (32).

This "modification", Equation (6), of the organoaluminum protecting shell can be used to tailor the dispersion characteristics of the original organosols. A vast spectrum of solubilities of the colloidal metals in hydrophobic and

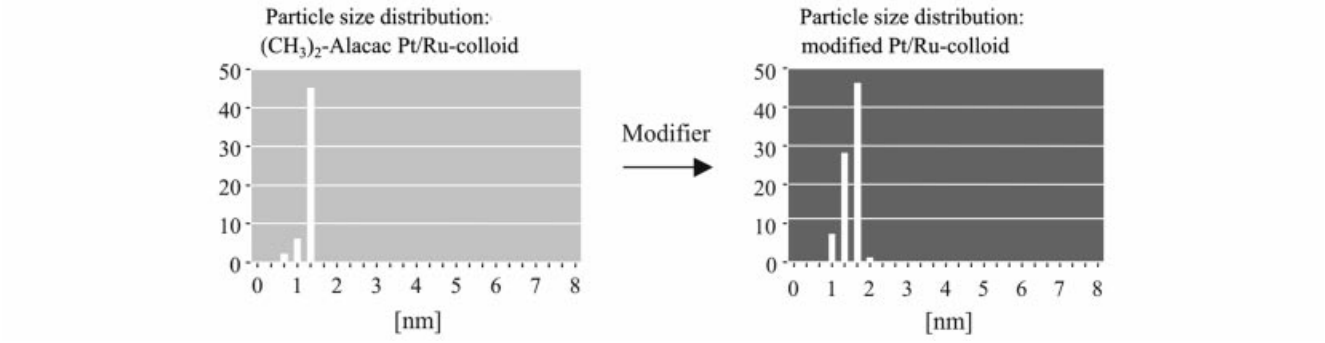

Figure 9. Size conservation of colloidal Pt/Ru particles under the hydrophilic modification of the $(CH_3)_nAl-acac$ protecting shell using polyethylene glycol/dodecyl ether

hydrophilic media (including water) has been achieved in this way. Inorganic surfaces bearing OH groups can react with the active Al−C bonds in the colloidal protecting shell, opening new possibilities for the preparation of heterogeneous catalysts. The modification process does not substantially alter the particle size of the metal core (see Figure 9).[101]

Electrochemical Synthesis

This very versatile means of preparing nanostructured mono- and bimetallic colloids has been further developed by Reetz and his group since 1994.[8,90,91] The overall process of electrochemical synthesis, Equation (7), can be divided into six elementary steps (see Figure 10).

1. Oxidative dissolution of the sacrificial M_{bulk} anode.
2. Migration of M^{n+} ions to the cathode.
3. Reductive formation of zerovalent metal atoms at the cathode.
4. Formation of metal particles by nucleation and growth.
5. Arrest of the growth process and stabilization of the particles by colloidal protecting agents, e.g., tetraalkylammonium ions.
6. Precipitation of the nanostructured metal colloids.

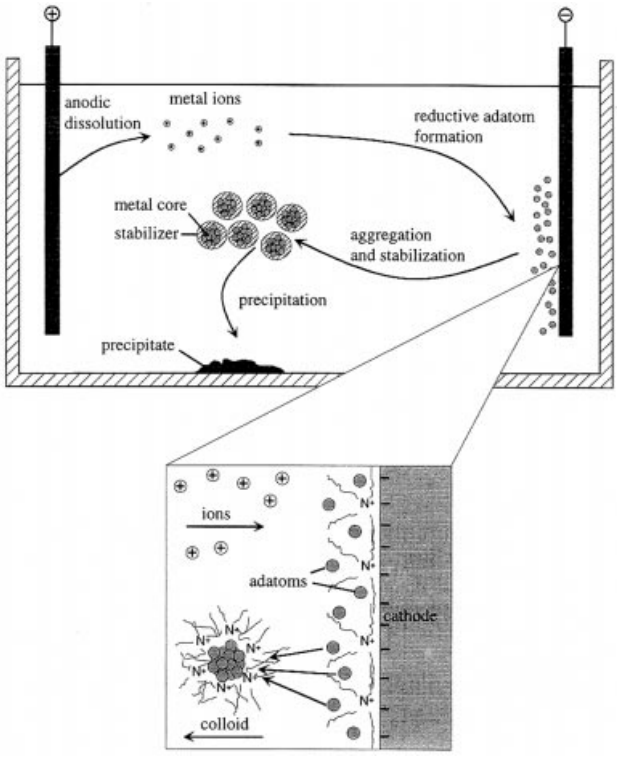

Figure 10. Electrochemical formation of $NR_4^+Cl^-$-stabilized nanometal (adapted with permission from ref.[8])

$$\begin{array}{lllll} \text{Anode:} & & M_{bulk} & \rightarrow & M^{n+} + n\,e^- \\ \text{Cathode:} & M^{n+} + n\,e^- + & \text{stabilizer} & \rightarrow & M_{coll}/\text{stabilizer} \\ \hline \text{Sum:} & M_{bulk} + & \text{stabilizer} & \rightarrow & M_{coll}/\text{stabilizer} \end{array} \quad (7)$$

Advantages of the electrochemical pathway are that contamination with by-products resulting from chemical reducing agents are avoided and that the products are easily isolated from the precipitate. Further, the electrochemical preparation allows for size-selective particle formation. Experiments using Pd as the sacrificial anode in the electrochemical cell to give $(C_8H_{17})_4N^+Br^-$-stabilized Pd^0 particles have indicated that the particle size depends on the current density applied: high current densities lead to small Pd particles (1.4 nm), whereas low current densities give larger particles (4.8 nm).[90] As was seen from a careful analysis of tetraalkylammonium-stabilized Pd and Ni by means of a combination of TEM and SAXS, the control of particle size does not have a single cause. It can be brought about by adjusting the following parameters:

– the distance between the electrodes,
– the reaction time and temperature,
– the polarity of the solvent.

Nearly monodisperse Pd^0 particles with sizes of 1–6 nm can be obtained by means of electrochemical synthesis. It was also shown that the size of NR_4^+-stabilized Ni^0 particles[92] can be adjusted at will. The electrochemical method[90–97] [Equation (7)] has been successfully applied in the preparation of a number of monometallic organosols and hydrosols, e.g. of Pd, Ni, Co, Fe, Ti, Ag, and Au, on a scale of several hundred milligrams (yields > 95%). Using the electrochemical pathway, solvent-stabilized (propylene carbonate) palladium particles (8–10 nm) have also been obtained.[85] Bimetallic nanocolloids (Pd/Ni, Fe/Co, Fe/Ni) are accessible[95] if two sacrificial M_{bulk} anodes are used in a single electrolysis cell. In the case of Pt, Rh, Ru, and Mo, which are anodically less readily soluble, the corresponding metal salts were electrochemically reduced at the cathode (see bottom part of Figure 10 and Table 3). Tetraalkylammonium acetate has been used as both the supporting electrolyte and the stabilizer in a Kolbe electrolysis at an anode [see Equation (8)].[96] By combining the electrochemical methods described in Equation (7) and Equation (8), bimetallic nanocolloids can be prepared (see Table 4).[96]

$$\begin{aligned} &\text{Cathode:} \quad Pt^{2+} + 2\,e^- \longrightarrow Pt^0 \\ &\text{Anode:} \quad 2\,CH_3CO_2^- \longrightarrow 2\,CH_3CO_2 + 2\,e^- \end{aligned} \tag{8}$$

By modifying the electrochemical method, the synthesis of layered bimetallic nanocolloids (e.g. of Pt/Pd) has been achieved.[92,97] A preformed $(Oct)_4NBr$-stabilized Pt colloid core (size 3.8 nm) was electrolyzed in 0.1 M $(Oct)_4NBr$ solution in THF with Pd as the sacrificial anode (Figure 11). The preformed Pt core may be regarded as a "living-metal-polymer", on which the Pd atoms are deposited to give "onion-type" bimetallic nanoparticles (5 nm).

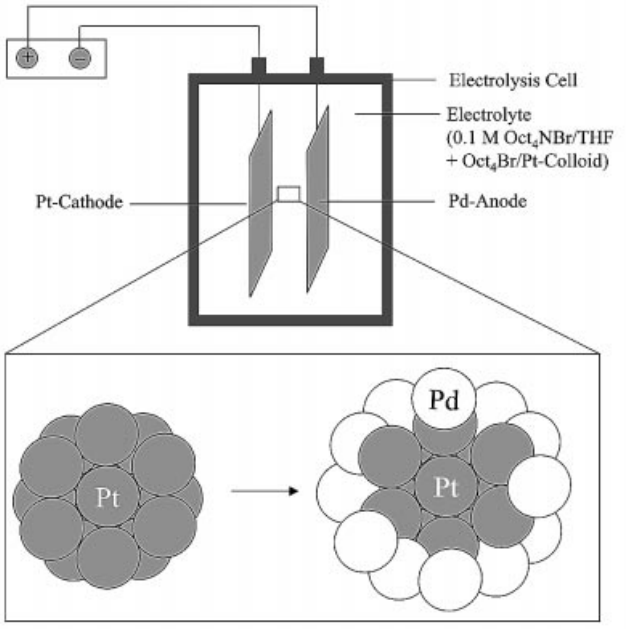

Figure 11. Modified electrolysis cell for the preparation of layered bimetallic Pt/Pd nanocolloids (adapted with permission from ref.[92])

Decomposition of Low-Valent Transition Metal Complexes

Low-valent organometallic complexes and several organic derivatives of the transition metals decompose under the action of heat, light, or ultrasound to give short-lived nucleation particles of zerovalent metals in solution, which may be stabilized by colloidal protecting agents. For example, thermolysis[138–143] leads to the rapid decomposition of carbonylcobalt complexes to give colloidal cobalt in organic solutions.[138,139] Thermolysis of labile precious metal salts in the absence of stabilizers yields colloidal Pd, Pt, and bimetallic Pd/Cu nanoparticles[140] with broad size distributions. These results were found to be greatly improved when the thermolysis was performed in the presence of stabilizing polymers, such as PVP.[141] Recently, heating in a simple household microwave oven has been proposed as a means of preparing nanosized metal particles and colloids.[142,143,326] The substrate is heated uniformly by the electromagnetic waves, leading to a more homogeneous nucleation and a shorter aggregation time. It is informative to compare the particle size of polymer-stabilized Pt colloids (spheres, 2–4 nm, narrow size distribution) prepared by dielectrical microwave heating with that of samples prepared by conventional heating under otherwise identical

Table 5. Comparison of conventional and microwave heating

No.[a]	PVP[b]	NaOH[b]	Average diameter [nm]	Standard deviation [nm]	Relative standard deviation
1	10	0	3.8	0.57	0.15

conditions (Table 5). Sonochemical decomposition methods have been successfully developed by Suslick[144] and Gedanken[145−147] and have yielded Fe, Mo_2C, Ni, Pd, and Ag nanoparticles in various stabilizing environments.

Isolable colloidal products can be prepared in multigram amounts by the controlled chemical decomposition of zero-valent transition metal complexes by the addition of CO or H_2 in the presence of appropriate stabilizers.[79−82,148−158] Bradley and Chaudret[79−82,149−155,327−333] have demonstrated the use of low-valent transition metal olefin complexes as a very clean source for the preparation of nanostructured mono- and bimetallic colloids. Nanoparticulate colloids have also been successfully prepared in micelles, inverse micelles, and by encapsulation.[32,33][86] Although beyond the focus of this article, we should also mention that a number of nanoparticulate metal oxide systems have been successfully developed.[7,157−162]

Particle Size Control

Metal colloid sols are generally described as "monodisperse" when the particle size deviates by less than 15% from the average value. Histograms with a standard deviation σ from the mean particle size of approximately 20% are described as showing a "narrow size distribution". The kinetics of the particle nucleation from atomic units and of the subsequent growth process cannot be directly observed by physical methods. In practice, the means available to the preparative chemist for controlling the particle size are size-selective separation[43,163,164] and size-selective synthesis.[41−56,90,135−137,165−181]

The so-called *size-selective precipitation* (SPP) method was predominantly developed by Pileni.[42,334] Monodisperse silver particles (2.3 nm, σ = 15%) are precipitated from a polydisperse silver colloid solution in hexane by adding pyridine in three iterative steps. Schmid has recently reported the two-dimensional "crystallization" of truly monodisperse Au_{55} clusters.[163] Schmid has also shown that the size of nanoparticles can be limited by steric restrictions imposed by a 3D polymer network.[335] Chromatographic separation methods proved unsuccessful because the colloid was decomposed after the colloidal protecting shell had been stripped off.[135] Colfen has developed the size-selective ultra-centrifuge separation of Pt colloids.[164] However, although this elegant separation method gives truly monodisperse metal colloids, as yet it can only provide milligram-scale samples. Turkevich was the first to describe size-selective colloid synthesis.[1,2] Using the salt reduction method, he was able to vary the particle size of colloidal Pd between 0.55 and 4.5 nm. The crucial parameters were the amount of reducing agent applied and the pH of the medium. According to the literature concerning the process of nucleation and particle growth, the essential factors that control the particle size are the strength of the metal−metal bond;[40] the molar ratio of metal salt; colloidal stabilizer; and reducing agent;[1,119,126,165−182] the extent of conversion or the reaction time;[119] the applied temperature;[1,166,178] and the pressure.[166] The preparation of nearly monodisperse nanostructured metal colloids using the salt reduction pathway is well documented in the literature. In practice, however, the "control", i.e. the variation of particle sizes (and shapes), in wet chemical colloid synthesis is left to the intuition of the chemist. Recently, Pileni has also demonstrated that control of particle size and composition can be achieved using oil-in-water micelles.[336] At present, the electrochemical synthesis of Reetz and co-workers offers the most rational method for selecting the particle size. Using variable current densities and making appropriate adjustments of further key parameters, these authors have been able to obtain at will almost monodisperse samples of colloidal Pd and Ni with sizes between 1 and 6 nm.[90−97] In the thermal decomposition method, the particle size obtained depends on the heat source (see Table 5).[143] Size control has also been reported for the sonochemical decompositon method and γ-radiolysis.[183,184]

The domain of preparation methods using constrained environments offers control over the metal particle shape

by predetermining the size and morphology of the products in nanoscale reaction chambers.[41−56] The controlled temperature-induced size and shape manipulation of 2−6 nm gold particles encapsulated in alkanethiolate monolayers[54] has recently been reported. The use of near-IR laser light has led to an enormous increase in the size of thiol-passivated gold particles up to ca. 200 nm.[54] A new medium-energy ion-scattering (MEIS) simulation program has successfully been applied in analyzing the composition and average particle size of Pt/Rh/α-Al_2O_3.[55]

Applications in Catalysis

"Quasi-Homogeneous" Reactions

Lipophilic or hydrophilic nanostructured metal colloids, dissolved in the form of organosols or hydrosols, can serve as catalysts in organic solutions and in the aqueous phase, respectively. Schmid[64] has referred to these quasi-homogeneous catalytic reactions, which involve solvated metal atom dispersions (SMAD),[26] as "heterogeneous catalysis in solution". Rhodium hydrosols, dissolved in water, were shown to be effective as hydrogenation catalysts in two-phase systems, where the olefin formed the organic phase.[185] Aqueous solutions of Moiseev's giant Pd colloids [Figure 5, a)][73−78] were shown to catalyze a number of reactions in the "quasi-homogeneous" phase, namely oxidative acetoxylation reactions,[73] the oxidative carbonylation of phenol to diphenyl carbonate,[186] the hydrogen-transfer reduction of multiple bonds by formic acid,[187] the reduction of nitriles and nitroarenes, and acetal formation,[188] all with high turnover frequencies and significant lifetimes (see ref.[11]). Remarkable catalytic lifetimes for polyoxoanion- and tetrabutylammonium-stabilized transition metal nanoclusters have been reported by Finke[113−117] (see Figure 5). For example, in the catalytic hydrogenation of cyclohexene, a common test for structure-insensitive reactions, the Ir^0 nanocluster[34] showed up to 18,000 total turnovers with turnover frequencies of 3200 h^{-1}.[189] Recently, as many as 190,000 turnovers were reported in the case of the Rh^0 analogue.[190] These results are quite unprecedented. Obviously, the polyoxoanion component prevents the precious metal nanoparticles from aggregating so that the active metals have high effective surface areas.[190] A recent review[7] compares this new approach with the catalytic properties of other nanometallic systems active in the "quasi-homogeneous" phase. When nanostructured Ti colloids (3 nm), stabilized by Bu_4NBr, were used, the formation of olefins from aldehydes and ketones through McMurry-type coupling reactions was observed.[191] THF-protected Ti_{13} nanoclusters[83] were found to hydrogenate Ti and Zr sponges in the "quasi-homogeneous" phase.[192,193] Using cinchonidine-stabilized Pt colloids, the enantioselective hydrogenation of ethyl pyruvate in HOAc/MeOH solution was performed.[177] Heck and Suzuki C−C bond coupling reactions were catalyzed by $NR_4^+X^-$-stabilized Pd and Pd/Ni colloids in dimethylacetamide. The same reactions have been observed using solvent-stabilized Pd particles in propylene carbonate as the catalyst.[85,194,195] Nanosized Pd colloids generated in situ by the reduction of Pd^{II} to Pd^0 are involved in the catalysis of phosphane-free Heck and Suzuki reactions.[196] Hexagonal or quasi-two-dimensional Pd nanoparticles (*hcp* structure, 53 nm) encapsulated in graphite have also been tested as catalysts for the Heck reaction. Microphotographs confirmed that the nanoparticles were located between the spacing layers of graphite. The catalyst is very stable: Although no strong interaction is present between the nanoparticles and the carbon lattice, the particles cannot be washed out and they are still found inside the carbon lattice after the Heck reaction.[197] The [3+2] cycloaddition of methylenecyclopropane to methyl acrylate is effectively catalyzed by nanostructured nickel colloids (2.5 nm) in solution.[198] The liquid-phase hydrogenation of isomeric undecenoic acids has been shown to be selectively catalyzed by Pt colloids encapsulated in polymerized micelles.[199] Metal colloids stabilized by amphiphilic block copolymers have been used as efficient catalysts in the "quasi-homogeneous" phase.[200−203] A generally applicable synthesis of metal colloids in microemulsions, in particular of nanostructured noble metals in amphiphilic block copolymers, has been devised by Antonietti and coworkers.[200][201] Micelles incorporating nanosized metals are very stable; they undergo no significant change of their colloidal properties such as size and polydispersity and are consequently effective hydrogenation catalysts. The morphology of the metal core can be varied between a "cherry"-type and a "raspberry"-type architecture depending on the strength of the reducing agent. Block copolymer stabilized Pd "raspberry" colloids have an extraordinarily high metal surface area and no additional support is needed for catalytic applications in solution. This type of colloid catalyst combines the advantages of homogeneous and heterogeneous catalysis, i.e. the high selectivity and reactivity of homogeneous hydrogenation catalysts is coupled with the long-term stability of heterogeneous systems. Nanostructured metal colloids, stabilized with synthetic polymers,[204−208] may be regarded as artificial enzyme models. The interaction between the "polymeric fields" and the reactive substrates determines the selectivity of the colloidal nanometal catalysts. Coordinating polymers such as poly(*N*-vinyl-2-pyrrolidone) have been shown to protect nanostructured mono- and bimetallic particles having an average diameter of ca. 1−3 nm and a narrow size distribution.[346−349] The resulting materials have proved to be effective catalysts for olefin hydrogenation,[205] nitrile hydration,[206] and photoinduced electron transfer.[207] The application of dendrimer-encapsulated Pd nanoparticles to fluorous phase soluble catalysts has recently been described.[208] The scope of ligand-stabilized transition metal nanoparticles in catalysis has recently been summarized by Schmid.[68,209]

Heterogeneous Reactions

Heterogeneous catalysts are obtained by depositing preprepared nanometal colloids on supports.[2] On this basis, the so-called "precursor concept" for the manufacture of

heterogeneous metal colloid catalysts was developed in the 1990s.[6,7,9,15,87−89] As a result, so-called *egg shell* catalysts were obtained, which contain the active metal particles as a thin layer (< 250 nm) on the surface of the support. Metal colloid catalysts of this type have been successfully applied in the hydrogenation of C−C double bonds, organic carbonyl groups, unsaturated C−N bonds, and in the reduction of N−O bonds.[210] An obvious advantage of the precursor concept over the conventional salt-impregnation method is that both the size and the composition of the colloidal metal precursors may be tailored independently of the support. Furthermore, the metal particle surface may be modified by lipophilic or hydrophilic protective shells and coated by intermediate layers, e.g., of oxide. The modification of the precursor by dopants is also possible. Such catalysts are manufactured by dipping the supports into organic or aqueous media containing the dispersed precursor at ambient temperature to adsorb the pre-prepared particles. This has been demonstrated for supports such as charcoal, various oxidic support materials, and even low-surface-area materials such as sapphire, quartz, and highly oriented pyrolitic graphite (HOPG), for which no subsequent calcination is required (see Figure 12). Researchers at Degussa have demonstrated the feasibility of preparing catalysts for industrial purposes in this way.

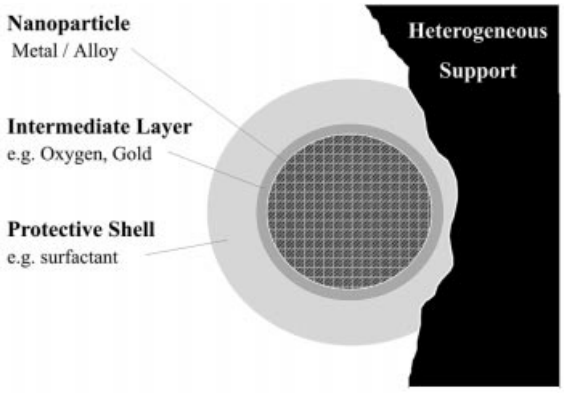

Figure 12. The precursor concept (adapted from ref.[7])

A combination of AFM, STM, and XPS[185] has been used to probe the interaction of platinum hydrosols with oxide (sapphire, quartz) and graphite single-crystal substrates (Figure 13). When dipped into aqueous Pt colloid solutions at 20 °C, the metal core is immediately adsorbed onto the support surface. The carpet-like coating formed over the particles by the protecting shell and the support surface cannot be removed from the particle surface even by repeated washing with solvents. The organic protecting shell decomposes on annealing at 280 °C and above in UHV. By monitoring the thermal degradation up to 800 °C by XPS and STM, it was shown that the Pt particles remain virtually unchanged up to ca. 800 °C, above which sintering processes take place.

Top: AFM investigation of a sulfobetaine-12 stabilized Pt hydrosol (3 nm) absorbed on highly oriented pyrolytic graphite (HOPG) after dipping (left) and after additional washing (right); bottom: scheme of the Pt hydrosol adsorbtion on HOPG derived from a combined STM and XPS study (ref.[212])

Reetz et al. have used $(octyl)_4NBr$-stabilized Pd colloids (of typical size 3 nm) as precursors of so-called "*cortex catalysts*", where the active metal forms an extremely fine shell less than 10 nm thick on the support (e.g. Al_2O_3).[213] The impregnation of Al_2O_3 pellets by dispersed nanostructured metal colloids occurs with a time-dependent penetration of the support over the first 1−4 s, and is complete after 10 s [see Figure 14, a)−c)].

"*Cortex catalysts*" were reported to exhibit a threefold higher activity in olefin hydrogenation than conventionally prepared catalysts of the same metal loading (5% Pd on Al_2O_3). Schmid[64] has described phosphane-stabilized Rh_{55} nanoclusters, namely $Rh_{55}[P(t\text{Bu})_3]_{12}Cl_{20}$ and $Rh_{55}(PPh_3)_{12}Cl_{20}$, which were deposited on TiO_2. These systems were reported to catalyze the heterogeneous hydroformylation of propene with high turnover numbers giving equal amounts of *n*- and *iso*-butanal. Although the observed turnover frequencies were higher than those seen with homogeneous complex catalysts, the selectivity was found to be too low for practical applications. In the butyronitrile hydrogenation test, the activity of surfactant-stabilized colloidal rhodium (5 wt-% on charcoal) was found to surpass that of conventional salt impregnation catalysts

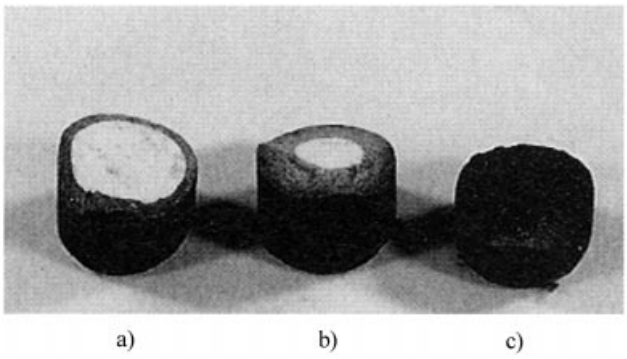

Figure 14. Heterogeneous Pd colloid catalysts of the *cortex*-type (adapted with permission from ref.[213]): a) Al_2O_3 pellets (3.2 mm) after penetration with a 0.5 M solution of $(octyl)_4NBr$-stabilized colloidal Pd in THF for 1 s, b) for 4 s, c) for 10 s

of the same metal loading. The addition of 0.2% colloidal Ti^0 to the supported noble metal[83] resulted in a significant enhancement of the activity (see Figure 15).[7]

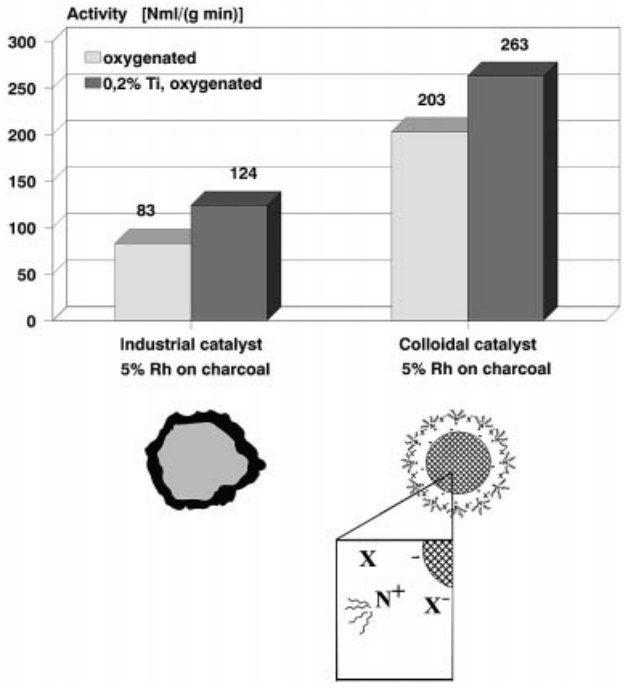

Figure 15. Activities of conventional and colloidal Rh/C catalysts, eventually doped with 2% colloidal Ti^0, compared in the butyronitrile hydrogenation test (adapted with permission from ref.[15])

The compounds used as dopants are not limited to those of the early transition metals. The addition of neodymium ions to the palladium particles was found to have a significant promoting effect on the hydrogenation of acrylic acid.[214] The selective transformation of 3,4-dichloronitrobenzene to the corresponding aniline has been selected to test pre-prepared Pt hydrosols as heterogeneous catalyst precursors (see Figure 16).[215]

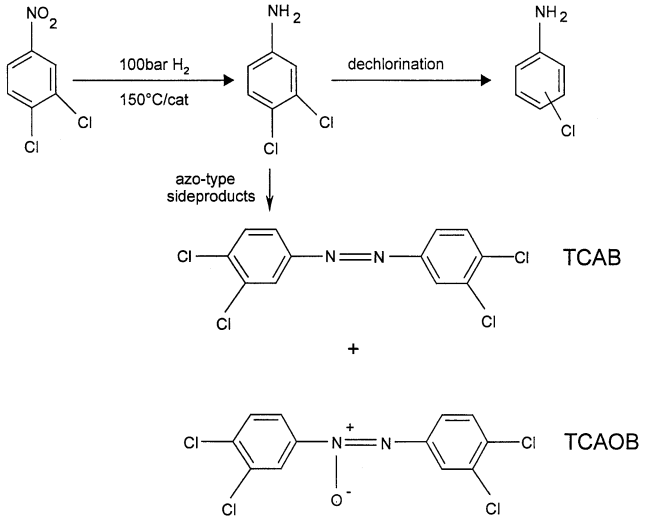

Figure 16. Reaction scheme for the hydrogenation of 3,4-dichloronitrobenzene

The performance of the colloidal catalyst system was evaluated in both batch and continuous tests and compared to that of conventional Pt/C systems. In summary, the potential of the colloidal heterogeneous catalyst stems from the fact that it is possible to tailor the properties for specific applications by the addition of specific dopants or "poisons" (such as sulfur). Further "fine tuning" of the complex process has been achieved by using the synergistic effect of bimetallic precursors (e.g. Pt/Cu). The influence of metal ions on the hydrogenation of *o*-chloronitrobenzene on platinum colloids and the effect of metal complexes on the catalytic performances of metal clusters have also been investigated.[216–218] It was found that the catalytic properties of platinum clusters for the hydrogenation of *o*-chloronitrobenzene to *o*-chloroaniline are very sensitive to the metallic cations added. Enhanced activity and selectivity was observed when Ni^{2+} ions were used as the modifier. The selectivity in the formation of *o*-chloroaniline increased from 44.7% to 66.3%, while the activity of the catalyst was almost doubled. The maximum activity and selectivity (82.9%) in the formation of *o*-chloroaniline was obtained with an Ni^{2+}/Pt molar ratio of 8:1.[216] The same authors also studied the "doping effect" of additional metal complexes on the activity and selectivity of platinum clusters in the homogeneous liquid-phase hydrogenation of cinnamaldehyde.[218] The conversion was increased from 65.5% to 78.0% by using Na_3FeF_6 as the additive, while the selectivity of cinnamic alcohol formation was increased from 17.7% to 75.0%. The addition of $Ni(bipy)_3Cl_2$ to the colloidal platinum catalyst increased the conversion to 82.1%, while the selectivity in the formation of hydrocinnamaldehyde was as high as 97.3%. By doping Rh colloid catalysts with Sn, it was found that the selectivity in the hydrogenation of cinnamic acid to cinnamic alcohol could be varied. A selectivity of 86% was achieved using a colloidal Rh/Sn (Rh/Sn = 1.5:1) catalyst on carbon.[15] Remarkably, the stabilizing surfactant was shown to modify the colloidal

metal surface and hence the catalytic properties.[215] Hanaoka et al.[219] have reported the selective photocatalytic transfer of hydrogen to 1,5-cyclooctadiene using a light transition metal modified rhodium colloid catalyst. Bulk industrial processes often rely on alloy-like bimetallic catalysts.[220−222] Here, nanostructured bimetallic colloid catalysts have provided a possibility of carrying out differential studies on the mutual influence of two different metals on the catalytic properties. The controlled co-reduction of two different metal ions has made bimetallic colloids readily accessible.[6,7,15,37−40,69,85,90−97,223] The structural characterization and some catalytic aspects of bimetallic colloids have recently been reviewed.[10] The successive reduction of different metal ions allows the homogeneous structure of bimetallic particles to be altered to one of colloidal particles having composition gradients from the core to the shell.[205,224−227] Truly layered particles consisting of, for example, a gold core plated by palladium or vice versa,[69] have also been synthesized. Bimetallic particles having a gradient metal distribution or a layered structure are most interesting for catalytic applications. In the catalytic hydrogenation of crotonic acid to give butanoic acid, a clear synergistic effect of Pt and Rh[6] was observed using bimetallic colloidal precursors ($Pt_{20}Rh_{80}$) having a gradient core/shell structure with an increase in the Rh content on going from the core to the surface of the particle (see Figure 17).[224] Toshima has discussed a similar effect in the partial hydrogenation of 1,3-cyclooctadiene with $Pt_{80}Pd_{20}$ and $Pd_{80}Au_{20}$ colloid catalysts.[10]

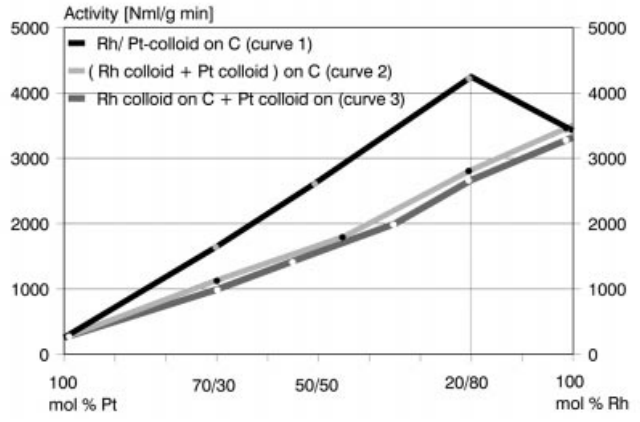

Figure 17. Activity plot of alloyed Rh/Pt/C and mixed Rh + Pt/C catalysts in the crotonic acid hydrogenation test (H_2 consumption) (adapted with permission from ref.[15])

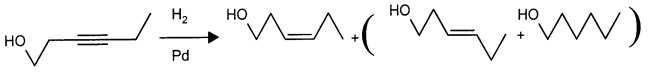
The difference in the electronegativities of Pd and Au, together with the combination of the partially filled d band of Pd and the completely filled d band of Au, result in a novel electronic structure that may account for the catalytic behavior of gold/palladium alloys.[228−237] Fascinating prospects for the design of new catalysts have been opened up using bimetallic particles with layered structures. Schmid et al.[69] have applied the classical seed growth method[238] to synthesize layered bimetallic Au/Pd and Pd/Au colloids with sizes of 20−56 nm. The Au core is coated with Pd by the sequential reduction of gold and palladium salts with sodium citrate. The layered bimetallic colloid is stabilized by trisulfonated triphenylphosphane and sodium sulfanilate. More than 90% of the metal can be recovered in the solid state and redispersion in water is possible in high concentration. Au/Pd and Pd/Au systems on a TiO_2 support have been used in stabilized and non-stabilized forms as heterogeneous catalysts for the hydrogenation of hex-2-yne to (*Z*)-hex-2-ene. Both the palladium-plated gold seeds and the gold-plated palladium particles showed considerably increased activities compared with either pure metal. The lifetimes of the ligand-stabilized colloid catalysts are considerably enhanced by the protecting ligand shell. The influence of the electronegativity difference between Au and Pd on the activity and selectivity of the hydrosilylation reaction[239] on colloidal Pt surfaces[120,121] has been carefully investigated. In essence, the results demonstrate that the activity, selectivity, and lifetime of a metal colloid catalyst may be optimized by a defined variation of the core/shell composition in the bimetallic precursor.

Residues of the stabilizing agents that are still present on the surface of the colloidal metal precursors (1−5 wt-% metal loading on charcoal, glassy carbon, zeolites, TiO_2, Al_2O_3, $CaCO_3$, SiO_2, single-crystal oxides, or HOPG) may act as effective catalyst modifiers, controlling the selectivity and durability of the heterogeneous colloid catalysts (see Figure 13). Ligands such as phosphanes or phenanthrolines,[68] surfactants of various types[7,15] or organic "envelopes" such as polymers[199,240,241] have been found to control the regio- and enantioselectivity of heterogeneous metal colloid catalysts. In the case of the partial hydrogenation of hex-2-yne to (*Z*)-hex-2-ene, Schmid has found that even subtle changes in the chain length of the substituents of the alkyl-substituted phenanthrolines used as colloid stabilizers have a significant effect on the regioselectivity.[242] Seven- and eight-shell palladium clusters on TiO_2, protected by phenanthroline, catalyze the partial hydrogenation of hex-2-yne to (*Z*)-hex-2-ene with a selectivity of 93%. A similar selectivity was achieved using 3-(*n*-decyl)phenanthroline as the stabilizer. On substitution of the phenanthroline with *n*-butyl or *n*-heptyl groups, however, the activity drops dramatically and the subsequent isomerization or total hydrogenation of the (*Z*)-hex-2-ene is completely suppressed. Geometrical, i.e. steric, factors were proposed to explain the strong influence on the selectivity, and indeed this has been illustrated by further examples. A surfactant was found to control the selectivity in the (*Z*)-selective partial hydrogenation of 3-hexyn-1-ol giving leaf alcohol, which is a valuable fragrance [Equation (9)].[243]



(9)

The performance in this reaction, Equation (9), of heterogeneous Pd colloid catalysts on $CaCO_3$,modified by a

number of surfactants, was compared with those of conventional Pd/C and Lindlar catalysts under optimized reaction conditions. The selectivity was found to be dependent on both the support and various promoters. The highest activity and best selectivity (98.1%) in formation of the desired (*Z*)-3-hexen-1-ol was found when a lead acetate promoted palladium colloid on $CaCO_3$, modified by the zwitterionic surfactant sulfobetaine-12 (*N*,*N*-dimethyldodecylammoniopropanesulfonate), was employed. Chemisorption measurements showed that residual amounts of the surfactant were still present on the surface of the immobilized particles. This colloid catalyst proved to be twice as active as a conventional Lindlar catalyst and gave 0.5% higher selectivity. Hydrophilic protecting shells allow improved contact between heterogenized metal colloid surfaces and substrates in aqueous media. For example, a hydrophilic ruthenium colloid catalyst on lanthanum oxide was shown to convert benzene into cyclohexene with 59% selectivity at 50% benzene conversion when suspended in an aqueous solution of sodium hydroxide.[244] Chiral molecules on the surface of the metal colloid can induce control of the enantioselectivity. In this context, a new type of enantioselective platinum sol catalyst, stabilized by the alkaloid dihydrocinchonidine, has been designed (see Figure 18).[177,245]

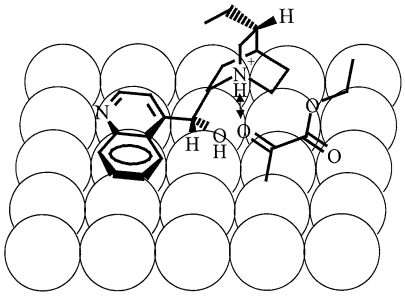


Figure 18. Enantioselective hydrogenation of ethyl pyruvate using dihydrocinchonidine-stabilized Pt colloids (adapted with permission from ref.[15])

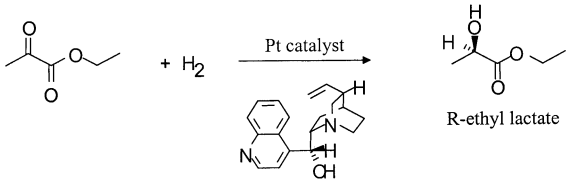
The colloidal catalysts were prepared with different particle sizes by reducing platinum tetrachloride with formic acid in the presence of different amounts of the alkaloid. Optical yields of 75−80% *ee* were obtained in the hydrogenation of ethyl pyruvate with chirally modified Pt sols, Equation (10). These catalysts were shown to be structure-insensitive since turnover frequencies (ca. 1 s^{-1}) and enantiomeric excess proved to be independent of the particle size.



(10)

In order to evaluate the catalytic characteristics of colloidal platinum, the efficiency of Pt nanoparticles in the "quasi-homogeneous" reaction shown in Equation (10) was compared with those of supported colloids of the same charge and of a conventional heterogeneous platinum catalyst. The "quasi-homogeneous" colloidal system was found to surpass the conventional catalyst in turnover frequency by a factor of three.[245] Bradley et al.[246,247] and Liu[248,249] have studied the enantioselectivity of the reaction according to Equation (10) in the presence of polyvinylpyrrolidone as a stabilizer. In addition, Bradley[246] has observed that the presence of HCl in such Pt sols, modified by cinchona alkaloids, has a marked effect on the rate and reproducibility. The performance of the catalysts was improved in terms of both reproducibility and rate by the removal of HCl by dialysis. These "purified" colloidal catalysts can be used as reliable test systems in the screening of alternative chiral modifiers to cinchona alkaloids and for precise rate studies. In addition, a systematic variation of the reaction parameters relevant to the catalyst performance is possible without unwanted side effects. It has been shown that an excess of polyvinylpyrrolidone present on a colloidal Pt catalyst is irrelevant to the access of modifier molecules to the colloidal metal surface. However, the polymer may be adsorbed at the metal surface, thereby reducing the number of modified surface sites available for the enantioselective hydrogenation.[247] The stereoselective and enantioselective transformation of specific prochiral substrates into valuable fine chemicals can be achieved through the use of nanostructured metal colloids. The application of rational ligand control based on molecular modeling, which has been successful in homogeneous metal complex catalysis, promises similar results in heterogeneous metal colloid catalysis.

Superior lifetimes can also be expected since it is reasonable to assume, on the basis of the chemisorption results, that the "coating" on catalytically active nanometal particles, which is permeable to small molecules such as H_2 or O_2, effectively prevents contact of the metal surface with poisons. In fact, the lifetimes of the colloid catalysts are considerably longer than those of conventional precipitation catalysts. For example, the activity of a conventional Pd/C catalyst expires completely in the hydrogenation of cyclooctene to cyclooctane after 38,000 catalytic cycles per Pd atom, but the Pd colloid/C catalyst still shows a residual activity after 96,000 catalytic turnovers (Figure 19).[250]

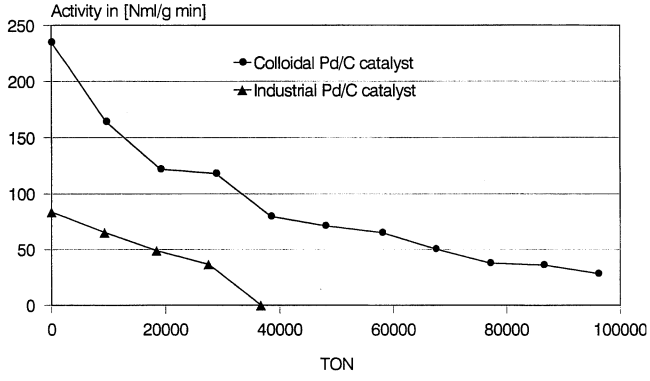


Figure 19. Durability of colloidal Pd/C catalysts in the cyclooctene hydrogenation test compared with a conventional Pd/C system (adapted with permission from ref.[15])

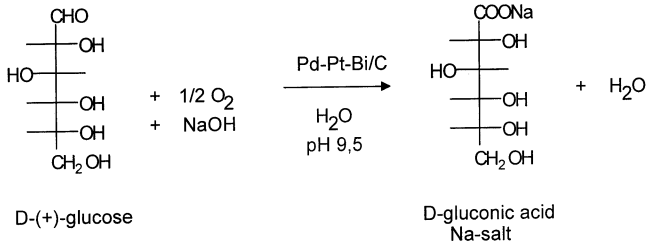
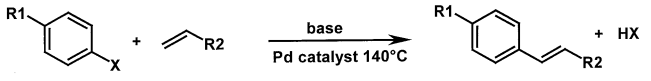
When surfactant-stabilized Pd/Pt precursors were supported on charcoal and promoted by bismuth, superior catalytic oxidation catalysts were obtained.[251] Compared



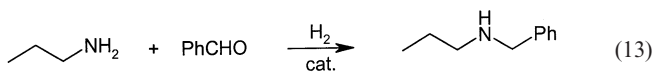
(11)

to industrial heterogeneous Pd/Pt catalysts, charcoal-supported $Pd_{88}/Pt_{12}-(oct)_4NCl$ alloy particles (1.5 to 3 nm) were found to offer an excellent activity combined with high selectivity in the oxidation of glucose to gluconic acid by molecular oxygen, see Equation (11).[251] An increased durability of the colloidal Pd/C catalysts was also observed in this case. Much greater retention of the catalytic activity was found for such a system as compared to a conventionally manufactured Pd/C catalyst after recycling both catalysts 25 times under similar conditions. Obviously, the lipophilic $(oct)_4NCl$ surfactant layer prevents the colloid particles from coagulating and being poisoned in the alkaline aqueous reaction medium. Shape-selective hydrocarbon oxidation catalysts have been described, where active Pt colloid particles are present exclusively in the pores of ultramicroscopic tungsten heteropoly compounds.[252] Phosphane-free Suzuki and Heck reactions involving iodo, bromo, or activated chloro substituents were performed using catalytic amounts of ammonium salt or poly(vinylpyrrolidone)-stabilized palladium or palladium nickel colloids [Equation (12)].[145,252]



(12)

The Pd-colloid-catalyzed Heck arylation of styrene with chlorobenzene gave (*E*)-stilbene as the exclusive product. This type of C−C linkage is valuable for the production of pharmaceutical intermediates and fine chemicals. Turnover frequencies (TOF) of more than 80,000 have been achieved in the coupling of *p*-bromobenzaldehyde with butyl acrylate using poly(vinylpyrrolidone)-stabilized palladium as the catalyst.[253] Reetz has applied colloidal, water-soluble PtO_2 (i.e. a colloidal "Adams catalyst") in the immobilized form for the reductive amination of benzaldehyde by *n*-propylamine [Equation (13)].[160,161]



(13)

The selectivity in favor of the desired monobenzylated product was found to be > 99% and the immobilized PtO_2 was found to be four to five times more active than the commercial Adams catalysts. The PtO_2 colloid proved to be effective in the hydrogenation of carbonyl compounds and of olefins, both in solution and in immobilized form. The heterogeneous catalytic amination of aryl bromides by immobilized Pd^0 particles has recently been reported.[252] Secondary amines such as piperidine and diethylamine were used in the amination of aryl bromides. The reactions proceeded with good turnover numbers and regiocontrol. The catalysts could be reused repeatedly without loss of activity or selectivity following filtration from the reaction mixture.

A new class of heterogeneous catalyst has emerged from the incorporation of mono- and bimetallic nanocolloids in the mesopores of MCM-41 or the entrapment of pre-prepared colloidal metals in sol-gel materials.[254−256] Pre-prepared Pd colloids stabilized by phenanthroline obtained by the Schmid method[57−72] have successfully been embedded in MCM-41 mesopores (some colloid is deposited on the external surface) to give CO-oxidation catalysts.[254]

Reetz has developed a strategy for the entrapment of monodisperse nanometal colloids, e.g. R_4NX-stabilized Pd particles.[255] The nanosized particles (2−3.5 nm) are pre-prepared by electrochemical synthesis.[85,90−97] The entrapment in hydrophobic sol-gel materials occurs through the fluoride-catalyzed hydrolysis of mixtures of $CH_3Si(OCH_3)$ and $Mg(OC_2H_5)_2$. Finally, the stabilizer is extracted and the "naked" nanometallic particles are left trapped in the pores (see Figure 20).

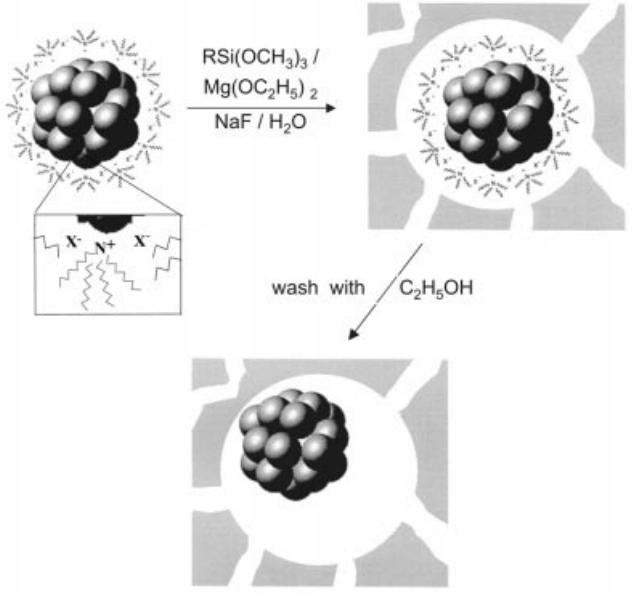


Figure 20. Incorporation of preformed metal colloids in sol−gel materials (adapted with permission from ref.[255])

Ultramicrotomic techniques in combination with shadow-casting TEM have confirmed that the Pd particles are embedded in the oxide matrix and are not fixed on the outer surface. Reetz et al.[255] have also investigated the catalytic properties of the new material. They were able to

control the hydrophobicity of the matrix by adjusting the relative amounts of the $CH_3Si(OCH_3)_3$ and $Mg(OC_2H_5)_2$ in the gel. The catalytic activity and selectivity was tested in the partial hydrogenation of COD to give cyclooctene: It was found that the activities of the new systems are governed by the specific pore volume and the hydrophobic properties of the wall. The selectivity for cyclooctene was 93% and the most active of these sol−gel-entrapped Pd catalysts exhibited a considerably higher activity than those of commercially available Pd/Al_2O_3 samples. The preparation of a fully alloyed Pd/Au colloid of 3.0 nm particle size by a modified sol−gel procedure using THF as the solvent and involving the co-reduction of Pd and Au salts with tetraalkylammonium triethylhydroborate,[6] and its subsequent embedding in silica, has been described.[256] The integrity of the incorporated Pd/Au alloy particles remained virtually unaffected. A mesoporous texture with a comparatively narrow pore distribution remained after the removal of the protecting surfactant. According to the physical characterization by a combination of techniques, the SiO_2-embedded Pd/Au colloid retains the size and structural characteristics of the colloidal metal precursor. The material exhibits excellent catalytic properties in selective hydrogenation test reactions. These few examples show that colloidal bimetallic precursors − embedded in matrices or deposited on various supports, and promoted by additives if necessary − may become of practical importance in heterogeneous catalysis.

Fuel Cell Catalysts

"Fuel cell technology" attracts a great deal of interest because it allows the direct conversion of chemical energy into electricity.[257] The catalyst systems are an integral part of the electrochemical reactor utilized in fuel cells. Among the wide-ranging applications of fuel cells are low-emission transport systems, stationary power stations, and combined heat and power sources. Classical studies were carried out in the early 1900s and major innovations and improvements have been achieved over the last few years. The first "new electric cars" are expected to be on the market around 2005, but further developments are still needed, most notably in the area of catalysts. Hydrogen fuel cell catalysts rely on pure Pt, whereas Pt alloy electrocatalysts are employed for the conversion of reformer gas or methanol into electricity. The active component in the latter cases are small Pt-containing bi- or trimetallic particles, 1−3 nm in size, which scatter X-rays as nearly perfect "single crystals". These systems offer improved efficiency and tolerance towards certain contaminants, especially CO, in the anode feed.[258−263] It was clear from patents filed in the early 1970s that finely particulate colloidal platinum sols should be the ideal precursors for the manufacture of fuel cell electrodes.[258]

This section of our microreview focuses on recent developments in catalysts for phosphoric acid fuel cells (PAFCs), proton-exchange membrane fuel cells (PEMFCs), and the aforementioned direct methanol fuel cell (DMFC). The six main types of fuel cell are described in recent reviews.[264−268] PAFCs operating at 160−220 °C use orthophosphoric acid as the electrolyte; the anode catalyst is Pt and the cathode can be, e.g., Pt/Cr/Co.[264−268] For this application, a trimetallic colloidal precursor of the composition $Pt_{50}Co_{30}Cr_{20}$ (size 3.8 nm) was prepared by the co-reduction of the appropriate metal salts.[269−271] The trimetallic particles are alloyed in an ordered *fcc* structure according to XRD analysis. The electrocatalytic performance in a standard half-cell was compared with that of an industrial standard catalyst (trimetallic crystallites of size 5.7 nm) manufactured by co-precipitation and subsequent annealing at 900 °C. The advantage of the trimetallic colloid catalyst lies in its improved durability, which is essential for PAFC applications. After 22 h, it was found that the potential had decayed by less than 10 mV.[272]

PEM fuel cells use a solid proton-conducting polymer as the electrolyte at 50−125 °C. The cathode catalyst is based on Pt alone, but because of the required tolerance to CO a combination of Pt and Ru is preferred for the anode.[258−263] Colloidal Pt/Ru catalysts are currently under widespread investigation for low-temperature (80 °C) polymer membrane fuel cells (PEMFCs).[350,351] They have also been proposed for the use in direct methanol fuel cells (DMFCs) or in PEMFCs, which are fed with CO-contaminated hydrogen produced in on-board methanol reformers. The ultimate dispersion state of the metals is essential for CO-tolerant PEMFCs, and truly alloyed Pt/Ru colloid particles less than 2 nm in size seem to fulfill these requirements.[17,18,20,258,260,273−276] Alternatively, bimetallic Pt/Ru PEM catalysts have been developed for the same purpose, where non-alloyed Pt nanoparticles of < 2 nm and Ru particles of < 1 nm are dispersed on a carbon support.[260] From the results obtained, it can be concluded that a Pt/Ru interface is essential for the CO tolerance of the catalyst, irrespective of whether the precious metals are alloyed. For the manufacture of DMFC catalysts, however, Pt/Ru nano*powders* of size 3−5 nm or thin films are used as the precursors.[261−263] For the electrocatalytic oxidation of methanol, a Pt or a Pt metal alloy catalyst has been developed, where a (phthalocyanine)Ru complex is added as a dopant to significantly enhance the catalytic effect.[271] For comparison, the electrocatalytic activity in the oxidation of CO and a CO/H_2 gas mixture (simulated reformer gas)[17] was compared with that of a bimetallic $Pt_{50}/Ru_{50}-(oct)_4NCl$ colloid prepared by the salt co-reduction method.[6][87−89] The mean particle diameter was 1.7 nm according to high-resolution transmission electron microscopy (HRTEM) [see Figure 21, a)]. The alloyed state of the particles was verified by point-resolved energy dispersive X-ray (EDX) analysis [Figure 21, b)].

Glassy carbon supported $Pt_{50}/Ru_{50}-(oct)_4NCl$ colloids were examined by CO-stripping voltammetry and the data were found to be essentially identical to those found in well-characterized bulk-alloy electrodes. The activity of the colloid in the continuous oxidation of 2% CO in H_2 at a rotating disk electrode was determined at 25 °C in 0.5 M H_2SO_4. The results led to the conclusion that these Pt/Ru colloids

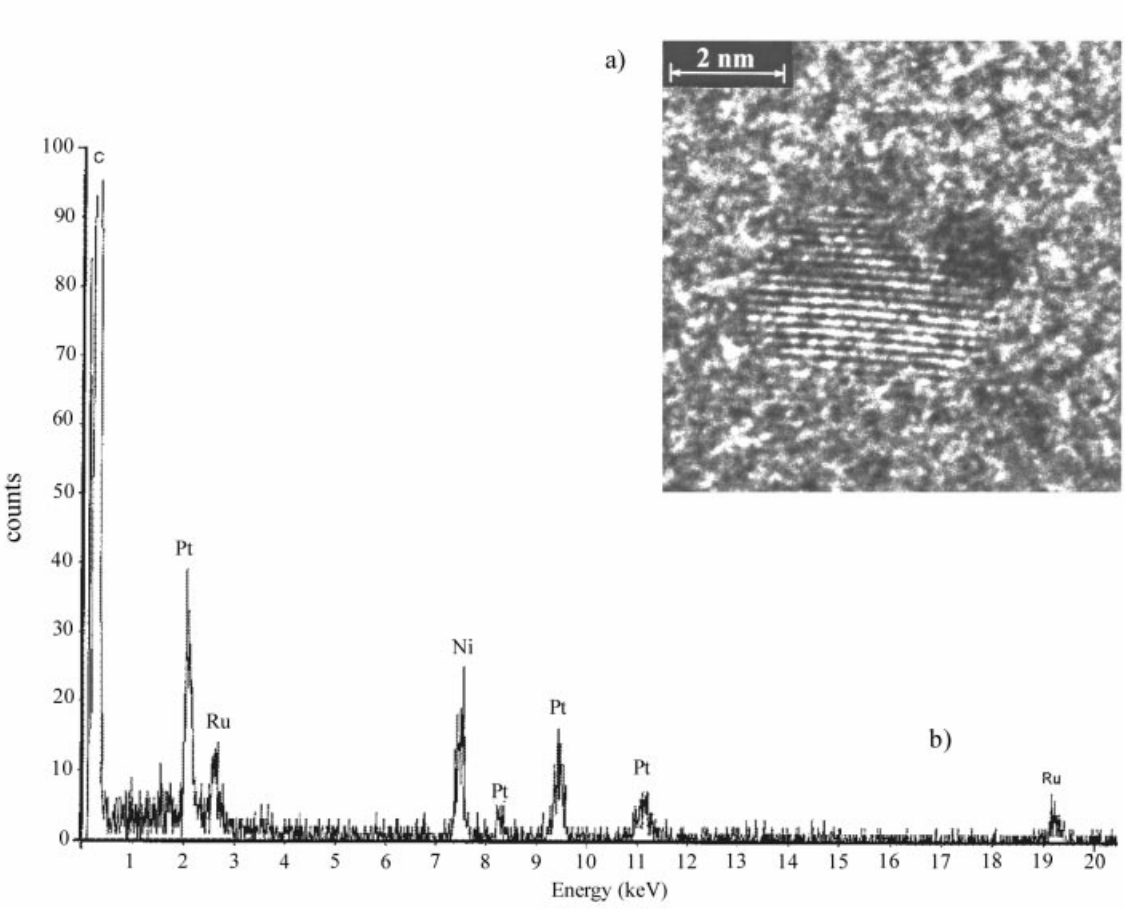

Figure 21. a) High-resolution TEM image of a single $Pt_{50}Ru_{50}$ particle (1.7 nm) (adapted from ref.[17]); b) EDX point analysis (focus 10 nm) of discrete $Pt_{50}Ru_{50}$ particles (adapted with permission from ref.[17])

are very suitable precursors for high-surface-area fuel cell catalysts.[20] XANES data were supportive of the bimetallic character of the particles. In addition, in situ XRD (by Debye function analysis) has revealed the catalytic function of the alloyed Ru in the CO oxidation: Oxide species are formed on the Ru surface at 280 °C, which slowly coalesce to form RuO_2 particles. After re-reduction, the catalyst shows a pure *hcp* ruthenium phase and larger platinum-enriched alloy particles.[277] Scanning probe microscopy (SPM) has been applied in order to characterize the real-space morphology of the electrode surfaces of supported nanostructured metal colloids on the nanometer scale.[278] Colloidal Pt_{50}/Ru_{50} precursors (< 2 nm) raise the tolerance to CO, allowing higher CO concentrations in the H_2 feed of a PEMFC without a significant drop in performance.[18−20] A selective Pt/Mo oxidation catalyst for the oxidation of H_2 in the presence of CO in fuel cells comprises Pt_xMo_y particles, where $x = 0.5-0.9$ and $y = 0.5-0.1$.[279] The colloid method was found to offer a highly suitable exploratory approach to finding improved formulations for binary and ternary anode electrocatalysts. The metals used include Pt, Ru, W, Mo, and Sn.[19] The combinatorial screening method has been successfully applied to electrocatalysts,[280] and it is an obvious step to include colloids in these experiments. As an alternative to the reductive metal colloid synthesis, the so-called "metal oxide concept" was developed, which allows the fabrication of binary and ternary colloidal metal oxides as electrocatalyst precursors [Equation (14)].[160−162]

$$PtCl_4 + RuCl_3 \xrightarrow[\text{stabilizer}]{H_2O/\text{base}} PtRuO_x \text{ colloid} \quad (14)$$

Colloidal Pt/RuO_x (1.5±0.4 nm) stabilized by a surfactant was prepared by co-hydrolysis of $PtCl_4$ and $RuCl_3$ under basic conditions. By variation of the stoichiometry of the transition metal salts, the Pt/Ru ratio in the colloids could be varied between 1:4 and 4:1. The corresponding zerovalent metal colloids were obtained by the subsequent application of H_2 to the colloidal Pt/Ru oxides (optionally in the immobilized form). Additional metals have been included in the "metal oxide concept" [Equation (14)], so as to prepare binary and ternary mixed metal oxides in colloidal form. $Pt/Ru/WO_x$ is regarded as a good pre-catalyst, especially for application in DMFCs. Main group elements such as Al have been included in multimetallic alloy systems in order to improve the durability of fuel cell catalysts. Alloys of $Pt_3AlC_{0.5}$ with Cr, Mo, or W particles of size 4−7 nm have been prepared by sequential precipitation on conducting carbon supports such as highly disperse Vulcan

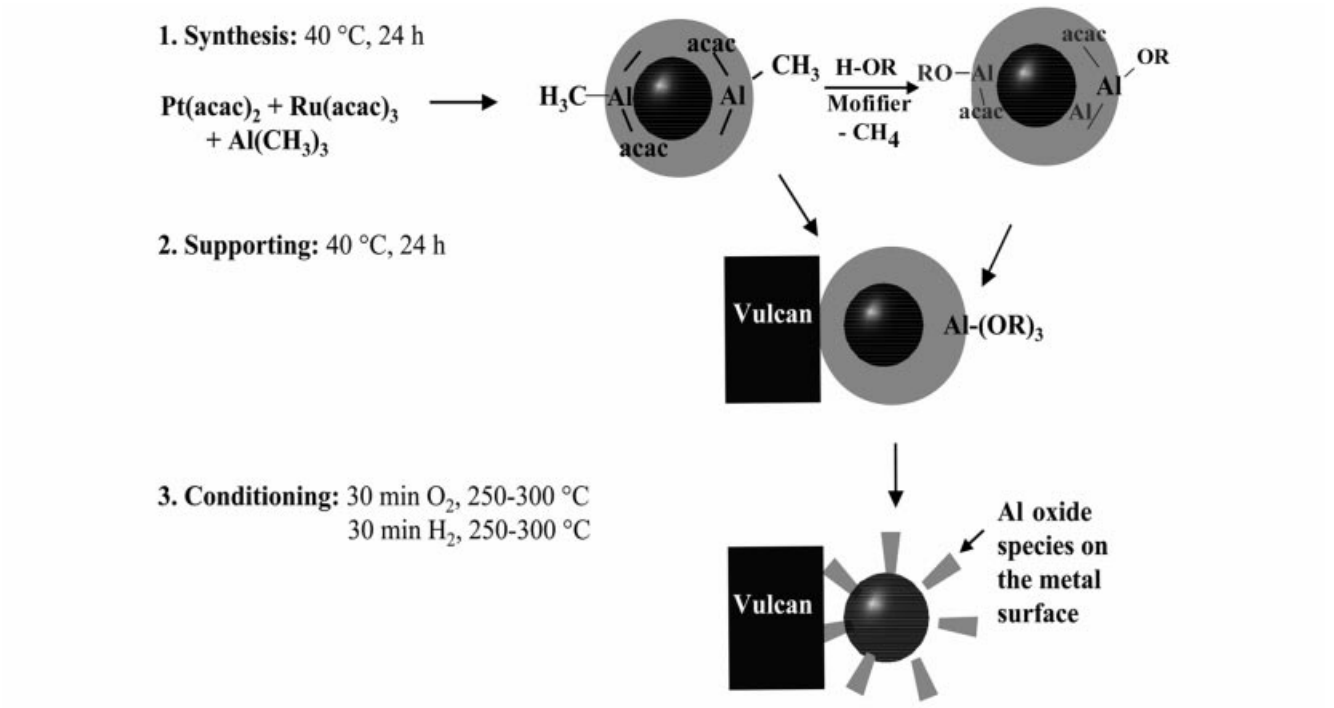

Figure 22. Scheme of the preparation of colloidal Pt/Ru/Al PEMFC anode catalysts (> 20% metal on Vulcan XC72®) by the "precursor concept"(adapted with permission from ref.[273])

XC72®.[281] Alternatively, colloidal precursors composed of Pt/Ru/Al allow the manufacture of multimetallic fuel cell catalysts (1−2 nm) having a metal loading of > 20%. The three-step catalyst preparation is summarized in Figure 22.

The colloidal Pt/Ru/Al precursor is pre-prepared by the organoaluminum route. In the absence of stabilizers, the co-reduction of organic Pt and Ru salts using $Al(CH_3)_3$ gives halogen-free, multimetallic Pt colloids, e.g. $Pt_{50}Ru_{50}$/Al (size 1.2±0.3 nm). By adjusting the stoichiometric ratio of the metal salts, the ratio of Pt to the second metal in the colloid can be adjusted. The addition of alcohols or suitable surfactants allows the dispersivity of the colloidal precursor in organic media or water to be tailored without affecting the particle size. In the second step, the Pt/Ru/Al colloid is adsorbed on high-surface-area carbon by treatment at 40 °C for 24 h. In the third step (conditioning), the dried Pt/Ru/Al Vulcan catalyst powders are exposed to O_2 and H_2 for 30 min each at 250−300 °C to completely remove the surfactants. The particle size of the Pt/Ru/Al colloid adsorbed on the support was found to be virtually unaffected by the treatment (1.3±0.4 nm) and after the thermal treatment only a moderate growth was evident (1.5±0.4 nm). The aluminum was found to be present on the Pt/Ru surface in an oxidized form. This accounts for the size-stabilization observed in the Pt/Ru particles and for the improved durability of the resulting electrocatalysts. Recently, a fuel cell for generating electric power from a liquid organic fuel ("synfuel") was described. It comprises a solid electrolyte membrane directly supporting the anode and cathode layers,

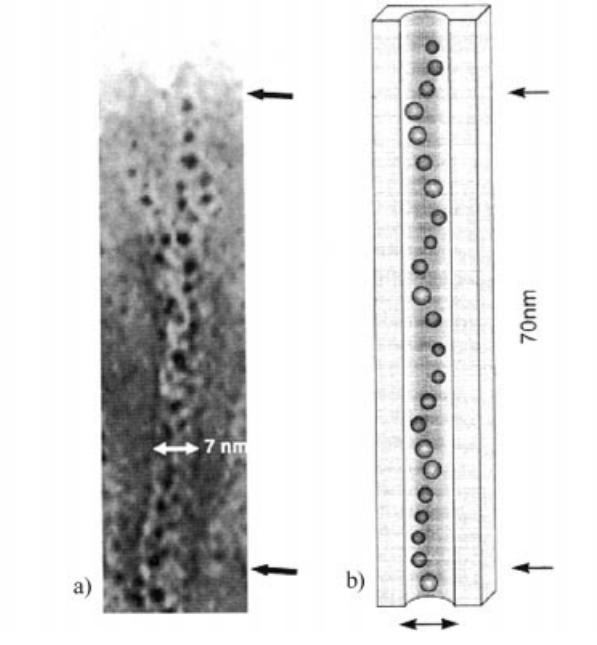

Figure 23. a) TEM image of a one-dimensional Au_{55} cluster wire in a nanoporous alumina membrane; b) schematic representation of the helical wire in a 7 nm pore (adapted with permission from ref.[277])

which contain 7−10% Pt and Ru, 70−80% perfluorovinylether sulfonic acid, and 15−20% polytetrafluoroethylene.[276] In conclusion, nanostructured metal colloids are

very promising precursors for manufacturing multimetallic fuel cell catalysts that are truly nanosized (i.e. < 2 nm) and have high metal loadings (20 wt-% of metal).

Potential Applications in Materials Science

It is expected that metal nanoparticles and their assemblies will find numerous applications in materials science. It has been demonstrated that physical properties, including magnetic, optical, melting points, specific heats, and surface reactivity are size-dependent. Quantum size effects are related to the "dimensionality" of a system in the nanometer range. "Zero-dimensional" metal particles might still comprise hundreds of atoms. One-dimensional nanoparticle arrangements (cluster wires) are of potential practical interest as semiconducting nanopaths for applications in nanoelectronics. 1D particle arrangements may be induced through the use of host templates. Using vacuum or electrophoretic methods, Schmid et al.[318−320] were able to fill the parallel channels of nanoporous alumina membranes with chains/rows of 1.4 nm gold particles giving one-dimensional "quantum wires" consisting of insulated 20−100 Au_{55} clusters in a helical array (see Figure 23). The diameter of the nanowire could be controlled by varying the pore size.

Interestingly, 1.4 nm Au particles were found to arrange themselves into a linear row when attached to single-stranded DNA oligonucleotides.[321] Driven by the technological significance associated with such architectures, the fabrication of ordered two-dimensional nanoparticle arrays has been successfully achieved by several research groups, whose work has recently been reviewed.[281][282] Planar arrays of uniform metal nanoparticles would allow the design of new "supercomputers" having a superior data storage capacity. Langmuir−Blodgett films of nanometal systems have frequently been studied in this context. Starting with nanoparticles of defined nuclearity, 2D lattices of thiolized Au_{55}, Pd_{561}, and Pd_{1415} have been prepared.[322] Recently, the first successful preparation of 2D hexagonal and cubic lattices of Au_{55} nanoparticles by self-assembly on polymer films was reported.[163] Simply dipping polyethylenimine-modified surfaces into aqueous solutions of acid-functionalized Au_{55} cluster generates the Au_{55} monolayers shown in Figure 24.

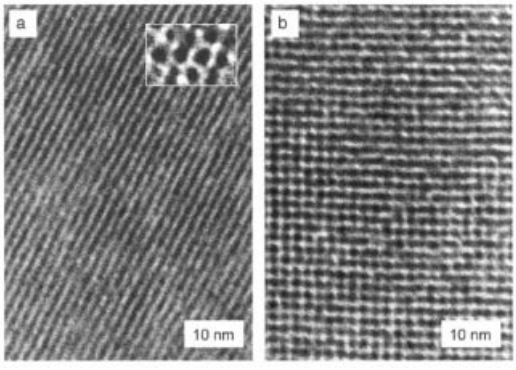

Figure 24. Au_{55} monolayers showing a hexagonal (a) and a cubic (b) structure; the insert in (a) shows single clusters in the hexagonal form (adapted with permission from ref.[163])

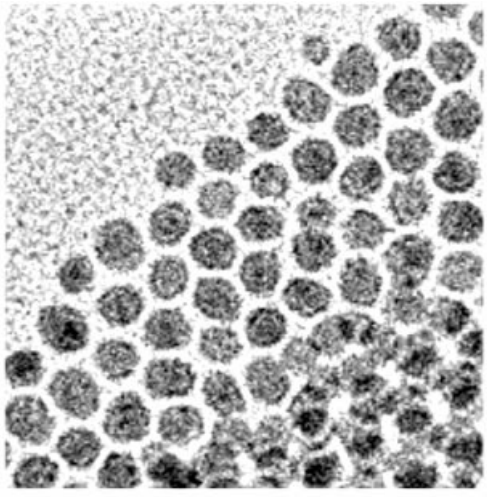

Figure 25. Pd colloid hexagonal close-packed arrangement in the first monolayer (adapted with permission from the Royal Chemical Society from ref.[291])

The interactions between the nanoparticles and the surface are obviously strong enough to prevent mechanical removal. Whereas the hexagonal form shown in Figure 24 (a) is normal for an ordered monolayer, the cubic orientation seen in Figure 24 (b) is unprecedented. Most of the work published on organized nanometal structures has been focused on gold particles and sulfur-containing groups in the various ligands.[283−288] Schiffrin et al. have achieved the self-organization of nanosized gold particles using $R_4N^+X^-$ surfactants.[289] Ramos et al. have recently reported the surfactant-mediated two-dimensional crystallization of colloidal crystals.[290] Making use of the attractive Coulomb interactions between colloids and surfactant structures offers a potential new route to the self-assembly of ordered colloidal structures. Nanostructured palladium clusters stabilized by a monomolecular coating of tetraalkylammonium halide surfactants self-assemble on carbon surfaces in an ordered manner with the formation of *hcp* structures (Figure 25).[291]

The self-organization of magnetic nanosized cobalt particles was studied by Pileni's group.[296,297] A comparison of the magnetic properties of deposited cobalt nanoparticles with those of particles dispersed in a solvent indicated a collective flip of the magnetizations of adjacent particles when they were self-assembled. Pileni et al. have recently published a number of papers concerning the self-assembly of nanoparticles and have developed a number of methods for the manipulation of these systems.[337−339] Mulvaney et al. have described two- and three-dimensional assemblies of metal core/silica shell nanoparticles in a recent review article.[298] A feature article by Balazcs[299] outlines how solid additives can be used to tailor the morphology of bin-

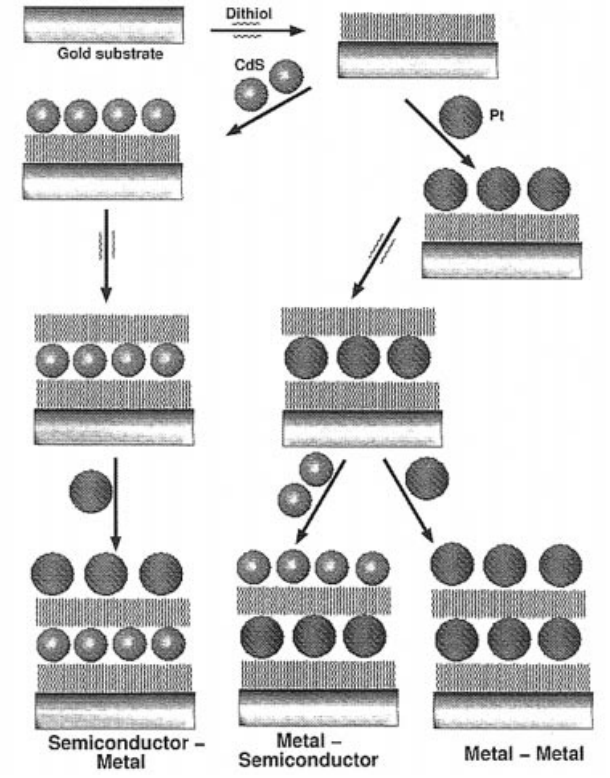

Figure 26. Three-dimensional superlattices obtained by layer-by-layer deposition of Pt particles (or CdS as a semiconductor) onto a dithiol-coated Au substrate (adapted from ref.[165])

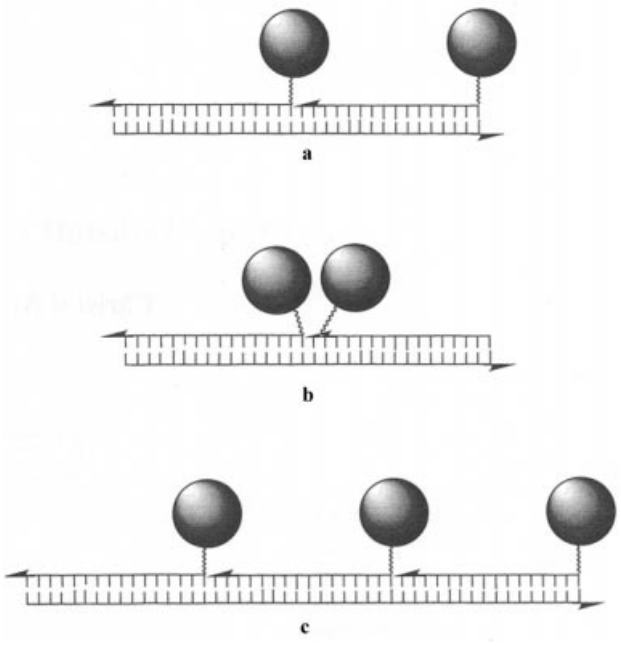

Figure 28. Self-organization of conjugates from gold particles (shaded spheres) and oligonucleotide codons to supramolecular assemblies by the addition of a template strand; derivatization of the oligonucleotides in the 3′- or 5′-position allows control over the mode of head-to-head (a) or head-to-tail (b) homodimers; the trimer (c) is formed using the complementary sequence in triplicate (adapted with permission from ref.[314])

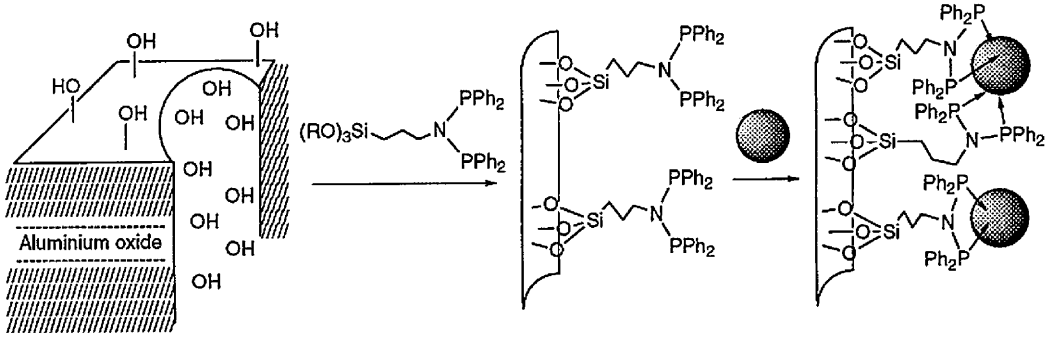

Figure 27. Functionalization of nanoporous alumina membranes and immobilization of metal colloids or clusters on the pore walls (adapted with permission from ref.[349])

ary mixtures containing nanoscopic particles and thereby control the macroscopic properties (e.g., the mechanical integrity) of composites. In addition, computer-aided design has been employed to establish how self-assembled nanostructures can be induced to form arbitrary functional arrays on surfaces.[300] Bifunctional spacer molecules such as diamines have been used in attempts to link nanoparticles three-dimensionally.[301] The multilayer deposition of particle arrays on gold has been successfully achieved by the sequential adsorption of dithiol and near-monodisperse nanometal or CdS particles (see Figure 26).

Several monometal, bimetal, and metal-semiconductor superlattices have been prepared by dipping a gold substrate into the appropriate solutions, with intermediate steps involving washing and drying.[302] The stepwise three-dimensional assembly of layered gold nanoparticles in porous silica matrices has also been reported.[303] Schmid has recently reported strategies for the anchoring of metal complexes, clusters, and colloids within nanoporous alumina (Figure 27).[349]

A different field of technological interest stems from the high spin density of nanostructured magnetic metals of the Fe, Co, Ni series.[304,305] THF-stabilized Mn^0 particles exhibiting superparamagnetism below 20 K were described as the first example of an antiferromagnetic metal colloid.[306]

New strategies utilizing DNA as a construction material for the generation of biometallic nanostructures have made it possible to develop larger "nanotechnology devices" (< 100 nm) for microelectronic photolithographic applications. DNA is regarded as a promising construction material for the selective positioning of molecular devices because of its recognition capabilities, physicochemical stability, and mechanical rigidity. Seeman was the first to propose DNA for the precise spatial arrangement of 3D networks.[307,308] Assemblies of DNA-derivatized gold colloids have recently been prepared by the DNA hybridization-based self-organization pathway and the resulting defined arrangements of nanometal particles have found applications in electronic, optical, and laser technologies.[309−313,340−345] For example, Alivisatos et al.[310] have obtained defined mono adducts from commercially available 1.4 nm gold clusters where one reactive maleimido group was attached to every particle. These were coupled with thiolated 18-mer oligonucleotides in order to add an individual "codon" sequence. When a single-stranded DNA template containing complementary codons was added, the self-assembly of nanocrystal molecules was observed (Figure 28).[310,314] This work has been the subject of recent reviews.[314−316]

Niemeyer[315] has recently reported the coupling of metal particles bearing a biotin substituent with the DNA−streptavidin hybrid. The growth of a 12 μm long, 100 nm wide conductive silver wire was achieved using a DNA molecule stretched between two gold electrodes as a template.[317] It remains to be seen how the practical applications of these materials will develop over the next few years.

Crystal Structure and Solution Behavior of the Iron(III) Complex of the Artificial Trihydroxamate Siderophore with a Tris(3-aminopropyl)amine Backbone

Kenji Matsumoto,[a] Naomi Suzuki,[a] Tomohiro Ozawa,[a] Koichiro Jitsukawa,[a] and Hideki Masuda*[a]

Keywords: Siderophores / Iron / Tripodal ligands / Hydroxamate

Tris[{3-(*N*-acetyl-*N*-hydroxy)-glycylamino}propyl]amine (TAGP) forms a 1:1 tris(hydroxamato)iron(III) complex even at a low pH(≈2), which promotes the growth of the siderophore-auxotrophic mutant *Microbacterium flavescens*.

Introduction

Microorganisms produce low molecular weight compounds called siderophores for an uptake of iron. A large number of siderophores have hydroxamates or catecholates as the iron binding site that exhibit very high affinities for iron(III), and thus form very stable iron(III) complexes.[1,2] The high stability of Fe^{III}-siderophore complexes is attributed to not only such chelating effects but also to hydrogen bonding, van der Waals interactions and the predisposition of the ligands.[3,4] Thus, the ligand backbones are quite important for the stabilization of iron(III) complexes. Many artificial tripodal siderophores have been synthesized as ferrichrome and enterobactin analogues; the synthetic siderophores possess various tripodal backbones such as follows tris(2-aminoethyl)amine (TREN),[5] triaminomethylbenzene,[6] 1,5,9-triazacyclododecane,[7] nitrilotriacetic acid,[8] and 1,1,1-tris[(2-carboxyethoxy)methyl]propane.[5] Among such tripodal backbones, TREN has been used most frequently. Recently, we have reported the synthesis of tris{2-[(*N*-acetyl-*N*-hydroxy)glycylamino]ethyl}amine (TAGE, Figure 1) as an artificial siderophore with a TREN anchor; its iron(III) complex showing an extremely high stability ($\log\beta = 28.7$).[5c] From the crystal structure of the iron(III) complex,[5c] this high stability was found to be due to the intramolecular hydrogen-bonding networks between amide hydrogens and coordinating *N*-hydroxy oxygens in the intra- and interstrands. However, tripodal anchors such as TREN have also been reported to form less-stable iron(III) complexes than the natural siderophore-iron(III) complexes, presumably due to the small size of the anchor for iron(III) chelation.[9]

Tris(3-aminopropyl)amine (TRPN), whose alkyl chains are one methylene group longer than TREN, has not been used much despite the similarities in its structure with TREN. We therefore synthesized tris{[3-(*N*-acetyl-*N*-hydroxy)glycylamino]propyl}amine (TAGP, Figure 1) as a trihydroxamate artificial siderophore with a TRPN anchor in order to examine the effect of the size. Here, we will describe the crystal structure and solution behavior of its iron(III) complex.

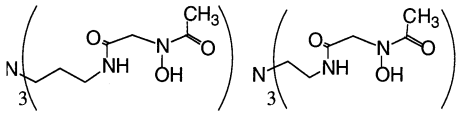

Figure 1. Ligands used in this study

Results and Discussion

As shown in Figure 2, the iron(III)-TAGP complex (**1**) was isolated as a hydrochloride salt with the tertiary amine nitrogen protonated. The quaternary amine is in the "out"

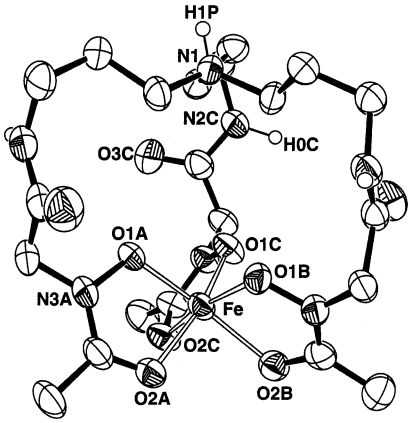

Figure 2. Crystal structure of **1**, showing the atom numbering schemes; selected bond lengths (Å) and angles (deg): Fe−O(1A) 1.971(4), Fe−O(1B) 1.992(3), Fe−O(1C) 1.967(3), Fe−O(2A) 2.036(3), Fe−O(2B) 2.081(3), Fe−O(2C) 2.041(4); O(1A)−Fe−O(2A) 79.3(1), O(1B)−Fe−O(2B) 77.6(1), O(1C)−Fe−O(2C) 78.6(1); all hydrogen atoms except for the amide and TRPN amine hydrogens and the counter anion have been omitted for clarity

conformation, which is in contrast to many iron(III) complexes with synthetic siderophores that are in the "in" conformation.[5c−5e] The iron(III) ion has a distorted octahedral geometry with three coordinated hydroxamates, and the overall structure is twisted with a pseudo-threefold axis. This crystal structure is very similar to the calculated lowest energy conformation of the iron(III) complex of the trishydroxamate with a triscarboxylate anchor that has previously been reported by Shanzer et al.[3b]

The average bond lengths between the iron(III) atom and the coordinating *N*-hydroxyl O(1) and carbonyl O(2) atoms are 1.977(3) and 2.053(3) Å, respectively, and the average O(1)−Fe−O(2) bond angle is 78.4(1)°. The average Fe−O(2) bond length is 0.01−0.02 Å longer than those of natural and artificial trihydroxamate siderophores (2.022−2.041 Å);[2][5c] this is due to the longer Fe−O(2B) bond (0.04−0.05 Å longer than normal). The rest of the Fe−O bonds are very similar to those for other iron(III)-siderophore complexes.[2][5c] The twist angle[10] determined for **1** is 43.9°, which is comparable to the calculated value (45.7°). Considering the definition of the twist angle, these findings suggest that the configuration around the metal ion is nearly the idealized C_3 symmetry.

The distance between the iron(III) ion and the quaternary amine nitrogen in **1** is 5.205 Å, which is only slightly longer than that in Fe^{III}TAGE ($Fe\cdots N_{amine}$ = 5.139 Å). In the catechol macrobicyclic ligand-metal complexes Na_3[Fe(BCT)] and Na_3[Fe(BCTPT)],[11a] the apical N−N distance between the two TRPN caps {Na_3[Fe(BCTPT)]: 10.70 Å} is longer than that in TREN {Na_3[Fe(BCT)]: 9.76 Å}.[11b] Thus, the short distance between the iron(III) ion and the amine nitrogen in Fe^{III}TAGP may be attributed to the electrostatic interaction between the protonated amines and the hydroxamate anions. The steric restriction of the TRPN anchor may be also reduced by adopting a configuration such that the iron(III) ion is wrapped into the TAGP ligand.

The TAGP amine proton forms a hydrogen bond with a chloride ion on the pseudo-threefold axis [N(1)···Cl(1) = 3.081(4) Å]. In the crystal, the amide groups form intermolecular hydrogen bonds between the nearest neighbor molecules [N(2B)···O(1B) = 3.070(5), N(2B)···O(2A)= 3.099(5) and N(2C)···O(3B) = 3.055(6) Å] and between the complex and the water molecules [N(2A)···O(1 W) = 2.838(8) and N(2C)···O(2 W) = 3.134(7) Å]. The intramolecular hydrogen bond found in Fe^{III}TAGE,[5c] however, was not observed.

The UV/Vis spectra of iron(III)-TAGP complex measured in various pH conditions showed a characteristic absorption band corresponding to an LMCT at 425 nm, which did not show a large spectral change over a wide pH range of 2−8 (Figure 3), indicating that TAGP forms a stable tris(hydroxamato)iron(III) complex even under strongly acidic conditions. However, the iron(III)-TAGE complex exhibited the same characteristic absorption band at only pH 4−8 in aqueous solution. The difference in the formation behaviors of the iron(III) complexes with TAGP and TAGE under acidic conditions is probably due to the different conformations of the tertiary amine, "in" and "out". That is, as the tertiary amine in Fe^{III}-TAGE complex takes the "in" conformation and is protected from the outer sphere by intramolecular hydrogen bonding networks,[5c] the tertiary amine is deprotonated, which probably contributes to the formation of the stable tris(hydroxamato)-type complex. In contrast, as the tertiary amine in the Fe^{III}-TAGP complex takes the "out" conformation, the protonated tertiary amine does not affect the formation of the complex. Hence, the stable tris(hydroxamato)-type Fe^{III}-TAGP complex is formed even under acidic conditions.

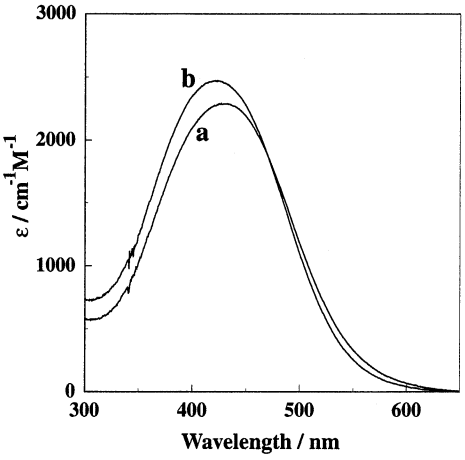

Figure 3. UV/Vis spectra of iron(III)-TAGP complexes (0.1 mM) in an aqueous solution (I = 0.1 M $NaClO_4$): (a) pH 2.0, (b) pH 7.4

The pK_a of the tertiary amine in TAGP is 7.61,[12] which is larger than that of TAGE (pK_a = 5.46), suggesting that the Fe^{III}-TAGP complex is protonated even in a neutral aqueous solution. Comparing the formation constants of the complexes, the protonated Fe^{III}-TAGP complex (log β_{111} = 30.6[12]) is more stable than the Fe^{III}-TAGE complex (log β_{110} = 28.7),[5c] and is similar to the natural siderophore ferrioxamine B (log β_{111} = 30.6).[13] These results indicate that the TRPN anchor brings about a larger stabilization of the complex than TREN, which is one of the important factors of the siderophore function. In contrast, the ferrichrome analogue with a C-terminated triscarboxylate anchor, Et-C($CH_2OCH_2CONHCH_2CONOHCH_3$)$_3$, which was previously reported by Dayan et al., forms polymeric and polynuclear complexes rather than a 1:1 Fe^{III}-ligand complex; this was explained in terms of the absence of stabilization factor such as intramolecular noncovalent interactions.[3a] In spite of the high structural similarity between our ligands and theirs, the complexation behaviors are very different. The substantial difference between the ligands is that the terminal atom of the tripodal ligand is either an amine nitrogen or an alkyl carbon. Thus, the high stability of the iron(III)-TAGP complex identified in the wide pH range of 2−8 is achieved by the electrostatic interaction between the positively charged TRPN anchor and the negatively charged aminohydoxyl oxygens.

The bioavailability of **1** was also investigated using *Microbacterium flavescens* (ATCC No. 25091), which cannot synthesize siderophores by itself. Although the growth of the strain was not observed in the siderophore-free ATCC No. 424 broth,[14] it was seen in the medium containing TAGP. This result indicates that TAGP has a siderophore function transporting an iron ion from the medium into the cell. A similar compound, TAGE, also promoted growth of the same strain under the same conditions; the difference between the TREN and TRPN anchors was not observed. However, the above-mentioned ferrichrome analogues with a C-terminated triscarboxylate anchor did not promote the growth of the siderophore-auxotrophic mutants of *Pseudomonas putida*,[3a,3c] although the strains examined are different from those which were used in this study. The microbial inactivity of these complexes is either because of the formation of polymeric and polynuclear complexes, or because the 1:1 Fe^{III}-ligand complexes, if they are formed, take a conformation that inhibits the receptor binding.[3a] As mentioned above, the substantial difference between **1** and these complexes is that the complex either has a positive charge or it does not; the former has a positive charge but the latter are neutral. Therefore, a positive charge on a complex may contribute to the promotion of biological activity.

The above findings suggest not only the availability of TRPN as an anchor in the siderophore function but also the biological implication of electrostatic interactions in the positively charged natural siderophores such as desferrioxamine B. Detailed investigations are in progress.

Experimental Section

Fe^{III}TAGP·HCl (1): The ligand TAGP was synthesized according to a modification of a previously published method.[15] The iron(III) complex of TAGP was prepared by the following method. A few drops of pyridine were added to a methanol solution containing $FeCl_3$ and TAGP in a 1:1 molar ratio.[16] Slow evaporation of the solution for a few weeks at room temperature gave a deep-red colored single crystal of **1** suitable for X-ray diffraction analysis.[17]

X-ray Crystallographic Study: Crystal data for $C_{22}H_{45}ClFeN_7O_{12}$ (molecular weight = 690.04): triclinic system with cell dimensions at 288 K of a = 11.711(7), b = 13.285(4) c = 10.974(6) Å, α = 93.04(5), β = 102.56(3), γ = 101.14(6) ° V = 1627(1) Å^3; μ(Mo-K_α) = 6.11 cm^{-1}; F(000) = 730.0; space group $P\bar{1}$ with Z = 2 and $D_{calcd.}$ = 1.41 g cm^{-3}. A selected specimen (0.56 × 0.25 × 0.19 mm.) was sealed in a thin-walled glass capillary. The unit cell parameters were derived from a least-squares refinement of 25 well-centered reflections by use of a Rigaku AFC-7R, and all diffractions were measured on a Rigaku R-AXIS-IV imaging plate area detector with graphite monochromated Mo-K_α radiation (λ = 0.71070 Å). A total of 5484 reflections with a maximum 2θ value of 51.4° were collected. The reflection data were corrected for Lorentz and polarization effects. No absorption correction was applied because of its small absorption coefficient.

The structure was solved by a combination of direct methods and Fourier techniques and refined anisotropically for non-hydrogen atoms by full-matrix least-squares calculations. Refinements were continued until all shifts were smaller than one-third of the standard deviations of the parameters involved. Atomic scattering factors and anomalous dispersion terms were taken from the literature.[18] Hydrogen atoms, which were located from the difference Fourier maps, were included for the structure factor calculation, but not refined. The final cycle of full-matrix least-squares refinement was based on 4725 observed reflections [$I > 3\sigma(I)$] and 388 variable parameters; final R and R_w values converged to 0.091 and 0.141, respectively, with the largest parameter being 0.04 times its esd. The standard deviation of an observation of unit weight was 1.28. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.75 and −1.24 e/Å^3, respectively, which were detected near the metal ion. All calculations were performed using the teXan[19] crystallographic software package from the Molecular Structure Corporation.

Formation of Peptides at Half-Sandwich Complexes Using β- and γ-Amino Acid Esters and a Facile Dipeptide Synthesis from an *N,O*-Glycinato Half Sandwich Complex $[RuCl(NH_2CH_2CO_2)(\eta^6\text{-}C_6Me_6)]$[‡]

Katharina Haas[a] and Wolfgang Beck*[a]

Dedicated to Professor Kurt Dehnicke on the occasion of his 70th birthday

Keywords: Peptides / Amino Acids / Ruthenium / Sandwich complexes

The tripeptide ester complexes **2** and **3** are obtained from the diglycine ester complex [RuCl(*N,N′*-glyglyOMe-H$^+$)(η^6-C_6Me_6)] and the amino acid esters $H_2N(CH_2)_nCO_2Me$ (n = 2, 3). The reaction of the *N,O*-glycinato complex $[RuCl(NH_2CH_2CO_2)(\eta^6\text{-}C_6Me_6)]$ with the β-, γ- and δ-amino acid methyl esters $H_2N(CH_2)_nCO_2Me$ (n = 2,3,4) in CH_3OH and in the presence of NaOMe affords the η^3-*N,N′O*-dipeptide complexes $[Ru\{H_2N(CH_2)_nCONCH_2CO_2\}(\eta^6\text{-}C_6Me_6)]$ **5**–**7** in good yields. These complexes are also obtained in a one pot reaction from $[RuCl(\mu\text{-}Cl)(\eta^6\text{-}C_6Me_6)]_2$, glycine and the amino acid ester. The formation of small peptides at the metal represents a facile procedure which does not require either a protecting/activating group or a coupling agent.

The formation of peptides from nonactivated α-amino acid esters,[2] α-amino acids[3] or from cyclopentadienyltitanium, -zirconium and -tantalum α-aminocarboxylates[4] at the metal centres has been reported by several groups. We have shown that half-sandwich complexes of Ru, Rh and Ir promote the formation of linear oligopeptides from amino acid esters[5a] and that the continuous addition of glycine or alanine esters to [RuCl(glyglyglyOMe-H$^+$)(*p*-cymene)] leads to complexes of higher peptides.[5b] Previously we have used di- or tripeptide ester complexes and α-amino acid esters for the elongation of the peptide chain with a defined amino acid sequence. In view of the recent high interest in β-amino acids,[6] which stems from the significant developments in β-peptide chemistry by Seebach[7] and Gellman[8] and their co-workers, we wanted to see whether β- or γ-amino acid esters could be used for peptide synthesis at half-sandwich complexes. We have also found that the condensation of amino acid esters even occurs with an *N,O*-chelate glycinate complex to give dipeptide complexes.

Formation of η^3-*N,N′,N′′*-Tripeptide Ester Ruthenium Complexes with N-terminal β-Alanine and γ-Amino Valeric Acid

The η^2-*N,N′*-diglycine ester complex **1**[9] was found to insert the amino acid esters $H_2N(CH_2)_nCO_2Me$ (n = 2,3) in the presence of NaOMe giving the tripeptide complexes **2** and **3** in high yields (ca. 90%; Scheme 1). The reactions were carried out at low temperatures in order to avoid side reactions, especially cyclisation[10] of the tripeptide ester at the ruthenium centre.

3	3

Scheme 1

Compounds **2** and **3** showed the molecular ions in the FAB-MS spectra. The new complexes contain a six- or seven-membered chelate ring as well as a five-membered ring. Other examples of bis(chelate) complexes with a five- and a seven-membered ring are half-sandwich complexes of Ru, Rh and Ir with L-methionylglycinate;[11] those containing a five- and a six-membered ring are, for example,

[‡] Metal Complexes of Biologically Important Ligands, CXXXVI. – Part CXXXV: see ref.[1]

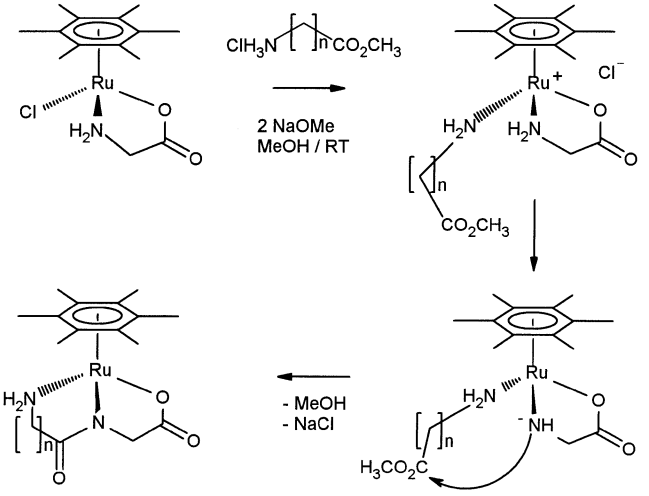
half-sandwich complexes of methioninate.[12] Side reactions (possibly cyclisation of the tripeptides) were observed when amino acid esters $H_2N(CH_2)_nCO_2R$ with longer carbon chains ($n > 3$) were used and the products proved not to be analytically pure.

The IR, ^1H and ^{13}C NMR spectra of **2** and **3** exhibit the expected signals (see Exp. Sect.)., and successful formation of the tripeptide at the metal is demonstrated by the appearance of only one ^{13}C NMR signal for the ester carbonyl group at $\delta = 175$.

Dipeptide Formation from [RuCl(glycinate)(η^6-C_6Me_6)] and Amino Acid Esters

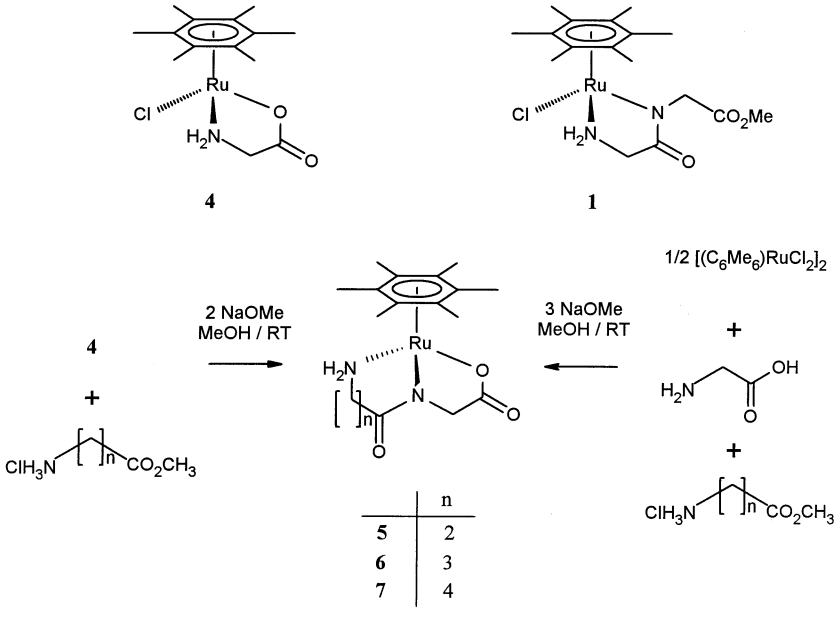
The *N,O*-glycinate ruthenium complex **4**[13] is isoelectronic with the dipeptide ester complex **1** which was successfully used for the peptide synthesis at a metal centre.[5] Complexes **1** and **4** contain three facial coordination sites and a leaving group. Indeed the reaction of **4** with the hydrochlorides of the β-, γ- and δ-amino acid methyl esters $H_2N(CH_2)_nCO_2Me$ ($n = 2-4$) in MeOH at room temperature and in the presence of NaOMe affords the stable, light yellow dipeptide complexes **5**−**7** with yields of up to 97%. The yield decreases with the C-chain length of the amino acid ester (**7**: 67%). No reaction was observed with the ε-amino acid ester $H_2N(CH_2)_5CO_2Me$ and **4**.

The compounds **5**−**7** are also available in a one pot reaction from the chloro-bridged complex [RuCl(μ-Cl)(η^6-C_6Me_6)]$_2$,[14] glycine and the hydrochloride of the amino acid methyl ester in the presence of NaOMe (Scheme 2).



Scheme 3

Side products could not be detected. We assume a mechanism similar to that proposed by Yamada et al.[2] and Rode[3] for the Cu^{II}-catalyzed formation of peptides from α-amino acids (Scheme 3). The sterically favoured annellation of a five- and a six- or seven-membered ring may promote the formation of the bis(chelate) complexes. This reaction represents a facile peptide formation from an unprotected α-amino carboxylate which doesn't require either an activating group for the free amino acid or a coupling agent. It differs from the formation of the dipeptide esters by the reaction of cyclopentadienyltantalum(V) amino acid carboxylates with free amino acid esters, where the metal carboxylates function as "activated amino acid esters".[4] The



Scheme 2

possibility that in the reaction of **4** with β-, γ- and δ-amino acid esters the latter are added to the metal-activated[4] carboxylate group can be excluded, since then a dipeptide ester complex should be formed that would show IR and NMR spectroscopic data different from those of **5**−**7**; for example, a carbonyl ester absorption at 1730 cm^{-1} would be present instead of a carboxylate band at 1620 cm^{-1}.

The peptide formation can be followed from the IR spectra. Compounds **5**−**7** exhibit a strong absorption at 1541−1571 cm^{-1} for the amide group. Further characteristic bands are observed at 3200 (NH) and 1620 cm^{-1} (CO_2). In the ^1H NMR spectra sharp signals are found which point to a slow epimerization[15] at the chiral metal centre. The ^{13}C NMR spectra show the expected signals.

Experimental Section

Preparation of 2 and 3: A solution of the hydrochloride of the amino acid methyl ester (0.2 mmol) and NaOMe (0.2 mmol) in methanol (5 mL) was stirred for 10 min. at room temperature. A solution of **1**[9] (0.2 mmol) in methanol (3 mL) was then added to this mixture, followed by the dropwise addition of a solution of NaOMe (0.2 mmol) in methanol (15 mL) at −15 °C during 2−3 h. The colour of the solution changed from orange to yellow. The solvent was then removed in vacuo and the yellow, oily residue was dissolved in dichloromethane. Sodium chloride was then centrifuged off and the solution was concentrated to 2 mL. The yellow product was precipitated by addition of 50 mL of pentane, washed with more pentane and dried in vacuo.

[Ru{η³-*N*,*N*′,*N*′′-(β-ala-gly-gly-OMe)}(η⁶-C_6Me_6)] (2): Light yellow powder, yield 91%. − IR (KBr): $\tilde{\nu}$ = 3266 cm^{-1} (m), 3157 (w) [NH_2], 1732 (s) [CO_2CH_3], 1566 (vs) [Amide-I]. − ^1H NMR (400 MHz, CD_3OD): δ = 4.72 (d, ^2J = 16.8 Hz, 1 H, *H*CH), 4.58 (d, ^2J = 16.8 Hz, 1 H, HC*H*), 3.66 (s, 3 H, CO_2CH_3), 3.46 (2 d, ^2J = 16.8 Hz, 2 H, CH_2), 2.97 (m, 1 H, NH_2-CH_2−CH_2−CO), 2.78 (m, 1 H, NH_2−CH_2−CH_2−CO), 2.1−2.3 (m, 2 H, NH_2−CH_2−CH_2−CO), 2.13 [s, 18 H, $C_6(CH_3)_6$]. − ^{13}C NMR (100.5 MHz, CD_3OD): δ = 182.6, 176.1, 175.6 (*C*ONR and CO_2CH_3), 94.8 [$C_6(CH_3)_6$], 55.0, 52.9 (CH_2), 50.2 (CO_2CH_3), 39.8, 39.4 (CH_2−CH_2), 16.5 [$C_6(CH_3)_6$]. − MS (FAB+, *m*NBA): *m*/*z* (%) = 480 (5) [M + H^+], 502 (4) [M + Na^+], 538 (1) [M + H^+ + NaCl].

General Procedure for the Synthesis of 5−7 from [RuCl(glycinate)(η⁶-C_6Me_6)]: A solution of 0.3 mmol of NaOMe in methanol was added dropwise to a solution of 0.15 mmol of **4**[13] and 0.15 mmol of the hydrochloride of the amino acid methyl ester in 5 mL of dried methanol. The yellow solution was then stirred for 2 h (**5**, **6**) or 6 h (**7**) at room temperature. The solvent was removed in vacuo and the residue dissolved in 5 mL of dichloromethane containing a very small amount of methanol (ca. 0.1 mL). Sodium chloride was then centrifuged off and the solution concentrated to 2 mL. The product was precipitated with diethyl ether, washed with Et_2O and dried in vacuo.

General Procedure for the Synthesis of 5−7 from [$RuCl_2$(η⁶-C_6Me_6)]₂: A solution of 0.6 mmol of NaOMe in methanol was added to a mixture of 0.1 mmol of [$RuCl_2$(η⁶-C_6Me_6)]₂,[14] 0.2 mmol of glycine and 0.2 mmol of the hydrochloride of the amino acid methyl ester in 5 mL of methanol. Stirring for 2−6 h gave a yellow solution from which the solvent was then removed in vacuo. The residue was dissolved in 5 mL of dichloromethane containing a very small amount of methanol (ca. 0.1 mL). Sodium chloride was centrifuged off and the solution concentrated to 2 mL. The product was precipitated with diethyl ether, washed with Et_2O and dried in vacuo.

A New Cubane-Type $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$ Tetramer Tailored for Water Photooxidation Catalysis

Edgar Rupp,[a] Frank Nowak,[a] Sebastian Fiechter,*[a] Günter Reck,[b] Volker Eyert,[c] Nicolas Alonso-Vante,[d] and Helmut Tributsch[a]

Keywords: Cubanes / Ruthenium / Structure determination / Density functional calculations / Catalysts

In an effort to tailor a transition metal complex for photoinduced water splitting, a new cubane-like ruthenium chalcogenide tetramer, $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$, has been synthesized and structurally characterized by single-crystal X-ray diffraction. The orange-red compound crystallizes in the cubic space group $I\bar{4}3m$. The geometry of the Ru_4Se_4 units remains undistorted in the cubic symmetry $3m$. Such a high symmetry is exceptional among cubane-type cluster compounds. Ruthenium atoms are octahedrally coordinated by three selenium atoms and three CO groups. $Ru_4Se_4(CO)_{12}$ clusters are linked via van der Waals forces by oxygen atoms which belong to CO ligands of two different cluster units. By stacking of the cluster units along the cubic axes two weakly coupled three-dimensional frameworks are formed. First principles band structure calculations reveal the strong influence of both the C–O bonding, which leads to a large splitting into bonding and antibonding states, as well as of metal–ligand bonding. The latter gives rise to several very sharp Ru d bands of t_{2g}-like symmetry just below the valence band maximum E_v, which are expected to be useful for oxidation catalysis. While these states are bonding below –1.3 eV, they are antibonding near the edge of the valence band. For this reason, we expect a stabilization of the cubane core on depopulation of the highest occupied bands. Consequently, it is likely that a dynamic interrelation between electron transfer and crystal structure occurs.

Introduction

Photoinduced water splitting for fuel generation is a subject which over the years has received significant attention.[1] The process has been demonstrated using UV-absorbing catalysts such as TiO_2 and $SrTiO_3$, but it turned out to be very difficult to identify a catalyst which split water using visible light. The semiconducting compound RuS_2, however, photo-oxidizes water with high quantum efficiency under assistance of an electrical potential involving Ru-centerd interfacial coordination chemistry. RuS_2 has an energy gap of 1.3 eV, which is too low for water splitting, so a supporting potential is needed, for energetic reasons to provide the theoretical minimum energy (including losses) which ranges from 1.6 to 2.1 eV depending on the catalytic performance of the material concerned. Synthesizing suitable transition metal compounds with d-energy bands, separated by 2 eV, is therefore a significant challenge for solar fuel generation[2,3] and the aim of this contribution.

In the past decades numerous efforts have been made to synthesize cubane-like cluster compounds in order to elucidate the relationship between geometry and electronic configuration.[4] Our interest was stimulated by the fact that hydrogen-producing hydrogenase, e.g. from *Clostridium pasteurianum*, contains redoxable thiocubane Fe_4S_4 cores.[5] One of these cores is covalently bridged by a cysteinate thiol to an Fe_2S_2 subcluster (H-cluster).[5,6] Besides sulfur, carbonyl and cyanide ligands coordinate the iron atoms. It is thought that multi-electron transfer, for example bi-electron transfer to reduce protons to yield dihydrogen, is corroborated with the presence of d-metal centers, which can vary their oxidation state over a wide range. In the past, Chevrel-type compounds were investigated, the characteristics of which are octahedral metal cores consisting of Re, Rh−Mo, Pt−Mo, Os−Mo and Ru−Mo, respectively, linked by chalcogen and halogen atoms.[7] Light enhanced oxygen reduction was observed in $Re_6S_8Cl_2$ [8] while $Re_4Mo_2Se_8$ and $Ru_2Mo_4Se_8$ are of interest as catalysts for the reduction of molecular oxygen in acidic media.[9,10] A facile chemical synthesis route using carbonyl compounds and elemental chalcogenides to tailor novel metal clustering compounds in the form of powder was recently reported.[11] To prepare new ruthenium- and molybdenum-containing cluster compounds, which are known to be highly catalytic for many purposes, under increased pressures and temperatures, the $Ru_3(CO)_{12}$ was treated in a selenium-saturated xylene solution. Using this preparation the new compound $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$ could be obtained.

Cubane-Type Compounds

Cubane-like clusters $(ML_3)_4(\mu_3\text{-}E)_4$, which contain tetrahedral structural units of four transition metal atoms, M_4, and four main group non-metal atoms, E_4, combined to give a cubic moiety, $M_4(\mu_3\text{-}E)_4$, have been the subject of

numerous papers.[4,12−28] Most of the cubic clusters show a distortion from the idealized T_d symmetry to D_{2d} (with 4 short and 2 long distances or 2 short and 4 long distances) or D_2 symmetry. In a series of papers, Dahl and co-workers[12−20] have analyzed the molecular and electronic structure of Fe- and Co-based cubane-like clusters such as $[Cp_4Fe_4(\mu_3\text{-}S)_4]^n$ (n = 0 to +2),[12,13] $[Cp_4Fe_4(\mu_3\text{-}CO)_4]^n$ (n = 0, +1),[14,15] $Fe_4(CO)_{12}(\mu_3\text{-}Se)_4$,[4] $[(NO)_4Fe_4(\mu_3\text{-}S)_4]^n$ (n = 0, −1),[16,17] $(CO)_{12}Fe_4(\mu_3\text{-}S)_4$,[4] $[Cp_4Co_4(\mu_3\text{-}S)_4]^n$ (n = 0, +1),[18] $(CO)_{12}Co_4(\mu_3\text{-}Sb)_4$ [19] and $(NO)_4Co_4(\mu_3\text{-}NR)_4$.[20]

Based on molecular orbital calculations using the Fenske−Hall model[4] Dahl and co-workers have successfully explained many of the structural variations. Employing qualitative MO diagrams they suggested that for the clusters of cubane-like structures one set of four orbitals may be considered as the nonbonding lone pair localized on the four terminal ligands at low energy. There are groups of 24 orbitals corresponding to metal−Cp and metal−S bonds in $[Cp_4Fe_4(\mu_3\text{-}S)_4]^n$ (Figure 1). At higher binding energies it follows a group of 12 orbitals mainly localized on the metal atoms. These metal-based orbitals have primarily d-orbital character and are responsible for the binding to the framework of the cluster, namely the bonds between the metal atoms along the edge of the tetrahedral metal core. The 24 antibonding combinations formed by M−L and M−E interactions are located at high energies. The interaction between the 12 metal-based orbitals forms two bonding sets, one of metal−metal bonding orbitals of symmetry $a_1 + e + t_2$ and a second set of metal−metal antibonding orbitals of symmetry $t_1 + t_2$.

