The MALDI-TOF mass spectra of solutions of the complexes feature major peaks corresponding to $[Cu(\mathbf{1})]^+$, $[Zn(\mathbf{6})]^+$, and $[Cu(\mathbf{7})]^+$ patterns with characteristic isotopic distributions for the relevant metal ions. Attempts to isolate zinc(II) complexes of the prepared ligands were successful only in the case of **6**, for which [Zn(**6**)]$(CH_3COO)_2$ was obtained.

The NMR data of the mononuclear zinc complex of **6** are consistent with tetradentate metal coordination. The ^1H NMR spectrum (solution in $CDCl_3$) is consistent with C_2 symmetry of the complex. In the NOESY spectrum, the signal due to the Pym-5 proton shows an intense cross-peak with the signal due to the Py′-3/Py-3 protons. This indicates that the pyrimidine ring is *cis*-oriented with respect to the internal pyridine ring, as expected for tetradentate coordination of the ligand.

Information about the copper coordination sphere in solution was obtained from EPR spectroscopic data. The EPR spectra of [Cu(**1**)]$(NO_3)_2\cdot 5H_2O$ and [Cu(**7**)]$(NO_3)_2\cdot 6H_2O$ in DMSO glass were recorded at liquid nitrogen temperature. In the spectrum of [Cu(**1**)]$(NO_3)_2\cdot 5H_2O$, specifically the part of perpendicular orientation, *N*-superhyperfine coupling with the nitrogen donor atoms is observed, but is poorly resolved. The spin Hamiltonian parameters obtained are $g_\perp = 2.06$, $g_\parallel = 2.26$, $A_\parallel = 166$ G, and $g_\perp = 2.07$, $g_\parallel = 2.32$, $A_\parallel = 151$ G for

[Cu(**1**)](NO$_3$)$_2$·5H$_2$O and [Cu(**7**)](NO$_3$)$_2$·6H$_2$O, respectively. These parameters are consistent with the presence in both complexes of a tetrahedrally distorted square-planar copper environment with a $d_{x^2-y^2}$ ground state ($g_{\|} > g_{\perp}$).[8] The values of the spin Hamiltonian parameters of these complexes agree well with those reported for flattened N_4 tetrahedral complexes of Cu^{2+} [8,9] and are distinctly different from those of square-planar tetradentate Cu^{2+} in the previously described LCu (L = ligand shown in Scheme 1), $g_{\|}$ = 2.207, $A_{\|}$ = 196 G.[10]

The EPR parameters indicate the degree of distortion of the CuN_4 moiety from planarity, which determines the preorganization of the bidentate, bipyridine-like chelating units in the mononuclear complexes. A near-planar N_4 coordination in LCu (L = ligand shown in Scheme 1), as suggested by the $g_{\|}$ and $A_{\|}$ values, was confirmed by a crystal structure determination of [LCu(MeOH)]ClO_4.[10] In this complex, two pyrimidine 2-H protons approach their van der Waals contact distance. Any decrease in the C−X−C bond angle at spacer atom X (Scheme 2), or any increase in the X−C bond length, should give rise to an increased helical twist of the mononuclear complex with tetrahedral distortion of the CuN_4 plane in order to minimize steric repulsion between the pyrimidine 2-H protons. Thus, the apparent increase in the degree of tetrahedral distortion in the order X = C, S, Se becomes understandable in terms of specific bonding parameters of these spacing atoms.

In our previous study on complexes of ligand L (Scheme 1), spectrophotometric titrations gave evidence concerning the metal complex species present in solution. Attempts to characterize the solution chemistry of the Cu complexes of **1** and **7** under the same conditions (water/DMSO, 3:1) were complicated by insufficient solubility of the ligands in the absence of the metal ion and by slow complex formation.

Fast complexation was observed in a 1:1 dichloromethane/acetonitrile medium, and UV titrations were indicative of the formation of both mononuclear and trinuclear complexes. Sharp isosbestic points were obtained for 0−1 equiv. of Cu when 5% DMSO was added to the solvent mixture (Figure 2 and Figure 3).

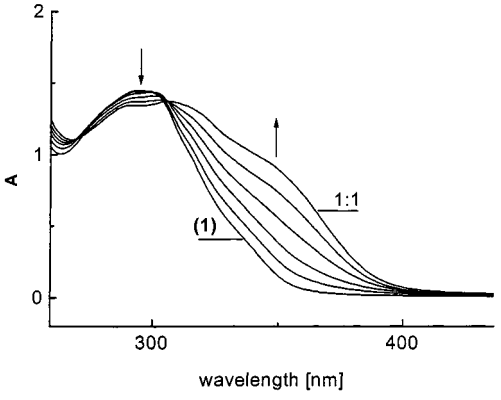

Figure 2. Spectrophotometric titration of **1** with copper(II) perchlorate in a CH_3CN/CH_2Cl_2 (1:1) solution containing 5% DMSO at 20 °C from 0−1 equiv. (spectra correspond to addition of Cu in 0.2-equiv. steps)

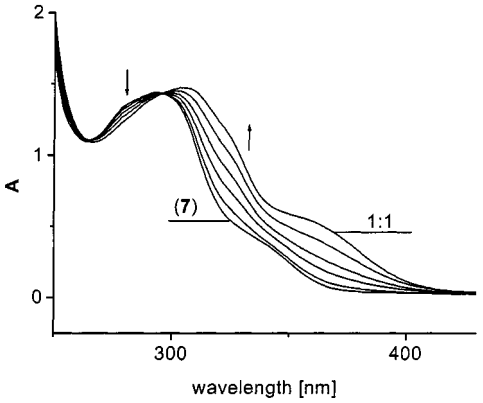

Figure 3. Spectrophotometric titration of **7** with copper(II) perchlorate in a CH_3CN/CH_2Cl_2 (1:1) solution containing 5% DMSO at 20 °C from 0−1 equiv. (spectra correspond to addition of Cu in 0.2-equiv. steps)

The absorbance maxima of the complexes (about 310 nm) are shifted toward higher wavelengths relative to the free ligands (about 290 nm). Interestingly, the competitive solvent DMSO inhibits the formation of polynuclear complexes; no significant spectral changes are observed on addition of > 1 equiv. of Cu (see also the absorbance diagrams, Figure 4 and Figure 5).

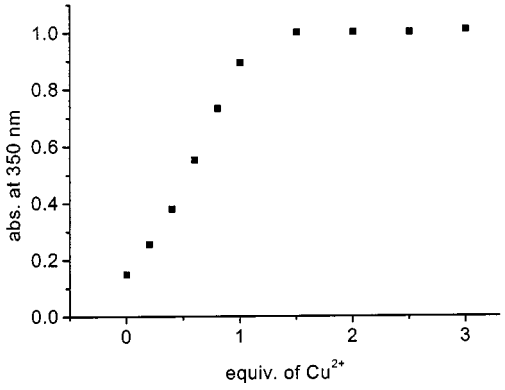

Figure 4. Increase of 350 nm absorbance on photometric titration of **1** ($5\cdot10^{-5}$ M) with copper(II) perchlorate solution; for conditions, refer to Figure 2

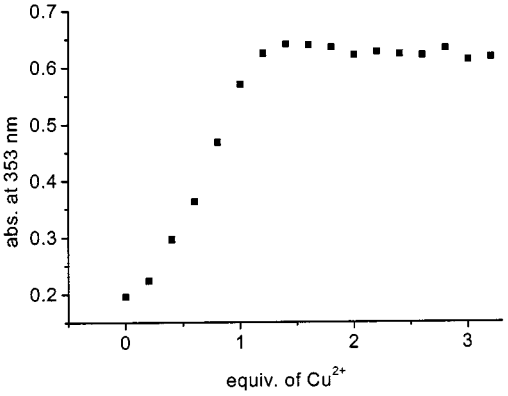

Figure 5. Increase of 353 nm absorbance on photometric titration of **7** ($5\cdot10^{-5}$ M) with copper(II) perchlorate solution; for conditions, refer to Figure 3

In a dichloromethane/acetonitrile (1:1) solution in the absence of DMSO, the lack of an isosbestic point for the titration 0 → 1 equiv. of Cu suggests the formation of an intermediate species when the ligand is present in excess {possibly formed by coordination of free ligand pyridyl groups to axial sites in [Cu(**1**,**7**)]; such species may not be stable in competitive solvents such as DMSO}. In clear contrast to the titrations shown in Figure 2 and Figure 3, the spectrum changes significantly when > 1 equiv. of Cu^{2+} is added and a rather sharp end point is seen after the addition of 3 equiv. of Cu (no further changes beyond 3 equiv. of Cu). For simplicity, Figure 6 shows selected spectra of free ligand **1** and at 1:1, 2:1, 3:1, and 4:1 Cu/**1** ratios.

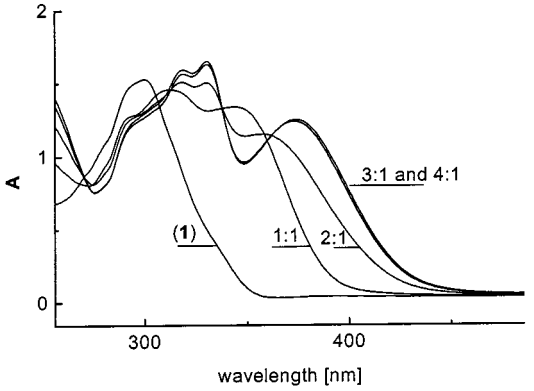

Figure 6. Spectrophotometric titration of **1** with copper(II) perchlorate in CH_3CN/CH_2Cl_2 (1:1) at 20 °C from 0−4 equiv. (spectra correspond to addition of Cu in 1-equiv. steps)

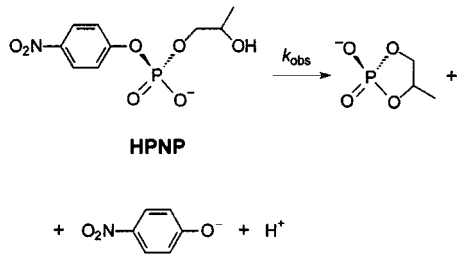
Very similar behaviour is observed for the Cu complexes of **7**, with the trinuclear complex showing nearly identical absorbance maxima.

Since catalytic studies (see below) are performed in buffered water/DMSO (3:1) mixtures, we tried to explore the formation of [(**1**)Cu] complexes under these conditions. The spectrum of [(**1**)Cu]$(ClO_4)_2$ is very similar to that observed in CH_2Cl_2/MeCN (1:1). On addition of Cu^{2+}, only subtle spectral changes are observed, polynuclear complexes apparently being much less stable than in the CH_2Cl_2/MeCN medium.

Interestingly, the spectral changes are qualitatively the same as those seen in CH_2Cl_2/CH_3CN (Figure 6), i.e. an increase in the absorbance maximum at 320 nm (Figure 6: 320 and 340 nm), an isosbestic point at 340 nm (Figure 6: 340 nm), a decrease in the absorbance at 350 nm, an isosbestic point at 370 nm (Figure 6: 360 nm, not sharp), and an increase in the absorbance at 390 nm (Figure 6: maximum at 375 nm).

By comparison with the spectra in Figure 6, we estimated that a maximum of 5% of the polynuclear complex was present after addition of 5 equiv. of Cu^{2+} under the conditions of Figure 7 (HPNP was replaced by the less reactive dimethyl phosphate).

We have examined the reactivity of in situ prepared polynuclear copper(II) complexes of **1** and **7** toward the phosphodiester 2-hydroxypropyl *p*-nitrophenyl phosphate (HPNP), an RNA analogue which is widely used to examine phosphoesterase activity of metal complexes. Intramolecular cyclization of this phosphodiester is easily followed photometrically by monitoring the 400 nm absorbance of the released nitrophenolate (Scheme 6).



Scheme 6. Intramolecular cleavage of the phosphodiester 2-hydroxypropyl *p*-nitrophenyl phosphate (HPNP)

Kinetic studies were performed at varying Cu^{2+} concentrations in a buffered water/DMSO (3:1) mixture at pH = 7.0, with 10^{-4} M ligand **1** or **7** and $5\cdot10^{-4}$ M HPNP (these conditions were used to allow direct comparison with previously reported kinetic studies on the complexes shown in Scheme 1).

As expected, the 1:1 complexes were found to be practically ineffective in HPNP cleavage. However, the rate increases dramatically when polynuclear complexes are formed upon addition of Cu^{2+}. The profiles in Figure 7 are consistent with our spectrophotometric observations. The concentration of the reactive polynuclear species would seem to increase linearly with Cu^{2+} concentration. This indicates that the bidentate sites of [(**1**)Cu]$^{2+}$ are far from being saturated with metal ions and that the polynuclear complex must be present in low concentration.

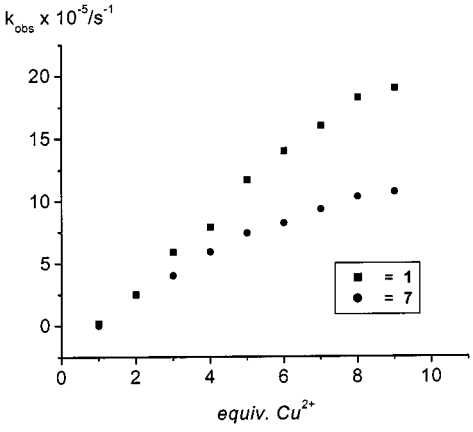


Figure 7. k_{obs} for cleavage of HPNP ($5\cdot10^{-4}$ M) in solutions containing **1** (10^{-4} M) and **7** (10^{-4} M) and varying copper(II) nitrate concentrations; water/DMSO (3:1), pH = 7.0, buffer 5 mM 3-morpholinopropanesulfonic acid (MOPS), T = 20 °C; cleavage by free Cu^{2+} is negligible

This is consistent with our results obtained by photometric titration of [(**1**)Cu]$^{2+}$ with Cu^{2+} in water/DMSO (3:1). In analogy with our previous work on LCu complexes (L = ligand shown in Scheme 1), we suggest that the reactive spe-

cies is a trinuclear complex. Under the conditions of Figure 7, a trinuclear Cu complex of L (Scheme 1) forms quantitatively with a slight excess of Cu and cleaves HPNP with $k_{obs} = 27 \cdot 10^{-5}$ s^{-1}.[4] Given that complexes $[(\mathbf{1})Cu_3]^{6+}$ and $[(\mathbf{7})Cu_3]^{6+}$ are the reactive species and are present only in low concentration, they must be even more reactive than $[LCu_3]^{5+}$ (L = ligand shown in Scheme 1). It is unlikely that a dinuclear complex $[(\mathbf{1}, \mathbf{7})Cu_2]^{4+}$ is the reactive species since the in situ prepared dinuclear Cu^{2+} complex of 4,6-di(2-pyridyl)pyrimidine (which compares to the aforementioned dinuclear complex with bridging pyrimidine) cleaves HPNP only with $k_{obs} = 8 \cdot 10^{-6}$ s^{-1} under the conditions of Figure 7.

The higher tendency of complex LCu (Scheme 1) to bind additional Cu^{2+} ions might, in part, be a result of the negative charge of the ligand, which, to some extent, compensates the electrostatic repulsion between the metal ions in the polynuclear complexes. It is evident from Figure 7 that the reactive Cu^{2+} species of **1** and **7**, presumably the trinuclear complexes, show different reactivity towards HPNP. In the presence of nine equivalents of Cu^{2+}, the complex of **1** is more efficient by a factor of 1.7. Thus, the spacer group (S or Se) clearly influences the catalytic activity of the complexes. In principle, variation of both the spacer groups X and the metal ion M (Scheme 2) promises to offer a versatile approach for fine-tuning the preorganization of two bipyridine-like chelating units and of their coordinated metal ions. Unfortunately, in preliminary attempts to prepare heteronuclear Ni^{II}/Cu^{II} and Pd^{II}/Cu^{II} complexes, it became evident that Ni and Pd are displaced from the tetradentate site by Cu. This is in contrast to the previously reported complexes of L (L = ligand shown in Scheme 1), which are not susceptible to metal exchange.[4]

Experimental Section

General Remarks: Reagents were obtained from either Aldrich or Fluka and were used as received. 4-(6-Bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine was synthesized as described previously.[5] The barium(II) salt of 2-hydroxypropyl *p*-nitrophenyl phosphate was prepared by a reported method.[11] All reactions were carried out in dry solvents (HPLC grade) under nitrogen using Schlenk techniques. Workup was performed using technical grade solvents without protection from air. − Preparative column chromatography was carried out on Merck silica gel 60 (0.040−0.063 mm). Retention factors (R_f) were determined using Macherey−Nagel alumina TLC plates. − ^{1}H,^{13}C COSY and NOESY NMR spectra were recorded with Bruker AC-300 (300.13 MHz) and Bruker AC-400 (400.13 MHz) spectrometers; chemical shifts are reported in ppm. Tetramethylsilane was used as an internal standard. − IR spectra were obtained with a Perkin−Elmer 983 G spectrometer (samples in KBr pellets). − FD and EI mass spectra were recorded with a Finnigan MAT 8230 instrument. MALDI-TOF mass spectra were recorded with a Bruker Biflex TOF-MS spectrometer in negative or positive linear mode. − Elemental analyses were performed by the Microanalytisches Laboratorium des Organisch-Chemischen Instituts der Universität Heidelberg and by the Microanalytisches Laboratorium des Instituts für Anorganische und Analytische Chemie der Universität Mainz.

Ligand Syntheses

Bis{6-[6-(2-pyridyl)-4-pyrimidinyl]-2-pyridyl} Sulfide (1): This ligand was prepared as outlined in Scheme 3. A solution of $Na_2S \cdot 10H_2O$ (2.1 g, 8.1 mmol) in DMF (10 mL) was added to a stirred solution of 4-(6-bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine (1.7 g, 5.4 mmol) in DMF (20 mL). The reaction mixture was stirred for 7 h at 90−100 °C, then allowed to cool, and kept at room temperature for 12 h. The white-yellow precipitate was collected by filtration, washed with DMF (15 mL), and dried in vacuo for 24 h (0.01 mbar). Water (100 mL) was added to the residue, and the product was extracted with chloroform (3 × 100 mL). The combined chloroform extracts were dried with $MgSO_4$, filtered, and concentrated to dryness, and the residue was dried in vacuo for 6 h. Yield: 0.8 g (30%), $R_f = 0.56$ (acetone/hexane, 3:7). − $C_{28}H_{18}N_8S$ (498.56): calcd. C 67.46, H 3.64, N 22.48, S 6.43; found C 67.21, H 3.61, N 22.32, S 5.99. − IR (KBr): $\tilde{\nu}$ [ν(S−R)] = 1100 cm^{-1} s. − ^{1}H NMR ($CDCl_3$): δ = 7.41 (ddd, 1 H, $J_{5,4}$ = 7.6 Hz, $J_{5,6}$ = 4.8 Hz, $J_{5,3}$ = 1.4 Hz, Py-5), 7.74 (dd, 1 H, $J_{5,4}$ = 7.8 Hz, $J_{5,3}$ = 0.9 Hz, Py′-5), 7.85 (td, $J_{4,5}$ = 7.8 Hz, $J_{4,3}$ = 7.8 Hz, Py-4), 7.91 (t, $J_{4,5}$ = 7.8 Hz, $J_{4,3}$ = 7.8 Hz, 1 H, Py′-4), 8.42 (dt, $J_{3,4}$ = 7.8 Hz, $J_{3,5}$ = 1.0 Hz, 1 H, Py-3), 8.46 (dd, $J_{3,4}$ = 7.8 Hz, $J_{3,5}$ = 1.0 Hz, 1 H, Py′-3), 8.75 (dq, $J_{6,5}$ = 4.8 Hz, $J_{6,4}$ = 0.9 Hz, 1 H, Py-6), 9.21 (d, $J_{2,5}$ = 1.4 Hz, 1 H, Pym-5), 9.314 (d, $J_{2,5}$ = 1.3 Hz, 1 H, Pym-2). − MS (FD); *m*/*z* (%): 498.2 (100) [M$^+$].

1,2-Bis{6-[6-(2-pyridyl)-4-pyrimidinyl]-2-pyridyl} Disulfide (2): A solution of $Na_2S \cdot 10H_2O$ (1.6 g, 6.5 mmol) in DMF (10 mL) was added to a stirred solution of 4-(6-bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine (0.39 g, 1.3 mmol) in DMF (30 mL). The reaction mixture was stirred for 12 h at 90−100 °C, then allowed to cool, and kept at room temperature for 12 h. The solvent was evaporated at 50 °C in a rotary evaporator. Water (100 mL) was then added and the by-products **1**, **3**, and **4** were extracted from the resulting suspension with chloroform (3 × 200 mL). The aqueous phase was treated with acetic acid (10 mL) and the solution was stirred for 1 h. The product **2** was then extracted with chloroform (3 × 200 mL). The combined chloroform extracts were dried with $MgSO_4$, filtered, and concentrated to dryness. Yield: 70 mg (10%). − $C_{28}H_{18}N_8S_2$ (530.62): calcd. C 63.38, H 3.42, N 21.12, S 12.08; found C 64.11, H 3.01, N 20.82, S 11.89. − IR (KBr): $\tilde{\nu}$ [ν(R−S)] = 1093 cm^{-1} s. − ^{1}H NMR ([D$_6$]DMSO): δ = 7.02 (t, $J_{4,5}$ = 7.8 Hz, Py-5), 7.98 (dd, $J_{4,5}$ = 7.8 Hz, $J_{3,5}$ = 0.9 Hz, 1 H, Py-4), 8.00 (td, $J_{4,5}$ = 7.8 Hz, $J_{3,5}$ = 7.8 Hz, 1 H, Py′-4), 8.08 (t, $J_{4,5}$ = 7.8 Hz, 1 H, Py′-3), 8.35 (d, $J_{4,5}$ = 1.3 Hz, 1 H, Py′-5), 8.45 (dd, $J_{4,3}$ = 7.8 Hz, $J_{3,5}$ = 1.0 Hz, 1 H, Py-3), 8.70 (dq, $J_{6,5}$ = 4.7 Hz, $J_{4,6}$ = 0.8 Hz, 1 H, Py-6), 9.15 (s, 1 H, Pym-5), 9.35 (s, 1 H, Pym-2). − MS (FD); *m*/*z* (%): 530.4 (100) [M$^+$].

4-[6-(2-Pyridyl)-2-pyridyl]-6-(2-pyridyl)pyrimidine (4): A solution of $Na_2S \cdot 10H_2O$ (0.57 g, 2.3 mmol) in pyridine (10 mL) was added to a stirred solution of 4-(6-bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine (0.7 g, 2.3 mmol) in pyridine (20 mL). The reaction mixture was stirred for 12 h at 90−100 °C, then allowed to cool, and kept at room temperature for 12 h. The solvent was evaporated at 50 °C in a rotary evaporator. Water (100 mL) was then added and **1**, **3**, and **4** were extracted from the resulting suspension with chloroform (3 × 200 mL). The combined chloroform extracts were dried with $MgSO_4$, filtered, and concentrated to dryness. The mixture of products **1**, **3**, and **4** was separated by column chromatography using 10% acetone in hexane as eluent. − 1st fraction: **3**, yield 0.18 g (42%), $R_f = 0.75$ (acetone/hexane, 3:7). − $C_{14}H_{10}N_4$ (234.26): calcd. C 71.78, H 4.30, N 23.92; found C 71.83, H 4.31, N 23.70. − ^{1}H NMR ([D$_6$]DMSO): δ = 7.43 (ddd, 2 H, $J_{3,5}$ = 1.1 Hz, $J_{4,5}$ = 7.8 Hz, $J_{5,6}$ = 4.8 Hz, Py-5), 7.89 (td, 2 H, $J_{3,4}$ = 7.8 Hz, $J_{4,6}$ =

1.2 Hz, Py-4), 8.52 (dt, 2 H, Py-3), 8.80 (ddd, 2 H, Py-6), 9.36 (d, 2 H, $J_{2,5}$ = 1.1 Hz, Pym-5), 9.39 (d, 2 H, Pym-2). − MS (FD); *m/z* (%): 234.3 (100) [M^+]. The data are identical to those reported in the literature.[10] − 2nd fraction: **4**, yield 0.2 g (35%), R_f = 0.68 (acetone/hexane, 3:7). − ^{1}H NMR ([D$_6$]acetone): δ = 7.37 (dd, *J* = 8.3 Hz, *J* = 5.0 Hz, 1 H), 7.45 (dd, *J* = 8.3 Hz, *J* = 5.0 Hz, 1 H), 7.97 (m, 2 H), 8.03 (t, *J* = 8.3 Hz, 1 H), 8.564 (m, 3 H), 8.72 (d, *J* = 1.3 Hz, 1 H), 8.75 (d, *J* = 1.4 Hz, 1 H), 8.84 (d, *J* = 1.3 Hz, 1 H), 9.38 (s, 1 H, Pym-5), 9.51 (s, 1 H, Pym-2). − MS (FD); *m/z* (%): 311.4 (100) [M^+]. − 3rd fraction: **1**, R_f = 0.56 (acetone/hexane, 3:7).

Methyl 6-[6-(2-Pyridyl)-4-pyrimidinyl]-2-pyridyl Selenide (5): A solution of CH_3Li (1.6 M in Et_2O, 2.5 mL, 4 mmol) was added dropwise to a suspension of selenium (316 mg, 4 mmol) in absolute THF (25 mL) and stirring was continued for a further 30 min. The clear solution thus obtained was added dropwise to a solution of 4-(6-bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine (1.25 g, 4 mmol) in absolute DMF (25 mL) and the resulting mixture was stirred for 15 min. The THF was then evaporated under high vacuum (0.01 mbar, 40 °C, 10 min) and the remaining DMF solution was stirred for 2.5 h at 70 °C and then cooled to room temperature. Water (200 mL) was added and the mixture was stirred for a further 12 h. The yellow precipitate formed was collected by filtration, recrystallized from chloroform, and purified by column chromatography eluting with MeOH/CH_2Cl_2 (1:100). Yield: 0.53 g (37%), R_f = 0.58 (hexane/acetone, 6:4). − $C_{15}H_{12}N_4Se$·MeOH (359.29): calcd. C 53.49, H 4.49, N 15.59; found C 52.16, H 4.38, N 14.73. − ^{1}H NMR ($CDCl_3$) δ = 2.64 (3 H, $SeCH_3$, *J* = 11.5 Hz), 7.43 (ddd, 1 H, $J_{4,5}$ = 7.8 Hz, $J_{5,6}$ = 4.8 Hz, $J_{3,5}$ = 0.9 Hz, Py-5), 7.43 [dd, 1 H, $J_{4,5}$ = 7.8 Hz, $J_{3,5}$ = 0.9 Hz, Py′-5 (?)],7.63 (t, 1 H, $J_{3,4}$ = 7.8 Hz, Py′-4), 7.89 (td, 1 H, $J_{3,4}$ = 7.8 Hz, $J_{4,6}$ = 1.9 Hz, Py-4), 8.25 [dd, 1 H, $J_{3,4}$ = 7.8 Hz, $J_{3,5}$ = 0.9 Hz, Py′-3 (?)], 8.50 (dt, 1 H, $J_{3,4}$ = 7.8 Hz, $J_{3,5}$ = 0.9 Hz, Py-3), 8.80 (dq, 1 H, $J_{5,6}$ = 4.6 Hz, $J_{4,6}$ = 0.9 Hz, Py-6), 9.33 (d, 1 H, $J_{2,5}$ = 1.3 Hz, Pym-2), 9.37 (d, 1 H, $J_{2,5}$ = 1.3 Hz, Pym-5). − MS (FAB+); *m/z* (%): 327.1 (40) [M^+ + H] with ^{78}Se, 329.1 (70) [M^+ + H] with ^{80}Se.

1,2-Bis{6-[6-(2-pyridyl)-4-pyrimidinyl]-2-pyridyl} Diselenide (6): The reaction was carried out in a similar fashion as described for **5**, but using a higher CH_3Li/Se to 4-(6-bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine ratio. Thus, a solution of CH_3Li (1.6 M in Et_2O, 5 mL, 8 mmol) was added dropwise to a suspension of selenium (632 mg, 8 mmol) in absolute THF (25 mL) and stirring was continued for a further 30 min. The resulting solution was added dropwise to a solution of 4-(6-bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine (1.25 g, 4 mmol) in absolute DMF (25 mL) and stirring was continued for 15 min. The THF was then evaporated under high vacuum (0.01 mbar, 40 °C, 10 min) and the remaining DMF solution was stirred for 2.5 h at 70 °C and then cooled to room temperature. Water (200 mL) was added and the mixture was stirred for a further 12 h. The yellow precipitate formed was collected by filtration, recrystallized from chloroform, and purified by column chromatography eluting with MeOH/CH_2Cl_2 (1:100). Yield: 0.69 g (27%), R_f = 0.46 (hexane/acetone, 6:4). − $C_{28}H_{18}N_8Se_2$·0.5 MeOH (640.44): calcd. C 53.45, H 3.15, N 17.50; found C 53.52, H 3.20, N 17.40. − ^{1}H NMR ($CDCl_3$): δ = 7.44 (ddd, 1 H, $J_{4,5}$ = 7.8 Hz, $J_{5,6}$ = 3.7 Hz, $J_{3,5}$ = 1.1 Hz, Py-5), 7.76 (t, 1 H, $J_{3,4}$ = 7.7 Hz, Py′-4), 7.90 (td, 1 H, $J_{3,4}$ = 7.7 Hz, $J_{4,6}$ = 1.8 Hz, Py-4), 8.02 [dd, 1 H, $J_{4,5}$ = 7.7 Hz, $J_{3,5}$ = 0.7 Hz, Py′-5 (?)], 8.32 [dd, 1 H, $J_{3,4}$ = 7.8 Hz, $J_{3,5}$ = 1.1 Hz, Py′-3 (?)], 8.50 (dt, 1 H, $J_{3,4}$ = 7.8 Hz, $J_{3,5}$ = 1.4 Hz, Py-3), 8.80 (dq, 1 H, $J_{5,6}$ = 3.7 Hz, $J_{4,6}$ = 0.8 Hz, Py-6), 9.34 (d, 1 H, $J_{2,5}$ = 1.3 Hz, Pym-2), 9.34 (d, 1 H, $J_{2,5}$ = 1.3 Hz, Pym-5). − MS (FAB+); *m/z* (%): 627.1 (40) [M^+ + H] with 2 × ^{80}Se, 625.1 (37) [M^+ + H] with ^{78}Se and ^{80}Se, 623.1 (22) [M^+ + H] with 2 × ^{78}Se. − MS (EI); *m/z*: 546.2 (100) [M^+ − Se] with ^{80}Se remaining, 544.2 (54) [M^+ − Se] with ^{78}Se remaining.

Bis{6-[6-(2-pyridyl)-4-pyrimidinyl]-2-pyridyl)} Selenide (7): According to a procedure for the preparation of bis(2-pyridyl) selenide,[12] a solution of methyl 6-[6-(2-pyridyl)-4-pyrimidinyl]-2-pyridyl selenide (**5**) (300 mg, 0.92 mmol) in hexamethylphosphortriamide (HMPA) (10 mL) was heated with small pieces of sodium (42 mg, 1.83 mmol) at 100 °C for 1.5 h. A solution of 4-(6-bromo-2-pyridyl)-6-(2-pyridyl)pyrimidine (288 mg, 0.92 mmol) in HMPA (10 mL) was then added dropwise. The red mixture was heated for 2.5 h at 120 °C. After cooling to room temperature, it was poured into cold water (100 mL) and the resulting suspension was stirred for 4 h. The brown precipitate formed was collected by filtration, washed with diethyl ether, and purified by column chromatography on SiO_2 eluting first with MeOH/CH_2Cl_2 (1:100) and then with pure $CHCl_3$. Yield 0.11 g (21%), R_f = 0.48 (hexane/acetone, 6:4). − $C_{28}H_{18}N_8Se$·MeOH (577.50): calcd. C 60.31, H 3.84, N 19.40; found C 61.13, H 3.98, N 18.13. − ^{1}H NMR ($CDCl_3$): δ = 7.47 (1 H, Py-5), 7.83 (2 H, Py-4, Py′-5), 7.92 (1 H, Py′-4), 8.44 (2 H, Py-3, Py′-3), 8.80 (1 H, Py-6), 9.25 (1 H, Pym-2), 9.33 (1 H, Pym-5). − MS (FAB$^+$); *m/z* (%): 547.2 (25) [M^+ + H] with ^{80}Se, 545.2 (15) [M^+ + H] with ^{78}Se.

Synthesis of the Complexes

[Cu(1)](NO$_3$)$_2$·5H$_2$O: To a stirred solution of **1** (12 mg, 0.024 mmol) in chloroform/methanol (1:3; 1 mL) was added a solution of $Cu(NO_3)_2$·3H_2O (6 mg, 0.024 mmol) in methanol (3 mL). The clear green solution thus obtained was stirred for 10 min at room temperature. After 1 h, diethyl ether (10 mL) was added, and the green precipitate formed was centrifuged off and dried under high vacuum for 6 h. Yield: 10 mg (54%). − $C_{28}H_{28}CuN_{10}O_{11}S$ (776.20): calcd. C 43.33, H 3.64, N 18.05; found C 42.75, H 3.38, N 18.11. − MS (MALDI); *m/z* (%): 561.5 (100) [^{63}Cu(**1**)]$^+$, 563.5 (54) [^{65}Cu(**1**)]$^+$, 596.5 (7) [^{63}Cu(**1**)(OH)]$^+$, 598.5 (6) [^{65}Cu(**1**)(OH)]$^+$.

[Cu(7)](ClO$_4$)$_2$·6H$_2$O: To a stirred solution of **7** (12 mg, 0.02 mmol) in chloroform (1 mL) was added a solution of $Cu(ClO_4)_2$·6H_2O (7.4 mg, 0.02 mmol) in acetonitrile (2 mL). The resulting mixture was stirred for 3 h at room temperature. The green precipitate formed was centrifuged off, washed with diethyl ether (10 mL), and dried under high vacuum for 4 h. Yield: 6.3 mg (38%). − $C_{28}H_{18}CuCl_2N_8O_8Se$·6$H_2O$ (915.91 g/mol): calcd. C 36.71, H 3.30, N 12.23; found C 35.68, H 2.99, N 10.92. − MS (MALDI); *m/z* (%): 607.2 (55) [^{63}Cu(**7**)]$^+$ with ^{78}Se, 609.2 (100) [^{63}Cu(**7**)]$^+$ with ^{80}Se, [^{65}Cu(**7**)]$^+$ with ^{78}Se, 611.2 (50) [^{65}Cu(**7**)]$^+$ with ^{80}Se.

[Zn(6)](CH$_3$COO)$_2$·CHCl$_3$·CH$_3$CN: A solution of 1,2-bis{6-[6-(2-pyridyl)-4-pyrimidinyl]-2-pyridyl} diselenide (**6**) (12 mg, 0.02 mmol) in chloroform (1.5 mL) was added dropwise to a stirred solution of $Zn(CH_3COO)_2$·2H_2O (4.4 mg, 0.02 mmol) in acetonitrile (2 mL).[13] After stirring for 3 h, a precipitate had formed, which was collected by filtration, washed with diethyl ether (2 × 5 mL), and dried in vacuo. Yield 8.4 mg (44%). − $C_{32}H_{24}N_8O_4Se_2Zn$·$CHCl_3$·CH_3CN (968.32): calcd. C 43.41, H 2.91, N 13.02; found C 42.08, H 3.00, N 12.73. − ^{1}H NMR ($CDCl_3$): δ = 1.90 (3 H, CH_3CN), 2.05 (6 H, CH_3COO), 7.53 (2 H, Py-5), 7.77 (2 H, Py′-4), 7.98 [4 H, Py-4 (?), Py′-5 (?)], 8.35 [4 H, Py-3 (?), Py′-3 (?)], 8.87 (2 H, Py-6), 9.21 (2 H, Pym-5), 9.43 (2 H, Pym-2). − MS (MALDI); *m/z* (%): 684.9 (66) [^{64}Zn(**6**)]$^+$ with 2 × ^{78}Se, 686.9 (91) [^{66}Zn(**6**)]$^+$ with 2 × ^{78}Se, [^{64}Zn(**6**)]$^+$ with 1 ×

^{78}Se and 1 × ^{80}Se, 688.9 (100) [^{66}Zn(**6**)]$^+$ with 1 × ^{78}Se and 1 × ^{80}Se, [^{64}Zn(**6**)]$^+$ with 2 × ^{80}Se, 690.9 (52) [^{66}Zn(**6**)]$^+$ with 2 × ^{80}Se.

Spectrophotometric Titrations: Stock solutions of **1** and **7** (10^{-3} M) were prepared in either DMSO (Figure 2, 3, 4, and 5) or CH_2Cl_2/CH_3CN (1:1) (Figure 6). These stock solutions were diluted with a CH_3CN/CH_2Cl_2 (1:1) mixture, and then the requisite amount of DMSO was added (5% v/v). The final ligand concentration in each case was $5\cdot10^{-5}$ M. Titrations were performed by addition of appropriate amounts of a $Cu(NO_3)_2\cdot3H_2O$ stock solution ($5\cdot10^{-4}$ M in CH_3CN). About 30 s after the addition of the copper salt, UV/Vis spectra were recorded at 25 °C. No further spectral changes with time were detectable on prolonged standing of the solutions.

Kinetics: Reaction solutions were prepared by combining appropriate amounts of the ligands **1** or **7** ($5\cdot10^{-4}$ M stock solutions in DMSO), $Cu(NO_3)_2\cdot3H_2O$ (2 mM stock solution in DMSO), the buffer 3-morpholinopropanesulfonic acid (MOPS) (0.5 M stock solution in H_2O, pH = 7.0), and water or DMSO solvent. Solutions were left to stand for 2 h. The reactions were initiated by addition of the substrate, 2-hydroxypropyl-*p*-nitrophenolphosphate (HPNP, 5 mM stock solution in H_2O). For the experiments summarized in Figure 7, the final concentrations in the reaction mixtures were 0.1 mM **1** or **7**, 0.5 mM HPNP, and 5 mM MOPS buffer in water/DMSO (3:1); the concentration of $Cu(NO_3)_2$ was varied from 0 to 1 mM. Transesterification of HPNP was followed spectrophotometrically by monitoring the release of *p*-nitrophenolate at 400 nm (ε = 18600 μ^{-1} cm^{-1}), considering the equilibrium *p*-nitrophenol/*p*-nitrophenolate at pH = 7.0 (pK_a = 7.15). The pseudo-first-order rate constants k_{obs} were determined from the initial rate of the reaction (< 5% conversion). All reported data are average values of at least three measurements (reproducibility within ± 15%). Measurements were made with a Carl-Zeiss-Technology Specord S 100 spectrophotometer at 20 °C.

X-ray Crystallographic Study of 4: Crystal data and details of the structure determination are listed in Table 2. Intensity data were collected at 173 K with a Bruker AXS CCD Smart 1000 diffractometer (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, ω scan). The structure was solved by direct methods and refined by least-squares methods based on F^2 with all measured reflections.[14] All non-hydrogen atoms were refined anisotropically; hydrogen atoms were placed in ideal positions and refined isotropically. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication number CCDC-149055. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.uk].

Kinetics and Mechanism of Water Substitution at Half-Sandwich Iridium(III) Aqua Cations $Cp^*Ir(A-B)(H_2O)^{2+/+}$ in Aqueous Solution (Cp^* = η^5-Pentamethylcyclopentadienyl Anion; A−B = Bidentate N,N or N,O Ligand)

Tilo Poth,[a] Helmut Paulus,[c] Horst Elias,*[a] Carlos Dücker-Benfer,[b] and Rudi van Eldik[b]

Keywords: Iridium / Sandwich complexes / Kinetics / N ligands / Reaction mechanisms

The perchlorate complexes of a series of half-sandwich monoaqua cations $Cp^*Ir(A–B)(H_2O)^{2+/+}$ with A–B = prol (D/L-proline anion), picac (picolinic acid anion), *R*,*R*-dach [(−)-(1*R*,2*R*)-1,2-diaminocyclohexane], *R*,*R*-dpen [(+)-(1*R*,2*R*)-1,2-diphenylethylenediamine], phen (*o*-phenanthroline), and bpy (2,2′-bipyridine) (Cp^* = η^5-pentamethylcyclopentadienyl anion) have been prepared and characterized. An X-ray structure analysis of $Cp^*Ir(R,R\text{-dach})(H_2O)(ClO_4)_2{\cdot}H_2O$ has revealed that the cation $Cp^*Ir(R,R\text{-dach})(H_2O)^{2+}$ has a distorted pseudo-octahedral coordination geometry. In the case of A–B = prol, crystallization from water led to the trinuclear complex $[Cp^*Ir(D\text{-prol})]_3(ClO_4)_3$, which has also been characterized by X-ray structure analysis. The experimental data suggest that in aqueous solution the trinuclear proline complex dissociates to form the cation $Cp^*Ir(D\text{-prol})(H_2O)^+$. The proton dissociation constants of the coordinated water in $Cp^*Ir(A–B)(H_2O)^{2+/+}$ have been determined as pK_a = 7.5 (A–B = bpy) and pK_a = 7.1 (A–B = *R*,*R*-dach and picac). Substitution of the water in $Cp^*Ir(A–B)(H_2O)^{2+/+}$ by the monodentate ligands L = py (pyridine), DMS (dimethyl sulfide), TU (thiourea), and monodentate anions according to the Equation $Cp^*Ir(A–B)(H_2O)^{2+/+} + L \rightarrow Cp^*Ir(A–B)L^{2+/+} + H_2O$ has been studied by multi-wavelength stopped-flow spectrophotometry in aqueous solution at I = 0.2 M. This kinetic investigation, carried out at different concentrations, temperatures, and pressures, showed that the process obeys second-order kinetics, where rate = $k_L[Cp^*Ir(A–B)H_2O^{2+/+}][L]$. The magnitude of the second-order rate constant k_L depends on the nature of both A–B and L. The data for k_L have been found to range from 6.4×10^4 $M^{-1}s^{-1}$ (A–B = D-prol; L = TU) to 10.5 $M^{-1}s^{-1}$ (A–B = bpy; L = py) at 298 K. The activation parameters for water substitution at $Cp^*Ir(A–B)(H_2O)^{2+/+}$ (A–B = bpy, *R*,*R*-dach, and picac) by L = TU have been evaluated. The activation volumes of $\Delta V^{\neq}$ = +2.3, +7.4, and +7.3 $cm^3\ mol^{-1}$, respectively, are supportive of an I_d mechanism. The results regarding the kinetic lability of the coordinated water in the monoaqua cations $Cp^*Ir(A–B)(H_2O)^{2+/+}$ are compared to those obtained for the triaqua cation $Cp^*Ir(H_2O)_3^{2+}$.

Introduction

The aqua cations $Cp^*Rh(H_2O)_3^{2+}$ and $Cp^*Ir(H_2O)_3^{2+}$ (**1**) belong to the small group of water-stable organometallic species in which water molecules and carbocyclic ligands, such as π-Cp* (= η^5-pentamethylcyclopentadienyl anion), are bound to the same metal centre.[1] There has been a wide spectrum of studies on the chemistry of these aqua cations, providing insight into the relatively new field of aqueous organometallic chemistry.[2−6]

Our interest in half-sandwich aqua cations lies mainly in their intriguing kinetic properties. The introduction of the Cp* group into the cation $Ir(H_2O)_6^{3+}$ leads to a dramatic increase of 14 orders of magnitude in the rate of water exchange, as described by rate constant k_{ex} in Equation (1), and in the rate of water substitution, as described by rate constant k_f in Equation (2) (L = monodentate ligand).[7−12]

$$Cp^*Ir(H_2O)_3^{2+} + H_2O^* \underset{}{\overset{k_{ex}}{\rightleftharpoons}} Cp^*Ir(H_2O)^*(H_2O)_2^{2+} + H_2O \quad (1)$$

$$Cp^*Ir(H_2O)_3^{2+} + L \underset{k_r}{\overset{k_f}{\rightleftharpoons}} Cp^*Ir(H_2O)_2L^{2+} + H_2O \quad (2)$$

Replacement of two of the coordinated water molecules in the cation **1** by bidentate ligands A−B generates the monoaqua species $Cp^*Ir(A-B)(H_2O)^{2+/+}$. The literature on such iridium compounds is still very limited,[13] but numerous examples of the monochloro analogues $Cp^*Ir(A-B)Cl^{+/0}$ have been described. These species have been found to be particularly effective as catalysts[14−19] and in the coordination of biologically important molecules.[20]

As an extension of our earlier work on the kinetics of Equations (1) and (2),[7,8] we now compare the labilizing effect of the Cp* group, as documented by the rate data available for Equations (1) and (2), with that of bidentate ligands A−B in the monoaqua species $Cp^*Ir(A-B)(H_2O)^{2+/+}$. The kinetics of water substitution according to Equation (3) have been studied in aqueous solution using a series of complexes $Cp^*Ir(A-B)(H_2O)^{2+/+}$

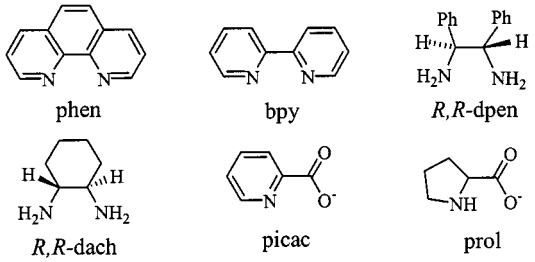
(**2**, **4**−**8**) containing neutral or anionic N,N and N,O ligands A−B (see Scheme 1). The incoming ligands L used in the study of the reaction according to Equation (3) have been either neutral species (py, py-nia, DMS, TU)[21] or anions (Br^-, I^-, SCN^-, N_3^-, NO_2^-).



Scheme 1. Bidentate ligands A−B coordinated in monoaqua complexes $Cp^*Ir(A-B)(H_2O)^{2+/+}$ and abbreviations[21]

$$Cp^*Ir(A\text{-}B)(H_2O)^{2+/+} + L \underset{k_{-L}}{\overset{k_L}{\rightleftharpoons}} Cp^*Ir(A\text{-}B)L^{2+/+} + H_2O \quad (3)$$

The present contribution summarizes the kinetic results obtained at various temperatures and pressures. We also present crystallographic data for the perchlorates of the cations $Cp^*Ir(R,R\text{-dach})(H_2O)^{2+}$ (**2**) and $[Cp^*Ir(prol)]_3^{3+}$ (**3**) (*R*,*R*-dach = 1,2-diaminocyclohexane; prol = anion of proline)[21] as well as acidity constants (pK_a) for the coordinated water in some of the mono aqua cations $Cp^*Ir(A-B)(H_2O)^{2+/+}$.

Results and Discussion

Properties of the Monoaqua Species $Cp^*Ir(A-B)(H_2O)^{2+/+}$

The UV spectra of aqueous solutions of the perchlorates of the cations $Cp^*Ir(A-B)(H_2O)^{2+/+}$ led to the absorption data listed in Table 2. The various cations absorb in the range 260−320 nm with absorptivities ε_{max} of the order of 10^3 $M^{-1}cm^{-1}$ in the case of aliphatic ligands A−B (dach, dpen, prol)[21] and 10^4 $M^{-1}cm^{-1}$ in the case of aromatic ligand systems (bpy, phen, picac).[21] In the case of the proline complex, the spectra were recorded using solutions of the trinuclear complex **3b**. However, the spectral data strongly suggest that the trinuclear complex dissociates to form the monoaqua cation $Cp^*Ir(\text{D-prol})(H_2O)^+$ (**4**). This follows from the fact that (i) the data for ε_{max}, when referenced to **4** instead of **3**, are close to those obtained for the other mono aqua species, and (ii) the data obtained for ε_{max} at pH = 2.0, 4.8, and 6.0 are identical.

Table 2. UV absorption {λ_{max} [nm] (ε_{max} [$M^{-1}cm^{-1}$])} of the cations $Cp^*Ir(A-B)(H_2O)^{2+/+}$ in aqueous solution at pH = 2.0 and 293 K

5 (A−B = bpy)	243 (15500), 308 (13500), 317 (13400)
8 (A−B = phen)	298 (4990), 276 (16100), 218 (13200), 201 (16500)
2 (A−B = *R*,*R*-dach)	269 (2070), 302 (1660)
7 (A−B = *R*,*R*-dpen)	265 (1690), 298 (1080)
4 (A−B = D-prol)	282 (1160), 300 (1150)[a][b]
6 (A−B = picac)	311 (4740), 260 (10600)

[a] The data obtained at pH = 6 are identical to those obtained at pH = 2.0. − [b] The values of λ_{max} and ε_{max} refer to 1 mol of **4**, not to 1 mol of **3**.

The spectral changes associated with substitution reaction according to Equation (3) are sufficient to allow reliable spectrophotometric monitoring. As an example, Figure 1 shows a series of spectra describing the reaction of **2** with bromide ions according to Equation (3). The existence of two sharp isosbestic points (at 257 nm and 267 nm) indicates that the reaction does not involve substantial concentrations of intermediates.

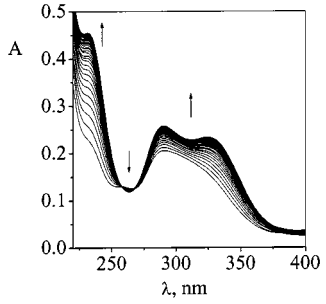


Figure 1. Spectral changes recorded for the reaction of **2** with bromide ions according to Equation (3) within 1.2 s {$[complex]_o$ = 1.0×10^{-4} M, $[Br^-]_o$ = 1.0×10^{-3} M; pH = 2.0 ($HClO_4$), I = 0.2 M ($NaClO_4$), 298 K}

It is well documented that, due to proton dissociation from coordinated water, aqueous solutions of the triaqua iridium species **1** are acidic.[9] For comparison purposes, the acid dissociation of some of the monoaqua species $Cp^*Ir(A-B)(H_2O)^{2+/+}$ according to Equation (4) was therefore investigated by means of spectrophotometric titrations. The pK_a values presented in Table 3 show that (i) the effect of the nature of the bidentate ligand A−B and of the overall charge of the cation on the pK_a is very minor, and (ii) the dissociation constant K_a of the monoaqua species is more than three orders of magnitude smaller than that of the triaqua species **1**. The chelate ligands A−B presumably reduce the electrophilicity of the Ir^{III} centre, such that less electron density is donated by the water oxygen atom. The coordinated water molecule thus becomes a weaker acid.

At pH ≤ 5, the formation of monohydroxo species Cp*Ir(A−B)$(OH)^{+/0}$ can be neglected.

$$Cp^*Ir(A\text{-}B)(H_2O)^{2+/+} \overset{K_a}{\rightleftharpoons} Cp^*Ir(A\text{-}B)(HO)^{+/0} + H^+ \quad (4)$$

Structures of the Complexes 2b and 3b

To the best of our knowledge, **2b** represents the first structurally characterized monoaqua half-sandwich iridium Cp* complex of the type Cp*Ir(A−B)$(H_2O)^{2+}$. As shown in Figure 2, the coordination geometry of the cation **2** is of the "three-legged piano stool" type[22] and can be classified as pseudo-octahedral. The perchlorate ions are disordered and the single water molecule of crystallization is far away from the coordination sphere of the iridium centre.

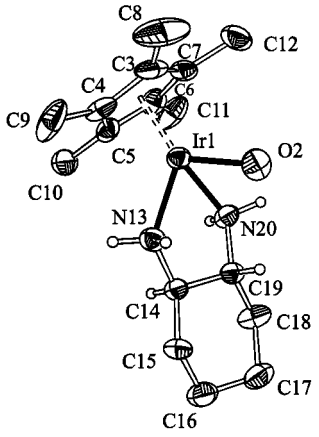

Figure 2. Molecular structure of the cation **2** with thermal ellipsoids drawn at a 30% probability level; most of the hydrogen atoms have been omitted for the sake of clarity

The crystal contains two crystallographically distinct units of **2**. The difference is small and is manifested, for example, in the relative positions of the Cp* and cyclohexane rings. In unit I, the angle between the plane of the Cp* ring and the plane formed by the donor atoms N13, N20, and O2 amounts to 2.7°. In unit II, this angle is found to be just 1.0°.

The bond lengths N13−Ir1 (2.127 Å) and N20−Ir1 (2.130 Å) are very similar (see Table 4), while the bond length O2−Ir1 is slightly longer (2.18 Å). The Ir−OH_2 bond length of 2.18 Å is significantly longer than those reported for other Ir^{III} aqua complexes, which range from 2.057 Å for oxo-bridged trinuclear iridium hexacarboxylate complexes to 2.074 Å for hydroxo-bridged bis(ethylenediamine)iridium complexes.[23,24] This ground-state bond lengthening must be due to the *trans* influence of the Cp* ligand and may account for the high lability of the coordinated water molecule. Ir−O distances in the even more labile cation **1** (longest distance 2.27 Å[6]) are in line with this conclusion. By comparison, the water exchange at $Ir(H_2O)_6^{3+}$ is 10^{14} times slower than that at **1**.[7,10] The bond angles N20−Ir1−N13, N20−Ir1−O2, and N13−Ir1−O2 in **2** are close to 80°, which indicates the deviation from ideal octahedral geometry of 90°. The iridium atom is a centre of asymmetry, but the C_2 symmetry of the ligand *R*,*R*-dach brings about a definite, nonracemic configuration.

		C(7)−Ir(1)−C(3)	38.9(5)

[a] The position X1a corresponds to the center of the Cp* ring.

While this work was being carried out, a series of complexes containing trinuclear units $[Cp^*M(aa)]_3^{3+}$ (M = Rh, Ir; aa = amino acid anion) was reported.[3,15,25] All of these complexes were obtained by crystallization from methanol. With regard to aqueous solutions, the possibility of trimer dissociation and the formation of mononuclear $Cp^*M(aa)(H_2O)^+$ units has yet to be fully explored.

In the presence of perchlorate ions, crystallization from an acidic aqueous solution of the cation **4** leads to yellow prisms, which are structurally composed of trinuclear units **3** with C_3 symmetry (see Figure 3). The structural backbone of these units is a 12-membered metallacycle, consisting of three iridium atoms and three doubly *O*-bonded carboxylate groups. The pseudo-octahedral coordination sphere about each iridium atom is made up by the η^5-bound Cp* ring, one *N*,*O*-bound proline, and another *O*-bound proline. As shown in Table 5, the Ir1−O18 bond to the *N*,*O*-bound proline (2.138 Å) is slightly longer than the Ir1−O19A bond to the singly coordinated neighbouring proline (2.108 Å).

The trinuclear unit 3 possesses 3 × 3 chiral centres (Ir, N, α-C) and the diastereomer within the crystal has to be described as ($R_CR_CR_C$,$R_NR_NR_N$,$R_{Ir}R_{Ir}R_{Ir}$)-**3b**. The unit is the mirror image of the (all-*S*)-configured analogue reported by Beck and co-workers.[26] The chirality at the metal centre is determined by the configuration of the

asymmetric carbon atom, making the complex an example of chiral self-recognition.

Kinetics of Water Substitution

A kinetic investigation of water substitution according to Equation (3) was undertaken to study the reactivity and mechanistic behaviour of the coordinated water in the monoaqua species $Cp^*Ir(A-B)(H_2O)^{2+/+}$ and to compare it with that in the triaqua species **1**. We recently reported that water substitution at the triaqua species follows an I_d mechanism[21] with the rate of substitution being close to the rate of water exchange.[9] For a variety of $Cp^*Ir(A-B)(H_2O)^{2+/+}$/L systems, systematic variation of A−B (with L = constant) and of L (with A−B = constant) was carried out to obtain detailed information on the effect of the bidentate ligands A−B on the kinetics and mechanism of the reaction according to Equation (3).

Water Substitution in Complexes $Cp^*Ir(A-B)(H_2O)^{2+/+}$ by Pyridine

In a series of experiments, water substitution in six monoaqua $Cp^*Ir(A-B)(H_2O)^{2+/+}$ complexes by pyridine was investigated at pH = 2.0 and 4.8. These substitution reactions were expected to be second-order processes. Accordingly, under pseudo-first-order conditions the change of absorbance with time was found to be monophasic and exponential. Fitting of Equation (5) to the (A,t) data led to the observed rate constant k_{obsd} (ΔA = amplitude). As an example, Figure 4a shows the dependence of k_{obsd} on $[py]_{tot}$ for the system **4**/py.

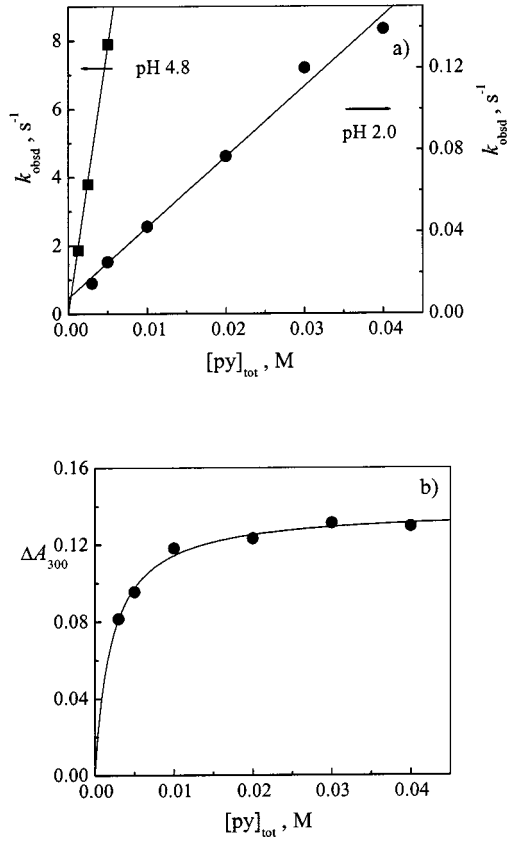

Figure 4. Dependence of the kinetic parameters k_{obsd} (a) and ΔA_{300} (b) on $[py]_{tot}$ for the reaction of the cation **4** with pyridine at pH = 2.0 and 4.8

$$A = \Delta A \exp(-k_{obsd} t) + A_\infty \quad (5)$$

$$k_{obsd} = k_L[py] = m[py]_{tot} \quad (6)$$

$$k_{obsd} = k_L[py] + k_{-L} = m[py]_{tot} + k_{-L} \quad (7)$$

At pH = 4.8, the dependence is linear and conforms to Equation (6) (irreversible pseudo-first-order reaction), whereas at pH = 2.0 the linear dependence has an intercept and conforms to Equation (7) (reversible pseudo-first-order reaction).[27] The slope m of the linear dependencies shown in Figure 4a leads to rate constant k_L and the intercept corresponds to k_{-L}.[28] At pH = 2.0, where most of the pyridine is protonated ($pK_a = 5.26$[29]), the reverse reaction (rate constant k_{-L}) is observed and the equilibrium constant K is obtained from the ratio k_L/k_{-L}. Independently and additionally, K can be derived from the concentration dependence of the amplitude ΔA, as described by Equation (8) and shown in Figure 4b.

Table 6. Rate constants k_L and k_{-L} and equilibrium constants K for water substitution in monoaqua cations Cp*Ir(A−B)$(H_2O)^{2+/+}$ and in the triaqua cation **1** by pyridine at 298 K

1	2.0	2610 ± 40[e]	–	–	–

[a] According to Equation (7), rate constant k_{-L} corresponds to the intercept of the plot of k_{obsd} vs. [L]; in most cases, the values of k_{-L} are therefore obtained with high error limits. – [b] As obtained from the amplitude ΔA according to Equation (8). – [c] Error limits too high to accept data for k_{-L} as sufficiently reliable. – [d] Substitution studied with py-nia[21] instead of py. – [e] First substitution step; data taken from ref.[9]

$$\Delta A = A_\infty K[py]_{tot}/(1 + K[py]_{tot}) \quad (8)$$

The values of k_L, k_{-L}, and K obtained are summarized in Table 6.

The data for the system **4**/py demonstrate that the pH value has no effect on k_L, which clearly indicates that in solutions at pH = 2.0 and 4.8 the reacting iridium species is the same. This is in line with the UV absorption data (see Table 2). Within the error limits, equilibrium constant K = 7.8 × 10^5 M^{-1}, as obtained according to $K = k_L/k_{-L}$, is in good agreement with K = 8.7 × 10^5 M^{-1}, as derived from the dependence of ΔA on $[py]_{tot}$ according to the relationship in Equation (8). It is noteworthy that the substitution of water in the proline complex by py is a monophasic process, properly described by a single exponential function. In agreement with the UV absorption data, this finding supports the interpretation that the trinuclear compound **3b** is hydrolyzed to form the monoaqua cation **4** when dissolved in water.[30] If the trinuclear cation **3** were to be present in solution, one should observe biphasic or even triphasic kinetic behaviour.

As described above, the acidity of the coordinated water in the species Cp*Ir(A−B)$(H_2O)^{2+/+}$ is not significantly affected by the nature of A−B (see Table 3). In contrast to this lack of dependence, the magnitude of the rate constant k_L clearly depends on A−B (see Table 6). The proline complex **4** (k_L = 6270 $M^{-1}s^{-1}$) reacts faster than the bipyridine complex **5** (k_L = 10.5 $M^{-1}s^{-1}$) by a factor in excess of 500. As a general rule, it is found that the singly charged complex cations (A−B = prol and picac) react more rapidly than the doubly charged ones (A−B = dpen, dach, phen, and bpy). However, the difference of a factor of 10 between the k_L data for **4** and the picolinic acid complex **6** clearly shows that the charge on the cations is not the only rate-determining parameter.

The reverse reaction is less affected by the nature of A−B. The values obtained for the rate constant k_{-L} only vary between 0.008 s^{-1} and 0.0008 s^{-1}. As a result of the effects of A−B on k_L and k_{-L}, the overall equilibrium constant K ranges from 7.8 × 10^5 M^{-1} (A−B = prol) to 4.2 × 10^3 M^{-1} (A−B = phen).

Due to pH-dependent protonation of the incoming pyridine ligand, rate constant k_{-L} for the reverse reaction was not reliably accessible for some of our complexes under certain conditions (see Table 6). Experiments in which the less basic pyridine derivative py-nia (= nicotinamide; pK_a = 3.47[29]), rather than pyridine (pK_a = 5.26[29]), was treated with Cp*Ir(*R*,*R*-dpen)$(H_2O)^{2+}$ (**7**) and **2** at pH = 2.0 led to reliable data for k_{-L} and K. Further evidence for the reversibility of substitution reaction according to Equation (3) was provided by the results of some pH-jump stopped-flow experiments performed on the system **2**/py-nia.[31] The change in absorbance with time associated with the pH-jump from pH = 2.0 to proton concentrations $[H^+]$ = 0.27, 0.55, and 1.5 M, respectively, proved to be exponential according to Equation (5). The experimental rate constant k_{obsd}, formally described by Equation (7), was found to be independent of $[H^+]$, with a mean value of k_{obsd} = (1.02 ± 0.03) × 10^{-3} s^{-1}.[31] Within the limits of error, this value is in agreement with k_{-L} = (0.8 ± 0.3) × 10^{-3} s^{-1} as determined from the kinetics of the complex formation reaction (see Table 6). This means that the pH-jump from pH = 2 to higher proton concentrations causes aquation of the cation Cp*Ir(*R*,*R*-dach)(py-nia)$^{2+}$ according to Equation (9). Due to pyridine protonation at the high proton concentrations employed, the contribution of the rate term k_L[py] in Equation (7) becomes negligibly small.

$$Cp^*Ir(R,R\text{-dach})(py\text{-nia})^{2+} + H_2O \xrightarrow{k_L} Cp^*Ir(R,R\text{-dach})(H_2O)^{2+} + py\text{-nia} \quad (9)$$

In comparison to other aqueous systems [e.g. $Ni(H_2O)_6^{2+}$/py; K = 81 M^{-1}],[32] the complexes Cp*Ir(A−B)$L^{2+/+}$ prove to be extraordinarily stable. Since the carbon−iridium bonds are resistant to hydrolysis even in very acidic solutions, high proton concentrations can be used to reduce the concentration of the pyridine ligand. It is thus possible to accurately determine large K values.

*Water Substitution in Cp*Ir(A−B)$(H_2O)^{2+/+}$ Complexes by Thiourea, Dimethyl Sulfide, and Monodentate Anions*

The rates of associatively controlled substitution reactions are strongly affected by the nucleophilicity of the in-

coming ligand L. In the case of associative substitutions at Pt^{II} complexes, the nucleophilic discrimination factor *S*, as obtained from n^{o}_{Pt} values according to Equation (10), is used to quantify this effect of the nucleophilicity of L on the rate of the reaction (k = second-order substitution rate constant; n^{o}_{Pt} = empirical measure of the nucleophilicity).[33]

$$\log k = Sn^{o}_{Pt} + c \quad (10)$$

To obtain information on the mechanism of water substitution according to Equation (3), the rate constant k_L was determined for the entry of various ligands L into the monoaqua complexes $Cp^*Ir(A-B)(H_2O)^{2+/+}$. Under pseudo-first-order conditions ($[L]_o \geq 10 \times [complex]_o$), substitution was found to be a practically irreversible process with the (A,t) data conforming to Equation (5). The dependence of k_{obsd} on $[L]_o$ according to Equation (6), led to the k_L data summarized in Table 6. Analysis of these data shows that (i) as found for L = py, water substitution at the various cations $Cp^*Ir(A-B)(H_2O)^{2+/+}$ by TU and DMS is more than two orders of magnitude faster for the singly charged proline and picolinic acid complexes than for the bipyridine complex, (ii) for a given cation $Cp^*Ir(A-B)(H_2O)^{2+/+}$, the magnitude of k_L follows the order TU > DMS > py, and (iii) water substitution at the cations **2** and **5** by the anions Br^-, I^-, SCN^-, N_3^-, and NO_2^- is faster than that by the neutral ligands TU, DMS, and py. The latter result is in line with expectation for charge effects according to the Eigen–Wilkins mechanism.[34]

A plot of log k_L vs. n^{o}_{Pt} for L = py, DMS, and TU is shown in Figure 5. It can be seen that the substitution rate constant k_L increases with increasing nucleophilicity of L, as characterized by the parameter n^{o}_{Pt}. This increase of k_L with n^{o}_{Pt} is found for all of the $Cp^*Ir(A-B)(H_2O)^{2+/+}$ complexes studied. The nucleophilic discrimination factor *S* ranges from 0.25 for the proline complex **4** to 0.41 for the *R*,*R*-dach complex **2**. In line with the second-order rate law obtained for substitution reaction according to Equation (3), this finding excludes a *D* mechanism. However, for typical associative substitutions at Pt^{II} complexes (*A* mechanism) it is found that *S* ranges from 0.6 to 1.4.[33] This im-

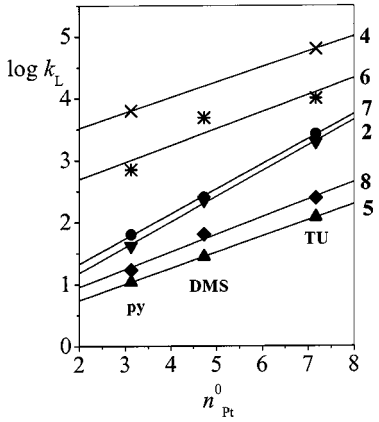

Figure 5. Dependence of rate constant k_L on the nucleophilicity of the neutral ligands py, DMS, and TU (**4**, S = 0.25; **6**, S = 0.27 ± 0.10; **7**, S = 0.40 ± 0.01; **2**, S = 0.41 ± 0.02; **8**, S = 0.28 ± 0.01; **5**, S = 0.26 ± 0.01)

plies that the substitution reactions under study have a rather weak dependence on the nucleophilicity of L.

Activation Parameters

The kinetics of water substitution at three monoaqua $Cp^*Ir(A-B)(H_2O)^{2+/+}$ cations by thiourea were studied at various temperatures and pressures. The corresponding activation parameters, along with related literature data, are listed in Table 8.

The values obtained for $\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta V^{\neq}$ are rather similar in magnitude for all three complexes. When compared to the data obtained for water substitution at the triaqua species **1**[9] and to corresponding data reported in the literature,[35−37] the positive volume of activation, which ranges from $\Delta V^{\neq} = +2.3$ cm^3 mol^{-1} for **5** to $\Delta V^{\neq} = +7.4$ cm^3 mol^{-1} for **2**, suggests the operation of a dissociatively controlled interchange mechanism (I_d). In line with the hypothesis of an I_d mechanism, the activation entropies listed in Table 8 are all positive and small. It is interesting to note that the activation volumes for the complexes **2** and **6** are significantly more positive than that for complex **5**. In the former cases, water substitution by thiourea is considerably faster, which may point to a more dissociative process than in the case of complex **5**. By way of comparison, the activation volumes quoted for water substitution at the triaqua complex **1** by a variety of nucleophiles vary between +3.9 and +5.4 cm^3 mol^{-1}, again typical for an I_d mechanism. All of these reactions are many orders of magnitude faster than water exchange and ligand substitution at hexaaqua iridium(III), which is characterized by a negative volume of activation as befits an I_a mechanism.[10,21] The significant labilization caused by the Cp* ligand is expected to result in a ground-state lengthening of the Ir−OH_2 bond (see earlier discussion). Compared to the case without ground-state labilization, this, in turn, will require a lesser degree of bond breakage (and a smaller volume increase) in going to a dissociative transition state. Therefore, in the absence of structural information on the Ir−O(water) bond lengths in all of the complexes appearing in Table 8, the reported volumes of activation do not rule out the operation of a limiting *D* mechanism.

Conclusions

Comparison of a series of half-sandwich monoaqua complexes $Cp^*Ir(A-B)(H_2O)^{2+/+}$ with the triaqua species **1** has shown that the acidity of the coordinated water in the pseudo-octahedral cations $Cp^*Ir(A-B)(H_2O)^{2+/+}$ is more than three orders of magnitude less than that in **1**. It follows from kinetic investigations of the substitution of water in the monoaqua complexes $Cp^*Ir(A-B)(H_2O)^{2+/+}$ by monodentate ligands L that the formation of the species $Cp^*Ir(A-B)L^{2+/+}$ is a second-order reaction, rate = k_L[complex][L]. The magnitude of the complex formation rate constant k_L is affected by the nature of both the bidentate ligand A−B and ligand L. For a given incoming ligand L, it is found that k_L is smallest for complexes with σ-donor/π-acceptor N,N ligands (bpy and phen), somewhat greater for those with σ-donor N,N ligands (*R*,*R*-dach and *R*,*R*-dpen), and greatest for those with σ-donor N,O$^-$ ligands (picac and prol). The reactivity of complex **6** is lower compared to that of **4**, which is probably due to the π-acceptor properties of the pyridine ring. For a given $Cp^*Ir(A-B)(H_2O)^{2+/+}$ complex, it is found that k_L increases with the nucleophilicity of L, as characterized by the empirical parameter n^o_{Pt}. The effect of L on the second-order rate constant k_L is very similar to the effect of the incoming ligand on the rate of water substitution in the triaqua complex **1**. The overall kinetic data suggest that water substitution in the species $Cp^*Ir(A-B)(H_2O)^{2+/+}$ follows an I_d mechanism.

Ligand substitution is thus mainly governed by the lability of the leaving water molecule. For L = py, the rate of aquation (rate constant k_{-L}) is less affected by the nature of A−B than the rate of water substitution (rate constant k_L). From the values of k_{-L}, it therefore follows that the lability of the coordinated pyridine is roughly of the same order of magnitude for all the $Cp^*Ir(A-B)(py)^{2+/+}$ complexes. The pronounced differences in the lability of the coordinated water are possibly a consequence of its limited polarizability or "hardness". As a general rule, it is found that the iridium centre in the monoaqua species $Cp^*Ir(A-B)(H_2O)^{2+/+}$ as well as in the triaqua cation **1** favours polarizable or "soft" ligands, so as to form kinetically and thermodynamically stable complexes.

Experimental Section

Unless stated otherwise, all manipulations were performed under aerobic conditions using commercial-grade solvents. The metal salts, organic solvents, and ligands (reagent grade) were obtained from commercial sources and were used without further purification. $[Cp^*IrCl_2]_2$ was synthesized according to published procedures.[38] Deionized water was doubly distilled in a quartz apparatus prior to use.

General Procedure for the Preparation of the Complexes: Portions of 0.100 g (0.126 mmol) of $[Cp^*IrCl_2]_2$ were suspended in methanol (5 mL) and 2 equiv. of the bidentate ligand A−B were added at ambient temperature to immediately produce a clear yellow solution. After stirring for 3 h, the solvent was evaporated. The residue was redissolved in water (7 mL) and the resulting solution was heated to ca. 80 °C. A solution of 4 equiv. (0.504 mmol) of $AgClO_4$ in water (5 mL) was added to the acidified solution (pH = 2−3, $HClO_4$) to remove chloride by precipitation of AgCl, which was separated by hot filtration after stirring for 2 h. The solvent was partially evaporated until crystallization occurred. The addition of 1 equiv. of $NaClO_4$ completed the crystallization. − To achieve deprotonation in the case of the ligands picac and prol,[21] following the addition of the ligand A−B, a stoichiometric amount of triethylamine was added to the reaction mixture. − ***Caution:*** Perchlorate salts are potentially explosive; they should be handled with care and in small portions only!

2b: Yellow needles from water (pH = 2−3, $HClO_4$). − Yield 0.118g (69%). − $C_{16}H_{33}Cl_2IrN_2O_{10}$ (676.57): calcd. C 28.40, H 4.92, N 4.14; found C 28.01, H 4.56, N 4.08. − ^{1}H NMR (D_2O): δ = 1.05−1.46 (m, 4 H, cycl.-H), 1.51−1.66 (m, 2 H, cycl.-H), 1.71 (s,

Instrumentation: UV/Vis spectra: diode-array spectrophotometer (Zeiss Specord S10); NMR spectra: FT NMR spectrometer (Bruker AM 200 and WM 300); IR spectra: FT-IR spectrometer (Nicolet Impact 400); pH measurements: glass electrode (Schott) in combination with a potentiometer (Metrohm 691), calibrated at I = 0.1 M ($NaNO_3$) and 25 °C to yield $-\log[H^+]$ = pH − 0.09; kinetics of reaction according to Equation (3): multi-wavelength stopped-flow spectrophotometer (J. & M., TIDAS)[39] and stopped-flow spectrophotometer in combination with a high-pressure cell.[40]

Spectrophotometric Titrations: The dissociation of the monoaqua complexes $Cp^*Ir(A-B)(H_2O)^{2+/+}$ according to Equation (4) was monitored by spectrophotometric titrations of acidic solutions of the complexes with 0.1 M NaOH. Least-squares fitting of Equation (11) to the (absorbance,[H^+]) data led to the acid dissociation constants K_a (A_{H2O} and A_{OH} refer to the absorbances of the aqua and hydroxy complexes, respectively, at the concentration [$complex]_{tot}$).

$$A = (A_{OH} + A_{H2O}[H^+]/K_a)/(1 + [H^+]/K_a) \quad (11)$$

Kinetic Measurements: The reaction according to Equation (3) was monitored in freshly prepared aqueous solutions in the wavelength range 200−500 nm under pseudo-first-order conditions ($[L]_o \geq 10 \times [complex]_o$) at various temperatures (285−318 K) and pressures (10−150 MPa). The ionic strength was fixed at I = 0.2 M ($NaClO_4$ or $NaNO_3$). Measurements were made at either pH = 2 (as adjusted with $HClO_4$) or 4.8 (as adjusted with the noncoordinating buffer 2,6-dimethylpyridine-3-sulfonic acid[41]). Least-squares fitting of the (absorbance,time) data with Equation (5) led to the experimental rate constant k_{obsd}, which is defined by Equations (6) and (7) for irreversible and reversible pseudo-first-order reactions, respectively. Rate constants k_L and k_{-L} were obtained from the dependence $k_{obsd} = f([L]_o)$ according to Equations (6) and (7), respectively. The amplitude ΔA in Equation (5) depends on $[L]_o$ according to Equation (8). Fitting of this Equation to the (ΔA,$[L]_o$) data led to the equilibrium constant $K = k_L/k_{-L}$. − The volume of activation was obtained from the pressure dependence of k_{obsd} according to Equation (12). A correction for the pressure dependence of the activity coefficients (less than 0.6 cm^3 mol^{-1} under the given conditions[42]) was not applied.

$$\Delta V^{\neq}_{exptl} = -RT(\partial \ln k_{obsd}/\partial P)_T \quad (12)$$

Crystallography: The crystals were obtained from aqueous solutions (pH = 2−3, $HClO_4$) as stated above. Measurements were made with a four-circle diffractometer (STOE-STADI-4) using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å); scan 2θ:ω = 1:1. Cell constants were determined by the least-squares method from the 2θ angles of 58 and 54 reflections for **2b** and **3b**, respectively. The structures were solved by direct methods with SHELXS-86 and refined by least squares to the R values given in Table 9 using the program package SHELXL-93. The non-hydrogen atoms were refined anisotropically. All hydrogen atoms were placed in their calculated positions. Crystal data and data collection parameters are listed in Table 9; selected bond lengths and

[27] One has to consider that at pH = 2.0 most of the pyridine base is protonated [pK_a(py) = 5.26[29]] and the low concentration of the incoming ligand L = py enables interference of the reverse reaction.
[28] To obtain the rate constant k_L from the slope m of the linear dependencies shown in Figure 4a, one has to correct for partial protonation of the pyridine according to $k_L = m\{1 + [H^+]/K_a[py]_0\}$.

[30] The UV spectrum of a solution of **3b** in methanol clearly differs from that in water, which suggests that, in contrast to the situation in water, the trinuclear structure is preserved in methanol. This would be in line with the results reported by Carmona et al.,[15] which showed that in solutions of the complexes [Cp* Ir(aa)$_3$](BF$_4$)$_3$ (aa = α-amino acid anion) in dichloromethane, acetone, or methanol, the complexes remain trinuclear.
[31] The pH-jump stopped-flow experiments were carried out by loading one syringe with the solution of the complex ([**2**] = 0.4×10^{-4} M, [py-nia] = 1×10^{-3} M, [$HClO_4$] = 0.01) and the other with acid ([$HClO_4$] = 0.53 M, 1.1 M, and 3.0 M, respectively). The (A,t) data for the decrease of absorbance at 300 nm were fitted with Equation (5), which led to k_{obsd} = (1.049 ± 0.004) × 10^{-3} s^{-1} ([$HClO_4$] = 0.27 M), k_{obsd} = (0.992 ± 0.003) × 10^{-3} s^{-1} ([$HClO_4$] = 0.55 M), and k_{obsd} = (1.02 ± 0.01) × 10^{-3} s^{-1} ([$HClO_4$] = 1.5 M).

[34] The Eigen−Wilkins mechanism postulates for ligand substitution reactions such as the reaction according to Equation (3) that $k_L = K_{os}k_i$, where K_{os} is the equilibrium constant for fast formation of an outer-sphere complex between Cp* Ir(A−B)$(H_2O)^{2+/+}$ and L, and k_i is the rate constant for rate-controlling ligand interchange in the outer-sphere complex. For electrostatic reasons, K_{os} is greater for cations interacting with anions than for cations interacting with neutral ligands.

Dedicated to Prof. H. G. Schnöckel on the occasion of his 60th birthday

Keywords: Sandwich complexes / Nickel / Arenes / EHMO calculations / Cyclopentadienyl ligands

Synthesis, structure, reactivity, and theoretical studies of a new type of Ni triple-decker complexes are reported. A prominent feature of its molecular structure is the (η^3:η^3)-bis-(enyl) coordination of two [(η^5-Me_4EtC_5)Ni] fragments to the central arene ring of the polycondensed π-perimeter decacyclene. The central arene ring of decacyclene displays a distinct chair conformation with significant tilt angles of 25.5 and 26.1°. The three naphthalene units are twisted in a propeller-like fashion with torsion angles of 16°, 16.6°, and 19°, which is twice the twisting observed for the free decacyclene ligand. According to Extended Hückel Molecular Orbital (EHMO) calculations, a qualitative measure for arene lability in the title compound and a number of related arene-bridged metal complexes can be attributed to a subsequent filling of metal–arene antibonding orbitals. The experimentally observed reactivities of π-arene exchange in these complexes are reproduced nicely by the EHMO calculations. The title compound offers access to a number of organonickel chalcogenato complexes under mild conditions by cleavage of the S–S, Se–Se, or Te–Te bonds of diorganyl dichalcogenides R–E–E–R. The title compound is also capable of C_{sp^2}–H activation of azobenzene and [(dimethylamino)methyl]ferrocene resulting in orthometallated complexes containing five-membered metallacycles. PES and semi-empirical ZINDO/S calculations were used to study the product of the orthometallation of the title compound with azobenzene. These studies reveal that the HOMO of the metallacycle (IE = 6.45 eV) has dominant Ni–Cp and Ni–C_{aryl} π-antibonding character.

Introduction

Recently we reported on the first binuclear transition metal complexes of decacyclene containing this large condensed π-perimeter,[1] whose organometallic chemistry is still virtually unexplored, probably owing to its low solubility.[2] During the course of our studies of this π-perimeter we have found that two [(η^5-Me_5C_5)Ni] fragments are able to coordinate in a triple-decker fashion to decacyclene.[1] At that time our findings were based exclusively on the analysis of the characteristic NMR spectroscopic data, which suggest a highly symmetrical coordination mode of the two [(η^5-Me_5C_5)Ni] fragments to decacyclene, and steric arguments were put forward in favor of an antarafacial coordination of the two M−L fragments.[1]

Herein we report on the molecular structure, reactivity, and theoretical studies of the unusual arene-bridged nickel triple-deckers **3** and **4** and their reaction products from reductive cleavage and cyclometallation reactions. A remarkable feature of **3** and **4** are their high capability for controlled release of 15e$^-$-[(C_5R_5)Ni] fragments under mild conditions. Although triple- and multiple-deckers with nickel constitute a most intriguing class of organometallic compounds,[3] such an unusual coordination as in **3** and **4** paired with a high reactivity of a π-coordinated middle deck is a rare case.

Results and Discussion

We found that reaction of [(η^5-Me_4EtC_5)Ni(acac)] (**1**) with the decacyclide dianion produces the title compound **3** in 74% yield as brown to black crystals [Equation (1)].

(1)

As for the Me_5C_5 derivative **4**,[1] the NMR spectra of **3** are characteristic for a symmetric coordination of two [(η^5-Me_4EtC_5)Ni] fragments to the decacyclene bridging unit. A high-field coordination shift of the three multiplets (doublet-triplet-doublet) of decacyclene is observed in agreement with a twofold metal coordination to the tris(anullated) center arene ring of decacyclene. However, from NMR experiments on **3** (as for **4**[1]) no distinction between either a symmetric or an asymmetric metal coordination to decacyclene could be made. For supra- and antarafacial complexes containing bridging arenes highly fluxional behavior is well known. However, low-temperature NMR measurements to prove such fluxional behavior for **3** and **4** are precluded by their low solubility. So far, no decision towards the fluxionality and subsequently the hapticity of **3** and **4** in solution could be made. However, we believe **3** and **4** to be highly fluxional in solution.

In contrast to **4**, the Me_4EtC_5 derivative **3** gave suitable crystals for an X-ray structure determination, which allow us to determine its molecular structure in the solid state (Figure 1).[4]

The two [(η^5-Me_4EtC_5)Ni] fragments of **3** display an η^3-enyl bonding in which both metal ligand fragments are bonded in an antarafacial fashion to the central benzene ring of decacyclene (Figure 2). This causes the distortion of the central ring into a chair conformation in which the plane defined by $C^1-C^2-C^3$ is tilted by 25.5°, and the plane defined by C^4, C^5, and C^6 is tilted by 26.1° towards the plane C^3, C^4, C^6, C^1. The η^3:η^3 coordination in **3** has some precedent in the literature when considering polynuclear arenes as bridging ligands (Figure 3).[5–8] However, **3** represents a rare case in which two Ni ligand fragments are coordinated to a single C_6 arene ring.[9]

In **3** both Ni atoms are equally displaced between the bridging η^3-bonded arene part of decacyclene (1.72 Å) and the η^5-Me_4EtC_5 ligands (1.73 Å). As a result of the antarafacial η^3:η^3 coordination, a substantial twist of the mean planes of the crystallographically independent naphthalene moieties of 16°, 16.6°, and 19° results. This exceeds the modest twist disposed on the naphthalene moieties of the free ligand by almost 100% (9.3° and 7.7°) and gives **3** a distinct propeller-like shape when compared to free decacyclene (see Figure 2).[10]

Reactivity Studies of 3 and 4

The decacyclene ligand in **3** and **4** can be displaced, resulting in the formation of dinuclear and mononuclear organonickel complexes. Common features of all exchange reactions are the mild reaction conditions (room temperature) and the possibility of the immediate visual progress of the ligand exchange by appearance of a precipitate of highly

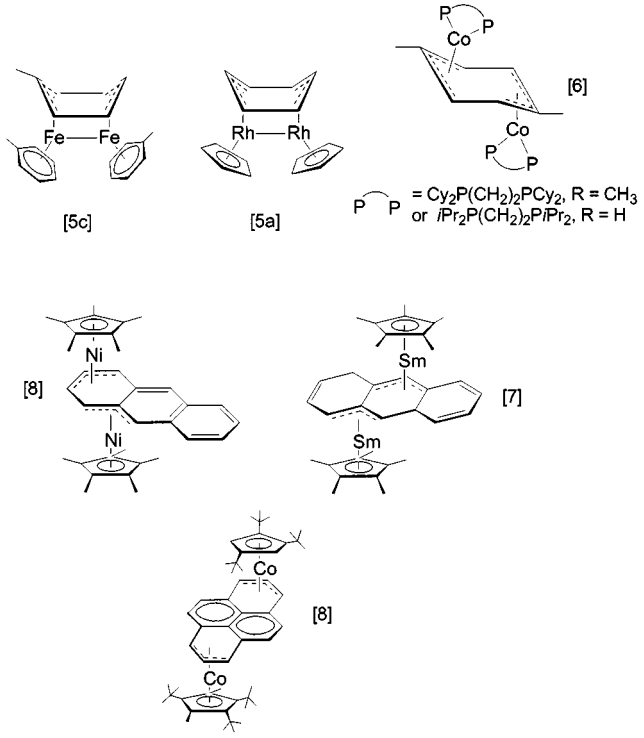

Figure 3. Selection of dinuclear complexes containing polynuclear arenes as bridging ligands

insoluble decacyclene **2**. This lability of the aromatic middle deck make **3** and **4** ideal, and so far rare sources for the mild in situ generation of 15e$^-$-[(η^5-C_5R_5)Ni]$_{solv}$ fragments with a high synthetic potential in organometallic synthesis. To the best of our knowledge, no other comparable sources for [(η^5-C_5R_5)Ni]$_{solv}$ fragments are known so far.

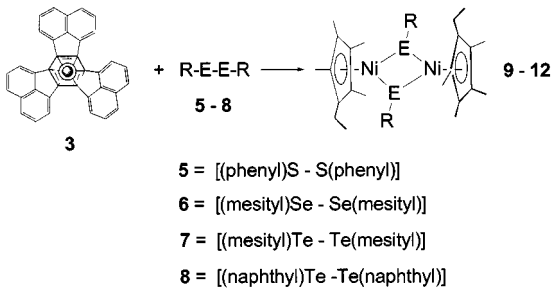
Reactions of 3 with Diphenyl Disulfide (5), Dimesityl Diselenide and Ditelluride (6 and 7), and Dinaphthyl Ditelluride (8) − Formation of (μ-Chalcogenato)dinickel Complexes 9−12

Diorganyl dichalcogenides are prone to homolytic cleavage of the E−E bond by transition metal ligand fragments, which generate reactive R−E fragments. Related oxidative additions of acyclic organic, cyclic organic, and organometallic dichalcogenides are also known.[11] Organonickel thiolate complexes are possible reaction products from cleavage reactions of R−S−S−R compounds. They are often electrochemically active but show a pronounced stability towards one-electron reduction and cleavage of their M−S bond(s).[12]

Our interest in binary and ternary transition metal chalcogen complexes and their electron-transfer properties[13] prompted us to study the reaction of **3** with dichalcogenides **5**−**8** with respect to a transfer of 15e$^-$-[(η^5-Cp^R)Ni] fragments.

Addition of a stoichiometric amount of the appropriate diorganyl dichalcogenide to a solution of **3** in diethyl ether resulted in the precipitation of decacyclene as a tan-colored powder. The chalcogenato complexes **9**−**12** could be isolated in high yields from the filtered solution [Equation (2)]. The formation of **9**−**12** can be understood by reductive cleavage of the E−E bond of the dichalcogenide by reactive [(η^5-Me_4EtC_5)Ni] fragments.

Dinuclear complexes of general type [{(η^5-C_5R_5)Ni(μ-ER)}$_2$] can exist in planar or bent conformations with regard to the Ni_2E_2 core.[14] Varying substituents at the bridging chalcogen atoms S, Se, and Te may cause the Ni_2E_2 core to adopt different orientations, reflecting different hybridization situations at the chalcogen atoms (Figure 4).



(2)

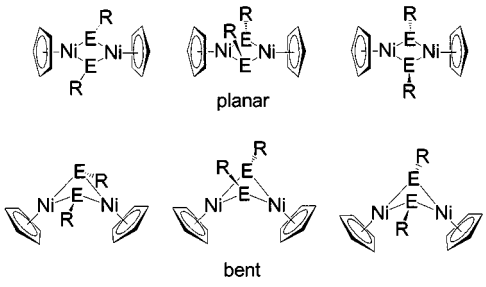


Figure 4. Possible conformations for complexes of the type [{(η^5-Cp^R)Ni(μ-SR)}$_2$]

Despite this possibility, the ^{1}H NMR spectra of the complexes **9**−**12**, show the presence of only one conformer. However, for [{(η^5-Me_4EtC_5)Ni}$_2$(μ-SeMes)$_2$] (**10**), unusually broad signals in the ^{1}H NMR might indeed indicate a dynamic behavior of this compound in solution.

The molecular structure of bis[(μ-benzenethiolato)(η^5-Me_4EtC_5)Ni] (**9**) in the solid state was confirmed by X-ray crystallography and revealed two independent molecules. However, no significant variation in bonding parameters was observed.[4] Each molecule of **9** has a centrosymmetric structure with a nearly square-planar Ni_2S_2 arrangement (Figure 5). The distances between the two nickel atoms are 3.078 Å (Ni^1−Ni$^{1'}$) and 3.109 Å (Ni^2−Ni$^{2'}$; not shown), which is obviously too large to consider Ni−Ni metal bonding when compared to the Ni−Ni distance of 2.4916 Å in metallic Ni.[15] Other bonding parameters for **9** are in close agreement to those in bis[(η^5-C_5H_5)Ni(μ-*S*-phenyl)].[12] Due to the diamagnetic nature of **9**−**12** the two sulfur atoms have either the formal oxidation state +2 or +4 giving the two nickel centers a 16e$^-$ or 18e$^-$ count in these complexes.

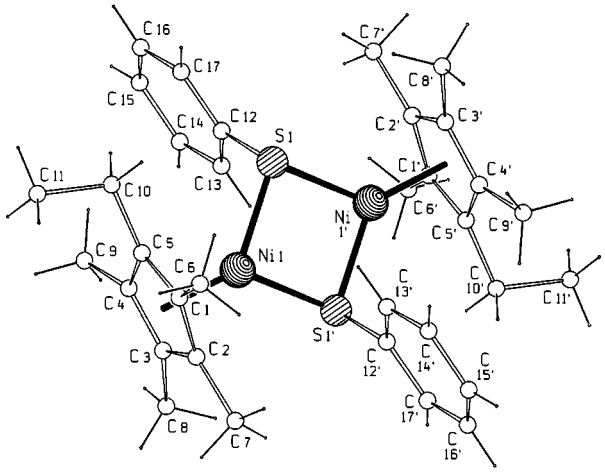

Figure 5. Molecular structure of **9** [only molecule **9**(1) is shown] as determined in the solid state; selected bond lengths [A] and angles [°] of **9**(1): Ni^1-S^1 2.194(2), $Ni^{1'}-S^1$ 2.198(4); $Ni^1-S^1-Ni^{1'}$ 89.00(6), $S^{1'}-Ni^1-S^1$ 91.00(6)

Reactivity Studies

$C_{sp^2}-H$-Activation of Azobenzene and [(Dimethylamino)methyl]ferrocene

Orthometallation reactions involving $C_{sp^2}-H$ bond activation processes represent an important class of reactions with various examples exemplified in the recent literature.[16] From a preparative point of view, transmetallation is a rather attractive preparative route that offers access to orthometallated complexes containing pseudoaromatic rings.[17] During the course of our studies, we have found that **3** and **4** are able to undergo $C_{sp^2}-H$ orthometallations with achiral and prochiral aromatic ring systems under mild conditions by transfer of the [(η^5-Cp^R)Ni] (R = Me_5, $EtMe_4$) moiety.

Reaction of 3 and 4 with Azobenzene

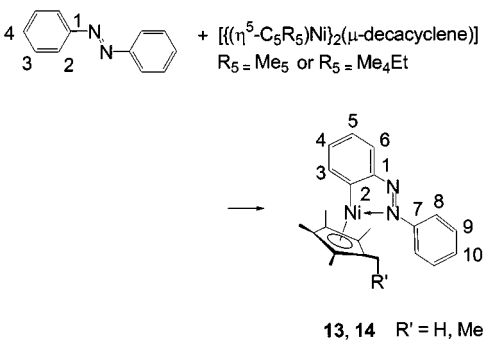
Nickelocene undergoes an orthometallation reaction with azobenzene at high temperatures, leading to a blue crystalline product formulated as [(η^5-Cp){(*o*-phenylazo)phenyl}Ni].[18] In addition, cyclopalladation reactions have been reported for a couple of substituted azobenzenes.[16a,19,20] The palladium−carbon bond is preferentially formed with the benzene ring bearing the electron-donating group, thus pointing towards the electrophilic character of the cyclopalladation reaction.[16a]

Addition of a twofold excess of azobenzene to a solution of **3** or **4** in diethyl ether gives an intense bright blue solution within minutes, accompanied by precipitation of solid decacyclene as tan-colored powder. Deep blue to black, air stable crystals of **13** and **14** could be isolated therefrom [Equation (3)]. The mass spectra of **13** and **14** display the corresponding molecular peaks as base signal, thus establishing a 1:1 ratio azobenzene/[(η^5-C_5R_5)Ni] for both complexes. The ^{1}H NMR spectrum of **13** gives clear evidence of one [(η^5-Me_4EtC_5)Ni] fragment asymmetrically bonded to the azobenzene moiety as a result of an orthometallation reaction. The signal of the α-proton of the metallated phenyl ring is shifted downfield to δ = 7.86 compared to free azobenzene (Δδ = −0.4). Similar ^{1}H NMR coordination shift effects have been observed e.g. for orthometallated pyridine.[21]

The ^{13}C NMR spectrum of **13** shows a characteristic downfield shift for the metallated carbon atom (C^2) compared to free azobenzene (Δδ = −59.2) well in accordance with the ^{1}H NMR spectrum.

The signals of the neighboring carbon atoms C^1 and C^3 are shifted 10 ppm down-field compared to those of free azobenzene. All other carbon resonances do not show significant and characteristic coordination shifts upon Ni coordination. The NMR spectroscopic data of **14** are in agreement with those of **13** (see Exp. Sect.).

Unfortunately, an X-ray crystal-structure analysis of **13** suffers from intense disorder of the $EtMe_4C_5$ ligand. However, the connectivities of all atoms except hydrogen could be unambiguously pinpointed from the crystallographic data set, thus surely confirming the existence and coordination of the orthometallated five-membered nickelabenzpyrazole ring, as it is shown in Equation (3). The (Cp)nickel moiety coordinates to the nitrogen atom of the diazo group via its lone pair, thus allowing the Ni center to attain an $18e^-$ count.



(3)

Corresponding to its elusive bright blue color, the relevant absorption for **13** is found at λ = 609 nm (ε = 6317) (Figure 6). The characteristic absorptions for the azobenzene residue are shifted to higher wavelengths compared to those of free azobenzene. The same effect is observed for the absorptions of the parent corresponding [{*o*-(phenylazo)phenyl}(η^5-Cp)Ni] complex[18] and for [({*o*-(phenylazo)phenyl}$PtCl)_2$],[19] both containing five-membered orthometallated ring systems incorporating the N=N azo group. It is interesting to note that differently alkyl-substituted *o*-hydroxyazobenzene compounds experience a similar bathochromic shift compared to azobenze resulting in a blue to purple color as observed for **13** and **14**.[22] The effect is attributed to hydrogen bonding of an *o*-OH group to the nitrogen atom of the azo group, resulting in formation of six-membered rings and the term *internal halochromism* has been coined for it.[22]

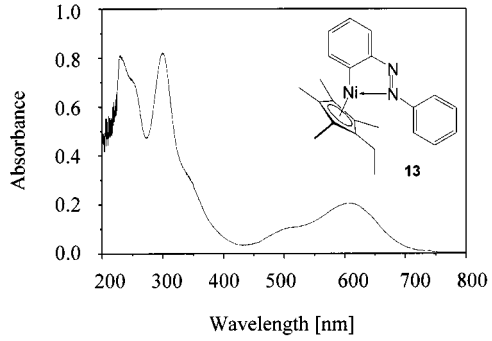


Figure 6. UV/Vis spectrum of **13** in CH_2Cl_2 (27 °C)

In contrast with the reaction of nickelocene with azobenzene, which requires drastic reaction conditions and prolonged reaction times to proceed to completion, the generation of 15e⁻-[(η^5-C_5R_5)Ni] fragments (R = Me_5, $EtMe_4$) from triple-deckers **3** and **4** undergoing the cyclometallation of azobenzene is already achieved at room temperature within minutes. This suggests that [(η^5-C_5R_5)Ni]$_{solv}$ fragments are easily generated by a dissociative pathway from triple-decker complexes **3** and **4**. A dissociative mechanism for ligand exchange has been proven recently for arene-bridged Co triple-deckers [{(η^5-C_5R_5)Co}$_2$(μ-η^4:η^4-arene)] (R = Me_5, 1,2,4 tri-*tert*-butyl) by kinetic and preparative studies.[23]

Photoelectron Spectroscopy (PES) of 13; Experimental and Theoretical Studies

The (He^I) PE spectrum of **13** is shown in Figure 7. Experimental vertical ionization energies are listed in Table 1. The calculated PE spectrum together with relevant MO contributions, obtained from semiempirical ZINDO/S calculations based on the corresponding model compound [(η^5-Cp)Ni(C_6H_4−N=N−C_6H_5-κ*C*,κ*N*)] ***A*** (simplification of alkyl ligand substituents by hydrogen) is depicted in Figure 8. Zerner (Z) et al. have employed an intermediate neglect of differential overlap (INDO) method with spectroscopic parametrization (ZINDO/S) in electronic calculations.[24] Following this work we have used the semi-empirical ZINDO/S method in the calculation of the PE spectrum of **13**.

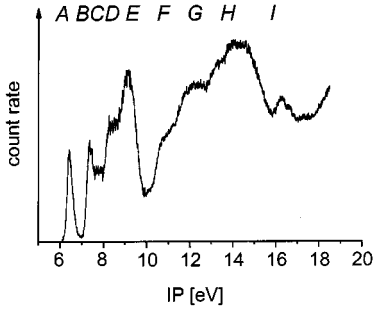

Figure 7. Experimental He^I PE spectrum of **13**; assignment see Figure 8

Table 1. Experimental vertical ionization energies (in eV; ca. 1.60 × 10^{-19} J) for **14**; for a detailed assignment see text and Figure 8

Band	$IE_{vert.}$	Assignment
A	6.45	HOMO: π antibonding
B	7.36	
C	7.50 7.81	HOMO1 − HOMO5:
D	8.43	π ligand
E	9.12	centered
F	10.77	HOMO6 −
I	16.28	HOMO11

The ionization energies of the nickel compound have been evaluated by Koopmans' theorem[25] as the negative of the eigenvalues of the ground state MOs of the neutral molecules. We are aware that Koopmans' approximation is often not valid in the case of organo transition metal complexes. Ferrocene, for example, is a well-known case where the breakdown of Koopmans' theorem was demonstrated.[26] However, the spectroscopic parameterization employed in the INDO/S method resulted in a rather large reduction of relaxation energy and Koopmans' theorem was found to give a correct order of ionization potentials.[24,27] As can be seen from Figure 7, Figure 8, and Table 1 the energies of the molecular orbitals based on a calculation of the model species ***A*** deviate less than 1.0 eV from observed ionization potentials. The low molecular symmetry of ***A*** leads to substantial atomic orbital mixing. This makes an assignment of characteristic molecular orbitals to spectral bands difficult. The band at 6.45 eV is assigned to the HOMO, which is an Ni−Cp and Ni−C_{aryl} π-antibonding orbital. The calculation gives 5 MOs (HOMO-1 to HOMO-5), which are assigned to the region between 7.36 and 9.4 eV. These MOs are dominated by ligand-centered π orbitals. Most prominent are aryl and cyclopentadienyl π sets that contribute significantly to these molecular orbitals (Figure 9). Some nickel d-character is also present, but except for one orbital (HOMO-4/-5) never prominent. There it is part of an Ni−C_{aryl} σ-bonding orbital.

From the HOMO-6 downward, the calculated MOs are assigned to the experimental ionization energy region above 10.7 eV. These not very well resolved bands start with Ni−Cp π-bonding orbitals (HOMO-6, -9) as well as nickel-centered nonbonding d-orbitals (HOMO-7, -8). Some weak Ni−C_{aryl} σ-bonding is also present (HOMO-8, -10). An Ni−N bonding and N-lone-pair combination is calculated around 11.2 eV (HOMO-11).

Reaction of 3 with Bis[2-[(dimethylamino)methyl)]-ferrocenyl]lead(II) (15)

Due to our continued interest in the synthesis of transition metal complexes containing stannylene species :MR_2

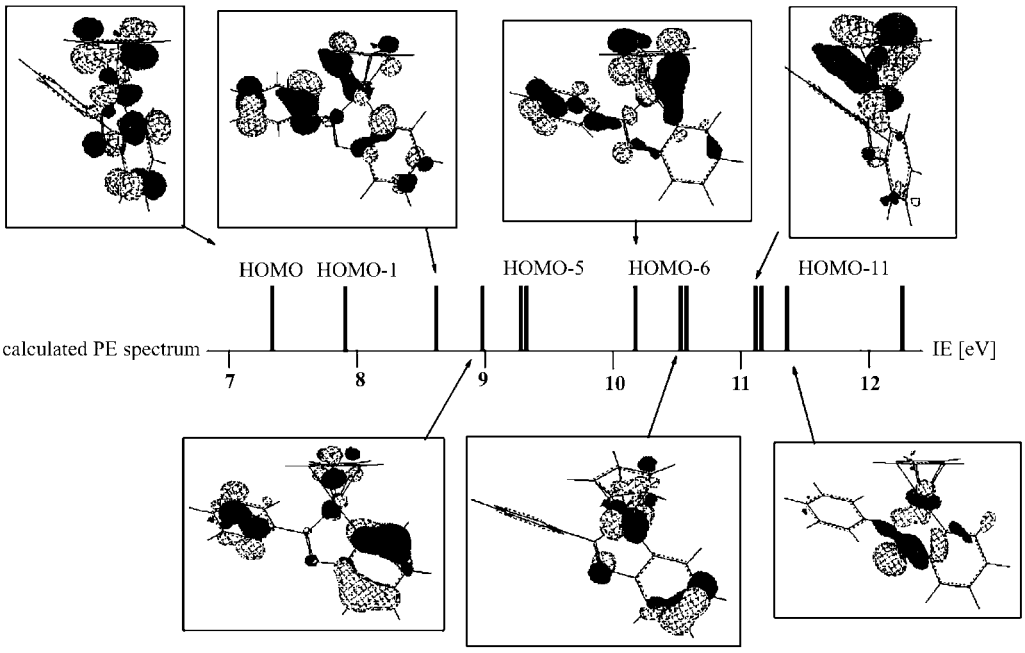

Figure 8. Calculated PE spectrum of **13** together with calculated ZINDO/S MOs assigned to the individual vertical ionization energies

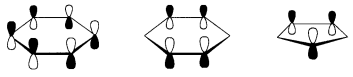

Figure 9. Prominent molecular orbital contributions from aryl and Cp π-sets in the energy window 7.36−9.4 eV

(Sn, Pb)[28] we studied the complexation behavior of **3** towards the unique intramolecular donor-stabilized plumbylene **15**.[29] The obvious ease with which 15e⁻-[(η^5-C_5R_5)Ni] fragments could be generated from **3** spurred our interest in the synthesis of new Ni−plumbylene complexes derived from **15**. Complex **15** is a uniquely chelated Pb^{II} compound, which owes its stability to an intramolecular twofold N-donor stabilization (Figure 10).[33] An intramolecular exchange process is responsible for equivalency of both Fc−N groups in solution, giving rise to temperature- and solvent-dependent equilibrium of *meso*/*rac* diastereoisomers of **15**.[29]

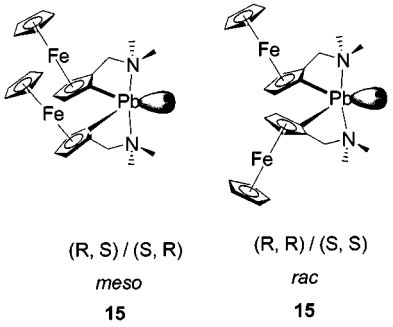

Figure 10. *meso* and *rac* isomer of **15**[29]

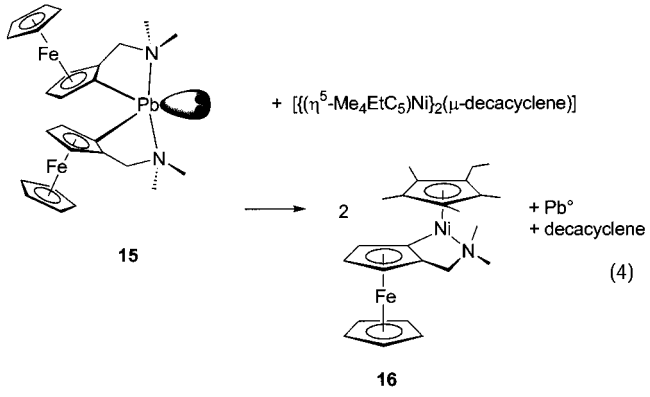
Addition of solid **3** to a yellow suspension of **15** in diethyl ether at −78 °C gave a magenta-colored solution, accompanied by immediate elimination of **2** as tan-colored precipitate. However, on warming up to ambient temperature the color changed from magenta to red. From this solution (*R*,*S*)-**16** could be isolated as a racemic mixture, as the only product [Equation (4)]. The cyclometallation of the [(dimethylamino)methyl]ferrocenyl ligand proceeds by a transmetallation reaction of the *meso*/*rac* diastereomer **15**. The intramolecular N→Pb stabilization present in **15** is obviously not sufficient to stabilize a Pb−Ni coordination bond at room temperature. It is obvious that the initially observed magenta color of the reaction mixture is indeed due to formation of a Pb^{II}−Ni species initially formed in the reaction between **3** and **15**. We have found that complexes containing similar Sn^{II}−Co(Fe) bonds do show the same characteristic magenta color; as do initial reaction solutions of **3** and **15**. However, the Sn^{II}−Co(Fe) complexes are fairly stable under ambient conditions.[29] In contrast, the Pb^{II}−Ni species do not prove to be stable and eliminate Pb^0, liberating the ferrocenyl ligands, which undergo subsequent orthometallation to give **16**.



In the ^{13}C NMR spectrum the signal of the metallated carbon atom C^2 ($\delta = 103.8$) is shifted by about 35 ppm to lower field compared with that of the nonmetallated Cp ligand of the ferrocene moiety ($\delta = 69.1$), well in agreement with the observations for the azobenzene complexes **13** and **14**. The ^1H NMR spectroscopic data are in close agreement to the related cationic Co^{III} complex $[(\eta^5\text{-}C_5H_5)Co(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_3CH_2NMe_2)(PMe_3)]^+PF_6^-$ reported recently.[30]

X-ray Analysis of 16

Figure 11 depicts the molecular structure of **16** as a result of a single-crystal X-ray diffraction study. As concluded from the NMR spectroscopic data, the $[(\eta^5\text{-}Me_4EtC_5)Ni]$ fragment is indeed coordinated to the *o*-carbon atom (C^{10}) and to the nitrogen atom of the [(dimethylamino)methyl]Cp ring of the ferrocene subunit, giving the nickel center a nearly trigonal-planar coordination. The planes of the Me_4EtC_5 ring and the five-membered metallacycle are nearly perpendicular to each other (87.8°) (Figure 12). The Fe distances to the ring centroids of the unsubstituted and the annulated Cp ring of the sandwich unit are equal within experimental error, thus indicating no significant influence of the Ni−chelate ring with respect to bonding in the ferrocene part. The distance $Ni-Cp_{centroid}$ equals that in **16** (1.74 Å). The nickelacycle is slightly puckered as can be seen when viewed along the Ni−N axis (Figure 12). The puckering is related to the torsion angles of the best planes defined by $C^9-C^{22}-Ni$ and $C^9-C^{10}-Ni-N$, which is 11.2°.

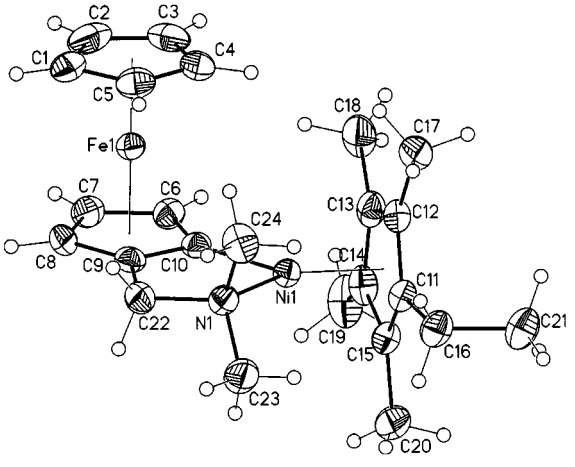


Figure 11. Molecular structure of **16** as determined in the solid state; selected bond lengths [Å] and angles [°]: N^1-C^{10} 1.881(3), Ni^1-N^1 2.001(2), N^1-C^{22} 1.513(3), $C^{10}-Ni^1-N^1$ 86.99(10); $C^9-C^{22}-N^1$ 108.9(2), $C^{22}-N^1-Ni^1$ 111.13(15)

Theoretical Studies on π-Arene Ligand Lability in Arene-Bridged Triple-Deckers of Co and Ni

An intriguing question regarding the reactivity of the (decacyclene)Ni triple-deckers **3** and **4** is the cause of their unusual arene lability under the mild conditions reported herein. Definite notation of arene lability in binuclear complexes has been reported for only a very limited number of cases so far. Thus, we were interested to see whether calculations on the EHMO level could provide, aside from our experimental studies, theoretical insight into this lability for **3** and **4**. Furthermore, we would like to compare our results with other related di- and mononuclear complexes showing related characteristic behavior towards arene exchange.

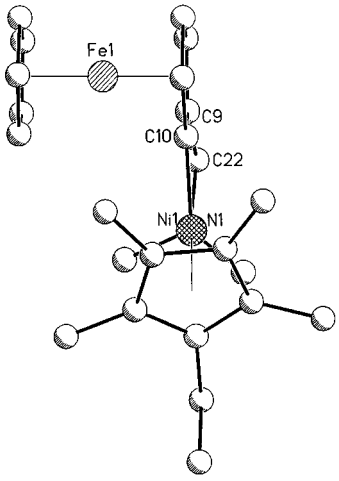

Figure 12. View along the Co−N bond axis of **16**, showing the slight puckering of the metallacycle; atom numbering scheme according to Figure 11

In choosing the EHMO approach we hoped to obtain reliable and still interpretable (at least in well-established chemical paradigms) semiqualitative information on this question.

The arene lability in the triple-decker complexes **3** and **4** can be compared to the following triple-decker compounds: (a) $[(\eta^5\text{-}C_5H_5)V(\mu\text{-}\eta^6\text{:}\eta^6\text{-}C_6H_6)V(\eta^5\text{-}C_5H_5)]$[31] (arene exchange only above 120 °C); (b) $[(\eta^5\text{-}C_5R_5)Co(\mu\text{-}\eta^4\text{:}\eta^4\text{-toluene})Co(\eta^5\text{-}C_5R_5)]$[23] ($R_5$ = 1,2,4-tBu$_3$, Me$_5$) (arene exchange at ambient temperature, compound stable in solution at ambient temperature). In addition the following mononuclear complexes are available for comparison: (c) $[(\eta^6\text{-toluene})Ni(C_6F_5)_2]$[32] (arene extremely labile, arene exchange at ambient temperature); (d) $[(\eta^6\text{-toluene})Co(C_6F_5)_2]$[32] (arene extremely labile, arene exchange at ambient temperature); (e) $[(\eta^6\text{-toluene})Fe(2,2'\text{-bipyridine})]$[33] (arene is not labile); (f) $[(\eta^6\text{-}C_6H_6)Ni(\eta^1\text{-}t\text{Bu}_2PCH_2P\text{-}t\text{Bu}_2)]$[34] (decomposition in solution above −30 °C, probably due to M−arene dissociation, e.g. the compound is not stable in solution at ambient temperature, however, between −80 to −30 °C no arene exchange was found on the NMR time scale).

From these complexes model compounds were constructed through the simplification of alkyl ligand substituents by hydrogen, i.e. in the calculations only C_5H_5 and C_6H_6 were employed. Calculations were performed on the symmetrical triple-decker complexes **A** [(Figure 13)]. The actual η^3:η^3 or η^4:η^4 coordination in the nickel and cobalt triple-deckers was considered by looking at the slipped

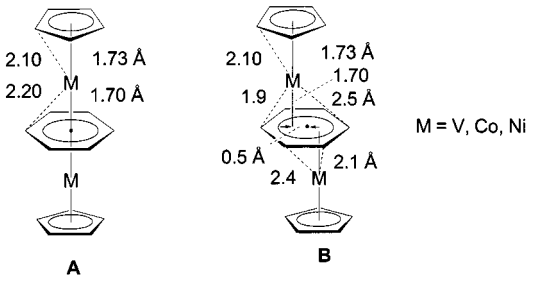

Figure 13. EHMO bonding parameters calculated for the symmetrical (**A**) and the slipped triple deckers (**B**)

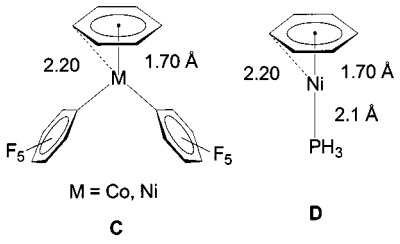

Figure 14. EHMO bonding parameters for the mononuclear complex types **C** and **D**

triple-decker complex **B**. For comparison the mononuclear arene complexes **C** and **D** were included in the calculations (Figure 14).

Triple-decker complexes with middle decks other than arenes have been theoretically analyzed before. Theoretical studies are available for sandwich complexes with middle decks such as C_5H_5,[35] P_5 and As_5, P_6, P_3 and P_4.[36] The orbital interactions of two C_5H_5M fragments with such a middle deck have been well described. In addition, a theoretical study on **C** is available.[37] Furthermore, a photoelectron spectroscopic study, and an MO calculation on **A** with M = V have been carried out.[38]

As a measure of metal−arene bond stability we have used the concept of overlap population. The Mulliken overlap population between two orbitals located on atoms or fragments **X** and **Y** in a molecule is $2c_ic_jS_{ij}$. This corresponds to the amount of electron density transferred to the region between **X** and **Y** on interaction of the two orbitals under consideration. Depending on the signs of the orbital coefficients c_i, c_j, the overlap population, representing the shared electron density of **X** and **Y**, can be positive or negative. A larger positive overlap population correlates with a stronger bond and a larger bond order between atoms **X** and **Y**. However, actual numbers can only be compared within a related series, keeping the atom pair **X**, **Y** constant. For example, the overlap population of a transition-metal−transition-metal bond should not be compared to that of a carbon−carbon bond. The orbital overlap (S_{ij}) term is different for different orbitals or atom pairs. Therefore, it is not so much the single, absolute number that is meaningful, but the trend that is observed upon variation of geometrical or electronic factors.[39,40]

From an Extended Hückel MO study on the model complexes **A**−**D** the following situation emerges: Taking the symmetrical triple-decker **A** we looked at the M−arene overlap population for M = V, Co, Ni in Figure 15. One has to be cautious about comparing the overlap population for different metals. However, this is not necessary by simulating the variation in metal by the electron count and thereby keeping the atom pairs constant. Starting from the neutral complex for M = V (26e$^-$) and Co (34e$^-$) it is obvious that the M−arene overlap drops when adding additional electrons. Conversely, taking electrons away for M = Co (34e$^-$) and Ni (36e$^-$) increases the M−arene overlap. This can be rationalized by the fact that the frontier orbitals are largely metal-centered, but also with metal-to-ligand antibonding combinations.

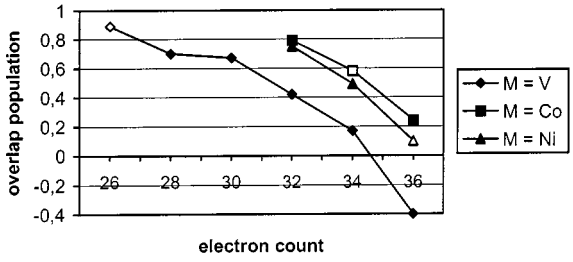

Figure 15. M−arene overlap population in **A** as a function of electron count (open field □, □, Δ is the neutral complex)

Figure 16 compares the M−arene overlap population for the symmetrical and the slipped triple-decker **A** and **B**. Upon slippage, the overlap population is slightly lower for M = V, but increases considerably for M = Co and Ni. This corresponds to the experimental finding of a symmetrical triple-decker for vanadium and η^3:η^3 or η^4:η^4 slipped sandwiches for cobalt and nickel.

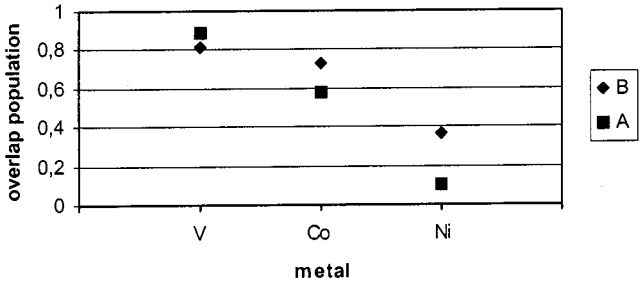

Figure 16. M−arene overlap population in **A** and **B** for M = V, Co, and Ni (neutral complexes)

As a means of calibration we checked the calculated overlap population towards M−arene overlap populations in the mononuclear complexes **C** and **D** with known arene lability. Figure 17 illustrates the results. The overlap population for **C** is lower than for **B** with the same metals. This results corresponds nicely to the experimental finding of a rather low activation energy of 10−11 kcal·mol^{-1} for arene exchange in **C** (M = Ni),[32] thus establishing a slightly higher reactivity for arene exchange for **C** compared to **B**. For **D** the overlap population is the lowest within the nickel series. The low overlap population in **D** compared with **B** or **C** (M = Ni) was surprising, because no arene exchange was reported by NMR techniques for **D**. A closer look re-

vealed, however, that [(η⁶-C_6H_6)Ni(η¹-*t*Bu_2PCH_2P*t*Bu_2)][34] was reported to be stable in solution only up to −30 °C. Above that temperature decomposition took place, probably due to M−arene bond dissociation. Hence, NMR exchange studies were not carried out under ambient conditions as for the other compounds but only at temperatures between −80 and −30 °C, and probably not for an extended period of time.[34] Hence, the instability of [(η⁶-C_6H_6)Ni(η¹-*t*Bu_2PCH_2P*t*Bu_2)] is well reflected in the low M−arene overlap population of **D**.

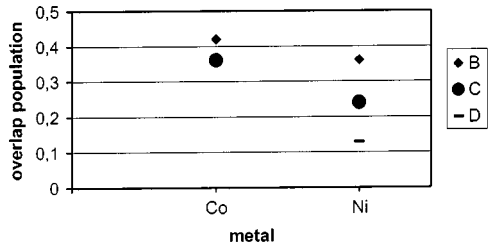

Figure 17. M−arene overlap population in **B**, **C** (M = Co, Ni), and **D**

For useful preparative purposes a labile, yet stable enough character of the M−arene bond is crucial. This results in the combination of two important factors: the ease of handling under ambient conditions, in connection with a still high reactivity for arene exchange under these same conditions. Complexes of type **B** and **C** ideally offer both prerequisites.

Conclusions

Reaction of [(η⁵-$EtMe_4C_5$)Ni(η²-acac)] with the dianion of decacyclene resulted in the formation of the slipped triple-decker **3** with a unique antarafacial bis(η³-enyl)nickel coordination in the solid state as revealed by X-ray crystallography. Complex **3** and its Me_5C_5 derivative **4** display a high reactivity towards ligand loss. This fact has been proven by formation of a number of organonickel chalcogenato complexes of type [(η⁵-Me_4EtC_5)$Ni_2(ER)_2$] (E = S, Se, Te; R = Ph, Mes, Naphth) that are formed by ligand displacement of the polynuclear aromatic middle deck decacyclene. Reaction of **3** and **4** with azobenzene under ligand exchange resulted in C_{sp2}−H activation of the *ortho* ring position giving a remarkable stable five-membered nickelacycle. Complex **3** reacts with the plumbylene **15** in a transmetallation reaction by elimination of Pb^0, giving **16**, which contains a cyclometallated ferrocenyl moiety.

The overlap population from EHMO calculations can be used as a qualitative measure for arene lability in metal−arene complexes. Results obtained from these calculations explain the variation of arene lability in this class of compounds. The increased metal−arene lability observed in cobalt and nickel complexes is due to a filling of metal−arene antibonding orbitals.

Experimental Section

General Information: All reactions were carried out under nitrogen using Schlenk techniques; all solvents were dried properly and distilled under appropriate conditions before use. They were stored under nitrogen prior to use. Products were purified by crystallization. Yields refer to analytically pure samples. Decacyclene (Aldrich) was sublimed in vacuo prior to use. Dichalcogenides R−E−E−R were synthesized according to the literature.[41] − NMR spectra were measured at 25 °C with a Bruker AMX300 or AMX500 and referenced against the deuterated solvents used; coupling constants are given in Hz. NMR samples were prepared by vacuum transfer of dried degassed solvents onto the appropriate amount of solid sample, followed by flame sealing of the NMR tube. − MS spectra were recorded with a MAT 8200 instrument using standard conditions (EI, 70 eV) and the fractional sublimation technique for compound inlet. − UV/Vis spectra were recorded with a Varian Cary 100 spectrometer under air in 10-mm thick cuvettes. − Microanalyses were performed by the microanalytical laboratory of the Chemistry Department of the University−GH Essen.

Photoelectron Spectroscopy Studies (PES): PE spectra were recorded with a Leybold Hereaus UPG200 spectrometer equipped with an He^I radiation source (21.21 eV). Samples were evaporated directly into the target chamber. In order to maintain sufficient vapor pressure of **13** a temperature of 200 °C was used. The energy scale was calibrated with xenon (12.130 and 13.436 eV) and argon (15.759 and 15.937 eV). The accuracy of the measurements was ± 0.03 eV for ionization energies, for broad and overlapping signals ± 0.1 eV.

Theoretical Studies: Qualitative MO computations were performed within the extended Hückel formalism[42] with weighted H_{ij} values[43] with the CACAO program (Version 4.0).[44] Geometrical parameters were taken from X-ray structural studies of the parent compounds[3,23,31,33,35] and averaged. For comparison, the same structural parameters were employed for the different metals in the model compounds [(η⁵-C_5H_5)M(μ-η⁶:η⁶-C_6H_6)M(η⁵-C_5H_5)] (**A**: M = V, Co, Ni), [(η⁵-C_5H_5)M(μ-η³:η³-C_6H_6)M(η⁵-C_5H_5)] (**B**: M = V, Co, Ni), [(η⁶-C_6H_6)M(C_6F_5)₂] (**C**: M = Co, Ni), and [(η⁶-C_6H_6)NiPH_3] (**D**). Keeping the metal−ligand distances constant when changing the metal atom allows for a better comparison on the effect of the metal center. The actual geometric parameters employed in the calculations were as follows (see also the drawings for **A**−**D**): M−C_6H_6(centroid) = 1.70 Å; M−C(η⁶-C_6H_6) = 2.20 Å; M−C_5H_5(centroid) = 1.73 Å; M−C(η⁵-C_5H_5) = 2.10 Å; M−C(σ-C_6F_5) = 1.90 Å; Ni−P = 2.10 Å; C−C(η⁵-C_5H_5) = 1.40 Å; C−C(η⁶-C_6H_6) = 1.39 Å; C−C(C_6F_5, bipy) = 1.40 Å; C−H = 1.05 Å; C−F = 1.35 Å. The distances of M−C(η⁶-arene) found in the X-ray structures lie within 0.15 Å of the 2.20 Å assumed for M−C(η⁶-C_6H_6) with M = V, Co, and Ni. The atomic parameters used were taken from established work and are listed in Table 2.

Horizontal ionization energy calculations were performed with the HyperChem computational package (Version 5.0, Hypercube Inc., Waterloo, Ontario, Canada). Geometry optimizations were carried out on the model complex [(η⁵-Cp)Ni(C_6H_4−N=N−C_6H_5-κ*C*,κ*N*)] ***A*** with the ZINDO/1 method. The Ni−C_{aryl} and Ni−N contacts were refined free to values of $Ni-C^{19}$ = 1.956 Å and $Ni-N^1$ = 1.949 Å. For comparison these values were also restrained to the experimental bond lengths of $Ni-C^{19}$ = 1.864 and Ni−N = 1.816 Å. In addition, the bond angle $C^{12}-N^1-N^2$ was restrained to 113°. No other restrictions were applied. Single-point LCAO−MO−SCF calculations using the ZINDO/S approxi-

mation with spectroscopic parameterization[24] have been performed on the model complex ***A*** in its respective ZINDO/1 optimized geometry. The restraints did not lead to large changes in orbital composition or energetic order.

Synthesis

[{(η⁵-Me₄EtC₅)Ni}₂(μ-η³:η³decacyclene)] (3): Decacyclene (250 mg, 0.6 mmol) was suspended in 50 mL of THF and transferred into a flask in which a metallic mirror from 60 mg (1.54 mmol) of potassium metal had been prepared. After 3 d, ca. 90% of the metal was dissolved, resulting in a deep red-brown solution. After cooling to −78 °C, [(η⁵-Me₄EtC₅)Ni(η²-acac)][47] (**1**) (370 mg, 1.2 mmol) was added to this solution in one batch under stirring, and the resulting mixture was allowed to warm to room temperature during several hours. After removal of all volatiles, the residue was dissolved in diethyl ether and crystallized from that solvent at −30 °C, resulting in 360 mg (0.42 mmol, 74%) of shimmering black crystals of **3**. − ^{1}H NMR (300 MHz, C_6D_6): δ = 0.52 (t, 6 H), 0.77 (s, 12 H), 0.78 (s, 12 H), 1.27 (q, 4 H), 7.42 (t, ^3J = 7.2 Hz, 6 H), 7.63 (d, ^3J = 7.2 Hz, 6 H), 8.36 (t, ^3J = 7.2 Hz, 6 H). − ^{13}C NMR (75 MHz, C_6D_6): δ = 7.8, 7.9, 14.6, 16.7, 97.5, 98.9, 104.6, 118.9, 123.2, 132.2, 135.9, 142.9. − IR (KBr): ṽ = 3048, 2963, 2925, 2857, 1581, 1482, 1457, 1435, 1378, 1355, 1301, 819, 800, 771, 758 cm^{-1}. − $C_{58}H_{52}Ni_2$ (866.47): calcd. C 80.40, H 6.05; found C 81.00, H 6.38.

The general experimental procedure for reactions of **3** with the dichalcogenides **5**−**8** was as follows: To solution of the dichalcogenide in diethyl ether at 0 °C a diethyl ether solution of **3** was added. Upon warming to ambient temperature precipitation of tan colored decacyclene occurred. The resulting mixture was reduced in volume and filtered through Celite. Crystallization at −30 °C afforded complexes **9**−**12**.

[{(η⁵-Me₄EtC₅)Ni}₂(μ-SPh)₂] (9): Brown crystals; yield: 300 mg (0.4 mmol, 84%). − ^{1}H NMR (300 MHz, C_6D_6): δ = 0.91 (t, 6 H), 1.13 (s, 12 H), 1.20 (s, 12 H), 1.85 (q, 4 H), 7.02 (m, 6 H), 8.36 (m, 4 H). − ^{13}C NMR (75 MHz, C_6D_6): δ = 8.9, 9.0, 14.3, 17.9, 97.6, 99.0, 99.3, 106.9, 125.3, 127.5, 136.1, 138.9. − MS (EI): *m*/*z* (%) = 632 (60) [M$^+$], 316 (100) [M$^+$/2]. − IR (KBr): ṽ = 3059, 2961, 2903, 2854, 1576, 1473, 1450, 1436, 1378, 1347, 1297, 1262, 1153, 1022, 819, 769, 738, 689 cm^{-1}. − $C_{34}H_{44}Ni_2S_2$ (634.266): calcd. C 64.39, H 6.99, S 10.11; found C 67.08, H 6.65, S 7.43.

[{(η⁵-Me₄EtC₅)Ni}₂(μ-SeMes)₂] (10): Brown microcrystals; yield: 360 mg (0.4 mmol, 79%). − ^{1}H NMR (300 MHz, C_6D_6): δ = 0.80 (t, 6 H), 1.23 (s, 24 H), 1.86 (q, 4 H), 2.11 (s, 6 H), 2.55 (s, 6 H) broad, 4.33 (s, 6 H) broad, 6.70 (s, 2 H) broad, 6.99 (s, 2 H) broad. − ^{13}C NMR (75 MHz, C_6D_6): δ = 9.1, 9.2, 14.2, 18.0, 21.0, 98.6, 105.5, 120.1, 135.0. − MS (EI): *m*/*z* (%) = 812 (20) [M$^+$], 406 (100) [M$^+$/2]. − $C_{40}H_{56}Ni_2Se_2$ (812.228): calcd. C 59.15, H 6.95; found C 54.72, H 6.72.

[{(η⁵-Me₄EtC₅)Ni}₂(μ-TeMes)₂] (11): Brown microcrystals; yield: 410 mg (0.4 mmol, 80%). − ^{1}H NMR (300 MHz, C_6D_6): δ = 0.83 (t, 6 H), 1.50 (s, 12 H), 1.52 (s, 6 H), 1.53 (s, 6 H), 2.03 (q, 4 H), 2.10 (s, 6 H), 2.70 (s, 6 H), 3.62 (s, 6 H), 6.68 (s, 2 H), 6.86 (s, 2 H). − ^{13}C NMR (75 MHz, C_6D_6): δ = 9.9, 10.0, 10.1, 10.2, 15.1, 18.9, 21.0, 29.9, 32.1, 98.1, 98.3, 99.4, 99.7, 104.8, 126.4, 127.0, 136.4, 144.6, 146.0. − MS (EI): *m*/*z* (%) = 910 (15) [M$^+$], 791 (17) [M$^+$ − mesitylene], 456 (18) [M$^+$/2], 119 (100) [mesitylene]. − $C_{40}H_{56}Ni_2Te_2$ (909.508): calcd. C 52.82, H 6.21; found C 53.10, H 6.18.

[{(η⁵-Me₄EtC₅)Ni}₂(μ-TeNaphth)₂] (12): Black crystals; yield: 380 mg (0.4 mmol, 73%). − ^{1}H NMR (300 MHz, C_6D_6): δ = 0.75 (t, 6 H), 1.38 (s, 12 H), 1.40 (s, 6 H), 1.41 (s, 6 H), 1.92 (q, 4 H), 7.05 (t, ^3J = 7.7 Hz, 2 H), 7.30 (m, 2 H), 7.45 (m, 2 H), 7.55 (d, ^3J = 8.1 Hz, 2 H), 7.61 (d, ^3J = 7.7 Hz, 2 H), 8.81 (d, ^3J = 7.7 Hz, 2 H), 9.38 (d, ^3J = 8.1 Hz, 2 H). − ^{13}C NMR (75 MHz, C_6D_6): δ = 10.1, 10.2, 10.3, 10.4, 15.3, 19.0, 98.5, 99.0, 99.9, 100.5, 100.7, 105.8, 125.3, 126.0, 126.1, 128.8, 132.8, 133.0, 138.4, 141.9. − MS (EI): *m*/*z* (%) = 926 (15) [M$^+$], 799 (10) [M$^+$ − naphthalene], 464 (15) [M$^+$/2], 253 (100) [binaphthalene]. − $C_{42}H_{48}Ni_2Te_2$ (925.466): calcd. C 54.51, H 5.23; found C 55.05, H 5.36.

[(η⁵-Me₄EtC₅)Ni(C₆H₄−N=N−C₆H₅-κ*C*,κ*N*)] (13): This compound was prepared by adding a stoichiometric amount of azobenzene to a solution of **3** in 500 mL of diethyl ether at room temperature. While stirring for 12 h, the color changed from brown red to deep blue. Crystallization from diethyl ether afforded dark blue crystals; yield: 380 mg (1.0 mmol, 88%). − ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 0.93 (t, 3 H), 1.62 (s, 6 H), 1.73 (s, 6 H), 2.15 (q, 2 H), 7.08 (m, 1 H, C^5−H), 7.13 (m, 1 H, C^4−H), 7.16 (m, 2 H, C$^{8,8'}$-H), 7.37 (m, 1 H, C^{10}−H), 7.47 (m, 2 H, C$^{9,9'}$-H), 7.86 (m, 1 H, C^3−H), 8.11 (m, 1 H, C^6−H). − ^{13}C NMR (75 MHz, CD_2Cl_2): δ = 9.3, 9.5, 15.1, 17.7, 100.4, 101.4, 108.2 [(η⁵-Me₄EtCp)Ni], 123.0 (C$^{8,8'}$), 123.2 (C^4), 123.8 (C^5), 127.5 (C^{10}), 127.6 (C^6), 128.8 (C^9), 138.5 (C^3), 157.4 (C^7), 163.1 (C^1), 181.9 (C^2). − MS (EI): *m*/*z* (%) = 388 (100) [M$^+$]. − IR (KBr): ṽ = 3082, 3055, 3039, 2961, 2912, 2867, 1588, 1567, 1484, 1447, 1296, 1287, 1262, 1032, 1017, 770, 753, 711, 698 cm^{-1}. − UV/Vis (CH_2Cl_2): λ_{max} (ε) = 230 (24923), 250 (21760), 300 (25237), 345 (9203), 510 (3243), 609 nm (6317). − $C_{23}H_{26}N_2Ni$ (389.18): calcd. C 70.98, H 6.73, N 7.20; found C 70.31, H 6.98, N 6.89.

[(η⁵-C₅Me₅)Ni(C₆H₄−N=N−C₆H₅-κ*C*,κ*N*)] (14): As with the synthesis of **13**. Blue, needle-like crystals, prepared from **4**; yield: 350 mg (0.9 mmol, 85%). − ^{1}H NMR (300 MHz, C_6D_6): δ = 1.50 (s, 15 H) 7.0 (m, 1 H, C^{10}−H), 7.06−7.22 (m, 6 H), 7.94 (dd, ^3J =

7.9 Hz, ^4J = 1.1 Hz, 1 H, C^3−H), 8.50 (dd, ^3J = 7.7 Hz, ^4J = 1.5 Hz, 1 H, C^6−H). − ^{13}C NMR (75 MHz, C_6D_6): δ = 9.4, 100.6, 123.2, 123.7, 124.0, 127.1, 138.4, 157.7, 164.1, 182.7. − MS (EI): *m/z* (%) = 374 (100) [M^+]. − IR (KBr): ṽ = 3058, 3039, 2979, 2952, 2898, 2851, 1589, 1484, 1420, 1385, 1297, 1263, 1154, 1068, 1017, 769, 758, 753, 711, 698 cm^{-1}. − $C_{22}H_{24}N_2Ni$ (375.16): calcd. C 70.44, H 6.45, N 7.47; found C 64.17, H 5.99, N 6.95. Although this analysis was repeated several times with recrystallized material, C,H,N values for **15** were repeatedly unsatisfactorily.

[(η^5-C_5H_5)Fe[μ-(η^5-$C_5H_3CH_2NMe_2$-κ*C*,κ*N*)]Ni(η^5-C_5EtMe_4)] (16): Solid **3** (180 mg, 0.2 mmol) was added to a yellow suspension of plumbylene **15** (140 mg, 0.2 mmol) in diethyl ether at −78 °C. Within a few hours precipitation of decacyclene (**2**) occurred and the color of the solution turned to purple, while upon warming to ambient temperature it changed to red-brown. The mixture was reduced in volume and filtered through Celite. Crystallization at −78 °C afforded 60 mg (0.1 mmol, 65%) of complex **16** as red to black crystals. − ^{1}H NMR (300 MHz, C_6D_6): δ = 1.11 (t, 3 H), 1.69 (s, 3 H), 1.70 (s, 3 H), 1.72 (s, 6 H), 1.86 [s, 3 H, $N(CH_3)_2$], 2.24 (q, 2 H), 2.33 [s, 3 H, $N(CH_3)_2$], 2.59 (d, ^2J = 13.6 Hz, 1 H, Fc−CH_2), 2.89 (d, ^2J = 13.6 Hz, 1 H, Fc−CH_2), 3.84 (d, ^3J = 2.1 Hz, 1 H, C_5H_3Fe), 3.98 (d, ^3J = 2.1 Hz, 1 H, C_5H_3Fe), 4.20 (s, 5 H, C_5H_5Fe), 4.24 (t, ^3J = 2.1 Hz, 1 H, C_5H_3Fe). − ^{13}C NMR (75 MHz, C_6D_6): δ = 10.4, 10.5, 15.2, 19.2, 53.2 [$N(CH_3)_2$], 53.4 [$N(CH_3)_2$], 60.8 (C_5H_3Fe), 66.5 (C^4), 68.4 (Fc−CH_2), 69.1 (C_5H_5Fe), 71.7 (C_5H_3Fe), 90.2 (C^1), 92.4 (C^2), 95.5, 96.1, 97.2, 97.4, 103.8. − MS (EI): *m/z* (%) = 449 (100) [M^+], 326 (45) [M^+ − C_5H_5Fe], 242 (20) [M^+ − $C_{11}H_{17}Ni$]. − IR (KBr): ṽ = 3079, 3026, 2961, 2922, 2852, 2769, 1451, 1415, 1383, 1353, 1302, 1227, 1158, 1105, 1043, 1022, 974, 947, 864, 846, 809, 795 cm^{-1}. − $C_{24}H_{33}FeNNi$ (450.09): calcd. C 64.05, H 7.39, N 3.11; found C 57.89, H 6.96, N 3.11. Probably due to excess [(dimethylamino)methyl]ferrocene that could not be removed completely by washing without dissolving most of **16**, the C value is found out of the usually acceptable range.

Acknowledgments

The work of J. J. S. was supported by the DFG (Heisenberg fellowship to J. J. S.), by the Stiftung Volkswagenwerk and the Fonds der Chemischen Industrie which is acknowledged with gratitude. We are grateful to the mass spectrometric department of the MPI für Kohlenforschung, Mülheim, for recording the mass spectra and Mr. K. Kowski, University of Essen, for recording the PE spectrum of **13**. The work of C. J. was supported by the DFG and the Fonds der Chemischen Industrie. A copy of the CACAO program was kindly provided by Dr. D. M. Proserpio.

Formation of Polyesters by Thermally Induced Polymerization Reactions of Molecular Solids

Oliver Herzberg[a] and Matthias Epple*[a]

Dedicated to Prof. Dr. R. D. Fischer on the occasion of his 65th birthday

Keywords: Solid-state polymerization / Halogenocarboxylates / Polymers / Biomaterials / Materials chemistry

The development of solid-state polycondensation reactions, starting in 1857, is reviewed. In many cases, the elimination of metal halides from halogenated carboxylates leads to the formation of polyesters, among them polyglycolide, polylactides, polybutyrates, polymandelide, and poly(hydroxymethyl benzoates). In some cases, a reaction in the solid state is observed, whereas in other cases temporary liquefaction occurs. The resulting polymers usually have a lower degree of polymerization than the products from solution- or melt-polymerization. In some cases, polymers with a distinct micromorphology (high porosity with pores in the sub-μm range) are obtained and may be of interest for special applications, e.g. in medical technology.

Introduction

Polymers constitute one of the major classes of materials. Owing to the tremendous progress made in polymer chemistry since the days of Hermann Staudinger, the properties of polymeric materials can now be fine-tuned within a wide range, so that they have replaced classical materials (metals, wood, ceramics) in many applications (the annual worldwide production of synthetic polymer fibers is approximately 20 Mio t/a). Usually, polymers are prepared in the melt or in solution.

An impressive number of solid-state polymerization reactions occurring in the solid state is known. They may be divided into radiation-induced reactions (photopolymerization reactions) and thermally induced reactions. However, although polymerization reactions in the solid state had been known since the last century,[1,2] they did not find an industrial application, probably due to the inherent difficulties involved in controlling a large-scale exothermic reaction in the solid state. In this article, we review one type of these reactions, i.e. thermally induced reactions that lead to polyesters, accompanied by salt elimination. In some special cases, the resulting materials may be useful for biomedical applications.

Oliver Herzberg was born in 1968 in Flensburg. After studying chemistry at the University of Hamburg from 1989 to 1996, he obtained his PhD in 2000 with M. Epple on the reactivity of molecular solids, including solid-state polymerization reactions of halogenomethylbenzoates.

Matthias Epple was born in Reutlingen in 1966. He finished his studies with a PhD in Physical Chemistry in 1992 (topic: solid-state reactions and solid-state phase transformations) at the Technical University of Braunschweig under the direction of Prof. H. K. Cammenga. In 1993, he worked as a postdoctoral fellow at the University of Washington (Seattle, USA) on colloid and polymer science (Prof. J. C. Berg). From 1994 to 1997 he performed his habilitation at the Institute of Inorganic and Applied Chemistry at the University of Hamburg (Prof. A. Reller), working in the field of molecular solid-state reactivity, including the application of synchrotron radiation techniques. His awards include the Netzsch-GEFTA Young Scientist Award (1995), a DFG Heisenberg stipend (1998) and a DFG Heinz−Maier−Leibnitz Award (1998). Since April 2000, he holds a professorship in Inorganic Chemistry at the Ruhr University of Bochum. He has authored more than 70 publications in reviewed journals. His current research interests include molecular solid-state chemistry, preparation and characterization of biomaterials (polymers, ceramics and metals) and studies on biomineralization (biological and medical).

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Some Background Information on Polyesters

Polyesters, i.e. macromolecules with ester bonds between the repeating units, constitute an important group of materials with a high number of applications. Among the well-known polyesters are poly(ethyleneterephthalic acid) [polyethyleneterephthalate; PET], poly(butyleneterephthalic acid) [polybutyleneterephthalate; PBT], polyglycolide [poly(hydroxyacetic acid); PGA] and polylactide [poly(2-hydroxypropionic acid); PLA]. Note that if the ester groups are placed in side chains in a graft polymer, the polymer is not called a polyester.

Biodegradable polyesters constitute an important subset. The potentially hydrolyzable ester bond is used in a number of poly(hydroxycarboxylic acids) with polyglycolide, polylactide and P-3HB [poly(3-hydroxybutyric acid)] being the most prominent examples. As a contribution to a sustainable development, they may replace nonbiodegradable polymers made from fossil fuels in consumer chemicals.[3] For example, the Cargill−Dow Polymer Corporation has announced that in 2002 it intends to start the production of polylactide from corn starch with an annual capacity of 140,000 t, under the trade name NatureWorks™ PLA. Other examples of commercially available biopolymers are poly[(*R*)-3-hydroxybutyrate] and its copolymer poly[(*R*)-3-hydroxybutyrate-*co*-(*R*)-3-hydroxyvalerate], trade name BIOPOL™, both produced by biofermentation. In 1994, the production of BIOPOL was approximately 1,000 t (ICI−Zeneca).[4] Although these materials from renewable resources have good mechanical and chemical properties, the replacement of fossil fuel based polymers (such as polyethylene and polypropylene) appears to be constrained by the higher price of biodegradable polymers. Another aspect is the existence of operational production facilities and established distribution pathways for conventional polymers, so that a number of companies have again abandoned research on and production of biodegradable polymers.

A more specialized application of biodegradable polymers is in the field of medical technology. As many polyesters and their monomers are nontoxic, they can be used as implants within the body, for example, where a mechanical support of tissue is required. Typical applications are surgical sutures, wound covers (artificial skin), bone-fixation or bone-replacement devices, and carriers for controlled drug release.[5−9] The lifetime in the body depends mainly on the nature of the polymer: While polyglycolide is absorbed within months, polylactide is degraded over years, and the degradation times for poly(3-hydroxybutyrate) are even longer. Fine-tuning of the mechanical properties and of the degradation rate is possible by preparing copolymers, e.g. poly(glycolide-*co*-lactide), PGLA, or poly(3-hydroxybutyrate-*co*-3-valerate), PHBHV. Usually, poly(hydroxycarboxylic acids) are prepared by ring-opening polymerization[10] [Equation (1)] (e.g., polyglycolide, polylactide) or by biotechnological fermentation [(poly(3-hydroxybutyrate)].[4]

Solid-State Polymerization Reactions

A considerable number of solid-state polymerization reactions has been reported in the literature. None of them are applied industrially, probably because exothermic solid-state reactions involving potentially flammable compounds (such as organic monomers and polymers) are difficult to scale up, and because of the more heterogeneous nature of the polymeric products. Reactions in the solid state depend on numerous parameters that are not significant in liquid-phase reactions (e.g., crystallinity, polymorphic phase, nucleation, defect structure, particle size). However, solid-state polymerization reactions may give:

- highly crystalline or oriented polymers[11−14]
- special product morphologies[15−18]
- high reaction extents[12,19]
- easily purified products without traces of monomers or catalyst.[11,20]

Table 1 contains a selection of unusual solid-state reactions that are initiated by thermal treatment. Some historical examples of solid-state polymerization reactions date back to the early days of chemistry, even before the concept of a polymer was developed.

The first example (to the best of our knowledge) is the thermally induced polycondensation that occurs in potassium chloroacetate, reported by Hoffmann in 1857.[21] The reaction leads to polyglycolide and potassium chloride as the only products (note that the product was originally postulated to be diglycolide, the cyclic dimer). In Figure 1, the original article from 1857 is shown.

It is interesting that the molecular formulae are different from those used today, because at the time the relative atomic weights of carbon and oxygen were thought to be 6 and 8, respectively. Therefore, potassium chloroacetate was represented as $C_4H_2ClKO_4$ instead of $C_2H_2ClKO_2$. One year later, Kekulé, Hoffmann's mentor, studied the reaction (Figure 2),[22] followed by Heintz in 1862,[23] and Norton and Tcherniak in 1878[24] who studied the reaction of sodium chloroacetate. In 1892, Anschütz studied polyglycolide obtained from such a solid-state reaction.[25,26] By cryoscopic measurements in molten phenol, he determined a molecular weight of approximately 5 to 6 glycolide units ($C_2H_2O_2$) without identifying it as a polymer. Systematic studies were then carried out by Bischoff and Walden in 1894 on sodium chloroacetate and sodium bromoacetate.[27,28] For the first time, a polymer was proposed instead of the dimer that had been suggested before.

In 1906, Emil Fischer observed the reaction of pentaglycylglycine methyl ester after prolonged heating at 100 °C to form an amorphous, water-insoluble, presumably polymeric product.[29,30] Fifty years later, this was corroborated by Sluyterman et al.[31] The product was never clearly identified, but it seems to have been polyglycine. The first oriented polymer from an organic solid-state reaction was prepared by Kohlschütter when he sublimed poly(oxymethylene) and obtained trioxane that contained some highly oriented polymer.[1] Six years later, two different groups independently discovered the solid-state polymerization of acet-

Table 1. A selection of "historical" solid-state polymerization reactions

Reaction	Product	Source (Year)
	Polyglycolide	Hoffmann (1857[21]), Kekulé (1858[22]), Heintz (1862[23]), Norton and Tcherniak (1878[24]), Anschütz (1892[25,26]), Bischoff and Walden (1893[27,28])
	Polyglycine (?)	Fischer (1906[29]) and Sluyterman (1952[31])
	Poly(oxymethylene) (para-formaldehyde)	Kohlschütter (1930[1])
	Poly(acetaldehyde)	Travers (1936[32]), Letort (1936[33])

	Poly(acetone)	Magat (1962[19])

aldehyde to poly(acetaldehyde), or poly(oxymethylmethylene).[32,33]

In some cases, high-quality polymers can only be obtained by solid-state reactions.[11] An example is the solid-state polymerization of alkali 4-halogenobenzothiolates. If the reaction is carried out in the solid state, a linear polymer results. The polymeric product is poly(4-phenylene sulfide). The eliminated alkali halides can be washed out easily with water. Until 1970, a linear polymer could only be prepared by this route, because the reaction in the melt was accompanied by cross-linking and chain-branching, leading to the formation of an insoluble product. Nowadays, linear poly(4-phenylene sulfide) can also be synthesized by melt polymerization of *p*-dichlorobenzene in the presence of sodium sulfide.[11] Acetone polymerizes only in the solid state due to the low thermal stability of the resulting polymer.[19] The solid-state polymerization of 4-amino-3,5-dihalobenzoyl chlorides to polybenzamides (with concomitant elimination of HCl) was recently shown by Sandor and Foxman. The preparation of this polymer in solution leads only to the formation of low-molecular weight polymers.[34]

Starting in the 1950s and 1960s, attention was mainly focused on radiation-induced solid-state polymerization reactions of unsaturated or cyclic monomers. Prominent examples are diacetylenes, divinyl compounds and acrylic acid derivatives. Details of radiation-induced solid-state polymerization reactions can be found in a number of reviews.[17,19,35−41]

Polyglycolide by Solid-State Reaction

As outlined above, the transformation of solid halogenoacetates to polyglycolide was discovered almost 150 years ago. Since the early studies in the 19th century, only few articles were published on this reaction. Nevertheless, the reaction received industrial interest. The parent compound for ring-opening polymerization, (di)glycolide, can be obtained by the pyrolysis of the (pre)polymer from the solid-state reaction in vacuo. The sublimed dimer is then subjected to ring-opening polymerization according to Equation (1). Little attention was paid to the raw product, and only few papers about this reaction were published until 1996.[42−46] In particular, no mechanistic studies were carried out, and the resulting polymer was not characterized. Essential details of our studies on this system are presented.

Formally, the elimination of metal halide MX from any halogenoacetate $MOOC-CH_2-X$ leads to the formation of polyglycolide (see Table 1). A systematic variation of most combinations of metal and halogen showed that almost all haloacetates undergo the desired reaction. The results are collected in Table 2.[20] Note that fluoroacetates were not included in the study as these compounds (as well as fluoroacetic acid) are highly toxic.

The three lithium salts, sodium iodoacetate and calcium chloroacetate are notable exceptions. The thermoanalytical data for all the compounds are collected in Table 3. It can be seen that the polymerization reaction is associated with a considerable exothermic heat of reaction. The underlying reason is probably the high lattice energy of the formed metal halide. There is a clear trend in the reaction temperatures, which are lowest for the combinations of large metal cations (like Cs^+) and small halogen anions (like Cl^-). Within the rectangle of alkali metals and halogens, the "corner of stability" is in the upper right, and the "corner of reactivity" is in the lower left of Table 3. The lack in

12 *Hoffmann, über Monochloressigsäure.*

Alkali's zu beseitigen, welches etwa erst in einem zweiten Stadium der Zersetzung zur Bildung von Chlormetall hätte Veranlassung geben können, erhielt ich eine wässerige Lösung der neutralen Salze oder auch der Säure selbst während längerer Zeit im Sieden. Die Zersetzung war in allen Fällen dieselbe wie vorher; es bildete sich sogleich Chlormetall und die Lösung wurde sauer, wenn sie vorher neutral gewesen war. Da aber in keinem Fall die Zersetzung vollständig war, erhitzte ich eine Portion des krystallisirten Kaliumsalzes im Luftbad bei allmählig gesteigerter Temperatur. Das Salz blieb unverändert bis etwas über 110°; bei dieser Temperatur verlor es sehr wenig an Gewicht, wurde matt von Ansehen und gelblich und nahm eine saure Reaction an. Durch kaltes Wasser liefs sich Chlorkalium ausziehen und es blieb ein weifses Pulver, welches sauer reagirte und sich in vielem heifsem Wasser auflöste und beim Erkalten wieder herausfiel. — Da ich in keinem der vorher erwähnten Fälle eines von den Producten nachweisen konnte, welche möglicherweise durch Spaltung der Monochloressigsäuren, oder durch eine theilweise Oxydation unter Rückbildung von Essigsäure entstehen könnten, so scheint es mir wahrscheinlich, dafs überhaupt nur Chlormetall austritt und der Rest der organischen Gruppe als ein Ganzes, wahrscheinlich unter Wasseraufnahme, vereinigt bleibt und von neuem eine Säure bildet, welche die Zusammensetzung der Glycocollsäure haben und etwa nach der Formel:

$$C_4H_2ClMO_4 + 2\,HO = C_4H_4O_6 + MCl$$

entstehen könnte. Ich hätte gewünscht, anstatt dieser Hypothese Thatsachen anführen zu können; allein da es mir weder jetzt noch in der nächsten Zeit vergönnt ist, meine Versuche weiter fortzusetzen, so mufs ich es einer späteren Untersuchung überlassen, dieselbe zu bestätigen, oder zu widerlegen.

Figure 1. Facsimile of the original article by R. Hoffmann in *Justus Liebigs Annalen der Chemie*, "Ueber Monochloressigsäure" (On Monochloroacetic Acid) in 1857, the first known example of a solid-state polymerization reaction (see ref.[21])

288 *Kekulé, Bildung von Glycolsäure*

während Wurtz*) bereits gezeigt hat, dafs sie aus dem Glycol durch dieselben Reactionen erhalten werden kann, wie die Essigsäure aus Alkohol.

Monochloressigsaures Kali verhält sich beim Erhitzen genau so, wie es Hoffmann angegeben hat: das weifse lufttrockene Salz wird bei längerem Erhitzen auf 110 bis 120° feucht, färbt sich gelblich und nimmt saure Reaction an. Bei Behandeln mit kaltem Wasser wird viel Chlorkalium und gleichzeitig Glycolsäure ausgezogen, und es bleibt in verhältnifsmäfsig geringer Menge ein weifses Pulver ungelöst, welches in heifsem Wasser etwas löslich ist und beim Erkalten zum Theil wieder ausfällt. Ich habe diefs Pulver immer in relativ geringer Menge und nie von so reinem Aussehen erhalten, dafs ich es der Analyse hätte unterwerfen können; da es indefs bei längerem Kochen mit Wasser zu Glycolsäure wird und beim Kochen mit Kalkwasser glycolsauren Kalk, das am meisten characteristische Salz der Glycolsäure, liefert, so kann kein Zweifel darüber sein, dafs es *Glycolid* ist, dessen Bildung nach dem Schema:

$$C_4H_3ClKO_4 = KCl + C_4H_2O_4$$

erfolgt. Dafs beim Erhitzen des krystallisirten und lufttrockenen monochloressigsauren Kali's nur wenig Glycolid und wesentlich Glycolsäure gebildet wird, erklärt sich daraus, dafs dieses Salz Krystallwasser enthält, welches ihm nicht entzogen werden kann, ohne dafs es selbst Zersetzung erleidet.

Aus der wässerigen Lösung, welche neben Glycolsäure noch viel Chlorkalium enthält, gewinnt man die Säure leicht,

Figure 2. Facsimile of the original article by A. Kekulé in *Justus Liebigs Annalen der Chemie* in 1858, "Bildung von Glycolsäure aus Essigsäure" (Formation of Glycolic Acid from Acetic Acid), in which he confirmed Hoffmann's observation (see ref.[22])

reactivity of the lithium salts and sodium iodoacetate corresponds well to this observation: These compounds appear to be have a high thermodynamical stability towards polymerization. After all, this depends on the difference between the free enthalpy of formation of the alkali halide and that of the alkali halogenoacetate, e.g. lithium chloroacetate vs. LiCl. Apparantly, these compounds undergo decomposition before they can polymerize. No thermodynamic data are known, therefore this is merely speculation. We will discuss structural aspects below.

The calcium salt of chloroacetic acid does not show any tendency to form polyglycolide. Hoffmann (1857) also studied barium chloroacetate dihydrate and observed decomposition upon heating.[21] However, no details were given about the decomposition products. Possibly, polymerization did not occur because the divalent cations (Ca and Ba) do not support a topochemical reaction. Note that this cannot be generalized to all solid-state polymerization reactions, as radiation-induced polymerization reactions of salts of acrylic and methacrylic acids were observed for a variety of cations, including alkali metals, alkaline earth metals and zinc (however, this is a different type of reaction).[47–50]

A molecular solid-state reaction relies on a suitable arrangement of the reactants in the crystal. The peculiarities of such reactions (low temperatures, bulky reactants, small diffusion coefficients) led to the formulation of the "topochemical principle" by Schmidt and co-workers in the 1960s: Solid-state reactions in molecular crystals take place with as little movement of the molecules as possible.[35,51,52] Consequently, knowledge of the crystal structures of all halogenoacetates is a prerequisite to understand the reactivity.

Table 3. Thermochemical data for halogenoacetates that in most cases react to form polyglycolide (values in italics: no polymerization); reaction temperatures are given as onsets and reaction enthalpies in kJ mol^{-1} for the polymerization reaction by DSC with 5 K min^{-1}

Unfortunately, the preparation of single crystals suitable for structural analysis is seldom possible for halogenoacetates because they tend to crystallize in the form of thin and disordered platelets or needles. In the literature, only the single-crystal structures of ammonium fluoroacetate[53] and of sodium fluoroacetate[54] are reported. It is unlikely that fluoroacetates undergo a polymerization reaction upon heating, owing to the fact that sodium fluoroacetate decomposes above 200 °C, with concomitant release of HF.

Only the structure of silver chloroacetate could be determined by single-crystal diffraction,[55] whereas the structures of lithium chloroacetate,[56] lithium bromoacetate,[56] lithium iodoacetate,[56] sodium chloroacetate,[57] and sodium bromoacetate[58] had to be solved from powder-diffraction data.

Analysis of the packing in the six known structures shows that the structure is determined by the metal ion rather than by the halide. The three lithium salts are isostructural, and the same is true for sodium chloro- and bromoacetate. Silver chloroacetate crystallizes with a completely different packing. The three structure types are shown in Figure 3.

Silver chloroacetate is discussed first. The structure consists of stacks of silver chloroacetate dimers. There is a short Ag−Cl distance of 2.90 Å that is only slightly longer than in silver chloride, the final reaction product (2.78 Å). We suspect that there is already some kind of interaction in silver chloroacetate. A side-view of the stacks shows that a nucleophilic attack of the carboxy group of a chloroacetate ion at an α-carbon atom is conceivable, a process that would finally lead to the formation of two antiparallel chains of polyglycolide from each stack of silver chloroacetate dimers (see ref.[55] for details). The crystal structure of polyglycolide actually consists of antiparallel chains of polyglycolide (Figure 4).[59] This crystalline phase of polyglycolide was unequivocally identified by X-ray powder diffraction studies.

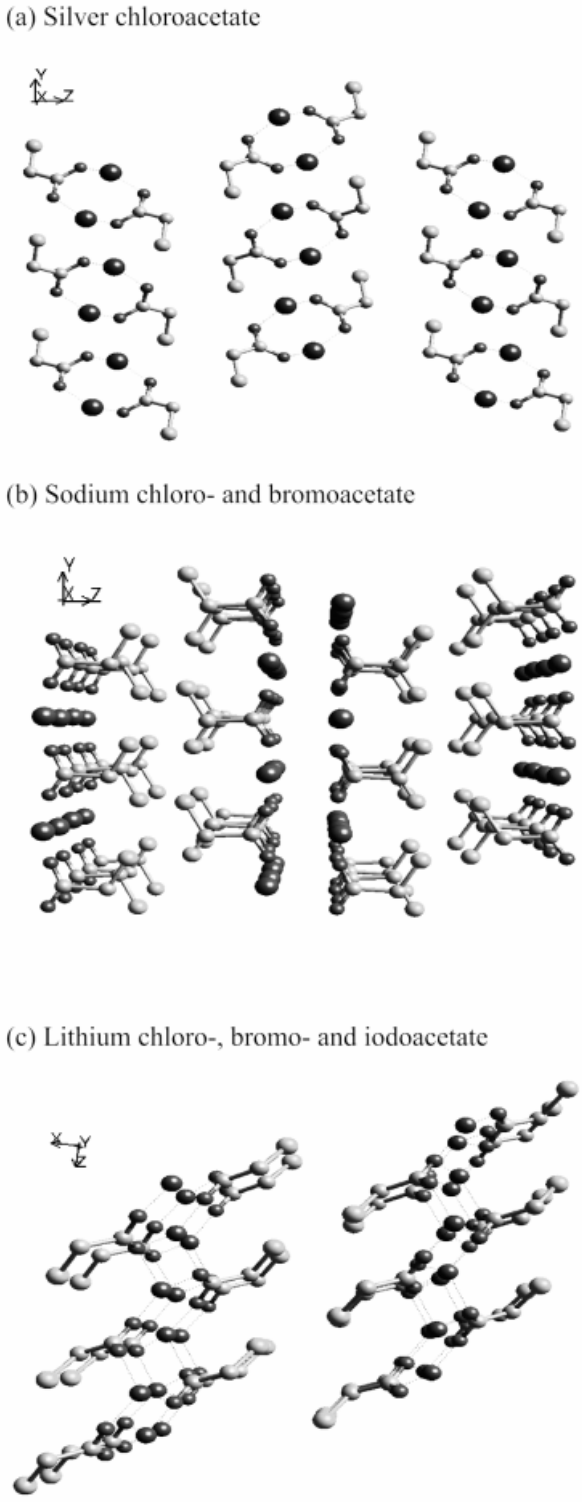

Figure 3. The structure types of silver chloroacetate (a), sodium chloro- and bromoacetate (b), and of lithium chloro-, bromo-, and iodoacetate (c); in cases (a) and (b), solid-state polymerization to form metal halide and polyglycolide is observed, whereas the lithium salts merely decompose

For the sodium salts, the mechanism is less obvious. There is no short distance between the metal and the halogen ions. Layers of metal ions alternate with layers of halogen atoms. However, a polymerization that occurs along

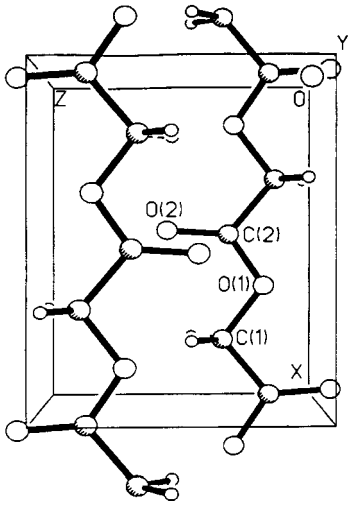

Figure 4. The crystal structure of polyglycolide shows antiparallel chains (see ref.[59])

the crystallographic *b* axis can be postulated (see ref.[57] for details).

The lithium salts do not polymerize. From the crystal structure this can be ascribed to the coordination of lithium by four oxygen atoms from four different carboxy groups. We speculate that the small, strongly polarizing lithium ion keeps the molecules from moving into a suitable orientation for polymerization (see ref.[56] for a detailed discussion).

Even when a topochemical mechanism can be postulated by inspection of the crystal structure, little is actually known about the way the molecules react:

- whether the reaction occurs in a single step,
- whether the crystal structure is preserved, and
- how two solid phases (salt and polyester) are formed from a single phase.

To acquire such information, it is necessary to follow the course of the reaction by suitable in-situ and ex-situ techniques that probe specific sample properties. The in-situ techniques are preferable as they yield more direct information.

The polycondensation reactions of halogenoacetates have been studied with a variety of techniques, each probing different structural features of the reaction. The results are summarized in Table 4. We now have a very detailed insight into this reaction and can therefore formulate a reaction mechanism as depicted in Figure 5.

This reaction can be considered as very well studied. Fortunately, the nature of the reaction makes it susceptible to techniques developed for inorganic solids, organic solids, and polymers and hence most available techniques to obtain structural information in situ have been applied. However, it is still clear that there is a line that we cannot cross, even with the most sophisticated techniques available today.

This is the question of how the actual processes occur on a molecular or on an atomic scale. All techniques probe *integral* sample properties. This does not give information about the changes going on in the actual reaction zone, i.e. the very thin layer between the parent compound and the product. The fraction of molecules that actually react is small at any given time, therefore we see mainly the parent compound and the reaction products, but not necessarily the small amount of transient molecules. We can only try to deduce this microscopic information from the integral parameters that we can measure. The same holds for deductions about the reaction pathway from the crystal structure.

For example, even if the structure of silver chloroacetate supports a topochemical polymerization mechanism, this is no proof but only a hint that the reaction actually follows this pathway. Also, the question as to how metal ions and halogen ions find themselves to form the salt lattice is still completely unresolved. In conclusion, it must be said that there are no experimental techniques available at the moment to answer these questions. Theoretical computations may be the only possible means to tackle such problems.

Finally, it should be mentioned that solvate crystals of halogenoacetates with halogenoacetic acid also undergo a solid-state polymerization. In these cases, an endothermic peak occurs in DSC, followed by an exothermic event. The endothermic event is associated with the release of halogenoacetic acid from the solvate crystal, and its sublimation or boiling. After this, the pure salt recrystallizes and begins to polymerize. This was demonstrated by in-situ EXAFS measurements of rubidium bromoacetate/bromoacetic acid[60] and by time- and temperature-resolved XRD measurements of potassium chloroacetate/chloroacetic acid. Table 5 shows the results collected from the literature.

Poly(hydroxypropionates) by Solid-State Reaction

At least on paper, the polycondensation of haloacetates can be transposed to all salts of halogenocarboxylic acids. The question is whether the actual chemical pathway of such a system lives up to this expectation.

The next higher homologues of halogenoacetates are 2-halogenopropionic acids and 3-halogenopropionic acids. In the first case, we expect poly(2-hydroxypropionic acid), that is, polylactic acid (or polylactide), a polymer with a stereogenic carbon atom. In the second case, the product would be the achiral poly(3-hydroxypropionic acid).

Polylactide was first prepared in 1845 by Pelouze, who heated lactic acid.[61] The known examples of polycondensation reactions of halogenopropionates are collected in Table 6, together with data on similar polycondensation reactions.

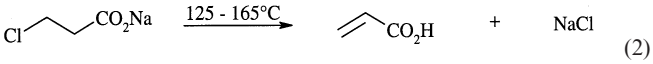
In 1894, Bischoff and Walden reported the formation of polyglycolide from sodium chloro- and bromoacetate. They extended their studies to sodium 2-bromopropionate, but obtained no polyester; the only product found was (di)lactide, which sublimed from the reaction mixture. This was probably due to the conditions of the experiments, as the salt was subjected to a temperature of more than 200 °C in vacuo. Under these conditions, pyrolysis of the formed polyester to lactide becomes dominant, and the intermediate product cannot be isolated from the reaction vessel. Furthermore, they did not analyze the solid residue.[62]

Table 4. Collection of facts about the solid-state polycondensation in halogenoacetates; note that side-products were not found with any technique; polyglycolide and the metal halide are the only products

Technique	in-situ?	Property probed	Compound	Results
DSC	yes	enthalpy change	all halogenoacetates	exothermic polymerization reaction (see ref.[18,20,74])
TG-DTA-MS	yes	volatile reaction products	all halogenoacetates	no mass loss during polymerization; at higher temperature, combustion of the formed polyglycolide (see ref.[20,74])
X-ray diffraction (XRD)	yes	crystalline phases	sodium chloroacetate	no detectable crystalline intermediates (see ref.[20])
EXAFS	no	short-range order (Cl) in all phases	sodium chloroacetate	no detectable intermediate containing chlorine (see ref.[74])
EXAFS	yes	short-range order (Br, Rb in all phases	rubidium bromoacetate/ bromoacetic acid	desolvation is followed by polymerization (see ref.[60])
EXAFS-XRD	yes	short-range order (Br) in all phases; crystalline phases	sodium bromoacetate	no detectable intermediates that either contain bromine or are crystalline;coalescence of small NaBr crystals to larger ones during annealing ("Ostwald ripening") (see ref.[79])
EXAFS-DSC	yes	short-range order (Br) in all phases; enthalpy changes	sodium bromoacetate	no detectable intermediates that contain bromine; the reaction enthalpy is proportional to the reaction extent (see ref.[76])
Small- and wide-angle X-ray scattering (SAXS-WAXS)	yes	structural order on different length scales	sodium chloroacetate	no detectable intermediates on all length scales; formation of short-range order in polyglycolide precedes formation of long-range order (long period of amorphous and crystalline domains) (see ref.[80])
Solid-state NMR (^{13}C)	yes	chemical environment of carbon	sodium bromoacetate	no detectable intermediates containing carbon (see ref.[58])
Solid-state NMR (^{23}Na)	yes	chemical environment of sodium	sodium chloroacetate; sodium bromoacetate	no detectable intermediates containing sodium (see ref.[58])
IR	yes	chemical bonds in all phases	sodium chloroacetate	no detectable intermediates (see ref.[75])
Scanning electron microscopy	no	morphologic changes	sodium chloroacetate	phase separation into a polymeric matrix containing microcrystals of NaCl (see ref.[74])
Mercury porosimetry	no	morphologic changes in the formed polyglycolide/NaCl	sodium chloroacetate	the NaCl microcrystals increase in diameter with increasing reaction extent (see ref.[73])
Viscosimetry	no	chain length of polyglycolide	sodium chloroacetate	the degree of polymerization increases with increasing reaction extent (polycondensation) (see ref.[73])
Thermomicroscopy	yes	morphologic changes	sodium chloroacetate; silver chloroacetate	the reaction starts from defects in the crystal or from the surface; the single-crystalline order is not preserved (see ref.[73])

In an explorative study, we showed that sodium 2-chloropropionate indeed gives polylactide if the reaction temperature is 160 °C.[63] Two fractions with degrees of polymerization of 520 and 11, respectively, were detected by GPC. This corroborates the interpretation of the results of Bischoff and Walden that the polylactide formed previously was pyrolyzed during the reaction, leading to volatile lactide.

We found that the corresponding isomer, sodium 3-chloropropionate, gives a mixture of different products upon heating.[63] Oligomers of the desired polymer were formed (weight-average molecular weight of 420 g mol^{-1}), but the main competitive reaction is the intramolecular elimination of NaCl, resulting in the formation of acrylic acid [Equation (2)].



(2)

This unwanted reaction is probably favored at higher temperatures due to the higher gain in entropy relative to polymerization. It also precludes the preparation of the precursor salt by simple neutralization of the acid by NaOH or Na_2CO_3 at room temperature, because elimination occurs readily. Sodium 3-chloropropionate had to be prepared by neutralization at −50 °C, whereas sodium 2-chloropropionate can easily be prepared at room temperature.

Poly(hydroxybutyrates) by Solid-State Reaction

Bischoff and Walden found the cyclic dimer and crotonic acid upon heating sodium 2-bromo-n-butyrate.[62] In contradiction to these results, Naruchi et al. obtained the corresponding polyester and oligomers from the alkaline and alkaline earth metal salts of 2-bromo-*n*-butyric acid.[64] The potassium and sodium salts gave polymeric products with number-average molecular weights between 1000 and 4000, and polydispersities close to 1.4. The alkaline earth and the lithium salts yielded only oligomers. The authors concluded that the crystallinity of the precursors played a decisive role because the salts of Na and K had a good crystallinity, whereas the Li, Mg, Ca, Sr, and Ba salts were of poor crystallinity, or even amorphous. We found oligomers with a degree of polymerization of 4 after heating sodium 2-chlorobutyrate at 160 °C for 30 min.[63]

Sodium 2-bromoisobutyrate starts to decompose at 30 °C, according to Bischoff and Walden. Sodium bromide was eliminated but the main product was methacrylic acid, which partially polymerized to form poly(methacrylic acid). Due to water incorporated in the crystal (they used the

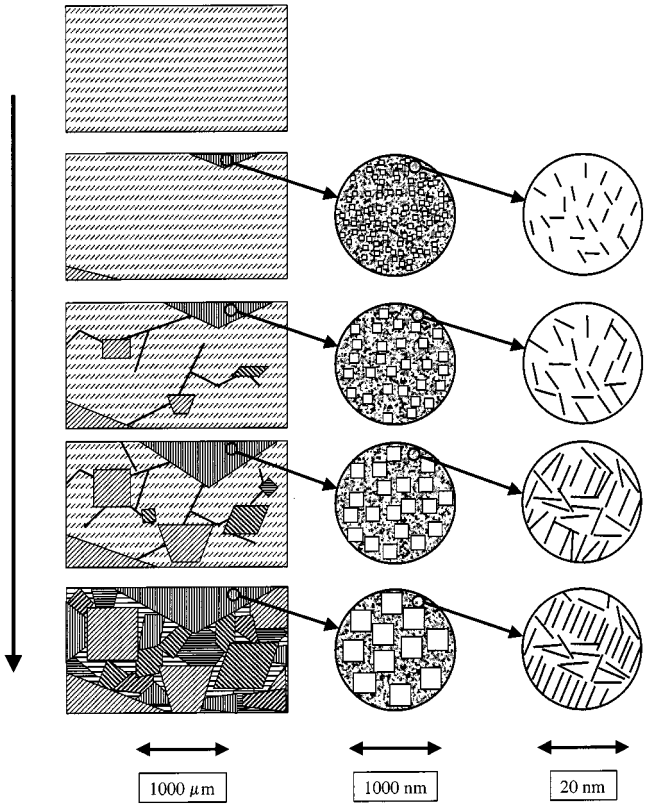


Figure 5. Schematic view of the solid-state polycondensation reaction of sodium chloroacetate to form polyglycolide and NaCl, viewed on different length scales; the following processes occur: 1. nuclei of reaction products form at the surface or at defects (left); 2. the new phase (polyglycolide and NaCl) grows within the halogenoacetate crystal; the local structure is damaged by a change in molar volume, thereby accelerating the reaction (left); 3. together with the phase separation, this leads to complete destruction of the single-crystalline order (left); 4. cubic NaCl crystals keep growing during the reaction within a matrix of polyglycolide (center); 5. after the reaction is complete, Ostwald ripening of the NaCl crystals occurs; larger crystals grow by consuming smaller ones (center); 6. the polyglycolide chains increase in length during the polycondensation reaction (right); 7. after larger amounts of polyglycolide have formed, ordering within the polymer phase into amorphous and crystalline domains occurs (right)

Table 6. Reactivity and resulting polyesters from simple aliphatic carboxylic acids; M = alkali, X = halogen

Precursor	Polymer (T_{fus})	Remarks
 Halogenoacetates	 Polyglycolide (220-233°C)	reacts quantitatively in the solid state[20]
 2-Halogenopropionates	 Polylactide (PLA; ~80°C)	dilactide (Na/Br; vacuum at 200°C)[62]; Polylactide (Na/Cl; 160°C)[63];
 3-Halogenopropionates	 Poly(3-hydroxypropionate) (~90°C)	oligomers, acrylic acid, 3-hydroxypropionic acid (Na/Cl; 120°C)[63]
 M= alkali ions 2-Halogenobutyrates	 Poly(2-hydroxybutyric acid)	cyclic dimer, crotonic acid (Na/Br; 200-270°C)[62]; oligomers (Na/Cl; 160°)[63]; polymer (Na/Br and K/Br; 110-150°C)[64]; oligomers (Li/Br)[64]
 M= alkaline earth ions 2-Halogenobutyrates	 Poly(2-hydroxybutyric acid)	oligomers (Mg, Ca, Sr, Ba/Br; 110-150°C) [64]
 Sodium 2,2,2-bromodimethylacetate	 Poly(dimethyl glycolide)	Methacrylic acid, poly(methacrylic acid (Na/Br; 30-130°C)[62]; poly(dimethyl glycolide) (Na/Br; 90-180°C)[66]

hemihydrate), 2-hydroxyisobutyric acid was also formed during the reaction.[62] However, Bezzi reported that he obtained poly(dimethyl glycolide) from sodium 2-bromoisobutyrate by heating the salt up to 90 °C,[65] 160 °C, or 180 °C.[66]

The most important poly(hydroxybutyrate) is P-3HB, as outlined above. Unfortunately, it is very difficult to prepare the corresponding precursor, sodium 3-chlorobutyrate, as elimination prevails even at low temperature. The same is true for sodium 4-chlorobutyrate. Therefore, there is no information available yet as to whether these polyesters can be obtained by solid-state polymerization.

Poly(hydroxymethylbenzoates) by Solid-State Reaction

All previous listed reactions gave aliphatic polyesters. As mentioned in the introduction, linear polyesters with aromatic groups in their backbone are of special interest for industrial applications. The simplest halogenocarboxylic acids containing the benzene ring are halogenobenzoic acids. If the salts of halogenobenzoic acids were to undergo a polymerization reaction in which poly(hydroxybenzoic

acid) were to be formed, a nucleophilic substitution on an aromatic ring system would be necessary (the chlorine atom acts as the leaving group). Therefore, strong nucleophiles or electron-withdrawing groups at the *ortho* or *para* position would be needed. The carboxylate group is an electron-donating substituent and its nucleophilicity is not very strong, thus substitution at the benzene ring appears to be unlikely. However, the polymerization of alkali *p*-halothiophenolates is possible,[11] but admittedly the thiophenoxide ion is a stronger nucleophile than the carboxylate anion. Anyway, the conditions may change in the solid state. For this reason, we prepared the alkali salts of 4-chlorobenzoic acid. No reaction was observed and decomposition took place at temperatures above 400 °C.

Introducing a benzene ring between the carbon−carbon bond in acetates leads to the formation of halogenomethylbenzoates (Table 7). Only the *meta*- and *para*-substituted compounds could be prepared, because the *ortho* compounds tend to form benzolactones by intramolecular substitution. The sodium, potassium and rubidium salts of 3- and 4-chloromethyl- and -bromomethylbenzoic acid undergo the desired polymerization to form poly(hydroxymethylbenzoic acid).[67] The lithium salts of the *para* compounds decompose at temperatures near 300 °C, without the formation of a polymeric product. This can be understood when analyzing the crystal structures of lithium 4-chloro- and 4-bromomethylbenzoate that were solved from powder-diffraction data.[68] They have a strong similarity to the corresponding acetates with the phenyl rings acting as "spacers". Lithium is tetrahedrally coordinated by four different oxygen atoms from four different carboxy groups, a fact that probably prevents polymerization. All attempts to solve the structures of the corresponding sodium or potassium compounds (that polymerize) failed, probably due to the presence of polymorphism, as suggested by solid-state NMR spectroscopy.[68]

For the *para*-halomethylbenzoates, the oxidation of the methylene group in the polyester as a side-reaction was found by IR spectroscopy. This reaction led to the formation of terephthalic acid as side product, via the carboxylic anhydride intermediate, even in the presence of small amounts of oxygen and water.

Table 7. Successful polymerization in other halocarboxylates; M = alkali, X = halogen

Precursor	Polymer (T_{fus})	Remarks
 *rac*-2,2-Halogenophenylacetates	 *rac*-Polymandelide (~80°C)	Unidentified solid product (Na/Cl; 117°C)[62]; polymandelide (Me_3Sb/Br; $SnMe_3$/Br; 170°C)[70]; polymandelide (Na, K/Cl, Br; 70-170°C) (this work)
 2,2,2-Halogenodiphenylacetates	 Poly(diphenylglycolide)	(Na/Cl; 90-180°C)[66]; poly(diphenylglycolide) ($SnMe_3$/Br; 25°C)[70]
 4-Halogenomethylbenzoates	 Poly(4-hydroxymethylbenzoic acid) (~250)	reacts in the solid state (Na,K,Rb/Cl,Br; 200-250°C)[68]
 3-Halogenomethylbenzoates	 Poly(3-hydroxymethylbenzoic acid) (~150)	reacts in the solid state (Na,K/Cl,Br; 100-160°C)[68]

Table 8. Unsuccessful attempts to induce polymerization in halogenocarboxylates; M = alkali, X = halogen

Precursor	Reaction	Remarks
 Potassium chloromalonate	no polymerization	decarboxylation at 115°C[71]
 Potassium chloromethylmalonate	no polymerization	decarboxylation at 200°C[71]
 Chlorodifluoroacetates	no polymerization	decomposition above 160°C
 4-Chlorobenzoates	no polymerization	decomposition above 400°C

Other Polyesters by Solid-State Reaction

Besides these major classes of potential precursors to polyesters, other miscellaneous substances were investigated, sometimes with success, and sometimes without. The results can be found in Table 7 and Table 8.

When Bischoff and Walden tried to distill sodium 2,2-chlorophenyl acetate, they obtained a yellowish oil and a solid residue that melted at 117 °C. Further characterization was not carried out. The oil was not identified, and the residue was presumed to be stilbene.[69] Our recent studies on alkali 2,2-halogenophenylacetates showed that poly(mandelide) can be formed by thermal elimination of alkali halides. Similar to the halogenoacetates, the lithium salts do not polymerize, but decompose upon heating. We found a degree of polymerization (obtained by ^{1}H NMR spectroscopic end-group analysis) ranging from 5 to very high numbers for sodium and potassium salts.

The first announcement of a polymeric product from 2,2-bromophenylacetates was in 1973. Okada and Okawara pyrolyzed the trimethyltin salt of the 2,2-bromophenylacetic acid and obtained poly(mandelide).[70] They also reported that the trimethyltin bromodiphenylacetate reacted in the same way. Bezzi reported the synthesis of poly(diphenylglycolide) from sodium chlorodiphenylacetate under the same conditions as for the poly(dimethylglycolide).[65]

Potassium chloromalonate and 2,2-chloromethylmalonate did not give any polymer or oligomer.[71] Instead of a polymeric product from the elimination, carbon dioxide was released in both cases at 115 °C and 200 °C. The mass loss during the reaction of potassium chloromalonate was in good agreement with the value calculated for the loss of one molecule of carbon dioxide per chloromalonate. Potassium chloride and an unidentified organic substance remained. Besides potassium chloride, the organic residue after the elimination reaction of the methylmalonate was identified as potassium acrylate.[71] The synthesis of the alkali salts of 4-bromo-2,2-diphenylbutyric acid was not successful at ambient temperature. It led to the conjugated lactone by intramolecular substitution of the bromo group by the carboxylate group.[72]

No polymerization is possible if further halogen atoms are inserted in the acetates as it is the case in di- and trichloroacetates, or in chlorodifluoroacetates. The additional halogen atoms apparently destabilize the carbon−carbon bond, resulting in bond cleavage if they are heated.

Comparison of Polyesters from Solid-State Reaction and from Conventional Synthesis

If we summarize the preceding paragraphs, we can state that a considerable number of polyesters can be obtained from solid precursors. It remains to be discussed whether or not the obtained polymers are identical to those available from conventional synthesis.

With respect to structural or spectroscopic properties, the polyesters from solid-state reactions are often almost indistinguishable from those obtained in a classical way. The main difference is the degree of polymerization. It seems that polymers from solid-state reactions have a smaller degree of polymerization, i.e. a lower molecular weight. This property was not reported in all examples, but we can demonstrate it for polyglycolide, in which we extensively studied the properties of the polymer.[73]

Polylactide and polyglycolide from ring-opening polymerization with tin catalyst can reach molecular weights of more than 100,000 Da, representing more than 1000 monomeric units in the polymeric chain. As mentioned above, the degree of polymerization reported in the literature for solid-state chemically prepared polyglycolide is not very high. A number-average molecular weight of about 300 Da was determined by Anschütz.[26]

Detailed studies on the solid-state polycondensation reactions of sodium chloroacetate were carried out, with special attention being paid to the polymerization mechanism, and to the development of polymeric properties.[18,56−58,60,73−76] For polyglycolide, we showed that the average chain length (by viscosimetry) passes a maximum of approximately 40 monomeric units before the reaction extent reaches 1.[73] After the maximum, the chain length decreases again. This can be explained by a counterplay between the polycondensation reaction (increasing the chain length) and the thermal degradation of the formed polyglycolide. Degradation plays a minor role, as long as only few and short polymer chains are present. With increasing chain length and with a higher number of ester groups that can be cleaved, the degradation becomes dominant while the chain growth loses importance.

As in most other studies, the conditions were not optimized and in most cases a long reaction time and a high temperature were chosen to ensure that the reaction was complete. Consequently, the polyglycolide from solid-state reaction was obtained with a low molecular weight, due to thermal degradation. It may be inferred that the degree of polymerization for other polyesters from solid-state reactions could also be increased by careful choice of the reaction temperature.

If we take into account the fact that the reaction of haloacetates with polyglycolide occurs in the solid state in a topochemical way, the crystal perfection should have a strong influence on the chain length of the polymer. We speculate that in larger, perfect crystals, the chains could grow longer than in small, disordered crystals in which a defect (such as a dislocation) would lead to chain scission. This statement may be limited by the fact that the single-crystalline order is destroyed during the reaction, probably due to volume change, but nevertheless it remains an interesting assumption.[77] However, this has not been investigated so far for any solid-state polycondensation reaction.

A special feature of polyesters from solid-state reactions is their distinct micromorphology. Generally, a nonvolatile salt is eliminated, and thus the reaction must lead to an intimate mixture of polymer and salt. The geometry of both phases is determined by nucleation and diffusion. In the cases that we have studied (polyglycolide, polylactide, poly(hydroxymethylbenzoic acid)], we have always found micrometer-sized salt crystals within the polymeric matrix. These can be conveniently removed by washing the polymer with water, leaving behind a polymer with micrometer-sized pores.[18,67,78]

The dependence of the pore size on the precursor was studied for polyglycolide. Figure 6 summarizes scanning-electron micrographs of polyglycolide from various halogenoacetates. There are considerable differences in the product morphology. Their origin is not known, but it is clear that the size of the pores (identical to the size of the precipitated salt crystals) depends on the kind of salt that is eliminated. However, it must be noted that different polyglycolides were obtained at different reaction temperatures for each precursor. The highly porous structure of polyglycolide may be advantageous for biomedical applications. Less material has to be absorbed by the body, and a free flow of body fluids is possible through such a highly porous implant. We recently demonstrated the excellent biocompatibility of composite implants of both porous and compact polyglycolide with calcium phosphate.[9]

Do These Reactions Really Occur in the Solid State?

All reactions that yield a polymer are initiated in the solid state, i.e. before the melting of the substance is observed. In

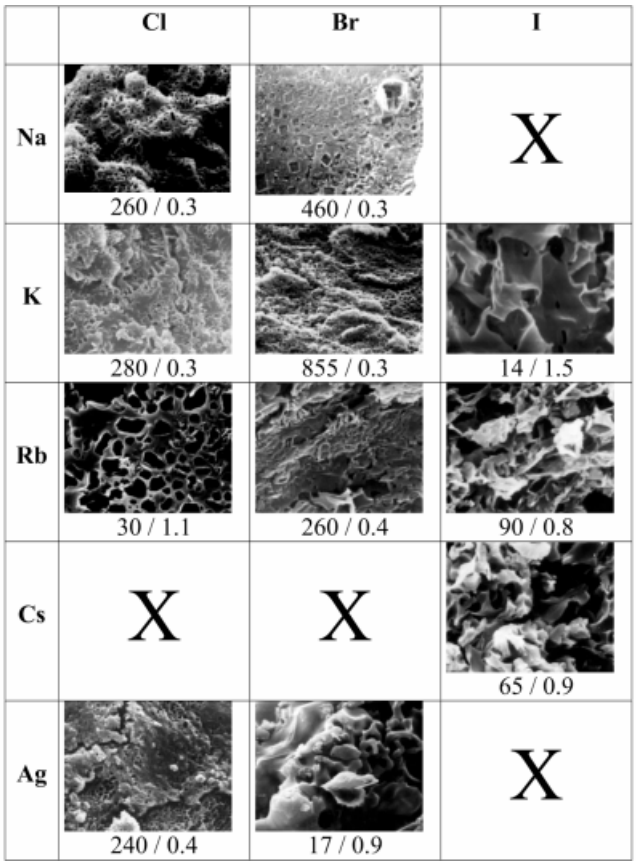

Figure 6. Polyglycolide from the solid-state reaction of various precursors; the polymers were washed out with water (in the case of silver salts, with sodium thiosulfate solution), to obtain the porous polymer; the magnification is 4020× in all cases, and the printed section is approximately 12.5 × 9.5 μm^2; the table illustrates how the different pore-size distribution is dependent on the precursor; X means that the polymer could not obtained in a pure form by solid-state polymerization reaction; the two numbers for each polymer give the number of pores per 100 μm^2, and the average pore size in μm (computed by analysis of larger areas than shown here)

the case of a reaction temperature being higher than the melting point of the corresponding polyester (such as polylactide), the reaction mixture will liquefy with increasing conversion. On the other hand, if the reaction temperature is lower than the melting point of the polyester, a true solid-state reaction is possible (as is the case with polyglycolide). Both cases have been observed. In general, it is rather difficult to unequivocally prove that no liquid intermediates are present. It has been shown for polyglycolide formed from halogenoacetates (see above), but in most other cases there might be temporary liquefaction, followed by recrystallization.

Nevertheless, systems with high-melting polymers can also liquefy locally during the reaction owing to poor heat conduction in powders and subsequent self-heating of the mixture. Polyakov et al. showed that for sodium chloroacetate, a high-temperature gradient appeared inside the reaction vessel between the center of the reactor and the wall. The heat difference reached up to 100 K, depending on the reactor diameter and on the external temperature. This self-heating caused the sample to melt, and in extreme cases the polyester was pyrolyzed.[46] In order to prevent this, it is possible to choose other reactor types with better heat conductance, such as fluid-bed reactors, or to add inert materials such as copper turnings to obtain a better conduction.

Conclusion

Many polyesters can be prepared without solvent. Unfortunately, the reaction pathway theoretically formulated beforehand is not always actually feasible. This is due to the peculiarities of solid-state reactions in which the crystal structure and intracrystalline interactions play a dominant role. This is a major difference from chemistry in solution, where the concept of functional groups is of decisive influence. In addition, thermodynamic data are usually not available and hence proposed reactions have to be tried out, and cannot be predicted.

Side-reactions that lead to different reaction pathways may occur. Possible side-reactions are:

- hydrolysis of the halogen group in the presence of moisture
- elimination of HX leading to the formation of unsaturated carboxylic acids
- decarboxylation
- cyclization to form lactones
- oxidation of the organic residue

However, the new properties of the resulting polymers (such as the porous micromorphology) may lead to applications in special cases. In any case, this is a fascinating field of research where expertise from solid-state chemistry, organic chemistry, physical chemistry and polymer chemistry can be combined to draw conclusions about the underlying processes.

Acknowledgments

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for generous support during the preparation of this work. We also thank our collaborators who performed many of the reported experiments, their names are given in the citations.

A Bis(carboxamido-*N*)diisocyanidobis(sulfenato-*S*)cobalt(III) Complex, Model for the Post-Translational Oxygenation of Nitrile Hydratase Thiolato Ligands

Laurent Heinrich,[a] Yun Li,[a] Jacqueline Vaissermann,[b] and Jean-Claude Chottard*[a]

Keywords: Cobalt / Nitrile hydratase / Isocyanide / Oxygenation / Sulfenato-*S* ligands

A square-planar cobalt(III) complex with an N_2S_2 bis(carboxamido-*N*)dithiolato tetradentate ligand was oxygenated by H_2O_2·urea, after axial coordination of *tert*-butyl isocyanide, to the first bis(carboxamido-*N*)bis(sulfenato-*S*)cobalt(III) complex.

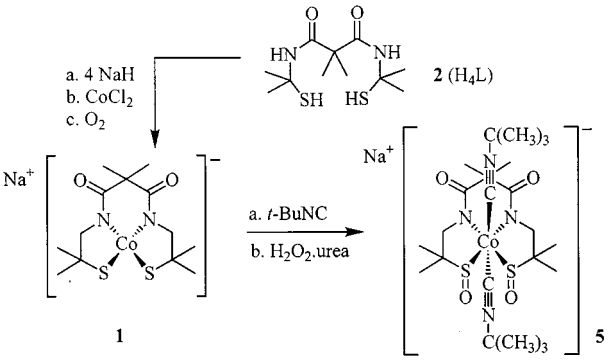
Introduction

Nitrile hydratases (NHases) are non-heme iron or non-corrinoid cobalt-containing enzymes which catalyze the hydration of nitriles to amides.[1a] Recent X-ray studies of NHases indicated that the iron center is bound to two peptide amide nitrogen atoms and three sulfur atoms from cystein-thiolate, cystein-sulfinic and cystein-sulfenic moieties, the latter two resulting from post-translational oxidation.[1a,1b] The two nitrogen atoms and the two sulfur atoms of the modified cystein groups belong to a planar tetradentate eleven-atom ligand from a Cys-Ser-Cys sequence. EXAFS data suggest that the iron and cobalt NHases have similar metal sites.[1c] However, there is no evidence whether post-translational oxidation of cystein-thiolates also occurs in cobalt sites.

A few Co^{III} complexes with both thiolato and carboxamido-*N* ligands have recently been reported as synthetic models of NHases.[2] Two of them have been oxidized by H_2O_2 to give the sulfinato-*S* species,[2b] but no sulfenato-*S* derivative was characterized.

We have recently reported[3] the first example of dioxygen oxidation of a (carboxamido-*N*)(thiolato)Fe^{III} complex $[FeN_2S_3]^{2-}$ into a sulfinato-*O* species $[FeN_2S_2OSO]^{2-}$. The sulfinato-*O* coordination suggested a preferred oxidation of the axial thiolato ligand, compared to that of the thiolates in the equatorial N_2S_2 plane. To address this question in the case of Co NHases, we have synthesized complex **1** ($[Co^{III}L]^-$) from the deprotonated ligand **2** (H_4L)[4] (Scheme 1). The structure of **1** was determined by X-ray diffraction.[5]

The square-planar complex **1** is stable in air, in the solid state and in solution. Its reaction with excess H_2O_2 or H_2O_2·urea leads to decomposition. We have shown by UV/Vis spectroscopy and EXAFS studies, that two CN^- or *t*BuNC ligands are able to bind at the axial positions of **1**, leading to the hexacoordinated diamagnetic complexes $[CoL(CN)_2]^{3-}$ (**3**) and $[CoL(tBuNC)_2]^-$ (**4**), respectively[5]. Here we report the oxygenation of the thiolato ligands in **4**, giving the corresponding bis(sulfenato-*S*) complex **5**.



Scheme 1. Synthesis of complexes **1** and **5**

Results and Discussion

At variance with **1**, complexes **3** and **4** undergo fast oxygenation reactions in aerated solution, giving a mixture of presumably sulfinato (-*O* or -*S*) and sulfenato (-*O* or -*S*) species. The addition of H_2O_2·urea to a solution of **1** in the presence of excess *t*BuNC gave the orange complex **5** {$Na[Co^{III}(L\text{-}N_2SOSO)(tBuNC)_2]$·urea·$2H_2O$} which precipitated spontaneously (Scheme 1). The X-ray structure of **5** (Figure 1) reveals the oxygenation of the two thiolato to sulfenato-*S* ligands. It is noteworthy that the urea molecules contribute to the crystal lattice through binding to oxygen atoms of the sulfenato-*S* and carboxamido-*N* ligands and by interaction with the Na^+ ions (Figure 2). Complex **5** contains two axial isocyanide ligands in a distorted octahedron. This suggests that the oxygenation occurred thanks to the formation of **4** {$Na[CoL(tBuNC)_2]$}. The presence of one Na^+ per Co in the unit cell of **5** supports a cobalt(III) state. The Co−N bond lengths are similar to those reported for carboxamido-*N* ligands in hexacoordinated Co^{III} complexes,[2] but are 0.07 Å longer than those in the square-

planar complex **1**. Very few complexes have been reported with structurally characterized sulfenato-*S*−cobalt(III) bonds; their lengths are in the range 2.198−2.253 Å,[6] in agreement with the 2.223 Å in **5**. The two oxygen atoms of the sulfenato-*S* ligands are on the same side of the N_2S_2 plane, leading to a slight asymmetry of **5**. To our knowledge, only two cyclopentadienyl compounds with isocyanido-*C*−cobalt(III) bonds are known with C−Co^{III} bond lengths of 1.83 and 1.79 Å,[7] comparable to the 1.83 Å in **5**. The isocyanides are linearly coordinated to the metal center, with the following angle values Co(1)−C(14)−N(4) = 175.1°, Co(1)−C(19)−N(3) = 179.5°, C(14)−N(4)−C(15) = 176.5°, C(19)−N(3)−C(20) = 176.6° and a 1.14 Å C−N bond length. This agrees with a C−N triple bond description. The IR spectrum (KBr pellet) of **5** shows the characteristic coordinated carboxamido-*N* ν_{CO} frequency at $\tilde{\nu}$ = 1555 cm^{-1} and a strong absorption at $\tilde{\nu}$ = 965 cm^{-1} corresponding to the ν_{SO} stretching of coordinated sulfenato-*S* ligands.[6b] The weak symmetric and strong asymmetric ν_{CN} stretching frequencies of the isocyanide groups are increased from $\tilde{\nu}$ = 2140 cm^{-1} to 2375 and 2195 cm^{-1} upon coordination, indicating a higher bond order in **5** than in the free ligand, fitting the C−N triple bond description and the σ-donor character of the isocyanide groups which dominates their potential π-acceptor contribution.

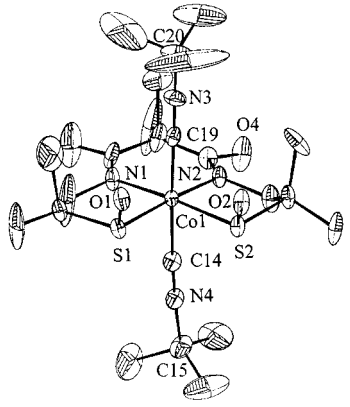

Figure 1. CAMERON representation (ellipsoid at 20% probability level) of **5**; H atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Co(1)−S(1) 2.223(4), Co(1)−S(2) 2.223(4), Co(1)−N(1) 1.94(1), Co(1)−N(2) 1.95(1), Co(1)−C(14) 1.84(2), Co(1)−C(19) 1.83(2), C(14)−N(4) 1.14(2), C(19)−N(3) 1.14(2); S(1)−Co(1)−S(2) 90.4(1), S(1)−Co(1)−N(1) 87.9(4), N(1)−Co(1)−N(2) 93.5(5), C(14)−Co(1)−C(19) 177.5(6), C(14)−N(4)−C(15) 176.5(17), C(19)−N(3)−C(20) 176.6(20)

The orange solutions of **5** in polar solvents (alcohols, DMSO, DMF, H_2O) are stable in air and the complex appears hexacoordinated with diamagnetic low-spin Co^{III} (Evans method). The electrospray mass spectrum exhibits peaks at *m*/*z* = 559 ([M − Na^+]$^-$) and at *m*/*z* = 476 ([M − Na^+ − *t*BuNC]$^-$), and weaker ones at *m*/*z* = 575 and 492, suggesting partial oxidation of these two species during the mass spectrometry analysis.

Whereas the oxidation of (thiolato)Co^{III} complexes by H_2O_2 is well known,[8] there are only two examples of oxygenation of bis(carboxamido-*N*)(dithiolato)Co^{III} complexes which give the bis(sulfinato-*S*) species.[2b] Sulfenato-*S* complexes are usually difficult to isolate due to their further oxidation to the sulfinato-*S* derivatives. The isolation of **5** was likely due to its precipitation, preventing further oxidation. The oxidation of the thiolato ligands is believed to start by nucleophilic attack on dioxygen or H_2O_2, as in the case of (thiolato)nickel complexes.[8b] The increase of the Co−S bond lengths upon addition of CN^- or *t*BuNC to **1**, to give **3** and **4** (2.13, 2.23 and 2.28 Å for **1**, **3** and **4**, respectively, according to our EXAFS studies)[5] shows that the thiolato ligands become much less tightly bound in the latter two and consequently more nucleophilic.

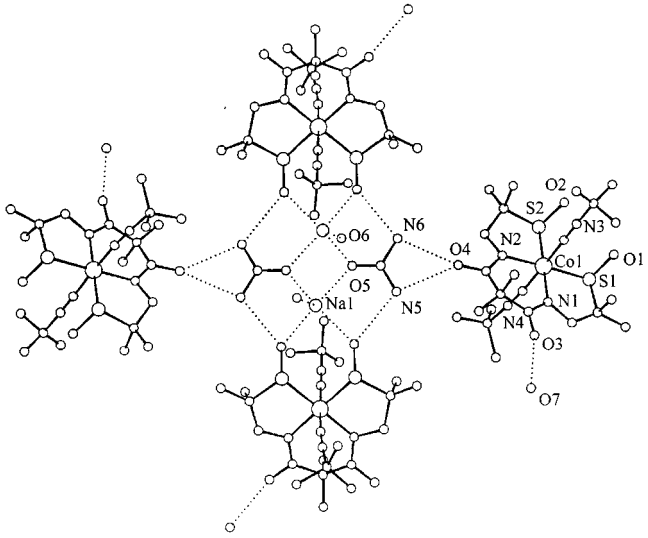

Figure 2. View of the Na^+/O interactions and hydrogen bonds stabilizing the crystal lattice of **5**·urea·$2H_2O$

A preliminary study of the catalytic hydration activity of **5** was conducted without acid or base in a 9:1 acetonitrile/water mixture at room temperature. After 24 h, acetamide was formed (2 turnovers) and **5** remained unchanged (^{1}H NMR criteria). No conversion was observed in the absence of **5**. Although **5** is not an efficient catalyst under these conditions, the hydration mechanism deserves interest. The known[2a] complex $[Co(PyPS)(OH)]^{2-}$ (with one pyridine, two carboxamido-*N* and one thiolato ligands in a plane, and the second thiolato ligand occupying an axial position) converts acetonitrile into acetamide only at 50°C and pH = 9.5 (Tris buffer), most probably via the Co^{III}-bound hydroxide ligand. It is noteworthy that **5** has no free coordination site that would allow either water or acetonitrile binding to Co^{III}. This suggests that the nucleophilicity of the coordinated sulfenato-*S* ligands[9] in **5** might play a crucial role in the hydration reaction of acetonitrile. Further work is in progress to test this hypothesis and its relevance to the case of NHase.

Conclusion

We have shown that H_2O_2·urea allowed the clean oxidation of the dithiolato complex **1** to its bis(sulfenato-*S*)Co^{III} derivative **5** after axial coordination of *tert*-butyl isocyanide.

It is the first example of a cobalt complex with a mixed carboxamido-*N* and sulfenato-*S* coordination sphere. These results suggest that the in-plane thiolates of the metallic site of Co NHases could undergo posttranslational oxidation, as observed for the Fe NHases. Such a reaction would require the presence of σ-donor ligands, a role which could be played by the axial cystein-thiolate and the external hydroxide bound to the metal center at the active site of the enzyme.[1] The coordinated sulfenate-*S* likely plays a key role in the activity of NHases.

Experimental Section

Complex 5: To a solution of **1** (42 mg, 0.1 mmol) and *t*BuNC (36 mg, 0.44 mmol) in degassed DMF (1 mL) cooled to 0°C was added a filtered solution of H_2O_2·urea (200 mg, 2.2 mmol) in degassed acetone (2 mL), leading to the formation of an orange precipitate. After 30 min at 0°C, the precipitate was isolated, dried under vacuum and dissolved in ethanol. Diethyl ether diffusion into this solution afforded **5** {Na[Co^{III}(L-N_2SOSO)(*t*BuN*C*)$_2$]·urea·$2H_2O$} as orange crystals (45 mg, 60%). − $C_{24}H_{48}CoN_6NaS_2O_7$ (678.73): calcd. C 42.47, H 7.13, N 12.38, S 9.45; found C 42.58, H 6.86, N 12.38, S 9.48. − UV/Vis (MeOH): λ_{max} (ε) = 460 (sh), 377 (9050), 297 (9380), 217 nm (12800 M^{-1} cm^{-1}). − IR (KBr) $\tilde{\nu}$ = 2375 (w, ν_{CN}) and 2195 (s, ν_{CN}), 1555 (s, ν_{CO}), 965 cm^{-1} (s, ν_{SO}). − ^{1}H NMR (250 MHz, [D_6]DMSO): δ = 7.65 (s, 4 H, H_2O), 5.44 (s, 4 H, urea), 3.60 (d, 2 H, NCH_AH_B, J = 13.3 Hz), 3.09 (d, 2 H, NCH_AH_B), 1.39 (s, 18 H, isocyanides), 1.28, 1.17 and 1.12 (3 s, 3 × 6 H, methyl groups). − Electrospray MS (MeOH); *m*/*z* (%): 476 (100), 492 (22), 559 (86), 575 (16).

Crystal Data for 5·Urea·2H$_2$O: $C_{24}H_{48}CoN_6NaS_2O_7$, M = 678.73, orange hexagonal block 0.20 × 0.40 × 0.80 mm, monoclinic, space group $P2_{1/m}$, a = 10.488(3), b = 18.789(18), c = 21.474(13) Å, Z = 4, β = 98.14(6)°, V = 4189(5) Å^3, D_c = 1.076 g·cm^{-3}, T = 295 K, Mo-K_α radiation (λ = 0.71069 Å), 8208 reflections were measured, 2227 of which were used in all calculations (R_{int} = 0.04). The structure was solved by SHELXS-86 and refined by least-squares analysis using anisotropic thermal parameters, H atoms were introduced in calculated positions, with $F_o > 3\sigma(F_o)$, the programs CRYSTALS and CAMERON were used. R = 0.0935, R_W = 0.1071. It is noteworthy that the refinement factors R and R_W could not be reduced despite several attempts including measurements at lower temperatures. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-146921. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Lithium Alkylselenolates and -tellurolates − A Solid-State and Solution Structural Study

William Clegg,[a] Robert P. Davies,*[b] Ronald Snaith,[c][†] and Andrew E. H. Wheatley[c]

Keywords: Chalcogens / Lithium / Insertion / NMR spectroscopy

Facile insertion of elemental Se or Te into the C–Li bond of *n*BuLi in the presence of TMEDA gives [*n*BuXLi·TMEDA]$_2$ (X = Se **1**; Te **2**). Both **1** and **2** have been fully characterised in the solid and solution states resulting in the first crystal structures of a lithium alkylselenolate and -tellurolate and giving a unique insight into the coordination chemistry of the less sterically demanding chalcogenolate ligands.

Introduction

The desire for new and efficient syntheses for both metal chalcogenolates (primarily used as precursors to semiconducting metal chalcogenolides[1] and as model systems for various biologically active metalloproteins[2]) and also for new reagents for the synthesis of selenium- and tellurium-containing organics[3] has resulted in a growing interest in alkali metal complexes with selenolate (RSe^-) and tellurolate (RTe^-) ligands. However, there still remains a scarcity of both solid-state and solution studies of these species, especially when compared to the multitude of data available on the analogous alkali metal alkoxide (RO^-) and thiolate (RS^-) complexes.[4] Moreover, the majority of studies to date have utilised sterically bulky ligands, such as substituted silyl chalcogenolates (R_3SiX^-; R = Me, $SiMe_3$; X = Se, Te)[5−9] or substituted aromatics (Mes*X^-; Mes* = 2,4,6-*t*Bu$_3$C$_6$H$_2$; X = Se, Te)[10−12] so as to confer extra kinetic stability upon the resulting complex. To the best of our knowledge the only other examples of alkali-metal organochalcogenolates to be structurally characterised are the 2,2′-bipyridine complexes [PhSeLi·bipy]$_2$ and [2-PyrSeLi·bipy]$_2$,[13] the phenylacetyl selenolate PhC≡CSeLi·TMEDA·THF[14] and the heterobimetallic species [CpFe{C$_5$H$_3$(CH$_2$NMe$_2$)TeLi·DME}],[15] [(C$_5$H$_5$)$_2$Lu(μ-SePh)$_2$Li·2THF][16] and [(py)$_2$Yb(SePh)$_2$(μ-SePh)$_2$Li(py)$_2$] (py = pyridine).[17] In order to confront this lack of structural knowledge, particularly of the less sterically demanding ligands, we report here the first solid-state characterisation of both a lithium alkylselenolate (*n*BuSeLi·TMEDA)$_2$ (**1**) and -tellurolate (*n*BuTeLi·TMEDA)$_2$ (**2**) [TMEDA = (Me$_2$NCH$_2$)$_2$].

Results and Discussion

Two main synthetic routes have been documented for the preparation of lithium chalcogenolates: metallation of an organic acid (RSeH or RTeH) and insertion of elemental Se or Te into a C−Li or Si−Li bond.[2,3] The second of these procedures was employed in the synthesis of **1** and **2** since it provided a clean, high yield of the desired products and avoided the synthesis of the readily oxidised butylselenol and butyltellurol species. Reaction in toluene of *n*BuLi with elemental Se or Te (1:1 ratio) in the presence of TMEDA (1 equivalent) resulted in the dissolution of the Group 16 element to give a clear pale yellow solution from which it proved possible to grow, at room temperature, crystals of the lithium chalcogenolates **1** and **2** in yields 36 and 52%, respectively. Both **1** and **2** are highly air sensitive and extremely pungent compounds.

A low temperature X-ray structural characterisation of **1** and **2** reveals that they both crystallise in the monoclinic space group *I*2/*a* and that they both contain two isostructural dimeric molecules within the asymmetric unit, each of which exhibits twofold symmetry (Figure 1). These dimeric units are based around a central Li_2X_2 (X = Se, Te) ring with the *n*-butyl groups in a *cis* conformation and each of the lithium ions solvated by one TMEDA molecule. The free ends of the butyl groups are disordered in the solid-state structures of both **1** and **2**. The Se−Li mean average bond length in **1** [2.583 Å; range 2.544(17) to 2.592(15) Å] is comparable to the Se−Li bond lengths of previously studied lithium selenolates [range 2.462(13) to 2.622(8) Å].[5,11−14] However, the Se−C bond lengths in **1** [1.98(1) and 2.02(2) Å] are longer than the Se−C bonds in the previously characterised arylselenolates [range 1.896(4) to 1.942(7) Å][11−13] and also longer than the Se-C bond [1.813(4) Å] in the alkylnylselenolate [PhC≡CSeLi·TMEDA·THF].[14] This can be accounted for by the sp^3 hybridisation of the α-carbon in **1** whose larger, more diffuse orbitals form longer bonds than the α-carbon sp^2 hybrid orbitals in the arylselenolates and the α-carbon sp orbitals in the alkynylselenolate. The C−Se−Li angle [mean 95.8°, range 92.9(5) to 97.4(7)°] is more acute than in any

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0606−1411 $ 17.50+.50/0

other selenolate previously reported [range 98.2(3) to 104.3(2)°][11−14] presumably by virtue of the low steric demands of the *n*-butyl group. The Li−Se−Li inter-ring angle is also very acute, 69.2(6) and 70.1(6)° in **1** *cf.* 77.0(2) and 75.8(4)° in the only other dimeric lithium selenolates [Li(DME)SeSi(SiMe$_3$)$_3$]$_2$ [5] and [Li(bipy)(SePh)]$_2$,[13] respectively.

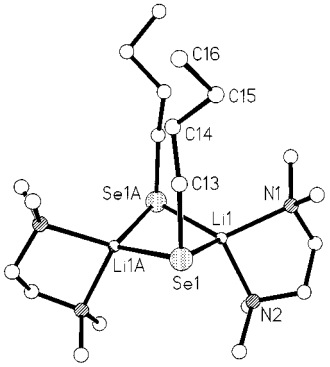

Figure 1. The solid-state structure of [*n*BuSeLi·TMEDA]$_2$ (**1**); only one of the two isostructural dimers in the asymmetric unit is shown; hydrogen atoms and disorder in the *n*-butyl group are omitted for clarity; the molecule lies on a crystallographic twofold rotation axis which relates Li1 and Se1 to Li1A and Se2A

In **2** the Te−Li distances [mean 2.813 Å, range 2.802(6) to 2.824(6) Å] are similar to previously reported Li−Te distances [range 2.70(1) to 2.88(2) Å][6−10,15] and the Te−C (sp^3) distances of 2.259(11) and 2.191(4) Å are larger than the Te−C(sp^2) distances of 2.142(2) Å in [(*o*-C$_6$H$_4$CH$_2$NMe$_2$)TeLi(DME)], 2.184(4) Å in [Mes*TeLi(THF)$_3$][10] and 2.122(2) Å in [CpFe{C$_5$H$_3$(CH$_2$NMe$_2$)TeLi·DME}].[15] The Li−Te−Li bond angles [both of which are 68.2(2) °] are more acute than those observed [75.1(1) °] in the only other dimeric lithium tellurolate [(DME)LiTeSi(SiMe$_3$)$_3$]$_2$,[9] and the mean C−Te−Li bond angle in **2** is 95.0° [range 93.5(2) to 97.2(2)°].

In addition to solid-state X-ray diffraction studies, the solution structures of both **1** and **2** were probed by multinuclear NMR spectroscopy and crysocopic relative molecular mass measurements. Cryoscopic measurements on a 0.030 M solution of **1** in benzene indicated an average association value *n* for [BuSeLi·TMEDA]$_n$ of 3.17 ± 0.08. One possible explanation of this association value is that in nondonor solvents a dimer/tetramer equilibrium is occurring, in which the tetramer is formed from the back-to-back stacking of two of the *cis* dimeric units to give a Li$_4$Se$_4$ cubane structure. A similar result was obtained with a 0.030 M solution of **2** (n = 3.30 ± 0.12). Despite this, ^{7}Li NMR spectroscopic studies at 25 °C on THF solutions of **1** and **2** showed only one peak (δ = −0.04 for a 0.023 M solution of **1**, and δ = 0.25 for a 0.020 M solution of **2**, referenced to PhLi in THF) indicating that any fluxional behaviour between different aggregation states is rapid. This dynamic equilibrium was still observed down to temperatures as low as −80 °C since even at these temperatures only one peak was visible by ^{7}Li NMR spectroscopy. The absence of any observable ^{7}Li coupling to either ^{77}Se or ^{125}Te in these spectra is also indicative of the fluxional behaviour of these species, since any change in aggregation state would involve the breaking and formation of Li−X (X = Se or Te) bonds. As expected, the ^{1}H and ^{13}C NMR spectra of **1** and **2** in [D$_6$]DMSO showed peaks attributable to the TMEDA and *n*-butyl groups, while the main difference between the two ^{13}C NMR spectra was the position of the α-carbon atoms: δ = −1.1 in **1** and δ = −19.4 in **2**. In addition, $^1J_{CTe}$ coupling was observed in the ^{13}C spectrum of **2**, with a coupling constant of 158.0 Hz (this is comparable to previously reported values for dialkyl tellurides).[18] It proved impossible to see Se−C coupling in the ^{13}C NMR spectrum of **1** due to the ready decomposition of this product, hence the poor resolution of its spectra. However, ^{77}Se{^{1}H} NMR spectroscopy of **1** was undertaken and showed a single peak at δ = −660 (referenced to SeMe$_2$ at δ = 0); again no Se−Li coupling was observable.

We now hope to extend this work to look at other sterically undemanding lithium chalcogenolates and also their transmetallation reactions, with particular emphasis placed upon their possible utility in the synthesis of single source precursors to semiconducting materials.[1]

Experimental Section

All reactions and manipulations were carried out under an inert atmosphere of dry nitrogen using standard double manifold and glove-box techniques.

[*n*BuSeLi·TMEDA]$_2$ (1): *n*BuLi (3.2 mL, 1.6 M in hexanes, 5.0 mmol) was added to a suspension of Se (0.40 g, 5 mmol) in toluene (10 mL) and TMEDA (0.75 mL, 5 mmol) under nitrogen at −78 °C. The mixture was then allowed to warm to room temperature with constant stirring to give a pale yellow solution. This solution was filtered under nitrogen and reduced in volume under vacuum to approximately 3 mL. Hexane (6 mL) was then added and the solution left at room temperature for 24 hours to yield a batch of yellow crystalline needles (0.46 g, 36%). − M.p. 128−130 °C. − ^{1}H NMR (400 MHz, C$_6$D$_6$): δ = 2.64 (t, 2 H, -C*H*$_2$Se-), 2.23 (s, 12 H, TMEDA), 2.13 (s, 4 H, TMEDA), 1.95 (m, 2 H, -C*H*$_2$-), 1.64 (m, 2 H, -C*H*$_2$-), 1.11 (t, 3 H, C*H*$_3$CH$_2$-).

[*n*BuTeLi·TMEDA]$_2$ (2): *n*BuLi (3.2 mL, 1.6 M in hexanes, 5.0 mmol) was added to a suspension of Te (0.644 g, 5 mmol) in toluene (15 mL) and TMEDA (0.75 mL, 5 mmol) under nitrogen at −78 °C. The mixture was then allowed to warm to room temperature with constant stirring to give an orange solution. This solution was filtered under nitrogen and left at room temperature for two days to yield a batch of dark-orange, needle-shaped crystals (0.80 g, 52%). − M.p. 144−148 °C. − ^{1}H NMR (400 MHz, C$_6$D$_6$): δ = 2.59 (t, 2 H, -C*H*$_2$Te-), 2.25 (s, 12 H, TMEDA), 2.05 (s, 4 H, TMEDA), 1.92 (m, 2 H, -C*H*$_2$-), 1.59 (m, 2 H, -C*H*$_2$-), 1.03 (t, 3 H, C*H*$_3$CH$_2$-).

X-ray Analysis: Crystals of **1** and **2** were mounted directly into the cold stream of an Oxford Crysotream crystal cooling apparatus, installed on either a Stoe−Siemens four-circle diffractometer (**1**) or a Siemens SMART CCD diffractometer (**2**), using perfluoropolyether oil.

Crystal data for 1: C$_{20}$H$_{50}$Li$_2$N$_4$Se$_2$, M = 518.44, monoclinic, space group *I*2/*a*, a = 16.736(4), b = 19.744(5), c = 17.730(4) Å, β =

91.13(3)°, U = 5857(2) Å^3, Z = 8, D_c = 1.176 g cm^{-3}, μ(Mo-K_α) = 2.535 mm^{-1}, T = 180(2) K. 5916 Reflections (5145 unique, R_{int} = 0.064) measured. Refinement on F^2 values of all data gave final *wR2* = 0.2195, conventional R = 0.0795 on F values of all reflections with $F^2 > 2\sigma(F^2)$, 292 parameters.

Crystal data for 2: $C_{20}H_{50}Li_2N_4Te_2$, M = 615.72, monoclinic, space group *I*2/*a*, a = 17.762(1), b = 19.811(2), c = 17.339(1) Å, β = 90.77(1) °, U = 6101.0(8) Å^3, Z = 8, D_c = 1.341 g cm^{-3}, μ(Mo-K_α) = 1.923 mm^{-1}, T = 160(2) K. 27244 Reflections (7512 unique, R_{int} = 0.036) measured. Refinement on F^2 values of all data gave final *wR2* = 0.1082, conventional R = 0.0375 on F values of all reflections with $F^2 > 2\sigma(F^2)$, 291 parameters.

Crystallographic data for compounds **1** and **2** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-151235 (**1**) and CCDC-152141 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax (internat.): +44-1223/336-033; Email: deposit@ccdc.cam.ac.uk; www: http://www.ccdc.cam.ac.uk].

Tris(pyrazolyl)methanesulfonate (Tpms) − A Versatile Alternative to Tris(pyrazolyl)borate in Rhodium(I) Chemistry

Wolfgang Kläui,*[a] Daniel Schramm,[a] Wilfried Peters,[a] Gerd Rheinwald,[b] and Heinrich Lang[b]

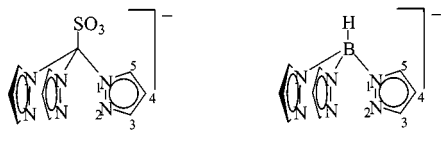
Keywords: Rhodium / Tripodal ligands / N ligands / Fluxionality / Carbonyl complexes

Thallium(I) tris(pyrazol-1-yl)methanesulfonate (TlTpms) has been prepared as a new versatile precursor for Tpms complexes. TlTpms readily reacts with the rhodium(I) complexes $[Rh(LL)Cl]_2$ [LL = $(CO)_2$, cod, nbd] to give the corresponding TpmsRh(LL) complexes [LL = $(CO)_2$ (**2a**), cod (**3**), and nbd (**4**)]. In solution, **2a** reversibly forms the binuclear complex TpmsRh(μ-CO)$_3$RhTpms (**2b**). **3** and **4** react with CO to form **2a**. TpmsRh(CO)(PR_3) complexes [PR_3 = PPh_3 (**5a**), PMe_3 (**5b**), PCy_3 (**5d**), $P(Ph)_2(PhSO_3K)$ (**5e**)] have been obtained by reaction of **2a** with the corresponding phosphanes. The solid-state structures of **2a**, **3**, **4**, and **5a** have been determined by X-ray analysis. **2a**, **3**, and **5a** have square-planar geometries with the Tpms ligand coordinating in a κ^2 mode. The non-coordinating pyrazole ring faces either away from (structure **2a**) or towards the rhodium atom (structures **3** and **5a**). **4** has a trigonal-bipyramidal coordination geometry with a genuine κ^3-bonded Tpms ligand. The non-rigid behaviour of the (Tpms)rhodium complexes has been followed by variable-temperature NMR studies. IR studies on **2a** and **5a–e** show that Tpms is a weakly donating ligand, comparable to the $Tp^{CF_3,Me}$ and Tp^{CF_3,CF_3} ligands. Compound **5e** is soluble and stable in dilute acids, showing that Tpms, unlike the Tp ligand, is hydrolytically stable.

Introduction

Since their original synthesis by Trofimenko in 1966,[1] tris(pyrazolyl)borates (Tp′)[2] have proved to be highly useful ligands and are widely used in the synthesis of novel transition metal complexes. Besides their advantages, which make them the most commonly used tripodal nitrogen ligands, tris(pyrazolyl)borates have the disadvantage of being unstable towards hydrolysis. This property can only be attenuated by using substituted pyrazoles in order to protect the labile B−N bonds.[3] Another problem is the low solubility of some (Tp)rhodium compounds. It has been reported several times that $TpRh(CO)_2$ could not be isolated. All attempts to synthesize this compound resulted in the formation of the highly insoluble TpRh(μ-CO)$_3$RhTp.[4]

We have recently reported[5] the synthesis of the novel tris(pyrazolyl)methanesulfonate ligand (Tpms), which was developed in analogy to the Tp ligand (Figure 1).



Trispyrazolylmethanesulfonate (Tpms) Trispyrazolylborate (Tp)

Just like Tp, Tpms is a monoanionic, C_{3v}-symmetrical nitrogen-donor ligand. Instead of the boron hydride unit of Tp, Tpms has a methanesulfonate unit, which imparts very good stability towards hydrolysis and an increased solubility in polar solvents.

We describe herein the preparation of the thallium salt of Tpms as a precursor for ligand-exchange reactions and its reactions with $[Rh(LL)Cl]_2$ [LL = cod, nbd, $(CO)_2$]. The solid-state and solution structures of olefin, carbonyl, and phosphane derivatives of (Tpms)rhodium(I) are presented.

Results and Discussion

Synthesis of TlTpms (1)

TlTpms (**1**) was prepared by adding an excess of thallium(I) carbonate to an aqueous solution of LiTpms. After recrystallization from methanol, analytically pure **1** was obtained in 60% yield. The product **1** was found to react readily with transition metal halide complexes.

Although **1** only dissolves freely in water, it has proved to be surprisingly reactive under heterogeneous reaction conditions.

Synthesis of TpmsRh(CO)$_2$ (2a) and TpmsRh(μ-CO)$_3$RhTpms (2b)

Reaction of **1** with $[Rh(CO)_2Cl]_2$ in THF at room temperature gives the corresponding dicarbonyl complex $TpmsRh(CO)_2$ (**2a**) in excellent yield. Solutions of **2a** in THF are unstable and form a pale-yellow deposit. This deposit is highly insoluble in all common organic solvents and has been identified as TpmsRh(μ-CO)$_3$RhTpms (**2b**) by

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0606−1415 $ 17.50+.50/0

infrared spectroscopy. The characteristic asymmetric μ-CO stretching vibration is found at $\tilde{\nu} = 1860\ cm^{-1}$. The analogous binuclear Tp compound shows a CO stretching vibration at $\tilde{\nu} = 1845\ cm^{-1}$.[4c] This indicates that Tpms is a weaker donor than Tp. Unlike the Tp compound, the Tpms complex **2a** can be kept in solution under a carbon monoxide pressure of about 3 atm. Under these conditions, it is possible to grow yellow crystals of **2a** by diffusion-controlled crystallization from THF/pentane.

Compound **2a** is well soluble in polar organic solvents such as THF and acetone, but only sparingly soluble in less polar solvents such as toluene and dichloromethane. The rate of formation of **2b** appears to be strongly dependent on the concentration of **2a** in solution. At a concentration of 1 g/L under nitrogen, the first traces of **2b** become visible after 30 min. Under 3−4 atm of carbon monoxide pressure, no precipitate is formed within 4 weeks. When the concentration exceeds 2 g/L, the formation of **2b** can only be prevented by higher carbon monoxide pressures. Pressures of 40 atm of carbon monoxide and temperatures up to 80 °C are needed to recover **2a** from **2b** within 24 h.

Just like the tris(pyrazolyl)borates, Tpms is capable of acting as a bidentate or tridentate ligand and thus of forming 16- and 18-electron complexes with the Rh^I d^8-metal centre. NMR studies on **2a** show that all three pyrazoles are equivalent in solution at room temperature. This observation is consistent with either a non-rigid tridentate structure or a bidentate geometry with a dynamic exchange that is fast on the NMR time scale, as is often found in Tp chemistry.[6] In variable-temperature NMR spectra, the signal pattern of the pyrazoles changes from one consistent with C_{3v} symmetry at room temperature to one consistent with C_s symmetry at 203 K. With $\nu_{(CO)}$ stretching bands (sym and asym) of $\tilde{\nu} = 2091$, 2032, and 2023 cm^{-1} in KBr and of $\tilde{\nu} = 2098$, 2090, 2036, and 2024 cm^{-1} in THF, the vibrational frequencies are within the characteristic range for four-coordinate rhodium complexes.[6]

Moreover, the appearance of four bands indicates that there are two different isomers (A and B) in a κ^2-bonding mode (Figure 2).

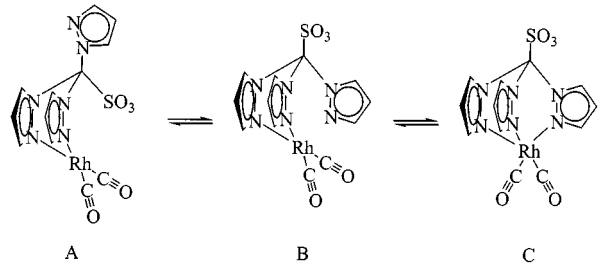

Figure 2. Three possible isomers of $TpmsRh(CO)_2$ (**2a**)

Although evidence for the existence of isomer C could not be observed by IR spectroscopic means, it is probably an intermediate in the dynamic equilibration of the pyrazoles observed by NMR, as ligand exchanges in square-planar d^8 complexes are known to proceed by an associative mechanism involving a five-coordinate intermediate.[7]

The electron-donating capabilities of a ligand can be estimated by comparing the CO stretching vibration bands of a *trans*-CO ligand. Table 1 shows a comparison between **2a** and $Tp'Rh(CO)_2$ compounds. The complexes $Tp^*Rh(CO)_2$,[6] $Tp^{Ph,Me}Rh(CO)_2$[8b] (**2d**), and $Tp^{CF_3,Me}Rh(CO)_2$[8c] (**2e**) show bands that are shifted towards lower energies compared to those of **2a**. Thus, the Tp′ ligands are evidently better donors. Only the highly fluorinated Tp^{CF_3,CF_3} ligand, which has been prepared in order to mimic fluorinated cyclopentadienyl ligands,[9] is a slightly weaker donor than the Tpms ligand. The donor properties of Tpms are intermediate between those of $Tp^{CF_3,Me}$ and Tp^{CF_3,CF_3} in analogous rhodium(I) compounds.

X-ray Structure of 2a

Crystals of **2a** suitable for X-ray analysis were obtained by diffusion-controlled crystallization from THF/pentane. The mother liquor was kept under a carbon monoxide pressure throughout the crystallization in order to avoid the formation of **2b**. **2a** crystallizes in the triclinic space group $P\bar{1}$ with two molecules of **2a** and one molecule of THF per cell unit. The ZORTEP plot given in Figure 3 shows one of the rhodium complexes of **2a**. Selected interatomic distances and angles are presented in Table 2.

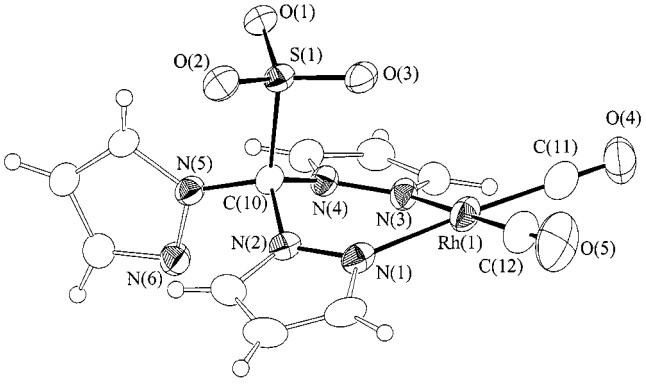

Figure 3. ZORTEP plot of $TpmsRh(CO)_2$ (**2a**) (50% probability)

The rhodium centre is coordinated in a slightly distorted planar geometry. The angle between the planes N(3)−Rh(1)−N(1) and C(11)−Rh(1)−C(12) is 3.0°, shifting the rhodium atom towards the oxygen atom O(3). Tpms acts as a bidentate ligand coordinating with two pyrazole

moieties; one of the sulfonate oxygen atoms points towards the rhodium centre but the Rh(1)−O(3) distance of 2.8941(18) Å exceeds the sum of their van der Waals radii.

From the crystal structures of **2c**, **2d**, **2e**, and **2a** (Table 3), it is evident that the Tpms complex **2a** has the shortest Rh−N bond lengths, which can be attributed to the fact that this complex has the smallest steric demand. The bite angle of **2a** is similar to those found for **2c** and **2d**, but significantly larger than that reported for **2e**.

Synthesis of TpmsRh(cod) (3) and TpmsRh(nbd) (4)

Reactions of **1** with $[Rh(cod)Cl]_2$ and $[Rh(nbd)Cl]_2$ in dichloromethane at room temperature give the corresponding complexes TpmsRh(cod) (**3**) and TpmsRh(nbd) (**4**) in very high yields. Both products were found to be well soluble in most organic solvents. At room temperature, both compounds show ^1H NMR patterns in agreement with C_{3v} symmetry. Again, this is consistent with either a non-rigid κ^3-bonded structure or a κ^2-mode geometry with a dynamic exchange that is fast on the NMR time scale down to 203 K. The methylene protons of the cyclooctadiene allow an assignment of the pyrazole protons by means of NOESY experiments. Complex **3** exhibits peaks at δ = 8.50, 7.68, and 6.55 attributable to the protons attached to C^5, C^3, and C^4, respectively. The corresponding peaks for TpRh(cod) are found at δ = 7.76, 7.58, and 6.21 (not fully assigned).[6]

The prominent downfield shift of the signal of the proton attached to C^5 in Tpms is caused by the deshielding effect of the sulfonate group. The $-I$ effect of the sulfonate group renders the pyrazole groups in the Tpms ligand less electron-rich, whereas the $+I$ effect of the BH group has the opposite effect.

