Nitrogen Tripod Ligand/Oxygen Tripod Ligand Indium(III) Complexes: The First Structurally Characterized Trofimenko−Kläui Complex $[\eta^5\text{-}(C_5H_5)Co\{P(OCH_3)_2(O)\}_3InHB(pz)_3][InCl_4]$ (pz = pyrazol-1-yl)

Wolfgang Kläui,*[a] Wilfried Peters,[a] Norbert Liedtke,[a] Swiatoslaw Trofimenko,[b] Arnold L. Rheingold,[b] and Roger D. Sommer[b]

Keywords: Hard and soft acids and bases concept (HSAB) / Symbiosis and antisymbiosis / Indium / (Cyclopentadienyl)tris(diorganylphosphito-*P*)cobaltate(1−) / Hydrotris(pyrazol-1-yl)borate / Mixed-ligand complexes

Indium(III) complexes $[L_RInTp^*]X$ {L_R = (cyclopentadienyl)-tris[diorganylphosphi(ni)to-*P*]cobaltate(1−) $[\eta^5\text{-}(C_5H_5)Co\{PR_2(O)\}_3]^-$, R = OCH_3, CH_2CH_3; Tp* = hydrotris(3,5-dimethylpyrazol-1-yl)borate} have been prepared from $[Tp^*InCl_2(NCCH_3)]$ and AgL_{OMe} or TlL_{Et}. Alternatively, equilibration of a 1:1 mixture of the homoleptic complexes $[In(L_{OMe})_2][PF_6]$ and $[In(Tp)_2][PF_6]$ in aqueous methanol slowly yielded the heteroleptic indium(III) complex $[L_{OMe}InTp][PF_6]$. An X-ray crystal structure determination revealed a *fac*-N_3O_3 coordination sphere for the $[L_{OMe}InTp][InCl_4]$ complex. These indium compounds represent the first structurally characterized complexes where the tripodal oxygen ligand L_R and the tripodal nitrogen ligand Tp are coordinated to the same metal center. Indium(III) is classified as a class a, i.e. a hard metal ion, but it evidently prefers an antisymbiotic arrangement of ligands.

Introduction

Jørgensen defined chemical symbiosis as the fact that hard bases (electronegative donor atoms) attached to a given central atom make it a harder Lewis acid by retaining their valence electrons thus maintaining a high positive charge on the central atom.[1] Soft bases (donor atoms of low electronegativity) attached to the same central atom give up their valence electrons thereby reducing its positive charge and making it a softer Lewis acid. Pearson, on the other hand, pointed out that class b metal ions very often behave in an antisymbiotic manner. Thus, soft bases attached to an already soft Lewis acid decrease its affinity towards another soft base.[2] Antisymbiosis can be explained on the basis of the *trans* effect or *trans* influence and is most pronounced in square planar $4d^8$ and $5d^8$ complexes. Symbiosis seems to be the preferred behaviour of class a, i.e. hard metal ions.

The tridentate oxygen and nitrogen ligands **1** and **2** (see Figure 1), that we introduced some time ago,[3,4] are both facially coordinating monoanionic six-electron ligands. The tripodal nitrogen ligands, abbreviated herein as Tp, exhibit coordination chemistry resembling that of cyclopentadienyl or pentamethylcyclopentadienyl ligands. On the other hand, tripodal oxygen ligands, abbreviated herein as L_R, are very hard and weak ligands. Indeed, they are weaker than water and nearly as hard as fluoride. Both form 2:1 complexes with a wide variety of main group and transition metal ions M^{2+} and M^{3+}. All our attempts to synthesize hard-soft mixed-ligand 2:1 complexes starting from metal salts MX_2 and alkali metal salts of **1** and **2** have been unsuccessful. We obtained only mixtures of the homoleptic complexes and the question that arises is whether this was a consequence of strict symbiosis? In the following, we describe the synthesis and characterization of octahedral mixed-ligand indium(III) complexes, i.e. indium(III) complexes with an InN_3O_3 coordination polyhedron.

Results and Discussion

Preparative Results

Reactions of the silver and thallium salts of the oxygen ligands, e.g. AgL_{OMe} (**1a**) and TlL_{Et} (**1b**), with the indium complex $[Tp^*InCl_2(NCCH_3)]$ (**6**)[5] lead to compounds $[L_{OMe}InTp^*][AgCl_2]$ (**3d**) and $[L_{Et}InTp^*]Cl$ (**3c**) (see Figure 2).

The reactions of the silver and thallium salts are fast and go to completion. The corresponding alkali metal salts re-

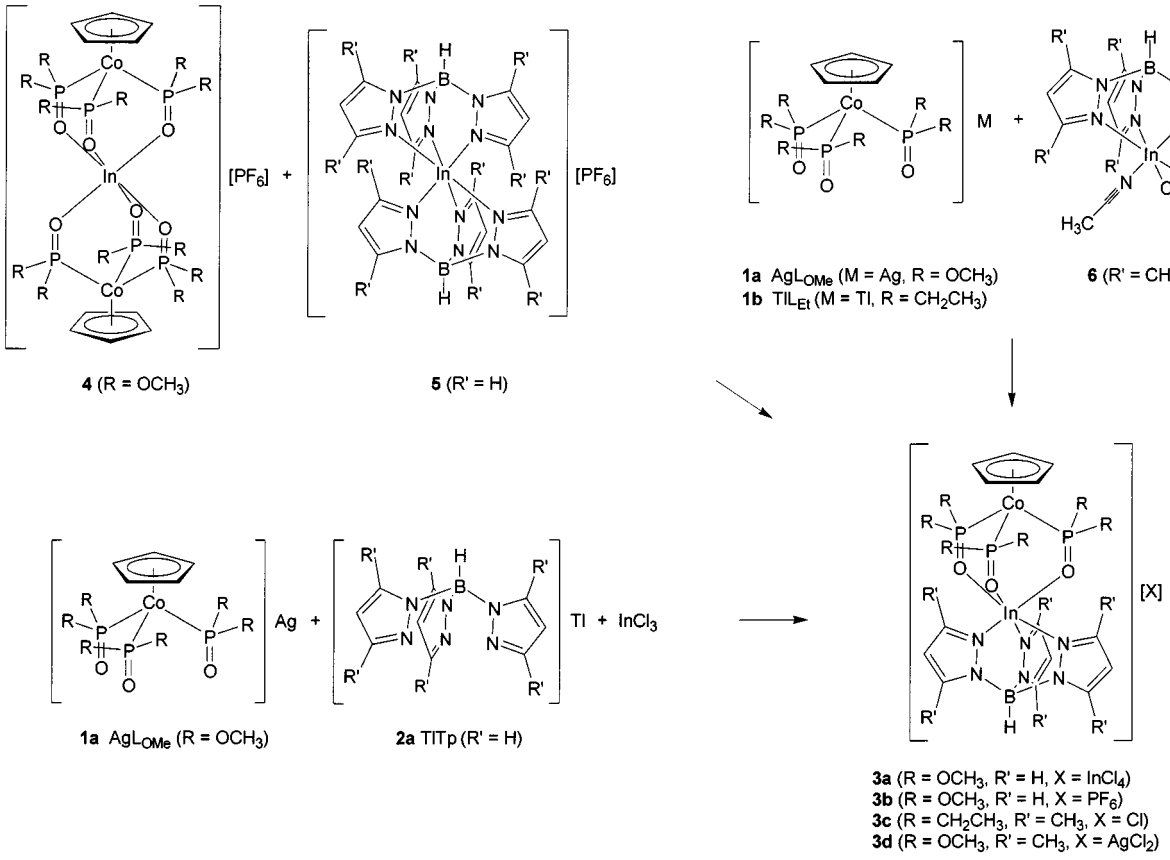

Figure 2. Synthesis and schematic structures of the indium(III) complexes

act more sluggishly and the need to separate the remaining starting compounds makes purification of the complexes **3** more difficult.

We had no evidence as to whether the successful preparation of the heteroleptic indium complexes $[L_{OMe}InTp^*]^+$ and $[L_{Et}InTp^*]^+$ was kinetically or thermodynamically controlled. Therefore, we performed a second experiment in which indium chloride was treated with AgL_{OMe} (**1a**) and TlTp (**2a**) in a mixture of dichloromethane, acetone, and methanol. $[L_{OMe}InTp][InCl_4]$ (**3a**) was isolated in almost quantitative yield. We could not detect any of the homoleptic complexes $[In(L_{OMe})_2]^+$ or $[In(Tp)_2]^+$. Finally, we tried to equilibrate an equimolar mixture of the homoleptic compounds $[In(L_{OMe})_2][PF_6]$ (**4**) and $[In(Tp)_2][PF_6]$ (**5**) in methanol/water. At room temperature, we found there to be very little or no ligand exchange. After refluxing the solution for 2 d, we were able to recover the heteroleptic compound $[L_{OMe}InTp][PF_6]$ (**3b**) together with some of the unchanged homoleptic complexes **4** and **5**. However, the solubilities of **3b**, **4**, and **5** are rather similar and we have not been able to separate the compounds. Identification of **3b**, **4**, and **5** was nevertheless possible on the basis of their ^1H and ^{31}P NMR spectra. Complete equilibration could not be attained by prolonged heating. The Tp ligand is slowly hydrolyzed under these conditions.

Complexes **3** were obtained as bright-yellow crystals, and were found to be stable in moist air and soluble in acetone, nitromethane, and dichloromethane, moderately soluble in chloroform, diethyl ether, and methanol/water mixtures, and insoluble in hydrocarbons.

MS Data, IR Spectra, and Conductivity Measurements

The mass spectra of complexes **3** were measured by the fast atom bombardment (FAB^+) ionization technique using a nitrobenzyl alcohol matrix. The molecular ion peaks $[L_RInTp]^+$ and $[L_RInTp^*]^+$ were the base peaks of the spectra and could easily be recognized from the characteristic isotope pattern. The only other strong peaks were those corresponding to the fragment $[L_RIn + H]^+$, generated by loss of the Tp or Tp* ligand from the molecular ion.

The IR spectra of complexes **3a**−**3d** were found to be dominated by the characteristic absorptions of the ligands **1**[6] and **2**.[4] Conductivity measurements[7] of 10^{-3} M solutions of **3a** and **3d** in nitromethane indicated that these compounds behave as 1:1 electrolytes in solution.

1D and 2D NMR Spectra

The ^1H NMR spectra of **3a**−**3d** feature only a few peaks that can easily be assigned to either ligand **1** or ligand **2**. In complexes **3a** and **3b**, the pyrazol-1-yl protons give rise to an AMX spin system and the ^1H NMR spectra reveal local C_{3v} symmetry of the ligands. In the ^1H NMR spectra of **3c** and **3d**, the protons of the methyl groups in the 3- and 5-positions of the pyrazol-1-yl rings appear as singlets, as do the 4-H protons (ratio 3:3:1), again indicating local C_{3v}

Table 1. Chemical shifts (δ) of the free ligands and of the heteroleptic complexes **3c** and **3d**; pz = pyrazol-1-yl, L_R^- = (cyclopentadienyl)tris-[diorganylphosphi(ni)to-*P*]cobaltate(1−)

[a] [D_1]Chloroform. – [b] [D_6]Acetone. – [c] The 3- and 5-positions of the pyrazol-1-yl rings were not distinguished.

symmetry of the ligands. The two upfield resonances due to the methyl groups cannot be unequivocally assigned to the 3- and 5-positions solely on the basis of the 1D ^{1}H NMR spectrum.[8]

In the ^{31}P{^{1}H} NMR spectra, the phosphito and phosphinito groups of the tripodal oxygen ligand give rise to a singlet resonance at δ ≈ 110, which is broadened by quadrupolar relaxation (^{59}Co, I = 7/2). Coordination of the ligand to indium(III) decreases the electronic shielding and δ^{31}P is consequently shifted to lower field by about 10 ppm to δ ≈ 120 (see Table 1).

The ^{1}H NMR spectrum of ligand **1a** features a four-line pattern ("*virtual* quadruplet") due to the methoxy groups of L_{OMe}^- (OCH_3, $[A[X_3]_2]_3$ spin system, $^3J_{H\text{-}P}$ = 11.1 Hz). These resonances are shifted to lower field in **3d** as compared to those in **1** (see Table 1). The ^{1}H NMR spectrum of the ligand L_{Et}^- (**1b**) features unresolved multiplet patterns due to the methyl groups (CH_2CH_3, $[A[X_3YZ]_2]_3$ spin system) and the methylene groups (CH_2CH_3, $[A[X_3YZ]_2]_3$ spin system), which are shifted to lower field in **3c**. Coordination to indium(III) also shifts the signals due to the pyrazol-1-yl ring protons and methyl groups to lower field (see Table 1).

All the NMR-spectroscopic data of compounds **3** are in agreement with their formulation as mixed-ligand complexes $[L_RInTp]^+$ and $[L_RInTp^*]^+$ in solution. However, the chemical shift differences between the mixed-ligand complexes and the homoleptic complexes are rather small and are not always sufficient to discern e.g. $[L_{Et}InTp^*]^+$ from an equimolar mixture of $[In(L_{Et})_2]^+$ and $[In(Tp^*)_2]^+$. We have recently found[9] that the coordination of an oxygen ligand and a nitrogen ligand to the same indium ion can be proven by 2D ^{1}H NOESY NMR spectroscopy. In this way, one can identify $[L_RInTp]^+$ and $[L_RInTp^*]^+$ and exclude fast ligand exchange between homoleptic and heteroleptic complexes.[9]

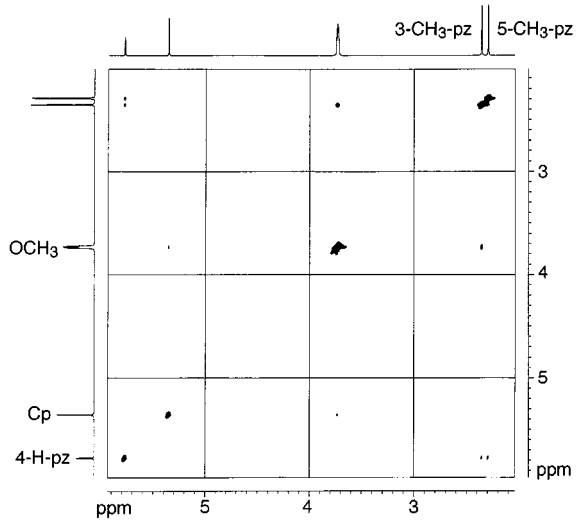

Figure 3. 2D ^{1}H NOESY NMR spectrum of **3d** ([D_6]acetone); a strong cross-peak is observed between the methoxy groups of the oxygen ligand and *only one* (!) of the pyrazol-1-yl ring methyl groups of the nitrogen ligand

Table 2. 2D ^{1}H NOESY NMR correlations in the heteroleptic complex $[L_{OMe}InTp^*][AgCl_2]$ (**3d**); pz = pyrazol-1-yl, L_{OMe}^- = (cyclopentadienyl)tris(dimethylphosphito-*P*)cobaltate(1−)

NOE correlation	
of H-	with H-
OCH_3 (L_{OMe}^-)	C_5H_5 (L_{OMe}^-), 3-CH_3-pz
C_5H_5 (L_{OMe}^-)	OCH_3 (L_{OMe}^-)
4-H-pz	3-CH_3-pz, 5-CH_3-pz
3-CH_3-pz	4-H-pz, OCH_3 (L_{OMe}^-)
5-CH_3-pz	4-H-pz

Such NOESY NMR spectra (see Figure 3, Table 2) show correlation signals between the cyclopentadienyl ligand and the methoxy groups of the oxygen ligand, as well as interac-

tions between the pyrazol-1-yl 4-H ring proton and the 3-CH_3-pz and 5-CH_3-pz methyl groups. Additionally, a strong cross-peak is observed between the methoxy groups of the oxygen ligand and only *one* of the pyrazol-1-yl ring methyl groups of the nitrogen ligand, a result that can only be obtained if both ligands are coordinated to the same metal ion, thus confirming the spatial proximity of the two ligands as depicted in Figure 2. This cross-peak also leaves no ambiguity concerning the assignment of 3-CH_3 and 5-CH_3 of the pyrazol-1-yl rings.

We expected the mixed-ligand complexes identified in solution to also exist in the solid state. A single-crystal X-ray analysis of complex **3a** confirmed this hypothesis (see Figure 4).

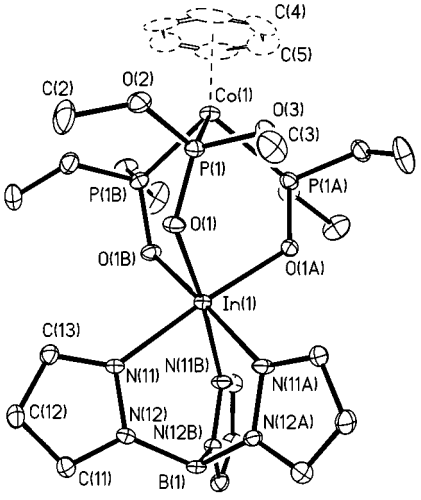

Figure 4. Thermal ellipsoid plot (at a 30% probability level) for the cation of **3a**; the disordered cyclopentadienyl ring is represented by the six atoms above Co(1); hydrogen atoms and the $[InCl_4]^-$ ion are omitted for the sake of clarity

Crystal Structure of $[L_{OMe}InTp][InCl_4]$ (3a)

A thermal ellipsoid plot of **3a** is shown in Figure 4; for crystal data see Table 3. Both ions in the lattice are positioned along a threefold axis. The Cp ring of the ligand is perpendicular to the crystallographic threefold axis. As a result, threefold disorder is imposed upon the five-membered ring. For the Cp system, two unique positions of the C atoms were found in the asymmetric unit. The occupancy for each position was set at 0.83325 so that C(4) and C(5) represent one-third of the cyclopentadienyl ring. The distance from Co(1) to the centroid of the calculated ring was found to be 1.69 Å. The hydrogen atoms on C(4) and C(5) were ignored.

Conclusions

The results of this study have shown that the hard class a metal ion indium(III) can behave in an antisymbiotic manner. The different steric properties of the Tp and Tp* ligands do not influence the course of the reaction.

As far as we are aware, there have been no detailed investigations of the preferences for symbiosis or antisymbiosis of hard metal ions. Hegetschweiler[10] has looked at the coordination chemistry of 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (taci) towards the Group 13 metal ions Al^{3+}, Ga^{3+}, and Tl^{3+}. It was found that taci can act as a tridentate ligand in four different binding modes (O_3, O_2N, ON_2, and N_3). X-ray crystal structure determinations revealed AlO_6, GaN_3O_3, and TlN_6 coordination spheres for the respective $[M(taci)_2]^{3+}$ complexes. These results fit nicely with our finding of an InN_3O_3 coordination sphere for the $[L_RInTp]^+$ and $[L_RInTp^*]^+$ complexes.

Largest diff. peak and hole	0.328 and −0.519 e Å^{-3}

Although the synthesis of $[L_RMTp]$ (M = Pb, Sn; R = OCH_2CH_3) has been reported in the literature,[11] the complexes were not characterized by X-ray analysis. We tried to synthesize $[L_{OEt}PbTp]$ (**9**) according to the published procedure (Figure 5). At 328 K, the 1D ^{1}H NMR spectrum of the product displayed two sets of signals like those reported in the literature,[11] which could readily be assigned to the two ligands with local C_{3v} symmetry. At 223 K, a doubling of the number of signals was observed. These well-separated signals were indicative of the presence of three species, which we assign as the heteroleptic complex $[L_{OEt}PbTp]$ (**9**) and the homoleptic complexes $[(L_{OEt})_2Pb]$ (**10**) and $[Tp_2Pb]$ (**11**). This hypothesis was supported by the relevant intensity ratios. The existence of **9** was corroborated by a 2D ^{1}H NOESY NMR spectrum (223 K), which showed a cross-peak between the OCH_2CH_3 groups of the oxygen ligand and only one of the pyrazol-1-yl ring protons of the nitrogen ligand. A 2D ^{1}H EXSY NMR spectrum (223 K) featured interchange signals between the pyrazol-1-yl ring protons in the 3- and 5-positions as well as between both Cp signals of the oxygen ligand, thus revealing an equilibrium

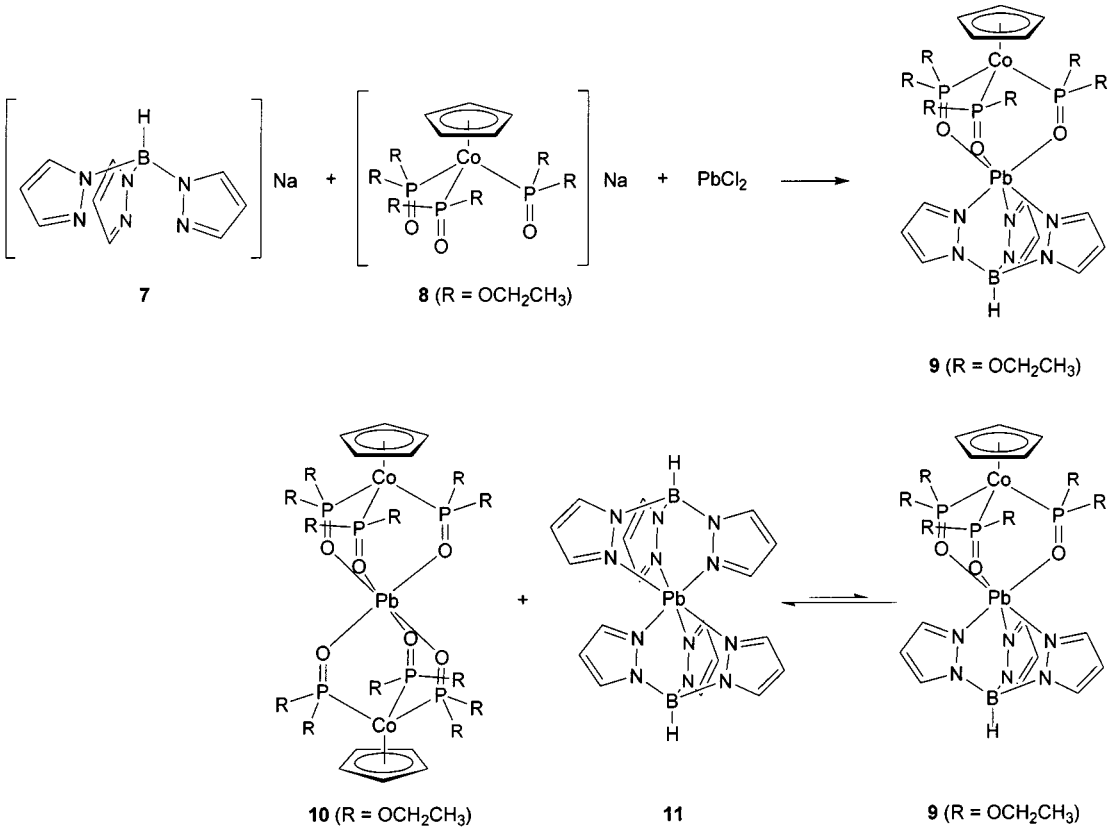

Figure 5. Equilibrium between the homoleptic and heteroleptic lead(II) complexes

Table 4. ^{207}Pb chemical shifts (δ) of the homoleptic and heteroleptic lead(II) complexes; Tp = tris(pyrazol-1-yl)borate, L_{OEt} = (cyclopentadienyl)tris(diethylphosphito-*P*)cobaltate; lead chemical shifts are highly dependent on temperature and concentration (0.05 M solution in $CDCl_3$)

between **9**, **10**, and **11** in solution. At ambient temperatures, this equilibrium is fast on the proton NMR time scale.

The ^{31}P{^{1}H} NMR spectrum featured two well-separated signals at 223 K, which could be assigned to **9** and **10**. The ^{207}Pb NMR spectrum showed the resonances of the homoleptic complexes **10** and **11**, as well as a third signal that could most probably be assigned to **9** (see Table 4).

A solution of a mixture of the homoleptic complexes **10** and **11** in a 1:1 molar ratio exhibits exactly the same spectroscopic properties and gives an identical elemental analysis as reported for **9** in the literature. The very similar physical properties of these complexes as well as the fast equilibrium between **9**, **10**, and **11** in solution most probably account for the fact that neither Reger[11] nor ourselves have been able to isolate **9** as a pure compound.

It seems impossible to make general predictions as to whether a class a, i.e. a hard metal ion, will prefer a symbiotic or an antisymbiotic ligand arrangement. A more systematic investigation should give better insight into the relationship between HSAB properties and symbiotic and antisymbiotic behaviour.

Experimental Section

General Procedures: Standard inert-atmosphere techniques were used for syntheses and sample manipulations. The solvents were dried by standard methods, distilled under nitrogen, and stored over 4 Å molecular sieves prior to use. Acetone p.a. and nitromethane p.a. (E. Merck, Darmstadt) were used as obtained and stored over 4 Å molecular sieves. – ^{1}H, 2D ^{1}H NOESY, 2D ^{1}H EXSY,

$^{31}P\{^1H\}$, and ^{207}Pb NMR spectra were recorded with a Bruker Analytische Meßtechnik DRX 500 NMR spectrometer from 0.05 M solutions. The ^1H NMR spectra were calibrated against the residual proton signals of the solvents as internal references ([D_6]acetone: δ_H = 2.08; [D_1]chloroform: δ_H = 7.24), while the $^{31}P\{^1H\}$ NMR spectra were referenced to external 85% H_3PO_4. Chemical shifts are accurate to within ±0.01 ppm for δ^1H, ±0.1 ppm for $\delta^{31}P$, and ±1 ppm for $\delta^{207}Pb$. For acquisition of the ^{207}Pb NMR spectra, the following parameters were typically used: sweep width 10^5 Hz, 4 k data points, 90° pulse. ^{207}Pb chemical shifts are reported downfield from tetramethyllead using 1 M aq. $Pb(NO_3)_2$ ($\delta^{207}Pb$ = −2961) as an external standard. The phase-sensitive NOESY spectra[12] were obtained with 512 t_1 increments and 2048 data points in t_2; 16 free induction decays were collected for each value of t_1. After zero-filling and multiplying both dimensions with a q sine function, the data were Fourier-transformed into a 1024 × 1024 matrix. The mixing time used was 0.9 s. − Infrared spectra were recorded with a Bruker Analytische Meßtechnik IFS 66 FT-IR spectrometer. − FAB^+ mass spectra were recorded with a Finnigan MAT 8200 mass spectrometer. − Elemental analyses were provided by the Institut für Pharmazeutische Chemie at the Heinrich-Heine-Universität Düsseldorf and the Mikroanalytisches Labor Pascher, Remagen. − Conductivity measurements were performed using a Schott CG 851 conductometer. − The sodium salt of **1**[13] and compounds **1a**,[9] **1b**,[14] **3a**,[9] **3b**,[9] **4**,[9] **5**,[9] **6**,[5] **7**,[4] **8**,[15] **10**,[16] and **11**[4] were prepared according to published procedures. The thallium salt **2a** was prepared from KTp and Tl_2CO_3 according to procedures for analogous TlTp compounds.[17] All other compounds were purchased from commercial sources.

Crystal Structure Determination of 3a: Diffraction data were collected with a Siemens P4 diffractometer equipped with a CCD area detector. Crystal data are presented in Table 3. The cubic unit cell was determined using reflections collected from three series of 15 frames in distinct regions of space. Final unit-cell refinement was performed by a least-squares fitting of 6886 reflections. The systematic absences were consistent with the space groups $P2_13$ and $P4_232$; Laue group symmetry supported the former choice. The E statistics for the data, with a value of 0.687, also supported this choice. The structure was solved by direct methods and the remaining atoms were located by difference Fourier synthesis. The reported absolute stereochemistry was confirmed by refinement of the Flack parameter [0.05(2)]. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions and treated as isotropic contributions with thermal parameters defined as 1.2 or 1.5 times that of the parent atom. All software and sources of scattering factors are contained in the SHELXTL program library (version 5.10, G. Sheldrick, Bruker-AXS, Madison, WI).

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-151641. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparations

{(Cyclopentadienyl)tris(dimethylphosphito-*P*)cobalt-*O*,*O*′,*O*′′}-{hydrotris(3,5-dimethylpyrazol-1-yl)borato-*N*,*N*′,*N*′′}indium Dichloroargentate [L_{OMe}InTp*][$AgCl_2$] (3d): A colourless solution of **6** (0.44 g, 0.92 mmol) in dichloromethane (20 mL) was treated with **1a** (0.52 g, 0.92 mmol) and the resulting mixture was stirred at room temperature. After a few minutes, the solution turned cloudy and the precipitation of a white solid was observed. The reaction mixture was stirred overnight, then filtered through Celite, and the filtrate was concentrated in vacuo. The resulting yellow residue was redissolved in the minimum volume of dichloromethane and this solution was treated with an excess of *n*-hexane. A pale-yellow oily residue precipitated immediately, which solidified on ultrasound treatment. The yellow solid was repeatedly washed with small amounts of *n*-hexane and dried in vacuo. Slow diffusion of diethyl ether into a dichloromethane solution yielded yellow crystals. Yield: 0.86 g (94%). − ^1H NMR (298 K, [D_1]chloroform): δ = 2.40 (s, 9 H, 5-CH_3-pz), 2.46 (s, 9 H, 3-CH_3-pz), 3.84 (virt. q, [A[X_3]$_2$]$_3$ $^3J_{H-P}$ = 11.1 Hz, 18 H, OCH_3 L_{OMe}), 5.46 (s, 5 H, C_5H_5 L_{OMe}), 5.88 (s, 3 H, 4-H-pz). − $^{31}P\{^1H\}$ NMR (298 K, [D_1]chloroform): δ = 117.8 {s, [*A*[X_3]$_2$]$_3$, *P*(O)OCH_3}. − IR (KBr): $\tilde{\nu}$ = 2559 cm^{-1} (m) ν(B−H), 1103 (vs), 1071 (vs) ν(P=O), 647 (m), 587 (s) δ(P=O). − $C_{26}H_{45}AgBCl_2CoInN_6O_9P_3$ (1041.94): calcd. The Heterotrimetallic Complex [Ni(acacen)KLa(pta)$_4$]: Structural and Thermochemical Studies

Natalia Kuzmina,[a] Mikhail Ryazanov,[a] Irina Malkerova,[b] Andrei Alikhanyan,[b] and Alain N. Gleizes*[c]

Keywords: Potassium / Lanthanum / Nickel / Mass spectrometry / Thermochemistry

The heterotrimetallic species [Ni(acacen)KLa(pta)$_4$] [H_2acacen and Hpta being *N,N′*-ethylenebis(acetylacetonimine) and 1,1,1-trifluoro-5,5-dimethyl-2,4-hexanedione, respectively] was obtained by interaction of Ni(acacen) with KLa(pta)$_4$ in chloroform. From the X-ray, single crystal structure determination, the potassium cation acts as a bridge between the complex anion [La(pta)$_4$]$^-$ and the neutral complex Ni(acacen). Sublimation, thermal behaviour, pressure, and composition of the vapour phase have been investigated for both [Ni(acacen)KLa(pta)$_4$] and the parent complexes Ni(acacen) and KLa(pta)$_4$, by means of thermal analysis and mass spectrometry using a Knudsen cell. The heterotrimetallic molecule was not found in the saturated vapour. Two processes take place upon heating: [Ni(acacen)KLa(pta)$_4$]$_{(s)}$ → [KLa(pta)$_4$]$_{(s)}$ + Ni(acacen)$_{(g)}$ and [KLa(pta)$_4$]$_{(s)}$ → [KLa(pta)$_4$]$_{(g)}$. The standard free energy of formation for [Ni(acacen)KLa(pta)$_4$] have been estimated ($\Delta G_f^0{}_{380K}$ = −6.1±2 kJ/mol). [Ni(acacen)KLa(pta)$_4$] can be sublimed completely at low pressure because both parent complexes KLa(pta)$_4$ and Ni(acacen) are volatile.

Introduction

Volatile heterometallic complexes are interesting as prospective single-source precursors for the growth of heterometallic thin-film materials by chemical vapour deposition from metal-organic precursor molecules (MOCVD).[1] The coordination chemist′s problem is then to combine at the least two metal elements, into a congruently vaporizing metal-organic complex. Generally, the metal elements do not belong to the same chemical family, and they present different metal complex chemistries and thermochemistries. Various synthetic strategies can be applied.[1] In order to prepare volatile complexes incorporating a *d* and an *f* or an *s* element, we have developed a strategy based on the use of *d* metal complexes as neutral ligands to coordinatively saturate an *f* or an *s* element cation in one of its β-diketonates.[2−5]

We present here results about an unusual heterotrimetallic complex, which results from interaction between the heterobimetallic complex KLa(pta)$_4$ and Ni(acacen).

Results and Discussion

Synthesis and Crystal Structure of [Ni(acacen)KLa(pta)$_4$]

The heterotrimetallic complex [Ni(acacen)KLa(pta)$_4$] was obtained as a single-phased, red-brown, crystalline product by simple interaction of Ni(acacen) with KLa(pta)$_4$ in chloroform. It crystallises in the triclinic system, with a space group of $P\bar{1}$, and unit-cell volume 2769 Å^3. The unit-cell comprises two centrosymmetrically related asymmetric units.

The asymmetric unit is made of one of each constituent: a complex anion [La(pta)$_4$]$^-$, a cation K$^+$, and a neutral complex Ni(acacen) (Figure 1). The potassium acts as a link

between the two metal complexes, being in contact with the two oxygen atoms of Ni(acacen), and three oxygen and two fluorine atoms of [La(pta)$_4$]$^-$. Selected bond lengths and angles are presented in Table 1.

Around La (Figure 2), the four triangles LaO(1a)O(2a), LaO(1b)O(2b), LaO(1c)O(2c), and LaO(1d)O(2d) are almost perpendicular to each other, making angles ranging from 85.5(1)° to 89.6(1)° with each other. Dihedral angles about O(1i)O(2i) between these planes and respective mean planes of atoms O(1i), O(2i), C(1i), C(2i), C(3i), C(4i), C(5i) are 12.4(1)° and 12.9(1)° for ligands *b* and *d*, and 4.0(2)° and 4.2(2)° for ligands *a* and *c*, respectively. The coordination polyhedron around La is close to a bicapped trigonal prism, with O(1a)O(2a)O(1b) and O(1d)O(2d)O(2c) as the triangular faces, O(2b) and O(1c) at the capping vertices.

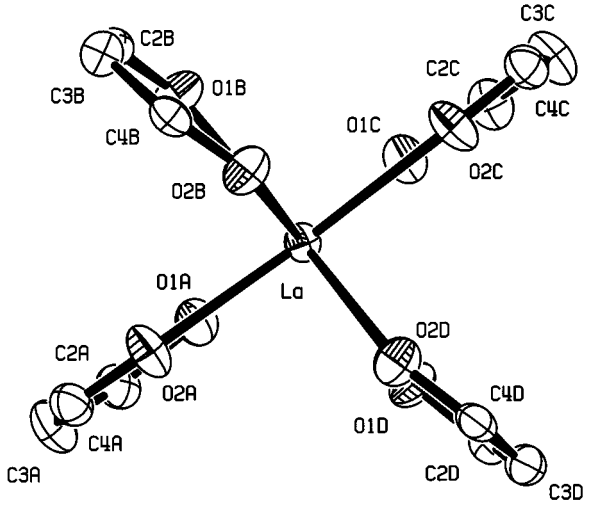

Figure 2. A view of the La(pta)$_4^-$ entity; for the sake of clarity, *tert*-butyl and trifluoromethyl groups have been omitted

Cerium(IV) in Ce(pta)$_4$ and cerium(III) in (NH$_4$)Ce(pta)$_4$ have been recently reported to have a square antiprism coordination geometry.[6] Distortion from expected square antiprism in the present compound is likely to result from the cation K$^+$, which tightly binds two *pta* oxygen atoms: K−O(1a) = 2.677(3) Å and K−O(1c) = 2.731(3) Å. Potassium next neighbouring atoms are the *acacen* oxygen atoms O(1) and O(2) at 2.742(3) Å and 2.661(3) Å, respectively, the *pta* oxygen O(1d) at 2.914(3) Å, and the fluorine atoms F(1c), F(1a), F(2d), and F(2a) at 2.843(4) Å, 2.949(4) Å, 3.295(3) Å, and 3.358(4) Å, respectively.

In Ni(acacen) (Figure 3−5), slight deviations from planarity are evident, besides the torsion angle N(1)C(11)C(12)N(2) of −35.9(4)°. The N_2O_2 environment of the nickel atom is slightly tetrahedrally distorted, with atom to mean plane distances of ±0.04 Å. The planes defined by atoms Ni, O(1), and N(1) on one hand and Ni, O(2), and N(2) on the other hand make an angle of 3.5(3)°. In both ketoimine moieties, planar OC_3 and NC_3 parts make an angle of circa 5° with each other. The Ni(acacen) entities are related by inversion. They partially overlap, giving rise to stacks parallel to the *a* axis with distances between mean planes alternatively equal to 3.66 Å for inversion through (1/2, 0, 1/2), and to 3.85 Å for inversion through (0, 0, 1/2). Figure 3 and Figure 4 show that the overlap is more extended for entities separated by 3.66 Å than by 3.85 Å. Intra-stack Ni···Ni distances are 4.800(1) Å and 6.569(1) Å, alternatively (Figure 5).

F(2c)···C(11)[g]	3.222(5)		
F(2c)···C(12)[g]	3.215(5)	CH$_3$···CH	
F(1d)···C(11)[f]	3.255(5)	C(3b)···C(52a)[h]	3.535(7)
		C(3d)···C(51c)[d]	3.757(6)
F···CH		C(52d)···C(3)[f]	3.976(7)
F(1d)···C(8)[i]	3.419(5)		

[a] Code of symmetry operations: $x, y-1, z$. – [b] $-x, 1-y, -z$; – [c] $-x, -y, 1-z$. – [d] $x-1, y, z$; – [e] $-x, -y, -z$; – [f] $x, 1+y, z$; – [g] $1-x, -y, 1-z$. – [h] $1+x, y, z$. – [i] $-x, 1-y, 1-z$.

Table 2 shows the results of a screening of van der Waals contacts. They consist of contacts between F atoms and $-CH_3$, $-CH_2$, or $-CH$ groups, and between $-CH_3$ and $-CH_3$ or $-CH$ groups. There are no van der Waals contacts between F atoms.

For Ni(acacen) entities separated by 3.66 Å, the distances from one entity to the centrosymmetrically related one [N(1)···N(1) = 3.66 Å and N(2)···C(4) = 3.70 Å] suggest interactions between π-electrons of partial double bonds N(1)–C(4) and N(2)–C(9). In the same way, a strong interaction between the methyl group about C(5) and electrons delocalized on bonds between atoms O(2), C(7), C(8), C(9), and N(2) of the centrosymmetrically related *acacen* ligand is suggested by the fact that C(5) is at 3.7–3.8 Å from these atoms and at 3.441(4) Å from the mean plane of the ligand. The methylene group about C(11) is possibly involved in the same kind of interaction to a lesser extent: C(11) is at 3.6–3.7 Å from atoms O(1) and N(1) of the related entity and 3.412(5) Å from mean plane of the corresponding *acacen*. For entities separated by 3.85 Å, the methyl group about C(10) for each entity is at 3.630(6) Å from the mean plane of atoms O(2), C(7), C(8), C(9), and N(2) of the related entity.

Thermal Analyses and Vacuum Sublimation

The results of thermal analyses for [Ni(acacen)KLa(pta)$_4$] have been correlated with those for parent complexes KLa(pta)$_4$ and Ni(acacen).

The thermogravimetric analysis curves for KLa(pta)$_4$ and Ni(acacen) are shown in Figure 6, a and 6, b respectively. A single-stepped, quasi total (>98%) weight loss occurs at 165–230 °C and 205–285 °C, respectively for KLa(pta)$_4$ and Ni(acacen). This corresponds predominantly to sublimation. The thermogravimetric curve for [Ni(acacen)KLa(pta)$_4$] (Figure 6, c) shows two stages of weight loss. The major weight loss (70%) occurs in the temperature range 180–330 °C, which corresponds to sublimation. The second, smoother stage (weight loss of about 20%) occurs in the range 330–500 °C. This may correspond to partial thermal decomposition of the complex. The nonvolatile residue amounted to 6% of the initial weight, confirming that sublimation is mainly responsible for the weight loss.

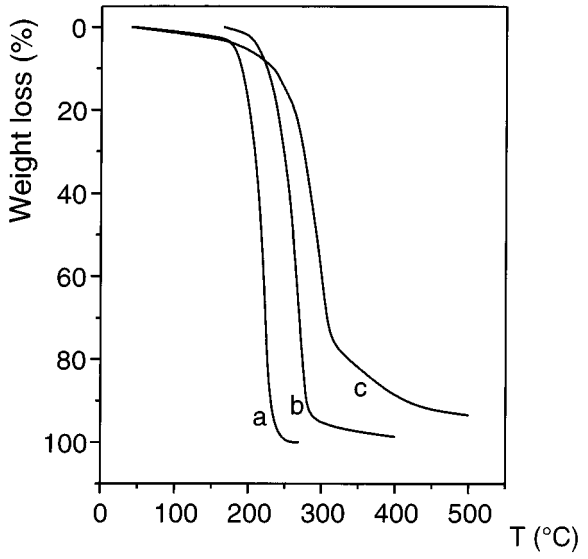

Figure 6. Thermal gravimetric analyses under vacuum (0.01 Torr) for a) KLa(pta)$_4$, b) Ni(acacen), c) [Ni(acacen)KLa(pta)$_4$]

[Ni(acacen)KLa(pta)$_4$] was submitted to isothermal vacuum sublimation (0.01 Torr). The sample was totally sub-

limed at 200 °C, yielding a single, homogeneous sublimate at the cold end of the reactor tube. Results of elemental analyses for the sublimate were the same as for the starting [Ni(acacen)KLa(pta)$_4$]. However, this experiment did not show whether sublimation occurred with or without dissociation. In order to determine whether [KLa(pta)$_4$Ni(acacen)] exists in the vapour phase, or dissociates into gaseous KLa(pta)$_4$ and Ni(acacen), which would recombine at the cold part of the reactor, mass-spectrometry experiments were carried out for [Ni(acacen)KLa(pta)$_4$] and the component complexes KLa(pta)$_4$ and Ni(acacen).

Mass Spectrometry of [Ni(acacen)], [KLa(pta)$_4$] and [Ni(acacen)KLa(pta)$_4$]

[KLa(pta)$_4$]

The mass spectra of [KLa(pta)$_4$] were recorded in the temperature range 394−420 K (Table 3). The major species were lanthanum-containing [La(pta)$_3$]$^+$, [La(pta)(OCCF$_3$CH$_2$)]$^+$ and [La(pta)$_4$]$^+$. However, the heterobimetallic molecular ion [KLa(pta)$_4$]$^+$ was observed over the temperature range, thus indicating that no decomposition of [KLa(pta)$_4$] into K(pta) and La(pta)$_3$ occurs upon sublimation. At 418 K, the vapour pressure of [KLa(pta)$_4$] is equal to $4.2\cdot10^{-2}$ Pa. Congruent sublimation has been reported for other ionic bimetallic complexes of lanthanide fluorinated β-diketonates. The compound [NaCe(pta)$_4$] sublimes without decomposition according to published mass spectrometry data.[6] A similar spectrum was obtained for Cs[Y(hafa)$_4$], which was the first volatile heterobimetallic complex investigated by mass spectrometry.[7] The tendency to form lanthanum-fluorine containing species is supported by our data too (Table 3). The formation of such species upon fragmentation is likely to result from migration of fluorine atoms from the ligands to the metal centre, a process favoured by the hard-acid character of lanthanides.[8]

[Ni(acacen)]

[Ni(acacen)] sublimes congruently in the temperature range 349−412 K. At 393 K, the vapour pressure of [Ni(acacen)] is equal to $1.4\cdot10^{-1}$ Pa. The standard enthalpy of sublimation for [Ni(acacen)] was found to be 127.7 ± 0.3 kJ/mol from mass spectrometry data (Table 4), in good agreement with the value of 129.1±0.9 kJ/mol, measured by effusion in the range 402−450 K.[9] [Ni(acacen)] is more volatile than the related nickel Schiff-base complex, Ni(salen), which sublimes in the range 459−545 K.[2] The difference in volatility is likely to result from stronger π interactions between the phenyl groups in solid Ni(salen)[10] with respect to Ni(acacen), which does not contain such groups. [Ni(acacen)] has a volatility that compares with those of nickel acetylacetonate[11] and nickel acetylacetoniminate.[12]

[Ni(acacen)KLa(pta)$_4$]

Mass spectra were recorded at 390 K and 419 K. They show ions containing either Ni, or La, or La and K (Table 3), thus indicating that the heterotrimetallic molecule is not present in the saturated vapour. Relative intensities of La-containing species tend to increase on increasing temperature. It may be inferred that two processes take place upon heating are, accroding to Equation (1) and Equation (2):

$$[Ni(acacen)KLa(pta)_4]_{(s)} \rightarrow [KLa(pta)_4]_{(s)} + Ni(acacen)_{(g)} \quad (1)$$

$$[KLa(pta)_4]_{(s)} \rightarrow [KLa(pta)_4]_{(g)} \quad (2)$$

The temperature dependence of ion current intensities was measured for Ni-containing species in the temperature range 350−419 K. The vapour pressure of Ni(acacen) over

				[LaOCC(CH$_3$)]$^+_3$	0.04		

Table 4. Temperature dependence of saturated vapour pressures of Ni(acacen) and [Ni(acacen)KLa(pta)$_4$)]

Complex	A[a]	B[a]	T range [K]	$\Delta_s H^0_T$ [kJ/mol]
Ni(acacen)	6667 ± 155	16.11 ± 0.08	349−412	128 ± 3
[Ni(acacen)KLa(pta)$_4$)]	7633 ± 160	17.74 ± 0.11	350−419	146 ± 10

[a] A and B are coefficients of the equation $\log P_{Pa} = -A/T + B$.

[Ni(acacen)KLa(pta)$_4$] (Table 4) is lower (2.1 10^{-2} Pa at 393 K) than over solid Ni(acacen), due to formation of the heterotrimetallic complex. From measured saturated vapour pressures of Ni(acacen) over [Ni(acacen)KLa(pta)$_4$] and over Ni(acacen), the activity of Ni(acacen) at 380 K was found to be $a_{[Ni(acacen)]} = 0.15$. The standard free energy of formation of [Ni(acacen)KLa(pta)$_4$] according to Equation (3) was found to be $\Delta G_f^0{}_{380K} = -6.1 \pm 2$ kJ/mol.

$$[KLa(pta)_4]_{(s)} + Ni(acacen)_{(s)} \rightarrow [Ni(acacen)KLa(pta)_4]_{(s)} \quad (3)$$

Conclusion

The complex [Ni(acacen)KLa(pta)$_4$] is an interesting example of a heterometallic compound in which a cation, namely K^+, acts as a bridge between two metal complexes. In coordination chemistry, examples of heterometallic compounds with bridging ligands abound, and usually, polydentate ligands act as bridges between two metal centres. One further possibility is to have a neutral metal complex acting as a ligand towards the coordinatively unsaturated metal centre of a second complex, as is the case for instance for the series of complexes of formulae [M(SB)Ln(β-dik)$_3$] (M = Cu, Ni, SB = Schiff base such as *saloph*, *salen*, *acacen*, β-dik = *thd*, *pta*, *hfa*, *fod*) that we are investigating.[2,3] In the case of [Ni(acacen)KLa(pta)$_4$], both complex entities [Ni(acacen)] and [La(pta)$_4^-$] are coordinatively saturated, but oxygen donor atoms from ligands *pta* and *acacen* may form additional bridging bonds. It is worth pointing out that some of the fluorine atoms of the β-diketone participate to this bridge, so that the question arises of the existence of such complexes with nonfluorinated β-diketones about the lanthanide cation.

According to thermodynamic data, the energy of interaction between Ni(acacen) and KLa(pta)$_4$] is rather weak. Upon heating, the complex [Ni(acacen)KLa(pta)$_4$] dissociates into its parent complexes Ni(acacen) and KLa(pta)$_4$, and sublimation may be complete thanks to the volatility of both components.

Experimental Section

Preparation and Characterization of the Complex [Ni(acacen)KLa(pta)$_4$]: The starting materials H_2(acacen), Ni(acacen), were obtained according to literature methods.[13] The preparation of KLa(pta)$_4$, was adapted from that of NaCe(thd)$_4$.[6] − Elemental analyses (C, H, N) were carried out by the Microanalytical Service of the Moscow State University. − IR spectra were recorded on a Perkin−Elmer 1750 FTIR spectrophotometer for KBr disks in the 4000−300 cm^{-1} region.

[Ni(acacen)KLa(pta)$_4$] was obtained as follows: A solution of Ni(acacen) (112 mg, 0.4 mmol) in 50 mL of chloroform was slowly added to a solution of [KLa(pta)$_4$] (383 mg 0.4 mmol) in chloroform. The red solution was then heated under reflux for 2 h. Slow evaporation of the resulting solution afforded dark red crystals (445 mg, yield 90%). − $C_{44}H_{58}F_{12}KLaN_2NiO_{10}$ (1239): calcd. C 42.61, H 4.68, N 2.26; found C 42.52, H 4.80, N 2.29. − IR: $\tilde{\nu}$ = 2980, 1635, 1540, 1520, 1480, 1425, 1380, 1360, 1285, 1240, 1160, 1120, 975, 950, 915, 840, 800, 760, 700, 650, 545, 485 cm^{-1}.

X-ray Structure Study: Crystal data: formula $C_{44}H_{58}F_{12}KLaN_2NiO_{10}$, mol. weight = 1239.6 amu, monoclinic, $P\bar{1}$, a = 9.984(2), b = 12.455(2), c = 23.064(4) Å, α = 101.68(2)°, β = 98.96(2)°, γ = 91.58(2)°, Z = 2, d = 1.487 g.cm^{-3}, μ = 1.27 mm^{-1}. − Data collection: Stoe Imaging Plate Diffraction System (IPDS), Oxford Cryosystems cooler device, monochromated Mo-K_α radiation, T = 140 K, crystal size 0.75×0.17×0.10 mm, crystal-to-detector distance 80 mm, 208 exposures (2 minutes/exposure), $0 < \varphi < 249.6°$, φ oscillation 1.2°, $1.45 < \theta_{max} < 24.20°$, coverage of the unique set 93%. Measured reflections 21835, observed (expected) unique reflections 8234 (8852). Crystal decay monitored by measuring 200 reflections per image, only statistical fluctuations observed. Intensities corrected for Lorentz and polarisation effects, not for absorption (average cylindrical μr = 0.1). − Structural analysis and refinement: analysis by Patterson and Fourier map techniques, refinement by full-matrix, least-squares techniques, using the SHELX-93 program.[14] All H atoms introduced at calculated positions using a riding model. Anisotropic displacement parameters for non-H atoms: 640 parameters for 8234 reflections. R = 0.034 [7208 $F_o > 4\sigma(F_o)$] and 0.040 for all data, R_w = 0.087, GooF = 1.06 e.

Thermal Analyses: Thermogravimetric and differential thermal analyses under vacuum (0.01 Torr) were carried out on a Sinku-Riko TGD-7000 thermal analyzer, at a heating rate of 10°/min. Isothermal dynamic sublimation experiments were run with samples (100 mg) placed in glass test tubes for periods of 30 min at 200 °C and a pressure of 0.01 Torr. Weight loss was equal to 100%. The sublimate was collected in cold part of reactor and analysed. − $C_{44}H_{58}F_{12}KLaN_2NiO_{10}$ (1239.6) : calcd. C 42.61, H 4.68, N 2.26; found C 42.76, H 4.76, N 1.81.

Mass Spectrometry and Study of the Vapour Phase: The mass spectra of Ni(acacen), KLa(pta)$_4$ and [Ni(acacen)KLa(pta)$_4$] were recorded on a MS 1301 spectrometer having a 50−1500 amu mass range, and using 60 eV ionising electrons. The complexes were vapourised from a Knudsen effusion cell. The ratio of surface of evaporation to surface of the effusion hole was about 600. The cell temperature was measured with a Pt/Pt(Rh) thermocouple (±0.1 K). The experiments were carried out in ranges 349−412 K for Ni(acacen), 394−420 K for KLa(pta)$_4$ and 350−420 K for [Ni(acacen)KLa(pta)$_4$]. The main ion peaks in mass spectra of Ni(acacen), KLa(pta)$_4$ and [Ni(acacen)KLa(pta)$_4$] are given in Table 3.

Vapour pressures *versus* temperature were determined by means of isothermal vapourisation experiments and use of the Herz−Knudsen equation. Enthalpies of sublimation were calculated from the temperature dependencies of ion current intensities by using Clausius−Clapeyron equation and a least-squares method.

Crystallographic data (excluding the structure factor tables) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication CCDC-147101. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(1223)336−033; E-mail: deposit@ccdc.cam.ac.uk].

On the Commonality of Speciation of Inorganic Solutes in Superacids, Strong Bases, Molten Salts, and Water

Thomas A. O'Donnell[a]

Keywords: Inorganic solute speciation / Superacids / Molten salts / Unusual oxidation states / Disproportionation

When dealing with inorganic solutes in protic solvents such as superacids, ammonia, and water, and especially in the case of molten salts, the authors of most textbooks and specialised reviews treat solution processes in each solvent or class of solvent separately, and rarely, if ever, draw the separate sections together to indicate the commonality of the solution processes from a generalised acid-base viewpoint. Initially in this review three chemically-simple solution media, H_2O, anhydrous HF, and molten chloroaluminates, are used to illustrate the generality of the behaviour of Cr^{III} in the three solvents. In neutral media "$Cr(OH)_3$", CrF_3, and $CrCl_3$ are sparingly soluble, whereas in basic media the solvo-anions $Cr(OH)_4^-$, CrF_6^{3-}, and $CrCl_6^{3-}$ are the dominant species. In acidic media Cr^{3+} cations, solvated to a greater or less extent, are formed. In highly acidic media, transition metal cations in very low oxidation states can be generated, e.g. Ti^{2+}, U^{3+}, and Sm^{2+}, as well as homopolyatomic cations, such as I_2^+, Se_8^{2+}, Te_6^{4+}, N_5^+, and Hg_3^{2+}. Each of these cations would disproportionate in aqueous solutions and, indeed, they do so on addition of sufficient base, even in HF or chloroaluminates. Under oxidising conditions solvo-anions in high oxidation states, e.g. CrO_4^{2-}, AgF_4^- and NiF_6^{2-}, are stable in basic media. Solute speciation in sulfur acids and ammonia is dealt with briefly because most investigation of homopolyatomic cations and anions has been carried out in these solvents. The overall aim of this review is to demonstrate the generality of inorganic solute speciation in all ionising solvents. It is proposed here that the primary determinant of speciation in all media is the level of acidity or basicity of the solvent rather than its chemical composition or its temperature domain.

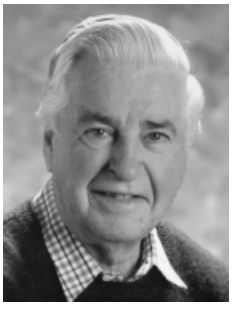
1. Introduction

Dissolution processes in ionising media for simple ionic solids, such as the halides, nitrates, sulfates, and other oxoanions of the elements of Groups I and II of the Periodic Table are relatively straightforward, yielding solvated cations and anions in aqueous and nonaqueous media unless the ions, usually the anions, undergo solvolysis. The vast majority of inorganic compounds, particularly those of the transition elements, do not follow this simple pattern. So the nature of solute-solvent interaction for these compounds assumes great importance in considering their solution processes.

[a] Department of Chemical Engineering,
The University of Melbourne,
Parkville Victoria 3010, Australia

All too frequently, in the presentation of the solution chemistry of inorganic compounds in a range of ionising media, textbooks, and even specialised monographs and book series deal in separate sections or chapters with ionisation, dissolution, and solvolysis processes in solvents such as water, basic solvents such as ammonia and amides, and in acidic media such as sulfuric acid, fluorosulfuric acid, and hydrogen fluoride. This is especially the case in the presentation of chemistry in molten salts which, being nonprotic and frequently in elevated temperature domains, are perceived as being very different from protic or even nonprotic solvents which are liquid at or near ambient temperature.

The six-volume series[1] which gives the most extensive coverage of chemistry in nonaqueous solvents is structured in this way. Furthermore, in most earlier presentations, solvents such as H_2SO_4 and liquid NH_3 have been referred to as being "acidic" or "basic" (relative to H_2O). It is im-



Tom O'Donnell was born at Ballarat, Australia, in 1923 and is a graduate of the University of Melbourne – Ph.D. (1954) and D.Sc. (1971). He was a member of the academic staff of the Melbourne School of Chemistry from 1949 to 1988 when he retired as Professor of Inorganic Chemistry. He spent a sabbatical year at Cambridge in 1955 with Professor H. J. Emeléus in order to commence research in inorganic fluorine chemistry. His earliest work was on systematisation of the chemical reactivity of the higher fluorides of d- and f-transition elements. Later he studied acid-base reactions and solute speciation in anhydrous HF and extended this to similar studies in other superacids. On retirement he joined the Melbourne Department of Chemical Engineering where he has worked collaboratively on fluoride-based chemistry directed towards development of novel commercial processes.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

portant to stress that, *as separate solvent systems*, 100% H_2SO_4 and anhydrous NH_3 are neutral media, each of which can be made more acidic by addition of appropriate Bronsted or Lewis acids (e.g. SO_3 or NH_4^+) or more basic by addition of suitable bases, such as HSO_4^- or NH_2^-.

Very rarely are the separate sections either presented or drawn together to indicate the commonality of the solution processes from a generalised acid-base viewpoint. This review sets out to demonstrate this commonality. Much of the material is drawn from a recent book[2] which was written, in part, to draw the attention of specialised researchers interested in chemistry in highly acidic media to these generalisations. The book also serves as a reference in the presentation and discussion of some superacid solution work carried out at the University of Melbourne which is not yet in readily available journals, as well as in the re-interpretation of some earlier published work from other groups. The present review extends the generalisation concept to include basic solvents such as ammonia and to describe recently reported chemistry in superacids, e.g. synthesis of the homopolyatomic cation N_5^+ and generation of AgF_4^- and NiF_6^{2-}, fluoro-anions of transition elements in very high oxidation states.

In the first two major sections of this review, solution speciation will be compared for three solvents only, namely water, anhydrous HF, and molten chloroaluminates. In most presentations of nonaqueous chemistry, water serves as the primary reference solvent. A vast amount of physical and inorganic chemistry has been studied in aqueous solution and a wide range of solvated cationic and anionic species has been characterised spectroscopically. These three solvent media have been chosen because comparison of spectra recorded in each of these media has allowed reliable postulations to be made about the extent of solvation of transition metal cations in these media. Additionally, HF and chloroaluminates were selected as the nonaqueous media because they have special properties concerned with their stability and self-ionisation, to be discussed below.

To those not familiar with solution chemistry in anhydrous HF, this solvent may seem to be an unlikely choice for a model solvent system, given its reactivity towards the usual materials of construction of scientific apparatus; but, with the availability of spectroscopic and electrochemical equipment constructed from fluorocarbons such as Teflon and KelF, synthetic sapphire and platinum, manipulation of and physico-chemical investigation of HF solutions in closed systems is now reasonably straightforward.

There are two main reasons why anhydrous HF is the superacid of choice for generation of highly-reducing stable monatomic transition metal cations in very low oxidation states, such as Ti^{2+} and Sm^{2+}, which reduce H_2O, and of highly oxidising transition metal solvo-anions with the metals in very high oxidation states, such as NiF_6^{2-} and AgF_4^- which oxidise water:

(i) it has a very large useable potential range of 4 to 4.5 volt between anodic and cathodic generation of F_2 and H_2. This compares with a range of about 2 volt, depending on pH, for H_2O.

(ii) it has the widest range of acidity-basicity of any of the superacids. HF exhibits this large acidity-basicity range because it undergoes a simple self-ionisation to about the same extent as H_2O, as discussed below.

Intrinsically, HF is so acidic that no compound is known to act as a Bronsted acid towards it. In the equations below, the self-ionisation equilibria [Equation (1)] are shown schematically as being shifted by the addition of the weak Lewis acid BF_3 [Equation (2)] and the strong Lewis acid SbF_5 [Equation (3)], to give the most acidic protic solutions yet generated:

$$3\,HF \rightleftharpoons H_2F^+ + HF_2^- \quad (1)$$

$$2\,HF + BF_3 \rightleftharpoons H_2F^+ + BF_4^- \quad (2)$$

$$2\,HF + SbF_5 \rightleftharpoons H_2F^+ + SbF_6^- \quad (3)$$

By simple addition of a soluble fluoride, e.g. NaF, HF can be made more basic than any other superacid.

Levels of acidity and basicity in different superacidic media can be compared reliably using values of the Hammett Acidity Function, H_o. These were measured by Gillespie and co-workers for HSO_3F[3] and HF[4] solutions. Table 1 shows that, whereas pure HSO_3F and pure HF have identical value for H_o, additions of only 0.4 m base (F^-) and 0.4 m acid (SbF_5) to HF cause much greater changes in acidity and basicity than additions of 0.4 m base (SO_3F^-) and 0.4 m acid [$SbF_2(SO_3F)_3$] to HSO_3F. This is a reflection of the magnitudes of the autoprotolysis constants for the two superacids, as cited in Table 1.

The very high levels of acidity, or more specifically, the very low levels of basicity in HF containing Lewis acids are such that stable unusual cationic species such as Ti^{2+} and Sm^{2+} (Section 2.2.2) and I_2^+ and the recently characterised N_5^+ (Section 2.2.3) can be generated in HF. Enhanced basicity allows generation of stable anions such as NiF_6^{2-} and AgF_4^- (Section 2.3.2).

The small value of the autoprotolysis constant for HF means that large increases in basicity of HF will occur as very small amounts of base added. A practical consequence is that "neat" HF, as obtained by repeated distillation, will contain sufficient of the most likely impurity, H_2O which acts as a strong Bronsted base, that such a liquid will have a value for H_o much less than that of −15.1 determined for pure HF. Gillespie and Liang[4] showed experimentally that addition to HF of as little as 0.1 mol% of water reduced the observed H_o to −10.66. Extrapolation of their plot of H_o vs. concentration of H_2O in HF suggests strongly that even minute concentrations of water and other impurities that can be protonated will produce a medium with values of H_o for "neat" HF of around −11, an observation that has been made experimentally.

The first transition metal cations generated in HF solutions acidified with the weak Lewis acid BF_3 were Ni^{2+}, Co^{2+}, Pr^{3+}, and Nd^{3+} [5] – all cations in "normal" oxidation states. These cations were characterised by comparison of their HF spectra with previously reported aqueous spec-

Table 1. Dependence of acidity/basicity levels of superacids on the magnitude of autoprotolysis constants

Superacid	Autoprotolysis constant [mol^2 kg^{-2}]	Values of Hammett Acidity Function, H_o		
		Lewis base added (0.4 m)	Pure acid	Lewis acid added (0.4 m)
HF	3×10^{-13}	−9.63	−15.1	−20.64
HSO_3F	3.8×10^{-8}	−13.24	−15.1	−17.71

tra and were so similar that the same level of solvation was postulated for the cations in both solvents.[5]

The term "normal" oxidation state is used here where an ion in that oxidation state is stable in aqueous solution. The terms "unusually low" or "unusually high" are used for ions which would be unstable in aqueous solution, e.g. Ti^{2+} or NiF_6^{2-}.

Another rich source of spectra available for comparative purposes with those for cations in HF was the work of Gruen and colleagues who recorded spectra of a range of dipositive transition metal cations in molten $AlCl_3$,[6] which is the pure acid of the chloroaluminate system, and in chloroaluminates at elevated temperatures.[7] Later workers carried out voltammetric investigations[8] in chloroaluminates which are liquid at room temperature and these also provided insights into the interpretation of ionic spectra in HF and other solvents.

Frequently ionisation in molten salt media is extremely complex, showing a multiplicity of interdependent ionic equilibria. This is particularly the case for melts of metallurgical or geological interest. Chloroaluminate melts are mixtures of $AlCl_3$ and an ionic chloride such as NaCl or, in the case of media which are liquid at or near ambient temperature, a salt such as *N*-butylpyridinium chloride ($BuPy^+Cl^-$). These exhibit relatively simple *solvent* speciation and so can be viewed as model systems for molten salt investigations. More importantly in the present context, they provide a nonprotic medium in which acidity and basicity can be controlled accurately. A 1:1 mixture of $AlCl_3$, the acid of the system, and NaCl (or BuPyCl) provides the neutral medium $Na^+AlCl_4^-$ (or $BuPy^+AlCl_4^-$), Cl^- being the base of the chloroaluminate solvent system. So any excess of NaCl over $AlCl_3$ constitutes a basic medium and, conversely, excess of $AlCl_3$ provides an acidic medium, as indicated in Figure 1. Consequently acid-base dependent *solute* speciation can be studied under controlled conditions and, as with HF, unusual ionic species which are unstable in H_2O can be generated, presenting a potentially rich area for new synthetic work.

High temperature chloroaluminates have a large useable potential range − from cathodic deposition of Al to anodic release of Cl_2. Room temperature chloroaluminates have a more restricted range because of oxidation or reduction of the organic cation.

2. Acid-base Dependence of Speciation of Transition Metals in H_2O, HF and Chloroaluminates

Figure 2 gives a brief summary of solution behaviour in the ionising media H_2O, HF, and chloroaluminates and provides the basis for a discussion of the general nature of the dependence of solute speciation on acidity or basicity of the medium. The solution behaviour of chromium(III), which is characteristic of many transition metals, is discussed first to illustrate typical solute speciation in each solvent in the absence of applied reduction or oxidation. Superimposed on this framework are several of the currently known species that can be generated when oxidants or reductants are added to the basic or acidic medium in each case.

2.1 Neutral Media

There is general acceptance of the insolubility of the so-called hydroxides of the transition metals in neutral water. The precipitates obtained when an aqueous solution is neutralised are not the simple hydroxides [idealised as $Cr(OH)_3$ in Figure 2] but are complex mixtures of metal centres with which are associated H_2O, OH^-, and even O^{2-} as bridging or terminal ligands. The key characteristic is that these aggregates carry no overall charge and so polymerise to form sparingly soluble nonstoichiometric compounds.

CrF_3 is typical of the neutral binary fluorides of First Row Transition Elements in "normal" oxidation states, each of which, along with some Main Group fluorides such as AlF_3, has very low solubility in anhydrous HF.

A survey of a large body of published work shows that neutral binary chlorides show similar behaviour in chloroaluminates. $CoCl_2$, $NiCl_2$, $FeCl_2$, $NpCl_3$, $NpCl_4$, and lanthanide trichlorides have all been reported as precipitating from neutral chloroaluminates. A specific reference is found in the work of Osteryoung and colleagues.[8] Cyclic voltammo-

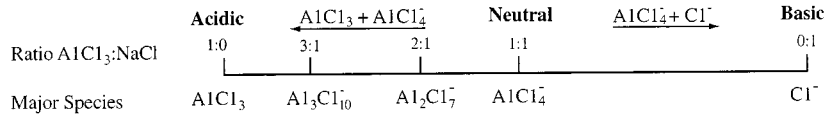

Figure 1. Acid-base dependence of solvent speciation in chloroaluminates (from *Superacids and Acidic Melts as Inorganic Chemical Reaction Media*, VCH, New York, **1993**)

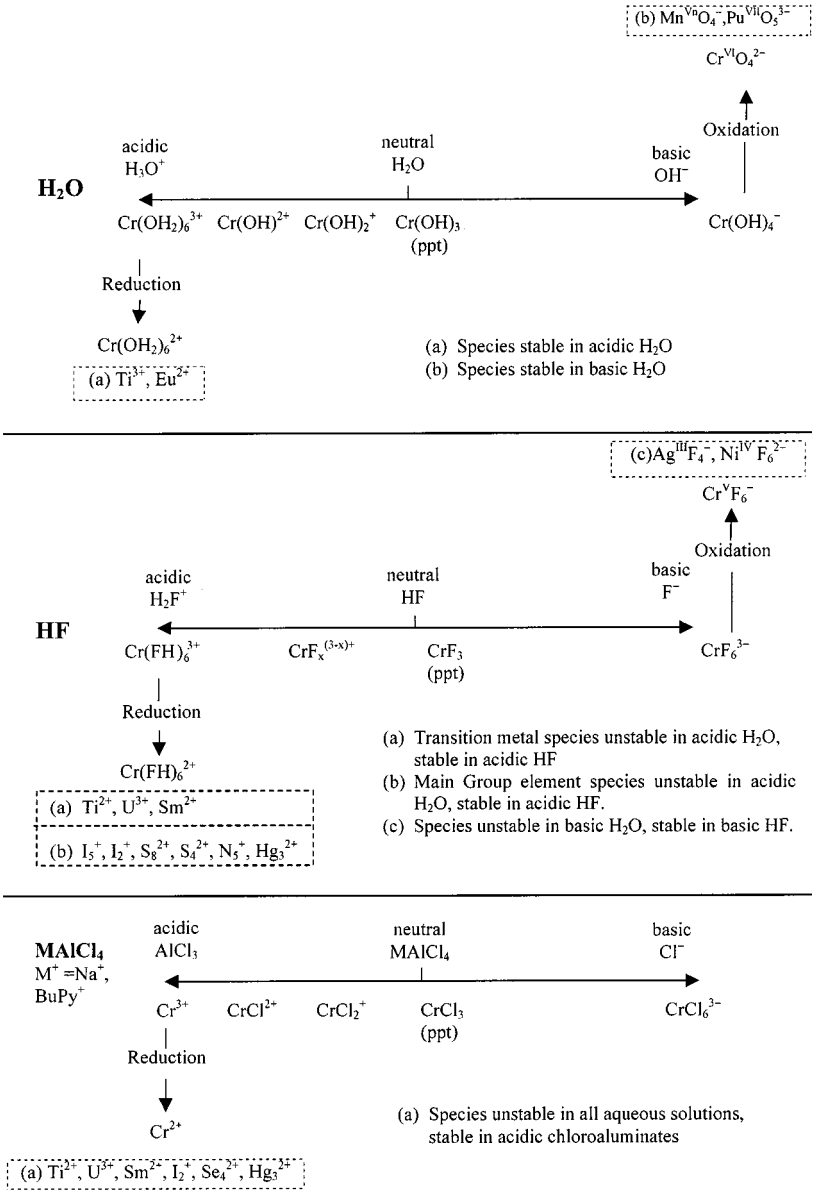

Figure 2. Generalised scheme for dependence of solute speciation on acidity and basicity in ionising solvents

grams were recorded in $AlCl_3-BuPyCl$ for the $Fe^{III}-Fe^{II}$ system from a basic medium ($AlCl_3/Cl^-$, 0.75:1) to acidic ($AlCl_3/Cl^-$, 2:1). This work will be discussed in greater detail in the section below; but in the present context, it is relevant to quote this report which shows that precipitation of $FeCl_2$ occurs near neutrality, commencing near a melt ratio of $AlCl_3/Cl^-$, 0.99:1 with redissolution occurring in the 1.1:1 acidic melt.

2.2 Acidified Media

2.2.1 Cations in "Normal" Oxidation States

First Row transition elements and metallic Main Group elements occur as aquo-cations, e.g. $Cr(OH_2)_6^{3+}$, $Fe(OH_2)_6^{3+}$ $Al(OH_2)_6^{3+}$, etc., in strongly acid, noncomplexing aqueous solution (e.g. in aqueous $HClO_4$). As indicated in Figure 2, hydroxo-complexation occurs progressively as the solution approaches neutrality, together with more complex species such as $Cr_2(OH)_2^{4+}$, $Cr_3(OH)_4^{5+}$, etc., the ratio of charge to metal decreasing as neutrality is approached. In addition to hydroxo-complexation, there is the possibility of a vast range of complexed cations, depending on the availability in the acidic aqueous solutions of other potential ligands. As the simplest of examples, species such as $[Cr(H_2O)_5Cl]^{2+}$ and $[Cr(H_2O)_4Cl_2]^+$ can be formed if the solution contains Cl^-.

As stated above, binary fluorides of transition metals are sparingly soluble in "neat" HF. The equilibrium [Equation (4)]

$$MF_n + (n + m)\,HF \rightleftharpoons M(HF)_m^{n+} + nHF_2^- \quad (4)$$

lies overwhelmingly to the left. The weak Lewis acid BF_3 and the strong Lewis acid SbF_5 react as in Equation (5) and Equation (6),

$$BF_3 + HF_2^- \rightleftharpoons BF_4^- + HF \quad (5)$$

$$SbF_5 + HF_2^- \rightleftharpoons SbF_6^- + HF \quad (6)$$

displacing the equilibrium in Equation (4) to markedly increase the concentration of solvated M^{n+} cations. The weak acid BF_3 produces solutions in HF of dispositive *d*-transition metal cations. The strong acid SbF_5 was required to dissolve *d*-transition metal trifluorides.

CrF_3 dissolves in HF−SbF_5 to give the lowest of the spectra in Figure 3.[9]

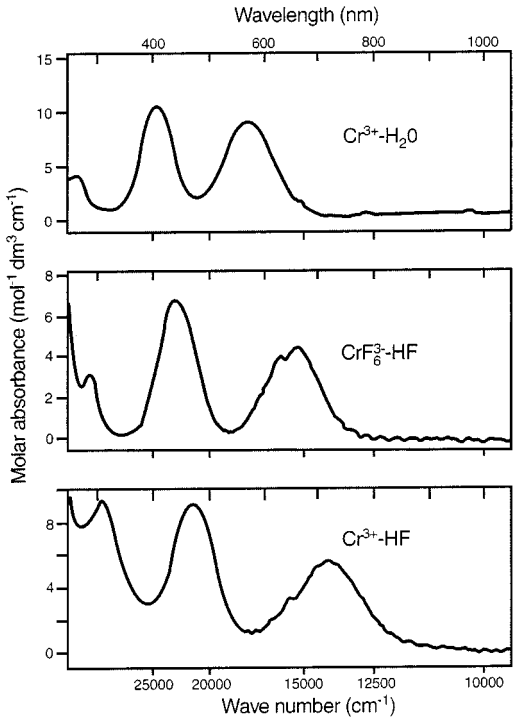

Figure 3. UV/Visible spectra of chromium(III) as $Cr(OH_2)_6^{3+}$ in H_2O, CrF_6^{3-} in HF, and $Cr(FH)_6^{3+}$ in HF (from *Superacids and Acidic Melts as Inorganic Chemical Reaction Media*, VCH, New York, **1993**)

Evidence for the existence of the six-coordinate cation $Cr(FH)_6^{3+}$ is provided by a comparison of the HF−SbF_5 spectrum with the known spectrum for $Cr(OH_2)_6^{3+}$ and with the experimentally observed spectra, which are virtually identical, for CrF_6^{3-} dissolved in both H_2O and HF. CoF_2 dissolved in HF−BF_3[5] gives a broad, shouldered peak very similar to that for $Co(H_2O)_6^{2+}$ in water and to that in Figure 4(b), indicating octahedral coordination, i.e. $Co(FH)_6^{2+}$, rather than tetrahedral coordination which would give a more intense and complex spectrum like that in Figure 4(a).

In the Melbourne research program, cations in acidified anhydrous HF were shown to have the same solvent coordination as in H_2O for Cr^{3+}, Co^{2+}, Ni^{2+}, Fe^{2+}, Cu^{2+}, Pr^{3+}, Nd^{3+}, and many others. Some degree of spectral band broadening with reduction in acidity was ascribed to formation of fluorocations in solutions nearer to neutrality. There was no spectroscopic evidence for coordination to the cations in HF solution of solvo-anions of the Lewis acids, eg. BF_4^-, SbF_6^-, etc.

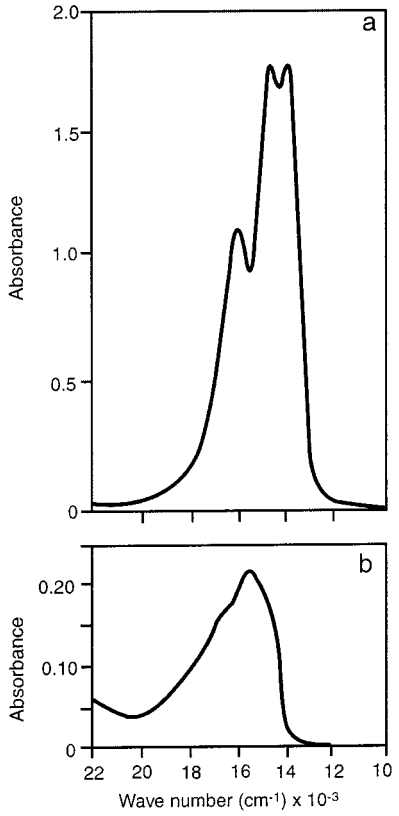

Figure 4. UV/Vis spectra of cobalt(II) (a) as $CoCl_4^{2-}$ in basic chloride melt and (b) as Co^{2+} in acidic chloroaluminate melt (from *Superacids and Acidic Melts as Inorganic Chemical Reaction Media*, VCH, New York, **1993**)

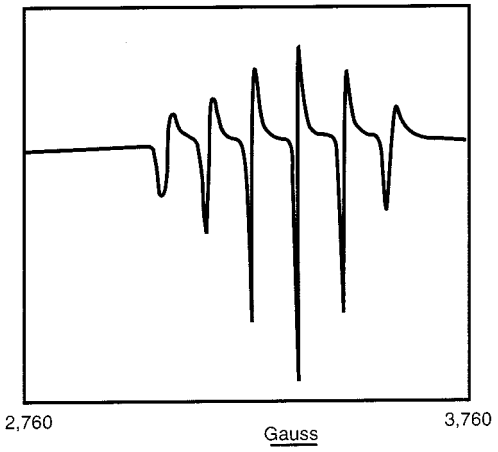

Figure 5. ESR spectrum of manganese(II) in AsF_5/HF (from *Superacids and Acidic Melts as Inorganic Chemical Reaction Media*, VCH, New York, **1993**)

The ESR spectrum of a solution of MnF_2 in HF−AsF_5 (Figure 5)[9] provided excellent evidence for existence of the cation $Mn(FH)_6^{2+}$. The ESR spectrum of the HF solution is very similar to that for $Mn(OH_2)_6^{2+}$ in H_2O, showing the characteristic six lines due to the interaction of the unpaired electrons with the nuclear spin of 5/2 on the manganese.

Øye and Gruen[6] recorded spectra of the dichlorides of the *3d* transition elements from Ti to Cu in $AlCl_3$, the pure acid of the chloroaluminate system, at 227°C. Their evidence points to cation formation in all cases. Their Co^{II} spectrum was the broad band of Figure 4(b), similar to that for $Co(OH_2)_6^{2+}$, whereas in earlier work in a basic chloride melt (the eutectic LiCl−KCl) Gruen and McBeth[7] had observed the spectrum in Figure 4(a), which is virtually identical to that for $CoCl_4^{2-}$ in an aqueous solution containing excess Cl^-.

Few researchers studying solutions of compounds of transition elements in chloroaluminates have been prepared to postulate directly the existence of solvated cations, as such, in acidic media whereas there is general agreement that the species in basic media are chloro-anions, as will be presented below.

Osteryoung's voltammetric investigation of the $Fe^{III}-Fe^{II}$ system in $AlCl_3$−BuPyCl[8] provides spectacular evidence for change in speciation as acidity and basicity of the medium are varied. Using potentiometry, they demonstrated the existence of $FeCl_4^-$ and $FeCl_4^{2-}$ in basic solution and they showed, as in Figure 6, that as the medium was made acidic the redox potential for $Fe^{III}-Fe^{II}$ changed by about 1.8 volt. Obviously there is a drastic change in solute speciation and it has been proposed[2a] that, on acidification, the electroactive species change from being anionic to being cationic.

In cyclic voltammetry, a value of 62 mV for ΔE_p, the difference between the cathodic and the anodic peak potentials, is observed for a system that is perfectly electrochemically reversible; but this value increases with decrease in reversibility. Reference to Figure 6 shows that, not only is there a vast and rapid change in peak positions in passing through neutrality, but electrochemical reversibility decreases as indicated by increase in values of ΔE_p.

A major criterion for electrochemical reversibility is that the stereochemistries of reduced and oxidised species are identical, as in basic melts. The present author has postulated[2a] that this would also be the case if, in strongly acidic chloroaluminate media, the electroactive species were the cations, Fe^{3+} and Fe^{2+}, each weakly but identically solvated. Some proposed intermediate equilibria, which are pCl dependent, are shown in Figure 6 and are based on the fact that Fe^{III} is known to form complexes with Cl^- and other ligands more strongly than does Fe^{II}, i.e. in weakly acidic medium $FeCl_2^+$ and $FeCl^+$ could be the dominant chloro complexes of Fe^{III} and Fe^{II}. Such nonidentical coordination geometry would contribute to nonreversibility leading to

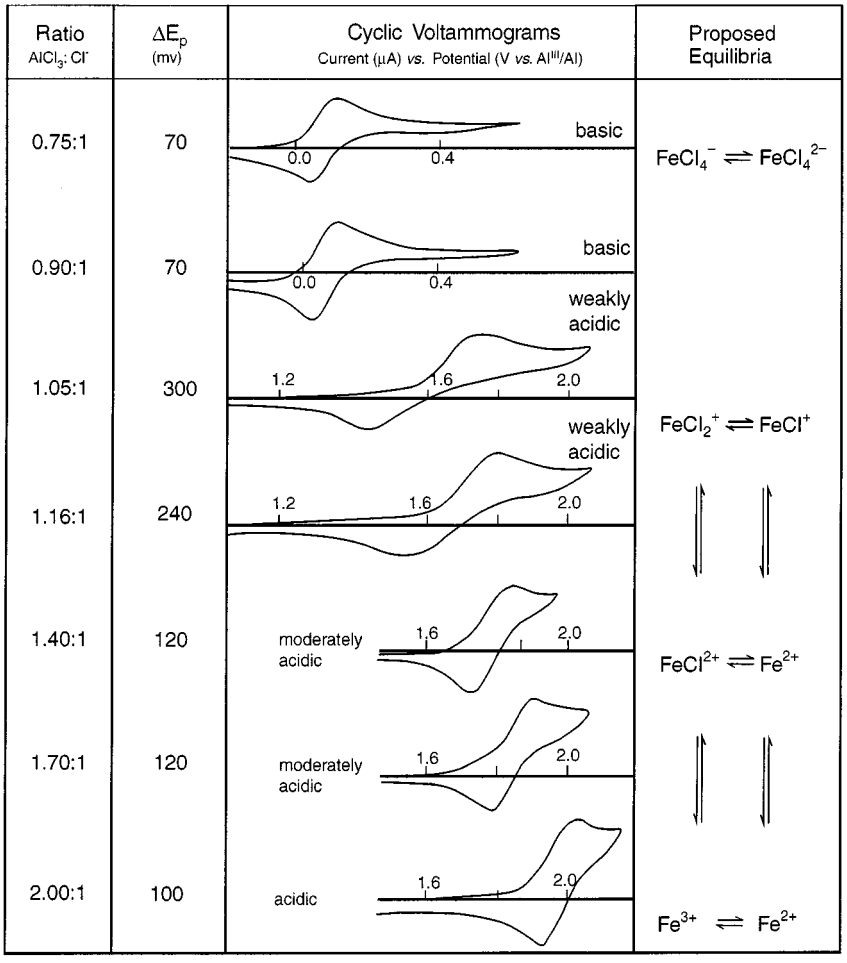

Figure 6. Cyclic voltammograms for $Fe^{III}-Fe^{II}$ in chloroaluminates of varying acidity and basicity (from *Superacids and Acidic Melts as Inorganic Chemical Reaction Media*, VCH, New York, **1993**)

greater values of ΔE_p. The present author has discussed the re-interpretation of this work and other evidence for simple cation formation in chloroaluminates in more detail elsewhere.[2b]

2.2.2 Transition Metal Cations in Unusually Low Oxidation States

Earlier, those cationic oxidation states which are stable in water were classified as "normal". There are certain low oxidation states which can be generated in aqueous solution only under strongly acidic conditions. It is possible to produce stable aqueous solutions of Cr^{2+} by reduction of Cr^{III} under acidic conditions in the absence of air. Similarly a few other low oxidation state cations can be generated in acidic aqueous solution, e.g., V^{2+}, Eu^{2+}, and Ti^{3+}. Ions such as Ti^{2+}, Yb^{2+}, Sm^{2+}, and Zr^{3+}, which can be generated in nonaqueous media, would reduce water, even when strongly acidified.

After being generated electrolytically or by chemical reduction in H_2O, U^{III} is known to be oxidised over relatively short time periods to U^{IV}, reducing H_2O. In 1976, O'Donnell treated metallic U with HF saturated with the weak nonoxidising Lewis acid BF_3 and generated lilac-coloured solutions containing U^{3+} which were stable indefinitely.[10] The acidified HF was reduced to H_2. Spectrum (b) in Figure 7 is that for U^{3+} in HF−BF_3 and can be compared with Spectrum 7(a) which was recorded while U was maintained in oxidation state III in acidic aqueous solution, using continuous electrolysis.[11]

Subsequently, treatment of metallic Ti with strongly acidic HF−SbF_5 yielded a solution containing Ti^{2+} [12]

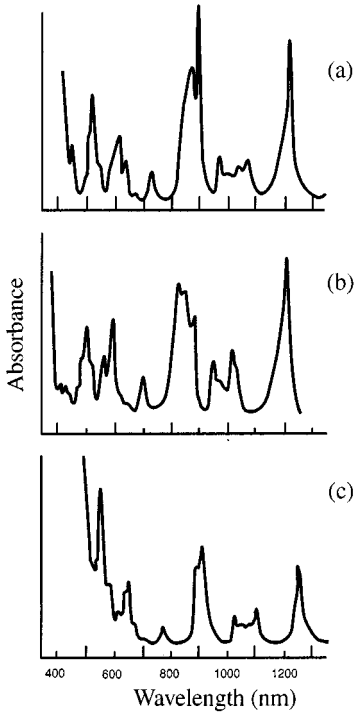

Figure 7. Spectra of uranium(III) in (a) 1 M $DClO_4$ (b) BF_3/HF, and (c) $AlCl_3$/BuPyCl, 2:1 (from *Superacids and Acidic Melts as Inorganic Chemical Reaction Media*, VCH, New York **1993**)

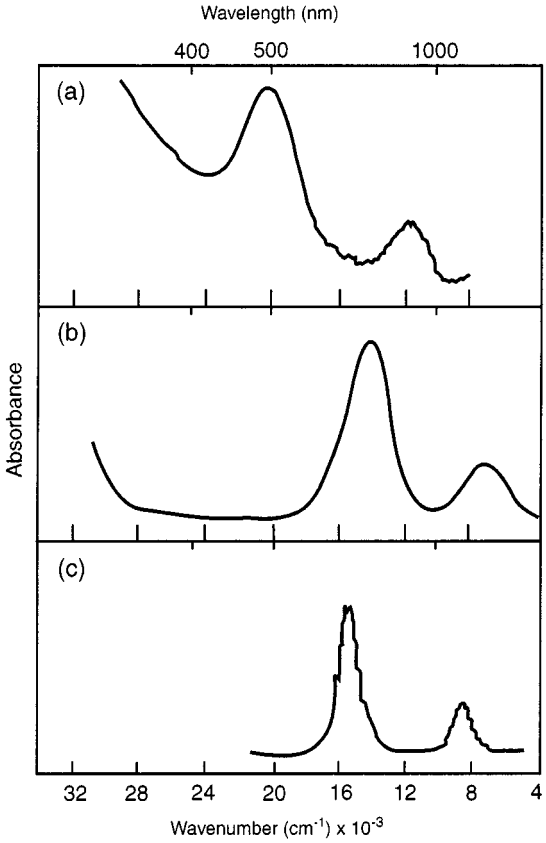

Figure 8. Spectra of titanium(II) in (a) SbF_5/HF, (b) molten $AlCl_3$ (c) crystalline NaCl at 10 K (doped at 1% level) (from *Superacids and Acidic Melts as Inorganic Chemical Reaction Media*, VCH, New York **1993**)

characterised initially by comparison of the HF spectrum (Figure 8a) with that previously reported[6] for that of $TiCl_2$ in molten $AlCl_3$ (Figure 8b), which has been interpreted[2c] as being the spectrum for weakly solvated Ti^{2+}.

Six-coordination in $Ti(HF)_6^{2+}$ was supported by similarity of the HF spectrum to that for $TiCl_2$ doped at 1% level into a host crystal of NaCl in which the coordination number is six (Figure 8c).[13] Not unexpectedly solvated V^{2+} and Cr^{2+}, generated in similar fashion, were observed in acidified HF.[12] The lanthanide metals Eu, Yb, and Sm reacted with neat anhydrous HF to give Eu^{2+}, Yb^{2+}, and Sm^{2+} and H_2.[14]

Belgian researchers[15] conducted potentiometric and spectroscopic studies of U^{III} and U^{IV} in the low temperature (40°C) melt BuPyCl−$AlCl_3$. The similarity of their spectrum (Figure 7c) in the acidic melt ($AlCl_3$/BuPyCl, 2:1) to the spectra for U^{3+} in H_2O and in HF (Figure 7a and 7b) strongly suggest the existence of cationic U^{III} in this melt. The spectrum for U^{III} in basic chloride melts,[16] where the absorbing species is postulated to be an anionic chloro-complex of U^{III}, is very different from that in the acidic melt, showing a broad very intense absorption in the region 400−700 nm and no sign of the sharp peak above 1200 nm observed in the acidic melt spectrum.

As indicated above, the spectrum (Figure 8b) recorded by Øye and Gruen[6] for a solution of $TiCl_2$ in the pure acid, $AlCl_3$, indicates the presence of Ti^{2+}.

Gilbert and co-workers[17] conducted electrochemical and spectroscopic studies for lanthanide(III)−lanthanide(II) systems in 40°C melts ranging from acidic ($AlCl_3$/BuPyCl, >60:<40), through weakly acidic ($AlCl_3$, 60 to 50.1 mol%) to neutral and basic. Over this acidity-basicity range, values of $E_{1/2}$ for the $Ln^{III}-Ln^{II}$ systems shifted to more cathodic potentials. They postulated formation of anionic chloro-complexes in basic media and they reported low solubilities of lanthanide dichlorides and trichlorides near neutrality. They proposed cationic species such as Sm^{3+} and Sm^{2+} in acidic melts, with $SmCl^{2+}$ nearer to neutrality and anionic species such as $SmCl_6^{3-}$ in basic media.

It will be demonstrated in Section 2.2.4 that addition of the base F^- to acidified HF or of the base Cl^- to acidic chloroaluminates containing cations such as U^{3+} and Ti^{2+} causes disproportionation of the cations to form the metal and a higher oxidation state fluoride or chloride in each case. Stability of these low oxidation state cations in these acidic media demonstrates the low basicity of these media, i.e. there is not sufficient of the base F^- or Cl^- to cause instability of the cations.

2.2.3 Homopolyatomic Cations of Non-metallic Elements

The pioneering work on generation of homopolyatomic cations such as I_2^+, I_3^+, Br_3^+, S_4^{2+}, Se_8^{2+}, and Te_6^{4+} *in solution* was initiated by Gillespie and the bulk of the experimental work was carried out by his co-workers who prepared them in oleums and in HSO_3F and characterised them spectroscopically. Their existence and stability in sulfur acids will be discussed in Section 3.1.1. These cations cannot exist even in acidified aqueous solution because the medium is too basic. They would disproportionate on contact with water, as will be discussed in Section 2.2.4.

A relatively small amount of work has been done on generation and stability of homopolyatomic cations in HF and in chloroaluminates − the two solvent systems other than H_2O being discussed in the major part of this review. Gillespie and Passmore[18] reported isolation of solid $S_8^{2+}(AsF_6^-)_2$ from addition of sulfur to an AsF_5-HF solution [Equation (7)]:

$$S_8 + 3\,AsF_5 \xrightarrow{HF} S_8^{2+} + 2\,AsF_6^- + AsF_3 \quad (7)$$

AsF_5 acts as oxidant, Lewis acid, and source of AsF_6^- to provide both a superacidic reaction medium and a counter-ion of sufficiently weak basicity to prevent disproportionation of the cation. *Electrophilic cations which are stable in strongly acidic solutions require very weakly nucleophilic counter-ions to be stabilised in the solid state.*

Using Gillespie's spectral data to identify iodine cations in HF solutions, Besida and O'Donnell[19] determined the acidity thresholds at which polyiodine cations were formed in HF solutions. They treated excess of iodine with controlled amounts of elemental F_2 in HF solutions ranging from basic to strongly acidic. In separate solutions, decreasing concentrations of NaF were used to reduce the basicity of the medium and known concentrations of the Lewis acids of increasing strength, NbF_5, TaF_5, and SbF_5, were used to increase the acidity in controlled fashion. They demonstrated that the only species detected in basic solutions were I_2 and IF_5, shown in Section 2.2.4 to be the final disproportionation products for polyiodine cations in basic media. I_5^+, the iodine cation with the smallest charge-to-atom ratio, was not formed until a threshold H_o value of −10.95 was reached, the value for neutral HF being −15.1, as stated earlier. I_5^+ and I_3^+ were in co-existence until an H_o value of about −15. Then, I_3^+ and I_2^+ co-existed, with I_2^+ becoming the dominant species. I_2^+ was the only species detectable for H_o values more negative than −16.20. These reactions were shown to be reversible in the manner shown in Section 2.2.4, i.e. cations of high charge-to-atom ratio disproportionate on addition of base.

Recently, Christe and colleagues[20] have reported a spectacular example of a stable homopolyatomic cation in N_5^+, the third known all-nitrogen entity after N_2 itself and N_3^-. The potentially unstable cation — its enthalpy of formation has been calculated as being about 1470 kJ mol^{-1} — was generated in superacidic medium at low temperature and isolated as a solid compound with the weakly basic anion AsF_6^-. They treated $N_2F^+AsF_6^-$, formed by direct reaction of *cis*-N_2F_2 and AsF_5, with HN_3 in anhydrous HF at −78°C and isolated the solid product $N_5^+AsF_6^-$, which is marginally stable at ambient temperature but stable indefinitely at −78°C. There is indirect chemical evidence that the acidity of the HF reaction medium may have been enhanced by availability of some free AsF_5 formed during the reaction.