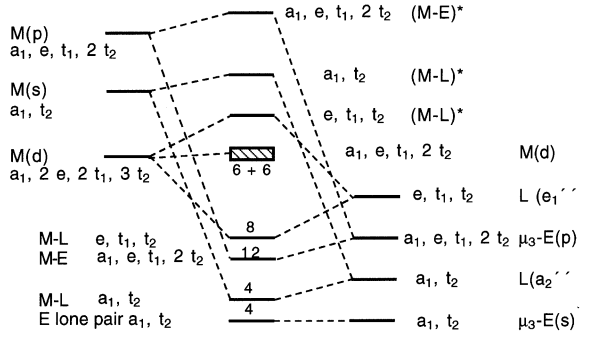

Figure 1. Qualitative energy orbital diagram of the cubane-type cluster unit $Fe_4(CO)_{12}(\mu_3\text{-}Se)_4$, inferred from molecular orbital calculations using the Fenske−Hall model (see ref.[4]); the diagram can also be used to qualitatively explain the bonding conditions in the ruthenium counterpart, investigated in this work

Lauher estimated the bonding capabilities of various transition metal clusters, based upon extended Hückel calculations on bare Rh clusters.[21] He proposed the molecular orbitals of a tetrahedral cluster to have six high-lying antibonding orbitals termed as $t_1 + t_2$ corresponding to the antibonding orbitals of metal−metal interaction of Dahl's model. Additionally, the 30 bonding cluster orbitals contain six orbitals of metal−metal interaction of symmetry $a_1 + e + t_2$ in agreement with Dahl's model. The remaining 24 bonding cluster orbitals are used for M−L and M−E bonding. The occasionally observed distortion of the metal−metal tetrahedron can be explained by an incomplete occupation of the bonding or antibonding set of metal−metal orbitals.

The Model Catalyst

In $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$, described in this paper, the 80 available valence electrons (i.e., 24 from the four d^6-Ru^{2+} atoms, 24 from the 12 CO ligands and 32 from the four bridging Se^{2-} atoms) completely fill the four lone pairs of the Se atoms, the 24 (4 + 12 + 8) bonding metal−ligand orbitals and the six bonding ($a_1 + e + t_2$) as well as the six antibonding metal−metal MOs (Figure 1). From this one would expect the tetrahedral bonds to be metal−metal nonbonding and the cubane core to be stabilized by the metal−ligand bonds. This energy level scheme nicely explains the observed distances and symmetry of cubane-like clusters with 80 valence electrons such as $(CO)_{12}Ru_4Se_4$, $Cp_4Co_4S_4$,[21] $(CO)_{12}Fe_4S_4$,[4] $(CO)_{12}Fe_4Se_4$ [4] and $(CO)_{12}Co_4Sb_4$.[19]

$Ru_4Se_4(CO)_{12}$ crystallizes in the cubic space group $I\bar{4}3m$. The coordination of the cubane-like Ru_4Se_4 core is illustrated in Figure 2 and the framework formed by the clusters in Figure 3. The ruthenium center is octahedrally coordinated by three selenium atoms and three CO groups (Figure 2). As is visible from Figure 3 the clusters are coupled by two pairs of oxygen atoms forming a common tetrahedron of 2.955 Å distance. The bonding angles Ru−Se−Ru and Se−Ru−Se are 95.05° and 84.71°. The six equivalent Ru−Ru distances amount to 3.778 Å corresponding to a nonbonding distance. The Ru−Se distance of 2.561 Å is comparable to the sum of covalent radii. The clusters are three-dimensionally interconnected via van der Waals bonds along the cubic axes and form an orthogonal framework. Due to the body-centerd Bravais lattice, a second identical framework appears diagonally translated by 1/2, 1/2, 1/2 with the origin in the center of the unit cell (Figure 2). Each oxygen atom of framework II (e.g. in cluster 3) is separated by the distance of 3.354 Å from four oxygen atoms belonging to framework I. These latter atoms show the distance to the cluster units 1 and 2, as well as the two oxygen atoms to cluster 2 and the two oxygen atoms to cluster 1 and a third cluster of framework I, not shown in Figure 4 for clarity reasons. Crystallographic data and atomic parameters are given in Tables 1 and 2. Bond lengths and angles are summarized in Table 3.

The presented structure is a highly symmetrical example of a structure with cubane-like Ru_4Se_4 cores. Such a high symmetry is exceptional among cubane-type cluster compounds and to the best of our knowledge $Ru_4Se_4(CO)_{12}$ is the first cubane-type compound of cubic symmetry described. All other known structures crystallize in lower symmetric space groups. For example in $Ru_4Se_4(CO)_{10}(Ph_2PCH_2PPh_2)$, whose cubane-like unit is closely related to our compound, the Ru−Se distances vary from

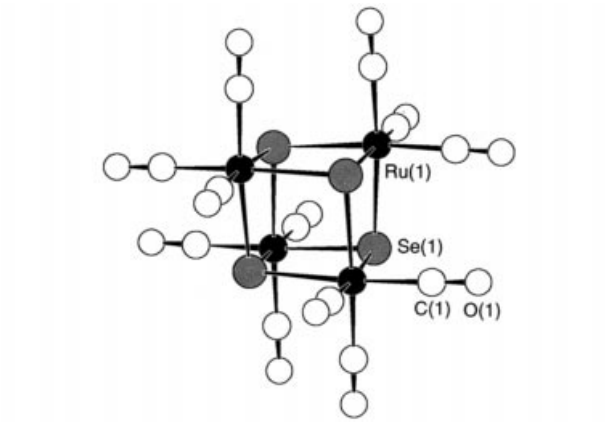

Figure 2. Cubane-type cluster unit $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$

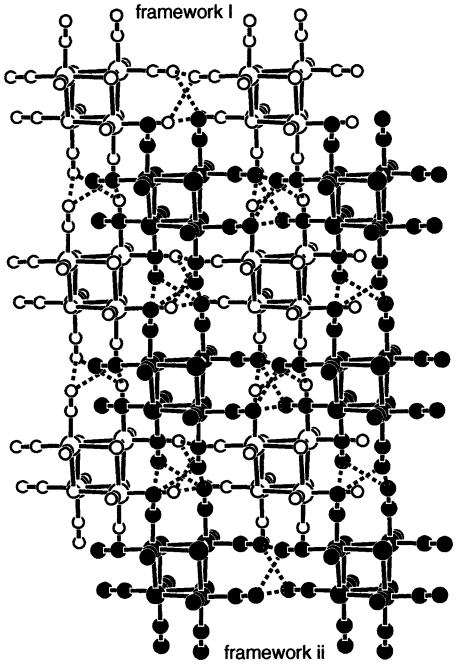

Figure 3. Arrays of cluster units of $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$ interconnected via van der Waals bonds along the cubic axes forming an orthogonal framework; due to the body-centerd Bravais lattice type, a second identical framework appears diagonally translated by 1/2, 1/2, 1/2

2.552 to 2.577Å, the inner bond angles Se−Ru−Se and Ru−Se−Ru range from 83.6 to 86.1° and from 93.4 to 96.4°. The average values (2.564 Å, 84.8° and 95°, respectively) are close to the angles and distances found in the present structure.[27]

Density Functional Calculation

The partial, i.e. orbital-projected densities of states, as determined from self-consistent calculations, are displayed in Figures 5 and 6, where we have included Ru-4d, Se-4p as well as C- and O-2p states; all other states gave only negligible contributions to the total density of states in the energy interval shown. In particular, while at lower energies there exist C- and O-2s states we find Ru-4s bands above 7 eV. In order to study the octahedral-like crystal-field splitting at the Ru sites we have separated the 4d partial DOS into its *xy*, *xz*, *yz* and $3z^2 - r^2$, $x^2 - y^2$ components, which, in an ideal octahedron, correspond to the t_{2g} and e_g or-

bitals. Finally, we give the calculated partial crystal orbital overlap populations (COOP) for selected bonds in Figure 7.

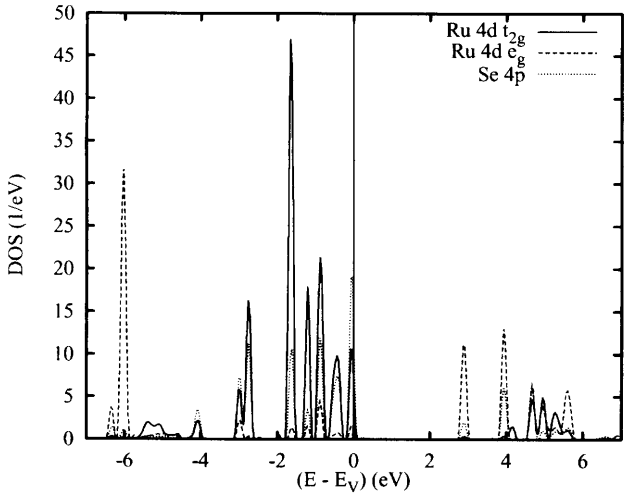

Figure 5. Partial Ru-4d-t_{2g} and -e_g as well as Se-4p densities of states; here and in the following figure energies refer to the valence band edge E_v

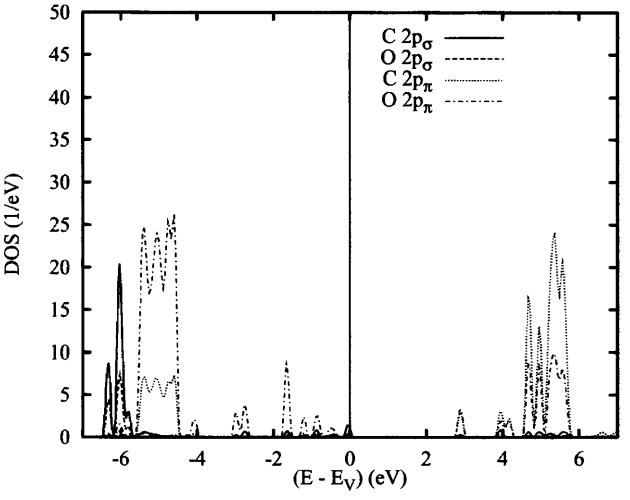

Figure 6. Partial C- and O-2p states of a single C−O pair separated into the p_π and p_σ states

In Figure 6 we display the C- and O-2p partial densities separated into their p_π and p_σ states. We observe two rather conspicuous groups of bands at ±5 eV, each separated into four sub-bands due to the small overlap of the Ru-4d states

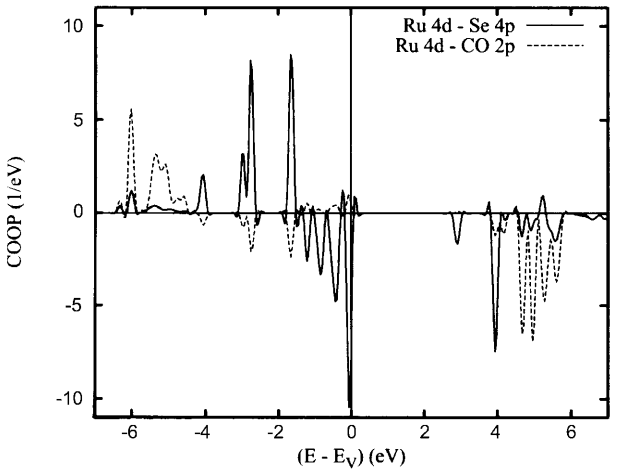

Figure 7. Partial crystal orbital overlap populations for selected bonds

with the bonding C−O orbitals as well as the low symmetry of the crystal field. According to additional analysis of the COOP, the two groups of bands at ±5 eV result from strong splitting of the C- and O-2p states into bonding and antibonding bands due to π-type overlap across the short bond of only 1.12Å. As expected, the occupied and unoccupied states have larger contributions from O and C, respectively. Since the bonding and antibonding states resulting from this π-type overlap are completely filled and empty, respectively, the C−O bonding adds the largest contribution to the stability of the compound. Furthermore, since these states are located well below and above the Fermi energy the corresponding bonds cannot be broken by simple electron transfer. This striking feature of the C−O cubane core interaction is suspected to be also relevant for the C−O terminated ferredoxins in an iron-only hydrogenase.[5]

An even larger splitting into bonding and antibonding states of about 16 eV is observed for the O- and C-2s and -$2p_\sigma$ states, where it gives rise to rather sharp peaks at about −24 and −8 eV, outside the energy range displayed in Figures 5−7. Yet, in contrast to the $2p_\pi$ bands, both these bonding and antibonding orbitals are fully occupied and thus neither contribute to the overall stability nor determine the low energy excitations of the compound. Finally, we observe a fifth group of bands derived from C- and O-2p states at approximately −6 eV below the valence band maximum. It comprises predominantly C- and O-$2p_\sigma$ as well as Ru-4d orbitals.

Bonding of Ru to its neighboring ligands is strongly influenced by the presence of two different types of ligands, namely, three selenium atoms and three C−O pairs, as well as their pseudo-octahedral coordination of the ruthenium sites. Although the particular arrangement of the ligands reduces the local symmetry at the Ru sites to C_{3v} the pseudo-octahedral coordination still allows the interpretation of the Ru-4d partial DOS in terms of its t_{2g} and e_g components as they would grow out of an ideal cubic crystal field. Whereas the t_{2g} states appear mainly in the energy

range from −4.2 eV to E_v, the e_g orbitals contribute to the sharp peaks at −6 eV as well as in the energy range from 2.8 to 6 eV above the valence band maximum. Interestingly, a finite t_{2g} partial DOS is also observed between 4.5 and 6 eV.

Due to the peculiarities of the crystal structure with two different types of ligands, selenium atoms and carbon−oxygen pairs, the ligand contributions to both the Ru-4d-t_{2g} and -e_g states change across the energy spectrum. To be specific, the occupied Ru-4d-t_{2g} states occurring in the upper part of the valence band are complemented with contributions from the Se-4p states resulting from π-type overlap. In contrast, contributions from the C−O-2p states to π-type metal−ligand bonding are rather small in this energy region. This is due to the bonding−antibonding splitting of the $2p_\pi$ states discussed above, which shifts these states to ±5 eV. As a consequence, Ru-4d-t_{2g} states, which form π bonds with the C−O-$2p_\pi$ states, are also found near ±5 eV.

A σ-type metal−ligand bonding is signalled by the ligand p contributions to the peak at approximately −6 eV as well as to the unoccupied Ru-4d-e_g dominated bands. Again, due to the special octahedral-like coordination of the metal sites by two different types of ligands the d−p overlap changes across the spectrum. While the bonding Ru-4d-e_g states overlap almost exclusively with the C−O-$2p_\sigma$ orbitals, the Ru-4d-e_g partial DOS above 2.8 eV is complemented by both Se-4p and small C−O-2p contributions. This finding is supported by the calculated COOP (Figure 7): Whereas the peak at approximately −6 eV results mainly from Ru−C−O bonding, the energy range from 2.8 to 4 eV is dominated by antibonding Ru−Se states. In conclusion, the cubane framework is predominantly stabilized by σ-type interaction between Ru and CO and π-type interactions between Ru and Se as depicted in Figure 8.

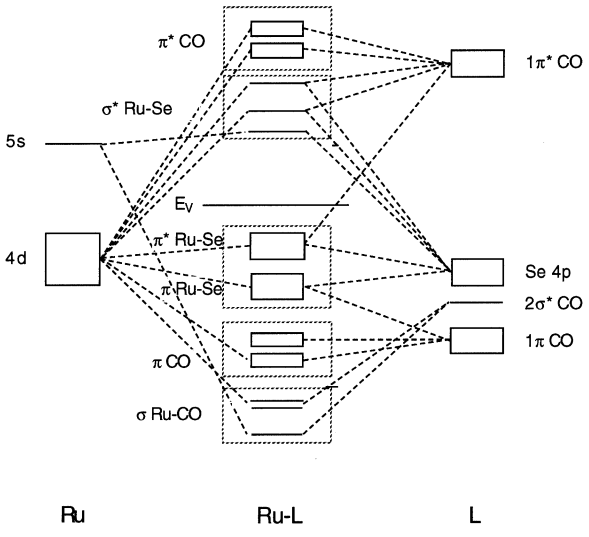

Figure 8. Qualitative energy orbital diagram of $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$

Electron-Induced Structure Dynamics

The different weighting of the ligand contributions to the Ru-4d-t_{2g} and -e_g states in the whole energy spectrum has striking consequences for the bonding properties and lays ground for the possible catalytic activity of this material. To be specific, while the metal−carbonyl bonding occurs mainly far away from the valence band edge at ±5 eV, bonding and antibonding Ru−Se states are found predominantly in the energy range from −3.2 eV to E_v. Strong bonding both within the carbonyl groups, as well as between these groups and the metal d states, shifts the corresponding states away from the gap. Furthermore, due to the rather weak π bonds both the Ru-4d−Se-4p bonding and antibonding states fall into the uppermost region of the occupied bands and give rise to the high density of states observed in this energy range. In particular, the antibonding sub-bands show up between −1.3 eV and E_v, hence, just below the Fermi energy. If these states are depopulated the Ru−Se bonds are strengthened and the cubane core that is built from penetrating coordination tetrahedra of both types of atoms will contract. In contrast, if these states are again populated, the bonding will decrease, thus causing a slight expansion of the cubane core. As a consequence, we expect substantial electron-lattice interaction, leading to a significant relationship between electron transfer and structural properties. To conclude, the presence of both strong C−O and rather weak Ru−Se bonds, which push the C−O bonding and antibonding states apart and leave room for antibonding Ru−Se states in the uppermost part of the valence band, thus provide the basis for a working mechanism for catalytic processes.

Conclusion

A new $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$ tetramer has been synthesized and characterized experimentally and theoretically. The compound fits nicely into a series of other transition metal cluster compounds possessing cubane-like cores. However, in contrast to the companion compounds, the present material crystallizes with an unusual high symmetry (space group $I\bar{4}3m$). The cluster units are weakly coupled by van der Waals interactions. In order to investigate the electronic structure we combined molecular orbital considerations and state-of-the-art band structure calculations. The theoretical results confirm the wide band gap of the material of E_g = 2.44 eV. In the cubane core Ru is pseudo-octahedrally coordinated by 3 Se and 3 CO ligands. The electronic structure of $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$ is dominated by three different types of bonds each having a characteristic strength: (i) strong π-type C−O overlap shifts the corresponding bonding and antibonding states far below and above the valence band maximum and is responsible for the overall stability of the compound; (ii) σ-type overlap of Ru-4d-e_g states with O/C-2p as well as Se-4p states as resulting from the pseudo-octahedral coordination of Ru likewise places these states at energies well below and above the edge of the valence

band; (iii) finally, rather weakly p-bonded Ru-4d-t_{2g} and Se-4p states dominate in the upper part of the valence band. The respective antibonding states are found at binding energies below 1.3 eV. As a consequence, on depopulation of these states the bonding within the cubane core will increase and the core itself will contract while repopulation will lead to a corresponding expansion. The thus expected coupling between electron and structural dynamics might support electron transfer processes and, hence, might be relevant for catalytic processes.

The prepared $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$ compound fulfils the most important theoretical criteria to act as photocatalyst for water oxidation: (i) a sufficiently large energy gap (2.44 eV) with valence states, which − as a consequence of photooxidation − are able to transfer electrons via Ru-d states; (ii) the oxidation states of ruthenium atoms in the compound can be increased to allow formation of peroxo complexes, which are able to release oxygen; (iii) the coupling between electronic and structural dynamics may favour multi-electron transfer.

However, preliminary photoelectrochemical experiments using small crystals of the synthesized complex have indicated a material property which at the moment seriously limits an application: A very high electrical resistivity was found, which has to be overcome by suitable doping techniques, by substituting ligands or by preparation of ultrathin layers.

Experimental Section

$Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$: 18 mg of selenium ($2.8\cdot10^{-2}$ mmol Se_8; ALFA, powder, −325 mesh, 5N) was dissolved in 100 mL of xylene (Merck, mixture of isomers, scintillation grade) under reflux at 140 °C. Then 72.87 mg of $Ru_3(CO)_{12}$ ($1.14\cdot10^{-1}$ mmol; STREM crystalline, 99%) was added to the solution and dissolved. The solution was then brought to ambient temperature. This solution (ca. 35−40 mL) was used to fill an ampoule of Duran glass and sealed under vacuum using a water-jet pump. Further treatment was performed in a high-pressure Morey-type autoclave with a Teflon inset and a Teflon seal. The ampoule was placed in the autoclave and heated. A counterpressure was applied filling the autoclave vessel to 80 vol% with water. The autoclave was heated to 250 °C for 30 d. After cooling, the ampoule was broken and the product separated using a PTFE filter. The residue was washed with small portions of diethyl ether. Optical analysis using a light microscope revealed that besides a black powder, which was identified as elemental ruthenium by X-ray powder diffractometry, orange red crystals had been formed with a yield of 5% (4.5 mg). − Depending on the reaction time orange-red crystals up to 100 μm length grew in a black powder of Ru particles of nanometer size. This growth behaviour is very similar to the preparation of the carbidocarbonyl $Ru_6C(CO)_{17}$ described by Johnson et al.[29] and by Braga et al.[30] which could also only be obtained in a moderate yield. − The purity of the crystals and the Ru/Se ratio of unity was confirmed within an error bar of 3% by using Energy Dispersive X-ray fluorescence. The carbon monoxide content was measured thermogravimetrically and the gases released were analysed by mass spectrometry. − FTIR measurements were performed using a Bruker IFS 113v spectrometer. By means of attenuated total reflection, two strong peaks at 2079 and 2008cm^{-1} in the CO region were detected employing a micro KRS5 crystal at 45°. − To determine the energy gap of the compound an absorption measurement was performed in the range from 400 to 800 nm using a Leitz microscope. − X-ray data collection was carried out with an Enraf−Nonius CAD-4 diffractometer at 293 K using Mo-K_α (λ = 71.073pm) radiation monochromatized by a graphite crystal. Data were collected employing the 2Θ-ω scan technique in the range $3° < 2\Theta < 60°$. The total number of reflections was 936 from which 191 were independent [R_i = 0.035, 169 observed ($I > 2\sigma(I)$)]. The dimensions of the prismatic crystal were $0.12 \times 0.10 \times 0.09$ mm. The structure was solved by direct methods using SHELXS-90[31] in the space group $I23$. But an inspection of the resulting atomic coordinates showed that the higher symmetry $I\bar{4}3m$ was also fulfilled. The refinement of 23 parameters in $I\bar{4}3m$ with SHELX-97[31] converged with R_1(on F) = 0.015 and wR_2(on F^2) = 0.046. The crystallographic data (excluding structure factors) for the structure reported in this publication have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-155020. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. − In order to obtain more insight into the electronic properties of solid $Ru_4(CO)_{12}(\mu_3\text{-}Se)_4$, band structure calculations were performed as based on density functional theory and the local density approximation (LDA). In doing so, we account in an optimal balance for both the electron−lattice and the electron−electron interaction, both of which are known to strongly influence the properties of transition metal compounds. For the LDA the parametrizations by both Moruzzi, Janak and Williams as well as by Vosko, Wilk and Nusair were used without essentially any difference in the results.[32,33] As a calculational scheme we employed the augmented spherical wave (ASW) method[34] (see ref.[35] for a more recent treatment), which is one of the most efficient band structure methods in use today and offers the advantage of a minimal basis set similar to atomic orbitals. The latter fact allows, in particular, for an intuitive interpretation of the results. The basis set included Ru-5s, -5p, -4d, Se-4s, -4p as well as C- and O-2s, -2p states. Care was taken to ensure convergence of the results with respect to the completeness of the basis set as well as the fineness of the k space grid; the Brillouin zone sampling used up to 158 points within the irreducible wedge. The interpretation of the electronic properties from the calculated band structure and partial densities of states was complemented by an analysis of the crystal orbital overlap population (COOP), which allows access to the chemical bonding in more detail.[36] − In the present work we performed two different sets of calculations. In the first set we used the experimentally determined lattice constants and atomic positions. In contrast, in the second set of calculations we used a hypothetical crystal structure where the Se atoms were adjusted to positions corresponding to an ideal cubic Ru−Se core and where, hence, some degeneracies were restored. This way we were able to make closer connection to symmetry considerations employed in previous work, which were based on an ideal cubic arrangement, and thus to cross-check our results obtained for the measured crystal structure.

Acknowledgments

Tris(indenyl)lanthanoid Complexes (Ln = La, Pr, Nd) Containing either (*S*)-(−)-Nicotine or Two Simpler Pyridine Bases

Jingwen Guan[a,b] and R. Dieter Fischer*[a]

Keywords: Lanthanides / N ligands / Chirality

Novel examples of the complex of the type [Ln(Ind)$_3$·Nic] [Ind = indenyl; Nic = (*S*)-(–)-nicotine] with Ln = La (**2**), Pr (**3**), and Nd (**4**) have been synthesised, along with their "parent" system [LaCp$_3$·Nic] (**1**). Complexes **2**–**4** were structurally, exhaustively characterised (XRS, ^{1}H NMR spectroscopy). Attempts to prepare homologues of **3** with achiral N-bases, pyridine, α-picoline, β-picoline, 2,6-dimethylpyridine, 2,6-bis(*tert*-butyl)pyridine, 2,2′-bipyridine, and 4,4′-dimethyl-2,2′-bipyridine, were successful with only the two least bulky bases, pyridine and β-picoline, which afforded the new adducts **5** and **6**, respectively. The chiral [Ln(Ind)$_3$·Nic] adducts are virtually isostructural, although subtle but systematic conformational variations emerge from the crystal structure analyses. While the unit cells of **2**–**4** contain two epimeric diastereomers, those of **5** and **6** involve genuine optical antipodes. The chiral carbon atom of nicotine lies approximately twice as far from the metal centre than the chiral sulfur atom of the methyl tolyl sulfoxide (MTSO) ligand in the previously reported [Ln(Ind)$_3$·MTSO] systems. As a result of this, the impact of the chiral MTSO ligand, both on the molecular structure and the ^{1}H NMR spectra, is found to be notably stronger than that of (*S*)-(–)-nicotine. The comparatively weak f-f circular dichroism of **3** is also compared with that of its (*S*)-(–)-MTSO-containing congener.

Introduction

Whilst the crystal structures of a few 1:1 adducts of a tris(cyclopentadienyl)lanthanoid(III) complex and pyridine (Py), or any pyridine derivative (Py*), have already been reported,[1−3] only one corresponding indenyl complex [Ce(Ind)$_3$·Py][4] has so far been characterised, also by X-ray crystallography. Structural studies on adducts containing the *chiral* pyridine derivative (*S*)-(−)-nicotine (Nic) are yet to be reported on, although several [LnCp$_3$·Nic] systems were prepared for early spectroscopic studies.[5,6]

Our current interest in the structural details of diverse [(Ind)$_3$Ln·Py*] systems results from more recent observations in which the three bulky benzo groups of the indenyl units may be oriented in various different ways[7−9] depending on the actual bulkiness of the metal-coordinated Lewis base. Moreover, a *chiral* Lewis base L is also expected to control the chirality of the {Ln(Ind)$_3$X} fragment[7] (X is the ligand atom that is bonded to the metal centre), provided that the chiral centre of the base resides only two bonds away from the metal centre, as in chiral sulfoxides[10] and 2-methyltetrahydrofuran.[11a] In the present study, our interest will be focused on whether a chiral centre located about twice as far from the metal centre than that in the recently investigated methyl tolyl sulfoxide (MTSO) adducts,[10] would still exert any detectable configuration controlling or electronic influence. While the chiral sulfur atom of the oxygen-coordinated MTSO ligand is separated from the metal ion by only one atom, three atoms would separate the chiral carbon atom of a *nicotine* ligand (coordinated via its pyridine N atom) from the metal centre (see Figure 1). Particular attention will therefore be paid to subtle conformational details in the crystal structures, to auxiliary ^{1}H NMR signal displacement or splitting effects due to the presence of paramagnetic metal ions, and even to potential f-f circular dichroism of the central Ln^{III} ions with an incomplete 4f^q configuration. We thus wish to present an exemplary description of the employment of suitable alternative techniques, in combination with X-ray crystallography, to elucidate the influence of paramagnetic 4f^q metal ions on distinct features of the ligand sphere, and, conversely, of notably remote chirogenic centres on the 4f electrons. In addition we report on the first successful synthesis of analytically pure [Ln(Ind)$_3$·Nic] compounds (Ln = La, Pr, Nd).

Results and Discussion

Synthesis and General Properties of [La(C$_5$H$_5$)$_3$·Nic] (1)

Facile ligand exchange was found to take place, when a solution of (*S*)-(−)-nicotine in toluene was added to a suspension of [La(C$_5$H$_5$)$_3$·THF][8] in toluene. The product precipitated as a faint yellow powder which dissolves readily in CH_2Cl_2 and THF, but only moderately in benzene or toluene. In THF the reverse reaction of Equation (1) was found to occur. In the mass spectrum, both metal-containing [Cp$_n$La]$^+$ fragments with n = 3, 2, 1, 0, and smaller purely organic fragments of nicotine were observed. In the ^{139}La NMR spectrum, one relatively broad resonance at δ = −534 ($w_{1/2}$ = 979 Hz), referenced to a solution of $LaCl_3$ in

D_2O, appears. This compares reasonably with corresponding results for $[La(C_5H_5)_3{\cdot}THF]$ ($\delta = -558$, 450 Hz) and $[La(C_5H_5)_3{\cdot}MTSO]$ ($\delta = -563$, 390 Hz).[8,10] In the ^1H NMR spectrum of **1**, *all* the resonances for the nicotine protons were assigned in a similar manner to those in the ^1H NMR spectrum of a previously reported paramagnetic $[PrCp_3{\cdot}Nic]$ complex.[6] However, several lines in the ^1H NMR spectrum of **1** are overlapping. For the full assignment of the spectroscopic results (see Exp. Sect.), the designation of the nicotine protons is adopted as given in Figure 1. While the ^1H NMR spectrum of the paramagnetic Pr^{III} complex had already revealed that the nicotine molecule is coordinated via its pyridine N atom,[6] this particular feature is not as convincingly apparent from the spectrum of diamagnetic **1**.

$$[La(C_5H_5)_3{\cdot}THF] + \text{(S)-(-)-nicotine} \xrightarrow{\textit{toluene}} [La(C_5H_5)_3{\cdot}Nic]\ (\mathbf{1}) + THF \quad (1)$$

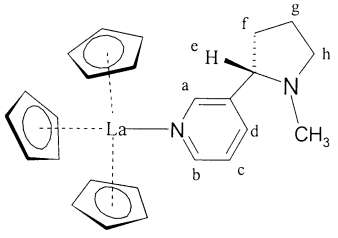

Figure 1. Schematic structure of complex **1**, including the designation of the protons on the nicotine ligand

Synthesis and General Properties of the $[Ln(Ind)_3{\cdot}Nic]$ Systems 2−4 (Ln = La, Pr, Nd)

The three nicotine adducts $[Ln(Ind)_3{\cdot}Nic]$ with Ln = La, Pr, and Nd (**2**−**4**) could be obtained similarly, by ligand exchange reactions, i.e. by adding a solution of nicotine in toluene, to a suspension of the corresponding THF adduct $[Ln(Ind)_3{\cdot}THF]$ as shown in Equation (2). Somewhat unexpectedly, all tris(indenyl) homologues of **1** resulted in viscous oils which are analytically pure. However, when the yellow-orange oil of **2** coexisted with a trace amount of toluene, the sticky syrup converted overnight into rod-like, bright yellow crystals of excellent X-ray quality. However, this simple technique was not suitable for the crystallisation of **3** and **4**. Crystals of the latter complexes could only be obtained when the viscous oils were first dissolved in small amounts of toluene, after which a large amount of hexane was slowly added. After some time, crystal-like products could be seen. Finally, the liquid phase was decanted, and the remaining solid was washed with hexane. The purified residues were redissolved in hot toluene and the temperature was lowered very slowly and steadily. Prismatic leek-green crystals of **3**, and grass-green crystals of **4**, were obtained which were of excellent quality for X-ray crystallographic studies. Toluene solutions of these crystals no longer afforded the viscous oils after the removal of the solvent.

$$[Ln(C_9H_7)_3{\cdot}THF] + \text{(S)-(-)-nicotine} \xrightarrow{\textit{toluene}} [Ln(C_9H_7)_3{\cdot}\text{(S)-nicotine}] + THF \quad (2)$$
$$Ln = La, Pr \text{ and } Nd$$

Complexes **2**−**4** are very soluble in toluene, benzene, THF, MeCN, and CH_2Cl_2, but insoluble in hexane. The nicotine adducts appear to be thermally more stable (under N_2) than their corresponding MTSO congeners.[10] In the mass spectra of all three complexes, signals corresponding to the metal-containing fragments $[Ind_nLn]^+$ with $n = 3$, 2, 1, and 0 were found. Several weaker peaks assigned to purely organic fragments such as $[Ind]^+$, $[Nic]^+$, $[C_5H_4NC_4H_7]^+$, $[C_5H_4NC_3H_5]^+$, $[C_4H_7NCH_3]^+$, etc. were observed as well. Variable-temperature ^{139}La NMR spectroscopic studies of **2** show that the signal is considerably broadened with decreasing temperature. Interestingly, this broadening effect seems to be notably more pronounced for tris(indenyl)- than for tris(cyclopentadienyl)lanthanum(III) complexes.[8] This suggests a more sensitive response of the large ^{139}La nuclear quadrupole moment on the presence of the less symmetrical (as compared with C_5H_5) indenyl ligands (see Table 1).

Table 1. Comparison of the ^{139}La NMR results (chemical shift and line width) for corresponding cyclopentadienyl and indenyl complexes $[LaCp'_3{\cdot}L]$ (Cp′= Cp or Ind)

L	Temp. [K]	δ(^{139}La) Cp	Ind	$w_{1/2}$ [Hz] Cp	Ind	Ref.
(*S*)-(−)-Nic	345	−534	−413	545	1221	
(*S*)-(−)-Nic	325	−535	−417	675	1695	
(*S*)-(−)-Nic	292	−539	−425	980	2765	
THF	320		−558		508	[8]
(*S*)-(−)-MTSO	320		−450		2480	[10]

Another interesting feature of the nicotine complexes **2**−**4** is that their melting points are quite low (**2**: 94−98; **3**: 129−132; **4**: 112−116 °C). Only the melting point of **3** compares with those of the reported $[Ln(Ind)_3{\cdot}MTSO]$ systems.[10] Possibly, the "tadpole-like" shape of a $[Ln(Ind)_3{\cdot}Nic]$ molecule, with its extended nicotine tail (vide infra), can undergo various facile conformational changes, which − with its pronounced flexibility − is likely to inhibit the arrival at a well-ordered crystalline phase.

Attempted Syntheses of Related $[Pr(Ind)_3{\cdot}Py^*]$ Adducts; Preparation and General Properties of $[Pr(Ind)_3{\cdot}Py]$ (5) and $[Pr(Ind)_3{\cdot}(3\text{-}MePy)]$ (6)

The corresponding pyridine and β-picoline adducts of complex **3** were prepared in a similar manner to complex **3** (Ln = Pr) as shown in Equation (3). In contrast to **2**−**4**, the simpler adducts **5** and **6** did not form viscous oils, but rather leek-green microcrystals formed, which could readily be recrystallised from hot toluene affording single crystals suitable for X-ray crystallography. Both compounds are reasonably soluble in toluene and benzene, but more soluble in MeCN, CH_2Cl_2, and THF. In the mass spectra, peaks of the metal-containing fragments $[Ind_nPr]^+$ with $n = 3$, 2, 1,

and the organic fragments $[Ind]^+$, $[Py]^+$, or $[MePy]^+$ were observed.

$$[Pr(Ind)_3{\cdot}THF] + Py^* \xrightarrow{toluene} [Pr(Ind)_3{\cdot}Py^*] + THF \quad (3)$$

Py^* = pyridine: **5**, 3-methylpyridine (β-picoline): **6**

^{1}H NMR spectroscopic data for the indenyl protons of **5** and **6** are included in Table 5, while the corresponding data for the protons of the Py* ligands are found in the Exp. Sect. Quite surprisingly, the chemical shifts of the H atoms next to the pyridine N atom, which are separated from the paramagnetic metal ion by one atom more than the indenyl H atoms, experience notably stronger "paramagnetic" displacements than the indenyl resonances.

Several attempts were made to vary the steric congestion of the potential ligand Py*, by changing the ring substituents and/or their positions on the pyridine fragment. Thus, the pyridine derivatives listed in Equation (4) were subjected to ligand (i.e. THF) exchange experiments, with the hope of initiating new conformational features in the final architecture of the expected complexes. However, all these preparative attempts remained unsuccessful, as the isolable leek-green, crystalline products turned out to be the starting compound $[Pr(Ind)_3{\cdot}THF]$ (as confirmed by elemental analysis, ^{1}H NMR spectroscopy, and crystal structure analysis).

$$[Pr(C_9H_7)_3{\cdot}THF] + Py^* \xrightarrow{toluene} \not\rightarrow [Pr(C_9H_7)_3{\cdot}Py^*] + THF \quad (4)$$

Py* = α-picoline, 2,6-dimethylpyridine, 2,6-bis(tert-butyl)pyridine
4,4'- dimethyl-2,2'-bipyridine and 2,2'-bipyridine

These results clearly indicate that just one methyl group in the 2-position of a pyridine molecule (i.e. α-picoline) no longer allows the indenyl ligands to adopt orientations that would provide enough space for the coordination of this pyridine derivative. This observation does not agree with recent findings in which 2-methyltetrahydrofuran (MeTHF) readily bonds to $\{Ln(\eta^5\text{-}Ind)_3\}$ fragments.[11a] Moreover, one or two of the three indenyl ligands might in principle abandon their usual η^5 coordination for a lower hapticity. This has been suggested for the recently prepared complex $[Lu(C_9H_7)_3{\cdot}3THF]$, in view of its notably higher THF content,[11b] and also for the well-documented crystalline $[LuCp_3]$ complex which has an η^1-coordinated Cp ligand.[12] The failure of α-picoline to enter the coordination sphere of a $\{Pr(Ind)_3\}$ fragment indicates that the required change from η^5 to η^1 (or η^3) coordination probably needs some auxiliary "support" to overcome the higher steric demand of the potential ligands listed in Equation (4).

Crystallographic Studies of the $[Ln(Ind)_3{\cdot}Nic]$ Complexes 2−4

Selected details of the data collection and structure refinement of **2**−**4** are listed in Table 7. Although the three complexes are virtually isostructural, their cell parameters differ significantly, suggesting at least some conformational variation (vide infra).

The C_5 fragments of the indenyl ligands are all η^5-coordinated, although the individual Ln−C distances vary considerably (Table 2). The nicotine ligand is bonded to the metal centre exclusively via its pyridine N atom. The unit cells of **2**, **3**, and **4** contain two rather similar-looking epimeric diastereomers (Figure 2). As the chiral carbon atom of the nicotine ligand lies relatively far from the metal centre, the chiral $\{Ln(Ind)_3{\cdot}N\}$ fragments for each epimeric pair behave as almost perfect mirror images. This situation strongly resembles that observed for several $[Ln(Ind)_3{\cdot}L]$ systems with an achiral L, e.g. L = THF (Ln = La or Pr),[8] L = diphenyl sulfoxide, DPSO (Ln = Nd),[10] and L = Py or β-MePy (Ln = Pr, i.e. in **5** and **6**, vide infra). Here, the unit cell of the crystal always involves both enantiomers (1:1) of a chiral $\{Ln(Ind)_3X\}$ fragment (X = either O or N). On the other hand, in the single crystals of the very closely related adducts $[Ln(Ind)_3{\cdot}L]$ with L = THF (Ln = Sm, Tm[8] and Gd[13]), and L = either (*R*)-(+)- or (*S*)-(−)-MTSO (Ln = La or Pr[10]), only one distinct $\{Ln(Ind)_3{\cdot}X\}$ enantiomer is present.

Initially, the evidence suggested that the three homologues crystallise in the centrosymmetric space group $P2_1/c$. However, after careful assessment of the systematic absence of numerous weak reflections, and along with the non-vanishing chirality of each metal complex, there is no doubt that all three homologues crystallise in the acentric and chiral space group $P2_1$. In Figure 2, the molecular structures of the three epimeric pairs of **2**, **3**, and **4** are depicted such that the orientation of their Ln1−N1−C33 and Ln2−N3−C43 vectors have been kept unchanged. While this particular view was chosen to demonstrate that large portions of each epimeric pair of molecules behave as mirror images, the two diastereomers are positioned face-to-face in the crystals of **2** and **3** (i.e. their nicotine tails turn away from each other), but back-to-back in the lattice of **4**. In all of the structures displayed in Figure 2, the methylated pyrrolidine N atom prefers just one distinct configuration. However, with respect to rotation about the ring-ring C−C bond, the two cyclic components of the nicotine ligand of **4** adopt another conformation than in **2** and **3**.

Selected bond lengths and angles of **2**, **3** and **4** are listed in Table 2. The Ln−C distances involving carbon atoms shared by the C_5 *and* C_6 units of each indenyl ligand are, as usual, significantly longer than the other Ln−C bonds of each C_5 fragment. The Ln−N distances compare well with that reported for $[Ce(C_9H_7)_3{\cdot}Py]$ [Ce−N 268.4(4) pm],[4] and are also in agreement with those in $[Nd(C_5H_5)_3{\cdot}Py]$ [266.8(5)] and in $[Sm(C_5H_5)_3{\cdot}Py]$ [265.6(3) pm].[2] Interestingly, these Ln−N distances are longer than the Ln−O distances in the corresponding $[Ln(Ind)_3{\cdot}MTSO]$ systems,[10] by about 20 pm. The Ce−N distance in $[Ce(MeC_5H_4)_3{\cdot}N(CH_2CH_2)_3CH]$ [278.6(4) pm] exceeds the aforementioned Ln−N distances by at least 10 pm.[14] Intramolecular Nd−N distances ≥ 280 pm are also reported for $[Nd(C_5H_4CH_2CH_2NMe_2)_2Cl]$ and $[Nd(C_5H_4CH_2CH_2NMe_2)_3]$[15,16] while the Nd−N(Py) distances are about 268 pm.[17]

The various molecular conformations, with respect to η^5-indenyl rotation about the individual Ln−Ct*i*5 axes (Ct15, Ct25, and Ct35 being the centres of the three C_5 fragments), of the diastereomers of crystalline **2**, **3**, and **4** may be quan-

tified by inspecting the distances of the three C_6 ring centres, Ct*i*6 (i = 1−3), from the best plane spanned by the three C_5 ring centres, Ct*i*5.[8,10] These quantities, along with the distance of the metal ion from the Ct15/Ct25/Ct35 plane, are listed in Table 3 for the complexes **2**−**7**. The second digit of the individual number of each indenyl carbon atom as found in Figure 2 (i.e. 0, 1, or 2), corresponds to the indenyl ring number *i* (1, 2, or 3) used in Table 3.

For an ideal paddlewheel-like conformation (the benzo groups are considered as "paddles"), with three *equatorially* oriented indenyl ligands, the Ct*i*6-to-plane distances should be minimal (i.e. ≤ 10 pm), whilst the ideal distance for *meridionally* oriented indenyl ligands should be ca. 220 pm.[10] The term "approximately *equatorial*" may be used for distances up to 150 pm, and the term "approximately *meridional*" may be used for distances > 150 pm. By this classification, complex **2** would have two, complex **3** one, and complex **4** no indenyl ligands of *meridional* orientation. This classification agrees well with earlier findings in which the paddlewheel-like conformation is gradually favoured as the radius of the metal ion decreases.[8,10] The opposite signs of the Ct*i*6-to-plane distances of the two meridional ligands of **2** (with i = 2 and 3) indicate that one of the two indenyl benzo groups is located *trans* to the nicotine ligand, and the other one *cis*. While the Ct*i*6-to-plane distances of the two diastereomers of **2** do not differ significantly, the corresponding data sets of **4** display more pronounced deviations. For instance, the Ct16- and Ct36-to-plane values of the two diastereomers have opposite signs. In view of these findings, the two {Nd(Ind)$_3$·N} fragments of **4** (see Figure 2), cannot even be considered as "approximate" mirror images.

Crystallographic Studies of [Pr(Ind)$_3$·Py] 5 and [Pr(Ind)$_3$·(3-MePy)] (6)

Crystals of the two complexes [Pr(Ind)$_3$·Py] (**5**) and [Pr(Ind)$_3$·3-MePy] (**6**) are orthorhombic and belong to the cubic space group *Pbca*. This can be seen in Table 8. Corresponding properties are reported for the cerium homologue [Ce(Ind)$_3$·Py] (**7**).[4] As the unit cell parameters of **5**, **6**, and **7** are similar, the three complexes are quasi-isostructural, although their molecular conformations may still

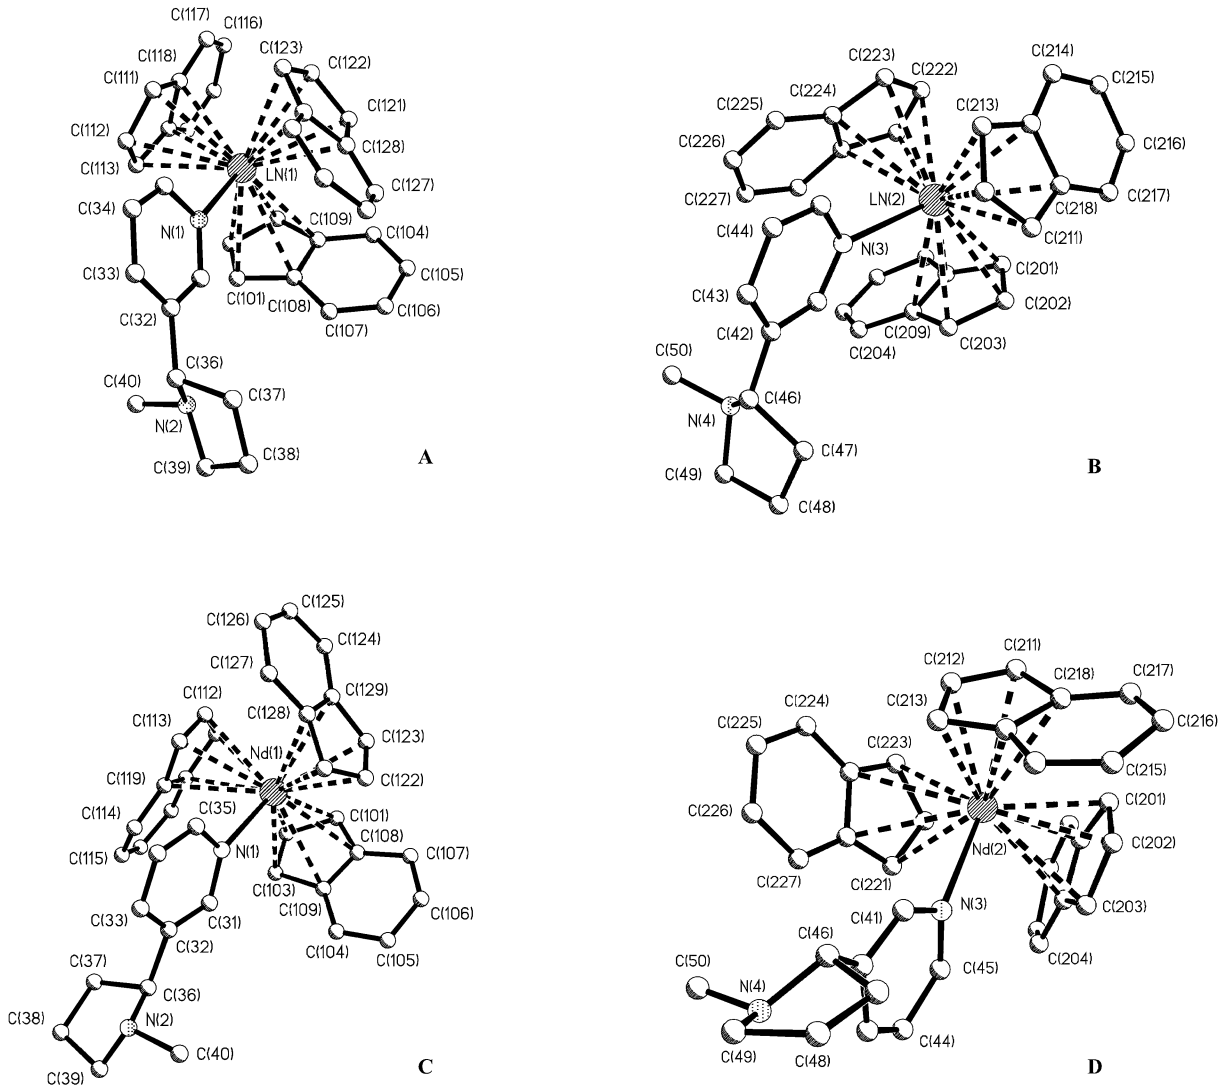

Figure 2. Molecular structure and atomic numbering scheme of the two epimeric diastereomers of **2** and **3** (**A/B**), and **4** (**C/D**), respectively; the drawings **A/B** refer to **2**, although **2** and **3** are almost isostructural; for the specific, pairwise orientation see the text

Table 3. Distances of the C_6 centers Ct*i*6 (i = 1−3), and the metal atom Ln, from the best plane spanned by the three C_5 centres, Ct*i*5, of each epimeric or racemic pair of **2**−**7** (distances in pm; a negative sign indicates the disposal of Ct*i*6 *transoid* to Py*)

Sample	Ln	Ct16	Ct26	Ct36
2 (La)	42.4/42.0	23.4/35.2	−216.4/−217.3	192.1/198.2
3 (Pr)	40.8/41.2	122.8/127.2	66.9/73.6	−218.6/−217.9
4 (Nd)	44.9/40.5	103.3/−78.1	109.6/83.1	−81.8/114.8
5 (Pr)	44.4	−107.1	113.2	113.1
6 (Pr)	50.0	153.9	152.5	88.2
7 (Ce)[4]	45.2	−106.5	113.9	114.2

vary. The molecular structures of **5** and **6** are shown in Figure 3. As the conformations of both complexes are approximately paddlewheel-like (vide supra) (Table 3), the {Ln(Ind)$_3$N} fragments are chiral. The crystal lattices of all three adducts with achiral Py* ligands involve racemic mixtures of molecules with both clockwise and anticlockwise (with respect to the Ln−N axis) oriented benzo groups.

Selected bond lengths and angles are listed in Table 4. The Pr−N distances again compare well with those of **7**[4] and with those of all other [Ln(Ind)$_3$·Py*] systems mentioned above. The Pr−C bond lengths vary between 273.8(4) and 301.8(4) pm, which is a feature also reported for **7**.[4]

Although the conformations of **5** and **6** are paddlewheel-like (like that of **4**), a closer look at the Ct*i*6-to-plane distances listed in Table 3 reveals that the data for **5** satisfactorily match with only one set of **4**. No counterpart exists for a set of three positive Ct*i*6 values (as actually found for **6**).

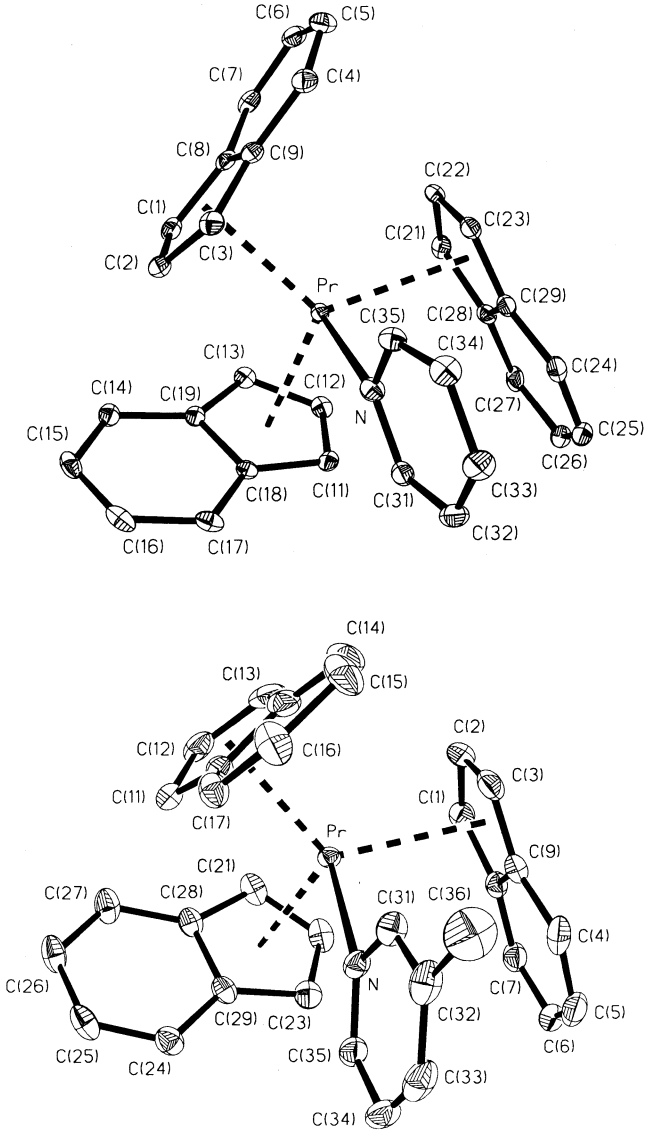

Figure 3. Molecular structure and atomic numbering scheme of the complexes **5** (top) and **6** (bottom)

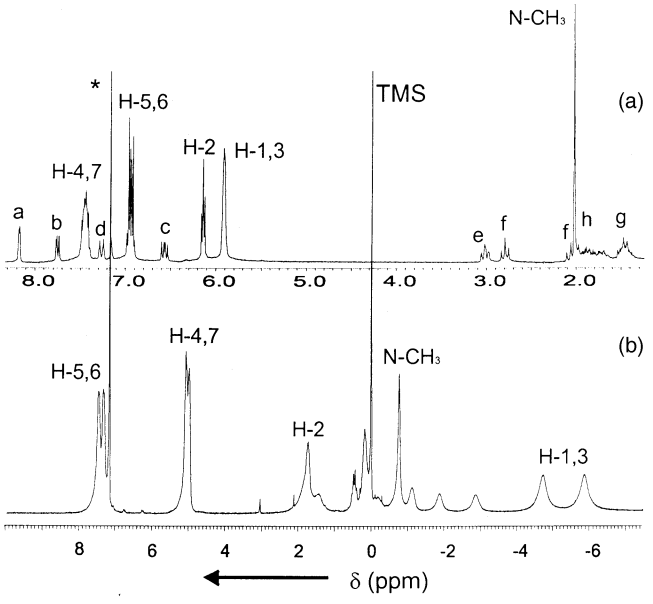

Figure 4. Room-temperature ^{1}H NMR spectra of **2** (a) and **4** (b); solvent: C_6D_6/TMS; signals of the indenyl protons are marked by asterisks; two resonances of **4** (beyond δ = −10, see Exp. Sect.) are not shown

Solution ^{1}H NMR Spectroscopy of 2, 3, and 4

The ^{1}H NMR spectrum of diamagnetic **2** (Figure 4, a) displays almost the same resonance pattern, with respect to the protons of its nicotine ligand, as the spectrum of **1** (see Exp. Sect.). The resonance pattern of the indenyl protons of **2** is consistent with the presence of three virtually equivalent C_9H_7 units. As in the case of [La(Ind)$_3$·THF],[8] no more than four multiplets (I_{rel} = 6:6:3:6) occur indicating that the six pairwise prochiral[10] C_9H_7 protons (see Figure 5) do not experience any significant diastereotopic splitting due to the relatively remote location of the chiral carbon atom of the (*S*)-(−)-nicotine ligand. In striking contrast, however, the three equivalent C_9H_7 ligands of the complex [La(Ind)$_3$·MTSO] [with either (*R*)-(+)- or (*S*)-(−)-MTSO] were found to display *seven* equally intense (I_{rel} = 3) multiplets.[7,10]

Table 5. Room-temperature chemical shifts (ppm) of the indenyl protons of various [Ln(Ind)$_3$·L] systems (solvent: C_6D_6; for the designation of the H atoms see Figure 5, a)

Ln	L	1/3-H	2-H	4/7-H	5/6-H
La	(*S*)-(−)-Nic (**2**)	5.90 (s, 6 H)	6.14 (t, 3 H)	7.46 (m,6 H)	6.94 (q,6 H)
Pr	(*S*)-(−)-Nic (**3**)	9.59 (s, 3 H); 8.79 (s, 3 H)	7.44 (s, 3 H)	8.15 (d, 3 H); 8.03 (d, 3 H)	4.19 (t, 3 H); 4.06 (t, 3 H)
Pr	Py (**5**)	10.03 (s, 6 H)	8.98 (s, 3 H)	7.88 (s, 6 H)	3.65 (s, 6 H)
Pr	3-MePy(**6**)	10.13 (s, 3 H)	7.66 (s, 3 H)	8.12 (s, 6 H)	3.68 (d, 6 H)
Pr	(*R*)-(+)-MTSO[10]	19.55 (s, 3 H); −0.52 (s, 3 H)	1.98 (s, 3 H)	10.41 (d, 3 H); 6.22 (d, 3 H)	4.95 (t, 3 H); 3.85 (t, 3 H)
Pr	DPSO[a] [10]	9.25 (s, 6 H)	4.16 (s, 3 H)	8.18 (q,6 H)	4.02 (dd,6 H)
Nd	(*S*)-(−)-Nic (**4**)	−4.73 (s, 3 H); −5.88 (s, 3 H)	1.74 (s, 3 H)[b]	7.40 (d, 6 H)[c]	5.00 (d, 6 H)[d]
Nd	(*R*)-(+)-MTSO[10]	−2.00 (s.3 H); −7.46 (s, 3 H)	6.09 (s, 3 H)	9.49 (s, 3 H); 6.10 (s, 3 H)	4.32 (s, 3 H); 3.30 (s, 3 H)
Nd	DPSO[a] [10]	−3.87 (s, 6 H)	−0.89 (s, 3 H)	7.66 (s, 6 H)	5.12 (s, 6 H)
Nd	TPPO[d] [11c]	−6.36 (s, 6 H)	−2.56 (s, 3 H)	7.27 (s, 6 H)	5.53 (s, 6 H)

[a] DPSO = diphenyl sulfoxide. − [b] With L = THF, δ(2-H) = 6.73, see ref.[8] − [c] Distance of the two components (in Hz): 480, ruling out any internuclear spin-spin coupling. − [d] TPPO = triphenylphosphane oxide (see also ref.[7]).

On the other hand, the expected diastereotopic splitting for L = (*S*)-(−)-nicotine (instead of MTSO) becomes observable in the ^{1}H NMR spectra of the *paramagnetic* homologues of **2** (i.e. of **3** and **4**) at room temperature. A survey of the relevant ^{1}H NMR spectroscopic data is given in Table 5. A detailed variable-temperature (VT) ^{1}H NMR study (between 353 and 188 K) of **3**, dissolved in [D_8]toluene, shows that the indenyl protons give rise to three singlets, two quasi-doublets and two quasi-triplets between ca. 320 and 260 K (see Figure 6, b, and Table 5). However, above room temperature (e.g. at 353 K, see Figure 6, a) the two quasi-doublets together with one of the singlets collapse to form one intense quasi-triplet, and the two initially present quasi-triplets merge to form one quasi-quadruplet. Below ca. 260 K, all residual spin-spin coupling is quenched, such that two pairs of distinct singlets appear instead of the two pairs of multiplets (Figure 6, c).

At least two different dynamic processes seem to influence the VT NMR results. Above room temperature all protons of the nicotine ligand (except those closest to the pyridine N atom, vide infra) give rise to fairly sharp singlets, or multiplets, between δ = +2 and −4 (Figure 6, a). Between ca. 300 and 250 K considerable broadening affects these signals (see Figure 6, b). On the other hand, after the recovery of these resonances to fairly sharp singlets (between δ ≈ 0 and −20), in particular two of the low-field singlets of the indenyl ligands are broadened considerably (see Figure 6, c). At the lowest accessible temperature (183 K), four of the seven indenyl resonances merge to form one broad singlet (not shown in Figure 6).

Interestingly, the chemical shifts of all indenyl resonances of **3** vary only slightly with temperature. In contrast, the α-protons of the substituted pyridine unit (see Figure 1) give rise to just one broad singlet at δ ≈ −16 at 353 K and to two broad signals at δ ≈ −65 and −75 at 188 K. This indirectly suggests that the magnetic susceptibility of the central Pr^{3+} ion of **3** should increase considerably with decreasing temperature. The singlet of the *N*-bonded methyl group of the nicotine ligand is shifted from δ = −0.85 at 353 K to δ = −8.00 at 193 K. The intermediate broadening of the nicotine resonances might be associated with the slowing down of the initially rapid (on the NMR timescale) internal motions of the nicotine molecule (e.g. the inversion of the non-planar pyrrolidine unit including that of the chiral NC_3 pyramid and/or rotation about the inter-ring C−C and N−Ln σ bonds). It should be noted that the resonances of the THF protons of the previously reported[8] adduct [Pr(Ind)$_3$·THF] show notable broadening between ca. 290 and 260 K (Figure 7), a feature which could be associated with ring inversion or restricted rotation about the O−Pr bond. Moreover, the temperature dependence of the indenyl resonances of this adduct is considerably less pronounced than that of the THF protons (Figure 8).

The unexpected broadening of the indenyl resonances of **3** below ca. 250 K most probably reflects some rapid intramolecular dynamics other than the bare rotation of each η^5-coordinated ligand about its Pr−C*ti*5 axis. We have speculated earlier[10] on periodic η^5-to-η^1 conversions affecting each of the three indenyl units equally and stereoselectively such that during this sequence of equilibria, the chiral intermediate η^1-coordinated C_5 ring carbon atom (i.e. C-1 or C-3) of each C_9H_7 ligand would maintain only one distinct configuration. Unfortunately, our present VT NMR spectroscopic study does not include results for temperatures around and below the coalescence of the dynamics, since the solvent starts crystallising below 180 K.

Most of the resonances of the indenyl protons of complex **4** (Ln = Nd) could be identified (Figure 4, b). A comparison with corresponding data for three previously reported adducts (Table 5) strongly suggests that the indenyl protons of **4** are also affected by the asymmetry of the nicotine ligand. While spin-spin coupling can be suggested as an explanation for the "doublet" character of the resonances assigned to protons in the positions 4/7 and 5/6, the assignment of the singlet at δ = 1.74 to 2-H (see Table 5) remains somewhat more uncertain. Alternatively, this signal might be assigned to the *N*-bonded methyl group of the nicotine ligand. The two equally intense signals at δ = −4.73 and −5.88 seem to be shifted too greatly by the paramagnetism of the Nd^{3+} ion, to justify the correlation of one of them

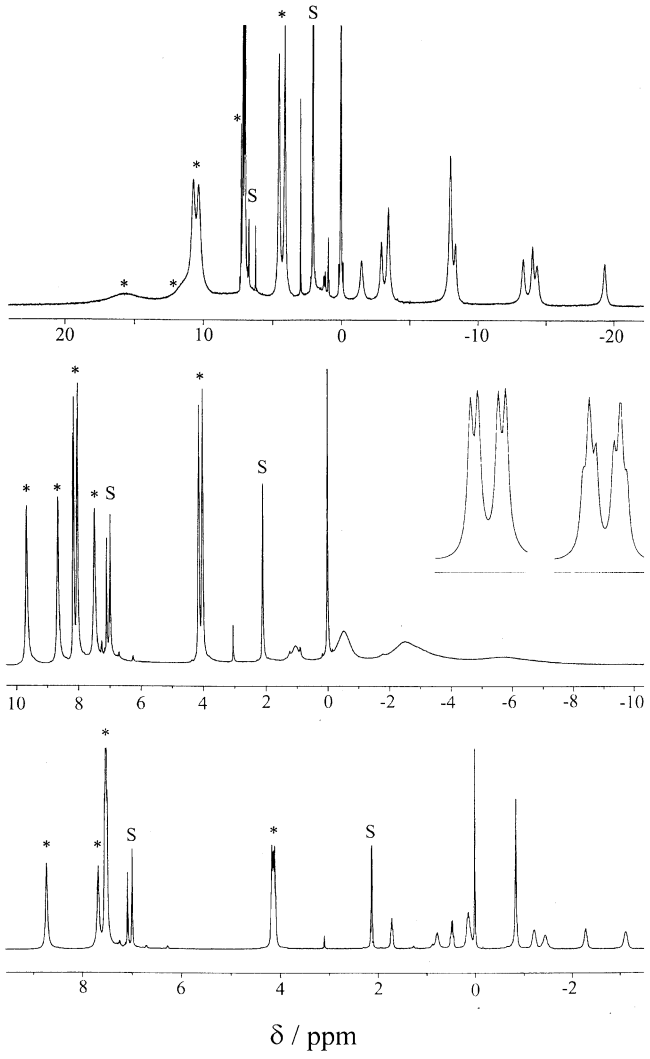

Figure 6. VT ^{1}H NMR spectra of **3** (solvent S: $CD_3C_6D_5$/TMS) at (from top to bottom) 193, 293 and 353 K; signals of the indenyl protons are marked by asterisks; the insert (for 293 K) shows the resonances of the indenyl protons 4/7-H and 5/6-H at an expanded δ scale; the spectra at 193 and 353 K do not include two additional nicotine resonances beyond δ = −20 and −4, respectively

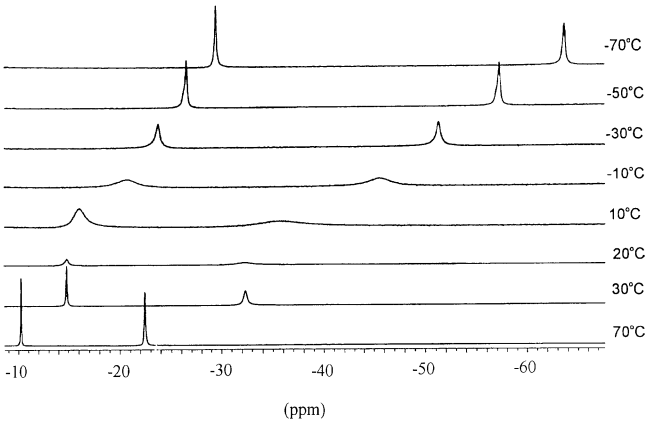

Figure 7. VT ^{1}H NMR spectra of the two THF resonances of [Pr(Ind)$_3$·THF] (solvent: $CD_3C_6D_5$)

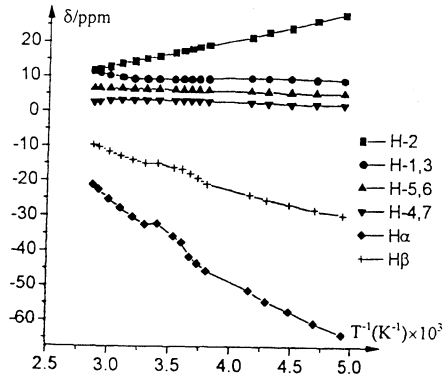

Figure 8. δ-vs-T^{-1} plots of all proton resonances of [Pr(Ind)$_3$·THF] (solvent: $CD_3C_6D_5$); the "humps" in the curves for Hα and Hβ (of THF) occur in the temperature range of pronounced line broadening (see Figure 7)

with the NCH_3 protons which are separated from the paramagnetic centre by *six* atoms. Equally far away from the metal ion are two of the CH_2 groups of the pyrrolidine unit (see Figure 1), the δ values of which should lie between δ = −2 and +2. Assuming that the signals at δ = −4.73 and −5.88 actually belong to the indenyl protons 1-H and 3-H (Figure 5, b, and Table 5), the experimentally found relative intensities of the six well-identified indenyl resonances (i.e. I_{rel} = 2 × 3, 2 × 3, 3, 3) simply require that one of the three appropriately intense signals at δ = 1.8, 0.2, or −0.8 be assigned to the proton 2-H.

f-f Circular Dichroism of 3 and 4

We have demonstrated recently that the 1:1 adducts of [Pr(Ind)$_3$] and (*R*)-(+)- and (*S*)-(−)-MTSO display, in the visible spectral range, significant circular dichroism (CD) of distinct f-f ligand-field excitations. However, the corres-

Table 6. Circular dichroism of [Pr(Ind)$_3$·(*R*)-(+)-MTSO][10] and [Pr(Ind)$_3$·(*S*)-(−)-Nic] (**3**) in the spectral range: 16100−21800 cm^{-1}

ponding adducts involving [$PrCp_3$] and chiral MTSO were found to be practically CD-silent.[10] The new adduct [$Pr(Ind)_3$·(*S*)-(−)-Nic] (**3**) is CD-active as well, although its $|\Delta\varepsilon_m|$ values throughout are notably smaller than those reported for the MTSO adducts (see Table 6). In particular, f-f ligand excitations of **3** to states resulting from the $^1D_2$ manifold of the free Pr^{3+} ion (between ca. 16000 and 17000 cm^{-1}), which are predicted (and known) to be chiroptically less sensitive than excitations of states originating from ^3P_J manifolds with $J = 0$, 1, and 2,[18] are strictly CD-silent. The surprisingly large $\Delta\varepsilon_m$ values of both homologues around ca. 21700 cm^{-1} are probably due to an appreciable non-4f orbital admixture to the wave functions of the excited states. According to some qualitative studies (not considering the exact concentration of the dissolved sample), the neodymium homologue **4** also displays notable f-f CD. In Figure 9, the CD spectrum of **4** between 14500 and 20000 cm^{-1} is compared with the regular f-f-absorption spectrum for that spectral range.

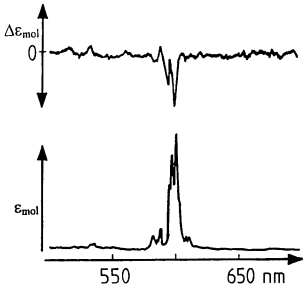

Figure 9. Absorption spectrum (bottom) and circular dichroism (top) of **4** (Ln = Nd) between 500 and 700 nm

Conclusions

According to the present study, only a relatively small selection of pyridine derivatives (Py*) is capable of occupying the vacant coordination site of an {$Ln(Ind)_3$} fragment, probably due to steric reasons. The nicotine molecule [i.e. 1-methyl-2-(3-pyridyl)pyrrolidine] *is* found to coordinate exclusively via its pyridine N atom, although *N*-methylpyrrolidine is known to combine with several {$LnCp_3$} fragments.[5] To the best of our knowledge, no crystal structure analysis of the generally liquid, free ligand has thus far been reported. The nicotine molecules coordinated in **2**, **3**, and **4** display a conformation very similar to that recently described[19] for a purely organic adduct, based upon O−H···N(Nic) hydrogen bonds.

The systematic assessment of the relevant crystallographic results for all new [$Ln(Ind)_3$·Py*] complexes supplements and confirms our earlier findings[7−10] in which the {$Ln(Ind)_3X$} fragment can adopt a large variety of mainly chiral conformations, wherein the benzo group of each indenyl ligand may be oriented either partially *meridionally* and partially *equatorially*, or all-*equatorially*. The latter situation is usually preferred as the ionic radius of the Ln^{3+} ion decreases.

By making use of the earlier described (for different types of complexes)[20] considerable amplification of the splitting of the resonance lines of initially prochiral nuclei by the auxiliary paramagnetism of Ln^{3+} ions with appropriate $4f^q$ configurations, the recognition of the remote chirality centre on the (*S*)-(−)-nicotine ligand by the indenyl protons could be readily achieved. Moreover, the 4f electrons of the ions Pr^{3+} (in **3**) and Nd^{3+} (in **4**) are capable of monitoring a chirogenic centre even more directly, such that various f-f ligand field transitions display weak, but significant circular dichroism, already at room temperature. Some very rapid (on the NMR timescale) and incompletely observable intermolecular reorganisation affecting essentially the indenyl ligands, is likely to imply a short-lived low-temperature modification of **3** involving another chirogenic centre, notably closer to the central metal ion than the dissymmetric carbon atom of the nicotine ligand.

Experimental Section

General Methods: All experimental manipulations, including sample preparation for instrumental measurements, were carried out under N_2 using vacuum-line and Schlenk techniques. The starting compound [$La(C_9H_7)_3$·THF] was prepared as described previously.[13] The nitrogen bases used were commercially available (Aldrich or Merck). − Infrared spectra were obtained with a Perkin−Elmer IR-1720 spectrometer. − ^1H NMR studies were carried out either with a Varian Gemini 200 (^1H, room temperature, solvent: [D_6]benzene) or with a Bruker AM 360 spectrometer (^1H-VT and ^{139}La-VT). Solvents for the VT studies were either [D_8]toluene (^1H) or a 3:7 mixture of [D_8]toluene and toluene and a 3:7 mixture of CD_2Cl_2 and CH_2Cl_2. ^{139}La NMR studies required the use of 10-mm NMR tubes under the following conditions: deuterium lock, SI = 4 K, TD = 8 K, SW = 71 kHz, DW = 7.0 μs, AQ =0.05s, NS = 825. A solution of either [$LaCp_3$·DMSO] in CD_2Cl_2 or of $LaCl_3$ in D_2O was used as an external standard. − Mass spectra were recorded with a Varian 3MA instrument with a spectrosystem MAT 188 (Finnigan) detector. The samples were prepared in carefully conditioned glass capillaries that could be fixed exactly on the head of the sample device, and were connected directly with the sample oven as soon as the capillary was cut off. − Optical (NIR/Vis) absorption spectra were recorded with a Cary 5E instrument, and the f-f CD spectra with a Jasco J 500 G dichrograph equipped with a DP-500 N data processor. The differential molar extinction values $\Delta\varepsilon_m$ were determined according to ref.[21]

X-ray Crystallography: Data collections were performed with a Hilger−Watts Y290 diffractometer at 153 K (Tables 7 and 8). All X-ray work was carried out with Mo-K_α radiation (λ = 70.926 pm) with the ω/2θ-scan technique. All calculations were based on SHELX-93 and SHELXTL-PLUS programme sets.[22] Heavy atoms were found from Patterson maps, and other non-hydrogen atoms were detected by Fourier techniques. Refinement was based on full-matrix least-squares techniques. Hydrogen atoms were included by use of a riding model with d(C−H) = 96 pm. $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR2 = [\Sigma w(F_o^2 - F_c^2)^2]/\Sigma w(F_o^2)^2]^{1/2}$; $S = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma(n - P)]^{1/2}$; $P = [\max(F_o^2, 0) + 2F_c^2]/3$. Further details on the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany [Fax: +49-7247/808-666; E-mail: crysdata@fiz-karlsruhe.de], on quoting the depository numbers CSD-380205 (**2**), -380204 (**3**), -380206 (**4**), -410174 (**5**), and -380201 (**6**).

Tris(cyclopentadienyl)[(*S*)-(−)-nicotine]lanthanum, [La(C_5H_5)$_3$·Nic] (1): A solution of (*S*)-(−)-nicotine (0.47 g, 2.93 mmol) in toluene (5.2 mL) was added to a suspension of [La(C_5H_5)$_3$·THF] (1.19 g, 2.93 mmol) in toluene (20 mL). After stirring (1 d) and filtration, the yellowish filtrate was concentrated and cooled to 0 °C. After washing (hexane) and drying (vacuum), the resulting precipitate was a colourless powder (yield: 1.32 g, ca. 91%; m.p. 165−170 °C). − $C_{25}H_{29}LaN_2$ (496.43): calcd. C 60.52, H 5.84, N 5.64; found C 59.67, H 5.88, N 5.84. − MS; *m*/*z*: 334, 269, 204, 162, 133, 119, 105, 83, 78 for [Cp$_n$La]$^+$ (*n* = 3, 2, 1); [nicotine]$^+$, [$C_5H_4NC_4H_7$]$^+$, [$C_5H_4NC_3H_5$]$^+$, [$C_5H_4NC_2H_3$]$^+$, [C_5H_4N]$^+$, [$C_4H_6NCH_3$]$^+$, [C_5H_5]$^+$. − ^{1}H NMR (C_6D_6/TMS, first-order as-

sessment, note that the signal assignment for the nicotine protons follows the designation chosen in Figure 1): δ = 6.13 (s, 15 H, Cp), 8.81 (s, 1 H, a), 8.30 (d, J = 5.16 Hz, b), 7.22 (d, J = 7.82 Hz, d) 6.57 (pseudo-q, 1 H, c), 2.96 (t, $J \approx$ 7.0 Hz, e) 2.68 and 1.99 (t, 1 H each, $J \approx$ 8.0 H, f) 1.95 (s, 3 H, NCH_3), 1.75, 1.39 (m, 2 H each, g/h). − ^{139}La NMR (in toluene, vide supra: see Table 1).

Tris(indenyl)[(*S*)-(−)-nicotine]lanthanum, [La(C$_9$H$_7$)$_3$·Nic] (2): A solution of (*S*)-(−)-nicotine (0.61 g, 3.76 mmol) in toluene (8.0 mL) was added at room temperature to a suspension of [La(C$_9$H$_7$)$_3$·THF] (2.09 g, 3.76 mmol) in toluene (30 mL). An almost transparent solution resulted which subsequently became turbid. The mixture was stirred overnight and finally heated to 70−80 °C. After filtration, when still warm, the solvent was removed from the yellow filtrate (in vacuo), after which a viscous yellow-orange residue was obtained. After addition of a trace amount of toluene, most of this residue converted overnight partially to yellow crystals and partially to a solid "gum". The solid product (including the crystals, some of which were suitable for X-ray studies) was washed with hexane and dried at room temperature. In total, 2.30 g (95%) of **2** was obtained. M.p. 94−98 °C. − $C_{37}H_{35}LaN_2$ (646.61): calcd. C 68.76, H 5.42, N 4.33; found C 68.51, H 5.47, N 4.45. − MS; *m*/*z*: 484, 369, 254, 115, 162, 133, 119, 84 for [Ind$_n$La]$^+$ (n = 3, 2, 1), [Ind]$^+$, [Nic]$^+$, [C$_5$H$_4$NC$_4$H$_7$]$^+$, [C$_5$H$_4$NC$_3$H$_5$]$^+$, [C$_4$H$_7$NCH$_3$]$^+$. − ^{1}H NMR (C$_6$D$_6$, TMS, first-order assessment): nicotine protons: δ = 8.17 (s, 1 H, a), 7.74 (d, J = 5.26 Hz, b), 7.26 (d, $J \approx$ 7.84 Hz, d), 6.56 (pseudo-q, $J \approx$ 5.20 and 2.62 Hz, c), 3.02 (t, $J \approx$ 8 Hz, e), 2.79 and 2.06 (t, 1 H each, $J \approx$ 8.0 Hz, f), 1.86 (m, 2 H, h), 1.49 (m, 2 H, g), 2.02 (s, 3 H, NCH_3); indenyl protons: δ = 7.46 (m, 6 H, 4,7-H), 6.94 (q, 6 H, $J \approx$ 3.0 Hz, 5,6-H), 6.14 (t, 3 H, $J \approx$ 3.30 Hz, 2-H), 5.90 (s, 6 H, 1,3-H). − ^{139}La NMR (in toluene, vide supra): see Table 1.

Tris(indenyl)[(*S*)-(−)-nicotine]praseodymium, [Pr(C$_9$H$_7$)$_3$·Nic] (3): The procedure resembled the synthesis of **2**, in that [Pr(C$_9$H$_7$)$_3$·THF] (2.64 g, 4.73 mmol) in toluene (30 mL) was treated with (*S*)-(−)-nicotine (0.77 g, 4.72 mmol) in toluene (8.5 mL). An analytically pure, yellow-green, viscous oil was obtained (yield: ≥ 85%). The oil was dissolved in a small amount of toluene, after which a large amount of hexane was added. The oil slowly converted into a yellow solid that was finally isolated and dried. Leek-green crystals suitable for an X-ray crystallographic study were obtained from a hot solution of this solid in toluene (the initially clear solution was slowly cooled down to room temperature). M.p. 129−132 °C. − $C_{37}H_{35}N_2Pr$ (648.61): calcd. C 68.54, H 5.39, N 4.32; found C 68.09, H 5.55, N 4.43. − MS; *m*/*z*: 486, 371, 256, 141, 115, 162, 133, 84 for [Ind$_n$Pr]$^+$ (n = 3, 2, 1, 0), [Ind]$^+$, [Nicotine]$^+$, [(C$_5$H$_4$N)(C$_4$H$_7$)]$^+$, [C$_4$H$_7$NCH$_3$]$^+$. − ^{1}H NMR (C$_6$D$_6$/TMS): nicotine protons a−d: δ = −32.80 (s, 1 H), −30.10 (s, 1 H), −6.74 (s, 1 H), −6.21 (s, 1 H); e−h: −5.77 (s, 1 H), −3.41 (s, 2 H), −0.75 (m, 2 + 1 H); NCH_3: δ = −2.85 (s, 3 H); indenyl protons: 1/2/3-H: δ = 9.59 (s, 3 H), 7.44 (s, 3 H), 8.79 (s, 3 H); 4/7-H: δ = 8.15 (d, 3 H, J = 7.52 Hz), 8.03 (d, 3 H, J = 7.54 Hz); 5/6-H: δ = 4.19 (t, 3 H), 4.06 (t, 3 H).

Tris(indenyl)[(*S*)-(−)-nicotine]neodymium, [Nd(C$_9$H$_7$)$_3$·Nic] (4): A procedure similar to that for the preparation of **2** was adopted, using [Nd(C$_9$H$_7$)$_3$·THF] (1.68 g, 2.99 mmol) in toluene (20 mL) and (*S*)-(−)-nicotine (0.48 g, 2.98 mmol) in toluene (5.0 mL). A red-green, analytically pure, viscous oil was obtained (1.34 g, 68.7%), which was redissolved in warm toluene. After addition of a small amount of hexane, and on slow cooling, green single crystals suitable for X-ray crystallographic studies were obtained. M.p. 112−116 °C. − $C_{37}H_{35}N_2Nd$ (651.94): calcd. C 68.20, H 5.37, N 4.29; found C 67.75, H 5.41, N 4.28. − MS; *m*/*z*: 489, 372, 259, 115, 162, 133, 84 for [Ind$_n$Nd]$^+$ (n = 3, 2, 1), [Ind]$^+$, [Nic]$^+$, [C$_5$H$_4$NC$_4$H$_7$]$^+$, [C$_4$H$_7$NCH$_3$]$^+$. − ^{1}H NMR (C$_6$D$_6$/TMS): nicotine protons: a−d: δ = −14.30 (s, 2 H), −13.40 (s, 1 H), −2.95 (s, 1 H); e−h: δ = −1.89 (s, 1 H), −1.15 (s, 1 H), 0.13 (s, 2 H), 0.42 (m, 1 H), 1.50 (br, 1 H); NCH_3: δ = −0.76 (s, 3 H); indenyl protons: δ = −5.88, −4.73 (s, 3 H each, 1,3-H), 1.74 (s, 3 H, 2-H), 7.40 (d, 6 H, 4,7-H), 5.00 (d, 6 H, 5,6-H).

Tris(indenyl)(pyridine)praseodymium, [Pr(C$_9$H$_7$)$_3$·Py] (5): The preparative procedure resembled those described before. A solution of pyridine (0.16 g, 2.07 mmol) in toluene (7 mL) was added to a suspension of [Pr(C$_9$H$_7$)$_3$·THF] (1.08 g, 1.93 mmol) in toluene (30 mL) at room temperature. After workup, 1.07 g (98%) of leek-green single crystals was collected. M.p. 199−203 °C. − $C_{32}H_{26}NPr$ (565.47): calcd. C 67.99, H 4.60, N 2.47; found C 67.17, H 4.69, N 2.49. − MS; *m*/*z*: 486, 372, 256, 141, 116, 78 for [Ind$_n$Pr]$^+$ (n = 3, 2, 1, 0), [Ind]$^+$, [Py]$^+$. − ^{1}H NMR(C$_6$D$_6$, TMS): indenyl protons: δ = 10.03 (s, 6 H, 1,3-H), 8.98 (s, 3 H, 2-H), 7.88 (s, 6 H, 5,6-H), 3.65 (s, 6 H, 4,7-H); pyridine protons: δ = −4.30 (s, 1 H, H-γ), −7.66 (s, 2 H, H-β), −33.42 (s, 2 H, H-α).

Tris(indenyl)(3-methylpyridine)praseodymium, [Pr(C$_9$H$_7$)$_3$·3-MePy] (6): As for the preparation of **5**, a solution of 3-methylpyridine (0.186 g, 2.01 mmol) in toluene (10 mL) was added to a suspension of [Pr(C$_9$H$_7$)$_3$·THF] (1.12 g, 2.06 mmol) in toluene (30 mL). 1.17 g (100%) of a crystalline product was obtained. M.p. 135−138 °C. − MS; *m*/*z*: 486, 372, 256, 116, 93, 78 for [Ind$_n$Pr]$^+$ (n = 3, 2, 1), [MePy]$^+$, [Py]$^+$. − $C_{33}H_{28}NPr$ (579.50): calcd. C 68.42, H 4.83, N 2.42; found C 68.03, H 4.94, N 2.42. − ^{1}H NMR (C$_6$D$_6$/TMS): indenyl protons: δ = 10.13 (s, 6 H, 1,3-H), 8.12 (s, 6 H, 5,6-H), 7.66 (s, 3 H, 2-H), 3.68 (d, 6 H, J = 3.30 Hz, 4,7-H); 3-methylpyridine protons: δ = −4.38 (s, 1 H, Hγ), −6.67 (s, 3 H +1 H), CH_3 + Hβ), −38.9, −30.0 (s, 1 H each, Hα)

Acknowledgments

J.-W. G. would like to express his gratitude to the Friedrich-Ebert-Stiftung (Bonn) for a fellowship. We also express our deep thanks to Mrs. S. Samba for technical assistance.

Fluorenyl and *ansa*-Dimethylsilyl*bis*(fluorenyl) Derivatives of Divalent Ytterbium and Samarium − Synthesis and Structure of the First Mixed-Ligand Ln^{II} Classic Sandwich Complex $(C_{13}H_9)(C_5Me_5)Yb(DME)$

Keywords: Lanthanides / Samarium / Cyclopentadienyl complexes / Fluorenyl complexes / *ansa*-Bis(fluorenyl) complexes / Crystal structure

Novel fluorenyl complexes of divalent ytterbium $(C_{13}H_9)_2Yb(L)_n$ [L = THF, n = 2 (**1**); L = DME, n = 1 (**2**)] have been prepared by reaction of $YbI_2(THF)_2$ with 2 equiv. of $C_{13}H_9K$ as well as by reaction of $(C_{10}H_8)Yb(THF)_2$ with fluorene in THF. Oxidation of **1** by *t*BuN=CHCH=N*t*Bu (DAD) resulted in the formation of $(C_{13}H_9)_2Yb(DAD)$ (**3**). The reaction of $\{YbI(DME)_2\}_2(\mu\text{-}C_{10}H_8)\}$ (**4**) with fluorene did not give $(C_{13}H_9)YbI(DME)$ (**5**), but the redistribution products $YbI_2(DME)$ and **2**. The first mixed-ligand sandwich complex of a divalent lanthanide metal $(C_{13}H_9)(C_5Me_5)Yb(DME)$ (**6**) was prepared in a one-pot reaction of **4** with C_5Me_5H and $C_{13}H_9K$ in DME. *ansa*-$Me_2Si(C_{13}H_8)_2Yb(THF)$ (**7**) and *ansa*-$Me_2Si(C_{13}H_8)_2Sm(THF)_4$ (**8**) were obtained by treatment of the appropriate Ln^{II} iodides with *ansa*-$Me_2Si(C_{13}H_9)_2K_2$ in THF. The molecular structures of **1** and **6** were determined by single-crystal X-ray diffraction.

Introduction

The increased attention given to the fluorenyl ligand and the extensive work in synthesis and investigation of its d-metal block complexes has been observed during the last decade. This was mainly provoked by the discovery of the high efficiency of fluorenylzirconium complexes in the stereospecific propylene polymerization.[1,2] The remarkable activity of fluorenyl-derived group-4 metallocene complexes in α-olefin polymerization was explained by the characteristics of the ligand, namely by the easy η^5-η^3-η^1 interconversion of the five-membered ring−metal bonding mode (ring slippage), providing a free site for a substrate in the metal center's coordination sphere.

The complexes with η^5- bonded aromatic carbocyclic (mainly cyclopentadienyl) ligands form the most explored class of organolanthanide compounds.[3,4] These ancillaries have proved themselves to be a suitable coordination environment of the lanthanide metal atom providing the unique reactivity of the derived hydrido and hydrocarbyl complexes in various reactions involving unsaturated substrates.[5−18] Some cyclopentadienyl derivatives of divalent lanthanides also show catalytic activity in α-olefin polymerization.[19−22]

To date the fluorenyl ligand has not been significantly involved in organolanthanide chemistry. The lanthanide fluorenyl complexes $(C_{13}H_9)_2Ce$[23] and $(C_{13}H_9)_2LnCl_2Li(THF)_2$ (Ln = La, Nd, Sm, Ho, Lu)[24,25] were described twenty years ago and are poorly characterized, but were classified by the authors as complexes with metal−ligand σ-bonds on the basis of spectroscopic data. The only fluorenyl derivative of a divalent lanthanide, $(C_{13}H_9)_2Sm(THF)_2$, was reported and structurally characterized by Evans.[26] X-ray diffraction has shown the coordination of the fluorenyl ligands in this complex to be partially distorted from η^5 towards η^3. Dramatic influence of ligation of the central atom on the fluorenyl ligand bonding mode has been found for (cyclopentadienyl)(*ansa*-fluorenyl)yttrocene complexes.[27] In *ansa*-$Me_2Si(\eta^3\text{-}C_{13}H_9)(\eta^5\text{-}Cp')YCl_2Li(OEt_2)_2$ an X-ray diffraction study revealed η^3-coordination of the central fluorenyl ring, while in the related amido derivative *ansa*-$Me_2Si(\eta^3\text{-}C_{13}H_9)(\eta^5\text{-}Cp')YN(SiMe_3)_2$, the fluorenyl ligand bonding is just partially tilted towards η^3-, but basically approaches an η^5-arrangement.

Being sterically demanding, the fluorenyl ligand is an attractive and easily available ancillary which is able to stabilize the Ln^{+2} oxidation state. This also proves that there is a well-defined environment around the metal center that allows control of reaction stereochemistry in its coordination sphere. In this paper we present the synthesis and structure investigations of novel (fluorenyl)Yb^{II} and -Sm^{II} sandwich complexes.

Results and Discussion

Two different approaches were used to synthesize the bis(fluorenyl) complex of divalent ytterbium: (i) the metathetic reaction of $YbI_2(THF)_2$ with 2 equiv. of $C_{13}H_9K$ in THF, which resulted in the formation of $(C_{13}H_9)_2Yb(THF)_2$ (**1**) in 72% yield, and (ii) by protolytic substitution of the naphthalene ligand in $(C_{10}H_8)Yb(THF)_2$[28] (**3**) by fluorene which also afforded **1** in reasonable yields. Although in the

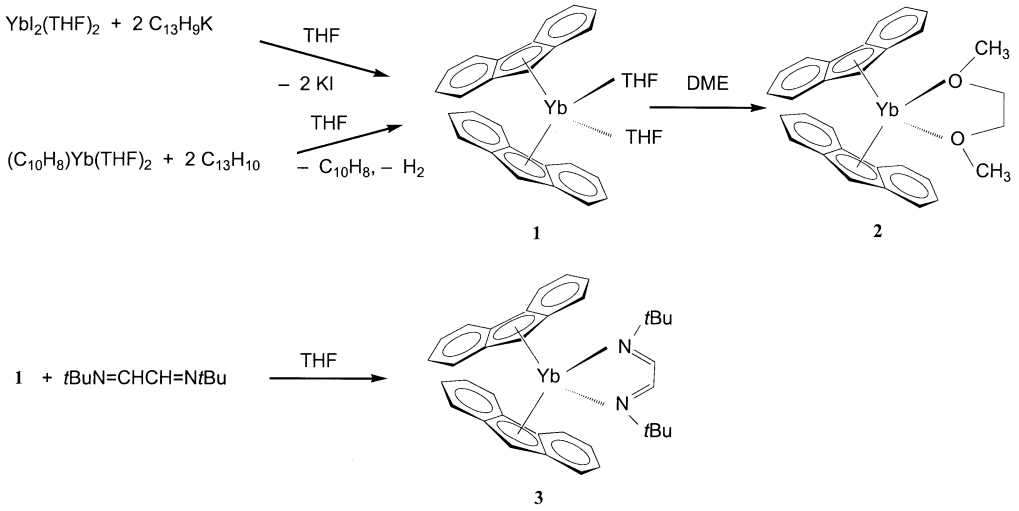


Scheme 1

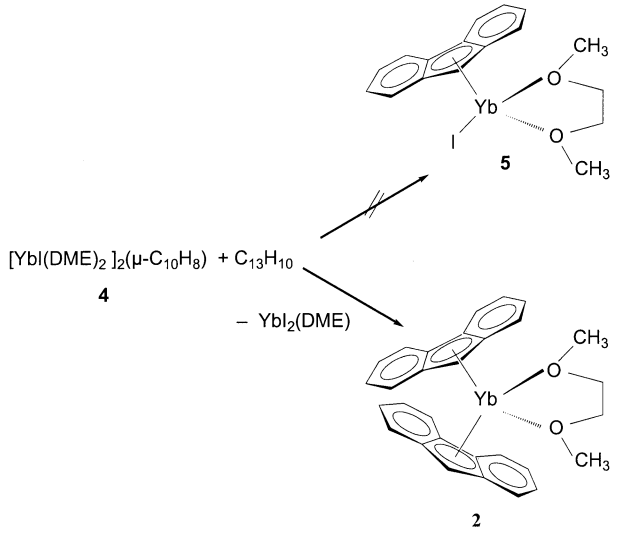
latter method the yield is somewhat lower, this allows the avoidance of the tedious procedure of KI separation (Scheme 1).

Bis(fluorenyl)bis(tetrahydrofuran)ytterbium(II) (**1**) is isolated after recrystallization from hot toluene/THF mixtures (30:1) in the form of ruby-red crystals, extremely sensitive towards moisture and air. It is soluble in THF, DME, and pyridine, moderately soluble in toluene and insoluble in aliphatic hydrocarbons. Recrystallization from DME produces $(C_{13}H_9)_2Yb(DME)$ (**2**) as deep yellow crystals, which show a slightly lower solubility in the solvents mentioned above compared to **1**. Both complexes **1** and **2** are diamagnetic corresponding to the Yb^{2+} oxidation state;[29] they were characterized by means of ^1H and ^{13}C NMR and IR spectroscopy as well as by elemental analysis, and an X-ray structural analysis was also performed on **1**.

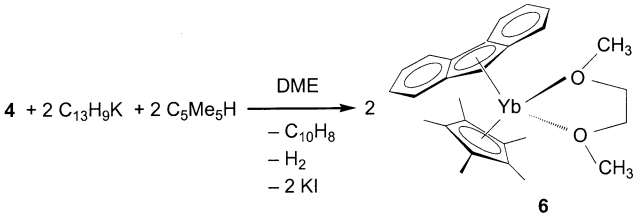
Compound **1** can easily be oxidized by *t*BuN=CHCH=N*t*Bu (DAD) in THF solution forming the corresponding (diazabutadiene)Yb^{III} derivative **3** as deep green crystals after recrystallization from hexane with nearly quantitative yield. It is very soluble in THF and toluene and moderately soluble in hexane. The magnetic moment of **3** (4.8 BM, 293 K) corresponds well to the values normally observed for complexes of trivalent ytterbium. For **3** as for other diazabutadiene derivatives of Yb^{III} [30,31] no signals of DAD radical anions were observed by ESR spectroscopy.

Heteroleptic sandwich complexes bearing different carbocyclic ligands are of essential practical interest since selection of ligands could be a useful tool for fine-tuning steric and electronic properties of the metal atom's environment. It is known from the literature,[4] that lanthanide mixed-ligand systems are predisposed to ligand redistribution, which favours the formation of homoleptic derivatives. To date, mixed ligand Ln^{II} classic sandwich complexes having two different π-donor carbocyclic ligands, are unknown. Heteroleptic Ln^{II} derivatives, in general, still remain rare. Recently, Evans described the synthesis and X-ray structure of $[Cp^*Yb(THF)]_2(\mu\text{-}\eta^8\text{:}\eta^8\text{-}C_8H_8)$, a binuclear (cyclooctatetraenyl)(pentamethylcyclopentadienyl) triple-decker complex.[32] Some (aryloxy)(cyclopentadienyl),[33,34] linked (η^6-carboranyl)(cyclopentadienyl),[35] linked (alkoxy)(cyclopentadienyl),[36–38] and (cyclopentadienyl)(pyrazolylborato) derivatives[39] have also been reported.

Our first attempts to obtain a starting material for heteroleptic fluorenyllanthanide complexes failed. Splitting of the naphthalene-bridged dinuclear complex $[(DME)_2(I)Yb(\mu\text{-}C_{10}H_8)Yb(I)(DME)_2]$ (**4**) by fluorene in DME did not yield the expected heteroleptic dimethoxyethane complex of fluorenylytterbium(II)iodide (**5**); the dis-



Scheme 2



Scheme 3

mutation products $YbI_2(DME)_2$ and **2** could be isolated instead (Scheme 2). The second experiment, the consecutive "one-pot" treatment of **4** with C_5Me_5H and $C_{13}H_9K$ in DME was successful. Ligand redistribution was avoided and $(C_{13}H_9)(C_5Me_5)Yb(DME)$ (**6**) crystallized in 46% yield as diamagnetic deep-green crystals from toluene (Scheme 3).

Compound **6** is stable at room temperature in the solid state as well as in benzene, toluene and DME, but not in THF. Thus, the ^1H NMR spectrum of **6** in [D$_6$]benzene shows a singlet signal at $\delta = 2.06$ due to the CH_3 protons of the pentamethylcyclopentadienyl ligand and a set of signals typical for the fluorenide anion[40,41] in the aromatic region. The proton signals of the CH_3O groups of the DME ligand appear as a broad multiplet, significantly high-field shifted, while the signals for the CH_2 protons keep their normal position. The high-field shift of the methyl proton signals of DME can be attributed either to the influence of coordination to the Yb^{II} ion or to the influence of the ring current of the coordinated fluorenyl ligand. In contrast, the ^1H NMR spectrum of **6**, on dissolving the compound in [D$_8$]THF, immediately shows two singlet signals for the Cp* protons at $\delta = 1.82$ and 1.87 (with the ratio 3:8 which does not change within 100 h) and a complex set of signals in the region between $\delta = 6.12$ and 7.93 for the protons of the fluorenyl ligand. The reason for this may be a dismutation reaction forming partly the symmetric products $(C_{13}H_9)_2Yb(THF)_2$ (**1**) and $(C_5Me_5)_2Yb(THF)_2$ in THF solution. This could be shown in the case of other lanthanoidocene derivatives, which undergo a facile transfer of η^5-bonded cyclopentadienyl ligands.[42–44] Neither **1** nor $Cp^*_2Yb(THF)_2$ could be isolated from the reaction mixture in a pure state.

With respect to catalytic activity, the *ansa*-bis(cyclopentadienyl) and *ansa*-bis(indenyl) framework provides a considerable opening of the metal coordination sphere in lanthanidocene complexes which facilitates the substrates access to the metal centers, improving its electronic properties as well as the configuration of its frontier orbitals.[7,45–47] The *ansa*-bis(fluorenyl) ancillary ligation is supposed to combine advantages of design of the metal atom environment peculiar to the *ansa* system and flexibility of coordination of the fluorenyl ligand. Therefore *ansa*-bis(fluorenyl) derivatives of Sm^{II} and Yb^{II} should be promising catalysts for olefin polymerization.

The *ansa*-bis(fluorenyl)lanthanide(II) complexes $Me_2Si(C_{13}H_8)_2Yb(THF)$ (**7**) and $Me_2Si(C_{13}H_8)_2Sm(THF)_4$ (**8**) were obtained in more than 70% yield as red and brown solids from the reaction of $YbI_2(THF)_2$ and $SmI_2(THF)_2$, respectively, with $Me_2Si(C_{13}H_8)_2K_2$ in THF (Scheme 4). Both complexes are only slightly soluble in THF and DME. All attempts to obtain single crystals useable for X-ray structure investigations, failed. They could be characterized by ^1H, ^{13}C NMR, IR spectroscopy, and elemental analysis. The IR spectrum of **7** only shows bands for coordinated THF molecules (860 and 1020 cm^{-1}), whereas that of **8** presents bands in the range of coordinated (860 and 1040 cm^{-1}) and noncoordinated THF (910 and 1070 cm^{-1}).

Scheme 4

Molecular Structure of 1 and 6

Compound **1** crystallizes with two crystallographically independent molecules in the asymmetric unit (Figure 1). **1** was found to be an eight-coordinate complex having a bent sandwich structure with bond angles of $(C_{13}H_9)_{Cent}-Yb-(C_{13}H_9)_{Cent}$ = 125.58(11) and

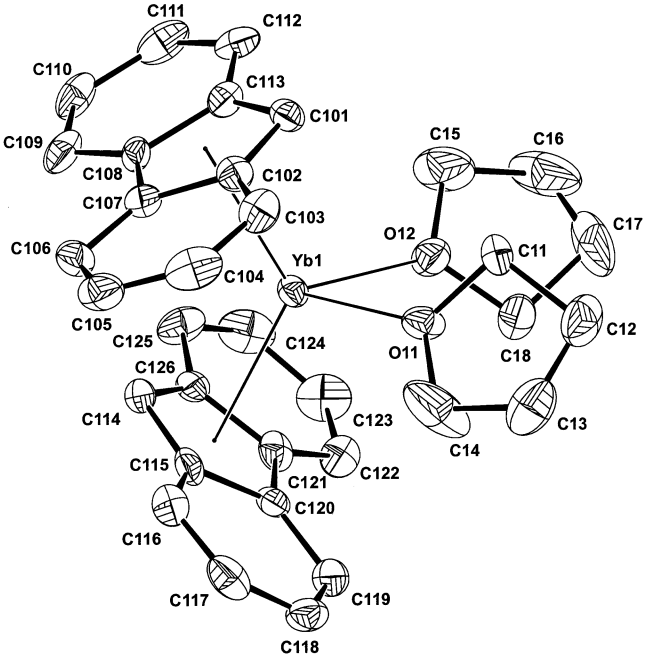

Figure 1. ORTEP[48] drawing and numbering scheme of the molecular structure of **1** with thermal ellipsoids drawn at the 50% probability level; only one of the two crystallographically independent molecules is shown; hydrogen atoms are omitted; selected bond lengths [Å] and angles [°] [Cg(1) and Cg(2) are defined by the ring atoms C(101), C(102), C(107), C(108), C(113) and C(114), C(115), C(120), C(121), C(126); Cg(3) and Cg(4) were defined by the ring atoms C(201), C(202), C(207), C(208), C(213) and C(214), C(215), C(220), C(221), C(226)]: Yb(1)–Cg(1) 2.503(3) [Yb(2)–Cg(3) 2.513(3)], Yb(1)–Cg(2) 2.512(4) [Yb(2)–Cg(4) 2.518(3)], Yb(1)–O(11) 2.389(5) [Yb(2)–O(21) 2.403(5)], Yb(1)–O(12) 2.398(5) [Yb(2)–O(22) 2.409(5)], Yb(1)–C(101) 2.663(7) [Yb(2)–C(201) 2.672(7)], Yb(1)–C(102) 2.756(7) [Yb(2)–C(202) 2.732(7)], Yb(1)–C(107) 2.852(7) [Yb(2)–C(207) 2.857(7)], Yb(1)–C(108) 2.867(6) [Yb(2)–C(208) 2.898(7)], Yb(1)–C(113) 2.774(7) [Yb(2)–C(213) 2.798(7)], Yb(1)–C(114) 2.626(7) [Yb(2)–C(214) 2.622(6)], Yb(1)–C(115) 2.780(7) [Yb(2)–C(215) 2.786(7)], Yb(1)–C(120) 2.952(7) [Yb(2)–C(220) 2.951(7)], Yb(1)–C(121) 2.893(7) [Yb(2)–C(221) 2.908(7)], Yb(1)–C(126) 2.696(7) [Yb(2)–C(226) 2.702(7)]; Cg(1)–Yb(1)–Cg(2) 125.58(11) [Cg(3)–Yb(2)–Cg(4) 124.87(10)], Cg(1)–Yb(1)–O(11) 104.63(15) [Cg(3)–Yb(2)–O(21) 106.21(15)], Cg(1)–Yb(1)–O(12) 118.14(15) [Cg(3)–Yb(2)–O(22) 116.44(15)], Cg(2)–Yb(1)–O(11) 115.40(15) [Cg(4)–Yb(2)–O(21) 114.32(15)], Cg(2)–Yb(1)–O(12) 105.25(2) [Cg(4)–Yb(2)–O(22) 106.22(15)], O(11)–Yb(1)–O(12) 78.37(18) [O(21)–Yb(2)–O(22) 80.14(18)]; ring slippage [Å]: Cg(1) 0.233, Cg(2) 0.384, Cg(3) 0.253, Cg(4) 0.392

124.87(10)°, respectively. The distances $(C_{13}H_9)_{Cent}-Yb$ are 2.503(3), 2.513(3), 2.512(4), and 2.518(3) Å for both molecules, however substantial scattering in $Yb-C_{Flu}$ bond lengths is observed for both ligands. Analysis of the bond situation reveals shorter distances between the ytterbium ion and three carbon atoms [C(113)−C(101)−C(102), C(115)−C(114)−C(126) and C(213)−C(201)−C(202), C(215)−C(214)−C(226)], while two Yb−C distances [C(107)−C(108), C(120)−C(121) and C(207)−C(208), C(220)−C(221)] are somewhat longer compared to the average value (2.78 Å). The deviation of the Yb−C distances in the range of 0.25 Å for one five-membered ring and 0.38 Å for the second one suggests a partial tilting of the fluorenyl ligand toward η^3-fashion as it has already been observed for $(C_{13}H_9)_2Sm(THF)_2$[26] and $Me_2Si(\eta^3\text{-}C_{13}H_9)(\eta^5\text{-}Cp')YN(SiMe_3)_2$.[27] It should be mentioned that in the case of the samarium analogue a significant deviation of the Sm−C distances occurs only in one of the fluorenyl ligands, while in **1** for both of them. This interesting structural feature obviously arises from the smaller radius of the Yb^{2+} ion and a consequent steric hindrance and repulsion of the bulky fluorenyl ligands.

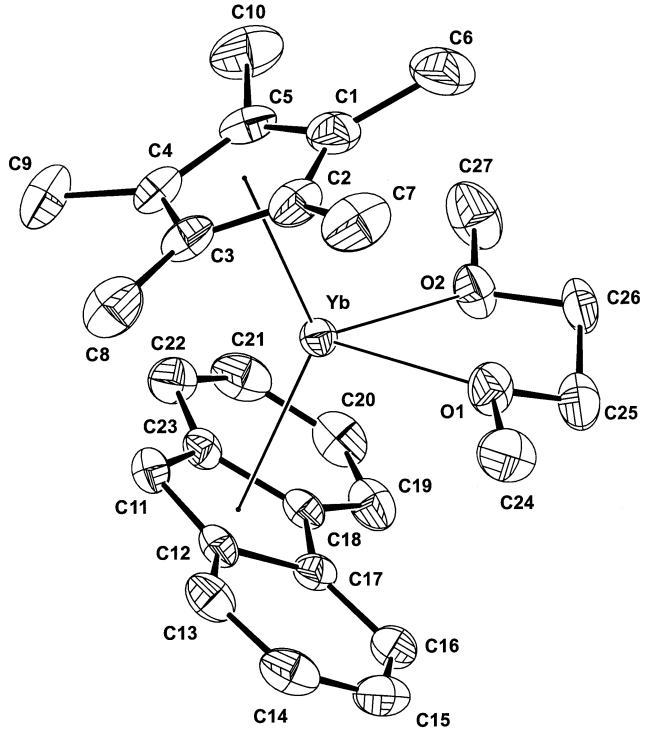

Figure 2. ORTEP[48] drawing and numbering scheme of the molecular structure of **6** with thermal ellipsoids drawn at the 50% probability level; hydrogen atoms are omitted; selected bond lengths [Å] and angles [°] [Cg(1) and Cg(2) were defined by the ring atoms C(1)−C(5) and C(11), C(12), C(17), C(18), C(23)]: Yb−Cg(1) 2.392(2), Yb−Cg(2) 2.505(2), Yb−O(1) 2.415(4), Yb−O(2) 2.440(3), Yb−C(1) 2.673(5), Yb−C(2) 2.663(5), Yb−C(3) 2.671(5), Yb−C(4) 2.695(5), Yb−C(5) 2.698(5), Yb−C(11) 2.661(4), Yb−C(12) 2.782(5), Yb−C(17) 2.915(5), Yb−C(18) 2.857(5), Yb−C(23) 2.710(4); Cg(1)−Yb−O(2) 112.73(10), Cg(2)−Yb−O(1) 107.23(9), Cg(1)−Yb−Cg(2) 134.86(8), Cg(1)−Yb−O(1) 110.07(10), Cg(2)−Yb−O(2) 104.14(9), O(1)−Yb−O(2) 68.05(12); ring slippage [Å]: Cg(1) 0.059, Cg(2) 0.286

The single-crystal X-ray structure determination of **6** shows a bent sandwich complex of divalent ytterbium with coordination number 8 (Figure 2). The $Yb-Cp^*_{Cent}$ bond length is 2.392(2) Å, and $Yb-(C_{13}H_9)_{Cent}$ = 2.505(2) Å, which is close to the value obtained for **1**. The difference of five bond lengths between the ytterbium ion and the carbon atoms of the central five-membered ring of the fluorenyl ligand (0.254 Å) indicates a partial distortion toward an η^3 coordination, while the Cp* ligand is η^5-bonded. The bond angle $Cp^*_{Cent}-Yb-(C_{13}H_9)_{Cent}$ [134.86(8)°] is significantly larger than the angle $(C_{13}H_9)_{Cent}-Yb-(C_{13}H_9)_{Cent}$ in **1** [125.58(11)/124.87(10)°] and is consistent with the higher steric demand of the Cp* ligand vs. $C_{13}H_9$.

Experimental Section

General Remarks: All experiments were performed in evacuated tubes, using standard Schlenk techniques with rigorous exclusion of traces of moisture and air. THF, DME, diethyl ether, toluene, and hexane were purified by distillation from sodium/benzophenone ketyl and were condensed under vacuum prior to use. Fluorene and pentamethylcyclopentadiene were commercially available and used as received. $YbI_2(THF)_2$,[3] $(C_{10}H_8)Yb(THF)_2$,[28] $(\mu\text{-}C_{10}H_8)[YbI(DME)_2]_2$ (**4**),[49] and $Me_2Si(C_{13}H_9)_2$[50] were prepared according to literature procedures. − IR spectra were recorded as Nujol mulls with a Specord M80 spectrophotometer, NMR spectra with a Bruker DPX200 spectrometer in [D_6]benzene or [D_8]THF at 298 K, chemical shifts for ^1H and ^{13}C NMR spectra were referenced internally using the residual solvent resonances and reported relative to TMS. − Magnetic susceptibility measurements were carried out according to the published procedure.[51]

$(C_{13}H_9)_2Yb(THF)_2$ (1). − a) To a solution of $C_{13}H_9K$ (2.21 g, 10.84 mmol) in THF (40 mL), $YbI_2(THF)_2$ (3.09 g, 5.42 mmol) was added slowly at 0 °C under rigorous stirring. The reaction mixture was allowed to warm up to room temperature and was stirred overnight. After filtration, THF was removed under vacuum and the resulting crude product was recrystallized from THF/toluene (1:30) to yield 2.52 g (72%) of **1**. − IR (Nujol): $\tilde{\nu}$ = 3020 (m), 1590 (m), 1320 (m), 1200 (m), 1090 (w), 1030 (s), 990 (w), 925 (w), 825 (m), 750 (s), 720 (s), 700 (s) cm^{-1}. − ^1H NMR (200 MHz, [D_8]THF): δ = 5.63 (s, 2 H, aryl-C^9), 6.76 [t, ^3J(H,H) = 14.4 Hz, 4 H, aryl-H^7], 7.04 [t, ^3J(H,H) = 14.6 Hz, 4 H, aryl-H^6], 7.44 [d, ^3J(H,H) = 8 Hz, 4 H, aryl-H^8], 7.93 [^3J(H,H) = 8 Hz, 4 H, aryl-H^5]. − ^{13}C NMR (50.3 MHz, [D_8]THF): δ = 113.8, 118.3, 119.8, 120.5, 122.3, 126.5, 133.7. − $C_{34}H_{34}O_2Yb$ (647.7): calcd. C 63.05, H 5.29, Yb 26.72; found C 62.76, H 4.87, Yb 26.92. − **b)** To a suspension of $(C_{10}H_8)Yb(THF)_2$ (2.13 g, 4.78 mmol) in THF (30 mL) was added fluorene (1.58 g, 9.56 mmol). The reaction mixture was heated to 60 °C for 8 h, filtered and THF was removed under vacuum. Recrystallization of the crude product from THF/toluene (1:30) yielded 2.06 g (64%) of **1**.

$(C_{13}H_9)_2Yb(DME)$ (2). − a) Compound **2** was obtained by recrystallization of **1** from DME as fine yellow crystals. − IR (Nujol): $\tilde{\nu}$ = 3020 (m), 1590 (m), 1320 (m), 1200 (m), 1090 (m), 1050 (s), 990 (w), 925 (w), 750 (s), 720 (s), 700 (s) cm^{-1}. − ^1H NMR (200 MHz, [D_8]THF): δ = 3.24 (s, 6 H, CH_3), 3.48 (s, 4 H, CH_2), 5.70 (s, 2 H, aryl-C^9), 6.72 [t, ^3J(H,H) = 14 Hz, 4 H, aryl-H^7], 7.00 [t, ^3J(H,H) = 14.2 Hz, 4 H, aryl-H^6], 7.50 [d, ^3J(H,H) = 8.8 Hz, 4 H, aryl-H^8], 8.00 [d, ^3J(H,H) = 8.2 Hz, 4 H, aryl-H^5]. − ^{13}C NMR (50.3 MHz, [D_8]THF): δ = 36.8, 83.0, 113.9, 118.2, 120.0, 120.4, 122.3, 126.5,

133.5. − $C_{30}H_{28}O_2Yb$ (594.1): calcd. C 60.59, H 4.71, Yb 29.28; found C 60.33, H 4.29, Yb 29.18. − **b)** To a suspension of [Yb-I(DME)$_2$]$_2$(μ-$C_{10}H_8$) (**4**) (2.11 g, 1.94 mmol) in DME (30 mL) was added a solution of fluorene (0.64 g, 3.88 mmol) in DME (10 mL) at room temperature and stirred for 12 h. The resulting yellowish-brown solution was separated from a precipitate of off-white crystals of YbI_2(DME) (0.82 g, 82%) by filtration, concentrated and cooled to 0 °C. Evaporation of DME yielded 0.64 g (56%) of **2**. IR and ^{1}H NMR spectra are identical to the spectra of **2** formed in the reaction pathway a).