Complexes **3** and **4** readily react with carbon monoxide to give **2a** [Equation (1)]. In the reverse reaction, considerable amounts of **2b** are formed.

$$TpmsRh(LL) \xrightarrow[-\,[LL]]{3 - 4\ atm.\ CO} TpmsRh(CO)_2 \qquad (1)$$

[LL] = 1,5-cyclooctadiene, norbornadiene

X-ray Structure of 3

Crystals of **3** suitable for X-ray analysis were obtained by diffusion-controlled crystallization from dichloromethane/pentane. This complex crystallizes as rods in the monoclinic space group $P2(1)/c$. Figure 4 shows a ZORTEP view of **3**. Selected interatomic distances and angles are given in Table 4.

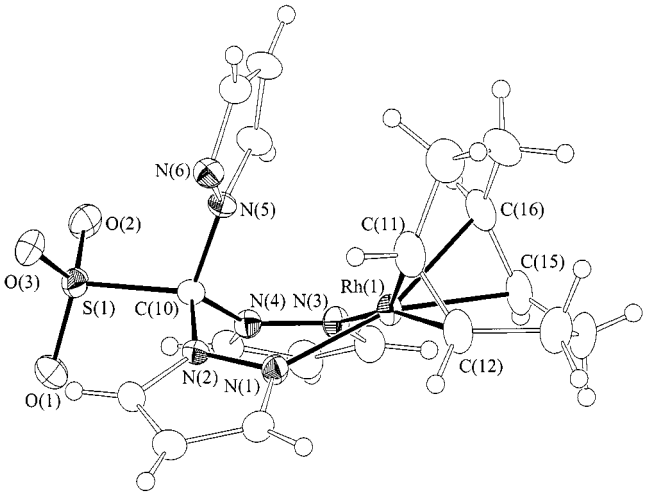

Figure 4. ZORTEP plot of TpmsRh(cod) (**3**) (50% probability)

The rhodium centre adopts a slightly distorted planar geometry with Tpms coordinating as a bidentate ligand. The third pyrazole ring is orientated parallel to the C(11)−Rh(1)−C(16) plane. The distance between the non-coordinating nitrogen atom N(6) and the rhodium centre Rh(1) is 3.535 Å, which exceeds the sum of their van der Waals radii. N(1), N(3), M(1), and M(2) [M(1) and M(2) are the centres of the bond between the olefinic carbon atoms C(11)−C(12) and C(15)−C(16)] deviate from a plane calculated by least-squares fitting by less than 0.05 Å. The rhodium centre is not significantly displaced from this plane. Comparison with the structurally characterized complexes $Tp^{4Bo,3Me}Rh(cod)$,[10] $Tp^{iPr,iPr}Rh(cod)$,[11] $Tp^{Ph}Rh(cod)$,[12] and $B(pz)_4Rh(cod)$[13] shows that the Rh−N and Rh−C bond lengths are equal within experimental errors. Only the bite angles show significant variations. The N−Rh−N angle in **3** [85.46(7)°] resembles the angles in $B(pz)_4Rh(cod)$ [86.6(1)°] and $Tp^{Ph}Rh(cod)$ [84.56(24)°]. The corresponding angles in $Tp^{iPr,iPr}Rh(cod)$

Table 4. Selected distances [Å] and angles [°] in TpmsRh(cod) (**3**)

[82.5(1)°] and $Tp^{4Bo,3Me}$Rh(cod) [82.3(2)°] are smaller, probably as a consequence of the levering effect of the bulky substituents in the 5-position of the pyrazoles.[3a]

X-ray Structure of 4

The norbornadiene complex **4** crystallizes in the form of dark-yellow plates in the orthorhombic space group *Pnma*. The ZORTEP plot is shown in Figure 5 and selected interatomic distances and angles are presented in Table 5. Unlike the other structurally characterized Tpms rhodium complexes, **4** has a distorted trigonal-bipyramidal coordination geometry with a genuine κ^3-bonded Tpms ligand. The pyrazole groups of the tripod occupy one axial and two equatorial coordination sites. The atoms N(1), N(1a), Rh(1), C(8), and C(8a) lie in the equatorial plane, while the "axis" N(3)−Rh(1)−M(3) [M(3) is the centre of the bond between the olefinic carbon atoms C(10)−C(10a)] is bent by 10.5°.

The structure resembles those of Tp^{Me}Rh(nbd)[6] (**4a**) and $Tp^{iPr,iPr}$Rh(nbd)[11] (**4b**), where the Tp′ ligands are also bonded in a κ^3-fashion, while in Tp^{Ph}Rh(nbd)[12] and $B(pz)_4$Rh(nbd),[13] the polypyrazolylborates coordinate in a κ^2-mode forming planar complexes. The X-ray analysis shows that all Rh−N separations are significantly shorter in **4** than those in **4a** and **4b** (Table 6), while the Rh−C separations as well as the C=C distances are the same within experimental errors. It is noteworthy that the Rh−N distances to the axially coordinated pyrazole ring in **4**, **4a**, and **4b** are significantly shorter than those to the equatorially coordinated rings. The reason for this is not clear. As a rule, axial bonds are longer than equatorial bonds in trigonal-bipyramidal compounds. However, relatively few trigonal-bipyramidal rhodium(I) complexes are known.[14] A structure correlation analysis of d^8 five-coordinated complexes does not shed any light on the role of trigonal-bipyramidal geometry in favouring the S_N2 pathway in rhodium(I) complexes.[15]

[a] KBr. − [b] CH_2Cl_2.

methylphosphane had to be added slowly in stoichiometric amounts in order to avoid displacement of the second carbon monoxide ligand or the tripod, as was observed in the case of Tp*Rh$(C_2H_4)_2$.[16] The less basic and sterically more crowded tricyclohexyl- and triphenylphosphane could be added in excess. The displacement of carbon monoxide is a fast reaction; it was not necessary to work under carbon monoxide pressure in order to avoid the formation of **2b**. The corresponding TpmsRh(CO)PR_3 complexes were obtained as bright-yellow crystals in excellent yields. They were found to be well soluble in most organic solvents.

At room temperature, all TpmsRh(CO)PR_3 compounds show ^1H NMR patterns in agreement with C_{3v} symmetry, indicating rapid exchange of the pyrazoles on the NMR time scale. ^1H NMR studies on **5a** show that two pyrazole groups become equivalent at 203 K, displaying a 2:1 intensity ratio, which is consistent with a C_s-symmetric complex or a fast exchange of only two pyrazole groups. Similar effects have been observed for the corresponding Tp′ compounds Tp*Rh(CO)PPh_3[17] (**5e**), $Tp^{Ph,Me}$Rh(CO)PPh_3[8b] (**5f**), and Tp*Rh(CO)PMe_3[18] (**5g**). The exchange mechanisms for **5f** and **5g** were suggested to proceed via trigonal-bipyramidal intermediates. The $\Delta G^{\neq}$ values estimated from the coalescence temperatures were 76.5 kJ/mol for the bulky **5f**[8b] and 63 kJ/mol for the less bulky **5g**.[18] As **5a** is even less sterically hindered, it is consistent that its $\Delta G^{\neq}$ value is considerably smaller (46±2 kJ/mol). It can be assumed that the exchange takes place between the free nitrogen atom N(6) and the nitrogen atom N(3) lying *trans* to the CO ligand, because the $\Delta G^{\neq}$ value is similar to those estimated for **2a** (47±2 kJ/mol) and **5b** (47±2 kJ/mol). This is consistent with the fact that CO has a larger *trans* effect than PR_3.[7] The $^{31}P\{^1H\}$ NMR spectrum of **5a** shows a doublet at $\delta = 44$ ($^1J_{RhP} = 158$ Hz), which is comparable with those of **5e**, **5f**, and TpRh(CO)PPh_3[19] (**5h**) (Table 7).

The CO stretching vibration of **5a** is found at considerably higher energy than those of **5e**, **5f**, and **5h**. This indicates that the electronic properties of the tripod have a big influence on the CO stretching vibration. Comparison of the Tp′ compounds **5e**, **5f**, and **5h** shows that the steric properties of the ligands have only small effects on the CO stretching vibration. A similar conclusion is reached on comparing **5b** and **5c** with the corresponding Tp′ compounds **5g** and **5i**.

X-ray Structure of 5a

The Tpms complex **5a** crystallizes as thin rods in the triclinic space group $P\bar{1}$. The asymmetric unit contains one molecule of **5a** and one molecule of THF. Figure 6 shows a ZORTEP plot of **5a**, and a selection of interatomic distances and angles is given in Table 8.

The rhodium atom is coordinated in a slightly distorted planar geometry. The Tpms coordinates as a bidentate ligand and the non-coordinating pyrazole group is located above the coordination plane. The distance between Rh(1) and the non-coordinating N(6) is 3.513 Å, which exceeds the sum of their van der Waals radii. The different *trans* effects of PPh_3 and CO are not manifested in different bond lengths Rh(1)−N(3) [2.100(3) Å] and Rh(1)−N(1) [2.093(3) Å].

Synthesis of $TpmsRh(CO)PPh_2PhSO_3K·H_2O$ (5d)

An excess of $PPh_2PhSO_3K·H_2O$ was added to a THF solution of the dicarbonyl compound **2a**. As this is a slow heterogeneous reaction, it was necessary to keep the mixture under carbon monoxide pressures of about 3 atm in order to avoid formation of the binuclear compound **2b**. The resulting complex **5d** was found to be soluble in wet THF and could be separated from the excess phosphane by filtration. It was then precipitated by overlaying the THF solution with pentane.

Compound **5d** was found to be well soluble in water, but formed colloidal rhodium within a few minutes. This decomposition of the complex was evidently not triggered by decomposition of the ligands, as free Tpms as well as the phosphane could be detected. We suspect that the rhodium centre is attacked by hydroxy ions, which leads to redox reactions and thus to decomposition of the complex. Indeed, it was found that the decomposition could be prevented by dissolving **5d** in very dilute phosphoric or sulfuric acid (pH = 3−4). Tpms is stable under these conditions.[5] At lower pH values, Tpms is protonated and thus loses its coordinative ability towards the rhodium centre. All three pyrazole groups are seen to be equivalent according to the ^1H NMR spectrum. The signals are slightly broadened at room temperature. We could not obtain single crystals of **5d**, but the similarity of its NMR and IR data to those of **5a** is evident.

Conclusion

The thallium salt of the novel ligand Tpms is a convenient starting material for the preparation of rhodium(I) complexes. The sulfonate group of Tpms ensures good solubility in polar solvents. This has allowed the isolation of the planar dicarbonyl complex $TpmsRh(CO)_2$ (**2a**). The corresponding complex of the Trofimenko ligand Tp is not sufficiently stable for a crystal structure analysis. The IR data (ν_{CO}) indicate that Tpms is a remarkably weaker donor than the Tp ligand in carbonylrhodium(I) complexes. Its donor strength is similar to that of the Tp^{CF_3,CF_3} ligand. The lower donor strength of Tpms does not result in longer rhodium−nitrogen bonds. In fact, the X-ray structures of $TpmsRh(CO)_2$ (**2a**) and TpmsRh(nbd) (**4**) show that Tpms forms shorter rhodium−nitrogen bonds than the sterically more demanding Tp ligands (Tp^{Me}, $Tp^{CF_3,Me}$, $Tp^{Ph,Me}$, $Tp^{iPr,iPr}$) in analogous compounds.

It is noteworthy that the Tpms ligand acts as a bis(chelating) ligand in TpmsRh(cod) (**3**) but as a tris(chelating) ligand in TpmsRh(nbd) (**4**). We can see no obvious reason for this behaviour. $TpRh^I$ complexes with a coordination number of five are very rare. To the best of our knowledge, $Tp^{iPr,iPr}$ is the only other Tp ligand that has been shown to act both as a bidentate and as a tridentate ligand in rhodium(I) complexes.[11] Jones et al. have found that the hapticity of Tp ligands correlates with the ^{11}B chemical shift.[20] The corresponding probe for the Tpms ligand would be the ^{13}C chemical shift of the methanesulfonato carbon atom. However, the ^{13}C chemical shifts for the structurally characterized compounds **3**, **4**, and **5a** are not significantly different. Thus, these data do not correlate with the solid-state structures, leaving the denticity of the Tpms ligand in solution ambiguous.

According to our preliminary experiments, all the $TpmsRh^I$ compounds described herein can be used as precursors for catalysts in hydroformylation reactions. We are currently investigating the differences between the ligands Tpms and Tp in rhodium-catalyzed reactions.

Experimental Section

General Remarks: The compounds tris(pyrazolyl)methane,[21] LiTpms,[5] $[\{Rh(CO)_2Cl\}_2]$,[22] $[\{Rh(nbd)Cl\}_2]$,[23] $[\{Rh(cod)Cl\}_2]$,[24] and $P(C_6H_5)_2(p\text{-}C_6H_4\text{-}SO_3K)·H_2O$[25] were synthesized according to literature procedures. All other reagents were commercial samples and were used as received. All reactions were carried out under nitrogen using standard Schlenk techniques unless stated otherwise. Solvents were purified and degassed by standard procedures. Methanol and ethanol used in the work-up of **1** were used without further purification. Filtration was carried out using 1-μm membrane filters (regenerated cellulose, Schleicher & Schuell). Reactions under 3−4 atm pressure were performed in glass tubes equipped with Teflon seals and valves. ***All operations in glass vessels at elevated pressures should be performed using effective body and face protection!*** − One-dimensional ^1H, ^{31}P, and ^{13}C NMR spectra were recorded with Bruker DRX 200 (at 293 K) or Bruker DRX 500 (at 298 K) spectrometers. Two-dimensional NOESY and COSY as well as one-dimensional DEPT spectra were recorded with a Bruker DRX 500 spectrometer. Chemical shifts (δ) are given in ppm referenced to the solvent peak. Spectra recorded using $[D_8]$THF as a solvent were referenced to tetramethylsilane. Spectra recorded using D_2O as a solvent were referenced to sodium

3-(trimethylsilyl)-1-propanesulfonate. The spectrum of **5d** was recorded in dilute D_3PO_4 solution (pH = 3−4), which was prepared from D_2O and P_4O_{10} under inert conditions. Chemical shifts were ±0.01 ppm for δ^1H, ±0.1 ppm for $\delta^{31}P$ and ±0.1 ppm for $\delta^{13}C$. − Infrared spectra were recorded with a Bruker IFS 66 FT spectrometer. − Electron impact (EI) mass spectra were recorded with a Varian MAT 311 A instrument with an ionization energy of 70 eV. FAB mass spectra were recorded with a Finnigan MAT 8200 instrument using an NBA matrix. − Elemental analyses were performed using a Perkin−Elmer CHN-2400/II elemental analyzer.

Thallium(I) Tris(pyrazol-1-yl)methanesulfonate, TlTpms (1): A solution of tris(pyrazolyl)methane (4.9 g, 23 mmol) in THF (100 mL) was cooled to −78 °C and a 1.6 M solution of *n*-butyllithium (16 mL, 26 mmol) was slowly added. The solution was stirred for 1 h while the temperature was allowed to rise to 0 °C. After subsequent cooling to −60 °C, trimethylamine−sulfur trioxide (4.2 g, 30 mmol) was added and the resulting suspension was stirred overnight while the temperature was allowed to rise to 25 °C. The mixture was then filtered through a membrane filter and the solid residue was added to a solution of thallium(I) carbonate (7.1 g, 15 mmol) in water (150 mL). The resulting mixture was stirred at 60−70 °C for 1 h and then the solvent was evaporated under reduced pressure. The residue was extracted for 4 h with wet ethanol to remove less polar by-products. The remaining residue was recrystallized from 1 L of wet methanol to give 6.9 g of colourless crystals (60%). − ^1H NMR (200 MHz, D_2O): δ = 6.56 (dd, $^3J_{HH}$ = 2.7 Hz, $^3J_{HH}$ = 1.8 Hz, 3 H, pyrazolyl 4-H), 7.65 (dd, $^3J_{HH}$ = 2.7 Hz, $^4J_{HH}$ = 0.6 Hz, 3 H, pyrazolyl 3-/5-H), 7.75 (dd, $^3J_{HH}$ = 1.8 Hz, $^4J_{HH}$ = 0.6 Hz, 3 H, pyrazolyl 3-/5-H). − $^{13}C\{^1H\}$ NMR (500 MHz, D_2O): δ = 98.7 (s, C−SO_3), 110.5 (s, pyrazolyl C^4), 135.2 (s, pyrazolyl $C^{3/5}$), 145.4 (s, pyrazolyl $C^{3/5}$). − IR (KBr): $\tilde{\nu}$ = 3150 cm^{-1}, 3137 (w, C−H), 1522 (s, C=C), 1089, 1059, 1052, 1039 (s, S=O). − MS (FAB^+): *m/z* (%) = 499 (1.3) $[M + H]^+$. − $C_{10}H_9N_6O_3STl$ (497.7): calcd. C 24.00, H 1.81, N 16.79; found C 24.04, H 1.80, N 16.87.

Dicarbonyl[tris(pyrazol-1-yl)methanesulfonato]rhodium(I), $TpmsRh(CO)_2$ (2a): A mixture of the carbonylrhodium chloride complex $[\{Rh(CO)_2Cl\}_2]$ (78 mg, 0.20 mmol) and **1** (0.20 g, 0.40 mmol) in THF (200 mL) was pressurized with 3−4 atm of carbon monoxide and stirred for 16 h at room temperature. Thereafter, the precipitated TlCl was allowed to settle and the supernatant solution was siphoned into another vessel by means of a cannula. From the clear yellow solution, 0.19 g (100%) of **2a** was obtained. To obtain yellow crystals of **2a** suitable for X-ray analysis, the solution was overlaid with pentane, pressurized with 3−4 atm of carbon monoxide, and left until crystallization occurred. − ^1H NMR (200 MHz, [D_6]acetone): δ = 6.73 (dd, $^3J_{HH}$ = 3.0 Hz, $^3J_{HH}$ = 2.1 Hz, 3 H, pyrazolyl 4-H), 8.19 (d, $^3J_{HH}$ = 2.1 Hz, 3 H, pyrazolyl 3-/5-H), 8.24 (d, $^3J_{HH}$ = 3.0 Hz, 3 H, pyrazolyl 3-/5-H).[26] − IR (KBr): $\tilde{\nu}$ = 3169 cm^{-1}, 3152 (w, C−H), 1520 (s, C=C), 2091, 2032, 2023 (vs, C=O) 1086, 1073, 1054, 1040 (s, S=O). − MS (FAB^+): *m/z* (%) = 453 (5.6) $[M + H]^+$. − $C_{12}H_9N_6O_5RhS$ (452.2): calcd. C 31.87, H 2.01, N 18.58; found C 32.13, H 2.20, N 18.49.

μ-Tricarbonylbis{[tris(pyrazol-1-yl)methanesulfonato]rhodium(I)}, $TpmsRh(\mu\text{-}CO)_3RhTpms$ (2b): Compound **2b** was formed when a solution of **2a** in THF was left without a positive pressure of carbon monoxide. The solvent was slowly evaporated from a solution of **2a** (45 mg, 0.10 mmol) in THF by passing a gentle stream of nitrogen over it. After 2 d, the residue was dried in vacuo to give 44 mg (100%) of **2b** as an amorphous pale-yellow powder. − IR (KBr): $\tilde{\nu}$ = 3191 cm^{-1}, 3150, 3110 (m, C−H), 1861 (vs, C=O), 1522 (s, C=C), 1081, 1068, 1051 (s, S=O). − $C_{23}H_{18}N_{12}O_9Rh_2S_2$ (876.4): calcd. C 31.52, H 2.07, N 19.18; found C 31.82, H 2.42, N 18.82.

(Cycloocta-1,5-diene)[tris(pyrazol-1-yl)methanesulfonato]rhodium(I), TpmsRh(cod) (3): A mixture of the (cyclooctadiene)rhodium chloride complex $[\{Rh(cod)Cl\}_2]$ (99 mg, 0.20 mmol) and **1** (0.20 g, 0.40 mmol) in dichloromethane (50 mL) was stirred for 16 h at room temperature. The precipitated TlCl was then separated by filtration. Evaporation of the solvent from the filtrate afforded 0.20 g (100%) of **3** as a yellow powder. To obtain yellow crystals of **3** suitable for X-ray analysis, the filtrate was concentrated to 10% of its original volume and then overlaid with pentane. − ^1H NMR (200 MHz, $CDCl_3$): δ = 1.9 (m, 4 H, cod CH_2), 2.3 (m, 4 H, cod CH_2), 4.15 (br. s, 4 H, cod CH), 6.55 (dd, $^3J_{HH}$ = 2.9 Hz, $^3J_{HH}$ = 2.1 Hz, 3 H, pyrazolyl 4-H), 7.68 (d, $^3J_{HH}$ = 2.1 Hz, 3 H, pyrazolyl 3-H), 8.50 (br. s, 3 H, pyrazolyl 5-H). − $^{13}C\{^1H\}$ NMR (500 MHz, CD_2Cl_2): δ = 29.2 (s, cod CH_2), 82.6 (d, $^1J_{RhC}$ = 12.7 Hz, cod = CH), 93.4 (s, C−SO_3), 106.5 (s, pyrazolyl C^4), 135.1 (s, pyrazolyl C^5), 141.2 (s, pyrazolyl C^3). − IR (KBr): $\tilde{\nu}$ = 3165 cm^{-1}, 3148, 3111 (m, C−H), 1521 (s, C=C), 1086, 1081, 1054, 1043 (s, S=O). − MS (EI, 300 °C): *m/z* (%) = 504 (12.7) $[M]^+$, 424 (1.9) $[M - SO_3]^+$, 357 (62.2) $[M - SO_3 - C_3H_3N_2]^+$. − $C_{18}H_{21}N_6O_3RhS$ (504.4): calcd. C 42.86, H 4.20, N 16.66; found C 42.67, H 4.26, N 16.74.

(Bicyclo[2.2.1]hepta-2,5-diene)[tris(pyrazol-1-yl)methanesulfonato]rhodium(I), TpmsRh(nbd) (4): A mixture of the (norbornadiene)rhodium chloride complex $[\{Rh(nbd)Cl\}_2]$ (23 mg, 0.050 mmol) and **1** (50 mg, 0.10 mmol) in dichloromethane (30 mL) was stirred for 16 h at room temperature. The precipitated TlCl was then separated by membrane filtration. Evaporation of the solvent from the filtrate afforded 48 mg (100%) of **4** as a yellow powder. To obtain dark-yellow crystals of **4** suitable for X-ray analysis, the filtrate was concentrated to 10% of its original volume and then overlaid with pentane. − ^1H NMR (200 MHz, CD_2Cl_2): δ = 1.38 (br. s, 2 H, nbd CH_2), 3.89 (br. s, 4 H, nbd =CH), 3.90 (br. s, 2 H, nbd CH), 6.50 (dd, $^3J_{HH}$ = 2.8 Hz, $^3J_{HH}$ = 2.0 Hz, 3 H, pyrazolyl 4-H), 7.55 (d, $^3J_{HH}$ = 2.0 Hz, 3 H, pyrazolyl 3-H), 8.20 (d, 3 H, $^3J_{HH}$ = 2.8 Hz, pyrazolyl 5-H). − $^{13}C\{^1H\}$ NMR (500 MHz, CD_2Cl_2): δ = 49.4 (d, $^2J_{RhC}$ = 2.6 Hz, nbd CH), 52.6 (d, $^1J_{RhC}$ = 11.2 Hz, nbd =CH), 60.4 (d, $^3J_{RhC}$ = 6.9 Hz, nbd CH_2), 93.5 (s, C−SO_3), 106.1 (s, pyrazolyl C^4), 134.6 (s, pyrazolyl C^5), 141.2 (s, pyrazolyl C^3). − IR (KBr): $\tilde{\nu}$ = 3142 cm^{-1}, 3121, 2994, 2898 (m, C−H), 1523 (s, C=C), 1083, 1068, 1053 (s, S=O). − MS (EI, 320 °C): *m/z* (%) = 488 (16.5) $[M]^+$, 408 (7.4) $[M - SO_3]^+$, 341 (100.0) $[M - SO_3 - C_3H_3N_2]^+$. − $C_{17}H_{17}N_6O_3RhS{\cdot}H_2O$ (506.4): calcd. C 40.33, H 3.78, N 16.60; found C 40.65, H 3.57, N 16.31.

Carbonyl(triphenylphosphane)[tris(pyrazol-1-yl)methanesulfonato]rhodium(I), $TpmsRh(CO)PPh_3$ (5a): Triphenylphosphane (0.52 g, 2.0 mmol) was added to solution of **2a** (0.19 g, 0.40 mmol) in THF (200 mL). After 1 h, the solution was concentrated to a volume of 10 mL and overlaid with pentane. Crystallization yielded 0.29 g (100%) of a THF adduct of **5a** as bright-yellow needles. The crystals obtained were suitable for X-ray analysis. − ^1H NMR (200 MHz, CD_2Cl_2): δ = 6.38 (dd, $^3J_{HH}$ = 2.8 Hz, $^3J_{HH}$ = 2.2 Hz, 3 H, pyrazolyl 4-H), 7.29 (d, $^3J_{HH}$ = 2.2 Hz, 3 H, pyrazolyl 3-H), 7.5 [m, 15 H, $P(C_6H_5)_3$], 8.44 (d, $^3J_{HH}$ = 2.8 Hz, 3 H, pyrazolyl 5-H). − $^{31}P\{^1H\}$ NMR (200 MHz, CD_2Cl_2): δ = 45 (d, $^1J_{RhP}$ = 158 Hz). − $^{13}C\{^1H\}$ NMR (500 MHz, CD_2Cl_2): δ = 93.2 (s, C−SO_3), 106.4 (s, pyrazolyl C^4), 127.9 (d, $^2J_{PC}$ = 10 Hz, PPh_3 C^2), 129.9 (br. s, PPh_3 C^4), 130.5 (d, $^1J_{PC}$ = 3 Hz, PPh_3 C^1), 133.7 (d, $^3J_{PC}$ = 12 Hz, PPh_3 C^3), 134.7 (s, pyrazolyl C^5), 143.3 (s, pyrazolyl C^3), 187.3 (dd, $^1J_{RhC}$ = 74 Hz, $^2J_{PC}$ = 23 Hz, CO). − IR (KBr):

$\tilde{\nu}$ = 3168 cm^{-1}, 3154, 3134, 3124 (s, C−H), 1989 (vs, C=O), 1627 (s, C−C C_6H_5), 1520 (s, C=C), 1438 (s, P−C), 1479, 1438, 1405 (s, C−C C_6H_5), 1081, 1070, 1056, 1040 (s, S=O). − MS (FAB$^+$): *m/z* (%) = 686 (0.5) $[M]^+$, 658 (1.3) $[M - CO]^+$. − $(C_{29}H_{24}N_6O_4PRhS)_4(C_4H_8O)_3$ (2962.3): calcd. C 51.90, H 4.08, N 11.35; found C 51.98, H 4.12, N 11.22.

Carbonyl(trimethylphosphane)[tris(pyrazol-1-yl)methanesulfonato]rhodium(I), TpmsRh(CO)PMe$_3$ (5b): A 1 M THF solution of trimethylphosphane (0.1 mL, 0.1 mmol) was slowly added to a solution of **2a** (45 mg, 0.10 mmol) in THF (50 mL). After 1 h, the solution was concentrated to a volume of 4 mL and overlaid with pentane. Crystallization yielded 56 mg (100%) of a THF adduct of **5b** as bright-yellow needles. − ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 1.48 [dd, $^3J_{RhH}$ = 10.3 Hz, $^2J_{PH}$ = 1.5 Hz, 9 H, $P(CH_3)_3$], 6.56 (dd, $^3J_{HH}$ = 2.9 Hz, $^3J_{HH}$ = 0.9 Hz, 3 H, pyrazolyl 4-H), 7.76 (d, $^3J_{HH}$ = 2.9 Hz, 3 H, pyrazolyl 3-H), 8.45 (br. s, 3 H, pyrazolyl 5-H). − ^{31}P{^{1}H} NMR (200 MHz, CD_2Cl_2): δ = 3 (d, $^1J_{RhP}$ = 148 Hz). − ^{13}C{^{1}H} (500 MHz, [D$_8$]THF): δ = 17.4 [d, $^1J_{PC}$ = 36.3 Hz, $P(CH_3)_3$], 107.2 (s, pyrazolyl C^4), 136.6 (s, pyrazolyl C^5), 144.0 (s, pyrazolyl C^3). − IR (KBr): $\tilde{\nu}$ = 3164 cm^{-1}, 3132 (s, C−H), 1990 (vs, C=O), 1519 (s, C=C), 1438 (s, P−C), 1081, 1068, 1057, 1044 (s, S=O). − MS (EI, 200 °C): *m/z* (%) = 500 (21.5) $[M]^+$, 472 (6.5) $[M - CO]^+$, 392 (19.9) $[M - CO - SO_3]^+$. − $(C_{14}H_{18}N_6O_4PRhS)\cdot(C_4H_8O)$ (560.4): calcd. C 37.77, H 4.58, N 14.68; found C 37.39, H 4.80, N 14.49.

Carbonyl(tricyclohexylphosphane)[tris(pyrazol-1-yl)methanesulfonato]rhodium(I), TpmsRh(CO)PCy$_3$ (5c): Tricyclohexylphosphane (0.14 g, 0.5 mmol) was added to solution of **2a** (45 mg, 0.10 mmol) in THF (50 mL). After 1 h, the solution was concentrated to a volume of 5 mL and overlaid with pentane. Crystallization yielded a bright-yellow THF adduct of **5c** (58 mg, 80%). − ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 1−2 [m, 33 H, $P(C_6H_{11})_3$], 6.54 (dd, $^3J_{HH}$ = 2.8 Hz, $^3J_{HH}$ = 0.7 Hz, 3 H, pyrazolyl 4-H), 7.78 (br. s, 3 H, pyrazolyl 3-H), 8.46 (br. s, 3 H, pyrazolyl 5-H). − ^{31}P{^{1}H} NMR (200 MHz, CD_2Cl_2): δ = 52 (d, $^1J_{RhP}$ = 153 Hz).[26] − IR (KBr): $\tilde{\nu}$ = 3168 cm^{-1} (vs, C−H), 2851, 2929 (vs, C−H), 1978 (vs,

Crystal Structure Analyses: For all compounds **2a**, **3**, **4**, and **5a**, data were collected with a SMART 1K CCD area detector from Bruker AXS GmbH using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Unless stated otherwise, data were collected at 173 K (Table 9). For protection against oxygen or moisture, single crystals were handled in a perfluoroalkyl ether from ABCR GmbH & Co KG (viscosity 1600 cSt). The unit cell was determined with the program SMART.[27] For data integration and refinement of the unit cell, the program SAINT[27] was used. The space group was determined using the programs XPREP[27] or ABSEN[28] and an empirical absorption correction was made using SADABS.[27] The structures were solved by direct methods using the programs SHELX-97[29] or SIR-97[30] and were refined by least-squares methods based on F^2 using SHELX-97.[29] Graphical representations of the molecular structures were generated using the program ZORTEP.[31] − The positions of disordered or non-refinable solvent molecules were calculated using the PLATON[32]-integrated SQUEEZE[33] procedure and the corresponding electron density was subtracted before the final refinement. − All non-hydrogen atoms were fully refined in the calculated positions; when possible, the hydrogen atoms were located from the electron density difference map and refined freely in both their positions and their thermal parameters. If a localization was not possible, the hydrogen atoms were positioned as a riding model on their neighbouring atoms and were refined depending on the positions of the latter. The figure in parentheses after each calculated value represents the standard deviation in units of the last significant digit. − Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-151585−151588. Generating a New Chiral Ligand System for High-Valent Early Transition Metals — Synthesis and Structural Characterization of C_3-Symmetrical Tripodal Alkyl/Silyl Amido Complexes

Patrick Renner,[a] Christian H. Galka,[a] Lutz H. Gade,*[a] Sanja Radojevic,[b] and Mary McPartlin[b]

Dedicated to Professor Max Herberhold on the occasion of his 65th birthday

Keywords: Lithium / Amides / Chirality / Tripodal ligands / Zirconium

The novel C_3-chiral tripodal amine HC{SiMe$_2$NH[(*S*)-3,3-dimethyl-2-butyl]}$_3$ (**1**) and its trilithium triamido derivative [HC{SiMe$_2$N(Li)[(*S*)-3,3-dimethyl-2-butyl]}$_3$] (**2**) have been synthesized and characterized by X-ray diffraction. The lithium reagent was used for the synthesis of a C_3-chiral amidozirconium complex [HC{SiMe$_2$N[(*S*)-3,3-dimethyl-2-butyl]}$_3$ZrCl] (**3**); the preparation of the analogous titanium compound was precluded by the redox activity of the metal. Instead, the lithium amide-lithium chloride adduct [HC{SiMe$_2$N(Li)[(*S*)-3,3-dimethyl-2-butyl]}$_3$LiCl(Et$_2$O)$_3$] (**4**) was isolated from these reactions and structurally characterized by X-ray structure analysis. In this cage compound the chloride ion bridges the three amido lithium atoms and is itself coordinated to an {(Et$_2$O)$_3$Li}$^+$ fragment. Its isolation sheds new light upon the complex reaction sequences leading to halide substitution by a polydentate amido ligand.

Introduction

Ligand design in early transition metal chemistry has, to a large extent, focussed on amides during the past decade.[1−4] It is the realization that the amido donor function R$_2$N$^-$ may be placed into a great variety of structural environments which has driven this development. It may be readily incorporated into complex polydentate ligand systems of podand or macrocyclic topology.[3] The synthesis of the ligands normally proceeds via the (secondary) amines, which can then be deprotonated and coordinated to transition metals.

We have developed a series of tripodal amido ligands which derive from such amine precursors.[5−7] Their synthesis is based either on the derivatization of a primary triamine containing the ligand backbone or the condensation of a suitably activated backbone unit with primary amines. The latter strategy has been applied in the preparation of triamido ligands derived from trisilylmethane (**A**) or trisilylsilane (**B**). An important point in this approach is the great variety of peripheral substituents at the N-functions which may be introduced in what is essentially a one-step synthesis. In this paper we report a novel tripodal ligand containing a trisilylmethane skeleton in which the peripheral substituents are chiral. The tridentate ligand therefore possesses C_3-chirality, and will be applied in the coordination chemistry of the early transition metals.

A **B**

In spite of the burgeoning interest in C_3-chiral reagents and molecules,[8−11] by far the majority of the known systems are late transition metal compounds. The coordination of high-valent early transition metals requires highly charged ligands with strong σ- and π-donor functions such as alkoxides and amides in which chirality may either be introduced in the backbone structure or the peripheral substituents. While the former strategy has been pursued by Nugent, Knochel and Moberg,[12] we report an amido system in which the chiral centre is in the α-position of the peripheral substituent and thus close to a potential reactive site.[13]

Results and Discussion

Synthesis and Crystal Structures of HC{SiMe$_2$NH[(*S*)-3,3-dimethyl-2-butyl]}$_3$ (1) and Its Trilithium Triamido Derivative [HC{SiMe$_2$N(Li)[(*S*)-3,3-dimethyl-2-butyl]}$_3$] (2)

Reaction of the previously characterized trisilylmethane derivative HC(SiMe$_2$Br)$_3$ [6,14] with three molar equivalents

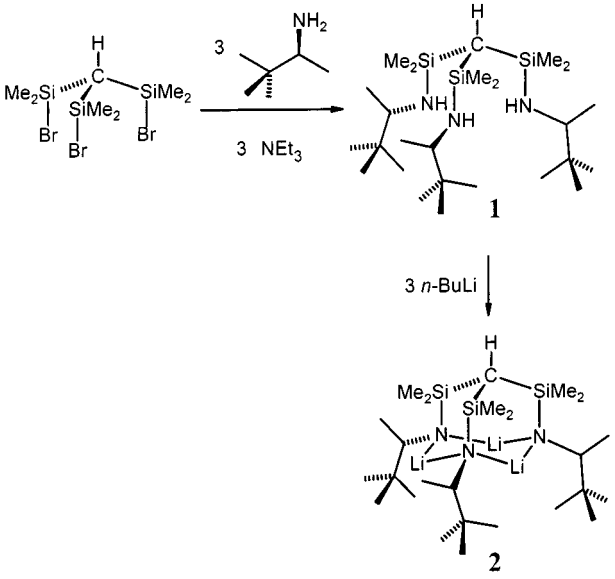
of (*S*)-3,3-dimethyl-2-butylamine in the presence of an excess of triethylamine as auxiliary base, after work up, cleanly gave the corresponding triamine HC{$SiMe_2NH$[(*S*)-3,3-dimethyl-2-butyl]}$_3$ (**1**) in good yield (Scheme 1). In a subsequent reaction step, the amine was converted into the corresponding trilithium triamide [HC{$SiMe_2N(Li)$[(*S*)-3,3-dimethyl-2-butyl]}$_3$] (**2**) by reaction with three equivalents of *n*BuLi.



Scheme 2. Synthesis of the triamine **1** and its lithiation giving **2**

The ^1H, ^{13}C and ^{29}Si NMR spectra of both compounds **1** and **2** are consistent with a threefold molecular symmetry on the time scale of the experiment. The ^1H NMR spectroscopic shifts of the apical CH protons in the trisilylmethane backbone are characteristically at high field. They are observed at $\delta = -0.81$ for the amine and at $\delta = -0.75$ in the spectrum of **2** recorded in C_6D_6. As a consequence of the chiral ligand periphery, the methyl groups of the $SiMe_2$ units are diastereotopic and are observed at $\delta = 0.27$ and 0.32 for **1** and slightly shifted to $\delta = 0.34$ and 0.38 for the lithiated derivative. In contrast to alkylamino derivatives of trisilylmethane which we studied previously,[6] the triamine **1** is stable in solution and no dissociation of a molecule of the chiral primary amine is observed even upon heating a sample to 70 °C.

It was possible to obtain single crystals of both compounds and thus establish their detailed molecular structure by an X-ray diffraction study. Both compounds **1** and **2** crystallize in the space group $P2_12_12_1$. The molecular structures of **1** and **2** are depicted in Figure 1 and 2, respectively, along with the principal bond lengths and angles. In both compounds the tripodal ligand adopts a "claw-like" arrangement which is part of an adamantane-related cage structure. In the amine **1** the base of this adamantane-related cage is formed by the three NH groups and, in contrast to the infrared data, the structure shows little evidence of intramolecular hydrogen bonding, with the N−H···N distances being in the range of 2.703−2.883 Å. This orientation of the ligand arms is in stark contrast to the "inverted" structural arrangement found for a range of aryl-substituted triamines of this type,[13a] but similar to the structure of the previously characterized chiral triamine HC{$SiMe_2NH$[(*S*)-1-phenylethyl]}$_3$.[13a] The positions of the NH hydrogen atoms in **1** were determined directly in difference Fourier maps, with the average N−H distance being 0.89 Å.

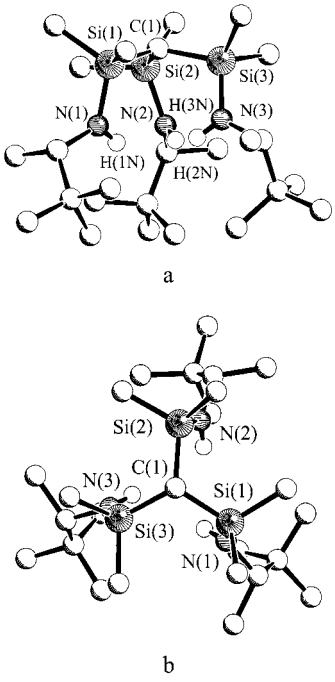


Figure 1. View of the molecular structure of **1** perpendicular (a) and along (b) the molecular axis of the tripod cage; the principal bond lengths (Å) and angles (°): C(1)−Si(1) 1.894(6), C(1)−Si(2) 1.874(6), C(1)−Si(3) 1.891(6), Si(1)−N(1) 1.720(5), Si(1)−C(2) 1.883(6), Si(1)−C(3) 1.884(6), N(1)−C(11) 1.472(7); Si(1)−C(1)−Si(3) 114.4(3), Si(1)−C(1)−Si(2) 114.7(3), Si(2)−C(1)−Si(3) 115.3(3), N(1)−Si(1)−C(1) 107.3(3), C(11)−N(1)−Si(1) 123.8(4), C(12)−C(11)−N(1) 110.0(5), C(13)−C(11)−N(1) 113.1(6)

The structural centrepiece of compound **2** is a heteroadamantane cage consisting of a puckered basal $(LiN)_3$ ring capped by the trisilylmethane unit. The Li−N−Li′−N′ torsion angles in the basal unit lie between 57.3(4) and 59.7(4)°, while the Li−N distances of between 1.890(6) and 1.983(6) Å are similar to those found in other cyclic lithium amides.[15] The lithium atoms are two coordinate [N−Li−N′ angles range between 124.2(3) and 127.8(3)°] although short Li····H−C contacts of between 2.04 and 2.17 Å with the isolated methyl groups of the $CH(CH_3)t$Bu units indicate "internal solvation" by the ligand periphery. Several cases of such interactions of low-coordinate lithium atoms and hydrocarbon units have previously been reported.[16]

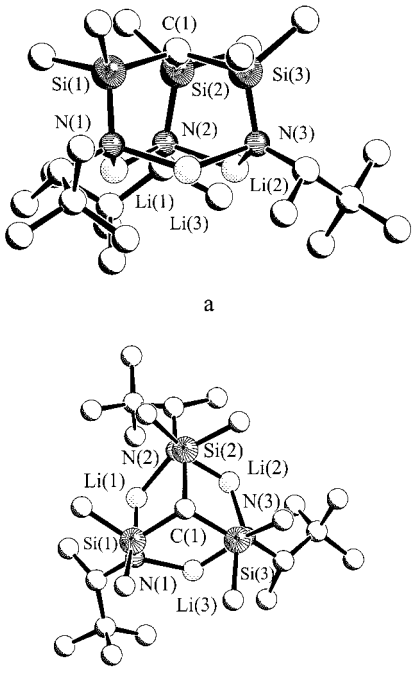

Figure 2. View of the molecular structure of **2** perpendicular (a) and along (b) the molecular axis of the metal-tripod cage; the principal bond lengths (Å) and angles (°): C(1)−Si(1) 1.899(3), C(1)−Si(2) 1.895(3), C(1)−Si(3) 1.904(3), Si(1)−N(1) 1.721(2), N(1)−Li(1) 1.968(6), N(1)−Li(3) 1.890(6), N(1)−C(10) 1.472(4); Si(1)−C(1)−Si(3) 114.36(15), Si(1)−C(1)−Si(2) 114.67(15), Si(2)−C(1)−Si(3) 113.82(14), N(1)−Si(1)−C(1) 107.51(12), N(1)−Li(1)−N(2) 127.8(3), Li(1)−N(1)−Li(3) 93.6(3), Si(1)−N(1)−Li(1) 95.5(2), C(10)−N(1)−Li(1) 107.6(2), Si(1)−N(1)−Li(3) 112.1(2)

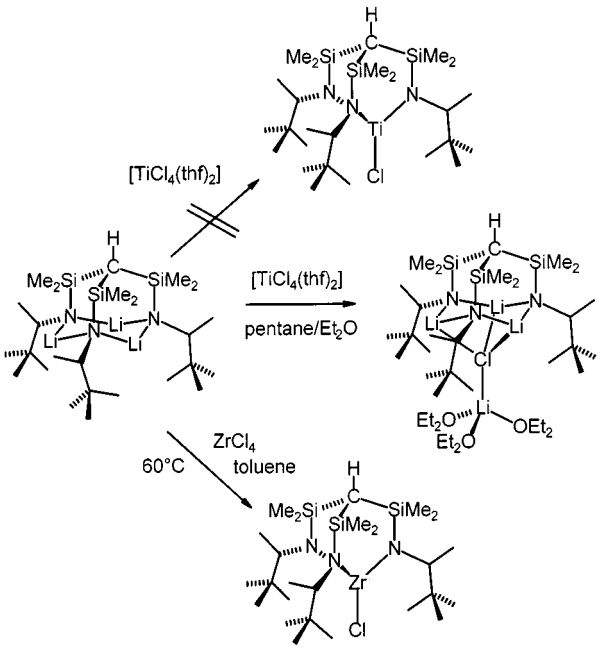

Scheme 2. Reaction of **2** with $[TiCl_4(THF)_2]$ and $ZrCl_4$

Synthesis of a C_3-Chiral Amidozirconium Complex and Isolation and Structural Characterization of the Lithium Amide−Lithium Chloride Adduct $[HC\{SiMe_2N(Li)[(S)\text{-}3,3\text{-dimethyl-2-butyl}]\}_3LiCl(Et_2O)_3]$ (4)

Complexation of the chiral amido tripod was first attempted by reaction of **2** with $[TiCl_4(THF)_2]$ (Scheme 2). However, even after stirring for four days in diethyl ether at ambient temperature, no titanium complex could be identified in the reaction mixture or isolated from it. This is surprising since the related C_3-chiral titanium complexes $[HC\{SiMe_2N[(S)\text{-1-phenylethyl}]\}_3TiCl]$ and $[HC\{SiMe_2N[(S)\text{-1-indanyl}]\}_3TiCl]$ were readily obtained.[17] The lack of reactivity may be due to the sterically crowed peripheral substituents in **2**. Attempts to induce complexation by heating the reaction mixture failed due to the redox activity of the titanium compound under these conditions. Immediate darkening of the solutions and the observation of paramagnetic species in the NMR spectra indicated reduction to Ti^{III}. However, none of these paramagnetic components could be isolated and further characterized.

Analogous to the reaction with $[TiCl_4(THF)_2]$ in diethyl ether, stirring of **2** with $ZrCl_4$ at room temperature did not give the corresponding zirconium complex. However, the synthesis of $[HC\{SiMe_2N[(S)\text{-3,3-dimethyl-2-butyl}]\}_3ZrCl]$ (**3**) was achieved by heating the starting materials in toluene at 60 °C for 1 hour (Scheme 2). The colourless compound was obtained as a microcrystalline solid after work up and its formulation established by elemental analysis. The NMR spectra recorded in solution are consistent with the threefold molecular symmetry of complex **3**. The apical C−H proton of the tripod is observed at $\delta = -0.48$ and the diastereotopic $SiMe_2$ methyl groups resonate at $\delta = 0.28$ and 0.39. A single resonance at $\delta = 1.1$ in the ^{29}Si NMR spectrum confirms the equivalence of all three "claws" in the tripod.

Whereas the titanium complex proved not to be isolable from the reaction mixtures of **2** with $[TiCl_4(THF)_2]$, a colourless highly crystalline solid precipitated from the solutions. While the quantities of this component varied, it was reproducibly obtained from these reactions. While the ^1H, ^{13}C and ^{29}Si NMR spectra were almost identical to those of **2**, the proton NMR spectrum displayed the signals of coordinated diethyl ether and two resonances at $\delta = 0.8$ and −2.9 were observed in the ^7Li NMR spectrum, indicating a second Li environment. Its identity was established by a single crystal X-ray structure analysis. The molecular structure is depicted in Figure 3 along with the principal bond lengths and angles.

The colourless product isolated from the reaction of **2** with $[TiCl_4(THF)_2]$ was found to be the LiCl adduct $[HC\{SiMe_2N(Li)[(S)\text{-3,3-dimethyl-2-butyl}]\}_3LiCl(Et_2O)_3]$ (**4**), the chloride deriving from the Ti complex. Compound **4** crystallizes in the polar trigonal space group *R*3 with two independent molecules in the asymmetric unit, each molecule aligned along a threefold crystallographic axis. The two molecules have virtually identical structures which are illustrated in Figure 3 by the first molecule. Chemically equivalent metric parameters are equal within experimental error

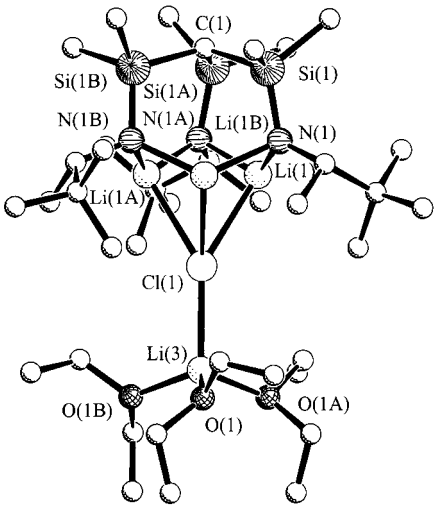

Figure 3. View of the molecular structure of **4** perpendicular to the molecular axis of the metal-tripod cage; the principal bond lengths (Å) and angles (°) (mean values): C(1)−Si(1) 1.887, Si(1)−N(1) 1.708, N(1)−Li(1) 1.990, N(1)−Li(1B) 1.993, Cl(1)−Li(1) 2.586, Cl(1)−Li(3) 2.396, Li(3)−O(1) 1.985; Si(1)−C(1)−Si(1A) 114.1, N(1)−Si(1)−C(1) 109.0, N(1)−Li(1)−N(1A) 122.2, Li(1)−N(1)−Li(1B) 82.0, O(1)−Li(3)−Cl(1) 107.9, Li(3)−Cl(1)−Li(1) 144.3, Cl(1)−Li(1)−N(1) 100.9, Li(1)−Cl(1)−Li(1A) 60.8

for the two molecules, and the mean values of selected bonds lengths and angles are given in the Caption to Figure 3. The chloride ion bridges the three amido lithium atoms and is itself coordinated to a $\{(Et_2O)_3Li\}^+$ fragment. The coordination environment of the anion is trigonally elongated along the molecular axis, probably in part because of the steric repulsion between the 3,3-dimethyl-2-butyl substituents and the Li-coordinated diethyl ether molecules. There are several examples in the literature of compounds in which a chloride ion connects four lithium centres in a fashion similar to that shown in Figure 3. Evans and co-workers reported the crystal structures of the yttrium complexes $[(Me_3SiCH_2)_x(Me_3CO)_{1-x}Y(\mu\text{-}OCMe_3)_4\{Li(THF)\}_4(\mu_4\text{-}Cl)]$ ($x = 0, 1$) in which the lithium atoms and the μ_4-chloride form pyramidal subunits,[18] while Floriani et al. reported $[MnCl(dag)_4Li_4(\mu_4\text{-}Cl)]$ (dag = mono anion of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose) with the same Li_4Cl unit.[19] A Li_4Cl unit, which is highly distorted with respect to the idealized trigonal symmetry, was found by Deacon and White in the structure of $[\{Li(L^1)Li(\mu_4\text{-}Cl)Li(L^1)(THF)_2]$ (HL^1 = *N*,*N*-dimethyl-*N*′-trimethylsilylethane-1,2-diamine).[20]

The isolation of the LiCl adduct of **2** sheds some light upon the possible mechanism of the ligand substitution reactions involving lithium amides. Rather than direct nucleophilic attack by the amide upon a metal centre, the lithium ions play the role of a Lewis-acidic chloride acceptor. This notion of the active alkali metal ion is supported by the well established variations in reactivity upon going from lithium amides to their heavier congeners.

Conclusion

In this paper we have reported the synthesis of a novel C_3-chiral amido ligand, the structural chemistry of its amine precursor and lithiated derivative. While the preparation of a chiral triamidotitanium complex was not achieved due to competing single electron transfer, its zirconium homologue $[HC\{SiMe_2N[(S)\text{-}3,3\text{-dimethyl-2-butyl}]\}_3ZrCl]$ (**3**) was obtained in a straightforward way. This compound probably marks an extreme of steric congestion in the ligand periphery attainable in this class of compounds and current and future studies aim to exploit this structural feature. The isolation of the LiCl adduct of the chiral tripodal lithium amide has shed some light upon the possible primary steps in the mechanism of halide substitution in the synthesis of polydentate amido complexes.

Experimental Section

All manipulations were performed under an inert gas atmosphere of dried argon in standard (Schlenk) glassware which was flame dried with a bunsen burner prior to use. Solvents were dried according to standard procedures and saturated with Ar. The deuterated solvents used for the NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried over 4Å molecular sieves.

The ^1H, ^{13}C, ^{29}Si and ^7Li NMR spectra were recorded on a Bruker AC 200 spectrometer equipped with a B-VT-2000 variable temperature unit (at 77.77 MHz) or on a Bruker AMX 400 spectrometer (at 400.13, 100.61 and 79.50 MHz, respectively) with tetramethylsilane or LiI/H_2O (1 M) as reference. The IR spectra were recorded on a Bruker IFS 25 FT-IR spectrometer.

Elemental analyses were carried out in the microanalytical laboratory of the chemistry department at Würzburg. The ligand pre cursor $HC(SiMe_2Br)_3$ was prepared as reported in the literature.[6,14]

Preparation of $HC\{SiMe_2NH[(S)\text{-}3,3\text{-dimethyl-2-butyl}]\}_3$ (1): To a stirred solution of (*S*)-3,3-dimethyl-2-butylamine (3.80 mL, 28.1 mmol) and NEt_3 (4.20 mL, 30.3 mmol) in diethyl ether (30 mL) was added $HC(SiMe_2Br)_3$ (4.00 g, 9.36 mmol) in diethyl ether (20 mL) at 0 °C. After stirring for 14 h at room temperature the ammonium salt formed during the reaction was removed by centrifugation and was washed three times with diethyl ether (ca. 20 mL). The solvent and the unreacted NEt_3 were removed under reduced pressure and the resulting yellow oil was redissolved in diethyl ether (ca. 10 mL) and stored at 4 °C. Compound **1** was obtained as a colourless, highly crystalline solid (yield: 3.87 g, 85%). − M.p.: 110 °C. − ^1H NMR (400.13 MHz, C_6D_6, 295 K): δ = −0.81 [s, 1 H, *H*C(Si...)$_3$], 0.27, 0.32 [2 × s, 2 × 9 H, Si(C*H*$_3$)$_2$], 0.93 [s, 27 H, C(C*H*$_3$)$_3$], 0.99 [d, $^3J_{HCNH}$ = 12.7 Hz, 3 H, N*H*), 1.09 (d, $^3J_{HH}$ = 6.9 Hz, 9 H, HCC*H*$_3$), 2.48 (dq, $^3J_{HCNH}$ = 12.7 Hz, $^3J_{HH}$ = 6.9 Hz, 3 H, *H*CCH$_3$). − $^{13}C\{^1H\}$ NMR (100.61 MHz, C_6D_6, 295 K): δ = 3.9, 4.4 [Si(*C*H$_3$)$_2$], 5.5 [H*C*(Si...)$_3$], 20.6 (HC*C*H$_3$), 27.0 [C(*C*H$_3$)$_3$], 35.4 [*C*(CH$_3$)$_3$], 56.6 (H*C*CH$_3$). − $^{29}Si\{^1H\}$ NMR (79.50 MHz, C_6D_6, 295 K): δ = 0.9. − IR (benzene): $\tilde{\nu}$ = 3355 (s), 2964 (vs), 2903 (s), 2869 (s), 1477 (w), 1412 (m), 1400 (m), 1369 (m), 1362 (w), 1252 (vs), 1122 (vs), 1011 (s), 956 (s), 870 (s), 826 (s), 812 (vs), 668 (m) cm^{-1}. − $C_{25}H_{61}N_3Si_3$ (488.04): calcd. C 61.53, H 12.60, N 8.61; found C 60.65, H 11.88, N 8.40.

Preparation of [HC{SiMe$_2$N(Li)[(*S*)-3,3-dimethyl-2-butyl]}$_3$] (2): To a stirred solution of **1** (3.39 g, 6.95 mmol) in *n*-pentane (30 mL) at −78 °C was added a 2.5 M solution of *n*BuLi in *n*-hexane (8.34 mL, 20.86 mmol). After stirring for 14 h at room temperature the yellow solution was concentrated to ca. 7 mL. Storage of the solution at 4 °C yielded colourless crystals of **2** (yield: 3.32 g, 94%). − M.p.: 172 °C. − ^{1}H NMR (400.13 MHz, C_6D_6, 295 K): δ = −0.75 [s, 1 H, *H*C(Si...)$_3$], 0.34, 0.38 [2 × s, 2 × 9 H, Si(C*H*$_3$)$_2$], 0.76 [s, 27 H, C(C*H*$_3$)$_3$], 0.95 (d, $^3J_{HH}$ = 6.2 Hz, 9 H, HCC*H*$_3$), 2.82 (q, $^3J_{HH}$ = 6.2 Hz, 3 H, *H*CCH$_3$). − ^{13}C{^{1}H} NMR (100.61 MHz, C_6D_6, 295 K): δ = 6.1, 7.1 [Si(*C*H$_3$)$_2$], 12.1 [H*C*(Si...)$_3$], 24.5 (HC*C*H$_3$), 27.7 [C(*C*H$_3$)$_3$], 36.0 [s, *C*(CH$_3$)$_3$], 60.5 (H*C*CH$_3$). − ^{29}Si{^{1}H} NMR (79.50 MHz, C_6D_6, 295 K): δ = −1.8. − ^{7}Li{^{1}H} NMR (77.77 MHz, C_6D_6, 295 K): δ = 0.7. $C_{25}H_{58}Li_3N_3Si_3$ (505.84): calcd. C 59.36, H 11.56, N 8.31; found C 58.82, H 11.16, N 7.94.

Preparation of [HC{SiMe$_2$N[(*S*)-3,3-dimethyl-2-butyl]}$_3$ZrCl] (3): To a stirred solution of **2** (0.35 g, 0.70 mmol) in toluene (5 mL) was added solid $ZrCl_4$ (0.38 mg, 1.60 mmol). After treatment in an ultrasonic bath for 24 h at 60 °C the precipitate of LiCl and unreacted $ZrCl_4$ was separated by centrifugation. Storage of the filtrate at −30 °C yielded the zirconium complex **3** as an off-white microcrystalline solid (yield: 0.14 g, 34%). − ^{1}H NMR (400.13 MHz, [D$_8$]toluene, 295 K): δ = −0.48 [s, 1 H, *H*C(Si...)$_3$], 0.28, 0.39 [2 × s, 2 × 9 H, Si(C*H*$_3$)$_2$], 1.03 [s, 27 H, C(C*H*$_3$)$_3$], 1.45 (d, 9 H, $^3J_{HH}$ = 6.2 Hz, HCC*H*$_3$), 2.88 (m, 3 H, *H*CCH$_3$). − ^{13}C{^{1}H} NMR (100.61 MHz, [D$_8$]toluene, 295 K): δ = 1.5 [H*C*(Si...)$_3$], 5.7, 5.9 [Si(*C*H$_3$)$_2$], 27.5 (HC*C*H$_3$), 27.8 [C(*C*H$_3$)$_3$], 36.4 [s, *C*(CH$_3$)$_3$], 62.5 (H*C*CH$_3$). − ^{29}Si{^{1}H} NMR (79.50 MHz, [D$_8$]toluene, 29: δ = 1.1. − IR (toluene): $\tilde{\nu}$ = 2960 (vs), 2964 (vs), 2871 (s), 1477 (s), 1458 (s), 1254 (vs), 1104 (vs), 1082 (vs), 1011 (m), 951 (vs), 868 (vs), 840 (vs), 815 (vs), 678 (w) cm^{-1}. − $C_{25}H_{58}ClN_3Si_3Zr$ (611.69): calcd. C 49.09, H 9.56, N 6.87; found C 48.66, H 9.45, N 6.99.

Preparation of [HC{SiMe$_2$N(Li)[(*S*)-3,3-dimethyl-2-butyl]}$_3$-LiCl(Et$_2$O)$_3$] (4): To a stirred solution of **2** (0.50 g, 0.99 mmol) in diethyl ether (10 mL) at −20 °C was added [$TiCl_4$(THF)$_2$] (0.33 g, 0.99 mmol). After stirring for four days at room temperature the precipitate was separated by centrifugation. Storage of the dark brown solution at 4 °C yielded colourless crystals of **4** (yield: 0.19 g, 24%). The yield obtained in several runs of this reaction varied between ca. 10% and 30%. Due to facile loss of diethyl ether it was not possible to obtain a correct elemental analysis. − M.p.: 31 °C (dec.). − ^{1}H NMR (400.13 MHz, [D$_8$]toluene, 295 K): δ = −0.75 [s, 1 H, *H*C(Si...)$_3$], 0.32, 0.37 [2 × s, 2 × 9 H, Si(C*H*$_3$)$_2$], 0.77 [s, 27 H, C(C*H*$_3$)$_3$], 0.96 (d, 9 H, $^3J_{HH}$ = 6.2 Hz, HCC*H*$_3$), 1.12 (t, Et$_2$O), 2.82 (q, 3 H, $^3J_{HH}$ = 6.2 Hz, *H*CCH$_3$), 3.28 (q, Et$_2$O). − ^{13}C{^{1}H} NMR (100.61 MHz, [D$_8$]toluene, 295 K): δ = 6.0, 7.0 [Si(*C*H$_3$)$_2$], 12.1 [H*C*(Si...)$_3$], 15.5 (Et$_2$O), 24.5 (HC*C*H$_3$), 27.7 [C(*C*H$_3$)$_3$], 36.0 [s, *C*(CH$_3$)$_3$], 60.6 (H*C*CH$_3$), 65.8 (Et$_2$O). − ^{29}Si{^{1}H} NMR (79.50 MHz, [D$_8$]toluene, 295 K): δ = −1.8. − ^{7}Li{^{1}H} NMR (77.77 MHz, [D$_8$]toluene, 295 K): δ = −2.9, 0.8.

and **4** were collected using an Enraf−Nonius CAD4 diffractometer at a temperature of 193(2) K with oil-coated shock-cooled crystals[21] mounted on the top of a glass pin under nitrogen. Crystal data and experimental details for the crystals of **1**, **2** and **4** are given in Table 1. All data for the structures **2** and **4** were corrected for absorption using Ψ-scans. No absorption correction was applied for structure **1**. The structures were solved by direct methods (SHELXS-97) and refined on F^2 (SHELXL-97).[22]

In the case of **2** one methyl and one *tert*-butyl group of a ligand arm were found to be 50:50 disordered and refined with anisotropic displacement parameters. In the case of **4**, disorder of all coordinated diethyl ether molecules in a 75:25 ratio was found and refined with isotropic displacement parameters. No hydrogen atoms could be calculated for C5S′ of a disordered Et_2O molecule. In the final cycles of refinement all non-hydrogen atoms of **1**, **2** and **4** were assigned anisotropic displacement parameters. The amino hydrogen atoms of **1** were found in a final difference Fourier transformation analysis, all other hydrogen atoms were included in idealized positions riding on the parent atoms and were assigned isotropic displacement parameters of 1.2 U_{eq} (CH, CH_2) and 1.5 U_{eq} (CH_3) of the parent atom.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-156281 (**1**), -156282 (**2**) and -156283 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$CsPd_2Cl_5$ – A New Structural Type Containing $^1_\infty[(PdCl_{3/2}Cl)_2^-]$ Chains

Barbara Schüpp[a] and Hans-Lothar Keller*[a]

Keywords: Palladium / Chlorine / Crystal structure / Cesium / MAPLE

$CsPd_2Cl_5$ has been obtained by hydrothermal reaction of cesium chloride and palladium chloride in a 1:2 ratio in quartz glass ampoules at 150 °C. Its crystal structure has been determined by single-crystal X-ray diffraction analysis [*Pnma*, $Z = 4$, $a = 15.725(3)$ Å, $b = 10.526(2)$ Å, $c = 5.275(1)$ Å]. $CsPd_2Cl_5$ represents the first example of a new structural type made up of infinite $^1_\infty[(PdCl_{3/2}Cl)_2^-]$ chains, in which $PdCl_4$ units are connected through their edges as well as their vertices.

Introduction

Halopalladates(II) invariably contain monomeric square-planar $[PdX_4]^{2-}$ groups, although fluoropalladates(II), MPd_2F_5 (M = K, Rb, Cs),[1–2] possess both square-planar and octahedrally coordinated Pd^{II}. Recent experiments have led to the structural characterization of halopalladates(II) with connected groups. Thus, $CsPdCl_3$[3] contains dinuclear $[(PdCl_{2/2}Cl_2)_2]^{2-}$ groups formed by edge connection, whereas $Tl_4Pd_3Cl_{10}$[4] contains corner-sharing tetrameric $[(PdCl_{2/2}Cl_2)_4]^{4-}$ units. The first compound shown to contain edge-to-edge and corner links in a pentameric $[Pd_5Br_{14}]^{4-}$ unit has been the ternary thallium(I) bromopalladate $Tl_8Pd_7Br_{22}$.[5]

The system $CsCl/PdCl_2$ seemed to be sufficiently interesting for further experiments. Safonov and Mireev[6] described the existence of two compounds – Cs_2PdCl_4 and $CsPd_3Cl_7$ – on the basis of phase equilibria studies, although no structural information was given for $CsPd_3Cl_7$. A compound of this formula would be of interest as one would expect it to contain condensed units of the monomeric $PdCl_4$ group. The characterization of the $CsCl/PdCl_2$ system by Safonov and Mireev[6] was incomplete, as was first shown by the detection of Cs_3PdCl_5[7] with a higher proportion of cesium. The first compound to be found with a lower CsCl content, $CsPdCl_3$, involves dinuclear Pd_2Cl_6 units. We expected to observe continuing linkage of these dinuclear units with increasing Pd content. Experiments aimed at preparing $CsPd_3Cl_7$ have not yet been successful, but single crystals of $CsPd_2Cl_5$ have been obtained, the structural characterization of which is reported herein. The compound does not crystallize isotypically to cesium pentafluoropalladate(II), $CsPd_2F_5$, but instead forms a hitherto unknown structural type.

Results and Discussion

Crystal Structure

$CsPd_2Cl_5$ was prepared under hydrothermal conditions. In contrast to the fluoropalladate of the same formula type, it shows exclusively planar coordination at Pd^{II}.

Pd–Cl distances in $CsPd_2Cl_5$ range from 2.260 to 2.326 Å. The average distance of 2.298 Å corresponds to that found in mononuclear $PdCl_4$ groups. The exclusive presence of planar coordinated Pd^{II} necessitates linkage of these units in order to achieve the formula $CsPd_2Cl_5$. In the crystal structures of $CsPdCl_3$ and $PdCl_2$, the linked units are assembled through their edges. In view of the formula type, we expected the formation of tetrameric linear or angular chains $[Pd_4Cl_{10}]^{2-}$, but this could not be confirmed. The $[Pd_2Cl_5]^-$ part stems from $[Pd_2Cl_6]^{2-}$ units, which are connected through opposite vertices forming one-dimensional infinite chains (see Figure 1, a).

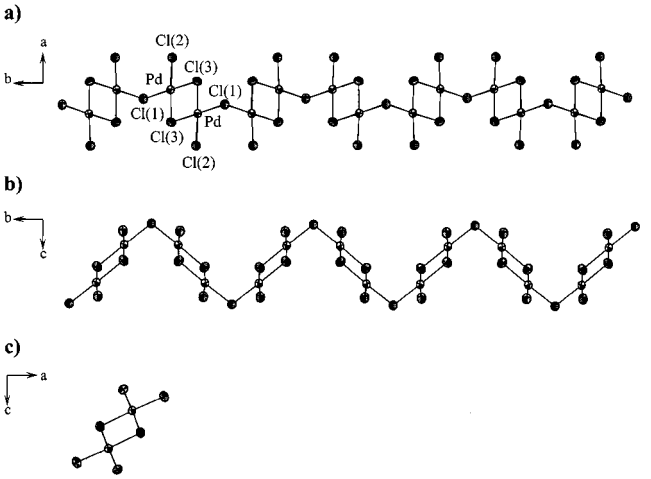

Figure 1. Part of the crystal structure of $CsPd_2Cl_5$; $^1_\infty[(PdCl_{3/2}Cl)_2^-]$ chain; (a) view along [001]; (b) view along [100]; (c) view along [010] (thermal ellipsoids are drawn at a 50% probability level)

The dinuclear Pd_2Cl_6 group is thus the basic unit, just as it is in $CsPdCl_3$. The angle Cl(3)–Pd–Cl(3) at the bridging edge is reduced [86.07(4)°] and is slightly smaller than the corresponding angle in $PdCl_2$.[8] Three crystallographic

atom positions for chlorine were found by X-ray analysis: Cl(3) are edge-bridging, Cl(2) are terminal chlorine atoms, and the infinite chains are built by corner-sharing Cl(1). Due to the symmetry, the corner-sharing atoms lie *trans* to one another. The terminal Cl(2) atoms show the shortest Pd−Cl distance and the $^1_\infty[(PdCl_{3/2}Cl)_2^-]$ chains are arranged in such a way that viewed along [100] (Figure 1, b) puckered infinite chains are observed. These are totally eclipsed in the view along [010] (Figure 1, c).

The Pd−Cl structural motif is reminiscent of the connection of Pd units in β-PdI_2,[9] where the dinuclear units build puckered layers. Figure 2 shows a section of the crystal structure of PdI_2. The substructure similar to the Pd−Cl unit in $CsPd_2Cl_5$ is marked. Comparison of these structural units indicates the different puckered sequence of the chains, even though they have almost the same Pd−X−Pd angle (see Figure 3).

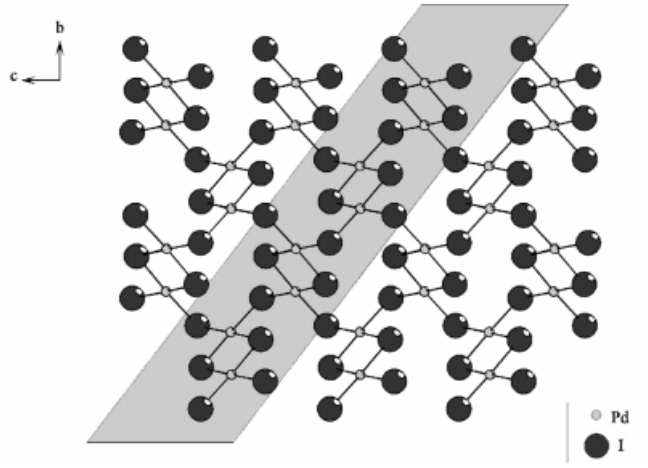

Figure 2. Part of the crystal structure of β-PdI_2

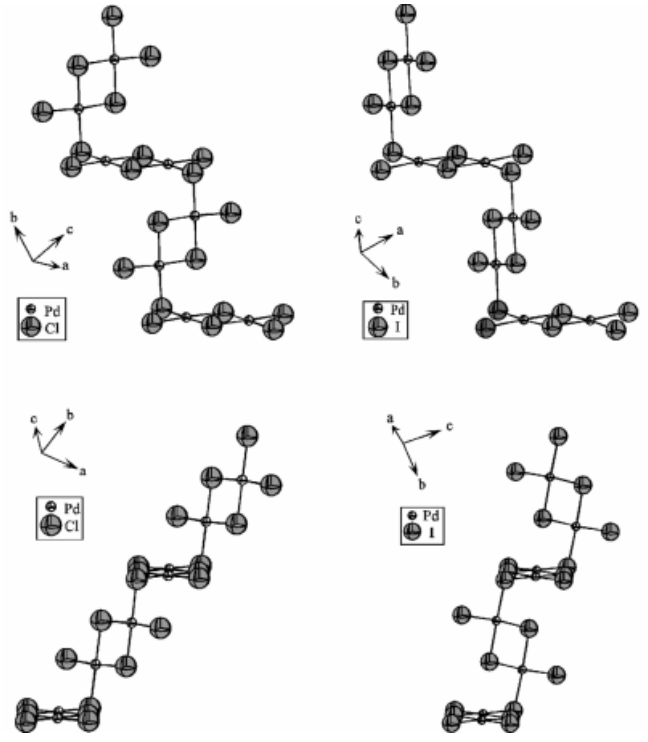

Figure 3. Comparison of a $^1_\infty[(PdCl_{3/2}Cl)_2^-]$ chain to part of the β-PdI_2 layer

The Pd−Cl motif is also reminiscent of the infinite chains in $PdCl_2$.[8] Opening these chains after every second palladium atom and adding a Cl atom leads to the $^1_\infty[(PdCl_{3/2}Cl)_2^-]$ chain found in $CsPd_2Cl_5$, as shown in Figure 1, a.

The arrangement in $CsPd_2Cl_5$ can be rationalized by considering the coordination spheres of the cesium cations. Each Cs is coordinated by nine chlorine atoms belonging to four different $^1_\infty[(PdCl_{3/2}Cl)_2^-]$ chains. We chose a distance of up to 3.85 Å as a first sphere for analysis of the Cs coordination by Cl. Four Cl atoms belong to the first chain, two pairs each come from two further chains, while the ninth Cl comes from the fourth chain. The relevant distances are shown in Table 1.

Table 1. Coordination of Cs by Cl

chain	atom	distance [Å]
1	Cl(2)	3.495(1) (2×)
	Cl(3)	3.722(1) (2×)
2	Cl(2)	3.507(1) (2×)
3	Cl(2)	3.537(1) (2×)
4	Cl(1)	3.818(2) (1×)

The average Cs−Cl distance of 3.593 Å falls within the expected range for Cs−Cl distances with CN 9 (3.519−3.738 Å, from a statistical analysis of ICSD data[10]). The polyhedra around Cs are mainly built-up from terminal chlorine atoms.

The bridging Cl atoms have a coordination number of 3, which is rather unusual. Cl(2) shows a more typical fourfold coordination. Selected distances and angles are collected in Table 2.

Table 2. Selected distances [Å] and angles [°] in $CsPd_2Cl_5$ (ORFFE[19])

Pd−Cl(2)	2.260(1)
Pd−Cl(1)	2.302(1)

Cl(1)−Pd−Cl(3)	178.73(5)
torsion angle Cl(1)−Cl(3)−Cl(3)−Cl(1)	180
torsion angle Cl(2)−Cl(3)−Cl(3)−Cl(2)	180

The $^1_\infty[(PdCl_{3/2}Cl)_2^-]$ chains are aligned along the crystallographic *b* axis. Their arrangement can be described as a distorted hexagonal packing of parallel rods separated only by cesium atoms (Figure 4).

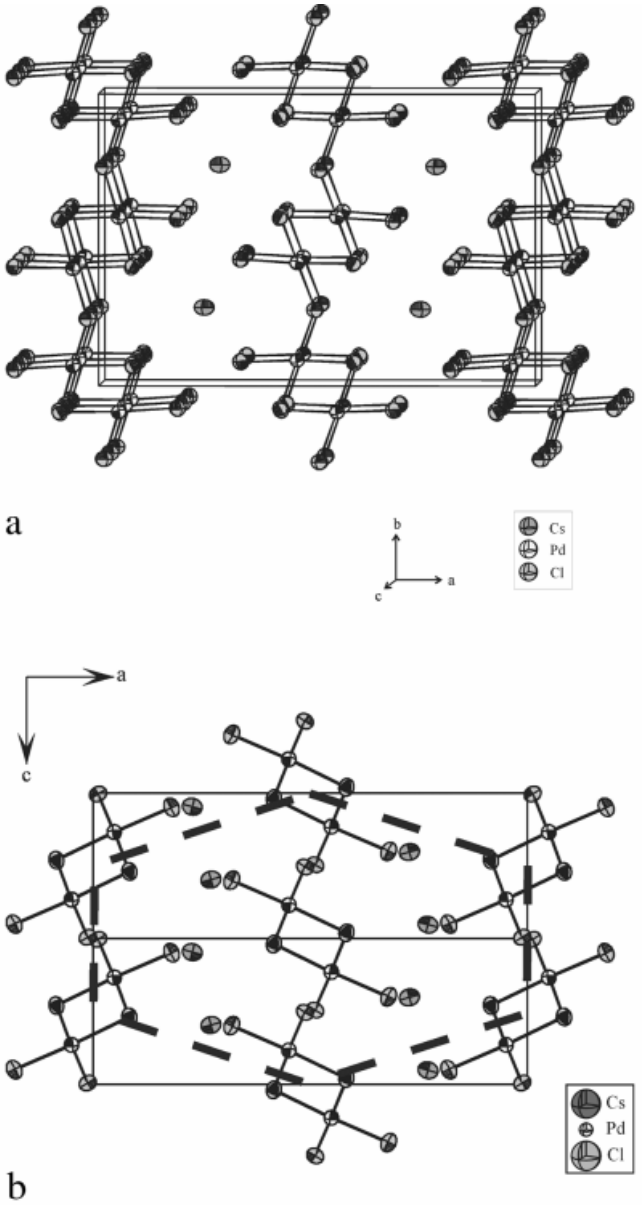

Figure 4. Part of the crystal structure of $CsPd_2Cl_5$; (a) unit cell; (b) hexagonal packing (thermal ellipsoids are drawn at a 50% probability level)

Comparison with Other Compounds of Formula Type AB_2X_5

Few compounds of the formula type AB_2X_5 have appeared in the literature, in which cations B^{2+} show planar coordination. $CsCu_2F_5$ [11] and fluoropalladates(II), MPd_2F_5 (M = K, Rb, Cs),[1,2] are known. $CsPd_2Cl_5$ is not isotypic with any of these.

MPd_2F_5 species, besides containing Pd(1) in square-planar coordination environment, also possess octahedrally coordinated Pd(2). The octahedra are connected through opposite corners forming infinite chains. The remaining fluorine atoms share corners with the planar PdF_4 units of Pd(2), thereby creating Pd–F layers. In contrast, $CsCu_2F_5$ has a complicated structure with CN = 4, 5, and 6 for Cu^{2+}. Consequently, $CsPd_2Cl_5$ represents the first example of a new structural type. Binary palladium halides are the only compounds to which the palladium–chlorine structural motif may be compared.

Calculation of Lattice Energy

The **MA**delung (coulombic) **P**art of **L**attice **E**nergy can be calculated using the program MAPLE.[12–14] Close correspondence between the calculated value and the sum $E_c(CsCl) + 2E_c(PdCl_2)$ lends support to the validity of our structure determination. The calculated Madelung Part of Lattice Energy of $CsPd_2Cl_5$ yields a value of 1358.55 kcal·mol^{-1}, as compared to the sum of 1347.11 kcal·mol^{-1}, a difference of just 0.85%. An analysis of the Madelung Part of Lattice Energy for the different chlorine positions proved interesting (Table 3). The highest MAPLE value was obtained for the corner-sharing Cl, whereas the lowest value was obtained for the terminal Cl. The obtained value was also lower than that for mononuclear $PdCl_4$ units, e.g. in Cs_2PdCl_4 (MAPLE $\approx$ 100–102 kcal·mol^{-1}). The edge-bridging Cl contributes 40% more to the overall lattice energy compared to the terminal ones. The value is also slightly increased compared to that in $PdCl_2$. The difference between the potentials of the corner-sharing and terminal Cl atoms is again increased (57%). The value for the corner-sharing atoms can only be compared with that for the tetrameric group $[(PdCl_{2/2}Cl_2)_4]^{4-}$ in $Tl_4Pd_3Cl_{10}$. The MAPLE value for the bridging atoms in $Tl_4Pd_3Cl_{10}$ amounts to 146 kcal·mol^{-1}, which is 10 kcal·mol^{-1} more than that for these atoms in $CsPd_2Cl_5$. A comparison of values for corner-sharing Cl atoms adjacent to edge-bridging ones is not

[a] Madelung constant: 9.2533; Madelung Part of Lattice Energy: 1358.5502 (2) kcal/mol, 5686.8924 (7) kJ/mol. – [b] Cl(1) corner-sharing, Cl(2) terminal, Cl(3) edge-bridging.

possible, because no chloropalladates with such structural characteristics have hitherto been isolated. The importance of the bridging Cl atoms in the adoption of the observed structural type is clearly highlighted by their increased potentials compared to those of the Cl atoms in CsCl, $PdCl_2$, and monomeric $PdCl_4$ units.

Conclusion

$CsPd_2Cl_5$ represents a new compound with a hitherto unknown structural type. Palladium is not coordinated octahedrally as it is in fluoropalladates of the same formula type. Instead, the planar $PdCl_4$ units build polynuclear infinite chains by sharing corners and edges. The bridging motif corresponds to the results of our experiments concerning higher cesium chloropalladates(II). Besides $CsPdCl_3$, we have been able to prepare two further compounds based on dinuclear Pd_2Cl_6 units. We propose following nomenclature for chloropalladates:

Cs_3PdCl_5 [7] = $(Cs^+)_3[PdCl_4]^{2-}Cl^-$
Cs_2PdCl_4 [15] = $(Cs^+)_2[PdCl_4]^{2-}$
$Cs_{12}Pd_9Cl_{30}\cdot 2H_2O$ [15] =
$(Cs^+)_{12}([PdCl_4]^{2-})_3\text{-}\{[(PdCl_{2/2}Cl_2)_2]^{2-}\}_3\cdot 2H_2O$
$Cs_6Pd_5Cl_{16}\cdot 2H_2O$ [15] =
$(Cs^+)_6([PdCl_4]^{2-})\text{-}\{[(PdCl_{2/2}Cl_2)_2]^{2-}\}_2\cdot 2H_2O$
$CsPdCl_3$ [3] = $(Cs^+)_2\{[(PdCl_{2/2}Cl_2)_2]^{2-}\}$
$CsPd_2Cl_5 = (Cs^+)\ {}^1_\infty[(PdCl_{3/2}Cl)_2^-]$

Increasing Pd content leads to additional linkage of the square-planar groups.

Perspective

Further investigations of the system $CsCl/PdCl_2$ can be expected to yield new compounds with several additional connecting patterns, e.g. $CsPd_3Cl_7$, as proposed by Safonov and Mireev.[6]

Experimental Section

Cesium Pentachloropalladate(II), $CsPd_2Cl_5$: The first indication of the existence of a compound containing an increased Pd content in the $CsCl/PdCl_2$ system was obtained in the course of heating experiments. A mixture of CsCl (Merck) and $PdCl_2$ (prepared according to Brauer[20]) in a molar ratio of 1:3 was melted, quenched, and annealed in an evacuated quartz glass ampoule. After heating the ampoule for 6 weeks at 280 °C, the powder diffraction pattern (PW 1050/25, Philips) showed unknown peaks, which did not correspond to those reported for $CsPd_3Cl_7$ in ref.[6]

Preparation under hydrothermal conditions proved more successful. A quartz glass ampoule was charged with 0.5 g of a mixture of

CsCl and $PdCl_2$ (molar ratio 1:2). After the addition of H_2O (0.5 mL), the solvent was frozen and the ampoule (ϕ 6 mm, length 60 mm) was evacuated and sealed. The reaction was carried out at 150 °C. After cooling, the mixture was filtered and the crude product was washed with H_2O, ethanol, and diethyl ether. Dark red-brown single crystals were selected for X-ray investigations.

X-ray Crystallographic Study: The crystal structure was determined by single-crystal X-ray analysis at 298 K. Data were collected on a CAD4 diffractometer (Enraf–Nonius). An empirical absorption correction employing psi-scans was applied to the data set (absorption coefficient = 9.66 mm^{-1}). The crystal structure was determined by direct methods (SHELXS-86[16]) and refined by full-matrix least-squares calculations using the program SHELXL-93.[17] Details of the structural investigations and salient crystallographic data are summarized in Table 4, whereas the final atomic coordinates, equivalent displacement parameters U_{eq}, as well as anisotropic displacement parameters are presented in Table 5. Selected interatomic distances and angles are given in Table 2.

Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-411722.

Synthesis and Complexation of the Metalloligand {(η^5-C_5H_5)[η^5-C_5Me_3-1,2-(PPh_2)$_2$]$TiCl_2$} (TiPHOS): The First Example of a 1,2-Bis(diphenylphosphanyl)titanocene Derivative

Pierre Le Gendre,[a] Emeline Maubrou,[a] Olivier Blacque,[a] Gilles Boni,[a] and Claude Moïse*[a]

Keywords: Phosphanes / Metallocenes / Rhodium / Titanium / Heterobimetallic complexes

The reaction of lithium 1,2-bis(diphenylphosphanyl)trimethylcyclopentadienide (**1**) with $CpTiCl_3$ leads to the formation of the titanocene diphosphane {(η^5-C_5H_5)[η^5-C_5Me_3-1,2-(PPh_2)$_2$]$TiCl_2$} (TiPHOS, **2**). This metalloligand reacts readily with (NBD)$Cr(CO)_4$ and $W(CO)_5$(THF) to give, in both cases, the bimetallic chelate complexes (TiPHOS)$Cr(CO)_4$ (**3**) and (TiPHOS)$W(CO)_4$ (**4**). The structure of **4** has been determined by X-ray diffraction. The synthesis of a new early-late heterobimetallic complex (TiPHOS)Rh(CO)Cl (**5**) is reported.

Introduction

Chelating diphosphanes constitute one of the most versatile ligands in organometallic chemistry.[1] Within this field, diphosphanes built on a bent metallocene skeleton are of particular interest. Indeed, the structural flexibility of such structures allows the chemist to synthesize a wide range of ligands. Furthermore, coordination of the metalloligand to an electron-rich metal leads to early-late heterobimetallic complexes with a high potential for homogeneous catalysis.[2]

Three types of diphosphanes with a bent metallocene framework have already been described (Figure 1).[3−5] Both the phosphorous groups can be linked either to each Cp unit (types I, I′) or directly to the metal (type II), or one to the Cp and one to the metal (type III).

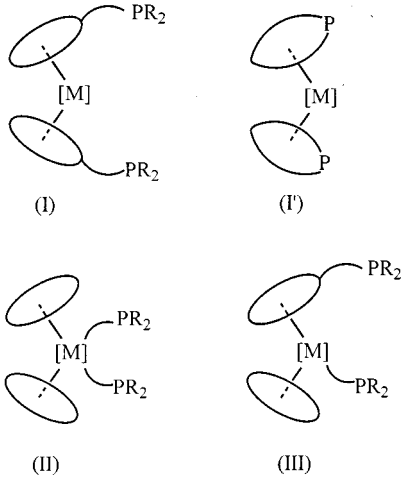

Figure 1. Diphosphanes with a bent metallocene framework

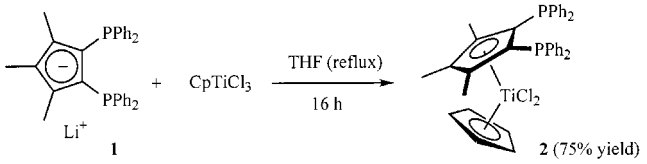
In this paper we describe the synthesis of a new titanocene dichloride metalloligand with the 1,2-bis(diphenylphosphanyl)trimethylcyclopentadienyl moiety. The 1,2-position of the phosphorus atoms on the cyclopentadienyl ring gives the ligand a rigid chelate structure often required for selective catalytic process. This diphosphane complex could, if necessary, be tuned by replacing the two chloride atoms on the titanium atom with other ligands. The synthesis and the characterisation of three new heterobimetallic complexes Ti−Cr, Ti−W and Ti−Rh are also reported.

Results and Discussion

The ligand **1** was prepared according to an earlier method involving the synthesis of 1,2,3-trimethylcyclopenta-1,3-diene, followed by two repeated sequences of deprotonation-addition to PPh_2Cl and then deprotonation.[6]

The reaction of the lithium salt **1** with $CpTiCl_3$ was carried out in THF at reflux. The reaction is complete after 16 h and leads to the targeted metalloligand **2** (TiPHOS) in good yield (Scheme 1). The ^{31}P NMR spectrum of **2** shows a singlet at $\delta = -21.8$ consistent with a diphosphane not coordinated to a metal atom. The ^1H NMR spectra of **2** displays two singlets at $\delta = 1.7$ and 2.0 for the C_5Me_3-1,2-(PPh_2)$_2$ ligand assignable to the central and to both lateral methyl groups, respectively.

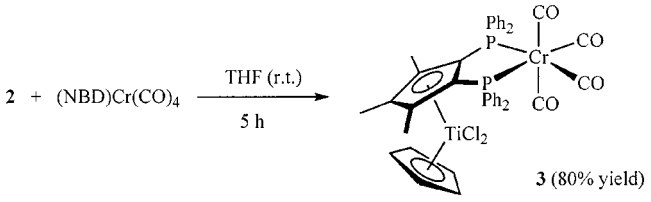


Scheme 1

In order to test the chelating properties of the TiPHOS ligand we coordinated it to the $Cr(CO)_4$ fragment. The metalloligand **2** readily displaces NBD from (NBD)$Cr(CO)_4$ in THF at room temperature to give the

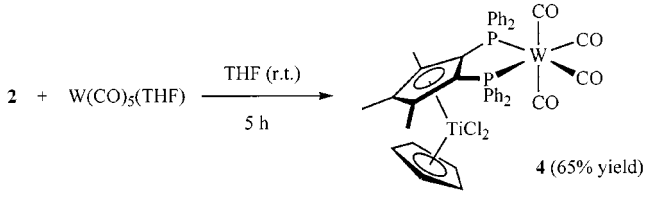
 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0606−1437 $ 17.50+.50/0

bimetallic complex **3** (Scheme 2). This complex may be recrystallized from the same solvent. The infrared spectrum in the CO stretching region exhibits four carbonyl stretching bands at 2008, 1922, 1901 and 1881 cm^{-1} consistent with a *cis*-$L_2Cr(CO)_4$ complex. The ^{31}P NMR spectrum of **3** displays only one singlet at $\delta = 70.70$ corresponding to a downfield shift of about 93 ppm relative to the original bis(diphenylphosphane) **2**. The ^1H NMR spectrum of **3** shows one singlet (intensity six) for both lateral methyl groups bonded to the cyclopentadienyl ring. The above data, closely similar to those obtained by Broussier et al. for a ferrocenic diphosphane,[7] are consistent with the symmetric chelate structure of **3** (Scheme 2).



Scheme 2

The easy formation of the bimetallic complex **3** prompted us to check the chelating abilities of TiPHOS with W^0 pentacarbonyl complexes. The reaction of **2** with $W(CO)_5(THF)$ in THF leads to the chelate structure **4** (Scheme 3). The ^{31}P NMR spectrum of **4** shows a singlet at $\delta = 33.60$ with ^{183}W satellites. The ^1H NMR and IR spectra of **4** are similar to those reported for **3** and confirm the structural features. It is worth noting that no trace of the $-W(CO)_5$ mono-coordinated intermediate derived from the chelating diphosphane **2** could be detected.



Scheme 3

Suitable crystals of **4** for X-ray measurements were obtained by crystallisation from warm THF. Its molecular structure is shown in Figure 2. The crystallographic study confirms its chelate structure and exhibits the usual tetrahedral (Ti) and distorted octahedral (W) geometries around the metallic fragments. The tungsten−phosphorus distances of 2.528(2) Å are similar to those observed for other tungsten−diphosphane structures (2.52−2.54 Å).[8] The P−W−P bite angle of 80.37(8)° corresponds well to that found in a *cis*-$W(CO)_4$ complex with 1,2-bis(diphenylphosphanyl)ferrocene.[7]

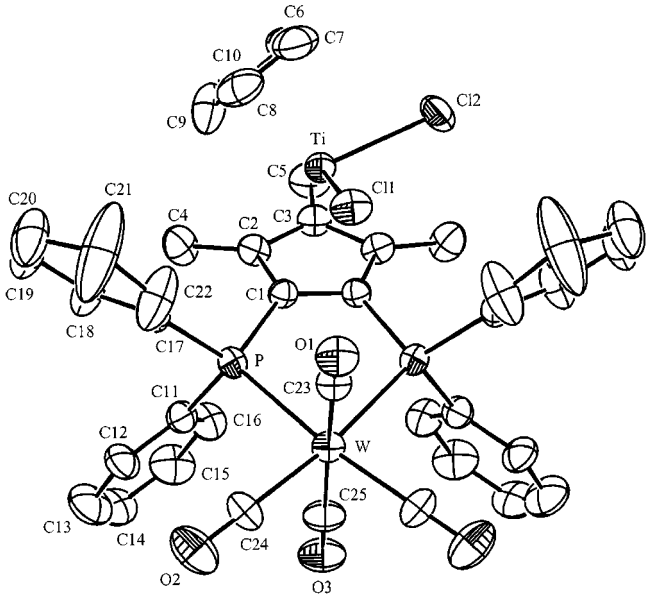


Figure 2. Molecular structure of complex **4**; for clarity the disordered atoms are not represented; selected bond lengths [Å] and angles [°]: Ti−Cp1 2.114, Ti−Cp2 2.072, Ti−Cl1 2.320(4), Ti−Cl2 2.364(9), W−P 2.528(2); P−W−P* 80.37(6), Cl1−Ti−Cl2 94.0(3)

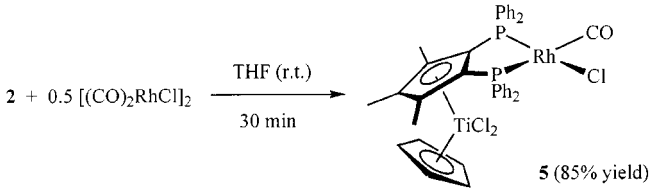
Once the chelating abilities of the metalloligand **2** had been revealed, we investigated its complexation with rhodium. Thus, the reaction with 0.5 molar equiv. of $[(CO)_2RhCl]_2$ gave the 1:1 adduct **5** which was isolated as a brown yellow powder (Scheme 4). The ^{31}P NMR spectrum of **5** reveals a single set of eight signals with an AB pattern split by Rh−P coupling ($^2J_{P-P}$ =36 Hz; $^1J_{P-Rh}$ = 127 Hz and 163 Hz) which is in accordance with the *cis*-coordination of both phosphorus atoms of TiPHOS to rhodium. The ^1H NMR spectrum of **5** differs from that of the precursor phosphane **2** and the other bimetallic systems **3** and **4** in that it displays three methyl resonances instead of two. This anisochrony is indicative of the loss of the plane of symmetry. Finally, the IR spectrum exhibits a single carbonyl stretch at 1984 cm^{-1} which corresponds to the terminal carbonyl band.



Scheme 4

Conclusion

We have described the preparation of a new class of titanocene diphosphane complexes. This synthesis involves the preparation of the lithium salt $[C_5Me_3$-1,2-$(PPh_2)_2]Li$ (**1**) followed by its treatment with $CpTiCl_3$. The chelating abilities of the metalloligand **2** (TiPHOS) has been revealed by its reaction with $(NBD)Cr(CO)_4$ and $W(CO)_5(THF)$ complexes. In both cases the heterobimetallic chelate complexes

have been obtained in good yields. Finally, the reaction of TiPHOS with the dimer $[(CO)_2RhCl]_2$ has led to the exclusive formation of a new early late Ti−Rh bimetallic complex. Further studies on bimetallic complexes containing the TiPHOS ligand and their catalytic activity are currently in progress.

Experimental Section

All manipulations were carried out under an argon atmosphere using vacuum line techniques. Solvents were dried and distilled under argon before use. $CpTiCl_3$,[9] $(NBD)Cr(CO)_4$,[10] $W(CO)_5(THF)$[11] and $[C_5Me_3$-1,2-$(PPh_2)_2]Li$[6] (**1**) were prepared by literature methods. NMR spectra were recorded on a BRUKER AC200 (200 MHz for ^1H, 81 MHz for ^{31}P, 50 MHz for ^{13}C) spectrometer. IR spectra were obtained on a Bruker IFS 66v; abbreviations: m (medium), s (strong), vs (very strong). Elemental analyses were performed on a FISON EA 1108 within the laboratory.

{(η^5-C_5H_5)[η^5-C_5Me_3-1,2-(PPh_2)$_2$]$TiCl_2$} (TiPHOS) (2): [C_5Me_3-1,2-$(PPh_2)_2$]Li (0.81 g, 1.7 mmol) in 10 mL of THF was added to $CpTiCl_3$ (0.37 g, 1.7 mmol) in 15 mL of THF. After stirring for 16 h at reflux, the solvent was removed in vacuo. The dark red residue was extracted with toluene and filtered through a piece of cotton. The solvent was removed in vacuo, the residue dissolved in CH_2Cl_2 and precipitated by the addition of hexane. The mixture was then placed in a freezer (−20 °C) for 1 h. The precipitate was collected by filtration and dried in vacuo (0.83 g, 75% yield). − ^1H NMR ($CDCl_3$): δ = 1.75 (s, 3 H, CH_3), 1.97 (s, 6 H, CH_3), 6.03 (s, 5 H, C_5H_5), 6.95 (m, 10 H, Ph), 7.26 (m, 4 H, Ph), 7.49 (m, 6 H, Ph). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, partial): δ = 12.9 (s, *C*H_3), 16.2 (s, *C*H_3), 121.6 (s, C_5H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −21.79 (s, PPh_2). − $C_{37}H_{34}Cl_2P_2Ti$ (659.41): calcd. C 67.39, H 5.20; found C 67.68, H 5.02.

(TiPHOS)Cr(CO)$_4$ (3): A 25 mL flask was charged with **2** (140 mg, 0.2 mmol), $(NBD)Cr(CO)_4$ (54 mg, 0.2 mmol) and 10 mL of THF. The solution was stirred at room temperature for 5 h. The solvent was concentrated in vacuo until an abundant precipitate was formed. The brown precipitate was collected by filtration and dried in vacuo (0.13 g, 80% yield). − IR ($CHCl_3$): ν(CO) = 2008 (m), 1922 (s), 1901 (vs), 1881 cm^{-1} (s). − ^1H NMR ($CDCl_3$): δ = 1.88 (s, 3 H, CH_3), 2.17 (s, 6 H, CH_3), 5.87 (s, 5 H, C_5H_5), 6.97 (m, 4 H, Ph), 7.29 (m, 6 H, Ph), 7.51 (m, 6 H, Ph), 8.14 (m, 4 H, Ph). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, partial): δ = 13.7 (s, *C*H_3), 18.1 (s, *C*H_3), 122.17 (s, C_5H_5), 216.9 (triplet, $^2J_{CP}$ = 10 Hz, *C*O), 223.7 (pseudotriplet, $^2J_{CP}$ = 13 Hz, *C*O), 227.9 (triplet, $^2J_{CP}$ = 8 Hz, *C*O). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 70.70 (s, PPh_2). − $C_{41}H_{34}Cl_2CrO_4P_2Ti$ (823.45): calcd. C 59.80, H 4.16; found C 59.29, H 3.96.

(TiPHOS)W(CO)$_4$ (4): This compound was obtained following the above procedure but with $W(CO)_5(THF)$ (0.12 g, 65% yield). − IR (KBr): ν(CO) = 2102 (m), 1905 (s), 1893 (vs), 1865 cm^{-1} (s). − ^1H NMR ($CDCl_3$): δ = 1.86 (s, 3 H, CH_3), 2.15 (s, 6 H, CH_3), 5.86 (s, 5 H, C_5H_5), 6.97 (m, 4 H, Ph), 7.28 (m, 6 H, Ph), 7.50 (m, 6 H, Ph), 8.10 (m, 4 H, Ph). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, partial): δ = 14.0 (s, *C*H_3), 18.0 (s, *C*H_3), 122.8 (s, C_5H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 33.59 (s + d, $^1J_{W-P}$ = 244 Hz, PPh_2). − $C_{41}H_{34}Cl_2O_4P_2TiW$ (955.30): calcd. C 51.55, H 3.59; found C 51.89, H 4.09.

(TiPHOS)Rh(CO)Cl (5): A 25-mL flask was charged with **2** (42 mg, 0.06 mmol), $[RhCl(CO)_2]_2$ (36 mg, 0.03 mmol) and 4 mL of THF. The mixture was stirred at room temperature for 30 min. during which time a brown yellow precipitate formed. The precipitate was collected by filtration and dried in vacuo (42 mg, 85% yield). − IR (KBr): ν(CO) = 1984 cm^{-1} (vs). − ^1H NMR ($CDCl_3$): δ = 1.95 (s, 3 H, CH_3), 2.09 (s, 3 H, CH_3), 2.10 (s, 3 H, CH_3), 5.93 (s, 5 H, C_5H_5), 7.21 (m, 10 H, Ph), 7.48 (m, 6 H, Ph), 8.08 (m, 4 H, Ph). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, partial): δ = 13.7 (s, *C*H_3), 16.8 (s, *C*H_3), 17.1 (s, *C*H_3), 122.0 (s, C_5H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 36.73 (dd, $^1J_{Rh-P}$ = 127 Hz, $^2J_{P-P}$ = 36 Hz, PPh_2), 56.00 (dd, $^1J_{Rh-P}$ = 163 Hz, $^2J_{P-P}$ = 36 Hz, PPh_2). − $C_{38}H_{34}Cl_3OP_2RhTi$ (825.78): calcd. C 55.27, H 4.15; found C 54.70, H 4.05.

X-ray Crystallographic Study of 4: $C_{41}H_{31}Cl_2O_4P_2TiW{\cdot}4C_4H_8O$, M = 1240.66, orthorhombic, space group $Pn2_1m$ (No. 31), a = 9.2830(2) Å, b = 16.6440(4) Å, c = 19.7850(6) Å, V = 3056.9(1) Å^3, Z = 2, $\rho_{calcd.}$ = 1.348 g·cm^{-3}, $F(000)$ = 1258, μ = 2.198 mm^{-1}, T = 110(2) K, 4720 independent reflections, 4123 observed reflections [$I \geq 2\sigma(I)$], 304 refined parameters, 10 restraints, $R(F)$ = 0.0576, $wR(F^2)$ = 0.1359 for all data and $R(F)$ = 0.0486, $wR(F^2)$ = 0.1276, S = 1.073 for observed reflections. A red crystal of **4** having the approximate dimensions 0.5 × 0.2 × 0.2 mm^3 and suitable for an X-ray analysis was sealed in a glass capillary in an inert oil and mounted on a Nonius KappaCCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). A total of 228 frames of data were collected at 110(2) K with an oscillation range of 1.5°/frame and an exposure time of 40 s/deg.[12] A total of 43869 reflections were indexed, integrated, and corrected for Lorentz and polarization effects using DENZO-SMN and SCALEPACK.[13] Data reduction yielded 4720 unique reflections of which 4123 had $I > 2\sigma(I)$. Refinement of the unit cell parameters gave a = 9.2830(2) Å, b = 16.6440(4) Å, c = 19.7850(6) Å and V = 3056.9(1) Å^3. Systematic absences were consistent with the compound having crystallised in the orthorhombic space group $Pn2_1m$ (No. 31).

The structure was solved by a Patterson search program[14] and refined by full-matrix least-squares on F^2 using SHELXL.[14] All non-hydrogen atoms were refined with anisotropic thermal parameters, except for solvent atoms which were refined with a global isotropic temperature factor (the complex crystallised with four THF solvate molecules). The hydrogen atoms of the complex were included in their calculated positions and refined in a riding model with isotropic displacement coefficients (the hydrogen atoms of solvent molecules were not introduced in the model). The nonsubstitued cyclopentadienyl ring and the two chlorine atoms were found to be disordered. The residual peaks on the final difference Fourier map ranged from −0.82 to 0.88 e·Å^{-3}.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-147166. Copies of the data can be obtained free of charge on application to CCDC, 12 union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

On the Relevance of Mono- and Dinuclear Iron Carbonyl Complexes to the Fixation and Stepwise Hydrogenation of N_2[‡]

Yu Chen,[a] Michael Hartmann,*[a] and Gernot Frenking*[a]

Dedicated to Professor Dieter Sellmann on the occasion of his 60th birthday

Keywords: Ab initio calculations / Density functional theory / Iron / Carbonyl ligands / Nitrogen fixation / Hydrogenation

Density functional theory and high-level ab initio calculations are used to evaluate the influence of mono- and dinuclear iron carbonyl complexes to the fixation and stepwise hydrogenation of dinitrogen via diazene and hydrazine to ammonia. In comparison to the reaction of isolated N_2, only the first step in this reaction sequence (i.e. the reduction of N_2 to N_2H_2) experiences a significant change in its thermochemistry when coordinated to mono- or dinuclear iron tetracarbonyl fragments. The reaction enthalpy ΔH_R^0 (T = 0 K) for the endothermic hydrogenation of $(CO)_4Fe–N_2$ to give $(CO)_4Fe–N_2H_2$ is lower than for the corresponding metal-free process by 16.1 kcal mol^{-1}. The analogous step involving the dinuclear species $(CO)_4Fe–N_2–Fe(CO_4)$ and $(CO)_4Fe–N_2H_2–Fe(CO)_4$ is even less endothermic than the reduction involving only one iron tetracarbonyl complex by 13.1 kcal mol^{-1}. In comparison to that, the second and third step of this reduction sequence, namely the conversion of coordinated diazene to $(CO)_4Fe–N_2H_4$ and the subsequent reduction of coordinated hydrazine to $(CO)_4Fe–NH_3$ show only relatively small thermodynamic changes compared to the analogous reactions of isolated N_2H_2 and N_2H_4. The reduction of $(CO)_4Fe–N_2H_2$ to $(CO)_4Fe–N_2H_4$ is almost as exothermic as the analogue reaction involving isolated N_2H_2, whereas the hydrogenation of $(CO)_4Fe–N_2H_4$ to $(CO)_4Fe–NH_3$ is less exothermic by 4.0 kcal mol^{-1}. Finally, the reduction of $(CO)_4Fe–N_2H_2–Fe(CO)_4$ and $(CO)_4Fe–N_2H_4–Fe(CO)_4$ are both predicted to be less exothermic than their mononuclear analogues by 4.0 and 1.1 kcal mol^{-1}, respectively. Moreover, we find that only N_2 and N_2H_2, which already show a noticeable π-acceptor behavior in their complexes with $Fe(CO)_4$, experience important structural changes in their corresponding dinuclear complexes, i.e. a shortening of the Fe–N bonds and a lengthening of the N–N bonds on going from $(CO)_4Fe–L$ to $(CO)_4Fe–L–Fe(CO)_4$ (L = N_2, N_2H_2). This behavior is in line with a slightly increased π-acceptor ability of these ligands in their respective dinuclear complexes. Such structural changes are absent for N_2H_4, which only exhibits a comparatively weak π-acceptor character in $(CO)_4Fe–N_2H_4$.

Introduction

The stepwise hydrogenation of dinitrogen to ammonia is one of the most important processes in biochemical research[1] and of utmost interest to chemical industry.[2] Besides the well-understood heterogeneously catalyzed reduction following the Haber−Bosch process,[3] deeper insight into the reduction of dinitrogen is necessary, particularly when dealing with biologically relevant systems. An example of this is the enzymatic fixation of N_2 catalyzed by nitrogenases.[4] Although the molecular structure of the Fe−Mo cofactor of a nitrogenase enzyme has been characterized by X-ray structure analysis,[5] details of the catalytically important features involved in the N_2 reduction have still not, however, been unequivocally answered.[6] To this end, the binding site, the binding mode of N_2 and the intermediates involved in the catalytic processes are still the source of much speculation.[4,6]

It is widely accepted that the initial binding of dinitrogen occurs at the iron rather than the molybdenum centers.[4] Theoretical studies based on different model systems of the Fe−Mo cofactor at various levels of theory are available.[7] However, due to the complexity of the overall reduction process and the structure of the Fe−Mo cofactor, a suitable model system for the Fe−Mo nitrogenases that reasonably mimics its catalytic activity may be too large for a quantum chemical treatment at a reasonable level of theory.[7] In addition to that, the nature of the actual intermediates of the enzymatic N_2 fixation process is still unknown.[8] Although there are numerous results indicating that biological N_2 fixation involves diazene and hydrazine species,[4] even the structure of the small four-atom diazene in solution was controversial until recently when Sellmann and Hennige isolated *trans*-N_2H_2 by complexation out of solution.[9] Beside the clarification of the nature of the intermediates involved in the stepwise hydrogenation of N_2 by nitrogenases, another pivotal question regarding the thermochemistry of these reduction steps is of utmost interest: Sellmann and

co-workers suggested that all of the three reduction steps involved in the hydrogenation sequence should benefit energetically from the coordination of the nitrogen-containing ligands to iron(II) sulfur complexes.[6b]

Due to our interest in the structure and reactivity of iron carbonyl complexes,[10] the present study focuses on the influence and relevance of mono- and dinuclear iron carbonyl complexes of the general type $[\{Fe(CO)_4\}_nL]$ (n = 1 for L = NH_3 and n = 1, 2 for L = N_2, N_2H_2, N_2H_4) to the fixation and stepwise hydrogenation of N_2. We want to emphasize that this approach is not primarily intended to serve as a model study of the Fe−Mo cofactor, but to gain a deeper insight into the reduction steps of N_2 that are most affected by coordination to iron carbonyl fragments.[6] Particular interest is thus drawn to thermodynamic changes between the "metalated" reaction in which the nitrogen-containing ligands are either coordinated by one or two iron tetracarbonyl fragments and the isolated, metal-free hydrogenation of N_2. Moreover, we address the bonding situation of the Fe−L (L = N_2, N_2H_2, N_2H_4 and NH_3) bond in terms of σ-donor/π-acceptor abilities and the preferred coordination site of the ligands.

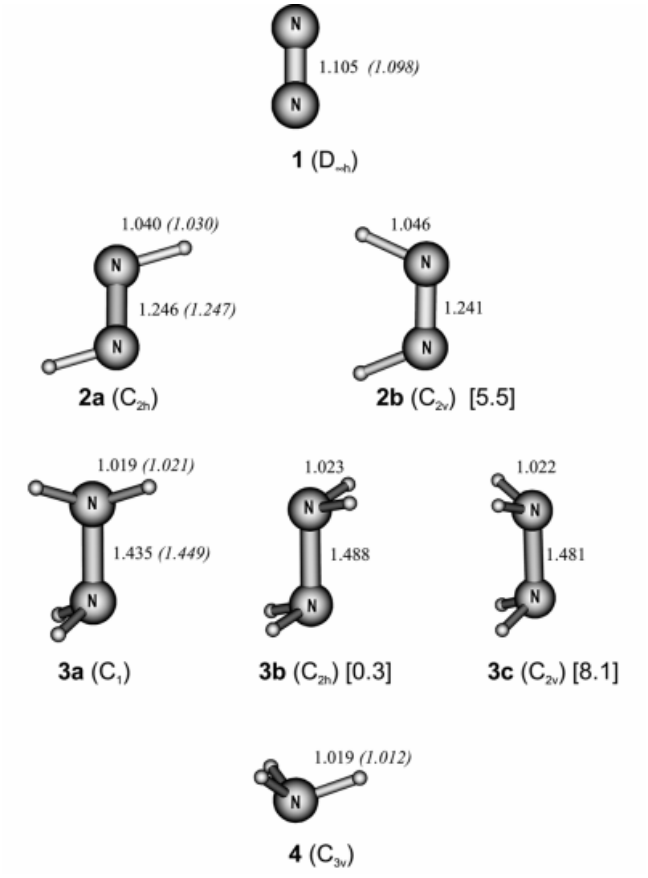

Figure 1. Optimized geometries of N_2 (**1**), N_2H_2 (**2**), N_2H_4 (**3**) and NH_3 (**4**); experimental values are given in italics; all bond lengths are in Å; the symmetry used for the geometry optimization is given in parentheses, while relative energies (kcal mol^{-1}) with respect to the most stable isomers are given in square brackets; angles are omitted for clarity and are provided separately in the Supplementary Information (Figure S1)

Results and Discussion

Stepwise Hydrogenation of Isolated Dinitrogen

The calculated geometries and structural parameters of dinitrogen **1**, diazene **2a** and **2b**, hydrazine **3a**−**3c** and ammonia **4** are shown in Figure 1. The reaction enthalpies obtained using a variety of energy evaluations based on the B3LYP/II geometries are summarized in Table 1. Details of the levels of theory necessary for a reasonable treatment of the stepwise hydrogenation of isolated dinitrogen to ammonia have been reported in a previous paper and the reaction enthalpies provided by this study serve as reference values for our present work.[21] Thus, for the individual hydrogenation steps shown in Equations (1)−(3), the benchmarks for the reaction enthalpies ΔH^0_R are 49.2 kcal mol^{-1} [Equation (1)], −23.1 kcal mol^{-1} [Equation (2)] and −44.7 kcal mol^{-1} [Equation (3)].[21]

$$N_2 + H_2 \rightarrow N_2H_2 \quad (1)$$

$$N_2H_2 + H_2 \rightarrow N_2H_4 \quad (2)$$

$$N_2H_4 + H_2 \rightarrow 2\,NH_3 \quad (3)$$

[a] Ref. [21]

The data summarized in Table 1 clearly show that for all three hydrogenation steps convergence of the results is achieved when basis sets of at least 6−311+G(d,p) quality are used. At our highest level of theory, the enthalpies of reaction are 51.4 kcal mol^{-1} for Equation (1), −19.3 kcal mol^{-1} for Equation (2) and −43.3 kcal mol^{-1} for Equa-

tion (3), which is in good agreement with the aforementioned reference data.[21] We note, however, that the predicted ΔH^0_R for the second reduction step [Equation (2)] is 3.8 kcal mol^{-1} too high, while the reaction enthalpies of reactions (1) and (3) are too high by 2.2 and 1.4 kcal mol^{-1}, respectively. A more economic, yet reasonably accurate, alternative is given by CCSD(T) energy evaluations in combination with the 6−311+G(d,p) basis set. The deviations from the reference values are then between 4.8 and 1.2 kcal mol^{-1}, i.e. the ΔH^0_R values are 51.9 kcal mol^{-1} for Equation (1), −18.3 kcal mol^{-1} for Equation (2) and −43.5 kcal mol^{-1} for Equation (3). For larger molecules, for which CCSD(T) is no longer affordable, B3LYP/{II & 6−311+G(d,p)} single-point energies are recommended. This approach leads to deviations from the reference that are particularly small for reactions (2) and (3). The calculated ΔH^0_R values of 45.3 kcal mol^{-1} for Equation (1), −22.4 kcal mol^{-1} for Equation (2) and −44.1 kcal mol^{-1} for Equation (3) thus show that this approach offers a very economic way to reliable hydrogenation enthalpies.

The calculated N−N bond length of **1** is 1.105 Å, whereas the analogous bond lengths of **2a** and **2b** are calculated to be 1.246 and 1.241 Å, respectively. Compared to corresponding experimental data, the differences are quite small and in the range of 0.001 to 0.007 Å.[22,23] The same also holds for the N−H bond length of NH_3 (**4**), that is, a small deviation from the experimental data by 0.007 Å is found.[24] Relatively large deviations from the experimental values are, however, found for the structural parameters of **3a**−**3c**. The experimental N−N bond length of 1.449 Å is larger than the one we calculated for the most stable hydrazine isomer **3a** by 0.014 Å.[24] Our calculated value is, however, in perfect agreement with other high-level ab initio estimates,[21] implying that a re-examination of the experimental N−N bond length might be worthwhile. The calculated bond angles of **2**, **3** and **4** are generally in good agreement with the available literature data and we do not find significant deviations. Further details are given in the Supplementary Information (Figure S1).

At our standard level of theory, *viz*. CCSD(T)/II//B3LYP/II the *trans* isomer of diazene **2a** is predicted to be more stable than the *cis* isomer **2b** by 5.5 kcal mol^{-1}, which is in line with previous results.[21,25] Furthermore, our calculations predict the *gauche* isomer **3a** to be the most stable form of hydrazine, which is consistent with other data.[25] The energy difference to the corresponding *trans* isomer **3b** is, however, very small at only 0.3 kcal mol^{-1}, whereas the analogous *cis* hydrazine **3c** is significantly less stable than **3a** by 8.1 kcal mol^{-1}.

Stepwise Hydrogenation in the Presence of Mononuclear Iron Carbonyl Complexes

The influence of mononuclear iron carbonyl complexes on the stepwise hydrogenation of coordinated N_2 is evaluated by comparing the individual reduction steps shown in Equations (4)−(6) with their metal-free analogues in Equations (1)−(3).

$$(CO)_4Fe{-}N_2 + H_2 \rightarrow (CO)_4Fe{-}N_2H_2 \quad (4)$$

$$(CO)_4Fe{-}N_2H_2 + H_2 \rightarrow (CO)_4Fe{-}N_2H_4 \quad (5)$$

$$(CO)_4Fe{-}N_2H_4 + H_2 \rightarrow (CO)_4Fe{-}NH_3 + NH_3 \quad (6)$$

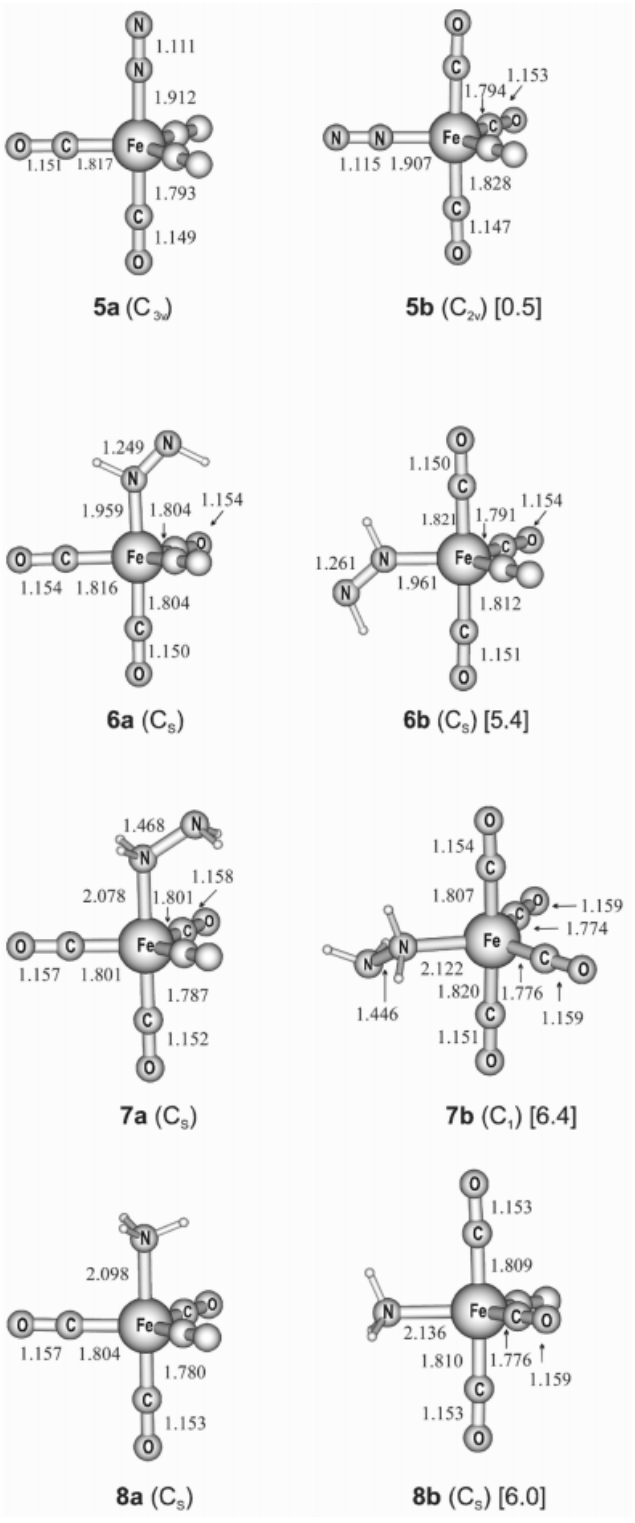

Figure 2. Optimized geometries of the complexes $(CO)_4Fe{-}N_2$ (**5**), $(CO)_4Fe{-}N_2H_2$ (**6**), $(CO)_4Fe{-}N_2H_4$ (**7**), and $(CO)_4Fe{-}NH_3$ (**8**); all bond lengths are in Å and the symmetry used for the geometry optimisation is given in parentheses; relative energies (kcal mol^{-1}) with respect to the most stable isomers are given in square brackets; angles and N−H bond lengths are omitted for clarity and are provided separately in the Supplementary Information (Figure S2)

The optimized geometries of the iron carbonyl complexes and the relative energies between the respective axial and equatorial isomers are shown in Figure 2. Table 2 summarizes the hydrogenation enthalpies ΔH^0_R for Equations (4)−(6) obtained at various levels of theory. Table 3 lists the calculated bond dissociation energies D_0 between the $Fe(CO)_4$ fragment and the nitrogen-containing ligands together with the NBO and CDA data.

Table 3. Bond dissociation energies D_o (kcal/mol) and NBO/CDA data for mononuclear iron tetracarbonyl complexes $(CO)_4Fe-L$ obtained at the CCSD(T)/II//B3LYP/II level of theory

			NBO[a]			CDA[a]	
Complex	D_o	L	q[$Fe(CO)_4$][b]	q(π)→L	q(σ)→[TM]	*b*	*d*
5a	22.9	N_2	−0.08	0.18	0.26	0.14	0.28

[a] [TM] = [$(CO)_4Fe$]; q(σ)→[TM] σ-donation (*d*) and q(π)→L π-back donation (*b*) according to the NBO (*CDA*) analysis. − [b] Total charge of the $Fe(CO)_4$ complex fragment.

The most intriguing effect of the $Fe(CO)_4$ fragment on the stepwise hydrogenation of coordinated N_2 is that the enthalpy of hydrogenation of 35.8 kcal mol^{-1} for the first reduction step [Equation (4)] is significantly lower by $\Delta\Delta H^0_R = -16.1$ kcal mol^{-1} compared to the analogous step of isolated N_2 [Equation (1)]. We do not observe a similarly drastic effect for the second and third reduction steps. To this end, the reduction of $(CO)_4Fe-N_2H_2$ [Equation (5)] is almost as exothermic as the corresponding hydrogenation [Equation (2)] of isolated N_2H_2 ($\Delta\Delta H^0_R = -0.2$ kcal mol^{-1}). For the hydrogenation of $(CO)_4Fe-N_2H_4$ [Equation (6)], we even find a less exothermic behavior than for the metal-free analogue [Equation (3)] and $\Delta\Delta H^0_R$ is calculated to be 4.00 kcal mol^{-1}.

Dinitrogen is both a weak σ-donor and π-acceptor ligand. The small energy difference between the two possible isomers **5a** and **5b** of the complex $(CO)_4Fe-N_2$, in which N_2 is either coordinated axially or equatorially, implies no pronounced coordination site preference.[26] The structures of **5a** and **5b** show $Fe-N_2$ bond lengths of 1.912 Å and 1.907 Å, respectively. This is in contrast to the results of Radius et al.,[27] who predicted the $Fe-N_2$ bond length of axial N_2 to be shorter than that of equatorial N_2. The energy difference of 0.5 kcal mol^{-1} between **5a** and **5b** is in favor of the axial isomer, which is again in contrast to the results of the aforementioned group.[27] Note, however, that the chosen level of theory is surely beyond chemical accuracy (≤ 1.0 kcal mol^{-1}) and therefore our small energy difference is not conclusive. Interestingly, however, the uncertainty of the relative energy between **5a** and **5b** is also found in experimental chemistry. On the one hand, the reaction of $Fe(CO)_5$ with N_2 in polyethylene film implies that N_2 *may* occupy an equatorial rather an axial coordination site,[28] whereas photolysis experiments of $Fe(CO)_5$ in nitrogen-containing matrices[29] show an opposite behavior, that is, a more stable axial than equatorial isomer. The N−N distances of isomers **5a** and **5b** are both slightly longer than in isolated dinitrogen. The bond elongation upon coordination is in the range of 0.006 to 0.010 Å indicating that the N−N triple bond only experiences a weak "activation". In addition, the calculated Fe−N bond energy of 22.9 kcal mol^{-1} also implies a relatively weak interaction between N_2 and the $Fe(CO)_4$ fragment.

The diazene complex formed by the first hydrogenation step [Equation (4)] shows a somewhat different behavior than the analogous dinitrogen complex. First, the energy difference of 5.4 kcal/mol^{-1} between the axial (**6a**) and equatorial (**6b**) isomers is indeed significant and in favor of the axial isomer. Second, this preference towards axial coordination is also mirrored by the σ-donor/π-acceptor abilities of diazene.[26] NBO as well as CDA data both imply that N_2H_2 is at least as poor a π-acceptor as N_2, but at the same time a slightly better σ-donor (Table 3). Finally, the Fe−N bond dissociation energy of **6a** is calculated to be 39.3 kcal mol^{-1}, which is considerably higher than the corresponding value calculated for **5a**. The much stronger bond in $(CO)_4Fe-N_2H_2$ than that in $(CO)_4Fe-N_2$ is the reason why the first hydrogenation step of N_2 becomes energetically more favored upon $Fe(CO)_4$ complexation. Any structural changes of diazene on complexation are again very small and the N−N bond is lengthened by only 0.003 Å.

Further hydrogenation of coordinated N_2H_2 leads to the corresponding hydrazine complex [Equation (5)]. NBO and CDA data suggest that hydrazine is a significantly stronger σ-donor than diazene or dinitrogen (Table 3). Axial coordination of N_2H_4 should therefore be predominant, which is supported by the large energy difference of 6.4 kcal mol^{-1} that favors the axial isomer **7a** over its equatorial analog **7b**. Interestingly, the former, more stable, isomer has hydrazine coordinated as *trans*-N_2H_4, which is not the most stable conformation for the isolated case. At the same time, the less-stable equatorial isomer has N_2H_4 coordinated in its most stable *gauche* conformation. Structural changes of N_2H_4 on coordination are significant as shown by the lengthening of the N−N bond in **7a** by 0.033 Å with respect to isolated N_2H_4. This relatively strong influence on the internal structure of N_2H_4 is also mirrored by the large Fe−N bond dissociation energy of 42.8 kcal mol^{-1}, which is, in fact, the highest D_0 value encountered in this study. Note, that at the same time the calculated Fe−N bond length of **7a** of 2.078 Å is significantly larger than the corresponding bond lengths found in complexes **5** and **6**, which exhibit weaker bonds between iron and the nitrogen-containing ligands.

In the final step [Equation (6)] of the overall reduction process, coordinated hydrazine is reduced to ammonia. The NH_3 ligand is found by CDA and NBO to be an equally strong σ-donor as N_2H_4, whereas its π-acceptor capability is close to zero (Table 3). Again we find a dominant preference of the axial $(CO)_4Fe-N_2$ isomer **8a** over the equatorial isomer by 6.0 kcal mol^{-1}, which is in line with crystallographic data and IR spectra.[30] Our estimate for the Fe−N bond dissociation energy is 38.9 kcal mol^{-1} and the calculated Fe−N bond length is 2.098 Å. Both values show slight deviations from those found for the analogous hydrazine complex **7a**. These differences are, however, small, thus indicating a close resemblance of these two complexes.

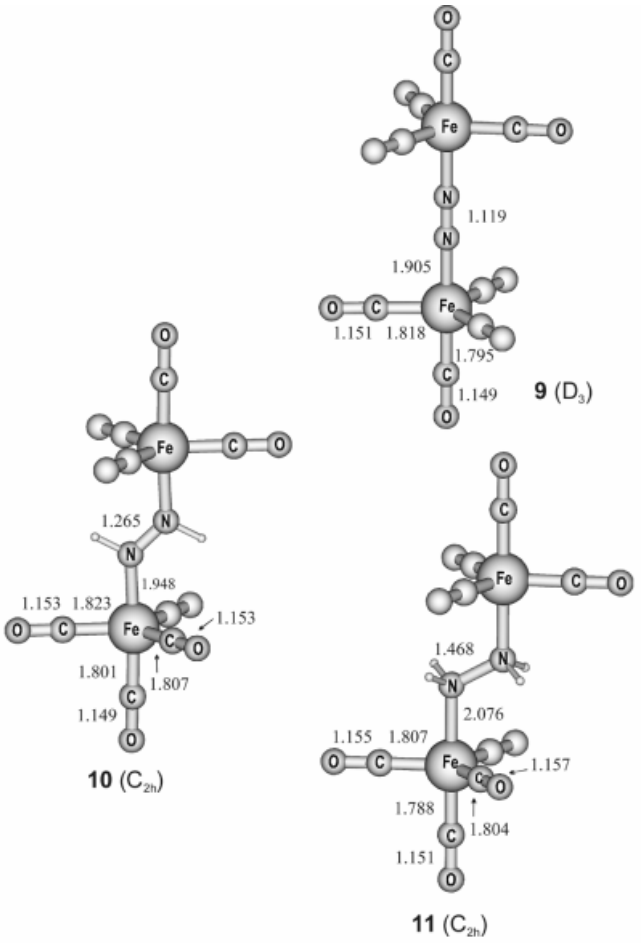

Figure 3. Optimized geometries of the dinuclear iron tetracarbonyl complexes $(CO)_4Fe-N_2-Fe(CO)_4$ (**9**), $(CO)_4Fe-N_2H_2-Fe(CO)_4$ (**10**), and $(CO)_4Fe-N_2H_4-Fe(CO)_4$ (**11**); all bond lengths are in Å; the symmetry used for the geometry optimization is given in parentheses; for more details regarding structural parameters see the Supporting Information (Figure S3)

Stepwise Hydrogenation in the Presence of Dinuclear Iron Carbonyl Complexes

Figure 3 shows the optimized geometries of the dinuclear complexes $(CO)_4Fe-N_2-Fe(CO)_4$ (**9**), $(CO)_4Fe-N_2H_2-Fe(CO)_4$ (**10**) and $(CO)_4Fe-N_2H_4-Fe(CO)_4$ (**11**), considered in the hydrogenation steps according to Equations (7)−(9). Table 4 and 5 summarize the hydrogenation enthalpies for the individual steps and the bond dissociation energies, as well as the NBO/CDA data, respectively.

$$(CO)_4Fe-N_2-Fe(CO)_4 + H_2 \rightarrow (CO)_4Fe-N_2H_2-Fe(CO)_4 \quad (7)$$

$$(CO)_4Fe-N_2H_2-Fe(CO)_4 + H_2 \rightarrow (CO)_4Fe-N_2H_4-Fe(CO)_4 \quad (8)$$

$$(CO)_4Fe-N_2H_4-Fe(CO)_4 + H_2 \rightarrow 2\,(CO)_4Fe-NH_3 \quad (9)$$

The coordination of dinitrogen by two iron tetracarbonyl fragments results in a further significant decrease of the hydrogenation enthalpy of the first reduction step [Equation (7)] by $\Delta\Delta H^0_R = -13.1$ kcal mol^{-1} compared to the analogous step [Equation (4)] involving only one $Fe(CO)_4$ fragment.[31] The overall decrease of the hydrogenation enthalpy with respect to the metal free reaction [Equation (1)] thus becomes 27.1 kcal mol^{-1}.[31] This considerable change of the thermochemistry is so much more interesting as it only affects the first reduction step. To this end, the second [Equation (8)] and third [Equation (9)] hydrogenation steps are even less exothermic than their mononuclear analogues [Equation (5) and (6)]. The $\Delta\Delta H^0_R$ values calculated on going from Equation (5) to (8) and from Equation (6) to (9) are 4.0 and 1.1 kcal mol^{-1}, respectively.

The $Fe(CO)_4$ fragments in **9** are twisted against each other by 8.7°. The rotation barrier is extremely low and we find several different isomers that are energetically not distinguishable from each other. In comparison to the mononuclear analogue **5a** we do not observe further significant alterations of structural parameters. Note that the Fe−N bond length becomes shorter by 0.007 Å, which is paralleled by the lengthening of the N−N bond by 0.008 Å. The CDA and NBO data in Table 5 show that the σ-donor properties of N_2 embraced by two iron tetracarbonyl fragments is hardly changed compared to **5a** — only the π-

11	26.1/57.7	N_2H_4	−0.24	0.18	0.66	0.11	0.63

[a] [TM] = [(CO)$_4$Fe]; q(σ)→[TM] σ-donation (*d*) and q(π)→L π-back donation (*b*) according to the NBO (*CDA*) analysis with respect to both Fe(CO)$_4$ fragments. Half of this value equals the charge transferred per Fe(CO)$_4$ unit. − [b] Fe−L bond dissociation energy per Fe(CO)$_4$ fragment according to: $[TM]_2L \rightarrow [TM]L + TM$. − [c] Total Fe−L bond dissociation energy according to: $[TM]_2L \rightarrow TM + TM + L$. − [d] Total charge of the Fe(CO)$_4$ complex fragment.

acceptor characteristics are somewhat enhanced. The overall $Fe-N_2-Fe$ bond dissociation energy is calculated to be 32.5 kcal mol^{-1}, which translates to a Fe−N bond dissociation energy per Fe(CO)$_4$ fragment of 16.0 kcal mol^{-1}. Comparison of these data with the bond dissociation energy obtained for **5a** implies a decreased bond strength between an *individual* Fe(CO)$_4$ subunit and N_2.

Further hydrogenation of **9** results in the formation of the corresponding diazene complex $(CO)_4Fe-N_2H_2-Fe(CO)_4$ (**10**). The Fe−N as well as the N−N bond lengths of **10** are calculated to be 1.948 Å and 1.265 Å, respectively. These values are in good agreement with the structural data of the related [μ-N_2H_2{Fe(PPr$_3$)('S$_4$')}$_2$] ['S$_4$'$^{2-}$ = 1,2-bis(2-mercaptophenylthio) ethane(2-)] complex reported by Sellmann and co-workers.[32] The small deviations of less than 0.052 Å are noteworthy as such Fe^{II}('S$_4$') complexes involving multidentate organosulfur ligands are often used as model compounds for the Fe-Mo, Fe−V and Fe−Fe nitrogenases.[4,6,32] We note a non-negligible shortening of the Fe−N bond by 0.011 Å and a lengthening of the N−N bond by 0.016 Å on going from **6a** to its dinuclear pendant **10**. Interestingly, CDA and NBO data indicate that the ability of diazene to act as σ-donor is almost unaltered. Only a slight increase of the π-acceptor capabilities of N_2H_2 is observed. The Fe−N bond dissociation energy of **10** follows the same trend as shown above for the corresponding dinitrogen complex; that is, the bond strength per Fe(CO)$_4$ fragment is smaller than in the mononuclear case, whereas the overall binding energy obtained by complexation with two Fe(CO)$_4$ fragments is significantly larger.

In the second step of the overall reduction process [Equation (8)], the analogous hydrazine complex $(CO)_4Fe-N_2H_4-Fe(CO)_4$ (**11**) is formed by hydrogenation of coordinated diazene. The comparison with complex **7a** shows hardly any shortening of the Fe−L bond length or lengthening of the N−N bond. We want to point out that the NBO data imply that both the σ-donor as well as the π-acceptor abilities of N_2H_4 decrease slightly on going from the mononuclear complex to **11**. With respect to the σ-donor character this is also supported by the corresponding CDA values. Although the analogue π-acceptor value implies a stronger π back-donation of N_2H_4 in the dinuclear complex **11**, the predicted magnitude is too small to account for a significant π-acceptor character of N_2H_4.

Conclusion

Density functional and ab initio calculations were used to evaluate the influence of iron tetracarbonyl complexes on the stepwise hydrogenation of dinitrogen. In comparison to the metal-free reduction process, we find that complexation by one or two Fe(CO)$_4$ fragments results in a pronounced change of the thermochemistry of the first hydrogenation step, namely the reduction of coordinated N_2 to N_2H_2. The effects on the second and third hydrogenation steps, *viz* the hydrogenation of coordinated N_2H_2 and N_2H_4, are much weaker, and even less-exothermic reduction processes compared with the metal-free hydrogenation are predicted. The decrease of the hydrogenation enthalpy is larger for the reduction of $(CO)_4Fe-N_2-Fe(CO)_4$ than it is for the reduction of $(CO)Fe-N_2$. In conclusion, our calculations thus clearly demonstrate that only one, namely the first, reduction step in the hydrogenation sequence of N_2 is

in fact favored in terms of the reaction enthalpy by complexation with iron tetracarbonyl fragments. Although the systems used in our study are not intended to primarily serve as model complexes for the mode of action of nitrogenase, we suggest that these results should be considered in further discussions of the thermochemistry of N_2 fixation and activation processes.

The binding characteristics of N_2, N_2H_2, N_2H_4 and NH_3 to $Fe(CO)_4$, analyzed in terms of the NBO and CDA partitioning schemes, imply a consistent trend of the σ-donor/π-acceptor behavior of these ligands that correlates with the relative energies between the respective isomers. Thus, ligands with comparatively high σ-donor capabilities like N_2H_4 and NH_3 give iron tetracarbonyl complexes in which the axial isomers are considerably more stable than their equatorial analogues. In addition to that, only ligands like N_2 and N_2H_2 that show noticeable π-acceptor quantities in their respective $Fe(CO)_4$ complexes are affected by the formation of dinuclear complexes. Thus, the Fe−N bond lengths are shorter and the N−N bonds are longer in the dinuclear complexes than in their mononuclear analogues. This behavior is also mirrored by a slight increase of the π-acceptor ability on going from $(CO)_4Fe-X$ to $(CO)_4Fe-X-Fe(CO)_4$ (X = N_2, N_2H_2) complexes. Such structural changes are absent for N_2H_4, and both its σ-donor as well as its π-acceptor behavior are less pronounced in $(CO)_4Fe-N_2H_4-Fe(CO)_4$ than in $(CO)_4Fe-N_2H_4$.

Experimental Section

Computational Details: Geometry optimizations were performed with Becke's three-parameter hybrid functional in combination with the correlation functional according to Lee, Yang and Parr (B3LYP).[11] A small core pseudopotential and a (441/2111/41) split-valence basis set according to Hay and Wadt were used for iron,[12] whereas an all-electron 6−31G(d) basis set was chosen for the main-group elements.[13] It was shown previously that this combination of basis sets (further abbreviated as basis set II) in combination with the aforementioned functional predicts equilibrium geometries of transition metal complexes reasonably well.[14] All structures discussed in this paper were verified to represent local minima on their potential energy surfaces by harmonic frequency calculations at the same level of theory. Refined estimates of relative energies were obtained by single-point calculations of the B3LYP/II geometries using both the B3LYP functional and coupled-cluster theory with singles, doubles and perturbative estimates of triple substitution [CCSD(T)].[15] CCSD(T) and basis set II were used for estimating relative energies between isomeric forms of diazene, hydrazine and all iron carbonyl complexes. Refined reaction enthalpies ΔH^0_R (T = 0 K) for the individual hydrogenation reactions, however, were predicted using basis sets that consisted of the aforementioned basis set for the metal and the elements C and O, but were extended by either the 6−31G(d,p) or the 6−311+G(d,p) basis sets for N and H. These combinations of basis sets are further abbreviated as {II & 6−31G(d,p)} and {II & 6−311+G(d,p)}, respectively.

The ΔH^0_R values obtained for the hydrogenation steps of the metal-free reactions were compared with their analogous steps involving mononuclear iron carbonyl fragments. The resulting $\Delta\Delta H^0_R$ values indicate whether the ΔH^0_R of an individual reduction step decreases ($\Delta\Delta H^0_R < 0$) or increases ($\Delta\Delta H^0_R > 0$) on going from the reactions of the isolated to the coordinated species. The corresponding $\Delta\Delta H^0_R$ values obtained for the individual reduction steps involving mono- and dinuclear iron carbonyl fragments were used likewise. Unless otherwise noted, relative enthalpies obtained at the CCSD(T)/{II & 6−311+G(d,p)}//B3LYP/II level of theory were the basis for the comparison between the metal-free hydrogenation steps of N_2 and the reactions following the reduction of $(CO)_4Fe-N_2$. With respect to the large resources needed for a proper description of the reactions involving dinuclear species, the comparisons between the hydrogenation steps involving mono and dinuclear iron carbonyl complexes were based on the B3LYP/{II & 6−311+G(d,p)}//B3LYP/II energies only. For the evaluation of the reaction enthalpies only the most stable isomers within a reaction sequence were considered.

Reaction enthalpies and relative energies are corrected by zero-point vibrational energy (ZPE) contributions obtained at the B3LYP/II level of theory. The nature of the Fe−N and N−N bonds was examined using the natural bond orbital (NBO)[16] partitioning scheme and the charge decomposition analysis (CDA).[17] All calculations used the program packages Gaussian94/98,[18] MOLPRO96/2000,[19] and CDA2.1.[20]

Co^{II} Complexes with Mixed Amino-*N* and Thiolato-*S* Donor Sets − Structural Characterization and Electronic Properties of a Stable Bis(μ-thiolato)-Bridged Binuclear Co^{II} Complex

Didier Bonnet,[a] Philippe Leduc,[a] Eckhard Bill,[b] Geneviève Chottard,[c] Daniel Mansuy,[a] and Isabelle Artaud*[a]

Keywords: Cobalt / S ligands / Electrochemistry / Raman spectroscopy / N ligands

Two different ligands [$S_2N_3^{py}$] and [S_2N_2], prepared from 2,6-bis[1-(2-mercaptoanilino)ethyl]pyridine and 2,3-bis(2-mercaptoanilino)butane, respectively, have been used to investigate cobalt coordination with mixed amine nitrogen/sulfur donor sets. The pentadentate [$S_2N_3^{py}$] ligand gave rise to a mononuclear [$Co^{II}(S_2N_3^{py})$] complex, which was found to be stable only at low temperatures under argon, and was characterized as having a high-spin Co^{II} state on the basis of ^1H NMR and EPR measurements. In contrast, the tetradentate [S_2N_2] ligand led to a binuclear bis(μ-thiolato) $[Co^{II}(S_2N_2)]_2$ complex, the structure of which was solved by X-ray crystallography. Each Co^{II} centre was found to reside in an N_2S_3 square-pyramidal environment in the crystal, the two Co atoms being bridged by one of the two thiolates of an [S_2N_2] ligand. On the basis of the temperature dependence of the magnetic susceptibility, the two Co^{II} centres were found to be in a low-spin state and slightly antiferromagnetically coupled with an absolute J value of less than 3 cm^{-1}. In aerated CH_2Cl_2 in the presence of CH_3SO_3H, the binuclear complex proved to be stable in its mixed valence state, [Co^{II}/Co^{III}], which could be converted back to [Co^{II}/Co^{II}] upon addition of NBu_4OH in MeOH. Three different stable oxidation states could be characterized by electro- and spectroelectrochemistry (E [Co^{II}/Co^{II}]/[Co^{II}/Co^{III}] = –0.19 V, E [Co^{II}/Co^{III}]/[Co^{III}/Co^{III}] = 0.2 V vs. SCE). The electronic spectrum of the [Co^{II}/Co^{II}] state features a broad absorption at 630 nm and a sharp band at 565 nm, while that of the [Co^{II}/Co^{III}] state shows two bands at 657 and 800 nm. The Raman spectrum of the [Co^{II}/Co^{II}] state was found to be dominated by a Co_2S_2 core vibration at 223 cm^{-1}, which proved to be strongly resonance-enhanced within the 565 nm absorption band, thus giving a sound basis for its assignment as an S→Co^{II} charge-transfer band. For the [Co^{II}/Co^{III}] state, a significant resonance Raman enhancement was observed within the 657 nm absorption band for a larger number of vibrations involving the Co_2S_2 core as well as the phenyl ring.

Introduction

While mixed nitrogen/sulfur coordination spheres about transition metals are often encountered in the active sites of iron-, copper-, and zinc-containing proteins,[1] only a few enzymes have a cobalt centre with a mixed N/S donor set, such as ATP sulfurylase,[2] nitrile hydratase,[3] and peptide deformylase.[4] The first two of these possess a native cobalt centre, which has been spectroscopically characterized. In contrast, peptide deformylase, which naturally contains iron or nickel as the metal centre for catalytic amide hydrolysis, has been characterized by X-ray crystallography of a cobalt-substituted form. ATP sulfurylase and peptide deformylase contain four-coordinate Co^{II} centres, with NS_3 and N_2SO donor sets, respectively. Co nitrile hydratases have a low-spin Co^{III}, which is thought to be six-coordinate with an N_2S_3 core, by analogy with the more extensively characterized iron-containing enzymes. These newly identified cobalt biological systems have fostered a growing interest in the investigation of new cobalt complexes with mixed nitrogen/sulfur coordination spheres.

In this study, we describe the synthesis and the spectroscopic characterization of two new Co^{II} complexes, a [$Co^{II}(S_2N_3^{py})$] mononuclear species and a $[Co^{II}(S_2N_2)]_2$ dimer derived from 2,6-bis[1-(2-mercaptoanilino)ethyl]pyridine and 2,3-bis(2-mercaptoanilino)butane, respectively. The binuclear complex, for which the structure has been solved, is easily converted in CH_2Cl_2 into the mixed valence state [Co^{II}/Co^{III}] and into the fully oxidized state [Co^{III}/Co^{III}].

Results and Discussion

Synthesis of the Ligands and Complexes

Thiolate-ligated zinc template complexes [S_2N_2Zn] (**1**) and [$S_2N_3^{py}Zn$] (**3**) (Scheme 1) were prepared in three steps according to published procedures:[5−7] (i) condensation of 2-aminobenzenethiol with 2,3-butanedione and 2,6-diacetylpyridine for **1** and **3**, respectively, (ii) opening of the resulting bis(benzothiazolyl) compound with zinc acetate, and (iii) reduction[6] of the zinc complex imine functions with $NaBH_4$.

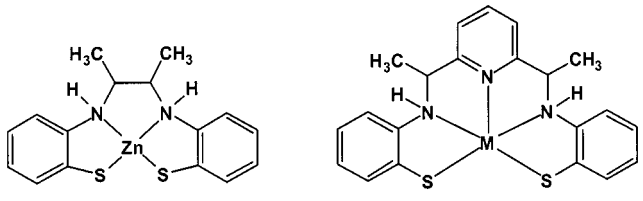

Scheme 1

After demetallation of the zinc derivatives under basic conditions, the free dithiolate ligands were metallated with $CoCl_2 \cdot 6H_2O$ in the presence of a slight excess of base. Complex $[Co^{II}(S_2N_2)]_2$ (**2**) was isolated as a microcrystalline purple powder by precipitation from a solution in dichloromethane by the addition of pentane. In contrast to complex **2**, which was found to be air-stable, complex $[Co^{II}(S_2N_3{}^{py})]$ (**4**), isolated from DMF by precipitation with diethyl ether, proved to be sensitive to trace amounts of dioxygen and consequently had to be handled under argon and at low temperature.

Characterization of Complex 2

Crystal Structure

Single crystals of **2** were grown by vapor diffusion of pentane into a dichloromethane solution of the complex. The ORTEP diagram of the neutral complex **2** is shown in Figure 1. Collection parameters and selected interatomic distances along with bond angles are listed in Table 1 and 2, respectively.

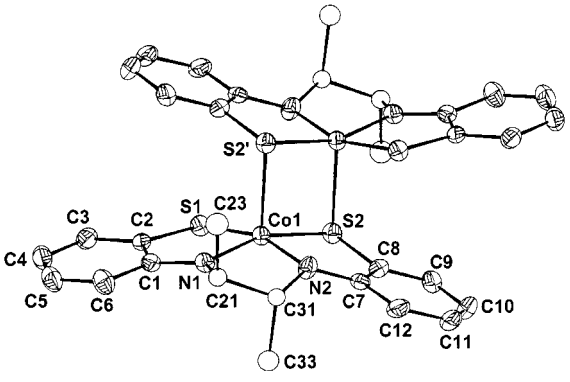

Figure 1. Thermal ellipsoid plot (50% probability level) of the neutral complex $[L_1Co^{II}]_2$ (**2**); carbon atoms C21, C23, C31, C33 are disordered and correspond to two equiprobable *trans* conformations of the methyl groups

The X-ray structure of the binuclear complex **2** reveals a nearly ideal square-pyramidal environment for each cobalt centre, with the four atoms (2 N and 2 S) of an S_2N_2 ligand in the mean equatorial plane and the thiolate of the second $[S_2N_2Co]$ moiety in the axial position. The two cobalt centres are connected through an inversion centre. The average lengths of the Co−S and Co−N bonds in the mean plane are 2.17 Å and 1.85 Å, respectively. These values are in agreement with those previously reported for a binuclear Co^{II} complex derived from thiosalen $[tsalenCo^{II}]_2$.[8] The four atoms (2 N and 2 S) are almost coplanar and deviate by no more than 0.07 Å from the mean plane, while the cobalt cation is displaced by 0.32 Å towards the axial ligand. With a dihedral angle between the (C1−C6, S1, N1) and (C7−C12, S2, N2) planes of only 4°, the two aromatic rings and the S_2N_2 core of the ligand are almost coplanar. The axial Co−S distance (2.37 Å) of the μ-thiolato bridge is 0.2 Å longer than the Co−S bond in the mean plane and is similar to that observed in $[tsalenCo^{II}]_2$ [Co−S(bridging) 2.44 Å].[8] Such a sulfur-bridging bis(μ-thiolato) mode has previously been observed in binuclear Co^{II} [8] and Fe^{II} [9] complexes derived from a tetradentate tsalen (N_2S_2) ligand, as well as in binuclear Co^{III} complexes derived from a

pentadentate N_3S_2 ligand[10] or a bidentate S_2 ligand.[11,12] As for all the other Co(μ-SR)$_2$Co dimers, the two sulfur atoms of the bridge and the two Co atoms are almost planar with a slight tetrahedral distortion, the (Co1−S2−Co′1) angle being close to 90° (97°). The structural parameters of **2** confirm the presence of two amine ligands with C21−N1 and C31−N2 bond lengths of 1.47 Å and 1.54 Å, respectively. If a dehydrogenation had occurred, the C−N distances of the corresponding imines would have been in the range of 1.2−1.3 Å.[13,14] Interestingly, the ESI^+ mass spectrum of **2** displays a 100% peak at $m/z = 718$, which corresponds to the mass of the dimer after the loss of four protons. This could result from the formation of one imine moiety per monomer during the ionization process. Such a dehydrogenation reaction of $[S_2N_2]$ has previously been observed in the one-electron reduction of a dioxomolybdenum complex $[S_2N_2Mo^{VI}O_2]$.[15]

Magnetism, EPR, and ^{1}H NMR

The temperature dependence of the magnetic susceptibility of a solid sample of the binuclear complex **2** was recorded over the range 290−4 K. The effective magnetic moment was found to have a value of 2.92 μB (1.46 μB per Co) at 290 K and dropped to 1.4 μB at 4 K (Supporting Information). This behaviour is consistent with the presence of two low-spin Co^{II} ions, antiferromagnetically coupled with an absolute J value of less than 3 cm^{-1} [$H = -2J\cdot\boldsymbol{S}_1\cdot\boldsymbol{S}_2$] (a tentative fit leading to $J = -\mathbf{1.6}$ cm^{-1} is shown in the Supporting Information). As expected for two antiferromagnetically coupled Co^{II} ions, complex **2** is EPR-silent. However, its ^{1}H NMR spectrum in [D$_6$]DMSO (Supporting Information) at 290 K extends over 270 ppm and is consistent with the two Co^{II} centres being only slightly coupled at this temperature. The ^{1}H NMR spectrum is completely symmetrical featuring only six shifted resonances. This suggests that the interconversion between the two conformations observed in the solid state is rapid in relation to the NMR time scale. Moreover, the S_2N_2 ligand seems to be planar with such a weak interaction between the two cobalt centres that the complex could be regarded as a monomer. The proton resonances of the ligand were assigned on the basis of their chemical shifts, relative integrals, and ^{1}H longitudinal relaxation times (T_1) correlated to the Co···H distances available from the crystal structure, as described in the Exp. Sect. The signals at δ = −18 (12 H) and δ = +166 (4 H) were assigned to the methyl protons and to the equivalent H(21) protons, respectively. The four aromatic rings are equivalent. However, it is difficult to assign the resonances to H(3) and H(6) as well as to H(4) and H(5). The protons H(4) and H(5), being furthest from the cobalt centre, have the largest T_1 values and are believed to be responsible for the signals at δ = +12 and/or δ = +16.5. Finally, the resonances at δ = −107 and δ = −111 were assigned to H(3) and/or H(6).

Electronic Spectra and Stability Towards O_2

In DMF under anaerobic or aerobic conditions, the electronic spectrum of complex **2** exhibits a complex pattern, as is often reported for Co^{II} complexes. It consists of a broad band centred at 630 nm [1000 L mol^{-1} cm^{-1}] with secondary maxima on the high energy side that are roughly spaced by 1300 cm^{-1}, the first maximum appearing at 565 nm [2500 L mol^{-1} cm^{-1}]. The 565-nm band is assigned to a thiolate-to-cobalt S→Co^{II} charge-transfer band on the basis of the resonance Raman experiments described below, whereas the broad band located at 630 nm should correspond to the superimposition of several d-d transitions very close in energy. In CH_2Cl_2 under anaerobic conditions, complex **2** not only exhibits an absorption at 565 nm, as it does in DMF, but also two other bands at 657 nm and 800 nm. Upon exposure to air, the blue-purple CH_2Cl_2 solution turned deep-blue and the spectrum obtained thereafter featured only a sharp absorption at 657 nm (5500 L mol^{-1} cm^{-1}) and a small one at 800 nm (1400 L mol^{-1} cm^{-1}). Thus, the spectrum of the dimer in CH_2Cl_2 under argon is that of a mixture of two species **2** and **2a** characterized by absorptions at 565 nm and 657/800 nm, respectively. In this solvent, complex **2** is obtained exclusively after adding 1 equiv. of NBu_4OH in MeOH, while complex **2a** is formed after adding 1 equiv. of CH_3SO_3H in the presence of dioxygen. The absolute requirement of dioxygen to convert **2** into **2a** under acidic conditions suggests that **2a** is probably an oxidized state of **2**. Finally, we note that under the conditions defined above, the conversion of **2** into **2a** is reversible, both in DMF and in CH_2Cl_2 [Equation (1)].

$$\mathbf{2} \underset{NBu_4OH,\ MeOH}{\overset{MeSO_3H,\ air}{\rightleftharpoons}} \mathbf{2a} \qquad (1)$$

Electro- and Spectroelectrochemistry

The cyclic voltammogram of **2** in DMF at 25 °C displays two quasi-reversible waves of equal intensity located at $E_1 = -0.19$ and $E_2 = +0.05$ V vs. SCE (Supporting Information). This indicates that **2** retains its binuclear [Co^{II}−Co^{II}] structure in DMF solution. On using NBu_4PF_6 instead of NBu_4Cl as the supporting electrolyte, the second oxidation wave was seen to be shifted from +0.05 to +0.2 V and became irreversible, suggesting that chloride anions were required to observe a reversible second oxidation of **2**.

The cyclic voltammogram of **2** obtained at 25 °C in CH_2Cl_2 containing NEt_4Cl as the supporting electrolyte exhibits two quasi-reversible waves as in DMF, located at $E_1 = -0.19$ V and $E_2 = +0.2$ V (Figure 2, A). Nevertheless, in contrast to DMF solution, the zero-current potential in CH_2Cl_2 ($E_0 = -0.19$ V) corresponds to the first potential E_1, indicating that, in agreement with the UV/Vis experiments, both [$Co^{II}Co^{II}$] (**2**) and its first oxidized species [$Co^{II}Co^{III}$]$^+$ (**2a**) are present in solution. As expected for a metal-centred oxidation, the shapes of the cyclic voltammograms of the pure species **2a** and **2**, recorded after the addition of 1 equiv. of $MeSO_3H$ in the presence of dioxygen or of 1 equiv. of NBu_4OH, respectively, remained identical. Only the zero-current potentials were shifted, from $E_0' =$

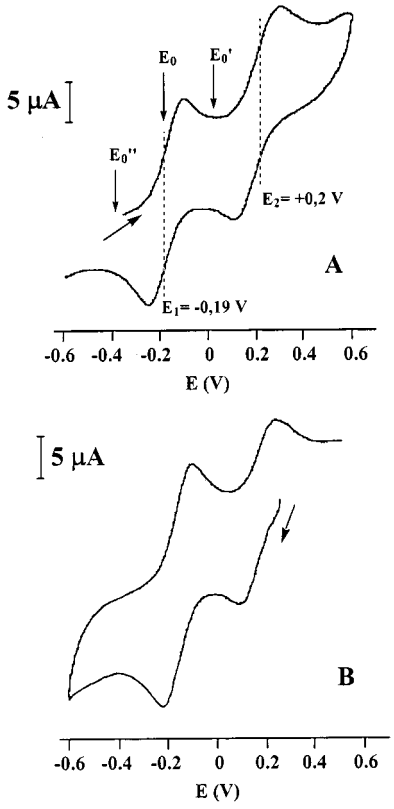

Figure 2. Cyclic voltammograms in CH_2Cl_2 solution at 25 °C (0.1 M Bu_4NCl; glassy carbon working electrode and saturated calomel reference electrode; 50 mV s^{-1}): A: $[Co^{II}Co^{II}]$ compound **2** ($\approx 10^{-3}$ M) obtained after addition of 1 equiv. of Bu_4NOH to a solution of $[S_2N_2Co]_2$ in dichloromethane; E_1 and E_2 correspond to $E_{1/2}$ potentials, E_0, E_0', and E_0'' to the zero-current potentials observed for the initial **2**/**2a** mixture in CH_2Cl_2 and for the unique species **2a** and **2** (obtained after addition of $MeSO_3H$ or Bu_4NOH), respectively; B: **2b** produced by electrolysis of a solution of **2a** at +0.45 V

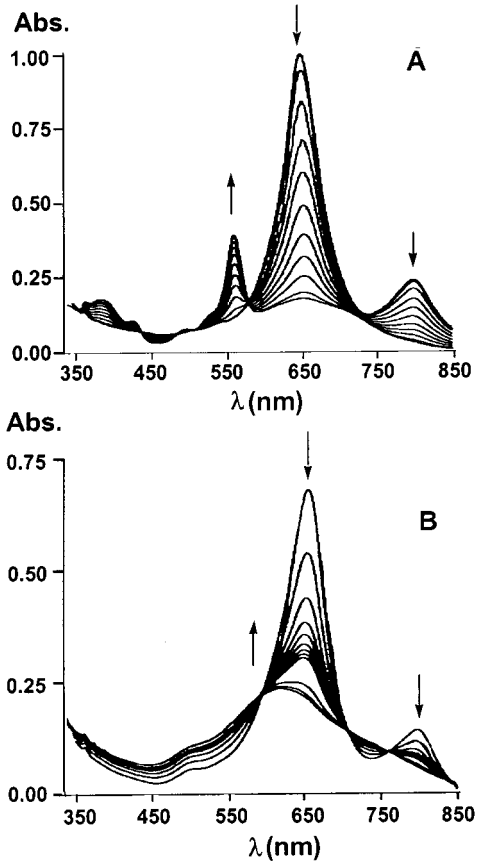

Figure 3. Spectroelectrochemistry of **2a** in CH_2Cl_2 at 25 °C: one-electron reduction (A) (isosbestic points: 435, 490, 585, 730 nm) and one-electron oxidation (B) (isosbestic points: 595, 715, and 795 nm) (conditions: [**2a**] $\approx 10^{-3}$ M with 0.1 M Bu_4NCl); the final spectra correspond to those of **2** and **2b**, respectively

−0.05 V for **2a** to $E_0'' = -0.27$ V for **2** (Figure 2, A). Any ligand-centred oxidation can be excluded since, using the zinc derivative **1**, the ligand is irreversibly oxidized in DMF at 560 mV vs. SCE.

To further investigate the electronic properties of the dimer, spectroelectrochemical reduction (Figure 3, A) and spectroelectrochemical oxidation (Figure 3, B) of **2a** were performed in CH_2Cl_2. Indeed, upon one-electron reduction of **2a** at −0.5 V, the characteristic UV/Vis spectrum of **2** was obtained. The one-electron oxidation of **2a** at 0.6 V led to a new species **2b**, exhibiting a broad absorption at 625 nm. Both reduction and oxidation were found to be reversible. The cyclic voltammogram of **2b** (Figure 2, B) displays the same characteristic binuclear pattern as seen for **2** and **2a**, with the exception of a zero-current potential of +0.45 V. Consequently, compound **2b** is proposed to be the fully oxidized binuclear Co^{III} complex $[LCo^{III}]_2^{2+}$. However, as chloride anions greatly increased its stability, it would be better described as a six-coordinate species $[LCo^{III}Cl]_2$.

Hence, complex **2** represents the first reported example of a bis(μ-thiolato) binuclear Co^{II} complex with a mixed nitrogen/sulfur environment, exhibiting three stable reversible oxidation steps in solution. Ghilardi et al.[16] have previously described a sulfide-bridged binuclear Co^{II}/Co^{III} complex and its corresponding di-Co^{II} and di-Co^{III} complexes, which were obtained by $NaBH_4$ reduction and $NOBF_4$ oxidation, respectively. However, none of the reduced or oxidized states were stable in solution. Both $[Co^{II}/Co^{II}]$ and $[Co^{II}/Co^{III}]$ states of the dimer were easily accessible in solution by treatment with acid or base. A similar reduction of Fe^{III} complexes in the presence of HO^- in MeOH or DMSO has been reported.[17] However, all attempts to crystallize the $[Co^{II}/Co^{III}]$ species failed since it reverted back to the $[Co^{II}/Co^{II}]$ complex in the solid state.

Raman Spectroscopy

The resonance Raman spectra of the $[Co^{II}/Co^{II}]$ and $[Co^{II}/Co^{III}]$ complexes in DMF solution, both recorded using an excitation frequency close to their respective visible absorption maxima, are shown in Figure 4. In the spectrum of **2**, two main bands are seen at 223 and 1295 cm^{-1}, while in that of **2a**, besides the same two bands, which are shifted

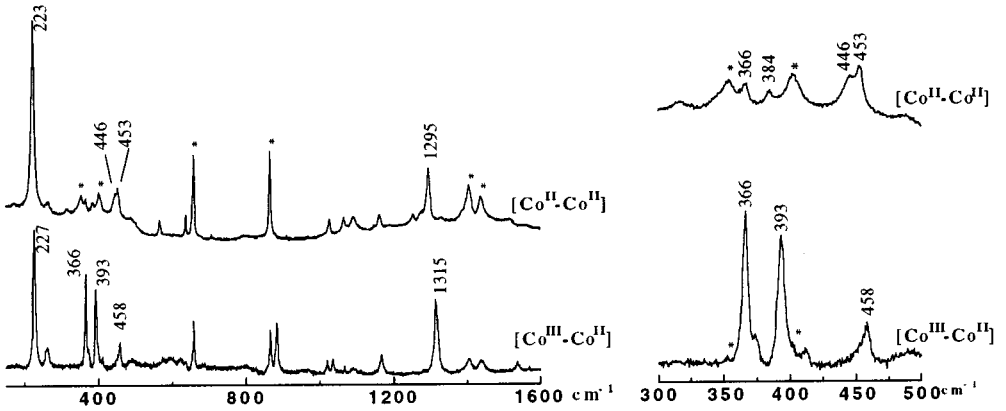

Figure 4. Resonance Raman spectra in DMF solution of the [$Co^{II}Co^{II}$] dimer **2** obtained with 568-nm excitation (upper trace) and of the [$Co^{II}Co^{III}$] complex **2a** obtained with 647-nm excitation (lower trace); * denotes solvent bands

to 227 and 1315 cm^{-1}, three additional bands with comparable intensities are seen at 366, 393, and 1019 cm^{-1}. Weaker bands are seen in the 1000−1150 cm^{-1} region for both complexes and in the 350−650 cm^{-1} region for the [Co^{II}/Co^{II}] complex.

The excitation profiles of these bands were established: They revealed a maximum at a wavelength close to the maximum of the strongest visible absorption band. For the [Co^{II}/Co^{II}] complex (Figure 5, A), an extremely strong enhancement factor was obtained for the 223 cm^{-1} band at 565 nm, at the maximum of the narrow absorption band; the other low-frequency bands were slightly enhanced, as were the high-frequency bands, with the exception of that at 1295 cm^{-1}, which displayed the second highest enhancement factor. We also note the selectivity of the enhancement of the low-frequency bands within the 565 nm band; in contrast, the high-frequency bands show residual intensity on the blue side of the absorption band. This is consistent with the assignment of the latter to phenyl ring vibrations, and of the former to cobalt ligand modes. The very strong and selective enhancement of the 223 cm^{-1} band and the presence of its first harmonic at 446 cm^{-1} suggest an A-term resonance (Franck−Condon mechanism). For the [Co^{II}/Co^{III}] complex (Figure 5, B), the low-frequency bands at 225, 366, and 393 cm^{-1} show the highest enhancement factors, followed by the 458, 1165, and 1315 cm^{-1} bands, the 1019 and 882 cm^{-1} bands being less enhanced.

To the best of our knowledge, no Raman data are available for binuclear bis(μ-thiolato)cobalt complexes, whereas numerous data on Fe−S and Cu−S vibrations have been reported, mainly for Fe−S and Cu−S proteins and some of their model compounds.[18,19] The M−S stretching vibrations have been located in the region 280−430 cm^{-1}. Raman bands in the region 400−280 cm^{-1}, resonance-enhanced within an absorption band at 510 nm, have also been observed for polymeric (thiolato)Co^{III} complexes, the structures of which have not been precisely determined.[20] Therefore, due to its low frequency, the most prominent band of the Co^{II} dimer cannot be assigned to a Co−S stretching vibration; it might correspond to the totally sym-

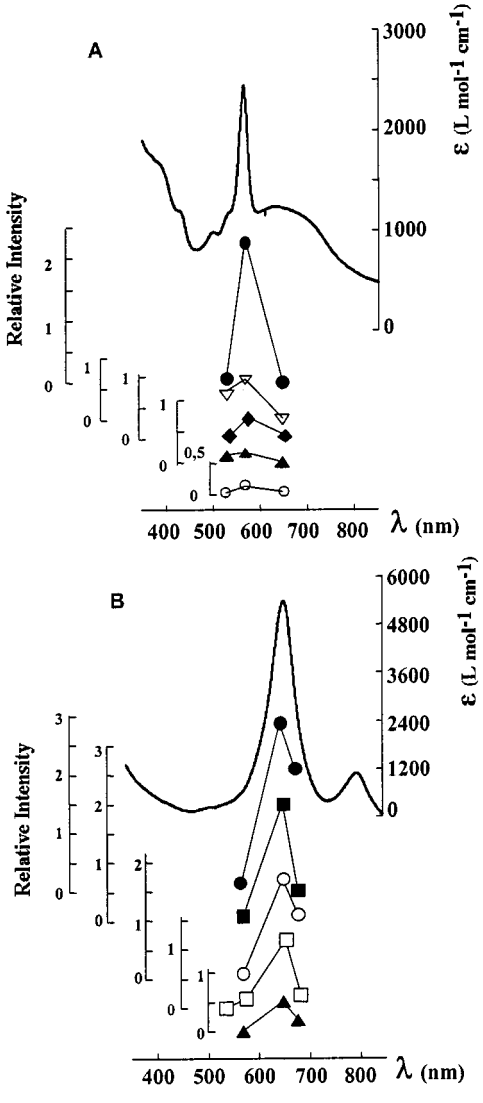

Figure 5. Absorption spectra and excitation profiles of the main Raman bands: A: **2**: ● 222 cm^{-1}, ○384 cm^{-1}, ◆ 453 cm^{-1}, ▲ 1162 cm^{-1}, ▽ 1295 cm^{-1}; B: [$Co^{II}Co^{III}$] dimer **2a**: ● 225 cm^{-1}, ■ 367 cm^{-1}, ▲ 459 cm^{-1}, □ 882 cm^{-1}, ○ 1315 cm^{-1}

metric bending mode of the Co1−S2−Co′1−S′2 core (involving both Co−S−Co and S−Co−S angular deformations): An analogous vibration has been observed at ca. 200 cm^{-1} for the Fe_2S_2 core in the model compound Fe_2S_2(*o*-xylenedithiolate)$_2$ [21] and has been considered as having Fe−Fe stretching character. The two stretching vibrations of the Co_2S_2 core might be located at 453 cm^{-1} (symmetric ring breathing) and 384 cm^{-1}, as these bands show significant enhancement within the 565-nm absorption band. The same three bands are present in the [Co^{II}/Co^{III}]$^+$ complex spectrum at slightly higher frequencies, i.e. 227, 458, and 393 cm^{-1}, respectively. The other strong low-frequency band at 366 cm^{-1} might be the $Co-S_{terminal}$ stretching mode that showed increased intensity in the mixed valence dimer.

Among the high-frequency bands, which correspond to vibrations of the phenylthiolate moiety, the band at ca. 1300 cm^{-1} was seen to be significantly enhanced: It might be analogous to the 1320 cm^{-1} band observed for catecholate complexes of human tyrosine hydroxylase, which has been assigned to a ring deformation of *ortho*-disubstituted benzene and proposed as a marker for bidentate catecholate-type coordination.[22]

Characterization of Complex 4

The electronic spectrum of **4** in DMF features an intense absorption at 420 nm [3000 mol^{-1} L cm^{-1}] and two weak bands at 640 and 350 nm. In the presence of dioxygen, a rapid change in the visible spectrum was observed, associated with complete degradation of the complex. This complex not only proved to be unstable towards dioxygen, but it had to be kept at low temperatures both in solution and in the solid state, otherwise it was very rapidly degraded. For this reason, we were unable to obtain a reliable elemental analysis or crystals suitable for X-ray analysis. Consequently, complex **4** could only be characterized at low temperatures by EPR and ^{1}H NMR spectroscopy. The X-band EPR spectrum in deaerated frozen DMF solution at 10 K (Figure 6) is consistent with a high-spin Co^{II} mononuclear complex. It shows a broad resonance at $g = 4.3$ and a small component at $g = 2$, the second derivative of which exhibits an eight-line hyperfine structure with a spacing of 100 G, a value typical of high-spin Co^{II} complexes. The ^{1}H NMR spectrum of **4** in [D_7]DMF, recorded at −40 °C under argon (Supporting Information), shows the 17 expected sharp signals in the range $\delta = -27$ to +161. The two methyl resonances were assigned to the signals at $\delta = +18$ and +14 on the basis of their integrals, which corresponded to three protons, whereas all the other peaks integrated as one proton.

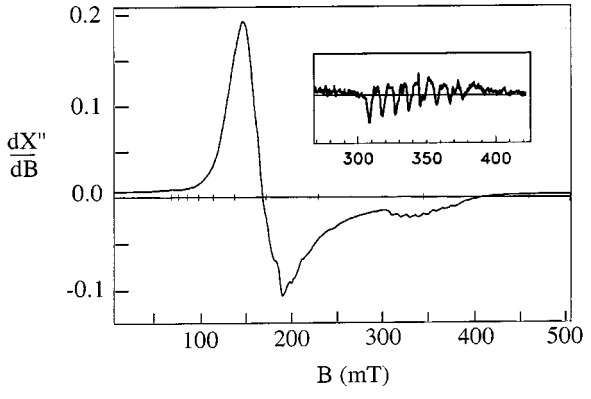

Figure 6. X-band EPR spectrum of **4** (ca. 5×10^{-4} M) in frozen DMF solution recorded at 10 K with a power of 10 mW (33 dB) at a frequency of 9.64 GHz; inset: second derivative signal (amplitude modulation)

Conclusion

Using two different amine/sulfur ligands, S_2N_2 and $S_2N_3^{py}$, we have obtained two new Co^{II} complexes. While the instability of the [$Co^{II}S_2N_3^{py}$] species prevented a complete study, the [$Co^{II}S_2N_2$]$_2$ dimer has been fully characterized both in the solid state and in solution. Its dimeric structure leads to an S_3N_2 coordination sphere for each Co centre, which is probably responsible for its increased stability; this complex can be reversibly oxidized by one and two oxidizing equivalents. A strong resonance Raman band at 220−230 cm^{-1} constitutes the vibrational signature of the Co_2S_2 core in the fully reduced as well as in the mixed valence state of the dimer.

Experimental Section

Caution: Attention is drawn to the highly toxic nature of 2-aminobenzenethiol. − All the syntheses were performed under argon using standard Schlenk techniques. All solvents were dried and distilled prior to use.

Physical Measurements: Electronic spectra were recorded with a Uvikon 820 double-beam spectrophotometer. − ^{1}H NMR spectra were recorded at 300 K with a Bruker ARX-250 spectrometer controlled by UXNMR software run with an Aspect 1 station. Chemical shifts are reported downfield from TMS. Magnetic susceptibilities of powder samples were measured in the range 2−293 K with a SQUID magnetometer (MPMS, Quantum Design) in a 1-T external magnetic field. Diamagnetic corrections were applied by using Pascal's constants. − X-band EPR spectra of samples in frozen solutions in quartz cells ($d = 0.3$ mm) were measured with a Bruker ESP 300E spectrometer operating at 9.5 GHz, equipped with an Oxford Instruments EPR 910 helium-flow cryostat. − Cyclic voltammetry and coulometric experiments were performed with Radiometer equipment using solutions containing 0.1 M tetrabutylammonium chloride (Bu_4NCl) or hexafluorophosphate (Bu_4NPF_6) as supporting electrolytes. The electrode system consisted of an NaCl-saturated calomel electrode (SCE) as the reference, a platinum auxiliary electrode, and a glassy carbon working electrode. The potential sweep rate was 50 mV s^{-1}. Ferrocene was used as an internal standard [$E_{1/2}$ (ferricinium/ferrocene) = +450 mV vs. SCE]. Spectroelectrochemistry was performed using an EG & G PAR-173 apparatus and a Varian spectrophotometer. − Electrospray mass spectra were measured from samples in dichloromethane solution. − Elemental analyses were carried out by the microanalysis service at the Paris VI University. − The crystal structure was solved by the X-ray service at the Paris VI University.

[S_2N_2Zn] {[2,3-Bis(2-mercaptoanilino)butane]zinc(II), 1}: The zinc complex **1** was prepared according to the published procedures of Bayer et al.[5] and Corbin et al.[6]

[$S_2N_2Co^{II}$]$_2$ (2): 2 equiv. of aqueous NaOH (108 μL of a 2 N solution) was added to a solution of [S_2N_2Zn] (40 mg, 0.11 mmol) in DMF (5 mL). After stirring for 10 min, the white precipitate of $Zn(OH)_2$ was removed. A solution of $CoCl_2{\cdot}6H_2O$ (26 mg, 1 equiv.) in DMF was then added dropwise to the free dithiolate ligand. Addition of aqueous NaOH (2 N, 50 μL) resulted in a purple solution of [$S_2N_2Co^{II}$]$_2$. After removal of the DMF in vacuo, the complex was redissolved in CH_2Cl_2 and precipitated by the addition of pentane. The microcrystalline purple precipitate was collected by filtration and washed with methanol (75 mg, 95% yield). Diffusion of pentane into a dichloromethane solution of **2** yielded purple crystals. − $C_{32}H_{36}Co_2N_4S_4{\cdot}0.5CH_2Cl_2$ (706.33): calcd. C 51.01, H 4.87, N 7.32; found C 50.9, H 4.2, N 7.4. − MS (ESI^+): *m*/*z* (%) = 718 (100) {[$S_2N_2Co^{II}$]$_2$ − 4 H; imine formation}. − ^1H NMR (250 MHz, [D_6]DMSO, in the presence of 1 equiv. of 1 M Bu_4NOH in MeOH; the proton resonances were assigned on the basis of their intensity ratios and ^1H longitudinal relaxation times (T_1), which have been correlated to the Co···H distances): CH_3: δ = −18 (s, 12 H), T_1 = 29 ms, Co(1)−C(23) = 3.583(18) Å; H(21): δ = +166 (s, 4 H), T_1 = 30 ms, Co(1)−C(21) = 2.855(15) Å; H(3) and/or H(6): δ = −101 (s, 4 H), T_1 = 32 ms, and δ = −107 (s, 4 H), T_1 = 61 ms, Co(1)−C(3) = 4.336(6) Å and Co(1)−C(6) = 4.167(7) Å; H(4) and/or H(5): δ = +12 (s, 4 H), T_1 = 261 ms and δ = +16.5 (s, 4 H), T_1 = 144 ms, Co(1)−C(4) = 5.263(6) Å and Co(1)−C(5) = 5.170(6) Å.

[$S_2N_3^{py}Zn$] ({2,6-Bis[1-(2-mercaptoanilino)ethyl]pyridine}zinc(II), 3): A solution of $NaBH_4$ (0.717 g, 4.5 mmol) in EtOH/DMF (1:4; 125 mL) was added dropwise to a solution of {2,6-bis[2-(2-mercaptophenyl)-1-methyl-2-azaethenyl]pyridine}zinc(II)[23] (2.0 g, 4.5 mmol) in DMF (120 mL) cooled to 0 °C. The initially red solution became progressively more orange. After stirring at room temperature for 2 h, the DMF and ethanol were removed in vacuo. The residual oil was dissolved in methanol and the product was precipitated by the addition of twice the volume of water. The resulting orange precipitate was isolated in quantitative yield (2.0 g, 100%). − $C_{21}H_{21}N_3S_2Zn$ (444.92): calcd. C 56.69, H 4.76, N 9.44; found C 56.93, H 4.84, N 9.24. − ^1H NMR (250 MHz, [D_6]DMSO): δ = 1.37 (m, 6 H, CH_3), 4.49 (d, 2 H, CH), 5.76 (m, 2 H, NH), 6.87 (m, 4 H, ArH), 7.13 (d, 2 H, ArH), 7.21 (d, 2 H, ArH), 7.68−8.12 (m, 3 H, pyrH). − MS (EI): *m*/*z* (%) = 443 (100) {[$S_2N_3^{py}Zn$] − H}, 428 (60) {[$S_2N_3^{py}Zn$] − CH_3 − H}, 318 (70) {[$S_2N_3^{py}Zn$] − C_6H_5S}.

[$S_2N_3^{py}Co^{II}$] (4): 2 equiv. of aqueous NaOH (2 N, 90 μL) was added to a solution of [$S_2N_3^{py}Zn$] (40 mg, 0.09 mmol) in DMF (5 mL). After removing $Zn(OH)_2$, a solution of $CoCl_2{\cdot}6H_2O$ (21 mg, 1 equiv.) in DMF was added dropwise to the free ligand solution to give a yellow-green solution of **4**. After partial evaporation of the DMF in vacuo, addition of anhydrous diethyl ether (40 mL) led to the deposition of a light-green precipitate, which remained stable only at 0 °C and under argon. The complex was stored at −40 °C and was handled under anaerobic conditions at low temperatures at all times. − ^1H NMR (250 MHz, [D_7]DMF, −40 °C): δ = −27.13 (s, 1 H), −25.47 (s, 1 H), −24.44 (s, 1 H), −20.19 (s, 1 H), −18.53 (s, 1 H), −14.23 (s, 1 H), −9.74 (s, 1 H), −4.31 (s, 1 H), +9.82 (s, 1 H), +11.96 (s, 3 H, CH_3), +14.09 (s, 1 H), +16.31 (s, 1 H), +18.31 (s, 3 H, CH_3), +94.06 (s, 1 H), +101.20 (s, 1 H), +108.83 (s, 1 H), +161.30 (s, 1 H).

X-ray Crystallographic Data and Structure Refinement: Crystals of $C_{32}H_{36}Co_2N_4S_4$ (**2**) suitable for X-ray analysis were obtained by vapour diffusion of pentane into a dichloromethane solution of the complex. A selected crystal of dimensions 0.2 × 0.3 × 0.4 mm was attached to the tip of a glass fibre. Accurate cell dimensions and an orientation matrix were obtained by least-squares refinement of 25 accurately centred reflections with a Nonius-CAD4 diffractometer using graphite-monochromated Mo-K_α radiation. The regular decay (ca. 28%) of two checked reflections data were scaled. Absorption corrections were applied using the DIFABS method with $T_{min.}$ = 0.86 and $T_{max.}$ = 1.[24] Collection parameters and selected crystallographic data for **2** are listed in Table 1 and 2. The data were corrected for Lorentz and polarization effects. Computations were performed using the PC version of CRYSTALS.[25] Scattering factors and corrections for anomalous dispersion were taken from Cromer.[10] The structure was solved by direct methods using SHELXS[27] and refined by full-matrix least squares with anisotropic thermal parameters for all atoms except disordered carbon atoms. The four carbon atoms of the 1,2-dimethylethyl bridge were disordered and were each located in two different sites with occupancies of 0.5, namely (C-21, C-22), (C-23, C-24), (C-31, C-32), (C-33, C-34). The complex is made up of two asymmetric units related through an inversion centre. Hence, all the unlabelled atoms are related to the labelled ones through the inversion centre symmetry operation. Atoms C-22, C-24, C-32, and C-34 are omitted for the sake of clarity. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-151295. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail deposit@ccdc.cam.ac.uk]

Resonance Raman Spectroscopy: The resonance Raman spectra were obtained with a J. Y. U1000 double monochromator, equipped with an AsGa photomultiplier and photon-counting electronics. Excitation wavelengths from Ar^+ and Kr^+ lasers (30−50 mW power) were used. The mechanical slit width was set at 400 μm, so that the spectral slit width varied from 2 cm^{-1} at 676.4 nm to 4 cm^{-1} at 528.7 nm. The complexes were studied in CH_2Cl_2 and DMF solutions in a rotating cell (concentration 1 mM). The 657 cm^{-1} band of DMF was used to measure the relative intensities of the bands (based on peak heights) at the various excitation wavelengths.

Supporting Information: Figures S1−S6 show the magnetic susceptibility of **2** as a function of temperature, the cyclic voltammogram of **2** in DMF, the ^1H NMR spectrum of **2**, the ^1H NMR spectrum of **4**, and the resonance Raman frequencies of **2** and **2a** (see footnote on page 1).

Dinuclear Zinc(II)−Iron(III) and Iron(II)−Iron(III) Complexes as Models for Purple Acid Phosphatases

Sabine Albedyhl,[c] Marie Therese Averbuch-Pouchot,[a] Catherine Belle,*[a] Bernt Krebs,*[c] Jean Louis Pierre,[a] Eric Saint-Aman,[b] and Stephane Torelli[a]

Keywords: $Zn^{II}Fe^{III}$ complex / $Fe^{II}Fe^{III}$ complex / Purple acid phosphatases / Phosphate ester hydrolysis

The heterodinuclear $Zn^{II}Fe^{III}$ complex **1** and the isostructural $Fe^{II}Fe^{III}$ complex **2** with the dinucleating ligand from 2,6-bis[{bis(2-pyridylmethyl)amino}methyl]-4-methoxyphenol (HBPMOP, **3**) were prepared and characterized by X-ray crystallography. Solution studies (UV/Vis spectroscopy; electrochemistry) are described. A pH-induced change in the coordination spheres of the metal centers is seen. These complexes serve as models for the mixed-valence oxidation state in purple acid phosphatases. The cleavage acceleration of the activated phosphodiester 2-hydroxypropyl *p*-nitrophenyl phosphate (HPNP) was investigated in acetonitrile/water (1:1) in the presence of complexes of the ligand BPMOP and its methyl analogue BPMP with regards to its dependence on the pH value. At the optimum pH value (8.5 ± 0.2), the Zn^{II}-Fe^{III} complex from BPMOP shows a 2-fold higher rate acceleration compared with that of the complex containing BPMP. The diiron complex from BPMOP is 4-fold more reactive than the homologous complex from BPMP. The heterodinuclear $Zn^{II}Fe^{III}$ catalysts are at least 10-fold more reactive than the homonuclear $Fe^{II}Fe^{III}$ catalysts.

Introduction

Purple acid phosphatases (PAPs) catalyse the hydrolysis of activated phosphoric esters like *p*-nitrophenyl phosphate, naphthyl phosphate or ATP, at a pH range from 4 to 7.[1] The active site of red kidney bean purple acid phosphatase (KBPAP) harbours an Fe^{III} and a Zn^{II} ion, while those of the mammalian PAPs, isolated from bovine spleen (BSPAP) or from porcine uterus, contain a diiron site in an $Fe^{II}Fe^{III}$ state for the active form. The inactive purple $Fe^{III}Fe^{III}$ form, involves two high-spin iron ions which are antiferromagnetically coupled ($-J > 150\ cm^{-1}$). In the active Fe^{II}-Fe^{III} pink form, the two iron ions are weakly antiferromagnetically coupled ($-J = 19.8\ cm^{-1}$). The crystal structure of KBPAP, firstly determined at a resolution of 2.9 Å[2] and further at 2.65 Å,[3] reveals a homodimeric 111 kDa enzyme, containing two domains in each subunit. In the active site, located in the carboxyl-terminal domain, the two metal ions are 3.26 Å apart and bridged by Asp164, each one involving octahedral coordination. The iron ion is further coordinated by Tyr167, His325, and Asp135 residues, and the zinc ion by His286, His323, and Asn201 residues. Three exogenous ligands are also included in the X-ray model to complete the coordination sphere: one terminal hydroxo ligand to the iron ion, one terminal water ligand to the zinc ion, and one μ-hydroxo group between the metal ions. The crystal structures of KBPAP complexed with phosphate (the product of the reaction) and with tungstate (a strong inhibitor), have also been determined[3] allowing the proposal of a mechanism for the hydrolysis of phosphomonoesters (Figure 1).

In the proposed mechanism, the phosphate group of the substrate binds to the zinc ion by displacing the presumed water ligand. The terminal Fe^{III}-bound hydroxide ion attacks the phosphorus atom to form a pentacoordinated intermediate, and the P−O bond, opposite from the hydroxide ion attack, breaks to form the leaving group and phosphate which is consistent with the inversion at the phosphorus atom. Another kinetically indistinguishable mechanism has been suggested,[4] involving a nucleophilic attack by a bridging oxide instead of iron-bound hydroxide.

In order to mimic the reactivity of PAPs, two isostructural dinuclear complexes, containing a $Zn^{II}Fe^{III}$ and an Fe^{II}-Fe^{III} center, respectively, have been prepared and studied with the aim of comparing their activity towards phosphate ester cleavage and to allow comparisons between KBPAP and BSPAP. The dinucleating ligand from HBPMOP, which is of the known HBPMP type[5,6] 2,6-bis[{bis(2-pyridylmethyl)amino}methyl]-4-methylphenol has been used. It bears a strong electron-donating methoxy group in the *para* position to the bridging phenoxo group: 2,6-bis[{bis(2-pyridylmethyl)amino}methyl]-4-methoxyphenol (**3**). Heterodinuclear $Zn^{II}Fe^{III}$ complexes have been described as models for the active site of KBPAP. The first heterodinuclear phosphate-bridged model compound, $[FeZn(BPMP)\{(O_2P(OPh)_2\}_2]$, could be obtained by using HBPMP.[5a] The Fe−Zn distance (3.695 Å) in this complex, is significantly larger than in the carboxylate-bridged complex (3.428 Å)[6] compared to the value of 3.33 Å measured on KBPAP in the presence of phosphate. Some other heter-

odinuclear $Zn^{II}Fe^{III}$ complexes have been described,[7−9] all of them containing symmetrical ligands. A Zn−Fe complex involving a constitutionally unsymmetrical ligand, but with identical chemical environments (two N_3O coordination spheres), has also been described in solution.[10] Mixed-valence phenoxo-bridged diiron complexes have also been reported as models for BSPAP by several authors.[5a,6,10−17] A recent review has been published, describing structural and functional model compounds of PAPs.[18]

Results and Discussion

Synthesis of the Complexes

The reaction of equimolecular amounts of $Zn(ClO_4)_2·6H_2O$ and $Fe(ClO_4)_3·H_2O$ with HBPMOP in methanol, yielded blue-green crystals of $[Zn^{II}Fe^{III}BPMOP\{O_2P(OPh)_2\}_2](ClO_4)_2·H_2O$ (**1**) after the addition of diphenyl phosphate. These were suitable for X-ray crystallography. Green crystals of $[Fe^{II}Fe^{III}BPMOP\{O_2P(OPh)_2\}_2](ClO_4)_2·H_2O$ (**2**) were obtained by the analogous reaction with 2 equiv. of $Fe(ClO_4)_3·H_2O$. The only metal species isolated was the mixed-valence diiron complex, indicating the participation of a redox process during complex formation. It is known that the diiron(III) species are strong oxidants, suggesting that the reductant is the methanol solvent.[6]

Crystal Structures of 1 and 2

Compounds **1** and **2** are isostructural complexes and are therefore described in comparison with each other. The triclinic elementary cells of **1** and **2** contain two formulas. The metal centers exhibit octahedral coordination. In the heterodinuclear complex **1** (Figure 2), the metal atoms are linked by a μ-phenoxo group from the ligand and by two μ-diphenylphosphato bridges with a distance of 3.7030(7) Å. The angle over Zn(1)−O(1)−Fe(1) is 122.9(1)°. The two iron centers in the analogous complex **2** (Figure 3) have a distance of 3.6400(6) Å, which is slightly shorter than the corresponding distance in **1**. The angle Fe(1)−O(1)−Fe(2) is 121.44(9)°. The nitrogen donor atoms from BPMOP complete the coordination sphere per facial coordination, resulting in an equivalent N_3O_3 donor set. Selected bond lengths and angles are given in Table 1.

The structure of **2** confirms the mixed valence state. The crystal structure of complex $[Zn^{II}Fe^{III}BPMP\{O_2P(OPh)_2\}_2](ClO_4)_2·1.5CH_3OH·H_2O$ which involves the same coordination sphere as in **1** has been reported.[5a] The Zn−Fe distance of 3.695(1) Å is in the range of the Zn−Fe distance in **1** [3.7030(7) Å]. This distance is significantly shorter in the carboxylate-bridged analogue [3.437(1) Å][6] and larger in the molybdato-bridged complex from 2,6-bis[{bis(2-pyridylmethyl)amino}methyl]-4-*tert*-butylphenol (HBPBP) [3.819(4) Å].[9] This can be due to the different bite distance of the phosphate group and therewith indi-

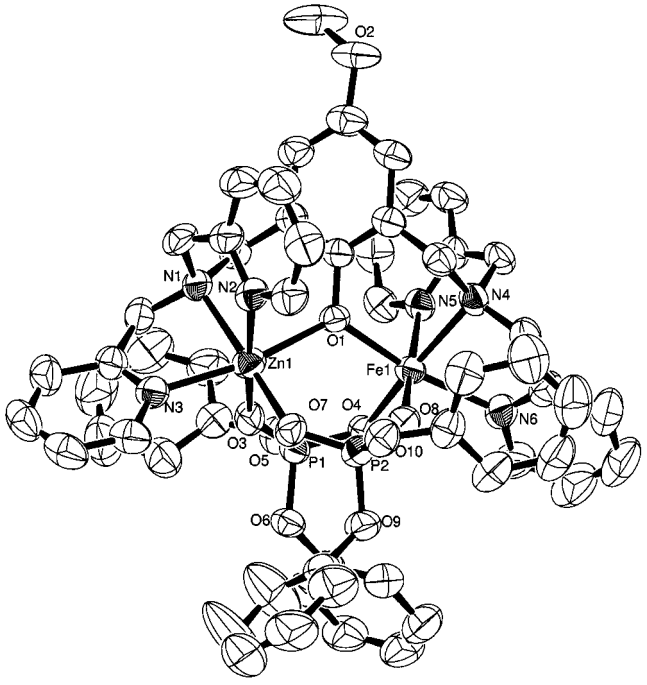

Figure 2. ORTEP molecular representation of complex **1** showing 50% probability displacement ellipsoids; H atoms, water molecule, and perchlorate ions have been omitted for clarity

cates a remarkable structural flexibility of the phenoxo-bridged intermetal(II,III) distance which may be important for the catalytic activity. The Zn−Fe distance in the native KBPAP is 3.33 Å in the presence of phosphate. The $Fe^{II}-Fe^{III}$ distance in **2** [3.6400(6) Å] is also significantly larger than in the carboxylate-bridged $Fe^{II}Fe^{III}$ complex from BPMP [3.365(1) Å][6] and slightly shorter than in the non-bridged $Fe^{II}Fe^{III}$ complex of the ligand BPBP [3.726(2) Å].[9]

Electronic Spectra

The main feature of the electronic spectra of **1** and **2** in acetonitrile is the LMCT transition from phenolate to iron(III) which is observed at λ_{max} = 654 nm ($\varepsilon \approx 900$) in **1** and 673 nm ($\varepsilon \approx 900$) in **2**, respectively. In addition, a shoulder is observed in **2**, at λ_{max} = 385 nm ($\varepsilon \approx 3000$) which can be assigned to a charge-transfer transition from Fe^{II} to pyridine. The analogous complexes from HBPMP[5a] show absorption maxima in methanol at λ_{max} = 569 nm ($\varepsilon \approx 800$) for the $Zn^{II}Fe^{III}$ complex and at λ_{max} = 610 nm ($\varepsilon \approx 950$) for the $Fe^{II}Fe^{III}$ complex. A shoulder in the spec-

trum of the latter is observed at λ_{max} = 365 nm ($\varepsilon \approx$ 3480).[6]

Electrochemistry

Although PAPs catalyse non-redox-active hydrolytic reactions, the catalytic activity is dependent on the oxidation state of the iron active site, the mixed-valence oxidation state being active towards the hydrolysis of the phosphate esters while the oxidized form is inactive. The determination of the electrochemical stability domain of synthetic models thus appears of prime importance. Electrochemical investigations by cyclic voltammetry (CV) of **1** in CH_3CN (Figure 4, A, curve 1) show two reversible one-electron waves at $E_{1/2}$ = 0.13 V and 1.36 V (vs. SCE). This is confirmed by rotating disc electrode (RDE) experiments. The RDE curve recorded under the same experimental conditions (Figure 4, A, curve 2) displays two well-behaved waves of very close intensity, without contamination of the $Fe^{II}Fe^{III}$ complex **2** electrochemical response (see below). The cathodic wave at $E_{1/2}$ = 0.13 V is attributed to the $Fe^{III}Zn^{II}/Fe^{II}Zn^{II}$ redox couple while the anodic wave corresponds to the ligand-based oxidation. The CV curve in CH_3CN of the BPMP analog of **1**, $[Zn^{II}Fe^{III}$ BPMP$\{O_2P(OPh)_2\}_2](ClO_4)_2 \cdot 1.5 \cdot CH_3OH \cdot H_2O$, shows a reversible one-electron transfer at a potential of 143 mV ($Fe^{III}Zn^{II}/Fe^{III}Zn^{II}$ redox couple) and a weak signal at +765 mV, which has been attributed to a slight contamination with Fe^{II}.[5a] The ligand-based oxidation is not observed in the accessible potential range. The electron-donating effect of the methoxy group in *para* position of the bridging phenolic moiety causes a stabilization of the oxidized form of the BPMOP ligand compared to the non-substituted BPMP ligand. In the case of **2**, two reversible one-electron waves are observed on the CV curve (Figure 4, B, curve 1) at $E_{1/2}$ = 0.12 V and 0.74 V (vs. SCE) which are assigned to the redox couples $Fe^{II}Fe^{II}/Fe^{II}Fe^{III}$ and $Fe^{II}Fe^{III}/Fe^{III}Fe^{III}$, respectively. The RDE curve (Figure 4, B, curve 2) is characterized by one cathodic and one anodic wave confirming the mixed-valence character of **2**.

Similar results have been found in the CV behavior of $[Fe^{II}Fe^{III}BPMP\{O_2P(OPh)_2\}_2](ClO_4)_2 \cdot CH_3OH \cdot H_2O$ ($E_{1/2}$ = +135 mV and +755 mV, respectively[5a]). Comparing the electrochemical features of **1** or **2** with those of their BPMP analogs, only a weak cathodic shift, around 20 mV, in the metal-centered electron transfers, are observed, i.e. the substitution by the methoxy group in the *para* position on the bridging phenolic moiety in **1** and **2** did not markedly influence the metal-centered electron transfer potential. From the separation of the redox potentials in **2**, we have determined the stability of the mixed-valence form of **2** by evaluating the comproportionation constant, K_{com}, for the equilibrium according to Equation (1).

$$Fe^{II}Fe^{II} + Fe^{III}Fe^{III} \rightarrow 2\,Fe^{II}Fe^{III},\ \Delta E_{1/2} = (RT/F) \cdot \ln(K_{com}) \qquad (1)$$

Using $\Delta E_{1/2}$ = 0.62 V, a value of $3.0 \cdot 10^{10}$ ($\Delta G = -59$ kJ mol^{-1}) is found, which is close to the value of $3.2 \cdot 10^{10}$ determined for the BPMP analog of **2**. Electron delocalization, electrostatic interaction and steric interaction are the main factors involved in the magnitude of K_{com} although, considering related complexes,[5b] the electron delocalization energy has been found to be too small to contribute significantly to the mixed-valence state stability. Electrostatic interactions may strongly influence the stability domain. Taking into account the close proximity of the two metal ions, the II,II form of the complex will be more readily oxidized than the II,III form leading to an increase in the stability domain of **2**. On the other hand, by comparing other related synthetic models of PAPs,[11,13] it is shown that the replacement of pyridyl groups in phenoxo-bridged diiron complexes by one and two phenolate terminal groups leads to a cathodic shift in the redox potentials by ca. −0.4 V and −1.0 V, respectively, the stability domain ranging between 0.5 and 1.0 V according to the substitution on the phenoxo-bridging ligand and to the exogeneous ligands. It must also be noticed that porcine purple acid phosphatase (uteroferrin) has a reduction potential ($Fe^{III}Fe^{III}/Fe^{II}Fe^{III}$ redox couple) of 367 mV[19] vs. NHE (i.e. 122 mV vs. SCE). This is close to the value of 0.12 V found for **2**.

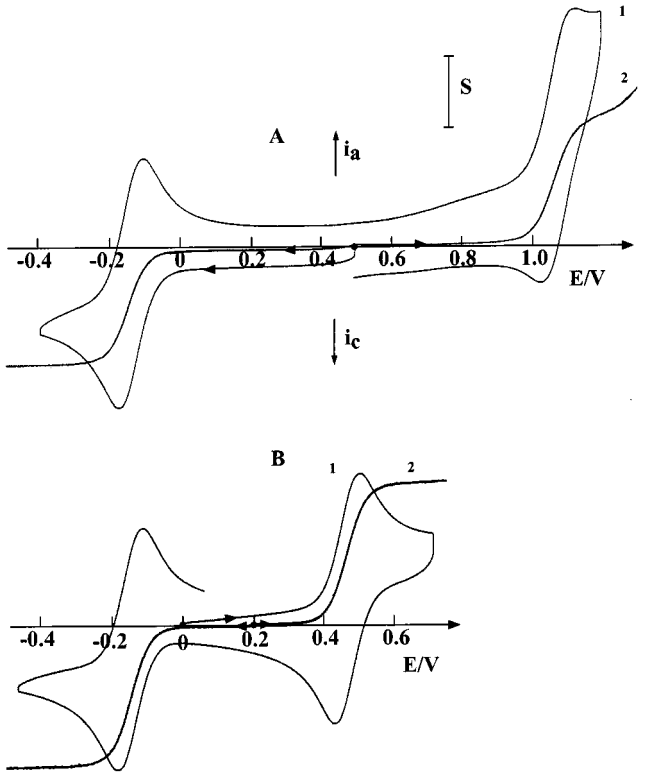

Figure 4. Voltammograms of **1** (A) and **2** (B), 0.9 mM, in CH_3CN + TBAP (0.1 M); *E* vs. $Ag/AgNO_3$ (10 mM) (+339 mV vs. SCE); curve 1: CV at a vitreous carbon disc electrode (5 mm diameter), v = 0.1 Vs^{-1}, *S* (scale) = 20 μA; curve 2: voltammetry at the RDE (3 mm diameter), 600 rpm, S = 10 μA

pH-Induced Changes in the Coordination Sphere

A UV/Vis titration (monitoring of the LMCT band) of a solution of HBPMOP and equimolar amounts of zinc(II) perchlorate and iron(III) perchlorate has been performed in acetonitrile/water (1:9) upon addition of concentrated aqueous solution of NaOH or $HClO_4$ (Figure 5). In the pH range 1.95−3.35, an isosbestic point is observed at 575 nm

indicating the presence of only two absorbing species (Figure 5, A). The spectrophotometric data were fitted and the calculations afforded a pK_1 value of 2.8±0.05. Another equilibrium occurs at higher pH values. At pH ≈ 5, the colour of the solution turns from blue to brown and a new isosbestic point is detected at 525 nm in pH range 4.5−6.1 (Figure 5, B).

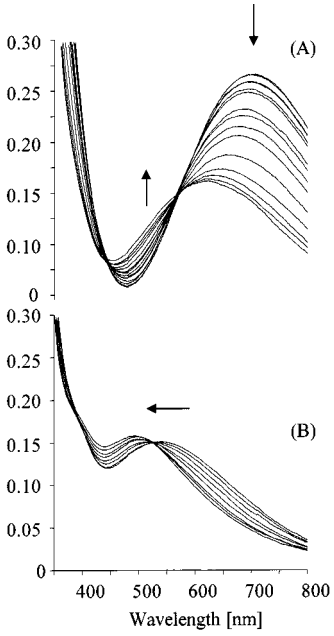

Figure 5. UV/Vis titration curves in acetonitrile/water of **1** as a function of the pH value: (A) in the range of 1.95 < pH < 3.35 and (B) in the range of 4.5 < pH < 6.1; arrows indicate the spectral trends upon increasing the pH value

The fitting of the values of absorbance vs. pH leads to a pK_2 = 4.9±0.26. The species distribution curves are shown in Figure 6, providing evidence for three pH-dependent species. It must be emphasized that the pH-driven conversion between these species is reversible. Same results were obtained by decreasing or increasing the pH value of the solution.

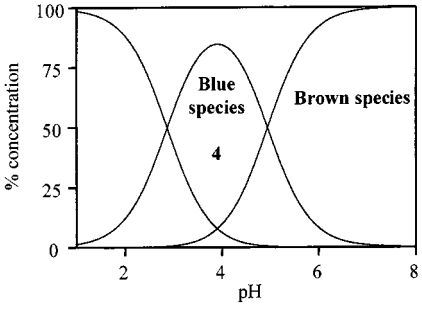

Figure 6. Species distribution curves of **1** as a function of the pH value

Attempts to isolate the pure products involved in this titration have not yet proved successful. Nevertheless by independent preparations, a blue product (**4**) was obtained by addition of equimolecular amounts of $Zn(ClO_4)_2 \cdot 6H_2O$ and $Fe(ClO_4)_3 \cdot H_2O$, dissolved in water, to a solution of HBPMOP in acetone and precipitation as a powder after addition of diethyl ether. The positive ion FAB mass spectrum of **4** exhibits a parent peak corresponding to the respective heterodinuclear core (no peak corresponding to the homodinuclear Zn−Zn or Fe−Fe species was observed). The molecular ion peak is m/z = 681 and corresponds to $[ZnFeBPMOP(OH)]^+$. The electronic spectrum of **4** in acetonitrile shows one absorption maximum at λ_{max} = 661 nm (ε = 2200); this band is shifted to 585 nm (ε = 900) in a solution of acetonitrile/water (1:9). In addition, the UV/Vis spectra of the titration described above, in the intermediate pH range 3−5 (Figure 6), exhibit the same features as the spectrum of the isolated complex **4** for which we propose a μ-OH-bridged heterodinuclear compound. At higher pH values (> 6), the brown species is formed following progressive and reversible deprotonation of **4**. This species will prove to be the active species towards the cleavage of phosphate diesters (vide infra). One possibility is that this complex has at least one pendant hydroxo ligand. Another possibility is that the bridging μ-OH (**4**) was deprotonated to form a μ-oxo ligand between the two metallic ions.[4]

Cleavage of Phosphate Diesters

Model studies have shown that simple dinuclear metal complexes can provide rate accelerations for hydrolyzing phosphate esters, shedding light on how metal ions may promote these reactions.[20−28] A heterodinuclear $Zn^{II}Fe^{III}$ complex has been reported by Komiyama et al. which hydrolyses RNA.[8]

In order to test the activity of complexes towards phosphate ester hydrolysis or cleavage, activated phosphoric acid esters are used. In this work 2-hydroxypropyl *p*-nitrophenyl phosphate (HPNP) was applied. In the absence of the metallocatalysts, HPNP is very stable.[24] The pH dependence of the HPNP cleavage acceleration, in the presence of $Zn^{II}Fe^{III}$ or $Fe^{II}Fe^{III}$ [29] complexes from the ligands BPMOP and BPMP respectively, has been studied. The rate increases corresponding to the pH and optimum values were obtained at pH = 8.5±0.2. The rate constant (k_{uncat}) for background hydrolysis was similarly obtained. Some observed rate constants are listed in Table 2. The rate acceleration was also measured in dependence of the substrate and complexes concentration, showing first order dependence in each case.

Table 2. Observed pseudo-first-order rate constants for transesterification of HPNP hydrolysis in CH_3CN/aqueous buffer CHES (1:1) at pH = 8.5 (± 0.2) and 25 °C with [catalyst] = 0.5 mM and [HPNP] = 0.82 mM

Catalyst	k_{obs} [$10^{-5}s^{-1}$]	k_{obs}/k_{uncat}
$[ZnFe(BPMOP)]^{4+}$	2.39	112
$[ZnFe(BPMP)]^{4+}$	1.14	54
$[Fe_2(BPMOP)]^{4+}$	0.227[a]	11
$[Fe_2(BPMP)]^{4+}$	0.065[a]	3
spontaneous	0.0213	1

[a] 10% of DMSO has been added to avoid precipitate.

The $Zn^{II}Fe^{III}$ complex of the ligand BPMOP shows a 2-fold higher rate acceleration compared with the complex

containing the ligand BPMP. The diiron complex from HBPMOP is 4-fold more reactive than the homologous complex from BPMP. The heterodinuclear $Zn^{II}Fe^{III}$ complexes from BPMOP and BPMP are 10-fold and 18-fold, respectively, more reactive than the corresponding homodinuclear $Fe^{II}Fe^{III}$ complexes. These differences in reactivities may be ascribed to the greater ability of the zinc center compared with the iron center, to coordinate the substrate. The optimum pH value for the hydrolysis of HPNP is notably higher than that for the enzymes. This observation confirms the necessity of a deprotonation process as underlined with the enzymes.[1b] The different activities of the complexes of BPMOP and BPMP can be attributed to the stronger electron donating effect of the methoxy group compared with that of the methyl group in the *para* position to the bridging oxygen atom.

Experimental Section

All chemicals were obtained from commercial sources and used as received. Solvents were purified by standard methods before use. ***Caution:*** Although no problems were encountered during the preparation of perchlorate salts, suitable care should be taken when handling such potentially hazardous compounds.

Spectrometry: Fast-atom bombardment (FAB) mass spectra in the positive mode were recorded with a Nermag R 1010C apparatus equipped with an M scan (Wallis) atom gun (8 kV, 20 mA). − UV/Vis spectra were obtained using a UVIKON 933 spectrometer of Kontron instrument equipped with 1.0-cm matched quartz cells and operating in the range 200−900 nm; ε values are given in $M^{-1}cm^{-1}$. − ^1H NMR and ^{13}C NMR spectra were recorded with a BRUKER AC 200 spectrometer at 25 °C, in $CDCl_3$ or $[D_6]$DMSO as solvent. Chemical shifts (ppm) were referenced to residual solvent peaks.

Electrochemistry: Electrochemical experiments were carried out using a PAR model 273 potentiostat equipped with a Kipp-Zonen *x-y* recorder. All experiments were run at room temperature under argon. A standard three-electrode cell was used. For the experiments performed in acetonitrile as solvent, potentials are referenced to an Ag/10 mM $AgNO_3$ reference electrode with 0.1 M tetra-*n*-butylammonium perchlorate (TBAP) as supporting electrolyte. Vitreous carbon disc electrodes for cyclic voltammetry (CV) (5 mm diameter) and rotating disc electrode (RDE) (3 mm diameter) were polished with 1 μm diamond paste.

X-ray Data Collection and Crystal Structure Determinations: The main details dealing with the diffraction data collections and the strategy used for the structure determinations are gathered in Table 3. The diffraction data were processed through the texSan software[30] for complex **1** and through the Collect Software Nonius BV for complex **2**.[31] Crystallographic data (excluding structure factors) for the two structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-140082 (**1**) and -140083 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Syntheses

HBPMOP: 2,6-Bis[{bis(2-pyridylmethyl)amino}methyl]-4-methoxyphenol has been synthesized in three steps from *p*-methoxyphenol.

2,6-Bis(hydroxymethyl)-4-methoxyphenol (5): To 4-methoxyphenol (10 g, 80.6 mmol) in 25 mL of methanol was added drop by drop a solution of sodium hydroxide (60 mL, 25%) under nitrogen at 0 °C. After 30 min of stirring, 120 mL of formaldehyde (37% in methanol) was added dropwise. The resulting mixture was refluxed during 12 h. Then the reaction mixture was neutralised at 0 °C to pH = 5 with 15 mL of pure acetic acid in 30 mL of water. Evaporation of the solvent yielded a solid. After addition of 200 mL of water, the product was extracted with ethyl acetate (3 × 200 mL). The combined organic layers were dried with sodium sulfate and concentrated to yield the crude product which was purified by flash chromatography (silica gel, ethyl acetate/cyclohexane, 1:1) and afforded **5** as a white powder (11.2 g, 75% yield); m.p. 114 °C. − ^{1}H NMR (200 MHz, [D$_6$]DMSO): δ = 3.66 (s, 3 H, OC*H*$_3$), 4.51 (s, 4 H, C*H*$_2$), 5.19 (s, 2 H, O*H*), 6.73 (s, 2 H, C*H*). − ^{13}C NMR (50 MHz, [D$_6$]DMSO): δ = 55.8, 59.9, 111.6, 130.4, 145.6, 153.0. − $C_9H_{12}O_4$ (184.19): calcd. C 58.69, H 6.57; found C 58.75, H 6.60. − MS (DCI, NH$_3$, isobutane): *m*/*z* = 202 [M$^+$ + NH$_4^+$], 184 [M$^+$].

2,6-Bis(chloromethyl)-4-methoxyphenol (6): 2,6-Bis(hydroxymethyl)-4-methoxyphenol (2.43 g, 13.2 mmol), suspended in 20 mL of dry dichloromethane under nitrogen atmosphere, was cooled with an ice bath. A solution of freshly distilled thionyl chloride (16 g, 132 mmol) in dry dichloromethane (20 mL) was added dropwise. The reaction was complete after 30 min. The excess thionyl chloride was removed in a rotary evaporator. The remaining solid was washed several times with dry pentane and 2.85 g (12.9 mmol, 98%) of **6** as a white powder was obtained. The product was used without any purification. − ^{1}H NMR (200 MHz, CDCl$_3$): δ = 3.77 (s, 3 H, OC*H*$_3$), 4.66 (s, 4 H, C*H*$_2$), 6.84 (s, 2 H, C*H*). − ^{13}C NMR (50 MHz, CDCl$_3$): δ = 42.4, 55.8, 116.1, 126.0, 146.7, 152.9.

2,6-Bis[bis(2-pyridylmethyl)aminomethyl]-4-methoxyphenol (3): 2,6-Bis(chloromethyl)-4-methoxyphenol (5.0 g, 22.6 mmol) and dry tetrahydrofuran (50 mL) were placed in a two-necked round-bottomed flask under nitrogen and the mixture was cooled with an ice bath. A solution containing dipicolylamine (9.0 g, 45.2 mmol), distilled triethylamine (15 mL, 90.4 mmol) and dry tetrahydrofuran (20 mL) was added dropwise. The reaction was controlled by thin-layer chromatography (ethyl acetate/dichloromethane, 1:1). After 2.5 d of stirring at room temperature, the reaction mixture was filtered, washed with tetrahydrofuran and the filtrate was concentrated to dryness. The resulting oil was dissolved in dichloromethane (150 mL) and water was added (100 mL). The organic phase was separated and the aqueous phase was extracted three times with dichloromethane (100 mL). The organic phases were combined and dried with sodium sulfate. Evaporation of the solvent yielded a yellow oil, which was further purified by flash chromatography (silica gel, acetone). Removal of the solvent afforded 8.9 g (16.3 mmol, 72%) of **3** as a pale yellow powder, m.p. 76 °C. − ^{1}H NMR (300 MHz, CDCl$_3$): δ = 3.75 (s, 3 H, OC*H*$_3$), 3.80 (s, 4 H, C*H*$_2$), 3.88 (s, 8 H, C*H*$_2$), 6.85 (s, 2 H, C*H*), 7.08−7.14 (m, 4 H, Py-*H*), 7.47−7.51 (m, 4 H, Py-*H*), 7.55−7.64 (m, 4 H, Py-*H*), 8.52 (d, *J* = 4.8 Hz, 4 H, Py-*H*), 10.9 (s, 1 H, O*H*). − ^{13}C NMR (75 MHz, CDCl$_3$): δ = 54.6, 55.5, 59.6, 114.1, 121.8, 122.7, 124.7, 136.4, 148.7, 149.5, 151.8, 159.0. − $C_{33}H_{34}N_6O_2$ (546.68): calcd. C 72.50, H 6.27, N 15.37; found C 72.55, H 6.25, N 15.41. − MS (DCI, NH$_3$, isobutane): *m*/*z* = 547 [M$^+$ + H$^+$].

[Zn^{II}Fe^{III}BPMOP{O$_2$P(OPh)$_2$}$_2$](ClO$_4$)$_2$·H$_2$O (1): To a solution of HBPMOP (23.5 mg, 0.043 mmol) in methanol (2 mL), a solution of Zn(ClO$_4$)$_2$·6H$_2$O (16.0 mg, 0.043 mmol) in methanol (1 mL) was added dropwise. Upon the subsequent addition of Fe(ClO$_4$)$_3$·H$_2$O (15.2 mg, 0.043 mmol), dissolved in methanol (1 mL), the solution turned blue-green. Diphenyl phosphate (21.6 mg, 0.086 mmol), dissolved in methanol (1 mL), was added and the solvent was allowed to evaporate slowly at room temperature. Blue-green crystals (13 mg, 0.010 mmol, 23%) suitable for X-ray crystallography were obtained after 2 d. − UV/Vis (acetonitrile): λ$_{max}$ = 654 (ε ≈ 900) nm. − FAB-MS (Matrix NBA): *m*/*z* = 1264 [{Zn^{II}Fe^{III}BPMOP[O$_2$P(OPh)$_2$]$_2$}ClO$_4$]$^+$. − $C_{57}H_{53}FeN_6O_{10}P_2Zn$·2ClO$_4$·H$_2$O (1382.18): calcd. C 48.53, H 4.01, N 6.08; found C 48.59, H 3.98, N 5.85.

[Fe^{II}Fe^{III}BPMOP{O$_2$P(OPh)$_2$}$_2$](ClO$_4$)$_2$·H$_2$O (2): Complex **2** was prepared in a similar manner to complex **1**. To a solution of HBPMOP (23.5 mg, 0.043 mmol) in methanol (2 mL) a solution of Fe(ClO$_4$)$_3$·H$_2$O (32 mg, 0.086 mmol) in methanol (2 mL) was added dropwise. Upon the addition, the solution turned dark green. Diphenyl phosphate (21.6 mg, 0.086 mmol), dissolved in methanol (1 mL), was added and the solvent was allowed to evaporate slowly at room temperature. Green crystals suitable for X-ray crystallography were obtained after 1 d. − UV/Vis (acetonitrile): λ$_{max}$ = 385 (ε ≈ 3000), 673 (ε ≈ 900) nm. − FAB-MS (Matrix NBA): *m*/*z* = 1155 [Fe^{II}Fe^{III}BPMOP{O$_2$P(OPh)$_2$}$_2$]ClO$_4$]$^+$. − $C_{57}H_{53}Fe_2N_6O_{10}P_2$·2ClO$_4$·H$_2$O (1372.65): calcd. C 49.88, H 4.04, N 6.12; found C 49.63, H 3.92, N 6.16.

Blue Powder (4): To a solution of HBPMOP (150 mg, 0.275 mmol) in acetone (2 mL) a solution of Zn(ClO$_4$)$_2$·6H$_2$O (100.5 mg, 0.275 mmol) in water (1 mL) was added dropwise. Upon the addition of Fe(ClO$_4$)$_3$·H$_2$O (95.7 mg, 0.275 mmol), dissolved in water (1 mL), the solution turned blue-green and was stirred for 1 h. The acetone was removed in a rotary evaporator and diethyl ether (100 mL) was added in small portions. The solution was placed in a refrigerator and after a few days a blue powder (134.0 mg, 0.120 mmol, 31%) precipitated which was filtered and washed with diethyl ether. − UV/Vis (acetonitrile): λ$_{max}$ = 661 nm (ε ≈ 2200). − FAB-MS (matrix NBA): *m*/*z* = 681 [Zn^{II}Fe^{III}BPMOP(OH)]$^+$.

The Deprotonation Constants by UV/Vis Spectroscopy: UV/Vis titration (monitoring of the LMCT band) of a solution of the ligand HBPMOP ($2.5 \cdot 10^{-4}$ M^{-1}) and equimolar amounts of zinc(II) perchlorate and iron(III) perchlorate in acetonitrile/water (1:9) with an aqueous solution of sodium hydroxide leads to a formation of new species. The ionic strength was fixed at 0.1 M with sodium perchlorate. The reaction is reversible by addition of an aqueous solution of perchloric acid. The spectrophotometric data were fitted with the LETAGROP-SPEFO program.[33] The program uses a non linear least-squares method and calculates the thermodynamic constants of the absorbing species and their corresponding electronic spectra. The calculations were done from absorbance data of seven wavelengths (between 400 and 800 nm) for 15 solutions in the pH range of 1.95 < pH < 3.35 and for eight solutions in the pH range of 4.5 < pH < 6.1.

HPNP (2-Hydroxypropyl *p*-Nitrophenyl Phosphate) was prepared according to a known procedure.[34]

Kinetic Investigations of the HPNP Cleavage by UV/Vis Spectroscopy: The kinetic investigations were made at 25 °C in buffered solutions of acetonitrile/water (1:1). HEPES {2-[4-(2-hydroxyethyl)-piperazin-1-yl]ethanesulfonic acid} and CHES [2-(cyclohexylamino)ethanesulfonic acid] were used as buffers. The ionic strength was fixed at 0.1 M with sodium perchlorate. The complexes were

synthesized in situ by adding an aqueous solution of $Zn(ClO_4)_2 \cdot 6H_2O$ and $Fe(ClO_4)_3 \cdot H_2O$ to a solution of the ligand in acetonitrile. The spontaneous hydrolysis under these conditions was measured in a buffered acetonitrile/water (1:1) solution containing the substrate and 0.1 M sodium perchlorate. The pH value varied less than 0.1 unit during the experiments. In a typical experiment, an aqueous solution (40 μL, 0.82 mM) of HPNP was injected into a cuvette which contained an aqueous solution of the buffer (400 μL, 0.01 M), an aqueous solution of perchlorate (200 μL, 0.1 M), a solution of the complex in acetonitrile/water (10:2) (120 μL, 8.25 mmol), acetonitrile (990 μL), and water (340 μL). In order to determine the activity towards phosphate ester cleavage, the increase of the concentration of *p*-nitrophenolate (PNPat), was followed by UV/Vis spectroscopy at 400 nm, (ε = 18500 $M^{-1}cm^{-1}$). All kinetic experiments were run twice and the obtained values were merged. In respect to a pH-dependent equilibrium between *p*-nitrophenol (PNP) and *p*-nitrophenolate (PNPat), the increase of the concentration of the reaction product can be calculated (pH = pK_S + log[PNPat]/[PNP]). The k_{obs} values were obtained by Equation (2).

$$k_{obs} \cdot dt = d([PNP]_{total})/[HPNP]_0 \quad (2)$$

Acknowledgments

The First Low-Spin Nickel Complex with Two Coordinated Water Molecules, [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2$ − Synthesis and Structural Characterization

Ingrid M. Angulo,[a] Elisabeth Bouwman,*[a] Sandra M. Lok,[a] Martin Lutz,[b] Wilhelmus P. Mul,[c] and Anthony L. Spek[b]

Keywords: Homogeneous catalysis / Nickel / Phosphanes / NMR spectroscopy / Structure elucidation

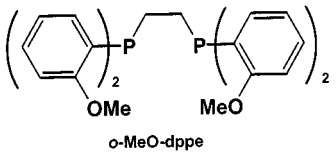
A series of nickel complexes of the didentate ligand 1,3-bis[di(*o*-methoxyphenyl)phosphanyl]propane (*o*-MeO-dppp) has been synthesized and characterized. The first low-spin nickel complex containing two coordinated water molecules, [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2$ (**1**), and compounds of the general formula [Ni(*o*-MeO-dppp)X_2] [X = Cl, Br, I, or trifluoroacetate (TFA)] are reported. Complex **1** has been characterized by X-ray crystallography. The nickel ion resides in a square-planar coordination environment with two phosphorus donors and two water molecules in a *cis* configuration (Ni–P distance 2.19 Å; Ni–O distance 1.97 Å). The structure of this complex and its behavior in solution are quite different from those of the complexes [Ni(*o*-MeO-dppp)X_2]. The halide complexes [Ni(*o*-MeO-dppp)Cl_2] (**2**) and [Ni(*o*-MeO-dppp)Br_2] (**3**) are seemingly mutually isostructural. In these complexes, the nickel ion also resides in a square-planar geometry, but with a significant tetrahedral distortion. The two different types of mono(*o*-MeO-dppp)nickel(II) complexes, i.e. [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2$ (**1**) and [Ni(*o*-MeO-dppp)X_2] [X = Cl (**2**), Br (**3**), I, or trifluoroacetate (TFA)] have been analyzed by electronic absorption and NMR spectroscopy. The differences in the crystal structures of **1** and **2** are helpful in rationalizing the fluxional behavior of these complexes, as has been studied by NMR spectroscopy.

Introduction

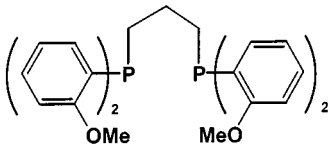
Recently, it was reported that selected diphosphanenickel(II) complexes are active catalysts in the homogeneous hydrogenation of 1-octene to *n*-octane.[1] In subsequent studies, it was observed that the catalytic hydrogenation activity of the nickel(II) catalyst incorporating the didentate phosphane ligand 1,3-bis[di(*o*-methoxyphenyl)-phosphanyl]propane (*o*-MeO-dppp) is much higher than that of a catalyst incorporating the ligand 1,2-bis[di-(*o*-methoxyphenyl)phosphanyl]ethane (*o*-MeO-dppe) (see Scheme 1).[2,3]

The presence of *ortho*-methoxy groups on the phenyl rings creates so-called hemi-labile ligands.[4] The enhanced enantioselectivities of hydrogenation catalysts bearing such methoxy groups have been attributed to possible metal−oxygen interactions.[5]

A systematic study was undertaken to investigate the nature of species in solution for both the *o*-MeO-dppe and *o*-MeO-dppp ligands, in order to obtain a better insight into the origin of the observed difference in catalytic activity. It appeared that the catalyst formed with the ligand *o*-MeO-dppe is involved in the auto-ionization equilibrium depicted in Scheme 2.[6]

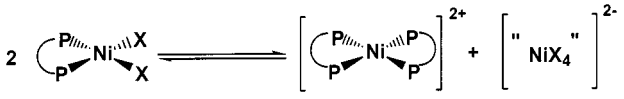


o-MeO-dppe



o-MeO-dppp

Scheme 1



Scheme 2

No bis(chelate) complexes of the unsubstituted ligand 1,3-bis(diphenylphosphanyl)propane (dppp) have hitherto been reported. The presence of the two bulky phenyl groups on each phosphorus atom in the C_3-bridged ligand presumably prevents the formation of the $[Ni(dppp)_2]^{2+}$ complex, which makes the possible auto-ionization reaction of *o*-MeO-dppp-containing nickel complexes doubtful. However, the formation of $[Ni(dppp)_2]^{n+}$ species in electrochemical experiments has been proposed.[7,8] In fact, bis(chelate) complexes have been observed with C_3-bridged ligands bearing smaller methyl groups on the phosphorus atoms[9] or with just one aryl group per phosphorus atom.[10] In the

former case, the bite angle of the C_3-bridged ligand forces the nickel(II) center to adopt a tetrahedral geometry.

In this paper, the synthesis of nickel complexes with the propylene-bridged, sterically crowded ligand *o*-MeO-dppp is described, and the results of NMR investigations are reported.

Results and Discussion

Syntheses

The unique complex [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2$ (**1**) was obtained in analytically pure form from a mixture of nickel acetate, the ligand *o*-MeO-dppp, and ammonium hexafluorophosphate. This complex represents the first low-spin nickel complex with coordinating water molecules (see below). Complexes of the type [Ni(*o*-MeO-dppp)X_2] [X = Cl (**2**), Br (**3**), I, or trifluoroacetate (TFA)] were readily obtained by reaction of the ligand either with the corresponding nickel(II) salt (X = Cl or Br), or with nickel(II) acetate with subsequent addition of the appropriate acid (X = Cl, I, or TFA).

It would appear that in the case of *o*-MeO-dppp no bis(chelate) complex can be formed. In the presence of the weakly coordinating anion TFA, [Ni(*o*-MeO-dppp)$(TFA)_2$] was obtained, whereas from an aqueous reaction mixture complex **1** crystallized. Therefore, attempts were made to obtain a bis(*o*-MeO-dppp)nickel(II) complex from a dry, apolar solvent. Nickel(II) acetate was heated in vacuo to remove all water molecules and was subsequently mixed with *o*-MeO-dppp in dry dichloromethane. After four months, brick-red crystals had precipitated, which analyzed as [Ni(*o*-MeO-dppp)Cl_2]. The only possible source of the chloride anions in this compound was the chlorinated solvent. The formation of a nickel(II) dichloride species starting from a nickel(0) species in the presence of chloroform has been reported.[11] It appears that such reactions involve oxidative addition of chloroform to the nickel(0) center. It has also been found that in the Kharasch reaction[12] and in atom-transfer radical addition reactions (ATRA),[13] a nickel(II) chloride species can be formed by a radical pathway involving a nickel(III) species. In the present case, a radical pathway might be possible as the chloride compound is formed more rapidly in chloroform than it is in dichloromethane when starting from nickel(II) acetate and the ligand. No further attempts have been undertaken to elucidate the mechanism of the chloride abstraction.

Characterization of the Synthesized Complexes in the Solid Phase

The infrared spectra of all the synthesized nickel(II) complexes are very similar and also resemble that of the free ligand *o*-MeO-dppp. In the infrared spectrum of [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2$, an additional band is observed at 1616 cm^{-1}, indicating that the complex contains coordinated water molecules. Diffuse reflectance absorption spectra of the halide compounds show only one strong band at around 20,000 cm^{-1}, as seen for the [Ni(dppp)X_2] complexes[14] (X = Cl, Br, or I), which can be ascribed to the $^1A_1 \rightarrow {}^1B_2$ transition for a square-planar geometry. This band shifts to higher energy in the order I (17,800 cm^{-1}) < Br (19,600 cm^{-1}) < Cl (20,600 cm^{-1}), consistent with the established spectrochemical series.[15] The positions of the strong absorption bands found for [Ni(*o*-MeO-dppp)$(TFA)_2$] and [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2$ at even higher energies (22,100 and 23,400 cm^{-1}, respectively) are also in accordance with the spectrochemical series.[15] The latter two complexes have also been assigned square-planar structures.

Crystal Structure of [Ni(o-MeO-dppp)$(H_2O)_2$]$(PF_6)_2$ (1)

A molecular plot of the structure of the complex cation showing 50% probability ellipsoids is presented in Figure 1. Selected interatomic distances and angles are given in Table 1.

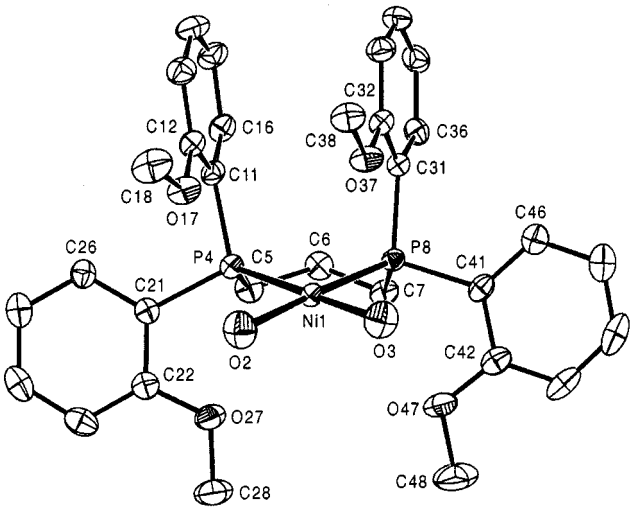

Figure 1. Displacement ellipsoid plot (50% probability) of the cationic unit in [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2 \cdot 0.6C_2H_5OH \cdot CHCl_3$ showing the atom-labeling scheme; hydrogen atoms are omitted for clarity

In complex **1**, the coordination geometry about the nickel(II) center is essentially square-planar with two phosphane donors and two water molecules in a *cis* configuration. The dihedral angle between the O−Ni−O and P−Ni−P planes does not deviate significantly from zero (2.06°). The water molecules are bound more tightly to the nickel center in a low-spin complex than in a high-spin complex, as indicated by the quite short Ni−O distances of 1.965(2) and 1.966(2) Å as compared to the Ni−O distance of 2.0418(8) Å in the octahedral complex [Ni$(H_2O)_6$](SiF_6).[16] The Ni−P distances are similar to that in the nickel(II) thiosalicylate complex [Ni(dppp)$(SC_6H_4CO_2)$] [2.1697(8) Å].[17] The bite angle of the bidentate phosphane ligand is 89.02(3)° in the present compound, similar to that of the unsubstituted analogue dppp in nickel complexes (87.3°).[18] The short Ni1···O37 distance [2.866(2) Å] indicates the presence of an electrostatic interaction between this

ortho-methoxy group and the nickel(II) center. The two axial rings (rings 1 and 3) are stacked, as indicated by the small angle between the planes of these rings of 4.99(14)° and the short interplanar distance of 3.736 Å. The coordinated water molecules in **1** are involved in several hydrogen bonds. Based on the positions of the hydrogen atoms located from the difference Fourier map, these hydrogen bonds are all intermolecular, with the PF_6^- anion and the ethanol solvent as hydrogen-bond acceptors. There are additional short intramolecular O···O contacts (see Figure 2 and Table 2), for which, however, the X-ray experiment provides no evidence for hydrogen-bonding. It must be stated that all observed O···O and O···F distances are relatively long, except for O2···O17, thus an interaction of the coordinated water molecules with the *ortho*-methoxy groups of the ligand cannot be excluded.

[a] Intramolecular contacts.

No crystal structure of a low-spin nickel complex with coordinated water molecules has hitherto been reported. However, the synthesis of the five-coordinate nickel(II) complex [Ni(dcpe)$(NO_3)_2(H_2O)$] has been reported by Connor and Riley.[19] It remains unclear as to whether this low-spin nickel complex really contains a coordinated water molecule, as this has not been proven unambiguously. The known structures of nickel complexes incorporating coordinated water molecules are all octahedral (high-spin) and do

not contain phosphane ligands.[20] The structures of nickel complexes incorporating phosphane ligands are predominantly square-planar (low-spin) or, due to steric constraints, are sometimes tetrahedral (high-spin). It seems that in complex **1** the electronic factors of the phosphorus atoms, which will favor a low-spin square-planar geometry, predominate over those of the water molecules, which would favor a high-spin octahedral geometry. It seems likely that the ligand *o*-MeO-dppp plays an important role in the formation of the low-spin nickel complex containing coordinated water molecules. The reaction of nickel(II) acetate with the unsubstituted ligand dppp in the presence of ammonium hexafluorophosphate results in a compound that can most probably be formulated as the dimeric hydroxo complex $[\{Ni(dppp)(\mu\text{-}OH)\}_2](PF_6)_2$.[21−23] Whereas the ligand *o*-MeO-dppp is able to stabilize the dicationic nickel atom through an interaction of one methoxy group with the metal center, in the case of dppp the complex is stabilized by the formation of two monocationic metal centers bridged by two hydroxy groups.

Crystal Structures of [Ni(o-MeO-dppp)Cl_2] (2) and [Ni(o-MeO-dppp)Br_2] (3)

A molecular plot of the structure of [Ni(*o*-MeO-dppp)Cl_2] (**2**) showing 50% probability ellipsoids is presented in Figure 3. Selected interatomic distances and angles are given in Table 1.