While several nonmetal homopolyatomic cations have been reported in chloroaluminates, very little definitive work has been reported on relating the stability of these cations to acidity-basicity levels in molten chloroaluminates. Initially I_5^+ and I_3^+ were synthesised by reacting fused stoichiometric amounts of I_2, ICl, and $AlCl_3$ to form I_5AlCl_4 and I_3AlCl_4 i.e. under neutral conditions, Cl^- reacting with $AlCl_3$ to form the neutral $AlCl_4^-$.[21] Increased acidity was required to stabilise I_2^+ in the melt 63 mol% $AlCl_3$/37 mol% NaCl.[22]

2.2.4 Base-induced Disproportionation of Cations

It has been seen that generation of stable solutions of monatomic cations of transition metals in unusually low oxidation states and of homopolyatomic nonmetal cations is possible in highly acidic media, i.e. in media of very low basicity. Addition of an appropriate base to such solutions renders the cations unstable due to disproportionation.

The necessity for an acidic medium for these cation is indicated by the observation that gradual addition of a basic solution of NaF to a solution of U^{3+} in HF/BF_3[2d] led to the formation of metallic U and solid UF_4 according to the Equation (8):

$$4\,U^{3+} + 12\,F^- \rightarrow U + 3\,UF_4 \quad (8)$$

A more complex disproportionation was observed when F^- was added to a solution of Ti^{2+} in $HF-SbF_5$ where the formation of metallic Ti was accompanied by formation of fluorides of Ti in oxidation states III and IV.[2e]

Homopolyatomic nonmetal cations are susceptible to step-wise disproportionation reactions on gradual addition of base to solutions of the cations in superacids. Quantitative investigation[19] has shown that with increasing basicity, the cation I_2^+ in $HF-SbF_5$ disproportionates firstly to I_3^+ and IF_5, Equation (9), then to I_5^+ and IF_5, Equation (10), and finally to I_2 and IF_5, Equation (11):

$$14\ I_2^+ + 5\ F^- \rightleftharpoons 9\ I_3^+ + IF_5 \quad (9)$$

$$12\ I_3^+ + 5\ F^- \rightleftharpoons 7\ I_5^+ + IF_5 \quad (10)$$

$$5\ I_5^+ + 5\ F^- \rightleftharpoons 12\ I_2 + IF_5 \quad (11)$$

These lead to the overall reaction, Equation (12):

$$10\ I_2^+ + 10\ F^- \rightleftharpoons 9\ I_2 + 2\ IF_5 \quad (12)$$

(IF_3 was shown spectroscopically to be a minor component of the products of disproportionation of polyiodine cations in HF solutions).

Small increases in available base cause disproportionation of I_2^+ to I_3^+ and I_5^+. When available F^- is comparable with or somewhat greater than the concentration of I_2^+, total disproportionation occurs to elemental I_2 and an essentially covalent compound of iodine in a higher oxidation state than in the parent cation. These reactions were shown to be reversible. When the disproportionation products I_2 and IF_5 were added to HF solutions of varying acidity, mutual oxidation and reduction, i.e., conproportionation, yielded the products I_5^+, I_3^+, and I_2^+ as the acidity was increased even when each reactant was in ten-fold excess. It is apparent that, *unless a very powerful oxidant or reductant is present*, the level of acidity of the medium is the principal determinant of cationic speciation, regardless of whether oxidant or reductant is in excess i.e. regardless of reaction stoichiometry.

This pattern of stabilization of cations in unusual oxidation states in media of low basicity and their disproportionation on addition of base, which has now been well established quantitatively for iodine cations, appears to be quite general for homopolyatomic cations and for cations of transition metals in low oxidation states. It applies, regardless of the nature of the cations or of the media, to all the cations listed in Section 3.1.1. Even though many of the experimental observations are fragmentary, reports on synthesis and stability of cations in superacids other than HF and in chloroaluminates are all consistent with the scheme outlined above.

It is interesting to note that Hg_2^{2+}, the only homopolyatomic cation which has been shown to be stable in aqueous solution, disproportionates to metallic Hg and a Hg^{II} compound on addition of base. Furthermore the less stable Hg_3^{2+}, prepared in both chloroaluminate and in HSO_3F, disproportionates to Hg and a compound of Hg^{II} on contact with water.[23]

There is indirect but highly plausible evidence for disproportionation of U^{III} in nearly-neutral chloroaluminates in the work of Morrey and colleagues,[24,25] who prepared UCl_3 in situ in a series of sealed tubes by heating small amounts of U with very much larger comparable volumes of metallic Al and of chloroaluminate melts which ranged from acidic ($AlCl_3$/KCl, 2:1) through neutral (1:1) to basic (0.4:1). After prolonged heating, followed by quenching, each of the immiscible layers, metallic Al and chloroaluminates, was analysed for U. The uranium content of the metallic Al phase was very low when the chloroaluminate phase was strongly acidic or strongly basic but very much higher when the salt layer was nearly neutral. They reported different spectra for the U^{III} species in acidic and in basic melts. The present author has reinterpreted[2f] their work by postulating that U^{III} is present as stable cationic and anionic species in acidic and in basic melts but that near neutrality, U^{III} disproportionates to U^0 and U^{IV} in similar fashion as in Equation 8. Metallic U dissolves preferentially in the Al^0 phase and U^{IV}, present as a chlorouranate(IV) in the melt layer, is reduced to U^{III} by Al providing a cyclic disproportionation reaction leading to continually increasing concentrations of U^0 in the Al^0 layer.

Sørlie and Øye[26] dissolved $TiCl_2$ in $AlCl_3$ and reproduced the earlier spectrum (Figure 8b) recorded by Øye and Gruen.[6] They then recorded spectra for $TiCl_2$ dissolved in chloroaluminates of increasing basicity by progressive addition of KCl until the molar ratio was KCl/$AlCl_3$, 51:49. As neutrality was approached a large new band, possibly for $TiCl^+$, was observed with the original two bands characteristic of Ti^{2+} still present. In the basic melt (51:49) the spectrum changed dramatically to that observed by them for $TiCl_3$ in a basic melt. They reported that metallic Ti deposited on the walls of the spectroscopic cell in this slightly basic melt. Their observations are consistent with an idealised disproportionation reaction, Equation (13):

$$3\ Ti^{2+} + 12\ Cl^- \rightarrow Ti + 2\ TiCl_6^{3-} \quad (13)$$

2.2.5 Anions in Acidified Media

While several cations in unusually low oxidation states can be generated in highly acidic aqueous media, there does not appear to be anything particularly unusual about anion speciation in these media. A wide range of simple, familiar anions, e.g. halides, oxo-anions, carboxylates etc. can exist in acidified aqueous solutions as stable species, free or protonated to molecular species.

A much more limited range of anions can exist in the extremely acidic solvent HF. These are F^- itself, anions formed by Lewis acid-base interaction in HF e.g. BF_4^-, SbF_6^- and anions of superacids of comparable strength with HF, e.g. SO_3F^-. Other anions are fully protonated or solvolysed. Cl^- is protonated to HCl which is expelled from solution because of its insolubility and volatility. Carboxylates are doubly protonated to cationic species. Most oxo-anions undergo solvolysis, e.g. NO_3^- gives NO_2^+ and SO_4^{2-} forms SO_3F^-. The nonavailability of those simple anions which act as strong ligands in aqueous solution, e.g. Cl^-, means that metal cations undergo simple solvation in HF with no further complexation of the type exemplified for chlorochromium (III) cations in Section 2.2.1.

Little information is available on possible anionic species in chloroaluminates other than those derived from the me-

dium or from solutes which are usually added as anhydrous chlorides. So the only anions reported in acidic media are Cl^- and those derived from the Lewis acid, namely $AlCl_4^-$, $Al_2Cl_7^-$ etc.

2.3 Base-enhanced Media

This section deals with H_2O, HF, and chloroaluminates to which the conjugate base of the solvent has been added. The anhydrous NH_3 solvent system, where the *neutral* medium is more basic than H_2O, will be discussed in section 3.2.

2.3.1 Anions in Normal Oxidation States

To an extent even greater than in acidic aqueous media, basic aqueous solutions can support a wide range of simple anions such as halides, oxo-anions, carboxylates, etc. In basic H_2O, solvo-anions of transition metals in normal oxidation states whose hydroxides are amphoteric can form e.g. $Cr(OH)_4^-$, $Zn(OH)_4^{2-}$, $Al(OH)_4^-$ etc.

The situation in basic HF is not very different from that in acidic HF. Most simple anions are protonated or solvolysed. In addition to F^-, the stable anions are those derived from interaction between F^- and a Lewis acid. Very weak Lewis acids will form fluoro-anions in basic HF more extensively than in acidic HF e.g. MoF_6^-, TiF_6^{2-} etc.

A similar situation exists in chloroaluminates. Cl^- interacts with binary chlorides to produce chlorometallate anions[7] with the metal in the same oxidation state as in the parent chloride, e.g., $CrCl_3$, $CoCl_2$, $NiCl_2$, $ZnCl_2$, etc. form $CrCl_6^{3-}$, $CoCl_4^{2-}$, $NiCl_4^{2-}$, $ZnCl_4^{2-}$, etc.

2.3.2 Solvo-anions of Metals in High Oxidation States

Reference to Figure 2 shows that, to the extent that information is available, a general property of solvents made strongly basic is the ability to allow preparation of stable anions based on metals in high oxidation states coordinated by ligands derived from the solvent. Thus, oxidation of chromate(III), $Cr(OH)_4^-$, in basic water yields chromate(VI), CrO_4^{2-}, Examples of other oxo-anions prepared by oxidation in strongly basic aqueous solution are MnO_4^- and PuO_5^{3-}, for which the metals are in oxidation state VII, the latter being very unusual for Pu.

The spectra in Figure 3 show that chromium(III) is soluble in basic HF as CrF_6^{3-}. Fluorochromate(V), CrF_6^- (see Figure 2) has been shown to be stable in basic anhydrous HF.[27] Solid CrF_5, prepared by fluorination of CrF_3, was added to an HF solution containing $NF_4^+HF_2^-$ – i.e. a basic solution – to yield $NF_4^+CrF_6^-$, a very powerful oxidant.

There have been several reported preparations of fluoronickelate(IV), NiF_6^{2-}, which is stable in HF. Stein and coworkers electrolysed strongly basic HF (0.5 to 1.5 M in KF) using a nickel anode and generated red NiF_6^{2-}, in solution.[28]

Žemva and colleagues used the very powerful oxidant KrF_2 to react with AgF_2 and NiF_2 in HF in the presence of XeF_6 at −60°C and produced the solids $[XeF_5^+Ag^{III}F_4^-]$[29] and $[(Xe_2F_{11}^+)_2Ni^{IV}F_6^{2-}]$.[30] XeF_6 ionises extensively in HF to form XeF_5^+ and F^-, providing both the basic HF solution necessary for the formation of the high oxidation state anions in solution and the counterions XeF_5^+ and $Xe_2F_{11}^+$ for isolation of the solid products.

More recently Bartlett has reported quantitative oxidation of NiF_2 and AgF_2 to $[Ni^{IV}F_6^{2-}]$[31] and $[Ag^{III}F_4^-]$[32] at room temperature using ultra violet – or sunlight – irradiated F_2 in very strongly basic HF (KF/HF ≈ 1:4). The anions were isolated as the stable solids K_2NiF_6 and $KAgF_4$.

There does not appear to have been any work done on generation in basic chloroaluminates of chloro-anions of metals in very high oxidation states. This would appear to be a potentially fruitful synthetic route to new chlorides and chloro-anions, particularly as the very reliable voltammetric procedures developed for investigations in room temperature chloroaluminates could be used to indicate attainability of high oxidation states.

3. Other Ionising Media

In order to demonstrate in some depth the general nature of the dependence of formation and stability of cationic and of anionic species on acidity and basicity of the medium, the content of this article, to date, has been limited to speciation in H_2O, HF, and chloroaluminates, media for which a reasonably broad range of experimental information is available.

There is good reason to believe that the generalities propounded for these three solvents hold good for all ionising acid-base media. Two other types of media will now be considered briefly, the anhydrous sulfur acids (oleums and fluorosulfuric acid) and strongly basic media, particularly anhydrous ammonia. The principal reasons for adding these are that homopolyatomic cations, which were discussed briefly for HF and chloroaluminates, were first identified systematically in sulfur acids. Further, it is a corollary of the fact that homopolyatomic cations are stable in highly acidic media that homopolyatomic anions, e.g., the Zintl ions, are generated in strongly basic media such as NH_3. To the extent that information is available, it can be shown that transition metal ionisation in these solvents follows the same trends as in the three solvents discussed to date.

3.1 Sulfur Acids

3.1.1 Homopolyatomic Non-metal Cations

Earlier, in Sections 2.2.3 and 2.2.4 there was an account of a quantitative Melbourne study of the dependence of stability of iodine cations on acidity and basicity levels in HF.[19] This is the only such study in HF that has been reported. However, virtually all of the pioneering work on generation in solution of cations of iodine, bromine, sulfur,

selenium, and tellurium had emanated earlier from Gillespie's group at McMaster University, Ontario. He and Passmore published an early review of that work which is relatively short and very readable.[33] More recently Passmore and colleagues have reviewed the field exhaustively.[34]

From nearly 200 years ago there had been reports of highly coloured solutions of I_2, S_8, Se_8, and Te in oleums (H_2SO_4 containing excess SO_3). Formation of oxo-cations or oxo-anions was proposed to account for these colours. Gillespie showed conclusively that the coloured species in oleums and in HSO_3F were the homopolyatomic cations I_2^+, I_4^{2+}, I_3^+, I_5^+, Br_3^+, Te_6^{4+}, Te_4^{2+}, Se_4^{2+}, Se_8^{2+}, Se_{10}^{2+}, S_4^{2+}, S_8^{2+}, and S_{19}^{2+}.

The basis for Gillespie's very elegant methodology in this area is illustrated below in the generation of Se_8^{2+} and Se_4^{2+}. He used the powerful oxidant peroxydisulfuryldifluoride ($S_2O_6F_2$) in appropriately varying stoichiometric amounts in the solvent HSO_3F to oxidise the elements, in this case Se. $S_2O_6F_2$, on reduction, yields two SO_3F^- anions. SO_3F^- is the base of the solvent and has a greatly enhanced ionic mobility in the solvent and so can be monitored conductometrically. After reaction, he and his coworkers determined the number of ionic particles in solution by cryoscopy and the number of SO_3F^- ions by an original specialised conductance method. For the oxidation of Se_8 by $S_2O_6F_2$ in the stoichiometric ratio 1:1 in HSO_3F, they demonstrated cryoscopically that there were three particles per mol of Se_8, two of which were shown to be SO_3F^- ions by conductance measurements, indicating that the third particle was doubly positively charged, Equation (14):

$$Se_8 + S_2O_6F_2 \rightarrow Se_8^{2+} + 2\,SO_3F^- \quad (14)$$

If 1:2 stoichiometry were to be used, six particles would be observed, four of which would be SO_3F^- ions, so that Se_4^{2+} would be the reaction product, Equation (15):

$$Se_8 + 2\,S_2O_6F_2 \rightarrow 2\,Se_4^{2+} + 4\,SO_3F^- \quad (15)$$

In the oleum experiments, SO_3 acted both as the Lewis acid and as a less specific oxidant.

The McMaster group recorded UV/Visible spectra to characterise each of the cations in oleums or HSO_3F and in many cases isolated solid products containing the cations, necessarily associated with weakly basic anions, and determined their structures by X-ray diffraction techniques.

On addition of base, SO_3F^- or HSO_4^-, all of these cations disproportionate to a cation of lower charge-to-atom ratio and a covalent compound in a higher oxidation state, in similar fashion to the disproportionation of iodine cations as discussed in Section 2.2.4. Ultimately, on addition of sufficient base, they disproportionate to the element and a covalent compound.

Table 2 shows two general trends for the dependence of the stability of polyatomic cations of S, Se and Te on the level of acidity of the medium. The media are all based on 100% H_2SO_4, made either acidic with SO_3 or, in one case, weakly basic with HSO_4^-. Values of H_o listed in Table 2 are taken from the work of Gillespie, Robinson, and Peel[35] and are based on the experimental conditions, such as addition of SO_3 or of HSO_4^- to H_2SO_4, cited in the reports of the preparation of each of the cations. Consideration of the threshold acidities for stabilisation of the sulfur cations shows that the higher the ratio of charge-to-atom, the higher is the required acidity, i.e., the lower the basicity of the medium. Less base is required to cause disproportionation of S_4^{2+} than for S_8^{2+} and S_{19}^{2+} in turn. For the cations of the same structure and charge S_4^{2+}, Se_4^{2+}, and Te_4^{2+}, the smaller the atomic number of the element the higher is the acidity required for stabilisation, i.e., the lower the basicity of the medium. There is greater attenuation of charge over Te_4^{2+} than for Se_4^{2+} and S_4^{2+}, in turn, i.e., Te_4^{2+} is the least electrophilic of the three cations and can exist with a greater availability of base without disproportionating. *These stability trends for chalcogen cations hold for all homopolyatomic cations of metals and nonmetals in other acidic solvents*, but less comprehensive data are available to allow similar quantitative comparisons for these other solvents.

3.1.2 Transition Metal Cations

Little work has been reported in the open literature on generation of cations or solvo-anions of transition metals in the sulfur acids. In Melbourne work the spectra of solvated Co^{2+}, Ni^{2+}, and Cr^{3+} were recorded after adding appropriate Lewis acids to oleums, HSO_3F, and CF_3SO_3H.[2g] $Co(HSO_4)_2$ was shown to be sparing soluble in 100% H_2SO_4. Addition of SO_3 caused marked increase in the Co^{II} concentration and the spectrum was that for six-coordinate Co^{II} (Figure 4b). Electrolysis was conducted in a three-compartment cell with Co^{II} in 20% $SO_3-H_2SO_4$ in the central compartment. Spectrometric analysis showed that Co^{II} moved quantitatively to the cathode compartment, with no detectable Co^{II} in the anode compartment, indicating the existence of solvated Co^{2+} in the oleum solution.

For most of these Melbourne studies,[2g] Co^{II} was chosen as a model solute because of the major differences in spectra for four-coordinate and six-coordinate Co^{II} (Figure 4a and 4b). $Co(SO_3F)_2$ and $Co(CF_3SO_3)_2$ were both found to be sparingly soluble in "neat" HSO_3F and CF_3SO_3H but dissolved when the Lewis acids SbF_5 and $B(OSO_2CF_3)_3$ were added to the two superacids. In each case spectra were very similar to that in Figure 4b indicating, as with $Co(H_2O)_6^{2+}$ and $Co(HF)_6^{2+}$, six-coordinate solvated cation formation in each case. Table 3 shows the similarity of the spectra in H_2O, the four superacids and $AlCl_3$. For spectra of all the *d*-transition metal cations studied, small shifts of peak positions relative to aqueous solutions were observed for all the superacids with larger shifts in chloroaluminates.

Table 2. Dependence of charge on chalcogen cations on acidity of the medium

Cation	S_4^{2+}	S_8^{2+}	S_{19}^{2+}
Medium	>40% $SO_3-H_2SO_4$	>15% $SO_3-H_2SO_4$	>5% $SO_3-H_2SO_4$
Hammett Function	−14.1	−13.2	−12.7
Cation	S_4^{2+}	Se_4^{2+}	Te_4^{2+}
Medium	>40% $SO_3-H_2SO_4$	100% H_2SO_4	$HSO_4^- - H_2SO_4$
Hammett Function	−14.1	−11.9	−11

Table 3. Peak positions for cobalt (II) in acidified water, superacids, and in acidic melts; sh = shoulder

Solvent	H_2O	HF	HSO_3F
Peak positions [nm]	458 sh 510	471 sh 532	477 sh 545
Solvent	CF_3SO_3H	$SO_3-H_2SO_4$	$AlCl_3$
Peak positions [nm]	482 sh 555	483 sh 540	590 sh 633

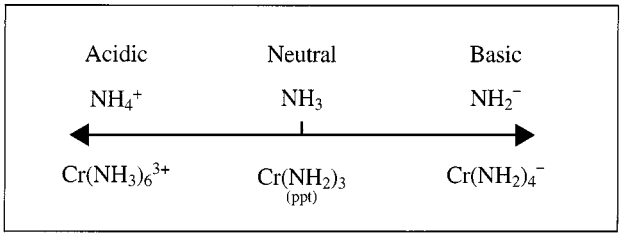

Figure 9. Dependence of Cr^{III} speciation in liquid NH_3 on acidity and basicity of the medium

3.2 Strongly Basic Media

3.2.1 Homopolyatomic Anions

The converse of stabilisation of homopolyatomic cations containing elements of fractional positive charge in strongly acidic (i.e. weakly basic) media is the formation of homopolyatomic anions containing elements of fractional negative charge in media which in the "neat" state are much more basic than H_2O.

Historically, this class of anion dates back to the work of Zintl in Germany about 1930. He reduced PbI_2, dissolved in NH_3, with strongly basic solutions of Na in NH_3 to produce the ions Pb_7^{4-} and Pb_9^{4-} in solution. Zintl also generated Sn_9^{4-} and a range of anions A_n^{3-} (for A = As, Sb, Bi and n = 3, 5, 7) as well as dinegative polyatomic anions of Se and Te. Some four decades later ethylenediamine, more basic than NH_3 and, unlike NH_3, a liquid at room temperature, was used as a medium to produce many more polyatomic anions. This field has been reviewed by Corbett.[36]

Much work has been done on isolation of solid products containing the polyatomic anions for structure determination; but that lies outside the scope of this very brief survey of these anions *in solution*. However very little systematic work has been done on deliberate variation of the acidity or basicity of NH_3 by adding NH_4^+ or NH_2^- to study anion stability. There are some incidental observations[2h] that suggest strongly that these anions are more stable when the base NH_2^- is added and that they decompose on addition of the acid NH_4^+ − the opposite of the behaviour of polyatomic cations in acidic media, as expected.

3.2.2 Solute Speciation of Transition Metals

Figure 2 was used to indicate the generality of solute speciation in H_2O, superacids and molten salts i.e. solvated cations exist in acidified medium, sparingly soluble "binary" uncharged polymeric compounds in neutral medium and solvo-anions in the medium to which excess base has been added. A survey of solute speciation[37] shows that a similar situation holds in liquid NH_3, as indicated in Figure 9.

$CrCl_3$ dissolves in "neat" NH_3 to give $Cr(NH_3)_6^{3+}$ as well as $Cr(NH_3)_5Cl^{2+}$ (c.f. $Cr(H_2O)_5Cl^{2+}$ in water).[37] At first sight, it might seem surprising that solvated cations, rather than polymeric amides, are formed in "neat" NH_3 which undergoes the self-ionisation, Equation (16):

$$2\,NH_3 \rightleftharpoons NH_4^+ + NH_2^- \qquad (16)$$

The self-ionisation constant, K_i, for this equilibrium is extremely small, being about 10^{-33} mol^2L^{-2} at −50 C.[37] The dependence of the acidity − basicity range in a protic solvent on its autoprotolysis constant was discussed in Section 1, where it was shown that minute traces of H_2O, acting as a Bronsted base in HF, could reduce the H_o value for HF by as much as four units. The most likely impurity in NH_3 is reported as being H_2O[37] which acts as a Bronsted acid to produce NH_4^+ and OH^-, the latter being an "innocent" ion in NH_3 in the acid-base sense. Because of the very small autoprotolysis constant for NH_3, traces of H_2O will greatly increase the acidity of the medium, favouring formation of cationic species.

Solute speciation in NH_3 parallels that in other solvents.[37] Thus addition of NH_2^- to $Cr(NH_3)_6^{3+}$ in NH_3 gives insoluble, polymeric chromium amide, $[Cr(NH_2)_3]_n$, which is amphoteric and forms soluble $Cr(NH_2)_4^-$ on further addition of NH_2^-. VCl_3 dissolves in "neat" NH_3 to form $V(NH_3)_6^{3+}$ as well as $[V(NH_3)_5NH_2]^{2+}$ which is the counterpart of $[V(H_2O)_5OH]^{2+}$ in water. Addition of NH_2^- gives $[V(NH_2)_3]_n$ and then $V(NH_2)_4^-$. The divalent metals Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, and Zn^{II} all form $M(NH_3)_6^{2+}$ in solution and give the amides $[M(NH_2)_2]_n$ on addition of NH_2^-.

Transition metals in higher "normal" oxidation states undergo more complex solvolysis[37] giving species like $TiCl(NH_2)_3$. Deprotonation of NH_3 to NH_2^- can proceed further to formation of imide, NH^{2-}, and nitride, N^{3-}, and many anionic species for metals in relatively high oxidation states are reported to be more complex through coordination of these latter two species, as in $[TiNH_2(NH)_2]^-$ and $[Zr(NH_3)_2(N)_2]^{2-}$. These are somewhat akin to Ti and Zr species containing OH^- and O^{2-} ligands in aqueous solution and in solids derived from aqueous solutions.

3.2.3 Anions of Transition Metals in Unusually Low Oxidation States

Unlike the situation in superacids where solvo-anions can be generated which contain transition metals in unusually high oxidation states (Section 2.3.2), anions based on transition metals in unusually low oxidation states have been generated in NH_3. Reduction by metallic K in NH_3 at −33°C of the entities $[Ni(CN)_4]^{2-}$, $[Pt(NH_3)_4]^{2+}$, $Mn_2(CO)_{10}$, and $Fe(CO)_5$ led to formation of $[Ni(CN)_4]^{4-}$, $Pt(NH_3)_4$, $[Mn(CO)_5]^-$, and $[Fe(CO_4]^{2-}$ with the metals in formal oxidation states Ni^0, Pt^0, Mn^{-1}, and Fe^{-II}.

Conclusion

In Figure 2 and Figure 9, chromium(III) has been used to show that there is a common pattern of acid-base dependent solute speciation in the solvents H_2O, HF, NH_3, and chloroaluminates. Uncharged binary polymeric precipitates form in neutral medium.

Moderate increase in acidity leads to formation of cations, solvated to greater or less degree, particularly when considering transition elements of the First Row of the Periodic Classification. (Transition elements of the Second and Third Rows normally occur in high oxidation states and rarely occur as discrete monatomic cations in aqueous solutions. For example Mo and W normally exist in aqueous solution as molybdates and tungstates which, in some instances, are polymeric).

Elements other than chromium have been used to demonstrate that provision of a *highly acidic* medium can allow generation and stabilisation of cations of metals in unusually low oxidation state or, except for H_2O, homopolyatomic cations of metallic and nonmetallic elements. More specifically, a highly acidic medium is one of very low basicity − sufficiently low to prevent disproportionation of the cations. Superacidic conditions happen to be a convenient way of providing media of very low basicity. H_2O is too basic to allow existence of the homopolyatomic cations or of many of the low-oxidation-state transition metal cations generated in superacids.

When the uncharged precipitate is amphoteric, moderate increase in basicity of the medium will lead to formation of solvo-anions − complexes of the metal and the base of each solvent, e.g. $Cr(OH)_4^-$, CrF_6^{3-}, and $CrCl_6^{3-}$. It appears that many more binary chlorides are amphoteric in molten chloride media than is the case for precipitates in H_2O, HF, and most solvents. When each of the media is made *very strongly basic*, generation of very high oxidation states is possible for chromium and other metals in the solvo-anions.

For most solvent systems there is less information available on solute speciation across a wide range of acidity and basicity than is the case for the three solvents presented in Figure 2. Sulfur acids and ammonia have been included to show that the available information on solute speciation is consistent with the patterns outlined in this review. Thus the solvated cation $Cr(NH_3)_6^{3+}$, the neutral polymer $[Cr(NH_2)_3]_n$ and the solvo-anion $Cr(NH_2)_4^-$ are generated in acidic, neutral and basic NH_3. Further, inclusion of these two solvent systems indicates that some converse relationships exist between highly acidic and highly basic media. Thus homopolyatomic cations are stable in superacidic media while homopolyatomic anions are stable in NH_3 and ethylenediamine. Solvo-anions of transition metals in very high oxidation states can be generated in superacidic media, such as HF, while anions of transition metals in very low oxidation states are formed in basic media such as NH_3.

The only class of molten salt system presented here has been the chloroaluminates because of the ease of adjusting the acidity or basicity of the medium and because of the relative simplicity of ionic speciation in the molten salt itself. By comparison, molten silicates for example, where the acid of the system is SiO_2, the base is O^{2-} and the species in a neutral silicate is SiO_4^{4-}, are extremely complex. However it is to be expected that extremely complex silicate systems, like geological magma or metallurgical slags, would lend themselves to similar investigation and interpretation of solute species.

There are good reasons to believe that the systematisation demonstrated in this review for a limited number of solvents holds generally for acid-base interaction of inorganic solutes with all ionising solvents. What emerges from this overview is that, as a generalisation, the levels of acidity or basicity of solvent systems, rather than their chemical composition or temperature domain, are the principal determinants of charge and oxidation state of ionic species in solution.

The Reductive and Oxidative Half-Reactions and the Role of Copper Ions in Plant and Mammalian Copper−Amine Oxidases

Alessandra Padiglia,[a] Rosaria Medda,[a] Andrea Bellelli,[b] Enzo Agostinelli,[c] Laura Morpurgo,[c] Bruno Mondovi',[c] Alessandro Finazzi Agrò,[d] and Giovanni Floris[a][‡]

Keywords: Oxidases / Mammalian amine oxidase / Copper / Cofactors / 6-Hydroxydopa

In this review, the nature and characteristics of the prosthetic group, the intermediates in the catalytic mechanism, and the role of the copper in plant copper–amine oxidases from pea and lentil seedlings are compared with the corresponding features of mammalian amine oxidase from bovine serum. All these enzymes contain the same organic cofactor derived from the modification of a protected tyrosyl residue. Considering the catalytic mechanism, plant amine oxidase may be referred to as a "protein radical enzyme", operating through a free radical located on the cofactor. This is in contrast to bovine serum amine oxidase, which forms the free-radical intermediate only to a minor extent in the course of the catalytic cycle. A scheme for the catalytic mechanism is proposed in order to account for this difference.

I. Introduction

Copper-containing amine oxidases [amine−oxygen oxidoreductase (deaminating) (copper/TPQ-containing); EC 1.4.3.6] are homodimers, in which each subunit (MW 70−90 KDa) contains one tightly bound Cu^{II} ion and one 6-hydroxydopa quinone (TPQ) moiety as prosthetic groups. These enzymes catalyze the oxidative deamination of primary amines by transferring two electrons from the amines to molecular oxygen. The catalytic mechanism can be divided into two half-reactions, namely enzyme reduction by the substrate [Equation (1)] followed by enzyme re-oxidation by molecular oxygen [Equation (2)].

$$E_{ox} + R-CH_2-NH_3^+ \rightarrow E_{red}-NH_2 + R-CHO \quad (1)$$

$$E_{red}-NH_2 + O_2 \rightarrow E_{ox} + NH_3 + H_2O_2 \quad (2)$$

Amine oxidases are ubiquitous enzymes, occurring in microorganisms (fungi and bacteria),[1] plants,[2] and mammals.[3] In the plant kingdom, the presence of amine oxidases was first demonstrated in 1949.[4] Since then, plant amine oxidases from various species of several families have been purified to homogeneity and characterized,[2] the best known and studied being those from seedlings of the pulses lentil[2] (*Lens esculenta*) and pea[5] (*Pisum sativum*) and that from *Euphorbia characias* (a shrub) latex.[6] Mammalian amine oxidases have also been actively investigated for over 40 years, well-studied examples being those from pig kidney,[7−9] human placenta,[10,11] bovine serum,[12−15] pig plasma,[16] and equine plasma.[17] The nature of the covalently bound cofactor and the number of active sites, as well as the role of copper and the reaction mechanism have been also investigated over many years.

Abbreviations used: Cu−AO: copper−amine oxidase; BSAO: bovine serum amine oxidase; LSAO: lentil seedling amine oxidase; PSAO: pea seedling amine oxidase; TPQ: 6-hydroxydopa (2,4,5-trihydroxyphenylethylamine) quinone.

II. The Organic Cofactor and Copper

The presence of an organic cofactor in copper−amine oxidases has been sought for almost 60 years and its nature has been the subject of much debate.[18] Prior to 1984, the most likely candidate was considered to be a covalently bound pyridoxal 5-phosphate[19] (Figure 1, A), but this hypothesis could never be proved. During the 1970s, a new dissociable cofactor was identified in bacterial glucose dehydrogenase and methanol dehydrogenase, which was eventually demonstrated to be pyrrole quinoline quinone by X-ray diffraction analysis[20] (Figure 1, B). This led to the suggestion that pyrrole quinoline quinone might be the active site cofactor of a range of eukaryotic proteins, including copper amine oxidases from bovine serum,[21,22] pig kidney,[23] and pea seedlings.[24] Finally, in 1990, Klinman and co-workers[25] demonstrated that 6-hydroxydopa quinone (TPQ, Figure 1, C), derived from the oxidation of an in

trinsic tyrosine in the amino acid sequence in a post-translational event, is in fact the redox cofactor of eukaryotic amine oxidases.[26] A sequence Asn−TPQ−Asp/Glu was identified in these enzymes,[27] and the cDNA-derived amino acid sequence of *Lens esculenta* (EMB Data Bank accession number X64201),[28] *Hansenula polymorpha*,[26] bovine serum (EMBL Data Bank accession number Q29437),[29] *Pisum sativum* (GB Data Bank accession number L39931),[30] *Cicer arietinum* (EMB Data Bank accession number AJ009825),[31] and *Euphorbia characias* (GB Data Bank accession number AF171698)[6] amine oxidases revealed that a tyrosine codon corresponds to the TPQ cofactor in the mature protein.

Besides TPQ, amine oxidases also contain copper in a 1:1 stoichiometric ratio with the organic cofactor. The crystal structure of PSAO[5] shows that the copper atom is coordinated by three histidine side chains and two water molecules (Figure 2), with the shortest distance between TPQ and the copper atom being ca. 6 Å. Extended X-ray absorption fine-structure (EXAFS) analysis has been used to define the

Alessandra Padiglia, PhD in Comparative Biochemistry of Ecosystems; specialized in Toxicology. Currently she is researcher of Biochemistry and Molecular Biology, Faculty of Science, University of Cagliari (Italy). She is working on purification and characterization of enzymatic proteins, and on plant genes.

Rosaria Medda, Researcher of Biochemistry, Faculty of Medicine, University of Cagliari (Italy). She is working on purification and characterization of enzymatic proteins, and on metabolism of diamines and polyamines.

Andrea Bellelli, Researcher at the "Centro di Biologia Molecolare", Consiglio Nazionale delle Ricerche (CNR), Rome, Italy. His main research interests are oxygen-carrying proteins and enzymes with oxidase activity.

Enzo Agostinelli, Associate Professor of Applied Biochemistry, Faculty of Pharmacy, University of Rome "La Sapienza" (Italy). He improved his knowledge on intracellular microinjection and electroporation techniques in U.S.A. He is studying the nature and functionality of the catalytic site of amine oxidase from bovine serum.

Laura Morpurgo, Researcher at the "Centro di Biologia Molecolare", Consiglio Nazionale delle Ricerche (CNR), Rome, Italy. She improved her knowledge at the Inorganic Chemistry Laboratory of Oxford (UK) and at the Laboratory of Chromatography of Rome (Italy). Her researche is concerned with metal complexes and with structure−function relationships in copper-containing proteins.

Bruno Mondovi', PhD in Biochemistry and PhD in Applied Biochememistry. Currently he is Full Professor of Applied Biochememistry, Faculty of Pharmacy, University of Rome "La Sapienza" (Italy). He is working on structure and function of copper proteins and on biochemical mechanisms of heat sensitivity of cancer cells.

Alessandro Finazzi Agrò, Full Professor of Enzymology, Faculty of Medicine, University of Rome "Tor Vergata" (Italy) and currently Rector of the same University. Since 35 years he is studying copper proteins and copper enzymes with respect to their biochemical, physiological and pathological roles.

Giovanni Floris, Associate Professor of Biochemistry and Molecular Biology, Faculty of Science, University of Cagliari (Italy). He is working on purification and characterization of enzymatic proteins, particularly on plant amine oxidases.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

structure of the copper site in both the oxidized and dithionite-reduced states of some amine oxidases.[32]

III. The Number of Actives Sites

Since all the amine oxidases described so far are homodimers, a problem arose concerning the number of active sites present in the molecule. This problem has mainly been tackled by titrating the enzyme with irreversible inhibitors. The conflicting results obtained on titrating amine oxidases with carbonyl reagents have been rationalized for LSAO and PSAO.[33,34] The titration of highly purified samples extrapolates to 1 mol of inhibitor per enzyme subunit, indicating the presence of two active quinones moieties per protein dimer. A similar result was reported for the titration of highly purified samples of BSAO with phenylhydrazine,[35] but Morpurgo et al.[14] subsequently found that only one enzyme subunit actually reacts with this inhibitor. A somewhat higher value, 1.1−1.3 mol/dimer, was obtained with other reagents, e.g. semicarbazide and 2-hydrazinopyridine.[36,37] In these cases, the reaction of one mol of inhibitor/dimer was faster than the subsequent reaction, which led to the generation of a spectroscopically different adduct.

IV. Optical and EPR Spectroscopy

In addition to the protein absorbance maximum at ca. 280 nm, oxidized Cu−AOs show an absorption band in the visible region associated with their distinctive pink color. The visible spectra of TPQ cofactor models show maxima at 480−484 nm,[38,39] consistent with theoretical calculations. Indeed, the maximum absorbance observed for most mammalian Cu−AOs is very close to 480 nm. In the plant enzymes, this band is red-shifted to 498 nm, probably because of specific interactions with amino acid residues in the active site. Removal of copper from the amino oxidases from both LSAO[40] and *Euphorbia* latex[6] under non-reducing conditions shifts the band to 480 nm. Reconstitution of the metal-depleted protein with cobalt does not restore the native spectrum of LSAO and the absorption maximum remains at 480 nm.[41] In the case of BSAO, the visible band maximum is unaffected by metal depletion and Co^{2+} substitution.[42] The extinction coefficients for some Cu−AOs are listed in Table 1.

Table 1. Extinction coefficients ($mM^{-1}\ cm^{-1}$) of the amine oxidases from pea and lentil seedlings and from bovine serum at pH = 7; wavelengths are given in italics

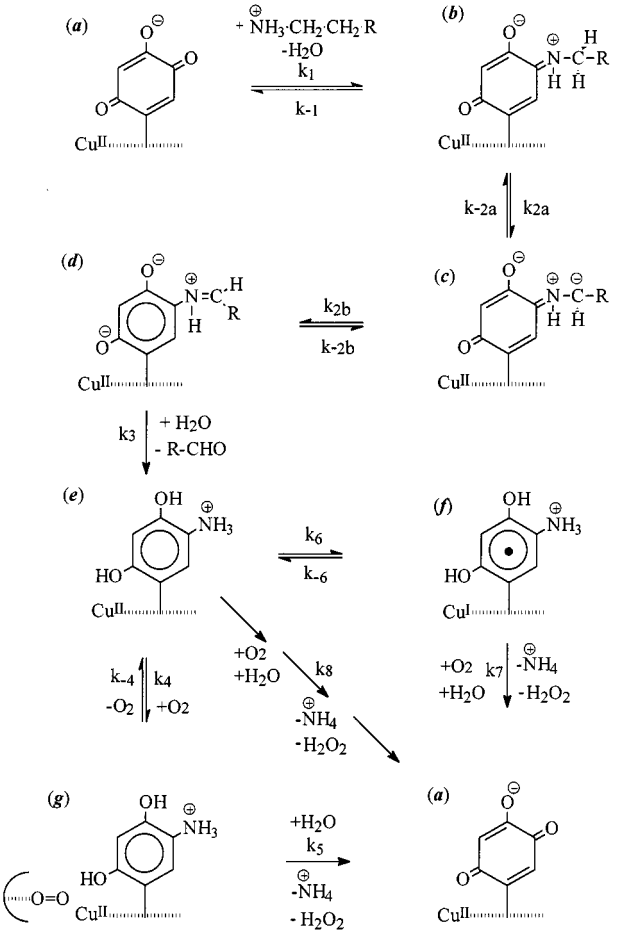
Enzyme	Oxidized form	Reduced form
PSAO	4.9 (*498*), 300 (*278*)[34]	–
LSAO	4.5 (*498*), 245 (*278*)[33]	7.1 (*464*) 4.6 (*434*)[47]
BSAO	3.8 (*480*), 310 (*280*)[74]	–

The copper ion in Cu−AOs is EPR-detectable and its spectrum falls in the category of so-called type-2 Cu EPR spectra.[43] Native LSAO exhibits a typical type-2 copper spectrum in a tetragonal field, characterized by $g_{\|} = 2.32$ and $A_{\perp} = 153$ G, and by the absence of superhyperfine structure.[44] The same applies to BSAO, for which the EPR parameters are $g_{\|} = 2.30$ and $A_{\perp} = 155$ G.[45]

V. The Reaction Mechanism

A. The Reductive Half-Reaction

A plausible kinetic scheme for the catalytic mechanism of Cu−AOs is presented in Scheme 1. It might be somewhat redundant since plant and mammalian enzymes behave differently and some of them may fail to populate all the intermediates, at least under the usual experimental conditions, as detailed below.



Scheme 1. Catalytic mechanism of Cu−AOs: (***a***) resting oxidized enzyme; (***b***) Cu^{II}−quinone ketimine, the substrate Schiff base; (***c***) Cu^{II}−carbanion species; (***d***) Cu^{II}−quinolaldimine, the product Schiff base; (***e***) Cu^{II}−aminoresorcinol; (***f***) Cu^{I}−semiquinolamine radical; (***g***) Cu^{II}−aminoresorcinol−oxygen complex

Step 1: Cu^{II}−Quinone Ketimine

The amine substrate binds to the carbonyl function of TPQ in the resting oxidized enzyme [Cu^{II}−TPQ (***a***)] to form a substrate Schiff base [Cu^{II}−quinone ketimine (***b***)]. In the case of BSAO, Hartmann and co-workers[46] demon-

strated that the quinone and quinone ketimine oxidized forms of the enzyme, both of which absorb at 480 nm, are spectroscopically distinguishable since only ***b*** shows a shoulder at 340 nm. In order to maximize the population of the quinone ketimine species in the catalytic cycle of LSAO, Floris and co-workers used different substrates. With γ-aminobutanoic acid as the substrate,[47] a marked delay (4 min) was observed before bleaching of the enzyme, indicative of the formation of the quinone ketimine intermediate. The authors were unable to distinguish the "pink" spectrum of the latter from that of the quinone species.

Step 2: Cu^{II}−Carbanion Species

The oxidation of the amine substrate involves base-catalyzed abstraction of a proton from C1 with the formation of a Cu^{II}−carbanion species (***c***). The formation of the carbanion species was demonstrated in the case of BSAO using *para*-substituted benzylamines.[48] The carbanion species generated in the case of LSAO was later trapped with the electrophilic reagent tetranitromethane.[49] The active site base was identified as Asp300 in PSAO.[5] It is worth noting that the stereospecificity of proton abstraction in the reaction with *Escherichia coli* AO, coupled with the mutagenesis data, shows beyond any doubt that Asp383 is the catalytic base.[50] The protected Asp381 seems to play a similar role in BSAO.[37]

Step 3: Cu^{II}−Quinolaldimine

Transformation of the Cu^{II}−carbanion (***c***) into the product Schiff base, the Cu^{II}−quinolaldimine (***d***), is associated with the bleaching of the 498 nm absorption band. This intermediate is the most elusive species involved in the reaction mechanism of AOs. The tautomeric form of the quinolaldimine (a quino-imine) was identified in both LSAO[40] and BSAO[46] using the poor substrate *p*-(dimethylamino)benzylamine.

Step 4: Cu^{II}−Aminoresorcinol

Oxidation of the bound substrate (followed by hydrolysis) releases the aldehydic product, leaving the Cu^{II}−aminoresorcinol derivative (***e***) bearing a bound ammonia molecule. This species is still colorless. Hartmann and co-workers[46] demonstrated a complex time evolution of the "colorless" component in BSAO, attributed to the transformation of quinolaldimine into aminoresorcinol, although they were unable to assign a defined difference spectrum to this reaction. That the aldehyde is released after hydrolysis of the imine, leaving the amino group bound to the cofactor, has been demonstrated in both mammalian and plant AOs.[6,35,40]

In conclusion, comparison of the spectroscopic changes described above with Scheme 1 clearly shows that the chemistry of TPQ implies the involvement of more than three different species. Indeed, the "pink" oxidized Cu^{II}−TPQ derivatives and the "colorless" reduced forms have at least been demonstrated to represent "families" of derivatives rather than pure chemical species. The species ***a***, ***b***, and ***c*** in Scheme 1 are believed to be pink, albeit with slightly different spectra,[50] whereas species ***d*** and ***e*** are colorless.

B. The Oxidative Half-Reaction

In contrast to the detailed studies on the reductive half-reaction [Equation (1)], little is known about the oxidative half-reaction in plant enzymes [Equation (2)]. This reaction has, however, been well characterized in the case of BSAO.[51,52]

Cu^{I}−Semiquinolamine Radical

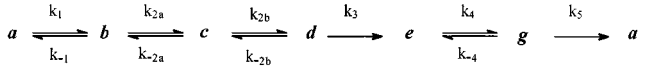
Hill and Mann[19] reported that solutions of PSAO turned from pink to yellow when an appropriate substrate was added under anaerobic conditions. The absorption band of the oxidized enzyme, with a maximum at about 500 nm, disappeared immediately and was replaced by three bands centered at 465, 435, and 350 nm. The authors concluded that the yellow product was the enzyme−substrate complex. Years after this observation, the yellow intermediate was proposed to be a free radical on the basis of its EPR spectrum, which shows a well-resolved hyperfine structure due to coupling with the various protons of an aromatic ring. The presence of copper ions has been shown to be essential for the observation of the free-radical EPR signal.[53] Since the identification of TPQ as the cofactor of several amine oxidases,[25] unequivocal evidence has been obtained for the generation of a Cu^{I}−semiquinone by substrate reduction under anaerobic conditions in plant amine oxidases.[40,54]

When a good substrate such as putrescine is added to LSAO, the broad absorption band at 498 nm disappears instantaneously, indicative of rapid conversion of the TPQ cofactor to a colorless species, the Cu^{II}−aminoresorcinol (***e***), which is predominant in the steady state. If the amine concentration is high enough to fully consume the available oxygen, the solution turns yellow owing to the emergence of new absorption bands centered at 434 and 464 nm.[40,47,54] These are indicative of the formation of Cu^{I}−semiquinolamine free radical species (***f***), in which the substrate-derived nitrogen is covalently bound to the aromatic ring system.[55−57] The extinction coefficients of substrate-reduced LSAO at pH = 7 and 298 K are reported in Table 1. It may be estimated from EPR measurements that under these experimental conditions the population of the radical species lies in the range 40−50%, the remaining fraction of the enzyme being in the form of Cu^{II}−aminoresorcinol. The yellow radical species ***f*** is in a sense "pure", since it does not share its spectrum with other species. However, it occurs in an equilibrium mixture with species ***e***.[54,58] It proved possible to stabilize the Cu^{I}−aminoresorcinol by treating the radical with dithionite, thus allowing the spectrum of the pure colorless species to be recorded.[47] The addition of substrate to LSAO under anaerobic conditions at room temperature led to a marked decrease in the EPR signal attributed to Cu^{II}, while a new signal appeared at $g \approx 2$, at a field modulation amplitude lower than 1 G. This signal intensified with time, reached a

maximum after 5 min of incubation, and thereafter was found to be stable in the frozen sample or in anaerobic liquid solutions. Admission of air led to a gradual disappearance of this signal. These features are indicative of a free radical. In the case of the pea enzyme, Dooley et al.[54] showed that ca. 40% of the Cu^{II} is reduced to Cu^{I} after the addition of substrate to the native enzyme under anaerobiotic conditions, indicating that the Cu^{I}−semiquinolamine and the Cu^{II}−aminoresorcinol are in equilibrium. The interconversion rate constants of these two species were estimated by *T*-jump methods to be $k_{+6} = k_{-6} = 2{\cdot}10^4\ s^{-1}$ [58] (Table 2), taking advantage of the large equilibrium ΔH. Indeed, the Cu^{I}−semiquinolamine EPR signal, monitored as a function of temperature, could not be detected below about 258 K, but was observed to increase on going from 283 to 298 K, the highest temperature investigated.[58][59]

Table 2. Rate constants for the individual steps described in Scheme 1; all data for BSAO are due to Bellelli et al.,[52] whereas those for LSAO are due to Bellelli et al.[65] and Medda et al.,[47] except the values for k_6/k_{-6} for LSAO, which are due to Turowski;[58] the value of k_7 for LSAO has been calculated assuming that the maximum population attained by the radical species is 50%[47]

BSAO Species



LSAO Species

	BSAO	LSAO
k_1 [$M^{-1}s^{-1}$]	$9{\cdot}10^4$	$4{\cdot}10^5$
k_{-1} [s^{-1}]	250	3
$k_{2\ (a\ and\ b)}$ [s^{-1}]	1.2	≥ 200
$k_{-2\ (a\ and\ b)}$ [s^{-1}]	0.01	negligible
k_3 [s^{-1}]	3.3	100
k_4 [$M^{-1}s^{-1}$]	$3.6{\cdot}10^5$	−
k_{-4} [s^{-1}]	33	−
k_5 [s^{-1}]	20	−
k_6 [s^{-1}]	−	$2{\cdot}10^4$
k_{-6} [s^{-1}]	−	$2{\cdot}10^4$
k_7 [$M^{-1}s^{-1}$]	−	$6{\cdot}10^7$
k_8 [$M^{-1}s^{-1}$]	−	$5{\cdot}10^5$

The intensities of the absorbances at 464 and 434 nm of reduced LSAO observed at pH = 7 were found to decrease at both acidic and alkaline pH values, and faded completely at extreme pH values (pH < 5 or > 10).[47] The titration data were fitted to an equilibrium between Cu^{I}−semiquinolamine and the bleached Cu^{II}−aminoresorcinol controlled by two independent ionizable groups with $pK_1 = 5.7$ and $pK_2 = 7.9$: Cu^{I}−semiquinolamine (pH = 7) ⟷ Cu^{II}−aminoresorcinol (pH= 5 or 10)

The shape and position, but not the relative intensities, of the absorption bands were found to be independent of the substrate used.[40,47][60]

Mechanism of Proton-Coupled Electron-Transfer to Dioxygen

In an extensive study of the re-oxidation of bovine serum Cu−amine oxidase (one of those enzymes that do not populate the Cu^{I}−semiquinolamine radical), Su and Klinman[51] reported a detailed analysis of the chemical and kinetic mechanisms of dioxygen conversion into hydrogen peroxide not requiring the conversion of Cu^{II} to Cu^{I}. A hydrophobic niche in the vicinity of the oxygen atom at the C2 position of the reduced cofactor has been identified as the putative dioxygen binding site in the X-ray structure of the active form of the eukaryotic yeast *Hansenula polymorpha*.[61] Reaction of dioxygen with the semiquinolamine does not lead to superoxide release, but two proton-transfer steps are probably coupled to the release of bound H_2O_2 after the formation of a metal-bound hydroperoxide.[62] Since in mammalian amine oxidases the radical species is not present to any significant extent (ca. 1%),[15] it is reasonable to assume that both forms of the reduced enzyme (***e*** and ***f***) can react with O_2 to release H_2O_2 and ammonia, thereby regenerating the Cu^{II}−quinone species.[47] This is also supported by kinetic evidence. It is worthy of note that at least in some Cu−AOs a labile complex with O_2 is formed before oxidation takes place.[51] The reaction of Cu^{II}−aminoresorcinol with oxygen should not be considered as surprising, since the model compound (2,4,5-trihydroxybenzyl)hydantoin is rapidly oxidized by atmospheric O_2 to TPQ−hydantoin.[25] A similar reaction has also been proposed for BSAO.[38]

Stopped-Flow Experiments

Since some of the TPQ derivatives encountered in the catalytic cycle are short-lived and elusive, transient spectroscopy (i.e. stopped-flow methodology) has been exploited in an effort to characterize the spectra and reactivities of as many intermediates as possible. In a typical stopped-flow experiment, the three spectroscopic components, i.e. pink, colorless, and yellow are easily resolved, at least in those Cu−AOs that populate the radical species. The spectroscopic information obtainable is, however, insufficient to resolve all the intermediates, given that some of them have very similar spectra, and a three- or four-step scheme is usually sufficient to describe the time courses recorded. For this review, we carried out an extensive re-evaluation of our data on BSAO and LSAO using the same kinetic scheme, in order to simplify the comparison.

When oxidized LSAO is mixed with putrescine, the bleaching of the 498-nm band is a second-order process, but does not reach completion as the steady-state mixture contains significant amounts of the quinone and aminoresorcinol derivatives. The precise amounts of the latter depend on the chemical nature and concentration of the substrate. This result is in contrast to that obtained for BSAO, for which bleaching is minimal and the steady-state mixture contains mostly the quinone and quinone ketimine derivatives. The following step, i.e. the conversion of ketimine into aldimine, is fast with LSAO and slow with BSAO, consistent with the

isotopic effect observed using dideuterated benzylamine.[63][64] Release of the aldehyde product is usually fast in plant Cu−AOs, at least when physiological substrates are used, and slow in BSAO. This step yields the aminoresorcinol derivative of TPQ, a reduced and bleached species that reacts slowly with oxygen. In the case of BSAO, a labile oxygen complex forms[51] (Scheme 1, ***g***), making the re-oxidation non-second-order,[52] while with LSAO the same complex decays immediately to the oxidized enzyme and the time courses recorded conform to second-order kinetics.

In plant Cu−AOs at a neutral pH value, the aminoresorcinol rapidly equilibrates with the semiquinolamine radical, which attains a population of 40−50%.[54,58] The reactivity of the radical towards dioxygen is 20- to 100-fold higher than that of aminoresorcinol, thus the apparent rate constant for re-oxidation is close to half of that of the radical species[65] (Table 2). Because of the high efficiency of the oxidation reaction, the value of K_m for dioxygen is low in most or all Cu−AOs, irrespective of the complexity of the reaction mechanism. From the rate constants reported in Table 2, a complete and consistent kinetic characterization of the catalytic cycle can be put forward, even though the accuracy of the parameters is low (with SDs between 20 and 50%) due to the redundancy of the kinetic mechanism. In our opinion, such a complete description, even if approximate, is desirable since it allows comparison with the steady-state parameters and hence guarantees a much higher degree of confidence than the determination of the rate constants for single steps.

Under the same experimental conditions as used for LSAO, BSAO does not show the 460−350-nm spectrum typical of the radical species,[46,52] while a radical giving a low-intensity signal 1−2% of the intensity of the copper signal is detected in the room-temperature EPR spectrum.[51,54] According to Dooley,[54] the low concentration does not preclude a catalytic relevance of this radical, while Su and Klinman[51] proposed that the predominant Cu^{II}−aminoresorcinol is the species that reacts with O_2 forming a Cu^{II}−peroxide intermediate. The latter hypothesis is consistent with much experimental data that show Co^{II}-substituted BSAO to be catalytically competent and thus suggest a metal structural function[42,66,69] and/or a Lewis acid role.[45] The nature of the radical in BSAO has recently been questioned, as it also forms when the enzyme is largely inactivated by reaction with hydrogen peroxide.[70]

The Role of Copper

As mentioned above, besides TPQ, amine oxidases also contain copper ions in a 1:1 stoichiometric ratio with the organic cofactor. Since TPQ undergoes reversible redox chemistry even in the absence of copper,[71,72] the function of the metal center in the catalytic mechanism is controversial. Crucial questions are the role of copper ions in the catalytic mechanism and their valence state during the catalytic cycle. Partial answers are now available for each of these questions. In plant enzymes, copper ions have been shown to be involved in the re-oxidation of the substrate-reduced enzyme in the presence of oxygen. It has been unequivocally demonstrated that copper ion reduction occurs in PSAO and LSAO,[40,47,54][58] and that this is coupled to the appearance of a characteristic radical species of the reduced TPQ (the Cu^{I}−semiquinolamine). Through a detailed analysis of fully Cu-depleted, half and fully Cu-reconstituted, and Co-, Ni-, and Zn-substituted lentil amine oxidase, Floris and co-workers[41] have shown that copper ions are also essential for the faster catalytic rate of plant enzymes as compared with mammalian amine oxidases.

The effects of copper ion removal and Co^{II} substitution have been studied in detail with BSAO. In the Cu-depleted protein, the rate of TPQ reduction by benzylamine was found to decrease by a factor of about 10^3 without a substantial change in the enzyme−substrate affinity, the rate of binding to hydrazine inhibitors decreased substantially, and the re-oxidation process was no longer observed.[42] Co^{II} substitution partly restored the catalytic activity (up to 10−40%), decreased K_m to an extent depending on the amino substrate, restored the reactivity towards hydrazine inhibitors to almost the native level,[69] and led to an almost 50-fold increase in the oxygen K_m.[73] Thus, the Co^{II} derivative represents a distinct enzyme from the native one, with quite different kinetic parameters. This implies that the metal center has no redox role in BSAO,[42,74,75] but it may have a structural role and may act as a Lewis acid by modulating the pK_a value of the water molecule through which it is bonded to TPQ−O_2.[37]

Concluding Remarks

Amine oxidases are extensively studied enzymes owing to their ubiquitous distribution in living systems, even though their role has not yet been unambiguously established. The kinetic mechanism of these copper−carbonyl enzymes has only recently been elucidated, following the discovery of the long-sought organic cofactor. Both, copper ions and TPQ, are essential for the enzyme function. However, while the redox cycling of TPQ has been well documented in every enzyme tested, a change in the valence of the copper ions is found only in plant enzymes, which are much more active than their animal homologues. The reduction of copper ions is accompanied by the appearance of a very characteristic radical species, although this has not been proven to be an essential step in the enzymatic mechanism. Nonetheless, plant amine oxidases are nowadays rightly considered as belonging to the group of so-called radical enzymes. A full understanding of their mode of action will require further experiments involving site-directed mutagenesis, while that of their physiological role might be advantageously applied in the construction of "knock-out" organisms lacking the amine oxidase gene.

Modelling the Hydrodenitrogenation of Aromatic N-Heterocycles in the Homogeneous Phase

Claudio Bianchini,*[a] Andrea Meli,[a] and Francesco Vizza[a]

Keywords: Hydrodenitrogenation / Homogeneous catalysis / Nitrogen heterocycles / C−N Bond cleavage

Recent legislation directed at reducing nitrogen levels in fossil fuels has led to numerous studies of the hydrodenitrogenation (HDN) process, whereby nitrogen is removed from organic compounds in petroleum feedstocks. In this review a comprehensive study of the coordination, activation, hydrogenation, hydrogenolysis and denitrogenation of N-heterocycles assisted by transition metal complexes in either fluid solution or single-site systems, is reported. Furthermore, similarities to the reactions occurring in the HDN process over commercial heterogeneous catalysts are also discussed.

Introduction

Under the business pull and environmental push, increasing research efforts are being made to design more efficient catalysts for the hydrodenitrogenation (HDN) of fossil fuels. To this purpose, studies applying molecular complexes have provided valuable mechanistic information on the adsorption modes of aromatic N-heterocycles as well as their hydrogenation and hydrogenolysis reactions. All relevant HDN modelling studies are reviewed in this paper that also provides a brief overview of the heterogeneous HDN mechanisms.

Petroleum and other fossil fuel feedstocks are contaminated by variable amounts of organic compounds containing sulfur, nitrogen and oxygen and, to a much lesser extent, by inorganic compounds, mainly in the form of metalloporphyrins. The presence of all these substances considerably damages the refining processes employed to upgrade feedstocks to product fuels, and ultimately lowers the quality of the latter. Indeed, besides poisoning the catalysts for the cracking and reforming reactions, hydrocarbons containing heteroatoms generate, upon combustion, dangerous polluting agents such as sulfur and nitrogen oxides (SO_x, NO_x).

Claudio Bianchini (left) was born in Florence, Italy, in 1949 and received his ''Laurea'' in Chemistry from the University of Florence in 1973. Upon graduation, he joined the Chemistry Department as a bourse-holder (1974−1975). He then moved to the Research Center of the pharmaceutical industry A. Menarini in Florence (1976−1977) as research officer. In 1977, he was offered a position at ISSECC-CNR, Florence, by Prof. L. Sacconi. Currently Director of ISSECC, his research interests include homogeneous and heterogeneous catalysis (HDS, HDN, polymerisation and copolymerisation of olefins), asymmetric catalysis and organometallic reactions. He has authored about 300 papers and patents.

Andrea Meli (center) was born in Florence, Italy, in 1948 and received his ''Laurea'' in Chemistry from the University of Florence in 1974. In 1976, he joined ISSECC-CNR where he is presently first-class researcher and responsible of the catalysis department. His current research interests are in the field of homogeneous and heterogeneous catalysis (HDS, HDN, polymerisation and copolymerisation of olefins) and high-pressure NMR spectroscopy. He has authored about 170 papers and patents.

Francesco Vizza (right) was born in Cirò, Italy, in 1957 and received his ''Laurea'' in Biology from the University of Florence in 1982. In 1986, he joined ISSECC-CNR where he is presently researcher and responsible of a catalysis laboratory. His current research interests are in the field of homogeneous and heterogeneous catalysis (HDS, HDN, polymerisation and copolymerisation of olefins), metal complexes in therapy and diagnostics, high-pressure NMR spectroscopy. He has authored about 85 papers and patents.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

The discovery of heavy oil reservoirs world-wide and the growing use of coal and oil shale for the production of fuels are pushing the petrochemical industry to invest an increasing amount of human and financial resources in the research and development of more efficient catalysts for removing heteroatoms from fossil fuels. This purification is currently carried out under hydrotreating conditions in the presence of heterogeneous catalysts and, depending on the element to be removed, involves four main chemical processes: hydrodesulfurisation (HDS), hydrodenitrogenation (HDN), hydrodeoxygenation (HDO) and hydrodemetalation (HDM) [Equations (1) to (4)].[1]

$$C_aH_bS + c\ H_2 \rightarrow H_2S + C_aH_d$$
Hydrodesulfurisation (HDS) (1)

$$C_aH_bN + c\ H_2 \rightarrow NH_3 + C_aH_d$$
Hydrodenitrogenation (HDN) (2)

$$C_aH_bO + c\ H_2 \rightarrow H_2O + C_aH_d$$
Hydrodeoxygenation (HDO) (3)

$$ML + a\ H_2 + b\ H_2S \rightarrow MS_b + LH_c$$
Hydrodemetalation (HDM) (4)

Of the four heterogeneous reactions outlined above, HDS has received, and is still receiving, the greatest attention for two principal reasons. Sulfur, contained in thiols, sulfides, disulfides and thiophenic molecules, is actually the most abundant heteroatom in fossil fuels and is also the element with the highest environmental impact. Furthermore, sulfur compounds are largely responsible for the poisoning of the hydrotreating catalysts. The importance of sulfur removal from crude oil feedstocks has therefore directed most of the R&D investments toward the HDS reaction, and in particular toward the design of more efficient heterogeneous catalysts. In parallel to studies under both actual and model reactor conditions, a considerable contribution to a better understanding of the HDS mechanism has been provided by homogeneous studies involving soluble metal complexes.[3−6] It is a common belief that many recent progresses in the field of heterogeneous HDS catalysis have been made with the contribution of the mechanistic information provided by the homogeneous studies.

Related to environmental push and business pull, increasing attention is now being paid to the HDN reaction. Indeed, the degradation of nitrogen compounds to ammonia and hydrocarbons consumes more hydrogen than any other hydrotreating reaction, and therefore any improvement in the efficiency of HDN catalysis would cause an immediate business advantage. From the environmental perspectives, nitrogen oxides and sulfur oxides contribute almost equally to the ravaging phenomenon known as "acid rain". Further, nitrogen oxides contribute to enhance the "greenhouse" effect and are certainly at the forefront in the undesired production of ground-level ozone that damages lung tissue, reduces lung function and sensitises the lungs to other irritants.[1,2]

Although nitrogen is largely produced in the combustion of air/hydrocarbon mixtures, the removal of nitrogen from feedstocks is of enormous importance and constitutes a major technological challenge for the 21st Century.

Nitrogen in petroleum and coal is contained in various organic compounds, which include five- and six-membered heterocycles, aliphatic and aromatic amines and nitriles. Some representative nitrogen compounds in fossil fuels are shown in Figure 1 (polyalkyl substitution is largely diffuse among cyclic compounds).

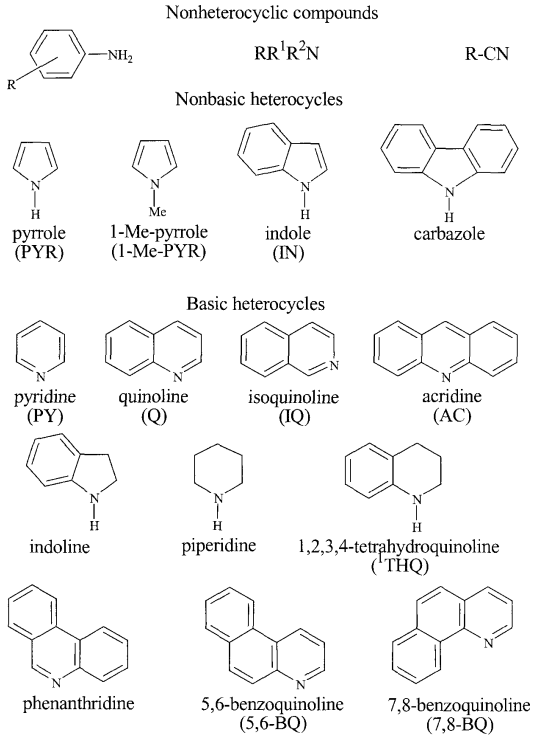

Figure 1. Some representative nitrogen compounds in fossil fuels

Amines and nitriles are less abundant and their degradation is efficiently performed under hydrotreating conditions applying commercial catalysts. The HDN of the aromatic heterocycles, generally pyrroles, indoles, quinolines and pyridines, is much more difficult to accomplish, even more than the HDS of fused-ring thiophenes. Moreover, HDN of the aromatic N-heterocycles requires a greater amount of H_2 than HDS of thiophenes, as the latter does not necessarily involve the saturation of the heterocyclic ring prior to hydrogenolysis.[1,7]

Although the intimate mechanism of metal-catalysed HDN is still far from being understood completely, a relatively rough mechanistic picture of this reaction is now available based on the combined efforts of heterogeneous and homogeneous studies. The former have provided data on product distribution, kinetics and selectivity, whereas the latter have contributed to the elucidation of the binding of the nitrogen substrates to metal centres and the mechanisms of fundamental steps such as the hydrogen-transfer from metal to coordinated substrate and the C-N bond scission.

Unlike HDS, no review article on homogeneous modelling studies of HDN has recently appeared, and therefore a complete overview of the interactions between single metal sites and N-heterocycles, alone or in combination with H_2, is missing in the relevant literature. Aimed at filling this gap, we have written this short review which takes into account

all recent results regarding the activation of N-heterocycles by soluble metal complexes, and also tries to provide some clues which will enable a comparison between heterogeneous and homogeneous HDN-related reactions.

The Heterogeneous HDN Reaction

General Information

In actual refinery reactors, HDN occurs simultaneously with all the other hydrotreating processes that include HDS, HDO, HDM, hydrodearomatisation (HDA), and hydrocracking. The reaction parameters are generally optimised for the HDS reaction, and therefore the experimental conditions and the catalysts employed are not the optimal ones for HDN, as the degradation of nitrogen compounds requires longer reaction times, as well as higher temperature and H_2 pressures than that of thiophenes.[1,7]

The HDN reaction is commonly performed at high temperatures (350−500 °C) and hydrogen pressures (200 bar), over heterogeneous catalysts composed of a γ-alumina support covered by metal sulfides. Mo or W are essential "components" but increased catalytic activity is achieved with the use of variable amounts of late transition metals such as Co, Ni, Ru, Rh, Ir, and Pt, which are called "promoters". Commercial catalysts are prepared by coimpregnation of γ-alumina with aqueous solutions of both a metal component salt (e.g. a Mo salt like $[NH_4][Mo_7O_{24}]$) and a promoter salt [e.g. a Co salt like $Co(NO_3)_3$], followed by reductive sulfidation with sulfur-containing compounds like H_2S, thiophene or CS_2. The Co and Mo exist primarily as Co_9S_8 and MoS_2.[8] The presence of H_2S during the reaction is believed to favour HDN, as it avoids the formation of metal oxides, which are much less active than metal sulfides. An active role of H_2S in the C−N bond scission step has also been demonstrated (vide infra).[9] The most efficacious HDN catalysts are based on Mo and Ni, probably because these catalysts exhibit the best performance in HDA.

In spite of significant progress in the field of surface characterisation (MES, EXAFS, FTIR, XAS, EPR spectroscopy, etc.), it has been concluded that the activity of the catalysts is related to sites located somewhere along the edges of small MoS_2 or Co(Ni)−Mo−S nanoclusters.[1a,10] In particular, the role of the promoters is still a matter of debate. According to a commonly accepted interpretation of HDS catalysed by "Co(Ni)−Mo(W)−S" phases,[1a,10,11] the active centres for the activation of the thiophenic molecules are the promoter atoms located at the edge plane of a MoS_2 single slab, whereas H_2 activation takes place on MoS_2 (or WS_2). The key role of the promoters in the activation of thiophenes has been confirmed by various homogeneous studies[3−6] that also agree with the conclusion that the desulfurisation requires the cooperation of more than one metal centre (component-promoter or promoter-promoter), and the multipoint coordination of the first C−S bond scission product (e.g. thiolate groups).[5a,12−14] A similar mechanistic picture may be proposed for HDN, e.g. the sulfur vacancies associated with Mo^{II} cations located at the edges of the MoS_2 crystallites are the sites where the hydrogenation of the N-heterocycles takes place, while the hydrogenolysis reactions would occur on acidic Mo−SH groups formed by interaction of M=S units with protons derived from the dissociation of H_2S over the catalyst surface.[1a]

It has been experimentally proven that aromatic nitrogen molecules undergo HDN via preliminary hydrogenation of the heterocyclic ring, followed by C−N bond scission (hydrogenolysis). The hydrogenation of the heterocyclic ring is necessary to reduce the high energy required to cleave the carbon−nitrogen bond that, in a typical N-heterocycle, is close to that of a C=N double bond.[7a]

Since the hydrogenation of the heterocycle to a saturated amine occurs prior to C−N bond cleavage, the position of the hydrogenation equilibrium actually controls the removal of the nitrogen atom, particularly when the hydrogenolysis rate is much slower than the hydrogenation rate. Unfavoured hydrogenation equilibria would result in a low concentration of saturated amine with the consequent decrease of the overall HDN rate. Accordingly, high pressures of H_2 are required for efficient HDN. The equilibrium constants for the hydrogenation of typical substrates such as quinoline (Q) and pyrrole (PYR) decrease with increasing temperatures as the ring reductions are exothermic. However, the hydrogenolysis and overall HDN equilibria are favourable, even at temperatures as high as 500 °C. Although the hydrogenation equilibria are unfavourable, the effect of higher hydrogen partial pressures, such as those used in industrial hydroprocessing, is to force the equilibria considerably toward the hydroprocessing products.[7a] Besides disfavouring the hydrogenation/hydrogenolysis equilibria, a low H_2 pressure may also lead to the undesired production of polycondensed N-heterocycles *via* catalytic dehydrogenation.[15] Indeed, kinetic modelling of the HDN process indicates that dehydrogenation of partially hydrogenated substrates such as tetrahydroquinoline (THQ) can be competitive with C−N bond cleavage, even in the presence of H_2.[7]

Adsorption Modes of N-Heterocycles over Heterogeneous Catalysts

In spite of many research efforts over the last twenty years and the progress made in developing surface spectroscopic techniques, very little is known about the detailed structure of the edges of the MoS_2 crystallites or Co(Ni)−Mo−S nanoclusters, as well as the nature of the active sites. This lack of information has strongly limited our knowledge of the interactions between N-heterocycles and the catalyst sites. As a result many hypotheses, often contradictory to each other, have been forwarded, but no precise conclusion has been reached.

A common belief is that basic heterocycles, such as Q, interact with the metal sites over the catalyst surface by two principal modes: *end-on* through the nitrogen atom and *side-on* through either ring (Figure 2). It is also agreed that in the absence of steric congestion provided by α-substituents, Q preferentially uses the nitrogen atom for interaction with the catalyst. In contrast, *side-on* coordination is fa-

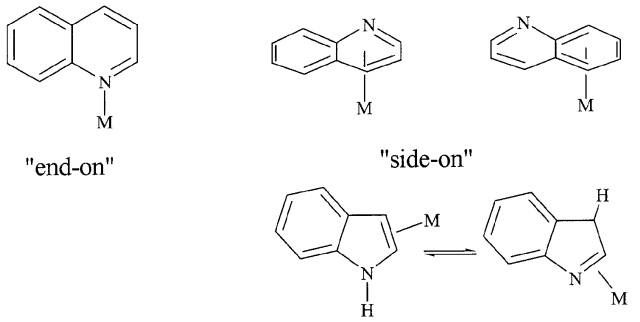

Figure 2. Postulated interactions of Q with the metal sites over the catalyst surface

voured for non-basic rings such as PYR and its higher homologues in which the nitrogen lone pair is not available for coordination.

In order to exemplify the level of uncertainty regarding the adsorption modes of N-heterocycles over the catalyst surface, Figure 3 shows the bonding modes of Q and THQ that have been proposed for HDN-active Ni^{2+} supported on SiO_2-Al_2O_3.[16]

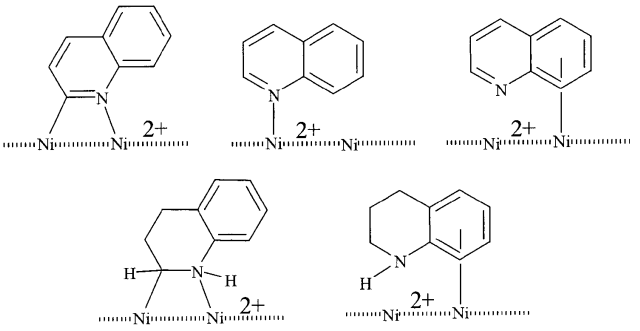

Figure 3. Proposed adsorption modes of Q and THQ over Ni^{2+} supported on SiO_2-Al_2O_3

HDN vs. Other Hydrotreating Processes

The nitrogen-containing compounds are more easily adsorbed over the catalyst surface than most of the heteroatom and aromatic compounds in fossil fuels. The adsorption of nitrogen compounds is so efficient that an almost continuous film may cover the catalyst surface. However, not all molecules undergo HDN due to the many possible unfavourable orientations. The strong tendency of nitrogen compounds for adsorption apparently disfavours adsorption of other substrates and ultimately inhibits other hydrotreating reactions, which, in some circumstances, may even favour HDN. Indeed, it has been found that the H_2S produced by HDS, although competing with the nitrogen compounds for adsorption (thus reducing the hydrogenation rate), promotes the hydrogenolysis step (vide infra).[9] Similarly, the H_2O formed in the HDO of many phenols and other O-heterocycles seems to enhance the overall HDN rate.[9a,17]

Principal Reaction Pathways and Mechanisms Proposed for Heterogeneous HDN

The principal reaction pathways proposed for the heterogeneous HDN of the model substrate Q[1,7,18] are shown in Scheme 1. A sequence of similar steps has also been suggested to occur for the HDN of PYR.

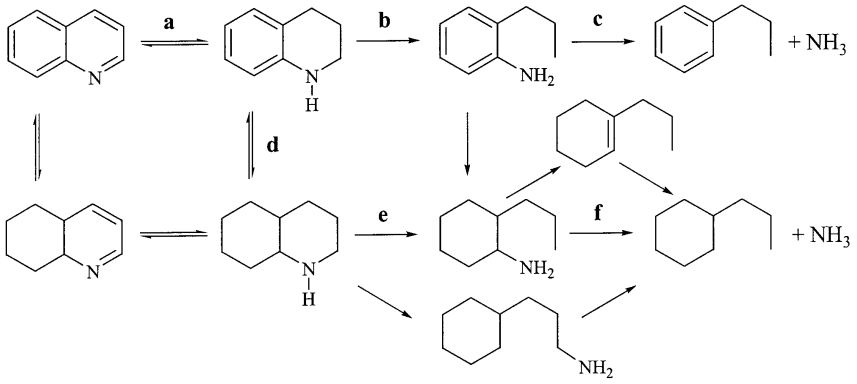
The most efficient and selective HDN of Q would proceed via the reaction sequence **a→b→c**, which does not involve the hydrogenation of the carbocyclic ring. The **a→b→c** sequence consumes less hydrogen than any other path, and also yields high quality product fuels as the residual aromaticity in the denitrogenated products increases the octane rating. However, most of Q undergoes HDN via the alternative sequence **a→d→e→f** that involves the hydrogenation of both rings and therefore consumes twice the amount of H_2, yielding propylcyclohexane. In neutral or basic media, the hydrogenation of the heterocyclic ring is faster than that of the carbocycle, i.e. the hydrogenation of Q to 1,2,3,4-tetrahydroquinoline (^{1}THQ) is faster than that of Q to 5,6,7,8-tetrahydroquinoline (^{5}THQ). In turn, the hydrogenation of ^{5}THQ to decahydroquinoline (DHQ) is faster than that of ^{1}THQ. This observation has been associated to the high π-electron density of the heterocyclic ring. It has been proposed that the hydrogenolysis of ^{1}THQ to *o*-propylaniline is slower than its hydrogenation to DHQ, because the adsorption of ^{1}THQ over the catalyst surface is hampered by its resonance form containing a double bond between the nitrogen atom and the proximal carbocyclic carbon atom.

Using the analogy of metal-catalysed hydrogenation of aromatics, it is proposed that the hydrogenation of N-heterocycles to saturated cyclic amines involves the formation of metal π-adducts, followed by a reductive π→s shift once the two consecutive hydrogen transfers have occurred from vicinal S−H groups. The mechanism is analogous to that reported by Kwart for the HDS of thiophene.[19] It has also been proposed that the metal centre activates the aromatic ring, behaving as an electrophile that delocalises the ring electron density.[7b]

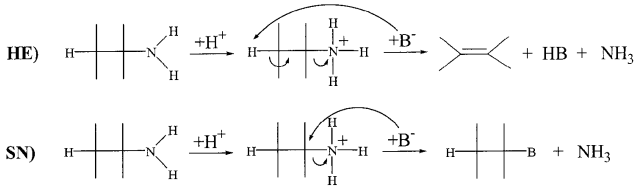
The hydrogenolysis of the C−N bonds in N-heterocycles is much more difficult to accomplish than the hydrogenation of the rings as well as the hydrogenolysis of C−S bonds. Indeed, homogeneous C−N scissions in N-heterocycles are very rare and exclusively stoichiometric in nature,[3c][3d] whereas several C−S bond insertions occurring in solution catalysts have been reported.[3−6] There is little doubt that the higher bond energy of C−N bonds as compared with C−S bonds (by 3−9 kcal mol^{-1}) contributes in making the catalysts less efficient for HDN than for HDS, under comparable experimental conditions.[7]

From a mechanistic viewpoint, the C−N bond cleavage has been suggested to occur through either a Hofmann-type elimination (HE) or a nucleophilic substitution (SN), both reactions being promoted by a base (Scheme 2).[20]

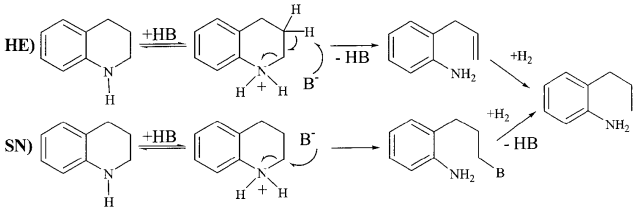
In this mechanistic picture, the first C−N bond cleavage in ^{1}THQ would require the cooperation of a protic acid whose conjugate base B^- may participate in either HE or SN mechanisms (Scheme 3). Many species present on the catalyst surface under hydrotreating conditions may act either as bases or nucleophiles: sulfydryl groups (SH^-) generated by the heterolytic splitting of H_2S, hydride ions (H^-), hydroxyl ions (OH^-) or even neutral molecules such as H_2S,



Scheme 1



Scheme 2



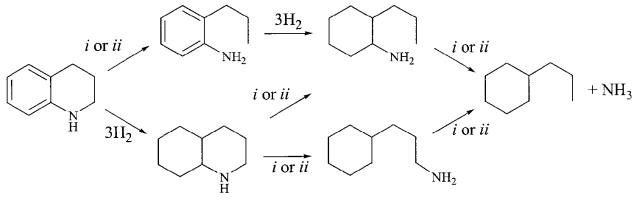
Scheme 3

H_2O, NH_3 or amines. In this mechanistic picture, the increase in the rate of hydrogenolysis by addition of H_2S, has been explained in terms of the enhanced production of H^+ and SH^- groups on the catalyst surface upon heterolytic splitting of H_2S.[7]

The second C−N bond cleavage to give NH_3 and *n*-propylcyclohexane completes the HDN process of Q consuming an overall amount of seven H_2 molecules per nitrogen atom. Furthermore, this step may occur through either HE or SN mechanisms.

It is worth noting that the saturation of the heterocyclic C_α atom is necessary to cleave the C−N bond *via* an SN mechanism, while both the C_α and C_β carbon atoms must have sp^3 hybridisation to allow for a C-N bond cleavage to occur *via* a HE mechanism. In the case of Q, this means that the hydrogenation of both rings is necessary to cleave the C−N bond *via* either mechanism, which is consistent with the formation of *n*-propylcyclohexane as the main HDN product (Scheme 4).

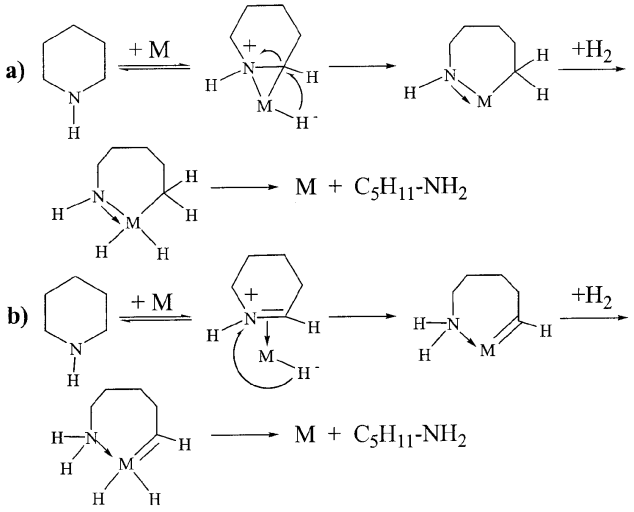
The interaction of the surface metal atoms with saturated N-heterocycles has been the object of model studies by Laine and co-workers.[7c,21] It has been suggested that the C−N scission in saturated heterocycles may not require acidic sites, but rather metal centres. Two possible pathways have been proposed for the HDN of piperidine which differ from each other with respect to the nature of the interme-



i = **HE** (+H^+, +B^-, -HB) + H_2
ii = **SN** (+H^+, +B^-) + (H_2, -HB)

Scheme 4

diate formed, either a metal alkyl species (**a**) or a metal alkylidene species (**b**) (Scheme 5). In either case, the first step has been suggested to involve the oxidative addition of the C−H bond adjacent to the nitrogen atom to give a metal(hydride) species. The subsequent migration of the hydride from the metal to either the C_α atom or the N atom of an η^2-piperidinyl ligand determines the nature of the intermediate that is ultimately hydrogenated to a primary amine.



Scheme 5

Model studies on the HDN of piperidine have also contributed to rationalise the beneficial effect of H_2S and H_2O on the rate of C−N hydrogenolysis. Nucleophilic attack by either molecule at the C_α atom would form sulfur-con-

taining intermediates that undergo hydrolytic C−N bond cleavage faster than in the absence of H_2S or H_2O.[7,9,17]

Similar mechanisms have also been proposed to account for the increased rate of C−N hydrogenolysis observed in the presence of other nucleophiles such as NH_3. However, under actual reactor conditions, the addition of NH_3 inhibits HDN, because NH_3 prevails over all the other nitrogen compounds for the interaction with the surface coordination vacancies.[7]

Homogeneous Modelling Studies

Homogeneous modelling studies involving soluble transition metal complexes represents one of the most fruitful approaches in providing mechanistic information on the elementary steps involved in the hydrotreating of fossil fuels. HDN model studies in solution are not as numerous and detailed as those involving HDS. Nonetheless, much of our current understanding of HDN is based on structural and reactivity information obtained in the homogeneous phase, in particular on four relevant issues: modes of bonding between N-heterocycles and metal centres, reactivity of coordinated N-heterocycles, elementary steps of metal-catalysed hydrogenation of N-heterocycles, insertion of metal centres into C−N bonds. A common strategy in HDN modelling is to react mononuclear or polynuclear metal complexes, containing either coordination vacancies or weakly bound ligands, with N-heterocycles.

Common model substrates are PYR, indole (IN), pyridine (PY), and Q together with their alkyl-substituted derivatives and/or their partially or completely hydrogenated products. These model substrates may be divided in two main categories according to the donor properties of the nitrogen atom. In compounds like PYR (pK_a = 0.4) and IN (pK_a = −3.6), the nitrogen lone pair is delocalised over the five-membered ring and is not available for interaction with electrophiles. In contrast, the nitrogen atom in PY (pK_a = 5.2) or Q (pK_a = 4.9) is a good nucleophile susceptible to attack by various electrophilic metal fragments. The different character of the nitrogen atom in the two types of substrates and the presence of aromatic carbocyclic rings is believed to remarkably influence their interaction with the heterogeneous catalyst surface and, consequently, the mechanisms for reduction. The homogeneous studies have indeed proved that both the basicity of the nitrogen atom and the presence of carbocyclic rings determine the binding mode of N-heterocycles to single metal sites, and ultimately control the further reactivity of the M−N heterocycle ensemble.

Binding Modes of N-Heterocycles in Transition Metal Complexes

A) Complexes with Pyrrole and Pyrrolyl Ligands

All known bonding modes of PYR and pyrrolyl ions, or their alkylated analogues, in mononuclear complexes are illustrated in Figure 4.

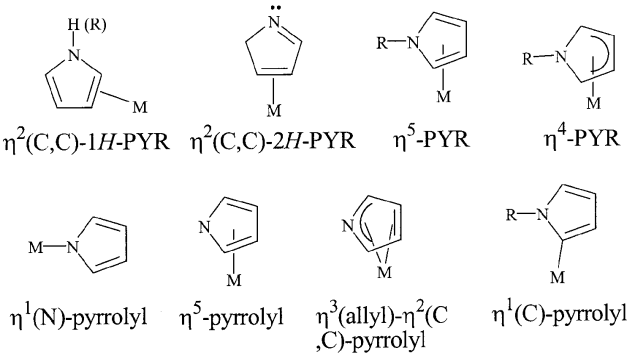


Figure 4. Known bonding modes of PYR and pyrrolyl ions in mononuclear complexes

No complex containing an η^1(N)-PYR ligand has ever been reported, even in the 3*H*-pyrrolidine structure which has been authenticated for IN (vide infra). The most numerous complexes are the η^5-PYR ones,[22] but some examples containing η^2(C,C)-PYR ligands have also been characterised.[23] The η^4 mode has been observed in one complex only.[24]

Metal complexes containing pyrrolyl ligands are ubiquitous in the periodic table, and common coordination modes are the η^1(N) and η^5 modes.[22a,25−27] However, depending on the nature of the supporting metal fragment, each bonding mode may be viewed as involving two distinct electronic forms.[27e]

The pyrrolyl group may be generated in situ by metal-assisted N−H activation of PYR,[26] or provided as a metal salt after N−H deprotonation with a base.[27] In the first case, a high-energy low-valent metal fragment is required to lower the energy barrier for N−H insertion, while $NC_4H_4^-M^+$ reagents (M = Na, K) are commonly reacted with electrophilic metal fragments. C−H bond activation to give η^1(C) pyrrolyl(hydride) metal complexes has also been described.[26c]

The interaction with polynuclear complexes to give an adduct containing intact PYR has never been reported. Either N−H and/or C−H bond activation is commonly observed, yielding bridging pyrrolyl ligands (Figure 5).[27a,27e,28,29]

Selective C−H bond cleavage of N-methylpyrrole is promoted by the dimer $[Cp^*IrH_3]_2$ ($Cp^* = C_5Me_5$), which, under comparable experimental conditions, is able to cleave both thiophene and 2-methylthiophene[28] (Scheme 6). This different reactivity is consistent with a higher energy barrier for C−N insertion than for C−S insertion, as is observed in heterogeneous HDN/HDS.

N−H activation, followed by two dehydrogenation steps has been found to transform pyrrolidine into an imidoyl ligand (Scheme 7).[30]

A particular type of pyrrolyl ligand is that found in the Mo dimer $[(Cp'Mo)_2(S_2CH_2)(\mu\text{-}S)(\mu\text{-}S\text{-pyrrolyl})]^+$, obtained by Rakowski DuBois upon nucleophilic attack by the electron-rich PYR molecule at the disulfide bond in $[(Cp'Mo)(\mu\text{-}S)_2(S_2CH_2)]_2^{2+}$ ($Cp' = C_5H_5$, C_5H_4Me) (Scheme 8).[31] A mechanism has been proposed which in-

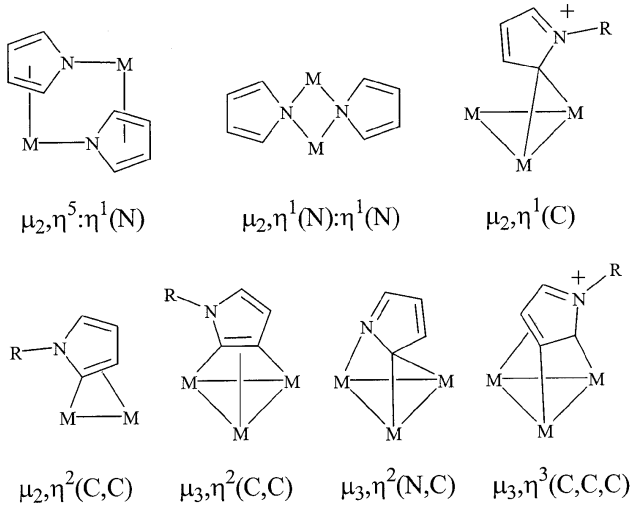

Figure 5. Bonding modes of pyrrolyl ligands in polynuclear complexes

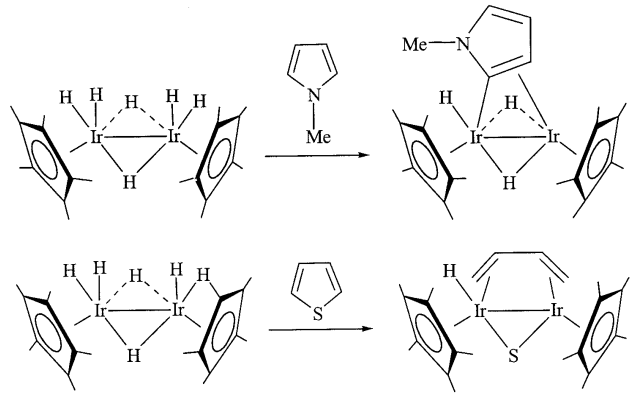


Scheme 6

volves heterolytic scission of the S-S bond by the nucleophilic ring, followed by loss of a proton from the heterocycle to give a 1:1 mixture of μ-pyrrolylthiolate and μ-SH dimers. Alkyl-substituted pyrroles such as 1-Me-PYR or 1,2,5-Me_3-PYR behave similarly, but the regiochemistry of electrophilic addition may vary depending on the position of the substituent.