($C_{13}H_9$)$_2$Yb(*t*BuN=CHCH=N*t*Bu) (3): To a solution of **1** (0.87 g, 1.34 mmol) in THF (15 mL), was added a solution of *t*BuN=CHCH=N*t*Bu (0.23 g, 1.36 mmol) in THF (2 mL) at room temperature. The red solution was stirred for 2 h, THF was removed in vacuo and the resulting greenish-brown solid was recrystallized from hexane yielding 0.88 g (98%) of deep-green crystals of **3**. − IR (Nujol): $\tilde{\nu}$ = 3160 (m), 2710 (w), 2280 (m), 1620 (m), 1300 (m), 1260 (s), 1200 (s), 995 (m), 900 (m), 790 (s), 720 (s) cm^{-1}. − $C_{36}H_{38}N_2Yb$ (672.2): calcd. C 64.26, H 5.70, Yb 25.87; found C 63.99, H 5.63, Yb 25.29.

($C_{13}H_9$)(C_5Me_5)Yb(DME) (6): To a suspension of **4** (2.70 g, 2.48 mmol) in DME (35 mL), was added a solution of C_5Me_5H (0.77 g, 4.96 mmol) in DME (5 mL) at room temperature. The reaction mixture was stirred at 60 °C for 18 h, $C_{13}H_9K$ (1.01 g, 4.96 mmol) in DME (10 mL) was added and the resulting suspension was stirred overnight at room temperature. The green solution was filtered, DME was removed in vacuo and the resulting solid was extracted with toluene. Recrystallization from toluene yielded 1.28 g (46%) of yellow crystals of **6**. − IR (Nujol): $\tilde{\nu}$ = 3050 (m), 1590 (m), 1320 (s), 1210 (s), 1110 (m), 1090 (s), 1050 (m), 890 (s), 750 (s), 720 (s), 700 (s) cm^{-1}. − ^{1}H NMR (200 MHz, [D$_6$]benzene): δ = 2.06 (s, 15 H, CH_3), 2.16 (m, 6 H, OCH_3), 3.49 [s(br), 4 H, CH_2O], 6.66 (s, 1 H, aryl-H), 6.94 [t, ^3J(H,H) = 14.6 Hz, 2 H, aryl-H], 7.65 [t, ^3J(H,H) = 14.6 Hz, 2 H, aryl-H], 7.86 [d, ^3J(H,H) = 8 Hz, 2 H, aryl-H], 7.97 [d, ^3J(H,H) = 7.8 Hz, 2 H, aryl-H]. − ^{13}C NMR (50.3 MHz, [D$_6$]benzene): δ = 11.1, 36.7, 82.9, 112.1, 114.1, 118.5, 120.0, 120.6, 122.9, 125.1, 126.8. − $C_{27}H_{34}O_2Yb$ (563.6): calcd. C 57.54, H 6.08, Yb 30.70; found C 57.14, H 5.77, Yb 30.58.

[$Me_2Si(C_{13}H_8)_2$]K_2: To a solution of $Me_2Si(C_{13}H_9)_2$ (1.20 g, 3.10 mmol) in THF (30 mL) was slowly added a solution of $C_{10}H_8K$, obtained from K (0.24 g, 6.20 mmol) and $C_{10}H_8$ (0.80 g, 6.25 mmol) in THF (30 mL) at room temperature while stirring. The reaction mixture was stirred for another 8 h and the solvent was removed in vacuo. The resulting residue was extracted with hexane (3 × 30 mL) to remove $C_{10}H_8$ and was dried in vacuo (80 °C, 3 h) to give 1.32 g (92%) of [$Me_2Si(C_{13}H_8)_2$]K_2 as a dark red solid. − IR (Nujol): $\tilde{\nu}$ = 3050 (m), 1550 (w), 1320 (m), 1290 (m), 1275 (m), 1240 (m), 1150 (m), 1130 (w), 1080 (w), 1005 (m), 990 (w), 970 (w), 875 (m), 830 (w), 820 (m), 805 (s), 755 (s), 740 (s), 715 (s), 690 (m), 630 (w) cm^{-1}. − ^{1}H NMR (200 MHz, [D$_8$]THF): δ = 6.5−8.2 (m, 16 H, Ar), 0.03 (s, 6 H, CH_3). − ^{13}C NMR (50.3 MHz, [D$_8$]THF): δ = 1.6, 116.5, 119.7, 124.9, 126.5, 127.9, 129.0, 142.0. − $C_{28}H_{22}K_2Si$ (464.1): calcd. C 72.40, H 4.78, K 16.79; found C 69.90, H 4.95, K 16.70.

$Me_2Si(C_{13}H_8)_2$Yb(THF) (7): To a solution of [$Me_2Si(C_{13}H_8)_2$]K_2 (1.43 g, 3.09 mmol) in THF (30 mL) was slowly added a solution of $YbI_2(THF)_2$ (1.76 g, 3.09 mmol) in THF (10 mL) at room temperature, and the reaction mixture was stirred for 20 h. The solution was concentrated in vacuo. Slow diffusion of toluene into the resulting solution produced red diamagnetic crystals of **7** (1.46 g, 75%). − IR (Nujol): $\tilde{\nu}$ = 3050 (m), 1600 (w), 1570 (w), 1330 (m), 1290 (m), 1275 (m), 1245 (m), 1200 (m), 1155 (m), 1130 (w), 1020 (m), 980 (w), 960 (s), 860 (m), 840 (m), 830 (m), 810 (s), 760 (s), 745 (s), 720 (s) cm^{-1}. − ^{1}H NMR (200 MHz, [D$_8$]THF): δ = 6.7−8.1 (m, 16 H, Ar), 0.034 (s, 6 H, CH_3). − ^{13}C NMR (50.3 MHz, [D$_8$]THF): δ = 1.7, 116.5, 119.7, 124.7, 126.5, 127.9, 128.7, 142.0. − $C_{32}H_{30}OSiYb$ (631.7): calcd. C 60.84, H 4.79, Yb 27.39; found C 59.96, H 5.03, Yb 27.20.

$Me_2Si(C_{13}H_8)_2Sm(THF)_4$ (8): To a solution of [$Me_2Si(C_{13}H_8)_2$]K_2 (2.38 g, 5.14 mmol) in THF (20 mL), was added a solution of $SmI_2(THF)_2$ (2.82 g, 5.14 mmol) in THF (30 mL) under rigorous stirring at room temperature and the reaction mixture was stirred for 20 h. The solution was concentrated in vacuo and filtered from the precipitated KI. Slow diffusion of toluene into the resulting solution produced brown crystals of **8** (3.61 g, 85%). μ_{eff} = 3.6 BM (298 K). − IR (Nujol): $\tilde{\nu}$ = 3050 (m), 1600 (m), 1570 (m), 1330 (s), 1290 (s), 1280 (s), 1240 (m), 1200 (m), 1155 (m), 1120 (m), 1070 (s), 1040 (s), 965 (m), 910 (m), 860 (m), 840 (m), 830 (m), 820 (m), 800 (m), 760 (s), 735 (s), 730 (s) cm^{-1}. − $C_{44}H_{54}O_4SiSm$ (825.4): calcd. C 64.03, H 6.59, Sm 18.22; found C 63.87, H 6.23, Sm 18.22.

X-ray Structure Determination of 1 and 6: Crystals suitable for single-crystal X-ray diffraction were obtained from toluene. The crystal and structure refinement data are listed in Table 1. Data were collected with a Siemens SMART CCD diffractometer (graphite monochromator, Mo-K_α radiation, λ = 0.71073 Å) with area detector by use of ω scans at 173 K. The structures were solved by direct methods using SHELXS-97[52] and refined on F^2 using all reflections with SHELXL-97.[53] All non-hydrogen atoms were

refined anisotropically. The hydrogen atoms were placed in calculated positions and assigned to an isotropic displacement parameter of 0.08 Å^2.The idealized methyl groups were allowed to rotate about their X−C bond. SADABS[54] was used to perform area-detector scaling and absorption corrections. The maximum and minimum transmission factors are summarized in Table 1. The PLATON[55] program was used for the geometric analysis of the structures. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-162390 (**1**) and -162391 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Crystal Engineering of 2-D and 3-D Multiporphyrin Architectures − The Versatile Topologies of Tetracarboxyphenylporphyrin-Based Materials

Yael Diskin-Posner,[a] Goutam Kumar Patra,[a] and Israel Goldberg*[a]

Keywords: Crystal engineering / Supramolecular chemistry / Porphyrinoids / Network solids

This study explores diverse crystal engineering concepts in the formulation of a series of new porphyrin-based supramolecular arrays, utilizing tetrakis(4-carboxyphenyl)porphyrin as an effective building block. Different modes of the supramolecular assembly are demonstrated. They include: (a) self-assembly of the porphyrin units into extended networks through multiple hydrogen bonding, (b) intermolecular coordination assisted by external sodium ion auxiliaries which link between the carboxylic/carboxylate groups of several units, (c) formation of coordination polymers with the aid of bidentate ligands as bridges between the metal centers of the porphyrin molecules, and (d) various combination motifs of concerted hydrogen bonding and coordination features. The resulting multiporphyrin architectures obtained in this study illustrate the expression of several motifs (synthons) of noncovalent interaction in the construction of network solids, which can be potentially useful in the design of new porphyrin-based materials with attractive properties.

Introduction

Supramolecular chemistry provides effective means for the formulation of a large variety of extended multiporphyrin architectures in solution as well as in the solid state by noncovalent forces.[1−3] The significance of such systems lies in their potential use as molecular sensing and delivery systems, charge and energy transport devices, and redox catalysts.[1] In recent years there has been a widespread interest in the design of complex porphyrin-based arrays in order to model light-harvesting systems or to construct novel solid-state receptors and microporous materials (zeolite mimics). In the latter context, we have introduced the tetrakis(carboxyphenyl)porphyrin moiety (TCPP, Scheme 1) as a uniquely versatile building block (tecton) in our efforts to crystal-engineer network solids.[4] This was followed by a demonstration that these building blocks can also be utilized effectively in the construction of molecular sieves and organic zeolite analogues.[5] The square-shaped TCPP is a robust tecton unit that can be assembled into rigid high-order structures in different ways through diverse interaction motifs (synthons). In the equatorial directions, the peripheral carboxylic functions (oriented roughly perpendicular to the porphyrin plane) provide self-complementary binding sites for a simultaneous association of every TCPP building block to several neighboring species.[4b][5b] The array of multiple hydrogen bonds that may form in such cases provides sufficient enthalpic driving force to overcome solvation and negative entropy effects and stabilize open network arrangements. The formation of other kinds of multiporphyrin arrays can be facilitated by the use of metal ion auxiliaries that prefer high coordination environments and may readily coordinate several carboxylic moieties at the same time.[4a] The preferred coordination geometries of these auxiliaries have a dominant influence on the topology of the formed supramolecular assembly (e.g., layered vs. diamondoid, and interpenetrating or grid-type networks). The additional positive charge introduced to the structure by the metal ions can be easily balanced by a single or multiple deprotonation of TCPP, without the need to incorporate additional anions (which is often the case in hybrid inorganic/organic coordination polymers).[6] This is a particularly useful feature of the TCPP framework, as the presence of external anionic species may hamper the construction of open architectures. The insertion of metal ions with high affinities for five- or six-coordinate environments into the porphyrin core (e.g., Zn^{II} or Mn^{III}, as opposed to Cu^{II}, which is usually four coordinate and not effective in axial coordination) provides another programming element for effective supramolecular design.[5a,7] These metal ions may allow additional coordination to other species in the axial direction (i.e., perpendicular to the porphyrin plane). A concerted expression of suitable molecular recognition algorithms along the lateral and axial directions in the same material represents the most desirable approach to the construction of multiporphyrin architectures with a high structural integrity.[8] The square-planar geometry of the porphyrin macrocycle, the directionality of *meso*-substituted carboxylic recognition groups of TCPP, and the coordination properties of the metal ions involved should provide effective means for inducing extended noncovalent connectivity in the design of supramolecular multiporphyrin arrays. This diversity of the TCPP building block is demonstrated by the preparation and structural characterization of four new MTCPP-based (M = Mn^{III}, Zn^{II}) materials (Scheme 1) which provide representative examples of characteristic 2-D and 3-D supramolecular assembly modes of the metalated porphyrin moiety. The considerable complexity associated with steering

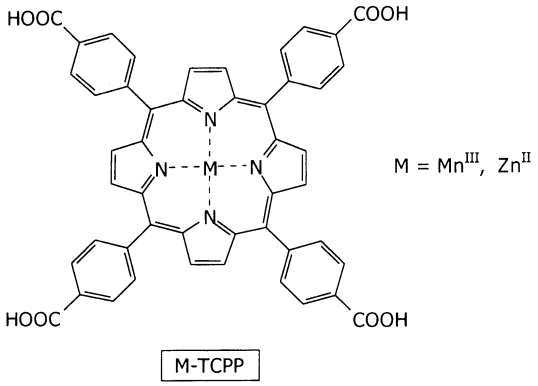

Scheme 1. The TCPP building block

the construction of stable high-order network structures of large organic species (such as the porphyrins in question) by noncovalent forces makes the current effort quite a challenging one.

Results and Discussion

Organic carboxylic acids tend to form supramolecular arrays in crystalline solids by interconnecting through hydrogen bonds into a wide variety of extended networks. These interaction motifs may consist either of the cyclic dimeric $(COOH)_2$ synthons, or of linear polymeric aggregates.[9] Although the hydrogen bonding interactions when considered alone are relatively weak (ca. 10−15 kJ/mol for a single dicarboxylic H bond involving uncharged species),[10] their cooperative effect appears to be sufficient to stabilize low-density supramolecular arrangements even in organic solids.[11] We have applied this concept to porphyrin supramolecular chemistry and demonstrated several formulations of interpenetrating as well as nonpenetrating hollow network architectures through self-complementary hydrogen bonding, without the use of external auxiliaries.[4b][4c] This includes the formation of two-dimensional arrays with either large interporphyrin voids (16 × 21 Å) or considerably smaller cavities (8.5 × 11 Å), depending on the size and nature of the template used. In the present study we describe a series of new MTCPP-based (Scheme 1) structures **1**−**4** of diverse architectures (their detailed composition is given in the Exp. Sect.). The following discussion focuses primarily on the unique features of the *supramolecular* assembly in these compounds; selected coordination and hydrogen bond lengths are summarized in Table 1.

Compound **1** (the ethyl benzoate solvate of the $Mn^{III}TCPP{\cdot}MeOH{\cdot}H_2O$ six-coordinate complex) provides a characteristic example in which multiple hydrogen bonds between the carboxylic functions positioned on the periphery of the square-shaped $Mn^{III}TCPP$ framework provide the main supramolecular organizing force of the observed assembly. Figure 1a illustrates the structure of the 2-D porphyrin β-networks formed in this case. It is directed by effective chain-polymeric-type hydrogen bonding between the carboxylic groups of adjacent molecules. These networks are anionic, as the extra positive charge of the trivalent manganese cation in the porphyrin core is balanced by the abstraction of one proton from the TCPP moiety. This is in line with the observed distribution of C−O distances in the carboxylic functions (1.22 and 1.31 Å for −COOH, and 1.24 and 1.28 Å for $-COO^-$, residues), as well as with the observed hydrogen bonding interactions ($OH\cdots O^-$ = 2.54−2.58 Å within the layer and OH···O = 2.72−2.78 Å between layers; see below). The networked supramolecular motif thus formed contains open spaces between the connecting units (Figure 1a). Only the larger voids are large enough (with van der Waals widths of about 7.0 Å) to host two molecules of the ethyl benzoate crystallization solvent oriented edge-on. The individual building blocks contain additional sites with hydrogen-bonding capacity, as the manganese cation has a high affinity for oxygen ligands and an octahedral coordination (the metalloporphyrin core is planar in such a case). Thus, under the applied conditions of crystallization the metal ion binds one water and one methanol molecule as axial ligands, which may then link further to other species. The porphyrin layers stack in the crystal in an offset manner, in which the porphyrin cores of one layer are positioned above the carboxylic sites of another layer (Figure 1b). This allows the axial water and methanol ligands (as proton donors) to approach the carboxylic groups to form interlayer hydrogen bonds. (Our efforts to cross-link between the overlapping H-bonded layers by a bidentate axial ligand that will coordinate on both sides to the Mn centers have not been successful as yet). In the observed arrangement, the ethyl benzoate molecules positioned within the inter-porphyrin voids of one layer perch on the smaller cavities (which are too small to fully accommodate a molecular species), thus yielding a rather

tight crystal packing of the layered porphyrin−ethyl benzoate arrays. The formulation of closely related structures has been achieved by using anionic Zn^{II}TCPP building blocks and M^+−18-crown-6 (M = Na, K) templates.[4b]

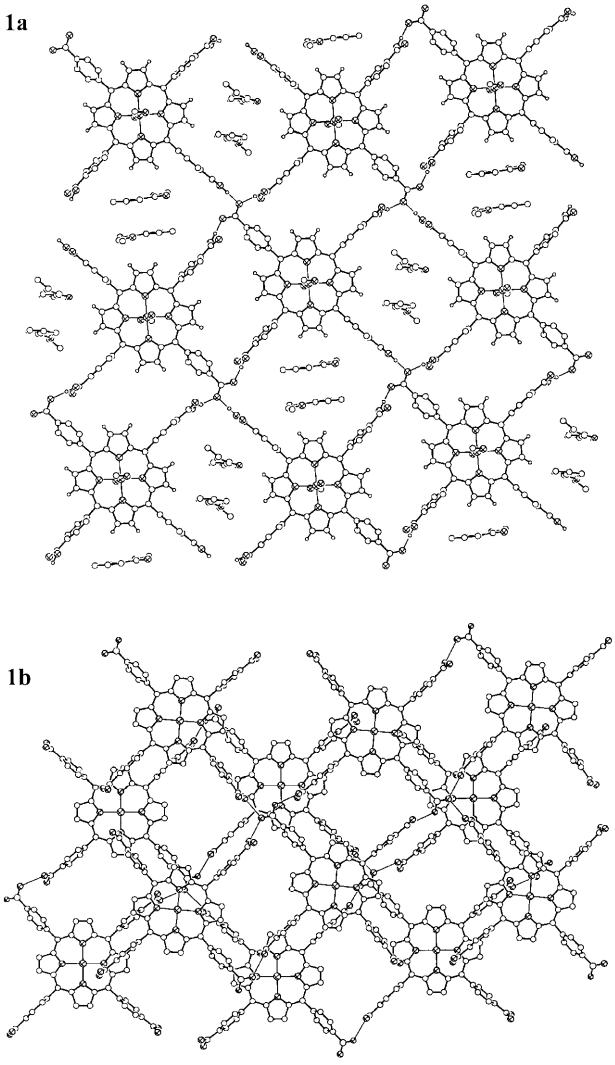

Figure 1. Intermolecular organization in **1**: (a) open layered arrays of the Mn^{III}TCPP building blocks, tessellated by chain-polymeric-type hydrogen bonding; the van der Waals width of the large inter-porphyrin enclosures that accommodate the solvent species is about 7.0 Å; (b) an offset stacking of two adjacent layers, approximately at 4.2 Å; the water and methanol axial ligands are omitted for clarity; the Mn, N and O atoms are denoted by crossed circles

Compound **2** (the ethyl benzoate solvate of the 1:1 Zn^{II}TCPP sodium benzoate complex) represents a supramolecular assembly process assisted by external sodium ion auxiliaries. As shown in Figure 2a, crystallization of Zn^{II}-TCPP in the presence of NaCl, ethyl benzoate and benzoic acid leads to the formation of 2-D multiporphyrin arrays sustained by the metal ions. In this arrangement every cation is coordinated (at 2.32−2.35 Å) to the carboxylic groups of four surrounding carboxylic moieties, forming a roughly square-planar mononuclear $Na^+(COOH)_4$ synthon (Scheme 2), and its positive charge is balanced by a neighboring molecule of deprotonated benzoic acid ($Na^+\cdots O^-$ 2.24 Å). The latter also serves as an excellent proton acceptor in hydrogen bonding interactions with the carboxylic groups ($O^-\cdots HO$ 2.56−2.68 Å) of the four converging porphyrins. The resulting supramolecular arrangement has a wavy layer structure, which consists of two differently oriented porphyrin moieties related to each other by a monoclinic twofold axis, and represents a rather robust coordination polymer in two dimensions. The absence of axial ligands on the porphyrin core in this case allows for a close stacking of the porphyrin layers (with a small offset) in the normal direction (Figure 2b). It is characterized by an average interlayer distance of 4.3 Å between the overlapping segments, as commonly observed in layered tetraarylporphyrin structures.[12] The observed architecture contains small (approximately 5 Å wide) channels which propagate through the layers along the *a* axis of the crystal, and are accommodated by molecules of the ethyl benzoate solvent. The four-coordinate metal ion in the center of the porphyrin has no role in the organization mechanism of the observed pattern. It is not surprising, therefore, that isomorphously structured coordination polymers have been obtained recently from the free-base TCPP building blocks when subjected to similar preparative conditions.[4a]

The large size and the aromatic nature of the porphyrin framework reveals a high propensity for strong dispersive attractions between the roughly flat molecular surfaces of these units (i.e., when it is not obstructed by axially ligating species). This fundamental property of the porphyrin−porphyrin interaction is well reflected in the commonly observed layered organization of the porphyrin moieties at a narrow distance range of 4−5 Å.[12,13] Its dominating role in crystals suggests, however, yet another tool for fine-tuning the supramolecular arrangement. This involves the incorporation of rigid, flat, aromatic residues of appropriate size as effective "van der Waals spacers" between the porphyrin units. We have demonstrated previously the validity of this idea in 2-D and 3-D hydrogen-bonded networks based on the tetrakis(4-hydroxyphenyl)-porphyrin unit and spaced by aromatic intermediates.[14] A similar modification of the interlayer organization by the insertion of an aromatic spacer was obtained in compound **3** (the ethyl benzoate solvate of a 2:1 adduct of $MeOH\cdot Zn^{II}TCPP^-\cdot Na^+$ and 2,7-diazapyrene) by treating Zn^{II}TCPP with a large and rigid aromatic framework such as 2,7-diazapyrene (Scheme 3) in the presence of NaCl. The latter was also used to effect inter-porphyrin coordination in the lateral directions by the sodium ion auxiliaries.

The formation of **3** is associated with the deprotonation of one carboxylic substituent of the porphyrin molecule to balance the charge of the sodium cation. Moreover, the assembly of the anionic porphyrin arrays by sodium ions in this case is via a binuclear $[(Na^+)_2(-COO^-)_2(-COOH)_4]$ synthon (centered on inversion), with two carboxylic groups bridging between the two cations (Scheme 2). The Na···O coordination distances lie within the range 2.25−2.44 Å, while the distance between the two sodium nuclei is 3.42 Å. The Zn^{II}TCPP units are now five-coordinate, revealing a

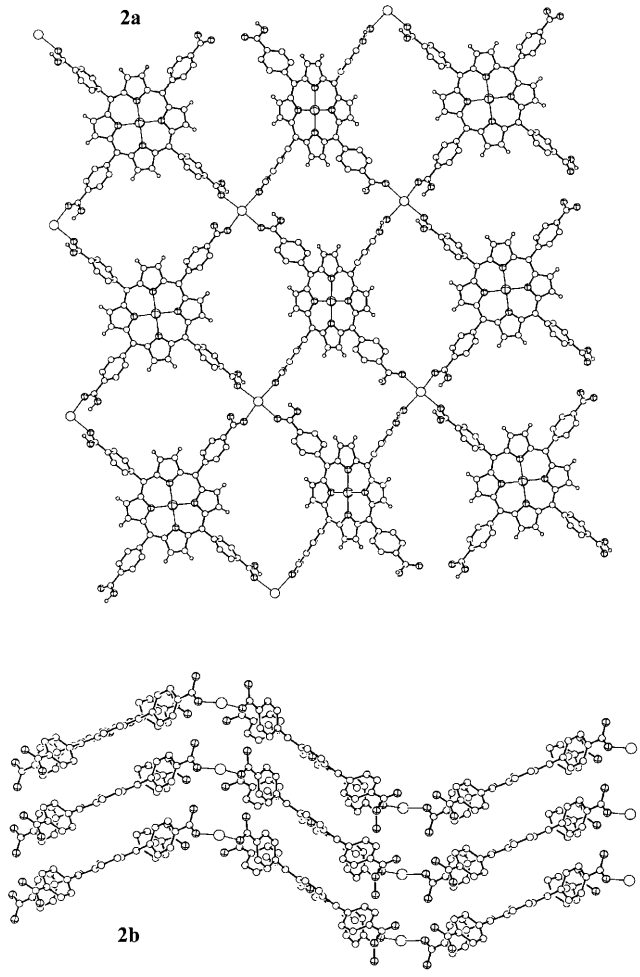

Figure 2. Interporphyrin networking and stacking in **2**: (a) two-dimensional layered arrays of the Zn^{II}TCPP building blocks sustained by metal ion auxiliaries (denoted by large open circles); every cation is strongly coordinated to the carboxylic functions of four different porphyrin units [forming an $Na^{+}(COOH)_4$ interaction synthon] and to the benzoate anion; molecules of the ethyl benzoate solvent are located, and diffused, within the interporphyrin cavities; the latter combine into straight channels in (b) the tightly stacked arrangement of the wavy multiporphyrin layers, at 4.3 Å intervals, along the *a* direction of the unit cell; the benzoate anion and the solvent species are omitted for clarity

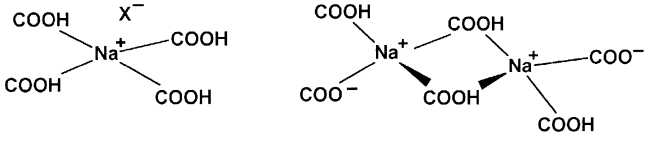
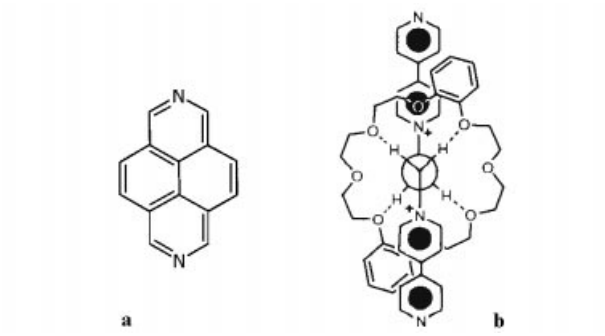


Scheme 2. The mononuclear and binuclear sodium−polycarboxyl synthons in **2** (left) and **3** (right); every carboxylic or carboxylate group shown is part of a different Zn^{II}TCPP unit

domed conformation with the zinc ion slightly displaced from the porphyrin plane (0.27 Å above the N_4 plane), and bearing a methanol species as an axial ligand. The diazapyrene spacer (also located on inversion) is inserted between, and aligned parallel to, the concave surfaces of two inverted



Scheme 3. The 2,7-diazapyrene (left), and [2]pseudorotaxane (right) ligands

porphyrin species. The mean separation distance of the former from the N_4 planes of the latter is 3.4 Å. The sodium ion auxiliaries link the enclosing porphyrin moieties on opposite sides, locking the diazapyrene inside a "sandwich"-type trimeric cluster (Figure 3a). A single dinuclear sodium carboxylic/carboxylate synthon interconnects two neighboring trimers displaced along the *a*+*c* axis of the crystal (parallel to the porphyrin plane), and two additional trimers displaced along a nearly perpendicular *a*+2*b*+*c* direction (Figure 3b,c). This gives rise to the formation of an extended coordination polymer, as every porphyrin unit takes part in three different coordination sites of this type. Adjacent trimers are further connected to each other sideways (along *a*+*b*) by hydrogen bonding. The N sites of the sandwiched diazapyrene entity act as good acceptors for the carboxylic groups of neighboring porphyrin moieties (OH···N 2.76 Å). In addition, the axial methanol ligands oriented perpendicularly to the porphyrin surface (roughly along *a*−*c*) provide proton-accepting sites for hydrogen bonds from other species located above and below (OH···O 2.71 Å). The concerted coordination polymerization and directional hydrogen bonding (all potential sites for intermolecular binding are utilized almost to capacity) yield a uniquely structured single framework lattice in which all porphyrin, diazapyrene and sodium components are interconnected to each other in three dimensions (Figure 3b,c). The resulting lattice is perforated by straight, ca. 4.5 Å wide, channels which are filled in this structure by diffused molecules of the ethyl benzoate solvent (three molecules of solvent per one porphyrin unit).

It should be pointed out that the different modes of interporphyrin coordination through the sodium ions in **2** and **3** occurred spontaneously, and could not be predicted or controlled. Yet, this and our previous[4a][5a] studies confirm that alkali metal auxiliaries readily induce the formation of TCPP-based coordination polymers. Evidently, the dominant nature of these ion-pairing interactions in **3** prevents the diazapyrenes from aligning perpendicular to the porphyrin plane and thus from acting as bridging ligands between adjacent porphyrin macrocycles.

Another variant of simultaneous coordination polymerization and hydrogen bonding is represented by compound **4**

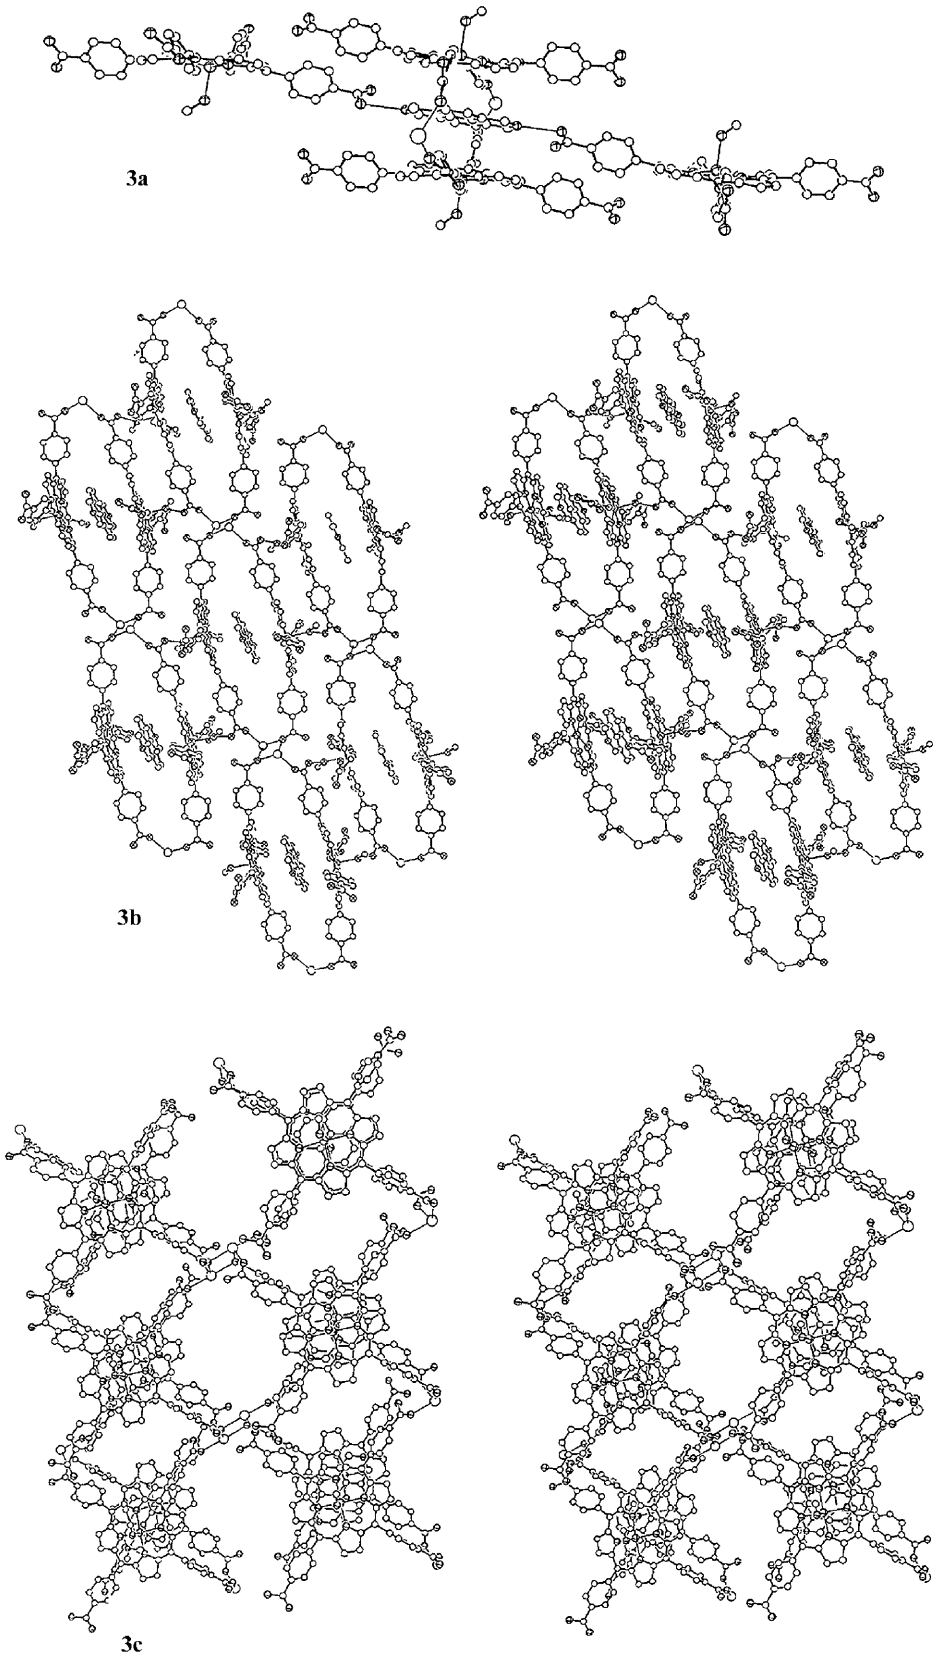


Figure 3. The complex intermolecular binding in **3**: (a) the 2,7-diazapyrene spacer held between four surrounding porphyrin units (by π−π stacking at 3.4 Å, as well as by hydrogen bonding) and two sodium cations (shown as large open circles); (b) stereoview of the structure parallel to the plane of the aromatic fragments, showing the concerted coordination and hydrogen bonding in a direction perpendicular to the porphyrin plane; (c) stereoview of the structure approximately down the open channels (the solvent molecules accommodated therein are omitted for clarity), showing interporphyrin coordination through the sodium ion auxiliaries in the equatorial direction

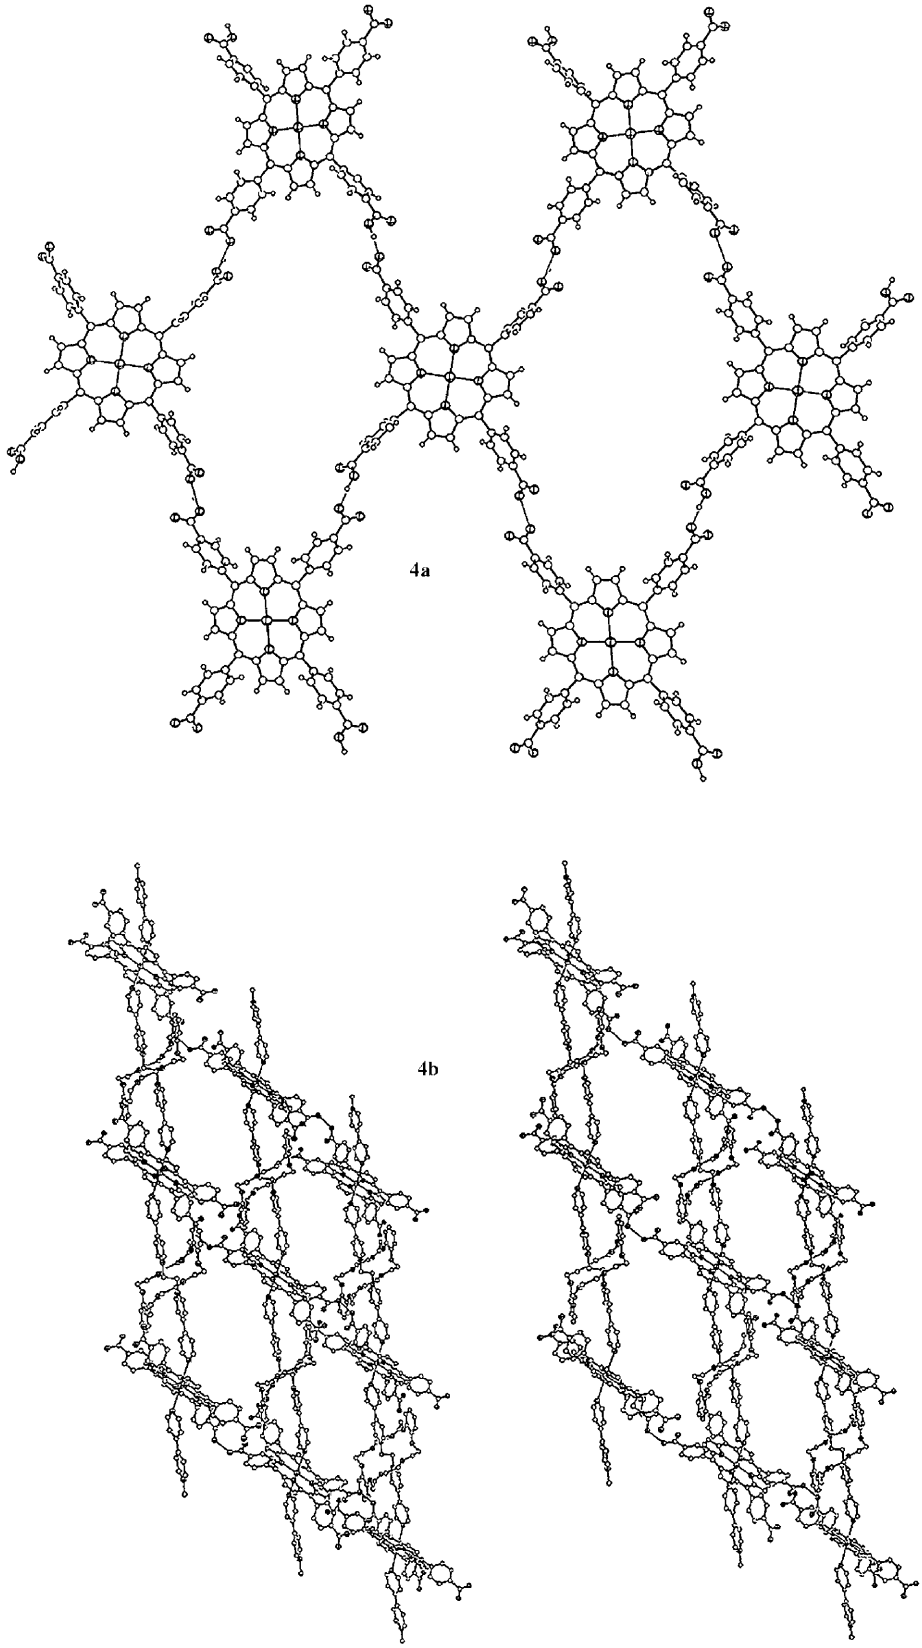

Figure 4. (a) β-Molecular networks of the Zn^{II}TCPP units in **4**; every porphyrin hydrogen atom bonds to four neighboring units and to four additional molecules of water; the van der Waals width of the interporphyrin voids is about 12 Å; (b) stereoscopic illustration of the linear coordination polymers in **4** and the cross-linking between them by interporphyring hydrogen bonds; the Zn, N and O atoms in the porphyrin and ligand moieties are denoted by dark circles

[the crystalline hydrate of the 1:1 complex between $Zn^{II}TCPP^{2-}$ and 1,2-bis(4,4′-bipyridinio)ethane−dibenzo-24-crown-8]. This involves coordination through the metal ion in the porphyrin center of $Zn^{II}TCPP$ without resorting to external auxiliaries. Indeed, earlier studies confirm that Zn^{II} may adopt a six-coordinate environment in the presence of pyridyl-type ligands, and that linear multiporphyrin oligomers and polymers may be obtained in solution as well as in the solid state with bridging bidentate ligands of this type.[7a,15] They have also indicated that a deprotonated TCPP is a better building block for the formation of robust anionic networks than the neutral unit.[7] These observations guided us to choose a cationic bidentate ligand for this synthesis. The [2]pseudorotaxane dication 1,2-bis(4,4′-bipyridinium)ethane−dibenzo-24-crown-8 (Scheme 3), which has been used in the synthesis of other supramolecular systems,[16,17] was assumed to be a perfect candidate to this aim. It is a linear doubly charged species containing a pyridyl fragments at both ends. The macrocyclic crown ring threaded on the molecular axle adds bulkiness and limits the conformational flexibility of the system. Figure 4b illustrates the structure of the anticipated polyrotaxane coordination polymer that forms. Along the linear polymer the pyridyl N atoms coordinate from both sides to the zinc ions in the porphyrin core at 2.691 Å, the Zn−N(pyridyl) bond forming an angle of about 78° with the porphyrin plane. Simultaneously, the deprotonated porphyrin units (located on crystallographic inversion) associate into continuous open networks through cooperative hydrogen bonding between their carboxylic/carboxylate groups (Figure 4a). Each of the latter is involved in one hydrogen bond to another porphyrin species (at OH···O^- 2.451 Å) and another H bond to an external molecule of water (at OH···O 2.679 and 2.789 Å). Every $Zn^{II}TCPP$ unit in this net is linked to four neighboring molecules at the corners of the square framework. The spacing between the molecular surfaces of adjacent units located across the width of the interporphyrin voids is about 12.0 Å. In the absence of a suitable template to fill such a large void space, the linear coordination polymers that propagate in a direction roughly perpendicular to the porphyrin plane interpenetrate through the hydrogen-bonded porphyrin networks. The [2]pseudorotaxane ligands that are embedded within a given layer, link to porphyrin units of neighboring layers located above and below. The resulting structure consists, therefore, of interlocked multiporphyrin β-molecular networks and linear [2]pseudorotaxane coordination polymers. The single-framework lattice is not porous in this case, as the crown-ether macrocycle framework threaded on the ligand molecular axle fills effectively the space available within the layered porphyrin arrays.

The above examples demonstrate useful synthetic tools that can be successfully applied in diverse combinations for the crystal engineering of porphyrin-based network solids. The metalated TCPP building block was found to be particularly attractive for this aim, as it allows the tessellation of multiporphyrin arrays in various ways, including through extensive hydrogen bonding, inter-coordination through external metal ion auxiliaries, and coordination polymerization assisted by bipyridyl-type axial ligands bridging between core metal ions of adjacent porphyrin units. The concerted utilization of coordination (of either type) and hydrogen bonding features yields network molecular solids with fascinating 3-D architectures. It is noteworthy that these formulations are directed primarily by specific noncovalent intermolecular interactions, and not by virtue of dispersion forces as is commonly observed in molecular crystals. Many of the multiporphyrin lattices obtained in this way contain channels accessible to other species that are not part of the supramolecular framework, providing useful models of microporous solids that may bear structural and functional resemblance to the inorganic zeolites. A priori prediction of the actual crystal structure that may form from solution in a particular case (and the detailed stoichiometric content of the interacting components in it) is still beyond reach, as many other factors are involved in the crystallization process (e.g., solubility problems, kinetic vs. thermodynamic control of crystal growth, composition and chemical reactivity of the crystallization environment, etc.). However, the above studies provide useful examples for an effective synthesis of supramolecular arrays with multidimensional architectures, and demonstrate effective tools for the solid-state synthesis of 2-D and 3-D multiporphyrin assemblies. They add to our previous reports on porphyrin-based molecular sieves and zeolite analogues with tunable architectures, and together represent an important step towards the programmed formulation of new molecular materials with useful properties.

Experimental Section

Materials: $Zn^{II}TCPP$ ($C_{48}H_{28}N_4O_8Zn$) and $Mn^{III}TCPP{\cdot}Cl$ ($C_{48}H_{28}N_4O_8MnCl$) were purchased from Porphyrin Systems GbR, and used as received. The dibenzo-24-crown-8, common solvents and other starting materials were purchased from Aldrich and used as received.

Preparative Procedures: The porphyrin phase used for the crystallizations was obtained by dissolving the commercial $Zn^{II}TCPP$ or $Mn^{III}TCPP{\cdot}Cl$ materials in hot wet methanol. Ethyl benzoate was found to be an effective crystallization solvent for obtaining X-ray quality crystals of compounds **1−3** by filling the voids in the open multiporphyrin lattices that formed. A series of different experiments is reported below to illustrate the versatile inter-porphyrin binding modes possible in these materials: (a) crystallization of TCPP networks without resorting to external ligands or metal ion auxiliaries, (b) reaction of the tetrakis(carboxy)porphyrin with sodium ion auxiliaries to effect lateral inter-coordination, also in the presence of a large aromatic spacer, and (c) crystallization of these building bocks with [2]pseudorotaxane dication (Scheme 3) as an effective bridging ligand between the porphyrin centers. They yielded four new supramolecular materials.

Compound 1 [($C_{48}H_{27}N_4O_8Mn$)·(CH_3OH)·(H_2O)·1.5($C_9H_{10}O_2$)]: A methanol solution (2 mL) of $Mn^{III}TCPP{\cdot}Cl$ (8.8 mg, 0.01 mmol) was heated to boiling (expelling HCl), and 0.2 mL of ethyl benzoate was added. The resulting solution was allowed to stand in ambient air until large, dark-red crystals were formed (ca. 2 mg).

Compound 2 [$(C_{48}H_{28}N_4O_8Zn)\cdot(C_9H_{10}O_2)\cdot Na^+\cdot(C_7H_5O_2)^-$]: A methanol solution (2 mL) of Zn^{II}TCPP (8.6 mg, 0.01 mmol) was heated to boiling in the presence of sodium chloride (one grain), and 0.1 mL of ethyl benzoate was added. This procedure was associated with partial degradation of the ethyl benzoate to benzoic acid and expulsion of HCl. The resulting solution was allowed to stand in ambient air, until a mixture of a small number of dark red crystals with mostly polycrystalline material was deposited in the reaction test tube.

Compound 3 [$(C_{48}H_{27}N_4O_8Zn)^-\cdot Na^+\cdot(CH_3OH)\cdot 0.5(C_{14}H_8N_2)\cdot 3(C_9H_{10}O_2)$]: 2,7-Diazapyrene (4.0 mg, 0.02 mmol) was added to a methanol solution (2 mL) of Zn^{II}TCPP (8.6 mg, 0.01 mmol), the mixture heated to boiling in the presence of sodium chloride, and 0.2 mL of ethyl benzoate added. In this case the preparative procedure was associated with deprotonation of the porphyrin molecule and expulsion of HCl. The resulting solution was allowed to stand in ambient air until dark red crystals were formed after a few days in relatively high yield (ca. 3 mg).

Compound 4 [$(C_{48}H_{26}N_4O_8Zn)^{2-}\cdot(C_{22}H_{20}N_4)^{2+}\cdot(C_{24}H_{32}O_8)\cdot 4(H_2O)$]: The 1,2-bis(4,4′-bipyridinio)ethane dibromide was synthesized first according to a known literature procedure and confirmed by NMR, UV and MS spectroscopy.[16] Then, a 1:4 mixture of this ligand (4 mg, 0.008 mmol) and dibenzo-24-crown-8 (15 mg, 0.033 mmol) was dissolved in chloroform (1.5 mL), and allowed to stand in air for a few days to yield a [2]pseudorotaxane (Scheme 3) in which the ligand is inserted in the crown ether ring (its formation was monitored by ^{1}H NMR spectroscopy).[17] In the next step, a methanolic solution (2 mL) of Zn^{II}TCPP (8.6 mg, 0.01 mmol) was carefully layered over the chloroform phase and allowed to stand. Slow diffusion produced numerous dark-red prisms of the composite crystals of compound **4** layered on the walls of the test tube.

Due to the small preparative scale (see above), the high content of volatile solvents in these crystals, and presence of metal ions therein, it was difficult to obtain reliable elemental analytical data. However, all the obtained crystalline compounds were unequivocally characterized by crystallographic techniques.

X-ray Crystallography: All diffraction measurements were carried out with a Nonius Kappa CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.7107 Å). The crystalline samples of the analyzed compounds were covered with a thin layer of light oil and cooled to 110 K in order to minimize structural disorder and thermal motion effects, and increase the precision of the results. This allowed us to locate most of the hydrogen atoms of the porphyrin network in residual electron-density maps. The structures were solved using direct methods (SHELXS-97 and SIR-92) and refined by full-matrix least squares on F^2 (SHELXL-97).[18] Hydrogen atoms were refined using a riding model with fixed thermal parameters [U_{ij} = 1.2 U_{ij} (equiv.) for the atom to which they are bonded].

1: $(C_{48}H_{27}N_4O_8Mn)\cdot(CH_3OH)\cdot(H_2O)\cdot 1.5(C_9H_{10}O_2)$, M = 1118.0, monoclinic, space group $P2_1/c$, a = 11.5160(1), b = 22.2430(2), c = 21.8340(2) Å, β = 97.95(1)°, V = 5539.05(9) Å^3, T = 110(2) K, Z = 4, $D_{calcd.}$ = 1.341 g·cm^{-3}, μ(Mo-K_α) = 0.31 mm^{-1}, 12828 unique reflections to $2\theta_{max}$ = 55.7°, R_1 = 0.068 for 9747 observations with $I > 2\sigma(I)$, R_1 = 0.097 (wR_2 = 0.214) for all unique data.

2: $(C_{48}H_{28}N_4O_8Zn)\cdot 3(C_9H_{10}O_2)\cdot Na^+\cdot(C_7H_5O_2)^-$, M = 1448.7, monoclinic, space group $P2_1$, a = 9.9730(2), b = 32.1410(6), c = 11.2750(2) Å, β = 110.80(1)°, V = 3378.5(1) Å^3, T = 110(2) K, Z = 2, $D_{calcd.}$ = 1.424 g·cm^{-3}, μ(Mo-K_α) = 0.45 mm^{-1}, 6052 unique reflections to $2\theta_{max}$ = 50.8°, R_1 = 0.057 for 4761 observations with $I > 2\sigma(I)$, R_1 = 0.079 (wR_2 = 0.157) for all unique data. The structure is a racemic twin.

3: $(C_{48}H_{27}N_4O_8Zn)^-\cdot Na^+\cdot(CH_3OH)\cdot 0.5(C_{14}H_8N_2)\cdot 3(C_9H_{10}O_2)$, M = 1460.8, triclinic, space group $P\bar{1}$, a = 13.7460(2), b = 15.5400(2), c = 18.2670(4) Å, α = 108.422(1), β = 93.223(1), γ = 108.670(1)°, V = 3453.1(1) Å^3, T = 110(2) K, Z = 2, $D_{calcd.}$ = 1.405 g·cm^{-3}, μ(Mo-K_α) = 0.44 mm^{-1}, 12717 unique reflections to $2\theta_{max}$ = 52.0°. Conventional refinement converged at R_1 = 0.095 for 8205 observations with $I > 2\sigma(I)$, R_1 = 0.141 (wR_2 = 0.279) for all unique data. It indicated severe disorder of the three ethyl benzoate solvent molecules within the interporphyrin voids of the crystal lattice, which could not be modeled with an adequate precision. Subtraction of their contribution to the diffraction pattern by the Bypass[19] procedure resulted in a considerably improved convergence of the main supramolecular framework at R_1 = 0.065 for 8205 observations with $I > 2\sigma(I)$, R_1 = 0.099 (wR_2 = 0.185) for 12717 unique data.

4: $(C_{48}H_{26}N_4O_8Zn)^{2-}\cdot(C_{22}H_{20}N_4)^{2+}\cdot(C_{24}H_{32}O_8)\cdot 4(H_2O)$, M = 1713.1, monoclinic, space group $P2_1/n$, a = 8.070(1), b = 23.570(1), c = 22.314(1) Å, β = 98.68(1)°, V = 4195.7(2) Å^3, T = 110(2) K, Z = 2, $D_{calcd.}$ = 1.356 g·cm^{-3}, μ(Mo-K_α) = 0.37 mm^{-1}, 7181 unique reflections to $2\theta_{max}$ = 50.8°. Conventional refinement converged at R_1 = 0.105 for 4823 observations with $I > 2\sigma(I)$, R_1 = 0.147 (wR_2 = 0.323) for all unique data. It indicated a low data-to-parameters ratio and severe disorder of the crown ether species, the atomic positions of which could thus be assigned with isotropic U only and determined with low precision.

Despite the considerable disorder in structures **3** and **4**, the supramolecular framework structures could be reliably determined. The observed covalent and coordination bond lengths and angles in the ordered fragments conform to normally observed values in related porphyrin compounds, as documented in the literature. This includes also clear distinction in most cases between C−O bond lengths in a carboxylic residue (one short, near 1.2 Å, and one long, near 1.3 Å), and in a carboxylate anion (roughly equal bond lengths usually within 1.24−1.27 Å), as well as between distances of carboxyl−carboxyl, and carboxyl−carboxylate hydrogen bonding interactions.[4b,10]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication nos. CCDC-160614 (**1**), -160615 (**2**), -160616 (**3**) and -160617 (**4**). Copies can be obtained free of charge on the application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

The Coordination Chemistry of *cis*-3,4-Diaminopyrrolidine and Related Polyamines[‡]

Dirk Kuppert,[a] Jürgen Sander,[a] Christian Roth,[a] Michael Wörle,[b] Thomas Weyhermüller,[c] Guido J. Reiss,[d] Uwe Schilde,[e] Iris Müller,[f] and Kaspar Hegetschweiler*[a]

Keywords: Chelates / N ligands / Ligand design / Stability constants / Coordination modes

cis-3,4-Diaminopyrrolidine (*cis*-dap), *trans*-3,4-diaminopyrrolidine (*trans*-dap), *cis*-1,2-cyclopentanediamine (*cis*-cptn), and *trans*-1,2-cyclopentanediamine (*trans*-cptn) have been prepared in multigram quantities. The complexation of these ligands and of 3-aminopyrrolidine (ampy) with Ni^{II}, Cu^{II}, Zn^{II}, and Cd^{II} has been studied in solution by means of potentiometric and spectrophotometric titrations. The complexes of the triamines *cis*-dap and *trans*-dap show a pronounced tendency to form protonated species such as $[M^{II}(HL)]^{3+}$, $[M^{II}(HL)_2]^{4+}$, and $[M^{II}(HL)L]^{3+}$, indicative of a bidentate coordination mode of the ligand L. The UV/Vis spectra of the corresponding Cu^{II} complexes further confirmed bidentate coordination with *trans*-CuN_4 geometry. The overall stabilities of the bis complexes $[ML_2]^{2+}$ decrease in the order *cis*-cptn > *cis*-dap > *trans*-cptn > ampy > *trans*-dap. The considerably lower stabilities of the ampy complexes as compared to the corresponding *cis*-dap complexes indicate metal binding to the two primary amino groups of the latter ligand. This was supported by molecular mechanics calculations (Cu^{II} and Co^{III} complexes) and confirmed by single-crystal X-ray diffraction studies of $[Pt(Hcis\text{-}dap)Cl_4]Cl\cdot H_2O$, $[Pd(Hcis\text{-}dap)_2](ClO_4)_4\cdot 2H_2O$, and $[Cu(Hcis\text{-}dap)_2(OH_2)_2](SO_4)_2\cdot 3.5H_2O$ – $2x\ H^+ + x\ Cu^{2+}$ with $0.01 \le x \le 0.11$. For the diamine ligands, coordination through the two exocyclic amino groups or through one exocyclic and one endocyclic amino group was established from the X-ray structure analyses of $[Ni(cis\text{-}cptn)_2](ClO_4)_2$ and $[Cu(3R\text{-}ampy)(3S\text{-}ampy)](ClO_4)_2$, respectively. The crystal structure determination of $[Co(cis\text{-}dap)(tach)][ZnCl_4]Cl\cdot C_2H_5OH$ (tach = *cis*-1,3,5-cyclohexanetriamine) revealed tridentate, facial coordination of *cis*-dap in this particular complex. However, the structural parameters of the $[Co(cis\text{-}dap)(tach)]^{3+}$ moiety indicate significant strain for this coordination mode. The coordinating properties of the ligand *cis*-dap are compared with those of other aliphatic and alicyclic triamines.

Introduction

Structure–stability correlations are a subject of continuing interest in coordination chemistry, and the dependence of complex stability on the individual structural properties of a ligand has been extensively discussed.[1] In this respect, cyclic polyamines that are restricted to a facial coordination (Scheme 1) are of particular interest because their rigidity considerably reduces the number of possible solution structures as compared to their open-chain analogues. Ligands based on the 1,4,7-triazacyclononane or all-*cis*-cyclohexane-1,3,5-triamine backbone are well established in the literature.[2,3] However, until recently, intermediate members of this series, such as *cis*-3,5-diaminopiperidine (dapi) or *cis*-3,4-diaminopyrrolidine (*cis*-dap), had not been investigated to any great extent. Crystal structures of Pd^{II}(dapi) complexes have been reported by Schwarzenbach,[4] and we recently published a comprehensive study of the complexation of dapi with a variety of metal cations.[5] The metal-binding properties of the related triamine *cis*-3,4-diaminopyrrolidine (*cis*-dap) have not yet been described. We have developed an efficient procedure for the preparation of *cis*-dap and wish to report herein its coordination chemistry both in aqueous solution and in the solid state. Additionally, some related cyclic di- and triamine ligands with a five-membered ring structure have also been studied (Scheme 2).

Results

Synthesis of the Ligands

The only hitherto known synthesis of *cis*-3,4-diaminopyrrolidine involves a complicated multi-step procedure and gives only unsatisfactory yields.[6] We have developed a new and efficient synthetic route that has allowed facile

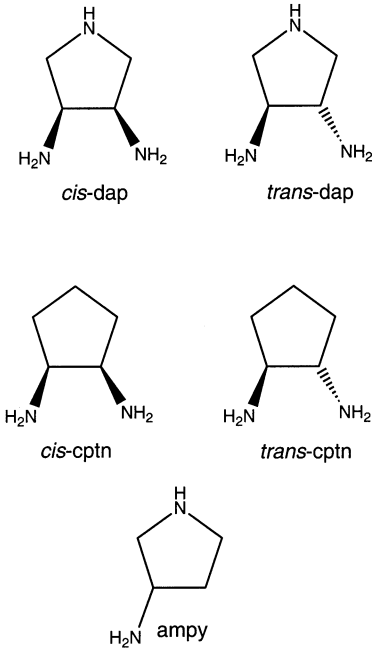

Scheme 2. Structures of the ligands and their abbreviations

preparation of this triamine in multigram quantities. Our procedure starts with 3-pyrroline, the amino group of which is protected by acetylation. The carbon−carbon double bond is then stereoselectively *cis*-dihydroxylated with OsO_4 to give 1-acetyl-*cis*-3,4-pyrrolidinediol. Subsequent conversion of the two hydroxy groups into amino groups is achieved through the corresponding diazide. After removal of the protecting acetyl group, the desired *cis*-3,4-diaminopyrrolidine can be isolated in excellent yield as the trihydrochloride salt. The *cis* configuration of the product was established by a single-crystal X-ray diffraction analysis (Figure 1, top). The corresponding chiral *trans* isomer was hitherto unknown and only some 1-substituted derivatives have been described.[7,8] We prepared this ligand from the *N*-benzylimide derivative of tartaric acid, which was again converted into the corresponding diazide. Subsequent hydrogenation resulted in reduction of the azido groups and in the removal of the benzyl group. The *trans* (3*R*,4*R*) configuration was again confirmed by a single-crystal X-ray diffraction analysis (Figure 1, bottom). The puckering parameters $Q = 0.405(2)$ Å, $\varphi = 83.0(4)°$ and $Q = 0.357(3)$ Å, $\varphi = 238.3(4)°$ for the pyrrolidine rings of H_3*cis*-dap^{3+} and H_3*trans*-dap^{3+} are indicative of a half-chair conformation with a slight twist towards an envelope form.[9] As expected, the N···N distance between the two primary amino groups in *trans*-dap is somewhat longer (3.28 Å) than that in *cis*-dap (3.00 Å).

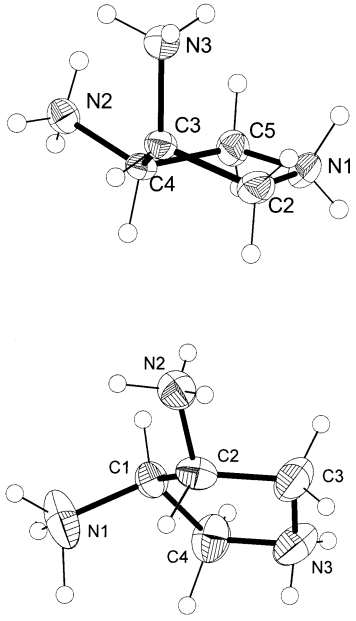

Figure 1. Molecular structures of the triply protonated triamines H_3*cis*-dap^{3+} (top) and H_3*trans*-dap^{3+} (bottom) showing the atom numbering scheme; thermal ellipsoids are drawn at a 50% probability level; hydrogen atoms are shown as spheres of arbitrary size; range of bond lengths [Å]: C−C 1.520(3)−1.533(3), C−N 1.478(3)−1.510(3); selected angles for H_3*cis*-dap^{3+} [°]: C2−C3−C4 100.93(16), N3−C3−C4 114.11(16), N2−C4−C3 116.80(17)

The structurally related diamines *cis*-1,2-cyclopentanediamine (*cis*-cptn) and *trans*-1,2-cyclopentanediamine (*trans*-cptn) were analogously prepared via the diazides using the corresponding cyclopentanediols as starting materials.[10−12] The chiral *trans*-cptn was obtained as a racemate. The two diastereomers can readily be distinguished by ^{1}H NMR spectroscopy. The *cis* isomer has C_s symmetry and shows four resonances due to the three methylene groups, whereas the chiral *trans* isomer exhibits C_2 symmetry showing only three signals for these six protons. The diamine 3-aminopyrrolidine (ampy) is commercially available and was again used as a racemate. A single-crystal X-ray diffraction analysis of H_2ampy$(ClO_4)_2$ has recently been published.[13]

Protonation Constants

The acidity constants of the protonated amines are listed in Table 1. For the two pairs of diastereomers H_3*cis*-dap^{3+}/H_3*trans*-dap^{3+} and H_2*cis*-cptn^{2+}/H_2*trans*-cptn^{2+}, the *cis* isomers of the fully protonated forms are slightly stronger acids. The triamines have different basic sites (primary and secondary amino groups) and this leads to different tautomers for species with an intermediate degree of protonation. In the case of *cis*-dap, the equilibria between these different microspecies were elucidated by ^{1}H NMR titration (Figure 2). An NOESY experiment allowed the unambiguous assignment of the two diastereotopic protons of the methylene groups. Only one proton (3-H) showed a significant NOE with the adjacent 1-H proton. The observed pH dependence of the chemical shifts could be reproduced using pK_a values of 2.15, 6.21, and 9.78 for the macrospecies H_x*cis*-dap^{x+} (Figure 2; $3 \geq x \geq 1$). These values (D_2O, 28 °C, no inert electrolyte) are in good agreement with the pK_a values obtained from the potentiometric measurements. As

Table 1. Protonation constants for the cyclic di- and triamine ligands (25 °C) at ionic strengths (I) of 0.1 mol dm^{-3} (KCl) and 1.0 mol dm^{-3} (KNO_3) as indicated

[a]	log K_1		log K_2		log K_3	
I [mol dm^{-3}]	0.1	1.0	0.1	1.0	0.1	1.0

described previously,[5] the deshielding of the (C−)H protons by protonation of a nearby basic site in a cyclic polyamine can be modeled using a limited set of deshielding constants. For the monoprotonated H*cis*-dap$^+$, such calcula-

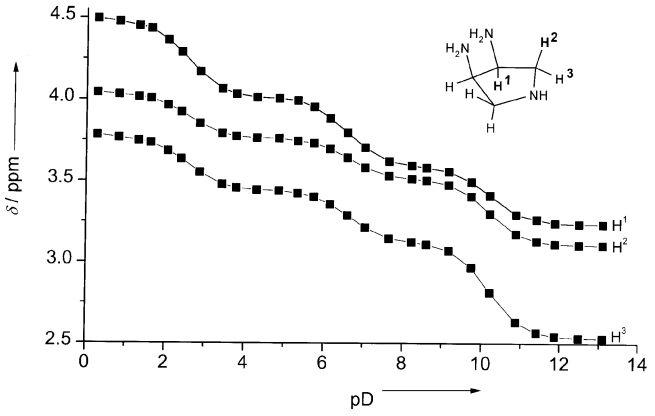

Figure 2. pD dependence of the ^{1}H NMR resonances of *cis*-dap; squares correspond to the experimental values; the lines are calculated (minimization of $[\delta_{obs} - \delta_{calcd.}]^2$) assuming a rapid equilibrium between the species H_x*cis*-dap^{x+} ($1 \leq x \leq 3$)

tions indicated that the two microspecies with a protonated primary amino group or a protonated secondary ring nitrogen atom are present in proportions of 57% and 43%, respectively. This ratio corresponds closely to a statistical distribution of the proton over the three basic sites. A different result is obtained for the doubly protonated H_2*cis*-dap^{2+}, for which the tautomer with a free primary amino group clearly predominates (75%). This result can be explained in terms of a simple electrostatic model (maximal separation of the two positive charges).

Metal Complex Formation

The coordination behavior of the polyamines in dilute aqueous solution (25 °C) was studied by means of pH-metric titration experiments. Formation constants of Ni^{II}, Cu^{II}, and Cd^{II} complexes were determined for ampy, *cis*-cptn, and *cis*-dap. Additionally, the complexation of *cis*-dap with Zn^{II} was studied. For the ligands *trans*-cptn and *trans*-dap, our study was confined to complexation with Cu^{II}. All formation constants are summarized in Tables 2 and 3. The measurements with Ni^{II}, Cu^{II}, and Zn^{II} were performed in 0.1 mol dm^{-3} KCl. Due to the relatively high affinity of Cd^{II} for Cl^-, these experiments were performed in 0.1 mol dm^{-3} KNO_3.[5]

Table 2. Formation constants of metal complexes with the triamine ligands (25 °C, 0.1 mol dm^{-3} KCl or KNO_3)

	Cu^{2+}		Ni^{2+}	Zn^{2+}	Cd^{2+}[a]
	cis-dap	*trans*-dap	*cis*-dap	*cis*-dap	*cis*-dap
log β_{xyz}[b] x,y,z					
1,1,0	–	–	6.41(1)	4.93(2)	4.44(2)
1,1,1	16.8(1)	14.68(1)	14.14(2)	12.68(2)	12.33(1)
1,2,2	32.38(2)	28.40(2)	27.06(2)	–	–
1,2,1	25.27(1)	21.59(2)	19.37(3)	–	–
1,2,0	17.53(1)	14.05(2)	11.24(2)	8.89(2)	7.90(2)
1,3,0	–	–	13.7(1)	–	–
1,2,−1	–	–	–	−0.38(2)	–

[a] Cd^{2+}: 0.1 mol dm^{-3} KNO_3; all other metal ions: 0.1 mol dm^{-3} KCl. – [b] $\beta_{xyz} = [M_xL_yH_z] \times [M]^{-x} \times [L]^{-y} \times [H]^{-z}$; estimated standard deviations (in parentheses) were calculated with HYPERQUAD[36] and multiplied by a factor of three.

The results indicate that the two triamines *cis*-dap and *trans*-dap show a pronounced tendency to form protonated complexes of the compositions $[M(HL)]^{3+}$ and $[M(HL)_2]^{4+}$ in acidic solution (Figure 3). In the presence of excess ligand, the main species formed are the bis(complexes) $[ML_2H_x]^{(2+x)+}$. The formation of a tris(chelate) $[ML_3]^{2+}$ was only verified in the case of Ni^{II}. [Ni(*cis*-dap)$_3$]$^{2+}$ was seen as a minor species at the end of a titration using an excess of the ligand. In the experiments with total Ni/total *cis*-dap = 1:2, formation of [Ni(*cis*-dap)(H*cis*-dap)]$^{3+}$ and [Ni(*cis*-dap)]$^{2+}$ was observed in the same pH range, and a fixed value of β_{ML}, as obtained from an independent 1:1 titration, was used in the evaluation to avoid mutual influ-

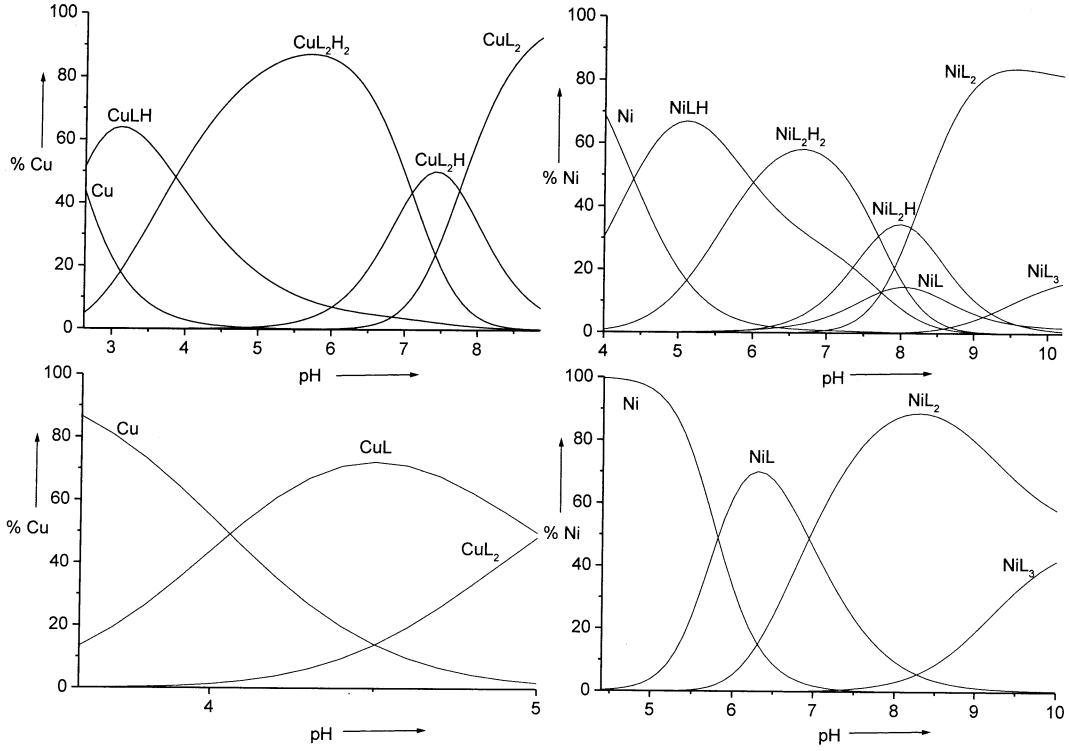

Figure 3. Species distribution plots for an equilibrated aqueous solution with a total metal ion (Ni, Cu) concentration of 10^{-3} mol dm^{-3} and a total ligand (L) concentration of 2×10^{-3} mol dm^{-3} (Cu) or 3×10^{-3} mol dm^{-3} (Ni); L = *cis*-dap (top), L = *cis*-cptn (bottom); only metal-containing species are shown; the equilibrium constants listed in Tables 2 and 3 were used for the calculations

ence (correlation effects) of the two formation constants. In the case of Cu^{II}, the unprotonated $[CuL]^{2+}$ complex was not observed.

As expected, the diamines ampy, *cis*-cptn, and *trans*-cptn do not form any protonated metal complexes and the titration curves could be evaluated simply in terms of $[ML]^{2+}$ and $[ML_2]^{2+}$ formation. In the case of *cis*-cptn and Ni^{II}, the formation of a complex of composition $[ML_3]^{2+}$ was additionally established. The complexation of Ni^{II} and Cd^{II} by ampy is rather weak and was only observed at pH > 8. To avoid precipitation of solid metal hydroxides, a large excess of ampy had to be used.

UV/Vis data of Ni^{II}- and Cu^{II}(amine) complexes provide a useful tool for assigning the structures of the different solution species.[14,15] The d-d transitions of Ni^{II} complexes with saturated amines are of rather low intensity ($\varepsilon \leq 10$) and hence rather concentrated solutions (0.1 M) had to be used. Under these conditions, both $[Ni(cis\text{-dap})_2]^{2+}$ and $[Ni(Hcis\text{-dap})_2]^{4+}$ form blue solutions, with $^3A_{2g}$-$^3T_{1g}(F)$ transitions at 571 and 577 nm, respectively. These values are consistent with an NiN_4O_2 chromophore and the minor shift upon deprotonation clearly indicates that incorporation of an additional nitrogen atom into the chromophore does not occur to any significant extent. We can therefore exclude both tridentate coordination and a bridging mode with the secondary nitrogen atom coordinated to an adjacent Ni^{II} center. In contrast to *cis*-dap, $[Ni(cis\text{-cptn})_2]^{2+}$ forms a bright-yellow solution (λ_{max} = 444 nm), indicative

of a diamagnetic complex.[10] It is noteworthy that the slightly less basic *cis*-dap does not form such a low-spin bis(complex). In the presence of excess *cis*-dap (Ni/L > 1:3), purple solutions with λ_{max} = 553 nm are observed. The considerable shift to shorter wavelengths is indicative of a tris(chelate) structure with an NiN_6 chromophore. Such an $[Ni(cis\text{-dap})_3]^{2+}$ complex had already been noted as a minor species in the aforementioned titration experiments. Since the significantly higher ligand concentration (0.3 mol dm^{-3}) favors complexation, the tris complex becomes the predominant species at pH > 10.

In aqueous solution, the d-d transitions of Cu^{II}(amine) complexes appear unresolved as a broad single band in the range 500−750 nm.[15] The intensity of this band is an order of magnitude higher than that seen for the corresponding Ni^{II} complexes, and this allowed the recording of solution spectra with a total Cu^{II} concentration of just 0.01−0.02 mol dm^{-3}. Measurements were made at an ionic strength of 1 mol dm^{-3} KNO_3 and were carried out in conjunction with an additional series of potentiometric titrations (Figure 4). These data allowed the determination of the stability constants by two independent methods. The agreement found was generally good (Table 4). Additionally, the measurements could be used for the calculation of spectra for each individual species (Figure 4, b). It is well established that for a tetragonally distorted geometry (C_{4v} or D_{4h}), successive replacement of the four water ligands by nitrogen donors in the equatorial plane results in a continuous shift of λ_{max} to shorter wavelengths, whereas substitution of the loosely bound axial water ligands results in a red shift (the "pentaammine effect").[16,17] $[Cu(H\textit{cis}\text{-dap})_2]^{4+}$, $[Cu(H\textit{cis}\text{-dap})(\textit{cis}\text{-dap})]^{3+}$, and $[Cu(\textit{cis}\text{-dap})_2]^{2+}$ were all found to exhibit absorbance maxima at 552−567 nm, indicative of a *trans*-CuN_4 chromophore. Similarly, the λ_{max} values of 560 nm (*trans*-dap), 550 nm (ampy), and 545 nm (*cis*-cptn)[18] indicate *trans*-CuN_4 geometries with one or two weakly bound water molecules at the apices in the corresponding bis complexes $[CuL_2]^{2+}$. The 1:1 complexes $[Cu(H\textit{cis}\text{-dap})]^{3+}$ (λ_{max} = 688 nm) and $[Cu(ampy)]^{2+}$ (λ_{max} = 668 nm) exhibit absorbance maxima at considerably longer wavelengths, as expected for *cis*-CuN_2 coordination.[14]

Structural Characterization of the Metal Complexes

In $[Pt(H\textit{cis}\text{-dap})Cl_4]Cl{\cdot}H_2O$, the ligand *cis*-dap coordinates to the Pt^{IV} center in a bidentate fashion through the two primary amino groups. The remaining secondary amino group of the pyrrolidine ring is protonated (Figure 5). The octahedral low-spin geometry of the Pt^{IV} center is completed by the coordination of four chloride ions. The positive charge of the complex cation is balanced by an additional chloride counterion. Considering the positions of the cations (A), represented by their centers of gravity, and of the counterions (B), the resulting AB-type packing can be described as a stack of layers consisting of fused six-membered rings with an alternating A−B−A−B−A−B sequence. The layers are oriented perpendicular to the *b* axis. This packing is related to the GeS structure,[19] although in GeS the six-membered Ge_3S_3 rings have a chair conformation, whereas in $[Pt(H\textit{cis}\text{-dap})Cl_4]Cl{\cdot}H_2O$ the A_3B_3 rings have a distorted boat conformation. In both cases, the nonisometric packing can be explained simply in terms of the nonisotropic shape of the cations. In $[Pt(H\textit{cis}\text{-dap})Cl_4]Cl{\cdot}H_2O$, the anions and cations within a layer are connected through N−H···Cl^- hydrogen bonds and the dif-

ferent layers are interconnected by N−H···O···H−N bridges between the coordinated amino groups and water molecules. The $[Pt(H\textit{cis}\text{-dap})Cl_4]^+$ complex cation is completely asymmetric as a consequence of the puckered conformation of the five-membered chelate ring. However, the NMR-spectroscopic data (two signals in the $^{13}C\{^1H\}$ NMR and three signals in the ^1H NMR spectrum) indicate the expected rapid ring inversion with average C_s symmetry for the complex in solution.

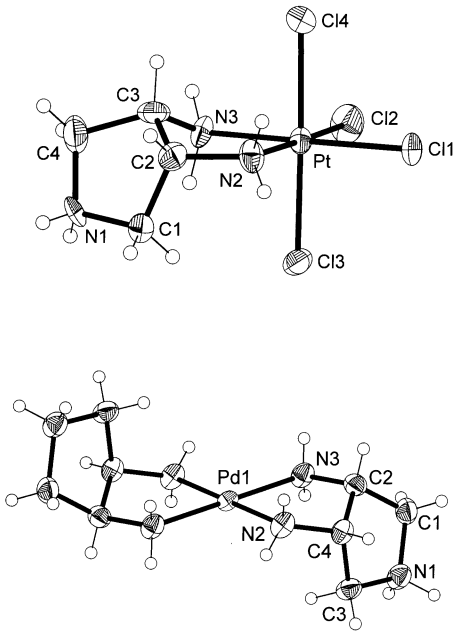

Figure 5. Molecular structures of $[Pt(H\textit{cis}\text{-dap})Cl_4]^+$ (top) and $[Pd(H\textit{cis}\text{-dap})_2]^{4+}$ (bottom); thermal ellipsoids are drawn at a 50% probability level; hydrogen atoms are shown as spheres of arbitrary size; selected bond lengths [Å] and angles [°]: (a) Pt−N2 2.075(10), Pt−N3 2.007(9), Pt−Cl1 2.333(3), Pt−Cl2 2.311(3), Pt−Cl3 2.322(3), Pt−Cl4 2.313(3), N2−Pt−N3 83.8(5); (b) Pd−N2 2.035(2), Pd−N3 2.039(2), N2−Pd−N3 83.86(9), N2−Pd−N3A 96.14(9)

A similar bidentate coordination of the protonated H*cis*-dap$^+$ ligand is observed for $[Pd(H\textit{cis}\text{-dap})_2](ClO_4)_4\cdot H_2O$ (Figure 5). The crystal structure of this compound can be described as a packing of neutral $\{[Pd(H\textit{cis}\text{-dap})_2](ClO_4)_4\}$ aggregates that are hydrogen-bonded through NH−H···OH−H···$OClO_3$···H−NH and NH−H···$OClO_3$···H−NH bridges. The Pd^{II} atom resides on a center of inversion and exhibits the well-known square-planar PdN_4 geometry (λδ conformation for the two five-membered chelate rings). The pyrrolidine rings are located at opposite sides of the PdN_4 plane and thus adopt a *transoid* orientation. A related structure with protonated endocyclic nitrogen atoms in a *transoid* geometry has been reported by Schwarzenbach et al. for the Pd complex of *cis*-3,5-diaminopiperidine (dapi).[4] These authors performed a potentiometric study to determine the acidity constants of the noncoordinating ammonium groups of $[Pd(Hdapi)_2]^{4+}$; an unusually slow equilibration was noted, which was discussed in terms of a slow rearrangement of the ligands (a change from the *transoid* to the *cisoid* form in the course of deprotonation). The required breaking and reforming of Pd^{II}−N bonds was invoked to account for the slow reaction rate. In our experiments, we found a related steady shift of pH for a freshly prepared 0.1 mol dm^{-3} aqueous solution of $[Pd(H\textit{cis}\text{-dap})_2](ClO_4)_4$. However, this shift proved to be very slow (5 mV per 24 h) and the data set of a rapid titration could be evaluated in terms of a simple two-step deprotonation with pK_a values of 6.27(1) and 7.04(1).

With Cu^{II}, a solid sample of composition $[Cu(H\textit{cis}\text{-dap})_2(OH_2)_2](SO_4)_2\cdot 3.5H_2O$ was obtained. This compound contains two crystallographically independent $[Cu(H\textit{cis}\text{-dap})_2(OH_2)_2]^{4+}$ cations (Figure 6). Cu1 is located on a twofold axis and its five-membered chelate rings thus have a λλ or δδ conformation, whereas Cu2 resides on a center of inversion with a λδ conformation of the rings. Again, the Cu centers are exclusively bound to the primary amino groups of the H*cis*-dap$^+$ ligands (square-planar $Cu^{II}N_4$ geometry with an average Cu−N bond length of 2.02 Å). The coordination sphere is completed by two loosely bound water ligands in the axial positions (average Cu−O bond length: 2.48 Å), giving the well-known tetragonally distorted CuN_4O_2 octahedron. The noncoordinating ring nitrogen atoms are protonated and the pyrrolidine rings are arranged in a *transoid* manner, akin to that described above for the Pd complex. Deprotonation of $[Cu(H\textit{cis}\text{-dap})_2(OH_2)_2]^{4+}$ could occur either at the noncoordinating ring nitrogen atoms or at the water ligands (with the formation of hydroxo complexes). In the first case, the liberation of an additional amino group would generate a potentially tridentate ligand. The additional amino group could either coordinate in a tripodal intramolecular fashion or intermolecularly as a bridging ligand to an adjacent metal center. The crystal structure of $[Cu(H\textit{cis}\text{-dap})_2(OH_2)_2](SO_4)_2\cdot 3.5H_2O$ provided evidence that the latter mode is observed with Cu^{II}. Close inspection of the difference Fourier map revealed a residual peak at $x = 3/4$, $y = 1/4$, $z = 0.2736$ with an electron density of 1.6 e/Å^3. This peak is located on a twofold axis in a cavity formed by the noncoordinating ammonium groups of two complex cations, two sulfate counterions, and a water molecule. The distances to the nearest atoms are 2 × 1.96 Å (O22 & O22A), 2.00 Å (O60), 2 × 2.19 Å (N1 & N1A). Further studies of additional specimens showed considerable variation in the intensity of this peak. Although the cell parameters and atom positions were almost the same for all the samples under investigation, the intensity of this peak corresponded to an electron density of up to 12.6 eÅ^{-3}. Based on the chemical composition of the mother liquor, the charge balance, and the distances to the five nearest neighboring atoms, we interpret this peak in terms of some additional incorporation of Cu^{II}, which is bound to the two pyrrolidine nitrogen atoms with the abstraction of two protons (Scheme 3). In fact, it became clear that this compound has a nonstoichiometric (berthollide) composition, for which the correct formula would be $[Cu(H\textit{cis}\text{-dap})_2(OH_2)_2](SO_4)_2\cdot 3.5\ H_2O - 2x\ H^+ + x\ Cu^{2+}$. In this study, the data for $x = 0.005$, 0.08, and 0.11 are reported. Although the cavity appears to

have an almost ideal size for accommodating Cu^{II}, some minor structural rearrangements are evidently required for the uptake of an additional Cu^{II} ion. This is indicated by a disorder that is found for those samples containing a large amount of additional Cu. This disorder is manifested in strong anisotropy of the displacement parameters for the atoms of the outer part of the pyrrolidine rings and the observation of two partially occupied positions for one of the oxygen atoms of the sulfate residue (Figure 6). The additional Cu^{II} center has trigonal-bipyramidal coordination with the two pyrrolidine nitrogen atoms in the axial positions and two sulfate ions and a water molecule in the equatorial positions. This additional Cu^{II} center interconnects two mononuclear $[Cu(H\textit{cis}\text{-dap})_2(OH_2)_2]^{4+}$ cations giving a trinuclear $[(H\textit{cis}\text{-dap})Cu(OH_2)_2(\mu\text{-}\textit{cis}\text{-dap})Cu(OH_2)(SO_4)_2(\mu\text{-}\textit{cis}\text{-dap})Cu(H\textit{cis}\text{-dap})(OH_2)_2]^{4+}$ entity. The observation of such trinuclear species nicely illustrates the ability of the neutral *cis*-dap molecule to participate in bridging interactions, and we regard this ligand as an interesting building block for the construction of coordination polymers.

A complex featuring a tridentate coordination mode of *cis*-dap, with all the nitrogen atoms of the ligand bound to the same metal center, could be obtained in the form of the heteroleptic $[Co^{III}(\textit{cis}\text{-dap})(tach)]^{3+}$. Attempts to prepare a homoleptic complex $[Co(\textit{cis}\text{-dap})_2]^{3+}$ by aerial oxidation of a solution of Co^{II} and *cis*-dap failed and the use of Co^{III} precursors such as $K_3[Co(CO_3)_3]$ or *trans*-$[CoCl_2(py)_4]Cl$ led to unresolved reaction mixtures. $[Co(\textit{cis}\text{-dap})(tach)]^{3+}$ was prepared from $[Co(tach)Cl_3]$, in which the relatively labile Cl^- ligands define a set of leaving groups having the required preformed facial geometry. The resulting mononuclear Co^{III} complex was crystallized as a chloride tetrachlorozincate salt. Its hexaamine geometry exhibits some rather unusual features. Bond lengths and angles for the Co(tach) moiety all fall within the expected ranges (Figure 7), whereas the $Co^{III}-N$ bonds in the Co(*cis*-dap) moiety are remarkably long. This is particularly true for the secondary nitrogen atom, which has a Co−N distance of 2.068(5) Å. The puckering parameters [$Q = 0.601(4)$ Å and $\varphi = 0.8(4)°$] for the pyrrolidine ring correspond to an almost ideal envelope conformation. This conformation implies an eclipsed orientation of the two CH protons with a torsional angle of only 8.7°, a rather short (N−)H···H(−N) separation of 2.24 Å for the primary amino groups, and a significantly elongated C7−C8 bond (1.60 Å). Owing to the rather long

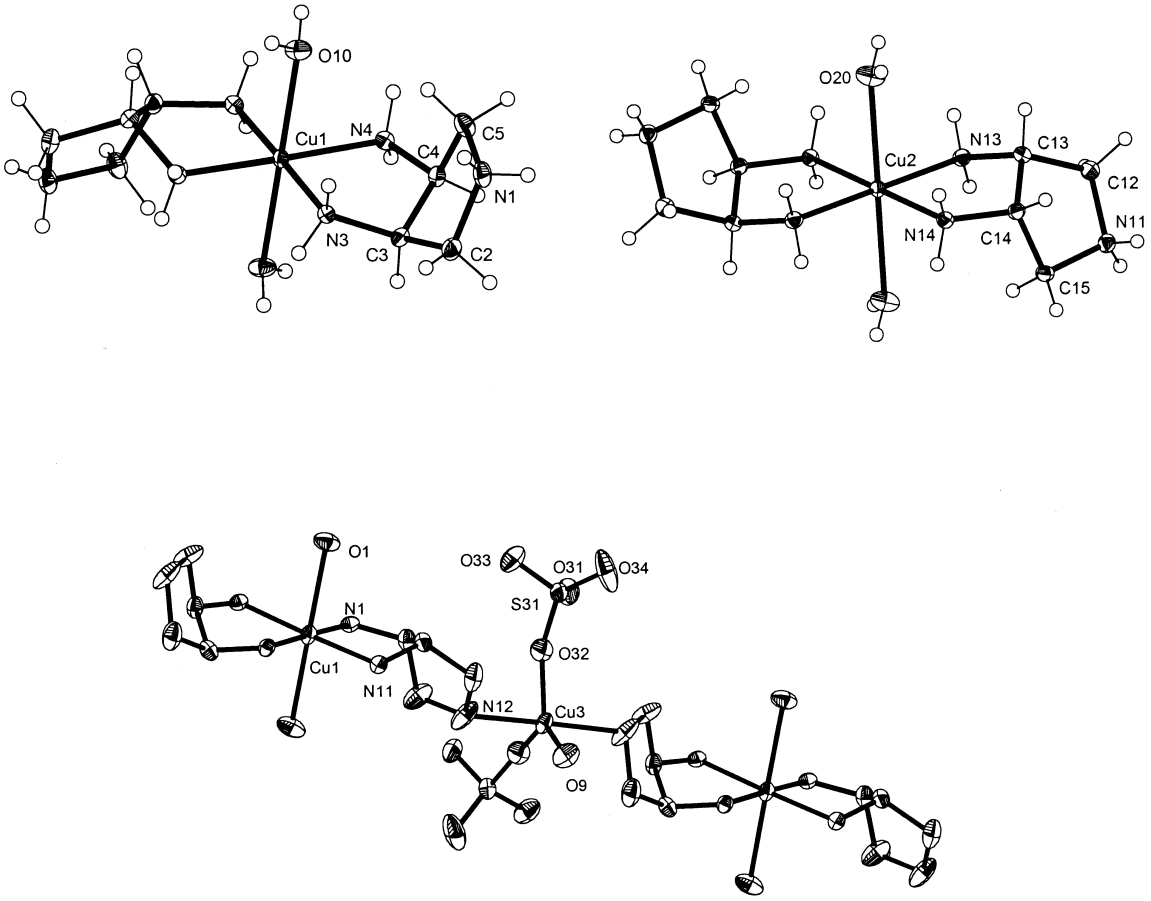

Figure 6. Structural representations of $[Cu(H\textit{cis}\text{-dap})_2(OH_2)_2](SO_4)_2{\cdot}3.5H_2O - 2x\ H^+ + x\ Cu^{2+}$: the two $[Cu(H\textit{cis}\text{-dap})_2(OH_2)_2]^{4+}$ cations for $x < 0.01$ (top); hydrogen atoms are shown as spheres of arbitrary size; selected bond lengths [Å] and angles [°]: Cu1−N3 2.0174(13), Cu1−N4 2.0271(13), Cu1−O10 2.4660(12), Cu2−N13 2.0144(13), Cu2−N14 2.0186(13), Cu2−O20 2.4985(13), N3−Cu1−N4 84.40(5), N13−Cu2−N14 84.73(5); view of the trimer with the partially occupied Cu3 position ($x = 0.11$) (bottom); hydrogen atoms are omitted for clarity; in the absence of Cu3 the ring nitrogen atom N12 is protonated, forming a hydrogen bond to the SO_4^{2-} counterion (O32); only one of the two positions of the disordered O32 is shown; thermal ellipsoids are drawn at a 50% probability level

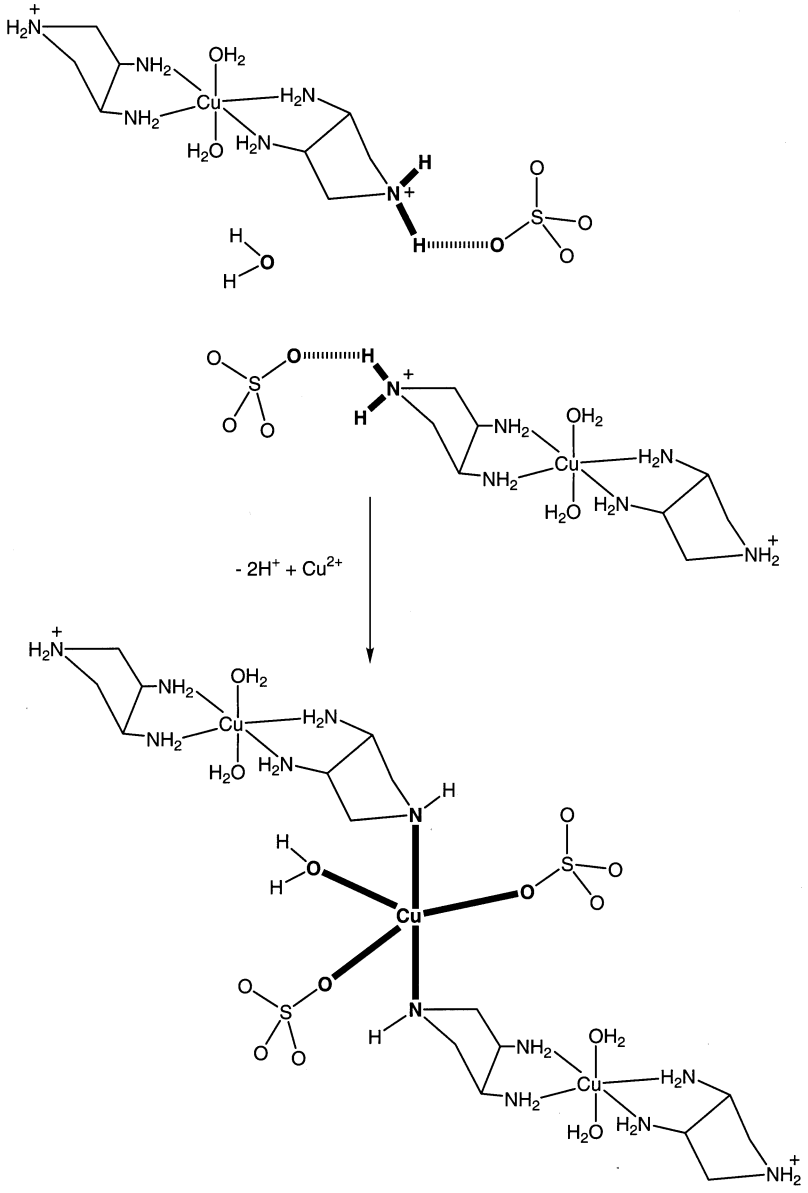

Scheme 3

$Co^{III}-N$ bonds in the Co(*cis*-dap) moiety, a decrease in ligand field and an increased tendency to form the corresponding Co^{II} complex could be expected.[20] However, [Co(*cis*-dap)(tach)]$^{3+}$ exhibits the usual yellow color with absorbance maxima at 351 and 475 nm, as expected for a normal Co^{III}(hexaamine) chromophore.[21] Cyclic voltammetry revealed quasi-reversible redox behavior with a redox potential of −0.21 V (versus NHE). Compared to the range usually observed for Co^{III}(hexaamine) complexes (0.3−0.5 V versus NHE), the potential of [Co(*cis*-dap)(tach)]$^{2/3+}$ indicates only a minor degree of stabilization of the Co^{II} species.[5,20,21]

The diamine ligands *cis*-cyclopentane-1,2-diamine (*cis*-cptn) and 3-aminopyrrolidine (ampy) have been included in this investigation as structural models for a coordination of a metal cation to either two exocyclic nitrogen donors or to one exocyclic and one endocyclic nitrogen donor, respectively. Toftlund et al. have previously reported the preparation of the yellow, diamagnetic complex [Ni(*cis*-cptn)$_2$]$^{2+}$.[10] We have crystallized this species as [Ni(*cis*-cptn)$_2$](ClO$_4$)$_2$ and report its crystal structure (Figure 8). As expected for a diamagnetic complex, the Ni center has a square-planar NiN_4 geometry with an average Ni−N bond length of 1.92 Å. Again, the two cyclopentane rings have a *transoid* arrangement with respect to the NiN_4 plane. [Cu(ampy)$_2$]$^{2+}$, which has also been crystallized as its perchlorate salt (Figure 8), represents an example of a structure where both endo- and exocyclic nitrogen donors are used for metal binding.[22−24] The ligand was used as a racemate and the crystal structure of [Cu(3*R*-ampy)(3*S*-ampy)](ClO$_4$)$_2$ showed the incorporation of both enantiomers in one complex entity. The Cu^{II} center has square-planar

Figure 7. CuN_4 geometry with a very weak interaction with one of the ClO_4^- counterions. The two endocyclic and the two exocyclic nitrogen donors each have a *trans* orientation. Each Cu(ampy) fragment can be regarded as a metalla derivative of norbornane. By analogy with the structure of this hydrocarbon,[25] the geometry at the bridging methylene groups deviates significantly from a tetrahedral arrangement (N−C−C angles: 98.9° and 97.6°) and, compared to the corresponding *cis*-cptn system, the M(ampy) structure appears to be considerably strained.

Discussion

Equilibria in Aqueous Solution

A comparison of the protonation constants of *cis*-dap, *trans*-dap, *cis*-cptn, *trans*-cptn, ampy, and related amines (Table 5) indicates some characteristic trends. Compared to related monoamines such as cyclopentylamine ($pK_a = 10.6$) or pyrrolidine ($pK_a = 11.2$),[26] the triamines *cis*-dap and *trans*-dap are weaker bases. On statistical grounds, the presence of three basic sites should increase the overall basicity; however, it seems that the electron-withdrawing influence of additional amino groups outweighs this effect. In contrast to the monoamine analogues, the ^1H NMR titration did not show a significant difference for the intrinsic basicities of the primary and secondary amino groups in *cis*-dap[5] and it appears that the different behavior of the individual diastereomers is based on steric rather than electronic effects. The cyclopentane or pyrrolidine frameworks give rise to particularly rigid molecules and the different basicities of the diastereomers can simply be explained in terms of electrostatic repulsion. In H_2*trans*-$cptn^{2+}$, the two amonio groups adopt a staggered (antiperiplanar) conformation and the relevant pK_a values of H_2*trans*-$cptn^{2+}$ are in close agreement with those of the open-chained H_2en^{2+} (en = ethane-1,2-diamine): the difference $pK_1 - pK_2 = \Delta pK$ is 2.70 for H_2*trans*-$cptn^{2+}$ and 2.80 for H_2en^{2+}. In H_2*cis*-$cptn^{2+}$, the interatomic distance between the two positive charges is shorter and consequently ΔpK_a for this isomer is increased to 3.60. Analogously, the acidity constants of monoprotonated H*cis*-dap^+ and H*trans*-dap^+ are in close agreement, whereas those of the triply protonated forms differ considerably with the *cis* isomer being the stronger acid.

Analysis of the formation constants together with the spectroscopic properties of *cis*-dap complexes in aqueous solution points to a bidentate rather than a tridentate coordination mode for this ligand:

(i) Ni^{II} forms a tris(chelate) with an NiN_6 chromophore, whereas the λ_{max} values of the two bis(complexes) $[Ni(cis\text{-dap})_2]^{2+}$ and $[Ni(Hcis\text{-dap})_2]^{4+}$ are both indicative of an NiN_4 chromophore.[14] Clearly, deprotonation of the ammonium groups is not followed by metal binding, and a third ligand is required to achieve hexaamine formation. Similarly, the bis(complexes) $[CuH_xL_2]^{(2+x)+}$ ($0 \le x \le 2$, L = *cis*-dap, *trans*-dap; and $x = 0$, L = *cis*-cptn) all show a characteristic band in their visible spectra with an absorption maximum at 550−570 nm (Table 6). These values are

indicative of a *trans* (square-planar) CuN_4 chromophore with additional loosely bound water molecules at the apices.[14] It is well known that the coordination of an additional *nitrogen* donor in an apical position would lead to a significant red shift (pentaammine effect).[16] The close similarity of the spectral properties of the differently protonated species again indicates that deprotonation at the third nitrogen atom does not result in a significant rearrangement of the chromophore.

(ii) Compared to other tridentate cyclic triamines such as 3,5-diaminopiperidine (dapi) or all-*cis*-2,4,6-trimethoxycyclohexane-1,3,5-triamine (tmca), the formation constants for $[M(cis\text{-dap})_2]^{2+}$ are remarkably low (Table 5). The formation constants of $[M(cis\text{-dap})]^{2+}$ are about one order of magnitude lower than those of $[M(en)]^{2+}$. For the 1:2 complexes, this effect is doubled.

(iii) As a consequence of the Jahn–Teller distortion, triamine ligands that are restricted to a tripodal, facial coordination usually show a characteristic inversion of the Irving–Williams series with higher stability for Ni^{II} than for Cu^{II}. For *cis*-dap, however, no such inversion is observed. As shown in Figure 9, the stabilities of the *cis*-dap complexes fall in the expected range based on the linear free-energy relationship of log β_{Ni} vs. log β_{Cu} for "normal" open-chained polyamines.

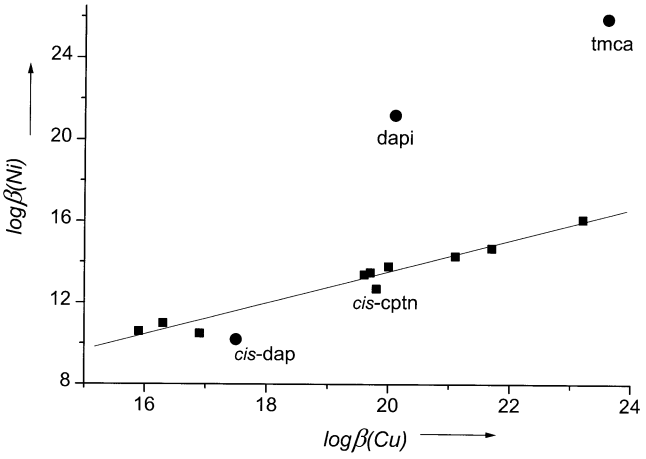

Figure 9. Comparison of formation constants for Cu^{II}- and Ni^{II}(amine) complexes; the linear free-energy relationship (squares) for selected diamines (log β_2), triamines $H_2N-(CH_2)_x-NH-(CH_2)_y-NH_2$ (log β_1), and tetraamines $H_2N-(CH_2)_x-NH-(CH_2)_y-NH-(CH_2)_z-NH_2$ (log β_1) is $\log \beta_{Ni} = 0.77 \times \log \beta_{Cu} - 1.84$; this is compared with log β_2 values of the potentially tripodal ligands *cis*-dap, dapi, and tmca (circles); the data are from refs.[5,25,27] and from this work (Tables 2 and 3)

(iv) All the *cis*-dap complexes show a pronounced tendency to form protonated species $[M^z(HL)]^{(z+1)+}$, $[M^z(HL)_2]^{(z+2)+}$, and $[M^z(HL)L]^{(z+1)+}$. $[Pt(Hcis\text{-dap})Cl_4]^+$, $[Pd(Hcis\text{-dap})_2]^{4+}$, and $[Cu(Hcis\text{-dap})_2(OH_2)_2]^{4+}$ are representative examples that have been structurally characterized by single-crystal X-ray diffraction analysis. For the divalent metal cations (M = Ni, Cu, Zn, Cd), the pK_a values for deprotonation of the partially protonated complexes fall in the range 7.1–8.1, indicating only a slight decrease in the basicity of *cis*-dap upon coordination. This effect would be incompatible with a significant interaction between the third amino group and the metal cation. It is also noteworthy that the pK_a values of $[Cu(HL)_2]^{4+}$ are very similar for L = *cis*-dap and L = *trans*-dap (7.1, 7.7 versus 6.8, 7.5, respectively). The *trans* isomer is even slightly more acidic. Since tridentate coordination of *trans*-dap can be ruled out on steric grounds, the even higher basicity of $[Cu(cis\text{-dap})_2]^{2+}$ would again be inconsistent with a significant interaction between the third nitrogen atom and the metal cation.

The arguments listed as (i)–(iv) clearly show that tridentate coordination of *cis*-dap is not observed in labile solution species. Additionally, monodentate coordination of any of

the studied ligands can also be excluded. Although some of the bis(complexes), particularly $[M(ampy)_2]^{2+}$ (M = Ni, Cu, Cd) and $[Cu(trans\text{-}dap)_2]^{2+}$, show rather low stabilities, their formation constants are still considerably higher than those for monodentate amines such as NH_3 or CH_3NH_2. Moreover, not only *cis*-dap but all the other ligands as well give rise to a visible spectrum for $[CuL_2]^{2+}$ that is indicative of a *trans*-CuN_4 chromophore.

The solid-state structures of $[Pt(Hcis\text{-}dap)Cl_4]^+$, $[Pd(Hcis\text{-}dap)_2]^{4+}$, and $[Cu(Hcis\text{-}dap)_2(OH_2)_2]^{4+}$ reveal exclusive coordination of the metal cation to the two primary amino groups. Although the potentiometric measurements do not of course allow a direct structural assignment, comparison of *cis*-dap with the model diamines provided ample evidence for a similar binding to the exocyclic nitrogen atoms in solution: Metal complexes of ampy are generally less stable than the corresponding *cis*-cptn complexes. Clearly, coordination to the two exocyclic donors is preferred. Molecular mechanics calculations on $[Cu(cis\text{-}dap)(OH_2)_4]^{2+}$ also showed that coordination to the two primary amino groups would be favored by about 9.3 kJ mol^{-1}. For $[Cu(cis\text{-}cptn)]^{2+}$ and $[Cu(ampy)]^{2+}$ the difference in stability ($\Delta\log\beta_1$) is 2.4, corresponding to a difference in free enthalpy of 13.5 kJ mol^{-1}.

Comparison of the metal complex stabilities of the different ligands investigated in this study reveals the order *cis*-cptn > *cis*-dap > *trans*-cptn > ampy > *trans*-dap. Regarding $[Cu(HL)]^{3+}$ formation, the formation constant of the *trans*-dap complex is lowered by about two orders of magnitude compared with that of the *cis*-dap derivative, and for the bis(complexes) $[Cu(HL)_2]^{4+}$, $[Cu(HL)L]^{3+}$, and $[CuL_2]^{2+}$ the decrease in stability is about four orders of magnitude. Similar effects are observed for *trans*-cptn and *cis*-cptn. The *cis*-cyclopentane-1,2-diamine structure is clearly favorable with regard to metal binding. This is in contrast to the cyclohexane-1,2-diamine structure, for which the *trans* isomer has been reported to be more stable.[26] The formation constants of the *cis*-cptn complexes are in close agreement with those reported for the corresponding en complexes. Evidently, the *cis*-cyclopentane-1,2-diamine framework does not provide any stabilization in terms of pre-organization of the donor groups. Again, this is in contrast to the cyclohexanediamines, where significantly increased stability is observed for the *trans*-cyclohexane-1,2-diamine. Since *cis*-cptn and *cis*-dap have related structures, the reduced ability of the latter to bind metal cations must be interpreted in terms of a lower nucleophilicity of the donor groups, caused by the electron-withdrawing effect of the endocyclic nitrogen atom. Consequently, the higher ligand field of *cis*-cptn is able to generate a low-spin electron configuration for $[Ni(cis\text{-}cptn)_2]^{2+}$, whereas $[Ni(cis\text{-}dap)_2]^{2+}$ is high spin. Similar considerations are applicable for the *trans*-cptn and *trans*-dap systems. The observed decrease in metal complex stability in the above series can thus be rationalized in terms of a combination of steric (a) and electronic (b) effects:

(a) For the five-membered ring frame, a steady decrease in metal complex stability is observed for the following geometries: two exocyclic nitrogen atoms in a *cis* arrangement > two exocyclic nitrogen atoms in a *trans* arrangement > one endocyclic and one exocyclic nitrogen atom.

(b) Since all the ligands coordinate in a bidentate fashion, the presence of an additional nitrogen atom reduces the nucleophilicity of the donor groups and, consequently, the triamines are generally weaker ligands than the corresponding diamines.

Although in terms of absolute stability, the metal binding ability of the triamines is lower, the opposite behavior is observed in neutral and acidic solutions. This is based upon the ability of the dap complexes to bind additional protons, which is, of course, not possible for the diamines. In terms of conditional stability,[29] *cis*-dap is a rather efficient complexing agent for Cu^{II} in acidic solution and is clearly superior to any of the known aliphatic or alicyclic diamines. It is in fact a remarkable property of this ligand that it is capable of significant complexation even under acidic conditions, such as at pH = 2.5 (Figure 3).

Structural Aspects of the Metal Complexes

Although the coordination behavior of *cis*-dap in labile complexes must be regarded as being mainly bidentate, in principal a facial tridentate coordination is possible, as exemplified by the inert Co^{III} complex $[Co(cis\text{-}dap)(tach)]^{3+}$. However, the structural parameters for this complex, particularly the long Co−N bonds, clearly reveal a severely strained structure. We were unable to model this particular $Co^{III}N_6$ geometry with a commercially available MM program.[30,31] It seems that a nonharmonic description of the Co^{III}−N bond would be required, which was not implemented by the force field used. In a complex with bidentate coordination, the noncoordinating endocyclic nitrogen atom can either accept a proton or bind to an additional metal center. The first possibility has been discussed extensively for solid-state and solution species in the previous section. Although we do not have any experimental evidence that the latter possibility is realized in aqueous solution, the crystal structure of $[Cu(Hcis\text{-}dap)_2(OH_2)_2](SO_4)_2{\cdot}3.5H_2O - 2x\ H^+ + x\ Cu^{2+}$, with its nonstoichiometric composition ($0.01 \le x \le 0.11$) shows that multiple binding of metal cations to a *cis*-dap molecule is at least possible in the solid state. It is noteworthy that *cis*-dap is structurally related to the open-chained propane-1,2,3-triamine (trap): The trap molecule can be regarded as a substructure of *cis*-dap. However, the open-chained trap is conformationally flexible whereas *cis*-dap is rigid, thus representing a model of the triamine with a locked conformation. Interestingly, the coordination behavior of these two ligands towards Cu^{II} is similar. The ligand trap, by analogy with *cis*-dap, forms similar protonated Cu complexes in acidic solution, and a bridging mode with bidentate and monodentate coordination has been established from the crystal structure of $[Cu(trap)_2]Cl_2$.[27] However, it appears that the locked conformation is not optimal for metal binding: The trap complexes are generally more stable than the corresponding *cis*-dap analogues. Moreover, with other metal cations such as Ni^{II}, the flexibility of trap allows tridentate coordination, which

is not accessible for *cis*-dap. Analogously, the structure of *trans*-dap represents another conformation of trap that is even more disfavored for metal binding.

Another interesting aspect is the comparison of the three cyclic triamine ligands tach, dapi, and *cis*-dap (Scheme 1). The ligand tach shows a very pronounced preference for facial tridentate coordination, giving an adamantane-like structure with all six-membered chelate rings. Attempts to enforce a bidentate coordination mode failed. Reaction with Pt^{II} resulted in oxidation to Pt^{IV} with a concomitant facial coordination of tach.[32] On the other hand, *cis*-dap shows a strong preference for bidentate coordination. A facial, tridentate coordination mode comprising exclusively five-membered chelate rings is severely strained. Such an [M(*cis*-dap)] structure can formally be derived from the [M(tach)] moiety by the removal of one CH_2 and one CH group. The [M(dapi)] structure contains one six-membered and two five-membered chelate rings, in analogy to noradamantane. As a true intermediate in this series, dapi predominantly coordinates in a tridentate mode. However, bidentate coordination is possible, as has been observed for Pd^{II}.[4]

Conclusion

The basic coordination mode of the cyclic triamine *cis*-3,4-diaminopyrrolidine is a bidentate coordination through the two exocyclic amino groups. This mode has been established in a variety of solid-state structures. The potentiometric data and the spectroscopic properties of *cis*-dap complexes have also provided evidence for this coordination mode in aqueous solution. The noncoordinated endocyclic nitrogen atom represents a comparatively strong basic site, and as such it is readily protonated. A facial, tridentate coordination mode results in a highly strained structure, as shown for the inert $[Co(\textit{cis}\text{-dap})(tach)]^{3+}$. The formation of such strained species is not trivial and requires specific synthetic strategies. Alternatively, coordination of *cis*-dap to two different metal cations is possible. In this mode, one metal cation is bound through the primary amino groups, whereas the other is coordinated to the endocyclic nitrogen donor. The coordination behavior of *cis*-dap is in marked contrast to that of other cyclic triamine ligands such as *cis*-3,5-diaminopiperidine or all-*cis*-cyclohexane-1,3,5-triamine, where bidentate coordination or a bridging mode are of minor importance or even unknown.

Experimental Section

Safety Notes: Organic polyazides and perchlorate salts of metal complexes with organic ligands are potentially explosive. The organic polyazides should only be handled in dilute solutions and should not be isolated as pure substances. The perchlorate salts should only be isolated in small quantities and should not be dried at elevated temperatures.