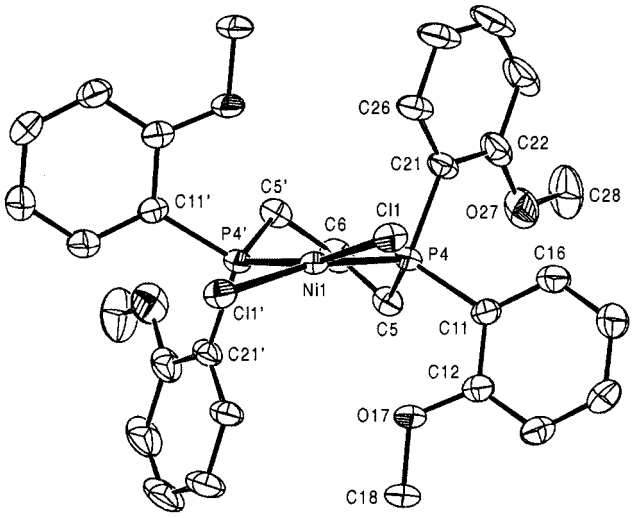

Figure 3. Displacement ellipsoid plot (50% probability) of [Ni(*o*-MeO-dppp)Cl_2] showing the atom-labeling scheme; hydrogen atoms are omitted for clarity; symmetry operation: $1 - x, y, 1.5 - z$

The complex [Ni(*o*-MeO-dppp)Br_2] is isostructural with [Ni(*o*-MeO-dppp)Cl_2], as can be seen from the crystallographic data in Table 3 and from the graphical representation in Figure 4a. Complexes **2** and **3** possess an exact, crystallographic twofold symmetry. In both complexes, the coordination geometry about the nickel(II) center is square-planar, with a significant tetrahedral distortion, as is evident from the dihedral angle between the X−Ni−X and P−Ni−P planes (16.65° for **2** and 19.45° for **3**). To date, no crystal structures of complexes of the parent ligand, [Ni(dppp)X_2] (X = Cl, Br, or I), have been reported. However, the structures of [Ni(*o*-MeO-dppp)X_2] [X = Cl (**2**) or Br (**3**)] resemble that of [Ni(*o*-MeO-dppe)I_2], which has been reported previously.[6] In Figure 4b, [Ni(*o*-MeO-dppe)I_2] and **2** are compared in a graphical representation. The Ni−P distances in **2** and **3** are similar to those in [Ni(*o*-MeO-dppe)I_2]. Due to the extra carbon atom in the bridge, the bite angles in **2** and **3** are larger than that in [Ni(*o*-MeO-dppe)I_2] [86.48(3)°]. The rather long Ni···O17 distances of 3.38 Å in **2** and 3.48 Å in **3** are indicative of an absence of any electrostatic interactions between the nickel ion and the *ortho*-methoxy groups. In Figure 3, it can be seen that the *ortho*-hydrogen atoms (H26, H26′) of the two axial aryl groups are directed towards the nickel atom. The Ni···H distances of 2.87 Å in **2** and 2.84 Å in **3** indicate the presence of either an agostic interaction or an Ni···H−C hydrogen bond, a phenomenon which has been observed previously.[6,24,25]

Comparison of the Structures of [Ni(o-MeO-dppp)-$(H_2O)_2$]$(PF_6)_2$ (1) and [Ni(o-MeO-dppp)X_2] (2 and 3)

In Figure 1 and Figure 3, it can be seen that the orientation of the diphosphane ligand in the two complexes is completely different. In **1**, the six-membered ring is in a chair conformation leading to two axial rings on one side of the coordination plane and two equatorial rings on the other. In **2** and **3**, two axial and two equatorial rings are again observed, but here the twist-boat conformation of the six-membered ring dictates alternating axial and equatorial positions of the aryl groups. The difference in conformation of the six-membered chelate ring in the two complexes may be related to the electrostatic interaction between the dicationic nickel center and the *ortho*-methoxy groups of the ligand. In **1**, all four *ortho*-methoxy groups lie in close proximity to the nickel(II) center, whereas in **2** and **3** only two *ortho*-methoxy groups point towards the nickel center (see torsion angles in Table 2). Complexes **2** and **3** are neutral, whereas **1** is a cationic complex, hence the nickel(II) center in **1** will have more electrophilic character than those in **2** and **3**. This provides a likely explanation for the presence of an electrostatic Ni···O interaction in **1**, while such an interaction is not significant in **2** and **3**. Moreover, the coordinated water molecules in **1** have the ability to form hydrogen bonds, resulting in an orientation of the ligand whereby possible hydrogen-bond acceptors lie in the proximity of these coordinated water molecules.

Characterization of the Synthesized Complexes in Solution

The essential preservation of the geometry seen in the solid-state upon dissolution is confirmed by a comparison of the electronic absorption spectra of **1** and **2** in CH_2Cl_2 solution with the diffuse reflectance electronic spectra of the solids. However, for the closely related nickel(II) species [Ni(dppp)X_2] (where X = Cl, Br, or I), both square-planar and tetrahedral species are observed in dichloromethane solution.[14] Apparently, the presence of the *ortho*-methoxy

groups in the *o*-MeO-dppp ligand contributes to the stability of the square-planar geometry. It is difficult to ascertain whether this stabilization is due to the altered electronic or steric features of the diphosphane ligand resulting from the introduction of the *ortho*-methoxy groups. All the new nickel(II) complexes presented in this paper exhibit rather sharp ^{1}H NMR signals, which indicates that they are predominantly diamagnetic (low-spin) in solution. However, some paramagnetism is present, which is mainly manifested in the phosphorus NMR spectra. For [Ni(*o*-MeO-dppp)$(H_2O)_2$](PF_6) (**1**), one sharp resonance is observed in the $^{31}P\{^1H\}$ NMR spectrum at room temperature (δ = −9.8), whereas for [Ni(*o*-MeO-dppp)$(TFA)_2$], a rather broad signal is observed (δ = 4.7). For the complex [Ni(*o*-MeO-dppp)Cl_2] (**2**), a sharp ^{31}P NMR signal can only be observed at −60 °C (δ = 7.2). Apparently, at room temperature, the ^{31}P NMR signal for this complex is very broad, and is not discernible above the spectral noise. This broadening could perhaps be due to a geometric equilibrium (square-planar ⇄ tetrahedral), as at room temperature the ^{1}H NMR signals are also slightly broadened. These differences in line broadening for the various complexes can be related to their solid-state structures. The essentially square-planar geometry about the central nickel atom observed for **1** in the solid phase is retained in solution, whereas the tetrahedral distortion observed for **2** is reflected in the absence of a distinct resonance in the ^{31}P NMR spectrum at room temperature. The difference in the chemical shift (Δδ) of the phosphorus atom between the free and coordinated ligands in these complexes amounts to 30−40 ppm, which is comparable to that seen for other six-membered chelate systems.[26]

Fluxional Behavior of [Ni(*o*-MeO-dppp)Cl_2] and [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2$

The temperature-dependent ^{1}H NMR spectra of [Ni(*o*-MeO-dppp)Cl_2] (**2**) and [Ni(*o*-MeO-dppp)$(H_2O)_2$](PF_6) (**1**) in CD_2Cl_2 are shown in Figure 5 and Figure 6, respectively.

Both complexes exhibit fluxional behavior. At 25−35 °C, one set of aryl resonances and one methoxy resonance is observed for both complexes, indicating that the four functionalized aryl groups of the *o*-MeO-dppp ligand of both **1** and **2** are spectroscopically equivalent. On lowering the temperature, the ^{1}H NMR resonances of both complexes broaden and ultimately appear as double sets of resonances at −50 °C. The low-temperature spectrum of [Ni(*o*-MeO-dppp)Cl_2] (**2**) is in agreement with the crystal structure, in

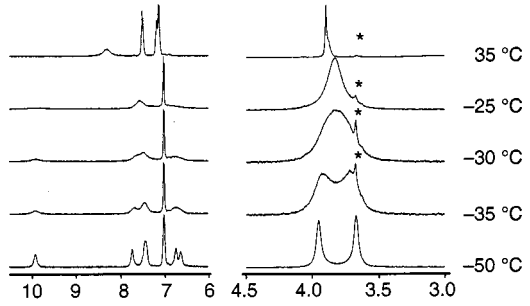

Figure 5. Two sections of the 400-MHz ^{1}H NMR spectra of [Ni(*o*-MeO-dppp)Cl$_2$] in CD_2Cl_2 as a function of temperature; section I: δ = 3−4.5, signals corresponding to the *ortho*-methoxy groups; section II: δ = 6−10.5, signals corresponding to the aryl groups; signals arising from the solvent or impurities are indicated with an asterisk

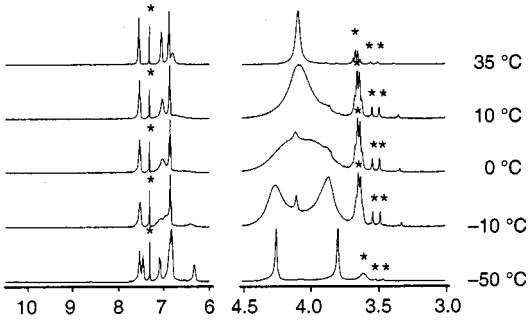

Figure 6. Two sections of the 400-MHz ^{1}H NMR spectra of [Ni(*o*-MeO-dppp)(H$_2$O)$_2$](PF$_6$)$_2$ in CD_2Cl_2 as a function of temperature; section I: δ = 3−4.5, signals corresponding to the *ortho*-methoxy groups; section II: δ = 6−10.5, signals corresponding to the aryl groups; signals arising from the solvent or impurities are indicated with an asterisk

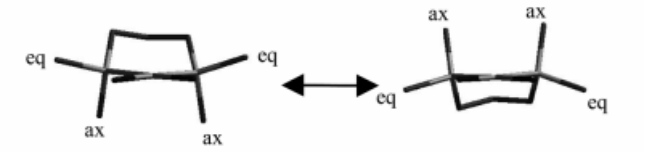
which pairs of the four aryl groups are equivalent: Two are oriented axially with respect to the six-membered chelate ring, while the other two are oriented equatorially. The observed fluxional behavior of **2** is best described as a rapid interchange of the equatorial and axial aryl groups (Scheme 3), which is a slow process on the NMR time scale at low temperature.

Scheme 3

In the low-temperature ^{1}H NMR spectrum of **2**, one of the *ortho*-aryl proton resonances is considerably shifted downfield and is found at δ = 9.9. This anomalous chemical shift can be attributed to the interaction of the two *ortho*-protons of the two spectroscopically identical axial aryl rings with the occupied d_{z^2} orbital of the nickel atom. The downfield shift of these protons in the ^{1}H NMR spectrum, together with the observed Ni···H interaction in the crystal structure of **2**, indicate that this interaction is better described as an Ni···H−C hydrogen bond rather than as an agostic interaction.[25] From the coalescence temperatures of the interconverting *ortho*-methoxy groups, and of two sets of the aryl protons, three estimates were obtained for the $\Delta G^{\ddagger}$ value[27] of the $(aryl)_{eq} \rightleftarrows (aryl)_{ax}$ exchange process: $\Delta G^{\ddagger}_{av}$ (**2**) = 47.6 kJ·mol^{-1}.

The low-temperature ^{1}H NMR spectrum of **1**, in which the fluxional behavior of the complex is in the slow exchange regime, is quite different from that of **2**. The resonances due to the aryl hydrogen atoms are all observed in the δ = 6−8 region, and none is observed further downfield like that seen for **2**, indicating that there is no Ni···H−C$_{aryl}$ interaction in **1**. This is in agreement with the crystal structure, which shows all four aryl rings to be oriented such that the *ortho*-methoxy groups are directed towards the nickel ion. Based on the crystal structure of **1**, four discrete sets of aryl resonances would be expected at low temperature; in fact, only two sets are observed. Apparently, a dynamic process is also operative at low temperatures.

The most likely interpretation of the low-temperature spectrum of **1** is that the $(aryl)_{eq} \rightleftarrows (aryl)_{ax}$ exchange process (see Scheme 4) is slow on the NMR time scale, but that the two slightly differently oriented axial aryl groups observed in the crystal structure are still in rapid exchange by a windshield wiper type of motion, as a result of which each of the *ortho*-methoxy groups of the axial aryl rings points to the metal center for half of the time. One of the two *ortho*-methoxy resonances in the low-temperature spectrum of **1** is shifted considerably downfield (δ = 4.3) with respect to the other (δ = 3.8), as well as to those of the free ligand (δ = 3.64) and those of **2** (δ = 3.67 and 3.95). This downfield resonance is tentatively ascribed to the two rapidly interconverting (axial) *ortho*-methoxy groups interacting with the metal center. From the coalescence temperatures of the *ortho*-methoxy signals, and one of the aryl proton signals, two estimates were obtained for the $\Delta G^{\ddagger}$ value[27] of the $(aryl)_{eq} \rightleftarrows (aryl)_{ax}$ exchange process: $\Delta G^{\ddagger}_{av}$ (**1**) = 51.8 kJ·mol^{-1}.



Scheme 4

Auto-Ionization

As discussed above, a complex containing the [Ni(*o*-MeO-dppp)$_2$]$^{2+}$ moiety could not be obtained. However, it has been reported[6] that nickel(II) complexes containing the ligand *o*-MeO-dppe and weakly coordinating anions (such as TFA or OAc) are completely auto-ionized in polar solvents, as observed by ^{1}H NMR spectroscopy. Therefore, the complexes [Ni(*o*-MeO-dppp)(H$_2$O)$_2$](PF$_6$)$_2$ and [Ni(*o*-MeO-dppp)(TFA)$_2$] were dissolved in CD_3OD and ana-

lyzed by ^{1}H NMR. Neither complex is very soluble in methanol, and in the ^{1}H NMR spectra only the monochelate complexes are observed. It seems likely that the *o*-MeO-dppp ligand is too bulky to allow formation of a square-planar bis(chelate) complex. However, this is not solely an effect of the *ortho*-methoxy groups; no complexes containing the $[Ni(dppp)_2]^{2+}$ moiety have hitherto been reported, although the formation of such species in electrochemical experiments has been proposed.[7,8] The presence of the two aryl groups on each phosphorus atom in the C_3-bridged ligand clearly prevents the formation of a bis(chelate)Ni^{II} complex. In fact, bis(chelate) complexes are observed with C_3-bridged ligands bearing smaller methyl groups on the phosphorus atoms[9] or with just one aryl group per phosphorus atom.[10] However, in the former case, the chelate bite angle of the C_3-bridged ligand forces the nickel(II) center to adopt a tetrahedral geometry. Only one structure of a bis(chelate)nickel(II) complex containing C_3-bridged ligands with two aryl groups per phosphorus atom has been reported, namely that of $[Ni\{H_3CC(CH_2PPh_2)_2(CH_2OH)\}_2](BF_4)_2$.[28] In this structure, the nickel(II) center adopts a tetrahedral geometry and the chelate bite angle is somewhat reduced as a result of the substituents on the central carbon atom of the bridge, so that all eight aryl rings can be fitted in the rather limited space around the rather small nickel(II) ion. For the somewhat larger palladium(II) ion, a square-planar bis(*o*-MeO-dppp)palladium(II) complex is easily formed.[29] It seems that the combination of the large bite angle of *o*-MeO-dppp and the rather small nickel(II) ion prevents the formation of the $[Ni(o\text{-MeO-dppp})_2]^{2+}$ moiety. It is for this same reason that nickel(II) complexes containing the ligand *o*-MeO-dppp, unlike their *o*-MeO-dppe counterparts, are not involved in an auto-ionization equilibrium as depicted in Scheme 2.

Conclusion

The first low-spin, square-planar nickel(II) complex with two coordinated water molecules has been synthesized and the presence of the water molecules has been unambiguously proven. The ligand *o*-MeO-dppp appears to be able to stabilize the dicationic nickel atom through interactions of its methoxy groups with the metal center.

It appears that, in contrast to *o*-MeO-dppe-based complexes, nickel(II) complexes containing the ligand *o*-MeO-dppp are not involved in the auto-ionization equilibrium, $2\,[Ni(P{-}P)X_2] \rightleftarrows [Ni(P{-}P)_2]^{2+} + [\text{“}NiX_4\text{”}]^{2-}$. This is not solely an effect of the *ortho*-methoxy groups, as no complexes containing the $[Ni(dppp)_2]^{2+}$ moiety have hitherto been reported. The inability to form a bis(chelate) complex is most likely due to a combination of the large bite angle dictated by the C_3 bridge and the rather small nickel(II) ion. The absence of the bis(chelate) complex might be one of the reasons for the considerably better hydrogenation activity of catalysts based on this ligand, compared to those based on *o*-MeO-dppe. The lower sensitivity to variations in solvents and anions[3] of the catalysts containing *o*-MeO-dppp might also be related to the absence of the auto-ionization equilibrium.

Experimental Section

General Remarks: Elemental analyses were performed with a Perkin−Elmer 2400 Series II analyzer. − Infrared spectra were recorded with a Perkin−Elmer Paragon 1000 IR spectrophotometer equipped with a Golden Gate ATR device, using the reflectance technique (4000−300 cm^{-1}). − Solid-state electronic absorption spectra were obtained with a Perkin−Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. − Solution electronic absorption spectra were recorded from samples in 1-cm path length cells at ambient temperature, using the neat solvent as the reference. − ^{1}H and ^{31}P{^{1}H} NMR spectra were recorded with a Varian VXR-200 spectrometer at 200.06 MHz and 80.98 MHz, respectively, or with a Bruker WM-300 spectrometer at 300.13 MHz and 121.50 MHz, respectively. The variable-temperature ^{1}H NMR measurements were performed with a Varian INOVA-400 spectrometer equipped with a variable-temperature probe at 399.97 MHz. ^{31}P and ^{1}H chemical shifts are quoted in δ units relative to triphenylphosphane ($\delta_P = -6$) and residual protons in the deuterated solvent (CD_2Cl_2: $\delta_H = 5.24$), respectively.

Syntheses: All chemicals were either reagent grade and were used as received, or were synthesized as described below. Reactions were carried out under dry argon or dry nitrogen, unless stated otherwise, by using standard Schlenk techniques. Tris(*o*-methoxyphenyl)phosphane[30] and 1,3-bis[di(*o*-methoxyphenyl)phosphanyl]-propane (*o*-MeO-dppp)[31] were synthesized according to literature procedures. Generally, the complexes were obtained in yields of 40−80%; no attempts have been undertaken to optimize the yields.

$[Ni(o\text{-MeO-dppp})(H_2O)_2](PF_6)_2$ (1): A solution of $Ni(OAc)_2{\cdot}4H_2O$ (0.12 g, 0.5 mmol) in ethanol (15 mL) was mixed with a solution of *o*-MeO-dppp (0.28 g, 0.55 mmol) in chloroform (15 mL), to give a clear, dark-orange solution. A solution of NH_4PF_6 (0.16 g, 1 mmol) in ethanol (5 mL) was then added, which led to a slight lightening of the orange colour. After several days, orange crystals precipitated from the solution. These crystals proved to be suitable for X-ray diffraction analysis. − $C_{31}H_{38}F_{12}NiO_6P_4{\cdot}CHCl_3$ (1036.58): calcd. C 37.08, H 3.79; found C 37.08, H 3.72. − ^{1}H NMR (CD_2Cl_2, 35 °C): δ = 1.69 (m, 2 H, $CH_2CH_2CH_2$), 2.30 (s, H_2O), 2.51 (m, 4 H, $CH_2CH_2CH_2$), 4.09 (s, 12 H, OCH_3), 6.81 (m, 4 H), 6.91 (t, 4 H, arom. H), 7.05 (d, 4 H, arom. H), 7.55 (t, 4 H, arom. H). − ^{1}H NMR (CD_2Cl_2, −50 °C): δ = 1.67 (m, 2 H, $CH_2CH_2CH_2$), 2.58 (s, H_2O), 2.79 (m, 4 H, $CH_2CH_2CH_2$), 3.79 (s, 6 H, OCH_3), 4.25 (s, 6 H, OCH_3), 6.33 (m, 2 H, arom. H), 6.83 (m, 8 H, arom. H), 7.09 (m, 2 H, arom. H), 7.46 (t, 2 H, arom. H), 7.54 (t, 2 H, arom. H). − ^{31}P{^{1}H} NMR (CD_2Cl_2, 25 °C): δ = −9.8 (s), 104.4 (septet, PF_6). − Diffuse reflectance electronic absorption of the solid: $\tilde{\nu}_{max}$ = 30,300 and 23,400 cm^{-1}. − Electronic absorption in CH_2Cl_2 [molar extinction coefficients (L mol^{-1} cm^{-1})]: $\tilde{\nu}_{max}$ = 30,900 (11,000) and 24,300 cm^{-1} (800).

$[Ni(o\text{-MeO-dppp})Cl_2]$ (2). − Method A: $Ni(OAc)_2{\cdot}4H_2O$ (50 mg, 0.2 mmol) was mixed with an equimolar amount of *o*-MeO-dppp (107 mg, 0.2 mmol) in ethanol (20 mL). The mixture was refluxed for 3.5 h and a clear orange solution was obtained. After the solution had cooled somewhat, HCl (1 M in Et_2O, 0.5 mL, 0.5 mmol) was added. The solution immediately turned red and after several

minutes a brick-red precipitate had formed. The solid was collected by filtration and dried in air. − **Method B:** $NiCl_2·6H_2O$ (0.35 g, 1.5 mmol) was dissolved in ethanol (10 mL) and then mixed with an equimolar amount of *o*-MeO-dppp (0.81 g, 1.5 mmol) dissolved in chloroform (10 mL). After a few seconds, a brick-red solid precipitated. The solid was collected by filtration and dried in air. Yield: 0.55 g (83%). − $C_{31}H_{34}Cl_2NiO_4P_2$ (662.15): calcd. C 56.23, H 5.18; found C 55.96, H 5.50. − ^{1}H NMR (CD_2Cl_2, 35 °C): δ = 1.67 (m, 2 H, $CH_2CH_2CH_2$), 3.07 (m, 4 H, $CH_2CH_2CH_2$), 3.90 (s, 12 H, OCH_3), 7.13 (m, 8 H, arom. H), 7.50 (t, 4 H, arom. H), 8.29 (m, 4 H, arom. H). − ^{1}H NMR (CD_2Cl_2, −50 °C): δ = 1.70 (m, 2 H, $CH_2CH_2CH_2$), 2.16 (m, 4 H, $CH_2CH_2CH_2$), 3.67 (s, 6 H, OCH_3), 3.95 (s, 6 H, OCH_3), 6.62 (m, 2 H, arom. H), 6.73 (m, 2 H, arom. H), 7.00 (m, 4 H, arom. H), 7.42 (m, 4 H, arom. H), 7.72 (m, 2 H, arom. H), 9.91 (m, 2 H, arom. H). − ^{31}P{^{1}H} NMR (H_3PO_4 external standard; $CDCl_3$): 25 °C: no peak; −60 °C: δ = 7.2 (s). − Diffuse reflectance electronic absorption of the solid: $\tilde{\nu}_{max}$ = 30,200 and 20,600 cm^{-1}. − Electronic absorption in CH_2Cl_2 [molar extinction coefficients (L mol^{-1} cm^{-1})]: $\tilde{\nu}_{max}$ = 31,300 (9,000) and 20,700 cm^{-1} (900).

[Ni(*o*-MeO-dppp)Br$_2$] (3): To a suspension of $NiBr_2$ (0.33 g, 1.5 mmol) in ethanol (10 mL) was added a solution of *o*-MeO-dppp (0.53 g, 1 mmol) in chloroform (10 mL) and the mixture immediately turned purple. After several minutes, a purple precipitate had formed. The solid was collected by filtration and dried in vacuo. Yield: 0.66 g (88%). Crystals of [Ni(*o*-MeO-dppp)Br_2] suitable for single-crystal X-ray diffraction analysis were obtained from an autoclave solution containing $NiBr_2$ (0.05 mmol) and *o*-MeO-dppp (0.055 mmol), in methanol (10 mL), dichloromethane (10 mL), toluene (4 mL), and 1-octene (15.6 mL). − $C_{31}H_{34}Br_2NiO_4P_2$ (751.05): calcd. C 49.58, H 4.56; found C 48.47, H 4.00. − Diffuse reflectance electronic absorption of the solid: $\tilde{\nu}_{max}$ = 29,600 and 19,600 cm^{-1}.

[Ni(*o*-MeO-dppp)I$_2$]: $Ni(OAc)_2·4H_2O$ (0.25 g, 1 mmol) was dissolved in ethanol (10 mL) and mixed with an equimolar amount of *o*-MeO-dppp (0.53 g, 1 mmol) in chloroform (10 mL). To the clear orange solution, HI (50% in water, 0.25 mL, 1.8 mmol) was added, and a purple solution was obtained. After several minutes, a dark-purple precipitate had formed. The solid was collected by filtration and dried in air. Yield: 0.61 g (72%). − $C_{31}H_{34}I_2NiO_4P_2·(CHCl_3)_{0.5}$ (904.74): calcd. C 41.82, H 3.84; found C 41.07, H 3.79. − Diffuse reflectance electronic absorption of the solid: $\tilde{\nu}_{max}$ = 24,300 and 17,800 cm^{-1}. − Electronic absorption in CH_2Cl_2 [molar extinction coefficients (L mol^{-1} cm^{-1})]: $\tilde{\nu}_{max}$ = 28,000 (10,000) and 17,800 cm^{-1} (1,600).

[Ni(*o*-MeO-dppp)(TFA)$_2$]: $Ni(OAc)_2·4H_2O$ (0.12 g, 0.5 mmol) was dissolved in methanol (1 mL) and a solution of *o*-MeO-dppp (0.27 g, 0.5 mmol) in dichloromethane (10 mL) was added. When a clear, dark-orange solution had been obtained, trifluoroacetic acid (0.1 mL, 1.3 mmol) was added. The reaction mixture was filtered and layered with diethyl ether, which resulted in the deposition of a dark-orange crystalline precipitate. Yield: 0.18 g (43%). − $C_{35}H_{34}NiF_6O_8P_2$ (817.27): calcd. C 51.44, H 4.19; found C 51.10, H 4.14. − ^{1}H NMR (CD_2Cl_2, 25 °C): δ = 1.82 (m, 2 H, $CH_2CH_2CH_2$), 2.16 (m, 4 H, $CH_2CH_2CH_2$), 3.68 (d, 12 H, OCH_3), 6.95 (m, 8 H, arom. H), 7.49 (m, 4 H, arom. H), 8.36 (m, 2 H, arom. H). − ^{31}P{^{1}H} NMR (CD_2Cl_2, 25 °C): δ = 4.7 (br. s). − Diffuse reflectance electronic absorption of the solid: $\tilde{\nu}_{max}$ = 29,500 and 22,100 cm^{-1}.

Attempted Synthesis of [Ni(*o*-MeO-dppp)$_2$](TFA)$_2$: In an attempt to synthesize this compound, $Ni(OAc)_2·4H_2O$ (0.12 g, 0.5 mmol) was mixed with *o*-MeO-dppp (0.53 g, 1 mmol) in a mixture of dichloromethane (10 mL) and methanol (1 mL). When a clear, dark-orange solution had been obtained, trifluoroacetic acid (0.1 mL, 1.3 mmol) was added. The solvents were partially evaporated in vacuo and diethyl ether was added, which resulted in the deposition of an orange precipitate. The supernatant solution was decanted off and the solid residue was dried in air. − ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 4.8 (s), −37.2 (s). − When methanol was added to the compound, an orange solution was obtained and a white solid remained that analyzed as the free ligand. After filtration and evaporation of the solvent from the filtrate, an orange compound was obtained. This compound appeared to be the mono-chelate complex [Ni(*o*-MeO-dppp)$(TFA)_2$].

Attempted Synthesis of [Ni(*o*-MeO-dppp)$_2$](OAc)$_2$: In an attempt to synthesize a bis(*o*-MeO-dppp) complex, $Ni(OAc)_24H_2O$ (0.12 g, 0.5 mmol) was first dried in vacuo in order to remove all water molecules. It was then taken-up in dichloromethane to give a green solution. The ligand *o*-MeO-dppp (0.58 g, 1.1 mmol) was dissolved in dichloromethane (20 mL) to give a colorless solution. On mixing the two solutions, a green solution was initially obtained. However, after stirring overnight, a clear orange solution was obtained. After 4 months at 4 °C, brick-red crystals suitable for single-crystal X-ray diffraction analysis had formed. These crystals were characterized as [Ni(*o*-MeO-dppp)Cl_2].

X-ray Crystal Structure Determinations of [Ni(*o*-MeO-dppp)$(H_2O)_2$]$(PF_6)_2·(C_2H_5OH)_{0.6}·CHCl_3$ (1), [Ni(*o*-MeO-dppp)Cl_2] (2), and [Ni(*o*-MeO-dppp)Br_2] (3): Intensities were measured with a Nonius-Kappa CCD diffractometer with a rotating anode (Mo-K_α, λ = 0.71073 Å) at 150 K. The structure was solved by Patterson methods (DIRDIF-97[32]) and refined against F^2 of all reflections up to a resolution of $(\sin\theta/\lambda)_{max}$ = 0.65 $Å^{-1}$ using the program SHELXL-97.[33] Non-hydrogen atoms were refined freely with anisotropic parameters; hydrogen atoms were refined as rigid groups. In the crystal structure of **1**, the hydrogen positions of the water and ethanol molecules were located from the difference Fourier map and were kept fixed during the refinement. The drawings were created and structure calculations and checks for higher symmetry were carried out using the program PLATON.[34] Further experimental details are given in Table 3. The crystal structures of **2** and **3** show large voids (1243 $Å^3$ for **2** and 1273 $Å^3$ for **3**), which are occupied by disordered solvent molecules (dichloromethane). Their contribution to the structure factors was assessed by back-Fourier transformation (program PLATON,[34] CALC SQUEEZE, 484 e^-/unit cell for **2**, 400 e^-/unit cell for **3**). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-151615 (**1**), -151616 (**2**), and -151617 (**3**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Fluorescent Chemosensors for Heavy Metal Ions Based on Bis(terpyridyl) Ruthenium(II) Complexes Containing Aza-Oxa and Polyaza Macrocycles

Miguel E. Padilla-Tosta,[a] José Manuel Lloris,[a] Ramón Martínez-Máñez,*[a] M. Dolores Marcos,[a] Miguel A. Miranda,[a] Teresa Pardo,[a] Felix Sancenón,[a] and Juan Soto[a]

Keywords: Ruthenium / Terpyridine / Aza-oxa crowns / Fluorescence / Chemosensors

Reactions of 4′-[4-(bromomethyl)phenyl]-2,2′:6′,2′′-terpyridine with 4,10-diaza-15-crown-5 and 1-aza-12-crown-4 in dichloromethane yielded the ligands L^1 and L^3, respectively. Reaction of an excess of 4′-[4-(bromomethyl)phenyl]-2,2′:6′,2′′-terpyridine with 4,10-diaza-15-crown-5 yielded L^2, while treatment of the same terpyridine ligand with 1,4,7,10,13-pentaazacyclopentadecane afforded L^4. Reactions of L^1, L^3, and L^4 with Ru(mtpy)Cl_3 (mtpy = 4′-methyl-2,2′:6′,2′′-terpyridine) in methanol yielded the metallo receptors $[Ru(L^1)(mtpy)][PF_6]_2$, $[Ru(L^3)(mtpy)][PF_6]_2$, and $[Ru(L^4)(mtpy)][PF_6]_2$ after precipitation with ammonium hexafluorophosphate and column chromatography. On treating L^3 with $RuCl_3$, the homoleptic ruthenium complex $[Ru(L^3)_2][PF_6]_2$ was obtained. The synthesized metallo receptors contain oxa-aza crown or polyazacycloalkane moieties as recognition sites and $[Ru(tpy)_2]^{2+}$ cores as the signal-generating centre. The electronic spectra of the complexes are as expected for an $Ru(tpy)_2^{2+}$ chromophore, with the main $Ru[d(\pi)] \rightarrow tpy(\pi^*)$ MLCT transition at ca. 484 nm and intense ligand-centred transitions in the UV region. One of the most interesting aspects of these ruthenium complexes is their multicomponent nature, as they contain both coordination sites and fluorescent $Ru(tpy)_2^{2+}$ cores. The cations $[Ru(L^1)(mtpy)]^{2+}$, $[Ru(L^3)(mtpy)]^{2+}$, and $[Ru(L^3)_2]^{2+}$ display an emission maximum at ca. 650 nm, the intensity of which is pH dependent, showing an enhancement upon protonation. The metallo receptor $[Ru(L^1)(mtpy)]^{2+}$ selectively senses Hg^{2+} in preference to Cu^{2+}, Cd^{2+}, and Pb^{2+}. The emission intensity vs. pH curve for $[Ru(L^2)(mtpy)]^{2+}$ in the presence of Cu^{2+} and Hg^{2+} ions is close to that of the free receptor, but the presence of Cd^{2+} or Pb^{2+} enhances the emission intensity in the range pH 4–6. For the $[Ru(L^3)_2]^{2+}$ complex, Cd^{2+}, Pb^{2+}, and Hg^{2+} induce an enhancement of the fluorescence of the $Ru(tpy)_2^{2+}$ core in the range pH 3.5–7.5. These results are compared with those obtained for the metallo receptor $[Ru(L^4)(mtpy)]^{2+}$ containing a polyazacycloalkane moiety as the binding domain.

Introduction

Ligands with a macrocyclic unit attached to a metal-polypyridyl core are potentially useful in the preparation of luminescent or electrochemical sensors, in which the macroscopic properties of the core are modified by molecular-level interactions between the recognition centre and the substrate.[1−4] The polypyridyl complexes of d^6 metals, with their strong metal-to-ligand charge transfer absorptions and emitting excited states, are good candidates as signalling subunits.[5,6] The metal−polypyridyl complex most widely used as a fluorophore is probably $Ru(bipy)_3^{2+}$.[7,8] In contrast, the ruthenium−terpyridine $Ru(tpy)_2^{2+}$ unit has been less well studied. Although the $Ru(tpy)_2^{2+}$ core is less fluorescent than $Ru(bipy)_3^{2+}$, terpyridine complexes may have some advantages over their bipyridine counterparts. Thus, for instance, it has been reported that the octahedral tpy-type complex has the advantage of being non-chiral (preventing the generation of stereoisomers that may arise with bipy-Ru complexes) and, through functionalization of the ligand at the appropriate position, allows the construction of multicomponent systems with fine control over the geometry of the assembly.[9,10] Additionally, from a practical viewpoint, emission in the visible part of the spectrum (as shown by Ru-tpy complexes) is much more convenient than emission near the UV region, where many other organic fluorophores typically emit.

We have recently reported the functionalization of the $Ru(tpy)_2^{2+}$ unit with cyclam and the use of the resulting compound as a potential sensing receptor for Cu^{2+} ions.[11] Further, we are interested in the development of potential chemosensors for heavy transition metal ions such as Cd^{2+}, Hg^{2+}, and Pb^{2+}. Sensing receptors for toxic heavy metal ions are of interest in areas such as environmental chemistry, where the development of highly selective analytical tools is of importance. In order to direct the sensing ability of $Ru(tpy)_2^{2+}$-based chemosensors towards the selective determination of these metals, we have covalently functionalized the fluorophore core with binding sites that are known to show greater stability constants with large transition metal ions than with smaller ones.[12,13] In fact, it has been established that a combination of O and N donor atoms on such macrocyclic structures promotes the formation of complexes with large-sized transition metal cations as opposed to those with smaller radii.[15] Based on the fact that large stability constants could lead to a high selectiv-

ity,[17] we report herein on the synthesis of three new oxa-aza functionalized $Ru(tpy)_2^{2+}$ receptors. The main goal of this work has been the quest for new potential chemosensors for toxic heavy metal cations.

Results and Discussion

Synthesis and Characterization

4′-[4-(Bromomethyl)phenyl]-2,2′:6′,2′′-terpyridine (Br-mphtpy) was synthesized according to the procedure of Spahni and Calzaferri.[18] From this derivative, terpyridine-functionalized crowns could be readily prepared by reaction with the appropriate macrocycle in dichloromethane in the presence of Et_3N at 30 °C for 24 h, followed by column chromatography on alumina using a mixture of CH_2Cl_2/MeOH as the eluent. This led to yields of ca. 30% for L^1 and L^2, of 35% for L^3, and of 50% for L^4.

Ligands L^1 and L^2 show very similar ^1H NMR spectra, the main difference being the appearance of the proton signal of the amine group at δ = 2.5 in the spectrum of L^1, which is not observed in the case of L^2. The pyridyl proton signals are seen in the range δ = 7.3−8.8. The spectra are completed by two groups of signals, one in the range δ = 2.7−3.0, corresponding to the protons of CH_2 groups attached to a nitrogen atom in the crown, and the other in the range δ = 3.6−3.9, attributable to benzylic protons and to the protons of CH_2 groups bonded to oxygen atoms. The ^1H NMR spectrum of L^3 shows signals due to the protons of CH_2 groups bonded to an N atom in the crown at δ = 2.8, and signals due to the protons of the CH_2 groups attached to an O atom as well as those of the benzylic protons in the range δ = 3.4−3.8. The ^1H NMR spectrum of L^4 is also in agreement with the proposed formulation.

Reactions of equimolar amounts of L^1, L^3, or L^4 with [Ru(mtpy)Cl_3] in methanol in the presence of *N*-ethylmorpholine as a mild reductant yielded the complexes $[Ru(L^1)(mtpy)][PF_6]_2$, $[Ru(L^3)(mtpy)][PF_6]_2$, and $[Ru(L^4)(mtpy)][PF_6]_2$, respectively, after precipitation with ammonium hexafluorophosphate and column chromatography on silica using acetonitrile/water/satd. aq. KNO_3 (17:1:2, *v*/*v*) as the eluent. The FAB mass spectra showed peaks at *m*/*z* = 1177, 1033, and 887 for $[Ru(L^1)(mtpy)][PF_6]_2$, at *m*/*z* = 1135, 990, and 845 for $[Ru(L^3)(mtpy)][PF_6]_2$, and at *m*/*z* = 1174, 1030, and 885 for $[Ru(L^4)(mtpy)][PF_6]_2$, corresponding to {$[Ru(L)(mtpy)][PF_6]_2$}, {$[Ru(L)(mtpy)][PF_6]^+$}, and {$[Ru(L)(mtpy)]^{2+}$}, respectively. The ^1H NMR spectra of the ruthenium complexes showed the expected signals due to the aromatic protons in the region δ = 7.1−9.1. They were fully assigned with the assistance of ^1H-^1H correlation spectroscopy (COSY). The spectra also featured signals due to the protons of the terminal CH_3 groups, at δ = 2.93 in each case. The signals due to the protons of the CH_2 groups

attached to a nitrogen atom appeared at ca. δ = 3.3, whereas those due to the protons of CH_2 groups bonded to oxygen atoms were seen at δ = 3.6−4.0. The ruthenium complex of L^4 shows signals due to the protons of the polyazacycloalkane ring in the region δ = 2.8−3.2.

The homoleptic complex of L^3 was obtained by treating $RuCl_3$ with two equivalents of L^3 in methanol in the presence of *N*-ethylmorpholine as a mild reductant, followed by precipitation with ammonium hexafluorophosphate and column chromatography. The FAB mass spectrum of $[Ru(L^3)_2][PF_6]_2$ showed peaks at *m*/*z* = 1240, 1094, and 920, corresponding to $\{[Ru(L^3)_2][PF_6]_2\}$, $\{[Ru(L^3)_2][PF_6]^+\}$, and $\{[Ru(L^3)_2]^{2+}\}$, respectively. The ^1H NMR spectrum of the $[Ru(L^3)_2][PF_6]_2$ complex was also in agreement with the proposed formulation.

Photophysical Characterization and pH-Dependence of the Fluorescence

The electronic spectra of the complexes were found to be as expected for an $[Ru(tpy)_2]^{2+}$ chromophore, with the main Ru[d(π)] → tpy(π*) MLCT transition at ca. 484 nm and the usual intense ligand-centred transitions in the UV region.[5,6] It is likely that the absorption band at ca. 484 nm corresponds to a mixture of dπ(Ru) → π(mtpy) and dπ(Ru) → π(L^n) transitions for the heteroleptic $[Ru(L^1)(mtpy)][PF_6]_2$, $[Ru(L^3)(mtpy)][PF_6]_2$, and $[Ru(L^4)(mtpy)][PF_6]_2$ complexes and to the transition dπ(Ru) → π(L^3) in the case of the homoleptic $[Ru(L^3)_2][PF_6]_2$ complex, which would otherwise give a narrower absorption band.[19] The photophysical properties of the complexes $[Ru(L^1)(mtpy)][PF_6]_2$, $[Ru(L^3)(mtpy)][PF_6]_2$, $[Ru(L^4)(mtpy)][PF_6]_2$, and $[Ru(L^3)_2][PF_6]_2$ in acetonitrile/water (70:30, *v*/*v*) at 298 K are summarized in Table 1.

Table 1. Photophysical properties of the complexes $[Ru(L^1)(mtpy)][PF_6]_2$, $[Ru(L^3)(mtpy)][PF_6]_2$, $[Ru(L^4)(mtpy)][PF_6]_2$, and $[Ru(L^3)_2][PF_6]_2$ in acetonitrile/water (70:30, *v*/*v*) at 298 K

	abs. (298 K)		em. (298 K)
	λ [nm]	ε [M^{-1} cm^{-1}]	λ [nm]
$[Ru[L^1](mtpy)][PF_6]_2$	480	17500	652
$[Ru(L^3)(mtpy)][PF_6]_2$	483	17700	650
$[Ru(L^4)(mtpy)][PF_6]_2$	484	17000	650
$[Ru(L^3)_2][PF_6]_2$	482	16800	652

One of the most attractive features of these complexes is their multicomponent nature as they contain sites suitable for coordinating metal ions in the vicinity of a fluorescent $Ru(tpy)_2^{2+}$ group. It is known that, compared to acyclic structures, macrocyclic receptors generally display more selective complexation. Additionally, the introduction of central oxygen donor atoms in macrocycles has been used to achieve selectivity for large metal ions as opposed to small ones.[15] The presence of aza-oxa macrocycles in the metallo receptors $[Ru(L^1)(mtpy)][PF_6]_2$, $[Ru(L^3)(mtpy)][PF_6]_2$, and $[Ru(L^3)_2][PF_6]_2$ thus makes them good candidates as fluorescent signalling systems for toxic heavy metal ions in solution.

The fluorescence behaviour of the complexes $[Ru(L^1)(mtpy)]^{2+}$, $[Ru(L^3)(mtpy)]^{2+}$, $[Ru(L^4)(mtpy)]^{2+}$, and $[Ru(L^3)_2]^{2+}$ was investigated in acetonitrile/water mixtures as a function of the pH, in the absence and presence of transition metal ions M^{2+} (M^{2+} = Cu^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+}) {see Figure 1 (a) for $[Ru(L^1)(mtpy)]^{2+}$, Figure 1 (b) for $[Ru(L^3)(mtpy)]^{2+}$, Figure 1 (c) for $[Ru(L^3)_2]^{2+}$, and Figure 1 (d) for $[Ru(L^4)(mtpy)]^{2+}$}.

The complexes $[Ru(L^1)(mtpy)]^{2+}$, $[Ru(L^3)(mtpy)]^{2+}$, and $[Ru(L^3)_2]^{2+}$ display an emission maximum at ca. 650 nm, the intensity of which is seen to be pH-dependent. In the case of $[Ru(L^1)(mtpy)]^{2+}$, an enhancement of the luminescence of ca. 60% is observed upon protonation, which is close to the enhancement seen for the $[Ru(L^3)(mtpy)]^{2+}$ complex. Remarkably, the enhancement in the emission intensity of $[Ru(L^3)_2]^{2+}$ upon protonation is ca. twice that observed for the heteroleptic complexes. In contrast, the emission intensity of the $[Ru(L^4)(mtpy)]^{2+}$ complex is seen to be almost pH-independent, showing only a slight increase at acidic pH. This suggests that the electron- or energy-transfer path from the amine to the $Ru(tpy)_2^{2+}$ fluorophore is more effective in aza-oxa derivatives than in the polyazacycloalkane. In fact, negligible pH-dependence was also found for the ruthenium(II) complex [Ru(cyphtpy)(mtpy)]$^{2+}$ {cyphtpy = 1-[4′-(*p*-tolyl)-2,2′:6′,2′′-terpyridyl]-1,4,8,11-tetraazacyclotetradecane}, which contains a cyclic tetraamine unit anchored to the ruthenium(II) bis(terpyridine) centre.[11]

Typical quantum yields for these complexes are around $5 \cdot 10^{-5}$, comparable to those reported for similar ruthenium bis(terpyridyl) complexes.[19] Unfortunately, these low quantum yields prevent further studies on the lifetimes of the excited states. As stated above, the intensities of the emission maxima (or quantum yields) of the $[Ru(L^1)(mtpy)]^{2+}$, $[Ru(L^3)(mtpy)]^{2+}$, and $[Ru(L^3)_2]^{2+}$ complexes are pH-dependent. In order to gain a better understanding of the pH-dependent fluorescent behaviour seen for the aza-oxa-functionalized bis(terpyridyl) ruthenium(II) complexes, further studies were carried out on the $[Ru(L^1)(mtpy)]^{2+}$ complex. Two possible mechanisms may be invoked to account for the fluorescence quenching of the $Ru(tpy)_2^{2+}$ signalling unit,[19] i.e. electron transfer and energy transfer. The occurrence or otherwise of an electron-transfer mechanism can be assessed on the basis of electrochemical and photophysical data. For instance, the free energy associated with the electron-transfer process $[Ru(tpy)_2^{2+}*-amine] \rightarrow [Ru(tpy)_2^{+}-amine^{+}]$, where an electron from the lone pair of the amine is transferred to an orbital of the fluorophore leading to a quenching process, can be calculated from the equation: $\Delta G = -(hcN_A/\lambda) + F[E^0_{amine+/amine} - E^0_{fl/fl-}]$ (fl = fluorophore), where $E^0_{amine+/amine}$ and $E^0_{fl/fl-}$ are the redox potentials associated with the redox processes 'amine$^+$ + 1 e^- → amine' and 'fl + 1 e^- → fl$^-$', respectively, and λ relates to the so-called spectroscopic energy that can be obtained from the emission fluorescence spectrum. Redox potentials were measured in dry acetonitrile (containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate) at 25 °C. Cyclic voltammograms

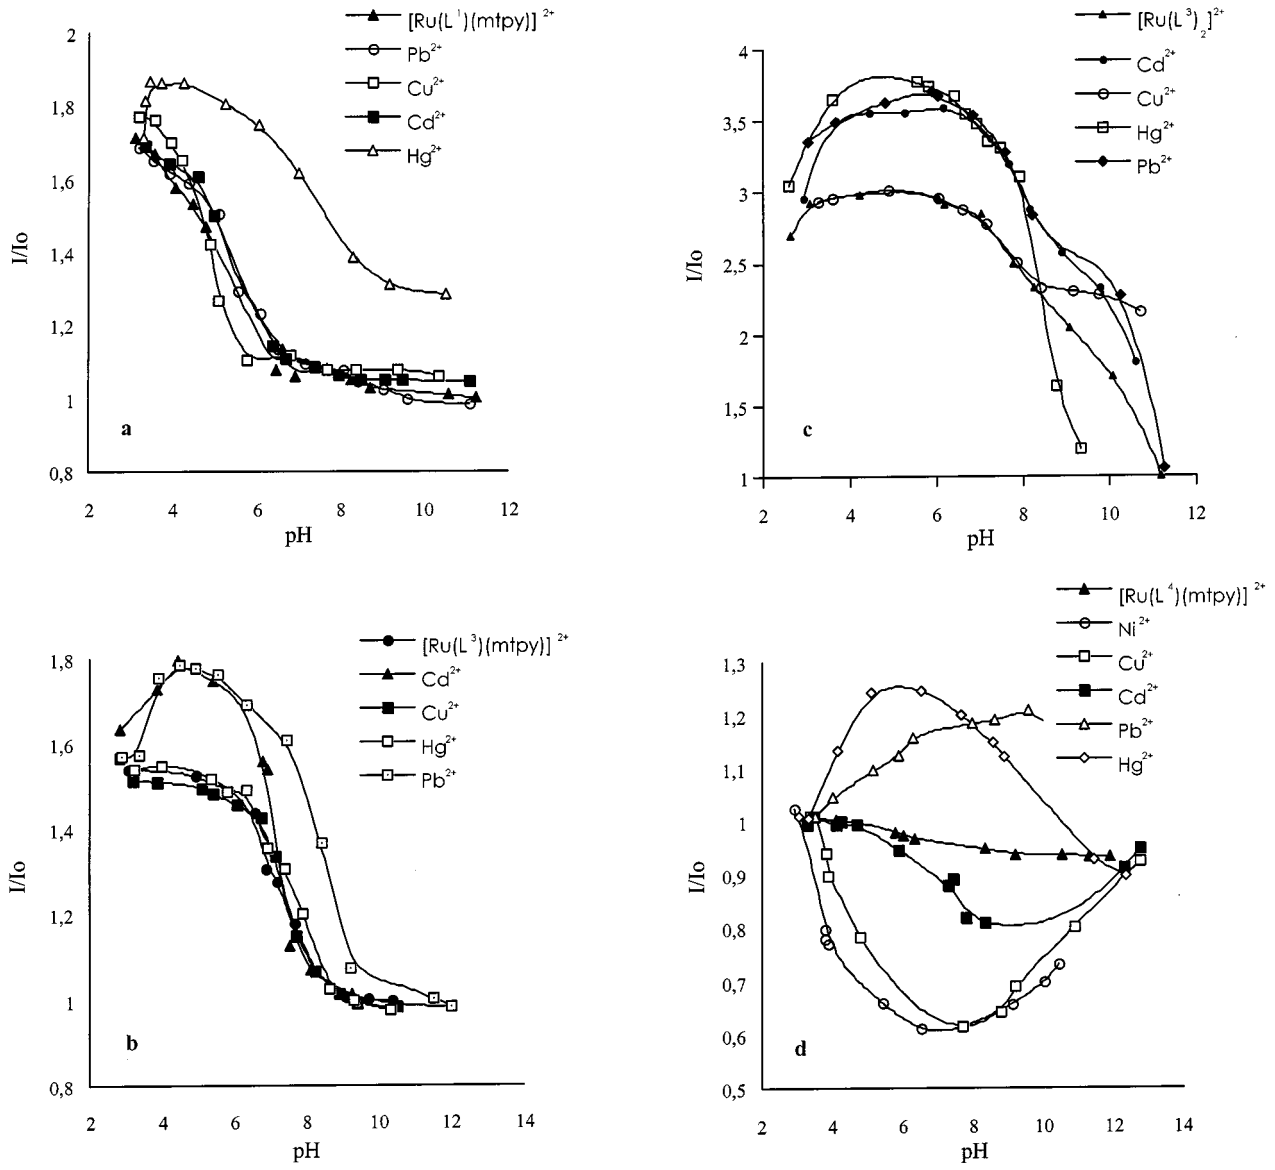

Figure 1. Relative emission intensity versus pH for the L and L−M^{2+} systems: (a) L = $[Ru(L^1)(mtpy)][PF_6]_2$, M^{2+} = Cu^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}; (b) L = $[Ru(L^3)(mtpy)][PF_6]_2$, M^{2+} = Cu^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}; (c) L = $[Ru(L^3)_2][PF_6]_2$, M^{2+} = Cu^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}; (d) L = $[Ru(L^4)(mtpy)][PF_6]_2$, M^{2+} = Ni^{2+}, Cu^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}

of the ruthenium complex $[Ru(L^1)(mtpy)]^{2+}$ show two oxidation processes, at 1.05 V and 1.23 V. The first of these is irreversible and can be ascribed to the oxidation of the 4,10-diaza-15-crown-5, whereas the second corresponds to the oxidation of the Ru^{II} centre. The complex $[Ru(L^1)(mtpy)]^{2+}$ also displays two quasi-reversible reduction processes at −1.25 and −1.52 V, attributable to the formal reduction of the $Ru(tpy)_2^{2+}$ core. Taking these data into account, the ΔG value obtained is ca. −6.5 kcal/mol. This negative value suggests that a photoinduced electron-transfer process from the amine to the $Ru(tpy)_2^{2+}$ fluorophore is possible. This is probably the mechanism that is operative under conditions of basic pH (where the amine is not protonated). When the pH is decreased, the amine groups are protonated, and the oxidation of the amine becomes more difficult, thus making ΔG positive. A positive value of the free energy reduces the probability of electron-transfer processes and therefore an increase in the emission intensity would be expected at acidic pH, as is indeed observed (Figure 1).

Sensing Response towards Transition Metal Ions

The I/I_0 vs. pH curve for the free receptor $[Ru(L^1)(mtpy)]^{2+}$ remains essentially unchanged in the presence of the transition metal ions Cu^{2+}, Cd^{2+}, and Pb^{2+} (see Figure 1). In contrast, in the presence of Hg^{2+}, a different I/I_0 vs. pH profile is seen over a wide pH range. The presence of Hg^{2+} led to an enhancement of the emission intensity by as much as 60% at pH 6.5, with some enhancement even being observed at lower pH. This intensity increase may be attributed to the formation of $[Ru(L^1)(mtpy)]^{2+}-Hg^{2+}$ species, in which the lone pair of the nitrogen atom would no longer be available for the photoinduced electron-transfer process owing to its involvement in the coordinative interaction. At this point it is interesting to note that the 4,10-

diaza-15-crown-5 cycle has also been *N*-functionalized with the organic anthrylmethyl fluorophore.[20] Whereas the metal ions Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} had no modifying effect on the fluorescence intensity vs. pH profile of the anthryl derivative, the presence of Hg^{2+} enhanced the emission intensity in the range pH 5−9. This result is similar to that found for the $[Ru(L^1)(mtpy)]^{2+}$ complex in the presence of metal ions, suggesting that both fluorophores, i.e. the $Ru(tpy)_2^{2+}$ and the anthryl signalling subunits, are able to selectively detect the presence of Hg^{2+} through a combination of coordination to an appropriate binding site (the 4,10-diaza-15-crown-5 cycle) and enhancement of the fluorescence.

To gain insight into the interaction of Hg^{2+} with $[Ru(L^1)(mtpy)]^{2+}$, protonation and coordination studies were carried out by means of potentiometric titrations of previously acidified solutions of the ruthenium(II) complex in acetonitrile/water (70:30, *v*/*v*, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) with KOH. Protonation constants are given in Table 2, while stability constants for the formation of Hg^{2+} complexes with $[Ru(L^1)(mtpy)]^{2+}$ are given in Table 3. The $[Ru(L^1)(mtpy)]^{2+}$ complex displays two protonation process with basicity constants of $\log K = 9.47$ and $\log K = 7.67$. These values are close to those found for the analogous ferrocenylmethyl-functionalized derivative 7,13-ferrocenylmethyl-7,13-diaza-15-crown-5 ($\log K = 8.49$ and $\log K = 6.69$ in dioxane/water, 70:30, *v*/*v*).[21]

Table 2. Stepwise protonation constants in acetonitrile/water (70:30, *v*/*v*, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) for $[Ru(L^1)(mtpy)]^{2+}$

Reaction	log *K*[a]
$[Ru(L^1)(mtpy)]^{2+} + H^+ \rightleftarrows [Ru(HL^1)(mtpy)]^{3+}$	9.47(1)
$[Ru(L^1)(mtpy)]^{2+} + 2\ H^+ \rightleftarrows [Ru(H_2L^1)(mtpy)]^{4+}$	17.14(2)

[a] Values in parentheses are standard deviations in the last significant digit.

Table 3. Stability constants (log *K*) for the formation of the Hg^{2+} complexes of $[Ru(L^1)(mtpy)]^{2+}$ in acetonitrile/water (70:30, *v*/*v*, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) at 25 °C

Reaction	log *K*[a]
$Hg^{2+} + [Ru(HL^1)(mtpy)]^{3+} \rightleftarrows \{Hg[Ru(HL^1)(mtpy)]\}^{5+}$	14.24(3)
$Hg^{2+} + [Ru(L^1)(mtpy)]^{2+} \rightleftarrows \{Hg[Ru(L^1)(mtpy)]\}^{4+}$	6.23(3)
$Hg^{2+} + [Ru(L^1)(mtpy)]^{2+} + H_2O \rightleftarrows \{Hg(OH)[Ru(L^1)(mtpy)]\}^{3+} + H^+$	−3.57(4)
$Hg^{2+} + [Ru(L^1)(mtpy)]^{2+} + 2\ H_2O \rightleftarrows \{Hg(OH)_2[Ru(L^1)(mtpy)]\}^{2+} + 2\ H^+$	−13.27(3)

[a] Values in parentheses are standard deviations in the last significant digit.

The coordination behaviour of the receptor $[Ru(L^1)(mtpy)]^{2+}$ towards Hg^{2+} has been studied. Our aim was to explore the coordination ability of the aza-oxa cycle and the effect of the presence of a bulky, charged $Ru(tpy)_2^{2+}$ group on the coordination of metal ions. Hg^{2+} was chosen because of the selective fluorescence response seen in the presence of this cation. An exhaustive and detailed coordination study was beyond the scope of this article, mainly due to the relatively low yields achieved in the synthesis of the complex $[Ru(L^1)(mtpy)][PF_6]_2$ and of the related complexes mentioned in this paper.

From the refinement of the potentiometric data in the range pH 2−10.5 in the presence of Hg^{2+}, the species $\{Hg[Ru(HL^1)(mtpy)]\}^{5+}$, $\{Hg[Ru(L^1)(mtpy)]\}^{4+}$, $\{Hg(OH)[Ru(L^1)(mtpy)]\}^{3+}$, and $\{Hg(OH)_2[Ru(L^1)(mtpy)]\}^{3+}$ were found. The stability constant for the equilibrium $Hg^{2+} + [Ru(L^1)(mtpy)]^{2+} \rightleftarrows \{Hg[Ru(L^1)(mtpy)]\}^{4+}$ was evaluated as $\log K = 6.23$. We have recently studied the interaction of Hg^{2+} with the ferrocene-functionalized ligand 7,13-ferrocenylmethyl-7,13-diaza-15-crown-5. In this case, the logarithm of the formation stability constant of the ligand with Hg^{2+} was measured as $\log K = 8.79$ in dioxane/water (70:30, *v*/*v*).[21] Although a different solvent system has been used for the study of the interaction between Hg^{2+} and the aforementioned $Ru(tpy)_2^{2+}$- and ferrocene-functionalized receptors, it seems that the presence of the positively charged, bulky $Ru(tpy)_2^{2+}$ signalling subunit might impose some constraints on the coordination of Hg^{2+} by the aza-oxa macrocycle and makes the stability constant with $[Ru(L^1)(mtpy)]^{2+}$ lower than that with the analogous ferrocene-functionalized derivative. Figure 2 shows the distribution diagram for the $[Ru(L^1)(mtpy)]^{2+}-Hg^{2+}-H^+$ system.

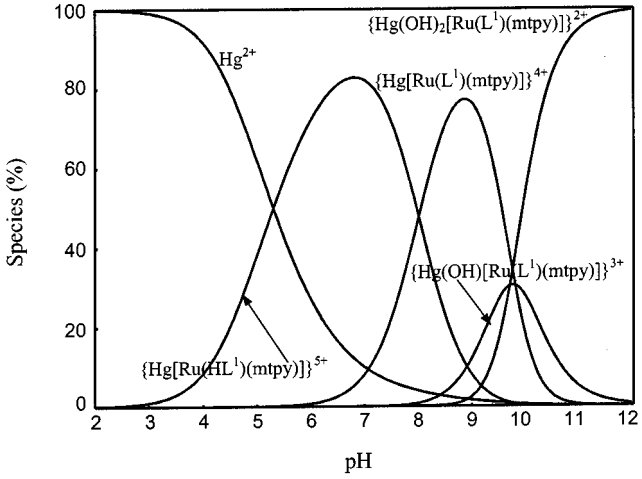

Figure 2. Distribution diagram of the species for the system $[Ru(L^1)(mtpy)]-Hg^{2+}-H^+$

Figure 1b shows the I/I_0 vs. pH curves for the $[Ru(L^3)(mtpy)]^{2+}$ complex in the presence of metal ions. The I/I_0 vs. pH profiles for this complex are similar with Cu^{2+} and Hg^{2+}, but in the presence of Cd^{2+} and Pb^{2+} an enhancement of the emission intensity of the order of 30% is observed in the range pH 4−6. The 1,4,7-trioxa-10-azacyclododecane unit has also been *N*-functionalized with anthryl groups as fluorescent signalling subunits.[20] In contrast to the fluorescent behaviour of the $[Ru(L^3)(mtpy)]^{2+}$ complex, the anthracene-containing derivative does not show any response in the presence of the metal ions Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, or Hg^{2+}. The signalling fluores-

cence behaviour of the ruthenium and anthrylazamacrocycle compounds in the presence of metal ions is quite different, highlighting the active role that the signalling subunit might play in the selectivity of the sensing event.

The fluorescence response of the $[Ru(L^3)_2]^{2+}$ complex has also been studied in acetonitrile/water (70:30, *v*/*v*) as a function of pH in the presence of two equivalents of Cu^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+}. This receptor contains two peripheral aza-oxa units, rather than just one as in the analogous $[Ru(L^3)(mtpy)]^{2+}$ complex. The *I* vs. pH curve for $[Ru(L^3)_2]^{2+}$ does not change in the presence of Cu^{2+}, but the presence of Cd^{2+}, Pb^{2+}, or Hg^{2+} induces an enhancement in the luminescence of the $Ru(tpy)_2^{2+}$ core in the range pH 3.5−7.5 (see Figure 1c). The behaviour observed for the $[Ru(L^3)_2]^{2+}$ complex is quite similar to that seen for $[Ru(L^3)(mtpy)]^{2+}$, the only difference being the sensing of Hg^{2+} by the homoleptic complex, which is not observed for the heteroleptic one. This behaviour is not easy to rationalize, but it nevertheless seems to highlight the importance of slight structural modifications of the receptor in determining the final fluorescent behaviour. It is noteworthy that the $[Ru(L^3)(mtpy)]^{2+}$ receptor is able to sense the presence of all three toxic heavy metal ions Cd^{2+}, Pb^{2+}, and Hg^{2+} in an aqueous environment (acetonitrile/water) at the commonly encountered neutral pH in preference to smaller metal ions such as Cu^{2+}.

Finally, the emission properties of the $[Ru(L^4)(mtpy)]^{2+}$ complex in the presence of Ni^{2+}, Cu^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+} were monitored as a function of pH. This receptor contains a polyazacycloalkane unit covalently attached to the $Ru(tpy)_2^{2+}$ fluorophore rather than an aza-oxa macrocycle as in $[Ru(L^1)(mtpy)]^{2+}$, $[Ru(L^3)(mtpy)]^{2+}$, and $[Ru(L^3)_2]^{2+}$. This is reflected in the observation of a quite different response towards metal ions. All five metals induce a change in the fluorescence response of the $[Ru(L^4)(mtpy)]^{2+}$ receptor, as shown in Figure 1d. Ni^{2+}, Cu^{2+}, and Cd^{2+} quench the fluorescence intensity of the free receptor over a wide pH range. In contrast, Pb^{2+} and Hg^{2+} enhance the fluorescence of the receptor. The fluorescent response as a function of the pH in the presence of Cu^{2+} resembles that found with the receptor $[Ru(cyphtpy)(mtpy)]^{2+}$, which contains a cyclic tetraamine moiety anchored to the ruthenium(II) bis(terpyridine) centre.[11] It is interesting to note that there seems to be a close relationship between the emission intensity and the radii of the metal cations; large metal ions enhance the fluorescence of the $Ru(tpy)_2^{2+}$ core, whereas smaller ones have a quenching effect. This represents rather unusual behaviour, which, to the best of our knowledge, has not been reported previously. In Figure 3, the relative fluorescence at pH 7.5 found in the presence of Ni^{2+}, Cu^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+} ions is plotted as a function of the cationic radius. A linear response between emission intensity and cation size can be seen.

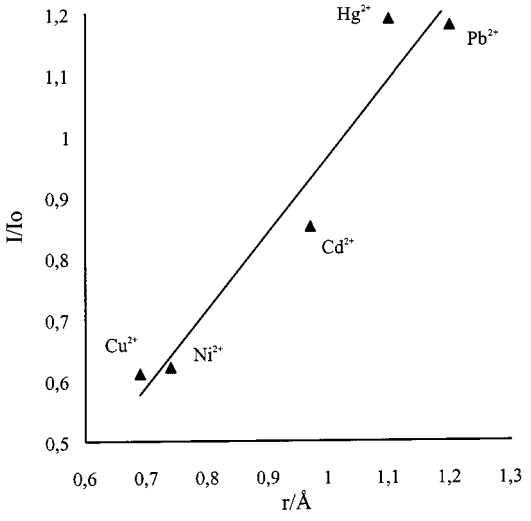

Figure 3. Relative fluorescence at pH 7.5 found for the interaction of Ni^{2+}, Cu^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+} ions with $[Ru(L^4)(mtpy)][PF_6]_2$ as a function of the cationic radius

Conclusions

New terpyridine derivatives attached to aza-oxa macrocycles have been synthesized and their homoleptic or heteroleptic ruthenium(II) complexes have been prepared. One of the most interesting features of these metallo receptors is their multicomponent nature, in that they consist of an $Ru(tpy)_2^{2+}$ core capable of acting as a fluorescent signalling subunit and an aza-oxa macrocycle unit that acts as a cation binding site. Studies have been mainly carried out with a view to achieving discrimination between toxic heavy metal ions by means of fluorescence techniques. The receptors $[Ru(L^1)(mtpy)]^{2+}$, $[Ru(L^3)(mtpy)]^{2+}$, and $[Ru(L^3)_2]^{2+}$ are capable of transforming a coordination event occurring at the molecular level into a measurable macroscopic signal, thus allowing the sensing of heavy metal ions such as Cd^{2+}, Pb^{2+}, and especially of Hg^{2+} in water/acetonitrile (70:30, *v*/*v*) mixtures. The $[Ru(L^4)(mtpy)]^{2+}$ receptor, containing a polyazacycloalkane moiety as a binding site, shows a quite different response with the fluorescence of the $Ru(tpy)_2^{2+}$ core being enhanced by large metal ions and quenched by smaller ones. A linear response between emission intensity and cation size was found for this metallo receptor.

Experimental Section

General Remarks: $[Ru(mtpy)Cl_3]$[22] and 4′-[4-(bromomethyl)-phenyl]-2,2′:6′,2′′-terpyridine (Br-mphtpy)[18] were prepared according to the published methods; all other reagents were obtained from commercial sources and were used as received.

Preparations

Synthesis of L^1 and L^3: A solution of 4′-[4-(bromomethyl)phenyl]-2,2′:6′,2′′-terpyridine (Br-mphtpy) (200 mg, 0.5 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a solution of 4,10-diaza-15-crown-5 (545 mg, 2.5 mmol) in order to obtain L^1, or to a solution of 1-aza-12-crown-4 (438 mg, 2.5 mmol) in CH_2Cl_2 (20 mL) in order to afford L^3. The respective solutions were treated with 5 drops of Et_3N and then heated at 30 °C for 24 h. Each reaction mixture was washed with water (3 × 3 mL). The organic phases were dried with $MgSO_4$ and concentrated under reduced pressure. The residues

were purified by column chromatography on alumina using CH_2Cl_2/CH_3OH (99:1, *v*/*v*) as the eluent. A yellow oil was obtained, which solidified on keeping the flask under reduced pressure. Yields: 81 mg, 30% for L^1; 87 mg, 35% for L^3.

L^1: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.4 (1 H, NH), 2.70−2.85 (8 H, CH_2N), 3.5−3.7 (12 H, CH_2O and 2 H, CH_2Ph), 7.28−7.32 (2 H, tpy 5-,5′′-H), 7.42−7.48 (2 H, Ph), 7.75−7.85 (2 H, tpy 4-,4′′-H and 2 H, Ph), 8.55−8.60 (2 H, tpy 6-,6′′-H), 8.65−8.70 (2 H, tpy 3-,3′′-H and 2 H, tpy 3′-,5′-H). − ^{13}C NMR ($CDCl_3$): δ = 48.8 (CH_2), 54.3 (CH_2), 60.1 (CH_2), 69.0−71.0 (CH_2), 118.8 (CH, tpy), 121.3 (CH, tpy), 123.8 (CH, tpy), 127.2 (CH, tolyl), 129.4 (CH, tolyl), 149.1 (CH, tpy), 155.9 (C, tpy), 156.1 (C, tpy). − $C_{32}H_{37}N_5O_3{\cdot}CH_2Cl_2$ (624.6): found C 64.0, H 6.0, N 10.8; L^1 requires C 63.5, H 6.2, N 11.2. − FAB MS: *m*/*z* (%) = 540 (60), 461 (35), 401 (30), 327 (65), 281 (50), 221 (55).

L^3: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.8 (4 H, CH_2N), 3.65−3.75 (12 H, CH_2O and 2 H, CH_2Ph), 7.33−7.36 (2 H, tpy 5-,5′′-H), 7.52−7.54 (2 H, Ph), 7.85−7.87 (2 H, tpy 4-,4′′-H and 2 H, Ph), 8.69−8.72 (2 H, tpy 6-,6′′-H), 8.72−8.73 (2 H, tpy 3-,3′′-H), 8.74 (s, 2 H, tpy 3′-,5′-H). − ^{13}C NMR ($CDCl_3$): δ = 54.9 (CH_2), 60.6 (CH_2), 70.2 (CH_2), 70.5 (CH_2), 71.3 (CH_2), 119.7 (CH, tpy), 121.3 (CH, tpy), 123.7 (CH, tpy), 127.1 (CH, tolyl), 129.5 (CH, tolyl), 136.8 (CH, tpy), 149.1 (CH, tpy), 150.7 (C, tolyl), 155.8 (C, tpy), 156.1 (C, tpy). − $C_{30}H_{32}N_4O_3{\cdot}CH_2Cl_2$ (581.5): found C 65.0, H 6.0, N 9.8; L^3 requires C 64.0, H 5.8, N 9.6. − FAB MS: *m*/*z* (%) = 497 (100), 322 (45), 193 (15).

Synthesis of L^2: A solution of 4′-[4-(bromomethyl)phenyl]-2,2′:6′,2′′-terpyridine (Br-mphtpy) (200 mg, 0.5 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a solution of 4,10-diaza-15-crown-5 (54.5 mg, 0.25 mmol) in CH_2Cl_2 (20 mL). The resulting mixture was treated with 5 drops of Et_3N and then heated at 30 °C for 24 h. It was subsequently washed with water (3 × 3 mL). The organic phase was dried with $MgSO_4$ and concentrated under reduced pressure. The residue was purified by column chromatography on alumina using CH_2Cl_2/CH_3OH (99:1, *v*/*v*) as the eluent. A yellow oil was obtained, which solidified on keeping the flask under reduced pressure. Yield: 63 mg, 30%.

L^2: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.7−2.85 (8 H, CH_2N), 3.40−3.70 (12 H, CH_2O), 4.5 (4 H, CH_2Ph), 7.2−7.3 (4 H, tpy 5-,5′′-H), 7.38−7.44 (4 H, Ph), 7.80−7.90 (4 H, tpy 4-,4′′-H and 4 H, Ph), 8.60−8.62 (2 H, tpy 6-,6′′-H), 8.66−8.72 (4 H, tpy 3-,3′′-H and 4 H, tpy 3′-,5′-H). − ^{13}C NMR ($CDCl_3$): δ = 54.4 (CH_2), 60.1 (CH_2), 69.5 (CH_2), 70.7 (CH_2), 118.1 (CH, tpy), 121.3 (CH, tpy), 123.8 (CH, tpy), 127.1 (CH, tolyl), 129.4 (CH, tolyl), 136.8 (CH, tpy), 149.1 (CH, tpy), 155.9 (C, tpy), 156.1 (C, tpy). − $C_{54}H_{52}N_8O_3{\cdot}CH_2Cl_2$ (946.0): found C 69.0, H 6.0, N 10.8; L^2 requires C 69.8, H 5.7, N 11.8. − FAB MS: *m*/*z* (%) = 861 (40), 322 (90), 281 (45), 207 (60).

Synthesis of L^4: A solution of 4′-[4-(bromomethyl)phenyl]-2,2′:6′,2′′-terpyridine (Br-mphtpy) (200 mg, 0.5 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a solution of 1,4,7,10,13-pentaazacyclopentadecane (500 mg, 2.5 mmol). The resulting mixture was treated with 5 drops of Et_3N and then heated at 30 °C for 24 h. It was subsequently washed with water (3 × 3 mL). The organic phase was dried with $MgSO_4$ and concentrated under reduced pressure. The residue was purified by column chromatography on alumina using CH_2Cl_2/CH_3OH (99:1, *v*/*v*) as the eluent. A yellow oil was obtained, which solidified on keeping the flask under reduced pressure. Yield: 120 mg, 50%.

L^4: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.5−2.9 (20 H, CH_2), 3.6 (2 H, CH_2Ph), 7.25−7.28 (2 H, tpy 5-,5′′-H), 7.40−7.42 (2 H, Ph), 7.70−7.80 (2 H, tpy 4-,4′′-H and 2 H, Ph), 8.55−8.60 (2 H, tpy 6-,6′′-H), 8.65−8.70 (2 H, tpy 3-,3′′-H and 2 H, tpy 3′-,5′-H). − ^{13}C NMR ($CDCl_3$): δ = 48.8 (CH_2), 56.3 (CH_2), 60.1 (CH_2), 68.5−71.0 (CH_2), 118.7 (CH, tpy), 121.2 (CH, tpy), 123.8 (CH, tpy), 127.2 (CH, tolyl), 129.4 (CH, tolyl), 148.9 (CH, tpy), 155.8 (C, tpy), 156.3 (C, tpy). − $C_{32}H_{40}N_8$ (536.7): found C 71.2, H 7.8, N 20.8; L^4 requires C 71.6, H 7.5, N 20.9. − FAB MS: *m*/*z* (%) = 537 (100), 323 (100), 281 (35), 237 (35).

Synthesis of $[Ru(L^1)(mtpy)][PF_6]_2$, $[Ru(L^3)(mtpy)][PF_6]_2$, and $[Ru(L^4)(mtpy)][PF_6]_2$: These ruthenium complexes were all prepared in the same way. A mixture of the appropriate ligand (L^1 108 mg, L^3 99.4 mg, L^4 107 mg; 0.2 mmol), $[Ru(mtpy)Cl_3]$ (90 mg, 0.2 mmol), and 3 drops of *N*-ethylmorpholine, as a mild reductant, in MeOH (20 mL) was heated to reflux under stirring for 1 h. The resulting deep-red solution was then filtered through Celite to remove any unchanged $[Ru(mtpy)Cl_3]$. Further purification was accomplished by chromatography on silica using acetonitrile/water/satd. aq. KNO_3 solution (17:2:1) as the eluent. The complexes were isolated as their hexafluorophosphate salts.

$[Ru(L^1)(mtpy)][PF_6]_2$: Yield 48 mg, 20%. − ^{1}H NMR (300 MHz, CD_3CN): δ = 2.98 (s, 3 H, CH_3), 3.3−3.4 (4 H, CH_2N), 3.60−3.65 (4 H, CH_2N), 3.7−3.9 (12 H, CH_2O and 2 H, CH_2Ph), 7.15−7.20 (4 H, tpy 5-,5′′-$H^{1,2}$), 7.40−7.45 (4 H, tpy 6-,6′′-$H^{1,2}$), 7.90−8.00 (2 H, Ph and 2 H, tpy 4-,4′′-$H^{1,2}$), 8.30−8.32 (2 H, Ph), 8.48−8.50 (2 H, tpy 3-,3′′-H^1), 8.68−8.70 (2 H, tpy 3-,3′′-H^2), 8.70 (s, 2 H, tpy 3′-,5′-H^1), 9.08 (s, 2 H, tpy 3′-,5′-H^2); 1 = mtpy; 2 = Phtpy. − $C_{48}H_{50}F_{12}N_8O_3P_2Ru{\cdot}CH_2Cl_2$ (1262.5): found C 45.9, H 3.8, N 9.3; $[Ru(L^1)(mtpy)][PF_6]_2$ requires C 46.4, H 4.1, N 8.8. − FAB MS: *m*/*z* (%) = 1177 (25), 1033 (65), 887 (100), 671 (10).

$[Ru(L^3)(mtpy)][PF_6]_2$: Yield 45 mg, 20%. − ^{1}H NMR (300 MHz, CD_3CN): δ = 2.97 (s, 3 H, CH_3), 3.5 (4 H, CH_2N), 3.7−3.8 (8 H, CH_2O), 3.95−4.0 (4 H, CH_2O), 4.52 (2 H, CH_2Ph), 7.15−7.25 (4 H, tpy 5-,5′′-$H^{1,2}$), 7.40−7.45 (4 H, tpy 6-,6′′-$H^{1,2}$), 7.84 (2 H, Ph), 7.95 (4 H, tpy 4-,4′′-$H^{1,2}$), 8.3 (2 H, Ph), 8.46−8.48 (2 H, tpy 3-,3′′-H^2), 8.66−8.68 (2 H, tpy 3-,3′′-H^1), 8.71 (s, 2 H, tpy 3′-,5′-H^2), 9.01 (s, 2 H, tpy 3′-,5′-H^1); 1 = mtpy; 2 = Phtpy. − $C_{46}H_{45}F_{12}N_7O_3P_2Ru{\cdot}2H_2O$ (1170.9): found C 47.3, H 3.9, N 8.3; $[Ru(L^3)(mtpy)][PF_6]_2$ requires C 47.2, H 4.2, N 8.4. − FAB MS: *m*/*z* (%) = 1135 (20), 990 (55), 845 (100), 671 (10).

Physical Measurements and Instrumentation

Photochemical data were obtained with an FS900CDT steady-state T-Geometry Fluorometer from Edinburgh Analytical Instruments. All solutions for photophysical studies were rigorously degassed. The concentrations of the ligand and of the metal ion were ca. $1.0{\cdot}10^{-4}$ mol dm^{-3}. ^1H NMR spectra were recorded on a Varian Gemini spectrometer. Potentiometric titrations were carried out in acetonitrile/water (70:30, *v*/*v*, 0.1 mol dm^{-3} tetrabutylammonium perchlorate) under nitrogen using a vessel water-thermostatted at 25.0 ± 0.1 °C. The titrant was added by means of a Crison microburette 2031. Further details of the potentiometric experiments have been published previously.[23] The concentrations of the metal ions were determined using standard methods. The computer program SUPERQUAD[24] was used to calculate the protonation and stability constants. The titration curves for each system (ca. 250 experimental points, corresponding to at least three titration curves; pH range investigated 2.5−10.2; ligand and metal ion concentrations ca. $1.0{\cdot}10^{-3}$ mol dm^{-3}) could be treated either as a single set or as separate entities without significant variation in the values of the stability constants. Finally, the sets of data were merged together and treated simultaneously to give the quoted stability constants.

Ground State Modulation in Nickel(III) Chemistry by Controlling Axial Ligation in Complexes with N_3O_2 Pentadentate Ligands

Dora Pinho,[a] Paula Gomes,[a][‡] Cristina Freire,*[a] and Baltazar de Castro*[a]

Keywords: EPR spectroscopy / Nickel / Redox chemistry / Schiff bases / Voltammetry

The accessibility of the +3 oxidation state for nickel(II) complexes with N_3O_2 pentadentate Schiff base ligands prepared by condensation of naphthaldehyde or 3,5-dichlorosalicylaldehyde with triamines (Scheme 1) has been assessed in several solvents, by combining cyclic voltammetry and EPR spectroscopy of the oxidised metal complexes. The data show that trien/Metrien-based ligands act in pentadentate fashion and allow for the stabilisation of electrochemically and chemically generated nickel(III) complexes in all solvents used. The complexes, formulated as $[Ni^{III}L(solv)]^+$, are low-spin and have a $^2A_1$, [$a\ d_{z^2} + b\ d_{x^2-y^2}$], ground state, with $a \geq b$. For dien-based ligands, steric constraints prevent coordination of the amine nitrogen atom of the pentadentate ligand to the metal centre, thus enforcing a fourfold coordination on the ligand. The resulting complexes can be oxidised to nickel(III) species, but only when using iodine as oxidant, in DMF or $(CH_3)_2SO$. The complexes are formulated as $[Ni^{III}L(solv)_2]^+$, and are low-spin and have a $^2A_1$, [$a\ d_{z^2} + b\ d_{x^2-y^2}$], ground state, with $a >> b$. The binding of pyridine and cyanide ion to Ni^{III} trien/Metrien-based complexes was studied by EPR. The data obtained show that these polydentate ligands provide a flexible coordination sphere, and that by varying the ratio equatorial/axial ligand field it is possible to obtain Ni^{III} in three different ground states. For pyridine adducts, the same ground state as the parent complex was observed with Metrien-based ligands, while for trien-based ligands an inverted ground state ($^2A_1$, [$a\ d_{z^2} + b\ d_{x^2-y^2}$], with $a << b$) was observed, as the latter provides a higher axial ligand field. On the other hand, coordination of cyanide adducts induces a change in the principal molecular axis of the Ni^{III} complexes, in which the cyanide ions occupy equatorial positions, and in which a $^2A_1$, [$a\ d_{z^2} + b\ d_{x^2-y^2}$], ground state, with $a >> b$, is observed.

Introduction

We have become interested in the redox chemistry of nickel(II) complexes with N_2O_2 Schiff ligands, obtained by condensation of salicylaldehyde/naphthaldehyde with diamines, and on the characterisation of the oxidised/reduced species.[1−10] These tetradentate ligands are noninnocent in oxidation and reduction processes, and their solution oxidative behaviour is intricate, as both the metal centre and the ligand can be the final electron donor. It has been found that, although ligands with substantial π delocalisation favour ligand oxidation, the solvent plays a determining role in controlling the final oxidation site,[1−8] since oxidation of square-planar Ni^{II} complexes proceeds with the simultaneous coordination of two solvent molecules. Consequently, complexes are oxidised to Ni^{III} only in strong donor solvents, such as DMF and $(CH_3)_2SO$, whereas in poorly coordinating solvents, ligand oxidation takes place and the products are radical Ni^{II} species[2,3,11] or Ni^{II} conducting polymers.[7,8]

Nickel(III) complexes with these Schiff ligands are six-coordinate, with the polydentate ligand defining the equatorial plane and with the two elongated axial bonds occupied by solvent molecules. The complexes are invariably low-spin, with a $^2A_1$ [$a\ d_{z^2} + b\ d_{x^2-y^2}$] ground state, with $a >> b$.[1−6] Axial bonds are labile, and substitution of solvent molecules by Lewis bases (such as pyridines, imidazole, phosphanes, and CN^-) is easily accomplished.[1−6] All these adducts have the same ground state as the parent Ni^{III} complex, but their decomposition to nickel(II) species is much faster.

In order to reduce solvent influence on the accessibility of the +3 oxidation state in nickel complexes with Schiff bases derived from salicylaldehyde/naphthaldehyde, and thus to increase the range of solvents in which Ni^{III} complexes can be obtained, we have synthesised similar ligands, but ones in which the diamines bear a nitrogen donor atom, thereby constituting potential pentadentate ligands. By changing the donor ability of the inserted nitrogen atom and the length of the carbon imine bridge, it is possible to control the structures of the complexes and the reactivities of the metal centres.

In this work, we report the characterisation, using EPR and electronic spectroscopy, of several electrochemically and chemically generated nickel(III) complexes with N_3O_2 pentadentate Schiff base ligands, prepared by condensation of naphthaldehyde or 3,5-dichlorosalicylaldehyde with a triamine (Scheme 1). The accessibility of the +3 oxidation state to nickel(II) complexes was assessed by cyclic voltammetry in several solvents. EPR was the technique of choice for studying nickel complex oxidation, as this technique allows a clear distinction to be made between metal-based

and ligand-based oxidised species. The characterisation of nickel(III) species has revealed that these pentadentate ligands make the nickel(III) complexes less solvent-dependent, and thus it was possible to observe Ni^{III} oxidised species in methanol, a solvent with moderate coordinating ability. Moreover, by replacing the axially bound atoms with increasingly strong donors, it was possible to demonstrate that the ligands were very flexible and to generate nickel(III) complexes with different ground states, by controlling the ratio of axial to equatorial ligand fields.

Results and Discussion

Structural and Electronic Data for Nickel(II) Complexes

Like those of similar Schiff base complexes,[12−15] the electronic spectra of nickel(II) complexes **1**−**6** can be grouped into two sets on the basis of the size of the imine bridge: complexes with dien-based ligands and with trien- and Metrien-based ligands.

Spectra of complexes with dien bridges (**1**, **2**) are very similar and exhibit high intensity bands in the range 380−460 nm, attributed on the basis of their extinction coefficients to CT and intraligand electronic transitions. The lack of any observed d-d bands above $\lambda \approx 500$ nm, since they must be masked by the high intensity bands, implies a four-coordinate environment for the nickel centre.[12,15] Thus, the amine nitrogen atom of the bridge is not bound to the metal centre and the ligand acts in tetradentate fashion in a *cis* conformation.

The crystal structure of [Ni(Cl_4salMetrien)] (**6**) has been determined;[16] the nickel atom was found to be in a distorted octahedral coordination geometry, with the pentadentate ligand acting effectively as an N_3O_2 donor and with a solvent molecule (1,4-dioxane) occupying the remaining coordination site, *trans* to the amine nitrogen atom. Electronic spectra are consistent with this geometry, exhibiting two d-d bands in the near-infrared region, λ_{max} (ε) = 1159 nm (8 $dm^3mol^{-1}cm^{-1}$) and 966 nm (10 $dm^3mol^{-1}cm^{-1}$), one low-intensity d-d band in the visible region, λ_{max} (ε) = 568 nm (36 $dm^3mol^{-1}cm^{-1}$), and high-intensity bands (CT and intraligand) at wavelengths < 500 nm.

The similarity between the electronic spectra of **6** in the solid state and those of the other trien- and Metrien-based complexes, for which no crystal data are available, is taken to imply that the latter complexes may have similar structures. The ligands are thus assumed to act as pentadentate and to bind in a *trans* conformation. Furthermore, the similarity of the electronic data for complexes **1**−**6** in the solid state and in DMF solution additionally suggests that, in solution, the complexes may have structures that resemble those in the solid, with the sixth position occupied by a solvent molecule.

For complexes with the same aldehyde moieties, those with trien bridges have the d-d bands at higher energies than those with Metrien bridges. This hypsochromic shift reflects the relative position of secondary and tertiary amine nitrogen atoms in the spectrochemical series.[17] On the other hand, the d-d bands of complexes derived from naphthaldehyde are red-shifted relative to those of the corresponding chlorosalicylaldehyde derivatives, implying that the latter are stronger ligands in the nickel(II) complexes studied.

Cyclic Voltammetry of Nickel(II) Complexes

Cyclic voltammetric data in MeOH, DMF, and $(CH_3)_2SO$ are presented in Table 1. As with the spectroscopic data, the electrochemical responses can be grouped into two sets: complexes with dien bridges, which are irreversibly oxidised in all solvents, and complexes with trien and Metrien bridges, for which one oxidation process is normally observed in the potential range studied.

For dien-based complexes, scan rates up to 1.0 V s^{-1} were used. For high sweep rates only one incipient anodic wave could be observed for [Ni(napdien)], and this only in DMF and in $(CH_3)_2SO$. Furthermore, when chemically oxidised with iodine, all dien-based complexes exhibit Ni^{III} EPR signals in frozen DMF and $(CH_3)_2SO$ solutions (see below). These observations suggest that a very fast chemical decomposition of the electrogenerated nickel species may occur in these strongly coordinating solvents after charge transfer, as the carbon backbone of the imine bridge is long enough to induce significant tetrahedral distortions in the com-

[a] All potentials in V vs. Ag/AgCl (1 mol·dm^{-3} NaCl). Solute concentration about 10^{-3} mol·dm^{-3}; scan rate: 0.50 V·s^{-1}; $\Delta E = E_{pa} - E_{pc}$; $E_{1/2} = {}^1/_2(E_{pa}+E_{pc})$; E_{pa} and E_{pc} are the anodic and cathodic peak potentials, respectively. Under the conditions used, $E_{1/2}$ (Fc^+/Fc) is 0.45 V in MeOH, 0.47 V in DMF and 0.48 V in Me_2SO. – [b] Irreversible processes. – [c] Values calculated with the Nicholson equation.[18]

plexes and to make it difficult for solvent molecules to coordinate to the metal centre, thus hindering stabilization of the +3 oxidation state.[2,3,11]

On the other hand, the cyclic voltammograms of trien- and Metrien-based complexes (**3**–**6**) show one anodic wave and the corresponding cathodic wave, with the exception of solutions of naphthaldehyde derivatives in MeOH, which are irreversibly oxidised (Figure 1). The $E_{1/2}$ values for complexes with naphthaldehyde derivatives are less positive than those of the corresponding chlorosalicylaldehyde derivatives. The anodic-cathodic peak potential separations in all solvents are similar to, or (in the case of chlorosalicylaldehyde derivatives) somewhat larger than, those observed for the Fc^+/Fc couple. The i_{pc}/i_{pa} ratios in DMF and $(CH_3)_2SO$ are practically constant and equal to 1 for the naphthaldehyde derivatives, whereas for the chlorosalicylaldehyde derivatives the ratios are smaller (ca. 0.80). With increasing scan rates, a linear dependence is observed between i_p and $v^{1/2}$.

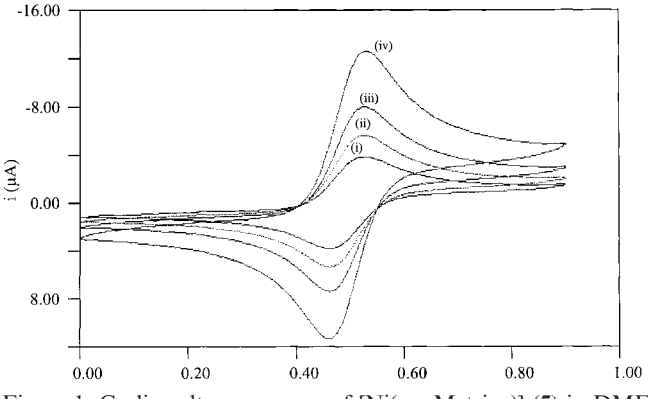

Figure 1. Cyclic voltammograms of [Ni(napMetrien)] (**5**) in DMF at: (i) 0.05; (ii) 0.10; (iii) 0.20, and (iv) 0.50 V·s^{-1}

Electrochemical data for the complexes with trien and Metrien bridges are consistent with one electron diffusion controlled oxidation process $Ni^{II} \rightarrow Ni^{III}$ [18] (see below). For complexes with 3,5-dichlorosalicylaldehyde-based ligands (**4**, **6**), there is direct evidence of a chemical decomposition path for the electrogenerated Ni^{III} species after charge transfer, whereas for naphthaldehyde derivatives, the decomposition path is not evidenced under the experimental conditions used for the cyclic voltammetry. However, during the electrolysis of the complexes (a longer timescale technique), decomposition of the oxidised species was observed for all complexes. Chemical decomposition of electrogenerated Ni^{III} species has also been observed in complexes with N_2O_2 tetradentate Schiff base ligands,[2,3,11] and although no quantitative studies have been performed for the complexes used in this work, we would like to point out that decomposition of the oxidised species are slower for complexes with pentadentate ligands as compared to Ni^{III} species with tetradentate N_2O_2 Schiff bases.

Redox Potentials

Our studies on the electrochemical properties of nickel(II) complexes with N_2O_2 coordination spheres[1–6] have shown that oxidation of the metal centre is markedly dependent on the donor capacity of the solvent, and is restricted to solvents with good donor properties, such as DMF and $(CH_3)_2SO$. When an axial nitrogen donor atom capable of binding to the metal centre is introduced into the ligand (as in trien and Metrien) we observe: (i) a stabilisation of the Ni^{III} species, as inferred from their lower $E_{1/2}$ values and slower decomposition relative to similar N_2O_2 nickel(II) complexes, and (ii) a less marked dependence on the solvent. However, in MeOH, a solvent with lower DN value, a reversible process could only be observed for chlorosalicylaldehyde derivatives (stronger ligands). Our results suggest that, even for these five-coordinate ligands, the oxidation requires a moderately strong solvent, which means that axial interactions with solvent molecules still play an important role in the stabilisation of the +3 oxidation state.

As regards the dependence of redox potential on the ligands for complexes **3**–**6**, those with Metrien bridges exhibit more positive $E_{1/2}$ values than those with trien bridges, contrary to prediction based upon the relative inductive effects of hydrogen atoms and methyl groups. Similar behaviour has been observed in other nickel complexes with similar trien- and Metrien-based ligands and has been attributed to a weakening of the axial bond due to steric constraints between the methyl groups and the propylene backbone of the bridge.[19,20] On the other hand, the complexes with ligands derived from naphthaldehyde exhibit

less positive $E_{1/2}$ values than those derived from chlorosalicylaldehyde, for which the strongly electron-withdrawing substituents (Cl) should reduce electron density on the chelate ring, and thus on the metal ion, making it harder to oxidise the metal centre.

EPR and Electronic Spectra of the Oxidised Species

When nickel(II) complexes **3−6** are oxidised electrochemically in DMF, the solution colour changes from greenish to yellow-brown, implying formation of new species. Frozen-matrix EPR spectra of all electrolysed solutions are similar, and show significant rhombicity and large g tensor anisotropy, with g_{av} [$g_{av} = (g_1 + g_2 + g_3)/3$] in the range 2.13−2.15 ($g_1 \approx 2.24-2.26$, $g_2 \approx 2.13-2.16$ and $g_3 \approx 2.02-2.04$): an indication that the oxidised species must correspond to nickel(III) complexes. Furthermore, all spectra show a well resolved 1:1:1 triplet in the high magnetic field region, with $a \approx 1.80-2.17$ mT. EPR spectra of nickel(III) species with naptrien and napMetrien in DMF are presented in Figure 2 (A) and Figure 3 (A), respectively; EPR data for the electrogenerated nickel(III) species in DMF are summarised in Table 2.

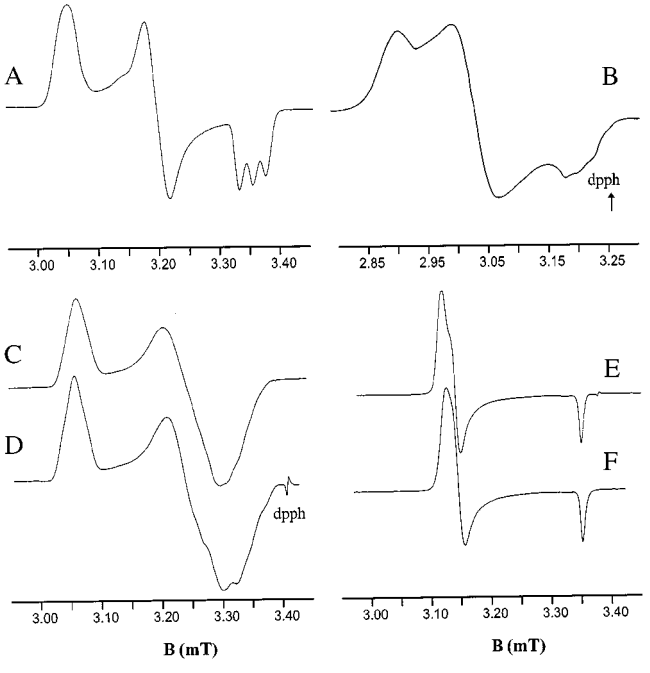

Figure 2. Frozen EPR spectra of $[Ni^{III}(naptrien)]^+$ in: (A) DMF; (B) CH_3CN; (C) pyridine; (D) [^{15}N]pyridine; (E) CN^-, and (F) $^{13}CN^-$

Chemical oxidation of complexes **3−6** with iodine were first performed in DMF. Frozen-matrix EPR spectra of these solutions are identical to those of electrolysed solutions and thus imply the same coordination environment for the nickel(III) species, regardless of the oxidation method used. We also observed that chemically oxidised solutions, owing to the presence in solution of excess oxidant, are more stable at room temperature than those obtained electrochemically.

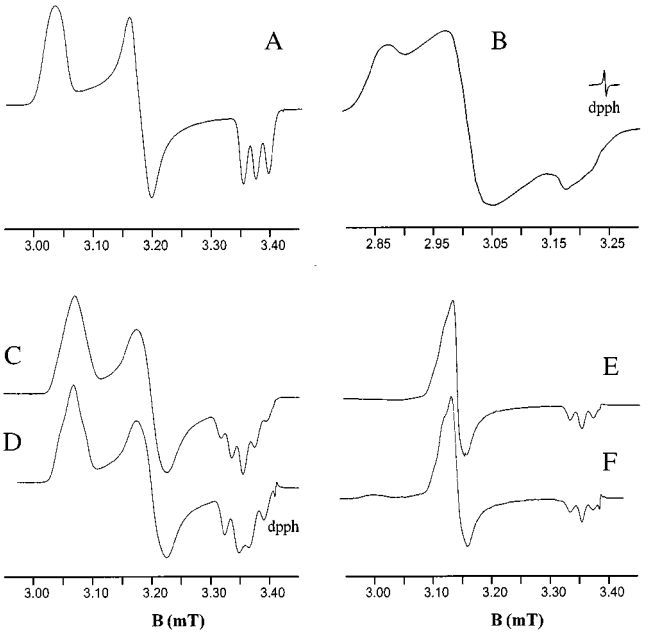

Figure 3. Frozen EPR spectra of $[Ni^{III}(napMetrien)]^+$ in: (A) DMF; (B) CH_3CN; (C) [^{15}N]pyridine; (D) pyridine; (E) CN^-, and (F) $^{13}CN^-$

The similarity of the EPR and the longer half-lives of the chemically oxidised solutions, prompted us to examine chemical oxidation of complexes **1−6** (hence including complexes with dien bridges) in other solvents. The study was extended to two other O-donor solvents, MeOH, and $(CH_3)_2SO$, and to acetonitrile, a N-donor solvent.

Chemically oxidised solutions of complexes **3−6** in MeOH and $(CH_3)_2SO$ exhibit frozen EPR spectra that are very similar to those in DMF, with g values in the same range, and a well resolved triplet (1:1:1) observed in the high magnetic field region, with $a_3 = 2.03-2.30$ mT. Frozen EPR spectra of the chemically oxidised solutions in MeCN exhibit the same g features as those in the O-donor solvents, but with a poorly resolved multiplet, *not a triplet*, in the high magnetic field region. The spectra for nickel(III) species with trien- and Metrien-based ligands in MeCN are presented in Figure 2 (B) and 3 (B), and the EPR parameters are summarised in Table 2.

Solutions of [Ni(napdien)] and [Ni(Cl_4saldien)] (**1**, **2**) were also chemically oxidised in the same solvents, and the oxidised samples were immediately frozen in liquid nitrogen. The oxidised solutions exhibit EPR spectra, but their g features depend on the solvent used. EPR data for **1−2** are presented in Table 2 and spectra of **1** are depicted in Figure 4. In DMF and $(CH_3)_2SO$, the spectra exhibit large g tensor anisotropy, with g_{av} in the range 2.15−2.16, and small rhombicity; however, no hyperfine couplings were detected in any g region (Figure 4, C,D). The EPR spectrum in MeCN shows two superimposed signals with similar intensities: one signal for which the low-field components have a g value similar to those of the chemically oxidised species in DMF and $(CH_3)_2SO$, and one isotropic signal, with $g \approx 2.00$, due to radical species, which masks the high-field component of the other signal (Figure 4, B); in MeOH

[a] The value of g_{av} was calculated as $(g_x + g_y + g_z)/3$. – [b] $a(N)$ values are expressed in mT. – [c] EPR spectrum typical of a radical species with $g = 2.003$. – [d] Two superimposed EPR spectra are observed: typical of Ni^{III} and radical species.

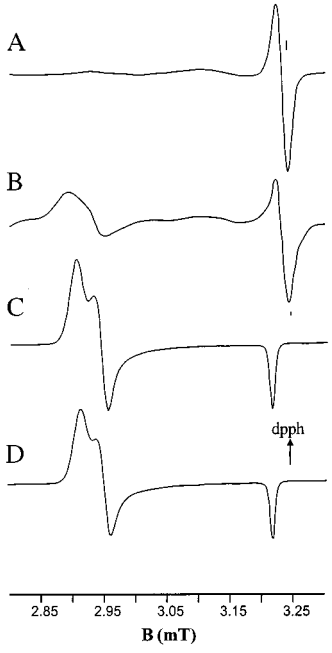

Figure 4. Frozen EPR spectra of $[Ni^{III}(napdien)]^+$ in: (A) CH_3OH; (B) CH_3CN; (C) DMF, and (D) $(CH_3)_2SO$

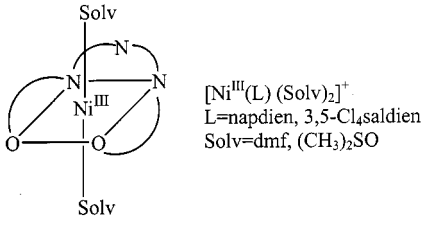
the spectrum exhibits only the isotropic signal at $g \approx 2.00$ (Figure 4, A).

The similarity between the g values in the spectra of the chemically oxidised [Ni(Cl_4saldien)] and [Ni(napdien)] and in those of low-spin, six-coordinate nickel(III) with N_2O_2-related Schiff ligands may be used as a basis for proposing that complexes **1**–**2** have the same $^2A_1$ ground state, [$a\ d_{z^2} + b\ d_{x^2-y^2}$], with $a >> b$: $C_{2v}(z)$.[1–6,21–25] Thus, the lack of observed hyperfine coupling with any nitrogen atom in the EPR spectra indicates that the amine nitrogen atom remains unbound; hence the ligand behaves as a tetradentate N_2O_2 donor towards Ni^{III}. The transient nickel(III) species are low-spin and six-coordinate, with two solvent molecules (Solv) axially bound, and can be formulated as $[Ni^{III}L(Solv)_2]^+$, with L = napdien or Cl_4saldien (Scheme 2).

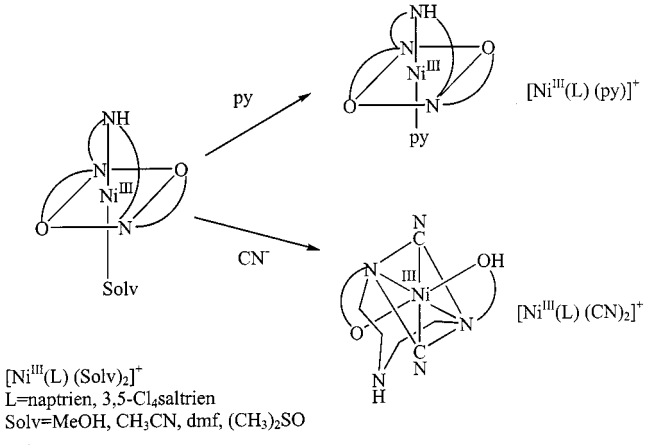


Scheme 2

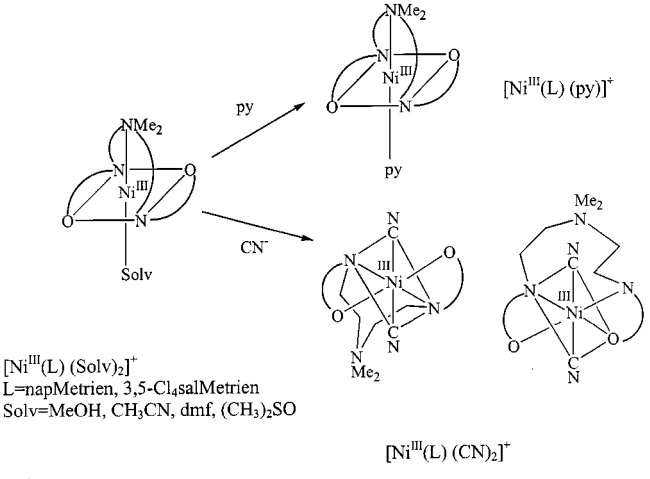
In MeCN, two EPR signals were observed: one of radical-type and another from one metal-centred oxidised species. The radical species may be short-lived intermediates in the chemical decomposition path of the oxidised Ni^{III} complexes. No analysis of the nickel(III) species can be performed, as the intense signal at $g = 2.00$ masks the high-

field component, but the similarity of the low-field components with those of nickel(III) species in DMF and $(CH_3)_2SO$ implies the formation of $[Ni^{III}L(MeCN)_2]^+$ in solution. In MeOH only the signal assigned to radical species was observed, but this signal cannot be assigned unambiguously, since two possible explanations can be invoked: it may (i) be due to short-lived intermediates in the chemical decomposition of putative Ni^{III} oxidised species, or (ii) be the end result of direct oxidation on the ligand.

In contrast, nickel(II) complexes **3−6** are oxidised to Ni^{III} species in all solvents used, and their EPR spectra show behaviour quite different from that of the related complexes with dien-based bridges (Figure 2, Figure 3, and Figure 4). The EPR spectra are more rhombic, but as the difference $g_1 - g_2$ is still smaller than $g_2 - g_3$, the ground state must also be $^2A_1$, [$a\ d_{z^2} + b\ d_{x^2-y^2}$], although with $a \geq b$, and thus $g_1 = g_x$, $g_2 = g_y$, and $g_3 = g_z$.[21−24] The observation of one well-resolved triplet in the low g region (g_z) in O-donor solvents, changing to a poorly resolved multiplet in MeCN, is indicative that: (i) the polydentate ligands act in pentadentate fashion, with the amine nitrogen atom axially bound as in the parent Ni^{II} complex, and (ii) the sixth coordination site is occupied by a solvent molecule. The Ni^{III} complexes are thus formulated as $[Ni^{III}L(Solv)]^+$, with L denoting pentadentate trien- or Metrien-based ligands (Scheme 3 and Scheme 4).



Scheme 3



Scheme 4

Electronic spectra of electrochemically and chemically oxidised solutions of complexes **3−6** in DMF are very similar in the NIR region, but the very intense bands due to the iodine/iodide pair in the chemically oxidised solutions prevent comparisons below $\lambda = 600$ nm. No electronic spectra could be obtained for electrochemically or chemically oxidised solutions of complexes **1−2** in DMF, since decomposition of oxidised species is very fast even in cold fluid solutions (just above the melting point).

Electronic spectra of electrochemically oxidised solutions of **3−6** in DMF exhibit a very broad, medium intensity band in the near IR region ($\lambda_{max} = 950-1100$ nm, $\varepsilon = 200-900$ mol^{-1}dm^{3}cm^{-1}) and very intense bands at $\lambda_{max} < 550$ nm ($\varepsilon > 3000$ mol^{-1}dm^{3}cm^{-1}). Spectra recorded sequentially at 5-min intervals reveal (i) a gradual weakening in the NIR band, until it disappears completely, and (ii) a simultaneous blue shift of the high intensity bands. The spectra obtained after the disappearance of the NIR band are typical of nickel(II) complexes and correspond to solutions in which all nickel(III) species have decomposed, as confirmed by their silent EPR spectra. Moreover, since no electronic bands due to nickel(II) precursors could be detected above 400 nm, the medium intensity NIR bands in the spectra of oxidised solutions may thus be unambiguously attributed to d-d transitions of nickel(III) species generated in situ. The high-intensity bands include charge-transfer bands attributed to Ni^{III} species and to Ni^{II} precursor complexes/nickel(II) decomposed species. Electronic spectral data for nickel(III) species are presented in Table 3.

Table 3. Electronic spectral data for Ni^{III} complexes in DMF and in the presence of Lewis bases

Complex	Co-ligand	λ_{max} (nm)/ε (mmol^{-1}dm^{3}cm^{-1})[a]

(3)	pyridine	980 br (1.1); < 500
	CN^-	700 br (0.37); < 500

[a] ε values were estimated assuming that all complexes had been quantitatively oxidised to Ni^{III} and that no decomposition of the oxidised species had taken place.

Electronic band maxima occur in the range of values observed for six-coordinate nickel(III) complexes with N_2O_2 Schiff base ligands derived from the same aldehyde derivatives and two solvent molecules.[2−6] Analysis of the data in Table 3 reveals that the general trends in band maxima observed for the precursor Ni^{II} complexes also apply to the corresponding nickel(III) species: (i) complexes with dichlo-

rosalicylaldehyde derivatives have electronic bands at shorter wavelengths than those with naphthaldehyde, hence suggesting that the latter ligands also act as weaker ligands for nickel(III), and (ii) given the same aldehyde moiety, complexes with Metrien bridges have band maxima at longer wavelengths than those with trien bridges, indicating that the methyl group, due to steric constraints as outlined for the parent nickel(II) complexes, does not increase the ligand field.

Pyridine Adducts

The solutions obtained by addition of pyridine, and of cyanide ions, to $[Ni^{III}L(Solv)_2]^+$, L = napdien and Cl_4saldien (**1**, **2**) were found to be EPR-silent, which suggests that the decomposition rate of the new species must be fast enough to prevent observation with the experimental set-up used.

Upon addition of pyridine (natural abundance and ^{15}N-enriched) to freshly prepared DMF solutions of $[Ni^{III}L(DMF)]^+$ (L = naptrien, napMetrien, Cl_4saltrien, Cl_4salMetrien), new species were formed, as could be inferred from the rapid colour change to dark brown. The resulting solutions are EPR-active and the frozen solution spectra of complexes with trien and Metrien bridges exhibit different *g* patterns.

Complexes with Metrien Bridge Ligands

The EPR spectra of $[^{14}N]$py adducts with $[Ni^{III}L(DMF)]^+$ (L = napMetrien, Cl_4salMetrien), are similar, with rhombic symmetry and a *g* pattern ($g_1 - g_2 \leq g_2 - g_3$) that resembles that of the nickel(III) precursor complexes. In the high magnetic field region, a well-resolved quintuplet is observed (Figure 3, C), with an apparent 1:2:3:2:1 intensity pattern with $a_3 = 0.19$ mT. The ground state is thus assumed to be $^2A_1$, $[a\ d_{z^2} + b\ d_{x^2-y^2}]$, with $a \geq b$, and $g_1 = g_x$, $g_2 = g_y$, and $g_3 = g_z$.[21−25]

The need to identify the origin of the quintuplet prompted us to perform the same experiments, but using $[^{15}N]$py (^{15}N; $I = {}^1/_2$). The multiplet in the high magnetic field region became a quadruplet (1:2:2:1), arising from the interaction of the unpaired electron with two nitrogen atoms with different *I* values [the amine nitrogen atom (N_{amine}; $I = 1$) and the pyridine nitrogen atom (N_{py}; $I = {}^1/_2$)], but with similar hyperfine couplings [$a_{N(amine)}$ = 1.20; 1.50, and 2.10 mT and $a_{N(py)}$ = 0.80; 0.10, and 2.10 mT]. In this context, the quintuplet observed in the $[^{14}N]$py adducts arises from coupling to two different nitrogen atoms − one from the pentadentate ligand and the other from pyridine − but with similar coupling constants (Table 4). The complexes are thus formulated as low-spin, six-coordinate complexes, $[Ni^{III}(L)(py)]^+$, in which the ligand L (L = napMetrien or Cl_4salMetrien) acts in pentadentate fashion, and one pyridine molecule is bound at the sixth position (Scheme 4).

Complexes with trien Bridge Ligands

The EPR spectra of $[^{14}N]$py adducts with $[Ni^{III}L(DMF)]^+$ when L = naptrien and Cl_4saltrien are different from those with Metrien bridges. They exhibit apparent axial symmetry with large *g* tensor anisotropy, and with a weakly resolved quintuplet ($a_3 \approx 0.17-0.20$ mT) in the high magnetic field region, but with a *g* pattern different to those of the nickel(III) precursor complexes and of the homologous Metrien-based compounds. The *g* pattern is now $g_1 - g_2 > g_2 - g_3$, with $g_1 \approx 2.21$, $g_2 \approx 2.09$ and $g_3 \approx 2.06$ (Table 4). These spectra are consistent with the presence in solution of axially compressed six-coordinate species with a ground state that is essentially $d_{x^2-y^2}$ ($^2A_1$, $[a\ d_{z^2} + b\ ]$, with $a << b$), and in this case $g_1 = g_z$, $g_2 = g_x$, and $g_3 = g_y$.[21−25] Furthermore, the adducts with $[^{15}N]$py exhibit EPR spectra that are identical to those with $[^{14}N]$py, which implies that the hyperfine splittings cannot be due to coordinate pyridine molecules but must arise from the equatorial plane imine nitrogen atoms of the pentadentate ligand, in accordance with the ground state assignment.

Electronic data for the pyridine adducts are summarised in Table 3. The spectra show a broad, medium-intensity band in the NIR region, $\lambda = 975-1000$ nm, and high-intensity bands below 450 nm. On monitoring the spectra at 5-min intervals it was possible to observe a continuous loss of band absorbance for the electronic transition at low energies and a blue shift of the intense bands at high energies, an unambiguous indication that the bands in the NIR are due to d-d transitions in Ni^{III} pyridine adducts. The d-d bands are shifted to higher energies relative to those of the Ni^{III} precursor species, and the shift is related to the increase in ligand field when the sixth axial ligand is changed from DMF to pyridine.

Although no direct information concerning the number of coordinated pyridine molecules could be obtained, we propose that, in the adducts with naptrien and Cl_4saltrien, only one pyridine should be bound (Scheme 3), since in complexes with Metrien base ligands, which impose weaker ligand fields, only one pyridine molecule is bound to the nickel centre.

Cyanide Adducts

Upon addition of potassium cyanide, the solution colour of freshly electrooxidised solutions of $[Ni^{III}L(DMF)]^+$ (with L = naptrien, napMetrien, Cl_4saltrien, Cl_4salMetrien) changes from yellow-brown to green. Frozen solutions of cyanide adducts show EPR spectra that are typical of Ni^{III} species, but with a *g* pattern different to that observed for the parent Ni^{III} complexes and to those of pyridine adducts. These observations provide a clear indication that cyanide binds to the nickel(III) centres.

Frozen-matrix EPR spectra of all cyanide adducts show quasi-axial symmetry and a *g* pattern typical of low-spin, six-coordinate complexes with axial elongation, and with a $^2A_1$ ground state, $[a\ d_{z^2} + b\ d_{x^2-y^2}]$, with $a >> b$; $g_1 = 2.18-2.16$, $g_2 = 2.16-2.15$, $g_3 \approx 2.02$, and $g_1 = g_x$, $g_2 = g_y$, and $g_3 = g_z$ in both cases (Table 4).[1−6,21−25] No hyperfine splittings were detected in the spectra of the adducts with trien-based ligands (Figure 2, E), but those of Metrien-based complexes exhibit a high-field signal split into three lines (not 1:1:1 triplet, $a = 0.19$ mT) (Figure 3, E). In order

Table 4. EPR parameters for nickel(III) species in the presence of pyridine and cyanide ions

[a] The value of g_{av} was calculated as $(g_x + g_y + g_z)/3$. – [b] $a(N)$ values are expressed in mT.

to interpret the spectra, we made use of $^{13}CN^-$ and found that the EPR spectra of the enriched adducts are identical to those with natural abundance CN^- (Figure 2, F, and Figure 3, F): a clear indication that no direct spin interaction of the nickel unpaired electron with the carbon atom of the cyanide ion takes place. Furthermore, we note that the spectrum of $[Ni^{III}(CN)_6]^{3-}$ is completely different from those reported here,[26] which implies that displacement of the pentadentate ligand by cyanide ions had not taken place.

The number of bound cyanide ions could not be determined, and the complexes may thus be formulated as $[Ni^{III}(L)(CN)]$ or, if the cyanide ions replace the solvent molecule and the N(amine) group, as $[Ni^{III}(L)(CN)_2]^{-1}$. However, the latter hypothesis gained some support by the large hypsochromic shift (stronger ligand field) in the d-d transitions, relative to those of the nickel(III) precursor complexes, observed upon cyanide coordination.

Before attempting to interpret the EPR spectra of the cyanide adducts, we must stress that, for all the other Ni^{III} species referred to above, the equatorial plane was defined by the ligand $\{[N_2(imine)O_2]\}$ atoms and the molecular z axis was the $[N(amine)-Ni^{III}-X]$ axis (X = solvent or py) (Scheme 3 and Scheme 4).

Complexes with trien Bridge Ligands

The recognition that the spectra are unambiguously attributable to an axially elongated d_{z^2} ground state and the non-observation of hyperfine splitting in any of the three g regions indicate that neither the cyanide ions ($^{13}CN^-$) nor any nitrogen atom interacts directly with the unpaired electron in the d_{z^2} orbital. Consequently, the oxygen atoms of the pentadentate ligand must occupy the axial positions. The z axis must be the $[O-Ni^{III}-O]$ axis, with the two cyanide ions and the two N(imine) atoms defining the equatorial plane. This arrangement is only possible if the polydentate ligand retains the *trans* configuration of the nickel(II) parent complex (Scheme 3). The ligand field in the $[CN^--Ni^{III}-CN^-]$ direction is very strong and weakens the ligand field in the perpendicular plane, which makes the $[O-Ni^{III}-O]$ bonds longer. A precedent for this proposal is provided by studies on the interaction of cyanide ions with tripeptide complexes of Ni^{III}, for which a change in molecular axis has also been observed upon ligation of cyanide ions.[26–28]

Complexes with Metrien Bridge Ligands

The key difference in the EPR spectra of *Metrien* derivatives is the observation of hyperfine splittings in g_z. As identical spectra were observed for $^{12}CN^-$ and $^{13}CN^-$, the cyanide ions cannot be considered as the origin for the observed splitting. The atoms causing the observed splittings must be the nitrogen atoms of the polydentate ligand, ^{14}N ($I = 1$). The only explanation for the observed multiplet is to assume that the spectra of Metrien derivatives are the superimposition of two spectra: (i) one without any hyperfine splitting and which is similar to those of the trien derivatives, and (ii) the other, which exhibits a 1:1:1 triplet in the g_z region ($a = 2.00-2.10$ mT). The former spectra must correspond to species with the same configuration as those

of $[Ni^{III}(L)(CN)_2]^{-1}$ (with L = naptrien, Cl_4saltrien), with the polydentate ligand in a *trans* conformation. The latter spectra can be accounted for by assuming that the same change in the *z* axis has occurred, but with the *z* axis defined by one imine nitrogen atom and one oxygen atom of the polydentate ligand, which implies a *cis* configuration for the polydentate ligand (Scheme 4).

Conclusions

The accessibility of the +3 oxidation state in the nickel(II) complexes **1−6** is determined primarily by the binding or non-binding of the polydentate ligand amine nitrogen atom to the metal centre, which in turn depends on the number of carbon atoms in the imine bridge. Complexes with dien bridges are irreversibly oxidised in all solvents, under the experimentally used cyclic voltammetric conditions, whereas complexes with trien/Metrien-based ligands show quasi-reversible processes. In the former, steric constraints prevent coordination of the amine nitrogen atom to Ni^{II}, thus enforcing a tetradentate coordination mode for the ligand, but with trien/Metrien bridges the ligand enforces a true N_3O_2 pentadentate coordination sphere.

Formation of nickel(III) complexes takes place with the simultaneous increase of the coordination number to 6, by binding of solvent molecules. Analysis of EPR spectra has permitted unambiguous identification of the oxidised species. Spectra of oxidized trien/Metrien-based complexes are anisotropic, with a $^2A_1$ ground state ($a \geq b$), and provide direct evidence for coordination of the imine bridge nitrogen atom. On the other hand, chemically oxidised dien-based complexes in DMF and $(CH_3)_2SO$ exhibit quasi-axial spectra with a $^2A_1$ ground state ($a >> b$) and no hyperfine couplings, which indicates that the amine nitrogen atom is not coordinated. The difference in stability of dien- and trien/Metrien-based complexes is thus attributable to the binding of the bridging amine nitrogen atom. With one axial coordination position occupied by a strong donor (the ligand amine nitrogen atom), the stabilization of species oxidised at the metal centre is less sensitive to the coordination ability of the solvent molecule bound to the other axial position.

The stability of the Ni^{III} trien/Metrien-based complexes has prompted the study of the interaction of these complexes with pyridine and cyanide ion, ligands of increasing ligand strength. EPR data have made it clear that these polydentate ligands provide a flexible coordination sphere, and that by varying the equatorial/axial ligand field ratio it is possible to obtain Ni^{III} species in three different ground states. Furthermore, it has become evident that the ground state of Ni^{III} species is also dependent on the substituents on the imine bridge nitrogen atom: −H (trien) or $-CH_3$ (Metrien).

For pyridine adducts of Metrien-based complexes, a ground state similar to that of the parent Ni^{III} complex, with $^2A_1$ and $a \geq b$, was obtained, whereas for trien-based complexes an inverted ground state, $^2A_1$, was observed, with $a << b$. The different behaviour was attributed to the stronger axial field induced by the unsubstituted amine nitrogen in the imine bridge, as compared with Metrien, which, when combined with the ligand strength of pyridine, is enough to invert the magnitude of the contribution of the two d orbitals defining the $^2A_1$ ground state.

Upon addition of cyanide ($^{13}CN^-$ and natural abundance CN^-), a more drastic change in the ground state was observed. The rhombic spectra of the parent complexes changed to axial EPR spectra, typical of complexes with a ground state that is formulated as $^2A_1$, with $a >> b$. Combining this result with the non-observation of any hyperfine splitting in trien-based complexes, we propose that the strong ligand field of cyanide ions causes a shortening of the Ni−C bond lengths, so as to change the principal molecular axis of Ni^{III} complexes, but in which the ligand exists in a *trans* conformation. For Metrien-based complexes, similar spectra have been observed, but with hyperfine splittings in the high magnetic field region. The same changes in the principal molecular axis are assumed, but analysis of the hyperfine splitting pattern has prompted us to propose the existence of Ni^{III} complexes in which the ligands exist in *trans* and *cis* conformations, probably a consequence of the steric requirements of the amine nitrogen methyl group.

Experimental Section

Reagents and Solvents: Solvents and reagents for synthesis were obtained from commercial sources and used as received. The solvents used in electrochemistry were from Merck (pro analysi). Pyridine and potassium cyanide were from Merck (p.a.). [^{15}N]Pyridine was purchased from Cambridge Isotope Laboratories and potassium [^{13}C]cyanide from Aldrich. Tetraethylammonium perchlorate (NEt_4ClO_4) was prepared by published procedures[29] from the bromide salt (Aldrich) and perchloric acid (Merck, p.a.).

CAUTION: Perchlorates are hazardous and may explode.

Synthesis of Ligands and Nickel(II) Complexes: The ligands H_2napdien (bis{2-[(2-hydroxynaphthyl)methylimido]ethyl}amine), H_2naptrien (bis{3-[(2-hydroxynaphthyl)methylimido]propyl}amine), H_2napMetrien (bis{3-[(2-hydroxynaphthyl)methylimido]propyl}-(methyl)amine), H_2Cl_4saldien {bis[2-(3,5-dichlorosalicylimido)-ethyl]amine}, H_2Cl_4saltrien {bis[3-(3,5-dichlorosalicylimido)propyl]amine}, and H_2Cl_4salMetrien {bis[3-(3,5-dichlorosalicylimido)propyl](methyl)amine} were prepared by standard methods.[12,17] Typically, the triamine [bis(2-aminoethyl)amine, bis(3-aminopropyl)amine or bis(3-aminopropyl)(methyl)amine] (0.01 mol) was added directly to a warm ethanolic solution of the aldehyde (naphthaldehyde and 3,5-dichlorosalicylaldehyde) (0.02 mol); the reaction mixture was heated to reflux for 30 min and then cooled on ice. The compounds H_2napdien, H_2Cl_4saldien and H_2naptrien precipitated from the solution, yielding yellow solids that were recrystallised from methanol; the other ligands were obtained as brown/yellow oils, after solvent removal.

H_2napdien: Yield: 3.7 g (90%). − $C_{26}H_{25}N_3O_2$ (411.5): calcd. C 75.89, H 6.12, N 10.21; found C 75.80, H 6.12, N 10.19. − ^{1}H NMR ($CDCl_3$, 200 MHz, 297 K): δ = 2.88−3.69 (8 H, *CH*$_2$), 6.68−8.02 (12 H, aromatic H), 9.06 (2 H, *N*=*CH*), 13.91 (2 H, O*H*).

H_2naptrien: Yield: 3.0 g (68%). − $C_{28}H_{29}N_3O_2 \cdot {}^5/_2H_2O$ (484.6): calcd. C 69.40, H 7.07, N 8.67; found C 69.27, H 7.00, N 8.66. − ^{1}H NMR ($CDCl_3$, 200 MHz, 297 K): δ = 1.80−3.70 (12 H, *CH_2*), 6.68−8.02 (12 H, aromatic H), 9.06 (2 H, *N=CH*), 13.95 (2 H, O*H*).

H_2napMetrien: Yield: 3.2 g (70%), obtained as an oil. − ^{1}H NMR ($CDCl_3$, 200 MHz, 297 K): δ = 2.20 (3 H, *CH_3*), 1.85−3.69 (12 H, *CH_2*), 6.69−8.03 (12 H, aromatic H), 9.01 (2 H, *N=CH*), 14.02 (2 H, *OH*).

H_2Cl_4saldien: Yield: 4.2 g (93%). − $C_{18}H_{17}Cl_4N_3O_2$ (449.2): calcd. C 46.03, H 3.86, N 7.67; found C 45.97, H 3.84, N 7.68. − ^{1}H NMR ($CDCl_3$, 200 MHz, 297 K): δ = 2.70−2.82 (8 H, *CH_2*), 7.09−7.38 (4 H, aromatic H), 8.23 (2 H, *N=CH*).

H_2Cl_4saltrien: Yield: 3.5 g (74%), obtained as oil. − ^{1}H NMR ($CDCl_3$, 200 MHz, 297 K): δ = 1.85−2.80 (12 H, *CH_2*), 7.10−7.38 (4 H, aromatic H), 9.86 (2 H, *N=CH*).

H_2Cl_4salMetrien: Yield: 3.4 g (72%), obtained as oil. − ^{1}H NMR ($CDCl_3$, 200 MHz, 297 K): δ = 2.20 (3 H, *CH_3*), 1.86−2.44 (12 H, *CH_2*), 7.08−7.38 (4 H, aromatic H), 8.21 (2 H, *N=CH*)

The nickel(II) complexes were also synthesised by standard procedures;[12,17] typically, ethanolic solutions of the ligands (5 mmol) were added to ethanolic nickel(II) acetate solutions (5 mmol); the resulting solutions were heated to reflux for 60 min. Upon cooling, green solids were collected by filtration, recrystallised from acetonitrile (except for dien-based complexes), and dried under vacuum for several hours.

[Ni(napdien)] (1): Yield: 1.7 g (72%). − $C_{26}H_{23}N_3NiO_2$ (468.2): calcd. C 75.89, H 6.12, N 10.21; found C 75.36, H 6.12, N 10.11. − UV/Vis: λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) = 402 (6600), 420 sh (DMF).

[Ni(naptrien)] (3): Yield: 1.5 g (60%). − $C_{28}H_{27}N_3NiO_2$ (496.3): calcd. C 67.77, H 5.48, N 8.47; found C 67.59, H 5.48, N 8.62. − UV/Vis: λ_{max}/nm (ε/dm^{3}mol^{-1}cm^{-1}) = 1143 (39), 1010 (33), 566 (85), 521 sh, 408 (9700), 389 (11300) (DMF); λ_{max}/nm = 606, 522 sh, 418 (Nujol).

[Ni(napMetrien)] (5): Yield: 1.8 g (68%). − $C_{29}H_{29}N_3NiO_2$ (510.3): calcd. C 68.26, H 5.73, N 8.23; found C 68.79, H 5.72, N 8.17. − UV/Vis: λ_{max}/nm (ε/dm^{3}mol^{-1}cm^{-1}) = 1200 (20), 1013 (10), 570 (63), 521 sh, 408 (10000), 388 (11900) (DMF); λ_{max}/nm = 584, 524 sh, 418 (Nujol).

[Ni(Cl_4saldien)] (2): Yield: 1.9 g (75%). − $C_{18}H_{15}Cl_4N_3NiO_2$ (505.9): calcd. C 48.13, H 3.81, N 9.36; found C 48.97, H 3.82, N 9.39. − UV/Vis: λ_{max}/nm (ε/dm^{3}mol^{-1}cm^{-1}) = 419 (5300), 450 sh (DMF).

[Ni(Cl_4saltrien)] (4): Yield: 1.4 g (53%). − $C_{20}H_{19}Cl_4N_3NiO_2 \cdot 2H_2O$ (533.9): calcd. C 42.15, H 4.07, N 7.37; found C 42.27, H 4.00, N 7.55. − UV/Vis: λ_{max}/nm (ε/dm^{3}mol^{-1}cm^{-1}) = 1088 (10), 935 (11), 564 (30), 384 (8500) (DMF); λ_{max}/nm = 564, 386 (Nujol).

[Ni(Cl_4salMetrien)] (6): Yield: 1.5 g (57%). − $C_{21}H_{21}Cl_4N_3NiO_2$ (547.9): calcd. C 46.03, H 3.86, N 7.67; found C 45.98, H 3.84, N 7.68. − UV/Vis: λ_{max}/nm (ε/dm^{3}mol^{-1}cm^{-1}) = 1159 (8), 966 (10), 568 (36), 381 (10100) (DMF); λ_{max}/nm = 590, 392 (Nujol).

Preparation of the Nickel(III) Complexes and Adduct Formation: Nickel(III) complexes were generated electrochemically by exhaustive electrolysis of DMF solutions 10^{-3} mol·dm^{-3} in nickel(II) precursor and 0.1 mol·dm^{-3} in NEt_4ClO_4 at ca. 4 °C. The time elapsing during the electrolysis was varied from 20 to 45 min; the upper limit was chosen to avoid extensive decomposition of the oxidised species. Chemically oxidised nickel(III) species were obtained by addition of a large excess (ca. 50%) of iodine to solutions of the nickel(II) precursors. Because of the instability of the electrogenerated Ni^{III} species it was not possible to isolate solids, and so these species were generated shortly before measurements and kept frozen in liquid nitrogen. The decay of Ni^{III} species is significantly lessened at low temperatures, and the samples are stable for several days when kept in liquid nitrogen. The adducts were prepared at temperatures just above the softening point of the frozen glass, by addition of freshly electrolysed solution of nickel(III) to frozen solutions or suspensions of the corresponding bases.

Physical Measurements: Elemental analysis (C, H, and N) were performed at the Departmento de Química, Faculdade de Ciências, Universidade do Porto. − Electrochemical measurements were made with a PAR 273 potentiostat, using solutions ca. 10^{-3} mol·dm^{-3} in nickel(II) complex and 0.1 mol·dm^{-3} in NEt_4ClO_4. − Cyclic voltammetry was performed in MeOH, DMF, and Me_2SO, using a platinum microsphere as working electrode, a platinum wire as counter-electrode, and an Ag/AgCl (1 mol·dm^{-3} NaCl) reference electrode. All potentials are reported relative to that of the reference electrode and to $E_{1/2}$ of the ferrocenium/ferrocene couple; under the experimental conditions used, $E_{1/2}$ for the latter couple is 0.48 V in Me_2SO, 0.47 V in DMF and 0.45 V in MeOH. Scan rates from 0.05 to 0.50 V·s^{-1} were used, and the low and high potential limits were 0.00 V and 1.20 V. − Electrolyses in DMF were carried out at controlled potential, at values about 0.10 V higher than the anodic peak potential in a three-electrode cell, using platinum gauze as working and counter-electrodes, and an Ag/AgCl (1 mol·dm^{-3} NaCl) reference electrode (all from Metrohm). − Electronic spectra were recorded with a Shimadzu UV 3101PC spectrophotometer, in the range 1500−300 nm. Conditions used were: room temperature, 10^{-2} and 10^{-4} mol·dm^{-3}, for nickel(II) complexes; and temperature about 4 °C and 10^{-3} mol·dm^{-3} Ni^{II} solutions for chemically and electrolysed Ni^{III} complexes. − EPR spectra were obtained at 77 K with a Bruker ESP 300E X-band spectrometer, using an insert Dewar. The magnetic field was calibrated by using Mn^{2+} in MgO, and diphenylpicrylhydrazyl was used as internal reference (dpph; g = 2.0037). The reported EPR parameters were obtained by spectral simulation using the programme WinEPR Simfonia (Bruker) and assuming rhombic Spin Hamiltonians; line widths were typically in the range 1.5−2.0 (z) to 1.5−3.0 (x, y) mT. The values of $a(N)_{x,y}$ are less accurate, due to the low spectral resolution. Typical experimental conditions used: microwave power 10−15 mW; modulation amplitude 0.5 mT; modulation frequency 100 kHz.

Synthesis and X-ray Crystal Structure of $[U(\eta\text{-}C_8H_8)(HMPA)_3][BPh_4]$, the First Cationic Monocyclooctatetraenyl Compound of Uranium (III), and its Neodymium Homologue

Sophie M. Cendrowski-Guillaume,*[a][‡] Martine Nierlich,[a] and Michel Ephritikhine*[a]

Keywords: Actinides / Uranium / Neodymium / Lanthanides / Cations / Monocyclooctatetraenyl complexes

The title compound was synthesized in 88% yield by reducing the uranium(IV) dication $[U(COT)(HMPA)_3][BPh_4]_2$ (COT = η-C_8H_8) with sodium amalgam while the neodymium analogue was prepared by substitution of the THF ligands in $[Nd(COT)(THF)_4][BPh_4]$. Comparison of the crystal structures of the complexes $[M(COT)(HMPA)_3][BPh_4]$ (M = U, Nd, Sm) shows that the variations in the M–ligand bond lengths simply reflect the differences in the ionic radii of the metals.

Introduction

Recently we reported the synthesis and structural characterization of the uranium(IV) complex $[U(COT)(HMPA)_3][BPh_4]_2$ (**1**) (COT = η-C_8H_8, HMPA = hexamethylphosphoramide), the first organometallic dication of an f-element, which was obtained by protonolysis of the parent borohydride $U(COT)(BH_4)_2$.[1] Cationic metal compounds are interesting since they are potential precursors in inorganic and organometallic syntheses as well as efficient catalysts in various organic reactions. In the course of our studies on the reactivity of **1**, we found that it could be reduced to the uranium(III) complex $[U(COT)(HMPA)_3][BPh_4]$ (**2**). Such cyclooctatetraenyl uranium compounds in the +3 oxidation state are quite rare, being limited to the anionic bis([8]annulene) complex $[K(diglyme)][U(\eta\text{-}C_8H_7Me)_2]$[2] and the neutral mixed-ring complex $[U(COT)(\eta\text{-}C_5Me_5)(L)]$ (L = THF, 4,4′-dimethyl-2,2′-bipyridine).[3] More generally, very few cationic organometallic complexes of uranium(III) have been described: the bis(pentadienyl) complex $[U(\eta\text{-}2,4\text{-}Me_2\text{-}C_5H_5)_2][BPh_4]$,[4] the metallocene complex $[U(\eta\text{-}C_5Me_5)_2(THF)_2][BPh_4]$,[5] and the trinuclear arene complex $[U_3(\eta\text{-}C_6Me_6)_3(AlCl_4)_3Cl_5][AlCl_4]$;[6] only these latter two have been crystallographically characterized. Here we present the synthesis and X-ray crystal structure of **2**, taking the opportunity to compare this structure with that of the U^{IV} dication of **1**, and also with those of the lanthanide analogues $[M(COT)(HMPA)_3]^+$ [M = Nd (**3**) and Sm (**4**)].

Results and Discussion

Synthesis and Characterization

The uranium(III) compound **2** was prepared by treating the orange dication **1** with a slight excess of sodium amalgam in tetrahydrofuran (THF), according to Equation (1).

$$\underset{\mathbf{1}}{[U(COT)(HMPA)_3][BPh_4]_2} + Na(Hg) \xrightarrow{THF} \underset{\mathbf{2}}{[U(COT)(HMPA)_3][BPh_4]} + NaBPh_4 \quad (1)$$

After stirring for 16 h at 20 °C, the green solution was filtered and a green microcrystalline powder of **2** was deposited upon addition of pentane (88% yield). Compound **2** was characterized by elemental analysis (C, H N) and X-ray crystallography (vide infra). The ^1H NMR spectrum exhibits two resonances at δ = 1.7 and −47.4 corresponding to the HMPA and COT ligands, respectively, and shows the presence of only one BPh_4 anion. Oxidation of **2** with $TlBPh_4$ failed to give back the dication **1** and afforded only insoluble unidentified products; this behaviour is not understood.

The synthesis of **2** was not affected by the small excess of sodium amalgam (<3 equivalents), although the monocation reacted further with larger amounts of the reducing agent (>9 equivalents) to give the uranium(IV) compound $U(COT)_2$ as the sole identifiable organometallic product. It is possible that the putative U^{II} species "U(COT)", formed by reduction of **2**, was transformed by disproportionation into uranium metal and uranocene, the latter being inert towards sodium amalgam. While the U^{III} compound $Na[U(\eta\text{-}C_5Me_5)_2Cl_2]$ is known to act as a uranium(II) synthetic equivalent,[7] it is only very recently that the toluene-bridged diuranium complex $[(\mu\text{-}C_7H_8)\{U[N(Ad)Ar]_2\}_2]$ (Ad = adamantyl, Ar = 3,5-C_6H_3-Me_2) was isolated and crystallographically characterized; this complex exhibits a reactivity which is consistent with the formality of divalent uranium.[8]

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0606−1495 $ 17.50+.50/0

The separation of lanthanide(III) and actinide(III) compounds is an important problem in the context of the reprocessing of nuclear wastes and from a basic point of view. Much attention is thus paid to the structural and chemical differentiation of homologous compounds of 4f and 5f elements.[9] In order to compare the crystal structure of **2** with that of lanthanide counterparts, the neodymium compound $[Nd(COT)(HMPA)_3][BPh_4]$ (**3**) was synthesized by substitution of the THF ligands in $[Nd(COT)(THF)_4][BPh_4]$[10] with HMPA, according to Equation (2).

$$[Nd(COT)(THF)_4][BPh_4] + 3\ HMPA \xrightarrow{\text{pyridine}} [Nd(COT)(HMPA)_3][BPh_4] + 4\ THF \quad (2)$$

3

Pink crystals of the solvate **3**.THF were obtained by crystallization from THF. The analogous samarium complex $[Sm(COT)(HMPA)_3]I$ (**4**) was recently prepared by reaction of samarium metal, cyclooctatetraene, and iodine in the presence of HMPA, and its crystal structure has been determined.[11]

Crystal Structures

The crystals of **2** and **3**·THF are composed of discrete cations and anions. The BPh_4 anions display the expected structural parameters. A view of one of the two independent and almost identical cations of **2** and a view of the cation of **3**·THF are shown in Figure 1 and 2, respectively, together with selected bond lengths and angles; the atom numbering scheme is the same for the uranium and neodymium compounds.

The two structures are very similar, both cations adopting a three-legged piano-stool configuration in which the O−M−O angles vary from 83.3(5) to 88.5(6)° for M = U, and from 83.81(16) to 85.95(16)° for M = Nd; the COT−M−O angles (COT = centroid of the C_8H_8 ring) range between 124.5(8) and 132.3(7)° (M = U), and between 125.6(2) and 131.1(2)° (M = Nd). The U(1) and U(2) atoms are 2.00(1) and 2.03(1) Å from the planar COT ring (within ±0.02 Å) and the mean U(1)−C and U(2)−C bond lengths are 2.71(4) and 2.74(6) Å, respectively. These values are almost identical to those found in the other two crystallographically characterized monocyclooctatetraenyl U^{III} complexes, $[K(diglyme)][U(\eta\text{-}C_8H_7Me)_2]$ [1.999 and 2.707(7) Å][2] and $[U(COT)(\eta\text{-}C_5Me_5)(Me_2bipy)]$ (2.01 and 2.703 Å).[3] The Nd−COT distance of 1.984(5) Å in **3** compares well with those determined in mono(COT) neodymium complexes; for example, 1.906(6) Å in $[Nd(COT)(THF)_4][BPh_4]$[10a] and 2.01(1) Å in $[Nd(COT)I(THF)_3]$.[12]

Not surprisingly, the structure of the cation $[Nd(COT)(HMPA)_3]^+$ is quite similar to that of the samarium analogue **4** (Table 1);[11] the Nd−C and Nd−O distances are systematically slightly longer than the Sm−C and Sm−O distances, in agreement with the 0.03 Å difference between the ionic radii of Nd^{3+} and Sm^{3+}.[13]

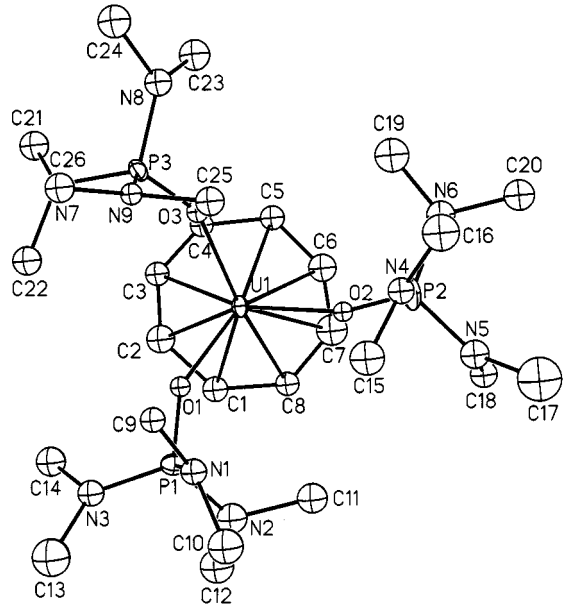

Figure 1. View of the crystal structure of one of the two independent cations $[U(COT)(HMPA)_3]^+$ with thermal ellipsoids drawn at the 30% probability level; selected bond lengths (Å) and angles (°): U(1)−C(1) 2.73(3), U(1)−C(2) 2.65(3), U(1)−C(3) 2.65(3), U(1)−C(4) 2.70(3), U(1)−C(5) 2.75(3), U(1)−C(6) 2.70(3), U(1)−C(7) 2.76(4), U(1)−C(8) 2.72(3), U(1)−O(1) 2.380(16), U(1)−O(2) 2.454(16), U(1)−O(3) 2.401(16), U(1)−COT 2.00(1); O(1)−U(1)−O(2) 84.9(5), O(1)−U(1)−O(3) 85.5(5), O(2)−U(1)−O(3) 83.3(5), COT−U(1)−O(1) 132.3(7), COT−U(1)−O(2) 128.1(8), COT−U(1)−O(3) 126.5(7); COT is the centroid of the C_8H_8 ring

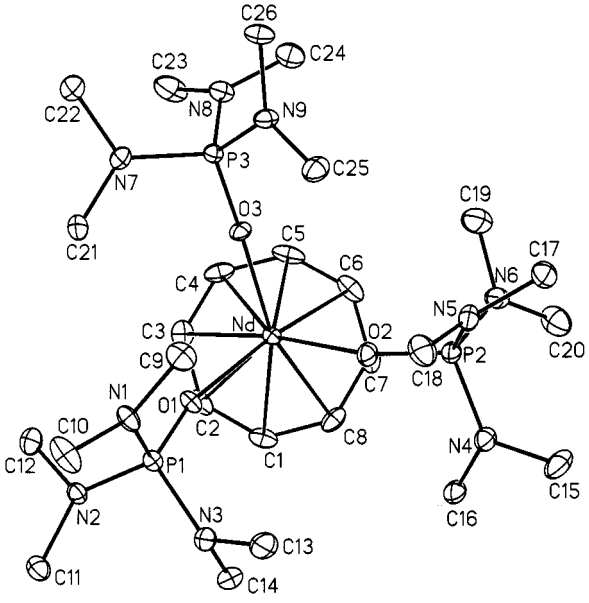

Figure 2. View of the crystal structure of the cation $[Nd(COT)(HMPA)_3]^+$ with thermal ellipsoids drawn at the 30% probability level; selected bond lengths (Å) and angles (°): Nd−C(1) 2.719(7), Nd−C(2) 2.709(7), Nd−C(3) 2.718(7), Nd−C(4) 2.698(7), Nd−C(5) 2.686(7), Nd−C(6) 2.697(7), Nd−C(7) 2.689(8), Nd−C(8) 2.704(7), Nd−O(1) 2.328(5), Nd−O(2) 2.392(5), Nd−O(3) 2.355(4), Nd−COT 1.984(5); O(1)−Nd−O(2) 85.95(16), O(1)−Nd−O(3) 85.76(16), O(2)−Nd−O(3) 83.81(16), COT−Nd−O(1) 125.6(2), COT−Nd−O(2) 131.1(2), COT−Nd−O(3) 129.1(2); COT is the centroid of the C_8H_8 ring

Table 1. Comparison of the geometrical parameters for the cations $[M(COT)L_3]^+$ (M = U, Nd, Sm[10]) and the dication $[U(COT)L_3]^{2+}$ [1] (L = HMPA)

	$[U(COT)L_3]^{+}$[a]	$[Nd(COT)L_3]^+$	$[Sm(COT)L_3]^+$	$[U(COT)L_3]^{2+}$[a]
<M−C> (Å)	2.71(4); 2.74(6)	2.70(1)	2.66	2.65(4); 2.65(3)
M−COT (Å)	2.00(1); 2.03(1)	1.984(5)	1.95	1.92(2); 1.92(2)
<M−O> (Å)	2.41(4); 2.40(6)	2.36(3)	2.31	2.22(2); 2.22(1)
<O−M−O> (deg)	84(1); 87(2)	85(1)	86	86(2); 87(3)

[a] The values for each independent cation are given.

The uranium cation **2** and its neodymium and samarium counterparts **3** and **4** permit a direct comparison of the structural data of homologous uranium(III) and lanthanide(III) compounds. Such comparative examinations have previously been made on only a few pairs of isostructural complexes, with the aim of evaluating and possibly differentiating the nature of the bonds in 4f and 5f element complexes.[14−16] In the cations **2**−**4**, the variations in the metal−ligand bond lengths, listed in Table 1, reflect the differences in the ionic radii of the metals (0.04 Å between U^{3+} and Nd^{3+}, 0.07 Å between U^{3+} and Sm^{3+}).[13] This regular trend agrees with that most generally observed, as for the complexes $[M(\eta\text{-}C_6Me_6)(AlCl_4)_3]$ (M = U, Sm)[14] or $[M(\eta\text{-}C_5Me_5)I_2(THF)_3]$ (M = U, Ce);[15] this was explained by the fact that f orbitals are not substantially involved in ligand bonding. To the best of our knowledge, it is only in the phosphorus complexes $[M(\eta\text{-}C_5H_4Me)_3L]$ (M = U, Ce; L = PMe_3 or $P(OCH_2)_3CEt$) that the U−P bond length was found to be significantly shorter than the Ce−P distance, whereas the U−L and Ce−L distances are the same in the derivatives with oxygen and nitrogen ligands (L = THF, quinuclidine).[16] This difference has been rationalised by postulating uranium-to-phosphorous π bonding which is absent in the lanthanide analogues.

If the structure of the U^{III} cation **2** is now compared with that of the parent U^{IV} dication **1**, it is noteworthy that the difference between the U−O bond lengths, 0.2 Å, is much greater than that observed between the U−C bond lengths, 0.1 Å, which corresponds to the ionic radii variation between U^{4+} and U^{3+}.[13] This feature certainly results from the more positive charge on the dicationic U^{IV} centre, which induces a stronger interaction with the Lewis base.

Experimental Section

General: All preparations were carried out under argon (less than 2 ppm oxygen and water) using standard Schlenk and vacuum line techniques or in a glove box. Solvents were thoroughly dried and deoxygenated by standard methods and distilled immediately before use. $[D_8]$THF was dried over Na-K alloy. The ^{1}H NMR spectra were recorded on a Bruker DPX 200 instrument and were referenced internally using the residual protio solvent resonances relative to tetramethylsilane (δ = 0). Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany). $[Nd(COT)(THF)_4][BPh_4]$ was synthesized as previously reported.[10]

Synthesis of $[U(\eta\text{-}C_8H_8)(HMPA)_3][BPh_4]_2$ (1): This compound was prepared by a slight modification of the published procedure,[1] resulting in an improved yield. A flask was charged with $[(COT)U(BH_4)_2(THF)]$ (0.488 g, 1.10 mmol) and NEt_3HBPh_4 (1.011 g, 2.40 mmol) in THF (40 mL) and HMPA (1.1 mL, 6.32 mmol) was introduced with a syringe. The reaction mixture was stirred for 5 h at 20 °C during which time evolution of gas was observed and an orange powder was deposited from the dark red solution. After evaporation, the crude solid was dried under dynamic vacuum for 18 h. It was then washed with THF (40 mL) and extracted with pyridine (40 mL). The solution was filtered and the solvent was evaporated in vacuo, leaving **1** as a bright orange powder (1.573 g, 94%).

Synthesis of $[U(\eta\text{-}C_8H_8)(HMPA)_3][BPh_4]$ (2): A flask was charged with **1** (592.9 mg, 0.390 mmol) and 2% Na(Hg) (620.0 mg, 0.539 mmol of Na) in THF (40 mL). The reaction mixture was magnetically stirred for 1 h at room temperature, then immersed in an ultrasound bath (60 W, 40 kHz) for 3 h, and finally magnetically stirred for 12 h at room temperature. The green solution was filtered and its volume reduced to ca 10 mL; a green microcrystalline powder of **2** was deposited upon addition of pentane (20 mL). The powder was filtered off and dried under vacuum (411 mg, 88%). − ^{1}H NMR ($[D_8]$THF): δ = 7.12 (br. t, 8 H, *o*-Ph), 6.72 (t, *J* = 6 Hz, 8 H, *m*-Ph), 6.60 (t, *J* = 6 Hz, 4 H, *p*-Ph), 1.7 (br. s, $w_{1/2}$ = 75 Hz, 54 H, HMPA), −47.4 (br. s, $w_{1/2}$ = 120 Hz, 8 H, COT). − $C_{50}H_{82}BN_9O_3P_3U$ (1199): calcd. C 50.09, H 6.90, N 10.51; found C 50.46, H 6.77, N 10.24.

Reaction of 2 with Na(Hg): An NMR tube was charged with **2** (8.1 mg, 6.76 μmol) and 2% Na(Hg) (72.3 mg, 62.9 μmol of Na) in $[D_8]$THF (0.5 mL). The spectra showed the progressive formation of $U(COT)_2$ as the sole identifiable organometallic product, the reaction being complete after 3 days at 20 °C.

Synthesis of $[Nd(\eta\text{-}C_8H_8)(HMPA)_3][BPh_4]$ (3): A flask was charged with $[Nd(\eta\text{-}C_8H_8)(THF)_4][BPh_4]$ (50.51 mg, 0.059 mmol) in pyridine (10 mL), and HMPA (150 μL, 0.862 mmol) was added with a microsyringe. The colour of the solution turned from green to blue; the volume of the solution was reduced to ca 5 mL by evaporation and upon addition of pentane (10 mL), blue microcrystals of **3**·1/$2C_5H_5N$ were deposited. These were filtered off and dried under vacuum (27.0 mg, 40%). − ^{1}H NMR ($[D_8]$THF): δ = 8.44 (s, 1 H, C_5H_5N), 7.53 (s, 1 H, C_5H_5N), 7.20 (br. t, 8.5 H, *o*-Ph + C_5H_5N), 6.78 (t, *J* = 7 Hz, 8 H, *m*-Ph), 6.63 (t, *J* = 7 Hz, 4 H, *p*-Ph), 2.3 (br. s, $w_{1/2}$ = 70 Hz, 54 H, HMPA), −9.9 (br. s, $w_{1/2}$ = 100 Hz, 8 H, COT). − $C_{52.5}H_{84.5}BN_{9.5}O_3P_3Nd$ (1144): calcd. C 55.08, H 7.44, N 11.62; found C 54.91, H 7.58, N 11.75.

X-ray Crystallography of 2: Single crystals of **2** were obtained by crystallization from THF. A crystal of approximate dimensions 0.25 × 0.20 × 0.10 mm was selected. Diffraction collection was carried out on a Nonius diffractometer equipped with a CCD detector. The lattice parameters were determined from ten images recorded with 2° Φ-scans and later refined on all data. The data were

recorded at 123 K. A 180° Φ-range was scanned with 2° steps with a crystal-to-detector distance fixed at 30 mm. Data were corrected for Lorentz-polarization and absorption[17] effects. The structure was solved by the heavy atom method and refined by full-matrix least-squares on F^2 with anisotropic thermal parameters for the U and P atoms. H atoms were introduced at calculated positions as riding atoms with an isotropic displacement parameter equal to 1.2 (CH) or 1.5 (CH_3) times that of the parent atom. $C_{100}H_{164}B_2N_{18}O_6P_6U_2$ (2397.99), monoclinic, space group $P2_1$, a = 10.419(2), b = 31.018(6), c = 17.601(4) Å, β = 100.46(3)°, V = 5593.7(19) Å^3, Z = 2, D_c = 1.424 g cm^{-1}, Mo-K_α (λ = 0.71073 Å), μ_{Mo} = 3.035 mm^{-1}, F(000) = 2444, total reflections = 18725, independent reflections = 7272 (R_{int} = 0.11), observed reflections [$I > 2\sigma(I)$] = 5613, R_1 = 0.075, wR_2 = 0.143. All calculations were performed on an O2 Silicon Graphics Station with the SHELXTL package.[18]

X-ray crystallography of 3·THF: Pink single crystals of **3**·THF were obtained by crystallization of **3**·1/2C_5H_5N from THF. A crystal of approximate dimensions 0.25 × 0.25 × 0.15 mm was selected. Diffraction collection was carried out on a Nonius diffractometer equipped with a CCD detector. The lattice parameters were determined from ten images recorded with 2° Φ-scans and later refined on all data. The data were recorded at 123 K. A 180° Φ-range was scanned with 2° steps with a crystal-to-detector distance fixed at 35 mm. Data were corrected for Lorentz-polarization and absorption [17] effects. The structure was solved by the heavy atom method and refined by full-matrix least-squares on F^2 with anisotropic thermal parameters for all non-H atoms. H atoms were introduced at calculated positions as riding atoms with an isotropic displacement parameter equal to 1.2 (CH) or 1.5 (CH_3) times that of the parent atom. $C_{54}H_{90}BN_9O_4P_3Nd$ (1177.31), monoclinic, space group $P2_1/c$, a = 10.520(2), b = 21.481(4), c = 27.279(6) Å, β = 101.16(3)°, V = 6048(2) Å^3, Z = 4, D_c = 1.293 g cm^{-1}, Mo-K_α (λ = 0.71073 Å), μ_{Mo} = 0.987 mm^{-1}, F(000) = 2476, total reflections = 29850, independent reflections = 8067 (R_{int} = 0.0842), observed reflections [$I > 2\sigma(I)$] = 5823, R_1 = 0.051, wR_2 = 0.122. All calculations were performed on an O2 Silicon Graphics Station with the SHELXTL package.[18]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-151390 (**2**) and -151391 (**3**·THF). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A Continuous Chirality Analysis of Homoleptic Hexacoordinated Complexes

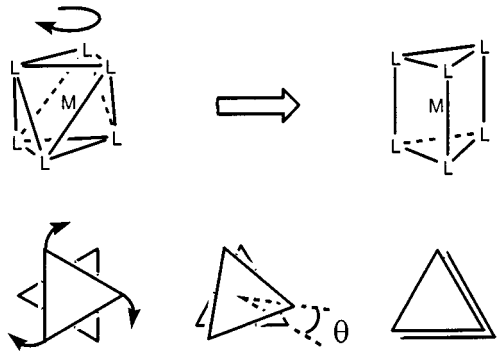
Santiago Alvarez,*[a] Mark Pinsky,[b,c] and David Avnir*[c]

Keywords: Chirality / Stereochemistry / Coordination chemistry / Molecular symmetry / Quantitative chirality

Hexacoordinated complexes are generally considered to be potentially chiral if they have either at least two bidentate ligands or at least three different monodentate ligands. Here we draw attention to a neglected general possibility, namely that homoleptic hexacoordinated complexes with molecular structures in between octahedral and trigonal prismatic, following the Bailar twisting route, are chiral. A quantitative evaluation of the degree of chirality of such hexakis(monodentate) complexes shows that they reach maximum chirality when the trigonal rotation angle of the prism reaches 23°. Model calculations and analysis of experimental X-ray structures are in good agreement. The most chiral of the complexes with monodentate ligands that have been analyzed is $[Zr(SC_6H_4\text{-}4\text{-}OMe)_6]^{2-}$. The validity of the theoretical prediction is also corroborated by an analysis of the chirality of the coordination sphere in twisted tris(chelate) complexes.

Introduction

The chirality of transition metal complexes is of much current interest mainly because of their potential applications as catalysts for asymmetric synthesis.[1] Following von Zelewsky (and somewhat modifying his list),[2] we note that chirality can be induced in coordination compounds by: (i) the existence of different ligands (as in [Mabcdef]); (ii) a special spatial arrangement of ligands (as in one of the stereoisomers of $[Ma_2b_2c_2]$); (iii) the removal of an improper symmetry element of a bidentate ligand through formation of chelate rings (including the mutual breaking of an improper rotation present in such ligands); (iv) coordination of chiral ligands, of ligands which assume chiral conformations or of prochiral ligands (i.e., ligands which become chiral upon coordination because an improper symmetry is broken); or (v) rotational symmetry wrapping of the ligands around the metal. Within the rotational wrapping option, we distinguish several sub-types, namely helical wrapping,[3] the propeller-type arrangement in bis- and tris(chelate) complexes and, of relevance to this report, the Bailar-type twist,[4] which links octahedricity and trigonal prismacity in hexacoordinated complexes, as shown in **1**.



1

Perhaps the most elementary option for obtaining chirality is the Bailar twist, which reduces the achiral point groups O_h and D_{3h} to the chiral D_3 symmetry point group. The simplicity of this option originates from the fact that it allows *homoleptic* $[ML_6]$ complexes to be chiral, with no special requirement for chirality or pro-chirality of the six ligands. Yet, to the best of our knowledge, no enantiomeric crystals of the two D_3 enantiomers have been reported. It is interesting to note that of all the options for obtaining chirality, the one that was highlighted since the dawn of coordination chemistry was option (iii), i.e. the use of bidentate ligands. Starting with the pioneering work of Alfred Werner, who resolved the two enantiomers of the cationic complexes $[CoX(NH_3)(en)_2]^{2+}$ (X = Cl, Br),[5] many other octahedral metal complexes with two or three bidentate ligands have been shown to be chiral.[2,6–12] In fact, option (iii) has overshadowed over the years all the other options for obtaining chirality in hexacoordinated complexes. Thus, it is common to find in textbooks statements such as: "Important examples [of chiral molecules] are bischelate and trischelate octahedral complexes" (ref.[11]); "Chiral complexes occur mainly when chelate rings are formed" (ref.[11] p. 683) "In practice, optical activity is largely confined to octahedral complexes of chelating ligands";[6] **"**The absolute configuration of a chiral complex is described by imagining a view along a threefold rotation axis of a regular octahedron and noting the handedness of the helix formed

by the ligands'', but again, the figure that accompanies the text shows a complex with bidentate ligands.[8,13]

The main purpose of this paper is to draw attention to the largely neglected possibility of obtaining chiral homoleptic [ML_6] complexes through the Bailar twist. We do so by reporting the results of a quantitative analysis of the chirality of homoleptic hexacoordinated complexes and its variation along the D_3 route, comparing in detail experiment with theory. It was found that *chirality in crystalline hexacoordinated complexes is much more common than previously appreciated*. While it is true that crystalline chirality may not show up in solution if the racemization process has a low energy barrier, one should recall that chiral crystals have been used successfully for product enantiocontrol in many chiral catalytic reactions[28] and that growing interest in crystals as useful materials for optical purposes renders crystal-packing-induced chirality an important issue. Furthermore, even if the handedness flips between the two enantiomers in solution it may be of importance in catalytic processes with chiral substrates since diastereomeric interactions will prefer one of the two enantiomers. We also mention here, computational analysis in progress in our laboratories shows that the energy barriers for racemization of D_3-chiral homoleptic [ML_6] complexes may be surprisingly high (e.g. of the order of 20 kcal/mol for the Zr^{IV} thiolato complex analyzed below).

Results and Discussion

Chirality Changes Along the Bailar-Twist Route

The ML_6 structures can be characterized by the Bailar twist angle θ (**1**) that indicates their deviations from the trigonal prism (θ = 0°) or from the octahedron (θ = 60°). While classically one labels all the intermediate D_3 geometries as simply ''chiral'', the intuitive need arises to express that, for example, a θ value of 0.1° represents much lower chirality than a θ value of 10°. A quantitative evaluation of the degree of chirality is therefore needed here, and such a structural measurement tool will allow one to follow, in a continuous way, how chirality changes with θ. The methodology we use for this purpose is the Continuous Chirality Measures approach,[14] which has already proved useful in numerous applications.[15] In short (readers interested in more details are referred to ref.[14]), the method seeks the minimal distances that the vertices of an object have to undergo to attain achirality. On the scale, which is a function of these distances, an achiral molecule has a chirality value of S = 0 and as the structure is more chiral S increases (up to a maximum value of 100). In most cases — and in all cases reported here — the nearest achiral structure has at least one reflection plane.[16]

The results of computing the S values along a hypothetical Bailar route are shown in Figure 1 (full line) beginning with the ideal, all-equal-edges trigonal prism (TP) at θ = 0° and ending at θ = 60° with the ideal octahedron.[17] Since the end points are achiral while those at intermediate θ values are D_3-chiral, one expects that (at least one) maximum chirality value will appear in between the two achiral ends. This is indeed found for the model at θ = 23° (Figure 1). In a way, this result resembles the chirality analysis of rotating ethane[18] for which an angle of 30° was found to give the maximal chiral rotamer. We proposed therefore to term conformers of maximal chirality *chiramers*, and this term can be used here as well, i.e., the 23° conformer of the hexacoordinated ML_6 group is its chiramer.

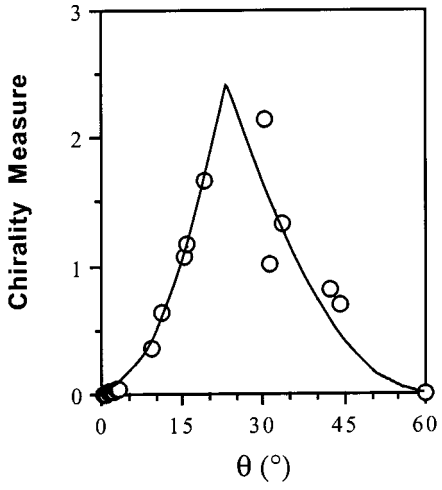

Figure 1. Chirality measure for a model MX_6 molecule (continuous line) along the trigonal twist (see **1**); the experimental chirality measures of heptaatomic MX_6 cores of homoleptic organometallic and thiolato complexes are shown as circles (more information can be found in Table 1)

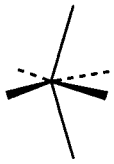
The fact that the chiramer of the hexacoordinated complexes does not appear halfway (i.e., at 30°) between the two ideal shapes may seem at first sight surprising, but is explained as follows: One of the main features of the CCM approach is that it not only computes the chirality content, but also provides the actual shape of the nearest achiral object. When these objects are observed for the full line in Figure 1, it is seen that from the maximum and to the right (θ = 60°), the nearest achiral structure is a distorted octahedron of C_{2v} symmetry, namely an octahedron that is bent along the z-axis, as shown by **2**. Between the ideal TP on the left of Figure 1 (θ = 0°) and the maximum at θ = 23°, the nearest achiral structure is always a D_{3h}-TP varying in height from point to point (although not very much. Thus, for θ = 0°, 10° and 20°, the edge-to-height ratios are 1.000, 1.028 and 1.049, respectively). The reason why it is that the two branches do not cross at the halfway angle but closer to the achiral distorted octahedron branch is now clear: Unlike the right branch of Figure 1, the left branch represents a more demanding nearest achiral structure in the sense that it does not have two reflection planes but four; therefore, departure from that branch to the less-demanding two-planes branch occurs earlier than 30°. Finally, it should be noted that at the peak (θ = 23°), the chirality measure represents an equal minimum distance to *two* achiral structures: a TP and a bent z-axis octahedron.

Chirality of Homoleptic Complexes

Does the theoretical line of Figure 1 represent a reality for $[ML_6]$ complexes? We have selected for the present study



2

the families of organometallic and thiolato homoleptic compounds,[19] and the chirality measures of their MX_6 cores (Table 1) are superimposed in Figure 1 on the Bailar model line. It is seen that all structures fall along that line, suggesting that they indeed represent the Bailar pathway from O_h to TP. It can also be seen that the octahedricity and the trigonal prismacity of such complexes correspond to the Bailar route, as discussed in more detail elsewhere.[20] Analysis of the bonding parameters of the actual structures confirms that these are of D_3-type, as illustrated in Figure 2 for three representative compounds. This observation indicates that chiral hexacoordinated homoleptic complexes have already been synthesized and structurally characterized *but their chirality not recognized and not reported*. Thus, despite the clear chirality of molecules with intermediate rotation angles, the experimental reports of the compounds presented in Figure 1 do not mention such a property and their optical activity has not been investigated. Most of these complexes, however, crystallize in space groups having improper symmetry operations, namely as racemic mixtures.[21] We note that these anionic complexes have been crystallized with achiral cations and propose that obtaining enantiomerically pure compounds may be possible through crystallization with optically pure chiral counter ions. Two complexes, $[NbMe_6]^-$ and $[TaMe_6]^-$, that crystallize[22] in the enantiomorphic space group $P2_12_12_1$ are only slightly-distorted from the octahedron ($\theta \approx 3°$) and have small chirality measures. To the best of our knowledge, only a Zr^{IV} thiolato complex reported recently[23] is expected to be optically active, since it crystallizes in the enantiomorphic *R32* group and has a ZrS_6 core with a high chirality measure ($S = 2.16$ at $\theta = 30.4°$).

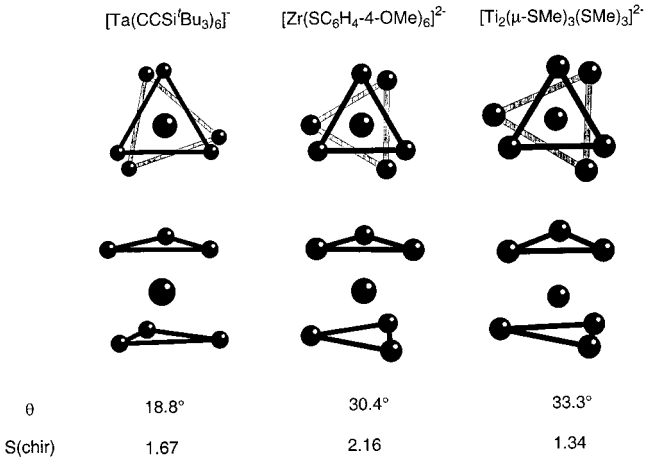

Figure 2. Perspective view and projection about the trigonal axis of the coordination spheres of three chiral homoleptic complexes with monodentate ligands that fall along the Bailar twist pathway **1** (see Table 1 for references)

As a further test of these observations and of the validity of the theoretical chirality line, we also analyzed the chirality of tris(chelate) complexes with twisted octahedra. Since the above analysis focused only on the MX_6 core, a corollary is that in the case of twisted tris(chelate) complexes the chirality is not associated only with the backbone of the bidentate ligands but also with the spatial arrangement of the donor atoms. To check this conclusion we have chosen

the tris(dithiolene), tris(diselenolene), tris(bipyridine) and tris(β-diketonato) metal complexes (structural information, references and symmetry measures are given as Supporting Information),[24] which are known to present structures throughout the whole range of twist angles. The chirality measures of the inner MX_6 core of such complexes, obtained from their crystal structural data (Figure 3 and 4) indeed corroborate the result of Figure 1. Note that the tris(bipyridine) and tris(β-diketonato) complexes appear at the ends of the twist-angle scale: most cluster in the range $45° < \theta \leq 68°$ but two structures are also found at $\theta \approx 2°$. It has been found[20] that the twist angle in nearly octahedral structures of bipyridine and diketonato complexes is associated with the normalized bites (b = L--L/M-L) of these ligands. Since bipyridine has a smaller bite than diketonates [the averages for first row transition metals are b = 1.27(4) and 1.41(5), respectively], the twist angles of the former family are smaller than in the latter. The existence of structures with twist angles larger than 60° corresponds to a rotation towards a trigonal prism (characterized by $\theta = 120°$) in which the bidentate ligand would be placed along the diagonal of a square face rather than along the edges (as happens for $\theta = 0°$). The two nearly trigonal prismatic structures of diketonato complexes correspond to complexes of Y^{III} and Cd^{II} with d^0 and d^{10} electron configurations (b = 1.21 and 1.28, respectively). We will return to these complexes in a separate report on a different issue, namely the relation between the chirality of the inner MX_6 core and the chirality of the ligand sphere.[25]

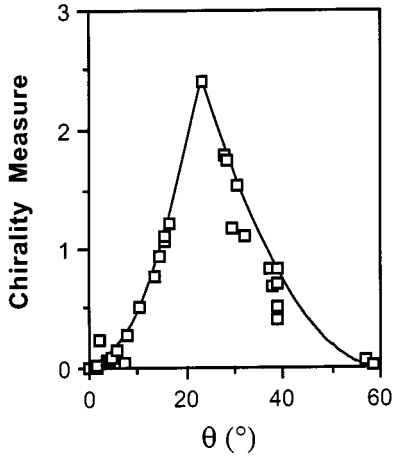

Figure 3. Chirality measures of the MX_6 cores of tris(dithiolene) and tris(diselenolene) complexes (X = S and Se), calculated from the experimental structural data as a function of the twist angle along the trigonal prism to octahedron interconversion path (data provided as Supporting Information); the solid line corresponds to a geometrical model, as in Figure 1

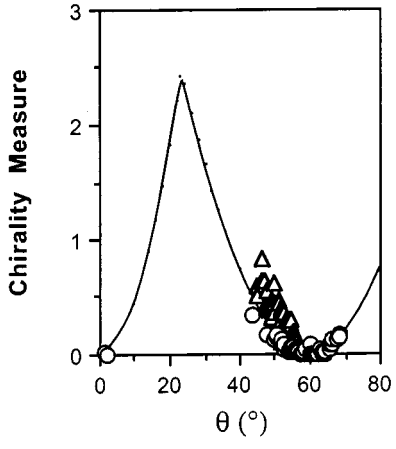

Figure 4. Chirality measures of the MX_6 cores of tris(bipyridine) (X = N, triangles) and tris(β-diketonato) (X = O, circles) complexes, calculated from the experimental structural data as a function of the twist angle along the trigonal prism to octahedron interconversion path (data provided as Supporting Information); the solid line corresponds to a geometrical model, as in Figure 1

In conclusion, we draw attention to $[Zr(SC_6H_4\text{-}4\text{-}OMe)_6]^{2-}$ which is the most chiral homoleptic complex with monodentate ligands among those that have been analyzed, and to the fact that the theoretical maximum at 23° is occupied in Figure 3 by the inner WS_6 core of $(AsPh_4)_2[W(S_2C_6H_4)_3]$,[27] with S = 2.40 making it the most chiral of all MS_6 coordination spheres analyzed in this report. To the best of our knowledge, these pronounced chiralities often go unnoticed. Thus our main message is that *chirality in hexacoordinated complexes with monodentate ligands is a more common phenomenon then currently appreciated*. We hope the stereochemical analysis presented in this report will encourage experimental search for as-yet undetected manifestations of chirality in transition metal complexes.

[16] In other cases, the nearest achiral object may have another improper symmetry element.

[17] The rotation was accompanied by gradually changing the bond angles around the metal in order to fulfill the definition of ideality, namely equal edges within each of the polyhedra. The boundaries for the bond angles are 90° in the octahedron and 81.79° in the trigonal prism, hence the bond-distance-to-edge-length ratio (normalized bite) is 1.414 in the octahedron and 1.309 in the trigonal prism.

[19] X-ray structural data were retrieved from the Cambridge Structural Database[26] (version 5.18) for the following families of homoleptic hexacoordinated complexes: $[MR_6]^{n-}$, $[M(SR)_6]^{n-}$, $[MCl_6]^{n-}$, $[M(NR_2)_6]^{n-}$, $[M(OR)_6]^{n-}$, $[M(SCN)_6]^{n-}$, $[M(CO)_6]$, $[M(CN)_6]^{n-}$ (where M is any metal belonging to periodic groups 3−12 and, in the case of MR_6, R indicates any group σ-bonded to a metal through a carbon atom). Of these, only the first two families were retained for our chirality analysis, since all structures in the remaining groups were found to be practically octahedral (i.e. $\theta \approx 60°$). Searches were restricted to crystal structures with no disorder and $R < 10\%$. The symmetry measures for the set of metal and six donor atoms were calculated from the experimental structural data with the computer program symm, available free from the authors.

Rare Earth Complexes of Bulky 2,6-Diphenylphenolates Containing Additional, Potentially Buttressing 3,5-Substituents[‡]

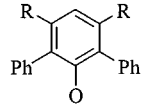
Glen B. Deacon,*[a] Phillip E. Fanwick,[b] Alex Gitlits,[a] Ian P. Rothwell,[b] Brian W. Skelton,[c] and Allan H. White[c]

Keywords: Mercury / Lanthanides / O ligands / Ytterbium

The rare earth aryloxide complexes, $[Yb(OAr^{tBu})_3(THF)]\cdot THF$, $[Sc(OAr^{tBu})_3(THF)]\cdot THF$, $[Yb(OAr^{Me})_3(THF)]$, and $[Sm(OAr^{Ph})_3(THF)_2]$ (OAr^R = 2,6-diphenyl-3,5-di-R-phenolate), have been prepared by redox transmetallation/ligand exchange between the rare earth metal, bis(pentafluorophenyl)mercury, and $HOAr^R$ in tetrahydrofuran. This reaction also provided $[Yb(OAr^{Ph})_3(DME)]\cdot 3/2THF$ by incorporation of adventitious 1,2-dimethoxyethane. A similar reaction between Yb metal, diphenylmercury, and $HOAr^{Me}$ gave $[Yb(OAr^{Me})_2(THF)_3]$. The homoleptic complexes $[Yb(OAr^{Ph})_3]$ and $[Sc(OAr^{H})_3]$ have been prepared by direct reaction of the rare earth element with $HOAr^R$ in a sealed tube in the presence of mercury at elevated temperatures (200–250 °C) and the latter was converted into $[Sc(OAr^{H})_3(THF)]$ by treatment with THF. X-ray crystal structure determinations of $[Yb(OAr^{tBu})_3(THF)]\cdot THF$, $[Sc(OAr^{tBu})_3(THF)]\cdot THF$, and $[Yb(OAr^{Me})_3(THF)]$ show the complexes to be monomeric and four coordinate with a trigonal pyramidal stereochemistry. These structures provide clear evidence that groups *meta* to the phenolate donor can modify the coordination behaviour of the 2,6-diphenylphenolate ligand. In $[Yb(OAr^{Ph})_3(DME)]\cdot 3/2THF$ a distorted square pyramidal stereochemistry is observed. The divalent complex $[Yb(OAr^{Me})_2(THF)_3]$ exhibits a distorted trigonal bipyramidal arrangement of the oxygen donor atoms with apical THF ligands. The homoleptic scandium 2,6-diphenylphenolate has three oxygen atoms in a triangular array with additional π-η^1-Ph···Sc interactions above and below the ScO_3 plane [C–Sc–C = 154.2(8)°], providing a new type of binding of this aryloxide ligand.

Introduction

Amongst rare earth aryloxides and alkoxides,[1] 2,6-di-*tert*-butyl-4-X-phenolates (X = H, Me, *t*Bu) have been seminal in stabilising low coordination numbers,[2] especially in homoleptic complexes.[2a−2c,2h,2i] With the less bulky[3a,3b] 2,6-diphenylphenolate, low coordination number complexes can still be obtained,[4] but the homoleptic lanthanoid(II or III) 2,6-di-phenylphenolates are noteworthy for intramolecular π-Ph···Ln interactions (η^1; η^2; η^3; η^4; η^6)[4a,4c,5] in addition to oxygen coordination, which can be quite irregular.[5a] One way of potentially increasing the bulkiness of 2,6-diphenylphenolate ligands[3b] is to add 3,5-substituents, which should reduce the flexibility of the phenyl groups and cause them to shield the donor atoms more. A range of such ligands is now available (e.g. **1b**−**c**) and exploration of their *d*-block and main group coordination chemistry has commenced.[6]



1a OAr^H, R = H
1b OAr^{Me}, R = Me
1c OAr^{tBu}, R = *t*Bu
1d OAr^{Ph}, R = Ph

We now examine the effect of buttressing substituents in rare earth chemistry with the synthesis and structural study of complexes with ligands **1b**−**1d**. In addition the homoleptic scandium complex with the parent ligand **1a** has been prepared and the structure determined. Previous studies of $[Ln(OAr^H)_3]$ complexes[5b] did not extend to the smaller (and much more expensive) Sc. It is of interest to determine the effect of reduced metal size on intramolecular π-Ph···Ln coordination, so far observed in $[Ln(OAr^H)_3]$ complexes as $\eta^6 + \eta^3$ (Ln = La) and $\eta^6 + \eta^1$ (Ln = Ce, Pr, Nd, Y, Yb, Lu).[4a,4c,5b]

Results and Discussion

Syntheses

Reaction of lanthanoid metals with bis(pentafluorophenyl)mercury, and 2,6-diphenyl-3,5-di-R-phenols **1b**−**1d** in tetrahydrofuran yielded the complexes $[Yb(OAr^R)_3THF]$

(R = Me or *t*Bu), [Sm(OAr^{Ph})$_3$(THF)$_2$], and [Sc(OAr^{tBu})$_3$(THF)] [Equation (1)].

$$2\,Ln + 3\,Hg(C_6F_5)_2 + 6\,HOAr^R \longrightarrow 2\,Ln(OAr^R)_3 + 3\,Hg + 6\,C_6F_5H \quad (1)$$

From an analogous reaction with ytterbium metal and HOAr^{Ph}, the product was found to contain fortuitously incorporated DME, even though it was isolated as a THF solvate, [Yb(OAr^{Ph})$_3$(DME)]·1.5THF [Equation (1); R = Ph]. The complex was also obtained as a DME solvate from a similar reaction in DME, but could not be obtained pure (see Experimental Section). When diphenylmercury was used in place of Hg(C$_6$F$_5$)$_2$ in the reaction with HOAr^{Me}, the divalent complex [Yb(OAr^{Me})$_2$(THF)$_3$] was obtained [Equation (2)].

$$Yb + HgPh_2 + 2\,HOAr^{Me} \longrightarrow Yb(OAr^{Me})_2 + Hg + 2\,PhH \quad (2)$$

In previous redox transmetallation/ligand exchange reactions with Hg(C$_6$F$_5$)$_2$, Yb^{III} complexes have been obtained with HOAr^H [4a] whereas Yb^{II} derivatives have been isolated with 2,6-di-*tert*-butylphenolate ligands,[2d−2f] despite the general use of an excess of lanthanoid metal. However, in redox transmetallation/ligand exchange reactions of ytterbium with 3,5-di-*tert*-butylpyrazole, use of Hg(C$_6$F$_5$)$_2$ gave trivalent complexes[7] whereas HgPh$_2$ provided divalent compounds,[8] a relationship now seen with 2,6-diphenyl-3,5-dimethylphenol. Electrochemical studies[9] as well as synthetic behaviour[7,8,10] show that Hg(C$_6$F$_5$)$_2$ is a more powerful oxidant than HgPh$_2$.

The synthesis of homoleptic complexes was also attempted by direct reaction of metals with HOAr^R (R = Ph or *t*Bu) at elevated temperature in the presence of mercury. In general, decomposition products were obtained or the resulting lanthanoid complexes could not be crystallised, viz. from Yb/HOAr^{tBu} at 250 °C, Yb/HOAr^{Ph} at 300 °C and at 200−220 °C, and Nd/HOAr^{Ph} at 200−300 °C. However, reaction of Yb with HOAr^{Ph} strictly at 200 °C (i.e. below the ligand melting point) allowed [Yb(OAr^{Ph})$_3$] to be prepared in good yield [Equation (3), Ln = Yb, R = Ph].

$$Ln + 3\,HOAr^R \xrightarrow{Hg} 3/2\,H_2 + Ln(OAr^R)_3 \quad (3)$$

This contrasts with the corresponding reaction of Yb with HOAr^H, which yields [Yb(OAr^H)$_2$]$_2$ and the mixed oxidation state complex [Yb$^{II}_2$(OAr^H)$_3$][Yb^{III}(OAr^H)$_4$].[5a] In addition, [Sc(OAr^H)$_3$] was obtained by reaction (3) (Ln = Sc, R = H), showing that for the 2,6-diphenylphenolate ligand, the method is applicable to the smallest rare earth metal. Crystallization from THF gave the solvate [Sc(OAr^H)$_3$(THF)].

Properties and Characterisation

Because of the difficulty in obtaining entirely satisfactory microanalyses for Ln(OAr^R)$_3$ (R = Me, *t*Bu, Ph), a feature previously noted for complexes of these buttressed ligands[6] and attributed to carbide formation,[6a] knowledge of the composition of the complexes is particularly dependent on X-ray structure determinations. These have been carried out for [Yb(OAr^{tBu})$_3$(THF)]·THF, [Yb(OAr^{Me})$_3$(THF)], [Sc(OAr^{tBu})$_3$(THF)]·THF, and [Yb(OAr^{Ph})$_3$(DME)]·1.5THF, as well as the analytically satisfactory [Yb(OAr^{Me})$_2$(THF)$_3$] and [Sc(OAr^H)$_3$] (next section). In contrast, complexes of the OAr^H ligand do not normally present analytical difficulties.[4,5] Microanalyses and metal analyses for bulk [Ln(OAr^{tBu})$_3$(THF)]·THF (Ln = Sc, Yb) and [Yb(OAr^{Me})$_3$(THF)] dried for 1−2 h under vacuum at room temperature, though somewhat divergent from calculated C values, suggested that these drying conditions did not remove coordinated THF or THF of solvation. This was supported by NMR integrations in the case of the scandium complex, although meaningful spectra could not be obtained for the paramagnetic Yb^{III} complexes. Both [Ln(OAr^{tBu})$_3$(THF)]·THF complexes have infrared absorptions at ca. 910 and 860 cm^{-1} plausibly attributable[10,11] to ring stretching of free (e.g. solvent of crystallisation) and coordinated THF, respectively. Tris(2,3,5,6-tetraphenylphenolato)samarium(III) was isolated with satisfactory analyses for a bis(THF) species. Since the sample was dried at 80 °C under vacuum, it is plausible that both ether molecules are coordinated, an effect of the larger size of Sm^{3+} than Yb^{3+}.[12] Aryloxide IR absorptions at 910−850 cm^{-1} (see [Yb(OAr^{Ph})$_3$]) rule out the use of IR spectroscopy to ascertain the nature of THF in the Sm complex. Single crystals of [Sc(OAr^H)$_3$(THF)] could not be grown, but it seems uncontentious that THF is coordinated in view of the structure of [Sc(OAr^{tBu})$_3$(THF)]·THF with a bulkier phenolate ligand, and since THF is retained on drying at 150 °C under vacuum. Moreover, the THF resonances are shifted from the "free" values consistent with coordination in solution (see Experimental Section). The analyses of the bulk sample of [Yb(OAr^{Ph})$_3$(DME)] dried at 80 °C are marginally closer for this composition than for [Yb(OAr^{Ph})$_3$(DME)]·1.5THF, which is the composition of the undried single crystals. An IR absorption at 1044 cm^{-1}, not observed for [Yb(OAr^{Ph})$_3$], is indicative of coordinated DME.[4d,13] A sample of the complex prepared in DME and dried at room temperature under vacuum was not obtained analytically pure but the analyses (especially for Yb) favoured the composition [Yb(OAr^{Ph})$_3$(DME)]·DME. The divalent complex [Yb(OAr^{Me})$_2$(THF)$_3$] gave satisfactory analyses and the ^{1}H NMR spectrum in C$_6$D$_6$ is consistent with this composition. However, the detection of two methyl resonances, a single, very broad THF resonance, and underlying broadness in the aromatic region suggests that an equilibrium occurs in C$_6$D$_6$ [Equation (4)] with both complexes detectable by their Me resonances.

$$[Yb(OAr^{Me})_2(THF)_3] \rightleftharpoons [Yb(OAr^{Me})_2(THF)_2] + THF \quad (4)$$

Complexes of both compositions have been observed for the bulky 2,6-di-*tert*-butylphenolate ligands.[2e,2f,2i]

The mass spectra of several representative complexes were recorded. Surprisingly, ions with three OAr^R ligands were detected only for [Yb(OAr^{Me})$_3$(THF)]. In other cases, as well as for [Yb(OAr^{Me})$_2$(THF)$_3$], [Ln(OAr^R)$_2$]$^+$ was the highest structurally significant feature. Near infrared ab-

sorption at 900−1000 nm was observed for the Yb^{III} complexes, as expected,[14] but appropriately was absent for $[Yb(OAr^{Me})_2(THF)_3]$.

Molecular Structures

The Complexes $[Ln(OAr^{tBu})_3(THF)]\cdot THF$ (Ln = Yb or Sc) and $[Yb(OAr^{Me})_3(THF)]$

The structures of these complexes are closely related. Two representative structures in which the metal size and the aryloxide ligand are varied are shown in Figure 1 and 2, with Ln-based distances and angles in Table 1. All three complexes are four-coordinate monomers, displaying a stereochemistry substantially distorted from tetrahedral, similar to that of $[Yb(OC_6H_2tBu_3\text{-}2,4,6)_3(THF)]$.[2g] The striking reduction in coordination number from five in $[Yb(OAr^{H})_3(THF)_2]$,[4a] especially given the further THF present as solvent of crystallisation, indicates that OAr^R (R = *t*Bu, Me and presumably also Ph) ligands can be considered bulkier than the simple 2,6-diphenylphenolate, consistent with buttressing of the 2,6-diphenyl substituents by the 3,5-substituents. There are no unusual features in the packing of the 2,6-diphenyl substituents, which are common to the three compounds, and they do not appear to have any overriding influence on the stereochemistry. Thus the interplanar angles involving the phenyl substituents (Table 2) vary markedly between the three complexes. Some similarity is evident between the two complexes with OAr^{tBu} ligands, but there are still some significant differences (Table 2).

The Ln−OAr^R bond lengths (Table 1) show little variation for each compound and between the two $[Yb(OAr^R)_3(THF)]$ (R = *t*Bu or Me) complexes. Subtraction of an extrapolated radius (from data in ref.[12]) for four coordinate Sc^{3+} or Yb^{3+} (0.62 and 0.75 Å, respectively) from <Ln−OAr^R> gives 1.29−1.30 Å, which is within the usual range for bulky lanthanoid aryloxides, including $[Yb(OC_6H_2tBu_3\text{-}2,4,6)_3(THF)]$ (1.28 Å).[2g] However, the latter compound shows a wider variation in Ln−OAr bond lengths [1.97(1)−2.09(1) Å].[2g] There are similar Yb−O(THF) distances for the two Yb compounds, and subtraction of the four-coordinate ionic radius from Ln−O(THF) values gives 1.49−1.50 Å for the three $[Ln(OAr^R)_3(THF)]$ complexes, at the low end of the range (1.49−1.59 Å) for THF complexes of bulky lanthanoid aryloxides.[2f,2g,4c,4d]

[a] Dihedral angles of the second disordered component of substituent ring 6 to its associated central and other peripheral planes are 68.6(6), 49.8(6), and to its first component 2.8(5)°. In $[Yb(OAr^{Ph})_3(DME)]$, 3,5-substituent C_6 planes in the three ligands lie at 55.6(6), 55.3(5); 57.9(5), 52.7(4); 57.1(6), 49.5(5)° to their central C_6 planes.

There are significant variations of the O−Ln−O angles within each of the three structures (Table 1), indicating considerable distortion from tetrahedral stereochemistry. The sum of the OAr^R−Ln−OAr^R angles in all three structures (Table 2) approaches 360°, whereas the sums of the O(THF)−Ln−OAr^R angles are below the 328.5° expected for tetrahedral angles. Thus, the data suggest that four coordination in the three structures can be considered near *triangular pyramidal*. The Ln−O−C angles in the three structures are appreciably nonlinear (Table 2) and are comparable with the average ($156._7$°) found for the more crowded $[Yb(OC_6H_2tBu_3\text{-}2,4,6)_3(THF)]$.[2g] The deviation of the rare earth ions from the LnO_3 (aryloxide) plane (Table 2) is marginally more than 0.392(1) Å for $[Yb(OC_6H_2tBu_2\text{-}2,6\text{-}Me\text{-}4)_3(THF)]$.[2g]

The Complex $[Yb(OAr^{Ph})_3(DME)]\cdot 1.5THF$

This complex has a five-coordinate array of three aryloxide and two DME oxygens (Figure 3). The best fit[15] polyhedron is a square pyramid (though very distorted) with O(11) as the apex, and *cisoid* aryloxides and DME in the base. It is thus very similar to the structures of $[Ln(OAr^H)_3(DME)]$ (Ln = Yb or Nd).[4d] Thus, the 3,5-substituents do not affect the coordination number in contrast to complexation with THF (above). This is because a chelating DME has less steric demand than two THF ligands.[3a]

Since the $Ar^{Ph}O$−Yb−OAr^{Ph} angles (Table 3) lie close to tetrahedral values (*cf.* Σ ArO^R−Yb−OAr^R, Table 2), there is an approximately tetrahedral array of aryloxide oxygens and the centre of the O···O vector of the DME. The *cisoid* aryloxide angle in the square plane [O(21)−Yb−O(31) 109.0(3)°] is surprisingly smaller than the corresponding *cisoid* angles in $[Ln(OAr^H)(DME)]$ [Ln = Nd (120.3(2) and Yb (113.3(2)°].[4d] Although the O(DME)−Yb−O(DME) and the Yb−O(n1)−C(n1) (n = 1 and 2) angles are similar in the two complexes (R = H[4d] or Ph), the Yb−O(31)−C(31) angle in $[Yb(OAr^{Ph})_3(DME)]\cdot 1.5THF$ is $23._4$° greater (Table 3) than in $[Yb(OAr^H)_3(DME)]\cdot 0.5DME$.[4d] Thus, the bond angles present no

clear picture as to the effect of 3,5-disubstitution on DME complexation. The <Yb−OAr> and <Yb−O(DME)> distances of $[Yb(OAr^{Ph})_3(DME)]\cdot 1.5THF$ correspond closely to those of $[Yb(OAr^{H})_3(DME)]\cdot 0.5DME$ (0.02, 0.03 Å difference).[4d]

The Complex $[Yb(OAr^{Me})_2(THF)_3]$

There is a five coordinate Yb^{II} centre in $[Yb(OAr^{Me})_2(THF)_3]$ (Figure 4), and the best fit polyhedron[15] of the donor atoms is a trigonal bipyramid with the THF oxygens O(31) and O(51) apical and the aryloxide oxygens and O(41) (THF) equatorial. The stereochemistry is severely distorted with a 156.7(3)° angle between the axial donors and considerable variation [100.7(2)−140.9(2)°] (Table 4) in the equatorial angles, though their sum is $358._7$°.

There is also a close approach of a carbon atom [Yb···C(126) = 3.177(9) Å] adjudged just on or outside the limit for meaningful binding. If viewed as six coordinate, subtraction of the appropriate Yb^{2+} ionic radius[12] from the Yb···C distance gives 2.16 Å, which is the upper limit for significant intramolecular π-C(Ph)···Ln interactions,[16] whereas subtraction of the extrapolated five coordinate radius gives 2.22 Å, beyond the range. The calculated position of H(126) is even closer to Yb [2.9(est.) Å] and intrudes into and can explain the large [140.9(2)°] O(11)−Yb−O(21) angle without postulation of an Yb···H interaction. Certainly, the large angle cannot be explained by repulsion between the bulky aryloxide ligands as *cisoid* $Ar^RO-Yb-OAr^R$ angles are well established, for example in $[Yb(OAr^{Ph})_3(DME)]$ (Table 3). Although $[Yb(OAr^{H})_2(THF)_3]$ is also distorted trigonal bipyramidal, the aryloxide ligands are apical [$Ar^HO-Yb-OAr^H$ = 164.6(3)°] with highly distorted angles between the equatorial THF ligands [O−Yb−O = 83.7(4), 138.8(3), 137.5(3)°].[4d] In this case, aryl hydrogens intrude into both of the large O(THF)−Yb−O(THF) angles, though at greater distances [Yb···H = 3.1, 3.2 Å; nearest associated C at 3.45(1) Å] than for $[Yb(OAr^{Me})_2(THF)_3]$.

The average Yb−OAr distance (2.21 Å) is in agreement with those (2.21−2.22 Å) of $[Yb(OAr^{H})_2(THF)_3]$[4d] and square pyramidal $[Yb(OC_6H_2tBu_2\text{-}2,6\text{-}X\text{-}4)_2(THF)_3]$. THF (X = Me, *t*Bu).[2e,2f] Whilst <Yb−O(THF)> (2.42 Å) agrees with that of $[Yb(OAr^{H})_2(THF)_3]$,[4d] it is shorter than those (2.48, 2.46 Å) of the two 2,6-di-*tert*-butylphenolate complexes.[2e,2f] Subtraction of the ionic radius for five coordinate Yb^{2+} gives 1.46 Å, rather lower than the usual range 1.48−1.60 Å for THF in bulky aryloxide complexes of Yb^{II}/Yb^{III}.[2f,2g,4a,4d] (It would be even lower if Yb^{II} were to be taken as six coordinate). Despite the similarity in <Yb−O(THF)> values between $[Yb(OAr^{R})_2(THF)_3]$ (R = H[4d] or Me) derivatives, the present complex shows a much smaller range of lengths (0.03_9 Å) than the earlier complex (0.1_5 Å).[4d] The $Yb-OAr^R-C$ angles are similar in the two

structures (Table 2 and ref.[4d]) despite the different arrangement of ligands.

[Sc(OAr)$_3$]

Single crystals of homoleptic [Yb(OAr^{Ph})$_3$] could not be obtained and hence the effect of 3,5-disubstitution on the structure of homoleptic lanthanoid 2,6-diphenylphenolates could not be determined. However, the complex [Sc(OAr^{H})$_3$] has been shown to be monomeric (Figure 5), with the coordination sphere comprising a triangular array of phenolate oxygens and capping π-η^1-Ph···Sc interactions above and below the ScO_3 plane (see below). Unlike [Ce(OC$_6$H$_3$*t*Bu$_2$-2,6)$_3$][2b] and [Ln(OAr^{H})$_3$] (Ln = Y, La, Ce, Nd, Pr, Yb, Lu)[4a,4c,5b] complexes, in which the LnO_3 units are distorted from triangular planar towards trigonal pyramidal, [Sc(OAr^{H})$_3$] is triangular planar (O−Sc−O deviation from 120°: ≤ 2.3°; Σ O−Sc−O 360°) with minimal deviation of Sc from the O_3 plane (Table 2), much like [Ln(OC$_6$H$_2$*t*Bu$_2$-2,6-Me-4)$_3$] (Ln = Sc, Y).[2a,2c] The <Sc−O> distance is 1.93 Å and is somewhat longer than that of [Sc(OC$_6$H$_2$*t*Bu$_2$-2,6-Me-4)$_3$][2a] (1.87 Å), presumably owing to the higher coordination number of Sc in [Sc(OAr^{H})$_3$] due to the C···Sc interactions.

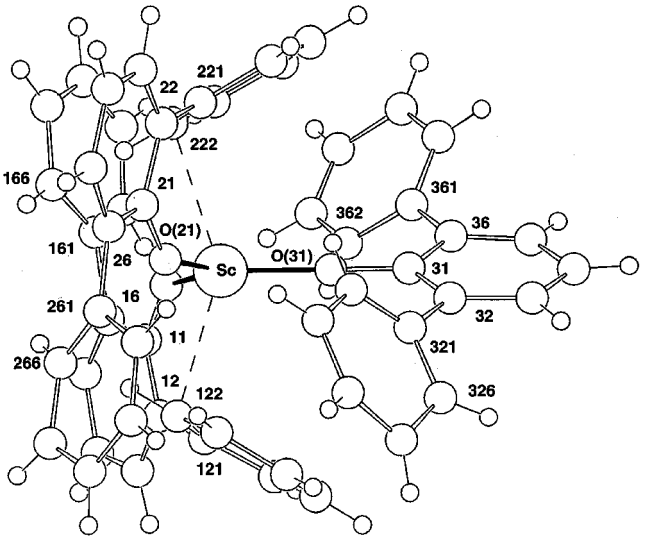

Figure 5. Molecular projection of [Sc(OAr^{H})$_3$]

The phenyl rings 12n and 22n approach the ScO_3 plane from above and below such that C(122) and C(222) are closer to Sc than the next nearest C atoms of the rings by ca. 0.45 Å (Table 5). The Sc···C(122) and Sc···C(222) distances (Table 5) are not greatly lengthened from the π-η^1-Cp−Sc bridging bonds [2.629(4), 2.519(4) Å] of [ScCp$_3$]$_n$,[17] for which the next closest contacts from the η^1-bonded rings are more distant by ca. 0.4−0.6 Å. Subtraction of an extrapolated (from data of ref.[12]) radius (0.68 Å) for five coordinate Sc^{3+} from Sc···C of [Sc(OAr^{H})$_3$] gives 1.94 and 2.00 Å, well within the upper limit (2.16 Å) for significant intramolecular π-Ph···Ln interactions.[16] Accordingly, C(122) and C(222) are considered to be weakly bound to Sc by π-η^1-Ph···Sc interactions. Even subtraction of a three coordinate Sc^{3+} radius from Sc···C(122) gives values within the 2.16 Å limit. With two π-η^1-Ph···Sc interactions, the capping phenyls have a different coordination mode than in [Ln(OAr^{H})$_3$] (Ln = Ce, Pr, Nd, Y, Yb, Lu) (η^6 + η^1)[4a,4c,5b] or [La(OAr^{H})$_3$] (η^6 + η^3),[5b] attributable to the small size of Sc^{3+}.[12] The similar Sc···C binding modes and bond lengths *transoid* to the O_3 plane probably account for the triangular ScO_3 arrangement and minimal deviation [0.011(9) Å] of Sc from the O_3 plane {cf. [Ln(OAr^{H})$_3$]: 0.150(1)−0.353(1) Å (La−Lu)}.[4a,4c,5b] Although the *transoid* C(122)−Sc−C(222) angle [145.2(8)°] deviates considerably from linear, the ring centroids are nearer linear [C(120)−Sc−C(220) = 165.$_7$°]), although still less than the range 173.$_2$−177.$_2$° for the other structurally characterised [Ln(OAr^{H})$_3$] complexes.[4a,4c,5b] The inclinations of the capping phenyl rings 12n and 22n to the ScO_3 plane [30.8(8)°, 28.9(8)° Table 5] are similar to those [28.1(2)−30.1°] of the π-η^1-Ph···Ln bonded rings of [Ln(OAr^{H})$_3$] (Ln = Ce, Pr, Nd, Yb, Lu).[4a,4c,5b] On the other hand, the rings are inclined to each other at 59.2(6)°, quite different from the dihedral angle of the η^6 and η^3 rings of [La(OAr^{H})$_3$] [19.9(3)°] or of the η^6 and η^1 rings of [Lu(OAr^{H})$_3$] [38.8(3)°].[5b]

Table 5. Scandium environment, [Sc(OAr^{H})$_3$]

Atom	*r*	O(21)	O(31)	C(122)	C(222)
O(11)	1.92(2)	122.1(7)	117.7(7)	77.8(8)	86.0(8)
O(21)	1.97(2)		120.2(7)	84.7(8)	78.2(8)
O(31)	1.91(1)			107.2(9)	107.5(9)
C(122)	2.62(3)[a]				145.2(8)
C(222)	2.68(3)[a]				

[a] Next closest Sc···C contacts: Sc···C(121, 123; 221, 223) are 3.12(3), 3.08(3); 3.12(3), 3.19(3) Å. Planes 12n, 22n lie at 30.8(8), 28.9(8) to the O_3 plane and 59.2(6)° to each other; Sc lies 2.56(2) and 2.63(2) Å out of them.

Further examination of the [Sc(OAr^{H})$_3$] structure shows that the Sc−O(11)−C(11) and Sc−O(21)−C(21) angles (ligands 1 and 2) are much smaller than 180° while Sc−O(31)−C(31) is nearly linear (Table 2). Furthermore, the dihedral angles (Table 2) between the C_6 central (phenolate) plane and the O_3 plane ($\theta_{c/}O_3$) are 83.6(8) and 79.4(8)° for ligands 1 and 2 respectively, whilst only 33.4(7)° for ligand 3 (Table 2). Moreover, the angles between the central C_6 ring and the phenyl substituent planes of ligands 1 and 2 average 57.$_8$ and 55.$_8$°, whilst the average value for ligand 3 is 44.4°. The interplanar angles between the 2- and 6-phenyl rings for ligands 1 and 2 also differ from that of ligand 3 (Table 2). These data, in conjunction with the substantial bending of the Sc−O−C angles of ligands 1 and 2, demonstrate the deviation of ligands 1 and 2 towards Sc associated with binding of their phenyl substituents.

Conclusions

The reduction in coordination number from five in [Yb(OAr^{H})$_3$(THF)$_2$][4a] to four in [Yb(OAr^{R})$_3$(THF)] (R =

*t*Bu or Me) (see Figure 2) indicates that the addition of 3,5-substituents to the 2,6-diphenylphenolate ligand is consistent with an increase in ligand bulk, possibly by buttressing the phenyl groups. This reduction in coordination number is foreshadowed by the anomalous "4.5 coordination" in $[Ln(OAr^H)_3(THF)_2]$ (Ln = La and Nd).[4b,4c] In contrast, similar five coordinate structures are observed in $[Yb(OAr^R)_3(DME)]$ [R = H[4d] or Ph (Figure 3)]. In five coordinate $[Yb(OAr^R)_2(THF)_3]$, there is a change from apical aryloxides (R = H)[4d] to (surprisingly) apical THF ligands (R = Me) (Figure 4) in their distorted trigonal bipyramidal stereochemistry. In homoleptic $[Sc(OAr^H)_3]$, the coordination motif, ScO_3 + two π-η^1-Ph···Sc interactions, is new and differs from the ligation in other $[Ln(OAr^H)_3]$ complexes.[4a][4c][5b]

Experimental Section

General: Rare earth aryloxides are extremely air- and water-sensitive hence all operations were carried out under an inert atmosphere (purified Ar or N_2). Handling methods, analytical procedures, and solvent purifications were generally as described previously,[5b,18] with the exception of some infra red spectra and the ^{1}H NMR spectrum of $[Yb(OAr^{Me})_2(THF)_3]$ which were recorded using a Perkin−Elmer Spectrum 2000 FTIR and a Varian Associates Gemini-200 spectrometer, respectively. IR data (4000−650 cm^{-1}) are for compounds as Nujol mulls. ^{1}H chemical shifts are referenced to internal solvent resonances and reported relative to $SiMe_4$. In assignments of ^{1}H NMR spectra involving the OAr^H ligand, primed numbers refer to phenyl protons. In the mass spectra, each listed *m*/*z* value for metal-containing ions (where the metal has more than one isotope) is the most intense peak of a cluster with an isotope pattern in good agreement with the calculated pattern. Those complexes containing OAr^R (R = *t*Bu, Ph) ligands for which data are not reported did not display any metal-containing ions in their mass spectra. Microanalyses were either by the Campbell Microanalytical Service, University of Otago, New Zealand or by Microanalytical services, Department of Chemistry at Purdue University, Indiana, USA. Complexes with THF or DME lose solvent on being heated in sealed capillaries under N_2 hence melting points have little significance (see examples below). 2,6-Diphenylphenol was purchased from Aldrich, while $HOAr^R$ reagents were prepared by previously reported procedures (R = Me,[6b,19] *t*Bu,[20] Ph[21]). Rare earth metals were obtained as powders or chunks from Rhône−Poulenc, Phoenix, USA.

Tris(2,6-diphenyl-3,5-di-*tert*-butylphenolato)tetrahydrofuranytterbium(III)-Tetrahydrofuran (1/1): A 100 mL Schlenk flask was charged with ytterbium powder (0.52 g, 3.01 mmol), bis-(pentafluorophenyl)mercury(II) (1.07 g, 2.00 mmol), 2,6-diphenyl-3,5-di-*tert*-butylphenol (1.43 g, 3.99 mmol) and THF (50 mL). The reaction mixture was stirred for 10 h at 80 °C yielding a dark red-brown solution upon filtration. The volume of the solution was reduced to 15 mL and yellow prismatic *single crystals* formed overnight which were used for X-ray crystal structure determination. More yellow crystals formed on storing the saturated solution at ambient temperature for several days. These were dried under vacuum at room temperature (0.75 g, 40%). − IR: $\tilde{\nu}$ = 1597w, 1576w, 1525w, 1296s, 1239w, 1171w, 1069m, 1027m, 1011m, 998s, 851w, 818w, 780w, 760m, 707s cm^{-1}. − Vis/near IR (THF): λ_{max} (ε) = 395 (52), 758 (25), 912 (3), 979 (10) nm (dm^3 mol^{-1} cm^{-1}). − $C_{82}H_{95}O_4Yb$ [$Yb(OAr^{tBu})_3(THF)$] (1317.62): calcd. C 74.74, H 7.27, Yb 13.13. − $C_{86}H_{103}O_5Yb$ (title compound) (1389.72): calcd. C 74.32, H 7.47, Yb 12.45; found C 73.36, H 7.44, Yb 11.33.

Tris(2,6-diphenyl-3,5-dimethylphenolato)(tetrahydrofuran)ytterbium(III): A mixture of 2,6-diphenyl-3,5-dimethylphenol (0.82 g, 3.00 mmol), bis(pentafluorophenyl)mercury(II) (0.80 g, 1.50 mmol) and ytterbium chips (0.52 g, 3.01 mmol) was stirred in THF (60 mL) at ambient temperature for 21 h. Filtration gave a bright yellow solution, which was partially evaporated and a small volume of hexane (10 mL) added. Large yellow crystals formed which were used for X-ray structure determination. The solution was then further reduced in volume producing more crystalline material which was dried under vacuum at room temperature (combined yield 0.43 g, 40%). − M.p. (sealed tube/N_2): 228−231 °C, prelim. dec. 80−90 °C. − IR: $\tilde{\nu}$ = 1598m, 1572w, 1554m, 1323s, 1169w, 1152w, 1089s, 1067m, 1027m, 1009m, 967m, 912w, 862m, 836m, 785w, 749s, 704s, 664s cm^{-1}. − Vis/near IR (THF): λ_{max} (ε) = 372 (364), 911 (14), 980 (50) nm (dm^3 mol^{-1} cm^{-1}). − MS (70 eV, EI): *m*/*z* (%) = 994 (37) $[Yb(OAr^{Me})_3 + H]^+$, 979 (2) $[Yb(OAr^{Me})_3 - CH_2]^+$, 720 (100) $[Yb(OAr^{Me})_2]^+$, 705 (2) $[Yb(OAr^{Me})_2 - Me]^+$, 447 (18) $[Yb(OAr^{Me})]^+$, 428 (2) $[Yb(OAr^{Me}) - MeH - 3H]^+$, 371 (3) $[Yb(OAr^{Me}) - C_6H_4]^+$, 274 (28) $[ArO^{Me}H]^+$, 273 (35) $[ArO^{Me}]^+$. − $C_{64}H_{59}O_4Yb$ (1065.15): calcd. C 72.16, H 5.58, Yb 16.25; found C 70.08, H 5.67, Yb 15.64.

Tris(2,6-diphenyl-3,5-di-*tert*-butylphenolato)(tetrahydrofuran)-scandium(III) -Tetrahydrofuran (1/1): A mixture of 2,6-diphenyl-3,5-di-*tert*-butylphenol (1.08 g, 3.01 mmol), bis(pentafluorophenyl)mercury(II) (0.80 g, 1.50 mmol), small scandium chunks (0.36 g, 8.01 mmol) and mercury (2 drops) in THF (50 mL) was ultrasonicated at ambient temperature for 227 h. The reaction mixture was filtered through a Celite pad, giving a clear very pale yellow solution which was evaporated to 10 mL. Small colourless crystals appeared in a few hours, and these were used for X-ray crystallography. Bulk crystalline solid deposited from the decanted mother liquor on further standing, and was dried under vacuum at room temperature. More solid crystallised from the filtrate and was similarly treated (combined yield 0.57 g, 45%). − M.p. (sealed tube/N_2): 203−205 °C (dec.), prelim. dec. ca. 150 °C − IR: $\tilde{\nu}$ = 1597m, 1576m, 1522m, 1288s, 1238m, 1200m, 1171m, 1070m, 1027m, 1012s, 998s, 912m, 870m, 819w 780w, 761m, 708s, 658s cm^{-1}. − ^{1}H NMR (C_6D_6): δ = 1.28 (s, 54 H, *t*Bu), 1.41 [br s, 8 H, β-H(THF)], 3.56 [br s, 8 H, α-H(thf)], 6.88−7.58 (m, 33 H, ArH). − MS (70 eV, EI): *m*/*z* (%) = 759 (1) $[Sc(OAr^{tBu})_2]^+$, 743 (3) $[Sc(OAr^{tBu})_2 - MeH]^+$, 727 (1) $[Sc(OAr^{tBu})_2 - 2MeH]^+$, 711 (<1) $[Sc(OAr^{tBu})_2 - 3MeH]^+$, 671 (<1) $[Sc(OAr^{tBu})_2 - MeH - Me - Bu]^+$, 655 (<1) $[Sc(OAr^{tBu})_2 - 2\ MeH - Me - Bu]^+$, 641 (<1) $[Sc(OAr^{tBu})_2 - 3Me - MeH - Bu]^+$, 358 (55) $[Ar^{tBu}OH]^+$, 57 (100) $[Bu]^+$. − $C_{86}H_{103}O_5Sc$, (1262.64): calcd. C 81.87, H 8.23, Sc 3.56; found C 80.89, H 8.26, Sc 4.13.

Tris(2,3,5,6-tetraphenylphenolato)bis(tetrahydrofuran)samarium(III): A mixture of 2,3,5,6-tetraphenylphenol, (1.32 g, 3.31 mmol), bis(pentafluorophenyl)mercury(II) (0.89 g, 1.66 mmol) and samarium powder (1.00 g, 6.65 mmol) was stirred in THF (40 mL) at room temperature for 29 h. Filtration gave a pale yellow solution which was evaporated to 10 mL. Pale yellow crystals formed in a few hours. The solid was dried under vacuum at 80 °C for 1 h giving a colourless-pale yellow powder (0.89 g, 54%). − IR: $\tilde{\nu}$ = 1597m, 1577w, 1531w, 1341s, 1307s, 1274m, 1138s, 1068m, 1025m, 1010m, 946s, 908w, 859w, 792w, 757s, 698s, 668s cm^{-1}. − ^{1}H NMR (C_7D_8): δ = −0.05 [br s, 8 H, β-H(THF)], 0.85 [br s, 8 H, α-H(THF)], 6.26−7.61 (complex m, 63 H, ArH). − $C_{94}H_{71}O_4Sm$ [$Sm(OAr^{Ph})_3(THF)$] (1414.91): C 79.79, H 5.05, Sm 10.63. −

$C_{98}H_{79}O_5Sm$ (1487.01): calcd. C 79.15, H 5.36, Sm 10.11; found C 78.32, H 5.44, Sm 10.02.

Adventitious Synthesis of Tris(2,3,5,6-tetraphenylphenolato)(1,2-dimethoxyethane)ytterbium(III): A mixture of 2,3,5,6-tetraphenylphenol, (1.59 g, 3.99 mmol), bis(pentafluorophenyl)mercury(II) (1.07 g, 2.00 mmol) and ytterbium powder (0.35 g, 2.02 mmol) was stirred in THF (50 mL) at 80 °C for 5 h. Filtration gave a dark red-brown solution which was evaporated to 20 mL and kept at −20 °C for 2 h. A very fine yellow crystalline solid, and later orange-yellow powder formed. This was dissolved in a minimal volume of hot toluene which was contaminated with a substantial amount of 1,2-dimethoxyethane. Meanwhile more crude product was obtained from the original THF solution. This was dissolved in hot toluene and the two toluene solutions were combined and left to stand at room temperature for several days resulting in initial formation of a large yellow crystal, which was cut in three and used for X-ray crystal structure identification as $[Yb(OAr^{Ph})_3(DME)]\cdot 1.5THF$, and then bulk yellow microcrystalline product which was dried under vacuum at 80 °C for 1 h. More microcrystalline yellow product deposited from the filtrate, and was collected and dried as before {combined yield 0.31 g, 16% for $[Yb(OAr^{Ph})_3(DME)]$}. − IR: $\tilde{\nu}$ = 1597m, 1578w, 1530m, 1345s, 1306m, 1275m, 1142s, 1091w, 1071w, 1044m, 1001w, 994w, 952s, 908w, 870w, 846w, 793w, 758s, 698s, 871s cm^{-1}. − Vis/near IR (THF): λ_{max} (ε) = 399 (161), 912 (7), 980 (43) nm ($dm^3\ mol^{-1}\ cm^{-1}$). − $C_{100}H_{85}O_{6.5}Yb$ ($[Yb(OAr^{Ph})_3(DME)]\cdot 1.5THF$] (1563.72): calcd. C 76.80, H 5.48, Yb 11.07. − $C_{94}H_{73}O_5Yb$ (THF-free) (1455.56): calcd. C 77.56, H 5.06, Yb 11.89; found C 78.72, H 5.44, Yb 11.43.

Bis(2,6-diphenyl-3,5-dimethylphenolato)tris(tetrahydrofuran)-ytterbium(II): A mixture of 2,6-diphenyl-3,5-dimethylphenol (1.10 g, 4.01 mmol), diphenylmercury(II) (0.71 g, 2.00 mmol), ytterbium chips (0.69 g, 3.99 mmol) and mercury (2 drops) was stirred in THF at 50 °C for 29 h. Filtration gave a dark red-brown solution, which was evaporated to 5 mL and layered with hexane yielding a dark red crystalline product from which single crystals for X-ray structure determination were derived. The remaining bulk crystalline material was dried under vacuum at ambient temperature (0.83 g, 44%). − IR: $\tilde{\nu}$ = 1598m, 1551m, 1325s, 1296s, 1239w, 1153w, 1089s, 1068s, 966w, 916m, 879w, 788w, 750m, 704s cm^{-1}. − Vis/near IR (THF): no absorptions occurred near 1000 nm. − ^1H NMR (C_6D_6): δ = 0.90 (s, 6 H, CH_3), 1.25 (s, 6 H, CH_3), 2.04 [br s, 24 H, CH_2 (THF)], 6.63−7.08 (m, 22 H, ArH). Integrations are approximate owing to the broadness of the THF peak, the complexity and underlying broadness of the aromatic resonances, and the proximity of strong solvent absorptions to the aromatic resonances. − MS (70 eV, EI): *m/z* (%) = 720 (13) $[Yb(OAr^{Me})_2]^+$, 447 (3) $[Yb(OAr^{Me})]^+$, 274 (100) $[ArO^{Me}H]^+$. Additional clusters centred on *m/z* = 795, 748, and 733 of very low intensity (<1%) did not have a recognizable isotope pattern and could not be assigned. − $C_{52}H_{58}O_5Yb$ (936.02): calcd. C 66.72, H 6.25, Yb 18.49; found C 66.38, H 6.02, Yb 18.70.

Tris(2,3,5,6-tetraphenylphenolato)ytterbium(III): A mixture of ytterbium chips (0.52 g, 3.01 mmol) and 2,3,5,6-tetraphenylphenol (0.60 g, 1.51 mmol) was heated at 200 °C in the presence of mercury (2 drops) in a sealed tube under vacuum for 24 h. The reaction mixture was extracted in hot toluene (70 mL) and filtered giving an orange solution. The volume of the solution was reduced to 2 mL and pentane was layered on top. A microcrystalline yellow solid formed overnight. This was isolated, washed with hexane (2 mL) and dried at 60 °C under vacuum (0.52 g, 76%). − M.p. (sealed tube/N_2): 282−285 °C. − IR: $\tilde{\nu}$ = 1597w, 1581w, 1574w, 1531w, 1513w, 1347s, 1307m, 1276m, 1140m, 1070w, 1027w, 1010w, 949m, 908w, 873, 863, and 855vw, 800w, 775w, 758s, 722m, 698s, 672m cm^{-1}. − Vis/near IR (THF): λ_{max} (ε) = 348 (1634), 913 (8), 980 (40) nm ($dm^3\ mol^{-1}\ cm^{-1}$). − $C_{90}H_{63}O_3Yb$ (1365.44): calcd. C 79.16, H 4.65, Yb 12.67; found C 79.51, H 4.89, Yb 12.12.

Tris(2,6-diphenylphenolato)scandium(III): A mixture of scandium chips (0.36 g, 8.01 mmol) and 2,6-diphenylphenol (0.99 g, 4.02 mmol) was heated in the presence of mercury (2 drops) in a sealed Carius tube at 200−250 °C for 160 h. The reaction mixture was worked up in toluene (70 mL) and filtered while hot giving a colourless solution, which was evaporated to 5 mL. Some colourless single crystals formed overnight which were used for an X-ray crystal structure determination. Further standing gave a colourless microcrystalline solid which was isolated and dried at 80 °C for 1 h (0.44 g, 42%). − M.p. >220 °C. − IR: $\tilde{\nu}$ = 1579m, 1411s, 1307m, 1282s, 1248s, 1172m, 1162w, 1154w, 1112w, 1094w, 1068m, 1026w, 1010w, 990w, 970w, 890s, 867s, 804w, 763s, 702s, 634s, 610s cm^{-1}. − ^1H NMR (C_6D_6): δ = 6.86−6.96 (m, 21 H, H4, H3′, H4′, H5′), 7.19 (d, $^3J_{H\text{-}H}$ = 7.5 Hz, 6 H, H3, H5), 7.31 (dd, $^3J_{H\text{-}H}$ = 7.0 Hz, $^4J_{H\text{-}H}$ = 1.4 Hz, 12 H, H2′, H6′). − MS (70 eV, EI): *m/z* (%) = 535 (21) $[Sc(OAr^H)_2]^+$, 246 (100) $[HOAr^H]^+$. − $C_{54}H_{39}O_3Sc$ (780.81): calcd. C 83.06, H 5.03, Sc 5.76; found C 82.88, H 5.19, Sc 5.65.

Tris(2,6-diphenylphenolato)(tetrahydrofuran)scandium(III): Tris(2,6-diphenylphenolato)scandium was prepared as above and on the same scale, but THF (90 mL) was used rather than toluene to work up the reaction mixture. Filtration gave a colourless solution, which was evaporated to 2 mL, but no solid formed. THF was then removed completely leaving a white solid. Crystallisation from toluene (20 mL) gave a white microcrystalline solid, which was dried under vacuum at 150 °C for 1 h (0.72 g, 63%). − M.p. (sealed tube/N_2): 218−220 °C, prelim. dec. ca. 170 °C. − IR: $\tilde{\nu}$ = 1595m, 1580m, 1410s, 1308m, 1281m, 1258s, 1172w, 1157w, 1085w, 1070m, 1025w, 1004w, 972w, 957w, 884s, 859s, 804w, 769m, 733m, 704s, 635s cm^{-1}. − ^1H NMR (C_6D_6): δ = 0.57 [s, 4 H, β-H(THF)], 2.12 [s, 4 H, α-H(THF)], 6.84−7.04 (m, 21 H, H4, H3′, H4′, H5′), 7.23 (d, $^3J_{H\text{-}H}$ = 7.5 Hz, 6 H, H3, H5), 7.34 (dd, $^3J_{H\text{-}H}$ = 7.5 Hz, $^4J_{H\text{-}H}$ = 1.4 Hz, 12 H, H2′, H6′). − $C_{58}H_{47}O_4Sc$, (852.92): calcd. C 81.67, H 5.55, Sc 5.27; found C 81.57, H 5.84, Sc 5.29.

Attempted Preparation of Tris(2,3,5,6-tetraphenylphenolato)(1,2-dimethoxyethane)ytterbium(III): A mixture of 2,3,5,6-tetraphenylphenol, (2.17 g, 5.45 mmol), bis(pentafluorophenyl)mercury(II) (1.46 g, 2.73 mmol) and ytterbium powder (0.63 g, 3.64 mmol) was stirred in DME (50 mL) at room temperature for 5 h. The reaction mixture turned brown-orange and was stirred for a further 24 h at 70 °C. Filtration gave a dark brown solution which was reduced in volume. Yellow needle-like crystals formed overnight and were dried under vacuum at room temperature (0.65 g, 23% for $[Yb(OAr^{Ph})_3(DME)]\cdot DME$). − IR: $\tilde{\nu}$ = 1597m, 1578w, 1531m, 1346s, 1306s, 1275m, 1143s, 1110m, 1072m, 1043m, 1025m, 952s, 917w, 869w, 840w, 794w, 758s, 699s, 672s cm^{-1}. − Vis/near IR (THF): λ_{max} (ε) = 410 (197), 912 (2), 980 (38) nm ($dm^3\ mol^{-1}\ cm^{-1}$). − $C_{94}H_{73}O_5Yb$ $[Yb(OAr^{Ph})_3(DME)]$ (1299.56): calcd. C 77.56, H 5.06, Yb 11.89; − $C_{98}H_{83}O_7Yb$ $[Yb(OAr^{Ph})_3(DME)_2]$ (1545.68): calcd. C 76.14, H 5.41, Yb 11.19; found C 72.51, H 5.43, Yb 11.20.

Structure Determinations: Full spheres of CCD area-detector data were measured at the specified temperature (Bruker AXS instrument; $2\theta_{max}$ as specified; monochromatic Mo-K_α radiation, λ = 0.7107$_3$ Å) yielding $N_{t(otal)}$ reflections, reducing to N unique (R_{int} quoted) after "empirical"/multiscan absorption correction

(proprietary software), N_o with $F > 4\sigma(F)$ being considered "observed" and used in the full-matrix least-squares refinement (anisotropic thermal parameter forms for the non-hydrogen atoms; (x, y, z, $U_{iso})_H$ constrained at estimated values). Conventional residuals R, R_w (weights: $[\sigma^2(F) + 0.0004\,F^2)^{-1}$] are quoted on $|F|$ at convergence. Neutral atom complex scattering factors were employed within the context of the Xtal 3.4 program system.[22] Pertinent results are given in the figures and tables. In the figures 20% displacement amplitudes are shown for the structures determined at low temperature, 50% for room temperature. Hydrogen atoms have arbitrary radii of 0.1 Å. Individual variations in procedure, idiosyncrasies, difficulties are noted below.

Crystal/Refinement Data

[Yb(OAr^{tBu})$_3$(THF)]·THF: $C_{86}H_{103}O_5Yb$, M = 1389.8. Triclinic, space group $P\bar{1}$ (C_i^1, no. 2), a = 14.930(1), b = 16.601(1), c = 17.281(1) Å, α = 110.491(1)°, β = 99.703(1)°, γ = 104.169(1)°, V = 3735 Å^3. D_c (Z = 2) = 1.23$_6$ g cm^{-3}. μ_{Mo} = 13.0 cm^{-1}; specimen: 0.55 × 0.40 × 0.15 mm; $'T'_{min.,max}$ = 0.61, 0.83. $2\theta_{max}$ = 58°; N_t = 43419, N = 18211 (R_{int} = 0.029), N_o = 12973; R = 0.038, R_w = 0.039. $|\Delta\rho_{max}|$ = 1.37(9) e Å^{-3}. T ca. 300 K. Displacement parameters of the lattice solvent were very large; site occupancy was set at unity after trial refinement.

[Sc(OAr^{tBu})$_3$(THF)]·THF: $C_{86}H_{103}O_5Sc$, M = 1261.7. Triclinic, space group $P\bar{1}$, a = 14.805(2), b = 16.208(2), c = 17.042(2) Å, α = 109.649(2)°, β = 99.719(2)°, γ = 103.981(2)°, V = 3595 Å^3. D_c (Z = 2) = 1.16$_6$ g cm^{-3}. μ_{Mo} = 1.5 cm^{-1}; specimen: 0.25 × 0.20 × 0.04 mm; $'T'_{min.,max}$ = 0.67, 0.82. $2\theta_{max}$ = 58°; N_t = 39461, N = 18825 (R_{int} = 0.079), N_o = 7579; R = 0.062, R_w = 0.055. $|\Delta\rho_{max}|$ = 0.67(6) e Å^{-3}. T ca. 153 K. All hydrogen atoms except those associated with the uncoordinated THF were refined in (x, y, z, U_{iso}).

[Yb(OAr^{Me})$_3$THF]: $C_{64}H_{59}O_4Yb$, M = 1065.2. Triclinic, space group $P\bar{1}$, a = 11.154(1), b = 11.818(1), c = 20.371(2) Å, α = 76.824(2)°, β = 77.809(2)°, γ = 78.415(2)°, V = 2522 Å^3. D_c (Z = 2) = 1.40$_2$ g cm^{-3}. μ_{Mo} = 19.0 cm^{-1}; specimen: 0.35 × 0.17 × 0.10 mm; $'T'_{min.,max}$ = 0.66, 0.83. $2\theta_{max}$ = 58°; N_t = 29447, N = 12359 (R_{int} = 0.028), N_o = 11025; R = 0.046, R_w = 0.065. $|\Delta\rho_{max}|$ = 2.4(1) e Å^{-3}. T ca. 153 K.

[Yb(OAr^{Ph})$_3$DME]·1.5THF: $C_{100}H_{85}O_{6.5}Yb$, M = 1563.8. Monoclinic, space group $P2_1/c$ (C_{2h}^5, no. 14), a = 13.0079(9), b = 32.407(2), c = 24.860(2) Å, β = 91.798(1)°, V = 10474 Å^3. D_c (Z = 4) = 0.99$_2$ g cm^{-3}. μ_{Mo} = 9.4 cm^{-1}; specimen: 0.30 × 0.25 × 0.10 mm; $'T'_{min.,max}$ = 0.62, 0.86. $2\theta_{max}$ = 58°; N_t = 114947, N = 18408 (R_{int} = 0.098), N_o = 11241; R = 0.060, R_w = 0.090. $|\Delta\rho_{max}|$ = 1.54(6) e Å^{-3}. T ca. 300 K. Lattice solvent residues were modelled as 0.5THF at each of three sites, with constrained geometries and isotropic thermal parameter forms.

[Yb(OAr^{Me})$_2$(THF)$_3$]: $C_{52}H_{58}O_5Yb$, M = 936.1. Monoclinic, space group Cc (C_s^4, no. 9), a = 19.945(1), b = 11.8084(5), c = 19.193(1) Å, β = 97.416(3)°, V = 4482 Å^3. D_c (Z = 4) = 1.38$_7$ g cm^{-3}. μ_{Mo} = 21.2 cm^{-1}; specimen: 0.17 × 0.15 × 0.08 mm; $'T'_{min.,max}$ = 0.50, 0.85. $2\theta_{max}$ = 53°; N_t = 23259, N = 7519 (R_{int} = 0.11; 'Friedel pairs' retained distinct), N_o = 6338; R = 0.053, R_w = 0.093. $|\Delta\rho_{max}|$ = 0.9 e Å^{-3}. T *ca* 193 K. Data were measured using a Nonius Kappa CCD instrument. Refinement was carried out using the SHELX-97 system.[23] The phenyl ring pendant at C(26) was modelled as disordered over two sets of sites of equal occupancy, with isotropic thermal parameter refinement for the carbon atoms. The absolute structure was indeterminate.

[Sc(OAr^{H})$_3$]: $C_{54}H_{39}O_3Sc$, M = 780.9. Monoclinic, space group $P2_1/c$, a = 11.261(8), b = 20.10(1), c = 17.81(1) Å, β = 100.02(1)°, V = 3970 Å^3. D_c = 1.30$_6$ g cm^{-3}. μ_{Mo} = 2.3 cm^{-1}; specimen: 0.25 × 0.15 × 0.03 mm; $'T'_{min.,max}$ = 0.59, 0.88. $2\theta_{max}$ = 50°; N_t = 19251, N = 6895 (R_{int} = 0.21), N_o = 1394; R = 0.088, R_w = 0.097. $|\Delta\rho_{max}|$ = 0.86(6) e Å^{-3}. T ca. 153 K. Weak and limited data from a very fragile leaf-like specimen would support meaningful anisotropic thermal parameter form refinement for Sc only, isotropic forms for C, O.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre. The supplementary publication nos. CCDC-153631, -153627, -153628, -153629, -153626, -153630 apply sequentially to the compounds in the Crystal/Refinement Data section. Copies of the data can be obtained free of charge on application to CCDC 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Two-Level Self-Organisation of Arrays of [2×2] Grid-Type Tetranuclear Metal Complexes by Hydrogen Bonding

Esther Breuning,[a] Ulrich Ziener,[a] Jean-Marie Lehn,*[a] Elina Wegelius,[b] and Kari Rissanen[b]

Keywords: Coordination chemistry / Crystal engineering / Grid-type complexes / Hydrogen bonding / Supramolecular chemistry

Here we report on the synthesis and characterisation of four new complexes of the [2×2] M_4^{II} grid-type (M = Co, Fe, Zn) with oligopyridine-derived ligands. The presence of aminopyrazine and aminopyrimidine moieties at the edge of the ligands potentially enables the formation of infinite hydrogen-bonded multi-grid networks. The ligands were synthesised by subsequent stannylations and Stille-type coupling reactions. The complexes were obtained by self-assembly of the ligand with the metal salt. The single-crystal X-ray structure was determined for the Co complex **7** containing aminopyrimidine as the hydrogen-bonding moiety [$P\bar{1}$; a = 15.4976(4), b = 18.2114(6), c = 31.9538(10) Å, α = 86.9809(13), β = 83.4137(18), γ = 67.2828(16)°]. The crystal structure reveals hydrogen bonding in one direction, thus forming infinite chains of grids, whereas in the second direction of a layer, only weak attractive interactions are found. Anions and solvent molecules are situated between the layers, thus inhibiting any direct interaction between them. Cocrystallisation of the complementary complexes should enable the recognition-controlled alternating arrangement of grids incorporating different metal ions in a chessboard-like manner.

Introduction

In the last few years, a vast amount of work has been dedicated to the generation of discrete inorganic architectures in order to establish the principles of inorganic self-assembly processes as well as in view of their possible application in nanotechnology.[1] Of particular interest is the combination of metal coordination with hydrogen bonding in order to achieve the controlled arrangement of such inorganic entities by means of molecular recognition-directed formation of well-defined two- and three-dimensional structures of hydrogen-bonded networks.[2] This amounts to a two-level, sequential self-organisation process in which the initial assembly of coordination architectures from given ligands and metal ions is followed by their organisation into specific arrangements. The use of ligands fitted with complementary hydrogen-bonding subunits provides the possibility of positioning inorganic entities which may contain different metal ions in extended arrays, a feature potentially of great interest to nanotechnology and molecular electronics.

Our laboratory has recently described a new class of polypyridine-derived, tetranuclear metal complexes of the [2×2] M_4^{II} grid-type (M = transition metal)[3,4] formed by self-assembly from ligands containing two tridentate, terpyridine-like, binding subunits and from metal ions of octahedral coordination geometry (Scheme 1). They have been found to present a range of interesting structural[3] and physicochemical (electrochemical,[3a,5] magnetic[6]) properties. In addition, it has been shown that these grid-type compounds self-assemble in monolayers on gold and can be examined and manipulated on a molecular level by means of scanning tunnelling microscopy (STM).[7] Although they assemble in a chessboard-like order, the stability of the monolayer is low and the mobility of the grids on the surface is still high. For possible future applications in the field of information storage devices, a high stability of the monolayer of grids will be required. Furthermore, it would be of great interest to be able to rigorously control the relative positioning of grid structures incorporating different metal ions (and therefore presenting different physicochemical properties) within either two-dimensional layers or three-dimensional lattices. This would for instance lead to "grid-of-grids"-type structures as schematically represented in Figure 1. It would also by-pass the demanding synthetic efforts involved in the generation of grids of higher nuclearity by the replacement of large grids by grids-of-grids, thus making further use of the powerful tool of self-assembly through a two-level sequential process.