The ability of the pyrrole ring to attack S-S bonds is not diminished, neither when a metal is bound to the nitrogen atom as in Scheme 9 for $[ReCl_2(PMe_2Ph)_3(\eta^1(N)\text{-pyrrolyl})]$, nor when the nitrogen and a β-carbon atom are engaged in bonding to a metal and to a sulfur atom (Scheme 10). The selectivity for substitution at the β-position has been attributed to the steric bulk of pyrrole N-substituent.[31]

The formation of the unusual (η^1(C)-pyrrolyl)-SMo_2, Re-(μ,η^1(N):η^1(C)-pyrrolyl)-SMo_2 and Re-(μ,η^1(N):η^1(C):η^1(C)-pyrroldiyl)-$(SMo_2)_2$ groupings represents quite interesting models of the potential interaction of electron-rich N-heterocycles with a sulfided metal surface. Indeed, the presence of disulfide moieties over HDS/HDN catalysts has been demonstrated. Moreover, previous studies of thiophene adsorption over MoS_2 catalysts have hypothesised a S−S interaction between the surface sulfur and the substrate.[1,7]

B) Complexes with Indole, Indolyl, Indoline, and Indolinyl Ligands

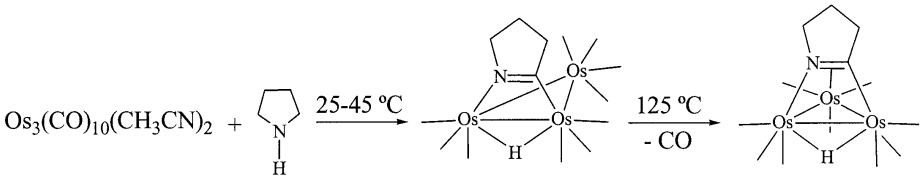
Indole (IN) differs from PYR by a condensed arene ring. This makes a great difference in the interaction with metal centres and produces a larger variety of possible coordination modes (Figure 6). Indeed, the presence of the carbocyclic ring allows IN to bind a metal centre using the arene ring, leading to the important η^6 mode.[32] Examples of η^1(N)-IN complexes have also been reported that may be better described as η^1(N)-3H-indolenine species.[33−35]

The indolyl anion coordinates mononuclear fragments using the nitrogen (η^1(N) mode),[26a][26e,35] the heterocyclic ring (η^5 mode),[32d,36] or the carbocyclic ring (η^6 mode).[32b]

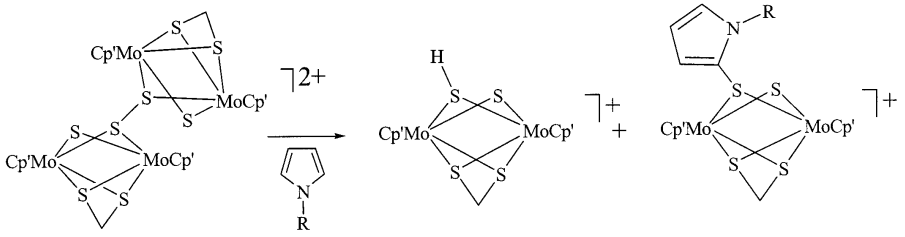
An interesting case of base-assisted η^6-IN → η^5-indolyl shift[32d] is illustrated in Scheme 11, while an acid-promoted η^1(N)-indolyl → η^1(N)-indolenine conversion[35] is shown in Scheme 12. Treating indolenine complexes with hydride produces η^1(N)-indolinyl derivatives.[32a][35b]

Electron-rich metal fragments can react with 2-substituted IN, yielding either kinetic C−H or thermodynamic N−H insertion products.[26d]

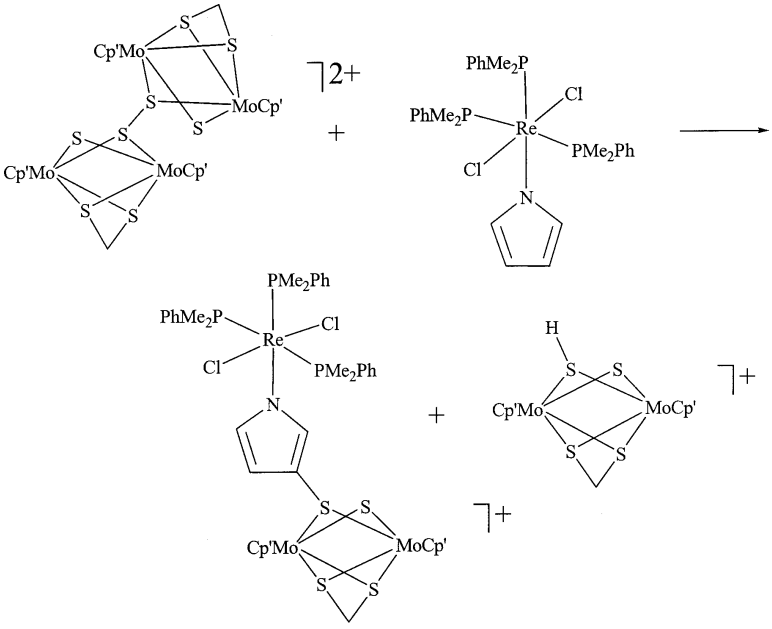
Like PYR,[31] 1-Me-IN has been found to react with the μ-S_2 tetramer $[(Cp'Mo\mu\text{-}S)_2(S_2CH_2)]_2^{2+}$ to give the elec-



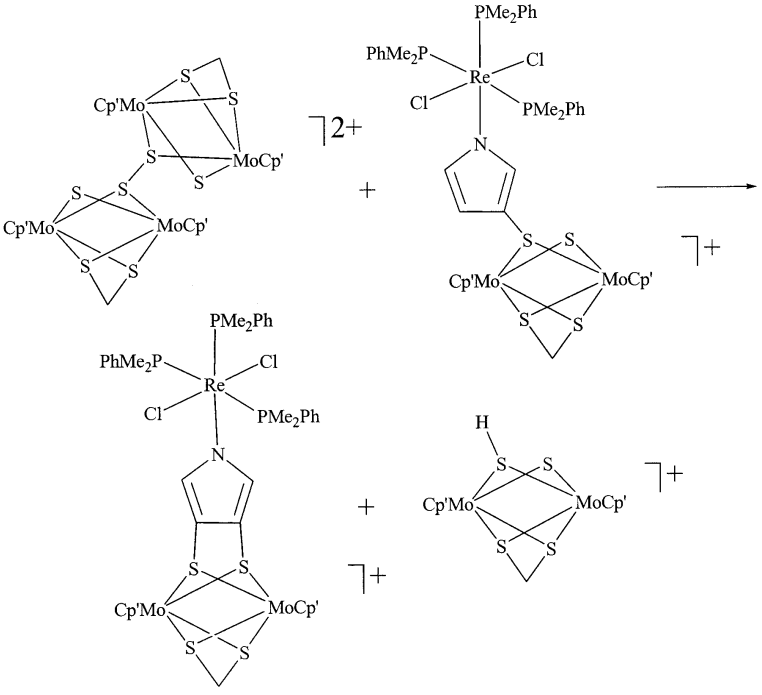
Scheme 7



Scheme 8



Scheme 9



Scheme 10

trophilic substitution product (Scheme 13). The reaction is mechanistically similar to that with PYR.

The coordination chemistry of indoline, obtained by selective hydrogenation of the heterocyclic ring of IN, has also been investigated.[32a] η^6 and η^1(N) Coordination modes, as well as their interconversion, have been reported.[31,35b,37] Of particular relevance are the studies carried out by Rakowski DuBois on the coordination, acid/base properties and activation of indoline by (*p*-cymene)Ru^{II} fragments.[32a,37] The complex [(*p*-cymene)Ru(η^1-indoline)$(CH_3CN)_2$)]$(OTf)_2$ converts to [(*p*-cymene)Ru(η^6-indoline)]$(OTf)_2$ upon gentle heating in CH_2Cl_2 and can be deprotonated to give the corresponding (η^1-indolinyl) complex[37] (Scheme 14). The reactivity of the latter compound is described in a following section.

The presence of the carbocyclic ring widens the range of possible bonding modes of IN to metal clusters.[34,38] As shown in Figure 7, IN, indolyl, indoline or indolinyl ligands may use both nitrogen and carbon atoms from either ring to bind metal centres.[34,38]

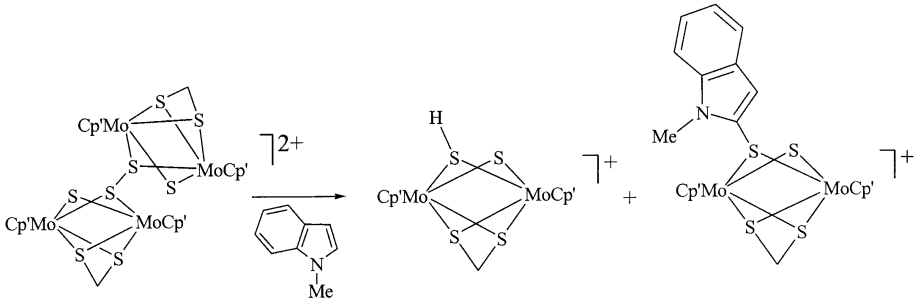
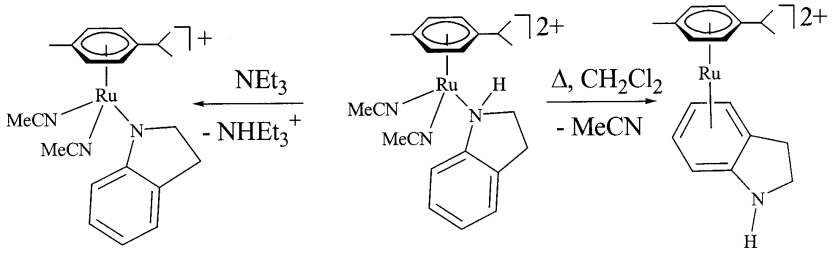


Scheme 13



Scheme 14

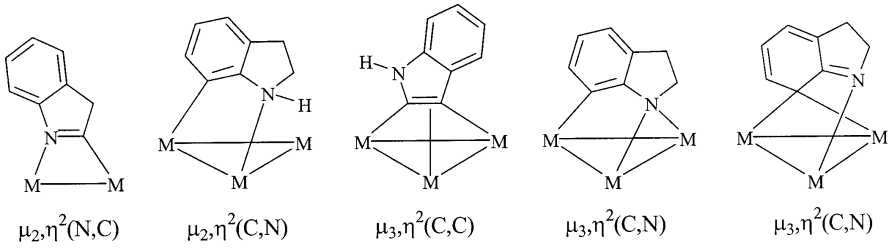


Figure 7. Bonding modes of IN to metal clusters

C) Complexes with Carbazole

The coordination chemistry of carbazole has scarcely been investigated. Only N−H bond activation to give η^1(N)-carbazoyl products has been reported.[26c,39] Interestingly, the reaction of [Cp*Rh(PMe_3)(H)(Ph)] with carbazole[26c] yields a C−H insertion kinetic product that thermally converts to a thermodynamic N-H insertion product (Figure 8).

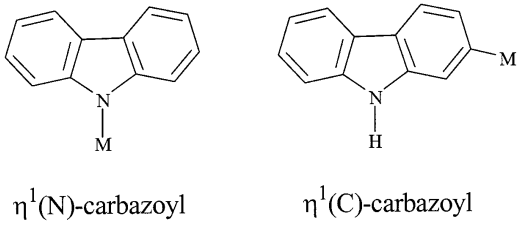

Figure 8. Known modes of carbazoyl coordination

D) Complexes with Pyridine, Quinoline, and Derivatives

The known bonding modes of PY and its alkyl-substituted derivatives to single metal sites are illustrated in Figure 9.

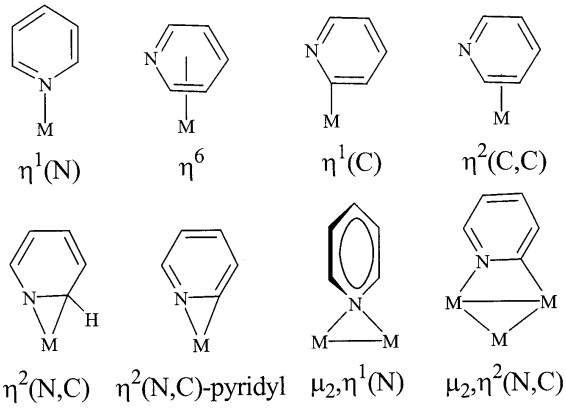

Figure 9. Known bonding modes of pyridine derviatives to single metal sites

The most common coordination for PY is through the nitrogen atom, which uses its lone pair for interaction with Lewis acceptors.[40,41] Unlike thiophene,[3−6] the nitrogen atom in η^1(N)-PY complexes is retained in the ring plane.[42] Formally, monohapto-PY complexes are also the η^1(C) ones obtained from C−H bond activation by electron-rich metal fragments.[43]

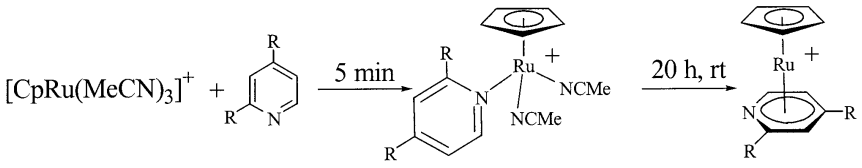
Another quite common coordination mode of PY is the η^6 mode, whose formation does not necessarily require the presence of alkyl substituents in the 2,6 positions of the ring to hinder the η^1(N) mode.[41,44]

Many homogeneous studies of PY coordination have centred on the η^1(N) and η^6 modes, and the factors controlling their interconversion and/or prevalence.[41] With the use of the isostructural and isolelectronic Ru^{II} and Rh^{III} complexes [Cp(or Cp*)M(CH_3CN)$_3$]$^{n+}$, Fish and co-workers have found that, in the absence of steric constraints, the η^1(N) mode prevails over the η^6 mode, particularly with the more electrophilic Rh^{III} centre.[41c] For example, [Cp*Rh(CH_3CN)$_3$]$^{2+}$ reacts with 2-methylpyridine and 2,6-dimethylpyridine yielding compounds of the formula [Cp*Rh(η^1(N)-PY)(CH_3CN)$_2$]$^{2+}$, while the sterically encumbered 2,4,6-trimethylpyridine[41c] forms the η^6 adduct [Cp*Rh(η^6-PY)]$^{2+}$. An interesting reactivity path is displayed by [CpRu(CH_3CN)$_3$]$^+$, in which the Ru^{II} centre is more electron-rich than Rh^{III} in the analogous complex. The greater propensity of Ru^{II} to stabilise the η^6 mode *via* π-backbonding from a filled metal orbital to a π* orbital of PY, has allowed Fish to follow the η^1(N)→η^6 interconversion of 2-methylpyridine and 2,4-dimethylpyridine illustrated in Scheme 15. The initially formed η^1(N) complex slowly loses MeCN and converts to the thermodynamic η^6-PY product. This rearrangement has been proposed to involve an η^4-PY intermediate.[41a,41d]

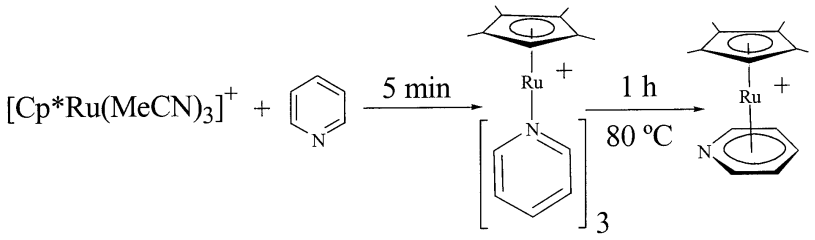
With unsubstituted PY, the stable adduct [CpRu(η^1(N)-PY)$_3$]$^+$ is obtained.[41d] However, when Cp* is employed to make the Ru centre more electron-rich, the complex [Cp*Ru(η^1(N)-PY)$_3$]$^+$ is a kinetic product that thermally converts to the corresponding η^6 derivative (Scheme 16).[41b]

The only example of PY acting as a bridge between two metal centres through the nitrogen atom has been found in Mo_2O_2[S_2P(O*i*Pr)$_2$]$_2$(μ-*O*)(μ-S)[μ,η^1(N)-PY] (Scheme 17).This compound is of particular relevance to HDN because of the presence of two Mo atoms in a sulfur-rich environment. In this Mo dimer, the PY ring is almost coplanar with the bridging O and S atoms, while the Mo-N distances are longer than regular Mo-N distances.[45]

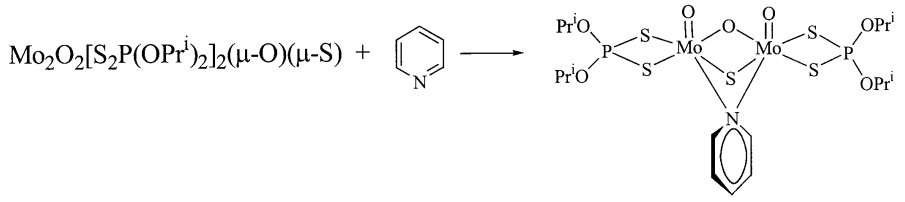
Another rare binding mode of a pyridine substrate is the η^2(C,C) mode which has been described by Taube and coworkers for 2,6-dimethylpyridine (lutidine) (Scheme 18).[46] This interesting coordination mode is exclusively stabilised by the electron-rich [Os(NH_3)$_5$]$^{2+}$ fragment, and rearranges to the η^1(N) mode a one-electron oxidation. The η^2(C,C)→η^1(N) rearrangement of lutidine raises much interest as it relates the bonding mode of the N-heterocycle with the metal oxidation state. Indeed, the active metal



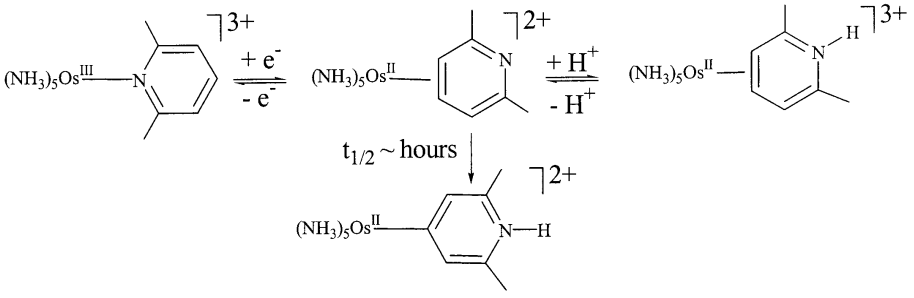
Scheme 15



Scheme 16



Scheme 17



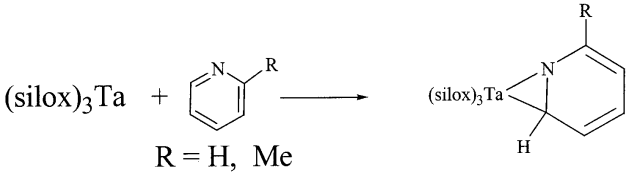
Scheme 18

centres of heterogeneous HDS/HDN catalysts may have different oxidation states due to electron-transfer processes involving both surface and bulk metal atoms.[1]

Interestingly, the η^2(C,C) mode of lutidine rearranges with time to give an Os^{II} lutidinium ylide. In contrast, the η^2(C,C) mode is maintained when $[Os(NH_3)_5(\eta^2$-lutidine$)]^{2+}$ is protonated to give a lutidinium derivative.

All the bonding modes that have been described so far represent valid models for the adsorption of PY over the catalyst surface. None of them, however, has been found to be a precursor to C−N bond scission. In contrast, the η^2(N,C) mode effectively activates the PY ring toward C−N scission. These C−N insertions will be commented on in a separate section, while the known η^2(N,C) metal complexes are reviewed below.

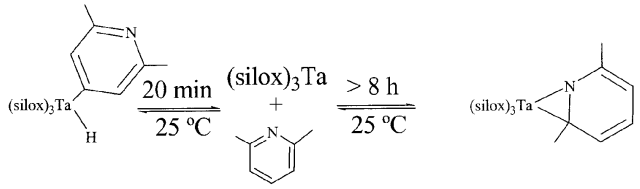
The first η^2(N,C)-PY complex, $[(silox)_3Ta(\eta^2$(N,C)-$NC_5H_5)]$, was prepared by Wolczanski in 1988 through the simple procedure illustrated in Scheme 19 (silox = tBu_3SiO^-).[47] The structure of $[(silox)_3Ta(\eta^2$(N,C)-$NC_5H_4R)]$ is consistent with a Ta^V metallaaziridine where the aromaticity of PY has been interrupted by strong Ta(dπ)→PY(π*) back-bonding.[47b]



Scheme 19

Reaction of $[(silox)_3Ta(\eta^2$(N,C)-$NC_5H_5)]$ with 2-picoline and lutidine give similar η^2(N,C) products whose formation have been proposed to occur by nucleophilic attack of the starting Ta^{III} compound at the LUMO of the N-heterocycle

(predominantly C=N π*). A detailed in situ NMR spectroscopic study with the sterically congested lutidine shows that C−H bond activation may compete kinetically with η^2(N,C) coordination (Scheme 20).



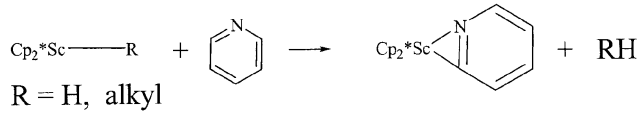
Scheme 20

Similar starting materials such as $(silox)_3M$ (M = Sc, Ti, V) react with PY in a conventional manner leading to η^1(N) derivatives.[47b] The absence of four electron repulsion problems in the Sc, Ti and V derivatives has been invoked to account for the selective formation of η^1(N) adducts.

Reduction of $[(silox)_3NbCl_2]$ with Na/Hg in PY affords a kinetic η^2(N,C)-PY product which thermally undergoes C−N insertion (vide infra).[47a]

Another Ta compound containing a η^2(N,C) pyridine ligand is $[(DIPP)_2ClTa(\eta^2(N,C)\text{-}2,4,6\text{-}NC_5H_2tBu_3)]$ (DIPP = $2,6\text{-}OC_6H_3iPr_2$) obtained by Wigley and co-workers by nitrile insertion into a tantallacyclopentadiene complex.[48]

Besides precursors to C−N bond scission, transients with η^2(N,C) pyridine ligands have been proposed to be critical to C_α−H activation leading to complexes containing a dihapto $NC_5H_4^-$ ligand.[49] The first of such compounds with unsubstituted PY, $Cp^*Lu(\eta^2(N,C)\text{-}NC_5H_4)$, was reported by Watson.[49b] A few years later, Bercaw reported the synthesis of $[Cp^*Sc(\eta^2(N,C)\text{-}NC_5H_4),]$[49a] while Ti derivatives with 2-substituted pyridines have been described by Teuben.[49c] A common synthetic procedure to these η^2(N,C)-pyridyl compounds involves the reaction of the substrate with alkyl or hydride complexes as shown in Scheme 21 for the Sc derivative. An in situ NMR spectroscopic study with the precursor Cp*ScMe has suggested the formation of the intermediate, the η^1(N)-PY adduct, prior to C−H insertion.[49a]



Scheme 21

PY uses the N atom and the C_α atom for coordination in the triosmium cluster $[Os_3(\mu\text{-}H)\ (\mu\text{-}NC_5H_4)(CO)_{10}]$, but two distinct metal centres are involved (Figure 9).[50]

The coordination chemistry of Q does not differ significantly from that of PY, except for the interactions with polynuclear metal complexes. In this case, the presence of the carbocyclic ring allows a larger variety of bonding modes.

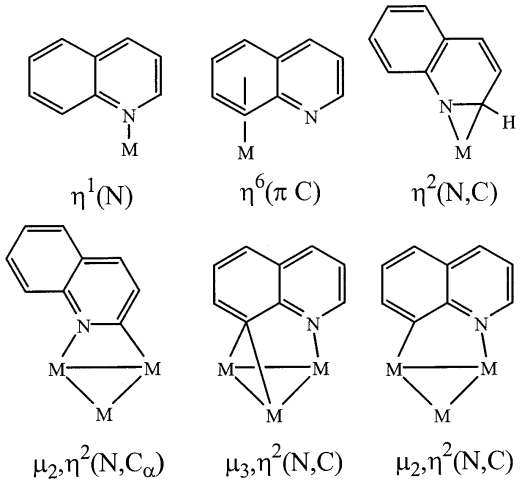


Figure 10. Known modes of Q coordination in transition metal complexes

Figure 10 summarises all the known coordination modes of Q in both mononuclear and polynuclear metal complexes.

Like PY, the most common coordination mode of Q in mononuclear complexes is the η^1(N),[40,41] which may be in equilibrium with the $\eta^6(\pi C)$.[41,44] No example of η^6coordination involving the heterocyclic ring (πN) has ever been reported.

An $\eta^1(N)\rightarrow\eta^6(\pi C)$ rearrangement analogous to that already described for PY is illustrated in Scheme 22.[41a][41d] The complex $[CpRu(CH_3CN)_3]^+$ reacts with Q yielding a kinetic η^1(N) product that converts to the thermodynamic $\eta^6(\pi C)$ derivative by decoordination of acetonitrile.

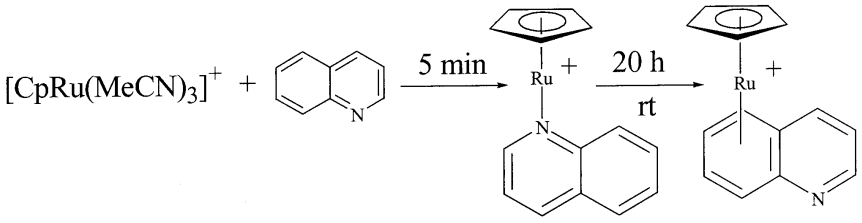
Substitution of Cp* for Cp increases the π back-bonding capability of the Ru centre, and the $\eta^6(\pi C)$ complex is formed in a straightforward manner with no evidence of the η^1(N) adduct.[41d]

The η^1(N)-Q mode may also be a precursor to the η^2(N,C) mode, as shown in Scheme 23, for the conversion of $[(DIPP)_3Ta\{\eta^1(N)\text{-}Q\}Cl_2]$ to $[(DIPP)_3Ta\{\eta^2(N,C)\text{-}Q\}]$ (DIPP = $2,6\text{-}OC_6H_3iPr_2$). This reaction requires an increase of the electron density at the metal centre to allow for an efficient $M(d\pi)\rightarrow Q(\pi^*)$ back-bonding interaction.[51]

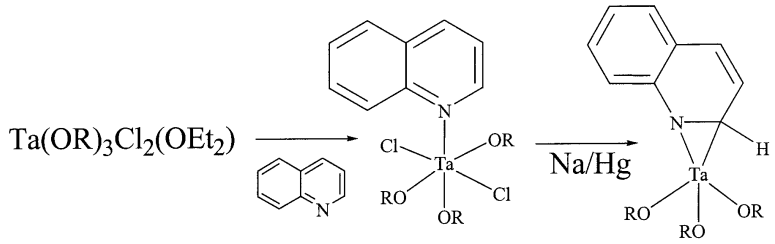
The multipoint activation of Q and alkyl-substituted quinolines has been studied with the clusters $Ru_3(CO)_{12}$ [52] and $Os_3(CO)_{10}(CH_3CN)_2$.[21a,53] The main bonding modes are summarised in Figure 10, while the reactivity of the resulting products will be reviewed in the next section. In all cases, N-coordination is accompanied by C-H insertion by an adjacent metal centre.

Tetrahydroquinoline (THQ) has been the subject of many studies aimed at investigating the dehydrogenation of partially reduced N-heterocycles over heterogeneous catalysts. $Ru_3(CO)_{12}$ reacts with THQ to give a bis-Q complex with a $\mu_2,\eta^2(N,C_\alpha)$ coordination mode (Scheme 24).[52] Dehydrogenation of THQ to Q has also been found to occur by reaction with either $[Os_3(CO)_{10}(CH_3CN)_2]$[53] or $Os_3(CO)_{12}$.[21a]

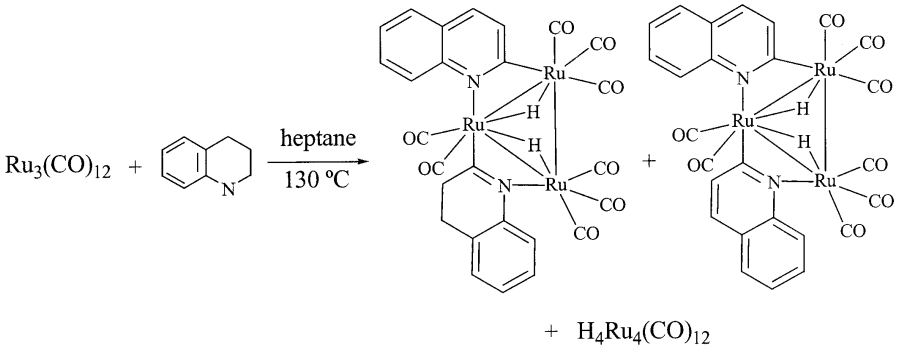
In conclusion, PY and Q exclusively use the nitrogen atom for coordination when the metal centre is electrophilic



Scheme 22



Scheme 23



Scheme 24

in nature and only one free site is available. When three coordination vacancies are available and the metal centre has filled dπ orbitals for πback bonding, the preferred bonding mode is the η^6, either πN or πC depending on the substrate. When two free sites are available, the electronic nature of the metal centre dictates whether the substrate binds the metal using two carbon atoms or the nitrogen and the C_α atom. Electron-rich systems based on late-transition metals prefer the olefinic η^2(C,C) mode, while electrophilic early-transition metal systems stabilise the η^2(N,C) mode. As will be shown in the next section, the binding mode of the N-heterocycle ultimately controls the reactivity of the activated substrate.

E) Complexes with Other Basic Polyaromatic N-Heterocycles

Isoquinoline, 5,6-benzoquinoline, 7,8-benzoquinoline, acridine, and phenanthridine have been found to bind single metal centres in either a η^1(N) or a η^6(πC) fashion.[41c,44a,53a]

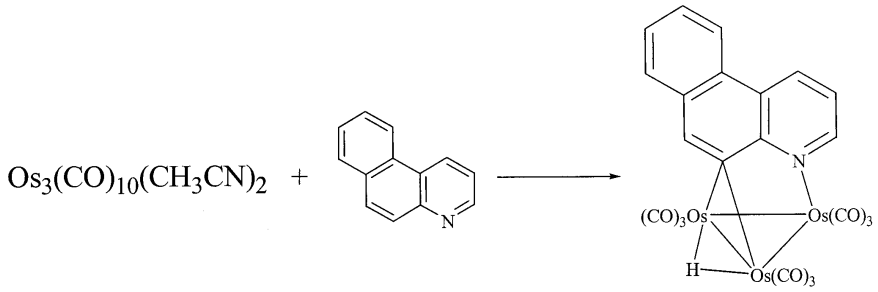
Like PY and Q, the triosmium cluster $[Os_3(CO)_{10}(CH_3CN)_2]$ reacts with polyaromatic N-heterocycles, such as 5,6-benzoquinoline and phenanthridine, yielding μ_3,η^2(N,C,C) complexes (Scheme 25).[53] Phenanthridine also forms a μ_2,η^2(N,C_α) complex similar to that with Q.

Reactivity of Coordinated N-Heterocycles

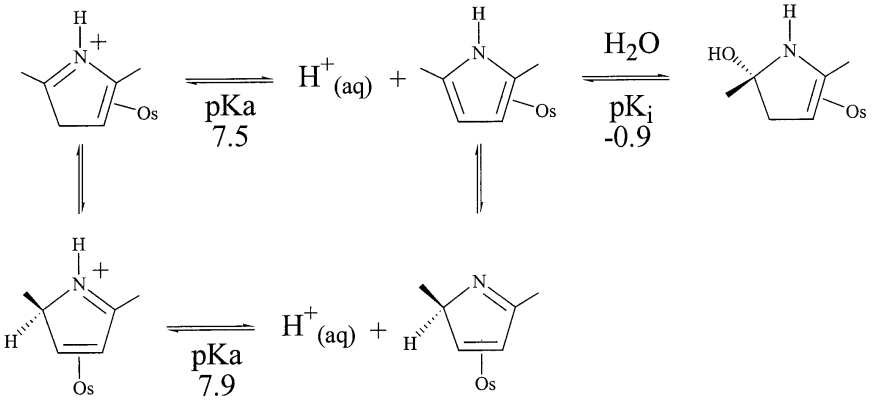
Upon coordination, the chemical reactivity of N-heterocycles is generally enhanced as compared with the free molecules. However, no general rule can be given. Indeed, besides the nature of the metal fragment, the reactivity of coordinated N-heterocycles depends on the substrate, the degree and regioselectivity of ring substitution, and the bonding mode. The reactivity studies reported in this section are just a selection of those that are representative of the possible chemical processes occurring during HDN. The catalytic hydrogenation reactions of N-heterocycles will be reviewed separately.

A) Pyrrole and Derivatives

In contrast to free PYR, which protonates at the α-position preferentially and under forcing conditions ($pK_a = -1$), η^2(C,C)-pyrrole in $[Os(NH_3)_5(2,3\text{-}\eta^2\text{-}2,5\text{-dimethylpyrrole})]^{2+}$, undergoes selective protonation by mild acids at the β-carbon away from the metal to produce a 3*H*-pyrrolium species (Scheme 26).[23a] In the presence of a weak base,



Scheme 25



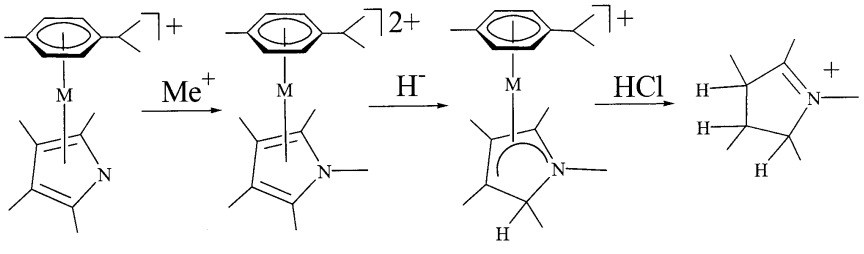
Scheme 26

the 3H-pyrrolium complex is converted into the 2H-pyrrolium tautomer that can be deprotonated at the nitrogen to give a neutral 2H-PYR ligand bonded to Os through the C_3-C_4 double bond. Nucleophilic addition of OH^-, from H_2O, to the enamine-like C=C bond in the starting η^2(C,C)-pyrrole complex has also been observed.

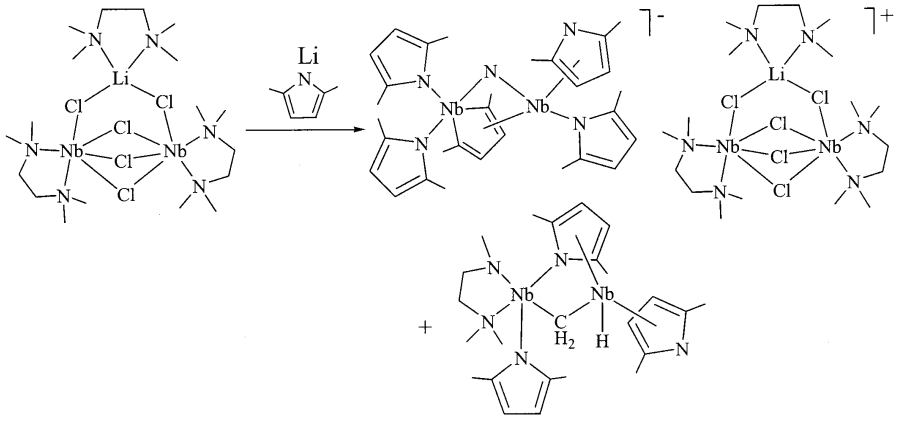
The η^5-pyrrolyl complexes [(*p*-cymene)M(NC_4Me_4)]OTf (M = Ru, Os) are readily converted into the corresponding η^5-PYR by selective alkylation at the nitrogen atom (Scheme 27).[22a] Interestingly, the η^5-PYR ligand in [(*p*-cymene)M($MeNC_4Me_4$)]($OTf)_2$ undergoes regio- and stereoselective hydride addition to an α-carbon atom to give a η^4-$MeNC_4Me_4H$ derivative. This compound reacts with protic acids, leading to further PYR reduction and dissociation from the metal as an iminium salt.

In a complex redox chemical process, the dimer [$(tmeda)_2$-Nb_2Cl_5Li(tmeda)] reacts with the 2,5-dimethylpyrrole lithium salt 2,5-$Me_2C_4H_2NLi$ to give a mixture of two products that have been confirmed by single-crystal X-ray analyses (Scheme 28) (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylendiamine).[27a]

The neutral product contains Nb^{III} and Nb^{IV} ions in different coordination geometries. The Nb^{IV} centre is coordinated by a terminal hydride ligand and by two η^5-pyrrolyl rings one of which is also η^1(N)-bonded to the Nb^{III} centre. The coordination of the latter metal is completed by another η^1(N)-pyrrolyl ligand, a bidentate tmeda molecule and a bridging CH_2 group that comes from the fragmentation of tmeda (N-Me cleavage, followed by C-H insertion). The anionic product [{(2,5-$Me_2C_4H_2N)_2Nb$}{(η^5-2,5-$Me_2C_4H_2N$)(2,5-$Me_2C_4H_2N$)Nb}(μ-N)(μ,η^1:η^1:η^4-1,4-$Me_2C_4H_2$)] is much more interesting as it contains a denitrogenated pyrrole ring. The anion, isolated as the $[(tmeda)_2Nb_2Cl_5Li(tmeda)]^+$ salt, contains two Nb^{IV}



Scheme 27



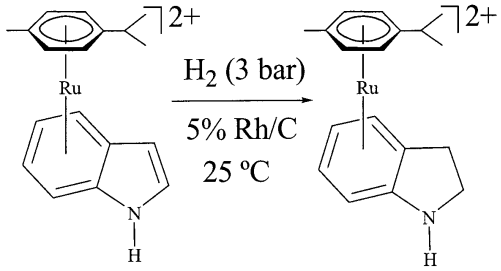
Scheme 28

centres connected by a nitride ligand and by a dienediyl group. Three η^1(N) and one η^5 pyrrolyl rings complete the coordination spheres.

The overall reaction (Scheme 28) thus corresponds to the simultaneous cleavages of C-N bonds in both the pyrrole ring and the saturated amine. The formation of the anionic product has been suggested to involve the cooperative attack of the two Nb^{II} centres on one pyrrolyl anion. The four electrons necessary to form the nitride and the dienediyl group are obtained from the five electrons provided by the oxidation of the four Nb^{II} centres during the formation of the anion and cation.

B) Indole and Derivatives

Besides undergoing deprotonation of the nitrogen atom to give η^5-indolyl complexes (Scheme 11), η^6-IN complexes are activated toward nucleophilic substitution at the carbocyclic ring,[32c,54] as well as reduction of the heterocyclic ring.[32a] Although the latter process has been found to involve a heterogeneous catalyst, 5% Rh/C, it is important to have demonstrated that η^6 coordination through the carbocyclic ring promotes the hydrogenation of the heterocyclic portion of the molecule to give an η^6-indoline complex (Scheme 29). Activation by carbanions towards nucleophilic addition has also been shown for η^6-indoline.[32a]



Scheme 29

A common reaction path of η^1(N)-indolyl complexes is their transformation into η^1(N)-indolenine derivatives upon selective protonation of the β-carbon atom (Scheme 12).[35]

The much lower propensity of N-heterocycles as compared with S- and O-heterocycles to undergo C-heteroatom insertion by metal fragments is shown by the reactions of $[Mn(CO)_3(\eta^6\text{-IN})]$, $[Mn(CO)_3(\eta^6\text{-BT})]$ (BT = benzothiophene) and $[Mn(CO)_3(\eta^6\text{-BF})]$ (BF = benzofuran) with $Pt(PPh_3)_3$ (Scheme 30).[55−57] Under comparable conditions, Pt inserts into the C_2-S[55] and C_2-O[56] bond of BT or BF, respectively, while the remote activation[55] of the IN heterocyclic[57] ring by $Mn(CO)_3$ exclusively results in N-H insertion with the formation of the heteronuclear trimer $[(CO)_3Mn(\mu^2,\eta^6,\eta^1(N)\text{-}C_8H_6N)]_2[Pt(PPh_3)_2]$.

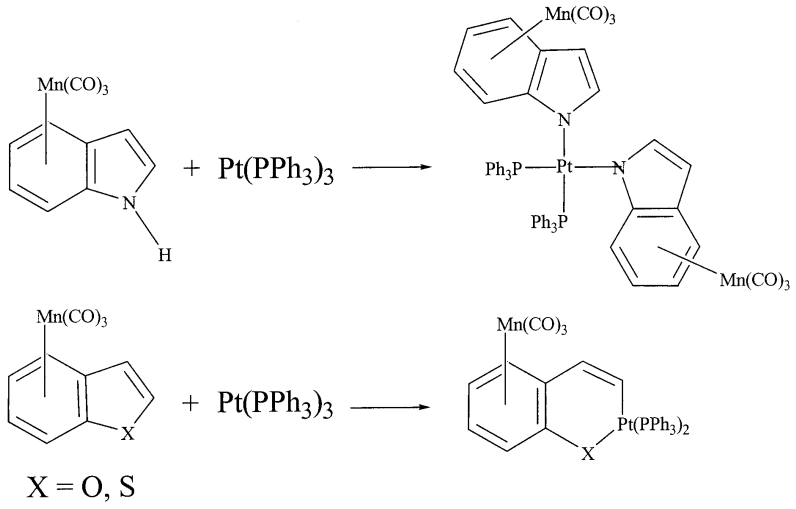
Unlike mononuclear species, polynuclear metal complexes containing bridging ligands derived from N−H or C−H activation of N-heterocycles (see Figure 5 and 7) generally behave as thermodynamic sinks and do not react further with H_2, nucleophiles or electrophiles even under harsh experimental conditions.

Dehydrogenation of indoline to indole by thermolysis of metal clusters containing C-H inserted indoline has been observed,[37] while indoline has been employed as a hydrogen source for the transfer hydrogenation of olefins in the presence of $[RhCl(PPh_3)_3]$.[57] A possible pathway for indoline dehydrogenation is shown in Scheme 31.

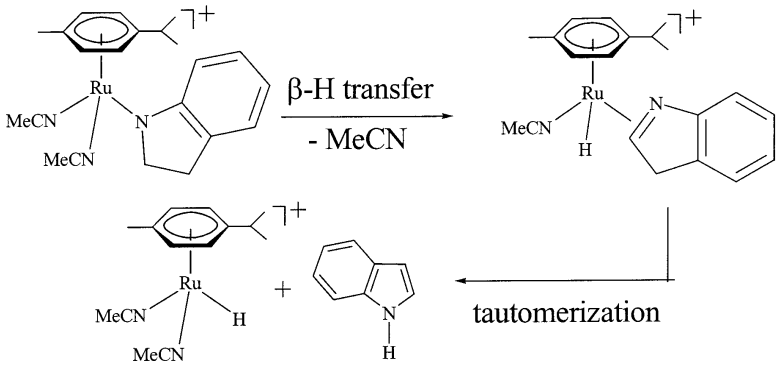
C) Pyridine, Quinoline and Derivatives

For PY the η^1(N) mode represents the simplest way of approaching a metal centre possessing a free coordination site. In the η^1-mode however, no activation of the heterocycle takes place. In order to increase the chemical reactivity of PY, a metal centre must have at least two free sites for coordination.

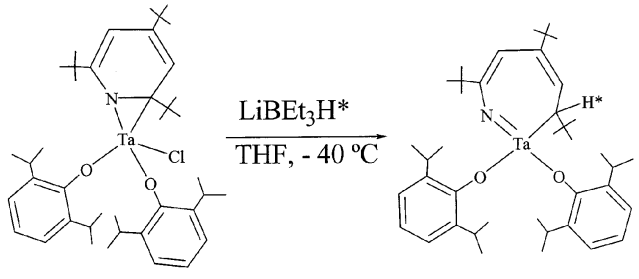
In the dihapto mode through two carbon atoms,[46] as in $[Os(NH_3)_5(\eta^2\text{-lutidine})]^{2+}$, the pyridine ring can be protonated intermolecularly at nitrogen, or even intramolecularly deprotonated at carbon as shown in Scheme 18. Although interesting, the transformations illustrated in Scheme 24 are by far less exciting than those observed when PY is activated by a metal centre through the η^2(N,C) mode: in this case, the HDN-crucial C−N bond cleavage may indeed occur. The first evidence for metal C−N insertion was reported by Wigley in 1992, who reacted the metallaaziridine complex $[(DIPP)_2ClTa(\eta^2(N,C)\text{-}2,4,6\text{-}NC_5H_2tBu_3)]$ with $LiHBEt_3$ in THF at low temperatures obtaining the C−N insertion product $[(DIPP)_2Ta\{=NCtBu=CHCtBu=CHCHtBu\}]$ (Scheme 32).[51d]



Scheme 30



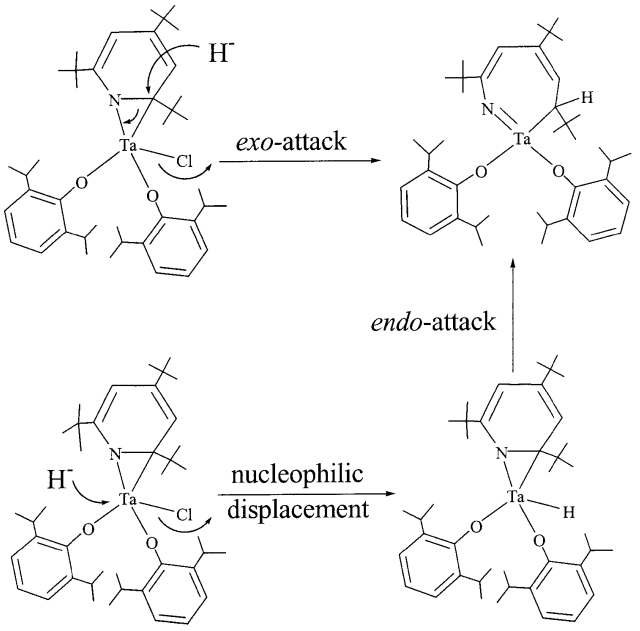
Scheme 31



Scheme 32

Experiments with carbon nucleophiles (RMgCl, MeLi) in place of $LiHBEt_3$, have provided valuable information to discriminate between the two possible pathways (*exo*-attack vs. *endo*-attack) to PY C−N scission (Scheme 33).[51b,51c] It has been established that the reaction occurs *via* an intramolecular *endo*-attack of the hydride that migrates to the PY Cα atom as a σ-nucleophile.

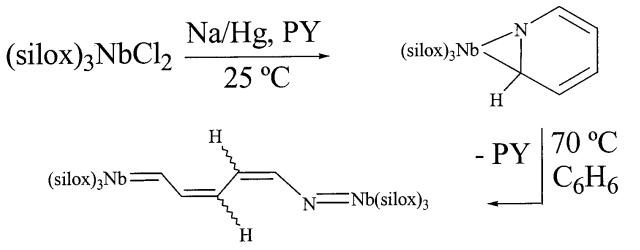
A major conclusion of Wigley's study is that bonding of PY in the η^2(N,C) fashion allows the Cα atom (a formal sp^2 carbon) to attain sp^3 hybridisation, and thereby renders this carbon atom susceptible to nucleophilic attack. However, the presence of the *t*Bu groups in $[(DIPP)_2ClTa\{\eta^2(N,C)\text{-}2,4,6\text{-}NC_5H_2tBu_3\}]$ is of mandatory importance for the occurrence of the nucleophile-promoted C-N bond cleavage. Indeed, neither the related Ta complex $[(silox)_3Ta\{\eta^2(N,C)\text{-}NC_5H_5\}]$[51a] nor the Q derivative $[(DIPP)_2Ta\{\eta^2(N,C)\text{-}Q\}]$[51a] undergoes C−N insertion upon nucleophilic addition. Nonetheless, Wigley's compound represents an excellent model to gain an insight into some relevant issues of HDN, e.g. it supports the hypothesis which states that the cobalt-promoter effect in the $MoS_2/\gamma\text{-}Al_2O_3$ catalyst is that where the electron density increases on the surface metal atoms *via* electron transfer.[1] Moreover, the fact that the C−N scission step occurs with the



Scheme 33

formation of an imido moiety (M=NR) is consistent with the ultimate elimination of ammonia by hydrogenolysis of the C−N inserted product.

An intriguing case of metal-assisted ring-opening of PY has been reported by Wolczanski using the low-valent $(silox)_3Nb$ fragment that binds PY in the η^2(N,C) mode (Scheme 34).[47a] Unlike $[(DIPP)_2ClTa\{\eta^2(N,C)$-2,4,6-$NC_5H_2tBu_3\}]$, $[(silox)_3Nb\{\eta^2(N,C)$-$NC_5H_5\}]$ undergoes C−N insertion by thermolysis in benzene at 70 °C only. The reaction gives 0.5 equiv. of PY and 0.5 equiv of $[(silox)_3Nb{=}CHCH{=}CHCH{=}CHN{=}Nb(silox)_3]$ as a thermodynamic mixture of *cis,cis*-, *trans,cis*-, *trans,trans*- and *cis,trans*-isomers.



Scheme 34

Hydrogenation and Hydrogenolysis of N-heterocycles Catalysed by Transition Metal Complexes

Under actual HDN conditions, the hydrogenation of N-heterocycles is much more facile than the subsequent C−N hydrogenolysis.[7] This trend is observed also when soluble metal complexes are used as models for heterogeneous HDN catalysts. Indeed, while several examples of hydrogenation of N-heterocycles to the corresponding cyclic amines (partially or fully saturated) have been reported, only one case of hydrogenolysis promoted by a homogeneous catalyst has been described so far. Moreover, the real nature of this hydrogenolysis process is still rather doubtful.

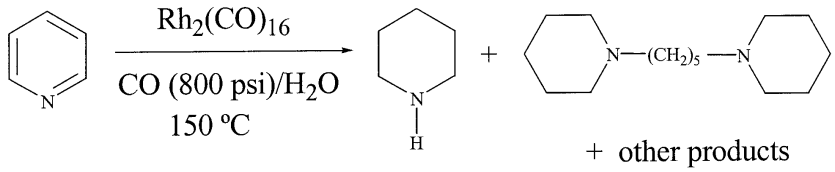
A) Hydrogenolysis of Pyridine

Under water-gas shift (wgs) conditions and in the presence of $Rh_6(CO)_{16}$, PY has been found to undergo both hydrogenation to piperidine and hydrogenolysis to various bis(piperidinyl)alkanes (Scheme 35).[58] The formation of the latter compounds has been proposed to involve extrusion of NH_3 from the intermediate 1,4-dihydropyridine to give glutaraldehyde, which in turn reacts with piperidine and hydrogen to form the bis(piperidinyl) products. The absence of both particulate metal in the reactor and reactivity when the rhodium metal was substituted for $Rh_6(CO)_{16}$ confirmed the homogeneous nature of the process. However, the lack of further studies supporting the homogeneity of this HDN reaction, the harsh experimental conditions (150 °C, 800 psi CO), and the proven capability of heterogeneous catalysts to promote the conversion of PY illustrated in Scheme 35,[59] have contributed in raising doubts on the homogeneous nature of the overall process.

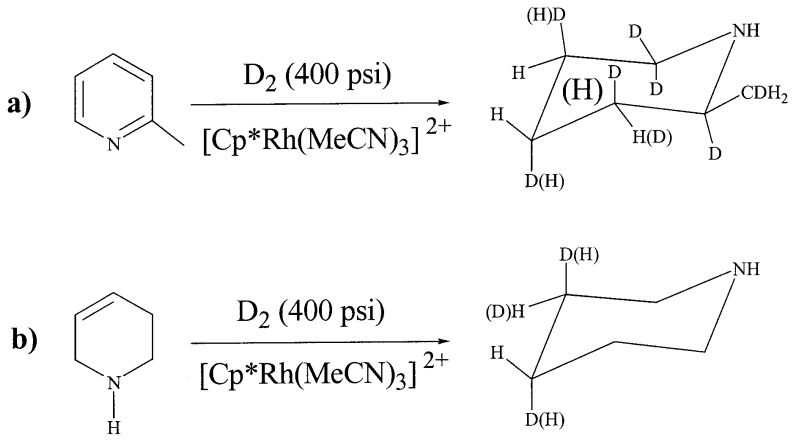
B) Hydrogenation of Pyridine, Quinoline, Indole and Derivatives

The first example of selective hydrogenation of PY to piperidine was reported in 1970 by Jardine and McQuillin.[60] The reaction was carried out in DMF at 1 bar H_2 in the presence of $Rh(PY)_3Cl_3/NaBH_4$. The same catalyst system was found to be effective for the reduction of Q to THQ (see below). In either case, no kinetic or mechanistic information was provided. In contrast, an in-depth study[61] is available for the hydrogenation of 2-methylpyridine to 2-methylpiperidine catalysed by $[Cp^*Rh(MeCN)_3]^{2+}$. Deuterium labelling experiments, competitive studies and reactions with isolated intermediates allowed Fish and co-workers to address many relevant issues regarding the hydrogenation of pyridines in the presence of this Rh^{III} precursor (Scheme 36a).[41,61]

On the basis of the deuteration pattern observed when D_2 was substituted for H_2, it was concluded that the reductions of the C=N and C=C bonds are reversible. The reversibility of H_2 addition to the C=N bond was suggested to be promoted by the allylic nature of the reduction product, i.e. $NH{-}CH_2{-}C{=}C$, which is highly activated toward rearomatisation of the N-ring by dehydrogenation. Another remarkable observation made by Fish was that six-membered mononuclear N-heterocycles such as PY and derivatives are much less prone to undergo hydrogenation than bi- and trinuclear N-ring compounds (e.g. quinolines, benzoquinolines, acridines) due to their higher resonance stabilisation energy. This finding led Fish to conclude that the initial C=N bond hydrogenation which actually disrupts the aromaticity of the molecule, is the most critical hydrogenation step in the overall reduction process. The reduction of 1,2,5,6-tetrahydropyridine (THPY) with D_2 in the presence of $[Cp^*Rh(MeCN)_3]^{2+}$ (exclusive deuterium incorporation in the C_3 and C_4 carbon atoms, Scheme 36b) and the independent synthesis of $[Cp^*Rh(\eta^1(N)$-THPY$(MeCN)_2]^{2+}$



Scheme 35



Scheme 36

provided two additional pieces of HDN-relevant information: i) η^1(N)-THPY complexes are not intermediate to piperidine production; ii) partially hydrogenated N-heterocycles are easily dehydrogenated to their aromatic precursors, thus confirming that C-N bond cleavage for cyclic amines is not thermodynamically favoured over rearomatisation.[61]

Laine's idea to use late transition metal carbonyls, capable of promoting the wgs reaction, for the hydrogenation of PY, prompted other researchers to follow this route. In all cases, however, polyaromatic heterocycles such as Q, 5,6-benzoquinoline (5,6-BQ), 7,8-benzoquinoline (7,8-BQ), acridine (AC) and derivatives, were employed as model substrates. In no case was the HDN of the N-heterocycle observed.

Under either wgs or synthesis-gas (sg) conditions, Fish employed a variety of metal carbonyls or phosphane-modified metal carbonyls for the reduction of polyaromatic heterocycles.[62] Selective hydrogenation of the heterocyclic ring was achieved with $Fe(CO)_5$, $Mn_2(CO)_8(PBu_3)_2$ and $Co_2(CO)_6(PBu_3)_2$. Under wgs conditions, $RuCl_2(CO)_2(PPh_3)_2$ and $H_4Ru_4(CO)_{12}$ proved to be inactive due to competitive coordination of CO, while efficient regioselective hydrogenation of the substrate was achieved using H_2 gas. In all cases, however, high temperatures (180−200 °C) were needed and very low turnovers [mol substrate (mol catalyst^{-1})] were obtained.[62] The reactivity of $Fe(CO)_5$ toward selective reduction of the heterocyclic ring under wgs conditions was also reported by Kaesz and co-workers for Q, isoquinoline (IQ) and AC.[63] Improved catalytic efficiency (up to 87 turnovers) was obtained adding both a base and a phase-transfer agent. Finally, various substituted quinolines and isoquinolines were selectively hydrogenated in the heterocyclic ring with $Rh_6(CO)_{16}$ under wgs conditions.[64] However, unlike PY,[58] no HDN product was formed. It was also reported that 4-methyl-Q was selectively converted into 4-methyl-THQ under wgs conditions, whereas 4-methyl-5,6,7,8-THQ was exclusively obtained using H_2 gas.[64]

It was possible to apply mild reaction conditions only with more complex ligand systems than CO, and hence study the mechanism and kinetics of hydrogenation of polyaromatic N-heterocycles.

The first detailed mechanistic studies of homogeneous hydrogenation of polyaromatic substrates have been reported by Fish and co-workers who employed the Rh^I and Ru^{II} precatalyts $[(PPh_3)_3RhCl]$[65] and $[(PPh_3)_3RuHCl]$[66] under mild experimental conditions (85 °C, 310 psi H_2, benzene). The Rh complex was actually shown to convert into $(PPh_3)_3Rh(H)_2Cl$ by treatment with H_2. As a general trend, the relative hydrogenation rates decreased in the order phenanthridine > AC > Q > 5,6-BQ > 7,8-BQ, which reflects the influence of both steric and electronic effects. All substrates were regioselectively hydrogenated at the heteroaromatic ring; only AC was converted into a mixture of 9,10-dihydroacridine and 1,2,3,4-tetrahydroacridine. The hydrogenation of Q was found to be inhibited by the presence of pyridines and THQ in the reaction mixture, due to competing coordination to the metal centre; all the other substrates had no appreciable effect on the rate of Q hydrogenation. In the case of the Rh catalyst, Q reduction was promoted in the presence of IN, PYR, carbazole and even of sulfur-heterocycles such as thiophene, benzothiophene and dibenzothiophene.

The substitution of D_2 for H_2 in the reduction of Q, catalysed by either $(PPh_3)_3RhCl$ or $(PPh_3)_3RuHCl$, provided the following pieces of information: i) the hydrogenation of the C=N bond is reversible; ii) the C_3-C_4 double bond is irre-

versibly hydrogenated in a stereoselective cis manner; iii) the C_8-H bond in the carbocyclic ring is activated (most likely by cyclometalation). Based on deuterium labelling experiments and of reactions with isolated compounds, Fish proposed a sound mechanism for the hydrogenation of Q with $[(PPh_3)_3Rh(H)_2Cl]$ or $[(PPh_3)_3RuHCl]$, which however, did not distinguish between intra- and intermolecular reduction of the C_3-C_4 double bond. This mechanism is not shown here for the simple reason that, some years later, the same author reported a similar and more complete mechanistic picture using $[Cp^*Rh(MeCN)_3]^{2+}$ as the catalyst precursor (vide infra).

The catalytic performances of $[(PPh_3)_3RuCl_2]$, $[(PPh_3)_3RhCl]$, $[(PPh_3)_3RuHCl(CO)]$, $[(PPh_3)_3OsHCl(CO)]$, $[Rh(cod)(PPh_3)_2]^+$ and $[Ir(cod)(PPh_3)_2]^+$ (cod = 1,5-cyclooctadiene) in the selective hydrogenation of Q to THQ have been investigated by Sánchez-Delgado and Gonzáles (150 °C, 30 bar H_2, toluene).[67] The Rh complex was by far the most active [initial rate ca. 200 mol Q (mol cat)$^{-1}$ h^{-1}], while the Os complex was the least efficient [initial rate ca. 5 mol Q (mol cat)$^{-1}$ h^{-1}]. The latter observation is consistent with the kinetic sluggishness of third-row metals. Some chemical factors affecting the activity of the Ru complex $[(PPh_3)_3RuHCl(CO)]$ were investigated in detail. Coordinating solvents such as MeCN or MeOH, or added ligands such as CO quenched the catalysis. The addition of acid or base gave adverse effects, the base acting as an inhibitor; water did not apparently affect the catalytic rate.

A study relating the rate of hydrogenation of Q to THQ with the nature of the metal centre has recently been reported by López-Linares and co-workers.[68] Several catalyst systems were prepared by adding either Tp or Tp* [Tp = tris(pyrazolyl)borate; Tp* = tris(3,5-dimethylpyrazolyl)borate] to toluene solutions of $[Rh(cod)Cl_2]_2$, $[Ir(cod)Cl_2]_2$, $[Ir(coe)Cl_2]_2$ (coe = cyclooctene) and $RuCl_2(MeCN)_4$. Preformed $TpIr(C_2H_4)_2$ was also tested. Rhodium formed the most active catalysts. As a general trend, the activity was found to increase with the ease of formation of Tp or Tp* complexes, while the presence of ligands capable of competing with Q for coordination decreased the hydrogenation rate, e.g. coe and ethylene which can undergo competitive metal insertion into sp^2 C−H bonds.

Deuterium gas experiments, monitored by both NMR spectroscopic and GC/MS analysis, and in situ high-pressure NMR spectroscopic reactions were very helpful to draw out the mechanism reported in Scheme 37 for the hydrogenation of Q to THQ catalysed by the Rh^{III} complex $[Cp^*Rh(MeCN)_3]^{2+}$ (40 °C, 500 psi H_2, CH_2Cl_2).[61] The regioselectivity and degree of deuterium incorporation are shown in the scheme just to help the reader in following the authors' conclusions.

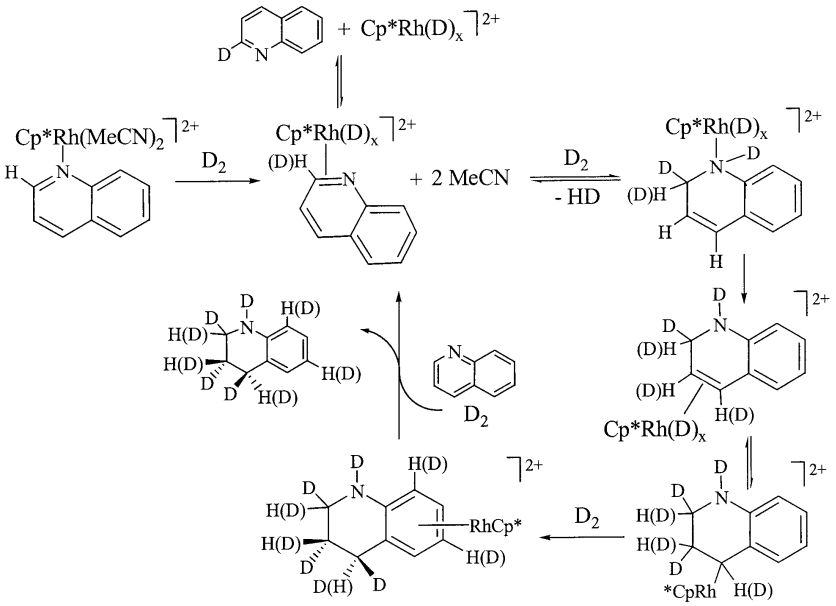
Salient features of the postulated mechanism are: i) η^1(N) bonding of Q to Rh with the loss of complexed MeCN, followed by the formation of a hydride; ii) reversible 1,2-N=C bond hydrogenation, most likely by a η^2(N,C) coordination as later shown by Wolczanski[47] and Wigley;[48] iii) migration of Cp*Rh from nitrogen to the C_3-C_4 double bond; iv) reversible C_3-C_4 double bond reduction; v) Cp*Rh complexation to the carbocyclic ring, followed by C_6-H and C_8-H bond activation; vi) $\eta^6(\pi C)$ coordination of THQ, followed by ligand exchange with Q to continue the catalytic cycle. In this mechanistic picture, the Rh centre goes through the catalytic process with the unusual III→V→III oxidation/reduction cycle. Some intermediate complexes[41e] in the catalytic cycle were isolated and characterised, i.e. $[Cp^*Rh(\eta^1(N)\text{-}Q)(MeCN)_2]^{2+}$ and $[Cp^*Rh(\eta^6(\pi C)\text{-}THQ)]^{2+}$. The critical role of η^1(N) coordination for selective nitrogen ring reduction was also demonstrated by the much higher catalytic activity of $[Cp^*Rh(MeCN)_3]^{2+}$ vs. the Ru analogue $[Cp^*Ru(MeCN)_3]^+$, which indeed forms a more stable $\eta^6(\pi N)$ complex.[41]

The mechanism illustrated in Scheme 37 also accounts for the $[Cp^*Rh(MeCN)_3]^{2+}$-assisted regioselective hydrogenation of pyridines, benzoquinolines, AC as well as indoles and benzothiophene.[61] The observation that the relative hydrogenation rates decreased in the order AC > Q > 5,6-BQ > 2-Me-Q > 2-Me-PY was attributed to both electronic and steric effects. In particular, the rate decreased with increasing basicity and steric hindrance at the nitrogen atom. A different case is represented by 7,8-BQ that showed the highest relative rate and, in competitive reactions, was found to remarkably enhance the rate of hydrogenation of Q and other substrates as well. It was proposed that the enhanced rate is due to a hydrogen transfer mechanism, which is consistent with the role of nitrogen compounds as hydrogen-donor solvents in coal liquefaction.[61]

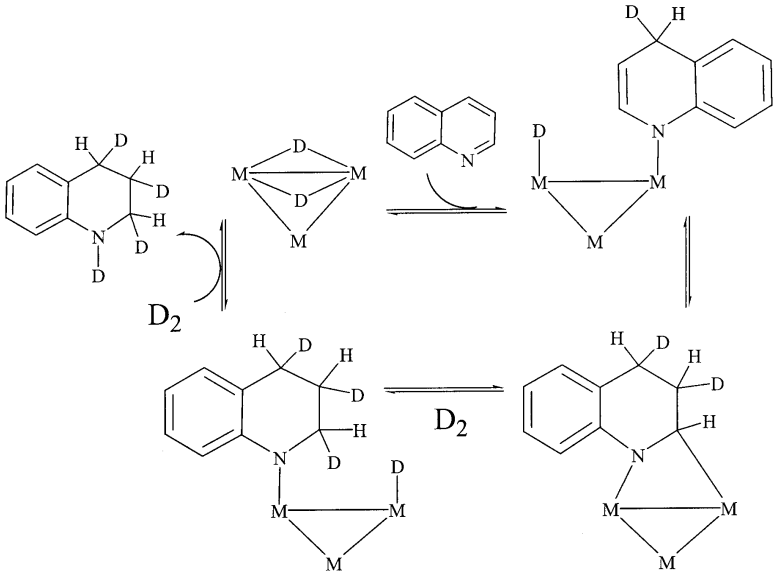
The deuteration pattern of THQ found by Fish is rather similar to that reported by Laine for the hydrogenation of Q with the clusters $H_2Os_3(CO)_{10}$ and $Os_3(CO)_{12}$, as well as real sulfided Co-Mo/γ-Al_2O_3 heterogeneous catalysts.[21a][69] Some differences in the deuteration pattern, in particular the presence of more deuterium in the 4-position and less in the 2-position, have been interpreted in terms of the occurrence of oxidative addition of the Os cluster to C-H bonds in Q and 1,4-hydrogenation as well (Scheme 38).

By combination of kinetic and chemical methods, and using $[Rh(cod)(PPh_3)_2]PF_6$ as the catalyst precursor, Sánchez-Delgado and co-workers have provided a further insight into the mechanism of the regioselective hydrogenation of Q to THQ.[70] The experimental rate law was $r_i = k_{cat}[Rh][H_2]^2$ with $k_{cat} = 50 \pm 6$ M^{-2} s^{-1} at 370 K and the following thermodynamic parameters were obtained: $\Delta H = 9 \pm 1$ kcal mol^{-1}, $\Delta S = -27.0 \pm 0.3$ eu. The isolation of $[Rh(cod)(Q)_2]PF_6$ at the end of the catalysis (370 K, ≤1 bar H_2, toluene), and the observation that the rate of hydrogenation of the partially reduced substrate dihydroquinoline (DHQ) was comparable with that of Q, allowed Sánchez-Delgado to propose the mechanism illustrated in Scheme 39.

The catalytic cycle starts with the displacement of PPh_3 by Q in the Rh^I precursor to give the bis-Q compound $[Rh(cod)(Q)_2]^+$, which then reacts with H_2 to give the Rh^{III} dihydride $[Rh(cod)(H)_2(Q)_2]^+$. After the C=N bond has been rapidly and reversibly reduced by two consecutive hydride transfers, a η^2(C,C)-DHQ complex is formed which



Scheme 37

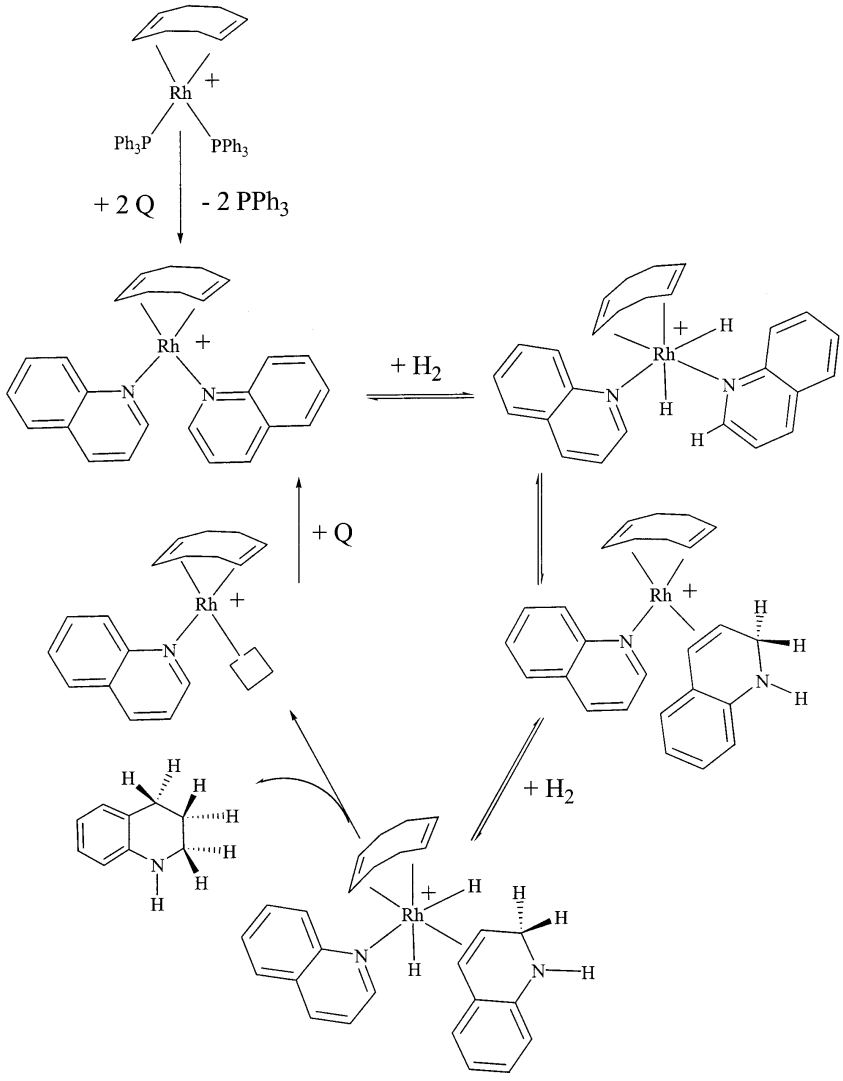


Scheme 38

slowly reacts with H_2 to give THQ. The irreversible displacement of THQ from rhodium by Q regenerates the bis-Q complex to continue the catalysis. According to the kinetic studies, the overall process that converts DHQ to THQ constitutes the rate-limiting step. Besides accounting for the kinetic results, the mechanism proposed by Sánchez-Delgado comprises steps that are commonly encountered in rhodium-catalysed olefin hydrogenation mechanisms where, unlike the Fish mechanism, the rhodium metal goes through the catalysis with the usual III→I→III reduction/oxidation cycle.

Kinetic studies for Q reduction to THQ have also been reported by Rosales and co-workers for the Ru^{II} complex $[RuH(CO)(MeCN)(PPh_3)_2]BF_4$.[71] At low hydrogen pressure, the experimental rate law $r_i = k_{cat}\,[Ru_0][H_2]^2$ (k_{cat} = 28.5 $M^{-2}\,s^{-1}$ at 398 K) was quite similar to that found by Sánchez-Delgado. In contrast, at high H_2 pressure, a first-order dependence of the reaction rate with respect to the hydrogen concentration was observed. The proposed mechanism involves a rapid and reversible partial hydrogenation of bonded Q, followed by a rate-determining second hydrogenation of DHQ.

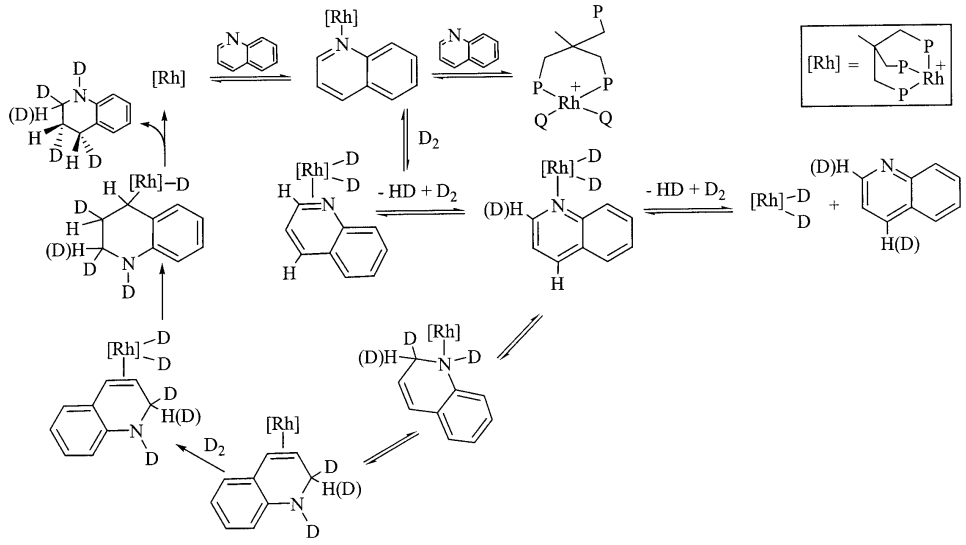
A zero-order dependence on the substrate concentration is not a general kinetic rule for the homogeneous hydrogenation of Q to THQ. A much more complex kinetic law was actually found for the reaction catalysed by the Rh^{I} complex [(triphos)Rh(DMAD)]PF_6 (triphos = $CH_3C(CH_2PPh_2)_3$; DMAD = dimethyl acetylenedicarboxylate).[72] Monitoring the formation of THQ with time by GC at a fixed temperature of 60 °C showed that the rate is



Scheme 39

first-order with respect to both H_2 (from 4 to 30 bar) and catalyst concentration (from 36 to 110 mM). In contrast, an inverse dependence of the hydrogenation rate with respect to Q concentration was found. The empirical rate law $r = k''\,[Rh][H_2][Q]^2$, where $k'' = k\,(a + b[Q] + c[Q]^2)^{-1}$, was proposed to account for the inhibiting effect of Q concentration and the experimental observation that the rate tends to be second-order for very low Q concentrations (< 30 mM) and zero-order for very high Q concentrations (> 70 mM). Depending on the concentration of Q, the experimental rate law thus simplifies to $r = k/c\,[Rh][H_2]$, to $r = k/a\,[Rh][H_2][Q]^2$ or to $r = k\,(b + c[Q])^{-1}[Rh][H_2][Q]$. On the basis of the kinetic study, deuterium labelling and high-pressure NMR spectroscopic experiments under catalytic conditions, as well as the identification of catalytically relevant intermediates, a mechanism was proposed which essentially differs from that reported by Sánchez-Delgado for the rate-limiting step, i.e. the reversible reduction of the C=N bond instead of that of the $C_3{=}C_4$ bond (irreversible) (Scheme 40). The overall hydrogenation of the C=N bond, which actually disrupts the aromaticity of Q, was proposed as rate-determining step also in light of the independent reduction of isolated 2,3-dihydroquinoline that, under comparable experimental conditions, was reduced faster than Q. Also, the lack of deuterium incorporation into the carbocyclic ring of both THQ and Q ruled out η^6-Q or η^6-THQ complexes.

The Rh catalyst generated from [(triphos)Rh(DMAD)]PF_6 underwent deactivation with time, due to the formation of catalytically inactive Rh^I monohydrido complexes by heterolytic splitting of H_2 promoted by the basic environment of the reaction.[73] The addition of an excess of strong protic acid such as triflic acid, CF_3SO_3H, to the catalytic mixture was sufficient to overcome this drawback and induce a remarkable rate enhancement: at 40 °C and 30 bar H_2, the tof [mol substrate (mol cat)$^{-1}$ h^{-1}] increased from 40 to 95 by addition of a 20-fold excess of acid.[72] The acid was shown to convert inactive Rh^I into active



Scheme 40

Rh^{III}. Based on this finding, the addition of strong protic acids was also found to be of mandatory importance for generating a catalytically active system from [(triphos)Ru(-MeCN)$_3$](O$_3$SCF$_3$)$_2$ which, under neutral conditions, is almost inactive for Q reduction. Indeed, treatment of the ruthenium compound with H_2 produces ammonia which preferentially coordinates, over Q, to the metal centre. Moreover, in the basic environment of the reaction, the presence of moisture[73a,74] was found to give the catalytically inactive dimer [(triphos)Ru(μ-OH)$_3$Ru(triphos)]$^+$. The protic acid inhibits the formation of both NH_3 adducts and the (μ-OH)$_3$ dimer, thus allowing the hydrogenation of Q to THQ to proceed smoothly with a tof of 65.[72]

The catalyst precursor [RuH(CO)(MeCN)$_2$(PPh$_3$)$_2$]BF$_4$ was also employed to catalyse the hydrogenation of various polyaromatic N-heterocycles under relatively mild conditions (125 °C, 4 bar H_2, xylene or toluene).[75] The reactivity order AC > Q >> 5,6-BQ > 7,8-BQ > IN > IQ was in line with previous trends and reflects steric and electronic effects. In particular, the greater propensity to reduction of AC as compared with Q was attributed to the higher resonance stabilisation energy of this latter, while the almost negligible reduction of IQ was accounted for by the higher basicity of the N atom in this substrate. A kinetic study was carried out for the reduction of AC to 9,10-dihydroacridine. Unlike Q, the experimental rate law was $r = k_{cat}$ [Ru][H_2] and the postulated mechanism involves, as the determining step, the hydrogenation of coordinated AC in [RuH(CO)(η^1(N)-AC)(MeCN)(PPh$_3$)$_2$]$^+$, yielding 9,10-dihydroacridine and the coordinatively unsaturated complex [RuH(CO)(MeCN)(PPh$_3$)$_2$]$^+$.

In homogeneous phase, IN is much more difficult to reduce than Q as shown by the limited number of known catalysts {e.g. (PPh$_3$)$_3$RuHCl[66] and [RuH(CO)(-MeCN)(PPh$_3$)$_2$]BF$_4$ [75]}, as well as their very scarce activity (tof's ≤1). Indeed, the η^1(N) coordination, which is critical for selective nitrogen ring reduction in Q, is virtually unknown for IN which prefers to bind to metal centres using the carbocyclic ring (vide infra). In the latter coordination mode, the C=N bond is not activated and too many sites at the metal centre are occupied so that the oxidative addition of H_2 is very difficult to accomplish. Consistently, the hydrogenation of IN is generally inhibited when the reaction mixture contains basic substrates such as Q, THQ, and PY. To the best of our knowledge, the only catalyst that is able to regioselectively hydrogenate IN to indoline with an acceptable tof is [(triphos)Rh(DMAD)]PF$_6$, on the condition that a protic acid is added to the catalytic mixture.[3a–3d,7] By using equivalent amounts of triflic acid and IN tof's as high as 100 were obtained already at 60 °C and 30 bar H_2. It was experimentally shown that indoline was actually formed by reduction of the protonated form of IN, the 3H-indolium cation which possesses a localised C=N bond.[72]

Aqueous-Biphase Hydrogenation of N-Heterocycles

The remarkable progress recently achieved in the field of water-soluble catalysts and the actual possibility of applying aqueous-biphase catalysis to large volume reactions[76] have encouraged the petrochemical industry to look at aqueous-catalysis as an alternative method for removing sulfur and nitrogen impurities from distillates. Recent publications[73c,77–79] and patents[80] show that the hydrogenation and hydrogenolysis of aromatic heterocycles in biphasic media is indeed technically feasible.

The selective hydrogenation of N-heterocycles has been achieved by researchers at PDVSA-INTEVEP with the use of water-soluble Ru^{II} catalysts stabilised by either triphenylphosphane trisulfonate (TPPTS) or triphenylphosphane monosulfonate (TPPMS) ligands.[77,80] As a general procedure, the catalysts were prepared in situ from RuCl$_3$·3H$_2$O and excess phosphane in water, and the resulting solution was added to a hydrocarbon solution containing various model N-heterocycles such as Q, AC, and IQ. The biphasic reactions were performed under relatively drastic experimental conditions (130–170 °C, 70–110 bar H_2) and gave

the selective reduction of the heterocyclic ring. It was generally observed that nitrogen compounds did not inhibit the hydrogenation of added thiophenic substrates. In fact, in some cases a promoting effect was observed. The beneficial effect of the N-compounds on the rate of hydrogenation of thiophenes has been attributed to the catalyst protection by amines, which are better nucleophiles than thioethers. As a matter of fact, the major ruthenium product isolated from the aqueous phase after hydrogenation of a BT/Q mixture with $RuCl_3 \cdot 3H_2O/TPPMS_{(excess)}$ in water/decalin was $RuHCl(TPPMS)_2(THQ)_2$ (**A** in Figure 11).

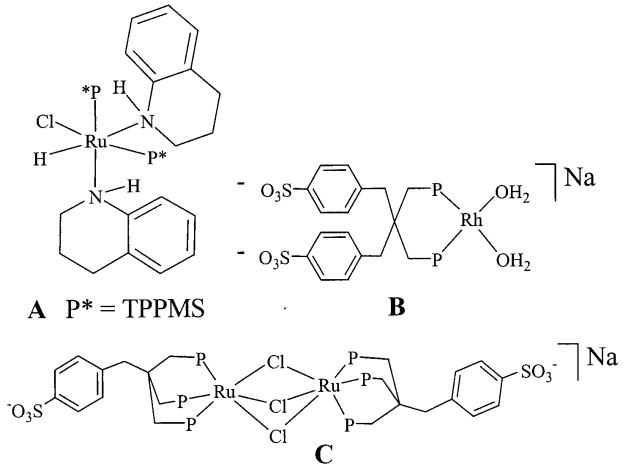


Figure 11. Water-soluble ruthenium complexes

The regioselective reduction of Q to THQ in water/hydrocarbon has been achieved also with bidentate and tridentate water-soluble ligands. In particular, the diphosphane $(NaO_3S(C_6H_4)CH_2)_2C(CH_2PPh_2)_2$ ($Na_2DPPPDS$) was found to form quite active systems in combination with rhodium and ruthenium.[5a,78] The Rh^I complex $[(DPPPDS)Rh(H_2O)_2]Na$ (**B** in Figure 11) was actually isolated and employed in water/*n*-octane to hydrogenate 1:1 mixtures of Q and BT at high temperatures (160 °C). Only the N-heterocycle was efficiently reduced (tof = 50), BT hydrogenation to 2,3-dihydrobenzothiophene (DHBT) being only marginal (tof = 2). A similar selectivity was found for the catalytic system $RuCl_3 \cdot H_2O/2Na_2DPPPDS$, prepared in situ. In contrast, the individual hydrogenation rates for Q and BT have been reported to be similar (tof = 30 at 140 °C, 30 bar H_2, water/*n*-heptane) and independent of the presence of either substrate when the dimeric complex $Na[\{(sulphos)Ru\}_2(\mu\text{-}Cl)_3]$ (**C** in Figure 11) was employed as precatalyst[79] [sulphos = tridentate ligand $^-O_3S(C_6H_4)CH_2C(CH_2PPh_2)_3$]. No attempt was made to determine whether the dimeric structure of the precursor was maintained during the catalysis. However, since the mononuclear complex $[(sulphos)Ru(MeCN)_3]^+$ has been found to catalyse the hydrogenation of BT to DHBT in water/decalin at a very similar rate,[79b] it is likely that disruption of the dimeric structure of C occurs under catalytic conditions. Under biphasic conditions, also the zwitterionic Rh^I complex (sulphos)Rh(cod) has been tested as a catalyst precursor for the hydrogenation of heterocycles. Although a modest catalyst for the hydrogenation of BT to DHBT, it is very efficient for the hydrogenation of Q to THQ (tof = 20 at 160 °C, 30 bar H_2, water/*n*-heptane).[79b]

Hydrogenation of N-Heterocycles by Supported Molecular Catalysts

In order to gain an insight into the reactivity of isolated metal surface sites under hydrotreating conditions, molecular catalysts of proven effectiveness for the hydrogenation of heteroaromatic rings have been heterogenised following different procedures.

The first of such approaches was reported by Fish in 1985. The molecular catalyst of choice was $Rh(PPh_3)_3Cl$, that the same author had shown to be active for the regioselective reduction of various polynuclear heteroaromatics.[81] The molecular precursor was tethered to 2% crosslinked phosphinated polystyrene-divinylbenzene and the resulting heterogeneous catalyst (**A** in Figure 12) was employed to hydrogenate Q, AC, 5,6-BQ and 7,8-BQ in benzene solution (85 °C, 310 psi H_2). The order of activity was identical to that in the homogeneous phase,[65] AC>Q>5,6-BQ>7,8-BQ, but the initial rates of the heterogeneous hydrogenations were from 10 to 20 times faster. This remarkable increased rate was essentially attributed to steric requirements surroundings the active metal centre in the tethered com-

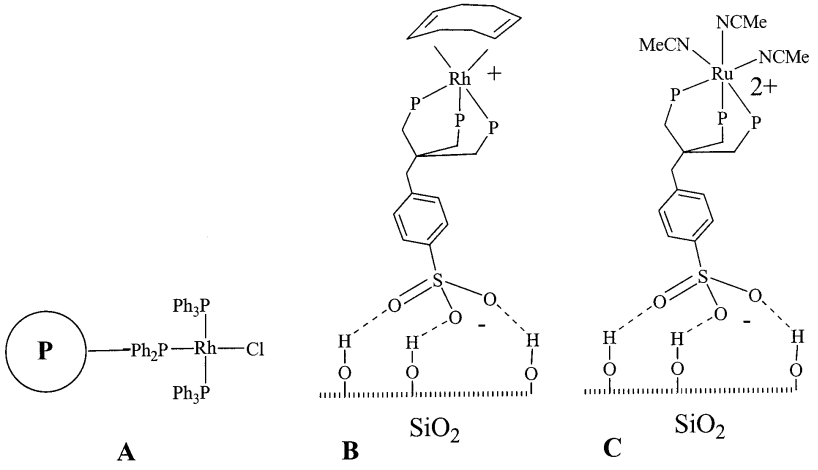

Figure 12. Supported molecular catalysts

plex, which apparently would favour the coordination of the N-heterocycles by disfavouring that of PPh_3. The regioselectivity of hydrogenation was even higher than that in the homogeneous phase as no formation of 1,2,3,4-tetrahydroacridine was observed. The deuteration pattern of the heteroaromatic ring after a catalytic reaction with D_2 was identical to that observed in the homogeneous phase, except for the lack of deuterium incorporation at position 8 of the carbocyclic ring. The supported catalyst was also employed to hydrogenate N-heterocycles in model coal liquid containing pyrene, tetralin, *p*-cresol, 2-methylpyridine and methylnaphthahalene. An increased rate was observed which was attributed to the ability of some constituents, especially *p*-cresol, to stabilise unsaturated rhodium species formed in the course of the catalysis.

The silica-supported hydrogen-bonded (SHB) rhodium complexes (sulphos)Rh(cod)/SiO_2 and [(sulphos)Ru(-MeCN)$_3$](SO$_3$CF$_3$)/SiO_2 (**B** and **C** in Figure 12), successfully employed to hydrogenate olefins in heterogeneous phase,[82][83] have been found to hydrogenate Q in *n*-octane (100 °C, 30 bar H_2) yielding selectively THQ with tof's as high as 100.[84] In line with the behaviour of the $Rh(PPh_3)_3Cl$/P-$Rh(PPh_2)_2Cl$ system,[81] both (sulphos)Rh(cod)/SiO_2 and [(sulphos)Ru(MeCN)$_3$](SO$_3$CF$_3$)/SiO_2 have been found to be more efficient catalysts than the homogeneous and aqueous-biphasic counterparts with triphos or sulphos ligands. The enhanced rate observed for the heterogeneous reactions has been attributed to the fact that, unlike in fluid solution systems, the heterogenised complexes do not undergo dimerisation to give catalytically inactive species.

Conclusions

The results described in this report define transition metal complexes as viable models for mimicking many steps occurring in heterogeneous HDN and allow the following conclusions to be drawn.

The η^1(N) and η^2(N,C) coordination modes of N-heterocycles are crucial for their hydrogenation and hydrogenolysis, respectively. In particular, it is evident that the regioselective hydrogenation of the heteroaromatic rings is effectively accomplished by late transition metals (promoters) in high oxidation states. Also, an acidic environment is generally found to promote efficient hydrogenation pathways. C−N bond cleavage is a difficult task that is best accomplished when the substrate uses the η^2(N,C) mode for binding an early transition metal in relatively low oxidation state. In all the cases reported, however, the C−N insertion step requires the transfer of a hydride ligand from the metal centre to the C−N carbon atom, which is consistent with a hydrolytic C−N insertion. The ultimate denitrogenation step apparently requires the cooperation of two metal centres as is commonly found for the homogeneous desulfurisation of thiophenes.[3−6,12] Accordingly, it does not seem likely that a single metal site can coordinate a N-heterocycle, insert into a C−N bond and finally remove the nitrogen atom.

Given the complexity of the HDN process and the many alternative or concomitant mechanisms that may be in operation even on the surface of the same catalyst, the homogeneous modelling studies must be considered with extreme caution. Most of the spectator ligands in solution reactions are actually not representative of the pool of ligands available to industrial hydrotreating catalysts. The model N-heterocycles generally employed (Q, PYR, IN) represent a fraction of nitrogen compounds in fossil fuels, and the environment of the reactions is extremely different. Nonetheless, we have shown here that many reactions involving transition metal complexes and N-heterocycles show sound analogies with related reactions occurring over the surface of heterogeneous catalysts. These analogies and the relative mechanistic information continue to give HDN modelling a great boost.

A Novel Dimanganese(II) Complex with Two Chloride Bridges − A Two-Electron Oxidation System

Isabel Romero,[a] Marie-Noëlle Collomb,*[a] Alain Deronzier,*[a] Antoni Llobet,[b] Emmanuel Perret,[c] Jacques Pécaut,[c] Laurent Le Pape,[c] and Jean-Marc Latour*[c]

Keywords: Manganese / N ligands / Biomimetic synthesis / Structure elucidation / Electrochemistry

A new kind of binuclear μ-chloro complex of manganese with two bpea ligands [bpea = *N*,*N*-bis(2-pyridyl methyl) ethylamine] has been synthesized and structurally characterized. A thorough electrochemical study shows that this complex exhibits a two-electron reversible oxidation leading to the stable dimanganese(III) complex.

Introduction

One-electron transfers are ubiquitous in chemistry as well as in biology.[1] However, activation of diatomic substrates such as dioxygen and dinitrogen requires multielectron transfers, which are often performed by metal clusters at enzyme active sites.[2] Moreover, in specific instances, multielectron transfers can be crucial because one-electron transfers may lead to deleterious effects. This is the case for catalases, the enzymes which carry out the disproportionation of hydrogen peroxide into water and molecular oxygen.

Most of these enzymes are hemoproteins, but a few bacterial catalases are known to possess a dinuclear manganese center at their active site.[3] It is generally believed that the Mn pair shuttles between the two oxidation states $Mn^{II}-Mn^{II}$ and $Mn^{III}-Mn^{III}$ during the catalytic cycle,[3a] thereby avoiding one-electron transfers which would produce hydroxyl radicals. The $Mn^{II}-Mn^{III}$ mixed-valent state is never observed under the normal conditions where the catalase reaction occurs. The structure and mechanism of action of this active center remains poorly defined, and in order to gain insight into the structure and the disproportionation mechanism, many efforts have been devoted in the past decade to designing simple model molecules.[4] Many of these model systems contain two Mn^{II} ions bridged by ligands like carboxylate,[5] phenoxide,[6] alkoxide[7] or, more rarely, by chloride.[8] These compounds can undergo the two following distinct one-electron exchanges [Equation (1) and (2)]:

$$Mn^{II}Mn^{II} \underset{\longleftarrow}{\xrightarrow{(E_{1/2})_1}} Mn^{II}Mn^{III} + e^- \quad (1)$$

$$Mn^{II}Mn^{III} \underset{\longleftarrow}{\xrightarrow{(E_{1/2})_2}} Mn^{III}Mn^{III} + e^- \quad (2)$$

with formation of a mixed-valence $Mn^{II}-Mn^{III}$ species[5] whose stability is expressed by the disproportionation constant (K_d), determined from the separation of the redox potentials of the two one-electron steps. The stability of the mixed-valent state depends on the degree of electronic coupling of the two metal ions[9] and, for uncoupled metal ions, a direct two-electron redox transition at a single electrochemical potential is expected. It has been stressed recently that for dimanganese(II) species to achieve a high efficiency of catalase-like activity, formation of the mixed-valence $Mn^{II}-Mn^{III}$ state must be disfavored.[3b] In this context, it is somewhat surprising that the electrochemical behavior of dimanganese $Mn^{II}-Mn^{II}$ complexes has been only scarcely examined in detail. Indeed, only for three of these systems a direct two-electron redox transition has been proposed.[5c,8b,10] We report here the synthesis, crystal structure and magnetic properties of a new di-Mn^{II} complex with a bis-μ-chloro unit $Mn_2(\mu\text{-}Cl)_2(bpea)_2Cl_2$ **(1)** [bpea = *N*,*N*-bis(2-pyridylmethyl)ethylamine]. A thorough electrochemical study reveals that **1** exhibits a clean , two-electron reversible oxidation system leading to the stable di-Mn^{III} complex.

Results

Solid State Structure

When $MnCl_2$ dissolved in water was allowed to react with an ethanolic solution of the bpea ligand at ambient temperature, the colorless solution turned yellow and **1** could be crystallized by slow evaporation of the solution. The structure of this binuclear complex was determined by an X-ray crystallographic study (Figure 1).