Instrumentation: ^1H and $^{13}C\{^1H\}$ NMR spectra were measured in D_2O, $CDCl_3$, CD_3CN, or [D_6]acetone at 28 °C with a Bruker DRX 500 MHz NMR spectrometer (resonance frequencies: 500.13 MHz for ^1H and 125.9 MHz for $^{13}C\{^1H\}$). Chemical shifts are given relative to [D_4]sodium (trimethylsilyl)propionate (D_2O) or tetramethylsilane (all other solvents) as internal standards ($\delta = 0$). pD values (corrected)[5] were determined with a glass electrode. The ^1H NMR titration experiment on *cis*-dap was performed and evaluated as reported previously for dapi.[5] – UV/Vis spectra of the Ni^{II} complexes were measured with a Uvikon 941 spectrophotometer (H_2O; 25 ± 3 °C). – Cyclic voltammograms were recorded as described previously (BAS C2 cell, BAS 100B/W2 potentiostat, Au working electrode, Pt counter electrode, Ag/AgCl reference electrode, ambient temperature).[5] – C,H,N analyses were performed by H. Feuerhake (Universität des Saarlandes).

Materials: Unless otherwise stated, all chemicals used for the synthetic work were commercially available products of reagent-grade quality. For the potentiometric and spectrophotometric titrations, metal salts of highest available quality (> 99.95%) were used. 3-Pyrroline[33] and (3*S*,4*S*)-1-benzyl-3,4-pyrrolidinediyl bis(methanesulfonate)[34] were prepared as described in the literature. [Co(tach)$(NO_3)_3$] was obtained from [Co(tach)Cl_3].[35] Dowex 50 W-X2 (100–200 mesh, H^+ form) and Dowex 2-X8 (50–100 mesh, Cl^- form) were purchased from Fluka. The anion resin was converted into the OH^- form using dilute aqueous NaOH.[5]

1-Acetyl-3-pyrroline: To an ice-cooled solution of 3-pyrroline (4.00 g, 57.88 mmol) in MeOH (50 mL), acetic anhydride (23.64 g, 231.56 mmol) was added dropwise. The clear solution was then stirred for 30 min at room temperature, cooled in an ice bath once more, and made alkaline with 2 M aq. NaOH. After extraction with dichloromethane (3 × 100 mL), the combined organic phases were dried with Na_2SO_4 and concentrated to dryness. The oily residue was sublimed (10^{-2} mbar, 40 °C) to yield 1-acetyl-3-pyrroline as white crystals (6.07 g, 94%). – C_6H_9NO (111.1): calcd. C 64.84, H 8.16, N 12.60; found C 64.92, H 8.41, N 12.51. – ^1H NMR ($CDCl_3$): $\delta = 2.08$ (s, 3 H), 4.25 (m, 4 H), 5.81 (m, 1 H), 5.88 (m, 1 H). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta = 22.1$ (CH_3), 52.8 (CH_2), 54.2 (CH_2), 125.0 (CH), 126.5 (CH), 169.1 (C).

1-Acetyl-*cis*-3,4-pyrrolidinediol: 1-Acetyl-3-pyrroline (8.93 g, 80.35 mmol) and 4-methylmorpholine 4-oxide monohydrate (12.99 g, 96.11 mmol) were dissolved in acetone/H_2O (1:1, v/v; 160 mL). A solution of OsO_4 (2.5% in *tert*-butyl alcohol; 1 mL) was added and the pale-yellow solution was stirred for 24 h. $Na_2S_2O_5$ (1.5 g) was then added and the mixture was stirred for a further 1 h. It was then acidified to pH = 2 with 50% H_2SO_4 and extracted with CH_2Cl_2 (3 × 100 mL). The aqueous layer was diluted to a total volume of 1000 mL with H_2O and was sorbed onto Dowex 50 W-X2. The resin was washed with H_2O until neutral and the collected eluent was sorbed onto Dowex 2-X8. This second column was rinsed with H_2O and the neutral eluent was concentrated to dryness yielding the diol as a colorless oil, which solidified after drying in vacuo (10.55 g, 90%). – $C_6H_{11}NO_3$ (145.2): calcd. C 49.65, H 7.64, N 9.65; found C 49.65, H 7.84, N 9.64. – ^1H NMR (D_2O): $\delta = 2.05$ (s, 3 H), 3.36 (dd, $J = 4.5$, 12.5 Hz, 1 H), 3.47 (dd, $J = 5.5$, 11.5 Hz, 1 H), 3.61 (dd, $J = 5.5$, 12.5 Hz, 1 H), 3.78 (dd, $J = 6.0$, 11.0 Hz, 1 H), 4.31 (m, 1 H), 4.35 (m, 1 H). – $^{13}C\{^1H\}$ NMR (D_2O): $\delta = 23.8$ (CH_3), 52.6 (CH_2), 54.2 (CH_2), 72.7 (CH), 73.5 (CH), 176.1 (C).

(3*S,4*R**)-1-Acetyl-3,4-pyrrolidinediyl Bis(methanesulfonate):** 1-Acetyl-*cis*-3,4-pyrrolidinediol (4.00 g, 27.56 mmol) was dissolved in dry pyridine (150 mL) and the resulting solution was cooled to –10 °C (ice/NaCl). Methanesulfonyl chloride (4.67 mL, 60.10 mmol) was added dropwise with stirring. The ice bath was removed and

the mixture was stirred for 1 h at room temperature. The suspension was then poured into Et_2O (1000 mL) and the resulting mixture was left to stand for 2 d at 4 °C. The Et_2O was decanted and the remaining white solid was redissolved in hot acetone (150 mL). This solution was subjected to flash chromatography (silica gel/acetone) and the eluate was concentrated to dryness. Yield 7.50 g (90%) of a white solid. − $C_8H_{15}NO_7S_2$ (301.3): calcd. C 31.89, H 5.02, N 4.65; found C 31.80, H 5.01, N 4.60. − ^{1}H NMR ([D$_6$]acetone): δ = 2.01 (s, 3 H), 3.26 (s, 3 H), 3.27 (s, 3 H), 3.62 (dd, *J* = 5.5, 10.0 Hz, 1 H), 3.74 (dd, *J* = 6.0, 11.0 Hz, 1 H), 3.83 (dd. *J* = 5.0, 10.0 Hz), 4.07 (dd, *J* = 6.0, 11.0 Hz, 1 H), 5.38 (m, 1 H), 5.43 (m, 1 H). − ^{13}C{^{1}H} NMR ([D$_6$]acetone): δ = 21.8 (CH_3), 38.5 (CH_3), 38.6 (CH_3), 48.8 (CH_2), 49.9 (CH_3), 77.1 (CH), 77.3 (CH), 169.4 (C).

1-Acetyl-*cis*-3,4-diaminopyrrolidine: A stirred mixture of (3*S**,4*R**)-1-acetyl-3,4-pyrrolidinediyl bis(methanesulfonate) (7.50 g, 24.89 mmol) and NaN_3 (8.10 g, 124.60 mmol) in dry DMF (200 mL) was heated at 100 °C for 4 h. The white solid formed was filtered off and washed with dry DMF (2 × 50 mL). To the dark-red solution was added 10% Pd/C (500 mg) and the suspension was immediately transferred to an autoclave for hydrogenation. A small sample was extracted from the reaction mixture with Et_2O for NMR characterization of the diazide. This sample was set aside, the Et_2O was evaporated, and the oily residue was redissolved in CD_3CN. − ^{1}H NMR (CD_3CN): δ = 1.91 (s, 3 H), 3.28 (dd, *J* = 5.0, 12.5 Hz, 1 H), 3.38 (dd, *J* = 5.5, 11.0 Hz, 1 H), 3.56 (dd, *J* = 5.0, 12.5 Hz, 1 H), 3.77 (dd, *J* = 6.0, 10.5 Hz, 1 H), 4.38 (m, 1 H), 4.43 (m, 1 H). − ^{13}C{^{1}H} NMR (CD_3CN): δ = 22.2 (CH_3), 49.0 (CH_2), 50.3 (CH_2), 62.0 (CH), 63.0 (CH), 171.6 (C). − The main portion of the reaction mixture was hydrogenated with vigorous stirring (room temp., 4 bar) for 12 h and then the mixture was filtered. The clear filtrate was acidified to pH = 2 with 3 M HCl, diluted to a total volume of 1000 mL with H_2O, and sorbed onto Dowex 50 W-X2. The column was washed with H_2O and 0.5 M HCl. Elution with 3 M HCl gave a yellow fraction, which was concentrated to dryness. ^{1}H NMR spectroscopy indicated mainly the formation of 1-acetyl-*cis*-3,4-diaminopyrrolidine (ca. 95%) besides some *cis*-3,4-diaminopyrrolidine (5.00 g of crude product). − ^{1}H NMR of the main component (D_2O; pD < 2): δ = 2.12 (s, 3 H), 3.74 (dd, *J* = 5.5, 13.0 Hz, 1 H), 3.87 (dd, *J* = 6.0, 12.0 Hz, 1 H), 3.94 (dd, *J* = 6.5, 13.0 Hz, 1 H), 4.16 (dd, *J* = 6.5, 12.0 Hz, 1 H), 4.35 (m, 1 H), 4.40 (m, 1 H); (D_2O; pD > 12): δ = 2.06 (s, 3 H), 3.25 (dd, *J* = 5.0, 12.0 Hz, 1 H), 3.35 (dd, *J* = 6.0, 11.0 Hz, 1 H), 3.47 (m, 1 H), 3.51 (m, 1 H), 3.59 (dd, *J* = 6.5, 12.5 Hz, 1 H), 3.76 (dd, *J* = 6.5, 11.0 Hz, 1 H). − ^{13}C{^{1}H} NMR for 1-acetyl-*cis*-3,4-diaminopyrrolidine (D_2O; pD < 2): δ = 24.1 (CH_3), 49.6 (CH_2), 51.0 (CH_2), 52.4 (CH), 53.3 (CH), 176.1 (C); (D_2O; pD > 12): δ = 23.8 (CH_3), 53.5 (CH_2), 54.6 (CH), 55.2 (CH_2), 55.6 (CH), 175.8 (C).

***cis*-3,4-Diaminopyrrolidine:** The crude 1-acetyl-*cis*-3,4-diaminopyrrolidine (7.40 g) was dissolved in 3 M HCl (150 mL) and the solution was heated to 100 °C for 1 h. It was then diluted to a total volume of 2000 mL with H_2O and sorbed onto Dowex 50 W-X2. The column was eluted with H_2O, 0.5 M HCl, and 3 M HCl. The last fraction was collected and concentrated to dryness. The white solid obtained was redissolved in H_2O (50 mL) and reprecipitated with conc. HCl (100 mL). The product was washed with EtOH and Et_2O and dried in air yielding *cis*-dap·3HCl·H_2O (5.37 g, 69%). − $C_4H_{16}Cl_3N_3O$ (228.5): calcd. C 21.02, H 7.06, N 18.39; found C 20.99, H 6.97, N 18.37. − ^{1}H NMR (D_2O; pD < 2): δ = 3.71 (m, 2 H), 3.99 (m, 2 H), 4.41 (m, 2 H); (D_2O; pD > 12): δ = 2.53 (m, 2 H), 3.11 (m, 2 H), 3.23 (m, 2 H). − ^{13}C{^{1}H} NMR (D_2O; pD < 2): δ = 49.4 (CH_2), 52.5 (CH); (D_2O; pD > 12): δ = 53.9 (CH_2), 56.2 (CH). − Single crystals were grown from an aqueous solution by slow evaporation of the water; *cis*-dap·3HNO_3·H_2O was prepared by deprotonation of *cis*-dap·3HCl·H_2O (1.00 g, 4.38 mmol) on Dowex 2-X8 (OH^- form). The alkaline fraction was concentrated to dryness and the residual oil was redissolved in MeOH (50 mL). The resulting solution was acidified with 3 equiv. of HNO_3 (3 M in H_2O) and left to stand at 4 °C for 14 h. The precipitate obtained was collected by filtration and dried in air. Yield 1.12 g (83%). − $C_4H_{16}N_6O_{10}$ (308.2): calcd. C 15.59, H 5.23, N 27.27; found C 15.71, H 5.26, N 26.95.

[Pd(H*cis*-dap)$_2$](ClO$_4$)$_4$·H$_2$O: A mixture of *cis*-dap·3HCl·H_2O (0.40 g, 1.75 mmol) and $PdCl_2$ (0.16 g, 0.87 mmol) in H_2O (50 mL) was refluxed for 3 h and the clear yellow solution was sorbed onto Dowex 2-X8 (OH^- form). The column was washed with H_2O until a neutral eluent was obtained. The combined alkaline fractions were acidified with 70% $HClO_4$ and the solvents were carefully evaporated under reduced pressure until a volume of 5 mL remained. Conc. $HClO_4$ (5 mL) was added and the solution was set aside at room temperature for 2 d. Slightly yellow crystals precipitated. These were collected by filtration and washed with EtOH and Et_2O (0.52 g, 82%). − $C_8H_{26}Cl_4N_6O_{17}Pd$ (726.6): calcd. C 13.22, H 3.61, N 11.57; found C 13.33, H 3.51, N 11.54. − ^{1}H NMR (D_2O; pD < 2): δ = 3.64 (m, 4 H), 3.82 (m, 4 H), 3.95 (m, 4 H); (D_2O; pD > 12): δ = 3.02 (m, 4 H), 3.28 (m, 4 H), 3.60 (m, 4 H). − ^{13}C{^{1}H} NMR (D_2O; pD < 2): δ = 50.8 (CH_2), 50.9 (CH_2), 62.4 (CH), 62.5 (CH); (D_2O; pD > 12): δ = 52.5 (CH_2), 52.6 (CH_2), 63.9 (CH), 64.0 (CH). − UV/Vis: λ_{max} (ε) = 290 (347). − Crystals were grown by slow evaporation of the water from an aqueous solution of [Pd(H*cis*-dap)$_2$](ClO$_4$)$_4$ that had been acidified with a few drops of $HClO_4$.

[Pt(H*cis*-dap)Cl$_4$]Cl·H$_2$O: *cis*-dap·3HCl·H_2O (250 mg, 1.09 mmol) was dissolved in H_2O (10 mL) and deprotonated using Dowex 2-X8 (OH^- form). The resulting solution was then concentrated to dryness under reduced pressure. The oily residue was redissolved in dry EtOH (5 mL) and this solution was cooled to 0 °C. A solution of H_2PtCl_6·$6H_2O$ (283 mg, 0.55 mmol) in dry EtOH (10 mL) was then added dropwise, which led to the deposition of a yellow precipitate. The suspension was stirred for 2 h at 65 °C. The solid was then collected by filtration, recrystallized from hot H_2O (3 mL) and conc. HCl (20 mL), and washed with EtOH and Et_2O. Yellow powder (150 mg, 55%). − $C_4H_{14}Cl_5N_3OPt$ (492.5): calcd. C 9.75, H 2.87, N 8.53; found C 10.16, H 2.89, N 8.68. − ^{1}H NMR (D_2O; pD < 2): δ = 3.96 (m, 4 H), 4.38 (m, 2 H). − ^{13}C{^{1}H} NMR (D_2O; pD < 2): δ = 48.9 (CH_2), 66.2 (CH).

[Cu(H*cis*-dap)$_2$(OH$_2$)$_2$](SO$_4$)·3.5H$_2$O: *cis*-dap·3HCl·H_2O (250 mg, 1.09 mmol) was dissolved in H_2O (10 mL) and deprotonated using Dowex 2-X8 (OH^- form). The resulting solution was concentrated to dryness under reduced pressure and the oily residue was redissolved in MeOH (50 mL). A solution of $CuSO_4$·$5H_2O$ (272 mg, 1.09 mmol) in H_2O (5 mL) was added, which led to the deposition of a blue precipitate. The suspension was diluted with H_2O (10 mL) and refluxed for 1 h. The insoluble solid was then removed by filtration. MeOH was added dropwise to the deep-blue solution until it became turbid. Single crystals were grown by heating the suspension until the precipitate redissolved and then allowing it to slowly cool to room temperature. − $C_8H_{35}CuN_6O_{13.5}S_2$ (559.1): calcd. C 17.19, H 6.31, N 15.03; found C 17.00, H 6.19, N 14.89.

[Co(*cis*-dap)(tach)]Cl$_3$·1.5H$_2$O: *cis*-dap·3HCl·H_2O (241 mg, 1.05 mmol) was dissolved in H_2O (10 mL) and deprotonated using Dowex 2-X8 (OH^- form). The resulting solution was concentrated to dryness under reduced pressure and the oily residue was redis-

solved in dry MeOH (50 mL). This solution was added dropwise to a purple solution of [Co(tach)$(NO_3)_3$] (3.16 mmol) in dry MeOH. The mixture was refluxed for 14 h and then concentrated to dryness. The brownish residue was suspended in H_2O (30 mL) and the suspension was acidified with 3 M HCl and heated to boiling for a few minutes. Insoluble components were removed by filtration. The orange-red filtrate was diluted to a volume of 500 mL with H_2O and sorbed onto Dowex 50 W-X2. The column was eluted with 0.5 M HCl to give a pink fraction, which was discarded. Further elution with 3 M HCl gave an orange fraction, which was concentrated to dryness. Recrystallization from 6 M HCl yielded 65 mg (14%) of the trichloride salt. – $C_{10}H_{29}CoCl_3N_6O_{1.5}$ (422.7): calcd. C 28.42, H 6.92, N 19.88; found C 28.41, H 6.68, N 19.75. – ^{1}H NMR (D_2O): δ = 1.88 (m, 3 H), 2.14 (m, 3 H), 2.60 (d, J = 11.0 Hz, 2 H), 2.79 (d, J = 11.0 Hz, 2 H), 2.84 (s, 1 H), 3.09 (s, 2 H), 3.78 (s, 2 H). – ^{13}C{^{1}H} NMR: δ = 33.6 (CH_2), 33.7 (CH_2), 42.4 (CH), 42.7 (CH), 59.3 (CH), 62.6 (CH_2). – UV/Vis: λ_{max} (ε) = 351 (142), 475 (102). – CV: E = −210 mV. – Crystals of the chloride tetrachlorozincate salt suitable for X-ray diffraction analysis were grown by layering a solution of [Co(*cis*-dap)(tach)]Cl_3 and $ZnCl_2$ in conc. HCl with EtOH at 4 °C.

***trans*-(3*R*,4*R*)-Diaminopyrrolidine:** A mixture of (3*S*,4*S*)-1-benzyl-3,4-pyrrolidinediyl bis(methanesulfonate) (11.9 g, 34.06 mmol) and NaN_3 (5.2 g, 80.00 mmol) in dry DMF (150 mL) was stirred at 100 °C for 4 h. After cooling to room temperature, the white solid was filtered off and the resulting solution was subjected to hydrogenation in a two-step procedure. (1) Reduction of the diazide: The solution was transferred into an autoclave and hydrogenated for 12 h at 4 bar in the presence of 10% Pd/C (500 mg) under vigorous stirring. The catalyst was removed by filtration. The filtrate was acidified with 3 M HCl and concentrated to dryness. The brownish residue was redissolved in H_2O (250 mL) and sorbed onto Dowex 50 W-X2. The column was washed with H_2O and eluted with HCl (0.5 M, 3.0 M, 6.0 M; 500 mL each). The latter two fractions were combined and concentrated to dryness. (2) Cleavage of the benzyl group: The product was taken up in a mixture of MeOH (100 mL), H_2O (50 mL), and acetic acid (20 mL) and the suspension was again hydrogenated in an autoclave for 12 h at 4 bar in the presence of 10% Pd/C (400 mg). The catalyst was removed and the clear solution was concentrated to dryness. The solid was then suspended in refluxing conc. HCl (100 mL) and small portions of H_2O were added until complete dissolution. After cooling to room temperature, the product was precipitated by adding EtOH (50 mL), collected by filtration, washed with EtOH and Et_2O, and dried in vacuo. White crystals of the composition *trans*-(3*R*,4*R*)-dap·3HCl·0.25H_2O were obtained (3.32 g, 45%). – $C_4H_{14.5}Cl_3N_3O_{0.25}$ (215.0): calcd. C 22.34, H 6.80, N 19.54; found C 22.25, H 6.82, N 19.54. – ^{1}H NMR (D_2O; pD < 2): δ = 3.70 (dd, J = 8.0, 10.0 Hz, 2 H), 4.12 (dd, J = 7.0, 10.0 Hz, 2 H), 4.42 (m, 2 H); (D_2O; pD > 12): δ = 2.53 (dd, J = 5.0, 10.0 Hz, 2 H), 3.02 (m, 2 H), 3.15 (dd, J = 6.0, 10.0 Hz, 2 H). – ^{13}C{^{1}H} NMR (D_2O; pD < 2): δ = 50.0 (CH_2), 54.6 (CH); (D_2O; pD > 12): δ = 54.9 (CH_2), 62.1 (CH). – Single crystals of *trans*-(3*R*,4*R*)-dap·3HCl·0.5H_2O were grown from an aqueous solution by slow evaporation of the water.

(1*S,2*R**)-1,2-Cyclopentanediyl Bis(methanesulfonate):** A solution of *cis*-1,2-cyclopentanediol (2.50 g, 24.48 mmol) in dry pyridine (50 mL) was cooled to 0 °C in an ice/NaCl bath. Methanesulfonyl chloride (3.89 mL, 50.00 mmol) was then added dropwise. A white precipitate appeared. The ice bath was removed and the solution was stirred at room temperature for 1 h and then cooled to 0 °C once more. Excess pyridine was neutralized by the addition of 3 M HCl (200 mL) in small portions whilst stirring. The product precipitated as a white solid, which was collected by filtration, washed with H_2O, and dried in vacuo (5.23 g, 83%). – $C_7H_{14}O_6S_2$ (258.31): calcd. C 32.55, H 5.46; found C 32.42, H 5.31. – ^{1}H NMR ($CDCl_3$): δ = 1.67–1.73 (m, 1 H), 1.98–2.12 (m, 5 H), 3.10 (s, 6 H), 5.00 (m, 2 H). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 18.3 (CH_2), 28.4 (CH_2), 38.5 (CH_3), 80.5 (CH).

***cis*-1,2-Diaminocyclopentane:** A mixture of (1*S**,2*R**)-1,2-cyclopentanediyl bis(methanesulfonate) (4.49 g, 17.38 mmol) and NaN_3 (3.40 g, 53.30 mmol) was heated at 100 °C whilst stirring in dry DMF (100 mL) for 4 h and then stirred for an additional 12 h at room temperature. H_2O (100 mL) was then added and the mixture was extracted with Et_2O (4 × 100 mL). The combined ethereal phases were washed with H_2O (100 mL) and dried with Na_2SO_4. A small sample (5 mL) was set aside until the ether evaporated, and the oily residue was dissolved in $CDCl_3$ for NMR characterization of the diazide. – ^{1}H NMR ($CDCl_3$): δ = 1.60–1.68 (m, 1 H), 1.76–1.94 (m, 5 H), 3.80 (m, 2 H). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 19.9 (CH_2), 27.9 (CH_2), 64.4 (CH). – The main portion of the ethereal solution was concentrated under reduced pressure to a volume of 200 mL and then diluted with EtOH (150 mL). This solution was transferred to an autoclave and hydrogenated for 26 h at 4 bar under vigorous stirring in the presence of 10% Pd/C (300 mg). The resulting suspension was heated to boiling for a few minutes and the catalyst was removed by filtration. The clear filtrate was concentrated under reduced pressure to a volume of 150 mL. Conc. HCl was added portionwise until the product precipitated (white needles). The solid was collected by filtration, washed with EtOH, and equilibrated in air, yielding *cis*-cptn·2HCl·0.5H_2O (1.57 g; 50% based on the amount of methanesulfonate). – $C_5H_{15}Cl_2N_2O_{0.5}$ (182.1): calcd. C 32.98, H 8.30, N 15.38; found C 33.00, H 8.30, N 15.35. – ^{1}H NMR (D_2O; pD < 2): δ = 1.80–1.93 (m, 3 H), 1.94–2.00 (m, 1 H), 2.23 (m, 2 H), 3.92 (m, 2 H); (D_2O; pD > 12): δ = 1.38 (m, 2 H), 1.52 (m, 1 H), 1.70 (m, 1 H), 1.86 (m, 2 H), 3.07 (m, 2 H). – ^{13}C{^{1}H} NMR (D_2O; pD < 2): δ = 21.7 (CH_2), 29.8 (CH_2), 55.6 (CH); (D_2O; pD > 12): δ = 22.7 (CH_2), 33.7 (CH_2), 57.3 (CH).

[Ni(*cis*-cptn)$_2$](ClO_4)$_2$: *cis*-cptn·2HCl·0.5H_2O (200 mg, 0.99 mmol) was dissolved in H_2O (10 mL) and deprotonated using Dowex 2-X8 (OH^- form). The resulting solution was concentrated to dryness under reduced pressure and the oily residue was redissolved in dry MeOH (100 mL). A solution of $Ni(ClO_4)_2$·6H_2O (183 mg, 0.50 mmol) in dry MeOH (25 mL) was added. The resulting yellow solution was stored at 4 °C for 14 h. Yellow crystals suitable for X-ray diffraction studies precipitated. These were collected by filtration and dried in air (227 mg, 85%). – $C_{10}H_{24}Cl_2N_4NiO_8$ (457.9): calcd. C 26.23, H 5.28, N 12.24; found C 26.24, H 5.26, N 12.21. – UV/Vis: λ_{max} (ε) = 357 (8.8), 444 (8.3), 574 (5.3).

(1*R,2*R**)-1,2-Cyclopentanediyl Bis(methanesulfonate):** Racemic *trans*-1,2-cyclopentanediol (1.86 g, 18.21 mmol) was converted into the bis(methanesulfonate) as described above for the *cis* isomer. Yield 2.71 g (58%). – $C_7H_{14}O_6S_2$ (258.3): calcd. C 32.55, H 5.46; found C 32.46, H 5.19. – ^{1}H NMR ($CDCl_3$): δ = 1.87 (quint, J = 7.0 Hz, 2 H), 1.91–1.97 (m, 2 H), 2.22 (m, 2 H), 3.07 (s, 6 H), 5.08 (m, 2 H). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 20.9 (CH_2), 30.5 (CH_2), 38.4 (CH_3), 84.8 (CH).

***trans*-1,2-Diaminocyclopentane:** A mixture of (1*R**,2*R**)-1,2-cyclopentanediyl bis(methanesulfonate) (2.71 g, 10.49 mmol) and NaN_3 (2.05 g, 31.53 mmol) in dry DMF (100 mL) was allowed to react and then hydrogenated as described above for the *cis* isomer. The catalyst was removed by filtration, and the filtrate was acidified

with 3 M HCl and concentrated to dryness. The residue was redissolved in H_2O (1000 mL) and sorbed onto Dowex 50 W-X2. The column was eluted with H_2O and aqueous HCl (0.5 M and 3.0 M; 500 mL each). The last fraction was concentrated to dryness and the residual white solid was dried in vacuo (1.13 g, 62%). − $C_5H_{14}Cl_2N_2$ (173.1): calcd. C 34.70, H 8.15, N 16.18; found C 34.73, H 8.03, N 16.09. − ^{1}H NMR (D_2O; pD < 2): δ = 1.83 (m, 2 H), 1.89 (quint, J = 7.0 Hz, 2 H), 2.32 (m, 2 H), 3.81 (m, 2 H); (D_2O; pD > 12): δ = 1.32 (m, 2 H), 1.64 (quint, J = 8.0 Hz, 2 H), 1.95 (m, 2 H), 2.77 (m, 2 H). − ^{13}C{^{1}H} NMR (D_2O; pD < 2): δ = 24.5 (CH_2), 32.5 (CH_2), 58.0 (CH); (D_2O; pD > 12): δ = 22.8 (CH_2), 34.9 (CH_2), 62.4 (CH).

[Cu(3*R*-ampy)(3*S*-ampy)](ClO$_4$)$_2$: Racemic ampy·2HCl (1.75 g, 11.19 mmol) was dissolved in H_2O (10 mL) and deprotonated using Dowex 2-X8 (OH^- form). The resulting solution was concentrated to dryness under reduced pressure and the oily residue was redissolved in dry EtOH (50 mL). A solution of $Cu(ClO_4)_2·6H_2O$ (1.85 g, 4.99 mmol) in dry EtOH (25 mL) was added dropwise. The blue precipitate was collected by filtration, washed with Et_2O, and dried in air (1.75 g, 81%). − $C_8H_{20}Cl_2CuN_4O_8$ (434.7): calcd. C 22.10, H 4.64, N 12.89; found C 21.76, H 4.56, N 12.81. − UV/Vis: λ_{max} (ε) = 554 (127). − Single crystals were grown by slow cooling of a hot saturated solution of $[Cu(ampy)_2](ClO_4)_2$ in MeOH.

Potentiometric Measurements: Potentiometric titrations were carried out with a Metrohm 713 pH/mV meter and a Metrohm combined glass electrode with an internal Ag/AgCl reference.[5,14] The sample solutions were titrated with 0.1 M or 1.0 M KOH using a Metrohm 665 piston burette. Addition of the titrant and the pH meter reading were controlled using an in-house computer program and a PC. The ionic strength of each 50-mL sample solution was 0.1 mol dm^{-3} KCl, 0.1 mol dm^{-3} KNO_3, or 1.0 mol dm^{-3} KNO_3 and the stability of the electrode was checked by calibration titrations prior to and after each measurement. All titrations were performed at 25.0 °C under nitrogen (scrubbed with an aqueous solution of the inert electrolyte). To determine the pK_a values of the ligands, several alkalimetric titrations were carried out with analytically pure samples of the corresponding hydrochlorides. Test solutions for the titration experiments were prepared using the solid hydrochlorides (*cis*-dap·3HCl, *cis*-cptn·2HCl, *trans*-cptn·2HCl) or a stock solution (ampy·2HCl), standardized aqueous stock solutions of the metal chlorides (Cu, Ni, Zn), or solid $Cd(NO_3)_2·4H_2O$. Complete equilibration was ensured by performing acidimetric back titrations (with 0.1 mol dm^{-3} HCl or 0.1 mol dm^{-3} HNO_3). The data were only considered reliable when no significant hysteresis was observed.

Spectrophotometric Titrations: The titrations were carried out as described in the previous section (50 mL sample solution, 0.01−0.02 mol dm^{-3} total Cu, 1 mol dm^{-3} KNO_3, 25.0 ± 0.1 °C). Additionally, the titration cell was equipped with an immersion probe (HELLMA), which was connected to a diode-array spectrophotometer (J & M, TIDAS-UV/NIR/100−1). An in-house computer program was used to control the addition of the titrant (1 mol dm^{-3} KOH). This program allowed a sample spectrum to be recorded prior to each addition of an aliquot of the titrant.

Calculation of the Equilibrium Constants: All equilibrium constants were calculated as concentration constants and pH was defined as −log [H^+]. The pK_a values of the ligands and the formation constants of the complexes were calculated using the computer program HYPERQUAD.[36] All equilibrium constants were evaluated with fixed values for the total concentrations of the reactants and for pK_w (13.78 for μ = 0.1 mol dm^{-3}, 13.71 for μ = 1.0 mol dm^{-3}).[26] For the refinement of the formation constants of the metal complexes, fixed values were used for the protonation con-

Table 7. Crystallographic data for H$_3$*cis*-dapCl$_3$·H$_2$O and H$_3$*trans*-dapCl$_3$·0.5H$_2$O

Compound	H$_3$*cis*-dapCl$_3$·H$_2$O	H$_3$*trans*-dapCl$_3$·0.5H$_2$O

stants of the ligands, as obtained from the pK_a determinations. The spectrophotometric measurements were evaluated using the computer program SPECFIT.[37,38] The spectrum of free Cu^{2+} was measured separately and was not refined. The free ligands and their protonation products were considered as colorless.

Crystal Structure Determination:[39] X-ray diffraction data were collected with the following diffractometers: STOE IPDS [protonated ligands, Ni complex, Cu(*cis*-dap) complexes with $x = 0.08$, 0.11], STOE STADI-4 (Pt complex), Nonius Kappa-CCD [Cu(*cis*-dap) complex with $x < 0.01$], Siemens SMART PLATFORM (Co complex, Pd complex), Siemens P4 four-circle diffractometer [Cu(ampy) complex]. The crystallographic data are compiled in Tables 7, 8 and 9. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used throughout. Low-temperature measurements at 233(2), 213(2), and 100(2) K were performed on the Co complex, the Cu(ampy) complex, and the Cu(*cis*-dap) complex with $x <$ 0.01, respectively. The data for all the other compounds were collected at ambient temperature. Standard reflections were monitored during the data collections. The standard reflections of the Pt complex and $[Cu(ampy)_2](ClO_4)_2$ decreased by 6.2% and 2%, respectively, during the measurements, and decay corrections were applied accordingly. All data sets were corrected for Lorentz and polarization effects. Absorption corrections were applied to the data for the Cu(*cis*-dap) complex with $x < 0.01$ (face-indexed numerical), the Pt complex (empirical with ψ-scans), the Cu(ampy) complex (empirical with DIFABS), and the Co and Pd complexes (empirical with SADABS). The structure of the Pt complex was solved by the heavy atom method; all other structures were solved by direct methods.[40] All structures were refined by full-matrix least-squares techniques[41] against F^2. One of the SO_4^{2-} counterions of the Cu(*cis*-dap) complex with $x > 0.01$ proved to be disordered. These anions exhibited two split positions for one of the oxygen atoms, which were refined with occupancies of 50% each. Non-hydrogen atoms were refined with anisotropic displacement parameters, except for the disordered oxygen positions (O32A, O32B) of the SO_4^{2-} counterions. In general, the positions of the hydrogen atoms were calculated (riding model with $U_{iso} = 1.2 \times U_{eq}$ of the bonded heavy atom), with the exception of the H_2O hydrogen atoms of H$_3$*trans*-dapCl$_3$·0.5H$_2$O, [Pt(H*cis*-dap)Cl$_4$]Cl·H$_2$O, and the Cu(*cis*-dap) complex with $x = 0.08$ and $x = 0.11$, which were not considered. All other hydrogen atoms of H$_3$*trans*-dapCl$_3$·0.5H$_2$O, all H(−N) and H(−O) hydrogen atoms of H$_3$*cis*-dapCl$_3$·H$_2$O, all hydrogen atoms of the Ni and Pd complexes (including H_2O), and the hydrogen atoms of the cation $[Co(cis\text{-dap})(tach)]^{3+}$, together with the OH hydrogen atom of EtOH, were located and refined with variable isotropic displacement parameters. The H(−N) atoms of the coordinated amino groups of [Pt(H*cis*-dap)Cl$_4$]Cl·H$_2$O were placed in calculated positions and were refined with $U_{iso} = 1.2 \times U_{eq}$. The positions of the hydrogen atoms of the noncoordinating ammonium groups and of all the H_2O molecules of the Cu(*cis*-dap) complex with $x = 0.005$ were located and refined isotropically with common bond lengths (0.775 ± 0.005 Å for H−O and 0.855 ± 0.005 Å for H−N). The small amount of additional Cu in this particular specimen (1.5 eÅ^{-3}, $x < 0.01$) was not considered in the refinement. The structures of H$_3$*cis*-dapCl$_3$·H$_2$O, H$_3$*trans*-dapCl$_3$·0.5H$_2$O, and [Pt(H*cis*-dap)Cl$_4$]Cl·H$_2$O were solved and refined in polar space groups. Their absolute structure parameters were refined to values of −0.03(6), −0.01(9), and −0.041(14), respectively.[42] The structure of $[Cu(ampy)_2](ClO_4)_2$ proved to be a racemic twin.

Molecular Modeling Calculations: Molecular modeling calculations were carried out using the commercially available program MOMEC97.[30]

Acknowledgments

We thank Anton Zaschka, Dr. Anja Zimmer, Dr. Volker Huch, Prof. Dr. Michael Veith (all Saarbrücken) and Dr. Peter Osvath (Melbourne) for valuable help and fruitful suggestions. The structure of $[Cu(cis\text{-cptn})_2](ClO_4)_2$ [18] was solved and refined by Manuela Winter (Bochum). Financial support from the Studienstiftung des Deutschen Volkes (D. K.) and the Fonds der Chemischen Industrie (K. H.) is gratefully acknowledged.

An ab initio MO Study of the Gas-Phase Reactions 2 $SF_2 \rightarrow FS-SF_3 \rightarrow S=SF_4$ − Molecular Structures, Reaction Enthalpies and Activation Energies[‡]

Yana Steudel,[a] Ralf Steudel,*[b] Ming Wah Wong,[c] and Dieter Lentz[a]

Keywords: Sulfur fluorides / Structures / Reaction mechanisms / Dimerizations / Ab initio calculations / 1,2-Shift / Transition states

High level ab initio MO calculations at the G3(MP2) level of theory were employed to study the molecular structures of SF_2, $FSSF_3$, and SSF_4, as well as the dimerization of gaseous SF_2 to $FSSF_3$ and the isomerization of $FSSF_3$ to SSF_4. The dimerization of SF_2 was calculated to be an exothermic process ($\Delta H°_{298}$ = −77 kJ·mol^{-1}) with an activation enthalpy ($\Delta H^{\neq}_{298}$) of 65 kJ·mol^{-1}. The transition state of the dimerization reaction is characterized by a bridging fluorine atom that undergoes a 1,2-shift, and a weak sulfur-sulfur single bond. The calculated lowest-energy structure of $FSSF_3$ (**2a**) is in excellent agreement with the experimentally derived structure, with the –SF group in an equatorial position of the distorted pseudo-trigonal-bipyramid at the central sulfur atom. A significantly less stable $FSSF_3$ conformer **2b**, 76 kJ·mol^{-1} higher in energy, has the –SF group in an axial position. Unimolecular rearrangement of $FSSF_3$ (**2a**) to the trigonal-bipyramidal SSF_4 (**3**), by a 1,2-fluorine shift (**TS2**), is endothermic by 37 kJ·mol^{-1} and is inhibited by a large activation barrier of 267 kJ·mol^{-1}. SSF_4 is predicted to be an observable species in the gas phase. Calculated infrared spectra of **2a** and **3** are also reported.

Introduction

Sulfur forms at least eight binary fluorides representing all seven oxidation numbers between 0 and +6:[1]

SF_2 SF_4 SF_6 $S=SF_2$ $FS=SF$
$FS-SF_3$ $FS-S-SF_3$ F_5S-SF_5

In addition, preparation of the chain-like difluorotrisulfane (S_3F_2) and difluorotetrasulfane (S_4F_2) have been reported.[2] While SF_4 and SF_6 are industrial products,[3] the other fluorides are too unstable, toxic, and/or reactive for any large scale production and application. However, these compounds are intermediates in the preparation of the higher sulfur fluorides and are therefore of fundamental interest.

Disproportionation reactions are a characteristic feature in the chemistry of all of the above mentioned species except for SF_4, S_2F_{10}, and SF_6. One of the most intriguing disproportionation reactions is the reversible dimerization of SF_2 to form S_2F_4, which was first observed by Seel et al.[4]

$$2\,SF_2 \rightleftarrows FS-SF_3 \quad (1)$$

In this reaction, a sulfur−sulfur bond is formed by combination of two atoms that must be positively charged because of the large difference in electronegativity between fluorine and sulfur. Willner et al. managed to determine the reaction enthalpy [$\Delta H°_{298}(1)$ = 69±2 kJ·mol^{-1}] despite enormous experimental difficulties, and observed that the reaction rate depends on the nature of the walls of the container.[5] The authors also noted that the equilibrium is established only partly because of the irreversible side reaction shown in Equation (2).

$$SF_2 + FS-SF_3 \rightarrow S=SF_2 + SF_4 \quad (2)$$

Subsequently, another side reaction according to Equation (3) was discovered: $FS-S-SF_3$ is formed when SF_2 and $S=SF_2$ are condensed together.[6]

$$SF_2 + S=SF_2 \rightarrow FS-S-SF_3 \quad (3)$$

The structure of SF_2 has been determined by microwave spectroscopy. The internuclear distances were obtained as 158.7 pm and the bond angle as 98.5° (C_{2v} symmetry).[7] SF_2 is rather unstable and can therefore only be studied in dilute vapour or using matrix isolation at low temperature. Because of reactions in Equation (1) and Equation (2), the formation of SF_2 is usually accompanied by S_2F_2 and S_2F_4. The latter compound is a colourless liquid, which is best prepared by fluorination of elemental sulfur or carbonyl sulfide followed by fractional distillation of the product mixture.[8] This reaction primarily yields gaseous SF_2 that dimerizes to S_2F_4 on condensation. The structure of S_2F_4 was investigated by electron diffraction (ED), microwave spectroscopy (MW), and ab initio MO calculations at the HF level.[9] The instability of the compound, the possible existence of several conformers and by-products, and the

low symmetry of the molecule resulting in twelve independent geometrical parameters, made the structural analysis using a single experimental method impossible. This molecule was even termed "recalcitrant".[9] The geometry derived from the combination of ED and MW data using force constants computed at HF level is shown in Figure 1.

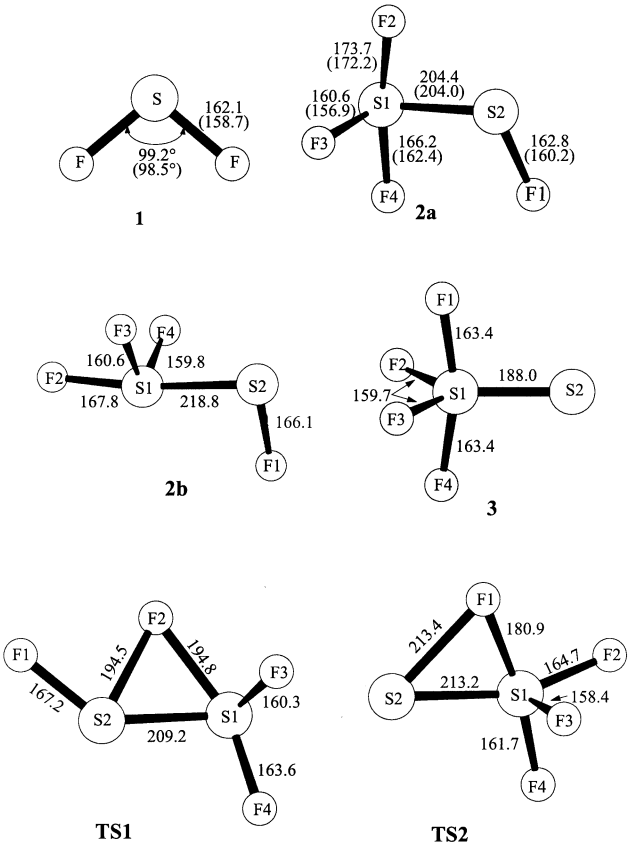

Figure 1. Calculated equilibrium structures of sulfur fluorides SF_2 (**1**), $FSSF_3$ (two conformers, **2a** and **2b**) and SSF_4 (**3**), and the transition states **TS1** and **TS2**. Internuclear distances in pm; experimental values of **1** and **2a** in parentheses. Bond angles and torsion angles are given in Table 1

There are various possible conformations of 1,2-difluorodisulfane-1,1-difluoride ($FSSF_3$). They can be considered as derivatives of the pseudo-trigonal-bipyramidal SF_4 molecule in which one equatorial (*e*) fluorine atom has been substituted by an −SF group. For the gas-phase structure of $FSSF_3$, the F_eSSF torsion angle was determined as 95° and the axial (*a*) F_aSF_a bond angle as 167.0°.[9] The ^{19}F NMR spectrum of liquid $FSSF_3$ recorded at −80° C shows signals for four non-equivalent fluorine atoms.[8] The same holds for gaseous $FSSF_3$ at ambient temperature,[10] in sharp contrast to SF_4 which undergoes rapid pseudo-rotation with an activation enthalpy of only 47 kJ·mol^{-1} at 298 K.[11]

No experimental evidence for the existence of other isomers of S_2F_4, such as $F_2S{=}SF_2$ and $S{=}SF_4$, has so far been reported in the literature. However, these species were investigated by ab initio MO calculations. Oberhammer et al. reported that $S{=}SF_4$ dissociated into SF_4 and S on attempts to optimize its geometry at the HF/3-3-21 level, although the oxygen derivative $O{=}SF_4$ is a well-known compound.[9] The same authors found that the hypothetical molecule $F_2S{=}SF_2$ corresponds to a minimum on the PES, but it lies 440 kJ·mol^{-1} above $FS{-}SF_3$ (HF/3-3-21 level).[9]

In this work, we report high level ab initio MO calculations on the structures and relative stabilities of SF_2, $FS{-}SF_3$, $S{=}SF_4$, and $F_2S{=}SF_2$. In addition, we examine the reaction profiles of the dimerization reaction of SF_2 and the rearrangement $FS{-}SF_3 \rightarrow S{=}SF_4$.

Computational Methods

Standard ab initio MO calculations were performed using the Gaussian 98 series of programs.[12] The energies of various equilibrium structures and transition states were examined using the G3(MP2) level of theory.[13] In brief, the G3(MP2) method is a composite procedure that aims at providing an accurate approximation to the high level of theory at QCISD(T)/GTMP2LARGE//MP2(full)/6-31G(d),

with the incorporation of the zero-point energy and higher level corrections. This level of theory is usually within ± 6 kJ·mol^{-1} of accurate experimental values.[13] Charge density analysis, at the MP2/6-31G* level, was performed using the natural bond orbital (NBO) approach.[14] Unless otherwise noted, all relative energies reported in this publication are given as $\Delta H°_{298}$ and correspond to the G3(MP2) level, while all structural parameters were obtained at the MP2(full)/6-31G* level.

Results and Discussion

Structures and Relative Stabilities

The calculated structures of all investigated molecules are shown in Figure 1, and further geometrical details are given in Table 1.

The experimental structure of SF_2 (**1**) is well reproduced by our calculations, although the calculated sulfur-fluorine distances are slightly shorter than the experimental values (see Figure 1). The sulfur atom bears an atomic charge (NBO) of +1.04 units. In the case of $FS-SF_3$, two conformers were located on the potential energy hypersurface. These conformers can be interconverted by pseudo-rotation, i.e. exchange of one equatorial for one axial ligand. As expected, the more stable isomer (**2a**) has the −SF group in an equatorial position and both axial positions occupied by fluorine as the most electronegative atoms in the molecule. In contrast, the less stable form (**2b**) has one axial position occupied by the −SF group. The total and relative energies of these species are given in Table 2.

Conformer **2a** was predicted to be more stable than **2b** by 76 kJ·mol^{-1}. This finding is in agreement with the observed structure of S_2F_4, which corresponds to **2a**. A comparison of the calculated and experimental structures of **2a** shows an excellent agreement for the SS bond length (within 0.4 pm), while the calculated SF bonds are 1.5−3.8 pm longer than the experimentally derived values. The bond angles agree within 3°. Only one torsional angle was reported for the experimental structure [τ(F3−S−S−F1) = 95±4°], in excellent accord with the calculated value (96.6°). The atoms F1−S−S−F4 are almost coplanar (τ = 7.3°). Interestingly, the S−F4 bond (166.2 pm) is significantly shorter than the other axial bond S−F2 (173.7 pm), although one would expect the opposite trend due to the repulsion between the atoms F4 and F1. Atoms F1 and F2 have a practically ideal *trans* position (τ = 178.3°).

The less stable $FS-SF_3$ conformer **2b** is also of C_1 symmetry, although the structure is just slightly distorted from a C_{2v} symmetry. In comparison with the structure of **2a**, the most remarkable differences are the rather long SS bond (218.8 pm) and the F2−S−S−F1 torsion angle of 173.4°. This places the atom F1 on the same side as one usually expects to find the "axial lone pair" at the sulfur atom in this pseudo-trigonal-bipyramidal geometry (Figure 1). These two structural features are probably the main reasons for the lower stability of **2b**. As in the case of **2a**, the axial SF bond (167.8 pm) of **2b** is longer than the two equatorial bonds (159.8 and 160.6 pm). The higher stability of **2a** compared to **2b** is in line with the valence shell electron pair repulsion (VSEPR) model,[15] which predicts that the conformer with the most electronegative substituents in the *axial* positions of a trigonal bipyramid is the most stable one.

A second isomer of S_2F_4, namely thiothionyltetrafluoride $S=SF_4$ (**3**), has a distorted trigonal-bipyramidal structure of C_{2v} symmetry. This derivative of hexavalent sulfur is 37 kJ·mol^{-1} less stable than **2a**, but surprisingly 39 kJ·mol^{-1} more stable than **2b**. The structure of **3** is very similar to that of the oxygen analogue, thionyltetrafluoride $O=SF_4$.[16] All SF bond lengths and bond angles show normal values. The SS bond length of 188.0 pm may be compared with those in the S_2 molecule (189.2 pm), S=S=O (188.2 pm), $S=SF_2$ (186.0 pm), and FS=SF (188.8 pm), which are considered as double bonds on the basis of their bond strength.[17] It is customary to indicate this strength by the symbol S=S, although it is not claimed that there exists a π bond in addition to the σ bond. In the case of **3**, the relatively short SS bond length may be attributed to the significant π interaction between the *d* orbital of S1 and *p* orbital of S2. The plausible description as a "semipolar" S^+S^- bond is only partly supported by the calculated atomic charges of SSF_4, which are given in Table 3. The NBO atomic charges of the central sulfur atoms (S1) in **2a**, **2b**, and **3** are +1.7, +1.8, and +2.4, respectively, while the terminal sulfur atom of **3** bears a rather small negative charge of −0.3 units. The dipole moment of **3** is 0.14 D, while **2a** has a dipole moment of 0.97 D.

[a] MP2/6-31G* level.

In contrast to the earlier findings,[16] we were unable to locate any stable equilibrium structure for the hypothetical isomer $F_2S{=}SF_2$, both on the HF/6-31G* and MP2/6-31G* levels of theory. It collapses to a weakly-bound SF_2 dimer upon geometry optimization (without symmetry constraints). The optimized C_{2h} structure has a short SS distance, but it corresponds to a second-order saddle point on the S_2F_4 potential energy surface.

Reaction Enthalpies and Transition States

As seen in Table 1, the calculated enthalpy of the dimerization reaction of Equation (1) is -77 kJ·mol^{-1}, slightly larger than the experimental value[5] of -69 ± 2 kJ·mol^{-1} which is probably less accurate due to the difficulties mentioned in the Introduction. The dimerization reaction proceeds by an interaction between the positively charged sulfur atom of one molecule and one of the negatively charged fluorine atoms of a neighbouring molecule, while the internuclear SS distance simultaneously decreases. In other words, the process occurs via an SS bond formation and a simultaneous 1,2-fluorine shift, which is readily reflected in the transition state **TS1** (Figure 1): the S1, F2, and S2 atoms form an almost symmetrical (C_{2v}) triangle with SF distances of 194.5 and 194.8 pm and an SS separation of 209.2 pm. The latter value corresponds approximately to a single bond.[17] The F1−S2−S1−F2 atoms are almost coplanar (τ = 2.4°) while the F1−S−S−F3 and F1−S−S−F4 torsion angles are 78.7° and 174.9°, respectively.

The calculated activation enthalpy of 65 kJ·mol^{-1} ($\Delta H^{\neq}_{298}$) for the dimerization of SF_2 suggests that this equilibrium is unlikely to be rapidly established at room temperature (see Figure 2). In fact, it has been observed that the reaction rate depends on the surface of the container,[5] which may act as a catalyst. Since **TS1** has a larger dipole moment (2.43 D; Table 3) than **2a** (0.97 D), polar surface sites may support its formation. The calculated activation enthalpy for the dissociation of $FSSF_3$, i.e. the reverse of reaction of Equation (1), is 142 kJ·mol^{-1}. The observed activation enthalpies $\Delta H^{\neq}_{298}$ (12.5 and 52 kJ·mol^{-1} in two experiments) are much lower, obviously because of the surface catalysis mentioned above.[5]

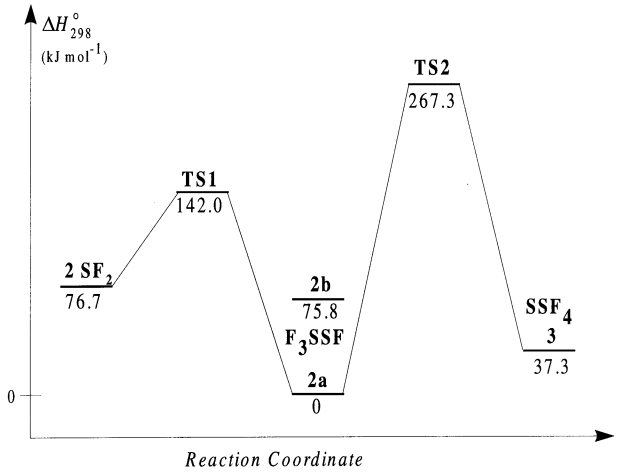

Figure 2. Schematic energy level diagram for the dimerization of SF_2 to $FSSF_3$ (**2a**) via transition state **TS1**, and for the isomerization of $FSSF_3$ (**2a**) to SSF_4 (**3**) via **TS2**. Calculated relative energy of the less stable conformer of $FSSF_3$ (**2b**) is also included

In the industrial production of SF_6 from elemental sulfur and fluorine, which is a highly exothermic process, the formation of SF_2 as an intermediate is very likely. Its exothermic dimerization to $FSSF_3$ explains the formation of the extremely toxic side-product S_2F_{10}; this species has the connectivity $F_5S{-}SF_5$ and is likely to originate from $FS{-}SF_3$ by partial fluorination.

The unimolecular isomerization of $FS{-}SF_3$ (**2a**) to $S{=}SF_4$ (**3**), by a 1,2-fluorine shift via transition state **TS2**, requires an activation enthalpy $\Delta H^{\neq}_{298}$ of 267 kJ·mol^{-1}. This means that **3** is protected by an energy barrier of 230 kJ·mol^{-1} against rearrangement back to **2a** (Figure 2). Thus we predict that species **3** is experimentally accessible, presumably in a matrix isolation experiment. The calculated vibrational wavenumbers of **3** are given below. The structure of the transition state **TS2** for the interconversion of **2a** and **3** (Figure 1) is of C_1 symmetry with a fluorine atom (F1) bridging the SS bond in an asymmetrical manner. This SS bond (213.2 pm) is longer than a typical single bond (205 pm)[17] and the bridging SF distances of 180.9 and 213.4 pm are also significantly longer than SF single bonds (160 pm). The other three SF bonds are of normal single bond lengths.

We have also computed the thermodynamic data of the formation of SSF_2 + SF_4 from SF_2 + $FSSF_3$, i.e. for reaction of Equation (2). The calculated reaction enthalpy is -6 kJ·mol^{-1} ($\Delta H°_{298}$) at the G3(MP2) level.

Harmonic Fundamental Vibrations

The calculated wavenumbers of the harmonic fundamental vibrations of $FSSF_3$ and SSF_4 were calculated at the MP2/6-311+G(2d) level of theory and are given in Table 4 together with the reported infrared absorptions[8] of $FSSF_3$.

Table 4. Fundamental harmonic vibrations [MP2/6-311+G(2d) level] of $FSSF_3$ (**2a**) and SSF_4 (**3**), and observed infrared spectrum of **2a**. 	136 (0.1)	$\tau(F_tSSF_a)$	a_1: 193 (0.5)	$\delta(F_aSF_a) + \delta(F_eSFF_e)$

The wavenumbers were scaled by a factor of 1.05, which was obtained by a linear least square fit to the experimental wavenumbers listed in the Table 4. There is a very good agreement between observed and calculated wavenumbers and infrared intensities of **2a**. The assignments of several normal modes are only approximate since there is a strong coupling between some fundamentals due to the low symmetry of the molecule. The same holds for the SS stretching mode and the symmetric stretching vibration of the equatorial SF_2 group in SSF_4 (**3**); these two fundamentals belong to the same symmetry class A_1.

Summary

We have shown that the molecular structure of $FSSF_3$ derived from microwave spectroscopy, electron diffraction data, and HF calculations[9] is essentially correct. For the first time, the energy differences between several S_2F_4 isomers were calculated at a high level of theory. The dimerization of SF_2, producing $FSSF_3$, proceeds via a triangular transition state that corresponds to a combination of a new SS bond formation and a 1,2-fluorine shift. The isomerization of $FSSF_3$ to SSF_4 proceeds via a 1,2-fluorine shift. Both reactions are calculated to have rather high activation barriers. With such a high barrier, the hypothetical SSF_4 molecule, which is metastable towards unimolecular rearrangement to the more stable $FSSF_3$, should be an observable species in the gas phase.

Molecular and Electronic Structure of (2,2′-Bidipyrrinato)nickel(II) Complexes

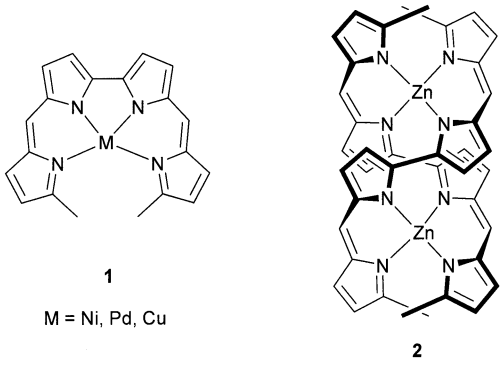
Martin Bröring,*[a] Carsten D. Brandt,[a] Johann Lex,[b] Hans-Ulrich Humpf,[c] Jordi Bley-Escrich,[d] and Jean-Paul Gisselbrecht[d]

Keywords: Porphyrinoids / Nitrogen ligands / Nickel / Helical structures / Electrochemistry

Nickel complexes of eight differently substituted 2,2′-bidipyrrins have been prepared and fully characterized. The X-ray analyses of three of these complexes revealed helical chiral molecules. Despite the tetrahedral deviation from the square-planar coordination geometry at the metal centres, all compounds were found to be diamagnetic in nature. For (3,3′,4,4′,8,8′,9,9′-octaethyl-10,10′-dimethyl-6,6′-diphenyl-2,2′-bidipyrrinato)nickel, a separation into the enantiomers by chiral MPLC could be achieved, and the first CD spectra of enantiomerically pure tetrapyrrole helicates are reported. An electrochemical study of the new complexes allowed a first insight into the electronic structure of (2,2′-bidipyrrinato)nickel(II), disclosing a rather high energy HOMO and metal–ligand interaction similar to that observed in metalloporphyrins.

Introduction

2,2′-Bidipyrrins constitute fully conjugated, open-chain tetrapyrroles, which serve as dianionic ligands in coordination compounds. Although known for 40 years, little work was performed towards an understanding of the coordinating properties of 2,2′-bidipyrrins, and their use as ligands has been very limited so far. The first 2,2′-bidipyrrins were obtained by Johnson et al. as the respective palladium(II) complexes by a coupling reaction of α,ω-dibromodipyrrins, using 3% palladium oxide on strontium carbonate as the reagent.[1] Only little later did the first free-base ligands as well as some nickel(II) and copper(II) chelates become accessible through a simple demetalation/remetalation protocol.[2,3] The tendency of the employed metal ions Ni^{II}, Pd^{II}, and Cu^{II} to bind to dianionic tetrapyrrole ligands in a square-planar fashion, and the UV/Vis-spectroscopic features observed led to the assignment of these compounds to the metalloporphyrin-like structure **1**. The first X-ray analysis of a metallobidipyrrin was reported in late 1998 by Dolphin et al.[4] Their study of a zinc complex revealed the M_2L_2 complex **2** and proved that 2,2′-bidipyrrin ligands are well suited for adopting different conformations in coordination compounds (Scheme 1). This behaviour, however, has been found earlier in a small number of other bile-pigment analogue complexes.[5,6] We recently showed, that 2,2′-bidipyrrins are in fact sufficiently flexible to stabilise even cluster fragments.[7]



Scheme 1. Known coordination modes of 2,2′-bidipyrrin ligands

Our interest in these ligands arose from the fact, that 2,2′-bidipyrrins contain a dianionic N_4 coordination site, rather than the trianionic one found in most other bile-pigment analogues.[8] In addition to this favourable similarity with the porphyrin ligand, 2,2′-bidipyrrins are easily prepared in substantial amounts,[9] and metal complexes like **1** can be expected to display helical chiral geometries like those of other metalated bilenes.[10–18] As part of our ongoing efforts to establish helical metallo-2,2′-bidipyrrins as chiral analogues of catalytically active metalloporphyrins,[19] the determination of chirality in these complexes and investigations towards the stability of the anticipated, but never proven helical arrangement are of vital importance. This paper reports molecular and electronic features of a set of eight (2,2′-bidipyrrinato)nickel complexes **11–18** with different substituents in the *meso* positions.

Results and Discussion

Synthesis and Characterization

The syntheses of (2,2′-bidipyrrinato)nickel complexes was achieved by stirring a solution of the respective ligands

Scheme 2. Synthesis of (2,2′-bidipyrrinato)nickel(II) complexes **11−18**

All compounds gave satisfactory elemental analyses and were further characterized by mass spectra (see Exp. Sect.). The ^{1}H-NMR-spectroscopic investigation of **12−18** revealed unsymmetric aryl groups as shown for the dinitro derivative **18** (Figure 1), in that the AA′BB′ system of the respective protons of the free-base ligand is split into four distinct groups of signals for the nickel complex. This observation can be interpreted in terms of a helical conformation of the new complexes. An accompanying diastereotopic splitting of the ethyl CH_2 groups, however, could not be detected, since the steric overcrowding of substituents in the periphery leads to hindered rotation with concomitant line broadening. This line broadening is so severe in the ^{13}C NMR spectra, that only incomplete sets of signals could be detected for **12−18**. Despite a tetrahedral distortion from the square-planar environment of the nickel(II) centre, all the complexes **11−18** are found to be low-spin and therefore are diamagnetic in nature. This finding is further supported by the result of variable-temperature NMR-spectroscopic studies conducted on **13**, showing sharp signals for all alkyl groups above 80 °C.

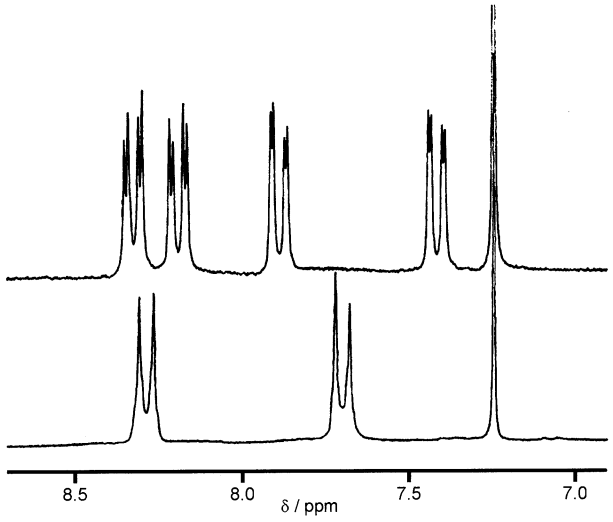

Figure 1. Aromatic regions of the ^{1}H NMR spectra of **10** (bottom) and **18** (top; 200 MHz, $CDCl_3$)

The fact, that the signal of the *meso* protons in **11** is detected $\Delta\delta = 0.62$ upfield with respect to the free base **3**, parallels the observations made in the porphyrin series ($\Delta\delta = 0.41$ for octaethylporphyrin and the respective nickel complex)[20] and gives a first indication, that the metal−ligand interactions are of a similar type in both cases. In agreement with this, the UV/Vis spectra of **11−18** and (porphyrinato)nickel complexes[21] show a somewhat related pattern with strong absorptions at 430 nm and several small ones between 500 and 900 nm (see Exp. Sect.). The red shift observed for **11−18** with respect to (porphyrinato)nickel complexes might be explained either in terms of a strained, nonplanar structure like in dodecasubstituted porphyrins,[22] and/or in a loss of symmetry, a scenario precedented by the absorption patterns of chlorins and bacteriochlorins.[23,24]

X-ray Analyses

The complexes **11**, **14**, and **16** were analysed by X-ray diffraction (Table 1). Crystals were grown in all cases by slow concentration of dichloromethane/*n*-hexane solutions. The pronounced helical structure of (2,2′-bidipyrrinato)-nickel complexes, which was already concluded from the NMR spectra, is the most striking feature of these complexes (**11**: Figure 2; **14**: Figure 3; **16**: Figure 4). The overlapping terminal methyl groups are located as close as 3.34 Å (**11**), 3.15 Å (**14**), and 3.66 Å (**16**) above each other, accounting for a certain degree of strain in these subunits. This strain has to be overcome by strong metal−nitrogen bonds. If the metal−nitrogen bonds are weak, the ligand will rather bind in an open, nonstrained fashion, as was demonstrated recently by Dolphin et al. on zinc complex **2**.[4]

The Ni−N bond lengths are also indicative of this strain, in that the nitrogen donors from the bipyrrolic units are bound more tightly [**11**: 1.8451(15) and 1.8498(14) Å; **14**:

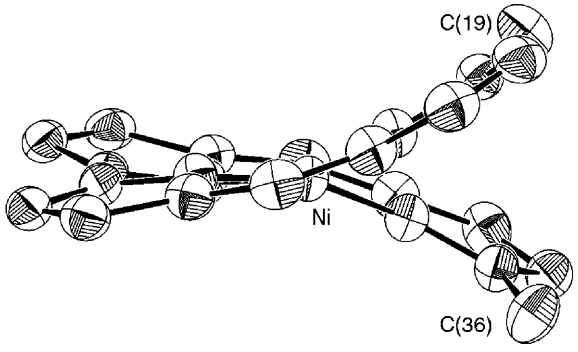

Figure 2. ORTEP plot of the molecular structure of **11** (side view)

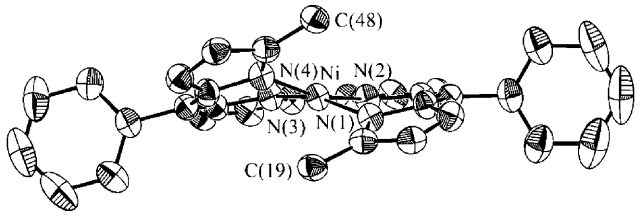

Figure 3. ORTEP plot of the molecular structure of **14** (front view)

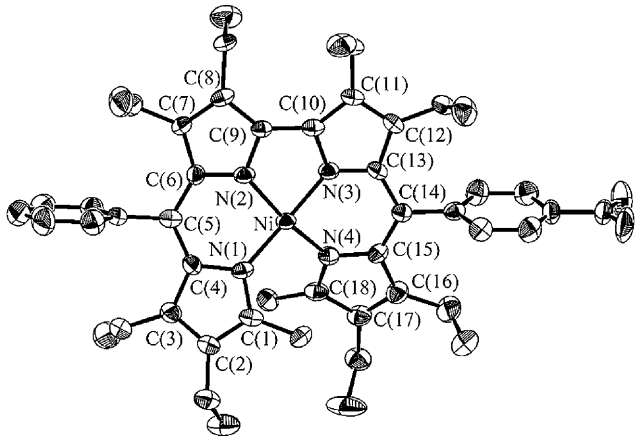

Figure 4. ORTEP plot of the molecular structure of **16** (top view)

1.834(2) and 1.834(2) Å; **16**: 1.835(3) and 1.840(3) Å] than those of the terminal C_4N rings [**11**: 1.9068(15) and 1.9088(15) Å; **14**: 1.885(2) and 1.889(2) Å; **16**: 1.865(3) and 1.893(3) Å]. All these bond lengths are shorter than those found for (porphyrinato)nickel complexes (1.90−1.96 Å), but still normal for low-spin Ni^{II}−N bonds. As a consequence of the helical ligand geometry the nickel coordination spheres show a tetrahedral distortion from planarity [angle between the planes {N(2),N(3),Ni} and {N(1),N(4),Ni} for **11**: 19.9°; for **14**: 18.8°; for **16**: 19.7°].

The steric influence of the additional peripheral aryl substituents in **14** and **16** results in reduced $C_\alpha-C_{meso}-C_\alpha$ angles [for **11**: 125.45(18)° and 125.33(17)°; for **14**: 124.3(2)° and 124.0(3)°; for **16**: 124.5(4)° and 123.2(3)°], and therefore induces a more pronounced overlap of the terminal methyl groups. Due to the open-chain character of 2,2′-bidipyrrins, the ligand framework appears to be sufficiently flexible to overcome steric encumbrance by *in-plane* distortions, and does not parallel the *out-of-plane* twisting modes, which are characteristic for dodecasubstituted porphyrins and their metal chelates.[22] The perpendicular arrangement of the aryl groups in **14** and **16** inhibits a strong electronic communication between the π-systems of the aryl rings and the tetrapyrrole moiety, so that only a small influence of the different substituents of **12**−**18** on the metal centre may be expected. Therefore, the rather distorted framework of the unsymmetrically substituted complex **16** should be addressed to crystal packing effects rather than to the electronic influence of the additional NO_2 functionality.

It is a typical bond-length characteristic of metalloporphyrins, that the $C_\beta-C_\beta$ bonds within the five-membered rings are shorter than the respective $C_\alpha-C_\beta$ bonds.[25,26] This very same characteristic can be claimed for the (bidipyrrinato)nickel complexes **11**, **14**, and **16**, accounting for a large degree of π-electron delocalization within these compounds. In contrast to this similarity, the $C_\alpha-N-C_\alpha$ moieties of the terminal C_4N rings are found to be non-symmetric (**11**: 1.34 Å/1.41 Å; **14**: 1.34 Å/1.42 Å; **16**: 1.34 and 1.35

Å/1.39 and 1.43 Å) and indicate a partial azafulvene character in these substructures.

Enantioseparation of 14

Although the helical chirality of bile-pigment analogue complexes was recognized early in the history of this branch of porphyrin chemistry, no enantiomerically pure compound has hitherto been published. In one instance, Smith and co-workers conducted an NMR-spectroscopic study on a (*meso*-oxobiladienato)nickel(II) complex bearing diastereotopic side chains, and reported a high racemisation barrier of at least 80 kJ mol^{-1}.[27,28] In a different approach, Mizutani et al. attempted to use the helicity of a zinc complex of a biliverdin derivative for the diastereoselective binding of amino acids and found, that upon addition of enantiomerically pure amines one of the helicates builds up, which is in accordance with a rather low helix inversion barrier.[29−31] Since the literature was not conclusive about the stability of the helical coordination geometry of open-chain metallotetrapyrroles we decided to separate (2,2′-bidipyrrinato)nickel complexes into the enantiomers and study them independently.

Our initial attempts to separate the isomers of **11**−**18** on an analytical Pirkle column disclosed that this is in fact possible for all aryl-substituted derivatives **12**−**18**, but not for **11**. Obviously, the interaction of the aryl moieties with the chiral stationary phase is the key to separation. Compound **14** showed the most promising solubility properties of the compounds studied and was therefore chosen for a preparative separation. Using a Pirkle column and 2% acetone in *n*-hexane as the mobile phase, an 85% enrichment was achieved; due to the rather low solubility, however, only 1.3 mg of material could be resolved at a time. Enantiopure complexes were obtained by fractionated crystallisation of the enriched material collected from several runs with dichloromethane/*n*-hexane, from which the racemate crystallises more readily. The optical purity of the helicates was proven by analytical chiral MPLC to be $> 97\%$.

The CD spectra of **14′** and **14′′**, recorded in dichloromethane ($c \approx 10^{-5}$ M), show a pattern similar to that known for biliverdin and its derivatives (Figure 5).[32,33] From the sign of the Cotton effect of the major band at 432 nm, the first eluted enantiomer **14′** can be assigned the *M* helical, and the other, **14′′**, the *P* helical isomer. This assignment is further supported by the recent findings by Vogel et al., who reported the same relationship between the sign of the Cotton effect and the helicity of the ligand for a (cyclooctaphyrinato)dipalladium.[34] The fact, that the maxima of the major CD and UV/Vis absorptions are found at the same wavelength (432 nm), is indicative of a strong electronic coupling, i.e. π-conjugation of both dipyrrin units in **14**, and is also found for biliverdin and other one-chromophore systems. For bilirubin-like tetrapyrroles, on the other hand, in which the dipyrrolic subunits are separated electronically by a CH_2 bridge, the two-chromophore arrangement leads to a bisignate CD signal within the major UV/Vis absorption, caused by exiton coupling of the independent subchromophores.[35,36]

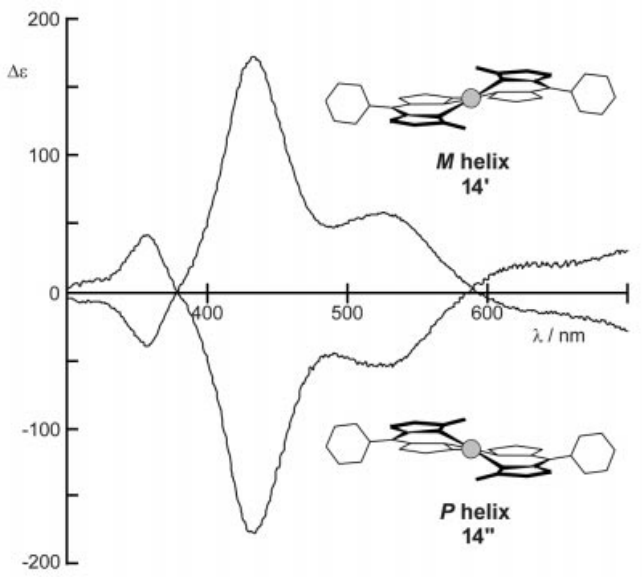

Figure 5. CD spectra of **14′** and **14′′** (CH_2Cl_2, $c \approx 10^{-5}$ M, 1 cm cell)

The stability of **14′** towards helix inversion was studied by prolonged heating of the complex in different solvents and determining the degree of racemisation by analytical chiral MPLC. Astonishingly, racemization was not ob-

served in any instance, and even after 14 h in molten naphthalene at 218 °C only the starting enantiomer could be detected. This result is in accordance with the one reported earlier by Smith and co-workers.[27,28] Despite the fact, that the small size of the low-spin d^8-nickel(II) ion and its strong binding to the ligand certainly supports the helix to a large extent, this extreme resistance against inversion processes suggests, that other metallo-2,2′-bidipyrrins will behave in a similar fashion.

Electrochemistry

In order to gain insight into the electronic structure of (bidipyrrinato)nickel complexes an electrochemical investigation was undertaken on the complexes **11**−**18**. Table 2 summarises the conditions and observed redox potentials for these as well as for the free-base ligand **3**.

All metallated compounds gave well-defined CVs, in which they undergo two reversible one-electron oxidations at rather low potentials. In reduction, the first step is reversible and well resolved (with exception of the nitrophenyl-substituted derivatives **16** and **18**), whereas the second step occurs close to the electrolytic discharge. The nitrophenyl derivatives **16** and **18** display a specific redox behaviour. The waves at −1.44 V (**16**) and −1.46 V (**18**) vs. Fc/Fc^+ involve one and two electrons, respectively, and correspond to the reduction of the nitrophenyl units, which act as independent redox centres. As no data on the redox behaviour of porphyrins bearing nitrophenyl substituents on the *meso* positions could be found in the literature, 4,4′-dinitrobiphenyl was used as a reference. This compound showed a similar two-electron wave at −1.49 V. The redox characteristics of the free-base ligand **3** obviously deviate severely from those of the metallated species (Table 2). This behaviour is most probably due to the open conformation of **3**.

When plotting the redox potentials of **12**−**18** versus the Hammett constants of the phenyl substituents σ, straight lines were obtained in agreement with the previously reported potential evolution for different tetraarylporphyrins (Figure 6). In our case, the observed slopes were equal to 52 and 47 mV for the first and second oxidation, respectively, whereas the slope for the first reduction equals 71 mV. These values also parallel the above-mentioned findings in the porphyrin series.[37] This linear evolution of the redox potentials with the substituents is a good indication of ligand-centred electron transfers as metal-centred electron transfers are less sensitive to substituent effects. Further spectroelectrochemical and EPR studies towards the electronic structure of one- and two-electron-oxidized (2,2′-bidipyrrinato)nickel(II) complexes are currently under investigation.

Comparing the electrochemical behaviour of **11** (NiOEBDP) and (octaethylporphyrinato)nickel(II) (NiOEP), a striking similarity appears in the LUMO energy levels of both compounds, while the HOMO of **11** is raised by 0.58 V with respect to NiOEP. The difference thus occurring in the HOMO−LUMO gaps of these complexes (Figure 7) corresponds qualitatively with the UV/Vis-spectroscopic observation, that the maximum of the longest-wavelength

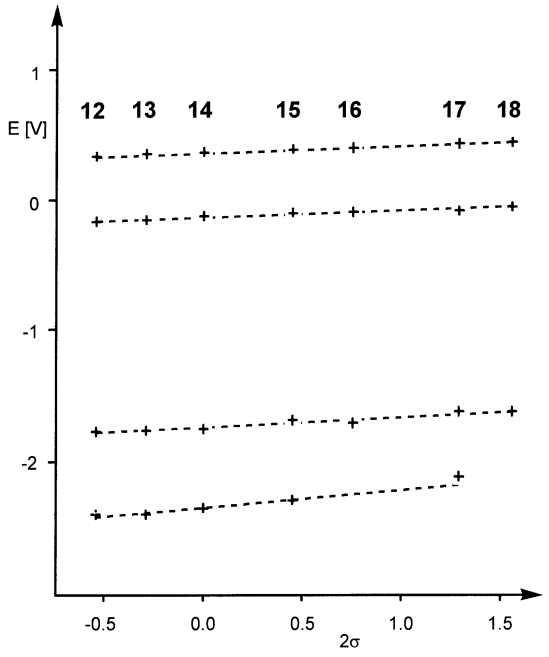

Figure 6. Evolution of redox potentials of **12**−**18** with Hammett constants σ

band is detected to be red-shifted from 551 nm in NiOEP to 863 nm in **11**.

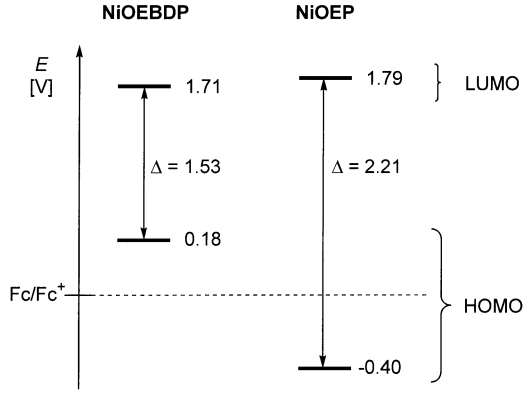

Figure 7. HOMO and LUMO energy levels of (2,2′-bidipyrrinato)nickel(II) (**9**) (NiOEBDP) and (octaethylporphyrinato)nickel(II) (NiOEP) as derived from electrochemical data

Conclusion

Our studies on the (2,2′-bidipyrrinato)nickel complexes **11**−**18** revealed complexes related to (porphyrinato)nickel complexes with respect to both, structural and electronic properties. Both ligands serve as dianionic N_4 chelates when interacting with the divalent nickel ion and produce low-spin, (distorted) square-planar coordination compounds. However, 2,2′-bidipyrrinato complexes show some special features due to their build-up as open-chain tetrapyrroles, of which the pronounced and stable helical conformation and the high-energy HOMO are the most obvious.

An interpretation of the differences found mainly in the electronic structures of (2,2′-bidipyrrinato)nickel(II) com-

plexes and (porphyrinato)nickel(II) complexes is not trivial at all, since the latter contain an aromatic 22π system, while the open-chain analogues constitute non-aromatic 20π-electron compounds without aromatic stabilisation. From the point of view of ligand electronics, any comparison of these differing classes must therefore fail, and it is quite surprising, that the spectral and structural features of (2,2′-bidipyrrinato)nickel complexes match so well with those obtained on aromatic (porphyrinato)nickel variants like chlorins, bacteriochlorins,[23,24] or overcrowded porphyrins.[22] Well-established interpretation schemes like energetic contributions through a strained, nonplanar structure and/or loss of symmetry do, when applied to these open-chain nickel(II) complexes, in fact, result in a useful description of the observed properties. While electronically the differences between the 2,2′-bidipyrrin and the porphyrin ligand are obvious, the influence on the central nickel(II) ion is too small to be detected by the applied methods. Two dipyrrin units arranged in a way as to form a (distorted) square-planar, dianionic N_4 chelate ligand thus appear sufficient to mimic at least some of the coordination chemistry of aromatic, porphyrinoid ligands.

The data presented here for a group of model complexes suggests, that helical chiral metallo-2,2′-bidipyrrins might well have the potential to serve as valuable porphyrinoid catalysts in enantioselective transformations. We are currently exploring this possibility.

Experimental Section

Solvents for chromatography were HPLC grade. All reagents and solvents were purchased from commercial sources and used as received. − NMR spectra were obtained in $CDCl_3$ solutions with a Bruker AC 200 spectrometer. Chemical shifts (δ) are given in ppm relative to residual protio solvent resonances (^{1}H spectra) or to chloroform (^{13}C). − Mass spectra (EI, 70 eV or FAB) were recorded with a Finnigan 90 MAT instrument; *m*/*z* alues are given for the most abundant isotopes only. − Melting points were measured by DTA with a Thermoanalyzer DuPont 9000. − Elemental analyses (C, H N) were performed at the microanalytical laboratory of the Institut für Anorganische Chemie, Universität Würzburg. − UV/Vis spectra were obtained in dichloromethane solution ($c \approx 10^{-4}$ mol l^{-1}) with a Hitachi U-3200 spectrophotometer. − Chiral MPLC was performed on Pirkle-type columns (D-phenylglycine on spherical silica gel; analytical: 25 cm × 4.6 mm, particle size 5 μ; preparative: 50 cm × 21.1 mm, particle size 10 μ), using a Latek P402 chromatographic system, and the fractions were detected by single-point UV absorption at 400 nm. − CD spectra were recorded as dichloromethane solutions in a 1-cm cell with a Jasco J 600 CD spectrometer. − Cyclic voltammetry was carried out in benzonitrile containing *n*Bu_4NPF_6 as supporting electrolyte (0.1 M). Benzonitrile (Aldrich) was dried with anhydrous $CaCl_2$ for 2 d, and further distilled from P_2O_5 under reduced pressure of argon. *n*Bu_4NPF_6 (Fluka, electrochemical grade) was dried under vacuum at 65 °C. Before use, the 0.1 M solution of *n*Bu_4NPF_6 in benzonitrile was purified in a glove box on activated neutral alumina (Merck). The measurements were carried out in the glove box using a classical three-electrode cell. The working electrode was a platinum disk (diameter 2 mm), the pseudo reference electrode and the counter electrode being platinum wires. All potentials are given against the ferrocene/ferrocenium couple used as internal standard. The cell was connected to an EG&G PAR potentiostat (Model 273) interfaced with a PC.

Preparation of the Nickel Complexes

(2,2′-Bidipyrrinato)nickel Complexes 11−18. − General Procedure: 0.1 mmol of 2,2′-bidipyrrin **3−10** and 566 mg (2 mmol) nickel(II) acetate tetrahydrate were stirred in a mixture of 30 mL of methanol and 30 mL of dichloromethane for 30 min (colour change from deep blue to brownish green). The reaction mixture was extracted twice with 100 mL of water, dried with sodium sulfate, and the solvent was removed in vacuo. Recrystallization from dichloromethane/methanol yielded the title compounds as violet crystals.

[3,3′,4,4′,8,8′,9,9′-Octaethyl-10,10′-dimethyl-2,2′-bi(dipyrrinato)]nickel (11): Yield 548 mg (92%); m.p. 257 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.81 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 0.99 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 1.01 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 1.05 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 1.99 (q, ^3J = 7.5 Hz, 4 H, 2 × CH_2CH_3), 2.31−2.16 (m, 12 H, 6 × CH_2CH_3), 2.32 (s, 6 H, terminal CH_3), 6.04 (s, 2 H, H_{meso}). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 14.1, 16.7, 17.1, 17.2, 17.4, 17.5, 17.6, 17.8, 18.2, 119.5, 127.8, 130.9, 132.9, 136.9, 140.4, 148.2, 151.5, 168.8. − UV/Vis (dichloromethane): λ_{max} (ε) = 306 (21200), 353 (21100), 432 (80700), 535 (17800), 609 sh (13300), 864 nm (5600 mol^{-1} dm^3 cm^{-1}). − MS (70 eV, EI): *m*/*z* = 594 [M$^+$], 297 [M^{2+}]. − $C_{36}H_{48}N_4Ni$ (595.49): calcd. C 72.61, H 8.12, N 9.41; found C 72.50, H 7.84, N 9.28.

Crystallographic Data for 11: $C_{36}H_{48}N_4Ni$, violet cubes obtained by slow concentration of a CH_2Cl_2/*n*-hexane solution, crystal size: 0.25 × 0.20 × 0.20 mm, monoclinic, space group $P2_1/c$, a = 12.867(1), b = 20.140(1), c = 13.270(1) Å, β = 110.42(1)°, V = 3222.7(4) Å^3, $\rho_{calcd.}$ = 1.227 g cm^{-3}, Z = 4, $2\theta_{max}$ = 54°, Mo-K_α radiation, λ = 0.71073 Å, scan mode: φ/ω-scans, T = 293(2) K, 24167 measured, 6701 independent reflections, 5457 reflections observed for $I > 2\sigma(I)$, μ = 0.632 mm^{-1}, solved with direct methods (MolEN, Enraf−Nonius), refined with full-matrix least squares on F^2 (SHELXL-97, G. Sheldrick, University of Göttingen), 563 parameters, H atoms refined with isotropic temperature factors. R = 0.0361, wR = 0.0906, residual electron density ρ = 0.338/−0.198 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-153981. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[6,6′-Bis(*p*-anisyl)-3,3′,4,4′,8,8′,9,9′-octaethyl-10,10′-dimethyl-2,2′-bidipyrrinato]nickel (12): Yield 759 mg (94%); m.p. 263 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.60 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 0.62 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 0.80 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 0.97 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 1.13 (m, 4 H, 2 × CH_2CH_3), 1.49 (br.s, 4 H, 2 × CH_2CH_3), 2.1, 2.27 (2 × br.s, 14 H, terminal CH_3 and 4 × CH_2CH_3), 3.85 (s, 6 H, OCH_3), 6.82 (d, ^3J = 8.4 Hz, 2 H, H_{aryl}), 6.92 (d, ^3J = 8.4 Hz, 2 H, H_{aryl}), 7.07 (d, ^3J = 8.4 Hz, 2 H, H_{aryl}), 7.53 (d, H ^3J = 8.4 Hz, H_{aryl}). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 14.3, 16.8, 17.4, 18.0, 18.5, 19.3, 55.3, 112.7, 113.0, 129.5, 129.8, 130.6, 130.7, 132.7, 142.6, 151.1, 159.4. − UV/Vis (dichloromethane): λ_{max} (ε) = 308 (26700), 354 (21200), 432 (79800), 532 (18100), 613 sh (13700), 859 nm (5900 mol^{-1} dm^3 cm^{-1}). − MS (FAB): *m*/*z* = 806 [M$^+$]. − $C_{50}H_{60}N_4NiO_2$ (807.73): calcd. C 74.35, H 7.49, N 6.94; found C 73.99, H 7.38, N 6.70.

[3,3′,4,4′,8,8′,9,9′-Octaethyl-10,10′-dimethyl-6,6′-bis(*p*-tolyl)-2,2′-bidipyrrinato]nickel (13): Yield 683 mg (88%); m.p. > 300 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.59 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 0.60 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 0.80 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 0.97 (t, 6 H, ^3J = 7.5 Hz, 2 × CH_3), 1.11 (m, 4 H, 2 × CH_2CH$_3$), 1.45 (br.s, 4 H, 2 × CH_2CH$_3$), 2.2 (m, 14 H, terminal CH_3 and 4 × CH_2CH$_3$), 2.40 (s, 6 H, ArCH_3), 7.06 (m, 4 H, H_{aryl}), 7.19 (d, ^3J = 7.6 Hz, 2 H, H_{aryl}), 7.51 (d, ^3J = 7.6 Hz, 2 H, H_{aryl}). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 14.4, 16.7, 16.9, 17.4, 17.7, 18.0, 18.5, 19.3, 21.4, 128.1, 129.5, 132.6, 134.4, 137.6, 142.5, 151.0, 168.1. − UV/Vis (dichloromethane): λ_{max} (ε) = 307 (26100), 353 (20800), 434 (78200), 534 (17700), 613 sh (13500), 863 nm (5700 mol^{-1} dm^3 cm^{-1}). − MS (FAB): *m*/*z* = 774 [M$^+$]. − $C_{50}H_{60}N_4Ni$ (775.73): calcd. Alkynyl Substitution and Linkage in Cobaltacarborane Sandwich Complexes[‡]

Dennis Malaba,[a][‡‡] Michal Sabat,[a] and Russell N. Grimes*[a]

Keywords: Carboranes / Alkyne complexes / Metallacarboranes / Cobalt / Palladium

Linkage of $Cp^*Co(Et_2C_2B_3H_5)$ sandwich units by alkynyl and diethynylphenylene connectors was explored by the synthesis of two classes of complexes in which the linking groups are attached to the Cp^* ligands and to the carborane rings, respectively. Thus, the complex *nido*-(η^5-C_5Me_4–C≡CH)$Co(Et_2C_2B_3H_5)$ (**6**) was prepared and converted in 87% yield to the novel 1,4-diethynylphenylene-linked bis(metallacarborane) 1,4-[*nido*-$(Et_2C_2B_3H_5)Co(\eta^5$-C_5Me_4–C≡C)]$_2C_6H_4$ (**7**), which was characterized by multinuclear NMR and mass spectra and X-ray crystallography. CuI-promoted coupling of **6** with $(MeCN)_2PdCl_2$ in excess diethylamine was employed to prepare a palladium derivative, *nido*-$(Et_2C_2B_3H_5)Co(C_5Me_4)$–C≡C–$Pd(NHEt_2)_2Cl$ (**10**). Complexes of the second type, in which the organic linker is attached directly to the carborane ring, were obtained by synthesis of a *B*-ethynylcobaltacarborane, *nido*-Cp^*Co-$[Et_2C_2B_3H_3(C{\equiv}CH)(C{\equiv}CSiMe_3)]$ (**15**), which was then coupled with 1,4-diiodobenzene to generate the bis(cobaltacarborane) 1,4-[*nido*-$Cp^*CoEt_2C_2B_3H_3(C{\equiv}CSiMe_3)(C{\equiv}C)]_2$-$C_6H_4$ (**16**) in 87% yield.

Introduction

Small metallacarborane units are versatile building blocks for the design and construction of organometallic frameworks in which metal centers are bound into stable environments;[2] typically, these are sufficiently robust to allow oxidation, reduction, and functionalization without disintegration of the system.[3] Examples include multidecker stacks,[4] arene-centered polymetallacarboranes,[5] and linked clusters.[6] Of particular interest are molecular arrays designed to promote electron delocalization between the metal centers. Such systems in general have two basic features: the presence of unpaired electrons, which can be introduced via paramagnetic metals, and connecting units that facilitate metal-to-metal electron transport. Unsaturated organic groups such as alkynes are prime candidates, and alkyne-linked organometallics are currently a subject of considerable interest as potential "molecular wires".[7] In the boron cluster area, Hawthorne and co-workers have synthesized ethynyl-linked rigid-rod derivatives of *p*-carborane ($1,12\text{-}C_2B_{10}H_{12}$) by Pd-catalyzed coupling.[7n] Here we report the development of preparative routes to alkyne-linked bis(metallacarborane) systems and their application to the synthesis of two types of target compounds in which the connectors are attached to the Cp* ligands and the carborane rings, respectively.

Results and Discussion

The synthon (η^5-C_5Me_4−C≡CH)$Co(Et_2C_2B_3H_5)$ (**6**) was prepared in several steps, starting with lithiation of 1-tetramethylcyclopentadienyl-2-trimethylsilylacetylene (**1**)[8] to generate **2** (Scheme 1), which reacted with $CoCl_2$ to give a green solution of the presumed dimer **3**. Treatment of this solution with the $Et_2C_2B_4H_5^-$ ion in THF gave the red-brown complex (C_5Me_4−C≡$CSiMe_3$)$Co(Et_2C_2B_4H_4)$ (**4**), which was isolated in 32% yield and decapped with TMEDA and water to afford *nido*-(η^5-C_5Me_4−C≡C−$SiMe_3$)$Co(Et_2C_2B_3H_5)$ (**5**) as a yellow solid. Desilylation of **5** with tetrabutylammonium fluoride in THF produced yellow **6** in 82% yield. Pd/Cu-catalyzed C−C coupling[7b,7c] with 1,4-diiodobenzene was effected by reaction of **6** with bis(benzonitrile)palladium(II) chloride, copper(I) iodide, triphenylphosphane, and diethylamine, which upon workup and chromatography on silica gave the diethynyl-linked dicobalt target complex 1,4-[*nido*-$(Et_2C_2B_3H_5)Co(\eta^5\text{-}C_5Me_4{-}C{\equiv}C)]_2C_6H_4$ (**7**), isolated as a yellow-brown solid in 87% yield. A minor product (4%) was tentatively identified from its proton NMR and mass spectra as the diethynyl-linked species [*nido*-$(Et_2C_2B_3H_5)Co(\eta^5$-C_5Me_4−C≡C)]$_2$ (**8**).

Complex **7** was fully characterized by multinuclear NMR and mass spectra and X-ray crystallography, which established the centrosymmetric geometry depicted in Scheme 1 and Figure 1. To our knowledge, the only prior example of a structurally characterized complex in which two metallacarborane units are linked by an alkynyl-containing chain is [Cp*$Co(Et_2C_2B_4H_3\text{-}7\text{-})]C_2$, whose C≡C group is attached to the apical boron atoms.[6a] Compound **7** is the first structurally characterized diethynylphenylene-linked metallacarborane complex, and some features are worth noting. As can be seen in Figure 1, the chain C1R1−C4−C5−C6---C6*−C5*−C4*−C1R1* forms an approximately linear ar-

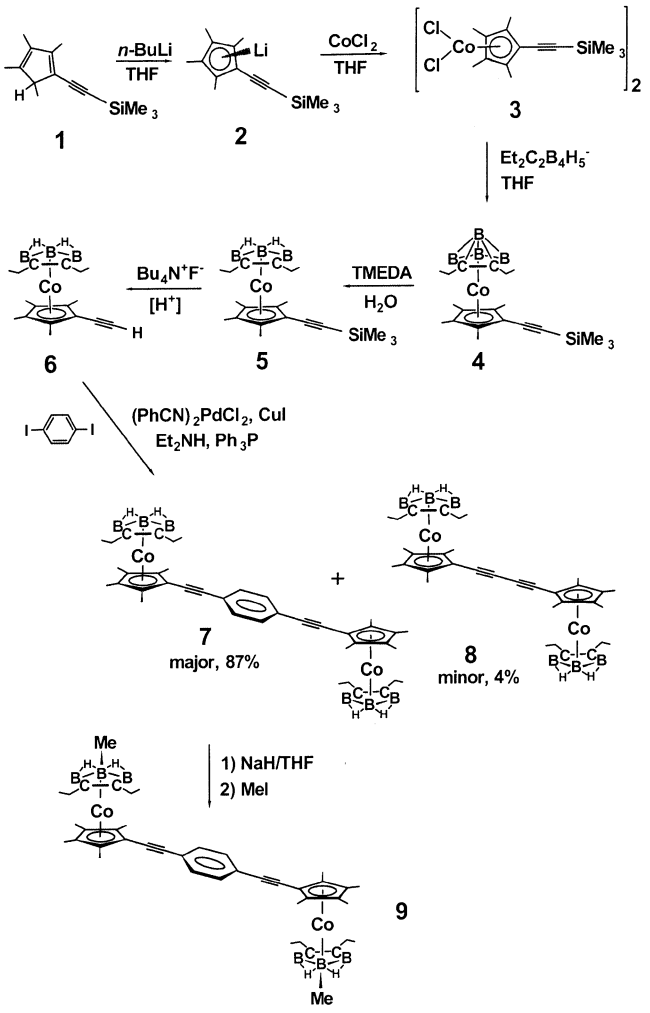

Scheme 1. B = BH, B

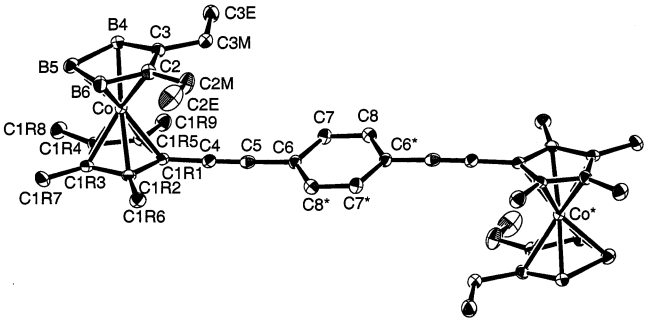

Figure 1. Molecular structure of **7** with 30% thermal ellipsoids (hydrogen atoms omitted for clarity); selected distances [Å]: C1R1−C4 1.424(7), C4−C5 1.185(7), C5−C6 1.454(7), C6−C7 1.394(7), C6−C8* 1.401(7), Co−C_5 plane 1.661, Co−C_2B_3 plane 1.508; the benzene ring subtends a dihedral angle of 13.1° with the C_5 ring plane

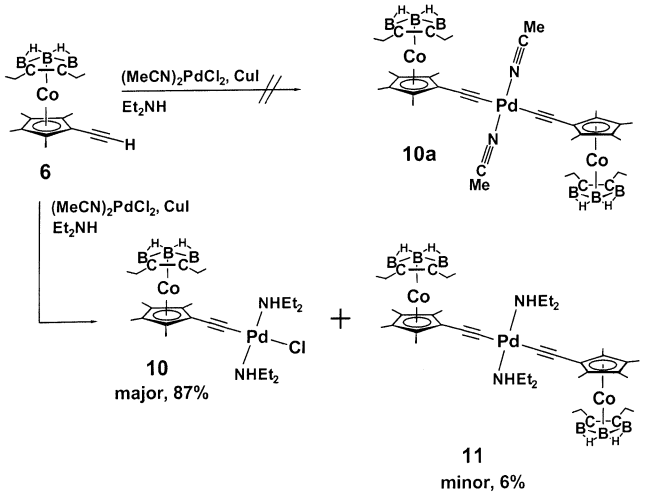
ray, but the phenylene ring is tilted 13° out of the plane defined by the C_5 rings. The C_2B_3 ring is not quite parallel with the C_5 plane (dihedral angle 9°) and the Co atom is closer to the carborane ring (1.508 Å) than the C_5 ring (1.66 Å), both values being typical of small cobaltacarboranes.[2−4] The short C4−C5 distance [1.185(7) Å] is within the normal range for C≡C bonds in alkynyl-linked dimetallic complexes,[9] although it is slightly shorter than that found in the previously mentioned [Cp*Co($Et_2C_2B_4H_3$−**7**−]$_2C_2$ [1.205(12) Å].[6a]

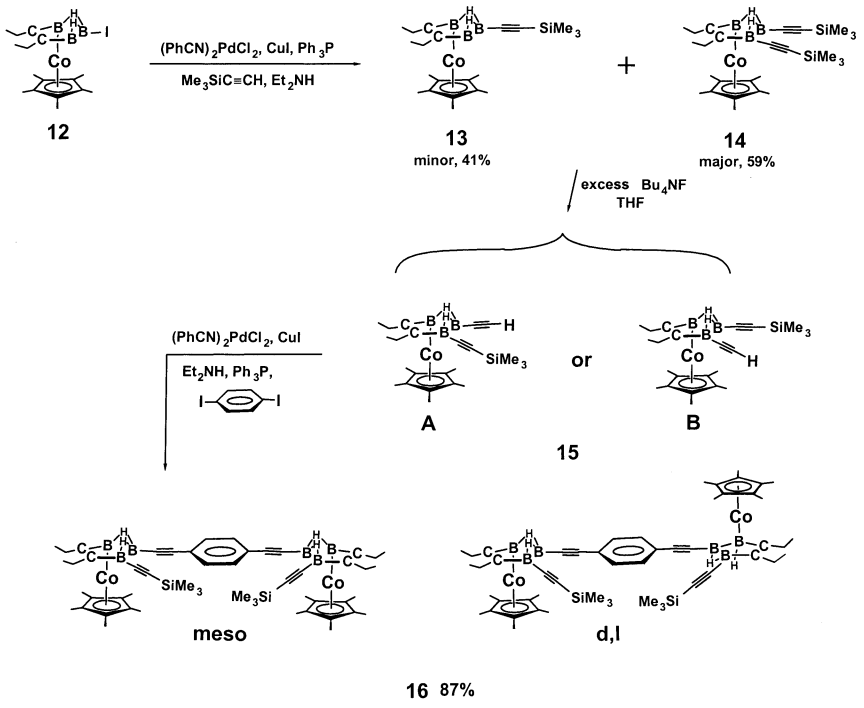
Since **7** is a bifunctional complex having two open carborane ligands available for bridge-deprotonation and η^5-coordination to metal ions,[1a] it is expected to be a useful synthon for the construction of long-chain metallacarborane oligomers or polymers containing [(C_5Me_4)Co($Et_2C_2B_3H_3$)]$_2$Co tetradecker sandwich units. This may be accomplished by removal of BHB bridging protons from both C_2B_3 end rings and stacking with transition metal ions, as was demonstrated earlier in the synthesis of phenylene- and fulvalene-bridged "staircase" oligomers.[10] It has been found, however, that such metal stacking reactions require modification of the electron population in the C_2B_3 end rings by introduction of methyl groups or halogen atoms.[3c,4,10] Accordingly, **7** was deprotonated and treated with methyl iodide to generate the *B,B′*-dimethyl derivative **9** (Scheme 1).

In an attempt to prepare the palladium-connected bis(cobaltacarborane) complex **10a** (Scheme 2), **6** was treated with bis(acetonitrile)palladium(II) chloride, copper(I) iodide, and diethylamine. However, the main product, isolated in 87% yield as a red-brown solid and characterized spectroscopically, was the mono(cobaltacarboranyl) species ($Et_2C_2B_3H_5$)Co(C_5Me_4)−C≡C−Pd($NHEt_2$)$_2$Cl (**10**). An accompanying low-yield side product was tentatively identified from its mass spectrum as [($Et_2C_2B_3H_5$)Co(C_5Me_4)−C≡C]$_2$Pd($NHEt_2$)$_2$ (**11**, Scheme 2).



Scheme 2. B = BH, B

An alternative approach to the preparation of alkynyl-linked Cp*Co($Et_2C_2B_3H_5$) units involves attachment of the organic chain to the carborane ring rather than the Cp* group as in the preceding chemistry. Scheme 3 shows the



Scheme 3. B = BH, B

exploration of this idea employing as starting material the 5-iodo complex **12**,[11] which reacted with trimethylsilyl acetylene in the presence of palladium and copper reagents to produce the mono- and bis(*B*-silylethynyl) complexes **13** and **14**. The disubstituted product **14** probably formed by partial *B*-chlorination of **12** with $(PhCN)_2PdCl_2$, a process we have observed in earlier work.[12]

Treatment of **14** with excess fluoride ion removed only one trimethylsilyl group to give a single product, formulated as $Cp^*Co[Et_2C_2B_3H_3(C{\equiv}CH)(C{\equiv}CSiMe_3)]$ (**15**), whose spectroscopic data do not distinguish between the structures **A** and **B** depicted in Scheme 3. In a procedure analogous to the synthesis of **7** and **8** described above, Pd/Cu-catalyzed alkyne linkage was carried out on **15** to produce yellow 1,4-$\{nido\text{-}Cp^*Co[Et_2C_2B_3H_3(C{\equiv}CSiMe_3)(C{\equiv}C)]\}_2$-$C_6H_4$ (**16**), which was isolated in 87% yield together with a yellow minor product whose mass spectrum is consistent with the diethynyl-linked dimer $\{nido\text{-}Cp^*Co[Et_2C_2B_3H_3(C{\equiv}CSiMe_3)(C{\equiv}C)]\}_2$. Although **16** is assumed to form in solution as a mixture of the nonchiral (*meso*) and chiral forms (Scheme 3),[13] the differences in proton NMR signals of these isomers are not detectable in our spectra. Compound **16** is multifunctional, having two $-C{\equiv}CSiMe_3$ groups that are convertible to $-C{\equiv}CH$ for use in subsequent metal-catalyzed linkage, as well as two C_2B_3 end rings that are available for deprotonation and multidecker stacking (vide supra).

Conclusion

This work combines small-metallacarborane synthetic chemistry with approaches that have been developed elsewhere for preparing alkynyl-linked organometallic complexes, to generate novel alkyne-connected bis(metallacarborane) systems that are designed as building-blocks for the assembly of multimetallic extended systems. For convenience and ease of compound characterization by NMR spectroscopy, the target compounds selected in the current study are diamagnetic systems incorporating Co^{III}, which should be readily convertible by redox or electrochemistry to paramagnetic complexes; the nature and extent of electron delocalization in such systems[3] are a prime focus of interest in our laboratory. Investigations in this area are continuing and will be reported in due course.

Experimental Section

Materials and Procedures: Unless otherwise stated, all reactions were performed under dry nitrogen, maintained by standard glove box and Schlenk techniques. Workup of products was generally carried out in air using benchtop techniques. Solvents were distilled from appropriate drying agents under an inert gas. $C_5Me_4H(C{\equiv}CSiMe_3)$ (**1**) was prepared according to a literature method.[8] The carborane $Et_2C_2B_4H_6$ was prepared on a multigram scale by the reaction of B_5H_9 and 3-hexyne in diethyl ether solution, in a modification[14] of the literature method.[15] – ^1H, ^{11}B, and ^{13}C NMR spectra were obtained at 25 °C at 300, 115.8, and 75.5 MHz, respectively.

$(C_5Me_4\text{-}C{\equiv}CSiMe_3)Co(Et_2C_2B_4H_4)$ (4): A sample of $C_5Me_4H(C{\equiv}CSiMe_3)$ (**1**; 2.20 g, 10.1 mmol) was placed in a 100-mL Schlenk flask, 50 mL of dry THF was added, and the solution was cooled to 0 °C in an ice bath. Addition of *n*-butyllithium in hexanes (6.40 mL, 1.54 M, 10.0 mmol) produced a bright yellow

solution of Li[$C_5Me_4(C{\equiv}CSiMe_3)$] (**2**), which was warmed to room temperature and stirred for 1 h, after which it was slowly added via cannula to a 250-mL Schlenk flask containing $CoCl_2$ (1.31 g, 10.1 mmol) and 100 mL of dry THF. The reaction mixture was stirred at room temperature for 1 h, producing a dark green solution of the complex $[C_5Me_4(C{\equiv}CSiMe_3)CoCl]_2$ (**3**). A solution containing 10.0 mmol of $Na^+[Et_2C_2B_4H_5]^-$ was prepared by injecting the neutral carborane (1.32 g, 10.1 mmol) into a suspension of excess (0.40 g) dry NaH (previously washed twice with hexane) in 20 mL of dry THF. Stirring was continued until bubbling ceased, the suspension was allowed to settle for 30 min, and the solution was transferred to the stirred solution of **3** by slow cannula filtration. The reaction mixture was stirred at room temperature overnight, forming a reddish-brown solution from which the volatiles were removed, leaving a dark brown solid. The product was extracted with CH_2Cl_2 and then passed through a plug (3 cm) of silica gel using CH_2Cl_2 as the eluent. Solvent removal gave a reddish-brown oil which solidified on standing to yield 1.30 g (32%) of **4**. − ^{1}H NMR ($CDCl_3$): δ = 2.62 (m, 2 H, CH_2), 2.26 (m, 2 H, CH_2), 1.89 (s, 6 H, C_5Me_4), 1.87 (s, 6 H, C_5Me_4), 1.23 (t, 6 H, Et CH_3), 0.27 (s, 9 H, $SiMe_3$). − ^{13}C NMR ($CDCl_3$): δ = 99.2 (C≡C), 97.4 (C≡C), 93.7 (C_5Me_4), 92.0 (C_5Me_4), 77.7 (C_5Me_4), 21.0 (Et CH_2), 14.7 (Et CH_3), 11.0 (C_5Me_4), 10.4 (C_5Me_4), −0.1 ($SiMe_3$). − CI^+ MS (CH_4): *m*/*z* (%) = 407 (100) $[M + 1]^+$.

***nido*-(η^5-C_5Me_4−C≡C−$SiMe_3$)Co($Et_2C_2B_3H_5$) (5) and (η^5-C_5Me_4−C≡CH)Co($Et_2C_2B_3H_5$) (6):** To a solution of 0.900 g (2.22 mmol) of **4** in 15 mL of TMEDA were added a few drops of water, and the mixture was stirred at room temperature for 3 h in air. The solvent was removed in vacuo and the product was taken up in hexane and purified by flashing through a 12-cm column of silica gel with hexane as the eluent. Removal of the solvent gave a yellowish-brown oil which on standing gave 0.755 g (86%) of yellow solid **5**. − ^{13}C NMR ($CDCl_3$): δ = 99.2 (C≡C), 98.2 (C≡C), 96.1 (C_5Me_4), 93.8 (C_5Me_4), 80.3 (C_5Me_4), 22.1 (Et CH_2), 17.1 (Et CH_3), 11.3 (C_5Me_4), 11.0 (C_5Me_4), 0.6 ($SiMe_3$). − Compound **5** (0.755 g, 1.91 mmol) was dissolved in 30 mL of dry THF and the resulting solution was cooled to 0 °C. A solution of Bu_4NF (1.0 mL, 1.0 M in THF) was added dropwise and the reaction mixture was stirred at 0 °C for 1 h in air, warmed to room temperature, and stirred for 30 min. The solvent was removed using a rotary evaporator and the product was subsequently taken up in CH_2Cl_2 and placed on a 12-cm column of silica gel and eluted with hexanes, giving a yellow solution. The solvent was removed in vacuo leaving a yellowish-brown oil which solidified on standing to afford 0.504 g (82%) of yellow **6**. − ^{1}H NMR ($CDCl_3$): δ = 3.05 (s, 1 H, C≡CH), 2.12 (m, 2 H, CH_2), 1.98 (m, 2 H, CH_2), 1.87 (s, 6 H, C_5Me_4), 1.85 (s, 6 H, C_5Me_4), 1.11 (t, 6 H, Et CH_3), −5.86 (broad s, 2 H, BHB). − ^{13}C NMR ($CDCl_3$): δ = 96.2 (*C*≡*C*), 94.0 (*C*≡*C*), 80.6 (C_5Me_4), 79.1 (C_5Me_4), 22.4 (Et CH_2), 17.2 (Et CH_3), 11.1 (C_5Me_4), 11.0 (C_5Me_4). − ^{11}B NMR (C_6D_6): δ = 3.9 (d, 2 B, J_{BH} = 158 Hz), 6.8 (d, 1 B, J_{BH} = 98 Hz). − CI^+ MS (CH_4): *m*/*z* (%) = 324 (100) $[M^+]$.

1,4-[*nido*-($Et_2C_2B_3H_5$)Co(η^5-C_5Me_4−C≡C)]$_2C_6H_4$ (7) and [*nido*-($Et_2C_2B_3H_5$)Co(C_5Me_4−C≡C)]$_2$ (8): Compound **6** (0.445 g, 1.37 mmol), diiodobenzene (0.277 g, 0.687 mmol), bis(benzonitrile-)palladium (II) chloride (0.0132 g, 0.0344 mmol), copper(I) iodide (0.0131 g, 0.0687 mmol), and triphenylphosphane (0.018 g, 0.0687 mmol) were placed in a Schlenk flask, vacuum-degassed and placed under N_2. Ca. 50 mL of dry diethylamine (freshly distilled from CaH_2) was added via cannula and the reaction mixture was stirred at room temperature for 36 h. The solvent was removed under vacuum and the resulting crude product was chromatographed on silica gel with CH_2Cl_2/hexane (1:5). The first product to elute was **7**, which was obtained as a yellow-brown solid (0.43 g, 87%) upon solvent removal. Recrystallization of **7** from CH_2Cl_2/hexane gave crystals suitable for X-ray analysis. − ^{1}H NMR ($CDCl_3$): δ = 7.46 (s, 4 H, C_6H_4), 2.14 (m, 4 H, Et CH_2), 2.03 (m, 4 H, Et CH_2), 1.95 (s, 12 H, C_5Me_4), 1.87 (s, 12 H, C_5Me_4), 1.12 (t, 12 H, Et CH_3), −5.86 (broad s, 4 H, BHB). − ^{13}C NMR ($CDCl_3$): δ = 131.0 (C_6H_4), 122.8 (C_6H_4), 95.0 (C_5Me_4), 93.3 (C_5Me_4), 91.8 (C_5Me_4), 84.7 (C≡C), 79.2 (C≡C), 21.8 (Et CH_2), 16.4 (Et CH_3), 10.5 (C_5Me_4). − ^{11}B {^{1}H} NMR (C_6D_6): δ = 4.0 (s, 2 B), 6.8 (s, 1 B). − CI^+ MS (CH_4): *m*/*z* (%) = 722 (100) $[M^+]$. − The second compound eluted was **8**, which was isolated as a yellow−brown solid (ca. 20 mg, 4%) upon solvent removal. Attempts to recrystallize **8** were unsuccessful and resulted in decomposition of the product. − ^{1}H NMR ($CDCl_3$): δ = 2.15 (m, 4 H, Et CH_2), 2.05 (m, 4 H, Et CH_2), 1.92 (s, 12 H, C_5Me_4), 1.87 (s, 12 H, C_5Me_4), 1.15 (t, 12 H, Et CH_3), −5.85 (broad s, 4 H, BHB). − CI^+ MS (CH_4): *m*/*z* (%) = 647 (100) $[M + 1]^+$.