In order to increase the stability of layers of grids as well as to allow the introduction of different metal ions into such an assembly, we synthesised the ligands **2** and **3** containing complementary and self-complementary hydrogen-bonding moieties and their corresponding metal complexes **4**–**7**. The complementary interaction of the ligands is schematically shown in Scheme 2. The suitability of aminopyrazine and aminopyrimidine as designed hydrogen-bonding motifs, as used here, has been shown before in mononuclear complexes with terpyridine-derived ligands.[8]

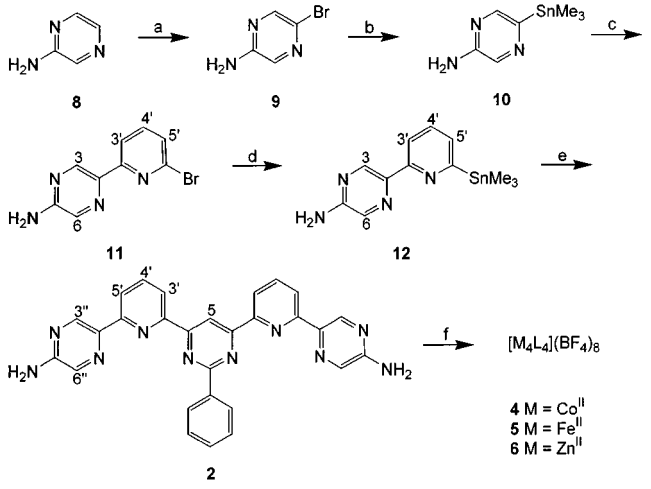
Results and Discussion

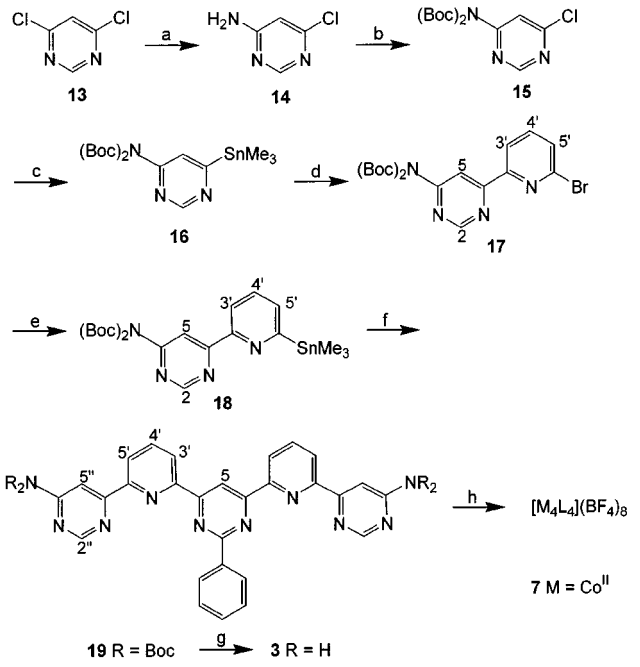
Synthesis of Ligands 2 and 3

The synthesis of ligand **2** and complexes **4**−**6** is outlined in Scheme 3.

Ligand **2** is produced by palladium-catalysed stannylations followed by coupling reactions of the Stille type. The yields obtained by using a one-pot reaction for the stannylation of **9** and the coupling of **10** with 2,6-dibromopyridine to give **11** were superior to those obtained when purification of the tin compound was performed. This can be explained by the rather low stability of the tin derivative during chromatographic purification. **2** precipitates from the reaction mixture as the analytically pure compound. It is insoluble in most organic solvents and only moderately sol-



Scheme 3. Synthesis of ligand **2**: a) Br_2, $CHCl_3$ (32%); b) Me_6Sn_2, $Pd(PPh_3)_4$, toluene; c) 2,6-dibromopyridine, $Pd(PPh_3)_4$, toluene (68% over 2 steps); d) Me_6Sn_2, $Pd(PPh_3)_4$, toluene; e) 4,6-dichloro-2-phenylpyrimidine, $PdCl_2(PPh_3)_2$, DMF (69% over 2 steps); f) $M(BF_4)_2{\cdot}xH_2O$ (**4**: M = Co^{II}; **5**: M = Fe^{II}; **6**: M = Zn^{II}), CH_3CN/H_2O



Scheme 4. Synthesis of ligand **3**: a) NH_3, MeOH (44%); b) $(Boc)_2O$, DMAP, CH_3CN (79%); c) Me_6Sn_2, $Pd(PPh_3)_4$, toluene; d) 2,6-dibromopyridine, $Pd(PPh_3)_4$, toluene (41% over 2 steps); e) Me_6Sn_2, $Pd(PPh_3)_4$, toluene; f) 4,6-dichloro-2-phenylpyrimidine, $Pd(PPh_3)_4$, toluene (50% over 2 steps); g) HCl, EtOAc (88%); h) $Co(BF_4)_2{\cdot}6H_2O$, CH_3CN/H_2O

uble in DMSO. This already points to the suitability of this compound for the formation of hydrogen-bonded networks as the low solubility can be explained by strong intermolecular hydrogen bonds between the self-complementary moieties on the edges of the ligand.

The synthesis of ligand **3** and complex **7** is outlined in Scheme 4. Whereas the amino group did not cause any problems in the palladium-catalysed stannylation of **9**, the stannylation of **14** required derivatisation of the amino group due to the low solubility of the starting material under the reaction conditions. We introduced two *tert*-butoxycarbonyl groups to solubilise the compound. The rest of the synthesis follows the same reaction pathway as for **2** and the protection groups were split off by HCl in the last step to give **3** as an extremely insoluble compound. As supported by the results of elemental analysis, **3** is probably formed as HCl salt during the reaction.The deprotonation was not possible even by washing with dilute NaOH, due to the low solubility of the compound which presumably includes the HCl in the solid.

Synthesis and Characterisation of the Complexes 4−7

So far complexes of the grid-type were usually obtained by reaction of the ligand with the metal acetate in methanol or with the metal tetrafluoroborate in acetonitrile or nitromethane;[3] however, these reactions failed for **2** and **3** because of their low solubility. For these ligands, the use of mixtures of acetonitrile and water in variable ratios, specific for each of the ligands, as well as elevated temperatures are required to break the intermolecular hydrogen bonds of the ligand and to solubilise the reaction mixtures. Substitution of the solvents by DMSO solubilised the reaction mixture, but did not result in the assembly of the grids. Even the highly charged complexes themselves are only moderately soluble at room temperature in the solvent mixture. Exchange of the tetrafluoroborate counterions for hexafluorophosphate, triflate or perchlorate did not result in an increased solubility.

The complexes were characterised by ^1H NMR spectroscopy, FAB mass spectrometry, elemental analysis, and in the case of **7** by single-crystal X-ray diffraction. The proton NMR spectrum of the diamagnetic complex **6** shows the signals of a symmetrically coordinated ligand as expected for the grid structure. The protons of the phenyl group on the pyrimidine ring give rise to five distinct signals due to inhibited rotation of the phenyl ring in the complex.[3b] The proton NMR spectra of **4**, **5**, and **7** show strongly shifted signals (Co complexes: δ from −100 to +180 ppm; Fe complex: δ from −30 to +80 ppm) as typical for paramagnetic compounds.[9] Although in all cases sharp signals are obtained, which are typically broader for the Fe complex than for the Co complexes, no coupling patterns can be resolved due to low resolution. However, the number of signals provides information about the symmetry of the complexes indicating that the symmetry of the ligand is maintained during the complexation. Combination of this information with the composition of the complexes obtained from mass spectrometry allows the deduction of the grid-type structure for all complexes described here.

The Fe^{II} cation can exist in the diamagnetic low-spin or in the paramagnetic high-spin state, depending on the ligand field strength. From the NMR spectroscopic data, it may be deduced that the Fe complex **5** is essentially high spin as no signals are found in the region expected for diamagnetic aromatic protons. Preliminary measurements of

the magnetic susceptibility, however, suggest that there remains a low-spin fraction of the complex at room temperature and that it shows thermal spin-crossover behaviour[10] similar to a Fe^{II} grid-type compound of ligand **1** already described.[6b]

Crystal Structure of Complex 7

Crystals of complex **7** were obtained by diffusion of THF into a solution of the complex in acetonitrile/water and its structure was determined by X-ray crystallography (Figure 2). The grid moiety of the complex is comparable to that of the structures of similar compounds.[3b] The four ligands of one entity are aligned in an almost perfect parallel and perpendicular fashion. The shortest distance between the plane of a phenyl ring on one ligand and a perpendicular ligand (3.30 Å) corresponds to a van der Waals contact and indicates that the grid is stabilised by π-stacking of the ligands with the phenyl substituent on the pyrimidine ring. The Co^{II} ions present pseudo-octahedral coordination. The Co−N bond lengths and N−Co−N bond angles are analogous to those found in the parent Co^{II} grid-type complex of ligand **1**.[3b] This may appear surprising as the electron-poor pyrimidine is usually a weaker binding site than pyridine, but in the present ligand this is compensated for by the electron-donating properties of the amino group in *para* position of the binding N atom. The presence of the hydrogen bonds in only one direction (see below) has no influence on the geometry of the grid unit itself.

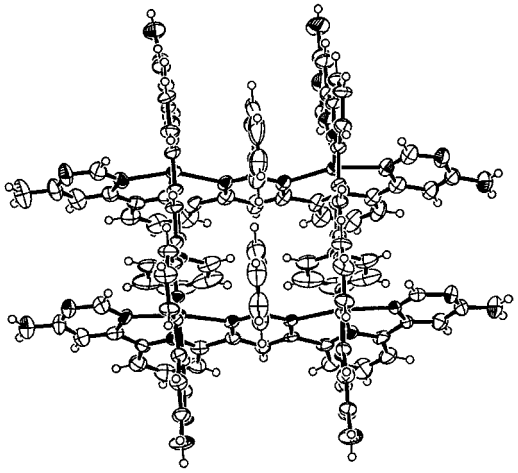


Figure 2. Single-crystal X-ray structure of the grid unit of complex **7** (anions are omitted for clarity); ORTEP representation

The self-complementarity of **2** and **3** enables their metal complexes to form hydrogen-bonded networks of grids. The availability of hydrogen-bonding sites on each edge of the grid might lead to saturation of the hydrogen bonds in two dimensions. The crystal structure of **7**, though, shows that the hydrogen-bonding motif is present in only one dimension, thus forming infinite one-dimensional chains of grids (Figure 3). The hydrogen bond lengths *d*(N−H−N) lie between 3.01(1) and 3.07(1) Å and are thus in the range of strong hydrogen bonds. The hydrogen bonds are almost linear with N−H−N bond angles between 173 and 180°. In the second dimension of the layer, no strong interactions are found between the grids. Neighbouring complexes without hydrogen-bonding contact show only weak π-stacking between their ligands. Although the rows of ligands are parallel with the shortest distance between their planes around 3.25 Å, they are slanted so that there is only a small overlap of the π-systems. A good overlap in the same range of distances can be found between the amino groups and the pyrimidine moieties of neighbouring complexes. It appears that the crystallisation of the complex in this packing is preferred to the saturation of all hydrogen bonds as it helps to avoid unfilled space in the crystal. Comparison with the similar structure of the parent Co_4^{II} [2×2] grid without hydrogen-bonding sites derived from ligand **1** shows that this complex forms layers with a larger overlap of some of the aromatic rings of neighbouring complexes. Although in that case only two out of eight of the edge pyridine rings show π-stacking, the better overlap results in a more efficient stacking.[3b] Thus, the hydrogen bonds in **7** partially break up this packing motif, but they are not strong enough to generate a completely hydrogen-bonded network which would imply the unfavourable formation of large cavities between the grids. The anions and solvent molecules of crystallisation are found between these layers, thus inhibiting any direct interaction between them.

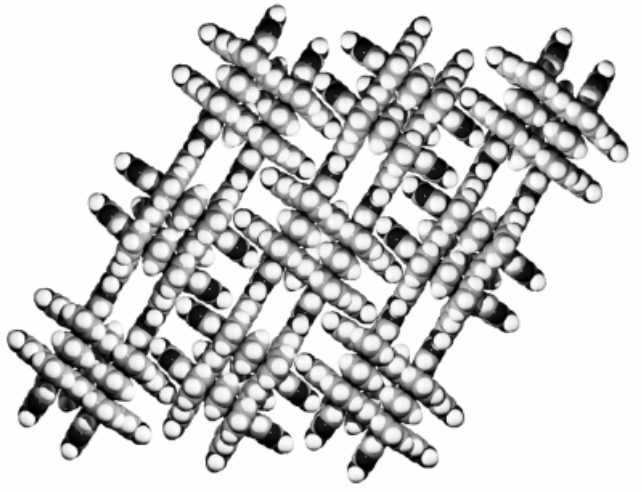

Figure 3. Crystal packing of complex **7** showing the hydrogen bonding in one direction and the formation of infinite chains of grids (anions and solvent molecules from crystallisation are omitted for clarity)

The crystals described here were obtained during an attempt at cocrystallising complexes **5** and **7**. Even though $Co(BF_4)_2{\cdot}6H_2O$ and $Fe(BF_4)_2{\cdot}6H_2O$ were used as metal salts for the complexation, no BF_4^- could be found in the crystal structure. Instead, two chloride anions originating from the last step of the synthesis of **3** and three SiF_6^{2-} units crystallised out. The last one stems probably from the reaction of some free fluoride with the glass vial in which the crystallisation was performed. These rather unexpected results could be further supported by energy-dispersive X-

ray scattering (EDX) of crystals of **5** and **7** which indeed showed significant amounts of Si.

Conclusion

As a further step in the recognition-directed self-organisation of metal complexes, the formation of arrays of four tetranuclear complexes, **4−7**, from the oligopyridine-derived ligands **2** and **3** has been achieved by sequential two-step self-assembly. These ligands were designed to form double self-complementary hydrogen bonds by introduction of aminopyrazine and aminopyrimidine moieties on the edges. Generating arrays of such metal complexes is of special interest in view of the remarkable physicochemical properties (e.g. magnetic,[6b] electrochemical[5]) displayed by [2×2] metallogrids. The single-crystal X-ray structure of Co complex **7** shows saturation of the hydrogen bonds in one direction, thus forming an infinite chain of hydrogen-bonded grids. In the other direction of each layer, weak π-stacking is present whereas no direct interactions are found between the layers of grids. Besides the self-complementarity of the ligands, the aminopyrazine and aminopyrimidine hydrogen-bonding units should also be capable of forming heterocomplementary hydrogen-bonding motifs by two-point interaction, thus allowing the arrangement of grids with different metals in a layered chessboard-like manner (Figure 1). Further experiments for the cocrystallisation of complementary hydrogen bonds between **4−7** with different anions are ongoing to explore these possibilities. In addition, the possibility of deposition of heterometallic arrays of these grids as monolayers on surfaces and their observation by STM (scanning tunnelling microscopy) is currently being investigated. The data described here may also be regarded as a step in the exploration of the ways and means to induce the spontaneous, but controlled generation of even larger organised arrays in view of assembling supramolecular architectures and devices of interest for nanotechnology.

Experimental Section

General: 5-Amino-2-bromopyrazine (**9**),[11] 4-amino-6-chloropyrimidine (**14**),[12] and 4,6-dichloro-2-phenylpyrimidine[13] were prepared according to the literature. Toluene was dried by heating under reflux with sodium under argon, acetonitrile by heating under reflux with CaH_2 for several hours. The other reagents and solvents were used without further purification. − The NMR spectroscopic data were obtained with Bruker AC 200 at 200.1 MHz (^1H) and 50.2 MHz (^{13}C), calibrated against the residue solvent signal ($CDCl_3$: δ = 7.24; [D_6]DMSO: δ = 2.50; CD_3CN: δ = 1.94) and are given in ppm. − IR data were collected with a Perkin−Elmer 1600 series FTIR spectrometer and are reported in cm^{-1}. − Microanalyses of metal complexes sometimes give unsatisfactory results due to incomplete combustion of the complex. It was not possible to obtain a good microanalysis for complex **7** because of this and perhaps also due to an undefined mixture of anions.

5-Amino-2-[6′-bromopyrid-2′-yl]pyrazine (11): 5-Amino-2-bromopyrazine (**9**) (500 mg, 2.87 mmol), hexamethyldistannane (1.04 g, 3.16 mmol), and $Pd(PPh_3)_4$ (183 mg, 0.16 mmol) were combined in toluene (15 mL), flushed with Ar, and heated under reflux for 1 h. After cooling to room temp., 2,6-dibromopyridine (952 mg, 4.02 mmol) and $Pd(PPh_3)_4$ (231 mg, 0.20 mmol) were added and the mixture was heated under reflux for 19 h. The solvent was evaporated and the residue purified by column chromatography on silica with hexane/EtOAc (1:1, v/v) to give **11** as a white powder. Yield 492 mg (68%). − ^1H NMR ($CDCl_3$): δ = 4.84 (s, br, 2 H, NH_2), 7.38 (dd, J = 0.9 Hz and 7.9 Hz, 1 H, $H_{3'\text{ or }5'}$), 7.58 (t, J = 7.9 Hz, 1 H, $H_{4'}$), 7.97 (d, J = 1.2 Hz, 1 H, $H_{3\text{ or }6}$), 8.08 (dd, J = 0.9 Hz and 7.6 Hz, 1 H, $H_{3'\text{ or }5'}$), 9.01 (d, J = 1.5 Hz, 1 H, $H_{3\text{ or }5}$). − ^{13}C NMR ($CDCl_3$): δ =118.3, 126.8, 130.9, 139.1, 139.9, 141.2, 141.6, 154.5, 156.2. − MS (FAB): m/z = 251.0 [M + H^+]. − IR (KBr): $\tilde{\nu}$ = 3436, 3316, 3163, 1641, 1586, 1541, 1432, 1380, 1286, 1154, 1124, 1012, 802, 776, 668, 604, 494, 416. − $C_9H_7BrN_4$ (251.1): calcd. C 43.05, H 2.79, N 22.32; found C 43.14, H 2.40, N 22.04.

5-Amino-2-[6′-(trimethylstannyl)pyrid-2′-yl]pyrazine (12): 5-Amino-2-(6′-bromopyrid-2′-yl)pyrazine (**11**) (550 mg, 2.19 mmol), hexamethyldistannane (789 mg, 2.41 mmol), and $Pd(PPh_3)_4$ (76 mg, 0.066 mmol) were combined in toluene (15 mL), flushed with Ar, and heated under reflux for 20 min. The solvent was evaporated and the residue was taken up in $CHCl_3$. The precipitated Pd was centrifuged off and the residue was used for the next coupling step after evaporation of the solvent without further purification. − ^1H NMR ($CDCl_3$): δ = 0.34 [s, 9 H, Sn(CH_3)$_3$], 4.94 (s, br, 2 H, NH_2), 7.35 (dd, J = 8 Hz and 1.2 Hz, 1 H, $H_{3'\text{ or }5'}$), 7.60 (t, J = 8 Hz, 1 H, $H_{4'}$), 7.95−7.99 (m, 2 H, $H_{3'\text{ or }5'}$ and $H_{3\text{ or }6}$), 9.19 (d, J = 1.4 Hz, 1 H, $H_{3\text{ or }6}$).

4,6-Bis[6′-(5′′-aminopyrazin-2′′-yl)pyrid-2′-yl]-2-phenylpyrimidine (2): 5-Amino-2-[6′-(trimethylstannyl)pyrid-2′-yl]pyrazine (**12**) (660 mg, 1.97 mmol), 4,6-dichloro-2-phenylpyrimidine (222 mg, 0.99 mmol), and $PdCl_2(PPh_3)_2$ (55 mg, 0.079 mmol) were combined in anhydrous DMF (15 mL), degassed, and heated to 100 °C for 21 h. The mixture was cooled to room temp. and the precipitation was centrifuged off, washed 2 × with MeOH/acetone and 1 × with Et_2O to give **2** as a white powder. Yield 373 mg (69% over 2 steps). − ^1H NMR ([D_6]DMSO): δ = 6.96 (s, br, 4 H, NH_2), 7.60−7.65 (m, 3 H, $H_{meta\text{ and }para}$), 8.03 (d, J = 1.2 Hz, 1 H, $H_{3''\text{ or }6''}$), 8.15 (t, J = 7.3, 2 H, $H_{4'}$), 8.31 (d, J = 7.9 Hz, 2 H, $H_{3'\text{ or }5'}$), 8.67 (d, J = 7.3 Hz, 2 H, $H_{3'\text{ or }5'}$), 8.70−8.76 (m, 2 H, H_{ortho}), 9.12 (d, J = 1.2 Hz, 2 H, $H_{3''\text{ or }6''}$), 9.36 (s, 1 H, H_5). − ^{13}C NMR ([D_6]DMSO): δ = 111.4, 121.2, 121.6, 129.0, 129.7, 132.0, 132.3, 138.0, 138.7, 139.5, 141.1, 153.7, 155.9, 157.1, 164.2, 164.8. − MS (FAB): m/z = 497.2 [M + H^+]. − IR (KBr): $\tilde{\nu}$ = 3313, 3159, 1654, 1564, 1534, 1488, 1378, 1298, 1019, 818, 752, 691, 637, 606, 415. − $C_{28}H_{20}N_{10}$ (496.5): calcd. C 67.37, H 4.06, N 28.21; found C 67.75, H 4.26, N 28.03.

Co Complex 4: 4,6-Bis[6′-(5′′-aminopyrazin-2′′-yl)pyrid-2′-yl]-2-phenylpyrimidine (**2**) (1.7 mg, 3.4 μmol) and $Co(BF_4)_2{\cdot}6H_2O$ (1.2 mg, 3.4 μmol) were heated under reflux in CD_3CN (0.4 mL) and D_2O (1 drop) for 3.5 h. The complex was isolated in quantitative yield as a brown powder by evaporation of the solvent. − ^1H NMR (CD_3CN/D_2O): δ = −137.98, −117.95, 12.37, 7.94, 12.70, 24.59, 36.79, 49.11, 80.22, 143.72, 166.16. − MS (FAB): m/z = 2742.5 $[Co_4L_4](BF_4)_6^+$, 2654.5 $[Co_4L_4](BF_4)_5^+$, 2568.4 $[Co_4L_4](BF_4)_4^+$, 2480.6 $[Co_4L_4](BF_4)_3^+$. − $C_{112}H_{80}B_8Co_4F_{32}N_{40}{\cdot}13H_2O$ (3150.5): calcd. C 42.70, H 3.39, N 17.78; found C 42.73, H 3.32, N 17.44.

Fe Complex 5: 4,6-Bis[6′-(5′′-aminopyrazin-2′′-yl)pyrid-2′-yl]-2-phenylpyrimidine (**2**) (10.0 mg, 20.1 μmol) and $Fe(BF_4)_2{\cdot}6H_2O$ (6.8 mg, 20.1 μmol) were heated under reflux in CH_3CN (4 mL)

and H_2O (0.5 mL) for 24 h. The complex was isolated as a dark brown powder by evaporation of the solvent in quantitative yield. − ^{1}H NMR (CD_3CN/D_2O): δ = −13.01, −9.14, −6.06, 40.79, 50.88, 64.64, 75.34. − MS (FAB): *m/z* = 2730.5 $[Fe_4L_4](BF_4)_6^+$, 2643.7 $[Fe_4L_4](BF_4)_5^+$, 2556.3 $[Fe_4L_4](BF_4)_4^+$, 2469.7 $[Fe_4L_4](BF_4)_3^+$. − $C_{112}H_{80}B_8F_{32}Fe_4N_{40}\cdot 7H_2O$ (3030.0): calcd. C 44.40, H 3.13, N 18.49; found C 44.70, H 2.87, N 18.05.

Zn Complex 6: 4,6-Bis[6′-(5′′-aminopyrazin-2′′-yl)pyrid-2′-yl]-2-phenylpyrimidine (**2**) (2.5 mg, 5.0 μmol) and $Zn(BF_4)_2\cdot 8H_2O$ (1.9 mg, 5.0 μmol) were heated under reflux in CD_3CN (0.5 mL) and D_2O (0.05 mL) for 3.5 h. The complex was isolated as an orange powder by evaporation of the solvent in quantitative yield. − ^{1}H NMR (CD_3CN/D_2O): δ = 5.68 (d, *J* = 6.9 Hz, 1 H, H_{ortho}), 5.95 (d, *J* = 7.3 Hz, 1 H, H_{ortho}), 6.08 (d, *J* = 1.5 Hz, 2 H, $H_{3'' \text{ or } 6''}$), 6.38 (t, *J* = 7.7 Hz, 1 H, $H_{meta \text{ or } para}$), 6.81 (t, *J* = 7.3 Hz, 1 H, $H_{meta \text{ or } para}$), 6.91 (t, *J* = 7.3 Hz, 1 H, $H_{meta \text{ or } para}$), 8.38 (t, *J* = 8.2 Hz, 2 H, $H_{4'}$), 8.47 (d, *J* = 8.0 Hz, 2 H, $H_{3' \text{ or } 5'}$), 8.79 (d, *J* = 1.1 Hz, 2 H, $H_{3'' \text{ or } 6''}$), 8.80 (d, *J* = 8.0 Hz, 2 H, $H_{3' \text{ or } 5'}$), 9.41 (s, 1 H, H_5). − MS (FAB): *m/z* = 2680.9 $[Zn_4L_4](BF_4)_5^+$, 2593.6 $[Zn_4L_4](BF_4)_4^+$, 2505.6 $[Zn_4L_4](BF_4)_3^+$, $[Zn_4L_4](BF_4)_2^+$. − $C_{112}H_{80}B_8F_{32}N_{40}Zn_4\cdot 13H_2O$ (3176.3): calcd. C 42.35, H 3.36, N 17.64; found C 42.20, H 3.42, N 17.80.

6-[Bis(*tert*-butoxycarbonyl)amino]-4-chloropyrimidine (15): 6-Amino-4-chloropyrimidine (**14**) (2.05 g, 15.8 mmol) was suspended in anhydrous acetonitrile (8 mL). Dimethylaminopyridine (483 mg, 1.45 mmol) and di-*tert*-butyl carbonate (7.37 g, 39.6 mmol) were added and stirred at room temp. for 23 h. The solvent was evaporated and the residue purified by column chromatography on silica with hexane/EtOAc (1:1, v/v) to give **15** as a white powder. Yield 4.12 g (79%). − ^{1}H NMR ($CDCl_3$): δ = 1.56 [s, 18 H, $C(CH_3)_3$], 7.85 (d, *J* = 0.9 Hz, 1 H, $H_{2 \text{ or } 5}$), 8.66 (d, *J* = 0.9 Hz, 1 H, $H_{2 \text{ or } 5}$). − ^{13}C NMR ($CDCl_3$): δ = 27.5, 84.8, 110.9, 149.4, 157.5, 158.7, 161.4. − MS (FAB): *m/z* = 330.0 $[M^+]$. − IR (KBr): ṽ = 3149, 2980, 1778, 1737, 1567, 1538, 1456, 1365, 1299, 1259, 1234, 1157, 1138, 983, 843, 786. − $C_{14}H_{20}ClN_3O_4$ (329.8): calcd. C 50.99, H 6.11, N 12.74; found C 50.70, H 5.72, N 12.54.

6-[Bis(*tert*-butoxycarbonyl)amino]-4-(trimethylstannyl)pyrimidine (16): 6-[Bis(*tert*-butoxycarbonyl)amino]-4-chloropyrimidine (**15**) (611 mg, 1.85 mmol), hexamethyldistannane (670 mg, 2.04 mmol), and $Pd(PPh_3)_4$ (86 mg, 0.074 mmol) were combined in toluene (10 mL), flushed with Ar, and heated under reflux for 45 min. The solvent was evaporated and the residue used for the following coupling reaction without further purification. − ^{1}H NMR ($CDCl_3$): δ = 0.35 [s, 9 H, $Sn(CH_3)_3$], 1.51 [s, 18 H, $C(CH_3)_3$], 7.77 (d, *J* = 1.5 Hz, 1 H, $H_{2 \text{ or } 5}$), 8.95 (d, *J* = 1.2 Hz, 1 H, $H_{2 \text{ or } 5}$).

4-[6′-Bromopyrid-2′-yl]-6-[bis(*tert*-butoxycarbonyl)amino]-pyrimidine (17): 6-[Bis(*tert*-butoxycarbonyl)amino]-4-(trimethylstannyl)pyrimidine (**16**) (763 mg, 1.76 mmol), 2,6-dibromopyridine (671 mg, 2.83 mmol), and $Pd(PPh_3)_4$ (98 mg, 0.084 mmol) were combined in toluene (10 mL), flushed with Ar, and heated under reflux for 21 h. The solvent was evaporated and the residue purified by column chromatography on silica with hexane/EtOAc (9:1 changing to 4:1, v/v) to give **17** as a white powder. Yield 345 mg (41%). − ^{1}H NMR ($CDCl_3$): δ = 1.53 [s, 9 H, $C(CH_3)_3$], 7.58 (dd, *J* = 0.9 and 7.9 Hz, 1 H, $H_{3' \text{ or } 5'}$), 7.71 (t, *J* = 7.6 Hz, 1 H, $H_{4'}$), 8.41 (dd, *J* = 1.2 and 7.3 Hz, 1 H, $H_{3' \text{ or } 5'}$), 8.53 (d, *J* = 1.2 Hz, 1 H, $H_{2 \text{ or } 5}$), 9.00 (d, *J* = 1.2 Hz, 1 H, $H_{2 \text{ or } 5}$). − ^{13}C NMR ($CDCl_3$): δ = 27.7, 84.3, 110.3, 120.5, 129.8, 139.3, 141.9, 154.8, 157.8, 159.9, 162.4. − MS (FAB): *m/z* = 452.9 $[M + H^+]$. − IR (KBr): ṽ = 2980, 2934, 1777, 1743, 1573, 1534, 1435, 1388, 1370, 1341, 1303, 1279, 1230, 1143, 985, 850, 807, 775, 697, 632. − $C_{19}H_{23}BrN_4O_4$ (451.3): calcd. C 50.57, H 5.41, N 12.41; found C 50.84, H 5.29, N 12.20.

6-[Bis(*tert*-butoxycarbonyl)amino]-4-[6′-(trimethylstannyl)pyrid-2′-yl]pyrimidine (18): 4-[6′-Bromopyrid-2′-yl]-6-[bis(*tert*-butoxycarbonyl)amino]pyrimidine (**17**) (140 mg, 0.32 mmol), hexamethyldistannane (120 mg, 0.36 mmol), and $Pd(PPh_3)_4$ (19 mg, 0.017 mmol) were combined in toluene (2 mL), flushed with Ar, and heated under reflux for 30 min. The solvent was evaporated and the residue used for the next coupling reaction without further purification. − ^{1}H NMR ($CDCl_3$): δ = 0.38 [s, 9 H, $Sn(CH_3)_3$], 1.53 [s, 18 H, $C(CH_3)_3$], 7.53 (dd, *J* = 1.5 and 7.3 Hz, 1 H, $H_{3' \text{ or } 5'}$), 7.68 (t, *J* = 7.3, 1 H, $H_{4'}$), 8.30 (dd, *J* = 1.5 and 7.9 Hz, 1 H, $H_{3' \text{ or } 5'}$), 8.60 (d, *J* = 1.2 Hz, 1 H, $H_{2 \text{ or } 5}$), 9.04 (d, *J* = 1.2 Hz, 1 H, $H_{2 \text{ or } 5}$).

4,6-Bis[6-{6-[bis(*tert*-butoxycarbonyl)amino]pyrimidin-4-yl}pyrid-2-yl]-2-phenylpyrimidine (19): 6-[Bis(*tert*-butoxycarbonyl)amino]-4-[6-(trimethylstannyl)pyrid-2-yl]pyrimidine (**18**) (151 mg, 0.28 mmol), 4,6-dichloro-2-phenylpyrimidine (34 mg, 0.15 mmol), and $Pd(PPh_3)_4$ (17 mg, 0.015 mmol) were combined in toluene (2 mL), flushed with Ar, and heated under reflux for 22 h. The solvent was evaporated and the residue purified by column chromatography on silica with hexane/EtOAc (4:1, changing to 1:1, v/v) to give **19** as a pale yellow powder. Yield 72 mg (50%). − ^{1}H NMR ($CDCl_3$): δ = 1.44 [s, 36 H, $C(CH_3)_3$], 7.52−7.6 (m, 3 H, $H_{meta \text{ and } para}$), 8.09 (t, *J* = 7.9 Hz, 2 H, $H_{4'}$), 8.60 (d, *J* = 7.6 Hz, 2 H, $H_{3' \text{ or } 5'}$), 8.69 (dd, *J* = 0.9 and 7.9 Hz, 2 H, $H_{3' \text{ or } 5'}$), 8.72−8.78 (m, 2 H, H_{ortho}), 8.85 (s, 2 H, $H_{2'' \text{ or } 5''}$), 9.03 (d, *J* = 0.9 Hz, 2 H, $H_{2'' \text{ or } 5''}$), 9.13 (s, 1 H, H_5). − ^{13}C NMR ($CDCl_3$): δ = 27.6, 84.1, 109.5, 112.9, 123.0, 123.9, 128.4, 128.5, 130.8, 137.7, 138.1, 150.2, 153.8, 155.2, 157.7, 159.7, 163.6, 164.3, 164.5. − MS (high-resolution FAB): calcd. for $C_{38}H_{34}N_{10}O_4$: *m/z* = 897.404784, found *m/z* = 897.405728 $[M + H^+]$. − IR (KBr): ṽ = 3059, 2979, 2933, 1777, 1744, 1576, 1537, 1459, 1394, 1370, 1342, 1304, 1282, 1260, 1142, 1109, 988, 847, 824, 759, 692. − $C_{48}H_{52}N_{10}O_8\cdot 3/4EtOAc$: calcd. C 63.65, H 6.00, N 14.56; found C 63.29, H 5.78, N 14.88.

4,6-Bis[6-(6-aminopyrimidin-4-yl)pyrid-2-yl]-2-phenylpyrimidine (3): EtOAc (5 mL) was saturated with HCl gas. This solution was added to 4,6-bis[6-{6′-[bis(*tert*-butoxycarbonyl)amino]pyrimidin-4-yl}pyrid-2-yl]-2-phenylpyrimidine (**19**) (72 mg, 0.080 mmol) and stirred at room temp. for 16 h. The precipitation was centrifuged off and washed with EtOAc, H_2O, NaOH, DMSO and acetone to give **3** as an off-white powder. Yield 35 mg (88%). Because of the low solubility of this compound, no NMR spectrum could be obtained. − MS (high-resolution FAB): calcd. for $C_{28}H_{21}N_{10}$: *m/z* = 497.195066, found *m/z* = 497.195923 $[M + H^+]$. − IR (KBr): ṽ = 3311, 3058, 1658, 1560, 1538, 1369, 1318, 1252, 1169, 1086, 992, 822, 760, 652.

Co Complex 7: 4,6-Bis[6-(6-aminopyrimidin-4-yl)pyrid-2-yl]-2-phenylpyrimidine (**3**) (2 mg, 4.03 μmol) and $Co(BF_4)_2\cdot 6H_2O$ (1.37 mg, 4.03 μmol) were heated under reflux in CD_3CN (0.25 mL) and D_2O (0.25 mL) for 23 h. The complex was isolated as a pale brown powder by evaporation of the solvent in quantitative yield. − ^{1}H NMR (CD_3CN/D_2O): δ = −89.59, −79.40, −42.99, −7.43, −7.18,16.73, 28.99, 49.42, 109.56, 146.53, 177.69. − MS (FAB): *m/z* = 2742.8 $[Co_4L_4](BF_4)_6^+$, 2655.7 $[Co_4L_4](BF_4)_5^+$, 2569.2 $[Co_4L_4](BF_4)_4^+$, 2481.2 $[Co_4L_4](BF_4)_3^+$.

X-ray Structural Analysis for Complex 7: A suitable orange crystal (0.4 × 0.1 × 0.05 mm) of $[C_{112}H_{80}N_{40}Co_4]^{8+} \times 2\ Cl^- \times 3\ SiF_6^{2-} \times 2\ CH_3CN \times 50\ H_2O$ was obtained from acetonitrile/water/THF during the attempt of cocrystallisation with Fe complex **5**; *M* = 3702.0 g mol^{-1}, triclinic $P\bar{1}$, *a* = 15.4976(4), *b* = 18.2114(6), *c* =

31.9538(10) Å, $\alpha = 86.9809(13)$, $\beta = 83.4137(18)$, $\gamma = 67.2828(16)°$, $V = 8263.6(4)$ Å^3, μ(Mo-K_α) = 0.559 mm^{-1}, $Z = 2$, $D_c = 1.447$ g cm^{-3}, $F(000) = 3644$, $T = 173.0(1)$ K. Data were recorded with a Nonius Kappa CCD diffractometer using graphite-monochromatised Mo-K_α ($\lambda = 0.71073$ Å) radiation. $\theta = 2.96-24.97°$ for data collection. 67652 collected reflections, 27325 unique reflections [16258 with $I > 2\sigma(I)$] were used for refinement. The data were processed with DENZO.[14] The absorption correction was made with SORTAV[15] ($T_{min} = 80.74$ and $T_{max} = 97.26°$) and L_p correction was applied. Structure solution was done by direct methods[16] and refinement on F^2.[17] The hydrogen atoms were calculated to their idealised positions with isotropic temp. factors (1.2 or 1.5 times the C temp. factor) and were refined as riding atoms. Four temperature factors were equalised. One Cl^- anion is disordered over two positions (occupancy 0.5). Fluorine atoms of one SiF_6^{2-} anion are disordered between two positions with site occupation values of 0.64 and 0.36. The hydrogen-bonded, complicated water system altogether includes 50 molecules of water (hydrogen atoms could not be located), of which 26 are treated with an occupancy of 1.0, while the others are disordered and refined with a population parameter of 0.5. Final R values were $R = 0.1185$, $wR^2 = 0.2778$ [$I > 2\sigma(I)$], $R = 0.1900$, $wR^2 = 0.3190$ (all data) for 2201 parameters, Goodness-of-fit on $F^2 = 1.057$. A final difference map displayed the highest electron density of 1.07 eÅ^{-3}, which is located near to water molecules. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-150832. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

E. B. thanks the French Government for an undergraduate and the "Ministère de l'Education Nationale, de la Recherche et de la Technologie" for a graduate fellowship. U. Z. thanks the "Deutsche Forschungsgemeinschaft" for a postdoctoral fellowship. Financial support from the "Finnish Ministry of Education" (E. W.) is gratefully acknowledged. We thank Dr. D. Bassani for preliminary work.

Hydrogen-Bonding and Metal-Ion-Mediated Self-Assembly of a Nanoporous Crystal Lattice

Dirk G. Kurth,[a][‡] Katharina M. Fromm,[a][‡‡] and Jean-Marie Lehn*[a]

Keywords: Hydrogen bonds / Self assembly / Mesoporous materials / Crystal engineering / Supramolecular chemistry

Hydrogen-bonding and metal-ion coordination are utilized to assemble a nanoporous crystal lattice. In the initial step of the assembly process, tecton **1** (4b,5,7,7a-tetrahydro-4b,7a-epiminomethanoimino-6*H*-imidazo[4,5-*f*][1,10]phenanthroline-6,13-dione) forms an octahedrally coordinated secondary building block with Fe^{II}, which in the final step assembles through hydrogen-bonding interactions to a nanoporous network. The secondary building blocks hydrogen-bond such that ribbons with two-membered channels are formed. Sheets are generated through hydrogen-bonding of the ribbons, which results in four-membered channels. In the crystal, the sheets are stacked parallel to each other, which results in a three-dimensional porosity.

Introduction

Supramolecular chemistry provides ways and means to design and generate organized equilibrium architectures of nanoscopic dimensions with novel structural and functional properties.[1,2] The final supramolecular entity (or a collection of such) evolves through a sequence of spontaneous but directed recognition, growth, and termination steps of suitably instructed components and specified interaction schemes. Non-covalent interactions, such as hydrogen bonding, metal ion coordnation, electrostatic and hydrophobic forces, permit precise positioning of molecular components in a well-defined supramolecular architecture.[1,2]

The implementation of the underlying principles of non-covalent interactions in molecular based materials allows the generation of spatially confined and macroscopically ordered ensembles. Long-range correlation of positions or orientations of the active constituents will be of paramount importance to fully explore the potential of supramolecular materials and of the derived functional devices. The improvement of existing and the development of novel methods to generate organized supramolecular assemblies represent a central objective and require the availability of structurally reliable, functional synthons to engineer periodic, three-dimensional architectures presenting specific structural characteristics.

Such is the case with nanoporous networks, which are at the focus of materials research due in particular to the commercial interest in chemical separation and heterogeneous catalysis.[3] Zeolites, pillared clays and related microporous materials, which have been studied extensively due to their useful catalytic properties, can now be engineered to some extent.[4−8] The challenges posed by the production of a well-defined porosity i.e. the formation of chiral and chemically functionalizable pores has recently stimulated the application of self-assembly principles originating from supramolecular chemistry based on hydrogen bonding and metal-ion coordination in this area.[1,2,9]

Metal-ion-containing devices are of particular interest as active components in functional materials because they possess a wide range of well-defined geometries and diverse properties that are relevant in electronic, optical, magnetic, and catalytic applications.[10] Self-assembly of the metallosupramolecular architecture is effected through ligands with suitable binding sites in a proper spatial arrangement.[1,2] On the other hand, hydrogen bonding is probably the most widely spread interaction motif in biological systems.[11] It, therefore, appeared of much interest to us to explore both interactions to pursue the goal of constructing well-defined nanoporous architectures containing functional components.[12]

Herein we describe the synthesis and structure of a nanoporous network through sequential self-assembly. Metal ion coordination of 4b,5,7,7a-tetrahydro-4b,7a-epiminomethanoimino-6*H*-imidazo[4,5-*f*][1,10]phenanthroline-6,13-dione (**1**) with Fe^{II} results in the octahedral secondary building block $[Fe^{II}(\mathbf{1})_3]Br_2$. Tecton **1** combines the versatile metal ion receptor phenanthroline[13] with urea[14] as the hy-

drogen-bonding component. As a result of the nonplanar topology of the metal ion and hydrogen bond receptors the secondary building block forms a nanoporous, crystal lattice.

Results and Discussion

Ligand **1** was obtained as an insoluble white powder in 61% yield from the condensation of 1,10-phenanthroline-5,6-dione, prepared from 1,10-phenanthroline according to literature procedures,[15] and urea.[16]

When three equivalents of **1** were treated with one equivalent of $FeBr_2$ in degassed water under Ar the reaction mixture turned red (λ = 523 nm, ε = 8825 $cm^{-2}mol^{-1}$), characteristic of tris-phenanthroline Fe^{II} complexes.[17] The complex $[Fe^{II}(\mathbf{1})_3]Br_2$ (**2**) was isolated as red powder. Due to the octahedral symmetry of the complex, the imide protons are diastereotopic and their NMR resonance splits into two signals. Compound **2** is diamagnetic at room temperature in agreement with an octahedral low spin Fe^{II} complex. Compound **2** shows a quantitative loss of ether at 333 K and continuous loss of water between 373 and 564 K, after which it decomposes thermally. The elemental analysis, ^1H NMR spectroscopy, mass spectrometry, and single-crystal X-ray structure analysis are in agreement with the formula mentioned above.

Single crystals of **2** were obtained by crystallization from a water solution layered with *n*-pentane and diethyl ether. The compound crystallizes in the monoclinic space group *P*2/*n* (no. 13) with two cationic building blocks of the composition $[Fe^{II}(\mathbf{1})_3]^{2+}$ and four free bromide ions per unit cell. In addition, there are solvent molecules such as water and diethyl ether in strongly disordered positions. The hydrogen-bonded network made up of the cationic building blocks was identified without ambiguity. The building blocks are composed of an octahedral, monometallic Fe^{II} complex and three ligands of **1** (Figure 1 and 2). Two of the ligands, denoted *A* and *A*′, are equivalent by symmetry; the third nonequivalent ligand is referred to as *B*. The central metal atom and ligand *B* of the cationic building block are located on a C_2 axis [1/4, y, 1/4 (e)]. The coordination sphere of the iron cation can be described as a distorted octahedron of six nitrogen donor atoms, which is flattened along the pseudo-C_3 axis of the complex. A different way of describing the structure is to say that the phenanthroline units of each ligand are coordinated in a helical fashion around the metal center. The Fe−N distances vary between 1.990(8) and 2.066(8) Å. The nitrogen atoms of ligands *A* and *A*′ are denoted as N1 and N2, while those of ligand *B* are denoted as N7 and N7′. The bite angles of the bipyridyl groups are 80.1(3)° for N1−Fe−N2 (*A* and *A*′) and 82.7(4)° for N7−Fe−N7′ (B). The *trans* N−Fe−N angles are 172.3(3)° for N2−Fe−N7 and 175.1(5)° for N1−Fe−N1′. These values are similar to other phenanthroline and bipyridine complexes.[17,18] The pyridine rings in *A* and *A*′ are out of plane from each other by 8.6(5)°, whereas ligand *B* is planar. The central rings of *A* and *A*′ formed by C4, C5, C6, C7, C11 and C12 and the corresponding symmetric equivalents are not planar, with C12 and C12′ being significantly out of plane by 0.27(1) Å. The planes of the urea groups make an angle of 68.8(5)° to each other. The inner-ring angles of the pyridine groups of the phenanthroline entity vary from 114.6 to 119.3° for the C−N−C angles, from 118.8 to 125.5° for the C−C−N angles and from 115.5 to 121.8° for the C−C−C angles. The corresponding angles in the central all-carbon ring range from 114.1 to 124.5°.

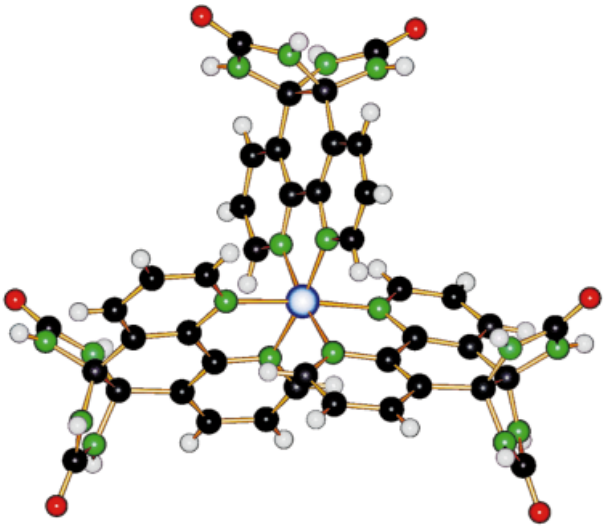

Figure 1. Crystal structure of the $[Fe^{II}(\mathbf{1})_3]$ building block

In the crystal, cationic units $[Fe(\mathbf{1})_3]^{2+}$ of the same helicity are arranged along the C_2 axes within one plane, the Λ-chains being oriented antiparallel to the Δ-chains. These linear strands of Λ- and Δ-building blocks are alternately linked to each other by hydrogen bonds through the urea part of the ligand, leading to a two-dimensional layered network. Thus, ligands *A* and *A*′ each form three (ligand *B* two) hydrogen bonds with two neighboring molecules of the same plane. In one cationic unit, the oxygen O1 of the urea group of *A* is bonded to H5(N5) of ligand *A*′ of the next cationic unit and vice versa: the oxygen O1′ of this neighboring molecule is hydrogen bonded to H5(N5) of the first cation. A crystallographic inversion center is found in the geometric middle of the hydrogen bonding system formed by O1−H5′(N5′) and O1′−H5(N5). The oxygen O2 of the second urea group of *A* is hydrogen bonded to H9(N9) of ligand *B*′ of a second neighboring molecule. The oxygen atom O3 of ligand *B* and its symmetry equivalents do not form hydrogen bonds to neighboring molecules because they point out of the plane in which the other hydrogen bonds are formed. In addition, the distance to the next layer is 11 Å (Fe−Fe distance), which is too far for binding. As a result, a Δ-helical cation only binds to four Λ-cations, and vice versa. Two types of channels are thus formed in the structure, one with an average diameter of about 10 Å, assembled from the formation of two hydrogen bonds between two ligands *B* and two ligands *A* of two neighboring

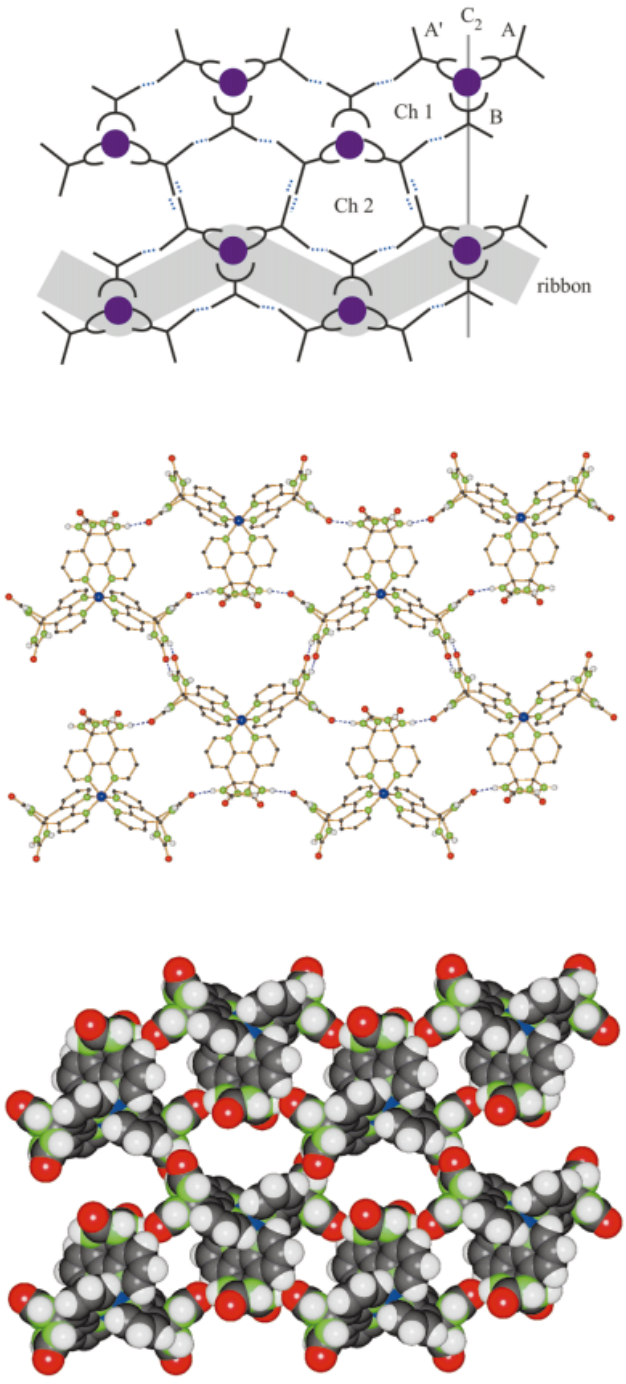

Figure 2. Schematic illustration, X-ray structure, and space-filling representation of a single sheet of the crystal lattice; ligands located on the C_2 axes are denoted *B* (in the plane of the sheet) while the other two ligands are denoted *A*; cationic units $[Fe^{II}(\mathbf{1})_3]$ of opposite chirality are hydrogen-bonded between *A* and *B* ligands, which results in an extended ribbon and a square cavity with a diameter of 1 nm (Ch 1); the ribbons form an extended sheet through the hydrogen bonds of *A* ligands such that homochiral $[Fe^{II}(\mathbf{1})_3]$ building blocks are located along the C_2 axes; four cationic units form a cavity with a diameter of approximately 1.2 nm (Ch 2) (all metal ions are in the plane of the sheet, some hydrogen atoms omitted for clarity)

cationic units, leading to a square two-membered ring system (channel 1). The other channel is due to six hydrogen bonds between ligands *A*, *A'*, and *B* of four cationic units and has the approximate dimensions 8 × 12 Å. It yields a heart-shaped, four-membered cavity (channel 2).

As the cationic units are arranged in a parallel manner, the maximum number of hydrogen bonds is formed with adjacent units in order to stabilize the structure. The bulky urea groups prevent a close approach and consequently a development of pi-stacking interactions of adjacent phenanthroline groups.

The total number of hydrogen bonds for one cationic building block, counting the donors and acceptors, is 18, six H-acceptors (oxygen) and 12 donors (N−H). Considering that the hydrogen bonds are only formed between ligands of different cationic units and that each acceptor reacts with one donor at a time, the maximum number of H-bonds formed is 12, of which only eight (4 donors + 4 acceptors) are used. The remaining donors and acceptors do not participate in bonding interactions due to the two-dimensional structure. Each of the six urea fragments of one cationic building block is thus involved in at least one H-bond. Considering the helical way in which the ligands are arranged around the metal ion, four of the six oxygen atoms come to lie in approximately one plane, whereas the other two are oriented perpendicular to this plane and cannot participate in H-bonding as the next layer is too far away. As for the N−H fragments, four of them are oriented in approximately the same plane as the four coplanar oxygen atoms and participate in the structure formation whereas the other eight point out of the plane of the layer.

The maximum number of strong, linear H-bonds is formed if the cationic units are arranged anti-parallel to each other on C_2 axes. This arrangement results in the formation of a ribbon with two-membered square channels of 1 nm diameter (channel 1). The ribbons are stacked in a plane by formation of six H-bonds to yield a four-membered ring with a heart-shaped cavity of approximately 1.2 nm in diameter (channel 2). Both channels run parallel to the *a* axis of the unit cell [1 0 0]. In the crystal, the layers are stacked parallel to each other in an alternating ABA-type fashion. Due to intercalating solvent molecules the interlayer distance is approx. 9.5 Å, which is too large for direct (short range) interactions.

Conclusion

In conclusion, we describe a potential tecton with a reliable structural paradigm such as is needed for the systematic design of metallosupramolecular crystalline materials with predictable structures and tailorable functions. Complex **2** yields a nanoporous, two-dimensional architecture which is stable up to 564 K. The formation of this material demonstrates self-organization by spontaneous self-assembly involving two types of molecular recognition phenomena, namely metal ion recognition in the first step and hydrogen bonding in the final step to establish the 3D architecture. Finally, it should be pointed out that the connectivity is reminiscent of inorganic architectures such as zeolites and clays. However, the intrinsically chiral metal-

losupramolecular constituents permit, in contrast to many achiral aluminosilicate precursors of other inorganic materials, the formation of chiral porous networks, which would offer attractive possibilities in recognition and catalysis. The nonparticipating H-bonding donors and acceptors may furthermore serve as anchors, for example for suitable amphiphiles, to functionalize the interior. Further studies on creating nano- and microporous architectures based on this compact synthon are in progress.

Experimental Section

Ligand 1: Condensation of 1,10-phenanthroline-5,6-dione (4 g, 119 mmol) and urea (2.5 g, 41.7 mmol) in toluene (100 mL) with trifluoroacetic acid (10.6 g, 93 mmol) yielded 61% (3.4 g, 11.6 mmol) of **1** as an insoluble white powder.[16] 1,10-Phenanthroline-5,6-dione was prepared from 1,10-phenanthroline according to literature procedures in 45% yield.[15] − MS: *m*/*z* = 295.2; calcd. 294.3 [M + H]. − ^{1}H NMR ([D$_6$]DMSO, room temperature): δ = 8.73 (d, J_1 = 4.3 Hz, 2 H), 8.32 (s, 4 H), 8.08 (d, J = 7.8 Hz, 2 H), 7.74 (dd, J_1 = 7.7 Hz, J_2 = 4.6 Hz, 2 H). − $C_{14}H_{10}N_6O_2$ (294.27): calcd. C 57.14, H 3.43, N 28.56; found C 57.29, H 3.51, N 28.52.

[Fe^{II}(1)$_3$]Br$_2$ (2): Three equiv. of **1** (1 g, 3.4 mmol) were treated with 1 equiv. of $FeBr_2$ (237 mg, 1.1 mmol) in degassed water (40 mL) under Ar. The reaction mixture turned red as a result of formation of the tris-phenanthroline Fe^{II} complex.[16] Complex **2** was isolated as red powder in 60% yield (725 mg) after recrystallisation. − MS: *m*/*z* = 724; calcd. 723 [Fe^{II}(**1**)$_2$Br]$^+$. − ^{1}H NMR ([D$_6$]DMSO, room temperature): δ = 7.39 (1 H), 7.71 (1 H), 8.27 (1 H), 8.43 (1 H), 8.70 (1 H). − ^{13}C NMR ([D$_6$]DMSO, 100 MHz, 25 °C): δ = 159.62, 155.39, 151.02, 137.62, 135.14, 129.58, 75.31. − $C_{42}H_{30}Br_2FeN_{18}O_6(H_2O)_{2.5}$ 1143.52): calcd. C 44.12, H 3.09, N 22.05; found C 44.13, H 3.02, N 21.9. − UV/Vis (H_2O): λ (ε [cm^{-2} mol^{-1}]) = 523 nm (8825), 493 (shoulder), 315 (34440).
Compound **2** shows quantitative loss of ether at 333 K and continuous loss of water between 373 and 564 K after which it decomposes thermally.

Crystal Structure Data for 2: $[Fe(C_{14}H_{10}N_6O_2)_3]\cdot 2Br\cdot 2CH_3CN\cdot(CH_3CH_2)_2O\cdot 9H_2O$. Diffractometer and data collection: STOE IPDS (−70 °C), graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), monoclinic, space group *P*2/*n*, *a* = 11.098(2) Å, *b* = 16.720(3) Å, *c* = 19.760(4) Å, β = 96.79(3)°, *V* = 3640.9(13) Å^3, *Z* = 2, μ = 1.373 mm^{-1}, *F*(000) = 1388, ρ = 1.261 Mg/m^3, $2\Theta_{max}$ = 51.8°. Primary structure solution by direct methods (SHELXS-92).[20] Anisotropic refinement for all non-hydrogen atoms of the cationic complex (SHELXL-93).[21] 6232 Measured reflections, 5961 independent [*R*(int) = 0.1994] of which 5961 reflections were used to refine 437 parameters. The solvent and anionic structure parts show multifold disorder. Therefore atoms of solvent were refined isotropically on split positions. The structure was refined against F^2 (full-matrix least-squares). *R*1 = 0.1395 [for 2994 reflections with $F > 4\sigma(F)$, *R*1 = 0.2717 (all data)] and *wR*2 = 0.2461 [*wR*2 = 0.3288 (all data)]. GooF on F^2 = *S* = 1.117; max./min. residual density +1.045/−0.403 e/Å^3. Silver Hydro Sodalite $[Ag_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$: Synthesis and Structure Determination by Combination of X-ray Rietveld Refinement, Thermogravimetry, FT-IR, and ^{1}H-MAS NMR Spectroscopy

Stefanie Eiden-Aßmann,*[a] Andreas M. Schneider,[b] Peter Behrens,[b] Guenter Engelhardt,[c] Hugo Mändar,[d] and Juergen Felsche[e]

Keywords: Silver / Sodalite / Ion exchange / Rietveld refinement

Sodium hydro sodalite $[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$ was subjected to ion exchange with aqueous $AgNO_3$ solutions to yield silver hydro sodalite $[Ag_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$. A Rietveld structure refinement of the silver hydro sodalite structure based on powder X-ray diffraction data recorded at room temperature (cubic, a = 8.950 Å, space group P-43n) led to a model where three silver cations form a triangle nearly parallel to a four-membered ring of the sodalite cage. In combination with the four water molecules, a disorder model $[Ag_3(\mu\text{-}H_2O)_2(H_2O)_2]^{3+}$ is suggested. This structural arrangement is clearly different from that found in sodium hydro sodalite. Whereas the sodium hydro sodalite structure is dominated by cation–water interactions, the silver hydro sodalite structure reflects strong interactions between the cations and the oxygen atoms of the framework, strong interactions between the water molecules, but only weak ones between the cations and water molecules. In addition, weak $Ag^+\cdots Ag^+$ interactions may play a role. ^{1}H MAS NMR spectra show that the hydrogen atoms (which were not found in the Rietveld analysis) of the water molecules are involved in hydrogen bonding of different strengths and dynamics.

Introduction

The framework of 1:1 aluminosilicate sodalites consists of a periodic array of space-filling $[4^66^8]$ polyhedra (β cages) formed by a network of alternating and corner-sharing SiO_4 and AlO_4 tetrahedra with a unit-cell content of $[Al_3Si_3O_{12}]_2^{6-}$.[1] In addition to cations M^+ compensating for the negative charge of the framework, the β cages may contain a large variety of encapsulated salts M^+A^-, hydroxides M^+OH^-, and/or water molecules. The general unit-cell composition of aluminosilicate sodalites can thus be given as $[M_{3+x}A_x(H_2O)_n]_2[Al_3Si_3O_{12}]_2$, where M and A are singly charged cations and anions, respectively. Owing to their structural relationship with the well-known and industrially important A-, X-, and Y-type zeolites, sodalites have been considered as model systems in order to investigate the various kinds of host–guest interactions, static-statistical and/or dynamical guest disorder phenomena, and structural-phase transitions.[2,3]

In addition, sodalites have also attracted considerable attention because of their intracage reaction chemistry and their interesting material properties such as cathodochromism, photochromism, and ion conduction. They are also considered as periodic host matrices for the spatial organization of quantum-sized semiconductor clusters and cluster arrays.[4] Phenomena such as blue shifts in optical absorption edges have been observed for aluminosilicate sodalites that contain silver salts[5] and have been interpreted as quantum-size effects. Stein et. al[6] reported a silver oxalato sodalite $[Ag_8(C_2O_4)][Al_3Si_3O_{12}]$ that can be reversibly marked and erased with a laser beam for many cycles. A large number of different silver sodalites have been synthesized[7] and some of them have been structurally characterized by Rietveld refinements of X-ray diffraction data.[8,9] Notably, the refinement of the structure of the silver hydro sodalite (SHS), i.e. a sodalite containing only Ag^+ ions and water molecules in its cages, did not converge easily and stopped at relatively high R values with the structural model reported.[10] The structure of anhydrous silver sodalite $[Ag_3]_2[Al_3Si_3O_{12}]_2$ was studied in detail at different temperatures and with regard to a phase transition.[11]

As part of our investigation into the synthesis, structure and properties of aluminosilicate sodalites containing heavy metal cations,[11,12] we have studied the ion exchange of the well-characterized sodium hydro sodalite $[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$ with aqueous $AgNO_3$ solution. This paper reports the characterization of SHS by means of a Rietveld structure refinement based on powder X-ray diffraction, as well as by ^{1}H MAS NMR, ^{29}Si MAS NMR and FT-IR spectroscopy and by thermal analysis.

Results

Treatment of the sodium hydro sodalite $[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$ with an aqueous solution of $AgNO_3$ (1 M) at

383 K affords complete exchange of all sodium cations with silver cations, with retention of the sodalite host structure. The combination of analytical techniques employed by us suggests that the idealized chemical composition $[Ag_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$ is present in the product phase. Powder X-ray photographs showed that the crystallinity of the reactant sodalite is essentially preserved during ion exchange, and that the product is a single-phase material. No amorphous by-product was visible on scanning electron micrographs, therefore all the analytic data refer to the crystalline compound. The degree of ion exchange, determined by flame photometry and titration according to the method of Volhard, amounts to 95%.

The ^{29}Si MAS NMR spectrum (Figure 1) shows a narrow line at $\delta = -85.4$, indicating that the ordered 1:1 aluminosilicate framework is retained after the ion-exchange reaction.[13]

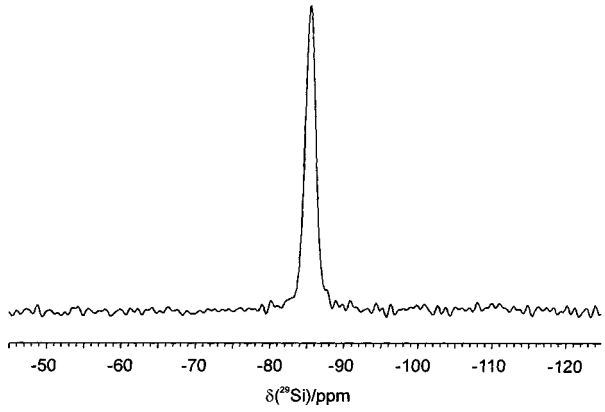

Figure 1. ^{29}Si MAS NMR spectrum of silver hydro sodalite

Thermal analysis (Figure 2) clearly demonstrates the presence of eight water molecules per unit cell. These water molecules are released from the SHS in a two-step reaction, in the temperature range from 400 to 600 K. The IR spectrum exhibits broad bands assigned to H_2O stretching vibrations in the range between 3000 and 3600 cm^{-1}, typical for water molecules involved in hydrogen bonding. In addition, a relatively narrow band appears at 1660 cm^{-1}, assigned to the H_2O deformation mode. The bands below 1200 cm^{-1} originate from framework vibrations.[14]

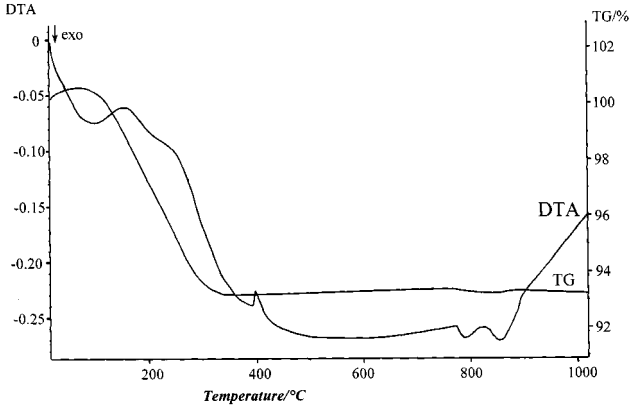

Figure 2. Simultaneous thermal analysis (TG/DTG/DTA) of silver hydro sodalite $[Ag_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$

Crystal Structure

Atomic coordinates and selected structural data of $[Ag_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$, as obtained from Rietveld refinement, are summarized in Table 1, Table 2, and Table 3.

Table 1. Fractional atomic coordinates, displacement parameters U and population parameter (PP) for $[Ag_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$ (data set 1)

Structural details are shown in Figure 3. The results are practically identical for both data sets, although some small deviations occur. In both refinement procedures, we were able to identify the positions of the silicon, aluminium, and oxygen atoms of the framework, the positions of the six silver cations and the positions of six out of the eight oxygen atoms of the occluded water molecules (Figure 3, **a** and **b**). In both cases it was not possible to determine the positions of the oxygen atoms of the two remaining water molecules. We assume that these are situated on a Wyckoff 8*e* position with a population parameter of 25%, close to the Wyckoff 8*e* position of the silver cation Ag1. The introduction of an oxygen atom O3 at this position during the re-

finement led to unreasonably short distances of d(O2−O3) ≈ 1.85 Å. Therefore the remaining oxygen atoms were neglected. We are conscious of the fact that this omission might lead to results which do not represent the true structure. Nevertheless, there are convincing arguments that the model which we will present is essentially correct.

Owing to the similar results of the two data sets, only the results of the refinement of the second data set will be discussed. Interatomic distances and angles of the framework structure were found mainly in the expected range. Silver cations were found at two 8*e*-Wyckoff positions. The population parameters of 50% for Ag1 and 25% for Ag2 were retained during the refinement procedure, but were relaxed several times to examine their behaviour and to ensure that no large deviations from the fixed values would occur. They were set back to their original values of 50% and 25%, respectively, after such test cycles. The occurrence of two Ag positions and the refined population parameters for the occluded silver cations and oxygen atoms of water molecules may be explained with a disorder model.

This disorder model of the non-framework atoms may be derived from the shortest distances to obtain a reasonable coordination sphere. In general, each sodalite cage contains a $[Ag_3(OH_2)_4]^{3+}$ cluster as a guest species, which is also found in silver-exchanged zeolite A.[15] The same number of metal cations and water molecules are also present as a $[Na_3(H_2O)_4]^{3+}$ cluster in $[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$. However, there are significant differences between these two compounds and $[Ag_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$. Whereas in silver zeolite A and in $[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$ the cations and water molecules are detected at one Wyckoff 8e position each (Figure 3, **e**), leading to coordination of the cations by three framework oxygen atoms and three water molecules, the arrangement is significantly different in SHS.

In SHS, each silver cation Ag1 is surrounded by three oxygen atoms of the framework [d(Ag1−O1) = 2.452(3) Å] and two oxygen atoms of water molecules [d(Ag1−O2) = 2.625(3) Å]. In addition, a relatively short contact between the silver cations Ag1 and Ag2 is found [d(Ag1−Ag2) = 3.270(4) Å], resulting in a sixfold (3+2+1) coordination (Figure 3, **c**). A distance of d(Ag2−O1) = 2.435(6) Å is found for the contacts between the silver cations Ag2 and the framework oxygen atoms. In addition to three framework oxygen atoms, this cation is coordinated to two neighbouring silver cations Ag1, and to one oxygen atom of an occluded water molecule (Figure 3, **d**), although the position of the oxygen atom of this water molecule could not be determined unequivocally. It is likely to be close to the position of the Ag1 silver cation with a population parameter of 25%, as mentioned before. Taken together, this results in a sixfold (3+1+2) coordination. Combining these results, we find an isosceles silver triangle composed of two Ag1 cations and one Ag2 cation, which is surrounded by oxygen atoms of the framework as well as of the occluded water molecules (Figure 3, **b**). The $[Ag_3]$ triangle is a very common motif in silver compounds, e.g. in dehydrated silver zeolite A[15] as well as in many ternary silver oxides.[16] Owing to the population parameters, the triangles show a fourfold orientational disorder with respect to the β-cage. Snapshot pictures of the structural model are given in Figure 3.

Oxygen atoms of the occluded water molecules are found on the corners of a tetrahedron (Wyckoff 8*e* position) with a population of 75%. Within the tetrahedron, the distance between two oxygen atoms was found to be d(O2−O2) = 2.545(4) Å, indicating the prevalence of strong hydrogen bonding between the water molecules at this position (Figure 3, **b**). The distance to the nearest oxygen atom of the host structure is d(O1−O2) = 3.24 Å, which is quite large but might still be indicative of weak hydrogen bonding between the occluded water molecules and the framework oxygen atoms. This is supported by the results of the ^{1}H NMR experiments (Figure 4). Two different types of hydrogen atoms were found. We ascribe these to hydrogen atoms involved in the stronger hydrogen bonding within the cluster of occluded water molecules (type 1, δ = 6), and hydrogen atoms involved in contacts from the water molecules to the framework oxygen atoms (type 2, δ = 5).

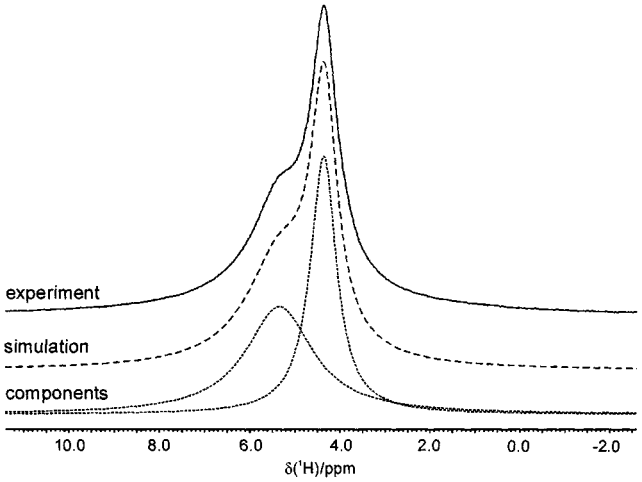

Figure 4. ^{1}H MAS NMR spectrum of silver hydro sodalite

The results of temperature-dependent ^{1}H MAS NMR spectroscopic investigations (Figure 5) indicate that at temperatures above 383 K, the dynamics of the water molecules

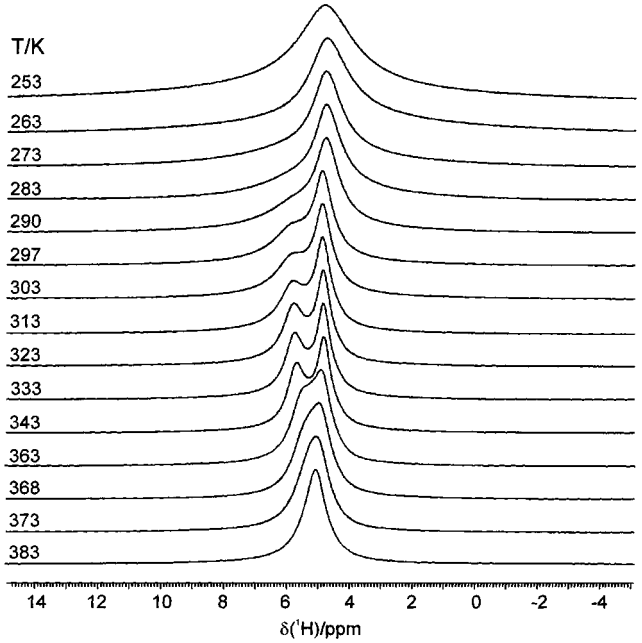

Figure 5. ^{1}H MAS NMR spectra of silver hydro sodalite at different temperatures

inside the sodalite cage is so fast, that the different types of hydrogen atoms become indistinguishable. In the temperature range from 368 K to 290 K, two separate signals were visible. At lower temperatures, one broad, slightly asymmetric peak was observed, and simulation of the spectra clearly shows the presence of two overlapping signals.

Discussion

Our studies demonstrate that the arrangement of the non-framework species in aluminosilicate silver hydro sodalite SHS is considerably different to the corresponding structures in its sodium analogue $[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$[17] and in the sodalite cages of hydrated silver zeolite A.[15] In all cases, one sodalite cage contains three metal cations and four water molecules. In the sodium hydro sodalite and in the silver zeolite, the metal ions are positioned at the corners of a tetrahedron, with a 75% occupancy and a corresponding disorder between the different cages. The oxygen atoms of the water molecules form another tetrahedron. The principle arrangement of the water molecules is similar in SHS, but the arrangement of the silver cations is different. They are positioned at the corners of a small isosceles triangle.

The distances between the silver ions and the oxygen atoms of the framework, and between the silver ions and the oxygen atoms of the water molecules, d(Ag−O1) = 2.452(3) Å and d(Ag−O2) = 2.625(3) Å, respectively, are similar to the corresponding distances in silver zeolite A [$d(Ag-O_{framework})$ = 2.47 Å, $d(Ag-O_{water})$ = 2.57 Å].[14] However, d(Ag−O1) is considerably larger than the corresponding distance in anhydrous silver sodalite $[Ag_3]_2[Al_3Si_3O_{12}]_2$:[11] $d(Ag-O_{framework})$ = 2.347 Å. This is due to the higher coordination number (*c.n.*) of the Ag^+ ions in the hydrated (*c.n.* = 6) versus the anhydrous (*c.n.* = 3) state. Also, the bonding in the anhydrous silver sodalite is more covalent than in the hydrated form. The silver−oxygen bond lengths in SHS and in hydrated silver zeolite A lie in the range found in ionic silver salts with high coordination numbers of Ag^+, e.g. d(Ag−O) = 2.48 Å in $AgNO_3$.

A comparison between the metal−metal, the metal−oxygen and the oxygen−oxygen distances in SHS and in the sodium analogue gives some indications for the cause of the different structural arrangements in these two compounds:

Coordination of the Metal Atoms

In $[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$, the metal−oxygen distances to the framework oxygen atoms and to those of the water molecules are very similar [$d(Na-O_{framework})$ = 2.51 Å, $d(Na-O_{water})$ = 2.46 Å].[17] This indicates that the Na^+ ions interact with similar strengths with the framework and with the water molecules. The corresponding values for SHS show that the Ag^+ cations prefer coordination to the framework oxygen atoms. This is in line with the general feature of Ag^+ chemistry that interactions between silver cations and water molecules are rare and weak. Consider, for example, the small number of hydrated silver salts. In SHS, the interactions between the water molecules and the non-framework Ag^+ ions are even weaker than in typical hydrates, e.g. $d(Ag-O_{water})$ = 2.46−2.48 Å in $Ag_2IF{\cdot}2\,H_2O$ or $d(Ag-O_{water})$ = 2.35−2.41 Å in $Ag_7I_2F_5 \cdot 2.5\,H_2O$.[18]

Interactions Between the Water Molecules

As in SHS the water molecules can interact only weakly with the non-framework Ag^+ ions, but undergo stronger hydrogen bonding with each other (Figure 3, **b**). Hence, in SHS, the distance d(O2−O2) between the oxygen atoms of the water molecules is only 2.64 Å, which is shorter than the corresponding value in bulk Ice-I_h (2.75 Å). On the contrary, in sodium hydro sodalite, the corresponding interatomic distance amounts to 3.22 Å, indicating only weak hydrogen bonding interactions between the water molecules (Figure 3, **e**).

Interactions Between Metal Cations

Since the work of Jansen,[19] it is well known that the structural chemistry of Ag^+ ions is often determined by relatively short Ag^+-Ag^+ contacts, and a tendency of the Ag^+ ions to segregate into specified regions of the structure, owing to $d^{10}-d^{10}$ interactions. In SHS, the interatomic Ag−Ag distance d(Ag1−Ag2) = 3.27 Å is at the upper limit of the range of distances in which such interactions can be assumed (the Ag−Ag van der Waals distance is ca. 3.4 Å). In contrast to our interpretation, Seff[20] and Gellens[15] assigned this distance unequivocally to Ag^+-Ag^0 bonding.

Summarizing these arguments, it is the general weakness of Ag^+-H_2O relative to Na^+-H_2O interactions that leads to strong hydrogen bonding between the water molecules in SHS and, in turn, to weak interactions between the water molecules and the framework. This effect is corroborated by weak $d^{10}-d^{10}$ interactions between the Ag^+ cations. Correspondingly, the disorder model shows a clear segregation of the metal ions and the water molecules into different parts of the sodalite cage (Figure 3, **b**).

The structural model derived here is consistent with all available experimental data. We wish to emphasise that our results are significantly different from the findings of Ozin et al.,[10] who on the basis of a Rietveld refinement of SHS suggested a structural model similar to that of sodium hydro sodalite.[18] The authors claimed to have detected only one 8*e* Wyckoff position for the Ag^+ cations (with a population parameter of 75%) and one fully occupied 8*e* Wyckoff position for the oxygen atoms of the water molecules. We were not able to reproduce these results of Ozin et al.[10] A Rietveld refinement taking these results as a starting model did not converge. Huge jumps occurred in the *x* parameter of the O2 atom (Δx = 0.05 corresponding to a distance of 0.8 Å); its population parameter increased to 185%. The attempt was stopped at this stage. We therefore conclude that either the silver hydro sodalite prepared by Ozin et al. was of a different nature to that prepared by us, or that their structure refinement is not correct. The synthesis of

the sodium hydro sodalite carried out by Ozin et al. is different to our synthesis, but the analytical data show that both sodalites are very similar apart from the degree of crystallinity. Ozin et al. work at low temperature and at low pressure; under these conditions the crystallinity of the product sodalites is not as high as when prepared under the high-temperature and high-pressure conditions used by us. The ion-exchange procedures were the same in our work and in that of Ozin et al., so that both SHS should be identical, apart from the degree of crystallinity. High cristallinity is of course very important for a reliable Rietveld refinement. Unfortunately, Ozin et al. did not show a powder pattern of the SHS, but they reported that their data for the silver hydro sodalite sample led to a poor refinement of the framework atoms. We therefore assume that the crystal structure and the structural model presented here give a more reliable picture of SHS than does the work of Ozin et al.[10]

Experimental Section

Synthesis and Methods of Characterization

SHS was prepared in a three-step procedure involving the synthesis of the basic sodium hydro sodalite $[Na_4(OH)(H_2O)]_2[Si_3Al_3O_{12}]_2$ in Teflon-lined steel autoclaves followed by Soxhlet extraction with water at 373 K to give the non-basic hydro sodalite $[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$.[3] Subsequent ion exchange was performed for one day with a 1 N $AgNO_3$ solution at 383 K in Teflon-lined steel autoclaves filled to 90%. The product was washed with distilled water and dried at 333 K. The degree of exchange was determined indirectly by flame photometry of the exchange solution (Na^+ content of the solution after the exchange reaction) and by titration according to Volhard (Ag^+ content of the solution after exchange). The water content was determined using a Netzsch thermoanalyzer STA 429 (N_2 atmosphere, heating rate 10 K/min) combining thermogravimetry (TG), difference thermogravimetry (DTG) and difference thermal analysis (DTA).

The crystallinity of the product and the purity of the compounds were monitored by powder X-ray diffraction employing a Guinier−Huber camera 600 with Cu-$K_{\alpha 1}$ radiation. Scanning electron micrographs were obtained on a JEOL scanning electron microscope (JSM-840A).

IR absorption analysis (KBr pellets) was performed on a Mattson Polaris TM FT spectrometer in the range of 4000 to 400 cm^{-1}.

^1H MAS NMR spectra were recorded at 400.13 MHz on a Bruker MSL-400 NMR spectrometer using a Bruker double-bearing MAS probe with 4-mm zirconia rotors. Single-pulse excitation was applied with a 4-s pulse width (corresponding to a 45° flip angle) and a 5-s pulse repetition. For each spectrum, 16 scans were accumulated at spinning rates of 10 kHz. Spectra simulations were performed using the PC program WINFIT, part of the Bruker WINNMR software package. ^{29}Si MAS NMR spectra were measured at 79.49 MHz using 7-mm rotors with a spinning speed of 4 kHz. Furthermore, 32 scans were recorded with a 3-s pulse width (corresponding to a 35° flip angle) and a 5-s pulse repetition. ^1H and ^{29}Si chemical shifts were related to tetramethylsilane using adamantane and Q_8M_8, respectively, as secondary standards.

X-ray Diffraction Studies

Powder photographs were taken on a Guinier camera (Huber system G600) with Cu-$K\alpha_1$ radiation (internal standard Si). The unit-cell constant of the cubic cell was obtained by LSQS refinement [8.950(2) Å] employing the software package AXES.[21]

Two different XRD patterns of SHS were recorded. The first was collected at room temperature on a Scintag powder diffractometer (Bragg−Brentano geometry) with Cu-$K\alpha$ radiation. The sample was prepared in a flat platinum sample holder which was spun during the measurement. The step width was set to 0.02 °2Θ in the range of 12 °2Θ to 110 °2Θ, resulting in 4900 data points. Some of the data points had to be removed owing to reflections of the platinum sample holder. Therefore only 3910 data points were considered for the refinement (data set 1). Further experimental details are given in Table 4.

The second data set was recorded on a Huber G642 powder camera with Cu-$K\alpha_1$ radiation (Ge monochromator) employing an X-ray sensitive storage film (Hamamatsu H6780). The sample was prepared between two transparent foils (flat sample), and the sample holder was moved tangentially to the focal circle during the measurement. The film was evaluated using a step width of 0.01 °2Θ in the range of 0 °2Θ to 100 °2Θ, resulting in 10 000 data points. During the Rietveld refinement, only data above 12.00 °2Θ were used (8750 data points, data set 2), because no reflections were detected below this value (Figure 6).

Further experimental details are given in Table 4. Both data sets were analysed in a similar way by the XRS-82 program[23] using the Rietveld method. Prior to refinement, the space group of the compound was determined to be *P*-43*n* (No. 218), the background of the pattern was subtracted manually and the contribution of Cu-$K\alpha_2$ radiation in data set 1 was eliminated by employing the algorithm of Ladell et al.[24] Two profile functions were determined employing Baerlocher's Learned Peak-Shape function,[25] one on the (211) reflection (24.204 °2Θ) and one on the (431) reflection (51.753 °2Θ). Atomic scattering factors were taken from reference 17. The least-squares refinement was started with the coordinates of the atoms Al, Si and O1 of the framework structure of ($[Na_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$).[17] We did not succeed in using the position and the population parameters of the sodium cations of this compound for the Ag^+ cations in SHS. Therefore the positions of the occluded Ag^+ cations and of the oxygen atoms of the water molecules were determined in subsequent difference Fourier syntheses of the electron density and from structural chemical arguments. All peaks detected in the range from 12.00 °2Θ to 100.00 °2Θ were used in the refinement process.

The first difference Fourier synthesis was carried out after the cautious adjustment of some profile parameters (zero-point and peak-asymmetry correction) and the first cautious relaxation of the position of the framework oxygen atoms. It revealed electron density approximately at positions (0.17, *x*, *x*) and (0.31, *x*, *x*) which were first attributed to the positions of the silver cations [(0.17, *x*, *x*), population parameter 0.75] and of the oxygen atoms of occluded water molecules [(0.31, *x*, *x*), population parameter 1.0]. Further refinement included the relaxation of all profile parameters as well as of the atomic positions and displacement parameters of the different atoms. However, release of the population parameter of the occluded silver cations led to a significant decrease below 0.6, while the refinement of the population parameter of the occluded oxygen atom led to a significant increase above 1.2. The silver cations and oxygen atoms were therefore removed from the system and a new difference Fourier synthesis was performed. The calculation again

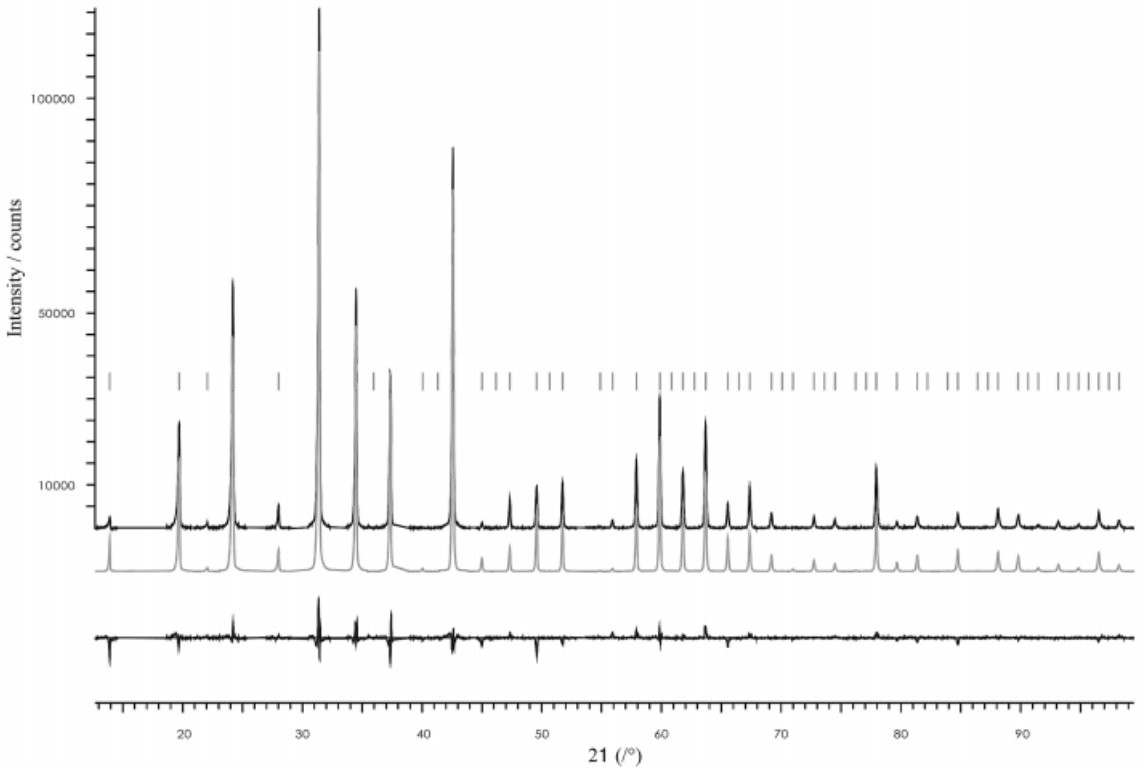

Figure 6. Observed (I_{obs}), calculated (I_{calc}) and difference ($I_{diff} = I_{obs} - I_{calc}$) powder diffraction patterns of $[Ag_3(H_2O)_4]_2[Al_3Si_3O_{12}]_2$ according to the Rietveld refinement

showed electron density at approximately (0.171, *x*, *x*) and at (0.311, *x*, *x*), with an intensity ratio of approximately 2:1. Therefore we concluded, that the silver cations may be located at these two different positions with population parameters of 0.5 for Ag1 and 0.25 for Ag2. After a few refinement cycles, an additional Fourier synthesis revealed remaining electron density at (0.35, *x*, *x*), close to the Ag2 cation. An oxygen atom O2 was placed at position (0.35, *x*, *x*). Taking into account the population parameter of the Ag2 cation (25%), O2 was assigned a population parameter of 75% to avoid very short distances *d*(Ag2−O2). Therefore only six oxygen atoms out of eight could be detected (eight water molecules per formula unit were found by thermal analysis, as shown below). We tested several different structural models in order to find the remaining two oxygen atoms. These models resulted either in very high temperature factors for the additional positions of the oxygen atoms, or unreasonably short distances between the occluded oxy-

gen atoms (shorter than 1.9 A). Therefore, this refinement led to the results given in Table 1−3, with a model containing only one position for the oxygen atoms of the occluded water molecules. In the last refinement cycle of our model, all the position parameters of the occluded atoms as well as all the isotropic displacement parameters were released. Other parameters such as the scaling factor, zero-point shift and peak parameters were released during another cycle. Evaluation of data set 2 followed a similar path and led to similar results. In the two last refinement cycles of the second data set 2, all the parameters were released. (Two refinement cycles were necessary since it is not possible to refine the profile parameters of the two profile functions simultaneously.) All the displacement parameters were treated isotropically. Using anisotropic displacement parameters for the silver cations (which led to a significant improvement in the result of the refinement of ASS[7]) did not lead to any improvement in the present case.

After isotropic refinement of all the atoms, remaining electron densities of approximately $\Delta\rho = 2.0$ $e^{-}Å^{-3}$ at (0.305, 0.014, 0.306) for the first data set and of approximately $\Delta\rho = 1.6$ $e^{-}Å^{-3}$ at (0.26, 0.26, 0.26) for the second set were detected. These positions are close to the centre of the six-membered ring of the framework. However, it was not possible to introduce an atom that could be refined at these positions. Therefore, we regard these electron densities as artefacts (e.g., Hu and Depmeier[26]).

Syntheses and Crystal Structures of Coinage Metal Thioether-Thiolato Complexes

Stephan Zeltner,[a] Svea Jelonek,[a] Joachim Sieler,[a] and Ruth-Maria Olk*[a]

Dedicated to Professor Dr. Eberhard Hoyer on the occasion of his 70th birthday

Keywords: Sulfur ligands / Copper / Silver / Gold

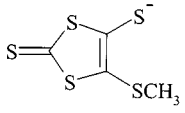
Copper(I), silver(I), and two gold(I) complexes of the type $(Ph_3P)_nM(\mathbf{L})$ [n = 1, 2, 3; **L** = 4-(methylthio)-2-thioxo-1,3-dithiole-5-thiolate ($\mathbf{L_a}$), 1,2-dicyano-1-(methylthio)ethene-2-thiolate ($\mathbf{L_b}$)] have been synthesized. The molecular structure of these complexes was determined by X-ray crystallography and shows differences in the coordinated sulfur atoms as well as in the coordination geometry of these $(Ph_3P)_nM(\mathbf{L})$ complexes. In $(Ph_3P)_2Cu(\mathbf{L})$ (**2**), the thioether thiolate ligands act as bidentate ligands, whereas in the silver and gold complexes $(Ph_3P)_3Ag(\mathbf{L})$ (**3**) and $(Ph_3P)_2Au(\mathbf{L})$ (**4**), only the thiolate sulfur is coordinated. Dissociation of one of the phosphane ligands of $(Ph_3P)_2Au(\mathbf{L_a})$ (**4a**) occurs in boiling acetone and a linear two-coordinate gold(I) center is obtained, $(Ph_3P)Au(\mathbf{L_a})$ (**5a**).

Introduction

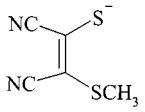
Metal complexes of 4-(methylthio)-2-thioxo-1,3-dithiole-5-thiolate ($C_3S_5^{2-}$) have been the subjects of numerous studies because some of them have been reported to exhibit conducting or superconducting properties.[1,2] The methylation of one thiolate donor atom of this delocalized dithiolate results in a thioether thiolate compound, 4-(methylthio)-2-thioxo-1,3-dithiole-5-thiolate ($\mathbf{L_a}$). The coordination ability of compounds with such sulfur donors is of interest because of the relevance to biological systems.[3] However, in marked contrast to their extensive studied transition-metal chelates,[4,5] thioether thiolato complexes with d^{10} metals are rare.

The principal difference between thiols and thioethers as ligands is that the former are more highly polarizable, but are not as effective d_π-electron acceptors as the latter.[6] Nevertheless, both kinds of sulfur atoms are soft donors and should be preferably coordinated by the soft coinage metals.[7]

We undertook the complexation of 4-(methylthio)-2-thioxo-1,3-dithiole-5-thiolate ($\mathbf{L_a}$) and 1,2-dicyano-1-(methylthio)ethene-2-thiolate ($\mathbf{L_b}$) with the d^{10} metal ions copper(I), silver(I) and gold(I) in order to examine the complexation behavior of thioether thiolate ligands. Comparison of the structures of these $(Ph_3P)_nM(\mathbf{L})$ chelates highlights differences in the coordinated donor-atom groups as well as in their coordination geometry.



$\mathbf{L_a}$



$\mathbf{L_b}$

Results and Discussion

The reaction of cesium 4-(methylthio)-2-thioxo-1,3-dithiole-5-thiolate (**1a**) and cesium 1,2-dicyano-1-(methylthio)-ethene-2-thiolate (**1b**) with the triphenylphosphane-coordinated closed-shell ions copper(I), silver(I), and gold(I) led to the coordination compounds $(Ph_3P)_2Cu(\mathbf{L})$ (**2a**, **2b**), $(Ph_3P)_3Ag(\mathbf{L})$ (**3a**, **3b**), and $(Ph_3P)_2Au(\mathbf{L})$ (**4a**, **4b**), respectively, in good yields.

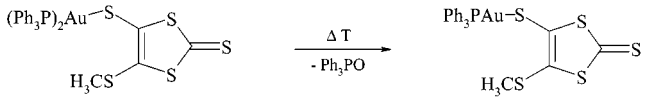
of conductivity measurements. The cumulative evidence from elemental analyses, IR, and NMR spectra establishes the composition of these compounds. Their ^{31}P NMR spectra measured in $CDCl_3$ at room temperature show only one singlet. However, from the spectrum of $(Ph_3P)_2Au(\mathbf{L_a})$ (**4a**), three nonequivalent phosphorus atoms are detectable after being allowed to stand for several weeks in chloroform. Two additional singlets are observed. These are shifted downfield relative to those of the starting complex **4a** (δ = 20.3); one was assigned to triphenylphosphane oxide (δ = 29.5) and the second at δ = 38.1 is characteristic of linearly coordinated gold(I).[8,9] Therefore it is probable that the gold complex $(Ph_3P)Au(\mathbf{L_a})$ (**5a**) is prepared from $(Ph_3P)_2Au(\mathbf{L_a})$ (**4a**). In fact, the complex **5a** can be isolated in good yields after boiling an acetone solution of the bistriphenylphosphane complex **4a** for few minutes. The trend in going from a trigonal-planar complex to a linear gold complex was not observed for the corresponding bistriphenylphosphane gold complex of 1,2-dicyano-1-(methylthio)ethene-2-thiolate (**4b**).



4a **5a**

However, from these results, the exact number of sulfur donors in the coordination sphere of the metal(I) ions remained open to investigation. Consequently, the complexes **2a**, **2b**, **3a**, **3b**, **4b**, and **5a** were further characterized by X-ray structure analysis, providing information about their sulfur-donor set. The complex $(Ph_3P)_2Cu(\mathbf{L})$ (**2**) has a distorted tetrahedral coordination geometry around the copper atom involving the two sulfur donor atoms S(1) and S(2) of $\mathbf{L_a}$ and $\mathbf{L_b}$, and two phosphorus atoms of the phosphanes. This arrangement is depicted in Figures 1 and 2, and selected interatomic distances and angles are given in Table 1.

It is notable, perhaps predictably, that the copper−sulfur (thioether) bond lengths are longer [2.4577(6) Å for **2a** and

2.3973(8) for **2b**] than those of the copper-sulfur(thiolate) [2.3223(6) Å and 2.3101(8) Å for **2a** and **2b**, respectively]. But the copper−sulfur (thiolate) bond length in **2a** is longer than the chelating distances [Cu−S: 2.237(2)] found for the complex of the non-methylated ligand with $Cu(Ph_3P)$.[10] An interesting pattern is also observed for the metallaheterocycle [−Cu−S(1)−C(1)−C(2)−S(2)−], which is distorted and folded along the sulfur−sulfur axis (**2a**: 12.7°, **2b**: 8.9°). The copper−phosphorus bond lengths and angles are typical.[11,12]

The silver compounds **3a** and **3b** were prepared by the chloride substitution reaction of chlorotris(triphenylphosphane)silver(I) with the corresponding thioether thiolate ligands. The yellowish orange complex $(Ph_3P)_3Ag(\mathbf{L_a})$ **3a** was found to incorporate solvent of crystallization (acetone). The molecular structures of complexes **3** are illustrated in Figure 3 and Figure 4, and selected bond lengths and angles are given in Table 2.

Three triphenylphosphane groups and a thioether thiolate ligand **L**, which is bonded only through the thiolate sulfur atom to silver, surround the silver ion in **3a** and **3b**. In compounds **3**, the configuration about the silver ion can be described as a distorted tetrahedron. The angles at the metal site range from 92.38(3) to 113.37(3)° and from 95.89(4) to 121.82(4)° for **3a** and **3b**, respectively. The Ag−P distances average 2.6 Å and are longer than the sum of the single-bond covalent radii (2.44 Å),[13] but are comparable with those determined for other triphenylphosphane silver(I) compounds [2.503(5) Å,[14] 2.557(6) Å,[15] and 2.616(3) Å[16]]. The observed silver−sulfur (thiolate) bond lengths of 2.5898(9) Å (**3a**) and 2.6406(12) Å (**3b**) are longer than single covalent bonds, but are appreciably shorter than the van der Waals contact (3.52 Å).[13] Chlorobis(triphenylphosphane) gold(I) reacts with the cesium thiolate salts **1** to $(Ph_3P)_2Au(\mathbf{L})$ (**4**). Figure 5 represents a view of the molecular structure of $(Ph_3P)_2Au(\mathbf{L_b})$ **4b**. Although the angles deviate somewhat from the idealized geometry of 120°, the coordination about the gold ion is essentially trigonal planar. Relevant bond lengths and angles are given in Table 3. The Au−P(2) distance of 2.3806(13) Å is considerably longer than the Au−P(1) distance of 2.3101(13) Å, and

is also longer than the Au−P distances of 2.323(4) Å and 2.339(4) Å in $(Ph_3P)_2AuCl$.[17] It is also interesting to observe that complex **4b** shows longer Au−P and Au−S distances than in the corresponding complexes with the non-methylated dithiolate ligands $[(Ph_3PAu)_2S_2C_2(CN)_2]$[18] and $(Bu_4N)[Ph_3PAu(S_2C_2(CN)_2]$.[19] In boiling acetone, one of the phosphane ligands dissociates from $(Ph_3P)_2Au(\mathbf{L_a})$ (**4a**), whereas $(Ph_3P)_2Au(\mathbf{L_b})$ (**4b**) remains unchanged. The structure of the resulting complex $(Ph_3P)Au(\mathbf{L_a})$ (**5a**) is shown in Figure 6, and selected bond lengths and angles are given in Table 3.

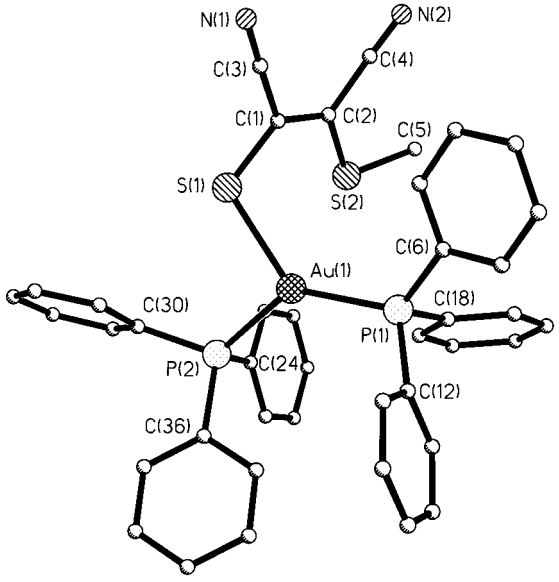

Figure 5. Molecule structure of $(Ph_3P)_2Au(\mathbf{L_b})$ **4b**, H atoms are omitted

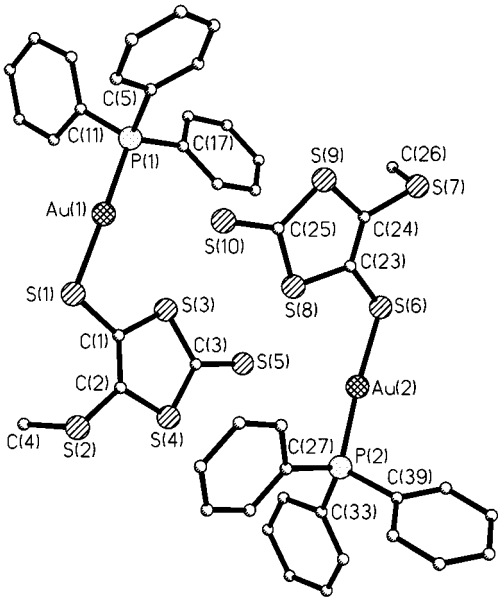

Figure 6. Molecule structure of $(Ph_3P)Au(\mathbf{L_a})$ **5a**, H atoms are omitted

Two crystallographically independent molecules of $(Ph_3P)Au(\mathbf{L_a})$ (**5a**) are present in the asymmetric unit. Each gold atom is bis-coordinated in a linear fashion to the thiolate sulfur of $\mathbf{L_a}$, and the phosphorus atom of the triphenylphosphane. The Au−S distances [2.3078(13) and 2.3144(14) Å] are slightly shorter than those found for triphenylphosphane gold (I) complexes with the non-methylated C_3S_5 ligand, such as $(Ph_3PAu)_2C_3S_5$ [2.3474(11), 2.3435(12) Å] and $(Bu_4N)[Ph_3PAu(C_3S_5)]$ [2.476(3), 2.405(3) and 2.413(3),

2.483(3) Å].[20] However, the gold−sulfur (thiolate) bond length in **5a** is very similar to those found for the bis-chelate of the non-methylated C_3S_5 with gold(III) (Bu_4N)-$[Au(C_3S_5)_2]$ [2.311 to 2.327 Å].[21,22]

The Au−P distances [2.2592(13) and 2.2685(13) Å] in **5a** are typical of two-coordinate gold(I) compounds, as are the P−Au−S angles of 177.76(5)° and 174.54(5)°.[8,9,23] This slight deviation from the linearity is common for gold(I) structures.[24]

The present work has shown that the thioether thiolate compounds 4-(methylthio)-2-thioxo-1,3-dithiole-5-thiolate (**L_a**) and 1,2-dicyano-1-(methylthio)ethene-2-thiolate (**L_b**) form stable complexes with closed-shell d^{10} ions. However, the molecular structure of these complexes is not predictable. We believe that the restricted bite angle of the sulfur donor atoms within **L** and their different donor abilities play an important role in determining the final structures of the metal(I) complexes. Additionally, the strong phosphane donors and their size are of relevance in the complexation of coinage metals.[8,12]

Experimental Section

General Remarks: All chemicals and solvents used in the synthesis were of reagent grade and were used without further purification. The metal salts $(Ph_3P)_3CuCl$, $(Ph_3P)_3AgCl$, and $(Ph_3P)_2AuCl$ were prepared by published methods.[17,25,26] − IR: Perkin−Elmer 2000 FT. − UV/Vis: Shimadzu 160A. − NMR: Varian Gemini 300 (300.075 MHz, 75.462 MHz and 121.470 MHz, for ^1H, ^{13}C and ^{31}P, respectively). For ^1H and ^{13}C NMR spectra, $CDCl_3$ was used as solvent with TMS as internal standard. For ^{31}P NMR spectra, $CDCl_3$ was used as solvent with H_3PO_4 (85%) as external standard, δ_P= 82.43. − Melting points: Boetius point apparatus, uncorrected. − Elemental analyses: Heraeus CHN rapid analyzer.

Cesium 4-(Methylthio)-2-thioxo-1,3-dithiole-5-thiolate (1a) and Cesium 1,2-Dicyano-1-(methylthio)ethene-2-thiolate (1b): To a stirred chloroform solution (50 mL) of 4-(benzoylthio)-5-(methylthio)-2-thioxo-1,3-dithiole[27] (10 mmol, 3.16 g) (for **1a**) or 1-(benzoylthio)-1,2-dicyano-2-(methylthio)ethene[28] (2.60 g) (for **1b**) was added cesium hydroxide hydrate (10 mmol, 1.70 g) in methanol (10 mL). After about 1 min, the cesium thiolates started to separate. Diethyl ether (100 mL) was added to precipitate the product completely. This cesium salt was recovered by filtration, washed with diethyl ether and air dried.

1a: Orange crystals (1.85 g, 54%), m.p. > 250 °C. − IR (KBr): $\tilde{\nu}$ = 2978 and 2911 cm^{-1} (CH), 1416 (CH, C=C) 1310 (CH), 1060 and 1030 (C=S). − ^1H NMR (CD_3OD): δ = 2.36 (s, 3 H, $-CH_3$). − ^{13}C NMR (CD_3OD): δ = 18.6 (-CH_3), 121.0 (C-4), 163.6 (C-5), 214.9 (C=S). − $C_4H_3CsS_5 \cdot 0.5\ H_2O$ (353.30): calcd. C 13.60, H 1.14, S 45.38; found C 13.99, H 1.20, S 45.67.

1b: Yellow crystals (2.70 g, 90%), m.p. > 250 °C. − IR (KBr): $\tilde{\nu}$ = 2181 (CN) cm^{-1}, 1457, 1421 (CH, C=C), 1159, 1117, 1050, 969, 858, 520, and 503 (CH). − ^1H NMR (CD_3OD): δ = 2.43 (s, 3 H, $-CH_3$). − ^{13}C NMR (CD_3OD): δ = 16.0 ($-CH_3$), 113.7 (C-1), 117.8 (CN), 119.5 (CN), 138.5 (C-2). − $C_5H_3N_2CsS_2 \cdot 0.5\ H_2O$ (297.14): calcd. C 20.21, H 1.36, N 9.43, S 21.58; found C 20.03, H 1.03, N 9.06, S 21.58.

Complexes $(Ph_3P)_2Cu(L)$, $(Ph_3P)_3Ag(L)$, and $(Ph_3P)_2Au(L)$ (2) − (4): Solid $(Ph_3P)_nMCl$ (0.5 mmol, M = Cu, *n* = 3: 440 mg; M = Ag, *n* = 3: 465 mg; M = Au, *n* = 2: 380 mg) was added to a solution of CsL (0.5 mmol, **1a**: 176 mg; **1b**: 148 mg) in acetone (50 mL). After being stirred for 20 min., the yellow−orange reaction mixture was filtered. The volume of this acetone solution was reduced to 20 mL, and cooled to −5 °C overnight, yielding a crystalline solid, which was filtered off, washed with 2-propanol and air dried.

Cu Complex $(Ph_3P)_2Cu(L_a)$ (2a): Tawny crystals (285 mg, 71%), m.p. 182−184 °C dec. − IR (KBr): $\tilde{\nu}$ = 3050, 3002, 2917, 1184, 1158, 1095, 1005, 961, 881, 741, and 694 cm^{-1} (CH), 1480, 1434, and 1424 (CH, C=C), 1307 (CH), 1054 and 1034 (C=S). − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 432 nm (3.72), 355 (3.91), 264 (4.43), 232 (4.47). − ^1H NMR ($CDCl_3$): δ = 1.80 (s, 3 H, $-CH_3$), 7.23−7.39 (m, 30 H, -P−C_6H_5). − ^{13}C NMR ($CDCl_3$): δ = 23.8 (-CH_3), 118.6 (C-4), 165.1 (C-5), 214.1 (C=S), 129.4 ($^3J_{C,P}$ = 8.7 Hz), 130.4, 134.0 ($^1J_{C,P}$ = 24.6 Hz), 134.2 ($^2J_{C,P}$ = 15.0 Hz). − ^{31}P NMR ($CDCl_3$): δ = 1.3. − $C_{40}H_{33}CuP_2S_5$ (799.44): calcd. C 60.10, H 4.16, S 20.05; found C 60.21, H 4.05, S 20.98.

Cu Complex $(Ph_3P)_2Cu(L_b)$ (2b): Orange crystals (220 mg, 60%), m.p. 202−205 °C dec. − IR (KBr): $\tilde{\nu}$ = 3470, 3054, 2917, 1183, 1156, 1125, 1095, 1027, 999, 751, 743, 707, 695, 527, 518, 503, and 492 cm^{-1} (CH), 2190 (CN), 1479, 1456, and 1434 (CH, C=C). − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 397 nm (3.52), 238 (4.32). − ^1H NMR ($CDCl_3$): δ = 1.87 (s, 3 H, $-CH_3$), 7.25−7.41 (m, 30 H, -P−C_6H_5). − ^{13}C NMR ($CDCl_3$): δ = 20.7 (-CH_3), 105.7 (C-1), 116.5 and 116.8 (CN), 147.9 (C-2), 128.8 ($^3J_{C,P}$ = 8.3 Hz), 130.1, 132.6 ($^1J_{C,P}$ = 28.4 Hz), 133.5 ($^2J_{C,P}$ = 13.7 Hz). − ^{31}P NMR ($CDCl_3$): δ = 0.4. − $C_{41}H_{33}CuN_2P_2S_2$ (743.35): calcd. C 66.25, H 4.47, N 3.77, S 8.63; found C 65.86, H 4.48, N 3.65, S 8.24.

Ag Complex $(Ph_3P)_3Ag(L_a)$ × Acetone (3a): Yellowish orange crystals (443 mg, 77%), m.p. 149−151 °C dec. − IR (KBr): $\tilde{\nu}$ = 3052, 3002, 2913, 1184, 1157, 1093, 997, 866, 743, and 694 cm^{-1} (CH), 1478, 1434, and 1414 (CH, C=C), 1307 (CH), 1056 and 1038 (C=S). − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 416 nm (3.78), 306 (3.92), 257 (4.38), 232 (4.44). − ^1H NMR ($CDCl_3$): δ = 1.91 (s, 3 H, $-CH_3$), 2.18 (s, 6 H, -$(CH_3)_2CO$), 7.30−7.41 (m, 45 H, -P−C_6H_5). − ^{13}C NMR ($CDCl_3$): δ = 21.1 (-CH_3), 31.6 ($CH_3)_2CO$), 118.6 (C-4), 164.3 (C-5), 207.6 ($(CH_3)_2CO$), 212.6 (C=S), 128.8 ($^3J_{C,P}$ = 8.4 Hz), 129.7, 133.7 ($^2J_{C,P}$ = 17.3 Hz), 134.2 ($^1J_{C,P}$ = 11.6 Hz). − ^{31}P NMR ($CDCl_3$): δ = 3.7. − $C_{61}H_{54}AgOP_3S_5$ (1164.12): calcd. X-ray Crystallographic Study: Crystals of $(Ph_3P)_2Cu(\mathbf{L})$ (**2a**, **2b**), $(Ph_3P)_3Ag(\mathbf{L})$ (**3a**, **3b**), $(Ph_3P)_2Au(\mathbf{L_b})$ (**4b**), and $(Ph_3P)Au(\mathbf{L_a})$ (**5a**) were formed by the slow evaporation of their solutions in acetone. Crystal data and crystallographic experimental data for the complexes **2a**, **2b**, **3a**, **3b**, **4b**, and **5a** are listed in Table 4. Data were collected on a Stoe STADI4 diffractometer (**2a**, **3a**, **4b**) and on a Bruker AXS SMART-CCD (**2b**, **3b**, **5a**), using Mo-K_α radiation.

The structures were solved by direct methods and the heavy-atom procedures were used (SHELXS-86[29]). An empirical absorption correction for **2a**, **3a**, **4b** (ψ-scan, 10 reflections) and **2b**, **3b**, and **5a** (SADABS[30]) was applied. Anisotropic displacement parameters for all non-hydrogen atoms were used. For **2a**, **2b**, **3a**, **3b**, and **4b** all hydrogen atoms could be localized unambiguously with a difference Fourier map. These hydrogen atoms were refined isotropically. The hydrogen atoms of the phenyl group of **5a** could not be localized completely, therefore these hydrogen atoms were refined with the "-1.2-option" of the riding modus. Molecular-numbering schemes are shown in Figure 1 [$(Ph_3P)_2Cu(L_a)$ **2a**], Figure 2 [$(Ph_3P)_2Cu(L_b)$ **2b**], Figure 3 [$(Ph_3P)_3Ag(L_a)$ × acetone, **3a**], Figure 4 [$(Ph_3P)_3Ag(L_b)$ **3b**], Figure 5 [$(Ph_3P)_2Au(L_b)$ **4b**], and Figure 6 [$(Ph_3P)Au(L_a)$ **5a**]. Selected bond length and angles are located in Tables 1, 2, and 3.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-147226 (**2a**), CCDC-147222 (**2b**), CCDC-147225 (**3a**), CCDC-147223 (**3b**), CCDC-147227 (**4b**), CCDC-147224 (**5a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(1223)336−033; E-mail: deposit@ccdc.cam.ac.uk].

Selective Recognition of Copper(II) by a Water-Soluble, Emitter-Receptor Conjugate Containing a Ruthenium Chromophore, a Lysine Bridge, and a Cyclen Unit

Bernd Geißer,[a] Burkhard König,[b] and Ralf Alsfasser*[a]

Dedicated to Prof. Dr. Dieter Sellmann on the occasion of his 60th birthday

Keywords: Bioinorganic chemistry / Amino acids / Luminescence / Macrocyclic ligands / Copper / Ruthenium / Molecular recognition

The amino acid derivative [H-Lys{Ru(bipy)$_2$m}-cyclenH$_2$](PF$_6$)$_5$ (**7**; Lys = lysine, bipy = 2,2′-bipyridyl, m = 4-carbonyl-4′-methyl-2,2′-bipyridyl, cyclen = 1,4,7,10-tetraazacyclododecane) has been synthesized. A modular approach was taken which involves only standard amide-coupling methods well-known from peptide synthesis. Compound **7** is readily soluble in water. It contains a luminescent ruthenium chromophore and a cyclen ligand which serves as a binding site for metal ions. The emission of **7** is pH-independent but efficiently quenched by Cu^{2+} ions in a pH range of 6–7. Copper(II) binding is reversible upon protonation of the ligand at pH values below 6. In contrast, no significant spectral changes are observed with Zn^{2+} and Ni^{2+}, respectively. Thus, **7** selectively recognizes copper(II) in aqueous solution under slightly acidic to neutral conditions. Unfortunately, applications at higher pH values are limited by metal-promoted hydrolysis of **7** under mildly basic conditions.

Introduction

Amino acids with nonnatural functional groups are versatile building blocks for the design of new peptides and synthetic proteins.[1−5] A particularly well-developed field in this research area is the incorporation of organic,[6,7] and inorganic[8−11] chromophores in biologically relevant molecules. However, chromophore-labeled peptides are not only useful as mechanistic probes of the reactivity and physical properties of biomolecules. Interesting applications as chemosensors for zinc(II) ions have been reported by the groups of Berg[12] and Imperiali.[13−15] Sensors generally consist of a signaling unit, a spacer, and a recognition unit.[16] Amino acid building blocks are perfectly suited for such a multicomponent design. They can easily be processed by standard peptide coupling methods and thereby offer excellent perspectives for the combinatorial optimization of each component.

Polypyridyl ruthenium-modified amino acids are well established as useful chromophores in photoredoxactive proteins,[8−11] peptides,[17,18] and chromophore-donor-acceptor triads.[19,20] Long lifetimes, a large Stokes shift of the emission spectra, and solubility in water are the particular benefits of [Ru(bipy)]$_3$ derivatives in luminescence spectroscopic investigations. We have recently studied the pH-dependent luminescence properties of ruthenium-modified amino acids in much detail.[21,22] Our results show that [Ru(bipy)$_2$m]$^{2+}$-substituted lysine (**8**; bipy = 2,2′-bipyridyl; m = 4-carbonyl-4′-methyl-2,2′-bipyridyl) is an ideal chromophore-spacer unit for the synthesis of pH-independent emitter-receptor conjugates. The butylamine side chain is long enough to prevent electronic coupling between the site of protonation and the chromophore. As a consequence, the [Ru(bipy)$_2$m]$^{2+}$-based emission spectrum is independent of the H^+ concentration above pH = 2. On the other hand, luminescence quenching is readily observed upon binding of a [Cu(phen)]$^{2+}$ fragment to the amino acid group.[23]

Several studies have described metal-ion-induced luminescence quenching in [Ru(bipy)$_3$]$^{2+}$ conjugates with a cyclam (cyclam = 1,4,8,11-tetraazacyclotetradecane) receptor.[24−27] However, cyclam traps divalent first row transition metal ions irreversibly. To the best of our knowledge, only one report exists on the use of a [Ru(bipy)$_3$]$^{2+}$ unit in a water soluble emitter-receptor conjugate which reversibly binds to copper(II) and nickel(II) ions.[28] The receptor in this study was dioxo-2,3,2-tet ligand (2,3,2-tet = 1,9-diamino-3,7-diazanonane-4,6-dione). It has also been reported that the binding of metal ions by cyclam derivatives can be tuned to be reversible by the introduction of two weakly coordinating amide functions in the macrocycle.[29] Another possibility should be the appropriate tuning of the ring size. Cyclen (cyclen = 1,4,7,10-tetraazacyclododecane) is too small to accommodate divalent metal ions such as Ni^{2+}, Cu^{2+}, or Zn^{2+} within the ring plane.[30,31] Conjugates of cyclen with naphthyl[32,33] and dansyl[34] chromophores have been synthesized as receptors for divalent metal ions

such as Zn^{2+} and Cd^{2+}. Its zinc(II) complexes have also been described as recognition units for nucleobases[35,36] and phenothiazine.[37]

Here we present the synthesis of the copper-selective emitter-receptor conjugate **7**, which consists of a tris(2,2′-bipyridyl)ruthenium(II) chromophore, an amide-substituted cyclen ligand as the metal ion receptor, and a lysine spacer. Compound **7** is water soluble, does not respond to pH changes and selectively binds copper(II) ions at pH 6−7 in the presence of zinc(II) and nickel(II) ions, respectively. The paper discusses advantages such as solubility, selectivity and reversibility, and severe limitations due to the relatively low stability of **7** at higher pH values in the presence of metal ions.

Results

Synthesis of 7 and its Reaction with $Zn(ClO_4)_2 \cdot 6\ H_2O$

Our preparation of **7** involves only well-known, straightforward methods developed for peptide synthesis. Details are shown in Scheme 1. The first step is the dicyclohexylcarbodiimide (DCC)/*N*-hydroxybenzotriazole (HOBt) supported coupling of orthogonally diprotected N_α-*tert*-butoxycarbonyl-N_ε-benzoxycarbonyl-lysine [Boc-Lys(*Z*)-OH, **1**] with 1,4,7-tri-*tert*-butoxycarbonylcyclen (**2**). This reaction produces the tertiary amide Boc-Lys(*Z*)-Boc_3Cyclen (**3**) with yields of over 90% after purification by reversed phase HPLC. Catalytic hydrogenation of **3** results in selective deprotection of its ε-amino function. The resulting free amine **4** is then reacted with the succinimide ester [Ru(bipy)$_2$(m-OSu)]$(PF_6)_2$ (**5**;[17] m = 4-carbonyl-4′-methyl-2,2′-bipyridyl; HOSu = *N*-hydroxysuccinimide). Finally, the coupling product **6** is treated with HCl in dioxane in order to remove the four *tert*-butoxycarbonyl protecting groups. The resulting complex **7** is conveniently purified by cation-exchange chromatography and obtained in its triprotonated form as the pentakis(hexafluorophosphate) salt. Reasonably good overall yields of ca. 50% with respect to Boc-Lys(*Z*)-OH (**1**) are obtained.

Only the first coupling product Boc-Lys(*Z*)-$(Boc)_3$Cyclen (**3**) and the final product [H-Lys{Ru(bipy)$_2$m}-cyclenH_2]$(PF_6)_5$ (**7**) were isolated and purified by HPLC (**3**), and ion-exchange (**7**) column chromatography. All other compounds, including [Ru(bipy)$_2$(m-OSu)]$(PF_6)_2$, were conveniently generated in situ or used as crude products without purification. Characterization was mainly achieved by FD- and FAB-mass spectrometry as well as by ^{1}H NMR spectroscopy.

We have studied the reaction of **7** with $Zn(ClO_4)_2 \cdot 6H_2O$ in methanol solution containing three equivalents of sodium methoxide as a base. However, the tertiary amide connecting the cyclen unit to the amino acid moiety of **7** is not stable under the reaction conditions, as shown in Scheme 2. The bond is cleaved and the ruthenium-modified amino acid [H-Lys{Ru(bipy)$_2$m}(OH)]$(PF_6)_3$ (**8**) can be isolated by ion-exchange chromatography with yields of ca. 70%. This finding has prompted us to study the pH-dependent luminescence properties of **7** alone and in the presence of different metal ions in order to learn more about the stability of the compound in solution.

Luminescence Titrations

Luminescence pH Titrations of 7 and 7-$M(ClO_4)_2$ (M = Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+})

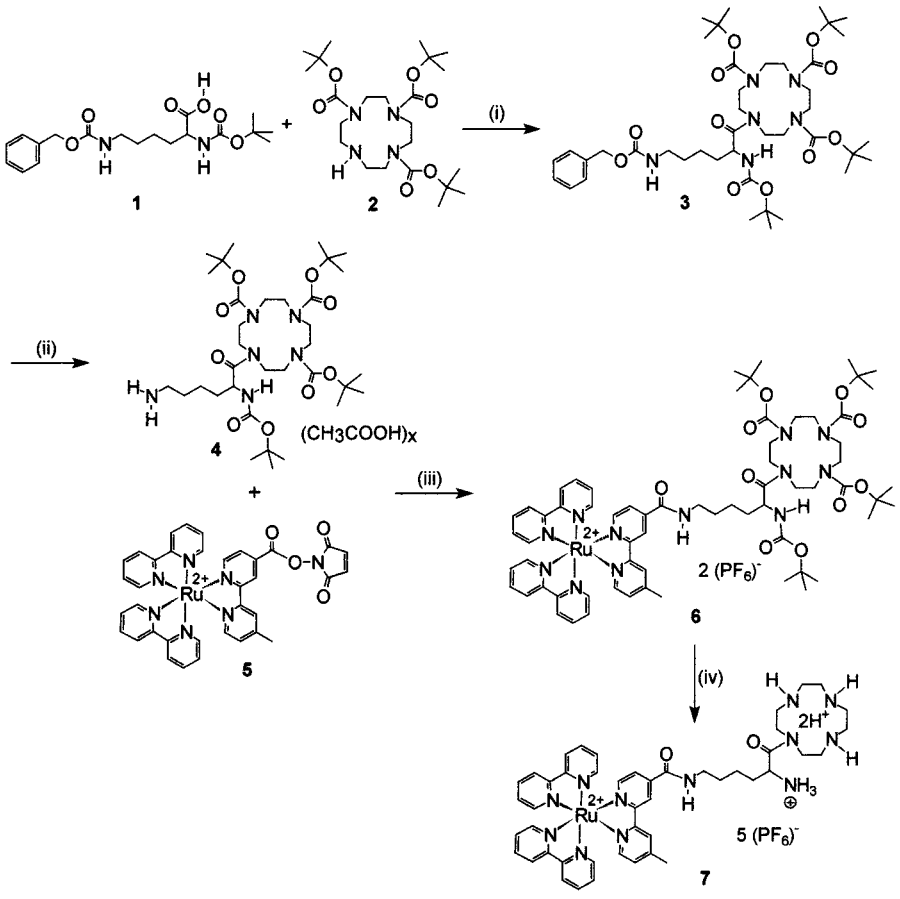
Luminescence spectra as a function of pH were collected for solutions containing **7**, and stoichiometric amounts of **7** and a perchlorate salt $M(ClO_4)_2$ (M = Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}). Plots of the maximum emission intensities versus pH for **7**, and **7**-$M(ClO_4)_2$ (M = Ni^{2+}, Cu^{2+}), are shown in Figure 1. The emission spectra of the free ligand **7** are almost invariant over the whole pH range. Only a shallow minimum is observed at about pH 9.5 which is insignificant within the experimental error. Interestingly, a more pronounced minimum at the same pH value is observed in the presence of nickel(II). However, the intensity change is still rather small (less than 20%). Manganese(II), iron(II), cobalt(II), and zinc(II) ions did not result in pH-dependent emission quenching. These curves are not shown since they do not differ significantly from that of the free complex **7**.

This is dramatically different for copper(II), which efficiently quenches the ruthenium-based emission at pH 6.8. The pH titration curve shows a distinct minimum at this value. Above pH 7 the emission intensities increase to approach their full maximum at about pH 9. This is due to the rapid cleavage of the tertiary amide bond at higher pH values as is evident from back titration of the basic solution with hydrochloric acid. The luminescence intensity remains at its maximum when the pH is decreased from 12 to 6, as expected for the emission properties of [H-Lys{Ru(bipy)$_2$m}(OH)]$^{3+}$ (**8**).[21] Figure 2 shows the pseudo first order kinetics of the cleavage reaction at pH 6.8 [k_{obs} = (1.96 ± 0.06) × 10^{-4} min^{-1}] and pH 9 [k_{obs} = (1.035 ± 0.009) × 10^{-2} min^{-1}].

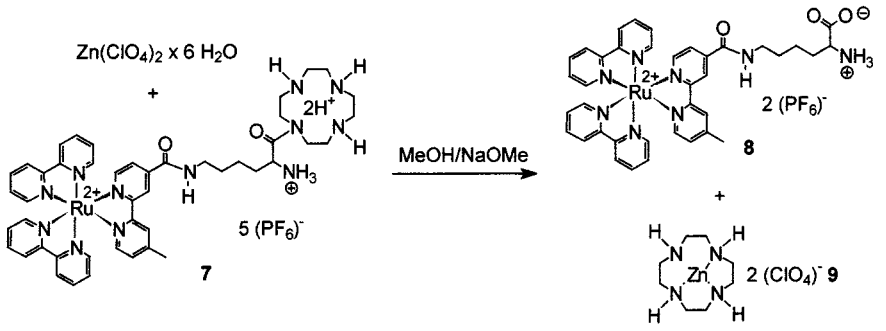
Binding of copper(II) by **7** is reversible upon protonation of the macrocycle. This is clearly demonstrated by Figure 3. Starting at pH 2 the emission intensity decreases to reach its minimum at pH 6.8. Back titration from pH 7 to pH 2 results in complete recovery of the original maximum. The cycle is almost reversible as is shown by its repetition. Small deviations are due to the slight decomposition of **7**-Cu-$(ClO_4)_2$ at about pH 7.

Titration of 7 with $M(ClO_4)_2 \cdot 6H_2O$ (M = Ni^{2+}, Cu^{2+}, Zn^{2+}) at Neutral pH

Buffered aqueous solutions (pH 6.8) of the ruthenium(II) complex **7** were titrated with aqueous solutions of nickel(II), copper(II), and zinc(II) perchlorate. The titration curves were followed by emission spectroscopy. Figure 4a contains plots of the maximum intensities as a function of the number of metal diperchlorate equivalents added. The complete spectra obtained at different $Cu(ClO_4)_2$ concentrations are shown in Figure 4b. It is clear from the titration curves that only addition of copper(II) results in a signific-



Scheme 1. Synthesis of the $[Ru(bipy)_2m]^{2+}$ labeled cyclen ligand **7**; (i) DCC, HOBt, NEt_3, CH_2Cl_2, 4 °C; (ii) H_2, Pd/C, CH_3COOH, MeOH, 40 °C; (iii) NEt_3, CH_3CN; (iv) HCl, dioxane



Scheme 2. Reaction of **7** with $Zn(CF_3SO_3)_2$

ant quenching of the ruthenium-based emission. The formation of a 1:1 complex is evident both from the sharp kink in the titration curve, as well as from the Jobs plot shown in Figure 5.[39] The observed deviations from the expected values are mainly due to experimental errors caused by the low metal ion concentrations (10^{-5} M). From several repetitions we estimate the accuracy of our data to be ±0.5 intensity units for the emission spectra, ±0.25 for $x(Cu^{2+})\cdot\Delta I_{Em}$ (Jobs Plot), and ±5% for the equivalents of copper(II) added in the titration experiments. Note that the latter error contains a contribution due to the ruthenium complex concentration. Corresponding error bars are added to both Figure 4b and Figure 5. Addition of nickel(II) results in a slight decrease of the emission intensity which does not reach saturation even in the presence of a more than threefold excess of the perchlorate salt. Finally, zinc(II) does not change the emission properties of the chromophore.

We have investigated the selectivity of metal binding processes involving the cyclen receptor by addition of one equivalent of copper(II) perchlorate to buffered solutions (pH 6.8) containing **7** and a 10-fold excess of zinc(II) and nickel(II) perchlorate. In both cases the emission is quenched equally well as in the absence of competing cations. Copper(II) ions obviously bind much more strongly to the macrocyclic ligand than either nickel(II) or zinc(II) ions.

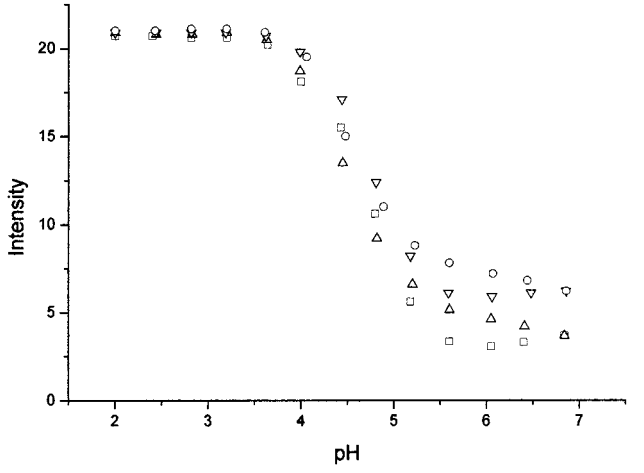

Figure 3. Luminescence pH titration of **7** in the presence of one equivalent of $Cu(ClO_4)_2 \cdot 6H_2O$; 1st cycle from pH 2 to pH 7 (□), then back to pH 2 (Δ); 2nd cycle from pH 2 to pH 7 (▽), then back to pH 2 (O)

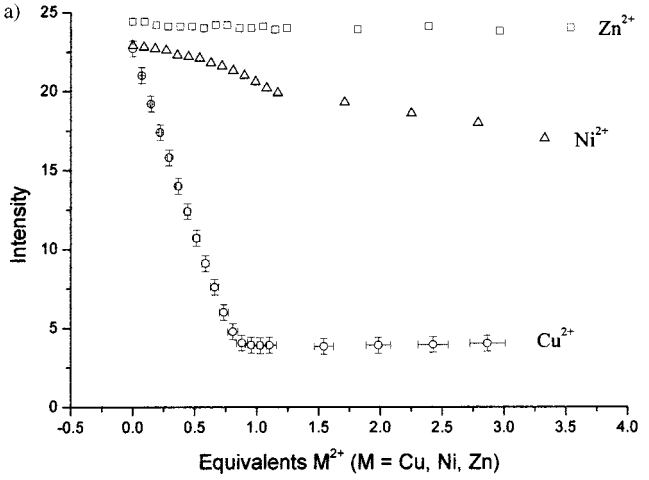

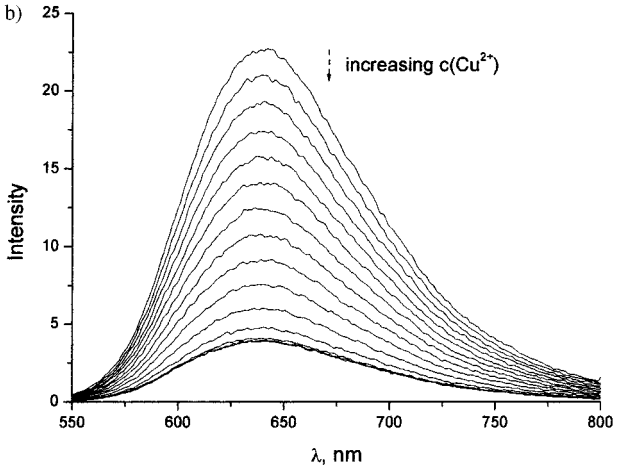

Figure 4. a) Emission titration curves for the reactions of **7** with $M(ClO_4)_2 \cdot 6H_2O$ (M = Ni, Δ; Cu, O; Zn, □) at pH 6.8 (maximum intensities are given with respect to the free ligand at pH 2); b) uncorrected luminescence spectra obtained during the titration of **7** with $Cu(ClO_4)_2 \cdot 6H_2O$

Discussion

The strategy described in Scheme 1 provides a facile route to chromophore-labeled polyamine ligands. Starting from a commercially available amino acid derivative only standard amide coupling methods are involved. We think that this scheme will be generally useful for the synthesis of related compounds with a variety of different chromophores and recognition units. However, a major drawback of the key compound **7** described in this paper is the insufficient stability of its tertiary amide function which couples the amino acid to the cyclen ligand. This amide bond is readily cleaved in the presence of metal ions even at neutral pH. The lability of tertiary amides with respect to transition metal-promoted solvolysis reactions is well-known in the literature. Our rate constant observed at pH 6.8 compares well with that reported by Sayre et al. for the copper-catalyzed hydrolysis of picolinylsarcosine.[40]

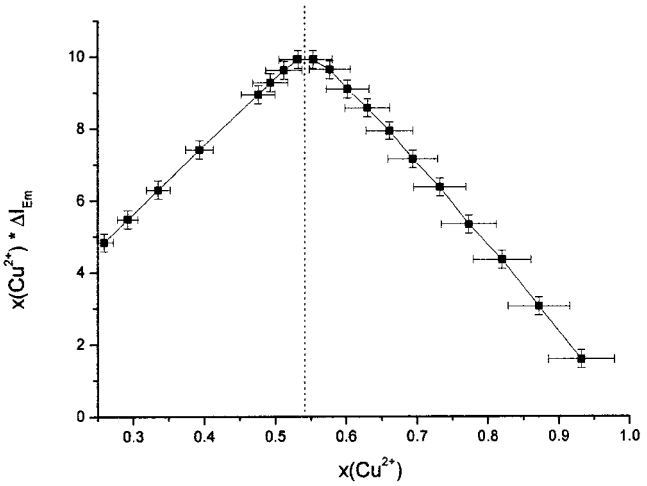

Figure 5. Plot of $x(Cu^{2+})\cdot\Delta I_{Em}$ vs. $x(Cu^{2+})$ [Jobs plot; $x(Cu^{2+})$ = mol fraction of Cu^{2+} in solution; $\Delta I_{Em} = I_{0Em} - I_{xEm}$, with I_{0Em} = emission intensity of **7** without Cu^{2+}, and I_{xEm} = emission intensity after addition of $x(Cu^{2+})$] for the titration of **7** with $Cu(ClO_4)_2\cdot 6H_2O$; a value of x = ca. 0.5 for the intercept of the two straight lines indicates a 1:1 stoichiometry of the complex formed

It is somewhat surprising that amide bond cleavage in **7**-$Cu(ClO_4)_2$ occurs at neutral pH. A similar tertiary amide linkage has been used to connect a zinc cyclen complex to a phenothiazine unit and this compound has been successfully applied in riboflavin recognition studies at pH 7.4.[37] At this time, we cannot offer a proven explanation for the instability of **7**. We suggest that the α-amino group of the lysine spacer may participate in metal ion binding and thereby cause a steric strain at the amide function. In any case, it will certainly be advantageous for our approach to use secondary rather than tertiary amides as coupling functions in future.

On the other hand, the presence of the tertiary amide group is probably beneficial for the metal ion recognition properties of **7**. The poorly electron donating amide is part of the macrocyclic ring and decreases the donor strength of the cyclen unit. Fabbrizzi et al. have demonstrated that neither selectivity nor reversibility can be achieved with a receptor ligand if its binding constants for different metal ions are too high. The lower stability of dioxocyclam complexes compared to cyclam complexes is a prerequisite for the design of copper-selective recognition units.[29] In our case, a second effect reduces the binding constants for metal coordination to the receptor. The cyclen ring is too small to accommodate nickel(II), copper(II), or zinc(II) ions within the ring plane.[30,31] Thus, its stabilizing macrocyclic effect is lower than that of cyclam.

Both features, the reduced electron donor properties and the small ring size, are important for the preference of our cyclen receptor unit for copper(II) over both nickel(II) and zinc(II) ions. As we have mentioned above, the other important prerequisite for an ion-selective recognition unit is the reversibility of the binding process.[29] Compound **7** satisfies both requirements, selectivity and reversibility, as is shown by the complexation-decomplexation cycles shown in Figure 4.

Finally, the properties of the signaling unit are of crucial importance for the performance of a metal-ion-selective emitter-receptor conjugate. Ruthenium chromophores are readily soluble in water which is certainly an advantage over organic compounds.[24] However, their luminescence signals are not as strong as those of, for example, anthracene derivatives.[31−45] Though this may cause some limitations regarding the detection limit, quenching by copper(II) ions is highly efficient in our system providing a sufficiently large effect for measurements at submicromolar concentration levels. Furthermore, the emission spectrum of **7** responds only to the addition of copper(II) ions. Other copper-selective emitter-receptor conjugates exhibit efficient emission quenching also by protons and/or nickel(II) ions in the absence of Cu^{2+}.[24,28,29,46] Most relevant for our study, it has been reported in the literature that the ruthenium-based emission of $[Ru(bipy)_3]^{2+}$-labeled cyclam ligands is readily quenched by nickel(II) ions.[24−28] We observe only a very small effect of Ni^{2+} on the luminescence of **6** at neutral pH. The results of Fabrizzi et al. indicate that Ni^{2+} may bind to the receptor at higher pH values than Cu^{2+}.[29,46] Unfortunately, we cannot access this basic pH range due to the instability of compound **7** in the presence of metal ions. It is therefore not clear whether nickel(II) does not efficiently quench the emission of the signaling unit or if the binding constant is simply not high enough in the accessible pH range. The absence of a signal induced by protonation of the macrocycle is an intended feature of our design. We have shown earlier that the lysine side chain is long enough to efficiently prevent inductive effects of protonated amine functions which modulate the photophysical properties of a ruthenium complex.[21] Consequently, the emission properties of **7** are pH independent in the absence of metal ions.

Conclusions

In our study we have used a commercially available amino acid for the synthesis of the metal ion selective emitter-receptor conjugate **7**. Desirable properties of this compound are its solubility in water, its high selectivity for copper(II) ions at almost neutral pH values between 6 and 7, and the reversibility of the recognition process upon protonation of the cyclen receptor unit. A serious drawback of **7** is its chemical lability in the presence of metal ions under mild basic conditions. This obstacle can most likely be overcome by the use of receptor ligands which bear primary amines as the coupling functions. Current research in our laboratories focuses on this aspect.

Experimental Section

Materials and Methods: The synthesis of $(Boc)_3$cyclen (**2**) has been described elsewhere.[47] $[Ru(bipy)_2(m\text{-}OH)]$ (m-OH = 4-carbonly-4′-methyl-2,2′-bipyridine) was prepared according to a published procedure by Erickson et al.[17] The synthesis of $[Ru(bipy)_2(m\text{-}OSu)](PF_6)_2$ (m-OSu = 4-carboxysuccinimidoester-4′-methyl-2,2′-bipyridine) described in the same report[17] was slightly modified.

$RuCl_3$ was a donation from Degussa. Absolute and reagent grade solvents were obtained from Fluka, NMR solvents from Aldrich and all other chemicals from Fluka. Water for preparations was demineralized. All reactions were carried out under argon.
Spectra were recorded with the following instruments: UV/Vis: Shimadzu UV-2101PC. − IR (KBr pellets): Mattson Polaris FT IR. − ^{1}H NMR: Bruker Avance DPX 300. All chemical shifts are referenced to residual solvent signals as internal standards previously referenced to TMS, with high-frequency shifts recorded as positive. − Elemental analysis: Carlo Erba EA 1106. − FAB: Micromass ZabSpec mass spectrometer. − Luminescence Spectra: Emission titration curves were followed by uncorrected luminescence spectra obtained with a Perkin−Elmer LS 50B spectrophotometer (λ_{exc} = 450 nm; λ_{obs} = 550−800 nm).

Boc-Lys(*Z*)-(Boc)$_3$cyclen (3): Boc-Lys(*Z*)-OH (**1**; 0.45 g, 1.18 mmol), (Boc)$_3$cyclen (**2**; 0.56 g, 1.18 mmol), HOBt (0.17 g, 1.26 mmol), and triethylamine (0.34 mL, 2.40 mmol) were dissolved in 50 mL of dichloromethane. The solution was cooled in an ice/water bath to 4 °C and dicyclohexylcarbodiimide (0.42 g, 2.02 mmol) was added with stirring. A suspension formed which was allowed to warm to room temperature overnight. The solid dicyclohexylurea was removed by filtration and the filtrate subsequently washed with 2 × 20 mL of 0.50 M $NaHCO_3$, 2 × 20 mL 0.05 M of citric acid, 25 mL of saturated NaCl, and 15 mL of water. The organic layer was dried over $MgSO_4$, filtered and evaporated to dryness. Purification was achieved by semipreparative isocratic reversed-phase HPLC (Kontron HPLC Pump 422) on a C18 ODS column (Grom-Sil 80 ODS-2 2FE 5µ, 250 × 20 mm) with acetonitrile as the eluent (7 mL/min.). The product eluted as the second fraction and was obtained as a colorless solid after removal of the solvent and drying under vacuum. Yield: 0.90 g (1.07 mmol, 91%). − FD-MS (CH_2Cl_2): *m*/*z* = 836 [M^+]. − ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 1.65 (m, 6 H, $^{\beta,\gamma,\delta}CH_2$), 2.58 (s, 3 H, m4′-$CH_3$), 3.30 (m, 16 H, 8 × cyclen-CH_2, $^{\varepsilon}CH_2$), 4.12 (m, 2 H, CH_2Ph), 4.39 (m, 1 H, $^{\alpha}CH$) 7.24 (m, 5 H, Ph).

Boc-Lys-(Boc)$_3$cyclen·CH_3COOH (4): Boc-Lys(*Z*)-(Boc$_3$)cyclen (0.90 mg, 1.07 mmol) was dissolved in 20 mL of methanol. Catalytic amounts of Pd/C and a 1.1-fold excess of acetic acid were added. A slow stream of H_2 was passed over the stirred solution for 2 h at 40 °C. The catalyst was then filtered off, all solvent removed by rotary evaporation and the remaining colorless solid dried under vacuum overnight. The crude product was characterized by FD-mass spectrometry and used without further purification. − FD-MS (CH_2Cl_2): *m*/*z* = 702 [HM^+].

[H-Lys{Ru(bipy)$_2$}-cyclenH$_2$](PF$_6$)$_5$ (7): [Ru(bipy)$_2$(m-OH)](PF$_6$)$_2$ (**5**; 0.92 g, 1.00 mmol) and HOSu (0.13 g, 1.10 mmol) were dissolved in 5 mL of absolute CH_3CN. The solution was cooled to 4 °C in an ice/water bath, DCC (0.43 mg, 2.10 mmol) was added and the resulting suspension stirred for 5 h. This mixture was filtered directly into a solution containing triethylamine (0.30 mL, 2.10 mmol) and all of the crude Boc-Lys-(Boc)$_3$cyclen (**4**) obtained as described above in 20 mL of CH_3CN. The resulting red solution was stirred for 1.5 h at 41 °C. After removal of all solvent under vacuum the solid residue was treated with 10 mL of a 4 M HCl/dioxane solution in order to cleave the Boc protecting groups. Deprotection was complete after stirring the mixture for 1 h at 0 °C. The solvent was removed by rotary evaporation and the residual red solid dried overnight under vacuum. The crude product was redissolved in 100 mL of water, neutralized with a 2.0 M NaOH solution, and applied to an ion exchange chromatography column (Sephadex CM-50) using a NaCl gradient in a 0.6 mM phosphate buffer (pH 7.2) solution. The product eluted as the second fraction with 0.25 M NaCl. All solvent was removed by rotary evaporation and the residue dried under vacuum. Most of the excess NaCl was removed by extraction of the orange solid with a minimum of absolute MeOH and subsequent filtration. The filtrate was evaporated to dryness and the product redissolved in 10 mL of water. Slow addition of 1 mL aqueous NH_4PF_6 (1.22 g, 7.50 mmol) resulted in precipitation of the product. The suspension was stirred for 1 h, the orange solid collected on a sintered glass filter funnel, washed with 3 × 5 mL of a cold 10 mM aqueous NH_4PF_6 solution, and dried over silica in a vacuum desiccator. Yield: 1.00 g (0.61 mmol, 61%). − $C_{46}H_{59}F_{30}N_{12}O_2P_5Ru·2H_2O$ (1637.95): calcd. C 32.99, H 3.79, N 10.04; found C 32.87, H 3.93, N 10.25. − FAB-MS (nitrobenzyl alcohol): *m*/*z* = 1347 [M^+ − 2HPF$_6$], 1201 [M^+ − 3HPF$_6$], 1055 [M^+ − 4HPF$_6$]. − ^{1}H NMR (300 MHz, CD_3OD): δ = 1.34 (m, 42 H, $^{\beta,\gamma,\delta}CH_2$, 4 × Boc), 3.23 (br. m, 16 H, 7 × cyclen-CH_2, $^{\varepsilon}CH_2$), 3.93 (m, 1 H, cyclen), 4.20 (m, 1 H, cyclen), 4.35 (m, 1 H, $^{\alpha}CH$), 7.33 (d, 1 H, m5‘), 7.46 (m, 4 H, 4 × b5), 7.60 (d, 1 H, m5), 7.84 (m, 6 H, 4 × b6, m6′, m6), 8.08 (m, 4 H, 4 × b4), 8.64 (m, 5 H, 4 × b3, m3′), 8.94 (s, 1 H, m3). − IR (KBr): $\tilde{\nu}$ = 3110 (m, 3079 (m), 2945 (m), 1637 (m), 1541 (m), 1460 (m), 1445 (m), 1241 (m), 1162 (m), 841 (vs, PF_6^-), 765 (s), 558 (s) cm^{-1}. − UV/Vis (MeOH): λ [nm] (ε, [M^{-1} cm^{-1}]) = 255 (27500), 289 (89500), 456 (15500).

Reaction of [H-Lys{Ru(bipy)$_2$m}-cyclenH$_2$](PF$_6$)$_5$ (7) with Zn(CF$_3$SO$_3$)$_2$: Compound **7** (0.42 g, 0.25 mmol) was dissolved in 20 mL of methanol and 15.5 mL of a 1.5 mM NaOMe/methanol solution. Solid $Zn(CF_3SO_3)_2$ (0.10 g, 0.27 mmol) was added in one portion and the solution stirred for 1 h under reflux conditions. The solvent was removed by rotary evaporation, the red solid residue dried under vacuum and redissolved in a minimum amount of water. A solution of NH_4PF_6 (0.02 g, 0.38 mmol) in 1 mL H_2O was added dropwise resulting in the precipitation of an orange solid. This was collected on a sintered glass filter funnel and dried under vacuum. ^{1}H NMR spectroscopy of the crude product indicated the presence of a complex product mixture. The solid was redissolved in water and applied to an ion exchange chromatography column using the conditions described above. A red band eluted with 50 mM NaCl and the product was isolated following the procedure described for **7**. The compound was identified by ^{1}H NMR spectroscopy and FAB mass spectrometry to be the ruthenium-substituted amino acid [H-Lys{Ru(bipy)$_2$m}-OH](PF$_6$)$_3$ (**8**; yield: 0.21 g, 69%) which has been reported earlier.[21]

Luminescence pH Titrations of 7 and [H-Lys{Ru(bipy)$_2$m}-cyclenM]$^{5+}$ [7-M(ClO$_4$)$_2$; M = Ni^{2+}, Cu^{2+}]: An aquarium pump, a three-neck round bottom flask equipped with a pH electrode, and a luminescence cuvette were connected by Teflon tubes. The flask was charged with an aqueous solution which was 10 µM both in **7** and the respective metal perchlorate salt. This solution was deaerated by bubbling with N_2 for 15 min. and continuously cycled through the apparatus. A slow stream of N_2 was passed through the solution in the flask throughout the measurement. The pH was adjusted with HCl and NaOH solutions. Luminescence spectra were measured after a period of cycling of 5 min. at each pH value.

Kinetics of the Amide Bond Cleavage in the Presence of Cu(ClO$_4$)$_2$·6H$_2$O at pH 6.8 and 9: A 10 µM solution of **7** in an aqueous phosphate buffer (pH 6.8), and a 10 mM solution of copper perchlorate hexahydrate in water were prepared. The ruthenium complex solution was deaerated by bubbling with N_2 for 15 min. through a syringe needle in a fluorescence cuvette which was sealed by a rubber septum. One equivalent of $Cu(ClO_4)_2$ was added and the time-dependent uncorrected luminescence intensity followed at a single emission wavelength of 645 nm (λ_{max}; λ_{exc} = 450 nm). For

the measurement at pH 9, the reaction mixture was also prepared at pH 6.8 and NaOH added to adjust to the new pH after a period of 15 min. This procedure is required to assure complete complex formation. If the reactants are mixed at pH 9, immediate formation of copper hydroxide results in a long induction period which obscures the kinetics.

Luminescence Titration of 7 with $M(ClO_4)_2 \cdot 6H_2O$ ($M = Ni^{2+}$, Cu^{2+}, Zn^{2+}) at pH 6.8: A 10 μM solution of **7** in an aqueous phosphate buffer (pH 6.8), and a 10 mM solution of the respective perchlorate salt in water were prepared. The ruthenium complex solution was deaerated by bubbling with N_2 for 15 min. through a syringe needle in a fluorescence cuvette which was sealed by a rubber septum. This solution was titrated with the respective metal perchlorate salt solution in 0.1 equiv. steps. After addition of 1 equiv. titration was continued in 0.4 equiv. steps. The titration curve was followed by luminescence spectroscopy. The solution was purged with N_2 for 5 min. prior to each measurement.

Detection of Cu^{2+} in the Presence of Ni^{2+} and Zn^{2+}: A 10 μM solution of **7** in an aqueous phosphate buffer (pH 6.8) was prepared. A 10 mM solution of $M(ClO_4)_2 \cdot 6H_2O$ (M = Ni, Zn) was added to adjust the M^{2+} concentration to 10 μM (Ni) or 100 μM (Zn). Luminescence spectra were measured after bubbling the resulting solution with Ar for 15 min. One equivalent of a 0.01 M $Cu(ClO_4)_2 \cdot 6H_2O$ solution was then added and luminescence spectra measured again after 15 min. of bubbling with Ar.

Novel Diazamesocyclic Ligands Functionalized with Pyridyl Donor Group(s) – Synthesis, Crystal Structures, and Properties of Their Copper(II) Complexes

Xian-He Bu,*[a] Miao Du,[a] Zhi-Liang Shang,[a] Lei Zhang,[a] Qi-Hua Zhao,[a] Ruo-Hua Zhang,[b] and Mitsuhiko Shionoya[c]

Keywords: Diazamesocyclic ligands / Copper(II) complexes / Crystal structures / Magnetic properties

Two novel diazamesocyclic ligands based on 1,5-diazacyclooctane (DACO) and functionalized with additional pyridyl donor groups, namely 1,5-bis(2-pyridylmethyl)-1,5-diazacyclooctane (**L¹**) and 1-(2-pyridylmethyl)-1,5-diazacyclooctane (**L²**), have been synthesized and characterized, as have their Cu^{II} complexes. Crystal structure analyses revealed that with $Cu(ClO_4)_2$ **L¹** forms a five-coordinate mononuclear complex $[Cu^{II}L^1Cl]ClO_4$ (**1**), whereas **L²** forms a μ-Cl^--bridged dinuclear complex $[Cu^{II}(L^2)Cl]_2(ClO_4)_2$ (**2**). Furthermore, it has been found that the apical chloride anion of **1** may be easily exchanged by azide anion, forming the mononuclear complex $[Cu^{II}L^1(N_3)]ClO_4$ (**3**). There is a notable difference between **3** and **1** in that **3** forms a quasi-two-dimensional network through intermolecular C–H···O hydrogen bonds and π–π stacking interactions. Each Cu^{II} center in the three complexes is pentacoordinated in a distorted square-pyramidal environment and the DACO ring of each ligand adopts a boat-chair configuration in all the complexes. In the mononuclear complexes **1** and **3**, the Cl^- or N_3^- anions occupy the apical sites, whereas in the dinuclear complex **2** the two bridging Cl^- anions occupy both axial positions as well as one equatorial position, leading to an intramolecular Cu···Cu separation of 3.396 Å. Variable-temperature magnetic susceptibility measurements on **2** in the range 4–300 K indicate a weak intramolecular ferromagnetic coupling between adjacent Cu^{II} centers with $2J = 2.28\ cm^{-1}$; the magneto-structural correlations are discussed in detail. The solution behavior of the complexes has been further studied by UV/vis and ESR techniques.

Introduction

Macrocyclic polyamines bearing functional groups and transition metal complexes thereof have been extensively studied in order to investigate the effects of the functional pendants on the coordination modes and properties of these complexes.[1] Mesocyclic diamines such as 1,5-diazacyclooctane (DACO), functionalized with pendant groups, can form stable metal complexes with unique conformational requirements,[2,3] and the coordinating abilities of such ligands can be adjusted through altering the donor groups on their skeletons.[4] This interesting chemistry prompted our investigation of DACO, in which we introduced functional donor groups on its backbone and examined the coordinating functionality of various pendant donors in relation to the structures and properties of the relevant metal complexes. Furthermore, the study of DACO derivatives and their metal complexes has been an active area of research owing to their use in analytical and biomimetic applications, in the stabilization of high oxidation states of some metal ions, in selective ion recognition, and as a result of their catalytic activities.[5]

Dinuclear Cu^{II} complexes play an important role in the elucidation of spin-coupling or magnetic-exchange phenomena between paramagnetic metal centers. They exemplify the simplest case where two unpaired electrons on two paramagnetic ions are separated by spacer ligands that may intramolecularly mediate the stabilization of a singlet. Several experimental and theoretical investigations have been carried out aimed at elucidating the structures and magnetic properties of bis(μ-chloro)-bridged Cu^{II} dimers, and different magnetic behavior ranging from ferro- to antiferromagnetic interactions has been found in these systems.[6] However, great difficulties remain in establishing a magneto-structural correlation for these complexes since they show pronounced Jahn−Teller distortion. Consequently, further investigations into the magneto-structural correlation of chloro-bridged Cu^{II} dinuclear complexes would seem necessary.

We report herein the synthesis of two new ligands based on DACO bearing one and two pyridine donor groups, respectively, as well as their Cu^{II} complexes (see Scheme 1). These tetra- and tridentate ligands form stable mononuclear and dinuclear complexes with Cu^{II}, the crystal structures of which have been elucidated by X-ray diffraction analysis. The magneto-structural correlations of **2** and the solution behavior of these Cu^{II} complexes have also been studied.

Results and Discussion

Syntheses and General Characterizations

The doubly-substituted ligand **L¹** was prepared by using an excess of 2-chloromethylpyridine hydrochloride, while an

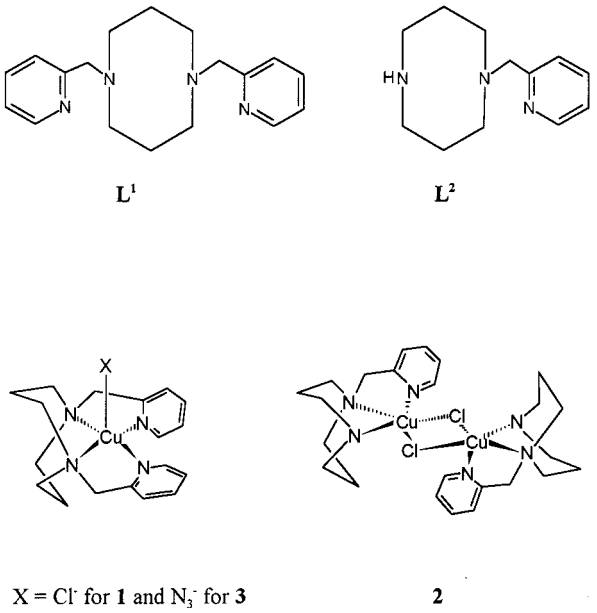

Scheme 1

excess of DACO was used to obtain the monoalkylated product $\mathbf{L^2}$; both ligands were purified by column chromatography on silica gel. Acid-free $\mathbf{L^1}$ and $\mathbf{L^2}$ could only be obtained as oils, hence they were converted into their HCl salts to obtain crystalline solids. The yields of both syntheses were in excess of 65% and all analytical data were in good agreement with the theoretical requirements of the two ligands.

The syntheses of **1** and **2** were accomplished by reacting the respective ligands with $Cu(ClO_4)_2{\cdot}6H_2O$. Since the ligands were handled as their HCl salts, they first had to be neutralized with aqueous NaOH solution prior to complexation. Electrical conductance values in methanol solution indicated that **1** and **3** behave as 1:1 electrolytes, while **2** acts as a 2:1 electrolyte,[7] these findings being consistent with the crystal structural analyses. The IR spectra of the three complexes show absorption bands resulting from the skeletal vibrations of the pyridine rings in the region 1400−1600 cm^{-1}. The absorption bands due to ClO_4^- appear at 1098−1082 and 623−621 cm^{-1} for all three complexes. In addition, **3** exhibits three strong absorption bands at 2125, 2031, and 1098 cm^{-1} due to the ν_{N-N} stretch of the apical azide anion.

X-ray Crystal Structures of Complexes 1−3

The crystal structure of **1** showing the atom numbering scheme is depicted in Figure 1. The structure consists of a discrete $[Cu\mathbf{L^1}Cl]^+$ cation and a perchlorate anion. The Cu^{II} center is coordinated by two pyridine nitrogen atoms and a pair of nitrogen donors of the DACO ring. A chloride anion completes the coordination polyhedron around the central metal ion. The Cu^{II} ion is pentacoordinated (CuN_4Cl) and the coordination polyhedron can best be described as a distorted square-pyramid with the chloride anion occupying the axial position. The Cu^{II} ion lies 0.425 Å above the basal least-squares plane defined by N(1), N(2), N(16), and N(26), in the direction of the apical Cl(1) anion, and the dihedral angle between the two pyridine rings is 36.1°. The ligand adopts a typical boat/chair configuration and with the central Cu^{II} ion forms two five-membered coordination rings N(1)−C(10)−C(11)−N(16)−Cu and N(2)−C(20)−C(21)−N(26)−Cu, resulting in an N(1)−Cu−N(16) angle of 79.8° and an N(1)−Cu−N(16) angle of 84.5°.

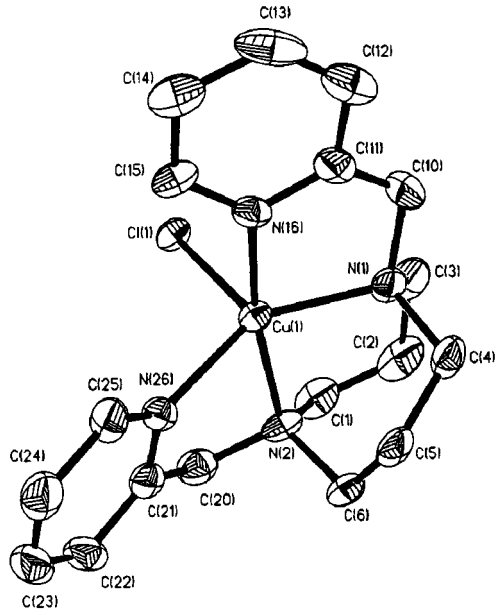

Figure 1. ORTEP view of **1** with thermal ellipsoids drawn at a 35% probability level

The two $Cu-N_{DACO}$ bond lengths are approximately equal (2.032 vs. 2.056 Å), both being normal Cu−N coordination bonds,[8] but the Cu−N(16) (pyridine) bond length is significantly shorter than the Cu−N(26) (pyridine) distance (1.991 vs. 2.113 Å), probably due to the steric interaction of the two pyridine groups.

The apical Cu−Cl(1) coordination bond measures 2.424 Å, which is close to the values reported for some similar complexes.[9,10] The weakly coordinated Cl^- anion may be easily exchanged by other donor molecules or ions, hence the complex may have potential application in homogeneous catalysis or as a functional building block for the construction of larger functional architectures. We have successfully modified this complex by axial ligand exchange of chloride with azide, thereby generating **3**.

The crystal structure of **3** is shown in Figure 2(a); the coordination environment of the central Cu^{II} ion can be seen to be very similar to that in **1**. The Cu^{II} ion lies 0.424 Å above the mean basal plane defined by N(1), N(2), N(3), and N(4), in the direction of the apical N(5) atom. The dihedral angle between the two pendant pyridine rings is 27.7°, which is smaller than that in **1**, probably as a result of the less severe distortion of the coordination geometry about the central Cu^{II} ion. The $Cu-N_{DACO}$ bond lengths (2.041 vs. 2.075 Å) are close to the value found in **1** while, in contrast to **1**, the $Cu-N_{py}$ bond lengths are approximately the same (2.075 vs. 2.114 Å).

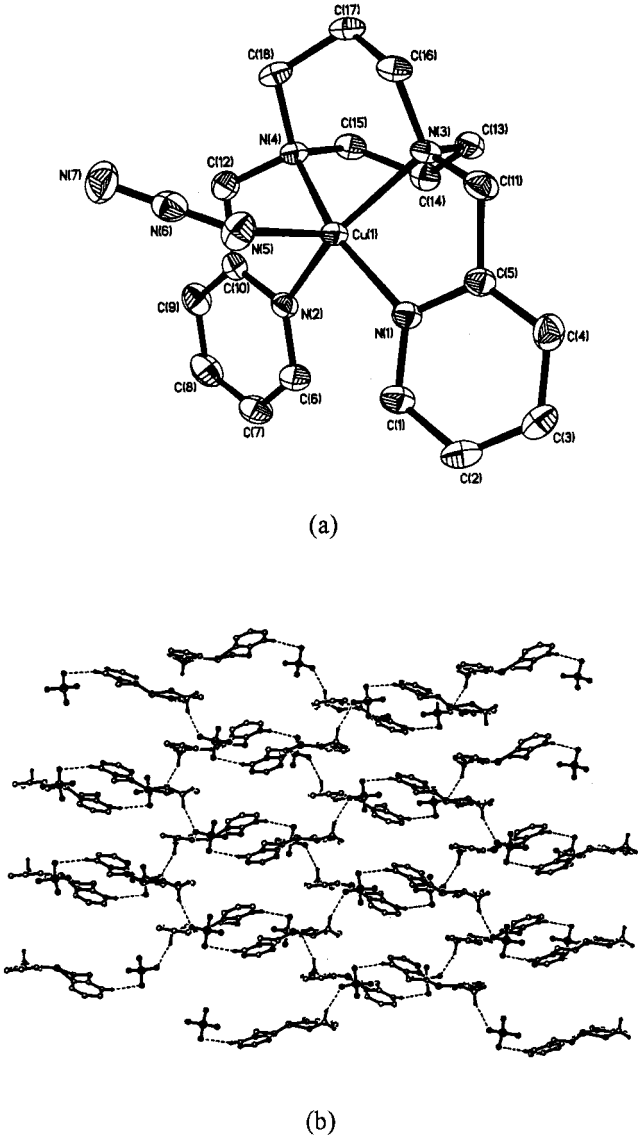

Figure 2. (a) ORTEP view of **3** with thermal ellipsoids drawn at a 30% probability level; (b) view of the two-dimensional network in **3** along the *b* axis; the methylene groups of the DACO ring and irrelevant hydrogen atoms have been omitted for clarity

Selected bond lengths and angles relevant to the Cu^{II} coordination spheres in both **1** and **3** are listed in Table 1. The stereo geometries of both of the five-coordinate (CuN_4X) complexes are distorted square-pyramids, as reflected in their τ values (0.38 and 0.29, respectively) defined by Addison et al. (τ = 0 for an ideal square-pyramid, τ = 1 for an ideal trigonal-bipyramid).[11] In both complexes, $\mathbf{L^1}$ acts as a tetradentate chelating agent. The coordination geometry around Cu^{II} is made up by a pair of nitrogen atoms of the DACO ring and the two nitrogen donors of the pyridine pendants, which occupy *cis* positions in the coordination polyhedron. In both complexes, the DACO ring of the ligand adopts a "boat/chair" configuration and is bent such that the central methylene C−H group of the boat form of the metalladiazacyclohexane ring shields the metal center with a H···Cu distance of 2.565 Å in **1** (2.555 Å in **3**) and a H−Cu−apex angle of 11.9° in **1** (7.9° in **3**). Thus, this methylene hydrogen effectively blocks the sixth coordination position, resulting in the observed five-coordinate metal complexes[4c] (see Scheme 2). The distances between the nitrogen atoms of the DACO ring are restricted to a narrow range with $N_{DACO}-Cu-N'_{DACO}$ angles of 87.2° and 86.7° in the two complexes. The $N_{py}-Cu-N'_{py}$ angles are also restricted within narrow limits (100.8° and 101.8°), due to the steric requirements of the ligand.

Table 1. Selected bond lengths [Å] and angles [°] in **1** and **3** (H* is the hydrogen of the central methylene group nearest to the Cu^{II} center in the boat forms of the metalladiazacyclohexane rings)

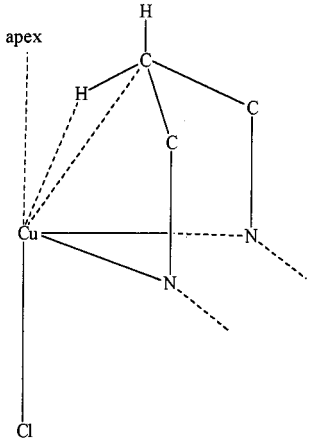

Scheme 2

The most notable difference between **3** and **1** is the ability of **3** to form a quasi-two-dimensional supramolecular network through weak intermolecular C−H···O hydrogen bonds and π−π stacking interactions. This is illustrated in Figure 2(b). The hydrogen atoms of the pyridine ring and of the methylene group connected to the pyridine ring of another adjacent molecule in the cation unit $[Cu\mathbf{L^1}(N_3)]^+$ are activated by the positive charge that arises due to the coordination of the N atoms to the Cu^{II} center. Each perchlorate anion acts as a hydrogen-bond acceptor from two

adjacent $[Cu\mathbf{L^1}(N_3)]^+$ cations, giving a one-dimensional infinite zigzag chain in the lattice. The C···O separations are 3.461 and 3.397 Å, with H···O separations of 2.561 and 2.484 Å. The C···O separations fall within the range of 3.0−4.0 Å suggested by Desiraju et al.,[12] while the bond angles of 161.5 and 163.4° are quite close to 180°. The Cu···Cu intermolecular distance between adjacent chains is 7.54 Å. Furthermore, the H-bonded chains are cross-linked in the unit cell. Two nearest pyridine planes, lying almost parallel to one another between the neighboring chains, show an average interfacial distance of 3.667 Å, indicating significant π-π stacking interactions.[13] As a result of these two types of weak intermolecular interaction, the $[Cu\mathbf{L^1}(N_3)]ClO_4$ molecules are self-assembled into a quasi-two-dimensional network in this complex.

An ORTEP representation of **2**, showing the atom numbering scheme, is depicted in Figure 3, while selected bond lengths and angles are listed in Table 2. The complex consists of a discrete $[Cu\mathbf{L^2}Cl]_2^{2+}$ cation and two perchlorate anions. In the $[Cu\mathbf{L^2}Cl]_2^{2+}$ cation, the two Cu^{II} centers are symmetrically bridged by two chloride anions. Each Cu^{II} ion is bound by $\mathbf{L^1}$ through one nitrogen atom of the pyridyl pendant group and two nitrogen donors of the DACO ring, which again adopts a "boat/chair" configuration. The two bridging chloride anions complete the coordination polyhedron around each Cu^{II} ion. The Cu^{II} ions are pentacoordinated (CuN_3Cl_2) and the coordination polyhedron around Cu^{II} may best be described as a distorted square-pyramid with $\tau = 0.34$.[11] The Cu^{II} ion lies 0.28 Å above the mean basal plane formed by N(1), N(2), N(11), and Cl(1a), in the direction of the apical Cl^- anion, and the axial Cu(1)−Cl(1) distance is ca. 0.29 Å longer than the Cu(1)−Cl(1a) bond length in the basal plane (2.581 vs. 2.291 Å).

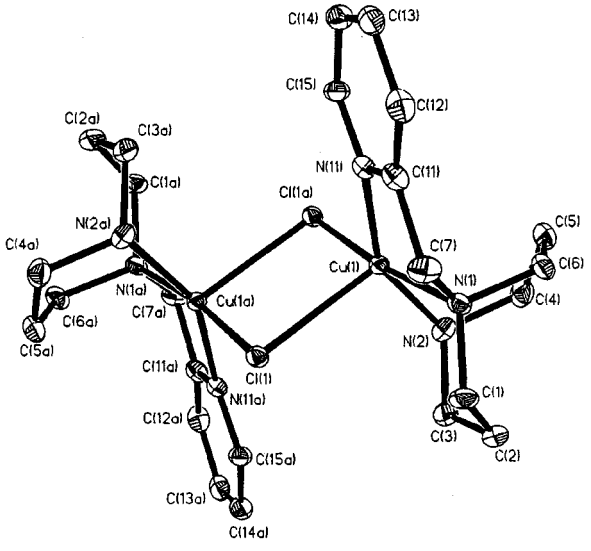

Figure 3. ORTEP representation of **2** with thermal ellipsoids drawn at a 35% probability level

The Cu^{II} centers and chloride anions form a rhombic plane with the angles Cl(1)−Cu(1)−Cl(1a) and Cu(1)−Cl(1)−Cu(1a) measuring 91.8° and 88.2°, respectively. The two intramolecular Cu^{II} centers in **2** have the same coordination configuration and structure. All the Cu−N and Cu−Cl bond lengths fall into the expected ranges for normal coordination bonds,[14] while the shortest Cu···Cu nonbonding length in the dimer is 3.396 Å.

Table 2. Selected bond lengths [Å] and angles [°] in **2**

Bond lengths [Å]			
Cu(1)−Cl(1)	2.581(1)	Cu(1)−N(1)	2.038(4)

Cl(1)−Cu(1)−Cl(1a)	91.8(1)	N(1)−Cu(1)−Cl(1a)	173.0(1)
N(2)−Cu(1)−Cl(1a)	91.4(1)	N(11)−Cu(1)−Cl(1a)	96.8(1)
Cu(1)−Cl(1)−Cu(1a)	88.2(1)	H−Cu−apex	13.45

Electronic and ESR Spectra

The UV/vis spectra of the three complexes in methanol solution show absorption maxima at 621, 622, and 618 nm, respectively, which is in agreement with the absorptions seen for other five-coordinated Cu^{II} complexes with similar coordination geometries. The absorption bands of **1** and **2** display a slightly higher λ_{max} than that of **3**, suggesting that their coordination geometries are more distorted toward trigonal-bipyramid;[15] this is consistent with the degrees of distortion found in the X-ray structural analyses. This spectral feature is typical of pentacoordinated Cu^{II} complexes with distorted square-pyramidal geometry, which generally exhibit a band in the 550−660 nm range (d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$).[15,16] In addition, the electronic spectra of all the complexes feature a characteristic absorption at about 260 nm attributable to a ligand $\pi \rightarrow \pi^*$ transition.

The X-band ESR spectra of **1** were measured in the polycrystalline state and in methanol solution, at room temperature and at 110 K. The following ESR parameters were obtained for polycrystalline powdered **1** at room temperature: $g_z = 2.21$, $g_y = 2.10$, and $g_x = 2.04$. The resolution did not improve very much upon cooling to 110 K, with parameters of $g_z = 2.26$, $g_y = 2.15$, and $g_x = 2.09$. Nevertheless, the spectra at 110 K did show some small splitting lines, probably due to the hyperfine splitting of the coordinated nitrogen donors. The g values conform to the relationship: $g_{\|} > g_{\perp} > g_e$, which indicates that the unpaired 3d electron of the Cu^{II} ion should occupy the $d_{x^2-y^2}$ orbital and a predominantly tetragonal component in the solid-state stereochemistry.[17] The different values of g_x and g_y for **1** imply that the Cu^{II} ground-state wavefunction is not pure $d_{x^2-y^2}$, but that it contains some contribution from d_{z^2} as a result of the decreased symmetry of the coordination polyhedron, which is consistent with the crystal structure data. The room-temperature solution spectra show hyperfine splitting lines characteristic of Cu^{II} complexes, as was also observed for a frozen solution of **1**. The approximate

ESR parameters obtained were: $g_{iso} = 2.11$ ($A_{iso} = 74$ G), $g_{\|} = 2.23$ ($A_{\|} = 94$ G), and $g_{\perp} = 2.05$ ($A_{\perp} = 64$ G), where $g_{\perp} = (3g_{iso} - g_{\|})/2$ and $A_{\perp} = (3A_{iso} - A_{\|})/2$.[18] The values again conform to the relationship $g_{\|} > g_{\perp} > g_e$, with a smaller $A_{\|}$ value, indicating some distortion of the coordination geometry about the Cu^{II} center from square-pyramidal in solution,[19] which is similar to the geometry observed in the solid state.

The X-band ESR spectrum of **2** in the solid state at room temperature shows isotropic character with $g_{av} = 2.10$, possibly as a result of exchange narrowing. No absorption is observed at half-field ($\Delta m_s = 2$, $g = 4$), indicating a small ZFS effect.[20] The spectrum of a frozen solution of **2** in methanol likewise exhibits only a quasi-isotropic feature, and the g value (2.10) is essentially the same as that of the polycrystalline sample. This indicates that there is no significant change in the coordination environment under the two sets of conditions.

Magnetic Properties

The magnetic behavior of **2** is shown in Figure 4 as the variation of χ_M (μ_{eff}) versus temperature. The molar magnetic susceptibility of the dinuclear Cu^{II} unit increases with decreasing temperature. However, the effective magnetic moment increases very smoothly on lowering the temperature down to 14 K and finally decreases rapidly at even lower temperatures. This behavior indicates the existence of an intradimer *ferromagnetic exchange interaction*. The experimental data were least-squares fitted to the analytical expression given as Equation (1), according to the modified Bleaney−Bowers model for a Cu^{II} dimer.[21] Here, all the symbols have their usual meanings; ρ is the percentage of non-coupled impurity and $N\alpha$ is the temperature-independent paramagnetism. The following parameters were obtained: $2J = 2.28$ cm^{-1}, $\rho = 0.005$, and $g = 2.12$, which is in good agreement with the average g value deduced from the ESR spectra. The agreement factor R [defined as $\Sigma(\chi_{obs} - \chi_{calc})^2/\Sigma(\chi_{obs})^2$] is equal to 2.0×10^{-5}.

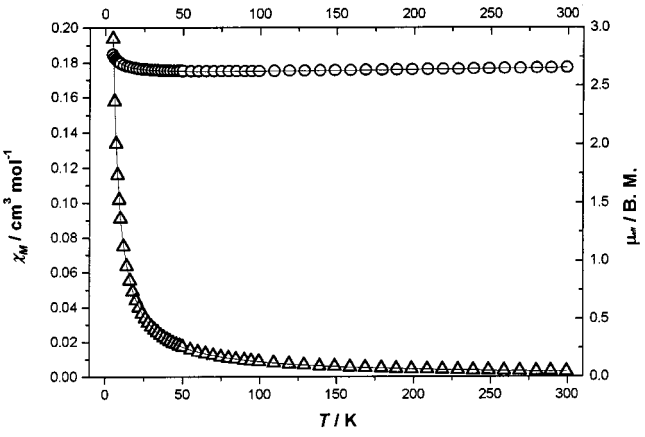

Figure 4. Magnetic coupling diagram of the μ-Cl^--bridged binuclear complex **2**

$$\chi_M = (2Ng^2\beta^2/KT)[3 + \exp(-2J/KT)]^{-1}(1 - \rho) + Ng^2\beta^2\rho/2KT + N\alpha \quad (1)$$

In order to discuss the relationship between the magnitude of the exchange constant and the structural parameters in distorted square-pyramidal coordinated Cu^{II} dimers with bis(μ-chloro) bridges, we have compiled the structural and magnetic parameters of several such Cu^{II} dimers in Table 3.

In **2**, the spin density lies in the parallel planes and the magnetic orbital is almost orthogonal, indicating that the overlap is very small, and this leads to the observed weak magnetic exchange interaction. Hatfield and co-workers[22] have shown that antiferromagnetic interactions are observed when the value of the quotient φ/R (°/Å) is lower than 32.6 or higher than 34.8, whereas ferromagnetic interactions are observed for quotient values falling between these limits. For **2**, the quotient value is 34.17°, falling just within the aforementioned limits, hence the ferromagnetic interaction may be satisfactorily understood. In Cu^{II} complexes, strict orthogonality does not occur,[23] and the ferromagnetic interaction is due to accidental orthogonality of the magnetic orbital involved and/or a polarization effect. In **2**, the π orbitals of the Cl(1) anion interact with the Cu(1) magnetic orbital; electron delocalization from the π orbital into the $d_{x^2-y^2}$ orbital of Cu(1) deposits some unpaired spin density of the same net orientation as that on Cu(1) onto the bridging Cl(1) anion. Therefore, coupling of the unpaired spins in the orthogonal orbitals, π and $d_{x^2-y^2}$ of Cu(2), leads to the triplet ground state.[24] According to the equation $J = J_F + J_{AF}$,[25] where $J_F = 2C$ and $J_{AF} = -2\Delta S$ (C is the two-electron exchange integral, S is the overlap integral, and Δ is the energy separation of the molecular magnetic orbital occupied by the unpaired electrons), J_F is the dominant term for **2**. It is worth noting that the Cu−Cl (equatorial) bond length is a key factor in

Table 3. The structural and magnetic properties of some bis(μ-Cl^-)-bridged Cu^{II} dimeric complexes

Complex	Cu···Cu (Å)	Cu···Cl′ (R/Å)	Cu−Cl−Cu′ (φ/°)	φ/R (°/Å)	$2J$ (cm^{-1})	Ref.
$[Cu(DMGH)Cl_2]_2$	3.445	2.698	88.0	32.62	+6.3	14

determining the spin-polarization effect, which governs the magnitude of the magnetic exchange interaction.

Conclusion

The described synthetic procedure provides a convenient access to a new family of macrocyclic species and their metal complexes. The effect of substituents and of the apical anion on the five-coordinated Cu^{II} structural geometry is discussed in detail. A study of the magnetic properties has shown that the main structural factor determining the strength of the magnetic interaction is the value of the quotient (φ/R), but that the influence of the Cu−Cl equatorial and axial distances must also be considered.

Experimental Section

Materials and General Methods: The starting compound, DACO·2HBr, was prepared according to a literature method.[29,30] Other commercially available chemical reagents and solvents were of analytical grade and were purified by standard procedures prior to use. − FT-IR spectra were recorded on a Nicolet 170SX spectrometer at room temperature. − ^{1}H NMR spectra were recorded on a Bruker AC-P 200 spectrometer (200 MHz) at 25 °C using tetramethylsilane as an internal reference. − Electronic absorption spectra were recorded on a Hitachi UV-3010 spectrophotometer. − Elemental analyses were carried out on a Perkin−Elmer 240C analyzer. − Solution and polycrystalline EPR spectra (X-band) were recorded on a Bruker ER-200-DSRC10 spectrometer.

Syntheses of Ligands: 1,5-Bis(pyrid-2-ylmethyl)-1,5-diazacyclooctane Tetrahydrochloride Monohydrate (L^1·4HCl·H_2O): A suspension of DACO·2HBr (1.76 g, 6.4 mmol) and potassium hydroxide (0.73 g, 12.9 mmol) in anhydrous ethanol (40 mL) was stirred for 4 h at room temperature. A solution of 2-(chloromethyl)pyridine hydrochloride (2.46 g, 15.0 mmol) and triethylamine (2.09 g, 15.0 mmol) in anhydrous ethanol (20 mL) was then added dropwise to the stirred mixture over a period of 2 h. After the addition was complete, additional triethylamine (5 mL) was added and the resulting mixture was stirred for ca. two days at room temperature. The solvent was then removed under reduced pressure, the residue was redissolved in water (15 mL), and the pH of the resulting solution was adjusted to ca. 10 with anhydrous K_2CO_3. The organic phase that separated from the mixture was concentrated in vacuo and the crude product was purified by column chromatography on silica gel (CH_2Cl_2/MeOH/NH_3·H_2O, 10:10:1). The free ligand was obtained as a colorless oil; it was converted to its HCl salt, which was obtained as a white crystalline material (2.06 g, 70% yield based on DACO). − $C_{18}H_{24}N_4$·4HCl·H_2O (460.3): calcd. C 47.0, H 6.57, N 12.2; found C 46.8, H 6.81, N 11.8. − ^{1}H NMR (D_2O): δ = 1.82−1.88 (m, 4 H, $CH_2CH_2CH_2$), 3.18 (t, J = 5.7 Hz, 8 H, NCH_2CH_2), 4.30 (s, 4 H, CH_2-py), 7.84−8.66 (m, 8 H, py). − IR (KBr pellet): $\tilde{\nu}$ = 2986 cm^{-1} w, 2958 m, 1636 vs, 1617 s, 1541 s, 1468 s, 1443 s, 1390 vs, 930 m, 780 vs.

1-(Pyrid-2-ylmethyl)-1,5-diazacyclooctane Trihydrochloride Dihydrate (L^2·3HCl·2H_2O): A solution of DACO·2HBr (8.68 g, 31.7 mmol) and potassium hydroxide (3.30 g, 58.8 mmol) in anhydrous methanol (50 mL) was stirred for 4 h at room temperature. A solution of 2-(chloromethyl)pyridine hydrochloride (1.23 g, 7.5 mmol) in anhydrous ethanol was then added dropwise. The resulting mixture was refluxed for 1 h and then stirred at room temperature for ca. two days. The solvent was subsequently evaporated under reduced pressure, the residue was redissolved in water (20 mL), the pH of the resulting solution was adjusted to ca. 10 with Na_2CO_3, and then it was extracted with $CHCl_3$ (3 × 100 mL). The combined $CHCl_3$ extracts were dried, the solvent was evaporated, and the residue was purified by column chromatography on silica gel eluting with CH_2Cl_2/MeOH/NH_3·H_2O (5:5:1). The free base, obtained as an oil, was dissolved in anhydrous ethanol; passage of HCl gas into this solution gave the salt as an off-white solid (1.7 g, 65% yield based on 2-(chloromethyl)pyridine hydrochloride used). − $C_{12}H_{19}N_3$·3HCl·2H_2O (350.7): calcd. C 41.1, H 7.47, N 12.0; found C 40.8, H 7.69, N 11.8. − ^{1}H NMR (D_2O): δ = 1.90−1.96 (m, 4 H, $CH_2CH_2CH_2$), 3.02 (t, J = 5.7 Hz, 4 H, NCH_2CH_2), 3.24 (t, J = 5.9 Hz, 4 H, NCH_2CH_2), 4.15 (s, 2 H, CH_2-py), 7.77−8.42 (m, 4 H, py). − IR (KBr pellet): $\tilde{\nu}$ = 2953 cm^{-1} m, 1619 vs, 1546 m, 1466 s, 1406 w, 1327 w, 1230 m, 1073 m, 1038 w, 771 s.

Preparation of the Complexes: The mononuclear complex **1**, [CuL^1Cl]ClO_4, was prepared by mixing $Cu(ClO_4)_2$·6H_2O (147 mg, 0.4 mmol) and L^1·4HCl·H_2O (184 mg, 0.4 mmol) in a 1:1 molar ratio in methanol/water solution. The pH of this solution was adjusted to ca. 6−7 with dilute aqueous NaOH solution. The resulting mixture was filtered and the filtrate was left to stand at room temperature. Blue single crystals suitable for X-ray analysis were obtained upon slow evaporation of the solvent. Yield: 119 mg (60%). − $C_{18}H_{24}Cl_2CuN_4O_4$ (494.9): calcd. C 43.7, H 4.89, N 11.1; found C 43.6, H 4.92, N 11.3. − FT-IR (KBr pellet): $\tilde{\nu}$ = 2952 cm^{-1} w, 2905 m, 1609 s, 1569 m, 1484 s, 1449 s, 1091 vs, 623 s. − Λ_M (methanol): 102 cm^2 Ω^{-1} mol^{-1}. − UV/vis: λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) (methanol): 622 (240), 260 (13300).

The dinuclear complex **2**, [CuL^2Cl]$_2$(ClO_4)$_2$, was obtained in a similar manner as described for the preparation of **1** (52%). − $C_{24}H_{38}Cl_4Cu_2N_6O_8$ (807.5): calcd. C 35.7, H 4.74, N 10.4; found C 35.4, H 4.88, N 10.3. − FT-IR (KBr pellet): $\tilde{\nu}$ = 2940 cm^{-1} w, 1610 s, 1573 m, 1481 m, 1454 s, 1082 vs, 1025 s, 621 s. − Λ_M (methanol): 184 cm^2 Ω^{-1} mol^{-1}. − UV/vis: λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) (methanol): 621 (330), 260 (17900).

[CuL^1(N_3)]ClO_4 (**3**), was synthesized by adding excess NaN_3 to a methanolic solution of **1**. The resulting mixture was filtered and the filtrate was left to stand at room temperature. Green single crystals suitable for X-ray analysis were obtained upon slow evaporation of the solvent (38%). − $C_{18}H_{24}ClCuN_7O_4$ (501.4): calcd. C 43.1, H 4.82, N 19.6; found C 42.9, H 4.98, N 19.3. − FT-IR (KBr pellet): $\tilde{\nu}$ = 2950 cm^{-1} m, 2125 s, 2031 vs, 1609 s, 1570 m, 1483 m, 1447 s, 1309 m, 1098 vs, 623 s. − Λ_M (methanol): 99 cm^2 Ω^{-1} mol^{-1}. − UV/vis: λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) (methanol): 618 (274), 263 (11200).

Magnetic Study: Variable-temperature magnetic susceptibility measurements on **2** were made on a SQUID magnetometer in the 5−300 K temperature range. The susceptibilities were corrected for diamagnetism using Pascal's constants for all the constituent atoms, and magnetic moments were calculated from the equation $\mu_{eff} = 2.828(\chi_M T)^{1/2}$.

Crystallographic Study: The reflection data were collected on an Enraf−Nonius CAD-4 X-ray diffractometer (for **1** and **2**) or a Bruker Smart 1000 CCD diffractometer (for **3**) equipped with a graphite crystal monochromator situated in the incident beam. The determination of unit cell parameters and data collections were performed with Mo-K_α radiation (λ = 0.71073 Å). Reflections in the range 4.5 ≤ θ ≤ 25° (for **1** and **2**) and 1.71 ≤ θ ≤ 25.03° (for **3**)

[a] $R = \Sigma(||F_o| - |F_c||/\Sigma|F_o|)$. – [b] $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2}$, $w^{-1} = \sigma^2(F) + 0.0001F^2$ (for complexes **1** and **2**); $Rw = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma w(F_o^2)^2\}^{1/2}$, $w^{-1} = s^2(F_o^2) + (0.0554P)^2 + 0.7119P$, where $P = (F_o^2 + 2F_c^2)/3$ (for complex **3**). – [c] $S = \{\Sigma[w(F_o^2 - F_c^2)^2]/(n - p)\}^{1/2}$, where n = number of reflections measured and p = number of parameters used.

were collected at room temperature. All the structures were solved by direct methods and empirical absorption corrections were applied. Cu^{II} atoms in each complex were located from *E*-maps. All non-hydrogen atoms were determined by successive Fourier syntheses and were refined isotropically. The final refinement was performed by full-matrix least-squares methods against F (for **1** and **2**) or F^2 (for **3**) with anisotropic thermal parameters for non-hydrogen atoms. The hydrogen atoms were placed in theoretical positions as riding on the relevant atoms and were refined with fixed thermal factors. Crystallographic and refinement data for all three complexes are summarized in Table 4. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre and allocated the deposition numbers CCDC-150458 (**1**), -150459 (**2**) and -150460 (**3**). Copies of the data may be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat). +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Reactivity of [1,2-Bis(dimethylphosphanyl)ethane](mesitylidyne)tungsten(IV) Hydride with Group 7 and 8 Transition Metal Carbonyl Complexes

Franck Furno,[a] Thomas Fox,[a] Montserrat Alfonso,[a] and Heinz Berke*[a]

Keywords: Hydride complexes / Formyl complexes / Decarbonylation

The reaction between the tungsten hydride complex *trans*-W(CMes)(dmpe)$_2$H [**1**, dmpe = 1,2-bis(dimethylphosphanylethane)] and a series of electrophilic transition metal carbonyl compounds has been investigated, to explore the generality of W–H reductions of coordinated CO. Hydride transfer to the mononuclear [Fe(CO)$_5$], and to the dinuclear [Re$_2$(CO)$_{10}$], yields the neutral heterobimetallic formyl complexes *trans*-W{(μ-OCH)Fe(CO)$_4$}(CMes)(dmpe)$_2$ (**2**) and *trans*-W{(μ-OCH)Re$_2$(CO)$_9$}(CMes)(dmpe)$_2$ (**3a**), respectively. In the latter case, after one week at room temperature, **3a** is smoothly converted into the stable ionic complex [W(CMes)(CO)(dmpe)$_2$]$^+$[Re$_2$(CO)$_9$H]$^-$ (**3b**). Reaction with the cluster [Ru$_3$(CO)$_{12}$] results in the formation of an unstable formyl complex, which undergoes a direct rearrangement at –20 °C to produce the ionic complex [W(CMes)(CO)(dmpe)$_2$]$^+$-[Ru$_3$(CO)$_{11}$H]$^-$ (**4**) as the final product. The molecular structure of **4** was unambiguously established by single-crystal X-ray diffraction.

Introduction

In recent years our group has investigated the chemistry of activated transition metal hydrides. It has been shown that the carbyne ligand plays a prominent role in the electronic activation of hydride units.[1,2]

The reactivity of **1** towards small unsaturated organic molecules has been studied.[2] These studies, together with density functional calculations,[3] have indicated an enhanced hydricity and a weakness of the W−H bond, due mainly to the mesityl carbyne ligand in the *trans* position, which is known to exert a strong *trans* influence/effect.[4] The use of dmpe ligands, which are strong σ-donors and less effective π-acceptors than (for example) CO, should lead to increased electron density on the metal, and also to enhanced stability of the corresponding metal formyl moieties. Until 1973, when the first isolated anionic formyl complex [(CO)$_4$Fe(CHO)]$^-$ was reported by Collman and Winter,[5] these compounds were conspicuous by their absence from the chemical literature. The first neutral formyl complex, Os(Cl)(CO)$_2$(PPh$_3$)$_2$(CHO), was reported by Collins and Roper in 1976.[6] In the same year, Casey, Gladysz, and Winter[7] reported the first anionic formyl complexes, formed by treatment of suitable hydride sources (in most cases, main group metal "super hydrides") with metal carbonyls. Nelson,[8] however, demonstrated that a transition metal hydride can also be effective as the hydride source. The vast majority of known metal formyl complexes are, however, thermally unstable with respect to decarbonylation.[9] Notable exceptions are the early transition metal complexes,[10] the rhodium porphyrin hydride complex RhOEP(H) (OEP = octaethylporphyrin) described by Wayland and co-workers,[11] and some actinohydrides[12] which produce η^2-formyl products. Transition metal formyl complexes and hydridometal carbonyls are commonly invoked as reactive intermediates in both catalytic and stoichiometric CO reduction reactions.[13] The synthesis and characterization of formyl-metal complexes remains important for fuller investigation of the mechanism of Fischer−Tropsch[14a] reductive hydrogenation of carbon monoxide to hydrocarbons and oxygenates proposed by Olivé and Olivé,[14b] in which the insertion of carbon monoxide into a metal−hydrogen bond to produce a formyl complex is considered to be the initial step. Coordinated CO can be inserted into the M−H bond of metal hydrides,[15] particularly when the reaction is driven by the oxophilic character of early transition metals, allowing formation of η^2-formyl complexes. The generation of η^1-formyl species is generally thermodynamically unfavourable, as demonstrated by several quantum chemical calculations.[16] We therefore examined the reaction between **1** and CO bound in metal carbonyl compounds, in order to explore the generality of W−H addition across the CO bond.

Results and Discussion

Treatment of **1** with one equivalent of [Fe(CO)$_5$] (at room temperature in THF for a few minutes) did indeed quantitatively produce the dinuclear formyl-bridged complex *trans*-W{(μ-OCH)Fe(CO)$_4$}(CMes)(dmpe)$_2$ (**2**, Scheme 1). The mechanism is presumed to involve H$^-$ transfer to a CO ligand, by direct nucleophilic attack on a metal-bound CO. Dedieu and Nakamura have carried out extensive ab initio SCF calculations on the hypothetical gas phase reaction between H$^-$ and [Fe(CO)$_5$], and have concluded that for the [(CO)$_4$FeCHO]$^-$ ion, direct H$^-$ addition to an axial CO is strongly exothermic and occurs without activation.[17] Casey and Neumann have reported a variety of metal formyl compounds, including [Fe(CO)$_4$CHO]$^-$, resulting from the reaction between [Na$^+$][HB(OR)$_3^-$] and M(CO)$_x$.[20]

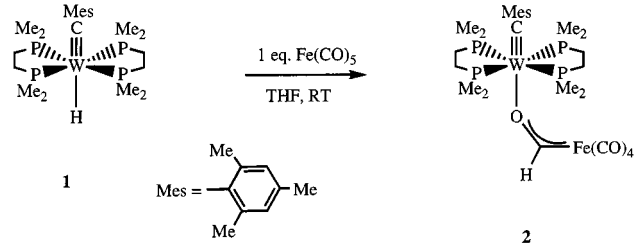
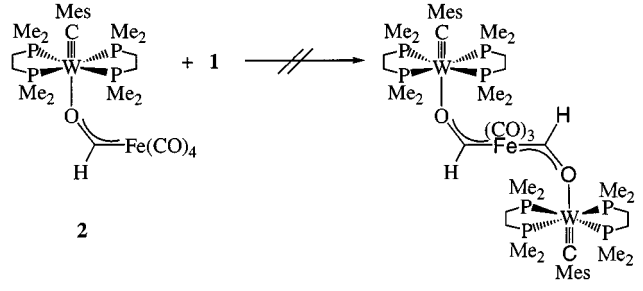


Scheme 1

Compound **2** was isolated, in 84% yield, as an orange, microcrystalline powder after recrystallisation from a saturated diethyl ether solution.

Among other resonances, the ^{1}H NMR spectrum of **2** features a characteristic H_{formyl} nucleus signal at $\delta = 13.67$, in the region reported for $K^+[Fe(CO)_4CHO]^-$ ($\delta = 15.0$)[7d] and *mer*-Mo{(μ-OCH)Fe(CO)$_4$}(CO)(NO)(PMe$_3$)$_3$ ($\delta = 14.09$).[19a] The ^{31}P{^{1}H} NMR spectrum features a singlet at $\delta = 32.2$ for the four equivalent phosphorus nuclei, with satellites from coupling to ^{183}W ($^1J_{PW} = 288$ Hz). The ^{13}C{^{1}H} NMR spectrum includes a quintet at $\delta = 298.6$ for the C_{formyl} atom ($^3J_{CP} = 5$ Hz), shifted by 39 ppm to lower field as compared to $[Fe(CO)_4CHO]^-$,[7b] and another quintet at $\delta = 275.3$ ($^2J_{CP} = 10$ Hz) for the carbyne carbon atom. These chemical shift values can be attributed to more efficient electron withdrawal in the bridging coordination mode. Evidence for the presence of a formyl ligand is most easily found in the IR spectral data. The THF solution infrared spectrum of **2** shows three bands at 2045 (m), 1967 (m) and 1932 (s) cm^{-1} − attributable to the terminal ν(CO) vibrations of the Fe(CO)$_4$ unit − and one other band at 1576 (m) for the iron formyl. This absorption pattern closely resembles that of the reported anion $[Fe(CO)_4CHO]^-$ complex.[18] Compound **2** provided an elemental analysis consistent with the proposed formula.

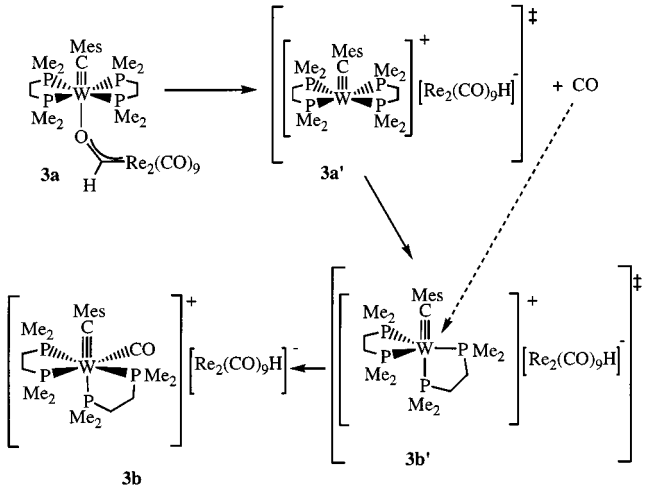
It was also expected that **2** would react further with excess **1**. Reaction with up to 10 equivalents of **1** at room temperature was therefore attempted, but no further transformations could be observed, indicating that the remaining carbonyls are inert towards further reduction to (for example) a bis(formyl) complex (Scheme 2).



Scheme 2

Steric hindrance probably makes the remaining CO ligands less susceptible to hydridic attack. On heating the reaction mixture at 60 °C for two days, the expected hydride migration to the iron was not detected, and neither was CO ejection. Compound **2** seems to be unusually stable; in the solid state it can be stored at room temperature under inert atmosphere for several weeks without any deterioration.

The reaction between **1** and one equivalent of $[Re_2(CO)_{10}]$ in THF was followed by ^{1}H and ^{31}P{^{1}H} NMR spectroscopy and the primary insertion product (i.e., the formyl-bridged compound *trans*-W{(μ-OCH)Re$_2$(CO)$_9$}(CMes)(dmpe)$_2$ (**3a**)) was detectable almost immediately (Scheme 3).



Scheme 3

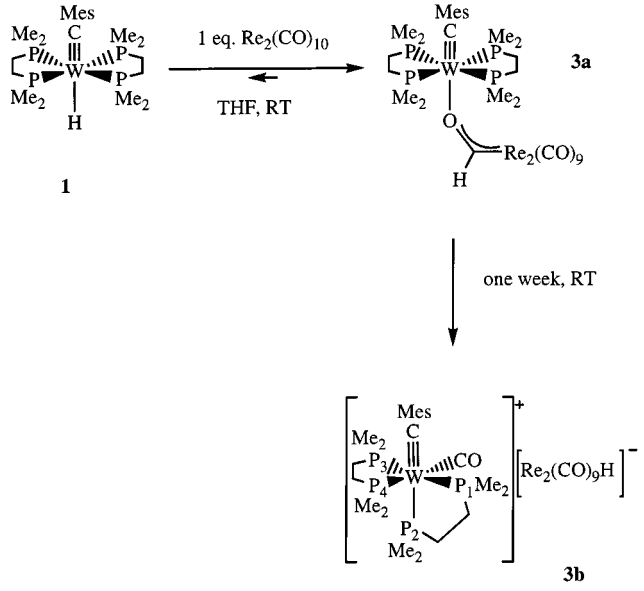
This reaction proceeds smoothly at room temperature, resulting in the formation of a clear orange/red solution. Here, again, the bridging formyl group of **3a** gives rise to characteristic NMR resonances. The ^{1}H NMR spectrum shows the H_{formyl} resonance at $\delta = 14.98$, close to those observed in $Li^+[Re_2(CO)_9(CHO)]^-$ [15,26] and *mer*-Mo{(μ-OCH)Re$_2$(CO)$_9$}(CO)(NO)(PMe$_3$)$_3$ ($\delta = 15.07$).[19a] ^{31}P{^{1}H} NMR spectroscopy reveals a singlet at $\delta = 29.9$ for the four equivalent phosphorus nuclei, with satellites from coupling to ^{183}W ($^1J_{PW} = 287$ Hz). The ^{13}C{^{1}H} NMR spectrum features a resonance at $\delta = 295.1$ for Re*C*HO. During the course of the reaction, the THF solution infrared spectrum had shown the ReCHO ν(C=O) band at 1535 cm^{-1}. However, unlike the reaction with [Fe(CO)$_5$], an equilibrium − lying to the right hand side, in favour of the product (ratio of **1**/**3a**, 2:3) − seems to have been reached after two days. This was also observed in the case of the similar compound *mer*-Mo{(μ-OCH)Re$_2$(CO)$_9$}(CO)(NO)(PMe$_3$)$_3$.[19a] At the same time, the emergence of a series of large multiplets in the dmpe region of the ^{1}H NMR spectrum was observed. The ^{31}P{^{1}H} NMR spectrum also displayed a number of new resonances. These signals are attributable to the isomeric ionic compound $[W(CMes)(CO)(dmpe)_2]^+[Re_2(CO)_9H]^-$ (**3b**). The colour of the solution mixture was brown at this point, and after one week at room temperature, almost 95% yield of this new salt material **3b** was observed spectroscopically (^{31}P{^{1}H} NMR). The ^{31}P{^{1}H} NMR spectrum features four multiplets of intensity 1:1:1:1 for the four chemically different phosphorus atoms at $\delta = 16.8$ (ddd, $^2J_{P3,P4} = 5$ Hz, $^2J_{P3,P2} = 21$ Hz, $^2J_{P3,P1} = 63$ Hz, $^1J_{P3,W} = 249$ Hz, P3), 14.4 (dd, $^2J_{P1,P3} = 65$ Hz, $^2J_{P1,P4} = 20$ Hz, $^1J_{P1,W} = 294$ Hz,

P1), 8.2 (ddd, $^2J_{P4,P1}$ = 20 Hz, $^2J_{P4,P2}$ = 25 Hz, $^2J_{P4,P3}$ = 5 Hz, $^1J_{P4,W}$ = 202 Hz, P4) and −15.5 (dd, $^2J_{P2,P3}$ = 21 Hz, $^2J_{P2,P4}$ = 23 Hz, $^1J_{P2,W}$ = 35 Hz, P2). The chemically distinct phosphorus atoms P1, P2, P3, and P4 have been assigned as described in Scheme 3. The assignments are in agreement with previously published data[4] and reflect the *trans* influence of the carbyne group on P2. It is therefore weakly bonded to the tungsten centre with a small coupling constant ($^1J_{P,W}$ = 35 Hz). For the same reason, $^2J_{P2,P1}$ is apparently so small as to be undetectable. The ^{1}H NMR spectrum shows a singlet at δ = −17.47 for the Re−H hydride and a series of multiplets in the dmpe region, due to the new arrangement of the dmpe ligands around the tungsten centre. The ^{13}C{^{1}H} NMR spectrum displays a multiplet at δ = 293.7 for the mesitylidyne carbon, due to the coupling with the four different phosphorus atoms, and another multiplet at δ = 230 for the W−CO carbon atom ($^2J_{C,P4}$ = 11 Hz). The THF solution infrared spectrum displays, among other characteristic resonances, one band at 1915 cm^{-1} (s), consistent with a terminal W−CO bond. After isolation, **3b** also gave satisfactory elemental microanalytical data.

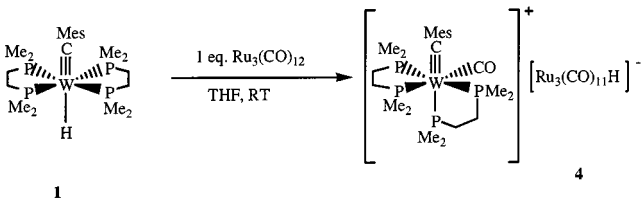
An intrinsic chemical property of transition metal formyl complexes is the capability to transfer a hydride ion to several classes of substrate (such as ketones, alkyl halides, or metal carbonyls), thereby acting as hydride donors. The lability of this metal formyl hydrogen was unambiguously demonstrated with isolated formyl complexes about twenty years ago.[7a,20,21] We propose, after initial attack by H$^-$ directly on coordinated CO, an intramolecular hydride migration from the formyl to the Re, presumably with initial loss of CO − i.e., a slow decarbonylation of **3a** at room temperature − to give the unsaturated complex **3a′**, with subsequent rearrangement around the tungsten centre to give **3b** (Scheme 4). The assumed five-coordinate, square-pyramidal cationic intermediate **3a′** is fluxional by the Berry mechanism (pseudorotation) and gives rise to the trigonal-bipyramidal **3b′** intermediate, which is then trapped by the free CO ligand to give **3b**. It is interesting at this stage to note that a CO ligand in a position *trans* to a carbyne unit has never been observed.[22] The rate-determining step in this reaction seems to be the decarbonylation step.

For *mer*-M(H)(CO)(NO)(PMe$_3$)$_3$ (M = Mo, W), it has been calculated that interaction with transition metal carbonyls such as [Fe(CO)$_5$] and [Re$_2$(CO)$_{10}$] is determined by secondary effects such as solvation or steric interactions, since both carbonyl complexes possess comparable hydride affinities.[19a][19b] For the related carbyne complexes, it is anticipated that similar selectivities with a similar physical background apply.

Compound **1** reacts with one equivalent of the triruthenium cluster [Ru$_3$(CO)$_{12}$] under ambient laboratory conditions in THF to afford the compound [W(CMes)(CO)(dmpe)$_2$]$^+$[Ru$_3$(CO)$_{11}$H]$^-$ (**4**) (Scheme 5), presumably formed via a formyl intermediate. In fact, when the reductive reaction is monitored at −50 °C in [D$_8$]THF, the ^{1}H NMR spectrum displays a resonance at δ = 15.6, suggesting that a pendant formyl moiety has been produced. However, upon raising the temperature in the NMR tube to −20 °C, the formyl signal gradually decreases, with concomitant appearance of a new band (s, Ru−H) at δ −12.05, assigned to **4**. It is known that most of the formyl intermediates are likely to decompose more rapidly than they form.[23] These decomposition reactions of formyl complexes, into the corresponding metal hydride with loss of CO, have received a great deal of attention,[9,24] and radical processes have been invoked in many cases. It is still not clear, however, whether this decomposition is determined by thermodynamic factors or is kinetic in origin.[25] The balance between these will depend on the mechanism of CO loss. For the anticipated cluster formyl complex *trans*-W{(μ-OCH)Ru$_3$(CO)$_{11}$}(CMes)(dmpe)$_2$, the decarbonylation step seems to be facilitated relative to that of **3a**. The fact that the stability of cluster formyl complexes is lower than that of the related mononuclear species has already been noted by Thornback et al.[26] These workers suggested that this instability is associated with the availability of an "α-elimination" mechanism in cluster systems, related to the β-elimination observed in mononuclear systems.



Scheme 4



Scheme 5

The reaction proceeds smoothly at room temperature in THF and is complete within a few minutes. Compound **4** can be isolated in 82% yield as a brown, microcrystalline powder after recrystallisation from a saturated diethyl ether solution. The ^{1}H NMR spectrum features a characteristic singlet at δ = −12.05 for the Ru−H hydride moiety in the cluster anion [HRu$_3$(CO)$_{11}$]$^-$,[27] which is consistent with

the value reported in the literature ($\delta = -12.9$).[28] The $^{31}P\{^1H\}$ NMR spectrum shows four different multiplet signals of intensity 1:1:1:1 at $\delta = 15.9$ (ddd, $^2J_{P3,P1} = 66$ Hz, $^2J_{P3,P2} = 20$ Hz, $^2J_{P3,P4} = 6$ Hz, $^1J_{P3,W} = 269$ Hz, P3), 13.9 (dd, $^2J_{P1,P3} = 65$ Hz, $^2J_{P1,P4} = 19$ Hz, $^1J_{P1,W} = 283$ Hz, P1), 7.8 (ddd, $^2J_{P4,P1} = 19$ Hz, $^2J_{P4,P2} = 25$ Hz, $^2J_{P4,P3} = 6$ Hz, $^1J_{P4,W} = 223$ Hz, P4), and -15.6 (dd, $^2J_{P2,P3} = 20$ Hz, $^2J_{P2,P4} = 25$ Hz, $^1J_{P2,W} = 20$ Hz, P2) for the four nonequivalent phosphorus nuclei. The different phosphorus atoms P1, P2, P3, and P4 have been assigned as described on Figure 1. Atom P2 is again, as in **3b**, very weakly bound with the tungsten centre, and therefore the $^1J_{PW}$ is very small: $^1J_{P2,W} = 20$ Hz. This is not surprising, given the assumed strong *trans* influence/effect of the carbyne ligand in the *trans* position. Consequently, the value of the coupling constant $J_{P2,P1}$ is also very small and has been calculated to be around 2 Hz (Table 1). This is also confirmed by the X-ray structure (Figure 2), in which the long W−P2 distance [2.664(4) Å], compared to the other W−P bond lengths, which are around 2.45, can be seen. Here, as for **3b**, the $^{13}C\{^1H\}$ NMR spectrum once more shows a multiplet at $\delta = 292$, which corresponds to the $C_{carbyne}$ carbon; this value is also further downfield than expected (shifted by 31.6 ppm relative to **1**), presumably due to the weakly bound phosphorus atom in the *trans* position. The infrared spectrum in THF solution exhibits, among other characteristic bands, one band at 1900 cm^{-1} (s) for the W-CO terminal carbonyl group. Compound **4** also gave a satisfactory elemental microanalysis. The $^{31}P\{^1H\}$ NMR spectrum of **4** (Figure 1) has been simulated and calculations carried out in order to evaluate the coupling constants between the four different phosphorus nuclei (Table 1).

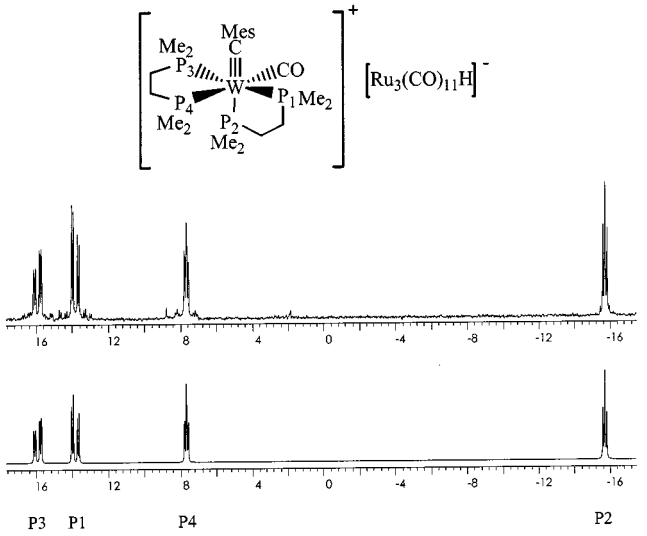


Figure 1. Measured (upper) and simulated (lower) spectra for the dmpe ligands in the $^{31}P\{^1H\}$ NMR spectrum of **4**

Table 1. Calculated shifts and coupling constants between P1, P2, P3, and P4 in compound **4**

Nucleus	Shift (ppm)	Width (Hz)	*J*, P1 (Hz)	*J*, P3 (Hz)	*J*, P4 (Hz)
P1	13.9	4.3		64.6	
P2	−15.7	5.5	2	20.8	23.5
P3	15.9	4.1			
P4	7.7	3.7	19.5	5.8	

Molecular Structure of 4

The structure of the separated ionic complex $[W(CMes)(CO)(dmpe)_2]^+[Ru_3(CO)_{11}H]^-$ (**4**) was finally established unequivocally by single-crystal X-ray diffraction (Figure 2 and Table 2). Suitable crystals were obtained by slow cooling of a saturated diethyl ether solution to −30 °C. Unfortunately, the X-ray structure analysis of **4** was hampered by the poor quality of the crystals, and attempts to achieve suitable crystals of **2** and **3b** were unsuccessful. Therefore, large standard deviations were found for the bond lengths and angles. Selected bond lengths (Å) and angles (°) are listed in Table 3.

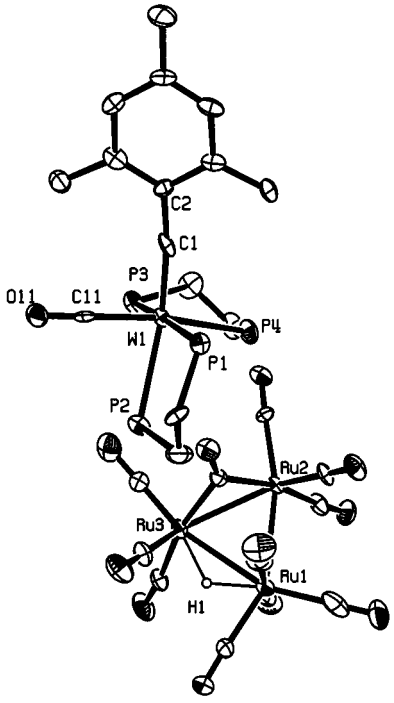

Figure 2. ORTEP plot of compound **4**. Thermal ellipsoids are drawn at the 30% probability level. Hydrogens (except H1) and the Me carbon atoms from the dmpe ligands are omitted for clarity

Compound **4** adopts a pseudo-octahedral geometry, with the carbyne and one phosphorus in axial positions and the equator defined by 3 phosphorus atoms and the carbonyl group.

Conclusions

The results discussed above show that the tungsten hydride complex *trans*-$W(CMes)(dmpe)_2H$ **1** readily reduces group 7 and 8 transition metal carbonyls, acting as a hydride-based nucleophile towards metal-bound CO.

[a] See Figure 2 for atom designations.

This observed high propensity towards carbonyl insertion into the W−H bond resembles that found for metallocene hydride compounds with early transition metal centres.[29]

Experimental Section

General: All manipulations of air-sensitive compounds were carried out either in a Braun Labstar glovebox under nitrogen (dried if appropriate) by conventional Schlenk techniques. Solvents were dried with appropriate drying agents[30] and freshly distilled under nitrogen prior to use. The different transition metal carbonyl compounds $Fe(CO)_5$ (Alfa products), $Re_2(CO)_{10}$ (Fluka), and $Ru_3(CO)_{12}$ (Aldrich) were commercial products and used as received. The deuterated solvents (C_6D_6, [D_8]toluene, and [D_8]THF) were also obtained from commercial suppliers and distilled from appropriate drying agents and vacuum transferred for storage in Schlenk flasks fitted with Teflon stopcocks. The dmpe ligand was synthesized by following modified literature procedures.[31] − ^{1}H, ^{13}C, and ^{31}P NMR spectra were run either on a Varian Gemini 300 spectrometer operating at 300, 75.4, and 121.5 MHz, respectively, or on a Bruker DRX 500 spectrometer at 500.2, 125.8, and 202.5 MHz, respectively. Values of δ(^{1} H), δ(^{13}C), relative to $SiMe_4$, δ(^{31}P) relative to 85% H_3PO_4. − Mass spectra (EI or FAB) were recorded on a Finnigan MAT 8230 mass spectrometer. − IR spectra: Bio-Rad FTS-45 instrument. − Elemental analyses: LECO CHNS-932 machine. − The simulation of the ^{31}P{^{1}H} NMR spectrum was carried out with the aid of the gNMR 4.1 program. The optimal fit was attained by simultaneous iteration of the chemical shifts and coupling constants.

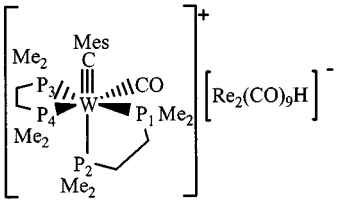
Preparation of *trans*-W(CMes)(dmpe)$_2$(H) (1): The synthesis of **1** has already been published elsewhere.[2] Only the spectroscopic data for **1** are given here. − ^{1}H NMR (C_6D_6, 298 K): δ = 6.72 (s, 2 H, Mes), 2.62 (s, 6 H, 2CH_3-Mes), 2.05 (s, 3 H, CH_3-Mes), 1.67 (s br, 12 H, PMe), 1.52 (m br, 4 H, PCH_2), 1.46 (s br, 12 H, PMe′), 1.42 (m br, 4 H, PCH_2′), −6.58 (quint, $^2J_{HP}$ = 32 Hz, $^1J_{HW}$ = 31 Hz, 1 H, WH). ^{31}P{^{1}H} NMR (C_6D_6, 298 K): δ = 24.4 (s, $^1J_{PW}$ = 281 Hz). ^{13}C {^{1}H} NMR (C_6D_6, 298 K): δ = 260.4 (quint, $^2J_{CP}$ = 10 Hz, CMes), 151.5 (s, *ipso*-Mes), 137.4 (s, *o*-Mes), 135.4 (s, *p*-Mes), 130.8 (s, *m*-Mes), 34.0 (quint, PCH_2), 27.8 (m, PMe), 25.4 (m, PMe′), 22.6 (s, 2CH_3-Mes), 21.5 (s, CH_3-Mes). ^{183}W{^{1}H} NMR ([D_8]toluene, 298 K): δ −1612 (pseudo-q, $^1J_{WP}$ = 281 Hz). MS (FAB, toluene): *m*/*z* = 615 [M$^+$], 310 (M$^+$ − 2dmpe). − $WC_{22}H_{44}P_4$ (615.73): calcd. C 42.87, H 7.15%; found C 42.67, H 7.28%.

Preparation of *trans*-W{(μ-OCH)[Fe(CO)$_4$]}(CMes)(dmpe)$_2$ (2): Compound **1** (30 mg, 0.0487 mmol) was dissolved in THF (5 mL) and $Fe(CO)_5$ (6.6 μL, 0.0487 mmol) added by microsyringe. The mixture was stirred for a few minutes at room temperature. After this period, the solvent was evaporated in vacuo and the precipitate recrystallised from a diethyl ether solution at −30 °C to afford **2** as orange crystals. Yield: 33 mg (84%). − IR (cm^{-1}, THF): 2045, 1967, 1932 [Fe(CO)$_4$], 1576 (formyl), 894 (CMes). − ^{1}H NMR ([D_8]THF, 298 K): δ = 13.67 (s, 1 H, OC*H*), 6.53 (s, 2 H, Mes), 2.25 (s, 6 H, 2CH_3-Mes), 1.94 (s, 3 H, CH_3-Mes), 1.40 (m br, 4 H, PCH_2), 1.34 (s br, 12 H, PMe), 1.28 (m br, 4 H, PCH_2′), 1.20 (s br, 12 H, PMe′). − ^{31}P{^{1}H} NMR ([D_8]THF, 298 K): δ = 32.2 (s, $^1J_{PW}$ = 288 Hz). − ^{13}C{^{1}H} NMR ([D_8]THF, 298 K): δ = 298.6 (q, $^3J_{CP}$ = 5 Hz, O*C*H), 275.3 (quintet, $^2J_{CP}$ = 10 Hz, CMes), 218.5 [s, Fe(CO)$_4$], 151.2 (s, *ipso*-Mes), 135.2 (s, *o*-Mes), 133.1 (s, *p*-Mes), 128.3 (s, *m*-Mes), 33.5 (m, $^1J_{CP}$ = 10 Hz, PCH_2), 22.2 (s, 2CH_3-Mes), 22.1 (m, $^1J_{CP}$ = 7 Hz, PMe), 20.4 (s, CH_3-Mes), 17.4 (m,

$^1J_{CP}$ = 7 Hz, PMe′). − $C_{27}H_{44}P_4O_5FeW$ (811.58): calcd. C 39.92, H 5.42%; found C 40.21, H 4.90%.

Preparations of *trans*-W{(μ-OCH)[$Re_2(CO)_9$]}(CMes)(dmpe)$_2$ (3a) and [W(CMes)(CO)(dmpe)$_2$]$^+$[$Re_2(CO)_9H$]$^-$ (3b): Compound **1** (30 mg, 0.0487 mmol) was dissolved in THF (5 mL), $Re_2(CO)_{10}$ (32 mg, 0.0487 mmol) was added, and the mixture was stirred for a few minutes at room temperature. After this period, NMR examination in [D_8]THF already showed a spectroscopically small amount (36%) of **3a**. After two days at room temperature, the amount of **3a** was about 67%. − IR (cm^{-1}, THF): 1535 (ReCHO). − ^{1}H NMR ([D_8]THF, 298 K): δ = 14.98 (s, 1 H, OC*H*), 6.50 (s, 2 H, Mes), 2.31 (s, 6 H, 2CH_3-Mes), 1.91 (s, 3 H, CH_3-Mes), large multiplets for the dmpe ligands between δ = 1.40 and 1.20. − ^{31}P{^{1}H} NMR ([D_8]THF, 298 K): δ = 29.9 (s, $^1J_{PW}$ = 287 Hz). − ^{13}C{^{1}H} NMR ([D_8]THF, 298 K): selected data: δ = 295.1 (Re-*C*HO), 205.1, 202.5, 195.4, 191.5 (Re-CO).

After one week at room temperature, an almost quantitative yield of **3b** was observed spectroscopically, and recrystallisation from a saturated diethyl ether solution gave a final yield of 72%.



3b

IR (cm^{-1}, THF): 2086, 2028, 1974, 1925, 1895 ($Re_2(CO)_9H^-$), 1915 (W−CO), 891 (CMes). − ^{1}H NMR ([D_8]THF, 298 K): δ = 6.71 (s, 2 H, Mes), 2.51 (s, 6 H, 2CH_3-Mes), 2.01 (s, 3 H, CH_3-Mes), series of large multiplets for the dmpe ligands between δ = 1.87 and 1.34, −17.47 (s, Re-H). − ^{31}P{^{1}H} NMR ([D_8]THF, 298 K): δ = 16.8 (ddd, $^2J_{P3,P4}$ = 5 Hz, $^2J_{P3,P2}$ = 21 Hz, $^2J_{P3,P1}$ = 63 Hz, $^1J_{P3,W}$ = 249 Hz, P3), 14.4 (dd, $^2J_{P1,P3}$ = 65 Hz, $^2J_{P1,P4}$ = 20 Hz, $^1J_{P1,W}$ = 294 Hz, P1), 8.2 (ddd, $^2J_{P4,P1}$ = 20 Hz, $^2J_{P4,P2}$ = 25 Hz, $^2J_{P4,P3}$ = 5 Hz, $^1J_{P4,W}$ = 202 Hz, P4), −15.5 (dd, $^2J_{P2,P3}$ = 21 Hz, $^2J_{P2,P4}$ = 23 Hz, $^1J_{P2,W}$ = 35 Hz, P2). − ^{13}C{^{1}H} NMR ([D_8]THF, 298 K): δ = 293.7 (m, CMes), 230.0 (m, $^2J_{C,P4}$ = 11 Hz, W-CO), 202.2, 201.9, 199.8, 198.7, 190.5 (5s, $Re_2(CO)_9H^-$), 147.0 (s, *ipso*-Mes), 139.2 (s, *o*-Mes), 138.3 (s, *p*-Mes), 129.3 (s, *m*-Mes), 12 multiplets between δ = 32 and 14 for the 12 different carbon atoms in the dmpe ligands, 21.6 (s, 2CH_3-Mes), 20.9 (s, CH_3-Mes). − $C_{32}H_{44}P_4O_{10}Re_2W{\cdot}1/2Et_2O$ (1305.13): calcd. C 30.34, H 3.75%; found C 30.82, H 3.40%.

Preparation of [W(CMes)(CO)(dmpe)$_2$]$^+$ [$Ru_3(CO)_{11}H$]$^-$ (4): A mixture of **1** (30 mg, 0.0487 mmol) and $Ru_3(CO)_{12}$ (31.10 mg, 0.0487 mmol) in THF (5 mL) was stirred for 1 hour at room temperature. After this period, the solvent was evaporated in vacuo and the precipitate recrystallised at −30 °C from a diethyl ether solution to afford **4** as brown microcrystals. Yield: 24.6 mg (82%). − IR (cm^{-1}, THF): 2073, 2014, 1987, 1952 ($Ru_3(CO)_{11}H^-$), 1900 (W−CO), 892 (CMes). − ^{1}H NMR ([D_8]THF, 298 K): δ = 6.49 (s, 2 H, Mes), 2.27 (s, 6 H, 2CH_3-Mes), 1.90 (s, 3 H, CH_3-Mes), series of large multiplets for the dmpe ligands between δ = 1.47 and 1.08, −12.05 (s, Ru-H). − ^{31}P{^{1}H} NMR ([D_8]THF, 298 K): δ = 15.9 (ddd, $^2J_{P3,P1}$ = 66 Hz, $^2J_{P3,P2}$ = 20 Hz, $^2J_{P3,P4}$ = 6 Hz, $^1J_{P3,W}$ = 269 Hz, P3), 13.9 (dd, $^2J_{P1,P3}$ = 65 Hz, $^2J_{P1,P4}$ = 19 Hz, $^1J_{P1,W}$ = 283 Hz, P1), 7.8 (ddd, $^2J_{P4,P1}$ = 19 Hz, $^2J_{P4,P2}$ = 25 Hz, $^2J_{P4,P3}$ = 6 Hz, $^1J_{P4,W}$ = 223 Hz, P4), −15.6 (dd, $^2J_{P2,P3}$ = 20 Hz, $^2J_{P2,P4}$ = 25 Hz, $^1J_{P2,W}$ = 20 Hz, P2). − ^{13}C{^{1}H} NMR ([D_8]THF, 298 K): δ = 292 (m, CMes), 229.1 (m, W-CO), 211 (s), 205 (s), 203 (s), 198 (s) $Ru_3(CO)_{11}H^-$, 146.0 (s, *ipso*-Mes), 138.2 (s, *o*-Mes), 134.1 (s, *p*-Mes), 130.5 (s, *m*-Mes), 12 multiplets between δ = 36 and 15 for the 12 different carbon atoms in the dmpe ligands, 22.6 (s, 2CH_3-Mes), 20.1 (s, CH_3-Mes). − $C_{34}H_{44}P_4O_{12}Ru_3W$ (1254.34): calcd. C 32.51, H 3.51%; found C 32.31, H 3.70%.

Crystallography: Single crystals of **4**, of rather poor quality for X-ray studies, were obtained directly from the preparation as described in the Experimental Section. A dark red crystal of **4** with dimensions 0.18 × 0.17 × 0.14 mm was selected and mounted on the top of a glass fibre covered with a small amount of hydrocarbon oil and immediately placed on the goniometer of a Stoe IPDS diffractometer. The radiation used was Mo-*Kα* (0.71073), monochromatised by a crystal of graphite [the crystal-to-image plate distance was set to 50 mm (θmax = 30.33°)]. Because of the long exposure time, the -oscillation scan mode was selected and a total of 223 images were collected at 183 K. Each exposure required 10 min. and covered 0.9° in . The intensities were integrated after using a dynamic peak profile analysis, and estimated mosaic spread check was performed to prevent overlapping intensities. 7998 reflections were selected out of the whole limiting sphere for the cell parameter refinement. A total of 27290 reflections were collected, of which 12450 reflections were unique (*R*int = 0.1016). A numerical absorption correction based on measured crystal faces was applied without any improvement. Therefore, an empirical absorption correction utilising the program (ABSCOR)[32] was considered (maximum and minimum values of the transmission factor were 0.6273 and 0.5577).

Compound **4** crystallised in the triclinic crystal system. The space group $P\bar{1}$ was assumed and confirmed by the successful solution and refinement of the structure. The structure was solved by a combination of direct methods and difference Fourier synthesis (SHELXS-97)[33] and refined on F^2 by full-matrix, least-squares techniques (SHELXL-97).[33] All non-hydrogen atoms were refined with anisotropic thermal parameters, except C30 which resulted as non-positive definite. All hydrogen atom positions on the ligands were calculated assuming idealised geometries. The position of the hydride was found in a difference Fourier synthesis, but its position could not be refined. It was added as a constant contribution without refinement. At convergence, *R*1 = 0.0827, *wR*2 = 0.2169 and GooF = 1.067 for 483 variables refined using 12450 unique data.

Supplementary Material: Crystallographic data for the structural analysis has been deposited with the Cambridge Crystallographic Data Centre, CCDC No 150504 for compound **4**. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk, or http://www.ccdc.cam.ac.uk].

Defective Double-Cubane, Tetranuclear Manganese(II) and Cobalt(II) Complexes with Simultaneous $\mu_{1,1}$-Azido and μ-O Bridges

Giannis S. Papaefstathiou,[a][‡] Albert Escuer,[b] Catherine P. Raptopoulou,[c] Aris Terzis,*[c] Spyros P. Perlepes,*[a] and Ramon Vicente*[b]

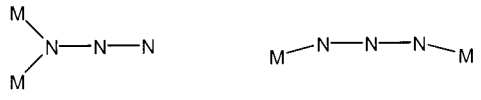
Keywords: Azides / Cobalt / Di-2-pyridyl ketone / Magnetic properties / Manganese

The reactions of $M(O_2CCH_3)_2{\cdot}4H_2O$ (M= Mn, Co) with di-2-pyridyl ketone, $(py)_2CO$, and NaN_3 in CH_3OH or CH_3OH/H_2O allow isolation of the tetranuclear compounds $[Mn_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]$ (**1**) and $[Co_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]{\cdot}2H_2O$ (**2**). X-ray diffraction analysis reveals defective double-cubane tetrameric entities in which the Mn^{II} or Co^{II} atoms are linked by $\mu_{1,1}\text{-}N_3$ bridges and two kinds of O-bridges. The molar magnetic susceptibility measurements of **1** and **2** in the 2–300 K range indicate weak antiferromagnetic coupling for **1** and clear bulk ferromagnetic coupling for **2**.

Introduction

There is currently a great deal of interest in the synthesis of polynuclear metal complexes exhibiting ground electronic states with a large number of unpaired electrons, since it has been discovered that a fairly large ground-state *S* value is one of the necessary requirements for molecules to be able to exhibit the behaviour of a single-molecule magnet.[1−3] The high-spin ground state results from either ferromagnetic (or ferrimagnetic) exchange interactions between the metal ions in the molecule, or topologically frustrated antiferromagnetic interactions.[4] In the known polynuclear SMM's, magnetic exchange interactions are propagated by bridging OH^-, OR^-, O^{2-}, or RCO_2^- ligands, or a combination of two or more of these groups. These interactions often lead to antiferromagnetic coupling and, thus, it is necessary to arrange the metal ions and bridging ligands in an appropriate manner so that they can give a high-spin ground state for the system. An alternative attractive approach would be the replacement of one or more of the above-mentioned bridging ligands with other groups that are more prone to ferromagnetic coupling.