Each Mn atom is bound by three nitrogen atoms from a facially coordinated bpea ligand, and three chloride ions, in an octahedrally distorted fashion. The two manganese atoms are bridged by a pair of chloride ions leading to an Mn_2Cl_2 diamond core. The two manganese atoms are equivalent since the complex has a rotational C_2 symmetry axis passing through the center of this core. Owing to the presence of the symmetry axis the Mn_2Cl_2 core is strictly planar and the Mn−Mn bond length is 3.786 Å. The two Mn−Cl bridging bond lengths are slightly different [2.5374(8) and 2.5683(7) Å] and longer than the terminal Mn−Cl bond lengths (2.4249 Å). All these structural features are similar to those of other structurally characterized $Mn^{II}Mn^{II}$ di-μ-chloro complexes.[10]

Magnetic and Spectroscopic Properties

The temperature dependence of the product of the molar susceptibility and temperature (χT) at 0.5, 1, 2.5 and 5 T is shown for **1** in Figure 2. In the range from 300 to 100 K, χT is constant at ca. 8.5 $cm^3 \cdot K \cdot mol^{-1}$, which is close to the value expected for two independent spins $S = 5/2$ (8.75 $cm^3 \cdot K \cdot mol^{-1}$). At lower temperatures, χT increases to reach a maximum whose value and temperature depends on the applied magnetic field (11.5 $cm^3 \cdot K \cdot mol^{-1}$ at 4 K for 0.5 T, 10.6 $cm^3 \cdot K \cdot mol^{-1}$ at 6 K for 1 T, 9.9 $cm^3 \cdot K \cdot mol^{-1}$ at 14 K for 2.5 T and 9.0 $cm^3 \cdot K \cdot mol^{-1}$ at 60 K for 5 T). This behavior is typical of a metal pair experiencing a ferromagnetic interaction. In those cases where the exchange interaction and the zero-field splittings are of comparable magnitudes, full diagonalization of the matrix is required to treat all field- and temperature-dependent data. Preliminary fit-

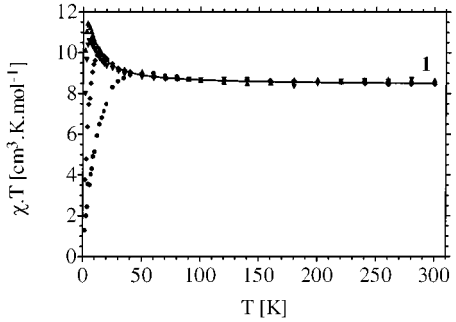

Figure 2. Temperature dependence of the product of the molar magnetic susceptibility and temperature for a microcrystalline sample of **1** (7.91×10^{-5} mol except at 2.5 T, 6.60×10^{-5} mol) at 0.5 (▲), 1 (▼), 2.5 (◆) and 5 T (•); solid line is the best least-square fit to the magnetic data

tings of the susceptibility data (Figure 2) with an expression based on a Heisenberg Hamiltonian ($J = -2J\ S_1S_2$), as described in the Experimental Section, were performed in the temperature range where the D effects are negligible. This led to an estimate of the magnetic exchange interaction of $J = 0.34$ (3) cm^{-1}.

The solution EPR spectra have been recorded in dichloromethane (Figure 3) and in acetonitrile to investigate the nuclearity of the complex, either in the absence or presence of the electrolyte $[(nBu)_4N]ClO_4$ in order to duplicate the electrochemical conditions. The two spectra are essentially identical, which points to the absence of chemical change induced by the electrolyte. They exhibit features extending from 50 to more than 800 mT as is normal for dimanganese(II) species.[12] Nevertheless, owing to the fact that some distorted mononuclear manganese(II) compounds possess similar transitions,[13] the dinuclearity of the complexes in solution cannot be taken for granted on the basis of these spectra. We were definitely able to prove this, however, through the observation of intense EPR transitions in the parallel mode, a property expected only for integer spins[14] and which rules out that the active species is mononuclear. The EPR spectra in acetonitrile are quite similar, except for a minor amount of mononuclear decomposition products. Therefore the EPR study undoubtedly shows that **1** exists as a dinuclear entity in solution as well as in the solid state. The very small modification of the

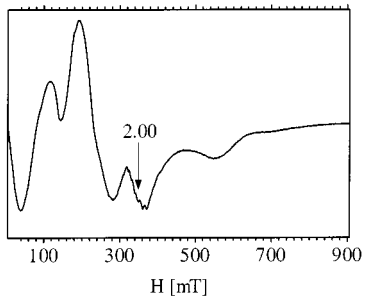

Figure 3. X-band EPR spectrum of **1** at a concentration of 1 mM in dichloromethane at 4.2 K; instrumental parameters: microwave frequency (9.6545 GHz), microwave power (0.2 mW), modulation amplitude (10 G), modulation frequency (100 kHz), sweep time 168 s; the six hyperfine lines centered at $g \approx 2.02$ are attributed to a minor mononuclear Mn(II) impurity

whole spectrum shape with temperature in the range 3.8−50 K is in agreement with the small exchange-coupling obtained from magnetization measurements.

The dinuclearity of the complex in solution is shown again by an electrospray mass spectral study. Indeed, the compound appears as a complex pattern at m/z = 669−677 which corresponds to $([(bpea)ClMn(\mu\text{-}Cl)_2Mn(bpea)]^+$. A theoretical mass analysis of the isotopic pattern confirms the presence of three chlorine atoms.

Electrochemical Properties

The cyclic voltammogram (CV) of **1** (1×10^{-3} M) in CH_3CN containing 0.1 M $[(nBu)_4N]ClO_4$ under Ar is shown in Figure 4. The CV exhibits a two-electron reversible oxidation wave corresponding to the $Mn^{II}Mn^{II}/Mn^{III}Mn^{III}$ redox system ($E_{1/2}$ = 0.63 V; ΔE_p = 80 mV, scan rate = 100 mVs^{-1}). A two-electron oxidation second wave only poorly reversible is also seen at $E_{1/2}$ = 1.41 V. The two-electron transfer nature of the waves is based on the intensity of the peaks compared to that of a one-electron transfer, and on coulometric experiments (v.i.). The first two-electron process [Equation (3)] can be decomposed in the two, reversible one-electron exchanges depicted in Equations (1) and (2) and the standard potentials $(E_{1/2})_1$ and $(E_{1/2})_2$ of each electron transfer can be calculated from the ΔE_p of the overall process.[15] The values of $(E_{1/2})_1$ and $(E_{1/2})_2$ are 0.60 and 0.66 V, respectively, giving $K_d = 1.2 \times 10^{-1}$. These data indicate that the two one-electron transfers occur at similar potentials and that the mixed-valence species $Mn^{II}Mn^{III}$ is only poorly stable.

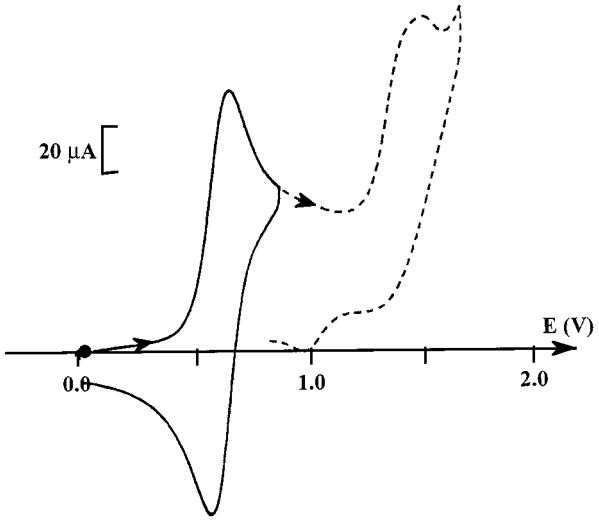

Figure 4. CV in CH_3CN + 0.1 M $[(nBu)_4N]ClO_4$ of a 1 mM solution of **1** at a platinum electrode (5 mm diameter); scan rate: 100 mV s^{-1}

$$Mn^{II}Mn^{II} \rightleftharpoons Mn^{III}Mn^{III} + 2e^- \qquad (3)$$

The $Mn^{III}Mn^{III}$ species could be prepared by an exhaustive electrolysis carried out at E_{appl} = 0.8V in CH_3CN. The initial yellow solution turned green-brown [λ_{max}= 416 (shoulder) and 534 nm]. The formation of a $Mn^{III}Mn^{III}$ species is clearly demonstrated by voltamperometry experiments conducted at a Pt rotating disk electrode. After electrolysis, the anodic initial wave at $E_{1/2}$ = 0.63 V is retained as a cathodic one. However, the yield of $Mn^{III}Mn^{III}$ species is only 85% as judged by a comparison of the height of the wave recorded before and after electrolysis. A slight excess of coulometry is observed (2.3 electrons per complex). EPR spectroscopy showed that the oxidized solution is EPR silent except for a small contribution from a mononuclear Mn(II) decomposition product. It should be noted, however, that besides the $Mn^{III}Mn^{III}$ complex, a species exhibiting a quasi reversible oxidation wave at $E_{1/2}$ = 0.98 V is generated in a 15% yield, as determined by the rotating disk experiment. No attempt has been made to identify this new species.

Discussion

Electrochemical and spectroscopic studies have revealed that **1** exhibits reversible two-electron exchanges between dimanganese(II) and dimanganese(III) states. The latter state can be oxidized further in a two-electron process, but this transfer is less reversible. A two-electron oxidation of dimanganese(II) centers has been proposed recently for two complexes with aliphatic bridges.[5c][8b] This behavior is interpreted as arising from the independency of the two metal sites in agreement with an insulating effect of the aliphatic chain. In this respect, it is worth noting that the ΔE_p of the overall process has been observed to decrease (from 128 to ca 75 mV) in dimanganese complexes of binucleating amine ligands when the length of the aliphatic chain distance increases from 2 to 3−4 methylene groups, and therefore the Mn−Mn distance from 6.3 to 8.3 Å.[8b] Such a two-electron transfer was proposed also for a (μ-alkoxo)(μ-acetato) compound[10] where the carboxylate was supposed to play a similar insulating role.[3b] Indeed the two sites must be electronically uncoupled in order not to bring any stabilization of the mixed-valent state. It therefore appears that in **1** the bridging chlorides, while structurally linking the two manganese ions, are actually isolating them electronically from one another. A comparison with the above-mentioned complexes reveals that in **1**, although ΔE_p is small (80 mV), the Mn−Mn distance is short 3.8 Å, which points to a strong effect of the chloride bridges. This electronic uncoupling is reflected in the very weak magnetic coupling of the two Mn ions.

Experimental Section

General: All syntheses and electrochemical experiments were performed under an argon atmosphere. Electrochemical equipment and procedures have been described previously.[16] Potentials are referred to an Ag | 10 mM Ag^+ reference electrode in CH_3CN + 0.1 M electrolyte. The potentials referenced to that system can be converted into SCE by adding 300 mV. The bpea ligand was prepared following a literature method.[11]

$Mn_2(\mu\text{-}Cl)_2(bpea)_2Cl_2$ (1): To an aqueous solution (4 mL) of $MnCl_2$ (0.110 g, 0.88 mmol) was added an ethanol solution (4 mL) of bpea ligand (0.200 g, 0.88 mmol) with stirring. The resulting pale yellow solution was stirred for one hour, then filtered three times to remove any impurity and evaporated to dryness at room temperature. The white microcrystalline powder formed was redissolved in acetonitrile and colorless crystals were obtained by slow evaporation of this solution at room temperature. The crystals of **1** (0.125 mg, yield 40%) were collected by filtration, washed with diethyl ether and dried in air.

IR (KBr): $\tilde{\nu}$ = 1600 (s), 1571 (m), 1475 (m), 1464 (w), 1432 (s), 1384 (m), 1361 (m), 1342 (w), 1303 (m), 1290 (m), 1268 (w), 1248 (w), 1211 (w), 1173 (w), 1150 (s), 1119 (m), 1099 (m), 1069 (w), 1044 (s), 1015 (s), 995 (m), 985 (w), 964 (w), 935 (w), 896 (w), 852 (w), 821 (m), 767 (s), 736 (w), 722 (w), 638 (m), 514 (w), 504 (w), 470 (w), 415 (m) cm^{-1}. – $C_{28}H_{34}Cl_4Mn_2N_6$ (706.29): calcd. C 47.59, H 4.81, N 11.89; found C 47.29, H 4.79, N 11.72.

X-ray Crystal Structure Analysis of 1: $C_{28}H_{34}Cl_4Mn_2N_6$, M = 706.29; monoclinic, space group $P2_1/c$, a = 10.1085(19), b = 16.399(7), c = 10.089(3) Å, α = 90, β = 109.771(17), γ = 90, V = 1573.9(9) $Å^3$, T = 298(2) K, Z = 2, F (000) = 724, D_c = 1.490 $g{\cdot}cm^{-3}$, μ = 1.171 mm^{-1}. The data sets for the single-crystal X-ray studies were collected with Mo-K_α radiation on a Bruker SMART diffractometer. All calculations were performed on a Silicon Graphics system, using the SHELXTL program.[17] The structure was solved by direct methods and refined by full-matrix least-squares on F_2.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-146219. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Magnetic measurements were performed using a Quantum Design MPMS SQUID magnetometer operating at 0.5–5 T over the temperature range 2–300 K. The powdered samples were contained in a kel-F bucket which was calibrated independently at the same fields and temperatures. The raw data were corrected for the sample holder contribution, and the molar susceptibility corresponds to the resulting magnetization per mol and per magnetic field unit. The subtracted diamagnetic contribution of **1** was evaluated at -429×10^{-6} $cm^3{\cdot}mol^{-1}$. The fitting procedure was effected in the range 12, 25, 60, 120–300 K at 0.5, 1, 2.5 and 5T, respectively. The fitting function, based on an Heisenberg Hamiltonian $-2J\ S_1{\cdot}S_2$, was c [(1 – α) 2Mn(II,II) + 8.75 α] + 2TIP. T, with c to take into account uncertainties concerning the exact composition of the powder; 2α, the proportion of mononuclear Mn(II) seen by EPR; 2Mn(II,II), the Van Vleck formula for such a complex including parameters g and J, and TIP the Temperature Independent Paramagnetism and/or a ferromagnetic contribution. G was fixed to 2. The fit gave J = +0.34 (3) cm^{-1}, c = 0.96 (1), α = 0 (fixed) and TIP = 0 (fixed).

Low temperature EPR spectra were recorded on an X-band Bruker EMX spectrometer equipped with an Oxford Instruments ESR-900 continuous-flow helium cryostat and an ER-4116 OM Bruker cavity. Magnetic field values were measured with an EMX-035M NMR gaussmeter.

Infrared spectra were recorded with a Perkin–Elmer Spectrum GX FTIR Spectrometer as KBR pellets.

Activation of C−H Bonds in Five-Membered Heterocycles by a Half-Sandwich Yttrium Alkyl Complex

Stefan Arndt,[a] Thomas P. Spaniol,[a] and Jun Okuda*[a]

Keywords: Yttrium / Chelates / C−H activation / Lewis acids / Heterocycles

The highly labile half-sandwich alkyl complex [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(CH_2SiMe_3)(THF)] smoothly undergoes σ-bond metathesis with furan and thiophene in pentane to give tetramethylsilane and the sparingly soluble complexes [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(μ-2-C_4H_3X)]$_2$ (X = O, S). They dissolve in THF to give the THF adducts [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(2-C_4H_3X)(THF)$_n$]. Pyrrole reacts with [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(CH_2SiMe_3)(THF)] to give the Lewis base-free pyrrolide [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(NC_4H_4)]$_n$.

Introduction

Since the first report by Watson on intermolecular C−H bond activation involving lanthanocene alkyl complexes,[1] systematic studies by Bercaw et al. have established the σ-bond metathesis to be a general reaction type whenever metal complexes with an $f^x d^0$-electron configuration undergo C−H bond activation reactions.[2] In particular, the decamethyllanthanocenes [Ln(η^5-C_5Me_5)$_2$X]$_2$ (X = H, alkyl) were shown to undergo a variety of reactions with aromatic compounds[3] including furan and thiophene.[3e] The latter reaction recently allowed the development of an elegant method to synthesize 2-thienyl-functionalized polyethylenes by combining C−H bond activation with ethylene insertion chemistry.[4] While exploring the polymerization activity of lanthanide alkyls and hydrides supported by the sterically more accessible linked amido-cyclopentadienyl ligands [Ln(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)X],[5a,5b] we have noticed the absence of C−H bond activation processes, e.g. involving aromatic solvents or THF. We wish to report here that the highly labile yttrium alkyl [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(CH_2SiMe_3)(THF)] undergoes a C−H bond activation reaction with furan and thiophene.

Results and Discussion

When the labile half-sandwich alkyl complex [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(CH_2SiMe_3)(THF)] (**1**), most conveniently prepared in situ from $YCl_3(THF)_{3.5}$ and $LiCH_2SiMe_3$, followed by reaction with $(C_5Me_4H)SiMe_2NHCMe_3$,[5] is treated with an excess of furan or thiophene in pentane at ambient temperature, tetramethylsilane and sparingly soluble precipitates of the presumably dimeric complexes [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(μ-2-C_4H_3X)]$_2$ (X = O, **2**; S, **3**) are formed in good yield (Scheme 1). Elemental analysis indicates the absence of THF in these complexes. In analogy to the crystallographically characterized 2-thienyl permethylyttrocene complex [Y(η^5-C_5Me_5)$_2$(μ-2-C_4H_3S)]$_2$, recently reported by Hessen et al.,[4] the crystal structure determination of **2**[6] reveals a dimeric structure. The two "metallocene-like" Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$) fragments are connected by two bridging 2-furyl ligands. The $C_5Me_4SiMe_2NCMe_3$ ligands are arranged in a transoidal fashion. Due to severe disorder of the 2-furyl bridges, details of the structure determination will be published in due course. Both complexes dissolve in THF to give the corresponding monomeric THF complexes that can be fully characterized by ^{1}H and ^{13}C NMR spectroscopy. Most diagnostically, the yttrium-bound 2-carbon atoms in **2** and **3** give rise to doublets at δ = 204 and 176, with $^1J_{YC}$ = 59 and 55 Hz, respectively. The NMR spectra at room temperature in [D_8]THF indicate the presence of a mirror plane. Upon cooling a solution of **2** below −60 °C, the enantiotopic $SiMe_2$ and C_5Me_4 resonances decoalesce, indicating the slowing down of the THF dissociation process. The aromatic resonances do not change significantly suggesting free

rotation about the yttrium-2-carbon bond without a strong yttrium-heteroatom coordination.

A pseudo first-order rate law was found for the reaction of [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(CH_2SiMe_3)(THF)] (**1**) with a 32-fold excess of thiophene in [D_8]THF to give **2** (Figure 1). The activation parameters $\Delta H^{\ddagger} = 68 \pm 1$ kJ mol^{-1} and $\Delta S^{\ddagger} = -85 \pm 3$ J K^{-1} mol^{-1} were calculated from the temperature dependence of the rate constants (Figure 2). The negative entropy is in accordance with an associative process. A well-defined arrangement of the reactants in the transition state can be inferred. Although the THF in **1** was previously shown to be labile,[5b] examples for stable five-coordinate complexes of the type [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(X)($L)_2$] (X = one-, L = two-electron ligand) were recently reported.[5b,5c]

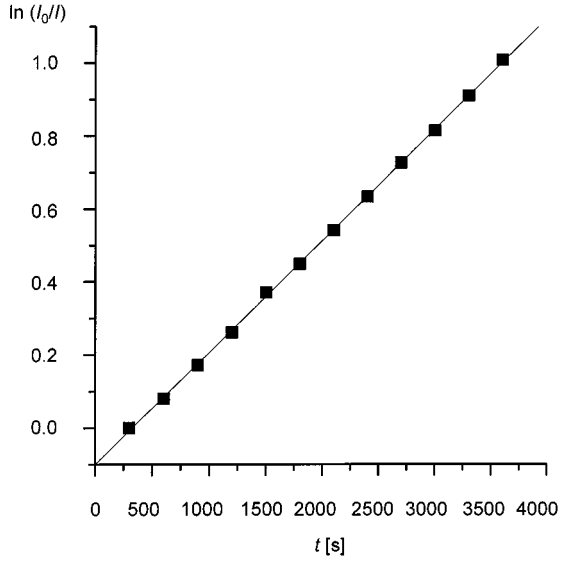

Figure 1. Reaction of [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(CH_2-$SiMe_3$)(THF)] (**1**) with thiophene in [D_8]THF: plot of ln(I_0/I) vs. t at 25 °C

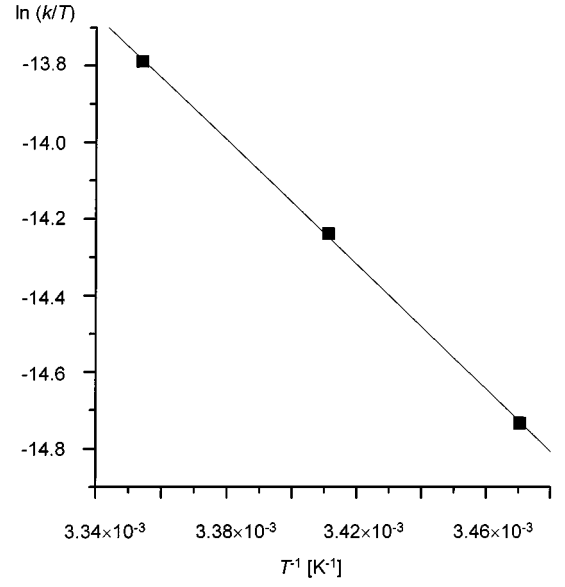

Figure 2. Reaction of [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(CH_2-$SiMe_3$)(THF)] (**1**) with thiophene in [D_8]THF: Eyring plot

In contrast to furan and thiophene, pyrrole reacts with the alkyl **1** in pentane in a stoichiometric ratio under protolysis to give the pyrrolide [Y(η^5:η^1-$C_5Me_4SiMe_2$-$NCMe_3$)(NC_4H_4)] (**4**) in good yield. This compound is sparingly soluble, even in THF, but dissolving in [D_5]pyridine allowed the recording of NMR spectra, presumably as the pyridine adduct [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)-(NC_4H_4)([D_5]pyridine)$_n$]. The low solubility suggests a dimeric structure for **4**, although the related amido complexes of the type [Ln(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$){$N(SiMe_3)_2$}] (Ln = Y, Nd, Sm, Lu) are all monomeric.[7] The crystallographically characterized monomeric lutetocene pyrrolide [Lu(η^5-$C_5H_5)_2$($NC_4H_2Me_2$-2,5)(THF)] (Ln = Y, Lu) was also reported to be insoluble.[8] The room temperature NMR spectroscopic data of the pyridine adduct of **4** [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(NC_4H_4)([D_5]pyridine)$_n$] are in agreement with the presence of a mirror plane, indicating a solution structure in which the pyridine ligand is rapidly exchanging its site at the chiral metal center.

In summary we have shown that the labile alkyl [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(CH_2SiMe_3)(THF)] smoothly undergoes σ-bond metathesis not only with dihydrogen[5a] and phenylsilane,[5b] but also with furan and thiophene to give metalated products. Further extension of this C−H bond activation chemistry is underway.

Experimental Section

General: All experiments were performed under argon by using standard Schlenk or glove-box techniques. Solvents were purified, dried and distilled under argon. − ^{1}H, ^{13}C, and ^{29}Si NMR: Bruker DRX 400; all spectra at 25 °C; ^{1}H: 400 MHz, ^{13}C: 101 MHz, ^{29}Si: 79.5 MHz. − Elemental analyses: Microanalytical laboratory of this department.

[Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(μ-2-C_4H_3O)]$_2$ (2) and [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(2-C_4H_3O)([D_8]THF)$_n$]: A solution of furan (750 μL, 10.0 mmol) in hexane (3 mL) was layered on neat hexane (4.5 mL) which was already layered on top of [Y(η^5:η^1-C_5Me_4Si-Me_2NCMe_3)(CH_2SiMe_3)(THF)] (**1**) (300 mg, 0.6 mmol) dissolved in toluene (3 mL). Colorless crystals (163 mg, 66%) formed upon standing over a period of 6 days at 5 °C. − ^{1}H NMR ([D_8]THF): δ = 0.39 [s, 6 H, $Si(CH_3)_2$], 1.26 [s, 9 H, $C(CH_3)_3$], 2.01, 2.02 [s, 2 × 3 H, $C_5(CH_3)_4$], 6.04 (m, 1 H, C_4H_3O-3), 6.22 (d, $^3J_{HH}$ = 2.9 Hz, 1 H, C_4H_3O-4), 7.46 (m, 1 H, C_4H_3O-5). − ^{1}H NMR ([D_8]THF, −100 °C): δ = 0.33, 0.36 [s, 2 × 3 H, $Si(CH_3)_2$], 1.26 [s, 9 H, $C(CH_3)_3$], 1.71, 1.84, 1.95, 2.01 [s, 4 × 3 H, $C_5(CH_3)_4$], 6.01 (br, 1 H, C_4H_3O-3), 6.17 (br, 1 H, C_4H_3O-4), 7.49 (m, 1 H, C_4H_3O-5). − ^{13}C{^{1}H} NMR ([D_8]THF): δ = 5.8 [$Si(CH_3)_2$], 8.6, 11.9 [$C_5(CH_3)_4$], 32.3 [$C(CH_3)_3$], 51.7 [s, $C(CH_3)_3$], 104.0 [$C_5(CH_3)_4$ at Si], 104.6, 116.4 (s, C_4H_3O), 118.7, 123.8 [$C_5(CH_3)_4$], 139.8 (s, C_4H_3O). 204.4 (d, $^1J_{YC}$ = 59 Hz, C_4H_3O-2). − ^{29}Si{^{1}H} NMR ([D_8]THF): δ = 28.8 (d, $^2J_{SiY}$ = 2 Hz). − $C_{38}H_{60}N_2O_2Si_2Y_2$ (810.9): calcd. C 56.29, H 7.46, N 3.45; found C 55.07, H 7.37, N 3.58.

[Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(μ-2-C_4H_3S)]$_2$ (3) and [Y(η^5:η^1-$C_5Me_4SiMe_2NCMe_3$)(2-C_4H_3S)([D_8]THF)$_n$]: A suspension of anhydrous YCl_3 (586 mg, 3.0 mmol) in THF (20 mL) was heated to 60 °C for 30 min. The solvent was then removed in vacuo and the residue taken up in pentane (24 mL). At −78 °C a solution of $LiCH_2SiMe_3$ (860 mg, 9.1 mmol) in pentane (24 mL) was added.

After stirring for 2 h at 0 °C the reaction mixture was filtered and the filtrate treated with neat $(C_5Me_4H)SiMe_2NHCMe_3$ (715 mg, 2.8 mmol). After stirring for 2 h at 0 °C and filtration, the filtrate containing the alkyl $[Y(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NCMe_3)(CH_2SiMe_3)(THF)]$ was treated with thiophene (3.9 mL, 48.0 mmol) and stirred for 1.5 h at room temperature. The supernatant was decanted off from the colorless precipitate which was washed with pentane (2 × 10 mL) to give colorless microcrystals (711 mg, 56%) − ^{1}H NMR ([D$_8$]THF): δ = 0.43 [s, 6 H, Si(CH$_3$)$_2$], 1.32 [s, 9 H, C(CH$_3$)$_3$], 1.98, 2.05 [s, 2 × 6 H, C$_5$(CH$_3$)$_4$], 6.97 (dd, $^3J_{HH}$ = 2.9 Hz and 4.4 Hz, 1 H, C$_4$H$_3$S-3), 7.09 (d, $^3J_{HH}$ = 2.9 Hz, 1 H, C$_4$H$_3$S-4), 7.31 (d, $^3J_{HH}$ = 4.4 Hz, 1 H, C$_4$H$_3$S-5). − ^{13}C{^{1}H} NMR ([D$_8$]THF): δ = 5.9 [Si(CH$_3$)$_2$], 8.9, 11.8 [C$_5$(*C*H$_3$)$_4$], 32.5 [C(*C*H$_3$)$_3$], 52.1 [*C*(CH$_3$)$_3$], 104.1 [*C*$_5$(CH$_3$)$_4$ attached to Si], 119.3, 123.6 [*C*$_5$(CH$_3$)$_4$], 124.2, 124.3, 131.4 (C$_4$H$_3$S), 176.7 (d, $^1J_{YC}$ = 55 Hz, C$_4$H$_3$S-2). − ^{29}Si{^{1}H} NMR ([D$_8$]THF): δ = 23.5. − $C_{38}H_{60}N_2S_2Si_2Y_2$ (843.0): calcd. C 54.14, H 7.17, N 3.32, S 7.61; found C 54.61, H 7.18, N 3.32, S 7.64.

Kinetics: Compound **1** (20 mg, 40 μmol) was dissolved in a mixture of [D$_8$]THF (400 μL) and thiophene (100 μL, 1260 μmol) and ^{1}H NMR spectra (2 scans) were recorded every 5 min. over a period of 1 h at 15, 20 and 25 °C. The rate constants were obtained by a plot of $\ln(I_0/I)$ vs. t. Integrals of the β-CH$_2$ groups of THF were used as internal standard for calibrating the integrals I of the YCH$_2$ group; $I_0 = I(t = 0\text{ s})$. $k(T = 288\text{ K}) = (1.15 \pm 0.04) \times 10^{-4}\text{ s}^{-1}$, $k(T = 293\text{ K}) = (1.92 \pm 0.02) \times 10^{-4}\text{ s}^{-1}$, $k(T = 298\text{ K}) = (3.06 \pm 0.02) \times 10^{-4}\text{ s}^{-1}$. The kinetic isotope effect using [D$_4$]thiophene at 298 K was $k_H/k_D = 6.4$.

$[Y(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NCMe_3)(NC_4H_4)]_n$ (4) and $[Y(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NCMe_3)(NC_4H_4)([D_5]pyridine)_m]_n$: A suspension of **1** (200 mg, 0.4 mmol) in hexane (3 mL) was treated with neat pyrrole (28 μL, 0.4 mmol) at 25 °C and the reaction mixture stirred at 0 °C for 2 h. Colorless microcrystals (107 mg, 65%) were obtained by filtration. − ^{1}H NMR ([D$_5$]pyridine): δ = 0.81 [s, 6 H, Si(CH$_3$)$_2$], 1.42 [s, 9 H, C(CH$_3$)$_3$], 1.74, 2.07 [s, 2 × 6 H, C$_5$(CH$_3$)$_4$], 6.69, 7.09 (br s, 2 × 2 H, NC$_4$H$_4$). − ^{13}C{^{1}H} NMR ([D$_5$]pyridine): δ = 9.0 [Si(*C*H$_3$)$_2$], 11.3, 15.0 [C$_5$(*C*H$_3$)$_4$], 34.8 [C(*C*H$_3$)$_3$], 54.7 [*C*(CH$_3$)$_3$], 107.2 [*C*$_5$(CH$_3$)$_4$ attached to Si], 108.6, 124.7 (s, NC$_4$H$_4$), 127.2 [*C*$_5$(CH$_3$)$_4$]; one signal for the C$_5$(CH$_3$)$_4$ carbon is obscured by solvent signals. − ^{29}Si{^{1}H} NMR ([D$_5$]pyridine): δ = 28.1 (d, $^2J_{SiY}$ = 2 Hz). − $C_{19}H_{31}N_2SiY$ (404.5): calcd. C 56.42, H 7.73, N 6.93; found C 56.51, H 7.62, N 7.25.

Mechanistic Comparison of the Nickel(0)-Catalyzed Homo-Oligomerization and Co-Oligomerization of Alkynes and Nitriles[‡]

John J. Eisch,*[a] Xin Ma,[a] Kyoung I. Han,[a] John N. Gitua,[a] and Carl Krüger[b]

Dedicated on the occasion of his 75th birthday to Professor Günther Wilke, an outstanding pioneer in transition metal catalyzed organic synthesis

Keywords: Organometallics / Metallacycles / Oligomerizations / Alkynes / Nitriles / Nickel

A comparative mechanistic study of the nickel(0)-catalyzed homo-oligomerization and co-oligomerization of alkynes and of nitriles has been undertaken, with diphenylacetylene and benzonitrile, towards an array of nickel(0) reagents, such as finely divided nickel, $(COD)_2Ni$, (Bpy)(COD)Ni, $(Et_3P)_4Ni$, (Bpy)(PhC≡CPh)Ni and $(COD)_2Ni$–$MeAlCl_2$ combinations in donor (THF) and nondonor (PhMe or neat substrate) solvents. Special attention has been given to the detailed molecular structures of the initial 1:1 adducts, (Bpy)(PhC≡CPh)Ni, $(Ph_3P)_3$(PhC≡CPh)Ni and $[(Ph_3P)(PhC{\equiv}N)Ni]_4$ by a consideration of XRD and IR data. Data from the single crystal XRD analysis of (Bpy)(PhC≡CPh)Ni, reported here for the first time, are shown to be in excellent accord with the presence of a 2,3-diphenylnickelacyclopropene ring for the (PhC≡CPh)Ni moiety with almost coplanar chelating coordination of the bipyridyl ligand, rather than with the presence of simple "side-on" coordination of the alkyne with the metal center. A parallel analysis of XRD and IR data for the two benzonitrile-nickel(0) complexes, which were drawn from previous publications, has concluded that the nickel in $(Ph_3P)_3$(PhC≡N)Ni is coordinated in an "end-on" fashion and the nickel centers in $[(Ph_3P)(PhC{\equiv}N)Ni]_4$ are coordinated as bridges between nitrile units in both an "end-on" and "side-on" manner. The stereochemistry of the acid hydrolysis of the nickelacyclopropene complex to (*E*)- or (Z)-alkene was shown to depend on the structure of the cleaving acid; parallel hydrolysis of nitrile-nickel complexes has shown that "end-on" complexes regenerate the nitrile, while "side-on" complexes lead to the aldehyde. In homo-oligomerization of diphenylacetylene or other alkyne the clean cyclotrimerization to the benzene derivative was shown to proceed by way of a nickelacyclopentadiene intermediate, as was evident by chemical trapping. The homo-oligomerization of benzonitrile by nickel(0) was found not to lead to 2,4,6-triphenyl-1,3,5-triazine, as claimed in the literature, but rather solely to benzyl phenyl ketone, the dimeric hydrolysis product. The attempted co-oligomerization of diphenylacetylene and benzonitrile with ordinary nickel(0) complexes led only to the homocyclotrimer of the alkyne. Only when the alkyne was prebonded to the nickel, as in (Bpy)(PhC≡N)Ni, could significant amounts of a codimerization product with the nitrile be observed. The origin of the triazine, claimed in a previous report to form from benzonitrile and Raney nickel, has been traced to the presence of adventitious moisture and air. Other unexpected products formed from nickel(0) complexes and benzonitrile have been shown to arise from oxidative addition reactions of nickel(0) with various σ C–E bonds.

Introduction

The nickel-catalyzed selective cyclooligomerizations of alkynes by Walter Reppe's group in the 1940s[1] and the analogous cyclooligomerizations of 1,3-alkadienes by Günther Wilke and co-workers[2] in the succeeding two decades were seminal discoveries in ushering in the current era of transition metal-mediated organic synthesis.[3] Wilke's studies in particular, with their focus on detecting and trapping reactive intermediates and on probing the steric and electronic effects of metal ligands on reactivity, have provided researchers in this flourishing field with a stellar paradigm for steering and optimizing such metal-catalyzed organic reactions.

Reppe's empirical findings that acetylene is principally cyclotrimerized into benzene by nickel(0) catalysts, such as $(Ph_3P)_2(CO)_2Ni$, but is largely cyclotetramerized into the unstable cyclooctatetraene by such nickel(II) salts as $Ni(CN)_2$ [1a,4] or by nickel(0) complexes having labile ligands $[(COD)_2Ni]$[5] have long piqued the curiosity of many chemists. Subsequent detailed mechanistic studies of these oligomerizations have adduced cogent and persuasive evidence that reactive nickelacyclopropene (**1**) and nickelacyclopentadiene (**2**) rings are pivotal intermediates in both cyclooligomerizations and that trimerization to **3** or tetramerization to **4** hinges on whether **2** reacts with a third alkyne (path a) or undergoes autodimerization (path b) (Scheme 1).[2c,6–13]

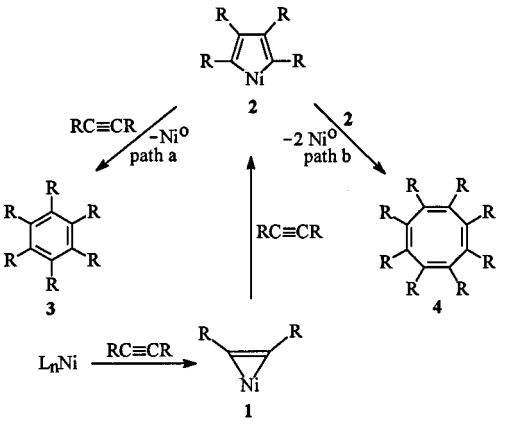
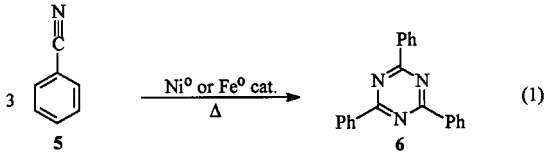


Scheme 1

The varying prevalence of path a or path b has been suggested to depend upon the ligands L_n on nickel and the substituents R on the acetylene monomer.[12]

In light of the intricate mechanistic features involved in such oligomerizations, we were curious to learn to what extent organic nitriles or azaacetylenes, R−C≡N, might undergo similar homo-cyclooligomerization or co-cyclotrimerization with alkynes by nickel metal catalysis. Two brief publications offered encouragement: benzonitrile (**5**) was reported to cyclotrimerize to 2,4,6-triphenyl-1,3,5-triazine (**6**) [Equation (1)] when heated at reflux with $Fe(CO)_5$ or $Fe_2(CO)_9$ [14] or when allowed to reflux with Raney nickel for many hours.[15] However, attempts by other workers to reproduce the formation of triazine **6** over carefully dried and deoxygenated Raney nickel or even on pure nickel surfaces were unsuccessful.[16] No reports of the nickel-catalyzed co-cyclotrimerization of alkynes and nitriles have been found, even though such oligomerizations by cobalt catalysis are common and have received much attention.[17] In the present report we establish that benzonitrile can be co-dimerized with an alkyne but only by intermediacy of an alkyne-nickel(0) complex. Furthermore, benzonitrile can indeed be oligomerized by nickel(0) complexes but in an entirely different manner not involving the formation of triazine **6**. The structural and electronic reasons for these divergent oligomerization pathways followed by alkynes and by nitriles under nickel(0)-mediation will be elucidated in light of the actual and probable organonickel intermediates.



(1)

Results and Discussion

Structures of Initial 1:1 Complexes of Nickel(0) with Alkynes or with Nitriles

Such cyclotrimerizations of alkynes have as their common starting intermediate 1:1 adducts with nickel(0) that have been isolated, where appropriate ligands are present, and characterized by spectroscopic and single crystal X-ray structural analyses. Here we present such characterization of 2,2-bipyridyl(η^2-diphenylacetylene)nickel (**7**), where an essentially planar interaction of both the bipyridyl group and the C≡C bond with the nickel center is evident (Figure 1). The average Ni−C (acetylenic) separation of 1.86 ± 0.01 Å is comparable with *sigma* Ni−C bonds involving sp^2-hybridized carbon centers, such as the Ni−C bond of 1.89 ± 0.01 Å in structure **8**.[18] Moreover, the supposed acetylenic C−C separation of 1.30 ± 0.005 Å is more congruent with the presence of a C=C rather than a C≡C bond in **7**[19] (Table 1). Finally, complex **7** displays a sharp absorption at 1770 cm^{-1} in its infrared spectrum, shifted by 330 cm^{-1} to lower frequencies than the C≡C stretch of unsymmetrically substituted acetylenes such as phenylacetylene. An absorption of 1770 cm^{-1} in complex **7** is in much closer agreement with a C=C bond stretching vibration,

Professor Günther Wilke was born in Heidelberg, Germany, on February 23, 1925, where he was to obtain both the Abitur at the Humanistisches Gymnasium and the doctorate degree in 1951 at the Universität Heidelberg upon completion of structural studies on lignin under the direction of Professor Karl Freudenberg. Shortly thereafter, he joined Karl Ziegler's research group as scientific assistant at the Max-Planck-Institut für Kohlenforschung in Mülheim (Ruhr) and participated in bringing Ziegler's recent discoveries in organoaluminum chemistry and low-pressure ethylene polymerization to economic fruition. Since his curiosity was strongly aroused by the seminal discovery of the Nickel Effect by Ziegler and Holzkamp, he launched his independent research program in 1956 with the systematic investigation of the effect of nickel and other transition metals on reactions of main-group organometallics. Over the next 40 years he pursued the exciting and unforeseen ramifications of such research, which have led to the novel template syntheses of medium-sized carbocycles, the regioselective oligomerizations of alkenes and alkadienes as well as the asymmetric syntheses of carbon skeletons. Interwoven with such discoveries have been many pioneering mechanistic studies that have elucidated the governing roles of the transition metal and its ligands in these novel carbon-carbon bond coupling processes. During the period of 1969-1993 as successor to Karl Ziegler, he directed the MPI during a flourishing period of expansion of its research activities and facilities. In over 220 publications and numerous patents he disseminated the classic research results of his many doctoral students and published with Peter Jolly the authoritative, two-volume treatment of "The Organic Chemistry of Nickel" (1974, Academic Press). Among many honors for his scientific discoveries may be cited the Ruhr-Preis für Kunst und Wissenschaften and both the Emil Fischer Medaille and the Karl-Ziegler-Preis of the Gesellschaft Deutscher Chemiker. His outstanding enthusiasm and skill in the art of laboratory experimentation finds a fitting parallel in his keen interest in and a notable private collection of contemporary art. As a young scientist it was this senior author's pleasure and honor to work closely with Günther Wilke, the master experimentalist, during a yearlong postdoctoral fellowship in Professor Ziegler's institute in 1956.

which in unconjugated disubstituted *cis*-alkenes absorb near 1670 cm^{-1}. Accordingly, a nickelacyclopropene or nickelirene structure seems to be a more important resonance structure contributor (**7a**) with a nickel(II) oxidation state than does resonance structure **7b** where the nickel center is viewed as in a Ni(0) oxidation state and as only accepting electron density from its ligand donors, diphenylacetylene and 2,2-bipyridyl. As will be evident, the nickelirene structure **7a** also proves to be the more useful molecular model for understanding the courses of chemical reactions undergone by **7** with various electrophilic or unsaturated organic reagents.

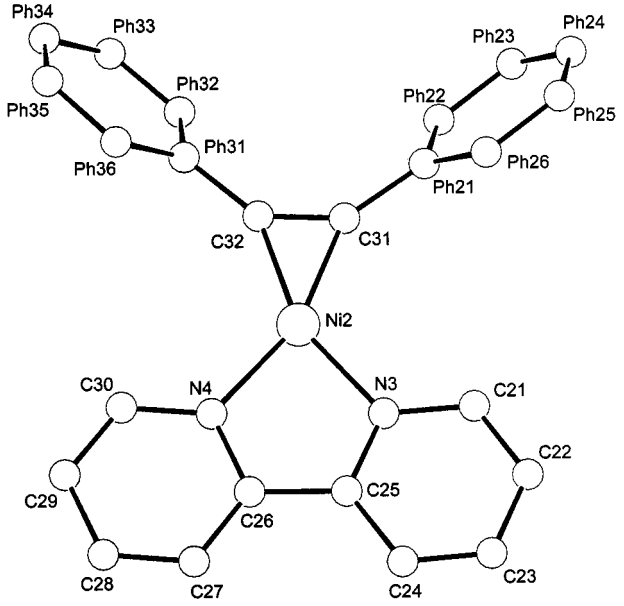


Figure 1. Structure and atom numeration of one of the independent molecules of 2,2-bipyridyl (η^2-diphenylacetylene)nickel found in the asymmetric unit cell of **7**

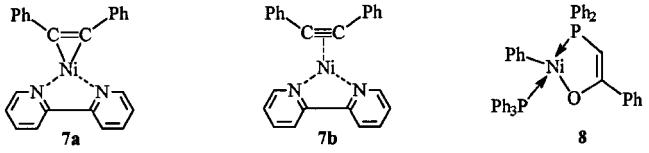

A number of spectroscopic and single crystal X-ray structural analyses of 1:1 adducts of benzonitrile with nickel(0) complexes have been published. The two XRD studies are most valuable in establishing that the nickel(0) center can coordinate with the nitrile group in both an "end-on" (**9a**) and a "side-on" (**9b**) manner.

As was established in the structure of (benzonitrile)tris(triphenylphosphane)nickel(0) (**10**), "end-on" coordination of Ni° was evident (Ni−N bond length of 1.89 ± 0.011 Å and Ni−N−C bond angle of 173 ± 7°).[20] Similarly, the

Table 1. Selected bond lengths and angles of 2,2′-bipyridyl(η^2-diphenylacetylene)nickel **(7)**

Bond lengths [Å][a]	Min. value	Max. value	Av. value

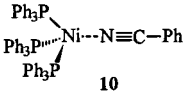
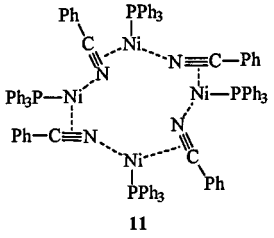
[a] The pairwise grouping of bond lengths and bond angles in the Table are the measured values for the two independent molecules of **7** found in the asymmetric cell. The first value in each pair is for the molecular and the atom numeration shown in Figure 1. The second value in each pair is that of the second molecule not shown in any figure. However, the atom numeration in the second molecule has the following atom correspondence to molecule one/ C_{11} = C_{31}; C_{12} = C_{32}; Ni_1 = Ni_2; Ph_1 = Ph_{21}; Ph_{11} = Ph_{31}.

structure of the clathrate compound, tetrakis[(benzonitrile)(triphenylphosphane)nickel(0)] (**11**),[21] incorporating various hydrocarbon solvent molecules, actually has the Ni^0 centers simultaneously coordinated to adjacent benzonitrile units in an "end-on" and a "side-on" manner (**11,** schematically drawn). Since complexes **10** and **11** are in equilibrium with each other, one can conclude that "end-on" coordination of the nickel center is the stronger primary binding mode with the nitrile group and that "side-on" bonding is only ancillary to it. The "end-on" Ni−N bond length of 1.90 Å is similar to that in **7** but the Ni−N−C bond angle at 167° deviates more from linearity. The "side-on" Ni−C bond length at 1.85 Å is comparable to Ni−C bonds with sp^3-hybridized carbons (vide supra).

Infrared spectral data on complexes **10** and **11** provide a useful insight into such "end-on" and "side-on" coordination. The nitrile stretch in uncomplexed benzonitrile at 2230 cm^{-1} is lowered to 2150 cm^{-1} by "end-on" coordination as in **10**.





On the other hand, complex **11** displays a strong band at 1850 cm^{-1}. Again, such a stretching frequency lies much closer to a C=N stretch (1470−1690 cm^{-1}) than to a C≡N

stretch (2100−2200 cm^{-1}). Thus, it again appears that for such "side-on" coordination, the resonance contribution of a nickel(II) system, namely, azanickelacyclopropene (**12a**) would seem to be more important than that of a nickel(0) *pi*-complex (**12b**).

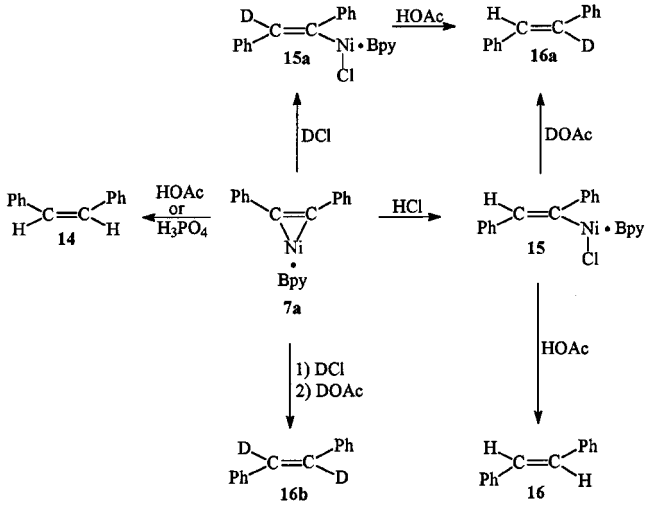
As confirmation of the importance of structure **12a** is the observed C−N bond length of 1.26 Å, considerably longer than the C≡N bond (1.16 Å) and very comparable with those of C=N linkages (1.26−1.30 Å).[21]

These infrared data from nickel(0)-benzonitrile complexes of known structure can now conversely be used to evaluate the type of bonding in unknown structures. Thus the complex, (benzonitrile) (2,2-bipyridyl)nickel(0) (**13**), which has a sharp absorption at 2105 cm^{-1} must have "end-on" coordination.[22] This is undoubtedly the complex formed initially when (2,2-bipyridyl)(1,5-cyclooctadiene) nickel(0) interacts with benzonitrile (vide infra).

Bipyridyl---Ni---N≡C—Ph
13

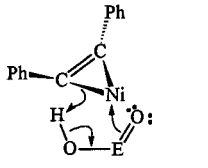
Protonolysis of the Initial 1:1 Complexes of Nickel(0) with Alkynes or with Nitriles

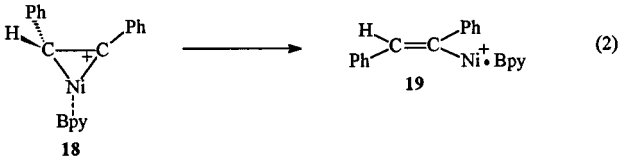
The stereochemical course of the protonolysis of 2,3-diphenylnickelirene·2,2-bipyridyl (**7a**) depends strikingly upon the solvent and the specific nature of the proton source. When **7a** was treated with 85% H_3PO_4 in THF or with glacial HOAc, almost quantitative yields of only *cis*-stilbene (**14**) were obtained. On the other hand, when the protonolysis was conducted with 6N aqueous HCl, a pale red precipitate of PhCH=CPh(NiCl·Bpy) (**15**) was formed almost immediately in 90% yield. The remaining 10% of the starting material had been converted into a 9:1 mixture of *cis*- and *trans*-stilbenes. The stereochemistry of the stilbenyl C−Ni bond in intermediate **15** was established by treating **15** first with HOAc and determining that only *trans*-stilbene (**16**) was produced. Then in a separate experiment **15** was treated with DOAc with the result that *trans*-stilbene-d_1 (**16a**) was formed. Since HOAc did not cause isomerization of the stilbenyl group in the protonolysis of **7a**, it is reasonable that it would not cause isomerization in the protonolysis of intermediate **15**. Therefore, isomerization of the stilbenyl group must have occurred during the formation of **15** from **7a** under the action of HCl. That only one proton is added in the formation of **15** from **7a** was verified by treating **7a** with DCl. The deuteriated **15a** formed was treated in separate experiments with either HOAc or DOAc. Both experiments generated only *trans*-stilbenes but the former experiment gave the d_1-isotope (**16a**) while the latter only the $d_{1,2}$-isotope (**16b**). These interrelated reactions are depicted in Scheme 2.



Scheme 2

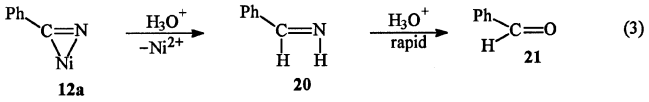
A congruent explanation for the retention of configuration on the protonolysis of the first C−Ni bond in **7a** by acetic acid or by phosphoric acid may lie in the ability of these acids to deliver a proton via a six-membered coordinated transition state (**17**). By contrast, the ionic transition state **18**, formed by HCl in water, can easily isomerize by ring-opening, to form the sterically most stable ion (**19**) [Equation (2)]:





Up to the present work, little has been known about the course of protonolysis of "end-on" or "side-on" nickel-nitrile complexes. It has been reported that complex **13**, which can now be assigned an "end-on" structure, regenerates benzonitrile essentially quantitatively after being treated with a weak acid like acetylacetone. Even dilute HNO_3 produces only recovered benzonitrile.[22] Given the known resistance of nitriles to reduction or to hydrolysis, this result may not be surprising. In the present work it is therefore noteworthy to report that the treatment of benzonitrile in THF with nickel complexes, such as $(COD)_2Ni$, (Bpy)(COD)Ni or $(Et_3P)_4Ni$ and hydrolytic workup produces benzaldehyde in yields of 5−15%. We conclude that such benzaldehyde must have arisen from the hydrolysis of a "side-on"-coordinated nickel complex like **12a**, which can

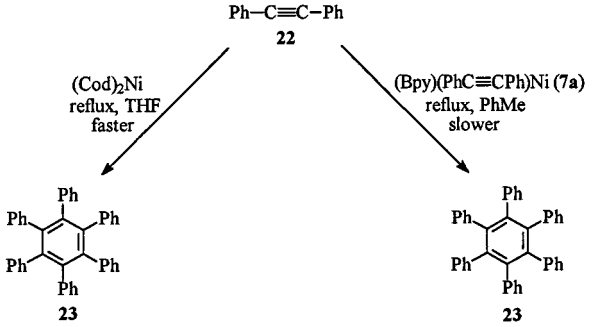
be considered as having much azanickelacyclopropene character (vide supra). The intermediate benzaldehyde imine (**20**) should hydrolyze easily to benzaldehyde (**21**) [Equation (3)].



Oligomerization Reactions of Alkynes and Nitriles by Nickel(0) Complexes

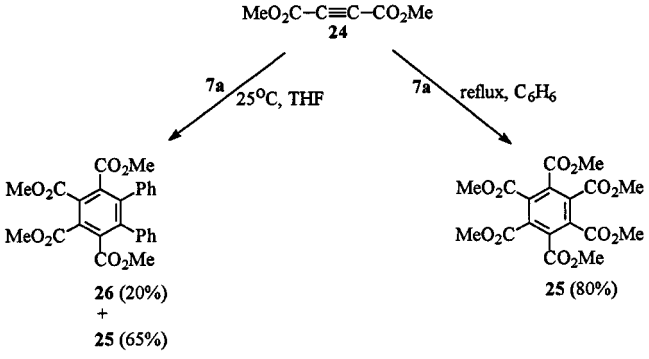
Oligomerizations with (2,2′-Bipyridyl)(diphenylacetylene)-nickel(0) (7a)

Complex **7a** catalyzes the cyclotrimerization of diphenylacetylene (**22**) to hexaphenylbenzene (**23**) in refluxing toluene but at a significantly slower rate than with $(COD)_2Ni$ as catalyst, which effects comparable conversions to **23** in refluxing THF in half the time (Scheme 3).



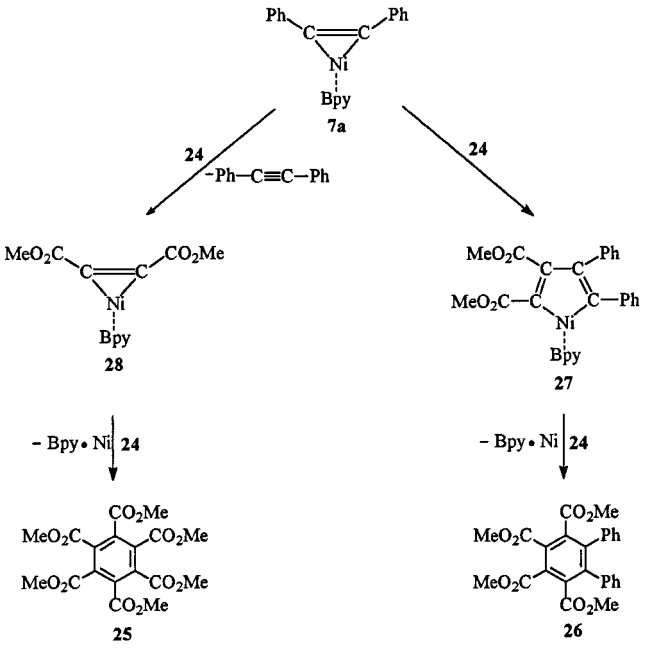
Scheme 3

The cyclotrimerization of dimethyl acetylenedicarboxylate (**24**) catalyzed by **7a** to hexamethyloxycarbonylbenzene (**25**) occurs in refluxing benzene faster than that of **22** in refluxing toluene. When the cyclotrimerization of **24** with **7a** was carried out at 25 °C in THF, up to 20% of the product was the mixed cyclotrimer, 1,2,3,4-tetramethyloxycarbonyl-5,6-diphenylbenzene (**26**) (Scheme 4). This finding supports the conclusion that at lower temperatures some of complex **7a** is stable and undergoes insertions of **24**, ultimately leading via **27** to **26.** At higher temperatures especially, **7a** decomposes with the transfer of Bpy·Ni to **24** with the formation of **28**, which leads to the formation of **25** (Scheme 5). These findings support the previously proposed



Scheme 4

hypothesis that nickelirenes, such as **7a** and **28**, are discrete and crucial intermediates in the cyclooligomerization of alkynes by nickel(0) complexes.[11−13]



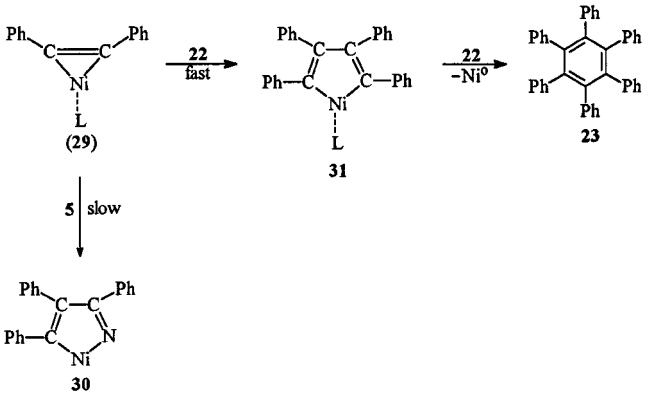
Scheme 5

Attempted Co-oligomerizations of Diphenylacetylene (22) and Benzonitrile (5) by Nickel(0) Complexes

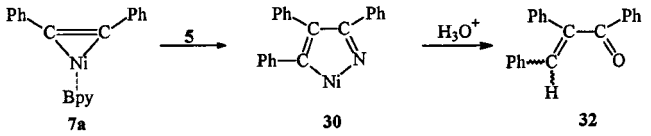
The interaction of a 2:1 mixture of **22** and **5** with one equivalent of $(COD)_2Ni$ in refluxing THF led to a 65% yield of hexaphenylbenzene (**23**) and 3% of *cis*-stilbene (**14**) but no discernible oligomer involving incorporation of benzonitrile, such as pentaphenylpyridine. This result implies that benzonitrile cannot compete with diphenylacetylene in the crucial insertion step with the nickelirene intermediate **29** (L = COD) (Scheme 6 depicting the competitively faster formation of **31** and hence **23** from **7a** and the much slower formation of **30**, which would lead to pentaphenylpyridine). The validity of this inference was substantiated by subjecting the more stable and less reactive nickel complex **7a** to the action of benzonitrile alone in THF at 25°C, without any competing alkyne. Indeed, hydrolytic workup gave up to 40% of the *cis*- and *trans*-isomeric 1,2,3-triphenylpropen-1-ones (**32**), convincing evidence that azanickelole **30** had formed from **7a** by insertion of benzonitrile (Scheme 7).

Attempted Homo-Oligomerizations of Benzonitrile (5) by Nickel(0) Complexes

Many careful and systematic variations have been attempted to reproduce the reported cyclotrimerization of **5** over Raney nickel in refluxing benzonitrile with the formation of 2,4,6-triphenyl-1,3,5-triazine (**6**) [Equation (1)].[15] To avoid possible contaminants present in the typical samples of Raney nickel, such as aluminum metal and NaOH, as well as moisture and dihydrogen, the attempted



Scheme 6.

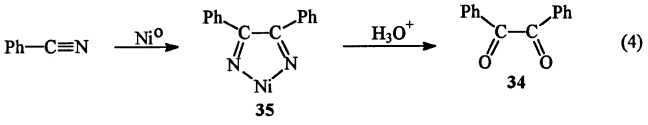


Scheme 7

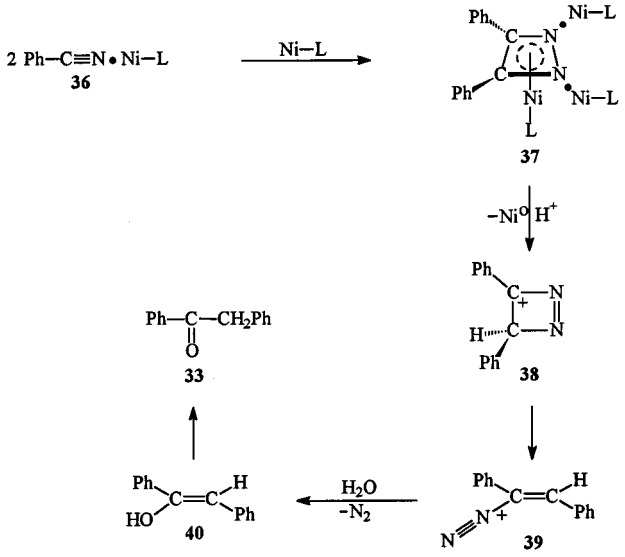
oligomerizations were also carried out with pure nickel metal powders, prepared under argon by the alkylative reduction of nickel salts with *n*-butyllithium in THF at −78°C. In the complete absence of traces of oxygen and of moisture, such nickel metal led to little or no **6** even after 2 days at 190 °C. Only when moist air was admitted during reflux did noticeable amounts of **6** form (5−10% of **5**) and other unusual reaction products appear (vide infra). We are forced to agree with the conclusion of Oehme and Pracejus[16] that a pure nickel metal surface is incapable of catalyzing the cyclotrimerization of benzonitrile under the conditions reported by Heldt.[15]

Since our previous experience with the coupling and cleavage reactions of nickel(0) complexes has shown that such reactions are especially favored in donor solvents at or below 25 °C, we then undertook a study of the reaction of benzonitrile with nickel(0) complexes in THF. As reported above, protonolysis of such reaction mixtures gave benzaldehyde (**21**), most likely stemming from the protonolysis of a "side-on" complex [Equation (3), **12a**]. But an additional, most surprising hydrolysis product was also isolated, namely benzyl phenyl ketone (**33**). No trace of any other dimeric or trimeric product, such as benzil (**34**) or triazine **6** was detected. The yields of benzaldehyde and benzyl phenyl ketone obtained with different ratios of $(COD)_2Ni$ and nitrile are noteworthy: with a 1:2 $(COD)_2Ni$:**5** ratio, the yields of **21** and **33** were 13% and 15%, with 70% of nitrile **5** remaining. When a reverse ratio of 2:1 $(COD)_2Ni$:**5** was employed, all of the benzonitrile was consumed and again only **33** and **21** were found in the reaction products, this time in a ratio of 96:4.

These results show that the formation of ketone **33** is fostered by the stoichiometric action of more than one nickel atom per nitrile. Clearly, when a 1:2 $(COD)_2Ni$:**5** ratio is employed, $(COD)_2Ni$ is the limiting reagent and hence only about one-third of the benzonitrile can react. In explaining the origin of ketone **33**, we suggest that the coupling of the nitrile carbons must occur in an unusual manner, certainly not involving a straightforward reductive dimerization as depicted in Equation 4.[23] Were such an ordinary reductive coupling to have occurred, an intermediate diazanickelole (**35**) would have formed and would undoubtedly have hydrolyzed to benzil (**34**), a product noteworthy by its absence in this reaction.



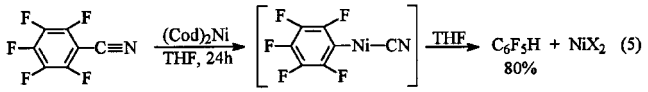
To account for the formation of ketone **33**, therefore, we propose a cyclodimerization of two "end-on"-coordinated nickel(0) complexes of benzonitrile (**36**) by agency of nickel(0) to form a (3,4,-diphenyl-1,2-diazacyclobutadiene)nickel(0) complex of type **37**. Protonolytic decomposition of **37** would reasonably be expected to lead via **38**−**40** to ketone **33** (Scheme 8). Currently, our efforts are directed toward isolating a suitably ligated derivative of **37** for confirmatory XRD and protonolysis studies. There is ample precedent for the stable complexation of the cyclobutadiene ring with nickel(0), typified by (η^4-tetraphenylcyclobutadiene)bis(triethylphosphane)nickel(0), whose structure has been confirmed by an XRD study.[11] Also, the mode of protonolytic cleavage of this latter structure partly resembles that of **35**: glacial acetic acid leads to the formation of (*E,E*)-1,2,3,4-tetraphenyl-1,3-butadiene.

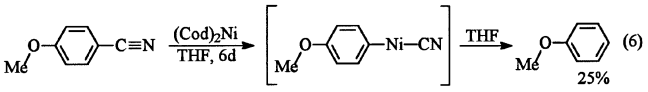


Scheme 8

Although such complexations between benzonitrile and nickel(0) are relatively stable at 25°C, they are easily disrupted at higher temperatures. For example, conducting the reaction of (Bpy)(COD)Ni with benzonitrile in THF at 25°C gives, upon hydrolysis, 20% of ketone **33**, whereas the same reaction conducted in refluxing THF gives no trace of **33**. Even at room temperature, such reactions can lead to decyanation of the nitrile, especially those nitriles with

electron-withdrawing substituents, as shown in Equation (5). With electron-donating substituents, oxidative addition of C−CN bonds to nickel(0) occurs more slowly [Equation (6)].





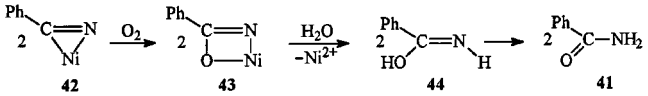
The usual aryl aldehyde and substituted benzyl phenyl ketone were also detected upon hydrolysis of the latter reaction mixture.

During our attempts to reproduce the cyclotrimerization of benzonitrile reported by Heldt[15] as occurring on nickel metal in refluxing **5**, we did observe significant decyanation, as was evident by low recovery of **5** (<50%) and by the detection of cyanide ion in the hydrolysis products with the "Prussian Blue" test.

Significant, Unexpected Reactions Occurring between Benzonitrile and Nickel(0) Complexes

Formation of Benzamide (41) and 2,4,6-Triphenyl-1,3,5-triazine (6)

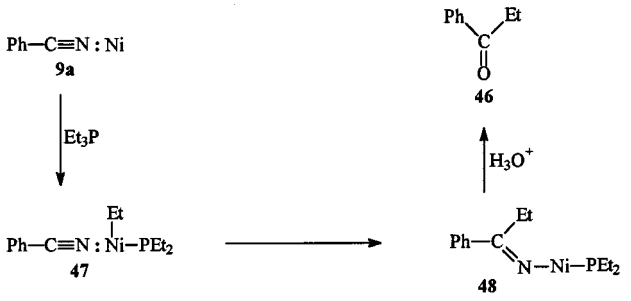
From the present study and the previous work of Oehme and Pracejus[16] it is clear that under a completely inert atmosphere and anhydrous conditions neither a clean nickel surface nor a nickel(0) complex reacts with pure benzonitrile at temperatures up to 200 °C to produce any triazine **6**. However, in the presence of adventitious moist air such nickel(0) complexes convert the nitrile to benzamide (**41**) even at 25 °C. Nickel(II) salts, in turn, have been shown to convert benzamide into the triazine **6** at elevated temperatures.[16] The so-called catalytic hydration of nitriles to amides, reported over 40 years ago, involves heating aqueous suspensions of amides with nickel metal catalysts of the Raney or Urushibara type under an air atmosphere.[24] In the light of our present findings, we can now propose a rational reaction mechanism involving the formation of a "side-on" complex on the nickel surface (**42,** with **5**), its air-oxidation to **43** and the hydrolysis via enaminate **44** to the amide **41** (Scheme 9). In keeping with the intermediacy of **42**, significant reduction of the nitrile to the amine or even reductive cleavage to ammonia has been observed.



Scheme 9

Ethylation of Benzonitrile (5) in the Presence of Tetrakis(triethylphosphane)nickel(0) (45)

As with other nickel(0) complexes, the triethylphosphane complex **45** reacted with benzonitrile to produce small amounts of benzaldehyde (5%) and benzyl phenyl ketone (10%) upon hydrolysis. But, surprisingly, ethyl phenyl ketone (**46**) was also formed in 60% yield. Since the only discernible source of the ethyl group is the Et_3P ligand, we are led to suggest that the Ni(0) center, in the presence of benzonitrile (**9a**) undergoes an oxidative addition into the ethyl-phosphorus bond of a Et_3P unit (Scheme 10). Decomposition of **47** in either a heterolytic or a homolytic fashion would yield **48**, whose hydrolysis would provide ketone **46**. Although an unusual reaction for phosphane complexes themselves at 25 °C, the following C−P bond cleavage reaction has been observed in refluxing hexane [Equation (7)].[25] Clearly an oxidative addition to the Ni(0) center must be involved. Pending further study, it remains unclear as to whether such reactions are promoted by light or radical sources.

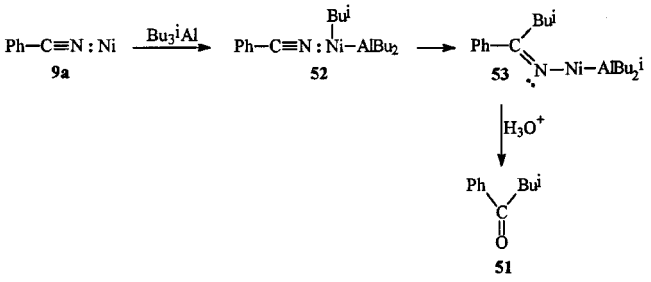


Scheme 10

Isobutylation of Benzonitrile (5) by Triisobutylaluminum (49) in the Presence of Bis(1,5-cyclooctadiene)nickel(0) (50)

Nitriles react with diisobutylaluminum hydride at 20−25 °C to give aldehydes upon hydrolysis but they do not react with triisobutylaluminum at such temperatures. Only when nitriles are heated with Bu_3Al does reaction occur but then hydroalumination, rather than carbalumination, is the observed outcome, leading again to aldehydes or primary amines.[26] Therefore, the extraordinary reaction of benzonitrile with 1:1 mixture of Bu_3Al and $(COD)_2Ni$ to yield isobutyl phenyl ketone (**51**) in 42% yield deserves particular attention. Such a yield results from reactions of 1:1:1 mixtures of the reactants conducted in toluene either over seven days at 25 °C or 24 hours at reflux. Traces of benzyl phenyl ketone (**33**) and benzophenone (1−5%) were also detected.

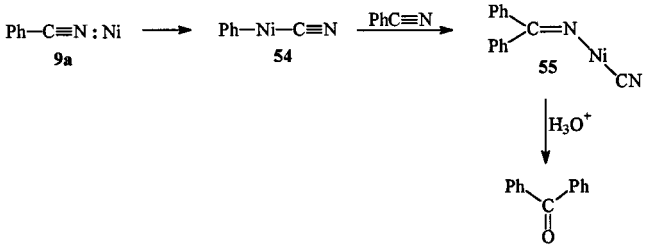
To account for the formation of ketone **51**, an oxidative addition of the Ni(0) center of **9a** into the isobutyl-aluminum bond is reasonable, similar to that depicted in Scheme 10 to form **52** which decomposes in an analogous fashion to **53**, whose hydrolysis would yield **51** (Scheme 11). That the yield of **51** levels off under 50% may be a consequence of strong Lewis base (**53**) complexing with half of



Scheme 11

the available Bu_3Al and preventing it from reacting with **9a**. As to the mechanism of reaction, there is evidence from the reaction of diphenylacetylene with 1:1 combinations of iBu_3Al and $(COD)_2Ni$ that both photochemical- and radical-promoted processes may be operative.[27]

The small but significant yield of benzophenone is noteworthy: the above-mentioned oxidative addition of Ni(0) into aryl-cyano bonds [Equations (5) and (6)] is undoubtedly the cause. At 25 °C the resulting phenylnickel cyanide (**54**) would be sufficiently stable to add to the nitrile **5** to form adduct **55**, whose hydrolysis would lead to benzophenone (Scheme 12):



Scheme 12

Conclusions

These parallel studies of the homo-oligomerization and co-oligomerization of alkynes and nitriles show how pivotal the initial 1:1 adduct of nickel(0) and the triple-bonded substrate is on the course of such oligomerizations. With alkynes the reactive "side-on" complex can best be viewed as a nickelacyclopropene or nickelirene both in terms of its molecular structural properties and its chemical reactions. The 1:1 nickel(0) complex with nitriles can be "end-on" as well as "side-on" (azanickelacyclopropene) with evidence existing that "end-on" complexation is the more stable mode and the more important precursor to the homo-oligomerization, nickelodecyanation and several unusual addition reactions of nitriles. In the co-oligomerization of alkynes and nitriles the greater stability of the "side-on" complex of nickel(0) with the alkyne monomer over the corresponding "side-on" complex of nickel(0) with nitriles results in essentially exclusive homocyclotrimerization of the alkyne. Only in the absence of free alkyne can the nickelacyclopropene apparently be intercepted by the nitrile leading to a co-dimer with the alkyne. In the homo-oligomerization of nitriles the 1:1 "end-on" complexation with nickel(0) appears to lead to an unusual stoichiometric dimerization apparently in the form of an $\eta^4-1,2$-diazacyclobutadiene-nickel(0) precursor complexed in a "corner-on" fashion with two nickel(0) units.

Experimental Section

Instrumentation, Analysis and Starting Reagents: All reactions were carried out under a positive pressure of anhydrous, oxygen-free argon. All solvents employed with organometallic compounds were dried and distilled from a sodium metal-benzophenone ketyl mixture prior to use.[28] The IR spectra were recorded with a Perkin−Elmer instrument, model 457 and samples were measured either as mineral oil mulls or as KBr films. The NMR spectra (^1H and ^{13}C) were recorded with a Bruker spectrometer, model EM-360 and tetramethylsilane (TMS) was used as the internal standard. The chemical shifts reported are expressed in the δ-scale and in parts per million (ppm) from the reference TMS signal. The GC/MS measurements and analyses were performed with a Hewlett-Packard GC 5890/Hewlett-Packard 5970 Mass-Selective-Detector instrument. The gas chromatographic analyses were carried out with a Hewlett-Packard instrument, model 5880, provided with a 6 ft OV-101 packed column or with a Hewlett-Packard instrument, model 5890, having a 30 m SE-30 capillary column, respectively. Melting points were determined on a Thomas-Hoover Unimelt capillary melting point apparatus and are uncorrected. The $(COD)_2Ni$ was prepared according to a procedure adapted from those of Semmelhack[29] and of Schunn.[30] The yield of product has been improved to 95% by purifying the starting materials with extreme care.

The $(Et_3P)_4Ni$ was prepared according to the method of Cundy[31] and the (Bpy)(COD)Ni by the procedure of Dinjus et al.[32] The complex, (Bpy)(Ph−C≡C−Ph)Ni (**7**), was prepared according to the following modified procedure, which is based upon the method of Eisch and Piotrowski.[33]

A suspension of $(COD)_2Ni$ (2.91 g, 10.6 mmol) in 40 mL THF was treated with 2,2′-bipyridyl (1.70 g, 10.7 mmol) in 10 mL THF at 25 °C and the reaction mixture stirred for 1 h. After the solvent was removed under reduced pressure, the viscous dark purple residue was dried under vacuum overnight. Then 50 mL of THF was introduced to dissolve this black-purple solid and diphenylacetylene (1.89 g, 10.6 mmol) in 20 mL of THF was then added dropwise. The reaction mixture was then stirred at 25 °C for 15 h, after which time THF was removed under reduced pressure and the black viscous residue dried under vacuum for 16 h in order to remove the cyclooctadiene. Then 50 mL of THF was used to extract the residue and the mixture filtered. The filtrate was concentrated to about 20 mL and pentane was then introduced in small portions. After the first precipitation was observed, another 15 mL of pentane was added. The mixture was allowed to stand at 25 °C for 2 h to complete the crystallization. The black crystalline solid was then filtered off and was washed with small portions of pentane three times and then dried under vacuum for 4 h. The yield of the product was 3.00 g (72%). Such crystals were employed for X-ray crystallographic structure determination. − IR (mineral oil): $\tilde{\nu}$ = 710(s), 730(s), 755(s), 765(m), 775(m), 850(w), 1025(s), 1490(m), 1570(w), 1590(s), 1740(br, w), 1770(m).

General Procedures: All steps in the preparation, transfer, and main reactions of the metal salts and organometallic reagents studied here were conducted under an atmosphere of anhydrous and oxygen-free argon. All solvents and apparatus were likewise freed of

traces of dissolved or adsorbed moisture and oxygen by published procedures and then maintained under argon. Methods and techniques for working under anhydrous and anaerobic conditions have been described previously.[28] In the hydrolysis procedure employed for the workup of all nickel(0) reaction mixtures, it proved essential that the aqueous HCl be thoroughly free of oxygen and that both freeze-thaw cycles in vacuum and readmission of argon be conducted to that end. Because of the small-scale runs the presence of oxygen during hydrolysis greatly reduced the amounts of benzaldehyde and benzyl phenyl ketone isolated.

Protonolysis of (Bpy)(Ph−C≡C−Ph)Ni (7): A solution of **7** (1.00 g, 2.55 mmol) in 20 mL of THF under argon was treated with 10 mL of degassed 85% H_3PO_4 at 25 °C for 4 h to form an off-white precipitate and a blue solution. Hydrolytic workup gave an organic extract containing only *cis*-stilbene (**14**) (0.73g, 95%), as determined by IR, ^1H and ^{13}C NMR spectroscopy.

A similar solution of **7** was treated with degassed 6 N aqueous HCl with prompt formation of a pale red-colored precipitate, which corresponded to a 90% yield of PhCH=CPh(NiCl·Bpy) (**15**) based upon a Ni analysis of 14.0% (calcd. 13.63%), as well as a positive test for Cl anion upon sodium fusion, and IR spectroscopy: $\tilde{\nu}$ = 700(s), 740(s), 790(s), 910(m), 1040(m), 1080(m), 1500 (m, occurring in C=C−M groupings), 1540 (vw), 1580(w), 1600(m). The filtrate was shown by GC/MS analysis to contain *cis*- and *trans*-stilbenes (**14** and **16**) in a 9:1 ratio.

Treatment of the pale red solid **15** with glacial acetic acid in THF gave, upon hydrolytic workup, a quantitative yield of only *trans*-stilbene.

Finally, a 1.00-g sample of **7** in THF was treated with degassed 6 N DCl in D_2O to give the deuteriated pale red solid, PhCD=CPh(NiCl·Bpy) (**15a**). In separate reactions then, **15a** was treated either with HOAc in THF or with DOAc in THF. In the former reaction, only *trans*-stilbene-d_1, $C_6H_5CD{=}CHC_6H_5$ (**16a**), was formed. In the latter reaction, only *trans*-stilbene-$d_{1,2}$, $C_6H_5CD{=}CDC_6H_5$ (**16b**), was found.

Cyclotrimerization of Diphenylacetylene (22) by (Bpy)(Ph−C≡C−Ph)Ni (7): A sample of **7** (395 mg, 1.0 mmol) and diphenylacetylene (1.00 g, 5.6 mmol) was heated in refluxing toluene for 2 days. During this time a white precipitate formed in the dark red solution. After hydrolytic workup the solid was filtered off and shown to be hexaphenylbenzene (**23**) (0.75g, 75%). − IR (mineral oil): $\tilde{\nu}$ = 700(m), 735(w), 790(w), 1380(m), 1465(s). − m.p. >400°C. The organic layer contained mainly unchanged **22** and traces of stilbenes **14** and **16**.

Cyclotrimerization of Dimethyl Acetylenedicarboxylate (24) by (Bpy)(Ph−C≡C−Ph)Ni(0): A sample of **7** (5.5 mmol, 2.17 g) and **24** (15 mmol, 2.13 g) was heated in refluxing benzene for 36 h. Usual hydrolytic workup provided an 80% yield (1.70 g) of hexamethyloxycarbonylbenzene (**25**) , m.p. 186−188°C (from THF/H_2O), identified by MS and ^1H NMR spectroscopic data. Traces of stilbenes, but no hexamethylbenzene, were observed.

Co-cyclotrimerization of Dimethyl Acetylenedicarboxylate (24) and Diphenylacetylene Derived from (Bpy)(Ph−C≡C−Ph)Ni (7): A sample of **7** (5.9 mmol, 2.33g) and **24** (13 mmol 1.85g) dissolved in 30 mL of THF was stirred for 18 h at 25 °C. After hydrolytic workup and column chromatographic separation of the organic products on silica gel (40−60 mesh) with ethyl ether/hexane as the eluting solvent, the following products were obtained and identified by MS and ^1H NMR spectroscopic data: hexamethyloxycarbonylbenzene (65%) (**25**); 1,2,3,4-tetramethyloxycarbonyl-5,6-diphenylbenzene (**26**) (20%), m.p. 221−222°C. − ^1H NMR ($CDCl_3$): δ = 3.42 (s, 6 H), 7.03 (s, 5 H). − IR (mineral oil): $\tilde{\nu}$ = 710(s), 1000(m), 1100(s), 1210(m), 1460(s). − dimethyl fumarate (10%). − m.p. 102−103°C. − ^1H NMR ($CDCl_3$): δ = 3.78 (s, 6 H), 6.80 (s, 2 H); and *trans*-stilbene (5%).

Attempted Co-oligomerization of Diphenylacetylene (22) and Benzonitrile (5) in the Presence of $(COD)_2Ni$: To a solution of $(COD)_2Ni$ (62.0 mg, 0.226 mmol) in 5 mL THF was added a mixture of benzonitrile (232 mg, 2.26 mmol) and diphenylacetylene (805 mg, 4.52 mmol) in 10 mL of THF. The reaction mixture was then stirred at 25 °C for 24 h. A 2-mL sample of the reaction mixture was hydrolyzed with 4 mL of 3N HCl. The organic layer was then neutralized with sodium bicarbonate and dried over magnesium sulfate. The solvent was removed under reduced pressure and the product mixture was analyzed by GC. Diphenylacetylene (conversion of 5%), benzonitrile (conversion of less than 1%) and *cis*-stilbene (yield of 3%) were identified by the co-injection of authentic samples.

The rest of the reaction mixture was heated at reflux for 24 h. After one hour of reflux a white solid separated and the color of the solution turned brown. When the reaction mixture was cooled to 25 °C, the crystalline solid was filtered off from the solution and washed twice with small amounts of THF. The organic layer was hydrolyzed with 20 mL of 3 N aqueous HCl and neutralized with aqueous $NaHCO_3$. The organic layer was dried over $MgSO_4$ and the solvent was removed under reduced pressure. Analysis by GC showed the presence of diphenylacetylene (**22**) (33%), benzonitrile (**5**) (85%) and *cis*-stilbene (3%) (**14**). The white solid, 512 mg (65%), was confirmed to be hexaphenylbenzene (**23**) by the following spectral characterization: ^1H NMR ($CDCl_3$, TMS): δ = 6.84 (m). − ^{13}C NMR ($CDCl_3$): δ = 125.13, 126.54, 131.36, 140.28 and 140.60 (m). − IR (KBr): $\tilde{\nu}$ = 559(vs), 690(vs), 728(vs), 780(vs), 1028(s), 1072(s), 1406(vs), 1448(vs), 1500(vs), 1607(vs), 3040(vs), 3070(s), 3090 (m) cm^{-1}. − MS (70eV): *m/z* = 534 [M^+]. A mass spectral search for the parent ion of pentaphenylpyridine, 548, was negative.

Reaction of (Bpy)(PhC≡CPh)Ni (7) with Benzonitrile (5): A solution of (Bpy)(PhC≡CPh)Ni (228 mg, 0.580 mmol) in 10 mL THF was cooled to −78 °C, after which pure benzonitrile (107 mg, 0.598 mmol) was added dropwise. The reaction mixture was warmed to 25 °C and stirred at this temperature for 2 days. The reaction mixture was then heated at reflux for 6 h and then quenched with 20 mL of 2N aqueous HCl. The organic layer was neutralized with aqueous $NaHCO_3$ and dried over anhydrous $MgSO_4$. According to GC/MS analysis and co-injection with authentic samples (provided by American Peptid Corp., Sunnyvale, CA), the *cis*- and *trans*-1,2,3-triphenylpropen-1-ones (**32**) were found to be the main products. Total yield of the *cis*- and *trans*-isomers was 40%. *cis*-Stilbene (**14**) (53%) was also one of the main products. Minor products (≈2%) were 1,2,3,4-tetraphenyl-1,3-butadiene isomers and *trans*-stilbene. Spectral characterization of the products by GC-MS analysis follows: *cis*- and *trans*-1,2,3-triphenylpropen-1-ones: $C_{21}H_{16}O$: *m/z* = 284 $[M]^{\cdot+}$, 179 $[C_{14}H_{11}]^{\cdot+}$, 105 $[C_7H_5O]^{\cdot+}$, 77 $[C_6H_5]^{\cdot+}$, isomeric butadiene derivatives of MF, $C_{28}H_{22}$: *m/z* = 358 $[M]^{\cdot+}$, 267 $[C_{21}H_{15}]^{\cdot+}$, 179 $[C_{14}H_{11}]^{\cdot+}$, 178 $[C_{14}H_{10}]^+$. − IR spectrum (thin film): C=O absorption of 1,2,3-triphenylpropen-1-one at 1652 cm^{-1}.

Similar reactions were carried out in toluene both at 25 °C and under reflux. The workup procedures were identical with that of the reaction carried out in THF. For the reaction in toluene at 25 °C for 8 days, the *cis*- and *trans*-stilbenes **14** and **16** were the main

products with a *cis*- to *trans* ratio of 1.3:1.0 and the total yield in stilbenes of 68%. Also 31% of diphenylacetylene was recovered from the nickel complex. The reaction carried out in toluene under reflux for 8 h gave only 10% of *cis*-stilbene with 85% of the diphenylacetylene recovered. Traces (<2%) of hexaphenylbenzene were found but neither the 1,2,3,-triphenylpropen-1-ones nor the 1,2,3,4-tetraphenyl-1,3-butadienes were detected.

Oligomerization of Benzonitrile (5) Mediated by Various Nickel(0) Complexes

By $(COD)_2Ni$: To a solution of $(COD)_2Ni$ (289 mg, 1.05 mmol) in 10 mL THF was added benzonitrile (0.215 mL, 216 mg, 2.10 mmol) dropwise at 25 °C and the reaction mixture then stirred for 7 days. The color of the solution changed immediately from yellow to red and then slowly to dark-brown. Samples withdrawn at reaction times of 24 h, 48 h and 7 days were hydrolyzed with 3 N aqueous HCl, neutralized with aqueous $NaHCO_3$ and finally dried over anhydrous $MgSO_4$. The resulting product mixtures were analyzed by GC and GC-MS. After 7 days at 25 °C the main products were identified as benzaldehyde (**21**) (13%) and benzyl phenyl ketone (**33**) (15%) with the conversion of benzonitrile at about 30%. When small amounts of dry air were slowly admitted to the reaction mixture, variable amounts of benzamide were detected in the hydrolysis products. Characterization of benzyl phenyl ketone by GC:MS: $C_{14}H_{12}O$: m/z = 196 $[M]^{\cdot+}$, 105 $[C_7H_5]^{\cdot+}$, 91 $[C_7C_7]^{\cdot+}$, 77 $[C_6H_5]^{\cdot+}$.

A similar reaction run to the foregoing was conducted, except that a 2:1 ratio of $(COD)_2Ni$:**5** was allowed to react in THF for 24 h. Hydrolytic workup showed that an 80% material recovery was obtained with the complete consumption of benzonitrile and the formation of a 96:4 molar ratio of **33:21**.

The reaction of benzonitrile with $(COD)_2Ni$ was also conducted in neat benzonitrile. Thus, freshly distilled and degassed benzonitrile (3 mL, 29.4 mmol) was added to $(COD)_2Ni$ (245 mg, 0.892 mmol) at 0 °C whereupon the reaction mixture changed immediately from yellow to bright red. After 10 min at 0 °C 15 mL of 3N hydrochloric acid was added. The usual workup procedure showed that 10% of benzaldehyde but less than 5% of benzyl phenyl ketone was formed. The same reaction carried out at 25 °C over 24 h yielded no **33** and only 10% of benzaldehyde.

By $(COD)_2Ni$ and iBu$_3$Al: The dropwise addition of iBu$_3$Al (0.25 mL, 1.00 mmol) to a solution of $(COD)_2Ni$ (275 mg, 1.00 mmol) in 10 mL of toluene turned the initially yellow solution brown. Subsequent introduction of benzonitrile (0.10 mL, 1.00 mmol) caused the gradual development of a red color. The resulting mixture was stirred for 7 days, hydrolyzed and after the usual workup analyzed by GC-MS procedures. A 42% yield (68 mg) of isobutyl phenyl ketone (**49**) was obtained: MS (70 eV): m/z = 162 $[M]^{\cdot+}$, 120 $[C_8H_8O]^{\cdot+}$, 105 $[C_6H_5CO]^{\cdot+}$, 77 $[C_6H_5]^{\cdot+}$. − IR (Film): $\tilde{\nu}$ = 1680 cm^{-1}. Benzyl phenyl ketone (5%) and benzophenone (1%) were also identified.

By $(Et_3P)_4Ni$: To a solution of the phosphane complex (458 mg, 0.914 mmol) in 15 mL of THF was added benzonitrile (0.186 mL, 188 mg, 1.83 mmol) of. The color of the solution changed from red-purple to green immediately. The reaction mixture was stirred at 25 °C for 7 days. Usual hydrolytic workup and a GC/MS analysis of the organic products showed that ethyl phenyl ketone (**44**) was the main product (60%, 130 mg) and **21** (5%) and **33** (10%) were minor products.

44: MS: m/z = 134 $[M]^{\cdot+}$, 105 $[PhCO]^{\cdot+}$, 77 $[C_6H_5]^{+}$. − IR (film): $\tilde{\nu}$ = 1684 cm^{-1}.

By (Bpy)(COD)Ni: To the freshly made complex **7** (0.82 mmol) were added 15 mL of THF and benzonitrile (0.166 mL, 168 mg, 1.63 mmol). The reaction mixture was stirred at 25 °C for 7 days with no apparent color change of the dark solution. The reaction was quenched with 20 mL of 2 N aqueous HCl and then neutralized with aqueous $NaHCO_3$. The GC analysis of the dried organic layer showed that benzyl phenyl ketone **33** had formed in 20% yield, but benzaldehyde was found in only 5% yield. The conversion of benzonitrile was 30%.

The same reaction carried out at reflux for 24 h, but only benzaldehyde was obtained in a yield less than 5%; no deoxybenzoin was detected.

By $Ni(acac)_2$/Et_3Al: To a mixture of $Ni(acac)_2$ (203 mg, 0.791 mmol) and benzonitrile (0.161 mL, 163 mg, 1.58 mmol) in 15 mL of toluene was added slowly triethylaluminum (0.216 mL, 180 mg, 1.58 mmol). The color of the solution turned immediately from green to dark brown. After the reaction mixture had been stirred at 25 °C for 24 h, hydrolytic workup and analysis showed that **33** was formed in 15% yield.

By $(COD)_2Ni/MeAlCl_2$: a) Adding Benzonitrile to the Mixture of $(COD)_2Ni$-$MeAlCl_2$ in Toluene: One milliliter of a 1 M hexane solution of $MeAlCl_2$ was added dropwise to a solution of $(COD)_2Ni$ (276 mg, 1.00 mmol) in 10 mL of toluene. The formation of a nickel mirror and a black precipitate were immediately formed. To this mixture was added benzonitrile (0.10 mL, 1 mmol) and the reaction mixture stirred at 25 °C for 24 h. The usual workup procedure and subsequent GC analysis showed that no reaction between benzonitrile and the nickel complex had occurred. Of interest is that about 90% of the 1,5-cyclooctadiene had been isomerized to its 1,3-isomer.

b) Adding $(COD)_2Ni$ to the Mixture of Benzonitrile and $MeAlCl_2$ in Toluene: A solution of $(COD)_2Ni$ (291 mg, 1.06 mmol) in 8 mL of toluene was added to a mixture of benzonitrile (0.11 mL, 1.06 mmol) and 1.06 mL of a 1 M hexane solution of $MeAlCl_2$ in 7 mL toluene and the reaction mixture then stirred for 24 h at 25 °C. After hydrolysis and GC analysis benzyl phenyl ketone (**33**) was found in 20% yield but no trace of benzaldehyde was detected.

By comparison, a similar reaction run in which the $MeAlCl_2$ was added to a mixture of $(COD)_2Ni$ and benzonitrile in toluene led to the formation of no organic products.

Oligomerization of Substituted Benzonitriles by $(COD)_2Ni$

Pentafluorobenzonitrile: A reddish solution of $(COD)_2Ni$ (1.27 mmol) and 2.54 mmol of the nitrile in 10 mL of THF was stirred at 25 °C for 24 h, during which time it turned pale yellow. Usual hydrolytic workup permitted the recovery of only 20% of the nitrile and yielded only pentafluorobenzene and no other organic products. It is assumed that any nickel(0) complex with the nitrile underwent decyanation with the loss of the C_6F_5 group (vide infra).

4-Methoxybenzonitrile: A red solution of $(COD)_2Ni$ (1.00 mmol) and 2.0 mmol of the nitrile in 10 mL of THF was stirred at 25 °C for 24 h, during which time it turned dark brown. Usual hydrolytic workup and GC-MS and NMR analysis showed the presence of 75% of the nitrile, 15% of 4-methoxybenzyl 4-methoxyphenyl ketone and 10% of 4-methoxybenzaldehyde with only a trace of anisole (material balance of 90%).

In an identical reaction extended over 6 days, the material balance fell to 60% and anisole was now a significant product (25%).

Reaction of Nickel Metal with Benzonitrile at Reflux: To a solution of $Ni(acac)_2$ (2.56 g 10.0 mmol) in 30 mL of THF was added *n*-

butyllithium (12.5 mL, 20.0 mmol, 1.6 M in hexane) at −78 °C, and the resulting mixture was allowed to come to 25 °C over 2 hours. The black suspension was then evaporated to dryness under reduced pressure. Under argon dry benzonitrile (degassed under Ar and freshly distilled from P_2O_5, 13 mL, 0.13 mol) was added and the reaction mixture was heated at reflux (190−195 °C) for 40 hours. The resulting dark gray suspension was evaporated to dryness under vacuum and the solid residue was then slurried with toluene and hydrolyzed with 3 N aqueous HCl. Concentration of the dried toluene extract led to the deposition of 2,4,6-triphenyltriazine (**6**) (50 mg, 0.5%): ^{1}H NMR ($CDCl_3$): δ = 7.61−7.58 (m, 9 H), 8.80−8.77 (d of d, 6 H). − ^{13}C NMR ($CDCl_3$): δ = 128.64, 128.99, 132.49, 136.31, 171.71). Evaporation of the toluene filtrate left a residue of 45% of recovered benzonitrile.

The reaction of nickel metal with refluxing benzonitrile was repeated six times, with the nickel metal being generated initially from either $NiBr_2$ or $Ni(acac)_2$ and two equivalents of *n*-butyllithium in THF, as described above. In each case, only traces of **6**, or none at all, were detected in the benzonitrile residue.