X-ray Crystallographic Study of 7: $C_{40}H_{58}B_6Co_2$ (721.62); monoclinic space group $P2_1/n$ (no. 14); a = 9.139(3), b = 16.423(5), c = 12.841(5) Å, β = 93.78(3)°, V = 1923(1) Å^3, Z = 2, $d_{calcd.}$ = 1.246 g/cm^3; μ(Mo-K_α) = 8.90 cm^{-1}. Data were collected with a Rigaku AFC6S diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) at −120 °C, employing an orange needle crystal having approximate dimensions of 0.28 × 0.24 × 0.48 mm mounted on a glass fiber. The ω-2θ scan technique was employed to a maximum 2θ value of 46°. Of 2978 measured reflections, 2782 were independent (R_{int} = 0.041, R_w = 0.065), 217 parameters, R = 0.047 [for reflections with $I > 3\sigma(I)$], max./min residual electron density 1.10/−0.049 e·Å^{-3}. The data were corrected for absorption, with transmission factors ranging from 0.93 to 1.00. The structure was solved by direct methods.[16] The final cycle of full-matrix least-squares refinement was based on 1875 observed reflections [$I > 3\sigma(I)$]. Hydrogen atoms were included but not refined. Neutral atom scattering factors were taken from Cromer and Waber.[17] All calculations were performed using the teXsan crystallographic software package of Molecular Structure Corporation.[18] Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-160497. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

***nido*-[($Et_2C_2B_3H_4Me$)Co(C_5Me_4-C≡C)]$_2C_6H_4$ (9):** Compound **7** (0.549 g, 0.761 mmol) was dissolved in 50 mL of dry THF and the solution was cooled to −78 °C using a dry ice/acetone bath. A solution of $(Me_3Si)_2NLi$ (1.70 mL, 2.2 mmol, 1.0 M in THF) was added dropwise producing a yellowish-brown precipitate. Upon warming to room temperature the precipitate dissolved and the resulting solution was stirred at room temperature for 1 h. Methyl iodide (0.216 g, 1.522 mmol) was added dropwise via a syringe and stirred at room temperature for 3 h. The solvent was removed in vacuo and the product was extracted with a small amount of CH_2Cl_2 which was then passed through a plug of silica gel. Removal of solvent gave yellow solid **9** (0.450 g, 80%). − ^{1}H NMR ($CDCl_3$): δ = 7.46 (s, 4 H, C_6H_4), 2.20 (m, 4 H, Et CH_2), 2.00 (m, 4 H, Et CH_2), 1.95 (s, 12 H, C_5Me_4), 1.81 (s, 12 H, C_5Me_4), 1.26 (s, 6 H, B-Me), 1.10 (t, 12 H, Et CH_3), −5.13 (broad s, 4 H, BHB). − CI^+ MS (CH_4): *m*/*z* (%) = 750 (100) $[M^+]$.

Metalated 1,3-Azaphospholes: *1H*-1,3-Benzazaphosphole and 1,3-Benzazaphospholide Tungsten(0) and Tungsten(II) Complexes

Joachim Heinicke,*[a] Anushka Surana,[a] Normen Peulecke,[a] Raj Kumar Bansal,[b] Alexander Murso,[c] and Dietmar Stalke[c]

Keywords: Phosphorus heterocycles / Tungsten / Metalation

2-*tert*-Butyl-1*H*-1,3-benzazaphosphole (**1a**) reacts with *t*BuLi without addition to the P=C bond to form a lithium benzazaphospholide that affords the η^1-(benzazaphospholide-*P*)tungsten(II) complex **2** upon reaction with [CpW(CO)$_3$Cl]. It is sensitive to alcoholysis and to air oxidation yielding **1a** and the *P*-oxo-benzazaphospholide complex **3**, respectively. The (1,3-benzazaphosphole)pentacarbonyltungsten complex **4**, obtained from **1b** and [W(CO)$_5$(THF)], reacts preferentially with *t*BuLi by lithiation of the NH function and is attacked by [CpW(CO)$_3$Cl] at phosphorus to give the mixed valence bimetallic tungsten(II)-tungsten(0) benzazaphospholide complex **5**. A side product, (3-*tert*-butyl-2-methyl-1,3-benzazaphosphole)pentacarbonyltungsten (**6**), is attributed to side-reaction where *t*BuLi adds to the P=C bond in **4**. The composition of the products was determined from X-ray structure analysis of **3** and spectroscopic data.

Introduction

Phospholide[1−4] and pyrrolide[3−6] complexes have attracted considerable interest in the past years, and some di- and triazaphosphol(id)e complexes have also been reported.[7] Azaphospholide complexes, analogues of pyrrolide or of diphospholide complexes, as well as 1,3-benzazaphospholide complexes are, however, still unknown. The recent discovery of a convenient synthetic access to 2-substituted 1*H*-1,3-benzazaphospholes[8] prompted us to fill this gap partly and to explore the reactivity and use of these very stable but under-investigated phosphaaromatic heterocycles as ligands.[8−11] The only 1,3-benzazaphosphole complex reported to date is pentacarbonyl-η^1-(2-phenyl-1,3-benzazaphosphole-*P*)chromium.[10] Lithiation of 2-phenylbenzazaphosphole by Et$_2$NLi has also been described,[10] although the lithium benzazaphospholide was not isolated and separated from the secondary amine, which is preferentially attacked by electrophiles other than alkyl halides. We report here on an alternative metalation procedure avoiding this problem and the synthesis of the first 1,3-benzazaphosphole and 1,3-benzazaphospholide tungsten complexes.

Results and Discussion

Synthesis

Whilst 1*H*-1,3-benzazaphospholes and *n*BuLi produce mixtures of addition and metalation products, a selective monolithiation of the NH function is achieved by treatment of **1a** with one equivalent of *t*BuLi in ether or THF at low temperature. Like ambident anions formed by the metalation of pyridylphosphanes,[12] the resulting lithium 1,3-benzazaphospholide **Li-1a** can be used directly for the synthesis of complexes as exemplified by the reaction with [CpW(CO)$_3$Cl] (Scheme 1). **Li-1a** reacts selectively at phosphorus to give the dark red-brown benzazaphospholide tungsten complex **2**. It is slightly soluble in hexane and readily soluble in more polar solvents like toluene or ethers. Like related Cp(CO)$_3$W-phospholide[13−15] or Cp(CO)$_3$W-phosphide[16] complexes, **2** is a very reactive compound. Although less sensitive towards hydrolysis than the extremely reactive *N*-silyl- or *P*-stannyl-benzazaphospholes,[17] the P−W bond of **2** is cleaved readily by OH/OD reagents, as shown by the addition of CD$_3$OD to yield **1b**. The latter is also formed on heating **2** to 80 °C in toluene for one day, whereas related but more stable Cp(CO)$_3$W complexes with non-anellated phospholide ligands form tungsten-bridged complexes.[15] Compound **2** is also sensitive to air oxidation. Crystallization of a sample oxidized in THF gave single crystals of the toluene monosolvate of the *P*-oxo-benzazaphospholide tungsten complex **3**, from toluene/hexane, which allowed an X-ray crystal structure analysis (Figure 1).

The (1,3-benzazaphosphole)pentacarbonyltungsten complex **4**, obtained from **1b** and [W(CO)$_5$(THF)], can be lithiated in an analogous manner with *tert*-butyllithium and trapped with [CpW(CO)$_3$Cl]. The formation of the mixed valence bimetallic complex **5**, with zero- and two-valent

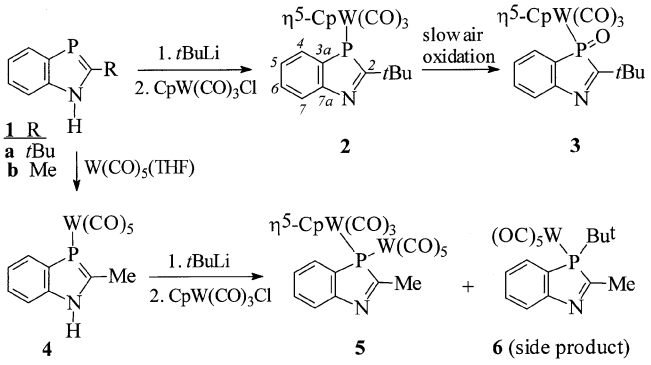

Scheme 1

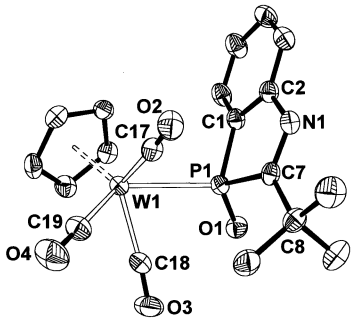

Figure 1. Solid state structure of **3** (anisotropic displacement parameters drawn at 50% probability level, hydrogen atoms and toluene omitted for clarity); selected bond lengths [Å] and angles[°]: W1−P1 2.5591(7), W−C(O) 1.989(3) − 2.005(3), W−C(Cp) 2.314(3) − 2.361(3), P1−O1 1.507(2); W1−P1−O1 116.91(8), O1−P1−C1 114.18(12), O1−P1−C7 113.32(12), W1−P1−C1 107.79(9), W1−P1−C7 113.12(8), P1−W1−C17 78.03(8), P1−W1−C18 73.43(8), C17−W1−C19 76.77(12), C19−W1−C18 77.28(12); for ring parameters see Table 1

tungsten bound at the phosphorus atom, shows that the blockage of the phosphorus lone electron pair does not favor an attack at nitrogen, but that the lithiated pentacarbonyl tungsten complex **Li·4** also prefers substitution at the softer nucleophilic site. The lithiation itself proceeds less selectively, as seen from the occurrence of **6**. It is assumed that **6** is formed by the addition of *t*BuLi to the P=C double bond of **4** followed by reaction with [$CpW(CO)_3Cl$] and elimination of [$CpW(CO)_3H$]. In the crude product the ratio **5**:**6** was found to be ca. 2:1.

Structure

The ^1H, ^{13}C and ^{31}P NMR chemical shifts and coupling patterns, the observance of molecular ions in the mass spectrum and satisfactory elemental analysis give evidence for the structures of **2**, **4** and **5**. Like related $Cp(CO)_3W$-phospholide complexes,[15] compound **2** ($\delta = -102.4$, $^1J_{P-W} = 50.1$ Hz) reveals a strong up-field coordination shift $\Delta\delta$(**2**−**Li·1a**) = −159 and a very small one-bond P−W coupling constant. The acyclic [$Cp(CO)_3W-PPh_2$] ($\delta = -63.3$, $^1J_{P-W} = 52$ Hz)[16] exhibits a similar low P−W coupling constant, but a much smaller upfield coordination shift relative to the corresponding alkali metal phosphides (Ph_2PLi: $\delta = -21.4$[18]). The larger upfield coordination shift in the formal 6π- or 10π-heterocyclic phosphido complexes with the same ML_n fragment reflects a larger increase in the electron density at phosphorus and may be attributed to a reduced ability of the π-electrons at phosphorus to take part in cyclodelocalization; it may also be supported by a more effective back donation compared to that in $Ph_2P-W(CO)_3Cp$ or in the $W^0(CO)_5$-benzazaphosphole complex **4**. The ^{13}C nuclei of the five-membered ring and of C-5 to C-7 are markedly deshielded by the complexation, $\Delta\delta$(**2**−**1a**) ≈ 20 (C-2), 12 (C-3a, C-7, C-7a) and 7 (C-5, C-6), whilst the one-bond P−C couplings show different trends, $^1J_{P-C2}$ increases from 57 Hz in **1a** to 61.8 Hz in **2**, and $^1J_{P-C3a}$ decreases from 41 to 14 Hz. The chemical shift values are significantly closer to those of 3*H*-1,3-benzazaphospholes[17,19,20] than to those of **1** although the one-bond coupling constants of **2** are significantly larger than in the 3*H*-isomers. These findings imply that the nature of **2** is in-between that of the aromatic 1*H*- and the non-aromatic 3*H*-3-alkyl-1,3-benzazaphospholes,[21−23] although probably closer to the latter. For the related phospholide $CpW(CO)_3$ complexes a similar situation was deduced from the X-ray crystal structure analysis.[15] The compounds were classified from the structural standpoint as halfway between phospholes with pyramidal P and localized π-bonds and phospholes with planar P and delocalized π-bonds.

In the oxidation product **3** the framework of **2** is preserved (Figure 1) but the transition to four-coordinate phosphorus consolidates a non-aromatic, 3*H*-indole-like π-system. The lack of cyclodelocalization becomes evident by comparison of selected bond lengths and angles of the five-membered ring in **3** and the corresponding parameters of its phosphaaromatic precursor **1a**[17] (Table 1). Within the P−C−N fragment the P−C bond is considerably widened and becomes longer than the P−C(aryl) bond, whilst the C−N bond is shortened. The smaller N1−C7 bond and the approximation of the C1−C2−N angle in **3** to an ideal sp^2 geometry at the expense of the C2−C1−P angle reflects the strengthening of a coplanar *N*-phenyl-azomethine π-system. In the acyclic metallaphosphane oxide [$oTol_2P(O)-W(CO)_3Cp$],[16b] the P1−W1 distances of the two independent molecules in the unit cell are slightly longer [2.571(8), 2.589(9) Å] than in **3**, although shorter than the sum of the covalent radii (2.65 Å),[24] and the P−O bonds (double bond character) are slightly shorter [1.46(2), 1.49(2) Å]. The W−P−O angle is larger in **3** due to the small C−P−C angle within the five-membered ring.

The known compound η^1-(2-phenyl-1,3-benzazaphosphole-*P*)pentacarbonylchromium exhibits a very low positive complexation shift ($\Delta\delta = 4.4$) and classifies 1*H*-1,3-benzazaphospholes as weak donors.[10] The tungsten pentacarbonyl complex **4** even displays a negative coordination shift ($\Delta\delta = -35.0$). The upfield shift of the tungsten relative to the related chromium complex reflects the typical core-effect in transition metal phosphane complexes[25] and is also observed for related (phosphaindolizine)metallapentacarbonyls (M = Cr, Mo, W).[26] The one bond $^{31}P-^{183}W$ coupling constant is much larger than in **2**, **5** and **6** and

similar to that in pentacarbonyltungsten complexes of less-basic triorganophosphanes.[25] The effect of the complexation on the 1*H*-1,3-benzazaphosphole π-system is rather small and limited mainly to the carbon atoms adjacent to phosphorus. C-2 and C-3a of **4** are shifted by $\Delta\delta \approx 7$ in the ^{13}C NMR spectrum and display much lower P−C coupling constants. For C-4 and the methyl carbon in the β-position to the phosphorus this trend is much smaller, and the other nuclei show no marked influence. In the tungsten complexes **5** and **6**, however, the cyclodelocalization seems to be lost. Both, the tungsten(II)- and the 3-*tert*-butyl-substituted 1,3-benzazaphosphole tungsten pentacarbonyl species, exhibit the signals of the ^{13}C nuclei C-5 to C-7a at significantly lower field than in **1** or **4**, in regions typical for 3-alkyl-1,3-benzazaphospholes.[17,19,20] The phosphido-character of the benzazaphospholide ligand is markedly reduced by complexation with $W(CO)_5$ as indicated by the less-negative phosphorus resonance of **5** relative to **2** ($\Delta\delta$ = 26.4) and the increased $^1J_{P-W}{}^{II}$ coupling constant, whereas $^1J_{P-W}{}^0$ is smaller than in **4** and **6** due to the higher donor strength of the benzazaphospholide relative to the 1*H*- and 3*H*-1,3-benzazaphospholes.

Conclusion

The aim of this work was to investigate the metalation of 1*H*-1,3-benzazaphospholes and to present novel 1,3-benzazaphospholide complexes as P−C homologues of indolides. It was shown that 1*H*-1,3-benzazaphospholes and tungsten pentacarbonyl complexes, represented by **1a** and **4**, may be lithiated by *t*BuLi selectively or preferentially at the NH function. The resulting ambident 1,3-benzazaphospholide anions react with the $[CpW(CO)_3Cl]$ exclusively at the softer nucleophilic site and furnish the η^1-*P*-coordinated tungsten(II) complex **2** and the mixed valence bimetallic tungsten(II)-tungsten(0) species **5**. The benzazaphospholide complexes are sensitive to hydrolysis and oxidation. A crystal structure analysis of the benzazaphospholide oxide complex **3** (toluene monosolvate) gave evidence of the molecular composition and, by comparing the bond lengths with those of **1a**, of a non-aromatic, 3*H*-indole-like π-system. The P-tetracoordinated di-tungsten complex **5** and the side product **6**, a 3-alkyl-benzazaphosphole $W(CO)_5$ complex, reveal ^{13}C NMR spectroscopic data which likewise are in accordance with a non-aromatic nature. Compound **2** is a borderline case: its carbon chemical shifts resemble those of 3*H*-1,3-benzazaphospholes whilst the magnitude of the $^1J_{P-C2}$ coupling constant is significantly larger. Only the electronic structure of the neutral benzazaphosphole $W(CO)_5$ complex **4** is similar to that in the phosphaaromatic heterocycles **1**.

Experimental Section

General: All manipulations were carried out under an atmosphere of dry argon using standard Schlenk and cannula techniques. Ether, THF and hydrocarbons were refluxed over sodium/benzophenone and distilled prior to use. C_6D_6 and $[D_8]$THF were dried with sodium or $LiAlH_4$ and recondensed. NMR spectra were recorded on a multinuclear FT NMR spectrometer Bruker Model ARX300 at 300.1 (^1H), 75.5 (^{13}C), and 121.5 (^{31}P) MHz. The ^1H, ^{13}C and ^{31}P chemical shifts are δ values relative to Me_4Si or H_3PO_4 (85%); coupling constants are quoted in Hz. IR spectra were measured on a Perkin−Elmer Model system 2000 and mass spectra on a single-focussing mass spectrometer AMD40 (Intectra). Melting points were determined in sealed capillaries under argon and are uncorrected. Elemental analyses were carried out using an elemental analyzer LECO Model CHNS-932 with standard combustion conditions (carbon combustion sometimes incomplete) and handling of the samples in air.

Materials: Compounds **1a** and **1b** were synthesized as reported recently;[8] $[W(CO)_5(THF)]$ and $[CpW(CO)_3Cl]$ were obtained by known procedures.[27] Other materials were used as purchased unless stated otherwise.

η^5-(2-*tert*-Butyl-1,3-benzazaphosphol-3-yl-*P*)(η^5-cyclopentadienyl)-tricarbonyltungsten (2): A solution of **1a** (290.6 mg, 1.52 mmol) in ether was cooled to −78 °C and lithiated with an equimolar amount of *t*BuLi dissolved in pentane (^{31}P NMR in $[D_8]$THF: δ = 56.6). After 30 min. a solution of $[CpW(CO)_3Cl]$ (560 mg, 1.52 mmol) in ether was added (−78 °C) affording a red brown mixture. This was allowed to warm to room temperature and stirred for one day. The precipitate was then removed, and the solvent was evaporated in vacuo. The residue was crystallized from hot toluene affording 614 mg (77%) of red solid **2**, slightly contaminated by **1a**. It is insoluble in hexane, m.p. 80−83 °C. − ^1H NMR ($[D_8]$THF): δ = 1.41 (d, $^4J_{P-H}$ = 0.6, 9 H, CMe_3), 5.34 (s, 5 H, Cp), 7.08 ("t"dd, ^3J = 7.5, $^4J_{P-H}$ = 3.3, ^4J = 1.2, 1 H, H-5), 7.22 (m, ^3J = 7.4, 7.7, $^4J \approx {}^5J_{P-H} \approx 1$, 1 H, H-6), 7.75 (br. d, ^3J = 7.7 Hz, 1 H) and 7.78 (d, ^3J = 8.1, 1 H) (H-4 and H-7). − $^{13}C\{^1H\}$ NMR ($[D_8]$THF): δ = 32.2 (d, ^3J = 5.6, C*Me*$_3$), 40.7 (d, ^2J = 20.3, *C*Me$_3$), 94.3 (Cp), 123.8 (d, ^3J = 6, C-5), 124.7 (C-7), 126.3 (C-6), 127.1 (d, ^2J = 20, C-4), 150.3 (d, ^1J = 14, C-3a), 155.5 (d, ^2J = 9, C-7a), 209.3 (d, ^1J = 62, C-2), 214.9, 218.3, 233.4 (3 CO). − $^{31}P\{^1H\}$ NMR ($[D_8]$THF): δ = −102.4 ($^1J_{P-W}$ = 50.1). − EI-MS (70 eV): *m*/*z* (%) = 523 (23) [M^+ (^{184}W)], 480 (27), 455 (44), 196 (72), 184 (93), 28 (100). − $C_{19}H_{18}NO_3PW$ (523.17): calcd. C 43.62, H 3.47, N 2.68; found C 40.52, H 3.50, N 2.47.

η^5-(2-*tert*-Butyl-3-oxo-1,3-benzazaphosphol-3-yl-*P*)(η^5-cyclopentadienyl)tricarbonyltungsten Toluene Monosolvate (3): A small amount of **2** dissolved in THF was oxidized by allowing slow diffusion of air into the Schlenk tube. Since addition of hexane failed

to give a precipitate the solvent was removed in vacuum and replaced by toluene. On addition of hexane small, pale-yellow single crystals of the toluene monosolvate **3** deposited at +4 °C within 3 days (yield not determined). The crystal and molecular structure was determined by X-ray diffraction (Table 1, Figure 1). – ^{1}H NMR (C_6D_6): δ = 1.71 (s, 9 H, CMe_3), 2.11 (s, 3 H, toluene), 4.60 (s, 5 H, Cp), 6.93 (ddd, ^3J = 7.1, J_{P-H} = 3.6, ^4J = 1.3, 1 H, 4- or 7-H), 6.97–7.13 (m, toluene), 7.05 and 7.40 (both "t"m, $^3J \approx$ 6, 7, 5- and 6-H, partially superimposed by C_6D_6 side band), 7.65 (ddd, ca. ^3J = 7.2, J = 2, 1, 1 H, 7- or 4-H). – ^{31}P{^{1}H} NMR ([D_8]THF): δ = 61.3 ($^1J_{P-W}$ = 135).

η^1-(2-Methyl-1*H*-1,3-benzazaphosphole-*P*)pentacarbonyltungsten (4): A solution of [W(CO)$_5$(THF)], prepared by irradiation of [W(CO)$_6$] (2.324 g, 6.60 mmol) in THF (300 mL; 145 mL of CO evolved), was added to a solution of **1b** (0.984 g, 6.60 mmol) in THF (5 mL). After one day at room temperature the solvent and volatile tungsten complexes were removed in vacuo and the residue fractionally extracted with hexane yielding in the later fractions 1.272 g (41%) of orange **4**, m.p. 122–124 °C. – ^{1}H NMR ($CDCl_3$): δ = 2.73 (d, $^3J_{P-H}$ = 17.8, 3 H, Me), 7.23 ("t"dd, $^3J \approx$ 7.6, 8, $^4J_{P-H}$ = 3.8, ^4J = 0.9, 1 H, H-5), 7.36 ("tt", $^3J \approx$ 7.6, $^5J_{P-H} \approx$ $^4J \approx$ 1.2, 1 H, H-6), 7.52 (d, ^3J = 8.6, 1 H, H-7), 7.87 ("t", $^3J \approx$ $^3J_{P-H} \approx$ 7.8, 1 H, H-4), 9.60 (br, 1 H, NH). – ^{1}H NMR (C_6D_6): δ = 2.04 (d, $^3J_{P-H}$ = 18, 3 H, Me), 6.98 (br. d, ^3J = 8.3, 1 H, H-7), 7.06 (dddd, ^3J = 7.0, 8.0, $^4J_{P-H}$ = 2.8, ^4J = 1.0, 1 H, H-5), 7.20 ("tt", ^3J = 8.3, 7.0, $^5J_{P-H} \approx$ $^4J \approx$ 1.3, 1 H, H-6), 7.98 ("t" br., $^3J \approx$ $^3J_{P-H} \approx$ 7, 8, 1 H, H-4). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 15.8 (d, ^2J = 15.0, Me), 114.3 (d, ^3J = 3.2, C-7), 121.4 (d, ^3J = 14.0, C-5), 125.8 (d, ^4J = 3.5, C-6), 126.5 (d, ^2J = 13.5, C-4), 136.3 (d, ^1J = 21.9, C-3a), 141.9 (s, C-7a), 167.6 (d, ^1J = 30.8, C-2), 194.6 (d sat, ^2J = 8.5, $^1J_{C-W}$= 124, 4 CO), 199.8 (d, ^2J = 29.1, 1 CO). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 36.7 (sat, $^1J_{P-W}$ = 242.6). – IR (Nujol): $\tilde{\nu}$ = 3405 m (NH), 2071 m, 1981 vs, 1946 vs, 1880 s (CO) cm^{-1}. – EI-MS (70 eV): *m*/*z* (%; data for ^{184}W) = 473 (80) [M$^+$], 445 (4), 417 (64) [M$^+$ – 2CO], 389 (68) [M$^+$ – 3CO], 361 (41) [M$^+$ – 4CO], 333 (62) [M$^+$ – 5CO], 149 (100) [**1b**$^+$], 148 (98). – $C_{13}H_8NO_5PW$ (473.02): calcd. C 33.01, H 1.70, N 2.96; found C 33.20, H 2.11, N 2.60.

η^1-{2-Methyl-3-[(η^5-cyclopentadienyl)tricarbonyltungsten]-1,3-benzazaphosphole-*P*}pentacarbonyltungsten (5) and η^1-(3-*tert*-Butyl-2-methyl-1,3-benzazaphosphole-*P*)pentacarbonyltungsten (6): [CpW(CO)$_3$Cl] (277 mg, 0.754 mmol) was added at –70 °C to a solution prepared from **4** (358 mg, 0.757 mmol) in ether (10 mL) and *t*BuLi in pentane (0.45 mL, 0.754 mmol) as described above. The mixture was allowed to stir at room temperature for 3 days. Then it was filtered and washed with ether. Removal of the solvent in vacuo afforded a mixture of **5** and **6** in a molar ratio of ca. 2:1 (based on ^{1}H integral ratio of the CH_3 signals) along with a small amount of unchanged **4**. Fractional crystallization with hexane and then with toluene gave 300 mg (49%) of **5** (from toluene) and 80 mg (20%) of **6** (from hexane) as red solids. Compound **6** was impure and identified by it's characteristic NMR spectroscopic data.

5: ^{1}H NMR ([D_8]THF): δ = 2.72 (d, ^3J = 7.4, 3 H, Me), 5.20 (d, J = 2.0, 5 H, Cp), 7.27–7.35 (m, 1 H H-5), 7.37 ("t", $^3J \approx$ 7.3, 1 H, H-6), 7.78 (d, ^3J = 7.6, 1 H, H-7), 7.85 (dd, ^3J = 6.7, $^3J_{P-H}$ = 5, 1 H, H-4). – ^{13}C{^{1}H} NMR ([D_8]THF): δ = 20.1 (d, ^2J = 28.8, Me), 94.9 (s, Cp), 124.7 (d, ^2J = 2.0, C-7), 126.7 (d, ^3J = 8.2, C-5), 127.3 (d, ^2J = 14.1, C-4), 129.9 (d, ^4J = 1.2, C-6), 148.4 (d, ^1J = 28.7, C-3a), 152.5 (d, ^2J = 16.6, C-7a), 193.1 (d, ^1J = 15.3, C-2), 198.6 (d, sat, ^2J = 5.4, $^1J_{C-W}$ = 126, 4 CO), 200.6 (d, ^2J = 18.3, 1 CO), 216.9 (d, ^2J = 17.7, 1 CO), 217.6 (d, ^2J = 18.2, 1 CO), 219.9 (d, ^2J = 5.5, 1 CO). – ^{31}P{^{1}H} NMR ([D_8]THF): δ = – 76.1 (sat, $^1J_{P-W}$ = 180.8, 90.8). – EI-MS (70 eV, 240 °C): *m*/*z* = 804 (34), [M$^+$ – 1 (^{184}W)], 776 (20), 749 (12) [M$^+$ – 2CO], 721 (32) [M$^+$ – 3CO], 683 (54) [M$^+$ – 2CO-Cp], 665 (100) [M$^+$ – 5CO], 645 (41), 625 (62), 604 (48), 396 (61), 341 (62), 309 (50), 149 (65). – $C_{21}H_{12}NO_8PW_2$ (804.77): calcd. C 31.34, H 1.50, N 1.74; found C 29.00, H 1.76, N 1.64.

6 (hexane): ^{1}H NMR ([D_8]THF): δ = 1.19 (d, ^3J = 16.1, 9 H, CMe_3), 2.63 (d, ^3J = 6.8 Hz, 3 H, Me), 7.41–7.45 (m, 1 H, H5), 7.54 ("tt", $^3J \approx$ 7.4, 7.8, $^4J \approx$ $^5J_{P-H} \approx$ 1.2, 1 H, H-6), 7.70–7.75 (m, 2 H, H-4, H-7). – ^{13}C{^{1}H} NMR ([D_8]THF): δ = 21.7 (d, ^2J = 15, Me), 124.7 (d, ^2J = 4, C-7), 127.8 (d, ^3J = 8.4, C-5), 130.2 (d, ^2J = 13.3, C-4), 132.5 (br., C-6), 133.5 (d, ^1J = 48.2, C-3a), 156.8 (d, ^2J = 16, C-7a), 181.3 (br., uncertain due to low intensity, C-2). – ^{31}P{^{1}H} NMR ([D_8]THF): δ = 50.8 (sat, $^1J_{P-W}$ = 216.4).

Crystal Data and Structure Determination for 3: The data set was collected at low temperature using an oil-coated shock-cooled crystal[28] on a Bruker APEX-CCD diffractometer equipped with Mo-K_α (λ = 71.073 pm) radiation and a low temperature device at 173(2) K. The structure was solved by Patterson methods (SHELXS-NT 97)[29] and refined by full-matrix least-squares methods against F^2 (SHELXL-NT 97).[30] R values defined as $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$, $w = [\sigma^2(F_o^2) + (g_1P)^2 + g_2P]^{-1}$, $P = 1/3[\max(F_o^2,0) + 2F_c^2]$. SADABS 2.0 was employed as the program for empirical absorption correction.[31]

3: $C_{26}H_{26}NO_4PW$, M = 631.30, monoclinic, space group $P2_1/n$, a = 11.3819(3), b = 10.4653(3), c = 21.1456(6) Å, β = 104.5600(10)°, V = 2.43787(12) nm^3, Z = 4, $\rho_{cal.}$ = 1.720 Mg/m^3, μ = 4.836 mm^{-1}, F(000) = 1240. 41621 reflections measured, 6055 unique, R(int) = 0.0383, $wR2$(all data) = 0.0545, $R1[I > 2\sigma(I)]$ = 0.0230, g_1 = 0.0301, g_2 = 0.8837 for 5742 data, 228 restraints and 363 parameters. In addition to the tungsten complex the unit cell contains a non-coordinating disordered toluene molecule. The occupancy factors of the solvent molecule refined to 0.788 and 0.272. The toluene molecule was assigned ideal positions and refined using ADP restraints. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the cyclopentadienyl ligand were taken from the difference Fourier map and refined freely, all other hydrogen atoms were geometrically idealized and refined using a riding model. Selected bond lengths and angles of **3** can be found in Table 1.

Crystallographic data for the structure of **3** has been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-161162. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Metal Complexes with Nitronyl Nitroxide Substituted Phenolate Ligands Providing New Magnetic Exchange Interaction Pathways − Synthesis, Structures, Magnetic Dilution Studies, and Ab Initio Calculations

Ulrich Schatzschneider,[a] Thomas Weyhermüller,[a] and Eva Rentschler*[a]

Keywords: Radicals / Nitronyl nitroxides / Copper / Nickel / Magnetic properties / Density functional calculations

The synthesis and magnetic properties of seven new nitronyl nitroxide substituted phenolates with chelating amine groups are reported. Copper(II) and nickel(II) complexes prepared with these ligands are structurally and magnetically characterized, showing exchange interactions between the metal and the radical ligands through the phenolate oxygen. Magnetically diluted samples are prepared by embedding the compounds in a poly(vinyl chloride) film to suppress intermolecular exchange interactions. This method is used for the first time in a quantitative way to separate intra- and intermolecular exchange interactions in radical-metal systems. The experimentally determined ground states are further confirmed by DFT calculations.

Introduction

In the preparation of molecular magnetic materials, transition metal complexes with organic radical ligands have found widespread interest in recent years. Research has focused on the nitronyl nitroxide family of radicals[1] since they are stable and easy to functionalize. A wide variety of transition metal complexes have been prepared with these ligands, most of them involving metal coordination to the NO groups. Since nitronyl nitroxide radicals are poor electron-donor ligands, the use of strongly electron-withdrawing coligands at the metal, like hexafluoroacetylacetonate, is required. The steric demand of these coligands restricts the dimensionality of the resulting metal-radical compounds. A large number of ring systems and infinite chain compounds have been prepared by this strategy,[2−4] but few showed ferromagnetic ordering at low temperatures due to small interchain interactions.[5−8] Only in the very last years has work been published in which the sterically demanding coligands are avoided. Functionalized nitronyl nitroxide radicals with electron-donating substituents like 2-pyridine, 2,2′-bipyridine, imidazole, benzimidazole, or 1,2,4-triazole were prepared.[9−22] In all cases the nitronyl nitroxide is in an *ortho* position to the aromatic nitrogen atom of the substituent and one NO group coordinates to the transition metal ion to form a chelate ring. This usually leads to small, discrete molecules, although some 1D- and 2D-systems were reported with imidazole-substituted nitronyl nitroxide ligands.[15,18] As we are interested in the magnetochemistry of spin systems of higher dimensionality, we were surprised that very few compounds are published in which the nitronyl nitroxide radicals are bound to transition metal ions by additional functional groups in the *para* position of the aromatic ring.[23−30] Even less work has been published in which a remarkable spin-exchange interaction between the unpaired electron of the nitronyl nitroxide and an open-shell transition metal ion, mediated by the functional group, is reported.[23,26,30] In order to try and work out a synthetic strategy to build up higher dimensional networks of radicals and transition metal ions in which the NO moiety and the functional group bind to different metal ions, we were prompted to use the phenolate group as a promising substituent. Although some nitronyl nitroxide

substituted phenols have been prepared in an approach to form purely organic ferromagnets,[31−37] their use as ligands for transition metals has not been explored. Since phenolates are fairly basic, a strong coordination towards metal ions is possible. Moreover, a delocalization pathway of the unpaired electron from the nitronyl nitroxide moiety onto the phenolic oxygen atom can be formulated (Scheme 1), leading to a spin-exchange interaction between the radical and a coordinated metal center.

We have synthesized a family of substituted nitronyl nitroxides with a phenolate group in the *para* position of the phenyl ring and an amine substituent in the *meta* position as an additional anchoring group (Scheme 2). This eliminates the need for coligands and leaves both the NO groups, as well as unoccupied coordination sites on the metal center, free for interconnection through bridging metal centers M′ or coligands L (Scheme 3a and 3b). In addition, oxidation of the phenolate group to a phenoxyl radical might lead to triplet radical ligands allowing the preparation of metal complexes in higher spin states (Scheme 3c). In this contribution, the synthesis and magnetic properties of seven new nitronyl nitroxide radicals are described. Copper(II) and nickel(II) compounds were prepared with these ligands. Their structural, magnetic, and electrochemical properties are reported here together with the results of density functional calculations. A method for the magnetic dilution of organic radicals as well as nitronyl nitroxide-metal complexes is quantified and applied to magnetic susceptibility measurements and EPR spectroscopy.

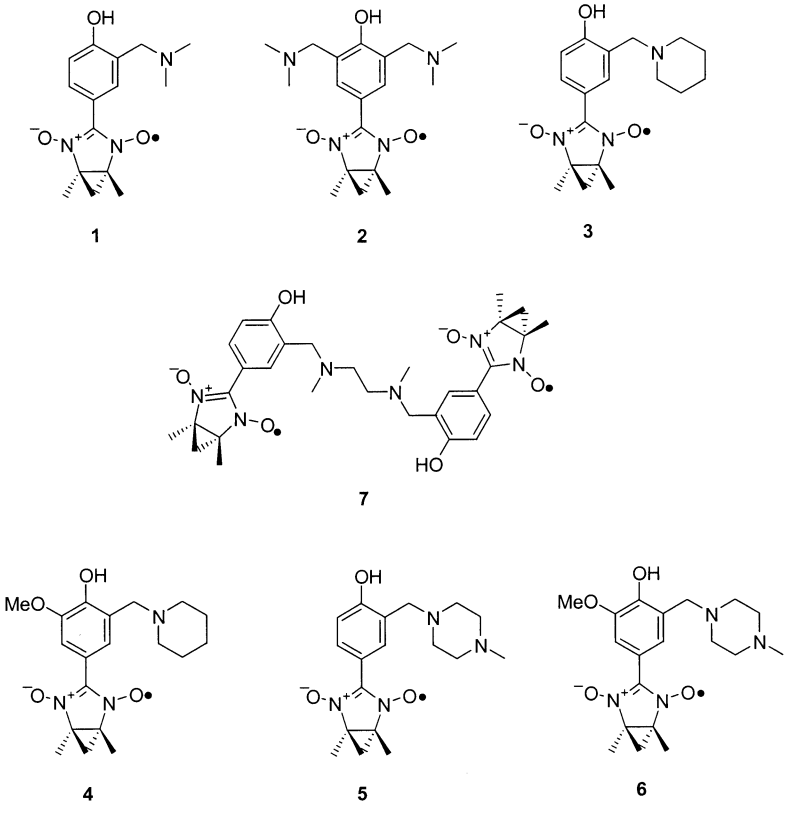
Results and Discussion

Synthesis

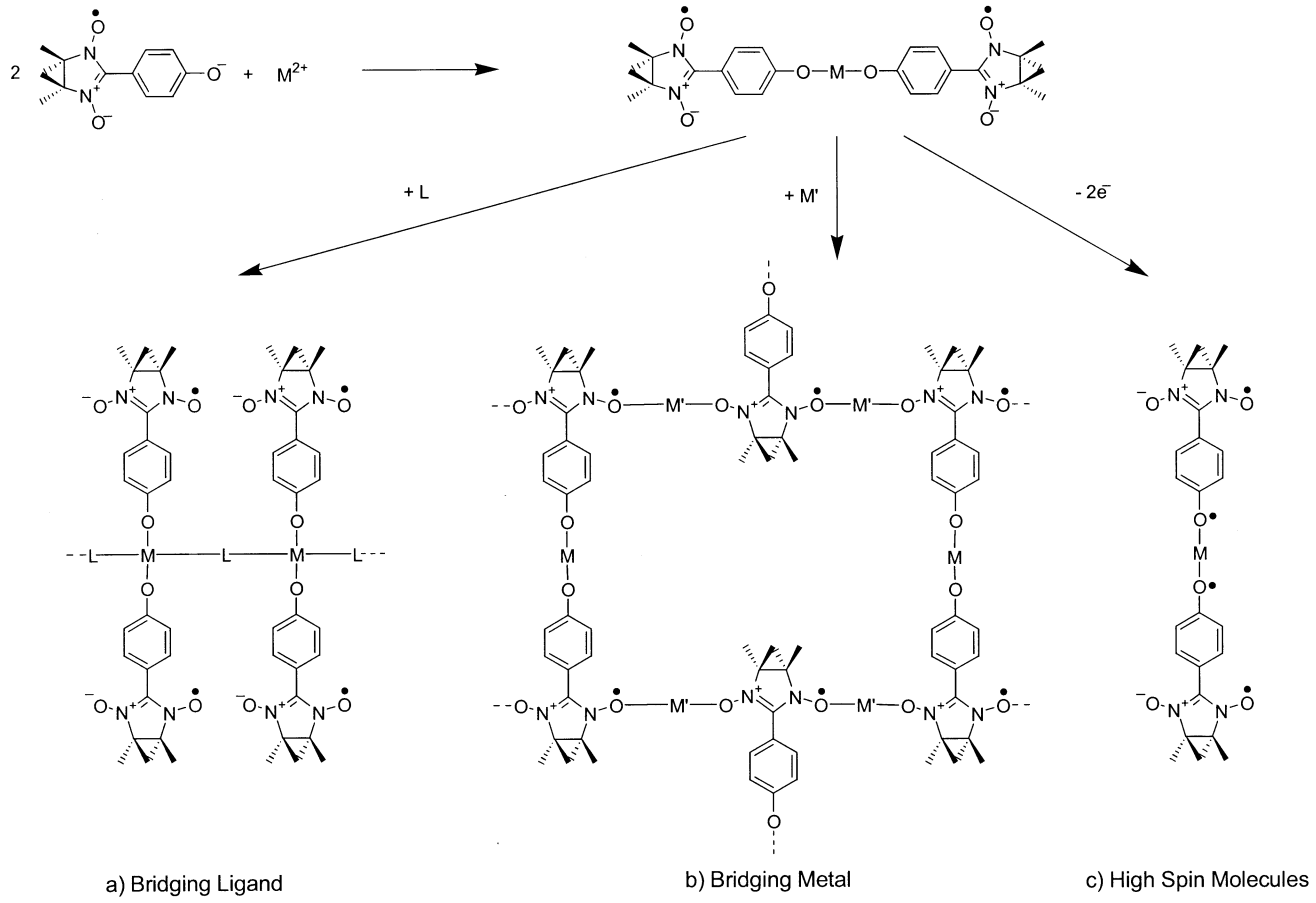
The nitronyl nitroxides **1**−**6** (see Scheme 2) were prepared by an aromatic Mannich reaction from 4-hydroxybenzaldehyde or vaniline, formaldehyde, and a secondary amine, followed by coupling of the resulting aldehyde with 2,3-bis(hydroxylamino)-2,3-dimethylbutane and oxidation, as described by Ullman et al.[38] In the cases of the piperidine- and piperazine-substituted compounds **3**−**6** the yields of the Mannich reaction were higher when the intermediate *N*-(alkoxymethyl)amines were prepared and purified separately. For the bis-nitronyl nitroxide ligand **7**, a different approach utilizing the reaction between 3-chloromethyl-4-hydroxybenzaldehyde and a secondary amine was employed to prevent the formation of polymeric by-products. This synthetic strategy allows the introduction of a wide variety of chelating amine substituents to accommodate different metal-binding preferences. The copper(II) and nickel(II) complexes **8**−**10** prepared with the nitronyl nitroxide ligands **1** and **3** precipitated upon the addition of anhydrous metal chlorides to a solution of the deprotonated ligand in dry methanol and can be separated from cocrystallized sodium chloride by simple recrystallization.

Magnetism and Crystal Structure of the Ligands

The magnetic properties of purely organic nitronyl nitroxide radicals are interesting in their own right, since the



Scheme 2. Prepared nitronyl nitroxide ligands **1** to **7**



Scheme 3. Substituted nitronyl nitroxides as building blocks for high-dimensional metal-radical assemblies by: a) bridging ligands, b) bridging metals, and c) high-spin molecules

β-phase of 4-nitrophenyl nitronyl nitroxide was the first organic ferromagnet reported.[39] Therefore, we measured the temperature dependence of the magnetic moment for compounds **1**−**7**. The susceptibility follows the Curie−Weiss law over the whole temperature range from room temperature down to 4 K with θ-Weiss constants of −0.56, −0.54, −2.00, −0.84, −0.96, and +0.58 K for **1**, **2**, **3**, **5**, **6**, and **7**, respectively. An exception is found for compound **4**, where the temperature dependence of the magnetic susceptibility clearly indicates a fairly strong overall antiferromagnetic exchange interaction of the radicals. As shown in Figure 1, the $\chi_M T$ product decreases from 0.34 emu·K·mol^{-1} at room temperature, steadily with decreasing temperature, to 0.02 emu·K·mol^{-1} at 4 K. To elucidate the intermolecular exchange interaction pathways operating in this system, and for uses as a reference guide for structural changes induced in the ligands when coordinated to transition metals, we determined the crystal structures of **1**, **3**, **4**, and **7**. The crystallographic data and details of the refinement procedures are collected in Table 1. All intramolecular bond lengths and angles of the five-membered rings are as expected and comparable to other substituted nitronyl nitroxides (see Tables S1 and S2 in the supporting information). The NO bond lengths of 1.275(5)−1.288(5) Å indicate delocalization of the unpaired electron over both NO groups. The molecular structure of **4** is depicted in Figure 2. As shown in Figure 3, the molecules are arranged in alternating chains along the *x* axes with remarkably short intermolecular contacts involving both NO groups of the nitronyl nitroxide. The distance O4···O4A is shortest (3.46 Å), although O1···O1A and N1···O1A are only slightly longer (3.69 Å

and 3.53 Å, respectively). The N1O1 groups are aligned antiparallel with angles N1−O1−N1A and O1−N1−O1A close to 90°, the two NO vectors thus forming a rectangle. The spin-carrying π*-orbitals are located in this plane with a distance between the NO vectors of 3.42 Å. A large overlap is therefore possible,[40,41] resulting in the observed strong antiferromagnetic exchange interaction.

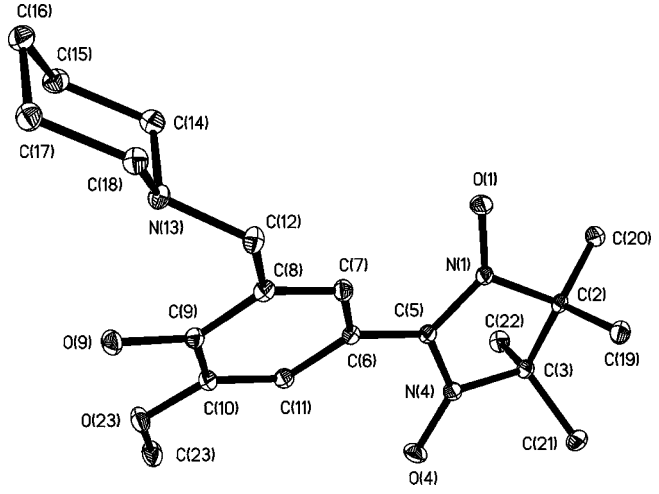

Figure 2. Molecular structure of **4**; ellipsoids are drawn at the 50% probability level

The magnetic susceptibility data can be interpreted in terms of two different models. First, assuming a dimer model with next-nearest neighbor interactions, the experimental data could be simulated applying the Heisenberg−Dirac−Van Vleck Hamiltonian [Equation (1)].

$$\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2 \quad (1)$$

The expression of magnetic susceptibility is given by Equation (2):

$$\chi_M = \frac{2N\beta^2 g^2}{3k(T-\Theta)}\left(1+\frac{1}{3\exp(-2J/kT)}\right)(1-\rho)+\left(\frac{N\beta^2 g^2}{2kT}\right)\rho \quad (2)$$

where N, g, β, k, T, Θ and ρ have their usual meanings. A least-squares fit to the magnetic susceptibility data gives the values $g = 2.00$ (fixed), $J = -21.47$ cm^{-1}, $\Theta = -4.42$ K, and $\rho = 0.066$ with $R = 1.14 \cdot 10^{-4}$ (Figure 1).

Alternatively, it was possible to fit the data according to the Heisenberg alternating chain model, with the appropriate Hamiltonian shown in Equation (3):

$$\hat{H} = -2J\sum_{i=1}^{n/2}[\hat{S}_{2i} \cdot \hat{S}_{2i-1} + \alpha\hat{S}_{2i} \cdot \hat{S}_{2i+1}] \quad (3)$$

where J and αJ are the two interaction parameters and α is the alternation parameter. The parameters $A-F$ in the expression for the magnetic susceptibility were calculated according to Hatfield et al. [Equation (4)]:[42]

$$\chi_m = \frac{N\beta^2 g^2}{kT}\frac{A+Bx+Cx^2}{1+Dx+Ex^2+Fx^3}(1-\rho)+\left(\frac{N\beta^2 g^2}{2kT}\right)\rho \quad (4)$$

with $x = |J|/(kT)$. The fit to data (inset in Figure 1) gave the parameters $g = 2.00$ (fixed), $|J| = 19.91$ cm^{-1}, $\alpha = 0.3$, and $\rho = 0.031$ with $R = 2.65 \cdot 10^{-4}$, which are in fairly good

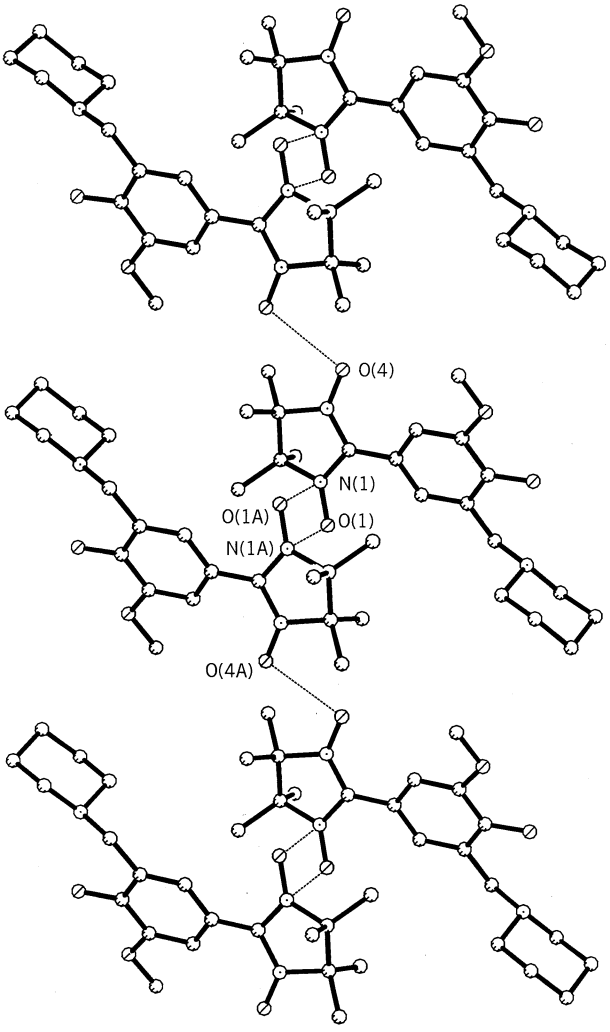

Figure 3. Molecular packing of **4** showing the intermolecular contacts between adjacent nitronyl nitroxide radicals

agreement with the parameters obtained with the previous model.

Magnetic Dilution

Since all the interactions are intermolecular in nature, compound **4** is an ideal candidate to improve a method of magnetic dilution in order to separate inter- and intramolecular exchange interactions. This experiment is essential in order to be able to analyze the transition metal complexes, in which intramolecular exchange interactions are small and have to be separated from intermolecular ones. For a pure organic radical like compound **4**, one expects to end up with an overall temperature dependence of the magnetic susceptibility of a simple paramagnet if it is possible to eliminate all intermolecular interactions. Compound **4** was therefore embedded in a poly(vinyl chloride) matrix of precisely determined weight. No chemical modification occurs during this process as proved by IR and UV/Vis spectroscopic measurements on the polymer films. The spectra obtained were identical for both the KBr disc and solution, except for additional IR bands resulting from vibrations of the polymer matrix. The diamagnetic correction for the poly(vinyl chloride) film was determined in a separate run of susceptibility measurement and subtracted from the χ_V probe measurement. The result for compound **4** is shown in Figure 1. As expected, the $\chi_M T$ product was found to be close to the theoretical value of 0.375 emu·K·mol^{-1} over the whole temperature range. The method can also be applied to EPR spectroscopy. The low temperature EPR spectrum of **4** embedded in a poly(vinyl chloride) film is depicted in Figure 4 and was found to be identical to that measured on a frozen solution. It shows the typical signal of a nitronyl nitroxide in a solid matrix[43] and was simulated with $g_1 = 2.0105$, $g_2 = 2.0120$, $g_3 = 2.0030$, $A_{11} = A_{22} = -4.5$ G, $A_{33} = 19.5$ G, and a line-width of 6 G. The anisotropy of the low temperature spectrum is in accordance with theory. Defining the local coordinates of the molecule so that the z axis is perpendicular to the O−N−C−N−O plane, we observe the smallest deviation from the Landé factor for the g value in the z direction. Contributions from the admixing of excited states into the ground state through spin-orbit coupling are negligible since the energy of the σ→σ* excitation is far too high in energy. In the xy plane, however, σ→π and π→π* excitations are more favorable which, as a result, lead to deviations from g_e for g_x and g_y. For the anisotropic hyperfine coupling constant we observe the largest value for the A_z tensor, since the spin density is highest in the p_z orbitals and the interaction of the nuclear spin with the magnetic field is most pronounced.

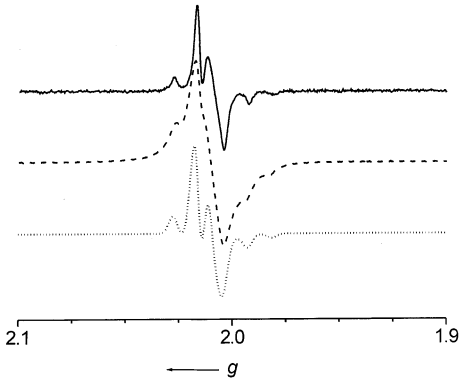

Figure 4. X-band EPR spectrum of **4** at 10 K of: a) a frozen methanol solution (microwave frequency 9.4371 GHz; power 196.7 nW; modulation amplitude 3.1 G; solid line), b) a polymer embedded sample (microwave frequency 9.443 GHz; power 1.0 μW; modulation amplitude 5.0 G; dashed line), and c) the simulated spectrum (dotted line, see text for parameters)

Crystal Structures of the Coordination Compounds 8, 9, and 11

Crystals suitable for an X-ray structure determination could be grown from acetonitrile or dichloromethane for compounds **8**, **9**, and **11**. The crystallographic data and details of the refinement procedures are collected in Table 2. Important bond lengths and angles are given in Tables 3 and 4. The molecules show the desired coordination of the

metal through the peripheral N,O donor set of the ligand without the participation of the nitronyl nitroxide groups. The coordination geometry at the metal and the supramolecular arrangement of the molecules is mainly affected by the steric demand of the ligand.

Bis[2-(piperidin-1-ylmethyl)-4-NIT-phenolato]copper(II) (8)

In this compound, the bulky piperidine side-arm forces the copper(II) into a tetragonally compressed tetrahedral coordination (Figure 5). Although the complex possesses no center of symmetry, the Cu−O bond lengths are almost identical [1.905(2) and 1.900(2) Å] as are the Cu−N distances, [2.041(2) and 2.039(2) Å]. The N−Cu−N and O−Cu−O angles of 157.06(9)° and 149.92(10)°, respectively, show a strong distortion of the tetrahedron towards a square-planar environment. The O−Cu−N angles are all close to 90° ranging from 91.16(9)−96.45(10)°. The phenolate rings show a small deviation from a benzoid to a quinoidal structure, with the two *ortho-meta* bonds [1.371(4)−1.386(4) Å] slightly shorter than the other four C−C bonds [1.405(4)−1.417(4) Å]. This is attributable to a contribution of the quinoidal form **B** to the electronic structure of the ligands (Scheme 1). A similar distortion was also found in a manganese complex with a bridging, nitronyl nitroxide substituted benzoic acid.[29] The nitronyl nitroxide groups exhibit the usual characteristics with NO bond lengths of 1.285(3)−1.295(3) Å, indicating the delocalization of the unpaired electron over both NO groups. The torsion angles between the phenolate rings and the ONCNO planes are rather small at 3.8° and 17.4°. The C9−O9−Cu1 and C39−O39−Cu1 angles α are 123.0° and 124.6°, respectively, as expected for an sp^2-hybridized oxygen atom. The planes of the phenolate rings and the coordination mean plane of the copper are twisted, enclosing torsion angles β of 34.9° and 43.5°, respectively. The piperidine groups are in a chair conformation and oriented almost perpendicular to the coordination mean plane of the copper. There are no intermolecular contacts involving the NO groups below 4.7 Å. The shortest intermolecular distances are found between O1 and C2A as well as C3A at 3.88 and 3.94 Å ($x - 0.5$, $0.5 - y$, $1 - z$), respectively. The shortest Cu···Cu distance is 6.43 Å ($1 - x$, $y - 0.5$, $1.5 - z$) between copper atoms forming a zigzag chain along the y-axis.

Aqua[bis(2-dimethylaminomethyl-4-NIT-phenolato)]-copper(II) (9)

The copper(II) complex **9** with the smaller dimethylamino ligand forms a distorted square-pyramidal complex with an additional water molecule in the apical position (Figure 6). The base plane of the pyramid is formed by an N_2O_2 donor set with Cu−N distances of 2.073(2) and 2.080(2) Å, and Cu−O distances of 1.930(2) and 1.902(2) Å. The N−Cu−N angle is 176.02(7)°, while the O9−Cu1−O29 angle is more bent [156.25(7)°]. The N−Cu−O angles at the base of the pyramid are in the range 85.13(7)−93.27(7)°, with the copper lying 0.223 Å above the base plane. The distance of the apical oxygen O10 to Cu1 is longer [2.293(2) Å], and the O10−Cu−N/O angles are 91.35(7)−105.31(7)°. As in compounds **8** and **11**, the phenolate rings are slightly distorted towards a quinoidal structure with the *ortho-meta* bonds slightly shorter [1.368(3) to 1.390(3) Å] than the other four C−C bonds [1.403(3) to 1.415(3) Å]. The bond lengths and angles within the nitronyl nitroxide groups are in the normal range, with N−O distances of 1.280(2)−1.296(2) Å. The torsion angles between the ONCNO planes and the phenolate rings are 19.0° and 19.4°. The

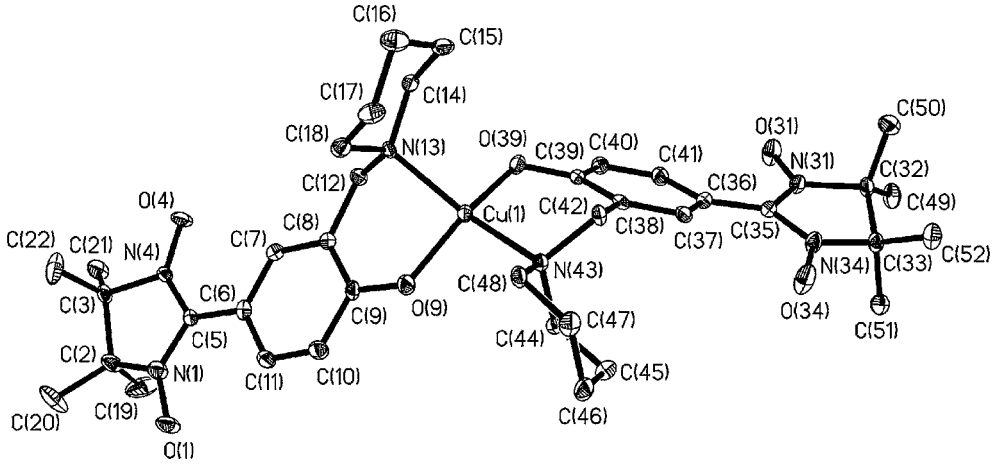

Figure 5. Molecular structure of **8**; ellipsoids are drawn at the 50% probability level

C(phenolate)−O−Cu angles α are 131.8° and 125.4°, while the torsion angles β between the coordination plane of the copper and the phenolate rings are 40.1° and 22.6°, the latter being significantly smaller than in complexes **8** and **11**. The apical water molecule is connected through hydrogen bonds to the nitronyl nitroxide groups of two adjacent molecules. The first hydrogen bond links O10 and O1A with a distance of 2.76 Å, forming a chain along the *y* axis (Figure 7). The second hydrogen bond links O10 with O21B over a distance of 2.72 Å, forming a zigzag chain along the *z* axis; these two hydrogen bonding interactions together result in a 2D network in the *yz* plane. There are additional short intermolecular contacts between adjacent nitronyl nitroxide groups, one between O24 and O24C ($-x$, $3 - y$, $-1 - z$) of two nitronyl nitroxides in a tail-to-tail arrangement, with a distance of 3.89 Å, and another one between O21 and O1D with a distance of 3.64 Å (x, $2.5 - y$, $0.5 + z$), forming another zigzag chain in the *z* direction.

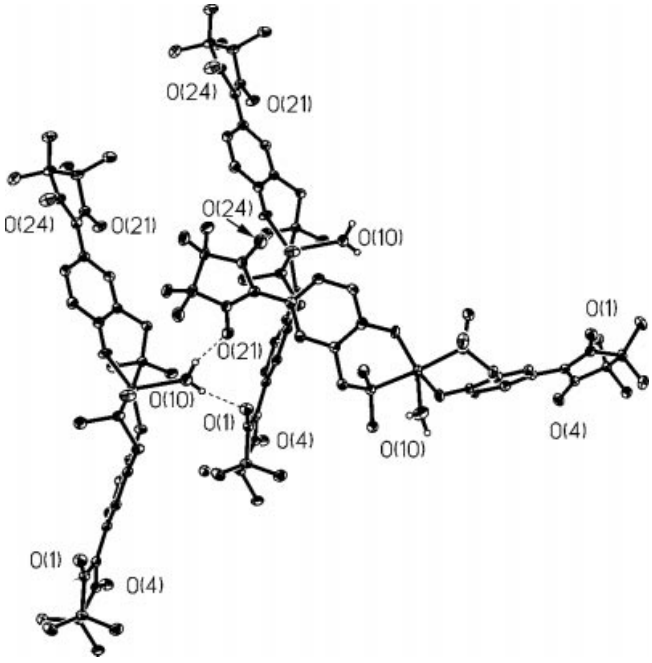

Figure 7. Crystal structure of **9**, showing the hydrogen bonds between the apical water molecule and the adjacent NO groups

Bis(2-dimethylaminomethyl-4-NIT-phenolato)nickel(II) (11)

With the smaller dimethylamino-ligand and nickel(II) one obtains a square-planar complex (Figure 8). The metal

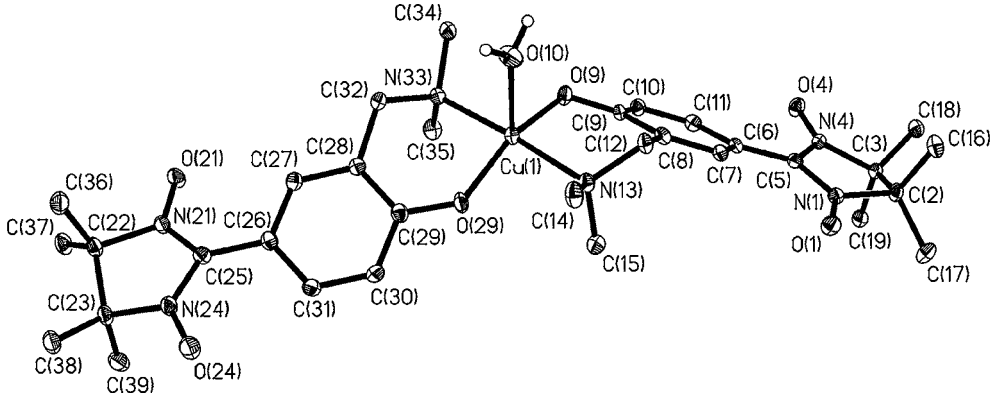

Figure 6. Molecular structure of **9**; ellipsoids are drawn at the 50% probability level

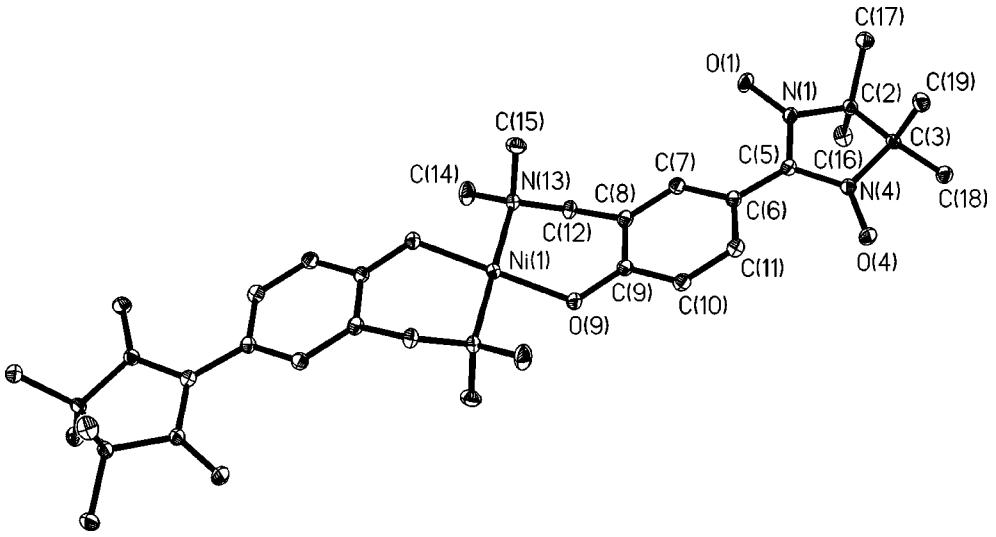

Figure 8. Molecular structure of **11**; ellipsoids are drawn at the 50% probability level

ion is located on an inversion center. The Ni−O distance is 1.86(1) Å and the Ni−N distance is 1.978(1) Å with an O−Ni−N angle of 93.57(3)°. The phenolate ring shows the same deviation from the benzoid structure as in the copper complexes **8** and **9** with both *ortho-meta* bond lengths at 1.381(2) Å, while the other carbon−carbon bond lengths are in the range 1.405(2)−1.410(2) Å. The bond lengths and angles within the nitronyl nitroxide group are in the expected range with N−O distances of 1.283(2) and 1.2871(14) Å. The torsion angle between the ONCNO plane and the phenolate ring is 18.6°. The angle α at the phenolate oxygen (C−O−Ni) is 125.9° — similar to that of the copper compound **8** — while the torsion angle β between the coordination mean plane of the nickel and the phenolate is 30.2°. Compound **11** forms an interesting 1D chain structure. Each oxygen atom O1 of the nitronyl nitroxide group points towards a nickel center of a neighboring complex with an O1···Ni1A distance of 4.33 Å, which is in turn connected in the same way, through O1A, to the Ni1 of the first complex, forming a molecular rectangle with the nickel atoms sitting in the two opposite corners. The diagonal distance between the Ni centers is 9.15 Å. Each rectangle shares the corners with its two neighbors, forming a chain of rectangles along the *y* axis (Figure 9). The chains are isolated from each other, with the shortest interchain distance being 4.19 Å between an O4 and the C3B of neighboring nitronyl nitroxide groups ($-x$, $y - 0.5$, $0.5 - z$).

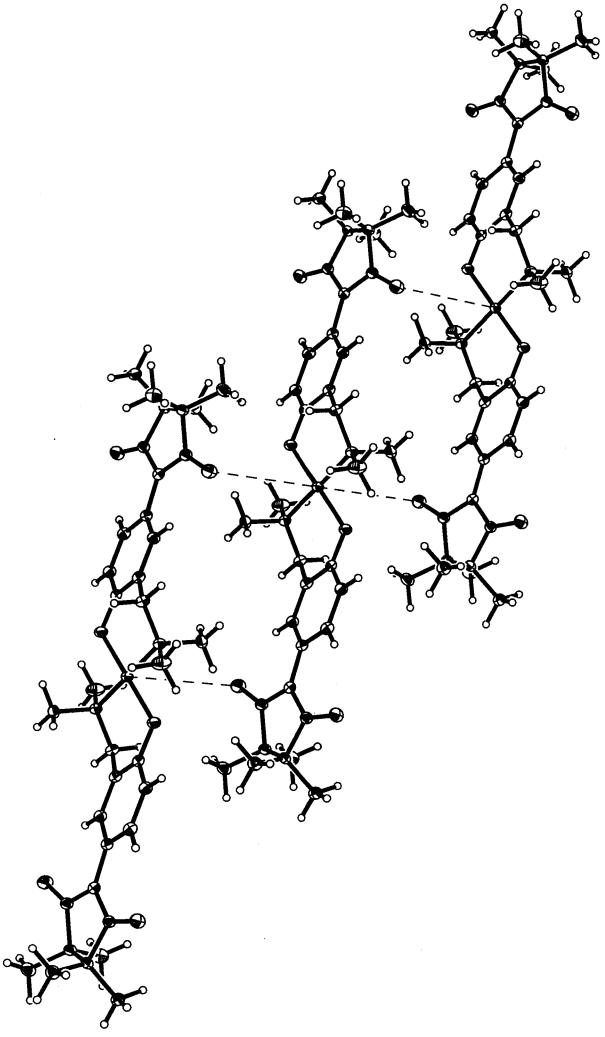

Figure 9. Crystal structure of **11**; dashed lines indicate the Ni1−O1A distances of 4.33 Å

Magnetic Properties of the Coordination Compounds

The temperature dependence of the molar magnetic susceptibility χ_M was measured in the 2−290 K range on polycrystalline samples of complexes **8**−**11**. Since nitronyl nitroxides often show considerable intermolecular exchange interactions due to close contacts between adjacent spin-carrying NO groups, it was crucial to this study to be able to differentiate between intra- and intermolecular exchange

interaction pathways. With the purely organic radical **4**, we were able to show that embedding the substance in a poly(vinyl chloride) film is a very efficient method of preparing magnetically diluted samples. No chemical modification occurs during this process. We could also apply this method to the transition metal complexes.

Bis[2-(piperidin-1-ylmethyl)-4-NIT-phenolato]copper(II) (8)

At room temperature, the value of the $\chi_M T$ product for the polycrystalline sample is 1.17 emu·K·mol^{-1}, which corresponds to that calculated for copper(II) and two nitronyl nitroxide radicals (1.125 emu·K·mol^{-1}). With decreasing temperature, $\chi_M T$ decreases continuously, reaching 0.40 emu·K·mol^{-1} at 2 K, close to the value of 0.375 emu·K·mol^{-1} expected for an isolated unpaired electron (Figure 10).

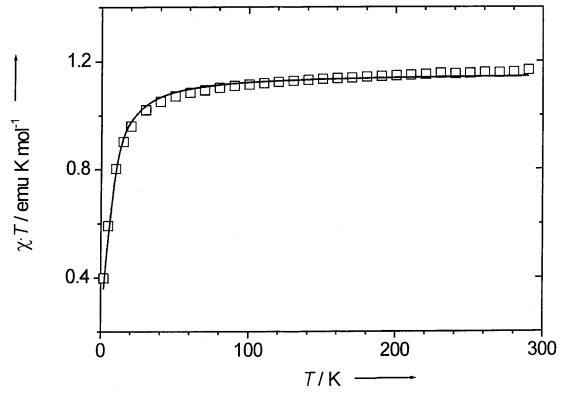

Figure 10. Temperature dependence of the product of the molar magnetic susceptibility with temperature ($\chi_M T$) for **8**; the solid line represents the best fit calculated data (see text for parameters)

The susceptibility was fitted to the Heisenberg–Dirac–Van Vleck Hamiltonian [Equation (5)]:

$$\hat{H} = -2J\left(\hat{S}_{NIT1}\hat{S}_M + \hat{S}_{NIT2}\hat{S}_M\right) \quad (5)$$

assuming the coupling between the two nitronyl nitroxides to be zero because of the large distance. The best result was obtained with the parameters $J = -2.90$ cm^{-1}, $g_{NIT} = 2.00$ (fixed), $g_{Cu} = 2.05$, and $R = 2.15 \times 10^{-4}$. In accordance with the presence of isolated molecules as seen in the solid state structure, measurements on polymer-embedded samples also showed antiferromagnetic coupling.

Aqua[bis(2-dimethylaminomethyl-4-NIT-phenolato)]copper(II) (9)

At room temperature, $\chi_M T$ has a value of 1.16 emu·K·mol^{-1}, which is close to that expected for three uncoupled $S = 1/2$ spins (1.125 emu·K·mol^{-1}). The $\chi_M T$ product decreases to 0.21 emu·K·mol^{-1} at 2 K (Figure 11). We fitted the magnetic data to the HDVV Hamiltonian [Equation (5)]. The best result was obtained with $J = -2.88$ cm^{-1}, $g_{NIT} = 2.00$ (fixed), $g_{Cu} = 2.11$ and $R = 6.11 \times 10^{-4}$. Compound **9** has a 2D network structure with several possible intra- and intermolecular exchange interaction pathways. To gain insight into the intramolecular exchange interactions in operation, we performed additional magnetic measurements on a magnetically diluted sample of **9** embedded in a poly(vinyl chloride) matrix. Here the compound shows an entirely different behavior. The room temperature value of $\chi_M T$ is 1.09 emu·K·mol^{-1}, slightly lower than expected for three uncoupled $S = 1/2$ spins (1.125 emu·K·mol^{-1}). Decreasing the temperature causes $\chi_M T$ to increase, reaching a maximum of 1.33 emu·K·mol^{-1} at 10 K. On further lowering of the temperature, the $\chi_M T$ value decreases to reach 1.13 emu·K·mol^{-1} at the lowest attainable temperature of 2 K (Figure 11). We could simulate the data down to very low temperature values satisfactorily with the values $J = +2.65$ cm^{-1}, $g_{NIT} = 2.00$ (fixed), $g_{Cu} = 2.07$, and $R = 7.24 \times 10^{-3}$. This shows that in the case of **9**, intramolecular ferromagnetic interactions are operative which are masked by the intermolecular interactions in the polycrystalline sample.

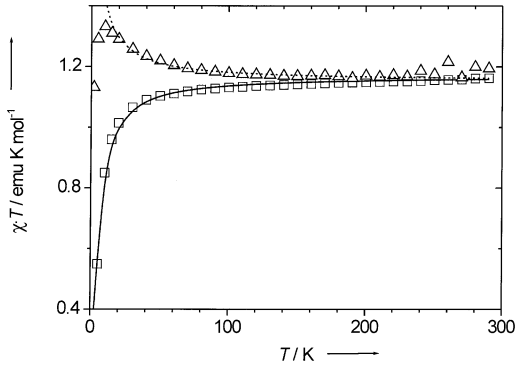

Figure 11. Temperature dependence of $\chi_M T$ for **9** as a powdered sample (□) and embedded in a poly(vinyl chloride) film (Δ); the solid and dashed lines represent the best fit calculated data (see text)

Bis(methanol)bis(2-dimethylaminomethyl-4-NIT-phenolato)nickel(II) (10)

The value of $\chi_M T$ at 290 K (1.83 emu·K·mol^{-1}) is as expected for an $S = 1$ of Ni^{II} in octahedral coordination with $g > 2$ and two nitronyl nitroxide radical ligands. When lowering the temperature, $\chi_M T$ decreases steadily to 0.81 emu·K·mol^{-1} at 2 K (Figure 12). The data were fitted to

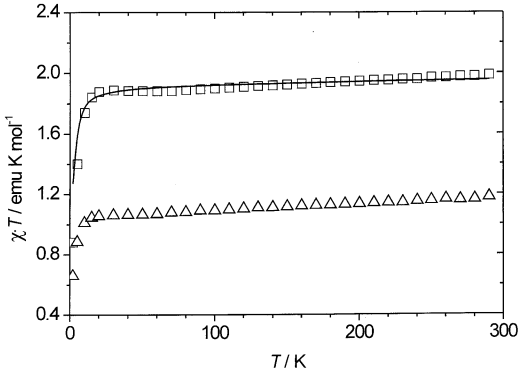

Figure 12. Temperature dependence of $\chi_M T$ for **10** (□) and **11** (Δ); the solid line represents the best fit calculated data (see text for parameters)

Equation (5) yielding $J = -0.40\ cm^{-1}$, $g_{NIT} = 2.00$ (fixed), $g_{Ni} = 2.16$ and $R = 1.99 \times 10^{-3}$. A polymer-embedded sample shows similar behavior, suggesting the presence of isolated molecules in the powdered samples.

Bis(2-dimethylaminomethyl-4-NIT-phenolato)nickel(II) (11)

The $\chi_M T$ product has a value of 1.18 emu·K·mol^{-1} at room temperature and decreases to 1.06 emu·K·mol^{-1} with decreasing temperature (Figure 12). This value is much higher than the value of 0.75 emu·K·mol^{-1} expected for two uncoupled nitronyl nitroxide ligands and an $S = 0$ for Ni^{II} in square-planar coordination, and significantly lower than the value calculated for an $S = 1$ plus two $S = 1/2$ radical spins as in **10**. However, it is very close to the value of 1.00 emu·K·mol^{-1} for an $S = 1$ state arising from a ferromagnetic coupling between the two nitronyl nitroxide ligands. Given the large distance between the two radical moieties of 13.81 Å (taken between C5 and C5′ related to each other by an inversion center), this is a surprising result, but was further confirmed by EPR spectroscopy and ab initio calculations.

Structural Correlation

In the structurally characterized copper complexes **8** and **9**, the sign of the exchange coupling constant can be related to the C(phenolate)−O−M angle α (with α = 180° denoting a linear arrangement) and the torsion angle β between the coordination mean plane at the metal center and the plane of the phenolate ligand, with β = 0° if the two planes are coplanar. In a tetrahedral environment of the copper(II) ion, its magnetic d_{xy} orbital is orthogonal to the spin-carrying p_z of the phenolate oxygen for β = 0°, irrespective of the size of α. However, with twisted planes and β > 0°, decreasing α from 180° enlarges the overlap, resulting in antiferromagnetic coupling (Figure 13). Only in the case of both α → 90° and β → 90°, the coupling becomes ferromagnetic again. In square-pyramidal coordination geometry at the copper(II), the magnetic $d_{x^2-y^2}$ orbital is also orthogonal to p_z for β = 0°, irrespective of α. In contrast to the d_{xy} orbital, the coupling stays antiferromagnetic when decreasing α for β values greater than 0°. At the intermediate values of α = 123.0° to 131.8° observed in compounds **8** and **9**, the sign of the coupling is therefore determined by the torsion angle β for both magnetic d_{xy} and $d_{x^2-y^2}$ orbitals. A ferromagnetic interaction should be observed for small angles, switching to antiferromagnetic upon increasing β. These simple considerations agree well with the experimental findings. Compound **8** with larger β angles (34.9° and 43.5°) shows an antiferromagnetic coupling, while compound **9**, in accordance with its one small value for β of 22.6°, exhibits an intramolecular ferromagnetic interaction between the metal and the nitronyl nitroxide radical ligands.

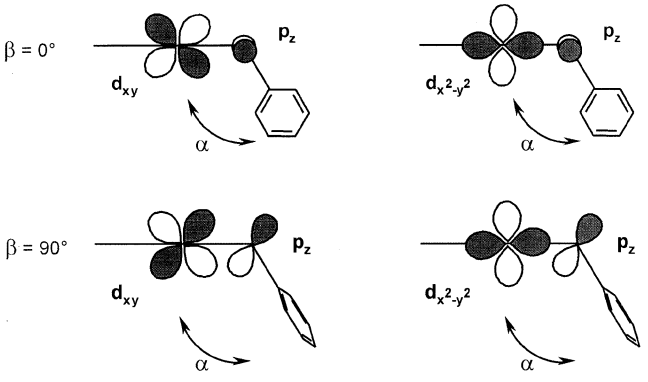

Figure 13. Depiction of the spatial arrangement of the orbitals relevant to the magnetic exchange interaction

EPR Spectroscopy

The X-band EPR spectra of **8**−**11** were measured as powders and in frozen solution at low temperature. Powdered samples of **8** show a broad isotropic signal at $g = 2.02$ with a line-width of 240 G. The spectra in frozen acetonitrile or chloroform solutions are dominated by the anisotropic signal of the nitronyl nitroxide group[43] at $g = 2.00$ with an additional broad tail between $g = 2.03$ to 2.20, better visible in the integrated spectrum. No signal clearly assignable to a copper(II) ion is observed. This is in accordance with an antiferromagnetic coupling between the copper(II) and the radical ligands, as determined from the susceptibility measurement. The spectrum measured on a polymer-embedded sample of **8** is identical to that obtained in frozen solution. The copper complex **9** in the powder has an isotropic signal centered at $g = 2.04$ with a line-width of 90 G. In frozen solution, the signal of the strongly coupled system shown in Figure 14a is observed. A quantitative evaluation of the signal intensity is not hampered by saturation, and comparison with a Cu^{II} standard shows that it accounts exactly for three electrons. In accordance with the intramolecular ferromagnetic coupling between the nitronyl nitroxide radicals and the copper(II) as seen in the susceptibility measurement on magnetically diluted samples, one observes a half-field signal at $g = 4.15$ (inset in Figure 14a). The spectrum obtained on a polymer-embedded sample of **9** is identical to that of the frozen solution. The EPR of **10**, in powder and frozen solution, is identical to that of the free protonated ligand and no signal indicative of a Ni^{II} ion is observed. The powder EPR of the nickel(II) complex **11** is shown in Figure 15. In addition to the small, intense signal at $g = 2.01$ with a line-width of only 20 G, two additional features occur that belong to an $S = 1$ system and that could be simulated assuming a zero-field splitting of $D = 0.0098\ cm^{-1}$, confirming the ferromagnetic coupling between the two radical ligands, although no half-field signal was observed.

Electrochemical Properties

We investigated the electrochemistry of the coordinated nitronyl nitroxide substituted phenolates by cyclic voltammetry, square-wave voltammetry, and spectro-electrochemistry to see if the coordinated ligands can be oxidized to singlet or triplet nitronyl nitroxide-phenoxyl diradicals, possibly leading to molecules in higher spin states (Scheme 2c).

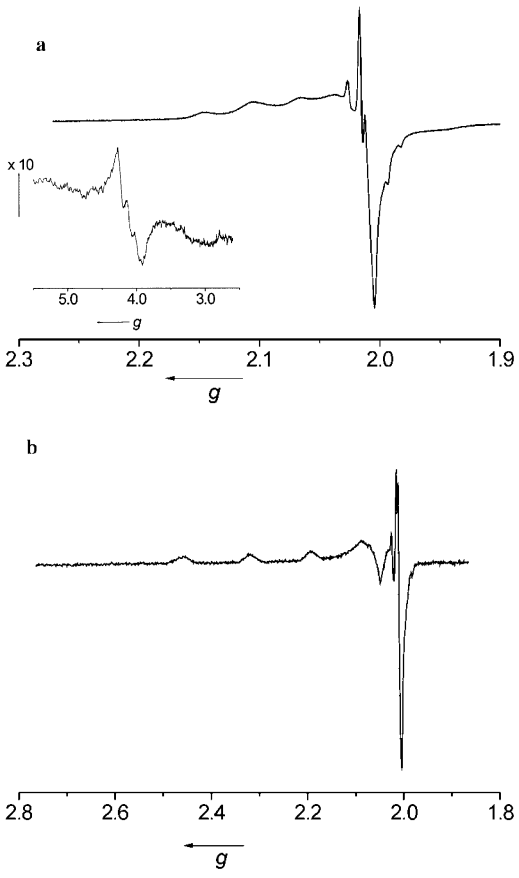

Figure 14. X-Band EPR of **9** at 60 K: a) before oxidation, with the inset showing the half-field signal, and b) after oxidation by two electrons

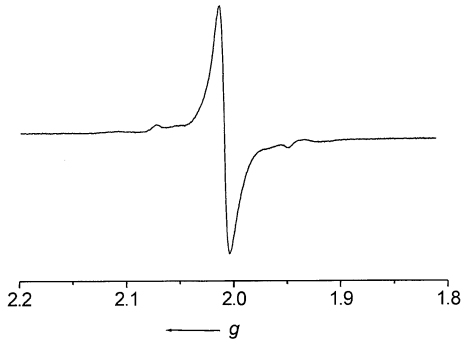

Figure 15. X-Band EPR of a powdered sample of **11** at 10 K

Compounds **8**−**10** undergo at least two oxidations in the range of 100−300 mV vs. ferrocenium/ferrocene (Fc^+/Fc), accompanied by an additional oxidative step depending on ligand, metal, and coordination geometry. The relevant data is collected in Table 5.

Compound **8** is simultaneously oxidized by three electrons at +228 mV vs. Fc^+/Fc. The most evident spectral change is the disappearance of the phenolate n→π* band at 298 nm and the simultaneous appearance of a new intense band at 412 nm, whose maximum shifts to a lower wavelength during the course of the oxidation (Figure 16a); after the complete removal of three electrons it appears at

Table 5. Half-wave potentials for **8**−**10** in mV vs. Fc^+/Fc at 100 mV/s, measured in acetonitrile solution (2×10^{-4} mol/L) containing 0.1 mol/L $TBAPF_6$

404 nm. In addition, the n→π* band of the nitronyl nitroxide group at 615 nm decreases in intensity. In the EPR spectrum of the oxidized form, the overall signal intensity decreases without the appearance of new features. A quantitative evaluation is not possible due to signal saturation even at the lowest microwave power in the concentration range required for coulometry. These results can be interpreted as a concerted oxidation of both nitronyl nitroxide groups to diamagnetic nitrosonium cations plus the oxidation of one phenolate to a phenoxyl radical. Phenoxyl rad-

icals show similar spectral patterns and are known to be strongly coupled to coordinated copper ions.[44,45] The copper compound **9** is reversibly oxidized by two electrons at +178 mV vs. Fc^+/Fc. In the UV/Vis spectrum, this is accompanied by the appearance of a very strong band at 424 nm with isosbestic points at 270, 340, 500, and 714 nm. The phenolate n→π* band at 326 nm as well as the n→π* absorption of the nitronyl nitroxide group at 633 nm vanish, as in **8** (Figure 16b). The EPR of the oxidized species is dominated by the axial signal typical of a copper(II) atom in a square-planar coordination environment, as depicted in Figure 14b, with $g_\perp = 2.04$, $g_\parallel = 2.255$, $A_\perp = 40$ G, and $A_\parallel = 180$ G. Its intensity accounts for exactly one electron. No signals attributable to triplet radical ligands were observed. To gain further insight into the electronic structure of the oxidized product, resonance Raman (RR) spectroscopic measurements were performed on this compound. To prevent decomposition of the oxidized species, which is unstable at room temperature, the spectra were measured at 138 K on frozen solutions using an excitation wavelength of 413 nm coincident with the strong absorption of the oxidized product. Three prominent bands were observed at 1435, 1515, and 1602 cm^{-1}, respectively (Figure 17). The latter two occur at positions similar to those reported for phenoxyl-metal compounds.[46,47] According to the literature, they are assigned to ν_{7a} and ν_{8a} modes having C−O stretching and $C_{ortho}-C_{meta}$ double bond character, arising from a quinoidal mesomeric structure. The strong band at 1435 cm^{-1} is absent in the RR spectra of reported phenoxyl-metal complexes and is thought to originate from modes of the nitronyl nitroxide group. To gain evidence for this assumption, the vibrational spectrum of NIT-H was calculated by DFT (see Exp. Sect. for details on the computational procedures used). The simplest nitronyl nitroxide was chosen as a model since the whole ligand is too large to be treated theoretically and we assumed the modes of the phenolate and nitronyl nitroxide groups to be only weakly coupled. The calculated frequency of the symmetric stretching mode involving both NO groups is 1448 cm^{-1} when employing an appropriate scaling factor,[46] close to the band at 1435 cm^{-1} in the experimental spectrum. The theoretically determined frequency of the asymmetric stretching mode of the NO groups is 1484 cm^{-1}. A weak vibration is observed close to this value at 1467 cm^{-1}. These results indicate that two mesomeric structures − **D** with a nitrosonium-quinone formulation, and **E** with a nitronyl nitroxide-phenoxyl structure (Scheme 4) − contribute equally to the electronic structure of the coordinated, oxidized ligands. Although a triplet ground state was reported for a free nitronyl nitroxide-phenoxyl diradical,[48−50] which we could also confirm by theoretical calculations, no evidence for triplet or sextet signals was found here in the EPR spectrum. The quinoidal structure **D** is probably stabilized upon coordination, leading to an $S = 0$ ground state for the oxidized ligand.

Density Functional Calculations

Density functional methods have recently been shown to give a good description of the electronic structure of nitronyl nitroxide radicals and at least a semi-quantitative picture of the spin-density distribution when compared with neutron diffraction data.[51−53] Combined with the broken symmetry approach as proposed by Noodleman,[54] they allow the theoretical determination of the exchange coupling constant in a wide variety of bimetallic compounds and diradicals to a good degree of accuracy.[55−60] To get a first idea of the exchange interaction pathways operative in our nitronyl nitroxide-metal complexes, we calculated the spin density distribution of the deprotonated nitronyl nitroxide **1** with the geometry taken from the crystal structure (see Exp. Sect. for details on computational procedures used). The HOMO (α83) is delocalized over both the five- and six-membered rings, with contributions from the phenolic oxygen and the lone pair of the amine nitrogen (Figure 18a), although the SOMO (α80) was found to be entirely localized on the ONCNO group (Figure 18b). This is also reflected in the spin density map (Figure 18c and Table 6), which shows only a minor contribution at the phenolic oxygen atom resulting from configuration interaction, and is in accordance with very recent calculations of the spin-density distribution in a large variety of structurally characterized substituted nitronyl nitroxides, which also showed localization of the unpaired electron on the ONCNO group.[61] The electronic structure of **1** is therefore

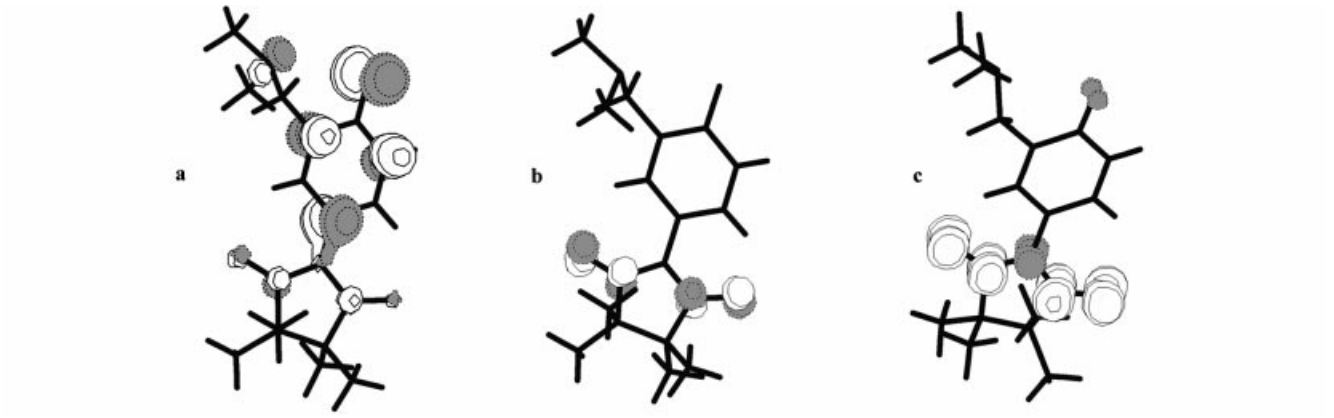

Figure 18. a) HOMO (α83) of deprotonated **1**, showing the contribution from the p_z of the phenolic oxygen, b) SOMO (α80) of deprotonated **1**, and c) spin density distribution

Table 6. Atomic spin densities of deprotonated **1** calculated at the B3LYP level; the numbering scheme is analogous to that used in Figure 2

N(1)	0.281	C(8)	−0.010
O(1)	0.365	C(9)	−0.002
C(2)	−0.017	O(9)	−0.042
C(3)	−0.013	C(10)	−0.009
N(4)	0.247	C(11)	−0.012
O(4)	0.321	C(19)	0.003
C(5)	−0.145	C(20)	0.000
C(6)	0.012	C(21)	0.018
C(7)	−0.013	C(22)	0.002

best described by the mesomeric structure **A** with little contribution from the phenoxyl form **C** (Scheme 1). This is in accordance with the observed weaker exchange interaction in the nitronyl nitroxide-metal complexes reported here, relative to published phenoxyl-metal complexes, which show a substantial spin density at the phenoxyl oxygen and in which the metal is therefore strongly coupled to the radical.[62,63]

To further substantiate the electronic ground states as determined by EPR and magnetic susceptibility measurements, we carried out broken symmetry DFT calculations at the B3LYP level on models of the copper complexes **8** and **9**, in which one of the nitronyl nitroxide groups was replaced by a hydrogen atom, to determine the energies of the triplet and singlet states. Since it has been shown that contamination from higher spin states is not significant in density functionals,[64−67] no spin projection was used and the exchange coupling parameter J was directly calculated from Equation (6):

$$J = E_{BS} - E_T \quad (6)$$

For copper models **8′** and **8′′**, referring to the different torsion angles of 3° and 17° between the five- and six-membered rings, a singlet ground state was found in accordance with the experimental data, with J calculated to be -13.0 cm^{-1} and -5.6 cm^{-1}, respectively. The triplet state was found to be lower in energy in model compound **9′** with J calculated as $+9.8$ cm^{-1}, thus confirming the intramolecular ferromagnetic coupling as observed in the magnetically diluted sample of this compound (just one calculation was done since the torsion angles on both ligands are almost equal in **9**).

For the nickel complex **11**, the calculation yielded a triplet ground state with $J = +64.0$ cm^{-1} in accordance with the EPR and susceptibility measurements. This large ferromagnetic coupling is rather surprising given the distance of 13.81 Å between the two radicals. It is thought to be mediated by the empty $d_{x^2-y^2}$ orbital of the Ni^{II} in a square-planar coordination. To gain further insight into the mechanism in operation, the corresponding zinc compound **$(1)_2$Zn**, which could not be obtained in pure form and characterized, was geometry optimized and the exchange-coupling constant calculated. With a completely filled 3d-shell, J was found to be zero within the accuracy of the calculation, thereby confirming the contribution of the empty metal $d_{x^2-y^2}$ orbital to the exchange-coupling pathway in **11**.

Conclusion

Nitronyl nitroxide substituted phenolate ligands with an additional chelating amine group were synthesized and provided the expected tight binding of transition metal ions at the periphery of the ligand without the participation of the NO groups. Four metal complexes of these ligands with copper(II) and nickel(II) were isolated and characterized. Their coordination geometry and supramolecular arrangement is controlled by the steric demand of the ligand, the preference of the metal ion for a certain geometry and the presence of coligands. The bulky piperidine group of ligand **3** forces copper(II) into a distorted tetrahedral coordination. No nickel(II) complexes could be obtained with this ligand. In addition, the large extent of the piperidine substituent prevented close intermolecular contacts between the molecular units, resulting in discrete molecules. The

smaller ligand **1** resulted in a planar arrangement of the N_2O_2 donor set of the two ligands in both its copper(II) and nickel(II) complexes, with coligands completing the preferred coordination number of the metal. With the smaller dimethylamino group, the molecular units are interconnected, forming 1D- and 2D-arrangements. The unpaired spin on the nitronyl nitroxide groups is coupled to the metal through the phenolic oxygen, as shown by susceptibility measurements and EPR spectroscopy. The intermolecular exchange interactions could be suppressed by embedding the compounds in a poly(vinyl chloride) film. The method was first tested and quantified on the free organic radical **4**, which shows strong intermolecular exchange interactions, and then successfully applied to the transition metal complexes. Both EPR and magnetic susceptibility measurements could be performed on magnetically diluted samples prepared this way, introducing it as a suitable method to investigate systems in which intra- and intermolecular exchange interactions of equal magnitude are operative. A structural relationship was found between the sign of the exchange coupling and the degree of torsion between the coordination mean plane of the metal center and the plane of the phenolate ligands. Density functional theory calculations further confirmed the experimentally determined electronic ground states. The obtained complexes will be used as synthons for supramolecular assemblies by both interconnection of the NO groups with Lewis acidic metal ions or replacement of the solvent molecules by bridging coligands.

Experimental Section

General: All reagents were purchased from commercial sources and used as received. Solvents were purified and dried by standard methods. Reactions were carried out under an atmosphere of argon where necessary. Elemental analyses were carried out by H. Kolbe, Mikroanalytisches Laboratorium, Mülheim an der Ruhr. Infrared spectra were recorded on a Perkin−Elmer FT-IR 2000. UV/Vis spectra were recorded on a Perkin−Elmer Lambda 19 spectrometer or a Hewlett Packard 8452A diode array spectrometer. EI mass spectra were measured on a Finnigan MAT 8200 instrument, and ESI mass spectra on a Finnigan MAT 95 instrument. Susceptibility measurements were performed on polycrystalline powders or polymer films on a Quantum Design MPMS SQUID magnetometer in the temperature range 2−295 K. Magnetically diluted samples were prepared by slowly evaporating a solution of poly(vinyl chloride) containing 5 wt. % of the compound under investigation in dichloromethane. The diamagnetic contribution of the polymer was determined in a separate run. EPR spectra were recorded as polycrystalline powders, in frozen solution, or on the polymer films used in the magnetic susceptibility measurements with a Bruker ESP 300 spectrometer with a Bruker ER041 XK-D microwave bridge and an Oxford Instruments cryostat model 910. Cyclic voltammograms and square-wave voltammograms were obtained with a three-electrode cell and an EG&G Princeton Applied Research 273A potentiostat. An $Ag/AgNO_3$ (0.01 mM) reference electrode, a glassy carbon disc working electrode and a Pt wire counter electrode were used. Acetonitrile solutions (10^{-4} M) contained 0.1 mol/L $(n\text{Bu})_4NPF_6$ as supporting electrolyte. Ferrocene was added as an internal standard after each measurement, its ΔE being +100 mV under these conditions. The coulometric measurements were performed at −25 °C with the same setup, and the spectral changes during oxidation were followed with a Hewlett Packard 8452A diode array spectrometer. EPR spectroscopic measurements on the oxidized species were performed on samples removed with a syringe under argon and immediately frozen in liquid nitrogen. RR spectra were obtained with the 413 nm excitation of a krypton ion laser (Coherent Innova 302) using a spectrograph (ISA U1000) equipped with a liquid nitrogen cooled CCD detector (Jobin Yvon). The spectral slit width was 5.6 cm^{-1}, and the wavenumber increment was 0.53 cm^{-1}. The sample holder was placed in a cryostat (Cryovac) at 138 K to prevent sample degradation and the scattered light collected in a 135° scattering geometry.

Preparation of the Nitronyl Nitroxide Radicals: The nitronyl nitroxide radicals were prepared from their aldehyde precursors (see Supporting Information) according to a literature procedure.[38] For **1**, **2**, **4**, **5**, and **6**, benzene was used as solvent for the coupling of the aldehyde with 2,3-bis(hydroxylamino)-2,3-dimethylbutane. Chloroform was used as solvent for **3** and tetrahydrofuran for **7**. Oxidation to the radical was carried out with lead(IV) oxide for **1**−**3** and with sodium periodate for **4**−**7**. All radicals were purified by preparative HPLC on a Phenomenex Luna-5-PhenylHexyl column with methanol/aqueous ammonium acetate as the eluent. After extraction from the buffer with chloroform, they were obtained as blue solids by crystallization from toluene for **1**, **2**, **5**−**7** and from diethyl ether for **3** and **4**.

3-Dimethylaminomethyl-4-hydroxyphenyl-NIT (1): Yield (after HPLC): 1.09 g (55%). − IR (KBr disc): $\tilde{\nu}$ = 2990, 2957, 2831, 2784, 1654, 1598, 1483, 1416, 1384, 1364, 1350, 1298, 1282, 1218, 1141, 1111, 1019, 826, 542 cm^{-1}. − EI-MS: *m*/*z* = 306 [M^+], 261, 176, 84, 69, 58, 44. − UV/Vis (MeOH): λ_{max} (ε) = 287 (12413), 317 (7926), 365 (4247), 615 nm (672 $L{\cdot}mol^{-1}{\cdot}cm^{-1}$). − EPR (solid, 60 K, 9.4391 GHz): g_{iso} = 2.0095. − EPR ($CHCl_3$, 80 K, 9.4374 GHz): g_x = 2.0105, g_y = 2.0130, g_z = 2.0040, $A_{xx} = A_{yy}$ = −4.5 G, A_{zz} = 19.5 G. − $C_{16}H_{24}N_3O_3$ (306.38): calcd. Preparation of Metal Complexes 8−11: The ligand (1.3 mmol) was dissolved in dry methanol (8 mL) under argon and deprotonated by addition of a fresh 1.2 M solution of sodium methanolate (1.6 mL; prepared by addition of a calculated quantity of sodium metal to dry methanol), resulting in a color change from deep blue to deep green. The anhydrous metal chloride (0.7 mmol) was then dissolved in dry methanol (8 mL) under argon and added dropwise to the solution of the deprotonated ligand over a period of 30 min. A crystalline precipitate began to form almost immediately. After complete addition this was collected by suction, washed with dry methanol, ether, and pentane before being dried in air. Recrystallization from the indicated solvents yielded the complexes in analytically pure form. Single crystals were grown from acetonitrile for **8** and **9**, while **11** was obtained in crystalline form by slow evaporation of a dichloromethane solution layered with ether.

Bis[2-(piperidin-1-ylmethyl)-4-NIT-phenolato]copper(II) (8): Yield: 0.60 g (99%). − IR (KBr disc): $\tilde{\nu}$ = 2922, 2854, 1599, 1470, 1408, 1382, 1357, 1309, 1260, 1117, 829, 636, 453 cm^{-1}. − ESI$^+$MS (MeOH): *m/z* = 754 [M + H], 776 [M + Na]. − UV/Vis ($CHCl_3$): λ_{max} (ε) = 298 (26500), 329 (25400), 372 (10280), 634 nm (2410 L·mol^{-1}·cm^{-1}). − $C_{38}H_{54}CuN_6O_6$ (754.43): calcd. C 60.50, H 7.21, N 11.14, Cu 8.42; found C 59.88, H 7.14, N 11.12, Cu 8.32.

Aqua[bis(2-dimethylaminomethyl-4-NIT-phenolato)]copper(II) (9): Yield: 0.39 g (73%). − IR (KBr disc): $\tilde{\nu}$ = 3416, 2983, 2923, 1599, 1473, 1408, 1381, 1348, 1323, 1301, 1117, 999, 823, 633, 541, 454 cm^{-1}. − ESI$^+$MS (MeCN): *m/z* = 674 [M − H_2O + H], 696 [M − H_2O + Na]. − UV/Vis ($CHCl_3$): λ_{max} (ε) = 329 (54620), 375 (10180), 633 (2550), 678 nm (2550 L·mol^{-1}·cm^{-1}). − $C_{32}H_{48}CuN_6O_7$ (692.32): calcd. C 55.52, H 6.99, N 12.14, Cu 9.18; found C 54.04, H 6.84, N 11.77, Cu 9.23.

Bis(methanol)bis(2-dimethylaminomethyl-4-NIT-phenolato)-nickel(II) (10): Yield: 0.32 g (87%). − IR (KBr disc): $\tilde{\nu}$ = 1595, 1484, 1471, 1410, 1376, 1333, 1297, 1118, 829, 628, 445, 453 cm^{-1}. − ESI$^+$MS (MeOH): *m/z* = 669 [M + H], 691 [M + Na]. − UV/Vis ($CHCl_3$): λ_{max} (ε) = 299 (23140), 371 (9200), 628 nm (1570 L·mol^{-1}·cm^{-1}). − $C_{34}H_{54}N_6NiO_8$ (733.53): calcd. C 55.67, H 7.42, N 11.46, Ni 8.00; found C 54.80, H 6.83, N 11.45, Ni 7.46.

Computational Details: The hybrid B3LYP method, as implemented in Gaussian 98,[68] was used in the calculation of the spin-density distribution and the energies, mixing the exact Hartree−Fock exchange with Becke′s expression for the exchange[69] and the Lee−Yang−Parr correlation functional.[70,71] A double-ζ quality basis set (Lanl2DZ) was employed throughout.[72−75] Because of the small energy differences, a tight convergence criterion with the limit set to 10^{-8} and the ultrafine grid were used. The vibrational spectrum of NIT-H was calculated with a cc-pVDZ basis set[76−78] and the BP86-functional.[79,80]

X-ray Crystallographic Collection and Refinement of the Structures: Dark blue single crystals of **1**, **3**, **3a**, **4**, **7**, **8**, **9**, and **11** were coated with perfluoropolyether, picked up with a glass fiber, and mounted on a diffractometer equipped with a nitrogen cold stream operating at 100 K. Graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) was used throughout. The crystallographic data of the compounds and the diffractometer types used are listed in Tables 1 and 2. Cell constants were obtained from a least-squares fit of the diffraction angles of several thousand strong reflections. Intensity data were corrected for Lorentz and polarization effects. The crystal faces of **4** were determined and the face-indexed correction routine embedded in SHELTXL[81] was used to correct for absorption. The intensity data of **8** were collected on a Siemens Smart CCD diffractometer system and the program SADABS[82] was used to correct for absorption. An absorption correction was carried out for the data set of **9**, for which the program MulScanAbs[83] was used. The Siemens SHELXTL[81] software package was used for solution, refinement, and artwork of the structures, and the neutral-atom scattering factors of the program were used. All structures were solved and refined by direct methods and difference Fourier techniques. Non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed at their calculated positions and refined as riding atoms with isotropic displacement parameters.
Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-149525, -149526, -149527, -149528, -157121, -157122, and -157123 for structures **1**, **3**, **3a**, **4**, **8**, **9**, and **11**, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information (see footnote on page 1)**:** Synthetic procedures for preparation of the nitronyl nitroxide precursors and figures showing the molecular structure and crystal packing of compounds **1**, **3**, **3a**, and **7** (13 pages**)**.

Acknowledgments

This work was supported by a grant from the Deutsche Forschungsgemeinschaft (DFG). Thanks go to Prof. Dr. Karl Wieg-

hardt for giving us access to all laboratory facilities. We gratefully acknowledge Manuela Trinoga for HPLC purification of the nitronyl nitroxides and Matthias Pickavé for technical assistance in their preparation. We are also grateful to Petra Höfer and Dr. Eberhard Bothe for help with the spectro-electrochemistry and to Dr. Susanne Döpner and Prof. Dr. Peter Hildebrandt for the RR spectroscopic measurements. E.R. would like to thank the Ministry of Education and Science of the Land Nordrhein-Westfalen for a Lise Meitner fellowship.

---

P−H-Functionalized 2-(Phosphanyl)ethanethiols, Their Titanocene Derivatives $[Cp_2Ti(SCH_2CH_2PHR)_2]$ (R = Ph, 2,4,6-$Me_3C_6H_2$, 2,4,6-$iPr_3C_6H_2$) and Reaction of $[Cp_2Ti(SCH_2CH_2PHPh)_2]$ with $[Cu(CH_3CN)_4]BF_4$

Satyajeet Chaudhury,[a] Steffen Blaurock,[a] and Evamarie Hey-Hawkins*[a]

Dedicated to Prof. M. Herberhold on the occasion of his 65th birthday

Keywords: P−H-Functionalized 2-(phosphanyl)ethanethiols / Titanium / Metallocenes / Bis(phosphanylethanethiolates) / Copper

The P–H-functionalized 2-(phosphanyl)ethanethiols $RHPCH_2CH_2SH$ [R = Ph (**1**), 2,4,6-$Me_3C_6H_2$ (Mes) (**2**), 2,4,6-$iPr_3C_6H_2$ (Tipp) (**3**)] were prepared by ring cleavage of ethylene sulfide with LiPHR, followed by hydrolytic workup and distillation. **1**–**3** react with $[Cp_2TiCl_2]$ in the presence of excess NEt_3 to yield a diastereomeric mixture (ratio ca. 1:1) of *rac*- and *meso*-$[Cp_2Ti(SCH_2CH_2PHR)_2]$ [R = Ph (**4**), Mes (**5**), Tipp (**6**)]. **6** is not obtained in pure form. Compound **4** reacts with $[Cu(CH_3CN)_4]BF_4$ to yield $[Cu\{P,P'\text{-}PHPhCH_2CH_2\text{-}SB(FH)SCH_2CH_2PPh(B\text{–}P)\}_2]BF_4$ (**7**). **1**–**7** were characterized spectroscopically. **7** exhibits dynamic behavior in solution, as shown by ^{31}P NMR spectroscopy. Crystal structure determinations were carried out on **5** and **7**. In **5**, both diastereomers cocrystallize in the asymmetric unit. Although the cation of **7** has six chiral centers, only the (R_P,R_P,R_P,R_P,R_B,R_B)/(S_P,S_P,S_P,S_P,S_B,S_B) diastereomer is present in the solid state.

Introduction

While tertiary phosphanyl alcohols have been known and employed as ligands in the synthesis of transition metal complexes with catalytic properties for a long time,[1] the synthetic potential of primary[2] and secondary[3] phosphanyl alcohols has only recently been recognized. The corresponding tertiary,[4−9] secondary[4,10,11] and primary[12] phosphanylalkanethiols have received comparatively less attention. The lack of investigations in this area reflects the paucity of commercially available primary phosphanes, the synthesis of which often requires tedious procedures.[13] Catalytic reactions have been reported in which the transition metal center bears a neutral bidentate P,S ligand, such as the chiral phosphanylalkyl thioether $PR_2CH_2CHR'SR''$ (R, R′, R″ = alkyl or aryl).[8] However, these are rare due to the possibility of metal poisoning by sulfur.

While several transition metal complexes with tertiary phosphanylalkanethiolato ligands[4,6,7,14−28] are known, mainly late "soft" transition metal complexes bearing primary (Ni, Pd, Pt,[12] Co, Rh[29]) or secondary phosphanylalkanethiolato ligands (Ni,[4,30] Pd, Pt,[30] Co,[4,30,31] Cu,[30] Rh[31]) have been described**.** Here, the phosphanylalkanethiolato ligand acts as a monoanionic bidentate S,P-chelating ligand. In main-group metal chemistry, group-14 metal derivatives $Me_2M(P,S\text{-}SCH_2CH_2PPh)$ (M = Si,[11] Sn,[11,32] Ge[11,33]) and $Sn\{S,P,S\text{-}SCH_2CH_2P(Ph)CH_2CH_2S\}$[34] are known. Only a small number of early transition metal complexes is known.[7,35,36] However, the use of mixed P,S ligands appears attractive for several reasons. Group-4 and other early transition metals have well-established thiolato complexes which can be employed in catalytic processes,[37] while the late transition and coinage metals form stable phosphane complexes which can also be used in catalysis.[38] Thus, the possibility of bridging two different metal centers by using ligands with mixed donor atoms appears feasible and could conceivably result in metal−metal interaction[7] and complexes with new and unique reactivity patterns. To date, only a few heterobimetallic complexes in which a phosphanylalkanethiolato ligand bridges an early and a late transition metal center are known, namely, $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Rh]^+$ or $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Rh]^0$,[7] $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Ni]$,[39] $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Ni(CO)_2]$,[39] $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Pd]^{2+}$,[39] and $[Cp_2Ti(SCH_2CH_2PPh_2)_2Cu]^+$.[35] Several homodi-[26,40−44] and -trinuclear[16,30,39,45] complexes and heterobimetallic bi-[46,47] and trinuclear[39−41] complexes, in which the P,S ligand bridges two late transition metal centers (Fe, Ni, Co, Pd, Pt, Cu, Ag) have also been reported. Some of these complexes have been structurally characterized.

We now report on the synthesis and spectroscopic studies of the soft-soft P−H-functionalized 2-(phosphanyl)ethanethiols $RHPCH_2CH_2SH$ [R = Ph (**1**), 2,4,6-$Me_3C_6H_2$ (Mes) (**2**), 2,4,6-$iPr_3C_6H_2$ (Tipp) (**3**)]. The synthesis of **1** from NaPHPh and ethylene sulfide in liquid ammonia, followed by hydrolysis with hydrochloric acid was reported by Issleib et al. in 1967.[4] However, characterization of the product was limited to elemental analysis and IR-spectroscopic studies.

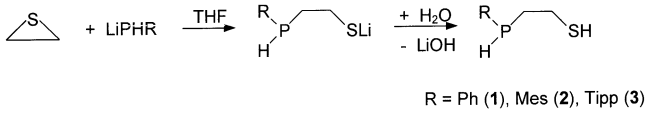
Results and Discussion

Synthesis and Characterization of the 2-(Phosphanyl)ethanethiols $RHPCH_2CH_2SH$ [R = Ph (1), Mes (2), Tipp (3)]

The P−H-functionalized 2-(phosphanyl)ethanethiols $RHPCH_2CH_2SH$ [R = Ph (**1**), Mes (**2**), Tipp (**3**)] were prepared by nucleophilic ring cleavage of ethylene sulfide with the lithium phosphanides LiPHR, prepared in situ from RPH_2 and BuLi, followed by hydrolytic workup and distillation (Scheme 1). A stoichiometric amount of ethylene sulfide had to be employed to prevent further reaction to $RP(CH_2CH_2SH)_2$.[6] **1**−**3** were obtained in good yields and gave satisfactory elemental analyses. They are readily oxidized by air. At room temperature, the 2-(phosphanyl)-ethanethiols are colorless oils that solidify at −30 °C.



Scheme 1

The 2-(phosphanyl)ethanethiols **1**−**3** were characterized spectroscopically (^1H, ^{31}P, ^{13}C NMR spectroscopy; MS; and IR spectroscopy). A comparison of the ^1H, ^{31}P and ^{13}C data for **1**−**3** is given in Table 1. In the proton-coupled ^{31}P NMR spectra, **1**−**3** give rise to doublets, and the signals of **1** are downfield relative to those of **2** and **3** (**1** < **2** < **3**; Table 1).

In the ^1H NMR spectra, the S−H proton gives rise to a triplet (**1** and **2**) or multiplet (**3**) at δ = 1.2−1.3 ($^3J_{H-H}$ = 7.8 Hz). The methylene protons of the $HPCH_2CH_2SH$ fragment appear as complex multiplets due to $^1H-^1H$ and $^1H-^{31}P$ coupling. The P−H signal is a doublet of doublets of doublets (**1** and **2**) or a doublet of triplets (**3**) at δ ≈ 4.0−4.3 ($^1J_{P-H}$ = 209−217, $^3J_{H-H}$ = 7−9 Hz). In the ^{13}C NMR spectra, the $P-CH_2$ and $S-CH_2$ groups give rise to doublets at δ = 24.4−24.8 (P−C, $^1J_{C-P}$ = 7.1 and 7.8 Hz for **1** and **2**, 12.6 Hz for **3**) and δ = 27.7 −30.4 (P−C−*C*−S, $^2J_{C-P}$ ca. 15.8−17.0 Hz). For all compounds, molecular ion peaks were observed in the mass spectra. In the IR spectra, the S−H stretching band is observed around 2560 cm^{-1}, and ν(P−H) is found in the 2280 to 2340 cm^{-1} region (cf. ref.[4]).