One of the most well-known ferromagnetic couplers is the azido ligand when it bridges metal ions in the 1,1-fashion. Azides usually bridge through the two terminal nitrogen atoms (μ-1,3-azido) or through only one of the terminal nitrogen atoms (μ-1,1-azido) (Scheme 1). In the latter case, the coupling between the bridged paramagnetic metal ions is ferromagnetic for a wide range of M−N−M angles.[5]



$\mu_{1,1}\text{-}N_3^-$ $\mu_{1,3}\text{-}N_3^-$

Scheme 1

The structural and electronic versatility of the azido ligand has prompted researchers to investigate its coordination chemistry in order to probe deeper into the exchange interactions of azido-bridged complexes and to correlate magnetic behaviour with molecular structure. For example, the work performed on azido-bridged polynuclear manganese(II) complexes has become a fast growing research field, not only due to the large variety of topologies that these compounds adopt, but also because of the interesting magnetic properties that arise from these systems.[6−25] In some of these compounds, the two different bridging coordination modes of the azido ligand (Scheme 1) can be found simultaneously in the same molecule, leading to materials which alternate the ferro- and antiferromagnetic superexchange pathways.

On the other hand, employment of di-2-pyridyl ketone, $(py)_2CO$ (**I**, Scheme 2), as a templating ligand for the synthesis of polynuclear complexes, has resulted, amongst others, in the construction of tetra-,[26−33] hepta-,[34] octa-,[35,36] nona-[32] and dodecanuclear[34] metal cages. The ability of $(py)_2CO$ to undergo metal-mediated nucleophilic addition of small molecules, such as water or alcohols (ROH), to the carbonyl group results in the formation of the hydrate **II** or the hemiacetal **III** (Scheme 2). The structural diversity of the resultant species stems from the ability of the singly and doubly deprotonated anions of the *gem*-diol form **II** to adopt a variety of coordination modes, and sometimes two different modes may also occur in the same complex. The monoanions of **II** and **III** usually bridge three and two metal ions, respectively (Scheme 3), giving rise to high nuclearity metal cages, while the dianion of **II** can bridge as many as five metal ions, resulting in higher nuclearity metal complexes. Since the degree of deprotonation of the *gem*-diol $(py)_2C(OH)_2$ (**II**) has been well established,

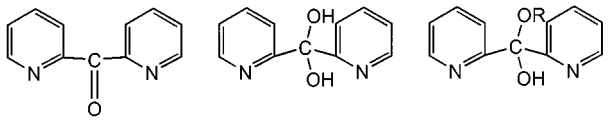
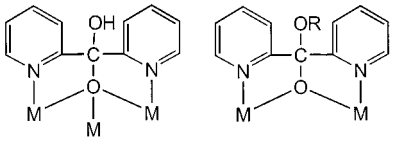
the nuclearity of the resultant species can be considered more or less as "controlled".



$(py)_2CO$, **I** $(py)_2C(OH)_2$, **II** $(py)_2C(OR)OH$, **III**

Scheme 2



$\eta^1:\eta^3:\eta^1:\mu_3$ $\eta^1:\eta^2:\eta^1:\mu_2$

Scheme 3

The magnetic properties of the metal cages based on the anions of **II** range from noninteracting[28] to antiferromagnetic[29,30,32,34–36] and ferromagnetic-coupled[26,27,31,32] systems. This variety of magnetic properties is a consequence of the metal topology that the cages adopt, which is influenced not only by the coordination mode of the $(py)_2CO$-based anions but also by the other ligands present in the structure. Therefore, an interesting possibility is to combine the azido and $(py)_2CO$-based anionic ligands in the same compound. We report here the synthesis and magneto-structural characterisation of the tetranuclear compound $[Mn_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]$ (**1**). In this compound the azido bridging coordination mode is end-on and should furnish a ferromagnetic superexchange pathway. We also report the synthesis and magneto-structural characterisation of the analogous cobalt(II) compound $[Co_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]\cdot 2H_2O$ (**2**). The interest in this new compound, apart from the above considerations, is found in the fact that polynuclear Co^{II} compounds with azido bridging ligands are rare.[37–44] Previously, only two mixed azido-$(py)_2CO$ complexes with Ni^{II} as the metal ion have been published.[26,27]

Results and Discussion

Synthesis

The preparation of compounds **1** and **2** can be achieved by the reaction of $M(O_2CH_3)_2 4H_2O$ with $(py)_2CO$ and NaN_3 in CH_3OH (**1**) or CH_3OH/H_2O (**2**) at room temperature. The preparation of both complexes can be summarised by Equation (1).

The metal(II)-mediated solvolysis of $(py)_2CO$ to give the monoanions of the hydrate **II** and the hemiacetal **III** (Scheme 2) involves a nucleophilic attack of ROH molecules (R = Me or H) on the carbonyl group. In such reactions it might not be necessary for the carbonyl atom to be coordinated to the metal centre; the induced polarisation from the pyridyl nitrogen atoms might be sufficient.[45] There are few examples in which the ketone group of $(py)_2CO$ is attacked by alcohols or water in the presence of metal ions, but the presence of the monoanions of both the hydrate and the hemiacetal in the same complex is rare, with the $[Ni_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]$[26] complex being the only example until now.

IR Spectra

Complexes **1** and **2** exhibit identical IR spectra and, thus, only the IR spectrum of **1** is discussed. This complex exhibits an intense band centred at 2061 cm^{-1}, assigned to the asymmetric stretching mode of the azide. This band is split (2074 and 2048 cm^{-1}) due to the presence of two coordination modes of the azide in the molecular structure of **1**. The spectrum does not exhibit a band in the region expected for $\nu(C{=}O)$ absorption [1684 cm^{-1} for the free $(py)_2CO$]. The nearest band is at 1600 cm^{-1} and is assigned as a pyridine stretching mode raised from 1582 cm^{-1} on coordination, as observed previously,[30] on complex formation involving the solvolysis of $(py)_2CO$. Additionally, the spectrum reveals the bands corresponding to the skeleton vibrations of the coordinated $(py)_2CO$ which appear at slightly shifted frequencies relative to the free ligand. Thus, bands for coordinated $\{(py)_2C(OR)O\}^-$ [free $(py)_2CO$] are: 1570 [1578/1544] and 1114 [998] cm^{-1} attributed to the pyridyl ring stretching, 774/754 [753/742] for the pyridyl ring C–H out-of-plane bending, and 680 [662] due to the pyridyl ring in-plane vibration.

X-ray Crystal Structures

$[Mn_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]$ (1)

A labelled plot of the structure of the tetranuclear compound $[Mn_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)\text{-}O\}_2]\cdot 2H_2O$ (**1**) is shown in Figure 1. Selected distances and angles are listed in Table 1. The structure consists of centrosymmetric tetranuclear molecules. The four Mn^{II} atoms are located at four corners of a defective double

$$4M(O_2CCH_3)_2\cdot 4H_2O + 4NaN_3 + 4(py)_2CO + 2CH_3OH + nH_2O \xrightarrow[20\,^\circ C]{S} [M_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]\cdot nH_2O + 4CH_3CO_2H + 4CH_3CO_2Na + 14H_2O \quad (1)$$

1: M = Mn^{II}, S = CH_3OH

2: M = Co^{II}, n = 2, S = CH_3OH/H_2O

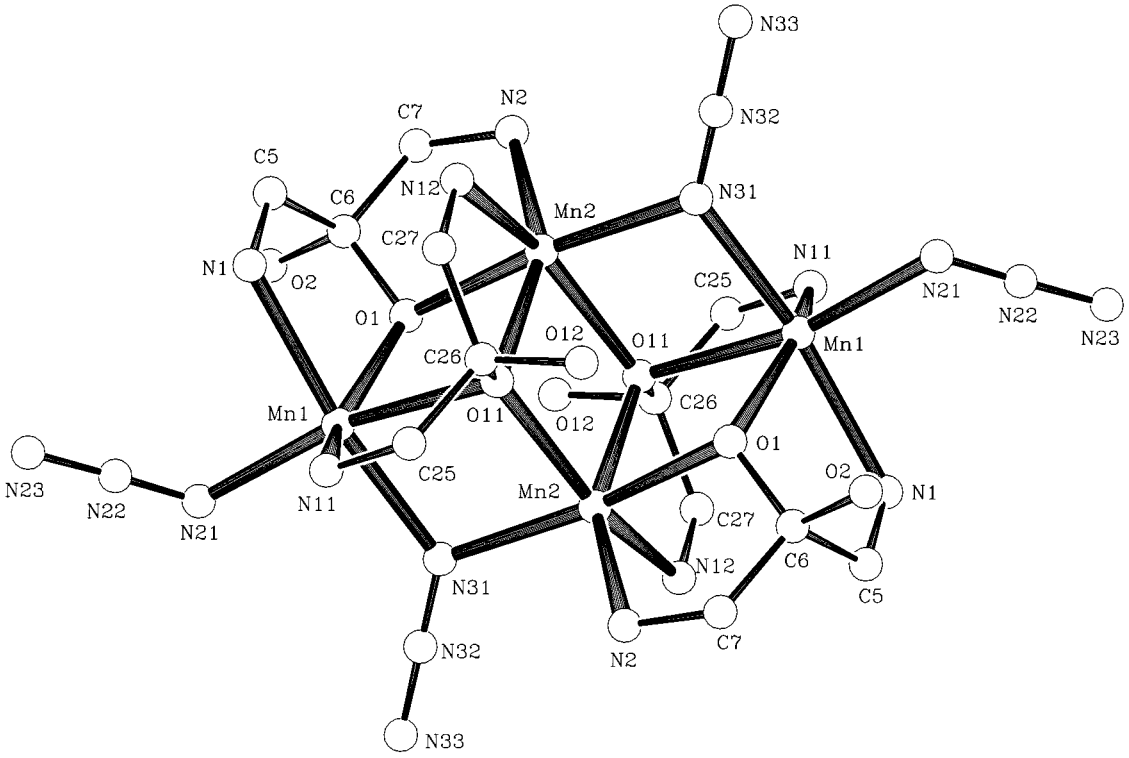


Figure 1. Labelled plot of $[Mn_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)\text{-}O\}_2]\cdot 2H_2O$ (**1**); the structure and numbering of the atoms is the same for compound **2**, replacing Mn(1) and Mn(2) with Co(1) and Co(2), respectively

[a] Symmetry transformations used to generate equivalent atoms #1: $-x+1, -y, -z+2$.

cubane (two cubanes sharing one face and each missing one vertex) and bridged by means of two end-on azido ligands and O atoms from the $(py)_2C(OH)O^-$ and $(py)_2C(OCH_3)O^-$ anions (Scheme 3). Peripheral ligation is provided by the nitrogen atoms of the two terminal azido ligands and the eight 2-pyridyl rings. The O(11) atoms of the $(py)_2C(OH)O^-$ ligands are triply bridging with distances to the Mn^{II} atoms in the range 2.137(3)−2.305(3) Å. The Mn(1)−O(11)−Mn(2) angles are 98.1(1)° and 98.6(1)°. The O(1) atoms of the $(py)_2C(OCH_3)O^-$ ligands are doubly bridging with distances of 2.155(3) and 2.242(3) Å to Mn(1) and Mn(2), respectively. The Mn(1)−O(1)−Mn(2) angle is 100.0(1)°. One O atom of each $(py)_2C(OH)O^-$ and $(py)_2C(OCH_3)O^-$ ligands remains protonated and unbound to the metal atoms. Mn(1) and Mn(2) are also bridged by the N(31) atom of the $\mu_{1,1}$-azido ligand. The Mn(1)−N(31) and Mn(2)−N(31) distances are 2.210(5) and 2.167(4) Å, respectively. The Mn(1)−N(31)−Mn(2) angle is 101.7(2)°. The Mn(1) octahedral coordination is completed by the N(11) atom of the $(py)_2C(OH)O^-$ ligand, the N(1) atom of the $(py)_2C(OCH_3)O^-$ ligand and the N(21) atom of the terminal azido ligand. The Mn(2) octahedral coordination is completed by the N(2) and the N(12) atoms of the $(py)_2C(OCH_3)O^-$ and $(py)_2C(OH)O^-$ ligands, respectively.

$Co_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]\cdot 2H_2O$ (2)

Selected distances and angles are presented in Table 2. The structure of **2** is very similar to the structure of **1**. As expected, distances and angles are slightly different with respect to the analogous parameters in **1**: bond lengths are shorter in **2** and bond angles in the bridging region are ±3°, for details see Table 2.

Magnetic Properties

The $\chi_M T$ vs. T plot of **1** in the 300−2 K range is shown in Figure 2. $\chi_M T$ has a practically constant value of 17.1 cm^3 K mol^{-1} in the 300−115 K range and then decreases to 14.3 cm^3 K mol^{-1} at 2 K. χ_M increases on cooling and does not have any maximum in the studied temperature range. The overall behaviour of **1** indicates a dominant weak antiferromagnetic coupling. The magnetic data of **1**, according to its structure (Scheme 4), should be analysed by an analytical expression based on the Hamiltonian in Equation (2)

$$H = -J_1(S_1S_2 + S_3S_4) - J_2(S_2S_3 + S_4S_1) - J_3(S_2S_4) - J_4(S_1S_3) \quad (2)$$

for local spin values $S = 5/2$. The number of the spins follows the numbering of the atoms in Scheme 4 (J_4 correlates atoms 1 and 3).

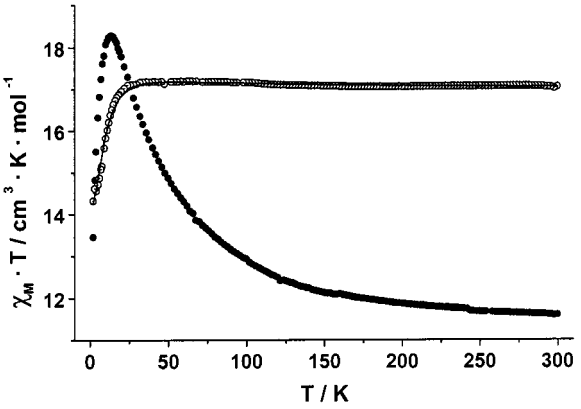

Figure 2. $\chi_M T$ plot versus T for compounds **1** (dot centred circles) and **2** (filled circles); solid lines correspond to the best fit obtained for **1**

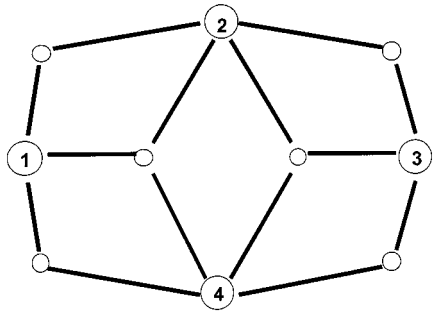

Scheme 4

Although the analytical expression with four different J values does not exist, the eigen values of the spin states can be calculated by means of the full-matrix diagonalisation of Equation (2), by using the CLUMAG program.[47] The best-fit parameters obtained were $J_1 = -1.56$ cm^{-1}, $J_2 = 0.53$ cm^{-1}, $J_3 = -1.49$ cm^{-1}, $J_4 = -0.01$ cm^{-1}, $g = 1.98$, $R = 2.1 \times 10^{-5}$.

The molar magnetisation data at 2 K in the 0−5 T range are shown in Figure 3. On increasing the field, the magnetisation value increases slowly with reference to the expected value for four isolated Mn^{II} atoms with $g = 2.0$, and the final value of 14.91 is far from the expected value of 20, which is in agreement with a dominant antiferromagnetic coupling. The coupling between Mn(2) and Mn(1) through the $\mu_{1,1}$-azido ligand with a Mn−N−Mn angle of 101.7(2)° should be ferromagnetic,[5] but for complexes containing the $\{Mn_2(\mu_2\text{-OR})_2\}^{2+}$ core and an Mn−O−Mn angle in the range of 80−110°, the coupling should be antiferromagnetic,[48] as is the case in **1**. For this reason the superexchange pathway through simultaneous $\mu_{1,1}$-azido and μ-O bridges is indeterminate in sign. From Equation (2), J_1 and J_2 are indistinguishable by symmetry; the values of $J_1 = -1.56$ cm^{-1} and $J_2 = 0.53$ cm^{-1} may be reasonably assigned, by sign, to the $(\mu_2\text{-OR})_2$ and {(μ-OR)($\mu_{1,1}$-Azido)} superexchange pathways, respectively. The value of $J_3 = -1.49$ cm^{-1} is in accordance with a superexchange pathway only through the μ-O bridges. The negligible value of J_4 is, as expected, due to the large distance between the 1 and 3 spin carriers. The EPR spectrum of **1** recorded on a powdered sample at room temperature shows an isotropic signal centred at $g = 2.02$ with a peak-to-peak line width of 1340 G. This signal is temperature dependent and the spectrum at 4 K shows a complicated pattern of signals.

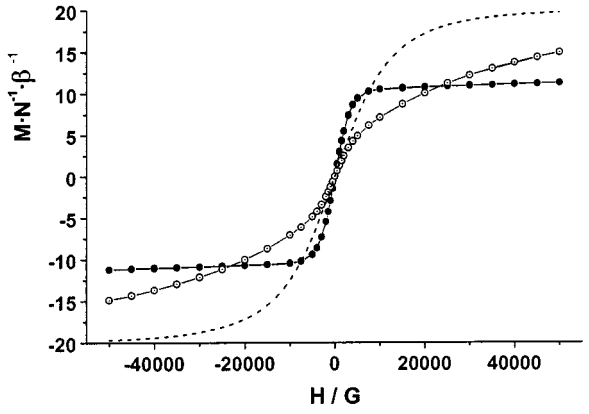

Figure 3. Molar magnetisation isotherms at 2 K for compounds **1** (dot centred circles) and **2** (filled circles); the dashed line corresponds to the generated Brillouin behaviour for four isolated Mn^{II} ions

The plot of $\chi_M T$ vs. T for **2** in the 300−2 K range is also shown in Figure 2 (filled circles). $\chi_M T$ increases quickly on cooling from 11.60 cm^3 K mol^{-1} at 300 K to a maximum of 18.3 cm^3 K mol^{-1} at 13 K, after which it decreases to 13.4 cm^3 K mol^{-1} at 2 K. χ_M increases on cooling and does not have any maximum in the temperature range studied. The overall behaviour of **2** corresponds to a ferromagnetically coupled system. The strong ferromagnetic interaction in **2** is confirmed by the molar magnetisation measurement at 2 K, which shows a quick increase in M by increasing the external field, arriving at a final value of 11.26 (Figure 3). This strong coupling between Co(2) and Co(1) permits us to assume that the interactions through the $\mu_{1,1}$-azido and the μ-OR$^-$ bridge with a Co−O−Co angle of 96.8(1)° are both ferromagnetic, indicating a magnetic behaviour close to the related Ni^{II} derivatives previously reported.[26,27] Analysis of the coupling constants for a high-spin rhombic cobalt(II) tetramer is not possible by means of an effective Hamiltonian based on four $S = 3/2$ spins, due to the large anisotropy of this ion. At low temperature the local spin of the Co^{II} is closer to 1/2, and hence the low-temperature data are better defined as an $S_T = 2$ system with a large g_{eff} value.

The above description is in agreement with the EPR spectrum of **2** recorded on a powdered sample at 4 K (Figure 4), which shows only one absorption at very low field. For an axial integer $S = 2$ spin system, the zero-field interaction (D parameter) splits the m_s levels into two doublets $m_s = |\pm 2>$ and $|\pm 1>$ and one $m_s = |0>$ state. Transitions be-

tween these Kramer doublets are not possible due to the large D value expected for the cobalt(II) ion. For a rhombic distortion, the E parameter splits the $m_s = |\pm 2>$ and $|\pm 1>$ Kramer doublets giving a Δ_2 and Δ_1 gap at zero field. The Δ_1 increase is strongly dependent on E and is usually much greater than the $g\beta H$ energy of an X-band measurement. In contrast, the Δ_2 increase is a function of E^2/D and the ± 2 transition usually lies in the low-field region of the spectra.[49] The expected spectra for an $S = 2$ system then consist of only one signal at very low field, which is in agreement with the experimental spectrum of **2**, and the above assumption to avoid treatment of this system as a simple tetramer of 3/2 spins is correct. This type of EPR spectra is similar to those of manganese(III) and iron(IV) spectra reported in the literature.[50,51]

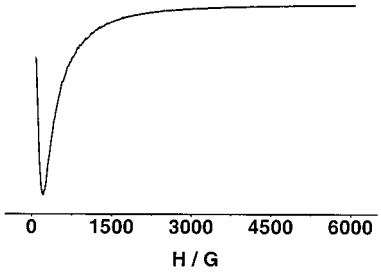

Figure 4. X-band EPR spectrum of a powdered sample of compound **2**, showing the ± 2 transition at low field corresponding to the $S = 2$ anisotropic ground state

Experimental Section

Physical Methods: Magnetic susceptibility measurements were carried out for polycrystalline samples of **1** and **2** with a SQUID susceptometer working in the range 2−300 K under magnetic fields of approximately 0.1 T. Diamagnetic corrections were estimated from Pascal Tables. The infrared spectra (4000−400 cm^{-1}) were recorded from KBr pellets on a Nicolet 520 FTIR spectrometer. EPR spectra were recorded on a Bruker ES200 spectrometer at X-band frequency.

Preparation of $[Mn_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]$ (1): Solid $Mn(O_2CCH_3)_2{\cdot}4H_2O$ (0.15 g, 0.61 mmol) was dissolved with stirring in a solution of $(py)_2CO$ (0.22 g, 1.19 mmol) and NaN_3 (0.08 g, 1.23 mmol) in CH_3OH (20 cm^3). The pale brown-yellow solution was allowed to slowly concentrate by evaporation at room temperature for 24 h. The resultant orange well-formed crystals were collected by filtration, washed with small amounts of CH_3OH (5 cm^3) and Et_2O (2 × 5 cm^3), and dried in vacuo. Yield: 95 mg, 50%. − $C_{46}H_{40}Mn_4N_{20}O_8$ (1220.7): calcd. C 45.26, H 3.30, N 22.95; found C 45.12, H 3.28, N 22.97. − Selected IR data (KBr pellet): $\tilde{\nu}$ = 3074 (w), 2964 (w), 2074 (vs), 2048 (vs), 1600 (s), 1570 (m), 1470 (m), 1438 (s), 1334 (m), 1060 (s), 1014 (m), 776 (m), 754 (m), 680 (m) cm^{-1}. Complex **1** can also be isolated by employing $Mn(O_2CCH_3)_2 4H_2O/(py)_2CO/NaN_3$ molar ratios of 1:1:1, 1:3:3, 1:2:4 and 1:4:4.

Preparation of $[Co_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]{\cdot}2H_2O$ (2): A solution of NaN_3 (0.04 g, 0.61 mmol) in H_2O (5 cm^3) was added to a stirred solution of $Co(O_2CCH_3)_2{\cdot}4H_2O$ (0.15 g, 0.61 mmol) and $(py)_2CO$ (0.11 g, 0.60 mmol) in CH_3OH (20 cm^3) at ambient temperature. Crystallisation of a pink solid began after ca. 20 min. When precipitation was judged to be complete, the pink microcrystalline solid was collected by filtration, washed with small amounts of CH_3OH (5 cm^3) and Et_2O (2 × 5 cm^3), and dried in vacuo. Yield: 140 mg, 75%. − $C_{46}H_{44}Co_4N_{20}O_{10}$ (1272.7): calcd. C 43.41, H 3.48, N 22.01; found C 43.60, H 3.32, N 22.38. − Selected IR data (KBr pellet): $\tilde{\nu}$ = 3074 (w), 2964 (w), 2074 (vs), 2048 (vs), 1600 (s), 1570 (m), 1470 (m), 1438 (s), 1334 (m), 1060 (s), 1014 (m), 776 (m), 754 (m), 680 (m) cm^{-1}. X-ray quality crystals of **2** were obtained by slow diffusion of a dilute methanolic solution of $(py)_2CO$ into a dilute aqueous solution of $Co(O_2CCH_3)_2 4H_2O$ and NaN_3. Complex **2** can also be isolated by employing $Co(O_2CCH_3)_2 4H_2O/(py)_2CO/NaN_3$ molar ratios of 1:2:2, 1:3:3, 1:2:4 and 1:4:4.

CAUTION: Azide salts are potentially explosive and should be handled in small quantities.

X-ray Structure Determinations: Crystals of **1** and **2** were mounted in air and in a capillary filled with drops of the mother liquor, respectively. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo-K_α radiation. Complete crystal data and parameters for data collection and refinement are listed in Table 3. Unit cell dimensions were determined and refined using the angular settings of 25 automatically centred reflections in the range $11 < 2\theta < 23°$.

Table 3. Crystal data and structure refinement for $[Mn_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)O\}_2]$ (**1**) and $[Co_4(\mu_{1,1}\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OCH_3)\text{-}O\}_2]{\cdot}2H_2O$ (**2**)

[a] $R1 = \Sigma(|F_o| - |F_c|)/\Sigma(|F_o|)$. − [b] $wR2 = \{\Sigma[w[(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

Intensity data were recorded using the θ-2θ scan method. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarisation and Ψ-scan absorption (only for **2**) corrections were applied with the Crystal Logic software.

The structures were solved by direct methods using SHELXS-86[52] and refined by full-matrix least-squares techniques on F^2 with SHELXL-93.[53] All hydrogen atoms [except those of C(12) in **2** which were introduced at calculated positions as riding on their bonded atom] were located by difference maps and their positions refined isotropically. All non-hydrogen atoms of **1** and **2** were refined anisotropically, with the exception of the oxygen atoms of the solvent H_2O molecules in **2** which were refined isotropically with fixed occupation factors. Further details (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-147441 (**1**) and CCDC-147442 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

X-ray Structure, Magnetic and Catalytic Properties of a Cyclic Trinuclear $Co^{II}/Co^{III}/Co^{III}$ Complex with a μ^3-Hydroxy Anion

Marta Łukasiewicz,[a] Zbigniew Ciunik,[a] Jarosław Mazurek,[a] Jarosław Sobczak,[a] Aldona Staroń,[b] Stanisław Wołowiec,*[b] and Józef J. Ziółkowski*[a]

Keywords: Cobalt / Mixed valent complexes / X-ray structure

The mixed-valent cyclic trinuclear cobalt(II)/cobalt(III)/cobalt(III) complex tris(dibenzoylmethanato-1κ^2O,O';2κ^2O,O';3κ^2O,O')(μ_3-hydroxo-1:2κ^2O;1:3κ^2O;2:3κ^2O)tetrakis(μ-pyrazolato-1:2$\kappa^4N^1N^2$;1:3$\kappa^2N^1N^2$;2:3$\kappa^2N^1N^2$)-1,2-dicobalt(III)-3-cobalt(II) with four bridging pyrazolate anions and a μ^3-hydroxy anion has been synthesized and its molecular structure has been elucidated on the basis of X-ray crystallographic, magnetic, NMR, and EPR studies. The remaining coordination sites of the pentacoordinate cobalt(II) and hexacoordinate cobalt(III) centers are occupied by oxygen donor atoms of dibenzoylmethanate anions, rendering the complex soluble in most organic solvents. The complex has been found to effectively catalyze the decomposition of *tert*-butyl hydroperoxide (TBHP) in chlorobenzene with a short induction period and a half-life of 80 min and to catalyze the oxidation of cyclohexene to 2-cyclohexen-1-one with oxygen and to 2-cyclohexen-1-ol with TBHP.

Introduction

Multinuclear complexes of transition metal ions attract a lot of attention due to their potential catalytic activity. They are constructed using many different polydentate ligands including oxygen donor anionic ligands such as carboxylates[1−8] and other oxy anions.[9,10] Nitrogen-donor bridging ligands, especially pyrazoles, which are well-suited for N,N-bridging, are frequently utilized in the construction of such systems.[11−16] Amongst polynuclear systems, cyclic trinuclear complexes constitute an important class of compounds.[1−10,14−17] Cyclic trinuclear cobalt complexes have been found to show some catalytic activity in the epoxidation of olefins[1,18] and in the autoxidation of hydrocarbons.[19] Therefore, we have focused on the synthesis, isolation, and structural characterization of another, mixed-valent trinuclear cobalt complex soluble in organic solvents. The ligands used in the synthesis were dibenzoylmethanate (DBM) and pyrazolate (pz) anions. Starting from cobalt(II) nitrate, the synthetic procedure led to the isolation of a trinuclear cyclic $Co^{III}/Co^{III}/Co^{II}$ complex, which has been characterized in the solid state by X-ray diffraction analysis. The product has been tested for its catalytic activity in the oxidation of hydrocarbons.

Results and Discussion

Synthetic Procedure and Analytical Data

The optimized synthetic route for obtaining a compound of the analytical formula $Co_3(DBM)_3(pz)_4(OH)\cdot 2THF$ (**1**·2THF) required the use of dibenzoylmethane (DBMH) and pyrazole (pzH) in a 4:3 stoichiometry and excess cobalt(II) salt under basic aerobic conditions. The yield was reasonable considering that a mixture of complexes was formed. The trinuclear complex **1**·2THF could be isolated as a pure compound by extraction into an organic solvent. Special care had to be taken due to the reactivity of **1** towards chlorinated hydrocarbons (vide infra). Brick-red crystals of **1**·2THF, which proved to be stable and analytically pure, were grown by crystallization from THF/hexane.

X-ray Crystallographic Results for the Cyclic Trinuclear Complex $Co_3(DBM)_3(pz)_4(OH)\cdot 2THF$

The molecular structure of **1**·2THF together with bond lengths and angles are presented in Figure 1. The core of the cyclic trinuclear complex **1** consists of three cobalt centers, pentacoordinate Co(1) and hexacoordinate Co(2) and Co(3) (for the numbering, see Figure 2). These are N,N-bridged by four pyrazolate anionic ligands, two of which bridge two cobalt ions, and are further bridged by a μ^3-hydroxide anion. The latter is displaced from the Co(1)-Co(2)Co(3) plane (P) by 0.441(1) Å. Three of the four bridging pyrazolate anions, i.e. pz_{1a}, pz_{1b}, and pz_{2a}, lie at the opposite side of the P plane in relation to μ_3-OH (i.e. in the *exo* position) and the angles between the pyrazolate ring planes and P are 38.5(1)°, 41.4(1)°, and 30.4(1)°, respectively. The fourth bridging pyrazolate, namely pz_{2a}, is *endo* with a pz_{2a} vs. P angle of 67.8(1)°. The three DBM ligands are each involved in O,O-chelation of the cobalt centers. The chelate ring planes of the DBM ligands are twisted in relation to the P plane by about 86.7(1)° (DBM_1 vs. P), 61.5(1)° (DBM_2 vs. P), and 68.4(1)° (DBM_3 vs. P). Consequently, the oxygen donors and phenyl groups of the DBM ligands are non-equivalent, as reflected in the dis-

tances of the oxygen atom donors from the P plane (see Figure 2). Three of the oxygen donors, i.e. O(2), O(3), and O(6), are *endo*, while O(1), O(4), and O(5) are *exo*. Thus, two sides of the molecule of **1** are different; the *endo* one is occupied by μ_3-OH, pz_{2a}, and mainly by DBM ligands, while the three remaining pyrazolate anions (*exo*) lie at the opposite side of the P plane. The cobalt centers are distinguished not only by their coordination numbers, but also in terms of the cobalt−donor atom distances. The bond lengths between the pentacoordinate Co(1) atom and both the bridging pyrazolate nitrogens and the DBM oxygen atoms are about 2.00 Å, whereas those between Co(2) and Co(3) and the corresponding pyrazolate nitrogen atoms and DBM oxygen atoms are 1.91 Å (Co−N averaged) and 1.89 Å (Co−O averaged), respectively. Furthermore, the bond lengths between the bridging hydroxy oxygen atom and Co(2) and Co(3) (1.91 Å) are shorter as compared to that between Co(1) and O(1B) (2.15 Å), which results in a lower value of Co(2)−O(1B)−Co(3) (108.6°) in comparison with the mean Co(1)−O(1B)−Co(*n*) angle (118.5°). It is also noteworthy that the pyrazolate anion pz_{2a} that bridges the Co(2) and Co(3) centers, i.e. the only *endo* pz, is the most strongly bound to the cobalt ions (1.89 Å) of all the bridging pyrazolate anions; the bond lengths between the pz_{2b} (*exo*) nitrogen atoms and the cobalt ions are longer (1.91 Å), and those between the pz_1 (*exo*) nitrogen atoms and the cobalt centers are longer still (1.92 Å). These structural features clearly demonstrate that the oxidation state of Co(1) is close to Co^{II}, whereas those of Co(2) and Co(3) centers are formally Co^{III}.[20] Analysis of the periphery of **1** revealed different conformations for the three DBM ligands; the phenyl rings at DBM_2 are almost coplanar with its chelate ring, while the *exo*-phenyl rings of the other two DBM ligands are twisted in relation to their chelate rings, presumably due to weak interactions between their *meta*-protons and the face of the *exo*-phenyl of DBM_1 (the contact distance is 2.78 Å, see Figure 1). However, the crystal puckering, including the interaction of **1** with two THF solvate molecules, may also affect the conformations of the DBM ligands.

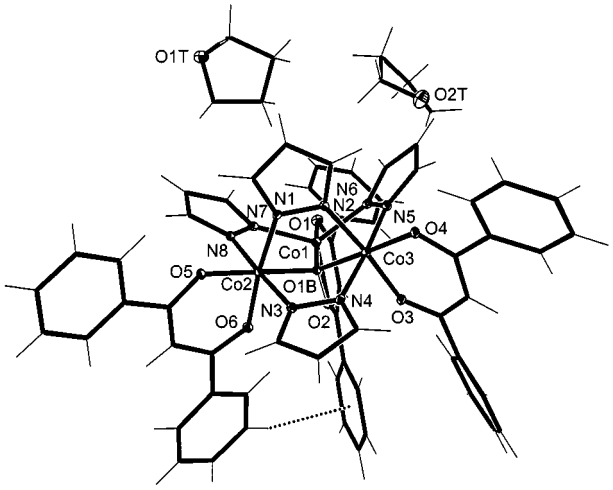

Figure 1. Projection[27] of the trinuclear cobalt complex; thermal ellipsoids are drawn at a 30% probability level; selected bond lengths [Å] and angles [°]: Co(1)−N(7) 1.991(2), Co(1)−N(6) 2.002(2), Co(1)−O(1) 2.014(2), Co(1)−O(2) 1.981(2), Co(1)−O(1B) 2.154(2), Co(2)−N(1) 1.886(2), Co(2)−N(3) 1.900(2), Co(2)−N(8) 1.920(2), Co(2)−O(5) 1.879(2), Co(2)−O(6) 1.881(2), Co(2)−O(1B) 1.912(2), Co(3)−N(2) 1.892(2), Co(3)−N(4) 1.917(2), Co(3)−N(5) 1.926(2), Co(3)−O(3) 1.898(2), Co(3)−O(4) 1.886(2), Co(3)−O(1B) 1.914(2); Co(2)−O(1B)−Co(3) 108.58(8), Co(2)−O(1B)−Co(1) 117.77(8), Co(3)−O(1B)−Co(1) 119.32(8); the ellipsoids at carbon atom positions and most of the atom labels are omitted for clarity; the contact between the *meta*-hydrogen atom of the *endo*-phenyl ring of DBM_2 and the face of the *endo*-phenyl ring of DBM_1 are shown with a dotted line (for acronyms used, see Figure 2)

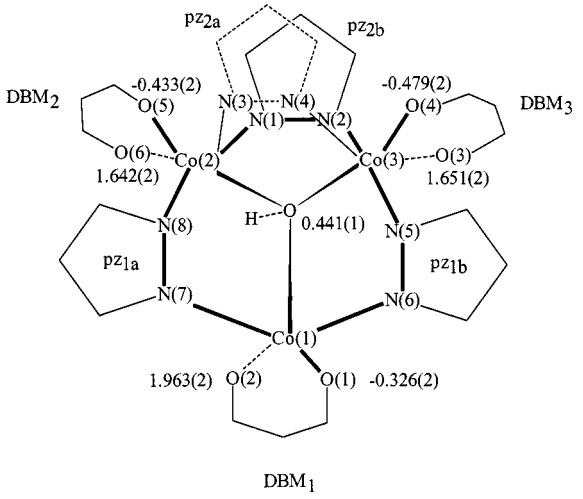

Figure 2. Simplified representation of **1** showing selected donor atoms and acronyms used throughout the discussion; the distances between the oxygen donor atoms of the DBM ligands and the mean Co(1)Co(2)Co(3) plane [Å] are indicated in the scheme; positive values are attributed to the *endo* side; bridging pyrazolates pz_{1a}, pz_{1b}, and pz_{2b} are bound at the *exo* side

Electronic Structure of 1

A rather unusual feature of **1** is that both a well-resolved ^{1}H NMR spectrum and an ESR spectrum (at liquid nitrogen temperature) could be obtained. Therefore, we have measured the magnetic susceptibility of **1**·2THF. The magnetic moment of **1**·2THF is indicative of a total spin of 3/2 and is slightly temperature-dependent (Figure 3, A). At 77 K, **1** gives a rhombic EPR spectrum with $g_1 = 5.35$, $g_2 = 3.34$, and $g_3 = 2.31$ (Figure 3, B). The extent of the delocalization of the unpaired electron could be estimated by ^{1}H NMR spectral studies of the high-spin complex **1**.

The spectrum consists of 22 resonances, which are partially overlapped (Figure 3, C). Although a total assignment could not be made, the two most shifted resonances, appearing at $\delta = 57$ and -59 with relative intensities of 2:1, could be attributed to 3,5-H and 4-H of one of the bridging pyrazolates (pz_2). The large number of resonances seen for **1** indicates that the asymmetry observed in the solid state is retained in solution, leading to a separation of the *o*-, *m*-, and *p*-H phenyl resonances of all three DBM ligands. On the other hand, the rotation of the phenyl groups within each DBM remains fast on the NMR time scale. Consequently, twelve resonances due to the DBM phenyl

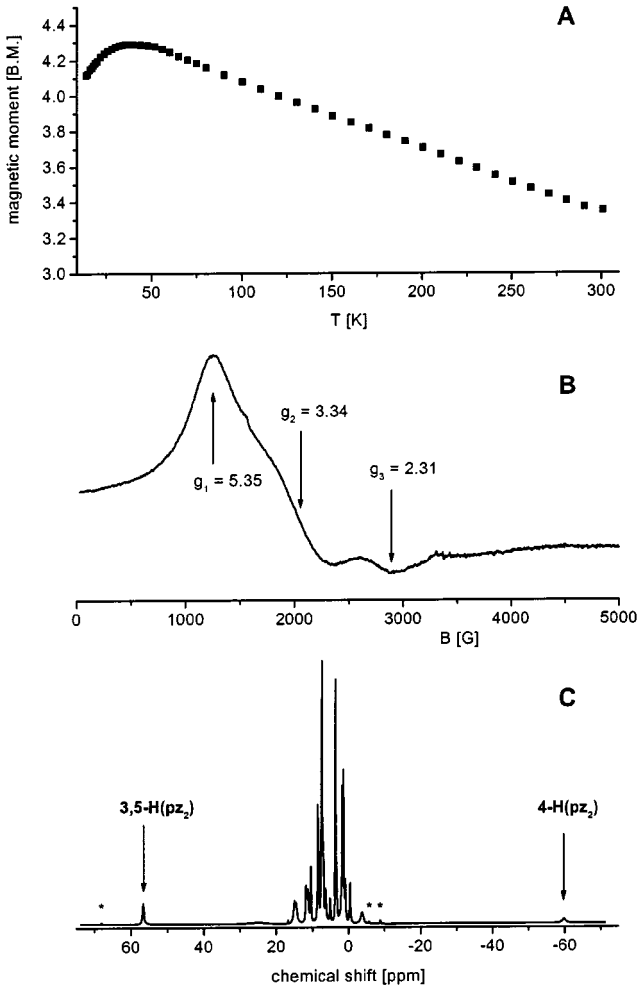

Figure 3. A: temperature dependence of the magnetic moment; B: ESR spectrum measured in toluene glass at 77 K; C: ^{1}H NMR spectrum of **1** in $CDCl_3$ at 293 K; the resonances due to the product of conversion of **1** are labeled with asterisks

groups, two resonances due to the C−H of DBM, the resonance of the central OH, three pz_1 signals, and four pz_2 signals give a total of 22 resonances for **1**. The well-resolved ^{1}H NMR spectrum of **1** is consistent with a high-spin configuration of the Co^{II} center and indicates rather extensive delocalization of the unpaired electron over the formally $Co^{II}/Co^{III}/Co^{III}$ core.

Complex **1** was found to be unstable in chlorinated solvents (chloroform and dichloromethane). Presumably, chloride ions are abstracted from the solvent through formation of a new complex **1′**; the half-life for this conversion was estimated to be ca. 24 h. The spectrum of **1′** is present even in a freshly prepared solution (Figure 3, C). Complex **1′** becomes predominant in a synthetic mixture if removal of CH_2Cl_2 is delayed. In the case of the analogous complex with acetylacetonate (acac) instead of DBM, the instability of the trinuclear OH-bridged complex is even greater and the only product isolated was $Co_3(acac)_3(pz)_4Cl$. We have attempted to replace the DBM in **1** with benzoylacetonate anions; the product thus obtained was found to be a mixture of complexes due to the additional asymmetry introduced by this β-diketonate, resulting in a multiplication of the 3(5)-H and 4-H (pz_2) resonances, although the chemical shift of the latter was very close to that in **1**. This observation confirmed the assignment of the ^{1}H NMR resonances of **1** on the basis of its symmetry and that of its analogues with other β-diketonate anions.

Catalytic Properties

Complex **1** has been found to catalyze the decomposition of *tert*-butyl hydroperoxide (TBHP) in chlorobenzene with a short induction period and a half-life of 80 min. We have tested **1** for its catalytic ability in the oxidation of cyclohexene by TBHP and dioxygen. These two oxidants showed different chemoselectivities; in the former case active oxygen was selectively transferred to the substrate with formation of 2-cyclohexen-1-ol, while in all other cases 2-cyclohexen-1-one was the dominant product (Table 1).

Generation of the active form of the catalyst from **1** in acetonitrile required a long induction period (Entry 3), whereas a short induction period was observed in chlorobenzene. This induction period is consistent with the building-up of an appropriately high concentration of ROOH from R (alkene, alkane) and O_2. Addition of TBHP to the reaction mixtures (Entry 4) obviated the need for such an induction period. The main products clearly showed the involvement of different catalytic forms of **1**, although both are the common products of oxygenated Fenton chemistry.[22−24] Generally, oxidation of organic substrates catalyzed by cobalt complexes can be divided into two categories based on the type of mechanism involved: free-radical autoxidation and catalytic oxygen transfer.[22] In the first type of reaction, the cobalt catalyst induces decomposition of an organic hydroperoxide (ROOH) to form radicals according to a Haber−Weiss mechanism. However, the primary chemistry of ROOH towards metal coordination complexes is nucleophilic addition and ligand substitution with formation of the reactive intermediate for Fenton chemistry and the precursor to the reactive intermediate for oxygenated Fenton chemistry (in the presence of O_2).[23] Catalytic oxygen transfer involves two major active species, namely the peroxometal and oxometal complexes, as the active oxidants.[24] The product derived from **1** in the presence of dioxygen led to the oxidation of cumene in a similar reaction. The products obtained were found to be those derived from attack of the active form of **1** on the secondary carbon atoms (cumene and ethylbenzene, Entries 5 and 7) and not the primary carbon atoms (*p*-xylene, Entry 6) of aliphatic substrates.

Although the catalytic activity and chemoselectivity of **1** are relatively low, we are currently modifying the trinuclear cyclic complexes by replacing DBM with unsymmetrical β-diketonates and by replacing the cobalt ions with other metal ions with a view to improving the catalytic activity of these systems.

Table 1. The results of tests of the catalytic ability of tris(dibenzoylmethanato-1κ^2*O*,*O*′;2κ^2*O*,*O*′;3κ^2*O*,*O*′)(μ$_3$-hydroxo-1:2κ^2*O*;1:3κ^2*O*;2:3κ^2*O*)tetrakis(μ-pyrazolato-1:2κ^4*N*^{1}*N*^{2};1:3κ^2*N*^{1}*N*^{2};2:3κ^2*N*^{1}*N*^{2})-1,2-dicobalt(III)-3-cobalt(II) (**1**)

Test[a]	Substrate (concentration)	Solvent	Oxidant	$\tau_{1/2}$ [min]	Products; yields [%][b]
1	cyclohexene (2.1 M)	chlorobenzene	TBHP (0.276 M)	120	2-cyclohexen-1-ol; 65.4 2-cyclohexen-1-one; 6.4 cyclohexane-1,2-epoxide; 3.2 total yield 75.0 (24 h)

[a] The concentration of **1** was $5\cdot10^{-4}$ mol/dm^3. – [b] Calculated on the basis of substrate consumed, except for Entry 1, where the yield was calculated on the basis of active oxygen transferred to the organic substrate. – [c] With an induction period of 30 min (Entry 2) and 300 min (Entry 3); $\tau_{1/2}$ calculated starting from the point at which consumption of oxygen commenced. – [d] No consumption of oxygen was noticed. – [e] The initial concentration of TBHP was $1.5\cdot10^{-4}$ M.

Experimental Section

Synthesis: In the optimized procedure, dibenzoylmethane (DBMH, 500 mg, 2.232 mmol) and pyrazole (pzH, 202 mg, 2.976 mmol) were dissolved in tetrahydrofuran (THF, 20 mL) and the resulting solution was added dropwise to a 0.3 mol·dm^{-3} aq. cobalt(II) nitrate solution (75 mL) under vigorous stirring. Then, freshly distilled dichloromethane (150 mL) was added to the mixture to extract the desired, non-electrolyte product into the organic phase. Additionally, 1 M aq. NaOH was added dropwise to the mixture under continuous stirring. After stirring for a further 10 min, the reddish-brown organic phase was collected and the CH_2Cl_2 was removed using a rotary evaporator. The solid residue was redissolved in THF and the crude product was crystallized from a THF/hexane mixture. Recrystallization from this solvent mixture led to the isolation of brick-red crystals of **1**·2THF. The best yield of the product was 14%. – $C_{65}H_{62}Co_3N_8O_9$ (1276.2): calcd. C 61.17, H 4.90, N 9.41; found C 60.49, H 4.88, N 9.60. – IR (KBr and Nujol): $\tilde{\nu}$ = 1591 (s), 1546 (s, br), 1521 (s, br), 1484 (s, br), 1450 (s), 1391 (s, br), 1377 (s), 1319 (m), 1308 (m, sh), 1225 (m), 1194 (w), 1180 (m, br), 1061 (s), 1025 (w), 999 (w), 951 (w), 751 (m, br), 740 (m), 721 (m), 687 (m), 626 (w), 581 (w, br), 543 cm^{-1} (w, br). – UV/Vis: λ (ε) = 537 nm ($3.26\cdot10^2$ mol^{-1}·dm^3·cm^{-1}).

Crystallographic Studies: Crystal data, together with details of the refinement, are given in Table 2. All measurements were made with a Kuma KM4CCD κ-axis diffractometer using graphite-monochromated Mo-K_α radiation. The crystal was positioned 65 mm from the KM4CCD camera; 612 frames were measured at 0.75° intervals with a counting time of 25 s. The data were corrected for Lorentz and polarization effects. No absorption correction was applied. Data reduction and analysis were carried out with the Kuma Diffraction (Wroclaw) programs. The structure was solved by direct methods (program SHELXS-97[25]) and refined by the full-matrix least-squares methods on all F^2 data using the program SHELXL-97.[26] Non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included in geometrical positions and were not refined. The crystallographic data have been deposited with the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. and are available on quoting the deposition number CCDC-150406.

Magnetic and Spectral Measurements: The magnetic susceptibility was measured as a function of temperature in the range 14−300 K using a Quantum Design SQUID magnetometer (type MPMS-5). Magnetic moments were calculated for the molecule of **1**·2THF after considering the appropriate diamagnetic corrections. – ^{1}H NMR spectra were recorded with a Bruker AMX 300 MHz instrument, while X-band EPR spectra were measured with a Bruker ESP 300E spectrometer, both for a solid sample and for a solution of **1** in toluene, at 77 K and at ambient temperatures. – UV/Vis spectra in appropriate solvents and IR spectra (Nujol mulls; KBr discs) were recorded with HP 8453 diode-array and Bruker IFS113V FT-IR spectrophotometers, respectively.

Catalytic Tests: The catalytic activity of **1** was tested in oxidations of various organic substrates using *tert*-butyl hydroperoxide (TBHP) and dioxygen as oxidants in chlorobenzene and acetonitrile solution at 348 K. The progress of reactions was monitored by iodometric titration of TBHP and by volumetric measurement of dioxygen consumed. The products were separated and determined

by GC-MS using a HP 5890 series II chromatograph coupled to a HP 5971 A mass spectrometer. The decomposition of 0.28 M TBHP in the presence of $5.2·10^{-4}$ M **1** in chlorobenzene at 348 K was monitored by iodometric titration. The half-life for the conversion was found to be 80 min. The products of TBHP decomposition (75% conversion after 180 min) were identified and determined by GC-MS as *tert*-butyl alcohol and a trace amount of bis(*tert*-butyl) peroxide. The results of the oxidation tests are summarized in Table 1.

A New Alternating Ferro- and Antiferromagnetic, One-Dimensional Manganese(II) Azide Complex, $[Mn(dpa)(N_3)_2]$ − Crystal Structure and Spectroscopic and Magnetic Properties

Mónica Villanueva,[a] José L. Mesa,[a] Miren K. Urtiaga,[a] Roberto Cortés,[b] Luis Lezama,[a] María I. Arriortua,[a] and Teófilo Rojo*[a]

Keywords: Coordination chemistry / EPR spectroscopy / Magnetic properties

The synthesis, crystal structure, and spectroscopic and magnetic properties of a new alternating ferro- and antiferromagnetic, one-dimensional manganese(II) azide complex, $[Mn(dpa)(N_3)_2]$ (where dpa is the 2,2′-dipyridylamine ligand), are reported. The compound's crystal structure has been resolved at room temperature. The complex crystallizes in the monoclinic $P2_1/c$ space group, with a = 7.089(2), b = 19.090(4), and c = 9.682(4) Å, β = 104.61(2) °, and Z = 4. The structure consists of neutral chains in which each Mn^{II} cation is alternatively bridged by two end-on and two end-to-end azido bridges. The octahedral coordination of the metallic cation is completed by two dpa ligand nitrogen atoms. Reflectance measurements confirm the hexacoordination of the Mn^{II} ions in the complex. The ESR spectra at room temperature and at 4.2 K are isotropic, with a mean g-value of 2.010(1). Magnetic data were analyzed on the basis of an alternating ferro- and antiferromagnetic Heisenberg chain of Mn^{II} ions. The J-exchange parameters found are 64.3 and –75.7 K. A spin canting phenomenon has been observed in this compound, with a remnant magnetization which vanishes above 15 K. Magnetostructural correlations in manganese(II) systems of alternating magnetic sign are discussed.

Introduction

The synthesis and characterization of new low-dimensional materials (one or two-dimensional) that may show ferromagnetic long-range cooperative phenomena (molecular magnets)[1−6] have in recent years been the main focus of interest in the molecular magnetism area. At present, the field of molecular magnetism is addressing the synthesis and study of discrete polynuclear molecules in an attempt to improve our understanding of the mechanism involved in magnetic coupling[7,8] and the production of new paramagnetic clusters with high spin and strong anisotropy (superparamagnetic molecules).[9,10]

The azide-pseudohalide anion is an excellent ligand for obtaining one-dimensional,[11,12] two-dimensional,[13] or three-dimensional[14] polynuclear systems with divalent metal ions. From the magnetic point of view, the most interesting characteristic of azido-bridged complexes is that the azido ligand can act as a very effective superexchange pathway, due to the different coordination modes. Normally, the end-to-end (EE) bridge produces antiferromagnetic coupling, whereas the end-on (EO) form gives ferromagnetic coupling. Both the EE and EO structural bridges may coexist within the same (one- or two-dimensional) system, owing to different distances and/or angles found in the structure. These systems are globally antiferro- or ferromagnetic, but they belong to the so-called "magnetic systems alternating in sign". In compounds of this kind, two or more exchange coupling parameters (J) are necessary to fit the experimental results, in contrast to the "uniform magnetic systems" in which all azido bridges have both the same coordination mode and the same structural parameters.

Taking the aspects mentioned above into account, this work was focused on the preparation and characterization of a new polynuclear azido complex. With this aim in mind, we used the bidentate ligand 2,2′-dipyridylamine with a metal/bidentate ligand 1:1 ratio, in such a way that the four coordination vacancies around the six-coordinated manganese(II) ion should be completed by the excess of the azido ligands. Following this procedure, we have synthesized a new alternating ferro/antiferromagnetic, one dimensional manganese(II) azide complex, which has been characterized by X-ray diffraction and spectroscopic techniques. Magnetic measurements indicate global antiferromagnetic behavior, with the presence of a weak ferromagnetic component intrinsic to the sample.

Results and Discussion

Description of the Structure

Selected bond lengths and angles of $[Mn(dpa)(N_3)_2]$ are given in Table 1. The structure consists of linear neutral chains extending along the [100] crystallographic direction (Figure 1). The Mn^{II} ions are alternatively linked by two EO (end-on) azido bridges [Mn(1)−N(4),N(4)^{i}; 2.231(2), 2.218(2) Å] and two EE (end-to-end) ones [Mn(1)−N(7),N(9)^{ii};

2.275(2), 2.274(2) Å]. The Mn^{II} ions exhibit octahedral coordination, completed by the two N(1) and N(3) nitrogen atoms of the 2,2′-dipyridylamine ligand [Mn(1)−N(1),N(3); 2.253(2), 2.243(2) Å]. The existence of an inversion center induces the Mn(1)−N(4)−Mn(1)^{i}−N(4)^{i} bridging unit to form a plane. The EO bridging azides are quasilinear [N(4)−N(5)−N(6), 178.7(3)°]. The Mn(1)−N(4)−Mn(1)^{i} angle in the EO mode is 102.92(7)°, in good agreement with the results obtained (100−105°) for this kind of bridging ligand.[15−17] For the EE bridges, the Mn(1)−N(7)−N(8) angle is 125.0 (1)° and the Mn(1)^{ii}−N(9)−N(8) angle is 127.74(2)°. The torsion angle τ between the mean plane of Mn(1)−N(7)−N(8)−N(9) and Mn(1)^{ii}−N(9)−N(8)−N(7) for a chair configuration is 64.2(2)°. The dihedral angle δ between the least-squares plane defined by the six nitrogen atoms of the EE bridging azides and the N(7)−Mn(1)−N(9)^{ii} system is 35.10(6)°. The intrachain Mn···Mn distances are 3.479(1) and 5.432(1)Å in the EO and EE bridges, respectively.

Table 1. Selected bond lengths [Å] and angles [°] for $[Mn(C_{10}H_9N_3)(N_3)_2]$, (e.s.d. in parentheses; Symmetry codes: $i = -x,-y,-z$; $ii = -x+1,-y,-z$)

The bond lengths and angles for the 2,2′-dipyridylamine molecule are in the range usually found in this kind of molecule. This ligand may be considered as nonplanar, since the value of the dihedral angle between the pyridine rings is 5.84(8)°.

IR and UV/Visible Spectroscopy

The points of interest in the IR spectrum of the $[Mn(dpa)(N_3)_2]$ complex lie mainly in the bands due to the azido groups. The asymmetrical stretch, $\nu_{asym}(N_3)$, appears split as a strong band at ca. 2095 and 2050 cm^{-1}, in good agreement with the simultaneous existence of EO and EE bridging modes in the complex.[18] The azide symmetric stretch $\nu_{sym}(N_3)$, corresponding to the EO bridging mode, can be observed as a band of medium intensity at about 1330 cm^{-1}. This mode is not active for the symmetrical EE coordination. Finally, the band corresponding to the deformation mode of the azido group, $\delta(N_3)$, is found at ca. 610, 600 cm^{-1}, in good agreement with that observed for all polynuclear azido compounds.[18] Furthermore, the IR spectrum of the title compound features the bands characteristic of the 2,2′-dipyridylamine molecule, seen in the stretching and bending modes of the C−C and C−N bonds in the ranges between ca. 1645−1360 and 1270−750 cm^{-1}.

The diffuse reflectance spectrum of $[Mn(dpa)(N_3)_2]$ exhibits several very weak, spin-forbidden d-d bands, at ca. 17240, 21275, 22990, 25974, and 30770 cm^{-1}, as would correspond to a d^5 high spin cation of ideal octahedral symmetry.[19−21]

ESR and Magnetic Properties

ESR spectra of $[Mn(dpa)(N_3)_2]$, at room temperature and at 4.2 K, were performed on a powdered sample. The spectra are isotropic, with a g-value of 2.010(1). The linewidths are of 116.0 and 304.0 Gauss at 300 and 4.2 K, respectively.

The magnetic susceptibility of $[Mn(dpa)(N_3)_2]$ was measured, using a powdered sample, from 4.2 to 300 K at magnetic fields of 0.1 and 0.01 T. The plots of χ_m and $\chi_m T$ vs. temperature, obtained when the magnetic measurements were recorded at a magnetic field of 0.1 T, are shown in Figure 2. The magnetic susceptibility increases with decreasing temperature down to about 27 K; after that it decreases down to ca. 18 K. An abrupt increase is then observed at about 13.5 K, followed by a decrease down to 4.2 K. A plot of reciprocal molar magnetic susceptibility vs. temperature shows classical Curie-Weiss behavior above 50 K. The calculated Curie and Curie−Weiss constants are $C_m = 4.77\ cm^3$ K/mol and $\theta = -27.5$ K, respectively. The magnetic susceptibility curve obtained using a magnetic field of 0.01 T shows similar features, but the increase observed after the magnetic ordering is more abrupt than that observed at 0.1 T (see inset in Figure 2). The negative Weiss temperature, together with the decrease in the effective magnetic moment observed when the temperature is lowered (5.90 BM at 300 K and 1.46 BM at 4.2 K (see Figure 2), are indicative of the existence of antiferromagnetic exchanges as major interactions for the $[Mn(dpa)(N_3)_2]$ compound. However, the increase in susceptibility at low temperatures indicates the presence of a weak intrinsic ferromagnetic contribution, possibly due to a spin canting effect in the compound.

In order to corroborate this result and to calculate the Neel temperature, magnetization measurements were carried out. Figure 3 shows the zero-field magnetization curve vs. temperature for the compound, previously cooled in a magnetic field of 0.01 T. It can be observed that the remnant magnetization decreases with increasing temperature and vanishes above $T_N = 15$ K. This fact implies the existence of a small amount of ferromagnetic component in the ordered state, which appears to be responsible for the steep

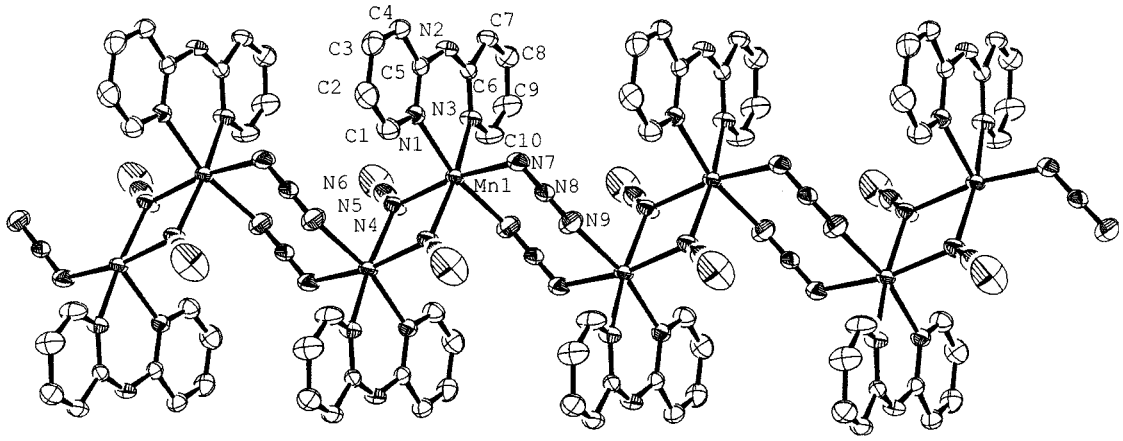

Figure 1. ORTEP drawing (50% thermal ellipsoids) of the $[Mn(dpa)(N_3)_2]$ chain complex showing the alternating end-on and end-to-end coordination of the azido ligands and atom-labeling scheme. The chain runs along the *a*-axis

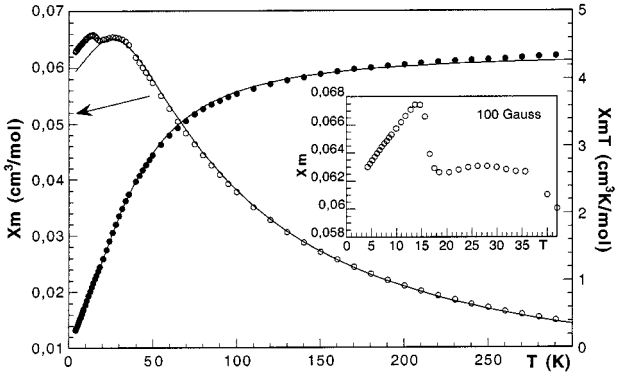

Figure 2. Thermal evolution of χ_m and χ_mT curves of $[Mn(dpa)(N_3)_2]$. The inset shows the χ_m vs. T curve at 100 Gauss. The solid lines show the fit of the χ_m and χ_mT experimental data to the model for alternating ferromagnetic-antiferromagnetic $S = {}^5/_2$ chain

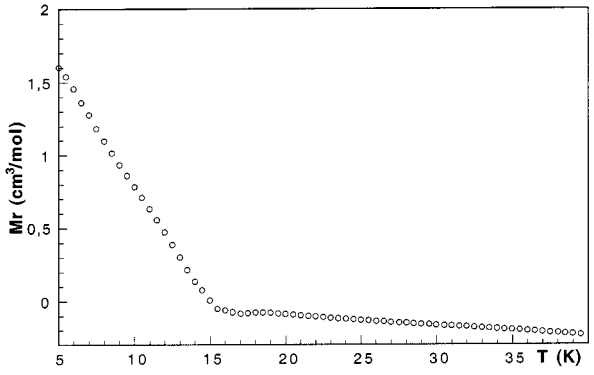

Figure 3. Remnant magnetization vs. temperature of $[Mn(dpa)(N_3)_2]$

increase observed in χ_m at temperatures lower than the ordering temperature.

The magnetic susceptibility data at 0.1 T have been interpreted on the basis of a theoretical model for the alternating ferromagnetic-antiferromagnetic $S = {}^5/_2$ chain, using the following expression for the susceptibility:[18]

$$\chi_m = [Ng^2\beta^2/3kT][1 + u_1 + u_2 + u_1u_2/1 - u_1u_2]$$

where, $u_1 = \coth(J_1/kT) - (kT/J_1)$ and $u_2 = \coth(J_2/kT) - (kT/J_2)$. In order to make a quantitative comparison with the theoretical expression deduced in the classical limit, we used the $J_i \rightarrow J_iS(S+1)$ and $g \rightarrow g[S(S+1)]^{1/2}$ scaling factors. Good agreement between the experimental magnetic data and the theoretical model was obtained when the two interactions, J_1 and J_2, had opposite signs. Fixing "*g*" to the value of 2.01 for manganese(II) ion (from the ESR spectra), the best agreement (solid lines in Figure 2) corresponds to the following parameters: $J_1 = 64.3$ K (45.3 cm^{-1}), and $J_2 = -75.7$ K (-53.3 cm^{-1}). The model used appears to provide a very good description of the susceptibility between 18 and 300 K, as the discrepancy does not exceed the experimental uncertainty. At very low temperature, the agreement is less satisfactory, due probably to the influence of small interchain interactions and the weak ferromagnetic contribution present in this compound.

Magnetostructural Correlations

It is possible to carry out a study concerning magnetostructural correlations in compounds with alternating double EO and EE azido bridges, as several complexes of this kind have recently been reported (Table 2).

The main factor controlling the intensity of the exchange ferromagnetic interactions in the EO bridge appears to be the bridging angle. Here, the larger the bridging angle is, the larger are the ferromagnetic interactions. For EE bridges, however, more structural parameters have recently been studied: namely δ [dihedral angle between the plane defined for the six N-azido atoms and the N(1)−Mn−N(3′) plane] and τ [angle between the mean planes Mn−N(1)−N(2)−N(3) and N(1)−N(2)−N(3)−Mn′]. For the d^5 EE azido-bridged compounds, the most useful parameter is the dihedral angle (δ).

In order to analyze the magnetostructural correlations between δ, τ, and the superexchange *J* parameter, the Hay−Thibeault−Hoffmann[22] relationship between $\Sigma\Delta^2$ and the antiferromagnetic component of *J* is useful. The Δ values (difference in energy between MOs, derived from magnetic orbitals, of the same symmetry) may easily be ob-

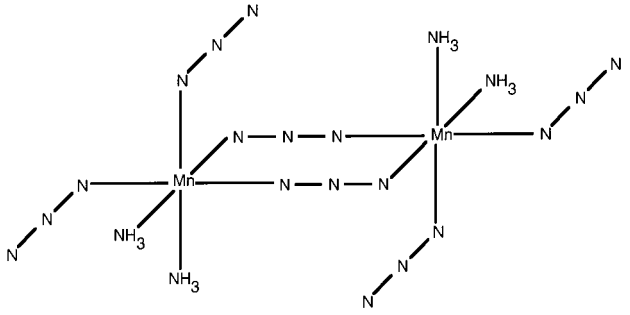
tained by means of MO extended Hückel (EHMO) calculations. The CACAO [23] program was used on a modeled fragment possessing double EE bridges − $[(NH_3)_4Mn(NNN)_2-Mn(NH_3)_4]$ (Scheme 1) − varying the δ and τ parameters inside the limits δ = 0°/60° (this range is used because larger angles seem to be sterically hindered) and equivalent τ = 0°/95°. The manganese(II) ions were positioned in a slightly distorted octahedral environment. The N−Mn−N angle was taken as 90°, and the Mn−N(NH_3) and Mn−N(azide) bond lengths were 2.15 and 2.20 Å, respectively, as observed from the structural data. The atomic parameters used for Mn, N, and H were the program standards.



Scheme 1

Ten molecular orbitals are generated from the five magnetic orbitals, with one electron each, corresponding to the two Mn^{II} ions. The antiferromagnetic contribution should be proportional to the sum: $\Sigma\Delta^2 = \Delta^2(d_{x^2-y^2}) + \Delta^2(d_{z^2}) + \Delta^2(d_{xz}) + \Delta^2(d_{xy}) + \Delta^2(d_{yz})$. However, priority was given in each modeled system to the orbitals mainly implicated in the exchange pathway. The results of the calculations were plotted as $\Sigma\Delta^2$ vs. δ or τ (Figure 4). In the light of these data, we can deduce that the antiferromagnetic coupling should decrease for larger δ values, indicating that the loss of overlap due to the increase in the torsion angles becomes the driving parameter controlling the magnitude of the antiferromagnetic coupling.

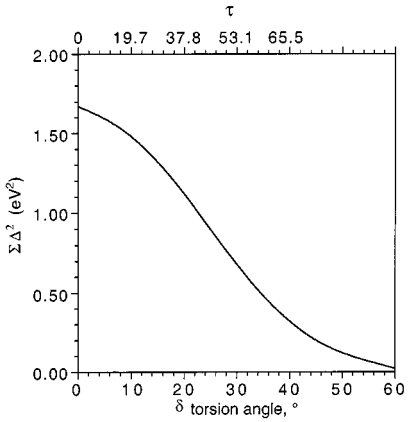


Figure 4. Evolution of the $\Sigma\Delta^2$ parameter vs. δ and τ angles

Several conclusions can be drawn from the magnetostructural parameters of the complexes, shown in Table 2. With respect to the EO bridges, it can be observed that the experimentally determined ferromagnetic J values increase with increasing bridging angle. This demonstrates the general validity of the proposed dependence of the experimental J value on α (the $|J_{EE}/J_{EO}|$ ratio) for this kind of bridging. In the case of the EE bridges, there seems to be a general tendency that the larger the torsion (δ) is, the lower

the antiferromagnetic interactions are. However, the title compound does not follow this general tendency and shows one of the largest antiferromagnetic interactions found experimentally for these alternating chains. For this kind of bridging, other factors may influence the magnitude of the antiferromagnetic exchange component. In fact, low values of Mn−N−N bridging angles have been shown to increase the antiferromagnetic interaction. In this sense, this may be the explanation for the larger J_{AF} value found in the $[Mn(dpa)(N_3)_2]$ compound, as it shows a smaller average bridging angle.

Conclusions

A new alternating ferro/antiferromagnetic, one-dimensional manganese(II) azide complex, $[Mn(dpa)(N_3)_2]$, has been synthesized and the crystal structure solved from single-crystal X-ray diffraction data. The complex exhibits a chain structure, extending along the *a*-axis with the azide anions simultaneously coordinated to the manganese(II) ions in both the end-on and the end-to-end modes. The weak bands observed in the diffuse reflectance spectrum are characteristic of the existence of manganese(II) ions in approximately octahedral environments. Isotropic signals are observed in the ESR spectra, with a mean *g*-value of 2.010(1). The linewidths of the spectra increase with decreasing temperature, probably due to the dipolar homogeneous broadening and a strong spin correlation. Magnetic measurements indicate the existence of a dominant antiferromagnetic coupling. The magnetic data have been analyzed on the basis of a model for alternating ferro- and antiferromagnetic chains of $S = 5.2$, the obtained values for the *J*-exchange parameters being of 64.3 and −75.7 K. Furthermore, the complex displays magnetization at low magnetic fields, probably due to the presence of a weak ferromagnetic component. From the magnetostructural correlations, it was possible to explain the high value obtained for the J_{AF} parameter in the $[Mn(dpa)(N_3)_2]$ complex on the basis of the low observed value of the Mn−N−N bridge angle in this compound.

Experimental Section

Syntheses: $[Mn(dpa)(N_3)_2]$ was synthesized from $Mn(NO_3)_2{\cdot}4H_2O$ (0.110 g, 0.438 mmol), 2,2′-dipyridylamine (0.075 g, 0.438 mmol), and NaN_3 (0.142 g, 2.190 mmol) in a water-methanol solution (1:1). The resulting light yellow solution was filtered off and left to stand at room temperature. After several days, prismatic, light pink, single crystals were obtained. They were separated by filtration, washed with diethyl ether, and dried over P_2O_5 for 1 h. Yield: ca. 80%. The results of CHN elemental analysis and the ICP-AES (inductively coupled plasma atomic emission spectroscopy) technique were: found C 38.4, H 2.7, N 40.3, Mn 17.5; calcd. for $C_{10}H_9MnN_9$ (310.2): C 38.7, H 2.9, N 40.6, Mn 17.7%. The density, measured by the flotation method in a mixture of $CHBr_3/CCl_4$, was 1.63(1) gcm^{-3}.

Crystal Structure Determination: A suitable single crystal of $[Mn(dpa)(N_3)_2]$ was carefully selected under a polarizing microscope and mounted on a glass fiber. Diffraction data were collected at room temperature on an Enraf−Nonius CAD4 automated diffractometer, using graphite-monochromated Mo-K_α radiation. Details of crystal data, intensity collection, and some features of the structure refinement are reported in Table 3. Lattice constants were obtained by a least-squares refinement of the setting angles of 25 reflections in the range $6° < \theta < 11°$. Intensities and angular positions of two standard reflections were measured each hour, and these showed neither decrease nor misalignment during data collection.

R [$I > 2\sigma(I)$]	$R1 = 0.039$, $wR2 = 0.096$[a]
Goodness of fit on F^2	1.065

[a] $R1 = [\Sigma(|F_o| - |F_c|)]/\Sigma|F_o|$; $wR2 = [\Sigma[w(|F_o|^2 - |F_c|^2)^2]/\Sigma[w(|F_o|^2)^2]]^{1/2}$; $w = 1/[\sigma^2|F_o|^2 + (x\,p)^2]$; where $p = [|F_o|^2 + 2|F_c|^2]/3$; $x = 0.0605$.

3944 reflections were measured, in the range $2.1° \le \theta \le 30.0°$. A total of 2664 were independent, applying the criterion $I > 2\sigma(I)$. Correction for Lorentz and polarization effects, and also for absorption with the empirical ψ scan method,[28] was performed by using the XRAYACS program.[29] Direct methods (SHELXS 97)[30] were employed to solve the structure. The metal ion was located first. The nitrogen and carbon atoms were found in difference Fourier maps. The structure was refined by the full-matrix, least-squares method based on F^2, using the SHELXL 97 computer program.[31] The scattering factors were taken from ref.[32] All non-hydrogen atoms were assigned anisotropic thermal parameters. The coordinates of the hydrogen atoms of the 2,2′-dipyridylamine ligand were obtained from difference Fourier maps. The final R factors were $R1 = 0.039$ [$wR2 = 0.096$]. Maximum and minimum peaks in final difference synthesis were 0.488, −0.397 $eÅ^{-3}$. The atomic coordinates and structure factors have been deposited at the Cambridge Crystallographic Data Centre (CCDC 146293). Drawing was made using ORTEP.[33]

Physical Measurements: CHN elemental analysis was carried out with a Perkin−Elmer Model 240 automatic analyzer. ICP-AES analysis was performed with an ARL Fisons 3410 spectrometer. The IR spectrum (KBr pellet) was obtained with a Nicolet FT-IR 740 spectrophotometer in the 400−4000 cm^{-1} range. The diffuse reflectance spectrum was recorded at room temperature on a Cary 2415 spectrometer in the 5000−47500 cm^{-1} range. A Bruker ESP

300 spectrometer was used to record the ESR polycrystalline spectra at room temperature and at 4.2 K. The temperature was stabilized by an Oxford Instrument (ITC 4) regulator. The magnetic field was measured with a Bruker BNM 200 gaussmeter and the frequency inside the cavity was determined using a Hewlett−Packard 5352B microwave frequency counter. Magnetic measurements of powdered sample were performed in the temperature range 4.2−300 K, using a Quantum Design MPMS-7 SQUID magnetometer. The magnetic field was approximately 0.1 T, a value in the range of linear dependence of magnetization vs. magnetic field even at 4.2 K.

Standard Enthalpies of Formation of Li, Na, K and Tl Cyclopentadienyls

João Paulo Leal,*[a] Vera Cachata,[a] and Adelaide Carvalho[a]

Keywords: Thermochemistry / Alkali metals / Heats of formation / Cyclopentadienyl ligands

The enthalpies of formation of lithium, sodium, potassium and thallium cyclopentadienyls were determined by reaction-solution calorimetry as $\Delta_f H°$ [LiCp] = −76.5 ± 2.9 kJ/mol, $\Delta_f H°$ [NaCp] = −39.7 ± 2.5 kJ/mol, $\Delta_f H°$ [KCp] = −83.2 ± 3.2 kJ/mol, and $\Delta_f H°$ [TlCp] = +117.7 ± 1.9 kJ/mol. Using a previously developed model, the enthalpies of formation of RbCp and CsCp were estimated.

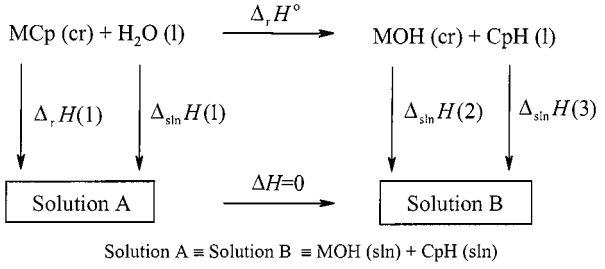
Introduction

Alkali metal compounds have a major importance in synthetic chemistry.[1] The cyclopentadienyl anion ($C_5H_5^-$, Cp^-) can form compounds with almost all metallic elements and is one of the most important ligands in organometallic chemistry.[2−4] The cyclopentadienyl salts of lithium, sodium and potassium have been known for almost a century,[5] and thallium cyclopentadienyl for more than 40 years.[6,7] All of them are basic compounds in organometallic synthesis. Many organometallic compounds whose energetics are known contain one or more Cp ligands and involve MCp (M = Li, Na, K and Tl) reagents in their synthesis.[8−11] However, thermochemical data for these substances are almost absent from literature (a value for TlCp is the exception).[12]

In the present paper the enthalpies of formation of Li, Na, K and Tl cyclopentadienyls were determined by reaction-solution calorimetry, using several different reactions in various environments (water, aqueous hydrochloric acid, ethanol and toluene). These results, together with a previously developed estimation method, allowed us to predict the enthalpies of formation of the Rb and Cs cyclopentadienyls.

Results and Discussion

Enthalpies of formation of metal cyclopentadienyls were calculated by using Scheme 1 (reaction with water, used for Li, Na and K compounds), Scheme 2 (reaction with 0.1 M HCl, used for all the compounds studied in this paper), Scheme 3 (reaction with ethanol, used for NaCp), and Scheme 4 (reaction with ethanol in toluene, used for NaCp). In these schemes, $\Delta_r H°$ represents the reaction enthalpy with all the compounds in their standard state, $\Delta_r H$ the measured reaction enthalpy, $\Delta_{sln}H(2)$ the dissolution enthalpy of stoichiometric amounts of MOH in H_2O, $\Delta_{sln}H(3)$ the dissolution enthalpy of CpH in H_2O + MOH, $\Delta_{sln}H(5)$ the dissolution of MCl in 0.1 M HCl, $\Delta_{sln}H(6)$ the dissolution or mixing of CpH in a 0.1 M HCl + MCl solution, $\Delta_{sln}H(7)$ the dissolution of water in 0.1 M HCl solution, $\Delta_{sln}H(9)$ the dissolution enthalpy of NaOEt in ethanol, $\Delta_{sln}H(10)$ the dissolution enthalpy of CpH in ethanol + NaOEt, $\Delta_{sln}H(11)$ the dissolution enthalpy of EtOH in toluene, $\Delta_{sln}H(12)$ the dissolution enthalpy of NaOEt in toluene + ethanol, and $\Delta_{sln}H(13)$ the dissolution enthalpy of CpH in toluene + ethanol + NaOEt. $\Delta_{sln}H(1)$ (dissolution of water in water), $\Delta_{sln}H(4)$ (dissolution of 0.1 M HCl in 0.1 M HCl), and $\Delta_{sln}H(8)$ (dissolution of ethanol in ethanol) are, obviously, zero.



Scheme 1

As the concentrations of MOH in solution were always very small (about 1 mol of MOH in 4×10^5 mol of water), infinite dilution can be assumed and $\Delta_{sln}H(2)$ can be calculated as −23.49 kJ/mol for lithium hydroxide, −44.50 kJ/mol for sodium hydroxide, and −57.61 kJ/mol for the potassium analogue from the data in Table 1.[13] As cyclopentadiene (CpH) is immiscible with water $\Delta_{sln}H(3)$ was taken as zero.

The enthalpies of formation of aqueous 0.1 M HCl and crystalline metal chlorides are known (Table 1).[13] The dissolution of water in the solvent is negligible (smaller than the detection limit of the apparatus) and even when multiplied by 552 [see Scheme 2 and Equation (2) below] yields a minor contribution to the final $\Delta_r H°$ value (smaller than the experimental error). Therefore, $\Delta_{sln}H(7)$ was neglected. All the other dissolution enthalpies needed were measured or calculated from literature data (Table 2).[13−16]

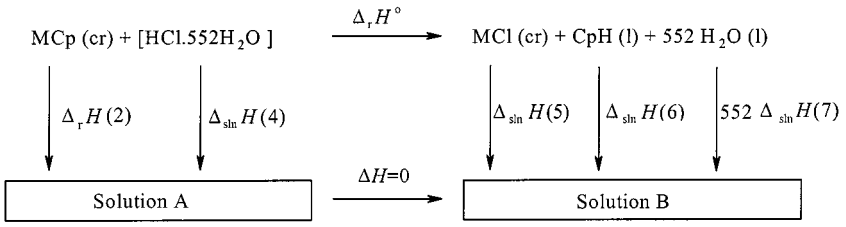
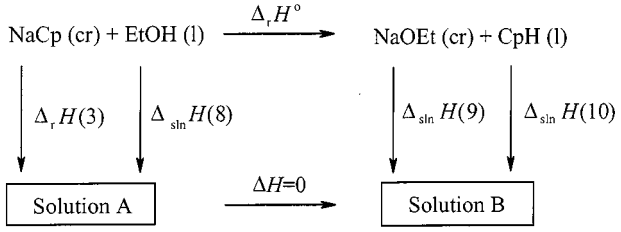


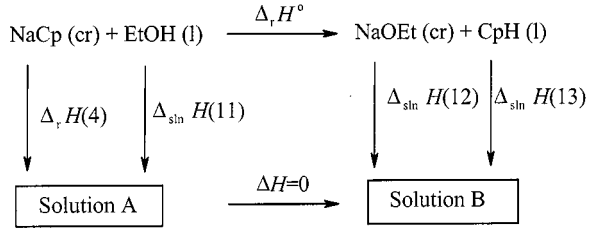
Scheme 2

Solution A ≡ Solution B ≡ MCl (sln) + CpH (sln) + n (HCl .552H_2O)



Solution A ≡ Solution B ≡ NaOEt (ethanol) + CpH (ethanol)

Scheme 3



Solution A ≡ Solution B ≡ NaOEt (toluene+ethanol) + CpH (toluene+ethanol)

Scheme 4

Schemes 1−4 lead to Equation (1)−(4), that allow the calculation of the enthalpies of formation of the metal cyclopentadienyls presented in Table 3.

$$\Delta_f H^o(\mathrm{MCp, cr}) = \Delta_f H^o(\mathrm{MOH, cr}) + \Delta_f H^o(\mathrm{CpH, l}) - \Delta_f H^o(\mathrm{H_2O, l}) - \Delta_r H(1) + \Delta_{sln} H(2) \quad (1)$$

$$\Delta_f H^o(\mathrm{MCp, cr}) = \Delta_f H^o(\mathrm{MCl, cr}) + \Delta_f H^o(\mathrm{CpH, 1}) - \Delta_f H^o(\mathrm{HCl{\cdot}552H_2O}) - \Delta_r H(2) + \Delta_{sln} H(5) + \Delta_{sln} H(6) + 552\Delta_{sln} H(7) \quad (2)$$

$$\Delta_f H^o(\mathrm{NaCp, cr}) = \Delta_f H^o(\mathrm{NaOEt, cr}) + \Delta_f H^o(\mathrm{CpH, l}) - \Delta_f H^o(\mathrm{EtOH, l}) - \Delta_r H(3) + \Delta_{sln} H(9) + \Delta_{sln} H(10) \quad (3)$$

$$\Delta_f H^o(\mathrm{NaCp, cr}) = \Delta_f H^o(\mathrm{NaOEt, cr}) + \Delta_f H^o(\mathrm{CpH, l}) - \Delta_f H^o(\mathrm{EtOH, l}) - \Delta_r H(4) - \Delta_{sln} H(11) + \Delta_{sln} H(12) + \Delta_{sln} H(13) \quad (4)$$

For the Li, Na, and K compounds, whose enthalpies of formation were determined from different reactions and thermodynamic cycles, a good agreement between the results is observed (see Table 3, column 3). The recommended values for $\Delta_f H^o$(MCp, cr), shown in Table 4, are weighted averages of the data in Table 3.[17]

[a] ai: aqueous solution, ionized substance standard, $m_{\pm}$ = 1 mol/kg; cr: crystalline.

A literature value for the enthalpy of formation of TlCp, $\Delta_f H^o$= 99.8 ± 2.5 kJ/mol, was obtained from measurements of the heat of reaction of aqueous TlOH with gaseous C_5H_6 at 25°C.[12] Recalculation of this value with more recent auxiliary data leading to 101.7 ± 2.6 kJ/mol,[18] only barely improves the discrepancy with the result in Table 4, 117.7 ± 1.2 kJ/mol. According to Hull and Turnbull, the heat of reaction relies on the mass of TlCp collected. If a small fraction of that mass was lost, the true value of the reaction enthalpy of TlOH with CpH would be less negative and the enthalpy of formation higher, in line with the result in Table 4.

The enthalpies of formation in Table 4 together with literature data,[13,19] were used to calculate the lattice energies ($\Delta_{lat} U^o$) of metal cyclopentadienyls, according to Scheme 5. These values are also displayed in Table 4. It is observed that the cyclopentadienyl compounds have a strong ionic character, as their lattice energies are only about 200 kJ/mol lower than the lattice energies for the corresponding hydroxides.[20]

Let us assume a simple ionic model and the Kapustinskii approximation represented by Equation (5).[21]

Table 2. Dissolution enthalpies (T = 298.15 K)

Compound	$\Delta_{sln}H(5)$ (kJ/mol)[a]	$\Delta_{sln}H(6)$ (kJ/mol)[b]	$\Delta_{sln}H(9)$ (kJ/mol)[c]	$\Delta_{sln}H(10)$ (kJ/mol)[d]	$\Delta_{sln}H(11)$ (kJ/mol)[e]	$\Delta_{sln}H(12)$ (kJ/mol)[e]	$\Delta_{sln}H(13)$ (kJ/mol)[f]

Table 4. Enthalpies of formation and lattice energies of cyclopentadienyls salts

Compound	$\Delta_fH°$(MCp,cr) kJ/mol	$\Delta_{lat}U°$(MCp)[a] kJ/mol
LiCp	−76.5 ± 2.9	823.4 ± 7.5
NaCp	−39.7 ± 2.5	710.2 ± 7.4
KCp	−83.2 ± 3.2	658.6 ± 7.6
TlCp	+117.7 ± 1.9	721.2 ± 7.2

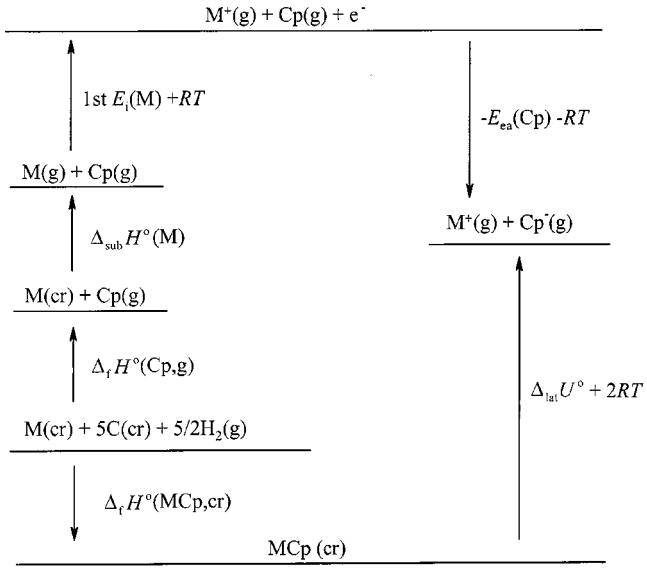
[a] $\Delta_fH°$(Cp, g) = 241 ± 6 kJ/mol,[19] E_{ea}(Cp) = 174.9 ± 3.5 kJ/mol (ref.[19], using only the values from LPES and LPD).

$$\Delta_{lat}U° = \frac{1.079 \times 10^5 . \nu . Z_+ Z_-}{r_+ + r_-} \quad (5)$$

In this expression, ν represents the number of ions in the molecule, Z_+ and Z_- the charges of the cation and the anion, and r_+ and r_- the respective radii in pm. As the ionic radii of Li^+, Na^+, K^+, and Tl^+ are known,[22] the ionic radius of the cyclopentadienide anion can be derived from the lattice energy in each case (Table 5).

The radii calculated through the above procedure are called "thermochemical radii" [they reproduce lattice energies when introduced in Equation (5)] and should not be interpreted as crystallographic radii. However, some correlation seems to exist and this can be confirmed by comparing the sum $r_+ + r_-$ with the crystallographic distances M−Cp (Table 5).[23−26]

When the values of the thermochemical radius for the Cp^- ligand are plotted together with the data for RO^-



Scheme 5

Table 5. Thermochemical radii calculated or estimated in cyclopentadienyl salts[a] and experimental distances

MCp	$r_+ + r_-$	r_+[b]	r_-	d(M−Cp)
LiCp	262.1 ± 2.4	90±1	172.1±2.6	196.9[c]
NaCp	303.9 ± 3.2	116±1	187.9±3.4	235.7[c]
KCp	327.7 ± 3.8	152±1	175.7±3.9	281.6[c][d]
TlCp	334.2 ± 3.3	164±1	170.2±3.4	319.0[e]
RbCp	(332 ± 5)	166±1	(166±5)	297.4[f][g]296.2[f][h]
CsCp	(347 ± 5)	181±1	(166±5)	312.3[i]

[a] Estimated values in parenthesis. – [b] Data from ref.[22]. – [c] Ref.[23]. – [d] Average value. – [e] Ref.[26]. – [f] Ref.[24]. – [g] Average phase I. – [h] Average phase II. – [i] Ref.[25].

(R = H, Me, Et)[13,15,16,27,28] a similar trend (with a maximum for sodium) is observed (Figure 1), allowing us to estimate the thermochemical radius for Cp^- in RbCp and CsCp as 166 ± 5 pm.[29] From this value, the lattice energy for RbCp and CsCp can be calculated: $\Delta_{lat}U^o$[RbCp] = 650.0 ± 9.8 kJ/mol, and $\Delta_{lat}U^o$[CsCp] = 621.9±9.0 kJ/mol. Finally, the lattice energies and auxiliary data[30] yield (Scheme 5) the enthalpies of formation of the rubidium and caesium compounds: −99 ± 12 kJ/mol and −103 ± 11 kJ/mol, respectively.

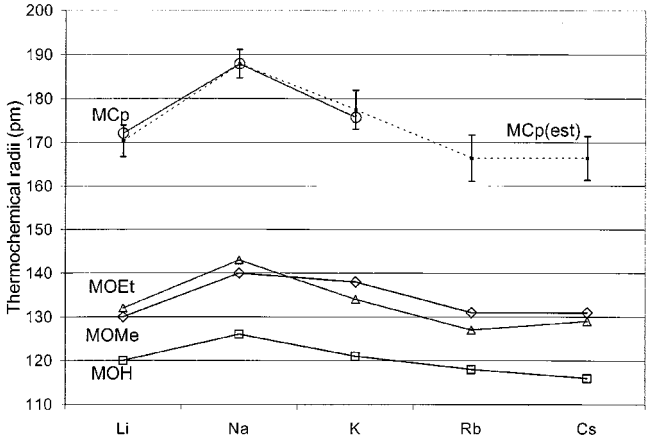


Figure 1. Thermochemical radii of anions (OH^-, OMe^-, OEt^-, and Cp^-); estimated values for Cp^- are presented with error bars (for a detailed calculation of these values see the Supporting Information).

The crystallographic M−C distances for $MgCp_2$, 233.9 pm,[31] 234.8 pm[32] in the gas phase and 230.4 pm[33] by X-ray crystallography are comparable to the Na−C distance in NaCp. There exists in the literature a value of 69.3 ± 4.2 kJ/mol for the enthalpy of formation of $MgCp_2$.[34] From this value and an approach similar to the one used for the compounds studied in this paper a thermochemical radius of 183 ± 8 pm for the Cp^- in $MgCp_2$ [35] is obtained, which is in keeping with the value obtained for Cp^- in NaCp (187.9 ± 3.4 pm).

The above results can be used to understand the stability of TlCp in the presence of water or oxygen when compared to other cyclopentadienyl derivatives of Tl or even with InCp.[36−39] TlCp is quite stable in water and reacts only slowly with oxygen.[40] For example, TlCp was found to be more stable than TlC_5H_4tBu or $TlC_5H_4(SiMe_3)$ (which are of similar stability), and of TlC_5H_4Me which is highly air- and water-sensitive. To explain this behaviour it has been argued that TlCp should have a much higher lattice energy than other cyclopentadienyl salts, such as thallium methylcyclopentadienide, due to different molecular symmetries.[41] We note, however, that the reactivity of thallium hydropentalenide in the presence of water is similar to TlCp.[37]

As noticed by Hull and Turnbull,[12] the enhanced stability of TlCp is mainly due to the low affinity of Tl for oxygen and the solubility of TlOH in water. To check this hypothesis, the enthalpy of the reaction in Equation (6) can be calculated for all four compounds studied, using the enthalpies of formation of MCp measured in this work and auxiliary data from Table 1.

$$MC_5H_5(cr) + H_2O(l) \rightarrow MOH(aq) + C_5H_6(l) \quad (6)$$

The results are −40.2 kJ/mol (Li), −38.7 kJ/mol (Na), −7.4 kJ/mol (K) and 49.4 kJ/mol (Tl). Therefore, only the reaction for TlCp is endothermic. Although the entropy change for this reaction is expected to be positive, the term $T\Delta_rS^o$ at 298.15 K will be much smaller than Δ_rH^o for TlCp, thus implying that $\Delta_rG^o > 0$.

Experimental Section

Materials: Ethanol (Merck, 99.8%) was pre-dried over calcium sulfate, refluxed over activated magnesium and iodine, and finally distilled. Lithium, sodium, potassium and thallium (Sigma) were kept inside an oxygen- and water-free glove-box and used as supplied. Pentane was distilled over P_2O_5 and kept in the glove-box over 4 Å molecular sieves. Tetrahydrofuran was dried over 4 Å molecular sieves, refluxed with sodium and benzophenone, and distilled. Toluene was dried over 4 Å molecular sieves, refluxed with sodium and benzophenone, and distilled. Cyclopentadiene was prepared by cracking the Cp_2 dimer under an inert atmosphere, using a Vigreux column, collected at 0° C and used immediately.

Physical Measurements: Infrared spectra were obtained on a Perkin−Elmer 577 spectrophotometer with samples mounted as Nujol mulls between KBr plates. Elemental analyses were performed on an automatic analyzer Perkin−Elmer 240 C (C, H). Instrumental neutron activation analysis (INAA) was performed on sodium, using sodium acetate as a standard (for experimental procedure and data processing see, for example, ref.[42]).

Cyclopentadienyl Salt Syntheses: The Li, Na, and K compounds are moisture sensitive. Therefore, all syntheses and handling were made inside an oxygen- and water-free (<5 ppm) glove-box or using Schlenk techniques.

The sodium and potassium cyclopentadienyl compounds were synthesised in THF solution according to a literature procedure.[6] The solution was then taken to dryness and the precipitate washed twice with pentane. The resulting compounds were analysed by IR spectroscopy and elemental analysis (C, H). Additionally, the sodium content in NaCp was measured by neutron activation. All analysis found the compounds to be pure.

Lithium cyclopentadienyl was synthesised in THF solution by a similar method to the one used for the sodium and potassium analogues, but instead of metallic lithium we used butylithium in solution. The final solution was then taken to dryness and the precipitate washed twice with pentane. The resulting compound was analysed by IR spectroscopy and elemental analysis (C, H).

Thallium cyclopentadienyl was synthesised from thallium sulfate, sodium hydroxide, and freshly cracked cyclopentadiene in water, according to a literature procedure.[43] After sublimation the yellow product was analysed by IR spectroscopy and elemental analysis (C, H).

Reaction-Solution Calorimetry: The calorimeter used was specially built for the study of oxygen- and water-sensitive compounds, and the experimental procedure was described in a previous paper.[15]

All measurements were made near 298.15 K, and the results are averages of at least four runs. The errors presented are twice the standard deviation of the mean in each case.

Note added in proof (February 1, 2001): During publication a previous value of the enthalpy of formation of NaCp (−14±25 J/mol; E. B. Evstigneeva, H. A. Bartolomeeva, T. H. Hukolskai, A. M. Moosu, *Zh. Fiz. Khim.* **1973**, *47*, 2727−2727) was brougth to our attention. Despite the poor quality of the result, their error bar overlaps the experimental value measured in this paper. The reference gives no details concerning the calculation of that value.

Acknowledgments

The authors thank Dr. Ângela Gouveia (ITN) for performing the instrumental neutron activation analysis (INAA). Financial support from FCT (PRAXIS/2/2.1/QUI/51/94) is gratefully acknowledged.

BF_3-Stabilized Metalated Sulfinylimides and Sulfurdiimides of the Type $Cp(NO)_2CrNSE{\cdot}BF_3$ (E = O, $NSiMe_3$)

Michael Limmert,[a] Ingo-Peter Lorenz,*[a] Jürgen Neubauer,[a] Heinrich Nöth,[a] and Tassilo Habereder[a]

Dedicated to Professor Kurt Dehnicke on the occasion of his 70th birthday

Keywords: Chromium / Metalation / Sulfur / N ligands / Lewis acids / Structure elucidation

The coordination behavior of the imido derivatives of sulfur Me_3SiNSE (E = O, $NSiMe_3$) towards the 16-electron complex $[CpCr(NO)_2]BF_4$ has been studied. In both cases coordination through an η^1-*N* linkage occurs as well as elimination of Me_3SiF to afford the metalated derivatives $Cp(NO)_2CrNSE$, which as N-nucleophiles are additionally bound to the also-formed electrophilic BF_3 molecule (**1**, **2**). Neither the possible addition products $[Cp(NO)_2Cr\{N(SiMe_3)SE\}]BF_4$ as intermediates in the synthesis of **1**, **2** nor the BF_3-free derivatives $Cp(NO)_2CrNSE$ as elimination products of **1**, **2** could be stabilized or generated. The molecular structures of **1**, **2** have been determined by single crystal X-ray analyses. Both compounds contain a distorted tetrahedrally configured chromium center and an almost planar zig-zag conformation of their sulfinyl imido (F_3BNSO) and sulfur diimido ligand ($F_3BNSNSiMe_3$), respectively.

Introduction

In contrast to SO_2 the isoelectronic molecules sulfinylimide HNSO and sulfurdiimide $S(NH)_2$ are not monomeric, are unstable and are difficult to generate and handle.[1] Thus, they more closely resemble the also isoelectronic methylenesulfine CH_2SO. The N-substituted derivatives RNSO and $S(NR)_2$, however, especially with R = aryl are easily accessible, more stable and have proven useful as synthons in organic synthesis.[2] Because of their heterocumulene structure their manifold coordination chemistry has been investigated.[3] They coordinate above all by η^2-*N*=*S*,[4,5] η^1-*S*[4a,6,7] or η^1-*N*[8,9] binding to various electrophilic complex fragments. There are two further ligand functions known. Whereas RNSO additionally undergoes the η^1-*O* linkage,[10] $S(NR)_2$ can also bind as a chelate ligand through both the N atoms (η^2-N_2;[11] see Scheme 1).

Recently we have been able to prepare some new sulfinylimide complexes of the type $CpMn(CO)_2\{S(O)NR\}$ (Cp = C_5H_5, $C_5H_4CH_3$; R = C_6H_5, $SiMe_3$) with η^1-*S* coordination.[12] In the beginning, and with respect to the silyl derivatives, our aim was to generate and stabilize the basic molecule HNSO within the coordination sphere of the transition metal by directed substitution reactions of, for example, Me_3SiX (X = OH, F, Cl). Our attempts, however, were not successful.[12] Hitherto, no HNSO complex has been structurally characterized, although some have been mentioned in the literature.[13–15] Here we report on further attempts at the synthesis of sulfinylimide (RNSO: R = $SiMe_3$, H) and, analogously, sulfurdiimide complexes [$S(NR)_2$: R = $SiMe_3$, H]. We have chosen the cation $[CpCr(NO)_2]^+$ which is isoelectronic with the neutral $CpMn(CO)_2$ used earlier[12] and which seemed to be a suitable complex fragment.

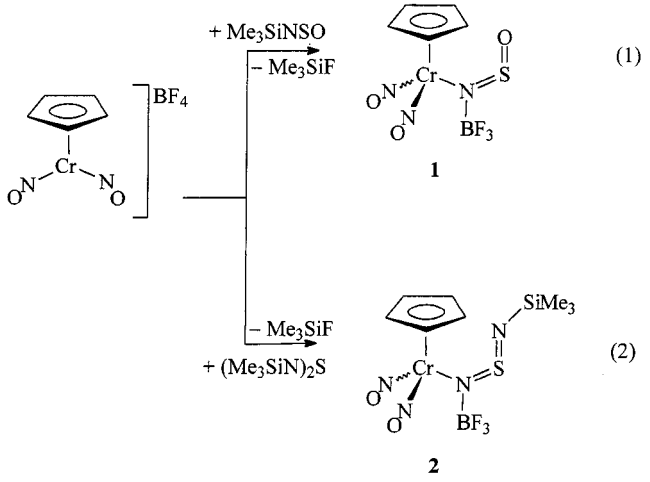
Results and Discussion

The 16-electron species $[CpCr(NO)_2]BF_4$ was generated from the chloride $CpCr(NO)_2Cl$ by dehalogenation with $AgBF_4$ and then reacted with the sulfinylimide Me_3SiNSO in CH_2Cl_2 to afford very surprisingly the neutral BF_3-containing complex $Cp(NO)_2Cr\{N(BF_3)SO\}$ (**1**) [Equation (1)]. The simultaneous elimination of Me_3SiF has been proved by ^1H NMR spectroscopy. Normally, and analogously,[12] we would have expected the formation of the addition compound $[Cp(NO)_2Cr\{N(SiMe_3)SO\}]BF_4$, although with an η^1-*N* linkage because of the strong electrophilicity of $CpCr(NO)_2^+$. The fragment $CpMn(CO)_2$ is amphoteric, has a soft center and forms an Mn−S bond to the same ligand Me_3SiNSO.[12]



The same reaction occurred when the salt $[CpCr(NO)_2]BF_4$ was reacted with the sulfurdiimide $S(NSiMe_3)_2$, and the neutral BF_3-containing product $Cp(NO)_2Cr\{N(BF_3)SNSiMe_3\}$ (**2**) was obtained [Equation (2)]. Both compounds are dark-green solids which are air stable, but sensitive towards moisture. They dissolve only moderately in $CDCl_3$ and decompose very easily in acetone. In both cases a Cr−N bond has been formed and one $SiMe_3$ group of the sulfinylimide or the sulfurdiimide has been substituted for the isolobal organometallic fragment $CpCr(NO)_2$. The reaction pathway, however, seems to be more complicated.

Despite many efforts, including the use of low reaction temperatures, we could not find any hint of the addition compound mentioned above as a possible intermediate for **1** or **2**. In separate experiments $AgBF_4$ reacts with the molecules Me_3SiNSO and $S(NSiMe_3)_2$ to eliminate Me_3SiF, although no further product could be identified or isolated. Therefore, we assume for the reaction mechanism that, after separation of AgCl, the silyl derivatives are attacked by the BF_4^- anion to give Me_3SiF and the corresponding anions NSO^- and $NSNSiMe_3^-$, respectively. These anions coordinate to the chromium center through the nucleophilic nitrogen, which has been proved previously as their preferred linkage mode.[14,16,17] The resulting metalated sulfinylimide **1** and sulfurdiimide **2** are finally stabilized by the remaining electrophile BF_3 molecule as Lewis acid−base adducts. On the other hand, BF_3 could already bind to the generated anions mentioned above. The presence of BF_4^- and BF_3 is obviously necessary. When $AgCF_3SO_3$ was used for dehalogenation of $CpCr(NO)_2Cl$ to form $[CpCr(NO)_2]CF_3SO_3$, no elimination of Me_3SiX and no coordination of the imides was observed.

The IR, ^1H, ^{11}B, $^{13}C\{^1H\}$, and ^{19}F NMR and mass spectra of compounds **1**, **2** were measured. The IR spectra of **1**, **2** exhibit two ν(NO) bands at about 1815 and 1710 cm^{-1} (in KBr). The frequency range is the same, although the frequency difference of both is less than in the starting material $CpCr(NO)_2Cl$ [IR (KBr): ν(NO) = 1824; 1707/1689 cm^{-1}]. The absorptions for ν(SO) and ν(SN) of **1** are assigned at 1245 and 1123 cm^{-1}, and ν(BF) is found at 1084 cm^{-1} as a broad unresolved absorption. Compound **2** shows two ν(SN) absorptions at 1246 and 1132 cm^{-1} and one broad ν(BF) absorption again at 1096 cm^{-1}.

In the ^1H NMR spectra of **1**, **2** the protons of the Cp ring give singlets at δ = 5.75 and 5.67, respectively. The protons of the $SiMe_3$ group in **2** absorb at δ = 0.30. In the $^{13}C\{^1H\}$ NMR spectrum of **2** singlets are found at δ = 0.9 ($SiMe_3$) and 102 (Cp).

Due to the low solubility of **1** in $CDCl_3$, the expected quadruplet signals in both the ^{11}B and ^{19}F NMR spectra of **1** only appear as unresolved broad signals at δ = 0.98 and 138.7, respectively. Compound **2**, however, dissolves better in $CDCl_3$ and does show, therefore, two quadruplets at δ = 1.0 ($^1J_{BF}$ = 21.2 Hz) and 139.5 ($^1J_{BF}$ = 18.8 Hz). In both the spectra the broadness of the signals and the values of the chemical shifts are similar, indicating that the influence of SO (in **1**) and $NSiMe_3$ (in **2**) on the coordinating N atom seems to be identical.

No mass spectrum of **1** could be recorded; that of **2** does not show the parent signal, but fragments at *m*/*z* = 310, 280, 250 [$M^+ - BF_3 - n$NO] (*n* = 0−2) and 207 [$CpCr(NO)SN_2^+$], confirming the molecular structure.

X-ray Structure Analyses of 1 and 2

Single crystals of **1** and **2** suitable for X-ray diffraction analysis were obtained by covering their CH_2Cl_2 solutions with a layer of *n*-hexane and cooling to −20 °C. The results of the structural determinations are summarized in Table 1 and the molecular structures of **1** and **2** with the most important bonding parameters are given in Figure 1 and 2, respectively.

The analysis of **1** confirms the pseudo-tetrahedral coordination of Cr(1), the trigonal planar environment of N(3) [sum of angles at N(3) = 359.9°], the almost linear NO ligands [Cr(1)−N−O ≈ 172°] and the Cr(1)−N(3) bond length of 2.049(2) Å (η^1-*N*), indicating a typical Cr−N single bond. The bond lengths S(1)−N(3) [1.526(2) Å] and S(1)−O(3) [1.441(2) Å], typical for double bond character, are not very different to free sulfinylimides.[18] The distance N(3)−B(1) [1.662(4) Å] is also typical for borane imino adducts;[19] the B(1)−F_n bonds have an average value of 1.37 Å.

[a] $w^{-1} = \sigma^2F_o^2 + (xP)^2 + yP$, where $P = (F_o^2 + 2F_c^2)/3$.

The angles at Cr(1) differ significantly. The angle N(1)−Cr(1)−N(2) [90.7(1)°] is the smallest of the three Cr-containing angles, the other two are 100.0(1)° for N(1)−Cr(1)−N(3) and 96.2(1)° for N(2)−Cr(1)−N(3). The same characteristic is found for the angles of N(3). Whereas the angle Cr(1)−N(3)−B(1) is exactly 120.2(2)°, those of Cr(1)−N(3)−S(1) and S(1)−N(3)−B(1) are 123.5(1)° and 116.2(2)°, respectively. The angle N(3)−S(1)−O(3) [115.4(1)°] of **1** is smaller than the analogous angle in $[Cp(CO)_2MnS(O)NSiMe_3]$ [118.8(3)°][12] due to the free electron pair on sulfur demanding more space. The angles N(3)−B(1)−F_n ≈ 108° are almost tetrahedral, the angles F_n−B(1)−F_n average 111°. The dihedral angle defined by O−S−N−B/Cr connectivity is only 1.4° so that the electron delocalization is almost perfect.

Compound **2** possesses structural configurations and parameters very similar to those found for **1**: pseudo-tetrahedral configuration at Cr(1), trigonal planar N(3) (sum of angles at N(3) = 360°), linear NO ligands (≈ 172°) and an almost identical Cr(1)−N(3) bond of 2.043(2) Å. The double-bond containing distances S(1)−N(4) [1.505(2) Å] and S(1)−N(3) [1.546(2) Å] differ due to the different substituents on N(4) and N(3). The distance N(3)−B(1) of 1.593(3) Å is a little bit smaller than that found in **1**.

The angle between both the NO ligands in **2** is, as in **1**, the smallest [N(1)−Cr(1)−N(2) = 95.8(3)°] of the three Cr(1)-containing angles, but it does not differ so much from the others as in **1**. The angles N(1)−Cr(1)−N(3) [98.90(8)°] and N(2)−Cr(1)−N(3) [97.05(8)°] differ only slightly. The angles around N(3) behave as in **1**: the angle Cr(1)−N(3)−S(1) is again 120.5(1)°, whereas the other two are Cr(1)−N(3)−S(1) = 123.0(1)° and S(1)−N(3)−B(1) = 116.5(1)°. The angle 112.0(1)° for N(3)−S(1)−N(4) is comparable to the analogous O(3)−S(1)−N(3) of the metalated

Figure 1. sulfinylimide **1**, but surprisingly much smaller than that in the free ligand $S(NSiMe_3)_2$ (129.5°) which was measured, however, by electron diffraction in the gas phase.[20] The bond angles with respect to the Lewis acid−base adduct part of **2** are very similar to those in **1** [N(3)−B(1)−F_n ≈ 108°; F_n−B(1)−F_n ≈ 110°].

Experimental Section

All operations were carried out under an argon atmosphere in dry, argon-saturated solvents. $CpCr(NO)_2Cl$,[21] Me_3SiNSO[22] and $S(NSiMe_3)_2$ [23] were prepared according to literature procedures. − IR: Nicolet 520 FT-IR (KBr). − NMR: Jeol EX-400 (^{1}H: 399.784 MHz; ^{11}B: 128.3 MHz; ^{13}C: 100.5 MHz; ^{19}F: 376.1 MHz). − MS: Jeol MS 700 (EI). − X-ray: Siemens P4 CCD area detector.

{*N*-η^5-Cyclopentadienyldinitrosylchromio}sulfinylimide·Trifluoroborane (1): A solution of $CpCr(NO)_2Cl$ (0.1 g, 0.47 mmol) in CH_2Cl_2 (5 mL) was stirred with $AgBF_4$ (0.1 mg, 0.48 mmol) until AgCl precipitated. After 10 min. Me_3SiNSO (0.08 mL, 0.5 mmol) was added to the filtered solution, which was then stirred for at least 20 min. The resulting yellow-green solution was covered with a layer of *n*-hexane and cooled to −20 °C. After one week green crystals of **1** separated, which were filtered off, washed with *n*-hexane and dried in vacuum. Yield: 0.035 g (25%), m.p. 132 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 3143, 3114 (C−H; Cp), 1816, 1705/1696 (N≡O), 1429, 1402 (C=C; Cp), 1298 (S=O), 1245, 1123 (S=N), 1084 (BF) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 5.74 (s, Cp). − ^{11}B NMR ($CDCl_3$): δ = 0.98 (br. m). − ^{19}F NMR ($CDCl_3$): δ = 138.7 (br. m). − Neither a ^{13}C NMR nor an ms spectrum of **1** could be recorded due to its low solubility in $CDCl_3$ and its instability in solution. − $C_5H_5BCrF_3N_3O_3S$ (306.97): calcd. C 19.45, H 1.63, N 13.68; found C 20.10, H 2.03, N 12.78.

{*N*-η^5-Cyclopentadienyldinitrosylchromio}(*N*′-trimethylsilyl)-sulfurdiimide·Trifluoroborane (2): The dehalogenation of $CpCr(NO)_2Cl$ (0.1 g, 0.47 mmol) with $AgBF_4$ (0.1 mg, 0.48 mmol) was carried out as described above for **1**. $S(NSiMe_3)_2$ (0.12 mL, 0.48 mmol) was added to the resulting solution. After stirring for 30 min. a yellow-green solution was formed, which was layered with *n*-hexane and stored at −20 °C for crystallization. After one week green crystals of **2** separated, which were filtered off, washed with *n*-hexane and dried in vacuum. Yield: 0.05 g (40%), m.p. 160 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 3118 (C−H; Cp), 2967, 2902 (C−H), $SiMe_3$), 1818, 1727/1696 (N≡O), 1432, 1417 (C=C; Cp), 1246, 1132 (S=N), 1096 (B−F) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 5.67 (s, Cp), 0.30 (s, $SiMe_3$). − ^{11}B NMR ($CDCl_3$): δ = 1.0 (q, $^1J_{BF}$ = 21.2 Hz, BF_3). − ^{19}F NMR ($CDCl_3$): δ =139.5 (q, $^1J_{BF}$ = 18.8 Hz). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 102.2 (s, Cp), 0.9 (s, $SiMe_3$). − EI-MS: *m*/*z* = 310, 280, 250 [M^+ − BF_3 − *n*NO] (*n* = 0−2), 207 [CpCr(NO)NSNF]. Despite repeated attempts no reliable elemental analyses were obtained.

X-ray Crystallography: Single crystals were selected and mounted with perfluoroether oil on the tip of a glass fiber. For all measurements a Siemens P4 diffractometer equipped with a CCD area detector and a low-temperature device LT2 was used with Mo-K_α radiation and a graphite monochromator. Preliminary dimensions of the unit cell were calculated from a strong reflection collected on four different sets of 15 frames. Data collection was performed by the hemisphere method and the data collected on 1360 frames by changing θ by 0.3° increments at two different χ settings. The data were reduced by the program SAINT followed by absorption correction with the program SADABS. The structures were solved by direct methods (SHELXS-97). All non-hydrogen atoms are given in anisotropic description. H atoms were put in calculated positions and included in the final cycles of refinement as riding on the respective C atoms with U_i = 1.2U_c. Relevant crystallographic data are summarized in Table 1.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cam-

bridge Crystallographic Data Centre as supplementary publication nos. CCDC-148949 (**1**) and -148948 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Heterodicarba-*nido*-hexaboranes from Hydroborations of Exocyclic Unsaturated Heterodiborolanes

Peter Greiwe,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

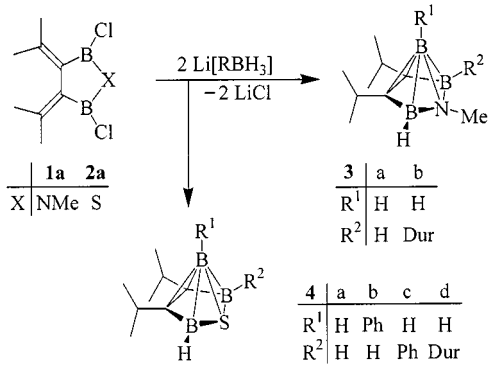
Dedicated to Prof. Dr. Dieter Sellmann on the occasion of his 60th birthday

Keywords: Boron / Carboranes / Sulfur / Nitrogen / Heterocycles / Hydroboration

The hydroboration of 1-aza-2,5-diduryl-3,4-diisopropylidene- and 2,5-diduryl-1-thia-3,4-diisopropylidene-2,5-diborolanes (**1b**, **2b**) with equimolar amounts of BH_3·thf leads to the corresponding 2-aza-4,5-dicarba- and 4,5-dicarba-2-thia-*nido*-hexaboranes **3c** and **4e**. When an excess of BH_3·thf reacts with the azadiborolane **1b** the azadiborole derivative **5** is obtained as the main product. This surprising result is explained by the addition of three BH_3·thf moieties and the subsequent loss of B_3H_7·thf. The reaction of the sterically less hindered *tert*-butylazadiborolane **1c** with BH_3·thf yields two 2-aza-4,5-dicarba-*nido*-hexaboranes (**3d,e**), both of which carry a *t*Bu group in the apical position. A possible reaction pathway is suggested. The new heterocarboranes **3c,d,e** and **4e** are identified by multinuclear NMR spectroscopy and mass spectrometry. X-ray crystallographic studies of **3c** and **4e** confirm the *nido*-arrangement of the cluster atoms.

Introduction

Recently we described the formation of the 2-aza-4,5-dicarba-*nido*-hexaboranes(6) **3a,b** by substitution/hydroboration reactions of a chlorine-substituted azadiborolane with lithium borates (Scheme 1).[1] The corresponding 4,5-dicarba-2-thia-hexaboranes(5) (**4a**−**d**) have also been prepared by us exploiting the same methodology.[2] This route only gives access to fully BH-substituted derivatives or compounds with one aryl/alkyl group. Since by-products are also formed and the desired compounds are sensitive liquids which are difficult to separate, only the thiacarborane **4d** could be isolated. In order to overcome this problem the aza- and thiadiduryldiborolanes **1b**, **2b** and the didurylox-adiborolane **6** were synthesized[1] as potential starting materials for the preparation of crystalline and more stable heterodicarbahexaboranes. This paper describes how this goal is achieved by using BH_3·thf as the hydroboration agent and presents the first completely refined crystal structure analysis of an azadicarba-*nido*-hexaborane(6) and a thiadicarba-*nido*-hexaborane(5). Ab initio calculations are used to model the reaction sequence and give an explanation for the formation of different products depending on the ratio azadiborolane/BH_3·thf.



Scheme 1

Results and Discussion

Hydroboration with BH_3·thf

Treatment of the heterodiborolanes **1b** and **2b** with equimolar amounts of BH_3·thf in hexane solution leads to 2-aza-4,5-dicarba-3,6-diduryl-4,5-diisopropyl-2-methyl-*nido*-hexaborane(6) (**3c**) and 4,5-dicarba-3,6-diduryl-4,5-diisopropyl-2-thia-*nido*-hexaborane(5) (**4e**) in good yields (Scheme 2). These colorless, moisture-sensitive compounds are obtained by recrystallization from hexane. The formation of the heterocarboranes is assumed to proceed by bridging hydroboration of the double bonds by one molecule of BH_3. This generates bicyclic heteroorganoboranes (**3e′**, **4e′**) as intermediates which transform into the more stable polyhedral heterocarborane structures.

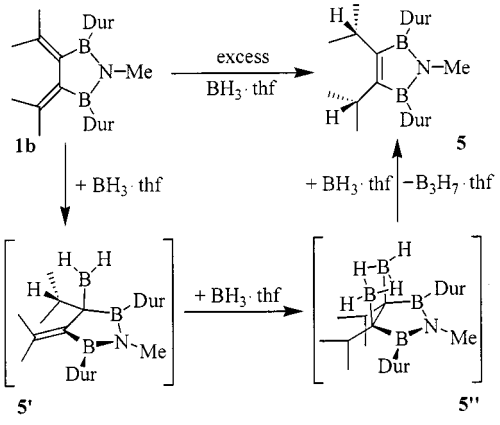
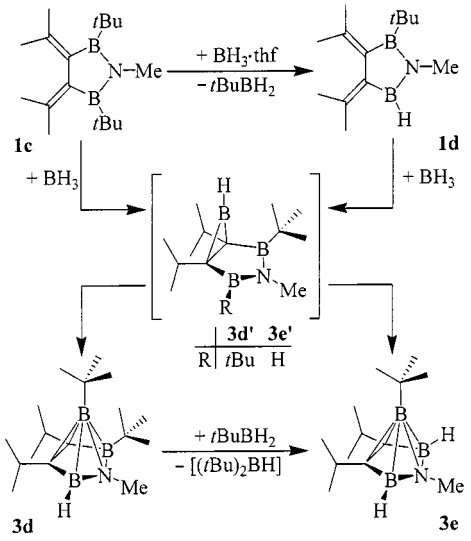
When an excess of BH_3·thf is employed for the hydroboration of **1b** the azadiborole **5**[3] is the main product instead of the azacarborane **3c**, which is now found in only small amounts. The reaction of **2b** with more than one equivalent of BH_3·thf, on the other hand, does not lead to the corresponding thiadiborole. In this case a partial exchange of substituents obviously takes place since, besides the thiacarborane **4e**, 1,2-diduryldiborane(6) is also found after workup. The formation of **5** formally corresponds to a 1,4-addition of H_2 to the hexadiene part of **1b**. In a related hydroboration reaction an exocyclic doubly unsaturated 1,3-diborolane yielded the expected tricarbahexaborane on treatment with $(EtBH_2)_2$ and, surprisingly, a diborole derivative.[4] Apparently, the excess of BH_3 present during the course of the reaction plays an important role. The addition of two BH_3 molecules to **1b**, one to each double bond, in a *syn* fashion would lead to the BH_2B bridged species **5′′** (via **5′**), which could lose B_2H_4 to give **5**. However, this process seems rather unlikely because of the inherent instability of B_2H_4 unless a suitable Lewis base (e.g. PMe_3) is present. More likely is an attack by a third BH_3·thf on the B_2H_4 moiety in **5′′** followed by the elimination of THF-stabilized B_3H_7 and the simultaneous generation of the azadiborole.

The second hydroboration of **1b** can either be intramolecular, leading to the bicyclic **3c′** (as shown in Scheme 2), or intermolecular involving an additional BH_3 molecule which yields **5′′** (according to Scheme 3). MP2 and DFT computations[5] indicate that the second possibility is favored over the intramolecular reaction by ca. 8 kcal/mol. It thus follows that if an excess of BH_3 is present in solution the BH_2B-bridged **5′′** is more likely to be formed than **3c′/3c**. The *anti* addition of two BH_3 molecules to **1b** is also possible but was not examined since only **5′′** can react to **5**. The transition states for the addition of the third BH_3 and the subsequent liberation of B_3H_7 could not be located. They are assumed to be low in energy. The proposed reaction pathway for the formation of **5** is shown in Scheme 3.



Scheme 3

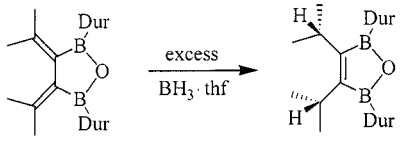
The reaction of the sterically less constrained di-*tert*-butylazadiborolane **1c** with one equivalent of BH_3·thf yields two azadicarbahexaborane(6) derivatives. Surprisingly, **3e** contains only one *t*Bu substituent, which is located in the apical position. Compound **3d** carries the expected two *t*Bu groups, one in the apical and the other in an equatorial position. At room temperature the ratio **3d:3e** is approximately 2.5:1. After the reaction no BH_3 is found, although $(tBuBH_2)_2$ and **1c** are detected. As ^{11}B NMR spectra reveal, refluxing the solution for some time gives about equal amounts of both azacarboranes and decreases the fraction of $(tBuBH_2)_2$. These findings suggest the following reaction sequence: BH_3 hydroborates **1c** to give a bicyclic intermediate **3d′** in which the BH group can easily exchange its position with one of the *t*BuB groups leading to **3d** (Scheme 4). Alternatively, prior to a hydroboration one of the *t*Bu groups or *t*BuB units in **1c** can be replaced by a hydrogen atom or a BH unit, which in both cases produces **1d** and $tBuBH_2$. After the addition of BH_3 to the double bonds the azaorganoborane **3e′** rearranges to **3e**. Since the ratio **3d:3e** changes at elevated temperatures, i.e. more **3e** is formed although no BH_3 is left in the mixture, additional reactions must occur. Two processes seem rational: **3d** and $(tBuBH_2)_2$ can exchange their H and *t*Bu substituents leading directly to **3e**, or additional BH_3 is generated from $tBuBH_2$. At higher temperatures the BH_3 immediately attacks the remaining **1c** to yield **3d** or **3e**, but now **3e** may be the favored product. Both routes imply the formation of $(tBu)_2BH$, which, however, was not observed in the NMR spectra. Nevertheless, this would explain why more of the azacarborane derivative with only one *t*Bu group is generated and less $tBuBH_2$ is found after heating.



Scheme 4

Hydroboration of the oxadiborolane **6** could in principle lead to an oxacarborane, a heterocarborane family which is as yet unknown. The reaction with BH_3·thf is considerably slower at ambient temperature than the above-mentioned BH_3 additions and produces a mostly insoluble colorless solid. No spectroscopic evidence for an oxacarborane or a bicyclic organoborane is found. In the mass spectrum of the soluble part peaks for the oxadiborole **7** are present (Scheme 5). Ab initio computations show that an oxadicarba-*nido*-hexaborane(5) structure should be more stable

than its bicyclic organoborane structure (of type **3d/e′**) if all substituents are H or only one boron atom carries a methyl group.[6] Accordingly, the reaction of **6** with BH_3 should yield an organoborane which might be highly reactive toward oligomerization and is thus not isolated.



6 **7**

Scheme 5

Hydroboration with Thexylborane

During the reaction of **1c** with BH_3·thf the starting material and $(t\text{BuBH}_2)_2$ are present in solution at the same time and no reaction between these components, i.e. the formation of an azacarborane carrying three *t*Bu groups, is observed. In order to evaluate the hydroboration ability of alkyldihydridoboranes $(\text{RBH}_2)_2$ thexylborane (thexyl = 1,1,2-trimethylpropyl) was allowed to react with the duryl-substituted heterodiborolanes **1b** and **2b** as well as with the *tert*-butyl-substituted **1c**. Compounds **1b** and **2b** do not react with $(\text{thexBH}_2)_2$ in refluxing hexane, probably for steric reasons. At room temperature **1c** also shows no reaction but refluxing the hexane solution for several days causes a slow exchange of substituents and a mixture of equatorially hydrogen-substituted azacarboranes is formed. Organodihydridoboranes are dimers in solution and must separate into monomeric species before they can react. Furthermore, it seems that a hydroboration reaction with RBH_2 is always preceded by an exchange of substituents reducing the steric bulk in the heterocycle and thereby allowing the reaction to take place. No fully alkyl-substituted azacarborane is found which means that a direct hydroboration of **1c** by thexBH_2 does not occur.

Spectroscopic and Structural Characterization

In the ^{1}H and ^{13}C NMR spectra of the heterocarboranes **3c** and **4e** all carbon atoms and methyl groups of the duryl rings and isopropyl substituents can be distinguished indicating a restricted rotation. The isopropyl protons of **4e** give two doublets and a septet, and for **3c** a septet and a pseudo triplet are observed. The signal of a cage carbon atom broadened by coupling to the neighboring boron atoms was observed only in the ^{13}C NMR spectrum of **3c**. The ^{11}B NMR spectra of the heterocarboranes show doublets at high field for the apical BH units at $\delta = -38.2$ ($^1J_{BH} \approx 202$ Hz) (**3c**) and $\delta = -35.2$ ($^1J_{BH} \approx 216$ Hz) (**4e**). The coupling constants have typical values for apical bonding situations. For the basal boron atoms singlets are observed at $\delta = 23.2$ (**3c**) and 28.5 (**4e**). Compounds **3d** and **3e** were obtained as a mixture and only their ^{11}B NMR spectroscopic data can be interpreted. Compound **3e** gives a singlet at $\delta = -34.2$ for the apical boron and a doublet at $\delta = 15.9$ ($^1J_{BH} \approx 160$ Hz) for the equatorial BH units whereas **3d** has a singlet at $\delta = -32.3$ (apical B), a singlet at $\delta = 30.1$ for the equatorial *t*Bu-substituted boron atom and a

doublet at δ = 15.9 ($^1J_{BH} \approx 160$ Hz). These data are in line with polyhedral *nido* structures.

The NMR spectroscopic data of **5** reflect its high symmetry. Two doublets and a septet are found for the isopropyl protons, the methyl groups of the freely rotating duryl rings give only two ^{1}H and ^{13}C NMR signals.

The solid state structures determined by X-ray crystallography (Table 1) confirm that the heterocarboranes **3c** (Figure 1) and **4e** (Figure 2) are *nido*-6<V> clusters as already suggested by their spectroscopic data. The shapes of the molecules are mostly determined by the bulky duryl and isopropyl groups; the apical BH units have only a minor influence. This is the reason for a disordered orientation of the molecules in the crystal, where the apical BH groups may lie above or below the idealized ring plane. The refinements of these disordered structures do not yield very accurate values for the distances and angles, which are in the expected ranges. The gross structural parameters of **3c** and **4e** are very similar. In both structures the substituents adopt almost identical positions: the duryl rings are virtually perpendicular to the B−C−C−B basal planes. The angles of these planes with the three-membered rings C1−B3−C2 in **3c** and C1−B2−C1′ in **4e** differ by 2.8° (58.4° vs. 55.6°) and, because of its smaller covalence radius, which results in shorter bond lengths, the distortion of the nitrogen atom from the B−C−C−B plane (24.8°) toward the apical atom is more pronounced than for the sulfur atom in **4e** (12.0°).

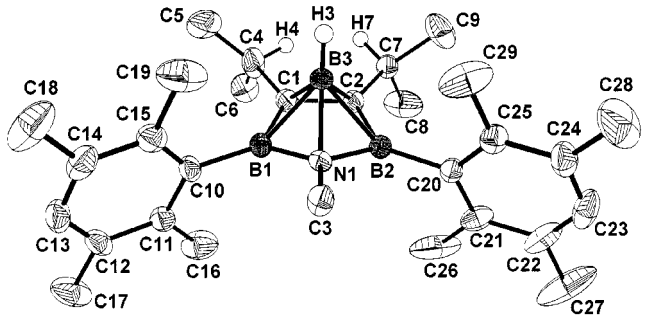

Figure 1. Molecular structure of **3c**; selected bond lengths [Å] and angles [°]: B1−C1 1.501(4), B2−C2 1.502(4), C1−C2 1.499(4), N1−B1/B2 1.491−1.547(8), B3−N1 1.676, 1.693(10), B3−B1/B2 1.901−1.963(8), B3−C1/C2 1.714−1.749(8); [C1−B3−C2]/[B1−C1−C2−B2] 58.4, [B1−C1−C2−B2]/[B1−N1−B2] 24.8

Conclusion

The above reactions clearly show the influence that the steric shielding of the boron atoms has during hydroborations. Compounds **1b** and **2b** carrying the most bulky groups give only apically BH-substituted heterocarboranes — a B-duryl unit in this location would interfere with the other substituents, especially with the second duryl group. However, under certain conditions, such as a large excess of BH_3·thf, other reactions also occur and $(DurBH_2)_2$ and the azadiborole **5** are obtained. On the other hand, the hydroboration of the double bonds in **1c** leads to **3d**, which surprisingly carries one of the *t*Bu groups in the apical position. In this case the smaller substituents also allow an exchange of *t*Bu for H generating $(tBuBH_2)_2$ and the azacarborane **3e** with only one *t*Bu group bound to the apical boron atom. This indicates that compounds with an apical *t*BuB unit are sterically and/or energetically highly favored over other possible *t*Bu substituted isomers. Compounds having apical BH and equatorial B*t*Bu units were not detected. Furthermore, it can be concluded that neither $tBuBH_2$ nor $thexBH_2$ is an efficient hydroborating agent in the above described cases. Again, steric reasons are the most likely factors inhibiting a reaction.

Experimental Section

General: All reactions and manipulations were performed in dry glassware under argon or nitrogen using standard Schlenk techniques. Solvents were distilled from appropriate drying agents under inert gas before use. − $Et_2O{\cdot}BF_3$ was used as the external standard for ^{11}B NMR. As internal references for ^{1}H and ^{13}C NMR spectra the signals of the deuterated solvents were used and calculated relative to TMS. NMR: Bruker AC 200 and Bruker DRX 200. − MS: Varian MAT CH7 and GCMS HP 5971. − The following starting materials were prepared by literature methods: **1b, 1c**, **2b**, and **6**,[1] 1,2-dithexyldiborane(6).[7] BH_3·thf (1 M) was commercially obtained (Aldrich).

2-Aza-4,5-dicarba-3,6-diduryl-4,5-diisopropyl-2-methyl-*nido*-hexaborane(6) (3c): To a solution of **1b** (330 mg, 0.78 mmol) and 25 mL of hexane was slowly added BH_3·thf (0.78 mL, 0.78 mmol) at −25 °C. The solution was stirred at this temperature for 15 min. and for 15 h at ambient temperature. The solvent was removed, the remaining solid dissolved in hexane and the solution filtered. From the concentrated solution 255 mg (0.58 mmol, 74%) of **3c** was obtained at −30 °C. − ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.22 [pseudo t, $^3J_{HH}$ = 7 Hz, 12 H, $CH(CH_3)_2$], 2.16, 2.18, 2.21, 2.34 (4 s, 4×6 H, C_{aryl}-CH_3), 2.44 [sept, $^3J_{HH}$ = 7 Hz, $CH(CH_3)_2$], 2.53 (N−CH_3), 6.97 (s, 2 H, duryl). − ^{11}B NMR (C_6D_6, 64 MHz): δ = −38.2 (d, B_{apical}, $^1J_{BH}$ = 202 ± 3 Hz), 23.2 ($B_{eq.}$). − ^{13}C NMR (C_6D_6, 50 MHz): δ = 19.8, 20.0, 20.5, 21.4 (4×C_{aryl}-CH_3), 24.5, 24.2 [2×$CH(CH_3)_2$], 25.5 [$CH(CH_3)_2$], 31.8 (N−CH_3), 90.1 [br, BC−$CH(CH_3)_2$], 132.1, 133.3, 133.5, 135.4, 138.0 (5×C_{aryl}). − EI-

MS: *m/z* (%) = 439 [M^+] (98), 427 [M^+ − BH] (81), 396 [M^+ − *i*Pr] (100), 384 (72). − CI-MS (isobutane): *m/z* (%) = 440 [M^+ + H] (100), 428 [M^+ − B] (46), 296 [M^+ + H − BDur] (29). − HR-EIMS ($^{12}C_{29}{}^{1}H_{44}{}^{14}N^{11}B_3$): calcd. 439.3757; found 439.3753 (Δmmu = +0.4).

4,5-Dicarba-3,6-diduryl-4,5-diisopropyl-2-thia-*nido*-hexaborane(5) (4e): The same procedure was used as described for **3c**. Yield: 74 mg (60%) − ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.12, 1.20 [2 d, 2×6 H, $^3J_{HH}$ = 7 Hz, CH(CH_3)$_2$], 2.14, 2.16, 2.33, 2.50 (4 s, 4×6 H, C_{aryl}-CH_3), 2.53 [sept, $^3J_{HH}$ = 7 Hz, CH(CH$_3$)$_2$], 6.95 (s, 2 H, duryl) − ^{11}B NMR (C_6D_6, 64 MHz): δ = −35.2 (d, B_{apical}, $^1J_{BH}$ = 216 ± 3 Hz), 28.5 ($B_{eq.}$) − ^{13}C NMR (C_6D_6, 50 MHz): δ = 20.0, 20.5, 20.7, 21.1 (4×C_{aryl}-CH$_3$), 23.23, 23.28 [2×CH(CH$_3$)$_2$], 28.6 [CH(CH$_3$)$_2$], 132.3, 133.57, 133.62, 134.9, 138.0 (5×C_{aryl}). − EI-MS: *m/z* (%) = 442 [M^+] (100), 399 [M^+ − CH(CH$_3$)$_2$] (21), 266 [M^+ − *i*Pr − Dur] (46), 223 [M^+ − *i*Pr$_2$ − Dur] (30). − HR-EIMS ($^{12}C_{28}{}^{1}H_{41}{}^{11}B_3{}^{32}S$): calcd. 442.32080; found 442.32037 (Δmmu = −0.4).

1-Aza-2,5-diduryl-1,2-dihydro-3,4-diisopropyl-1-methyl-2,5-diborole (5): A sample of **1b** (80 mg 0.19 mmol) was dissolved in 5 mL of hexane and treated with BH_3·thf (0.6 mL, 0.6 mmol, excess) at ambient temperature. The mixture was stirred for 15 h, all volatile components were removed in vacuo and the residue was dissolved in hexane. The filtered and concentrated solution gave, at −30 °C, 42 mg (0.1 mmol, 50%) of crystalline, colorless and air-stable **5**. − ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.07, 1.11 [2 d, 2×6 H, $^3J_{HH}$ = 7 Hz, CH(CH_3)$_2$], 2.14, 2.27 (2 s, 2×12 H, C_{aryl}-CH_3), 2.34 (s, 3 H, N−CH_3), 3.01 [sept, $^3J_{HH}$ = 7 Hz, CH(CH$_3$)$_2$], 6.92 (s, 2 H, duryl). − ^{11}B NMR (C_6D_6, 64 MHz): δ = 54. − ^{13}C NMR (C_6D_6, 50 MHz): δ = 19.3, 19.7 (2×C_{aryl}-CH$_3$), 22.5 [CH(CH$_3$)$_2$], 28.9 [CH(CH$_3$)$_2$], 31.9 (N−CH_3), 131.4, 133.2, 133.5 (3×C_{aryl}), 141.6 [br, BC−C(CH$_3$)$_2$], 142.6 (B-C_{aryl}). − EI-MS: *m/z* (%) = 427 [M^+] (100), 384 [M^+ − *i*Pr] (62), 293 [M^+ − durylH] (30).

2-Aza-1,3-di-*tert*-butyl-4,5-dicarba-4,5-diisopropyl-2-methyl-*nido*-hexaborane(6) (3d) and 2-aza-1-*tert*-butyl-4,5-dicarba-4,5-diisopropyl-2-methyl-*nido*-hexaborane(6) (3e): BH_3·thf (2.1 mL, 2.1 mmol) was slowly added to a solution of **1c** (560 mg, 2.1 mmol) in 25 mL of hexane at −60 °C. The mixture was stirred for 15 h and analyzed by ^{11}B NMR spectroscopy and GC/MS showing a ratio **3e:3d** of 1:2.5. After refluxing the solution for 6 h, samples were again taken and analyzed. The ratio **3e:3d** was now 1:1. All volatile components were removed at about 10 mbar leaving behind a colorless oil (a mixture of **3d**, **3e**) and starting material **1c**. − ^{11}B NMR (C_6D_6, 64 MHz): δ = −34.2 (s, **3e**), −32.3 (s, **3d**), 15.9 (d, $^1J_{BH}$ ≈ 160 Hz, **3e,d**), 30 (s, **3d**). − EI-MS (**3e**): *m/z* (%) = 231 [M^+] (27), 216 [M^+ − Me] (4), 188 [M^+ − *i*Pr] (23), 174 [M^+ − *t*Bu] (13), 41 (100). − EI-MS (**3d**): *m/z* (%) = 287 [M^+] (5), 230 [M^+ − *t*Bu] (4), 41 (100).

X-ray Crystallographic Study: Crystallographic data and details of the structure determinations are presented in Table 1. Data collection: Bruker AXS Smart 1000 area detector (Mo-K_α, ω-scans) at −100 °C. The structures were solved by direct methods and refined by least-squares based on F^2 with all measured reflections[8] and using anisotropic temperature factors for non-hydrogen atoms. Hydrogen atoms were located and refined isotropically or inserted in calculated positions. A refinement of **4e** in the space group *Cc* gave no satisfactory results.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-151546 (**3c**) and -151547 (**4e**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CBV2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank Dr. Matthias Hofmann for performing ab initio computations and the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm Polyeder) for financial support.

[3] A structure analysis of a single crystal of **5** was carried out. Only a limited data set was obtained which allowed the solution of the structure but not a reliable refinement. Nevertheless, the analysis supports the connectivity and geometry of an azadiborole derivative. All the bond lengths and angles lie in the expected ranges but, due to the great variations, the values are not discussed here. The structure of **5** has approximate C_{2v} symmetry, the five-membered ring and the directly connected atoms define a plane perpendicular to the duryl and isopropyl groups.

Interionic Solution Structure of Acetyl Ru^{II} Complexes Bearing Diimine and Diamine Ligands by ^1H-NOESY and $^{19}F\{^1H\}$-HOESY NMR: Still More Specific Anion−Cation Interactions

Gianfranco Bellachioma,[a] Giuseppe Cardaci,[a] Francesca D'Onofrio,[a] Alceo Macchioni,*[a] Stefano Sabatini,[a] and Cristiano Zuccaccia[a]

Keywords: Ruthenium / Acetyl complexes / Ion pairs / ^1H-NOESY / $^{19}F\{^1H\}$-HOESY / NMR

Complexes *trans*-[$Ru(PMe_3)_2(CO)(COMe)(N,N)$]X (N,N = diimine or diamine ligand, $X^- = BF_4^-$ or BPh_4^-) have been synthesized by the reaction of *cis*,*trans*-[$RuI(Me)(CO)_2(PMe_3)_2$] with N,N ligands having different steric and electronic properties. The syntheses were only successful with moderately hindered ligands; in other cases, solvento complexes were formed. Some of these were isolated and characterized. The interionic structures of the aforementioned cationic complexes have been investigated in dichloromethane solution by means of ^1H-NOESY and $^{19}F\{^1H\}$-HOESY NMR experiments. The anion–cation interactions (especially for the diamine complexes) were found to be more specific than those in analogous compounds bearing aromatic N,N ligands. For the first time, we have found that the anion preferentially resides close to the N arm *trans* to the COMe group.

Introduction

Even though the phenomenon of ion-pairing is of great importance in several chemical processes mediated by cationic transition metal complexes,[1] structural studies of such ion pairs in solution are still rare. The principal reason for this is that it is difficult to obtain detailed structural information about ion pairs using classical techniques.

Recently, we showed[2] that direct and detailed structural information about ion pairs containing transition metals can be obtained quite easily using NOE NMR spectroscopy, based on the dependence of the NOE between the interacting nuclei on their distance.[3] In principle, this also makes it possible to investigate the relative structures of non-covalently bonded moieties, such as two charged fragments of an ion pair. In practice, several complications and limitations arise that hamper such investigations to some extent. The first limitation stems from the limit of detection of the NOE, which is ca. 5 Å. Thus, (1) only intimate ion pairs can be investigated. A complication arises if we want to quantify the NOE in order to estimate average interionic distances. Due to the possibility of relative anion−cation motion (2), the rotational correlation times of nuclei belonging to both fragments must be measured in order to check the meaning of the estimated average interionic distances. The first limitation (1) is not so severe because, as might reasonably be assumed, the anion−cation interactions mainly affect the chemical reactivity of the ion-pair under conditions conducive to intimate ion-pair formation (a solvent of moderate dielectric constant, high concentrations, low temperature, etc.). The second complication (2) is more serious,[4] although very often it is not necessary to have explicit knowledge of interionic distances but only of the preferred mutual orientation eventually adopted by the anion and cation. This information can be gleaned in a semi-quantitative manner through observing the NOE contacts (weak, medium, strong, etc.).

Our previous studies were principally carried out on model cationic Ru^{II} compounds bearing bidentate (N,N) or tridentate (N,N,N) ligands,[2a−2e] where the N atoms were incorporated into aromatic rings. These studies were performed in dichloromethane solution, using both symmetrical and unsymmetrical counterions.[2e] In all cases, we observed a remarkable degree of specificity in the NOE interionic contacts. The counterion was found to reside close to the N,N or N,N,N ligands, and, in the case of unsymmetrical counterions, showed a tendency to maximize the lyophilic interactions. With the help of quantum mechanical and molecular mechanics calculations,[2c] we rationalized such specificity in terms of non-centrosymmetric charge distribution and, in particular, an accumulation of positive charge in the aromatic rings containing the N atoms. In order to ascertain whether the presence of N-aromatic ligands is necessary for the delocalization of the positive charge, we decided to synthesize and investigate analogous complexes containing non-aromatic N,N ligands.

In this paper, we report the synthesis and characterization of complexes *trans*-[$Ru(PMe_3)_2(CO)(COMe)(N,N)$]X (N,N = diimine or diamine ligand; see Scheme 1) and the determination of their interionic structure in dichloromethane.

Results and Discussion

Synthesis

The starting material for the synthesis of complexes **2−10** was *cis*,*trans*-[$RuI(Me)(CO)_2(PMe_3)_2$] (**1**).[5] In solvents with

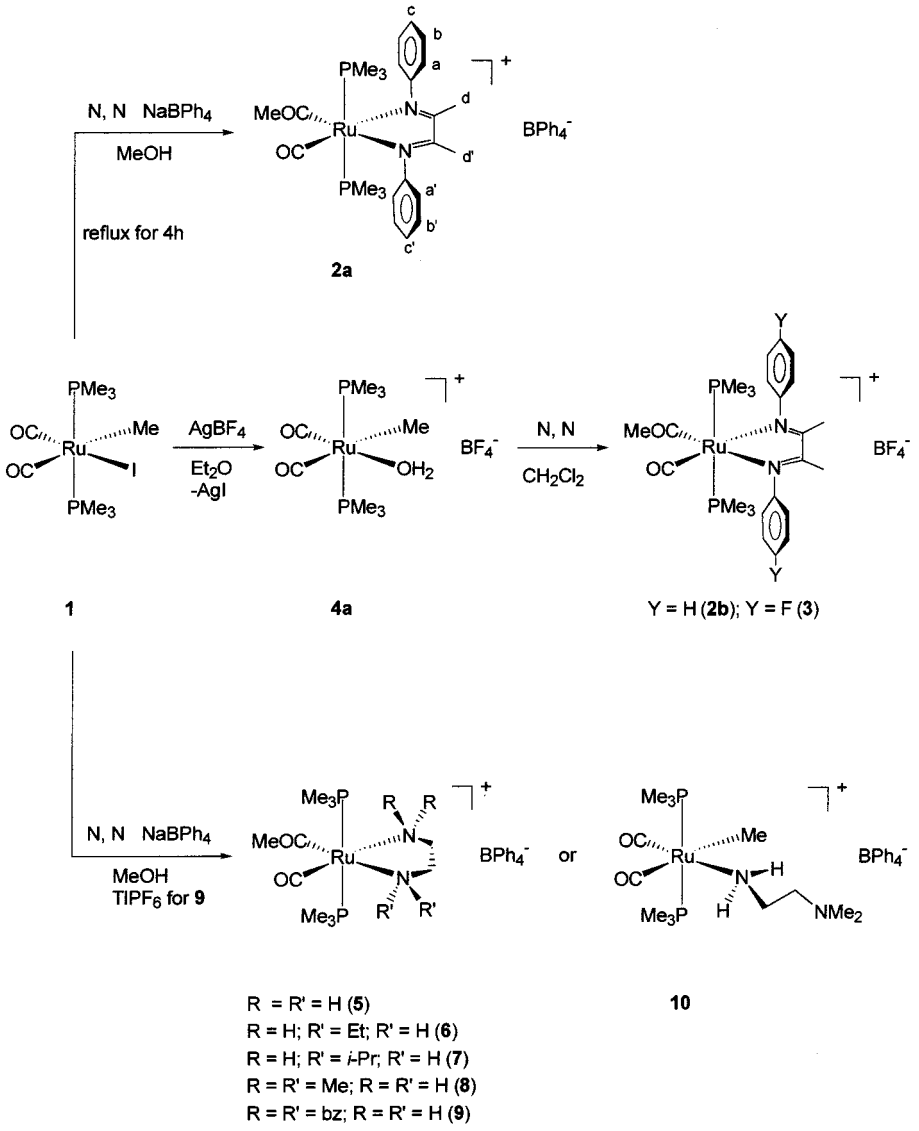


Scheme 1

suitable dielectric constants, complex **1** undergoes dissociation of the Ru−I bond and migration of Me onto a *cis* CO, thereby making two coordination sites available. The reaction of complex **1** with diacetyl bis(phenylimine) ligands in methanol containing excess $NaBPh_4$ at room temperature did not afford the desired acetyl products. Furthermore, it showed that methanol and water may act as competing ligands. The methanolic complex *trans,cis*-[Ru(PMe_3)$_2$(CO)$_2$(Me)(MeOH)]BPh_4 (**4b**) was obtained in good yield by the reaction of complex **1** with $TlPF_6$ in MeOH followed by the addition of a large excess of $NaBPh_4$. By refluxing a methanolic solution of complex **1** for 4 h, complex **2a** was synthesized in low yield (Scheme 1). Complexes **2b**−**3** were synthesized under mild conditions and in acceptable yields by treating **1** with $AgBF_4$ in diethyl ether (see Scheme 1). In each case, the precipitate formed, containing AgI and a solvento complex intermediate, was treated with a solution of the appropriate ligand in dichloromethane. The complexes **2b** or **3** thus obtained were precipitated by adding *n*-hexane. When this synthetic procedure was attempted using diimine ligands bearing substituents in their *ortho* positions (Me, Et, *i*Pr), the reactions were unsuccessful. When the same procedure was carried out in the absence of any ligand, complex **4a** was formed.

The reactions of complex **1** with the diamine ligands were found to proceed quite quickly in methanol at room temperature with *N*-substituted diamines and with *N*,*N*′-disubstituted diamines bearing small substituents (see Scheme 1). In the case of *N*,*N*′-dibenzylethylenediamine, it was found necessary to force the ionization of the Ru−I bond by adding $TlPF_6$ in order to obtain the desired complex in a reasonable time and, consequently, to avoid formation of the methanol complex. The reaction with *N*,*N*-disubstituted ethylenediamine afforded a methyl complex with a η^1-coordinated diamine ligand.

The reactions with both the diimine and diamine ligands indicate that steric factors play a crucial role. In the case of diimine ligands, the interactions of the *ortho* substituents with the acetyl and PMe_3 groups are the limiting factors. In the case of the diamine ligands, the sp^3 nature of the N

atom makes the interaction of the R, R′, and PMe_3 groups the most important. The formation of complex **10** demonstrates that two methyl groups cannot remain on the same coordinated nitrogen.

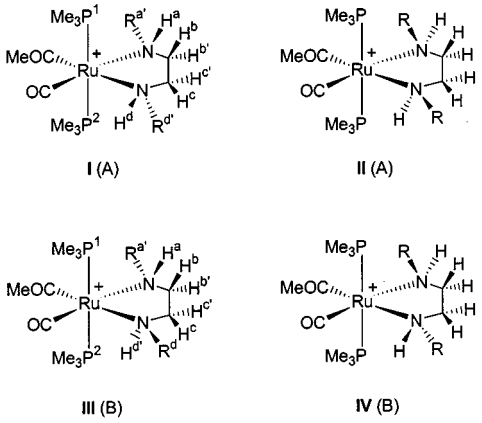
Intramolecular Characterization

The intramolecular characterization was carried out by IR and ^1H, ^{13}C, ^{31}P, and ^{19}F NMR spectroscopy. The structures of complexes **2−9** could easily be established by considering that: (1) two CO stretching bands were observed, one in the typical region for terminal carbonyls and the other in the region for acyl groups; (2) a deceptive triplet,[6] typical of the *trans* position, was observed for PMe_3 in both the ^1H and $^{13}C\{^1H\}$ NMR spectra of complexes **1−5**, while for the other complexes the observed $^2J_{PP}$ coupling constants were consistent with two mutually *trans* PMe_3 groups, and (3) the protons and carbons of the two N arms are chemically non-equivalent. In the ^1H-NOESY spectra of the *N*-substituted complexes **6** and **7**, no contact between the COMe and the substituents was observed. Consequently, the *N*-substituted arm must lie *trans* to the COMe group. An assignment of all the proton and carbon resonances, a prerequisite for a detailed determination of the interionic structure, proved more difficult. This was especially true for complexes with *N*,*N*′-disubstituted ethylenediamine ligands incorporating two chiral nitrogen atoms. In such cases, a pair of racemic diastereoisomers A (I and II) and B (III and IV) are present in solution (see Scheme 2).[7] For example, two species are discernible in the case of complex **8**. The $^{31}P\{^1H\}$ NMR spectrum features two doublets with relative integrals of 1 and another two with relative integrals of 3 (Figure 1). Even though the aliphatic region of the ^1H NMR spectrum is quite complicated, the four doublets of doublets due to the PMe_3 groups and the four doublets due to the Me groups bonded to N atoms are sufficiently resolved. The ^1H-NOESY spectrum (Figure 2) indicates that: (a) one PMe_3 of the more abundant isomer shows NOE contacts with both Me groups while the other shows none; (b) each PMe_3 group of the less abundant isomer shows an NOE contact with one Me group. The major stereoisomers present in solution are those labelled A in Scheme 2, in which the two substituents are oriented towards the same PMe_3 group. In hindsight, it can be seen that for these isomers the difference in chemical shift of the two P nuclei is greater than for the others, due to the higher extent of octahedral distortion of the ligand sphere. By combining the information provided by ^1H-COSY, ^1H-NOESY, and "normal" and long-range ^1H-^{13}C HMQC experiments, and assuming that N−H and N−Me resonances *cis* to COMe resonate at higher frequencies (due to the previously observed deshielding effect of COMe), it was possible to assign most of the resonances (see Exp. Sect.).

Interionic Structure in Solution by NMR

The relative anion−cation orientation (interionic structure) was investigated in dichloromethane solution by detecting interionic "contacts" in the ^1H-NOESY and $^{19}F\{^1H\}$-HOESY NMR spectra. The most significant results can be summarized as follows.

The ^1H-NOESY spectrum of complex **2a** shows (1) that PMe_3 protons interact quite strongly with all the aromatic protons of BPh_4^-, and (2) that the Me groups of the diimine ligand interact with *o*-H and *m*-H (Figure 3). The interactions between the counterion and the aromatic protons



Scheme 2

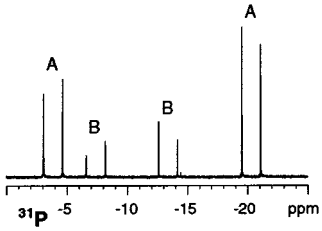


Figure 1. $^{31}P\{^1H\}$ NMR spectrum of complex **8** recorded at 298 K in $[D_2]$dichloromethane showing the presence of two species in a 1:3 ratio

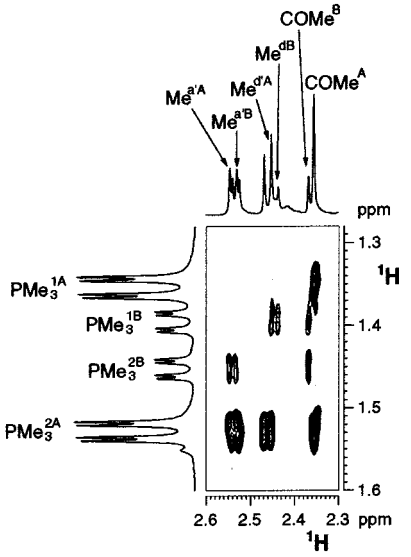

Figure 2. A section of the ^1H-NOESY NMR spectrum of complex **8** recorded at 298 K in $[D_2]$dichloromethane showing the interactions of $PMe_3{}^2$ with both Me groups in the A stereoisomers and the interactions of $PMe_3{}^2$ with $Me^{a'}$ and of $PMe_3{}^1$ with Me^d in the B stereoisomers

of the cation can be detected more readily in the $^{19}F\{^1H\}$-HOESY NMR spectrum of **2b** (Figure 4): BF_4^- shows "contacts" with o^a and $o^{a'}$ and weaker ones with m^b and $m^{b'}$. The same contacts were observed for complex **3**. No contacts were observed between the counterion and the COMe protons or *p*-H or *p*-F in any of the three complexes. The average interionic structure that can be inferred from these observations is one in which the counterion preferentially resides on the side of the N,N ligand above or below the plane defined by the N,N, CO, and COMe ligands.

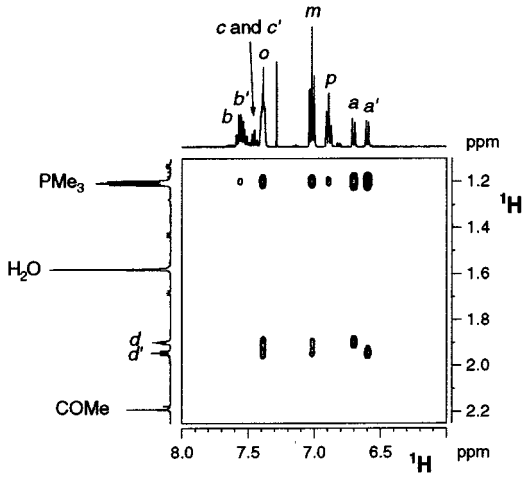

Figure 3. A section of the ^1H-NOESY NMR spectrum of complex **2a** recorded at 298 K in $[D_2]$dichloromethane showing the interionic contacts between the PMe_3 groups and all the aromatic protons of BPh_4^- and between the Me^d protons and *o*-H and *m*-H

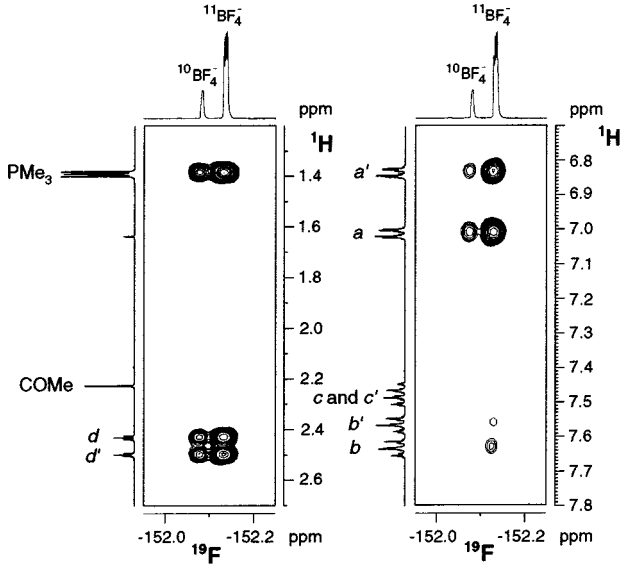

Figure 4. Two sections of the $^{19}F\{^1H\}$-HOESY NMR spectrum of complex **2b** recorded at 298 K in $[D_2]$dichloromethane showing the interionic contacts between BF_4^- and PMe_3 and the *d*, *d'*, *a*, and *a'* protons, as well as weaker contacts with *b* and *b'*

Besides showing strong contacts between PMe_3 and all the aromatic protons of BPh_4^-, the ^1H-NOESY spectrum of complex **5** shows contacts between NH_2^d, CH_2^c, and CH_2^b (very weak) and *o*-H and *m*-H. COMe and NH_2^a do not interact with the counterion (Figure 5). This indicates that the counterion is located close to the N,N ligand and prefers to stay close to the N arm *trans* to the acetyl group.

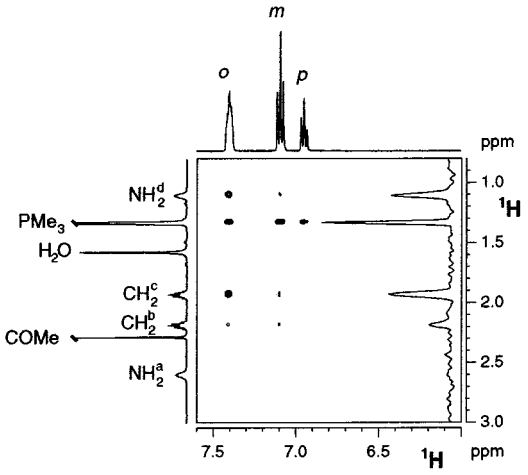

figure 5. A section of the ^1H-NOESY NMR spectrum of complex **5** recorded at 298 K in $[D_2]$dichloromethane showing the gradual decrease of the interionic contact intensity on going from positions *d* to *a*; the 1D trace along the axis corresponding to the *ortho* protons is shown on the right

The ^1H-NOESY spectrum of the two A stereoisomers **8** depicted in Scheme 2 indicates that the counterion shows two preferential interactions, (1) with the protons of the arm *trans* to the COMe group, and (2) with the protons of the less hindered phosphane PMe_3[1]. Once again, there is no interaction with the COMe. The same is true for complex **9**. The position of the counterion is remarkably well defined; it stays on the side of the N,N ligand, shifted towards the arm *trans* to COMe and close to the phosphane that is not hindered by the methyl groups of the N,N ligand.

The interionic structure of the diamine complexes reported here is the most specific that we have never observed in octahedral complexes. The use of non-aromatic N,N ligands does not affect the delocalization of the positive charge that accumulates on the N,N side. In addition, it seems that the positive charge is prevalently delocalized over the N arm *trans* to the COMe group, as indicated by the selective interionic interactions of the protons of this arm with those associated with the counterion.

Conclusions

The use of non-aromatic N,N ligands has unexpectedly led to a higher specificity in the anion−cation interactions, particularly for the diamine complexes. From previous studies,[2c] we know that the stabilization of ion pairs in such complexes is mainly electrostatic, and the fact that the interionic structure is not dependent on the nature of the counterion (BF_4^- or BPh_4^-) further confirms this. The observed specificity can only be attributed to an accumulation of positive charge on the N,N ligands. Not only the lack of unsaturation (as in the diamine ligands) does not affect this accumulation, but it also interrupts the communication be-

tween the two N arms, imparting them with different affinities towards the anion. Steric interactions become important in determining the fine structure, as demonstrated by the interionic structure of the A stereoisomers of complex **9**; here, the electrostatic energy gain directs the counterion to the side of the N,N ligand, while the less hindered P^1-phosphane is favoured by the reduced steric repulsions.

Experimental Section

General Remarks: Complex **1** was prepared according to the literature.[5] Reactions were carried out in dried apparatus under an inert atmosphere of dry nitrogen using standard Schlenk techniques. Solvents were purified by conventional methods prior to use.[8] The diimine ligands were synthesized according to the literature.[9] Diamines were obtained commercially and were used without further purification. − IR spectra were recorded on a Perkin−Elmer 1725 X FTIR spectrophotometer. − One- and two-dimensional ^{1}H, ^{13}C, ^{19}F, and ^{31}P NMR spectra were recorded on Bruker DPX 200 and DRX 400 NMR spectrometers. Spectra were referenced to external TMS (^{1}H and ^{13}C), $CFCl_3$ (^{19}F), and 85% H_3PO_4 (^{31}P). NMR samples were prepared by dissolving about 20 mg of the compound in 0.5 mL of deuterated solvent. Two-dimensional ^{1}H-NOESY and ^{19}F{^{1}H}-HOESY spectra were recorded with a mixing time of 500−800 ms. The assignment of all the resonances was achieved by a combination of ^{1}H-COSY, ^{1}H-NOESY, and "normal" and long-range ^{1}H-^{13}C HMQC experiments.

Synthesis of Complex 2a: Solid diacetyl bis(phenylimine) (131 mg, 0.55 mmol) and $NaBPh_4$ (large excess) were added to a solution of complex **1** (100 mg, 0.22 mmol) in methanol (10 mL). The resulting mixture was stirred and refluxed for 4 h, in the course of which its colour changed from yellow to deep-red. After cooling, the solution was placed in a refrigerator. A white solid precipitated after 15 h, which was filtered off. A red crystalline product precipitated from the remaining solution (10 mg, yield 5%). − $C_{49}H_{57}BN_2O_2P_2Ru$ (879.8): calcd. C 66.90, H 6.53, N 3.18; found C 66.96, H 6.72, N 3.21. − IR (CH_2Cl_2, 298 K): ν_{CO} = 1958 cm^{-1}, ν_{COMe} = 1625 cm^{-1}. − ^{1}H NMR ($CDCl_3$, 298 K, 400.13 MHz): δ = 1.20 (Harris t, $|^2J_{HP} + {}^4J_{HP}|$ = 7.2, PMe_3), 1.90 (t, $^5J_{HP}$ = 2.0, Me^d), 1.94 (t, $^5J_{HP}$ = 2.8, Me$^{d'}$), 2.18 (s, COMe), 6.60 (dd, $^3J_{HH}$ = 6.6, $^4J_{HH}$ = 1.8, $o^{a'}$), 6.69 (dd, $^3J_{HH}$ = 7.3, $^4J_{HH}$ = 1.2, o^a), 6.88 (t, $^3J_{HH}$ = 7.2, *p*), 7.01 (t, $^3J_{HH}$ = 7.3, *m*), 7.41 (br, *o*), 7.45 (m, p^c and $p^{c'}$), 7.53 (m, $m^{b'}$ and m^b). − ^{13}C{^{1}H} NMR (CD_2Cl_2, 298 K, 100.55 MHz): δ = 15.5 (Harris t, $|^1J_{CP} + {}^3J_{CP}|$ = 30.1, PMe_3), 21.7 (s, Me^d), 23.2 (s, Me$^{d'}$), 51.3 (s, CO*Me*), 120.3 (s, $o^{a'}$), 121.5 (s, o^a), 122.1 (s, *p*), 125.9 (q, $^3J_{C11B}$ = 2.6, *m*), 128.5 (s, $p^{c'}$), 128.8 (s, p^c), 129.6 (s, $m^{b'}$), 130.5 (s, m^b), 136.7 (s, *o*), 149.28 (s, C_{ipso}−N), 149.29 (s, C_{ipso}−N), 164.5 (q, $^1J_{C11B}$ = 49.3, C_{ipso}), 173.4 (s, C=N), 176.0 (s, C=N), 204.3 (s, CO), 253.6 (s, *C*OMe). − ^{31}P{^{1}H} NMR (CD_2Cl_2, 298 K, 161.98 MHz): δ = −11.8 (s, PMe_3).

Synthesis of Complex 2b: Complex **1** (100 mg, 0.22 mmol) was dissolved in diethyl ether (5 mL). Solid $AgBF_4$ (41 mg, 0.21 mmol) was then added and the mixture was stirred for 24 h. The precipitate containing AgI and a solvento intermediate complex was collected by filtration, dried, and washed with a solution of diacetyl bis(phenylimine) (78.6 mg, 0.33 mmol) in CH_2Cl_2 (10 mL). The resulting solution was stirred for 4 h; *n*-hexane was then added until precipitation commenced. On placing the solution in a refrigerator at −18 °C, a red solid precipitated, which was collected by filtration, washed with *n*-hexane, and dried in vacuo (30 mg, yield 21%). − $C_{25}H_{37}BF_4N_2O_2P_2Ru$ (647.4): calcd. C 46.39, H 5.76, N 4.33; found C 46.58, H 5.80, N 4.12. − IR (CH_2Cl_2, 298 K): ν_{CO} = 1956 cm^{-1}, ν_{COMe} = 1623 cm^{-1}. − ^{1}H NMR (CD_2Cl_2, 298 K, 400.13 MHz): δ = 1.38 (Harris t, $|^2J_{HP} + {}^4J_{HP}|$ = 7.2, PMe_3), 2.23 (s, COMe), 2.43 (t, $^5J_{HP}$ = 2.7, Me$^{d'}$), 2.49 (t, $^5J_{HP}$ = 1.9, Me^d), 6.84 (dd, $^3J_{HH}$ = 8.4, $^4J_{HH}$ = 1.2, $o^{a'}$), 7.01 (dd, $^3J_{HH}$ = 8.2, $^4J_{HH}$ = 1.1, o^a), 7.46 (tt, $^3J_{HH}$ = 8.6, $^4J_{HH}$ = 1.1, m^c), 7.49 (tt, $^3J_{HH}$ = 7.5, $^4J_{HH}$ = 1.2, $m^{c'}$), 7.56 (t, $^3J_{HH}$ = 7.1, $m^{b'}$), 7.63 (t, $^3J_{HH}$ = 7.5, m^b). − ^{31}P{^{1}H} NMR (CD_2Cl_2, 298 K, 161.98 MHz): δ = −11.7 (s, PMe_3). − ^{19}F NMR (CD_2Cl_2, 298 K, 376.50 MHz): δ = −152.08 (br, $^{10}BF_4^-$), −152.13 (br, $^{11}BF_4^-$).

Synthesis of Complex 3: The procedure was the same as that used for complex **2b**. At the final stage, a mixture of complexes **3** and **4a** was obtained. Characterization of complex **3:** IR (CH_2Cl_2, 298 K): ν_{CO} = 1953 cm^{-1}, ν_{COMe} = 1641 cm^{-1}. − ^{1}H NMR (CD_2Cl_2, 298 K, 400.13 MHz): δ = 1.36 (Harris t, $|^2J_{HP} + {}^4J_{HP}|$ = 7.2, PMe_3), 2.26 (s, COMe), 2.46 (t, $^5J_{HP}$ = 2.8, Me$^{c'}$), 2.53 (t, $^5J_{HP}$ = 1.9, Me^c), 6.84 (dd, $^3J_{HH}$ = 9.0, $^4J_{HF}$ = 4.6, $o^{a'}$), 7.05 (dd, $^3J_{HH}$ = 9.0, $^4J_{HF}$ = 4.6, o^a), 7.27 (t, $^3J_{HH}$ = 9.0, $^3J_{HF}$ = 8.3, $m^{b'}$), 7.33 (t, $^3J_{HH}$ = 9.0, $^3J_{HF}$ = 8.2, m^b). − ^{13}C{^{1}H} NMR (CD_2Cl_2, 298 K, 100.55 MHz): δ = 15.5 (Harris t, $|^1J_{CP} + {}^3J_{CP}|$ = 30.1, PMe_3), 21.8 (s, Me$^{d'}$), 23.3 (s, Me^d), 50.8 (t, $^4J_{CP}$ = 1.6, CO*Me*), 115.9 (d, $^2J_{CF}$ = 28.2, $m^{b'}$), 117.2 (d, $^2J_{CF}$ = 30.6, m^b), 123.2 (d, $^3J_{CF}$ = 9.0, $o^{a'}$), 124.3 (d, $^3J_{CF}$ = 9.6, o^a), 145.4 (s, $p^{d'}$), 145.7 (s, p^d), 161.93 (d, $^1J_{CF}$ = 248.8, C_{ipso}−N), 161.94 (d, $^1J_{CF}$ = 246.6, C_{ipso}−N), 174.6 (s, C=N), 177.6 (s, C=N), 204.8 (t, $^2J_{CP}$ = 14.7, CO), 253.2 (t, $^2J_{CP}$ = 10.5, *C*OMe). − ^{31}P{^{1}H} NMR (CD_2Cl_2, 298 K, 161.98 MHz): δ = −11.6 (s, PMe_3). − ^{19}F NMR (CD_2Cl_2, 298 K, 376.50 MHz): δ = −114.2 (tt, $^3J_{FH}$ = 9.0, $^4J_{FH}$ = 8.0, $p^{d'}$), −115.5 (tt, $^3J_{FH}$ = 9.0, $^4J_{FH}$ = 8.0, p^d), −150.6 (br, $^{10}BF_4^-$), −150.7 (br, $^{11}BF_4^-$).

Synthesis of Complex 4a: The procedure was similar to that used for complex **2b**, but the precipitate was washed with neat dichloromethane free from any ligands (yield 30%). The coordinated water was probably present in the hygroscopic $AgBF_4$ salt. − $C_9H_{23}BF_4O_3P_2Ru$ (429.1): calcd. C 25.20, H 5.40; found C 25.36, H 5.45. − IR (CH_2Cl_2, 298 K): ν_{CO} = 1973, 2042 cm^{-1}. − ^{1}H NMR (CD_2Cl_2, 298 K, 400.13 MHz): δ = 0.08 (t, $^3J_{HP}$ = 7.9, Me), 1.57 (Harris t, $|^2J_{HP} + {}^4J_{HP}|$ = 7.4, PMe_3), 3.93 (s, H_2O). − ^{13}C{^{1}H} NMR (CD_2Cl_2, 298 K, 100.55 MHz): δ = −3.68 (s, Me), 15.0 (Harris t, $|^1J_{CP} + {}^3J_{CP}|$ = 31.7, PMe_3), 189.9 (s, CO), 201.0 (s, CO). − ^{31}P{^{1}H} NMR (CD_2Cl_2, 298 K, 161.98 MHz): δ = −3.21 (s, PMe_3). − ^{19}F NMR (CD_2Cl_2, 298 K, 376.50 MHz): δ = −149.8 (vbr, $^{10}BF_4^-$), −149.9 (br, $^{11}BF_4^-$).

Synthesis of Complex 4b: Solid $TlPF_6$ (73 mg, 0.21 mmol) was added to a solution of complex **1** (100 mg, 0.22 mmol) in methanol (5 mL). Immediately, TlI precipitated from the solution and was filtered off. The filtrate was treated with a large excess of solid $NaBPh_4$. After a few minutes, complex **4b** precipitated; it was collected by filtration, washed with cold methanol, and dried in vacuo (140 mg, yield 94%). − $C_{34}H_{45}BO_3P_2Ru$ (675.6): calcd. C 60.46, H 6.71; found C 60.54, H 6.78. − IR (CH_2Cl_2, 298 K): ν_{CO} = 1975, 2033 cm^{-1}. − ^{1}H NMR (CD_2Cl_2, 298 K, 400.13 MHz): δ = −0.85 (br, *Me*OH), −0.61 (t, $^3J_{HP}$ = 8.0, Me), 1.33 (Harris t, $|^2J_{HP} + {}^4J_{HP}|$ = 7.0, PMe_3), 3.45 (s, MeO*H*), 6.96 (t, $^3J_{HP}$ = 7.2, *p*), 7.10 (t, $^3J_{HP}$ = 7.4, *m*), 7.56 (br, *o*). − ^{13}C{^{1}H} NMR (CD_2Cl_2, 298 K, 100.55 MHz): δ = −6.98 (t, $^2J_{CP}$ = 9.3, Me), 15.6 (Harris t, $|^1J_{CP} + {}^3J_{CP}|$ = 31.7, PMe_3), 30.0 (s, MeOH), 122.8 (s, *p*), 126.6 (s, *m*), 136.1 (s, *o*), 165.0 (q, $^1J_{C11B}$ = 49.5, C_{ipso}), 190.5 (t, $^2J_{CP}$ = 8.6, CO), 199.5 (t, $^2J_{CP}$ = 13.5, CO). − ^{31}P{^{1}H} NMR (CD_2Cl_2, 298 K, 161.98 MHz): δ = −5.57 (s, PMe_3).

Synthesis of Complex 5: Ethylenediamine (22 μL, ca. 0.33 mmol) was added to a solution of complex **1** (100 mg, 0.22 mmol) in methanol (5 mL) and the solution was stirred for 10 min. A large excess of $NaBPh_4$ was then added, which resulted in the precipitation of a white solid. It was collected by filtration, washed with cold methanol, and dried in vacuo (130 mg, yield 85%). − $C_{35}H_{49}BN_2O_2P_2Ru$ (703.6): calcd. [7] The atom labels for compounds **2–3** are shown in the upper part of Scheme 1. The numeration adopted for distinguishing the atoms of the diamine compounds **5–9** is indicated in Scheme 2. For compounds bearing *N,N′*-disubstituted amines, two possibilities exist: (1) structure A: the PMe_3 group that is far away from the R substituents is labelled as PMe_3^1, the other is denoted as PMe_3^2; (2) structure B: the PMe_3 group that "sees" the R group *trans* to COMe is labelled as PMe_3^1. For compounds bearing *N*-substituted amines, we observe that the substituted N arm lies *trans* to COMe (this is deduced from the higher resonance frequency of the NH_2 protons compared to the NHR proton, which is attributed to the deshielding effect of the *cis* COMe group). The numeration is then based on structure I in Scheme 2; the PMe_3 group that interacts with the R substituent is labelled as PMe_3^2.

Synthesis and Structures of Vinamidine Mn^{II}, Zn^{II}, and Cd^{II} Iodine Derivatives

Jörg Prust,[a] Kerstin Most,[a] Ilka Müller,[a] Andreas Stasch,[a] Herbert W. Roesky,*[a] and Isabel Usón[a]

Dedicated to Professor Glen B. Deacon on the occasion of his 65th birthday

Keywords: Cadmium / Manganese / N ligands / Zinc

We have focused on the synthesis of monomeric, functionalized starting materials containing manganese(II), zinc(II), and cadmium(II) by taking advantage of the sterically demanding and chelating property of the substituted vinamidine ligand 2-[(2,6-diisopropylphenyl)amino]-4-[(2,6-diisopropylphenyl)imino]pent-2-ene (NacNacH). Metal iodine derivatives containing vinamidines as the bulky ligand can be regarded as interesting precursors for preparing complexes with low-valent metal centers by reduction as long as they are free of coordinated ether. The vinamidine complexes NacNacM(μ-I)$_2$Li(OEt$_2$)$_2$ [M = Mn (**3**), Zn (**4**), Cd (**5**)] are obtained from the corresponding vinamidine lithium complex and MI_2 (M = Mn, Zn, Cd) in good yields. A crystal structure analysis of **3**, **4**, and **5** shows them to be isostructural. All three structures have the vinamidine backbone in a boat conformation with the tetrahedrally coordinated metal center at the prow and the opposing carbon atom at the stern.

Introduction

Vinamidines were first used in inorganic synthesis by Holm et al. and McGeachin et al. to synthesize moisture-stable Ni^{II}, Co^{II}, and Cu^{II} complexes.[1] In further research the surprising catalytic activity of vinamidine derivatives of various transition and main group metals was analyzed. Feldman et al. synthesized catalytically active aryl-substituted vinamidine complexes of Pd^{II} and Ni^{II}, and Theopold et al. and Gibson et al. tested vinamidine complexes of Ti^{III}, V^{II}, Cr^{III} for olefin polymerization.[2,3]

In the last few years the interest in the synthesis of monomeric and coordinatively unsaturated metal complexes with bulky vinamidine ligands has increased. In this research field several new compounds have been reported.[4] The vinamidine 2-[(2,6-diisopropylphenyl)amino]-4-[(2,6-diisopropylphenyl)imino]pent-2-ene (**1**) (NacNacH) is suitable for the synthesis of derivatives with unusually low coordinate main group elements. Recently we synthesized a monomeric Al^{I} compound using **1** as a stable carbene analogue, and Gibson et al. have prepared a mono-alkylmagnesium complex stabilized by **1**.[5,6] Our research focused on the synthesis of complexes with low coordinate Mn, Zn and Cd atoms.

Preparing the iodine-containing metal complexes of **1** has two functions: the size of the ligand should have a shielding effect on the metal center and therefore the nucleophilic attack should be minimized; these systems should also be interesting precursors for the preparation of complexes with low-valent metal atoms by reduction of the iodine complexes using alkali metals.

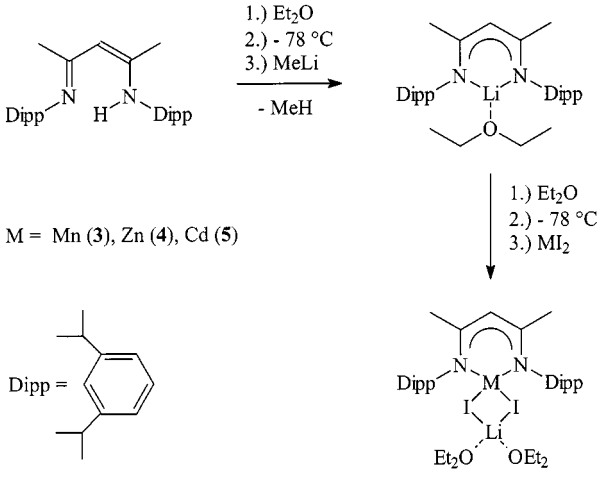
We have focused on the synthesis of NacNacMI (M = Mn, Zn, Cd) as monomeric, functionalized starting materials due to the sterically demanding and chelating properties of **1**.

Results and Discussion

The reaction of MeLi with NacNacH (**1**) gives the pale yellow compound NacNacLi·OEt$_2$ (**2**) in good yield (> 95%). This ether-soluble lithium compound is a useful reagent for metathesis reactions with metal halides. Thus, the reaction of **2** with MI_2 affords the iodide complexes NacNacM(μ-I)$_2$Li(OEt$_2$)$_2$ (M = Mn, Zn, Cd) in reasonable yields (77−85%) (Scheme 1).



Scheme 1

Unfortunately compounds **3**, **4**, and **5** are moisture sensitive and give **1** as the primary hydrolysis product. ^{1}H NMR

spectroscopic data and the elemental analysis of **4** and **5** are consistent with the solid state structures, whereas the mass spectra of **3**, **4**, and **5** show several fragments assignable to the species free of $LiI(Et_2O)_2$.[7]

The X-ray structure analysis of **3**, **4** (shown in Figure 1), and **5** shows that these compounds are isostructural. The crystallographic data are summarized in Table 1. Selected bond lengths and angles for **3**, **4**, and **5** are given in Table 2.

Figure 2 shows a superposition of **3**, **4**, and **5**. The only differences between the three structures are those derived from the different bond lengths in the coordination of the various metals. Therefore, we discuss the overall structure.

The central structural element is a NacNacM(μ-I)$_2$Li unit. The vinamidine ligand NacNac acts as a chelating ligand through its two N atoms, forming a six-membered ring with the metal. The central metal (**3**: Mn, **4**: Zn, **5**: Cd) and the lithium cation are bridged by the two iodine atoms. The N−M−N-angle is about 95° (**3**: 94.2°, **4**: 98.6°, **5**: 91.5°) and the I−M−I-angle is 101° (**3**:101°, **4**:101°, **5**:101°). The tetrahedral coordination of the metal is distorted due to the strain imposed by the six-membered ring of the chelate, and the four-membered ring of the bridging halides.

The M−N−C(CH$_3$)−CH−C(CH$_3$)−N unit is not planar. The six-membered ring displays a boat conformation with the metal at the prow and C(2) at the stern. This deviation from planarity is imposed by the metal, as the planar situation implies more distortion in the tetrahedral environment of the metal. Thus, deviation from planarity increases with the metal radius. The metal is about 0.30 Å (**3**: 0.33 Å, **4**: 0.29 Å, **5**: 0.34 Å) out of the plane defined by

I(1)−Li(1)−I(2)	94.5(3)	91.3(2)	95.33(15)

N(1)−C(1)C(10)−C(3)C(30)−N(2) and C(2) is about 0.19 Å (**3**: 0.18 Å, **4**: 0.19 Å, **5**: 0.19 Å) out of this plane.

Nevertheless, the π-electrons of the vinamidine are delocalized since the C(1)−C(2) and the C(2)−C(3) as well as the C(1)−N(1) and the C(3)−N(2) bond lengths are equal within the experimental error and correspond to C−C and C−N distances in aromatic systems. Both N−M bond lengths are equal.

Although the bond lengths of the metal center to I(1) and I(2) are equal within the experimental error (**3**: 2.73/2.72 Å, **4**: 2.66/2.61Å, **5**: 2.79/2.75 Å), the bond lengths of Li to I(1) and I(2) are significantly different (**3**: 2.81/2.92 Å, **4**: 2.78/2.92Å, **5**: 2.82/2.98 Å). We suggest packing effects to be responsible for these differences. The M−I−Li−I ring is not planar (dihedral angle, **3**: 15.5°, **4**: 17.7°, **5**: 14.1°).

The coordination sphere of the Li cation is completed by two diethyl ether molecules.

Conclusion

Unfortunately, the synthesis of low coordinate monomeric metal iodides has so far not been successful as $LiI(Et_2O)_2$ is always found coordinated to the metal centers. Moreover, the reduction of iodides with sodium or potassium was also not successful. Consequently further research is directed toward the synthesis of metal complexes free of $LiI(Et_2O)_2$ using hydrocarbons as solvent.

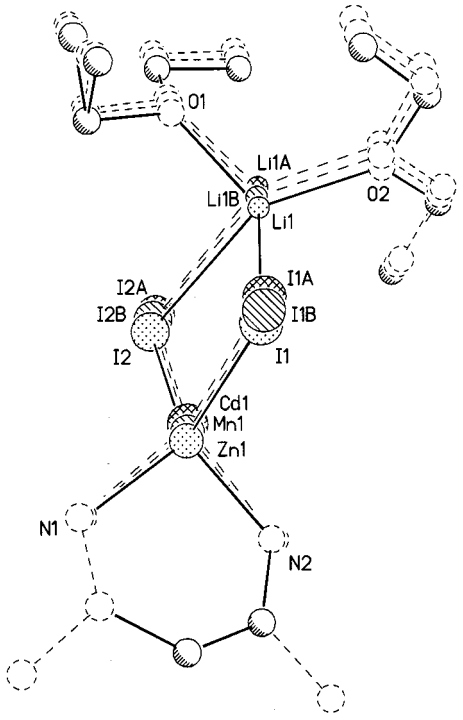

Figure 2. Comparison of the molecular structures of **3**, **4**, and **5**. (organic substituents have been omitted for clarity)

Experimental Section

General: All reactions were performed using standard Schlenk and dry box techniques. Solvents were appropriately dried and distilled under dinitrogen prior to use. All NMR spectra were obtained in 5 mm tubes using dry degassed [D_6]benzene as a solvent, referenced to external $SiMe_4$. Elemental analyses were performed by the Analytisch-Chemisches Laboratorium des Instituts für Anorganische Chemie, Göttingen.

Compound **1** was prepared according to the literature method.[3]

Preparation of 2: MeLi (22.9 mL, 36.6 mmol, 1.6 M in Et_2O) was added dropwise with a syringe over 10 min. to a stirred solution of **1** (15.3 g, 36.6 mmol) in Et_2O (200 mL) at −78 °C. The mixture was stirred at −78 °C for an additional 10 min. and allowed to warm to room temperature, stirred overnight, and reduced in volume to approximately 30 mL. Pale yellow solid **2** was isolated by filtration, washed with pentane (3 × 10 mL), and dried in vacuo. (16.2 g, 89% yield). M.p.: 142−144 °C. − ^{1}H NMR (400 MHz, C_6D_6): δ = 1.03 (t, *J* = 6.8 Hz, 12 H, OCH_2CH_3), 1.19 [d, *J* = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.22 [d, *J* = 6.8 Hz, 12 H, $CH(CH_3)_2$], 1.93 (s, 6 H, CH_3), 3.33 (q, *J* = 6.8 Hz, 8 H, OCH_2CH_3), 3.40 [sept., *J* = 6.8 Hz, 4 H, $CH(CH_3)_2$], 5.00 (s, 1 H, C*H*), 7.17 (m, 6 H, Ar*H*). − ^{7}Li NMR [155 MHz, C_6D_6, ($LiCl/D_2O$)]: δ = 1.61 (s). − $C_{33}H_{51}LiN_2O$ (498.45): C 79.48, H 10.31, N 5.62; found C 80.26, H 10.21, N 5.63.

Preparation of 3: Compound **2** (2.50 g, 5.01 mmol) in Et_2O (20 mL) was added to a suspension of MnI_2 (1.54 g, 5.01 mmol) in Et_2O (20 mL) at −78 °C. The reaction mixture was stirred at −78 °C for an additional 10 min. and allowed to warm to room temperature. After stirring the pink solution overnight the color changed to yellow. The yellow solution was filtered and the solvent removed under reduced pressure to a volume of 10 mL. Yellow crystals were obtained after 1 day at −24 °C. (3.75 g, 85% yield).[8] − MS (EI): *m/z* (%) = 202 (47) [DippNCCH$_3$], 599 (100) [NacNacMnI]. − IR (Nujol): $\tilde{\nu}$ = 1655 (m), 1625 (m), 1262 (m), 1079 (s), 793 (s), 290 (m) cm^{-1}. − $C_{37}H_{61}I_2LiMnN_2O_2$ (881.58): C 50.41, H 6.97, N 3.18; found C 50.43, H 6.89, N 3.23.[7]

Preparation of 4: Compound **2** (1.26 g, 2.54 mmol) in Et_2O (20 mL) was added to a suspension of ZnI_2 (811 mg, 2.54 mmol) in Et_2O (20 mL) at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred for an additional 24 h. The solution was filtered and the solvent removed under reduced pressure to a volume of 5 mL. Colorless crystals were obtained after 4 days at 2 °C. (1.79 g, 79% yield).[8] − ^{1}H NMR (500 MHz, C_6D_6): δ = 1.05 (t, *J* = 6.8 Hz, 12 H, C*H*$_3$CH$_2$O), 1.14 [d, *J* = 6.8 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.36 [d, *J* = 6.8 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.68 (s, 6 H, C*H*$_3$), 3.20 (t, *J* = 6.8 Hz, 12 H, CH$_3$C*H*$_2$O), 3.51 [sept., *J* = 6.8 Hz, 4 H, C*H*(CH$_3$)$_2$], 4.86 (s, 1 H, C*H*), 7.13 (m, 6 H, Ar*H*). − ^{13}C NMR (125 MHz, C_6D_6): δ = 23.3 (s), 24.3 (s), 24.5 (s), 27.8 (s), 28.9 (s), 97.0 (s), 123.6 (s), 123.7 (s), 124.7 (s), 125.3 (s), 125.9 (s), 126.9 (s), 143.9 (s), 171.2 (s). − MS (EI): *m/z* (%) = 202 (100) [DippNCCH$_3$], 608 (47) [NacNacZnI]. − IR (Nujol): $\tilde{\nu}$ = 1701 (m), 1615 (s), 1465 (m), 1412 (m), 1255 (s), 1054 (s), 763 (m), 243 (m) cm^{-1}. − $C_{37}H_{61}I_2LiN_2O_2Zn$ (892.03): C 49.82, H 6.89, N 3.14; found C 49.60, H 6.61, N 3.59.

Preparation of 5: Compound **2** (1.00 g, 2.01 mmol) in Et_2O (20 mL) was added to a suspension of CdI_2 (733 mg, 2.01 mmol) in Et_2O (20 mL) at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred for an additional 36 h. After filtration from the residue the solvent was removed under reduced pressure to a volume of 10 mL. Colorless crystals were obtained after 6 days at 2 °C. (1.45 g, 77% yield).[8] − ^{1}H NMR (500 MHz, C_6D_6): δ = 1.02 (t, *J* = 6.8 Hz, 12 H, C*H*$_3$CH$_2$O), 1.12 [d, *J* = 6.8 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.33 [d, *J* = 6.8 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.63 (s, 6 H, C*H*$_3$), 3.21 (t, *J* = 6.8 Hz, 12 H, CH$_3$C*H*$_2$O), 3.44 [sept., *J* = 6.8 Hz, 4 H, C*H*(CH$_3$)$_2$], 4.81 (s, 1 H, C*H*), 7.11 (m, 6 H, Ar*H*). − ^{13}C NMR (125 MHz, C_6D_6): δ = 23.4 (s), 24.1 (s), 24.4 (s), 27.9 (s), 28.6 (s), 28.9 (s), 96.8 (s), 123.5 (s), 123.7 (s), 124.8 (s), 125.2 (s), 125.8 (s), 127.1 (s), 145.4 (s), 170.0 (s). − MS (EI): *m/z* (%) = 202 (100) [DippNCCH$_3$], 417 (52) [NacNac], 658 (58) [NacNacCdI]. − IR (Nujol): $\tilde{\nu}$ = 1732 (m), 1440 (m), 1406 (s), 1268 (s), 1021 (m), 759 (s), 435 (m) cm^{-1}. − $C_{37}H_{61}CdI_2LiN_2O_2$ (939.05): C 47.32, H 6.55, N 2.98; found C 46.89, H 6.32, N 2.77.

X-ray Crystallography: Crystals of **3** (mol. wt. 881.58), **4** (892.03), and **5** (939.05) were grown from a concentrated Et_2O solution cooled to −24 °C (**3**) or 2 °C (**4**, **5**). They crystallized in the triclinic crystal system with space group $P\bar{1}$. Relevant details and data statistics are summarized in Table 1. The crystals were mounted on a glass fiber in a rapidly cooled perfluoropolyether.[9] Diffraction data were collected on a Stoe−Siemens−Huber four-circle diffractometer coupled to a Siemens CCD area detector at 133(2) K, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods using SHELXS-97[10] and refined against F^2 on all data by full-matrix least-squares with SHELXL-97.[11] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included in the model at geometrically calculated positions and refined using a riding model. The hydrogen atoms on C(10) in the structures of **4** and **5**, however, were refined as an idealized disordered methyl group with two half-occupied positions related to one another by a rotation of 60°. These hydrogen atoms were allowed to ride on the carbon atom and rotate about the C(10)−C(1) bond. In all three structures the disordered methyl group of one of the diethyl ether molecules was modeled with the help of similarity restraints for 1−2 and 1−3 distances and displacement parameters. In all three structures there are residual electron density maxima near the iodine atoms and Li(1), presumably due to disorder which could not be modeled. This unmodeled disorder could play a role in the apparently distorted geometry at Li(1).

Crystallographic data (excluding structure factors) for the structures included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC 154416 (**3**), CCDC 154417 (**4**), CCDC 154418 (**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Bis(cyclopentadienyl) Diimido Complexes of Molybdenum and Tungsten $[Cp_2M(NR)_2]$ at the Limit of Pi-Bond Saturation

Udo Radius,[a] Jörg Sundermeyer,*[b] Karl Peters,[c] and Hans-Georg von Schnering[c]

Dedicated to Professor Max Schmidt on the occasion of his 75th birthday

Keywords: Imides / Molybdenum / Tungsten / Cyclopentadienyl ligands / Rearrangements

The new imido compounds $[(\eta^5\text{-}C_5H_5)M(NR)_2(\eta^1\text{-}C_5H_5)]$ (R = *t*Bu: M = Mo **2a**, W **2b**; R = Mes: M = W **2c**) have been prepared and the crystal structure of **2c** has been determined. Three fluxional processes can be detected by variable temperature proton NMR spectroscopic studies of these cyclopentadienyl complexes, namely: (i) rotation of the $\sigma\text{-}C_5H_5$ ligand about the M–C_{ipso}-bonding axis, (ii) migration of the metal complex fragment between the carbon atoms of the σ-bonded C_5H_5 ligand (metallotropic migration, sigmatropic rearrangement), and (iii) the interconversion of hapticity of σ- and π-bonded C_5H_5 ligands.

Introduction

Molybdenum(VI) and tungsten(VI) bis(organyl) imido complexes of the type $[M(NR)_2R^1R^2]$ (M = Mo, W) have been known for twenty years.[1,2] In the early eighties, the imido-bridged compounds $[M(N\textit{t}Bu)(\mu\text{-}N\textit{t}Bu)(CH_3)_2]_2$ were synthesized and characterized by Nugent and coworkers as the first examples of unsymmetrically bridged dinuclear imido compounds. Mononuclear complexes can be obtained by increasing the steric demand of the organyl ligand of the imido compound. Wilkinson et al.,[3] for example, reported the syntheses of symmetrically substituted bis(aryl) derivatives (R = *t*Bu, $R^1 = R^2$ = mesityl, *o*-tolyl), whereas bis(neopentyl) compounds, like those prepared by the groups of Schrock and Osborn,[4] are attractive starting materials for the synthesis of high valent alkylidene complexes.

Important intermediates for unsymmetrically substituted bis(organyls) ($R^1 \neq R^2$) are monoorganyl complexes of the type $[M(NR)_2R^1Cl]$. During our studies on reactive, N-basic [Mo=NR] and [W=NR] functionalities, we intended to reduce the Lewis acidity of the metal centers of imido complexes $[M(NR)_2Cl_2]$ by introducing excellent σ,π donor ligands. This can be achieved by a formal exchange of a [M−Cl] functionality by $[M(\eta^5\text{-}C_5R'_5)]$ (R′ = H, CH_3).[5] Complexes of the type $[(\eta^5\text{-}C_5H_5)M(N\textit{t}Bu)_2Cl]$ or mixed substituted organyl complexes of the type $[(\eta^5\text{-}C_5H_5)M(N\textit{t}Bu)_2R^2]$ (R^2 = alkyl, aryl)[5] are no longer typical d-metal Lewis acids.[6] Here we wish to report the syntheses, molecular structure and dynamic behavior of the highly π-bond saturated bis(cyclopentadienyl) complexes $[(\eta^5\text{-}C_5H_5)M(NR)_2(\eta^1\text{-}C_5H_5)]$.

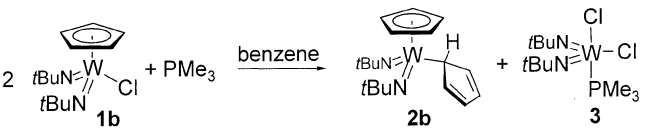
Results and Discussion

Complex Synthesis

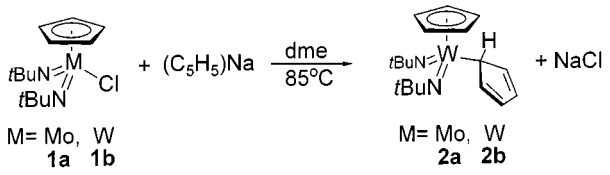
The cyclopentadienyl imido complexes $[(\eta^5\text{-}C_5H_5)M(N\textit{t}Bu)_2Cl]$ (M = Mo **1a**; M = W **1b**) were reacted with typical Lewis bases in order to probe the Lewis acidity of these compounds. Reaction of trimethylphosphane with $[(\eta^5\text{-}C_5H_5)W(N\textit{t}Bu)_2Cl]$ (**1b**) led to an ocher colored solid and a brownish oil. One of the products, $[W(N\textit{t}Bu)_2Cl_2(PMe_3)]$ (**3**),[7] was identified by ^{31}P NMR spectroscopy, but no phosphorus resonance was obtained for the second product. The proton NMR spectrum of the oily residue shows one sharp singlet in the *t*Bu imido region at approximately $\delta = 1.2$, and a very broad resonance in the cyclopentadienyl region. The integration of both signals shows a ratio of 9:5. These experimental results are in accordance with a ligand *dismutation* of $[(\eta^5\text{-}C_5H_5)W(N\textit{t}Bu)_2Cl]$ (**1b**) to give $[(C_5H_5)_2W(N\textit{t}Bu)_2]$ (**2b**) and $[W(N\textit{t}Bu)_2Cl_2]$ by a phosphane-induced exchange of a chloride and a cyclopentadienide ligand. The latter Lewis acid is trapped by the phosphane to yield $[W(N\textit{t}Bu)_2Cl_2(PMe_3)]$ (**3**).



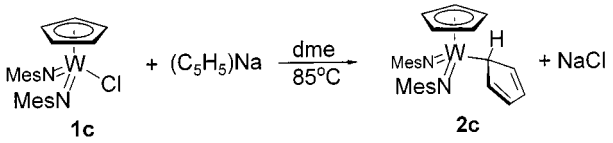
Green and co-workers observed a similar unexpected substitution reaction of a cyclopentadienyl ligand, with stabilization of the resulting Mo^{IV} species, whilst studying the reduction reactions of $[(\eta^5\text{-}C_5H_4Me)Mo(N\textit{t}Bu)Cl_2]$ in the presence of phosphanes.[8]

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0606−1617 $ 17.50+.50/0

To confirm the results of this rather unusual displacement of an anionic C_5H_5 ligand by a phosphane, we prepared **2b** independently. All experiments to obtain **2b** or its molybdenum analogue $[(C_5H_5)_2Mo(NtBu)_2]$ **2a**, by reaction of the chloro complexes $[(\eta^5\text{-}C_5H_5)M(NtBu)_2Cl]$ **1a,b** with $(C_5H_5)Li$ were unsuccessful. However, refluxing **1a,b** with $(C_5H_5)Na$ in dimethoxyethane for several hours led to the formation of the bis(cyclopentadienyl) compounds $[(C_5H_5)_2M(NtBu)_2]$ **2a,b** isolated as yellow-brown oils. These highly covalent organo imides **2a,b** can be purified by high-vacuum distillation or condensation.



As we were not able to obtain crystalline material of the *tert*-butyl imido complexes **2a,b** by low temperature crystallization techniques, we synthesized the corresponding mesityl imido tungsten complex $[(C_5H_5)_2W(NMes)_2]$ (**2c**) This complex can also be obtained from the reaction of $[(C_5H_5)W(NMes)_2Cl]$ (**1c**) with sodium cyclopentadienide in dimethoxyethane. Single crystals of **2c** were grown by the slow cooling of saturated hexane solutions of **2c** to −60 °C.



Molecular Structure of 2c

$[(C_5H_5)_2W(NMes)_2]$ (**2c**) crystallizes in the triclinic space group $P\bar{1}$. The molecular structure is shown in Figure 1. Selected bond lengths and angles are given in the caption. Further details of the crystallographic characterization are given in Table 1.

$[(C_5H_5)_2W(NMes)_2]$ (**2c**) is a monomer in the solid state. The tungsten atom is pseudotetrahedrally coordinated by the two imido nitrogen atoms, by the coordinating carbon atom of a σ-bonded cyclopentadienyl ligand, and by the centroid of a π-coordinated cyclopentadienyl unit. The bonding angles N(1)−W−N(2) 107.7(2)°, N(1)−W−C(6) 97.3(2)°, and N(2)−W−C(6) 99.7(2)° reflect some distortion of the coordination polyhedron. The W−N bond lengths of 176.6(4) pm and 175.9(4) pm are consistent, to some degree, with tungsten imido-nitrogen triple bonding, corresponding to a bond order of 2.5[9a] and comparable with that of the π-bond saturated complex $[W(NPh)(NMe_2)_4]$ [W−N(imido) = 175.8(5)].[9b] The W−C(6) distance of 220.0(6) pm is in the range of tungsten(VI)−carbon σ-bonds. The tungsten−carbon bond lengths of the π-coordinated cyclopentadienyl ring show some interesting irregularities: W−C(1) [233.4(6) pm] falls into the range of expected tungsten ring carbon bond

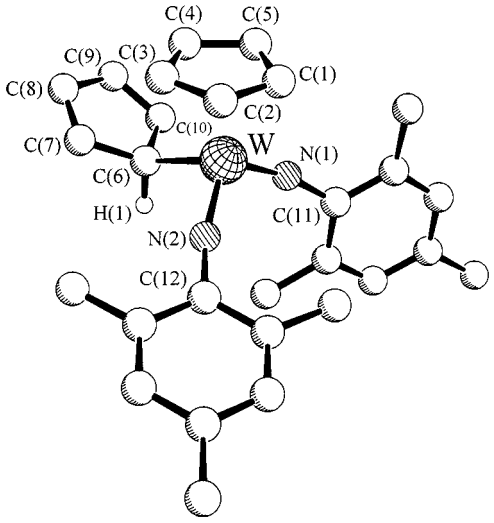


Figure 1. Molecular structure of **2c** in the solid state; SCHAKAL[27] plot; hydrogen atoms are omitted for clarity; selected bond lengths (pm) and angles (°): W−N(1) 176.6(4), W−N(2) 175.9(4), W−C(1) 233.4(6), W−C(2) 244.0(6), W−C(3) 250.2(6), W−C(4) 247.4(6), W−C(5) 241.6(6), W−C(6) 220.0(6), N(1)−C(11) 138.7(7), N(2)−C(12) 139.2(6), C(1)−C(5) 139.9(8), C(1)−C(2) 140.4(10), C(2)−C(3) 139.6(9), C(3)−C(4) 139.9(9), C(4)−C(5) 137.2(11), C(6)−C(7) 149.1(9), C(7)−C(8) 133.5(10), C(8)−C(9) 142.6(11), C(9)−C(10) 136.5(12), C(6)−C(10) 146.5(8); N(1)−W−N(2) 107.7(2), N(1)−W−C(6) 97.3(2), W−N(1)−C(11) 164.4(3), W−N(2)−C(12) 166.8(4), N(2)−W−C(6) 99.7(2)

lengths,[9c] whereas the distances W−C(5) [241.6(6) pm], W−C(2) [244.0(0) pm], W−C(3) [250.2(6) pm], and W−C(4) [247.4(6) pm], are significantly elongated. Comparable elongations of the W−C(ring) bonds trans to strong π-donor ligands have been observed by Bercaw et al. for $[(\eta^5\text{-}C_5Me_5)W(O)_2(O\text{-}C_5Me_5)]$ and $[(\eta^5\text{-}C_5Me_5)W(O)_2(\eta^1\text{-}C_5Me_5)]$, and were attributed to the *trans* influence of the oxo ligands.[10] We have observed similar effects in the structurally characterized half-sandwich imido complex $[(\eta^5\text{-}C_5Me_5)Mo(NtBu)Cl_3]$,[5c] but they are also characteristic for the nitrosyl compounds of the type $[(\eta^5\text{-}C_5H_5)_2Mo(NO)R]$ (R = alkyl)[11] and for the metallocene imido derivatives $[(\eta^5\text{-}C_5H_5)_2V(NoTol)]$[12] and $[(\eta^5\text{-}C_5H_4Me)_2Mo(NtBu)]$.[13] Calculations on the latter 19 and 20 valence electron (VE) complexes show that the HOMO of these compounds is a ligand-centered orbital with significant contributions to the nitrogen atoms of the imido group and to the π-system of the cyclopentadienyl units. In a MO bond description, one of the p orbitals located on the imido nitrogen atoms competes with the two group orbitals of π-symmetry (e_1) of the η^5-coordinated ring for stabilization with one empty d orbital located on the metal center. As a result, a high degree of metal−nitrogen bonding (e.g. M−N triple bond contributions) leads to a decrease in metal−cyclopentadienyl π-bonding, and thus to a ring slippage of the $\eta^5\text{-}C_5R_5$ ring.

Variable Temperature ^{1}H NMR Spectra

The proton NMR spectra of the compounds $[(C_5H_5)_2M(NR)_2]$ **2a−c** are temperature dependant. Three

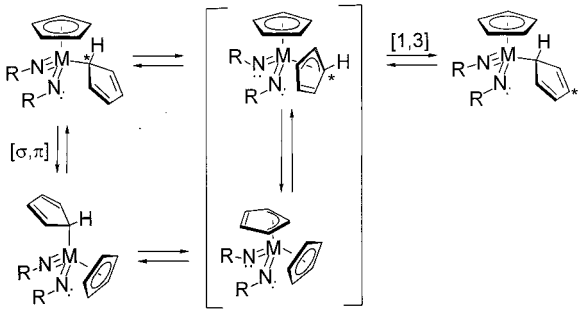
dynamic processes, which have been observed previously in solutions of other η^1/η^5 bis(cyclopentadienyl) complexes, are responsible for this dynamic behavior (see Scheme 1), namely: (i) hapticity change of σ- and π-coordinated cyclopentadienyl rings, (ii) metallotropic migration of the fragment $[(\eta^5\text{-}C_5H_5)M(NR)_2]$ between the carbon atoms of the monohapto-coordinated cyclopentadienyl ring, and (iii) rotation of the σ-cyclopentadienyl ligand around the $M-C_{ipso}$ bonding axis.

The cyclopentadienyl region between δ = 4.0 and 8.5 in the proton NMR spectra of $[(C_5H_5)_2Mo(NtBu)_2]$ (**2a**), recorded at different temperatures, is shown in Figure 2. At 363 K, the ^{1}H NMR spectrum of **2a** shows one averaged signal at δ = 5.78 assigned to the cyclopentadienyl protons and a resonance at δ = 1.13 assigned to the protons of the imido group (not shown in Figure 2), with a ratio of integration of 5:9. On cooling the signal of the *tert*-butyl imido group remains constant within experimental error, while the cyclopentadienyl resonance broadens and splits into two signals below the coalescence temperature of 308 K. At 283 K, two broad signals of similar width are detectable [$\Delta G^{\neq}$(308 K) = 61.0 kJ/mol]. The signal at δ = 6.26 is assigned to the protons of the η^1-coordinated cyclopentadienyl ring due to its chemical shift[15] and the characteristic splitting at lower temperatures. The resonance at higher field (δ = 5.33) can be assigned to the protons of the η^5-coordinated cyclopentadienyl ligand. A further decrease in the temperature from 308 K (the point of coalescence for the σ/π exchange) to 196 K (the point of coalescence for the metallotropic rearrangement) leads to a broadening of the resonance at δ = 6.26 and to a



Scheme 1. Hapticity change and mechanistic proposal of a metallotropic rearrangement via allyl intermediates in complexes of the type $[(\eta^5\text{-}C_5H_5)M(NR)_2(\eta^1\text{-}C_5H_5)]$ (M = Mo, W)

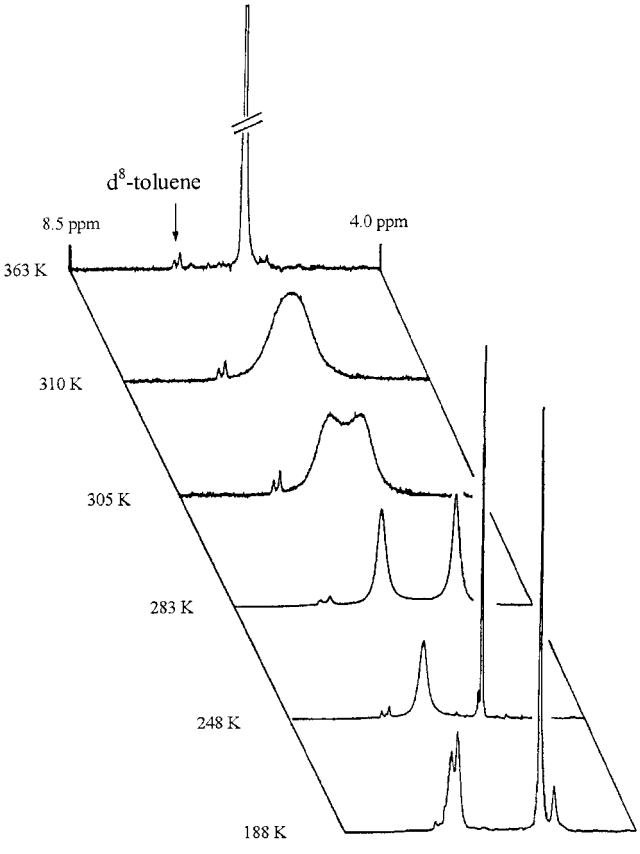


Figure 2. Variable temperature proton NMR spectra of $[(\eta^5\text{-}C_5H_5)Mo(NtBu)_2(\eta^1\text{-}C_5H_5)]$ (**2a**) in [D$_8$]toluene showing the C_5H_5 region from δ = 4.00 to 8.50

sharpening of the η^5-cyclopentadienyl resonance. Below this second coalescence temperature of 196 K, the signal of the η^1-C_5H_5 group splits into two resonances for the olefinic protons at δ = 6.82 and 6.71 (at 188 K), and one signal at δ = 5.05 for the proton of the CH group bound to the metal atom, as expected for a not-yet-resolved AA′BB′X spin-spin system.

Similar spectra can be recorded for the tungsten compound $[(C_5H_5)_2W(N\mathit{t}Bu)_2]$ (**2b**). The coalescence temperature for σ,π exchange is slightly higher for the tungsten complex **2b** [$\Delta G^{\neq}$(310 K) = 64.4 kJ/mol] than for the molybdenum analogue **2a**.

The temperature-dependent ^{1}H NMR spectra of the tungsten compound $[(C_5H_5)_2W(NMes)_2]$ (**2c**) offer some peculiarities. At a relatively high coalescence temperature of 328 K [compared with the *tert*-butyl derivatives **2a** (308 K) and **2b** (310 K)], the resonance for the cyclopentadienyl protons of **2c** splits into two signals at δ = 6.25 and 5.47. By lowering the temperature, the signal at δ = 6.25 further splits into a set of five resonances. They are assigned to the vinylic protons of **2c** $H_{A/A'}$ (δ = 7.01 and 6.90) and $H_{B/B'}$ (δ = 6.57 and 6.55) and to the proton H_X at the *ipso* carbon (δ = 6.57). At 210 K coalescence of the vinylic pairs of protons is observed. In the low temperature limiting spectrum at 193 K, every proton of the η^1-coordinated cyclopentadienyl ligand is chemically inequivalent indicating that at very low temperatures the rotation about the metal *ipso*-carbon bond as a third dynamic process, besides the hapticity change and the metallotropic migration, is slowly resolved on the NMR time scale. The significantly higher coalescence temperature for the mesityl complex **2c** than for **2a,b** may be explained by the higher mass and by the increased steric demand of the migrating group $[(\eta^5\text{-}C_5H_5)W(NMes)_2]$ compared with $[(\eta^5\text{-}C_5H_5)_2M(N\mathit{t}Bu)_2]$ (M = Mo, W). In a similar manner it has been reported by Werner et al.[16] that the rate of the σ/π exchange in $[(\eta^5\text{-}C_5H_5)Pd(\eta^1\text{-}C_5H_5)(PR_3)]$ is dependant on the cone angle[17] of the phosphane ligand PR_3.

Mechanistic Considerations

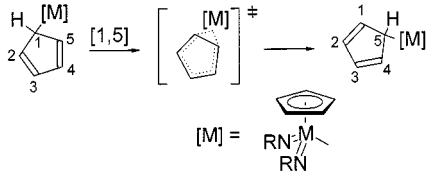
Hapticity Change

The exchange reaction between σ- and π-bonded cyclopentadienyl ligands has been well investigated, for example, for $[(\eta^5\text{-}C_5H_5)_3Ti(\eta^1\text{-}C_5H_5)]$,[18] $[(\eta^5\text{-}C_5H_5)_2Mo(\eta^1\text{-}C_5H_5)(NO)]$,[11] $[(\eta^5\text{-}C_5H_5)Mo(\eta^1\text{-}C_5H_5)(S_2CNR_2)_2]$ (R = Me, Bu),[19] $[(\eta^5\text{-}C_5H_5)Pd(\eta^1\text{-}C_5H_5)(P\mathit{i}Pr_3)]$,[16] $[(\eta^5\text{-}C_5H_5)V(N\mathit{t}Bu)(\eta^1\text{-}C_5H_5)(O\mathit{t}Bu)]$,[20] and $[(\eta^5\text{-}C_5H_5)_2Nb(N\mathit{t}Bu)(\eta^1\text{-}C_5H_5)]$.[21] Scheme 1 shows a mechanistic proposal for the hapticity change in the imido compounds $[(C_5H_5)_2M(NR)_2]$ (M = Mo, W).

As observed in other molecular compounds with η^1- and η^5-coordinating cyclopentadienyl ligands, for example in $[(\eta^5\text{-}C_5H_5)_2Mo(\eta^1\text{-}C_5H_5)(NO)]$,[11] a stepwise or concerted hapticity change is promoted by additional, electronically flexible ligands. The reduction of the imido ligand bond order (BO) from a six VE donor $[NR]^{2-}$ (BO = 3) to a four VE donor $[NR]^{2-}$ (BO = 2) makes the slippage of an η^1-bonded cyclopentadienyl ligand to η^3-coordination more easy, thus it might initiate the exchange from an η^1- via η^3- to an η^5-coordination. A similar flexibility is characteristic for the NO ligand. A mechanism as proposed in Scheme 1 via intermediates of the type $[(\eta^5\text{-}C_5H_5)(\eta^3\text{-}C_5H_5)M(NR)_2]$ has been observed for $[(C_5H_5)_2W(CO)_2]$, in which one cyclopentadienyl ligand adopts an η^3-, and the other one an η^5-coordination mode.[22]

Metallotropic Migration

Over the last 40 years a large number of η^1-C_5H_5 compounds of main group elements and transition metals have been described.[23] Whilst the migration of the metal substituent between the ring carbon atoms has recently been recognized as an intramolecular process,[24] the exact mechanism of the metallotropic rearrangement has remained an unresolved problem for some time. Conclusions were finally drawn from statistical considerations of the different processes under consideration (1,2 shift vs. 1,3 shift vs. random walk) and the initial broadening of the resonances of the vinyl protons below coalescence temperature. Investigations with prochiral complex fragments finally established the [1,2]-metallotropic migration (see Scheme 2) as the energetically most favorable mechanism.[25] The latter may be regarded as a symmetry-allowed [1,5]-sigmatropic rearrangement.



Scheme 2. [1,2]-metallotropic migration as [1,5]-sigmatropic rearrangement

According to Cotton and co-workers,[25] [1,2]-migration can be identified by a preferred broadening of the signals of $H_{A/A'}$ below the coalescence temperature of this process, while a [1,3]-shift can be detected by a preferred broadening of the resonances of $H_{B/B'}$. The proton NMR spectra of **2c** in the relevant temperature range between 220 K and 260 K show a larger broadening for the $H_{A/A'}$ and H_X signals than for $H_{B/B'}$. This is in agreement with a nonrandom mechanism of the metallotropic rearrangement, and the qualitative consideration indicates a [1,2] shift of the molybdenum or tungsten center between the carbon atoms of the σ-(C_5H_5) ligand. It seems that a concerted [1,5]-sigmatropic rearrangement has a lower energy barrier than the formation of an allylic intermediate. However, due to the flexibility in the electron count of the imido ligand it cannot be excluded that, at higher temperatures, both the [1,2]- and the energetically less favorable [1,3]-migration might contribute to the metallotropic migration. We examined the possibility of determining rate constants of the low temperature rearrangements by recording the spectra at higher frequency; how-

ever, the rather complex exchange system turned out to be intractable by the methods available to us.

Conclusions

The new imido complexes $[(\eta^5\text{-}C_5H_5)M(NR)_2(\eta^1\text{-}C_5H_5)]$ (M = Mo, W, R = *t*Bu; M = W, R = Mes) **2a**−**c** have been prepared. Although the metal atoms of the bis(organyl) compounds **2a**−**c** are in their highest formal oxidation state, the Lewis acidity of the d^0 metal centers is well compensated by both types of the excellent σ-,2π- donor ligands $[NR]^{2-}$ and $[C_5H_5]^-$. The compounds **2a**−**c** are π-bond saturated. That means two potential π-bonds of each C_5H_5 ligand (e_1 group orbitals of C_5H_5) and two potential π-bonds of each imido ligand (p orbitals of N atoms) add to a number exceeding the maximum of five π-bonds theoretically possible from orbital symmetry considerations in tetrahedral transition metal complexes.[26] It has been proven that in their competition for π-bonding with the d^0 metal acid, the stronger π-donors $[NR]^{2-}$ are driving the weaker π-donors $[C_5H_5]^-$ out of the π-coordination. Therefore, these complexes may be considered as 18 VE complexes of a d^0 metal center stabilized by four σ-bonds to two C_5H_5 and to two imido ligands, as well as by five π-bonds, two to the $\eta^5\text{-}C_5H_5$ ligand and three π-bonds to both imido ligands, leading to an average bond order of 2.5. This consideration implies that a certain amount of π-electron density remains in ligand-centered nonbonding orbitals. Structural data and the σ,π dynamic behavior of the compounds **2a**−**c** in solution are consistent with this conclusion. The stronger π-donor ability of imido vs. cyclopentadienyl ligands at a d^0 metal center has also been demonstrated by Green et al. for the isolobally related niobium compound $[(\eta^5\text{-}C_5H_5)_2Nb(N\textit{t}Bu)(\eta^1\text{-}C_5H_5)]$.[21] Due to the electronic flexibility of the four vs. six electron imido ligand $[NR]^{2-}$, an allylic species $[(\eta^5\text{-}C_5H_5)(\eta^3\text{-}C_5H_5)M(NR)_2]$ (M = Mo, W) might be considered as an intermediate of the η^5/η^1 exchange process and for the metallotropic [1,3] migration; however, as in the related niobium imido complex, the [1,2]-metallotropic rearrangement is the dominant mechanism in the dynamic behavior at the low temperature limit.

Experimental Section

General: All reactions and subsequent manipulations involving organometallic reagents were performed under argon (4.8) using standard Schlenk techniques. Solvents were dried according to standard procedures, stored over activated 4 Å molecular sieves and degassed prior to use. − Melting and decomposition points were determined in closed capillaries on a Büchi SMP 20 or as DTAs on a duPont 9000 apparatus. − Infrared spectra were recorded as Nujol mulls on KBr windows on a Bruker IFS 25 − NMR spectra were recorded on a Jeol FX90Q, a Bruker AC 200 and a Bruker AMX400 spectrometer. − $[W(NMes)_2Cl_2(dme)]$ (M = Mo, W)[6] and $[(\eta^5\text{-}C_5H_5)M(NR)_2Cl]$[5a] were prepared as described in the literature.

Chloro(cyclopentadienyl)bis(mesitylimido)tungsten(VI) (1c): $[W(NMes)_2Cl_2(dme)]$ (600 mg, 0.96 mmol) was added at −78 °C to a suspension of C_5H_5Li (72.0 mg, 1.00 mmol) in 50 mL diethyl ether. The yellow solution was brought to room temperature within 30 minutes. After 2 h at room temperature, all volatiles were removed and the residue was dried at 50 °C in vacuo and finally extracted into 15 mL toluene. The dark red extract was concentrated to 3 mL. On addition of 15 mL hexane, a red solid precipitated, which was collected and dried in vacuo. − Yield: 333 mg (75%); dec.: 101 °C − IR (nujol): $\tilde{\nu}$ = 3104 w ν(C−H_{ar}), 1600 m ν (C=C), 1348 s, 1320 vs and 1288 vs ν (W=N−C), 1036 w, 1006 w, 988 m, 936 m, 856 m, 812 s ν (C−H_{ar})$_{oop}$, 724 m, 504 w, 460 m, 424 m cm^{-1}. − ^1H NMR (200.1 MHz, $CDCl_3$): δ = 2.32 (s, 18 H, Mes-CH_3), 6.56 (s, 5 H, C_5H_5), 6.84 (s, 4 H, Mes-*H*). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 18.70 (s, *o*-CH_3), 20.69 (s, *p*-CH_3), 109.64 (s, C_5H_5), 127.74 (s, Mes-*C*3), 131.16 (s, Mes-*C*2), 133.46 (s, Mes-*C*4), 152.73 (s, $^2J_{WC}$ = 33.3 Hz, Mes-*C*1). − EI-MS: *m*/*z* (%) = 550 (100) $[M^+]$, 485 (67) $[M^+ - C_5H_5]$. − $C_{23}H_{27}ClN_2W$ (550.8): calcd. C 50.16, H 4.94, N 5.09; found C 49.69, H 5.06, N 5.03.

Bis(*tert*-butylimido)bis(cyclopentadienyl)molybdenum(VI) (2a): Finely powdered **1a** (339 mg, 1.00 mmol) was added to a suspension of $(C_5H_5)Na$ (106 mg, 1.20 mmol) in 20 mL 1,2 dimethoxyethane at −50 °C. The orange colored mixture was brought to room temperature within 30 min. and refluxed for 6 h. All volatiles of the reddish brown suspension were removed in vacuo and the brown, oily residue was extracted with 20 mL hexane. The evaporated hexane extract was distilled at 6×10^{-3} mbar onto a cooled finger (−30 °C). The product separated as an orange-brown solid at the finger, which melted at room temperature to give a brown oil. − Yield: 229 mg (63%). − IR (film): $\tilde{\nu}$ = 3084 m ν(C−H_{ar}), 2968 s, 2920 s, 2892 s, 2860 m, 1696 w, 1660 w, 1588 m ν(C=C), 1440 m, 1356 s, 1248 vs and 1216 vs ν(Mo=N−C), 1116 m, 1080 m, 1020 m, 964 m, 888 w, 840 m, 800 vs and 736 s ν (C−H_{ar})$_{oop}$, 632 w, 584 w, 548 w, 464 w cm^{-1}. −^1H NMR (89.6 MHz, C_7D_8, 188 K): δ = 1.15 (s, 18 H, NCCH_3), 5.05 (br, 1 H, η^1-H_X), 5.30 (s, 5 H, η^5-C_5H_5), 6.71 (br, 2 H, η^1-$H_{B/B'}$), 6.82 (br, 2 H, η^1-$H_{A/A'}$); (89.6 MHz, C_7D_8, 283 K): δ = 1.14 (s, 18 H, NCCH_3), 5.33 (s, 5 H, η^5-C_5H_5), 6.29 (br, 5 H, η^1-C_5H_5); (89.6 MHz, C_7D_8, 363 K): δ = 1.13 (s, 18 H, NCCH_3), 5.78 (s, 10 H, C_5H_5); − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 30.98 (s, NCCH_3), 68.84 (s, N*C*CH_3), 107.95 (br, C_5H_5). − EI-MS: *m*/*z* (%) = 370 (1) $[M^+]$. − $C_{18}H_{28}MoN$ (368.4): calcd. C 58.69, H 7.66, N 7.61; found C 59.01, H 7.98, N 7.74.

Bis(*tert*-butylimido)bis(cyclopentadienyl)tungsten(VI) (2b): Finely powdered **1b** (384 mg, 0.90 mmol) was added to a suspension of $(C_5H_5)Na$ (87.4 mg, 0.99 mmol) in 20 mL 1,2 dimethoxyethane at −50 °C. The temperature of the orange colored mixture was raised to room temperature within 30 min. and refluxed for 6 h. All volatile materials of the brown suspension were removed in vacuo and the brown, oily residue was extracted with 20 mL hexane. The evaporated hexane extract was distilled at 6×10^{-3} mbar onto a cooled finger (−30 °C). The product separated as an orange-brown solid at the finger, which melted at room temperature to give a brown oil. − Yield: 252 mg (61%). − IR (film): $\tilde{\nu}$ = 3084 m ν(C−H_{ar}), 2986 s, 2920 s, 2896 s, 2860 s, 2804 m, 1660 sh, 1612 w ν(C=C), 1448 m, 1356 m, 1288 vs and 1248 vs ν(W=N−C), 1212 s, 1140 w, 1080 m, 1020 m, 960 w, 868 s and 808 vs and 740 vs ν(C−H_{ar})$_{oop}$, 632 w, 576 w, 544 w, 472 w cm^{-1}. − ^1H NMR (89.6 MHz, C_7D_8, 360 K): δ = 1.15 (s, 18 H, NCCH_3), 5.77 (s, 10 H, C_5H_5); (89.6 MHz, C_7D_8, 273 K): δ = 1.16 (s, 18 H, NCCH_3), 5.36 (s, 5 H, η^5-C_5H_5), 6.56 (br, 5 H, η^1-C_5H_5); (89.6 MHz, C_7D_8, 193 K): δ = 1.19 (s, 18 H, NCCH_3), 4.69 (br, 1 H, η^1-H_X), 5.30 (s,

5 H, η^5-C_5H_5), 6.65 (br, 2 H, η^1-$H_{B/B'}$), 6.80 (br, 2 H, η^1-$H_{A/A'}$). – ^{13}C NMR (100.7 MHz, C_7D_8): δ = 31.88 (s, NC*C*H$_3$), 66.69 (s, N*C*CH$_3$), 106.90 (br, *C*$_5$H$_5$). – EI-MS: *m*/*z* (%) = 456 (63) [M$^+$], 441 (59) [M$^+$ – CH$_3$]. – $C_{18}H_{18}N_2W$ (456.3): calcd. C 47.38, H 6.19, N 6.14; found C 47.09, H 6.02, N 6.11.

Bis(cyclopentadienyl)bis(mesitylimido)tungsten(VI) (2c): Finely powdered **1b** (551 mg, 1.00 mmol) was added to a suspension of (C_5H_5)Na (96.1 mg, 1.10 mmol) in 20 mL 1,2 dimethoxyethane at −50 °C. The temperature of the red mixture was raised to room temperature within 30 min. and refluxed for 12 h. All volatile materials of the orange red suspension were removed in vacuo and the oily residue was extracted with 30 mL hexane. The extract was concentrated to approximately 8 mL. Any precipitating product was redissolved by warming the solution. Orange red crystals were isolated after one day at room temperature, and washed with 2 mL cold pentane (−70 °C), and dried in vacuo. – Yield: 429 mg (74%). m.p.: 176 °C. – IR (nujol): $\tilde{\nu}$ = 2986 s, 2920 s, 2896 s, 2860 s, 2804 m, 1604 w ν(C=C), 1448 m, 1356 m, 1311 s and 1281 vs ν(W=N−C), 1153 s, 1056 w, 1024 w, 1010 w, 980 w, 866 s and 810 s and 740 s ν(C−H$_{ar}$)$_{oop}$, 595 w, 582 w, 544 w, 505 w, 440 w cm^{-1}. – ^{1}H NMR (200.1 MHz, C_7D_8, 375 K): δ = 2.07 (s, 6 H, Mes-*p*-C*H*$_3$), 2.19 (s, 12 H, Mes-*o*-C*H*$_3$), 5.88 (s, 10 H, C_5H_5), 6.63 (s, 4 H, Mes-*H*); (200.1 MHz, C_7D_8, 310 K): δ = 2.09 (s, 6 H, Mes-*p*-C*H*$_3$), 2.19 (s, 12 H, Mes-*o*-C*H*$_3$), 5.47 (br, 5 H, C_5H_5), 6.25 (br, 5 H, C_5H_5), 6.60 (s, 4 H, Mes-*H*); (200.1 MHz, C_7D_8, 193 K): δ = 2.15 (s, 6 H, Mes-*p*-C*H*$_3$), 2.24 (s, 12 H, Mes-*o*-C*H*$_3$), 5.15 (s, 1 H, η^1-H_X), 5.26 (s, 5 H, η^5-C_5H_5), 6.55 (s, 2 H, η^1-H_B), 6.57 (s, 1 H, η^1-$H_{B'}$), 6.71 (s, 4 H, Mes-*H*) 6.90 (s, 1 H, η^1-H_A), 7.01 (s, 1 H, η^1-$H_{A'}$). – ^{13}C NMR (50.3 MHz, C_6D_6): δ = 19.47 (s, Mes-*o*-*C*H$_3$), 20.92 (s, Mes-*p*-*C*H$_3$), 108.40 (s, *C*$_5$H$_5$), 128.58 (s, Mes-*C*3), 131.01 (s, Mes-*C*2), 132.76 (s, Mes-*C*4), 153.71 (s, $^2J_{WC}$ = 32.7 Hz, Mes-*C*1). – EI-MS: *m*/*z* (%) = 580 (70) [M$^+$], 515 (100) [M$^+$ – C_5H_5]. – $C_{28}H_{32}N_2W$ (580.4): calcd. C 57.94, H 5.56, N 4.83; found C 57.06, H 5.66, N 4.83.

Bis(*tert*-butylimido)dichloro(trimethylphosphane)tungsten(VI) (3): PMe_3 (100 mg, 1.31 mmol) was added to a solution of **1b** (430 mg, 1.01 mmol) in 15 mL toluene. After 2 h at room temperature, all volatile materials were removed in vacuo, and 15 mL pentane was added to the brown oily residue. Insoluble, ocher colored **3** was filtered off, washed with 5 mL pentane and was dried in vacuo. The mother liquor contained 230 mg (0.50 mmol) of slightly impure **2b**. – Yield: 201 mg (85%). – ^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 1.35 (s, 18 H, NCC*H*$_3$), 1.73 (d, $^2J_{PH}$ = 10.4 Hz, 9 H, PC*H*$_3$); – ^{31}P{^{1}H} NMR (162.0 MHz, $CDCl_3$): δ = 7.55 (s, $^1J_{WP}$ = 363 Hz, *P*CH$_3$); – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 16.63 (d, $^1J_{PC}$ = 34.5 Hz, P-*C*H$_3$), 31.82 (d, $^4J_{PC}$ = 2.0 Hz, NC*C*H$_3$), 69.61 (d, $^3J_{PC}$ = 2.0 Hz, $^2J_{WC}$ = 26.5 Hz, N*C*CH$_3$).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-133165. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Radical Cation Salts with the Nonplanar $[ReO(dmit)_2]^-$ Complex

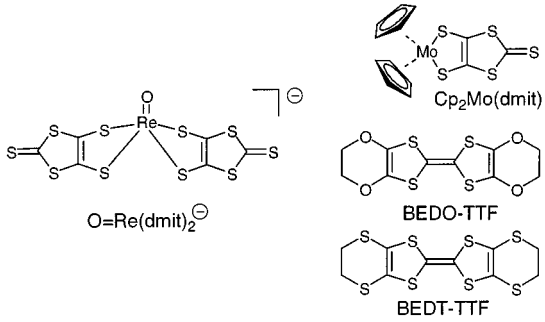
Benoît Domercq[a] and Marc Fourmigué*[a]

Keywords: S ligands / Rhenium / Oxo complexes / Magnetic properties / Radical ions

An optimized synthesis of $[PPh_4][ReO(dmit)_2]$ ($dmit^{2-}$ = 2-thioxo-1,3-dithiole-4,5-dithiolato) is reported as well as electrocrystallization experiments of various donor molecules with this electrolyte. Three 1:1 salts have been obtained with $Cp_2Mo(dmit)$, BEDT-TTF [BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene] and BEDO-TTF [BEDO-TTF = bis(ethylenedioxo)tetrathiafulvalene] and their X-ray crystal structures determined. In the three salts, the closed-shell, d^2, $[ReO(dmit)_2]^-$ anions push apart the radical cations, stabilizing structures with noninteracting donors [with $Cp_2Mo(dmit)$] or donor dimers (with BEDT-TTF or BEDO-TTF), as confirmed by conductivity and SQUID magnetic susceptibility measurements.