The low recovery of benzonitrile in certain runs (<50%) was an indication of decomposition of **5** by catalytic decyanation.[34] Verification of this side reaction was obtained by cooling the unhydrolyzed reaction mixture and filtering off the yellow brown precipitate. This solid was freed of organic matter by extraction with toluene to leave a residue of nickel metal and $Ni(CN)_2$. The presence of $Ni(CN)_2$ was established by a "Prussian Blue" test. The addition of aqueous ammonium hydroxide dissolved the $Ni(CN)_2$, leaving the Ni metal residue. To this ammoniacal extract were added, successively, aqueous $FeSO_4$ and then aqueous $FeCl_3$, whereupon a deep blue precipitate formed.

Reaction of Nickel Metal with Benzonitrile at Reflux (Presence of Oxygen and Moisture): In conducting the foregoing reaction it was observed in certain runs that the initially dark gray nickel suspensions turned to a yellow-green color. This color change was shown to be caused by adventitious entry of moist air into the reaction vessel. In such runs, 2,4,6-triphenyl-1,3,5-triazine and other reaction products were found upon hydrolysis. Thus a reaction run as the foregoing with $Ni(acac)_2$ as the source of Ni metal gave a yellow-brown suspension after 50 h at 195 °C under an argon atmosphere. The toluene extract was concentrated to 25 mL and then was allowed to stand at −10 °C for several days to allow crystallization. After the supernatant liquid was removed with a cannula the cluster of deposited red crystals, which proved unsuitable for XRD analysis, was quenched with degassed 6 N HCl. After Et_2O extraction the organic layer was neutralized with sodium bicarbonate, dried over anhydrous magnesium sulfate and evaporated under reduced pressure. The major organic product proved to be 1,3-diphenyl-1,3-propanedione (30 mg, 5%). − ^{1}H NMR ($CDCl_3$) δ = 4.63 (s, 2 H, diketone tautomer), 6.86 (s, 1 H, enolate vinyl hydrogen), 7.57−7.47 (m, 6 H), 8.11 (d, 4 H), 16.85 (s, 1 H, enolate OH). − ^{13}C NMR ($CDCl_3$): δ = 93.17, 127.17, 128.68, 132.47, 135.61, 185.78. − MS (Positive Ion Electrospray): *m*/*z* = 225 $[MH]^+$, 105.

After the usual hydrolytic workup of the supernatant liquid the organic residue obtained was purified by flash chromatography [silica gel, gradient elution with hexanes, hexanes/dichloromethane (4:1), and hexanes/ethyl acetate (3:1)] to give 2,4,6-triphenyl,1,3,5-triazine (**6**, 2%, based on starting **5**) and 4,5,6-triphenylpyrimidine (0.3%), for which latter product the following spectral data were obtained: ^{1}H NMR ($CDCl_3$): δ = 7.60−7.52 (m, 9 H), 8.03 (s, 1 H), 8.31−8.29 (d of d, 4 H), 8.74−8.72 (d of d, 2 H). − ^{13}C NMR ($CDCl_3$): δ = 110.31, 127.31, 128.45, 128.50, 128.92, 130.62, 130.76, 137.63, 164.82. − DEPT (CH only): δ = 110.30, 127.29, 128.44, 128.49, 128.92, 130.63, 130.76. − CIMS: 309 $[MH]^+$, 205, 102).

The product mixture from the last chromatographic fraction was concentrated and the residue was analyzed by ^{1}H and ^{13}C NMR spectroscopy. Small amounts of hexaphenylbenzene and benzamide (<1%) were observed. The origin of these products can be reasonably ascribed to the benzamide formed from benzonitrile by adventitious moist air[35] and detailed consideration of their generation will be the subject of future publications.

X-ray Crystallographic Study of 2,2′-Bipyridyl(η^2-diphenylacetylene)nickel (7): Crystal Mounting and Data Collection: A black crystal of **7**, 0.58 × 0.58 × 0.14 mm in size, was mounted with a perfluorinated polyether oil on the tip of a glass fiber on the goniometer head and cooled immediately by an argon current to −173 °C. Intensity data were collected with an Enraf−Nonius CAD4 diffractometer by a coupled ω-2θ scan technique with speeds varying from 1.0 to 10.0°/min depending on the standard deviation to intensity ratio of a preliminary 10°/min scan. The radiation employed was Mo-K_α with a graphite monochromator. The crystals of molecular weight 393.1 g mol^{-1} have two independent molecules per unit cell and have a calculated density of 1.35 Mg m^{-3}; they belong to the monoclinic crystal system and the space group of $P2_1/c$, No. 14. The two independent molecules in the asymmetric unit cell of **7** have the same atom separations within the margin of experimental error. They differ only with respect to their torsion angles. Both Ni centers are absolutely planar (sum of angles equals 360°. All other geometrical data correspond to expected values.

The absorption corrections were made by the ψ-scan method. Observed reflections were defined as those reflections with $I \geq 2\sigma(I)$. Only these were used in the solution and refinement of the structure (*F* refinement). For refinement based on F^2 all reflections were used. Refinement was done by least-squares; the quantity minimized was $\Sigma w(|Y_o| - |Y_c|)^2$, with $Y = F$ or F^2. Computations were done using VAX, Sun4, and Silicon Graphics computers. In addition to several locally written programs, the following software was used: S. L. Lawton, R. A. [5] The actual catalyst for the cyclotetramerization of acetylene is thought to be "naked" nickel(0) in all cases ("naked" meaning, in G. Wilke's view, that the ligands available to nickel, such as COD, are easily displaced by the alkyne.) The induction period observed for the oligomerization with nickel(II) salts is thought to entail the necessary reduction of nickel(II) to nickel(0), the actual catalyst. If nickel(0) is added at the start, there is no induction period and the oligomerization starts promptly (Professor Günther Wilke, observations and views communicated personally to J. J. E., **1985**). In addition, cf. G. Wilke, *Pure Appl. Chem.* **1978**, *50*, 677.

Reductive Activation of Tripod Cobalt Compounds: Oxidative Addition of H−H, P−H, and Sn−H Functions

Ute Winterhalter,[a] Laszlo Zsolnai,[a] Peter Kircher,[a] Katja Heinze,[a] and Gottfried Huttner*[a]

Dedicated to Prof. Dr. Peter Paetzold on the occasion of his 65th birthday

Keywords: Tripodal ligands / Cobalt / Reductive activation / Oxidative addition / Tin hydrides / Diphosphene

Treatment of the *tripod* compounds *tripod*$CoCl_2$ (**1**), and *tripod*CoCl (**2**), [*tripod* = $CH_3C(CH_2PPh_2)_3$] in THF solution under argon atmosphere with strong reducing agents such as KC_8 leads to the generation of reactive species. While the dinitrogen compound *tripod*$Co(N_2)$Co*tripod* (**3**), which is formed under N_2 atmosphere, is rather unreactive, the species formed under argon atmosphere undergo selective reactions with compounds containing P–H or Sn–H functions. With $PhPH_2$ as the reagent, the diphosphene compound *tripod*Co(η^2-PhP=PPh) (**8**), is formed in a yield (44%) similar to that achieved in the preparation of **8** from **2** and PhPHNa (60%). With Ph_3SnH as the reagent, *tripod*$CoSnPh_3$ (**9**), is obtained (yield 61%), while reaction with Bu_3SnH produces *tripod*$Co(H)_2SnBu_3$ (**10a**, 50%). The Co^I species **9** undergoes oxidative addition of dihydrogen to produce the Co^{III} compound *tripod*$Co(H)_2SnPh_3$ (**10b**), which is an analogue of **10a**. The properties of these new compounds are characterized by the usual analytical techniques, including NMR spectroscopy, cyclic voltammetry, and X-ray analysis.

Introduction

The chemistry of [*tripod*Co] templates − *tripod* = $CH_3C(CH_2PPh_2)_3$ − is well developed for the Co^{II} [1] and Co^{III} [2] oxidation states, while low-valent derivatives are still rare. On the other hand, it is well-known that templates L_3Co (L = PMe_3)[3] also possess a rich chemistry with Co in lower oxidation states. A possible entry into the chemistry of low-valent [*tripod*Co] compounds is the reduction of easily accessible [*tripod*Co^{II}] compounds such as *tripod*$CoCl_2$ (**1**) (Scheme 1),[4] by electropositive metals. Using zinc powder as the reductant,[5] the Co^I compound *tripod*CoCl (**2**), is produced,[4,6] which in itself allows access to the chemistry of [*tripod*Co^I] derivatives.[5] Reduction of **1** with Na/Hg has been found to produce *tripod*$Co(N_2)$Co*tripod* (**3**).[7]

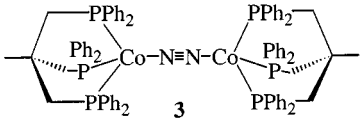
2



3

Scheme 1

The Co^0 compound **3** has already been tested with regard to its propensity to act as a precursor for other low-valent [*tripod*Co] species.[8] It was found, however, to be rather unreactive, while the solutions from which it is obtained are reactive due to the presence of some undefined by-products.[8] Although the reactions of such solutions with CO_2 or CS_2 furnished only the oxidized products incorporating η^2-CO_3 and η^2-S_2CO ligands,[8] their observed reactivity indicates that reduction of the metal in **1** produces highly reactive species.

In this paper, we report on the results obtained upon reduction of **1** in THF solution by KC_8 or activated Mg (Scheme 2). While *tripod*$Co(N_2)$Co*tripod* (**3**), is obtained as one of the products when this reduction is carried out under dinitrogen, reduction under argon atmosphere produces highly reactive species that undergo oxidative addition with P−H and Sn−H functions, thereby leading to derivatives such as *tripod*$Co(P_2Ph_2)$ (**8**), and *tripod*$Co(H)_2(SnR_3)$ (**10**).

Results and Discussion

Reductions of 1 and 2: Products and By-Products

Products

Reduction of a THF solution of **1** with various reductants was monitored by UV/Vis/NIR spectrophotometry,

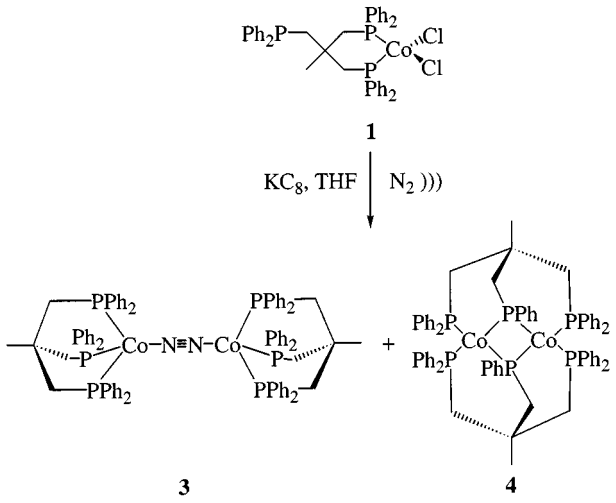

Scheme 2

this being the only simple tool suitable for analysing these highly sensitive and strongly paramagnetic solutions. Reduction with KC_8 as well as with Na/Hg under N_2 was found to produce solutions showing a strong band at around 1130 nm and a weaker absorption at around 680 nm (Figure 1b; Table 1). The relative intensities of these two bands was found to vary to some extent in different experiments, while no conditions could be found under which one of these two bands was absent. Reduction of **1** under an N_2 atmosphere with activated Mg led to spectra of type a (Figure 1a) with just one prominent band at 1130 nm. The same type of spectrum was obtained when **2** was reduced with KC_8 under N_2. Reduction of **1** or **2** under argon atmosphere with KC_8 produced solutions that characteristically showed spectra of type c (Figure 1c). The same type of spectrum was observed when **1** was reduced with Na/Hg under Ar. If the spectrum contained any signature of *tripod*-Co(N_2)Co*tripod*, **3**, this should be the band at around 1130 nm (Figure 1a). For comparison purposes, **3** was prepared by reacting **2** with KC_8 under N_2. On layering the THF solution obtained by this procedure with petroleum ether (boiling range 40−60 °C), crystals of **3** were produced. These crystals were analysed by measuring the lattice constants [a = 1794(3) pm, b = 1531.1(9) pm, c = 1279(1) pm, α = 90°, β = 94.16(6)°, γ = 90°], which were found to be identical to those reported for **3** in the literature.[7] The UV/Vis/NIR spectrum of a solution of this authentic crystalline sample of **3** in THF was recorded. The band at around 1130 nm (Figure 1a) was found to coincide with the intrinsic absorption of **3** [λ_{max} (ε) = 405 (8000), 718 (550), 1134 nm (4700) $M^{-1}cm^{-1}$]. This result, together with the result obtained by comparing the UV/Vis/NIR spectra in Figure 1 (a, b: N_2 atmosphere; c: Ar atmosphere), indicates that the compound giving rise to the band at 1130 nm, which is only present when the experiment is performed under N_2, is the dinitrogen compound **3** itself. The compound giving rise to the band at 680 nm (Figure 1, b and c) is not identified as such. Again, on the basis of the UV/Vis/NIR spectra, it cannot be the Co^I species *tripod*CoCl that shows a completely different spectrum[4] [λ_{max} (ε) = 530 (120, sh), 826 (150), 1131 (430), 1224 (450) $M^{-1}cm^{-1}$].

2	KC_8	Ar	c
1	Na/Hg	Ar	c

By-Products

The nature of the compound giving rise to the absorption at 680 nm is not known. It is, however, known that this species is the reactive one since **3** (band at 1130 nm, Figure 1a and 1b) is unreactive with respect to the reactions reported in this paper. Only solutions showing the absorption at 680 nm have been found to undergo reactions with

the reagents used. Among the products generated upon reduction of **1**, the dicobalt species $[CH_3C(CH_2PPh_2)_2CH_2PPh]_2Co_2$ (**4**), is occasionally obtained in low yields in the form of a crystalline material.

The constitution of **4** shows that it is only a minor by-product that cannot be responsible for the generation of the compounds obtained upon reactions of solutions showing the band at 680 nm with various substrates (see later). Thus, **4** has been dephenylated at the *tripod* ligand, whereas all the products described herein contain an intact ligand. The FAB mass spectrum of crystalline **4** shows peaks at m/z = 1212 [M^+] and 606 [M^{2+}]. The structure of **4** has been determined by X-ray analysis (Figure 2, Table 2 and 8).

[a] Atom labels refer to Figure 2. The molecular structure shows centrosymmetric symmetry. In Figure 2, the atom related to atom *i* by this symmetry is labelled as atom *i*A.

The formation of **4** from **1** may possibly be rationalized by considering that in THF solutions of **1** the *tripod* ligand is present in a bidentate binding mode with only two of its donor groups coordinated to the metal and the third one remaining as a dangling arm.[4] Since it has been shown that reductive dephenylation[9] of *tripod* ligands may occur in complexes as well as in the free ligand, it is tempting to assume that in the case of **1** the noncoordinated PPh_2 group is preferentially dephenylated. This assumption might explain the formation of the phosphido group of the ligand $[CH_3C(CH_2PPh_2)_2CH_2PPh]^-$ in **4**.

The molecules of **4** are centrosymmetric, containing a dicobalt unit at the centre. This unit is bridged by two CH_2PPh^- phosphido groups in a μ_2 manner. Each of these phosphido groups is part of one $[CH_3C(CH_2PPh_2)_2CH_2PPh]^-$ tripodal entity, with the two CH_2PPh_2 groups of each of these ligands coordinating to a Co centre (Figure 2). Each Co centre is thus coordinated by four P atoms in a coordination polyhedron that is best described as distorted tetrahedral, with the corresponding P−Co−P angles in the range 92.5−126.9° (Table 2). The binding mode of the $[CH_3C(CH_2PPh_2)_2CH_2PPh]^-$ ligand in **4** is similar to that observed for the $[CH_3C(CH_2PPh_2)_2CH_2S]^-$ ligand in $\{[CH_3C(CH_2PPh_2)_2CH_2S]_2Ni_2\}^{2+}$,[10] where the thiolate function acts as a μ_2 bridging group. In this dinickel compound, the coordination geometry about the Ni centres is idealized square planar, in contrast to the idealized tetrahedral surroundings of the Co centres in **4**. As a consequence, there is some strain in the chelate scaffolding of **4**. The six-membered chelate rings formed by the phosphido phosphorus, one phosphane donor, and the three-carbon chain at each of the two Co centres (Figure 2) have rather irregular twist conformations (torsion angles in Table 2). The most marked twists are seen along the sequences P2−Co1−P3−C3 (56.1°) and C3−C4−C2−P2 (50.4°). These torsion angles are of similar size and equal sign as characteristic for a twist conformation. The corresponding torsion angles P2−Co1A−P1−C1 (−44.6°) and C1−C4−C2−P2 (−75.8°) in the chelate cycle about Co1A are also similar in size and equal in sign as befits a twist conformation.

In terms of its bonding, **4** is an analogue of $(PMe_3)_4(\mu_2\text{-}PMe_2)_2Co_2$,[3c] in which the phosphane and phosphido groups act as isolated ligands as opposed to being covalently linked in **4**. The basic geometries of these two compounds are correspondingly similar. Both compounds show a planar $[Co_2(\mu_2\text{-}P_2)]$ cyclic arrangement with short transannular Co−Co distances of just 236 pm in the PMe_3 derivative and 233 pm in **4**. The short Co−Co distance in the

former has been interpreted in terms of the formation of a Co−Co double bond, in agreement with the diamagnetism of this compound as inferred from its NMR spectra. No NMR spectra of **4** could be recorded since, once crystallized, the compound proved to be insoluble in both apolar (toluene) and polar (CH_2Cl_2, DMA, THF) solvents. Although the diamagnetism of **4** has not been proved experimentally, the close similarity of the basic structural arrangements in $(PMe_3)_4(\mu_2\text{-}PMe_2)_2Co_2$ and **4** can be taken to indicate similar bonding.

A selective synthesis of **4** might be envisaged as being possible through the reaction of $[CH_3C(CH_2PPh_2)_2CH_2PPh]^-$ with Co salts under reductive conditions. For this purpose, the *tripod* ligand $CH_3C(CH_2PPh_2)_2CH_2PHPh$ (**6**), was synthesized from the easily accessible precursor $CH_3C(CH_2PPh_2)_2CH_2Cl$, **5** (Scheme 3).[10]

5 **6**

Scheme 3

Thus, a solution of **5** in DMSO was treated with a solution of PhPHK, prepared from KO*t*Bu and $PhPH_2$, in the same solvent, to furnish the *tripod* ligand **6**. After chromatographic workup, **6** was obtained as a viscous, colourless oil in 82% yield.

When a THF solution of **6** was treated with $CoCl_2$, a green solution was obtained, which, by analogy with the reaction of *tripod* with $CoCl_2$, could be expected to contain η^2-**6**·$CoCl_2$.

Addition of KC_8 to such a solution resulted in a brown slurry, from which minor amounts ($\leq$ 5%) of **4** could be isolated by crystallization. That **4** had indeed been formed was confirmed by the mass spectrum of the material produced, which was identical to those obtained from crystalline samples of **4** prepared starting from *tripod* (see above), as well as by comparison of the unit cell dimensions determined for crystals of the relevant samples.

The formation of **4** from *tripod*$CoCl_2$ under the strongly reducing conditions used to generate the dinitrogen compound **3** under an atmosphere of dinitrogen (Figure 1a) or a reactive species (Figure 1c) under argon is evidently a minor side reaction since all the other products described in this paper, as obtained from such strongly reducing solutions, are found to contain the intact $CH_3C(CH_2PPh_2)_3$ ligand showing no signs of dephenylation.

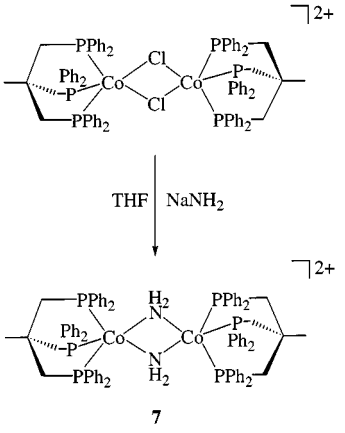
Reactivity of the Solutions Obtained from 1 or 2 by Reduction in THF under Argon

The THF solutions obtained by reducing *tripod*$CoCl_2$ (**1**), or *tripod*CoCl (**2**), with strong reducing agents such as KC_8 or Na/Hg under argon atmosphere all showed the same type of UV/Vis/NIR spectrum (Figure 1c). Irrespective of the coordination compound (**1** or **2**) or reductant (KC_8, Na/Hg) from which they are obtained (Table 1), these solutions are henceforth referred to as "solution **A**". Once formed, solution **A** does not react with N_2. The spectral signature remains unchanged when the argon atmosphere is replaced by N_2. Condidering their method of preparation, it is probable that these solutions contain [*tripod*Co] species with Co in a low oxidation state. With this in mind, it seemed appropriate to test their reactivity with regard to oxidative addition reactions. A series of substrates containing N−H, P−H, or Sn−H bonds as constituents potentially able to undergo oxidative addition was therefore tested.

N−H Functions

With $H_2N-NHPh$ as the substrate, initial oxidative addition might well be followed by a dehydrogenation reaction leading to compounds containing PhN_2H as the ligand.[11b] Since [*tripod*Co] compounds containing hydrazido ligands in a η^2 coordination mode are well-characterized species,[11] it was hoped that formation of any such products would be recognized by comparison with the authentic compounds. When solution **A** was treated with $H_2N-NHPh$, a colour change from red-brown to red was observed. Evaporation of the solvent left an oily residue, which solidified after repeated treatment with petroleum ether (boiling range 40−60 °C). FAB mass spectrometric analysis showed that this solid contained $[tripodCo(H)_3Cotripod]^+$ [*m*/*z* = 1369 (M^+)] and presumably also *tripod*Co(η^2-PhNNH) [*m*/*z* = 789 (M^+)]. The latter compound has previously been prepared from $[tripodCo(\eta^2\text{-}PhNNH_2)]^+$ by deprotonation[11b] All attempts to isolate it in a pure state from the above reaction were unsuccessful.

Besides N−H bond addition, the oxidative addition of hydrazine might also involve oxidative cleavage of the N−N bond. In order to obtain a model for the type of compound that might ensue from such an N−N bond scission, the diamido derivative $[tripodCo(\mu\text{-}NH_2)_2Cotripod](BPh_4)_2$ (**7**), was prepared from *tripod*$CoCl_2$, **1**, and $NaNH_2$ (Scheme 4).



7

Scheme 4

The BPh_4^- salt of **7** was obtained as a microcrystalline brown powder and was completely characterized by all the appropriate analytical techniques (Table 6 and 7, see exp.

Section), including by single-crystal X-ray analysis (Figure 3).

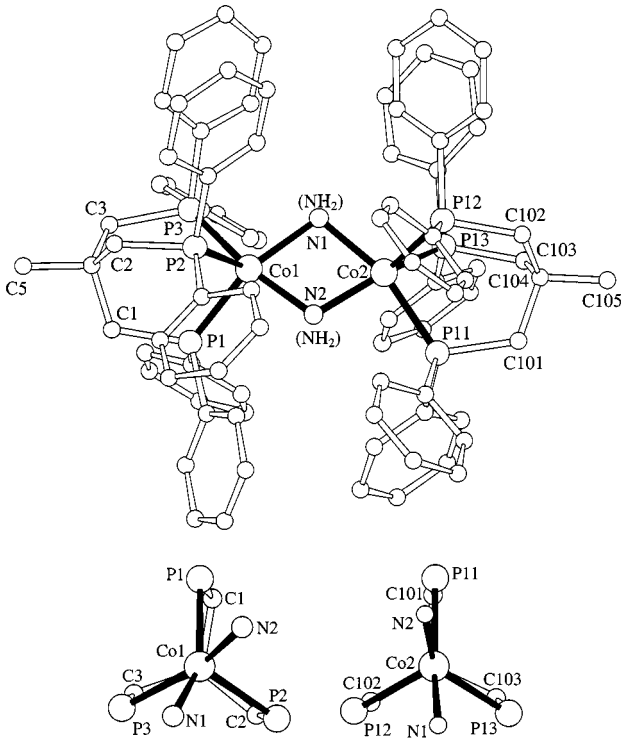


Figure 3. Structure of **7**: Bridging by the NH_2 groups is asymmetric (not shown); the individual positions of the bridging NH_2 groups could be refined using the split-atom technique; the bottom part of the figure shows the coordination polyhedra in a projection onto the relevant P_3 planes; the environment around Co1 (left-hand side) is idealized square pyramidal, while the coordination of Co2 is better described as idealized trigonal bipyramidal (right-hand side). Due to disorder problems, individual geometrical parameters are not accurate and hence are not explicitly given in this paper. Crystallographic data are nevertheless available (see exp. Section, X-ray Crystallographic Study).

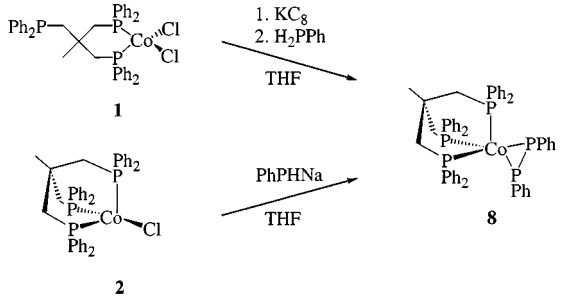
Elucidation of the molecular structure of **7** is hampered by partial disorder of the bridging ligands. Its crystal structure is isotypical with that of [*tripod*Co(μ-OH)$_2$Co*tripod*](BPh$_4$)$_2$,[12] where the same type of disorder phenomena, with a minimum of two split positions for each OH group, has been found.[12] Although, in spite of this disorder, the constitution and overall geometry of **7** are clearly apparent, the individual distances and angles are subject to large errors. The Co−Co distance in **7** amounts to 308 pm, while that in its hydroxy analogue is 306 pm.[12] The Co−P distances range from 220 to 231 pm in **7**; in its OH analogue they lie in the range 223−229 pm.[12] The Co−N distances in **7** were determined as 197 pm and 189 pm, while the Co−O distances in the analogue measure 195 pm and 184 pm. It is clear from these figures that X-ray analysis cannot differentiate between the presence of μ-OH or μ-NH_2 bridges. The presence of μ-NH_2 bridges in **7** could, however, be proved by IR spectroscopy (CsI). The μ-OH groups in [*tripod*Co(μ-OH)$_2$Co*tripod*]$^{2+}$ give rise to an infrared absorption at 3260 cm^{-1}.[12] **7** shows no absorption in this region, but has absorptions at 3350 (m), 3313 (w), 3248 (m), 3197 (w), 3158 (w), and 3120 (w) cm^{-1} in the range characteristic for N−H vibrations. **7** crystallizes in the space group *P*1 with one molecule per unit cell such that no crystallographic symmetry restriction is imposed on it. The observed structure has no apparent symmetry higher than C_1 and hence four N−H vibrations are to be expected. The fact that six N−H vibrations are observed is in agreement with the observation that the individual NH_2 groups occupy different positions with respect to the [*tripod*Co Co*tripod*] entity, since the apparent disorder could be resolved by the split-atom technique. The coordination geometries about the Co centres are close to square pyramidal in one part of the molecule (Co1) and close to trigonal bipyramidal in the other part (Co2) (Figure 3, bottom). From these structural data, it appears that **7** may exist in different isomeric forms, a hypothesis that is supported by the fact that a total of six N−H bands are observed. The ESR data of the paramagnetic compound **7** [μ_{eff} (295 K) = 2.1 μ_B per molecule] are also in agreement with this hypothesis. Dichloromethane solutions of **7** show two signals at 298 K {g_1 = 2.11 [A_1 = 24 G]; g_2 = 2.09 [A_2 = 28 G]}. At least two different d^7 Co^{II} centres are therefore present in **7**. ESR spectra obtained in a CH_2Cl_2/THF glass at 100 K are not sufficiently resolved to determine the number of isomers present. An average *g* value of 2.11 and hyperfine coupling modulations corresponding to coupling constants of 34 G and 29 G are observed.

Having established the properties of **7**, the possibility of similar compounds having been formed in the reaction of solution **A** with $H_2N-NHPh$ can be ruled out. Reaction of solution **A** with NH_3 neither produced any species similar to **7**, nor could any secondary product resulting from this reaction be identified.

P−H Functions

In view of the well-documented capacity of [*tripod*Co] templates to generate[13] and bind ligands containing P−P bonds, $PhPH_2$ was tested as a substrate potentially able to undergo oxidative addition with the species present in solution **A**. While the initial product of this reaction could not be observed, the dehydrogenation product *tripod*Co(P_2Ph_2) (**8,** Scheme 5) was obtained in 44% yield. The reaction of solution **A** with $PhPH_2$ was accompanied by a gradual colour change from red-brown to red. Evaporation of the solvent left a red powder, from which analytically pure **8** was isolated by chromatography.



Scheme 5

Single crystals of **8** were obtained by layering a concentrated solution in acetone first with ethanol and then with

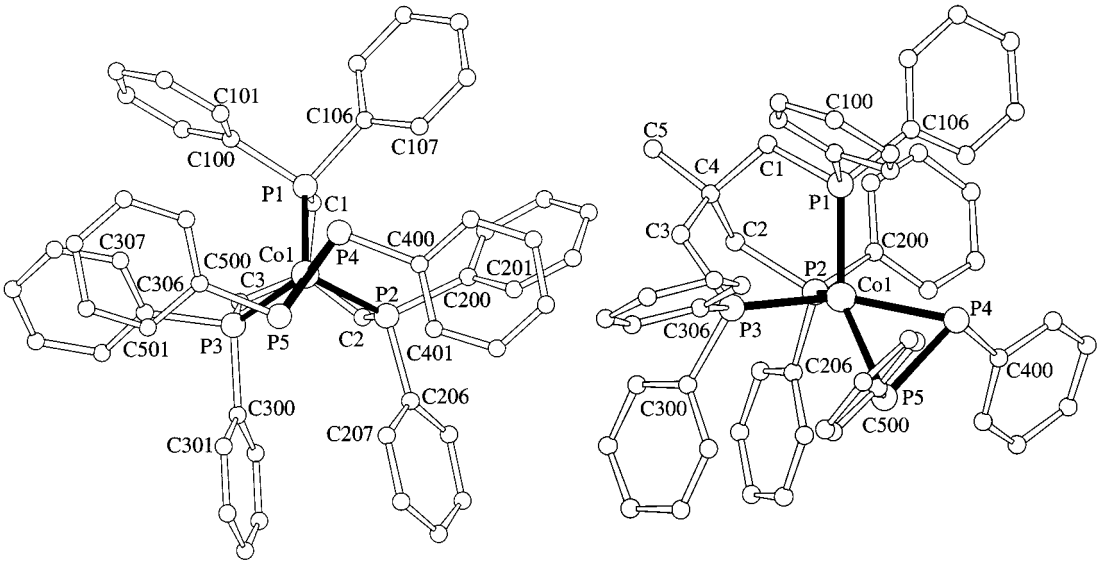


Figure 4. Structure of the diphosphene derivative **8**: Left-hand side: projection onto the plane formed by the three *tripod* phosphorus donor atoms; the torsion angles in Table 3 involving Hz_i refer to this projection; right-hand side: general view

petroleum ether (boiling range 40−60 °C). Its structure is shown in Figure 4 and the salient distances and angles are presented in Table 3. Crystallographic details are given in Table 8. The coordination geometry about cobalt may be viewed as idealized tetrahedral if the centre of the P−P bond is seen as occupying one corner of this idealized tetrahedron (Figure 4). In another view, an idealized square-pyramidal coordination geometry is apparent, with the two phosphorus centres of the diphosphene ligand, P4 and P5, and the two phosphorus donors of the *tripod* ligand, P1 and P3, forming the base and P2 the apex (Figure 4). Considering the distances between the phosphorus centres of the *tripod* ligand and the cobalt atom, this latter view appears to be more realistic since the apical bond Co1−P2 (225 pm) is significantly longer than the equatorial ones Co1−P1 (219 pm), Co1−P3 (219 pm) (see Table 3). The Co−P bonds involving the phosphorus centres of the diphosphene ligand are distinctly longer (234 pm, Table 3) than those to the *tripod* ligand. The distance P4−P5 (212.8 pm, Table 3) is characteristic of a side-on-coordinated P−P double bond. It is longer than the uncoordinated P−P double bond in free diphosphenes.[14−17] The diphosphene ligand in **8** shows a *trans* configuration (Figure 4). The bonds to the phenyl groups point slightly outwards, away from the Co atom. The torsion angle C400−P4−P5−C500 is 149°. This torsion is symmetrical with respect to the Co1−P4−P5 coordination plane, with the two torsion angles Co1−P4−P5−C500 (−103.3°) and Co1−P5−P4−C400 (−108.0°) being almost equal (Figure 4).

An independent synthesis of **8** was achieved by the reaction of *tripod*CoCl, **2**, with PhPHNa, which furnished the compound in 60% yield [a somewhat higher yield (70%) was obtained when *tripod*$CoCl_2$, **1**, was used as the starting compound]. The straightforward formation of **8** by reaction of PhPHNa with **1** or **2** is in contrast to the reaction of MesPHLi or IsPHLi (Mes = 2,4,6-trimethylphenyl, Is = 2,4,6-triisopropylphenyl) with these starting compounds.

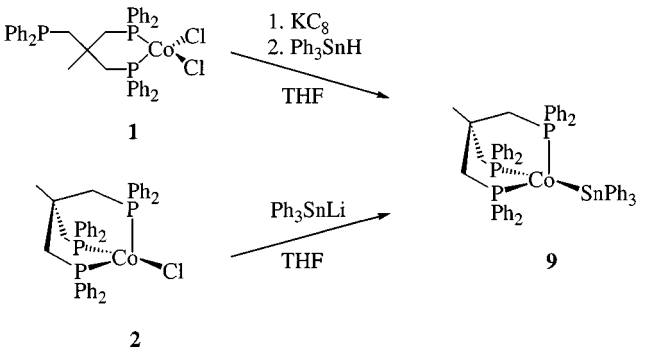
[a] The torsion angles involving Hz at the bottom of the table are defined as follows: P−Hz designates a vector that is vertical with respect to the plane formed by the three *tripod* phosphorus donor atoms and points towards the observer when, in a projection onto this plane, the vector Co−C4 points away from the observer, such that C4 lies below this plane. [1c]

With these reactants, inseparable mixtures were obtained. Mass spectra gave no indication of the formation of products analogous to **8**. It thus appears that the bulky organic substituents (Mes, Is) impede the formation of the corresponding R_2P_2 ligands. Analysis of the product mixtures obtained from these bulky phosphanes is complicated by the fact that the compounds are paramagnetic, thus preventing the use of many analytical methods. This is a problem pertaining to many of the reactions described in this paper. The only reliable means of assessment is single-crystal X-ray analysis, which, however, requires suitable single crystals, which are not always easy to obtain.

Sn−H Functions

Next we analysed the reactivity of Sn−H functions in the given context. The reason for selecting stannanes as substrates was due to the fact that phosphane Co templates are known to form stable Co−Sn bonds.[3a] When solutions **A** were treated with Ph_3SnH, a slight colour change from red-brown to red was observed over a period of 12 hours. By chromatographic workup, the compound *tripod*$CoSnPh_3$ (**9**, Scheme 6), was isolated from the reaction mixture in yields of around 60%. **9** could also be obtained through the reaction of **2** with Ph_3SnLi. As an analogue of **9**, $(PMe_3)_3$-$CoSnPh_3$ [3a] has previously been prepared by Klein et al. by means of a salt metathesis reaction starting from $(PMe_3)_3CoCl$. The 16-electron d^8 compound **9** is paramagnetic, as expected for tetrahedral coordination. Its magnetic moment amounts to 3.2 μ_B, indicating the presence of two unpaired electrons. The UV/Vis/NIR spectrum of **9** (Table 7) exhibits features characteristic for compounds of the type *tripod*CoX[6] with one band at 950 nm (ε = 95) and a broad maximum at 1470 nm (ε = 170). In comparison with the spectrum of *tripod*CoCl {530 nm [ε = 120, sh], 826 nm [ε = 150], 1131 nm [ε = 430], 1224 nm [ε = 450]},[4] where the two long-wavelength bands are resolved into two individual maxima, the long-wavelength band of **9** must correspond to the envelope of two unresolved absorptions. The reaction of **2** with Ph_3SnLi could be monitored by UV/Vis/NIR spectroscopy. It was found that with the protocol described in the Experimental Section, the reaction is quantitative. Single crystals of **9** were obtained by layering THF solutions with petroleum ether (boiling range 40−60 °C).



Scheme 6

X-ray analysis confirmed the idealized tetrahedral coordination of the Co centre in **9** (Figure 5). The mutual arrangement of the three phenyl groups of the $SnPh_3$ ligand and the six phenyl groups of the *tripod* ligand appears to impose steric problems. One of the phenyl groups of the *tripod* ligand (C100−C105 at P1) and one of the phenyl groups of the $SnPh_3$ unit (C400−C405) show disorder with respect to their rotational positions about their P−C_{ipso} and Sn−C_{ipso} axes, respectively. The positions shown for these groups in Figure 5 correspond to the orientation that is adopted by 70% of the molecules within the crystal.

The fact that this disorder is seen for both of these rings to approximately the same extent (relative occupancies of 70:30) indicates that the rotational motions of the phenyl groups are strongly coupled. It would appear that this steric interference is mirrored in the position of the tin centre. For an undisturbed molecule of the type *tripod*CoX, the ligand

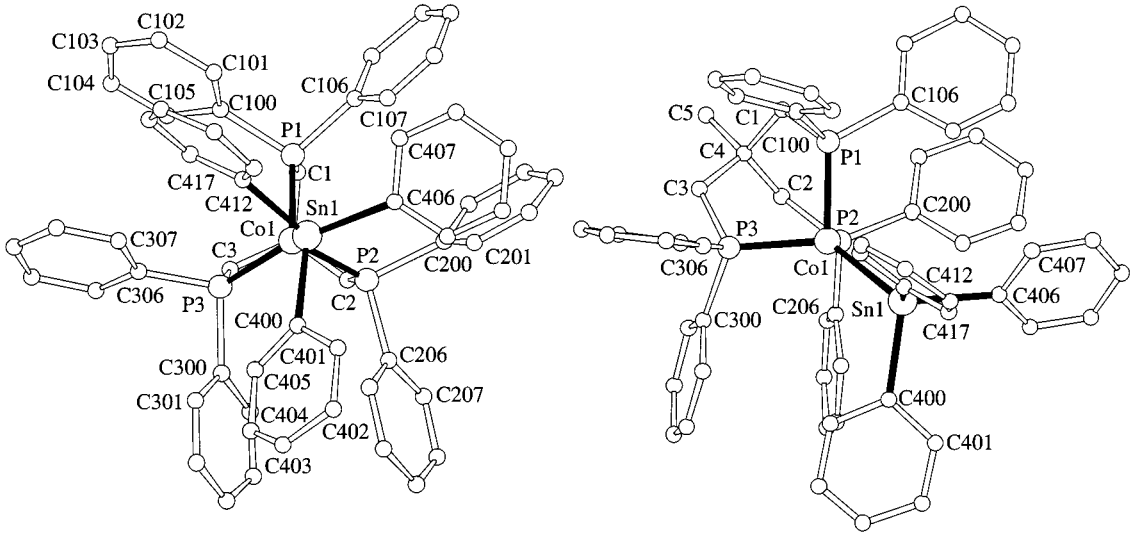


Figure 5. Structure of **9**: In the solid state the phenyl rings C100−C105 and C400−C405 are found to be disordered over two rotational positions in a 7:3 ratio; the major conformer is shown here; the left-hand figure corresponds to a projection of the structure onto the plane formed by the three *tripod* phosphorus donor atoms; the right-hand figure gives a general view of the compound

atom X would be expected to be located on the idealized trigonal axis of the P_3Co entity. This is indeed found for compounds such as *tripod*CoX (X = Cl,[4] Br,[6] NO[18]). In **9**, the tin centre shows a significant deviation from this coaxial position (Figure 5, left-hand side). The Co−P distances [219.6(3)−220.9(4) pm] are marginally shorter than those in *tripod*CoCl, **2** [224.2(3) pm][4] or $(PMe_3)_3CoSnPh_3$ [222(1) pm].[3a] The Co−Sn distance of 258.5(2) pm (Table 4) closely resembles that found in $(PMe_3)_3CoSnPh_3$ [259.0(2) pm].[3a]

In contrast to the reaction of Ph_3SnH with solution **A** [obtained by reduction of *tripod*$CoCl_2$ (**1**), with KC_8], which gives *tripod*$CoSnPh_3$, **9**, Bu_3SnH produces the dihydride compound *tripod*$Co(H)_2SnBu_3$, **10a** (Scheme 7).

[a] **10b** with X = H1, Y = H2. − [b] **11** with X = C6−O6. − [c] The torsion angles involving Hz at the bottom of the table are defined as follows: P−Hz designates a vector that is vertical with respect to the plane formed by the three *tripod* phosphorus donor atoms and points towards the observer when, in a projection onto this plane, the vector Co−C4 points away from the observer, such that C4 lies below this plane [1c] (see Figures 5−7). − [d] C_{ortho} refers to the C atom that points towards the observer when viewed along the Sn−Co axis.

10a was obtained in the form of a yellow-brown crystalline material in about 50% yield after chromatographic separation. In accordance with its formal Co^{III} oxidation state, it is a diamagnetic compound. Its ^1H NMR spectrum shows well-resolved signals in the appropriate integral ratios for all the organic groups (Table 5). The signal due to the Co-bonded hydrogens is observed at $\delta = -13.4$ with a relative intensity corresponding to two protons. This signal shows satellites induced by ^{119}Sn coupling with a coupling constant of 170 Hz, which is clearly too small for covalent Sn−H bonding (*cf.* Ph_3SnH: $^1J_{^{119}SnH} = 1900$ Hz), but rather indicates a secondary interaction of the metal-bonded hydrogen atoms with the tin nucleus.

For compounds involving this type of agostic interaction, coupling constants in the range 150−330 Hz[19] have been found to be characteristic. $^2J_{PH}$ coupling is not resolved at 200 MHz, the only effect of ^{31}P decoupling being a marginal reduction in the line width. The presence of Co−H bonds in **10a** is also indicated by infrared absorptions at 1948 and 1909 cm^{-1} (Table 7), the intensities of which are similar to those of the C−H vibrations at around 3000 cm^{-1}. This high relative intensity rules out the possible interpretation that these two bands might originate from a harmonic or combination vibration. The energy of the vibrations corresponds to energies reported for Co−H vibrations in other hydride compounds.[20] The appearance of two $\tilde{\nu}$(Co−H) absorptions corresponds to the symmetric and antisymmetric vibrations. The $^{31}P\{^1H\}$ NMR spectrum of **10a** shows a broad resonance at $\delta = 46$ (line width 380 Hz). The appearance of this signal does not change significantly on cooling to 193 K, the only effect being a reduction of the line width (105 Hz). Observations of this nature have occasionally been made with [*tripod*Co^{III}] derivatives in the past.[2e] From this observation, it is evident that − over the temperature range studied − the relative orientation of the *tripod* ligand with respect to the coligands is dynamic. The ^{119}Sn NMR spectrum of **10a** shows one signal at $\delta = 17.8$ (Table 5), in the typical range for metal−bonded SnR_3 groups.[19b]

Cyclic voltammograms show − rather unexpectedly at first glance − that **10a** is reversibly oxidized at $E_{1/2} = -390$ mV. Since the formal oxidation state of the cobalt in compound **10a** is +III, oxidation of the metal would imply the formation of Co^{IV}, which is highly improbable given the nature of the ligands present. A possible explanation for this finding is the hypothesis that oxidation of **10a** leads to oxidative coupling of its hydride ligands to produce a η^2-coordinated dihydrogen ligand (Scheme 8).

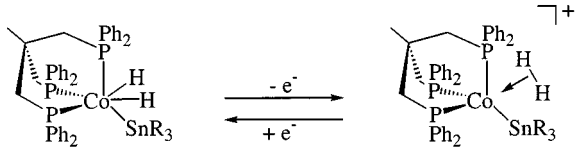
[a] The data for **10a** were collected on a Bruker Avance DRX 300 instrument at 300.130 MHz (^{1}H), 121.495 MHz (^{31}P{^{1}H}), 75.468 MHz (^{13}C{^{1}H}); ^{13}C{^{1}H} NMR spectroscopic data for **11** were measured on a Bruker Avance DRX 500 spectrometer at 125.758 MHz; all the other data refer to measurements on a Bruker Avance DPX 200 instrument. − [b] T = 178 K.



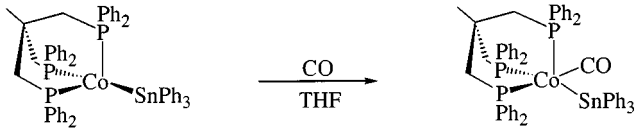
10a, b **B**

a: R = Bu
b: R = Ph

Scheme 8

In the 17-electron species **B** obtained after oxidation, cobalt is in its conventional +II oxidation state. Attempts to isolate **B** after oxidation of **10a** with ferrocenium salts have not yet been successful.

The fact that the 16-electron Co^{I} compound **9** and the 18-electron Co^{III} compound **10a** are both stable suggests that **9** should react with Lewis bases to form 18-electron Co^{I} compounds *tripod*CoSnPh$_3$L′.[21] This expectation is borne out by the reaction of **9** with carbon monoxide, which leads to the carbonyl derivative *tripod*Co(CO)SnPh$_3$ (**11**, Scheme 9).



9 **11**

Scheme 9

Solutions of **9** change their colour from red to orange-yellow after a few minutes of exposure to carbon monoxide. From such a solution, **11** was isolated in 70% yield as a microcrystalline orange powder. Crystals were obtained by vapour diffusion of diethyl ether into a dichloromethane solution (Figure 6, Table 4 and 8)

The coordination of the cobalt centre in **11** is intermediate between trigonal bipyramidal and square pyramidal, as is often observed for compounds of the type *tripod*CoLL′. Angles and distances fall within their normal ranges (Table 4).

Analytical data (Table 6 and 7) and the NMR spectra (Table 5) of **11** are in full agreement with its constitution. The ^{119}Sn resonance is observed at δ = −31.4. Only one ^{31}P signal is observed, in agreement with the usual dynamic behaviour of five-coordinate compounds. No change in the appearance of the ^{31}P{^{1}H} NMR signal in the temperature range 293−193 K is observed. In the IR spectrum, the carbonyl group gives rise to a strong absorption at ν(CO) = 1853 cm^{-1} (Table 7). The cyclic voltammogram shows that the Co^{I} species **11** is reversibly oxidized at $E_{1/2}$ = −140 mV, indicating the relative stability of the cationic Co^{II} species [*tripod*Co(CO)SnPh$_3$]$^+$.

The carbonyl addition reaction of **9** is analogous to the reaction of (PMe$_3$)$_3$CoSnPh$_3$ with CO.[3a] In contrast to the (PMe$_3$)$_3$Co template, for which prolonged exposure of (PMe$_3$)$_3$Co(CO)SnPh$_3$ to CO leads to substitution of PMe$_3$ by CO, producing (PMe$_3$)$_2$Co(CO)$_2$SnPh$_3$, the *tripod* metal template of **11** remains unaffected. Solutions of **11** may be kept under CO for hours without any noticeable decomposition.

Comparing **9** with **10a**, the most plausible "oxidant" should be the dihydrogen. When a THF solution of **9** was stirred under 1 bar of H$_2$, the red colour of **9** was replaced by the yellow colour of **10b** within six hours (Scheme 10).

After chromatography, **10b** was isolated as a yellow microcrystalline powder. The ^{1}H NMR resonance of the hydride groups is observed at δ = −13.2, and ^{119}Sn satellites ($^1J_{^{119}SnH}$ = 220 Hz) indicate agostic HSn interactions.[19] In the IR spectrum, bands corresponding to the Co−H vibrations[20] are found at 1903 and 1888 cm^{-1} (Table 7). The intensities of these bands are again comparable to that of the strongest band in the ν̃(C−H) vibration region. The

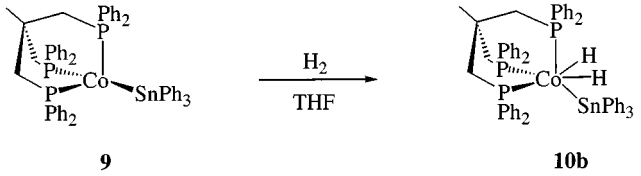
[a] All measurements were performed in CH_2Cl_2 solutions at scan speeds of 200 mVs^{-1}. – [b] Solvent: CH_2Cl_2. – [c] CsI. – [d] Solvent: THF. – [e] KBr.

$^{31}P\{^1H\}$ NMR spectrum of **10b** shows one signal at 298 K, which, in terms of its line width and shift, corresponds to that observed for **10a**. On cooling solutions of **10b** in CD_2Cl_2, the signal increases in intensity and starts to split into two components with an approximate ratio of 2:1 at 193 K. At 178 K, the lowest attainable temperature due to



9 **10b**

Scheme 10

solubility problems, the individual absorptions are not yet separated and the signals are still broad (line width = 170 Hz).[2e] The signal with a relative intensity of one is seen at $\delta = 47$, that corresponding to a relative intensity of two at $\delta = 44$. Resolution of the individual resonances of the phosphorus nuclei of coordinated *tripod* ligands has occasionally been observed and has also been quantitatively analysed in terms of the rotation of the *tripod*Co template relative to the co-ligands.[5] The splitting of the $^{31}P\{^1H\}$ NMR signal of **10b** into two components with relative intensities of 2:1 indicates that the rigid conformation observed at low temperatures should have approximate C_S symmetry. Like **10a**, the Co^{III} compound **10b** was found to be reversibly oxidized. Oxidation occurs at $E_{1/2} = -140$ mV and, by the same arguments as discussed for **10a**, it is assumed that the oxidation process is not metal-centred but transforms the hydride ligands into a coordinated dihydrogen ligand leading to a compound of type **B** (Scheme 8).

The structure of **10b** has been elucidated by single-crystal X-ray analysis (Figure 7, Table 4 and 8).

Crystals of **10b** were obtained of exposing THF solutions of **10b** to a vapour phase of petroleum ether (boiling range 40−60 °C) for several days. The conformation adopted by **10b** in the solid state (Figure 7) is close to mirror symmetric with respect to the bonds radiating from the cobalt and tin centres (Figure 7, left-hand side). The rotational positions of the phenyl rings at P2 and P3 are also close to being mirror symmetric, within a range of about 30° (see torsion angles in Table 4). The rotational positions of the phenyl groups at the $SnPh_3$ ligand also conform to this idealized mirror symmetry, with the phenyl group C412−C417 lying in the mirror plane and the two remaining phenyl groups lying in positions mirror symmetric to each other [the torsion angles $Co-Sn-C_x-C_{ortho}$ refer to the *ortho* carbons C401, C407, and C417, as shown in Figure 7. This selection follows the convention of measuring the rotational positions of aryl groups with respect to the *ortho* carbon atom that is closest to the observer with respect to the projection shown in Figure 7 (left-hand side). With the selection of torsion angles thus made, a mirror symmetric arrangement of the phenyl groups of C400, C406 is indicated by torsion angles of equal size and equal sign, as is indeed found (−97.5° and −101.0°, Table 4)].

The approximate mirror symmetry exhibited by **10b** in the solid state must correspond to a globally optimal conformation since $^{31}P\{^1H\}$ NMR spectroscopy (see above) shows that the low-temperature conformation of **10b** is in fact mirror symmetric.

The positions of the hydride ligands have been inferred from electron density maps and refined by least-squares methods. The Co−H distances are around 136 pm, with an H−Co−H angle of around 90° (Table 4). The distances of these hydride ligands from the tin centre are around 230 pm (Table 4), making them definitely too long for a conventional Sn−H bond. Their interaction with the tin nucleus is nevertheless apparent from the Sn−H coupling constant of 220 Hz (Table 5). In spite of the fact that the cobalt centre is six-coordinate in **10b**, its coordination geometry is not octahedral (Figure 7, right-hand side). While all the Co-centred angles involving a phosphorus and a hydrogen ligand are close to 90° (or 180°, respectively; see Table 4), the angles involving the tin centre deviate from the ideal octahedral values by 20−30° throughout (Table 4). With **10b** being a Co^{III} derivative, the expected coordination polyhedron would be an octahedron. Considering the wealth of information available concerning the structures of six-coordinate Co^{III} compounds, **10b** represents a rare

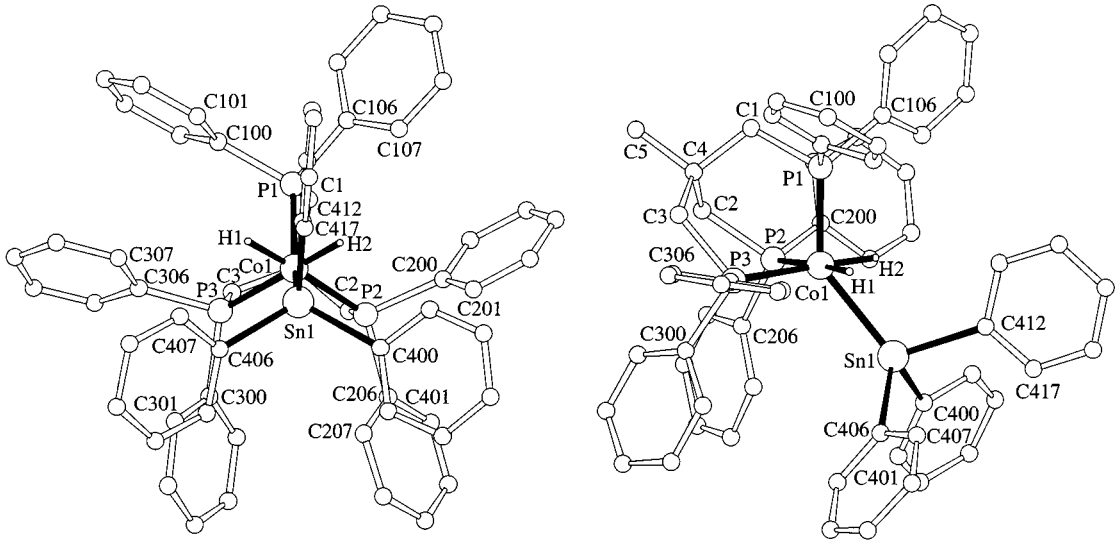


Figure 7. Structure of **10b**: The left-hand side diagram shows a projection of the structure onto the plane defined by the three *tripod* phosphorus donor atoms; the dummy vectors P_i-Hz_i in Table 4 refer to this view; the right-hand figure shows a general view of **10b**

example of a significant deviation from the prototype octahedral coordination. Figure 7 (right-hand side) suggests that steric factors alone cannot be responsible for this observation. It thus appears that the agostic interactions between the cobalt-bonded hydrogens and the cobalt−tin bond might be the driving force for the observed distortion.

Conclusion

Solutions obtained by reduction of *tripod*$CoCl_2$ (**1**) or *tripod*CoCl (**2**) with electropositive metals in THF are highly reactive. Upon reaction with $PhPH_2$, they produce the diphosphene derivative *tripod*Co(η^2-PhP=PPh) (**8**). With R_3SnH they form *tripod*$CoSnR_3$ (**9**) or *tripod*$Co(H)_2SnR_3$ (**10**). The paramagnetic Co^I species *tripod*$CoSnPh_3$ undergoes oxidative addition of H_2 to produce *tripod*$Co(H)_2SnPh_3$ (**10b**). The Co^{III} compound **10b** is unique in so far as it has a very distorted octahedral geometry that allows for agostic H−Sn interactions and in that it undergoes reversible one-electron oxidation, which is assumed to be ligand-centred, producing the Co^{II} species [*tripod*Co(η^2-H_2)$SnPh_3$]$^+$.

Experimental Section

General Remarks: Unless otherwise noted, all manipulations were carried out under argon using standard Schlenk techniques. All solvents were dried by standard methods and distilled under argon or dinitrogen.[22] For ultrasonic activation of reaction mixtures, a "Bender & Hobein, Laboson 200" ultrasonic bath was used. The solvents CD_2Cl_2 and $CDCl_3$ used for NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried with 4 Å molecular sieves. − NMR: Bruker Avance DPX 200 at 200.120 MHz (^{1}H), 50.323 MHz (^{13}C{^{1}H}), 81.015 MHz (^{31}P), and 74.631 MHz (^{119}Sn); T = 303 K unless stated otherwise; chemical shifts (δ) in ppm with respect to (residual protons in) CD_2Cl_2 (^{1}H: δ = 5.32; ^{13}C: δ = 53.80) and $CDCl_3$ (^{1}H: δ = 7.27; ^{13}C: δ = 77.00) as internal standards; ^{31}P chemical shifts (δ) in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0) as external standard. − IR: Bruker IFS-66; CsI or KBr discs or Nujol mulls. − EPR: Bruker ESP 300E (X-band, external standard diphenylpicrylhydrazyl). All measurements were made at 293 K and 100 K in a standard cavity ER 4102St. − Magnetic measurements: Faraday balance, Bruker B-E 15 C8 electromagnet, Bruker B-H 15 field controller, Sartorius M 25 D-S vacuum microbalance; calibration with $K_3[Fe(CN)_6]$. All measurements were carried out at 293 K. − UV/Vis/NIR: Perkin−Elmer Lambda 19. − Fast-atom bombardment (FAB) MS: Finnigan MAT 8230, xenon, matrix: 4-nitrobenzyl alcohol; electron impact (EI) MS: 70 eV. − Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. With the techniques used, problems arise with highly air- and temperature-sensitive compounds such as **9**, **10a**, and **10b** during the preparation of the test samples. The customary degree of accuracy is therefore not always attainable with these materials. The wet chemical analysis of phosphorus contents is occasionally disturbed by the presence of tin in the same sample. The corresponding analytical data will therefore also have higher margins of error. − Melting points: Gallenkamp MFB-595 010 apparatus; uncorrected values. − Cyclic voltammetry: Metrohm "Universal Meß- und Titriergefäß", Metrohm RDE 628 GC electrode, platinum electrode, SCE electrode, Princeton Applied Re-

search potentiostat model 273; samples 10^{-3} M in 0.1 M nBu_4NPF_6/CH_2Cl_2. Reactions described as reversible show a square-root dependence of current vs. scan speed in the range 50 to 1000 mVs^{-1}. All potentials are quoted relative to the saturated calomel electrode.

Materials: 1,1,1-Tris[(diphenylphosphanyl)methyl]ethane, *triphos*,[23] was prepared according to the literature procedure. All other materials were obtained from commercial sources and were used as received. Silica gel (Kieselgel z.A. 0.06−0.20 mm, J. T. Baker Chemicals B. V.) used for chromatography and kieselgur (Erg. B.6, Riedel de Haen AG) were degassed at 1 mbar for 24 h and saturated with argon.

General Procedure for the Synthesis of Solution A: A solution of **1**[4] (377 mg, 0.50 mmol) in THF (20 mL) was added to KC_8 (1.25 mmol), prepared by heating potassium (50 mg, 1.25 mmol) with graphite (120 mg, 10 mmol), and the suspension was sonicated until the colour changed to orange-brown. The reaction mixture was then filtered through kieselgur.

Synthesis of *tripod*Co(N_2)Co*tripod* (3): The following manipulations were carried out under a dry N_2 atmosphere:

Method a: A suspension of **2**[5] (359 mg, 0.50 mmol) in THF (20 mL) was added to KC_8 (1.50 mmol) and the mixture was sonicated until the colour turned to dark red. The supernatant reaction mixture was then removed from the insoluble material by means of a syringe. On layering this solution with petroleum ether (boiling range 40−60 °C), red crystals were obtained.

Method b: A solution of **1**[4] (377 mg, 0.50 mmol) in THF (20 mL) was added to activated Mg (2 g) (for activation: Mg filings were vigorously stirred in vacuo at 250 °C for 1 h) and the mixture was stirred until a dark-red colour developed. The supernatant reaction mixture was then removed from the unchanged Mg by means of a syringe. On layering this solution with petroleum ether (boiling range 40−60 °C), red crystals were obtained. − UV/Vis/NIR (THF): λ_{max} (ε) = 405 (8000), 718 (550), 1134 nm (4700 M^{-1} cm^{-1}). − Crystallographic data: see text.

Synthesis of [1,1-Bis(diphenylphosphanomethyl)-1-(phenylphosphanomethyl)]ethane (6): A solution of KO*t*Bu (689 mg, 6.14 mmol) and $PhPH_2$ (675 mg, 6.14 mmol) in DMSO (40 mL) was slowly added to a solution of 1-chloro-2-bis(diphenylphosphanylmethyl)propane (**5**)[10] (1.95 g, 4.10 mmol) in DMSO (30 mL). The reaction mixture was stirred for 4 h at 100 °C. The solvent was then removed in vacuo and the residue was purified by column chromatography on silica gel, eluting with petroleum ether (boiling range 40−60 °C)/diethyl ether, 9:1; R_f = 0.47. Yield: 1.84 g (3.35 mmol, 82%) as a colourless, viscous substance. − $C_{35}H_{35}P_3$ (548.58): calcd. C 76.63, H 6.43, P 16.94; found C 76.73, H 6.70, P 16.54. − ^{1}H NMR ($CDCl_3$): δ = 1.2 (br. s, 3 H, CH_3), 2.3 (br. s, 2 H, CH_2PHPh), 2.6 (br. s, 4 H, C$H_2$$PPh_2$), 4.0 (br. s, $^1J_{PH}$ = 204 Hz, 1 H, P*H*Ph), 6.9−7.9 (m, 25 H, arom. H). − ^{31}P NMR ($CDCl_3$): δ = −71.4 (d, $^1J_{PH}$ = 204 Hz, 1 P, PHPh), −26.8 (s, 2 P, PPh_2). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 29.3 (m, CH_3), 37.3−38.3 (m, *C*H_2PHPh, Cq), 43.1 (m, *C*$H_2$$PPh_2$), 128.0−140.6 (arom. C). − MS (EI); *m*/*z* (%): 547 (17) [M^+ − H], 471 (100) [M^+ − Ph], 363 (19) [M^+ − PPh_2]. − IR (Nujol): $\tilde{\nu}$(P−H) = 2282 (vs) cm^{-1}.

Synthesis of [*tripod*Co(NH_2)$_2$Co*tripod*](BPh_4)$_2$ (7): To a solution of **1**[4] (754 mg, 1.00 mmol) in THF (40 mL) (blue solution) were added $NaBPh_4$ (342 mg, 1.00 mmol) (solution turned red) and $NaNH_2$ (78 mg, 2.00 mmol). After the colour of the mixture had turned brown, the solvent was removed in vacuo. The residue was redissolved in CH_2Cl_2, this solution was filtered through 5 cm kieselgur, and the solvent was removed to leave 682 mg (0.67 mmol, 67%) of a brown powder. Recrystallization from acetone/diethyl ether yielded orange crystals suitable for X-ray structure analysis (see exp. Section, X-ray Crystallographic Study). − EPR (CH_2Cl_2, 295 K): g_1 = 2.11 (A_1 = 24 G); g_2 = 2.09 (A_2 = 28 G). − EPR (THF/CH_2Cl_2, 100 K): g_{av} = 2.11 (A = 34, 29 G). − For additional analytical data, see Table 6 and 7.

Synthesis of *tripod*Co(P_2Ph_2) (8). − Method a: At −60 °C, a solution of **1**[4] (566 mg, 0.75 mmol) in THF (30 mL) was added to a solution of PhPHLi [24b] (1.65 mmol), prepared by adding *n*BuLi (0.66 mL, 2.5 M in hexane) to a solution of $PhPH_2$ (182 mg, 0.18 mL, 1.65 mmol) in THF (20 mL). The colour changed from blue to red and the mixture was stirred for 30 min. at room temperature. The solvent was then removed in vacuo, and the residue was suspended in petroleum ether (boiling range 40−60 °C) and flash chromatographed on silica gel. After elution with 200 mL of petroleum ether (boiling range 40−60 °C), the product was eluted with diethyl ether as a red band, removal of the solvent from which gave 485 mg (0.54 mmol, 72%) of a microcrystalline powder. Red crystals, suitable for X-ray structure analysis, were obtained by layering a saturated acetone solution with ethanol and petroleum ether (boiling range 40−60 °C).

Method b: To solution **A**, prepared from **1**[4] (0.50 mmol) and KC_8 (1.25 mmol) (see above), was added $PhPH_2$ (170 mg, 0.17 mL, 1.54 mmol). After stirring for 2 h, the colour had changed to red and the solvent was removed in vacuo. The residue was taken up in petroleum ether (boiling range 40−60 °C). Chromatographic workup as described above gave 198 mg (0.22 mmol, 44%) of **8**.

Method c: A modification of Method a, starting from **1**[4] (566 mg, 0.75 mmol) and PhPHNa [24a] (1.65 mmol) [prepared by adding Na (38 mg, 1.65 mmol) to a solution of $PhPH_2$ (182 mg, 0.18 mL, 1.65 mmol) in THF (20 mL) and sonicating until the Na had dissolved] gave 472 mg (0.53 mmol, 70%) of compound **8**.

Method d: In a further modification of Method a, **8** was prepared starting from **2**[5] (359 mg, 0.50 mmol) suspended in THF (25 mL) and a solution of PhPHLi [24b] or PhPHNa[24a] (1.10 mmol) in THF (20 mL). Yield: 270 mg (0.30 mmol, 60%). − For analytical data, see Table 6 and 7.

Synthesis of *tripod*CoSnPh_3 (9). − Method a: A suspension of **2**[5] (359 mg, 0.50 mmol) in THF (15 mL) was added to a THF solution of Ph_3SnLi[25] (0.90 mmol), prepared by adding *n*BuLi (0.36 mL, 2.5 M in toluene) to a solution of Ph_3SnH (315 mg, 0.90 mmol) in THF (15 mL). The initially brown suspension turned red and the reaction mixture was stirred overnight. After removal of the solvent, the residue was suspended in petroleum ether (boiling range 40−60 °C) and flash chromatographed on silica gel. After elution with 200 mL of petroleum ether (boiling range 40−60 °C), the product was eluted with diethyl ether as a red band, removal of the solvent from which gave 340 mg (0.33 mmol, 66%) of a red microcrystalline powder. Red crystals, suitable for X-ray structural analysis, were obtained by layering a saturated THF solution with petroleum ether (boiling range 40−60 °C).

Method b: Compound **9** was prepared by adding Ph_3SnH (895 mg, 2.55 mmol) to solution **A**, prepared from **1**[4] (0.85 mmol) and KC_8 (2.13 mmol) (see above), and stirring overnight. Chromatographic workup (as described above) yielded 540 mg (0.52 mmol, 61%) of **9**. − For analytical data, see Table 6 and 7.

Synthesis of *tripod*Co($H)_2SnBu_3$ (10a): To solution **A**, prepared from **1**[4] (0.85 mmol) and KC_8 (2.13 mmol) (see above), was added

Bu_3SnH (745 mg, 0.68 mL, 2.56 mmol). After stirring overnight, the solvent was removed in vacuo. The residue was suspended in petroleum ether (boiling range 40−60 °C). Chromatographic workup (as described for compound **9**) gave 410 mg (0.42 mmol, 50%) of a yellow-brown microcrystalline solid. Recrystallization from acetone at −20 °C afforded 210 mg (0.22 mmol, 25%) as yellow crystals. − For analytical data, see Table 6 and 7.

Synthesis of *tripod*Co(H)$_2$SnPh$_3$ (10b): A solution of **9** (620 mg, 0.60 mmol) in THF (30 mL) was saturated with H_2 at 1 bar and stirred for 6 h. The red colour of the reaction mixture turned yellow. After removal of the solvent, the residue was suspended in petroleum ether (boiling range 40−60 °C). Chromatographic workup (as described for compound **9**) gave upon removal of the solvent 420 mg (0.41 mmol, 68%) of a yellow microcrystalline powder. A concentrated THF solution was distributed between several test tubes (Ø = 1 cm), which were placed in a Schlenk tube (250 mL). Petroleum ether (boiling range 40−60 °C) was introduced into the Schlenk tube, vapour diffusion of which into the THF solutions yielded yellow single crystals suitable for X-ray structure analysis. − For analytical data, see Table 6 and 7.

Synthesis of *tripod*Co(CO)SnPh$_3$ (11): CO was bubbled through a solution of **9** (620 mg, 0.60 mmol) in THF (30 mL) for 10 min. The red colour of the solution turned orange. The solvent was then removed in vacuo, the residue was suspended in petroleum ether (boiling range 40−60 °C), and chromatographed on kieselgur. After elution with 200 mL of petroleum ether (boiling range 40−60 °C), the orange product was eluted with toluene. Removal of the solvent in vacuo from the appropriate fraction gave 445 mg (0.42 mmol, 70%) of **11** as an orange microcrystalline solid. A concentrated dichloromethane solution was distributed between several test tubes (Ø = 1 cm), which were placed in a Schlenk tube (250 mL). Diethyl ether was introduced into the Schlenk tube, vapour diffusion of which into the CH_2Cl_2 solutions yielded orange single crystals suitable for X-ray structure analysis. − For analytical data, see Table 6 and 7.

X-ray Crystallographic Study: Measurements were made on a Siemens P4 four-circle diffractometer (**7**, **9**) or on a Nonius-Kappa CCD diffractometer (**4**, **8**, **10b**, **11**) using graphite-monochromated Mo-K_α radiation throughout. For the measurements on the Siemens P4 four-circle diffractometer, the intensities of three check reflections (measured every 100 reflections) remained constant throughout the data collection, thus indicating crystal and electronic stability. The data collected on the Siemens P4 diffractometer were corrected in the usual manner, including by an experimental absorption correction. The data collected on the Nonius Kappa CCD device were processed using the standard Nonius software.[26] All calculations were performed using the SHELXT-PLUS software package. Structures were solved by direct methods with the SHELXS-97 program and refined with the SHELXL-97 program.[27,28] Graphical handling of the structural data during solution and refinement was performed with XPMA.[29] Structural representations were generated using Winray 32.[30] Atomic coordinates and anisotropic thermal parameters of nonhydrogen atoms were refined by full-matrix least-squares calculations. The data relating to the structure determinations are compiled in Table 8. Compound **7**: The nitrogens of the amido groups are disordered over two positions with s.o.f.s of 0.75 and 0.25. The acetone solvent molecules were found to be distributed over four sites with s.o.f.s of 0.5, 0.4, 0.35, and 0.25. The disordered atoms were refined isotropically. Due to these disorder problems, the refinement converged only to $R_1 = 9.0\%$ and $R_2 = 26.6\%$, hence discussion of the bond lengths and angles is omitted. Compound **9**: One phenyl ring (C100−C105) was found to be disordered over two orthogonal orientations with s.o.f.s of 0.7 and 0.3. These atoms were refined isotropically. One phenyl ring of the $SnPh_3$ ligand (C400−C405) was found to be disordered over two rotational positions with s.o.f.s of 0.6 and 0.4. The angle between the orientations is 40°. Compound **10b**: The crystal of **10b** examined was found to be a racemic twin, the Flack *x* parameter being 0.267. The metal-bonded hydrogens H1 and H2 were located in the difference map and refined isotropically.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-143127 (**4**), CCDC-143131 (**7**), CCDC-143130 (**8**), CCDC-143129 (**9**), CCDC-143126 (**10b**), and CCDC-143128 (**11**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and X-ray Structure of Metalated Rhodium(II) Catalysts with a Chiral Phospholane

Francisco Estevan,[a] Peter Krueger,[b] Pascual Lahuerta,*[a] Eduardo Moreno,[a] Julia Pérez-Prieto,*[c] Mercedes Sanaú,[a] and Helmut Werner*[b]

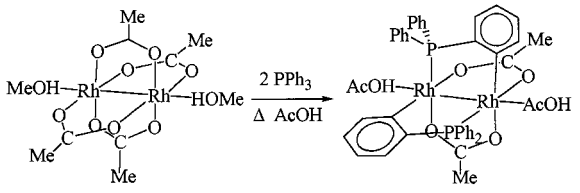
Dedicated to Professor R. Uson on the occasion of his 75th birthday

Keywords: Carbocycles / Chirality / Diazo compounds / P ligands / Rhodium

The reaction of $Rh_2(O_2CR)_4$ (R = CH_3, CF_3) with the chiral phosphane (2*S*,5*S*)-2,5-dimethyl-1-phenylphospholane (PC* H), results in the formation of two diastereoisomers of $Rh_2(O_2CCR)_2(PC^*)_2$, with (*P*) and (*M*) configuration. These can easily be isolated by chromatographic methods to obtain enantiomerically pure Rh^{II} compounds. Preliminary catalytic studies have shown that they induce moderate asymmetry in the cyclization of 5-aryl-1-diazo-2-pentanones and 1-diazo-5-hexen-2-one. X-ray analysis of the (*M*) diastereoisomer with formula $Rh_2(O_2CCCH_3)_2(PC^*)_2$ is reported. The crystallographic parameters are as follows: space group $P2_12_12$ (orthorhombic) with *a* = 12.1347(11) Å, *b* = 14.5870(13) Å, *c* = 9.8171(9) Å.

Introduction

After the first report that the reaction of rhodium acetate and triphenylphosphane readily forms the bis(cyclometalated) compound $Rh_2(O_2CCH_3)_2[(C_6H_4)PPh_2]_2$,[1] it has been confirmed that this reaction can be extended to other rhodium carboxylates and to other arylphosphanes,[2−4] yielding the homologous metalated compounds $Rh_2(O_2CR)_2(PC)_2$, (PC = metalated phosphane; R = CH_3, CF_3; Scheme 1). Kinetic studies confirmed that the cyclometalation reaction was catalysed by protic acids.[5]



Scheme 1. *ortho*-Metalation reactions in binuclear dirhodium compounds

Different transition-metal compounds have been used as catalysts in the transformation of α-diazocarbonyl compounds, but the compounds of rhodium(II) have shown general utility.[6] We have reported that the bis(cyclometalated) complexes $Rh_2(O_2CR)_2(PC)_2$, exhibit excellent chemoselectivity in the catalytic intramolecular C−H insertion reactions of α-diazo compounds, where this reaction is competing with aromatic substitution.[7] In these compounds, the presence of two different ligands, the metalated phosphane and the carboxylate, allowed for a modulation of the electronic and steric properties of the catalyst which influence the activity and selectivity of the catalytic reactions.

Many efforts have been devoted to obtain chiral rhodium(II) complexes suitable for asymmetric induction in carbene transfer reactions. In this context, great success has been achieved by using rhodium(II) compounds having four chiral carboxylates[8] or amidate groups[9] as bridging ligands. As the bis(cyclometalated) complexes $Rh_2(O_2CR)_2(PC)_2$ with head-to-tail arrangement are inherently chiral, we have recently reported the isolation of the pure enantiomers [see (*P*) and (*M*) notation in Scheme 2]

resulting from the metalation of PPh_3.[10] These enantiomers induced identical enantiomeric control, but with opposite *ee* values (36% *ee*; 70% yield), in the C−H insertion reaction of 1-diazo-5-phenyl-2-pentanone.

An alternative and previously unused approach to the preparation of chiral bis(cyclometalated) rhodium(II) compounds, is by the reaction of rhodium(II) carboxylates with a chiral $PhPR_2$* phosphane. Owing to the inherent chirality of $Rh_2(O_2CR)_2(PC)_2$ dimers,[10] this process would result in the formation of two diastereoisomers, which could be isolated to perform catalytic assays. Furthermore, since bis(cyclometalated) compounds having basic phosphanes have proved to be reactive and selective in carbene transfer reactions,[7] our primary objective was the generation of new, enantiomerically pure, cyclometalated rhodium(II) derivatives with chiral, electron-rich phospholanes[5] as ligands.

We describe in this paper the synthesis of several cyclometalated rhodium(II) compounds resulting from the reaction of rhodium acetate or rhodium trifluoroacetate and (2*S*,5*S*)-2,5-dimethyl-1-phenylphospholane (PC*H). The crystal structure of one of the isolated diastereoisomers of formula $Rh_2(O_2CCH_3)_2(PC^*)_2 \cdot 2\,CH_3CO_2H$ is also reported. Their utility in asymmetric induction has been studied in C−H insertion and cyclopropanation reactions of model diazo ketones. The observed enantioselectivities, though moderate, compare favourably with those obtained for other types of chiral rhodium(II) complexes[11,12] and reveal the great potential of these compounds in asymmetric catalysis.

Results and Discussion

Rhodium(II) acetate and (2*S*,5*S*)-2,5-dimethyl-1-phenylphospholane (molar ratio 1:2.2) were heated at reflux in a mixture of toluene and acetic acid (3:1). The reaction was considerably slow and did not go to completion even after 33 h. From this reaction mixture, three new compounds were isolated by column chromatography: the monometalated compound $Rh_2(O_2CCH_3)_3(PC^*)$ (**1**) (43%) and the two diastereoisomers $Rh_2(O_2CCH_3)_2(PC^*)_2$ [(*P*) isomer] (**2**) (23%) and $Rh_2(O_2CCH_3)_2(PC^*)_2$ [(*M*) isomer] (**3**) (13%).

These compounds exchange the carboxylate groups upon treatment with trifluoroacetic acid, to form the corresponding trifluoroacetate derivatives $Rh_2(O_2CCF_3)_3(PC^*)$ (**4**), $Rh_2(O_2CCF_3)_2(PC^*)_2$ [(*P*) isomer] (**5**), and $Rh_2(O_2CCF_3)_2(PC^*)_2$ [(*M*) isomer] (**6**) (Scheme 2).

The reaction of rhodium(II) trifluoroacetate and the phospholane was considerably faster and, after 16 h at room temperature in CH_2Cl_2 solution, the two bismetalated compounds **5** (32%) and **6** (14%) were formed. Under these conditions, the monometalated compound **4** was not detected in solution.

Crystal Structure of 3

A schematic drawing of the structure of compound **3** together with selected bond lengths and angles, is presented in Figure 1. In the dinuclear complex **3**, the two rhodium atoms are bridged by two acetate groups and by two phospholane molecules metalated at the phenyl ring; two oxygen atoms of two acetic acid molecules occupying the axial positions, complete the slightly distorted octahedral coordination (bond angles in the range 83.00−93.90 Å) around the metal centres. As observed in all the related compounds, each of these acetic acid molecules undergoes an O···H−O interaction with one oxygen atom of each bridging acetate group. The value of the Rh−Rh bond length 2.5036(6) Å falls within the range reported for dirhodium compounds of comparable structure.[13]

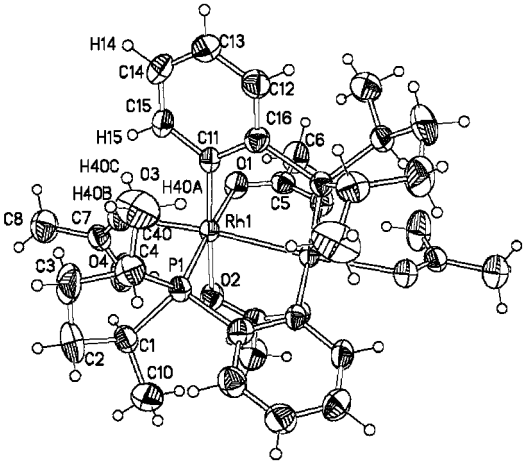

Figure 1. ORTEP diagram of the complex (*M*)-**3**·$(HO_2CCH_3)_2$; selected bond lengths [A] and angles [°]: Rh1−Rh1A 2.5036(6), Rh1−C16 1.992(4), Rh1−O2 2.196(2), Rh1−O3 2.370(3), Rh1−O1 2.139(2), Rh1−P1 2.2187(10); C16−Rh1−O1 89.45(12), O1−Rh1−O2 83.00(10), O1−Rh1−P1 175.15(8), C16−Rh1−O3 94.59(12), C16−Rh1−O2 172.43(12), P1−Rh1−O3 93.90(7)

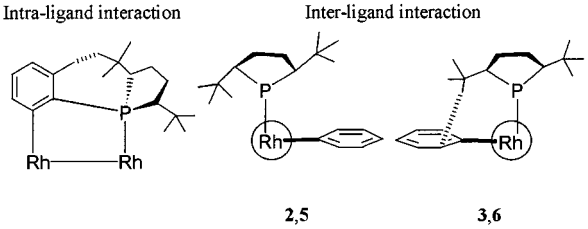
The crystal structure determination confirmed that compound **3** has the (*M*) configuration. Consequently, compound **6** will have the same configuration while compounds **2** and **5** must have the (*P*) configuration (Scheme 2). An interesting feature in compound **3** is that the methyl group attached to C1 of the phospholane ring is oriented toward the metalated phenyl ring of the same phosphane ligand (intra-ligand interaction), while the methyl group attached to C4 points towards the metalated phenyl ring of the other phosphane (inter-ligand interaction). A simple molecular model built for compound **2** (or **5**) shows that for the (*P*) configuration only the intra-ligand interaction can be generated as is shown in Scheme 3.



Scheme 3. Model of inter- and intra-ligand interactions in compounds **2**, **3**, **5**, **6**

Spectroscopic Data

All the new compounds were characterised by ^1H, ^{13}C, and ^{31}P NMR spectroscopy. The ^{31}P NMR spectrum of

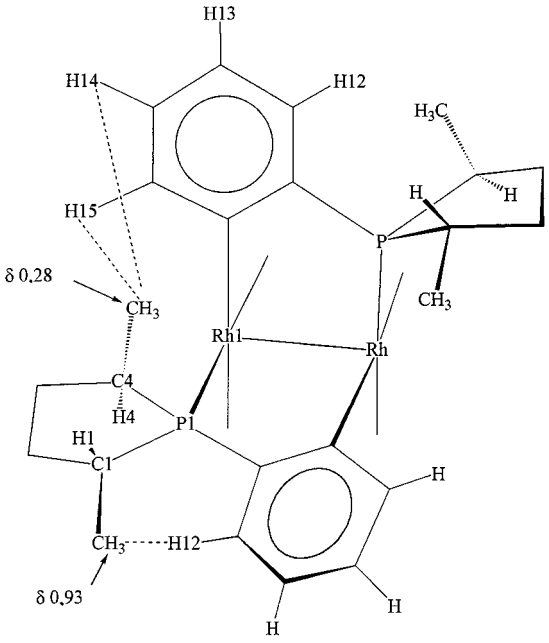
compound **1**, with only one metalated phosphane ligand, displays a characteristic doublet of doublets due to the coupling to both rhodium nuclei ($\delta = 35.9$; $^1J_{RhP} = 152$ Hz, $^2J_{RhP} = 3$ Hz). In contrast, the bis(cyclometalated) compounds show a multiplet corresponding to the AA′ part of an AA′XX′ system at lower chemical shift values ($\delta = 27.4$ and 28.3). As expected, the three acetate groups of compound **1** are magnetically different and this is reflected in the ^{1}H and ^{13}C NMR spectroscopic data.

The molecules of compound **3** have a crystallographic C_2 symmetry axis. This symmetry is apparently retained in solution as the four methyl groups of the phospholane ligands are equivalent in the ^{1}H NMR spectrum in a pairwise manner. These two signals are of equal intensity and integrate as 6 H each. They appear as doublets of doublets, showing coupling to one proton and to the phosphorus atom. The other three bis(cyclometalated) compounds show a similar pattern of signals for the phospholane ligands. The difference in chemical shift values for the methyl groups of the phospholane ligands is relatively small ($\delta \approx 0.6$) for compounds **2** and **5** but it is larger for complexes **3** and **6** ($\delta \approx 1.2$). This can be attributed to the different environments of the methyl groups in the (*P*) and (*M*) configurations and also to the possible H···H interactions (Scheme 3).

A careful NMR spectroscopy study carried out for compounds **5** and **6** confirmed that the supposed H···H interactions (see above) also occur in solution. The ^{1}H NMR spectrum of **6** displays three multiplet signals in the aromatic region which, based on COSY experiments, were assigned as following: $\delta = 6.85$ (H^{12}), 6.95 (H^{13} and H^{14}), and 7.56 (H^{15}). The signals at $\delta = 0.28$ and 0.93 were assigned to the methyl groups of the phospholane and appeared as very characteristic doublets of doublets owing to the coupling to the phosphorus atom and to the H^1 and H^4 protons whose signals appeared as multiplets at $\delta = 2.86$ and 2.33 , respectively. The assignment of these signals was made with an NOE experiment.

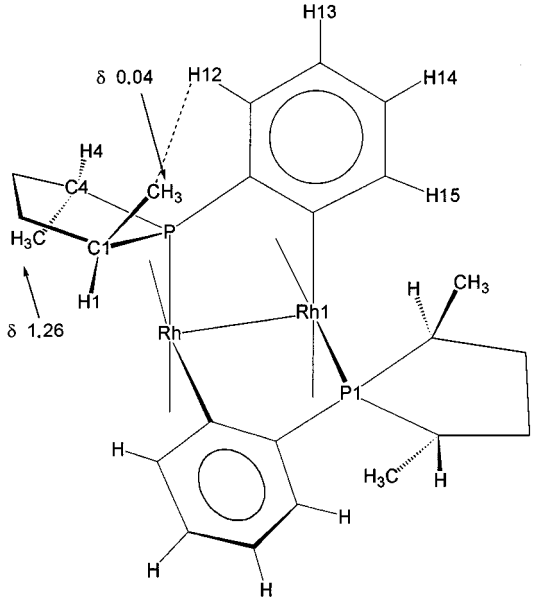
Irradiation of the methyl resonance at $\delta = 0.93$ led to an enhancement of the signal at $\delta = 2.86$, assigned to H^1, and also of the signal at $\delta = 6.85$ (Scheme 4). This is in agreement with an intra-ligand interaction between H^{12} and the protons of the methyl group attached to C^1. Irradiation of the methyl signal at $\delta = 0.28$ resulted in an enhancement of the intensity of the signal at $\delta = 2.33$, assigned to H^4, and also of the signals at $\delta = 6.95$ and 7.56. This result supports the interaction between the protons of the methyl group attached to C^4 and two aromatic protons, H^{15} and probably H^{14}.

Different results were obtained when this experiment was performed with isomer **5**. The ^{1}H NMR spectrum of **5** displays four signals in the aromatic region which, based on COSY experiments, were assigned as follows: $\delta = 6.74$ (H^{12}), 6.86 (H^{13}), 6.98 (H^{14}), 7.57 (H^{15}). We use the same labelling scheme as in compound **6** to identify the hydrogen atoms in compound **5**. The signals at $\delta = 0.04$ and 1.26 were assigned to the methyl groups of the phospholane and appeared again doublets of doublets. The protons H^1 and H^4 gave rise to a broad signal at $\delta = 2.37$.



Scheme 4. NOE experiment for compound **6**

In an NOE experiment (Scheme 5), irradiation of the methyl signal at $\delta = 0.04$ led to an enhancement of the intensity of the signal at $\delta = 2.37$, due to an interaction with H^1, and to that of the signal at $\delta = 6.74$. This result is indicative of an interaction between the protons of the methyl group attached to C^1 and the aromatic proton H^{12}. Irradiation of the methyl resonance at $\delta = 1.26$ gave only an enhancement of the signal at $\delta = 2.37$, due to an interaction with H^4, but not of any other signal in the aromatic region. These results support the *P*-configuration of compound **5**.



Scheme 5. NOE experiment for compound **5**

Exploratory Catalytic Studies

1-Diazo-2-alkanones were prepared from the corresponding acid by reaction with ethyl chloroformate, followed by treatment with freshly prepared diazomethane.

Catalytic reactions were performed by the addition of the rhodium(II) complex (1 mol-%) to an anhydrous dichloromethane solution containing the diazo compound; the reaction mixture was heated at reflux for 1 h. After cooling, the solution was filtered through a short plug of silica gel to remove the catalyst, and the solvent was evaporated under reduced pressure. The residue was analysed by ^1H and ^{13}C NMR spectroscopy.

We mainly studied the ability of the diastereoisomers (*P*)-**5** and (*M*)-**6** to induce a C−H insertion reaction of diazo compounds **7** (Scheme 6). Complex (*M*)-**6** catalysed the cyclisation of **7** with high yield but only a small variation in enantiomeric control was observed by the introduction of electron-withdrawing or electron-donating groups on the benzene ring of the organic substrate (Scheme 6). It is worth mentioning that although the enantiomeric control offered by these rhodium(II) compounds was modest, complexes containing chiral carboxamidates catalyse intramolecular aliphatic C−H insertion of 1-diazo-2-alkanones with practically no asymmetric induction.[11] Surprisingly, in the case of (*P*)-**5**, the diazo compounds **7** were recovered unchanged after several hours of heating in the presence of the rhodium catalyst.

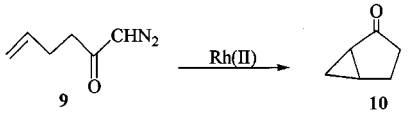
X = OCH_3	80	37

Scheme 6. C−H insertion of 1-diazo-5-aryl-2-pentanones

Both diastereoisomers (*M*)-**6** and (*P*)-**5** were able to transform the 1-diazo ketone **9** in high yield, but the sense and extent of the enantiotopic selection were different (Scheme 7). It is interesting to note that low enantiomeric control has been achieved in the intramolecular cyclopropanation of this type of diazo compound catalysed by chiral rhodium(II) carboxamides.[14] In particular, the cyclisation of the diazo ketone **9** using those catalysts have only provided levels of enantiomeric control in the 3−23% *ee* range.[12]



9 10

	Yield (%)	% ee[15]

Rh_2(carboxamidates)$_4$[12]	50-94	3-23	

Scheme 7. Cyclopropanation of 1-diazo-5-hexen-2-one

Conclusion

In summary, we explored the synthesis of chiral bis(cyclometalated) rhodium(II) compounds based on the use of a chiral phosphane. The reaction of dirhodium carboxylates with (2*S*,5*S*)-2,5-dimethyl-1-phenylphospholane led to two types of dimers with different environments around the Rh centre. Diastereoisomers were easily isolated by chromatographic methods. Preliminary catalytic studies showed their different efficiencies in inducing asymmetry in the cyclisation of model 1-diazo carbonyl compounds. The level of enantiomeric control, although moderate, is promising since other rhodium(II) catalysts have shown less selectivity in the transformation of this type of diazo compound. The availability of other chiral 2,5-disubstituted phospholanes[18] can allow further studies to determine the influence of the electronic and steric effects of the phosphane ligand on the reactivity and selectivity of these new chiral rhodium(II) catalysts.

Experimental Section

All reactions were carried out under argon, using standard Schlenk techniques. $Rh_2(O_2CCF_3)_4$ was prepared by literature procedures.[19] Other starting materials (besides the phospholane) were commercially available and used as received. Solvents were degassed and used without further purification. − NMR spectra were recorded with Bruker AC-200 and Varian Unity-300 spectrometers. Chemical shifts (δ values) are given relative to TMS (^1H, ^{13}C), and to 85% H_3PO_4 aqueous solution (^{31}P). Coupling constants (*J*) are given in Hertz.

Preparation of (2*S*,5*S*)-2,5-Dimethyl-1-phenylphospholane: This ligand was prepared according to literature procedures.[18]

Synthesis of Acetate Complexes 1−3: $Rh_2(O_2CCH_3)_4$ (206 mg, 0.433 mmol) and (2*S*,5*S*)-2,5-dimethyl-1-phenylphospholane (183 mg, 0.952 mmol) were heated at reflux in a mixture of toluene/acetic acid (6 mL, 3:1) for 33 h. After cooling, the solvent was evaporated under reduced pressure and the resulting violet solid was dissolved in CH_2Cl_2.The solution was purified by chromatography on silica gel. Elution with CH_2Cl_2/ether/acetone (50:10:1) separated a dark blue band from a green band. The blue band was collected and the solvent was evaporated. Crystallisation of the residue from acetone/hexane gave $Rh_2(O_2CCH_3)_3$(PC) (**1**) as a dark blue solid. Yield 115 mg (43%). − ^1H NMR ($CDCl_3$): δ = 0.63 (dd, J_{PH} = 13.8, J_{HH} = 6.8, 3 H, CH_3 ring), 1.03 (dd, J_{PH} = 15.6, J_{HH} = 6.9, 3 H, CH_3 ring), 1.71 (s, 3 H, CH_3 *cis*), 1.78 (s, 3 H, CH_3 *cis*), 2.11 (s, 3 H, CH_3 *trans*), 1.20−2.90 (m, 6 H, CH_2, CH ring), 6.60−9.00 (m, 4 H, C_6H_4). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 35.9 (dd, $^1J_{RhP}$ = 152, $^2J_{RhP}$ = 3). − The green band was redissolved in CH_2Cl_2.The solution was chromatographed on silica gel. Elution with CH_2Cl_2/acetone (5:1) led to a separation into two green bands. The green solutions were concentrated to dryness and dissolved in acetone. Addition of hexane precipitated green solids, which were dried in vacuum.

Fraction 1: Compound **2** [(*P*) isomer], 75 mg (23%). − ^1H NMR ($CDCl_3$): δ = 0.04 (dd, J_{PH} = 14.3, J_{HH} = 7.0, 6 H, CH_3 ring), 1.21 (dd, J_{PH} = 15.5, J_{HH} = 7.0, 6 H, CH_3 ring), 1.40−3.00 (m, 12 H, CH_2, CH ring), 2.15−2.25 (s, 6 H, CH_3COO) 6.70−7.52 (m, 8 H, C_6H_4). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 27.9 (AA′XX′ system).

Fraction 2: Compound **3** [(*M*) isomer], 41 mg (13%). – ^{1}H NMR ($CDCl_3$): δ = 0.33 (dd, J_{PH} = 15.1, J_{HH} = 7.1, 6 H, CH_3 ring), 0.97 (dd, J_{PH} = 13.6, J_{HH} = 6.9, 6 H, CH_3 ring), 1.40−3.00 (m, 12 H, CH_2, CH ring), 2.07−2.2 (s, 6 H, CH_3CO_2) 6.80−7.00 (m, 6 H, C_6H_4), 7.58 (dd J = 5.2, J = 2.7 2 H, C_6H_4). – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 27.4 (AA′XX′ system).