Synthesis and Characterization of *rac*- and *meso*-$[Cp_2Ti(SCH_2CH_2PHR)_2]$ [R = Ph (4), Mes (5), Tipp (6)]

The P−H-functionalized 2-(phosphanyl)ethanethiols **1**−**3** react with $[Cp_2TiCl_2]$ in the presence of excess triethylamine to give the disubstituted products $[Cp_2Ti(SCH_2CH_2PHR)_2]$ [R = Ph (**4**), Mes (**5**), Tipp (**6**)], and $(NEt_3H)Cl$ (Scheme 2). In the $^{31}P\{^1H\}$ NMR spectra (Table 2), two singlets of equal intensity are present, in accordance with the presence of two diastereomers due to the chiral center at the phosphorus atom. Separation of the diastereomers was not achieved, even after repeated recrystallization. The chemical shifts of the 2-(phosphanyl)ethanethiols and of the titanium complexes are similar, the latter exhibiting a downfield shift of only δ ≈ 2.5. This indicates no Ti−P interaction in solution. In complexes in which the phosphanylalkanethiolato ligand acts as bidentate ligand, a downfield shift of δ ≈ 80 is observed in the ^{31}P NMR

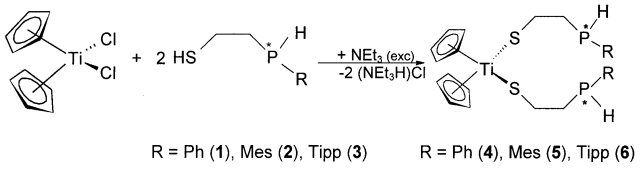
spectrum.[12] In the ^{13}C NMR spectra of **4** and **5**, the signal of the S−CH_2 group is shifted downfield by ca. 19 ppm relative to the free ligand.



Scheme 2

For **4** and **6**, separation of the titanium complex and the 2-(phosphanyl)ethanethiol could not be achieved by column chromatography or recrystallization. When the purple oil was heated to ca. 46 °C at 10^{-3} Torr (**4**) or ca. 113 °C at 10^{-3} Torr (**6**), the 2-(phosphanyl)ethanethiol could be distilled off, but decomposition of the titanium complex also occurred.

The related Ti complexes $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2]$[7] and $[Cp_2Ti(SCH_2CH_2PPh_2)_2]$[35] were obtained in a similar way, as a purple solid and a viscous purple oil that could not be crystallized, respectively. The difference in chemical shifts [$\Delta\delta^{31}P$(complex − ligand) = 1.3 or 0.9 ppm] is comparable to that observed for **4**−**6** relative to **1**−**3**.

Molecular Structure of $[Cp_2Ti(SCH_2CH_2PHMes)_2]$ (5)

Dark purple crystals of **5** were obtained from a saturated hexane solution at room temperature. **5** crystallizes in the centrosymmetric triclinic space group $P\bar{1}$ with four molecules in the unit cell. Both diastereomers, *rac*- and *meso*-$[Cp_2Ti(SCH_2CH_2PHMes)_2]$, are present in the asymmetric unit (Figure 1, Table 3). Cocrystallization of the two diastereomers would appear to be the major reason for the failure to separate them by fractional crystallization. Both diastereomers have similar bond lengths and bond angles.

The titanium atom is coordinated in a pseudotetrahedral fashion by two Cp rings and the S atoms of 2-(phosphanyl)-ethanethiolato ligands. The Ti−S bond lengths of 2.3699(7) to 2.4155(7) Å [average 2.3925(7) Å] and the S−Ti−S bond angles of 96.04(2) and 96.09(3)° are slightly larger than those of the related complex $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2]$ [Ti−S 2.378(6), 2.384(6) Å, S−Ti−S 93.3(2)°].[7] One of the C−S−Ti bond angles in **5** is large [C(11)−S(1)−Ti(1) 114.6(1); C(43)−S(3)−Ti(2) 114.70(9)°], and the other is smaller, by ca. 5 to 7° [C(22)−S(2)−Ti(1) 109.08(8); C(54)−S(4)−Ti(2) 107.63(8)°]. This suggests some degree of backbonding from S(1) and S(3) to Ti, which are also involved in the shorter Ti−S bonds [Ti(1)−S(1) 2.3899(6); Ti(2)−S(3) 2.3699(7) Å]. In $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2]$, the C−S−Ti bond angles are similar, 109.7(6) and 110.0(6)°.[7] In the titanocene dithiolato complexes, $[Cp^R_2Ti(SR')_2]$[48] (Cp^R = Cp, R′ = Me,[49] Et,[50] *t*Bu,[51] Ph;[52] Cp^R = $C_5H_4SiMe_3$, R′ = C_6F_5 [53]) and $[Cp^*_2Ti(SH)_2]$ (Cp^* = C_5Me_5),[54] the Ti−S bond lengths range from 2.387(3) (R′ = Et) to 2.438(2) Å (R′ = C_6F_5), and the S−Ti−S angles from 93.6(1) (R′ = Me) to 100.6(1)° (R′ = C_6F_5). The values observed for **5** fall inside this range. In titanocene complexes with chelating S,S ligands, the S−Ti−S angles are smaller (ca. 83°) due to the geometric requirements.[48,51,55,56]

The related heterobimetallic complexes $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Rh]^+$ [Ti−S 2.409(3), 2.438(3) Å],[7] $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Ni]$ [Ti−S 2.484(5), 2.483(5) Å],[39] $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Ni(CO)_2]$ [Ti−S 2.398(2), 2.398(4) Å],[39] and $[Cp_2Ti(SCH_2CH_2PPh_2)_2Cu]^+$ [Ti−S 2.465(2), 2.484(3) Å][35] have been structurally characterized. Here, the Ti−S bonds are longer when the S atom is also bonded to a second transition metal.

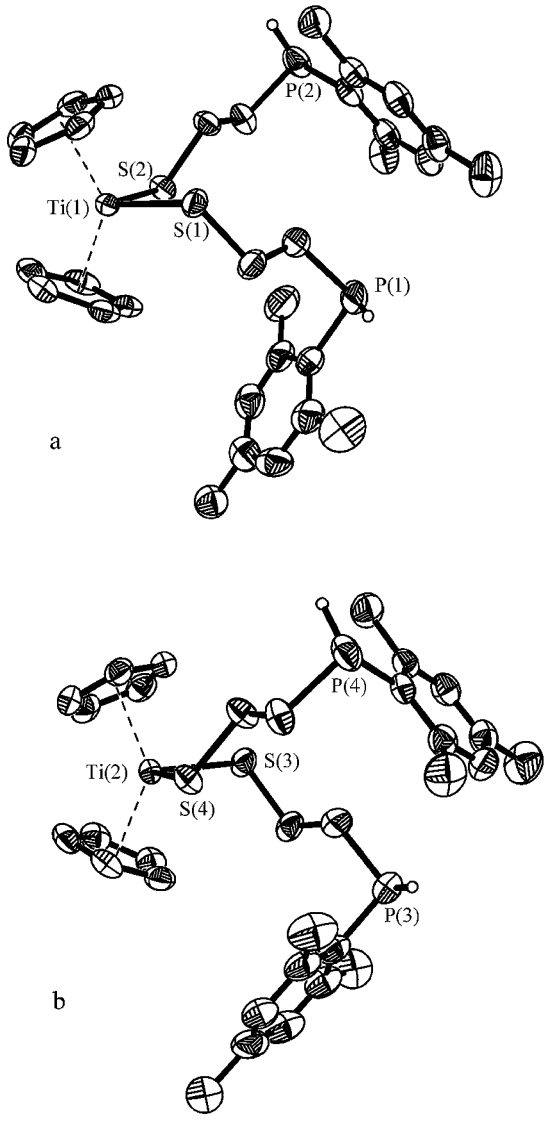


Figure 1. Molecular structure of $[Cp_2Ti(SCH_2CH_2PHMes)_2]$ (**5**) showing the atom numbering scheme employed (ORTEP, 50% probability, SHELXTL PLUS; XP);[70] a) *rac* isomer; b) *meso* isomer; hydrogen atoms (other than P−H) are omitted for clarity

Other related mononuclear transition metal complexes with S,P chelating phosphanylalkanethiolato ligands which have been structurally characterized include $[MoX(S,P\text{-}SCH_2CH_2PPh_2)_2]^{n+}$ ($n = 0$, X = O;[18] $n = 1$, X = Cp[36]), $[Re(SCH_2Ph)(S,P\text{-}SCH_2CH_2PPh_2)_2]$,[22] $[Tc(S,P\text{-}SC_6H_4PPh_2)_3]$,[14] $[Tc(S,P\text{-}SCH_2CH_2PPh_2)_2(S\text{-}SCH_2CH_2POPh_2)]$,[15] $[FeCl(CO)(PPh_3)(S,P\text{-}SC\{(t\text{Bu})(SCOMe)\}CH_2PPh_2)]$,[21] $[Fe\{\eta^2\text{-}C(OMe)S\}P(OMe)_3(S,P\text{-}SC(t\text{Bu})=CHPPh_2)]$,[24] $[Ir(H)(S,P\text{-}SCH_2CH_2PPh_2)(S,P\text{-}HSCH_2CH_2PPh_2)(CO)]^+$,[17] $[Ni(S,P\text{-}SCH_2CH_2PR_2)_2]$ (R = Me,[23] Ph[25]). Complexes with tri-, tetra- or hexadentate phosphanylalkanethiolato ligands which also have been studied are $[Mo\{S,P,S\text{-}(SCH_2CH_2)_2PPh\}_2]$,[6] $[Ni\{S,S,P,P\text{-}SCH_2CH_2P(Ph)CH_2CH_2CH_2P(Ph)CH_2CH_2S\}]$,[20] and $[Os\{P,P,S,S,S,S\text{-}P(CH_2CH_2S)(CH_2CH_2SSCH_2CH_2)_2P(CH_2CH_2S)\}]$.[9]

P,S ligands without a carbon spacer between P and S are present in thiophosphoryltitanocene complexes such as $[Cp'_2Ti\{\eta^2\text{-}S,S\text{-}SP(S)(R)P(S)(R)S\}]$ and $[Cp'_2Ti\{\eta^2\text{-}S,S\text{-}S_2P(S)R\}]$ ($Cp' = C_5H_4Me$, R = p-$OMeC_6H_4$),[57] in the (phosphane sulfide)titanocene compounds $[Cp_2Ti(SPCy_2)_2]$ and $[Cp_2Ti\{\eta^2\text{-}S,S\text{-}S_2PCy_2\}]$[58] and in the inorganic titanium(IV) complexes $[TiCl_2\{\eta^2\text{-}S,S\text{-}S_2PEt_2\}_2]$.[59] In $[Cp'_2Ti\{\eta^2\text{-}S,S\text{-}S_2P(S)R\}]$ [2.4898(8), 2.4639(8) Å],[57] $[Cp_2Ti\{\eta^2\text{-}S,S\text{-}S_2PCy_2\}]$ [2.586(4) and 2.611(5) Å],[58] and $[TiCl_2\{\eta^2\text{-}S,S\text{-}S_2PEt_2\}_2]$ [2.503(3) and 2.442(3) Å],[59] which contain chelating P,S ligands, the Ti−S bond lengths are in the range of dinuclear complexes in which the S atom of the thiolato substituent is bonded to two metal atoms. In the complex $[Cp_2Ti(SPCy_2)_2]$, with a nonchelating S,P ligand, the Ti−S bond lengths [2.420(3), 2.427(3) Å][58] are in the range observed for **5**.

Reaction of $[Cu(CH_3CN)_4]BF_4$ with $[Cp_2Ti(SCH_2CH_2PHPh)_2]$ (4) − Molecular Structure of $[Cu\{P,P'\text{-}PHPhCH_2CH_2SB(FH)SCH_2CH_2PPh(B-P)\}_2]BF_4$ (7)

When **4** was treated with $[Cu(CH_3CN)_4]BF_4$ we expected the formation of the heterodinuclear complex $[Cp_2Ti(SCH_2CH_2PHPh)_2Cu]BF_4$, analogous to the formation of the green-black complex $[Cp_2Ti(SCH_2CH_2PPh_2)_2Cu]BF_4$ (obtained in 55% yield).[35] However, although the experiment was carried out in exactly the same way as that leading to the heterodinuclear Ti−Cu complex, we were unable to isolate a heterodinuclear complex. Instead, we observed the formation of a Cu^I complex, $[Cu\{P,P'\text{-}PHPhCH_2CH_2SB(FH)SCH_2CH_2PPh(B-P)\}_2]BF_4$ (**7**), in a low yield. Apparently this was formed in a complex reaction in which ligand exchange between the BF_4^- anion and the titanium complex occurred with the formation of $[PHPhCH_2CH_2SB(F_2)SCH_2CH_2PHPh]^-$, followed by the substitution of one fluoride atom by the phosphanyl group with the transfer of the P−H proton to the remaining fluoride, to give the cyclized ligand $PHPhCH_2CH_2SB(FH)SCH_2CH_2PPh(B-P)$. Coordination of this bis(phosphane) ligand to Cu^I gives the cation $[Cu\{P,P'\text{-}PHPhCH_2CH_2SB(FH)SCH_2CH_2PPh(B-P)\}_2]^+$ (**7**) (Scheme 3). Elimination of HX from the adducts $R_2BX-PHR'_2$, with the formation of B−P single bonds, has been observed before.[60]

The participation of the BF_4^- anion in the reaction was rather unexpected and, to the best of our knowledge, is unprecedented. The only reaction reported involving BF_4^- is that with difluorophosphoric acid (HPO_2F_2) in $P_2O_3F_4$ to give $HB(PO_2F_2)_4$.[61] In addition, Stephan et al. were able to synthesize the heterodinuclear complexes $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2Rh]^+$ [7] and $[Cp_2Ti(SCH_2CH_2PPh_2)_2Cu]^+$ [35] in ca. 60% yield starting from the corresponding BF_4^- salts of $[Rh(NBD)_2]^+$ (NBD = norbornadiene) and $[Cu(CH_3CN)_4]^+$. However, when $[Ni(CH_3CN)_4](BF_4)_2$ was treated with $[Cp_2Ti(SCH_2CH_2CH_2PPh_2)_2]$, the trinuclear Ni complex $[Ni\{(SCH_2CH_2PPh_2)_2Ni\}_2]^{2+}$ was obtained in a 75% yield due to ligand exchange.[39] Other heterodinuclear complexes with phosphanylalkanethiolato bridges are $[Ni(\mu\text{-}SCH_2CH_2PPh_2)_2Mo(CO)_4]$,[47] accessible from $[Ni(S,P\text{-}SCH_2CH_2PPh_2)_2]$ and $[Mo(CO)_4(NBD)]$, and $[Pt\{\mu$-

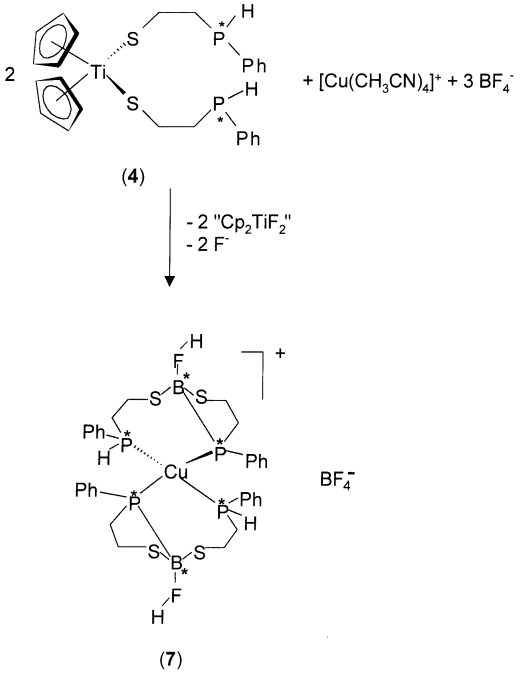

Scheme 3

$SCH_2CH_2PEt_2)_2Ag\}]_\infty(NO_3)_\infty$,[46] which is obtained from $[Pt(S,P\text{-}SCH_2CH_2PEt_2)_2]$ and $AgNO_3$.

At room temperature, two broad sets of signals are observed at $\delta \approx -32$ and $\delta \approx -43$ in the ^{31}P NMR spectrum of **7.** The absence of a signal in the EPR spectrum indicates the presence of Cu^I. The signals at $\delta \approx -43$ show further proton coupling and are thus assigned to the PHPh groups. In **7**, there are six chiral centers present (two boron and four phosphorus atoms), and hence numerous diastereomers (2^6 enantiomers) can be formed resulting in the observation of a large number of signals in the appropriate region of the NMR spectrum. Additionally, (phosphane)Cu^I complexes exhibit dynamic behavior in solution, and Cu has a quadrupole moment, hence broad signals are usually observed in the ^{31}P NMR spectra.

Only one singlet at $\delta = -0.97$ is observed in the ^{11}B NMR spectrum of **7** in $CDCl_3$. This is assigned to the BF_4^- anion by comparison with the starting material, $[Cu(CH_3CN)_4]BF_4$.[62] Apparently, the signal for the boron atom of the bis(phosphane) ligand is too broad to be observed, and this is probably due to the quadrupole moment of boron, the observed dynamic behavior, and the presence of several possible diastereomers in solution.

7 crystallizes in the monoclinic space group $P2_1/n$ with four formula units in the unit cell. One molecule of CH_2Cl_2

is present in the asymmetric unit. The BF_4^- anion is highly disordered. Although the cation of **7** has six chiral centers (two boron and four phosphorus atoms) and numerous diastereomers are observed in solution, there is only one diastereomer present in the solid state. In this diastereomer, all six chiral centers have either (*R*) or (*S*) configuration (Figure 2, Table 4). The two enantiomers are related by a crystallographic center of inversion in the centrosymmetric space group $P2_1/n$. To the best of our knowledge, this is the first structurally characterized chiral bis(diphosphane)copper(I) complex.

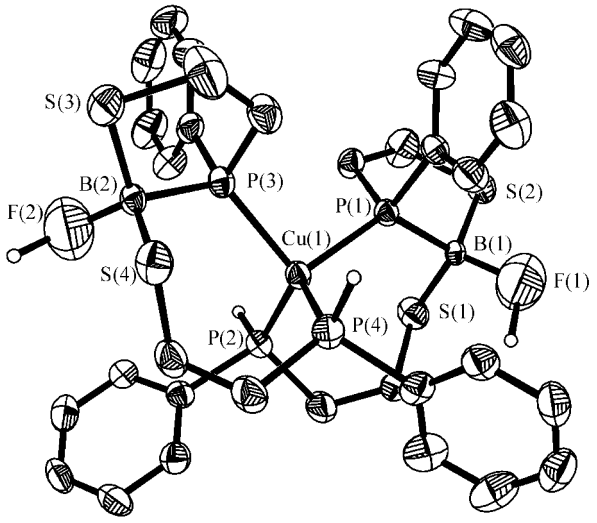

Figure 2. Molecular structure of $(R_P,R_P,R_P,R_P,R_B,R_B)$/$(S_P,S_P,S_P,S_P,S_B,S_B)$-[Cu{*P*,*P*′-$PHPhCH_2CH_2SB(FH)SCH_2CH_2PPh(B-P)$}$_2$]$BF_4$ (**7**) showing the atom numbering scheme employed (ORTEP, 50% probability, SHELXTL PLUS; XP);[70] only the cation is shown; hydrogen atoms (other than P−H or F−H) are omitted for clarity

In **7**, the copper(I) center is coordinated in a distorted tetrahedral fashion to four P atoms of two neutral chelating bis(phosphane) ligands, $PHPhCH_2CH_2SB(FH)SCH_2CH_2PPh(B-P)$. The Cu−P bond lengths of the secondary phosphane groups [Cu(1)−P(2) 2.268(1), Cu(1)−P(4) 2.276(1) Å] in **7** are slightly smaller than those of the other two phosphane ligands [Cu(1)−P(1) 2.287(1), Cu(1)−P(3) 2.295(1) Å]. The P−Cu−P bond angles of the chelating phosphanes are large [P(4)−Cu(1)−P(1) 115.26(5), P(2)−Cu(1)−P(3) 116.90(5)°], as is the P(2)−Cu(1)−P(4) bond angle [117.44(5)°]. The other P−Cu−P angles range from 101.15(4) to 104.00(4)°.

Several (tetraphosphane)copper(I) [63] and bis(diphosphane) complexes[64] have been structurally characterized (Table 5). The Cu−P bond lengths are comparable with those of **7**, while the P−Cu−P bite angle of the chelating phosphanes is dependent on the ring size. Thus, five-membered rings exhibit P−Cu−P bond angles ranging from 88.3(1) to 90.9(1)°, while these angles are larger in $[Cu(PPh_2CH_2CH_2CH_2PPh_2)_2]X$, which has a six-membered ring [X = ClO_4: 94.56(9), 96.94(9)°;[64c] BF_4: 97.66(5), 98.22(5)°[64a]]. In **7**, which has a seven-membered ring [the largest chelate ring reported for structurally characterized bis(diphosphane)Cu^I complexes to date], the bite angles of 115.26(5), 116.90(5)° are the largest observed so far. Dinuclear Cu^I complexes with bridging bis(phosphane) ligands are generally formed when the chain length of the bis(phosphane) increases to six $[PPh_2CH_2(CH_2)_2CH_2PPh_2]$ or eight atoms $[PPh_2CH_2(CH_2)_4CH_2PPh_2]$.[64c]

The bis(phosphane) ligands in **7** contain P−B bonds, presumably formed by elimination of HF. The P−B bond lengths of 1.872(4) and 1.877(5) Å agree well with those of other phosphanidoboranes of the general formula $R_2B-PR'_2$.[60] In **7**, the B−S bond lengths of 1.817(4) [S(2)−B(1)], 1.844(5) [S(1)−B(1)], 1.821(5) [S(3)−B(2)] and 1.840(5) Å [S(4)−B(2)] are in the range observed for thioboranes.[65]

[a] L^1 = 2,3-bis(diphenylphosphanyl)maleic anhydride

We are presently further investigating the potential of **1**−**3** as thiolato- and/or phosphanido ligands in transition metal chemistry.

Experimental Section

General: All experiments were carried out under purified dry argon. Solvents were dried and freshly distilled under argon. − NMR spectra: Avance DRX 400 (Bruker), standards: ^1H NMR (400 MHz): trace amounts of protonated solvent, C_6D_6; ^{13}C NMR (100.6 MHz): internal solvent; ^{31}P NMR (162 MHz): external 85% H_3PO_4. − The IR spectra were recorded as KBr mulls with a Perkin−Elmer FT-IR spectrometer System 2000 in the range 350−4000 cm^{-1}. − The mass spectra were recorded with a Sektorfeldgerät AMD 402 (AMD Intectra GmbH; EI, 70 eV). − The melting points were determined in sealed capillaries under argon and are uncorrected. RPH_2 (R = Ph,[66] Mes,[67] Tipp[13]), and $[Cu(CH_3CN)_4]BF_4$ [68] were prepared according to literature procedures. $[Cp_2TiCl_2]$ and ethylene sulfide are commercially available (Aldrich).

Preparation of 2-(Phenylphosphanyl)ethanethiol (1): $PhPH_2$ (5 mL, 45 mmol) was dissolved in degassed THF (250 mL) and cooled to −70 °C. BuLi (30.7 mL of a 1.48 M solution, 45 mmol) in hexane was added dropwise over 30 min. The color of the solution changed to turbid orange. After stirring for 1 h at room temp., the solution was cooled again to −70 °C, and ethylene sulfide (3 mL, 49.9 mmol) was added slowly. The color of the solution became clear yellow. After stirring for 30 min at room temp., about 2 mL of degassed water was added. The solution turned turbid white due to the formation of LiOH, which was filtered off. The solvent was then evaporated, and the colorless viscous residue distilled to give **1** (5.4 g, 70%, b.p. 46 °C/10^{-3} Torr; ref.[4]: b.p. 135−137 °C/10 Torr). − EI MS: *m*/*z* (%) = 170 (57) [M^+], 142 (14) [$M^+ - 2\ CH_2$], 137 (82) [M^+ − SH], 109 (100) [$PHPh^+$], and fragments thereof. − IR [cm^{-1}]: $\tilde{\nu}$ = 2564 m (νSH; ref.[4]: 2560 cm^{-1}), 2285 vs (νPH; ref.[4]: 2290 cm^{-1}). − $C_8H_{11}PS$ (170.2): calcd. C 56.45, H 6.51, S 18.8; found C 55.00, H 6.59, S 17.6.

Preparation of 2-(Mesitylphosphanyl)ethanethiol (2): $MesPH_2$ (4.88 g, 32 mmol) was dissolved in degassed THF (250 mL), and the solution cooled to −70 °C. BuLi (22 mL of a 1.48 M solution, 32.6 mmol) in hexane was added dropwise over 30 min. The color of the solution changed to turbid orange. After stirring for 1 h at room temp., the solution was cooled again to −70 °C, and ethylene sulfide (2 mL, 33.2 mmol) was added slowly. The color of the solution became clear yellow. After stirring for 30 min at room temp., about 0.8 mL of degassed water was added. The solution turned turbid white due to the formation of LiOH, which was filtered off. The solvent was then evaporated, and the colorless viscous residue distilled to give **2** (4.3 g, 63%, b.p. 100 °C/$10^{-2.5}$ Torr). − EI MS: *m*/*z* (%) = 212 (84) [M^+], 208 (8) [$M^+ - 2\ H_2$], 179 (47) [M^+ − SH], 151 (73) [$PHMes^+$], and fragments thereof. − IR [cm^{-1}]: $\tilde{\nu}$ = 2560 m (νSH), 2334 vs (νPH). − $C_{11}H_{17}PS$ (212.3): calcd. C 62.23, H 8.67; found C 61.9, H 8.21.

Preparation of 2-(Triisopropylphenylphosphanyl)ethanethiol (3): $TippPH_2$ (5.18 g, 22 mmol) was dissolved in degassed THF (250 mL), and the solution cooled to −70 °C. BuLi (18.7 mL of a 1.17 M solution, 22 mmol) in hexane was added dropwise over a period of 30 min. The color of the solution changed to yellow, and LiPHTipp precipitated from the solution. This was isolated by filtration (3 g, 57.2%, confirmed by ^{31}P NMR[13]). LiPHTipp (2 g, 8.35 mmol) was then dissolved in THF (200 mL), and the solution cooled to −70 °C. Ethylene sulfide (0.5 mL, 8.39 mmol) was added slowly. The color of the solution became light yellow. After stirring for 30 min at room temp., about 0.2 mL of degassed water was added, and the solution turned turbid white due to the formation of LiOH, which was filtered off. The solvent was then evaporated, and the colorless viscous residue distilled to give **3** (2.1 g, 83%, b.p. 113 °C/10^{-3} Torr). − EI MS: *m*/*z* (%) = 296 (19) [M^+], 263 (100) [M^+ − SH], 235 (17) [$PHTipp^+$], and fragments thereof. − $C_{17}H_{29}PS$ (296.4): calcd. C 68.88, H 9.86; found C 69.30, H 9.96.

Preparation of $[Cp_2Ti(SCH_2CH_2PHPh)_2]$ (4): $PhPHCH_2CH_2SH$ (0.60 g, 3.5 mmol) was added to a solution of $[Cp_2TiCl_2]$ (0.35 g, 1.4 mmol) in THF (25 mL). A solution of triethylamine (0.9 mL, 6.4 mmol) in THF (25 mL) was added dropwise over 30 min. The solution was stirred for 24 h during which its color changed from red to purple. $(Et_3NH)Cl$ was removed by filtration, and the solvent was removed from the filtrate in vacuum. The oily residue was washed three times with 10 mL of hexane, then recrystallized from toluene/hexane to give **4** as a viscous oil. Yield: 0.65 g (90%). NMR spectra showed that there is a minor impurity of **1** present which could not be eliminated by recrystallization or heating to ca. 46 °C at 10^{-3} Torr (decomp. of **4** occurred). − EI MS: *m*/*z* (%) = 347 (9) [$M^+ - SCH_2CH_2PHPh$], 109 (52) [$PHPh^+$], and fragments thereof. − IR [cm^{-1}]: $\tilde{\nu}$ = 2281 vs (νPH).

Preparation of $[Cp_2Ti(SCH_2CH_2PHMes)_2]$ (5): $MesPHCH_2CH_2SH$ (1.1 g, 5.1 mmol) was added to a solution of $[Cp_2TiCl_2]$ (0.59 g, 2.3 mmol) in THF (25 mL). A solution of triethylamine (1.0 mL, 7.1 mmol) in THF (25 mL) was added dropwise over 30 min. The solution was stirred for 24 h during which its color changed from red to purple. $(Et_3NH)Cl$ was separated by filtration. The solvent was removed from the filtrate in vacuum. The oily residue was dissolved in 25 mL hexane and filtered. At room temperature, crystals of **5** formed. Yield: 0.45 g (32%), m.p. 105−108 °C. − EI MS: *m*/*z* (%) = 600 (2) [M^+], 389 (17) [$M^+ - SCH_2CH_2PHMes$], 212 (57) [$HSCH_2CH_2PHMes^+$], 178 (32) [Cp_2Ti^+], 152 (58) [PH_2Mes^+], 119 (100) [Mes^+], and fragments thereof. − $C_{32}H_{42}P_2S_2Ti$ (600.62): calcd. C 63.99, H 7.05, S 10.68; found C 63.9, H 6.57, S 10.5.

Preparation of $[Cp_2Ti(SCH_2CH_2PHTipp)_2]$ (6). $TippPHCH_2CH_2SH$ (1.03 g, 3.4 mmol) was added to a solution of $[Cp_2TiCl_2]$ (0.39 g, 1.5 mmol) in THF (25 mL). A solution of triethylamine (1.0 mL, 7.1 mmol) in THF (25 mL) was added dropwise over 30 min. The solution was stirred for 24 h during which its color changed from red to purple. $(Et_3NH)Cl$ was separated by filtration. The solvent was removed from the filtrate in vacuum. The oily residue was dissolved in 25 mL hexane and filtered. The resulting oily residue was recrystallized repeatedly from hexane. However, the NMR spectra showed the presence of an impurity of **3**, which could not be eliminated by recrystallization or heating to ca. 113 °C at 10^{-3} Torr (decomp. of **6** occurred).

Reaction of $[Cu(CH_3CN)_4BF_4]$ with $[Cp_2Ti(SCH_2CH_2PHPh)_2]$ (4): A solution of **4** (0.18 g, 0.35 mmol) in acetonitrile (20 mL) was added dropwise to a solution of $[Cu(CH_3CN)_4]BF_4$ (0.11 g, 0.35 mmol) in acetonitrile (10 mL). The solution was stirred overnight, after which it was concentrated under vacuum, and diethyl ether was added. A brownish solid precipitated. This was isolated, dissolved in CH_2Cl_2, layered with hexane and then connected to another flask containing toluene. Some yellow crystals formed over a black residue. The yellow crystals were isolated.

Data Collection and Structural Refinement of 5 and 7: Crystallographic data are given in Table 6. Data [λ(Mo-K_α) = 0.71073 Å] were collected with a Siemens CCD (SMART) diffractometer. All observed reflections were used for the determination of the unit cell parameters. Empirical absorption correction with SADABS.[69] The structures were solved by direct methods (SHELXTL PLUS[70]). Restrictions for **5**: Zr, S, P, and C atoms anisotropic; restrictions for **7**: Cu, P, B, F, S, and C atoms anisotropic; H atoms located by difference maps and refined isotropically. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre (**5**: CCDC-159594; **7**: CCDC-159593). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) + 1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Calix[6]arene-Based N_3-Donors − A Versatile Supramolecular System with Tunable Electronic and Steric Properties − Study on the Formation of Tetrahedral Dicationic Zinc Complexes in a Biomimetic Environment

Olivier Sénèque,[a] Yannick Rondelez,[a] Loïc Le Clainche,[a] Claude Inisan,[a] Marie-Noëlle Rager,[b] Michel Giorgi,[c] and Olivia Reinaud*[a]

Keywords: Calixarenes / Zinc / *N* ligands / Bioinorganic chemistry / Coordination chemistry

Novel tridentate *N*-ligands containing tertiary amines, pyrazoles, or benzimidazole groups were synthesized from *t*Bu-calix[6]arene. Together with the previously described pyridine and imidazole-based ligands, they form a large family of biomimetic ligands ($X_6Me_3N_3$) with different electronic and steric properties. Their capacity at stabilizing a tetrahedral Zn dicationic center in acetonitrile was investigated. Tertiary amines were too basic and sterically hindered, leading to precipitation of $Zn(OH)_2$. The resulting protonated ligand was, in one case, structurally characterized by X-ray analysis. Ligands with pyrazole, benzimidazole and imidazole donors, all formed a stable Zn complex under stoichiometric conditions in acetonitrile. An ^1H NMR spectroscopic study together with X-ray crystallography showed that the metal ion is coordinated to the three nitrogen arms with MeCN as a fourth ligand included in the calixarene conic pocket. These complexes provide new but rare examples of stable dicationic tetrahedral Zn species. The calixarene functionalized by three pyridine groups, on the other hand, did not appear to be a good ligand, which stands in contrast with its remarkable ability at stabilizing copper(I). Finally, these *funnel complexes* are chiral due to their helical shape. In solution, both enantiomers are in equilibrium. However, sterically hindered *N*-donors increased the enantiomerization barrier above 16 kcal/mol.

Introduction

Zinc enzymes constitute an important class of metalloproteins. These are ubiquitous and play a fundamental role in living systems. They are mainly involved in hydrolytic processes but also catalyze hydride transfer reactions. Zn^{2+} is usually maintained in the active site through its coordination to three amino acid residues, either His, Cys, Asp, or Glu. In mononuclear zinc enzymes that have been structurally characterized, the most recurrent binding site is tris-histidine. Indeed this N_3 core has been found in snake venom proteases, matrix metalloproteases, collagenases, deaminases, β-lactamase, carbonic anhydrase, and a carboxypeptidase.[1] Model chemistry is a fundamental tool for understanding these important biological systems. To mimic the role of a tris(imidazole) core, the most widely used N_3-ligands[2,3] are macrocyclic triamines,[4] anionic tris(pyrazolyl)borates,[5−7] or neutral tris(imidazolyl)methane and -phosphane.[8] Although the steric hindrance at each synthetic core can be tuned through the introduction of appropriate substituents, their electronic properties can hardly be modulated (particularly through the change of the *N*-donor).

In the present paper, we report on a calix[6]arene-based system that not only preorganizes a binding site for the metal center but also provides a cavity next to it. This system is highly versatile since it allows the tuning of both the steric hindrance and the electronic properties due to the *N*-donor set. Here, we first describe the synthesis of a series of novel calix[6]arene-based N_3-ligands. They offer a wide variety of potential binding sites, either tertiary or aromatic amines, with various steric encumbrance. We then report on their relative ability at stabilizing a metal ion in a biomimetic environment. We previously described the first members of this family with pyridine-based Cu^I [9,10] and imidazole-based Zn^{II} complexes.[11] These so-called *funnel complexes* present a hydrophobic cavity that wraps around the free coordination site of the metal ion, thereby acting like a selective molecular funnel for small exogenous ligands and mimicking the enzyme pocket. Here, we focus on the binding part of these supramolecular systems and compare the ability of the various *N*-donors at stabilizing a tetrahedral Zn^{2+} ion.

Results and Discussion

Synthesis of Ligands

The calix[6]arene-based N_3-ligands $X_6Me_3N_3$ were synthesized in two steps starting from *t*Bu-calix[6]arene

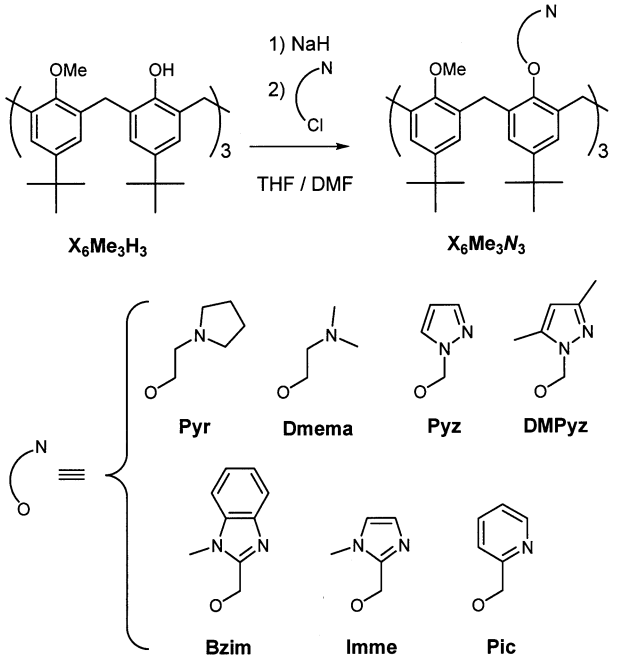
(X_6H_6).[12] The latter was first converted into its 1,3,5-trimethyl ether derivative ($X_6Me_3H_3$),[13] then treated with various alkyl chlorides in a THF/DMF mixture in the presence of excess NaH. The products $X_6Me_3N_3$ were obtained in good yields from $X_6Me_3H_3$ (ca. 80%). They constitute a very large family of tridentate ligands, presenting various *N*-donors: pyrrolidine (Pyr), dimethylamine (Dmema), pyrazole Pyz, 3,5-dimethylpyrazole (DMPyz), benzimidazole (Bzim), imidazole (Imme), and pyridine (Pic). All of them show good solubility in chlorinated solvents and are almost insoluble in acetonitrile (Scheme 1).



Scheme 1. Synthesis of the calix[6]arene-based N_3-ligands $X_6Me_3N_3$

Crystal Structures of $X_6Me_3Pyz_3$ and $[X_6Me_3Pyr_3.H_3](ClO_4)_3$

Two of these molecules were characterized by X-ray diffraction analysis. The molecular structures of ligand **$X_6Me_3Pyz_3$** and of the perchlorate salt of the ligand **$X_6Me_3Pyr_3$** are displayed in Figure 1 and 2, respectively. Both calix[6]arene structures stand in a flattened C_3-symmetrical cone conformation. The smallest *O*-substituents, the methoxy groups, point toward the inside of the cavity, close to the C_3 axis with the related *t*Bu groups lying in the *out*-position. The nitrogenous arms, which are the largest *O*-substituents, are projected outwards whereas the corresponding *t*Bu groups lie in the *in*-position. Figure 2 shows the regular head to head stacking of the protonated ligands forming a sandwich around a layer of perchlorates anions.

NMR Study of the Ligands

The $X_6Me_3N_3$ ligands underwent NMR spectroscopic analysis. In agreement with the X-ray structure of $X_6Me_3Pyz_3$, all of them displayed, at 298 K in $CDCl_3$, ^1H NMR spectroscopic profiles typical of a major cone conformer.

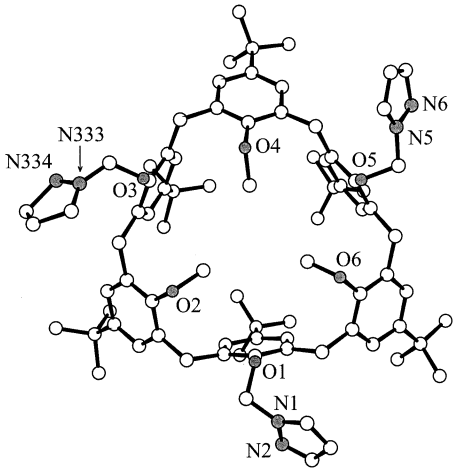


Figure 1. X-ray structure of $X_6Me_3Pyz_3$. Hydrogen atoms and solvent of crystallization were omitted for clarity. Only one out of the two isomers is shown (see Exp. Sect.)

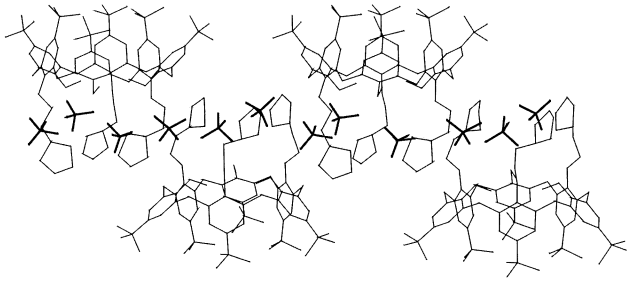

Figure 2. X-ray structure of $[X_6Me_3Pyr_3.H_3](ClO_4)_3$. Hydrogen atoms and solvent of crystallization were omitted for clarity

The high-field shift of the methoxy protons (δ_{OMe} = 2.14−2.33) attested to their partial inclusion in the calixarene π-basic cavity. It is well-known that calix[6]arenes are highly mobile molecules since interconversion processes between multiple conformers can occur via rotation through the annulus of both the *O*-alkyl and the *t*Bu groups.[14] Indeed, compounds $X_6Me_3Pyz_3$ and $X_6Me_3Dmema_3$ showed broad resonances with two large singlets for their bridging methylene protons, which is indicative of the beginning of a coalescence process at room temperature (Figure 2). In contrast, spectra of all others were sharp and well defined, with two doublets for the $ArCH_2Ar$ methylene protons. This indicated that the cone−cone interconversion was slower than the NMR timescale. In the specific case of compounds with the more sterically encumbered nitrogen arms (*N* = Pyr, DMPyz, and Bzim) a minor conformer was clearly detected at room temperature as six extra well-defined doublets for the bridging methylene groups were observed. This minor isomer probably corresponds to the 1,2,3-alternate conformer that was identified in the case of the closely related calix[6]arenes.[15] Hence, the comparative $ArCH_2Ar$ areas of the ^1H NMR spectra (displayed in Figure 3) are a good probe for the evaluation of calix[6]arene mobility.[16] A qualitative classification according to a decreasing mobility of the molecules can be made: $X_6Me_3Pyz_3$ and $X_6Me_3Dmema_3$ > $X_6Me_3Imme_3$ and $X_6Me_3Pic_3$ > $X_6Me_3Pyr_3$,

$X_6Me_3DMPyz_3$, and $X_6Me_3Bzim_3$. This indeed corresponds to an increasing steric encumbrance of the nitrogenous arms, that slows down their rotation through the annulus of the calix[6]arene.

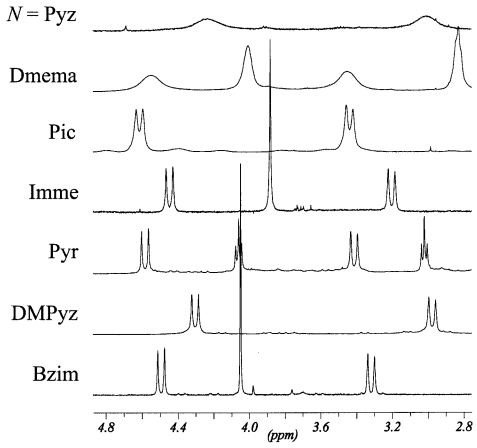

Figure 3. $ArCH_2Ar$ regions of the ^1H NMR spectra (400 MHz) of ligands $X_6Me_3N_3$ at 298 K in $CDCl_3$

Reaction with Zinc(II)

Compounds $X_6Me_3N_3$ were treated in acetonitrile with a stoichiometric quantity of $Zn(H_2O)_6(ClO_4)_2$ and the products were submitted for NMR spectroscopic analyses in CD_3CN.[17] In the case of ligands containing tertiary amine moieties ($X_6Me_3Dmema_3$ and $X_6Me_3Pyr_3$), the ^1H NMR spectra of the isolated compounds together with elemental analyses indicated the presence of three chlorine atoms per ligand which was due to the perchlorate salt of the tris-protonated ligands $[X_6Me_3N_3{\cdot}H_3](ClO_4)_3$ (N = Pyr and Dmema). Confirmation of these assignments was obtained by comparison with the authentic samples prepared with $HClO_4$. From these first results, it appears that the strong basicity of the tertiary amines-based ligands $X_6Me_3Pyr_3$ and $X_6Me_3Dmema_3$ together with the high steric hindrance at the nitrogen atoms, disfavors the formation of stable complexes and rather lead to their protonation with concomitant precipitation of $Zn(OH)_2$.

In contrast to these tertiary amine-based systems, calixarenes that have been functionalized with either pyrazole (Pyz and DMPyz), imidazole (Imme) or benzimidazole (Bzim) groups led to products with a 1:1 ligand/Zn ratio. One of them, $[Zn(X_6Me_3Imme_3)(CH_3CN)](ClO_4)_2$, was structurally characterized by X-ray analysis.

Crystal Structure of $[Zn(X_6Me_3Imme_3)(CH_3CN)](ClO_4)_2$

Single crystals were obtained by slow diffusion of Et_2O into a $CHCl_3/CH_3CN$ solution of $[Zn(X_6Me_3Imme_3)(CH_3CN)](ClO_4)_2$. The structure, displayed in Figure 4, shows a tetrahedral zinc center coordinated to all three imidazole arms and to an acetonitrile molecule. The latter is situated inside the calixarene cavity, along the C_3 axis. The calixarene is constrained in a flattened cone conformation with all OMe groups projected away from the cavity. The anisole *t*Bu groups are now in the *in*-position and the others are *out*. The average $Zn-N_{Im}$ bond length (1.973 Å) and the zinc−nitrile distance (2.008 Å) are particularly short, in accordance with the highly acidic nature of a tetrahedral zinc dication.[18] Finally, as previously observed for all other X-ray characterized *funnel complexes*, the coordinating arms (here the imidazole groups) form a chiral helix around the metal center and both enantiomers are present in the lattice.

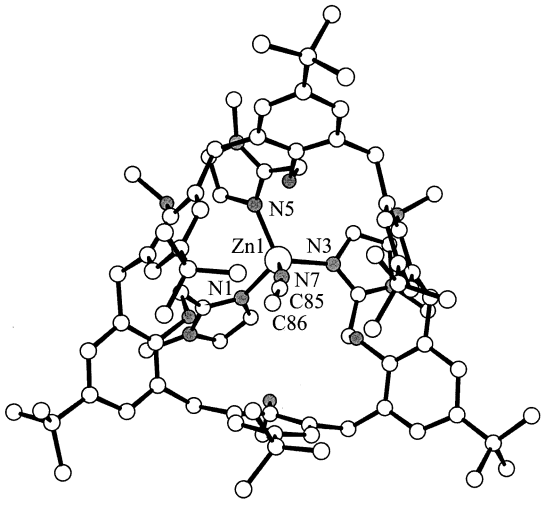

Figure 4. Crystal structure of complex $[Zn(X_6Me_3Imme_3)(CH_3CN)](ClO_4)_2$. Hydrogen atoms, counterions and solvent of crystallization were omitted for clarity. Selected bond lengths [Å] and angles [°]: Zn1−N1 1.956(9), Zn1−N3 1.993(10), Zn1−N5 1.972(9), Zn1−N7 2.008(11), N7−C85 1.132(15), N1−Zn1−N3 111.8(4), N1−Zn1−N5 110.5(4), N3−Zn1−N5 115.9(4), N1−Zn1−N7 106.3(4), N3−Zn1−N7 107.0(4), N5−Zn1−N7 104.4(4), Zn1−N7−C85 173.4(9), N7−C85−C86 174.2(2)

NMR Study of Zinc Complexes $[Zn(X_6Me_3N_3)(MeCN)](ClO_4)_2$

The Zn complexes obtained with ligands $X_6Me_3N_3$ (N = Pyz, DMPyz, Imme, Bzim) were analyzed by ^1H NMR spectroscopy in acetonitrile. Upon dissolution in CD_3CN, one equivalent of free CH_3CN was released, indicating that the isolated products possessed an acetonitrile molecule coordinated to the zinc ion.[19] In the case of $X_6Me_3Bzim_3$, the exchange process was slow enough to allow the observation of a vanishing resonance at $\delta = -0.80$.[20] This indeed corresponded to the coordinated protio-acetonitrile and its high-field shift attested to its location inside the calixarene π-basic cavity.

All NMR profiles displayed in Figure 5 are sharp and characteristic of a calix[6]arene in a C_3-symmetrical cone conformation. The methoxy protons are downfield shifted compared to the free ligand ($\delta = 3.6$ instead of ca. $\delta = 2.3$[21]). This is indicative of the change in the calixarene conformation due to the Zn^{II} coordination. The small rim of the cone is now closed up by the three nitrogen arms, which are linked together by the metal ion, thereby projecting the OMe groups outwards. An acetonitrile molecule (here the solvent) completes the coordination sphere of the

tetrahedral metal ion and fills in the empty space offered by the cavity (Scheme 2).[22] HMQC and HMBC experiments showed that the *t*Bu groups connected to the anisole present the higher shift (ca. $\delta = 0.8$ compared to $\delta = 1.4$ for the other *t*Bu) and form a gate at the entrance of the hydrophobic pocket. Hence, the calixarene adopts the same conformation in CD_3CN solution as the one depicted by the X-ray structure shown in Figure 4. Interestingly, this conformation is the opposite of that observed[10] for the related copper(I) complex $[Cu(X_6Me_3Pic_3)(CH_3CH_2CN)]^+$. As it does not seem to be ligand dependent, this different behavior may be attributed to the nature of the coordinated metal ion, and more precisely to its charge. Indeed, in the zinc conformation, the cone is flatter than in the copper(I) conformation and the metal cation gets closer to the basic oxygen of the phenoxyl moieties (3.8 vs. 4.1 Å).

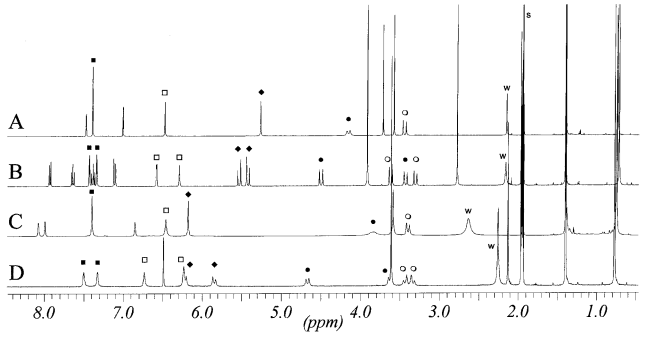

Figure 5. ^1H NMR spectra (400 MHz) of complexes $[Zn(X_6Me_3N_3)(CD_3CN)](ClO_4)_2$ at 298 K in CD_3CN. **A**: *N* = Imme, **B**: *N* = Bzim, **C**: *N* = Pyz, **D**: *N* = DMPyz. H_{Ar}: ■ and □; OCH_2: ◆; $ArCH_{ax}CH_{eq}Ar$: ●; $ArCH_{ax}CH_{eq}Ar$: ○. Solvent and water are labeled "s" and "w", respectively

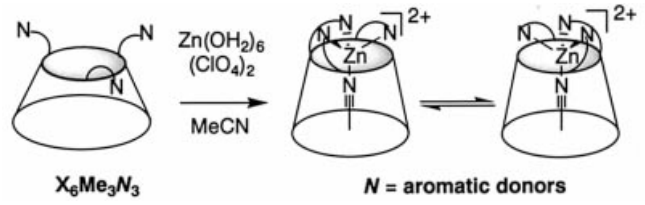

Scheme 2. Formation of "Zn-funnel complexes"

Lastly, no compound of defined stoichiometry could be isolated through the reaction of one molar equivalent of zinc perchlorate with the pyridine-based ligand $X_6Me_3Pic_3$. The ^1H NMR spectrum of the crude product presented broad signals and was hardly interpretable. However, the addition of an excess of $Zn(H_2O)_6(ClO_4)_2$ directly into an NMR tube containing ligand $X_6Me_3Pic_3$ resulted in a sharp C_3 symmetrical spectrum, which was not that of $[X_6Me_3Pic_3{\cdot}H_3](ClO_4)_3$. The down-field shift of the OMe and pyridine resonances compared to the free ligand were indicative of the formation of the complex, $[Zn(X_6Me_3Pic_3)(CD_3CN)](ClO_4)_2$, with the same conformation as the other above described Zn complexes. However, the equilibrium constant for its formation in acetonitrile is probably weak, as an excess of zinc salt was needed for its NMR characterization. This stands in contrast with the very stable tetrahedral Cu^I complexes that were obtained with the same ligand $X_6Me_3Pic_3$.[9,10]

The Zn Complexes are Chiral

As observed in the crystal structure, each complex exists as a pair of enantiomers due to its helical structure. In solution, these enantiomers are in conformational equilibrium as depicted in Scheme 2. However, the diastereotopic protons could be differentiated by ^1H NMR spectroscopy at various temperatures, depending on the ligand. The calixarene aromatic protons appeared as two pairs of singlets of equal intensity. The OCH_2 and the bridging methylene ($Ar-CH_{eq}$ and $Ar-CH_{ax}$) groups were represented by one and two pairs of doublets, respectively. Interestingly, whereas with *N* = Pyz and Imme a low temperature study was required to observe the coalescence processes, for complexes based on $X_6Me_3DMPyz_3$ and $X_6Me_3Bzim_3$, the splitting of the resonances was observed above 298 K. This different behavior may be related to the steric hindrance next to the heart of the helix, i.e. the metal center. With *N* = DMPyz and Bzim there is an extra substituent in α-position of the coordinating nitrogen atoms: a methyl group on the pyrazole when *N* = DMPyz (to be compared with Pyz) and an aromatic CH from the benzimidazole for *N* = Bzim (to compare with the imidazole from Imme). Saturation transfer experiments, however, unambiguously demonstrated that the chemical exchange still occurs for these complexes. An estimation of the enantiomerization barriers, calculated from the variable temperature experiments,[23] is given in Table 1.

Table 1. Estimation of the enantiomerization barriers for the helical complexes $[Zn(X_6Me_3N_3)(MeCN)](ClO_4)_2$

N-donor	Imme	Bzim	Pyz	DMPyz
$\Delta G^{\neq}$ (kcal·mol^{-1})[a]	< 12[b]	> 17[c]	< 12[b]	16.0 (0.2)[d]

[a] $\Delta G^{\neq}$ was determined from the relationship[23] $k_c = \sqrt{(2.22)}\ (\delta\upsilon^2 + 6J^2_{AB})$. – [b] T_c for protons Ar-αCH$_{ax}$ were 278 and 258 K, respectively. However, the whole coalescence processes could not be observed. Therefore, only lower limits for the Δυ values were obtained. – [c] Only the beginning of the first coalescence process could be observed. Hence, T_c for OCH_2 was estimated to be just above 338 K. – [d] The diastereotopic protons Ar-αCHeq, ArH, and OCH_2 coalesced at T_c = 325, 328, and 338 K, respectively. Variation of the calculated $\Delta G^{\neq}$ values over this range of temperature was not significant.

Such a behavior was also observed for some copper(I) complexes, but only at low temperature.[9,24] These zinc complexes represent the first examples where the diastereotopic protons are differentiated above room temperature. Lastly, the more flattened helical structure of Zn^{II} complexes compared to the $(X_6Me_3Pic_3)$-based Cu^I complexes is reflected by a larger splitting of the diastereotopic proton resonances. All these observations are very promising for chiral recognition and we are currently working on this aspect.

Conclusion

We have here described the synthesis of novel calix[6]arene-based N_3-ligands and studied the comparative ability of the whole series to stabilize a tetrahedral zinc dication in a biomimetic neutral environment. We previously described the first examples of such model compounds with the imidazole-based ligand. The present study shows that benzimidazole and pyrazole are also appropriate *N*-donors for the stabilization of such complexes. Indeed, stable tetrahedral Zn complexes of general formula $[Zn(X_6Me_3N_3)(MeCN)](ClO_4)_2$ were obtained in acetonitrile. The calixarene structure is constrained in a flattened cone conformation, thereby providing a hydrophobic cavity that envelops the exogeneous ligand, MeCN. The calixarene presenting three pyridine groups, however, did not give rise to a well-defined complex under stoichiometric conditions. Hence, pyridine appeared to be a *N*-donor not good enough for the stabilization of tetrahedral dicationic zinc complexes. This stands in contrast with its good capacity at stabilizing Cu^I and may be related to its relative softness. Calixarenes presenting tertiary amine groups did not behave as ligands, but rather acted as bases leading to the formation of zinc hydroxide.[25] Lastly, as revealed by X-ray and NMR analyses, complexes $[Zn(X_6Me_3N_3)(MeCN)](ClO_4)_2$ exist as a pair of helical enantiomers that are in conformational equilibrium in solution. Increasing the steric hindrance at the level of the coordinating atoms, however, considerably slowed the enantiomerization process. We are actively exploring the recognition and catalytic properties of these promising supramolecular biomimetic systems.

Experimental Section

Materials and Methods: All solvents and reagents were obtained commercially. DMF was stored over 4-Å molecular sieves under argon. THF and acetonitrile were distilled under argon over sodium/benzophenone and P_2O_5, respectively. − ^1H and ^{13}C NMR spectra were recorded on Bruker Avance 400 and Bruker AC 200 spectrometers. ^1H and ^{13}C resonances corresponding to anisole moieties are noted as ^{1} (e.g. tBu^1, ArH^1, C^1_{Ar}) and the others are noted as ^{2}. They were assigned with HMBC and HMQC experiments. − IR spectra were recorded on a Perkin−Elmer 783 spectrometer. − Elemental analyses were performed at the Institut de Chimie des Substances Naturelles, France. − 1-Chloromethylpyrazole hydrochloride (PyzCl·HCl) and 1-chloromethyl-3,5-dimethylpyrazole hydrochloride (DMPyzCl·HCl) were obtained from the corresponding alcohols.[26] (2-Chloroethyl)dimethylamine hydrochloride (DmemaCl·HCl) and 1-(2-chloroethyl)pyrrolidine hydrochloride (PyrCl·HCl) were obtained commercially. 2-Chloromethyl-1-methylbenzymidazole (BzimCl) was synthesized through the reaction of *N*-methylphenylen-1,2-diamine with chloroacetic acid in 4 N HCl.[27]

Safety Note: ***Caution!*** Although we have not encountered any problems, it is noted that perchlorate salts of metal complexes with organic ligands are potentially explosive and should be handled only in small quantities with appropriate precautions.

5,11,17,23,29,35-Hexa-*tert*-butyl-37,39,41-trimethoxy-38,40,42-tris[(1-pyrazolyl)methoxy]calix[6]arene ($X_6Me_3Pyz_3$): Under an argon atmosphere, a solution of 5,11,23,29,35-Hexa-*tert*-butyl-37,39,41-trimethoxycalix[6]aren-38,40,42-triol ($X_6Me_3H_3$) (1.0 g, 0.99 mmol) in dry THF (20 mL) was introduced into a flask containing NaH (60% in oil, washed with pentane; 1.18 g, 29.5 mmol), dry THF (20 mL), and DMF (10 mL). The mixture was stirred for 20 minutes and 1-chloromethylpyrazole hydrochloride (PyzCl·HCl) (1.50 g, 9.85 mmol) was added over a period of 10 minutes. After 3 hours on refluxing, the solvents were concentrated under reduced pressure to a quarter of the volume and water (150 mL) was poured into the solution. The resulting precipitate was collected by filtration and dried under vacuum. The crude product was washed with pentane and filtration led to $X_6Me_3Pyz_3$ as a white solid (800 mg). The filtrate was evaporated. The residue was recrystallized from MeOH/pentane to yield $X_6Me_3Pyz_3$ as a white solid (242 mg). For elemental analyses, a sample was filtered through silica gel (CH_2Cl_2/MeOH 95:5 as eluent) and dried overnight under vacuum (0.1 Torr, 50 °C). − Yield: 83%. − M.p. 265 °C (decomp.). − ^1H NMR (400 MHz, $CDCl_3$): δ = 0.82 (s, 27 H, tBu^2), 1.33 (s, 27 H, tBu^1), 2.22 (s, 9 H, OCH_3), 3.01 (br. s, 6 H, Ar-αCH$_{eq}$), 4.23 (br. s, 6 H, Ar-αCH$_{ax}$), 5.83 (s, 6 H, Pz-αCH$_2$), 6.31 (s, 3 H, PzH), 6.64 (s, 6 H, ArH^2), 7.13 (s, 6 H, ArH^1), 7.56 (s, 6 H, PzH). − ^{13}C NMR (100 MHz, $CDCl_3$): δ = 28.8 (Ar-αCH$_2$), 30.2 [C(*C*H$_3$)$_3$], 30.7 [C(*C*H$_3$)$_3$], 33.1 [*C*(CH$_3$)$_3$], 33.3 [*C*(CH$_3$)$_3$], 59.0 (OCH_3), 80.8 (Pz-αCH$_2$), 106.4 ($C_{Pz}H$), 123.1 ($C_{Ar}H$), 126.8 ($C_{Ar}H$), 129.6 ($C_{Pz}H$), 132.1 (C_{Ar}-CH$_2$), 132.7 (C_{Ar}-CH$_2$), 139.8 ($C_{Pz}H$), 144.9 (C_{Ar}), 146.6 (C_{Ar}), 149.0 ($C_{Ar}O$), 153.4 ($C_{Ar}O$). − IR (KBr): $\tilde{\nu}$ = 3480 (H_2O), 1522 (C=N), 1440, 1417, 1395, 1365 cm^{-1}. − $C_{81}H_{102}N_6O_6\cdot H_2O$ (1273.75): calcd. Crystal Structure Determinations:[28] Diffraction data were measured on a Nonius KappaCCD diffractometer. Structures were solved by direct methods and refined using the program SHELXL97.[29] In all cases, the crystals were very sensitive to desolvation. Data are listed in Table 2.

$X_6Me_3Pyz_3$: Crystals were obtained by slow evaporation of a solution of ligand in a $CHCl_3/CH_3OH/CH_3CN$ mixture. The two ligands of the asymmetric unit co-crystallized with a CH_3CN solvate and one molecule of methanol. Interestingly, a mixture of two conformations could be determined from these molecules: one conformer corresponds to a ligand in which one pyrazole moiety is in the same relative orientation as the other two, with a methanol solvate inserted between the two molecules of the asymmetric unit; the second conformer corresponds to a ligand in which the same pyrazole is in a reverse orientation relative to the others, without methanol co-crystallized. The multiplicity of the disordered pyrazole arm and of the MeOH molecule was found to be equal to 0.5.

$[X_6Me_3Pyr_3{\cdot}H_3](ClO_4)_3$: Single crystals were grown by slow diffusion of Et_2O into an acetonitrile solution of the perchlorate salt. Each ligand co-crystallized with two molecules of Et_2O, and three ClO_4^- counterions. A static disorder could be determined for one pyrrolidine moiety in each molecule of the asymmetric unit, and they were split into two sites of equal multiplicity of 0.5. Due to the low data to parameter ratio, the structure was refined as two anisotropic blocs of parameters of roughly equal size, including some overlapping between them.

$[Zn(X_6Me_3Imme_3)(CH_3CN)](ClO_4)_2$: Single crystals were obtained by slow diffusion of Et_2O into a $CHCl_3/CH_3CN$ solution of the complex. The complex co-crystallized with some amount of $CHCl_3$ solvate, most of these molecules being characterized without ambiguity. However, two fragments were not well identified and correspond probably to disordered solvate. Due to the low data to parameter ratio, the structure was refined as two anisotropic blocs of parameters of roughly equal size, including some overlapping between them.

[17] Reaction of $X_6Me_3Imme_3$ with $Zn(H_2O)_6(ClO_4)_2$ in THF was described in ref. [11]. $[Zn(X_6Me_3Imme_3)(MeCN)](ClO_4)_2$ was directly obtained by dissolving the aqua complex $[Zn(X_6Me_3Imme_3)(H_2O)](ClO_4)_2$ in CD_3CN.
[18] This average $Zn-N_{Im}$ bond length is slightly shorter and the zinc-nitrile distance slightly longer than those reported for the parent propionitrile adduct (1.996 Å and 1.985 Å, respectively), see ref.[11] This is in accordance with the lower donor ability of MeCN compared to EtCN.
[19] Except for $[Zn(X_6Me_3Pyz_3)(MeCN)](ClO_4)_2$, which was too soluble to be crystallized out of an acetonitrile solution.
[20] Under millimolar conditions, the half-life time was ca. 5 minutes. Kinetic and mechanistic studies on the exchange process are under investigation.
[21] In the case of $[Zn(X_6Me_3Bzim_3)(MeCN)](ClO_4)_2$ an unusual up-field shift for the OMe resonance is observed. A Dreiding model in fact showed that these methoxy groups are situated in the anisotropic cone of the aromatic benzimidazole moieties.
[22] Similar NMR profiles were obtained when the complexes were dissolved in $CDCl_3$ in the presence of CH_3CN, with a broad resonance at δ = –0.7. This confirmed the presence of a coordinating acetonitrile molecule inside the aromatic cavity in solution; see ref. [11].

[25] The ability of these N-donors to act as a zinc ligand indeed does not follow their basicity, which increases in the order pyrazole < pyridine < benzimidazole ≈ imidazole < tertiary amines. The p*K*a values of the conjugate acids (BH^+) of pyrazole, pyridine, imidazole, and aliphatic amines are 2.5, 5.3, 7.0, and 9–11, respectively.

Synthesis, X-ray Crystal Structure, and Stability of Novel Trialkylalane−Triorganylbismuthane Adducts

Andreas Kuczkowski,[a] Stephan Schulz,*[a] and Martin Nieger[a]

Dedicated to Prof. Dr. Wolfgang W. Schoeller on the occasion of his 60th birthday

Keywords: Main group elements / Donor−acceptor systems / Aluminum / Bismuth

Reactions of trialkylalanes AlR_3 (R = Me, Et, *t*Bu) and triorganylbismuthanes BiR'_3 (R′ = *i*Pr, $SiMe_3$) were performed and the products investigated both in solution and in the solid state. $Et_3Al–Bi(SiMe_3)_3$ (**2**), $tBu_3Al–Bi(SiMe_3)_3$ (**3**), and $tBu_3Al–Bi(iPr)_3$ (**6**) are stable Lewis acid–base adducts in pure form while only **3** and **6** are adducts in solution. Their dissociation enthalpies, as determined by temperature-dependent NMR spectroscopy, were estimated to 6.3 (**3**) and 6.9 kcal/mol (**6**). In contrast, $Me_3Al–Bi(SiMe_3)_3$ (**1**), $Et_3Al–Bi(SiMe_3)_3$ (**2**), $Me_3Al–Bi(iPr)_3$ (**4**), and $Et_3Al–Bi(iPr)_3$ (**5**) are fully dissociated in solution. Compounds **1**–**6** were characterized by multinuclear NMR spectroscopy (^1H, ^{13}C), mass spectrometry, and elemental analysis. In addition, the crystal structures of **2** and **6** were determined by single-crystal X-ray diffraction. Compounds **2** and **6** are the first structurally characterized alane–triorganylbismuthane Lewis acid–base adducts.

Introduction

Group-13 trialkyl compounds generally tend to form adducts with Lewis bases by utilizing their vacant p-valence orbital.[1] This basic reaction, in particular toward group-15 compounds, has been widely studied, not only due to the interesting structural features that have been discovered during the last decades, but also to the potential application of so-formed Lewis acid−base adducts to serve as single source precursors for the preparation of the corresponding binary III−V materials by CVD processes. Both the influence of the central group-13 and -15 element as well as the role of the substituents on the adduct stability, which usually is expressed by their dissociation energy, has been studied experimentally and theoretically.[2] As generally accepted, the Lewis basicity of triorganyl pnicogenides R'_3E decreases with increasing atomic number of the central pnicogenide E. Consequently, amine and phosphane adducts of a constant Lewis acid R_3M (M = B, Al, Ga, In) are much more stable than stibane and bismuthane adducts. Experimental studies strongly support these findings. While numerous adducts of boranes (BR_3) and alanes (AlR_3) (R = halogen, H or Me) with amines (R_3N) and phosphanes (R_3P) have been prepared and structurally characterized, adducts with the higher homologues of group 15, such as stibanes (R_3Sb)[3] and bismuthanes (R_3Bi), have been studied to a far lesser extend. Coates described in the early 1950s the reaction of $GaMe_3$ with trimethyl pnicogenides EMe_3 (E = N, P, As, Sb, and Bi)[4] and experimentally verified the steadily decreasing Lewis basicity of EMe_3 toward $GaMe_3$ with increasing atomic number. This tendency reaches its maximum at Me_3Bi, which did not react with Me_3Ga. The decrease of the Lewis basicity results from the increased s-character of the *lone pair*. Detailed investigations show two significant steps within the decrease of the basicity: Arsanes AsR_3 exhibit a much lower basicity than phosphanes PR_3 due to the post transition metal effect (d-contraction) and bismuthanes BiR_3 are less basic than stibanes SbR_3 both due to the lanthanoid contraction (inert pair effect) and to relativistic effects.[5]

We and others have focused on the coordination chemistry of the heavier group-15 elements during the last few years, leading to the synthesis and structural characterization of several group-13−stibane adducts.[6] Very recently, we reported on the synthesis and structural characterization of the first stable trialkylgallane−triorganylbismuthane adducts.[7]

In an attempt to expand these studies to other group-13 elements and to gain further insights into the structural properties of adducts containing a group-13−Bi linkage, we studied reactions of trialkylalanes with triorganylbismuthanes. Herein, we describe the synthesis and structural characterization of trialkylalane−bismuthane adducts. In addition, temperature-dependent NMR studies were performed to estimate the stability of these adducts in solution.

Results and Discussion

Equimolar amounts of pure trialkylalanes R_3Al (R = Me, Et, *t*Bu) and triorganylbismuthanes R'_3Bi (R′ = $SiMe_3$, *i*Pr) were combined in a glovebox. While tBu_3Al immediately formed white solids with both bismuthanes, clearly indicating the formation of the adducts

tBu$_3$Al−Bi(SiMe$_3$)$_3$ (**3**) and tBu$_3$Al−Bi(iPr)$_3$ (**6**), analogous reactions of Me$_3$Al yielded colorless liquids Me$_3$Al/Bi(SiMe$_3$)$_3$ (**1**) and Me$_3$Al/Bi(iPr)$_3$ (**4**). Et$_3$Al, however, reacted with Bi(SiMe$_3$)$_3$ to give the solid adduct Et$_3$Al−Bi(SiMe$_3$)$_3$ (**2**), while the combination with iPr$_3$Bi led to a colorless liquid [Et$_3$Al/Bi(iPr)$_3$ (**5**)].

$$R_3Al + R'_3Bi \longrightarrow R_3Al{-}BiR'_3$$
$$R = Me, Et, tBu; R' = SiMe_3, iPr$$

Pure **1**−**6** have been characterized by elemental analysis. In addition, mass spectra were recorded in the electron impact (EI) mode at 10 eV to obtain further information about the stability of the adducts in the gas phase. However, the peaks with the highest mass observed for **1**−**6** correspond to the respective trialkylalane and triorganylbismuthane fragments. The adduct molecular ion peak was never detected.

The adduct formation is obvious in case of the solid products **2**, **3**, and **6**, while it is questionable for the liquid reaction products **1**, **4**, and **5**, which could merely be simple 1:1 mixtures in pure form. Since gas phase measurements could not be performed due to the lack of suitable instrumentation, it was not possible for us to distinguish between these two possible forms. However, to the best of our knowledge, **2**, **3**, and **6** are the first stable Lewis acid−base adducts in pure form.

1−**6** have also been consequently investigated in solution by ^{1}H and ^{13}C NMR spectroscopy. ^{1}H NMR spectra of **1**−**6** show signals due to the organic groups almost at the same chemical shift as the starting compounds.[8]

Table 1. Selected ^{1}H and ^{13}C NMR shifts and Δ(H) and Δ(C) values of the trialkylalanes and the adducts **1**−**6** as obtained from solutions in C$_6$D$_6$

Compound	δ = ^{1}H[a]	δ = ^{13}C[b]	Δ(H)[c]	Δ(C)[d]
Me$_3$Al	−0.36	−6.8	−	−

Et$_3$Al−Bi(iPr)$_3$ (**5**)	0.30	0.9	0.01	0
tBu$_3$Al−Bi(iPr)$_3$ (**6**)	1.10	21.1	0.02	0

[a] Me$_3$Al and Et$_3$Al: δ = ^{1}H(α-H); tBu$_3$Al: δ = ^{1}H(β-H). − [b] δ = ^{13}C(α-C). − [c] Me$_3$Al and Et$_3$Al: Δ(H) = δ(α-H)$_{adduct}$ − δ(α-H)$_{trialkylalane}$; tBu$_3$Al: Δ(H) = δ(β-H)$_{adduct}$ − δ(β-H)$_{trialkylalane}$. − [d] Δ(C) = δ(α-C)$_{adduct}$ − δ(α-C)$_{trialkylalane}$.

This is in contrast to the corresponding alane−stibane adducts[6b,6d] and to alane−phosphane adducts,[9] which show resonances typically shifted to lower field (ligands bound to Al) and higher field (ligands bound to P and Sb), respectively. These results strongly indicate **1**−**6** to be at least extensively dissociated in solution at ambient temperature. Unfortunately, we were not able to study the degree of dissociation by cryoscopic molecular mass determination, due to the extreme sensitivity of **1**−**6** in solution toward traces of oxygen and water. Therefore, temperature-dependent NMR studies were performed. These clearly proved the products of the reaction of Bi(iPr)$_3$ and Bi(SiMe$_3$)$_3$ with Me$_3$Al (**1**, **4**) and Et$_3$Al (**2**, **5**) to be fully dissociated in solution. While at ambient temperature the ^{1}H NMR spectra only show one resonance due to the Al−Me and Al−Et groups, at −70 °C two resonances of the Me and Et groups of relative intensities of 1:2 were observed. This clearly show the presence of (Me$_3$Al)$_2$ and (Et$_3$Al)$_2$ dimers (terminal and bridging substituents), eliminating the possibility for the presence of the desired adduct in solution. The two resonances coalesce between −25 and −40 °C. In contrast, the tBu$_3$Al−BiR$_3$ adducts **3** and **6** are not fully dissociated in solution. This was also demonstrated by temperature-dependent ^{1}H NMR spectroscopy. The dissociation enthalpy of the adducts R$_3$Bi−Al(tBu)$_3$ (R = SiMe$_3$, iRr) may be derived from the temperature dependence of the equilibrium constant K_{eq}, with Equations (1) and (2).

$$tBu_3Al + Bi(R)_3 \underset{}{\overset{K_{eq}}{\rightleftharpoons}} R_3Bi{-}Al(tBu)_3 \quad (1)$$

$$\ln K_{eq} = \frac{-\Delta H_D}{R}\left(\frac{1}{T}\right) + \frac{\Delta S_D}{R} \quad (2)$$

The equilibrium constant can be expressed in terms of the mol fraction of the alane present as free tBu$_3$Al and the total initial concentration, [total], with Equation (3).

$$K_{eq} = \frac{[\text{total}]\cdot(\chi_{free})^2}{(1-\chi_{free})} \quad (3)$$

Since the time-dependent ^{1}H NMR spectra only show a single resonance due to the Al(tBu) group over the complete temperature range, and assuming the ^{1}H NMR shift of the Al(tBu) group to be directly proportional to the mol fraction of the total species present as free tBu$_3$Al, χ_{free} may be calculated by the ^{1}H NMR chemical shift of Al(tBu) at a given temperature with Equation (5); δ_{free} is the chemical shift of the uncomplexed tBu$_3$Al and δ_{sample} is obtained directly from the sample. The "real" chemical shift of the adduct (fully coordinated species) is given by δ_{coord}. This was estimated by addition of a fivefold excess of the corresponding bismuthane R$_3$Bi to tBu$_3$Al, which was then measured at −70 °C, assuming tBu$_3$Al to be fully coordinated under these conditions.[10]

$$\chi_{free} = \frac{\delta_{sample} - \delta_{coord}}{\delta_{free} - \delta_{coord}} \quad (4)$$

1.43	1.18	0.04 M		28.9	86.2

[a] β-H resonance of tBu$_3$Al.

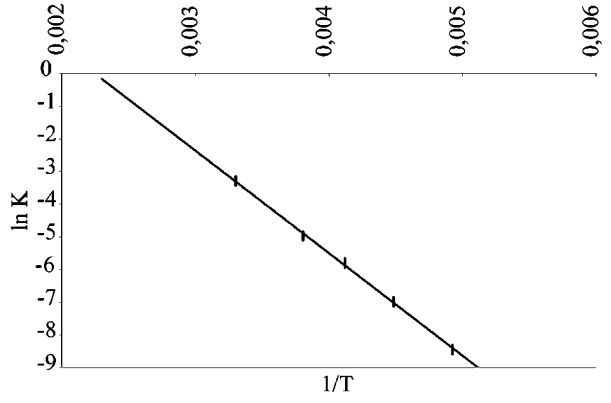

Figure 1. Temperature dependence of the equilibrium constant K_{eq} for the dissociation of **3** (R = 0.999)

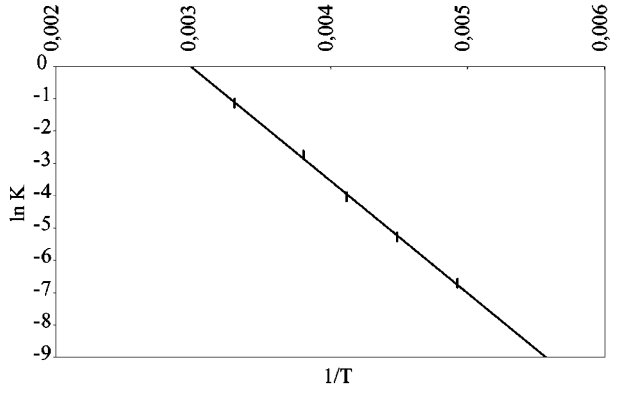

Figure 2. Temperature dependence of the equilibrium constant K_{eq} for the dissociation of **6** (R = 0.998)

The dissociation enthalpies of **3** and **6** were calculated to 26.3 kJ/mol (6.3 kcal/mol) and 28.9 kJ/mol (6.9 kcal/mol), respectively, indicating the interaction between tBu$_3$Al and the bismuthanes to be weak in solution. The ΔS values of 59.6 kJ/mol (14.2 kcal/mol) and 86.2 kJ/mol (20.6 kcal/mol) are very large and positive, as is typical for a dissociative process. However, the absolute values are erroneous due to several potential sources of errors, in particular the values for the "real" adducts. A small variation in these so-calculated values of only δ = 0.01 would lead to ΔH values which differ by about ± 2 kJ/mol.

The results obtained from temperature-dependent ^{1}H NMR spectroscopy prove the dimerization of Me$_3$Al and Et$_3$Al to be thermodynamically more favored in solution compared to the formation of a bismuthane adduct. Therefore, the preparative key for the synthesis of stable alane−bismuthane adducts in solution seems to be the use of trialkylalanes, which do not dimerize. In addition, bismuthanes containing sterically bulky and electropositive substituents, which increase the Lewis basicity due to steric (partial rehybridization of the lone pair leading to a higher p-character) and electronic reasons (+I effect of the substituents), lead to more stable adducts.[11] Repulsive interactions between the ligands of the Lewis base and acid, which play an important role for the stability of borane− and alane−amine adducts,[12] seem to be less important due to the bigger central pnicogen atom, leading to reduced steric interactions.

However, the results obtained in solution do not necessarily mean that Me$_3$Al and Et$_3$Al cannot form stable adducts with bismuthanes in general. This is obvious for the reaction product of Et$_3$Al and Bi(SiMe$_3$)$_3$, which is a solid, indicating the formation of the adduct Et$_3$Al−Bi(SiMe$_3$)$_3$ (**2**). Unfortunately, the reactions of Me$_3$Al with both bismuthanes and of Et$_3$Al with Bi(iPr)$_3$ led to liquid products. Whether these compounds are adducts or only mixtures of

the starting compounds could not be determined conclusively.

X-ray quality single crystals of $Et_3Al-Bi(SiMe_3)_3$ (**2**) and $(tBu)_3Al-Bi(iPr)_3$ (**6**) were grown from solutions in pentane at −30 °C. Figures 3 and 4 show the solid-state structures of **2** and **6.**

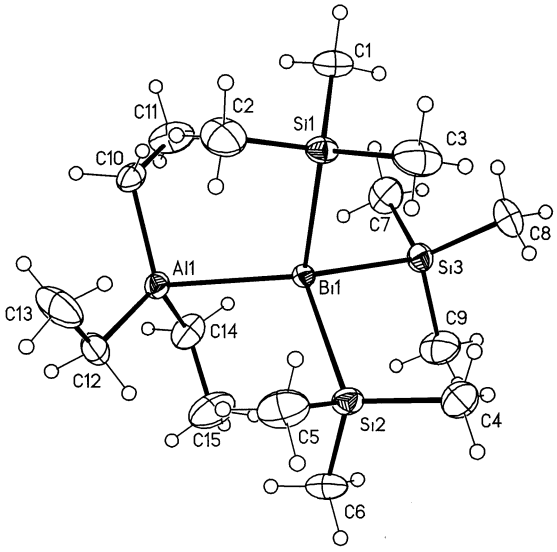

Figure 3. ORTEP diagram (50% probability ellipsoids) showing the solid-state structure and atom-numbering scheme for $Et_3Al-Bi(SiMe_3)_3$ (**2**); selected bond lengths [Å] and angles [°]: Al1−Bi1 2.921(2), Al1−C10 1.989(6), Al1−C12 1.973(5), Al1−C14 1.972(5), Bi1−Si1 2.634(2), Bi1−Si2 2.628(2), Bi1−Si3 2.635(2); C10−Al1−C12 116.0(2), C10−Al1−C14 117.3(2), C12−Al1−C14 117.5(3), Si1−Bi1−Si2 103.2(1), Si1−Bi1−Si3 100.5(1), Si2−Bi1−Si3 101.9(1)

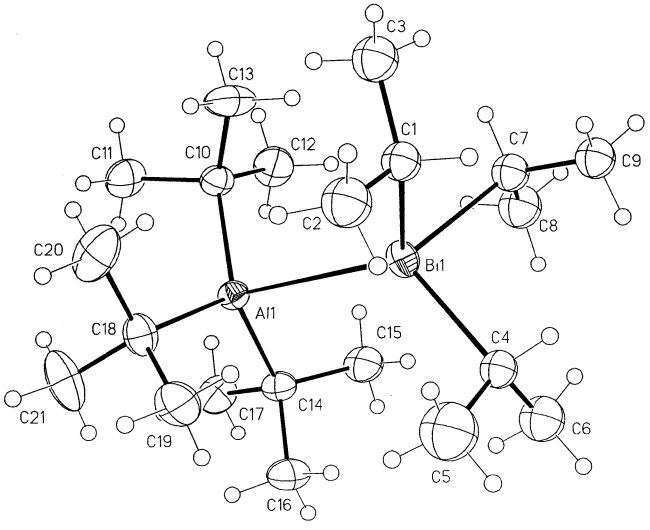

Figure 4. ORTEP diagram (50% probability ellipsoids) showing the solid-state structure and atom-numbering scheme for $tBu_3Al-Bi(iPr)_3$ (**6**); selected bond lengths [Å] and angles [°]: Al1−Bi1 308.8(2), Al1−C10 2.014(5), Al1−C14 2.014(5), Al1−C18 2.025(5), Bi1−C1 2.313(5), Bi1−C4 2.246(5), Bi1−C7 2.326(5); C10−Al1−C14 117.4(2), C10−Al1−C18 116.7(2), C14−Al1−C18 116.3(2), C1−Bi1−C4 95.8(2), C1−Bi1−C7 93.1(2), C4−Bi1−C7 97.6(2); only one orientation of the disordered *i*Pr groups is shown; in addition, only the data of the major compound are included in the tables

The Al and Bi atoms in **2** and **6** reside in distorted tetrahedral environments with their substituents adopting a staggered conformation relative to one another. The same was observed for the corresponding gallane−bismuthane adducts $Et_3Ga-Bi(SiMe_3)_3$ and $(tBu)_3Ga-Bi(iPr)_3$,[7] and alane−stibane adducts $Et_3Al-Sb(SiMe_3)_3$ [6b] and $(tBu)_3Al-Sb(iPr)_3$ [6d] The Al−Bi bond lengths of 2.921(2) Å in **2** and 3.088(1) Å in **6** are significantly elongated compared to the sum of the covalent radii of 2.75 Å (Al: 1.25 Å; Bi: 1.50 Å).[13] $[Me_2AlBi(SiMe_3)_2]_3$, (dmap)$Al(Me_2)Bi(SiMe_3)_2$ and (dmap)$Al(Et_2)Bi(SiMe_3)_2$ [dmap = 4-(dimethylamino)pyridine], so far the only structurally characterized organometallic compounds containing Al−Bi σ-bonds, also show significantly shorter Al−Bi distances [2.774 Å (average),[14] 2.755(2) Å and 2.750(2) Å[7]]. In particular the Al−Bi distance observed in **6** is very long. However, the Al−Bi bond lengths in **2** and **6** are shorter than the Ga−Bi distances found in the analogously substituted gallane−bismuthane adducts $Et_3Ga-Bi(SiMe_3)_3$ [2.966(1) Å] and $(tBu)_3Ga-Bi(iPr)_3$ [3.135(1) Å], respectively.[7] These findings agree with the decreased Lewis acidity of the gallanes compared to the alanes, leading to weaker acid−base interactions. As was found for the gallane−bismuthane adducts, the lower Lewis basicity of the triorganylbismuthanes R_3Bi compared to the corresponding triorganylstibanes R_3Sb can be observed by comparison of **2** and **6** with the analogously substituted alane−stibane adducts $Et_3Al-Sb(SiMe_3)_3$ and $(tBu)_3Al-Sb(iPr)_3$, showing Al−Sb bond lengths of 2.841(1) and 2.927(1) Å, respectively. In particular the difference of 16 pm for the $(tBu)_3Al-E(iPr)_3$ adducts [E = Sb: 2.927(1) Å, Bi: 3.088(1) Å] is significantly increased relative to the difference of the covalent radii (Sb: 1.41 Å, Bi: 1.50 Å[13]). The lower basicity of the bismuthanes in relation to the corresponding stibanes is also indicated by the smaller Si−Bi−Si and C−Bi−C angles (sum of the bond angles: 305.7° for **2** and 286.4° for **6**) compared to the Si−Sb−Si and C−Sb−C angles (sum of the bond angles: Si−Sb−Si = 310.8°; C−Sb−C = 301.5°), which might express the degree of hybridization, and therefore the Lewis basicity of the pnicogenides. The same tendency was found for trihydrides EH_3 and triorganyl pnicogenides ER_3 (R = Me, Ph). The H−E−H and C−E−C angles steadily decrease from almost tetrahedral (amines) to 90° (bismuthanes), indicating a significant increase in s-character of the *lone pair*.[15]

Haaland[2a][2b] and Frenking et al.[2e] demonstrated for borane and alane adducts, that the adduct formation between a group-13 trialkyl compound and an amine or a phosphane leads to a decrease of the C−M−C bond angle (from 120° towards tetrahedral) and an increase of the M−C bond length (M = B, Al). According to this model, a smaller C−M−C angle and a longer M−C bond within analogously substituted group-13/15 adducts indicate a weakening of the adduct. According to this model, the slightly larger C−Al−C bond angles in **2** and **6** (sum of the bond angles: 350.8° for **2** and 350.4° for **6**) compared to those of the stibane adducts [$Et_3Al-Sb(SiMe_3)_3$ 347.3°, $(tBu)_3Al-Sb(iPr)_3$ 346.9°] and the shorter Al−C bonds [av-

erage values: 1.978 Å (**2**), 2.019 Å (**6**); $Et_3Al-Sb(SiMe_3)_3$ = 1.984 Å, $(tBu)_3Al-Sb(iPr)_3$, = 2.030 Å] also demonstrate **2** and **6** to be weaker adducts than the corresponding stibane adducts. This is in agreement with the generally accepted decreasing donor capacity of triorganyl pnicogenides with increasing atomic number of the central group-15 element.[16]

Experimental Section

General Remarks: All manipulations were performed in a glovebox under N_2, or by standard Schlenk techniques. Me_3Al and Et_3Al were commercially available from Aldrich and used as received, while tBu_3Al,[17] $Bi(SiMe_3)_3$,[18] and $Bi(iPr)_3$ [19] were prepared by literature methods. − ^1H and $^{13}C\{^1H\}$ spectra were recorded using a Bruker AMX 300 spectrometer and are referenced to internal C_6D_5H (δ^1H = 7.154; $\delta^{13}C$ = 128.0), while low-temperature NMR spectra are referenced to internal [D_8]toluene (δ^1H = 7.20). − Melting points were measured in sealed capillaries and are not corrected. − Elemental analyses were performed at the Mikroanalytisches Labor der Universität Bonn.

General Experimental Procedure: Pure R_3Al (2 mmol) and R_3Bi (2 mmol) were combined in the glovebox in 10-mL flasks. $Bi(SiMe_3)_3$ immediately formed a white solid with Et_3Al and tBu_3Al, while the same occurred between $Bi(iPr)_3$ and tBu_3Al, indicating the formation of the adducts $Et_3Al-Bi(SiMe_3)_3$ (**2**), $tBu_3Al-Bi(SiMe_3)_3$ (**3**), and $tBu_3Al-Bi(iPr)_3$ (**6**). In contrast, the products of the reaction of both bismuthanes with Me_3Al and of $Bi(iPr)_3$ with Et_3Al stayed liquid at ambient temperature. Compounds **2**, **3**, and **6** were dissolved in pentane (5 mL) and stored at −30 °C, resulting in the formation of colorless crystals in almost quantitative yield. Compounds **1**, **4**, and **5** were characterized without further purification.

X-ray Structure Solution and Refinement: Crystallographic data for **2** and **6** are summarized in Table 3. The ORTEP diagrams of the solid state structures including selected bond lengths and angles of **2** and **6** are shown in Figures 3 and 4. Data were collected with a Nonius Kappa CCD diffractometer. The structures of **2** and **6** were solved by Patterson methods (SHELXS-97)[20] and refined by full-matrix least squares on F^2 (SHELXL-97).[21] All non-hydrogen atoms were refined anisotropically and hydrogen atoms by a riding model. The *i*Pr groups in **6** are disordered (58:42). Empirical absorption corrections were applied. The crystallographic data of **2** and **6** (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-158549 (**2**) and -158550 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB21EZ [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[8] The chemical shifts of Me_3Al and Et_3Al, which were obtained at ambient temperature, have to be interpreted cautiously because they display an equilibrium of terminal and bridging shifts for the Al−Me and Al−Et groups, since Me_3Al and Et_3Al are both dimeric in solution. In contrast, tBu$_3$Al is monomeric in solution.

[9] See for example: A. R. Barron, *J. Chem. Soc., Dalton Trans.* **1988**, 3047.

[10] M. B. Power, J. R. Nash, M. D. Healy, A. R. Barron, *Organometallics* **1992**, *11*, 1830.

[11] In contrast, the reaction of Me_3Bi with tBu$_3$Al gave no stable adduct; S. Schulz, unpublished result.

[12] For example, this was observed for trimethylborane adducts with NH_3, NH_2Me, $NHMe_2$ and NMe_3. The Lewis basicity increases in the following order: $NH_3 < NH_2Me < NHMe_2 < NMe_3$. However, the dissociation enthalpies as obtained from the gas phase take the following order: $Me_3B{-}NH_3 < Me_3B{-}NH_2Me = Me_3B{-}NMe_3 < Me_3B{-}NHMe_2$. Due to reduced steric interactions, Me_2NH forms a more stable adduct with BMe_3 than the electronically stronger Lewis base NMe_3. An analogous tendency was observed for the corresponding $AlMe_3$ adducts: E. N. Guryanova, I. P. Goldstein, I. P. Romm, *The Donor−Acceptor Bond*, John Wiley & Sons, New York, **1975**.

The Photochemistry of $[CpMo(CO)_3(\eta^1\text{-}C_3H_5)]$ in Frozen Gas Matrices at 10 K and the Behaviour of $[CpMo(CO)_2(\eta^3\text{-}C_3H_5)]$ Isomers in Different Media

Christian Limberg,*[a] Anthony J. Downs,[b] Tim M. Greene,[b] and Tobias Wistuba[a]

Keywords: Photochemistry / Matrix isolation / Molybdenum / Allyl ligands

On photolysis of $[CpMo(CO)_3(\eta^1\text{-}C_3H_5)]$ in solid inert matrices at low temperature, one CO molecule is eliminated yielding the *exo* and *endo* isomers of $[CpMo(CO)_2(\eta^3\text{-}C_3H_5)]$ in almost 1:1 proportions, although the fraction of the *exo* conformer is increased by prolonged broad-band UV irradiation. If gaseous $[CpMo(CO)_2(\eta^3\text{-}C_3H_5)]$ is isolated in an Ar matrix the proportions of the two conformers are again about 1:1, indicating that they possess almost equal energies, as confirmed by DFT calculations (B3LYP/SDD). This situation changes in a solvent environment, where increasing the polarity of the solvent favours the *exo* isomer, as indicated by the ratios *exo*/*endo* = 1.7:1 (pentane or cyclohexane), 3.0:1 (benzene) and 3.3:1 (CH_2Cl_2) determined by IR and NMR measurements. Such a finding is consistent with the results of DFT calculations, which reveal that the *exo* isomer is more polar.

Introduction

The dynamics of allylmolybdenum moieties have relevance not only to the formation of new C−C bonds by way of nucleophilic attack on the coordinated allyl groups,[1] but also to catalytic processes involving olefin functionalisation. One example is the oxidation of propene in the presence of a heterogeneous molybdenum oxide catalyst, a process which is believed to proceed by the trapping of allyl radicals by Mo atoms on the catalyst surface; the resulting allyl-Mo fragments are thought subsequently to undergo several shift and rearrangement reactions, finally yielding acrolein.[2] Interest in the mechanisms of this and other reactions involving allylmolybdenum fragments initiated the present investigation of the photolytic behaviour of $[CpMo(CO)_3(\eta^1\text{-}C_3H_5)]$ (**1**)[3] in solid inert matrices at low temperatures.

The matrix photochemistry of the analogous tungsten compound $[CpW(CO)_3(\eta^1\text{-}C_3H_5)]$ has already been examined by Rest et al.[4] They found evidence for photodecarbonylation yielding products displaying two pairs of bands in the ν(CO) region of the IR spectrum. The bands were assigned to a mixture of $[CpW(CO)_2(C_3H_5)]$ isomers involving either an η^1- or an η^3-coordinated allyl group and formed in accordance with the reaction sequence set out in Figure 1. In the light of these intriguing results, it was hoped to shed more light on the fate of $[CpM(CO)_2(\eta^1\text{-}C_3H_5)]$ intermediates (M = Cr, Mo, W) generated through photodecarbonylation by investigation of the corresponding molybdenum compound. These new spectroscopic studies were to be supported by quantum mechanical calculations focussed on the proposed products of the changes.

Results and Discussion

Photolysis of 1 in Low Temperature Matrices

The vapour of **1** was co-condensed with an excess of argon on a CsI window at 10 K. The IR spectrum of the resulting matrix showed three (matrix-split) bands in the ν(CO) region characteristic of the molecule $[CpMo(CO)_3(\eta^1\text{-}C_3H_5)]$ [Figure 2(a)]. Photolysis of the matrix with light having wavelengths near 369 or 313 nm or with broad-band UV light resulted in the quantitative decomposition of the starting material and gave rise to two pairs of bands (which will subsequently be referred to as "doublets") of almost equal intensity in the ν(CO) region of the IR spectrum (one at 1966/1891 cm^{-1} and the other at 1974/1907 cm^{-1}), together with a band near 2140 cm^{-1} due to free CO. The results are thus very similar to those observed previously in the case of the tungsten compound.[4] Furthermore, as with the tungsten system, prolonged photolysis caused one set of bands to grow somewhat in intensity at the expense of the other set. This immediately prompted the impression that molybdenum follows tungsten in the formation of two species of the type $[CpM(CO)_2(C_3H_5)]$ (M = Mo or W) with η^1- and η^3-coordinated allyl groups, respectively. It seems very surprising, however, that photolysis of both the molybdenum and tungsten compounds gives rise to 16- and 18-electron species $[CpM(CO)_2(C_3H_5)]$ in almost equal proportions, when the

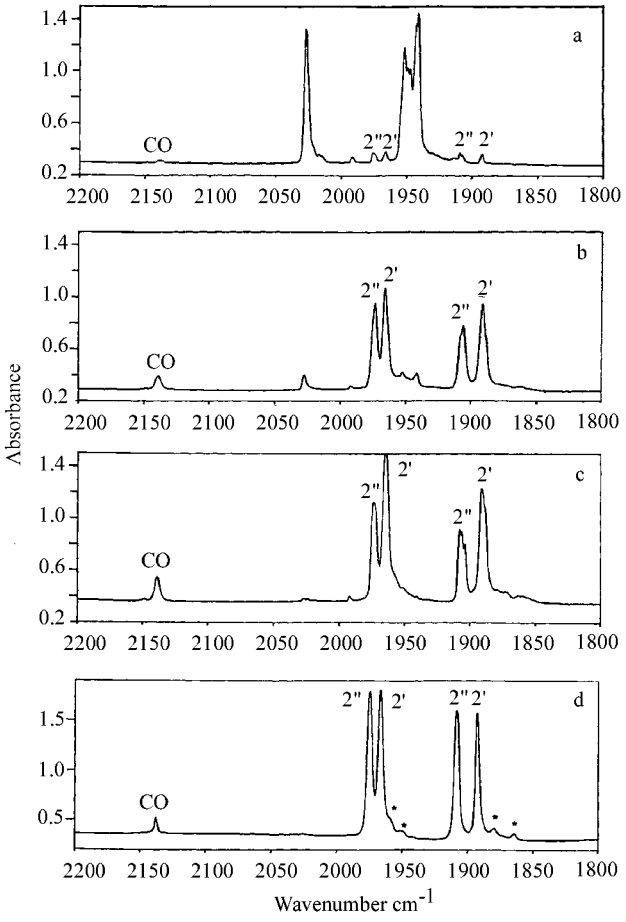

Figure 2. IR absorption spectrum in the region 2200−1800 cm^{-1} displayed by a solid Ar matrix containing [$CpMo(CO)_3(\eta^1\text{-}C_3H_5)$] at 10 K (a); showing the effects of photolysis with broad-band UV radiation for 10 min (b); and of prolonged photolysis (c); trace (d) shows the spectrum of [$CpMo(CO)_2(\eta^3\text{-}C_3H_5)$] isolated in an Ar matrix at 10 K; bands marked with an asterisk arise from [$CpMo(^{12}CO)(^{13}CO)(\eta^3\text{-}C_3H_5)$] present in natural abundance

16-electron compound is likely to be much less stable than the 18-electron one.

In order to shed more light on this finding, the compound [$CpMo(CO)_2(\eta^3\text{-}C_3H_5)$] (**2**)[3] was isolated in an argon matrix [Figure 2(d), Table 1]. Although this material contains only η^3-allyl groups, the IR spectrum of the matrix-isolated vapour showed the same two sets of doublets as did the spectrum of the matrix after photolysis of **1**. Moreover, the two doublet absorptions exhibited by the IR spectrum of **2** were observed to be almost exactly equal in intensity. It seems unlikely that [$CpMo(CO)_2(\eta^3\text{-}C_3H_5)$] rearranges in the gas phase *en route* to the cold window to the 16-electron compound [$CpMo(CO)_2(\eta^1\text{-}C_3H_5)$], with which it then co-exists in equilibrium. This finding is therefore at odds with an assignment of one of the doublets to a 16-electron compound of Mo or W, and accordingly the real origin of the extra bands has still to be unravelled.

One possible explanation for the observation of a multiplet instead of a single band is so-called "matrix splitting" caused by the residence of trapped species in different matrix sites.[5] However, the doublet splitting observed for **2** isolated in an argon matrix would be rather large (8 and 16 cm^{-1}), and the possibility of matrix splitting can be more or less excluded by the results of experiments with different matrices, for example Kr, CH_4 and CO, in which **2** continued to show two ν(CO) doublets of roughly equal intensity. Changing the matrix normally alters or eliminates any splitting that depends on the character of the solid host. Therefore the two doublets must belong to different dicarbonyl isomers, both bearing η^3-bonded allyl ligands. These are designated **2′** and **2′′** in the following text.

Dynamic Behaviour of 2 in Solution

High- and low-temperature NMR studies had suggested previously[6] that **2** enters into a conformational equilibrium in solution. There are two conformers, which can be interconverted by *formal* rotation of the η^3-allyl group [**2A** (allyl rotation angle θ = 180°) and **2B** (θ = 0°) in Figure 3]. Apart from a simple rotation of the allyl group, there are in general four possible mechanisms that might explain the dynamic behaviour of allyl groups bound to metal centres:[6−9]

(i) The olefin rotation mechanism involves an intermediate with the C^1 and C^2 atoms of the allyl group remaining bonded to the metal while rotation proceeds around the C^2-C^3 axis.

(ii) Alternatively, the C^1 and C^3 atoms in the intermediate can remain coordinated while C^2 flips from one side to the other.

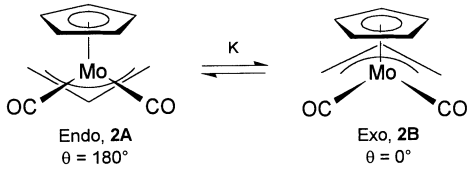

Figure 3. Conformational isomers of [$CpMo(CO)_2(\eta^3\text{-}C_3H_5)$] (**2**) in solution and their allyl rotation angle θ relative to the carbonyl ligands

(iii) In the π-σ-π mechanism, the intermediate contains an η^1-bonded allyl group which can freely rotate around the C^1-C^2 axis.
(iv) There is also the possibility that the isomers are interconverted by a kind of pseudorotation reflecting the non-rigidity of the parent ligand-metal framework.

Mechanism (iii) is commonly accepted to operate, for instance, for compounds of the type [CpMoI(NO)(η^3-C_3H_5)],[10,11] while NMR spectroscopic investigations[6] led Faller et al. to propose mechanism (iv) for **2**. The ^{1}H NMR spectra of the two individual conformers of **2** (in solution in [D_6]benzene) can be observed independently as broad signals at ambient temperatures, the relative intensities of the signals implying an equilibrium constant *K* of 3.0 at 5 °C. The two sets of resonances coalesce at 86 °C. Whatever mechanism is responsible for the isomerisation, the change is slow on the NMR timescale, with an activation barrier estimated to be 51.5 kJ/mol.[6] Compound **2** crystallises from solution with the η^3-allyl ligand in the preferred *exo* conformation (isomer **2B**).[10] Thus, the *endo*-*exo* equilibrium adjusts the solution concentrations as the *exo*-form crystallises. It follows that evaporation of the solvent affords only the *exo* conformer **2B**. Previous reports of the IR spectrum of **2** in solution referred to the presence of two doublets in the ν(CO) region,[12] and these too have been rationalised on the assumption of a conformational equilibrium between **2A** and **2B**.[13,14]

Isomerism of 2 in Low Temperature Matrices and Quantum Mechanical Calculations

Bearing all these findings in mind, it is tempting to identify the species **2′** and **2′′** observed after quenching the vapour of **2** with a large excess of matrix gas at 10 K with the two conformers **2B** and **2A**, respectively. According to the NMR results for solutions, **2A** and **2B** must then be present in the gas phase. To test this conclusion, further experiments were performed.

Rest et al. have reported that the three species present after photolysis of matrices containing [CpW(CO)$_3$(η^1-C_3H_5)] (see Figure 1) are all interconvertible, so that, for instance, the photolysis of the W(CO)$_2$ compounds regenerated the W(CO)$_3$ compound.[4,15] When **2** was isolated in a solid carbon monoxide matrix, however, it could not be converted into **1** either by photolysis with light of various wavelengths or by annealing, indicating that the η^3-allyl ligand is resistant to changing the mode of its ligation {unlike the one in [Co(CO)$_3$(η^3-C_3H_5)], which reacts to give [Co(CO)$_4$(η^1-C_3H_5)] in the presence of CO on photolysis}.[15b] On the other hand, compound **1** could be converted quantitatively into **2** in a carbon monoxide matrix by photolysis with broad-band UV light for 1 h. The CO ejection thus seems to be followed by a very rapid, irreversible η^1-η^3 ligation change, as suggested previously for [Re(CO)$_5$(η^1-C_7H_7)].[15d]

In all the matrices studied, the proportions of **2′** and **2′′** could be varied by broad-band UV photolysis, the ν(CO) bands at 1966 and 1891 cm^{-1} belonging to **2′** increasing at the expense of those at 1974 and 1907 cm^{-1} belonging to **2′′**.

These results may be summarised as follows: UV photolysis of **1** isolated in an Ar matrix results in the loss of one CO ligand, possibly to produce first the 16-electron product [CpMo(CO)$_2$(η^1-C_3H_5)] **2C** (see Figure 4), which is not observed since it isomerises rapidly to give the two (η^3-C_3H_5)Mo conformers **2′** and **2′′** in almost equal proportions. The two different sets of ν(CO) bands characterising **2′** and **2′′** are also observed, again with roughly equal intensity, after quenching the vapour of **2** initially at room temperature with a large excess of matrix gas at 10 K. Compounds **2′** and **2′′** must therefore also be present in the vapour of **2**.

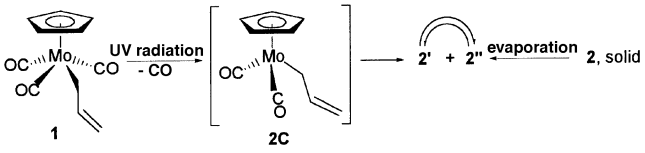

Figure 4. Proposed mechanism for the photochemistry of **1** in low temperature matrices

If energy is conveyed to such a matrix in the form of UV light (photolysis), isomer interconversion proceeds and the proportions of the two forms change in favour of what seems to be the more stable species **2′**. It has to be emphasised at this stage that the rigidity of the solid matrices at 10 K does not allow the system to reach the equilibrium state that might be anticipated for this temperature. If a π-σ-π mechanism was in operation, it would involve an intermediate **2C**. On photo-inducement of the isomerisation, however, even in the presence of an excess of CO, such an intermediate **2C** cannot revert to **1**, since the experimental results show that this is highly photolabile. The experimental results are unable therefore to argue for or against such a mechanism. On the other hand, it is possible that photoexcitation raises an electron from the low-lying HOMO (the Mo-allyl π-bonding orbital[16]) to the LUMO (the Mo-allyl π-antibonding orbital[16]). This would weaken the Mo-allyl π-bond, while the σ bond remains intact, and the allyl ligand would then be able to rotate more freely, whereas the barrier to this change is too large to be overcome by modest thermal activation of the electronic ground state.[17] A photo-isomerisation process, which has been observed previously for matrix-isolated metal *carbene* complexes,[18] is similar to the one found for **2** in that occupation of an antibonding orbital in the photo-excited state there allows free rotation around a bond, which is a rigid multiple bond in the ground state.

There is no reason therefore to question the identification of **2′** and **2′′** with **2B** and **2A**, respectively, and in order to obtain more information about these species, we set out to calculate their structures on the basis of density functional theory (B3LYP/SDD). The optimised geometries are shown

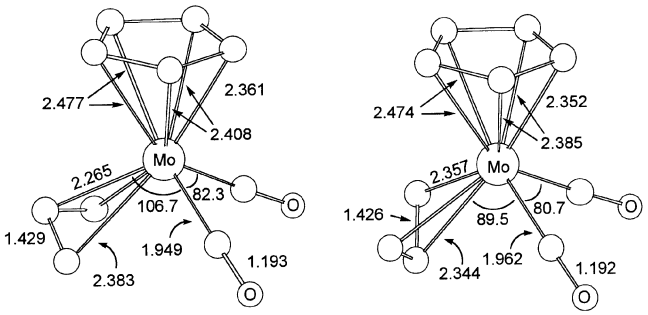

Figure 5. Structures of **2A** and **2B** as optimized by DFT calculations (B3LYP/SDD); for comparison, selected bond lengths and angles found[10] in the crystal structure of **2B** are: Mo−C_{meso} 2.236(4), Mo−C_t 2.359, Mo−CO 1.951(3), Mo−C_{Cp} 2.321(4)-2.348(6) Å; OC−Mo−CO 82.5(2), OC−Mo−C_{meso} 105.0(1)°

in Figure 5, which thus provides for the first time structural information about the *endo* conformer **2A**. The results obtained for the *exo* conformer **2B** can on the other hand be compared directly with the solid state structure.[10] As can be seen, the deviations are not unreasonable considering that theory predicts the geometry of the molecule in the gas phase, while intermolecular interactions and packing forces influence the solid state structure. Regarding the vibrational frequencies calculated for the two species, it turns out that **2B**, which had been found to be more stable in solution,[6] is indeed predicted to show a ν(CO) doublet at lower frequencies as compared with the corresponding features of **2A**. This matches the finding that the low frequency doublet observed in the matrix experiments also belongs to the more stable species **2′**. The calculations also indicate that the IR intensities of the ν(CO) modes of **2A** are very similar to those of **2B**.

It should be noted, though, that according to the NMR measurements we performed with CD_2Cl_2 as the solvent the ratio **2B/2A** (i.e. *K* in Figure 3) amounts to ca. 3.3:1 (in line with the value of $K = 3.0$ derived from previous results for a benzene solution at 5 °C[6]). At first sight, this might appear to clash with the almost equal proportions of **2′** and **2′′** implied by the nearly equal intensity of the two sets of carbonyl bands observed in the IR spectrum of **2** after matrix isolation of its vapour (see Figure 2d). Such a 1:1 intensity ratio has previously been reported for the IR spectrum of **2** in cyclohexane solution,[12−14] with the inference (based on the assumption of very similar extinction coefficients) that the equilibrium constant *K* is close to 1 at room temperature.[14] The rather large differences between *K* as deduced from the ν(CO) bands in the IR and *K* as deduced from the ^{1}H NMR spectrum were ascribed to solvent effects,[14] since different solvents had been used for the two sets of measurements [the splitting of the ν(CO) bands can be resolved only for solutions in non-polar solvents]. In order to check this explanation, we recorded a ^{1}H NMR spectrum of **2** in [D_{12}]cyclohexane solution and so concluded that $K = 1.7$ and not 1.0 at 15 °C! Careful reinvestigation of the IR spectrum of **2** in cyclohexane and pentane solutions then revealed that the *exo* bands (unlike those in the matrix spectra) are much broader than the *endo* bands (see Figure 6), and *integration* of the band areas (as opposed to

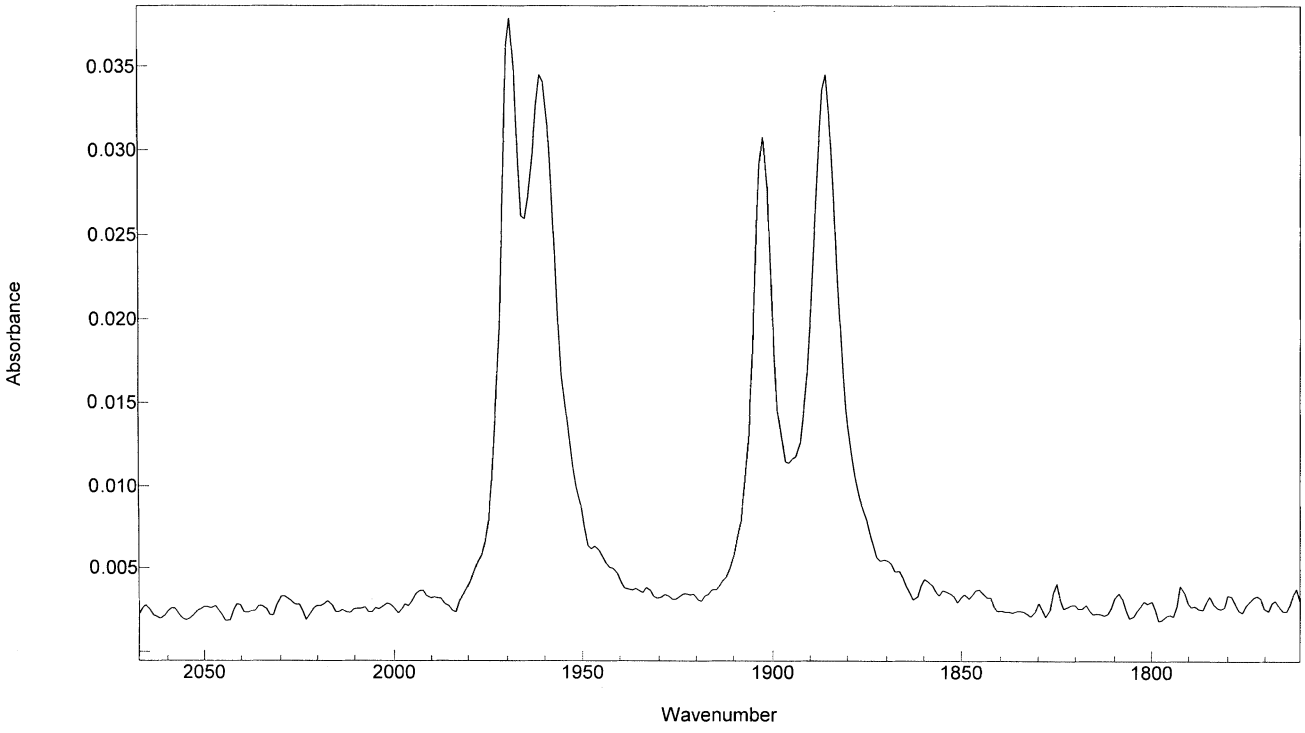

Figure 6. The IR spectrum of a pentane solution of **2** at room temperature (2 cm^{-1} resolution)

simple absorbance measurements) does indeed give a value of K close to 1.7.