Introduction

Planar bis(dithiolene) complexes, and particularly with the sulfur-rich $dmit^{2-}$ ligand, have been extensively used for the elaboration of conducting molecular materials,[1,2] as, for example, the mixed-valence salts derived from $Ni(dmit)_2^-$, $[TTF][Ni(dmit)_2]_2$ with the open-shell $TTF^{+\cdot}$ counter cation,[3] or $[NMe_4][Ni(dmit)_2]_2$ with the closed shell NMe_4^+ ammonium cation,[4] both of them reported to become superconductors. On the other hand, their nonplanar tris(dithiolene) analogs such as $[Mo(dmit)_3]^-$ or $[V(dddt)_3]^-$ have been scarcely investigated for the elaboration of conducting salts,[5,6] probably because their more spherical shape hinders a proper overlap interaction network in the solid state. In this respect, heteroleptic complexes with one of the three dithiolene ligands replaced by a smaller one, such as an oxo or a nitrido group, offer an attractive alternative since more compact structures can be anticipated. Several of those heteroleptic complexes have been described with the $dmit^{2-}$ ligand, some of them diamagnetic (d^2), such as $[MoO(dmit)_2]^{2-}$,[7,8] $[ReO(dmit)_2]^-$,[9] $[TcN(dmit)_2]^{2-}$,[10] and $[OsN(dmit)_2]^-$ [11] and some of them paramagnetic (d^1), such as $[VO(dmit)_2]^{2-}$ [12] or $[MoO(dmit)_2]^-$.[7,8] Among these compounds, only $[MoO(dmit)_2]^-$ forms cation radical salts with TTF to afford a 1:1 salt, $[TTF][MoO(dmit)_2]$ which was not structurally characterized.[8] We therefore decided to investigate more closely the cation radical salts derived from those heteroleptic dithiolene oxo complexes, and present here our results with the closed-shell, diamagnetic Re^V $[ReO(dmit)_2]^-$ anion (Scheme 1). Planar donor molecules such as BEDT-TTF or BEDO-TTF were engaged in electrocrystallization experiments with $[ReO(dmit)_2]^-$ as well as the nonplanar Mo^{IV} molybdenum complex, $Cp_2Mo(dmit)$



Scheme 1

(Scheme 1),[13] which has been described to be readily oxidized to the corresponding $[Cp_2Mo(dmit)]^{+\cdot}$ radical cation.[14–16]

Results and Discussion

Synthesis

The preparation of $[ReO(dmit)_2]^-$ has been described by Matsubayashi from the reaction of $ReCl_5$ with two equivalents of $dmit^{2-}$ in EtOH.[9] The uncontrolled partial hydrolysis of $ReCl_5$ under those conditions gave the desired anion in only 30% yield, while a similar reaction in anhydrous CH_3CN gave the homoleptic $[Re(dmit)_3]^-$ dithiolene complex. We felt that a higher yield could be obtained by using a preformed $ReOX_4$ moiety, as described for the synthesis[17] of $[ReO(mnt)_2]^-$ or $[ReO(S_2C_2B_{10}H_{10})_2]^-$,[18] and chose accordingly to engage the $ReOBr_4^-$ anion, as its tetraphenylphosphonium salt,[19] in a substitution reaction with two equivalents of $dmit^{2-}$, affording $[PPh_4][ReO(dmit)_2]$ in very good yield (88%) after recrystallization, and identical in every respect to the described compound.[9]

Structure and Electronic Properties of the $ReO(dmit)_2^-$ Cation Radical Salts

The electrocrystallization of $Cp_2Mo(dmit)$, BEDT-TTF and BEDO-TTF in the presence of $[PPh_4][ReO(dmit)_2]$ as electrolyte allowed the isolation of the three corresponding

1:1 salts. $[Cp_2Mo(dmit)][ReO(dmit)_2]$ crystallizes in the monoclinic system, space group $P2_1/c$, with both cation and anion in general positions in the unit cell (Figure 1).

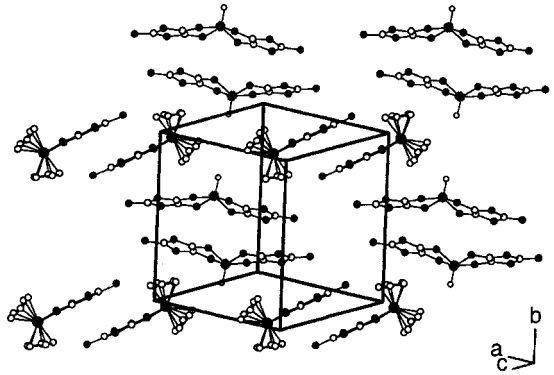

Figure 1. A view of the mixed cation-anion ($a + c$, b) layer in $[Cp_2Mo(dmit)][ReO(dmit)_2]$

The geometry of the $[ReO(dmit)_2]^-$ anion (Figure 2) is very close to that described for its PPh_4^+ salt (Table 1), although the folding angles of the two ReS_2C_2 metallacycles slightly increase from 11−15° to 17°. Bond length evolution within the organometallic cation (Table 2) confirms the oxidized character of the complex, which changes to a more dithioketonic-type structure for the dithiolene ligand (shortening of the C−S bonds and lengthening of the C=C bond). Note also the weak folding angle θ of the MoS_2C_2 metallacycle along the S···S axis in $Cp_2Mo(dmit)^{+\cdot}$ [5.6(5)°] which should be compared to the distortions observed in $[Cp_2Mo(dmit)][TCNQF_4]$ [θ = 10.2(1)°],[14] while a fully planar metallacycle was observed in $[Cp_2Mo(dmit)][AsF_6]$ (θ = 0.0°).[15] The cations are organized into inversion-related dimers with a somewhat large interplanar dmit/dmit distance of 3.58 Å, associated with a lateral offset of 5.51 Å. Those dimers organize into layers in the (a,c) plane, separated from each other by the diamagnetic $ReO(dmit)_2^-$ anions. As a consequence of the weakly interacting radical cations, the closed-shell character of the anion and the full charge-transfer, the salt is insulating with $\sigma_{RT} = 4 \times 10^{-7}$ S cm^{-1}. Its magnetic behavior was deduced from the SQUID susceptibility measurements which show a Curie−Weiss behavior in the whole temperature range with θ = 0.3 K, excluding the possibility of sizeable intermolecular interactions in this salt. $[Cp_2Mo(dmit)][ReO(dmit)_2]$ can therefore be described as paramagnetic $[Cp_2Mo(dmit)]^{+\cdot}$ radical cations, essentially isolated from each other by the closed-shell $[ReO(dmit)_2]^-$ anions. The situation is more complex in the BEDT-TTF and BEDO-TTT salts.

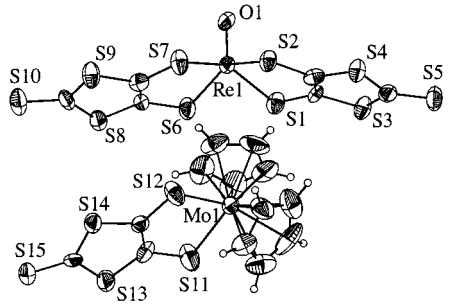

Figure 2. ORTEP view of the $[Cp_2Mo(dmit)]^{+\cdot}$ cation and the $[ReO(dmit)_2]^-$ anion in $[Cp_2Mo(dmit)][ReO(dmit)_2]$; thermal ellipsoids at the 50% probability level

[BEDT-TTF][$ReO(dmit)_2$] crystallizes in the monoclinic system, space group $P2_1/n$, with both anion and cation in general positions in the unit cell (Figure 3). The bond lengths within the $[ReO(dmit)_2]^-$ are similar to those observed above (Table 1). Within the BEDT-TTF moieties, the bond length evolution relative to the neutral molecules con-

firms the fully oxidized character of the BEDT-$TTF^{+\cdot}$ cation radical (Table 3) when compared with reference compounds,[20,21] hence the formulation [BEDT-$TTF]^{+\cdot}[ReO(dmit)_2]^-$. The organic cation radicals are organized into layers parallel to the (a-c, b) plane (Figure 4), separated from each other by the diamagnetic $[ReO(dmit)_2]^-$ counter anions. Within each organic layer (Figure 5), the $BEDT^{+\cdot}$ cation radicals arrange into inversion-centered dimers with short S···S distances (3.42−3.78 Å) and a short interplanar plane-to-plane distance (2.72−2.74 Å). Those dimers interact only weakly with their neighbors in the plane through S···S overlap (S···S distances at 3.67 Å) with the sulfur atoms of the outer dithioethylene moieties.

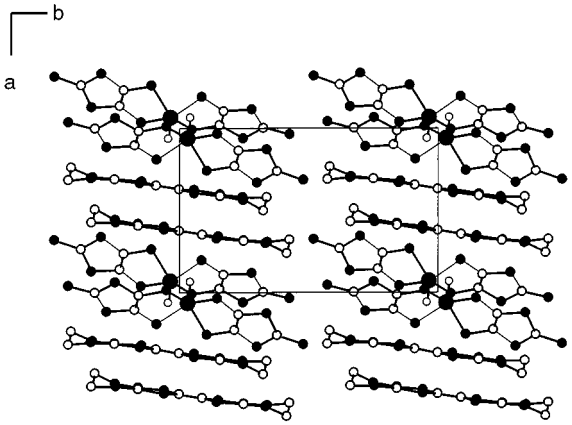

Figure 3. Projection view (along *c*) of the mixed organic-inorganic layers identified in the structure of [BEDT-TTF][$ReO(dmit)_2$]

Table 3. Bond length evolution within the TTF core and charge transfer degree (ρ) in BEDT-TTF and BEDO-TTF, in the neutral donor molecules, the two salts with $[ReO(dmit)]^-$ and reference salts

	ρ	C=C bond (a)	C−S bonds (b)	ref.
BEDT-TTF neutral	0	1.343(3)	1.756(3)	20
[BEDT-TTF][ReO(dmit)]	1	1.397(13)	1.716(11)	this work
BEDT-$TTF^{+\cdot}$ in [BEDT-TTF][PF_6]	1	1.394(5)	1.722(4)	21
BEDO-TTF neutral	0	1.357(6)	1.761(5)	22
[BEDO-TTF][ReO(dmit)]	1	1.368(10)	1.719(8)	this work
BEDO-$TTF^{+\cdot}$ in $[BEDO]_2[Pd(dto)]$	1	1.390(14)	1.729(18)	23

[BEDO-TTF][$ReO(dmit)_2$], on the other hand, crystallizes in the monoclinic system, space group $P2_1/c$, with two crystallographically independent anions and cations in the unit cell. This differentiation originates from different orientations of the ethylenedioxo groups of the BEDO-TTF molecules. The bond lengths within the central TTF core also confirm the oxidized character of the donor molecule (Table 3) when compared with reference compounds.[22,23]

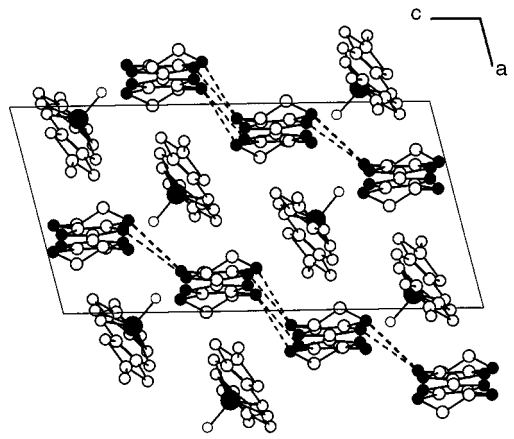

Figure 4. Projection view along *b* in [BEDT-TTF][$ReO(dmit)_2$]; the dotted lines indicate the shortest intermolecular S···S contacts between radical BEDT-$TTF^{+\cdot}$ moieties; the Re atom and the sulfur atoms of the BEDT-$TTF^{+\cdot}$ molecules are shaded

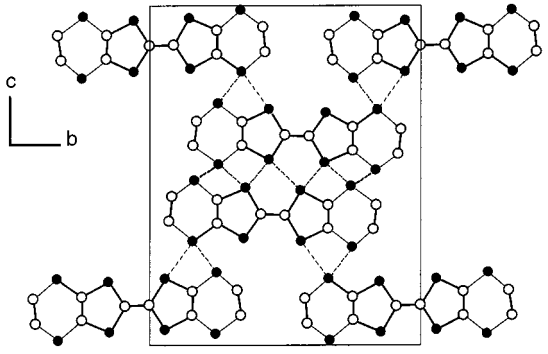

Figure 5. Detail of the intermolecular interaction network between organic BEDT-$TTF^{+\cdot}$ cation radicals in [BEDT-TTF][$ReO(dmit)_2$]

A similar dimer organization of the cation radicals is observed with short S···S (3.56−3.67 Å) and S···O (3.35−3.52 Å) intermolecular contacts (Figure 6), while the dimeric entities are fully isolated from each other by the $[ReO(dmit)_2]^-$ counter ions.

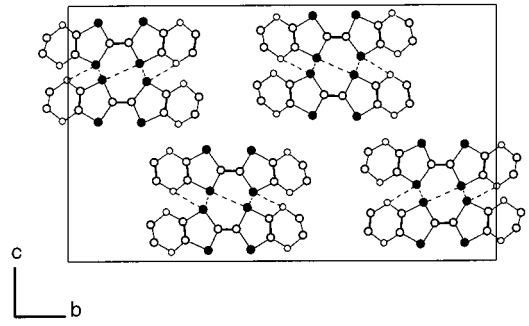

Figure 6. The interaction network identified in the organic layers of BEDO-$TTF^{+\cdot}$ cation radicals in the structure of [BEDO-TTF][$ReO(dmit)_2$]

Conductivity measurements (on compressed pellets) reveal a semi-conducting behavior for both salts with $\sigma_{RT} = 1-3 \times 10^{-6}$ S·cm^{-1}. SQUID measurements of the temperature dependence of the magnetic susceptibility (Figure 7) show, for both salts, an activated behavior in the 100−300 K range together with a Curie tail at low temper-

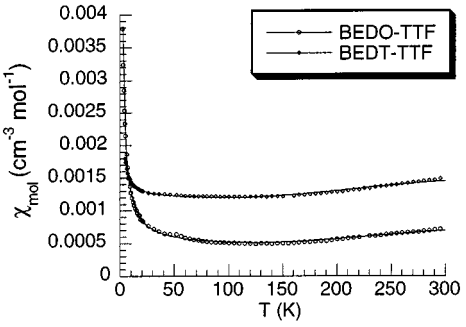

Figure 7. Temperature dependence of the magnetic susceptibility of [BEDT-TTF][ReO(dmit)$_2$] and [BEDO-TTF][ReO(dmit)$_2$]; the solid lines are a fit to the singlet-triplet Bleaney−Bower equation with a low-temperature Curie tail (see text)

ature. The latter represents 0.8 and 2.2% $S = 1/2$ magnetic defects in the BEDT-TTF and BEDO-TTF salts respectively. The structural description of these salts indicates the presence of donor dimers, essentially isolated from each other by the diamagnetic anions. The HOMO−HOMO overlap interaction within those dimers leads therefore to bonding and antibonding combinations which house the two remaining electrons. Accordingly, the conductivity is very low and we expect a singlet-triplet magnetic behavior with a maximum for the susceptibility whose temperature $T(\chi_{max})$ depends upon the HOMO−HOMO interaction energy. The fit of the magnetic susceptibility with the Bleaney−Bower equation,[24] together with the Curie law encompassing the magnetic defects identified at low temperature, affords J/k values of −826(5) and −880(7) K for the BEDT-TFF and BEDO-TTF salts, respectively. The close proximity of those two values is indeed in agreement with the extended-Hückel calculated HOMO−HOMO interaction energies within the dimers, which amount to 0.408 and 0.411 eV in the two salts.

Contrary to the situation encountered in organic conductors based on BEDT-TFF or BEDO-TTF, which is characterized by a two-dimensional segregation of the organic donor molecules and the counter ions, we observed here the formation of mixed cationic/anionic layers with the diamagnetic [ReO(dmit)$_2$]$^-$ units interspersed between the oxidized donor molecules, thus hindering the stabilization of mixed valence, a prerequisite for metallic conductivity. The peculiar alternated structures observed here might be of interest for their magnetic properties, particularly if the diamagnetic [ReO(dmit)$_2$]$^-$ could be replaced by analogous paramagnetic complexes such as the unknown [MoO(dmit)$_2$]$^{-\cdot}$ or [ReN(dmit)]$^{-\cdot}$. Preliminary experiments along those lines showed that ferricinium oxidation of the dianionic [MoO(dmit)$_2$]$^{2-}$ described by Matsubayashi[7,8] afforded a bimetallic [Mo$_2$O$_2$(μ-O)$_2$(dmit)$_2$]$^{2-}$ complex[25] rather than the expected [MoO(dmit)$_2$]$^{-\cdot}$.

Experimental Section

Synthesis: All reactions were performed under nitrogen using vacuum line techniques. Solvents were dried prior to use. $[PPh_4][ReOBr_4]$ was prepared according to Cotton et al.[19] in 44.3% yield. – $C_{24}H_{20}Br_4OPRe$: calcd. C 33.47, H 2.34, Br 37.11, P 3.60; found C 33.72, H 2.39, Br 37.38, P 3.60.

$[PPh_4][ReO(dmit)_2]$: A solution of $dmit(COPh)_2$ (0.5 g, 1.23 mmol) in dry MeOH (5 mL) was treated with a MeOH solution of NaOMe (2.1 equiv.). After stirring for 1 h, the dark red solution was precipitated with Et_2O (20 mL), and the red dithiolene salt decanted, washed with Et_2O and dried. $Na_2(dmit)$ was dissolved in MeOH (40 mL) and added dropwise to a solution of $[PPh_4][ReOBr_4]$ (0.5 g, 0.58 mmol) in MeOH (50 mL). A red solid immediately precipitated. After stirring overnight it was filtered and recrystallized from CH_2Cl_2/EtOH, affording 0.48 g (88%) of the salt as dark red crystals. M.p. 224–225 °C. – $C_{30}H_{20}OPReS_{10}$: calcd. C 38.57, H 2.16, P 3.32, S 34.32; found C 36.18, H 1.98, P 3.71, S 36.15.

Electrocrystallization Experiments: Two-compartment cells with platinum electrodes (l = 2 cm, Ø = 1 mm) were used in the galvanostatic mode at 20 °C. Crystals were harvested on the anode after the indicated time and washed with CH_2Cl_2. Details for each individual compound are given in Table 4.

Data Collection and Structure Determination: Table 5 summarizes the crystallographic data. Data were collected at room temperature on an Imaging Plate Diffraction System (Stoe-IPDS). Structures were solved by direct methods using SHELXS-86 and refined by the full-matrix least-squares method on F^2, using SHELXL-93 (G. M. Sheldrick, University of Göttingen, **1993**) with anisotropic thermal parameters for all non-hydrogen atoms. The hydrogen atoms were introduced at calculated positions (riding model).
Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-149592–149594 for the $Cp_2Mo(dmit)$, the BEDT-TTF and the BEDO-TTF salts, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Magnetic Measurements: Magnetic susceptibilities were measured on a Quantum Design MPMS-2 SQUID magnetometer operating in the range 2.5–300 K at 1 T ($[BEDT\text{-}TTF][ReO(dmit)_2]$, 12.32 mg) or 0.5 T ($[BEDO\text{-}TTF][ReO(dmit)_2]$, 6.53 mg). Data were corrected for sample holder contribution and Pascal diamagnetism.

Synthesis of Novel Heterotetrametallic (d^6-d^{10}-d^8) Polyalkynyl Complexes Starting from Heterobimetallic Chloride-Bridged (d^6-d^8) Compounds

Irene Ara,[a] Jesús R. Berenguer,[b] Eduardo Eguizábal,[b] Juan Forniés,*[a] Elena Lalinde,*[b] and Antonio Martín[a]

Dedicated to Prof. R. Usón on the occasion of his 75th birthday

Keywords: Iridium / Rhodium / Heteropolymetallics / Chloro-bridged complexes / Alkynide-bridged complexes

The reaction between the half-sandwich cyclopentadienyl complexes [M(η^5-C_5Me_5)Cl_2(PEt_3)] (M = Rh, Ir) and [*cis*-M′(C_6F_5)$_2$(thf)$_2$] (M′ = Pt, Pd; thf = tetrahydrofuran) affords the corresponding chloride-bridged heterobinuclear Rh,Ir/Pt,Pd complexes [(PEt_3)(η^5-C_5Me_5)M(μ-Cl)$_2$M′(C_6F_5)$_2$] (**1**–**4**). In contrast, similar reactions with the chloro-bridged binuclear compounds [{M(η^5-C_5Me_5)Cl(μ-Cl)}$_2$] (M = Rh, Ir) lead instead to the unexpected mixed salt complexes {Cp*M(μ-Cl)$_3$MCp*}$_2$[{(C_6F_5)$_2$M′(μ-Cl)}$_2$] (M = Rh, Ir; M′ = Pt, Pd) (**5**–**8**) as a result of chloride transfer. The structures of [(PEt_3)(η^5-C_5Me_5)Rh(μ-Cl)$_2$Pt(C_6F_5)$_2$] (**1**) and {Cp*Rh(μ-Cl)$_3$RhCp*}$_2$[{(C_6F_5)$_2$Pd(μ-Cl)}$_2$] (**6**) have been determined by X-ray diffraction analyses. The reactivity of the new chloride-bridged heterobinuclear compounds **1**–**4** towards the alkynylating agents [M′′(C≡CR)]$_n$ (M′′ = Cu, Ag) has also been investigated: a new type of tetranuclear product, [(PEt_3)Cp*M(μ-1κC^α:η^2-C≡CPh)$_2$M′′$_2$(μ-4κC^α:η^2-C≡CPh)$_2$Pt(C_6F_5)$_2$] (M = Rh, Ir; M′′ = Cu, Ag) (**9**–**12**), was obtained, and fully characterized in the case of complex [(PEt_3)Cp*Rh(μ-1κC^α:η^2-C≡CPh)$_2$Cu$_2$(μ-4κC^α:η^2-C≡CPh)$_2$Pt(C_6F_5)$_2$] (**9**).

Introduction

The chemistry of bimetallic complexes has aroused much interest and has led to great development in the field of organometallic chemistry.[1] In this area, there have been many reports detailing the preparation and chemistry of symmetrical or asymmetrical dichloro-bridged homobinuclear complexes,[2][3l] mainly because they play a prominent role as starting materials in organometallic chemistry and because of their relevance in catalysis. In marked contrast, the heterobinuclear analogues L_m(μ-Cl)$_2$M′L_n[3a−3e] are very scarce and their chemistry remains essentially undocumented, although efforts to develop this chemistry have recently been reported.[3f−3p]

This paucity of heterobinuclear compounds containing chloride bridging ligands, as well as the potentially rich chemistry that may be expected in these systems, prompted us to prepare binuclear compounds containing Rh^{III} or Ir^{III} fragments together with [*cis*-M′(C_6F_5)$_2$] (M′ = Pt, Pd) units. We were interested in using these systems as precursors for alkynyl-bridged heteropolynuclear complexes.[4] In the course of our ongoing research on alkynyl complexes, we have recently succeeded in synthesizing the first homobridged bis(μ-alkynyl) [(PEt_3)Cp*M(μ-C≡CR)$_2$M′(C_6F_5)$_2$] and hetero-bridged μ-alkynyl,μ-halide [(PEt_3)Cp*M(μ-C≡CR)(μ-X)M′(C_6F_5)$_2$] heterobinuclear Rh,Ir^{III}/Pt,Pd^{II} complexes,[4g] simply by treating mono [MCp*(C≡CR)X(PEt_3)] or bis(alkynyl) [MCp*(C≡CR)$_2$(PEt_3)] compounds with [*cis*-M′(C_6F_5)$_2$(thf)$_2$]. As a continuation of our work in this field, and in order to complete this series with respect to the bridging system, we report herein the synthesis of the dichloro-bridged heterobinuclear complexes [(PEt_3)Cp*M(μ-Cl)$_2$M′(C_6F_5)$_2$] (M = Rh, M′ = Pt: **1**, Pd: **2**; M = Ir, M′ = Pt: **3**, Pd: **4**) and the crystal structure of **1**. Furthermore, in order to explore the potential utility of these new compounds, we have attempted the preparation of alkynyl-bridged complexes by treating them with ethynylating agents such as [CuC≡CR]$_x$ and [Ag(C≡CR)]$_x$. These reactions led to the synthesis of a new type of heteropolynuclear alkynyl-bridged complexes [(PEt_3)Cp*M(μ-1κC^α:η^2-C≡CPh)$_2$M′′$_2$(μ-4κC^α:η^2-C≡CPh)$_2$Pt(C_6F_5)$_2$] (M = Rh, Ir; M′′ = Cu, Ag) (**9**−**12**), in which two widely divergent bis(alkynyl) metal fragments (d^6 and d^8) are connected through d^{10} (Cu or Ag) metal ions. We also describe similar reactions between [{MCp*Cl(μ-Cl)}$_2$] (M = Rh, Ir) and [*cis*-M′(C_6F_5)$_2$(thf)$_2$] (M′ = Pt, Pd) that involve chloride-transfer to yield the mixed salt complexes {Cp*M(μ-Cl)$_3$MCp*}$_2$[{(C_6F_5)$_2$M′(μ-Cl)}$_2$] (M = Rh, Ir; M′ = Pt, Pd) (**5**−**8**), and we present the crystal structure of {Cp*Rh(μ-Cl)$_3$RhCp*}$_2$[{(C_6F_5)$_2$Pd(μ-Cl)}$_2$] (**6**).

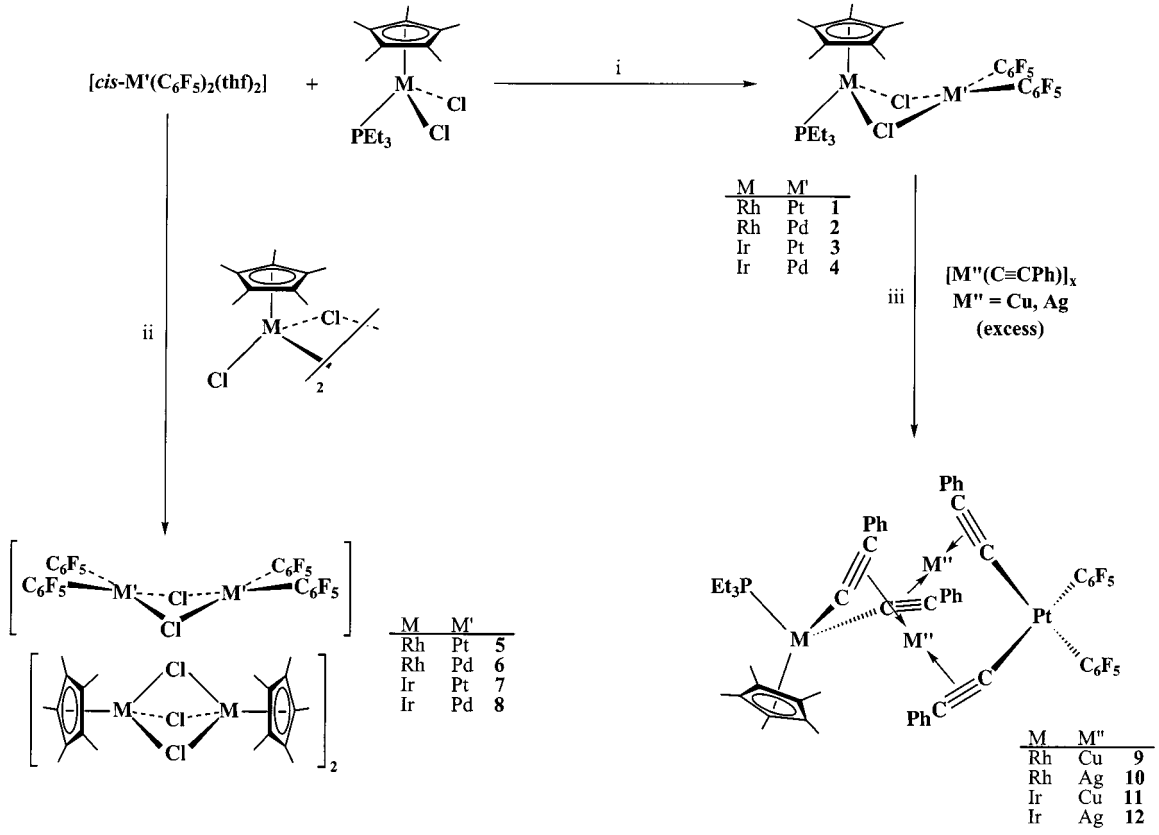
Results and Discussion

Synthesis of Hetero- and Homobimetallic Chloride-Bridged Complexes

The preparative results are summarized in Scheme 1. The reaction of compounds [*cis*-M′(C_6F_5)$_2$(thf)$_2$] (M′ = Pt, Pd)

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0606−1631 $ 17.50+.50/0



Scheme 1

with metallo species bearing potentially bridging groups in *cis* or even *trans* positions has proved to be an excellent preparative method for the synthesis of bi- and polymetallic complexes.[4a,4g,5] Therefore, we considered it appropriate to use this strategy for the synthesis of the desired doubly chloride-bridged heterobinuclear complexes **1**–**4**. Treatment of a red solution of $[MCp^*Cl_2(PEt_3)]$ (M = Rh, Ir) in acetone with 1 equivalent of the solvated platinum or palladium complex $[cis\text{-}M'(C_6F_5)_2(thf)_2]$ immediately gave an orange solution, from which the corresponding complexes **1**–**4** could be isolated as orange solids in high yields (i, Scheme 1). It should be mentioned that several neutral $[(ppy)_2M(\mu\text{-}Cl)_2M'(PR_3)Cl]$ (M = Rh, Ir; M′ = Pt, Pd; ppy = 2-phenylpyridine anion; R = Bu, Et) or cationic $[(chel)M(\mu\text{-}Cl)_2M'(PEt_3)_2](BF_4)$ (M = Rh, Ir; M′ = Pt, Pd; chel = anion of 2-phenylpyridine, benzo[4]quinoline, $C_6H_5CHRNMe_2$, or η^3-allyl) heterobinuclear (d^6-d^8) chloride-bridged complexes have been very recently prepared by metathesis reactions from the respective chloro-bridged homodimeric compounds.[3l,3o] In addition, related dicationic $[(PMe_3)(\eta^5\text{-}C_5Me_5)M(\mu\text{-}Cl)_2PtL_2]^{2+}(OTf)_2^-$ (M = Rh, Ir; L_2 = dppp, 2 PPh_3) complexes have been prepared by a similar route starting from the bis(triflate) species $[MCp^*(PMe_3)(OTf)_2]$ (M = Rh, Ir) and the corresponding dichloroplatinum derivatives.[3g]

The heterobinuclear platinum complexes **1** and **3** remain stable indefinitely, both in the solid state and in solution, but the mixed palladium compounds are only stable in the solid state. In solution, **2** and **4** slowly decompose with the deposition of metallic palladium. The complexes have been characterized by analytical and spectroscopic techniques. In addition, the structure of complex **1** has been established by an X-ray diffraction study. The IR spectra show two absorptions in the 785–812 cm^{-1} region attributable to the x-sensitive mode of the C_6F_5 groups (A′, A″; C_s), thus indicating the presence of a *cis*-$M(C_6F_5)$ moiety.[6] Furthermore, all the complexes show bands (247–277 cm^{-1}) associated with the ν(M–Cl) stretching vibrations (2A′ + 2 A″; C_s) of the bridges.

The NMR spectroscopic data are consistent with the solid-state structure of complex **1**. This complex crystallizes with a bent $RhCl_2Pt$ central core, and the conformer found (see Figure 1) is that in which the $Pt(C_6F_5)_2$ unit lies *endo* to the Cp* ligand. The room and low-temperature NMR spectroscopic data (^1H, $^{31}P\{^1H\}$, ^{19}F, and $^{13}C\{^1H\}$) reveal no evidence of possible conformers (see Experimental Section for details), although a possible rapid interconversion of conformers (fast inversion of the central $RhCl_2Pt$ core) cannot be excluded. Only the ^{19}F NMR spectra are temperature dependent. Thus, in accordance with the structure depicted in Scheme 1 (see also Figure 1), the room temperature ^{19}F NMR spectra in $[D_6]$acetone show only one type of C_6F_5 ligand, confirming the equivalence of the two C_6F_5 moieties. However, they exhibit the typical AA′MXX′ pattern of three signals of relative intensity 2:1:2, evidencing that the two halves of each C_6F_5 ring appear equivalent at room temperature, and indicating that these complexes are not rigid in solution. As expected, on lowering the temper-

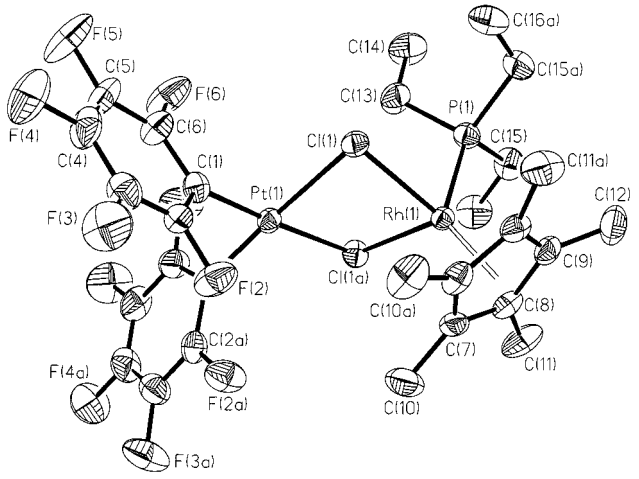


Figure 1. Molecular structure of $[(PEt_3)(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}Cl)_2Pt(C_6F_5)_2]$ (**1**) showing the atom labelling scheme (ellipsoids are drawn at a 50% probability level; hydrogen atoms have been omitted for clarity)

ature (to −50 °C), five distinct fluorine resonances become clearly resolved for all the complexes. We note that a possible fast inversion of the central MCl_2M' core, which cannot be excluded, would not exchange the two halves of each C_6F_5 moiety. Therefore, the most likely dynamic process that would account for the exchange of the halves of the C_6F_5 rings is their free rotation about the $Pt-C_i(C_6F_5)$ bonds. From the coalescence temperature T_c (258 K) and the difference in chemical shift $\Delta\nu$ of the F_o signals, a $\Delta G^{\#}$ value of 51 kJ·mol^{-1} has been calculated for **4**.[7] For complex **1**, the ^{19}F NMR spectra have also been recorded in $CDCl_3$ and both the room and low-temperature (−50 °C) spectra were found to be almost identical to those obtained in [D$_6$]acetone solution. This fact suggests that dissociative processes, such as the dissociation of an $M'(C_6F_5)_2$ unit or chloride−M′ (M′ = Pt, Pd) bond breaking, which would probably be solvent dependent, are unlikely.

A definitive structural assignment of the heterobimetallic complexes **1**−**4** has been established by an X-ray diffraction study on complex $[(PEt_3)(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}Cl)_2Pt(C_6F_5)_2]$ (**1**, Figure 1). Suitable dark-orange crystals were obtained by slow diffusion of hexane into a solution of **1** in acetone at low temperature (−30 °C). Selected bond lengths and angles are collected in Table 1. The structure confirms that the complex contains an Rh(III) centre in a pseudo-octahedral environment, formed by the η^5-bonded C_5Me_5 group, which occupies three formal coordination sites, the PEt_3, and the two bridging chlorides, and a Pt atom that completes its usual square-planar coordination with two σ-C_6F_5 groups. The geometries around both metal centres are unexceptional for fragments of this type and are similar to those previously observed in related homo-bridged μ-bis(alkynyl) and hetero-bridged (μ-Cl)(μ-alkynyl) d^6-d^8 systems.[4g] The central $Rh(\mu\text{-}Cl)_2Pt$ core shows a marked deviation from planarity, with a dihedral angle between the ClRhCl plane and the platinum coordination plane of 31.5°. This structural feature contrasts with the planar cores previously found in the corresponding doubly chloride-bridged symmetrical bimetallic species $(NBu_4)_2[(C_6F_5)_2Pt(\mu\text{-}Cl)_2Pt(C_6F_5)_2]$[8] and $[\{Rh(\eta^5\text{-}C_5Me_5)Cl(\mu\text{-}Cl)\}_2]$.[9] A recent theoretical study seems to confirm the observation that asymmetric chloro-bridged complexes tend to have a bent structural arrangement.[3p] Thus, the cationic mixed derivative $[(bzq)_2Rh(\mu\text{-}Cl)_2Pt(PBu_3)_2]^+$ is also considerably bent (29.4°)[3o] and similar nonplanar structures, albeit less severely distorted, have also been found in $[(PMe_3)Cp^*Ir(\mu\text{-}Cl)_2Pt(dppp)]^{2+}$ (ca. 11°)[3g] and $[(ppy)_2Rh(\mu\text{-}Cl)_2PtCl(PBu_3)]$ (13.2°).[3l] However, other theoretical and structural analyses of square-planar d^8 metal complexes of the type $[L_2M(\mu\text{-}Cl)_2ML_2]$ seem to suggest that attractive metal−metal interactions are one of the main factors responsible for the observed bending.[10] In complex **1**, the Pt−Rh distance of 3.407(1) Å suggests that the observed puckering does not lead to any significant metal−metal bonding interaction. However, this distance is markedly shorter than those observed in the respective homobimetallic species $[\{(C_6F_5)_2Pt(\mu\text{-}Cl)\}_2]^{2-}$ [3.528(1) Å][8] and $[\{Rh(\eta^5\text{-}C_5Me_5)Cl(\mu\text{-}Cl)\}_2]$ [3.719(1) Å][9] and in the mixed $Rh^{III}-Pt^{II}$ *ortho*-metallated derivatives $[(ppy)_2Rh(\mu\text{-}Cl)_2PtCl(PBu_3)]$ (3.61 Å)[3l] and $[(bzq)_2Rh(\mu\text{-}Cl)_2Pt(PBu_3)_2]^+$ (3.63 Å).[3o] Clearly, the value mentioned above is more akin to that found in the chloride/alkynide hetero-bridged compound $[(PEt_3)Cp^*Rh(\mu\text{-}Cl)(\mu\text{-}C{\equiv}CPh)Pt(C_6F_5)_2]$ [3.371(1) Å].[4g]

Table 1. Selected bond lengths [Å] and angles [deg.] in complex $[(PEt_3)Cp^*Rh(\mu\text{-}Cl)_2Pt(C_6F_5)_2]$ (**1**) (Cp^*_{cent}: centroid of the Cp* group. Symmetry transformations used to generate equivalent atoms (a): $x, -y + 1/2, z$)

Rh−Cl(1)	2.409(1)	Rh−P	2.313(2)
$Rh-Cp^*_{cent}$	1.799(1)	Pt−C(1)	1.959(4)
Pt−Cl(1)	2.381(1)	Rh···Pt	3.407(1)
P−Rh−Cl(1)	89.27(4)	Cl(1)−Rh−Cl(1a)	84.02(5)
$P-Rh-Cp^*_{cent}$	133.04(5)	$Cl(1)-Rh-Cp^*_{cent}$	123.48(3)
Pt−Cl(1)−Rh	90.65(3)	C(1)−Pt−C(1a)	90.6(2)
C(1)−Pt−Cl(1)	92.07(12)	Cl(1)−Pt−Cl(1a)	85.22(5)

The bridging chloride is slightly asymmetric, with metal−chlorine distances [Rh−Cl(1) 2.409(1) Å; Pt−Cl(2) 2.381(1) Å] rather similar to those found in $[(PEt_3)Cp^*Rh(\mu\text{-}Cl)(\mu\text{-}C{\equiv}CPh)Pt(C_6F_5)_2]$ (≈ 2.43 Å). This structural feature is in marked contrast to the dichloro bridges in the cationic $[(bzq)_2Rh(\mu\text{-}Cl)_2Pt(PBu_3)_2]^+$ and neutral $[(ppy)_2Rh(\mu\text{-}Cl)_2PtCl(PBu_3)]$ complexes, which are highly asymmetric (Rh−Cl ≈ 2.53 Å; Pt−Cl 2.36−2.40 Å). The Cl(1)RhCl(1a) [84.02(5)°] and Cl(1)PtCl(1a) [85.22(5)°] angles are almost identical and are slightly smaller than the angle at the chlorine atom [90.65(3)°].

With the aim of obtaining binuclear derivatives of the general formula $[(S)Cp^*M(\mu\text{-}Cl)_2M'(C_6F_5)_2]$ with one vacant site for bonding, where S could be a solvent molecule such as acetone or thf, we also explored the reactivity of the tetrahydrofuran adducts $[cis\text{-}M'(C_6F_5)_2(thf)_2]$ towards the binuclear derivatives $[\{MCp^*Cl(\mu\text{-}Cl)\}_2]$ in acetone in a 2:1 molar ratio. However, contrary to our expectations,

these reactions did not afford the desired heterobimetallic complexes; instead, low yields of the mixed ionic 2:1 salts $[Cp^*M(\mu\text{-}Cl)_3MCp^*]_2[\{(C_6F_5)_2M'(\mu\text{-}Cl)\}_2]$ (**5**–**8**) (ii, Scheme 1) were obtained. Predictably, better yields were obtained when the reactions were carried out in a 1:1 molar ratio (see Experimental Section). In these reactions, the platinum and palladium fragments "*cis*-$M'(C_6F_5)_2$" act as abstractors of chloride ligands giving $[cis\text{-}(C_6F_5)_2M'Cl]^-$, which dimerizes to $[(C_6F_5)_2M'(\mu\text{-}Cl)_2M'(C_6F_5)_2]^{2-}$, thus leaving the binuclear half-sandwich cationic complexes $[Cp^*M(\mu\text{-}Cl)_3MCp^*]^+$ with the chloro-bridges. Both cationic $[(Cp^*M)_2(\mu\text{-}Cl)_3]BF_4$ (M = Rh, Ir)[11a] species have previously been generated in a more rational manner by treating the binuclear neutral derivatives with $AgClO_4$ or $TlBF_4$ in CH_2Cl_2 and, in the case of $[Cp^*Rh(\mu\text{-}Cl)_3RhCp^*]^+$, also by reaction of $[\{RhCp^*Cl(\mu\text{-}Cl)\}_2]$ with $NaBPh_4$.[11b] We also note that chloride-transfer reactions between the highly charged fragments $[PtCl_6]^{2-}$ and $[RhCp^*(NCMe)_3]^{2+}$,[12] as well as between the neutral half-sandwich complexes $[\{(p\text{-cym})RuCl(\mu\text{-}Cl)\}_2]$ or $[\{MCp^*Cl(\mu\text{-}Cl)\}_2]$ (M = Rh, Ir) and the cationic chloride-bridged palladium(II) substrate,[3o] have been reported previously.

The ionic compounds **5**–**8**, which were obtained as orange (**5**, **6**) or yellow (**7**, **8**) solids, are only slightly soluble in organic solvents, the solubility being especially low in the case of the iridium derivatives. These complexes have been characterized by a combination of microanalysis, mass spectrometry [ES(+) and ES(−)], and spectroscopic methods (IR, ^1H and ^{19}F NMR) (see Experimental Section). Mass spectra in the ES(+) mode feature the expected $[M_2Cp^*_2Cl_3]^+$ (M = Rh, Ir) ion molecular fragment and in the ES(−) or APCI(−) modes they feature the $[M'(C_6F_5)_2Cl]^-$ (M′ = Pt, Pd) ion fragment arising from a fragmentation of the binuclear anion.

The molecular structure of **6** was confirmed by single-crystal X-ray analysis (Figure 2, Table 2). As can be seen, it comprises two $[(Cp^*Rh)_2(\mu\text{-}Cl)_3]^+$ ions and a binuclear dianionic $[(C_6F_5)_2Pd(\mu\text{-}Cl)_2Pd(C_6F_5)_2]^{2-}$ ion. The structural features of the cationic fragment are identical to those reported previously[12,13] hence they are not discussed here.

In contrast, although the crystal structures of the anions $[(C_6F_5)_2Pt(\mu\text{-}Cl)_2Pt(C_6F_5)_2]^{2-}$ [8] and $[(C_6F_5)_2Ni(\mu\text{-}Cl)_2Ni(C_6F_5)_2]^{2-}$ [14] have been published, the structure of the corresponding dipalladium species remains unknown. Therefore, this study completes the series with its final member, $[(C_6F_5)_2Pd(\mu\text{-}Cl)_2Pd(C_6F_5)_2]^{2-}$, providing an opportunity for quantitative structural comparisons. Selected distances and angles are compared in Table 3. It is interesting to note that one of the most remarkable differences can be seen in the M'_2Cl_2 core. Thus, while the nickel and platinum anions exhibit typical[3p,10] $M'_2Cl_2C_4$ planar cores (both have a crystallographic centre of inversion), the anion $[(C_6F_5)_2Pd(\mu\text{-}Cl)_2Pd(C_6F_5)_2]^{2-}$ found in **6** displays a slightly bent chloro-bridge, with the dihedral angle defined by the corresponding palladium coordination planes being 13°. The resulting Pd···Pd distance of 3.464(2) Å is, as expected, longer than that found in the nickel derivative [Ni···Ni 3.28 Å].[14] However, assuming covalent radii for Pd and Pt of

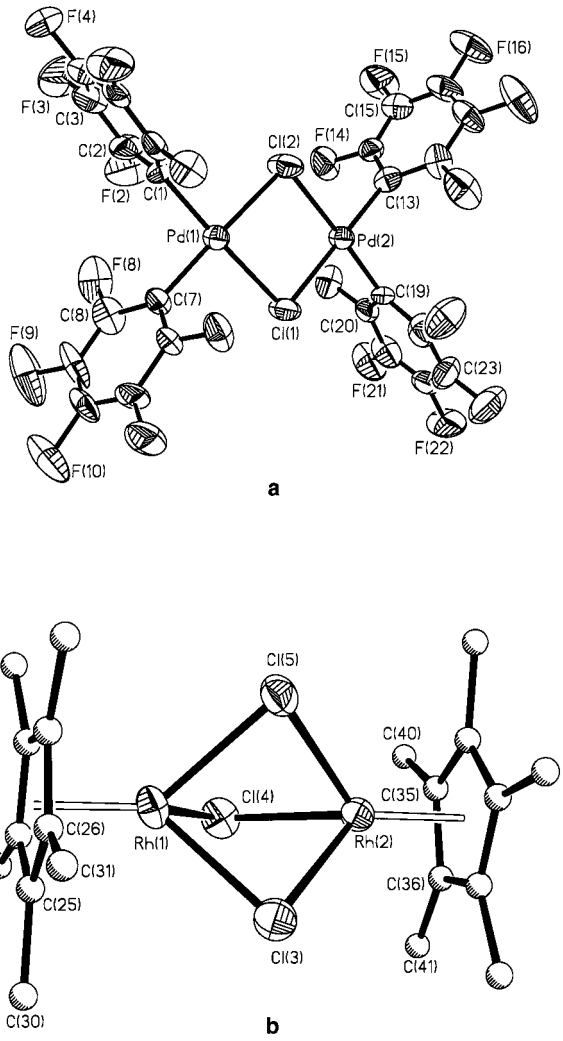

Figure 2. Structure and atom numbering scheme for the anion $[\{(C_6F_5)_2Pd(\mu\text{-}Cl)\}_2]^{2-}$ (a) and one of the cations $[Cp^*Rh(\mu\text{-}Cl)_3RhCp^*]^+$ (b) in complex **6** (ellipsoids are drawn at a 50% probability level; hydrogen atoms have been omitted for clarity)

1.31 and 1.28 Å, respectively,[15] the Pd···Pd distance should be ca. 0.06 Å longer than that found in the diplatinum anion [Pt···Pt 3.528(1) Å],[8] thus suggesting that the experimental value found in the dipalladium anion [3.464(2) Å] might be reduced due to the small degree of bending.

The Pd–C [2.001(13)–2.023(12) Å] and Pd–Cl [2.404(4)–2.421(4) Å] bridging lengths are comparable with those seen in $[(C_6F_5)_2Pd(\mu\text{-}Cl)_2Pt(PEt_3)_2]$ [Pd–C 1.980(7), 1.992(7) Å; Pd–Cl 2.402(2), 2.449(2) Å], which is the only derivative to be crystallographically characterized that also contains the "$(C_6F_5)_2PdCl_2$" fragment.[3f]

Synthesis of Tetranuclear $[(PEt_3)Cp^*M(\mu\text{-}C{\equiv}CPh)_2M''_2(\mu\text{-}C{\equiv}CPh)_2Pt(C_6F_5)_2]$ Complexes (9–12)

We have recently been interested in exploring the reactivity of alkynyl platinate(II) complexes towards suitable electrophilic metal fragments as a useful route to heteropolynuclear complexes containing alkynyl bridging ligands.[4a,4b,4d–4g,4i–4k] As an alternative route, we decided to examine the potential utility of the new chloride-bridged

Table 2. Selected bond lengths (Å) and angles (deg.) in complex $\{Cp^*Rh(\mu\text{-}Cl)_3RhCp^*\}_2[\{(C_6F_5)_2Pd(\mu\text{-}Cl)\}_2]$ (**6**) (C*1, C*2, C*3, C*4: centroids of the Cp* groups)

heterobinuclear compounds **1**−**4** as precursors to alkynyl-bridged species by exploring their reactivity towards the well-known ethynylating agents $[M''(C{\equiv}CR)]_x$ (M′′ = Cu, Ag; R = Ph, *t*Bu). The reactions of the polymeric acetylides $[Cu(C{\equiv}CR)]_x$ and $[Ag(C{\equiv}CR)]_x$ with transition metal halide complexes $[ML_nX_m]$ have been extensively investigated. Simple substitution processes giving the corresponding mononuclear complexes $[ML_n(C{\equiv}CR)_m]$, as well as the formation of polynuclear species generated by further interaction of the latter with MX species (X = halide or C≡CR), have been reported.[4g,16]

The results of the reactions of **1**−**4** with $[M''(C{\equiv}CR)]_x$ (M′′ = Cu, Ag; R = Ph, *t*Bu) are shown in Scheme 1 (iii). As can be seen, only the treatment of the platinum mixed species $[(PEt_3)Cp^*M(\mu\text{-}Cl)Pt(C_6F_5)_2]$ (**1**, **3**) with the phenylethynyl substrates (10 equiv. for **9** and 4.5 equiv. for **10**−**12**) produces, after standard work-up, moderate (61−75%) or low yields ($RhAg_2Pt$ **10**, 27%) of yellow products that can be formulated as tetrametallic compounds $[(PEt_3)Cp^*M(\mu\text{-}1\kappa C^{\alpha}{:}\eta^2\text{-}C{\equiv}CPh)_2M''_2(\mu\text{-}4\kappa C^{\alpha}{:}\eta^2\text{-}C{\equiv}CPh)_2Pt(C_6F_5)_2]$ (M = Rh, Ir; M′′ = Cu, Ag) (**9**−**12**). Unfortunately, starting from the mixed palladium complexes **2** and **4**, considerable decomposition takes place and the analogous reactions with the *tert*-butyl alkynyl substrates $[M''C{\equiv}Ct\text{Bu}]_x$ (M = Cu, Ag) yield only complicated mixtures of products, which we have not been able to separate. We also note that the reactions of **1** and **3** with a smaller excess of the polymeric alkynides (2 equivalents) produced mixtures of compounds in which the final tetranuclear species and the heterobinuclear $[(PEt_3)Cp^*M(\mu\text{-}C{\equiv}CPh)(\mu\text{-}Cl)Pt(C_6F_5)_2]$ were easily detectable by $^{31}P\{^1H\}$ NMR spectroscopy.

The new tetranuclear compounds **9**−**12** have been fully characterized by analytical and spectroscopic means and the molecular structure of **9** has been unambiguously confirmed by X-ray diffraction analysis. The presence of bridging alkynyl ligands is evident from the IR spectra, which show two ν(C≡C) absorptions in the expected region (1969−2070 cm^{-1}).[4,16] These bands appear at lower frequencies in the copper derivatives [2009 (s br), 1969 (sh) cm^{-1} **9**; 2006 (s), 1969 (s) cm^{-1} **11**] than in their silver counterparts [2059 (s br) cm^{-1} **10**; 2070 (m), 2036 (m) cm^{-1} **12**] suggesting, in line with previous observations,[16−18] that the η^2-alkyne metal interaction is stronger in copper than in silver complexes. Their NMR spectra (^1H, ^{31}P) confirm the presence of different groups (Cp*, PEt_3, C≡CPh) and, in particular, the room temperature ^{19}F NMR spectra reveal effective mirror planes that render the two C_6F_5 ligands equivalent. Simple AA′MXX′ (2 F_o, F_p, 2 F_m) patterns are seen for all the complexes, presumably because the free rotation of the C_6F_5 rings is relatively fast at room temperature. However, low-temperature spectra could not be obtained due to the low solubilities of the complexes. Furthermore, their relatively low stabilities in solution at room temperature also precluded characterization by $^{13}C\{^1H\}$ NMR spectroscopy. Yellow crystals of $[(PEt_3)Cp^*Rh(\mu\text{-}C{\equiv}CPh)_2Cu_2(\mu\text{-}C{\equiv}CPh)_2Pt(C_6F_5)_2]$ **9** suitable for an X-ray diffraction study were isolated by slow diffusion of hexane into a CH_2Cl_2 solution at low temperature (−30 °C). Figure 3 depicts its molecular structure, while selected bond lengths and angles are summarized in Table 4.

The most remarkable aspect of the structure is that two very different bis(alkynyl) metal fragments "$RhCp^*(C{\equiv}CPh)_2(PEt_3)$" and "*cis*-$Pt(C_6F_5)_2(C{\equiv}CPh)_2$" are connected through two copper centres. As for complex **1**, of the two possible conformers of complex **9**, only that in which the platinum unit lies *endo* to the Cp* ring is observed (Figure 3, b). As expected, the Rh centre is tetrahedrally coordinated, being surrounded by the centroid of the Cp* ring, the PEt_3, and two σ-carbon atoms of the alkynyl groups, which act as bridging ligands between the two copper atoms. The Pt atom is located in a slightly distorted square-planar coordination environment made up of four σ-carbon atoms, two from the mutually *cis* C_6F_5 rings and two from the C≡CPh ligands, the latter also being η^2-bon-

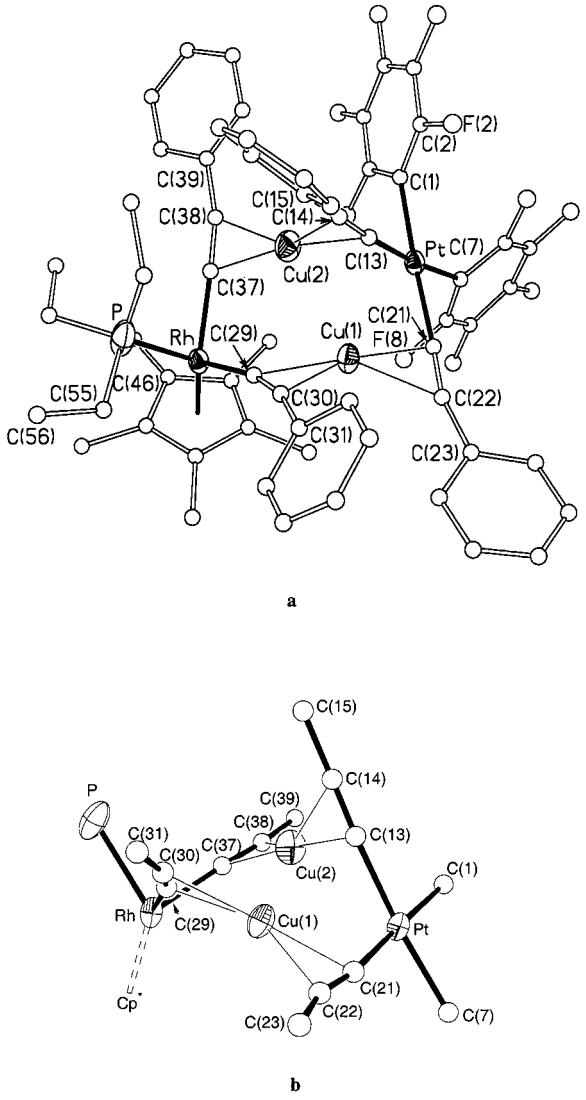

Figure 3. (a) View of the molecular structure of $[(PEt_3)Cp^*Rh(\mu\text{-}1\kappa C^{\alpha}{:}\eta^2\text{-}C{\equiv}CPh)_2Cu_2(\mu\text{-}4\kappa C^{\alpha}{:}\eta^2\text{-}C{\equiv}CPh)_2Pt(C_6F_5)_2]$ (**9**) (ellipsoids are drawn at a 50% probability level; hydrogen atoms have been omitted for clarity; (b) schematic view of the central core of **9**)

ded to the copper centres. The structural parameters for this fragment [Pt−C_α 2.014(8), 2.001(8) Å; C_α−Pt−C_α' 92.1(3)°] are rather similar to those previously observed for the tetranuclear anion $[Pt_2Ag_2(C_6F_5)_4(C{\equiv}CPh)_4]^{2-}$, in which two identical [*cis*-$Pt(C_6F_5)_2(C{\equiv}CPh)_2]^{2-}$ units are connected via two silver centres through η^2-alkyne−silver interactions.[16j]

The most remarkable feature of the rhodium fragment is that the C_α−Rh−C_α' angle (99.3°) is substantially larger compared to related bite angles in doubly alkynyl-bridged complexes $[(PEt_3)Cp^*Ir(\mu\text{-}C{\equiv}CR)_2M'(C_6F_5)_2]$ [M′ = Pt, R = Ph 79.9(8)°; R = $SiMe_3$ 76.9(6)°; M′ = Pd, R = Ph 81.0(7)°], in which the 3-irida-1,4-diyne fragments $[Ir](C{\equiv}CR)_2$ act as chelating bidentate ligands.[4g] This structural feature may be tentatively attributed to the bidentate bridging nature of the $[Rh](C{\equiv}CPh)_2$ unit.

All the alkynyl ligands are η^2-bonded to Cu atoms in such a way that each Cu is stabilized by two alkyne entities (one associated with each metal fragment). The Cu−C_α [1.984(8)−2.098(7) Å] and Cu−C_β [2.080(7)−2.230(8) Å] distances are, as expected, shorter than the corresponding Ag−C distances in $[Pt_2Ag_2(C_6F_5)_4(C{\equiv}CPh)_4]^{2-}$,[16j] but are comparable to those found in related systems such as $[Pt_2Cu_4(C{\equiv}CPh)_8]_3$ [Cu−C_α = 1.981(8)−2.019(8) Å; Cu−C_β = 2.141(9)−2.161(9) Å],[19] $[Ir_2Cu_4(C{\equiv}CPh)_8(PPh_3)_2]$ [Cu−C_α = 1.981(8)−2.019(8) Å; Cu−C_β = 2.141(9)−2.161(9) Å],[16a,16b] $[Mn_2Cu(\mu\text{-}C{\equiv}CtBu)_2(CO)_6(dppe)_2]^+$ [Cu−$C_{average}$ = 2.081(10) Å],[20] and $[\{Re(CO)_5{-}C{\equiv}C{-}Re(CO)_5\}_2Cu]^+$ [Cu−$C_{average}$ = 2.055(10) Å].[17] The parameters for the acetylenic fragments (C−C distances, angles at C_α and C_β) lie within the normal ranges for alkynyl σ,π bonding modes.[4,16−20]

The Cu(1)···Cu(2) distance [2.841(2) Å] is slightly shorter than those found in the cluster $[Pt_2Cu_4(C{\equiv}CPh)_8]_3$ [3.031(2) Å, 3.301(2) Å][19] and is comparable with those observed in the cluster $[Ir_2Cu_4(C{\equiv}CPh)_8(PPh_3)_2]$ [2.665(6) Å, 2.823(5) Å][16a,16b] and in other more common alkynyl polynuclear copper(I) complexes.[21] Nevertheless, it still slightly exceeds the van der Waals limit (2.80 Å),[15] excluding any significant bonding interaction. The Rh···Cu separations of 3.217 and 3.528 Å are considerably longer than the Pt···Cu distances of 2.9226(14) and 2.9384(13) Å, respectively. These latter values are comparable to those seen in $[Pt_2Cu_4(C{\equiv}CPh)_8]_3$ [2.9187(12)−3.0272(10) Å][19] and are considerably shorter than the sum of the van der Waals radii (3.15 Å),[15] probably suggesting the presence of some weak Pt···Cu bonding interactions.[22]

Table 4. Selected bond lengths (Å) and angles (deg.) in complex $[(PEt_3)Cp^*Rh(\mu\text{-}1\kappa C^{\alpha}{:}\eta^2\text{-}C{\equiv}CPh)_2Cu_2(\mu\text{-}4\kappa C^{\alpha}{:}\eta^2\text{-}C{\equiv}CPh)_2Pt(C_6F_5)_2]$ (**9**) (Cp^*_{cent}: centroid of the Cp* group)

Experimental Section

General Remarks: All reactions were carried out under nitrogen atmosphere. Solvents (hexane, alkane mixtures) were dried by

standard procedures and distilled under dry N_2 before use; acetone was treated with $KMnO_4$ and distilled under dry N_2 prior to use. $[MCp^*Cl_2(PEt_3)]$,[4g] $[MCp^*Cl_2]_2$ (M = Rh, Ir),[23] $[MC{\equiv}CPh]_x$ (M = Ag,[24] Cu[25]), and $[cis\text{-}M'(C_6F_5)_2(thf)_2]$ (M′ = Pt, Pd)[26] were prepared by published methods. − ^1H, ^{13}C, ^{19}F, and ^{31}P NMR spectra were recorded on a Bruker ARX-300 spectrometer. Chemical shifts are reported in ppm relative to external standards ($SiMe_4$, $CFCl_3$, and 88% H_3PO_4) and coupling constants are given in Hz. − Infrared spectra were recorded on a Perkin−Elmer 883 spectrometer with samples as Nujol mulls between polyethylene sheets. − C, H, N analyses were carried out with Perkin−Elmer 2400 CHNS/O or Carlo Erba EA1110 CHNS-O microanalyzers. − Mass spectra were obtained on VG Autospec double-focusing (FAB) or HP-5989B (APCI and ES) mass spectrometers. − Conductivities were measured in ca. $5{\cdot}10^{-4}$ M acetone solutions using a Philips 950/01 conductimeter.

Synthesis of $[(PEt_3)Cp^*M(\mu\text{-}Cl)_2M'(C_6F_5)_2]$ (M = Rh, M′ = Pt 1, M′ = Pd 2; M = Ir, M′ = Pt 3, M′ = Pd 4): A red solution of $[RhCp^*Cl_2(PEt_3)]$ (0.10 g, 0.23 mmol) in acetone (10 mL) was treated with $[cis\text{-}Pt(C_6F_5)_2(thf)_2]$ (0.15 g, 0.23 mmol), which immediately afforded an orange solution. The mixture was stirred for 5 min and then concentrated to dryness. Treatment of the solid residue with cold EtOH (ca. 5 mL) furnished complex **1** as an orange solid. Complexes **2**−**4** (also orange solids) were similarly prepared but with omission of the stirring for 5 min in the case of the palladium complexes **2** and **4**. Reagents and quantities used: $[cis\text{-}Pd(C_6F_5)_2(thf)_2]$ (0.14 g, 0.23 mmol) and $[RhCp^*Cl_2(PEt_3)]$ (0.10 g, 0.23 mmol) for **2**; $[cis\text{-}Pt(C_6F_5)_2(thf)_2]$ (0.34 g, 0.51 mmol) and $[IrCp^*Cl_2(PEt_3)]$ (0.26 g, 0.51 mmol) for **3**; $[cis\text{-}Pd(C_6F_5)_2(thf)_2]$ (0.11 g, 0.19 mmol) and $[IrCp^*Cl_2(PEt_3)]$ (0.10 g, 0.19 mmol) for **4**.

4: (0.13 g, 71%) (analyses for a sample recrystallized from $CHCl_3$/hexane, which retained a $^1/_2$ molecule of $CHCl_3$ as observed by ^1H NMR in [D$_6$]acetone). − $C_{28}H_{30}Cl_2F_{10}IrPPd{\cdot}0.5CHCl_3$ requires C 33.67, H 3.02; found C 33.99, H 2.74. − IR: $\tilde{\nu}$ = 798 (s), 785 (s) cm^{-1} $(C_6F_5)_{x-sens}$; 285, 280 (s), 268 (m), 247 (sh) cm^{-1} (M−Cl). − ^1H NMR ([D$_6$]acetone): at 20 °C: δ = 1.16 (m, 9 H, CH_3, PEt_3), 1.81 (d, $^4J_{P-H}$ = 1.3, 15 H, Cp*), 2.43 (m, 6 H, CH_2, PEt_3); at −50 °C: δ = 1.14 (m, 9 H, CH_3, PEt_3), 1.81 (s, 15 H, Cp*), 2.43 (m, 6 H, CH_2, PEt_3). − ^{13}C NMR ([D$_6$]acetone): at −50 °C: δ = 7.1 (d, $^2J_{P-C}$ = 3.5, CH_3, PEt_3), 9.05 [s, $C_5(CH_3)_5$], 13.5 (d, $^1J_{P-C}$ = 35, CH_2, PEt_3), 94.5 (d, $^2J_{P-C}$ = 2.5, C_5Me_5), 135.9 (dm, $^1J_{F-C}$ = 244, C_m, C_6F_5), 137.3 (dm, $^1J_{F-C}$ = 241, C_p, C_6F_5), 147.5 (dm, $^1J_{F-C}$ = 228, C_o, C_6F_5). − ^{19}F NMR ([D$_6$]acetone): at 20 °C: δ = −165.50 (m, 4 F_m), −162.95 (t, 2 F_p), −114.87 (d, 4 F_o); at −50 °C: δ = −164.82 (m, 4 F_m), −162.11 (t, 2 F_p), −114.89 (d, 2 F_o), −114.48 (d, 2 F_o). − ^{31}P NMR ([D$_6$]acetone): at 20 °C: δ = 2.13 (s); at −50 °C: δ = 3.07 (s). − FAB(−) MS: *m/z* (%) = 917 (3) [M^- − Cl − 4], 477 (100) [$Pd(C_6F_5)_2Cl^-$].

Synthesis of $[Cp^*Rh(\mu\text{-}Cl_3)RhCp^*]_2[(C_6F_5)_2Pt(\mu\text{-}Cl_2)Pt(C_6F_5)_2]$ (5): To a red solution of $[RhCp^*Cl_2]_2$ (0.10 g, 0.162 mmol) in acetone (20 mL) was added $[cis\text{-}Pt(C_6F_5)_2(thf)_2]$ (0.11 g, 0.162 mmol) (molar ratio 1:1) and the mixture was stirred for 30 min. Evaporation of the solvent from the orange suspension and treatment of the solid residue with Et_2O (ca. 5 mL) yielded complex **5** (0.13 g, 68%) as an orange solid. − $C_{64}H_{60}Cl_8F_{20}Pt_2Rh_4$ (2294.60): calcd. C 33.50, H 2.63; found C 33.45, H 2.65. − Λ_m (acetone) = 184 $ohm^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. − IR: $\tilde{\nu}$ = 811 (vs), 799 (vs) cm^{-1} $(C_6F_5)_{x-sens}$; 289 (m), 261 (m), 255 (s), 250 (s) cm^{-1} (M−Cl). − ^1H NMR ([D$_6$]acetone): at 20 °C: δ = 1.77 (s, Cp*). − ^{19}F NMR ([D$_6$]acetone): at 20 °C: δ = −167.87 (m, 8 F_m), −166.87 (t, 4 F_p), −117.51 (dd, $^3J_{Pt-F}$ = 526.7, 8 F_o). − APCI(+) MS: *m/z* (%) = 581 (16) [$Rh_2Cp^*_2Cl_3^+$]. − APCI(−) MS: *m/z* (%) = 565 (100) [$Pt(C_6F_5)_2Cl^-$].

Complex **5** could also be obtained, albeit in lower yield (0.09 g, 42% based on Rh), by carrying out the reaction starting from $[RhCp^*Cl_2]_2$ (0.11 g, 0.18 mmol) and $[cis\text{-}Pt(C_6F_5)_2(thf)_2]$ (0.24 g, 0.36 mmol) (molar ratio 1:2) and following the same procedure as above.

Synthesis of $[Cp^*Rh(\mu\text{-}Cl_3)RhCp^*]_2[(C_6F_5)_2Pd(\mu\text{-}Cl_2)Pd(C_6F_5)_2]$ (6): $[cis\text{-}Pd(C_6F_5)_2(thf)_2]$ (0.10 g, 0.16 mmol) was added to a red solution of $[RhCp^*Cl_2]_2$ (0.10 g, 0.16 mmol) in CH_2Cl_2 (20 mL)

(molar ratio 1:1) and the mixture was stirred for 30 min. The resulting solution was then concentrated to a small volume (ca. 5 mL), whereupon **6** (0.14 g, 80%) was precipitated as an orange solid. − $C_{64}H_{60}Cl_8F_{20}Pd_2Rh_4$ (2117.26): calcd. C 36.31, H 2.86; found C 36.16, H 2.58. − Λ_m (acetone) = 167 $ohm^{-1}\cdot cm^2\cdot mol^{-1}$. − IR: $\tilde{\nu}$ = 796 (s), 783 (s) cm^{-1} $(C_6F_5)_{x-sens}$; 288 (m), 278 (m), 249 (s) cm^{-1} (M−Cl). − ^1H NMR ([D$_6$]acetone): at 20 °C: δ = 1.77 (s, Cp*). − ^{19}F NMR ([D$_6$]acetone): at 20 °C: δ = 166.77 (m, 8 F_m), −165.24 (t, 4 F_p), −113.29 (d, 8 F_o). − APCI(+) MS: *m/z* (%) = 581 (100) [$Rh_2Cp^*_2Cl_3^+$]. − APCI(−) MS: *m/z* (%) = 477 (16) [$Pd(C_6F_5)_2Cl^-$].

Complex **6** could also be obtained, albeit in lower yield (0.09 g, 58% based on Rh), by carrying out the reaction starting from [$RhCp^*Cl_2]_2$ (0.09 g, 0.15 mmol) and [*cis*-$Pd(C_6F_5)_2(thf)_2$] (0.17 g, 0.30 mmol) (molar ratio 1:2) and following the same procedure as described for **5**.

Synthesis of [Cp*Ir(μ-Cl$_3$)IrCp*]$_2$[(C$_6$F$_5$)$_2$M′(μ-Cl$_2$)M′(C$_6$F$_5$)$_2$] (M′ = Pt 7, Pd 8): Complexes **7** and **8** were prepared in a manner similar to that described for **5**. Reagents and quantities used: [$IrCp^*Cl_2]_2$ (0.10 g, 0.13 mmol) and [*cis*-$Pt(C_6F_5)_2(thf)_2$] (0.09 g, 0.13 mmol) for **7**; [$IrCp^*Cl_2]_2$ (0.08 g, 0.10 mmol) and [*cis*-$Pd(C_6F_5)_2(thf)_2$] (0.06 g, 0.10 mmol) for **8** (molar ratio 1:1). They were obtained as yellow solids.

7: (0.13 g, 78%). − $C_{64}H_{60}Cl_8F_{20}Ir_4Pt_2$ (2651.86): calcd. 8: (0.1 g, 79%). − $C_{64}H_{60}Cl_8F_{20}Ir_4Pd_2$ (2474.52): calcd. C 31.07, H 2.44; found C 30.86, H 2.08. − IR: $\tilde{\nu}$ = 796 (s), 782 (s) cm^{-1} $(C_6F_5)_{x-sens}$; 287 (m), 261 (m) cm^{-1} (M−Cl). − ^1H NMR ([D$_6$]acetone): at 20 °C: δ = 1.77 (s, Cp*). − ^{19}F NMR ([D$_6$]acetone): at 20 °C: δ = −166.81 (m, 8 F_m), −165.29 (t, 4 F_p), −113.28 (d, 8 F_o). − ES(+) MS: *m/z* (%) = 761 (100) [$Ir_2Cp^*_2Cl_3^+$]. − ES(−) MS: *m/z* (%) = 477 (42) [$Pd(C_6F_5)_2Cl^-$].

Complexes **7** and **8** could also be obtained, albeit in lower yields (0.05 g, 46% for **7**; 0.04 g, 31% for **8**, based on Ir), by carrying out the reactions starting from [$IrCp^*Cl_2]_2$ (0.07 g, 0.09 mmol) and [*cis*-$Pt(C_6F_5)_2(thf)_2$] (0.12 g, 0.18 mmol) for **7** and [$IrCp^*Cl_2]_2$ (0.08 g, 0.10 mmol) and [*cis*-$Pd(C_6F_5)_2(thf)_2$] (0.12 g, 0.20 mmol) for **8** (molar ratio 1:2), following the same procedure as described for **5**.

Synthesis of [(PEt$_3$)Cp*M(μ-1κ*C*^{α}:η^2-C≡CPh)$_2$M′′$_2$(μ-4κ*C*^{α}:η^2-C≡CPh)$_2$Pt(C$_6$F$_5$)$_2$] (M = Rh, M′′ = Cu 9, M′′ = Ag 10; M = Ir, M′′ = Cu 11, M′′ = Ag 12): An orange solution of [$(PEt_3)Cp^*Rh(\mu\text{-}Cl)_2Pt(C_6F_5)_2$] (**1**) (0.15 g, 0.16 mmol) in acetone (10 mL) was treated with $[CuC{\equiv}CPh]_x$ (0.26 g, 1.58 mmol) and the mixture was stirred for 2 h. The resulting yellow suspension was concentrated to dryness, the solid residue was extracted with CH_2Cl_2 (30 mL), and the extract was filtered through Celite to eliminate the excess $[CuC{\equiv}CPh]_x$ and the CuCl formed. The resulting yellow solution was concentrated to dryness and the residue was treated with cold Et_2O (5 mL) to yield complex **9** as a yellow solid. Complexes **10**−**12** were similarly prepared, also as yellow solids. In the case of complex **10**, the pale-brown solid thus obtained was recrystallized from acetone/Et_2O to give **10** as a pure yellow solid; in the case of complex **12**, the solid residue was treated with acetone instead of diethyl ether. Reagents and quantities used: **1** (0.15 g, 0.16 mmol) and $[AgC{\equiv}CPh]_x$ (0.15 g, 0.72 mmol) for **10**; [$(PEt_3)Cp^*Ir(\mu\text{-}Cl)_2Pt(C_6F_5)_2$] (**3**) (0.16 g, 0.15 mmol) and $[CuC{\equiv}CPh]_x$ (0.11 g, 0.69 mmol) for **11**; **3** (0.20 g, 0.19 mmol) and $[AgC{\equiv}CPh]_x$ (0.17 g, 0.81 mmol) for **12**.

9: (0.17 g, 75%). − $C_{60}H_{50}Cu_2F_{10}PPtRh$ (1417.13): calcd. X-ray Crystal Structure Determinations: Suitable crystals of **1**·Me_2CO, **6**, and **9**·CH_2Cl_2 were obtained by slow diffusion of hexane into acetone (**1**, **6**) or CH_2Cl_2 (**9**) solutions of these complexes at −30 °C. Relevant crystal data are listed in Table 5. Intensity data for **1**·Me_2CO and **6** were collected on a Siemens P4 four-circle diffractometer and cell constants were calculated from 30 reflections (**1**·Me_2CO) or 52 reflections (**6**) with 2θ angles ranging from 24 to 26°. Intensity data for **9**·CH_2Cl_2 were collected on a Siemens/STOE AED4 four-circle diffractometer and cell constants were refined from 2θ values of 36 reflections ($22.5 < 2\theta < 31.7°$). An absorption correction based on azimuthal data was applied; transmission coefficients were in the range 1.000 to 0.677

Table 5. Crystal data and structure refinement parameters for **1**·Me_2CO, **6**, and **9**·CH_2Cl_2 ($wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{0.5}$; $R1 = \Sigma|F_o| - |F_c|/\Sigma|F_o|$)

(**1**·Me_2CO), 0.974 to 0.704 (**6**), and 1.000 to 0.669 (**9**·CH_2Cl_2). The structures were solved by Patterson (**1**, **9**) or direct (**6**) methods and refined against F^2 using the program SHELXL-93.[27] All non-hydrogen atoms were assigned anisotropic displacement parameters and were refined without positional constraints, except for the disordered carbon atoms of one of the ethyl groups of the PEt_3 ligand in **9**·CH_2Cl_2 (see below), for which the interatomic distances were restrained to be 1.54 Å. A phenyl ring of one phenylacetylide ligand was found to be disordered over two positions, which were refined with partial occupancy factors of 0.5/0.5. One methyl carbon atom of the PEt_3 ligand was found to be disordered over two positions, which were refined with partial occupancy factors of 0.67/0.33. In all three structures, all hydrogen atoms were constrained to idealized geometries and were assigned a refined isotropic displacement parameter equal to 1.2 times that of their parent C atoms (1.5 times for methyl hydrogen atoms). Complex **1**·Me_2CO has a symmetry plane, and so some atoms lying in certain positions were refined at half-occupancy. The crystal of **6** is a racemic twin, with a Flack parameter of 0.49(9).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-151398 (**1**·Me_2CO), -151399 (**6**), and -151400 (**9**·CH_2Cl_2). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax. (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Substituted Cyclooctatetraenes as Ligands in *f*-Metal Chemistry

Peter W. Roesky[a]

Dedicated to Professor Dr. Dr. h.c. Oskar Glemser on the occasion of his 90th birthday

Keywords: Actinides / Cyclooctatetraenes / Lanthanides / Sandwich complexes

The use of substituted cyclooctatetraenes confers various desired properties on the resulting metal complexes such as a higher thermal and kinetic stability as well as higher solubility relative to the nonsubstituted systems. Furthermore, the formation of polymeric structures is inhibited because intermolecular interactions are reduced. Alkyl- and aryl-substituted cyclooctatetraenes were mainly used as ligands in the 1970s and 1980s. The vast majority of known complexes containing these ligands in the coordination sphere are uranium compounds. Since then the alkyl- and aryl-substituted cyclooctatetraenes have been replaced almost exclusively in synthesis by silyl-substituted ones. Complexes with silyl-substituted cyclooctatetraenes are known for both 4*f* and 5*f* elements.

1. Introduction

The replacement of the classic cyclopentadienyl ligand (C_5H_5 = Cp) with bulkier analogues such as C_5Me_5 (Cp*) and $C_5H_3(SiMe_3)_2$ (Cp′′) in main group and transition metal chemistry has led to complexes with more convenient properties.[1,2] Due to the steric shielding of the metal centers with Cp* and Cp′′ ligands, the resulting compounds are thermally and kinetically more stable. They are more soluble, crystallize more readily, and the formation of polymeric structures is inhibited because intermolecular interactions are reduced. These advantages led to the isolation and structural characterization of a number of main group and transition metal complexes which are difficult to obtain with the unsubstituted Cp ligand.[1,3−7] In particular, in *f*-element chemistry the use of bulky cyclopentadienyl ligands has paved the way for the exploration of their organometallic chemistry.[2,6]

In contrast to the rich chemistry of complexes with substituted cyclopentadienyl ligands, the number of complexes with η^8-coordinated substituted cyclooctatetraenes in the ligand sphere is virtually underdeveloped. Part of the reason for this stems from the fact that the 10-π-aromatic cyclooctatetraene dianion $C_8H_8^{2-}$ can be η^8-coordinated to a limited number of elements only (groups 3 and 4, the lanthanides and the actinides). Furthermore, there is no relevant industrial application for cyclooctatetraene complexes of the *f*-elements.

Since the cyclooctatetraene dianion is one of the most important ligands in organo-f-element chemistry,[8−12] this account presents the conceptual foundations for metal complexes with η^8-coordinated substituted cyclooctatetraenes in the ligand sphere.

2. Discussion

2.1. Alkyl-, Aryl-, Amino-, and Alkoxy-Substituted Cyclooctatetraenes

Most of the alkyl-, aryl-, amino-, and alkoxy-substituted cyclooctatetraenes C_8H_7-R which have been used as ligands in *f*-metal chemistry were first prepared in the 1950s by A. C. Cope et al.[13−17] The synthesis of these compounds

Peter W. Roesky was born in Göttingen, Germany, in 1967. He obtained his diploma in 1992 from the University of Würzburg and his doctoral degree from the Technical University of Munich (with Prof. W. A. Herrmann) in 1994. He was introduced to lanthanide chemistry as a postdoc with Prof. T. J. Marks at Northwestern University (1995–1996). In 1999 he completed his Habilitation at the University of Karlsruhe under the guidance of Prof. D. Fenske. In 1996 he received a Liebig-Stipendium of the Fonds der Chemischen Industrie, in 1999 a Heisenberg-Stipendium, and in 2000 a Karl-Winnacker-Stipendium. His current research interest revolves around the use of coordination compounds of the lanthanides for catalytic applications and for material science.

MICROREVIEWS: This feature introduces the readers to the authors′ research through a concise overview of the selected topic. Reference to important work from others in the field is included.

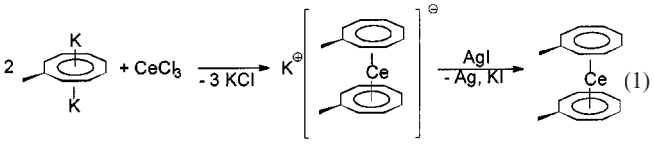
has been reviewed.[18,19] Therefore, only the most common routes leading to C_8H_7-R will be discussed here. Alkyl cyclooctatetraenes can be obtained either by the reaction of C_8H_8 with alkyllithium reagents,[13,14] by the reaction of C_8H_7-Br with the corresponding dialkylcuprates,[20,21] or by a modified Reppe synthesis (the cyclization of ethyne with the corresponding substituted alkyne).[15,16] Many functionalized cyclooctatetraenes such as C_8H_7-$(CH_2)_3NMe_2$ were prepared starting from C_8H_7-$(CH_2)_3OH$, which itself was obtained by copolymerization of ethyne with HC≡C-$(CH_2)_3OH$.[16,17]Alkoxy cyclooctatetraenes, C_8H_7-OR, are obtained by the Williamson reaction of bromocyclooctatetraene, C_8H_7-Br, and the corresponding sodium alkoxides.[22]

Very few lanthanide complexes have been prepared with C_8H_7-R as a ligand. The substituents on the eight-membered ring in these compounds were alkyl groups such as Me, *n*Bu or *t*Bu. Using these ligands the chloride $[(n\text{BuC}_8\text{H}_7)\text{LuCl(THF)}_2]$,[23] the amide $\text{Li}[(n\text{BuC}_8\text{H}_7)\text{Lu}\{\text{NMeCH}_2\text{CH}_2\text{NMe}_2\}_2]$,[23] and the sandwich complex $[\text{K(diglyme)}][\text{Yb}(t\text{BuC}_8\text{H}_7)_2]$[24] were made. The synthesis of these compounds begins with the reaction of C_8H_7-R with potassium which leads to $K_2C_8H_7$-R. The dipotassium salt is then further reacted with the corresponding lanthanide chlorides. Since only $[\text{K(diglyme)}][\text{Yb}(t\text{BuC}_8\text{H}_7)_2]$ has been characterized by X-ray diffraction, the influence of the substituents on the eight-membered ring is hard to judge. The cerocene $[\text{Ce}(\text{MeC}_8\text{H}_7)_2]$ was reported by a two step procedure. In the first step, $K_2(\text{MeC}_8\text{H}_7)$ was reacted with $CeCl_3$ which led to $\text{K}[\text{Ce}(\text{MeC}_8\text{H}_7)_2]$. The anion was then oxidized with AgI to yield $[\text{Ce}(\text{MeC}_8\text{H}_7)_2]$ [Equation (1)].[25] The sandwich complex $[\text{Ce}(\text{C}_8\text{H}_8)_2]$ has conclusively shown to be a Ce^{3+} ($4f^1$) complex by theoretical as well as experimental investigations. Cerocene is best formulated as a sandwich complex containing two coordinated $(C_8H_8)^{1.5-}$ ions. This topic was recently reviewed and therefore will not be discussed further here.[26]



(1)

In contrast to the few reported 4*f*-metal complexes a large number of substituted uranocenes were reported mainly by A. Streitwieser et al. Most of this work was reviewed in 1979[27] and 1985.[28] The majority of the known substituted uranocenes can be prepared by three types of methods: 1) Reaction of $(C_8H_7\text{-R})^{2-}$ with UCl_4;[22,29,30] 2) Reaction of C_8H_7-R with finely divided uranium powder;[28] 3) Functional group reactions of substituted uranocenes.[22] By using these methods 1,1′ substituted uranocenes, $[\text{U}(\text{C}_8\text{H}_7\text{-R})_2]$ were prepared (Table 1).[22,27−37] The first of these methods is also the most common. $K_2C_8H_7$-R, which is obtained from C_8H_7-R and potassium, is reacted with UCl_4 [Equation (2)]. The second method leads more or less to the same products. Functional groups that are not stable in the presence of elemental potassium or uranium can be

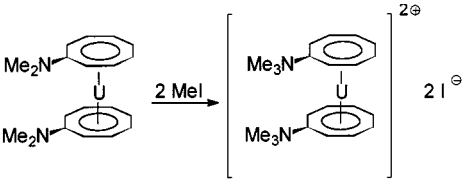
attached to the eight-membered ring by performing functional group reactions of substituted uranocenes (third method). With this method, amino groups can be transformed into ammonium ions, for example [Equation (3)]. Whereas uranocene itself has low solubility many substituted uranocenes have greater solubility and thus are easier to purify. Strong intramolecular interactions are observed only for very large substituents on the eight membered ring. For R = mesityl, the two groups are markedly bent away from the opposite ring in solution. The ^1H NMR spectrum shows the mesityl groups in a locked position with *exo*- and



(3)

endo-methyl groups.[27,38,39] A striking example in this series is bis(bicyclooctatetraenyl)diuranium (biuranocenylene) in which two U^{4+} ions are bridged by two $(C_8H_7-C_8H_7)^{4-}$ units (Figure 1).[40,41] Substituted thorocenes,[42,43] plutocenes[44] and neptunocenes[44] are also known, but their number in comparison to uranocenes is more limited. With the exception of the uranocenes, only aryl and alkyl-substituted actinocenes are known (Table 1).

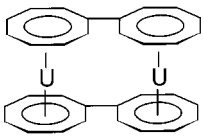


Figure 1. Bis(bicyclooctatetraenyl)diuranium (biuranocenylene)

Similar synthetic routes to those outlined above have been used to prepare di- and multiple ring substituted bis(cyclooctatetraene)actinocenes $[An(C_8H_{8-n}\text{-}R_n)_2]$ (Table 2).[45−51] Most common in this series are the octamethyl compounds $[An(1,3,5,7\text{-}Me_4C_8H_4)_2]$.[27,48,49] The structure of $[U(1,3,5,7\text{-}Me_4C_8H_4)_2]$ was established by single crystal X-ray diffraction (Figure 2).[50] This complex crystallizes as molecules in two rotameric configurations. In one form the methyl groups are essentially eclipsed whereas in the other form the methyl groups are essentially staggered. A truly remarkable species is the highly substituted 1,3,5,7,1′,3′,5′,7′-octaphenyluranocene.[27,51] In contrast to pyrophoric $[U(C_8H_8)_2]$, this material is completely air stable due to the effective shielding of the metal center by eight phenyl groups. Another interesting example in this series is an uranocene in which two (1,6)cyclooctatetraenyl(1,4)cyclophanes were used as ligands (Figure 3).[52]

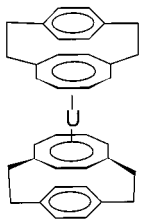

Figure 3. A uranocene containing two (1,6)cyclooctatetraenyl(1,4)-cyclophanes as ligands

Ring fused cyclooctatetraens, which are shown in Table 3, have also been used as ligands for thorocenes and also for uranocenes.[53−56] The structures of dicyclobutenouranocene (Figure 4) and dicyclopentenouranocene were characterized by X-ray diffraction. It was shown that the two annulated four- or five-membered rings are located in *trans* positions. Thus the molecule had approximate C_2 symmetry.[53,54]

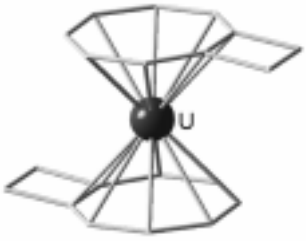

Figure 4. Crystal structure of dicyclobutenouranocene

Besides substituted actinocenes, in which the metal centers are formally in oxidation state +4, there are also some substituted actinocenes(III), $K[An(C_8H_7\text{-}R)_2]$. These compounds can be compared with the lanthanidocenes which are usually found in the same oxidation state. The uranocene(III) [K(diglyme)][U(MeC$_8$H$_7$)$_2$] was obtained by potassium reduction of the corresponding uranocene (Figure 5).[25] The structure shows that the uranium(III) and

potassium ions are bridged by a MeC_8H_7 ligand to give a nearly linear $(MeC_8H_7)U(\mu\text{-}MeC_8H_7)K$ arrangement. The neptunium and plutonium compounds $K[An(tBuC_8H_7)_2]$ (An = Np, Pu) were prepared from the corresponding hexachloride salts, $(Et_4N)_2[AnCl_6]$, and $tBuC_8H_7$. A mixture of $K[An(tBuC_8H_7)_2]$ and $[An(tBuC_8H_7)_2]$ shows rapid electron exchange.[57]

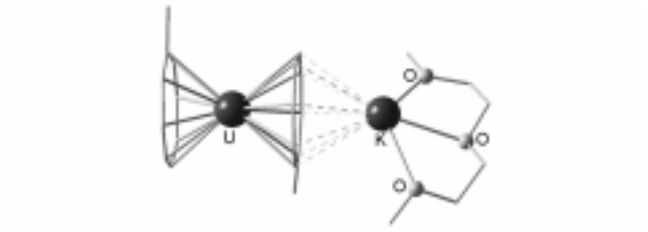

Figure 5. Crystal structure of $[K(diglyme)][U(MeC_8H_7)_2]$

Only a few substituted cyclooctatetraene half-sandwich complexes of the actinides are known. Their synthesis proved to be significantly more difficult than the synthesis of the corresponding sandwich complexes. The thorium complexes $[(C_8H_7\text{-}R)ThCl_2]$ and $[(1,3,5,7\text{-}Me_4C_8H_4)ThCl_2]$ were obtained by a ligand redistribution between the corresponding thorocene and $ThCl_4$.[58] $[(nBuC_8H_7)Th(BH_4)_2]$ can be prepared in a similar reaction of $[(nBuC_8H_7)_2Th]$ and $Th(BH_4)_4$ or by reaction of $[Th(BH_4)_4(THF)_2]$ with $K_2(nBuC_8H_7)$.

2.1. Silyl-Substituted Cyclooctatetraenes

The disadvantage of multiple alkyl-substituted cyclooctatetraenes such as $1,4\text{-}tBu_2C_8H_6$ [47] or $1,3,5,7\text{-}Me_4C_8H_4$ [59] is their lengthy preparation and the resulting low yields. Moreover, C_8H_8 which is used as a starting material for a number of substituted cyclooctatetraenes is getting more and more expensive. This has recently limited the use of alkyl-substituted cyclooctatetraenes as ligands for metal complexes. In 1993, F. G. N. Cloke et al. developed a cheap and convenient one pot synthesis of the silyl-substituted cyclooctatriene $1,4\text{-}(Me_3Si)_2C_8H_8$ which can easily be deprotonated with *n*-butyllithium to yield $[Li_2(THF)_n][1,4\text{-}(Me_3Si)_2C_8H_6]$ (**1a**) (Scheme 1).[60,61] By analogy, the *t*Bu-substituted salt $[Li_2(THF)_n][1,4\text{-}(Me_2tBuSi)_2C_8H_6]$ (**1b**) was also obtained.[62] Further treatment of **1a** with Me_3SiCl and subsequent reaction with KH gave the tris(trimethylsilyl)-substituted compound $[K_2(THF)_3][1,3,6\text{-}(Me_3Si)_3C_8H_5]$ (**2**) (Scheme 1).[63] The easy accessibility of **1a,b** and **2** paved the way to a number of new actinide and lanthanide complexes.

The treatment of various anhydrous lanthanide trichlorides with two equivalents of **1a** gave the ionic sandwich complexes $[Li(THF)_4][Ln\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$ (Ln = Y, Ce, Pr, Nd, Sm) [Equation (4)]. Ion exchange of $[Li(THF)_4][Sm\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$ with [PPN]Cl afforded $[PPN][Sm\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$ (Table 4).[64] The derivatives of **2**, $[K(THF)_3][Ln\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]$ (Ln = Ce, Tb), were obtained in a similar manner (Table 4). Both

cerium complexes could be oxidized with AgI to the corresponding neutral sandwich complexes [Ce{1,4-$(Me_3Si)_2C_8H_6$}$_2$] and [Ce{1,3,6-$(Me_3Si)_3C_8H_5$}$_2$] (**3**) (Scheme 2).[63] In contrast to the nonsubstituted complex [Ce$(C_8H_8)_2$] both compounds have good solubility in organic solvents and can be handled in air for a short time. Complex **3** was also characterized by X-ray diffraction (Figure 6). It was shown that the complex crystallizes in a staggered-like conformation.[63] XANES spectra give the assignment of the oxidation state of the cerium ion of **3** as trivalent.[65] In a few investigations **3** was used as an oxidizing reagent. Thus the redox reaction of **3** with ytterbium metal gave the first heterobimetallic organolanthanide complex [Yb$(THF)_6$][Ce{1,3,6-$(Me_3Si)_3C_8H_5$}$_2$]$_2$ (Scheme 2),[66] whereas the redox reaction of **3** and cobaltocene yielded [$CoCp_2$][Ce{1,3,6-$(Me_3Si)_3C_8H_5$}$_2$]$_2$.[63]

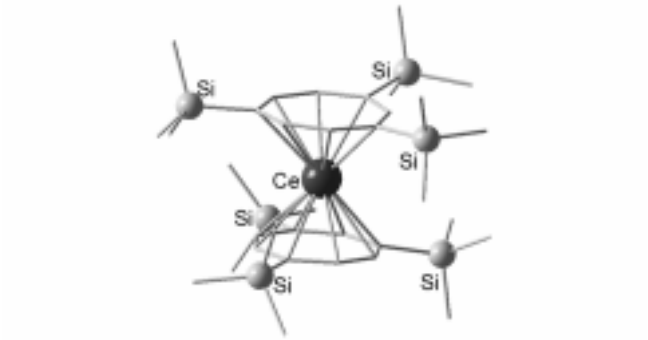

Figure 6. Crystal structure of [Ce{1,3,6-$(Me_3Si)_3C_8H_5$}$_2$] (**3**)

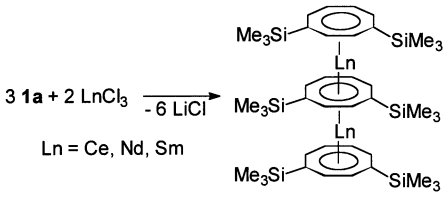
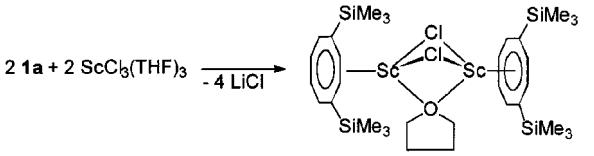
Treatment of anhydrous lanthanide trichlorides with **1a** in a 2:3 molar ratio afforded the first well defined organolanthanide triple-decker sandwich complexes of composition [Ln_2{1,4-$(Me_3Si)_2C_8H_6$}$_3$] (Ln = Ce, Nd, Sm) [Equation (5)].[67] Due to the presence of six trimethylsilyl substituents in the molecules, the intensely colored complexes are readily soluble in most common organic solvents.

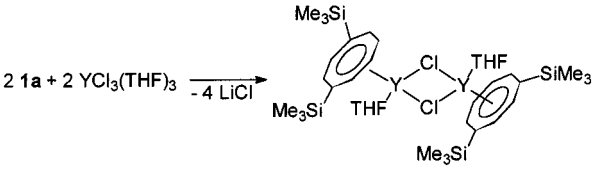


(5)

Cyclooctatetraene half-sandwich complexes of yttrium and scandium were the first complexes with silyl substituents on the eight-membered ring. Reaction of **1a** with [$LnCl_3(THF)_3$] (Ln = Sc, Y) gave the half-sandwich complexes [{{1,4-$(Me_3Si)_2C_8H_6$}Sc(μ-Cl)}$_2$(μ-THF)] and [{1,4-$(Me_3Si)_2C_8H_6$}Y(THF)(μ-Cl)]$_2$, respectively [Equation (6) and (7)].[68] The structure of the scandium compound was determined by single crystal X-ray diffraction (Figure 7). The most interesting feature of the dimeric structure concerns the THF ligand, which is in a bridging position. This structure has no parent C_8H_8 analogue.



(6)



(7)

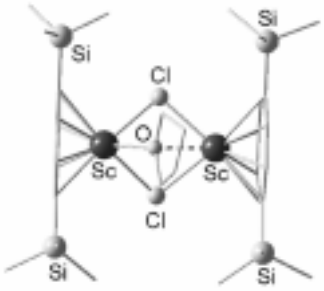


Figure 7. Crystal structure of [{{1,4-$(Me_3Si)_2C_8H_6$}Sc(μ-Cl)}$_2$(μ-THF)]

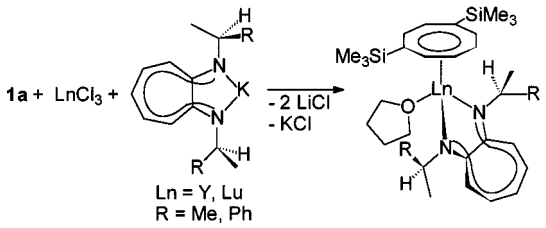
Derivatives of the cyclooctatetraene half-sandwich halides were usually made in a one-pot reaction starting from $LnCl_3$ and **1a** without isolation of the halogen intermediate (Table 5). Thus, the polysilylated complexes of composition [{1,4-$(Me_3Si)_2C_8H_6$}Ln{1,3-$(Me_3Si)_2C_5H_3$}] (Ln = Pr, Sm, Tb) were prepared by treatment of $LnCl_3$ simultaneously with equivalent amounts of **1a** and Li{1,3-$(Me_3Si)_2C_5H_3$}.[69] The isopropyl-aminotroponimate complexes [{1,4-$(Me_3Si)_2C_8H_6$}Ln{(iPr)$_2$ATI}(THF)] [Ln = Y, Lu; (iPr)$_2$ATI = *N*-isopropyl-2-(isopropylamino)troponiminate] and the enantiomerically pure (*S*)-phenylethyl-aminotroponimate complex [{1,4-$(Me_3Si)_2C_8H_6$}Y{((*S*)-$PhCHCH_3)_2$ATI}(THF)] were obtained by the consecutive treatment of $LnCl_3$ with **1a** and {$(R)_2$ATI}K [Equation (8)].[70] The structure of [{1,4-$(Me_3Si)_2$-C_8H_6}Y{(iPr)$_2$ATI}(THF)] was confirmed by single crystal X-ray diffraction. In contrast, the 1,4-diazadiene (DAD) complexes [{1,4-$(Me_3Si)_2C_8H_6$}Ln(DAD)(THF)] (Ln =

Table 5. Monomeric half-sandwich complexes of the general formula [{1,4-$(Me_3Si)_2C_8H_6$}Ln-R]

Ln	R	Ref.
Pr, Sm, Tb	1,3-$(Me_3Si)_2C_5H_3$	69
Y, Lu	{(iPr)$_2$ATI}(THF)[a]	70
Y	{((*S*)-$PhCHCH_3)_2$ATI}(THF)	70
Sm, Yb	(DAD)(THF)[b]	71

[a] (iPr)$_2$ATI = *N*-isopropyl-2-(isopropylamino)troponiminate. – [b] 1,4-Diazadiene.

Sm, Yb) have been prepared by reacting the cyclooctatriene 1,4-$(Me_3Si)_2C_8H_8$ with the elemental lanthanides and 1,4-diazadienes. As shown by NMR techniques, the interesting feature of these complexes is that by using the same reaction pathway the samarium complex is in the oxidation state +3, whereas the corresponding ytterbium compound is only divalent.[71] The silylated and thus very bulky cyclooctatetraene dianion provides higher solubility and often better crystallinity to organolanthanide derivatives relative to the parent C_8H_8 complexes.



(8)

Recently, by using $[Li_2(THF)_n][1,4\text{-}(o\text{-}Me_2N\text{-}C_6H_4Me_2Si)_2\text{-}C_8H_6]$ (**4**) the first donor-functionalized lanthanide cyclooctatetraene complexes were prepared. Transmetallation of **4** with anhydrous $NdCl_3$ or $SmCl_3$ in a 2:1 stoichiometric ratio gave the sandwich complexes $[Li(diglyme)_2][Ln(1,4\text{-}R_2C_8H_6)_2]$ [Ln = Nd, Sm; R = *ortho*-(dimethylsilyl)-*N,N*-dimethylaniline] (Scheme 3).[72] The single crystal X-ray structures of both complexes show that the dimethylamino group of the aniline ring is turned away from the metal center (Figure 8). Obviously the metal atom is shielded by the two eight-membered rings of the ligand. Thus, neither intra- nor intermolecular coordination is observed in the solid state. The dimeric ionic half-sandwich complex $[Li(diglyme)_2][\{1,4\text{-}R_2C_8H_6\}_2Sm_2(\mu\text{-}Cl)_3]$ was synthesized by the reaction of **4** with $SmCl_3$ in a 1:1 stoichiometric ratio (Scheme 3).[73] The anion of the new complex is a unique example of a dimeric organolanthanide complex that is bridged by three chlorine atoms. In the solid state the donor functionality does not coordinate to the samarium center. As shown by spin lattice relaxation experiments there is a coordination of one amino group to the samarium atom in solution. Density Functional Theory (DFT) calculations show that this coordination might in principle be in an intramolecular fashion.[73]

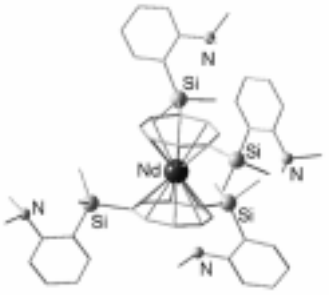


Figure 8. Crystal structure of the anion of $[Li(diglyme)_2][Nd(1,4\text{-}R_2C_8H_6)_2]$ [R = *ortho*-(dimethylsilyl)-*N,N*-dimethylaniline]

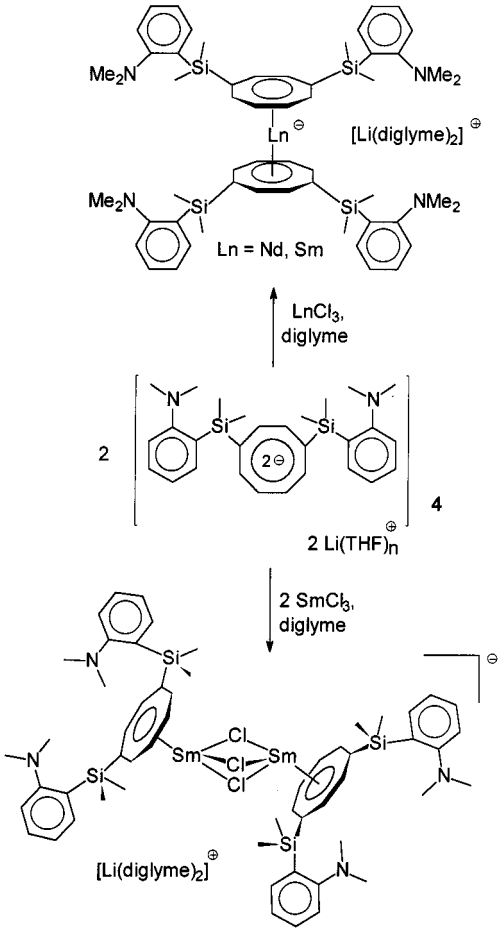
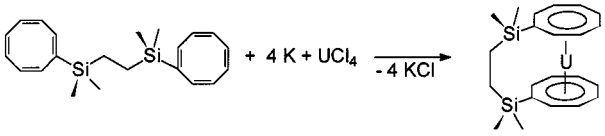


Scheme 3

In contrast to the large number of alkyl-substituted actinocenes only a few silyl-substituted actinocenes are known. Complexes of composition $[An\{1,4\text{-}(Me_3Si)_2C_8H_6\}_2]$ (An = Th, U),[68] $[An\{1,4\text{-}(Me_2tBuSi)_2C_8H_6\}_2]$ (An = Th, U),[62] and $[An\{1,3,6\text{-}(Me_3Si)_3C_8H_5\}_2]_2$ (An = Th, U, Np)[63,74] were obtained by reaction of $AnCl_4$ with **1a,b** and **2**, respectively. Reduction of $[An\{1,4\text{-}(Me_2tBuSi)_2C_8H_6\}_2]$ by potassium in DME yielded the anionic compounds $[K(DME_2)][An\{1,4\text{-}(Me_2tBuSi)_2C_8H_6\}_2]$, which were crystallographically characterized.[62] The thorium complex was the first Th^{III} sandwich to be discovered. EPR spectroscopic studies indicated that the molecule possesses a $6d^1$ ground state.

The first bridged uranocene is also a silyl-substituted complex. The ligand 1,2-bis(cyclooctatetraenyldimethylsilyl)ethane, $C_8H_7\text{-}Si(Me_2)\text{-}CH_2CH_2\text{-}Si(Me_2)\text{-}C_8H_7$, was prepared by the reaction of LiC_8H_7 and 1,2-bis(chlorodimethylsilyl)ethane. Further reaction of the ligand with potassium and UCl_4 gave the corresponding bridged uranocene [Equation (9)].[75] The only known half-sandwich complex of the actinides with silyl-substituted cyclooctatetraenes is $[\{1,4\text{-}(Me_3Si)_2C_8H_6\}U(BH_4)_2]$ which was obtained from **1a** and $[UCl_2(BH_4)_2]$.[68]



(9)

3. Conclusion

The recent developments in the chemistry of substituted cyclooctatetraenes has shown that silyl-substituted cyclooctatetraenes are becoming more and more popular in *f*-metal chemistry. There are several reasons for this development. In contrast to alkyl-substituted cyclooctatetraenes the silylated ligands are easily accessible from cheap starting materials. As observed for highly substituted alkyl complexes, the silyl groups are bulky enough to shield the highly reactive metal centers. Thus, more stable complexes are available. Furthermore, due to the silyl groups the solubility of the resulting metal complexes is increased. This facilitates the purification of some of the complexes such as half-sandwich lanthanide halides. Additionally, in some cases the steric bulk of the substituents on the eight-membered ring led to new coordination modes on the center metal. Finally, the introduction of the silicon atom facilitates the attachment of functional groups on to the ligand. Due to these advantages all recent publications on substituted cyclooctatetraenes deal exclusively with the silyl-substituted form.

Different Transformation Pathways in the Photolysis of [Cp*P{W(CO)$_5$}$_2$]

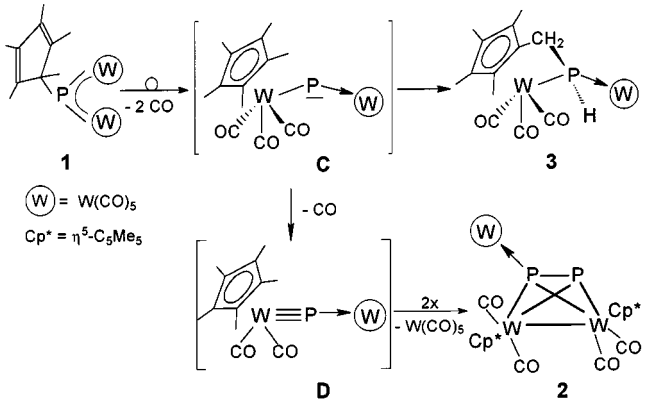
Michael Schiffer,[a] Eva Leiner,[a] and Manfred Scheer*[a]

Dedicated to Professor Marianne Baudler on the occasion of her 80th birthday

Keywords: Photolysis / Cyclopentadienyl ligands / Tungsten / P ligands

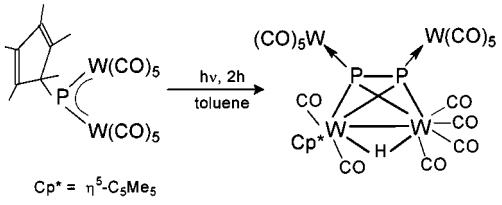
Photolysis of [Cp*P{W(CO)$_5$}$_2$] (**1**) leads to the novel complex [{Cp*(CO)$_6$W$_2$}(μ-H)(μ-η^1:η^1:η^1-P$_2$){W(CO)$_5$}$_2$] (**4**), which was structurally and spectroscopically characterised. The product is formed by a Cp* migration within **1** to give the phosphido complex intermediate [Cp*(CO)$_2$W≡P→W(CO)$_5$], as well as by a Cp* elimination to form an intermediate of the type [P{W(CO)$_5$}$_2$], both of which dimerise to yield product **4**.

The novel class of complexes with a metal−phosphorus triple bond[1] contains two different types of compounds: [L$_n$M≡P] **A**[2] and [L$_n$M≡P→M′(CO)$_5$] **B** (M′ = Cr, W).[3] If in both types of complexes the transition metal is in a high oxidation state, stable compounds are obtained. In the case of a low oxidation state of the transition metal, these complexes exist as highly reactive intermediates.[1] We recently found a synthetic approach to generate complexes **B** directly as highly reactive intermediates.[4] In contrast to the sterically demanding complexes of type **A**, they reveal a high "side-on" reactivity. The principle of their generation is based on the migration of a σ-bound Cp* substituent at the phosphorus atom to an η^5-coordination at the transition metal (Scheme 1). Thus, the thermolysis of [Cp*P{W(CO)$_5$}$_2$] (**1**) leads, via CO elimination, to an intermediate of the formula **D** containing a phosphorus−tungsten triple bond. This intermediate dimerises to form the tetrahedral complex **2** as the major product. As a side-reaction, a C−H activation in a possible precursor intermediate **C** gives the complex **3**. The chemistry of this highly reactive intermediate **D** offers promising synthetic routes to a large variety of unprecedented phosphametallocycles.[5] Herein we report on the photolysis of **1**, which reveals a different transformation pathway in contrast to the transformation involved in the thermolysis reaction of **1**.



Scheme 1. Proposed reaction pathway of the thermolysis of [Cp*P{W(CO)$_5$}$_2$] (**1**)

The photolysis of **1** in toluene at room temperature results in a colour change from blue to brown after two hours indicating the completeness of the transformation of **1** [Equation (1)]. Column chromatographic workup resulted in a yellow fraction of the minor product **3** as well as an orange fraction from which **4** could be obtained as a red crystalline compound in 60% yield. Complex **4** is sparingly soluble in toluene and readily soluble in THF and CH_2Cl_2. The IR spectrum reveals absorptions for terminal CO ligands. In the mass spectrum of **4**, the highest mass peak found corresponds to the molecular ion peak minus W(CO)$_5$.



(1)

The $^{31}P\{^1H\}$ NMR spectrum of **4** reveals two doublets at δ = −166.2 and −223.7 with a $^1J_{P,P}$ coupling constant of 447 Hz, indicating magnetically nonequivalent P atoms. This magnetic nonequivalency probably results from the different orientations of the P atoms to the Cp* ligand at one of the W atoms of the stereochemically rigid tetrahedral P_2W_2 framework. While the first doublet shows one $J_{W,P}$ coupling of 233 Hz, the other doublet reveals two $J_{W,P}$ couplings of 69 and 209 Hz, respectively. Since the larger $J_{W,P}$ usually corresponds to the coupling to the terminal W(CO)$_5$ groups, the smaller must reflect the coupling to the W atoms of the W_2P_2 tetrahedral framework, which is probably not resolved in the signal at δ = −166.2

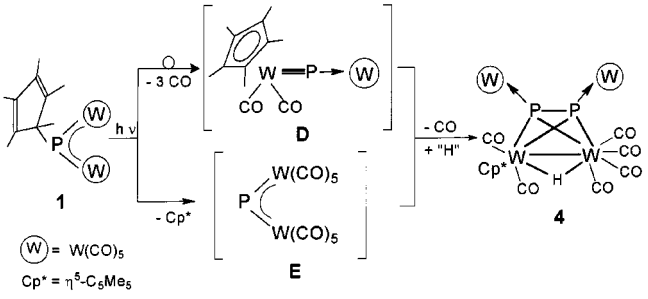
($w_{1/2} > 50$ Hz). For $[\{Cp^*W(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$[6] and $[\{CpW(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$,[7] no $^1J_{W,P}$ couplings are observed in the singlets found at $\delta = -154.6$ and -299.0, respectively. In the ^{1}H NMR spectra of **4**, a singlet for the methyl protons of the Cp* ligand is found at $\delta = 2.29$. Furthermore, a singlet at $\delta = -16.7$ for the (μ-H) ligand is observed containing two different $^1J_{W,H}$ couplings of 30 and 38 Hz. The magnitude of the coupling is in good agreement with the data obtained for $[W_2(\mu\text{-}H)(CO)_xL_y]$ (L = NO, RNC, PPh_3; R = Me, *t*Bu, $PhCH_2$, *i*Pr; $x = 6-9$; $y = 1, 2$), where the signal for the μ-hydrido ligand was found between $\delta = -5.21$ and -13.1, with each of them containing two $^1J_{W,H}$ couplings of between 30 and 60 Hz.[8] The origin of the μ-H ligand in **4**, which completes the electronically precise nature of this compound, was confirmed by carrying out the reaction in Equation (1) in $[D_8]$toluene (99% labeled with D) as solvent. Since the obtained compound **4a** contains only traces of the protonated complex **4**, one can speculate that the solvent acts as the source of the proton.

The molecular structure of **4** (Figure 1) shows a slightly distorted W_2P_2 tetrahedron containing a $Cp^*(CO)_2W$ and a $W(CO)_4$ unit. Both of the phosphorus atoms coordinate to $W(CO)_5$ groups. The bond length P(1)−P(2) of 2.166(6) Å is shorter than a single bond length found, for example, in the structure of β-P_4 at −185 °C [2.190−2.212 Å].[9] Since the P−P bond length in **4** is longer than in the non-substituted tetrahedral P_2W_2 complex $[\{CpW(CO)_2\}_2(\mu,\eta^2\text{-}P_2)]$ [2.104(4) Å],[7] and also longer than in the monosubstituted complex $[Cp^*W(CO)_2\}_2(\mu,\eta^2{:}\eta^1\text{-}P_2)\{W(CO)_5\}]$ [2.092(4) Å],[4] one can conclude that the coordination of the phosphorus lone pairs in **4** lengthens the P−P bond. Furthermore, each of the P atoms of **4** is more closely bound to a different W atom of the tetrahedral P_2W_2 moiety. Thus, the bond lengths P(1)−W(1) and P(2)−W(2) are 2.492(4) Å and 2.510(4) Å, respectively, in comparison to the other P(1)−W(2) and P(2)−W(1) bond lengths of 2.540(4) Å and 2.554(4) Å, respectively. The W(1)−W(2) bond length [3.1417(9) Å] in **4** is slightly longer than the W−W bond length in other W_2P_2 tetrahedral complexes: $[\{Cp^*(CO)_2W\}_2\{\mu,\eta^2{:}\eta^1\text{-}P_2W(CO)_5\}]$ [3.0920(7) Å][4] and $[\{Cp(CO)_2W\}_2(\mu,\eta^2\text{-}P_2)]$ [3.0026(11) Å].[7]

The formation of **4** from the photolysis of $[Cp^*P\{W(CO)_5\}_2]$ (**1**) can be regarded as a dimerisation of two reactive intermediates (Scheme 2): the triple bond intermediate **D**, formed by Cp* migration as described in Scheme 1, and a second intermediate **E** created by elimination of the Cp* ligand. Since complex **4** is obtained in high isolated yields, both of the pathways can be regarded as equivalent. Each of these intermediates opens up broad perspectives for trapping reactions to obtain novel main-group−transition-metal cage compounds with unusual coordination polyhedrons.



Scheme 2. Proposed reaction pathway of the photolysis of $[Cp^*P\{W(CO)_5\}_2]$ (**1**)

Experimental Section

General: All reactions were performed under an atmosphere of dry argon using Schlenk techniques. Solvents were purified and degassed by standard procedures. NMR spectra were recorded on a Bruker AC 250 [^{1}H: 250.13 MHz; ^{31}P: 101.256 MHz; standard Me_4Si (^{1}H), 85% H_3PO_4 (^{31}P)]. The IR spectra were recorded in KBr on a Bruker IFS 28 FT-IR spectrometer, the mass spectrum on a Finnigan MAT 711 at 70 eV and the UV spectra on a Perkin−Elmer Lambda 900 UV/Vis/NIR. Photolysis reactions were carried out with a Hanau type TQ150 mercury lamp.

Synthesis of 4: A solution of **1** (0.39 g, 0.48 mmol)[10] in 50 mL of toluene was photolysed for 2 h until the colour of the solution changed from deep blue to brown. The solvent was completely removed in vacuo, and the resulting brown residue was coated onto 6 g of silica gel and separated by column chromatography (1.5 × 45 cm). Elution with *n*-hexane/toluene (5:1) gave a yellow fraction of **3** (20 mg, 5.6%) followed by an orange fraction (*n*-hexane/toluene 1:1) containing **4**, which was recrystallised to give 0.2 g (60%) of red platelets at −30 °C. − ^{31}P{^{1}H} NMR (C_6D_6): $\delta = -166.2$ (d, $^1J_{PP} = 447$ Hz, $^1J_{WP} = 233$); −223.7 (d, $^1J_{PP} = 447$ Hz, $^1J_{WP} = 69$ Hz, 209 Hz). − ^{1}H NMR ($[D_8]$THF): $\delta = 2.29$ (s, 15 H, Cp*), −16.7 (s, 1 H, $J_{W,H} = 30$ and 38 Hz). − IR (KBr): ν(CO) = 2074 (m), 2063 (w), 1970 (sh), 1930 (s, br) cm^{-1}. − MS (EI): *m*/*z* (%) =

1058 (2) [M − W(CO)$_5$]$^+$, 1002 (1) [M − W(CO)$_7$]$^+$, 890 (3) [M − W(CO)$_{11}$]$^+$. − $C_{26}H_{16}O_{16}P_2W_4$ (1381.75): calcd. C 22.60, H 1.17; found C 22.32, H 1.53

1: UV/Vis (toluene): λ_{max} [nm] (ε) [M^{-1} cm^{-1}] = 572 (13400), 350 (sh, 10300).

4: UV/Vis (toluene): λ_{max} [nm] (ε) [M^{-1} cm^{-1}] = 320 (sh, 6900).

Crystal Structure Determination of 4:[11] A red crystal, obtained from toluene, with the dimensions 0.20 × 0.12 × 0.02 mm was used for data collection at 210(2) K on a STOE IPDS diffractometer with Mo-K_α radiation (λ = 0.71073 Å) with numerical absorption corrections. The structure was solved by direct methods using SHELXS-86,[12a] with full-matrix least-squares refinement on F^2 using SHELXL-97[12b] and anisotropic displacement for non-H atoms (except those of the atoms O6 and C21, due to the insufficient crystal quality). Hydrogen atoms were located in idealised positions and refined isotropically according to a riding model. The bridging H(1) atom was found as residual electron density and was freely refined [U(eq) = 0.06 Å^2]. The flack parameter of the acentric structure of **4** came to a value of −0.07(2). The relatively high residual electron density in the structure of **4** is located close to the atom W(2). Further data of the X-ray structure analysis are given in Table 1.

Two Isomers of a Tris(dimethylamino)bis(trimethylstannyl) Triborane(5) and the Reaction of $(Me_3Sn)_2B_2(NMe_2)_2$ with $(Ph_3P)_2Pt(\eta^2\text{-}C_2H_4)$[‡]

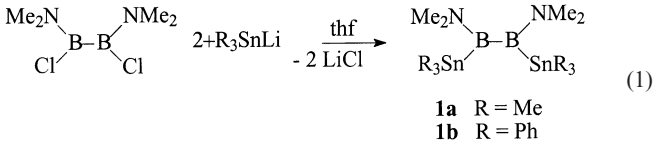
Tassilo Habereder,[a] Heinrich Nöth,*[a] and Matthias Wagner[a]

Keywords: Boranes / Isomers / Structure elucidation / Platinum

Reactions of $LiSnR_3$ (R = Me, Ph) with $Cl(Me_2N)B–B(NMe_2)Cl$ lead to the corresponding 1,2-(triorganylstannyl)diboranes(4) **1a,b**. Similarly, when the triborane(5) $Cl(Me_2N)B–BNMe_2–B(NMe_2)Cl$ is reacted with Me_3SnLi at low temperature the bis(trimethylstannyl)triborane **2a** is formed. In contrast, when the dibromide $Br(Me_2N)B–BNMe_2–B(NMe_2)Br$ is allowed to react with Me_3SnLi only small amounts of **2a** are formed; the main product being the cyclic isomer **2b**. Compounds **1a** and **2b** were characterized by X-ray crystal structure analysis. Compound **2b** has quite short B–Sn bonds. Oxidative addition of **1a** with ethylenebis(triphenylphosphane)platinum(0) yields *cis*-bis(trimethylstannyl)bis(triphenylphosphane)platinum(II) (**3**) besides trimethylstannyl[trimethylstannylbis(dimethylamino)diboranyl(4)]bis(triphenylphosphane)platinum **4**. These compounds were characterized by NMR spectroscopy.

Transition metal-boryl compounds have come into focus in recent years as they have been proposed as intermediates in a number of catalytic systems. Many well-characterized transition metal-boryl compounds are known today, and the state of the art has been reviewed several times.[2] Many of these complexes were obtained by oxidative addition of diborane(4) compounds to various metal-complex fragments. The oxidative addition of boron−halogen bonds[3] or boron−tin bonds[4] was also successful. So far, no reactivity scale has been developed, although it has recently been shown that the B−B bond of diborane(4) halides is more reactive than the boron−halogen bond. For example the reaction of $B_2Cl_2(NMe_2)_2$ or B_2F_4 with $(C_2H_4)Pt(PPh_3)_2$ leads to $[Pt(PPh_3)_2\{BCl(NMe_2)\}_2]$[5] and $[Pt(PPh_3)_2(BF_2)_2]$,[6] respectively. However, the formation of diborane(4)-1-yl derivatives is also known.[7] In our studies on silyl-, germyl- and stannylboranes, as well as polyboranes,[4,8−10] we became interested in the competition of B−Sn bonds vs. B−B bonds in the oxidative addition of stannyldiboranes(4) and stannyltriboranes(5). In preparing suitable starting materials we detected an interesting pair of isomers derived from a triborane(5) derivative, which we report here together with a new stannyldiborane(4).

Some time ago we described the preparation of $B_2(SnMe_3)_2(NMe_2)_2$ (**1a**) by treatment of $B_2Cl_2(NMe_2)_2$ with Me_3SnLi [Equation (1)].[8a] In analogy to **1a** we have now also obtained $B_2(SnPh_3)_2(NMe_2)_2$ (**1b**).



(1)

1a R = Me
1b R = Ph

The ^{11}B NMR spectrum of **1b** shows a broad signal within the expected range at $\delta^{11}B = 61$ ($h_{1/2} = \approx 1500$ Hz). Two different signal sets for the NMe_2 groups were found in the ^1H and ^{13}C NMR spectra consistent with a rotation barrier about the B−N bonds resulting from strong B−N π-bonding. In contrast to **1a**, which is a liquid, **1b** could be obtained as single crystals suitable for an X-ray structure determination (Figure 1). The B−N bond lengths support the view that strong π-bonding is present in **1b** as indicated by an average B−N bond length of 1.384(3) Å. The planes made up of the atoms bonded to the N atoms are almost coplanar with the planes at the boron atoms to which the nitrogen atoms are attached: [B(1)−N(1) = 5.3°,

$\delta^{119}Sn$	−152.0	−8.5 ($^1J_{BSn}$ = 415 Hz)

B(2)−N(2) = 2.9°]. The B−B−N−Sn planes of the two boron atoms are twisted relative to each other by 85.6°. Therefore, there is no electron delocalization across the B−B bond in this molecule although the molecule is isoelectronic and isolobal with a 1,3-butadiene. Rather, the space requirements of the substituents are taken care of by minimizing steric interactions, which results in the observed conformation. The B−B bond is a single bond although the B−B bond length [1.677(4) Å] is on the short side amongst the bond lengths known for diborane(4) molecules.[11] For the B−Sn bonds, atom distances of 2.282(3) Å and 2.276(3) Å were determined. These lengths are consistent with B−Sn bonds in molecules with minor steric hindrance.[1,10a]

The preparation of the corresponding triorganylstannyl triborane(5) compounds was much more complicated. The reaction of $Cl_2B_3(NMe_2)_3$ with two equivalents of Me_3SnLi affords compound **2a** in high yield [Equation (2)]. However, minor changes in the reaction conditions lead to a different product **2b** [Equation (3)] which proved to be an isomer of **2a**. Isomer **2b** is predominantly formed in the reaction of $Br_2B_3(NMe_2)_3$ with Me_3SnLi, whereas compound **2a** was formed only to an extent of about 30%. Compounds **2a** and **2b** can be separated and **2b** purified by fractional crystallization: This allowed an unequivocal assignment of their NMR spectroscopic data (listed in Table 1).

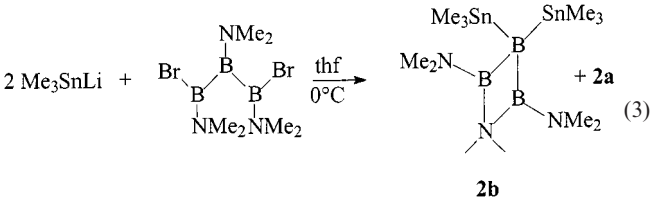
2a



(3)

2b

The acyclic triborane **2a** shows NMR spectra which are typical for symmetric, terminally substituted tris(dimethylamino)triborane(5) compounds. In the ^{11}B NMR spectrum two broad signals in the region for tricoordinate boron atoms are found.[12] The ^1H and ^{13}C NMR signals for the dimethylamino groups (three signal sets each) are consistent with a hindered rotation. The central amino group is represented by a single signal for symmetry reasons. These data point to the presence of strong B−N π-bonding. The ^{119}Sn NMR spectrum shows the expected[12] broad signal at $\delta^{119}Sn$ = −152. In contrast, the NMR spectroscopic data of **2b** seemed, at first sight, not to be compatible with a triborane(5) framework, as a signal for a tetracoordinate boron atom was unexpected, and, as only one signal with double intensity for a tricoordinate boron atom was found, this NMR spectrum could only be explained by the presence of a tetracoordinate boron atom in the center of a chain of three boron atoms. The observed coupling constants: $^1J_{BSn}$ = 415 Hz, $^1J_{CSn}$ = 205 Hz and $^3J_{CSn}$ = 19 Hz confirm that the tetracoordinate boron atom bears the $SnMe_3$ groups. The chemical shift of the central boron atom in **2b** is also unusual with $\delta^{11}{}_B$ = −51.1. As the ^1H and ^{13}C NMR spectra indicate a high symmetry for the molecule the structure depicted for **2b** was deduced. However, the high-field shift of the tetracoordinate boron atom has so far no parallel as no boron atom carrying two boron and two tin atoms is known to date. The closest analogues for high-field shielding are $LiB(SiMe_3)_4$ [13] with $\delta^{11}B$ = −53.4, $LiBH_3SnMe_3$ with $\delta^{11}B$ = −43.7[8a] and $LiB(SnMe_3)_3$-NMePh with $\delta^{11}B$ = −13.1.[1] This indicates that the central boron atom bears a significant negative charge. This assumption is confirmed by a signal at $\delta\delta^{119}Sn$ = −8.5 as this Sn atom is deshielded by about 45 ppm relative to the tin atoms in the two stannyl-borates, and much more so than the tin atoms in isomer **2a.** The low-field singlet in the ^1H and ^{13}C NMR spectra of **2b** confirms the presence of a dimethylammonium group in a planar B_3N four-membered ring. Moreover, the remaining two signals for the dimethylamino groups fit with the suggested structure if they are coplanar with the ring. In this case the two methyl groups at each Me_2N group are nonequivalent, and, moreover, there is hindered rotation about these B−N bonds.

The structure derived from NMR spectroscopic data was fully confirmed by X-ray structure analysis: The molecular structure of **2b** is shown in Figure 2.

The striking key feature of the structure of **2b** is the 1-azonia-2,4-dibora-3-boratacyclobutane ring. The closest

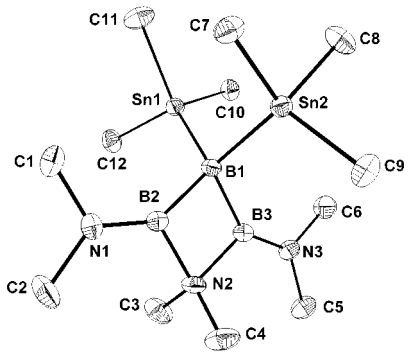


Figure 2. Molecular structure of **2b** in the crystal; hydrogen atoms are not depicted; thermal ellipsoids are drawn at a 25% probability level; selected bond lengths [Å] and bond angles [°]: Sn1−B1 2.223(3), Sn2−B1 2.225(3), N1−B2 1.382(4), N2−B2 1.605(4), N2−B3 1.603(4), N3−B3 1.379(4), B1−B2 1.660(4), B1−B3 1.662(5), N2−C3 1.483(4), N2−C4 1.498(4); Sn1−B1−Sn2 107.7(1), Sn1−B1−B2 116.6(2), Sn1−B1−B3 120.6(2), Sn2−B1−B2 116.7(2), Sn2−B1−B3 112.5(2), B2−B1−B3 81.3(2), B1−B3−N2 96.9(2), B1−B2−N2 96.9(2), B2−N2−B3 84.9(2)

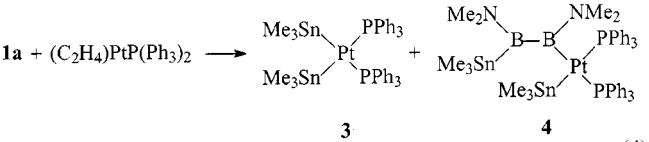
other system for comparison would be an azapolyborane such as hypho-2,3-μ-(*t*BuNH)B_5H_{10} [14] which also has an alkylammonium fragment, although this compound is actually not best suited for a comparison with **2b**. The B_3N four-membered ring is exactly planar (angle sum = 360°). The intra-ring angles at the tetracoordinate atoms B1 and N1 are 81.3(2)° and 84.9(2)°, respectively. The compression at B1 is 12.6° (from tetrahedral symmetry) and for B2 and B3 38.7° (from trigonal-planar symmetry). Therefore, the four-membered ring is highly strained. In spite of this, the B−B bond lengths [av.: 1.661 Å] are almost unaffected as they are the same as in compound **1b**. They are actually only slightly longer than the B−N distances to the coordinated N atom [av.: 1.603 Å]. Thus, the expected increase in the B−B bond lengths that is normally observed upon changing to higher coordination is not found in this case. Therefore, the B−B distances in **2b** can be regarded as rather short. The sums of the bond angles at the nitrogen atoms N1 and N3 are 360° for both atoms and their bonding planes are coplanar with the B_3N ring. The two tricoordinate boron atoms are electronically stabilized by B−N double bonds as confirmed by the short B−N bonds. The two B−N bonds to the tetracoordinate N atom are single bonds. The B−Sn bonds are very short; they are the shortest found to date. Similar results were recently observed for B−Si[8d] and B−Ge[1] compounds. This indicates that for compounds of boron with the higher group 14 elements, a bond shortening with an increasing coordination number at the B atom seems to be a general rule.

Compound **2b** is, to the best of our knowledge, the first example of a tris(amino)triborane(5) in which the central B atom and not just the terminal boron atoms are doubly substituted. The mechanism by which **2b** is formed remains unclear. No equilibrium between the two isomers could be observed by NMR spectroscopy when a pure sample of either **2a** or **2b** was dissolved. The initial formation of **2a**, followed by a subsequent rearrangement to **2b**, can therefore be excluded. With regard to mechanistic speculations it is important to note that two conditions are in any case necessary for the formation of **2b**: The use of $Br_2B_3(NMe_2)_3$ as starting material, and reaction conditions which provide an initial excess of Me_3SnLi. This might indicate that the first step of the formation of **2b** could be a double substitution at one of the terminal boron atoms followed by a rearrangement of the substituents. The final formation of an azonia-bridged cyclic structure is also very likely. Anderson et al.[15] recently reported the favored formation of various 1-azonia-2-borata-5-borol compounds also bearing tri- and tetracoordinate boron and nitrogen atoms.

As we intended to explore whether the B−B or the B−Sn bond is more reactive towards transition metal centers, compound **1a** was reacted with $(C_2H_4)Pt(PPh_3)_2$. However, the product formed was not either of the expected B−B or B−Sn oxidative addition products but rather $(Me_3Sn)_2Pt(PPh_3)_2$ (**3**).[16]

The formation of **3** also requires the formation of a compound like $[B(NMe_2)]_n$, but the only other boron-containing compound which could be isolated was a small quantity of the diborane(4)-1-yl platinum compound **4** [Equation (4)].



(4)

The structure of **4** was derived from its NMR spectroscopic data. The ^{11}B NMR spectrum of compound **4** shows two signals at $\delta^{11}B = 59.8$ ($h_{1/2} = 480$ Hz) and $\delta^{11}B = 47.0$ ($h_{1/2} = 1840$ Hz). While the latter signal is almost the same as for the starting material, the signal of the boron atom bonded to the platinum atom is found in the range of platinum-boryl complexes.[9b] Apart from this, the B−Pt bond is confirmed by a very large half-width of its ^{11}B NMR signal of 1840 Hz. In the ^{31}P NMR spectrum two signal sets at $\delta^{31}P = 32.9$ [$^1J(^{31}P^{195}Pt) = 2895$ Hz; $^2J_{PP} = 12$ Hz; $^2J(^{31}P^{119}Sn) = 1364$ Hz, $^2J(^{31}P^{117}Sn) = 1304$ Hz] and $\delta^{31}P = 31.2$ [$^1J(^{31}P^{195}Pt) = 1656$ Hz; $^2J(^{31}P^{117}Sn) = 142$ Hz] are found proving the *cis* position of the phosphane groups in **4**. As this compound was obtained only in poor yield, attempts to grow single crystals failed. Nevertheless, the formation of **4** indicates that the B−Sn bonds in **1a** are more reactive than the B−B bonds.

Experimental Section

Experimental conditions, spectrometers and diffractometer are as described in previous contributions.[1]

1,2-Bis(triphenylstannyl)-1,2-bis(dimethylamino)diborane(4) (1b): Ph_3SnLi (2.9 mmol) was added to 50 mL of THF.[17] The solution was cooled to −78 °C and slowly treated with a solution of 1,2-dichloro-1,2-bis(dimethylamino)diborane(4)[18] (0.26 g, 1.44 mmol) in 25 mL of hexane. After stirring for 30 min. at ambient temperature all volatile components were removed in vacuo. The solid

residue was treated with 50 mL of toluene and the resulting suspension filtered. The volume of the filtrate was reduced in vacuo to 30 mL and then layered with 30 mL of hexane. This afforded, after some days standing at room temp., 0.81 g (71%) of **1b** as colorless crystals, m.p.: 119 °C. – ^{1}H NMR (400 MHz, C_6D_6): δ = 2.65 (s, 6 H, CH_3), 2.80 (s, 6 H, CH_3), 7.17–7.22 (m, 18 H, *m*-Ph-*H* and *p*-Ph-*H*), 7.58 (ddd, $^3J_{HH}$ = 5.9 Hz, $^4J_{HH}$ = 2.5 Hz, $^3J_{HSn}$ = 39.4 Hz, 12 H, *o*-Ph-*H*). – ^{11}B NMR (64 MHz, C_6D_6): δ = 60.8 ($h_{1/2}$ = 1500 Hz). – ^{13}C NMR (100 MHz, C_6D_6): δ = 47.6 (NCH_3), 49.3 (NCH_3), 128.5 (t, J_{CSn} = 39.1 Hz, *C*-arom.), 128.9 (t, J_{CSn} = 30.2 Hz, *C*-arom.), 137.6 (t, J_{CSn} = 39.1 Hz, *C*-arom.), 137.8 (t, J_{CSn} = 36.9 Hz, *C*-arom.), 139.2 (*C*-arom.), 142.4 (*C*-arom.). – ^{119}Sn NMR (149 MHz, C_6D_6): no signal observed. – $C_{40}H_{42}B_2N_2Sn_2$ (809.7): calcd. C 59.32, H 5.23, N 3.46; found C 58.71, H 5.23, N 3.32.

1,2,3-Tris(dimethylamino)-1,2-bis(trimethylstannyl)triborane(5) (2a): 1,3-Dichloro-1,2,3-tris(dimethylamino)triborane(5)[12] (2.31 g, 9.8 mmol) was dissolved in 30 mL of hexane. The solution was then cooled to −78 °C and treated dropwise with a THF solution of Me_3SnLi (19.6 mmol).[19] After stirring for 12 h at ambient temperature all volatile components were removed in vacuo. The solid residue was then treated with 30 mL of toluene. After filtration the solution was reduced in volume to 20 mL and then cooled at −78 °C. This afforded 3.18 g (66%) of **2a** as a colorless, polycrystalline solid, m.p.: 51–53 °C. For spectroscopic data see Table 1. – $C_{12}H_{36}B_3N_3Sn_2$ (492.3): calcd. C 29.28, H 7.37, N 8.54; found C 29.64, H 7.55, N 8.75.

1-Azonia-2,4-dibora-3-borata-2,4-bis(dimethylamino)-3-bis(trimethylstannyl)-1-dimethylcyclobutane (2b): A stirred solution of Me_3SnLi[19] (5.2 mmol) in THF was cooled to 0 °C and treated with 1,3-dibromo-1,2,3-tris(dimethylamino)triborane(5)[12] (0.86 g, 2.6 mmol) in 30 mL of toluene. After stirring for 5 h at ambient temperature a suspension had been formed, and the solution showed an ^{11}B NMR spectrum with signals at δ^{11}B = 66.5, 56.9, 50.4, 46.5, 36.2, −33.2 ($h_{1/2}$ = 300 Hz), and −49.8 (d, $^1J_{BSn}$ = 415 Hz). Those at δ = 66.5 and 36.2 are assigned to compound **2a**, and those at δ = 46.5 and −49.8 to **2b**. The signals at δ = 56.9, 50.4 and −33.2 could not be assigned. As the signals were broad and not well separated, integration was not possible, but the ratio of **2a** and **2b** can be roughly estimated as 6:3. All volatile components were removed from the suspension in vacuo. The residue was treated with 50 mL of hexane. Cooling the filtrate to −78 °C afforded 0.8. g (62%) of **2b** as colorless prisms. m.p.: 110 °C. – Spectroscopic data see Table 1. – $C_{12}H_{36}B_3N_3Sn_2$ (492.3): calcd. C 29.28, H 7.37, N 8.54; found C 28.52, H 7.09, N 8.07.

Reaction of 1a with (η^2-Ethene)bis(triphenylphosphane)platinum(0): Compound **1a** (0.41 g, 1.0 mmol) was dissolved in about 40 mL of toluene and treated with (η^2-ethene)bis(triphenylphosphane)platinum(0).[20] After stirring for 12 h at ambient temperature, a brownish precipitate had been formed. The precipitate was filtered, washed with hexane and crystallized from $CHCl_3$/hexane. This afforded colorless crystals, which were identified as **3**.[16] The filtrate was reduced in volume to 20 mL and layered with 20 mL of hexane. Within a few days about 0.03 g of a brown solid separated which was identified as **4** by NMR spectroscopy. Yield: 0.96 g of **3** (92%).
3: ^{31}P (109 MHz, −60 °C, C_6D_6): δ = 32.5 (dd, $^1J_{PPt}$ = 3774 Hz, $^2J_{SnP}$ = 646 Hz). – ^{119}Sn NMR (100 MHz, $CDCl_3$): δ = −13.2 (d, $^2J_{PSn}$ = 646 Hz).
4: ^{1}H (270 MHz, C_6D_6): δ = −0.51 [3 H, Sn(CH_3)$_3$], 0.29 [3 H, Sn(CH_3)$_3$], 0.39 [Sn(CH_3)$_3$], 0.67 [3 H, Sn(CH_3)$_3$], 0.89 [6 H, Sn(CH_3)$_3$], 2.56 (s, 3 H, NCH_3), 2.72 (s, 3 H, NCH_3), 2.76 (s, 3 H, NCH_3), 2.86 (s, 3 H, NCH_3), 6.93 (br. m, 18 H, Ph-*H*), 7.50 (br. m, 12 H, Ph-*H*); – ^{31}P (109 MHz, C_6D_6): δ = 32.9 ($^1J_{PPt}$ = 2895 Hz, $^2J_{PP}$ = 12 Hz, $^2J_P{}^{119}{}_{Sn}$ = 1364 Hz, $^2J_P{}^{117}{}_{Sn}$ = 1304 Hz, P_{cis}B), 31.2 (broad, $^1J_{PPt}$ = 1656 Hz, $^2J_{PSn}$ = 142 Hz, P_{trans}B); – ^{11}B (64 MHz, C_6D_6): δ = 47.0 ($h_{1/2}$ = 1840 Hz, *B*Pt), 59.8 ($h_{1/2}$ = 480 Hz, *B*Sn).

Crystal Structure Determination: A suitable single crystal was covered with perfluoroether oil, mounted on the end of a glass fiber and placed on a goniometer head. The crystal was cooled to −80 °C with a cold stream of dinitrogen using an LT2 device. The unit cell was determined from the reflections of five series of 15 frames each taken at different angles and sweeping φ by 0.3°. A Siemens P4 diffractometer equipped with an area detector and graphite-monochromated Mo-K_α radiation was used. Data collection was performed with the hemisphere mode of the SMART programs.[21] Data were reduced by SAINT[22] and an absorption correction applied with the program SADABS.[23] Structure solution and refinement was carried out with the SHELX-97 program suite. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were placed in calculated positions and included in the refinement as riding on the respective C atoms. Crystallographic and structure solution data are summarized in Table 2.
Crystallographic data (excluding structure factors) for the structures included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-157308 (**1b**) and -157309 (**2b**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road,

Neutral Mononuclear and Binuclear Hexacoordinate Silicon Complexes with SiO_5C Skeletons

Reinhold Tacke,*[a] Christian Burschka,[a] Meike Willeke,[a] and Reiner Willeke[a]

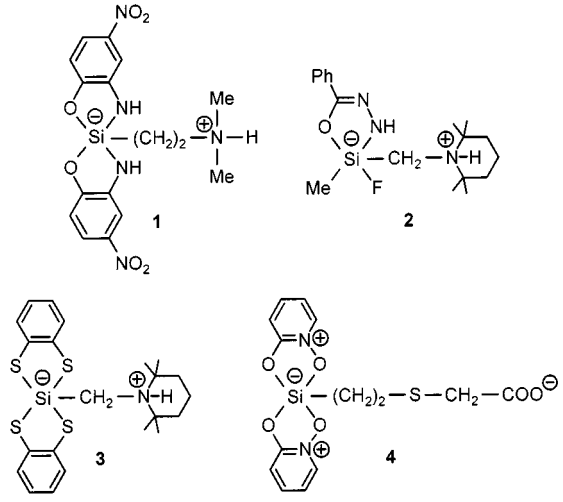
Dedicated to Professor Ernst Mutschler on the occasion of his 70th birthday

Keywords: Chelates / Coordination chemistry / Silicates / Macrocycles / Silicon

Treatment of the silanes $(EtO)_3Si(CH_2)_2SCH_2C(O)OSiMe_3$ and $(EtO)_3Si(CH_2)_3OSiMe_3$ with two molar equivalents of 1-hydroxy-2-pyridone in acetonitrile yielded the neutral hexacoordinate silicon complexes bis[μ-(3-thiapentanoato(2–)-$C^5,O':C^{5'},O$)]tetrakis[1-oxopyridin-2-olato(1–)]disilicon(IV) (**6**) and bis[1-oxopyridin-2-olato(1–)][propanolato(2–)-C^3,O]-silicon(IV) (**8**), respectively. The compounds **6**·$2CH_3CN$ and **8** were characterized by solid-state ^{29}Si VACP/MAS NMR spectroscopy, mass spectrometry (FAB MS), and single-crystal X-ray diffraction.

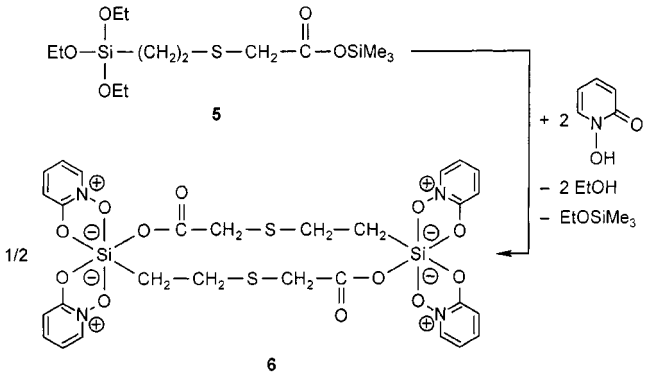
Introduction

In recent years, significant contributions to the chemistry of pentacoordinate silicon[1] have been made by investigating a new family of compounds, the zwitterionic pentacoordinate silicates.[2] Several hitherto unknown binding situations of pentacoordinate silicon could be realized and studied experimentally by taking advantage of the "zwitterion trick".[3] Compounds **1**,[4] **2**,[5] and **3**[6] with their SiO_2N_2C, $SiONFC_2$, or SiS_4C skeleton are examples of this.[7] To extend this successful concept, we decided to aim for novel zwitterionic pentacoordinate silicate systems with formally positively charged bidentate ligands. For this purpose, we attempted to synthesize compound **4**.



Results and Discussion

To synthesize the pentacoordinate silicon complex **4**, the silane **5** was treated with two molar equivalents of 1-hydroxy-2-pyridone;[8] however, instead of compound **4** the binuclear hexacoordinate silicon complex **6** was obtained (yield 72%; Scheme 1).



Scheme 1. Synthesis of the binuclear hexacoordinate silicon complex **6**

Formation of **6** can be rationalized (at least from a formal point of view) in terms of a dimerization of **4** through intermolecular Si−O interactions resulting in the generation of two SiO_5C skeletons. Likewise, a related mononuclear hexacoordinate silicon complex with an SiO_5C framework, compound **8**, could be obtained by treatment of the silane **7** with two molar equivalents of 1-hydroxy-2-pyridone (yield 66%; Scheme 2).

Both syntheses were carried out in acetonitrile at room temperature, and the products **6**·$2CH_3CN$ and **8** were isolated as crystalline solids. Their identities were established by elemental analyses (C, H N, S), mass spectrometry (FAB MS), solid-state ^{29}Si VACP/MAS NMR studies,[9] and crystal structure analyses.

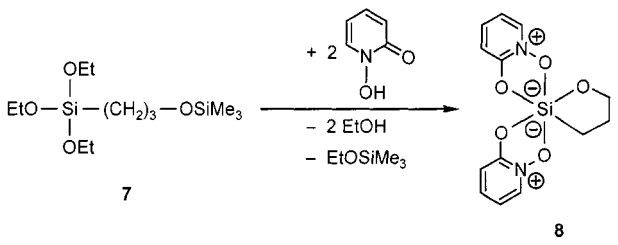

Scheme 2. Synthesis of the mononuclear hexacoordinate silicon complex **8**

The crystal structure of the binuclear complex **6** is characterized by a center of symmetry located in the middle of the macrocyclic 14-membered ring system. The silicon atoms of **6**·2CH_3CN and **8** are octahedrally coordinated (Figure 1 and 2),[10] the maximum deviations from the ideal 90° (180°) angle amounting to 11.9° (11.3°) (**6**·2CH_3CN) and 9.0° (13.9°) (**8**). The Si−O distances are in the ranges 1.7809(18)−1.8644(19) Å (**6**·2CH_3CN) and 1.7096(13)−1.8946(13) Å (**8**). The Si−C distances amount to 1.902(3) Å (**6**·2CH_3CN) and 1.8904(17) Å (**8**). Compounds **6**·2CH_3CN and **8** represent the first hexacoordinate silicon complexes with an *Si*O_5C skeleton that have been characterized by single-crystal X-ray diffraction.[11]

The isotropic chemical shifts of **6**·2CH_3CN ($\delta = -141.8$) and **8** ($\delta = -120.7$) determined by solid-state ^{29}Si VACP/MAS NMR experiments differ significantly from one another ($\Delta\delta = 21.1$). As the geometric data for the *Si*O_5C skeletons of both compounds are quite similar, it is likely that this difference can be attributed to the different nature of the respective O5 oxygen atoms (carboxylate versus alcoholate oxygen atom; see crystal structures). The broadening of the resonance signals in the solid-state ^{29}Si NMR spectra of **6**·2CH_3CN and **8** ($\nu_{1/2} = 80$ Hz) are in accordance with the disorder observed for the oxygen-linked carbon and nitrogen atoms of the 1-oxopyridin-2-olato(1−) ligands.[10]

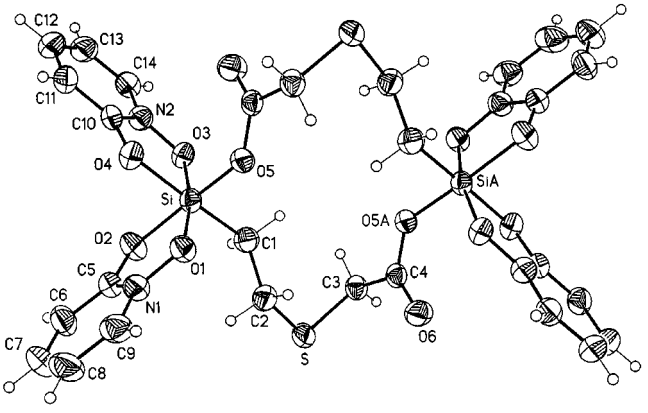

Figure 1. Molecular structure of **6** in the crystal of **6**·2CH_3CN (probability level of displacement ellipsoids 50%), showing the atomic numbering scheme; selected distances [Å] and angles [°]: Si−O1 1.8093(19), Si−O2 1.8644(19), Si−O3 1.7965(19), Si−O4 1.846(2), Si−O5 1.7809(18), Si−C1 1.902(3); O1−Si−O2 84.54(9), O1−Si−O3 168.69(9), O1−Si−O4 86.37(9), O1−Si−O5 84.77(9), O1−Si−C1 100.47(11), O2−Si−O3 88.14(9), O2−Si−O4 87.23(10), O2−Si−O5 168.68(9), O2−Si−C1 91.32(12), O3−Si−O4 84.66(9), O3−Si−O5 101.85(9), O3−Si−C1 88.29(11), O4−Si−O5 88.40(9), O4−Si−C1 172.85(11), O5−Si−C1 94.26(12)

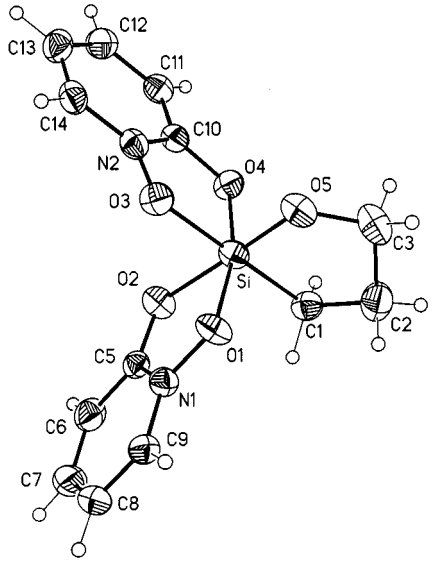

Figure 2. Molecular structure of **8** in the crystal (probability level of displacement ellipsoids 50%), showing the atomic numbering scheme; selected distances [Å] and angles [°]: Si−O1 1.8323(12), Si−O2 1.8946(13), Si−O3 1.8543(12), Si−O4 1.8172(12), Si−O5 1.7096(13), Si−C1 1.8904(17); O1−Si−O2 83.94(5), O1−Si−O3 85.39(6), O1−Si−O4 166.09(6), O1−Si−O5 90.25(6), O1−Si−C1 96.97(7), O2−Si−O3 86.25(6), O2−Si−O4 85.98(6), O2−Si−O5 172.59(6), O2−Si−C1 92.62(7), O3−Si−O4 84.42(6), O3−Si−O5 88.70(6), O3−Si−C1 177.27(6), O4−Si−O5 98.95(6), O4−Si−C1 93.02(7), O5−Si−C1 92.64(7)

In conclusion, we have developed a simple preparative method (EtOH/$EtOSiMe_3$ elimination) for the synthesis of neutral hexacoordinate silicon complexes containing two 1-oxopyridin-2-olato(1−) ligands and one variable ligand of the alkanolato(2−)/alkanoato(2−) type. The hexacoordinate silicon atoms are incorporated in heterocycles with varying ring sizes by one Si−O bond and one Si−C bond. The easy formation of the macrocyclic 14-membered ring system **6** is especially remarkable. It is likely that the preparative method described in this paper will have a great synthetic potential for the preparation of a wide variety of novel neutral heterocycles containing hexacoordinate silicon atoms as integral part of the ring system. Depending on the interplay of thermodynamic and kinetic control, both mononuclear and binuclear hexacoordinate silicon complexes can be formed. In principle, the formation of polymeric species (polynuclear coordination polymers) should also be possible.

Experimental Section

General: All syntheses were carried out under dry nitrogen. The organic solvents used were dried and purified according to standard procedures and stored under nitrogen. Melting points were determined with a DuPont Instruments differential scanning calorimeter, type Thermal-Analyzer 910. Solid-state ^{29}Si VACP/MAS NMR spectra were recorded at 22 °C on a Bruker DSX-400 NMR spectrometer with bottom layer rotors of ZrO_2 (diameter 7 mm)

containing ca. 300 mg of sample [79.5 MHz; TMS as external standard (δ = 0); spinning rate, 5 kHz; contact time, 5 ms; 90° ^{1}H transmitter pulse length, 3.6 μs; repetition time, 4 s]. Mass spectra were obtained with a Finnigan MAT-8430 mass spectrometer (FAB MS; 3-nitrobenzylic alcohol as liquid matrix; xenon as FAB source). The selected *m*/*z* values given refer to the isotopes ^{1}H, ^{12}C, ^{14}N, ^{16}O, ^{28}Si, and ^{32}S.

Synthesis of Bis[μ-{3-thiapentanoato(2−)-*C*^{5},*O*′:*C*$^{5'}$,*O*}]tetrakis[1-oxopyridin-2-olato(1−)]disilicon(IV)−Diacetonitrile (6·2CH$_3$CN): Compound **5**[12] (1.00 g, 2.82 mmol) was added to a solution of 1-hydroxy-2-pyridone (627 mg, 5.64 mmol) in acetonitrile (80 mL) and the mixture left undisturbed at room temperature for 42 h. The resulting crystals were isolated by filtration, washed with acetonitrile (3 × 5 mL), and dried in vacuo (10^{-3} mbar, 20 °C, 12 h); yield 825 mg (1.01 mmol, 72%). M.p. 177 °C (dec.). − ^{29}Si VACP/MAS NMR: δ = −141.8 ($\nu_{1/2}$ = 80 Hz). − FAB MS (positive mode): *m*/*z* (%) = 733 (4) [M + H$^+$], 154 (100) [matrix + H$^+$]. − $C_{32}H_{34}N_6O_{12}S_2Si_2$ (815.0): calcd. C 47.16, H 4.21, N 10.31, S 7.87; found C 47.1, H 4.4, N 10.2, S 7.8.

Synthesis of Bis[1-oxopyridin-2-olato(1−)][propanolato(2−)-*C*^{3},*O*]-silicon(IV) (8): Compound **7**[13] (2.00 g, 6.79 mmol) was added to a solution of 1-hydroxy-2-pyridone (1.51 g, 13.6 mmol) in acetonitrile (80 mL) and the mixture left undisturbed for 4 days at room temperature. The resulting crystals were isolated by filtration, and part of the solvent (50 mL) of the filtrate was removed under reduced pressure (again formation of a precipitate). The precipitate was isolated by filtration, and the combined solids were washed with acetonitrile (2 × 2 mL) and dried in vacuo (10^{-3} mbar, 20 °C, 12 h); yield 1.38 g (4.50 mmol, 66%). M.p. 240 °C (dec.). − ^{29}Si VACP/MAS NMR: δ = −120.7 ($\nu_{1/2}$ = 76 Hz). − FAB MS (positive mode): *m*/*z* (%) = 307 (47) [M + H$^+$], 196 (100) [(M − $C_5H_4NO_2$)$^+$]. − $C_{13}H_{14}N_2O_5Si$ (306.4): calcd. C 50.97, H 4.61, N 9.14; found C 50.8, H 4.7, N 9.2.

Crystal Structure Analyses of 6·2CH$_3$CN and 8: Suitable single crystals were mounted in inert oil (perfluoroalkyl ether, ABCR) on a glass fiber and then transferred to the cold nitrogen-gas stream of the diffractometer (Stoe IPDS; graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å). The structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-squares on F^2 with all unique reflections (SHELXL-97). For the hydrogen atoms, a riding model was employed.

Selected Data for 6·2CH$_3$CN: Single crystal (0.3 × 0.3 × 0.1 mm) obtained from acetonitrile/*n*-pentane at 20 °C, $C_{28}H_{28}N_4O_{12}S_2Si_2$·2CH$_3$CN, M_r = 814.95, analysis at 233(2) K, triclinic, space group $P\bar{1}$, *a* = 8.4667(17), *b* = 9.1712(18), *c* = 12.697(3) Å, α = 105.86(3), β = 92.02(3), γ = 100.07(3)°, *V* = 930.2(3) Å^3, *Z* = 1, $\rho_{calcd.}$ = 1.455 g cm^{-3}, μ = 0.277 mm^{-1}, *F*(000) = 424, $2\theta_{max}$ = 49.42°, 15518 collected reflections, 2975 unique reflections (R_{int} = 0.0441), 241 parameters, R_1 = 0.0393 [$I > 2\sigma(I)$], wR_2 (all data) = 0.1033, *S* = 0.958, largest difference peak and hole 0.200 and −0.270 e·Å^{-3}. The crystal structure contains tubes along [100] which are occupied by the acetonitrile molecules.

Selected Data for 8: Single crystal (0.3 × 0.2 × 0.1 mm) obtained by slow cooling of a boiling solution in acetonitrile to 20 °C, $C_{13}H_{14}N_2O_5Si$, M_r = 306.35, analysis at 173(2) K, monoclinic, space group $P2_1/n$, *a* = 12.351(3), *b* = 8.3092(17), *c* = 13.078(3) Å, β = 98.49(3)°, *V* = 1327.5(5) Å^3, *Z* = 4, $\rho_{calcd.}$ = 1.533 g cm^{-3}, μ = 0.202 mm^{-1}, *F*(000) = 640, $2\theta_{max}$ = 54.12°, 12577 collected reflections, 2863 unique reflections (R_{int} = 0.0261), 192 parameters, R_1 = 0.0371 [$I > 2\sigma(I)$], wR_2 (all data) = 0.1108, *S* = 1.057, largest difference peak and hole 0.479 and −0.259 e·Å^{-3}.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-153448 (**6**·2CH$_3$CN) and CCDC-153449 (**8**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[2] Review dealing with zwitterionic pentacoordinate silicates: R. Tacke, M. Pülm, B. Wagner, *Adv. Organomet. Chem.* **1999**, *44*, 221−273.

[3] Generally, these zwitterionic pentacoordinate silicates (which contain a formally negatively charged silicon atom and a formally positively charged nitrogen atom) are characterized by an excellent crystallizability. This particular property is very advantageous for their preparation and isolation and for their structural characterization by single-crystal X-ray diffraction and solid-state NMR spectroscopy. In addition, most of these neutral molecular compounds also exist in solution and can be studied for their structure and dynamic behavior by solution NMR spectroscopy.

Dinuclear Pentamethylcyclopentadienyl Rhodium and Iridium Complexes from C=C-Bridged Amino Acid Dimers[‡]

Harald Dialer,[a] Susanne Schumann,[a] Kurt Polborn,[a] Wolfgang Steglich,*[a] and Wolfgang Beck*[a]

Dedicated to Professor Marianne Baudler on the occasion of her 80th birthday

Keywords: Rhodium / Iridium / Amino acids / Amides / N,O ligands

Hippuric acid dimers bridged by a C=C double bond react with the chloro-bridged complexes $(Cp^*)(Cl)M(\mu\text{-}Cl)_2M(Cp^*)(Cl)$ with decarboxylation or loss of a benzoyl group to give the unexpected ligand-bridged dinuclear complexes **2** and **4**, which were characterized by X-ray diffraction. In the iridium complex **2** an oxazolone derivative forms a C,O-N,N′-coordinated bridge, whereas in the rhodium complex **4** a chlorine atom and an amide group bridge the two metal atoms.

Recently, the synthesis and characterization of α-amino acid and peptide dimers bridged by C=C double bonds was reported.[1] These dimers are formed as *Z* and *E* isomers by condensation of α-chloroglycine derivatives with triphenylphosphane and base and are of interest for peptides with a cross-linked backbone. We investigated the coordination behavior of these novel compounds in order to get information on the configuration at the C=C bond of the amino acid dimers. By reaction of chloro-bridged, half-sandwich complexes of rhodium, iridium and ruthenium of the type $(L)ClM(\mu\text{-}Cl)_2M(L)Cl$ with α-amino acids and peptides a series of organometallic N,O- and N,N′-chelate complexes was obtained.[2]

Using this established strategy, the chloro-bridged pentamethylcyclopentadienyl iridium complex $Cp^*(Cl)Ir(\mu\text{-}Cl)_2Ir(Cl)(Cp^*)$ was reacted with the dimeric hippuric acid derivative **1** in the presence of NaOMe or LiOH. Compound **1** was prepared by hydrolysis of the corresponding *Z*-configured dimethyl ester.[1]

The reaction resulted in the formation of the unexpected product **2**, whose structure was solved by X-ray diffraction (Figure 1). Formation of complex **2** occurs by decarboxylation of one carboxylic group of **1** and formation of an oxazolone ring. Decarboxylation is typical for α,β-unsaturated carboxylic acids.[3] Oxazolones are usually formed by dehydration of *N*-acyl-α-amino acids with carbodiimides or carboxylic acid anhydrides.[4] Cyclization to an oxazolone to give **2** is obviously favorable in the coordination sphere of a metal. The X-ray structure determination also reveals metalation at the former C=C bridge of **1**. It is worthwhile to note that the reactions of the dimer $[Cp^*IrCl_2]_2$ with substituted oxazolones afforded either orthometalation [5] or metalation of the oxazolone ring.[6]

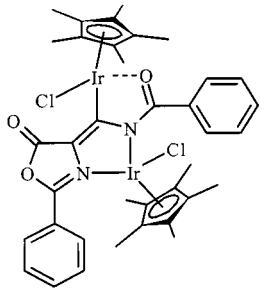
1. NaOMe
2. $[Cp^*IrCl_2]_2$



2

Complex **2** contains two different stereogenic centers at the iridium atoms, and the two expected diastereoisomers (as pairs of enantiomers) are observed in the ^1H NMR spectrum. Each diastereoisomer should exhibit two ^1H NMR signals for the nonequivalent Cp* units. In fact four ^1H NMR singlets (δ = 0.97, 1.07, 1.75 and 1.85) are found

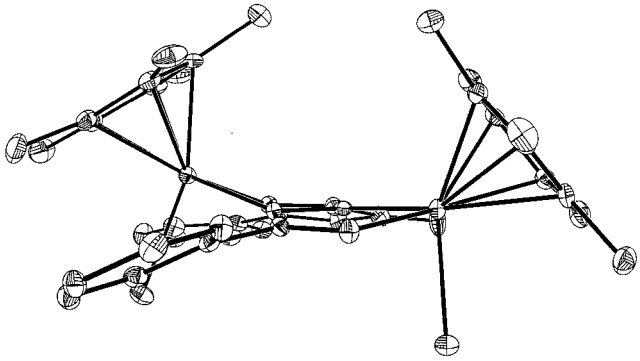

Figure 2. Side view of the molecular structure of **2** in the crystal

in the spectrum of the solution of product **2**. The two diastereoisomers could be separated: from a methanol solution of **2** only one diastereoisomer crystallized, and the crystal of **2** contained only one diastereoisomer as a racemate R_{Ir1}-S_{Ir2} and $S_{Ir1}R_{Ir2}$. In Figure 1 the $S_{Ir1}R_{Ir2}$ isomer is shown. As expected, the solution of the crystal exhibited only two Cp* ^{1}H NMR signals at δ = 1.07 and 1.85. In the ^{13}C NMR spectra the high downfield shift of the NMR signal for the metalated carbon atom at δ = 206 is remarkable, which corresponds to a quite short Ir2−C21 bond length of 1.995(6) Å (Figure 1) in the crystal. For the above-mentioned oxazolones a signal in the area of δ = 70 and 174 was observed.[5,6] On the other hand, the central C=C bond (C21−C29) is, with 1.382(8) Å, longer than the uncomplexed amino acid dimer (1.32−1.33 Å[1,8]). Figure 2 shows a side view of **2** demonstrating the almost planar arrangement of the novel bridging ligand.

A second unexpected product is formed from the reaction of the amino acid dimer **3** with $[Cp^*RhCl_2]_2$ in the presence of NaOMe. It is a chloro- and amido-bridged[7] dinuclear complex **4**, which is formed by cleavage of one benzoyl group from **3** and which was also characterized by X-ray structure determination (Figure 3, Table 1).

The fourth coordination sites of the rhodium atoms are occupied by a carboxylate oxygen donor and a chloro ligand. The formation of **4** involves a $Z \rightarrow E$ isomerization[1] of the amino acid dimer **3**. In the crystal of **4** both enantiomers $R_{Rh1}R_{Rh2}$ and $S_{Rh1}S_{Rh2}$ are present giving rise to two Cp* ^{1}H NMR signals in solution. In Figure 2 the structure of the $R_{Rh1}R_{Rh2}$ isomer with the chiral N1 atom in the *S* configuration is shown. Two hydrogen bonds NH···O−C(O) which fix the amino acid dimer in the *E* configuration can be detected both in solution and in the crystal. The two NH signals appear at rather low field (δ = 10.8 for the bridging amide and δ = 8.21 for the uncoordinated amide group) in the ^{1}H NMR spectra, and relatively short distances N1(H1)···O4 (2.244 Å) and N2(H2)···O2 (2.114 Å) are found in the solid. The crystal data show only a slight elongation of the central C=C bond [C22−C23 1.360(9) Å] in **4**. In both dinuclear complexes **2** and **4** the metal atoms have a distorted tetrahedral environment.

Figure 3. Conclusion

Different products were obtained from the reactions of the C=C-bridged amino acid dimers **1** and **3** with chloro-bridged complexes. Protection of one carboxylic group by esterification in **3** prevents decarboxylation and formation of an oxazolone ring as was observed with **1**. One can speculate why the two reactions proceed so differently. An explanation could arise if one considers the first step of these reactions. With **1** formation of an N,N(amide) and an O,O(carboxylate) chelate diiridium complex seems possible, which, after decarboxylation of one carboxylic group followed by metalation at the C=C bond and condensation of the benzoyl and carboxylic groups, gives the product **2**. Coordination of the two former amide nitrogen atoms of the *Z* amino acid dimer is found in the product **2**. In contrast, **3** can coordinate in the first step through the amide and carboxylate group of one half of the *Z*-amino acid dimer to form a chelate, as is present in product **4**. The noncoordinated second half of the amino acid dimer with the carboxylic ester can then undergo the $Z \rightarrow E$ isomerization which is necessary to form product **4**. Base-induced $Z \rightarrow E$ isomerization of C=C-bridged amino acid dimers has already been observed.[8] The fate of the lost benzoyl group remains unclear.

Experimental Section

NMR measurements were recorded on Jeol GSX 270 and Jeol EX 400 spectrometers. IR analyses were obtained on a Nicolet 520 FT-IR spectrometer. FAB MS was performed on a Finnigan MAT 90 instrument. The X-ray structure determination was carried out with a NONIUS CAD4 diffractometer. The dimeric hippuric acid derivatives **1** and **3** were prepared by deprotection of (*Z*)-2,3-bis(*N*,*N*′-benzoylamino)maleic acid dimethyl ester, which was synthesized according to a literature procedure.[9]

To a suspension of the dimethyl ester (382 mg, 1 mmol) in THF (9 mL) and water (3 mL) was added LiOH (72 mg, 3 mmol) at 0 °C and the mixture was stirred overnight. The resulting solution was acidified to pH 2 with a 1.1 M solution of $KHSO_4$ and extracted three times with ethyl acetate (20 mL). The combined organic fractions were washed with 20 mL of water and 20 mL of brine and dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure yielded the free acid **1** which was used without further purification. If the deprotection reaction was carried out with a molar ratio dimethyl ester/LiOH of 1:1 the main product was (*Z*)-2,3-bis(*N*,*N*′-benzoylamino)maleic acid mono methyl ester **3**, which was isolated by column chromatography.

2: A solution of (*Z*)-2,3-bis(*N*,*N*′-benzoylamino)maleic acid (**1**; 54 mg, 0.15 mmol) in 5 mL of methanol was stirred with a 1.65 M solution of NaOMe in methanol (185 μL, 0.30 mmol). $[Cp^*IrCl_2]_2$ [10] (121 mg, 0.15 mmol) was added to the resulting yellow solution and the mixture stirred for an additional 15 min. The resulting orange solution was set aside overnight leading to the precipitation of orange crystals suitable for X-ray diffraction. Yield 67 mg (44%). − IR (KBr): $\tilde{\nu}$ = 3063 w, 2918 w, 1776 vs (C=O), 1742 m, 1606 w (C=N), 1590 m, 1469 vs, 1392 s, 1374 s, 1162 m, 1073 m 834 m, 702 cm^{-1} m. − ^1H NMR (270 MHz, CD_2Cl_2): δ = 1.07 [s, 15 H, $C_5(CH_3)_5$], 1.85 [s, 15 H, $C_5(CH_3)_5$], 7.43−7.57 (m, 6 H, *m*- and *p*-C_6H_5), 8.44−8.52 (m, 4 H, *o*-C_6H_5). − ^{13}C NMR (67.9 MHz, CD_2Cl_2): δ = 8.6 [$C_5(CH_3)_5$], 8.9 [$C_5(CH_3)_5$], 86.8 [$C_5(CH_3)_5$], 90.1 [$C_5(CH_3)_5$], 125.7 (*C*=C), 126.6, 127.9, 128.7, 130.3, 131.5, 131.7, 132.3, 134.1 (Ph), 154.7 (C=N), 163.4 (CO_2), 187.0 (CON), 205.9 (C-Ir). − MS(FAB): *m*/*z* = 1016 (17) $[M]^+$. − $C_{37}H_{40}Cl_2Ir_2N_2O_3$ (1016.01): calcd. C 43.74, H 3.97, N 2.76; found C 43.90, H 3.97, N 2.75.

4: A solution of (*Z*)-2,3-bis(*N*,*N*′-benzoylamino)maleic acid monomethyl ester (**3**; 30 mg, 0.08 mmol) in 7 mL of methanol was stirred with a 1.65 M solution of NaOMe in methanol (99 μL, 0.16 mmol). $[Cp^*RhCl_2]_2$ [10] (50 mg, 0.08 mmol) was added to the resulting yellow solution and the mixture stirred overnight. The solvent was removed in vacuo and the residue redissolved in 3 mL of dichloromethane. The red solution was filtered through Celite and concentrated under reduced pressure. Recrystallisation from dichloromethane/*n*-hexane yielded red crystals suitable for X-ray analysis. Yield 22 mg (34%). − IR (KBr): $\tilde{\nu}$ = 3296 w, 2958 w, 2917 m, 2851 m, 1725 w, 1692 w, 1664 s, 1601 vs, 1588 vs, 1540 m, 1478 vs, 1455 vs, 1443 m, 1375 s, 1310 s, 1264 m, 1161 m, 1080 m, 1025 s, 933 w, 801 m, 717 s, 615 cm^{-1} m. − ^1H NMR (400 MHz, CD_2Cl_2): δ = 1.41 [s, 15 H, $C_5(CH_3)_5$], 1.55 [s, 15 H, $C_5(CH_3)_5$], 3.86 (s, 3 H, OCH_3), 7.45−7.57 (m, 3 H, *m*- and *p*-C_6H_5), 7.91−7.94 (m, 2 H, *o*-C_6H_5), 8.21 (d, ^3J = 9.2 Hz, 1 H, NH), 10.81 (s, 1 H, NH−Rh). − ^{13}C NMR (100.5 MHz, CD_2Cl_2): δ = 8.4 [$C_5(CH_3)_5$], 8.5 [$C_5(CH_3)_5$], 52.1 (OCH_3), 92.9 [d, J_{RhC} = 9.3 Hz, $C_5(CH_3)_5$], 93.9 [d, J_{RhC} = 8.4 Hz, $C_5(CH_3)_5$], 117.5 (*C*=C), 127.5, 128.6, 131.8, 133.6 (Ph), 164.9 (CON), 166.1 (CO_2CH_3), 173.7 (CO_2). − MS (FAB): *m*/*z* = 809 (2) $[M]^+$, 774 (23) $[M - Cl]^+$.

Varying Topology of Dendrimers − A New Approach toward the Synthesis of Di-Block Dendrimers

Valérie Maraval,[a] Rosa-Maria Sebastian,[a] Frédéric Ben,[a] Régis Laurent,[a] Anne-Marie Caminade,*[a] and Jean-Pierre Majoral*[a]

Keywords: Dendrimers / Phosphorus / Hydrazones / Aldehydes / Azides

A new way to synthesise di-block dendrimers having two types of end groups located in two different areas of their surface is reported. It consists in growing, step-by-step, a second dendritic wedge from the core of a first dendron. This method is mainly applied to the synthesis of di-block dendrimers having phosphanyl groups on one part of the surface.

Introduction

The need for advanced materials has created a tremendous area of research in which dendrimers occupy a growing place.[1−8] Indeed, their very particular, highly branched architectures often exhibit unusual behaviours and properties. It has been largely demonstrated that both the nature of the branches and the nature of the terminal functions influence these properties, but less attention has been paid to the modification of shape or topology. One of the challenges in this area consists of synthesising dendritic molecules having two different properties, due to the location of two types of functional groups in definite areas of the molecular surface. Very few papers have reported the synthesis of this type of di-block dendrimer,[9−18] and all of them to date concern the grafting of two different dendrons by their cores. This type of approach appears to be the most straightforward, but is inapplicable when the surface functions of one dendron may interact with the core function of the other dendron. An alternative route to avoid this problem should consist in a step-by-step, divergent synthesis of a new dendritic wedge starting from the core of a dendron.

In the course of our research on the synthesis[19−29] and applications[30−38] of phosphorus-containing dendrimers, we report here our efforts to find suitable methodologies for obtaining di-block dendrimers by growing a second dendritic wedge from the core of one dendron. The crucial point in the envisaged strategy is the choice of the function that will be located at the core of the first dendron. We decided to use R−P=N−P=S linkages, since we have already demonstrated on one hand that the P=S group can be easily desulfurized to yield a tricoordinated phosphorus atom usable in Staudinger reactions,[24−27,39] and on the other hand that the electronic influence of the P=N−P=S group upon R, when R is a vinyl group, allows us to perform Michael-type additions of amines.[17−18] Depending on the nature of R, other reactions could be envisaged, and chosen in order to be compatible with the nature of the terminal functions. Due to their wide range of uses, particularly in catalysis, phosphanyl groups appear as an interesting function to be linked to one part of the surface of the final dendrimer, the other part of the surface being variously functionalized, for instance with ammonium salts, leading to water-soluble derivatives.

Results and Discussion

Most of the work that will be described here was carried out with low generation of dendrons, in order to be able to detect any defects. In fact, our aim was to validate, on relatively small compounds, methods that could also be used for larger compounds. The desired P=N−P=S linkages are easily obtained using the Staudinger reaction between phosphanes **1a−c** and the azide-dialdehyde **2**,[40] leading to dendrons **3a−c-[G′0]**. The next step in growing these dendrons was the condensation with the phosphorus hydrazide **4**, affording the first generation dendron **3a−c-[G1]** (Scheme 1).

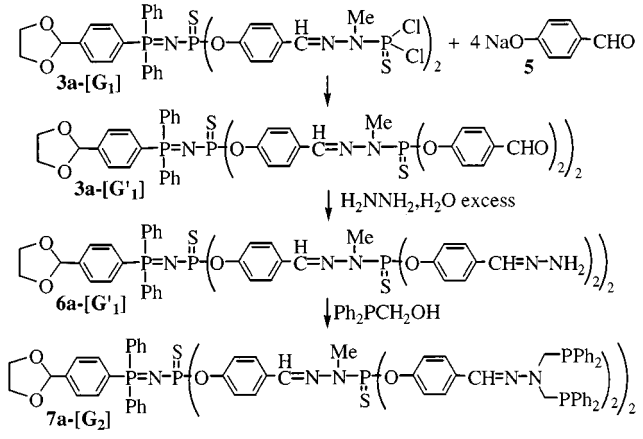
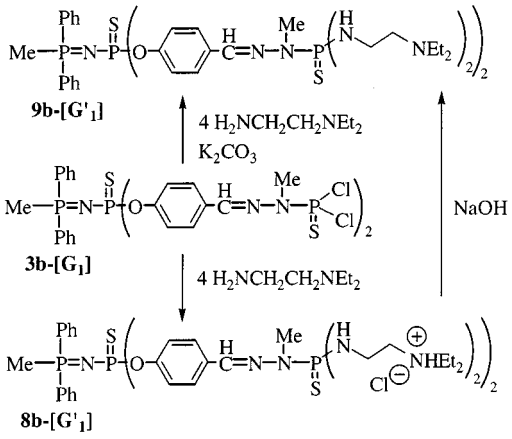
The continuation of the synthesis depends on the type of reactions envisaged at the core after the growing of the first dendron. For instance, the deprotection of the core of **3a-[G_1]** should regenerate an aldehyde group, whose reactivity with various amines could allow us to grow the second dendritic wedge. Thus, the functions located on the surface of the first dendron must be neither aldehydes, nor any group able to react with primary amines. We decided to graft diphosphanyl groups to the surface, using three steps from **3a-[G_1]**: i) substitution with hydroxybenzaldehyde sodium salt (**5**) leading to **3a-[G'_1]**, ii) condensation with hydrazine leading to **6a-[G'_1]**, iii) condensation with Ph_2PCH_2OH leading finally to **7a-[G_2]** (Scheme 2). The characterisation of compound **7a-[G_2]** shows that none of the preceding steps has damaged the acetal function, with the presence of multiplets at $\delta = 4.0$ for the CH_2CH_2 group and one singlet at $\delta = 5.79$ for the OCHO group in the ^1H NMR spectrum. Furthermore, no aldehyde group is detectable by ^1H or ^{13}C NMR. The next step should be the deprotection of the core. For this purpose, we used the classical method already applied to the deprotection of **1a**,[41] i.e. a catalytic amount (5%) of *p*-toluenesulfonic acid in acetone at 60 °C. However, a side reaction occurs at the level of the external groups of **7a-[G_2]**, which induces the total disappearance of the signal corresponding to the diphosphanyl groups in the ^{31}P NMR spectrum ($\delta = -25$) in favour of the appearance of new signals, in particular a singlet at $\delta = -41$, corresponding to Ph_2PH. The cleavage of the surface end groups precludes any use of **7a-[G_2]** for the growing of a second dendron from its core, consequently we decided to study the reactivity of **3b-[G_1]**, applying another strategy to obtain di-block dendrimers.



Scheme 2

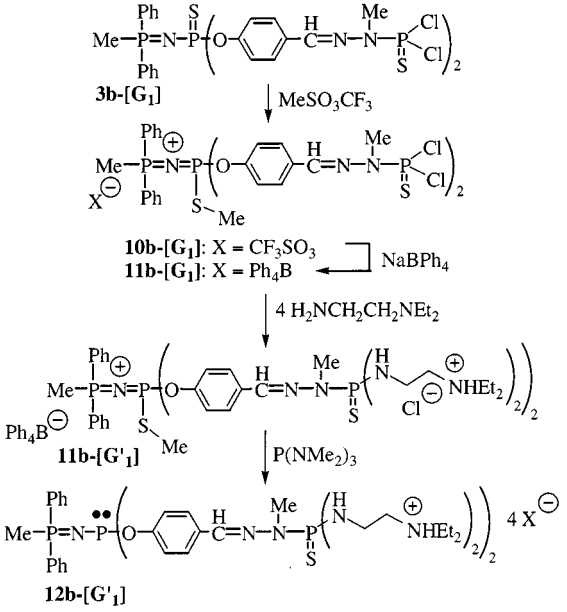
The only possible reactivity at the core of compound **3b-[G_1]** concerns the alkylation and desulfurization of the P=N−P=S linkage using $MeSO_3CF_3$ and $P(NMe_2)_3$ successively.[24−27,39] The first reagent is incompatible with the presence of phosphane groups on the surface of the first dendron, and the second one is incompatible with the P−Cl groups of **3b-[G_1]**, due to Cl/NMe_2 exchanges. Taking into account these constraints, we decided to graft ammonium groups to the surface of **3b-[G_1]**. Indeed, these functions should render the future di-block dendrimer water-soluble. The reaction of **3b-[G_1]** with 4 equiv. of $H_2NCH_2CH_2NEt_2$ affords compound **8b-[G'_1]** (Scheme 3) as expected.[17−18] This compound is soluble in a variety of solvents, either organic solvents such as chloroform and dichloromethane, or protic solvents such as ethanol, methanol, or water. Remarkably, compound **8b-[G'_1]** is stable for more than three weeks in water, even under acidic conditions at pH = 4.



Scheme 3

We tried to apply the first step of the desulfurization process, i.e. the alkylation of the P=S group by $MeSO_3CF_3$ to **8b-[G'_1]** in CH_2Cl_2 solution. Unexpectedly, addition of an excess of $MeSO_3CF_3$ is needed to observe the alkylation, characterised in the ^{31}P NMR spectra by the total disappearance of both doublets corresponding to the PNPS linkage at $\delta = 15.8$ (P=N) and 52.4 (P=S) ($^2J_{PP} = 32$ Hz) and the appearance of a singlet at $\delta = 23.6$. This signal is an AB system, totally degenerated, corresponding to the PNPSMe linkage.[24−27,39] However, other signals are also observed, corresponding to a side reaction presumably inducing the cleavage of the PNP linkage. This side reaction could be due to a reaction with CF_3SO_3H, which could be generated by an H/Me exchange on some ammonium groups. A way of avoiding this problem could be to deprotonate the ammonium groups before using CF_3SO_3Me. The neutral compound **9b-[G'_1]** is easily obtained from **8b-[G'_1]**, using NaOH in water. However, it was extremely difficult to eliminate the last traces of water, which should also generate triflic acid, thus we synthesised **9b-[G'_1]** by another way, the direct reaction of *N*,*N*-diethylethylenediamine with **3b-[G_1]** in the presence of potassium carbonate (Scheme 3); 3 equiv. of CF_3SO_3Me are then added to **9b-[G'_1]**, in order to alkylate both the PNPS and the NEt_2 groups. However, a side and unidentified product appears along with the expected product, thus we decided to avoid the presence of amine in the molecule, and to directly treat **3b-[G_1]** with CF_3SO_3Me.

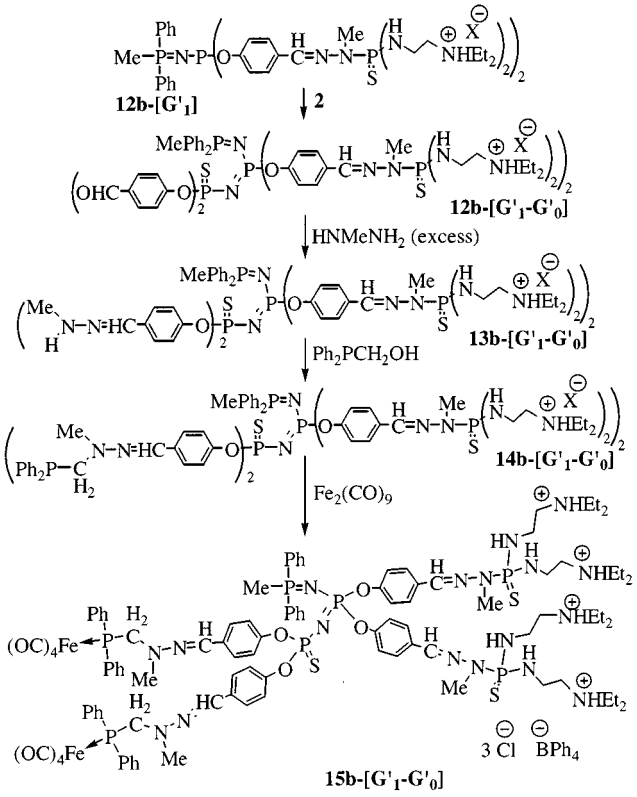
Addition of methyl triflate to **3b-[G_1]** cleanly affords compound **10b-[G_1]**, characterised in the ^{31}P NMR spectrum by the presence of two doublets (AB system) at $\delta = 23.8$ and 24.1 ($^2J_{PP} = 18.2$ Hz) for the PNPSMe linkage and one



Scheme 4

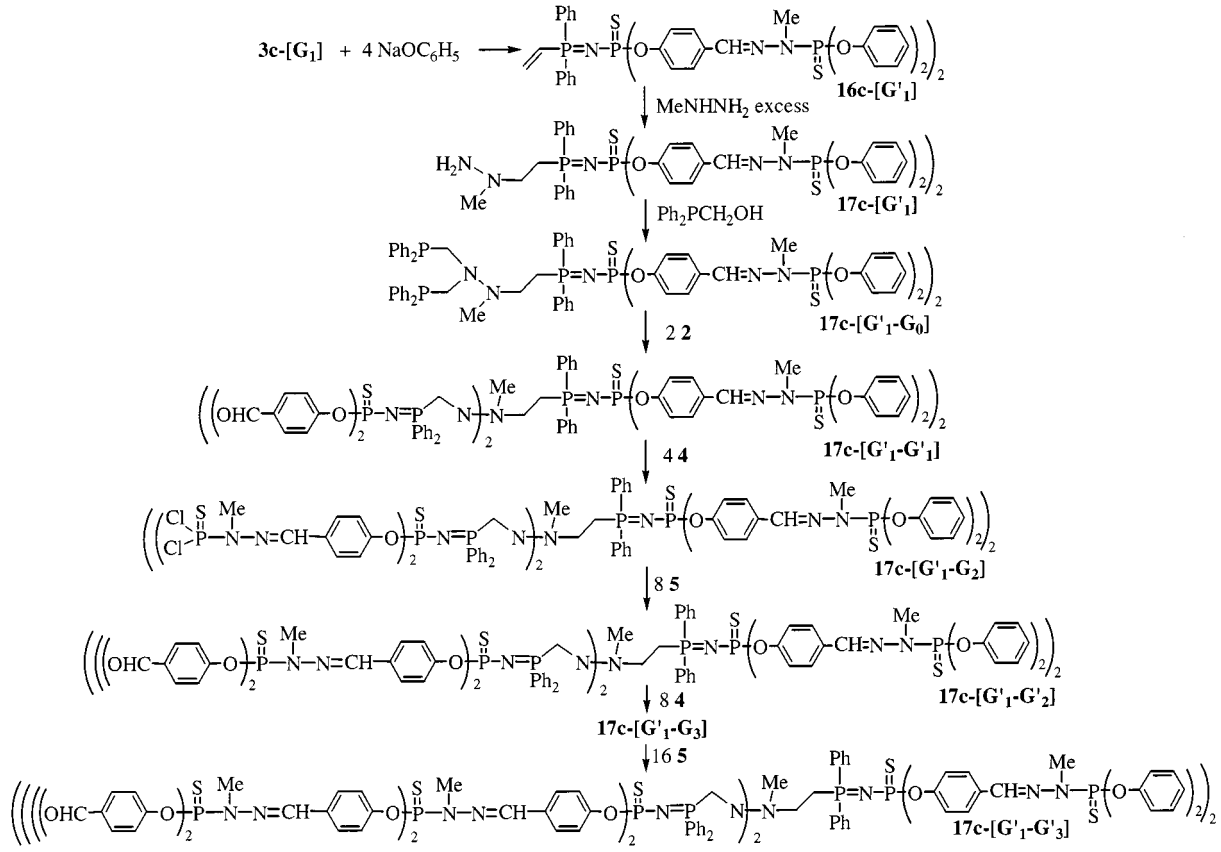
singlet at δ = 62.8 for the $P(S)Cl_2$ groups (Scheme 4). The second step of the desulfurization process, i.e. the reaction with $P(NMe_2)_3$ cannot be used with **10b-[G$_1$]**. Indeed, exchange reactions can take place, leading to partial or total substitution of the P−Cl bonds, with formation of $P(S)Cl(NMe_2)$ or $P(S)(NMe_2)_2$ end groups; thus, the P−Cl functions must be substituted first. The reaction of **10b-[G$_1$]** with *N*,*N*-diethylethylenediamine did not appear desirable, since it could also generate triflic acid. Thus, we decided first to proceed to an anion exchange with $NaBPh_4$. Elimination of CF_3SO_3Na allowed us to isolate **11b-[G$_1$]**. The anion exchange induces a broadening of the AB system, which gives only a signal having the appearance of a singlet for **11b-[G$_1$]**. No signal is detectable in the ^{19}F NMR spectrum, confirming the total exchange. Compound **11b-[G$_1$]** reacts cleanly with *N*,*N*-diethylenediamine to afford **11b-[G′$_1$]** (Scheme 4). The full substitution of the chlorine atoms is characterised in the ^{31}P NMR spectrum by the deshielding of the signal corresponding to the end groups from δ = 62.7 for **11b-[G$_1$]** to δ = 68.5 for **11b-[G′$_1$]**.

Reaction of **11b-[G′$_1$]** with $P(NMe_2)_3$ induces the expected desulfurization, as shown by the appearance of two doublets for the core at δ = 144.2 (P:) and δ = 10.3 (P=N) ($^2J_{PP}$ = 31.6 Hz) for **12b-[G′$_1$]**. This compound was not fully characterised due to its high sensitivity toward oxidation, but directly treated with the azide **2** (Scheme 5). The formation of the P=N−P=N−P=S linkage of compound **12b-[G′$_1$-G′$_0$]** is characterised by the appearance of two doublets at δ = 18.4 (P=N, $^2J_{PP}$ = 26 Hz) and δ = 47.5 (P=S, $^2J_{PP}$ = 58.4 Hz), and a doublet of doublet at δ = −9.6 (central P=N). The ^1H NMR spectrum shows the remaining end groups are in the cationic form. Indeed, all CH_2 and CH_3N groups form a multiplet for **12b-[G′$_1$-G′$_0$]**, as well as for the other compounds having a cationic form (see data for **8b-[G′$_1$]** and **11b-[G′$_1$]**), whereas the neutral form gives a quadruplet at δ = 3.39 for the NCH_2CH_3 groups, clearly distinguishable and separated from all the other CH_2 and CH_3N groups[32] (see data for **9b-[G′$_1$]**). Concerning the nature of the anionic part of **12b-[G′$_1$-G′$_0$]** (only Cl or a mixture of Cl and BPh_4), one can say that all the signals attributed to BPh_4 in the ^{13}C NMR spectra of **11b-[G$_1$]** and **11b-[G′$_1$]** are also detected for **12b-[G′$_1$-G′$_0$]**, and that the integration of the ^1H NMR spectrum indicates the presence of 1 equiv. of BPh_4. At least 95% of the initial quantity of BPh_4 remains in **12b-[G′$_1$-G′$_0$]**, thus its anionic part is constituted by 3 Cl^- and 1 BPh_4^-.



Scheme 5

Compound **12b-[G′$_1$-G′$_0$]** possesses two aldehyde groups that could allow the growing of the second dendritic wedge, using for instance the phosphorus hydrazide **4** followed by hydroxybenzaldehyde sodium salt (**5**). However, we decided to try the grafting of phosphanes. The first step in this process is the condensation of the aldehyde groups with methylhydrazine, leading to **13b-[G′$_1$-G′$_0$]**, characterised by the disappearance of the aldehyde signals in the ^1H and ^{13}C NMR and IR spectra. The grafting of phosphanes is carried out with Ph_2PCH_2OH, affording **14b-[G′$_1$-G′$_0$]**. Then, the phosphanes are readily complexed, in order to avoid any oxidation problem. As an example, the complexation was carried out with $Fe_2(CO)_9$ (Scheme 5). The formation of the complex **15b-[G′$_1$-G′$_0$]** is characterised by the large deshielding of the signal corresponding to the phosphane from δ = −22.9 for **14b-[G′$_1$-G′$_0$]** to δ = 67.5 for **15b-[G′$_1$-G′$_0$]**. The grafting of phosphanes at the previous step is confirmed by the deshielding of the signal of the methyl



Scheme 6

groups in the ^{13}C NMR spectrum from $\delta = 34.0$ for CH_3NH in **13b-[G′$_1$-G′$_0$]** to $\delta = 39.0$ for CH_3NCH_2 in **15b-[G′$_1$-G′$_0$]**.

Compound **15b-[G′$_1$-G′$_0$]** is a rather small compound, but it possesses all the characteristics of a di-block dendrimer, and the methodology developed here should be applicable to the synthesis of larger compounds. However, the full process is rather lengthy, thus we tried to find a more rapid method. Compound **3c-[G$_1$]** should offer such opportunity, since we have shown that a vinyl group linked to a P=N−P=S moiety reacts with primary and secondary amines under mild conditions.[17−18] However, amines also react with the P−Cl groups, so such reactions are inapplicable to **3c-[G$_1$]**. In order to avoid any problem in the future reactions, we decided to react **3c-[G$_1$]** with sodium phenolate, which gives neutral and poorly reactive end groups (Scheme 6). The reaction of **16c-[G′$_1$]** thus obtained with methylhydrazine leads to compound **17c-[G′$_1$]** by a Michael-type addition of the NHMe moieties on the vinyl group. The phosphanes are then grafted using again Ph_2PCH_2OH, leading to **17c-[G′$_1$-G$_0$]**. This compound is another example of a small di-block dendrimer possessing phosphanes in one part of the molecule.

It would be interesting to complex these phosphanes with transition metal ions, but we decided to use them to grow the second part of the di-block dendrimer by a Staudinger reaction with the azide **2**. The formation of **17c-[G′$_1$-G′$_1$]** is characterised in the ^{31}P NMR spectrum by the presence of two sets of two doublets corresponding to two types of P=N−P=S linkages in a 2:1 ratio at $\delta = 14.0$ and 50.0 ($^2J_{PP}$ = 26.0 Hz) for the NCH_2P=N−P=S groups and at $\delta = 16.7$ and 50.2 ($^2J_{PP}$ = 33.9 Hz) for the CH_2CH_2P=N−P=S group. The growing of the molecule is then carried out without any problem, using alternatively the phosphorus hydrazide **4** and hydroxybenzaldehyde sodium salt (**5**) (Scheme 6). The synthesis was stopped after obtaining dendrimer **17c-[G′$_1$-G′$_3$]** (Figure 1), but it could have been continued to higher generations. The presence of aldehyde groups on part of the surface of **17c-[G′$_1$-G′$_3$]** will open the way to a versatile reactivity, including for instance the grafting of phosphanyl groups, using the method already described in Scheme 2.

Conclusion

We have demonstrated that the growing of a second dendritic wedge from the core of a first dendron is an alternative route for the obtaining di-block dendrimers. This approach is less straightforward than the direct coupling of two dendrons by their cores, but it offers the possibility to have a variety of functional groups located in different areas. Even if several of the molecules presented in this paper are relatively small, we have shown that the methodologies developed here can also be applied to larger com-

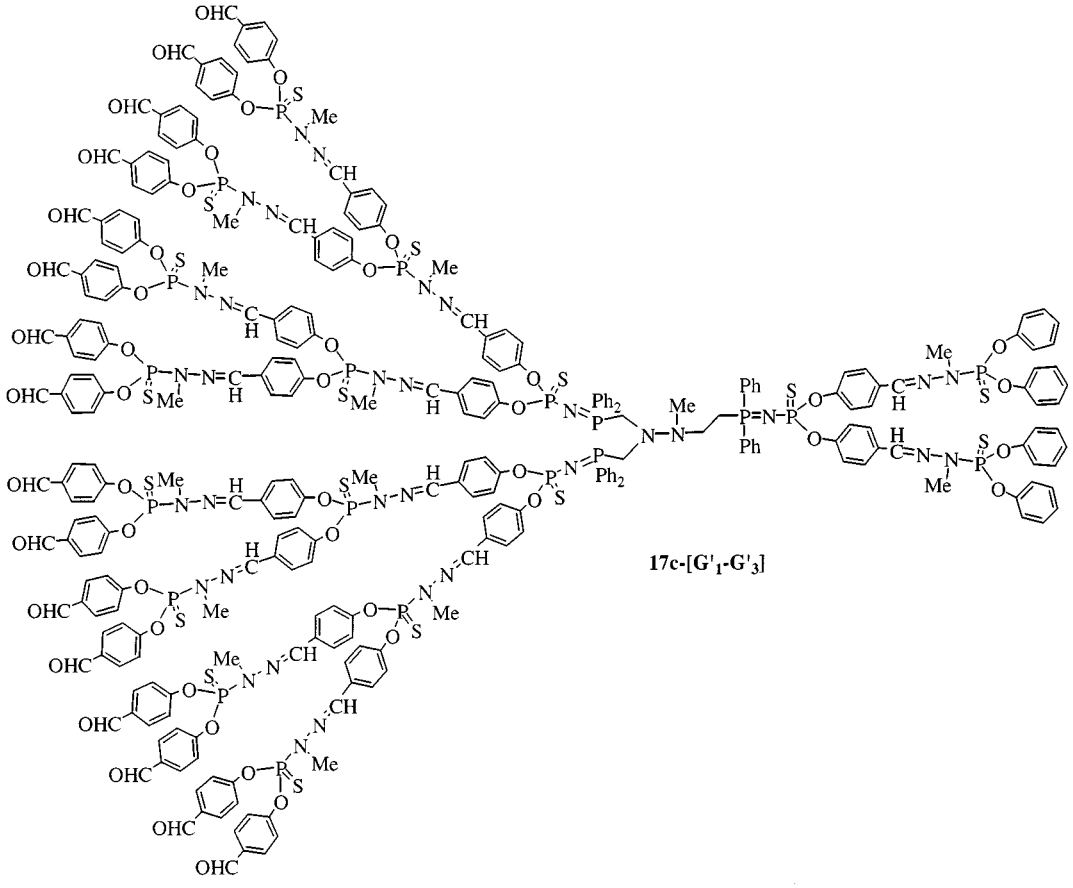


Figure 1. The di-block dendrimer **17c-[G′$_1$-G′$_3$]**

pounds, as indicated by the synthesis of the unsymmetrical third generation dendrimer **17c-[G′$_1$-G′$_3$]**. The presence of two types of end groups should provide new tools for chemistry. The presence of ammonium salts on one side and phosphanes on the other side, i.e. compounds such as **14b-[G′$_1$-G′$_0$]** should lead to biphasic dendritic catalysts. Furthermore, the presence of aldehydes on one side and of other functional groups on the other side of a di-block dendrimer should lead to covalent tailored material surface modifications as already shown with more classical dendrimers.[30−31]

Experimental Section

General Remarks: All reactions except those done in water, were carried out under argon, in the absence of air, using standard Schlenk techniques and vacuum-line manipulations. All solvents were dried and distilled before use. Solvents were also degassed when phosphanes were used. − Perkin−Elmer 1725X was used for FT-IR. − NMR spectra were recorded with Bruker AC80, AC200, or AM250 for ^{1}H, ^{13}C, ^{31}P and ^{19}F NMR, with $SiMe_4$, H_3PO_4, and CF_3CO_2H as references, respectively. The attribution of ^{13}C NMR signals was done using Jmod, two-dimensional HMBC and HMQC, broad-band or CW ^{31}P decoupling experiments when necessary. The numbering scheme used for NMR is depicted Figure 2. − Compounds **1a**,[41] **2**,[40] **3c-[G′$_0$]** and **3c-[G$_1$]**[17] were synthesised according to published procedures.

Synthesis of 3a-[G′$_0$] and 3b-[G′$_0$]: A solution of azide **2** (1.911 g, 5.5 mmol) in THF (20 mL) was added to a solution of phosphane **1a** or **1b** (5 mmol) in THF (10 mL). The reaction induces a strong evolution of N_2. The reaction mixture was stirred for 6 h (**1a**) or 1 h (**1b**) at room temperature, then concentrated to dryness. The residue was dissolved in a minimum amount of CH_2Cl_2 (**1a**) or THF (**1b**) and precipitated with pentane (twice). Compound **3a-[G′$_0$]** was isolated as a white powder (2.482 g, 76% yield), and **3b-[G′$_0$]** was isolated as a pale beige oil (2.031 g, 78% yield).

3a-[G′$_0$]: ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 14.6 (d, $^2J_{PP}$ = 30.6 Hz, P_{00}), 50.2 (d, $^2J_{PP}$ = 30.6 Hz, P_0). − ^{1}H NMR ($CDCl_3$): δ = 4.03 (m, 2 H, CH_2), 4.11 (m, 2 H, CH_2), 5.82 (s, 1 H, OCHO), 7.28 (d, $^3J_{HH}$ = 8.5 Hz, 4 H, $C_0{}^2$H), 7.24−7.69 (m, 14 H, C_6H_5, C_6H_4), 7.77 (d, $^3J_{HH}$ = 8.5 Hz, 4 H, $C_0{}^3$H), 9.92 (s, 2 H, CHO). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 65.5 (s, CH_2), 102.7 (s, OCHO), 122.1 (d, $^3J_{CP}$ = 5 Hz, $C_0{}^2$), 126.8 (d, $^3J_{CP}$ = 14 Hz, $C^{3\prime}$), 128.0 (dd, $^1J_{CP}$ = 106 Hz, $^3J_{CP}$ = 4 Hz, $C_0{}^i$), 128. 8 (d, $^3J_{CP}$ = 14 Hz, $C_0{}^m$), 129.2 (br. d, $^1J_{CP}$ = 106 Hz, $C^{1\prime}$), 131.2 (s, $C_0{}^3$), 132.6 (s, $C_0{}^4$), 132.7 (d, $^2J_{CP}$ = 12 Hz, $C_0{}^o$), 132.9 (d, $^2J_{CP}$ = 11 Hz, $C^{2\prime}$), 132.9 (s, $C_0{}^p$), 142.9 (s, $C^{4\prime}$), 156.9 (d, $^2J_{CP}$ = 10 Hz, $C_0{}^1$), 191.1 (s, CHO). − IR (KBr): 1702 cm^{-1} ($\nu_{C=O}$). − $C_{35}H_{29}NO_6P_2S$ (653.63): calcd. C 64.32, H 4.47, N 2.14; found C 64.25, H 4.50, N 2.09.

3b-[G′$_0$]: ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 16.8 (d, $^2J_{PP}$ = 32.2 Hz, P_{00}), 51.0 (m, $^2J_{PP}$ = 32.2 Hz, P_0). − ^{1}H NMR ($CDCl_3$): δ = 2.19 (d, $^2J_{HP}$ = 13.2 Hz, 3 H, CH_3−P), 7.25−7.69 (m, 18 H, C_6H_5,

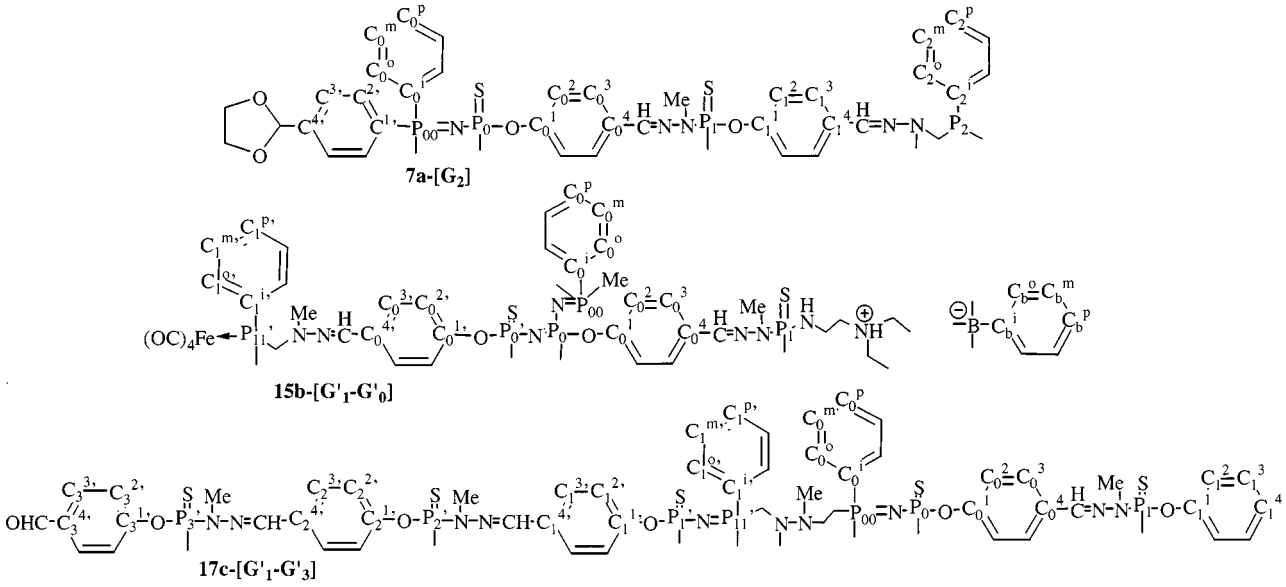

Figure 2. Numbering scheme used for NMR

C_6H_4), 9.77 (s, 2 H, CHO). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 14.4 (d, $^1J_{CP}$ = 67.4 Hz, CH_3–P), 122.0 (d, $^3J_{CP}$ = 5.9 Hz, C_0^2), 128.8 (s, C_0^3), 128.9 (d, $^3J_{CP}$ = 13.4 Hz, C_0^m), 129.7 (dd, $^1J_{CP}$ = 102.6 Hz, $^3J_{CP}$ = 6.5 Hz, C_0^i), 130.9 (d, $^2J_{CP}$ = 9.7 Hz, C_0^o), 131.2 (s, C_0^p), 132.7 (s, C_0^4), 156.8 (d, $^2J_{CP}$ = 9.9 Hz, C_0^1), 190.9 (s, CHO). – IR (KBr): 1702 cm^{-1} ($\nu_{C=O}$). – $C_{27}H_{23}NO_4P_2S$ (519.50): calcd. C 62.42, H 4.46, N 2.69; found C 62.28, H 4.41, N 2.75.

Synthesis of 3a-[G$_1$] and 3b-[G$_1$]: To a solution of compound **3a-[G′$_0$]** or **3b-[G′$_0$]** (1 mmol) in THF (20 mL) was added a 0.3 M solution of dichloro(1-methylhydrazido)thiophosphane (**4**) (2.2 mmol, slight excess). The reaction mixture was stirred overnight, then concentrated to dryness. Washing the residue twice with CH_2Cl_2/pentane afforded compounds **3a-[G$_1$]** (0.820 g, 84% yield) and **3b-[G$_1$]** (0.724 g, 86% yield) as white powders.

3a-[G$_1$]: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 13.8 (d, $^2J_{PP}$ = 30.2 Hz, P_{00}), 51.4 (d, $^2J_{PP}$ = 30.2 Hz, P_0), 63.5 (s, P_1). – ^1H NMR ($CDCl_3$): δ = 3.45 (d, $^3J_{HP}$ = 14.1 Hz, 6 H, CH_3N), 4.03 (m, 2 H, CH_2), 4.11 (m, 2 H, CH_2), 5.81 (s, 1 H, OCHO), 7.20 (dd, $^3J_{HH}$ = 8.1 Hz, $^3J_{HP}$ = 1 Hz, 4 H, C_0^2H), 7.39–7.69 (m, 16 H, C_6H_5, C_6H_4), 7.62 (d, $^3J_{HH}$ = 8.1 Hz, 4 H, C_0^3H). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 31.9 (d, $^2J_{CP}$ = 13 Hz, CH_3N), 65.5 (s, CH_2), 102.7 (s, OCHO), 122.1 (d, $^3J_{CP}$ = 6 Hz, C_0^2), 126.7 (d, $^3J_{CP}$ = 14 Hz, C$^{3\prime}$), 128.4 (dd, $^1J_{CP}$ = 106 Hz, $^3J_{CP}$ = 4 Hz, C_0^i), 128.5 (s, C_0^3), 128.8 (d, $^3J_{CP}$ = 12 Hz, C_0^m), 129.5 (br. d, $^1J_{CP}$ = 106 Hz, C$^{1\prime}$), 130.2 (s, C_0^4), 132.8 (d, $^2J_{CP}$ = 11 Hz, C_0^o), 132.8 (s, C_0^p), 132.9 (d, $^2J_{CP}$ = 12 Hz, C$^{2\prime}$), 141.5 (d, $^3J_{CP}$ = 18 Hz, CH=N), 142.6 (s, C$^{4\prime}$), 153.6 (d, $^2J_{CP}$ = 10 Hz, C_0^1). – $C_{37}H_{35}Cl_4N_5O_4P_4S_3$ (975.62): calcd. C 45.55, H 3.62, N 7.18; found C 45.47, H 3.55, N 7.21.

3b-[G$_1$]: $^{31}P\{^1H\}$ NMR ($CHCl_3$): δ = 15.5 (d, $^2J_{PP}$ = 34.6 Hz, P_{00}), 52.4 (d, $^2J_{PP}$ = 34.6 Hz, P_0), 62.1 (s, P_1). – ^1H NMR ($CDCl_3$): δ = 2.28 (d, $^2J_{HP}$ = 13.2 Hz, 3 H, CH_3–P), 3.46 (d, $^2J_{HP}$ = 14.1 Hz, 6 H, CH_3–N–P), 7.24–7.65 (m, 20 H, C_6H_5, C_6H_4, CH=N). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 14.6 (d, $^1J_{CP}$ = 68 Hz, CH_3–P), 31.8 (d, $^2J_{CP}$ = 14 Hz, CH_3–N–P), 122.0 (d, $^3J_{CP}$ = 4 Hz, C_0^2), 128.4 (s, C_0^3), 128.8 (d, $^3J_{CP}$ = 14 Hz, C_0^m), 130.2 (s, C_0^p), 131.0 (d, $^2J_{CP}$ = 12 Hz, C_0^o), 132.5 (d, $^4J_{CP}$ = 3 Hz, C_0^4), 141.3 (d, $^3J_{CP}$ = 19 Hz, CH=N), 153.5 (d, $^2J_{CP}$ = 8 Hz, C_0^1). – $C_{29}H_{29}Cl_4N_5O_2P_4S_3$ (841.48): calcd. C 41.39, H 3.47, N 8.32; found C 41.27, H 3.42, N 8.25.

Synthesis of 3a-[G′$_1$]: A solution of **3a-[G$_1$]** (0.293 g, 0.3 mmol) in THF (20 mL) was added to hydroxybenzaldehyde sodium salt (**5**) (0.181 g, 1.26 mmol, 5% excess). The resulting mixture was stirred overnight at room temperature, then centrifuged. The solution was concentrated to dryness and the residue was washed with THF/pentane. Compound **3a-[G′$_1$]** was isolated as a white powder (0.308 g, 78% yield).

3a-[G′$_1$]: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 13.8 (d, $^2J_{PP}$ = 30.0 Hz, P_{00}), 51.6 (d, $^2J_{PP}$ = 30.0 Hz, P_0), 60.8 (s, P_1). – ^1H NMR ($CDCl_3$): δ = 3.37 (d, $^3J_{HP}$ = 10.8 Hz, 6 H, CH_3N), 4.01 (m, 2 H, CH_2), 4.04 (m, 2 H, CH_2), 5.79 (s, 1 H, OCHO), 7.19 (d, $^3J_{HH}$ = 7.8 Hz, 4 H, C_0^2H), 7.38 (d, $^3J_{HH}$ = 7.9 Hz, 8 H, C_1^2H), 7.4–7.7 (m, 16 H, CH=N, C_6H_5, C_6H_4), 7.57 (d, $^3J_{HH}$ = 7.8 Hz, 4 H, C_0^3H), 7.85 (d, $^3J_{HH}$ = 7.9 Hz, 8 H, C_1^3H), 9.91 (s, 4 H, CHO). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 32.5 (d, $^2J_{CP}$ = 13 Hz, CH_3N), 65.5 (s, CH_2), 102.7 (s, OCHO), 122.0 (d, $^3J_{CP}$ = 6 Hz, C_0^2, C_1^2), 126.7 (d, $^3J_{CP}$ = 14 Hz, C$^{3\prime}$), 128.1 (s, C_0^3), 128.4 (dd, $^1J_{CP}$ = 106 Hz, $^3J_{CP}$ = 4 Hz, C_0^i), 128.8 (d, $^3J_{CP}$ = 13 Hz, C_0^m), 129.5 (br. d, $^1J_{CP}$ = 106 Hz, C$^{1\prime}$), 130.5 (s, C_0^4), 131.5 (s, C_1^3), 132.8 (d, $^2J_{CP}$ = 9 Hz, C_0^o), 132.8 (s, C_0^p), 132.9 (d, $^2J_{CP}$ = 12 Hz, C$^{2\prime}$), 133.7 (s, C_1^4), 140.3 (d, $^3J_{CP}$ = 14 Hz, CH=N), 142.7 (s, C$^{4\prime}$), 153.3 (d, $^2J_{CP}$ = 10 Hz, C_0^1), 155.2 (d, $^2J_{CP}$ = 6 Hz, C_1^1), 190.8 (s, CHO). – IR (KBr): 1702 cm^{-1} ($\nu_{C=O}$). – $C_{65}H_{55}N_5O_{12}P_4S_3$ (1318.27): calcd. C 59.22, H 4.21, N 5.31; found C 59.10, H 4.15, N 5.24.

Synthesis of 6a-[G′$_1$]: A solution of **3a-[G′$_1$]** (0.264 g, 0.2 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a strongly stirred solution of hydrazine hydrate (40 mmol, very large excess) in CH_2Cl_2 (30 mL). The resulting mixture was stirred for 2 h at room temperature. The organic phase was separated, dried with Na_2SO_4, filtered, and concentrated to dryness. The residue was washed twice with CH_2Cl_2/pentane to give **6a-[G′$_1$]** as a white powder (0.256 g, 93% yield).

6a-[G′$_1$]: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 13.8 (d, $^2J_{PP}$ = 29.0 Hz, P_{00}), 51.5 (d, $^2J_{PP}$ = 29.0 Hz, P_0), 62.4 (s, P_1). − ^1H NMR ($CDCl_3$): δ = 3.30 (d, $^3J_{HP}$ = 10.7 Hz, 6 H, CH_3N), 3.99 (m, 2 H, CH_2), 4.02 (m, 2 H, CH_2), 5.48 (br. s, 8 H, NH_2), 5.78 (s, 1 H, OCHO), 7.17 (d, $^3J_{HH}$ = 8.5 Hz, 12 H, C_0^2H, C_1^2H), 7.45 (d, $^3J_{HH}$ = 8.5 Hz, 8 H, C_1^3H), 7.4−7.7 (m, 24 H, CH=N, C_6H_5, C_6H_4). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 32.9 (d, $^2J_{CP}$ = 13 Hz, CH_3N), 65.3 (s, CH_2), 102.5 (s, OCHO), 121.5 (d, $^3J_{CP}$ = 5 Hz, C_1^2), 121.8 (d, $^3J_{CP}$ = 5 Hz, C_0^2), 126.6 (d, $^3J_{CP}$ = 13 Hz, $C^{3\prime}$), 127.0 (s, C_1^3), 127.8 (s, C_0^3), 128.2 (dd, $^1J_{CP}$ = 106 Hz, $^3J_{CP}$ = 3 Hz, C_0^i), 128.5 (d, $^3J_{CP}$ = 13 Hz, C_0^m), 130.0 (dd, $^1J_{CP}$ = 106 Hz, $^3J_{CP}$ = 4 Hz, $C^{1\prime}$), 130.7 (s, C_0^4), 132.4 (s, C_1^4), 132.6 (d, $^2J_{CP}$ = 10 Hz, C_0^o), 132.7 (s, C_0^p), 132.8 (d, $^2J_{CP}$ = 11 Hz, $C^{2\prime}$), 139.2 [d, $^3J_{CP}$ = 13 Hz, $(CH=N)_1$], 141.7 [s, $(CH=N)_2$], 142.4 (s, $C^{4\prime}$), 150.6 (d, $^2J_{CP}$ = 7 Hz, C_1^1), 152.9 (d, $^2J_{CP}$ = 9 Hz, C_0^1). − $C_{65}H_{63}N_{13}O_8P_4S_3$ (1374.4): calcd. C 56.81, H 4.62, N 13.25; found C 56.96, H 4.57, N 13.16.

Synthesis of 7a-[G$_2$]: A mixture of 1.0 mmol of paraformaldehyde and 1.0 mmol of diphenylphosphane was heated without solvent for 2 h at 120 °C in a closed reactor to afford Ph_2PCH_2OH. To this crude product was added a solution of **6a-[G′$_1$]** (0.137 g, 0.1 mmol) in THF (10 mL). The resulting mixture was stirred overnight at 80 °C, then concentrated to dryness. The residue was washed first with CH_2Cl_2/pentane, then with ether/pentane to afford **7a-[G$_2$]** as a white powder (0.219 g, 74% yield).

7a-[G$_2$]: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −25.1 (s, P_2), 13.7 (d, $^2J_{PP}$ = 29.6 Hz, P_{00}), 51.7 (d, $^2J_{PP}$ = 29.6 Hz, P_0), 63.2 (s, P_1). − ^1H NMR ($CDCl_3$): δ = 3.33 (d, $^3J_{HP}$ = 9.3 Hz, 6 H, CH_3N), 3.98 (m, 2 H, CH_2), 4.03 (m, 2 H, CH_2), 4.19 (s, 16 H, CH_2), 5.79 (s, 1 H, OCHO), 7.10−7.80 (m, 124 H, CH=N, C_6H_5, C_6H_4). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 33.0 (d, $^2J_{CP}$ = 13 Hz, CH_3N), 56.8 (d, $^1J_{CP}$ = 7 Hz, CH_2P), 65.4 (s, CH_2O), 102.6 (s, OCHO), 121.5 (d, $^3J_{CP}$ = 5 Hz, C_1^2), 121.8 (d, $^3J_{CP}$ = 5 Hz, C_0^2), 126.6 (d, $^3J_{CP}$ = 14 Hz, $C^{3\prime}$), 127.2 (s, C_0^3, C_1^3), 128.2 (dd, $^1J_{CP}$ = 106 Hz, $^3J_{CP}$ = 3 Hz, C_0^i), 128.5 (d, $^3J_{CP}$ = 13 Hz, C_0^m), 128.6 (d, $^3J_{CP}$ = 13 Hz, C_2^m), 128.9 (s, C_2^p), 129.9 (dd, $^1J_{CP}$ = 106 Hz, $^3J_{CP}$ = 4 Hz, $C^{1\prime}$), 130.7 (s, C_0^4), 131.3 (s, C_1^4), 132.6 (d, $^2J_{CP}$ = 10 Hz, C_0^o), 132.7 (s, C_0^p), 132.8 (d, $^2J_{CP}$ = 11 Hz, $C^{2\prime}$), 133.1 (d, $^2J_{CP}$ = 20 Hz, C_2^o), 133.1 [s, $(CH=N)_2$], 137.3 (d, $^1J_{CP}$ = 14 Hz, C_2^i), 139.3 [d, $^3J_{CP}$ = 13 Hz, $(CH=N)_1$], 142.5 (s, $C^{4\prime}$), 150.6 (d, $^2J_{CP}$ = 8 Hz, C_1^1), 152.9 (d, $^2J_{CP}$ = 9 Hz, C_0^1).

Synthesis of 8b-[G′$_1$]: To a solution of compound **3b-[G$_1$]** (0.500 g, 0.594 mmol) in THF (20 mL) was added dropwise a solution of *N*,*N*-diethylethylenediamine (334 μL, 2.377 mmol) in THF (20 mL). The reaction mixture was stirred for 12 h at room temperature, and a precipitate of compound **8b-[G′$_1$]** appears. The precipitate was recovered by filtration and washed twice with ether. Compound **8b-[G′$_1$]** was obtained as a white powder (0.528 g, 68% yield).

8b-[G′$_1$]: $^{31}P\{^1H\}$ NMR (THF): δ = 15.8 (d, $^2J_{PP}$ = 32 Hz, P_{00}), 52.4 (d, $^2J_{PP}$ = 32 Hz, P_0), 69.2 (s, P_1). − ^1H NMR ($CDCl_3$): δ = 1.29 (t, $^3J_{HH}$ = 7 Hz, 24 H, CH_2-CH_3), 2.27 (d, $^2J_{HP}$ = 13.2 Hz, 3 H, CH_3-P), 3.16 (m, 6 H, CH_3-N), 3.27 (br. s, 16 H, CH_2-CH_2), 3.44 (q, $^3J_{HH}$ = 7 Hz, 16 H, CH_2-CH_3), 5.31 (d, $^2J_{HP}$ = 5.5 Hz, 4 H, NH), 7.13−7.70 (m, 20 H, C_6H_5, C_6H_4, CH=N), 9.18 (br. s, 4 H, NH^+). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 8.7 (s, CH_2-CH_3), 14.7 (d, $^2J_{CP}$ = 68 Hz, CH_3-P), 32.2 (d, $^2J_{CP}$ = 11 Hz, CH_3-N), 36.5 (s, CH_2-N^+), 47.4 (s, CH_2-CH_3), 52.9 (s, $NH-CH_2$), 121.7 (s, C_0^2), 127.7 (s, C_0^3), 128.9 (d, $^3J_{CP}$ = 12 Hz, C_0^m), 130.9 (d, $^2J_{CP}$ = 11 Hz, C_0^o), 131.7 (s, C_0^p), 132.5 (s, C_0^4), 137.3 (br. s, CH=N), 152.3 (d, $^2J_{CP}$ = 9 Hz, C_0^1). − $C_{53}H_{93}Cl_4N_{13}O_2P_4S_3$ (1306.3): calcd. C 48.73, H 7.17, N 13.93; found C 48.65, H 7.14, N 13.89.

Synthesis of 9b-[G′$_1$]: To a solution of compound **3b-[G$_1$]** (0.400 g, 0.473 mmol) and potassium carbonate (0.263 g, 1.9 mmol) in CH_2Cl_2 (20 mL), was added *N*,*N*-diethylethylenediamine (267 μL, 1.9 mmol). The reaction mixture was stirred for 6 h at room temperature, then centrifuged (10000 rpm) and filtered. The resulting solution was concentrated to dryness to give compound **9b-[G′$_1$]** as a white powder after two washings with ether (0.423 g, 77% yield).

9b-[G′$_1$]: $^{31}P\{^1H\}$ NMR (CH_2Cl_2): δ = 16.2 (d, $^2J_{PP}$ = 31 Hz, P_{00}), 52.7 (d, $^2J_{PP}$ = 31 Hz, P_0), 68.1 (s, P_1). − ^1H NMR ($CDCl_3$): δ = 1.25 (t, $^3J_{HH}$ = 6.9 Hz, 24 H, CH_2-CH_3), 2.21 (d, $^2J_{HP}$ = 13.2 Hz, 3 H, CH_3-P), 3.08 (m, 6 H, CH_3-N), 3.19 (br. s, 16 H, CH_2-CH_2), 3.39 (q, $^3J_{HH}$ = 6.9 Hz, 16 H, CH_2-CH_3), 5.21 (d, $^2J_{HP}$ = 5.4 Hz, 4 H, NH), 7.10−7.64 (m, 20 H, C_6H_5, C_6H_4, CH=N). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 8.7 (s, CH_2-CH_3), 14.7 (d, $^1J_{CP}$ = 68 Hz, CH_3-P), 32.1 (d, $^2J_{CP}$ = 11 Hz, CH_3-N-P), 36.6 (s, CH_2-N), 47.4 (s, CH_2-CH_3), 53.1 (d, $^2J_{CP}$ = 6 Hz, $NH-CH_2$), 121.7 (s, C_0^2), 127.7 (s, C_0^3), 128.9 (d, $^3J_{CP}$ = 13 Hz, C_0^m), 130.9 (d, $^2J_{CP}$ = 10 Hz, C_0^o), 131.7 (s, C_0^p), 132.5 (s, C_0^4), 137.3 (d, $^3J_{CP}$ = 13 Hz, CH=N), 152.4 (d, $^2J_{CP}$ = 8 Hz, C_0^1). − $C_{53}H_{89}N_{13}O_2P_4S_3$ (1160.5): calcd. Versatile Behavior of β-Heterosubstituted Zirconaindene Complexes: M−Cl Bond Activation (M = Si, P, Au Fragments)

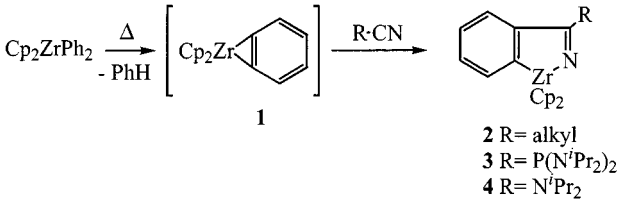
Krzysztof Owsianik,[a] Maria Zablocka,[a] Alain Igau,[b] Jean-Pierre Majoral,*[b] and Aleksandra Skowronska*[a]

Keywords: Addition / Bond activation / Gold / Phosphorus / Zirconium

A new way of M–Cl bond activation (M = Si, P, Au fragments) is reported. It consists on the 1,2-addition of M–Cl containing species on the Zr–N bond of azazirconaindene complexes. Unprecedented imino gold complexes incorporating two electron-deficient metallic centers (Au, Zr) have been prepared.

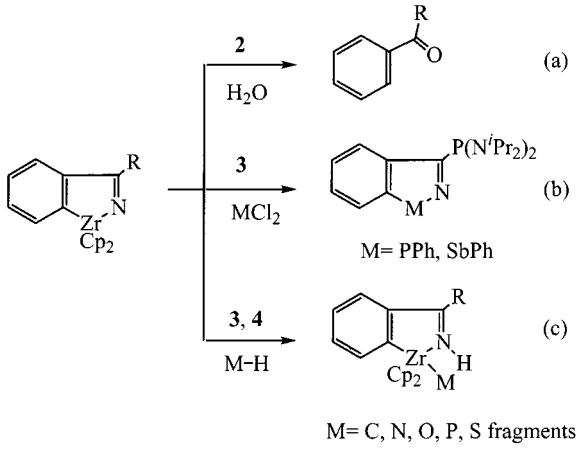
Introduction

The organic and organometallic chemistry of neutral zirconium derivatives is blossoming probably because of the new perspectives zirconium reagents bring in a number of research areas.[1] Among the zirconium synthons generally used, benzyne zirconocene **1** (prepared in situ by photolysis or thermolysis of diphenylzirconocene) is of particular interest because of its high reactivity towards chalcogens, inorganic unsaturated species, alkenes, alkynes, etc.[2] Reactions generally proceed with insertion of the organic or inorganic fragment into Zr−C bonds of the arynezirconocene complex. It is also known that thermolysis of diphenylzirconocene in the presence of nitriles generates azazirconaindenes **2**−**4**,[2,3] (Scheme 1).



Scheme 1. Insertion of nitriles into a Zr−C bond of benzynezirconocene

These metallacycles are versatile tools allowing the development of new strategies of synthesis of useful linear or heterocyclic reagents and ligands. For example, hydrolysis of azazirconaindenes **2** produces ketones in good to excellent yields[2] [Scheme 2, reaction (a)]. Moreover exchange reactions involving **3** and various dihalogenated species allow the preparation of new heterocycles incorporating



Scheme 2. Reactivity of β-substituted zirconaindenes

phosphorus or antimony, and nitrogen[3] [Scheme 2, reaction (b)]. Furthermore, azazirconaindenes act as unusual bases for the deprotonation of several M−H bonds [Scheme 2, reaction (c)]. However the chemical behavior of these complexes depends on the nature of the C-imino substituent. Indeed stable azazirconacyclopentene-substituted phosphanes **3** or amines **4** {R = -P[N(iPr)2]2, -P[N(Cy)2]2, -N(iPr)2} when reacted with acetylenic systems, malonitrile derivatives, vinyl acetate, diazo compounds, etc., allow sp^2-, and sp^3-C−H bond activations.[4,5] Similarly, activation of N−H, O−H, P−H, S−H bonds easily occurs in very mild conditions when the same complexes **3**−**4** are treated with aromatic amines, alcohols, phenols, phosphonates or thiols[4] [Scheme 2, reaction (c)].

In marked contrast, azazirconaindenes **2** (R = alkyl group) do not react with derivatives incorporating C−H or M−H bonds. Therefore, the basicity of the endocyclic imino nitrogen atom appears to be the driving force in all these M−H bond activations.

The halophilicity of zirconium is also the driving force for many reactions involving zirconium-containing species, but, as illustrated above [Scheme 2, reaction (b)], the reactions generally proceed with Zr−X bond cleavage (X = C, N...) and loss of Cp_2ZrCl_2.

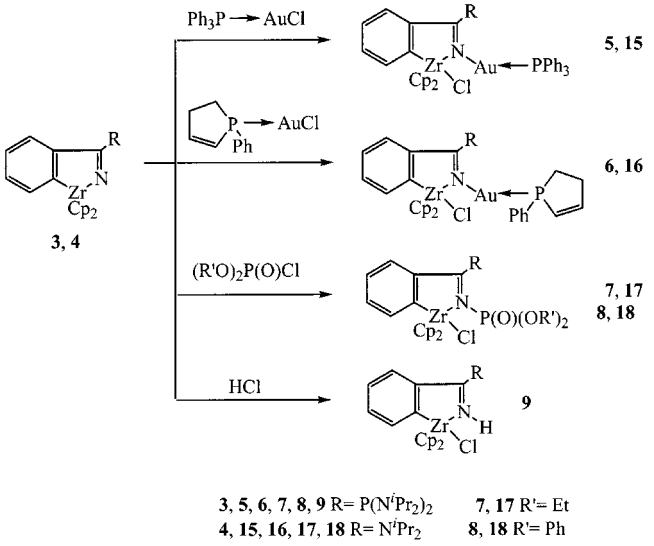
We wish to report here a new facet of the reactivity of azazirconaindene-substituted phosphanes **3** or amines **4**: activation of M−Cl bonds (M = Si, P, Au, H) involving formal 1,2-addition of halogenated compounds to the Zr−N bond of **3** or **4**. These reactions take place without cleavage of the Zr−N and Zr−C bonds, and lead to unprecedented cyclic mono- or bimetallic complexes.

Results and Discussion

Treatment of the azazirconaindene-substituted phosphane **3** with the gold complex $Ph_3P\rightarrow AuCl$ in THF at 0 °C for 30 min. leads to the formation of the zirconium-gold complex **5** in 73% isolated yield (Scheme 3). The reaction can be monitored by ^{31}P NMR spectroscopy which shows the disappearance of the singlets due to **3** (δ = 45.0) and $Ph_3P\rightarrow AuCl$ (δ = 32.5) and the growth of two doublets at δ = 86.0 [$P(N^iPr_2)_2$] and δ = 44.0 (Ph_3P) with $^4J_{PP}$ = 4.5 Hz. If the same reaction is performed with the phospholene gold complex (δ = 40.6), the azazirconaindene gold complex **6** is formed in 89% yield {δ = 86.8 [$P(N^iPr_2)_2$] and 52.9 (Ph−P), $^4J_{PP} < 1$ Hz}. ^1H and ^{13}C NMR and IR spectroscopic data are in agreement with the proposed structures for **5** and **6**, which therefore come from a unique 1,2-addition of the Au−Cl bond to the zirconium−nitrogen bond of the starting zirconaindene **3**.