Synthesis of Trifluoroacetate Derivative 4: $Rh_2(O_2CCH_3)_3(PC)$ (**1**) (58 mg, 0.1 mmol) was dissolved in CH_2Cl_2 and after trifluoroacetic acid (0.77 mL, 10 mmol) was added, the solution was stirred for 2 h. The solvent was removed under vacuum and the crude solid was dissolved in CH_2Cl_2 (1 mL).The solution was purified by chromatography on silica gel. Elution with CH_2Cl_2 gave a blue band from which a blue solid was obtained after evaporation of the solvent. – ^{1}H NMR ($CDCl_3$): δ = 0.60 (dd, J_{PH} = 15.8, J_{HH} = 6.6, 3 H, CH_3 ring), 1.22 (dd, J_{PH} = 16.6, J_{HH} = 6.9, 3 H, CH_3 ring), 0.94−2.80 (m, 6 H, CH_2, CH ring), 6.98−8.53 (m, 4 H, C_6H_4). – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 36.3 (dd, $^1J_{RhP}$ = 141, $^2J_{RhP}$ = 4).

Synthesis of Trifluoroacetate Derivatives 5 and 6: $Rh_2(O_2CCF_3)_4$ (100 mg, 0.21 mmol) and (2*S*,5*S*)-2,5-dimethyl-1-phenylphospholane (188 mg, 0.46 mmol) were stirred in CH_2Cl_2 (6 mL) for 16 h. The solvent was evaporated under reduced pressure and the resulting violet solid was worked up as described for the acetate derivatives **2** and **3**.

Compound 5 [(*P*) Isomer]: 116 mg (32%). – ^{1}H NMR ($CDCl_3$): δ = 0.04 (dd, J_{PH} = 15.5, J_{HH} = 7.0, 6 H, CH_3 ring), 1.26 (dd, J_{PH} = 16.0, J_{HH} = 6.2, 6 H, CH_3 ring), 0.80−2.50 (m, 12 H, CH_2, CH ring), 6.74 (t, J = 7.7, 2 H, C_6H_4), 6.86 (t, J = 7.4, 2 H, C_6H_4), 6.98 (t, J = 7.5, 2 H, C_6H_4), 7.58 (dd J = 7.9, J = 3.6, 2 H, C_6H_4). – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 29.1 (AA′XX′ system).

Compound 6 [(*M*] Isomer]: 48 mg (14%). – $[\alpha]_D$ = +423 (c = 0.04, $CHCl_3$). – ^{1}H NMR ($CDCl_3$): δ = 0.28 (dd, J_{PH} = 15.4, J_{HH} = 7.2, 6 H, CH_3 ring), 0.93 (dd, J_{PH} = 15.5, J_{HH} = 8.5, 6 H, CH_3 ring), 1.4−3.00 (m, 12 H, CH_2, CH ring), 6.85 (m, 2 H, aromatic H), 6.95 (m, 4 H, aromatic H), 7.56 (m, 2 H, aromatic H). – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 27.4 (AA′XX′ system).

Crystallographic Data Collection and Refinement of the Structure: A Siemens SMART CCD diffractometer was used for data collection on crystals of the compound. Unit-cell dimensions were determined by a least fit of 50 reflections, ($2.07° < \theta < 23.32°$) The crystal structure determination was done by direct methods, using SHELXTL V 5.05;[20] the refinement on F^2 was done using all reflections. The positions of all non-hydrogen atoms were deduced from difference Fourier maps and were refined anisotropically. Hydrogen atoms were placed in their geometrically generated positions and were refined riding on the carbon atom to which they are attached. Green single crystals were grown in CH_2Cl_2/hexane. $C_{32}H_{46}O_8P_2Rh_2$: crystal size 0.3 × 0.25 × 0.3 mm, M = 826.45, orthorhombic, space group $P2_12_12$ with a = 12.1347(11), b = 14.5870(13), c = 9.8171(9) Å, V = 1737.7(3) Å^3 and Z = 2 ($\rho_{calcd.}$ = 1.579 g cm^{-3}), μ (Mo-K_α) = 1.088 mm^{-1}. 3932 reflections measured, 2174 unique (R_{int} = 0.0212), which were used in all calculations. Data/parameters 2174:205. The final R value was 0.0187 ($wR2$ = 0.042). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-142404. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1 EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Disc-Like Chiral Palladium and Platinum Complexes: Synthesis and Mesomorphic Properties

Belkiz Bilgin Eran,*[a] Dirk Singer,[b] and Klaus Praefcke[c]

Dedicated to Professor Dr. R. Miethchen on the occasion of his 60th birthday

Keywords: Liquid crystals / Metallomesogens / Charge-transfer complexes / Palladium organyls / Platinum organyls

ortho-Palladated and -platinated benzalimines are a widely studied novel type of liquid-crystals. These sheet-shaped materials contain two or even four metal atoms and carry eight and twelve flexible side-chains, respectively. Here we present the preparation and mesomorphic properties of dinuclear chiral homologues of such sheet-like compounds. On their own, the chiral members of the dinuclear cyclopalladated series exhibit no liquid-crystalline properties, but show mesophase inductions (Col_h-phase) in mixtures with an electron-acceptor, e.g., 2,4,7-trinitrofluorenone (**TNF**). A diplatinated chiral analogue, however, monotropically exhibits the cholesteric nematic discotic (N_D^*) type of mesophase. Mixtures of this platinum nematogen with **TNF** also show the induction of a columnar mesophase (Col_h) due to charge-transfer interactions.

Introduction

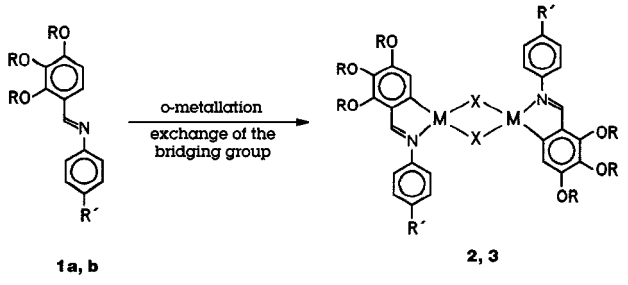
Cyclometallated complexes containing platinum group metals are of considerable academic and commercial interest and have grown to be a significant subject in current liquid-crystal research.[1,2] Within this field *ortho*-palladated metal organyls − organometallic compounds with metal-carbon bonds − originally attracted interest because of their promising combinations of properties attributed to transition-metal complexes and to the self-organization in liquid-crystalline phases.[1,2] Most cyclopalladated mesogens found so far are calamitic in nature, and they are either rod-shaped in the case of mononuclear complexes or can be viewed as twin-mesogens made up by two rod-shaped moieties fused by means of bridging groups. Consequently, usually typical nematic and/or smectic phases consistent with their rod-like structures are observed.

However, by changing the number and position of the peripheral alkyl chains of such *ortho*-metallated mesogens more sheet-like or ellipsoid shapes can be obtained, leading to the formation of the nematic discotic (N_D) type of mesophase.[2,3] We have studied structure-property relations for such sheet-like *ortho*-metallated complexes by varying both their core section (bridging ligands and the metal atom) as well as their aliphatic periphery.[3−7]

Chiral mesophases formed by chiral mesogens are of special interest with respect to their electro-optical properties and possible applications resulting from these properties. The number of sheet- or disc-like chiral mesogens in general and particularly of those exhibiting the cholesteric-nematic discotic (N_D^*) type of mesophase found so far is quite limited.[8,9] Here, we report the synthesis and liquid-crystalline properties of the first chiral members of flat, sheet-like dinuclear palladium and platinum organyls.

Result and Discussion

Chirality can be introduced into sheet-like dinuclear palladium or platinum organometallic compounds of the type



1a, 2: R = C_6H_{13}, R´ = O

1b, 3: R = C_6H_{13}, R´ = O

2: M = Pd, **a**: X = Cl; **b**: X = Br; **c**: X = SCN; **3**: M = Pt, X = Cl

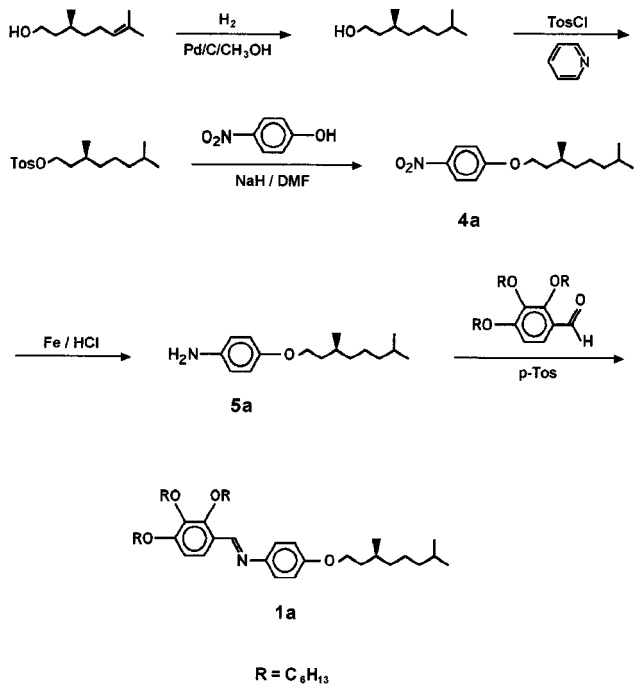
studied here (see Scheme 1) through their peripheral aliphatic chains, either in the aniline- or in the benzaldehyde-derived[10] parts of the ligands.

Dinuclear palladium organyls in general can be obtained from imines, for example **1a** in Scheme 1, by *ortho*-palladation of the ligands with palladium acetate in glacial acetic acid. Exchange of the acetato-bridges with hydrochloric acid leads to chloro-bridged dinuclear palladium complexes (**2a**) from which the bromo- and thiocyanato-bridged homologues **2b** and **c** are accessible by simple exchange reactions with KBr and KSCN, respectively. The dinuclear chloro-bridged platinum complexe **3** (cf. Scheme 1) on the other hand, was obtained by direct *ortho*-platination of the respective imine ligand **1b** with (di-μ-chloro-bis(η^3-2-methylallylplatinum).

The chiral ligands **1a** and **b** were synthesized from 4-nitrophenol, by the usual etherification with the corresponding alkyl tosylates. These tosylates[9] are easily prepared from the hydrogenation product of (*S*)-β-*citronellol* and from (*S*)-*2-methylbutyl alcohol*, respectively, and the citronellol derivative is given as an example in Scheme 2. Reduction of the 4-nitrophenol ethers with Fe/HCl followed by acid-catalyzed condensation with 2,3,4-tri(hexyloxy)-benzaldehyde[11] gave the new chiral imines **1a** and **b**.



Scheme 2

The new ligands **1a** and **b** as well as their metal complexes **2a**−**c** and **3** were characterized by ^{1}H and ^{13}C NMR spectroscopy and gave correct elemental analysis (see Experimental Section). Furthermore, ^{1}H and ^{13}C NMR spectroscopic data for the dipalladium organyls **2a**−**c** and the diplatinum organyl **3** are very similar to those of non-chiral analogs with planar structures and antiparallel orientations of their ligands, as shown by X-ray analysis.[6]

No mesophase formation could be observed for the chloro-, bromo- and thiocyanato-bridged chiral dinuclear palladium organometallic compounds **2a**, **b** or **c**, respectively, in contrast to their achiral analogs,[4] which all exhibit the nematic-discotic ($\mathbf{N_D}$) type of mesophase monotropically. These palladium and platinum organometallic compounds with eight peripheral chains all show a tendency for significant supercooling and slow crystallization. However, when using hot-stage polarizing microscopy even with cooling rates as high as 100 K/min, no formation of a mesophase could be observed by cooling **2a**−**c** from their isotropic phases.

The new diplatinum organyl **3**, on the other hand, carrying two short chiral side-chains exhibits a monotropic cholesteric nematic-discotic mesophase (N_D^*).

The thermal transition data of these four new chiral metallocyclic compounds are summarized in Table 1.

Table 1. Phase transition temperatures *T* (°C) and enthalpies (kJ mol^{-1}) of **2a**−**c** and **3**:
Cr: crystalline, N_D*: cholesteric nematic discotic and Iso: isotropic

Organometallic compound	M	X	Cr	*T*[a]	N_D^*	Iso
2a	Pd	Cl	•	65.3 (38.6)	–	•
2b	Pd	Br	•	67.2 (58.4)	–	•
2c	Pd	SCN	•	98.7 (53.8)	–	•
3	Pt	Cl	•	90.1 (39.1)	{• 72.2 (0.3) }	•

[a] Mettler TA 3000/DSC-30 S with TA 72.5 software. Heating rates 5 K min^{-1} for the melting process, the entalpies are given in parentheses. To prevent crystallization the clearing process of **3** was measured with 10 K min^{-1}.

The properties of the sheet-like[3−7] and calamitic[12] dinuclear palladium and platinum organyls found so far allow for the conclusion that the number and kind of side-chains play a determining role in the formation of the liquid-crystalline phase. The type of metal (Pd or Pt), on the other hand, has only very little or no influence on the type and stability of the mesophase formed. In general, for sheet-like members a more or less coplanar arrangement of the ligands is a further requirement for the formation of nematic discotic phases. A comparison of the phase transition data of the chiral dinuclear palladium organyls **2a**−**c** with their achiral analogs[4] shows that the two bulkier and chiral 3,7-dimethyloctyloxy chains in **2a**−**c** led to lower melting temperatures and prevented the formation of a mesophase, at least in the observable temperature range. We attribute this to the steric hindrance to a nematic packing due to the methyl groups and not to an effect of the chirality per se.

It should be emphasized here that the two chiral lateral chains in the ligands of the dinuclear platinum organyl **3** differ from those present in the series of di-palladium complexes **2**. In the diplatino mesogen **3**, the chiral center is nearer to the molecular core and, most probably more important, these two chains are significantly shorter and lack the terminal branching. Therefore, a very fluid cholesteric nematic discotic (N_D^*) mesophase with "strain" or fingerprint texture and strong thermal fluctuations is observed on cooling **3** from the isotropic melt. The phase transition from

the N_D^* phase to the isotropic liquid is very sharp; the clearing enthalpy of 0.3 kJ/mol is within the range of 0.1−0.4 kJ/mol, common for nematic discotic mesophases.[4,6,11,13]

Nematic discotic phases are usually observed in systems composed of flat, sheet-like molecules lacking significant intermolecular interactions perpendicular to their molecular plane. For such systems, even minor changes in the packing of the peripheral aliphatic chains can favor or prevent the self-organization in a mesophase.

In systems composed of electron-rich flat molecules, strong attractive interactions between these molecules can often be introduced by charge-transfer interactions with a suitable electron-acceptor, for example 2,4,7-trinitrofluorenone (**TNF**). In these systems, the mixed interactions perpendicular to the molecular planes are significantly stronger than those between molecules of the same kind, leading to the formation of columnar mesophases with an alternating stacking of electron-donor and -acceptor molecules.[13−15]

The new chiral sheet-like dinuclear palladium organometallic compounds **2a**−**c**, not liquid-crystalline in their pure state, all formed charge-transfer complexes with 2,4,7-trinitrofluorenone (**TNF**) as indicated by a change of color to brown-red. As expected, an induced mesophase was formed in mixtures of the chiral sheet-like dinuclear chloro- and bromo-bridged compounds **2a** and **b**, respectively. In contact preparations with **TNF**, each showed the formation of induced hexagonal columnar (Col_h) mesophases, a behavior already observed for their achiral dipalladium and diplatinum analogs.[4,6,13] On cooling from the isotropic phase, droplets with linear defects as well as star-shaped domains with homeotropic orientation and hexagonal symmetry were formed, developing into a mosaic texture similar to that observed for the Col_h phase of **TNF** complexes of the achiral dinuclear palladium and platinum analogs.[4,6,13]

Contact mixtures of the thiocyanato-bridged derivative **2c** with **TNF**, on the other hand, show the stabilization of the nematic cholesteric phase in the contact zone, as was observed for its achiral thiocyanato-bridged palladium and platinum analogs.[4,6,13] So far, dinuclear palladium and platinum organyls with eight peripheral chains and a thiocyanato- and (in one case) a iodo-bridge are the only examples[13] showing the stabilization of the nematic discotic type of mesophase by charge-transfer interactions with a strong electron acceptor, for example **TNF**, rather then the induction of a nematic columnar one.[15−17]

The maximum clearing temperatures of the charge-transfer complexes of the dipalladium organometallic compounds **2a**−**c** and the diplatinum mesogen **3** with **TNF** in contact preparations are summarized in Table 2, as determined by polarizing microscopy.

It is interesting to note that in contact mixtures of the palladium organyl **2c** and **TNF,** on cooling from the isotropic phase, textures typical for cholesteric nematic phases are only formed in regions with low **TNF** concentrations; in the areas of higher **TNF** contents, Schlieren textures characteristic of achiral nematic phases are observed.

Table 2. Thermomesomorphic properties of charge-transfer complexes generated by mixing the chiral dinuclear palladium organyls **2a**−**c** and platinum organyl **3**, respectively, with 2,4,7-trinitrofluorenone (**TNF**). The maxima of the clearing temperatures are put in parentheses; Col_h: hexagonal columnar, N: nematic

TNF complex of	M	X	mesophase[a]
2a	Pd	Cl	Col_h (145 °C)
2b	Pd	Br	Col_h (86 °C)
2c	Pd	SCN	N* and N (79 °C)
3	Pt	Cl	Col_h (189 °C)

[a] Results based on contact preparations. The phase transition temperatures have been determined by hot stage polarizing microscopy (heating rate 5 K min^{-1}).

As expected, an induced mesophase is also formed in mixtures of the chiral sheet-like dinuclear platinum organometallic compound **3** with **TNF**. Contact preparations of **3** with **TNF** exhibit a highly viscous induced mesophase up to 189 °C. On cooling from the isotropic liquid, droplets with linear defects as well as star-shaped domains with homeotropic orientation and hexagonal symmetry are formed, developing into a mosaic texture similar to that observed for the Col_h phases of **TNF** complexes of dinuclear palladium and platinum analogs.[4,6,13]

Conclusion

The series of dinuclear palladium organometallic compounds **2a**−**c** with two chiral peripheral chains each are not liquid-crystalline, most probably because of the space requirements of these citronellol-derived side-chains. The shorter chiral (*S*)-2-methylbutyloxy chains present in the diplatinum complex **3**, on the other hand, allow for the formation of a monotropic cholesteric nematic discotic mesophase. All of the dipalladium organyls **2a**−**c** and the diplatinum complex **3** form charge-transfer complexes with strong electron acceptors such as 2,4,7-trinitrofluorenone (**TNF**). These charge-transfer complexes exhibit enantiotropic columnar hexagonal (Col_h) induced mesophases or in the case of the thiocyanato-bridged di-palladium complex **2c**, a stabilized cholesteric nematic discotic phase. Dinuclear chiral *ortho*-metallated compounds of the type studied here seem to be incapable of forming enantiotropic cholesteric nematic mesophases, similar to their achiral analogs, which also only form monotropic nematic-discotic phases. However, the charge-transfer induced hexagonal columnar mesophases of mixtures of **TNF** with **2a**, **b** and **3** and the stabilized cholesteric nematic phase in the binary system **TNF/2c** make these dinuclear metal organometallic compounds suitable for studying the relationship between molecular chirality and mesophase chirality in the nematic as well as in higher-ordered hexagonal columnar phases. Besides charge-transfer complexes with achiral electron-acceptors such as **TNF**, those with the enantiomers of 2-(2,4,5,7-tetranitrofluorenyliden aminooxy propionic acid (**TAPA**) should allow for a detailed study of the influence of molecular chirality on mesophase properties.

Experimental Section

The characterizations of the compounds **1**−**5** presented here are based on correct elemental analyses (Perkin−Elmer Series II CHNS/O Analyzer 2400) and on various spectroscopic data, e.g., ^{1}H, ^{13}C NMR (Bruker WH-400 or AM-270 spectrometers, respectively, $CDCl_3$ solutions), IR (Beckmann 9, CCl_4 solutions) and MS (Varian MAT 711). Only structurally relevant resonances are given below.

Phase transition data were determined by differential scanning calorimetry (Mettler TA 3000/DSC-30 S with TA 72.5 software) and by polarizing microscopy (Leitz Laborlux 12 Pol with a hotstage Mettler FP 82 with heating rates of 5 or 10 K min^{-1} in both methods. To obtain cooling rates of up to 100 K/min a Linkam hotstage THMS 600 system with a TMS 91/C 9196 controller combination was employed).

Synthesis of the 4-Nitrophenol Ethers 4a and b: A solution of 4-nitrophenol (13.91 g, 100 mmol) {**4b**: (8.35 g, 60 mmol)} in dry DMF (80 mL) {**4b**: 50 mL} was added dropwise at ambient temperature under argon and with stirring to a suspension of sodium hydride (60 wt.% suspension in paraffin oil, 4.40 g, 110 mmol) {**4b**: (2.64 g, 66 mmol)} in dry DMF (30 mL) {**4b**: 20 ml}. After stirring this mixture for 2h at room temperature, a solution of (*S*)-3,7-dimethyloctyl tosylate[9] (31.25 g, 100 mmol, prepared by hydrogenation of commercially available citronellol followed by routine tosylation, Scheme 2) in dry DMF (50 mL) or (*S*)-2-methylbutyl tosylate[9] (14.54 g, 60 mmol) in dry DMF (30 mL), respectively, was added. The reaction mixtures were stirred at 80 °C for 12 h or 4 h, respectively, and, after cooling, poured into ice water. After extraction with diethyl ether and usual workup procedures, the crude products were purified by flash-column chromatography on silica gel with petroleum ether/ethyl acetate mixtures (20:1 and 10:1) as eluents.

(*S*)-4-(3,7-Dimethyloctyloxy)nitrobenzene (4a): Yield: 24.30 g (87%) yellow oil. − ^{1}H NMR: δ = 8.18, 6.93 (2d, $J \approx 9$ Hz each; 2 arom. H), 4.14−4.03 (m; OCH_2). − ^{13}C NMR: δ =164.19, 141.27 (2s, 2 arom. C), 125.85, 114.36 (2d, 2 arom. CH each), 67.21 (t, OCH_2). − GC/MS; *m*/*z* (%): 279 (6) [M$^+$], 140 (7) [$C_{10}H_{20}$], 57 (100). − $C_{16}H_{25}NO_3$ (279.4): MS (HR); *m*/*z*: 279.1834 [M$^+$]; calcd.: 279.1834.

(*S*)-4-(2-Methylbutyloxy)nitrobenzene[18] **(4b):** Yield: 10.53 g (84%) yellow oil. − ^{1}H NMR: δ = 8.19, 6.94 (2d, $J \approx 9$ Hz each; 2 arom. H), 3.91, 3.83 (2 dd, $J \approx 6.5$ Hz and 9 Hz, respectively, OCH_2). − ^{13}C NMR: δ =164.37, 141.26 (2s, 2 arom. C), 125.85, 114.36 (2d, 2 arom. CH each), 73.58 (t, OCH_2). − GC/MS; *m*/*z* (%): 209 (12) [M$^+$], 139 (28) [M$^+$ − C_5H_{10}], 70 (100) [C_5H_{10}]. − $C_{11}H_{15}NO_3$ (209.2): MS (HR); *m*/*z*: 209.1052 [M$^+$]; calcd. 209.1052.

Synthesis of the Chiral Aniline Compounds 5a and b: A mixture of (*S*)-4-(3,7-dimethyloctyloxy)nitrobenzene (**4a**, 5.59 g, 20 mmol) or (*S*)-4-(2-methylbutyloxy)nitrobenzene (**4b**, 4.18 g, 20 mmol),[18] respectively, with a suspension of iron powder (6.14 g, 110 mmol) in ethanol/water (50 mL:10 mL) and HCl (20%, 0.6 mL) was heated at reflux for 4 h or 2 h. After the addition of $NaHCO_3$ powder (1.93 g, 23 mmol) to the boiling reaction mixture, the mixture was heated at reflux for 1 h and filtered hot. The crude products were extracted from the residues with hot ethanol and, after removal of the solvent, purified by flash column chromatography on silica gel using petroleum ether/ethyl acetate (5:1) as eluent.

(*S*)-4-(3,7-Dimethyloctyloxy)aniline (5a): Yield: 3.90 g (78%) orange oil. − ^{1}H NMR: δ = 6.75, 6.64 (2d, $J \approx 9$ Hz each; 2 arom. H), 3.96−3.86 (m, OCH_2), 3.41 (s, broad, NH_2). − ^{13}C NMR: δ = 152.25, 139.76 (2s, 2 arom. C), 116.34, 115.58 (2d, 2 arom. CH each), 66.92 (t, OCH_2). − GC/MS; *m*/*z* (%): 249 (2.7) [M$^+$], 109 (100) [M$^+$ − $C_{10}H_{20}$]. − IR (CCl_4): $\tilde{\nu}$ = 3460 and 3383 cm^{-1} (NH_2). − $C_{16}H_{27}NO$ (249.4): MS (HR); *m*/*z*: 249.2093 [M$^+$]; calcd.: 249.2093.

(*S*)-4-(2-Methylbutyloxy)aniline[18] **(5b):** Yield: 3.10 g (86%) yellow oil. − ^{1}H NMR: δ = 6.75, 6.64 (2d, $J \approx 9$ Hz each; 2 arom. H), 3.75, 3.65 (2 dd; $J \approx 6.5$ Hz and 9 Hz, respectively, OCH_2), 3.41 (s, broad, NH_2). − ^{13}C NMR: δ =152.46, 139.69 (2s, 2 arom. C), 116.32, 115.58 (2d, 2 arom. CH each), 73.58 (t, OCH_2). − GC/MS; *m*/*z* (%): 179 (13) [M$^+$], 109 (100) [M$^+$ − C_5H_{10}]. − IR (CCl_4): $\tilde{\nu}$ = 3460 and 3383 cm^{-1} (NH_2). − $C_{11}H_{17}NO$ (179.3): MS (HR); *m*/*z*: 179.1310 [M$^+$]; calcd.: 179.1310.

Synthesis of the Imine Ligands 1a and b: The imines **1a** and **b** were prepared in the usual way[4] by a *p*-toluenesulfonic acid (40 mg) catalyzed condensation of 2,3,4-tri(hexyloxy)benzaldehyde[11] (4.07 g, 10 mmol) with **5a** (3.74 g, 15 mmol) or with **5b** (2.69 g, 15 mmol) in toluene (50 mL) and purified by column chromatography on basic aluminum oxide using petroleum ether/ethyl acetate (20:1 to 5:1) as eluent.

(*S*)-*N*-[4-(3,7-Dimethyloctyloxy)phenyl]-2,3,4-tris(hexyloxy)-benzalimine (1a): Yield: 5.79 g (91%) orange oil. − ^{1}H NMR: δ = 8.77 (s, HC=N), 7.83, 6.73 (2 d, $J \approx 9$ Hz each; 2 arom. H of the benzyliden rings), 7.19, 6.91 (2 d, $J \approx 9$ Hz each; 4 arom. H of the N-substituted phenyl rings), 4.10 (t, $J \approx 6.5$ Hz; OCH_2), 4.06−3.94 (m, 3 OCH_2). − ^{13}C NMR: δ =157.46, 156.09, 154.03, 145.64, 141.29, 123.24 (6 s, 6 arom. C), 154.44 (d, HC=N), 122.11, 122.07, 114.92, 108.59 (4 d; 1, 2, 2 and 1 arom. CH), 74.84, 73.67, 68.76, 66.58 (4 t, 4 OCH_2). − MS; *m*/*z* (%): 637 (12) [M$^+$], 496 (2) [M$^+$ − $C_{10}H_{21}$], 389 (100) [M$^+$ − $C_{16}H_{26}NO$]. − $C_{41}H_{67}NO_4$ (637.9): MS (HR); *m*/*z*: 637.5070 [M$^+$]; calcd.: 637.5070.

(*S*)-*N*-[4-(2-Methylbutyloxy)phenyl]-2,3,4-tris(hexyloxy)benzalimine (1b): Yield: 4.80 g (85%) orange oil. − ^{1}H NMR: δ = 8.77 (s, HC=N), 7.84, 6.74 (2 d, $J \approx 9$ Hz each; 2 arom. H of the benzyliden rings), 7.19, 6.92 (2 d, $J \approx 9$ Hz each; 4 arom. H of the N-substituted phenyl rings), 4.11 (t, $J \approx 6.5$ Hz; OCH_2), 4.07−3.92 (m, 2 OCH_2), 3.84, 3.75 (2 dd, $J \approx 6.5$ Hz and 9 Hz, respectively; OCH_2 of the chiral alkyl chain). − ^{13}C NMR: δ =157.67, 156.09, 154.03, 145.62, 141.29, 123.25 (6 s, 6 arom. C), 154.43 (d, HC=N), 122.09, 122.07, 114.93, 108.59 (4 d; 1, 2, 2 and 1 arom. CH), 74.85, 73.68, 73.16, 68.76 (4 t, 4 OCH_2). − MS; *m*/*z* (%): 567 (6.5) [M$^+$], 496 (6.2) [M$^+$ − C_5H_{11}], 389 (100) [M$^+$ − $C_{11}H_{16}NO$]. − $C_{36}H_{57}NO_4$ (567.8): MS (HR); *m*/*z*: 567.4288 [M$^+$]; calcd.: 567.4288.

Synthesis of the Dinuclear Chloro-Bridged Palladium Organyl 2a: The palladium organometallic compound **2a** was prepared in two steps from the chiral imine ligand **1a** first by reacting 1**a** (5 mmol) with palladium acetate $Pd_3(OAc)_6$ (5 mmol) in glacial acetic acid followed by treatment of the red intermediate product (2 mmol) with a mixture of 2-propanolic hydrochloric acid (0.1 N) according to a description regarding the achiral analogs published elsewhere.[4,5] The desired palladium organometallic compound **2a** was purified by several recrystallizations from ethanol/acetone.

Di-μ-chlorobis[3,4,5-tris(hexyloxy)-2-{[[(*S*)-4-(3,7-dimethyloctyloxy)phenyl]imino]-methyl}phenyl-*C*,*N*]dipalladium(II) (2a): Yield: 2.30 g (74%) yellow crystals. − ^{1}H NMR: δ = 7.99 (s, 2 HC=N), 7.31−7.19, 6.88−6.79 (2 m, broad; 8 arom. H of the N-substituted phenyl rings), 6.57 (s, broad; 2 arom. H of the Pd-substituted phenyl rings), 4.11, 3.85 (2 t, $J \approx 6.5$ Hz each; 2 OCH_2

each), 4.03−3.92 (m, 4 OCH_2). − ^{13}C NMR: δ =170.16 (d, 2 HC=N), 158.63, 155.15, 152.01, 148.87, 140.92, 137.90, 131.68 (7 s, 14 arom. C), 124.00, 114.58, 111.33 (3 d; 4, 4 and 2 arom. CH), 74.64, 73.68, 68.98, 66.53 (4 t, 8 OCH_2). − $C_{82}H_{132}Cl_2N_2O_8Pd_2$ (1557.7): calcd. C 63.23, H 8.54, N 1.80; found C 62.94, H 8.59, N 2.12.

Synthesis of the Bromo- and Thiocyanato-Bridged Palladium Organyls 2b and c: The bromo- and thiocyanato-bridged palladium organometallic compounds **2b** and **2c** were prepared from the analogous chloro-bridged compound **2a** by simple exchange reactions with potassium bromide and potassium thiocyanate, respectively, in dichloromethane/acetone under argon at room temperature. The crude products were purified by recrystallization from methanol/acetone.

Di-μ-bromobis[3,4,5-tris(hexyloxy)-2-{[[(*S*)-4-(3,7-dimethyloctyloxy)phenyl]imino]-methyl}phenyl-*C*,*N*]dipalladium(II)(2b): The halogen-exchange reaction (Cl → Br) was carried out by stirring **2a** (0.31 g, 0.2 mmol) and KBr (0.71 g, 6 mmol) in a mixture of CH_2Cl_2 (60 mL) with acetone (30 mL) for 5 d. Yield: 280 mg (85%) yellow crystals. − ^1H NMR: δ = 8.03 (s, 2 HC=N), 7.28−7.21, 6.89−6.82 (2 d, broad; 8 arom. H of the *N*-substituted phenyl rings), 6.76 (s, broad; 2 arom. H of the Pd-substituted phenyl rings), 4.10, 3.85 (2 t, $J \approx 6.5$ Hz each; 2 OCH_2 each), 4.04−3.93 (m, 4 OCH_2). − ^{13}C NMR: δ =170.76 (d, 2 HC=N), 158.20, 155.35, 151.95, 150.80, 143.10, 137.55, 132.36 (7 s, 14 arom. C), 124.56, 114.61, 114.09 (3 d; 4, 2 and 4 arom. CH), 74.62, 73.60, 68.72, 66.52 (4 t, 8 OCH_2). − $C_{82}H_{132}Br_2N_2O_8Pd_2$ (1646.6): calcd. C 59.81, H 8.08, N 1.70; found C 59.16, H 8.13, N 1.82.

Bis[μ-(thiocyanato-*N*:*S*)]bis[3,4,5-tris(hexyloxy)-2-{[[(*S*)-4-(3,7-dimethyloctyloxy)phenyl]imino]methyl}phenyl-*C*,*N*]dipalladium(II) (2c):The halogen-exchange reaction (Cl → SCN) was carried out by stirring **2a** (0.31 g, 0.2 mmol) and KSCN (0.58 g, 6 mmol) in a mixture of CH_2Cl_2 (60 mL) with acetone (30 mL) for 5 d. Yield: 290 mg (90%) yellow green crystals. − ^1H NMR: δ = 8.12 (s, 2 HC=N), 7.26, 6.91 (2 d, $J \approx 9$ Hz each; 8 arom. H of the N-substituted phenyl rings), 6.18 (s, 2 arom. H of the Pd-substituted phenyl rings), 4.11, 3.85 (2 t, $J \approx 6.5$ Hz each; 2 OCH_2 each), 4.07−3.97 (m, 4 OCH_2). − ^{13}C NMR: δ =170.25 (d, 2 HC=N), 158.37, 155.56, 152.63, 149.69, 143.38, 137.81, 133.60, 126.02 (8 s, 14 arom. C and 2 SCN), 123.95, 114.30, 114.85 (3 d; 4, 4 and 2 arom. CH), 74.64, 73.61, 68.71, 66.65 (4 t, 8 OCH_2). − IR (CCl_4): $\tilde{\nu}$ = 2151 cm^{-1} (SCN). − $C_{84}H_{132}N_4O_8S_2Pd_2$ (1603.0): calcd. C 62.94, H 8.30, N 3.49; found C 62.75, H 8.48, N 3.47.

Synthesis of the Dinuclear Platinum Organyl 3: A solution of the chiral imine **1b** (1.16 g, 2.05 mmol) in dichloromethane (20 mL) was added under Ar to a suspension of di-μ-chloro-bis(η^3-2-methylallylplatinum)[19] (0.57 g, 1.0 mmol) in dry methanol (15 mL). After stirring the reaction mixture at room temperature for 25 d, an orange precipitate was filtered off. The chiral platinum organometallic compound **3** was purified by several crystallizations from methanol/acetone.

Based on the ^1H NMR spectroscopic data for **3** we assume this chiral platinum organometallic compound to be a mixture of two isomers, at least in solution, as reported in a previous paper for the achiral diplatinum analogue.[6] This is probably due to the different orientations of the two ligands i.e., parallel or antiparallel to each other.

Di-μ-chlorobis[3,4,5-tris(hexyloxy)-2-{[[(*S*)-4-(2-methylbutyloxy)phenyl]imino]-methyl}phenyl-*C*,*N*]diplatin(II) (3): Yield: 635 mg (40%) orange crystals. − ^1H NMR: δ = 8.12, 8.09 (2 s, ratio 1 (*anti*):0.2 (*syn*); HC=N), 7.30, 6.88 as well as 7.20, 6.80 (2 × 2 d, $J \approx 8.5$ Hz each; arom. H of the *N*-substituted phenyl rings), 6.64, 6.46 (2 s, ratio 0.2 (*syn*):1 (*anti*); arom. H of the Pt-substituted phenyl rings), 4.12, 3.98 (2 t, $J \approx 6.5$ Hz each; 2 OCH_2 each), 3.90−3.68 (m, 4 OCH_2). − ^{13}C NMR: δ =172.12 (d, 2 HC=N), 158.77, 157.15, 152.76, 142.19, 136.69, 134.75, 131.09 (7 s, 14 arom. C), 124.77, 114.23, 110.27 (3 d; 4, 4 and 2 arom. CH), 74.52, 73.45, 73.15, 68.64 (4 t, 8 OCH_2). − $C_{72}H_{112}Cl_2N_2O_8Pt_2$ (1594.8): calcd. C 54.23, H 7.08, N 1.76; found C 54.05, H 6.89, N 1.62.

Acknowledgments

B. Bilgin Eran wishes to thank the Yildiz Teknik Üniversitesi Research Fond and Devlet Planlama Teskilati (DPT) (State Planning Organization Turkey) for supplying a polarizing microscope. K. Praefcke is grateful to the Deutsche Forschungsgemeinschaft, Bonn (Sonderforschungsbereich Sfb 335 "Anisotrope Fluide", project C 3), the Fonds der Chemischen Industrie, Frankfurt/Main, the Gesellschaft von Freunden der Technischen Universität Berlin, and to the Technische Universität Berlin, Germany, for financial support of their liquid-crystal work.

Vanadium(III) and -(IV) Complexes with *O,N*-Chelating Aminophenolate Ligands: Synthesis, Characterization and Activity in Ethene/Propene Copolymerization

Henk Hagen,[a] Jaap Boersma,[a] Martin Lutz,[b] Anthony L. Spek,[b] and Gerard van Koten*[a]

Keywords: Vanadium / Phenolates / Catalysis / Polymerizations / Alkenes

Monoanionic, potentially bi- or terdentate aminophenolates, ($[OC_6H_3(CH_2NMe_2)$-2-R-4$)]^-$, R = H (**a**), Me (**b**), *t*Bu (**c**), Cl (**d**), N=NPh (**e**), MeO (**f**) and $[OC_6H_2(CH_2NMe_2)_2$-2,6-Me-4$]^-$ (**g**)), have been used in the synthesis of well-defined vanadium-based catalysts for the polymerization of α-olefins. The reaction of $[Cp_2V]$ with the parent phenol of **g** resulted in oxidation of the vanadium(II) nucleus to obtain the vanadium(III) (tris)phenolate $[V(OC_6H_2(CH_2NMe_2)_2$-2,6-Me-4$)_3]$ (**1**). Vanadium(III) aminophenolates could not be obtained by reaction of $[VCl_3(THF)_3]$ with the sodium phenolates because of incorporation of NaCl. However, use of the corresponding silyl ether $Me_3SiOC_6H_3(CH_2NMe_2)$-2-Me-4 (**2**) resulted in the formation of the chlorovanadium (bis)phenolate $[VCl(OC_6H_3(CH_2NMe_2)$-2-Me-4$)_2]$ (**3**). Attempts to oxidize **3** to the corresponding dichlorovanadium(IV) (bis)phenolate were not successful. No reaction was observed with CuCl, AgCl and $PbCl_2$. A dark blue compound **4** was obtained with $CuCl_2$, which was tentatively assigned as a V^{III}/Cu^{II} dinuclear species. Treatment of the vanadium(IV) oxo (bis)phenolates **5a**–**5f** with $SOCl_2$ in benzene at room temperature or in toluene at reflux temperature resulted in the formation of dark blue compounds **6a**–**6f**, whose stoichiometries indicated excess chloride. Only when **5a** and **5d** were reacted with $SOCl_2$ at −70 °C could the desired dichlorovanadium (bis)phenolates $[VCl_2(OC_6H_4(CH_2NMe_2)-2)_2]$ (**7a**) and $[VCl_2(OC_6H_3(CH_2NMe_2)$-2-Cl-4$)_2]$ (**7d**) be obtained. X-ray crystal structure determination of **1** and **3** showed that both compounds have a trigonal bipyramidal geometry with two aminophenolate ligands bound in a bidentate η^2-*O,N* fashion to the vanadium center in similar ways. The compounds **1**, **3**, **6** and **7** were tested for ethene/propene copolymerization.

Introduction

Although the activity of vanadium-based catalysts is often inferior to that of other systems, their use has several advantages, such as (1) the preparation of high molecular weight polymers with narrow molecular weight distributions, (2) the preparation of ethene/α-olefin copolymers with high α-olefin incorporation, and (3) the preparation of syndiotactic polypropene.[1] One of the reasons for the reduced activity of vanadium-based catalysts is their deactivation during the polymerization process due to the reduction of catalytically active vanadium species to less active or even inactive low-valent species. One way to overcome this problem would be the stabilization of the higher oxidation states of the vanadium center by ancillary ligands. To this end, we recently set out to study the use of mono-anionic, potentially bidentate aminophenolate ligands (see Figure 1). These ligands have been chosen since vanadium systems with oxygen-containing ligands are known to give polymers with narrow molecular weight distributions,[2] while the nitrogen donor atom can help in stabilizing the high oxidation state of the vanadium center by V−N coordination. In addition to the latter effect, an *ortho*-amino functionality itself represents a substituent with considerable bulk, which can prevent bimolecular deactivation pathways of the vanadium catalyst.[1,3] Finally, the electronic properties of the vanadium center can be considerably influenced by varying the *meta* and *para* substituents on the phenolate ring, as we have recently shown for vanadium(IV) oxo (bis)phenolate complexes.[4] It turns out that these ligands cannot be employed in vanadium(V) chemistry, since the *ortho*-amino function causes reduction of the vanadium(V) center to vanadium(IV).[5] Therefore, in our further studies we have focused on employing these *ortho*-aminophenolate ligands in systems with the vanadium center in the formal 3^+ or 4^+ oxidation state.

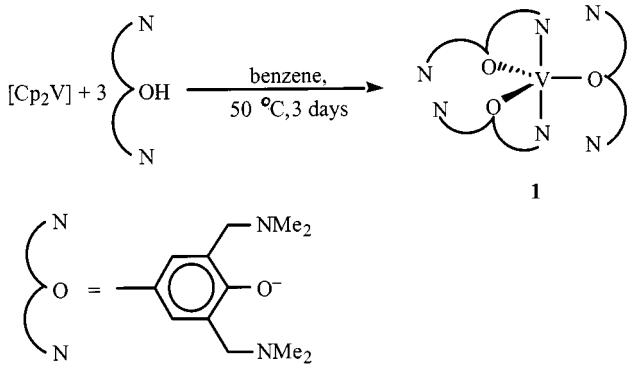
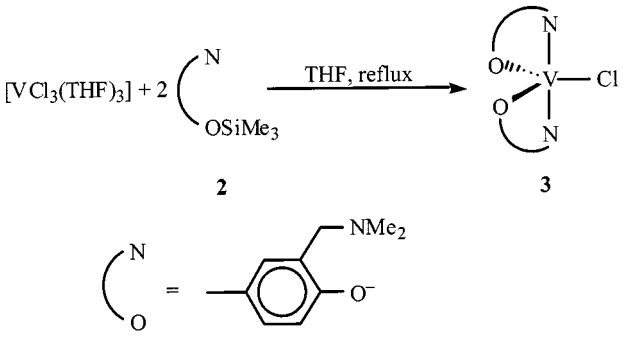
Results and Discussion

In the course of our attempts to synthesize vanadium(II) phenolates, we have treated $[Cp_2V]$ with the bis(amino)-phenol $HOC_6H_2(CH_2NMe_2)_2$–2,6-Me-4 (see Scheme 1). Instead of the expected vanadium(II) (bis)phenolate, this reaction gave a bright orange compound, which was identified by X-ray crystallography (vide infra) as the vanadium(III) (tris)phenolate $[V(OC_6H_2(CH_2NMe_2)_2\text{-}2,6\text{-}Me\text{-}4)_3]$ (**1**). The formal 3^+ oxidation state of vanadium in **1** was confirmed by its magnetic susceptibility ($\mu_{eff} = 2.52\ \mu_b$), which is characteristic of a d^2 high-spin complex.[6] Oxidation of low-valent vanadium(II) to vanadium(III) by phenols with the concomitant formation of molecular hydrogen is not uncommon. The formation of vanadium(III) species can be avoided only when phenols with larger *ortho*-substituents like *i*Pr, *t*Bu or Ph are used.[7] This oxidation is not restricted to phenols themselves, but also occurs when sodium phenolates are used. In the latter case, however, a disproportionation reaction occurs with the formation of the vanadium(III) phenolate and metallic vanadium.[8]



Scheme 1. Synthesis of the vanadium(III) (tris)phenolate **1**

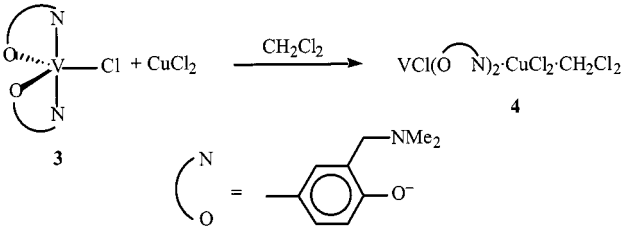
In our further studies $[VCl_3(THF)_3]$ was used as the starting material for the synthesis of vanadium(III) aminophenolate complexes. It must be noted that a salt metathesis reaction with the corresponding sodium phenolate gave non-reproducible results. Depending on the temperature and the solvent used, none or only part of the expected amount of NaCl precipitated from the reaction mixture, indicating the formation of hetero di- or tri-nuclear complexes. The exact nature of these complexes was not determined but examples of such compounds are known in lanthanide chemistry.[9] In this kind of complex the aminophenolate ligands form bridges between different metal atoms via the oxygen atoms while the amino nitrogen atoms coordinate to either the metal or sodium. To overcome the problem of NaCl incorporation the corresponding silyl ether, $Me_3Si\text{-}OC_6H_3(CH_2NMe_2)$-2-Me-4 (**2**), was used. Treatment of $[VCl_3(THF)_3]$ with two equivalents of the silyl ether **2** in refluxing THF (see Scheme 2) resulted in the formation of the chlorovanadium (bis)phenolate $[VCl(OC_6H_3(CH_2NMe_2)\text{-}2\text{-}Me\text{-}4)_2]$ (**3**), which was isolated as a moderately air-sensitive, crystalline orange solid.



Scheme 2. Synthesis of the chlorovanadium (bis)phenolate **3**

Synthesis of Vanadium(IV) Phenolates

Rather than using VCl_4, which is an inconvenient starting material because of its volatility and oxidative nature, we attempted to use the chlorovanadium (bis)phenolate **3** as starting material for the synthesis of the corresponding dichlorovanadium(IV) (bis)phenolate. Attempts to oxidize **3** with CuCl, AgCl or $PbCl_2$ were in vain, as no reaction was observed. However, when $CuCl_2$ was used a dark blue complex (**4**) was almost immediately formed (Scheme 3). Although the exact nature of **4** remains unclear, elemental analysis indicated the isolation of a complex with a $V(OR)_2CuCl_3{\cdot}CH_2Cl_2$ stoichiometry (OR = $OC_6H_3(CH_2NMe_2)$-2-Me-4). Complex **4** is insoluble in alkanes, aromatic solvents like benzene and toluene, and Et_2O. It is poorly soluble in chloroform and reasonably soluble in CH_2Cl_2 and THF. The severe line-broadening in the ^1H NMR spectrum of **4** in CD_2Cl_2 indicates that it is a paramagnetic species.



Scheme 3. Synthesis of the dinuclear vanadium/copper compound **4**

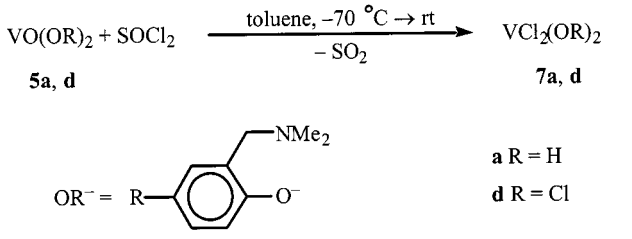
For a complex with the observed V:Cu:anion stoichiometry, three combinations of V/Cu oxidation states are conceivable, viz. V^{III}/Cu^{II}, V^{IV}/Cu^{I} or V^{V}/Cu^{0}. In view of the V^{IV}/V^{V} oxidation potential, the V^{V}/Cu^{0} combination is not likely. Oxidation of the vanadium nucleus in **4** by $CuCl_2$ to vanadium(IV) would result in the formation of a complex with a paramagnetic, EPR active vanadium center and a diamagnetic copper(I) center. EPR analysis of a 2 mM solution of **4** in CH_2Cl_2 showed the characteristic octet of a vanadium(IV) compound. Since the signal was very weak, it is most likely caused by an impurity. This would mean that the vanadium nucleus has not been oxidized in the re-

action with $CuCl_2$ and we believe that **4** is best described as a V^{III}/Cu^{II} dinuclear species.

In view of these results, another route to dichlorovanadium(IV) (bis)phenolate complexes was studied, i.e. the reaction of vanadyl complexes, $[VO(OR)_2]$ (**5a**−**5f**),[4] with thionyl chloride. In this reaction the $[V{=}O]^{2+}$ unit is transformed into a $[VCl_2]^{2+}$ unit with the liberation of SO_2.[10] Treatment of compounds **5** with excess $SOCl_2$ in benzene at room temperature or in toluene at reflux temperature gave dark blue/green compounds (**6a**−**6f**), which are insoluble in alkanes, aromatics like benzene and toluene, and Et_2O. They are slightly to very soluble in THF, CH_2Cl_2 and MeCN.

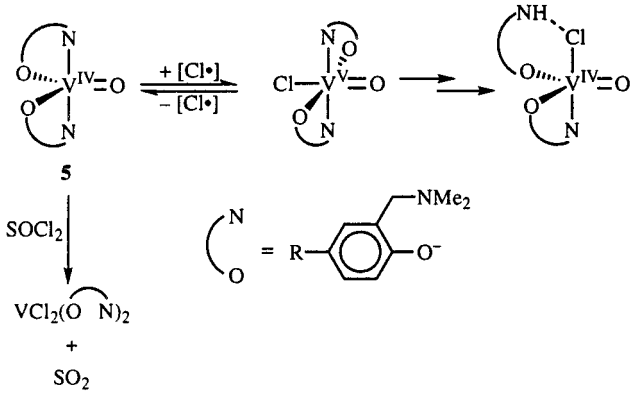
None of the elemental analyses of compounds **6**[11] agreed with the formula $VCl_2(OR)_2$, but they all had stoichiometries containing various amounts of excess chlorine. The amount of additional chlorine appears to be independent of both reaction time and reaction temperature. Also the presence of approximately half an equivalent of sulfur is remarkable. Attempts to grow crystals suitable for a crystal structure determination failed and so far this has hampered the identification of these complexes.

When exactly one equivalent of thionyl chloride was added to **5a** at −70 °C the desired dichlorovanadium (bis)-phenolate, $[VCl_2(OC_6H_4(CH_2NMe_2)\text{-}2)_2]$ (**7a**) was obtained in a 76% yield (see Scheme 4). During this reaction a toluene-insoluble solid with a Cl:V ratio greater than two was also formed, as is also the case when the reaction is carried out at room temperature (vide supra).[12] Treatment of the vanadyl (bis)phenolates **5c** and **5d** with thionyl chloride at −70 °C resulted in the formation of the desired dichloro compound $[VCl_2(OC_6H_3(CH_2NMe_2)\text{-}2\text{-}Cl\text{-}4)_2]$ (**7d**) in the case of **5d**, whereas for **5c** a compound (**7c**) with a Cl:V ratio of 3.5 was found.[13] Compounds **7a**, **7c** and **7d** are dark blue, insoluble in alkanes, sparingly soluble in aromatics like benzene and toluene, but very soluble in polar solvents like CH_2Cl_2, THF and MeCN.



Scheme 4. Synthesis of the vanadium dichloro (bis)phenolates **7a** and **7d**

The difference in reactivity between compounds **5** and a large number of vanadyl Schiff base complexes, $[VOL_2]$, is remarkable. The latter all give the corresponding dichlorovanadium complexes in high yields.[14] The only difference between the present $[VO(OR)_2]$ complexes and the Schiff base containing $[VOL_2]$ complexes is the presence of an sp^3 amine nitrogen in the former vs. an sp^2 imine nitrogen atom in the latter. Unfortunately, the mechanism of the reaction of $[VOL_2]$ with thionyl chloride is not known. If, however, a vanadium(V) species is formed in a side reaction, then this could be an explanation for the different results in the reactions of compounds **5**. It is known that vanadium(V) compounds can be reduced by trialkylamines. Moreover, when the vanadium(V) species contains a halogen, this amine will be recovered as the trialkylammonium halide.[15] The source of the proton in this reaction is not known. Recently we reported that the use of *ortho*-aminophenolates in vanadium(V) chemistry gave rise to the formation of vanadium(IV) compounds.[5] Consequently, the formation of a vanadium(V) chloride in the reaction of **5** with $SOCl_2$ would immediately result in the reduction of the vanadium(V) nucleus to yield a vanadium(IV) vanadate species and a quaternary ammonium substituent (see Scheme 5). As two amine functionalities are present in the molecule, the reaction sequence can occur twice. The results we obtained in the synthesis of compounds **7** led us to believe that indeed a change in oxidation state is responsible for this behavior. The oxidation potential of the *t*Bu-substituted vanadyl complex is lower than those of the H- and Cl-substituted complexes (ΔE_{ox} = 60 and 130 mV, respectively).[4] A complex with a lower oxidation potential would easily lead to the formation of an unstable vanadium(V) complex, and from there to a vanadium(IV) complex with ammonium substituents and excess chlorine. The reason that this behavior is not observed for the Schiff base complexes could be twofold. Firstly, the side-reaction involving the oxidation to vanadium(V) does not occur because of their higher oxidation potentials. Secondly, the side reaction is an equilibrium. If the oxidation to vanadium(V) would occur, no chlorovanadate species would be formed as the vanadium(V) center is not reduced by an imine function. Instead it may react to return to the starting vanadium(IV) compound and subsequently react with $SOCl_2$ to form the dichlorovanadium compound.



Scheme 5. Postulated reaction mechanism for the formation of an ammonium vanadate(IV) species

IR analysis corroborated the suggestion that **6** are ammonium chlorovanadate complexes. Comparison of the IR spectrum of **6b**[16] with the one of the ammonium chlorovanadate complex $[VOCl_2(OC_6H_2(CH_2NMe_2)\text{-}2\text{-}Me\text{-}4\text{-}(CH_2NHMe_2)\text{-}6)]$,[4] revealed that the 2900−2800 cm^{-1} regions (i.e., the region in which the complex resonance pattern for the intramolecular hydrogen bond is found) are very similar.

Solid-State Structures of 1 and 3

The ^{1}H NMR spectra of the vanadium(III) complexes display broad peaks with no substructure due to the paramagnetism of these d^2 compounds. This means little or no structural information can be obtained with NMR. The high-spin state of these compounds makes them also inaccessible to conventional X-band EPR analysis.[17] Consequently, in order to get information about the structure, a single crystal X-ray structure determination is of great importance. Crystallization of **1** from hexane gave single crystals suitable for X-ray crystal structure analysis. The molecular structure of **1** is depicted in Figure 2. Selected bond lengths and angles are given in Table 1. The geometry around the vanadium center is a distorted trigonal bipyramid (21% on the Berry pseudorotation path between D_{3h} and C_{4v} [18]). The three oxygen atoms are in the equatorial plane (Σ(O−V−O) = 359.82°) while the two coordinating nitrogen atoms are in the apical positions (N1−V−N3 = 171.74(8)°); i.e., two bis(amino)phenolate ligands are bonded in a bidentate η^2-*O*,*N* fashion to the vanadium center in a similar way. The third phenolate ligand is bonded in an η^1-*O* monodentate fashion. The V-O and O-C bond lengths and the V-O-C bond angles fall within the range reported for vanadium(III) phenolates (1.818-1.927 Å, 1.315-1.378 Å and 132.2-158.3°, respectively).[19] The V−O−C angle of the monodentate bonded ligand is considerably larger than those in the chelate rings. This allows more π-bonding to the vanadium center, which is reflected in a slight shortening of the V−O bond.

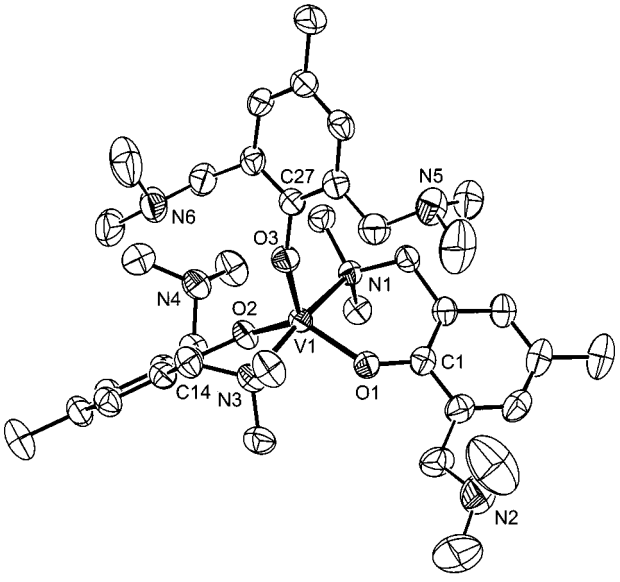


Figure 2. Displacement ellipsoid plot of **1**, drawn at 50% probability; hydrogen atoms are omitted for clarity; only one conformation of the disordered aminobenzyl groups is shown

Crystallization of **3** from toluene gave single crystals suitable for an X-ray crystal structure determination. The molecular structure is depicted in Figure 3 and pertinent bond lengths and bond angles are given in Table 2. The geometry around the vanadium center is trigonal bipyramidal as in **1**. It has crystallographic C_2 symmetry with the symmetry axis along the V−Cl bond. The equatorial plane is formed by the two oxygen atoms of the phenolate ligands and the chlorine atom. The apical positions are occupied by the coordinating nitrogen atoms (N1−V−N1′ = 175.65(18)°). The V−Cl bond length (2.2923(16) Å) lies in the range reported for vanadium(III) chlorides (2.277−2.418 Å).[20a,20c] The bond lengths and bond angles involving the bidentate η^2-*O*,*N* bonded ligand are comparable to those in **1**. Compound **3** cocrystallizes with one equivalent of toluene.

Polymerization Tests

The vanadium(III) and -(IV) compounds obtained in this work were tested for ethene/propene copolymerization. The

polymerization tests were carried out in pentamethylheptane (PMH) at 30° C for a period of 10 minutes. The ethene/propene pressure was 8 bar and the ethene/propene molar ratio was kept constant at 1:2. $Et_{1.5}AlCl_{1.5}$ was used as cocatalyst. The reaction vessel was loaded with 500 mL of PMH, 20 equivalents of cocatalyst and the monomers. The catalysts (± 25 μmol), dissolved or suspended in toluene, were injected into the reaction vessel without premixing of the cocatalyst. The results of these preliminary tests are listed in Table 3.

Table 3. Ethene/propene copolymerization results with vanadium aminophenolate complexes

Complex [a]	Yield (g)	Activity[b]	C_3 (mass%)	η[c] (dL/g)	Mw[d]

7c	7.4	222	32.3	4.95	5.0
7d	6.3	189	29.5	5.95	6.3

[a] Polymerization conditions: 25 μmol [V], 20 equiv. $Et_{1.5}AlCl_{1.5}$, 500 mL PMH, 30 °C, 8 bar ethene/propene ratio 1:2, 10 min. reaction time. – [b] Activity in kg/mol[V]·h·bar. – [c] Intrinsic viscosity measured in decalin at 135 °C. – [d] Molecular weight in g/mol $\times 10^{-5}$.

The activities found vary over one order of magnitude, with the activities of complexes **6** significantly lower than those of **7**. The reason for these lower activities is probably the poor solubility of the former complexes, as only **6e** is slightly soluble in toluene whereas **6a**, **6c** and **6f** are completely insoluble in toluene. The activity of **1** is low in comparison with **3**. The reason for this difference is probably the rate of formation of the catalytically active species. The steric bulk of the pendant amino substituents probably hinders the approach of an aluminium species, which is necessary for ligand exchange with subsequent formation of a vanadium alkyl compound.

IR analysis of the polymers shows that the incorporation of propene varied between approximately 30 and 40%. The molecular weights of the polymers were calculated based on their intrinsic viscosities (in decalin at 135°). The molecular weights varied between 5.0×10^5 and 10.5×10^5 g/mol. When these results are compared to those reported by Gambarotta and co-workers for tetravalent $(R_2N)_2VCl_2$ (R = *i*Pr, Cy) complexes[21] some differences can be noted. The activities are of the same order of magnitude (430 and 165 kg EP/mol[V]·h·bar, respectively). The molecular weight (Mw = 2293000 for R = *i*Pr) is much higher, but the propene incorporation is slightly lower (27%). Unfortunately, it is difficult, if not impossible, to make a fair comparison with the results reported in the literature. Often the conditions are different or details of the polymerization reactions are not mentioned.

Experimental Section

General: All reactions were performed in an atmosphere of dry, oxygen-free dinitrogen using standard Schlenk techniques. Solvents were carefully dried and distilled prior to use. $[Cp_2V]$,[22] $[VCl_3(THF)_3]$,[23] the phenols **b** and **g**,[24] and the vanadium oxo (bis)phenolates **5a**–**5f** were prepared according to literature procedures. $SOCl_2$ was distilled from quinoline. Et_3N was distilled from CaH_2. All other chemicals were obtained from commercial sources and used as received. Elemental analyses were performed by H. Kolbe, Mikroanalytisches Laboratorium, Mülheim, Germany. ^1H NMR spectra were recorded on a Bruker AC300 spectrometer or a Varian Unity Inova 300 spectrometer. EPR spectra were recorded on a Bruker ESP 300 spectrometer.

Synthesis of $[V(OC_6H_2(CH_2NMe_2)_2$–2,6-Me-4$)_3]$ (1): A mixture of $[Cp_2V]$ (0.44 g, 2.42 mmol) and $HOC_6H_2(CH_2NMe_2)_2$–2,6-Me-4 (1.96 g, 8.82 mmol) in benzene (40 mL) was stirred for 50 hours at 70 °C during which time the color slowly changed from purple to green. After removal of the solvent in vacuo a green oil was obtained. Leaving the oil to stand yielded two crops of a red solid (1.04 g; 60%). Recrystallization from hexane at 4 °C gave bright orange crystals. Mp: 129 °C. – $C_{39}H_{63}N_6O_3V$: calcd. C 65.52, H 8.88, N 11.76; found C 65.33, H 8.89, N 11.80. – IR (KBr, cm^{-1}): 2998(m), 2972(s), 2941(s), 2903(s), 2851(s), 2828(s), 2909(s), 2758(s), 2728(m), 2714(m), 1780(w), 1609(w), 1576(w), 1468(s), 1362(m), 1300(s), 1283(s), 1256(s), 1172(m), 1146(m), 1042(m), 1005(m), 984(m), 872(s), 845(s), 826(s), 638(m), 600(m), 557(m). – Magnetic susceptibility: $\mu_{eff} = 2.52\mu_b$.

Synthesis of $Me_3SiOC_6H_3(CH_2NMe_2)$-2-Me-4 (2): A solution of $HOC_6H_4(CH_2NMe_2)$-2-Me-4 (**b**) (11.41 g, 68.63 mmol) in Et_2O (25 mL) was added dropwise to a stirred solution of Me_3SiCl (11.3 mL, 89.3 mmol) and Et_3N (12.4 mL, 89.3 mmol) in Et_2O (300 mL). A white precipitate was immediately formed and the resulting mixture was stirred for 16 hours. The precipitate was subsequently removed by filtration. The filtrate was concentrated in vacuo to give a yellowish oil. This oil was flash-distilled to give **2** as a colorless oil (13.13 g; 80%). – ^1H NMR (300 MHz, $CDCl_3$): δ = 0.27 (s, 9 H, $SiMe_3$), 2.25 (s, 6 H, NMe_2), 2.28 (s, 3 H, Me), 3.37 (s, 2 H, CH_2), 6.69 (d, 1 H, $^3J_{H,H}$ = 8 Hz, Ar-H^6), 6.92 (dd, 1 H, $^3J_{H,H}$ = 8 Hz, $^4J_{H,H}$ = 2 Hz, Ar–H^5), 7.13 (d, 1 H, $^4J_{H,H}$ = 2 Hz, Ar–H^3).

Synthesis of $[VCl(OC_6H_3(CH_2NMe_2)$-2-Me-4$)_2]$ (3): A solution of $Me_3SiOC_6H_3(CH_2NMe_2)$-2-Me-4 (**2**) (4.44 g, 18.70 mmol) in THF (20 mL) was added dropwise to a stirred suspension of $[VCl_3(THF)_3]$ (3.52 g, 9.42 mmol) in THF (50 mL). A dark red solution was immediately obtained, which was then heated at reflux for one hour. After removal of the solvent in vacuo the residue was extracted with toluene (80 mL) and the resulting solution was left to stand for several days, yielding bright orange crystals (0.74 g; 16%). Cooling the supernatant solution to −20 °C gave a second crop (0.98 g; 21%). M.p.: 122 °C. – $C_{20}H_{28}N_2O_2VCl{\cdot}C_7H_8$: calcd. C 63.97, H 7.16, N 5.53; found C, 63.29, H 6.83, N 5.50.

Synthesis of $[VCl(OC_6H_3(CH_2NMe_2)$-2-Me-4$)_2CuCl_2]$ (4): $CuCl_2$ (0.39 g, 2.90 mmol) was added as solid to a stirred solution of $[VCl(OC_6H_3(CH_2NMe_2)$-2-Me-4$)_2{\cdot}C_7H_8]$ (**3**) (0.9 g, 1.7 mmol) in CH_2Cl_2 (50 mL). The color changed to dark blue within a few minutes. The mixture was stirred for two days after which it was filtered. The volume of the solution was reduced to 30 mL in vacuo. The solution was layered with Et_2O (30 mL) and left to stand for three days. A dark blue oil was formed which upon drying in vacuo yielded a dark blue solid (0.94 g; 87%). – $C_{21}H_{30}N_2O_2VCuCl_3{\cdot}CH_2Cl_2$: calcd. C 39.77, H 4.77, N 4.42; Cl, 27.95; found C, 39.73, H 5.38, N 4.39; Cl, 27.60.

Synthesis of $[VCl_2(OC_6H_4(CH_2NMe_2)-2)_2]$ (7a): $SOCl_2$ (1.5 mL, 2.1 M in toluene, 3.2 mmol) was added to a stirred suspension of

$[VO(OC_6H_4(CH_2NMe_2)\text{-}2)_2]$ (**5a**) (1.14 g, 3.10 mmol) in toluene (40 mL) at −70 °C. The solution was allowed to slowly warm to room temperature, during which it turned dark green and a dark colored precipitate was formed. After stirring for an additional 16 hours the solution was separated from the precipitate by centrifugation/decantation and the residue was extracted twice with toluene (40/20 mL). The volume of the combined toluene fractions was reduced to 15 mL in vacuo after which pentane (40 mL) was added. The solvent was removed by centrifugation/decantation and the residue was washed with pentane (2 × 25 mL). Compound **7a** was obtained as a dark blue powder after drying in vacuo (0.99 g, 76). − $C_{18}H_{24}N_2O_2VCl_2$: calcd. C 51.20, H 5.73, N 6.63; V, 12.06; Cl, 16.79; found C, 50.99, H 5.75, N 6.49; V, 11.83; Cl, 16.65. − EPR (toluene): A_{iso} = 84.1 Gauss; g_{iso} = 1.955.

Synthesis of $[VCl_2(OC_6H_3(CH_2NMe_2)\text{-}2\text{-}Cl\text{-}4)_2]$ (7d): Compound **7d** was prepared in a similar way to **7a** starting from $[VO(OC_6H_3(CH_2NMe_2)\text{-}2\text{-}Cl\text{-}4)_2]$ (**5d**) (0.53 g, 1.22 mmol) and $SOCl_2$ (0.6 mL, 2.1 M in toluene, 1.2 mmol) and was obtained as a dark blue powder (0.32 g, 54). − $C_{18}H_{22}N_2O_2VCl_4$: calcd. C 44.02, H 4.52, N 5.70; Cl, 28.87; found C, 43.88, H 4.50, N 5.67; Cl, 28.84. − EPR (toluene): A_{iso} = 84.00; g_{iso} = 1.953.

X-ray Crystallographic Structure Determination and Refinements. Orange crystals of **1** suitable for X-ray diffraction were grown by cooling a saturated hexane solution to 4 °C while orange crystals of **3**·C_7H_8 were grown from toluene at room temperature. X-ray intensities were measured on an Enraf−Nonius CAD4T diffractometer with rotating anode and graphite monochromator (Mo−$K\alpha$, λ = 0.71073 Å).

Crystal structure of **1**: Yellow block, 0.25 × 0.25 × 0.25 mm^3. The structure was solved with direct methods (SHELXS86[25]) and refined with the program SHELXL93[26] against F^2 for all reflections up to a resolution of $(\sin\theta/\lambda)_{max}$ = 0.65 Å^{-1}. An absorption correction was not considered necessary. Non-hydrogen atoms were refined freely with anisotropic displacement parameters; hydrogen atoms were refined as rigid groups. Three of the uncoordinated aminobenzyl groups were refined with disorder models.

Crystal structure of **3**: Yellow plate, 0.38 × 0.30 × 0.05 mm^3. The structure was solved with Patterson methods (DIRDIF97[27]) and refined with the program SHELXL97[28] against F^2 of all reflections up to a resolution of $(\sin\theta/\lambda)_{max}$ = 0.59 Å^{-1}. An absorption correction based on Psi-scans was applied (0.87−0.97 transmission). Non-hydrogen atoms were refined freely with anisotropic displacement parameters; hydrogen atoms were refined as rigid groups. The crystal structure contains large voids (670 Å^3) filled with disordered toluene molecules. Their contribution to the structure factors was secured by back-Fourier transformation (program PLATON,[29] CALC SQUEEZE, 196 e/unit cell)

Both structures were checked for higher symmetry with the program PLATON.[29] Crystal data and details of the data collection are shown in Table 4. Geometrical calculations and illustrations were performed with PLATON.[29]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-139534 (**1**) and -139535 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Bis(*ortho*)-Chelated Bis(phosphanyl)aryl Ruthenium(II) Complexes Containing an η^1-*P*-Monodentate or μ-Bridging η^1-*P*,η^1-*P*′ Bonded R−PCHP Arene Ligand, 1-R-3,5-$(CH_2PPh_2)_2C_6H_3$ [R = H, Br, or, Si(*n*-$CH_2CH_2C_8F_{17})_3$] — Cyclometalation Reaction Intermediates and Potential Catalysts for Use in Fluorinated Biphasic Systems

Paulo Dani,[a] Bodo Richter,[a] Gerard P. M. van Klink,[a] and Gerard van Koten*[a]

Keywords: Ruthenium / Monoanionic terdentate *P,C,P*′-bisphospanylaryl / Cyclometalation / P ligands / Fluorine

Mono- and binuclear ruthenium(II) complexes containing ligands derived from the *meta*-bis(phosphanyl)arene ligand 1-R-3,5-$(CH_2PPh_2)_2C_6H_3$ [R–PCHP: R = H (**5**), Br (**3**), or Si(*n*-$CH_2CH_2C_8F_{17})_3$ (**4**)] have been synthesized and fully characterized. On reaction of equimolar amounts of the ruthenium starting material (e.g. $[RuCl_2(PPh_3)_3]$) and the *meta*-bis(phosphanyl)arene, complexes of the type $[RuCl\{C_6H_2(CH_2PPh_2)_2$-2,6-R-4$\}(PPh_3)]$ are invariably isolated, which contain only one $[C_6H_3(CH_2PPh_2)_2$-2,6$]^-$ monoanionic ligand η^3-*P,C,P*′-bonded to Ru. Monitoring of this reaction by ^1H and ^{31}P NMR has shown it to proceed via intermediate species having an apparently η^3-*P,C,P*′-bonded PCP ligand and a second *meta*-bis(phosphanyl)arene ligand that is either η^1-P-bonded or μ-η^1-P,η^1-P′-bridging between two [RuCl(PCP)] units. The synthesis of the first PCP "pincer"-type ligand with a polyfluorinated "pony tail" is detailed, viz. compound **4** as well as the corresponding ruthenium complex [RuCl{(*n*-C_8F_{17}-$CH_2CH_2)_3$Si–PCP}], **7**. The latter compound is soluble in fluorinated solvents and hence represents the first ruthenium "pincer" complex that may find use in fluorinated biphasic systems.

Introduction

Bis(phosphanes) exhibit a rich coordination chemistry upon interaction with a wide range of metal centers. As shown in Figure 1, various mono- and multimetallic complexes can be formed. Complexes with *cis*-η^2-*P,P*′-coordinated ligands are by far the most common as compared with the so-called "dangling" η^1-*P* (monodentate) coordination motif.[1] The coordination mode can be greatly affected by the length of the chain linking the two donor groups and by the type of substituents present either in the organic backbone or at the donor atoms.[2] The use of bis(phosphane) ligands capable of forming *trans*-spanning complexes (often with a carbon chain containing five or more atoms) is likely to lead to the observation of a different binding mode. This involves not only the coordination of the two P-donors, but also that of a formal carbanion localized at a central position in the backbone. This is clearly a result of C−H bond activation (i.e. orthometalation).[3] Thus, true organometallic species can be generated from bis(phosphane) ligands through appropriate choice of the linking backbone. This is exemplified by the "pincer" ligands of the general formula shown in Figure 1 (the monoanionic η^3-*P,C,P*′-coordinating PCP ligand) and Figure 2.

Such properties of *trans*-spanning ligands are particularly evident in the coordination behavior of bis(phosphane) ligands of the type R−PCHP (Figure 2), in which a rigid *m*-xylylenediyl organic fragment links the two P donor groups.[3a,4]

Reaction of these R−PCHP ligands with transition metal complexes frequently results in the formation of metalated complexes containing a formal monoanionic (i.e. η^3-*P,C,P*′)-coordinated R−PCP ligand. Only a few cases are known where the ligand is bonded as a neutral (noncyclometalated) R−PCHP species. Examples of this type of bonding are observed in just a few square-planar d^8 metal complexes,[5−7] tetrahedral silver compounds,[8] and the octahedral ruthenium species **1**[9] and **2**[10] (Figure 3).

In the present paper, the coordination and cyclometalation properties of the R−PCHP ligands 1-Br-3,5-$(CH_2PPh_2)_2C_6H_3$ (**3**), 1-(*n*-$C_8F_{17}CH_2CH_2)_3$Si-3,5-$(CH_2PPh_2)_2C_6H_3$ (**4**), and 3,5-$(CH_2PPh_2)_2C_6H_4$ (**5**) (R = H, see Figure 2) are reported in more detail. The formation of species with *P*-coordinated neutral R−PCHP ligands and their involvement in the generation of cyclometalated compounds with monoanionic η^3-*P,C,P*′-coordinated R−PCP ligands has been observed.

Results and Discussion

Ruthenium Complexes of R−PCP Ligands

The fluorine-rich ligand (*n*-$C_8F_{17}CH_2CH_2)_3$Si−PCHP (**4**) (Scheme 1) was obtained in excellent yield (94%) by dir-

Scheme 1. Synthesis of [RuCl(R−PCP)(PPh_3)] complexes

In the $^{31}P\{^1H\}$ NMR spectrum of **6**, the phosphorus resonance attributable to the cyclometalated Br−PCP ligand appears as a doublet at $\delta = 36.74$ while the phosphorus nucleus of the PPh_3 moiety resonates as a triplet at $\delta = 80.62$ ($^2J_{PP} = 32$ Hz). A coupling constant of this magnitude is characteristic of a *cis* arrangement of the PPh_3 unit in relation to the two magnetically equivalent PCP phosphorus nuclei.[11] The ^1H NMR spectrum of **6** shows a set of two multiplets attributable to the diastereotopic benzylic protons, indicating the absence of a plane of symmetry containing the benzylic carbon atoms, but showing the presence of an apparent plane of symmetry bisecting the Ru−Cl−P(PPh_3)−C_{ipso} atoms. This leads to enantiotopic *ortho*-CH_2PPh_2 substituents. Similar ^1H and ^{31}P NMR spectra have been observed for the fluorinated-tail complex **7**. In addition to the respective resonances observed for **6**, the ^1H NMR spectrum of **7** shows two multiplets in the ranges $\delta = 0.90-1.10$ and $1.95-2.25$, each set of signals integrating for six protons, clearly attributable to the methylene protons present in the fluorinated chain.

All the spectroscopic features suggest that **6** and **7** are structural analogues of the reported parent complex [RuCl(H−PCP)(PPh_3)] (**8**, cf. **6** with R = H).[12−14] Thus, these new complexes have a distorted square-pyramidal geometry in solution, with a PPh_3 ligand in the apical position and a basal plane formed by the monoanionic η^3-*P,C,P′*-coordinated R−PCP ligand and the Cl ligand.

Ruthenium Complexes Containing One Neutral R−PCHP Ligand

The method outlined in Scheme 1 was one of our initial synthetic protocols that we applied to the synthesis of [RuCl(R−PCP)(PPh_3)] [R = H (**8**), Ph][12] complexes. This method has proven to be of general use. However, some drawbacks have been encountered for R groups containing sensitive functionalities (e.g., when R = $SiMe_3$, desilylation can occur).[10,15] Other chlorinated solvents can be used as the reaction medium, such as CH_2Cl_2 or *o*-dichlorobenzene. However, 1,2-dichloroethane has been shown to be the best choice in terms of reaction times (typically 1−2 h), yields, and ease of work-up of the resulting products. When the reactions are carried out in refluxing CH_2Cl_2, the lower temperature leads to an appreciable decrease in the rate of the reaction such that the final complex is obtained only after three days. On the other hand, this retardation has allowed us the opportunity to gain insight into the various

stages of the reaction leading to the formation of species such as **6** and **8**.

On monitoring the 1:1 molar reaction of **3** with $[RuCl_2(PPh_3)_3]$ in refluxing CH_2Cl_2 by ^{31}P NMR spectroscopy, the signal attributable to **3** ($\delta = -9.07$) is seen to disappear within 5 min. At the same time, a broad and intense singlet at $\delta \approx -4.5$ is observed, which is characteristic of free PPh_3, together with intense but very broad signals between $\delta = 30$ and 90. This suggests the occurrence of intra- and/or intermolecular exchange processes involving displacement of PPh_3 ligand(s) of $[RuCl_2(PPh_3)_3]$ by the more basic benzylic ligand **3**. This results in the formation of a complex mixture of oligomeric species. Within 1−2 h, the broad signals gradually fade in intensity with the concomitant appearance of a set of two doublets located at $\delta =$ 40.05 and 40.30 (the latter is normally very weak), a triplet at $\delta = 83.75$ ($J_{PP} = 30$ Hz), and a singlet at $\delta = -10.06$. At this stage, it is already possible to observe very weak patterns due to the final compound **6** (doublet and triplet resonances at $\delta = 36.74$ and 80.62, respectively). Obviously, as the reaction progresses the signals due to **6** become stronger at the expense of the other signals present. It should be noted that similar behavior was observed when ligand **5** was used in such an experiment.

The magnitude and multiplicity of J_{PP} gives an excellent indication of the mutual arrangement of the phosphanes[11] around the metal center and allows the assignment of structural features of the intermediate species formed en route to the final product (e.g. **6**). The coupling constant data pointed to the presence of Ru complexes containing an η^2-*P,P′*-bonded ligand as exemplified, for instance, by structures **A** and **B** (Figure 4). Such complexes have often been postulated as precursors in cyclometalations of bis(phosphane) donor ligands. However, the chemical shifts are typical for a bis(*ortho*)-metalated η^3-*P,C,P′*-bonded PCP ligand containing a third phosphorus nucleus in an apical position *trans* to a vacant site.[10−13,16] For instance, in the ^{31}P NMR spectrum of the cationic Ru^{II} complex **2**, the only known complex containing both an η^2-*P,P′* PCHP and an η^3-*P,C,P′*-coordinated PCP ligand attached to the same metal center, the ^{31}P resonance of the P nuclei of the bidentate bonded *meta*-bis(phosphane) PCHP ligand is seen at around $\delta = 18-20$, while the nuclei of the η^3-*P,C,P′*-coordinated PCP ligand give rise to a broad signal (room temp.) centered at $\delta = 40$.[17] Therefore, the initially formed species consists of the μ-η^1-*P*,η^1-*P′* (cf. **C**) or the η^1-*P*-coordinated species **D** (Figure 4). The latter compounds already contain a bis(*ortho*)-metalated η^3-*P,C,P′* R−PCP ligand but differ from the final complex **6** in that the apical position is occupied by a second R−PCHP ligand instead of PPh_3. In this way, the singlet at $\delta = -10.06$ can be assigned to the dangling PPh_2 group of **D** and the doublet at $\delta = 40.30$ to the phosphorus of the bis(*ortho*)-metalated ligand. On this basis, the signal at $\delta = 83.75$ should therefore be comprised of two superimposed triplets.

In accordance with this hypothesis, compounds **9** and **10** were detected when $[RuCl_2(PPh_3)_3]$ was reacted with excess Br−PCHP (2 to 3 equiv. of Br−PCHP were used instead of 1, cf. step *a* in Scheme 2), and when **6** was directly reacted with one equiv. of Br−PCHP (step *b* in Scheme 2). Furthermore, the addition of further $[RuCl_2(PPh_3)_3]$ to a mixture of complexes **9** and **10** (CH_2Cl_2) followed by refluxing overnight (step *c* in Scheme 2) afforded **6** in 53% isolated yield.

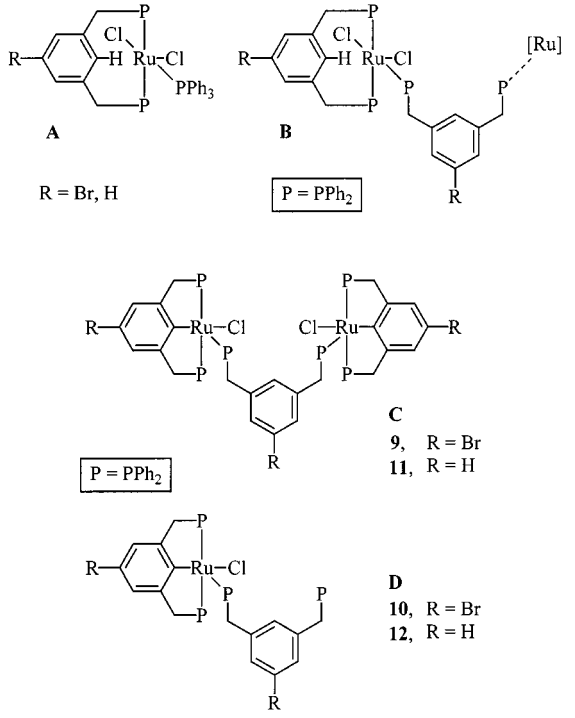

Figure 4. Postulated and observed intermediates in cyclometallation of bis(phosphane) donor ligands

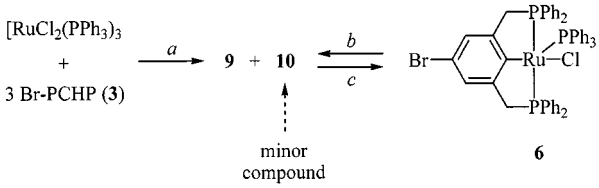


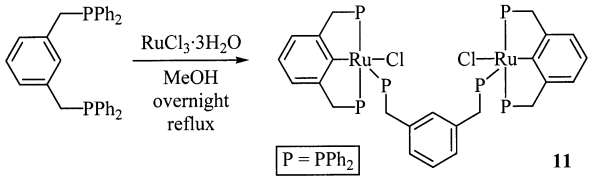
Scheme 2. Conditions: (a) CH_2Cl_2, reflux for 3 days; (b) 1 equiv. of Br−PCHP, CH_2Cl_2, 1 h at room temp.; (c) 1 equiv. of $[RuCl_2(PPh_3)_3]$, CH_2Cl_2, overnight reflux

From the ^1H and ^{13}C NMR spectra of a mixture of **9** and **10** (the latter present to an extent of 11%), most of the features of **9** and some of the features of **10** could be established. Thus, the presence of a bis(*ortho*)-metalated Br−PCP ligand is clearly apparent from the ^{13}C NMR spectrum, where $Ru-C_{ipso}$ of **9** appears at $\delta = 173.85$ as a characteristic doublet ($^2J_{CP} = 16$ Hz).[14] The diastereotopic benzylic protons of the cyclometalated ligand give rise to signals at $\delta = 2.67$ and 3.63 in the ^1H NMR spectrum, each with integrals corresponding to four protons. On the other hand, all of the benzylic protons of the bridging Br−PCHP ligand appear as a single doublet at $\delta = 3.10$ ($^2J_{HP} = 9$ Hz). The aromatic protons of the xylylene group of the Br−PCHP ligand give rise to two singlets at considerably higher field, at $\delta = 4.82$ and 5.47, respectively, with relative integrals of 1:2. These features further confirm the idealized square-pyramidal structure of this compound and emphas-

ize the symmetric disposition of the bridging ligand, where the diastereotopic benzylic protons are magnetically equivalent. In the case of **10**, two of the benzylic protons of the bis(*ortho*)-metalated ligand and all the benzylic protons of the η^1-*P*-bonded Br−PCHP ligand are coincidentally located in the same spectral region (δ = 3.30−3.80), while the two remaining benzylic protons appear as a multiplet at δ = 2.83. The xylylene protons of the Br−PCHP ligand are nonequivalent and appear as singlets at δ = 5.68, 5.82, and 5.90. It should be mentioned that transition metal complexes containing a neutral η^1-*P* monodentate R−PCHP ligand have not previously been reported. To the best of our knowledge, this coordination mode has only been observed in Ag compounds of the H−PCHP ligand (P = PPh_2).[25]

The **C**- and **D**-type species were also observed in similar reactions involving **5** (i.e. complexes **11** and **12**). However, in the case of the H−PCHP ligand, the concentration of species **12** was too low to allow its characterization by ^1H and ^{13}C NMR spectroscopy.

Further evidence for the absence of PPh_3 in complexes such as **C** was obtained from the reaction of $RuCl_3 \cdot 3H_2O$ with an excess of H−PCHP in methanol (Scheme 3). Spectroscopically pure complex **11** was isolated as a green solid in low yield (14%). Similar spectroscopic features to those of **9** were observed, with the exception of the multiplicity of the xylylene protons of the bridging H−PCHP ligand. In **11**, they appear as a singlet (δ = 5.42), a doublet (δ = 5.69, $^3J_{HH}$ = 8 Hz), and a triplet (δ = 5.99, $^3J_{HH}$ = 8 Hz).



Scheme 3. Formation of **11** using $RuCl_3 \cdot 3\,H_2O$ as starting material

The fluorinated arylruthenium(II) "pincer" complex **7** is the first example of a ruthenium compound containing three fluorinated C_{10} tails ("pony tails") connected to the *para*-position of the PCP ligand through a silicon branching point. A very interesting feature of **7**, which has 43.2 wt% of fluorine, is its solubility in fluorocarbon solvents. Initially, **7** was synthesized to facilitate the separation of the arylruthenium(II) compound from the free PPh_3 present in the crude reaction mixture. Thus, the mixture could be separated by dissolving **7** in FC-72 (perfluorohexanes), a solvent in which PPh_3 is insoluble. This property also gives a clear indication of the presence of an $(n\text{-}C_8F_{17}CH_2CH_2)_3Si$ group in the complex molecule for species such as **6** and **8**, which would otherwise be completely insoluble in FC-72. Our intention for **7** and analogous fluorinated organometallic compounds is to explore their chemistry in fluorinated biphasic catalysis.[18] In this context, we have already prepared the NCN complex **13** (Figure 5) containing 35.8 wt% of fluorine, and have used it as a model complex for the selective addition of CCl_4 to methyl methacrylate (Kharasch addition) under both standard and fluorinated biphasic conditions.[19,20]

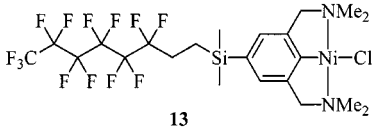


Figure 5. Fluorinated arylruthenium(II) pincer **13** used for the Kharasch addition reaction under biphasic conditions

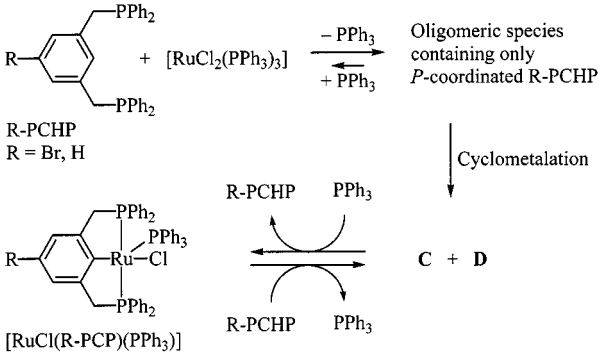
It is interesting to note that in the syntheses of **6** and **7**, the Br−C and Si−C bonds remain unaffected by the applied synthetic protocol. This is in sharp contrast to the Si−aryl bond cleavage observed using the ligand Me_3Si−PCHP under similar conditions.[13,15] Such a process (i.e. desilylation) is thought to be promoted by HCl formed in the ruthenation reaction[13,15] and to follow an electrophilic aromatic substitution mechanism.[21] Therefore, the presence of electron-withdrawing groups on the aromatic ring can be expected to disfavor such reactivity. Indeed, it is observed that the electron density at the Si atom, as measured by ^{29}Si NMR spectroscopy, is significantly lower in $(n\text{-}C_8F_{17}CH_2CH_2)_3Si$−aryl compounds than in their Me_3Si−aryl analogues.[22]

Oxidative addition of low-valent (coordinatively unsaturated) ruthenium complexes to C−halide bonds is a well-documented process.[23] However, in the synthesis of **6** no species originating from this type of reactivity were detected and the retention of the C−Br bond in the product was clearly established by ^{13}C NMR spectroscopy and elemental analysis. This bond was also unaffected during an attempt to form a bimetallic complex through the coupling of two molecules of **6**. This was performed in combination with a nickel-containing catalyst. The starting complex **6** was recovered quantitatively at the end of the procedure.

The observations made thus far suggest that the displacement of the η^1-*P* or μ-η^1-*P*,η^1-*P*′ bonded R−PCHP ligand from species such as **C** and **D** is probably the rate-limiting step of this reaction, rather than the C−H activation that occurs during the cyclometalation step. In the early stages of the reaction of $[RuCl_2(PPh_3)_3]$ with R−PCHP, the latter readily displaces the PPh_3 ligands coordinated at the ruthenium center, forming a mixture of species, most likely oligomeric in nature (Scheme 4). The extent to which this process occurs is likely to be dictated by the chelate-coordinative properties of the R−PCHP ligand relative to those of PPh_3. A fast and, under the applied reaction conditions, irreversible cyclometalation reaction proceeds, this being the origin of species of types **C** and **D**. As in this reaction the molar ratio of $[RuCl_2(PPh_3)_3]$ to R−PCHP is 1:1, the formation of complexes such as **C** and **D** implies the existence of Ru centers depleted of such ligands. The excess free PPh_3 present slowly displaces coordinated R−PCHP ligands, which are then trapped by the metal centers lacking a cyclometalated R−PCP ligand. Therefore, one of the roles of complexes such as **9**, **10**, **11**, and **12** in the formation of [RuCl(R−PCP)(PPh_3)] complexes would appear to be to serve as reservoirs of R−PCHP ligands. Naturally, the R−PCHP released from species **C** and **D** can also react

with the final complex [RuCl(R−PCP)(PPh_3)], replacing the PPh_3 and reforming **C** and **D**. However, this does not lead to any progress in the overall process in the direction of formation of complexes [RuCl(R−PCP)(PPh_3)].



Scheme 4. Formation of [RuCl(R−PCP)(PPh_3)] complexes by reacting [$RuCl_2(PPh_3)_3$] with R−PCHP ligands

Conclusions

In this paper, we have focussed on the reaction of the [$RuCl_2(PPh_3)_3$] starting material with R−PCHP ligands having PPh_2 groups connected through a rigid *m*-xylylenediyl organic fragment. When equimolar amounts of [$RuCl_2(PPh_3)_3$] and the R−PCHP ligands were mixed, a chemo- and regioselective reaction was observed involving one of the C−H bonds of the *m*-xylylenediyl fragment, thereby leading to the exclusive formation of complexes of the type [RuCl(R−PCP)(PPh_3)]. Analysis carried out in the course of the reaction has shown the intermediacy of monomeric and dimeric Ru complexes containing an η^3-*P,C,P′* R−PCP ligand and an η^1-*P* R−PCHP ligand bonded to the same metal center. The displacement of the R−PCHP ligand apparently constitutes the rate-determining step in this reaction, and hence C−H bond activation does not greatly affect the overall rate. In this sense, the observed intermediates operate as reservoirs, slowly releasing R−PCHP fragments during the course of the reaction.

In the R−PCHP-type ligand, the R group, located in the *meta*-position in relation to the two CH_2PPh_2 fragments, offers an additional potentially reactive site to the metal center or to species present in the reaction mixture under the employed conditions. However, no interactions involving this part of the ligand molecule were observed.

Finally, complex **7** represents the first example of an Ru compound bearing three fluorinated tails connected to the *para*-position of a PCP ligand. An interesting solubility in a fluorinated solvent (FC-72) has been shown, which is a prerequisite for future investigations concerning the use of **7** as a catalyst or catalyst precursor in biphasic systems.