In conclusion, the observation of a 1:1 intensity ratio for the bands belonging to **2′** and **2′′** (which will be referred to as **2B** and **2A** from now on) after vapour deposition of **2** in a solid matrix at low temperature indicates that the conformers have almost equal energies in the absence of any solvent, but differ quite significantly in energy when dissolved in a polar solvent like CD_2Cl_2. As the polarity of the supporting medium decreases, so the energy difference ΔE(**2A**−**2B**) decreases, until with the vapour at ambient temperatures it becomes so small that the thermal populations of the two forms are almost equal.[19] These conclusions are well supported by the results of the DFT calculations (B3LYP/SDD). For the optimum geometries depicted in Figure 5, which of course represent gas phase structures, ΔE(**2A**−**2B**) was calculated to amount to only 1.4 kJ mol^{-1}. Furthermore, the calculations indicate that **2B** is more polar (5.08 D) than **2A** (4.34 D), so that **2B** is inevitably favoured by a polar solvent environment.

In summary, there would seem to be little doubt that **2′** and **2′′** are the conformers **2B** and **2A**, respectively. In the light of these findings and those of Bitterwolf et al.,[17] it is very likely that Rest et al. were mistaken in their interpretation of the matrix photochemistry of the analogous tungsten system, which probably merits reinvestigation. Furthermore, we have shown: (i) that the different polarities of the *endo* and *exo* conformers cause the position of the equilibrium between them to be a sensitive function of solvation, and (ii) that the conformers can be interconverted by photoexcitation.

Experimental Section

Matrix samples were formed on a CsI window held at ca. 10 K with the aid of an Air Products CS 202 Displex unit (a two-stage, closed cycle helium refrigerator) enclosed by an evacuated shroud, or alternatively by the use of a liquid helium cryostat. The temperature of the window could be varied continuously between ca. 10 and 150 K by means of a resistive heating wire wound around the cold stage of the Displex refrigerator. Temperatures were measured with a chromel vs. iron-doped gold thermocouple or with a hydrogen vapour bulb. The matrix carrier gases used were Ar, N_2, Kr and CO (B.O.C., Research grade). Samples (held at 0 °C) were deposited continuously, typically over a period of 2 hours, the rate of deposition of the material to be isolated being regulated by its own low volatility. Photolysis experiments made use of an Oriel 500-W medium pressure mercury arc. A water filter was employed to minimise the intensity of IR radiation incident upon the matrix during photolysis. In addition, absorption or Balzer's interference filters provided the means of selecting photolysis radiation confined to a predetermined range of wavelengths.

$[CpMo(CO)_2(\eta^3\text{-}C_3H_5)]$ and $[CpMo(CO)_3(\eta^1\text{-}C_3H_5)]$ were prepared according to literature procedures.[3] IR spectra were recorded with a Bruker IFS 66 FTIR spectrometer. ^{1}H and ^{13}C NMR spectra of solutions were recorded using a Bruker AC 200 instrument operating at 200 MHz (^{1}H).

Density Functional Theory calculations were carried out with the Gaussian/DFT series of programs.[20] The B3LYP formulation of density functional theory was used employing the basis set SDD.[20] Harmonic vibrational frequencies and infrared intensities were predicted at these levels by numerical second derivatives using analytically calculated first derivatives.

[19] Bearing in mind the shortness of the time the molecules of **2** spend in the gas phase after vaporisation from the solid until they are frozen out in Ar, we are bound to draw the following conclusions about the solid sample. If it consisted solely of **2B**, as suggested by a single crystal X-ray analysis after recrystallisation of **2** from organic solvents, and if moreover the isomerisation barrier between **2A** and **2B** really amounted to 51.5 $kJmol^{-1}$ as determined in benzene solution, the time the molecules would require to reach thermal equilibrium of the two forms would certainly be much longer than the time actually available to them. This means either that the isomerisation barrier almost vanishes in the gas phase or — more likely — that the solid, having been collected in the vessel by condensation of gaseous **2**, already contained both isomers in almost equal proportions. The second possibility is difficult to prove, however, since it has not been possible to resolve the distinct carbonyl bands of the two isomers in the vibrational spectra of solid samples.

Organic Matrix and Solution Photochemical Studies of (Allyl)dicarbonyl(cyclopentadienyl)molybdenum Compounds

Thomas E. Bitterwolf,*[a] J. Timothy Bays,[a] Bruce Scallorn,[a] Callie Ann Weiss,[a] Michael W. George,[b] Ian G. Virrels,[b] John C. Linehan,[c] and Clement R. Yonker[c]

Keywords: Photochemistry / Matrix isolation / Molybdenum / Allyl ligands

Photolysis of fresh samples of the η^3-allyl compounds $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_5)]$ or $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_4CH_3)]$ in a Nujol matrix at ca. 90 K at a wavelength greater than 400 nm was found by IR spectroscopy to cause conversion of the *endo* rotamer to the *exo* rotamer. Photolysis of *exo* enriched samples of $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_5)]$ at wavelengths of between 360 and 400 nm reversed the photoconversion leading to an *exo* to *endo* conversion. At higher energies photochemical CO loss was also observed. In the case of the 2-methylallyl derivative, a photoproduct believed to be $[(\eta^5\text{-}C_5H_5)Mo(H)(CO)(\eta^4\text{-}C_4H_6)]$ was observed along with CO loss. Time-resolved IR studies of the flash photolysis of $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_5)]$ in *n*-heptane confirm both *endo* to *exo* rotamer conversion and CO loss. Under these conditions, the species formed after CO loss is probably $[(\eta^5\text{-}C_5H_5)Mo(CO)(n\text{-heptane})(\eta^3\text{-}C_3H_5)]$. When $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_5)]$ was dissolved in supercritical ethylene and photolyzed, $[(\eta^5\text{-}C_5H_5)Mo(CO)(C_2H_4)(\eta^3\text{-}C_3H_5)]$ was formed. A mechanism involving two distinct excited states is proposed to account for the photoreversible *endo*/*exo* transformations.

Introduction

In 1963 Cousins and Green[1] reported the synthesis of $[(\eta^5\text{-}C_5H_5)Mo(CO)_3(\eta^1\text{-}C_3H_5)]$ (**1**) and $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_5)]$ (**2**) by reaction of $[(\eta^5\text{-}C_5H_5)Mo(CO)_3]^-$ with allyl chloride. Compound **2** could also be efficiently formed from **1** by photolysis with ultraviolet radiation. Several years after the initial discovery, King noted that **2** appeared to exist in solution as two species.[2] Davidson,[3] Faller[4] and their co-workers correctly established the structures of the two conformers to be the *endo* and *exo* rotamers shown in Figure 1 with an *exo*/*endo* ratio of 3:1 in benzene. Introduction of a methyl group into the 2-position on the allyl group in **3** reverses the orientational preference so that the *endo* rotamer becomes strongly favored. Curiously absent in this early literature were comments concerning thermal or photochemical substitution of the carbonyl groups in **2** or **3**.

As part of our ongoing studies on the photochemistry of organometallic compounds, we have examined the photolysis of **1**, **2**, and **3** in Nujol and 2-methyltetrahydrofuran (MeTHF) glass matrices at 90 K. These studies have revealed a previously unknown photochemically driven rotation of the η^3-allyl group, as well as other haptotropic transformations. Time-resolved IR studies and photochemical reactions in supercritical ethylene have been carried out to provide additional evidence for the observed intermediates. We have previously reported Nujol matrix studies of molybdenum and chromium compounds in which a pendant η^3-cyclopentenyl ring was attached to the cyclopentadienyl ring.[5] A brief study of the photochemistry of the tungsten analog of **1** in a methane matrix has been reported by Rest.[6] The results of the present study along with those of Limberg et al.[7] on the photolysis of **1** in a frozen argon matrix reported in this issue, shed new light on the interpretation of the earlier spectroscopic data.

Results and Discussion

Organic Matrix Photochemistry

Compounds **1, 2** and **3** were prepared by standard literature procedures.[8] Nujol matrix studies were carried out us-

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/1010−2619 $ 17.50+.50/0

ing a cryostat developed by Rest and procedures as previously described.[9] MeTHF glass matrix studies were carried out using a Specac Model 21525 Variable Temperature Cell.

The electronic spectrum of **2** has a strong absorption band below 290 nm that is probably associated with a metal-to-ligand charge-transfer band. A medium intensity band is observed at 345 nm with a shoulder at about 400 nm. At high concentrations of **2**, a tail of these visible bands can be seen to extend as high as 600 nm.

A Nujol solution of **2** was frozen to ca. 90 K and the IR spectrum recorded as shown in Figure 2a. IR data for all compounds are presented in Table 1. IR bands for both the *endo* (1964 and 1896 cm^{-1}) and *exo* (1955 and 1879 cm^{-1}) rotamers were found to be in an approximate 1:2 ratio. Photolysis of fresh samples at a wavelength greater than 360 nm was found by difference IR spectra to result in depletion of the *endo* rotamer bands and growth of the *exo* rotamer bands (Figure 2b). No other photochemical products were observed for photolysis at wavelengths greater than 400 nm even upon extended photolysis. When the *exo*-enriched samples formed at $\lambda_{irr} > 400$ nm were photolyzed at a wavelength between 360 and 400 nm, we were surprised to find a reversal of the photoisomerization, with conversion of the *exo* form to the *endo* form (Figure 2c). Photolysis of a fresh sample of **2** ($\lambda_{irr} = 360 \pm 10$ nm) for 3 h (Figure 2d) showed *endo* depletion and *exo* growth, and, in addition, produced a small band at 2132 cm^{-1} and a broad feature at 1843 cm^{-1}. The sample was annealed to ca. 153 K and then returned to ca. 77 K to record the IR spectrum. Under these conditions the bands at 2131 and 1843 cm^{-1} decreased while the bands of **2** increased, with the *exo* rotamer being substantially favored over the *endo* rotamer.

To further clarify the photochemical behavior of **2**, the compound was taken up in MeTHF and the solution frozen to 90 K. In this matrix the *exo* rotamer is strongly favored over the *endo* rotamer. The symmetric stretch of the *endo* isomer is detectable only as a slight asymmetry of the higher energy carbonyl stretching band, while the asymmetric *endo* band is observed as a shoulder on the lower energy band (Figure 3a). The carbonyl bands are strongly shifted (21−30 cm^{-1}) to lower energy in MeTHF relative to Nujol. Photolysis ($\lambda_{irr} = 450 \pm 70$ nm) resulted in bleaching of the *endo* rotamer bands at 1943 and 1864 cm^{-1} and growth of the *exo* rotamer bands at 1935 and 1851 cm^{-1} (Figure 3b). This process was reversed when the irradiation energy was increased ($\lambda_{irr} = 400 \pm 70$ nm) (Figure 3c). The small shifts of these band positions in the spectra in Figure 3 are subtraction artifacts. Higher energy photolysis ($330 < \lambda_{irr} < 400$ nm) resulted in the bands of both the *endo* and *exo* rotamers being bleached, with growth of new bands at 2031, 1816, 1789, 1744 and 1600 cm^{-1} (Figure 4a). Back photolysis of this sample ($\lambda_{irr} > 400$ nm) caused the bands at 1744 and 1600 cm^{-1} to decrease simultaneously while the bands at 1816 and 1789 cm^{-1} grew (Figure 4b). The 1789 cm^{-1} band was very weak compared to the 1816 cm^{-1} band. An *endo* to *exo* transformation was also observed upon this irradiation. It should be noted that there was no increase or decrease of the free CO band (2131 cm^{-1}) upon back photolysis.

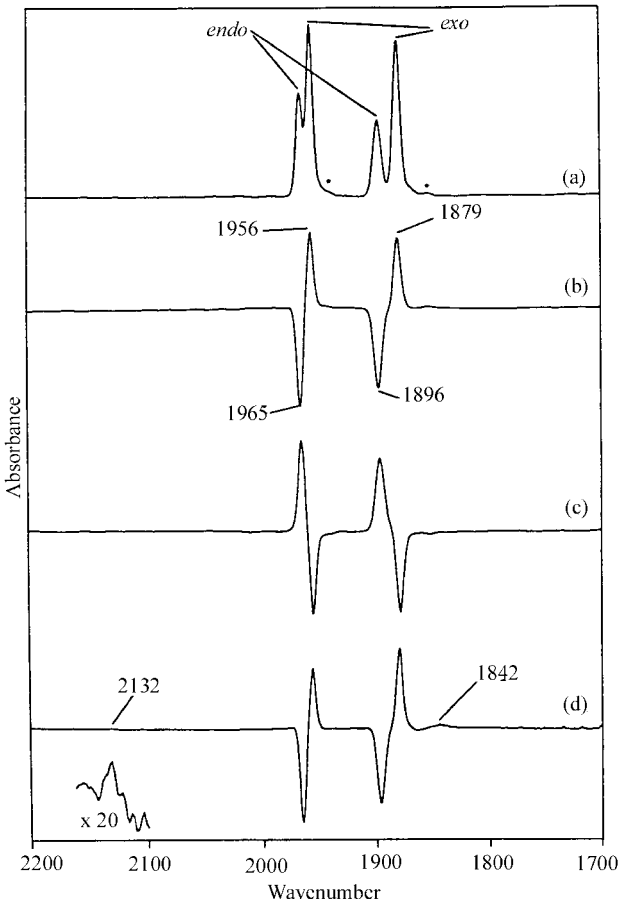

Figure 2. IR spectra of **2** isolated in a Nujol matrix: (a) starting material, ca. 90 K; (b) difference spectrum, 150 min. irradiation ($400 \text{ nm} < \lambda < 470$ nm) minus starting material; (c) difference spectrum, 30 min. irradiation ($360 \text{ nm} < \lambda < 450$ nm) minus 150 min. irradiation ($400 \text{ nm} < \lambda < 470$ nm); (d) difference spectrum, 90 min. irradiation ($350 \text{ nm} < \lambda < 370$ nm) minus starting material; bands marked with an asterisk arise from natural abundance ^{13}CO

Compound **1** is well-known to form **2** upon photolysis. In order to further clarify the photochemical behavior of these allyl complexes, a Nujol solution of **1** contaminated with about 10% **2** was prepared. At ca. 90 K, **1** has three terminal carbonyl stretching bands at 2020, 1942, and 1931 cm^{-1}, as expected for a molecule with C_s symmetry, and a weak band at 1609 cm^{-1} associated with the unbound olefin. After photolysis ($\lambda_{irr} = 500 \pm 70$ nm) for 30 min., an IR difference spectrum demonstrated that **1** is efficiently decarbonylated ("free" CO band at 2132 cm^{-1}) and converted into both rotamers of **2** in approximately equal proportions. It is not possible to establish whether **1** preferentially forms the *endo* isomer, which then undergoes subsequent photoconversion into the *exo* isomer, or whether both *endo* and *exo* isomers are actually formed upon CO loss. Under these conditions there was no evidence for the presumed $[Mo(CO)_2(\eta^1\text{-}C_3H_5)(\eta^5\text{-}C_5H_5)]$ intermediate. Again, these results parallel those observed by Limberg in a frozen Ar matrix.[7]

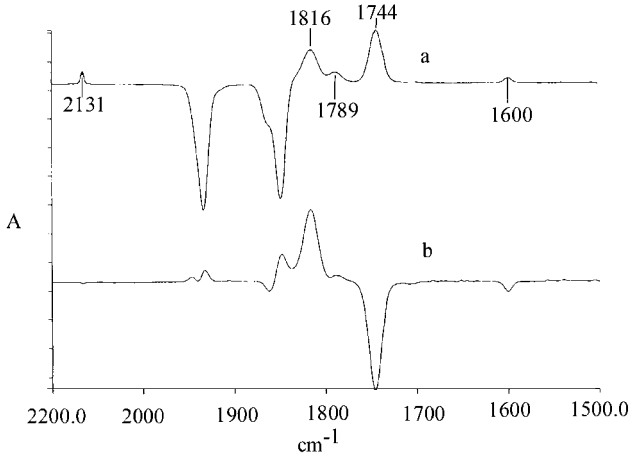

Figure 4. IR spectrum of **2** isolated in a 2-methyltetrahydrofuran matrix: (a) difference spectrum, 10 min. irradiation (330 nm < λ_{irr} < 400 nm) minus 10 min. irradiation (λ_{irr} = 400 α 70 nm); (b) difference spectrum 10 min. irradiation (λ_{irr} > 400 nm) minus 10 min. irradiation (330 nm < λ_{irr} < 400 nm)

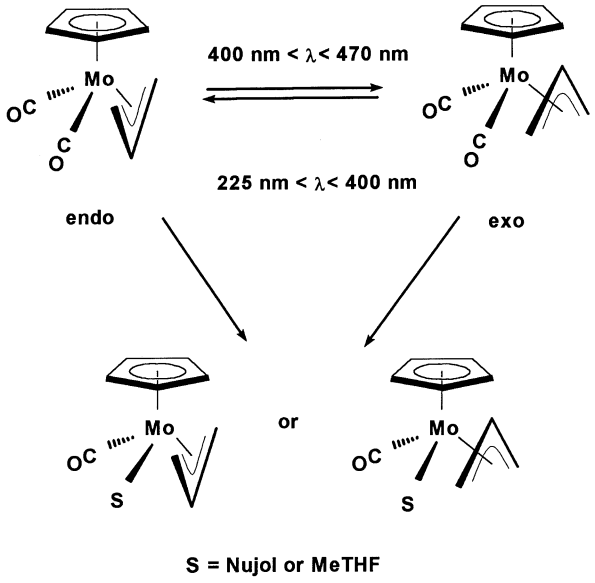
Our interpretation of the observed photochemical transformations in Nujol and MeTHF is presented in Scheme 1. As also observed by Limberg in a frozen Ar matrix,[7] the major feature of the photolysis of **2** at longer wavelengths is the photochemical interconversion of the *endo* to the *exo* rotamers. At high energy a species formed by CO loss is observed at 1842 cm^{-1} that we assign as [Mo(CO)(η^3-C_3H_5)(η^5-C_5H_5)].



Scheme 1. Proposed photochemical transformations of [(η^5-C_5H_5)Mo(CO)$_2$(η^3-C_3H_5)]

The donor matrix solvent MeTHF has no effect on either the low energy conversion of the *endo* rotamer to the *exo* rotamer, or on the higher energy photochemical reverse of this reaction. There was no evidence for formation of [Mo(CO)$_2$(MeTHF)(η^1-C_3H_5)(η^5-C_5H_5)] under these conditions.

High energy photolysis (λ_{irr} = 330−400 nm) forms three new monocarbonyl species as well as free CO. Back photolysis bleaches the bands at 1744 and 1600 cm^{-1} and causes the bands at 1816 and 1789 cm^{-1} to grow, with no apparent gain or loss of CO. The band at 1600 cm^{-1}, consistent with a dangling η^1-allyl group, and the single, low energy carbonyl band at 1744 cm^{-1} suggest that this species is probably [Mo(CO)(MeTHF)$_2$(η^1-C_3H_5)(η^5-C_5H_5)]. Back photolysis ejects an MeTHF ligand to reform the *exo* and *endo* rotamers of [Mo(CO)(MeTHF)(η^3-C_3H_5)(η^5-C_5H_5)].

The absence of bands that might be attributable to [Mo(CO)$_2$(MeTHF)(η^1-C_3H_5)(η^5-C_5H_5)] makes it impossible to establish whether such a species is an intermediate in the formation of the observed MeTHF complexed photoproducts. The ease with which [Mo(CO)(MeTHF)$_2$(η^1-C_3H_5)(η^5-C_5H_5)] is converted into [Mo(CO)(MeTHF)(η^3-C_3H_5)(η^5-C_5H_5)] suggests that [Mo(CO)$_2$(MeTHF)(η^1-C_3H_5)(η^5-C_5H_5)] might be equally sensitive to photoreversal. Rest and co-workers have reported that [Co(CO)$_3$(η^3-C_3H_5)] undergoes photolysis in a frozen CO matrix to give [Co(CO)$_4$(η^1-C_3H_5)].[10]

Compound **3** exists almost exclusively in the *endo* form at room temperature and in Nujol at 90 K (Figure 5a), with bands at 1961 and 1888 cm^{-1}. Photolysis of **3** at long wavelengths (λ_{irr} = 450 ± 70 nm) results in a decrease of the bands associated with the *endo* rotamer and growth of new bands at 1955 and 1878 cm^{-1} which are assigned to the thermodynamically unfavorable, and previously unobserved, *exo* rotamer (Figure 5b). No bands at 2132 ± 2 cm^{-1} associated with "free" carbon monoxide were observed at these wavelengths. Photolysis of an *exo*-enriched sample (330 nm < λ_{irr} < 470 nm) (Figure 5c) results in depletion of the bands of the *exo* rotamer and growth of bands at 2131, 1961 (*endo*), 1936, 1888 (*endo*), 1866, and 1843 cm^{-1}. Continued photolysis at these wavelengths resulted in depletion of the bands of both the *exo* and *endo* rotamers and growth of the new bands. Further photolysis of this sample at high energy (270 < λ_{irr} < 290 nm) resulted in depletion of the band at 1936 cm^{-1} and those of the *endo* rotamer, and growth of the bands at 2131, 1866 and 1844 cm^{-1}. Careful wavelength-selective photolysis established that the *exo* rotamer was associated with the species with a single band at 1842 cm^{-1}, while the *endo* rotamer was associated with the species having a single band at 1866 cm^{-1}. Both of these new species were converted photochemically into the species with a single band at 1936 cm^{-1}. Upon annealing to ca. 133 K, the bands at 1866 and 1841 cm^{-1} decreased while the bands of the *endo* rotamer and the band at 1936 cm^{-1} grew in.

As found for **2**, long wavelength photolysis of **3** results in conversion of the *endo* rotamer to the *exo* rotamer, while photolysis at higher energy of a sample enriched in the *exo* isomer reforms the *endo* isomer. For **3**, photolysis at slightly higher energy is also found to stimulate carbon monoxide loss with the *endo* rotamer giving rise to a monocarbonyl species with an IR band at 1866 cm^{-1} and the *exo* rotamer producing a similar species with an IR band at 1844 cm^{-1}. Both monocarbonyl species give rise to a third monocarbonyl species with a single band 1936 cm^{-1}. We propose that the species initially formed by CO loss are the *endo* and *exo* isomers of [Mo(CO)(η^5-C_5H_5)(η^3-C_4H_7)] in which the orientation of the allyl group is retained. These species in turn undergo oxidative addition of the electron-deficient molybdenum into a C−H bond of the 2-methyl group to yield a trimethylenemethane ligand. The resulting compound, [Mo(CO)(H)(η^5-C_5H_5)(η^4-C_4H_6)], would be analogous to [Mo(CO)(CH_3)(η^5-C_5Me_5)(η^4-C_4H_6)] for which the carbon monoxide stretching frequency is reported to be 1925 cm^{-1}.[11] We have reported a similar hydride shift in the photolysis of [Mo(CO)$_2${η^5,η^3-$C_5H_4C(CH_3)_2C_5H_6$}] giving a species believed to be [Mo(CO)$_2$(H){η^5,η^4-$C_5H_4C(CH_3)_2C_5H_5$}] with a carbonyl band at 1917 cm^{-1}.[12] These reactions are functionally identical to a beta-hydride transfer such as those observed by Rest for [M(CO)$_3$(C_2H_5)(η^5-C_5H_5)], where M = Mo or W.[13] Upon photolysis both the 16-electron intermediate [M(CO)$_2$(C_2H_5)(η^5-C_5H_5)] and the ethene, hydride species [M(CO)$_2$(H)(η^2-C_2H_4)(η^5-C_5H_5)], were observed. Metal hydride bands are often weak, thus our inability to locate such a band in these spectra is not surprising. A summary of the proposed photochemical transformations for **3** is presented in Scheme 2.

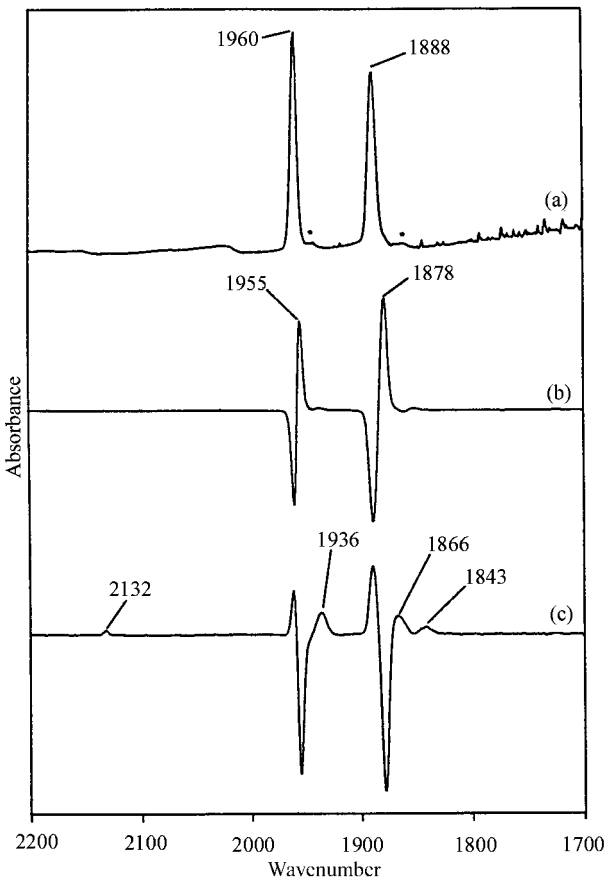


Figure 5. IR spectra of **3** isolated in a Nujol matrix: (a) starting material, ca. 90 K; (b) difference spectrum, 30 min. irradiation (380 nm < λ < 520 nm) minus starting material; (c) difference spectrum, 30 min. irradiation (330 nm < λ < 470 nm) minus 60 min. irradiation (380 nm < λ < 520 nm); the bands marked with an asterisk arise from natural abundance ^{13}CO

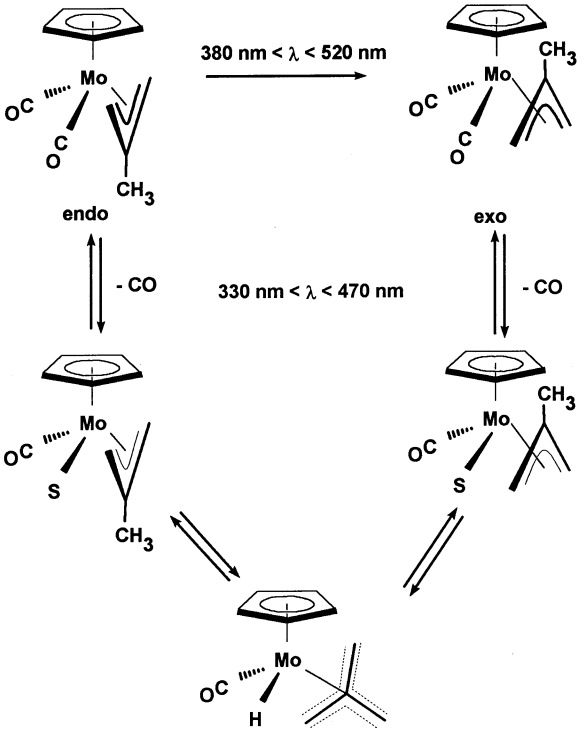
Time-Resolved IR Studies

In order to further clarify the intermediates in these processes, time-resolved IR (TRIR) photochemical studies of **2** in *n*-heptane were carried out at room temperature. A 355 nm laser flash was employed to initiate the chemistry. Flash photolysis at this energy results in both CO loss to form the solvated intermediate [(η^5-C_5H_5)Mo(CO)(*n*-heptane)(η^3-C_3H_5)], which has a single IR band at 1851 cm^{-1},



Scheme 2. Proposed photochemical transformations of $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_4CH_3)]$

and *endo* to *exo* photoisomerization. The observed IR band at 1851 cm^{-1} is completely consistent with our observation of the equivalent Nujol-solvated species at 1842 cm^{-1}. The rate of reaction of $[(\eta^5\text{-}C_5H_5)Mo(CO)(n\text{-heptane})(\eta^3\text{-}C_3H_5)]$ with CO was linear with [CO] and a second order rate constant, $k_2 = 1.5 \times 10^7$ $M^{-1}s^{-1}$, was obtained.

Photoisomerization of the *endo* rotamer to the *exo* rotamer under argon was observed. The *exo* species decays, with $k_{obs} = 2 \times 10^5$ s^{-1}, but does not appear to reform the *endo* species. The fate of this species is not clear at this time and additional work will be performed to clarify these observations.

Supercritical Ethene Studies

Compound **2** was found to be soluble in supercritical ethylene at 170 atm. and 40 °C with approximately equal concentrations of the *endo* and *exo* rotamers. Photolysis of this solution with an unfiltered high pressure Hg/Xe lamp (45 min.) resulted in bleaching of the bands associated with **2** and growth of a new band at 1918 cm^{-1}. A small band at 2032 cm^{-1} attributable to free CO was also observed. It is believed that the species being formed in this case is $[(\eta^5\text{-}C_5H_5)Mo(CO)(\eta^2\text{-ethene})(\eta^3\text{-}C_3H_5)]$. No effort was made to recover this compound.

Discussion

An explanation of the photochemistry of **2** and **3** must take into account the observed wavelength dependence of the *endo* to *exo* transformation. It is reasonable to postulate the existence of two distinct photochemical mechanisms, one operating at low energy ($\lambda_{irr} > 400$ nm) and a second at higher energy ($\lambda_{irr} < 400$ nm). The high-energy transformation may have its origins in the same excited state responsible for CO loss.

Molecular orbital analyses of $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_5)]$ have been conducted by Hoffmann[14,15] and Rosenblum[16] and their co-workers. The relevant molecular orbitals are illustrated in Figure 6. The allyl π orbital interacts with the s and p_z orbitals of the metal fragment, while the non-bonding allyl orbital (n) interacts with the a" level. The metal-based orbitals 1a′ and 2a′ are effectively non-bonding and are the highest occupied molecular orbitals, while the LUMO is the antibonding combination of the n allyl orbital and the a" (a" − n). The MO analysis is supported by ultraviolet photoelectron spectral studies,[17] in which the six observed bands were assigned to: I_1 and I_2 (metal d orbitals, 1a′ and 2a′), I_3 (allyl π HOMO, n + a"), I_4 and I_5 (cyclopentadienyl orbitals) and I_6 (second allyl π orbital, π + s + p_z).

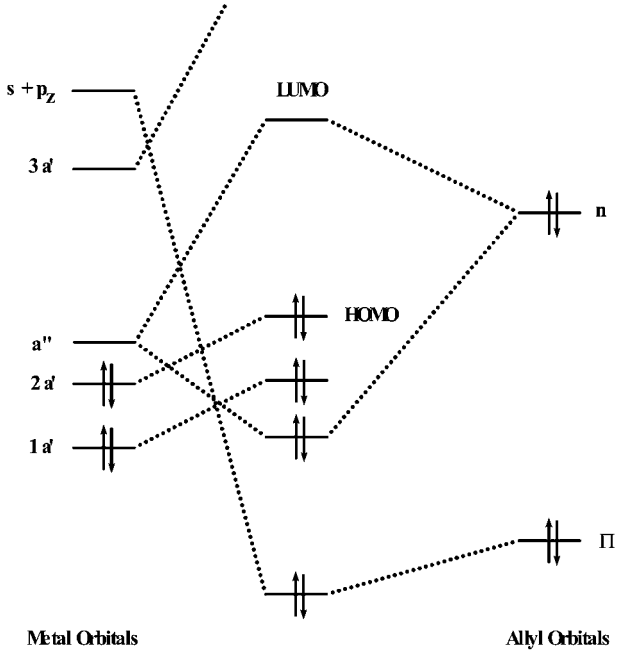


Figure 6. Molecular Orbital diagram for $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\eta^3\text{-}C_3H_5)]$ based on the previous work of Hoffmann[11,12] and Rosenblum[13]

Hoffmann has argued that *endo* to *exo* exchange observed by NMR spectroscopy should not involve simple rotation of the allyl fragment since such a rotation brings the allyl non-bonding orbitals into an orientation where the bonding with the metal is lost. However, the photochemical promotion of a 1a′ or 2a′ d electron to the LUMO level weakens this interaction permitting rotation about the symmetric allyl π − metal (π + s + p_z) orbital. Such a process is functionally identical to that which results in *cis* to *trans* olefin photoisomerization in organic chemistry. We assign the shoulder at 400 nm to the 1a′, 2a′ → a" − n transition. The band at 345 nm is assigned to the d → d transition (1a′, 2a′ → 3a′), while higher energy bands are assigned to

metal-to-ligand charge transfers. The wavelength selectivity of the filters used in this study are not sufficiently narrow to distinguish with certainty whether the excitations leading to *exo* to *endo* transformations and carbonyl loss are associated with the band at 345 nm or with the tails of the higher energy bands.

The mechanism of the higher energy *exo* to *endo* transformations is not entirely clear. The concurrent appearance of species formed by CO loss indicates that sufficient energy may available for an $\eta^3 \rightarrow \eta^1 \rightarrow \eta^3$ sequence, even though no η^1 species was observed in either Nujol or in the donor solvent MeTHF. We have, however, observed an analogous transformation in the case of $[Mo(CO)_2\{\eta^5,\eta^3\text{-}C_5H_4\text{-}C(CH_3)_2\text{-}C_5H_6\}]$ in which a pendant cyclopentenyl group is connected to the cyclopentadienyl ring by an isopropyl link. Matrix isolation studies have established that low energy photolysis results in an $\eta^3 \rightarrow \eta^1$ opening, and higher energy photolysis results in loss of CO. The comparative ease in stimulating the hapticity change in the case of this pendant allyl is attributed to the relief of strain in the open form.[5]

Our work and that of Limberg et al.[7] require a reinterpretation of the observations reported by Rest et al.[6] on the gas matrix photolysis of $[W(\eta^5\text{-}C_5H_5)(CO)_3(\eta^1\text{-}C_3H_5)]$. These workers observed loss of CO and the appearance of four bands attributable to metal carbonyl species. Continued photolysis resulted in the decrease of one pair of these new bands and growth of the second pair. Reexamination of the reported spectra in light of the present work strongly suggest that the four bands that arise upon photolysis are due to the *endo* and *exo* rotamers of $[W(\eta^5\text{-}C_5H_5)(CO)_2(\eta^3\text{-}C_3H_5)]$, and that the subsequent growth of one pair of these bands at the expense of the second is identical to the behavior of the molybdenum analogue reported herein.

Experimental Section

Compounds **1**, **2**, and **3** were prepared by standard literature procedures.[8]

Nujol matrix studies were carried out using a glass cryostat designed by Dr. A. J. Rest of the University of Southampton (UK). This apparatus and experimental procedures have been described previously.[9] Nujol solutions were prepared by dissolving 1−2 mg of sample in Nujol at room temperature. All samples were centrifuged to remove particulates and eliminate the possibility of having microcrystals in the photolysis sample. MTHF glass matrices were carried out using a Specac Model 21525 variable temperature cell with a sample temperature of ca. 90 K.

Photolyses were carried out at ca. 90 K using a 350 watt high pressure mercury lamp. A water filter was used to remove IR radiation from the beam and optical filters were used to carry out wavelength selective photochemistry. In some cases, the photolyzed sample was annealed to permit the Nujol glass to soften and allow either recombination or rearrangement reactions. The temperature of the sample during the annealing steps was monitored by a thermocouple mounted on the sample cell. All spectra are recorded at 4 cm^{-1} resolution.

Time-resolved IR studies were carried out at the University of Nottingham employing a pulsed Nd:YAG laser (Quanta-Ray GCR-12, ca. 7 ns, 355 nm) to initiate photochemical reactions. A continuous wave IR diode laser (Mütek MDS 1100) was used to monitor the transient IR absorptions. Details of the apparatus and procedures have been reported.[18]

Photolyses in supercritical ethene were conducted using a high pressure cell with diamond IR windows and a sapphire window for photolysis. Photolyses were carried out using a high pressure Hg/Xe lamp.

Self-Assembly of Tetranuclear Iron(II) Compounds by a Combination of Rod- and Clamp-Shaped Bridging Units

Volker Jacob,[a] Susanne Mann,[a] Gottfried Huttner,*[a] Olaf Walter,[b] Laszlo Zsolnai,[a] Elisabeth Kaifer,[a] Peter Rutsch,[a] Peter Kircher,[a] and Eckhard Bill[c]

Dedicated to Prof. Marianne Baudler on the occasion of her 80th birthday

Keywords: Self-assembly / Tetranuclear compounds / Iron(II) complexes / *tripod* ligand / Cyanides / Dicyanomethanides

Dicyanomethanides, $[RC(CN)_2]^-$ (**1**$^-$), are bridging ligands with an angular clamp-type shape. In the *tripod*/iron(II) system, [*tripod* = $CH_3C(CH_2PPh_2)_3$], they form binuclear species with three of the clamp-type ligands bridging two iron centers. An appropriate stoichiometric mixture of the *tripod* ligand, iron(II) salts and the dicyanomethanide ligand leads to the exclusive formation of [*tripod*Fe{μ-NC–C(R)–CN}$_3$-Fe*tripod*]$^+$ (**3**$^+$). Altogether, seven constituent groups arrange themselves in this type of aggregate. The process of self-aggregation is distinctly modified by the presence of cyanide ions that may act as linear rod-type bridging ligands. Equimolar mixtures of *tripod*, iron(II) salts, dicyanomethanide ligands and cyanide form tetranuclear aggregates [{*tripod*Fe}$_3$(μ-NC–C(R)–CN}$_3${μ-CN}$_3$FeX]$^+$ (**5**$^+$). In these species, the iron centers form a trigonal-pyramidal arrangement with three octahedrally coordinated *low-spin tripod*iron(II) entities in the basal plane and a tetrahedrally coordinated *high-spin* iron(II) at the apex. The iron centers in the basal plane are connected by μ^2-bridging dicyanomethanide ligands. The apical iron center is coordinated by the N-termini of three cyano ligands, which complete the octahedral coordination of the basal *low-spin* iron(II) centers. The fourth, external ligand X at the tetrahedrally coordinated *high-spin* iron(II) apex can be varied, but in most cases it is found to be a terminally coordinated dicyanomethanide entity. Without counting this variable ligand X, thirteen constituent groups of four different types selectively aggregate to form the cage compounds **5**$^+$. While the dinuclear compounds **3**$^+$ are diamagnetic, the tetranuclear species **5**$^+$ have magnetic moments close to the *spin-only* value of $\mu_{s.o.}$ = 4.9 μ_B, for tetrahedral *high-spin* iron(II). The Mössbauer spectra are in agreement with the description of **5**$^+$ above, which contain three *low-spin tripod*iron(II) entities and one *high-spin* iron(II) center. The synthesis, spectroscopic data, cyclic voltammetric data, Mössbauer data and X-ray analytical data for a series of compounds of types **3**$^+$ and **5**$^+$ are presented in this paper.

Introduction

The templates *tripod*iron(II) [*tripod* = $CH_3C(CH_2PPh_2)_3$] may serve as building blocks for supramolecular aggregates. With dinitriles such as NC−CH=CH−CN, they form tetranuclear cages [(*tripod*Fe)$_4${μ-NC−CH=CH−CN}$_6$-BF_4]$^{7+}$ in which the *tripod*iron(II) entities serve to bind three nitrile functionalities at each corner of an overall tetrahedral cage, which encloses an anion in its cavity.[1] Nitrile functionalities are ideal for engaging in this type of a supramolecular aggregation process, since the binding of RCN ligands to *tripod*iron(II) templates is reversible and flexible.[2] Reversibility of metal−ligand binding is an essential prerequisite for the controlled formation of coordination oligomers.[3−7] Based on the above reasoning, the reactivity of *tripod*iron(II) templates with anionic geminal dinitriles $[RC(CN)_2]^-$ was analyzed. Neutral geminal dinitriles have been found to promote dinuclear aggregation giving [(*tripod*Fe)$_2${μ-NC−X−CN}$_3$]$^{4+}$ [X = $C(CR_2)$, $(CH_2)_2$, $(CH_2)_3$, *o*-C_6H_4].[8] Anionic dinitriles were expected to show stronger metal−ligand-bonding, which might possibly allow for the construction and stability of aggregates of higher nuclearity. A series of dinuclear and tetranuclear aggregates derived from *tripod*iron(II) and $[RC(CN)_2]^-$ is described in this paper.

Results and Discussion

Dinuclear Compounds

The anionic geminal dinitriles **1a**$^-$−**f**$^-$ [9−16] were examined with regard to their propensity to selectively form co-

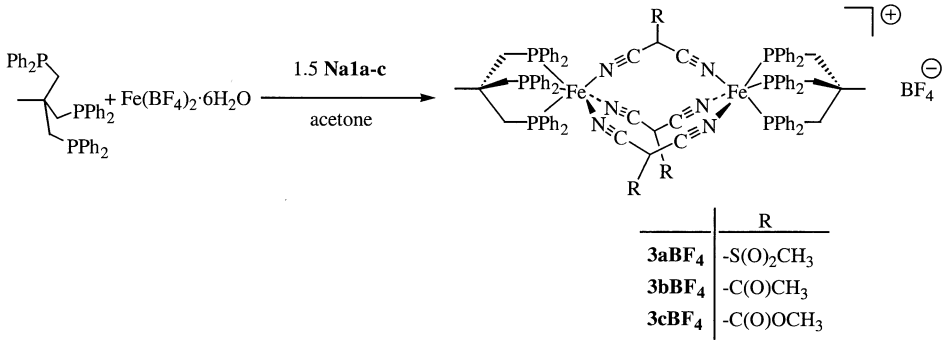

Scheme 2. Synthesis of the dinuclear compounds **3aBF$_4$**, **3bBF$_4$** and **3cBF$_4$**

ordination oligomers with *tripod*iron(II) templates (Scheme 1).

The sodium-salts of **1a**−**c**$^-$ were added to an acetone solution containing equivalent amounts of $Fe^{II}aq(BF_4)_2$ and *tripod*, in a molar ratio of 3:2 [ligand/iron(II) salt] (Scheme 2). The pale yellow solutions immediately turned red on addition of the ligands. Workup by filtration and crystallization yielded the BF_4^- salts of **3a**−**c**$^+$ as red microcrystalline solids.

Elemental analyses and mass spectra agree with the assigned constitution in each case. Coordination of the nitrile groups is evident from the observed pattern of the ν_{CN} vibrations, which are shifted to higher energies relative to the free ligands in each case (Table 2).

^{31}P NMR spectra (Table 1) show the presence of only one type of coordinated phosphorus for **3aBF$_4$**. For **3bBF$_4$**, a complicated pattern of ^{31}P NMR resonances is observed, which has not been analyzed in detail. This pattern does not change its phenotype for the temperature range 203−303 K. A rationale for this observation may be found in the assumption that the $CH_3C(O)$ substituents are not free to rotate. Conjugation within the acetyldicyanomethanido ligands will force these groups to lie within the $C(CN)_2$ planes. For the free ligand this coplanarity is evident by the observation of two ^{13}C NMR signals for the CN carbon atoms (δ = 123.9 and 121.8). One of these signals must be due to a carbon atom on the oxygen side of the acetyl substituent, and the other signal to the nitrile carbon atom at the methyl side. If the acetyl groups are in the same plane as the $C(CN)_2$ ligand entity in the coordination compound as well, and if the symmetry of the $Fe(NCCCN)_3Fe$ core is D_{3h}, there are two possible diastereomers. The statistical probability of the formation of the diastereomer, which has all three CO groups pointing to only one iron atom, is just

[a] The ^{1}H-NMR resonances of the sodium salts of the ligands are found at δ = 2.88 (**Na1a**, [D$_6$]acetone), 1.86 (**Na1b**, [D$_6$]DMSO) and 3.51 (**Na1c**, [D$_6$]acetone). The resonance of H_2TCNE, **H1d** (CD_3NO_2), is found at δ = 5.16. − [b] The ^{13}C-NMR resonances of the sodium salts of the ligands are found at δ = 42.2 (C_q), 46.3 (CH_3) and 120.4 (CN) (**Na1a**, [D$_6$]DMSO); 26.4 (CH_3) , 47.9 (C_q), 123.9 and 121.8 (CN) and 191.0 (CO) (**Na1b**, [D$_6$]DMSO); 32.3 (C_q), 51.0 (CH_3), 123.1 and 122.0 (CN) and 168.8 (COO) (**Na1c**, [D$_6$]acetone); 119.4 s (**Na2**, [D$_6$]DMSO). The resonances of H_2TCNE, **H1d**, (CD_3NO_2) are found at δ = 26.1 (CH) and 109.1 (CN). − [c] Signal not observed. − [d] These signals interfere with signals for aromatic carbons of the *tripod* ligand.

one third of the probability of the formation of the other diastereomer, which has two CO groups pointing in the direction of one iron atom and the remaining CO group arranged in the opposite direction. In the less probable isomer all three phosphorus nuclei at each iron center are equivalent, such that a single resonance would be expected for each of the two chemically different *tripod*iron entities. In the other isomer there are two different types of phosphorus nuclei at each *tripod*iron entity, such that a doublet and a triplet resonance would be expected for each of the two different *tripod*iron entities. PP-COSY spectra show four different types of *tripod*iron entities. Due to the small differences in the chemical shifts (δ = 31.5−39) and the large coupling constants ($^2J_{PP}$ = 60 Hz), the spectrum is more complicated and has not been analyzed completely, but its general appearance is in agreement with the above hypothesis.

The ^{31}P NMR spectrum of **3cBF$_4$** shows one broad unresolved signal only, with no significant change in appearance in the temperature range from 203−303 K. With regard to the orientation of the MeOC(O) substituents relative to the coordination scaffolding, the situation is the same as discussed for **3bBF$_4$**, i.e. at least two diastereomers are expected. The coplanarity of the C(O)OR substituent with the $C(CN)_2$ part of the ligand is again evident for the free ligand from its ^{13}C NMR spectrum, which shows two different signals for the nitrile carbon atoms (δ = 123.1 and 122.0). However, in comparison with the situation in **3bBF$_4$**, the electronic differentiation between the two sides of the substituents is smaller for the methoxycarbonyl group than for the acetyl substituent. The differentiation of the chemical environment of the *tripod*iron entities by the orientation of these groups will hence be smaller for **3cBF$_4$** than for **3bBF$_4$**. This means, that the ^{31}P NMR pattern, which could still be partly resolved for **3bBF$_4$**, is no longer resolved for **3cBF$_4$** such that one broad signal is all that can be seen.

The reaction of $Fe^{II}aq(BF_4)_2$ and *tripod* with **H1d**[14] in acetone leads to the dinuclear compound **3dBF$_4$**, under spontaneous deprotonation of **H1d**.[17] Short reaction times allow for the isolation of the BF_4^- salt of **3d**$^+$ as a red microcrystalline compound, in yields of about 50% (Scheme 3).

The analytical data are in agreement with the assigned constitution (Tables 1 and 2). The ^{31}P NMR spectra (Table 1) show one sharp singlet resonance as expected for two chemically equivalent *tripod*iron(II) units. The ^{1}H NMR resonance of the dicyanomethyl substituent is found at δ = 2.88 (**3dBF$_4$**, CD_2Cl_2). With the proton signal of the neutral ligand lying at δ = 5.16 (**H1d**, CD_3NO_2), the coordination shift is remarkably high.

Sodium dicyanamide, **Na2**, also reacts in the typical way yielding the dinuclear compound **4BF$_4$** as a red violet microcrystalline material (90%) (Scheme 4).

The analytical data (Table 2) and NMR spectra (Table 1) are in agreement with the assigned constitution. The ^{13}C NMR signals of the nitrile groups shift from δ = 119.4 (**Na2**, [D$_6$]DMSO) to δ = 124.8 (**4BF$_4$**, CD_2Cl_2), on coordination (Table 1).

Crystals suitable for X-ray analysis could be grown for three compounds of the series **3BF$_4$** (**3aBF$_4$**, **3bBF$_4$**, **3dBF$_4$**). Structural analysis revealed the same principal type of coordination for all three compounds. Therefore, only the structure of **3b**$^+$ is shown in Figure 1. The structural data for all three compounds are presented (Exp. Sect., Table 5).

The $Fe(NCCCN)_3Fe$ core shows an approximate C_3 symmetry in each case (Figure 1). The distances between the iron centers are almost the same in the three compounds [Fe···Fe 692 pm (**3a**$^+$), 680 pm (**3b**$^+$), 687 pm (**3d**$^+$)]. They are determined by the geometry of the NCCCN bridging entity, which is the same in all three compounds. With almost ideal octahedral coordination at the iron centers, ligand geometry does not allow for strictly linear Fe−N−C arrangements (Figure 1). Throughout the series of the three compounds Fe−N−C angles are in the range of 157−169°. The substituents at the $C(CN)_2$ ligand constituent show no pπ−pπ conjugation with the $C(CN)_2$ unit in **3a**$^+$ and **3d**$^+$, whereas the acetyl substituent in **3b**$^+$ definitely does so. The corresponding C−C distances are only 143.7 pm in **3b**$^+$, while they are 150 pm in **3d**$^+$. This π conjugation seen in **3b**$^+$ is also evident from the strict coplanarity of all nonhydrogen atoms of each ligand in **3b**$^+$. The relevant torsion angles are around 0° and 180°, ±5°. The interpretation of the spectroscopic data for **3bBF$_4$** as given above (Table 1 and 2), is in full accord with the observed structure of **3b**$^+$, which conforms to the statistically preferred isomer with regard to the rotational position of the acetyl groups (Figure 1).

All compounds **3BF$_4$** and **4BF$_4$** show reversible one-electron oxidations to the mixed-valent Fe^{II}/Fe^{III} species. Oxidation occurs at around 1000 mV vs. SCE, with a slight variation depending on the specific type of ligand (Table 4). The lowest oxidation potential is observed for **4BF$_4$** ($E_{1/2}$ = 910 mV vs. SCE), oxidation is most difficult for **3aBF$_4$** ($E_{1/2}$ = 1120 mV vs. SCE) with its electron-withdrawing

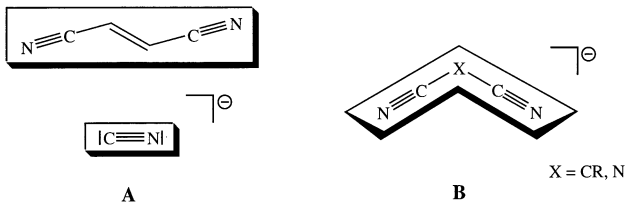
sulfonylmethyl substituents. A second reversible one-electron oxidation step is observed for all compounds except **3dBF$_4$** (Table 4). The separation between the first and second one-electron oxidation potential, $E_{1/2}{}^1 - E_{1/2}{}^2$, is approximately 300 mV throughout.

Tetranuclear compounds

The above results show that geminal anionic dinitriles tend to form dinuclear compounds with *tripod*iron(II) units. This cannot be a consequence of the anionic charge on the ligands, since neutral dinitriles show the same preference of forming dinuclear, triply bridged diiron compounds. Therefore, it must be a consequence of the geometry of the bridging ligands. In these dicyanomethanide derivatives, the two nitrile groups are separated by just one linker atom, thus spanning an angle between 109 and 120°. The geometry of these ligands thus differs distinctly from the one in fumaric dinitrile, where the nitrile groups are separated by two spacer atoms such that the nitrile groups are parallel to each other. Thus, with fumaric dinitrile as a bridging ligand, the ligand − including the linker entity − and the metal centers bound to it are roughly colinear (Scheme 5 **A**). However, with dicyanomethanide-type ligands, the bridging ligand and the two metal centers bound to it arrange themselves in a roughly triangular shape with the space segment along the line connecting the metals centers being empty (Scheme 5 **B**).



Scheme 5. Linear rod-type and triangular clamp-type bridging ligands

The main geometric difference between these two types of ligands is that fumaric dinitrile behaves as a rod-like building block, while dicyanomethanide derivatives and their analogues serve as a kind of "triangular clamp". This corresponds to the difference in behavior of these building blocks if they are used to construct oligonuclear metal com-

pounds by a self-organized process. With a linear rod-type ligand, only one ligand fits between two metal centers. With ligands forming triangular clamp-like arrangements, there is no such restriction and up to three ligands can easily be arranged to form a triply bridged dinuclear compound (e.g. **3BF$_4$** and **4BF$_4$**).

If the goal is to achieve higher nuclearity in self-arrangement processes, linear rod-type ligands would hence be the proper choice since three such ligands fixed in a monodentate way to one metal center can never ligate to another one with their other end. In fact, under conditions similar to the ones used for the preparation of compounds of the type **3BF$_4$** and **4BF$_4$** (this work), or [*tripod*Fe{μ-NC−C(CR$_2$)−CN}$_3$Fe*tripod*]$^{4+}$,[8] fumaric dinitrile yields a tetranuclear compound [(*tripod*Fe)$_4${μ-NC−CH=CH−CN}$_6$BF$_4$]$^{7+}$ [1] with a tetrahedral arrangement of the metal atoms. The opposite tendency of dicyanomethanide-derived ligands to result in triply bridged dinuclear compounds, might then be overcome in a self-organization process in which both linear rod-type ligands and triangular clamp-type species are used. This hypothesis was tested by repeating the reaction leading to **3BF$_4$** and **4BF$_4$** in the presence of varying amounts of cyanide as a linear rod-type linker (Scheme 5 **A**). It was found that tetranuclear compounds **5BF$_4$** are in fact formed with the appropriate molar ratio (Scheme 6).

When the sodium salt of **1a**$^-$ is added to a mixture of Fe^{II}aq(BF$_4$)$_2$ and *tripod* in dichloromethane/ethanol (1:1), a color change from pale yellow to red immediately occurs and up to this point the appearance of the reaction mixture is very similar to that observed in the preparation of **3a**$^+$. Solid sodium cyanide is added to this mixture. A gradual color change from red to orange-red is observed over a period of 10 h. On concentration, an orange-red material precipitates, which is purified by dissolution in dichloromethane, filtration and crystallization from dichloromethane/ethanol. Analysis of the orange microcrystalline product shows that it is **5aBF$_4$**. The ν_{CN} IR spectra show a prominent long-wavelength band at 2106 cm^{-1} (CsI) (Table 3), which is assigned to the vibration of a μ^2-bridging cyanide ligand.[18] In dichloromethane, this band is found to split into two components, which is assigned to the symmetric (A_1, 2111 cm^{-1}) and asymmetric (E, 2105 cm^{-1}) vibrations of the locally C_3-symmetric Fe(NC)$_3$ unit. This assignment is corroborated by the observation that a band at around this wavelength is present in the IR spectra of all compounds of the type **5BF$_4$**, while it is absent in the IR spectra of compounds of the type **3BF$_4$** which do not contain a bridging cyanide ligand. The ν_{CN} bands, which are characteristic of the bridging dicyanomethanide ligands in **3BF$_4$**, are found at shorter wavelengths in the range of 2180−2230 cm^{-1} (Table 2). In the tetranuclear compounds **5BF$_4$**, vibrations in the same range are hence assigned to μ^2-bridging dicyanomethanide ligands (Table 3). For **5aBF$_4$**, these bands are found at 2216 and 2184 cm^{-1}. A shoulder at 2166 cm^{-1} indicates the presence of a terminally coordinated dicyanomethanide ligand.[19,20] The shoulder observed in the CsI phase, appears as a separate band in the dichloromethane phase at 2163 cm^{-1} (Table 3). A band at this frequency (2165 ± 10 cm^{-1}) is observed for all compounds (**5aBF$_4$**, **5bBF$_4$**, **5cBF$_4$**, **6BF$_4$**) which have a geminal dinitrile coordinated as the terminal ligand to the apical iron center (Table 3). FAB$^+$ mass spectra show the signal for the parent molecular ion **5a**$^+$ at *m*/*z* = 2748. Fragments corresponding to the consecutive loss of *tripod* ligands (*m*/*z* = 2123 [M$^+$ − *tripod*], 1498 [M$^+$ − 2*tripod*]) are also observed. The Mössbauer spectrum of **5aBF$_4$** shows a pattern with four absorbance maxima, which is clearly a convolution of two doublets. One of these is centered at δ = 0.272 mm/s, with a quadrupole splitting of *q* = 0.743 mm/s. The other one occurs at δ = 0.935 mm/s, with a quadrupole splitting of *q* = 3.184 mm/s. The intensity ratio between these two signals is 3:1, corresponding to the presence of the two different types of iron centers in this ratio (Figure 2).

The observed shifts and quadrupole splittings are in agreement with the assigned structure of **5aBF$_4$**; the signal

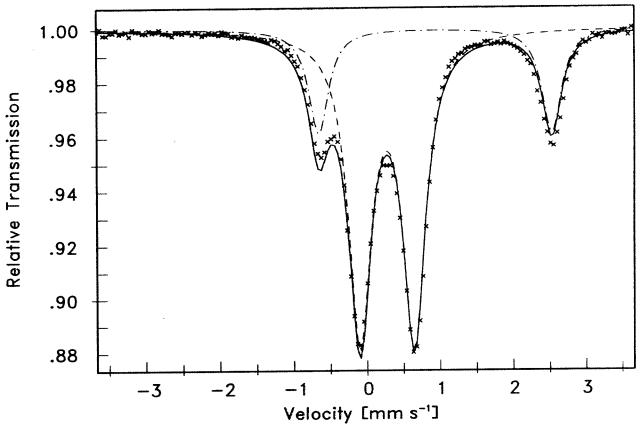

Figure 2. ^{57}Fe Mössbauer spectrum of **5aBF$_4$** (80 K)

of relative intensity 3 corresponds to three *low-spin* iron(II) units i.e. to the *tripod*iron(II) groups, each of which is coordinated to two bridging dicyanomethanide ligands and one bridging cyanide group. For comparative purposes, the Mössbauer spectrum of the tetranuclear compound [(*tripod*Fe)$_4${μ-NC−CH=CH−CN}$_6$BF$_4$](BF$_4$)$_7$,[1] which contains four *low-spin tripod*iron(II) units each coordinated to three nitrile bridging ligands, was measured. One doublet (δ = 0.363 mm/s; q = 0.255 mm/s) is observed for this compound. Shift and quadrupole splitting agree with the corresponding values of the signals assigned to *low-spin tripod*iron(II) in **5aBF$_4$**. The assignment of a *C*-coordinated μ-CN ligand to this entity, is inferred from a comparison of its Mössbauer signal with the Mössbauer data obtained for [*tripod*Fe{μ-CN}{μ-NCC(COOEt)CHC(COOEt)CN}$_2$-Fe*tripod*]BF$_4$,[21] in which one *tripod*Fe(NCR)$_2$ entity is coordinated to the carbon end of the bridging cyanide ligand and the other is coordinated to the nitrogen atom of the same ligand. One of the two observed doublets corresponds almost exactly to the doublet observed for [(*tripod*Fe)$_4${μ-NC−CH=CH−CN}$_6$BF$_4$](BF$_4$)$_7$ with three *N*-coordinated nitrile ligands; the other is characterized by the parameters (δ = 0.341 mm/s; q = 0.688 mm/s), which are very similar to those characterizing the Mössbauer data of the *tripod*iron(II) entity in **5aBF$_4$**. This is taken as a strong indication for the *C*-coordination of the cyano groups to the *tripod*iron(II) entities in **5aBF$_4$**. The magnetic moment observed for **5aBF$_4$** (μ = 5.3 μ_B, Table 3) corresponds closely to the *spin-only* value ($\mu_{s.o.}$ = 4.9 μ_B) for a tetrahedral *high-spin* iron(II) center. The Mössbauer data for this type of iron compound are in a range [$(FeCl_4)^{2-}$: δ = 1.0 mm/s; q = 2.55 mm/s[22−24]] which indicates that the apical iron(II) center with its three *N*-coordinated cyano ligands and one terminal nitrile ligand has a *high-spin* electron configuration.

The same type of reaction, as has been explicitly described for **Na1a** leading to **5aBF$_4$**, occurs if **Na1b** and **Na1c** are used as the dinitrile components, hence leading to **5bBF$_4$** and **5cBF$_4$** respectively (Scheme 6). The spectroscopic and magnetic properties of **5bBF$_4$** and **5cBF$_4$** (Table 3) are very similar to those discussed in detail for **5aBF$_4$**. Microanalyses are also in agreement with the formulae given (Table 3).

A definite proof of the structure of compounds $\mathbf{5BF_4}$ comes from the X-ray analysis of $\mathbf{5aBF_4}$. Suitable single crystals of $\mathbf{5aBF_4}\cdot 1.5\ CH_3NO_2\cdot 2.2\ C_4H_8O_2$ could be grown from nitromethane solutions of $\mathbf{5aBF_4}$, by slow vapor phase diffusion of ethyl acetate at room temperature (Figure 3).

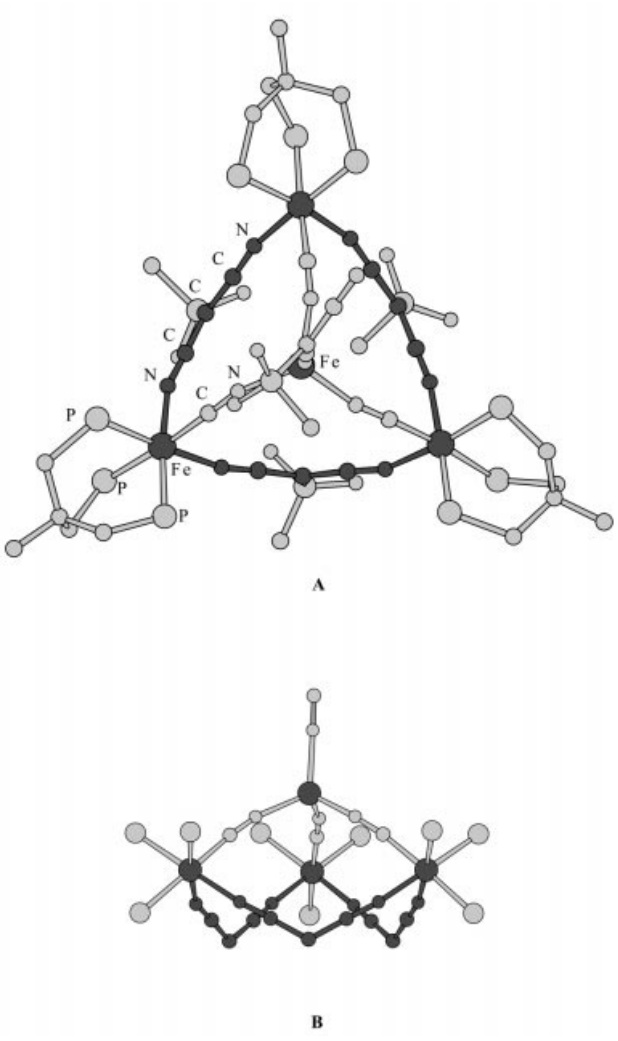

Figure 3. Two views of the cation $\mathbf{5a^+}$; for the sake of clarity only part of the ligand periphery is shown; Fe_{oct}= octahedrally coordinated iron(II); Fe_{tet}= tetrahedrally coordinated iron(II); selected bond lengths [pm] and angles [°]: $Fe_{oct}-P_{\mathit{cis}CN}$ 224.9(2) to 226.7(2), $Fe_{oct}-P_{\mathit{trans}CN}$ 231.7(2) to 232.6(2), $Fe_{oct}-N$ 196.0(7) to 200.5(7), $Fe_{oct}-C_{CN}$ 191(1) to 193(1), $Fe_{tet}-N_{CN}$ 199.2(6) to 201.1(7), $Fe_{tet}-N$ 204.3(7), $C_{CN}-N_{CN}$ 115(1) to 118(1), C−N 113(1) to 117(1), $C-C_{CN}$ 139(1) to 144(1); P−Fe−P 85.1(1) to 91.3(1), P−Fe−C 91.8(3) to 94.0(3), 174.4(3) to 177.6(3), P−Fe−N 90.1(3) to 98.2(3), $N-Fe_{oct}-N$ 83.8(3) to 84.7(3), $N_{CN}-Fe_{tet}-N_{CN}$ 104.1(2) to 107.6(2), $N_{CN}-Fe_{tet}-N$ 110.0(3) to 116.1(3), $Fe_{oct}-C_{CN}-N_{CN}$ 173(1) to 175(1), $Fe_{tet}-N_{CN}-C_{CN}$ 165(1) to 167(1)

The cation $\mathbf{5a^+}$ consists of a triangle spanned by three *tripod*iron(II) units, which are linked by three bridging (methylsulfonyl)dicyanomethanide ligands (Figure 3 **A**). Five coordination sites of the octahedrally coordinated *tripod*iron(II) centers (Fe_{oct}) are thus used to form the bonds within this triangle and to the *tripod* ligands. In each case the sixth position is occupied by a *C*-bonded cyano ligand. The N-termini of these three cyano ligands coordinate to the apical iron center, which has a tetrahedral coordination (Fe_{tet}), with the fourth position being occupied by a terminal (methylsulfonyl)dicyanomethanide ligand, which is coordinated by one nitrile functionality (Figure 3 **A**). The angles around Fe_{oct} are close to the ideal values of a coordination octahedron, although individual deviations of up to 8° (Figure 3) indicate some strain within the cage as a whole. The assumption that the μ-CN groups are *C*-bonded to the *tripod*iron(II) entities, which had been inferred from Mössbauer analysis, is corroborated by the observation that with this assignment of atom types to the bridging cyano groups, reasonable temperature factors are obtained for both carbon and nitrogen during such a refinement. Another argument in favor of this hypothesis comes from the observation that the Fe−P distances involving phosphorus atoms *trans* to the cyano ligands are some 6 pm longer than the remaining Fe−P distances, which involve phosphorus atoms which are *trans* to the organic nitrile groups (Figure 3). In addition, the Fe−C bonds are distinctly shorter than the Fe−N bonds for all three basal iron centers. The $Fe_{oct}-C_{CN}-N_{CN}$-groups are only slightly bent, while the angles $Fe_{tet}-N_{CN}-C_{CN}$ deviate from 180° to a larger extent (Figure 3). The distances $Fe_{tet}-N_{CN}$ are around 200 pm. The $Fe_{tet}-N$ distance to the terminal ligand is 204 pm. The $Fe_{tet}-N$ bonds, radiating from the tetrahedrally coordinated apical *high-spin* iron center, are definitely longer than those involving the basal, octahedrally coordinated, *low-spin* iron centers. The observed $Fe_{tet}-N$ distances (Figure 3) are in agreement with the observed values for other tetrahedrally coordinated *high-spin* iron(II) species.[25] When $\mathbf{1e^-}$ and $\mathbf{1f^-}$ are used as the dicyanomethanide components in the synthesis of $\mathbf{5BF_4}$, the reaction proceeds in a similar way (Scheme 7).

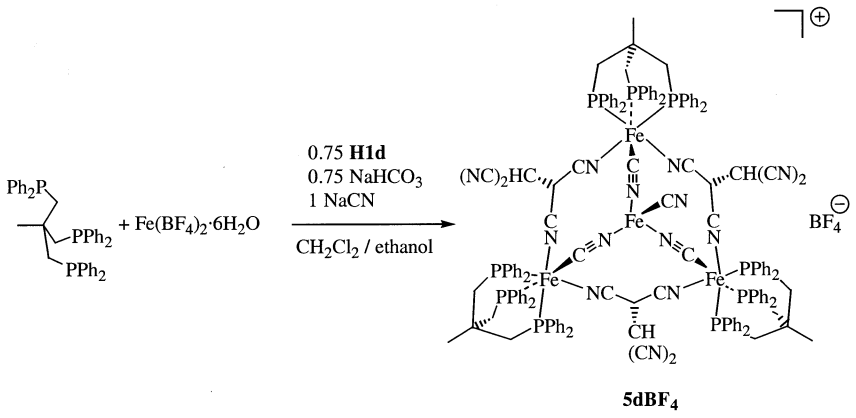
The resulting compounds $\mathbf{5eBF_4}$ and $\mathbf{5fBF_4}$ are less soluble than $\mathbf{5aBF_4}$, $\mathbf{5bBF_4}$ and $\mathbf{5cBF_4}$. They are obtained as red precipitates from the reaction solutions. These precipitates are dissolved in nitromethane for purification. After filtration through silica gel, pure samples of $\mathbf{5eBF_4}$ and $\mathbf{5fBF_4}$ are obtained from these solutions by crystallization. Cubic crystals are obtained by vapor phase diffusion of diethyl ether into nitromethane solutions of $\mathbf{5eBF_4}$ and $\mathbf{5fBF_4}$. Both compounds crystallize in the cubic space group $P\bar{4}3n$. In both cases the structures are strongly affected by disorder problems. There are positions within the crystals that are occupied by solvent molecules with varying degrees of disorder. There is also disorder with respect to the apical ligand of the tetrahedrally coordinated iron center, which is confined by crystallographic symmetry to lie on a crystallographic C_3 axis. This disorder cannot be completely resolved, neither for $\mathbf{5eBF_4}$, nor for $\mathbf{5fBF_4}$. The best solution for $\mathbf{5e^+}$ is obtained by assigning a fluoride ligand to this position. For $\mathbf{5f^+}$ a chloride ligand gives the most satisfactory result. The overall geometry of the framework of the tetrahedral cage in $\mathbf{5e^+}$, including the *tripod* ligands, is determined by structure analysis without any doubt. The only problem with regard to assigning individual atoms to the otherwise well-defined positions, remains for the μ-CN groups. The best solution is obtained if the CN groups are

	R	X
5eBF$_4$	-C(O)CN	**1e$^-$**
5fBF$_4$	-NO	Cl

Scheme 7. Synthesis of the tetranuclear compounds **5eBF$_4$** and **5fBF$_4$**

oriented as described for **5a**$^+$. For **5f** $^+$ the overall cage structure is similarly well defined. Here however, the C(NO) linkers joining the coordinated nitrile groups of the bridging dicyanomethanide ligands show disorder, indicating that the symmetry of the η^2-coordination of this ligand does not conform exactly to the crystallographically imposed C_3 symmetry. In view of their inaccuracy in quantitative detail and their close similarity in the overall structure of the cage and the coordination environments, individual data are not discussed here. However, the structural data have been deposited. It appears that the fact that **5aBF$_4$** contains a large C_s-symmetric organic ligand in the apical position is responsible for effectively breaking the *pseudo* symmetry of the crystals. As a result, its structure could be solved without major interference by disorder problems, the only compound in the series of compounds **5BF$_4$**. The lower crystal symmetry of **5aBF$_4$** ($P2_1/n$) as compared with **5eBF$_4$** and **5fBF$_4$** (and also with **5dBF$_4$**, see below) is already macroscopically apparent by looking at the shape of the crystals. The crystals of **5aBF$_4$** form parallelepipeds, whilst those of the others form cubes or hexagonal plates.

A problem associated with compounds **5BF$_4$** is that they undergo easy exchange of their apical ligand. Thus, structure analysis showed that in the crystal specimen analyzed, **5e**$^+$ has an apical ligand with the diffraction power of a fluoride or a hydroxy group. It definitely shows that the molecule in the crystal does not contain a ligand such as **1e**$^-$ or a chloride ion in the apical position. On the other hand, FAB$^+$ mass spectrometry (Table 3) of the bulk crystalline material clarifies that the parent molecular ions observed in the gas phase do not contain either F^- or OH^-. Three types of parent ions are observed, together with their daughter ion $[(tripod\text{Fe})_3\{\mu\text{-NC}-\text{C[C(O)CN]}-\text{CN}\}_3\{\mu\text{-CN}\}_3\text{Fe}]^+$ (m/z = 2530). The mass differences between these three types of parent ions and the daughter ions are 35, 118 and 166, respectively. These mass differences are interpreted as being due to the loss of three different types of apical ligands; chloride, tricyanoethenolate (**1e**$^-$) and pentacyanopropenide ($C_8N_5^-$). Elemental analysis of the bulk material of **5eBF$_4$** shows that **1e**$^-$ is the apical ligand in the original sample (Table 3). It appears that the different processes of handling the probes during FAB$^+$ mass spectrometry, as well as during crystal growth, causes the exchange of the apical ligand. The fluoride ion (crystal structure) may have been incorporated whilst **5eBF$_4$** was in solution for several days which is necessary in order to obtain crystals. The only explanation for the observed incorporation of the chloride ion is an exchange during the processing steps where dichloromethane was used as a solvent. The presence of a pentacyanopropenide ion as an apical ligand, which is seen by mass spectrometry, can be explained by the tendency of polycyano-substituted C_2 entities to form this anion under various conditions.[15] Small peaks attributed to the exchange of the apical ligand by pentacyanopropenide are also observed for **5aBF$_4$**, **5cBF$_4$** and **5fBF$_4$**. The peak corresponding to the molecular ion **5e**$^+$ has a lower intensity than the peaks observed for the chloride and pentacyanopropenide derivative. These two latter molecular ions show daughter ions at m/z = 1940 and 2071, respectively, which correspond to the loss of one *tripod* ligand. This is consistent with the observation that **5a**, **5b**$^+$ and **5c**$^+$, as well as **6**$^+$, show prominent peaks which can be attributed to the loss of one or two *tripod* ligands from their parent ions (Table 3). The mass spectrum of **5fBF$_4$** shows a strong signal for the parent ion with the chloride ion as the apical ligand. This is consistent with the result from the X-ray analysis of **5fBF$_4$**. In addition, the mass spectrum of **5fBF$_4$** shows a molecular ion which corresponds to the exchange of the apical chloride ligand by **1f**$^-$ [m/z (%) = 2552 (8)], and a peak which corresponds to the exchange by pentacyanopropenide [m/z (%) = 2624 (3)]. The ease of exchange of the apical ligands as observed in the mass-spectrometric analyses, and the tendency to include solvent molecules as seen by the X-ray analyses, is mirrored by the microanalytical data (Table 3), which are, in some cases, not as accurate as could be expected. The magnetic moments



Scheme 8. Synthesis of the tetranuclear compound **5dBF$_4$** according to method **A**

of **5eBF$_4$** and **5fBF$_4$** are around the value of $\mu_{s.o.} = 4.9\ \mu_B$, as expected for a *high-spin* tetrahedral d^6 species (Table 3). It is known that with iron(II) as the d^6 center, spin−orbit coupling tends to result in moments slightly higher than the *spin-only* values.[26] The IR data of **5eBF$_4$** and **5fBF$_4$** (Table 3) are in agreement with the formulae given; the ν_{CN} bands compare well with the ones discussed for **5aBF$_4$**, **5bBF$_4$** and **5cBF$_4$**.

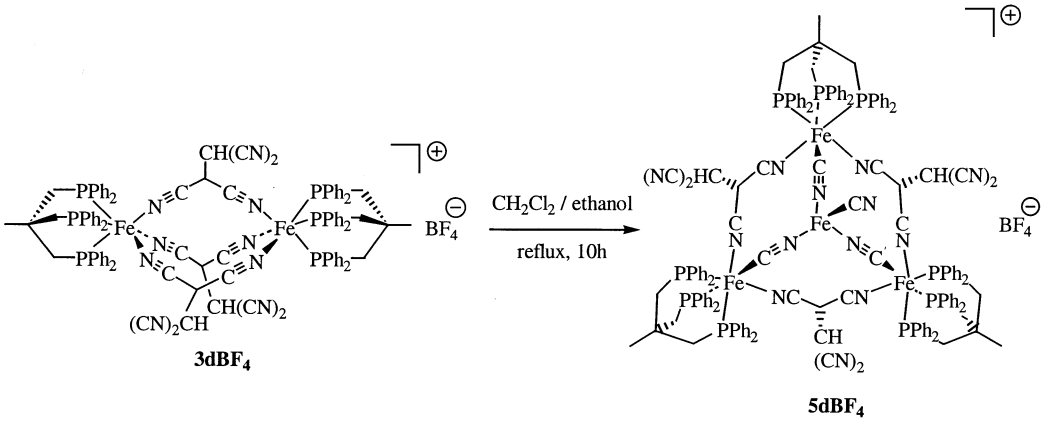
The reaction of $Fe^{II}aq(BF_4)_2$ and *tripod* in dichloromethane/ethanol (1:1) with 1,1,2,2-tetracyanoethane, **H1d**, produces **5dBF$_4$** on addition of stoichiometric amounts of sodium cyanide and sodium bicarbonate (method **A**) (Scheme 8). The initial pale yellow color of the $Fe^{II}aq(BF_4)_2$/*tripod* mixture immediately turns red on addition of **H1d**. No further color change is observed when sodium cyanide and sodium bicarbonate are added to the solution. However, over a period of 10 h the color of the solution changes to black, while an orange-brown precipitate forms. This precipitate is dissolved in nitromethane and purified by filtration and crystallization from nitromethane/dichloromethane/diethyl ether giving **5dBF$_4$** (40%).

An alternative synthesis of **5dBF$_4$** consists of heating **3dBF$_4$** to reflux in dichloromethane/ethanol (1:1) for 10 h (method **B**) (Scheme 9). The initial red color (**3dBF$_4$**) gradually changes to a dark red-brown. Purification by chromatography and crystallization yields **5dBF$_4$** (40%).

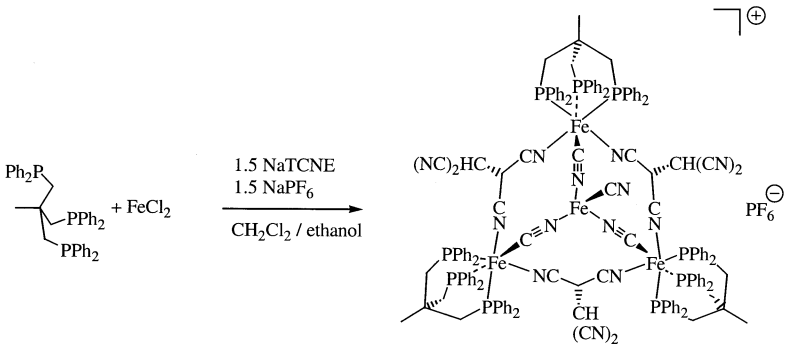
Yet another procedure for the synthesis of **5d$^+$** consists of the reaction of a mixture of *tripod* and $FeCl_2$ in dichloromethane/ethanol (1:1) with NaTCNE [27,28] (method **C**) (Scheme 10). On addition of NaTCNE, the solution becomes very dark which is characteristic of solutions of NaTCNE. Over a period of 10 h at room temperature, an orange-red precipitate forms, which is purified by crystallization giving **5dPF$_6$** (55%).

The cyanide ligands in **5d$^+$** must result from a partial disintegration of the TCNE-type precursors in the last two procedures **B** and **C**.

Crystals of **5dBF$_4$** have been obtained from batches produced in routes **B** and **C**. In an independent method, principally according to method **C** but by adding tetrafluoroborate as the counterion, another batch was produced from which crystals could also be obtained. The problem encountered with the structure analyses of these three different types of crystals is very similar to the one already discussed with regard to the structure analyses of **5eBF$_4$** and **5fBF$_4$**. All three types of crystals belong to highly symmetric space groups ($P\bar{4}3n$ and $P31c$), that impose crystallographic trigonal symmetry onto the tetranuclear cations. This symmetry does not correspond to the true molecular symmetry, since the $C(CN)_2H$ groups show disorder around their $C-C(CN)_2H$ bond. In addition, as already observed for **5eBF$_4$** and **5fBF$_4$**, the apical ligands of the tetrahedrally co-



Scheme 9. Synthesis of the tetranuclear compound **5dBF$_4$** according to method **B**



5dPF$_6$

Scheme 10. Synthesis of the tetranuclear compound **5dPF$_6$** according to method **C**

ordinated iron centers can be easily exchanged. In the crystals obtained by method **C** with hexafluorophosphate as the counterion, a chloride ion is in the apical position. The crystals produced by the same method, but with tetrafluoroborate as the counterion, are found to have cyanide as the apical ligand. In these crystals, there is not only rotational disorder of the $C(CN)_2H$ groups, but also a strong indication for the presence of $C(CN)H_2$ groups instead of $C(CN)_2H$ entities. With this assignment, the structure can be refined to an agreement factor of $R_1 = 8.7\%$ (Table 7). The quality of the individual geometric parameters is nevertheless low, due to the many disordered solvent molecules involved. The crystals produced according to method **B** are found to contain F^- or OH^- as the apical ligand. The organic bridging groups show the same type of disorder as discussed above, with the best solution being obtained by describing the rotationally disordered substituent as the $C(CN)H_2$ group. While all these structure analyses unequivocally prove the persistence of a [(*tripod*Fe)$_3${μ-NC−C(R)−CN}$_3${μ-CN}$_3$Fe−X] core, they cannot definitely elucidate the nature of R and X. FAB^+ mass spectra are more conclusive with regard to the nature of R in the bulk materials. The molecular ions are consistent with R = $C(CN)_2H$. Satellite peaks are found for R = $C(CN)H_2$. This indicates that the bulk material contains R = $C(CN)_2H$, as well as R = $C(CN)H_2$ as the substituent at the $RC(CN)_2$ bridging unit. Mass spectra are less conclusive with respect to the nature of the apical ligand X. In all spectra there is a prominent peak for the parent ion with X = CN^-. However, there are peaks for X = F^-/OH^-, Cl^-, CNO^- and $C_8N_5^-$ as well. The situation is thus very similar to the one described for **5eBF$_4$** and **5fBF$_4$**, and the final answer must be obtained from elemental analysis. Considering all combinations of possible constituents, the most satisfactory agreement is X = CN^- (Table 3). The magnetic moment of **5dBF$_4$** is in the range observed for the other compounds **5BF$_4$** (Table 3). The bridging cyano ligands are evident from their IR absorptions, as are the $RC(CN)_2$ building blocks (Table 3).

The reaction of $Fe^{II}aq(BF_4)_2$ and *tripod* in dichloromethane/ethanol (1:1) with sodium dicyanamide, **Na2**, and sodium cyanide gives **6BF$_4$** in a procedure very similar to the one used for the preparation of compounds **5BF$_4$** (Scheme 11). **6BF$_4$** is obtained as a red precipitate, which is purified by crystallization giving a red crystalline material. Although none of the many analyzed crystals gave good diffraction patterns so as to allow X-ray analysis, the spectroscopic and analytical data (Table 3) clearly prove that **6**$^+$ has a framework analogous to the one which characterizes the series of cations **5**$^+$. The magnetic moment and the infrared data (Table 3) support the above statement. The IR spectra show ν_{CN} bands that are characteristic of the dicyanamide ligand and the Fe(μ-NC)$_3$ group. The FAB^+ mass spectrum shows prominent peaks for the molecular

ion **6**$^+$ and for the daughter ions derived from the consecutive loss of two *tripod* ligands. The Mössbauer spectrum of **6BF$_4$** shows a signature which is very similar to the one observed for **5aBF$_4$** (Table 3). It demonstrates the presence of *high-spin* iron(II) and *low-spin* iron(II) in a ratio of 1:3. The microanalytical data are in full accord with the assigned formula.

Electrochemistry and UV/Vis Spectra

All compounds **3BF$_4$** to **6BF$_4$** undergo at least one one-electron oxidation. For the binuclear compounds **3BF$_4$**, the corresponding potentials are between $E_{1/2}$ = 910 mV (**4BF$_4$**) and 1120 mV (**3aBF$_4$**) (Table 4).

A second one-electron oxidation step is observed between $E_{1/2}$ = 1150 mV (**4BF$_4$**) and 1400 mV (**3aBF$_4$**) (Table 4). This second step is reversible for all binuclear compounds except **3dBF$_4$**, for which an irreversible electron transfer at E_{pa} = 1430 mV is observed. The observation of two distinctly different one-electron oxidation steps demonstrates that the iron centers take notice of each other. The distance between the two iron centers is around 700 pm (Figure 1) and the iron centers are joined by five-atom linkers. Both these facts are in favor of the stability of a mixed-valence Fe^{II}/Fe^{III} species. The equilibrium constant K_C for the comproportionation reaction (Scheme 12), as deduced from the oxidation potentials, is in fact rather high throughout (Table 4).[29] With a value of around 10^5, it characterizes the Fe^{II}/Fe^{III} complexes as class III mixed-valent species.[30]

$$M\sim\sim M + M^{ox}\sim\sim M^{ox} \underset{}{\overset{K_C}{\rightleftharpoons}} 2\ M\sim\sim M^{ox}$$

Scheme 12. Comproportionation equilibrium for mixed-valent dinuclear complexes

This means, that the iron centers and the ligands form a conjugated system together.[31,32]

The tetranuclear compounds **5BF$_4$** show only one reversible one-electron oxidation. A second reversible oxidation is observed for **6BF$_4$**, with its dicyanamide ligands (Table 4). Within each pair of compounds **3BF$_4$** and **5BF$_4$** (**4BF$_4$** and **6BF$_4$**), the first one-electron oxidation step occurs at similar potentials (Table 4), with a tendency of compounds **5BF$_4$** to be somewhat easier to oxidize than the corresponding compounds **3BF$_4$**. The similarity of the oxidation potentials of **3BF$_4$** and **5BF$_4$** shows that the oxidation of **5BF$_4$** is not centered at its *high-spin* iron(II) center.

The UV/Vis spectra of the different compounds **3BF$_4$** are rather similar (Figure 4). Bands occur at $\lambda \approx$ 19500 and 24000 cm^{-1} (Figure 4, Table 4). A similar pattern is observed for [*tripod*$Fe^{II}(NCMe)_3]^{2+}$ [33] (λ = 20500 and 26000 cm^{-1}), which has three organonitrile groups coordinated to a *tripod*iron(II) entity and is a *low-spin* compound, as are compounds **3BF$_4$**. Therefore, it is assumed that the bands observed for **3BF$_4$** correspond to the spectral signature of *low-spin tripod*$Fe^{II}(NCR)_3$ entities. Within the series of compounds **3BF$_4$** there is a slight shift of the relevant absorption energies (Table 4).

Compounds **5BF$_4$** and **6BF$_4$** show similar absorption patterns through their whole series. The bands at $\lambda \approx$ 19500 and 23000 cm^{-1} (Figure 4, Table 4) are typical for *low-spin tripod*$Fe^{II}L_3$ compounds. In the case of **5BF$_4$** and **6BF$_4$**, two of these ligands are nitrile groups from the organic bridging ligand, the third ligand is a cyano group acting as a bridging ligand to bind a tetrahedral *high-spin* iron(II) center. There is no indication in the spectra of **5BF$_4$** and **6BF$_4$** of any significant contribution from this *high-spin*

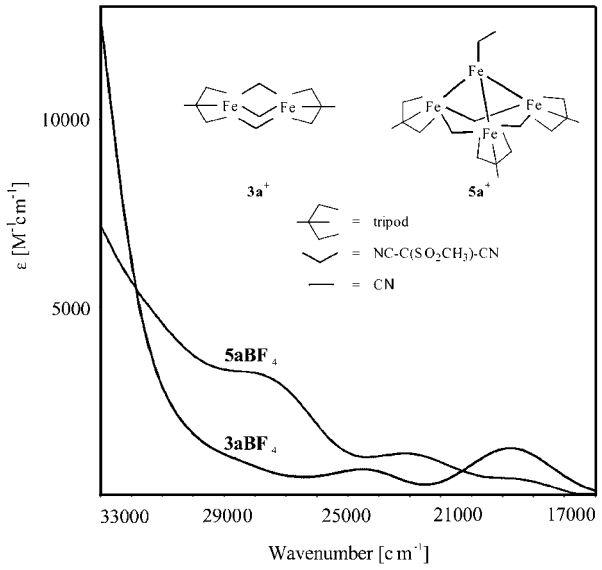

Figure 4. UV/Vis spectra of **3aBF$_4$** and **5aBF$_4$**

iron(II) center occurring in the long-wavelength range of the spectra (Figure 4, Table 4).

Conclusion

The *tripod* ligands, $Fe^{II}aq(BF_4)_2$ and dinitrile constituents engage in a self-assembly process to produce binuclear $[tripodFe\{\mu\text{-}NC-C(R)-CN\}_3Fetripod]^+$ or − in the presence of cyanide − tetranuclear compounds $[(tripodFe)_3\{\mu\text{-}NC-C(R)-CN\}_3\{\mu\text{-}CN\}_3Fe-X]^+$, exclusively. The self-organization process, which exclusively leads to $[tripodFe\{\mu\text{-}NC-C(R)-CN\}_3Fetripod]^+$ with the angular clamp-type ligands $[NC-C(R)-CN]^-$, may be switched to the exclusive formation of tetrahedral aggregates $[(tripodFe)_3\{\mu\text{-}NC-C(R)-CN\}_3\{\mu\text{-}CN\}_3Fe-X]^+$ by the interference of the linear rod-type ligand cyanide. The tetranuclear compounds $[(tripodFe)_3\{\mu\text{-}NC-C(R)-CN\}_3\{\mu\text{-}CN\}_3Fe-X]^+$ contain three *low-spin* $tripodFe^{II}L_3$ units and one tetrahedral *high-spin* iron(II) entity in one supramolecular aggregate.

The electrochemistry shows that compounds $[tripodFe\{\mu\text{-}NC-C(R)-CN\}_3Fetripod]^+$ form mixed-valent Fe^{II}/Fe^{III}-species of type III. They are stable against disproportionation into Fe^{II}/Fe^{II}- and Fe^{III}/Fe^{III}-species.

Experimental Section

General: All manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods [34] and distilled under argon. Silica gel and Kieselgur, used for filtration operations and chromatography, were degassed at 1 mbar for 24 h and saturated with argon. The compounds *tripod*,[35,36] $Fe(BF_4)_2{\cdot}6H_2O$,[37] (methylsulfonyl)malononitrile hydrochloride,[9] 1,1,2,2-tetracyanoethane,[14] NaTCNE,[27] tetramethylammonium tricyanethenolate[15] and sodium nitrosodicyanmethanide[16] were prepared in accordance to, or by adaptation of, literature procedures. All other chemicals were obtained from commercial suppliers and used without further purification. − NMR: Bruker Avance DPX200 spectrometer at 200.13 MHz (^{1}H), 50.323 MHz (^{13}C), 81.014 MHz (^{31}P); T = 303 K; chemical shifts (δ) in ppm with respect to CD_2Cl_2 (^{1}H: δ = 5.32; ^{13}C: δ = 53.5), [D$_6$]acetone (^{1}H: δ = 2.05; ^{13}C: δ = 20.8, 206.1) or [D$_6$]DMSO, (^{1}H: δ = 2.50; ^{13}C: δ = 39.4) as internal standards; ^{31}P chemical shifts (δ) in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0) as external standard; CD_2Cl_2, [D$_6$]acetone and [D$_6$]DMSO used, for NMR-spectroscopic measurements, were degassed by three successive "freeze-pump-thaw" cycles and dried over 4-Å molecular sieves. − Magnetic measurements: Faraday method: electromagnet B-E 1 C-8 and controller unit B-H 15 (Bruker); M 25 D-S balance (Sartorius). Gouy method: Sherwood Scientific Magnetic Susceptibility Balance (Johnson & Matthey). Evans method: Bruker Avance DPX200 spectrometer at 200.13 MHz (^{1}H); solvent: CD_2Cl_2; standard: DPPH (diphenylpikrylhydrazyl); T = 303 K. − IR: Biorad Excalibur spectralphotometer FTS 3000 [CsI discs or solutions (CaF_2 windows)]. − UV/Vis spectra: Perkin−Elmer UV/Vis spectralphotometer Lambda 9; ca.10^{-3} M solutions in CH_2Cl_2. − MS: Finnigan MAT 8320, VG ZAB 2F; FAB (Xenon; matrix: 4-nitrobenzyl alcohol). − Cyclic voltammetry: EG&G Princeton Applied Research model 273; potentials in mV versus SCE at a glassy carbon electrode at 25 °C; solutions of compounds: ca.10^{-3} M in 0.1 M Bu_4NPF_6 in CH_3CN or CH_2Cl_2. − Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg.

Preparation of the Compounds

Na[NCC(R)CN] [Na1: R = SO_2CH_3 (Na1a), $COCH_3$ (Na1b), CO_2CH_3 (Na1c)]:[10,12,13] **Na1a** was synthesized from the hydrochloride of (methylsulfonyl)malononitrile (279 mg; 1.54 mmol) by reaction with a slight excess of sodium bicarbonate (267 mg; 3.18 mmol) in water.[9] After drying the reaction mixture and filtering with 5 mL acetone, the product was isolated by precipitation with excess diethyl ether. 187 mg (73%) of a white solid was obtained after isolation and drying in vacuo. − $C_4H_3N_2NaO_2S$ (166.1): calcd. C 28.92, H 1.82, N 16.86; found C 29.23, H 2.56, N 16.88. − ^{1}H NMR ([D$_6$]acetone): δ = 2.88 (s). − ^{13}C NMR ([D$_6$]DMSO): δ = 42.2 (s, NC*C*CN), 46.3 (s, CH_3), 120.4 (s, CN). − IR (CsI): $\tilde{\nu}$ = 2187 m, 2160 s (CN); 1295 vs, 1137 vs (SO_2) cm^{-1}. − **Na1b** was prepared by dropwise addition of acetyl chloride (5.3 g; 68 mmol) to an ice-cooled solution of malononitrile (4.5 g; 68 mmol) in 10 mL of THF and sodium hydroxide (5.2 g; 130 mmol) in 10 mL of water. A light brown suspension formed, which was filtered after warming to room temperature. The precipitate was washed twice with 2 mL of ice-cold water, dried in vacuo and recrystallized from ethyl acetate/ethanol (20:1; 100 mL) yielding 6.4 g (65%) of a white powder. For elemental analysis the product was recrystallized from acetone/diethyl ether and dried in vacuo. − $C_5H_3N_2NaO$ (130.1): calcd. C 46.17, H 2.32, N 21.54; found C 46.25, H 2.52, N 21.36. − ^{1}H NMR ([D$_6$]DMSO): δ = 1.86 (s). − ^{13}C NMR ([D$_6$]DMSO): δ = 26.4 (s, CH_3); 47.9 (s, NC*C*CN); 121.8 (s, CN); 123.9 (s, CN); 191.0 (s, CO). − **IR** (CsI): $\tilde{\nu}$ = 2219 vs, 2193 vs, 2184 s,sh (CN); 1572 vs. (CO) cm^{-1}.− **Na1c** was prepared by dropwise addition of a mixture of methyl chloroformate (7.8 g; 82 mmol) and malononitrile (5.1 g; 77 mmol) in 10 mL of THF, to an ice-cooled solution of sodium hydroxide (6.2 g; 154 mmol) in 15 mL of water. A white suspension formed, which was filtered after warming to room temperature. The white precipitate was washed twice with 3 mL of ice-cold water, dried in vacuo and recrystallized from ethyl acetate (100 mL) yielding 6.0 g (48%) of light yellow needle-type crystals. − $C_5H_3N_2NaO_2$ (146.1): calcd.

C 41.11, H 2.07, N 19.18; found C 41.08, H 2.34, N 19.07. − ^{1}H NMR ([D$_6$]acetone): δ = 3.51 (s). − ^{13}C NMR ([D$_6$]acetone): δ = 32.3 (s, NC*C*CN); 51.0 (s, CH_3); 122.0 (s, CN); 123.1 (s, CN); 172.7 (s, COO). − IR (CsI): $\tilde{\nu}$ = 2216 vs, 2184 s (CN); 1648 vs, br (CO) cm^{-1}.

[(*tripod*Fe)$_2${μ-NCC(R)CN}$_3$]BF$_4$ [3BF$_4$: R = SO_2CH_3 (3aBF$_4$), $COCH_3$ (3bBF$_4$), CO_2CH_3 (3cBF$_4$)] and [(*tripod*Fe)$_2${μ-NCNCN}$_3$]BF$_4$ (4BF$_4$): Na1a, **Na1a**, **Na1c** or **Na2** (1.5 mmol) was added as a solid, in one portion, to a solution of Fe^{II}aq(BF$_4$)$_2$ (338 mg, 1 mmol) and *tripod* (625 mg, 1 mmol) in acetone. An immediate color change from pale yellow to red was observed. After stirring for 1 h at room temperature, the solvent was evaporated. The red residue was washed once with diethyl ether and dried in vacuo. Filtration with dichloromethane through 1 cm of Kieselgur and concentration of the red filtrate yielded the products as red to violet microcrystalline solids. For purification, the products were recrystallized. Yields and solvents of crystallization: **3aBF$_4$** [74% (acetone/diethyl ether)], **3bBF$_4$** [70% (dichloromethane/ethanol)], **3cBF$_4$** [78% (acetone/diethyl ether)], **4BF$_4$** [59% (dichloromethane/ethanol)]. For further analytical and spectroscopic data of the compounds see Tables 1, 2 and 4.

[(*tripod*Fe)$_2${μ-NCC[CH(CN)$_2$]CN}$_3$]BF$_4$ (3dBF$_4$): Solid **H1d** (1.5 mmol) was added in one portion to a solution of Fe^{II}aq(BF$_4$)$_2$ (338 mg, 1 mmol) and *tripod* (625 mg, 1 mmol) in 15 mL of acetone. An immediate color change from pale yellow to violet red was observed. After stirring for 5 min at room temperature, a red solid precipitated. This precipitate was isolated by filtration. After dissolving the precipitate in dichloromethane, filtration and evaporation of the dichloromethane gave **3dBF$_4$** as a red-violet microcrystalline solid (460 mg, 48%). Crystals for X-ray diffraction studies were grown by layering a concentrated solution of **3dBF$_4$** in dichloromethane with acetone at −20 °C. For analytical data of **3dBF$_4$** see Tables 1, 2 and 4.

[(*tripod*Fe)$_3${μ-NCC(R)CN}$_3${μ-CN}$_3$Fe−NCC(R)CN]BF$_4$ [5BF$_4$: R = SO_2CH_3 (5aBF$_4$), $COCH_3$ (5bBF$_4$), CO_2CH_3 (5cBF$_4$)] and [(*tripod*Fe)$_3${μ-NCNCN}$_3${μ-CN}$_3$Fe−NCNCN]BF$_4$ (6BF$_4$): Na1a, **Na1a**, **Na1c** or **Na2** (1 mmol) and sodium cyanide (49 mg, 1 mmol) were added, in one portion, to a solution of Fe^{II}aq(BF$_4$)$_2$ (338 mg, 1 mmol) and *tripod* (625 mg, 1 mmol) in dichloromethane/ethanol (1:1; 40 mL). An immediate color change from pale yellow to red was observed. After stirring for 10 h at room temperature the color had changed to orange-red. After stirring for an additional period of 10 h, the resulting turbid orange to red solution was concentrated in vacuo to a volume of 10 mL and filtered. The orange to red precipitate was washed with ethanol and diethyl ether and dried in vacuo. Filtration with dichloromethane through 1 cm of Kieselgur and concentration of the red filtrate yielded the products as orange to red solids. The products were recrystallized from dichloromethane/ethanol yielding the compounds as orange to red crystallized solids. Yields: **5aBF$_4$** (50%), **5bBF$_4$** (38%), **5cBF$_4$** (51%), **6BF$_4$** (46%). For analytical and spectroscopic data of compounds **5aBF$_4$**, **5bBF$_4$**, **5cBF$_4$** and **6BF$_4$** see Tables 3 and 4.

[a] The quality of the analysis achieved for **3bBF$_4$** is reduced by the fact, that the crystal contains solvent molecules in disordered arrangements. In addition, there is suspicion, that there is some rotational disorder of the acetyl substituents, which could, however, not be resolved by the split-atom technique. The rotational position, which at least dominates by far is shown in Figure 1. − [b] The solution of the structure of **3dBF$_4$** is as well affected by disorder problems. **3dBF$_4$** is bound to have crystallographic C_2 symmetry, such that there is disorder for the C(CN)$_2$H group, whose central carbon atom lies at the C_2 axis. The disorder was not completely resolved.

[a] The data for X-ray analysis of **5aBF$_4$** were collected with a Siemens SMART 1000-CCD diffractometer. Lorentz, polarisation and absorption correction (Siemens Area Detector Absorption Correction, Siemens) were carried out. – [b] The structure is affected by disorder. The apical ligand is fluoride in the analyzed sample instead of **1e**$^-$, which is present in the bulk (Table 3). – [c] Disorder of solvate and rotational disorder of the substituents of the bridging ligands.

[(*tripod*Fe)$_3${μ-NCC[C(O)CN]CN}$_3${μ-CN}$_3$Fe–NCC-[C(O)CN]CN]BF$_4$ (5eBF$_4$) and [(*tripod*Fe)$_3${μ-NCC(NO)CN}$_3${μ-CN}$_3$Fe–Cl]BF$_4$ (5fBF$_4$): [N(CH$_3$)$_4$]1e and **Na1f** (1 mmol) and sodium cyanide (49 mg, 1 mmol) were added in one portion to a solution of $Fe^{II}aq(BF_4)_2$ (338 mg, 1 mmol) and *tripod* (625 mg, 1 mmol) in dichloromethane/ethanol (1:1; 40 mL). An immediate color change from pale yellow to violet red was observed. After stirring for 10 h at room temperature, a red precipitate had formed. Stirring for an additional period of 10 h, followed by isolation of the red precipitate, filtration with nitromethane through 1 cm of silica gel (ICN Biomedicals, 32–63 μm, 60 Å) and evaporation of the solvent, yielded the products in the form of red solids. Yields: **5eBF$_4$** (67%), **5fBF$_4$** (62%). For purification, the products were crystallized by vapor phase diffusion of diethyl ether into dilute nitromethane solutions. For analytical data of compounds **5eBF$_4$** and **5fBF$_4$** see Tables 3 and 4.

[(*tripod*Fe)$_3${μ-NCC[CH(CN)$_2$]CN}$_3${μ-CN}$_3$FeCN]BF$_4$ (5dBF$_4$) and [(*tripod*Fe)$_3${μ-NCC[CH(CN)$_2$]CN}$_3${μ-CN}$_3$FeCN]PF$_6$ (5dPF$_6$). – Method A: H1d (98 mg, 0.75 mmol), sodium bicarbonate (64 mg, 0.80 mmol) and sodium cyanide (49 mg, 1 mmol) were added in one portion to a solution of $Fe^{II}aq(BF_4)_2$ (338 mg, 1 mmol) and *tripod* (625 mg, 1 mmol) in dichloromethane/ethanol (1:1; 40 mL). An immediate change of color from pale yellow to violet red was observed. After stirring for 10 h at room temperature, an orange red precipitate had formed. Stirring for an additional period of 10 h, followed by isolation of the red precipitate, filtration with nitromethane through 1 cm of Kieselgel (ICN Biomedicals, 32–63 μm, 60 Å) and concentration of the filtrate, yielded **5dBF$_4$** in the form of an orange-brown microcrystalline solid (250 mg, 37%). For purification, the product was recrystallized by vapor phase diffusion of diethyl ether into a concentrated nitromethane/dichloromethane solution of the crude product in an almost quantitative yield. – **Method B:** A solution of **3dBF$_4$** (1700 mg, 0.93 mmol) in dichloromethane/ethanol (1:1; 70 mL) was heated to reflux. After heating for 2 h, the color of the reaction mixture had changed from violet-red to dark-brown. After 10 h of heating, the ν_{CN} absorptions of **3dBF$_4$** had completely disappeared. The mixture was cooled to room temperature, the solvent was evaporated in vacuo and the residue was purified by chromatography on silica gel (ICN Biomedicals, 32–63 μm, 60 Å). Gradually changing the solvent polarity from dichloromethane to dichloromethane/nitromethane (1:1) **5dBF$_4$** was eluted as a brown-red band. After drying in vacuo, 850 mg (70%) **5dBF$_4$** was obtained as a brown solid. Further purification by recrystallization from dichloromethane/ethanol yielded 510 mg (41%) of violet-red hexagonal and cube-shaped crystals of **5dBF$_4$**. – **Method C:** A solution of NaTCNE (227 mg, 1.5 mmol) and sodium hexafluorophosphate (218 mg, 1.3 mmol) in 30 mL of ethanol was added to a suspension of $FeCl_2$ (338 mg, 1 mmol) and *tripod* (625 mg, 1 mmol) in 30 mL of dichloromethane. Stirring of the dark solution for 20 h at room temperature resulted in the formation of a brown-red precipitate, which was isolated, extracted with nitromethane and filtered through 1 cm of silica gel (ICN Biomedicals, 32–63 μm, 60 Å). Evaporation of the solvent from the filtrate left 455 mg (68%) **5dPF$_6$** as a brown solid. For purification, this product was recrystallized by vapor phase diffusion of diethyl ether into a concentrated nitromethane/dichloromethane solution of the crude product giving 370 mg (55%) of violet cube-shaped

[a] The counterion BF_4^- is replaced by CN^- in about 50 % of the molecules within the crystal. The $CH(CN)_2$ substituent is exchanged by a CH_2CN group in 65 % of the molecules. – [b] The substituents at the bridging dicyanomethanide units are found to be CH_2CN groups. – [c] Data for **5dPF$_6$** were collected with a Siemens (Nicolet synthex) R3m/V diffractometer.

crystals of **5dPF$_6$**. Analytical and spectroscopic data of compound **5dBF$_4$** are listed in Tables 3 and 4.

X-ray Crystallographic Study: Suitable crystals were taken directly out of the mother liquor, immersed in perfluorinated polyether oil and fixed to a glass capillary. The measurements were carried out with a Nonius-Kappa CCD diffractometer (low-temperature unit, graphite-monochromated Mo-K_α radiation), unless stated otherwise. The data were processed by the standard Nonius software.[38] All calculations were performed using the SHELX software package. Structures were solved by direct methods with the program SHELXS-97[39] and refined with the program SHELXL-97.[40] Graphical handling of the structural data during solution and refinement was performed with XPMA.[41] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data for the structure determinations are compiled in Tables 5, 6 and 7. Figures 1 and 3 were prepared using WinRay-32 [42] and WinRay-GL.[43] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-156047 to -156055. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are indebted to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support. The unselfish cooperation of Dr. J. Groß and co-workers of the mass spectrometry department and the workers of the microanalytical laboratory of the Organisch-Chemisches Institut der Universität Heidelberg is gratefully acknowledged. We are indebted to Mr. D. Günauer for the cyclic voltammetric measurements.

Mixed-Ligand Copper(II) Complexes with the Rigid Bidentate Bis(*N*-arylimino)acenaphthene Ligand: Synthesis, Spectroscopic-, and X-ray Structural Characterization

Adriana Paulovicova,[a] Usama El-Ayaan,[a,b] Koichi Shibayama,[c] Takeharu Morita,[c] and Yutaka Fukuda*[a]

Keywords: N ligands / Copper / X-ray crystal structures / Magnetic properties

Reported are the synthesis, characterization, and crystal structures of two mixed-ligand copper(II) complexes containing bis[*N*-(2,6-diisopropylphenyl)imino]acenaphthene (*o,o′*-*i*$Pr_2C_6H_3$-BIAN). In both complexes, namely [Cu(AcOH)(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)Cl_2] (**1**) and [Cu(acac)(AcOH)(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)](ClO_4) (**2**) (acac = acetylacetonate and AcOH = acetic acid), the copper ions are in a distorted square-pyramidal coordination environment with an acetic acid molecule in each apical position. The two imine nitrogen atoms of *o,o′*-*i*$Pr_2C_6H_3$-BIAN occupy the basal plane with the two chloride atoms and the two oxygen atoms of acac in complexes **1** and **2**, respectively. Complex formation results in certain structural changes inside the rigid N–N ligand. Such changes led to an increased planarity of the *o,o′*-*i*$Pr_2C_6H_3$-BIAN backbone, and produced a nearly perpendicular angle between the naphthalene and the aromatic imine planes. In complex **2**, the more perpendicular arrangement of the *o,o′*-diisopropylphenyl groups shielding the copper centre was structurally allowed by the elongation of one of the metal-to-ligand bonds and by the relatively larger N–Cu–N bite angle. Also discussed are IR, magnetic, and UV/Vis measurements.

Introduction

During the last decade there has been an increased interest in the use of bidentate and tridentate ligands in catalysis.[1−4] Recently, special attention has focused on the catalytic reactivity of late transition metals, for example, rhodium, palladium, and platinum, and their complexation with rigid bidentate ligands[5−9] such as bis(*N*-arylimino)acenaphthene (Ar-BIAN), which was first introduced by van Asselt and Elsevier in the early 1990s.[10] It has been shown that such metal systems containing Ar-BIAN are efficient catalysts in, for example, the homogeneous catalytic hydrogenation of alkynes,[11] in catalytic multi-component C−C coupling reactions,[10,12] and as models for co-polymerization or as catalysts in polymerization of alkenes.[13,14]

These (Ar-BIAN) ligands contain two conjugated imine functions, but they differ markedly from the commonly used diimine ligands such as 2,2′-bipyridine (bpy) and 1,10-phenanthroline (phen). Firstly, the presence of two exocyclic imines, that are not part of the heteroaromatic ring system, is expected to lead to better σ-donating and π-accepting properties as compared to bpy and phen.[15−17] This property allows (Ar-BIAN) ligands to stabilize both the higher and lower oxidation states of the coordinated metal ions. Secondly, the rigidity of the acenaphthene backbone forces the imine *N*-atoms to remain in a fixed *cis* orientation, favouring the chelating coordination to a metal centre. Despite all the effort that has been put into the chemistry of rigid bidentate nitrogen ligands, there is a lack of available structural data. This is probably caused by the difficulties in growing single crystals for X-ray determination.

Our current interest is focused on the structural accommodation of bulky derivatives of 1,10-phenanthroline around the copper ion.[18] Therefore, we thought it would be reasonable to investigate coordination possibilities of such a huge, rigid ligand, namely bis[*N*-(2,6-diisopropylphenyl)imino]acenaphthene (*o,o′*-*i*$Pr_2C_6H_3$-BIAN) (Figure 1) when imposed on a copper centre. In this paper, we describe the isolation and full characterization, including X-ray structures, of two novel mixed-ligand copper(II) complexes, namely [Cu(AcOH)(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)Cl_2] (**1**), and [Cu(acac)(AcOH)(*o,o′*-*i*$Pr_2C_6H_3$−BIAN)](ClO_4) (**2**).

per(II) moiety with two imine nitrogen atoms and two chloride atoms occupying the basal plane, as well as an acetic acid molecule in the apical site. This acetic acid ligand has the relatively longer bond length of 2.467(3) Å compared to those of the basal plane. X-ray analysis of complex **1** indicates that the imine C=N bonds N(1)−C(1) and N(2)−C(5) of 1.284(3) and 1.286(3) Å, respectively, are slightly longer than the standard N(sp^2)=C(sp^2) double bond (1.27 Å).[19] This is simply due to the coordination to the copper(II) centre. Upon coordination, a lowering of the strain in the naphthalene backbone occurs, which is indicated by the C(1)−C(5) bond shortening to 1.500(3) Å as compared to the corresponding bond length of 1.535(3) Å in case of free bis(*p*-tolylimino)acenaphthene (*p*-Tol-BIAN).[15] Torsion angels N(1)−C(1)−C(5)−N(2) of −0.3(3)° and C(2)−C(1)−C(5)−C(4) of −0.4(3)° reflect a planarity of the bis(imino)acenaphthene moiety. Angles between the planes of the naphthalene and aromatic N substituents are close to perpendicular (84°), and in good agreement with the corresponding angles of (84°) in [Pd(Me)Cl(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)][15] and (85°) in [Pd(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)(MA)][20] (MA = maleic anhydride), but larger than in [Pd(*p,p′*-$Me_2C_6H_3$-BIAN)(MA)][21] of (55°) and the free *p*-Tol-BIAN ligand of (61°). This must certainly be ascribed to the presence of *o*-isopropyl substituents rather than to the coordination to the metal ion.

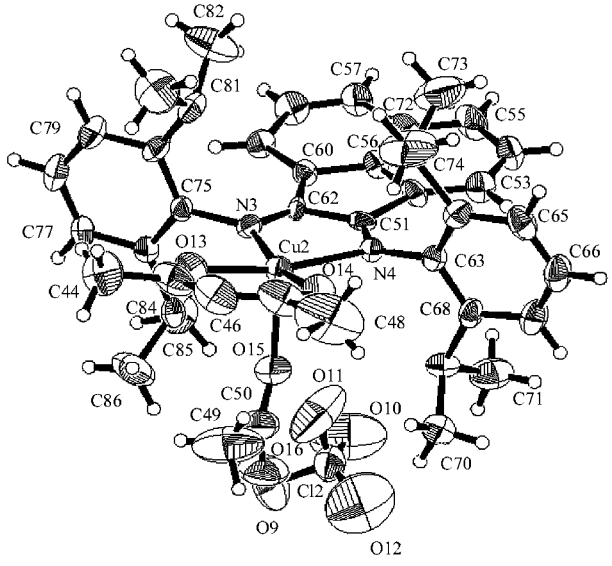

Figure 3. An ORTEP view of [Cu(acac)(AcOH)(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)]·(ClO_4) (**2**)

[Cu(acac)(AcOH)(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)]·(ClO_4) (2)

An ORTEP plot (30% thermal ellipsoids) showing the atomic-numbering scheme employed is given in Figure 3. The monodentate acetic acid, the bidentate acac, and (N−N) ligands coordinate to Cu^{II} to form a slightly-distorted square-pyramidal coordination geometry. Its basal plane contains two oxygen atoms of acac and two imine nitrogen atoms of *o,o′*-*i*$Pr_2C_6H_3$-BIAN, while the monodentate acetic acid is accommodated in the apical position. Selected bond lengths and angles of both complex **1** and **2** are given in Table 1.