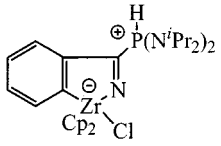
Such a 1,2-addition can be performed with chlorophosphates $(R'O)_2P(O)Cl$. Insertion of the P−Cl bond of diethoxychlorophosphate or diphenoxychlorophosphate takes place at room temperature, leading to the *N*-aminophosphate, C-phosphanyl-disubstituted azazirconaindenes **7** and **8**, respectively. ^{31}P NMR spectroscopy appears to be the tool of choice to establish the structure of **7** and **8**. Two doublets {**7:** δ = 45.4 [$P(N^iPr_2)_2$], 42.0 [$(O)P(OEt)_2$], J_{PP} = 15.8 Hz; **8:** δ = 45.0 [$P(N^iPr_2)_2$], 50.3 [$(O)P(OPh)_2$], J_{PP} = 17.1 Hz}



Scheme 3. 1,2-Addition of halogenated compounds to the Zr−N bond of β-heterosubstituted zirconaindenes

were detected strongly suggesting the formation of the $(N^iPr_2)_2P-C=N-P(O)(OEt)_2$ and $(N^iPr_2)_2P-C=N-P(O)(OPh)_2$ imino fragments, respectively.

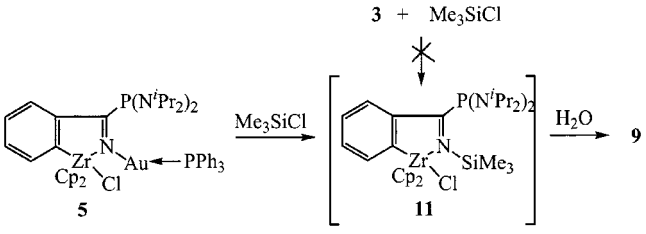
A similar 1,2-addition can be observed when hydrogen chloride (1 M diethyl ether solution) is added to a toluene solution of **3**. The 18-electron zirconium complex **9** is formed as the unique product of the reaction and was isolated in 92% yield after workup. Monitoring the reaction by ^{31}P and ^1H NMR spectroscopy did not show any intermediate or by-product such as, for example, the zwitterion **10**, which might be generated by protonation of the phosphanyl group. It should be noted that a complex similar to **9** was formed, along with other unidentified products, during an unexpected intramolecular alkylation involving the reaction of the benzyne zirconocene **1** with $Br(CH_2)_3CN$.[2]



10

Interestingly, complex **9** can be also formed by different strategies: i) cleavage of the N−M bond (M = Au, P fragments) of the 18-electron azazirconaindenes **5** or **7**, or ii) cleavage of the Zr−M bond (M = P, O) of the zirconaindenes **13** and **14**.

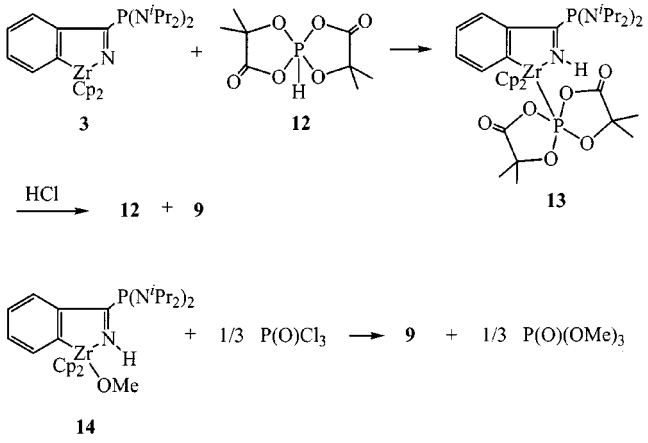
The first strategy (Scheme 4) can be illustrated as follows: addition of chlorotrimethylsilane to the gold complex **5** leads to the formation of $Ph_3P\rightarrow AuCl$ and to the unstable azazirconaindene **11** ($\delta^{31}P$ = 61) which, during workup, is transformed into the corresponding NH derivative **9**. It is noteworthy that Si−Cl bond activation is not observed when the 16-electron zirconaindene **3** is reacted directly with chlorotrimethylsilane: no traces of complex **11** (or **9**) are detected in this case.



Scheme 4. Reactivity of the β-phosphanyl-substituted zirconaindene **5**

The second strategy implies the direct cleavage of Zr−M bonds with hydrogen chloride or with halogenated phosphane oxide. A phosphoranide-chloride anion exchange with $Zr-P^V$ bond cleavage is observed when the still unique, stable zirconaspirophosphorane **13** (prepared in high yield from the oxidative addition of the P−H spirophosphorane **12** to the azazirconaindene **3**), is treated with hydrogen chloride: the spirophosphorane **12** and the com-

plex **9** (Scheme 5) are the only phosphorus species which can be detected by ^{31}P NMR spectroscopy.



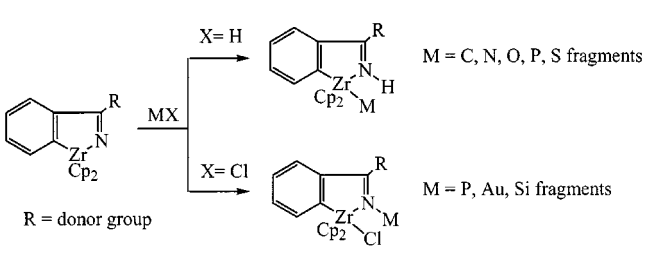
Scheme 5. Synthesis of the β-phosphanyl-substituted zirconaindene **9**

Similarly, the Zr−O bond of the complex **14**,[4] obtained by adding methanol to **3**, can be easily cleaved with trichlorophosphane oxide. The use of 1/3 equiv. of $P(O)Cl_3$ per equivalent of **14** allows us to form **9** and trimethoxyphosphane oxide quantitatively (Scheme 5).

Therefore the 16 electron azazirconaindene-substituted phosphane **3** easily reacts with a variety of halogenated species and is an useful starting reagent for the formation of a number of 18-electron N- and C-disubstituted azazirconaindenes. The corresponding amine **4** presents the same chemical behavior towards gold(I) chloride and chlorophosphates. Thus, complexes **15**−**18** were isolated and fully characterized (Scheme 3).

Conclusion

The versatile behavior of zirconaindene complexes was fully demonstrated. If all the reactions involving these derivatives proceed by a formal 1,2-addition of M−H or M−X reagents to the Zr−N intracyclic bond, the manner of the addition differs dramatically from M−X to M−H species: metallation or phosphorylation at the imino nitrogen atom occurs when halogenated reagents are reacted with zirconaindenes, while protonation takes place with P−H spirophosphorane (Scheme 6). Protonation at nitrogen is also observed with hydrogen chloride. To the best of our knowledge, the gold complexes **5**, **6**, **15**, **16** are the first



Scheme 6. Versatile behavior of the β-heterosubstituted zirconaindene towards MX (X = Cl, H) derivatives

examples of *N*-imino gold complexes incorporating two electron-deficient metallic centers (Au, Zr). Studies aimed at the generalization of the reactions depicted in Scheme 1 and concerning the use of all these new complexes in organic synthesis is under active investigation.

Experimental Section

General: All reactions were carried out in the absence of air, under argon, using standard Schlenk techniques and vacuum-line manipulations. All solvents were dried, degassed and distilled before use. A Perkin−Elmer 1725X spectrometer was used for FT-IR. NMR spectra were recorded on Bruker AC80, AC200, or AM250 spectrometers for ^{1}H, ^{13}C and ^{31}P NMR spectroscopy, with $SiMe_4$ (^{1}H, ^{13}C) and H_3PO_4 (^{31}P) as references. The assignment of the ^{13}C NMR signals was done using Jmod, two dimensional HMBC and HMQC, broad band or CW ^{31}P decoupling experiments when necessary.

Compound 5: To a solution of **3** (0.232 g, 0.418 mmol) in THF (5 mL) at room temperature was added triphenylphosphanegold(I) chloride (0.207 g, 0.418 mmol solution in 5 mL of THF). The mixture was stirred at room temperature for 15 min. and then evaporated to dryness. The resulting solid residue was extracted with pentane (20 mL) and filtered. The volatiles were removed from the solution to give **5** as a yellow solid in 73% yield (0.321 g). − IR (KBr): $\tilde{\nu}$ = 1579 cm^{-1} ($\nu_{C=N}$). − ^{1}H NMR (CD_2Cl_2): δ = 0.98 (d, J_{HH} = 6.0 Hz, 6 H, CH_3), 1.12 (d, J_{HH} = 6.0 Hz, 6 H, CH_3), 1.22 (d, J_{HH} = 5.9 Hz, 6 H, CH_3), 1.32 (d, J_{HH} = 5.9 Hz, 3 H, CH_3), 1.36 (d, J_{HH} = 6.0 Hz, 3 H, CH_3), 3.35 (sept, J_{HH} = 6.1 Hz, 4 H, NCH), 6.00 (s, 10 H, CH_{Cp}), 7.02−7.66 (m, 19 H, CH_{arom}). − $^{13}C\{^{1}H\}$ NMR (CD_2Cl_2): δ = 24.5 (d, J_{CP} = 5.5 Hz, CH_3), 25.0 (d, J_{CP} = 5.3 Hz, CH_3), 49.1 (d, J_{CP} = 11.4 Hz, NCH), 49.3 (d, J_{CP} = 12.9 Hz, NCH), 49.7 (d, J_{CP} = 11.9 Hz, NCH), 110.9 (s, CH_{Cp}), 124.9 (s, CH_{arom}), 125.8 (d, J_{CP} = 4.4 Hz, CH_{arom}), 126.7 (d, J_{CP} = 5.9 Hz, CH_{arom}), 128.9 (d, J_{CP} = 10.3 Hz, CH_{arom}), 131.0 (s, CH_{arom}), 131.7 (d, J_{CP} = 48.4 Hz, i-Ph), 133.9 (d, J_{CP} = 16.5 Hz, CH_{arom}), 134.4 (d, J_{CP} = 13.8 Hz, CH_{arom}), 139.3 (d, J_{CP} = 7.8 Hz, CH_{arom}), 154.0 (d, J_{CP} = 29.7 Hz, ZrC*C*), 168.8 (d, J_{CP} = 20.0 Hz, ZrC), 198.9 (d, J_{CP} = 3.1 Hz, J_{CP} = 13.2 Hz, PC=N). − $^{31}P\{^{1}H\}$ NMR (CD_2Cl_2): δ = 44.0 (d, J_{PP} = 5.8 Hz, PPh_3), 86.0 [d, J_{PP} = 5.8 Hz, ($iPr_2N)_2P$]. − $C_{47}H_{57}AuClN_3P_2Zr$ (1049.57): calcd. C 53.78, H 5.47; found C 53.89, H 5.54.

Compound 6: To a solution of **3** (0.270 g, 0.486 mmol) in THF (7 mL) at 0 °C was added dihydrophospholegold (I) chloride (0.191 g, 0.486 mmol, solution in 5 mL of THF). The mixture was stirred at room temperature for 0.5 h and then evaporated to dryness. The resulting solid residue was extracted with pentane and filtered. The volatiles were removed from the solution to give **6** as a yellow-brown solid in 89% yield (0.410 g). − IR (KBr): $\tilde{\nu}$ = 1572 cm^{-1} ($\nu_{C=N}$). − ^{1}H NMR (CD_2Cl_2): 0.80−1.52 (m, 24 H, CH_3), 2.34 (m, 1 H, CH_2), 2.92 (m, 2 H, CH_2), 3.28 (m, 4 H, NCH), 3.68 (m, 1 H, CH_2), 5.98 (s, 5 H, CH_{Cp}), 6.00 (s, 5 H, CH_{Cp}), 6.83 (m, 1 H, CH=CH), 7.10 (m, 1 H, CH=CH), 7.11−7.90 (m, 9 H, CH_{arom}),. − $^{13}C\{^{1}H\}$ (CD_2Cl_2): δ = 24.6 (d, J_{CP} = 5.4 Hz, CH_3), 25.1 (d, J_{CP} = 5.7 Hz, CH_3), 27.0 (d, J_{CP} = 32.6 Hz, CH_2), 33.8 (s, PCH_2), 49.7 (d, J_{CP} = 10.8 Hz, NCH), 110.8 (s, CH_{Cp}), 124.5 (s, CH_{arom}), 124.7 (d, J_{CP} = 40.4 Hz, CH_{arom}), 125.8 (s, CH_{arom}), 126.4 (d, J_{CP} = 5.8 Hz, CH_{arom}), 128.8 (d, J_{CP} = 9.9 Hz, CH_{arom}), 131.1 (s, CH_{arom}), 132.9 (d, J_{CP} = 13.9 Hz, CH_{arom}), 139.1 (d, J_{CP} = 8.4 Hz, CH_{arom}), 148.9 (d, J_{CP} = 8.7 Hz, CH_{arom}), 154.4 (d, J_{CP} = 22.8 Hz, ZrCC), 168.8 (d, J_{CP} = 18.0 Hz, ZrC), 198.0 (dd, J_{CP} = 4.1 Hz, J_{CP} = 11.3 Hz, PC=N). − $^{31}P\{^{1}H\}$ (CD_2Cl_2): δ = 52.9 (Au−P),

86.8 [(iPr$_2$N)$_2$P]. − $C_{39}H_{53}AuClN_3P_2Zr$ (949.45): calcd. C 49.34, H 5.63; found C 49.47, H 5.68.

Compound 7: To a solution of **3** (0.262 g, 0.472 mmol) in toluene (5 mL) at room temperature was added chlorodiethylphosphate (0.091 mL, 0.472 mmol). The mixture was stirred at room temperature for 12 h and then evaporated to dryness. The resulting solid residue was extracted with pentane/toluene (5:1, 20 mL) and filtered. The volatiles were removed from the solution to give **7** as a yellow solid in 72% yield (0.342 g). − IR (KBr): $\tilde{\nu}$ = 1579 cm^{-1} ($\nu_{C=N}$), 1247 ($\nu_{P=O}$). − ^{1}H NMR (C_6D_6): δ = 1.09 (t, J_{HH} = 7.1 Hz, 6 H, OCH_2CH_3), 1.20 (d, J_{HH} = 6.6 Hz, 12 H, CH_3), 1.23 (d, J_{HH} = 6.6 Hz, 12 H, CH_3), 3.48 (sept, J_{HH} = 6.6 Hz, 4 H, NCH), 3.94 (dq, J_{HH} = 7.1 Hz, 2 H, OCH_2CH_3), 4.12 (dq, J_{HH} = 7.1 Hz, 2 H, OCH_2CH_3), 6.11 (s, 10 H, CH_{Cp}), 6.89−7.11 (m, 3 H, CH_{arom}), 7.55−8.03 (m, 1 H, CH_{arom}). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 17.2 (d, J_{CP} = 4.7 Hz, OCH_2CH_3), 24.5 (d, J_{CP} = 5.3 Hz, CH_3), 24.7 (d, J_{CP} = 6.0 Hz, CH_3), 48.9 (d, J_{CP} = 11.1 Hz, NCH), 62.8 (d, J_{CP} = 6.1 Hz, OCH_2CH_3), 114.7 (s, CH_{Cp}), 125.4 (dd, J_{CP} = 10.1 Hz, J_{CP} = 17.2 Hz, CH_{arom}), 128.4 (d, J_{CP} = 11.1 Hz, CH_{arom}), 131.4 (d, J_{CP} = 10.5 Hz, CH_{arom}), 132.4 (d, J_{CP} = 2.5 Hz, CH_{arom}), 142.7 (dd, J_{CP} = 36.1 Hz, J_{CP} = 50.7 Hz, ZrC), 192.1 (dd, J_{CP} = 11.3 Hz, J_{CP} = 19.9 Hz, ZrC), 202.4 (d, J_{CP} = 33.9 Hz, PC=N). − ^{31}P{^{1}H} (C_6D_6): δ = 42.0 (d, J_{PP} = 15.8 Hz, P=O), 45.4 [d, J_{PP} = 15.8 Hz, (iPr$_2$N)$_2$P]. − $C_{33}H_{52}ClN_3O_3P_2Zr$ (727.41): calcd. Synthesis, Crystal Structure and Solution Behaviour of Palladium(II) Complexes with Tetrazenido or Amido Ligands and Potentially Tridentate Ligands

Laurent Barloy,[a] Régis M. Gauvin,[a] John A. Osborn,*[a][†] Christina Sizun,[b] Roland Graff,[c] and Nathalie Kyritsakas[d]

Keywords: Palladium / Azides / Amides / Tripodal ligands / Fluxionality

$Pd(DBA)_2$ reacts with the azide $C_6F_5N_3$ in the presence of terpy* to form the tetrazenido palladium(II) complex [(η^2-terpy*)Pd{η^2-$N_4(C_6F_5)_2$}] **1**, whereas with TsN_3 the amido complex [(η^3-terpy*)Pd(NHTs)]$^+$ is obtained. Another synthetic route involving abstraction of chloride ions from [(L)PdCl]Cl and transmetallation with KNHTs yields the complexes [(η^3-L)Pd(NHTs)](BF_4) (**4**: L = terpy*; **5**: L = triphos). Compounds **1**, **4** and **5** have been characterized in the solid state by single-crystal X-ray analysis as mononuclear, square-planar complexes. ^{1}H and ^{19}F NMR spectroscopy reveal that **1** is a fluxional molecule. Rotation of both C_6F_5 rings is hindered, with energy barriers of 53.9 kJ·mol^{-1} (293 K) and 60.7 kJ·mol^{-1} (325 K). Additionally, the lateral pyridines and the C_6F_5 rings exchange through an oscillatory process where one terminal pyridine enters the coordination sphere while the other leaves it. The corresponding energy barrier (74.9 kJ·mol^{-1} at 298 K) has been determined from selective inversion NMR experiments.

Introduction

The covalent bond between a late transition metal of the second or third series and nitrogen has received much attention recently. It is frequently involved in important steps of stoichiometric or catalytic reactions; for instance, palladium amido complexes are involved in the formation of C−N bonds.[1] It has long been considered that the high reactivity of the metal−nitrogen bond is a consequence of the mismatch between the soft metal and the hard nitrogen atom, although this interpretation has been put in question.[2]

The synthesis and reactivity of polynuclear palladium(II) complexes with bridging imido ligands has been reported.[2] On the contrary, mononuclear palladium imido complexes have never been fully characterized,[3] although they have frequently been postulated as transient intermediates in reactions such as the palladium-catalyzed carbonylation of nitroaromatics.[4] Thus, it would be desirable to stabilize and isolate such species. In principle, imido complexes could be obtained from azides, or from the deprotonation of an amido complex. Yet the reaction of organic azides with zerovalent group 10 metals leads instead to tetrazenido, amido or azido complexes, or to polymers.[5,6a,6b,7] It has nevertheless been proposed that transient mononuclear imido intermediates should be involved in the formation of the tetrazenido complexes.

We have been interested lately in the use of tridentate ligands in the coordination chemistry of palladium.[8] Such ligands have been found to stabilize reactive organometallic species,[9] and it could be expected that they might stabilize those imido compounds. In addition, a bridged complex should be avoided in favour of a mononuclear complex, provided that only one coordination site remains in a tetracoordinate palladium complex.

We report here the synthesis and characterization of new palladium tetrazenido and amido complexes obtained from the reaction of Pd^0 with organic azides or the reaction of Pd^{II} complexes with potassium tosylamide, in the presence of the potentially tridentate ligands 4,4′,4"-tri(*tert*-butyl)-2,2′:6′,2"-terpyridine (terpy*)[10] or bis(2-diphenylphosphanylethyl)phenylphosphane (triphos).

Results and Discussion

Tetrazenido Palladium Complexes

The reaction of palladium(0) bis(dibenzylideneacetone) $Pd(DBA)_2$ with an excess of terpy* and pentafluorophenyl azide in toluene at room temperature leads to the η^2-terpy* tetrazenido palladium(II) complex **1** (Scheme 1). The yield is moderate (39%), mainly owing to the difficulty of separa-

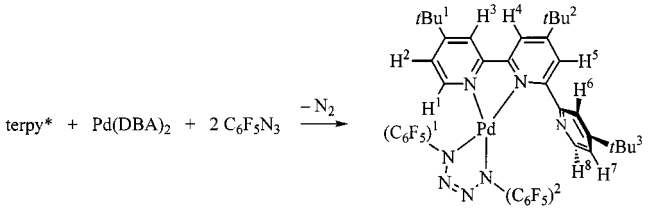
tion from other by-products; however, the yield of the synthesis of tetrazenido or tetrazadiene metal complexes from organic azides is usually lower than 50%.[5] If an equimolar amount of terpy* and azide are used in the synthesis, complex **1** is still obtained as the only product, although with a lower yield. To the best of our knowledge, the only other palladium tetrazenido complex reported to date was prepared by another synthetic route.[5a]



1

Scheme 1. Synthesis of the tetrazenido palladium complex **1**

Compound **1** is soluble in organic solvents like THF, CH_2Cl_2, toluene or even pentane. In general, the complex is not stable in solution, and it slowly decomposes at room temperature in chloroform or methanol, yielding pentafluorophenyl azide and pentafluoroaniline according to ^{19}F NMR analysis. This kind of transformation has been reported for rhodium, iridium or platinum tetrazenido complexes upon treatment with an acid.[11]

The molecular structure of **1** is depicted Figure 1, and selected bond lengths and angles are given in Table 1. Two crystallographically independent, but closely similar, molecules of **1** and two molecules of diisopropyl ether are present within the asymmetric unit; only one molecule of **1** is discussed in the following section. The ORTEP drawing shows a palladium atom coordinated by a bidentate bis(pentafluorophenyl)tetrazenido ligand and a bidentate terpy* ligand. The complex is square planar, but slightly distorted toward a tetrahedral geometry. Pd1, N4, N5, N6, and N7 are nearly coplanar within ±0.03 Å, and their mean plane makes an angle of 19.9(1)° with the N1−Pd1−N2 plane; N1 is located 0.597(3) Å below the mean plane and N2 0.242(3) Å above. The palladium atom deviates from the plane of the coordinating pyridines, as shown by the Pd1−N1−C5−C10 torsion angle of −19(1)°. Those distortions, which arise from steric interactions between terpy* and the tetrazenido ligand, are minimized by the roughly parallel positioning of the uncoordinating pyridine plane and the adjacent pentafluorophenyl plane. Both planes are ca. 3 Å distant one from the other, which is consistent with some π-stacking. The N2−C14−C19−N3 torsion angle is much larger [156.9(9)°] than that found in other η^2-terpy metal complexes;[8a,12,13] the other rotamer, i.e. where this torsion angle would be close to 0°, is not observed in the unit cell. As a consequence of the minimized steric interactions between the two ligands, the difference between the Pd1−N1 and the Pd1−N2 bond lengths (0.02 Å) is small.

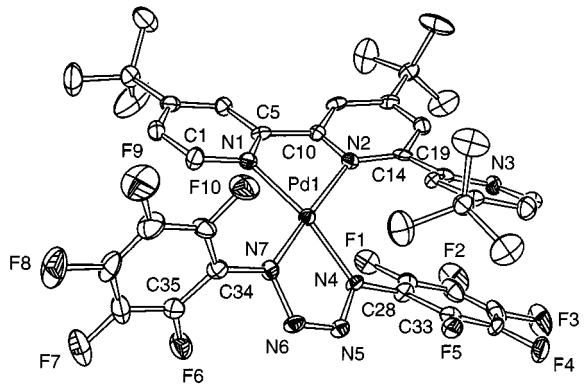


Figure 1. ORTEP drawing of **1** showing 30% probability thermal ellipsoids and the atom-numbering scheme; hydrogen atoms and $i Pr_2O$ are omitted for clarity

Table 1. Selected bond lengths [Å] and bond angles [°] for complex **1**

Pd1−N1	2.052(9)	N4−C28	1.39(1)
Pd1−N2	2.073(9)	N4−N5	1.39(1)
Pd1−N4	1.988(8)	N5−N6	1.25(1)
Pd1−N7	1.986(8)	N6−N7	1.41(1)
		N7−C34	1.39(1)
N1−Pd1−N2	78.9(4)	Pd1−N2−C10	111.2(7)
N1−Pd1−N4	162.9(4)	Pd1−N2−C14	130.4(8)
N1−Pd1−N7	104.0(4)	Pd1−N4−C28	131.7(7)
N2−Pd1−N4	103.4(4)	Pd1−N4−N5	116.6(6)
N2−Pd1−N7	172.7(4)	Pd1−N7−C34	132.7(8)
N4−Pd1−N7	75.9(4)	Pd1−N7−N6	117.2(6)
Pd1−N1−C1	128.4(8)	N4−N5−N6	116.1(9)
Pd1−N1−C5	112.3(7)	N5−N6−N7	114.0(9)

Like the tetrazenido palladium complex $[Pd(PEt_3)_2(N_4Ph_2)]$ described by Trogler et al.,[5a] the N4−N5 and N6−N7 bond lengths [1.39(1) and 1.41(1) Å, respectively] correspond to single bonds, whereas the N5−N6 bond length [1.25(1) Å] is characteristic of a double bond. However, the Pd1−N4 and Pd1−N7 bonds are shorter than in Trogler's complex [1.988(8) and 1.986(8) Å, respectively], which can be related to the lower *trans* influence of pyridines compared to phosphorus ligands. The pentafluorophenyl rings are tilted, as shown by the torsion angles N6−N7−C34−C35 [−54(1)°] and N5−N4−C28−C33 [−43(1)°]. This is another characteristic of the tetrazenido form in contrast to the tetrazadiene form.[5c]

The room-temperature NMR spectrum of **1** is characteristic of an unsymmetrical, bidentate terpy* ligand (Figure 2), and is in agreement with the X-ray structure. The protons of the noncoordinating pyridine are all deshielded in comparison with the equivalent protons of the lateral coordinating pyridine, although the tendency is generally the reverse in η^2-terpy metal complexes.[8,12,14] The latter protons, in particular H^1 and H^2, lie in the anisotropy cone of the pentafluorophenyl ring A, with chemical shifts as low as $\delta = 6.40$ (H^2). In contrast, H^6 is strongly deshielded at $\delta = 10.12$. This may be the effect of a weak agostic CH···Pd

interaction or of the paramagnetic anisotropy of the metal atom;[15] the X-ray structure indicates that H^6 is located ca. 2.7 Å above the palladium atom. The deshielding effect of the nitrogen that is located close to H^5, i.e. N3 on the solid-state structure (vide supra), must also explain the difference between the chemical shifts of H^5 and H^4 ($\Delta\delta$ = 1.14 ppm).[12b]

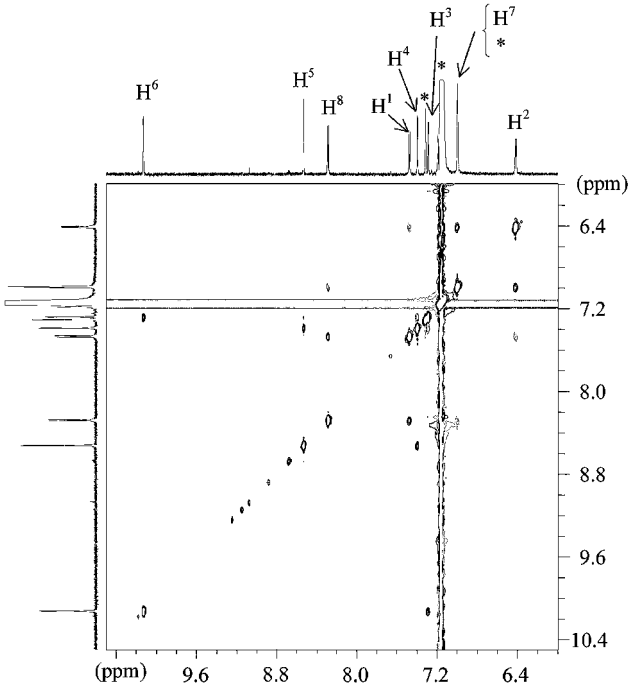

Figure 2. Section of the phase-sensitive $^1H-^1H$ ROESY spectrum of complex **1** (C_6D_6, 298 K, 500 MHz), showing exchange cross-peaks (positive, darker lines) and NOE cross peaks (negative, lighter lines); see Scheme 2 for hydrogen labelling; the asterisks correspond to the solvent

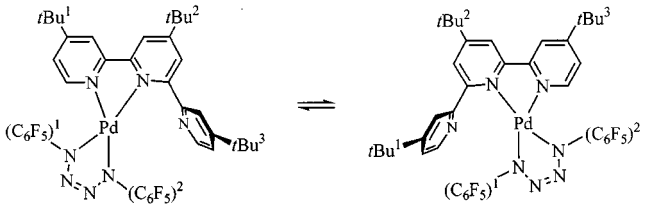
The ^1H-^1H ROESY spectrum shows negative (NOE) cross-peaks that allow us to assign unambiguously the proton signals. In particular, H^3 presents a strong NOE cross-peak with H^4. This was expected since they lie in close proximity, both coordinating pyridines being coplanar. The absence of an NOE interaction between H^5 and H^6 is consistent with the N2−C14−C19−N3 dihedral angle found in the X-ray structure (vide supra).

Exchange (positive) cross-peaks for the H^1/H^8, H^2/H^7, H^3/H^6 and H^4/H^5 pairs (Figure 2), and for the tBu^1/tBu^3 pair are observed in the ROESY spectrum. This fluxionality can be interpreted by the well-known oscillatory mechanism of (η^2-terpy) metal complexes (Scheme 2).[12,14,16] This mechanism is also supported by a ^{19}F-^{19}F NOESY spectrum recorded at room temperature in C_6D_6, which shows that the *para* fluorines of rings A and B exchange with one another. In order to determine the exchange rate of this fluxional mechanism, we ran a selective inversion-recovery NMR experiment.[17] The recovery of the tBu^1 and tBu^3 protons was followed as a function of time after the selective inversion of tBu^1 (Figure 3); the initial decrease in intensity of the tBu^3 signal reflects the chemical exchange. We determined from these NMR spectroscopic data the exchange rate at 298 K as $k = 0.47 \pm 0.05$ s^{-1}, which corresponds to $\Delta G^{\ddagger} = 74.9 \pm 0.3$ kJ·mol^{-1}. The experiment was confirmed by the selective inversion of the tBu^3 protons, leading in turn to an alteration of the intensity of the tBu^1 signal and to the same value of k. This $\Delta G^{\ddagger}_{298}$ value is, to the best of our knowledge, the highest known for an η^2-terpy palladium complex; this is probably linked with the bulkiness of the tetrazenido ligand.



Scheme 2. Fluxional behaviour of complex **1**

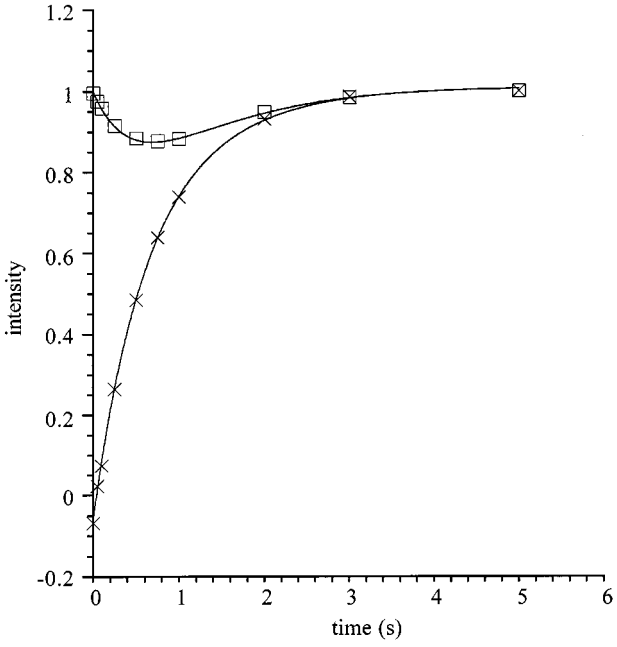


Figure 3. Result of the selective inversion-recovery of the tBu^1 protons of complex **1** at 298 K: evolution vs. time of the intensity of the tBu^1 signal at δ = 0.81 (×) and the tBu^3 signal at δ = 1.46 (square)

The low-temperature ^{19}F NMR spectrum of complex **1** in deuterated chloroform displays ten distinct signals between δ = −170 and −145 (Figure 4). Therefore at this temperature both the oscillatory mechanism and the rotation of the pentafluorophenyl rings around the carbon−nitrogen bonds are frozen; the complex is present as a single conformer, very probably the one which was observed by X-ray crystallography. Upon raising the temperature, we first observe the coalescence of one pair of *meta* signals at δ = −163.52/−162.61 (T_c = 285 K) and one pair of *ortho* signals at δ = −147.62/−145.90 (T_c = 293 K). The same value of $\Delta G^{\ddagger}$ was calculated for both pairs of exchanging signals, i.e. 54.0 kJ·mol^{-1}. Above 272 K, another set

of *ortho* (δ = −151.43/−146.98) and *meta* (δ = −166.06/−164.66) signal pairs starts to coalesce. The complete coalescence into one signal is not reached for any of them at the boiling temperature of the solvent; yet T_c can be estimated for the *meta* signals at 325 K, with a corresponding $\Delta G^{\ddagger} = 60.7\ kJ{\cdot}mol^{-1}$. All those coalescences are obviously the effect of the rotation of the pentafluorophenyl rings. As the rotation of $(C_6F_5)^2$ must be more restricted than the rotation of $(C_6F_5)^1$ because of the proximity of the uncoordinated pyridine, we can assign the values of $53.9\ kJ{\cdot}mol^{-1}$ to ring 1 and of $60.7\ kJ{\cdot}mol^{-1}$ to ring 2. Thus all the signals of the low-temperature ^{19}F NMR spectrum could be assigned. We note that, in general, the fluorines borne by ring 2 are more shielded than the equivalent fluorines of ring 1.

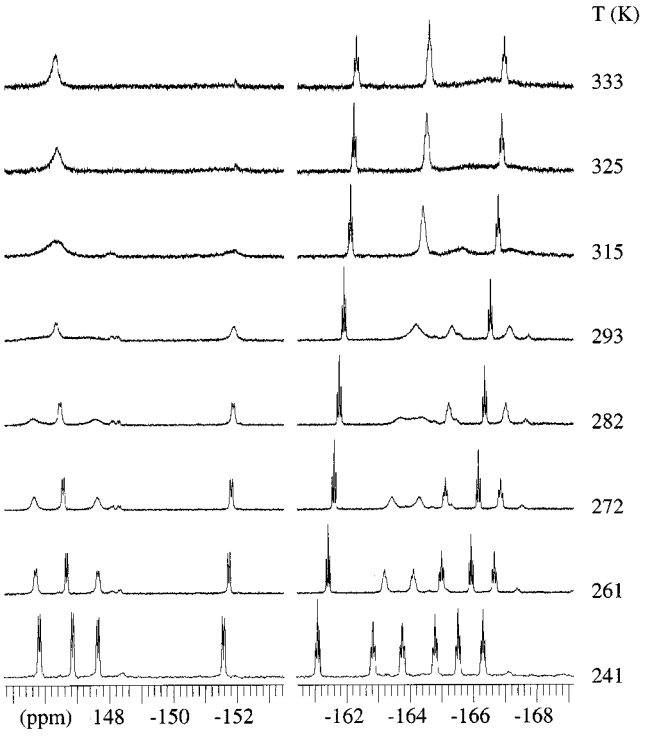

Figure 4. ^{19}F NMR spectra of complex **1** ($CDCl_3$, 376.5 MHz) in the range 241−333 K; see Exp. Section for the complete assignment

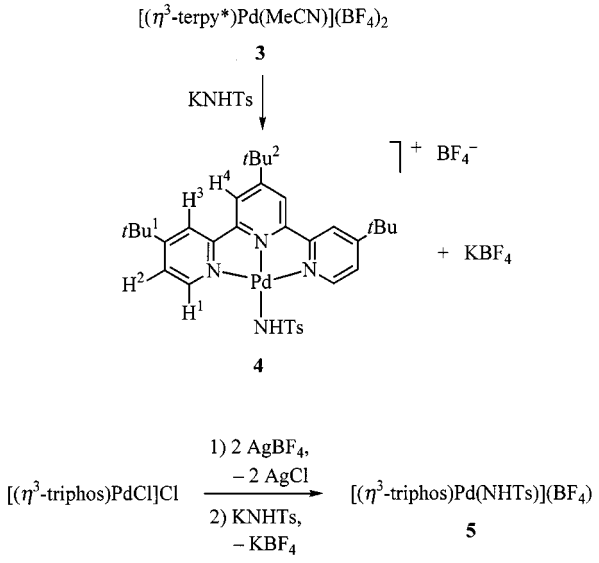
the solvent. We therefore had to prepare this cationic amido complex by another synthetic pathway in order to characterize it completely.

The amido complexes **4** and **5** were prepared in very good yield from potassium tosylamide (Scheme 3), since it had been shown that potassium anilide is an efficient reagent for the preparation of palladium amido complexes.[18] The terpy* palladium(II) precursor **3** bearing a labile CH_3CN ligand could be synthesized from terpy* and $[Pd(CH_3CN)_4](BF_4)_2$, following the method described with terpy.[19] An alternative pathway consisted of preparing [(η³-terpy*)PdCl]Cl (**2**) from terpy* and $[Pd(PhCN)_2Cl_2]$, and then removing the chloride anions with silver tetrafluoroborate. The ^1H NMR characteristics of **4** are exactly the same as those of the product obtained from $Pd(DBA)_2$, terpy* and TsN_3. Complex **5** was obtained in a one-pot reaction from [(η³-triphos)PdCl]Cl, removing first the chloride ions with a silver salt at room temperature and then allowing the palladium complex to react at −78° C with the amide anion. Other palladium or platinum sulfonamido complexes have been reported in the literature,[6] but **4** and **5** are, to the best of our knowledge, the first cationic ones reported to date.



Scheme 3. Synthesis of the amido complexes **4** and **5**

Amido Palladium Complexes

Following the reaction conditions that led to complex **1**, we replaced pentafluorophenyl azide by tosyl azide. It is worth noting that $[Pd(PPh_3)_4]$ reacts with tosyl azide to give, presumably, a polymeric triphenylphosphane derivative of Pd^0.[5b] In spite of our best efforts, the product of the reaction of $Pd(DBA)_2$ with TsN_3 and terpy* could not be completely purified. However, its NMR features reveal one tosylamido moiety and a symmetrical terpy* ligand, suggesting the expected tridentate coordination. In addition, its FAB^+-MS spectrum shows a peak at $m/z = 677.1$ that corresponds to a $[(terpy^*)Pd(NHTs)]^+$ cation. We suppose that the NH proton originates from some residual water in

Complexes **4** and **5** are not air-sensitive, but **5** slowly decomposes in solution at room temperature. Their relative stability is probably connected with the electron-withdrawing tosyl fragment; it has been suggested that amido palladium complexes are stabilized by substituents that can accommodate π-donation from the nitrogen lone pair.[18] The ^1H NMR N*H* signals appear at δ = 3.61 (**4**) and δ = 2.55 (**5**), and are therefore in the same region as for reported palladium or platinum sulfonamido complexes.[6]

The molecular structures of complexes **4** and **5** are depicted in Figure 5 and 6, and selected bond lengths and angles are given Table 2 and 3. Both of them consist of slightly distorted square-planar $[(\eta^3\text{-L})Pd(NHTs)]^+$ cationic

complexes, where L is either terpy* (**4**) or triphos (**5**), and noncoordinating tetrafluoroborate anions. Complex **4** co-crystallizes with two molecules of water each with an occupancy ratio of 50% and 25%. In the case of complex **5**, the asymmetric unit contains two crystallographically independent molecules of **5** and one acetonitrile; those molecules are practically equivalent and only one is discussed.

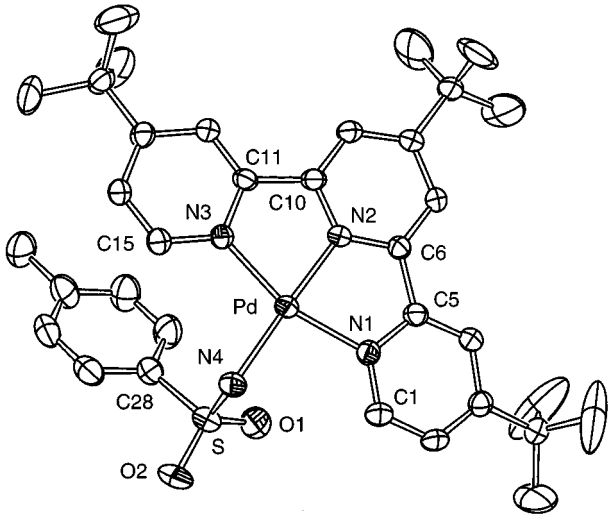


Figure 5. ORTEP drawing of **4** showing 30% probability thermal ellipsoids and the atom-numbering scheme; hydrogen atoms, BF_4^- and H_2O are omitted for clarity

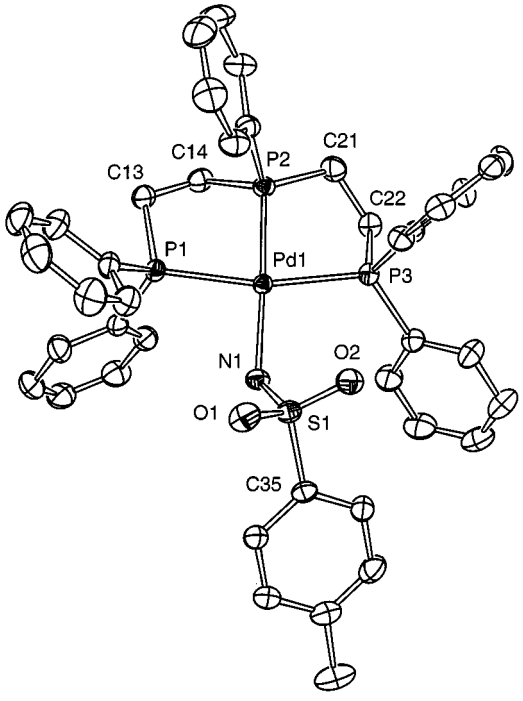

Figure 6. ORTEP drawing of **5** showing 30% probability thermal ellipsoids and the atom-numbering scheme; hydrogen atoms, BF_4^- and CH_3CN are omitted for clarity

For both complexes, the characteristics of the (η^3-L)Pd fragments are very close to those of related terpy[20] or triphos[21] complexes, with the short bond angles N−Pd−N [N1−Pd−N2 = 81.0(3)°, N2−Pd−N3 = 80.5(3)°] or P−Pd−P [P1−Pd1−P2 = 82.64(3)°, P2−Pd1−P3 = 82.07(3)°] expected for five-membered metallacycles. The palladium atom lies out of the N_4 mean plane by only 0.0375(2) Å in complex **4**, and out of the NP_3 mean plane by 0.1178(1) Å in complex **5**.

Table 2. Selected bond lengths [Å] and bond angles [°] for complex **4**

Pd−N1	2.023(7)	Pd−N4	2.027(7)
Pd−N2	1.935(6)	N4−S	1.604(9)
Pd−N3	2.022(7)	S−C28	1.78(1)
N1−Pd−N2	81.0(3)	Pd−N1−C5	113.2(5)
N1−Pd−N3	161.5(3)	Pd−N2−C6	118.4(5)
N1−Pd−N4	96.5(3)	Pd−N2−C10	118.6(6)
N2−Pd−N3	80.5(3)	Pd−N3−C11	114.3(5)
N2−Pd−N4	176.4(3)	Pd−N3−C15	128.3(6)
N3−Pd−N4	101.9(3)	Pd−N4−S	117.1(4)
Pd−N1−C1	128.1(6)	N4−S−C28	107.4(5)

Table 3. Selected bond lengths [Å] and bond angles [°] for complex **5**

Pd1−P1	2.3416(7)	Pd1−N1	2.084(2)
Pd1−P2	2.2293(7)	N1−S1	1.592(2)
Pd1−P3	2.3309(7)	S1−C35	1.778(3)
P1−Pd1−P2	82.64(3)	Pd1−P1−C13	107.12(4)
P1−Pd1−P3	163.32(3)	Pd1−P2−C14	106.15(5)
P1−Pd1−N1	94.96(7)	Pd1−P2−C21	112.06(6)
P2−Pd1−P3	82.07(3)	Pd1−P3−C22	102.29(4)
P2−Pd1−N1	174.84(7)	Pd1−N1−S1	123.50(5)
P3−Pd1−N1	99.72(7)	N1−S1−C35	105.4(1)

Concerning the sulfonamido fragments, the palladium−nitrogen bond length [**4**: 2.027(7) Å; **5**: 2.084(2) Å] is typical of a single bond; it is somewhat longer in **5** than in **4** because of the *trans* influence of the phosphane. In fact, the Pd−N bond in palladium amido complexes is generally a single bond,[6,18] as long as no ligand-to-metal π-donation is possible in d^8 metal complexes.[22] The nitrogen−sulfur bond is rather short [**4**: 1.604(9) Å; **5**: 1.592(2) Å], whereas the N−S bond length measured on a tungsten tosylamido complex is larger [1.641(5) Å].[23] This is indicative of a delocalization of the nitrogen lone pair onto the adjacent electron-withdrawing SO_2 function as in other palladium sulfonamido complexes.[6] We observe a higher value for the Pd1−N1−S1 angle in **5** [123.50(5)°] than for the Pd−N4−S angle in **4** [117.1(4)°]; the phenyl substituents borne by triphos exert a steric influence that may be the origin of this difference.

In complex **4**, the Pd−N−S plane is roughly perpendicular to the coordination plane, with an angle of 87.7(1)° with the N_4 plane, although in complex **5** the angle with the P_3N plane is somewhat smaller [60.39(5)°]. Those large angles can stem from a minimized interaction between the nitrogen lone pair and the filled *d*-orbitals of palladium,[24]

and/or from a reduced steric strain between the tridentate ligand and the tosylamido ligand.

In addition, the tetrafluoroborate anion is disordered in the X-ray structure of **4**. We can, however, observe that some of the fluorine atoms are less than 3 Å distant from N4, suggesting an NH···F hydrogen bond between the complex and BF_4.

Like some other Pd and Rh amido complexes,[2] **4** and **5** could not be deprotonated to imido complexes, despite the electron-withdrawing effect of the tosyl substituent. Most of the reactions with bases like organolithium reagents or LDA led to decomposition and intractable mixtures. The CD_2CN^- anion generated by reaction of butyllithium with CD_3CN substituted the tosylamido ligand in complex **5** according to FAB-MS analysis. Similarly, the reaction of **5** with Cs_2CO_3 in methanol led to a (triphos)Pd(OH)$^+$ cation. We also noted the absence of reactivity of **5** towards CO.

Conclusion

The results described in this paper show that under identical conditions, the reaction of $Pd(DBA)_2$ and terpy* with $C_6F_5N_3$ leads to the tetrazenido complex **1**, whereas with TsN_3 the product is an amido complex. These results contrast with the reported reactions of Pd^0 complexes with azides, which give either bis-azido Pd^{II} complexes[7] or polymeric triphenylphosphane derivatives of Pd^0.[5b] The terpyridine ligand obviously plays a key role in the orientation of the reaction; however, no imido complexes were obtained.

In the product **1**, derived from $C_6F_5N_3$, terpy* binds palladium in a bidentate manner and the complex is fluxional via an oscillatory mechanism. The X-ray structure and NMR properties of **1** also reveal that the rotations of the C_6F_5 rings around the C−N bonds are hindered. In contrast, terpy* is tridentate and the fourth coordination position is occupied by $TsNH^-$ in the product derived from TsN_3. We suspect that steric interactions between the large, tetrahedral sulfonamide function and the pendant pyridine of terpy* would be too important to make a tosyl analogue of **1** stable.

Experimental Section

General: All experiments were carried out at room temperature under a nitrogen or argon atmosphere, using a vacuum line or Vacuum Atmospheres glovebox equipped with Dri-Train HE-493 inert gas purifier, unless otherwise stated. All solvents were dried by standard methods and distilled under nitrogen, except benzonitrile (Fluka) which was used as received. $[Pd(CH_3CN)_4](BF_4)_2$ and $AgBF_4$ were purchased from Strem and used as received. Tosyl azide,[25] pentafluorophenyl azide,[26] potassium tosylamide,[27] 4,4′,4"-tri(*tert*-butyl)-2,2′:6′,2"-terpyridine (terpy*),[10] $Pd(DBA)_2$,[28] $[Pd(PhCN)_2Cl_2]$,[29] [(triphos)PdCl]Cl[30] were prepared following reported procedures.

The NMR spectra were obtained at room temperature (unless otherwise indicated) on Bruker spectrometers. ^1H NMR spectra were recorded at 200.13 MHz (AC-200 instrument), 300.16 MHz (AC-300) or 500.13 MHz (ARX-500) and referenced to $SiMe_4$; the assignments were supported by irradiations and/or 2D analysis. $^{13}C\{^1H\}$ NMR spectra (broadband decoupled) were recorded at 50.32 MHz (AC-200) or 100.62 MHz (AM-400) and referenced to $SiMe_4$; the assignments were supported by DEPT-135° or ^1H-^{13}C HMQC analysis. $^{31}P\{^1H\}$ NMR spectra (broadband decoupled) were recorded at 121.51 MHz (AC-300) and referenced to 85% aqueous H_3PO_4. $^{19}F\{^1H\}$ NMR spectra (broadband decoupled) were recorded at 376.50 MHz (AM-400) and referenced to $CFCl_3$; the assignments were supported by ^{19}F-^{19}F COSY analysis. For variable-temperature spectra, the probe temperature was controlled (±1 K) by a B-VT 2000 unit calibrated with a methanol NMR tube. The $\Delta G^{\ddagger}$ values were calculated with the Eyring equation $\Delta G^{\ddagger} = RT_c\,(22.96 + \ln T_c/\Delta\nu)$ [J·mol^{-1}] where T_c (K) is the temperature of coalescence of two given signals and $\Delta\nu$ (Hz) their difference in chemical shift at low exchange temperature;[31] the error is estimated to be ±1 kJ·mol^{-1}. The phase-sensitive ^1H-^1H ROESY spectrum (mixing time 0.3 s) and the selective inversion-recovery experiments were recorded on the ARX-500 spectrometer, and the phase-sensitive ^{19}F-^{19}F NOESY spectrum on the AM-400 spectrometer (mixing time 0.4 s). The selective inversion-recovery experiments were achieved using a 50 ms Gaussian 180° pulse (5%−truncated waveform) and a 20 s interpulse delay; the curves were fitted either as pairs or all four simultaneously according to Bloch's equations modified for exchange,[32] with a home-written C program using the Powell algorithm from the Numerical Recipes package.[33] The $\Delta G^{\ddagger}$ value was deduced from the equation $\Delta G^{\ddagger} = RT\,(23.76 - \ln k/T)$.[31]

FT-IR spectra were recorded on a Perkin−Elmer 1600 Series spectrometer on KBr pellets.

MS spectra and elemental analyses were carried out by the corresponding facilities at the Centre de Recherche de Chimie, Université Louis Pasteur, Strasbourg.

[(η²-terpy*)Pd{η²-N₄(C₆F₅)₂}] (1): $Pd(DBA)_2$ (1.00 g, 1.74 mmol) was added to a solution of terpy* (1.00 g, 2.49 mmol) in toluene (50 mL) while stirring. A solution of pentafluorophenyl azide (2.00 g, 9.57 mmol) in toluene (10 mL) was added dropwise. After 18 h stirring at room temperature, the colour had turned from reddish-violet to dark-greenish. The solution was filtered and evaporated to dryness, and the residue washed with pentane (4 × 50 mL) and toluene (20 mL). The complex was recrystallized from THF/pentane as an air-stable, dark grey-blue powder (0.61 g, 39%). − $C_{39}H_{35}F_{10}N_7Pd$ (898.14): calcd. C 52.16, H 3.93, N 10.92; found C 51.61, H 3.80, N 10.85. − ^1H NMR (300 MHz, C_6D_6): δ = 0.81 (s, 9 H, *t*Bu^1), 1.04 (s, 9 H, *t*Bu^2), 1.46 (s, 9 H, *t*Bu^3), 6.40 (dd, $^3J_{HH}$ = 6.1 Hz, $^4J_{HH}$ = 1.7 Hz, 1 H, H^2), 6.99 (dd, $^3J_{HH}$ = 5.1 Hz, $^4J_{HH}$ = 1.7 Hz, 1 H, H^7), 7.27 (d, $^4J_{HH}$ = 1.5 Hz, 1 H, H^3), 7.38 (d, $^4J_{HH}$ = 2.0 Hz, 1 H, H^4), 7.47 (d, $^3J_{HH}$ = 6.1 Hz, 1 H, H^1), 8.28 (d, $^3J_{HH}$ = 5.1 Hz, 1 H, H^8), 8.52 (d, $^4J_{HH}$ = 2.0 Hz, 1 H, H^5), 10.12 (d, $^4J_{HH}$ = 1.7 Hz, 1 H, H^6). − $^{19}F\{^1H\}$ NMR (376.5 MHz, $CDCl_3$, 230 K): δ = −166.06, −164.66 (2 dd app. t, $^3J_{FF}$ = 23 Hz, 2 F, F^{2meta}), −165.26 (dd app. t, $^3J_{FF}$ = 22 Hz, 1 F, F^{2para}), −163.52, −162.61 (2 dd app. t, $^3J_{FF}$ = 23 Hz, 2 F, F^{1meta}), −160.86 (dd app. t, $^3J_{FF}$ = 23 Hz, 1 F, F^{1para}), −151.43, −146.98 (2 d, $^3J_{FF}$ = 24 Hz, 2 F, F^{2ortho}), −147.62, −145.90 (2 d, $^3J_{FF}$ = 22 Hz, 2 F, F^{1ortho}).

Reaction of Pd(DBA)₂ with Terpy* and Tosyl Azide: $Pd(DBA)_2$ (0.500 g, 0.870 mmol) was added to a solution of terpy* (0.698 g, 1.74 mmol) in toluene (50 mL) while stirring. A solution of tosyl

azide (1.20 g, 6.08 mmol) in toluene (5 mL) was added dropwise. After 18 h stirring at room temperature, the colour had turned from reddish-violet to dark brown. The suspension was filtered, and the product collected on a frit as a brown-greenish powder was washed with toluene and dried. − MS (FAB^+, NBA matrix): *m*/*z* (%) = 677.1 (79) [(terpy*)Pd(NHTs)$^+$], 507.1 (100) [(terpy*)Pd$^+$]. − ^{1}H NMR (200 MHz, CD_3CN): δ = 1.42 (s, 18 H, *t*Bu^1), 1.52 (s, 9 H, *t*Bu^2), 2.26 (s, 3 H, Me), 3.61 (br s, 1 H, NH), 7.12 (d, $^3J_{HH}$ = 7.8 Hz, 2 H, H$^{arom\ Ts}$), 7.54 (dd, $^3J_{HH}$ = 6.1 Hz, $^4J_{HH}$ = 2.1 Hz, 2 H, H^2), 7.93 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, H$^{arom\ Ts}$), 8.14 (d, $^3J_{HH}$ = 6.0 Hz, 2 H, H^1), 8.28 (m, 4 H, H^3 + H^4). − ^{13}C{^{1}H} NMR (50 MHz, [D$_6$]DMSO): δ = 20.7 (s, 1 C, Me), 29.8 [s, 6 C, *t*Bu^1, C(*C*H$_3$)$_3$], 30.2 [s, 3 C, *t*Bu^2, C(*C*H$_3$)$_3$], 36.0 [s, 2 C, *t*Bu^1, *C*(CH$_3$)$_3$], 37.0 [s, 1 C, *t*Bu^2, *C*(CH$_3$)$_3$], 121.4 (s, 2 C, C−H^4), 122.2 (s, 2 C, C−H^3), 124.1 (s, 2 C, C−H^2), 125.9, 128.7 (2 s, 2 × 2 C, C−H^{Ts}), 140.1, 143.8 (2 s, 2 × 1 C, C−S + C−Me), 151.7 (s, 2 C, C−H^1), 154.1, 157.0 (2 s, 2 × 2 C, C−N), 166.3 (s, 2 C, C−*t*Bu^1), 167.7 (s, 1 C, C−*t*Bu^2).

[(η^3-terpy*)PdCl]Cl (2): Terpy* (1.20 g, 3.00 mmol) was partly dissolved in 250 mL methanol in a round-bottomed flask, and [Pd(PhCN)$_2$Cl$_2$] (1.15 g, 3.00 mmol) was added to the solution. A clear solution was obtained after 3 h reflux, which was cooled and filtered. Evaporation under reduced pressure led to an orange oil, which was recrystallized from a CH_2Cl_2/Et_2O mixture to yield the complex as a pale yellow powder (1.62 g, 94%). − $C_{27}H_{35}Cl_2N_3Pd{\cdot}H_2O$ (596.92): calcd. C 54.33, H 6.25, N 7.04, Cl 11.88; found C 54.56, H 6.28, N 6.93, Cl 11.86. − MS (ES^+): *m*/*z* (%) = 542.3 (100) [M$^+$ − Cl]. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.54 (s, 18 H, *t*Bu^1), 1.70 (s, 9 H, *t*Bu^2), 7.56 (dd, $^3J_{HH}$ = 6.0 Hz, $^4J_{HH}$ = 2.0 Hz, 2 H, H^2), 8.78 (d, $^3J_{HH}$ = 6.0 Hz, 2 H, H^1), 8.98 (d, $^4J_{HH}$ = 1.8 Hz, 2 H, H^3), 9.06 (s, 2 H, H^4).

[(η^3-terpy*)Pd(CH$_3$CN)](BF$_4$)$_2$ (3). Method A: A solution of terpy* (45 mg, 0.112 mmol) dissolved in benzonitrile (2 mL) was added to a yellow solution of [Pd(CH$_3$CN)$_4$](BF$_4$)$_2$ (50 mg, 0.112 mmol) in benzonitrile (5 mL), after which the colour faded slightly. Addition of 60 mL diethyl ether led to an off-white precipitate which was collected on a frit and washed with diethyl ether (79 mg, 98%). The complex could be recrystallized from CH_3CN/Et_2O. − $C_{29}H_{38}B_2F_8N_4Pd$ (722.66): calcd. C 48.20, H 5.30, N 7.75; found C 48.11, H 5.32, N 7.61. − IR: $\nu_{C\equiv N}$ = 2305, 2333 cm^{-1}. − ^{1}H NMR (300 MHz, CD_3CN): δ = 1.47 (s, 18 H, *t*Bu^1), 1.53 (s, 9 H, *t*Bu^2), 7.77 (dd, $^3J_{HH}$ = 6.1 Hz, $^4J_{HH}$ = 2.1 Hz, 2 H, H^2), 8.30 (s, 2 H, H^4), 8.35 (d, $^4J_{HH}$ = 2.0 Hz, 2 H, H^3), 8.42 (d, $^3J_{HH}$ = 6.1 Hz, 2 H, H^1).

Method B: To a solution of **2** (50 mg, 0.0864 mmol) in acetonitrile (5 mL) was added a solution of $AgBF_4$ (67 mg, 0.344 mmol) in acetonitrile (2 mL). The solution was stirred for 18 h in the dark, and the resulting suspension was filtered. The filtrate was evaporated to dryness and the residue recrystallized from a CH_2Cl_2/CH_3CN mixture to yield the complex (51 mg, 82%).

[(η^3-terpy*)Pd(NHTs)](BF$_4$) (4): A suspension of TsNHK (44 mg, 0.210 mmol) in dichloromethane (6 mL) was added to a suspension of **3** (150 mg, 0.208 mmol) in dichloromethane (7 mL) while stirring. The reagents slowly dissolved while the solution turned yellow. After 18 h stirring at room temperature, the resulting suspension was filtered and the solvent was evaporated to dryness. The complex was recrystallized from THF/Et_2O as an air-stable, yellow powder (125 mg, 79%). – $C_{34}H_{43}BF_4N_4O_2PdS$ (765.01): calcd. C 53.38, H 5.67, N 7.32; found C 53.53, H 5.47, N 7.33.

[(η^3-triphos)Pd(NHTs)](BF$_4$) (5): To a solution of [(triphos)PdCl]Cl (136 mg, 0.191 mmol) in dichloromethane (4 mL) was added a suspension of $AgBF_4$ (74 mg, 0.380 mmol) in dichloromethane (2 mL). The mixture was stirred at room temperature for 30 min. and filtered. The filtrate was cooled to −78° C and a suspension of TsNHK (40 mg, 0.191 mmol) in dichloromethane (1 mL) was added. After stirring at −78° C for 30 min., the temperature was raised to 20° C and the suspension filtered. The solvent was evaporated to dryness and the crude product was obtained as an air-stable, orange powder (160 mg, 93%). The complex was recrystallized from acetonitrile/diethyl ether. – $C_{41}H_{41}BF_4NO_2P_3PdS$ (897.98): calcd. C 54.84, H 4.60, N 1.56; found C 54.96, H 4.65, N 1.85. – IR: ν_{NH} = 3303, 3263 cm^{-1}. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 2.1−3.4 (m, 8 H, CH_2), 2.31 (s, 3 H, Me), 2.55 (t, $^3J_{HP}$ = 3.1 Hz, 1 H, NH), 6.84, 6.90 (2 d, $^3J_{HH}$ = 8.7 Hz, 4 H, $H^{arom.\ Ts}$), 7.4−8.0 (m, 25 H, H^{Ph}). – $^{13}C\{^1H\}$ NMR (100 MHz, CD_3CN): δ = 21.4 (s, 1 C, Me), 28.3 (d virtual t, $^1J_{CP}$ = 34 Hz, $|^2J_{CP} + {}^4J_{CP'}|$ = 14 Hz, 2 C, C−PPh), 31.3 (d virtual t, $^2J_{CP}$ = 9 Hz, $|^1J_{CP} + {}^3J_{CP'}|$ = 32 Hz, 2 C, C−PPh_2), 126.1, 129.8 (2 s, 2 × 2 C, C−H^{Ts}), 126.6 (d, $^1J_{CP}$ = 52 Hz, 1 C, $C^{ipso\ PPh}$), 128.1, 129.5 (2 virtual t, $|^1J_{CP} + {}^3J_{CP'}|$ = 47 Hz, 2 × 2 C, $C^{ipso\ PPh}{}_2$), 130.3, 130.4 (2 virtual t, $|^3J_{CP} + {}^5J_{CP'}|$ = 11 Hz, 2 × 4 C, $C^{meta\ PPh}{}_2$), 131.0 (d, $^3J_{CP}$ = 11 Hz, 2 C, $C^{meta\ PPh}$), 133.3, 133.4 (2 s, 2 × 2 C, $C^{para\ PPh}{}_2$), 134.4, 134.7 (2 virtual t, $|^2J_{CP} + {}^4J_{CP'}|$ = 14 Hz, 2 × 4 C, $C^{ortho\ PPh}{}_2$), 134.6 (d, $^2J_{CP}$ = 12 Hz, 2 C, $C^{ortho\ PPh}$), 134.8 (d, $^4J_{CP}$ = 2 Hz, 1 C, $C^{para\ PPh}$), 141.4, 145.6 (2 s, 2 C, C−S + C−Me). – $^{31}P\{^1H\}$ NMR (121.5 MHz, CD_3CN): δ = 49.9 (d, $^2J_{PP}$ = 13 Hz, 2 P, PPh_2), 110.9 (t, $^2J_{PP}$ = 13 Hz, 1 P, PPh).

X-ray Crystallographic Study: Single crystals of **1** were obtained from a saturated diisopropyl ether solution cooled to −20° C. Single crystals of **4** and **5** were obtained with the double-layer method: a water layer was stratified with a saturated solution of **4** in an acetone/water mixture, and a saturated solution of **5** in an acetonitrile/toluene/pentane mixture was stratified with a pentane layer. The crystal data were collected at 173 K for complex **1** and at 294 K for complexes **4** and **5** on a Kappa CCD diffractometer for **1** and on a CAD4-MACH3 for **4** and **5**, using monochromated Mo-K_α radiation (λ = 0.71073 Å). Details of data collection parameters and refinements results are listed in Table 4. The structures were solved using direct methods. After refinement of the non-hydrogen atoms, difference-Fourier maps revealed maxima of residual electron density close to positions expected for hydrogen atoms. Hydrogen atoms were introduced as fixed contributors at calculated positions [C−H = 0.95 Å, B(H) = 1.3B_{eq})]. Final difference maps revealed no significant maxima. All calculations were done using the Nonius OpenMoleN package.[34] Neutral atom scattering factor coefficients and anomalous dispersion coefficients were taken from a standard source.[35]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-156069 (**1**), CCDC-156070 (**4**) and CCDC-156071 (**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Cyanide Exchange on $Tl(CN)_4^-$ in Aqueous Solution Studied by ^{205}Tl and ^{13}C NMR Spectroscopy

István Bányai,*[a] Julius Glaser,*[b] and Imre Tóth[c]

Keywords: Ligand exchange / Thallium / Cyanides / Tl NMR

Dynamics of cyanide exchange between $Tl(^{13}CN)_4^-$ and $^{13}CN^-$ was studied by means ^{205}Tl and ^{13}C NMR. The rate law consists of two parts: $w = k_{CN}[Tl(CN)_4^-][CN^-] + k_{OH}[Tl(CN)_4^-][CN^-][OH^-]$ with $k_{CN} = 9.7(\pm0.4) \times 10^6$ $M^{-1}s^{-1}$ and $k_{OH} = 5.4(\pm0.4) \times 10^{10}$ $M^{-2}s^{-1}$. It was shown that the exchange between the two cyano species can be studied, not only by ^{13}C NMR, but also by ^{205}Tl NMR using the heteronuclear carbon–thallium scalar coupling as an indicator, despite the fact that only one Tl site is present in the system. The reaction mechanism is discussed in terms of an associative interchange mechanism, I_A. Penetration of the incoming cyanide ion into the coordination sphere of $Tl(CN)_4^-$ and $Tl(CN)_4(OH)^-$ is suggested to be the rate-determining step for the two parallel reactions paths. Possible reasons for the strong labilizing effect of the cyanide ligand is discussed in the light of thermodynamic and structural data. The possibility of detection of an exceptional exchange reaction, namely cyanide exchange between two $Tl(CN)_4^-$ entities by a direct encounter was theoretically settled, but found to be too slow to be detected.

Introduction

Recently, the formation of strong complexes between Tl^{III} and cyanide, $Tl(CN)_n^{3-n}$, $n = 1-4$, was established, and their stability constants determined.[1] A detailed multimethod study was published on the structure, symmetry, and coordination numbers of chloro, bromo, and cyano Tl^{III} complexes in aqueous solution.[2] In the monocyano complex, Tl^{III} is six-coordinate, $TlCN(OH_2)_5^{2+}$. In the second complex, *trans*-$TlCN_2(OH_2)_4^+$, the thallium ion retains the six-coordination; the Tl−CN bond length is almost the same as in the first complex, 2.11 Å, and Tl−O is 2.42 Å, that is 0.2 Å longer than in the hydrated thallium(3+) ion, $Tl(OH_2)_6^{3+}$. Upon the formation of the third complex, $Tl(CN)_3(OH_2)$, the coordination number decreases to four and the symmetry is C_{3v} with Tl−C 2.15 Å and Tl−O 2.42 Å. The fourth complex is tetrahedral with the Tl−C bond length equal to 2.19 Å.

The dynamics of the ions of group-13 elements in solution has not been well studied, because of the difficulty of monitoring the reactions.[3−8] The dynamic properties of thallium(III) are not well known. The kinetics of complex formation with semixylenol orange and 4-(2-pyridylazo)resorcinol were studied by stopped-flow methods.[9,10] The complex $Tl(OH)^{2+}$ was found to be the active species in complex formation kinetics. Lincoln et al. reported a lower limit of the pseudo-first-order rate constant of the Cl^- ligand substitution on the $TlCl_6^{3-}$ complex.[11] There are only four recent papers dealing in detail with the ligand exchange of hydrated complexed thallium(III) ions in chemical equilibrium. In these papers,[12−14] high-field ^{205}Tl NMR spectroscopy was established as a powerful tool for elucidating exchange paths using line-shape analysis and two-dimensional exchange spectroscopy (2D EXSY).[15] Three types of exchange paths were identified for thallium(III) cyanide complexes.[14] The first path is a ligand "self-exchange" between complexes with no net chemical change, for example according to Equation (1).

$$Tl(*CN)(CN)^+ + Tl(CN)_3 \underset{}{\overset{k_{23}}{\rightleftharpoons}} Tl(*CN)(CN)_2 + Tl(CN)_2^+ \quad (1)$$

The second path is the common anation (or complex formation) reaction of thallium(III) complexes, e.g. according to Equation (2).

$$Tl(CN)_2^+ + CN^- \underset{}{\overset{k'_{23}}{\rightleftharpoons}} Tl(CN)_3 \quad (2)$$

The third path is a ligand substitution according to Equation (3).

$$Tl(*CN)(CN)^+ + HCN \underset{k_{HCN,2}}{\overset{k_{2,HCN}}{\rightleftharpoons}} Tl(CN)_2^+ + H*CN \quad (3)$$

Rate constants for all dominating ligand exchange pathways were determined (see Table 1). The first type of reaction, according to Equation (1), is a very rarely encountered kind of ligand exchange, related to the inner-sphere electron transfer as far as the ligand-bridged transition state is concerned.[16−18] This exchange pattern dominates at low ligand/metal ratios, and the reason why it is observable at all is the very low free-ligand concentration due to the strong complex formation. Taking into account the effect of different ligands and the activation parameters, a dissociatively activated interchange process was suggested to oper-

Table 1. Kinetic parameters for some exchange reactions of Tl^{III} halide and cyanide complexes in aqueous solution at 298 K; details for the rate-determining step (r.d.s.) are also given

Reaction	Determined rate constant, k_{ij}	Rate constant for r.d.s./s^{-1}, k_{ij}/K_{os}	Leaving/exchanging group	Ref.
$Tl(CN)_3 + Tl(CN)_4^- \rightleftarrows Tl(CN)_4^- + Tl(CN)_3$	444 $M^{-1}s^{-1}$	1500	CN^-	[14]
$Tl(CN)_2^+ + Tl(CN)_4^- \rightleftarrows 2\ Tl(CN)_3$	712 $M^{-1}s^{-1}$	500	CN^-	[14]
$Tl(CN)_2^+ + Tl(CN)_3 \rightleftarrows Tl(CN)_3 + Tl(CN)_2^+$	161 $M^{-1}s^{-1}$	500	CN^-	[14]
$Tl^{3+} + Tl(CN)_2^+ \rightleftarrows 2\ Tl(CN)^{2+}$	4.1 $M^{-1}s^{-1}$	900	CN^-	[14]
$Tl(CN)_2 + CN^- \rightleftarrows Tl(CN)_3$	3.9×10^9 $M^{-1}s^{-1}$	1.1×10^{10}	H_2O	[14]
$Tl(CN)_3 + CN^- \rightleftarrows Tl(CN)_4^-$	4.5×10^8 $M^{-1}s^{-1}$	1.5×10^9	H_2O	[14]
$Tl(*CN)(CN)^+ + CN^- \rightleftarrows Tl(CN)_2^+ + *CN^-$	6×10^9 $M^{-1}s^{-1}$	4×10^9	CN^-	[14]
$Tl(*CN)(CN)_3^- + CN^- \rightleftarrows Tl(CN)_4^- + *CN^-$	9.7×10^6 $M^{-1}s^{-1}$	1.3×10^8	CN^-	this work
$Tl(*CN)(CN)_3^- + CN^- (+OH^-) \rightleftarrows Tl(CN)_4^- + *CN^-$	5.4×10^{10} $M^{-2}s^{-1}$	–	CN^-	this work
$Tl(*Cl)(Cl)_{i-1}^{(3-i)} + Cl^- \rightleftarrows Tl(Cl)_i^{(3-i)} + *Cl^-$		10^6	Cl^-	[11]

ate for bromide and chloride in reactions according to Equation (1), i.e. after the encounter of the two complexes and formation of an outer-sphere complex, the leaving of a water ligand from the first coordination sphere of Tl^{III} is the rate-determining step. However, for the cyano Tl^{III} complexes $Tl(CN)_n(OH_2)_m^{3-n}$, the ligand "self-exchange" was found to be much slower than for the halide systems; hence, breaking of the Tl−CN bond, which is about 0.3 Å shorter than the Tl−halide bond, was suggested to be the rate-determining step.[14]

The anation reactions according to Equation (2) dominate the exchange for higher complexes and the rate of reaction depends on the entering ligand. Therefore, an associatively activated rate-determining step was proposed for both halide and cyanide complexes, where the entering ligand labilizes the coordinated water.

Also, it has been possible to determine the rate constants for the ligand substitution reaction according to Equation (3) on $Tl(CN)_2^+$ by means of ^{13}C NMR.[14] Two parallel reaction paths were identified, one with formal contribution of HCN and the other with CN^-. If the common Eigen−Wilkins-type reaction mechanism is assumed for the reaction path, with contribution of CN^-, then the incoming cyanide ion would have to labilize the bonded cyanide ion with 7 orders of magnitude in first-order rate constant units. This was judged to be less probable, and an alternative mechanism was suggested with the participation of HCN, which proceeded by deprotonation of the transition state.[14] In order to provide more confidence to the mechanism of the ligand substitution process according to Equation (3), additional experimental support was needed.

For the present study, the system $Tl(^{13}CN)_4^-/^{13}CN^-$ in aqueous media was selected. The usual tool for studying the chemical exchange in this system would be ^{13}C NMR, because (i) ^{13}C enrichment provides short measurement time and (ii) there are two exchanging carbon sites. Thus, basic conditions for a dynamic study of such an exchange reaction are fulfilled.[19] The convenient ^{205}Tl NMR [high natural abundance of the NMR active isotope(s), high NMR sensitivity, spin 1/2] can principally not be used in this case because only one chemical environment of Tl^{III} is present.

However, different magnetic thallium sites occur due to the scalar ^{205}Tl-^{13}C coupling, resulting in five signals in the ^{205}Tl NMR spectrum with an intensity ratio of 1:4:6:4:1. In the current paper it is shown that this fact makes the detection of the cyanide exchange possible by means of ^{205}Tl NMR. An additional advantage is provided by the fact that in ^{205}Tl NMR the observed line shape and the transfer of longitudinal magnetization is not affected by other exchange reactions in which the cyanide ion takes part; therefore, evaluation of the rate constants is more facile.

Results and Calculations

Determination of pH

Since knowledge of the pH is vital for the studied system, and the experiments had to be performed in a small volume, the NMR technique was the most straightforward way of measuring the pH. At first, 7 mM phosphate solution was prepared in the same medium as the real experiments. The pH was read using a pH meter with combined glass electrode (its internal solution contained NaCl instead of KCl in order to avoid the precipitation of $KClO_4$), and the chemical shift of the ^{31}P signal was determined. The pH was corrected according to Irving's method,[20] and from the dependence of ^{31}P NMR chemical shift vs. pH the actual pK values (protonation constants) and chemical shift values for the different protonated forms of phosphate were determined. For the actual ionic medium, the following values were obtained: $K_1 = (1.9\pm0.2)\times10^{11}$, $K_2 = (3.4\pm0.4)\times10^6$; $\delta(PO_4^{3-}) = 6.2\pm0.05$, $\delta(HPO_4^{2-}) = 3.47\pm0.06$, $\delta(H_2PO_4^-) = 0.7\pm0.03$. These values were then used for the determination of the actual $\log K_{HCN} = 9.9\pm0.2$ M^{-1}, which is in good agreement with the literature.[21] The latter stability constant was used for calculation of proton exchange rate constants between HCN and CN^-, which affects the ^{13}C NMR dynamics strongly.[22]

1D NMR Line-Shape Analysis

Some representative ^{205}Tl NMR and ^{13}C NMR spectra as a function of pH are shown in Figures 1 and 2, together

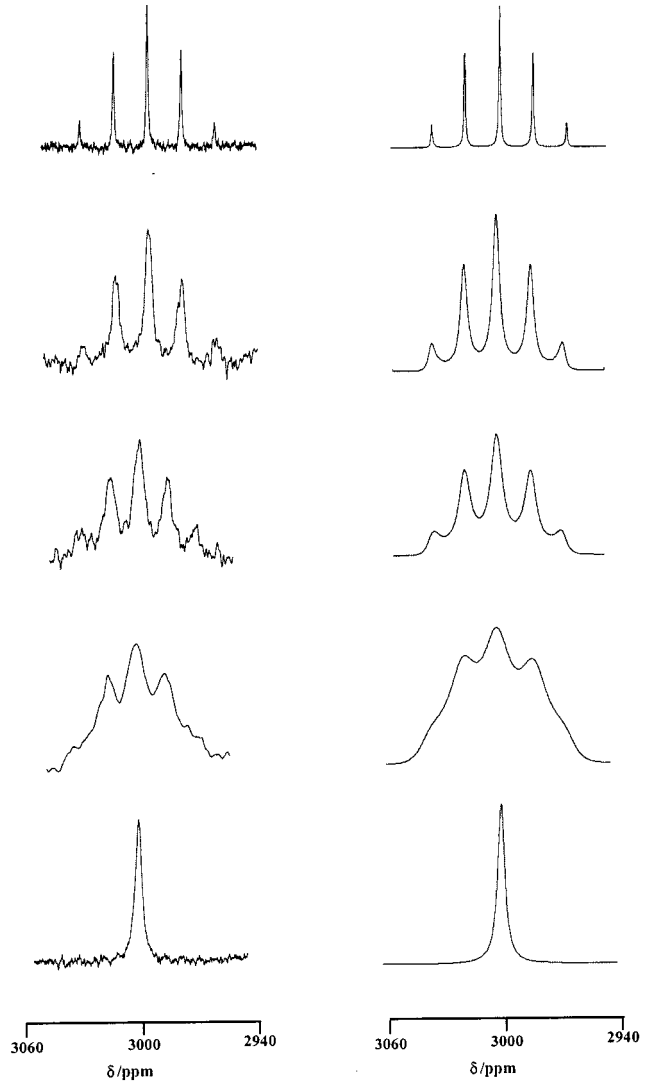

Figure 1. Measured and calculated ^{205}Tl NMR spectra of a solution where $[Tl^{3+}]_{tot}$ = 0.0504 M and $[CN^-]_{tot}$ = 0.135 M as a function of pH; from top to bottom: pH = 6.08 and k_{obs} = 176 s^{-1}, pH = 6.77 and k_{obs} = 861 s^{-1}, pH = 6.98 and k_{obs} = 1400 s^{-1}, pH = 7.16 and k_{obs} = 2120 s^{-1}, pH = 9.15 and k_{obs} = 18400 s^{-1}

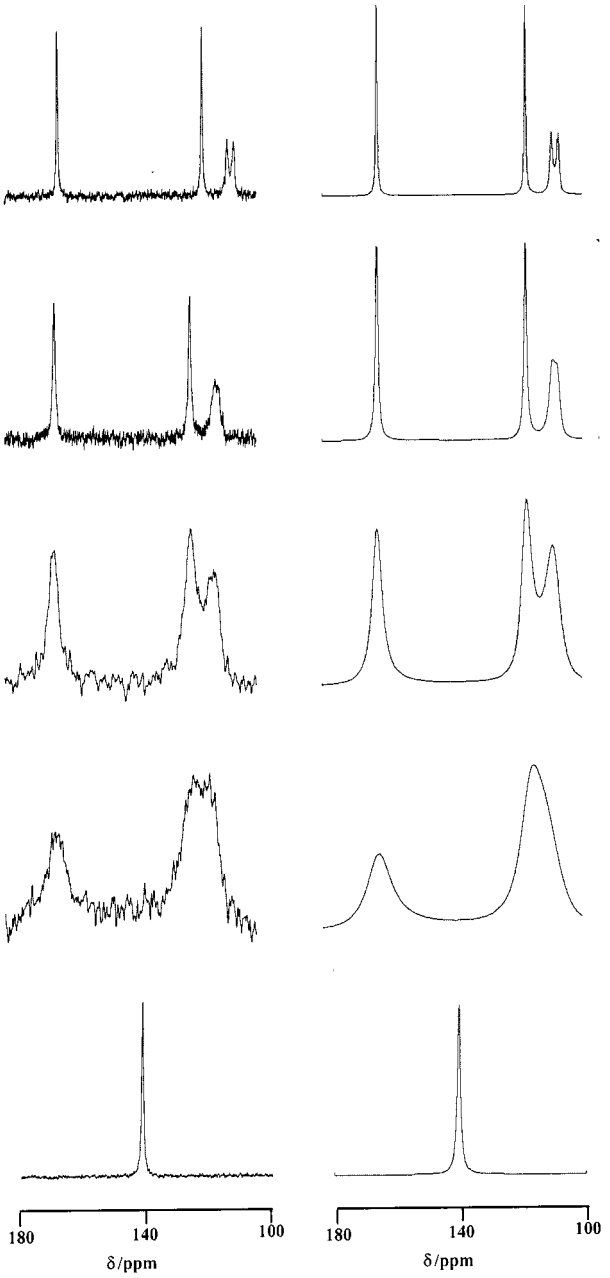

Figure 2. Measured and calculated ^{13}C NMR spectra of a solution in which $[Tl^{3+}]_{tot}$ = 0.0504 M and $[CN^-]_{tot}$ = 0.135 M as a function of pH; from top to bottom pH = 5.53, 6.08, 6.98, 7.16, and 9.82 (see text for details)

with the calculated spectra. It is apparent that complete band-shape analysis had to be used for both ^{205}Tl NMR and ^{13}C NMR.

The simulation of the spectra was made according to Equation (4) given by Reeves and Shaw[23,24] where V is the function of the frequency variable, **P** is the column vector of molar fractions (1/15,4/15,6/15,4/15,1/15 in the thallium pentet), and **C** is a matrix, Equation (5).

$$V = const\,\mathbf{C}^{-1}\,\mathbf{P} \tag{4}$$

$$\mathbf{C} = \mathbf{R_2} + \mathbf{w}\boldsymbol{\varepsilon}\mathbf{w} \tag{5}$$

$\mathbf{R_2}$ is the complete relaxation matrix given as a sum of diagonal matrix of the reciprocal relaxation times $\mathbf{T_{2i}}$ and rate matrix **K**, which contains the pseudo-first-order rate constants. $\boldsymbol{\varepsilon_2} = \mathbf{R_2}^{-1}$, and $\mathbf{w_i}$ is the diagonal matrix of chemical shifts in frequency units. In this case, the creation of the $\mathbf{R_2}$ rate matrix is crucial. It was written in the form for ^{205}Tl NMR [Equation (6)]; k_{obs} is the pseudo-first-order rate constant for all processes that result in exchange of transverse magnetisation between the spin-labelled Tl sites, defined in the usual way from the rate of the exchange reaction $w/[Tl(CN)_4^-]$.[19]

$$\mathbf{K} = \begin{pmatrix} -4k_{obs} & k_{obs} & 0 & 0 & 0 \\ 4k_{obs} & -4k_{obs} & 2k_{obs} & 0 & 0 \\ 0 & 3k_{obs} & -4k_{obs} & 3k_{obs} & 0 \\ 0 & 0 & 2k_{obs} & -4k_{obs} & 4k_{obs} \\ 0 & 0 & 0 & k_{obs} & -4k_{obs} \end{pmatrix} \tag{6}$$

Construction of the rate matrix was made as follows (see Appendix for details). The thallium sites in the ^{205}Tl NMR spectra are observed as five peaks because of the ^{13}C scalar coupling, which can simply be modelled by the spin states α and β of ^{13}C(N) around the thallium ion. The five peaks are Tl(α,α,α,α), Tl(α,α,α,β), Tl(α,α,β,β), Tl(α,β,β,β), and Tl(β,β,β,β) with the intensities according to the probability of existence of each species.[25,26] An exchange reaction, using simplified symbols for the species present, can therefore be written according to Equation (7).

$$\mathrm{Tl}(4\alpha) + \mathrm{CN}(\beta) \underset{}{\overset{k_{4\alpha,3\alpha}}{\rightleftharpoons}} \mathrm{Tl}(3\alpha1\beta) + \mathrm{CN}(\alpha) \qquad (7)$$

Taking into account the ratio of the concentrations of the different forms, and the fact that the rate is the same in both directions, the matrix **K** can be constructed. The principle of microscopic reversibility is fulfilled because the sum of the columns gives 0, while for the off-diagonal elements of the matrix $p_i k_{ij} = p_j k_{ji}$ (where p_i is the ith element of vector **P** and k_{ij} is an element of matrix **K** in ith line and jth column).

In contrast to the apparent simplicity of the rate matrix for ^{205}Tl NMR, the situation for ^{13}C NMR is more complicated both from a kinetic and a spectroscopic point of view. The species H^{13}CN (doublet at δ = 112.7, $^1J_{\mathrm{H\text{-}C}}$ = 270 Hz) exchanges with CN^-, causing line broadening in their signals. The cyanide ions exchange between the free cyanide ion and Tl(^{13}CN)$_4^-$ causing an additional broadening of the signals of the participating sites. Moreover, the species Tl(^{13}CN)$_4^-$ appears in the ^{13}C NMR spectrum as four signals; although the chemical shift is δ = 142.75, the isotopomers containing ^{205}Tl and ^{203}Tl, respectively, have different coupling constants to ^{13}C, resulting in two pairs of doublets.[1] The exchange system therefore requires a 7×7 matrix with rate constants for exchange between Tl(CN)$_4^-$ and CN^-/HCN, and HCN and CN^-. The latter exchange is known from the literature.[22] After a considerable effort the rate matrix could be constructed [see Appendix and Equation (8)]; $k_{\mathrm{HCN}}{}^{\mathrm{H}}$, $k_{\mathrm{CN}}{}^{\mathrm{H}}$ are the rate constants of the proton exchange between HCN and CN^-; k_{HCN} and k_{CN} are the rate constants of cyanide exchange between Tl(CN)$_4^-$ and HCN/CN^-, respectively. Half of the isotopomer ratios of ^{203}Tl and ^{205}Tl, are represented as r_3 (0.295/2) and r_5 (0.705/2), respectively, while the division factors 2 are due to the spin-spin coupling. The diagonal elements (Σ) were set up so that the sum of each column is zero.

Kinetic Analysis

First, the ^{205}Tl NMR spectra were analysed by giving different values for k_{obs} in Equation (6), and comparing the calculated line shapes to the experimental ones. In this way a set of pseudo-first-order rate constants was obtained and analysed as a function of pH (cf. Figure 3). The two models according to Equation (9) could describe the cyanide exchange at constant cyanide concentration.

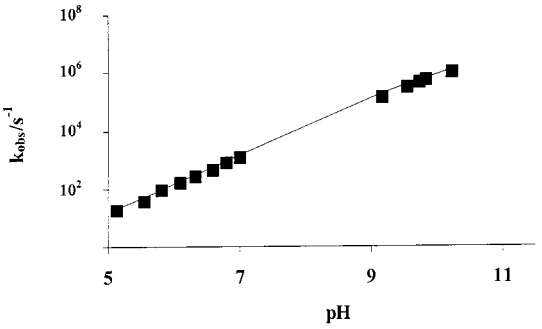

Figure 3. The dependence of the pseudo-first-order rate constants on the [H$^+$] concentration (squares); the line represents the best fit according to Equation (10b) with k_{CN} = (9.7±0.4)×10^6 M^{-1}s^{-1} and k_{OH} = (5.4±0.4)×10^{10} M^{-2}s^{-1}

$$w = k_{\mathrm{CN}}[\mathrm{CN}^-][\mathrm{Tl(CN)_4}^-] + k_{\mathrm{OH}}[\mathrm{OH}^-][\mathrm{Tl(CN)_4}^-] \qquad (9a)$$

or

$$w = k_{\mathrm{CN}}[\mathrm{CN}^-][\mathrm{Tl(CN)_4}^-] + k_{\mathrm{OH}}[\mathrm{OH}^-][\mathrm{CN}^-][\mathrm{Tl(CN)_4}^-] \qquad (9b)$$

Taking into account the facts that w/[Tl(CN)$_4^-$] equals k_{obs} and K_{HCN} = [HCN]/[H$^+$][CN^-], the dependencies on the pH are according to Equation (10), where K_w is the water ion product and T_{CN} is the total concentration of the uncomplexed cyanide.

$$k_{obs} = \frac{k_{OH}K_w + (k_{OH}K_{HCN}K_w + k_{CN}T_{CN})[\mathrm{H}^+]}{(1 + K_{HCN}[\mathrm{H}^+])[\mathrm{H}^+]} \qquad (10a)$$

$$k_{obs} = \frac{k_{OH}T_{CN}K_w + k_{CN}T_{CN}[\mathrm{H}^+]}{(1 + K_{HCN}[\mathrm{H}^+])[\mathrm{H}^+]} \qquad (10b)$$

In order to distinguish between the two possibilities [Equations (9a) and (9b)], the line width was also measured in a solution that had ten times lower free cyanide concentration. At the same pH the line width decreased with a factor of about ten, which shows that the rate Equation (9b) is operative. The results of the least-squares fitting are shown in Figure 3, and the calculated rate constants are:

$$\mathbf{K} = \begin{pmatrix} \Sigma & 0 & \frac{1}{2}k_{HCN}[\mathrm{HCN}] & \frac{1}{2}k_{HCN}[\mathrm{HCN}] & \frac{1}{2}k_{HCN}[\mathrm{HCN}] & \frac{1}{2}k_{HCN}[\mathrm{HCN}] & k_{CN}^H \\ 0 & \Sigma & \frac{1}{2}k_{HCN}[\mathrm{HCN}] & \frac{1}{2}k_{HCN}[\mathrm{HCN}] & \frac{1}{2}k_{HCN}[\mathrm{HCN}] & \frac{1}{2}k_{HCN}[\mathrm{HCN}] & k_{CN}^H \\ k_{HCN}r_5[\mathrm{Tl}] & k_{HCN}r_5[\mathrm{Tl}] & \Sigma & 0 & 0 & 0 & k_{CN}r_5[\mathrm{Tl}] \\ k_{HCN}r_3[\mathrm{Tl}] & k_{HCN}r_3[\mathrm{Tl}] & 0 & \Sigma & 0 & 0 & k_{CN}r_3[\mathrm{Tl}] \\ k_{HCN}r_3[\mathrm{Tl}] & k_{HCN}r_3[\mathrm{Tl}] & 0 & 0 & \Sigma & 0 & k_{CN}r_3[\mathrm{Tl}] \\ k_{HCN}r_5[\mathrm{Tl}] & k_{HCN}r_5[\mathrm{Tl}] & 0 & 0 & 0 & \Sigma & k_{CN}r_5[\mathrm{Tl}] \\ 2\times k_{HCN}^H & 2\times k_{HCN}^H & k_{CN}[\mathrm{CN}] & k_{CN}[\mathrm{CN}] & k_{CN}[\mathrm{CN}] & k_{CN}[\mathrm{CN}] & \Sigma \end{pmatrix} \qquad (8)$$

$k_{CN} = (9.7\pm0.4)\times10^6$ M^{-1}s^{-1} and $k_{OH} = (5.4\pm0.4)\times10^{10}$ M^{-2}s^{-1}.

In order to further verify the rate constants determined by ^{205}Tl NMR these were introduced into the rate matrix of ^{13}C NMR [Equation (8)], and the proton exchange rate constants were taken from the literature.[22] Then, ^{13}C NMR spectra were simulated (Figure 2, right side); good agreement was found considering that the literature values were obtained for a different ionic medium. The largest deviation in the line widths was generally below 10%.

Similarly to the recently established existence of the ligand "self-exchange" between complexes, e.g. $Tl(CN)_3$ and $Tl(CN)_4^-$,[14] it was now considered that cyanide exchange can also occur between two $Tl(CN)_4^-$ species according to Equation (11).

$$Tl(^*CN)_4^- + Tl(CN)_4^- \underset{}{\overset{k_{4,4}}{\rightleftharpoons}} Tl(CN)_4^- + Tl(^*CN)_4^- \qquad (11a)$$

Use of the short notations introduced above, and considering an encounter of two thallium complexes with different spin states of ^{13}C yields Equation (11b).

$$Tl(4\alpha) + Tl(3\alpha\beta) \overset{k_{4,4}}{\rightleftharpoons} Tl(3\alpha\beta) + Tl(4\alpha) \qquad (11b)$$

If this reaction were to occur, then it would be possible to study it by both ^{13}C and ^{205}Tl NMR because of the scalar coupling present in these systems.[25] A solution sample was prepared, suitable for detection of such a reaction, i.e. pH and cyanide concentration was kept as low as possible in order to slow down the exchange paths described by Equations (9a) and (9b). However, pH could not be decreased below a certain value, in order to avoid the exchange between $Tl(CN)_3$ and $Tl(CN)_4^-$. The composition of the sample was: $[Tl^{3+}]_{tot} = 0.0434$ M, $[^{13}CN^-]_{tot} = 0.1816$ (in 3.0 M $NaClO_4$), and the pH was carefully regulated to 6.5 as monitored by ^{31}P NMR. Both ^{205}Tl and ^{13}C NMR spectra were recorded for this sample in order to assure that no significant amount of $Tl(CN)_3$ was present. In order to determine the exchange rate matrix in a facile way, ^{205}Tl NMR 2D-EXSY experiments were run on the sample using mixing times of 4 ms and 8 ms. Cross peaks were detected (cf. Figure 4), indicating chemical exchange between the magnetically labelled spin sites of $Tl(CN)_4^-$. A quantitative analysis resulted in the rate matrices for 4 ms mixing time [Equation (12a)] and for 8 ms mixing time [Equation (12b)].[27]

-	-	49.4	-2.9	119.2
-	-	-	29.8	39.6

(12b)

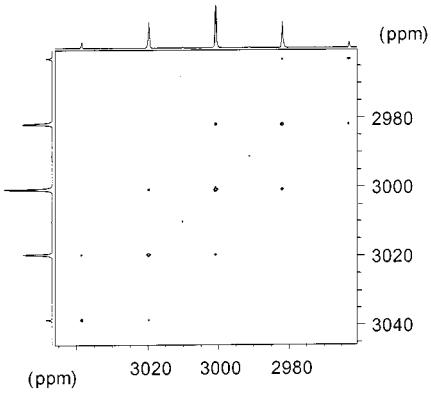

Figure 4. ^{205}Tl 2D EXSY of $Tl(^{13}CN)_4^-$ aqueous solution with mixing time 4 ms; $T = 298$ K; ^{12}C satellites are also visible at $\delta = 2990$ and 3010

The matrix elements denoted by "−" have no real meaning and have been removed. Also, the diagonal elements are not the real ones because we did not use zero mixing time for the calculation.[27] Then, using the rate constants determined above from the 1D NMR spectra, the rate matrix was calculated [Equation (12c)].

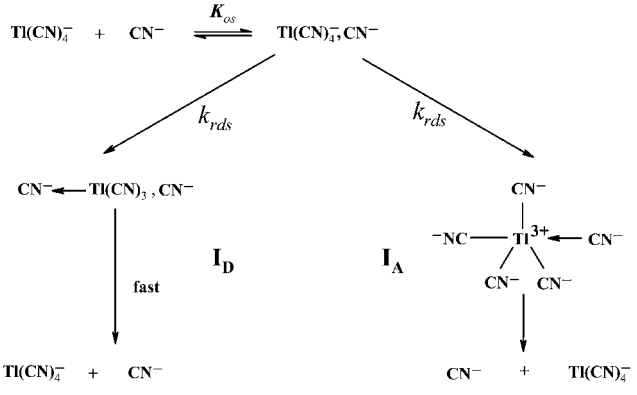
-120	30	0	0	0
120	-120	60	0	0
0	90	-120	90	0
0	0	60	-120	120
0	0	0	30	-120

(12c)

Good agreement can be recognized in the off diagonal elements of the matrices [Equation (12)]. Therefore, no further detectable parallel reaction path is needed to describe the system, even at very small cyanide excess. Thus, it can be concluded that NMR makes it possible to detect the otherwise undetectable exchange reactions according to Equation (11), if they match the NMR criteria (lifetime comparable to the NMR relaxation times) and kinetic criteria (high enough exchange rate).

Discussion

For the ligand substitution process according to Equation (13) the rate Equation (14) was found.



Scheme 1

$$Tl(CN)_4^- + *CN^- \underset{k_{CN,4}}{\overset{k_{4,CN}}{\rightleftharpoons}} Tl(*CN)(CN)_3^- + CN^- \quad (13)$$

$$w = k_{4,CN}[CN^-][Tl(CN)_4^-] + k_{OH}[OH^-][CN^-][Tl(CN)_4^-] \quad (14)$$

In Equations (13) and (14) the notation of the rate constant is $k_{4,CN}$ (instead of k_{CN}), i.e. the same as in our earlier papers on the same or related subject.[12–14]. Usually, the Eigen–Wilkins-type mechanism[28] is used to describe such reactions according to Scheme 1.

During the first, generally fast step an ion pair is formed for which the stability constant can be estimated using the Fuoss equation, by considering only the electrostatic interactions.[28] For the present case this stability constant $K_{os}(-1,-1)$ is 0.074, from which the rate constant of the rate-determining step can be calculated as $k_{rds} = k_{4,CN}/K_{os} = 1.3\ 10^8\ s^{-1}$. There are two parallel paths according to Scheme 1. If the rate of dissociation of a CN^- ligand determines the exchange rate, the path is a dissociative interchange I_D. If the incoming cyano ligand forces out one of the complexed ligands, the process is an associative interchange I_A (or limiting associative A, if a complex with a higher coordination number can be detected).

The hitherto reported rate constants concerning pertinent ligand exchange reactions in chemical equilibrium have been collected (cf. Table 1) and can be helpful for suggesting the mechanism of the presently studied reaction. In the case of a "self-exchange" reaction, when one cyanide ion goes from one metal ion to another (see Table 1, first four lines), it was found that the rupture of a Tl–C bond is a slow process with rate constant of a few hundred s^{-1}.[14] For complex formation reactions (Table 1, lines 6–7) these rate constants are several orders of magnitude larger, because the bottle-neck of these reactions is the rupture of the $Tl-OH_2$ bond activated by the entering ligand, or sometimes the diffusion.[29] These rate constants are equally high for the thallium(III) halide and cyanide complexes, and larger than the estimated water exchange rate.[12] Therefore, it was concluded that an associatively activated process I_A operates. There was some doubt about this, because no pronounced entering ligand effect was found when comparing the chloride, bromide, and cyanide complexes. However, this was attributed to the fact that these complex formation reactions had a rate close to the diffusion control limit; therefore, the differences cannot be observed.[14]

In the case of ligand substitution reactions of $Tl(CN)_2^+$ [Equation (3)] it was difficult to characterise the mechanism: rupture of the Tl–C bond must occur in any case because of the symmetric nature of the reaction according to Equation (3). However, the calculated rate constant of the rate-determining step was also found to be much higher than those found for the ligand exchange between complexes, according to Equation (1).[14] This was surprising, and an alternative mechanism was suggested in the case of $Tl(CN)_2^+$ with participation of HCN (rather than CN^-).[14] In the present work, another rate constant has been determined for ligand substitution, e.g. on $Tl(CN)_4^-$, with an equally fast rate-determining step. A probable explanation is that the incoming cyanide ion coordinates, forming a transition state where the complexes are highly labile. Therefore, an associative interchange or associative mechanism is supposed to be operative.

In order to interpret the details of the reaction mechanism of the ligand substitution reaction paths the data in Table 1 can be utilised. Let us start with ligand exchange reaction between complexes [Equation (1)]. If we suppose that binuclear complexes are temporarily formed so that the attacking "ligand" is complexed as well, it is difficult to assume any labilizing effect of the incoming reactants. Therefore, the most probable rate-determining step is a rupture of the metal–ligand bond in the transition state containing a ligand in a bridging position. The kinetic stability, i.e. inertness, of these intermediates could well be controlled by the lability of the metal–ligand bond. This interpretation is supported by the similarity of the halide ligands in this so called "self exchange", whereas there is a significant difference between the halide ions and the more covalently bonded cyanide ion. For the species $Tl(CN)_n^{3-n}$ this reaction is slower by a few orders of magnitude compared to that for the thallium(III) halide complexes.

If it is accepted that the ligand "self-exchange" [Equation (1)] mirrors the Tl–CN bond breaking with little external influence then the high rate of ligand substitution [Equation (13)] is unexpected. At this point, the physical/chemical properties of the studied species should be considered. The thermodynamic stability of the thallium cyanide complexes[1] is: $\log K_i = 13.21, 13.39, 8.67$, and 7.44, for $i =$ 1 to 4, respectively. The first two Tl^{III} halide complexes are five orders of magnitude stronger, which can serve as an indication for changing of the character of the metal–ligand bond.[31] The first two cyanide complexes show similarity with covalently bonded organometallic Tl^{3+} compounds,[32,33] while $Tl(CN)_3$ and $Tl(CN)_4^-$ show similarity to the usual inorganic ligand coordination mainly by donation of the electrons to the metal ion. This difference can also be discerned in the behaviour of Tl^{III} complexes in organometallic reactions.[33]

The steric arrangement and change of the coordination geometry may play a key role in kinetics and in mechanistic considerations. For the cyano Tl^{III} species, $Tl(CN)_n(OH_2)_{6-n}^{n-3}$ ($n = 1$ and 2) in solution, the coordination number is six with equal and very short Tl–CN bond lengths, 2.10–2.11 Å.[2] For $n = 3$ and 4 this bond is significantly longer, 2.15 and 2.19 Å, respectively, and these complexes are both tetrahedral. However, the bond lengths are still 0.2–0.4 Å shorter than the corresponding bonds of the halides.

Ligand substitution kinetic data for cyanide exchange is known for two species only, $Tl(CN)_2(OH_2)_4^{2+}$ [14] and $Tl(CN)_4^-$ (this work). For $Tl(CN)_2(OH_2)_4^{2+}$, after the attack of the incoming cyanide ligand a new species forms as a transition state in which the Tl–CN bond resembles the one in $Tl(CN)_3$, but still with a number of water molecules (probably four) in the first coordination sphere of the thallium ion. Presumably, this Tl–CN bond is more labile due to the much higher coordination number than the one in the thermodynamically stable third complex, namely

$Tl(CN)_3(OH_2)$.[2] With this argument, the fast ligand substitution can be understood.

For $Tl(CN)_4^-$, a transition state species with five-coordination is expected to be labile. Also in this case, the rate of insertion of the entering ligand determines the rate of leaving of the coordinated ligand; therefore, an associative interchange mechanism is probable.

The hydroxide-dependent parallel path also needs some consideration: (i) Such a path is not often encountered in ligand substitution reactions, but if it exists it proceeds by OH^- catalysis and deprotonation of the coordinated ligands.[28] (ii) Hitherto, formation of ternary hydroxo Tl^{3+} cyanide complexes has not been reported, although binary hydroxo complexes with high stability are well known.[30] However, all earlier investigations were made in acidic solution in order to avoid hydrolysis. In Figure 5, relative contributions of the two reaction paths are presented. It can be seen that the contribution of the hydroxide-assisted reaction path starts to be effective for pH > 9.5.

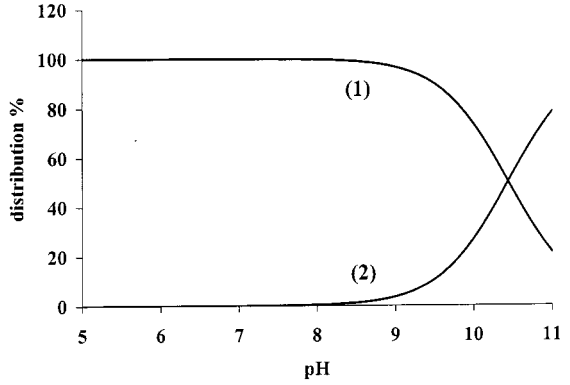


Figure 5. The relative contribution of the two reaction paths, (1) without and (2) with OH contribution, as a function of the pH

A first approximation was to consider both HCN and CN^- as reactive species; however, this was not compatible with the experiments. If $Tl(CN)_3OH^-$ were assumed to be the active species then the rate equation would not have the form of Equation (9b). It is possible that a five-coordinate $Tl(CN)_4OH^{2-}$ acts as kinetically active species which would give a rate equation consistent with the one obtained [Equation (10)]. However, the calculation of the rate-determining step is difficult because the stability constant of the suggested $Tl(CN)_4OH^{2-}$ is not known. In fact, when the pH is increased to > 11 the solution containing Tl^{III} and excess cyanide turns brownish, indicating that in spite of the high stability of the cyanide complexes they can be transferred into (mixed) hydroxo species. In this case, the penetration of the incoming cyanide ion would determine the exchange rate in the same way as discussed above. The limiting associative mechanism, that is the formation of six-coordinate species from $Tl(CN)_4OH^{2-}$, would not be compatible with the experimental findings, namely that a maximum of four cyanide ligands can coordinate to the thallium(III) ion, even at a large cyanide excess.[1] Also, other kinetic data are consistent with the suggested reaction mechanism. Mixed complexes with exceptionally high coordination numbers, for example those between $Tl(edta)^-$ on one side and Cl^-, Br^-, CN^-, and SCN^- on the other side also show high kinetic lability.[34]

In conclusion, two new examples of ligand substitution reactions for cyanothallium(III) complexes were established. The new reactions, similar to the previously described one [Equation (3)], proceed by an associatively activated interchange mechanism.

^{205}Tl NMR was confirmed to be the experimental technique of choice for studies of thallium solution chemistry. In this specific case, due to the magnetic spin labelling it was possible to utilise its power despite the fact that only one thallium-containing species was participating in the chemical process under study.

Experimental Section

Preparation and Analysis of Solutions: A ca. 1.2 M aqueous stock solution of $Tl(ClO_4)_3$ in 3.8 M $HClO_4$ was prepared by anodic oxidation of a $TlClO_4$ solution.[30,31] The concentrations of acid and thallium content in the stock solution were determined as described elsewhere.[35] The samples were prepared from the appropriate volume of the stock solution, solutions of 0.3 M $HClO_4$ and 5 M $NaClO_4$, and a weighted amount of solid $Na^{13}CN$ (Cambridge Isotope Laboratories, > 99% ^{13}C enrichment). In order to keep the activity coefficients of the reacting species approximately constant, the total sodium concentration, $[Na^+]_{tot}$, was kept at 3 M. The composition of the samples was determined by quantitative ^{205}Tl and ^{13}C NMR. Some details of sample preparation and analysis were described in a previous paper.[12] The pH dependence of the ^{205}Tl NMR and ^{13}C NMR spectra was recorded by titration of a 1-mL sample with 0.3 M $HClO_4$ (containing the same ionic medium, i.e. 3 M $NaClO_4$) in an NMR tube using a micro syringe, between pH = 7.4 and pH = 5.12. The change of pH was measured by ^{31}P chemical shifts; this "potentiometer" was calibrated by pH potentiometry in independent experiments.[36] The sample contained 7 mM total PO_4^{3-} in different protonated forms. Another 1 mL of the solution was titrated with NaOH in a similar way. In this case, the $^{13}CN/HCN$ signal was also used for checking the pH.

NMR Measurements: All NMR spectra were recorded at a probe temperature of 25±0.5 °C with a Bruker DMX500 spectrometer. The magnetic field was unlocked; field drift was found to be negligible. ^{205}Tl NMR: spectrometer frequency 289.4 MHz, flip angle 90° (12 μs), pulse repetition time of 5 s was found long enough for complete magnetic relaxation. The chemical shifts are reported in ppm toward higher frequency with respect to an aqueous solution of $TlClO_4$ extrapolated to infinite dilution. ^{13}C NMR: spectrometer frequency 125.8 MHz, flip angle ca. 30° (8 μs), relaxation delay was in the range 4−16 s depending on the relaxation rates of the investigated species. The chemical shifts are reported in ppm toward higher frequency with respect to an external water-soluble sodium derivative of TMS. ^{205}Tl 2D-EXSY NMR spectra were recorded with 512 increment experiments, each consisting of 8 scans and with 5 s relaxation delay. Fourier transformations were performed in a 1K×1K data-point matrix with a window function cosine and an SSB = 2 filter. The Fourier transformation, volume integration and other NMR spectroscopic data treatment was performed using a Bruker program package (2D WinNMR®).

APPENDIX

Construction of Rate Matrices for ^{205}Tl NMR

As was found in a previous paper from this laboratory, in an exchange process between two complexed cyano species only one cyanide ligand changes its position.[15] Therefore, only this type of transition is considered. As an example, we choose the process when one cyanide ion goes from $Tl[CN_4(4\alpha)]^-$ [denoted for the sake of simplicity as Tl(4α)] to $Tl(CN)(3\alpha,1\beta)^-$ [denoted as Tl(3α)]. The labels in brackets give the concentrations of the various carbon-labelled Tl sites. For example: $Tl[CN_4(4\alpha)]^-$ has four α-carbon atoms and the concentration is [4α] while for $Tl(CN)(3\alpha,1\beta)^-$ the notation is [3α]. The rate of exchange from site i to j is written using pseudo-first-order rate constants (or observed rate constants) k_{ij}, as in Equation (15).

$$w_{43} = w_{34} = k_{43}[4\alpha] = k_{34}[3\alpha] \quad (15)$$

From Equation (15) the most important consequence is the relation between the forward and backward observed rate constants [Equation (16)].

$$k_{34}=k_{43}\frac{[4\alpha]}{[3\alpha]}=\frac{1}{4}k_{43} \quad (16)$$

It is easy to generalize Equations (15) and (16) as Equations (17) and (18).

$$w_{ij} = w_{ji} = k_{ij}[j\alpha] = k_{ij}[i\alpha] \quad (17)$$

$$k_{ij} = k_{ij}([i\alpha]/[j\alpha]) = p_j/p_i \quad (18)$$

From these considerations Equation (19) follows.

$$k_{34} = k_{43}\frac{1}{4}; k_{23} = k_{32}\frac{2}{3}; k_{12} = k_{21}\frac{3}{2}; k_{01} = k_{10}\frac{4}{1}; \quad (19)$$

It is obvious that since all exchanges are identical reactions from a chemical point of view (i.e. one cyano ligand is substituted) they cannot be characterized by four different rate constants. Let us consider that if a Tl(3α,1β) meets $CN^-(\alpha)$ the probability of forming Tl(4α) is one, but if this interaction happens between $CN^-(\alpha)$ and Tl(2α,2β) then this probability is twice as high because there are two cyanide ions with β spin state. Following this consideration up to Tl(4α) we can find a series of relations as in Equation (20).

$$k_{10} = k^{obs}; k_{01} = 4k^{obs}; k_{12} = 3k^{obs}; k_{21} = 2k^{obs}; k_{23} = 2k^{obs}; k_{32} = 3k^{obs}; k_{34} = k^{obs}; k_{43} = 4k^{obs} \quad (20)$$

These considerations are a consequent application of microscopic reversibility, therefore the sum of the elements of each column of the rate matrix **K** should be zero provided that the matrix was correctly constructed. It is easy to make mistakes in setting up the rate matrix, especially when the number of elements is large. However, in the test phase of the model, reaching the so called "fast exchange" regime − when only one peak appears − calculation of the chemical shift will be wrong if the matrix setup is not correct, indicating the error. The model calculation was performed so that the k_{obs} values were varied until the band shape of the calculated spectra were identical with the experimental ones. Then, the dependence of the obtained observed rate constant on the pH was analyzed.

Construction of Rate Matrices for ^{13}C NMR

The construction of the ^{13}C rate matrix required somewhat longer, but not more complicated algebra. While for ^{205}Tl NMR we knew that all peaks are determined by one exchange reaction, and as they were side-bands of a main peak they had to behave in exactly the same way, for ^{13}C NMR it is not the case. Still, there are multiplets in the spectrum: Hα and Hβ, Tlα5 and Tlβ5 (for the ^{205}Tl isotope), or Tlα3 and Tlβ3 (for the ^{203}Tl isotope) which behave identically. However, the isotopomers behave as independent species and have different line widths caused by the exchange, because of their different populations. Furthermore, the proton exchange between HCN and CN^- should also be taken into account. First, we denote the seven signals a follows: Hα and Hβ are HCN doublets; Tlα5 and Tlβ5 are the ^{205}Tl-coupled doublets; Tlα3 and Tlβ3 are the ^{203}Tl-coupled doublets; CN is the signal of the cyanide ion. The concentrations according to the previous paragraph are the notations in brackets, e. g. [Hα] is the concentration of the α-spin-state proton-containing HCN. The task is to find the smallest number of observed rate constants from which we can combine the possible 42 elements of the **K** rate matrix. Take a reaction between $Tl(CN)_4^-$ (Tlα5) and H(α)CN. According to Equation (15) the Equations (21) and (22) follow.

$$w_{H\alpha\alpha5} = w_{\alpha5H\alpha} = k_{H\alpha\alpha5}[H\alpha] = k_{\alpha5H\alpha}[Tl\alpha5] \quad (21)$$

$$k_{H\alpha\alpha5} = k_{\alpha5H\alpha}([Tl\alpha5]/[H\alpha]) \quad (22)$$

According to Equations (21) and (22) we can obtain 8 relations between 16 elements of **K**, i. e. exchange between Hα and Tlα5, Tlα3, Tlβ5, Tlβ3; and between Hβ and Tlα5, Tlα3, Tlβ5, Tlβ3. Of course, there is only one chemically determined rate process, namely according to Equation (23).

$$w = k_{HCN}[HCN][Tl(CN)4^-] \quad (23)$$

The rate constant is independent of the spin labelling, therefore Equation (24) follows.

$$w_{H\alpha\alpha5} = w_{\alpha5H\alpha} = k_{HCN}[H\alpha][Tl\alpha5] \quad (24)$$

Considering the relation between the concentration of the chemically identical but magnetically labelled species Equation (25) is given, where 0.705 is the isotopic ratio of the ^{205}Tl isotope.

$$w_{H\alpha\alpha5} = w_{\alpha5H\alpha} = k_{HCN}\frac{1}{2}[HCN]\frac{0.705}{2}[Tl(CN)_4^-] \quad (25)$$

Therefore, the pseudo-first-order rate constants for the forward and backward reaction is given by Equation (26).

$$k_{H\alpha\alpha5} = w/\frac{1}{2}[HCN] = k_{HCN}\frac{0.705}{2}[Tl(CN)_4^-] \quad (26a)$$

$$k_{\alpha5H\alpha} = w/\left(\frac{0.705}{2}[Tl(CN)_4^-]\right) = k_{HCN}\frac{1}{2}[HCN] \quad (26b)$$

Another three pairs of this type of relation is valid for the rest of exchange processes in which H(α)CN is involved [Equation (27) to (29)].

$$k_{H\alpha\alpha3} = w/\frac{1}{2}[HCN] = k_{HCN}\frac{0.295}{2}[Tl(CN)_4^-] \quad (27a)$$

$$k_{\alpha3H\alpha} = w/\left(\frac{0.295}{2}[Tl(CN)_4^-]\right) = k_{HCN}\frac{1}{2}[HCN] \quad (27b)$$

$$k_{H\alpha\beta5} = w/\frac{1}{2}[HCN] = k_{HCN}\frac{0.705}{2}[Tl(CN)_4^-] \quad (28a)$$

$$k_{\beta5H\alpha} = w/\left(\frac{0.705}{2}[Tl(CN)_4^-]\right) = k_{HCN}\frac{1}{2}[HCN] \quad (28b)$$

$$k_{H\alpha\beta3} = w/\frac{1}{2}[HCN] = k_{HCN}\frac{0.295}{2}[Tl(CN)_4^-] \quad (29a)$$

$$k_{\beta3H\alpha} = w/\left(\frac{0.295}{2}[Tl(CN)_4^-]\right) = k_{HCN}\frac{1}{2}[HCN] \quad (29c)$$

Of course, we have four pairs of relations for exchanges where H(β)CN is involved which are exactly the same. Therefore, 16 elements are already determined. Another 8 elements come from the reaction between CN^- and Tlα5, Tlα3, Tlβ5, Tlβ3 [Equations (30) and (31)].

$$w_{CN\alpha5} = w_{\alpha5CN} = k_{CN\alpha5}[CN^-] = k_{\alpha5CN}[\alpha5] \quad (30)$$

$$k_{CN\alpha5} = k_{\alpha5CN}([\alpha5]/[CN^-]) \quad (31)$$

Also here, only one chemical reaction should be taken into account, namely according to Equations (32) and (33).

$$w = k_{CN}[CN^-][Tl(CN)_4^-] \quad (32)$$

$$w_{CN\alpha5} = w_{\alpha5CN} = k_{CN}[CN^-][Tl\alpha5] \quad (33)$$

It is important to note that we consider principally only one reaction path. Of course, there can be many parallel reaction paths, but it principally does not change the final results.

Substitution of the concentrations of the different Tl species into Equation (33) yields Equation (34), which leads to the pseudo-first-order rate constants according to Equations (35) to (38).

$$w_{CN\alpha5} = w_{a5CN} = k_{CN}\left[CN^-\right]\frac{0.705}{2}\left[Tl(CN)_4^-\right] \quad (34)$$

$$w_{CN\alpha5} / \left[CN^-\right] = k_{CN}\frac{0.705}{2}\left[Tl(CN)_4^-\right] \quad (35a)$$

$$w_{\alpha5CN} / \frac{0.705}{2}\left[Tl(CN)_4^-\right] = k_{CN}\left[CN^-\right] \quad (35b)$$

$$w_{CN\alpha3} / \left[CN^-\right] = k_{CN}\frac{0.295}{2}\left[Tl(CN)_4^-\right] \quad (36a)$$

$$w_{\alpha3CN} / \frac{0.295}{2}\left[Tl(CN)_4^-\right] = k_{CN}\left[CN^-\right] \quad (36b)$$

$$w_{CN\beta5} / \left[CN^-\right] = k_{CN}\frac{0.705}{2}\left[Tl(CN)_4^-\right] \quad (37a)$$

$$w_{\beta5CN} / \frac{0.705}{2}\left[Tl(CN)_4^-\right] = k_{CN}\left[CN^-\right] \quad (37b)$$

$$w_{CN\beta3} / \left[CN^-\right] = k_{CN}\frac{0.295}{2}\left[Tl(CN)_4^-\right] \quad (38a)$$

$$w_{\alpha5CN} / \frac{0.295}{2}\left[Tl(CN)_4^-\right] = k_{CN}\left[CN^-\right] \quad (38b)$$

Since it turned out that the reactions between the magnetically labelled Tl species, e.g. Tlα5 and Tlβ5, do not occur, we do not show how they were introduced into the rate matrix.

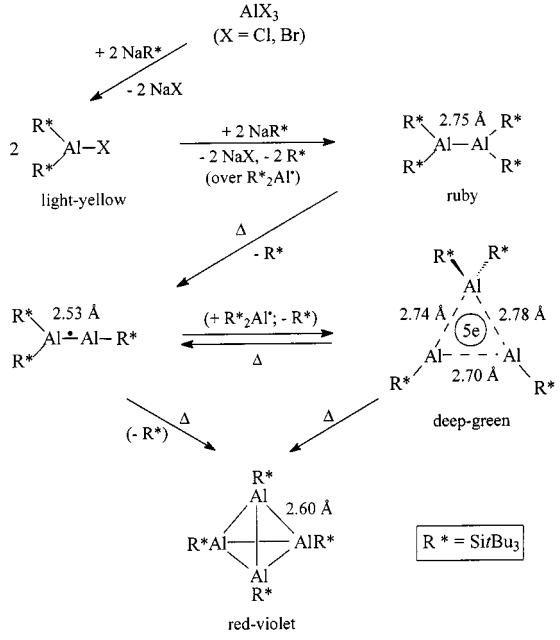
Keywords: Anions / EPR spectroscopy / Gallium / Radicals / Silicon / X-ray structural analyses

The reduction of black-blue tris(supersilyl)digallanyl $[R^*_2Ga–GaR^*]^{\cdot}$ (R^* = Si*t*Bu$_3$ = supersilyl) in organic solvents with Na, $NaC_{10}H_8$, or NaR^* leads to deep-red sodium tris(supersilyl)digallanide–THF(1/3) $NaGa_2R^*_3\times3THF$ = $[R^*_2Ga–GaR^*Na(THF)_3]$, which transforms in the presence of 18-crown-6 into deep-blue sodium tetrakis(supersilyl)trigallanide–18-crown-6(1/1)–THF(1/2) $[Na(18\text{-}C\text{-}6)(THF)_2]^+[R^*_2Ga–GaR^*–GaR^*]^-$.The oxidation of the latter anion with R^*Br or TCNE as well as the reaction of the digallanyl $R^*_3Ga_2^{\cdot}$ with R^*Br leads to deep-green tetra(supersilyl)cyclotrigallanyl $[\cdots R^*Ga–GaR^*_2–GaR^*\cdots]^{\cdot}$. The latter radical thermolizes at 100 °C to dark-violet tetrakis(supersilyl)-*tetrahedro*-tetragallane $R^*_4Ga_4$ besides the digallanyl $R^*_3Ga_2^{\cdot}$. This is also prepared from NaR^* and $GaCl_3$ or R^*_2GaCl, as well as by oxidation of $R^*_3Ga_2^-$, and itself thermolizes with formation of the tetrahedrane $R^*_4Ga_4$. According to X-ray structure analyses of the mentioned compounds, the Ga–Ga bond of the digallanide $NaGa_2R^*_3\times3THF$ (NMR spectroscopically observed) is comparably short (2.380 Å), approaching a bond order of 2. In fact, it is distinctly shorter than the Ga–Ga bond (2.420 Å) in the digallanyl $R^*_3Ga_2^{\cdot}$ (EPR spectroscopically observed). The Ga atoms of the trigallanyl $R^*_4Ga_3^{\cdot}$ (EPR spectroscopically observed) are located at the corners of a triangle with two shorter $R^*_2Ga–GaR^*$ sides (2.527 Å) and a comparably longer $R^*Ga–GaR^*$ basis (2.879 Å). The mean value of the two Ga–Ga bonds in the trigallanide $R^*_4Ga_3^-$ (NMR spectroscopically observed) is as long (2.53 Å) as the short Ga–Ga bonds in $R^*_4Ga_3^{\cdot}$. The anion shows an intramolecular $CH_3\cdots Ga$ contact (C–Ga 2.10 Å) between one peripheral methyl group of the R^*_2Ga entity and the anionic Ga atom in $[R^*_2Ga–GaR^*–GaR^*]^-$.

Introduction

As recently reported,[1,2] the reaction of supersilylsodium NaR^* (R^* = Si*t*Bu$_3$ = supersilyl) with aluminium trihalides AlX_3 (X = Cl, Br) in alkanes leads, at room temperature, via isolable bis(supersilyl)aluminium halides R^*_2AlX to tetrakis(supersilyl)dialane $R^*_2Al–AlR^*_2$ (cf. Scheme 1). Thereby, NaR^* reacts with R^*_2AlCl by formation of NaCl as well as of radicals $R^{*\cdot}$ and $R^*_2Al^{\cdot}$. For steric reasons, only dimerization of $R^{*\cdot}$ and $R^*_2Al^{\cdot}$ is possible, but no recombination of both radicals under formation of R^*_3Al. The mentioned dialane $R^*_4Al_2$ thermolizes in heptane at 80 °C in a reversible reaction to bis(supersilyl)alanyl $R^*_2Al^{\cdot}$ in low equillibrium concentration ($R^*_4Al_2 \rightleftarrows 2\ R^*_2Al^{\cdot}$). In an irreversible reaction it thermolizes to tris(supersilyl)dialanyl $R^*_3Al_2^{\cdot}$ as well as to tetrakis(supersilyl)cyclotrialanyl $R^*_4Al_3^{\cdot}$ and to tetrakis(supersilyl)-*tetrahedro*-tetraalane $R^*_4Al_4$ (Scheme 1).[2] Possibly, $R^*_4Al_3^{\cdot}$ forms by a reaction of the monoalanyl $R^*_2Al^{\cdot}$ with the dialanyl $R^*_3Al_2^{\cdot}$. The cyclotrialanyl $R^*_4Al_3^{\cdot}$ itself transforms slowly into $R^*_3Al_2^{\cdot}$ and $R^*_4Al_4$ [1] (cf. Scheme 1).



Scheme 1. Syntheses, reactions, colors, Al−Al distances of dialane $R^*_4Al_2$, alanyls $R^*_3Al_2^{\cdot}$ and $R^*_4Al_3^{\cdot}$ as well as tetrahedrane $R^*_4Al_4$ [equations in part not exactly formulated; R^* dimerizes to $(R^*)_2$ or − at higher temperatures − transforms into R^*H)

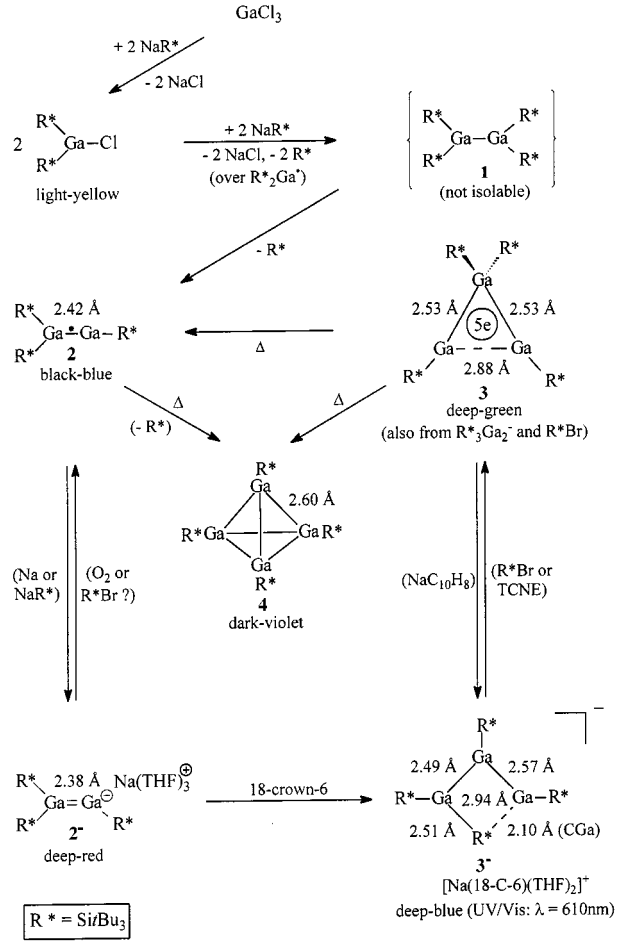
On the other hand, tetrakis(supersilyl)digallane $R^*_2Ga-GaR^*_2$ (**1**) thermolizes at much lower temperature than the dialane. Therefore, the reaction of gallium trichloride with supersilylsodium NaR* in heptane at room temperature leads, via isolable bis(supersilyl)gallium chloride R^*_2GaCl, not at all to the digallane **1**, which is unknown to date, but directly to tris(supersilyl)digallanyl $R^*_3Ga_2^{\cdot}$ (**2**) (Scheme 2).[3] The latter radicals thermolize in heptane at 100 °C exclusively to tetrakis(supersilyl)-*tetrahedro*-tetragallane $R^*_4Ga_4$ (**4**) (cf. preliminary communication[4]). No tetrakis(supersilyl)cyclotrigallanyl $R^*_4Ga_3^{\cdot}$ (**3**) is formed in this case. Therefore, we tried to prepare the cyclotrigallanyl **2** by another route from the digallanyl **2**. These studies are presented here.



Scheme 2. Syntheses, reactions, colors, and Ga−Ga distances of gallanyls $R^*_3Ga_2^{\cdot}$ (**2**) and $R^*_4Ga_3^{\cdot}$ (**3**), gallanides $R^*_3Ga_2^-$ (**2**$^-$) and $R^*_4Ga_3^-$ (**3**$^-$) as well as tetrahedrane $R^*_4Ga_4$ (**4**) [equations in part not exactly formulated; R* dimerizes to $(R^*)_2$ or − at higher temperatures − transforms into R*H]

Results

Syntheses and Properties of $R^*_3Ga_2^{\cdot}$, $R^*_4Ga_3^{\cdot}$, $R^*_3Ga_2^-$, and $R^*_4Ga_3^-$

According to Scheme 2, the digallanyl $R^*_3Ga_2^{\cdot}$ (**2**) can be reduced in pentane, benzene, or tetrahydrofuran (THF) with sodium in the presence or absence of naphthalene, or with supersilylsodium NaR*×2THF ($NaR^* \rightarrow Na^+ + R^* + e^-$) to sodium tris(supersilyl)digallanide−tetrahydrofuran(1/3) [$NaGa_2R^*_3\times3THF$, **2**$^-$; cation $Na(THF)_3^+$]. In fact, one starts with bis(supersilyl)gallium chloride R^*_2GaCl, which is easily reduced by NaR* or by $NaC_{10}H_8$ in THF. The digallanide **2**$^-$ forms deep-red, air- and moisture-sensitive crystals, which give red solutions in alkanes and benzene, but a blue solution in tetrahydrofuran (THF). The digallanide **2**$^-$ reacts in pentane with Me_3SiCl at low temperature with formation of light-red tris(supersilyl)(trimethylsilyl)digallane [$R^*_2Ga-GaR^*(SiMe_3)$; evidence of the existence of a digallanide; first tetrasilyldigallane to date].

If 18-crown-6 is added to a deep-red solution of **2**$^-$ in benzene, the color of the reaction mixture immediately changes to dark-blue. In fact, **2**$^-$ reacts according to Scheme 2 to give dark-blue, air- and moisture-sensitive sodium tetrakis(supersilyl)trigallanide−18-crown-6(1/1)−tetrahydrofuran(1/2) {$[Na(18\text{-}C\text{-}6)(THF)_2]^+[Ga_3R^*_4]^-$}, which is soluble in benzene and THF, but insoluble in alkanes (for X-ray structure analysis see below). Possibly, a transfer of supersilylgallium R*Ga between two digallanide anions **2**$^-$ takes place as described by $2R^*_3Ga_2^- \rightarrow R^*_2Ga^- + R^*_4Ga_3^-$, whereby the monogallanide $R^*_2Ga^-$ may transfer another supersilylgallium by $R^*_2Ga^- + R^*_3Ga_2^- \rightarrow R^{*-} + R^*_4Ga_3^-$ (R^{*-} is unstable in the presence of 18-C-6 to produce R*H).[5]

The trigallanide $R^*_4Ga_3^-$(**3**$^-$) is oxidized in benzene with supersilyl bromide ($R^*Br + e^- \rightarrow R^* + Br^-$) or tetracyanoethylene ($TCNE + 2e^- \rightarrow TCNE^{2-}$) to deep-green air- and moisture-sensitive, tetrakis(supersilyl)cyclotrigallanyl ($R^*_4Ga_3^{\cdot}$; **3**), soluble in organic media. The latter is itself reduced by sodium naphthalenide to $R^*_4Ga_3^-$ (cf. Scheme 2; for EPR spectrum and X-ray structure analysis see below). Unexpectedly, $R^*_4Ga_3^{\cdot}$ (**3**) besides $(R^*)_2$ is also very simply obtained by reaction of the digallanide $NaGa_2R^*_3\times3THF$ {$Na(THF)_3^+$ **2**$^-$} in pentane with supersilyl bromide R*Br. As the radical **3** is formed faster from $R^*_3Ga_2^-$ (**2**$^-$) and R*Br than from $R^*_4Ga_3^-$ (**3**$^-$) and R*Br, the former reaction obviously does not proceed via anion **3**$^-$, but may involve the radical $R^*_3Ga_2^{\cdot}$ (**2**), which eventually reacts with **3**$^-$ by transfer of R*Ga (cf. production of **3**$^-$ from **2**$^-$).

Radical $R^*_4Ga_3^{\cdot}$ (**3**) thermolizes at 45 °C slowly (within 1 d) with formation of $R^*_3Ga_2^{\cdot}$, besides $R^*_4Ga_4$ (Scheme 2, cf. thermolysis of $R^*_4Al_3^{\cdot}$).[6] The black-blue, air- and moisture-sensitive, in organic media soluble tris(supersilyl)digallanyl $R^*_3Ga_2^{\cdot}$ (**2**) is also synthesized in alkanes from $GaCl_3$ and NaR*, or from R^*_2GaCl and NaR* as well as Na,[3] or from $R^*_3Ga_2^-$ (**2**$^-$) by oxidation. Formally, the radical **3** decomposes with elimination of supersilylgallium R*Ga into the digallanyl **2**, whereby R*Ga tetramerizes. Because the digallanyl **2** itself decomposes at 100 °C in heptane to dark-violet air- and moisture-sensitive, in organic media soluble tetrakis(supersilyl)-*tetrahedro*-tetragallane ($R^*_4Ga_4$; **4**) and $(R^*)_2$,[4] the trigallanyl **3** finally decomposes in pentane at 100 °C exclusively into $(R^*)_2$ and thermostable **4**

(almost no decomposition in solution at 100 °C; decomposition of the solid at the melting point 322 °C).

Characterization of $R^*_3Ga_2^{\cdot}$, $R^*_4Ga_3^{\cdot}$, $R^*_3Ga_2^-$, and $R^*_4Ga_3^-$

The ^{29}Si NMR signals of digallanide $[R^*_2Ga-GaR^*]^-$ [**2**$^-$; the Ga−Na bond in $NaGa_2R^*_3\times3THF$ is according to the formulation $Na(THF)_3^+$ **2**$^-$ undoubtedly ionic[5]] and trigallanide $[R^*_2Ga-GaR^*-GaR^*]^-$ (**3**$^-$) appear at low field [δ = 37.1/54.3 in the first case (area ratio ca. 2:1) and δ = 53.5/42.0/42.3 in the second case (area ratio 2:1:1)]. The ^{29}Si NMR signals of the R* groups in the digallane $R^*_2Ga-GaR^*(SiMe_3)$ show comparable shifts (δ = 48.80/44.80 for 2 Si*t*Bu$_3$/1 Si*t*Bu$_3$). It is worth mentioning in this context that the ^{29}Si NMR signals of alkali metal supersilanides MR* and of supersilyl halides R*Hal appear in the same region at δ = 30−40.[5]

On the other hand, the radicals $R^*_3Ga_2^{\cdot}$ (**2**) and $R^*_4Ga_3^{\cdot}$ (**3**) − not observed in NMR − are characterized by EPR. As the EPR spectrum of **2** has been discussed in detail in a preliminary publication,[3] the following remarks refer only to the EPR spectrum of **3**. Freshly dissolved in cyclohexane, **3** exhibits an unresolved, unsymmetrical EPR signal of $H_T \approx 20$ mT total width at $g = 1.998$. The lack of resolution and the asymmetry point to insufficient averaging of anisotropic contributions to the *g* and *A* (hyperfine) tensors. Similar, but less pronounced effects were observed for the paramagnetic systems $R^*_3Ga_2^{\cdot}$ (**2**)[3] and $R'_4Ga_2^{\cdot-}$with R′ = $CH(SiMe_3)_2$.[6a] In comparison with $R^*_4Al_3$ [1] (g = 2.0053), the gallium analogue exhibits a *g* factor lower than *g*(electron) = 2.0023, which agrees[7] with the presence of low-lying unoccupied orbitals. On the other hand, a glassy frozen solution of **3** at 110 K in cyclohexane produces a broad (H_T = 55 mT), partially resolved EPR spectrum. While the signal could not be unambiguously analyzed due to overlapping *g* components in the X band, the large spectral width confirms the sizeable *g* and *A* anisotropy (^{69}Ga:I = 3:2, 60.1% natural abundance, isotropic hyperfine constant a_0 = 435.68 mT; ^{71}Ga:I = 3:2, 39.9%, a_o = 553.58 mT[8]). The width of the low-temperature spectrum is in agreement with H_T = 15.0 mT for $R^*_4Al_3$ [1] (^{27}Al:I = 5:2, 100%, a_o = 139.55 mT[8]). On prolonged standing or warming, the solution of **3** produces a new EPR signal that could be identified as that of **2**.[3]

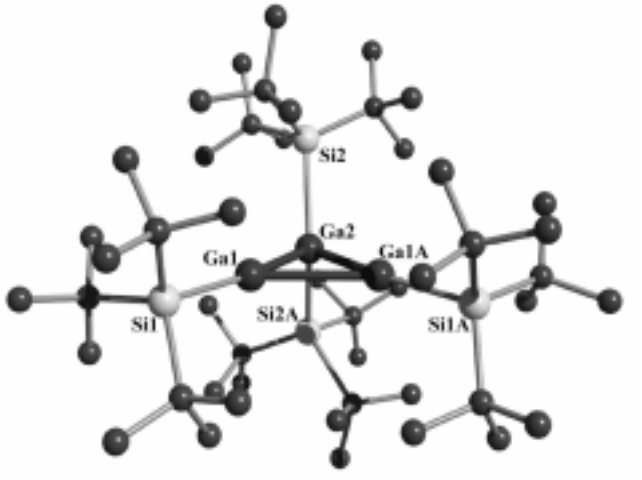


Figure 1. Structure of $R^*_4Ga_3^{\cdot}$ (**3**) in the crystal; atom numbering used (SCHAKAL plot; H atoms omitted for clarity); selected distances [Å] and angles [°] with standard deviations: Ga1−Ga2 2.5267(7), Ga1−Ga1A 2.879(1), Ga1−Si1 2.513(1), Ga2−Si2A 2.536(1), Ga2−Si2 2.536(1), Si−C (mean value) 1.98; Si1−Ga1−Ga2 169.88(4), Si1−Ga1−Ga1A, 134.83(3), Ga2−Ga1−Ga1A 55.27 (2) [angles sum at Ga1/Ga1A 359.98], Ga1−Ga2−Ga1A 69.47(3), Ga1−Ga2−Si2A 106.77(4), Ga1A−Ga2−Si2A 108.85(3), Ga1−Ga2−Si2 108.85(3), Ga1A−Ga2−Si2 106.77(4), Si2A−Ga2−Si2 136.30(7), C−Si−Ga (mean value) 108.62, C−Si−C (mean value) 111.99; Si2−Ga2−Ga1−Si1 81.97, Si1−Ga1−Ga1A−Si1A 1.67

Structures of $R^*_3Ga_2^{\cdot}$, $R^*_4Ga_3^{\cdot}$, $R^*_3Ga_2^-$, and $R^*_4Ga_3^-$

The structures of the trigallanyl $R^*_4Ga_3^{\cdot}$ (**3**), the digallanide $NaGa_2R^*_3\times3THF$ [**2**$^-$; cation $Na(THF)_3^+$], and the trigallanide $[Ga_3R^*_4]^-$ [**3**$^-$; cation $Na(18\text{-}C\text{-}6)(THF)_2^+$] are shown in the Figures 1, 2, and 3, respectively, together with selected bond lengths and angles. The structure of the digallanyl $R^*_3Ga_2^{\cdot}$ (**2**) has already been published.[3]

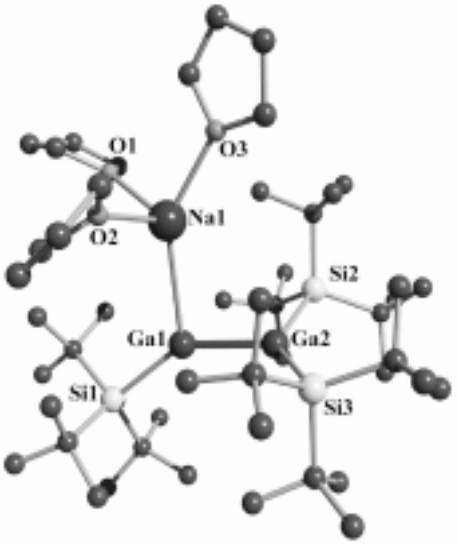

Figure 2. Structure of $NaGa_2R^*_3\times3THF$ [$Na(THF)_3^+\cdot$**2**$^-$] in the crystal; atom numbering used (SCHAKAL plot; H atoms omitted for clarity); selected distances [Å] and angles [°] with standard deviations: Ga1−Ga2 2.3797(6), Ga1−Si1 2.500(1), Ga1−Na1 3.205(2), Ga2−Si2 2.517 (1), Ga2−Si3 2.519(1), Na1−O3 2.316(4), Na1−O1 2.337(5), Na1−O2 2.404(5), Si−C (mean value) 1.96; Ga2−Ga1−Si1 142.41(4), Ga2−Ga1−Na1 91.40(4), Si1−Ga1−Na1 126.14(5) [angles sum at Ga1 359.94], Ga1−Ga2−Si2 112.09(3), Ga1−Ga2−Si3 112.59(3), Si2−Ga2−Si3 133.72(4) [angles sum at Ga2 358.34], O3−Na1−O1 91.3(2), O3−Na1−O2 88.1(2), O1−Na1−O2 97.6(2), O3−Na1−Ga1 112.9 (1), O1−Na1−Ga1 108.2 (1), O2−Na1−Ga1 145.7 (1), C−Si−Ga (mean value) 109.77, C−Si−C (mean value) 109.1; Si1−Ga1−Ga2−Si2/Si3 100.43/−91.99, Na1−Ga1−Ga2−Si2/Si3 82.52/−85.06

As stated elsewhere,[3] the structure of tris(supersilyl)digallanyl ($R^*_3Ga_2^{\cdot}$, **2**) is comparable with the structure of $R^*_3Al_2^{\cdot}$. Both radicals show an almost planar Si_2E-ESi skeleton from which only the Si atom bonded to the biva-

lent E centre deviates by few degrees in line with the E−E vector (E = Al/Ga: 5.1/10°; the E−E−Si plane stands almost orthogonal to the Si−E−Si plane). In both cases, the E−E distance is comparatively short (cf. Schemes 1 and 2). This points to an E−E bonding order greater than one, whereby the shortening of the E−E bond length by going from $R^*_3Al_2^{\cdot}$ to $R^*_3Ga_2^{\cdot}$ may be due to a decrease of the radius by going from Al atoms to Ga atoms. According tothis, and in agreement with EPR studies,[3,9] the radicals $R^*_3E_2^{\cdot}$ contain sp^2- and sp-hybridized E atoms, which are connected via two-electron δ- and one-electron π-bonds. This fact is best described by the formulation $R^*_2E\div ER^*$.

On the other hand, the structure of tetrakis(supersilyl)trigallanyl ($R^*_4Ga_3^{\cdot}$, **3**), shown in Figure 1, is in many respects different from the structure of $R^*_4Al_3^{\cdot}$[1] − except for the Si atoms of the 4 R* groups which occupy in both radicals the corners of a distorted tetrahedron: In $R^*_4Al_3^{\cdot}$ the three Al atoms occupy the corners of a triangle with two longer but unequal $R^*_2AlAlR^*$ sides and a shorter R*AlAlR* basis (cf. Scheme 1), whereas in $R^*_4Ga_3^{\cdot}$ (**3**) the three gallium atoms form a triangle with two shorter and equal long $R^*_2GaGaR^*$ sides and a longer R*GaGaR* basis (cf. Scheme 2). These structural data suggest that the R*Al groups are more weakly bonded to R^*_2Al than to each other, whereas the opposite holds for the R*Ga groups. In addition, the R^*_2Al plane in $R^*_4Al_3^{\cdot}$ stands not orthogonal to the E_3 plane and one R* substituent of the R*AlAlR* group does not lie in the E_3 plane. This is unlike the R^*_2Ga plane in $R^*_4Ga_3^{\cdot}$ (orthogonal to E_3) and the R* substituents of the R*GaGaR* group (both in plane). Intuitively, one might argue that the observed geometry of both radicals looks as if cyclisation of the compounds *catena*-$R^*_2E-ER^*\div ER^*$ (E = Al, Ga), which are homologues of the mentioned radicals *catena*-$R^*_2E\div ER^*$ (see above), stopped half way on the reaction coordinate in the case of $R^*_4Al_3^{\cdot}$, but is finished in the case of $R^*_4Ga_3^{\cdot}$. In the course of this (hypothetic) cyclisation of *catena*-$R^*_2E-ER^*\div ER^*$ the $R^*E\div ER^*$ bond became weaker and the connection between R^*_2E and ER^* − not existing in *catena*-$R^*_4E_3^{\cdot}$ − stronger.

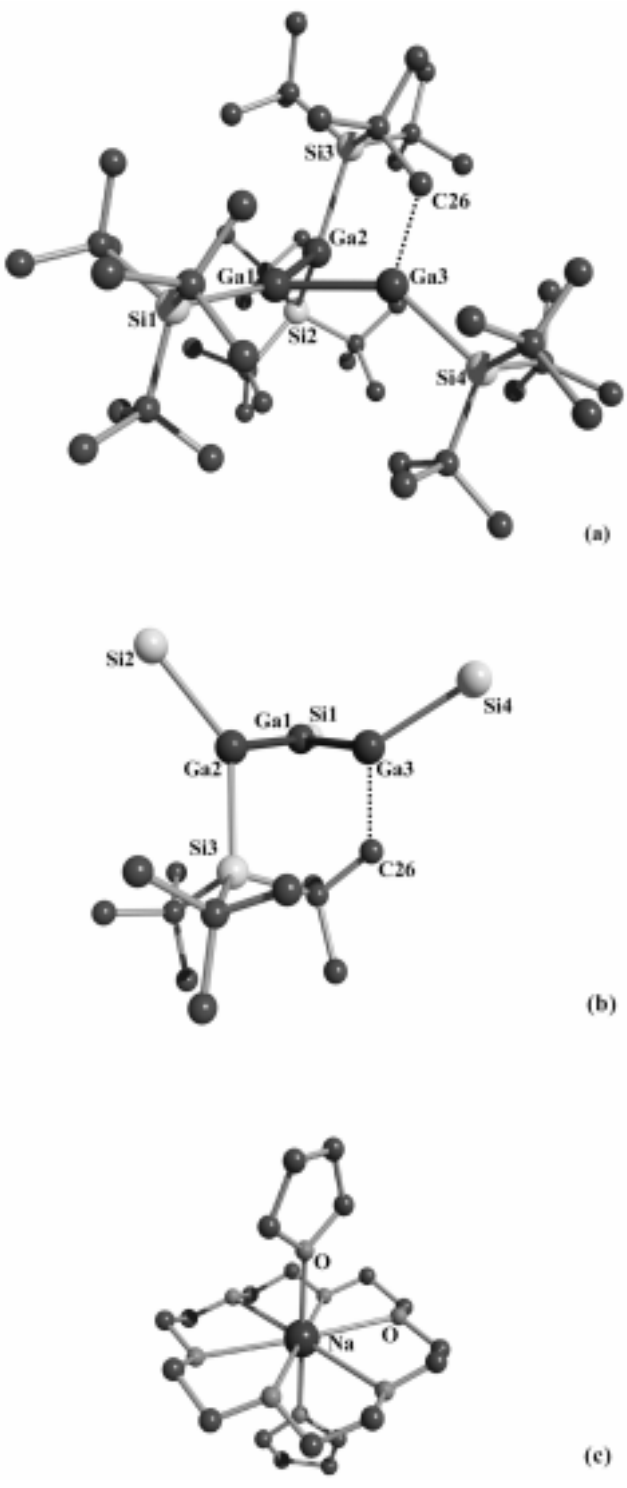

Figure 3. Structure of $R^*_4Ga_3^-$ (**3**$^-$) in the crystal, seen in two directions [(a) and (b)], and of $Na(18\text{-}C\text{-}6)(THF)_2^+$ [(c)]; atom numbering used [SCHAKAL plot; H atoms in (a) and (b), and some *t*Bu groups in (b) omitted for clarity; the dotted line represents the intramolecular $CH_3\cdots Ga$ contact]; selected distances [Å] and angles [°] with standard deviations: anion: Ga1−Ga3 2.494 (1), Ga1−Ga2 2.569 (2), Ga2···Ga3 2.935(2), Ga1−Si1 2.485(3), Ga2−Si3 2.513(3), Ga2−Si2 2.520(3), Ga3−Si4 2.486(3), Ga3···C26 2.10, Si−C (mean value) 1.96; Si1−Ga1−Ga3 137.89(9), Si1−Ga1−Ga2 151.09(8); Ga3−Ga1−Ga2 70.83(5) [angles sum at Ga1 359.81], Si3−Ga2−Si2 133.52(11), Si3−Ga2−Ga1 105.83(8), Si2−Ga2−Ga1 118.76(8) [angles sum at Ga2 358.11], Si4−Ga3−Ga1 136.28(8), Ga1−Ga3−C26 105.6(3), Si4−Ga3−C26 112.7(3) [angles sum at Ga3 354.6], Si4−Ga3−Ga2 140.19(8), Ga1−Ga3−Ga2 55.77(4), Ga1−Ga2−Ga3 53.40(4), C−Si−Ga (mean value) 109.39, C−Si−C (mean value) 109.5; Si2(Si3)−Ga2−Ga1−Si1 67.77/98.65, Si4−Ga3−Ga1−Si1 54.83, C26−Ga3−Ga1−Si1 95.84, Si2(Si3)−Ga2−Ga1−Ga3 117.91/75.67, Si4−Ga3−Ga1−Ga2 129.26, C26−Ga3−Ga1−Ga2 80.77; cation: Na−O(THF) (mean value) 2.31, Na−O(18−C-6) (mean value) 2.76; O−Na−O(THF) 179.24, O−Na−O(18-C-6) (mean value) 60.53, angles sum at O(THF) 359.78, angles sum at O(18-C-6) 343.40; the O_6 ring of 18-C-6 is something corrugated

If the R^*_2E group provides one and each R*E group two electrons for the E_3 framework (Al, Ga), there are 5 electrons available for the E_3 cluster in $R^*_4E_3^{\cdot}$ or $^5/_3 = 1.67$ electron per E−E bond as compared with 3 electrons available for the E_2 group in $R^*_3E_2^{\cdot}$. As a result, the mean value of the E−E distances is evidently larger in $R^*_4E_3^{\cdot}$ (2.74 Å for $R^*_4Al_3^{\cdot}$, 2.65 Å for $R^*_4Ga_3^{\cdot}$) than in $R^*_3E_2^{\cdot}$ (2.53 Å for $R^*_3Al_2^{\cdot}$, 2.42 Å for $R^*_3Ga_2^{\cdot}$). Altogether one might expect that the groups R*Ga in $R^*_4Ga_3^{\cdot}$ are connected with R^*_2Ga by two-electron bonds, and among one another by a one-electron bond.

The structure of sodium tris(supersilyl)digallanide−tetrahydrofuran(1/3) [$NaGa_2R^*_3\times3THF$, **2**$^-$; cation: $Na(THF)_3^+$], shown in Figure 2, resembles that of the radical $R^*_3Ga_2^{\cdot}$ (**2**; see above). Thus, in both molecules the Si_2*Ga*Ga groups are nearly planar (angles sum at *Ga* for **2**$^-$/**2** 358.4/359.7°). The same holds for the Ga*Ga*NaSi group of the anion **2**$^-$ (angles sum at *Ga* 360.0°), whereas the Na center itself is coordinated, distorted tetrahedrally by one Ga and three O atoms (the latter from THF). Moreover, the planes Si−Ga−Si and Ga−Ga−Si are almost orthogonal arranged not only in the anion **2**$^-$ but also in the radical **2**. The Ga−*Ga*−Si group in **2**$^-$ is, however, far away from being linear (angles for **2**$^-$/**2** 142.4°/170.0°). This is obviously a consequence of the Na center, which in addition coordinates the *Ga* atom in **2**$^-$. Certainly, the Ga−Na bond, which runs nearly orthogonal to the Ga−Ga bond (angle Ga−Ga−Na 91.4°) is highly ionic. Therefore, the free electron pair at the anionic Ga atom of **2**$^-$ is available for a π-bond, leading − according to the formulation $[R^*_2Ga-GaR^* \rightleftarrows R^*_2Ga=GaR^*]^-$ − to a comparable short central bond of the anion (Ga−Ga distance for **2**$^-$/**2** 2.38/2.42), approaching a bond order of 2 (Ga=Ga double bond length ca. 2.32 Å; cf. Table 1).

In a way, the tris(supersilyl)digallanide $R^*_3Ga_2^-$ (**2**$^-$) and tetrakis(supersilyl)trigallanide ($R^*_4Ga_3^-$) **3**$^-$, the structure of the latter is now discussed (Figure 3, a), play the role of the second and third member in a homologous row of anions: $R^*_2Ga^-$, $R^*_2Ga-GaR^*{}^-$, $R^*_2Ga-GaR^*-GaR^*{}^-$, $R^*_2Ga-GaR^*-GaR^*-GaR^*{}^-$ {for the structure of $[Na(18\text{-}C\text{-}6)(THF)_2]^+$ cf. Figure 3 (c)}. In fact, the structure of the trigallanide **3**$^-$ differs markedly from the structure of the digallanide **2**$^-$ in showing an intramolecular H contact between one peripheral methyl group of the R^*_2Ga entity and the anionic Ga atom in $[R^*_2Ga-GaR^*-GaR^*]^-$ (cf. Scheme 2). As the contact between the C atom of the mentioned methyl group and gallium atom is also very short (2.10 Å; normal Ga−C single bond lengths 1.99−2.02 Å),[9] it seems not out of question that in addition to H···Ga contacts C···Ga contacts must be taken into account. The latter possibility is in good agreement with a comparable long R^*_2Ga) R*Ga−GaR* distance (2.57 Å), pointing to a Ga−Ga single bond (cf. Ga−Ga bond length of 2.38 Å in $R^*_2Ga-GaR^*{}^-$). Each of the three Ga atoms in $R^*_4Ga_3^-$ (**3**$^-$) are nearly planar coordinated by adjacent atoms [angles sum at *Ga* for Si_2*Ga*Ga/Ga*Ga*SiGa/Ga*Ga*SiC 358.1/359.9/354.8°; the angles between the mentioned planes are 82.89/76.20°; cf. Figure 3 (b)]. The Ga atoms in **3**$^-$ themselves occupy the corners of a triangle with two shorter sides and a much longer basis, which certainly do not represent any chemical bond (cf. Scheme 2). In regard to the central Ga_3 group in $[R^{*(2)}R^{*(3)}Ga-GaR^{*(1)}-GaR^{*(4)}]^-$ the supersilyl groups $R^{*(1)}/R^{*(2)}/R^{*(3)}/R^{*(4)}$ lie − according to Figure 3 (b) − in/below/above/below the Ga_3 plane; thereby the Si atoms of the 4 R* groups form a distorted tetrahedron.

The one-electron reduction of the trigallanyl $R^*_4Ga_3^{\cdot}$ (**3**) to $R^*_4Ga_3^-$ (**3**$^-$) is connected with a structural change (anticyclization process), whereby the bonds $R^*_2Ga-GaR^*$/ according to Figure 3 (b) − in/below/above/below the Ga_3 Scheme 2). Altogether, the mentioned reduction leads to a shortening of the mean Ga−Ga distances [(2.53 + 2.53 + 2.88):3 = 2.65 Å in **3** and (2.49 + 2.57):2 = 2.53 Å in **3**$^-$], but the Ga−Ga distances in **3**$^-$ are distinctly longer than in **2**$^-$. This could be due to the fact that in the former the free electron pair contacts a methyl group [$-CH_3\cdots$:Ga< $\rightleftarrows$ $-CH_2-GaH$<], whereas in the latter the free electron is involved in the Ga−Ga bond [>Ga−Ga$^{\cdot}$− $\rightleftarrows$ >Ga÷Ga−]. On the other hand, the longer Ga−Ga bonds perhaps are simply due to the fact that the extra electron is delocalised over three instead of over two Ga centers such as in **2**$^-$.

Concluding Remarks

The gallium cluster compounds discussed here are further examples of many known compounds with two connected Ga atoms and of some known compounds with three connected Ga atoms.[6,10−25] All these clusters are shown in Table 1, together with their colors and geometries [the bond orders are determined from the single and double Ga−Ga bond lengths (2.52 and 2.32 Å), which themselves are twice the single and double bond radius of Ga[26]].

According to Table 1, the Ga−Ga bond lengths of organyl and certainly also of silyl-substituted digallanes >Ga−Ga< with a two-electron Ga−Ga bond (bond order 1) and tricoordinated Ga atoms span the region 2.48−2.54 Å. Clearly, the Ga−Ga distances of the discussed digallanide $R_3Ga_2^-$ (R = R*) or digallanediide $R_2Ga_2^{2-}$ [R = 2,6-$(Tip)_2C_6H_3$] as well as of the digallanyl $R_3Ga_2^{\cdot}$ (R = R*) or the radical anion $R_4Ga_2^{-\cdot}$ [R = Tip, $(SiMe_3)_2CH$], which formally derive from R_4Ga_2 by removing one or two R^+ cations or one R$^{\cdot}$ radical as well as introducing one electron, are distinctly shorter, due to the presence of more than two electrons per Ga−Ga bond, leading to bond orders of 1.5 to 2, respectively (cf. Table 1). Obviously, substitution of the organyl substituents in R_4Ga_2 by more electronegative groups, shortens the Ga−Ga bonds, as is shown for (2,4,6-$tBu_3C_6H_2)_2Ga_2Cl_2$ (Table 1). The yet unknown monomeric tetrahalides Ga_2Hal_4 should have − due to *electronic effects* of 4 halogen atoms − very short Ga−Ga bond lengths. The comparable long Ga−Ga bond in R_4Ga_2 with four electronegative substituents R = 2,2,4,4-$Me_4C_5H_6N$ probably is due to *steric effects.* On the other hand, addition of two donors to digallanes >Ga−Ga< with formation of tetracoordinated Ga atoms certainly lengthens the Ga−Ga bonds.

Table 1. Compounds with clusters of two and three Ga atoms [R = organyl, silyl, aminyl. X = halogen; D = donor; Fo = formula; CN = coordination number of Ga atoms (including Ga-bonded counter ions); τ = torsion angle R−Ga−Ga−R; BL = Ga−Ga bond length; BO = Ga−Ga bond order, determined from Ga−Ga single bond (2.52 Å) and double bond (2.32 Å); Ref. = references (here = this publication)]

[a] Disyl = $(SiMe_3)_2CH$; Pip = 2,2,4,4-$Me_4C_5H_6N$; Tip = 2,4,6-$iPr_3C_6H_2$; Mes = 2,4,6-$Me_3C_6H_2$; Mes_F = 2,4,6-$(CF_3)_3C_6H_2$; R* = tBu_3Si; Mes* = 2,4,6-$tBu_3C_6H_2$; R′ = $(SiMe_3)_3Si$; Diox = dioxane; Py = pyridine. – [b] d = deep, dark; l = light. – [c] st = staggered; e = eclipsed. – [d] R = [−*t*BuN−SiMe(N*t*Bu)−N*t*Bu−SiMe(N*t*Bu)−]. – [e] Ga−Ga bond lengths slightly depend on the counter ion. – [f] The gallium(II) chalcogenides GaY also contain Ga−Ga groups with tetracoordinated Ga atoms and Ga−Ga distances of 2.447/2.456/2.437 Å (Y = S/Se/Te). – [g] R = 2,4-bis(trimethylsilyl)-2,4-dicarba-*nido*-hexaboryl. – [h] R = 2,6-$(Tip)_2C_6H_3$. – [i] Mean value of the two shorter Ga−Ga bonds (cf. Scheme 2). – [k] R = 2,6-$(Mes)_2C_6H_3$.

As to Table 1, this "*coordination effect*" is or might be observed by going from $R_2Ga_2Hal_2$ (R = 2,4,6-$tBu_3C_6H_2$) to $[R_2Ga_2Hal_4]^-$ [R = $Si(SiMe_3)_3$] or from Ga_2Hal_4 (unknown) to $[Ga_2Hal_6]^{2-}$.

Unlike triorganylgallium compounds R_3Ga with gallium in oxidation state III, which have been known for a long time,[27] organylgallium compounds R_mGa_n with gallium in oxidation states < III were synthesized and characterized only very recently. This is due to their high tendency of decomposition into R_3Ga and Ga. According to the following equation, the disproportionation of the mentioned gallium cluster compounds R_mGa_n − where R is not only an organic but also an inorganic group [e.g. $(SiMe_3)_2N$] − may proceed over intermediates $R_{m'}Ga_{n'}$ with constantly decreasing m'/n' ratio.

$$R_mGa_n \xrightarrow[(m'/n' < m/n)]{\text{over } R_{m'}Ga_{n'}} R_3Ga/Ga \text{ or } R_2/Ga$$

Substituents R with *greater bulkiness* may inhibit the full scale of this disproportionation at a point which will be specifically determined by the nature of R and the reaction conditions (suitable donors that coordinate with Ga atoms of R_mGa_n may also have a directing effect). This is illustrated by the discussed reaction of gallium trihalides $GaHal_3$ with supersilylsodium NaR*, which according to Scheme 2 leads via R^*_2GaCl to the digallanyl $R^*_3Ga_2^{\cdot}$ (**2**). The latter is metastable at room temperature, but at higher temperatures disproportionates further into R* and the *tetrahedro*-tetragallane $R^*_4Ga_4$ (**4**; cf. Scheme 2). Obviously, the Ga_4 tetrahedrane in $R^*_4Ga_4$ is completely shielded by four supersilyl groups, leading to a high thermal stability of the Ga cluster compound (see above). In accordance with this, the trigallanyl $R^*_4Ga_3^{\cdot}$ (**3**) finally − at elevated temperatures − disproportionates into R* and **4** (cf. Scheme 2).[6] Certainly, **4** reacts further with Na in THF under formation of $Na_2Ga_4R^*_4\times 2THF$.[28]

It is worth mentioning in this context that gallium monohalides GaHal react with supersilylsodium in a different manner to gallium trihalides. Products are the gallanides $R^*_6Ga_{10}^-$ and $R^*_6Ga_{13}^-$ besides $R^*_4Ga_4$ [17] as well as the gallanes $R^*_8Ga_{18}$ and $R^*_8Ga_{22}$.[29] Noticeable, in the course of reactions of NaR* with $GaHal_3$ the products obtained have equal or more supersilyl groups than Ga atoms, whereas reactions of NaR* with GaHal lead to products with equal or less supersilyl groups than Ga atoms. Certainly, this is due to different reaction paths, the nature of which have to be investigated.

Some insights into the mechanisms of the building up of clusters come from the isolated primary and secondary products of the reaction of NaR* with $GaHal_3$. Here, the efficiency of supersilylsodium for acting as reducing agent ($R^*_2GaCl + NaR^* \rightarrow R^*_2Ga^{\cdot} + NaCl + R^*$ and $R^*_3Ga_2^{\cdot} + NaR^* \rightarrow NaGa_2R^*_3 + R^*$) as well as the tendency of the gallium cluster compounds for elimination of R* ($R^*_4Ga_2 \rightarrow R^*_3Ga_2^{\cdot} + R^*$) or transfering group R*Ga ($2\,Ga_2R^*_3^- \rightarrow GaR^*_2^- + Ga_3R^*_4^-$) is important. Certainly, supersilylgallium R*Ga also plays an essential part in the reaction of NaR* and GaHal. The gallylene, which is obviously obtained by supersilylanidation of GaHal, may combine with GaHal, whereby dehalogenations as well as R* eliminations of the formed Ga cluster compounds will produce "naked" Ga atoms in the cluster. These latter clusters may themselves be reduced by NaR* to anions, which may react with GaHal by introducing new "naked" Ga atoms into the Ga cluster framework.

Experimental Section

All experiments were carried out in flame-dried glass apparatus with standard Schlenk techniques under dry argon or nitrogen. During all manipulations, air and moisture were strictly excluded. The solvents (pentane, heptane, THF, C_6D_6, C_6D_{12}) were distilled from sodium/lead or sodium/benzophenone. Available for use were: $GaCl_3$, Na, Me_3SiCl, 18-crown-6, TCNE (tetracyanoethylene). The following compounds were synthesized according to literature procedures: NaR*×2THF,[5] R^*_2GaCl,[30] $NaC_{10}H_8$ (sodium naphthalenide) in THF.[31] − For NMR spectra a Jeol GSX-270 (^1H/^{13}C/^{29}Si: 270.17/67.94/53.67 MHz) and Jeol EX-400 (^1H/^{13}C/^{29}Si: 399.78/100.54/79.43 MHz) were available. The ^{29}Si NMR spectra were recorded with the INEPT or DEPT pulse sequence using empirically optimized parameters for the mentioned groups. − The EPR spectra were recorded with a Bruker System ESP 300.

Syntheses and Reactions of 2. − (i): A solution of NaR*×2THF (0.826 mmol) in heptane (15 mL) was added dropwise to a solution of R^*_2GaCl (0.208 g, 0.413 mmol) in heptane (10 mL) at −78 °C. As the mixture warmed to room temperature, the color of the initially formed yellow solution (R^*_2GaCl, NaR*) changed to green, and finally to intense blue. According to ^1H NMR (exchange of heptane by C_6D_6) and to EPR, the solution contained $(R^*)_2$ and the radical **2**. The former substance is not observed by EPR, the latter not in NMR. After removal of the volatile components (ca. 10^{-3} mbar), the residue was placed in pentane (10 mL), the white precipitate (NaCl) removed by filtration, and the resulting solution reduced in volume to about 5 mL. Within 0.5 d at −23 °C, colorless crystals of $(R^*)_2$ precipitated which were removed by decanting the blue solution. Black-blue crystals of air- and water-sensitive **2** − which at about 80 °C thermolize under formation of the tetrahedrane **4**[4] and react with Na or NaR* in organic solvents under formation of $Na(THF)_3^+\cdot\mathbf{2}^-$ − form from the mother liquor after 5 d at −23 °C (ca. 10%). The identification of products results from comparison with authentic samples of $(R^*)_2$ [5] and **2**.[3] − **(ii):** The radical **2** is also formed from $GaCl_3$ and NaR*×2THF (molar ratio 1:3) in heptane.[3] In addition, the digallanyl **2** seems − according to EPR − to be the first product of the oxidation of $\mathbf{2}^-$ with oxygen. Finally, **2** probably is formed as first product of the reaction of $Na(THF)_2^+\cdot\mathbf{2}^-$ in pentane with R*Br (see below).

Syntheses and Reactions of $Na(THF)_3^+$ $\mathbf{2}^-$. − (i): A solution of NaR*×2THF (3.58 mmol) in THF (6 mL)/pentane (10 mL) was added dropwise to a solution of R^*_2GaCl (0.902 g, 1.79 mmol) in pentane (50 mL). The color of the initially yellow solution (R^*_2-GaCl) changed to green and finally to dark-blue. According to ^1H NMR (exchange of pentane by C_6D_6), the solution contained $(R^*)_2$ [5] and $Na(THF)_3^+$ $\mathbf{2}^-$ [molar ratio ca. 2:1; $2\,R^*_2GaCl + 3\,NaR^* \rightarrow Na^+\cdot\mathbf{2}^0 + 2\,(R^*)_2 + 2\,NaCl$] besides unreacted NaR* ×2THF (all R^*_2GaCl consumed). After removal of the volatile components (ca. 10^{-3} mbar), the residue (now brown-red) was placed in pentane (50 mL), the precipitate (NaCl) removed by filtration, and the resulting dark-red solution reduced in volume to about 15 mL. Within 1 d at −23 °C, deep-red crystals of air- and water-sensitive $Na(THF)_3^+\cdot\mathbf{2}^-$ (0.22 g; 0.26 mmol; 15%) formed from the solution, which reacted with Me_3SiCl and R*Br (see below). − ^1H NMR (C_6D_6, internal TMS): δ = 1.47 (broad; 3 Si*t*Bu$_3$), 1.34/3.42 (m/m; 6-CH_2CH_2O/6-CH_2CH_2O). − $^{13}C\{^1H\}$ NMR (C_6D_6, internal TMS): δ = 24.3/25.3 (6-*C*Me$_3$/6-*C*Me$_3$), 33.2/33.9 (3-C*Me*$_3$/3-C*Me*$_3$), 25.6/67.9 (6-CH_2CH_2O/6-CH_2CH_2O). − $^{29}Si\{^1H\}$ NMR (C_6D_6, external TMS): δ = 37.1 (2 Si*t*Bu$_3$), 54.3 (Si*t*Bu$_3$). − X-ray structure analysis: cf. Figure 2. − It has not yet been possible to obtain a satisfactory elemental analysis. − **(ii):** $NaC_{10}H_8$ (0.272 mmol) in THF (5 mL) was added dropwise to a solution of R^*_2GaCl (0.092 g; 0.181 mmol) in heptane (10 mL) at −78 °C. The color of the initially yellow solution (R^*_2GaCl) changed to violet (**2**) and finally brown-red [$Na(THF)_3^+\cdot\mathbf{2}^-$]. After 6 h, the reaction mixture was warmed to room temperature. According to ^1H NMR (exchange of THF/pentane by C_6D_6) the solution contained $(R^*)_2$ [5] and the digallanide $Na(THF)_3^+\cdot\mathbf{2}^-$ [molar ratio 1:2; $2\,R^*_2GaCl + 3\,Na \rightarrow Na^+\cdot\mathbf{2}^- + 0.5\,(R^*)_2 + 2\,NaCl$]. After removal of the volatile components (ca. 10^{-3} mbar), the residue (brown-red) was placed in heptane (30 mL), the precipitate (NaCl) removed by filtration, and the resulting dark-red solution reduced in volume to 5 mL. Within 1 d at −23 °C, deep-red crystals of $Na(THF)_3^+$ $\mathbf{2}^-$ (0.064 g; 0.066 mmol; 73%) formed from the solution [cf. (i) for characterization]. − **(iii):** In an NMR tube the radical **2** (ca. 0.015 g; 0.02 mmol) and Na (ca. 0.9 mmol) in C_6D_6 (0.6 mL) were heated for 1 d at 60 °C. The color of the initially intensive blue solution changed finally to red. According to ^1H NMR it contained $(R^*)_2$ [5] besides the digallanide Na^+ $\mathbf{2}^-$ (doubtless as the benzene adduct). − ^1H NMR (C_6D_6, internal TMS): δ = 1.421 (s; 2 Si*t*Bu$_3$), 1.434 (s; Si*t*Bu$_3$). − **(iv) Reaction of $Na(THF)_3^+$ $\mathbf{2}^-$ with Me_3SiCl:** A solution of Me_3SiCl (0.220 mmol) in heptane (5 mL) was added dropwise to a solution of $Na(THF)_3^+$ $\mathbf{2}^-$ (0.215 g; 0.220 mmol) in heptane (10 mL). The color of the initially formed dark-blue solution of the starting material changeed to light-red. After removal of the volatile components at −78 °C and ca. 10^{-3} mbar, the residue was warmed to room temperature and dissolved in C_6D_6. According to NMR spectra, $Na(THF)_3^+$ $\mathbf{2}^-$ has exclusively reacted under formation of a new substance, the nature of which is probably the digallane $R^*_2Ga-GaR^*(SiMe_3)$. − ^1H NMR (C_6D_6, internal TMS): δ = 0.173 (s; $SiMe_3$), 1.258 (s; Si*t*Bu$_3$), 2.277 (s; 2 Si*t*Bu$_3$). − $^{13}C\{^1H\}$ NMR (C_6D_6, internal TMS): δ = 1.29 ($SiMe_3$), 25.4/25.6 (6-*C*Me$_3$/3-*C*Me$_3$), 32.4/33.9 (6-C*Me*$_3$/3-C*Me*$_3$). − $^{29}Si\{^1H\}$ NMR (C_6D_6, external TMS): δ = 19.41 ($SiMe_3$), 44.80 (Si*t*Bu$_3$), 48.42 (2Si*t*Bu$_3$).

Syntheses and Reactions of $[Na(18\text{-}C\text{-}6)(THF)_2]^+[\mathbf{3}]^-$. − (i): To a solution of $Na(THF)_3^+$ $\mathbf{2}^0$ (0.147 g; 0.15 mmol) in 0.6 mL of C_6D_6 at room temperature was added 18-crown-6 (0.053 g; 0.20 mmol). The color of the initially red solution immediately changed to dark-blue. According to NMR recorded after 20 h, the trigallanide $[Na(18\text{-}C\text{-}6)(THF)_2]^+[\mathbf{3}]^-$ had formed. From this solution at 5 °C within 2 weeks dark-blue, air- and moisture-sensitive crystals of $[Na(18\text{-}C\text{-}6)(THF)_2]^+[\mathbf{3}]^-$, insoluble in pentane and soluble in benzene or THF, and which may be oxidized by R*Br or TCNE under formation of the radical **3** (see below), were obtained. − ^1H NMR (C_6D_6, internal TMS): δ = 1.532 (broad; 2 Si*t*Bu$_3$), 1.621 (broad; 2 Si*t*Bu$_3$), 1.439/3.545 (m/m; 4-CH_2CH_2O/4-CH_2CH_2O), 3.326 (18-C-6). − $^{13}C\{^1H\}$ NMR (C_6D_6, internal TMS): δ = 22.7/24.9 (6-*C*Me$_3$/6-*C*Me$_3$), 32.2/35.0 (6-C*Me*$_3$/6-C*Me*$_3$), 25.8/67.8 (4-CH_2CH_2O/4-CH_2CH_2O), 70.0 (18-C-6). − $^{29}Si\{^1H\}$ NMR (C_6D_6, external TMS): δ = 42.0/42.3/53.2 (Si*t*Bu$_3$/Si*t*Bu$_3$/2 Si*t*Bu$_3$). − X-ray structure analysis: cf. Figure 3. − It has not yet been possible to obtain a satisfactory elemental analysis. − **(ii):** Deep-blue $[Na(18\text{-}C\text{-}6)(THF)_2]^+[\mathbf{3}]^-$ was formed as an insoluble precipitate by addition of 18-crown-6 (0.010 g; 0.038 mmol) to a red solution of $Na(THF)_3^+$ $\mathbf{2}^-$ (0.033 g; 0.034 mmol) in pentane (3 mL) at room temperature, which dissolved after addition of THF (1 mL). From this solution in 5 d at −23 °C dark-blue crystals of the trigallanide $[Na(18\text{-}C\text{-}6)(THF)_2]^+[\mathbf{3}]^-$ were obtained. − **(iii):** Obviously, the deep-blue trigallanide **3** formed by reduction of the trigallanyl **3** (see below) in THF with $NaC_{10}H_8$ in THF at room temperature.

Syntheses and Reactions of 3. − (i): A solution of R*Br (0.672 g; 2.41 mmol) in pentane (10 mL) was added dropwise to a solution

Table 2. Selected parameters of the X-ray structure analyses of the compounds $R^*_4Ga_3^{\cdot}$ (**3**), $Na(THF)_3^+Ga_2R^*_3^-$ (M^+ $\mathbf{2}^-$) and $[Na(18\text{-}C\text{-}6)(THF)_2]^+[Ga_3R^*_4]^-$ (M^+ $\mathbf{3}^-$)

of $Na(THF)_3^+$ $\mathbf{2}^0$ (2.353 g; 2.41 mmol) in pentane (15 mL) at −100 °C. After 5 h, the mixture was warmed to room temperature. The color of the initially formed deep-blue solution changed finally to deep-green. According to ^{1}H NMR (exchange of heptane by C_6D_6) and EPR, the solution contained $(R^*)_2$ [5] and the radical **3** (the former substance not seen in EPR, the latter not seen in NMR). After removal of the volatile components (ca. 10^{-3} mbar), the residue was placed in pentane (30 mL) and the precipitate (NaBr) removed by filtration. Within 2 months at −23 °C, deep-green, air- and moisture-sensitive crystals of **3** (0.412 g; 0.41 mmol; 36%) were formed. − NMR spectra: Not observable. − EPR spectrum: cf. main section. − X-ray structure analysis: cf. Figure 1. − UV/Vis (heptane): $\lambda_{max.}$ = 610 nm. − **(ii):** The deep-green radical **3** was also formed from $[Na(18\text{-}C\text{-}6)(THF)_2]^+[\mathbf{3}]^-$ (0.086 g; 0.060 mmol) and R*Br (0.027 g; 0.090 mmol) in C_6D_6 (0.8 mL) within a few days as well as from $[Na(18\text{-}C\text{-}6)(THF)_2]^+[\mathbf{3}]^-$ (0.072 g; 0.050 mmol) and TCNE (0.006 g; 0.05 mmol) in C_6D_6 (0.8 mL) at room temperature immediately. In both cases, the color of the initial dark-blue solutions changed to deep green [cf. (i) for characterization]. − **(iii) Thermolysis of 3:** At 25 °C, deep-green **3** in heptane decomposed very slowly into black-blue **2** (observed in EPR) and dark-violet $R^*_4Ga_4$ (observed in NMR).[6] The mentioned decomposition was complete by heating **3** (0.170 g; 0.169 mmol) for 17 h in heptane (2 mL) at 45 °C. After removal of the volatile components (ca. 10^{-3} mbar) and dissolving the residue in pentane (1.5 mL), within 3 d at −23 °C dark-blue crystals of the radical **2** were obtained (for another synthesis cf. above, for characterization cf. ref.[3]). As **2** itself decomposed at higher temperatures under formation of the tetrahedrane **4** besides $(R^*)_2$ (see above), the thermolysis of dark-green **3** (0.151 g; 0.150 mmol) in heptane (5 mL) at 100 °C led within 3 h exclusively to dark-violet **4**. After removal of the volatile components (ca. 10^{-3} mbar) and dissolving the residue in pentane (3 mL), within 3 d at −23 °C dark-violet crystals of **4** (0.075 g; 0.07 mmol; 44%) were obtained (for another synthesis and for characterization see ref.[4]). Compound **4** is itself very thermostable; the tetrahedrane remains almost undecomposed even after heating a solution in C_6D_{12} for 5 d at 100 °C (the NMR spectrum shows only a small amount of R*D formed). As a solid, **4** does not decompose below 322 °C (m.p.).

X-ray Structure Determinations: Siemens SMART Area-detector, Mo-K_α with λ = 0.71073 Å, *T* = 163(2) or 193(2) K ($R^*_4Ga_2^{\cdot}$), graphite monochromator, image plate detector, fixed on glass fibre, crystals mounted in perfluoropolyether oil. − Structure determination: The structures were solved by direct methods, SHELX-93. All non-hydrogen atoms were refined anisotropically and H atoms were included in the refinement at calculated positions with a riding model and fixed isotropic U_i values. There is still a large peak in $[Na(18\text{-}C\text{-}6)(THF)_2]^+[Ga_3R^*_4]^-$ of 5.70 e/Å^3, 1.02 Å from Ga3, that could be due to strong H···Ga and C···Ga contacts between one peripheral methyl group of R^*_2Ga and the anionic Ga atom of the trigallanide $[R^*_2Ga-GaR^*-GaR^*]^-$. The structures of the compounds are shown in Figures 1, 2, and 3, and crystallographic details are summarized in Table 2. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-152470 (**3**), -152469 $[Na(THF)_3^+$ $\mathbf{2}^-]$, -152583 $\{[Na(18\text{-}C\text{-}6)(THF)_2]^+[\mathbf{3}^-]\}$. Copies of

Keywords: NMR spectroscopy / Structure elucidation / Phosphanes / Configuration determination

The title compound has been synthesised, and characterised by multinuclear magnetic resonance spectroscopy, both in solution and in the solid state. The bandshapes of variable-temperature solution-state ^{19}F NMR spectra have been iteratively fitted to obtain information on the kinetics of rotation about the PC bond for one of the aryl groups, and values for the enthalpy and entropy of activation of the process have been derived. Magic-angle spinning NMR techniques have been extensively applied to the solid, using ^{19}F, ^{31}P and ^{13}C nuclei. Triple-channel methods and different magnetic field strengths have been employed to yield a range of complementary information. Heteronuclear interactions and intramolecular motions have been investigated. Bandshapes arising from (P, Cl) residual dipolar coupling have been analysed. Satisfactory agreement is found between experimental spectra and those simulated with estimated values of the parameters involved, and it is confirmed that the electric field gradient at chlorine is co-axial with the PCl bond. The sign of the isotropic (PCl) indirect coupling constant is obtained for the first time and is shown to be negative. The crystal structure of the compound at 150K confirms the presence of two different aromatic residues, as deduced from the spectroscopic studies.

Introduction

The novel compound 2,6-bis(trifluoromethyl)phenyl-2,4-bis(trifluoromethyl)phenyl-chlorophosphane (**1**) has been synthesised as part of a continuing study of low-coordinate phosphorus compounds containing bulky electron-withdrawing aromatic groups.[18] The formation of this compound with different bis(trifluoromethyl)phenyl groups arises (Exp. Section) because 1,5-bis(trifluoromethyl) benzene can be lithiated by butyllithium in two different positions: Either *ortho* to both CF_3 groups, giving a 2,6-bis(trifluoromethyl)phenyl-lithio derivative, or *ortho* to one of the CF_3 groups only, yielding the analogous 2,4-substituted compound. These groups are designated Ar and Ar respectively herein. On treatment with PCl_3, both of the dichlorophosphanes are obtained, with the 2,6 derivative (Ar) present in the larger amount. The isomers can be readily distinguished by their ^{31}P and ^{19}F solution-state spectra. The solid disubstituted product isolated from the reaction mixture was shown to be the title compound ArArPCl (Figure1), firstly by solution-state NMR and secondly by extensive (^{31}P, ^{19}F and ^{13}C) solid-state NMR investigations. Its structure was eventually determined by single-crystal X-ray diffraction at 150K. Variable-temperature solution-state ^{19}F NMR spectroscopy was used to determine the enthalpy and entropy of activation for internal rotation about the PC bond of the Ar group. The aims of the solid-state NMR experiments were to gain further structural information, and to investigate the interaction between phosphorus and the quadrupolar chlorine nucleus, as shown by residual dipolar splitting.

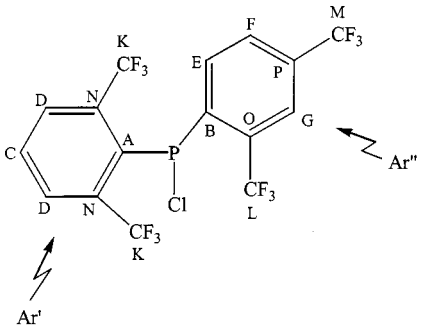

Figure 1. Lettering scheme for carbon atoms in ArArPCl (**1**)

A major feature of interest in the solid-state NMR spectrum of **1** is the bandshape of the ^{31}P resonance. Indirect isotropic (PCl) coupling should split the NMR signal of ^{31}P bonded to a single chlorine into a quadruplet of lines of equal spacing and intensity. In the solid state, dipolar coupling may also come into play; however, such coupling between two spin 1/2 nuclei is generally eliminated by MAS if the spin rate is fast enough. In the case of coupling to a quadrupolar nucleus, however, this may not be true and, although MAS will cause partial averaging, the spin 1/2 spectrum may retain a residual dipolar splitting, with powder bandshapes involved for each of the quadruplet lines mentioned above. Such effects have been fully discussed in many articles and reviews.[9] Most examples refer to $^{13}C^{14}N$

interactions, but such effects have been seen[10] for the P/Cl pair in phosphonitrile chloride cyclic trimer. The case of PCl_5 has also been studied, and the effect on the ^{31}P spectrum of such residual dipolar coupling (RDC) to the four and six chlorines of the two counter-ions investigated*((AUTHOR: But PCl_5 doesnt have any counter-ions. Please rephrase this sentence))*.[11] At high temperature, however, both phosphorus environments give rise to sharp singlets because of fast isotropic reorientation and/or short spin-lattice relaxation times of the chlorine nuclei (self decoupling). Isotropic indirect (scalar) effects, when these are present, would only be affected by fast spin-lattice relaxation.

Provided the relevant quadrupole coupling constant, $= e^2qQ/h$, is small compared to the Larmor frequency of the quadrupolar spin, the residual dipolar splitting can be treated by perturbation theory.[9] In such a situation the outer pair of lines in the ^{31}P spectrum influenced by isotropic indirect coupling to a chlorine nucleus will be shifted according to Equation(1):

$$\Delta = -\frac{3}{10}\chi D / \nu_{Cl} \quad (1) \qquad (1)$$

where D is the (PCl) dipolar coupling constant and $_{Cl}$ is the Larmor frequency of the chlorine nuclei. The inner pair of lines move by the same amount but in the opposite direction. In these cases it is often assumed that the electric field gradient tensor, q, is axially symmetric and that q and D (the dipolar tensor) are coaxial, but this is not necessarily true. A further common assumption is that the indirect coupling anisotropy, J, is negligible. Otherwise, D must be replaced by $D = D\ J/3$, though even this assumes that J is axially symmetric and that D and J are coaxial. However, these simple situations are not necessarily the case for the P/Cl nuclear pair, so that use of the full Hamiltonian may be required.

The interactions between phosphorus and chlorine may, in principle, be complicated by the presence of the two different spin 3/2 isotopes for chlorine, ^{35}Cl and ^{37}Cl. However, due to their differing natural abundances and similar nuclear properties, it can be expected that the separate effects will not be resolved, given the observed linewidths. In simulations both isotopes can be accounted for.

Results and Discussion

Solution-State NMR Measurements

The molecular structure of the title compound was first established by solution-state NMR spectroscopy. The ^{31}P spectrum (for a solution in $CH_2Cl_2/CDCl_3$) consists of a complex multiplet at = 67.3. The ^{19}F spectrum (obtained for a $[D_8]$toluene solution) was expected to be composed of two doublets, one having double intensity (from the Ar group), and one singlet (in principle a doublet but with $^6J_{PF}$ negligibly small). At ambient probe temperature, however, a doublet at = 58.9 ($^4J_{PF}$ = 58.3Hz), and two singlets (a broad double-intensity line at = 55 and a sharp peak at = 63.6) were observed. At 98 C, the broad signal was resolved into the expected doublet [= 54.9 ($^4J_{PF}$ = 41.7Hz)], demonstrating that rotation of the Ar group about the PC bond is fast enough on the NMR timescale for the two CF_3 groups to become equivalent. At 90 C, however, two doublets and two singlets were detected (Figure2).

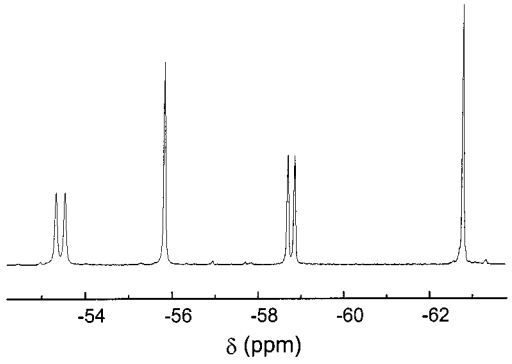

Figure 2. Fluorine-19 spectrum at 376.35MHz and 90 C of a solution of ArAr"PCl in $[D_8]$toluene; the high-frequency doublet and the high-frequency singlet are assigned to the Ar group and are the resonances which broaden and coalesce at higher temperatures; spectrometer operating conditions: pulse angle 34.8, 16 transients, recycle delay 4.0 s

The doublet and singlet assigned to the Ar group were at virtually identical positions to those at room temperature (= 58.8 and 62.8, respectively), suggesting either that rotation about the PAr bond is rapid on the NMR timescale even at low temperature or that there is a single fixed conformation about the PAr bond. For the Ar moiety, a doublet at = 53.4 ($^4J_{PF}$ = 76.7Hz) and a singlet at = 55.8 were found (consistent with the average and J observed at +98 C). We believe that the values of $^4J_{PF}$ in systems involving ArP or ArP linkages may contain a strong contribution from through-space effects. Therefore, this result implies that not only are the two CF_3 groups of Ar inequivalent at 83 C, but also that one of them may be appreciably further away from the phosphorus atom. This was subsequently confirmed by the crystal structure, determined at 123 C (see below). ^{19}F NMR spectroscopic data are summarised in Table1.

The Ar group rotation about the PC bond was investigated in detail by bandshape fitting for 12 temperatures between 15 C and 90 C on the basis of two-site equal-population mutual exchange. The coupling to ^{31}P involves summing the intensity of two such exchange pairs, with equal intensity but slightly different effective chemical shifts for one of the sites. Figure3 shows the Eyring plot for the exchange. The resulting thermodynamic parameters are: H = 51.0 0.6kJ mol^1 and S = 8 3 J K^1 mol^1, the errors quoted representing only the statistics of the linear fit.

The $^{13}C\{^1H\}$ NMR spectrum was also recorded for a toluene/$CDCl_3$ solution at ambient temperature. Probable assignments (see Figure1 for the notation) are shown in Table2, though some of these are necessarily tentative. In particular the signals from the carbons to which the CF_3

groups were attached were of low intensity (presumably because the recycle delay used to secure good S/N for the other peaks was inadequate for relaxation of these carbons), and in a similar region to other signals. The presence of two distinct resonances for carbons *ipso* to phosphorus confirms the asymmetric nature of the title compound, as does the observation of three different *C*F_3 signals, one of double intensity.2

[a] See Figure 1. [b] Only the magnitudes of coupling constants were obtained, not the signs. [c] Although the absolute accuracy of the chemical shifts is only quoted to one decimal place, a further digit is given when two signals are very close but resolved.

Residual Dipolar Coupling Between ^{31}P and $^{35/37}Cl$

A single phosphorus environment for **1** in the solid state is indicated by the ^{31}P CPMAS spectrum, as expected from the fact that the crystallographic asymmetric unit is one molecule (see below). However, the signal was split into four lines at the lowest applied magnetic field used due to the effect of the adjacent chlorine (Figure4, lowest trace). The apparent chemical shifts of these lines were = 75, 72, 66 and 62 for the 200MHz spectrometer, the last two not being completely resolved (though a shoulder was easily observable). The four shifts were obtained by deconvolution using the Spinsight software.[12]

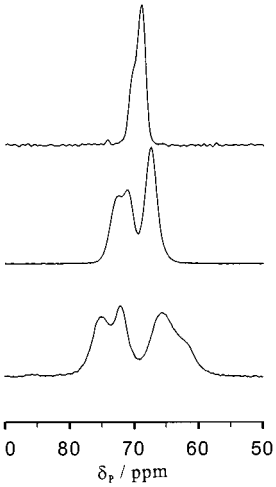

Figure 4. Phosphorus-31 {^1H} spectra of solid ArArPCl; centreband region only; spectral frequencies (top to bottom) 242.95MHz, 121.42MHz, 81.02MHz; cross-polarisation from protons; contact time 9 ms, recycle delay 5 s, number of acquisitions between 150 and 450

The nature of the splitting was identified by running spectra at different field strengths, namely on the 200, 300 and 600MHz (proton) spectrometers (Figure4). The splitting decreased on both a frequency and a ppm scale, confirming that there is a single phosphorus resonance affected by residual dipolar coupling to the adjacent quadrupolar chlorine. Such coupling can be contrasted with the cases of isotropic (indirect) coupling or crystallographic splittings, which decrease in ppm and increase in Hz, respectively, on going to higher magnetic field strength. Where all four lines can be seen (for the CMX 200 spectrometer), the separations of the lines are 228, 602 and 287Hz (from high to low frequency). The first two splittings were still resolved at 121.42MHz and are 188 and 449Hz respectively. At the highest field no splitting was observed within the linewidth

of 650Hz (the separation of a high-frequency shoulder peak from the signal maximum was approximately 350Hz). At each field the individual bandshapes did not show any significant changes over the spinning sideband manifold. The value of the isotropic coupling constant, J_{PCl}, is likely to be around 100130Hz in magnitude,[13] so it is not surprising that no splitting from this cause is resolved at the highest field. At 121.42MHz the appearance of the spectrum approached that of a doublet (i.e. J_{PCl} not significantly effective),[14] whereas at lower field there was further perturbation, producing a more complex multiplet.

From ab initio calculations using Gaussian94,[15] the electric field gradient (EFG) of the quadrupolar chlorine nucleus can be estimated. For this computation the full molecular structure was used, and the calculations to give the NMR parameters also included a structural energy minimisation. Results were converted to an appropriate axis system within a Mathcad worksheet. is calculated by multiplying q (obtained in atomic units as the largest component of the electric field gradient from a HartreeFock approximation using the 631g* basis set) by 2.3495 10^{36} C J^1 s^1. Values of of 55 and 44MHz were calculated for ^{35}Cl and ^{37}Cl respectively, with the major EFG axis approximately along the PCl bond and a low value (but nonzero) for the asymmetry parameter. NQR frequencies of magnitude 25.5, 25.7 and 26.3MHz have been reported for Et_2PCl, Bu_2PCl and $(C_6H_5)_2PCl$, respectively.[16] These represent the magnitude of $1/2e^2Qq/h$ (i.e.1/2) if the asymmetry parameter is zero, and therefore show that the values used in the calculations for the compound studied here are reasonable. The value of D may be obtained for **1** from the known PCl distance of 2.0608(6) Å (this work). For ^{31}P, ^{35}Cl the result is D = 662Hz, whereas for ^{31}P, ^{37}Cl it is 551Hz. Thus values of , the parameter defining the second-order effects under perturbation theory, may be calculated, assuming $D = D$ (i.e. ignoring J). These results are given in Table3. The predicted values are of the correct order of magnitude to account for the observed splittings, but a reasonable fit to the spectra at the different fields cannot be obtained, so a more accurate calculation is required.

tween the PCl interatomic distance and the EFG axis). A nonzero value of the isotropic scalar coupling, J_{PCl}, can also be incorporated. The values of used were: 55MHz for the ^{35}Cl isotope and 44MHz for ^{37}Cl (vide supra). The magnitude of J(^{31}P, ^{35}Cl) was set to a little lower than the literature values for related systems,[13] i.e. to 100Hz (which implies that J(^{31}P, ^{37}Cl) is 83Hz), since this seemed to yield a slight improvement in the fitting, and D was given the value calculated from the crystal structure (therefore assuming a negligible value of the anisotropy in J). As indicated before, a splitting of ca. 100Hz is significantly less than the observed linewidths and so will not be resolved, but it may, however, contribute to the distortion of the multiplet pattern. The relevant parameters were varied in the simulation and fitting by eye attempted. Altering D to include a possible anisotropy in J_{PCl} would lead to a slight change in the total width of the whole pattern, but changing the value of D (D) from 500 to 660Hz does not, in practice, have a significant effect on the simulated spectrum. A larger magnitude of J_{PCl} than 100Hz does lead to an increase in the outer splittings and a smaller value for the largest central splitting. However, changing the sign of J_{PCl} has a much more marked effect. Whereas a positive value led to substantial discrepancies between observed and simulated spectra, a negative value resulted in a good fit (see Figure3 and 4) at both 81.02 and 121.42MHz. Several different angles were used (in the range 0 to 180) and the approximate splittings of the simulated bands compared to the experimental data. The best agreement at 81.02MHz was found with = 0, giving approximate splittings of 200, 670 and 300Hz measured between the centres of gravity of the simulated powder patterns involving ^{35}Cl (experimental values are 228, 602 and 287Hz). If is increased to 20, the splittings move significantly away from the experimental values, giving four bands with more nearly equal separation. At higher values of , of around 90, the lines converge and the difference between the experimental and simulated spectra is obvious. Given that this system consists of a directly bonded spin-pair involving a monovalent quadrupolar nucleus, co-axiality of the EFG and the PCl bond is expected, so this result

Table 3. Theoretical parameters for the reduced P,Cl dipolar splittings observed for compound **1**

^{31}P frequencyMHz	Isotope	DHz[a]	MHz	Hz	2Hz	Observed splittingHz[b]
81.02	^{35}Cl	662	55	557	1114	860
	^{37}Cl	551	44	446	892

	^{37}Cl	551	44	149	298	

[a] Assuming r_{PCl} = 1.93 Å. [b] Doublet splitting at the highest field, and approximate separation of the midpoints of the pairs of doublets at 81.02 and 121.42MHz.

Using a program based on the full Hamiltonian approach,[9,17] the bandshapes at 200 and 300MHz were simulated (Figure5). This calculates the MAS spectrum of a spin 1/2 nucleus under the influence of a quadrupolar (I = 3/2) spin, with the assumption of axial symmetry of the electric field gradient, but with variation allowed for the angle (be-

gives confidence in the methods used. The calculated splittings (for = 0) involving ^{35}Cl at 121.42MHz are 270, 470 and 230Hz (compared with measured values 188 and 449Hz, the third splitting being unresolved in this experimental spectrum). At 242.95MHz, there is not sufficient resolution in the experimental spectrum to make any mean-

ingful comparison with the simulated lineshapes. However, the overall width of the lines shows reasonable agreement with the width of the unresolved doublet.

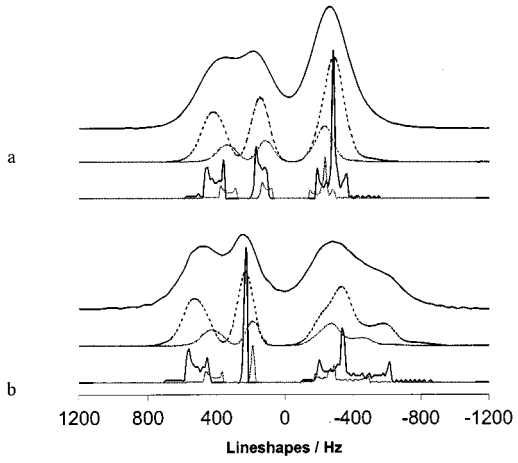

Figure 5. Experimental (upper solid lines) and simulated centreband shapes for the ^{31}P spectra of solid ArArPCl run at 121.42MHz (a) and 81.02MHz (b); the calculated powder bandshapes are shown below for coupling to ^{35}Cl (black lines) and ^{37}Cl (grey lines) in the appropriate proportions, with $J(^{31}P, ^{35}Cl)$ = 100Hz and $J(^{31}P, ^{37}Cl)$ = 83Hz, respectively; the dotted lines represent the two simulated spectra, with a line broadening of 100Hz

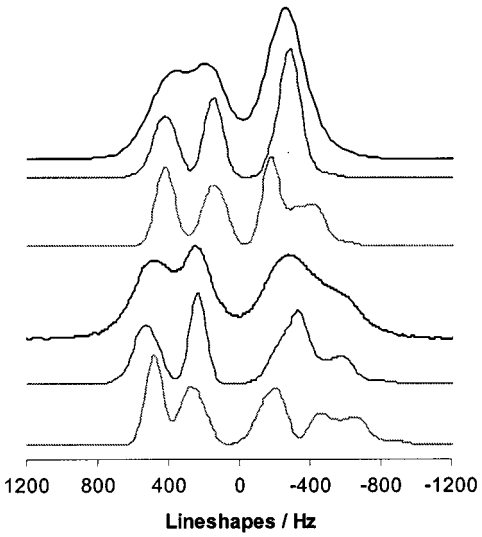

Figure 6. Centreband ^{31}P bandshapes for solid ArArPCl at 121.42MHz (top 3 spectra) and 81.02MHz (bottom 3 spectra); for each trio of spectra the top one is as experimentally observed, the middle one is as simulated for $J(^{35}Cl, ^{31}P)$ = 100Hz and the bottom one as simulated for $J(^{35}Cl, ^{31}P)$ = +100Hz; note that the simulations do not include a contribution from molecules containing the ^{37}Cl isotope

A value of slightly lower in magnitude (around 50MHz) than that calculated by ab initio methods was found to be perhaps more appropriate for the most abundant isotope, ^{35}Cl. In this case the simulated bands are brought slightly more in line with the experimental data. With an even lower value of the intensity differences between calculated and experimental spectra become more significant. Perturbation theory makes it clear that the principal variable is the product *D*.

Figure5 shows a comparison of the experimental and final simulated lineshapes. There is obviously significantly more broadening of the experimental lineshapes, but for ease of distinguishing the individual lines the simulation linewidth was kept low. The contribution from ^{37}Cl gives significantly different lineshapes to that from ^{35}Cl (see Figure5). The simulated spectra were obtained by summing the two contributions in the appropriate proportions. After line broadening has been applied there are only minor discrepancies between observed and simulated spectra, so it is clear that the parameters used for the latter are close to their correct values. In particular, it is proved that isotropic J_{PCl} is negative (Figure6). Because of the quadrupolar nature of the chlorine isotopes, very few values of this coupling constant have been reported, and this is the first determination of the sign.

Of course, there are still assumptions involved in the spectral simulation, especially axial symmetry in the EFG tensor, and there were limitations of not being able to optimise all the parameters by small increments because of the computational time involved in the calculation of each spectrum. This work represents the first time a ^{31}P reduced dipolar coupling pattern has been successfully simulated, including the first use of combined ^{35}Cl and ^{37}Cl effects.

Cross-Polarisation Experiments

Both ^{19}F and ^{1}H nuclei were used for polarisation transfer to phosphorus. All three nuclei are abundant in the sense that their natural isotopic proportion of the element is 99.9%. Therefore cross-polarisation dynamics are more complex than may appear at first sight. For instance, although results from a $^{1}H^{31}P$ variable-contact-time experiment may in general be fitted to only two parameters (a rise time T_{HP}^{eff} and a decay time T_1^{eff}) these cannot be simply related to the specific cross-polarisation time T_{HP} and single-nucleus T_1^H respectively. Instead, both measured parameters depend on T_{CP}, T_1^H and T_1^P. A detailed analysis of this problem may be found in refs.[18,19] On the other hand, for compound **1**, phosphorus is chemically dilute in the sense that there is only one ^{31}P per molecule, which is likely to result in a long T_1^P (motional questions notwithstanding), as for the common case of ^{13}C. When the ratio of spins $_{YX} = N_Y/N_X$ for a system involved in an XY CP experiment is low, deviations from simple behaviour are expected to be small. In the present case $_{PF}$ is 1:12 and $_{PH}$ is 1:6. It is found that for both $^{19}F^{31}P$ and $^{1}H^{31}P$ the rise of magnetisation during a variable contact time is substantially faster than the T_1-dependent decay. For ^{19}F to ^{31}P cross polarisation, both the TORQUE (TOneRhoQUEnching)[20] curve (for which the total constant spin-lock time was 10 ms) and the standard cross-polarisation experiment show an almost horizontal region at long spin-lock times. This implies that T_1^F and T_1^P are both long. The measured cross-polarisation time T_{FP}^{eff} is relatively short (ca. 0.5 ms) and T_1^{eff} is a lot longer than the maximum duration of spin-

lock pulse available from the amplifiers. It is therefore difficult to measure these accurately, but a value for T_1^F of approximately 100 ms was obtained from a $^{19}F^{31}P$ CP experiment, with a variable pre-contact spin-lock time. The effective value of T_{HP} derived from $^1H^{31}P$ cross polarisation is longer, at 3.5 ms, than T_{FP}^{eff}. In the $^1H^{31}P$ experiment the TORQUE curve has a positive slope at long spin-lock time, suggesting[17,18] T_1^H T_1^P, as expected.

Solid-State ^{19}F Spectra

High-resolution ^{19}F spectroscopy of solids containing hydrogen as well as fluorine has been the subject of relatively few investigations to date because the proximity of ^1H and ^{19}F resonance frequencies requires a specialised probe to facilitate proton decoupling with sufficient frequency filtering. The present experiments provide evidence of the value of solid-state ^{19}F NMR spectroscopy for structural characterisation when such problems are overcome. ^{19}F spectra (Figure7) of the solid powdered sample were obtained over the temperature range 120 C to +50 C.

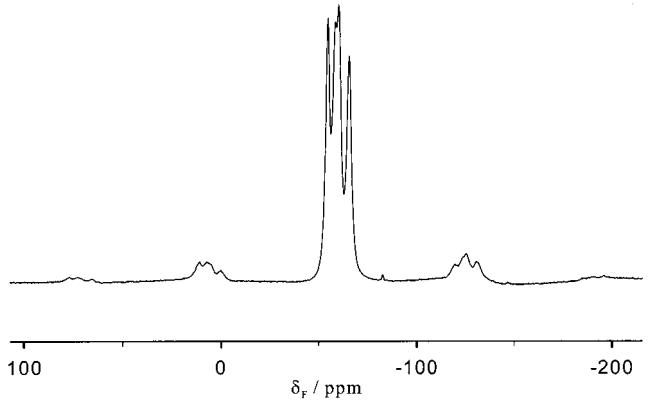

Figure 7. Fluorine-19 direct-polarisation spectrum of solid Ar-ArPCl; spectral frequency 188.3MHz, recycle delay 2 s, number of acquisitions 400, spin rate 12kHz

Throughout this range, the spectra show four peaks of approximately equal intensity within experimental error (considering the overlap of lines), with chemical shifts of = 54, 58, 60, and 65, although no splitting arising from $^4J_{PF}$ was resolved because the linewidths are broader than in solution. These observations indicate that there are different environments for all four CF_3 groups, indicating the lack of molecular symmetry and in conformity to the solution-state spectra. Rapid internal rotation will cause averaging of the positions, and therefore also of the chemical shifts of the three fluorines in each CF_3 group. It is also observed that, in contrast to the solution state differences in splitting due to PF coupling between the four CF_3 bands, there were no obvious variations in linewidths from deconvolution of the four peaks for the solid state, so only average values are quoted in Table1. There was little change in the spectrum as the temperature was lowered, and the value of T_1^F remained relatively constant at around 0.9 0.1 s, within experimental error, from 20 down to 80 C, with a slightly lower value of 0.6 s at ambient temperature (27 C). All four peaks showed small, similar trends in chemical shift to lower values as the temperature decreased, possibly arising from a variation in the referencing.

Solid-State ^{13}C Spectra

The ^{13}C spectrum of the solid (with cross polarisation from protons, using a recycle delay of 5s and a contact time of 8 ms) appears to consist of three peaks with chemical shifts = 134, 133, and 129 (by deconvolution) (Figure8). All these peaks were also observed in a dipolar dephasing experiment[21] in which only quaternary (or methyl) carbons remain. With an echo experiment run with identical conditions apart from the presence of the 50 s dephasing time, a subtraction of the normal and dipolar dephased spectra was made, resulting in a spectrum of protonated carbons only. In this case a broad underlying peak was observed with a maximum intensity at = 134. By taking advantage of the different cross polarisation and decoupling combinations possible in a fluorinated molecule and the triple-channel HFX probe, further conclusions about the carbon spectrum can be made. The low-frequency peak increases significantly in intensity on application of cross polarisation from fluorine, as does that at the highest frequency, indicating proximity of these carbons to the CF_3 groups. The lowest frequency peak also displays narrowing on application of fluorine decoupling. Although all these peaks appear in the aromatic ^{13}C region, no peaks were observed in any other region of this spectrum. It is concluded that the CF_3 resonances are also contained within this region. This result is supported by the solution-state spectrum described earlier, where all the relevant resonances lie between = 138 and 123.

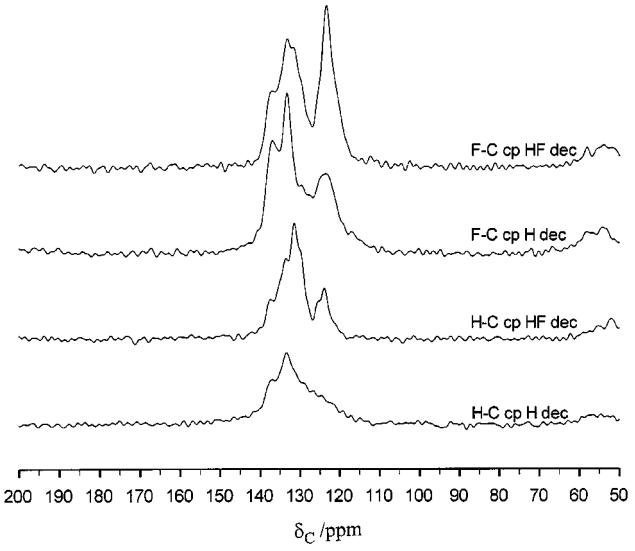

Figure 8. Solid-state ^{13}C spectra at 50.33MHz for compound **1** under various experimental regimes: cross polarisation, with contact time 7 ms, recycle delay 10 s, spin rate 4kHz; $^{19}F^{13}C$ CP and $^1H^{13}C$ CP used 280 and 64 acquisitions, respectively

X-ray Structure of ArArPCl

The crystal structure of the title compound at 150K is shown in Figure9, together with selected bond lengths and angles; according to the October 1999 release of the Cambridge Structural Database (CSD),[22] this is the first Ar_2PCl compound to be structurally characterised. The structure shows some interesting features arising from steric and intramolecular interactions. The three covalent bonds to the P atom have a pyramidal configuration, complemented by two relatively short intramolecular contacts PF(1) at 2.890(1) Å and PF(8) at 2.897(1) Å, approximately in *trans* positions to covalent bonds [angles C(9)PF(1) = 172.45(5); ClPF(8) = 163.08(3)]. These contacts are shorter than the sums of the empirical van der Waals radii[23] of P (1.91 Å) and F (1.40 Å), as well as the theoretical ones (estimated as 2.05 and 1.42 Å respectively).[24] As deduced from the ^{19}F solution-state NMR spectra at low temperatures, there are marked differences in the fluorine-to-phosphorus distances for the two *ortho* CF_3 groups in the Ar moiety. The calculated distances to F(5) and F(6) are 3.68 and 3.25 Å, respectively, compared with 2.89 Å to F(1) or F(2). Rapid rotation of each of these groups about the CCF_3 bonds is expected at higher temperatures, but the average PF distance will still be longer to one CF_3 group than the other. These observations allow the ^{19}F signal at 83 C at $_F$ = 53.4 to be assigned to F(1,2,3), assuming there is a significant through-space contribution to $^4J_{PF}$ (see above). The short PF(8) distance is then consistent with the existence of a moderately large ^4J[P,F(8)]. Such conclusions assume the structure of the molecule in solution is very similar to that in the crystalline solid. There is a possible hydrogen bond between the chlorine and the *ortho* hydrogen of the Ar group, at a calculated distance of 2.52 Å. This H-bond lies in the same plane as that of the aromatic ring of Ar, and may thus play an important role in determining the conformation of the compound. Because of the influence of the bulky CF_3 groups, the two aromatic rings form a dihedral angle of 94.

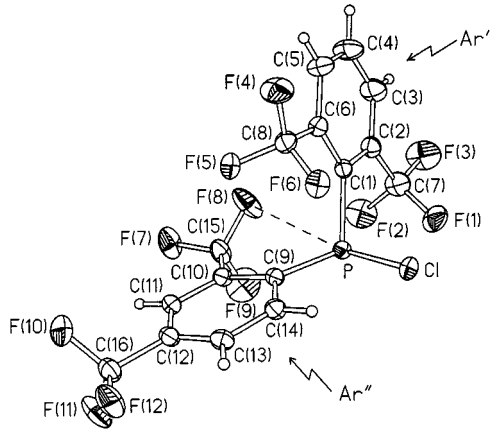

Figure 9. Molecular structure of **1**, showing 50% thermal ellipsoids; selected bond lengths (Å) and angles (): PCl 2.061(1), PC(1) 1.875(1), PC(9) 1.852(1); ClPC(1) 100.23(4), ClPC(9) 102.10(5), C(1)PC(9) 109.23(6)

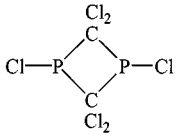
The PCl bond of 2.061(1) Å is relatively short; in eleven previously reported R_2PCl (where at least one of the R groups is alkyl) structures (CSD) this distance varies from 2.06 to 2.35 Å, with the exception of the four-membered ring compound **II**, where it is reduced to between 2.01 and 2.03 Å.[25] The PCl distance is clearly sensitive to electronic effects from other groups bonded to phosphorus, and its shortening here can be attributed to the electron-withdrawing properties of the CF_3 groups on the aromatic rings.



II

Experimental Section

Synthesis of AArPCl: *n*BuLi (57 mL of a 1.6 M solution in hexanes, 91.2mmol) was added dropwise over 10 minutes to a solution of 1,3,5-tris(trifluoromethyl)benzene (ArH) (20.03g, 94mmol) in ether (200 mL) at 78 C. The solution was allowed to warm to room temperature and left stirring for four hours. A dark brown solution containing ArLi and ArLi was formed. It was added dropwise at 78 C to a solution of PCl_3 (16 mL, 25.2g, 162mmol) in ether (100 mL) over 10 minutes. The mixture was allowed to warm to room temperature, and a precipitate of LiCl slowly formed. This was filtered off, and the solvent and excess PCl_3 removed from the filtrate in vacuo, leaving a brown intractable oil. A mixture of $ArPCl_2$ and $ArPCl_2$ (9.46g, 42%) was obtained by distillation at 45 and 0.01 Torr. Further distillation led to ArArPCl at 93 C (0.01 Torr); yield (based on ArH) 7.45g, 26%. The compound was purified by recrystallisation from hexanes. $C_{16}H_6ClF_{12}P$ (492.63): calcd. C 39.01, H 1.23; found C 38.94, H 1.24.

Solution-State NMR Spectroscopy: Solution-state NMR spectra were recorded in 5mm o.d. sample tubes on a Varian VXR 400 Fourier-transform spectrometer, operating at 100.57 (^{13}C), 161.91 (^{31}P) and 376.35 (^{19}F) MHz. Internal reference signals of TMS or $CFCl_3$ were used for ^{13}C and ^{19}F spectra, respectively, while an external reference of 85% H_3PO_4 was employed for all ^{31}P spectra. For the ^{13}C spectrum, 12824 FIDs were accumulated, using pulse angle 48.7 and recycle delay 3 s. The corresponding values for the ^{19}F spectra were 16, 34.8 and 4 s, respectively, whereas those for the ^{31}P spectra were 492, 36 and 3 s, respectively. Fluorine-19 bandshape fitting for the exchange process was carried out using an in-house computer program involving a complete Liouville treatment (including exchange rates, chemical shifts and transverse relaxation rates as variables). This program was developed in the MATLAB environment. Iteration to the bandshape was optimised to ^{2}. Temperatures were calibrated using the chemical shift differences between the CH_3 and OH resonances of methanol (for temperatures below ambient) and between the CH_2 and OH resonances of glycol (for high temperatures). The standard Varian hardware was employed for temperature control.

Solid-state NMR Spectroscopy: Because the sample could be subject to possible decomposition if exposed to moist air, it was sealed in a small plastic insert, which then fitted tightly into the rotors used.

The spectrometers used for solid-state NMR were: Chemagnetics CMX200, Varian Unity Plus 300, and Chemagnetics Infinity 600. Most of the results were obtained on the lowest field spectrometer with which three main probes were used. The diameters of the rotors are: HX and HFX probes, 7.5mm, and HF probe, 4mm. These allow almost any combination of observation, cross polarisation and decoupling to be carried out, with the use of appropriate filters. Recycle delays were initially determined by variable delay-time experiments and checked by measurement of T_1^H where appropriate. A recycle delay of 5 s and a 1 ms contact time were found to be optimum for the ^{31}P spectra. For cross-polarisation experiments, optimum contact times were found by arraying this parameter and choosing that with the greatest signal intensity. Spin rates used were generally 46kHz with the 7.5mm rotors and 1015kHz for the 4mm rotor. However, the small (3.2mm diameter) rotor system used with the Chemagnetics 600 spectrometer meant that a speed of 16.5kHz was easily attained. The frequencies of the individual nuclei on the three spectrometers are: (i) for the Chemagnetics CMX200: ^{31}P, 81.02MHz; ^{13}C, 50.33MHz; ^{19}F, 188.29MHz; ^{1}H 200.13MHz, (ii) for the Varian Unity Plus 300: ^{31}P, 121.42MHz; ^{13}C, 75.43MHz; ^{1}H 299.95MHz, and (iii) for the Chemagnetics Infinity 600: ^{31}P, 242.95MHz; ^{1}H 600.13MHz.

Referencing was done by replacement, setting the chemical shift scales as follows using the compounds named: ^{31}P, $CaHPO_4$ set to = 1.2 (w.r.t. the signal for 85% H_3PO_4 at zero ppm, though this primary standard was used directly as the reference on the 300MHz instrument); ^{19}F, C_6F_6 set to = 166.4 w.r.t. the signal for $CFCl_3$; ^{13}C, high-frequency peak of adamantane set to = 38.4 w.r.t. the signal for $(CH_3)_4Si$. Fluorine shifts are corrected for the BlochSiegert effect[26] at ambient probe temperature by recording the reference ^{19}F resonance with high-power irradiation at the proton frequency applied. The same correction is assumed to apply at low temperatures. In all cases, the standard MAS, direct- or cross-polarisation sequences gave good ^{19}F spectra with sufficient resolution to be able to use deconvolution to extract shift, intensity and linewidth parameters, so that CRAMPS operation was not necessary. Cross polarisation operation has the advantage of removing the small, broad probe background ^{19}F signal (which is observed with direct polarisation), but as direct polarisation for fluorine can lead to a better signal-to-noise ratio, in a comparable time, this may be favoured when the background and desired signals are easily distinguished or where the latter is much greater than the former. Because of the resulting increased averaging of the strong homonuclear interactions, spinning at the higher spin rates (ca.12kHz) was found to give good resolution. Most spectra were recorded at ambient probe temperature, but this may be in excess of room temperature[27,28] by up to 15 degrees for the faster spin rates.

Fluorine-19 and phosphorus-31 spin-lattice relaxation times were measured using the Torchia sequence,[29] i.e. by ^{1}H ^{19}F (or ^{31}P) CP followed by a 90 ^{19}F (or ^{31}P) pulse, a variable delay, and a 90 ^{19}F (or ^{31}P) read pulse. Proton decoupling was applied during acquisition but not during relaxation. In general, coupled spin systems will not yield single-exponential plots for relaxation times. However, the present measurements generally showed reasonably single-exponential curves. For proton spin-lattice relaxation times the pulse sequence used consisted of a 180 pulse on the proton channel followed by a variable delay, then a 90 ^{1}H pulse and contact to observe ^{31}P spectra. The fitting of intensities in relaxation experiments was done within Chemagnetics Spinsight software. That for T_1 used a three-parameter fit, taking into account the efficiency of the inversion. The number of data points recorded at each temperature was 1520 for T_1^F. For all T_1 and T_1 measurements for ^{31}P and ^{1}H 12 data points were recorded, the maximum spin-lock time (an instrumental restriction) for the latter being 20 ms, which obviously limits the accuracy of measurement for long rotating frame relaxation times. Measurements of T_1 and T_1 generally have statistical errors of 28%, with the larger values being for longer relaxation times (where the end of the decay is not observed due to, for instance, limits on spin-lock time).

Spinning sideband analysis was carried out using an in-house program, ssb97,[30] based on the theory of Maricq and Waugh,[31] which includes the error analysis of Olivieri.[17] Between 5 and 11 peaks were fitted for the sideband manifolds analysed. The program anychi-x, used for calculating bandshapes of spin 1/2 spectra involving dipolar coupling to a quadrupolar nucleus, was written in BASIC and provided by Olivieri.[32]

X-ray Diffraction: The X-ray diffraction experiment was performed on a SMART 1K CCD area detector, using graphite-monochromated Mo-K radiation (= 0.71073 Å). The structure was solved by direct methods and refined by full-matrix least-squares against F^2 of all reflections, using SHELXL-97 programs.[33] *Crystal data*: $C_{16}H_6ClF_{12}P$, M = 492.63, T = 150K, triclinic, space group $P\bar{1}$ (No. 2), a = 7.949(1), b = 9.313(1), c = 12.369(1) Å, = 104.25(1), = 90.49(1), = 96.35(1), U = 881.4(2) Å^3, Z = 2, D_c = 1.856g cm^3, = 0.43 mm^1, crystal size 0.36 0.34 0.34mm, 10579 reflections (4735 unique), R = 0.032 [4253 data, I 2(I)], $wR(F^2)$ = 0.086, $_{max}$ = 0.58 eÅ^3.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-148986. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Acknowledgments

Two of us (L.A.C. and S.M.C.) thank the EPSRC for a studentship and another (M.D.R.) is grateful to the Department of Chemistry, University of Durham, for a studentship. We thank the EPSRC also for access both to the Durham-based research service in solid-state NMR (UDIRL) and to the Chemagnetics 600 system at Warwick. We acknowledge the receipt of research grants GR/L02906 and L24250 from the U.K. Engineering and Physical Sciences Research Council in support of this work. We are grateful to A. C. Olivieri for programming details and A. M.Kenwright and C. F. Heffernan for obtaining the solution-state ^{13}C and ^{19}F spectra.

Thermodynamics of Hydrogen Bonding between CO and the Supercage Brønsted Acid Sites of the H-Y Zeolite − Studies from Variable Temperature IR Spectrometry

Carlos Otero Areán,*[a] Olga V. Manoilova,[b] Alexey A. Tsyganenko,[b] Gemma Turnes Palomino,[a] Margarita Peñarroya Mentruit,[a] Francesco Geobaldo,[c] and Edoardo Garrone[c]

Keywords: Adsorptions / Thermodynamics / Hydrogen bonds / IR spectroscopy / Zeolites

A procedure was developed for studying the thermodynamics involved in the interaction of carbon monoxide with Brønsted acid sites in zeolites, without the need for microcalorimetric measurements. The observables are the integrated infrared intensity of the C–O stretching mode of the OH···CO adducts, temperature, and equilibrium pressure. These quantities were measured by means of variable-temperature IR spectroscopy, using a home made IR cell equipped with a capacitance pressure gauge. Interaction of CO with Brønsted acid sites at the supercage of the faujasite-type H-Y zeolite involves a standard enthalpy change, $\Delta H°$ of –25.6 kJ mol^{-1}, and a standard entropy change, $\Delta S°$ of –161 J mol^{-1} K^{-1}. These values were compared with the corresponding figures obtained from the calorimetric determination of CO adsorption on a number of metal oxides and zeolites.

Introduction

Carbon monoxide is by far the most extensively used probe molecule for IR spectroscopic studies in surface chemistry, involving both metal oxides[1−5] and zeolites.[5−10] For a detailed characterisation of active solids, which is relevant to the general field of surface chemistry and (in particular) to the more specialised field of heterogeneous catalysis, it is desirable to have a detailed knowledge of the energy involved in the adsorbent-adsorbate interaction, and not only of the spectroscopic changes involving the probe molecule. Relatively strong interactions between CO and strongly adsorbing surface centres, such as coordinatively unsaturated transition metal ions, are readily studied by performing the spectroscopic measurements at room temperature. Interactions with weaker centres, such as alkali metal ions or protons, usually require IR measurements at a lower temperature, typically around the boiling point of nitrogen.[8−12] The same applies to calorimetric studies,[13] although measurements at room temperature are sometimes possible.[14]

Recent infrared spectroscopic[15−18] and quantum chemical[16,19] studies have shown that carbon monoxide can interact with extra-framework alkali[15−17] and alkaline earth[18] metal cations in zeolites forming both, C-bonded and O-bonded adducts; there is strong evidence[16,20] that suggests hydrogen-bonding between CO and Brønsted acid OH groups, however, protonic zeolites have been less studied in this context. The two linkage isomers are characterised by C−O stretching frequencies, which are both higher (C-bonded adduct) and lower (O-bonded adduct) than the 2143 cm^{-1} value corresponding to free CO. Variable temperature FTIR studies[15,17] on Na-ZSM-5 and Na-Y zeolites have shown that the population of the two isomers is a function of temperature, the O-bonded adducts are always a minority, but their relative population grows as the temperature increases.

The only observables needed for the above mentioned studies are the integrated areas of the IR absorption peaks corresponding to the C-bonded and O-bonded CO measured over a large temperature range, and the corresponding temperature values. However, if the equilibrium pressure could be measured simultaneously,[21] a more detailed thermodynamic study of the CO/zeolite system could, in principle, be carried out. The variable temperature IR cell used in our previous studies[15,17] has now been equipped with suitable pressure gauges, and here we report on the results obtained on the CO/H-Y system. It is shown that the whole set of experimental data, which includes temperature, pressure, and integrated IR intensity, allows a full thermodynamic description of the system to be obtained without resorting to microcalorimetric studies. To the best of our knowledge this experimental approach has never been reported before. It opens up a new strategy for the thermodynamic study of weakly interacting adsorbate-adsorbent systems, for which direct calorimetric studies are very cumbersome and very difficult to carry out due to the small energies involved.

Results and Discussion

Data analysed in this paper correspond to two independent sets of measurements. In one of them (series I), 3 Torr of carbon monoxide was admitted into the IR cell which contained a self-supported H-Y zeolite wafer. The cell was then closed and IR spectra were obtained at different temperatures (starting from 77 K), simultaneously recording the equilibrium CO pressure inside the cell (see Experimental Section). After completing this series of measurements, the cell was outgassed and a second run (series II) was started after dosing with 13 Torr of CO.

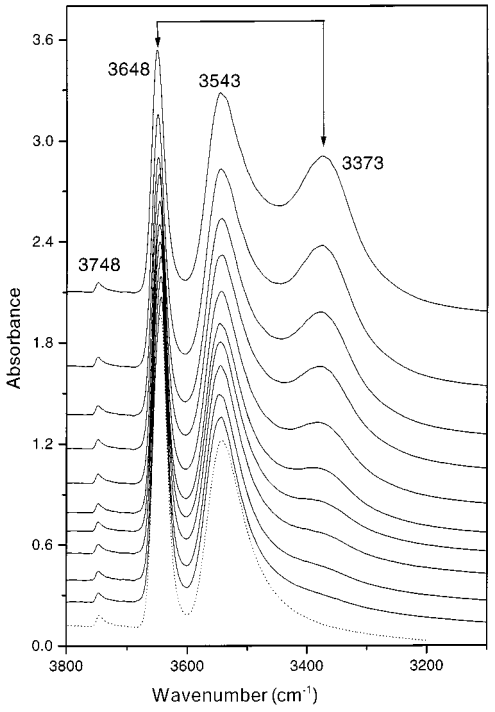

Figure 1. IR spectra, in the O−H stretching region, of CO adsorbed on H-Y. The dotted line is the zeolite blank spectrum at 77 K. Continuous line spectra correspond (from top to bottom) to I1 to I10 in Table 1. For clarity, the spectra have been offset on the vertical scale

Figure 1 reports the IR spectra (in the O−H stretching region) of the blank zeolite sample at 77 K, and at several different temperatures after admitting a dose of CO into the IR cell; corresponding values of temperature and equilibrium pressure are given in Table 1. Note that, although the total amount of CO inside the cell remains fixed, the fraction adsorbed diminishes when the temperature is raised, and this contributes to the increase in pressure. The zeolite blank spectrum shows a sharp band at 3648 cm^{-1}, which corresponds to bridged Si(OH)Al hydroxy groups (Brønsted acid sites) located in the supercage of the faujasite-type structure, and another band at 3543 cm^{-1} which is due to the Si(OH)Al species situated inside sodalite cages.[8] The weak band seen at 3748 cm^{-1} is readily assigned to silanols.[8,9]

Table 1. Numerical data corresponding to two independent runs

Spectra	Temp. (K)	Pressure (Torr)	Absorbance (cm^{-1})	Coverage
Small CO dose				
I1	145	0.14	9.04	0.430
I2	153	0.33	8.39	0.399
I3	159	0.63	7.31	0.348
I4	166	1.03	6.00	0.286
I5	173	1.48	4.54	0.216

II6	184	9.12	7.94	0.378
II7	190	9.79	5.96	0.284

The band due to the Brønsted acid sites in the supercages decreases upon interaction with the adsorbed CO molecule, and a new broad band (from the hydrogen-bonded OH···CO species[8,22]) develops at 3373 cm^{-1}. This is in accordance with the accessibility of the Brønsted acid sites to the adsorbed CO. In contrast, the band at 3543 cm^{-1} was not affected by the CO. This was expected due to the inaccessibility of the sodalite cages. The shift of the O−H stretching mode (from 3648 down to 3373 cm^{-1}) can be considered to be a measure of the acidity of the Si(OH)Al species available for interaction with the adsorbed (basic) CO molecule.[8,23−25] Although Brønsted acid sites are perhaps not completely homogeneous, the shift observed is quite the same for all coverage values, thus indicating that heterogeneity is in fact very limited. This has implications for the treatment of data given below, where all Si(OH)Al acid centres located in the zeolite supercages are considered to be equivalent and noninteracting, i.e. they constitute an ideal ensemble in the thermodynamic sense.

Figure 2 depicts the same spectra as in Figure 1 in the C−O stretching region. The spectra are dominated by a strong band at 2173 cm^{-1} which corresponds to the fundamental C−O stretching mode of hydrogen-bonded OH···CO adducts.[8,9] A weak band is also observed at 2124 cm^{-1}, which is mainly due to carbon monoxide interacting with the acidic Si(OH)Al species via the oxygen atom of the CO molecule;[15,16] it also contains the ^{13}CO counterpart (natural abundance about 1%) of the band at 2173 cm^{-1}. For the purposes of the present paper the weak band at 2124 cm^{-1} constitutes a minor feature, which shall not be considered any further.

With increasing temperature, the intensity of the 2173 cm^{-1} band decreases, the concomitant increase in pressure notwithstanding. Table 1 reports the integrated intensity

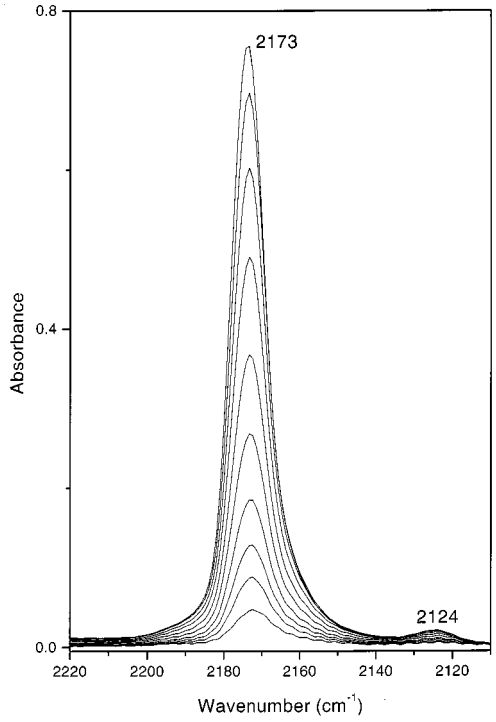

Figure 2. C−O stretching region of the same IR spectra as reported in Figure 1, increasing temperature from top to bottom. The zeolite blank was subtracted from all spectra shown

(A) of the peak at 2173 cm^{-1} (absorbance), and the temperature and pressure for all spectra considered for further treatment. They correspond to the two different CO doses (I and II) in separate experiments. The number of adsorbed molecules should be proportional to the integrated intensity of the 2173 cm^{-1} band, according to the Beer−Lambert law.

At temperatures lower than those reported in Table 1, small shifts (to higher frequency) in the peak position were observed. The corresponding spectra have been consequently discarded from the present treatment, as a small change in the molar absorption coefficient could have taken place and the intensities are not necessarily related to the coverage.

The observables, band intensity (A), temperature (T), and pressure (p), are interrelated by an equation of state. On the basis of the assumption of ideality made above, this equation of state is proposed to be according to Equation (1) which corresponds to the Langmuir isotherm at constant temperature.

$$A/A_M = \theta = K(T)p/[1 + K(T)p] \quad (1)$$

A_M is the highest integrated intensity, corresponding to full coverage, and θ is the fractional coverage. Note that pressure and temperature are not really independent, even for each individual set of measurements, but this is not important in the present context. The equilibrium constant, K, may be written as in Equation (2).

$$K(T) = \exp[\Delta S°(T)/R] \exp[-\Delta H°(T)/RT] \quad (2)$$

As is normally the case, the standard changes in both enthalpy and entropy may be assumed to be constant, in the first instance. This is equivalent to neglecting any role of the standard change in specific heat in the adsorption process. Under this assumption, the equation of state becomes as shown in Equation (3).

$$\theta = \exp(\Delta S°/R) \exp(-\Delta H°/RT)\cdot p/[1 + \exp(\Delta S°/R) \exp(-\Delta H°/RT)\cdot p] \quad (3)$$

It can be linearised as in Equation (4).

$$\ln\{p[(1/\theta) - 1]\} = -\Delta S°/R + \Delta H°/RT \quad (4)$$

For the highest coverage (temperatures close to 77 K in series II), the measured values of the integrated intensity were found to be in the range 20 to 23 cm^{-1}. Transforming the set of intensity data in Table 1 into a corresponding set of θ values, and assuming that $A_M = 21.0$ cm^{-1} for the present set of data (see below), the validity of Equation (4) can be examined as shown in Figure 3, where the left hand side of the equation is plotted against the inverse of the temperature. The two sets of experimental data are seen to line up in a very satisfactory manner, which allowed the determination of $\Delta S°$ and $\Delta H°$. The values obtained are $\Delta S° = -161$ J $mol^{-1}K^{-1}$ and $\Delta H° = -25.6$ kJ mol^{-1}.