Experimental Section

General Remarks: All experiments were performed under a dry nitrogen atmosphere using standard Schlenk techniques. Benzene, alkanes, and Et_2O were dried with sodium using benzophenone as indicator. Dichloromethane was dried with CaH_2. 1,2-Dichloroethane and FC-72 were degassed using the freeze-pump-thaw technique. − ^1H, ^{13}C, ^{19}Si, and ^{31}P NMR spectra were recorded at 25 °C on a Bruker AC200 or on a Varian Unity INOVA 300 NMR spectrometer. Chemical shifts are given in ppm relative to $(CH_3)_4Si$ (^1H, ^{13}C, and ^{19}Si NMR spectra) or a capillary containing 85% H_3PO_4 (^{31}P NMR spectra). − 5-Bromo-*m*-xylene was purchased from Aldrich Chem. Co. and was used without further purification. [$RuCl_2(PPh_3)_3$],[24] **5**,[25] **8**,[12] 1-Br-3,5-$(CH_2Br)_2C_6H_3$,[26] and $BrSi(n\text{-}CH_2CH_2C_8F_{17})_3$ [27] were prepared according to literature procedures. Attempted homocouplings using a nickel catalyst were performed following a procedure described previously.[28]

Synthesis of 1-Br-3,5-$(CH_2PPh_2)_2C_6H_3$ (3): A three-necked 500 mL round-bottomed flask containing an ammonia condenser and a magnetic stirring bar was connected to a nitrogen line and then immersed in an acetone/dry-ice bath. After about 250 mL of ammonia had been condensed, sodium (1.38 g, 60 mmol) was added in small chunks. After 30 min, solid PPh_3 (7.87 g, 30 mmol) was added to the intensely blue-colored solution, causing a color change to pale-yellow. After a further 40 min, dry ammonium bromide (2.94 g, 30 mmol) was slowly added, followed after another 15 min by solid 1-Br-3,5-$(CH_2Br)_2C_6H_3$ (5.14 g, 15 mmol) in a single portion. The acetone/dry-ice bath was then removed. After evaporation of the ammonia (4 h), the residual material was extracted with degassed water (2 × 100 mL) and diethyl ether (4 × 100 mL). The combined organic extracts were dried with $MgSO_4$. After filtration, the volatiles were removed in vacuo from the filtrate to leave a white solid. Recrystallization from MeOH was sometimes necessary to purify the compound. Yield: 60−70%. − $C_{32}H_{27}BrP_2$ (553.5): calcd. C 69.45, H 4.92; found C 69.41, H 4.88. − M.p. 95−97 °C. − ^1H NMR (200 MHz, $CDCl_3$): δ = 3.26 (s, 4 H, CH_2), 6.75 (s, 1 H, CH-4), 6.91 (s, 2 H, CH-2,6), 7.20−7.45 (m, 20 H, aromatic). − $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 35.9 (d, $^1J_{CP}$ = 17 Hz, CH_2), 122.2 (s, CBr), 128.7 (d, $^3J_{CP}$ = 7 Hz, *m*-Ph), 129.1 (s, *p*-Ph), 129.4 (t, $^3J_{CP}$ = 7 Hz, CH-4), 130.1 (d, $^3J_{CP}$ = 9 Hz, CH-2,6), 133.1 (d, $^2J_{CP}$ = 19 Hz, *o*-Ph), 138.1 (d, $^1J_{CP}$ = 15 Hz, C_{quat} of Ph), 139.8 (d, $^2J_{CP}$ = 9 Hz, C-3,5). − $^{31}P\{^1H\}$ NMR (81 MHz, $CDCl_3$): δ = −9.07 (s).

Synthesis of 1-Si(n-$CH_2CH_2C_8F_{17})_3$-3,5-$(CH_2PPh_2)_2C_6H_3$ (4): To a solution of **3** (1.11 g, 2 mmol) in diethyl ether (50 mL) at −80 °C was added 2 equiv. of a hexane solution of *t*BuLi. After 40 min., a solution of $BrSi(n\text{-}CH_2CH_2C_8F_{17})_3$ (2.90 g, 2 mmol) in diethyl ether (80 mL) was transferred into the organolithium solution at −80 °C by means of a cannula. After 1 h, the system was slowly allowed to warm to room temperature (overnight). A $^{31}P\{^1H\}$ NMR spectrum recorded thereafter indicated quantitative conversion. Compound **4** was separated from the LiBr by repeated extractions with pentane. Yield: 3.46 g (1.9 mmol, 94%). − $C_{62}H_{39}F_{51}P_2Si$ (1842.9): calcd. C 40.41, H 2.13, F 52.58, P 3.36, Si 1.52; found C 40.54, H 2.23, F 52.46, P 3.28, Si 1.55. − ^1H NMR (300 MHz, $CDCl_3$): δ = 0.85−0.97 (m, 6 H, CH_2−Si), 1.80−2.10 (m, 6 H, CH_2−CF_2), 3.45 (s, 4 H, CH_2−P), 6.65 (m, 2 H, CH-2,6), 7.25 (s, 1 H, CH-4), 7.30−7.55 (m, 20 H, P−Ph). − $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 1.5 (s, CH_2−Si), 25.8 (t, $^2J_{CF}$ = 24 Hz, CH_2−CF_2), 36.2 (vt, CH_2−P), 100.0−126.0 (m, all C−F), 128.7 (d, $^3J_{CP}$ = 6.72 Hz, *m*-Ph), 129.2 (s, *p*-Ph), 131.1 (s, Si−C_{quat}), 132.4 (m, CH-4), 133.4 (d, $^2J_{CP}$ = 18 Hz, *o*-Ph), 138.2 (m, C_{quat}−CH_2PPh_2), 138.4 (d, $^1J_{CP}$ = 15 Hz, C_{quat} of P−Ph); CH-2,6 was not found. − $^{31}P\{^1H\}$ NMR (81 MHz, C_6D_6): δ = −8.66 (s). − $^{29}Si\{^1H\}$ NMR (60 MHz, $CDCl_3$): δ = 0.49 (s).

Synthesis of [RuCl{4-Br-2,6-$(CH_2PPh_2)_2C_6H_2$}(PPh_3)] (6). − Method A: A solution of 1-Br-3,5-$(CH_2PPh_2)_2C_6H_3$ (0.58 g,

1.1 mmol) in 1,2-dichloroethane (10 mL) was added dropwise to a hot solution of $[RuCl_2(PPh_3)_3]$ (1.05 g, 1.1 mmol) in 40 mL of the same solvent. After refluxing for 2 h, the volatiles were removed under reduced pressure and the remaining solid was washed sequentially with hexane (2 × 5 mL), a 1:1 mixture of hexane/diethyl ether (1 × 5 mL), and diethyl ether (2 × 5 mL). Yield: 0.72 g (72%).

Method B: Complex **9** (0.0681 g, containing 11% of **10**) and $[RuCl_2(PPh_3)_3]$ (0.0316 g, 0.033 mmol) were dissolved in CH_2Cl_2 (10 mL) and the solution was refluxed overnight. The volatiles were then removed under reduced pressure and the remaining solid was washed sequentially with hexane (2 × 5 mL), a 1:1 mixture of hexane/diethyl ether (1 × 5 mL), and diethyl ether (2 × 5 mL). Yield: 0.0500 g (50%).

6: M.p. > 200 °C. − $C_{50}H_{41}BrClP_3Ru$ (951.2): calcd. C 63.13, H 4.34, P 9.77, Cl 3.73, Br 8.40, Ru 10.63; found C 63.08, H 4.26, P 9.65, Cl 3.79, Br 8.28, Ru 10.78. − ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 2.37 (br. d, $^2J_{HH}$ = 16 Hz, 2 H, CH_2), 3.45 (dvt, $^2J_{HH}$ = 16 Hz, $^2J_{HP}$ = 6 Hz, 2 H, CH_2), 6.86 (m, 6 H, *m*-PPh_3), 6.95 (m, 4 H, *m*-PPh_2), 7.08 (m, 6 H, *o*-PPh_3), 7.11 (m, 4 H, *o*-PPh_2), 7.12−7.15 (m, 5 H, *p*-PPh_2 and *p*-PPh_3), 7.13 (2 H, CH-3,5), 7.39 (m, 4 H, *m*-PPh_2), 7.44 (m, 2 H, *p*-PPh_2), 7.85 (m, 4 H, *o*-PPh_2). − ^{13}C{^{1}H} NMR (75.5 MHz, CD_2Cl_2): δ = 39.1 (vt, $^{vt}J_{CP}$ = 15 Hz, CH_2), 116.0 (s, C−Br), 125.7 (vt, $^{vt}J_{CP}$ = 9 Hz, C-3,5), 127.4 (d, $^3J_{CP}$ = 10 Hz, *m*-PPh_3), 128.4 (vt, $^{vt}J_{CP}$ = 4 Hz, *m*-PPh_2), 128.8 (vt, $^{vt}J_{CP}$ = 4 Hz, *m*-PPh_2), 129.45−129.50 (two s, *p*-PPh_3 and *p*-PPh_2), 130.3 (s, *p*-PPh_2), 132.7 (vt, $^{vt}J_{CP}$ = 5 Hz, *o*-PPh_2), 133.1 (vt, $^{vt}J_{CP}$ = 5 Hz, *o*-PPh_2), 134.0 (m, C_{quat}−PPh_2), 134.4 (d, $^2J_{CP}$ = 10 Hz, *o*-PPh_3), 135.5 (vt, $^{vt}J_{CP}$ = 17 Hz, C_{quat}−PPh_2), 136.4 (d, $^1J_{CP}$ = 52 Hz, C_{quat}−PPh_3), 153.0 (vt, $^{vt}J_{CP}$ = 9 Hz, C-2,6), 172.8 (d, $^2J_{CP}$ = 17 Hz, Ru−C_{ipso}). − ^{31}P{^{1}H} NMR (121 MHz, CD_2Cl_2): δ = 36.74 (d, 2 P, Br−PCP), 80.62 (t, $^2J_{PP}$ = 32 Hz, 1 P, PPh_3).

Synthesis of [RuCl{$C_6H_2(CH_2PPh_2)_2$-2,6-Si(*n*-$CH_2CH_2C_8F_{17})_3$-4}-(PPh_3)] (7): $[RuCl_2(PPh_3)_3]$ (0.16 g, 0.17 mmol) and *meta*-bis(phosphane) **4** (0.31 g, 0.17 mmol) were dissolved in 1,2-dichlorobenzene and the solution was refluxed for 2 h. The volatiles were then removed under reduced pressure and the green-colored solid residue was extracted with FC-72 (5 × 2 mL). The insoluble material (free PPh_3) was separated from the green solution by filtration through Celite mounted in a disposable pipette. This extraction−filtration operation was performed twice in order to obtain the final product **7** free from PPh_3. Yield: 0.27 g (0.12 mmol, 71%). − FAB-MS showed a fragmentation peak at *m*/*z* = 2205.71 [M^+ − Cl] and also peaks characteristic of the loss of C_nF_m fragments. − ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 0.90−1.10 (m, 6 H, CH_2−Si), 1.95−2.25 (m, 6 H, CF_2−CH_2), 2.73 (br. d, $^2J_{HH}$ = 16 Hz, 2 H, CH_2−P), 3.44 (m, 2 H, CH_2−P), 6.20−7.90 (m, aromatic), 8.08 (br. s, 4 H, *o*-PPh_2). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 1.5 (s, CH_2−Si), 26.0 (t, $^3J_{CF}$ = 24 Hz, *C*H_2−CF_2), 38.9 (t, $^1J_{CP}$ = 15 Hz, CH_2−P), 100.0−124.0 (m, CF_n), 121.8 (s), 127.1 (d, $^4J_{CP}$ = 11 Hz, *m*-PPh_3), 128.06 (vt, *m*-PPh_2), 128.59 (m, *m*-PPh_2), 129.0−129.5 (m, *p*-PPh_3 and *p*-PPh_2), 130.1 (s, *p*-PPh_2), 132.5 (vt, *o*-PPh_2), 134.1 (d, $^3J_{CP}$ = 8 Hz, *o*-PPh_3), 135.6 (m, C_{quat}), 136.7 (s, C_{quat}), 151.9 (vt, C_{quat}); resonances of Ru−C_{ipso} and C_{quat}−PPh_2 were too weak to be located). − ^{31}P{^{1}H} NMR (81 MHz, C_6D_6): δ = 36.11 (d, 2 P, PPh_2), 82.26 (t, $^2J_{PP}$ = 32 Hz, 1 P, PPh_3).

Synthesis of [{RuCl[$C_6H_2(CH_2PPh_2)_2$-2,6-Br-4]}$_2${μ-η^1-*P*,η^1-*P*′-[$C_6H_3(CH_2PPh_2)_2$-3′,5′-Br-1′]}] (9) and (10). − Method A: A solution of $[RuCl_2(PPh_3)_3]$ (0.96 g, 1.0 mmol) and **3** (1.11 g, 2.0 mmol) in CH_2Cl_2 (30 mL) was refluxed for 3 days. The volatiles were then removed under reduced pressure and the residual dark-green material was washed with hexane (8 × 10 mL) and Et_2O (2 × 4 mL). After drying in vacuo, 0.95 g of a light-green solid was obtained, which was found to consist of **9** (89%) and **10** (11%).

Method B: Addition of ligand **3** (0.0200 g, 0.0360 mmol) to a solution of **6** (0.0688 g, 0.0720 mmol) in CH_2Cl_2 (10 mL) and stirring for 1 h at room temp. led to a mixture of complexes **9** and **10** in a 2:1 ratio. However, starting materials were still present, despite the use of excess ligand, which thwarted the isolation of **9** and **10** from the reactants after the standard work-up (see above) with hexane and Et_2O.

[{RuCl[$C_6H_2(CH_2PPh_2)_2$-2,6-Br-4]}$_2${μ-η^1-*P*,η^1-*P*′-[$C_6H_3(CH_2PPh_2)_2$-3′,5′-Br-1′]}] (9): ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.67 (br. d, $^2J_{HH}$ = 16 Hz, 4 H, CH_2 of Br−PCP), 3.10 (d, $^2J_{HP}$ = 9 Hz, 4 H, CH_2 of Br−PCHP), 3.63 (dm, $^2J_{HH}$ = 16 Hz, 4 H, CH_2 of Br−PCP), 4.82 (s, 1 H, CH-4′), 5.47 (s, 2 H, CH-2′,3′), 6.30−7.90 (m, aromatic), 8.00−8.20 (m, 8 H, *o*-PPh_2). − ^{13}C{^{1}H} NMR (75.5 MHz, CD_3Cl): δ = 39.6 (m, all CH_2), 115.3 (s, C−Br of Br−PCP), 119.9 (s, C−Br of Br−PCHP), 125.0 (m, aromatic CH), 126.8 (m, aromatic CH), 128.3 (m, aromatic CH), 128.6 (m, aromatic CH), 129.1 (s, aromatic CH), 129.8 (s, aromatic CH), 130.3 (m, aromatic CH), 131.1 (m), 131.7 (m, aromatic CH), 132.8 (d, J_{CP} = 9 Hz, aromatic CH), 133.0 (m), 134.2 (m, C_{quat}), 136.2 (d, J_{CP} = 12 Hz, C_{quat}), 151.3 (vt, $^{vt}J_{CP}$ = 9 Hz, C-2,6 of Br−PCP), 173.9 (br. d, $^2J_{CP}$ = 16 Hz, Ru−C_{ipso}). − ^{31}P{^{1}H} NMR (81 MHz, CD_3Cl): δ = 40.05 (d, 4 P, Br−PCP), 83.75 (t, $^2J_{PP}$ = 31 Hz, 2 P, Br−PCHP).

[RuCl{$C_6H_2(CH_2PPh_2)_2$-2,6-Br-4}{η^1-*P*-[$C_6H_3(CH_2PPh_2)_2$-3′,5′-Br-1′]}] (10): Due to the low concentration of this compound, as well as to overlap with the stronger signals of the bridging complex, only a few of its ^{1}H NMR resonances could be assigned. For the same reasons, the carbon resonances were to weak too be detected. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.83 (m, 2 H, CH_2 of the non-coordinated CH_2PPh_2 group), 3.30−3.80 (m, 6 H, CH_2 of the coordinated CH_2PPh_2 groups), 5.68 (s, 1 H, CH-2′ or 4′ or 6′), 5.82 (s, 1 H, CH-2′ or 4′ or 6′), 5.90 (s, 1 H, CH-2′ or 4′ or 6′). − ^{31}P{^{1}H} NMR (81 MHz, CD_3Cl): δ = −10.06 (s, 1 P, non-coordinated PPh_2), 40.3 (d, 2 P, Br−PCP), 83.8 (t, 1 P, coordinated PPh_2 of Br−PCHP , $^2J_{PP}$ = 31 Hz).

Synthesis of [{RuCl[$C_6H_3(CH_2PPh_2)_2$-2,6]}$_2${μ-η^1-*P*,η^1-*P*′-[C_6H_4-$(CH_2PPh_2)_2$-1′,3′]}] (11): A solution of $RuCl_3{\cdot}3H_2O$ (0.18 g, 0.70 mmol) in methanol (10 mL) was refluxed for 1 h. Compound **5** (0.50 g, 1.05 mmol) was then added as a solid and reflux was continued overnight. After removal of the volatiles under reduced pressure, pure **11** could be extracted from the green-colored solid residue with benzene. Yield: 0.0700 g (14%). − ^{1}H NMR (300 MHz, C_6D_6): δ = 2.81 (br. d, $^2J_{HH}$ = 16 Hz, 4 H, CH_2 of H−PCP), 3.42 (d, $^2J_{HP}$ = 9 Hz, 4 H, CH_2 of H−PCHP), 3.62 (dvt, $^2J_{HH}$ = 16 Hz, 4 H, CH_2 of H−PCP), 5.42 (s, 1 H, CH-2′), 5.69 (d, $^3J_{HH}$ = 8 Hz, 2 H, CH-2′,4′), 5.99 (t, $^3J_{HH}$ = 8 Hz, 1 H, CH-3′), 6.60−6.85 (m, 22 H, aromatic), 6.90−7.25 (m, 26 H, aromatic), 7.35−7.45 (m, 10 H, aromatic), 8.10−8.20 (m, 8 H, *o*-Ph); not all resonances were detected due to overlapping with C_6D_6 carbon signal. − ^{13}C{^{1}H} NMR (75.5 MHz, C_6D_6): δ = 40.6 (m, all CH_2), 121.6 (s, CH aromatic), 122.9 (t, J_{CP} = 9 Hz), 126.6 (s), 126.9 (d, J_{CP} = 10 Hz), 130.8−131.3 (m), 132.4 (vt, $^{vt}J_{CP}$ = 5 Hz), 133.5−133.9 (m), 135.2−136.1 (m), 151.1 (vt, $^{vt}J_{CP}$ = 9 Hz, C_{quat}, C-2,6), 175.3−175.9 (m, Ru−C_{ipso}). − ^{31}P{^{1}H} NMR (81 MHz, C_6D_6): δ = 40.90 (d, 4 P, H−PCP), 85.22 (t, $^2J_{PP}$ = 32 Hz, 2 P, H−PCHP).

Acknowledgments

This work was financially supported by the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Brazil, and the Council for Chemical Sciences of the Netherlands Organization for Scientific Research (CW-NWO). Dr. R. A. Gossage (Department of Chemistry, Acadia University, Wolfville, Nova Scotia, Canada) is kindly thanked for discussions and corrections of the manuscript.

[7] In the absence of other interactions, the square-planar complexes containing μ-η^1-*P*,η^1-*P*′-PCEP ligands (E = H or alkyl group) are expected to be symmetrical with equivalent phosphorus nuclei. This is observed for the platinum complexes reported in refs. [5] and [6]. However, we recently isolated a dimeric platinum complex containing two μ-η^1-*P*,η^1-*P*′-H−PCHP ligands, in which the phosphorus atoms are nonequivalent as a result of additional non-bonding interactions. Steric Factors Affecting the Brønsted Acidity of Aluminosilsesquioxanes

Maria D. Skowronska-Ptasinska,[a] Robbert Duchateau,*[a] Rutger A. van Santen,[a] and Glenn P. A. Yap[b]

Keywords: Aluminosilicates / Silsesquioxanes / Aluminum / Silicon / Zeolite analogues

By reacting $AlMe_3$ with two equivalents of (*c*-$C_5H_9)_7Si_7O_9(OH)_2OSiR_3$, the corresponding Brønsted acidic aluminosilsesquioxanes [(*c*-$C_5H_9)_7Si_7O_{11}(OSiR_3)$]Al[(*c*-$C_5H_9)_7Si_7O_{10}(OH)OSiR_3$] [$SiR_3$ = $SiMe_3$ (**1a**), $SiMePh_2$ (**1b**)] are obtained. These complexes readily react with triethylamine to yield the corresponding ammonium salts {[(*c*-$C_5H_9)_7Si_7O_{11}(OSiR_3)]_2Al$}$^-${$HNEt_3$}$^+$ (**2a**,**b**). Hydrogen bonding between the acidic SiO(H)→Al proton and the pendant silyl ether function is effectively reduced by increasing the steric bulk of the silyl ether substituents, resulting in a higher acidity for **1b** compared to that of **1a**. With the silsesquioxane ligand (*c*-$C_5H_9)_8Si_8O_{11}(OH)_2$, which lacks pendant silyl ether functions, the acidic proton cannot satisfactorily be stabilized and this renders the putative Brønsted acid [(*c*-$C_5H_9)_8Si_8O_{13}$]Al[(*c*-$C_5H_9)_8Si_8O_{12}(OH)$] unstable. In the absence of proton acceptors, the disproportionation product [(*c*-$C_5H_9)_8Si_8O_{13}]_3Al_2$ (**3**) is formed instead of the Brønsted acid. However, in the presence of triethylamine, the initially formed Brønsted acid readily transfers its proton to the amine, affording the ammonium salt {[(*c*-$C_5H_9)_8Si_8O_{13}]_2Al$}$^-${$HNEt_3$}$^+$ (**4**).

Introduction

Acidic aluminum sites in zeolites, clays, and aluminosilicates play an important role in acid-catalyzed reactions.[1] In recent years, several soluble aluminum complexes based on incompletely condensed silsesquioxanes have been prepared and successfully employed as homogeneous models for aluminosilicates and zeolites.[2−5] This paper concerns the further development of molecular cluster analogues of zeolitic acidic sites, which are either inherently useful as catalysts or serve as model systems facilitating detailed mechanistic analysis. Recently, we reported the synthesis and characterization of the aluminosilsesquioxane {[(*c*-$C_5H_9)_7Si_7O_{11}(OSiMe_3)$]Al[(*c*-$C_5H_9)_7Si_7O_{10}(OH)OSiMe_3$]} (**1a**),[4] the first homogeneous model of a hydrogen-bonded Brønsted acidic aluminosilicate site as found, for example, in zeolite HY.[1] The strong intramolecular hydrogen bond between the acidic SiO(*H*)→Al proton and the pendant silyl ether oxygen (Si*O*$SiMe_3$) was found to dramatically lower the Brønsted acidity of this complex. In an effort to produce more acidic aluminosilsesquioxanes, we have now synthesized aluminosilsesquioxane complexes with diminished intramolecular hydrogen bonding.

Results and Discussion

To reduce hydrogen bonding as observed in **1a**,[4] the silsesquioxane (*c*-$C_5H_9)_7Si_7O_9(OH)_2OSiMePh_2$ with a considerably more bulky silyl ether substituent was synthesized.[6] Brønsted acids of the type {[(*c*-$C_5H_9)_7Si_7O_{11}(OSiR_3)$]Al[(*c*-$C_5H_9)_7Si_7O_{10}(OH)OSiR_3$]} [$SiR_3$ = $SiMe_3$ (**1a**); $SiMePh_2$ (**1b**)] may readily be prepared by treatment of silsesquioxane solutions with $AlMe_3$ in toluene, although the reaction rate strongly depends on the silyl ether substituent (Scheme 1). Whereas for SiR_3 = $SiMe_3$ the reaction reaches completion within minutes at 0 °C, when R is the more bulky $MePh_2$ group, significant retardation is seen and heating to reflux (1 h) is required in order to obtain the Brønsted acid {[(*c*-$C_5H_9)_7Si_7O_{11}(OSiMePh_2)$]Al[(*c*-$C_5H_9)_7Si_7O_{10}(OH)OSiMePh_2$]} (**1b**) in reasonable yield. In the presence of triethylamine, the Brønsted acids (**1a**,**b**) are selectively transformed into the corresponding ammonium salts {[(*c*-$C_5H_9)_7Si_7O_{11}(OSiR_3)]_2Al$}$^-${$HNEt_3$}$^+$ [SiR_3 = $SiMe_3$ (**2a**),[4] $SiMePh_2$ (**2b**); Scheme 1].

In the ^{1}H NMR spectrum of **1a**, the OH resonance is seen at δ = 8.50, characteristic of a hydrogen-bonded acidic hydroxyl group.[7] In contrast, the OH resonance of **1b** is significantly shifted to higher field, appearing at δ = 4.90. This high-field shift may conceivably be the result of either reduced hydrogen bonding or of decreased acidity of the hydroxyl group.[4,7] The observed higher frequency of the O−H stretching vibration of **1b** (3366 cm^{-1}) compared to that of **1a** (3150 cm^{-1}) is in line with decreased hydrogen bonding. Hence, it can be concluded that increasing the steric bulk of the pendant silyl ether function does indeed reduce hydrogen bonding and should render **1b** more acidic than **1a**.

To determine the relative acidities of **1a** and **1b**, the ammonium salt {[(*c*-$C_5H_9)_7Si_7O_{11}(OSiMe_3)]_2Al$}$^-${$HNEt_3$}$^+$ (**2a**) was treated with an equimolar amount of the Brønsted acid {[(*c*-$C_5H_9)_7Si_7O_{11}(OSiMePh_2)$]Al[(*c*-$C_5H_9)_7Si_7O_{10}(OH)OSiMePh_2$]} (**1b**). As was assumed on the basis of the

NMR and IR spectroscopic data, the equilibrium (^{1}H NMR) that was set up revealed that **1b** is indeed a stronger acid than **1a** ($\Delta pK_{a(\mathbf{1a}-\mathbf{1b})} = 1.1$).

The NMR spectra of the ammonium salts **2a**,**b** are significantly simplified compared to those of the corresponding asymmetric Brønsted acids **1a**,**b** and are consistent with a C_2 symmetric structure.[4] With shifts ranging from δ =

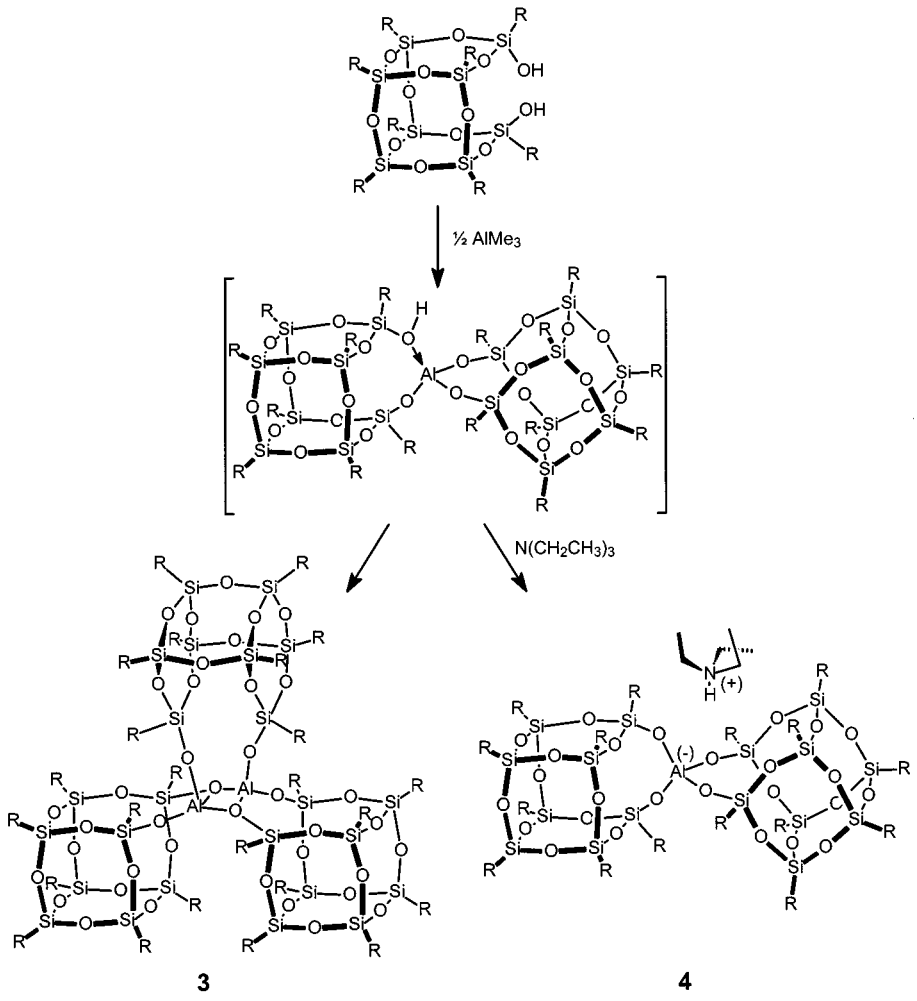

Scheme 2

9.69−9.27, the Et_3NH resonances for **2a**,**b** are virtually identical. It is interesting to note that for **2b** the $HNEt_3$ methylene protons appear as a doublet of multiplets ($^3J_{HH}$ = 68 Hz), whereas for **2a** only a single multiplet is observed. This effect may possibly be attributed to a difference in hydrogen bonding between the ammonium proton and the Al−O−Si oxygen in **2a**,**b**. The X-ray structure of **2a** reveals that the ammonium ion is hydrogen bonded to the aluminosilsesquioxane fragment.[4] In contrast, the molecular structure of the slightly more bulky cyclohexyl analogue of **2a** consists of a nonbonded ion pair.[3] Although still hydrogen bonded, due to its larger steric bulk the ammonium cation in **2b** (Figure 1) is coordinated significantly less effectively than in **2a**. Therefore, the $^3J_{HH}$ coupling, and thus the N−H bond strength, can be expected to increase on going from **2a** to **2b**, as is indeed observed.

The above results support the proposition that hydrogen bonding between the SiO(*H*)→Al proton and the silyl ether function is effectively reduced by increasing the steric bulk of the pendant silyl ether function, which, in turn, results in increased acidity of the complex. If instead a silsesquioxane ligand lacking such a silyl ether function is used, such hydrogen bonding will be prevented, which may result in an even stronger Brønsted acid. To test this hypothesis, we studied the silsesquioxane $(c\text{-}C_5H_9)_8Si_8O_{11}(OH)_2$, which is accessible by a similar route as its cyclohexyl-substituted analogue, as recently reported by Feher et al.[8] Treatment of toluene solutions of $(c\text{-}C_5H_9)_8Si_8O_{11}(OH)_2$ with half an equivalent of $AlMe_3$ led to a rapid reaction. The only aluminosilsesquioxane compound recovered after crystallization was the bimetallic $[(c\text{-}C_5H_9)_8Si_8O_{13}]_3Al_2$ (**3**), and not the expected Brønsted acid, $[(c\text{-}C_5H_9)_8Si_8O_{13}]Al[(c\text{-}C_5H_9)_8Si_8O_{12}(OH)]$ (Scheme 2). However, when the reaction of $(c\text{-}C_5H_9)_8Si_8O_{11}(OH)_2$ with $AlMe_3$ was carried out in the presence of NEt_3, the ammonium salt $\{[(c\text{-}C_5H_9)_8Si_8O_{13}]_2Al\}^-\{HNEt_3\}^+$ (**4**) was formed (Scheme 2). The fact that in the presence of an amine the ammonium salt **4** is obtained suggests that, in the absence of a proton acceptor, the proton of the initially formed Brønsted acid is highly reactive. Consequently, the unstable Brønsted acid disproportionates into the thermodynamically more stable complex **3**.

Figure 2 shows the molecular structure of **3**. The tetrahedral aluminum centers are connected by two bridging μ-OSi groups and by one silsesquioxane ligand, which is bonded in an η^1-fashion to each aluminum atom. The average η^1-O_{Si}−Al bond length of 1.675(7) Å compares well with those in $[(Ph_3SiO)_2Al(O\mathit{t}Bu)]_2$ [av. η^1-O_{Si}−Al = 1.690(3)

Å][9a] and $[(Ph_2Si)_2O_3]_4Al_4(OH)_4{\cdot}4OEt_2$ [av. η^1-O_{Si}−Al = 1.698(3) Å][9a] and is significantly shorter than, for example, that in the Lewis base adduct $[(c\text{-}C_6H_{11})_7Si_7O_{12}]AlO{=}PPh_3$ [av. η^1-O_{Si}−Al = 1.717(4) Å][2] or those in the anionic $\{[(c\text{-}C_5H_9)_7Si_7O_{11}(OSiR'_3)]_2Al\}^-\{HNEt_3\}^+$ {av. η^1-O_{Si}−Al: 1.741(5) Å [SiR'_3 = $SiMe_3$ (**2a**)],[4] 1.740(4) [SiR'_3 = $SiMePh_2$ (**2b**)]}. With an average distance of 1.833(7) Å, the (μ-O_{Si})−Al bonds are normal for bridging (μ-RO)−Al bonds.[9] The Si−O bond lengths [av. 1.605(7) Å] are similar to those found in the silsesquioxane compounds ($c\text{-}C_6H_{11})_8Si_8O_{13}[N(H)Ph]_2$ [1.609(2)−1.630(2) Å] and ($c\text{-}C_6H_{11})_8Si_8O_{13}S$ [1.610(2)−1.693(2) Å].[10]

Concluding Remarks

In summary, the strength of the intramolecular hydrogen bond found in **1a−b** may be effectively tuned by altering the steric bulk of the silyl ether substituent. Increased steric bulk leads to less effective hydrogen bonding, which, in turn, renders the complex more acidic. However, when the acidic proton is not satisfactorily stabilized (as, for example, by hydrogen bonding), then the Brønsted acid becomes unstable and is liable to undergo further reactions.

Experimental Section

General Remarks: All manipulations were performed under an argon atmosphere using glove box (Braun MB-150 GI) and Schlenk techniques. Solvents were distilled from Na (toluene), K (THF), or Na/K alloy (hexanes, [D_6]benzene) and stored under argon. Triethylamine and [D_1]chloroform were dried over 4 Å molecular sieves. − IR spectra were recorded on a Nicolet Avatar 360 spectrophotometer equipped with an ATR (golden gate) device. − NMR spectra were recorded on a Varian Mercury 400 MHz (^{1}H, 400 MHz; ^{13}C, 100 MHz) or a Varian Inova 500 MHz (^{29}Si, 99 MHz) spectrometer at 25 °C. Chemical shifts are reported in ppm and are referenced to residual solvent resonances (^{1}H, ^{13}C) or an external standard (^{29}Si, TMS, δ = 0). − $(c\text{-}C_5H_9)_7Si_7O_9(OH)_3$[2] and $(c\text{-}C_5H_9)_7Si_7O_9(OSiMePh_2)(OH)_2$[11] were prepared according to literature procedures. $(c\text{-}C_5H_9)_8Si_8O_{12}$ was prepared by the Pt-catalyzed hydrosilylation of $(c\text{-}C_5H_9)_7Si_8O_{12}H$ in refluxing cyclopentene. $(c\text{-}C_5H_9)_8Si_8O_{11}(OH)_2$ was prepared by treating $(c\text{-}C_5H_9)_8Si_8O_{12}$ with CF_3SO_3H as described by Feher et al.[8]

$[(c\text{-}C_5H_9)_7Si_7O_{11}(OSiMePh_2)]Al[(c\text{-}C_5H_9)_7Si_7O_{10}(OH)(OSiMePh_2)]$ (1b): To a solution of $(c\text{-}C_5H_9)_7Si_7O_9(OH)_2OSiMe_2Ph$ (3.22 g, 3.00 mmol) in toluene (25 mL) was added $AlMe_3$ (0.75 mL, 2.0 M solution in *n*-heptane, 1.5 mmol) at 0 °C. After stirring for 1 h at room temperature, the mixture was refluxed for a further 1 h. The volatiles were then evaporated and the product was recrystallized from hexane (7 mL) at room temperature, yielding **1b** (2.33 g, 1.07 mmol, 72%) as colorless crystals. − ^{1}H NMR ([D_6]benzene): δ = 0.88 (m, 6 H, $SiCH_3$), 1.17 (m, 14 H, $CH{-}C_5H_9$), 1.65 (m, 112 H, $CH_2{-}C_5H_9$), 4.90 (s, 1 H, OH), 7.30 (m, 6 H, Ph), 7.85 (m, 4 H, Ph). − ^{13}C{^{1}H} NMR ([D_6]benzene): δ = 0.03 (s, $SiCH_3$), 22.67, 22.87, 22.90, 23.62, 24.93 (s, $CH{-}C_5H_9$), 27.27, 27.36, 27.43, 27.52, 27.98, 28.09, 28.50 (s, $CH_2{-}C_5H_9$), 128.07, 130.26, 134.57 (Ph). − ^{29}Si{^{1}H} NMR ([D_6]benzene): δ = −67.48, −66.91, −64.66, −64.29, −63.53 [s, $(\equiv O)_3SiC_5H_9$], −9.89 (s, $SiMePh_2$) (1:1:1:2:2:1 ratio). − $C_{96}H_{153}AlO_{24}Si_{16}$ (2167.61): calcd. C 53.19, H 7.11; found C 53.03, H 7.24.

$\{[(c\text{-}C_5H_9)_7Si_7O_{11}(OSiMePh_2)]_2Al\}^-\{Et_3NH\}^+$ (2b): At 0 °C, $AlMe_3$ (0.5 mL, 2.0 M solution in *n*-heptane, 1.0 mmol) was added to a stirred solution of $(c\text{-}C_5H_9)_7Si_7O_9(OH)_2OSiMePh_2$ (2.15 g, 2.01 mmol) and NEt_3 (0.3 mL, 2.2 mmol) in toluene (30 mL). After stirring at room temperature for 1 h, the volatiles were evaporated. The crude product was recrystallized from hexane (15 mL) at 0 °C, yielding **2b** (1.20 g, 0.53 mmol, 53%) as colorless crystals. − ^{1}H NMR ([D_6]benzene): δ = 0.73 (s, 6 H, $SiCH_3$), 0.89 [m, 9 H, $HN(CH_2CH_3)_3$], 1.23 (m, 14 H, $CH{-}C_5H_9$), 1.65 (m, 112 H, $CH_2{-}C_5H_9$), 2.63 [dm, ^3J(H,H) = 68 Hz, 6 H, $HN(CH_2CH_3)_3$], 7.23 (m, 12 H, Ph), 7.70 (m, 8 H, Ph), 9.29 (s, 1 H, $HNEt_3$). − ^{13}C{^{1}H} NMR ([D_6]benzene): δ = 0.21 (s, $SiCH_3$), 8.84 (s, NCH_2CH_3), 23.05, 23.31, 24.31, 24.50, 24.63, 25.51, 25.91 (s, $CH{-}C_5H_9$, 1:1:1:1:1:1:1 ratio), 27.05, 27.13, 27.25, 27.33, 27.46, 27.62, 28.06, 28.12, 28.30, 28.57, 28.67, 28.93 (s, $CH_2{-}C_5H_9$), 45.59 (s, NCH_2CH_3), 127.99, 128.04, 129.87, 134.43, 134.50, 137.57, 137.86, (s, Ph). − ^{29}Si{^{1}H} NMR ([D_6]benzene): δ = −67.03, −66.46, −64.48, −64.23, −64.14, −63.61 [s, $(\equiv O)_3SiC_5H_9$], −11.79 (s, $SiMePh_2$) (1:1:1:2:1:1:1 ratio). − $C_{102}H_{168}AlNO_{24}Si_{16}$ (2268.81): calcd. C 54.00, H 7.46; found C 53.63, H 7.52.

$[(c\text{-}C_5H_9)_8Si_8O_{13}]_3Al_2$ (3): At 0 °C, $AlMe_3$ (0.5 mL, 2.0 M in *n*-heptane, 1.0 mmol) was added to a stirred solution of $(c\text{-}C_5H_9)_8Si_8O_{11}(OH)_2$ (1.98 g, 2.00 mmol) in toluene (10 mL). After stirring overnight at room temperature, the volatiles were removed in vacuo and the remaining white solid was crystallized from hexane (5 mL) to yield **3** (1.00 g, 0.33 mmol, 66%) as colorless crystals. − ^{1}H NMR ([D_6]benzene): δ = 1.23 (m, 8 H, $CH{-}C_5H_9$), 1.75 (br. m, 64 H, $CH_2{-}C_5H_9$). − ^{13}C{^{1}H} NMR ([D_6]benzene): δ = 22.62, 22.69, 22.93, 23.20, 23.78, 24.44, 25.52 (s, $CH{-}C_5H_9$), 27.39, 27.45, 27.64, 27.76, 28.01, 28.58 ($CH_2{-}C_5H_9$). − ^{29}Si{^{1}H} NMR ([D_6]benzene): δ = −69.89, −69.51, −68.85, −68.40, −68.23, −67.56, −67.40, −65.78, −64.98, −60.56. − $C_{120}H_{216}Al_2O_{39}Si_{24}$ (3011.04): calcd. C 47.87, H 7.23; found C 47.93, H 7.29.

$\{[(c\text{-}C_5H_9)_8Si_8O_{13}]_2Al\}^-\{Et_3NH\}^+$ (4): The procedure used was similar to that described for **2b**, starting from $(c\text{-}C_5H_9)_8Si_8O_{11}(OH)_2$ (0.64 g, 0.65 mmol). The crude product was recrystallized from hexane (6 mL) at 0 °C, yielding **4** (0.42 g, 0.20 mmol, 61%) as colorless crystals. − ^{1}H NMR ([D_6]benzene): δ = 0.92 [m, 9 H, $N(CH_2CH_3)_3$], 1.06 (m, 4 H, $CH{-}C_5H_9$), 1.21 (m, 12 H, $CH{-}C_5H_9$), 1.80 (m, 128 H, $CH_2{-}C_5H_9$), 2.78 [m, 6 H, $N(CH_2CH_3)_3$], 9.94 (s, 1 H, $HNEt_3$). − ^{13}C{^{1}H} NMR ([D_6]benzene): δ = 8.26 [s, $N(CH_2CH_3)_3$], 22.89, 23.87, 26.42 (s, $CH{-}C_5H_9$, 2:4:2 ratio), 27.44, 27.52, 27.58, 27.61, 27.84, 28.67, 28.43, 28.72 (s, $CH_2{-}C_5H_9$), 45.02 [s, $N(CH_2CH_3)_3$]. − ^{29}Si{^{1}H} NMR ([D_6]benzene): δ = −68.66, −67.39, −65.17 (s, 2:1:1 ratio). − $C_{86}H_{160}AlNO_{26}Si_{16}$ (2100.56): calcd. C 49.17, H 7.68; found C 49.75, H 7.84.

X-ray Crystal Structure Analyses of 2b and 3: Single crystals of **2b** and **3** suitable for X-ray structure analysis were grown from saturated hexane solutions. Data were collected on a Bruker AX SMART 1 K CCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å).

For **2b**: $C_{102}H_{168}AlNO_{24}Si_{16}{\cdot}(C_6H_{14})$ (M_r: 2345.59): T = 203(2) K, 0.2 × 0.1 × 0.1 mm, monoclinic, $P2_1/n$, a = 24.947(2) Å, b = 19.032(2) Å, c = 28.629(3) Å, β = 111.718(2)°, V = 12628(2) Å^3, Z = 4, $\rho_{calcd.}$ = 1.234 gcm^{-3}, μ(Mo-K_α) = 2.32 cm^{-1}. A total of 81069 reflections were collected, of which 13217 were considered unique. The structure was solved by direct methods using SHELXS-97[12] and subsequent difference Fourier maps. A final refinement on F^2 converged at R_1 = 0.0595, wR_2 = 0.1662.

For **3**: $C_{120}H_{216}Al_2O_{39}Si_{24}$ (M_r: 3011.05): T = 236(2) K, 0.1 × 0.1 × 0.02 mm, triclinic $P1$(bar), a = 19.047(4) Å, b = 19.355(4) Å, c = 24.662(6) Å, α = 105.540(4)°, β = 91.650(5)°, γ = 103.428(5)°, V = 8480(3) Å^3, Z = 2, $\rho_{calcd.}$ = 1.179 gcm^{-3}, μ(Mo-K_α) = 2.52 cm^{-1}. A total of 66657 reflections were collected, of which 15296 were considered unique. The structure was solved by direct methods using SHELXS-97[12] and subsequent difference Fourier maps. A final refinement on F^2 converged at R_1 = 0.0831, wR_2 = 0.2347.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-143922 (**26**) and -143923 (**3**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax (internat.): +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Zinc / Aldehydes / Phenoxide complexes / Structural chemistry / Pyrazolylborate complexes

The zinc hydroxide complex $Tp^{Cum,Me}Zn–OH$ [**1**, $Tp^{Cum,Me}$ = tris(3-cumenyl-5-methylpyrazolyl)borate] reacts with trichloroacetaldehyde and pentafluorobenzaldehyde to form the complexes $Tp^{Cum,Me}Zn–O(CHOH)R$, containing the aldehyde ligands as the deprotonated aldehyde hydrates. **1** and 2-formylphenol, 2,6-diformylphenol and 2-formylthiophenol undergo condensation with the formation of the corresponding phenolate and thiophenolate complexes, in which one formyl group of each is coordinated to the zinc center as part of a six-membered chelate ring. The aldehyde–hydrate and aldehyde–phenolate bonding modes, which were confirmed by three structure determinations, represent two new kinds of aldehyde attachment to transition metal centers.

Introduction

Aldehyde functions belong to the standard functions of preparative organic chemistry, and metal salts are frequently used to increase their reactivity by Lewis acid activation.[1,2] For mechanistic considerations and for improving the knowledge about their basic coordination chemistry, it is therefore worthwhile to gain information on the bonding interactions between metal ions and the aldehyde CO functions. Due to the fact that aldehydes are very poor donor ligands, the number of isolated and structurally characterized aldehyde complexes is limited. Prior to our own work, only nine structures of such complexes with monodentate *O*-coordinated aldehyde ligands have been reported.[3]

Zinc salts, specifically zinc chloride, are among the most common activators for the reactivity of organic carbonyl functions. This holds for preparative organic chemistry,[1,2] as well as for enzymatic reactions: Two prominent representatives of the alcohol dehydrogenase class of enzymes, horse liver alcohol dehydrogenase (LADH, converting alcohols to aldehydes)[5,6] and yeast alcohol dehydrogenase (YADH, converting aldehydes to alcohols),[7,8] are zinc enzymes. All this provides ample motivation to study the coordination chemistry of zinc with alcohol and aldehyde ligands and to find out about the zinc-mediated reactivity of the corresponding substrates.

As we began our work in the preparative and structural chemistry of zinc−aldehyde complexes, only a small handful of these complexes had been described and only three structures reported.[3,9] We contributed several dozen compounds, including structural models for the alcohol dehydrogenases, and determined their structures.[4,9−12] Our findings underlined the general statement that monodentate aldehydes are very weak donors, and can be attached to zinc ions only in the absence of nitrogen or even weak oxygen donors, and that the combination with nitrogen donors is possible only when the aldehyde function forms a favorable chelate ligand together with them. Thus, one important bonding type, i.e. the monodentate attachment of an aldehyde molecule to a zinc ion in a "natural" environment, that is one with N and O or S donors, is still unknown.

We had experienced that encapsulating tris(pyrazolyl)borate (Tp) ligands are good mimics for a protein-like environment for zinc ions, thus allowing for the synthesis of structural models and mechanistic investigations of enzyme-like situations.[13] Moreover, the counterparts of the aldehydes in LADH or YADH reactivity, the alcohols, had already been attached to zinc ions together with the Tp ligands.[14−18] We therefore hoped that in a suitable TpZn environment, aldehydes might be induced to bind to the zinc center with their C=O functions. In order to ensure maximum protection of the substrates, we chose $Tp^{Cum,Me}$ as the Tp ligand with the most spacious substituents, and we used $Tp^{Cum,Me}Zn−OH$ (**1**),[19] bearing OH as a good leaving group,[13,20] as the reagent for the aldehyde substrates.

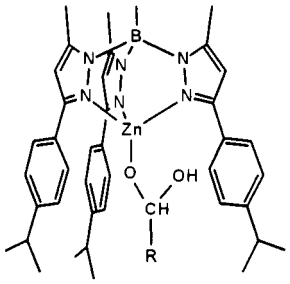
effects in the ^{1}H NMR spectra, and the reagents remained unchanged after removal of the solvent. However, aldehydes with electronegative substituents did react with **1**. Trichloroacetaldehyde and pentafluorobenzaldehyde were converted into complexes **2** and **3**. This conversion is accompanied by a shift of the ν(OH) band in the IR spectra to 3532 (**2**) and 3597 (**3**) cm^{-1}, and a shift of the OH resonance in the NMR spectra to δ = 4.10 (in $CDCl_3$) in both cases.



2: R = CCl_3 **3**: R = C_6F_5

Compounds **2** and **3** are α-hydroxyalkoxide complexes, i.e. they can be derived from the hydrated aldehydes. This could be verified for **2** by the synthesis from **1** and trichloroacetaldehyde hydrate (chloral hydrate). These hydrates, just like the aliphatic alcohols with electronegative substituents,[17] are sufficiently acidic to react with **1** by condensation. The direct formation of **2** and **3** under anhydrous conditions, however, is not a condensation reaction. It results from a nucleophilic attack of the Zn−OH function at the aldehyde carbon atom, followed by a concerted process of Zn−O(aldehyde) bond formation and Zn−O(OH) bond breaking. We have elucidated a trajectory for this type of reactions of TpZn−OH complexes by kinetic, structural and theoretical investigations.[20,21] In specific cases it corresponds to the initial stage of aldehyde hydration which is catalyzed as an abiotic process by zinc enzymes like carbonic anhydrase,[22] and which has been modeled for the catalytic hydration of acetaldehyde with zinc complexes of macrocyclic ligands.[23,24,25] The encapsulation provided by the Tp ligand and the uncharged nature of **2** and **3** renders these complexes stable and inert enough to be isolable as images of catalytic intermediates. This has been observed many times before for such images in the form of TpZn−X complexes.[13]

The structure determination of **2** (Figure 1) identifies the complex as belonging to the basic class of TpZn−OX complexes with monodentate OX ligands. There is little distortion of the threefold symmetry of the TpZn unit [O−Zn−N 120.9-124.6(1)°, N−Zn−N 91.1-96.9(1)°, Zn−O roughly on the threefold symmetry axis], and the Zn····O(OH) distance of 3.37 Å is outside the bonding range. The Zn−O bond length is as short as those in other TpZn−OR and TpZn−OH complexes,[14,17,18,19] and the bending angle Zn−O−C is at the lower end of its range.[17,18]

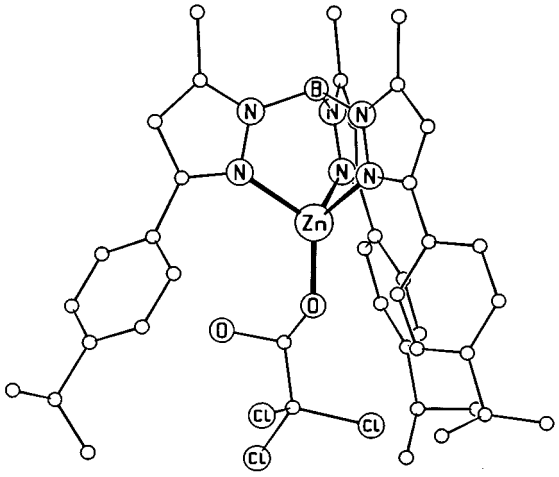


Figure 1. Molecular structure of complex **2**; selected bond lengths [Å] and angles [°]: Zn−O 1.865(2), Zn−N 2.063(3), 2.036(3), 2.040(3), C−O(Zn) 1.364(5), C−O(OH) 1.395(5), Zn−O−C 125.5(2)

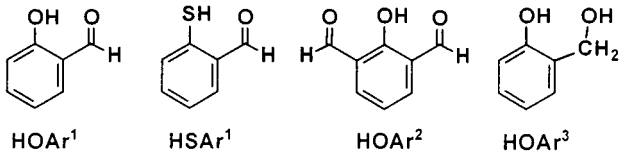
In terms of a mechanistic discussion the structure of **2** corresponds to the completion of the first step of catalytic aldehyde hydration, i.e. the complete breaking of the old Zn−O bond and the complete formation of the new Zn−O bond. There are no other α-hydroxyalkoxide complexes of zinc available for comparison, but the situation resembles that in zinc carboxylate complexes. The structures of the latter[26] display a smooth transition from symmetrically bidentate to purely monodentate coordination of the carboxylate ligand, thereby outlining a simple trajectory for the reaction discussed here, namely the hydration of an aldehyde. Thus, there is good evidence that this reaction proceeds by the four-center mechanism which also applies to all other hydrolytic reactions of the TpZn−OH complexes.[20] This mechanism might be verified here by ^{17}O labeling studies. However, this would be doomed to be futile, as Parkin[27] showed that the lability and mobility of these systems lead to rapid ^{17}O scrambling over all possible positions.

Complexes of 2-Formylphenols

We had observed previously[17] that TpZn−phenolates, unlike simple TpZn−alkoxides, are easy to isolate and are stable against hydrolysis. In the course of these studies we had found IR-spectroscopic evidence for chelating aldehyde coordination in the TpZn complex of $HOAr^2$. Subsequent studies[20] then showed that, other than what was originally thought, five-coordinate zinc ions in TpZn complexes are not uncommon and CO coordination to zinc ions as part of five- or six-membered chelate rings is possible in TpZn complexes of e.g. hydroxamates, β-hydroxy ketonates or β-diketonates.[15,28] We therefore extended our investigations of the TpZn−phenolate complexes to those of phenolates with carbonyl-containing functional groups in the β-positions. We found evidence for aldehyde coordination with the formyl-substituted phenols $HOAr^1$ and $HOAr^2$, as well as with the thiophenol $HSAr^1$. The 2-hydroxymethylphenol

($HOAr^3$) was included in this investigation for comparative purposes.



$HOAr^1$ $HSAr^1$ $HOAr^2$ $HOAr^3$

We have already described the preparation of complexes **6** and **7**, derived from $HOAr^2$ and $HOAr^3$.[17] The new complexes **4** and **5** were formed in reasonable yields from **1** and the corresponding phenol in dichloromethane. Two significant pieces of evidence point to the zinc−aldehyde coordination in **4**−**6**, firstly a shift of −15 to −20 cm^{-1} for the aldehyde bands in the IR spectra of **4** (1655 cm^{-1}), **5** (1651 cm^{-1}) and **6** (1648 cm^{-1}) in comparison with those of the free aldehydes; and secondly a shift of more than −2 ppm for the aldehyde proton in the NMR spectra (see Experimental Section). In comparison, the ^1H NMR resonances of the OCH_2 groups of the ligand $HOAr^3$ appear virtually unchanged in its complex **7**.

$Tp^{Cum,Me}Zn\text{-}OAr^1$ **4** $Tp^{Cum,Me}Zn\text{-}SAr^1$ **5**

$Tp^{Cum,Me}Zn\text{-}OAr^2$ **6** $Tp^{Cum,Me}Zn\text{-}OAr^3$ **7**

The structures of complexes **4**, **6** and **7** were determined, see Figure 2 and 3 and Table 1. Complex **7** can be compared with **2** or the other phenolate and alkoxide complexes[17,18] having a symmetrical coordination of the Tp ligand, a roughly trigonal symmetry of the TpZn−O unit, a rather short Zn−O bond, and a distinctly noncoordinating CH_2OH unit. Complexes **4** and **6**, on the other hand, are quite similar, having one aldehyde function attached as a fifth donor to the zinc center, and containing the aldehyde−phenolate ligand as part of a six-membered chelate ring.

The coordination geometry of the zinc center in **4** and **6** is very close to trigonal bipyramidal, as seen by the nearly linear O2−Zn−N1 arrangement. In agreement with this, the Zn−N bond lengths differ significantly and the Zn−O1 line is bent away from the Zn−B line defining a trigonal axis of the Tp ligand. The Zn−O2 bond is 0.27 (**4**) and 0.19 (**6**) Å longer than the Zn−O1 bond. This is because of two reasons, the Zn−O(aldehyde) interaction is weaker than the Zn−O(phenolate) interaction, and Zn−O2 defines the axial direction of the trigonal bipyramid. The O1−C bond lengths are typical for zinc phenolates,[17,29] the O2−C bond lengths are characteristically short and almost unchanged in comparison with those in free aldehydes.[10−12]

There is a considerable variation in the Zn−O(aldehyde) bond lengths, mostly due to changes in coordination numbers and geometries around the zinc center.[4,10−12] Five-coordinated zinc complexes of pyridine-2-carbaldehydes[11] have the closest geometrical relation to **4** and **6**; but their Zn−O distances vary extensively. It can be stated, however, that for complexes in which nitrogen donors compete with aldehyde ligands, **4** and **6** are among those that have the

shortest, i.e. strongest, Zn−O(aldehyde) interactions. In this respect **4** and **6** resemble the TpZn−β-diketonate complexes[17,28] which also have six-membered chelate rings and short Zn−O bonds. Apparently, in a TpZn(X)(Y) environment the six-membered chelate ring is a more strain-free alternative for the attachment of X and Y to the zinc ion than the common five-membered chelate ring. This has helped to create stable Zn−O(aldehyde) ligation inside the TpZn pocket, which yields the significant information that zinc−aldehyde interactions can be strong enough to overcome the reluctance of the encapsulated TpZn−X complexes to increase the coordination number of the zinc ion from four to five.

Conclusions

This work has provided two new bonding modes of aldehydes to zinc ions, the attachment as anions of the aldehyde hydrates and the attachment as part of bidentate O,O donors forming six-membered chelate rings. Unlike in the previous examples, the aldehydes under these conditions can form stable zinc complexes even in the presence of several good nitrogen donors. It is likely that the protection offered by the encapsulating pyrazolylborate ligands and the uncharged molecular nature of the complexes have helped to make them accessible.

The structures of the aldehyde complexes yield two pieces of information in terms of catalytic or enzymatic aldehyde interconversions. Firstly, they support a consistent mechanistic picture of the nucleophilic attack at carbonyl functions, exemplified here by aldehyde hydration. Secondly, they visualize the increase of the coordination number of the zinc ion from four to five, even when the weakly coordinating aldehydes are the fifth ligands. For the processes during the action of the LADH or YADH enzymes, this means that a coligand, cosubstrate or reagent may be present at the zinc ion during the catalytic turnover.

Experimental Section

The general working and measuring conditions were as in ref. [30] Reagents, except for **1**,[19] $HSAr^1$ [31] and $HOAr^2$,[32] were obtained commercially.

Complex 2: A solution of **1** (500 mg, 0.72 mmol) in 30 mL of dichloromethane and 40 mL of acetonitrile was treated with freshly distilled trichloroacetaldehyde (531 mg, 528 μL, 3.60 mmol) and stirred for 20 h. After concentrating to 30 mL in vacuo, the solution was left standing at −4 °C for several weeks. 341 mg (49%) of **2** was precipitated as colorless crystals, m.p. 178 °C, which were washed with a few mL of petroleum ether. − $C_{41}H_{48}BCl_3N_6O_2Zn{\cdot}2CH_3CN{\cdot}2H_2O$ (839.4 + 82.1 + 36.0): calcd. C 56.44, H 6.10, N 11.70; found C 56.47, H 5.68, N 10.44. − ^{1}H NMR ($CDCl_3$): δ = 1.18 (d, *J* = 6.9 Hz, 18 H, *i*Pr), 1.55 (s, 4 H, H_2O), 1.98 (s, 6 H, CH_3CN), 2.45 [s, 9 H, Me(pz)], 2.83 (sept, *J* = 6.9 Hz, 3 H, *i*Pr), 4.00 [s, 1 H, CH (aldehyde)], 6.11 [s, 3 H, H (pz)], 7.22 (d, *J* = 8.2 Hz, 6 H, Ph), 7.55 (d, *J* = 8.2 Hz, 6 H, Ph).

Complex 3: 1 (200 mg, 0.29 mmol) and C_6F_5CHO (569 mg, 2.90 mmol) in 40 mL of dichloromethane were stirred for 20 h. The solvent was removed in vacuo and the residue washed with a few mL of acetonitrile. Recrystallization from acetonitrile/dichloromethane (3:1) yielded 86 mg (33%) of **3** as colorless crystals, m.p. 225 °C. − $C_{46}H_{48}BF_5N_6O_2Zn$ (888.1): calcd. C 62.21, H 5.45, N 9.46; found C 61.15, H 5.90, N 10.15. − ^{1}H NMR ($CDCl_3$): δ = 1.23 (d, *J* = 6.9 Hz, 18 H, *i*Pr), 2.53 [s, 9 H, Me (pz)], 2.91 (sept, *J* = 6.9 Hz, 3 H, *i*Pr), 4.09 [s, 1 H, CH (aldehyde)], 6.19 [s, 3 H, H (pz)], 7.29 (d, *J* = 8.2 Hz, 6 H, Ph), 7.64 (d, *J* = 8.2 Hz, 6 H, Ph).

Complex 4: 1 (200 mg, 0.29 mmol) and $HOAr^1$ (35 mg, 0.31 μL, 0.29 mmol) in 30 mL of dichloromethane were stirred for 4 h. The solvent was removed in vacuo and the residue dissolved in 20 mL of acetone. Slow concentration over several weeks yielded 179 mg (53%) of **4** as yellow crystals, m.p. 181 °C. − $C_{46}H_{51}BN_6O_2Zn$ (796.2): calcd. C 69.40, H 6.46, N 10.56; found C 68.37, H 6.40, N 10.46. − ^{1}H NMR ($CDCl_3$): δ = 1.16 (d, *J* = 6.9 Hz, 18 H, *i*Pr), 2.58 [s, 9 H, Me (pz)], 2.78 (sept, *J* = 6.9 Hz, 3 H, *i*Pr), 6.21 [s, 3 H, H(pz)], 6.41 (t, *J* = 7.8 Hz, 1 H, OPh), 6.65 (d, *J* = 7.8 Hz, 1 H, OPh), 7.09 (d, *J* = 8.2 Hz, 6 H, Ph), 7.22 (m, 2 H, OPh), 7.54 (d, *J* = 8.2 Hz, 6 H, Ph), 7.87 [s, 1 H, CH (aldehyde)].

Complex 5: 1 (200 mg, 0.29 mmol) and $HSAr^1$ (46 mg, 0.89 mmol) in 40 mL of dichloromethane were stirred for 4 h. The solvent was removed in vacuo and the residue dissolved in 30 mL of methanol/dichloromethane (4:1). Slow concentration over several weeks yielded 121 mg (49%) of **5** as yellow crystals, m.p. 217 °C. − $C_{46}H_{51}BN_6OSZn$ (812.2): calcd. C 68.02, H 6.33, N 10.35; found C 66.73, H 6.65, N 9.25. − ^{1}H NMR ($CDCl_3$): δ = 1.21 (d, *J* = 6.9 Hz, 18 H, *i*Pr), 2.51 [s, 9 H, Me(pz)], 2.81 (sept, *J* = 6.9 Hz, 3 H, *i*Pr), 6.19 [s, 3 H, H (pz)], 7.09 (d, *J* = 8.2 Hz, 6 H, Ph), 7.22 (m, 3 H, SPh), 7.49 (d, *J* = 8.2 Hz, 6 H, Ph), 7.64 (d, *J* = 8.4 Hz, 1 H, SPh), 7.95 [s, 1 H, CH (aldehyde)].

Structure Determinations:[33] The crystals were obtained directly from the reaction solutions and used without drying in vacuo. They were immersed in fluorinated polyether oil and immediately placed in the nitrogen stream of the diffractometer's cooling system. Diffraction data were recorded at ca. −100 °C using the ω/2θ technique with a Nonius CAD4 diffractometer fitted with a molybdenum tube (K_α, λ = 0.7107 Å) and a graphite monochromator and treated without absorption corrections. The structures were solved with direct methods and refined anisotropically with the SHELX program suite.[34] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. Parameters were refined against F^2. The *R* values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[34] Table 2 lists the crystallographic data.

Structural Studies and Solution Dynamics of Complexes of Magnesium with the *N,N*-Dimethylaminomethylferrocenyl Ligand

Naka Seidel,[a] Klaus Jacob,*[a] Axel K. Fischer,[b] Claus Pietzsch,[c] Pierro Zanello,[d] and Marco Fontani[d]

Keywords: Chelates / Chirality / Cyclic voltammetry / Magnesium / Moessbauer spectroscopy

The reaction of {*C,N*-[Fe(η^5-C_5H_5)(η^5-C_5H_3(CH_2NMe_2)-2)]}Li, (FcN)Li, with magnesium bromide affords the magnesate complex $Li_2Mg(FcN)_2Br_2(OEt_2)_2$ **(1)**. Extraction of **1** with diethyl ether yields $(FcN)_2Mg(OEt_2)$ **(2).** The reaction of (FcN)Li with magnesium halides and THF directly affords $(FcN)_2Mg(THF)$ **(3)**. In solution, these compounds appear as a mixture of diastereomers, whereas in the solid state they each crystallize as a single *rac*-diastereomer. The ratio of *rac*-*meso*-diastereomers in solution is solvent- and temperature-dependent, consistent with an intermolecular exchange between the diastereomers. An intramolecular dynamic phenomenon involving dissociation and recoordination of Mg–N bonds was also observed.

Introduction

In the last decade the dimethylaminomethylferrocenyl unit (FcN) has become an extremely versatile ligand for the synthesis of stable organometallic complexes containing metals from the entire periodic table. On the one hand the geometric properties of the ligand give rise to effective steric shielding and stabilization upon coordination to a metal, and, on the other hand, the ligand is flexible enough to adapt various coordination modes.[1] The most abundant coordination mode is (*C,N*)-bidentate, with the α-carbon atom from the substituted Cp-ring and the amine nitrogen as donors to the same metal (Figure 1), such as found in the following compounds: $(FcN)_2TlCl$,[2] $(FcN)SiCl_3$,[3] $(FcN)_2Pt$,[4] (FcN)PtCl(DMSO),[5] $(FcN)_2VCl$,[6] and $CpTi(FcN)Cl_2$.[6] The X-ray diffraction analyses of $Cp_2M(FcN)_2$ (M = Ti, Zr, Hf),[7] $Cp_2Ti(FcN)Cl$[6] and $(FcN)_2Yb(\mu\text{-}Cl)_2Li(THF)_2$ [8] revealed a monodentate *C*-bonded FcN. The FcN ligand can also act as a carbon bridging ligand, as found in $Li[Cp_2Y(FcN)_2]$,[9] $[(FcN)Cu]_4$ [10] and $[(FcN)Ag]_4$.[11] Another μ-(*C,N*)-bridging mode is found in $[(FcN)HgCl]_2$ [12] and $[(FcN)Au]_2$.[4] Some compounds show more than one coordination mode around the same metal, as, for instance, in the thallium compound $(FcN)_3Tl$,[13] with two bidentate and one monodentate FcN ligands. In solution, this compound appears to be dynamic, but this aspect was not well investigated. Recently, we investigated the dynamic behavior of the lead compound $(FcN)_2Pb$.[14] A rapid dissociation of one of the Pb−N bonds and recoordination occurs in solution, whereas in the solid state both FcN ligands are (*C,N*)-bidentate bonded.

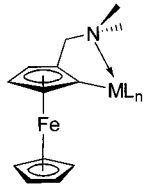

Figure 1. FcN as a bidentate ligand

The FcN ligand is chiral.[15] Therefore, when two or more FcN ligands are coordinated in one molecule this could give rise to the formation of diastereomers. Moreover, the chirality can be used as a "marker" to study intermolecular exchange processes, that could not have been observed otherwise. For instance, in the case of $(FcN)_2SiCl_2$ only the *meso*-form was found, whereas for $(FcN)_2SiMe_2$ both *rac*- and *meso*-diastereomers were formed, which could subsequently be separated by crystallization.[16] The silicon diastereomers obviously do not exchange. In contrast, for the first time, an intermolecular exchange between the diastereomers was demonstrated for $(FcN)_2Pb$.

Organomagnesium compounds, and in particular Grignard reagents, play an important role in organic synthesis. In order to explain the outcome and selectivity of alkylations with these compounds, it is of utmost importance to understand their structures in solution as well as in the solid state.[17,18] With this in mind, it was decided to use the FcN ligand for a thorough study of the structure and dynamics of this highly useful class of reagents.

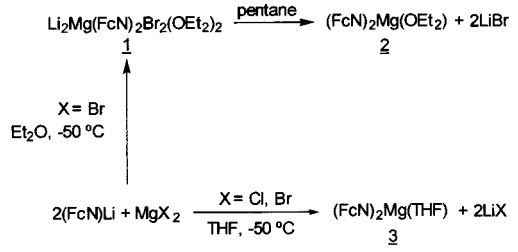
Results and Discussion

The reaction of magnesium bromide with two equivalents of (FcN)Li,[19] in diethyl ether at room temperature, furnishes deep-red crystals of $[Li_2Mg(FcN)_2Br_2(OEt_2)_2]$ **(1)**, in 80% yield (Scheme 1). The same product is formed when the starting compounds are mixed in a ratio of 1:1; half of the $MgBr_2$ is left unchanged. Compound **1** may be considered as a trapped intermediate during the formation of the diorganomagnesium compounds $(FcN)_2Mg$ discussed below. It is interesting to note that in these and other reactions with (FcN)Li and MgX_2 no Grignard compounds (FcN)MgX are formed.[20]



Scheme 1

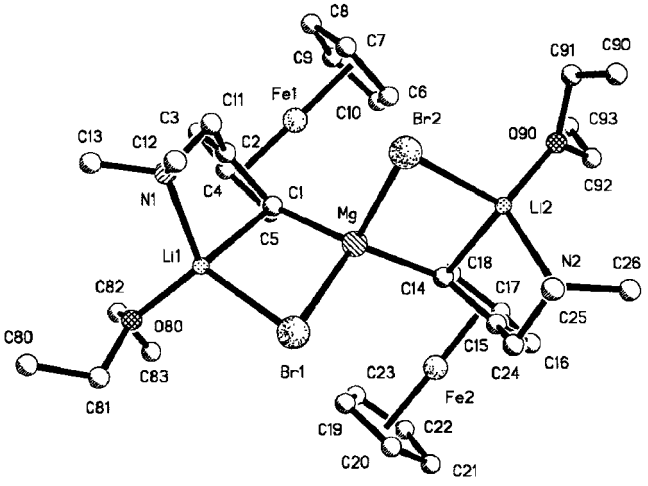


Figure 2. The molecular structure of **1**

Compound **1** crystallizes solely as a *rac*-diastereomer. The results of the X-ray diffraction analysis show that **1** is a magnesate compound where $Li(OEt_2)$ moieties are linked to the "$MgBr_2$" unit by *C*-bridging FcN groups. The molecular structure of **1** is shown in Figure 2 and the most important molecular dimensions are summarized in Table 1. The central magnesium atom shows a distorted tetrahedral coordination geometry with angles ranging from 98.06(4)°(Br1−Mg−Br2) to 119.8(2)° (C14−Mg−C1). The magnesium-bromide bond distances correspond approximately with the sum of the ionic radii of Br^- and Mg^{2+} [sum of ionic radii 263 pm,[21] Mg−Br1 = 260.08(13), Mg−Br2 = 260.52(13) pm]. The bromide-lithium bonds are somewhat shorter than the sum of the ionic radii [Br1−Li1 250.8(7), Br2−Li2 249.3(7) pm; sum of ionic radii 255 pm].[21] The lithium atoms are also four coordinate with angles ranging from 92.2(3)° (N1−Li1−C1) to 117.8(4)° (O80−Li1−C1) for Li1 and from 95.2(3)° (N2−Li2−C14) to 118.9(4)° (O90−Li2−N2) for Li2. The nitrogen atoms show an appreciable deviation from a tetrahedral geometry. The angles range from 97.1(3)° (C24−N2−Li2) to 118.2(3)° (C25−N2−Li2). The sum of the angles around the oxygens of the coordinating diethyl ether molecules is 359.5(5) [O80], and 359.0(4) pm [O90]. The best planes of the spiro system (Li1−C1−Mg−Br1, Li2−C14−Mg−Br1) are almost rectangular (82.6°).

Extraction of compound **1** with boiling pentane affords $[(FcN)_2Mg(OEt_2)]$ **(2)** in quantitative yield in the form of orange crystals (Scheme 1). The X-ray diffraction analysis of **2** (vide infra) reveals that the compound exists in the solid state as a *rac*-diastereomer.

Reaction of magnesium chloride with two equivalents of (FcN)Li and a small excess of tetrahydrofuran in ether furnishes orange crystals of $[(FcN)_2Mg(THF)]$ **(3)**, in 80% yield (see Scheme 1). The X-ray diffraction analysis shows that **3** also crystallizes as a *rac*-diastereomer. The alternative method of preparing **3** is from the reaction of magnesium

bromide with two equivalents of (FcN)Li in a mixture of tetrahydrofuran and toluene.

The crystal structures of **2** and **3** are very similar, and therefore they will be discussed together, with parameters for compound **3** given in square brackets. Compound **2** crystallizes in the space group $P2_12_12_1$, and compound **3** in the space group $P2_1/n$. The X-ray structures of **2** and **3**, with their atomic numbering schemes, are shown in Figure 3 and 4. Bond distances and angles are given in Table 2. The crystal structures of both compounds are built up from discrete monomers. The magnesium atom is five-coordinate with two (*C,N*)-chelate-bonded FcN ligands and one *O*-bonded ether molecule in **2** (tetrahydrofuran in **3**). The coordination geometry shows a 59% [63%] distortion from a trigonal bipyramid towards a square pyramid along the Berry pseudorotation coordinate.[22] The distortion is defined by bending of the C1−Mg−C14 angle around the N1−Mg−N2 axis. The small bite angle of the FcN ligands (C−Mg−N ca 79°) causes distortions around the α-carbon atoms and nitrogen atoms. For instance, although the C−N−C angles have ideal values, the Mg−N1−C11 and Mg−N2−C24 angles {99.85(1) [100.90(3)] and 97.89(2)° [102.46(3)°], respectively} are smaller than the other Mg−N−C angles. Similarly, the C2−C1−Mg and C15−C14−Mg angles {110.1(1)° [110.8(2)°] and 110.0(2)° [111.1(2)°], respectively} are smaller than C5−C1−Mg and C18−C14−Mg angles {144.4(2) [144.2(2)] and 145.0(2)° [145.2(2)°], respectively}. The sum of the angles around the oxygen atom is 359.9(2)° [359.9(2)°], indicating an almost perfect trigonal geometry. The puckering in the tetrahydrofuran molecule in **3** is described as an envelope with C29 sticking out of the plane defined by the other four atoms in the ring.

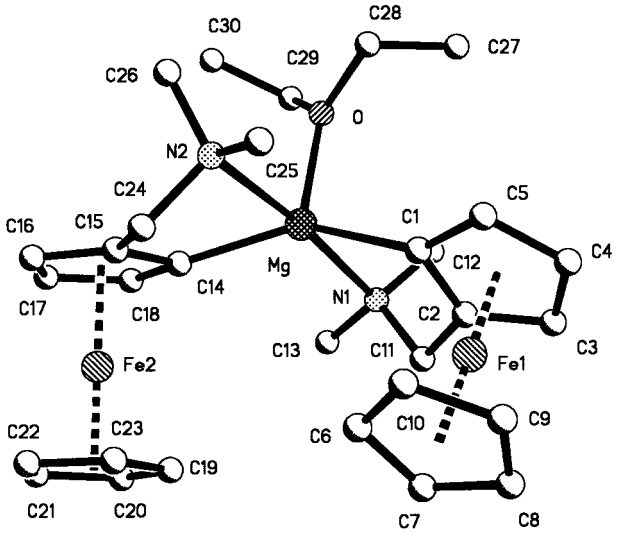

Figure 3. The molecular structure of **2**

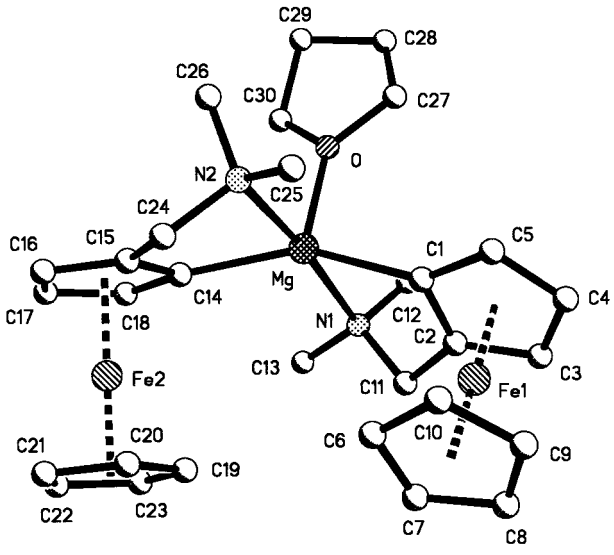

Figure 4. The molecular structure of **3**

The ^1H and ^{13}C NMR spectroscopic data in $[D_8]$THF at 21 °C of all three compounds are virtually identical and correspond to the solvated $(FcN)_2Mg$ species. The solution data show the presence of two diastereomers in a ratio of 3:1. In order to distinguish both diastereomers in solution, it occurred to us that **2**, as a chiral compound, crystallizes

[a] The suffix 'm' denotes the centroid of a Cp ring.

in the asymmetrical space group $P2_12_12_1$. Therefore in a single crystal, compound **2** exists as either the (*R*,*R*)- or (*S*,*S*)-diastereomer, which should prevent the conversion into the *meso*-diastereomer in solution, and therefore result in only one set of signals in the NMR spectra. The ^{1}H NMR spectrum of one single crystal indeed revealed signals of only one compound. By comparison, it was deduced that these signals belong to the major diastereomer, indicating that the *rac*-diastereomer is prevalent in solution at room temperature.

The NMR spectroscopic data at room temperature show only one set of signals for both FcN groups in each diastereomer, indicating intramolecular exchange (Table 3). Below −20 °C in [D$_8$]THF the signals of the methyl groups of the *rac* diastereomer start to broaden; those of the *meso*-(FcN)$_2$Mg broaden at −40 °C. At −60 °C there are two signals for the methyl groups of *rac*-(FcN)$_2$Mg at δ = 2.25 and 2.95. This diastereomer has C_2-symmetry along the Mg−O axis and therefore both FcN ligands are equivalent and only two signals for the methyl groups are expected. In contrast, due to lack of symmetry, *meso*-(FcN)$_2$Mg should exhibit four signals for the methyl groups. At −90 °C we observed two broad signals at δ = 2.10 and 2.65, and it is likely that the signals of the *meso*-diastereomer have not reached decoalescence completely. The temperature-dependent NMR spectroscopic data could be explained by a rapid dissociation and recoordination of the Mg−N bonds.

The ratio of diastereomers measured in different solvents ([D$_8$]THF, [D$_8$]toluene, C$_6$D$_6$) is temperature dependent (at room temp. 2.8, 2.5, and 2, respectively). This suggests an intermolecular exchange between diastereomers. The proportion of the *rac*-diastereomer is higher at lower temperatures. This observation is reminiscent to those of the plumbylene compound (FcN)$_2$Pb, with the difference that, for the latter compound, the *meso*-diastereomer is prevalent. The equilibrium constant K (*rac*/*meso*) gradually changes from 2.8 at +25 °C to 12.0 at −90 °C in [D$_8$]THF. Plotting ln$K$ against 1/T (Van't Hoff plot) gives a straight line from which the thermodynamic parameters ΔH = −5.92 kJ mol^{-1} K^{-1} and ΔS = −12.1 J mol^{-1} K^{-1} were obtained (r = 0.9819).

The mechanistic pathway for the observed intermolecular exchange most likely involves electron-deficient three-center two-electron interactions (see Scheme 2). It invokes a simultaneous migration of two σ-bonded FcN groups through an intermediate with carbon-bridged FcN groups. Although this mechanism is very similar to that proposed for (FcN)$_2$Pb, it is fundamentally different. In the lead compound, exchange of FcN ligand probably proceeds via a preliminary Pb−Pb interaction, whereas for the magnesium compound such an interaction is highly unlikely.

The redox behavior of complex **3** has been examined by electrochemical techniques. At any rate, the appearance of a primary, single-stepped two-electron oxidation points out that the two ferrocene units do not communicate electronically each other.

Figure 5 shows the anodic cyclic voltammetric profile exhibited by complex **3** in dichloromethane solution.

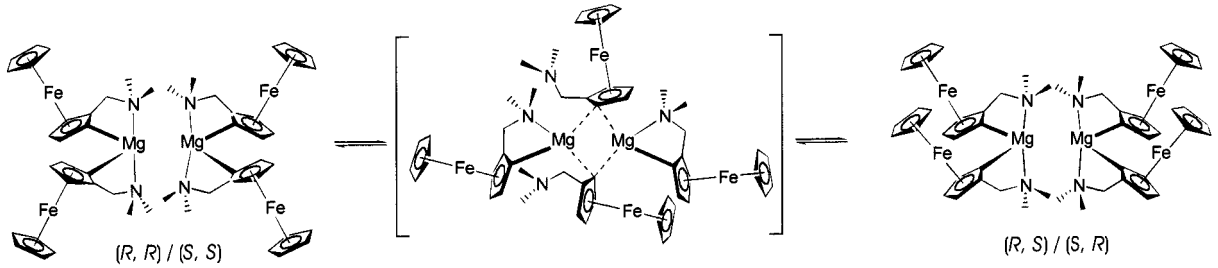
The single-stepped two-electron oxidation at $E^{\circ\prime}$ = +0.41 V (accompanied with a yellow-to-blue color change) has features of chemical reversibility (at 0.05 Vs^{-1}: i_{pc}/i_{pa} = 0.9; ΔE_p = 70 mV, blue-to-yellow change). The blue color is typical of the formation of the ferrocenium cation.

The oxidation potential may be compared with that of FcNH ($E^{\circ\prime}$ = +0.38 V). After exhaustive two-electron oxidation-reduction it displays a reversible anodic process at

Table 3. ^{1}H NMR spectroscopic data for **2** in [D$_8$]THF

[a]		NMe_2	CH_2N	CpFe	C_5H_3
21 °C	*rac*-	2.55 (s, 12 H)	3.03 (d, 2 H, J = 14) 3.59 (d, 2 H, J = 14)	4.06 (s, 10 H)	3.84 (s, 2 H) 4.00 (s, 2 H) 4.13 (s, 2 H)
	meso-	2.42 (s, 12 H)	2.86 (d, 2 H, J = 13) 3.83 (d, 2 H, J = 13)	4.11 (s, 10 H)	3.88 (s, 2 H) 3.98 (s, 2 H)[b]
−90 °C	*rac*-	2.25 (s, 6 H) 2.95 (s, 6 H)	3.11 (d, 2 H, J = 14) 3.50 (d, 2 H, J = 14)	4.13 (s, 10 H)	4.11 (s)[b] 4.16 (s, 2 H)
	meso-	2.10 (s, br, 6 H) 2.65 (s, br, 6 H)	2.49 (d, 2 H, J = 13)[b]	4.16 (s, 10 H)	3.92 (s, 2 H) 4.07 (s, br, 4 H)[b]

[a] The ^{1}H NMR spectroscopic data of **1** and **3** are virtually identical. − [b] Not all signals were observed, due to the overlap with other signals.



Scheme 2

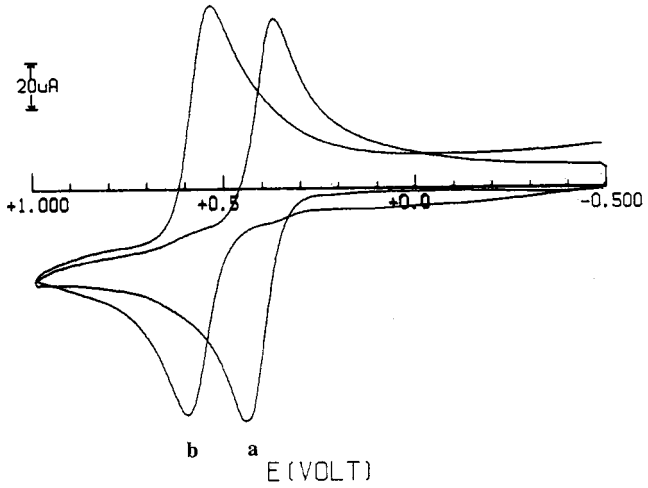


Figure 5. Cyclic voltammograms recorded on a platinum electrode in CH_2Cl_2 solution containing **1** (1.8×10^{-3} mol dm^{-3}) and $[NBu_4][PF_6]$ (0.2 mol dm^{-3}) before (a) and after (b) a cycle of exhaustive oxidation and reduction

$E^{\circ\prime}$ = +0.57 V (at 0.05 Vs^{-1}: ΔE_p = 76 mV), indicating decomposition of the compound (Figure 5b).

The Mössbauer parameters of **1** and **3** are shown in Table 4. The isomer shifts do not differ significantly from those of (FcN)Li,[23] titanium or vanadium compounds.[6]

Table 4. Mössbauer parameters for compounds **1** and **3** (78 K, referenced against α-iron foil)

Compound[a]	δ[b] [mm s^{-1}]	q.s.[c] [mm s^{-1}]	Γ[d] [mm s^{-1}]
1	0.520(2)	2.367(4)	0.324(7)
2	0.485(7)	2.33(2)	0.36(2)

[a] Numbers in parentheses correspond to the experimental error in the last significant figures. – [b] Isomer shift. – [c] Quadrupole splitting. – [d] Half-width at half height.

The data in Table 4 show lower values of *q.s.* for measured compounds relative to the *q.s.* in ferrocene [2.40(3) mm s^{-1}].[23] Such a decrease in *q.s.* is associated with electron-withdrawing substituents on the ferrocenyl moieties, and may be due to the binding of the Mg units to the FcN ligand. Nevertheless, this change is very small, indicating that the Fe^{II} orbitals are not very sensitive to ring substituents.

Conclusions

The diorganomagnesium compounds **1**–**3** are highly dynamic in solution. Although all three compounds only crystallize as (*C,N*)-bonded *rac*-diastereomers, a mixture of *meso*- and *rac*-diastereomers forms in solution. The *rac*/*meso*-ratio is solvent- and temperature-dependent, and consistent with an intermolecular exchange between diastereomers. An intramolecular dynamic process of dissociation and recoordination of Mg–N bonds is responsible for the equivalency of both FcN groups in solution.

Experimental Section

General Remarks: All experiments were carried out using standard Schlenk techniques under purified argon atmosphere. Solvents were distilled from sodium benzophenone ketyl prior to use. The commercial products *n*-butyllithium (1.6 M solution in hexane), magnesium chloride, magnesium bromide and dimethylaminomethylferrocenylferrocene were used without further purification. The known starting material (FcN)Li was prepared according to the literature.[19] – ^{1}H and ^{13}C NMR spectra were recorded on a Varian Unity 500 spectrometer. – Materials and apparatus for electrochemistry have been described elsewhere.[24] All potential values are referred to the Saturated Calomel Electrode (SCE). Under the present experimental conditions {dichloromethane solution containing $[NBu_4][PF_6]$ (0.2 mol dm^{-3})} the one-electron oxidation of ferrocene occurs at $E^{\circ\prime}$ = + 0.38 V. – Mössbauer data were recorded at 78 K on a Wissel spectrometer with a ^{57}Co source in a rhodium matrix, 1.8 GBq.

Synthesis of $[Li_2Mg(FcN)_2Br_2(OEt_2)_2]$ (1): (FcN)Li (5.00 g, 20.1 mmol) was added to a suspension of $MgBr_2$ (1.84 g, 10.0 mmol) in diethyl ether (150 mL) at −50 °C with vigorous stirring. After 1 h the reaction mixture was allowed to warm to room temperature whilst stirring, affording a clear orange-colored solution. The volume of the solution was reduced to the point of crystallization after one day and stored at 7 °C to give product **1** as orange air- and moisture-sensitive crystals. Yield: 6.64 g, 80%. – $C_{34}H_{52}Br_2Fe_2Li_2MgN_2O_2$ (830.49): calcd. C 49.17, H 6.31, N 3.37, Br 19.24; found C 49.21, H 6.35, N 3.32, Br 19.31. – ^{1}H NMR ([D$_8$]THF, room temp.; *meso*-diastereomer in square brackets): δ = 2.57 (s, 12 H, NMe_2) [2.42 (s, 12 H, NMe_2)], 3.03 (d, $^1J_{C,H}$ = 14 Hz, 2 H, CH_2N) [2.85 (d, $^1J_{C,H}$ = 13 Hz, 2 H, CH_2N], 3.60 (d, $^1J_{C,H}$ = 14 Hz, 2 H, CH_2N) [3.83 (d, $^1J_{C,H}$ = 13 Hz, 2 H, CH_2N], 4.06 (s, 10 H, C_5H_5) [4.11 (s, 10 H, C_5H_5)], 3.83 (s, 2 H, C_5H_3) [3.88 (s, 2 H, C_5H_3)], 3.99 (s, 2 H, C_5H_3) [3.97 (s, 4 H, C_5H_3)], 4.12 (s, 2 H, C_5H_3).

Synthesis of $[(FcN)_2Mg(OEt_2)]$ (2): Crystals of **1** were filtered off, and exhaustively extracted with pentane. The pentane solution was stored in a freezer at −30 °C to give product **2** as deep-reddish air- and moisture-sensitive crystals. Yield: 5.31 g, 80%. – $C_{30}H_{42}Fe_2MgN_2O$ (582.67): calcd. C 61.84, H 7.26, N 4.81; found C 61.92, H 7.32, N 4.75. – ^{13}C{^{1}H} NMR ([D$_8$]THF, room temp.; *meso*-diastereomer in square brackets): δ = 47.1 [46.7] (NMe_2), 63.0 [63.4] ($-CH_2N$), 76.5 [77.2] ($C_5H_3-CH_2NMe_2$), 95.4 [95.0] (C_5H_3-Mg).

Synthesis of $[(FcN)_2Mg(THF)$ (3)]: (FcN)Li (2.90 g, 11.6 mmol) was added to a suspension of $MgBr_2$ (1.07 g, 5.8 mmol) in 150 mL of toluene and 5 mL tetrahydrofuran at −78 °C with constant stirring. The orange-colored reaction mixture was stirred for 24 h. Workup as for **2**. Deep-reddish crystals of **3** were obtained after cooling the pentane solution to −30 °C. Yield: 2.93 g, 85%. – $C_{30}H_{40}Fe_2MgN_2O$ (580.65): calcd. C 62.05, H 6.94, N 4.83; found C 61.98, H 6.89, N 4.90. – ^{1}H NMR ([D$_8$]THF, room temp.; *meso*-diastereomer in square brackets): δ = 2.55 (s, 12 H, NMe_2) [2.42 (s, 12 H, NMe_2)], 3.03 (d, $^1J_{C,H}$ = 14 Hz, 2 H, CH_2N) [2.86 (d, $^1J_{C,H}$ = 13 Hz, 2 H, CH_2N)], 3.59 (d, $^1J_{C,H}$ = 13 Hz, 2 H, CH_2N) [3.83 (d, $^1J_{C,H}$ = 13 Hz, 2 H, CH_2N)], 4.06 (s, 10 H, C_5H_5) [4.11 (s, 10 H, C_5H_5)], 3.84 (s, 2 H, C_5H_3) [3.88 (s, 2 H, C_5H_3)], 4.00 (s, 2 H, C_5H_3) [3.98 (s, 4 H, C_5H_3)], 4.13 (s, 2 H, C_5H_3).

X-ray Structure Analyses of 1, 2 and 3: Crystal and numerical data of the structure determinations are given in Table 5. Crystals were covered with inert oil and mounted on a glass fiber, and then trans-

ferred to the diffractometer in a stream of a cold gas (Bruker AXS Smart CCD System with LT-2 low-temperature adapter). Monochromatic Mo-K_α radiation (λ = 71.073 pm) was used. Data were corrected for Lorentz and polarization effects. Absorption correction (multi-scan method SADABS) was employed. The structures were solved by direct methods using the SHELXS program and refined by full-matrix least-squares against F^2 with SHELXL-97.[25] All non-hydrogen atoms were refined with anisotropic thermal parameters. All hydrogen atoms were found in the difference Fourier map and refined isotropically.

Crystallographic data (excluding structure factors) for the reported structures have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-113801 (**1**), -113802 (**2**), -113803 (**3**). Copies of data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-093; E-mail: deposit@ccdc.cam.ac.uk].

The First Spacer-Bridged Tetraorganodistannoxanes with a Mixed Double Ladder Structure[‡]

Michael Mehring,[a] Ingo Paulus,[a] Bernhard Zobel,[a] Markus Schürmann,[a] Klaus Jurkschat,*[a] Andrew Duthie,[b] and Dainis Dakternieks*[b]

Keywords: Tin / Distannoxanes / Oxo complexes / Electrospray mass spectrometry

The reaction of $Me_3SiCH_2Cl_2Sn(CH_2)_3SnCl_2Ph$ (**6**) with $(tBu_2SnO)_3$ gave a statistical mixture of the corresponding tetraorganodistannoxanes whereas the reaction of the spacer-bridged ditin tetrachlorides $RCl_2Sn(CH_2)_4SnCl_2R$ (**3**, R = Me_3CCH_2; **4**, R = Me_2CHCH_2; **10**, R = Me_3SiCH_2) with the polymeric spacer-bridged ditin oxides $[R(O)Sn(CH_2)_4Sn(O)R]_n$ (**7**, R = Me_2CHCH_2; **8**, R = Me_3CCH_2; **11**, R = Me_3SiCH_2) provided the mixed double ladder compounds $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R][R'(Cl)Sn(CH_2)_4Sn(Cl)R']O_2\}_2$ (**9**, R = Me_3CCH_2, R′ = Me_2CHCH_2; **12**, R = Me_3CCH_2, R′ = Me_3SiCH_2) in almost quantitative yield. In solution, **9** and **12** are in equilibrium with their corresponding dimers, as was evidenced by ^{119}Sn NMR spectroscopy, molecular mass determination, and electrospray mass spectrometry. The molecular structures of **9** and **12** were established by single crystal X-ray diffraction.