The crystallographic asymmetry of complex **2** is clearly reflected by the different imine (N−C) bond lengths: N(3)−C(62) is 1.286(3) Å and N(4)−C(51) is 1.359(2) Å. A comparison with complex **1** shows a more planar bis(imino)acenaphthene skeleton as confirmed by the smaller torsion angles [N(3)−C(62)−C(51)−N(4) = 0.1(2)° and C(60)−C(62)−C(51)−C(52) = 0.3(2)°] and the rather shorter C(62)−C(51) bond length of 1.433(2) Å.

The *o,o′*-diisopropylphenyl groups are bent towards the naphthalene backbone, away from the copper centre, with nearly perpendicular angles between the planes of naphthalene and the aromatic imine. This approximately perpendicular arrangement of the *o,o′*-diisopropylphenyl groups in complex **2** shields the copper centre more effectively above and below the coordination plane. This extra shielding makes it difficult to accommodate the (acac) ligand within the basal plane. This problem is perfectly solved by the appropriate structural changes inside the *o,o′*-*i*$Pr_2C_6H_3$-BIAN ligand, namely by the elongation of N(4)−C(51) to 1.359(2) Å, and the larger bite angle N(3)−Cu(2)−N(4) of 82°, as compared to the corresponding angle of 80° in case of **1**. There is also a shortening of the C(62)−C(51) bond to 1.433(2) Å. Consequently, all these changes within the *o,o′*-

i$Pr_2C_6H_3$-BIAN ligand led to one relatively long Cu(2)−N(4) distance of 2.0755(13) Å compared to the [Cu(2)−N(3) distance of 2.0153(14) Å]. Complex **2** with the structural index parameter value, τ, of 2.6% shows a more regular square-pyramidal geometry than complex **1** with a τ equal to 4.5%. According to Addison et al.,[22] τ should have a value of 0% for a perfect square-pyramid and 100% for a perfect trigonal pyramidal structure: $\tau = \{(\theta - \varphi)/60\} \times 100$, where θ and φ are the largest and the second largest basal angles, respectively.

The Cu−O(acac) distances, namely Cu(2)−O(13) = 1.8924(17) Å and Cu(2)−O(14) = 1.8982(16) Å, and the bite angle O(13)−Cu(2)−O(14) of 94.87(7)° are similar to the corresponding distances and bite angles observed in other mixed ligand copper(II) complexes containing the acac ligand.[18,23,24]

It is reasonable to make a structural comparison of complex **2** with the [Cu(acac)(dmph)(NO_3)] complex[18] (dmph = 2,9-dimethyl-1,10-phenanthroline). Namely, in the former complex, the two isopropylphenyl moieties allow only a planar coordination of the diimine, while in the latter, the methyl substituents that are in the same diimine plane prevent both N donors from occupying the basal plane together with the acac ligand (Figure 4).

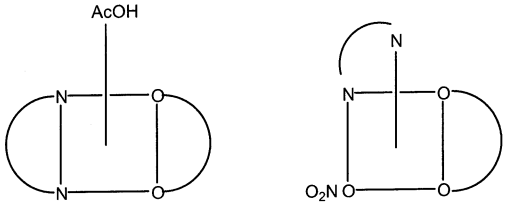

Figure 4. Schematic structures of complex **2** and [Cu(acac)(dmph)(NO_3)]

IR and UV/Vis Spectroscopy

Infrared spectroscopic data for the free *o,o′*-*i*$Pr_2C_6H_3$-BIAN ligand and both complexes **1** and **2** are listed in Table 2. Formation of the free *o,o′*-*i*$Pr_2C_6H_3$-BIAN ligand can be determined from the IR spectroscopy where only C=N stretching vibrations were observed in the 1642−1671 cm^{-1} range and no C=O stretching vibrations of the starting diketones in the 1700−1800 cm^{-1} region. The bands

assigned to ν(C=N) are shifted to lower wavenumbers in the complex formation indicating, the coordination of both diimine nitrogen atoms of *o,o′*-*i*$Pr_2C_6H_3$-BIAN ligand to the copper(II) ion. Strong bands observed in the 1695 and 1705 cm^{-1} regions for complex **1** and **2**, respectively, indicate the coordination of an acetic acid molecule.

Table 2. IR spectra (cm^{-1}) of *o,o′*-*i*$Pr_2C_6H_3$-BIAN ligand and complexes **1** and **2**

Compound	ν(C=N)	ν(ClO_4^-)	ν(AcOH)
o,o′-*i*$Pr_2C_6H_3$-BIAN	1671, 1652, 1642	–	–
Complex **1**	1661, 1635	–	1695
Complex **2**	1668, 1640	1110, 622	1705

IR spectra of complex **2** show two peaks, 1570 and 1519 cm^{-1}, that can be assigned to ν(C=O) and ν(C=C) of the acac ligands, respectively, consistent with those observed for [Cu(acac)$_2$].[25] The strong band observed at 1110 cm^{-1} (antisymmetric stretch) and the sharp band at 622 cm^{-1} (antisymmetric bend), suggest uncoordinated perchlorate anions[26] in agreement with the X-ray structure of **2**.

Solid-state room-temperature electronic spectra of **1** and **2** exhibit a broad d-d band at 700 and 625 nm, respectively, typical for square-pyramidal copper(II) complexes.[27−29] Another band appeared in the visible spectral region, 558 and 545 nm, of complexes **1** and **2**, respectively, assigned to the MLCT transitions from copper(II) to the π* orbitals of *o,o′*-*i*$Pr_2C_6H_3$-BIAN. This shift to much longer wavelength than those of other diimine ligands can be explained on the basis that the *o,o′*-*i*$Pr_2C_6H_3$-BIAN ligand provides π* orbitals at rather low energies[17,30,31] that results in the increased overlap with the metal d orbitals. Consequently, this results in a stronger π-bonding interaction accompanied by a red-shift of the MLCT transition. Electrochemical studies[32] on the π-acceptor properties of the bis(arylimino) acenaphthene reveal a much larger positive potential than those of other diimine ligands confirming the larger π-acceptor strength of bis(arylimino)acenaphthene.

Absorption spectra of both complexes show various bands below 420 nm that can be assigned to intraligand transitions of the free diimine ligand, which absorbs in the same spectral region. Electronic spectra were also recorded in solution using a variety of solvents (DCE, THF, toluene, and chloroform). All solution spectra of both complexes **1** and **2** are very similar to the corresponding solid-state spectra.

Conclusion

From the X-ray structure analysis of both copper(II) complexes **1** and **2** we can conclude that the two diisopropylphenyl moieties on the imine nitrogens of the *o,o′*-*i*$Pr_2C_6H_3$-BIAN ligand are flexible and show no conjugation with the naphthalene-diimine backbone. We have shown the difference in the coordination behaviour of this ligand when bound to the copper(II) ion. In complex **1**, a common equal-in-length bidentate coordination of *o,o′*-*i*$Pr_2C_6H_3$-BIAN was observed. In complex **2**, the pronounced shielding effect introduced by the *o,o′*-diisopropylphenyl groups, resulting from the more perpendicular arrangement, was identified by the relatively longer (Cu−N) bond, and by the respective changes inside the *o,o′*-*i*$Pr_2C_6H_3$-BIAN ligand. UV/Vis absorption spectra of both complexes indicate a strong π-back-bonding and a smaller HOMO−LUMO energy gap.

Experimental Section

Materials and Instrumentation: All chemicals were purchased from the Wako Pure Chemical Industries Ltd., and used without further purification.

Elemental analyses (C, H, N) were performed on a PE 2400 Series II CHNS/O Analyzer. − Electronic spectra were recorded on a UV-3100PC Shimadzu spectrophotometer using 10 mm quartz cells at room temperature. Powder reflectance spectra were obtained using the same instrument equipped with an integrating sphere and using $BaSO_4$ as a reference. − Infrared spectra were recorded on a Perkin−Elmer FT-IR Spectrometer Spectrum 2000 in a KBr pellet and as a Nujol mull in the 4000−370 cm^{-1} spectral range. − Magnetic susceptibilities were measured at room temperature on a Shimadzu MB-100 Torsion Magnetometer. Diamagnetic corrections were considered by using Pascal's constants.[33] − Thermogravimetric measurements were performed on a DTG-50 Shimadzu instrument. − ^1H and ^{13}C NMR spectra were run on a JEOL JNM LA 300 WB spectrometer at 300.40 and 75.45 MHz, respectively, using a 5 mm probe head. CD_2Cl_2 and $CDCl_3$ were used as a solvent. Chemical shifts are given in ppm relative to the internal TMS standard. The typical pulse width was 6.25 μs for ^1H and 4.25 μs for ^{13}C measurements. Assignment of the ^{13}C signals based on ref.[15] was confirmed by off-resonance decoupled and DEPT-135 measurements.

Synthesis of [*N*-(2,6-Diisopropylphenyl)imino]acenaphthene: This ligand was prepared using a method different to that published by Asselt, Elsevier et al.[15] Acenaphthenequinone (1.35 g, 7.4 mmol) in 65 mL of acetonitrile was heated under reflux (80 °C) for 30 min. Then 12 mL of acetic acid was added and heating was continued until the acenaphthenequinone had completely dissolved. To this hot solution, 3 mL (16 mmol) of 2,6-diisopropylaniline was added directly and the solution was heated under reflux for a further 1.5 h. It was then cooled to room temperature and the solid filtered off to give a yellow product that was washed with hexane and air-dried. Yield 3.15 g (85%). − $C_{36}H_{40}N_2$ (500.7): calcd. C 86.35, H 8.05, N 5.60; found. C 85.85, H 8.03, N 5.34%. − ^1H NMR ($CDCl_3$, 300.40 MHz, 24 °C): δ = (0.97 d, 15-H), 1.23 (d, 16-H), 3.03 (sept, 14-H), 6.63 (d, 3-H), 7.26 (s, 12-H, 11-H, 10-H), 7.36 (pst, 4-H), 7.88 (d, 5-H). − ^{13}C NMR (CD_2Cl_2, 300.40 MHz, 25.4 °C): δ = 23.1 (C-16), 23.2 (C-15), 29.1 (C-14), 123.5 (C-11), 123.9 (C-10, C-12), 124.6 (C-3), 128.3 (C-4), 129.2 (C-5), 130.0 (C-2), 131.6 (C-6), 135.5 (C-9, C-13), 141.2 (C-7), 148.0 (C-8), 161.1 (C-1).

Synthesis of [Cu(AcOH)(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)Cl_2] (1): Bis[*N*-(2,6-diisopropylphenyl)imino]acenaphthene, *o,o′*-*i*$Pr_2C_6H_3$-BIAN, (0.35 g, 0.7 mmol) was dissolved in a small amount of chloroform (99%). A mixture of chloroform/acetic acid (15 mL, the 2:1 ratio) was then added, and the solution was heated for 10 min at 60 °C. Subsequently, a methanolic solution (7 mL) of $CuCl_2 \cdot 2H_2O$ (0.12 g, 0.7 mmol) was added dropwise to the *o,o′*-*i*$Pr_2C_6H_3$-BIAN solu-

tion. This mixture was then stirred for 2 h at room temperature. After 2 days of slow evaporation in air, dark-green prism-shaped crystals formed and were suitable for the single X-ray measurement. Yield 0.39 g (80%). − $C_{38}H_{44}Cl_2CuN_2O_2$ (695.20): calcd. C 65.65, H 6.38, N 4.03; found. C 66.30, H 6.35, N 3.95%. μ_{eff}: 2.0 B.M. (19 °C).

Synthesis of [Cu(acac)(AcOH)(*o,o′*-*i*$Pr_2C_6H_3$-BIAN)]·(ClO_4) (2): Two preparation methods were used.

Method A: To a suspension of 0.26 g (0.7 mmol) of $Cu(ClO_4)_2·6H_2O$ and 0.35 g (0.7 mmol) of *o,o′*-*i*$Pr_2C_6H_3$-BIAN in 15 mL of AcOH, 0.07 mL (0.7 mmol) of acetylacetonate was added directly and the mixture was stirred at room temperature. After 3 hours the microcrystalline product precipitated from the dark green solution. This solid was filtered, washed with cyclohexane and dried in air. The yield of the green micro-crystals was 0.48 g (82%). − $C_{43}H_{51}ClCuN_2O_8$ (822.86): calcd. C 62.76, H 6.25, N 3.41; found C 62.55, H 6.33, N 3.58%. μ_{eff}: 1.7 B.M. (24 °C).

Method B: (The same amounts were used as in method A). Acetylacetonate was added directly to a methanolic solution (5 mL) of $Cu(ClO_4)_2·6H_2O$. This mixture was stirred (while heating) for 10 min. A hot 2:1 chloroform/acetic acid solution (10:5 mL) of *o,o′*-*i*$Pr_2C_6H_3$-BIAN was then added. The resulting clear (i.e. no solid) green solution was stirred for 1 h and left to stand in air. After 3 days, needle-shaped and prism-shaped crystals appeared, both of which were suitable for X-ray measurements. Data were collected from a needle-shaped single crystal. − Elem. anal. found: C 61.82, H 6.26, N 3.36%.

X-ray Structure Determination of 1 and 2: Crystallographic data for both complexes are summarized in Table 3. Single crystals of **1** and **2** were obtained directly from a chloroform/acetic acid solution. Crystal data for complex **1** were collected (Mo-K_α radiation, graphite monochromator) with a Mac Science DIP2030 K diffractometer. While for complex **2**, a SMART/RA CCD diffractometer was used. Accurate unit cell parameters and orientation matrices were determined by a least-squares refinement of setting angles of a set of well-centred reflections. An Image Plate for **1** and ω scan method for **2** were used. In both cases, the initial structure was solved by SIR92[34] and refined by least-squares methods based on F^2 using SHELXL-97.[35] Thermal ellipsoids (30% probability) and molecular plots were drawn using the maXus (MacScience) and ORTEP programs, for **1** and **2**, respectively. Absorption corrections were applied by multiscan (T_{min}/T_{max} of 0.691:0.740) for **1** and SADABS[36] (T_{min}/T_{max} of 0.829:1.000) for **2**. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were added at calculated positions and refined while riding on their respective carrier atoms using three common isotropic thermal motion parameters (constrained for **1**, and mixed treatment for **2**).

Since the space groups of both complexes are polar, it was necessary to use the Flack absolute structure parameter,[37] which refined to $x = 0.056(13)$ in **1** and to $x = 0.00$ in **2**. There were two independent molecules in the asymmetric unit of complex **2**. The crystallographic data for both structures reported in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication numbers CCDC-158181 and CCDC-158307 for **1** and **2**, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was partly supported by a Grand-in-Aid (Scientific Research No. 11304046) from the Ministry of Education, Science, Culture and Sports of Japan. Usama El-Ayaan thanks the Ochanomizu University for supporting his stay in Japan. Authors are grateful to Prof. Yuji Ohashi and Ms. Champika Vithana, Tokyo Institute of Technology, for their help with the X-ray structure determinations.

Copper(II)-Promoted Chemical Transformations of 3-Substituted 5-(2′-Pyridyl)-1,4-benzodiazepin-2-one Derivatives. Crystal Structures and Spectroscopic Characterisation of Metal Complexes

Aleksandar Višnjevac,[a] Ljerka Tušek-Božić,[a] Maja Majerić-Elenkov,[a] Vitomir Šunjić,[a] and Biserka Kojić-Prodić*[a]

Keywords: N ligands / Racemization / Oxygenations / Ring contractions / Copper / IR spectroscopy

Enantiomerically pure 7-bromo-1,3-dihydro-3-hydroxymethyl-1-methyl-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one, (+)-**1**, affords the dichloro adduct **3**, [$CuCl_2$(**1**)], when treated with a solution of $CuCl_2 \cdot 2H_2O$ in ethanol. Complex **3** is isolated as a racemic compound. The replacement of one chlorine atom with DMSO gives complex **4**, [CuCl(**1**-H)(DMSO)]. The C(3)-oxygenated product appears as a racemic *N,N,O*-tridentate ligand in the square-pyramidal complex **5**. Oxidative ring contraction of (+)-**1** yields 6-bromo-4-ethoxy-1,4-dihydro-1-methyl-4-(2′-pyridyl)-1,3-quinazoline, which acts as an *N,N*-bidentate ligand in the tetrahedral complex **6**. Reaction of 3-acetoxymethyl-7-bromo-1,3-dihydro-1-methyl-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one, (±)-**2**, with $CuCl_2 \cdot 2H_2O$, affords the square-pyramidal complex **7**, [$CuCl_2$(**2**)]. In this complex the lactam oxygen atom of a neighbouring molecule binds to the fifth coordination site, hence forming an infinite chain of connected polyhedra in the crystal. Oxidative ring contraction of **2** leads to 6-bromo-1,4-dihydro-4-hydroxy-1-methyl-4-(2′pyridyl)-1,3-quinazoline, which acts as an *N,N*-bidentate ligand in the centrosymmetric binuclear five-coordinate Cu^{II} complex **8**. In this complex the di-μ-chloro bridges are asymmetrical: one Cl atom is in an apical position [Cu–Cl, 2.820 (7) Å], whereas the other is in an equatorial position [Cu–Cl, 2.252 (5) Å]. The complexes are characterised by IR spectroscopy and X-ray structure analysis. Mechanisms of racemisation, oxygenation and ring contraction are discussed.

Introduction

The tranquilising and sedative-hypnotic activity of 1,4-benzodiazepines prompted chemists to investigate their complexation properties with transition metals,[1−3] in an attempt to prepare even more potent drugs. Among the first isolated was $Cu^{II}Cl_2$(diazepam)$_2$ (diazepam known as Valium®), with a square-planar geometry around Cu^{II}.[4] To the best of our knowledge, few crystal structures of 1,4-benzodiazepine complexes are known so far.[5,6] Generally, it has been of practical interest to design ligands which can enforce specific metal coordinations of suitable geometry and electronic properties which lead to desired catalytically active coordination compounds. Such complexes can also serve as good models for studying the activity of metalloenzymes.[7,8] Thus, it was interesting to examine the chelation properties of 5-substituted 1,4-benzodiazepin-2-one ligands, and to study the substitution effect at the stereogenic centre (C3) on metal complexation.[9,10] In our previous studies we investigated the use of metal complexes of C(3)-substituted 5-phenyl- and 5-pyridyl-1,4-benzodiazepin-2-ones in non-catalytic, catalytic, and biocatalytic reactions.[9−16] We have already reported on the oxidative C(3)-acetoxylation of the 5-pyridyl-1,4-benzodiazepine derivative to the 3-acetoxy derivative promoted by a mixed reagent [$Pb^{IV}(AcO)_4$]/I_2.[17] In vitro metal-catalysed C(3)-oxygenation of 1,4-benzodiazepin-2-ones has been unprecedented. However, the stereochemistry of an analogous in vivo process, which is catalysed by cytochrome P450, has already been described in detail.[18−20]

In this work we report on the preparation and characterisation of Cu^{II} complexes with ligands (+)-**1** and (±)-**2** (Scheme 1), which have undergone oxygenation at C(3) and a ring contraction. The mechanism for ligand transformations in the presence of the copper ion is explained (Scheme 2). The understanding of the mechanism is based upon the structure of the initial components and the isolated complexes. This mechanism is strongly supported in similar transformations of (5-phenyl)-1,4-benzodiazepin-2-ones already reported.[21−25]

Results and Discussion

Preparation of the Complexes

The reactions of benzodiazepine ligands (+)-**1** and (±)-**2** with $CuCl_2$ dihydrate in ethanol have yielded various types of complexes as presented in Scheme 1. It was observed that both ligands (+)-**1** and (±)-**2** initially formed the dichloro adduct (±)-**3** and (±)-**7**, respectively. Recrystallisation of (±)-**3** in ethanol at room temperature gave a mixture of the complexes (±)-**5** and (±)-**6**. Heating (±)-**7** in a mixture of ethanol and acetonitrile afforded the complex (±)-**8**. The green dichloro adduct (**3**), containing ligands bonded through two α-diimine nitrogens, a hydroxymethyl oxygen and two chlorine atoms, was isolated immediately after its formation, i.e. after about 5 minutes of stirring the reactants

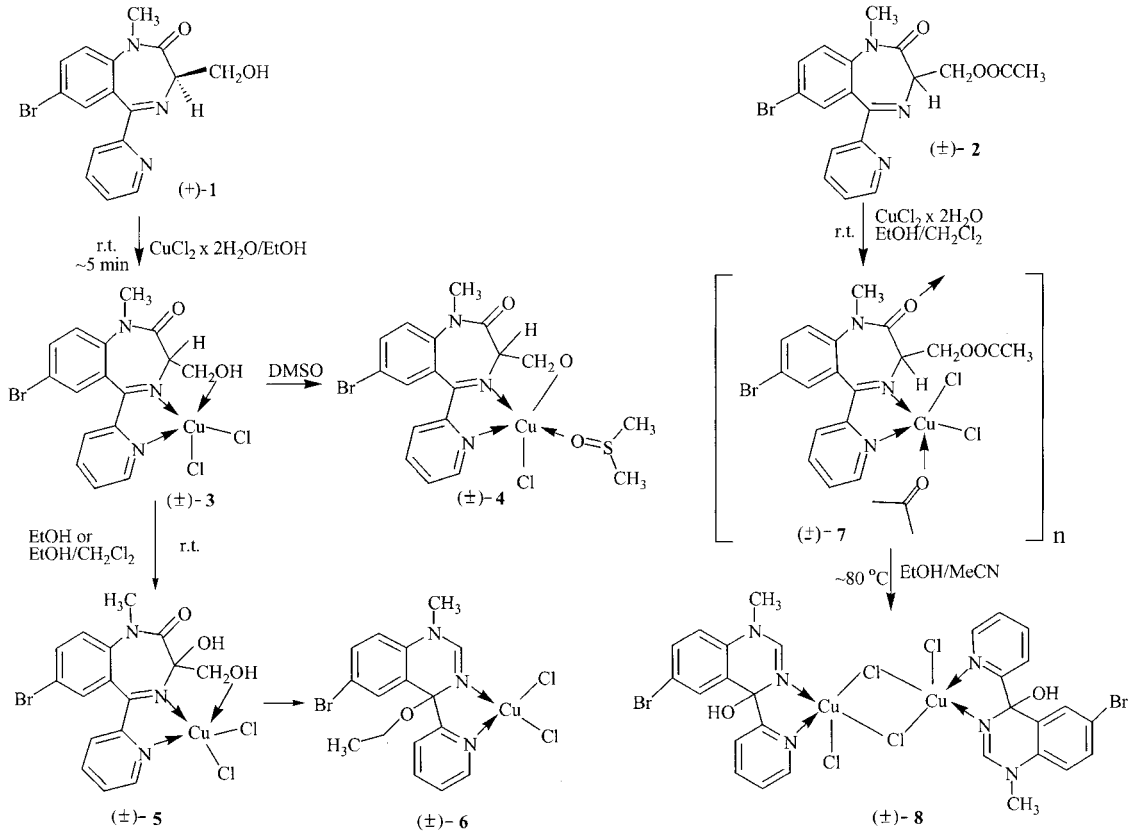
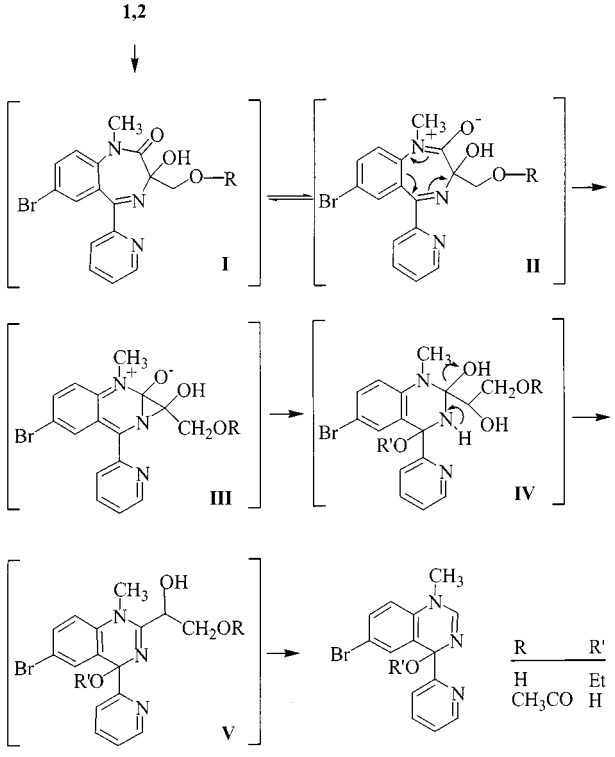


Scheme 1. Chemical diagrams of ligands and copper(II) complexes



Scheme 2. Possible transition states on the route of chemical modifications of **1** and **2** to 1,3-quinazolines in the presence of Cu^{II}

in absolute ethanol at room temperature. Prolonged stirring caused the slow dissolution of this complex and the formation of a mixture of complexes; a green square-pyramidal complex **5**, dichloro-[7-bromo-1,3-dihydro-3-hydroxy-3-hydroxymethyl-1-methyl-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one-*N*,*N*,*O*]copper(II) and a black tetrahedral complex **6**, dichloro-[6-bromo-4-ethoxy-1,4-dihydro-1-methyl-4-(2′-pyridyl)-1,3-quinazoline-*N*,*N*]copper(II). Recrystallisation of the complex **3** from DMSO yielded a reddish-brown complex **4**, in which one chlorine atom is replaced by a DMSO molecule (coordinated via an oxygen atom). The reaction of ligand **2** with $CuCl_2$ in a mixture of ethanol and dichloromethane, without an inert atmosphere, gave a green dichloro adduct **7**, which is insoluble in pure ethanol. Complex **7** dissolved on heating a mixture of ethanol and acetonitrile. The benzodiazepine ligand **2** was converted into the 1,3-quinazoline derivative in an ethanol and acetonitrile mixture, which then formed a dark-brown chloro-bridged dinuclear complex **8**, di-μ-chloro-bis[6-bromo-1,4-dihydro-4-hydroxy-1-methyl-4-(2′-pyridyl)-1,3-quinazoline-*N*,*N*]dichlorodicopper(II). Ligand (+)-**1** undergoes a Cu^{II} catalysed oxygenation at C(3), which is detected in the complex **5**. The amide-imide enolate equilibrium (Scheme 2, **I** ⇄ **II**) of 3-hydroxy benzodiazepine derivatives, presumably proceeds pericyclic ring-contraction leading to a tricyclic intermediate **III**, which after nucleophilic attack by an alcohol or water molecule undergoes opening of the cyclopropane ring and rearomatisation to

IV. This intermediate easily eliminates a molecule of water to form **V**, in which oxidative carbon-carbon bond splitting affords the 4-substituted 1,3-quinazoline derivatives found in the complexes **6** and **8**. Since racemisation has not been observed with C(3)-alkyl-5-pyridyl-1,4-benzodiazepines in the presence of Cu^{I} or Cu^{II} ions,[16] the racemisation and formation of complexes **5** and **6** reveal a key role of the C(3)−CH_2OH 'arm' in these processes. They probably comprise the coordination of Cu^{II}, and thus the activation of the C(3)−H bond for racemisation and oxygen insertion. However, under an inert N_2 atmosphere, similar chiral 1,4-benzodiazepines and Cu^{II} ions act catalytically in a cyclopropanation reaction, without oxygenation of the ligand.[16] The role of the Cu^{II} ion as an oxidising agent in biological and chemical catalytic systems has been repeatedly described; at the active site of galactose oxidase, the Cu^{II} ion oxidises primary alcohols to aldehydes.[21,22] Cu^{II} complexes containing *N,N*- and *N,O*-bidentate ligands proved effective in the chiral variant of Bayer−Villiger-type metal-catalysed oxidation of ketones to lactones with molecular oxygen.[23] Racemisation of (+)-**1** is a result of enolisation, since it was observed during C(3) enantiomerisation of 3-carbethoxy-1,4-benzodiazepines.[24] Ring contraction of a 1,4-benzodiazepin-2-one system has been repeatedly observed, either under acidic,[24] basic,[25] or thermal[25] conditions. A pericyclic process has already been postulated in the key ring contraction step.[24] Ring contraction is followed by substitution at the benzylic cation and elimination of the 2C fragment from the C(2) position in 1,4-dihydro-1,3-quinazoline ring, as already observed in similar substrates.[24,25]

The Crystal Structures

Both ligands **1** and **2** are chiral molecules and were used in the preparation of complexes (+)-**1** and (±)-**2**. In separate experiments we proved that enantiomerically pure compounds undergo fast racemisation in an ethanol solution and in the presence of Cu^{II} ions. Thus, during the preparation of the Cu^{II} complexes, racemic compounds were obtained from both homochiral (**1**) and racemic (**2**) ligands. Crystals of all the complexes and the ligand **2** (Scheme 1) crystallise in the centrosymmetric space groups (details given in the Experimental section, X-ray structure analysis, Tables 2 and 3). This indicates that on complexation the configurational stability of the C(3) stereogenic centre is lowered, presumably by the Cu^{II}-promoted enolisation. The Cu^{II} ion enhances the C(3)-acidity during complexation and promotes the above enolisation, which results in the racemisation of the optically active structures. In the crystal structure of **2** (Figure 1), the molecule appears in a *boat*

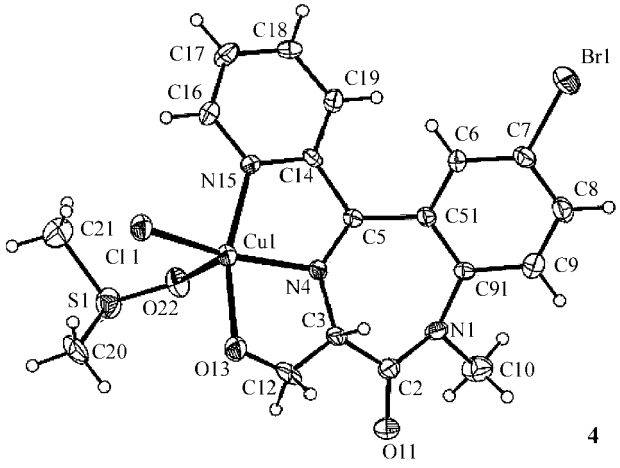
conformation which is preserved in the crystal structure of its complex **7** and also in the complexes **4** and **5**. In spite of numerous efforts, crystallisation of ligand **1** and its complex **3** failed to produce good quality crystals needed for X-ray structure analysis.

Complexation with Cu^{II} ions resulted in structural changes of the ligands as was unambiguously proven by the X-ray structure analysis of the isolated complexes. The coordination geometries of the complexes are given in Table 1. The crystal structures of the complexes **5** (Figure 2) and **7** (Figure 3) reveal a distorted square-pyramidal Cu^{II} coordination. The five coordination sites are occupied by two chlorine atoms, azomethine and pyridine nitrogen atoms in both complexes, and by the hydroxymethyl oxygen in **5** and the lactam oxygen of the neighbouring molecule in **7**. Thus, in the crystal structure of **7** the coordination polyhedra are connected through a common corner into an infinite chain (Figure 3) running along the *b* axis.

In order to prove the mode of coordination of the ligand (+)-**1** in the complex **3**, it was recrystallised from DMSO, yielding the complex **4**. The crystal structure of **4** reveals



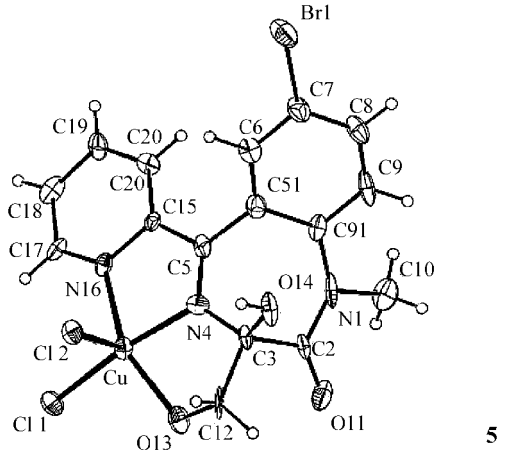


Figure 2. The ORTEP drawings of the five-coordinated chloro-{[7-bromo-1,3-dihydro-1-methyl-3-oxomethyl-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one-*N*,*N*](dimethylsulfoxide)}copper(II) (**4**) and dichloro-[7-bromo-1,3-dihydro-3-hydroxy-3-hydroxymethyl-1-methyl-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one-*N*,*N*,*O*]copper-(II) (**5**). Thermal ellipsoids are scaled at the 30% probability level

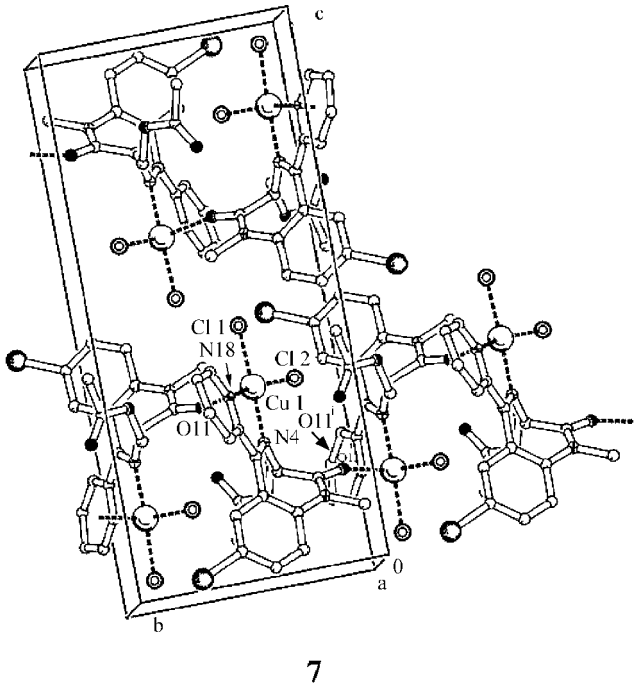

Figure 3. An infinite chain with the five-coordinated Cu^{II} coordination polyhedra of dichloro-[3-acetoxymethyl-7-bromo-1,3-dihydro-1-methyl-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one-*N*,*N*,*O*]-copper(II) (**7**), connected through a common corner occupied by a lactam oxygen $O11^{i}$ of 1,4-benzodiazepine ligand running along the crystallographic axis *b*. The symmetry operation *i* is defined as $0.5 + x$, $0.5 + y$, $0.5 - z$

that the five coordination sites are occupied by the deprotonated hydroxymethyl oxygen, both nitrogen atoms of the azomethine and pyridine moieties, the chlorine atom, and the oxygen atom of a DMSO molecule (Figure 2).

The crystal structure analysis of complexes **6** and **8** reveal the ring contraction of 5-(2′-pyridyl)-1,4-benzodiazepin-2-one of **1** and **2**, respectively, into the 1,4-dihydro-1,3-quinazoline derivatives (Scheme 1, Scheme 2 and Figure 4). The tetrahedral coordination in **6** involves two nitrogens of the 1,4-dihydro-4-pyridyl-1,3-quinazoline derivative and two chlorine atoms. However, the ring contraction of ligand **2**, detected in **8**, was accompanied by the formation of the centrosymmetric dinuclear Cu^{II} complex with di-μ-chloro bridges. The Cu−Cl bond lengths are 2.252 (5) and 2.820 (7) Å (Table 1), and the Cu···Cu distance is 3.62 Å. The apical chlorine atom with the Cu^{II}−Cl distance of 2.820 (7) Å is part of a bridging system. The asymmetrical bond lengths are common in Cu^{II} binuclear species.[26−28] Such a species, with a distant ligand, might be considered as a stable transition state formed on conversion from a four to five, or vice versa, coordination complex. The third terminal chlorine atom, which completes the five-coordination, has a Cu−Cl bond length of 2.282 (7) Å.

In the crystal structures of **4** and **5**, the benzodiazepine ligands act as ***N,N,O***-tridentate ligands whereas the 1,4-dihydro-1,3-quinazoline ligand acts as an *N,N*-bidentate ligand. Both types of ligands introduce considerable distortions of the Cu^{II}-coordination polyhedra. Bite angles of these chelating ligands are in the range of 78.7(2) to 81.4(5)°

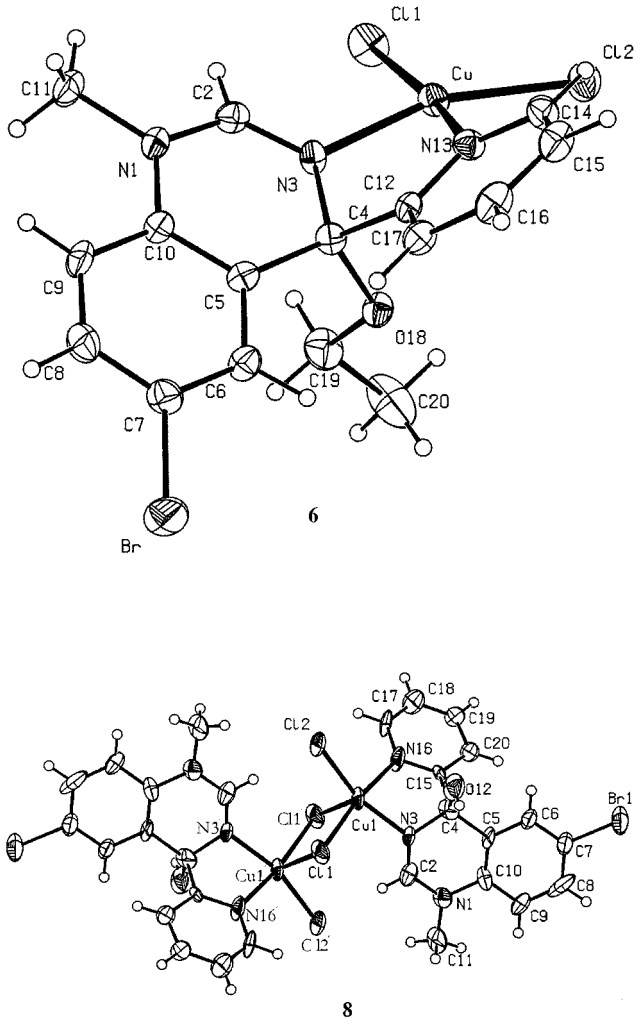

Figure 4. The ORTEP drawings of dichloro-[6-bromo-4-ethoxy-1,4-dihydro-1-methyl-4-(2′-pyridyl)-1,3-quinazoline-*N,N*]copper(II) (**6**) and di-μ-chloro-bis[6-bromo-1,4-dihydro-4-hydroxy-1-methyl-4-(2′-pyridyl)-1,3-quinazoline-*N,N*]dichlorodicopper(II) (**8**). Thermal ellipsoids are scaled at the 30% probability level

(Table 1). The atoms in the equatorial positions, as well as the Cu^{II} atom, of the square-pyramidal geometry are not coplanar (in the structures studied deviations are larger than 0.1 Å). The only exception is the structure of **5**, where deviations from the equatorial plane range from 0.012 (4) to 0.018 (9) Å.

Infrared Spectra

The IR spectra of the complexes provide some structural information of these compounds, whereas the ^1H NMR spectra show broad and badly resolved signals of little diagnostic value. When comparing the spectroscopic data of complexes with those of the free ligands,[16] the greatest changes may be noticed in the range 1750−1500 cm^{-1}. In this region bands arising from the stretching modes of the azomethine and pyridine C=N groups, as well as those from the lactam and acetate C=O, and the aromatic C=C vibrations, occur.[13,29,30] A very strong band at 1675 cm^{-1} and three weak bands at 1611, 1588, and 1562 cm^{-1} are characteristic of the free ligand (+)-**1**. On coordination of both nitrogen atoms, most of these bands in complexes **3** and **5** shift slightly to higher frequencies, and the intensity of the lower frequency bands increases. This behaviour is associated with a general π-electronic redistribution by metallation. The OH stretching mode over the 3000 cm^{-1} region is not informative due to the presence of the crystalline solvent. The spectra of the acetoxy derivative of **2** and its complex **7**, show a more complicated spectral pattern due to the strong absorptions of the acetate group. The transformation of ligand **1** to the 1,3-quinazoline derivative in complex **6** is supported by the absence of the lactam carbonyl band at 1675 cm^{-1}, as well as by the appearance of the very strong absorption at 1267 cm^{-1} due to the ν_{as}(C−O−C) vibration of the 4-substituted ethoxy group.

The far-IR spectra of the complexes show a number of bands in the 400−200 cm^{-1} region, where stretching modes of the metal-ligand vibrations occur. The low symmetry of the present complexes, particularly that of the [*N,N,O*] chelates **3**, **5**, and **7**, does not allow the characterisation of the copper-specific vibrations. In complexes **3** and **5**, a broad band around 325 cm^{-1} with a few shoulders on the lower frequency side, as well as absorption at 276 cm^{-1}, could be assigned to the ν(Cu−Cl) and ν(Cu−N) vibrations. The metal-halogen/nitrogen stretching frequency is observed over a wide range. This may be due to the variation in the two Cu−Cl and Cu−N bonds in the structure of the complex(Table 1). On the other hand coupled Cu−Cl and Cu−N bands could also be expected. The band at 364 cm^{-1} may be assigned to the ν(Cu−O) vibration, since it was found that ν(Cu−O) > ν(Cu−N) for this kind of metal complex.[31,32] The situation is more complicated in complex **7**, where the internal deformation modes of the acetate ligand also falls into the same spectral region as the metal-ligand vibrations.

Conclusion

Generally, the understanding of the structural and catalytic properties of copper complexes contributes to a better understanding of the catalytic reactions and functions of copper containing enzymes. We focused on the use of substituted 1,4-benzodiazepin-2-ones as the complexing agents for Cu^{II}. An unexpected reactivity of the 5-pyridyl-1,4-benzodiazepin-2-one derivatives (+)-**1** and (±)-**2** in the presence of Cu^{II} ions in ethanol was observed. Both starting compounds can coordinate through two oxygen atoms (hydroxy/acetoxy and lactam) and two nitrogen atoms (azomethine and pyridine) to Cu^{II}. Coordination through specific functional groups of the ligands used, and the electronic properties of the copper ions favour racemisation, (in complex **3**), oxygenation (in complex **5**) and ring contraction leading to the 1,4-dihydro-1,3-quinazoline derivatives (complexes **6** and **8**). The study presented suggests that 5-pyridyl-1,4-benzodiazepin-2-one chiral ligands in metal complexes, which are used as catalysts in enantioselective reactions, have to be employed with great caution.

Experimental Section

Materials and Instrumentation: (+)-7-Bromo-1,3-dihydro-3-hydroxymethyl-1-methyl-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one, (+)-**1**, was prepared by lipase-catalysed kinetic resolution[16], whereas *rac*-3-acetoxymethyl-7-bromo-2,3-dihydro-1-methyl-5-(2′-pyridyl)-2*H*-1,4-benzodiazepin-2-one, (±)-**2**, was prepared according to the reported method.[15] All other reagents and solvents were of analytical grade and were used without purification. − FTIR spectra were recorded on a Perkin−Elmer 2000 spectrophotometer using KBr (4000−400 cm^{-1}) and polyethylene (400−200 cm^{-1}) pellets. − Elemental analyses were performed with a Perkin−Elmer Elemental Analyser E-2400 Series 2 (CHN) and thermogravimetric analyses with a Cahn RG electromicrobalance in an air atmosphere.

Preparation of Complexes 3 and 4: A solution of (+)-**1** (0.080 g, 0.22 mmol) in absolute EtOH (2 mL) was added dropwise to a stirred solution of $CuCl_2·2H_2O$ (0.038 g, 0.22 mmol) in absolute EtOH (3.0 mL) at ambient temperature, whereupon the colour of the reaction mixture changed to brown. After ca. 5 minutes the stirred solution became green again, and a green precipitate was observed. The precipitate was immediately separated by filtration, washed with cold absolute EtOH and the hygroscopic solid stored overnight under vacuum at ambient temperature. Elemental and thermogravimetric analyses indicated the formation of complex **3** as a trihydrate (yield 0.055 g, 46%). − $C_{16}H_{14}BrCl_2CuN_3O_2·3H_2O$ (548.95): calcd. C 35.00, H 3.67, N 7.69, H_2O 9.84; found C 34.80, H 3.08, N 7.30, H_2O 9.29. − IR (KBr): $\tilde{\nu}$ = 3420 m br [ν(OH], 1684 vs br [ν(C=O)], 1635 m, 1629 m, 1596 m and 1559 w-m [δ(HOH), ν(C=N), ν(C=C)], 1486 m, 1469 m, 1446 m, 1402 m, 1340 s, 1301 w, 1253 m, 1123 m, 1106 m, 1035 w, 1024 m, 972 w, 925 w, 890 w, 831 m, 800 m, 756 w-m, 741 w, 725 w, 673 m, 649 w cm^{-1}. − IR (polyethylene): $\tilde{\nu}$ = 364 w, 322 w-m br, 300 sh, 288 sh and 275 w cm^{-1}. Recrystallisation of complex **3** from DMSO gave reddish-brown single crystals of complex **4**.

Preparation of Complexes 5 and 6: Recrystallisation of complex **3**, either from absolute EtOH or a mixture of absolute EtOH and CH_2Cl_2, afforded a mixture of green (complex **5**) and black (complex **6**) crystals, both suitable for X-ray structural analysis. The solutions were subjected to slow solvent evaporation in a desiccator over silica gel. A small amount of the mixture of complexes **5** and **6** was also gradually formed from the mother solution (ethanol), after the preparation and isolation of complex **3**. Complexes were separated by hand under a microscope. Complex **5**: − IR (KBr): $\tilde{\nu}$ = 3300 w [ν(OH], 1688 vs [ν(C=O)], 1626 m, 1596 m, and 1560 w [δ(HOH), ν(C=N), ν(C=C)], 1487 m, 1468 m, 1445 m, 1399 m, 1332 s, 1303 w, 1252 m-s, 1146 m, 1100 s, 1070 m, 1026s, 1008 w-m, 989 w, 891 w, 848 w-m, 822 m, 793 m, 754 w, 684 m, 659 w, 650 w cm^{-1}. − IR (polyethylene): $\tilde{\nu}$ = 364 w, 324 w-m br, 300 sh, 286 sh, 276 w cm^{-1}. Complex **6**: − IR (KBr): $\tilde{\nu}$ = 1629s, 1595m-s, 1553m-s, 1503vs [ν(C=N), ν(C=C)], 1458 m-s, 1439 w-m, 1425 w, 1391 m, 1328 m, 1297 s, 1267 vs, 1245 m, 1202 w-m, 1175 w, 1117 w-m, 1092 w, 1039 w, 1024 m, 1001 m, 965 w, 916 w, 861 m, 825 m, 788 m, 754 w-m, 731w, 655 w-m, 643 w, 619 w cm^{-1}. − IR (polyethylene): $\tilde{\nu}$ = 340 w, 314 w, 301 w, 290 sh, 280 w cm^{-1}.

Preparation of Complexes 7 and 8: A solution of **2** (0.080 g, 0.20 mmol) in a 1:1 mixture of absolute EtOH and CH_2Cl_2 (5 mL) was added dropwise to a stirred solution of $CuCl_2{\cdot}2H_2O$ (0.034 g, 0.20 mmol) in the same solvent mixture (5 mL). After complete addition, the reaction mixture was continuously stirred for 1 h at ambient temperature, and the green precipitate formed was filtered off, washed with cold CH_2Cl_2 and dried under vacuum (yield 0.103 g, 96%). Green single crystals of complex **7** were obtained from MeCN on cooling at 4 °C. − $C_{18}H_{16}BrCl_2CuN_3O_3$ (536.70): calcd. C 40.28, H 3.01, N 7.83; found C 39.83, H 3.14, N 7.60. − IR (KBr): $\tilde{\nu}$ = 1750 vs and 1727 vs [ν(C=O) acetate], 1686 vs br [ν(C=O) lactam, ν_{as}(COO)], 1589 s, 1568 m, and 1557 m [ν(C=N), ν(C=C)], 1480 m, 1470 m-s, 1429 m, 1404 m, 1389 w, 1369 m, 1340 m, 1261 s, 1250 s, 1187 w, 1119 m-s, 1107 m-s, 1050 m, 1038 m, 1023 m, 980 w, 955 w, 888 w, 876 w, 835 m, 802 m, 782 w, 760 m, 743 w, 714 w, 677 m, 647 w-m, 605 w cm^{-1}. − IR (polyethylene): $\tilde{\nu}$ = 338 m, 315 m br, 294 m-s, 276 m cm^{-1}. Recrystallisation of complex **7** from a hot mixture of MeCN and absolute EtOH yielded a mixture of complex **7** (predominantly) and dark-brown single crystals of complex **8**, which were separated manually under a microscope.

X-ray Structure Analysis: Suitable single crystals were obtained by slow evaporation from different solvents; solvents used and crystallisation temperatures are listed in Table 2 and Table 3, which also summarises crystal data, experimental details of data collections and refinements. Intensities were measured on an Enraf−Nonius CAD4 diffractometer, with graphite monochromated Mo-K_α radiation, wavelength 0.71083 Å, using ω/2θ scan technique. For the compounds **5** and **7** data collections were at 100 K, whereas the others were performed at 293(±2) K. During data collections there were no significant variations in intensities of the three control reflections, which were measured every 120 minutes. The data were corrected for Lorentz and polarisation effects.[33] The absorption correction was based on a ψ-scan of seven reflections. Structures were solved using the package SIR97[34] and refined by the package SHELXL97.[35] The crystal quality of **5** was rather poor and in spite of low-temperature data the final R [for $F_o > 4\sigma$ (F_o)] was 0.1146. However, electron density maps unambiguously revealed the molecular structure of the complex. Molecular geometry calculations and illustrations of the crystal packing were prepared by PLATON98.[36] Plots of the molecules with thermal ellipsoids scaled at the probability level 30% were prepared by ORTEP.[37] Atomic scattering factors were those included in SHELXL97. The H-atom coordinates were calculated geometrically and refined using the SHELX97 riding model.

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-158707 (**2**), CCDC-158708 (**4**), CCDC-158709 (**5**), CCDC-158710 (**6**), CCDC-158711 (**7**) and CCDC-158712 (**8**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Structure of Heterobimetallic Compounds with a Single Thiolato-Bridged Ligand

Md. Munkir Hossain,[a] Hsiu-Mei Lin,[a] and Shin-Guang Shyu*[a]

Keywords: Tungsten / Molybdenum / S ligands / Bridging ligands

Reactions between $CpFe(CO)_2SPh$ and $M(CO)_5THF$ (M = Cr, Mo, and W) in a mixture of benzene and THF at room temperature afforded compounds of the type $CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5$ (**1**) [M = Cr (**1a**), Mo (**1b**), and W (**1c**)] in high yield. However, migration of the thiolato ligand occurred during reactions between $CpM(CO)_xSPh$ (M = Fe, x = 2; M = Mo and W, x = 3) and $Fe_2(CO)_9$ forming compounds $[Fe(\mu\text{-}SPh)(CO)_3]_2$ and $[CpM(CO)_x]_2$ (M = Fe, x = 2; M = Mo and W, x = 3). Single-crystal X-ray diffraction analyses reveal that **1c** is a single thiolato-bridged hererobimetallic compound without a metal–metal bond. Metal–metal bond formation in compounds **1** by decarbonylation under thermal or photolytic condition was not observed. Reactions between compounds **1** and PPh_3 produced $CpFe(CO)_2SPh$ and $PPh_3M(CO)_5$ (M = Cr, Mo, and W) by M–S bond cleavage in **1**.

Introduction

Recent investigations of the chemical properties of phosphido-bridged bimetallic complexes have revealed several interesting cooperative effects between metals in these bimetallic complexes.[1] The dative metal−metal bond between metals can activate the substitution of the carbonyl ligands [1b−1f] and transfer the substitution site from one metal to the other.[1e] Interestingly, having a similar dative metal−metal bond, sulfido-bridged $CpW(CO)_2(\mu\text{-}SMe)W(CO)_5$(*W*−*W*) and phosphido-bridged $CpW(CO)_2(\mu\text{-}PPh_2)W(CO)_5$(*W*−*W*) complexes behave differently on substitution towards phosphanes. Thus, reaction between $CpW(CO)_2(\mu\text{-}SMe)W(CO)_5$(*W*−*W*) and phosphanes formed $CpW(PR_3)(CO)_2(\mu\text{-}SMe)W(CO)_5$ [2] while its phosphido-bridged analogue $CpW(CO)_2(\mu\text{-}PPh_2)W(CO)_5$(*W*−*W*) gave $CpW(CO)_2(\mu\text{-}PPh_2)W(PR_3)(CO)_4$(*W*−*W*).[1c] In addition, compounds with thiols as a ligand are significantly related to catalysts and biological activity.[3−8] Many of them are bimetallic complexes.[3,4,5a,6,7] As thiols having strong bridging abilities in coordination, enormous numbers of bimetallic compounds containing $(\mu\text{-}SR)_2$ bridges are reported.[9] For complexes with only one (μ-SR) bridge, only a small number of heterobimetallic compounds, without a metal−metal bond, have been synthesized.[10,11] Thus, evaluation of the influence of the thiolate ligands in the chemical behavior of bimetallic complexes could be valuable in order to compare those with phosphido-bridged analogues.

In continuing our interest in the search for cooperative effects in phosphido-bridged heterobimetallic compounds, we attempted to synthesize thiolato-bridged heterobimetallic compounds with and without metal−metal bonds. Herein, we report the synthesis and characterization of single thiolato-bridged heterobimetallic compounds $CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5$ (M = Cr, Mo, and W). Removal of CO to form their metal−metal-bonded analogues $CpFe(CO)(\mu\text{-}SPh)M(CO)_5$(*Fe*−*M*) (M = Cr, Mo, and W) was unsuccessful. The M−S bond cleavage in compounds **1** by PPh_3 as well as thiolato ligand transfer from the metallothiolates $CpM(CO)_xSPh$ (M = Fe, x = 2; M = Mo and W, x = 3) to $Fe_2(CO)_9$ to form $[Fe(\mu\text{-}SPh)(CO)_3]_2$ at ambient temperature is also described.

Results and Discussion

Synthesis of Compound 1 and Structure of 1c

Stirring of a benzene solution of $CpFe(CO)_2SPh$ with a THF solution of $M(CO)_5THF$ (M = Cr, Mo, and W) at room temperature afforded compounds **1a**, **1b**, and **1c** in high yield [Equation (1)]. The compound $[W(\mu\text{-}SPh)(CO)_4]_2$ [12] was also obtained in trace amounts during isolation of compound **1c**. Compounds **1a**, **1b**, and **1c** can also be prepared in good yield by using $M(NBD)(CO)_4$ (NBD = norbornadiene; M = Cr, Mo, and W)[13] instead of $M(CO)_5THF$, but formation of the heterobimetallic compounds is comparatively slow. They are reddish-orange solids, soluble in common organic solvents, and are air-stable.

$$CpFe(CO)_2SPh + M(CO)_5THF \rightarrow CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5 + THF \quad (1)$$

M = Cr (**1a**), Mo (**1b**), W (**1c**)

Single-crystal X-ray diffraction analysis of compound **1c** revealed that two independent molecules crystallized in the asymmetric unit cell. The independent two molecules are crystallographically nonidentical, where they are distinguished by the chirality of the S atom. The molecular struc-

tures are shown in Figures 1 and 2. Selected bond lengths and bond angles are listed in Table 1.

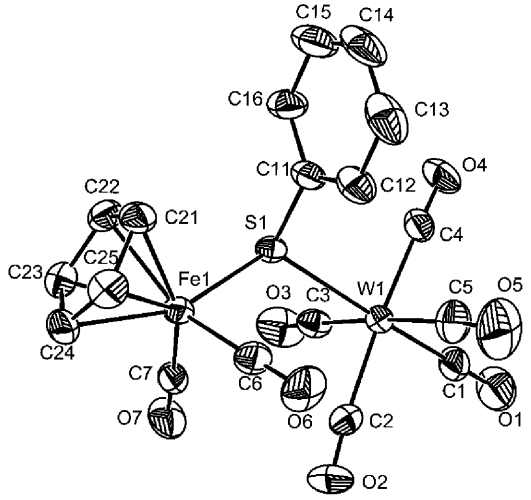

Figure 1. ORTEP drawing of **1c** (molecule 1); hydrogen atoms are omitted

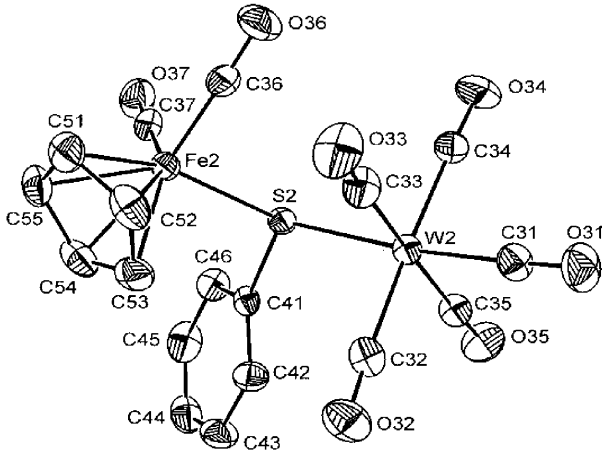

Figure 2. ORTEP drawing of **1c** (molecule 2); hydrogen atoms are omitted

There is no metal−metal bond present in any of the molecules as the bond lengths Fe1−W1 [4.2236(9) Å] and Fe2−W2 [4.1987(8) Å] are longer than the sum the covalent radii of the metal atoms. The tungsten atom has a distorted octahedral geometry, coordinated to five carbonyl groups and a bridging thiolato ligand. The W1−C1 [1.952(7) Å] and W2−C31 [1.959(5) Å] distances *trans* to the bridging thiolato ligand are shorter than the four equatorial W−C distances 2.036(7) Å (av.) and 2.039(6) Å (av.), respectively. This indicates that the thiolato ligand is a better σ-donor but a poorer π-acceptor compared to the CO ligand. The bond lengths Fe1−S1 [2.3007(15) Å], Fe2−S2 [2.3166(14) Å], W1−S1 [2.5772(13) Å], and W2−S2 [2.5865(12) Å] are comparable to the reported values.[10a] The bond angles W1−S1−Fe1 [119.86(5)°] and W2−S2−Fe2 [117.71(5)°] are also within the range of other reported M−S−M bond angles.[10a,11]

Thiolato Ligand Transfer from $CpM(CO)_xSPh$ (M = Fe, $x = 2$; M = Mo and W, $x = 3$) to $Fe(CO)_4$ by $Fe_2(CO)_9$

The reaction between $Fe_2(CO)_9$ and $CpFe(CO)_2SPh$ in THF at room temperature leads to the formation of $[CpFe(CO)(\mu\text{-}CO)]_2$ [14] and $[Fe(\mu\text{-}SPh)(CO)_3]_2$ [15] in good yield. Metallothiolates of the type $CpM(CO)_3SPh$ (M = Mo and W) also react with $Fe_2(CO)_9$ in a similar way and give the compounds $[Fe(\mu\text{-}SPh)(CO)_3]_2$ and their respective dimers $Cp_2M_2(CO)_6$ (M = Mo and W).[16,17] The above

transformation indicates that instead of obtaining any bimetallic compound like those of compounds **1,** the thiolato ligand is transferred from the CpM unit to the $Fe(CO)_4$ moiety during the reaction by M−S bond cleavage. The exact mechanism is not clear but it is believed to proceed via an associative pathway forming a bimetallic intermediate with the bridging thiolato ligand (Scheme 1).[18,19]

$$Fe_2(CO)_9 + THF \rightarrow Fe(CO)_4THF + Fe(CO)_5 \quad (a)$$

$$Fe(CO)_4THF + CpFe(CO)_2SPh \rightarrow CpFe(CO)_2(\mu\text{-}SPh)Fe(CO)_4 + THF \quad (b)$$

$$CpFe(CO)_2(\mu\text{-}SPh)Fe(CO)_4 \rightarrow CpFe(CO)_2 + Fe(CO)_4SPh \quad (c)$$

$$2CpFe(CO)_2 \rightarrow [CpFe(\mu\text{-}CO)(CO)]_2 \quad (d)$$

$$2Fe(CO)_4SPh \rightarrow [Fe(\mu\text{-}SPh)(CO)_3]_2 + 2CO \quad (e)$$

Scheme 1

$Fe_2(CO)_9$ can exist in THF solution as $Fe(CO)_4THF$ [Scheme 1, (a)].[20] Then $Fe(CO)_4THF$ can easily release the solvent molecule during the reaction, and the resultant reactive fragment $Fe(CO)_4$ coordinates to the sulfur lone pair of $CpFe(CO)_2SPh$ to generate the bimetallic intermediate $CpFe(CO)_2(\mu\text{-}SPh)Fe(CO)_4$ [Scheme 1, (b)].[18,19] It is then fragmented to $CpFe(CO)_2$ and $Fe(CO)_4SPh$ units by cleavage of the CpFe−S bond [Scheme 1, (c)]. Compound $[Fe(\mu\text{-}SPh)(CO)_3]_2$ is then formed by decarbonylation and dimerization of $Fe(CO)_4SPh$ according to Scheme1, (e).[21] Thiolato ligand transfer and formation of $[Fe(\mu\text{-}SPh)(CO)_3]_2$ in the case of $CpM(CO)_3SPh$ (M = Mo and W) is most likely to follow similar reaction paths.

Thiolato ligand transfer is reported for a few cases, these are the early to late transition metals such as titanium to cobalt,[22] rhodium,[23] or platinum.[18] It is due to the hard and soft mismatching of coordination between the titanium and thiolato ligand.[18] Thiolato ligand transfer from late to late transition metals is rare, but when it does occur it is between two different metals and under thermal conditions.[24] Thus, thiolate ligand transfer from iron to iron at ambient temperature in the above reaction is notable.

Reactivities of Compound 1

Reactions of compounds **1** with PPh_3 generate $CpFe(CO)_2SPh$ and $M(CO)_5PPh_3$ (M = Cr, Mo, and W).[25] This indicates that substitution of the metallothiolate with phosphane occurs on the W center in compounds **1**. It also suggests that PPh_3 is not only a stronger Lewis base, but also π-acceptor, in contrast to $CpFe(CO)_2SPh$. Interestingly, the reaction of $CpW(CO)_3(\mu\text{-}SMe)W(CO)_5$ and $CpW(CO)_3(\mu\text{-}SPh)W(CO)_5$ with hexafluorobut-2-yne produced $CpW(CO)(\eta^2\text{-}CF_3C_2CF_3)(\mu\text{-}SMe)W(CO)_5$ and $CpW(CO)(\eta^2\text{-}CF_3C_2CF_3)(SPh)$, respectively.[10a] In addition, the CO on Fe in $CpFe(CO)_2(\mu\text{-}PPh_2)W(CO)_5$ can be replaced by PMe_3 to produce $CpFe(CO)(PMe_3)(\mu\text{-}PPh_2)W(CO)_5$ under mild conditions.[1e] This indicates that the carbonyl ligands on the CpM moieties in these two compounds are labile towards substitution.

Under thermolytic or photolytic conditions, the CO ligand cannot be removed from compounds **1** to form $CpFe(CO)(\mu\text{-}SPh)M(CO)_5$(*Fe−M*) (M = Cr, Mo, and W). Instead, decomposition of the complex was observed. This indicates that the CO ligand on Fe cannot be substituted by the M−Fe bond formation under the reaction conditions. This observation is consistent with the results of the reaction between compounds **1** and phosphane discussed in the previous paragraph.

Conclusions

Reactions between $CpFe(CO)_2SPh$ and $M(CO)_5THF$ (M = Cr, Mo, and W) or $M(CO)_4(NDB)$ (M = Cr, Mo, and W) produce $CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5$ (M = Cr, Mo, and W) in good yield. However, reactions of metallothiolates $CpFe(CO)_2SPh$ and $CpM(CO)_3SPh$ (M = Mo and W) with $Fe_2(CO)_9$ resulted in the transfer of SR from metallothiolates to $Fe_2(CO)_9$ to produce $[Fe(\mu\text{-}SPh)(CO)_3]_2$. Attempts to remove CO from $CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5$ (M = Cr, Mo, and W) to form the metal−metal-bonded $CpFe(CO)(\mu\text{-}SPh)M(CO)_5$(*Fe−M*) were unsuccessful. The fact that the carbonyl ligands are inert towards substitution by the metal−metal dative-bond formation is proposed as a reason. Replacement of the metallothiolate moiety $CpFe(CO)_2SPh$ from $CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5$ (M = Cr, Mo, and W) by PPh_3 and formation of $M(CO)_5(PPh_3)$ supports the above argument.

Experimental Section

General Procedures: All reactions and other manipulations were performed using standard Schlenk techniques under nitrogen at ambient temperature. Commercially available chemicals were purchased and used without further purification. All solvents were dried and distilled immediately prior to use. The compounds $CpFe(CO)_2SPh$,[26] $M(NBD)(CO)_4$ (M = Cr, Mo, and W),[13] and $CpM(CO)_3SPh$ (M = Cr, Mo, and W)[27] were prepared according to the reported procedures. − A 450-W Hanovia medium-pressure quartz mercury lamp (Ace-Glass) and a pyrex Schlenk tube, used as a reaction vessel, were used in the photoreactions. − Infrared spectra were recorded with a Perkin−Elmer 882 infrared spectrophotometer. − The ^1H NMR spectra were recorded with a Bruker Ac-200 spectrometer. − Electron impact (EI) and fast-atom bombardment (FAB) mass spectra were recorded with a VG 70−2505 or a JEOL JMS-HX 100 mass spectrometer. − Microanalyses were performed using a Perkin−Elmer 2400 CHN analyzer.

Synthesis of Compounds 1: To a benzene solution (50 mL) of $CpFe(CO)_2SPh$ (0.50 g, 1.75 mmol), a THF solution (250 mL) of $M(CO)_5THF$ (M = Cr, Mo, and W) [prepared by photolysis of $M(CO)_6$ (2.0 mmol)] was added, and the solution was stirred for 0.5 h at room temperature. The reaction mixture was concentrated to dryness. The residue was dissolved in dichloromethane/hexane (1:10) and then filtered using Celite. The filtrate was concentrated

to10 mL and subjected to silica gel chromatography using dichloromethane/hexane (1:2) as the eluent. The reddish-orange bands were collected and dried. Compounds **1** were recrystallized from the mixture of dichloromethane and hexane in high yield. − **Compound 1a:** Yield 0.66 g (79%). − $C_{18}H_{10}CrFeO_7S$ (477.89): calcd. C 45.19, H 2.09; found C 45.09, H 2.08. − IR (hexane, νCO): $\tilde{\nu}$ = 2064 m, 2039 s, 2005 s, 1988 w, 1937 vs, 1915 vs cm^{-1}. − ^1H NMR (CD_3COCD_3): δ = 7.40−7.249 (m, 5 H, C_6H_5), 5.20 (s, 5 H, C_5H_5). − MS (FAB): *m*/*z* = 478 [M^+], 450 [M^+ − CO], 422 [M^+ − 2 CO], 366 [M^+ − 4 CO], 282 [M^+ − 7 CO]. − **Compound 1b:** Yield 0.467 g (51%). − $C_{18}H_{10}FeMoO_7S$ (523.85): calcd. C 41.38, H 1.92; found C 41.46, H 2.11. − IR (hexane, νCO): $\tilde{\nu}$ = 2072m, 2041 s, 2006 s, 1989 m, 1942 vs, 1933 sh. 1916 vs cm^{-1}. − ^1H NMR (CD_3COCD_3): δ = 7.52−7.159 (m, 5 H, C_6H_5), 5.30 (s, 5 H, C_5H_5). − MS (FAB): *m*/*z* = 524 [M^+], 468 [M^+ − 2 CO], 412 [M^+ − 4 CO], 356 [M^+ − 6 CO], 328 [M^+ − 7 CO]. − **Compound 1c:** Yield 0.789 g (74%). − $C_{18}H_{10}FeO_7SW$ (610.02): calcd. C 35.41, H 1.64; found C 35.48, H 1.83. − IR (hexane, νCO): $\tilde{\nu}$ = 2068 m, 2041 s, 2006 s, 1981 m, 1965 w, 1933 vs, 1912 vs cm^{-1}. − ^1H NMR (CD_3COCD_3): δ = 7.62−7.299 (m, 5 H, C_6H_5), 5.23 (s, 5 H, C_5H_5). − MS (FAB): *m*/*z* = 610 [M^+], 554 [M^+ − 2 CO], 526 [M^+ − 3 CO], 470 [M^+ − 5 CO], 442 [M^+ − 6 CO], 414 [M^+ − 7CO].

Synthesis of Compounds 1 from M(NBD)(CO)$_4$ (M = Cr, Mo, and W; NBD = Norbornadiene): To a solid mixture of $CpFe(CO)_2SPh$ (0.5 g, 1.75 mmol) and M(NBD)(CO)$_4$ (2.5 mmol) (M = Cr, Mo, and W) 50 mL of THF was added and stirred for 2 d at room temperature. The resulting reaction mixture was concentrated to dryness. The residue was dissolved in dichloromethane and filtered through Celite. The filtrate was concentrated to 5 mL and subjected to chromatography on a silica gel column using dichloromethane/hexane (1:3) as the eluent. The reddish-orange bands were collected and dried. Recrystallization of the residues from a mixture of dichloromethane and hexane afforded compounds **1**. Yield 0.594 g (71%) (**1a**), 0.449 g (49%) (**1b**), 0.715 g (67%) (**1c**).

Reactions of CpM(CO)$_x$SPh (M = Fe, *x* = 2; M = Mo and W, *x* = 3) with Fe$_2$(CO)$_9$: To a THF (50 mL) solution of $CpM(CO)_xSPh$ (M = Fe, *x* = 2; M = Mo and W, *x* = 3) (0.5 mmol) $Fe_2(CO)_9$ (0.728 g, 2.0 mmol) was added and stirred for 2 d at room temperature. The reaction mixture was concentrated to dryness. The residue was dissolved in dichloromethane and filtered through Celite. The filtrate was concentrated to 5 mL. Silica gel chromatography of each filtrate using dichloromethane/hexane (1:3) as the eluent gave the dimers $[CpM(CO)_x]_2$ (M = Fe, *x* = 2; M = Mo and W, *x* = 3) and [Fe(μ-SPh)(CO)$_3$]$_2$ (**A**).[15] Yield 0.041 g (23%) ([FeCp(μ-CO)(CO)]$_2$),[14] 0.102 g (41%) (**A**); 0.046 g (19%) ([CpMo(CO)$_3$]$_2$),[16] 0.117 g (47%) (**A**); 0.070 g (21%) ([CpW(CO)$_3$]$_2$),[17] 0.112 g (45%) (**A**).

Reactions of CpFe(CO)$_2$(μ-SPh)M(CO)$_5$ (M = Cr, Mo, and W) with PPh$_3$: To a THF solution of $CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5$ (0.5 mmol) [M = Cr (0.240 g), Mo (0.264 g) and W (0.305 g)] PPh_3 (0.262 g, 1.0 mmol) was added and the mixture stirred for 2 d at room temperature. The reaction mixture was concentrated to dryness. The residue was dissolved and then filtered through Celite. The filtrate was concentrated to 5 mL and subjected to chromatography on a silica gel column using dichloromethane and hexane as the eluent. The compounds $M(CO)_5PPh_3$ (M = Cr, Mo, and W)[25] and $CpFe(CO)_2SPh$ (B) were obtained by removing solvents from the first pale yellow band and the third reddish-orange band, respectively. The second reddish-orange band is unchanged starting materials $CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5$ (M = Cr, Mo, and W). Yield 0.045 g (19%) [$CpFe(CO)_2(\mu\text{-}SPh)Cr(CO)_5$], 0.129 g (69%) [$Cr(CO)_5PPh_3$], 0.085 g (73%) (**B**); 0.062 g (24%) [$CpFe(CO)_2(\mu\text{-}SPh)Mo(CO)_5$], 0.134 g (71%) [$Mo(CO)_5PPh_3$] 0.083 g, (77%) (**B**); 0.095 g (29%) [$CpFe(CO)_2(\mu\text{-}SPh)W(CO)_5$] 0.159 g (79%) [$W(CO)_5PPh_3$], 0.079 g (81%) (**B**). Yields of the products are calculated based on that of the reacted $CpFe(CO)_2(\mu\text{-}SPh)M(CO)_5$.

Crystal Structure Determination of Compound 1c: Single crystals of compound **1c** were grown by slow vapor diffusion of hexane into a dichloromethane solution of **1c** at 0 °C. A lath yellow crystal (0.25 × 0.18 × 0.34 mm) was mounted on a glass fiber for data collection using Mo-K_α radiation of an Enraf−Nonius CAD4 diffractometer at room temperature. Detailed data collection parameters are given in Table 2. Cell parameters were refined from 25 reflections with the 2θ range 20−36°. Three standard reflections were monitored every hour throughout the data collection. The variation was within 6%. Lorentz and polarization corrections were applied. A semiempirical absorption correction was applied based on azimuthal scans of three reflections. The structure was solved by direct methods. The atomic and isotropic thermal parameters for all hydrogen atoms were fixed. Structure refinement was performed by using the NRCSDP[28] program and a VAX workstation machine. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-158994. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 IEZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 2. Summary of crystal data for compound **1c**

Empirical formula	$C_{18}H_{10}FeO_7SW$
Formula mass	610.02

Facile Synthesis and Ambident Coordination of Cyclohexylbis-(2-pyridyl)phosphane: Novel Dinuclear Complexes of Cu^{+1}, Ag^{+1}, and Co^{+2} Ions

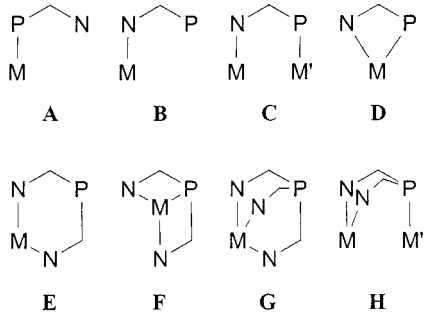
Matthias Driess,*[a] Felix Franke,[a] and Klaus Merz[a]

Keywords: Phosphanes / Cross-coupling / Copper / Silver / N ligands

The title compound cyclohexylbis(2-pyridyl)phosphane (**1**) was synthesized by a Pd^0-catalyzed cross-coupling reaction from 2-bromopyridine and cyclohexylphosphane in 98% yield. Compound **1** formed colorless crystals that were moderately air-stable. It reacted, in CH_3CN, with CuOTf (OTf = OSO_2CF_3), $AgBF_4$, and $Co(BF_4)_2$ to form the complexes $[Cu_2\{CyP(2\text{-}Py)_2\}_2(NCCH_3)_2](OTf)_2$ (**2**), $[Ag_2\{CyP(2\text{-}Py)_2\}_2(NCCH_3)_2](BF_4)_2$ (**3**), and $[Co_2\{CyP(2\text{-}Py)_2\}_2(NCCH_3)_2](BF_4)_4$ (**4**), respectively. In these complexes, the pyridylphosphane ligands coordinate to two metal centers in a head-to-tail fashion involving both the P and the N atoms simultaneously. The compounds represent the first structurally characterized examples of dimeric dinuclear pyridylphosphane complexes showing the *P*,*N*,*N*′ coordination. Reactions of **1** with other salts containing Cu^{+1} and Co^{+2} centers and coordinating anions resulted in different coordination modes. Thus, CuI reacted with **1** to form the complex $[Cu_2\{CyP(2\text{-}Py)_2\}_2I_2]$ (**5**) with both coordinated P and N donor centers and a terminal iodide. In contrast, the reaction of **1** with $CoCl_2$ afforded the mononuclear complex $[Co\{CyP(2\text{-}Py)_2\}Cl_2]$ (**6**) in which only the pyridyl N atoms and the chlorine ligands were coordinated to the metal center. X-ray analyses of the compounds **1**, **2**, **3**, **5**, and **6** are reported.

Introduction

Since 2-pyridylphosphanes can act as monodentate (*P*-coordinated), bidentate (*P*,*N*- or *N*,*N*′-chelating or *P*,*N*-bridging), or tridentate (*P*,*N*,*N*′-chelating or *N*,*N*′,*N*′′′-chelating) ligands with both hard (N) and soft (P) donor centers, they have been a topic of interest in the last 30 years.[1,2] Scheme 1 shows the various possible coordination modes for pyridylphosphanes **A**−**H**. All displayed modes have been described, except the coordination mode **H**.



Scheme 1. Some possible coordination modes **A**−**H** for pyridylphosphanes toward metal centers

Apart from the interesting structural features, pyridylphosphane metal complexes have been shown to act as good catalysts for reactions like the carbonylation of alkynes to form methacrylate,[3] showing surprisingly high turnover rates combined with an excellent product selectivity.

In contrast to the extensive use of diphenyl-2-pyridylphosphane[4] and its derivatives,[5] and the numerous complexes described with tris(2-pyridyl)phosphane,[6] the knowledge of bis-2-pyridylphosphanes is scarce.[7,8] Only recently, Ag^{+1} and Au^{+1} complexes of 1,2-bis(dipyridylphosphanyl)-ethane have been shown to provide a promising approach in cancer research for their potent and selective antitumor activity.[9]

Usually, the synthesis of 2-pyridylphosphanes is achieved by the reaction of the 2-lithium pyridine with the appropriate chlorophosphane at very low temperatures (less than −90 °C). In searching for a convenient and more selective way of synthesizing pyridylphosphanes with varying alkyl substituents we have found that the reaction of cyclohexylphosphane with 2-bromopyridine in acetonitrile in a Pd^0-catalysed cross-coupling reaction[10] furnished cyclohexyl(2-pyridyl)phosphane (**1**) in 98% yield. This reaction type, which resembles the Stille coupling reaction,[11] has been extended to phosphanes without silyl or stannyl groups by Stelzer et al., and tolerates a number of functional groups that limit the versatility of the lithium pyridyl method.[12] Reactions of cyclohexylbis(2-pyridyl)phosphane (**1**) in acetonitrile with different Cu^{+1}, Ag^{+1}, and Co^{+2} salts containing weakly coordinating anions ($CF_3OSO_2^-$, BF_4^-) furnished the dinuclear complexes **2**, **3**, and **4**, respectively. In these complexes, the pyridylphosphane ligands coordinate in a head-to-tail bridging mode involving both the P and the N donor centers. To the best of our knowledge, these are the first structurally characterized complexes of (2-pyridyl)phosphanes that represent the coordination mode **H** (Scheme 1). CuI with the stronger coordinating iodide anion reacted with **1** to form the isostructural complex **5**, while $CoCl_2$ lead to the mononuclear complex **6**, which represents the coordination mode **E**, involving only the pyridyl

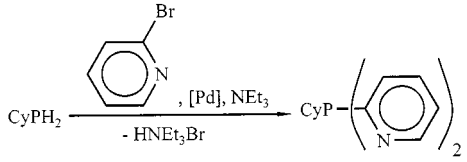
N atoms and the two chlorine atoms as donor centers toward the Co atom.

Results and Discussion

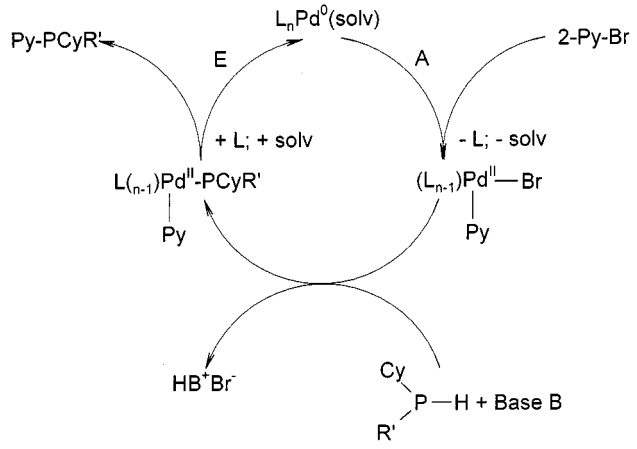
Synthesis of Cyclohexylbis(2-pyridyl)phosphane (1)

If cyclohexylphosphane is allowed to react with two molar equivalents 2-bromopyridine and triethylamine in the presence of catalytic amounts of tetrakis(triphenylphosphane)palladium(0) in acetonitrile for 24 hours, the desired cyclohexylbis(2-pyridyl)phosphane (**1**) is formed in 98% yield. The reaction can easily be monitored by ^{31}P-NMR spectroscopy, and proceeds stepwise via cyclohexyl-2-pyridylphosphane as the initial product. The latter can be identified by its diagnostic ^{31}P NMR signal ($\delta = -26.8$, $^1J_{PH} = 212.6$ Hz).



1 : Cy = C_6H_{11}

This type of Pd-catalyzed cross-coupling reaction has been described previously by Stelzer et al.,[10] and resembles the Stille coupling reaction.[11] The synthesis of **1** is the first example in which a primary aliphatic phosphane and 2-bromopyridine have been successfully coupled. The mechanism of the reaction involves the oxidative addition of 2-bromopyridine to the palladium catalyst, followed by the substitution of one triphenylphosphane ligand by cyclohexylphosphane or cyclohexyl-2-pyridylphosphane, respectively. Finally, the product is formed through a P−C bond formation in a reductive-elimination step (Scheme 2).[12]



Scheme 2. Proposed mechanism for the Pd^0-catalyzed synthesis of **1** based on previous results, starting from $CyPH_2$, 2-bromopyridine, and a Base. R′ = H, L = PPh_3, solv = solvent

Compound **1** forms colorless, fairly air-stable crystals that are soluble in most organic solvents. The ^{31}P NMR spectrum of **1** in C_6D_6 shows a singlet at $\delta = -3.2$, similar to the values observed for tris(2-pyridyl)phosphane ($\delta = -1.3$), phenylbis(2-pyridyl)phosphane ($\delta = -2.9$), and diphenyl(2-pyridyl)phosphane ($\delta = -1.9$).[13]

Crystal Structure of 1

Crystals of **1** suitable for an X-ray diffraction analysis were obtained from solutions in hexane. A view of its molecular structure is shown in Figure 1 and the crystallographic details are given in the Experim. Section.

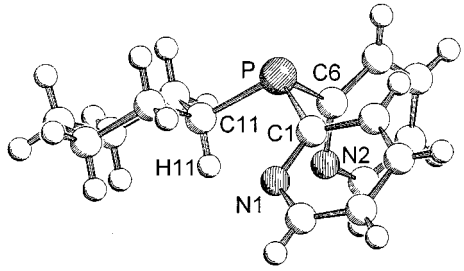


Figure 1. Molecular structure of cyclohexylbis(2-pyridyl)phosphane **1**. Selected distances [Å] and angles [°]: P1−C11 1.847(4), P1−C6 1.851(4), P1−C1 1.854(5), C11−P−C6 101.6(1), C11−P−C1 101.4(1), C6−P−C1 97.6(1)

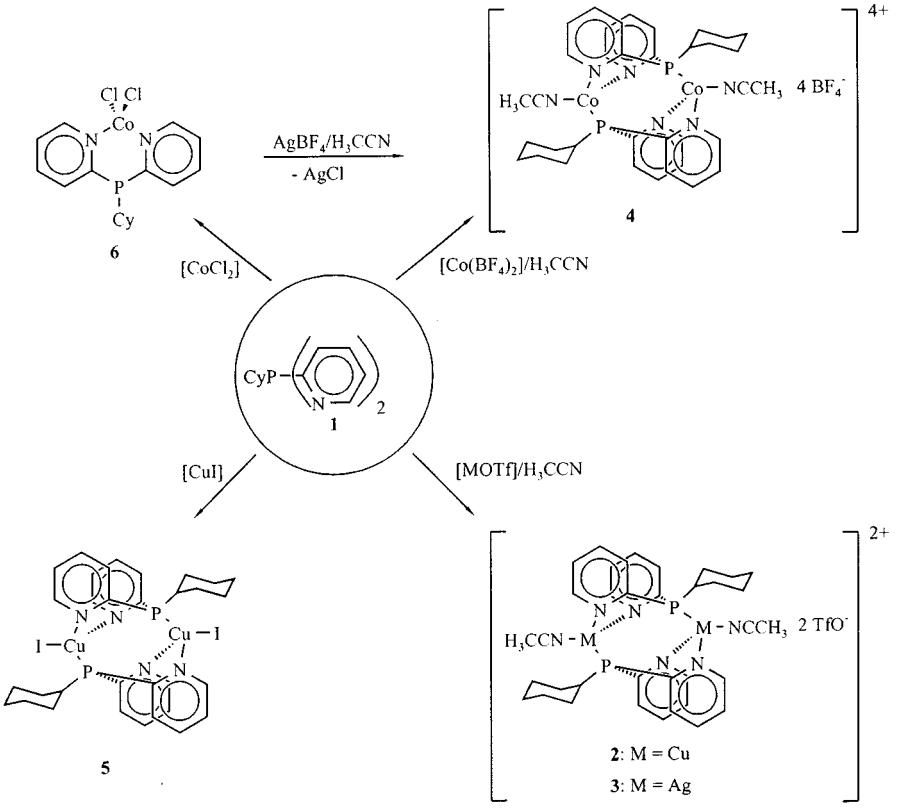
The P−C distance of 1.847(4) Å in **1** is similar to those in tris(2-pyridyl)phosphane (1.83 Å and 1.82 Å). As expected, the P atom has a pyramidal coordination, with the sum of bond angles at phosphorus of 300.6°. The latter value is only slightly smaller than that in tris(2-pyridyl)phosphane (305.6°).

While the C11−P−C6 and the C11−P−C1 angles [101.6(1) and 101.4(1)°] are practically identical to the corresponding angles in tris(2-pyridyl)phosphane, the C6−P1−C1 angle of 97.6(1)° is notably smaller. The N centers are directed away from the lone pair at the P atom. A similar orientation is also found for two pyridyl groups in tris(2-pyridyl)phosphane, while the third pyridyl substituent in the latter compound is rotated away from the other two.[14]

Coordination Reactions of 1 with Cu^{+1}, Ag^{+1}, and Co^{+2} Salts

Treatment of acetonitrile solutions of $Cu(O_3SCF_3)$, $AgBF_4$, and $Co(BF_4)_2$ with **1** at room temperature affords the dinuclear complexes **2**, **3**, and **4**, respectively. All three complexes form colorless (**2**, **3**) or pink (**4**) crystals from acetonitrile solution and are practically insoluble in other common solvents.

A ligand exchange of acetonitrile by other solvent molecules, as has been found in similar complexes,[15,16] could therefore not be achieved. The ^{31}P-NMR spectra show singlet signals at $\delta = 0.2$ for **2** and at $\delta = 23.6$ for **3**, thus confirming the coordination of the phosphorus atom by a downfield shift with respect to the value for the "free" ligand **1**. These values compare well with those in similar Cu and Ag complexes with bridging pyridylphosphanes, as observed in $[Cu_2(\mu\text{-}Ph_2P\text{-}Py)_3CH_3CN]^{2+}$ ($\delta = 5.45$)[15] and $[Ag_2(Ph_2P-Py)_2]^{2+}$ ($\delta = 25.7$), respectively.[17]



In order to investigate the influence of the anion on the coordination mode, and also to overcome the poor solubility properties of the ion pairs **2**, **3**, and **4**, CuI was allowed to react with **1** in THF at 50 °C. Yellow crystals of **5** precipitated as the desired product from the reaction mixture. Compound **5** turned out to be well soluble in THF, CH_2Cl_2, $CHCl_3$, and acetone. Its ^{31}P-NMR spectrum reveals a singlet at $\delta = 1.5$, very similar to that chemical shift observed for **2**. The crystal structure, which is described below, indeed shows that **5** is isostructural with the cation in **2**, except that the terminal acetonitrile ligands were replaced by iodine ions.

In contrast, the reaction of $CoCl_2$ with **1** yielded the complex **6** in good yields, which implies a different coordination mode of the dipyridylphosphane **1**, involving only the pyridyl N donor atoms and the Cl ligands as donor centers. As expected for a Co^{+2} complex, **6** is paramagnetic and unlike the other complexes, which are rather sensitive to air and water, is indefinitely resistant in air and moisture. It is soluble in most organic solvents and reacts with two equiv. of $AgBF_4$ in acetonitrile giving the separated ion pair **4** and AgCl.

Crystal Structures of 2, 3, and 4

The molecular structures of **2** and **3** are shown in Figure 2 and 3, while experimental details of the X-ray analyses are described in the Experim. Section and in Table 2. In all three complexes, the metal centers are held together in close proximity by the two bridging ligands that coordinate in a head-to-tail fashion and resemble the dimeric form of the coordination mode **H**, according to Scheme 1. In addition, both metal centers bear an acetonitrile ligand to achieve a distorted tetrahedral coordination sphere. Espinet et al. have merely described several dipyridylphosphane Mo^0 complexes for one of which the *P*,*N*,*N*′-coordination mode **F** was postulated, but crystallographic evidence could not be achieved.[18]

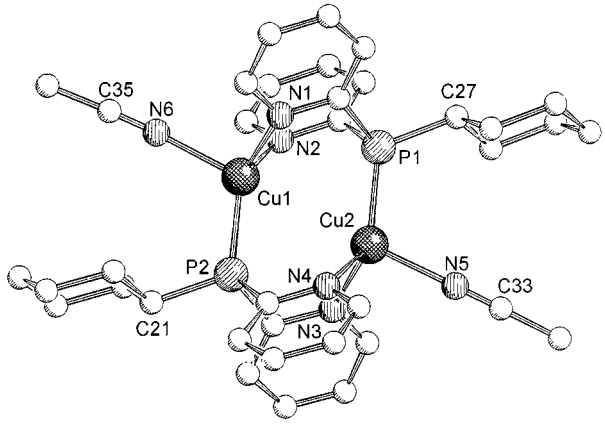


Figure 2. Molecular structure of the dication in **2**. For the sake of clarity, the H atoms have been omitted. Selected distances [A] and angles [°]: Cu2···Cu1 3.225(2), Cu−N(Py, average) 2.077(3), Cu−N (acetonitrile, average) 2.093(3), Cu1−P2 2.202(1), Cu2−P1 2.186(1); N2−Cu1−N1 94.2(1), N2−Cu1−P2 123.7(1), N1−Cu1−P2 126.2(1), N3−Cu2−N4 90.7(1), N3−Cu2−P1 125.2(1), N4−Cu2−P1 127.9(1), Cu2−N5−C33 171.0(4), Cu1−N6−C35 171.5(4)

In **2**, the copper centers are surrounded, in a distorted tetrahedral geometry, by one phosphorus and three nitro-

gen donors. The Cu centers lie about 48 pm outside of the P,N,N′-plane. The N(Py)−Cu−N(Py) bond angles of 90.7(1) and 94.2(1)°, respectively, are considerably smaller than those of the P−Cu−N(Py) angles, which vary between 123.7(1) and 127.9(1)°, respectively. Such a difference has also been observed in the $[Cu_2(\mu\text{-dppy})_3(CH_3CN)]^{2+}$ ion [dppy = diphenyl(2-pyridyl)phosphane],[15] in which one Cu center is also coordinated in a distorted tetrahedral arrangement. However, the differences between the N(Py)−Cu−N(Py)- and the P−Cu−N(Py) angles, respectively, are less significant in the latter complex, due to stronger geometric constraints in the ligand backbone in **2** than in dppy in $[Cu_2(\mu\text{-dppy})_3(CH_3CN)]^{2+}$. The Cu···Cu distance of 3.225(2) Å is larger than the respective distance in $[Cu_2(\mu\text{-dppy})_3(CH_3CN)]^{2+}$ (2.72 Å), in which one Cu center is tetrahedral and the other trigonal-planar coordinated.[19] It is, however, shorter than in $[Cu_2(dppy)_2(CH_3CN)_2]^{2+}$ (3.58 Å) with both Cu atoms being trigonal coordinated.[19] The value is also considerably shorter than in $[Cu_2(\mu\text{-}Ph_2PCH_2PPh_2)_2(CH_3CN)_4]^{2+}$ (3.75 Å),[20] in which both Cu centers are surrounded by four donor atoms. The close proximity between the Cu atoms in **2** compared with that in $[Cu_2(\mu\text{-}Ph_2PCH_2PPh_2)_2(CH_3CN)_4]^{2+}$ probably reflects the higher ring strain induced by the relatively rigid threefold coordination within the ligand backbone rather than suggesting attractive intermetallic interactions. According to Figure 3, the dinuclear Ag complex **3** adopts the same core structure as **2**. However, the tetrahedral coordination geometry around the Ag centers is even more distorted than that in **2** with P−Ag−N(Py) angles varying between 126.6(1) and 135.2(1)°, while the N(Py)−Ag−N(Py) angles are 86.7(2) and 87.4(2)°, respectively.

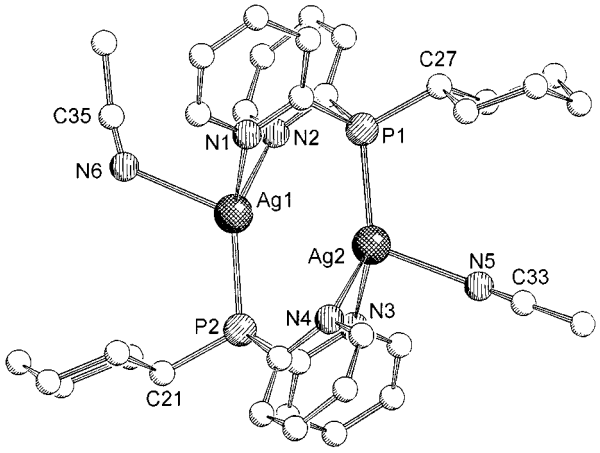

Figure 3. Molecular structure of the dication in **3**. For the sake of clarity, the H atoms have been omitted. Selected distances [Å] and angles [°]: Ag1···Ag2 2.932(4), Ag−N(Py, average) 2.397(5), Ag1−N6 2.466(7), Ag2−N5 2.373(6), Ag1−P2 2.390(1), Ag2−P1 2.383(2); N2−Ag1−N1 86.7(2), N1−Ag1−P2 129.5(1), N2−Ag1−P2 134.6(1), N3−Ag2−N4 87.4(2), N3−Ag2−P1 135.2(1), N4−Ag2−P1 126.6(1), Ag1−N6−C35 125.9(7), Ag2−N5−C33 158.9(5)

The Ag···Ag distance of 2.932(4) Å is shorter than that in other complexes with bridging pyridylphosphanes like $[Ag_2(Ph_2P\text{-}Py)_2](NO_3)_2$ (3.14 Å),[21] $[Ag_2(\eta^1\text{-}Ph_2P\text{-}Py)(\mu\text{-}Ph_2P\text{-}Py)_2](ClO_4)_2$ (3.07 Å),[17] $[Ag_2(Ph_2P\text{-}Py)_3]Cl_2$ (3.08 Å),[22] and $[Ag_2(\mu\text{-}L)_2(CH_3CN)_2](ClO_4)_2$ [L = 2-(diphenylphosphanyl)-6-(pyrazol-1-yl)pyridine] (2.96 Å).[23]

Surprisingly, the Ag···Ag distance in **3** is smaller than the Cu···Cu distance in **2**, and the same is true for the homologous complexes $[Ag_2(\mu\text{-}L)_2(CH_3CN)_2](ClO_4)_2$ and $[Cu_2(\mu\text{-}L)_2(CH_3CN)_2](ClO_4)_2$ [L = 2-(diphenylphosphanyl)-6-(pyrazol-1-yl)pyridine].[23,24] This observation may indicate attractive interactions between the Ag centers due to a larger contribution of relativistic effects. However, in the case of bridging ligands, it is difficult to distinguish between ligand-induced effects (strain) and true "metallophilic" d^{10}-d^{10} dispersion-type interactions.[25] It is also noteworthy that one of the acetonitrile molecules is coordinated to the Ag center with an Ag−N−C angle of 125.9(7)°, while the other Ag−N−C moiety adopts an angle of 158.9(5)°. A similar small Cu−N−C bond angle of 129.2° has also been observed in the case of the Cu(+1) complex [Cu(acac)(phen)(CH_3CN)](ClO_4) (acac = acetylacetonate; phen = 1,10-phenanthroline),[26] but **3** represents the first Ag^{+1} acetonitrile complexes with an Ag−N−C angle < 140° (Table 1).

Table 1. Comparison of Ag−N bond length and the Ag−N−C angle in different Ag(+1)-acetonitrile complexes

AgNC[a]	Ag−N[b]	compound	ref.

[a] Ag−N−C angle at the coordinated CH_3CN (°). − [b] Bond length (Å). − [c] L^1 = μ_3-6,13,20-trimethoxycalix(3)pyridine. − [d] L^2 = μ_2-1,11-(1,2)Ph-3,6,9,13,16,19-hexathiacycloicosaphane. − [e] Pyr = pyridazine. − [f] L^3 = μ_2-3,7-di-*tert*-butyl-2,8-dioxa-5-aza-1-phosphabicyclo(3.3.0)octa-2,4,6-triene. − [g] Pyz = pyrazole

It has been proposed that the M−N−C angle of the acetonitrile ligand corresponds well with the M−N(acetonitrile) distance in such a way that longer M−N bonds imply a smaller M−N−C angle, thereby representing a rather early stage of acetonitrile coordination.[15] This trend is supported by the respective data of CH_3CN−Ag^{+1} complexes that are summarized in Table 1. However, the $[AgL^3(NCCH_3)_2]$ cation [L^3 = μ_2-3,7-di-*tert*-butyl-2,8-dioxa-5-aza-1-phosphabicyclo(3.3.0)octa-2,4,6-triene] is an exception, revealing two different Ag−N−C angles (Δ = 10°), and at the same time, equidistant Ag−N

bonds (2.28 Å).[32] Quantitative correlation of the Ag^{+1} complexes seems very difficult because a clear distinction between electronic effects, steric influences, and possible packing effects cannot be made. Nonetheless, the relatively small Ag−N−C angle of 125.6(1) at one Ag center and the much shorter Ag···Ag distance in **3** [2.932(4) Å] are consistent with the presence of metallophilic Ag(donor)−Ag(acceptor) interactions. This is because its Cu-homologue **2** is apparently different, possessing a much longer M···M distance of 3.225(2) Å and both acetonitrile ligands are inconspicuously coordinated to the Cu^{+1} centers [averaged Cu−N−C angle 171.2(4)°].

The paramagnetic dicobalt complex **4** shows basically the same core-structure as **2** and **3**. According to a preliminary X-ray structure analysis of moderate crystals of **4**, which crystallizes in the monoclinic space group $P2_1/c$ [$R1$ = 0.1319, $wR2$ (all data) = 0.3397], the Co···Co distance of 2.976(5) Å is larger than that in other dinuclear complexes like $[Co^{I}Co^{0}(\mu\text{-}Ph_2PPy)_2(\mu\text{-}CO)(CO)Cl]$[27,34] and $[Co^{0}_{2}(\mu\text{-}Ph_2PPy)(\eta^2\text{-}\mu\text{-}HC{\equiv}CSiMe_3)]$.[28,35] The latter complexes imply Co−Co bonds due to short intermetallic distances and electron deficiency. In the acetylene complex, the observed diamagnetism, shown by a ^{31}P-NMR spectrum, provides further proof of an antiferromagnetic coupling of the unpaired electrons at the Co centers. This is, however, not the case in **4**, which is reluctant to undergo direct- or ligand-induced coupling of the d^7-Co centers even at 15 K. This was proven by temperature-dependent magnetic susceptibility measurements and fitting of the observed data with the calculated values. The effective magnetic moment of η_{eff} = 5.5 B.M. at room temperature seems relatively large in comparison to mononuclear tetrahedral Co^{+2} complexes that show η_{eff} values in the range between 4.3 and 5.2 B.M. However, larger values can be expected due to the different nature of the ligands and their ligand fields.[36,37] In line with that, simulations of the magnetic moment of high-spin Co^{+2} ions in a tetrahedral ligand field revealed the η_{eff} value of 4.82 B.M., which can be increased using appropriate ligands. The results suggest that spin-spin coupling between the Co^{+2} ions in **4** is negligible.

Crystal Structure of 5

Crystals of **5** suitable for an X-ray diffraction analysis were obtained by recrystallization in CH_2Cl_2. Its structure is shown in Figure 4. As expected, the structure of **5** is identical with that of **2**, but in place of the terminal acetonitrile ligands, iodine ions are coordinated to the Cu centers of **5**. This can be explained by the superior coordinating ability of the iodine ions compared to the triflate anion. The Cu···Cu distance of 3.333(3) Å is ca. 0.1 Å longer than that in **2**, and the tetrahedral coordination geometry of the Cu centers is notably distorted. The two N(Py)−Cu−N(Py) angles of 93.9(2) and 100.8(2)° are considerably different from the corresponding values in **2** [90.7(1) and 94.2(1)°]. Several attempts to exchange the iodine atoms at copper by organo substituents, through reaction of **5** with MeLi, BuLi, and lithium phenylacetylide, did not lead to any isolable product.

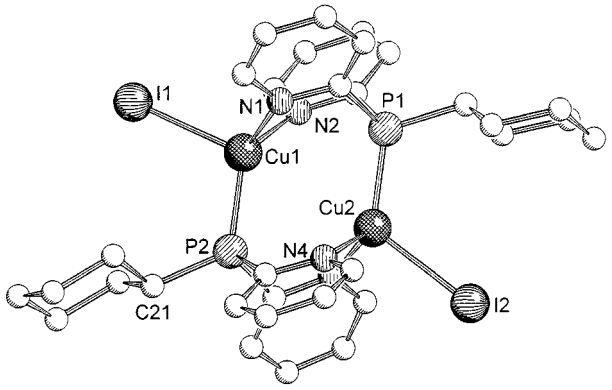

Figure 4. Molecular structure of **5**. For the sake of clarity, the H atoms have been omitted. Selected distances [Å] and angles [°]: Cu1···Cu2 3.333(3), Cu1−I1 2.7201(8), Cu2−I2 2.6978(8), Cu−N(Py, average) 2.052(4), Cu1−P2 2.189(2), Cu2−P1 2.218(2); N2−Cu1−N1 100.8(2), N2−Cu1−P2 114.6(1), N1−Cu1−P2 122.5(1), N3−Cu2−N4 93.9(2), N3−Cu2−P1 116.6(1), N4−Cu2−P1 127.5(1)

Crystal Structure of 6

The $CoCl_2$ complex **6** affords dark-blue crystals that could be recrystallized in most organic solvents. According to its X-ray diffraction analysis, the ligand **1** adopts a different coordination mode in the mononuclear complex than in the dimeric acetonitrile complex **4**, which is also apparent from their different color. Crystallographic details for **6** are summarized in Table 2 and Figure 5 shows a model of its crystal structure. In **6**, both N donor atoms of the ligand coordinate to the Co^{+2} center, affording a distorted tetrahedral N_2Cl_2 coordination geometry around the Co atom, while the P atom is only a spectator, bridging center. The ligand and the metal form a six-membered CoN_2C_2P ring that prefers the thermodynamically favorable chair conformation. As expected, the structure is similar to that of $[Co(N,N'\text{-}PhPPy_2)Cl_2]$.[38] The Co−N distances are identical with those in other Co(+2) dipyridyl complexes like

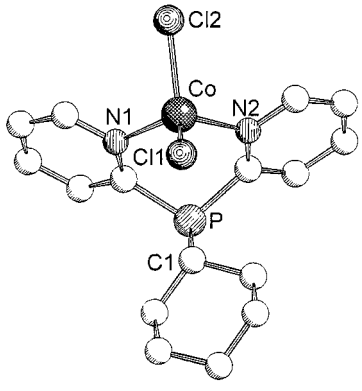

Figure 5. Molecular structure of **6**. For the sake of clarity, the H atoms have been omitted. Selected distances [Å] and angles [°]: Co−Cl1 2.213(1), Co−Cl2 2.222(1), Co−N1 2.034(3), Co−N2 2.028(3); Cl1−Co−Cl2 113.34(5), N1−Co−N2 99.5(1), N1−Co−Cl1 115.18(8), N2−Co−Cl1 116.32(8)

[Co(4-vinylpyridine)$_2$Cl$_2$][29,39] and [Co(4-methyl pyridine)$_2$Cl$_2$], respectively.[40] The tetrahedral coordination geometry at the Co(+2) center is somewhat more distorted than in the latter because of the phosphane linkage between the pyridyl rings in the *meta* positions. The N−Co−N angle of 99.5° in **6**, especially, shows a considerable deviation from the ideal tetrahedral angle. An even smaller N−Co−N angle of 94.8° is observed in [Co(*N*,*N*′-PhPPy$_2$)Cl$_2$].[38]

Conclusion

We reported here on an economical and at the same time facile synthesis of (cyclohexyl)bis(2-pyridyl)phosphane (**1**). The formation of its new complexes **2**−**5** proves the existence of the missing *P*,*N*,*N*′-coordination mode **H** for dipyridylphosphanes. Apparently, this coordination mode supports the formation of dinuclear complexes. The metals in **2**−**5** are in close proximity, which in general permits intermetallic interactions influenced by the terminal ligands at the metal center. The formation of the mononuclear Co complex **6** illustrates the directing influence of the hardness of the anion and its coordination ability on the coordination properties of the metal toward the chelate ligand **1**. Further investigations to synthesize related water-soluble dinuclear complexes and to probe their use in metal-assisted organic synthesis are in progress.

Experimental Section

All reactions and manipulations were carried out under an atmosphere of dry argon using standard Schlenk techniques unless otherwise stated. Solvents and reagents were dried by standard methods and distilled prior to use. − The ^{31}P- and ^{1}H-NMR spectra were measured on a Bruker Avance 250 spectrometer at 250 MHz (^{1}H) and 101.3 MHz (^{31}P), respectively. Chemical shifts are given in ppm relative to respective standards. External standards for ^{1}H NMR: $SiMe_4$; ^{31}P NMR: H_3PO_4 (85% aq. solution). − Elemental analyses were performed on an Elementar VarioEL microanalyser.

Synthesis of CyP(2-Py)$_2$ (1): A solution of 1.0 g (8.6 mmol) of cyclohexylphosphane, 2.7 g (17.2 mmol) of 2-bromopyridine, 1.8 g (17.8 mmol) of triethylamine, and ca. 0.1 g of tetrakis(triphenylphosphanyl)palladium(0) in 20 mL of acetonitrile were degassed thoroughly in a Schlenk tube and sealed under vacuum. The reaction mixture was heated under reflux for 36 h, monitoring the progress of the reaction by ^{31}P-NMR spectroscopy. Then the solvent was evaporated in vacuo at 25 °C and the residue was taken up with 30 mL of hexane. The triethylammonium bromide was then filtered off and washed with two 5 mL portions of hexane. The filtrates were combined and the solvent removed in vacuo. Distillation gave the crude product that was recrystallized in hexane at −20 °C and dried in vacuo to give 2.25 g (8.4 mmol, 98%) of the colorless crystalline product. − ^{31}P NMR: δ = 3.2 (s). − ^{1}H NMR: δ = 1.2−2.2 [m, 10 H, C*H*(C*H*$_2$)$_5$], 3.2 [m, 1H, C*H*(CH$_2$)$_5$], 6.7 (m, 2 H, Py), 7.1 (m, 2 H, Py), 7.5 (m, 2 H, Py), 8.6 (m, 2 H, Py). − MS (EI, 70 eV): *m*/*z* (%) = 270 (35) [M$^+$], 193 ([M − C$_6$H$_4$N]$^+$, 80), 187 ([M − C$_6$H$_{11}$]$^+$, 100), 109 ([M − C$_6$H$_{11}$-C$_6$H$_4$N], 75). − HR-MS: calcd. *m*/*z* = 270.1283 for C$_{16}$H$_{19}$N$_2$P, found 270.1281.

Synthesis of {Cu$_2$[CyP(2-Py)$_2$]$_2$(NCCH$_3$)$_2$}(OTf)$_2$ (2): A solution of 0.33 g (0.7 mmol) of (CuOTf)$_2$·C$_6$H$_6$ in 10 mL of acetonitrile was allowed to react with 0.35 g (1.3 mmol) of **1** in 5 mL of acetonitrile at room temperature. After stirring the mixture overnight, a white precipitate formed that was recrystallized in acetonitrile to afford slightly yellowish crystals in 79% yield (1.0 g). − ^{31}P NMR: δ = 0.2 (s); elemental analysis calcd. (%): calcd. C 43.55, H 4.23, N 8.02; found (%) C 43.05, H 4.18, N 7.90.

Synthesis of {Ag$_2$[CyP(2-Py)$_2$]$_2$(NCCH$_3$)$_2$}(BF$_4$)$_2$ (3): To 0.20 g (1.0 mmol) of $AgBF_4$ in 10 mL of acetonitrile a solution of 0.30 g (1.0 mmol) of **1** in 5 mL of acetonitrile was added at room temperature. After stirring the mixture overnight, a white precipitate was formed that was recrystallized in acetonitrile to form colorless crystals in 85% yield (0.86 g). − ^{31}P NMR: δ = 0.2 (s); elemental analysis calcd. (%): calcd. C 42.72, H 4.38, N 8.30; found (%) C 43.21, H 4.35, N 8.35.

Synthesis of {Co$_2$[CyP(2-Py)$_2$]$_2$(NCCH$_3$)$_2$}(BF$_4$)$_4$ (4): A blue solution of 0.26 g (1.0 mmol) of $CoCl_2$ in 20 mL of CH_3CN was added to 0.40 g (2.0 mmol) of $AgBF_4$ at room temperature, from which the color of the solution turned pink and AgCl precipitated. The latter was filtered off and the clear filtrate allowed to react with 0.30 g (1.0 mmol) of **1** in 10 mL of CH_3CN at room temperature. After stirring the pink solution for 12 h, the reaction mixture was reduced to 2 mL in vacuo and stored at −25 °C. The product precipitated in the form of pink crystals in 58% yield (0.34 g, 0.58 mmol). Elemental analysis of the mono-solvate with CH_3CN, calcd. (%): calcd. C 39.77, H 3.95, N 7.74; found (%): C 39.36, H 4.19, N 7.51.

Synthesis of {Cu$_2$[CyP(2-Py)$_2$]$_2$I$_2$} (5): CuI (0.70 g, 3.7 mmol) was dissolved in 120 mL of THF at 50 °C and a solution of 0.99 g (3.7 mmol) of **1** in 30 mL of THF was added with vigorous stirring. The reaction mixture turned yellow and standing of the solution at room temperature yielded, after 3 d, 1.75 g (1.64 mmol, 89%) of the product in the form of yellow crystals. − ^{31}P NMR ($CDCl_3$): δ = 1.5 (s, *w*1/2 = 22.8 Hz). − ^{1}H NMR ($CDCl_3$): δ = 1.2−2.2 [m, 20 H, CH(C*H*$_2$)$_5$], 3.1 [m, 2 H, *CH*(CH$_2$)$_5$], 7.5 (m, 4 H, Py), 7.8 (m, 8 H, Py), 9.1 (m, 4 H, Py); elemental analysis (solvate with two molecules THF) calcd. (%): calcd. C 45.08, H 5.12, N 5.26; found (%) C 44.14, H 5.10, N 5.36.

Synthesis of {Co[CyP(2-Py$_2$]Cl$_2$] (6): $CoCl_2$ (0.13 g, 1.0 mmol) was dissolved in 20 mL of CH_3CN at room temperature. To this deep-blue mixture a solution of **1** (0.27 g, 1.0 mmol) in 10 mL of CH_3CN was added, and the reaction mixture was stirred for 12 hours. Solvent was removed in vacuo to leave 5 mL of a dark-blue solution from which **6** crystallized in the form of dark-blue crystals. Yield: 0.37 g (0.93 mmol, 93%). − MS (EI, 70 eV): *m*/*z* (%) = 399 ([M]$^+$, 0.5), 364 ([M − Cl]$^+$, 3), 327 ([M − 2Cl]$^+$, 10), 270 ([CyPPy$_2$]$^+$, 80), 193 ([CyPPy$_2$-C$_6$H$_4$N]$^+$, 82), 187 ([CyPPy$_2$-C$_6$H$_{11}$]$^+$, 100), 109 ([CyPPy$_2$ -C$_6$H$_{11}$-C$_6$H$_4$N], 78); elemental analysis calcd. (%): calcd. C 48.03, H 4.79, N 7.00; found (%): calcd. C 47.80, H 5.22, N 6.99.

X-ray Structural Determinations: The intensities were measured with a Bruker-axs-SMART diffractometer (Mo-K_α radiation, λ = 0.7170 Å, ω scan). The structures were solved by direct methods (SHELXS97), and refined against F^2 with all measured reflections (SHELXL97). All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were introduced in calculated positions. Other experimental details are summarized in Table 2.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary

First Example of Supported Microwave-Assisted Synthesis of New Chiral Bipyridines and a Terpyridine − Use in Asymmetric Cyclopropanation

Frédéric Pezet,[a] Isabelle Sasaki,*[a] Jean-Claude Daran,[a] Jérôme Hydrio,[a] Hassan Aït-Haddou,*[b] and Gilbert Balavoine[a]

Keywords: N ligands / Asymmetric catalysis / Cyclopropanation / Copper / Zinc

We present herein the first alumina-supported synthesis of chiral bipyridines and of a chiral C2-symmetric terpyridine conducted under microwave irradiation, and our preliminary results from copper-mediated enantioselective cyclopropanation with this terpyridine. Reaction yields were excellent and enantioselectivities of up to 87% were observed. Moreover, with *trans*-β-methylstyrene, a remarkable diastereoselectivity (ratio *trans*/*cis* = 7:93) was observed.

Introduction