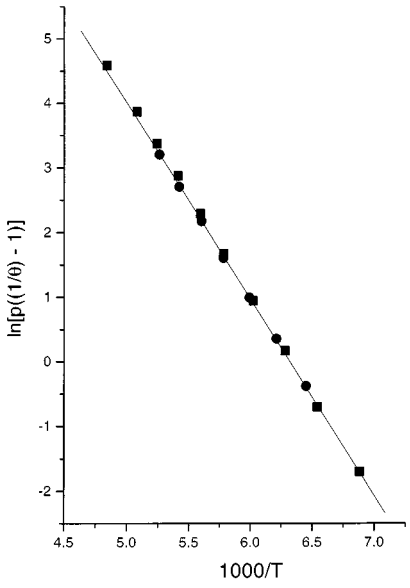

Figure 3. Check of the validity of an ideal model for adsorption; dose I: squares, dose II: circles

Note that the linear plot in Figure 3 was obtained by selecting a value of 21.0 cm^{-1} for the highest intensity, A_M. The selection of an A_M value differing from 21.0 cm^{-1} by as little as ±0.5 cm^{-1}, resulted in a loss of linearity of the plot in Figure 3. Therefore, the accuracy with which A_M can be determined is 0.5 cm^{-1}.

The feasibility of assuming constant $\Delta H°$ and $\Delta S°$ values over a rather wide temperature range (ca. 60 K, i.e. some 30% of the highest temperature used) has been verified as follows. If the opposite assumption is made, i.e. that the

standard change in specific heat, Δc_p°, is not negligible, we can write [Equation (5)].

$$\Delta c_p^\circ = -\gamma R \quad (5)$$

where R is the gas constant and γ is a positive number. Note that Δc_p° is expected to be negative for an adsorption process, since translational degrees of freedom are lost, and rotational degrees of freedom are substituted by intermolecular modes. From Equation (5) the following expressions can be derived [Equation (6) and Equation (7)].

$$\Delta S^\circ(T) = \Delta S^* - \gamma R \ln(T/T^*) \quad (6)$$

$$\Delta H^\circ(T) = \Delta H^* - \gamma R (T - T^*) \quad (7)$$

T^* is a reference temperature, e.g. the ambient one, and ΔH^* and ΔS^* are the standard changes in enthalpy and entropy at that temperature. Accordingly, Equation (4) should be written as Equation (8).

$$\ln \{p[(1/\theta) - 1)]\} - \gamma [\ln(T/T^*) - (1 - T^*/T)] = -\Delta S^*/R + \Delta H^*/RT \quad (8)$$

The choice of different γ values in Equation (8), up to 3/2 (corresponding to complete loss of translational freedom), does not significantly alter the values calculated for the standard enthalpy and entropy changes. As a result the standard enthalpy and entropy changes are considered to be temperature independent.

The values obtained for ΔS° and ΔH° can be directly checked against independent experimental evidence. Concerning the standard enthalpy change, the present value of $\Delta H^\circ = -25.6$ kJ mol^{-1} for the CO/H-Y system compares well with the calorimetrically determined heat of interaction of CO with the protonic form of ZSM-5, which was found to be[13] $\Delta H^\circ = -27$ kJ mol^{-1}. It is well-known[26–28] that the H-Y zeolite is slightly less acidic than H-ZSM-5. Therefore, a slightly smaller value of ΔH° for the CO/H-Y system relative to that of the CO/H-ZSM-5 system was expected.

With respect to the standard change in entropy, the present value of $\Delta S^\circ = -161$ J mol^{-1}K^{-1} can be compared with a set of calorimetrically determined values for the adsorption of CO performed under nearly ideal conditions on different metal oxides and on the zeolite Na-ZSM-5, reported in the literature[14,29,30]. This comparison is made in Figure 4, which shows a linear correlation between log ($-\Delta S^\circ$) and log ($-\Delta H^\circ$) for several CO/adsorbent systems. The discussion of such a linear correlation, usually called the *compensation effect*,[31,32] is outside the scope of this paper. However, it should be noted that the ΔS° value found for the CO/H-Y system satisfactorily fits into the correlation, thereby supporting the overall validity of the thermodynamic treatment developed here. Note that a general criticism can be raised against many correlation diagrams similar to that in Figure 4, because correlation can be an artefact when ΔS° and ΔH° values are simultaneously determined from the variation of an equilibrium constant experimentally measured within a narrow temperature range. However, data in Figure 4 are not biased in this sense, since ΔH° values taken from the cited literature were determined calorimetrically, and the ΔS° and ΔH° values corresponding to the CO/H-Y system were obtained from measurements covering a fairly large temperature range.

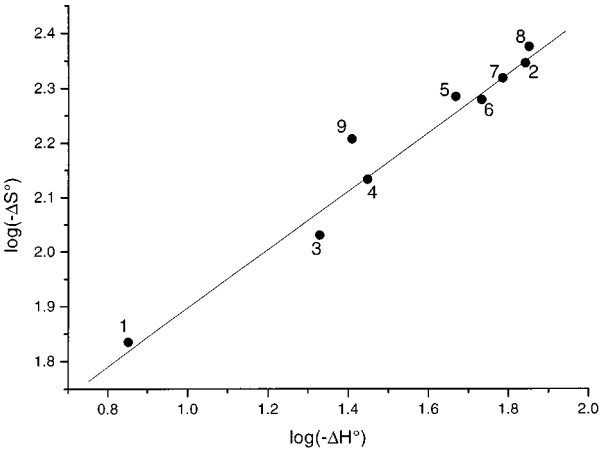

Figure 4. Correlation between ΔS° and ΔH° for CO adsorbed on: 1) alumina (weak Lewis site); 2) alumina (strong Lewis site); 3) silica-supported (reduced) chromia; 4) Na-ZSM-5; 5) zinc oxide; 6) titania (weak Lewis site); 7) titania (intermediate site); 8) titania (strong Lewis site); 9) H-Y. References: metal oxides [29, 30], Na-ZSM-5 [14], H-Y: present work

Conclusions

The integrated intensities observed for the 2173 cm^{-1} band, corresponding to the stretching mode of CO interacting via the carbon atom with Si(OH)Al hydroxy groups inside the supercage of the H-Y zeolite, satisfy a model for ideal adsorption. The derived value of $\Delta H^\circ = -25.6$ kJ mol^{-1} is close to that of $\Delta H^\circ = -27$ kJ mol^{-1} determined calorimetrically for the analogous CO/H-ZSM-5 system. Remarkably also, the value of $\Delta S^\circ = -161$ J mol^{-1}K^{-1} obtained for CO/H-Y fits a correlation diagram applicable to a number of systems involving CO adsorbed on metal oxides and on the zeolite Na-ZSM-5. These facts provide strong evidence that the experimental strategy used in this work yields reliable equilibrium data for thermodynamic studies. Both the experimental and calculation procedures described here should have a general validity for other systems. Furthermore, they can advantageously be used in cases where the weakness of adsorbate-adsorbent interactions precludes the use of calorimetric methods.

Experimental Section

The H-Y zeolite used was synthesized following standard methods;[33] it had a nominal Si/Al ratio of 5.6. Powder X-ray diffraction showed good crystallinity and the absence of any diffraction lines not assignable to the corresponding structure type.

Figure 5 depicts a scheme of the home-made variable temperature IR cell used. It was equipped with a platinum resistance thermo-

meter and a capacitance pressure gauge (Edwards, 600). The accuracy of pressure measurements was ± 0.02 Torr. For IR measurements, a thin self-supported wafer of the zeolite was prepared and activated (outgassed) in a dynamic vacuum (residual pressure $<10^{-4}$ Torr) for 2 h at 680 K, inside the IR cell. For variable temperature infrared spectroscopy, liquid nitrogen was used for refrigeration. For better thermal contact between the zeolite wafer and the cooled environment, 0.5 Torr of helium was admitted into the sample compartment before recording the background spectrum at liquid-nitrogen temperature. CO was then dosed to an equilibrium pressure of 3 or 13 Torr (at room temperature), in two different sets of measurements. After dosing with CO, the cell was closed and IR spectra were recorded at 77 K and on gradual warming up of the IR cell following the removal of liquid nitrogen. Transmission IR spectra were recorded, at 2 cm^{-1} resolution, by means of a Bruker IFS66 FTIR spectrometer.

In order to allow for the pressure due to the helium inside the IR cell, a blank experiment was conducted in which a fixed amount of helium was dosed into the cell and the corresponding pressure was measured at different temperatures. These measurements gave a calibration plot from which the pressure correction was deduced.

Keywords: Circular dichroism / Chiral resolution / Ruthenium / NMR spectroscopy / Polymers

Partial resolution of the *rac*-$[Ru(bpy)_2(ppy)]^+$ monocation into $[\Delta$-$Ru(bpy)_2(ppy)]PF_6$ (**1Δ**) (*ee* = 44%) and $[\Lambda$-$Ru(bpy)_2(ppy)]PF_6$ (**1Λ**) (*ee* = 50%) enantiomers was achieved by an unprecedented resolving process which involves the diastereoselective preparation of optically active networks of the type $\{[\Lambda$-$Ru(bpy)_2(ppy)][Mn$-Λ-$Co(ox)_3]\}_n$ (**2Λ**) and $\{[\Delta$-$Ru(bpy)_2(ppy)][Mn$-Δ-$Co(ox)_3]\}_n$ (**2Δ**). In these optically active inorganic polymers, the counter-monocation $[Ru(bpy)_2(ppy)]^+$ of appropriate configuration occupies the cavities while the excess $[Ru(bpy)_2(ppy)]^+$, of opposite configuration, remains in solution and is thus recovered. Anion metathesis of the optically active $[Ru(bpy)_2(ppy)]PF_6$ (**1Δ**) (*ee* = 44%) and (**1Λ**) (*ee* = 50%) with [l-cinchonidinium]-[Δ-trisphat] [trisphat = tris(tetrachlorobenzenediolato)-phosphate(V)] provides the related diastereomers $[\Delta$-$Ru(bpy)_2(ppy)][\Delta$-trisphat] (**3Δ**) (*de* = 44%) and $[\Lambda$-$Ru(bpy)_2(ppy)][\Delta$-trisphat] (**3Λ**) (*de* = 50%) in 60% yield. Their diastereomeric excesses were assessed by ^1H NMR analysis. All products were fully characterized and the absolute configuration was determined by circular dichroism techniques in solution or in the solid state. Additionally the X-ray structure of $[Ru(bpy)_2(ppy)]PF_6$ (**1**) was determined.

Introduction

The design and synthesis of networks possessing chiral cavities aimed to resolve optically active molecules represents a big challenge in the area of supramolecular material chemistry.[1] Ruthenium bis-bipyridine complexes $[Ru(bpy)_2L]^{n+}$ (L = bpy, phen...) (bpy = bipyridine; phen = phenanthroline) have been extensively studied for many years for their properties in biology,[2,3] and photo- and electrochemistry.[4−7] Most of these species have already been reported in the literature by several groups, with emphasis on the preparation of pure enantiomers of such propeller-like coordination complexes (Δ and Λ). Various resolution methods have commonly been used such as diastereomeric salt formation[8,9] or chromatographic separation techniques.[8,10] Another route to obtain optically active $[Ru(bpy)_2L]^{n+}$ complexes is based on the use of chiral precursors such as *cis*-$[Ru(bpy)_2(py)_2]^{2+}$ [11,12] (py = pyridine), *cis*-$[Ru(bpy)_2(CO)_2]^{2+}$ [8,13] or *cis*-$[Ru(bpy)_2(DMSO)Cl]^+$;[14−16] subsequent treatment with nucleophiles (phen, bpy...) provides the target complexes with retention of the configuration at the metal center. More recently a stereoselective synthesis has been proposed by Hesek[17] using the chiral ligand *R*-(+)- or *S*-(−)-methyl *p*-tolylsulfoxide that leads to the corresponding ruthenium bis-bipyridine complex with a diastereomeric excess of 50%.

In a pioneering work, Decurtins[18−21] described the synthesis of racemic bimetallic oxalate-bridged networks $\{[M^1(bpy)_3][M^2M^3(ox)_3]\}_n$ (M^1 = Ni^{II}, Fe^{II}; M^2 = Li^I and M^3 = Cr^{III} or M^2 = M^3 = Mn^{II}) starting from racemic materials. We recently reported the synthesis[22,23] of optically active homochiral polymers $\{[M^1(bpy)_3][M^2M^3(ox)_3]\}_n$ (M^1 = Ni^{II}, Ru^{II}; M^2 = Li^I and M^3 = Cr^{III} or M^2 = M^3 = Mn^{II}) and $\{[Ru^{II}(bpy)_2(ppy)][MCr^{III}(ox)_3]\}_n$ (M = Ni^{II}, Mn^{II}, ppy = phenylpyridine) using the tris-chelate complexes $[Cr(ox)_3]^{3-}$, $[M^1(bpy)_3]^{2+}$ and $[Ru^{II}(bpy)_2(ppy)]PF_6$ described by Constable.[24] We have shown that the formation of these polymers is highly diastereoselective and that the chirality control of only one type of building block leads to the selective precipitation of the corresponding homochiral enantiomeric polymer. Furthermore, the $\{[M^{II}M^{III}(ox)_3]^-\}_n$ network presented magnetic properties which can be tuned by modifying the nature of the M^{II}-M^{III} couple. As some of the $[M^{III}(ox)_3]^{3-}$ cannot always be resolved, we have to ensure the control of the chirality of the polymer via an optically active $[Ru(bpy)_2(ppy)]^+$ complex acting as a template. The separation of the latter into its two enantiomeric forms has not been reported so far. All attempts to resolve this $[Ru(bpy)_2(ppy)]^+$ complex by conventional procedures have been unsuccessful. Therefore we explored the possibility of employing the same resolution method that we have applied for $[Ni(bpy)_3]^{2+}$. Previously,[22] we have shown that using resolved $[\Delta$-$Cr(ox)_3]^{3-}$, a twofold excess of racemic $[Ni(bpy)_3]^{2+}$ and Li^+, afforded

an optically active insoluble polymer in which all the metal centers possessed the Δ configuration, leaving in solution the unreacted enriched [Λ-Ni(bpy)$_3$]$^{2+}$. Therefore the diastereomeric formation of these polymers could be of general use for the separation of the two enantiomers of tris-chelate complexes.

In this paper, we describe the partial resolution of the racemic [Ru(bpy)$_2$(ppy)]PF$_6$ (**1**) complex into [Δ-Ru(bpy)$_2$(ppy)]PF$_6$ (**1Δ**) (*ee* = 44%) and [Λ-Ru(bpy)$_2$(ppy)]PF$_6$ (**1Λ**) (*ee* = 50%) enantiomers via the formation of the polymers {[Λ-Ru(bpy)$_2$(ppy)][Mn-Λ-Co(ox)$_3$]}$_n$ (**2Λ**) and {[Δ-Ru(bpy)$_2$(ppy)][Mn-Δ-Co(ox)$_3$]}$_n$ (**2Δ**), respectively. Their absolute configuration was determined by circular dichroism. In addition we describe the preparation of the diastereomeric salts [Δ-Ru(bpy)$_2$(ppy)][Δ-trisphat] (**3Δ**) (*de* = 44%) and [Λ-Ru(bpy)$_2$(ppy)][Δ-trisphat] (**3Λ**) (*de* = 50%) from [l-cinchonidinium][Δ-trisphat] and the enriched [Ru(bpy)$_2$(ppy)]PF$_6$ complexes **1Δ** and **1Λ**, respectively. Finally the optical purity of these species was determined by ^{1}H NMR spectroscopy.

Results and Discussion

X-ray Structure of [Ru(bpy)$_2$(ppy)]PF$_6$

Single crystals of [Ru(bpy)$_2$(ppy)]PF$_6$ (**1**) were obtained by diffusion of diethyl ether into a solution of **1** in acetone. The crystallographic data and structure determination parameters obtained by X-ray diffraction studies for [Ru(bpy)$_2$(ppy)]PF$_6$ (**1**) are given in Table 1. [Ru(bpy)$_2$(ppy)]PF$_6$ crystallizes in the space group *C*2/*c* with $Z = 8$. As depicted in Figure 1, we notice that the [Ru(bpy)$_2$(ppy)]$^+$ cation is hexacoordinated and presents a structure similar to that of the dication [Ru(bpy)$_3$]$^{2+}$ [a C atom (C31) replaces an N atom]. The C atom (C31) was arbitrarily placed on the Figure 1 (in fact its distribution is equal on the six atomic sites bonded to the Ru atom). The bond lengths and angles for [Ru(bpy)$_2$(ppy)]PF$_6$ (**1**) and in [Ru(bpy)$_3$]Cl$_2$ [22,25] are quite similar (Table 2). The symmetry of the monocation [Ru(bpy)$_2$ppy]$^+$ is formally C_1. However, as the external shell geometry is very close to that of [Ru(bpy)$_3$]$^{2+}$, one can assume that [Ru(bpy)$_2$ppy]$^+$ has a quasi D_3 symmetry.

Ideally, to differentiate a chiral cationic complex of D_3 symmetry such as [Ru(bpy)$_2$ppy]$^+$, it is essential to choose a chiral shift anionic reagent that also possesses a D_3 symmetry. Therefore we choose the [Δ-trisphat] anion (previously described by Lacour[26–28]) to prepare the related diastereomers of [Ru(bpy)$_2$ppy]$^+$; the results are shown in the next section.

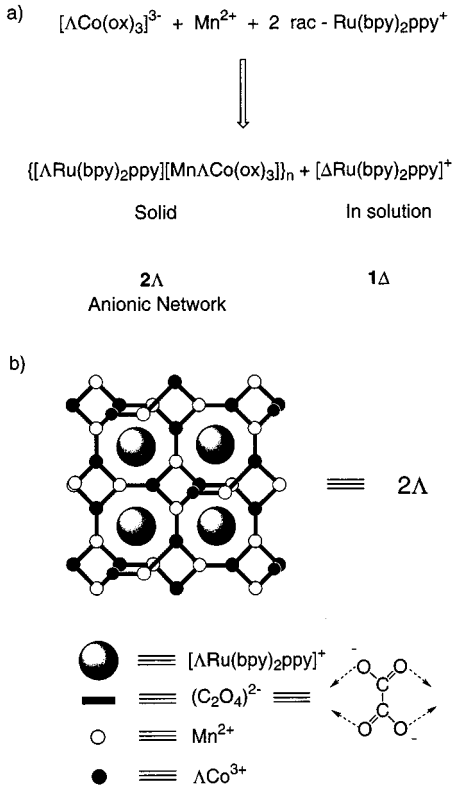
dichroism and ^1H NMR spectroscopy showed that this material is composed only of nonenriched $[Ru(bpy)_2(ppy)][\Delta$-trisphat] (**3**) (equal amounts of the two diastereomers, *de* = 0%). Hence using the [Δ-trisphat] anion, we were unable to resolve the *rac*-$[Ru(bpy)_2(ppy)]^+$ complex by selective crystallization of one diastereomer.

To resolve the *rac*-$[Ru(bpy)_2(ppy)]PF_6$ complex we finally applied the "polymer formation" strategy. To ensure good enantiomeric excess for the unreacted optically active $[Ru(bpy)_2(ppy)]^+$, three conditions were required: i) A full diastereoselectivity in the formation of the polymers. ii) A rapid precipitation relative to the racemization rate of the starting anionic brick $[M^{III}(ox)_3]^{3-}$ to keep a good chiral induction over the synthesized polymer and also on the excess cation left in solution. iii) A good yield for the reaction (almost quantitative). *These conditions are fulfilled in our system*. It should be noted that tris-oxalate cobalt $[Co(ox)_3]^{3-}$ was used instead of $[Cr(ox)_3]^{3-}$ (as previously) because its racemization rate is slower,[29] affording an enhanced enantiomeric excess for the resolved cation (*ee* = 34% versus 44% or 50% according to NMR studies). Thus, the use of resolved $K_3[Co(ox)_3]$ $\{[\alpha]_D = +1667$ (Δ form) or -1892 (Λ form)} (maximum rotation reported in the literature:[30] $[\alpha]_D = +1928$ or -1940), $MnCl_2$ and racemic $[Ru(bpy)_2(ppy)]PF_6$ (**1**) (twofold excess) in a $DMSO/H_2O$ solution results, after five minutes, in the precipitation of the respective polymers either $\{[\Delta\text{-}Ru(bpy)_2(ppy)][Mn\text{-}\Delta\text{-}Co(ox)_3]\}_n$ (**2Δ**) or $\{[\Lambda\text{-}Ru(bpy)_2(ppy)][Mn\text{-}\Lambda\text{-}Co(ox)_3]\}_n$ (**2Λ**) (yield = 90%), depending on the configuration of the $[Co(ox)_3]^{3-}$ building block. As a consequence, the mother liquor phase is now enriched in the opposite enantiomer of $[Ru(bpy)_2(ppy)]PF_6$ (either **1Λ** or **1Δ**) and is thus recovered from the filtrate as a precipitate by addition of diethyl ether (Scheme 1a). Scheme 1b shows a schematic representation[22] of the anionic optically active polymer **2Λ** hosting the $[\Lambda\text{-}Ru(bpy)_2(ppy)]^+$ monocation counter part.



Scheme 1. (a) Preparation of the bimetallic optically active polymer $\{[\Lambda\text{-}Ru(bpy)_2ppy][Mn\text{-}\Lambda\text{-}Co(ox)_3]\}_n$ (**2Λ**) along with the enriched monocation $[\Delta\text{-}Ru(bpy)_2(ppy)]^+$ (**1Δ**); (b) schematic representation[22] of the polymer **2Λ** hosting the $[\Lambda\text{-}Ru(bpy)_2(ppy)]^+$ cation counter part

Assignment of the Metallic Configurations in the Polymers 2Δ and 2Λ and in the Resolved Cations 1Δ and 1Λ by Circular Dichroism

The absolute configuration of the Co and Ru centers in the polymers **2Δ** and **2Λ** and in the enriched cations **1Δ** and **1Λ** was determined by circular dichroism by comparison of their spectra with those of Δ and Λ enantiomers of $[Co(ox)_3]^{3-}$ and $[Ru(bpy)_2L]$. This is based on the principle that two related optically active molecules have the same absolute configuration if they give a Cotton effect of the same sign in the absorption wavelength region of an electronic transition common to both molecules.[31] Due to the extreme insolubility of the polymers, solid state circular dichroism was employed for all compounds. The circular dichroism curves of the polymers **2Δ** and **2Λ** are depicted in Figure 2. They show optical activity and opposite signals typical for two enantiomers. All bands (λ_{max} = 548, 493, 432, 376, 322, 311, 279 nm) are essentially due to intra-ligand or MLCT transitions of $[Ru(bpy)_2ppy]^+$. Indeed, these bands are very strong in comparison with the weak $d \rightarrow d$ bands of $[Co(ox)_3]^{3-}$(in the monomer at λ_{max} = 618, 518, 415, 291 nm) which are totally masked. Therefore the absolute configuration of the Co centers cannot be assigned directly. However, it can be easily predicted from the configuration of the starting optically active $[Co(ox)_3]^{3-}$ salt. The Ru absolute configurations in **2Δ** and **2Λ** are assigned owing to the sign of the band due to the bipyridine ligand at λ_{max} = 322 nm (a positive Cotton effect in the 300−330 nm region is characteristic of the Λ configuration for the metal center[8,9,11,13−17,22]). The Co and Ru centers adopt the same configuration in these polymers, as is the case in the bimetallic polymers templated by $[Ru(bpy)_3]^{2+}$ obtained previously.[22]

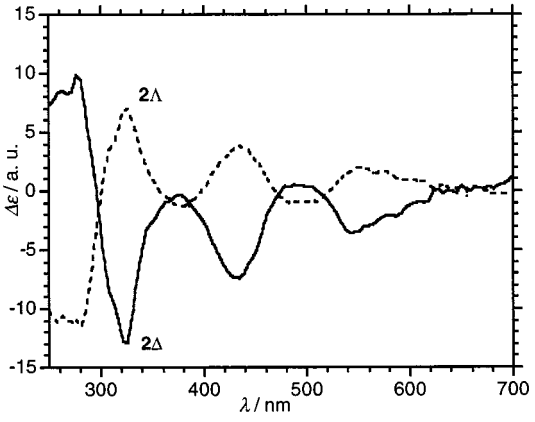


Figure 2. Circular dichroism spectra of **2Δ** and **2Λ** polymers in KBr dispersions

As expected, the circular dichroism curves of the enriched $[Ru(bpy)_2ppy]^+$ (**1Δ** or **1Λ**) (Figure 3) display signals due to the bipyridine ligands (λ_{max} = 598, 494, 390, 307, 259 nm) opposite to that of the respective precipitated polymers **2Λ** or **2Δ**, confirming the partial resolution of the monocation. The typical bipyridine band mentioned above again allows the determination of the Ru absolute configurations. It is worth noting that the dichroism spectra of the compounds **1Δ** and **1Λ** (in CH_2Cl_2 or acetone solutions) remain unchanged after five hours, showing that the racemization of $[Ru(bpy)_2(ppy)]^+$ is very slow in solution.

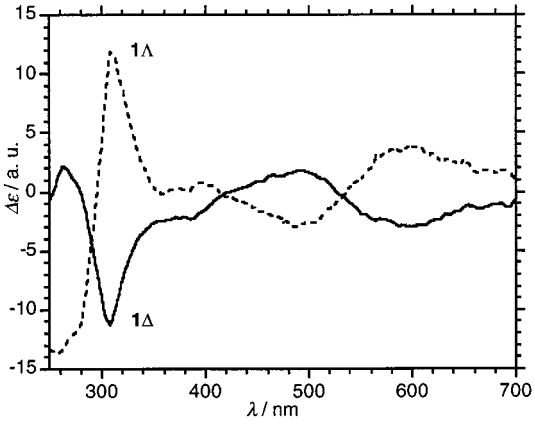

Figure 3. Circular dichroism spectra of **1Δ** and **1Λ** in KBr dispersions

Synthesis and Circular Dichroism of 3Δ and 3Λ

Even if circular dichroism in the solid state allows us to assign the absolute configurations of metal complexes in the optically active compounds, it cannot be used as a device to measure the enantiomeric or diastereomeric excesses.[22] The circular dichroism spectrum of pure $[Ru(bpy)_2(ppy)]^+$ (*ee* = 100%) is still unknown, precluding a useful comparison of the relative intensities. The very deep purple color of the $[Ru(bpy)_2(ppy)]^+$ complex (due to the intraligand bipyridine transitions) also wrecked all attempts to measure the optical rotation. For this purpose the optically active enriched **1Δ** and **1Λ** $[Ru(bpy)_2ppy]^+$ salts were converted into their enriched diastereomeric salts [Δ-$Ru(bpy)_2$-(ppy)][Δ-trisphat] (**3Δ**) and [Λ-$Ru(bpy)_2$(ppy)][Δ-trisphat] (**3Λ**) with [Δ-trisphat] as the counter-anion. The diastereomeric excesses in these two species were determined by ^1H NMR spectroscopy.

Treatment of a solution of **1Δ** (or **1Λ**) with one equivalent of [l-cinchonidinium][Δ-trisphat] for 30 minutes in acetone at room temperature afforded either **3Δ** (or **3Λ**). Subsequent separation of the mixture by column chromatography on an aluminum oxide column (10 cm, CH_2Cl_2) provided **3Δ** (or **3Λ**) as the less-polar purple band while the starting $[Ru(bpy)_2(ppy)]PF_6$ **1Δ** (or **1Λ**) was then eluted as the more polar fraction. We assume in this reaction that the diastereomeric excess in **3Δ** and **3Λ** reflects exactly the enantiomeric excess in **1Δ** and **1Λ** for the following reasons:

– the [l-cinchonidinium][Δ-trisphat] salt is optically pure (*de* = 98%).

– the [l-cinchonidinium][Δ-trisphat] reacts equally (see above and ref.[32]) with both enantiomers of $[Ru(bpy)_2ppy]^+$ even if the transformation of $[Ru(bpy)_2ppy]^+$ into the related diastereomeric salt $[Ru(bpy)_2(ppy)]$[Δ-trisphat] is not quantitative (yield: 60%).

Circular dichroism measurements of **3Δ** and **3Λ** were performed in CH_2Cl_2 (Figure 4). The curves of the two diastereomers exhibited two well-separated regions where the borderline is centered at 270 nm. For the region $\lambda > 270$ nm, the spectra present opposite signals due exclusively to the optically active $[Ru(bpy)_2(ppy)]^+$. Below 270 nm, [Δ-trisphat] bands are predominant exhibiting similar and negative Cotton effects.

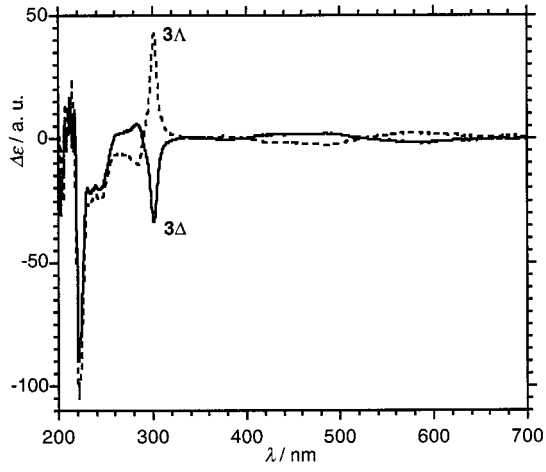

Figure 4. Circular dichroism spectra of **3Δ** and **3Λ** in CH_2Cl_2 solutions ($c = 7.5-9.10^{-5}$ mol·L^{-1})

Determination of the Diastereomeric Excess of [Δ-$Ru(bpy)_2$(ppy)][Δ-trisphat] (3Δ) and [Λ-$Ru(bpy)_2$(ppy)][Δ-trisphat] (3Λ) by ^1H NMR Spectroscopy

The ^1H NMR spectra of *rac*-$[Ru(bpy)_2ppy]PF_6$ (**1**), $[Ru(bpy)_2(ppy)]$[Δ-trisphat] (**3**) (*de* = 0%) and enriched [Δ-$Ru(bpy)_2$(ppy)][Δ-trisphat] (**3Δ**) and [Λ-$Ru(bpy)_2$(ppy)][Δ-

trisphat] (**3Λ**) were recorded in acetone solution (Figure 5a−d). These ^1H NMR studies allowed us to determine the enantiomeric excess of the enriched complex [Δ-$Ru(bpy)_2ppy]PF_6$ (**1Δ**) and [Λ-$Ru(bpy)_2ppy]PF_6$ (**1Λ**) by measurement of the diastereomeric excess in **3Δ** and **3Λ**. As a first approach, we measured the ^1H NMR spectrum of *rac*-$[Ru(bpy)_2ppy]PF_6$. The latter was previously studied by Constable[24] in $[D_6]$DMSO solution. Based on previous studies, and on our own ^1H-^1H NMR homonuclear decoupling and 2D ^1H-^1H experiments, we assigned the multiplet centered at δ = 7.57 to the proton H-10. The spectrum of $[Ru(bpy)_2(ppy)]$[Δ-trisphat] in its nonenriched form **3** appears more intricate than that of the $[Ru(bpy)_2ppy]PF_6$ complex; some resonances split into two components because the two diastereomers exhibit different chemical shifts in their ^1H NMR spectra. The spectra of **3Δ** and **3Λ** clearly show an enrichment in one of the two diastereomers. For quantitative purposes we chose the well-resolved multiplet H-10, which exhibits the most pronounced splitting in the diastereomer formation. The appearance of this multiplet in **1**, **3**, **3Δ**, **3Λ** is shown in Figure 5 (a−d). We were able to assign each peak to each of the two diastereomers by examining and comparing the spectra of **3Δ** and **3Λ**. Thus, the most and the least deshielded doublets of the multiplet are assigned respectively to the [Λ-$Ru(bpy)_2(ppy)$][Δ-trisphat] and [Δ-$Ru(bpy)_2(ppy)$][Δ-trisphat] diastereomers. These signals are sufficiently well separated to afford a precise measurement of the respective ratio of the two diastereomers, and so of the diastereomeric excesses, by integration. As can easily be seen, in the nonenriched product **3** they appear of equal intensity whereas for the enriched compounds **3Δ** and **3Λ** the ratio between the two diastereomers (ΔΔ/ΛΔ) is 72:28 and 25:75, respectively, providing an estimate of the diastereomeric excess in **3Δ** and **3Λ**, and so the enantiomeric excess in **1Δ** and **1Λ**, to be 44% and 50%, respectively.

Conclusion

In this paper we described the preparation of optically active bimetallic networks of the type $\{[\Lambda\text{-}Ru(bpy)_2(ppy)][Mn\text{-}\Lambda\text{-}Co(ox)_3]\}_n$ (**2Λ**) and $\{[\Delta\text{-}Ru(bpy)_2(ppy)][Mn\text{-}\Delta\text{-}Co(ox)_3]\}_n$ (**2Δ**) and showed for the first time that the synthesis of these chiral polymers is a good strategy for resolving the $[Ru(bpy)_2(ppy)]^+$ complex. Furthermore, **2Λ** and **2Δ** can be obtained via either the resolved tris-oxalato $[M^{III}(ox)_3]^{3-}$ anion or $[Ru(bpy)_2(ppy)]^+$ cation building block, whereby each species can play the role of the chiral template-inducer. This implies that an optically active form of either tris-chelated brick (anion or cation) affords the partial resolution of the other one owing to the matrix effect induced by the formation of the optically active polymer. This feature opens new horizons in the resolution of the hexacoordinated quasi-D_3 monocations $[Ru(bpy)_2L]^+$ (L is a bidentate monocharged ligand such as the 8-quinolate). Therefore, separation of enantiomers induced by specific interactions between chiral molecules and optically active molecular frameworks appears to be one of the most promising alternatives to the conventional procedures.

The use of the optically active and configurationally stable $[Ru(bpy)_2(ppy)]^+$ complex will provide an important control over chirality in the building of optically active polymers with various tandems M^{II}-M^{III} displaying interesting magnetic behavior.

Experimental Section

Materials: The following compounds were prepared according to literature methods: $K_3[Co(ox)_3]\cdot 3H_2O$,[33] *rac*-$[Ru(bpy)_2ppy]PF_6$,[24,34] [l-cinchonidinium][Δ-trisphat].[28] The resolution procedure described previously was followed to obtain the Δ and Λ $K_3[Co(ox)_3]\cdot 3H_2O$ enantiomers.[30] The other reagents are commercially available and were used as purchased.

General Procedures: The IR spectra were recorded on a Bio-Rad IRFT spectrophotometer as KBr pellets in the 4000−250 cm^{-1} region. Elemental analyses were performed at the SIARE-UPMC, Paris. Metal analyses were completed at the Service Central d'Analyse-CNRS, Vernaison. The specific rotations of the starting materials were measured at 20 °C, in a 1 dm-tube containing the solutions, using the D-line in an Ameria AA5 polarimeter. The enantiomeric or diastereomeric excess was calculated by comparison with the maximum specific rotation values found in the literature.[28,30] Circular dichroism spectra were measured with a Jasco model J-710 spectropolarimeter. Solid state measurements were made on compounds **1Δ**, **1Λ**, **2Δ** and **2Λ** as dispersions of 0.1−0.5 mg in 100−110 mg of oven-dried KBr. 13 mm-diameter disks were made in a standard disk press. For **3Δ** and **3Λ**, measurements were carried out in CH_2Cl_2 solutions (c = 7.5−9.10^{-5} mol·L^{-1}) in a 1 mm cuvette. The baseline correction was performed with the spectrum of a pure KBr disk or of CH_2Cl_2 prepared under the same conditions. The displayed absorption spectra result from subtraction of the spectrum of the standard KBr disk or of CH_2Cl_2. Spectra were recorded in the wavelength range 700−200 nm for all compounds. The ^1H NMR spectra (300 MHz) were obtained at room temperature in 5 mm o.d. tubes on a Bruker AC 300 spectrometer equipped with a QNP probehead (solutions of $[D_6]$acetone, c = 0.014 mol·L^{-1}). Chemical shifts are given according to the IUPAC convention with respect to $SiMe_4$. The ^{31}P NMR (121.5 MHz) spectra were measured as for ^1H spectra on the same tubes. The chromatography separations were carried out on a 3 cm-diameter column of alumina (10 cm; 0.05−0.15 mm neutral aluminium oxide; eluent: CH_2Cl_2).

X-ray Crystallographic Analysis: Accurate cell dimensions and orientation matrix were obtained by least-squares refinement of 25 accurately centered reflections. The data were corrected for Lorentz and polarization effects. Computations were performed by using Crystals 2000 version. Scattering factors and corrections for anomalous dispersion were taken from reference.[35] The structures were solved by direct methods (SHELXS). All final refinements were carried out by full-matrix least-squares using anisotropic displacement parameters for all phosphorus, fluorine and non-hydrogen atoms. Hydrogen atoms were introduced in calculated positions and only one overall isotropic displacement parameter was refined. All crystallographic data and diffraction parameters are listed in Table 1.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge

Preparation of 1Δ, 1Λ, 2Δ and 2Λ: In a hemolysis tube, an aqueous solution (0.2 mL) of optically active $K_3[\Lambda Co(ox)_3]\cdot 3H_2O$ {39.4 mg, 0.08 mmol; $[\alpha]_D = -1892$ (c = 0.02 in H_2O); maximum rotation reported in the literature:[30] $[\alpha]_D = -1940$} and $MnCl_2\cdot 4H_2O$ (15.7 mg, 0.08 mmol) was added quickly to a DMSO solution (0.4 mL) of racemic $[Ru(bpy)_2ppy]PF_6$ (**1**) (100.2 mg, 0.14 mmol; not completely dissolved. To ensure the complete precipitation of the $[\Lambda\text{-}Ru(bpy)_2ppy]^+$ as a polymer we used less than two equivalents of the $[Ru(bpy)_2ppy]PF_6$ complex). During 5 minutes, acetone and H_2O were successively added scratching continuously the walls of the tube with a Pasteur pipette (the additions were made in this order: acetone-H_2O-acetone-H_2O-acetone, 1.2 mL each time). The purple precipitate was filtered off, washed with H_2O (5 mL) and acetone (until the filtrate became colorless) and air-dried leading to the green $\{[\Lambda\text{-}Ru(bpy)_2(ppy)][Mn\text{-}\Lambda\text{-}Co(ox)_3]\}_n$ (**2Λ**) (68.6 mg, 0.0724 mmol; yield: 91%). The purple filtrate was concentrated by rotary evaporator to remove acetone and, after precipitation by addition of diethyl ether (200 mL), the purple enriched [Δ-Ru-(bpy)$_2$ppy]PF$_6$ (**1Δ**) (43.7 mg, 0.0612 mmol) was filtered off and air-dried. The same procedure was employed for the other enantiomers **1Λ** and **2Δ** using $K_3[\Delta Co(ox)_3]\cdot 3H_2O$ {$[\alpha]_D = +1667$ (c = 0.02 in H_2O); maximum rotation reported in the literature:[30] $[\alpha]_D = +1928$}.

2Λ: $C_{37}H_{24}CoMnN_5O_{12}Ru$ (945.56): calcd. C 47.0, H 2.56, N 7.41, Ru 10.69, Mn 5.81, Co 6.23; found C 41.93; H 2.72, N 6.11, Ru 8.15, Mn 5.66, Co 5.87. − IR (KBr): $\tilde{\nu}$ = 1652s, 1629vs, 1600vs (C=O), 1310m, 798m, 780m cm^{-1}.

1Δ: ^{1}H NMR (300.13 MHz, C_3D_6O, 300 K, TMS): δ = 6.48 (d, 1 H), 6.85 (m, 2 H), 7.02 (t, 1 H), 7.36 (m, 3 H), 7.57 (t, 1 H), 7.70 (d, 1 H), 7.76 (t, 1 H), 7.91 (m, 6 H), 8.03 (d, 1 H), 8.12 (m, 3 H), 8.57 (pseudo-t, 2 H), 8.65 (d, 1 H), 8.73 (d,1 H). − ^{31}P NMR (121.5 MHz, C_3D_6O, 300 K, 85% H_3PO_4): δ= −142.72 (sept).

Preparation of 3Δ and 3Λ: [Δ-Ru(bpy)$_2$(ppy)]PF$_6$ (**1Δ**) (128.3 mg, 0.18 mmol) and [l-cinchonidinium][Δ-trisphat] ($[\alpha]_D$=-369 (c = 0.1 in EtOH), *de* = 98%)(1-fold) (191.3 mg, 0.18 mmol) were dissolved in a minimum amount of acetone and stirred for about 30 minutes. The product was first adsorbed on aluminium oxide and then chromatographed on a column of alumina (10 cm, CH_2Cl_2). The less-polar fraction contained exclusively the deep purple diastereomer **3Δ** (or **3Λ**). Enriched [Δ-Ru(bpy)$_2$(ppy)]PF$_6$ **1Δ** (or **1Λ**) appeared afterwards as a second fraction of the same color. [Δ-Ru-(bpy)$_2$(ppy)][Δ-trisphat] (**3Δ**) (150.8 mg, 0.11 mmol; yield: 61%) and [Δ-Ru(bpy)$_2$(ppy)]PF$_6$ (**1Δ**) (46.4 mg, 0.065 mmol) were recuperated after evaporation of the solvent on a rotary evaporator.

$C_{49}H_{24}N_5Cl_{12}O_6PRu$ (%): calcd. C 44.01, H 1.81, N 5.24; found C 44.26; H 2.03, N 5.61;IR (KBr): $\tilde{\nu}$ = 1451vs, 1421s, 1389s, 992vs, 825vs, 757s, 730s, 719m, 672vs, 650s, 620s cm^{-1}. − ^{1}H NMR (300.13 MHz, C_3D_6O, 300 K, TMS): δ = 6.48 (d, 1 H), 6.84 (m, 2 H), 7.00 (m, 1 H), 7.34 (m, 3 H), 7.55 (m, 1 H), 7.73 (m.2 H), 7.90 (m, 6 H), 8.03 (m, 1 H), 8.13 (m, 3 H), 8.55 (pseudo-t, 2 H), 8.63 (d, 1 H), 8.71 (d, 1 H). − ^{31}P NMR (121.5 MHz, C_3D_6O, 300 K, 85 % H_3PO_4): δ = −79.14 (s).

Acknowledgments

We gratefully acknowledge Dr. H. Amouri and Dr. R. Andrès for helpful discussions and Dr. M. Takahashi (Institut Curie, CNRS) for assistance in performing the circular dichroism measurements. We thank CNRS and Université Pierre et Marie Curie for financial support.

[32] Similar experiments were carried out using the same method of synthesis of the polymers **2Δ** and **2Λ** for the partial resolution of the monocation but starting from the nonenriched $[Ru(bpy)_2(ppy)][\Delta\text{-trisphat}]$ (**3**) instead of *rac*-$[Ru(bpy)_2(ppy)]PF_6$ (**1**). Thus, enriched $[Ru(bpy)_2(ppy)][\Delta\text{-trisphat}]$ **3Δ** and **3Λ** can be directly obtained after filtration of the polymer and precipitated by addition of water. Diastereomeric excesses calculated by ^1H NMR on these compounds leads to the same results that for the experiments with *rac*-$[Ru(bpy)_2(ppy)]PF_6$ (**1**). This fact confirms that the reaction of transformation of $[Ru(bpy)_2ppy]^+$ into diastereomer is no diastereoselective and that the partial resolution of the monocation is exclusively due to the diastereoselective formation of the polymer **2Δ** and **2Λ**.

Proton Transfer to CpRuH(CO)(PCy_3) Studied by Low-Temperature IR and NMR Spectroscopy

Natalia V. Belkova,[a] Alexei V. Ionidis,[a] Lina M. Epstein,[a] Elena S. Shubina,*[a] Stephan Gruendemann,[b] Nikolai S. Golubev,[b] and Hans-Heinrich Limbach*[b]

Keywords: Hydrido complexes / Hydrogen bonds / Proton transfer / Kinetics / IR spectroscopy / NMR spectroscopy

The interaction of the ruthenium hydride complex RuH ≡ CpRuH(CO)(PCy_3) (**1**) with various proton donors AH ≡ CF_3CH_2OH (**2a**), $(CF_3)_2CHOH$ (**2b**), $(CF_3)_3COH$ (**2c**), CF_3COOH (**2d**), and HBF_4 (**2e**) has been studied by variable-temperature IR spectroscopy using hexane and CH_2Cl_2 as solvents of different polarity. A low-temperature NMR study of the interaction of **1** with **2c** was performed using [D_8]methylcyclohexane, CD_2Cl_2, and a liquefied mixture of CDF_2Cl/CDF_3 (2:1). The first stage of the proton transfer process was found to be the formation of hydrogen-bonded complexes of the type RuH···HA. The hydrogen bonds in these complexes are of medium strength ($-\Delta H°$ = 5.3–7.6 kcal mol^{-1}). The second stage is the slow conversion of the H-complex to a dihydrogen complex to which a hydrogen-bonded ion-pair structure [Ru(η^2-H_2)]$^+$···A^- was assigned. The kinetics of this unusually slow proton transfer reaction was monitored in the case of **2c** at 200 K in CH_2Cl_2. Fast protonation of **1** by **2d** leads additionally to a species assigned as the free cationic complex [Ru(η^2-H_2)]$^+$, whose formation is driven by the formation of the homoconjugated anionic complex [AHA]$^-$. At temperatures above 220 K both the hydrogen-bonded ion pair and the free cationic complex easily release dihydrogen, producing RuA.

Introduction

The protonation of transition metal hydrides by proton donors constitutes an important pathway for the synthesis of cationic non-classical dihydrogen complexes.[1] The elementary steps of this reaction are, however, still unclear up to date. Usually, proton transfer between a neutral proton donor AH and a neutral base is preceded by the formation of a hydrogen-bonded complex of the type A−H···B, which is converted rapidly into the hydrogen-bonded ion pair A^-···H−B^+, leading finally to the free ions as reaction products. It has therefore been an exciting discovery that proton donors can form "unconventional" intramolecular[2−7] and intermolecular[8−16] hydrogen bonds to the hydride moieties of transition metal complexes MH, taking the role as proton acceptors. For example, intermolecular hydrogen-bonded complexes were observed in the case of rhenium hydrides in the solid state,[8,9] as well as of tungsten and rhenium hydrides in solution.[11−14] The idea that these complexes constitute important intermediates of transition metal hydride protonation was subsequently proposed in a number of papers,[9,11] although evidence for this idea has been obtained only very recently.[17−21] For example, the application of IR and NMR methods in a wide range of temperatures allowed some of us to establish the existence of an unusually slow equilibrium between M−H···H−A and M−H_2^+ A^- in the case of $RuH_2(dppm)_2$,[17] and {$MeC(CH_2PPh_2)_3$}-$Re(CO)_2H$[19]. NMR alone was used similarly in the case of $Cp^*Ru(PCy_3)H_3$.[21] In the latter study where NMR experiments were performed using both toluene and a liquefied freon mixture CDF_2Cl/CDF_3 (2:1) as solvents − where the latter allows measurements down to 100 K − it was realized that protonation takes place if the solvent polarity is large enough. Interestingly, both the above freon mixture as well as CH_2Cl_2 exhibit similar dielectric constants that increase dramatically by lowering the temperature. As a consequence, protonation is a solvent-assisted process occurring at low temperatures. On the other hand, in the case of nonpolar solvents such as hexane or toluene, only the hydrogen-bonded complex M−H···H−A is formed without subsequent protonation.[21]

In order to study the mechanism of a reaction one usually monitors its kinetics. For the systems mentioned above such experiments have not yet been reported. We are aware only of recent papers of Basallote et al.[22−24] that followed the protonation kinetics of two iron and one ruthenium hydrides with strong acids using electrochemical methods. However, this method does not provide information about the structure of reaction intermediates.

In order to identify the various reaction steps and hence the reaction mechanism we decided to study the interaction of a simple transition metal monohydride with proton donors of different strengths, using a combination of IR and NMR spectroscopy. For this purpose we chose the ruthenium hydride CpRuH(CO)(PCy_3) (≡ RuH, **1**), which was first synthesized by Heinekey et al.[25] and is known to

form a stable cationic dihydrogen complex[25,26] under the action of HBF_4. On the other hand this hydride contains a CO group whose stretching band constitutes an excellent IR marker sensitive to hydrogen bond formation and protonation.[11−15,19,27−29]

Thus, in this paper we report the results of variable-temperature IR and NMR studies of interactions of the hydride **1** with CF_3CH_2OH (**2a**), $(CF_3)_2CHOH$ (**2b**), $(CF_3)_3COH$ (**2c**), CF_3COOH (**2d**), and HBF_4 (**2e**) in the nonpolar medium hexane and in the polar media CH_2Cl_2, and CDF_2Cl/CDF_3 (2:1). The results of these experiments will be discussed in terms of the general reaction model depicted in Scheme 1. In addition to free **1**, the hydrogen-bonded complex **3**, and the cationic dihydrogen complex **5**, we have found for the first time, evidence for a further intermediate **4**, a hydrogen-bonded ion pair. We will show that the interconversion between **3** and **4** constitutes the rate-limiting step of the proton transfer. The dissociation of **4** into the free dihydrogen complex **5** is assisted in the case of **2d** by the formation of homoconjugated ions $[AHA]^-$ (**6**). Finally, **5** easily looses a dihydrogen molecule forming the reaction product **7**.

IR Studies of the Dihydrogen Bonding and Protonation of 1 with Proton Donors

The OH Stretching Region − Dihydrogen Bond of 1 with Weak Proton Donors in Hexane and Dichloromethane

The stretching vibrations ν_{OH} of proton donors at 3600−3000 cm^{-1} are well known to be sensitive to hydrogen bonding. Figure 1 (a) shows the OH stretching region of CF_3CH_2OH (**2a**) at low concentrations in an excess of **1**. We observe a sharp monomer band at 3630 cm^{-1} and a broad bonded band, which is shifted considerably to lower frequencies. Because of the low proton donor concentration and excess of **1**, there are no apparent contributions from complexes $(AH)_n$ or $RuH\cdots(H-A)_n$ involving more than one proton donor molecule. Therefore, the broad band can be assigned to the complex **3a**, and the observed frequency shifts listed in Table 1 are identified as $\Delta\nu_{OH} = \nu_{OH}(AH) - \nu_{OH}(RuH\cdots HA)$, where the position of the broad band corresponds to its center of gravity ($s = \pm 3$ cm^{-1}).

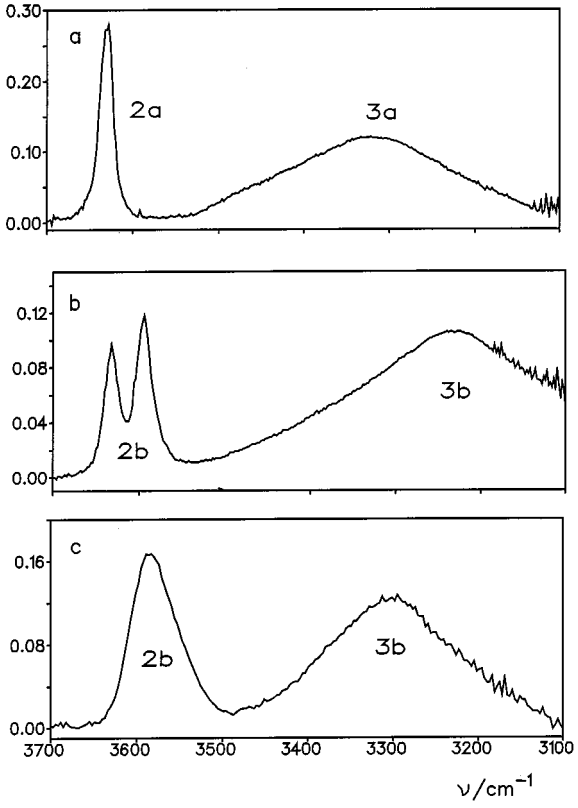

Figure 1. Room-temperature ν_{OH} stretching bands of proton donors (0.02 mol/L) in the presence of a 2.5-fold excess of $CpRu(CO)(PCy_3)H$ (**1**); (a) CF_3CH_2OH (**2a**), hexane; (b) $(CF_3)_2CHOH$ (**2b**), hexane; (c) $(CF_3)_2CHOH$ (**2b**), CH_2Cl_2

When the proton-donating power is increased, $\Delta\nu_{OH}$ increases as illustrated in Figure 1 (b) for the case of complex **2b**. Here, monomeric $(CF_3)_2CHOH$ (**2b**) exhibits two different bands that are due to conformational heterogeneity (two conformers exist) and intermolecular interactions.[30,31] A strong solvent effect is observed in the sense that the hydrogen bond shift $\Delta\nu_{OH}$ is smaller when CH_2Cl_2 is used as solvent (Figure 1, c). In the case of **2c** $\nu_{OH}(RuH\cdots HA)$ was shifted so much that it strongly overlapped with the CH stretching band of the solvent, so that $\Delta\nu_{OH}$ could not be determined properly.

As is known, this region clearly shows the hydrogen bond formation, and is useful for ΔH determination.[11,13,15] It does not, however, give any information on the site of coordination. Therefore, a study of all vibrations should be performed in order to decide whether the hydride atom of **1** is the only hydrogen bond site as assumed in Scheme 1, or whether the oxygen atoms of the CO groups or even the metal center itself acts as proton acceptor site. Unfortunately, the RuH stretching vibration of **1** did not give rise to an observable band, in contrast to the tungsten and rhenium hydrides studied previously.[11,13] Therefore, most of

the information came from a detailed study of the stretching vibrations of the carbonyl ligand (ν_{CO}) of **1**.

The CO Stretching Region – Dihydrogen Bond Formation and Protonation of 1 by Weak Proton Donors in Hexane and Dichloromethane

The changes in the CO stretching region of **1** observed in the presence of proton donors allowed us to show the formation of the dihydrogen-bonded complexes, and to monitor their following transformations. In Figure 2 (a) we have depicted ν_{CO}(**1**) of pure hydride obtained at 200 K using hexane as solvent. This strong band appears at 1905 cm^{-1} and is quite narrow exhibiting a line width of only 7 cm^{-1}. When a proton donor is added, a new band is observed at slightly larger wave numbers, e.g. at 1920 cm^{-1} in the case of **2c** (Figure 2, a). The new band is shifted by $\Delta\nu_{CO}$ = +12 cm^{-1} in the case of **2b** and +15 cm^{-1} in the case of **2c**. These high-frequency shifts show that the oxygen atom of the CO group does not participate in hydrogen bonding.[11–13] Hence, we assign the new band to the ν_{CO} stretching vibrations of the 1:1 complexes RuH···HA (**3**). As the stretching vibration ν_{RuH} could not be observed, the assignment of the structures **3** containing a dihydrogen bond between the proton donor and the hydride site, and not with the metal atom is then tentative. However, further information supporting this assignment comes from the NMR spectroscopy study, as shown below.

The ν_{CO} band of pure **1**, dissolved in CH_2Cl_2, appears at 1890 cm^{-1} as depicted in Figure 2 (b), again using a sample temperature of 200 K. The band is broader than in hexane and exhibits a half width of 22 cm^{-1}, so in the presence of a proton donor we observe only the summary band of **1** and **3c** with a high-frequency shift of +6 cm^{-1} as depicted in Figure 2 (b) for the case of **2c**. These small changes are not unusual; e.g. we observed similar effects for the dihydrogen bonds with {$MeC(CH_2PPh_2)_3$}$Re(CO)_2H$.[19]

We observed an interesting phenomenon, concerning the spectral changes in time. The intensity of ν_{CO}(**1**+**3c**) band decreases after several minutes, and the new high-frequency band at 1960 cm^{-1} appears and grows in intensity (Figure 2, c). After about 30 min, equilibrium is reached, where both bands are present. We assign this new band to an ion pair of the type **4c**. Arguments for this structure arise from the study of the interaction of **1** with stronger proton donors described below. We do not assign this band to the reaction product **7c**, because upon heating to 250 K the band at 1960 cm^{-1} decreases while a new ν_{CO} band at 1944 cm^{-1} appears. This new band we assign to **7c**.

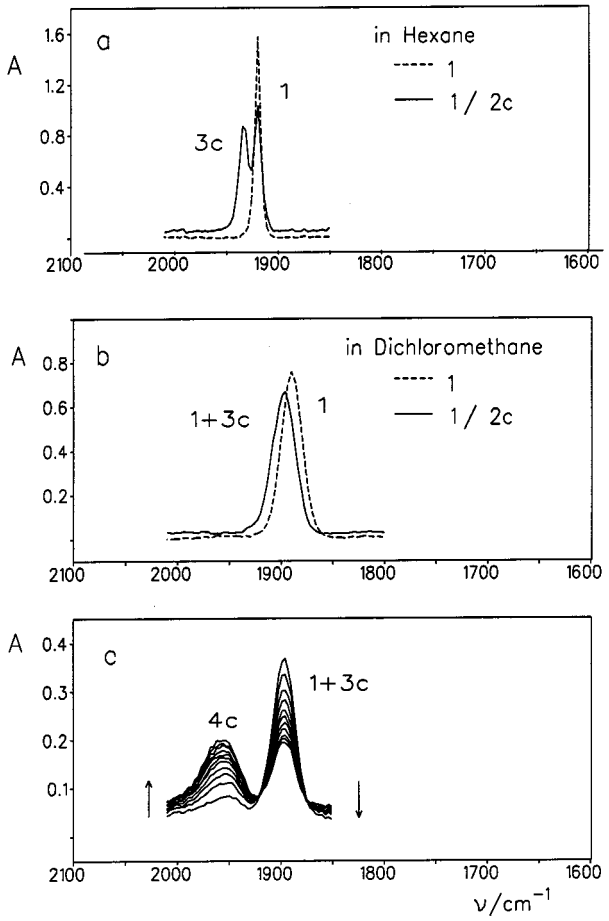

Figure 2. IR spectra in the ν_{CO} range of CpRu(CO)(PCy_3)H (**1**) (0.005 mol/L) at 200 K in hexane (a) and CH_2Cl_2 (b, c) without proton donor (- - - -) and in the presence of 4 equiv. of $(CF_3)_3COH$ (**2c**) (——); (c) time-dependent changes of the sample **1/2c** over a period of 30 min

The CO Stretching Region – Dihydrogen Bond Formation and Protonation of 1 with Strong Proton Donors in Dichloromethane

In principle, the interaction of metal hydrides with strong proton donors will lead to their protonation, constituting a routine procedure for the generation of cationic dihydrogen complexes. However, the choice of acid is crucial for their

stability. There are numerous examples where the labile dihydrogen ligand can be easily displaced by anionic ligands.[13,19,32,33] In the present case, the interaction of hydride **1** with proton donors such as fluorinated alcohols and carboxylic acids also leads to unstable (η^2-H_2) complexes due to the high coordinating ability of the corresponding anions (R^FO^- and CF_3COO^-). The elimination of an H_2 molecule and the addition of an anion upon warming results in the formation of organyloxy derivatives **7**. We succeeded in minimizing and even preventing this unwanted process by carrying out the mixing of the reagents and IR measurements at 200 K.

In order to elucidate the protonation of **1** in more detail, we performed various IR studies of **1** with stronger acids, i.e. CF_3COOH (**2d**) and HBF_4 (**2e**). As mentioned in the introduction, the interaction of hydride **1** with HBF_4 results in the formation of the stable dihydrogen complex [CpRu(CO)(PCy_3)(η^2-H_2)]$^+$ (**5**) with BF_4^- as counter ion, exhibiting a ν_{CO} band at 2020 cm^{-1} in the solid state.[26] Here, upon mixing of the hydride **1** with HBF_4 in CH_2Cl_2 at 200 K we observe a similar value. The position of this band does not change with increasing temperature. These results indicate that the ν_{CO} band at 2020 cm^{-1} indeed belongs to the free protonated complex **5** in CH_2Cl_2, formed upon interaction of **1** with HBF_4.

If **5** is not directly involved in an interaction with the counterion it should be possible to generate **5** also with other acids. For this purpose we chose CF_3COOH (**2d**) and carried out experiments at 200 K using again CH_2Cl_2 as solvent. In addition to ν_{CO} of the CO ligand absorbing in the 2100−1850 cm^{-1} range this system exhibits additional CO stretching vibrations ν_{CO} of the acid and the antisymmetric stretching band ν_{OCO}^{as} of trifluroacetate between 1800 and 1600 cm^{-1}.

The ν_{CO} bands of the separate monomeric **1** and the dimeric CF_3COOH molecules (**2d**) in CH_2Cl_2 are represented by the graphs a and b in Figure 3. The band ν_{CO}(**2d**) appears at 1790 cm^{-1}. However, when both reactants are mixed at low concentrations of **1** (10^{-3} mol/L) in the presence of an excess of **2d**, we obtain spectrum c in Figure 3. Again, at 2020 cm^{-1} we observe a new band that coincides with the ν_{CO} band of **5** with BF_4^- as counter anion. Therefore, we can now safely assign this new band to the free protonated ion **5**. Moreover, another new band arises at 1648 cm^{-1}, which we attribute to ν_{OCO}^{as} of the homoconjugated trifluoroacetate.[34−38] The excess of the acid is demonstrated by the band at 1790 cm^{-1}. We note that there is no band arising from the dihydrogen-bonded complex **3d**.

Interesting spectral changes are observed when the ratio of the hydride to the acid is increased, as indicated by the spectral traces d, e, and f in Figure 3. First, we note again ν_{CO} of **5** at 2020 cm^{-1} whose intensity is gradually reduced, then the typical strong band of ν_{CO}(**1**+**3d**) at 1910 cm^{-1} and for hydrogen-bonded acid in **3d** at 1760 cm^{-1}. These species were already identified before. However, in addition, a new band is observed at 1996 cm^{-1}, which is located closer to the band of **5** than of **3d**. We assign this new band to the ionic hydrogen-bonded complex **4d**. The corresponding ν_{OCO}^{as} vibration of the hydrogen-bonded acetate in this complex is assigned to the new sharp band at 1710 cm^{-1}, which is located between the band of dimeric **2d** and of the homoconjugated anion **6d**. This assignment is in agreement with previous studies of molecular and ionic hydrogen-bonded complexes of trifluoroacetic acid with organic and metal-containing bases.[34−38] Finally, before we discuss the spectral changes between spectra d, f, and g in Figure 3 we have to discuss the origin of the remaining two bands that are assigned to the CO ligand and trifluoroacetate group of **7d**. This assignment was confirmed by the experiment depicted by spectra g and h, where spectrum g is identical with spectrum f. Spectrum h was obtained after heating the sample to 260 K. The bands of **7d** are now increased in intensity after elimination of H_2. The spectral changes are irreversible, i.e. lowering of the temperature does not lead to spectrum g.

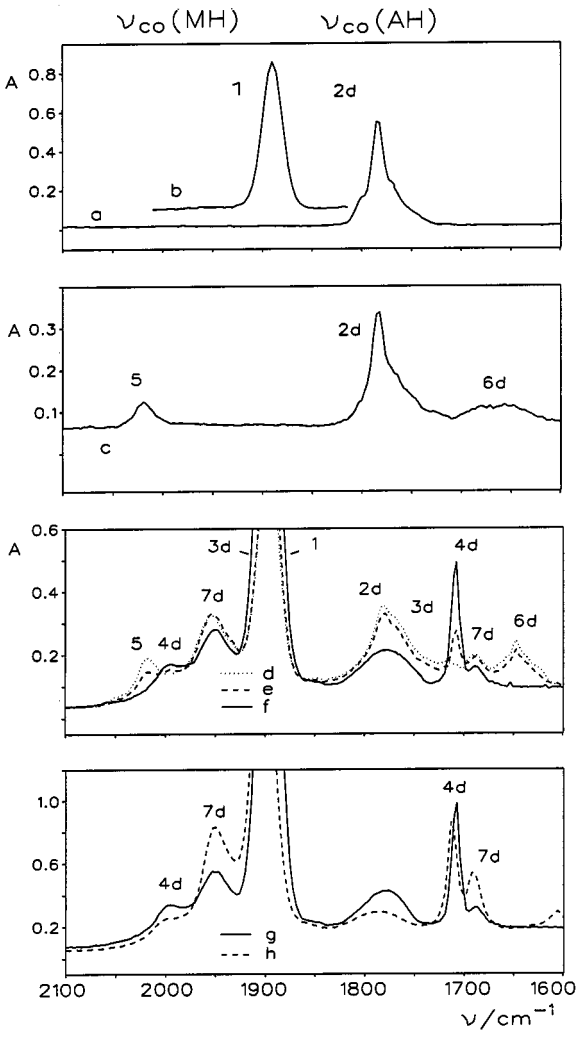

Figure 3. IR spectra of CpRu(CO)(PCy_3)H (**1**) [0.001 mol/L (c), 0.01 mol/L (d−f), 0.03 mol/L (g, h)] in the presence of excess CF_3COOH (**2d**) and a deficiency in CH_2Cl_2; ratio **1/2d** = 1:5 (c), 1:1.5 (d), 1:1 (e), 3:2 (f), 3:1 (g, h); reference spectra of **1** (0.01 mol/L) and of **2d** (0.01 mol/L) are given in b and a, respectively; temperature 200 K (a−g), 260 K (h)

We now consider the series of spectra d, e, and f, where the hydride/acid ratio was increased as indicated by the de-

crease of the band for dimer **2d**, and the relative increase of the acid band of **3d** at 1760 cm^{-1}. We observe in this series that both the bands of **5** and **6d** are reduced in intensity, and these bands have disappeared in spectrum f. On the other hand, **4d** increases in this series. The structure of this species, indicated in Scheme 1, with two hydrogen bonds to the dihydrogen group is speculative.

Finally, the finding of **4d** as a hydrogen bond stabilized ion-pair intermediate between the dihydrogen-bonded complex **3d** and the free protonated ion **5** allows us to confirm the above assignment of the 1960 cm^{-1} band in Figure 2 (c) to the ion pair **4c**. The lower ν_{CO} band position of **4c** as compared to **4d** is probably associated with a higher basicity of the $(CF_3)_3CO^-$ anion as compared to CF_3COO^-. The assignment of this band to ν_{CO} of the product (**7c**) is excluded since this would result in an irreversible appearance of this band, which is in contrast to the experimental findings.

Thermodynamics of Dihydrogen Bonding of 1 with Proton Donors in Hexane and Dichloromethane

The thermodynamics of dihydrogen bond formation of **1** with **2c** as proton donor in hexane was elucidated by analyzing the relative band intensities of **1** and of **3c** in spectra of the type shown in Figure 2 (a), between 250 K and 290 K. Because the ν_{CO} bands of **1** and **3c** in hexane are reasonably well resolved, the equilibrium concentration of free hydride [**1**] can be easily obtained from the spectra. The [**2c**] and [**3c**] concentrations could then be obtained from the total concentrations of **1** and of the proton donor. Thus, we obtained the values of the equilibrium constant defined in Scheme 1 as a function of temperature [Equation (1)].

$$K_1 = [\mathbf{3c}]/([\mathbf{1}][\mathbf{2c}]) = \exp(-\Delta H_1^0/RT + \Delta S_1^0/R) \quad (1)$$

The corresponding van't Hoff plot is depicted in Figure 4, from which we obtain the values of the enthalpy $\Delta H_1^0 = -7.3\pm0.2$ kcal mol^{-1} and $\Delta S_1^0 = -21.6\pm0.6$ cal K^{-1} mol^{-1}. The entropy value decrease is larger here than in the case of rhenium and tungsten hydrides.[11–13]

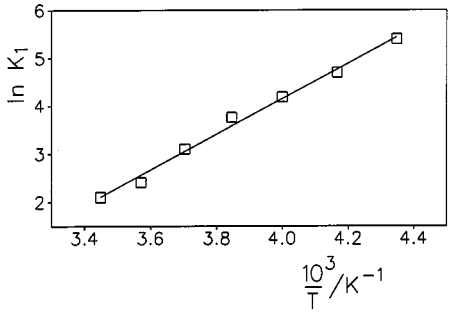

Figure 4. Van't Hoff plot of the hydrogen bonding of CpRu(CO)(P-Cy_3)H (**1**) (0.005 mol/L) in the presence of 4 equiv. of **2c** in hexane

In the case of the other fluorinated alcohols **2a** and **2b** we did not perform extended temperature experiments as we could estimate ΔH_1^0 from the frequency shifts $\Delta\nu_{OH} = \nu_{OH}(\mathbf{2}) - \nu_{OH}(\mathbf{3})$ listed in Table 1 using the correlation proposed for conventional hydrogen bonded complexes[39] according to Equation (2).

$$\Delta H_1^0 = -18\,\Delta\nu_{OH}/(720+\Delta\nu_{OH})\ [\text{kcal mol}^{-1}],\ \Delta\nu_{OH}\ \text{in cm}^{-1} \quad (2)$$

As has been shown, Equation (2) is perfectly applicable to dihydrogen bonding M−H···H−A.[11,12] The values of ΔH^0 obtained in this way for **2a** and **2b** are included in Table 1. Unfortunately, as mentioned above, we could not determine $\Delta\nu_{OH}$ for **2c**. As expected, the dihydrogen bond is stronger in hexane than in CH_2Cl_2. The basicity factors E_j[15,39] of the hydride atom for hydride **1** were calculated using the "rule of factors" equation [Equation (3)].

$$E_j = \Delta H_{ij} / \Delta H_{11} P_i \quad (3)$$

It is noteworthy that the basicity factor E_j[39,40] values of **1** are constant for all proton donors (Table 1) showing good agreement of enthalpy values obtained from empirical correlation [Equation (2)] and from K_1 temperature dependence [Equation (1)].

Thermodynamics and Kinetics of Protonation of 1 by $(CF_3)_3COH$ (2c) in CH_2Cl_2

In this section we quantitatively analyze the experiment that was illustrated in Figure 2 (c), where protonation of the dihydrogen-bonded complex **3c** slowly leads to an equilibrium with the ion pair **4c**. We studied the kinetics of process at 200 K following in time the ν_{CO}(**4c**) and ν_{CO}(**1**+**3c**) intensity changes at different **1**/**2c** ratios (Table 2). The representative kinetic curve (absorbance A vs. time) for **4c** and its first-order logarithmic plot [$\ln(A_\infty - A_t)$ vs. time] are presented in Figure 5.

Table 2. Rate constants k_{obs} for the reaction of hydride **1** with **2c** and conversion ratios α [Equation (5)]

1/**2c** ratio	α [%]	k_{obs} [s^{-1}] (**3**)	k_{obs} [s^{-1}] (**1**+**2**)
1:4	37.5	$1.4\cdot10^{-3}$	$1.6\cdot10^{-3}$
1:6	47.5	$1.7\cdot10^{-3}$	$1.5\cdot10^{-3}$
1:8	55.0	$1.5\cdot10^{-3}$	$1.6\cdot10^{-3}$
1:10	62.5	$1.6\cdot10^{-3}$	$1.4\cdot10^{-3}$

The rate constants k_{obs} obtained from intensity changes of the ν_{CO}(**4c**) band are practically the same as those obtained from ν_{CO}(**1**+**3c**) intensity changes. The k_{obs} values do not depend on the alcohol concentration in the concentration range studied, and the average k_{obs} value is $(1.6\pm0.2)\times10^{-3}$ s^{-1} (Table 2). The process in Scheme 1 is a typical reaction with so-called rapid pre-equilibria:

the diffusion-controlled first stage $\mathbf{1} + \mathbf{2c} \overset{K_1}{\rightleftharpoons} \mathbf{3c}$

and the rate-limiting step $\mathbf{3c} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathbf{4c}$

The observed rate constant of dihydrogen complex **4c** formation (k_{obs}) can be described by Equation (4).

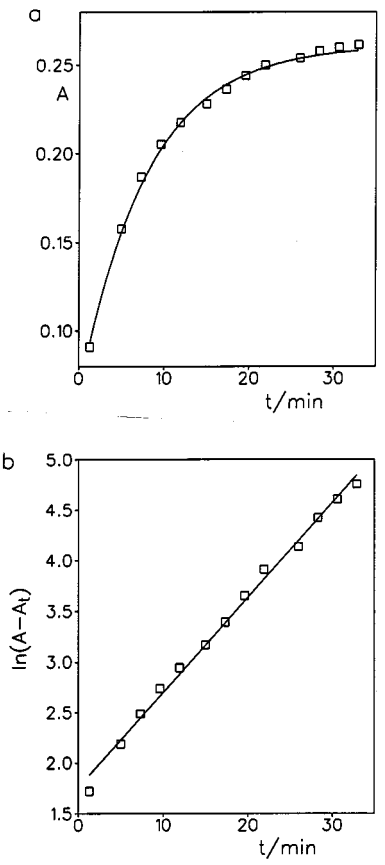

Figure 5. Kinetic curve (a) and its first-order logarithmic plot (b) for the reaction of CpRu(CO)(PCy_3)H (**1**) (0.004 mol/L) with 8 equiv. of $(CF_3)_3COH$ (**2c**) in CH_2Cl_2 at 200 K

$$k_{obs} = k_2\left(\frac{K_1[HA]}{1+K_1[HA]}\right) + k_{-2} \quad (4)$$

In the present case the k_{obs} value does not depend on the alcohol concentration, meaning the value in parentheses is approximately 1. In this case, the product of K_1 by [HA] should be >> 1. Lets suggest it is about 10. So, simple calculation using the **2c** concentrations of the order of 10^{-2} mol/L gives $K_1 \approx 10^3$ L/mol, which looks reasonable because the K_1 value in hexane at 200 K is ca. 2300 L/mol.

We were unable to determine the equilibrium constant K_2 (Scheme 1) due to the overlapping of the ν_{CO}(**1**) and ν_{CO}(**3c**) bands, but we could estimate the conversion ratio α [Equation (5)], where C_1 is the total concentration of hydride **1**, based on the ν_{CO}(**1**+**3c**) intensity fall upon the settlement of the equilibrium.

$$\alpha = [\mathbf{4c}]/C_1 \quad (5)$$

As one can expect, the α value increases as the **2c** concentration increases (Table 2). Although we cannot determine the K_2 equilibrium constant we can estimate its value assuming that at 10-fold alcohol excess and $K_1 \approx 10^3$ L/mol at 200 K, the hydrogen bonding equilibrium should be completely shifted toward **3c**. So, we can determine both **3c** and **4c** concentrations from the corresponding ν_{CO} bands and estimate K_2 = [**4c**]/[**3c**] to be 1.7. The K_2 value estimated seems to be realistic, and the same one has already been observed in other cases.[41] These values correspond to $\Delta G_{200K} \approx -2.7$ kcal/mol for hydrogen bond formation and only −0.2 kcal/mol for proton transfer, showing that the driving force of the proton transfer reaction in the present case is dihydrogen bond formation.

The Study of the Interaction of Hydride 1 with $(CF_3)_3COH$ (2c) by NMR Spectroscopy

The measurements in CD_2Cl_2 and [D_8]methylcyclohexane were carried out at 190−270 K. In the presence of hydride **1**, the proton signal of **2c** shifts to low field from δ = 4.5 to δ = 6. A change of the hydride signal position in the ^{1}H NMR spectra (−12.5 ppm) could not be detected, but a substantial shortening of the relaxation time of the hydride signal was observed. In the presence of **2c** T_1 min. of this signal decreases 1.5−2 times from 753 ms to 389 ms in CD_2Cl_2 and 383 ms in C_7D_8, at 200 K. Such changes of T_1 min. are typical for MH···HA bond formation.[11,19] The ^{1}H-NMR spectra of **1** in the presence of a 5-fold CF_3COOH (**2d**) excess show the signal of the η^2-H_2 ligand of **3** at δ = −7.95, with relaxation time T_1 = 11 ms (200 K, 400 MHz). For comparison, an NMR spectrum of [CpRu(η^2-H_2)(CO)(PCy_3)]BF_4 (**5**) in CD_2Cl_2 was recorded. It shows the signal of the η^2-H_2 ligand at δ = −7.95. The T_1 relaxation time of this signal is 9 ms at 210 K (200 MHz) and matches the value found by Heinekey and coworkers.[25,26]

NMR studies in liquid freons have been shown[14,21] as potential tools in obtaining additional information about hydrogen bonds. Therefore, the interaction of hydride **1** with **2c** was studied in a freon mixture ($CDClF_2$/CDF_3, 2:1) at different ratios hydride/alcohol.

The OH signal of monomeric alcohol molecules is observed at δ = 4.1. This alcohol is not susceptible to self-association and chemical shift of its proton drifts insignificantly with concentration and temperature changes. In the presence of hydride **1** a strong low-field shift (up to δ = 8.5 at 140 K), characteristic for the hydrogen bond formation, is observed.

The resonance of the hydride ligand in **1** is shifted to high field from δ = −12.5 to −12.7 at 170 K when 12 equiv.

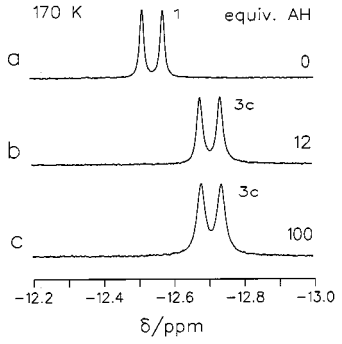

Figure 6. Hydride region of the 500-MHz ^{1}H NMR spectra of CpRu(CO)(PCy_3)H (**1**) at 170 K in $CDClF_2$/CDF_3 (2:1) (a) without proton donor, (b) in the presence of 12 equiv. of **2c**, (c) in the presence of 100 equiv. of **2c**

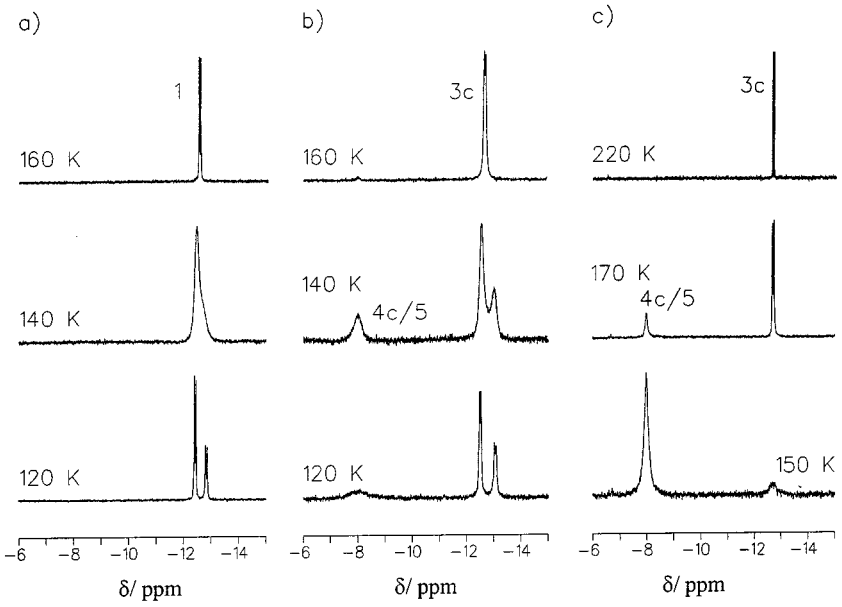

Figure 7. Hydride region of the 500-MHz ^{1}H NMR spectra of CpRu(CO)(PCy_3)H (**1**) at different temperatures in $CDClF_2/CDF_3$ (2:1) (a) without proton donor, (b) in the presence of 12 equiv. of **2c**, (c) in the presence of 100 equiv. of **2c**

of **2c** is added (Figure 6, a, b). Further increase in alcohol concentration (Figure 6, c) does not change the position of this resonance. A slight high-field shift of the hydride ligand signal ($\Delta\delta$ = 0.2 ppm) is normal for RuH···HOR bonding, and has been observed before.[11,14,19,21]

^{1}H NMR spectra of **1** without alcohol at different temperatures show that the position of the hydride signal does not change when the temperature is lowered to 150 K. Below that temperature the signal reversibly splits into two doublets with the intensity ratio 2:1 (Figure 7, a). A similar splitting was observed for Cp*$RuH_3(PCy_3)$ and is suggested to be due to the frozen motion of cyclohexyl rings.[42]

The η^2-H_2 ligand signal at $\delta = -8.0$ appears at 150 K, and increases in intensity down to 140 K in the presence of 12 equiv. of **2c** (Figure 7, b). The broadening of the signal at $\delta = -8.0$ in Figure 7 (b) could be explained by the existence of the equilibrium between forms **4c** and **5**, and fast exchange between them. This suggestion is in accordance with IR-spectroscopic data which showed the formation of ion pair **4c** for this concentration ratio. In the presence of 100 equiv. of **2c** the η^2-H_2 ligand signal of **4/5** appears already at 170 K (Figure 7, c). The increase of medium polarity could lead to partial dissociation of **4c**, and the signal becomes narrower. Full proton transfer is already observed at 150 K. At 110 K the signal of the η^2-H_2 ligand broadens into the baseline. The increase of the temperature leads to restoration of the initial spectrum revealing the reversibility of the process.

Discussion

The analysis of results obtained by low-temperature IR and NMR studies enables us to propose the stepwise mechanism of reaction between hydride **1** and proton donors **2**, resulting in the formation of the dihydrogen complex **5** according to Scheme 1. The first step of the interaction is the formation of a hydrogen bond between proton donors and hydride hydrogen atom (**3**). The determined thermodynamic characteristics of hydrogen-bonded complexes **3** showed that the ruthenium hydride **1** forms H-bonds of medium strength ($-\Delta H$ = 5.3−7.6 kcal mol^{-1}). The $-\Delta H^0$ values increase with ROH proton-donating abilities in the sequence CF_3CH_2OH (**2a**) < $(CF_3)_2CHOH$ (**2b**) < $(CF_3)_3COH$ (**2c**).

The proton-accepting ability E_j of the hydride hydrogen atom in **1** does not depend on the strength of the proton donor or on the media. It equals 1.02±0.02 and is somewhat larger than that in rhenium dihydrides $H_2Re(NO)(CO)(PR_3)_2$ (0.68−0.79).[13] The increased basicity of the hydride atom is responsible for proton transfer not only from strong proton donors such as CF_3COOH (**2d**) and HBF_4 (**2e**), but also from weaker proton donors such as $(CF_3)_2CHOH$ (**2b**) and $(CF_3)_3COH$ (**2c**) when in excess, as well as in the case of {$MeC(CH_2PPh_2)_3$}$Re(CO)_2H$ (E_j = 0.97).[19]

The next step − proton transfer from the H···H complex and generation of the dihydrogen complex − was shown to be an equilibrium process. After proton transfer, the cationic dihydrogen complex forms a contact ion pair **4**, stabilised by hydrogen bonding with the anion. The formation of ion pairs **4**, and the equilibrium between them and free cation **5** was studied using the known very high sensitivity of ν_{CO} vibrations to weak intermolecular interactions. Thus, depending on the ratio **1/2d**, only contact ion pair **4d** (ν_{CO} = 1996 cm^{-1}), only free cation **5** (ν_{CO} = 2020 cm^{-1}), or both forms can exist in solution simultaneously (Fig-

ure 3). The concentration dependence of ν_{CO} of **2d** and ν_{OCO}^{as} of **6d** anion bands confirms this conclusion. The existence of the equilibrium between free cation and ion pair $Cp^*M(CO)_2H^+\cdots{}^-OOCCF_3$ was established before for protonation of $Cp^*M(CO)_2$ (M = Rh, Ir) with CF_3COOH (**2d**),[36−38] and the spectral changes were similar to those observed here. The proton transfer to the metal atom has been shown to cause a large high-frequency shift of the ν_{CO} bands ($\Delta\nu$ = +95 to +143 cm^{-1}). Formation of ion pairs $Cp^*M(CO)_2H^+\cdots{}^-OOCCF_3$ resulted in a low-frequency shift of the ν_{CO} band of the cation in the range −20 to −50 cm^{-1}, depending on the nature of the metal atom. Moreover, the low-frequency shift of this band should also depend on the proton-accepting ability of an anion. Indeed, in the present case, the formation of the ion pair of $[Ru(\eta^2\text{-}H_2)]^+\cdots{}^-OC(CF_3)_3$ (**4c**) causes the larger low-frequency shift of the ν_{CO} band of cation **5** than that caused by the CF_3COO^- anion in **4d**. The position of ν_{CO} bands of **4c** is 1960 cm^{-1} compared to 1996 cm^{-1} for **4d**. That is in agreement with the larger proton-accepting ability of $(CF_3)_3CO^-$ compared to that of CF_3COO^-. It is noteworthy that the experimental observation of ion-paired H-complex $[Ru(\eta^2\text{-}H_2)]^+\cdots OR^-$ formation is in accordance with ion-molecular $[Ru(\eta^2\text{-}H_2)]^+\cdots OH_2$ hydrogen bonding determined in DFT calculations.[43]

Thus, the results obtained allow us to believe that proton transfer takes place within dihydrogen-bonded intermediate **3**, leading to complex **4** with a hydrogen bond between the η^2-H_2 ligand and the anion. A series of transition states of similar hydrogen-bonded structures was proposed recently by Basallote et al.[22] on the basis of inverse kinetic isotope effect data for the protonation of *cis*-$[FeH_2\{P(CH_2CH_2PPh_2)_3\}]$ with strong acids. They were, however, unable to provide experimental information on the structure of the intermediates and to elucidate the rate-determining step of the reaction. Here the sensitivity of the IR-spectral method allows us to observe different intermediates and to support such a stepwise proton transfer mechanism.

The proton transfer step appeared to be a slow process − the formation of **4c** and the settling of the equilibrium take about 30 min. Since the hydrogen bond formation is well known to be diffusion-controlled process, we assume that the *intra*-complex conversion of **3c** into **4c** is the rate-determining step in the proton transfer reaction. First-order rate constants obtained (Table 2) do not depend on the concentration of the reagents [k_{obs} = (1.6±0.2) × 10^{-3} s^{-1}] and support this idea.

Very recently,[41] studying the protonation of $\{MeC(CH_2PPh_2)_3\}Re(CO)_2H$ by $(CF_3)_3COH$ (**2c**) we suggested that the proton transfer barrier ($\Delta G^{\#}$) in this system should be about 12 kcal/mol. In the present work the value of k_{obs} obtained gives us an opportunity to estimate the barrier of proton transfer $\Delta G^{\#}$ (14.3 kcal/mol at 200 K). We can suggest that the low rate and high barrier are determined by steric hindrance of the PCy_3 ligand that embarrasses the proton transfer, as well as the accompanying complex reorganization. In this system even H···H hydrogen bonding has substantial steric hindrance and the large change of entropy (ΔS^0 = −21.6±0.6 e.u.) was determined. Such a value is near the highest values of H-complex formation entropy. The steric effects of the ligand and acid perhaps affect the proton transfer. The electronic factors determining the proton transfer barrier height were considered in the theoretical work.[43] The results of the DFT calculations for model hydride $CpRuH(CO)(PH_3)$ show that in the case of a weak proton donor such as H_2O the barrier for proton transfer from the H···H complex to the η^2-H_2 complex reaches about 40 kcal/mol, and proton transfer does not occur. When the strong proton donor H_3O^+ is used as a model the barrier drops significantly. These data are in good agreement with our results. In the case of moderate proton donors like $(CF_3)_2CHOH$ (**2b**) and $(CF_3)_3COH$ (**2c**), the barrier is high and proton transfer yielding the η^2-H_2 complex is slow. In the case of the strong acid CF_3COOH (**2d**) the barrier height becomes negligible, and protonation proceeds immediately.

Conclusions

By varying the proton donor strength, concentration, and temperature (250−140 K) we were able to find experimental evidence of a stepwise mechanism for the protonation of $CpRuH(CO)(PCy_3)$ (**1**). The spectral and thermodynamic characteristics of hydrogen bonding preceding the proton transfer and the formation of a dihydrogen complex were determined. The formation of ion pairs stabilized by hydrogen bonds between dihydrogen complex and anions [CF_3COO^-, $(CF_3)_3CO^-$] was observed in CH_2Cl_2. Low-rate constants and a high barrier of low-temperature protonation were determined for the first time. The results obtained seem to offer good experimental support for the long since suspected mechanism of protonation leading to the cationic dihydrogen complexes. Of course, further studies are required to determine the influence of solvent polarity and proton donor strength on the kinetic and thermodynamic characteristics of this interaction, and to establish the generality of mechanism suggested in this paper.

Experimental Section

$CpRuH(CO)PCy_3$ (**1**) was prepared as previously described.[25,26] IR measurements were carried out with a "Specord M82" spectrometer using 0.1-cm CaF_2 cells. For the low-temperature measurements a cryostat Carl Zeiss Jena was employed in the temperature range 190−300 K using a stream of liquid nitrogen. The accuracy of temperature adjustment was ±0.5 °C. The cell width was 0.04−0.12 cm. The reagents were mixed at low temperatures to prevent the dihydrogen evolution. The cold solution was then transferred into the cryostat pre-cooled to the required temperature. All samples were prepared under dry argon using standard Schlenk techniques. Anhydrous solvents were freshly distilled and degassed prior to use. The ^1H NMR spectra were recorded with Bruker WP-200, AMX 400, and AMX-500 spectrometers. Standard Bruker software was used for the inversion-recovery T_1 determination. The temperature was calibrated externally by a Pt100 thermo device.

The preparation of deuterated freon mixtures and of the samples using high-vacuum techniques were performed according to known procedures.[44−46]

Acknowledgments

We are extremely grateful to Prof. V. I. Bakhmutov and E. V. Vorontsov for NMR measurement in CD_2Cl_2 and C_7D_8, and for useful discussions. Thanks are expressed to P&M company (Moscow, Russian Federation) for providing the fluorinated alcohols. The authors thank RFBR-INTAS (N 95-136) and Russian Foundation for Basic Research (N 96-03-34114, 99-03-33270) for financial support.

Ligational Properties of Two New Phenolic Aza Cages towards Proton and Alkali Metal Ions − a Theoretical and an Experimental Approach

Paolo Dapporto,[a] Mauro Formica,[b] Vieri Fusi,*[b] Luca Giorgi,[b] Mauro Micheloni,*[b] Roberto Pontellini,[b] Paola Paoli,*[a] and Patrizia Rossi[a]

Keywords: Synthesis / Aza cages / Crystal structures / Thermodynamics / Molecular dynamics

Molecular Dynamics (MD) simulations were performed on several species (anion, zwitterion, and neutral metal complexes) of two phenolic aza cages (**L1** and **L2**) in aqueous solution. The anionic species of the smaller **L1** ligand appears to be able to selectively encapsulate Li^+, while the other alkaline metal ions tested (Na^+ and K^+) are too large to be encapsulated. The larger cage **L2** does not show any selectivity; the anion binds all the alkaline metal ions. The two aza cages **L1** and **L2** were synthesized. Both basicity and alkali metal complex formation were studied in aqueous solution at 25 °C in 0.15 mol dm^{-3} Me_4NCl, using potentiometric, UV/Vis- and NMR-spectroscopic techniques. Both cages behave as triprotic bases in the pH range investigated; $\log K_1$ = 12.15(6), $\log K_2$ = 7.39(5), $\log K_3$ = 1.4(1) for **L1** and $\log K_1$ = 11.76(5), $\log K_2$ = 8.24(5), $\log K_3$ = 2.9(2) for **L2**. The last proton cannot be removed because both compounds are strongly basic under the experimental conditions studied. Proton localization was studied by UV/Vis and NMR spectroscopy, both in water and nonaqueous solutions. The crystal structures of [H**L1**](ClO_4) and [Na**L2**](ClO_4) were determined by X-ray analysis. The crystals of [H**L1**](ClO_4) are triclinic, space group $P(\bar{1})$; cell parameters are a = 10.3628(8), b = 11.938(1), c = 12.201(4) Å, α = 117.53(1), β = 101.25(1), γ = 102.774°. The crystals of [Na**L2**](ClO_4) are monoclinic, space group $P2_1/n$; cell parameters are a = 10.6154(7), b = 17.0418(9), c = 14.9452(9) Å, β = 95.634(6)°.

Introduction

The design of macrocyclic molecules to achieve selective host recognition is a widely used synthetic strategy.[1−6] To complex small, spherical guests such as metal ions, only macropolycyclic hosts are able to provide many binding sites directed towards the guest in a convergent manner, thus making the resulting metal complex thermodynamically stable. A further advantage of cage-like hosts is that solvation inside the cavity is weaker than with hosts where the binding sites are more exposed to the solvent.[7]

Alkali and alkaline earth cations are the simplest guests; they are spherical in shape and utilize only electrostatic forces for binding. In order to achieve selectivity among the alkali metal ions the size of the cavity of the macropolycyclic host should exactly match that of the alkali metal ion.

In our laboratory we have synthesized many small aza cages,[8−22] some of which are able to selectively encapsulate the lithium ion.[11,13,15,17,18] In some cases these molecules behave as "*fast proton sponges*",[8,9,11,12,19] indicating that the smallest cation, the proton, is also selectively encapsulated. In order to gain spectroscopic information about the binding event, chromoionophores such as nitro and/or phenolic groups have been inserted into the molecular frameworks.[23−26] One of the latest small aza cages studied in our laboratories thus far is compound **L** (see Scheme 1).[27] The ligand is able to selectively encapsulate the lithium ion, a $\log K > 3$ is expected for the complexation process $Li^+ + [H_{-1}L]^- = [LiH_{-1}L]$.[27] At 300 K the molecule, both in the $[H_2L]^{2+}$ [27] and the $[H_{-1}L]^-$ species, appeared rather rigid in the MD simulations performed in aqueous solution [the solvent was mimicked by using a distance-dependent dielectric constant $\varepsilon(r) = 80r$, unpublished results]. In particular, the phenolic moiety does not change its orientation with respect to the [12]aneN_4 ring. It is almost parallel to the *trans*-dimethylated tetraazamacrocycle with the oxygen atom pointing "outside" the macrobicyclic cavity. We designed the trial molecules **L1** and **L2** (see Scheme 1) starting from this molecule, with the aim to obtain a more flexible macrobicyclic skeleton which can better accommodate the donors around the metal guest. The promising theoretical results obtained encouraged us to synthesize these two new molecules. Their ligational properties towards proton (i.e. their basicity) and alkali metal ions were investigated both in solution (by potentiometric titrations, UV/Vis and NMR spectra) and in the solid state (by

X-ray diffraction), and then compared with the modeled behavior.

Results and Discussion

Molecular Dynamics Simulations

(i) *Anion Species*

During the MD simulation of $[H_{-1}\mathbf{L1}]^-$, the dominant conformation was found to be characterized by a phenolate group which is nearly parallel to the mean plane described by the four nitrogen atoms. In this case, the oxygen atom of the bridging unit is always directed towards the methyl moiety disposed above the *trans*-dimethylated cyclen ring. As a consequence, during the MD run at least one $-CH_3\cdots O$ intramolecular interaction (< 2.7 Å) takes place. The two *trans*-disposed methyl groups point in opposite directions with respect to the [12]aneN$_4$ mean plane, with the exception of just a few conformations. Figure 1 (a) reports the average structure from snapshots of the coordinates for $[H_{-1}\mathbf{L1}]^-$. However, during the simulation time a few conformations were observed to have the phenolate moiety almost perpendicular to the [12]aneN$_4$ ring. As expected, the propyl chains allow the phenolate ring greater conformational freedom relative to the ligand **L**. In this regard the $[H_{-1}\mathbf{L2}]^-$ anion is more rigid, with the benzene ring always in the same orientation with respect to the 15-membered ring. Thus, the lengthening of the polyaza ring does not provide greater conformational freedom of the bridging moiety. As in **L** and **L1**, the phenolate ring of **L2** is almost parallel to the N_5 mean plane and the oxygen atom is oriented towards the longer chain bearing the two methyl groups of the [15]aneN$_5$ base. The latter groups are always pointing in the opposite direction to the [15]aneN$_5$ ring, while the third methyl group is always positioned below the mean plane. Figure 1 shows the average conformation resulting from MD. Furthermore, the collected conformations show at least one intramolecular interaction between the phenolic oxygen atom and a hydrogen atom of a methyl group.

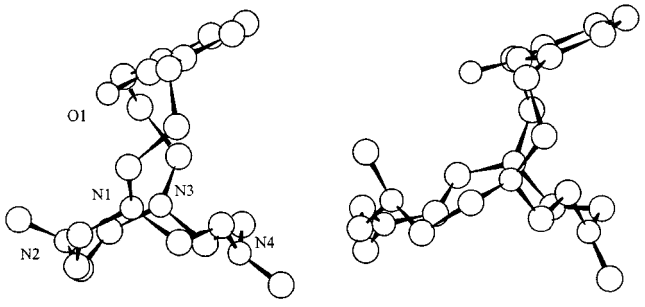

Figure 1. Average conformation from snapshots of coordinates for (a) $[H_{-1}\mathbf{L1}]^-$, (b) $[H_{-1}\mathbf{L2}]^-$

In order to evaluate the approximate size of the three-dimensional cavity inside the two macrocyclic ligands that is able to accommodate the cation, the distances between the geometric center defined by the donors and each donor atom itself were calculated throughout the simulations. Table 1 lists these average distances for the $[H_{-1}\mathbf{L1}]^-$ and $[H_{-1}\mathbf{L2}]^-$ species, as well as an estimate of the metal–donor bond lengths obtained from crystal structures of metal ($M = Li^+$, Na^+, and K^+) complexes having nitrogen and/or oxygen atoms as donors, which have been deposited at the CCDC.[28] With regard to the $[H_{-1}\mathbf{L1}]^-$ ligand, comparison between the distance values reported in Table 1 seems to indicate that the molecular cavity is too small to encapsulate the sodium and potassium ions, whereas it is well suited to the size of the Li^+ ion. On the contrary, the donors of the larger $[H_{-1}\mathbf{L2}]^-$ host appear to be suitable to bind the sodium and potassium cations, while the lighter lithium is probably too small.

Table 1. Mean X (center of donors)–donor atoms distances [Å] obtained from MD simulations and mean metal–donor bond lengths [Å] obtained from the crystal structures of the metal ($M = Li^+$, Na^+, and K^+) complexes having nitrogen and/or oxygen atoms as donors deposited at the CCDC

	X–N5 3.05			

(ii) *Neutral Species*

Both cages in their neutral form still contain one proton and are zwitterions. The acidic hydrogen atom (H1) was bound to a bridgehead nitrogen atom, as found in previous work involving similar monoprotonated cages.[29] Once again, during the MD runs the phenolate ring is almost coplanar to the N_4 and N_5 mean planes of **L1** and **L2**, respectively. However, in **L1** the propyl chains connecting the phenolate group to the [12]aneN$_4$ are more stretched out than in the anionic form. As a result, the phenolic oxygen atom is further from the mean N_4 plane in **L1** than in $[H_{-1}\mathbf{L1}]^-$ (see Figure 2, a), and the stabilization of the zwitterion can be entirely ascribed to the nitrogen atoms (vide infra). Conversely, the introduction of an acidic proton within the molecular framework of $[H_{-1}\mathbf{L2}]^-$ does not significantly affect the overall shape of the molecule, the only noteworthy difference is that the two adjacent methylated nitrogen atoms are always pointing above the N_5 mean plane (see Figure 2, b).

In order to gain some information concerning the relative basicity of both compounds in the reaction $[H_{-1}L]^- + H^+ \rightarrow L$, the inter-atomic distances of the H···donor atoms were collected during the simulations. In both zwitterions, the acidic proton appears to be involved in essentially two H-bonding interactions (see Table 2). In **L1** the acidic hydrogen atom interacts more closely with the two methylated nitrogen atoms. The interaction with the phenolic oxygen atom is weaker as it is more distant. Most conformations of the larger compound **L2**, show an N–H···O hydrogen

	H−N5 2.66

bond and an interaction involving the closer methylated nitrogen atom N5 belonging to the longer arm of the [15]aneN$_5$ ring. In both forms the mean H···acceptor distances are very similar; as a result, we can infer that the basicity properties of the two polyaminic bases should be similar.

(iii)−(iv) *Metal Complexes*

The results from the simulations performed in the two media studied are practically identical. Table 3 reports the average distances of the M−donors extracted from the MD simulations. In both cases [H$_{-1}$**L1**]$^-$ appears to be able to bind only the smallest alkaline cation. The sodium ion comes out from the molecular cavity, remaining close to the phenolic oxygen atom throughout the entire simulation time (mean Na−O distance 2.22 Å). The largest ion, potassium, moves away from the macrocycle very quickly, thus confirming the results of the preliminary studies concerning the cavity size of the ligands in the anionic form. The mean Li−N distances monitored during the MD run ranged from 2.09 to 2.34 Å. The phenolic oxygen atom interacts strongly with the lithium cation. The mean Li−O distance is 1.75 Å, with the Li−O bond pointing inside the molecular cavity. As a result of this interaction, the phenyl ring is almost perpendicular to the N$_4$ ring and the overall shape of the metal complex is different from that observed for the anion and the zwitterion (see Figure 3, a). The coordination geometry around the metal guest is trigonal-bipyramidal, with the bridgehead nitrogen atoms occupying the axial positions, as already found in the solid-state X-ray structures of analogous tbp macrobicycle−Li$^+$ complexes (SEKSAC[15a] and SONJAC[17] refcode). In the latter complexes, all the donor atoms were nitrogen atoms and the Li−N distances were shorter (mean 2.04 Å) than in [LiH$_{-1}$**L1**]. Furthermore, in the lithium complex with 4,7,13-trioxa-1,10-diazabicyclo[8.5.5]icosane (FENHIP[30]), whose chain lengths are comparable with those of **L2**, the coordination distances are very similar to those observed during the MD simulation of [LiH$_{-1}$**L2**] (vide infra).

Table 3. Mean M−donor atoms distances [Å] obtained from MD simulations

H$_{-1}$**L1**	LiH$_{-1}$**L2**
Li−O1 1.75	Li−O1 1.81
Li−N1 2.34	Li−N1 2.79
Li−N2 2.09	Li−N2 2.29
Li−N3 2.21	Li−N3 2.44
Li−N4 2.13	Li−N4 2.17
	Li−N5 2.90
NaH$_{-1}$L2	**KH$_{-1}$L2**
Na−O1 2.15	K−O1 2.51
Na−N1 2.66	K−N1 2.76
Na−N2 2.47	K−N2 2.72
Na−N3 2.59	K−N3 2.72
Na−N4 2.63	K−N4 2.71
Na−N5 2.44	K−N5 2.63

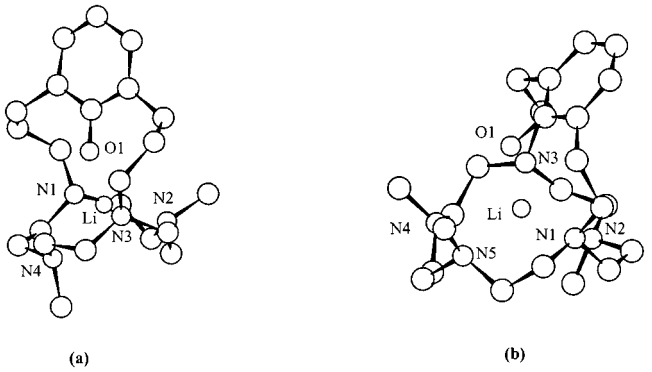

Figure 3. Average conformation from snapshots of coordinates for (a) [Li**L1**], (b) [Li**L2**]

The [H$_{-1}$**L2**] species behaved in a similar manner towards the lithium, sodium, and potassium cations. During the MD runs the cation was encapsulated within the ligand cavity in all cases. These results seem to indicate that the larger ligand is not a selective binder of the lithium ion. In the [LiH$_{-1}$**L2**] complex the mean Li−N distances range from 2.2 to 2.9 Å, with a mean Li−O bond length of 1.8 Å (see Table 3). Essentially, the molecular cavity appears to be too large to accommodate the smallest alkaline cation, while the monitored M−donor distances for the sodium and potassium complexes are in agreement with the corresponding experimental values retrieved from the CCDC. In terms of bond lengths, the coordination of the lithium ion appears to be of the 4+2 type which is in agreement with the trend observed in the solid-state structures of hexacoordinated Li$^+$−macrobicyclic complexes with nitrogen and/or oxygen donor atoms, retrieved from the CCDC.

The phenyl ring gradually changes its orientation with respect to the N_5 mean plane, in the lithium complex it is almost perpendicular, while in the potassium one it is almost coplanar (see Figure 3, b, and Figure 4).

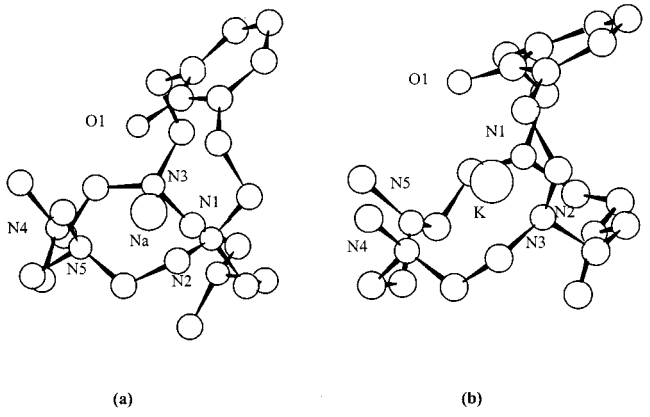

Figure 4. Average conformation from snapshots of coordinates for (a) [Na**L2**], (b) [K**L2**]

Synthesis

The cages **L1** and **L2** were prepared according to the synthetic procedures depicted in Figure 5. The two cages were obtained by following the synthetic procedure reported for the analogous phenolic aza cage **L**.[25] This procedure involves the use of a dimesyl derivative of 2,6-dimethylanisole, and of an aza crown base as the reactants to increase the 1 + 1 product in the final cyclization. In order to obtain **L2**, the new aza crown base **7** was synthesized (see Figure 6). The synthesis of **7**, according to the Richman–Atkins method, requires the use of the ditosylated polyamine **3**, obtained by the extension of *N*,*N*′-dimethylethylendiamine (**1**) with 2 equiv. of *N*-(*p*-tolylsulfonyl)aziridine (**2**). The reaction of the disodium salt of **3** with bis(2-chloroethyl)methylamine (**5**) in DMF leads to the ditosylated macrocycle **6**, which was detosylated with strong acid giving **7**. By treating the aza base **7** with methyl 2-[2-methoxy-3-(2-methylsulfonyloxyethyl)phenyl]ethanesulfonate (**16**) in acetonitrile in the presence of an alkaline carbonate base, we obtained the phenol-protected cage **18** (see Figure 5). To synthesize the cage **L1**, a longer dimesyl derivative **15** of 2,6-dimethylanisole was prepared (see Figure 7). In order to obtain reagent **10**, which is the starting material used to prepare **15**, we followed a different synthetic scheme than that reported previously,[31] thus achieving a higher reaction yield. Compound **15** was obtained from **10** using a classic elongation method of an alkyl chain. The cyclization of **15** with the macrocyclic aza base **17**, gives the phenol-protected cage **19**. For both ligands **18** and **19**, no template effect was found in the cyclization step; moreover, they were deprotected in the same way, with sodium ethanethiolate in DMF. This afforded the phenolic aza cages **L1** and **L2**, after the purification steps.

Protonation and Complex Formation Equilibria

Table 4 reports the protonation constants of **L1** and **L2**. The ligands have a total of five and six protonation sites respectively, and all of the nitrogen atoms are tertiary. Both cages accept three protons under the experimental conditions employed. It should be noted that both cages in their neutral species still contain one proton. This proton cannot be removed in the pH range investigated because the fully deprotonated species $[H_{-1}\mathbf{L1}]^-$ and $[H_{-1}\mathbf{L2}]^-$ are strongly

basic. As expected, the molecular topology strongly influences the basicity behavior of **L1** and **L2**; both compounds are much stronger bases than both the phenolate and the polyaminic tertiary nitrogen atom.[32]

Table 4. Protonation constants of **L1** and **L2** (log *K*) determined by potentiometry in 0.15 mol dm^{-3} Me_4NCl aqueous solution at 298±0.1 K

Reaction	**L1**	**L2**
$L + H^+ = HL^+$	12.15(6)[a]	11.76(5)
$HL^+ + H^+ = H_2L^{2+}$	7.39(5)	8.24(5)
$H_2L^{2+} + H^+ = H_3L^{3+}$	1.4(1)	2.9(2)

[a] Values in parentheses are the standard deviation to the last significant figure.

In order to understand how the phenolic moiety is involved in the protonation steps, absorption electronic spectra and NMR experiments were performed on the compounds **L1** and **L2** in water and in nonaqueous solvents. For both ligands, the absorption and NMR spectra show the involvement of the phenolic group in the protonation steps. For example, the UV spectra of **L1** recorded in aqueous solution, are different in acidic and basic solution. The spectrum shows a band with λ_{max} = 272 nm ($\varepsilon_{\lambda max}$ = 950 M^{-1} cm^{-1}) in the acidic region, while at a pH value slightly over 12, where the neutral species is prevalent in solution, two bands appear in the spectra at λ_{max} = 239 ($\varepsilon_{\lambda max}$ = 5900 M^{-1} cm^{-1}) and 295 nm ($\varepsilon_{\lambda max}$ = 2600 M^{-1} cm^{-1}). This latter spectrum is also maintained at more alkaline pH values. The different behavior of the chromophore in the acidic and basic solution is due to the presence of the phenol hydroxy form at low pH values and to the phenolate form at high pH values. This spectral feature suggests that in the neutral species the ligand is in the zwitterionic form in aqueous solution, with the acidic proton located on the aza base. ^1H NMR spectra of **L1** recorded in aqueous solution, confirmed this hypothesis. The spectrum at pH = 2 in fact shows broad resonances in the aliphatic field, while the aromatic protons give rise to a doublet at δ = 7.15 integrating for two protons (the aromatic protons in *meta* position), and a triplet at δ = 7.00 integrating for one proton (the aromatic proton in *para* position). These resonances undergo an upfield shift in the spectrum recorded at pH = 12, resonating at δ = 6.86 and 6.38 for the doublet and the triplet, respectively. This indicates the deprotonation of the phenolic group at alkaline pH values. Compound **L2** shows a similar behavior with very small differences in wavelengths and in chemical shifts.

The behavior of **L1** and **L2** is different in methanol. The absorption spectra for the phenolic group do not change significantly in acidic or strong alkaline solution, the maximum wavelength and molar absorptivity remain the same [one band with λ_{max} = 276 nm (ε = 1400 M^{-1} cm^{-1})]. In other words, the phenolic group appears in its hydroxy form even in the neutral species. This behavior was also found for **L**, as already reported,[27] and can be explained by the different solvating power of the two media; the charge−charge separation in water is successful, however, in methanol it is not. Nevertheless, it was possible to record the spectrum of the $[H\mathbf{L1}]^+$ species in methanol which shows a different absorption spectrum from the previous ones. Two bands appear at λ_{max} = 236 nm ($\varepsilon_{\lambda max}$ = 4300 M^{-1} cm^{-1}) and λ_{max} = 292 nm ($\varepsilon_{\lambda max}$ = 700 M^{-1} cm^{-1}). The spectrum is similar to that recorded in aqueous solution at an alkaline pH value, highlighting the presence of the phenolate form in the $[H\mathbf{L1}]^+$ species in methanol.

^1H and ^{13}C NMR spectra were recorded to better analyze the $[H\mathbf{L1}]^+$ species in solution. The ^1H NMR spectrum of the $[H\mathbf{L1}]^+$ species, carried out in $CDCl_3$, is shown in Figure 8a. It shows a broad deshielded resonance at δ = 9.97 integrating for two protons which can be assigned to the acidic protons of the ligand. After the addition of a small amount of H_2O or CH_3OH to the chloroform solution, the signal remains. This indicates a slow exchange, on the NMR time scale, of the two protons with the mobile protons of the solvent. However, when D_2O or CD_3OD was added the resonance disappeared. These experimental data suggest that the two protons are positioned inside the macrocyclic cavity and are stabilized by a strong hydrogen-bonding network involving the donor functions. This is in agreement with the X-ray structure (vide infra). The ^1H NMR spectrum of the same species recorded in CD_3OD (Figure 8, b) reveals the disappearance of the deshielded resonance, while the pattern of the other resonances remain quite similar. The addition of Me_4NOH to the species $[H\mathbf{L1}]^+$ in CD_3OD solution (Figure 8, c) leads to a downfield shift of the triplet

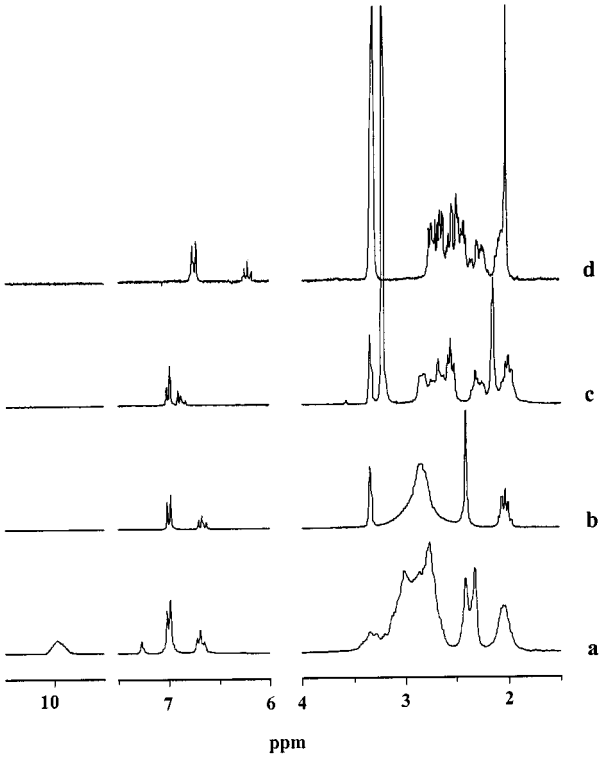

Figure 8. (a) The ^1H NMR spectrum of $[H\mathbf{L1}]^+$ in $CDCl_3$, (b) ^1H NMR spectrum of $[H\mathbf{L1}]^+$ in CD_3OD, (c) ^1H NMR spectrum after the addition of Me_4NOH, (d) ^1H NMR spectrum of $[LiH_{-1}\mathbf{L1}]$ in CD_3OD

due to the aromatic proton in the *para* position, together with an upfield shift of almost all the aliphatic resonances, thus indicating the loss of positive charge density on the amine groups and the protonation of the phenolate oxygen atom. This is in agreement with the UV spectra. In conclusion we can say that in the $[H\mathbf{L1}]^+$ species, the nature of the acidic proton, in water and in organic solvents, seems to be the same as that found in the solid state. In organic solvents the removal of one proton results in the redistribution of the last acidic proton, it is located on the oxygen atom. However, in aqueous solution the last acidic proton remains on the aza base. The ^{13}C NMR spectra recorded in the same solvents, also support this hypothesis. Moreover, **L2** and the smallest compound **L** display similar behavior.[27]

Alkali Metal Ions Complexation

The coordination of the alkali metal ions by ligands **L1** and **L2** was also investigated by ^1H, ^{13}C, and ^7Li NMR spectroscopy and by UV/Vis absorption electronic spectra in water and in organic solvents. Potentiometry was also employed to investigate the formation equilibria of alkali metal complexes (see Table 5). The equilibrium constants reported in Table 5 refer to an overall process in which the alkali metal ion M^+ is bound and, at the same time, the last proton present in the cages is removed, yielding a neutral species $MH_{-1}L$ [$M^+ + L = MH_{-1}L + H^+$]. The stability constants relative to the net complexation process $M^+ + H_{-1}L^- = MH_{-1}L$ can only be estimated since the first protonation constant for both cages **L1** and **L2** is too high to be measured under the chosen experimental conditions. The log*K* value for the first protonation step $H^+ + H_{-1}L = L$ should be greater than 12.15 and 11.76 for **L1** and **L2**, respectively. Also, log*K* > 4 and log*K* > 3 are expected for the net complexation process ($Li^+ + H_{-1}L^- =$ LiL) for **L1** and **L2**, respectively, since the values for the complexation of Li^+ (8.03 and 8.91, see Table 5) should be subtracted. For cage **L2** all three metal ions can be complexed, potentiometric studies show that the estimated stability constants are very similar (see Table 5). For ligand **L1**, the spectroscopic experiments do not reveal any complex formation with sodium and potassium ions in water or in the alcohol solution. **L1** does form a complex with the smallest ion Li^+ and the complex was also isolated in the solid state. As is often the case with aza cage lithium complexes,[11,13,15,17,18] the solid complex is soluble in organic solvents such as $CDCl_3$. The ^7Li NMR spectrum shows a sharp peak which is shifted downfield (0.53 ppm) with respect to that of the free Li^+ ion. The spectra of $[LiH_{-1}\mathbf{L1}]$ show the same signal with an approximately equal chemical shift both in water and in methanol. When an excess amount of Li^+ is added to the solution of the complex, the ^7Li NMR spectrum shows the appearance of a new sharp peak at $\delta = 0$ due to the free lithium ion, together with that of the complexed lithium ion. The simultaneous presence of two peaks in the spectrum denotes a slow exchange (on the NMR time scale) of the complexed lithium ion with the free lithium. The independence of the ^7Li chemical shift from the solvent, and the slow exchange on the NMR time scale between the free and bound lithium ion suggest that it is encapsulated inside the macrocyclic cavity and hence is quite isolated from the medium. The ^1H NMR spectrum of the $[LiH_{-1}\mathbf{L1}]$ in CD_3OD (see Figure 8 spectrum d) shows a marked upfield shift of the triplet signal due to the aromatic proton in the *para* position relative to that of the neutral species (see Figure 8 spectrum c). This suggests the deprotonation of the phenol group with lithium complexation. The ^1H NMR spectrum of the lithium complex recorded in aqueous solution shows broader signals with approximately the same chemical shifts in the resonances. The UV spectra recorded in water and in methanol of the lithium complex show the two characteristic bands of the phenolate form with an increased molar absorptivity in water with respect to the free ligand at the same pH values [λ_{max} = 241 nm ($\varepsilon_{\lambda max}$ = 8250 M^{-1} cm^{-1}), λ_{max} = 296 nm ($\varepsilon_{\lambda max}$ = 4200 M^{-1} cm^{-1})].

Table 5. Logarithms of the equilibrium constants determined in 0.15 mol dm^{-3} Me_4NCl at 298.1 K for the complexation reactions of **L1** and **L2** with Li^+, Na^+, and K^+ ions

	Li^+	Na^+	K^+
$M^+ + \mathbf{L1} = MH_{-1}\mathbf{L1} + H^+$	−8.03	–	–
$M^+ + \mathbf{L2} = MH_{-1}\mathbf{L2} + H^+$	−8.91	−8.33	−8.65

A different behavior is shown by the larger compound **L2**. No selectivity was found in aqueous solution by the spectroscopic techniques which is in agreement with the MD simulations. However, some interesting aspects were revealed. The ^7Li NMR spectra recorded in aqueous solution and in methanol show only one signal that rapidly interchanges with the free lithium ion, thus denoting the easy access of the solvent to the ion sphere, together with the poor fit of the ion in the macrocyclic cavity as previously inferred from MD simulation results. In both media, the ^1H NMR spectra of the $[MH_{-1}\mathbf{L2}]$ metal complexes reveal the lack of selectivity of the ligand; for example, the spectrum of each complex can also be obtained by adding a small excess of the metal ion to a solution of another complex. However, some interesting results were found in the case of the sodium complexes. Solution studies performed in methanol in fact reveal that the $[Na\mathbf{L2}]^+$ species, which is probably in a conformation similar to that found in the crystal structure, rapidly evolves into another species upon addition of a small amount of a base. This is well depicted by monitoring the aromatic region of the ^1H NMR spectra of $[Na\mathbf{L2}]^+$ and the UV/Vis absorption electronic spectra of these species (Figure 9). The new species corresponds to that of the $[NaH_{-1}\mathbf{L2}]$ sodium complex which is isolated in the solid state as reported in the Exp. Sect. As depicted in the aromatic part of the ^1H NMR spectrum of the $[NaH_{-1}\mathbf{L2}]$ species, there are two stable conformers on the NMR time scale that give rise to a high number of signals in the ^{13}C NMR spectra as well (see Exp. Sect.). However, in both conformers, the upfield shift of the proton located

in the *para* position, as compared with that in the $[NaL2]^+$ spectrum, suggests the deprotonation of the phenolic group of **L2** due to metal complexation. This hypothesis was confirmed by the comparison of the UV spectra of the $[NaL2]^+$ and $[NaH_{-1}L2]$ complexes, each of which has the spectral characteristics of one of the two forms of the phenol, thus suggesting a conformation of $[NaL2]^+$ in solution which is similar to that found in the solid state and leading to the deprotonation of the ligand in more basic solutions.

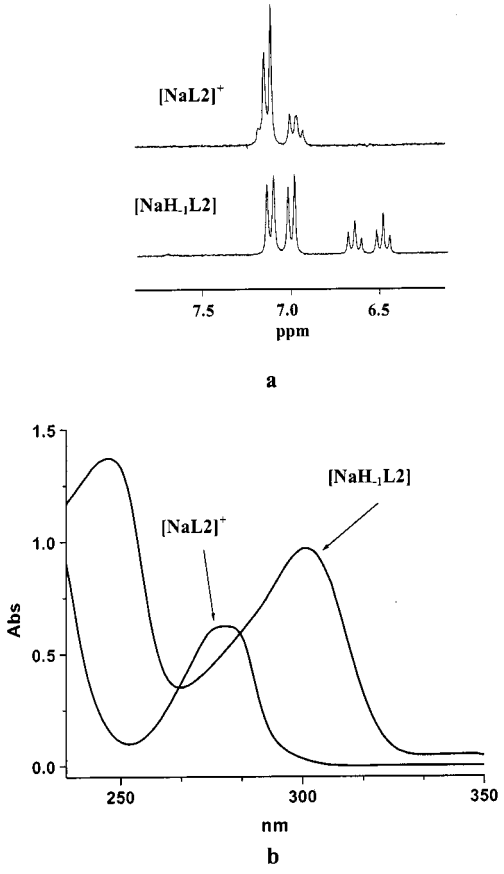

Figure 9. (a) The ^1H NMR spectra of the Na^+/**L2** system, (b) UV/Vis absorption electronic spectra of $[NaL2]^+$ and $[NaH_{-1}L2]$

X-ray Structures

$[HL1]^+(ClO_4)^-$

The crystal structure consists of $[HL1]^+$ cations and $(ClO_4)^-$ anions. Figure 10 shows an ORTEP[33] view of the $[HL1]^+$ cation with the atom labelling. Crystal and structure refinement data are reported in Table 6. With regard to the protonation sites, the two acidic hydrogen atoms are bound to the bridgehead nitrogen atoms N1 and N3 and form short hydrogen bonds with the oxygen atom O1 [H1N···O1 1.70(7), H3N···O1 1.79(6) Å]. The interactions between these hydrogen atoms and the other two donor atoms (N2 and N4) are significantly weaker than those involving the oxygen atom with distances 2.56(7) and 2.90(7) Å for [H3N···N2] and [H1N···N2], respectively, and 2.67(5) and 2.79(5) Å for [H1N···N4] and [H3N···N4], respectively. The atoms N1 and N3 are pointing toward the phenolic group. The nitrogen atoms N2 and N4 are on the opposite side of the N_4 mean plane, with their bonded methyl groups equatorial and axial with respect to the N_4 mean plane, respectively. In the crystal there are no strong intermolecular interactions. The conformation assumed by the [12]aneN$_4$ ring is of the [2424] C-corners type.[34] This is not a very common conformation for this class of compounds; in fact, the analysis of the solid-state structures collected in the Cambridge Structural Database v.5.19 revealed that the most common conformation assumed by [12]aneN$_4$ diprotonated rings is [3333].

$[NaL2]^+(ClO_4)^-$

The structure consists of $[NaL2]^+$ cations and of $(ClO_4)^-$ anions. Figure 11 shows a perspective view of the complex cation. In Table 6 crystal and structure refinement data are reported. Selected bond lengths and angles are given in Table 7. The sodium ion is bound to the five nitrogen atoms of the ligand and to the oxygen atom of the phenol group. The coordination geometry around the sodium ion can be described as a strongly distorted pyramid having a pentagonal base, with the apex occupied by the oxygen atom. The five nitrogen atoms at the corners of the pentagonal base are not in a plane as seen by the deviations from the mean plane passing through them [minimum deviation 0.045(3) Å (N5), maximum deviation 0.750(3) Å (N3), mean deviation 0.507(3) Å]. The Na−N distances range from 2.455(3) to 2.731(3) Å. It is worthy to note that the two bridgehead nitrogen atoms are significantly further (see Table 7), perhaps because of the conformational requirements of the ethylenic chains connecting the phenol ring to the 15-membered macrocycle. The complex cation possesses a pseudo-symmetry plane crossing the phenol moiety and the bond between the C17 and C18 atoms. In this plane lie the Na, N2, and O1 atoms. An examination of the dihedral angles of the macrobicycle shows that the greatest deviation from this pseudo-symmetry is due to the N4−C17−C18−N5 fragment; the dihedral angle around N4−C17 is −175°, versus a value of 96° for the angle about the N5−C18 bond. The phenol ring forms an angle of 18.4(1)° with the N_5 mean plane. Both the methyl groups bound to N4 and N5 are pointing towards the same side of the N_5 ring, with the other methyl group (bound to N2) pointing in the opposite direction. This is in agreement with the results of MD simulations performed on the zwitterionic species. No interesting intramolecular interactions were observed, while a short intermolecular interaction between the hydrogen atom of the phenol group and an oxygen atom of the perchlorate anion was observed [O1−H10····O2 = 2.09(4) Å].

Experimental Section

General Remarks: ^1H, ^{13}C, and ^7Li NMR spectra were recorded with a Bruker AC-200 instrument, operating at 200.13, 50.33, and 77.78 MHz, respectively. In the ^1H NMR experiments peak positions are reported in relation to HOD ($\delta = 4.75$) and dioxane was used as the reference in the ^{13}C NMR spectra ($\delta = 67.4$). ^7Li peaks are reported in relation to free $LiClO_4$. ^1H-^1H and ^1H-^{13}C correlation experiments were performed to assign the signals. Solvents and starting products were used as purchased.

Molecular Dynamics (MD) Simulation Protocol: The studied species were the anions $[H_{-1}L1]^-$ and $[H_{-1}L2]^-$, the neutral ligands **L1** and **L2** (zwitterionic forms) and the neutral metal complexes $M[H_{-1}L1]$ and $M[H_{-1}L2]$ ($M = Li^+$, Na^+, and K^+). The MSI software programs InsightII and Discover version 98.0[35] were used for all the molecular modeling studies. Based on the good results of a previous computational study performed on monoprotonated macrocyclic compounds[29] of the same family, the Amber[36] force field was used (all the 1−4 nonbonding interactions were scaled by a factor of 0.5). Atomic charge distributions were calculated according to the ChelpG scheme at the single point 6−31G* level of theory using Guassian94 (revision D3).[37] As initial geometries for each species in vacuo, fully optimized model-built structures were used. In addition, before starting with the MD procedures the initial molecular assembly was further optimized until the convergence criterion was met (< 0.01 kcal mol^{-1}). The MD simulation temperature was set at 298 K and the Verlet leapfrog algorithm, with a time step of 1 fs, was used for integration of equations of motion in all simulations. In energy calculations 9.5 and 12.5 Å nonbonded cutoff distances (buffer width 0.5 Å) were employed for van der Waals and Coulomb terms, respectively. In a preliminary

MD study (**i**) on the $[H_{-1}\mathbf{L1}]^-$ and $[H_{-1}\mathbf{L2}]^-$ species, performed to evaluate the molecular cavity, the system was allowed to equilibrate for 8 ps, then MD simulations were run for 80 ps with snapshot conformations saved every ps, and a distance-dependent dielectric constant [$\varepsilon(r) = 80r$] was used. The dynamic behavior of the zwitterionic ligand forms, **L1** and **L2**, (**ii**) was investigated by placing the studied species in a cubic cell (25 Å edge) containing SPC model water molecules (equilibration time 8 ps, data collection time 80 ps, snapshot conformations saved every ps). The geometry of the water molecules was fixed by means of the rattle option. Periodic boundary conditions were applied. In addition, calculations on $M[H_{-1}\mathbf{L1}]$ and $M[H_{-1}\mathbf{L2}]$ were performed both by mimicking the solvent with a distance-dependent dielectric constant $\varepsilon(r) = 80r$ [equilibration time 20 ps, data collection time 200 ps, (**iii**)] and by surrounding the solute species with water molecules occupying the volume of a cube (25 Å edge) as previously reported (**iv**).

Spectrophotometric Measurements: Absorption spectra were recorded at 298 K with a Varian Cary-100 spectrophotometer, equipped with a temperature control unit.

Potentiometric Measurements: All potentiometric measurements were carried out in 0.15 mol dm^{-3} Me_4NCl at 298.0±0.1 K, in the pH range 2.4−10.5, using the fully automatic equipment that has already been described.[38] The emf data were acquired with the PASAT computer program.[38] The electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free Me_4NOH solutions and determining the equivalent point by Gran's method,[39] which gives the standard potential E° and the ionic product of water K_w. At least two to three measurements were performed for each ligand. The HYPERQUAD[40] computer programs were used to process the potentiometric data and calculate the protonation constants.

Ligand Synthesis: The precursor reagents **7** and **15** were synthesized as depicted in Figure 6 and Figure 7, respectively. Ligands **L1** and **L2** were obtained according to the synthetic procedure reported in Figure 5. *N*-(*p*-Tolylsulfonyl)aziridine (**2**),[41] bis(2-chloroethyl)methylamine (**5**),[42] 2,6-bis(bromomethyl)anisole (**8**),[43] and **16**[43] were prepared as previously described. The solvents and the starting materials not mentioned were used as purchased. All reactions were carried out under nitrogen.

4,7-Dimethyl-1,10-bis(*p*-tolylsulfonyl)-1,4,7,10-tetraazadecane (3): A solution of *N*-(*p*-tolylsulfonyl)aziridine (6.7 g, 0.034 mol) in anhydrous benzene (200 mL) was added dropwise at room temperature to a stirred solution of *N*,*N*′-dimethyl-1,2-ethylendiamine (3.0 g, 0.034 mol) in anhydrous benzene (400 mL) over a period of 7 h. The resulting solution was kept at room temperature for ca. 12 h and then a further 6.7 g (0.0034 mol) of **2** in 200 mL of benzene was added under the same experimental conditions. After 12 h, the turbid solution was filtered and concentrated under reduced pressure to give the crude compound **3** as a yellowish solid. The product was dissolved in 150 mL of ethanol and an excess of 37% HCl was added to the solution, obtaining **3** as the dihydrochloride salt. Yield: 14.7 g (78%). − $C_{22}H_{36}Cl_2N_4O_4S_2$ (555.6): calcd. C 47.56, H 6.53, N 10.08; found C 47.6, H 6.6, N 10.0. − ^{1}H NMR (D_2O, 25 °C): δ = 2.34 (s, 6 H), 2.94 (s, 6 H), 3.23 (t, 4 H), 3.36 (t, 4 H), 3.67 (s, 4 H), 7.38 (d, 4 H), 7.69 (d, 4 H). − ^{13}C NMR (D_2O, 25 °C): δ = 21.9, 38.7, 42.3, 50.6, 57.1, 128.1, 131.5, 135.1, 146.9.

1,7,10-Trimethyl-4,13-bis(*p*-tolylsulfonyl)-1,4,7,10,13-pentaazacyclopentadecane (6): A solution of sodium (0.96 g, 0.042 mol) in dry ethanol (50 mL) was added to a hot solution of **3**·2HCl (5.6 g, 0.01 mol) in dry ethanol (100 mL). The resulting suspension was refluxed for 30 min, after which time the solvent was removed under reduced pressure. The solid residue was dissolved in dry DMF (50 mL) and to the resulting solution, heated at 110 °C, a solution of bis(2-chloroethyl)methylamine (**5**) (1.6 g, 0.01 mol), dissolved in 100 mL of dry DMF, was added. The reaction mixture was stirred over a period of 4 h. It was kept at 110 °C for a further 2 h. The suspension was then cooled, filtered, and concentrated under reduced pressure to give a yellowish solid, which was chromatographed on neutral alumina using $CHCl_3$ as the eluent. The eluted fractions containing the product having $R_f = 0.77$ were collected and concentrated to dryness, affording **6** as a white solid. Yield: 3.1 g (55%). − $C_{27}H_{43}N_5O_4S_2$ (565.8): calcd. C 57.32, H 7.66, N 12.38; found C 57.5, H 7.7, N 12.5. − MS (FAB): 567 [M + H^+]. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 2.14 (s, 6 H), 2.37 (s, 3 H), 2.42 (s, 6 H), 2.54 (t, 4 H), 2.67 (t, 4 H), 2.96 (s, 4 H), 3.28 (m, 8 H) 7.28 (d, 4 H), 7.68 (d, 4 H). − ^{13}C NMR ($CDCl_3$, 25 °C): δ = 21.5, 42.5, 43.7, 46.9, 47.4, 55.6, 56.4, 58.4 127.1, 129.7, 136.7, 143.2.

1,7,10-Trimethyl-1,4,7,10,13-pentaazacyclopentadecane (7): A solution of **6** (3.0 g, 0.005 mol) was dissolved in 8 mL of 96% H_2SO_4 and the resulting solution kept at 100 °C for 72 h. The solution was cooled and added to 200 mL of diethyl ether with stirring. It gave a brown solid, which was filtered and washed with diethyl ether. The residue was dissolved in the minimum amount of water and made alkaline with concentrated aqueous NaOH. The Na_2SO_4 precipitate was filtered off and the alkaline solution was extracted with $CHCl_3$ (6 × 100 mL). The organic solutions were combined, dried with Na_2SO_4 and concentrated under reduced pressure to obtain **7** as a colorless oil. Yield: 1.2 g (88%). − $C_{13}H_{31}N_5$ (257.4): calcd. C 60.66, H 12.14, N 27.21; found C 60.5, H 12.3, N 27.0. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 2.13 (s, 6 H), 2.24 (s, 3 H), 2.41 (m, 8 H), 2.51 (t, 4 H), 2.67 (t, 4 H), 2.76 (s, 4 H),. − ^{13}C NMR ($CDCl_3$, 25 °C): δ = 42.1, 42.4, 47.1, 47.2, 55.6, 57.0, 57.5.

Diethyl 2-{3-[2,2-Bis(ethoxycarbonyl)ethyl]-2-methoxybenzyl}-malonate (10): A solution of **8** (11.8 g, 0.04 mol) in 150 mL of acetonitrile was added to a refluxing suspension of **9** (12.8 g, 0.08 mol) and K_2CO_3 (27.6 g, 0.2 mol) in 300 mL of acetonitrile over a period of 1 h. The reaction mixture was maintained under reflux for a further 3 d. The mixture was then cooled to room temperature and the resulting suspension was filtered and the solution concentrated under reduced pressure, giving the crude product, which was chromatographed on neutral alumina ($CHCl_3$). The eluted fractions ($R_f = 0.79$) were collected and concentrated to dryness, affording **10** as a colorless oil. Yield: 16.7 g (92%). − $C_{23}H_{32}O_9$ (452.5): calcd. C 61.05, H 7.13; found C 60.9, H 7.2. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 1.20 (t, 12 H), 3.22 (d, 4 H) 3.79 (t, 2 H), 3.81 (s, 3 H), 4.14 (q, 8 H), 6.92(t, 1 H), 7.08 (d, 2 H). − ^{13}C NMR ($CDCl_3$, 25 °C): δ = 13.9, 29.5, 52.1, 60.7, 60.9, 124.1, 129.6, 131.4, 157.7, 169.1.

2-[3-(2,2-Dicarboxyethyl)-2-methoxybenzyl]malonic Acid (11): A solution of **10** (9.0 g, 0.02 mol) and NaOH (12.0 g, 0.3 mol) in 100 mL of ethanol was refluxed for 7 h. The mixture was cooled, 50 mL of ethanol was added. The solution was maintained under stirring for further 12 h. Acetonitrile (80 mL) was added to the resulting deliquescent mixture until the complete precipitation of a white solid was obtained. The dried solid was dissolved in the minimum amount of water and the solution, made acidic with 37% HCl, was extracted with ethyl ether (5 × 30 mL). The organic solutions were combined, dried with Na_2SO_4 and concentrated under reduced pressure to obtain **11** as a colorless oil. Yield: 5.4 g (79%). − $C_{15}H_{16}O_9$ (340.3): calcd. C 52.95, H 4.74; found C 53.1, H 4.8. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 3.10 (d, 4 H) 3.67 (s, 3 H), 3.77 (t, 2 H), 6.92(t, 1 H), 7.00 (d, 2 H). − ^{13}C NMR ($CDCl_3$, 25 °C): δ = 30.3, 53.5, 62.3, 126.1, 130.8, 132.2, 158.2, 174.2.

3-[3-(2-Carboxyethyl)-2-methoxyphenyl]propionic Acid (12): A solution of **11** (6.8 g, 0.02 mol) and diphenyl ether (150 g) was refluxed for 2 h. The solution was cooled and 50 mL of $CHCl_3$ was added. This solution was then washed with 0.1 mol dm^{-3} NaOH (6 × 25 mL). The collected aqueous part was acidified with 96% H_2SO_4 and the solution extracted with diethyl ether (6 × 25 mL). The organic solutions were combined, dried with Na_2SO_4 and concentrated under reduced pressure to obtain **12** as a yellowish solid. Yield: 3.9 g (77%). − $C_{13}H_{16}O_5$ (252.3): calcd. C 61.90, H 6.39; found C 61.8, H 6.3. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 2.70 (t, 4 H) 2.99 (t, 4 H), 3.78 (s, 3 H), 7.08 (m, 3 H), 10.32 (b, 2 H). − ^{13}C NMR ($CDCl_3$, 25 °C): δ = 25.2, 34.5, 61.0, 124.5, 128.4, 133.4, 157.1, 179.4.

Ethyl 3-[3-(2-Ethoxycarbonylethyl)-2-methoxyphenyl]propionate (13): A solution of **12** (7.6 g, 0.03 mol) and *p*-toluenesulfonic acid (8.6 g, 0.045 mol) in 100 mL of ethanol was kept under reflux for a period of 12 h. An aqueous solution of $NaHCO_3$ was added to the reaction mixture (cooled to room temperature) until neutralization was achieved. The mixture was extracted with CH_2Cl_2 (3 × 50 mL), and the organic layer was combined, dried with Na_2SO_4 and concentrated under reduced pressure to obtain **13** as an oil. Yield: 8.2 g (89%). − $C_{17}H_{24}O_5$ (308.4): calcd. C 66.21, H 7.84; found C 66.0, H 7.9. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 1.25 (t, 6 H), 2.62 (t, 4 H), 2.98 (t, 4 H), 3.77 (s, 3 H), 4.14 (q, 4 H), 7.02 (m, 3 H). − ^{13}C NMR ($CDCl_3$, 25 °C): δ = 14.2, 25.5, 34.9, 60.4, 61.3, 124.3, 128.2, 133.8, 157.3, 173.2.

3-[3-(3-Hydroxypropyl)-2-methoxyphenyl]propanol (14): A solution of **13** (6.2 g, 0.02 mol) in 50 mL of anhydrous diethyl ether was carefully added to a suspension of $LiAlH_4$ in 100 mL of anhydrous ethyl ether. The mixture was allowed to react for 3 h at room temperature. An aqueous solution of $NaHCO_3$ was added to the mixture until excess $LiAlH_4$ was completely destroyed. The suspension was extracted with $CHCl_3$ (6 × 50 mL) and the organic solutions were combined, dried with Na_2SO_4 and concentrated under reduced pressure to obtain **14** as a yellowish oil. Yield: 4.1 g (91%). − $C_{13}H_{20}O_3$ (224.3): calcd. C 69.61, H 8.99; found C 69.7, H 9.1. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 1.87 (q, 4 H), 2.34 (s, 2 H), 2.75 (t, 4 H), 3.58 (t, 4 H), 3.78 (s, 3 H), 7.05 (m, 3 H). − ^{13}C NMR ($CDCl_3$, 25 °C): δ = 25.7, 33.5, 61.4, 61.6, 124.8, 128.3, 134.5, 156.5.

Methyl 3-[2-Methoxy-3-(3-methylsulfonyloxypropyl)phenyl]propylsulfonate (15): A solution of methylsulfonyl chloride in anhydrous CH_2Cl_2 (40 mL) was added to an ice-cold solution of **14** (4.0 g, 0.018 mol) and triethylamine in 50 mL of anhydrous CH_2Cl_2, over a period of 1 h. The solution was kept at this temperature for a further 2 h, and then washed with 5% HCl aqueous solution (3 × 50 mL), 10% $NaHCO_3$ aqueous solution (3 × 50 mL) and water (3 × 50 mL). The organic part was dried with Na_2SO_4 and concentrated under reduced pressure to give **15** as an oil. Yield: 6.5 g (95%). − $C_{15}H_{24}O_7S_2$ (380.5): calcd. C 47.35, H 6.36; found C 47.2, H 6.5. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 2.09 (q, 4 H), 2.77 (t, 4 H), 3.01 (s, 6 H), 3.74 (s, 3 H), 4.24 (t, 4 H), 7.06 (m, 3 H). − ^{13}C NMR ($CDCl_3$, 25 °C): δ = 26.0, 29.9, 37.3, 61.2, 69.6, 124.5, 128.6, 133.7, 156.7.

Cryptand 18 (18·4HCl): Amine **7** (1.3 g, 5 mmol) and Na_2CO_3 (2.65 g, 25 mmol) were suspended in refluxing CH_3CN (100 mL). To this mixture, a solution of **15** (1.8 g, 5 mmol) in CH_3CN (100 mL) was added dropwise over 6 h, after which the suspension was refluxed for 72 h and then filtered. The solution was concentrated under vacuum to yield the crude product, which was chromatographed on neutral alumina ($CHCl_3$/CH_3OH, 100:4). The eluted fractions were collected and concentrated to yield an oil, which was dissolved in ethanol and treated with 37% hydrochloride acid to give **18** as a tetrahydrochloride salt (1.2 g, 42%). − $C_{24}H_{47}Cl_4N_5O$ (**18**·4HCl: 563.5): calcd. C 51.16, H 8.41, N 12.43; found C 51.1, H 8.3, N 12.3. − MS (FAB), *m*/*z*: 419 [M + H^+]. − ^{13}C NMR: δ = 25.8, 29.7, 43.2, 43.3, 44.6, 52.3, 52.7, 53.8, 55.3, 56.1, 62.0, 64.1, 127.2, 128.3, 129.6, 131.5, 135.3, 157.5, 158.2.

Cryptand L2 (L2·4HCl): A solution of cryptand **18**·4HCl (1.1 g, 2 mmol), EtSNa (1.7 g, 20 mmol) and LiBr (0.51 g, 6 mmol) in dry DMF (50 mL) was heated at 150 °C for 6 h. The solvent was then vacuum-evaporated and the residue was suspended in CH_2Cl_2 and filtered. The organic layer was concentrated and the crude product was chromatographed on neutral alumina (CH_2Cl_2/MeOH, 100:1). The eluted fractions were collected and concentrated to dryness. The crude product was dissolved in ethanol and treated with 37% hydrochloric acid to give the **L2** tetrahydrochloride salt as a white solid (0.69 g, 63%). − $C_{23}H_{45}Cl_4N_5O$ (**L2**·4HCl: 549.5): calcd. C 50.28, H 8.25, N 12.75; found C 55.3, H 8.4, N 12.6. − ^{1}H NMR (D_2O, pH = 7): δ = 2.32 (s, 3 H) 2.63 (s, 6 H), 3.28 (b, 28 H), 6.72 (t, 1 H), 7.02 (d, 2 H). − ^{13}C NMR (D_2O, pH = 7): δ = 30.4, 41.5, 41.7, 52.1, 54.9, 55.3, 56.0, 58.8, 120.7, 129.1, 131.7, 156.5.

Cryptand 19 (19·2HClO$_4$): This compound was synthesized from amine **17** (2.0 g, 0.01 mol), Na_2CO_3 (5.3 g, 0.05 mol) and **15** (3.5 g, 0.01 mol) according to the same procedure reported for **18**. The crude product **17** was dissolved in ethanol and treated with 65% perchloric acid to give the diperchlorate salt as a white solid (2.3 g, 39%). − $C_{23}H_{42}Cl_2N_4O_9$ (**19**·2$HClO_4$: 589.5): calcd. C 48.86, H 7.18, N 9.50; found C 48.9, H 7.1, N 9.4. − MS (FAB), *m*/*z*: 390 [M + H^+]. − ^{1}H NMR (D_2O, pH = 7, 25° C): δ = 2.14 (b, 4 H), 2.36 (s, 6 H), 2.83 (b, 16 H), 3.19 (b, 4 H), 3.39 (b, 4 H), 3.80 (s, 3 H), 7.27 (m, 3 H). − ^{13}C NMR (D_2O, pH = 7, 25° C): δ = 25.2, 29.0, 43.6, 45.2, 49.4, 52.8, 53.4, 54.0, 55.6, 62.2, 127.1, 130.2, 136.1, 157.2.

Cryptand L1 (L1·3HCl): This compound was synthesized from cryptand **19**·2$HClO_4$ (1.2 g, 2 mmol), according to the same procedure reported for **L2**. The crude product **L1** was dissolved in ethanol and treated with 37% hydrochloric acid to give the trihydrochloride salt as a white solid (0.57 g, 59%). − $C_{22}H_{41}Cl_3N_4O$ (**L1**·3HCl: 484.0): calcd. C 54.60, H 8.54, N 11.58; found C 54.5, H 8.7, N 11.4. − ^{1}H NMR (D_2O, pH = 3): δ = 2.03 (m, 4 H) 2.66 (s, 6 H), 2.76 (m, 16 H), 3.16 (m, 8 H), 6.99 (t, 1 H), 7.14 (d, 2 H). − ^{13}C NMR (D_2O, pH = 3): δ = 25.7, 29.4, 44.6, 49.8, 53.7, 54.4, 124.3, 130.2, 132.6, 156.2.

Preparation of the Complexes. − [LiH$_{-1}$L1]: A solution of LiOH (10 mg, 0.44 mmol) in 15 mL of methanol was added to a solution of **L1**·3HCl_3 (48 mg, 0.1 mmol) in methanol (15 mL). The reaction mixture was stirred for 15 min and then concentrated to dryness. The solid was suspended in 20 mL of $CHCl_3$ and the mixture filtered to separate the inorganic excess. The organic solution was dried with Na_2SO_4. On addition of cyclohexane (25 mL) a white precipitate formed. Yield 31 mg (81%). − $C_{22}H_{37}LiN_4O$ (380.5): calcd. C 69.45, H 9.80, N 14.72; found C 69.3, H 9.7, N 14.6. − ^{13}C NMR ($CDCl_3$): δ = 29.9, 34.2, 43.7, 54.3, 55.5, 59.3, 119.5, 129.4, 132.7, 160.4. − **[NaL2]:** An excess of $NaClO_4$ was added to a solution of **L2**·4HCl (165 mg, 0.3 mmol) in 50 mL of water. A 0.1 mol dm^{-3} NaOH solution was added until complete precipitation of a white precipitate was obtained. The solid was then suspended in 20 mL of $CHCl_3$ and the mixture filtered. The liquid part was dried with Na_2SO_4 and concentrated to dryness. The solid was recrystallized by slow concentration of a mixture of $CHCl_3$/cyclohexane, obtaining white crystals suitable for X-ray analysis.

Yield 60 mg (38%). − $C_{23}H_{41}ClN_5NaO_5$ (526.1): calcd. C 52.51, H 7.86, N 13.31; found C 52.6, H 7.9, N 13.2. − ^{13}C NMR ($CDCl_3$): δ = 30.6, 42.7, 42.9, 55.3, 56.7, 58.3, 58.6, 63.0, 121.1, 127.4, 133.0, 153.8. − **[NaH$_{-1}$L2]:** This compound was synthesized from [Na**L2**] (53 mg, 0.1 mmol) according to the same procedure reported for [LiH$_{-1}$**L1**], giving [NaH$_{-1}$**L2**] as a white solid. Yield: 30 mg, 69%). − $C_{23}H_{40}N_5NaO$ (425.6): calcd. C 64.91, H 9.47, N 16.46; found C 64.3, H 9.3, N 16.4. − ^{13}C NMR (CD_3OD): δ = 29.1, 31.3, 41.2, 41.8, 43.1, 43.2, 52.6, 54.4, 54.5, 57.1, 57.2, 57.3, 57.5, 58.2, 59.3, 60.9, 66.7, 111.2, 114.69, 127.2, 128.7, 130.7, 132.4, 163.2, 163.4.

Cambridge Structural Database Search: The Cambridge Structural Database (CCDC) V5.19 was used to retrieve structural information about the penta- and hexacoordinated complexes of lithium, sodium and potassium by nitrogen and/or oxygen atoms. The VISTA V2.1 software was used to analyze the retrieved fragments.

X-ray Crystallographic Studies: Cell parameters and intensity data for the two structures were obtained with a Siemens P4 diffractometer, using graphite-monochromated Cu-K_α radiation (λ = 1.54184 Å). Cell parameters were determined by least-squares fitting of 25 centered reflections. The intensities of three standard reflections were measured every 60 min to check the stability of the diffractometer and the decay of the crystals. Intensity data were corrected for Lorentz and polarization effects, and an absorption correction was applied once the structure had been solved by using the Walker and Stuart method.[44] The two structures were solved using the SIR-97 program[45] and subsequently refined by the full-matrix least-squares program SHELX-97.[46] Protonation hydrogen atoms of ligand **L1** were found in difference syntheses and their positions were refined, as well as their isotropic displacement parameters. The other hydrogen atoms of the molecule were introduced in calculated positions and their coordinates refined in agreement with those of the linked atoms [overall isotropic temperature factor U = 0.048(2) Å^2]. The H10 atom of compound **L2** was found in a difference synthesis and its position was refined, as well as its thermal parameter. The other hydrogen atoms of the complex were introduced in calculated positions and their coordinates refined in agreement with those of the linked atoms [U = 0.0126(3) Å^2]. All the non-hydrogen atoms of the two structures were refined anisotropically. Atomic scattering factors and anomalous dispersion corrections for all the atoms were taken from ref.[47] Geometrical calculations were performed using PARST97.[48] The molecular plot was produced by the ORTEP program.[33] Crystallographic data (excluding structural factors) for the structures reported in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-152533 and -152534 for [H**L1**](ClO_4) and [Na**L2**](ClO_4), respectively. Copies may be obtained without charge from CCDC, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Support for this research from MURST (Ministero per l'Università e la Ricerca Scientifica e Tecnologica, COFIN98) and CNR (Consiglio Nazionale delle Ricerche) is gratefully acknowledged.

Metallophthalocyanines Linked to Organic Copolymers as Efficient Oxidative Supported Catalysts

Muriel Sanchez,[a] Nicolas Chap,[a] Jean-Bernard Cazaux,[b] and Bernard Meunier*[a]

Keywords: Phthalocyanines / Supported catalysts / Polymers / Oxidations

The covalent anchoring of metallo(chlorosulfonyl)phthalocyanines **1** onto the acrylic copolymers **2** and **3** has been achieved. When using H_2O_2 or $KHSO_5$ as oxidant, these supported catalysts are able to oxidize a poorly biodegradable molecule such as 2,4,6-trichlorophenol or a tannin model such as 3,5-di-*tert*-butylcatechol. The influence of the spacer and the nature of the reaction medium on the catalytic activities have been studied, as well as the recycling of these supported metallophthalocyanine catalysts.

Introduction

Metallophthalocyanines (e.g., **1** and **4**, Scheme 1) have attracted considerable interest because of their structural similarity to metalloporphyrin complexes found at the active sites of metalloenzymes.[1] These phthalocyanine complexes are often more easily prepared than synthetic metalloporphyrins, and exhibit interesting properties in areas such as sensitizers[1,2] (e.g., in photodynamic cancer therapy), catalysts[1,3] (e.g., for thiol oxidation in gasoline fractions), electrocatalysts[1,4] (e.g., for O_2 reduction in fuel cells), sensors[1][3c,5] (e.g., NO_x and O_2 gas sensors) or nonlinear optical devices.[1,6]

Scheme 1. Structure of the metallo[2,9,16,23-tetrakis(chlorosulfonyl) and -tetrasulfo]phthalocyanines **1** and **4**

In the field of bio-inspired oxidations, it has been shown in our laboratory that water-soluble metallo(sulfo)phthalocyanines **4** (Scheme 1) can be used as oxidation catalysts with H_2O_2 or $KHSO_5$.[7] Highly reactive metal−peroxo (e.g., $Fe^{III}-OOY$) and metal−oxo ($Fe^{IV}=O$) species are probably involved in the catalytic oxidations of poorly biodegradable molecules such as polychlorinated phenols, catechols, and polycondensed aromatics.[7] One limitation of these catalysts is the formation in solution of inactive aggregates and dimers of the metallophthalocyanine complexes, which significantly affects their catalytic properties. This aggregation phenomenon is usually depicted as a coplanar association of the aromatic rings driven by enhanced van der Waals forces and dimer formation through μ-oxo bridges.[7a,8] In solution, the monomerization of water-soluble metallophthalocyanines can be achieved by adding an organic co-solvent[7a] or a detergent.[9] Another strategy used to obtain a monomolecular dispersion of these macrocyclic complexes is based upon their heterogenization on the surface of a support. Several types of carrier have been used for this task, such as charcoal,[10] organic polymers,[11] silica,[12] zeolites,[13] and clays.[14] Among the advantages of using supported catalysts is the easy separation of the catalysts from products and the subsequent possible recycling of the catalyst.[15]

Recently, we have described the covalent attachment of the chlorosulfonyl-substituted iron-phthalocyanine **1a** (Scheme 1) to functionalized 3-aminopropyl-silica via a sulfonamide linkage.[16] This supported catalyst, when using hydrogen peroxide as oxidant, is able to degrade a recalcitrant pollutant. However, the efficiency of this catalytic system was lower than that obtained under homogeneous conditions. This probably results from diffusion-limitation effects inherent to the use of silica as support, despite the fact that mineral supports have a better reputation of chemical stability compared to organic polymers in catalytic oxidations with supported catalysts.[17]

Here, we report the preparation of new organic polymers-supported metallophthalocyanines, and their efficiency as oxidation catalysts.

Results and Discussion

Preparation of the Supported Catalysts

We have previously shown that a sulfonamide linkage used to immobilize an iron-phthalocyanine onto modified

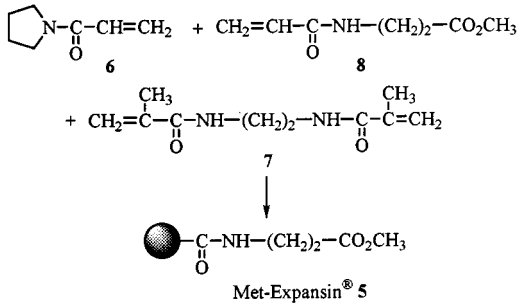
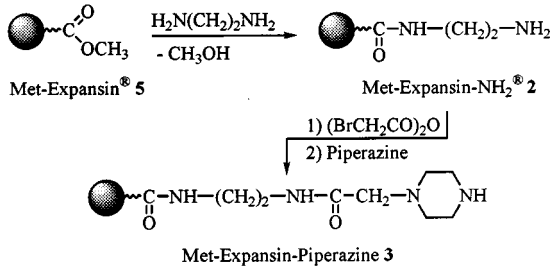
silica is stable under oxidative conditions.[15] Therefore, we decided to use the same type of linkage for the attachment of chlorosulfonyl-substituted phthalocyanine complexes **1** onto organic supports. The organic supports used were the acrylic copolymers Met-Expansin-NH_2® (**2**) and Met-Expansin-Piperazine (**3**), which both possess an amino-functionalized pendant arm and were prepared from Met-Expansin® (**5**) by EXPANSIA. These resins were synthesized from the polymerization of the monomer *N*-acryloylpyrrolidine (**6**), the cross-linking agent *N*,*N*′-bis(methacryloyl)-1,2-diaminoethane (**7**), and *N*-acryloyl-β-alanine methyl ester (**8**) as functionalizing agent (Patent EP 79842, 1982) (Scheme 2).



Scheme 2. Synthesis of Met-Expansin® (**5**)

The polyacrylamide **5** can be treated with ethylenediamine to afford **2** (Patent EP 81408, 1982) (Scheme 3). This resin contains 0.56 mmol-equiv. of NH_2 per gram of dry material that can be used to covalently anchor the metallo(chlorosulfonyl)phthalocyanines **1**. A spacer can also be used to increase the distance between the catalyst and the polymer surface. This modification of the tether helps to increase the solvent, substrate, and oxidant access, similar to homogeneous reaction conditions. Copolymer **3** was prepared by treating **2** with bromoacetic anhydride, followed by the addition of piperazine (Patent Fr. Dem. 9904135, 1999). It contains 0.5 mmol-equiv. of terminal NH functions per gram of dry resin.



Scheme 3. Synthesis of Met-Expansin-NH_2® (**2**) and Met-Expansin-Piperazine (**3**)

The two organic copolymers **2** and **3** are insoluble in organic solvents and in aqueous media; however, these resins swell in protic solvents to form gels. This property is certainly important for the preparation of supported catalysts, because the surface area of the carrier is considerably increased making the active catalytic centers more accessible.

The immobilization of the chlorosulfonyl derivatives **1** of the iron- and cobalt-phthalocyanines was achieved by heating a mixture of resin and complex in pyridine to reflux. The supported catalysts FePc-SO_2NH-Met-Expansin (**9**) (20.0 μmol of iron per gram of dry resin), FePc-SO_2N(pip)-Met-Expansin (**10a**) (26.5 μmol Fe/g), and CoPc-SO_2N-(pip)-Met-Expansin (**10b**) (42.0 μmol Co/g) were thus obtained from the polyacrylamides **2** and **3** (Scheme 4).

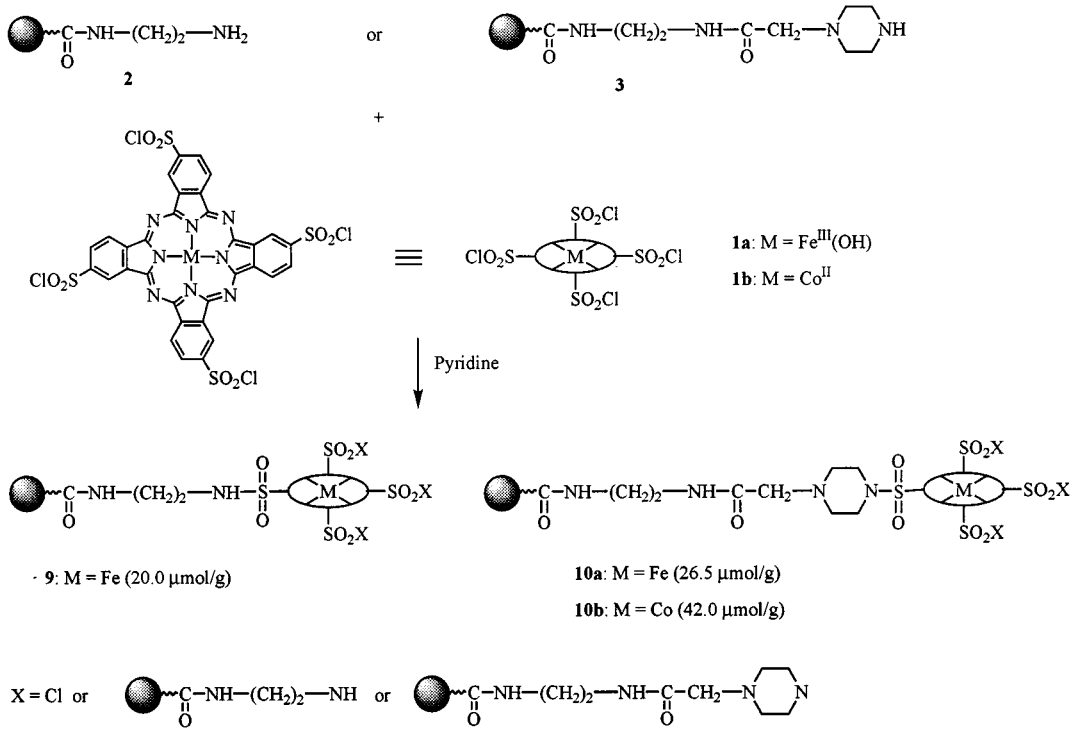
After filtration, the loading of the supports was indirectly calculated by determining the amount of **1** remaining in solution by UV/Vis spectroscopy. No release of metallophthalocyanine was observed after several washings with water, dimethylformamide, and ethanol. The green color of these modified polymers obtained after the washing procedures strongly suggested that the metallophthalocyanine complexes were attached in monomeric form (μ-oxo-metallophthalocyanine dimers and aggregates are generally blue).[7a] It is important to note that no desorption of the metallophthalocyanine catalysts was detected under oxidative conditions (e.g., after addition of H_2O_2 or $KHSO_5$) according to UV/Visible measurements.

For comparison, the silica-supported catalysts FePc-SO_2NH-Silica (**11**) (42.0 μmol Fe/g) and FePc-SO_2N(pip)-Silica (**12**) (40.0 μmol Fe/g) were also prepared. The grafted polymer **11** comes from the direct fixation of **1** onto a commercially available modified silica featuring primary amine linkers, whereas **12** contains the piperazine spacer introduced by the same procedure used for the preparation of **3** from **2** (Scheme 5).

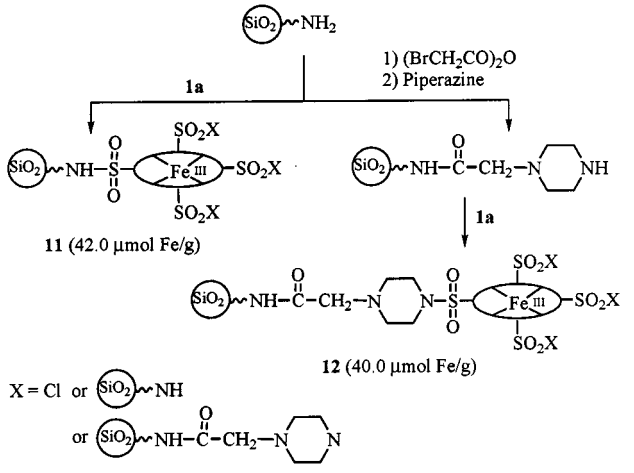
Catalytic Activities of the Grafted Complexes 9−11 for the H_2O_2 Oxidation of a Chlorinated Pollutant

2,4,6-Trichlorophenol (TCP) is produced by paper mills during the oxidative chlorine degradation of lignin in white paper manufacturing.[18] Due to its slow biodegradation by aerobic or anaerobic microorganisms and its resistance to oxidative or reductive chemical treatments, this substrate is extremely persistent in the environment. Thus, TCP is commonly used as a pollutant model. It has been shown that ligninase (a peroxidase isolated from the white-rot fungus *Phanerochaete chrysosporium*) is able to degrade TCP by an oxidative pathway, although the conversion is slow.[18b] Synthetic metalloporphyrins, which are efficient peroxidase models, are able to oxidize TCP to the corresponding quinone, but are unable to cleave the aromatic ring of TCP.[19] Using either soluble metallophthalocyanines, or the corresponding immobilized catalysts onto a support (silica or Amberlite), with H_2O_2 as a "green" oxidant, TCP has been converted in two classes of compounds: aromatic ring cleavage products (C_4 diacids, with chloromaleic acid being the major product) and oxidative coupling products (Scheme 6).[7,20]

Under the same experimental conditions [1 mM TCP solution in a mixture of 50 mM phosphate buffer (pH = 7)/acetone (80:20), 6 mM H_2O_2, and 2 mol-% of catalyst], however, the reaction was markedly faster with the iron-tetrasulfophthalocyanine catalyst **4b** under homogeneous condi-



Scheme 4. Immobilization of the metallophthalocyanines **1** onto **2** and **3**



Scheme 5. Immobilization of the metallophthalocyanines **1** onto silica

tions, compared to the iron complex **11** grafted onto silica modified with primary amine linkers. Indeed, full conversion of TCP was achieved within 45 min with **4b** (Run 2, Table 1), while it took 1 h for the supported catalyst **11** to oxidize only 52% of TCP (Run 3).

The oxidative properties of the metallophthalocyanines immobilized onto the organic polymers **2** and **3** were also investigated. First, we checked that the TCP substrate was not oxidized by H_2O_2 and the support material alone, in the absence of metallophthalocyanine catalyst (Run 1). In addition, this control experiment confirmed that there is no physisorption of the substrate onto the surface of the support. In the presence of phosphate buffer, but without any organic co-solvent, the supported iron catalysts **9** and **10a** with H_2O_2 were able to degrade 85% (Run 4) and 62% (Run 10) of the TCP, respectively, within 1 h. The presence of an organic co-solvent such as ethanol or acetone, which allowed a better solubilization of the poorly water-soluble TCP substrate, improved the degradation process up to full conversion of TCP within 1 h (Runs 5, 6, 11, and 12). Also, with acetone as co-solvent, the degradation of TCP was complete after 20 min with **9** and after 25 min with **10a**. The turnover rates (based on the first 30 min of the reaction) of these two supported catalysts are 150 and 120 cycles per hour, respectively. These results are of great interest, since the catalytic activities of these new supported metallophthalocyanines are comparable to those observed under homogeneous conditions.

The recycling of **10a**, a key point for supported catalysts, was then investigated. After a first catalytic oxidation, a second portion of pollutant and oxidant was added to the reaction mixture. In this second run, 91% of TCP was converted in 15 min (Run 13) indicating that the catalytic activity of the metallophthalocyanine remained intact.

For comparison, the catalytic activity of the supported cobalt complex **10b** was also checked (Runs 14−17). The full conversion of TCP could be achieved in 30 min with 4 mol-% of **10b** and with 20% of acetone in the reaction mixture (Run 17). Although the results obtained with this supported catalyst are less impressive than with the corresponding iron(III) complex, they are also of potential commercial interest. Indeed, the (chlorosulfonyl)phthalocyanine **1b** used for the immobilization on the organic copolymer was synthesized from the readily available sulfo precursor

4c, which is widely used in the industrial mercaptan oxidation process (Merox) for the treatment of petroleum distillates.[3]

The covalent attachment of the metallophthalocyanines **1** onto the organic copolymers **2** and **3** proved to be suitable for the preparation of active systems for the catalytic oxidative degradation of recalcitrant pollutants such as 2,4,6-trichlorophenol. The different properties (flexibility, swelling, etc.) of these carriers make them excellent candidates for catalytic supports.

It should be noted that the behavior of **9** and **10a** are almost identical, with **9** being only slightly more efficient than the corresponding piperazine-containing polymer. These organic copolymers **2** and **3** are relatively flexible, consequently the role of an additional spacer to increase the distance between the catalyst and the support is rather limited. In contrast, with a more rigid carrier material like silica, this modification could notably change the catalytic properties of a metallophthalocyanine complex covalently linked to silica. In order to verify this hypothesis, we determined the oxidative properties of the silica-supported iron complex **12**, which features the same piperazine spacer as in **10a**.

Influence of the Piperazine Spacer

In order to determine the influence of the spacer, we compared the oxidative properties of **12** (containing 40.0 μmol of iron per gram of resin) to those of **11** with the same catalyst loading (42.0 μmol/g). In the oxidative degradation of TCP with H_2O_2, the catalytic activity of the

supported catalyst containing the piperazine spacer was 3 times higher after 30 min (Runs 3 and 18, Table 1). In addition, for the first time, it was possible to achieve a full conversion of TCP in 1 h with a metallophthalocyanine grafted onto modified silica (Run 18). *This result strongly indicates that when anchoring a large catalyst molecule like a metallophthalocyanine (a macrocyclic molecule with a diameter of ca. 25 Å) onto a rigid support such as silica, it is necessary to introduce a long spacer between the catalyst and the surface of the support.* Without this modification, the oxidative activities of the corresponding supported catalysts are reduced. These results provide further motivation to use the flexible organic copolymers **2** and **3** as supports in catalytic oxidations.

Catalytic Oxidation of TCP in Pure Aqueous Medium (without Buffer)

The experiments described above for the degradation of TCP were carried out in phosphate buffer (pH = 7) medium. Under homogeneous conditions it has been shown that this pH value is optimal for a good catalytic activity. This can be explained by the fact that the first step of TCP degradation is a one-electron oxidation of the phenolate anion [7a] (pK_a value of TCP: 6.2).[21] However, since the final aim of this work is the decontamination of industrial waste waters, the presence of phosphate ions is ecologically not appropriate.

With this in mind, we tried to degrade TCP in a pure aqueous medium, using the most active polyacrylamide- and silica-supported catalysts **9** and **12**. The pH value of the reaction mixture was adjusted to 7 with sodium hydroxide in order to have only the more oxidizable phenolate form of the substrate in solution. With a 2 mol-% ratio catalyst/TCP, the supported catalyst **9** and H_2O_2 are able to oxidize 55% of the starting TCP after 1 h (Run 7, Table 1), whereas, under the same conditions, the iron-phthalocyanine grafted onto the modified piperazine-silica **12** converted only 11% of TCP (Run 19). Since the tetrasulfophthalocyanine **4b** is totally inactive in a purely aqueous medium under homogeneous conditions,[22] these results were encouraging. The ratio catalyst/substrate was raised to 3 mol-% for **9** and the conversion of TCP increased to 65% after 1 h and to 79% after 2 h (Run 8). With a sequential addition of the oxidant in 4 aliquots, every 10 min, a quasi-complete degradation of TCP can be achieved in a purely aqueous medium within 2 h (Run 9). The sequential addition of H_2O_2 disfavors its consumption by a disproportionation reaction (leading to water and molecular oxygen) induced by the catalase-like reactivity of the metallophthalocyanine complex.[7a]

Catalytic Degradation of TCP with $KHSO_5$ as Oxidant

Potassium monopersulfate ($KHSO_5$) is an oxygen atom donor that has been shown to be highly efficient for the activation of metallophthalocyanines and metalloporphyrins.[7,19] It is commercially available as the triple salt $2KHSO_5{\cdot}KHSO_4{\cdot}K_2SO_4$, and is a classic reagent in Baeyer−Villiger oxidations.[23] An initial control experiment was made to ensure that TCP was not oxidized by $KHSO_5$ without catalyst (Run 1, Table 2) and that there was no leaching of the iron-phthalocyanine under these new oxidation conditions [8 mg of **9** suspended in 8 mL of a phosphate buffer (pH =7) with 5 equiv. of $KHSO_5$].

In a purely aqueous medium, the degradation of TCP by the catalytic **9** (2 mol-%)/$KHSO_5$ system is very fast (79% in 5 min, Run 2, Table 2). However, the conversion of TCP reached a plateau after 10 min and a bleaching of the supported catalyst was observed. The pH measurement of the solution gave a value of 2.5, which was attributed to the intrinsic acidity of $KHSO_5$. At such a low pH value, the supported catalyst is probably decomposed. In contrast, when the reaction mixture was buffered at pH = 7 using a phosphate buffer, the conversion of TCP was complete in 5 min (Run 3). Under these conditions, the turnover rate of this supported iron-(sulfonamido)phthalocyanine was 10 catalytic cycles per minute (based on the first five minutes of the reaction). With the catalytic **9**/$KHSO_5$ system, the turnover rate can be increased up to 16 cycles/min using 1 mol-% of catalyst (Run 4). In contrast, with only 0.1 mol-% of catalyst, the degradation of TCP was incomplete after 1 h (Run 5).

We also checked the possibility of recycling this supported catalyst under these strong oxidation conditions. After a first catalytic reaction, new portions of substrate and oxidant were added every 5 min (Run 6). The results were very surprising: the catalytic system was still efficient after the addition of 3 new portions of pollutant and had retained its initial catalytic activity.

We have established that the activation of metallophthalocyanines anchored onto **2** and **3** with either hydrogen peroxide or potassium monopersulfate as oxidants is an efficient method for the oxidative degradation of a notable pollutant such as TCP. Moreover, NMR studies carried out after the catalytic oxidation of TCP with H_2O_2 (as well as with $KHSO_5$) have shown the formation of ring cleavage products, which are biodegradable. For example, for the H_2O_2 oxidation of TCP catalyzed by **10a**, we observed the formation of 12% of chloromaleic acid, 3% of chlorofumaric acid, 4% of maleic acid, 3% of fumaric acid and 6% of coupling products. Thus, these catalytic systems might be useful for the oxidative treatment of industrial waste waters. However, these bio-inspired supported oxidative catalysts might also be useful as bleaching agents in a new generation of washing powders, able to operate at room temperature.

H_2O_2 Oxidative Degradation of 3,5-Di-*tert*-butylcatechol Catalyzed by 9

Catechol and its derivatives are often used as substrates for the evaluation of bleaching agents since they are considered good models of stains (catechols are the most common structure encountered in condensed tannins, which are among the main stains).[24] Under homogeneous conditions, the iron-sulfophthalocyanine **4b** in conjunction with an oxidant was able to degrade several catechols such as catechol itself, as well as its 3-methyl, 3-methoxy, 3,5-di-

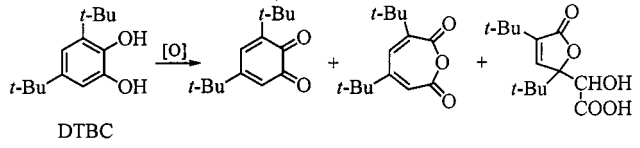
[a] T.O.: Turn over numbers calculated after 5 min. – [b] PB: Phosphate buffer (pH = 7). – [c] Pure aqueous media (pH = 2.5). – [d] Recycling of the supported catalyst: after 5 min of a first oxidation reaction with 3.75 equiv. of $KHSO_5$, new portions of TCP and $KHSO_5$ were added every 5 min in the same batch.

tert-butyl, and tetrachloro derivatives.[25] The degradation products from 3,5-di-*tert*-butylcatechol (DTBC) were identified by ^1H NMR as 3,5-di-*tert*-butyl-1,2-benzoquinone, 3,5-di-*tert*-butylmuconic anhydride, and 3,5-di-*tert*-butyl-5-(carboxyhydroxymethyl)-2-furanone (Scheme 7).



Scheme 7. Degradation products of 3,5-di-*tert*-butylcatechol catalyzed by the iron-tetrasulfophthalocyanine **4b**

When H_2O_2 was used as oxidant, the noncatalyzed reaction with DTBC was negligible (Run 1, Table 3). The oxidative properties of the **9**/H_2O_2 system were used for the catalytic degradation of DTBC. We first noted that the substrate was not physisorbed on the surface of the support. Three reaction media were then checked for the degradation of DTBC at room temperature: borate buffer (pH = 9)/CH_3CN (50:50, v/v), phosphate buffer (pH = 7)/CH_3CN (50:50, v/v) and H_2O/CH_3CN (50:50, v/v). The presence of acetonitrile is necessary as organic co-solvent for a good solubility of DTBC. With 2 mol-% of catalyst, the results for the degradation of DTBC are quite similar in the three different reaction media (Runs 2–4, Table 3). The most interesting results were obtained without buffering the reaction solution (which can be considered as an advantage), and as a result, attempts were made to optimize this reaction. By increasing the catalyst/substrate ratio to 3 mol-%, full conversion of DTBC was achieved in 1 h (Run 5, Table 3). ^1H NMR studies carried out after the catalytic oxidation of DTBC in a water/acetonitrile mixture revealed the formation of 3,5-di-*tert*-butyl-1,2-benzoquinone (50% yield, no other products could be detected).

The recycling capacity of **9** was also studied in the degradation of DTBC. In this case, this supported catalyst also showed excellent behavior without loss of its oxidative properties, as expected for an efficient long-life catalyst. In fact, after having converted 82% of DTBC in a first catalytic oxidation, the same system was still able to degrade 4 new portions of substrate (Run 6, Table 3). However, for an application in washing powders, it would be accurate and realistic to work with a water-soluble catechol such as 3,4-dihydroxybenzoic acid, current work is underway in this direction.

Conclusion

The covalent anchoring of metallophthalocyanines onto the acrylic copolymers Met-Expansin-NH_2® (**2**) and Met-Expansin-Piperazine (**3**) allowed the fixation of these macrocyclic complexes in a monomolecular dispersion, resistant to oxidative conditions. These bio-inspired supported catalysts, when activated with H_2O_2 (the "green" oxidant) or $KHSO_5$ were able to fully degrade a recalcitrant pollutant such as 2,4,6-trichlorophenol. The organic carriers proved flexible enough as to eliminate the need to introduce an additional piperazine spacer between catalyst and support as observed with modified silica. Furthermore, it has been possible to use these polyacrylamide-supported catalysts in a purely aqueous medium, whilst retaining a good catalytic activity of the metallophthalocyanine complex.

These new efficient supported catalysts could easily be used for the oxidative treatment of waste water or industrial effluents. Another possible field of application could also be related to the development of bleaching agents operating at room temperature, since such catalytic systems are able to oxidize a tannin model such as 3,5-di-*tert*-butylcatechol.

Experimental Section

General Remarks: The conversions of 2,4,6-trichlorophenol (TCP) and 3,5-di-*tert*-butylcatechol (DTBC) were monitored by HPLC (Waters) equipped with a μ-Bondapak C18 column using a methanol/ammonium acetate buffer mixture [7:3, v/v; 50 mM acetate buffer (pH = 5) acidified to pH = 4 with acetic acid] with detection at 220 nm for TCP and a methanol/water mixture (8:2, v/v) with detection at 226 nm for DTBC. − The UV/Vis absorption spectra were recorded with a Hewlett Packard 8452A spectrophotometer. Met-Expansin-NH_2® (**2**) (0.56 mmol-equiv. NH_2/g) and Met-Expansin-Piperazine (**3**) (0.50 mmol-equiv. NH/g) copolymers were a gift from EXPANSIA. The 3-aminopropyl-functionalized silica gel (0.90 mmol-equiv. NH_2/g) was purchased from Aldrich.[26] The reactants bromoacetic acid, dicyclohexylcarbodiimide and piperazine are commercially available and were used without further purification. 2,4,6-Trichlorophenol was obtained from Janssen and 3,5-di-*tert*-butylcatechol from Aldrich. Hydrogen peroxide was supplied from Acros as a 35 wt-% aqueous solution. Curox® ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) was a gift from Peroxid Chemie GmbH. All solvents used were of analytical grade and milliQ-water was always used to prepare aqueous solutions. Iron(III) and cobalt(II) tetrasulfophthalocyanines (**4b** and **4c**) were prepared according to previously published modifications[7a] of the method of Weber and Busch.[27]

Attachment of the Piperazine Linker on Silica: A solution of dicyclohexylcarbodiimide (0.56 g, 2.70 mmol) in CH_2Cl_2 (10 mL) was added dropwise at 0 °C to a solution of bromoacetic acid (0.75 g, 5.40 mmol) in CH_2Cl_2 (10 mL). The solution was allowed to warm to room temperature and stirred for 1 h. The dicyclohexylurea precipitate that formed was removed by filtration, the solid was washed three times with CH_2Cl_2 (3 × 20 mL), and the washings were combined. The bromoacetic anhydride solution thus obtained was directly added to the commercially available silica containing primary amine linkers (1.00 g, 0.90 mmol of NH_2 functions) and stirred for 12 h at room temperature. The modified silica was filtered, washed three times with CH_2Cl_2 (3 × 20 mL), and dried for 12 h at 50 °C. A suspension of the carrier containing CH_2Br end groups in DMF (5 mL) was added to a solution of piperazine (0.77 g, 9.00 mmol) in DMF (5 mL) and stirred 24 h at room temperature. The modified support thus obtained was isolated by filtration, washed three times with water (3 × 20 mL), ethanol (3 × 20 mL) and acetone (3 × 20 mL) prior to drying at 50 °C for 12 h. Yield: 0.78 g (78%).

General Procedure for the Immobilization of the Metallophthalocyanines: In a typical experiment, a suspension of the metallo(chlorosulfonyl)phthalocyanine **1a** or **1b** in pyridine (20 mL) and the carrier was heated at reflux for 24 h. The mixture was filtered and the solid obtained washed three times with a dimethylformamide/water mixture (80:20, v/v) (3 × 20 mL) and then ether (3 × 20 mL) prior to drying at 53 °C for 12 h. The supported metallo(sulfonamido)phthalocyanines were obtained as green powders. The contents of catalyst fixed onto the carriers were determined indirectly by calculating the amount of unchanged **1** using UV/Vis spectroscopy. The quantities used and yields obtained are given in Table 4.

Table 4. Quantities and yields for the preparation of the supported metallophthalocyanines

Product	**1**		Support		Loading	Yield
	mg	μmol	g	μmol (NH)	[μmol/g]	(%)
9	25.6	22.8	1.00	560	20.0	88
10a	50.0	44.5	1.00	500	26.5	60
10b	25.0	22.2	0.50	280	42.0	100
11	32.6	29.0	0.50	450	42.0	100
12	20.3	18.0	0.40	360	40.0	89

General Procedure for Catalytic TCP Degradation: In a typical experiment, for a catalyst/TCP ratio of 2 mol-%, 0.16 μmol of Fe^{III} or Co^{II} of the supported catalyst [i.e., 8.0 mg of **9** (loading 20.0 μmol/g), 6.0 mg of **10a** (loading 26.5 μmol/g), 3.8 mg of **10b** (loading 42.0 μmol/g), 3.8 mg of **11** (loading 42.0 μmol/g), 4.0 mg of **12** (loading 40.0 μmol/g)] and 40 μL of a 1.2 M aqueous solution of hydrogen peroxide (48.0 μmol) were added to a 1 mM TCP solution (8 mL, 8.0 μmol) in phosphate buffer 50 mM (pH = 7). The reaction mixture was stirred at room temperature and analyzed by HPLC. For the experiments carried out in the presence of an organic co-solvent, a 1 mM TCP solution was prepared in a mixture of 50 mM phosphate buffer/ethanol or acetone (80:20, v/v). Run 7 in Table 1 was carried out with a 1 mM TCP aqueous solution adjusted to pH = 7 with NaOH (final concentration of NaOH: 1 mM). When $KHSO_5$ was used as oxidant, a solution of Curox® (12.3 mg, 40.0 μmol) in water (100 μL) was added to the reaction mixture.

^{1}H NMR Analysis of the Degradation Products of TCP by the Catalytic 10a/H_2O_2 System: The supported catalyst **10a** (loading 26.5 μmol/g) (60.0 mg, 1.6 μmol) and 400 μL of a 1.2 M aqueous solution of hydrogen peroxide (480.0 μmol) were added to a 1 mM TCP solution (80 mL, 80.0 μmol) in a 50 mM phosphate buffer (pH = 7)/ethanol (80:20, v/v) mixture. The reaction mixture was stirred for 1 h at room temperature. After filtration of the supported catalyst **10a** and several washings with acetonitrile, the reaction mixture was dried under vacuum. Then 7 mL of 1 M HCl, saturated with NaCl, was added to the dry residue and the organic products were extracted with diethyl ether (3 × 60 mL). After concentration of the ether extracts, the solid residue was dissolved in deuterated dimethyl sulfoxide ([D_6]DMSO) for NMR analysis. Then 5 μL of $CHCl_3$ (62.0 μmol) was added as an internal standard to quantify the oxidation products. − ^{1}H NMR ([D_6]DMSO): δ =

6.39 (s, 2 H, maleic acid, 4%), 6.69 (s, 1 H, chloromaleic acid, 12%), 6.74 (s, 2 H, fumaric acid, 3%), 7.30 (s, 1 H, chlorofumaric acid, 3%), 7.80−8.10 (br, 2 H, coupling products, 6%). − It should be noted that these yields differ from one experiment to another, depending on the time the oxidation reaction was stopped.

General Procedure for Catalytic DTBC Degradation: In a typical experiment, for a catalyst/TCP ratio of 2 mol-%, 8.0 mg of the supported catalyst **9** (loading 20.0 μmol/g) (0.16 μmol) and 40 μL of a 1.2 M aqueous solution of hydrogen peroxide (48.0 μmol) were added to a 1 mM DTBC solution (8 mL, 8.0 μmol) in a 50 mM borate buffer (pH = 9)/acetonitrile (1:1, v/v) mixture or in 50 mM phosphate buffer (pH = 7)/acetonitrile (1:1, v/v) or in water/acetonitrile (1:1, v/v). The reaction mixture was stirred at room temperature and analyzed by HPLC.

^{1}H NMR Analysis of the Degradation Products of DTBC by the Catalytic 9/H_2O_2 System: The supported catalyst **9** (loading 20.0 μmol/g) (80.0 mg, 1.5 μmol) and 250 μL of a 1.2 M aqueous solution of hydrogen peroxide (300.0 μmol) were added to a 6.25 mM DTBC solution (8 mL, 50.0 μmol) in a water/acetonitrile (1:1, v/v) mixture. The reaction mixture was stirred for 45 min at room temperature. After filtration of the supported catalyst and several washings with acetonitrile, the reaction mixture was dried under vacuum. Then 7 mL of 1 M HCl, saturated with NaCl, was added to the dry residue and the organic products were extracted with diethyl ether (3 × 60 mL). After concentration of the ether extracts, the solid residue was dissolved in deuterated dimethyl sulfoxide ([D_6]DMSO) for NMR analysis. Then 2 μL of $CHCl_3$ (25.0 μmol) was added as an internal standard to quantify the oxidation products. − ^{1}H NMR ([D_6]DMSO): δ = 1.30 (s, 9 H, *t*Bu), 1.33 (s, 9 H, *t*Bu), 6.25 (d, *J* = 2.2 Hz, 1 H, HC=), 7.08 (d, *J* = 2.2 Hz, 1 H, HC=). − ^{13}C{^{1}H} NMR ([D_6]DMSO): δ = 27.7 (s, CH_3C), 29.1 (s, CH_3C), 35.1 (s, CH_3*C*), 35.8 (s, CH_3*C*), 121.9 (s, HC=), 133.5 (s, HC=), 149.0 (s, C=), 162.6 (s, C=), 180.0 (s, C=O), 180.6 (s, C=O).

Recycling of the Supported Catalysts in the Oxidative Degradation of TCP and DTBC

TCP Degradation by 10a and H_2O_2: The supported metallophthalocyanine **10a** [6.0 mg, loading 26.5 μmol/g (0.16 μmol of iron, 2 mol-%)] and 40 μL of a 1.2 M aqueous solution of H_2O_2 (48.0 μmol) were added to a 1 mM TCP solution (8 mL, 8.0 μmol) in a 50 mM phosphate buffer (pH = 7)/acetone (80:20, v/v) mixture. The oxidation reaction was stirred for 30 min at room temperature. A 0.16 M TCP solution (50 μL, 8.0 μmol) in acetone and 40 μL of a 1.2 M aqueous solution of H_2O_2 (48.0 μmol) were then added to the reaction mixture. The TCP conversion was monitored by HPLC analysis.

TCP Degradation by 9 and $KHSO_5$: The supported metallophthalocyanine **9** [(8.0 mg, loading 20.0 μmol/g (0.16 μmol of iron, 2 mol-%)] and 50 μL of a 0.8 M Curox® solution (40.0 μmol) in water were added to a 1 mM TCP solution (8 mL, 8.0 μmol) in 50 mM phosphate buffer (pH = 7). The oxidation reaction mixture was stirred for 5 min at room temperature. A 0.8 M TCP solution (10 μL, 8.0 μmol) in acetonitrile and 50 μL of a 0.8 M Curox® solution (40.0 μmol) were then added to the reaction mixture every 5 min. The TCP conversion was monitored by HPLC analysis.

DTBC Degradation by 9 and H_2O_2: The supported metallophthalocyanine **9** [(12.0 mg, loading 20.0 μmol/g (0.24 μmol of iron, 3 mol-%)] and 40 μL of a 1.2 M aqueous solution of H_2O_2 (48.0 μmol) were added to a 1 mM DTBC solution (8 mL, 8.0 μmol) in a water/acetonitrile (1:1, v/v) mixture. The oxidation reaction mixture was stirred for 30 min at room temperature. A 0.4 M DTBC solution (20 μL, 8.0 μmol) in acetonitrile and 40 μL of a 1.2 M aqueous solution of H_2O_2 (48.0 μmol) were then added to the reaction mixture every 30 min. The DTBC conversion was monitored by HPLC analysis.

Synthesis, Structure and Reactivity of a Zirconocene Dichloride with $(Me_3Si)_2NSiMe_2$ Side-Chains

Alexander Rau,*[a] Hans-Peter Dornik,[a] Helmut Paulus,[b] and Gerhard Luft[a]

Keywords: Metallocenes / Zirconium / N ligands / Structure elucidation / Cyclopentadienyl ligands

The new zirconocene $[(\eta^5\text{-}C_5H_4SiMe_2N(SiMe_3)_2]_2ZrCl_2$ (**1**) has been prepared in a convenient three-step synthesis. A crystal structure determination of **1** shows two molecules in the unit cell, one in which the $(Me_3Si)_2NSiMe_2$ groups are accommodated in a nearly synperiplanar conformation directly above and below the $ZrCl_2$ group, and one in which these groups exhibit a synclinal conformation. The reaction of **1** with a mixture of $SOCl_2/SO_2Cl_2$ leads to the formation of $[(\eta^5\text{-}C_5H_4SiMe_2Cl]_2ZrCl_2$ (**2**).

Introduction

Group 4 metallocene complexes bearing side-chains that can modify the steric and electronic properties of the metal centre have attracted growing interest in recent years due to their potential catalytic applications. The influence of alkyl groups attached to the cyclopentadienyl (Cp) unit on the structure-reactivity relation of metallocene catalysts has been intensively studied.[1−3] Metallocenes with side-chains containing NR_2, PR_2, OR and SR functions are found to have interesting catalytic properties due to intra- or intermolecular donor acceptor interactions.[4,5] Furthermore, ROSi[6−8] and ClSi[8] functions can be used for anchoring metallocene pre-catalysts *covalently* on solid surfaces.

In this paper we describe the synthesis of the new zirconocene $[(\eta^5\text{-}C_5H_4SiMe_2N(SiMe_3)_2]_2ZrCl_2$ (**1**). The influence of the bulky group attached to the Cp fragment on the molecular structure is discussed. In addition, we report on the conversion of complex **1** into $[(\eta^5\text{-}C_5H_4SiMe_2Cl]_2ZrCl_2$ (**2**).

Results and Discussion

$[(\eta^5\text{-}C_5H_4SiMe_2N(SiMe_3)_2]_2ZrCl_2$ (**1**) was prepared on a large scale by the synthetic route depicted in Scheme 1. All the synthetic steps were performed at room temperature. In the first step, potassium bis(trimethylsilyl)amide was reacted with an excess of Me_2SiCl_2 to give $(Me_3Si)_2NSiMe_2Cl$, which was obtained as a colourless oil after distillation. Reaction of $(Me_3Si)_2NSiMe_2Cl$ with CpNa in THF resulted in the new cyclopentadiene $(Me_3Si)_2NSiMe_2Cp$, which was isolated as a mixture of three isomers after distillation.[9] The target complex **1** was synthesized by deprotonation of $(Me_3Si)_2NSiMe_2Cp$ with *n*BuLi and a subsequent salt metathesis reaction of the resulting lithium cyclopentadienyl compound with $ZrCl_4$.

$$KN(SiMe_3)_2 \xrightarrow{Me_2SiCl_2} (Me_3Si)_2NSiMe_2Cl \xrightarrow{NaCp} CpSiMe_2N(SiMe_3)_2$$

$$2\ CpSiMe_2N(SiMe_3)_2 \xrightarrow[2)\ ZrCl_4]{1)\ n\text{BuLi}} [\eta^5\text{-}C_5H_4SiMe_2N(SiMe_3)_2]_2ZrCl_2$$

1

Scheme 1

Due to the lipophilic trimethylsilyl groups,[10,11] complex **1** is highly soluble in hydrocarbons, which made necessary two successive low-temperature crystallisations from the mother liquor to obtain a 58% yield of **1** as colourless crystals. The NMR spectra of **1** recorded at room temperature give no indication of a hindered rotation of the Cp moieties, as is known for related metallocenes with sterically demanding cyclopentadienyl ligands.[12] In the ^1H NMR spectrum, the Cp hydrogens appear as two multiplets centred at $\delta = 6.67$ and 6.37, and the trimethyl silyl groups appear as two sharp singlets at $\delta = 0.04$ and 0.48.

Single crystals of **1** suitable for X-ray diffraction were obtained by slow cooling of toluene solutions. Figure 1 shows the two molecular structures of **1** that are found in the unit cell in a 1:1 ratio. Both molecular structures show the expected pseudo-tetrahedral coordination of the zirconium atom. As shown in Figure 2 and listed in Table 1, the molecular structures of $(RC_5H_4)_2ZrCl_2$ compounds with bulky R groups can be divided into three distinct types with different conformations of the cyclopentadiene moieties.[10,13−15] According to the data in Table 1, the size and the degree of rotational freedom of the R groups seem to determine what type of structure is formed: compounds that contain bulky substituent groups with a fixed geometry adopt structure type I, whereas the other compounds prefer the structure types II or III. Remarkably, single crystals of complex **1** contain the structure types II and III, whereas

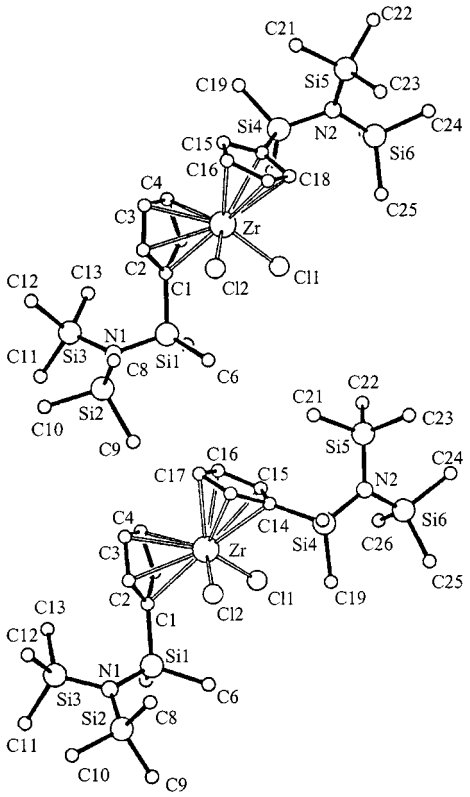

Figure 1. Molecular structures of 1 together with atomic labelling scheme

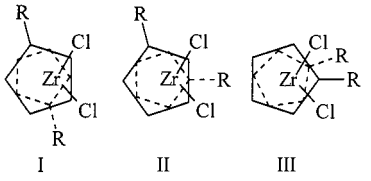

Figure 2. Structure types of $(\eta^5\text{-}RC_5H_4)_2ZrCl_2$ compounds

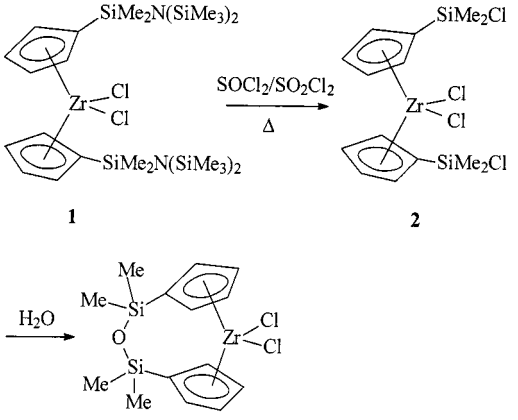
the unit cells of the other compounds contain only one single molecular structure.

As displayed in Table 1, the (Cp centroid)−Zr−(Cp centroid) bond angles and the Zr−(Cp centroid) bond lengths of complex **1** are in the range of other $(RC_5H_4)_2ZrCl_2$ compounds, whereas the Cl−Zr−Cl bond angles of **1** are increased relative to those of related compounds. In particular, the structure type III of **1** shows a widened Cl−Zr−Cl bond angle (105.7°). This is probably due to the steric bulk of the Cp ligands. The same trend concerning the Cl−Zr−Cl bond angle was found with $(R_2C_5H_3)_2ZrX_2$ metallocenes.[10]

Attempts to prepare the mono-cyclopentadienyl complex $[(\eta^5\text{-}C_5H_4SiMe_2N(SiMe_3)_2]ZrCl_3$ by reaction of $[(Me_3Si)_2NSiMe_2C_5H_4]Li$ with one equivalent $ZrCl_4$ failed. Even if the reaction was performed with a large excess of $ZrCl_4$, only the sandwich complex **1** could be isolated. This must be due to ligand redistribution reactions of the zirconium trichloride leading to complex **1** and $ZrCl_4$, as has already been reported by Lappert and co-workers for $(\eta^5\text{-}C_5H_4Bu^t)_2ZrCl_2$ in the presence of THF.[11] Apart from some exceptions, such as $[(\eta^5\text{-}C_5H_3(SiMe_3)_2]_2ZrCl_2$, they observed that in the absence of THF, in toluene as solvent, the redistribution reaction of $(\eta^5\text{-}C_5H_{5-n}R_n)ZrCl_2$ with $ZrCl_4$ can be directed to the monocyclopentadienyl zirconium trichlorides. However, we observed no reaction of complex **1** with $ZrCl_4$ in toluene at room temperature.

Another method for the preparation of mono-cyclopentadienyl complexes from the corresponding dichlorides has been described by Garg and co-workers.[16] They refluxed Cp_2TiCl_2 with a mixture of $SOCl_2/SO_2Cl_2$ to produce $CpTiCl_3$ in more than 90% yield. However, we found that the reaction of $[(\eta^5\text{-}C_5H_4SiMe_2N(SiMe_3)_2]_2ZrCl_2$ (**1**) in refluxing $SOCl_2/SO_2Cl_2$ leads to $(\eta^5\text{-}C_5H_4SiMe_2Cl)_2ZrCl_2$ (**2**). No trichloride products were found (Scheme 2). Complex **2** is extremely sensitive to moisture and reacts on addition of a stoichiometric amount of water to form the bridged complex $[(\eta^5\text{-}C_5H_4)SiMe_2OSiMe_2(\eta^5\text{-}C_5H_4)]ZrCl_2$,



Scheme 2

as already described by Royo and co-workers for the analogous Ti and Hf complexes of **2**.[17]

Group 4 metallocenes bearing reactive groups like Me_3OSi or $ClSiMe_2$ cannot be produced by the classic salt metathesis reaction of alkali metal cyclopentadienyl compounds with transition metal chlorides.[6] Instead of this synthetic pathway, the central metal has to be introduced by the reaction of the cyclopentadiene compounds with metal amides,[6] or, if groups attached to the cyclopentadiene ring increase its acidity, by refluxing the cyclopentadiene compound in the presence of metal tetrachlorides and triethylamine.[17] As we have shown, the $(Me_3Si)_2NSiMe_2$ group is not sensitive to strong bases like *n*BuLi and, in complex **1**, is easily transformed to the $ClSiMe_2$ group, which opens up the classic synthetic pathway to zirconocenes with the $ClSiMe_2$ function.

Conclusion

The new metallocene complex $[(Me_3Si)_2NSiMe_2C_5H_4]_2ZrCl_2$ (**1**) bearing bulky, functionalized side-chains was prepared on a large scale in a convenient three-step synthesis. The X-ray analysis of **1** shows that the unit cell contains two different molecular structures in a 1:1 ratio. The structures differ from the conformation of the cyclopentadiene rings. In one of these conformations, the side-chains are positioned in a nearly synperiplanar conformation at the open side of the sandwich complex. When the molecular structures of **1** and related $(RCp)_2ZrCl_2$ compounds with bulky R groups are compared, it can be concluded that this conformation requires R groups with a certain degree of rotational freedom, which allows less steric congestion in this conformation.

The reaction of complex **1** with $SOCl_2/SO_2Cl_2$ leads to $(\eta^5\text{-}C_5H_4SiMe_2Cl)_2ZrCl_2$ (**2**) in good yields. Group 4 metallocenes with reactive side-chains containing $ClSiMe_2$ functions are interesting precursors for heterogeneous catalysts. Because of the reactive group these metallocenes cannot be produced by the classic reaction of metal chloride salts with the alkali metal derivatives of the ligand system. In one example, we have shown that the $(Me_3Si)_2NSiMe_2$ group can be used as a protecting group of the $ClSiMe_2$ function in zirconocene synthesis, which opens up the classic synthetic pathway to zirconocenes bearing the $ClSiMe_2$ group.

Experimental Section

General: All experiments with air-sensitive materials were carried out under an atmosphere of argon using standard Schlenk techniques. Solvents were dried over Na-K alloy (THF, hexane, toluene, diethyl ether) or calcium hydride (dichloromethane), followed by distillation and storage under argon. ^1H (300 MHz) and ^{13}C (75 MHz) NMR spectra were recorded on either a Bruker ARX 300 or a Bruker AC 300 spectrometer. The mass spectra were determined using a Varian MAT 311A instrument. The elemental analyses were obtained using a Perkin−Elmer CHN 240B instrument.

$(Me_3Si)_2NSiMe_2Cl$: $KN(SiMe_3)_2$ (100.82 g, 0.505 mol) and 500 mL of toluene were added to a three-necked flask equipped with a stirring device. Then, Me_2SiCl_2 (400 mL, 3.298 mol) was added dropwise within 2 h. The resulting mixture was stirred for 4 days. The volatiles were then removed in vacuo. The resulting suspension was filtered, and the residue was washed three times with 75 mL of hexane. The volatiles of the filtrate were removed in vacuo and the residue was distilled at 10^{-2} mbar. The fraction between 99 and 101 °C yielded 108.39 g (0.427 mol, 84.5%) of $(Me_3Si)_2NSiMe_2Cl$ as a colourless oil. − ^1H NMR ($CDCl_3$): δ = 0.25 (s, 18 H, $SiMe_3$), 0.55 (s, 6 H, $SiMe_2$). − MS (FI): *m*/*z* = 254 $[M]^+$, 219 $[M - Cl]^+$.

$(Me_3Si)_2NSiMe_2Cp$: $(Me_3Si)_2NSiMe_2Cl$ (107.95 g, 0.425 mol) and 100 mL of THF were placed in a flask, and then 232 mL of NaCp solution (0.464 mol, 2 M in THF) were added dropwise. The resulting mixture was stirred for 2 days. Most of the solvent was removed in vacuo and then 200 mL of hexane was added. The resulting suspension was filtered and the brown residue was washed three times with 50 mL hexane. The volatiles of the filtrate were removed in vacuo to give 106.74 g (0.376 mol) of the crude product as a brown oil, which was further purified by distillation at 10^{-2} mbar. The fraction between 148 and 150 °C yielded $(Me_3Si)_2NSiMe_2Cp$ (54.59 g, 0.193 mol, 45%) as a pale yellow oil (mixture of three isomers 10:10:1 by ^1H NMR spectroscopy). − ^1H NMR of all isomers ($CDCl_3$): δ = −0.01 (s, 6 H, $SiMe_2$), 0.13 (s, 18 H, $SiMe_3$), 0.14 (s, 6 H, $SiMe_2$), 0.23 (s, 18 H, $SiMe_3$), 0.29 (s, 18 H, $SiMe_3$), 0.30 (s, 6 H, $SiMe_2$), 2.99 (br. s, 2 H, CH_2, both main isomers), 3.64 (br. s, 1 H, CH saturated), 6.41−6.77 (m, CH, unsaturated, all isomers). − MS (FD): *m*/*z* = 283 $[M]^+$, 218 $[M - C_5H_5]^+$. − $C_{13}H_{29}NSi_3$ (283.64): calcd. C 55.05, H 10.31, N 4.94; found C 54.78, H 10.55, N 4.69.

$[(Me_3Si)_2NSiMe_2C_5H_4]_2ZrCl_2$ (1): $(Me_3Si)_2NSiMe_2Cp$ (22.08 g, 0.078 mol), 200 mL of hexane and 200 mL of toluene were placed into a flask, and then 50 mL of *n*BuLi (0.080 mol, 1.6 M in hexane) were added dropwise. The resulting solution was stirred for 18 h and then added to a suspension of $ZrCl_4$ (9.32 g, 0.040 mol) in 200 mL of toluene. Next, 150 mL of THF were slowly added dropwise to the suspension and the resulting mixture was stirred for 2 days. After sedimentation of the solids, the liquid phase was removed with a cannula, and the residue was washed with 100 mL of hexane and filtered. The resulting liquids were combined, and the volatiles were removed in vacuo to produce a brown solid residue. Crystallisation from hexane/toluene at low temperatures gave colourless crystals of **1** (22.89 g, 0.031 mol, 39.7%). From two successive crystallisations of the mother liquor, further 10.45 g (0.014 mol, 17.9%) of **1** could be isolated. − ^1H NMR ($CDCl_3$): δ = 0.08 (s, 36 H, $SiMe_3$), 0.52 (s, 18 H, $SiMe_2$), 6.41 ("t", 4 H, Cp), 6.71 ("t", 4 H, Cp). − ^{13}C NMR ($CDCl_3$): δ = 5.38 ($SiMe_2$), 5.67 ($SiMe_3$), 114.42 (CH), 127.99 (C_q), 129.06 (CH). − MS (FD): *m*/*z* = 727 $[M^+]$. − $C_{26}H_{56}Cl_2N_2Si_6Zr$ (727.38): calcd. C 42.93, H 7.76, N 3.85; found C 42.63, H 7.86, N 3.91.

X-ray Crystal Structure Analysis of 1

Structural analysis SHELXS-86, refinement on F^2, hydrogen positions geom., R_1 = 0.0370 and wR_2 = 0.0815. Programs used SHELXS-86 and SHELXL-93.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-152331. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$(ClMe_2SiC_5H_4)_2ZrCl_2$ (2): Compound **1** (3.40 g, 4.68 mmol) was placed in a flask and a solution of SO_2Cl_2 (5 mL, 62.24 mmol) and $SOCl_2$ (14 mL, 191.93 mmol) was added dropwise. The resulting mixture was refluxed for 2 h and then filtered. The volatiles of the filtrate were removed in vacuo to produce a light brown residue. Recrystallisation from toluene/hexane yielded **2** (1.10 g, 2.30 mmol; 50%). – ^{1}H NMR ($CDCl_3$): δ = 0.72 (s, 12 H, $SiMe_2Cl$), 6.57 (m, 4 H, C_5H_4), 6.78 (m, 4 H, C_5H_4). – ^{13}C NMR ($CDCl_3$): δ = 3.2 ($SiMe_2$), 116.7 (C_{ipso} (C_5H_4), 122.5, 126.3 [CH of (C_5H_4)]. – MS (EI): *m*/*z* = 478 $[M]^+$, 320 $[M - C_5H_4SiClMe_2]^+$, 122 $[C_5H_4SiMe_2]^+$. – $C_{14}H_{20}Cl_4Si_2Zr$ (477.52): calcd. C 35.21, H 4.22; found C 35.48, H 4.35.

$[(\eta^5\text{-}C_5H_4)SiMe_2OSiMe_2(\eta^5\text{-}C_5H_5)]ZrCl_2$: Water (35 μL) was added to a solution of **2** (810 mg, 1.69 mmol) in 25 mL of toluene. The resulting solution was stirred for 12 h at room temperature, and then the volatiles were removed in vacuo. Recrystallisation of the residue from toluene/hexane yielded $[(\eta^5\text{-}C_5H_4)SiMe_2OSiMe_2(\eta^5\text{-}C_5H_5)]ZrCl_2$ (574 mg, 1.36 mmol; 80%) as pale yellow crystals. – ^{1}H NMR ($CDCl_3$): δ = 0.36 (s, 12 H, $SiMe_2$), 6.53 ("tr", 4 H, C_5H_4), 6.84 ("tr", 4 H, C_5H_4). – ^{13}C NMR ($CDCl_3$): δ = 0.9 ($SiMe_2$), 117.2 [(C_{ipso} (C_5H_4)], 122.4, 125.7 [CH (C_5H_4)]. – MS (EI): *m*/*z* = 422 $[M]^+$, 407 $[M - CH_3]$. – $C_{14}H_{20}Cl_2OSi_2Zr$ (422.61): calcd. C 39.79, H 4.77, found C 39.76, H 5.92.

New Polypodal Polycarboxylic Ligands − Complexation of Rare-Earth Ions in Aqueous Solution

Romain Viguier,[a] Guy Serratrice,*[b] Agnes Dupraz,[a] and Claude Dupuy[a]

Keywords: Lanthanides / Carboxylic acids / Thermodynamics / N ligands / NMR spectroscopy

The complexation ability of new polypodal carboxylic ligands prepared from 2,2-bis(hydroxymethyl)-1-alkanols was investigated in aqueous solution with Y^{3+} and various lanthanide ions (La^{3+}, Sm^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}). The values of the stability constants for ML complexes are of the order of 10^4 for the hexadentate trioxypropionates, 10^7 for the hexadentate trioxyacetates and 10^{14} for the nonadentate triaminohexaacetates. In these systems, the nitrogens of the amino groups seem to be better chelating atoms than the oxygens of the ether groups. The hydration numbers of dysprosium(III) complexes have been determined from the Dy^{III}-induced ^{17}O NMR water shifts.

Introduction

The design of polypodal ligands capable of forming stable complexes for in vivo use has received increasing interest in the past decade.[1] With a view towards the preparation of new complexing systems for yttrium and some lanthanide ions which could be used for radiotherapy or as biomedical radiolabels (^{90}Y, ^{153}Sm, ^{165}Dy), we undertook the synthesis of a series of new polypodal ligands: trioxypropionic acids (TOTP),[2] trioxytriacetic acids (TOTA)[3] and triaminohexaacetic acids (TAHA) (see Figure 1). Derivatives of these compounds for conjugation with a biomolecule (such as a monoclonal antibody or peptide) should be easier to prepare than macrocyclic ligands bearing carboxylate groups, which are well-known for their ability to complex yttrium and lanthanides ions.[1,4]

In this paper we report the stability constants of the 1:1 complexes (ML) of these ligands with yttrium(III) and a variety of lanthanide(III) cations in aqueous solution as determined potentiometrically. The ^{17}O NMR spectra in variable pH solutions of the Dy^{III} complexes are also described in order to gain information on their coordination sphere in aqueous solution. A shift of the water ^{17}O NMR signal (Dysprosium Induced Shift, DIS) is induced upon addition of dysprosium(III) complexes to water that is related to the number of coordinated water molecules in the complex.

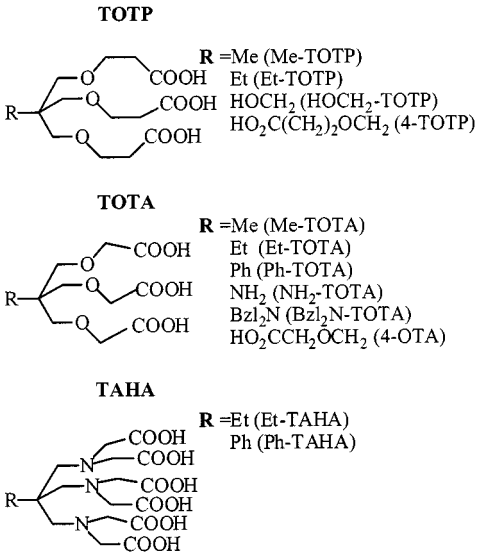

Figure 1. Structure of the ligands

Results

Ligands Synthesis

The TOTP and TOTA ligands are easily accessible from inexpensive commercial primary polyols. These preparations involve two steps: the formation of the ether linkages followed by the hydrolysis of the *tert*-butyl ester functions with formic acid. The polyetherifications were accomplished by phase-transfer catalysis[2,3] with *tert*-butyl acrylate or *tert*-butyl bromoacetate (Figure 2).

The TAHA ligands were also synthesised from primary polyols using the procedure described by Hellmann and coworkers[5] to prepare 1,1,1-tris(aminomethyl)phenylmethane (Figure 3).

Ligand Deprotonation Constants

The deprotonation constants K_a of the ligands investigated in this research were studied by potentiometric titration. Analysis of the potentiometric titration curves (see Figure 4 for examples and details in Exp. Section) by the SUPERQUAD[6] program yielded the pK_{an} values defined by Equation (1) and (2) (charges omitted for clarity):

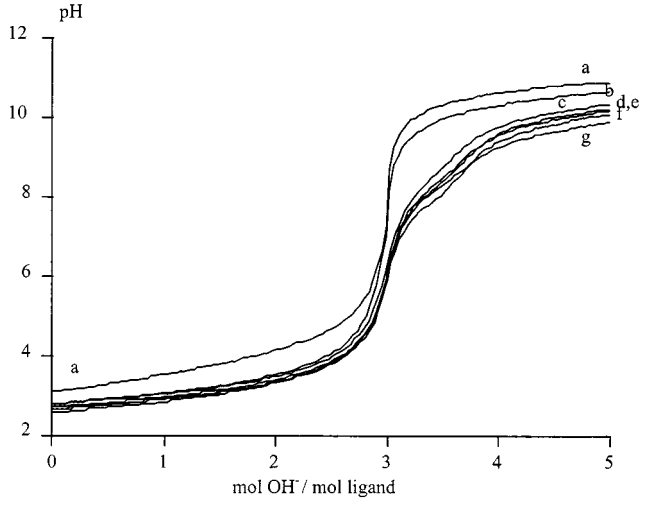

Figure 4. Potentiometric titration curves for (a) 1 mM ligand Me-TOTA and (1:1 1 mM Me-TOTA + (b) La^{3+}, (c) Sm^{3+}, (d) Eu^{3+}, (e) Tb^{3+}, (f) Gd^{3+}, (g) Y^{3+}; all solutions were at 25 °C and $I = 0.1$ M (NMe_4Cl); the data were refined by the SUPERQUAD program

$$LH_n \rightleftarrows LH_{n-1} + H^+ \quad (1)$$

$$K_{an} = [LH_{n-1}]\,[H^+]/[LH_n] \quad (2)$$

The ligands of the series TOTA and TOTP possess three carboxylic groups and the tetrapodal ligands 4-OTA and 4-TOTP four carboxylic groups. The two derivatives NH_2-TOTA and $N(Bz)_2$-TOTA have a fourth ionizable proton in an ammonium group. The pK_{an} values are listed in Table 1. For the ligand of the tri(amino)hexaacetic acid series, denoted Ph-TAHA, the pK_{an} of three carboxylic groups (three pK_{an} values are too low to be determined from potentiometric titration) and of the three ammonium groups have been determined. The values are reported in Table 2 together with literature data for tripodal ligands incorporating aminocarboxylate groups.

Stability Constants of the Metal Complexes

The stability constants were determined from potentiometric titration of ligand/metal solutions at a molar ratio of 1:1. (for example, as shown in Figure 4). The titration curves for ligands Me, Et, Ph-TOTA and *R*-TOTP exhibit buffer regions over the pH range 7−10 owing to the formation of hydroxo complexes; however, a precipitation occurred and precluded the use of the data in refinement program. No precipitation was observed below pH 10 for ligands the NH_2, $N(Bz)_2$ and 4-OTA. Analysis of the titration curves was performed over the pH range 2.5−6 by the

SUPERQUAD program[6] yielding the K_{ML} and K_{MLH_n} constants. The best fit of the data was obtained by considering only the 1:1 species. The values are reported in Table 3 (*R*-TOTA) and Table 4 (*R*-TOTP).

served DIS represents a concentration-weighted average of the shifts of the individual species in solution. The experimental DIS was measured for different Dy^{III} concentrations. The plot of the DIS versus [Dy^{III}] gives a straight line

With the ligand Ph-TAHA we investigated the complexation of the cations Sm^{3+}, for comparison with the other ligands, Dy^{3+}, for comparison with the NMR study, and Ce^{3+}. No precipitation occurred above pH 7 and the titration data were refined over the pH range 2.5–8. A comparison of the titration curves of the ligand solution and of the metal-ligand solution (Figure 5) indicates that no hydroxo complexes are formed at basic pH's, which is contrary to the ligands of the TOTA and TOTP series. The stability constants are shown in Table 5.

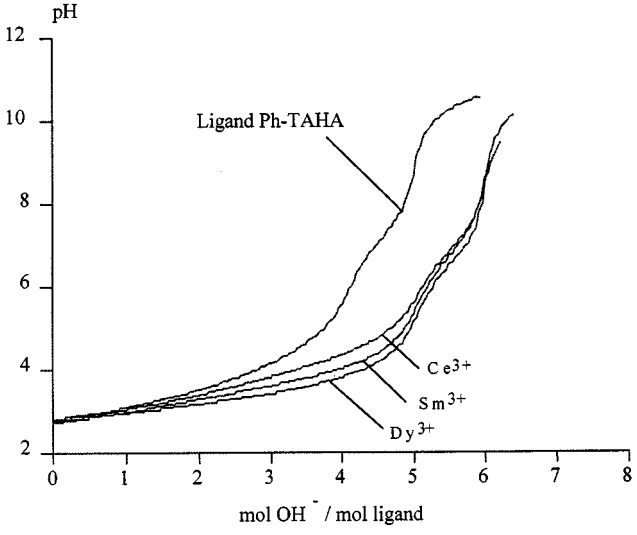

Figure 5. Potentiometric titration curves for 1 mM Ph-TAHA and Ph-TAHA + Ln^{III} (1:1; 1 mM); all solutions were at 25 °C and I = 0.1 M (NMe_4Cl); the data were refined by the SUPERQUAD program

^{17}O NMR Spectroscopy

The number of water molecules present in the lanthanide complexes was investigated by dysprosium-induced ^{17}O shift measurements. From these a qualitative picture of the lanthanide coordination sphere can be deduced. Addition of Dy^{III} complexes to water results in a shift of the water signal in the ^{17}O NMR spectrum to lower frequencies. Peters and co-workers[7] have shown that the dysprosium-induced shift of water (DIS) can be utilised to estimate the number of bound water molecules associated with the lanthanide complexes. The exchange between bound and bulk water is fast on the NMR time scale. Accordingly, the ob-

	log K(MLH_2)[d]	4.53(2)	4.17(1)	3.95(7)	
	log K(MLH_4)[e]	7.30(6)	6.88(2)	6.59(9)	

[a] All values are determined at 25 °C and I = 0.1 M (NMe_4Cl); standard deviation of the last significant digit (95% confidence level) in parentheses. – [b] calculated for $[L]_{tot} = 10^{-3}$ M, $[Sm^{3+}]_{tot} = 10^{-3}$ M and pH = 7. – [c] K(ML) = [ML]/[M][L]. – [d] $K(MLH_n) = [MLH_n]/[MLH_{n-1}][H]$. – [e] $K(MLH_4) = [MLH_4]/[MLH_2][H]^2$.

with a slope proportional to the number of bound water molecules in the complex. DIS measurements were carried out for the ligands Ph-TOTA, 4-OTP and Ph-TAHA. Following the procedure described by Peters,[7] the DIS for solutions of the hydrated cation $[Dy(H_2O)_8]^{3+}$ at pH 6.5 were measured, these results produced a slope of 358 ppm M^{-1} (Figure 6a or 7a) which is in excellent agreement with that obtained in Peters's paper (−357 ppm M^{-1}). Therefore, a value of 45 ppm M^{-1} can be calculated for one coordinated water molecule if the cation is hydrated by eight water molecules.[8] DIS measurements were also performed for solutions of the complex $[Dy(ligand)(H_2O)_q]^{3+}$ over the pH range 1−5 for Ph-TOTA, 2−5 for 4-OTP and 1−9 for Ph-TAHA. The experimental slopes p of the plots of the DIS versus $[Dy(ligand)(H_2O)_q]$ (Figure 6 and 7) were determined. The p values and the calculated water coordination numbers, q, are shown in Table 6. The q values indicate that the number of coordination positions for the ligand increase as the pH increases (Table 6) which agrees with the existence of different protonated species.

Discussion

Ligand Deprotonation Constants

For the ligands of the series *R*-TOTA it should be noted that the average values of the carboxylic pK_a over a range 3.21−3.61 in the tripodal ligands are close to the value of 3.31 for the analogous monodentate methoxyacetic acid.[9] For the ligands of the series TOTP the pK_{an} values are higher than those for the ligands *R*-TOTA, owing to the presence of a second methylene group which acts as an electron donor. A similar effect is observed in 3-hydroxypropionic acid (pK_a = 4.32[9]) in comparison to hydroxyacetic acid (pK_a = 3.63).[9] Furthermore, the separation of the pK_{an} values for a given ligand is in the range 0.39−1.05 [except for a value of 0.29 for $N(Bz)_2$-TOTA]. This reflects a rough statistical separation (log 3 or 0.48), which is consistent with noninteracting pendant arms. For the ligand Ph-TAHA, the three highest and the three lowest pK_a values are attributed to the ammonium and carboxylic

groups, respectively. The acidities of the ammonium groups are close to those of the ligands TAMETA [1,1,1-tris-(aminomethyl)ethane-*N*,*N*′,*N*′′-triacetic acid][10] which has a similar tripodal structure. The pK_a's of the carboxylic groups are comparable to those of the ligand TAPHA (1,2,3-triaminopropanehexaacetic acid)[11] which contains three aminodiacetic arms.

Stability Constants of the Metal Complexes

A small change in the stability constant *K*(ML) is observed on going from Sm^{3+} to Tb^{3+} and for Y^{3+}. The values for La^{3+} are smaller than those for the other cations owing to its larger size and its lower Lewis acidity. The same trend has been observed for EDTA complexes.[9] The ligands TOTP appear to be poor chelators of Ln^{III} ions, since their stability constants are two or three orders of magnitude lower than those of the TOTA series. This result shows that the presence of longer chains in TOTP than in TOTA ligands makes the complexation of Ln^{III} ions unfavorable, probably due to their higher flexibility. Furthermore, the coordination of carboxylic groups could be hindered by their weak acidity. Accordingly, the water coordination number of 6 (Table 6) (corresponding to a ligand coordination number of 2 or 3) for 4-OTP, as determined by ^{17}O NMR spectroscopy, is not unexpected even for a tetrapodal ligand. For the complex with Ph-TOTA, the value $q = 5$ suggests a coordination of three carboxylates in the ML species. These results clearly show that the ether oxygens are not involved in the coordination to the cation. The complexation constants for the lanthanides with ligands having the same backbone as the TOTA series, each arm containing one or two ethylenoxy moieties ($CH_2CH_2OCH_2CH_2CO_2H$ or $CH_2CH_2OCH_2CH_2OCH_2CH_2CO_2$ H), have also been measured (not described here).[12] These ligands were found to have stability constants *K*(ML) approximately equal to those for the *R*-TOTP ligands. This result also supports the fact that the ether oxygens are not involved in the complexation to the cations and that the carboxylate anions alone are responsible for the complexation.

Since the ligands are weak acids, proton competition occurs depending on their pK_a and the pH. The pM (= −log[M]) is thus a more reliable parameter for a comparison of ligand effectiveness under given conditions of pH, M and L concentrations: the larger the pM values, the more effective the ligand. The pM values for the cation Sm^{3+} ($[L]_{tot} = 10^{-3}$ M, $[Sm^{3+}]_{tot} = 10^{-3}$ M) over the pH range 3−7 for the ligands *R*-TOTA and 3−9 for the ligand Ph-TAHA have been calculated and are presented on the plot of pSm vs. pH in Figure 8. The values of pSm at pH 7 are reported in Table 3 and 5. For the ligands *R*-TOTA, the pSm values for R = Me, Et or Ph are very close and much higher than those for the ligands NH_2-TOTA and $N(Bz)_2$-TOTA at acidic pH. These ligands are protonated at the nitrogen and the positive charge is assumed to reduce the affinity of the ligand for the lanthanide cation. However, at pH > 6 for $N(Bz)_2$-TOTA and pH > 7 for NH_2-TOTA, this affinity is greatly enhanced. This could be ascribed to the coordination of the cation with the nitrogen of the amine. The pSm value for the ligand 4-OTA is about 0.5 units higher than those for the *R*-TOTA ligands, showing that a fourth arm increases the affinity for the cation, and is probably involved in the coordination. Furthermore, it can be seen that these three ligands prevent the precipitation of hydroxo complexes in neutral and basic mediums.

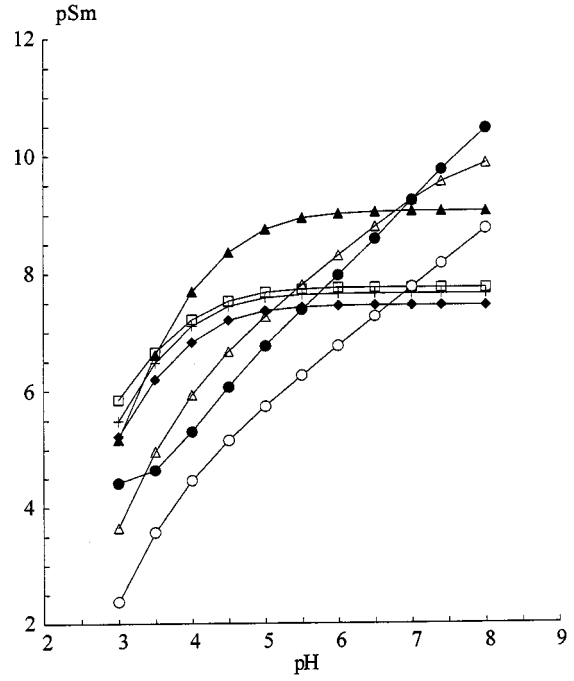

Figure 8. Plot of pSm vs. pH for the ligands; pSm was calculated for $[L]_{tot} = 10^{-3}$ M, $[Sm^{3+}]_{tot} = 10^{-3}$ M using the known constants of Me-TOTA (◆), Et-TOTA (□), Ph-TOTA (+), NH_2-TOTA (○), NBz_2-TOTA (Δ), 4-OTA (▲) and Ph-TAHA (●)

The pSm vs. pH curve indicates that the ligand Ph-TAHA is a poorer complexing agent in an acidic medium, but is more efficient at pH above 7, than the other ligands described in this paper. The obvious advantage of this ligand is much greater efficiency of complexation in basic media and an increase in the coordination number as the pH increases, as determined by the ^{17}O NMR study. The water coordination number *q* varies from a mean value of 4 over the pH range 1−3 to a mean value of 1.5 over the pH range 4−6. The latest value reflects the contribution of several species, among which [DyLH] is predominant with a hexadentate ligand. At pH 9, the *q* value of 1.1 attributed to the [DyL] species indicates that the coordination to the ligand is heptadentate with one water molecule. This suggests that the six carboxylate oxygens and one nitrogen are involved in the coordination to the cation. As a consequence, no hydroxo complexes are formed at basic pH. This reflects the low Lewis acidic character of the cation in the complex ML.

Conclusion

Our results have shown that the coordination to the lanthanides ions involves the carboxylate groups alone and not

the oxygens from the ether groups (TOTP or TOTA), while the nitrogen in similar polypodal ligands does participate in the chelation (TAHA). The presence of amino groups enhances the stability constants of the complexes, thus preventing the formation of hydroxo complexes or precipitation of metal hydroxides at pH close to or above 7. The formation of 1:1 complexes leads to a relatively high hydration number as determined by Dy^{III}-induced ^{17}O NMR water shifts. A value of 5 has been obtained for the tris(carboxylate) ligands and a value of 2 for the tris(aminocarboxylate) ligands. This hydration state is expected to provide interesting relaxivity properties for these complexes. However, the results in terms of the potentialities of these ligands in biomedical applications are still not satisfactory. With some ligands of the TOTP series, the bioconjugation with a fragment of monoclonal antibody [*anti*-ACE(F6)] has been realized.[2] A study of ^{111}In radiolabelling indicated that one ligand is linked to the $F(ab')_2$ but the complexes of these bioconjugated polypodal ligands with ^{153}Sm are not stable enough to be purified.

Experimental Section

Materials: Hydrated lanthanide chlorides were obtained from Aldrich. All other compounds were of reagent grade and were used without further purification.

Instrumentation: ^1H NMR spectra (200, 250 and 300 MHz) are referenced to TMS and recorded on Bruker AC 200, Bruker AWM 250 or Bruker AM 300 spectrometers. ^{17}O NMR spectra (natural abundance) were recorded at 54.24 MHz on a Bruker AM 300 spectrometer, using 5 mm sample tubes. Mass spectra were obtained with a NERMAGT1OC quadrupolar instrument. Infrared spectra were obtained as KBr disks for solid compounds and as pure film products between two NaCl discs for oils on a Nicolet Impact 400 spectrometer driven by the OMNIC program on a PC. Elemental analyses were performed by Le Service Central d'Analyses du CNRS in Vernaison (France). Melting points were measured on a Buchi-Tottoli apparatus and are uncorrected.

Synthesis of *R*-TOTP and *R*-TOTA: These ligands were prepared by acid hydrolysis from the corresponding polyesters, which were themselves prepared by a previously described method.[2,3]

Synthesis of Ph-TAHA

1,1,1-Tris(hydroxymethyl)phenylmethane: A solution of phenylacetaldehyde (10.75 g, 0.09 mol), paraformaldehyde (16.8 g, 0.56 mol) and $Ca(OH)_2$ (5.2 g, 0.70 mol) in THF (60 mL) was stirred at 60−65 °C for four days. After cooling to room temperature, the mixture was filtered through celite gel and the solvent was evaporated under vacuum (0.05 Torr). The residual oil was dissolved in hot ethyl acetate. Under standing at room temperature the product crystallized as a white powder (9.55 g, 58%), m.p. 80−81 °C. − $C_{10}H_{14}O_3$ (182.22): calcd. C 65.32, H 7.50; found C 65.93, H 7.69. − ^1H NMR ($CDCl_3$): δ = 3.92 (s, 6 H, CH_2OH), 7.18−7.46 (m, 5 H, aromatic CH). − ^{13}C NMR ($CDCl_3$): δ = 48.7 (C_6H_5-*C*), 65.8 (CH_2OH), 126.7, 127.2, 129.0 and 138.4 (C_6H_5).

1,1,1-Tris[(4-tolylsulfonyl)methyl]phenylmethane: *p*-Toluenesulfonyl chloride (36.5 g, 0.191 mol) was slowly added to a solution of 1,1,1-tris(hydroxymethyl)phenylmethane (8.717 g, 0.048 mol) in cold pyridine (90 mL) at a rate such that the temperature remained between 5 and 10 °C. After stirring at room temperature for half an hour, the mixture was poured into 15 mL of cold water. The product obtained was filtered, washed with diethyl ether (3 × 20 mL) and dried in vacuo for a few days to yield 27.76g (90%) of a white powder, m.p. 136 °C. − $C_{31}H_{32}O_9S_3$ (644.77): calcd. C 57.66, H 5.06; found C 57.75, H 5.00. − ^1H NMR ($CDCl_3$): δ = 2.45 (s, 9 H, CH_3), 4.18 (s, 6 H, CH_2), 6.94−7.19 (m, 5 H, C_6H_5), 7.29 and 7.32 (d, *J* = 7.13 Hz, 6 H, Tos-H^2), 7.60 and 7.62 (d, *J* = 6.34 Hz, 6 H, Tos-H^3). − ^{13}C NMR ($CDCl_3$): δ = 21.7 (CH_3), 46.0 (C_6H_5-*C*), 68.9 (CH_2), 126.1 (C_6H_5-C^4), 127.6 (Tos-C^2), 127.9 (Tos-C^3), 128.7 (C_6H_5-C^2), 130.0 (Tos-C^3), 131.6 (Tos-C^4), 134.7 (C_6H_5-C^1), 135.2 (Tos-C^1).

1,1,1-Tris(azidomethyl)phenylmethane: 1,1,1-Tris[(4-tolylsulfonyl)-methyl]phenylmethane (3.22 g, 5 mmol) and NaN_3 (2.94 g, 45 mmol) in DMSO (50 mL) were stirred at 90 °C for three hours. After cooling to room temperature the solution was poured into water (250 mL). The suspension was then extracted with ethyl acetate (250 mL). The organic fraction was washed with a saturated ammonium chloride solution, and dried with anhydrous sodium sulfate. The solution was filtered and the solvent was carefully removed under vacuum yielding 1.471 g of a crude transparent oil which was used directly in the following step. − ^1H NMR ($CDCl_3$): δ = 3.65 (s, 6 H, C−CH_2N_3), 7.22−7.40 (m, 5 H, aromatics CH). − ^{13}C NMR ($CDCl_3$): δ = 46.9 (C_6H_5-*C*), 54.3 (CH_2), 126.2, 127.8 and 128.8 (aromatics CH), 138.3 (aromatic C). − IR (NaCl disk): ν_{N_3} = 2103 cm^{-1}.