Introduction

Currently, there is much interest in dimeric tetraorganodistannoxanes $[R_2(X)SnOSn(X)R_2]_2$ (X = halogen, OH, $R'CO_2$, NCS; R, R′ = alkyl, aryl)[1−5] since these compounds are reported to be efficient homogeneous catalysts in various organic reactions such as transesterification under virtually neutral conditions,[6] highly selective acylation of alcohols,[7] urethane formation,[8] and alkyl carbonate synthesis.[9] X-ray crystallography has illustrated the dimeric nature of a large number of tetraorganodistannoxanes and NMR spectroscopic studies show that this structural arrangement is retained in solution.[1−5] However, only a few examples of monomeric species for both solution and in the solid state have been reported.[2,4,10−13]

In contrast to the symmetrically substituted tetraorganodistannoxanes, unsymmetrically substituted ones, such as $[Bu_2(X)SnOSn(Y)Bu_2]_2$ (X = O_2CMe, Cl, OPh, OMe; Y = Cl, OPh, OMe),[2,4] $[tBu_2(Cl)SnOSn(Cl)R_2]_2$ (R = Me, Et, *i*Pr, *n*Bu),[14] $[tBu_2(OH)SnOSn(Cl)R_2]_2$ (R = *n*Bu, cyclohexyl),[14,15] $[Ph_2(Cl)SnOSn(OH)Ph_2]_2{\cdot}2(CH_3)_2CO$[16] and $Et_2BrSnOSnBrPr_2$[17] have attracted less attention and only four of these compounds have been characterized by X-ray crystallography.[14−16]

For some time we have been interested in the synthesis, structure, and catalytic activity of the spacer-bridged tetraorganodistannoxanes $\{[R(X)Sn-Z-Sn(X)R]O\}_n$ [X = Cl, F, OH, OAc; R = alkyl; Z = $(CH_2)_3$, $(CH_2)_4$, $CH_2SiMe_2CH_2$, $CH_2SiMe_2CCSiMe_2CH_2$].[18−21] In the solid state, these compounds exhibit either a dimeric (*n* = 2) or a double ladder structure (*n* = 4). Furthermore, the first triple ladder $\{[R(Cl)Sn(CH_2)_3Sn(Cl)(CH_2)_3Sn(Cl)R]O_{1.5}\}_4$ (R = Me_3SiCH_2) was reported, in which three $Sn_4Cl_4O_2$ layers are connected through trimethylene bridges.[22] The most convenient synthetic methodologies for the preparation of compounds of the type $\{[R(Cl)Sn-Z-Sn(Cl)R]O\}_n$ (*n* = 2, 4) are (i) the reaction of a spacer-bridged ditin tetrachloride $RCl_2Sn-Z-SnCl_2R$ with $(tBu_2SnO)_3$ as the oxygen transfer reagent and (ii) the reaction of a spacer-bridged ditin tetrachloride with the corresponding spacer-bridged polymeric ditin oxide $[R(O)Sn-Z-Sn(O)R]_n$.

In solution, most of the spacer-bridged distannoxanes retain their solid-state structure, but in the cases of Z = $(CH_2)_4$ and X = Cl, OAc, and Z = $(CH_2)_3$ and X = OAc, equilibria between dimers and tetramers have been observed. These kinetically labile species show higher catalytic activity in acylation reactions than the kinetically more inert double ladder compounds.[18]

Here we report our attempts to prepare mixed tetraorganodistannoxanes and present the X-ray single crystal structure analyses of $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R][R'(Cl)Sn(CH_2)_4Sn(Cl)R']O_2\}_2$ (**9**, R = Me_3CCH_2, R′ = Me_2CHCH_2; **12**, R = Me_3CCH_2, R′ = Me_3SiCH_2), the first mixed double ladders containing two different organic groups R and R′.

Results and Discussion

The unsymmetrically substituted ditin precursor $Me_3SiCH_2Cl_2Sn(CH_2)_3SnCl_2Ph$ (**6**) was prepared by reac-

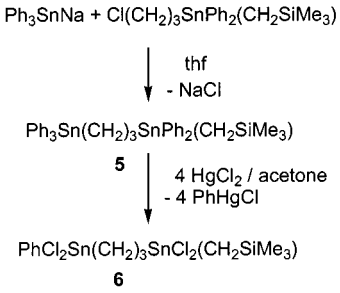
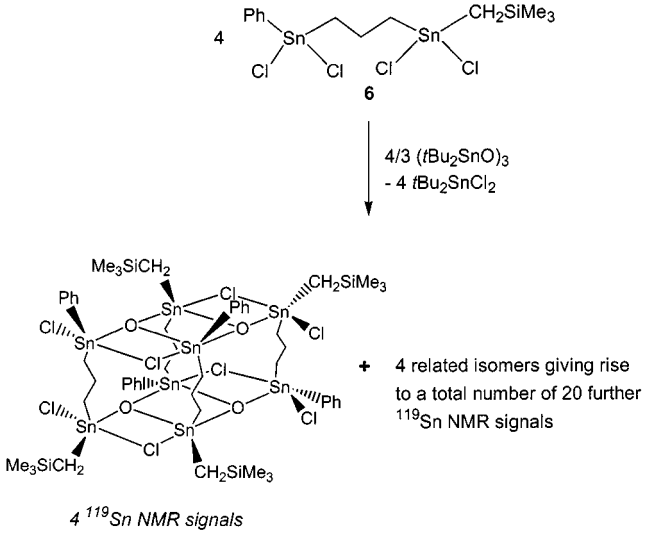
tion of Ph_3SnNa (**1**) with $Cl(CH_2)_3SnPh_2CH_2SiMe_3$[22] (**2**) to give $Me_3SiCH_2Ph_2Sn(CH_2)_3SnPh_3$ (**5**) which was converted into its tetrachloro-substituted derivative **6** by reaction with $HgCl_2$ (Scheme 1).



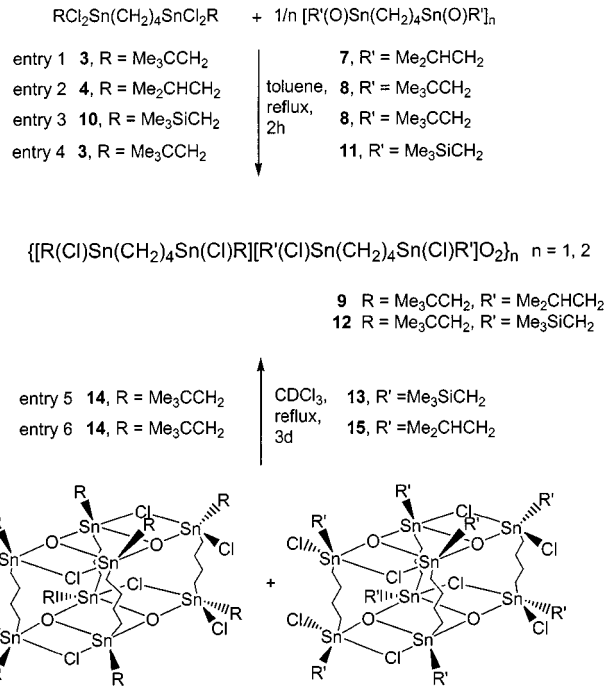
Scheme 1. Synthesis of the unsymmetrically substituted trimethylene-bridged ditin compound **6**

The reaction of compound **6** with one-third molar equivalent $(tBu_2SnO)_3$ gave a complex reaction mixture. The ^{119}Sn NMR spectrum of this mixture displayed 23 signals in the range of $\delta = -90$ to -210, in addition to the resonance at $\delta = 55$ (assigned to tBu_2SnCl_2). This is close to the 24 signals expected for a statistical distribution of 5 possible isomers with a double ladder arrangement (Scheme 2). It is most likely that the missing signal is superimposed with one of the 23 signals. Attempts to isolate a single isomer failed.



Scheme 2. Reaction of compound **6** with $(tBu_2SnO)_3$ giving a statistical mixture of double ladder isomers

However, the reaction of the spacer-bridged ditin tetrachloride $RCl_2Sn(CH_2)_4SnCl_2R$ (**3**, R = Me_3CCH_2) with the spacer-bridged ditin oxide $[R(O)Sn(CH_2)_4Sn(O)R]_n$ (**7**, R = Me_2CHCH_2), as well as the reaction of $RCl_2Sn(CH_2)_4SnCl_2R$ (**4**, R = Me_2CHCH_2) with $[R(O)Sn(CH_2)_4Sn(O)R]_n$ (**8**, R = Me_3CCH_2) in toluene resulted in the almost quantitative formation of the mixed double ladder compound $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R][R'(Cl)Sn(CH_2)_4Sn(Cl)R']O_2\}_2$ (**9**, R = Me_3CCH_2, R′ = Me_2CHCH_2) (Scheme 3). Analogously, the reactions of $RCl_2Sn(CH_2)_4SnCl_2R$ (**10**, R = Me_3SiCH_2) with $[R(O)Sn(CH_2)_4Sn(O)R]_n$ (**8**, R = Me_3CCH_2), and $RCl_2Sn(CH_2)_4SnCl_2R$ (**3**, R = Me_3CCH_2) with $[R(O)Sn(CH_2)_4Sn(O)R]_n$ (**11**, R = Me_3SiCH_2), gave $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R][R'(Cl)Sn(CH_2)_4Sn(Cl)R']O_2\}_2$ (**12**, R = Me_3CCH_2, R′ = Me_3SiCH_2) in almost quantitative yield. The mixed double ladder compounds **9** and **12** were also formed by mixing equimolar amounts of the symmetrically substituted double ladders $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]O\}_4$, **14** (R = Me_3CCH_2) and **15** (R = Me_2CHCH_2), and **13** (R = Me_3SiCH_2) and **14** (R = Me_3CCH_2), respectively, as was shown by ^{119}Sn NMR experiments in $CHCl_3/CDCl_3$ (Scheme 3). After 2 h of heating at reflux, a complex mixture of different double ladders was observed, whereas after 3 d of heating at reflux, the conversion of the starting double ladders into the mixed ones **9** and **12**, was complete. In contrast to the tetramethylene-bridged double ladders reported here the trimethylene-bridged double ladders $\{[R(Cl)Sn(CH_2)_3Sn(Cl)R]O\}_4$ are kinetically inert and do not show the formation of mixed double ladders.[23]



Scheme 3. Syntheses of the mixed tetramethylene-bridged tetraorganodistannoxanes **9** and **12**

The molecular structure of compounds **9** and **12** are shown in Figure 1 and Figure 2, respectively. Crystallographic data are given in Table 3 and selected geometrical parameters are listed in Table 1. The compounds **9** and **12** form centrosymmetric tetramers in which two $Sn_4Cl_4O_2$ units are linked through four tetramethylene bridges giving a double ladder arrangement. The $Sn_4Cl_4O_2$ layer is almost planar with the greatest deviation from the plane for Cl(2) [0.232(2) Å] in **9** and Cl(3) [0.360(2) Å] in **12**. Each tin atom has a distorted trigonal-bipyramidal geometry. For the exocyclic tin atoms, two carbon atoms and one oxygen atom occupy the equatorial positions and two chlorine atoms the axial positions, while for the endocyclic tin atoms the equat-

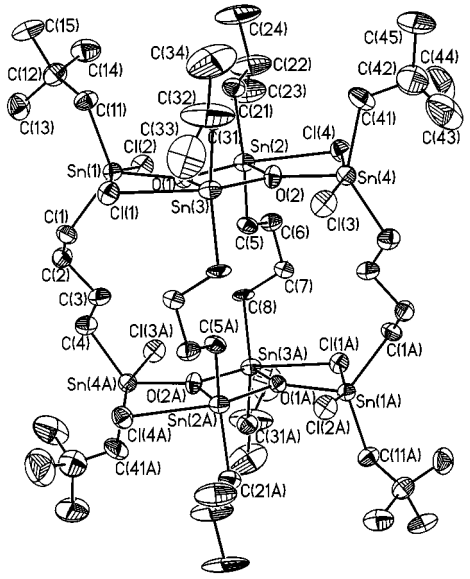


Figure 1. General view (SHELXTL-Plus) of **9** showing 30% probability displacement ellipsoids and the atom numbering scheme (symmetry transformations used to generate equivalent atoms: $a = -x + 1, -y, -z - 1$)

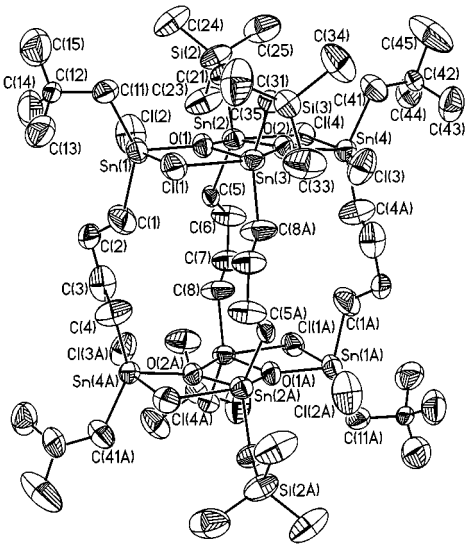

Figure 2. General view (SHELXTL-Plus) of **12** showing 30% probability displacement ellipsoids and the atom numbering scheme (symmetry transformations used to generate equivalent atoms: $a = -x + 1, -y, -z - 1$)

orial positions are occupied by two carbon atoms and one oxygen atom and the axial positions by one oxygen atom and one chlorine atom. In both structures the neopentyl groups Me_3CCH_2 are attached to the exocyclic tin atoms, and the isobutyl groups Me_2CHCH_2 (in **9**) and the trimethylsilylmethyl groups Me_3SiCH_2 (in **12**) are bound to the endocyclic ones. The bond lengths and bond angles (Table 1) correspond to those of previously described ladder[14] and double ladder structures.[18,19] The Sn−O bond lengths for the exocyclic tin atoms, Sn(1)−O(1) and Sn(4)−O(2), are 2.021(5) and 2.017(5) Å, respectively, for **9**, and 2.017(3) and 2.009(3) Å, respectively, for **12**. In the four-membered Sn_2O_2 ring the Sn−O bonds are somewhat

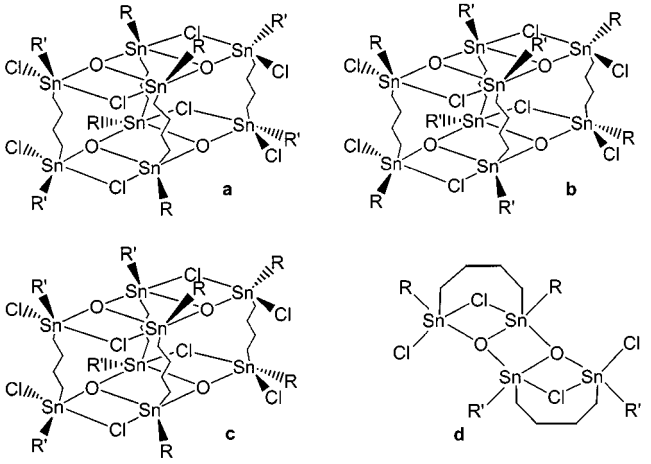
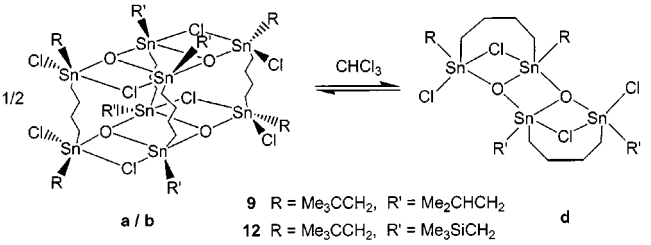
lengthened, with the longest bonds found for Sn(2)−O(1) [2.125(5) Å] and Sn(3)−O(2) [2.134(5) Å] (**9**), and for Sn(2)−O(1) [2.127(3) Å] and Sn(3)−O(2) [2.140(3) Å] (**12**). Two of the chlorine atoms of each monolayer form Sn−Cl−Sn bridges [Sn(1)−Cl(1)−Sn(3) 82.5(1)° (**9**), 82.0(1)° (**12**), Sn(2)−Cl(4)−Sn(4) 82.2(1)° (**9**), 82.2(1)° (**12**)], with Sn(1)−Cl(1), Sn(3)−Cl(1), Sn(4)−Cl(4) and Sn(2)−Cl(4) bond lengths of 2.809(2), 2.686(2), 2.733(2), and 2.760(2) Å (**9**), respectively, and 2.751(2), 2.752(2), 2.760(2), and 2.724(2) Å (**12**), respectively. The chlorine atoms Cl(2) and Cl(4) can be regarded as non-bridging, although the Sn(2)−Cl(2) [3.320(2) Å (**9**), 3.248 (2) Å (**12**)] and Sn(3)−Cl(3) [3.326(3) Å (**9**), 3.272 (2) Å (**12**)] distances are shorter than the sum of the van der Waals radii of tin and chlorine (3.97 Å).[24] The Sn(1)−Cl(2) and Sn(4)−Cl(3) bond lengths are 2.434(2) and 2.488(2) Å (**9**), respectively, and 2.478(2) and 2.474(2) Å (**12**), respectively, which are slightly longer than the Sn−Cl single bond length of 2.39 Å.[22]

An equilibrium between tetrameric double ladder structures ($n = 4$) and dimers ($n = 2$) has been previously reported for $CHCl_3$ solutions of the tetramethylene-bridged tetraorganodistannoxanes $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]O\}_n$ (**13**, R = Me_3SiCH_2; **14**, R = Me_3CCH_2; **15**, Me_2CHCH_2), which showed degrees of association with $n = 3.9$, 2.3, and 2.5, respectively.[18] The molecular mass determination of **9** in $CHCl_3$ showed $M = 1639$ g mol^{-1} ($c = 20$ mg mL^{-1}), which is indicative of the existence in solution of an equilibrium between double ladder structures (**9a−c**) (calcd. for **9a−c**: $M = 2035$ g mol^{-1}) and the dimer **9d** (calcd. for **9d**: $M = 1018$ g mol^{-1}) (Scheme 4). Compound **12** has a molecular mass $M = 1191$ g mol^{-1} ($c = 20$ mg mL^{-1}) in $CHCl_3$, showing that the dimer **12d** (calcd. for **12d**: $M = 1077$ g mol^{-1}) dominates at this concentration (Scheme 4). The molecular mass of **12** increases at higher concentration ($M = 1689$ g mol^{-1}, $c = 145$ mg mL^{-1}), showing that the equilibrium is shifted towards formation of double ladders **12a−c** (calcd. for **12a−c**: $M = 2155$ g mol^{-1}) (Scheme 5).



Scheme 4



Scheme 5. Dimer-tetramer equilibrium in solutions of **9** (R = Me_3CCH_2, R′ = Me_2CHCH_2) and **12** (R = Me_3CCH_2, R′ = Me_3SiCH_2)

The ^{119}Sn NMR spectroscopic data in $CDCl_3$ of the mixed double ladders **9** and **12**, and of the related simple double ladders **13−15** are given in Table 2. A solution of crystalline **9** in toluene shows two pairs of signals of equal integral ratio at δ = −85.2 (26%)/−148.5 (27%) and at δ = −86.4 (15%)/−147.9 (15%) which are assigned with caution to **9a** and **9b**. The resonances at δ = −78.7 (5%),−150.2 (5%), and −85.4 (4%),−152.7 (3%) are assigned with caution to one of the two possible isomers of the dimer **9d**, but we were not able to discriminate the *cis* and the *trans* isomer. In principal, these signals could also be assigned to the tetramer **9c** (Scheme 4), for which four signals of equal integral ratio are expected. However, the molecular mass determination of a solution of **9** in $CHCl_3$ is indicative of an equilibrium between tetramers and dimers, and thus we assign the four signals to the dimer **9d** rather than to the tetramer **9c**. In $CDCl_3$ solution, **9** displays two signals of equal integral ratio at δ = −83.0 (36%) and δ = −145.2 (35%) which are assigned to **9a** and/or **9b,** and three signals for the dimer **9d** [δ = −78.2 (7%), −84.2 (7%), −144.4 (14%)]. The missing signal is likely to be superimposed with the signal at δ = −144.4. Furthermore, one signal of minor intensity was observed at δ = −146.9 (1%).

Table 2. ^{119}Sn NMR spectroscopic data in $CDCl_3$ for compounds of the type $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R][R'(Cl)Sn(CH_2)_4Sn(Cl)R']O_2\}_2$; chemical shifts are given in δ values and coupling constants [$^2J(^{119}Sn-O-^{119/117}Sn)$] in Hz

		Sn_{exo}		Sn_{endo}	
9	R = Me_3CCH_2	−78.2 [74]	7%	−144.4 [66]	14%
	R′ = Me_2CHCH_2	−84.2 [57]	7%		
		−83.0 [61]	36%	−145.2 [70]	35%
				−146.9	1%
12	R = Me_3CCH_2	−68.5	5%	−144.9	5%
	R′ = Me_3SiCH_2	−83.8	5%		
		−70.6	1%	−143.2	2%
		−85.6	1%		
		−84.5 [64]	27%	−140.7 [64]	33%
		−87.0 [60]	11%	−139.5 [62]	10%
13	R = R′ = Me_3SiCH_2	−66.7	50%	−137.3	50%
14	R = R′ = Me_3CCH_2	−83.1	25%	−146.8	25%
		−85.4	25%	−147.3	25%
15	R = R′ = Me_2CHCH_2	−78.7 [62]	8%	−143.1 [70]	8%
		−79.1 [66]	42%	−144.8 [61]	42%

The ^{119}Sn NMR spectrum of **12** in toluene shows two pairs of signals of equal integral ratio at δ = −83.8 (23%)/−145.5 (23%) and at δ = −86.9 (11%)/−144.3 (12%), which are assigned with caution to the tetramers **12a** and **12b**

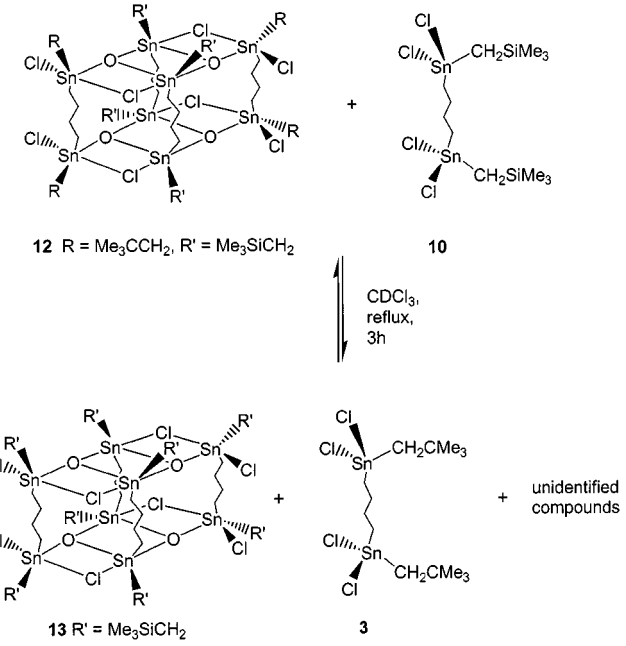
(Scheme 4). Furthermore, two sets of four signals are observed at δ = −68.8 (5%), −83.3 (5%), −146.2 (5%), and −149.4 (5%) and at δ = −71.3 (2%), −85.4 (3%), −143.0 (3%), and −147.9 (3%), which are assigned to the *cis* and *trans* isomer of **12d** (Scheme 4). The ^{119}Sn NMR spectroscopic experiments of **12** in $CDCl_3$ at concentrations of c = 145 mg mL^{-1} and c = 290 mg mL^{-1} gave similar results: The tetramers **12a** and **12b** are characterized by two sets of signals at −84.5 (27%)/−140.7 (33%) and at δ = −87.0 (11%)/−139.5 (10%). It is most likely that the signal at δ = −140.7 is superimposed with two resonances of the corresponding dimer. This assumption is supported by the observation of only six additional resonances at δ = −68.5 (5%), −70.6 (1%), −83.8 (5%), −85.6 (1%), −143.2 (2%), and −144.9 (5%) for the *cis* and the *trans* isomer of the dimer **12d** instead of the expected eight signals.

On the basis of the ^{119}Sn NMR spectroscopic experiments in $CDCl_3$ at c = 145 mg mL^{-1} the dimer/tetramer ratio of **12** was estimated to be approximately 1:1, which is in accordance with the molecular mass determination at the same concentration. It is worth noting that signals of the symmetrically substituted double ladders **13**−**15** are not detected in the ^{119}Sn NMR spectra of analytically pure **9** or **12**.

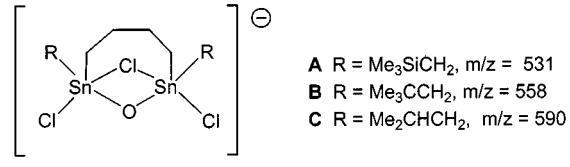
The structure of the double ladders can formally be divided into a spacer-bridged organostannoxane core to which two spacer-bridged ditin tetrachlorides $RCl_2Sn(CH_2)_4SnCl_2R$ are coordinated. The addition of $RCl_2Sn(CH_2)_4SnCl_2R$ (**10**, R = Me_3SiCH_2) to a solution of **12** in a 1:1 molar ratio gave a partial exchange (Scheme 6). The ^{119}Sn NMR spectrum in $CDCl_3$ shows the signals of the starting materials $RCl_2Sn(CH_2)_4SnCl_2R$ (**10**, R = Me_3SiCH_2) and **12**, a resonance at δ = −113.0 assigned to $RCl_2Sn(CH_2)_4SnCl_2R$ (**3**, R = Me_3CCH_2), two resonances at δ = −67.7 and −138.4 assigned to the simple double ladder **13**, and additional resonances at δ = −85.7, −100 ($W_{1/2}$ = 600 Hz), and −147 ($W_{1/2}$ = 600 Hz), for which no assignment is made.

In the case of the trimethylene-bridged double ladder $\{[R(Cl)Sn(CH_2)_3Sn(Cl)R]O\}_4$ (R = Me_3SiCH_2), no exchange was observed upon addition of a trimethylene-bridged ditin tetrachloride $RCl_2Sn(CH_2)_3SnCl_2R$ (R = Me_3CCH_2), which hints at the higher kinetic stability of the former compound compared with the tetramethylene-bridged double ladders.

The electrospray mass spectra of **9** and **12**, in acetonitrile/dichloromethane solution (9:1), show cluster patterns that are consistent with the species formed by ionization of dimers as well as of tetrameric double ladder compounds. The negative ion ESMS spectrum of **9** shows a cluster pattern which is centered at m/z = 2040 and which is assigned to the major species [**9a**−**c** + Cl]$^-$ (calcd. m/z = 2071), [**9a**−**c** + OH]$^-$ (calcd. m/z = 2051), and [**9a**−**c** − Cl + 2 OH]$^-$ (calcd. m/z = 2033). Compound **12** shows a similar cluster pattern centered at m/z = 2170 which is indicative of the species [**12a**−**c** + Cl]$^-$ (calcd. m/z = 2191), [**12a**−**c** + OH]$^-$ (calcd. m/z = 2173), and [**12a**−**c** − Cl + 2 OH]$^-$ (calcd. m/z = 2153). Species corresponding to the symmetrically substituted double ladders $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]O\}_4$ (**13**, R = Me_3SiCH_2; **14**, R = Me_3CCH_2; **15**, R = Me_2CHCH_2) were not observed, which, in accordance with the NMR spectroscopic experiments discussed above, shows that there is no equilibrium between mixed double ladders and symmetrically substituted double ladders. In the ESMS spectrum of **9** and **12**, additional cluster patterns are observed which are centered at m/z = 1032 and m/z = 1105, respectively. These patterns are assigned to doubly charged species such as [**9a**−**c** + 2 OH]$^{2-}$ (calcd. m/z = 1034) and [**9a**−**c** − Cl + 3 OH]$^{2-}$ (calcd. m/z = 1025) and [**12a**−**c** + 2 OH]$^{2-}$ (calcd. m/z = 1095) and [**12a**−**c** + 2 Cl]$^{2-}$ (calcd. m/z = 1113), rather than to the corresponding anions of the dimers **9d** and **12d**. Nevertheless, we cannot exclude that the cluster patterns of the latter are superimposed by the patterns of the doubly charged species. There are also cluster patterns of low intensity at m/z = 531 and m/z = 558 (**9**), and m/z = 558 and m/z = 590 (**12**), which are consistent with the anions **A**−**C** (Scheme 7). The formation of **A**−**C** can be explained by the dissociation of the dimers **9d**/**12d** and the complexation of a chloride.



Scheme 6. Reaction of the mixed tetramethylene-bridged tetraorganodistannoxane **12** with the tetramethylene-bridged ditin tetrachloride **10**



Scheme 7

In the ESMS spectra of both **9** and **12**, patterns of high intensity were observed, which are assigned to the complexes [$RCl_2Sn(CH_2)_4SnCl_2R$ + Cl]$^-$ (**9**, R = Me_3CCH_2

with m/z = 613, Me_2CHCH_2 with m/z = 585; **12**, R = Me_3CCH_2 with m/z = 613, Me_3SiCH_2 with m/z = 645). This observation is in agreement with the NMR spectroscopic experiment showing partial exchange of the tetrachloride fragment $RCl_2Sn(CH_2)_4SnCl_2R$ (**3**, R = Me_3CCH_2) in **12** upon addition of $RCl_2Sn(CH_2)_4SnCl_2R$ (**10**, R = Me_3SiCH_2) to a $CHCl_3$ solution of **12** (Scheme 6).

Conclusion

The synthesis of a mixed double ladder starting from the unsymmetrically substituted $(Me_3SiCH_2)Cl_2Sn(CH_2)_3SnCl_2Ph$ (**6**) failed. However, two convenient synthetic methods for the preparation of the first mixed double ladders $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R][R'(Cl)Sn(CH_2)_4Sn(Cl)R']O_2\}_2$ (**9**, R = Me_3CCH_2, R′ = Me_2CHCH_2; **12**, R = Me_3CCH_2, R′ = Me_3SiCH_2) and their characterization by X-ray crystallography are given. In contrast to the previously reported trimethylene-bridged double ladders, the tetramethylene-bridged species are kinetically labile in solution and mixed double ladders are formed by scrambling reactions between the related simple double ladders. Furthermore, the mixed tetramethylene-bridged species seem to be thermodynamically more stable than the related simple species, since no simple double ladders were detected after the quantitative formation of the mixed double ladder compounds. Nevertheless, the partial substitution of fragments such as $RCl_2Sn(CH_2)_4SnCl_2R$ in the mixed double ladders is possible. These observations give an explanation for the fact that tetramethylene-bridged organostannoxanes are more efficient catalysts in transesterification reactions than the trimethylene-bridged analogues.[18] This work is a further step toward the fine tuned catalyst design of spacer-bridged distannoxanes.

Experimental Section

General Remarks: All solvents were dried and purified by standard procedures. − Bruker DPX-300 and DRX-400 spectrometers were used to obtain ^1H and ^{119}Sn NMR spectra. ^1H and ^{119}Sn chemical shifts δ are given in ppm and were referenced against Me_4Si and Me_4Sn, respectively. No integration of the signals in the ^1H NMR spectra is given as a result of their partial superimposition. − Molecular mass determinations were performed with a Knaur osmometer in $CHCl_3$ at 59 °C. − The organotin chlorides $RCl_2Sn(CH_2)_4SnCl_2R$ (**3**, R = Me_3CCH_2; **4**, R = Me_2CHCH_2; **10**, R = Me_3SiCH_2) and oxides $[R(O)Sn(CH_2)_4Sn(O)_2R]_n$ (**8**, R = Me_3CCH_2; **7**, R = Me_2CHCH_2; **11**, R = Me_3SiCH_2) were prepared according to literature procedures.[18] − Electrospray mass spectra were obtained with a Platform II single quadrupole mass spectrometer (Micromass, Altrincham, UK) using an acetonitrile/dichloromethane (9:1) mobile phase. Acetonitrile/dichloromethane solutions (0.1 mM) of the compounds were injected directly into the spectrometer using a Rheodyne injector equipped with a 100 μL loop. A Harvard 22 syringe pump delivered the solutions to the vaporization nozzle of the electrospray ion source at a flow rate of 10 μL min^{-1}. Nitrogen was used as both a drying gas and for nebulization with flow rates of approximately 200 mL min^{-1} and 20 mL min^{-1}, respectively. Pressure in the mass analyzer region was usually about $4\cdot10^{-5}$ mbar. Typically, 50 signal-averaged spectra were collected.

Synthesis of $(Me_3SiCH_2)Cl_2Sn(CH_2)_3SnCl_2Ph$ (6): To a solution of hexaphenyldistannane (2.00 g, 2.86 mmol) and naphthalene (100 mg, 1.28 mmol) in THF (30 mL), sodium (0.14 g, 6.09 mmol) was added in small portions. After stirring the resulting solution for 18 h, a solution of (3-chloropropyl)diphenyl(trimethylsilylmethyl)tin (**2**) (1.25 g, 2.86 mmol) in THF (10 mL) was added dropwise at −50 °C. The resulting suspension was stirred for 48 h during which time it was warmed up. The resulting solid material was filtered. After evaporation of the solvent, the resulting crude oily product was dissolved in hot hexane (5 mL) and the solid material was filtered. The solvent was removed in vacuo, giving 2.99 g 1-[diphenyl(trimethylsilylmethyl)stannyl]-3-(triphenylstannyl)-propane (**5**) as a yellow oil {^{119}Sn NMR ($CHCl_3/CDCl_3$, 111.92 MHz): δ = −63.5 [$^4J(^{119}Sn-^{117/119}Sn)$ = 56 Hz], −103.9 [$^4J(^{119}Sn-^{117/119}Sn)$ = 54 Hz]}. The intermediate product **5** was dissolved in acetone (20 mL) and a solution of $HgCl_2$ (4.32 g, 15.88 mmol) in acetone (20 mL) was added dropwise at 0 °C. The suspension was stirred overnight and filtered. The solvent was removed in vacuo giving an oily residue, which was suspended in diethyl ether (50 mL). Again, it was filtered and the solvent was evaporated. The resulting solid residue was extracted with hexane (40 mL) in a Soxhlet apparatus for 72 h, giving 1.77 g (53%) of **6** as a beige solid with a m.p. of 74−75 °C. − ^1H NMR (400.13 MHz, $CDCl_3$): δ = 0.17 (s, 9 H, $SiMe_3$), 0.88 [s, 2 H, $SiCH_2$, $^2J(^{119}Sn-^1H)$ = 93 Hz], 1.83 (t, 2 H, $SnCH_2$), 2.07 (t, 2 H, $SnCH_2$), 2.39 (quint, 2 H, CH_2), 7.48−7.63 (m, 5 H, H_{Ph}). − ^{13}C NMR ($CDCl_3$, 100.63 MHz): δ = 1.0 ($SiMe_3$), 11.9 [$^1J(^{13}C-^{119}Sn)$ = 226 Hz, CH_2Si], 20.9 (CH_2), 27.6 [$^1J(^{13}C-^{119}Sn)$ = 369 Hz, CH_2Sn], 29.2 [$^1J(^{13}C-^{119}Sn)$ = 331 Hz, CH_2Sn], 129.6 [$^3J(^{13}C-^{119}Sn)$ = 60 Hz, C_m], 131.7 [$^4J(^{13}C-^{119}Sn)$ = 27 Hz, C_p], 134.6 [$^2J(^{13}C-^{119}Sn)$ = 48 Hz, C_o], 138.6 [$^1J(^{13}C-^{119}Sn)$ = 598 Hz, C_i]. − ^{119}Sn NMR (111.92 MHz, $CHCl_3/CDCl_3$): δ = 38.2 [$^4J(^{119}Sn-^{117/119}Sn)$ = 158 Hz], 130.0 [$^4J(^{119}Sn-^{117/119}Sn)$ = 159 Hz]. − $C_{13}H_{22}Cl_4SiSn_2$ (585.7): calcd. C 26.66, H 3.79; found C 26.30, H 3.80.

Reaction of $(Me_3SiCH_2)Cl_2Sn(CH_2)_3SnCl_2Ph$ (6) with $(tBu_2SnO)_3$ (NMR Spectroscopic Experiment): $(tBu_2SnO)_3$ (140 mg, 0.56 mmol) was added to a solution of $(Me_3SiCH_2)Cl_2Sn(CH_2)_3SnCl_2Ph$ (**6**) (330 mg, 0.56 mmol) in CH_2Cl_2 (3 mL). The resulting solution was heated at reflux for 5 min. The solvent was evaporated, the residue washed with pentane (5 mL) and dissolved in CH_2Cl_2 (2.5 mL). A ^{119}Sn NMR spectrum of this solution was measured. − ^{119}Sn NMR (111.91 MHz, $CH_2Cl_2/D_2O_{capillary}$) δ = −53.7 ($tBu_2SnCl_2$), −84.5 [$^2J(^{119}Sn-^{117/119}Sn)$ = 73 Hz], −86.4 [$^2J(^{119}Sn-^{117/119}Sn)$ = 75 Hz], −90.8 [$^2J(^{119}Sn-^{117/119}Sn)$ = 73 Hz], −92.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 72 Hz], −94.2, −96.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 60 Hz], −100.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 62 Hz], −132.1 [$^2J(^{119}Sn-^{117/119}Sn)$ = 71 Hz], −132.3, −132.5 [$^2J(^{119}Sn-^{117/119}Sn)$ = 72 Hz], −134.5 [$^2J(^{119}Sn-^{117/119}Sn)$ = 68 Hz], −137.6 [$^2J(^{119}Sn-^{117/119}Sn)$ = 63 Hz], −164.1, −165.4, −166.2, −168.5 [$^2J(^{119}Sn-^{117/119}Sn)$ = 78 Hz], −170.5, −209.5, −209.7, −210.9 [$^2J(^{119}Sn-^{117/119}Sn)$ = 83 Hz], −212.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 88 Hz], −214.0 [$^2J(^{119}Sn-^{117/119}Sn)$ = 73 Hz], −214.9 [$^2J(^{119}Sn-^{117/119}Sn)$ = 82 Hz].

[Synthesis of $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]_2[R'(Cl)Sn(CH_2)_4Sn(Cl)R']_2O_2\}_2$ (9, R = Me_3CCH_2, R′ = Me_2CHCH_2). − Method A:

$[R(O)Sn(CH_2)_4Sn(O)R]_n$ (R = Me_2CHCH_2) (100 mg, 0.23 mmol) was added to a solution of $RCl_2Sn(CH_2)_4SnCl_2R$ (R = Me_3CCH_2) (131 mg, 0.23 mmol) in toluene (25 mL) at room temperature. The resulting suspension was stirred at room temperature for 1 h and heated at reflux for 2 h until the solution became clear. Crystallization from toluene at room temperature yielded 218 mg (94%) of **9** as colorless crystals with m.p. 214−216 °C. − **Method B:** $[R(O)Sn(CH_2)_4Sn(O)_2R]_n$ (R = Me_3CCH_2) (100 mg, 0.21 mmol) was added to a solution of $RCl_2Sn(CH_2)_4SnCl_2R$ (R = Me_2CHCH_2) (117 mg, 0.21 mmol) in toluene (25 mL) at room temperature. The resulting suspension was stirred at room temperature for 1 h and heated at reflux for 2 h until the solution became clear. Crystallization from toluene at room temperature yielded 203 mg (94%) of **9** as colorless crystals with m.p. 214−216 °C. − **Method C (in situ Preparation, NMR Spectroscopic Experiment):** $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]O\}_4$ (**15**, R = Me_2CHCH_2) (53 mg, 0.24 mmol) was added to a solution of $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]O\}_4$ (**14**, R = Me_3CCH_2) (50 mg, 0.24 mmol) in $CDCl_3$ (2 mL), and the resulting solution was heated at reflux for 3 d. A ^{119}Sn NMR spectrum of this solution was recorded after t = 4 d. − ^{119}Sn NMR (149.21 MHz, $CDCl_3$) δ = −78.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 74 Hz, 7%], −83.0 [$^2J(^{119}Sn-^{117/119}Sn)$ = 61 Hz, 36%], −84.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 57 Hz, 7%], −144.4 [$^2J(^{119}Sn-^{117/119}Sn)$ = 66 Hz, 14%], −145.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 70 Hz, 35%], −146.9 (1%). − ^{119}Sn NMR (111.92 MHz, toluene/D_2O cap.): δ = −78.7 [$^2J(^{119}Sn-^{117/119}Sn)$ = 67 Hz, 5%], −85.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 65 Hz, 26%], −85.4 (4%), −86.4 [$^2J(^{119}Sn-^{117/119}Sn)$ = 65 Hz, 15%], −147.9 [$^2J(^{119}Sn-^{117/119}Sn)$ = 66 Hz, 15%], −148.5 [$^2J(^{119}Sn-^{117/119}Sn)$ = 67 Hz, 27%], −150.2 (5%), −152.7 (3%). − ^{1}H NMR (400.13 MHz, C_6D_6): δ = 1.04 (d, Me_2CH), 1.16 (s, Me_3C), 1.17 (s, Me_3C), 1.23 (d, Me_2CH), 1.24 (d, Me_2CH), 1.40 (s, Me_3C), 1.90−2.42 (complex pattern, CH_2), 2.47 (m, Me_2CH), 2.76 (m, Me_2CH). − Molecular mass determination ($CHCl_3$, 20 mg mL^{-1}): 1639 g mol^{-1}. − $C_{52}H_{112}Cl_8O_4Sn_8$ (2035.0): calcd. C 30.69, H 5.55; found calcd. C 30.61, H 5.58%.

Synthesis of $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]_2[R'(Cl)Sn(CH_2)_4Sn(Cl)R']_2O_2\}_2$ (12, R = Me_3CCH_2, R′ = Me_3SiCH_2). − Method A: In a similar manner to compound **9** the distannoxane **12** was prepared from $RCl_2Sn(CH_2)_4SnCl_2R$ (R = Me_3CCH_2) (347 mg, 0.60 mmol) and $[R(O)Sn(CH_2)_4Sn(O)R]_n$ (R = Me_3SiCH_2) (300 mg, 0.60 mmol), and obtained as a colorless solid (0.62 g, 96%) with m.p. 197−198 °C. − **Method B:** Analogously the reaction of $RCl_2Sn(CH_2)_4SnCl_2R$ (R = Me_3SiCH_2) (456 mg, 0.75 mmol) and $[R(O)Sn(CH_2)_4Sn(O)R]_n$ (R = Me_3CCH_2) (350 mg, 0.75 mmol) gave **12** as a colorless solid (0.79 g, 98%). − **Method C (NMR Spectroscopic Experiment):** $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]O\}_4$ (**13**, R = Me_3SiCH_2) (53 mg, 0.24 mmol) was added to a solution of $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]O\}_4$ (**14**, R = Me_3CCH_2) (50 mg, 0.24 mmol) in $CDCl_3$ (2 mL), and the resulting solution was heated at reflux for 3 d. ^{119}Sn NMR spectra of this solution were recorded after t = 1 h, 1 d, and 3 d. − ^{119}Sn NMR (149.21 MHz, $CDCl_3$): δ = −68.5 (5%), −70.6 (1%), −83.8 (5%), −84.5 (27%), −85.6 (1%), −87.0 (11%), −139.5 (10%), −140.7 (33%), −143.2 (2%), −144.9 (5%). − ^{119}Sn NMR (111.92 MHz, toluene, D_2O cap.): δ = −68.8 (5%), −71.3 (2%), −83.3 [$^2J(^{119}Sn-^{117/119}Sn)$ = 67 Hz, 5%], −83.8 [$^2J(^{119}Sn-^{117/119}Sn)$ = 66 Hz, 23%], −85.4(3%), −86.9 [$^2J(^{119}Sn-^{117/119}Sn)$ = 66 Hz, 11%], −143.0 (3%), −144.3 [$^2J(^{119}Sn-^{117/119}Sn)$ = 66 Hz, 12%], −145.5 [$^2J(^{119}Sn-^{117/119}Sn)$ = 67 Hz, 23%], −146.2 [$^2J(^{119}Sn-^{117/119}Sn)$ = 67 Hz, 5%], −147.9 (3%), −149.4 [$^2J(^{119}Sn-^{117/119}Sn)$ = 67 Hz, 5%]. − ^{1}H NMR (400.13 MHz, [D_8]toluene): δ = 0.21 (s, Me_3Si), 0.22 (s, Me_3Si), 0.41 (s, Me_3Si), 1.08 (s, Me_3C), 1.11 (s, CH_2Si), 1.15 (s, Me_3C), 1.19 (s, CH_2Si), 1.34 (s, Me_3C), 1.36 (s, CH_2Si), 1.85−2.21 (complex pattern, CH_2). − Molecular mass determination ($CHCl_3$, 20 mg mL^{-1}): 1191 g mol^{-1}, ($CHCl_3$, 145 mg mL^{-1}): 1689 g mol^{-1}. −

$C_{52}H_{120}Cl_8O_4Si_4Sn_8$ (2155.4): calcd. C 28.98, H 5.61; found calcd. C 29.35, H 5.45.

Reaction of $\{[R(Cl)Sn(CH_2)_4Sn(Cl)R]_2[R'(Cl)Sn(CH_2)_4Sn(Cl)R']_2O_2\}_2$ (12, R = Me_3CCH_2, R' = Me_3SiCH_2) with $RCl_2Sn(CH_2)_4SnCl_2R$ (3, R = Me_3CCH_2) (NMR Spectroscopic Experiment): Compound **3** (72 mg, 0.34 mmol) was added to a solution of **12** (72 mg, 0.34 mmol) in $CDCl_3$ (2 mL). The resulting solution was heated at reflux for 3 h and a ^{119}Sn NMR spectrum was recorded. − ^{119}Sn NMR (149.21 MHz, $CDCl_3$): δ = −131.4, −113.0, −66.7, −67.5, −69.7, −82.9, − 83.5, −84.7, −85.3, −86.1, −100 ($W_{1/2}$ = 600 Hz), −137.4, −138.5, −139.6, −142.4, −144.8, −147 ($W_{1/2}$ = 600).

Addition of $RCl_2Sn(CH_2)_3SnCl_2R$ (R = Me_3CCH_2) to a Solution of $\{[R(Cl)Sn(CH_2)_3Sn(Cl)R]O\}_4$ (R = Me_3SiCH_2) (NMR Spectroscopic Experiment): $RCl_2Sn(CH_2)_3SnCl_2R$ (R = Me_3CCH_2) (56 mg, 0.10 mmol) was added to a solution of the double ladder (216 mg, 0.10 mmol) in CH_2Cl_2 (3 mL). The resulting solution was heated at reflux for 2 h and a ^{119}Sn NMR spectrum (149.21 MHz, CH_2Cl_2/D_2O cap.) was recorded which showed the signals of the starting materials at δ = −96.1 [$^2J(^{119}Sn-^{117/119}Sn)$ = 67 Hz], −132.9 [$^2J(^{119}Sn-^{117/119}Sn)$ = 69 Hz] and δ = 107.9 [$RCl_2Sn(CH_2)_3SnCl_2R$, R = Me_3CCH_2].

Crystallography: Intensity data for the colorless crystals grown from benzene were collected with a Nonius KappaCCD diffractometer with graphite-monochromated Mo-K_α (0.71069 Å) radiation at 291 K. The data collection covered almost the whole sphere of reciprocal space with 360 frames by ω-rotation (Δ/ω = 1°) at two times 10 s (**9**) and 20 s (**12**) per frame. The crystal-to-detector distance was 2.7 cm (**9**) and 3.0 cm with a detector-θ-offset of 5° (**2**). Crystal decay was monitored by repeating the initial frames at the end of data collection. On analysis of the duplicate reflections, there was no indication for any decay. The data were not corrected for absorption effects. The structure was solved by direct methods SHELXS97[25] (Sheldrick, **1990**) and successive difference Fourier syntheses. Refinement applied full-matrix least-squares methods SHELXL97[26] (Sheldrick, **1997**). − The H atoms were placed in geometrically calculated positions using a riding model ($C-H_{prim.}$ 0.96 Å, $C-H_{sec.}$ 0.97 Å; H_{aryl} C−H 0.93), and for **9** refined with a common isotropic temperature factor [U_{iso} 0.148(7) Å^2] and for **12** with isotropic temperature factors constrained to be 1.5 times those of the carrier atom. − Disordered tetramethylene, *tert*-butyl (**12**), and isobutyl (**9**) groups were found with occupancies of 0.3333 [C(43′), C(44′)], 0.5 [C(3), C(5), C(3′), C(5′)], and 0.6666 [C(43), C(44)] in **12** and of 0.15 [C(32′)] and 0.85 [C(32)] in **9**. − Atomic scattering factors for neutral atoms and real and imaginary dispersion terms were taken from International Tables for X-ray Crystallography.[27] The figures were created by SHELXTL[28] (Sheldrick, **1991**). Crystallographic data are given in Table 3 and selected bond lengths and angles in Table 1. Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-144264 (**9**) and CCDC-144265 (**12**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A General Synthetic Pathway to Lewis Base-Stabilized, Monomeric Group 13/15 Compounds

Florian Thomas,[a] Stephan Schulz,*[a] and Martin Nieger[a]

Keywords: Semiconductors / Heterocycles / Donor-acceptor systems / Cage compounds / Aluminum / Gallium

Reactions of an equimolar amount of 4-(dimethylamino)pyridine (dmap) with several Al–E heterocycles $[R_2AlE(SiMe_3)_2]_x$ (E = P, As; R = Me, x = 3; R = Et, x = 2) and Ga–Sb heterocycles $[R_2GaSb(SiMe_3)_2]_x$ (R = Me, x = 3; R = Et, x = 2) in hexane offers a general pathway for the formation of monomeric, Lewis base-stabilized compounds of the type dmap–$(R_2)ME(SiMe_3)_2$ (M = Al, R = Me, E = P **1**, As **2**; R = Et, E = As **3**; M = Ga, E = Sb, R = Me **4**, Et **5**). Compounds **1**, **2**, **3** and **5** have been characterized by single-crystal X-ray diffraction.

Introduction

Over the last two decades, the synthesis of monomeric group 13/15 compounds of the type $R_2MER'_2$ has received growing interest owing to their fascinating bonding properties.[1] In addition, compounds of the type $[R_2MER'_2]_x$, which may serve as so-called single-source precursors for the preparation of the corresponding semiconducting binary materials, are still in the focus of very intense studies. These compounds are usually obtained in the form of heterocycles (x = 2, 3), heterocubanes (x = 4) or more highly associated cages (x > 4), both in solution and in the solid state, as a result of the tendency of the triele atom to utilize its vacant p-valence orbital by increasing its coordination number from 3 to 4. Monomeric group 13/15 compounds $R_2MER'_2$ are only formed with sterically extremely bulky ligands on both M and E, which inhibit the formation of oligomers and lead to the formation of kinetically stabilized monomers.[2] Recently, we demonstrated a synthetic route for the formation of electronically stabilized monomeric compounds. Monomeric, Lewis base-stabilized organoaluminum stibides[3] and bismuthides[4] of the type dmap−$(R_2)AlE(SiMe_3)_2$ (E = Sb, Bi) were obtained by ring-cleavage reactions of the corresponding heterocycles $[R_2AlER'_2]_x$ with 4-(dimethylamino)pyridine (dmap). The triele atom is coordinatively and electronically saturated by interaction with the strong base, while the *lone pair* of the pentele atom is still active for coordination chemistry. Prior to our studies, only a few examples of structurally characterized, Lewis base-stabilized amino-, phosphanyl-, and arsanylalane monomers had been reported. $Me_3N-Al(H_2)NR_2$ and $Me_3N-Al(H_2)As(SiMe_3)_2$ were synthesized by the reaction of $H_3Al-NMe_3$ with sterically bulky secondary amines[5] and $As(SiMe_3)_3$,[6] respectively. Reactions of $H_2AlCl-NMe_3$ with $LiEMes_2$ (E = P, As; Mes = 2,4,6-$Me_3C_6H_2$) led to the formation of $Me_3N-Al(H_2)EMes_2$.[7] Unfortunately, no general pathway for the synthesis of this specific class of compounds has been developed so far. The reactions are limited to Me_3N-stabilized AlH_3 or H_2AlCl as starting compounds. However, the desired monomeric compounds are of particular interest because they may serve as general building blocks for the synthesis of bimetallic complexes of the type dmap−$(R_2)ME(R'_2)-M'L_n$ (M = triele; E = pentele; M′ = transition metal),[8] where the pentele atom bridges a "soft" transition metal and a "hard" main-group metal fragment.[9] Complexes of this type can be considered as transition metal derivatives of an amphoteric main group element ligand.[10] Up to now, $Me_3N-(Me_3SiCH_2)_2-AlP(Ph)_2-Cr(CO)_5$ is the only structurally characterized compound of this type, which was prepared in a very special reaction by Beachley et al.[10a,11] However, this specific reaction pathway couldn't be successfully expanded to the synthesis of other comparable bimetallic complexes.

In this paper we wish to present our extended studies on ring-cleavage reactions of Al−E heterocycles containing the lighter homologues of group 15, P and As, as well as on Ga−Sb heterocycles, demonstrating the general and convenient purpose of this particular reaction type for the synthesis of the desired class of compounds.

Results

The reaction of equimolar amounts of 4-(dimethylamino)-pyridine (dmap) with several Al−E heterocycles $[R_2AlE(SiMe_3)_2]_2$ (E = P, As; R = Me, Et) in hexane resulted in the formation of the corresponding Lewis base-stabilized monomers **1**−**3** in almost quantitative yield (Scheme 1). Monomers prepared in this way are extremely sensitive to-

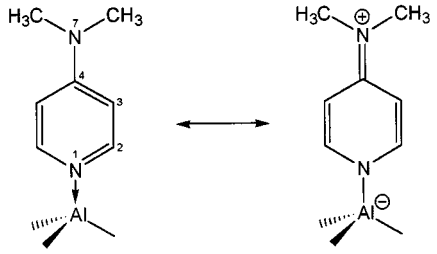
wards air and moisture, particularly in solution. At −30 °C, compounds **1**−**3** were obtained as crystalline, light yellow solids.

The ^{1}H and ^{13}C NMR spectra of **1**−**3** show resonances due to the organic ligands bound to the metal centers and the expected resonances of dmap. Integration of the signals due to the organic ligands and dmap indicated a 1:1 stoichiometry of dmap:$R_2AlE(SiMe_3)_2$ (E = P, As; R = Me, Et). The proton resonances of the organic ligands bound to the metal centers appear further downfield (MeAl, EtAl, and Me_3Si resonances) than those of the starting heterocycles, while those of the dmap molecule are shifted upfield. These findings are in agreement with results observed for similar borane adducts,[12] and correspond to a partial rearrangement of the charge distribution within the aromatic ring as shown in Scheme 2.



Scheme 2

Single-crystal X-ray analyses of **1** (Figure 1), **2** (Figure 2), and **3** (Figure 3) clearly show the presence of monomeric $R_2AlE(SiMe_3)_2$ molecules, to which one dmap molecule is coordinated. Compounds **2** and **3** crystallize in the triclinic space group $P\bar{1}$ (no. 2), while **1** crystallizes in the monoclinic space group $P2_1/c$ (no. 14). Both **1** and **2** crystallize with two independent molecules in the asymmetric unit.

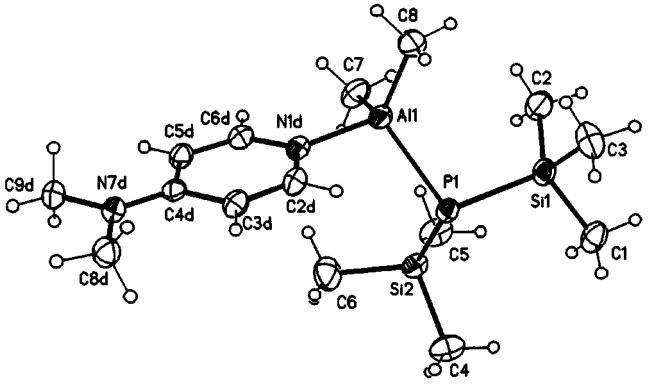


Figure 1. ORTEP diagram (50% probability ellipsoids) showing the solid-state structure and atom-numbering scheme for **1**; for clarity, only one independent molecule of the asymmetric unit is presented; selected bond lengths [pm] and angles [°]: Al1−N1d 198.4(2), Al1−P1 237.9(1), Al1−C7 197.7(2), Al1−C8 197.7(2), P1−Si1 223.6(1), P1−Si2 223.7(1); C7−Al1−C8 115.3(1), Si1−P1−Si2 104.8(1), N1d−Al1−P1 101.0(1), Si1−P1−Al1 102.5(1), Si2−P1−Al1 101.8(1)

As found in the corresponding monomers of the higher homologues dmap−$Al(R_2)E(SiMe_3)_2$ (R = Me, Et, E = Sb, Bi),[3,4] the substituents bonded to Al and the particular pentele atom adopt a staggered conformation relative to one another. The average Al−C bond lengths (**1**: 197.7, 197.5; **2**: 196.9, 196.6; **3**: 197.7 pm) and C−Al−C bond angles [**1**: 115.3(1), 114.6(1)°; **2**: 114.7(2), 115.7(2)°; **3**: 115.3(2)°] are within the expected ranges, while the E−Si bond lengths (**1**: 223.7, 222.9; **2**: 233.8, 233.9; **3**: 233.8 pm) are at the lower end of typical E−Si bond lengths.[13] They are only slightly shorter than in the starting compounds {average E−Si distances found in $[Me_2AlP(SiMe_3)_2]_2$: 225.9

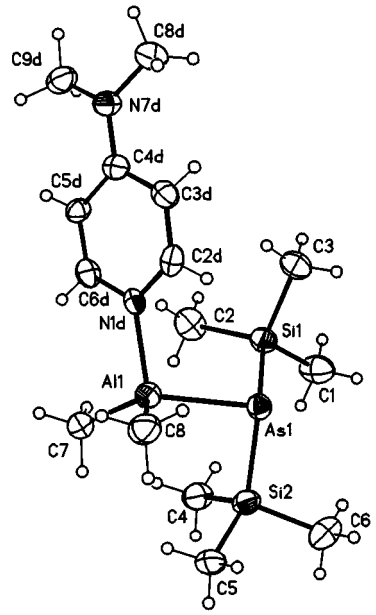

Figure 2. ORTEP diagram (50% probability ellipsoids) showing the solid-state structure and atom-numbering scheme for **2**; for clarity, only one molecule of the asymmetric unit is presented; selected bond lengths [pm] and angles [°]: Al1−N1d 197.5(4), Al1−As1 247.2(2), Al1−C7 196.5(4), Al1−C8 197.3(4), As1−Si1 233.7(2), As1−Si2 233.8(2); C7−Al1−C8 114.7(2), Si1−As1−Si2 101.1(1), N1d−Al1−As1 104.5(2), Si1−As1−Al1 105.0(1), Si2−As1−Al1 98.0(1)

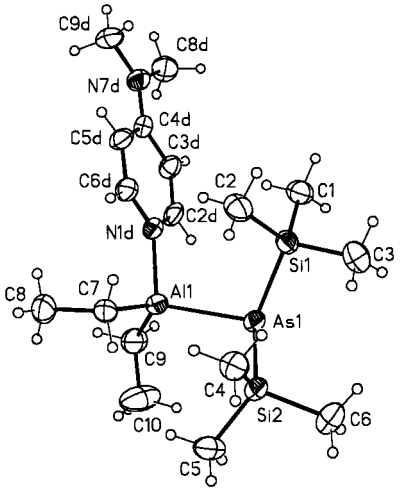

Figure 3. ORTEP diagram (50% probability ellipsoids) showing the solid-state structure and atom-numbering scheme for **3**; selected bond lengths [pm] and angles [°]: Al1−N1d 198.8(3), Al1−As1 247.3(1), Al1−C7 196.5(4), Al1−C9 198.9(3), As1−Si1 233.4(1), As1−Si2 234.1(1); C7−Al1−C9 115.3(2), Si1−As1−Si2 101.3(1), N1d−Al1−As1 105.0(1), Si1−As1−Al1 103.5(1), Si2−As1−Al1 101.8(1)

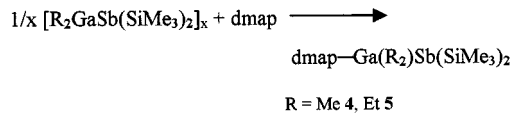
pm; $[Me_2AlAs(SiMe_3)_2]_2$: 234.5 pm; $[Et_2AlAs(SiMe_3)_2]_2$: 234.9 pm}.

The Al−N bond lengths [**1**: 198.4(2), 197.7(2); **2**: 197.5(4), 198.9(4); **3**: 198.8(3) pm] are almost the same as those observed in the corresponding monomeric compounds of the heavier group 15 elements dmap−(R_2)AlE$(SiMe_3)_2$ (R = Me, Et, E = Sb, Bi), indicating the strong donor capacity of dmap. In addition, the almost equal Al−N distances demonstrate that the particular pentele atom does not have a significant electronic influence on the Lewis acidity of the Al fragment. Typical Al−N distances of adducts with tricoordinated N centers are comparable [e.g. 2-methylpyridine−$AlCl_3$: 194.2(2) pm, stronger Lewis acid],[14] while adducts with tetracoordinated N centers show significantly longer Al−N distances [e.g. $Me_3Al-NMe_3$: 210(1) pm; $H_3Al-NMe_3$: 206.3(8) pm (gas phase); Me_3Al-NH_3: 200.4(5) pm (powder diffraction); H_3Al-tmp (tmp = 2,2,6,6-tetramethylpiperidine): 204(1) pm].[15] However, compounds containing stronger Lewis acids [e.g. $Cl_3Al-NMe_3$: 196(1) pm (single-crystal analysis)[16]; 194.5(35) pm (electron diffraction)[17]] show comparable Al−N distances. Compared to analogous Lewis base-stabilized monomers of the type $Me_3N\rightarrow Al(R_2)ER'_2$, the dmap adducts show the shortest Al−N distances [Al−N (in pm): $Me_3N\rightarrow Al(H_2)N(tmp)_2$ 205.8(2);[5a] $Me_3N\rightarrow Al(H)(Cl)N(SiMe_3)_2$ 201.6(5);[5b] $Me_3N\rightarrow Al(H_2)As(SiMe_3)_2$ 199.8(7);[6] $Me_3N\rightarrow Al(H_2)PMes_2$ 200.9(8)[7]].

The Al−P [237.9(1), 237.4(1) pm **(1)**] and Al−As bond lengths [247.2(2), 247.0(2) **(2)**, 247.3(1) pm **(3)**] are also relatively short. Comparable Al−P distances in phosphanylalanes were found in the monomeric compounds $Trip_2AlP(Ada)(SiPh_3)$ [234.2(2) pm][18] (Trip = 2,4,6-iPr$_3$C$_6$H$_2$) and Tmp_2AlPPh_2 [237.7(1) pm],[2a] while the Lewis base-stabilized monomer $Me_3N\rightarrow Al(H_2)PMes_2$ shows a slightly longer distance [240.9(3) pm].[7] The Al−As distances in **2** and **3** [247.2(2), 247.0(2); 247.3(1) pm] are almost the same as those in monomeric $Tmp_2AlAsPh_2$ [248.5(2) pm][2a] but slightly longer than those in $Me_3N\rightarrow Al(H_2)As(SiMe_3)_2$ [243.8(2) pm][6] and $Me_3N-Al(H)AsSi(iPr)_3]_2$.[19] The shortest Al−As distances were found in the borazine analogue [Mes*AlAsPh]$_3$·Et$_2$O (Mes* = 2,4,6-tBu$_3$C$_6$H$_2$), which, however, only has tricoordinated Al centers.[20] The comparable Lewis base-stabilized monomer $Me_3N-Al(H_2)As(SiMe_3)_2$ is sterically less hindered than **2** and **3** and contains a slightly stronger Lewis acidic Al center due to the weaker +I effect of the H- relative to the Me-substituents. The Al−P and Al−As distances agree very well with the sum of the covalent radii of the corresponding central atoms (Al−P: 235 pm; Al−As: 246 pm).[21] Interestingly, the starting heterocycles show significantly longer Al−E distances. The average Al−E distances found in $[Me_2AlP(SiMe_3)_2]_2$ (245.7 pm), $[Me_2AlAs(SiMe_3)_2]_2$ (253.6 pm) and $[Et_2AlAs(SiMe_3)_2]_2$ (253.5 pm) are elongated by 8 (Al−P) and 6 pm (Al−As), respectively. In contrast, the Al−E distances of the corresponding monomeric stibides [dmap−(Me_2)AlSb$(SiMe_3)_2$: 269.1(1) pm; dmap−(Et_2)AlSb$(SiMe_3)_2$: 267.9(1) pm][3] and bismuthide [dmap−(Me_2)AlBi$(SiMe_3)_2$: 275.5(2) pm][4] are on average less shortened (Al−Sb: 3−5 pm; Al−Bi: 2 pm) compared to those of the starting heterocycles {$[Me_2AlSb(SiMe_3)_2]_3$: 271.9 pm;[22] $[Et_2AlSb(SiMe_3)_2]_2$: 273.5 pm;[23] $[Me_2AlBi(SiMe_3)_2]_3$: 277.4 pm[24]}. Obviously, intramolecular steric repulsion between the ligands is less intense within the heterocycles of the heavier homologues of group 15 owing to the increasing atomic radii of the penteles from P to Bi.

Besides the structural similarity of **1**, **2**, **3**, and the higher homologues dmap−(R_2)AlE$(SiMe_3)_2$ (R = Me, Et, E = Sb, Bi)[3,4] in almost every structural feature, the compounds show one remarkable difference: The Si−E−Si and Si−E−Al bond angles decrease significantly with increasing atomic number of the group 15 element. While the Si−P−Si angles in **1** are 104.8(1) and 102.9(1)°, the corresponding Si−As−Si angles in **2** [101.1(1) and 101.9(1)°] and **3** [101.3(1)°] are smaller. The corresponding stibides dmap−Al(R_2)Sb$(SiMe_3)_2$ [R = Me 97.6(2)°; Et 99.1(1)°] and bismuthides dmap−Al(R_2)Bi$(SiMe_3)_2$ [R = Me 95.7(1)°; Et 97.4(1)°] again show significantly reduced angles. These findings are in agreement with the well-known tendency within group 15 trihydrides H_3E, which show constantly decreasing H−E−H angles from 106.8° (NH_3)[25] to 91.3° (SbH_3),[26] as well as in triphenyl [C−E−C angles decrease from 102.8° (PPh_3), 100.1° ($AsPh_3$), 97.8° ($SbPh_3$) to 93.9° ($BiPh_3$)][27] and trimethyl derivatives Me_3E [C−E−C angles decrease from 110.6° (NMe_3)[28] to 94.2° ($SbMe_3$)].[29] Only $BiMe_3$ shows a slightly bigger C−Bi−C angle of 96.7°.[30] The smaller bond angles of the stibides and bismuthides relative to the amides result both from the decreased steric repulsion between the $SiMe_3$ groups owing to the increased E−Si bond length and from the increased s-character of the *lone pair* and the increased p-character of the bonding electron pairs due to relativistic effects and the lanthanide-contraction (inert-pair effect).[31]

In an attempt to prove the generality of the described reaction pathway for the synthesis of group 13/15 monomers, we also investigated reactions of Ga−Sb heterocycles $[R_2GaSb(SiMe_3)_2]_x$ (R = Me, x = 3; R = Et, x = 2) with dmap. Again, the monomeric compounds dmap−Ga(R_2)Sb$(SiMe_3)_2$ (R = Me **4**, Et **5**, Scheme 3) were obtained in almost quantitative yield. However, they are more temperature labile than the Al derivatives and start to decompose significantly at room temperature both in solution and in the solid state. Therefore, the reaction has to be performed between −10 and 0 °C and the resulting monomers have to be stored at −30 °C.



Scheme 3. Synthesis of monomeric, Lewis base-stabilized stibinogallanes

Single crystals of **5** were obtained from a solution in hexane at −30 °C. Compound **5** crystallizes in the triclinic space group $P\bar{1}$ (no. 2). **5** (Figure 4) is isostructural to the corresponding Al derivative dmap−Al(Et_2)Sb$(SiMe_3)_2$[3] and shows comparable Ga−C (199.4 pm) and Sb−Si distances

(255.0 pm) as well as C−Ga−C [117.2(2) °] and Si−Sb−Si bond angles [99.3(1) °].

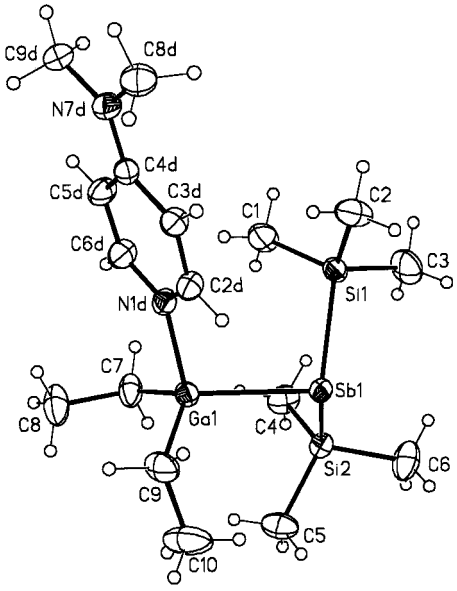


Figure 4. ORTEP diagram (50% probability ellipsoids) showing the solid-state structure and atom-numbering scheme for **5**; selected bond lengths [pm] and angles [°]: Ga1−N1d 206.6(2), Ga1−Sb1 264.8(1), Ga1−C7 198.5(2), Ga1−C9 200.3(2), Sb1−Si1 254.8(1), Sb1−Si2 255.3(1); C7−Ga1−C9 117.2(2), Si1−Sb1−Si2 99.3(1), N1d−Ga1−Sb1 103.6(1), Si1−Sb1−Ga1 100.6(1), Si2−Sb1−Ga1 99.3(1)

In contrast, the Ga−N distance is much longer [206.6(2) pm], demonstrating the reduced Lewis acidity of the Et_2Ga- relative to the Et_2Al-fragment, but almost the same as in 2-(methyl)pyridine−$Ga(Me_2)Cl$ [206.6(3) pm].[32] However, 4-(methyl)pyridine−$Ga(Mes_2)SeMes$, which also contains a tricoordinated N base, shows a slightly longer Ga−N distance [209.5(3) pm],[33] while in the methylene-bridged compound $Me_3N{-}Ga(CH_2CMe_2)CH_2P(Ph_2){-}Cr(CO)_5$, which contains a tetracoordinated N center, the Ga−N distance is significantly increased [223.5(3) pm].[10c] Very recently, Gladfelter et al. described the synthesis of several quinuclidine-stabilized amido- and azidogallanes by the reaction of quinuclidine-stabilized dichlorogallane quin−$Ga(H)Cl_2$ with Li amides and azides. The X-ray structures of four compounds showed dative Ga−N distances between 206 and 210 pm,[34] which are comparable to that found in $Me_3N{-}GaH_3$ [208.1(4) pm].[35] The Ga−Sb distance of 264.8(1) pm found in **5** is the shortest Ga−Sb bond length ever observed. It is also shorter than the Al−Sb distances found in the Lewis base-stabilized Al−Sb monomers (267−270 pm).[3] An analogous tendency was observed for the Al−Sb and Ga−Sb heterocycles {e.g. $[Me_2MSb(SiMe_3)_2]_3$: 270.2(1)−273.8(1) pm (M = Al),[22] 267.7(1)−271.4(1) pm (M = Ga)[36]; $[Et_2MSb(SiMe_3)_2]_2$: 272.3(1), 272.9(1) pm (M = Al),[23] 271.8(1), 272.9(1) pm (M = Ga)[37]}. Although the covalent radii of Al and Ga are almost the same (Al 125 pm; Ga 126 pm), the Ga−Sb heterocycles tend to have slightly shorter inter-metallic bond lengths than the Al−Sb compounds.

Conclusions

Four- and six-membered group 13/15 heterocycles can be cleaved by reaction with the strong Lewis base 4-(dimethylamino)pyridine (dmap). Previous reports on Al−Sb and Al−Bi heterocycles are extended in these studies to the corresponding Al−P and Al−As heterocycles as well as to Ga−Sb compounds. In all cases, Lewis base stabilized monomers of the type dmap−$M(R_2)E(SiMe_3)_2$ were formed in almost quantitative yield. This convenient reaction type seems to be a general, useful synthetic pathway for the synthesis of the desired class of compounds, allowing access to a wide variety of monomeric group 13/15 compounds. The coordination chemistry of the resulting monomers is currently under investigation.

Experimental Section

General Considerations: All manipulations were performed in a glovebox under a Ar-atmosphere or by standard Schlenk techniques. $[Me_2GaSb(SiMe_3)_2]_3$ [36] and $[Et_2GaSb(SiMe_3)_2]_2$ [37] were prepared by literature methods. Although the synthesis of $[Me_2AlP(SiMe_3)_2]_2$,[38] $[Me_2AlAs(SiMe_3)_2]_2$,[39] and $[Et_2AlAs(SiMe_3)_2]_2$ [40] is described in the literature, these compounds were prepared by the dehydrosilylation reaction between the corresponding alane R_2AlH and $E(SiMe_3)_3$ according to a procedure described previously.[22,23] − ^1H and $^{13}C\{^1H\}$ spectra were recorded using a Bruker AMX 300 spectrometer, using C_6D_5H as internal reference (δ^1H = 7.154; $\delta^{13}C$ = 128.0). − Elemental analyses were performed at the Mikroanalytisches Laboratorium der Universität Bonn.

General Preparation of dmap −Al(R$_2$)E(SiMe$_3$)$_2$: 4-(Dimethylamino)pyridine (2.00 mmol) was added to a solution of the respective Al−E heterocycle (1.00 mmol) in hexane and the resulting suspension was heated at reflux for 30 min. The resulting clear, slightly yellow solution was stored at −30 °C. After 10 h, compounds **1**−**3** were obtained as colorless or light yellow solids.

dmap −Al(Me$_2$)P(SiMe$_3$)$_2$ (1): Yield 0.66 g (1.85 mmol, 93%). − ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.02 (d, $^3J_{P-H}$ = 1.6 Hz, 6 H, AlMe), 0.56 (d, $^3J_{P-H}$ = 3.9 Hz, 18 H, $SiMe_3$), 2.00 (s, 6 H, NMe_2), 5.71 [d, $^3J_{H-H}$ = 6.4 Hz, 2 H, C(3)-H], 8.26 [dd, $^{3,4}J_{H-H}$ = 5.6 / 1.5 Hz (AA′XX′), 2 H, C(2)-H]. − $^{13}C\{^1H\}$ NMR (50 MHz, C_6D_6, 25 °C): δ = −4.4 [AlMe (d, $^2J_{C-P}$ = 12.5 Hz)], 6.1 [$SiMe_3$ (d, $^2J_{C-P}$ = 10.4 Hz)], 38.6 (NMe_2), 106.9 [C(3)-H], 148.0 [C(2)-H], 155.3 [C(4)]. − $C_{15}H_{34}AlN_2PSi_2$ (356.57): calcd. C 50.50, H 9.64; found C 50.71, H 9.88.

dmap −Al(Me$_2$)As(SiMe$_3$)$_2$ (2): Yield 0.75 g (1.88 mmol, 94%). − ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.03 (s, 6 H, AlMe), 0.61 (s, 18 H, $SiMe_3$), 1.92 (s, 6 H, NMe_2), 5.58 (d, $^3J_{H-H}$ = 6.6 Hz, 2 H, C(3)-H), 8.18 (dd, $^{3,4}J_{H-H}$ = 5.8 / 1.5 Hz, 2 H, C(2)-H). − $^{13}C\{^1H\}$ NMR (50 MHz, C_6D_6, 25 °C): δ = −4.1 (AlMe), 6.3 ($SiMe_3$), 38.6 (NMe_2), 106.8 [C(3)-H], 147.3 [C(2)-H], 155.5 [C(4)]. − $C_{15}H_{34}AlAsN_2Si_2$ (400.52): calcd. C 45.14, H 8.60; found C 45.28, H 8.71.

dmap −Al(Et$_2$)As(SiMe$_3$)$_2$ (3): Yield 0.74 g (1.72 mmol, 86%). − ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.60 (s, 18 H, $SiMe_3$), 0.86 (q, $^3J_{H-H}$ = 8.1 Hz, 4 H, Et-CH_2), 1.51 (t, $^3J_{H-H}$ = 8.1 Hz, 6 H, Et-CH_3), 1.91 (s, 6 H, NMe_2), 5.58 [d, $^3J_{H-H}$ = 7.3 Hz, 2 H, C(3)-H], 8.20 [dd, $^{3,4}J_{H-H}$ = 5.9 / 1.4 Hz, 2 H, C(2)-H]. − $^{13}C\{^1H\}$

Table 1. Crystallographic data and measurements for dmap−Al(Me_2)P($SiMe_3$)$_2$ (**1**), dmap−Al(Me_2)As($SiMe_3$)$_2$ (**2**), dmap−Al(Et_2)As($SiMe_3$)$_2$ (**3**), and dmap−Ga(Et_2)Sb($SiMe_3$)$_2$ (**5**)

[a] $R1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$ [for $I > 2\sigma(I)$]. − [b] $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. − [c] Goodness of fit = $\{\Sigma[w(|F_o^2| - |F_c^2|)^2]/(N_{observns} - N_{params})\}^{1/2}$.

NMR (50 MHz, C_6D_6, 25 °C): δ = 4.3 (Et-CH_2), 6.1 ($SiMe_3$), 10.6 (Et-CH_3), 38.1 (NMe_2), 106.4 [C(3)-H], 147.0 [C(2)-H], 155.1 [C(4)]. − $C_{17}H_{38}AlAsN_2Si_2$ (428.57): calcd. C 47.63, H 8.91; found C 47.46, H 8.67.

General Preparation of dmap −Ga(R_2)Sb($SiMe_3$)$_2$: 4-(Dimethylamino)pyridine (2.00 mmol) was added to a solution of the respective Ga−Sb heterocycle (1.00 mmol of the dimer, 0.67 mmol of the trimer) in hexane at −10 °C. The resulting suspension was stirred at this temperature for 1 h, slowly warmed to 0 °C over 2 h, filtered, and stored at −30 °C. After 10 h, compounds **4** and **5** were obtained as colorless or light yellow solids, which are thermolabile. They decompose significantly in solution at 25 °C within 30 min. ^{13}C NMR spectra could therefore not be obtained.

dmap −Ga(Me_2)Sb($SiMe_3$)$_2$ (4): Yield 0.66 g (1.34 mmol, 67%). − ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.39 (s, 4.4 H, $GaMe_2$), 0.65 (s, 14 H, $SiMe_3$), 2.05 (s, 6 H, NMe_2), 5.69 [d, $^3J_{H-H}$ = 6.9 Hz, 2 H, C(3)-H], 8.10 [d, $^3J_{H-H}$ = 5.7 Hz, 2 H, C(2)-H]. − $C_{15}H_{34}GaN_2SbSi_2$ (489.45): calcd. C 36.73, H 6.95; found C 35.81, H 6.78.

dmap −Ga(Et_2)Sb($SiMe_3$)$_2$ (5): Yield 0.67 g (1.29 mmol, 60%). − ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.67 (s, 18 H, $SiMe_3$), 1.03 (q, $^3J_{H-H}$ = 7.9 Hz, 4 H, Et-CH_2), 1.52 (t, $^3J_{H-H}$ = 8.0 Hz, 6 H, Et-CH_3), 1.99 (s, 6 H, NMe_2), 5.67 [d, $^3J_{H-H}$ = 5.7 Hz, 2 H, C(3)-H], 8.13 [d, $^3J_{H-H}$ = 6.0 Hz, 2 H, C(2)-H]. − $C_{17}H_{38}GaN_2SbSi_2$ (518.14): calcd. C 39.43, H 7.41; found C 39.11, H 7.02.

X-ray Structure Solution and Refinement: Crystallographic data of **1**, **2**, **3**, and **5** are summarized in Table 1. Figure 1−4 show the ORTEP diagrams of the solid-state structures of **1**, **2**, **3**, and **5**. Data were collected on a Nonius Kappa-CCD diffractometer. The structures of **1**, **2**, **3**, and **5** were solved by Patterson methods (SHELXS-97)[41] and refined by full-matrix least-squares on F^2 (SHELXL-97).[42] All non-hydrogen atoms were refined anisotropically and hydrogen atoms by a riding model. Empirical absorption corrections were applied (**2**, **3**, and **5**). The crystallographic data of **1**, **2**, **3**, and **5** (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-144769 (**1**), CCDC-144768 (**2**), CCDC-144767 (**3**), and CCDC-144770 (**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB21EZ [Fax: (Internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam-ak.uk].

Isolation and Structural Characterization of New Indium(III) Aqua Complexes: *trans*-$[InCl_2(H_2O)_4]^+$ and *trans*-$[InCl_4(H_2O)_2]^-$ as Supramolecular Adducts with Cucurbituril and Related Studies

Denis G. Samsonenko,[a] Maxim N. Sokolov,[a] Alexander V. Virovets,[a] Natalya V. Pervukhina,[a] and Vladimir P. Fedin*[a]

Keywords: Indium / Aluminum / Solid-state structures / Supramolecular chemistry / Aqua complexes / Cucurbituril

Aqua and aqua-chloride complexes of Al^{III} and In^{III} have been isolated from aqueous solutions and structurally characterized by X-ray analysis as supramolecular adducts with cucurbituril. Using this approach, *trans*-$[InCl_2(H_2O)_4]^+$ and *trans*-$[InCl_4(H_2O)_2]^-$ species were detected and isolated for the first time as parts of supramolecular assemblies of $[InCl_2(H_2O)_4]_3Cl_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot4H_2O$ (**1**) and $(H_3O)_3[InCl_4(H_2O)_2]_3\cdot2(C_{36}H_{36}N_{24}O_{12})\cdot17H_2O$ (**2**). The hexaaqua indium(III) cation is present in $[In(H_2O)_6](NO_3)_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot9H_2O$ (**3**), and its geometry has been established by X-ray crystallography for the first time. The preparation and crystal structure of an Al^{III} hexaaqua ion – cucurbituril adduct $[Al(H_2O)_6]Cl_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot18H_2O$ (**4**) is also reported. A comparison of In^{III} with its analogs in Group 13 shows closer similarity between In^{III} and Tl^{III} in the chloroaqua complexes than between In and its lighter congeners.

Introduction

Knowledge about coordination chemistry of Group 13 metals (Al − Tl) has rapidly expanded in the last decade.[1,2] This development involves both the introduction of new ligands and more careful examining of "old" and "simple" compounds. Still, detailed information of the nature of the species that are present even in simple systems is often lacking. Thus, from solutions of In^{III} in aqueous HCl, only $[InCl_6]^{3-}$ [2] and $[InCl_5(H_2O)]^{2-}$ [3] could be isolated so far. No other ionic species with higher H_2O/Cl ratios have been identified, except for a serendipitous preparation of a thiotrithiazyl salt, $[S_4N_3]^+[cis\text{-}InCl_4(H_2O)_2]^-$.[4] The *fac*-isomer of $[InCl_3(H_2O)_3]$ is also known. It is formed as a side-product from the reaction of $InCl_3$ with *n*-butyl acetate in hexane.[5a] The same *fac*-$[InCl_3(H_2O)_3]$ moieties also exist in $[InCl_3(H_2O)_3]\cdot$18-crown-6[5b] and in $[InCl_3(H_2O)_3]\cdot$3dioxane.[5c] Curiously enough, $InCl_3\cdot4H_2O$ contains five-coordinate $[InCl_3(H_2O)_2]$ units enmeshed in a network of hydrogen bonding with solvated water molecules.[6]

Recently we became interested in the isolation and structural characterization of often elusive aqua-complexes and mixed-ligand species containing coordinated aqua ligands by employing a supramolecular approach − crystallization with cucurbituril (*Cuc*).[7] Cucurbituril is a macrocyclic cavitand with two identical carbonyl-fringed portals.[8] It can coordinate alkali metal ions such as Na^+, K^+, Rb^+, Cs^+, Ca^{2+} directly, acting as a ligand.[9] It also forms strong hydrogen bonds of the N−H···O type with aliphatic and aromatic amines [10] and we expected even stronger hydrogen bonding with coordinated water molecules of aqua complexes which would enable their crystallization. This expectation has been validated and we wish to report the structures of $[InCl_2(H_2O)_4]_3Cl_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot4H_2O$ (**1**), $(H_3O)_3[InCl_4(H_2O)_2]_3\cdot2(C_{36}H_{36}N_{24}O_{12})\cdot17H_2O$ (**2**), and $[In(H_2O)_6](NO_3)_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot9H_2O$ (**3**) as well as of an Al complex, $[Al(H_2O)_6]Cl_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot18H_2O$ (**4**).

Results and Discussion

The synthesis of the supramolecular adducts **1**−**4** is straightforward. Cucurbituril is not soluble in water, but moderately soluble in 3 M HCl, in neutral KNO_3 solution as well as in solutions of other alkaline metals (due to the metal coordination to the C=O groups of *Cuc*). We also found that *Cuc* is soluble in aqueous solutions of In^{III} and Al^{III} salts, and in this case that the hydrogen bonding between the coordinated waters and the carbonyls of *Cuc* is operative, instead of the expected direct coordination as X-ray analyses show. The products are separated as colorless single crystals suitable for X-ray studies. They lose their water of crystallization very easily, so that **3** and **4** become opaque and lose their crystallinity in air within a few minutes. This fact explains the unsatisfactory agreement between the analytically deduced formula of **3** as the heptahydrate and the stoichiometry found by X-ray analysis (nonahydrate).

The structure of the *trans*-$[InCl_2(H_2O)_4]^+$ cation and the crystal packing in **1** are shown in Figure 1 and Figure 2. This is the first crystal structure in which *Cuc* molecules occupy a crystallographic position with the highest possible symmetry, D_{6h} (6/*mmm*). They form one-layered hexagonal packing with channels running along the *c* axis. There are outer-sphere Cl^- anions [Cl(3)] disordered over 12 positions around the centers of *Cuc* molecules, the Cl···Cl distances being 0.83 − 2.21 Å. The cation lies in the positions with

[a] Institute of Inorganic Chemistry, Russian Academy of Sciences, pr. Lavrentjeva 3, Novosibirsk 630090, Russia

D_{2h} (*mmm*) site symmetry and is also disordered over two orientations around the Cl−In−Cl (*c*) axis. Solvent water molecules [O(1w)] and another counterion Cl^- [Cl(2)] form columns along the $\bar{6}$ axis, Cl···O distances being 3.19 Å. Our attempts to resolve the disorder by assuming a space group with lower symmetry were unsuccessful. Selected bond lengths and angles are given in Table 1.

In the crystal structure of **2**, there are two different isomers, *cis* and *trans*, of the $[InCl_4(H_2O)_2]^-$ anion (Figure 3). The In−Cl and In−OH_2 bond lengths are similar in both isomers. The *cis* anion forms a hydrogen bond with and

In the crystal, the *Cuc* molecules form parquet-like packing with anions between them (Figure 4). There are a lot of intermolecular hydrogen bonds between coordinated, solvent water, and the *Cuc* molecules. Our attempts to locate H_3O^+ cations were unsuccessful. Selected bond lengths and angles are given in Table 2.

The crystal structure of **3** gives the first example of a structurally characterized $[In(H_2O)_6]^{3+}$ cation (Figure 5). The $In-OH_2$ distances are shorter than those found in the $[InCl_4(H_2O)_2]^-$ anion in **2**. Cucurbituril molecules are associated with indium aqua-cations by hydrogen bonds between portal oxygen atoms and water molecules, the O···O distances being 2.637 − 2.835 Å. In the crystal packing, these aggregates form parquet-like layers (Figure 6) connected by hydrogen bonds to solvent water molecules. Selected bond lengths and angles are given in Table 3.

The crystal of compound **4** contains $[Al(H_2O)_6]^{3+}$ cations, Cl^- anions, water and *Cuc* molecules associated by hydrogen bonds. One of the cations is disordered over two

orientations with relative weights 0.793(6)/0.207(6) (Figure 7). Crystal packing (Figure 8) is based on the *pseudo*-body-centered motif of *Cuc* molecules with aluminum aqua-cations between them. Each *Cuc* molecule contains water molecule disordered over six positions around its

center. Selected bond lengths and angles are given in Table 4.

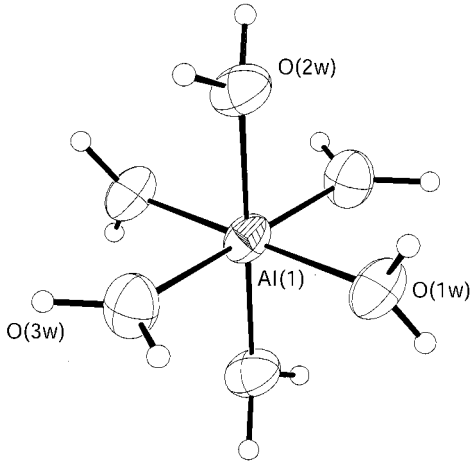

Figure 7. Crystallographically independent $[Al(H_2O)_6]^{3+}$ cations in **4** (50% probability ellipsoids)

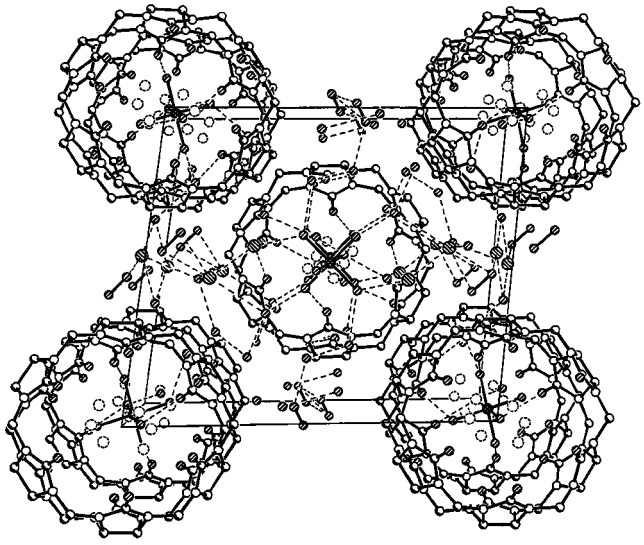

Figure 8. Crystal packing in **4**, view along the *a* axis. Hydrogen bonds are shown as dashed lines

The observed In−O distances in the hexaaqua indium cation of **3** are in good agreement with the value obtained from the X-ray study of aqueous solutions of In^{III} perchlorate, 2.16 Å.[11a] The same cation is present in the crystals of In alums, $M^{I}In(SO_4)_2{\cdot}12H_2O$, though here quantitative structural data are lacking.[11b] In^{III} nitrate forms hydrates with 3, 4 or 5 water molecules, but to the best of our knowledge there is no direct structural information for any of these hydrates. Both the stoichiometry and the spectroscopic evidence of NO_3^- coordination exclude the presence of $[In(H_2O)_6]^{3+}$ in these compounds.[11c] In^{III} also coordinates nitrate in solutions,[11c] where the species $[In(H_2O)_5(\eta^1\text{-}NO_3)]^{2+}$ has been postulated, but in our case all three nitrates are in the outer sphere. The *trans*-$[InCl_2(H_2O)_4]^+$ cation found in **1** has its counterpart in Tl chemistry − *trans*-$[TlX_2(H_2O)_4]^+$ (X = Cl, Br, CN).[12] The analogy with Tl extends further still, because for both metals, crystals of the tetrahydrates $MCl_3{\cdot}4H_2O$ contain trigonal bipyramidal $MCl_3(H_2O)_2$ molecules.[6,13] But for the tetrahalo complexes this analogy does not hold, with Tl^{III} giving only tetrahedral species $TlCl_4^-$,[12] whereas for In^{III} both *cis*- and *trans*-$[InCl_4(H_2O)_2]^-$ have been isolated, although $InCl_4^-$ [14] is also known. Of the lighter Group 13 metals, no evidence exists for Al of any mixed $[AlX_{6-n}(H_2O)_n]^{n-3}$ (X = Cl, Br, I) species both in the solid state and in solution, whereas for Ga there is ample evidence for them.[15] However, only $[GaX_4]^-$ salts with large organic cations could be isolated from aqueous solutions of Ga^{III} halides.[1] Thus, the $[InCl_4(H_2O)_2]^-$ species so far have no analogs among the other Group 13 metals.

Experimental Section

General: The salts, $AlCl_3{\cdot}6H_2O$ and "$In(NO_3)_3{\cdot}4.5H_2O$" were of commercial quality and used without further purification. Cucur-

bituril hydrate (water content corresponds approximately to that of the hexahydrate) was from Merck. *p*-Toluenesulfonic acid was purchases from Aldrich Chemical Company, Inc. Elemental analysis was performed by the analytical service of the Institute of Organic Chemistry SB RAS (Novosibirsk). The nitrate in **3** was determined by ion-exchange chromatography.

X-ray Structure Determination: The diffraction measurements for compounds **1**−**4** were performed at room temperature (293 K) with Bruker P4 (**1**, **4**) and Enraf−Nonius CAD4 (**2**, **3**) four-cycle diffractometers using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The crystals of **3** and **4** were sealed onto quartz capillaries with traces of mother liquor to avoid decomposition by dehydration. The unit cell was determined from setting angles of 24 reflections in the $9 \leq \theta \leq 15°$ range. Data were collected using standard techniques (θ/2θ scans with variable speed) up to $2\theta_{max} = 50°$. Structures were solved by direct methods using SHELXS97[16] (**1**, **4**) and SIR97[17] (**2**, **3**) programs. The hydrogen atoms of cucurbituril molecules were refined in rigid-body approximation. Some hydrogen atoms of water molecules were found in difference electron-density maps and refined by applying geometrical constraints. In the structure **3**, one of the NO_3^- ions appears to be disordered over several positions and therefore our attempts to locate it were unsuccessful. Nevertheless, the chemical analysis data for **3** are in good agreement with the proposed formula.

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-144322 (**1**), -144323 (**2**), -144324 (**3**), -144325 (**4**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

$[InCl_2(H_2O)_4]_3Cl_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot 4H_2O$ (1): $In(NO_3)_3\cdot 4.5H_2O$ (0.70 g, 1.8 mmol) was dissolved in a solution of cucurbituril (5 mL, 20 mM) in HCl (3 M) and kept at room temperature in an open beaker. Colorless hexagonal prisms of **1** separated after one week. Yield − 0.025 g (13%). − $C_{36}H_{68}N_{24}O_{28}Cl_9In_3$: calcd. C 22.19, H 3.52, N 17.25, Cl 16.37; found C 20.18, H 3.80, N 16.16, Cl 16.32.

$(H_3O)_3[InCl_4(H_2O)_2]_3\cdot 2(C_{36}H_{36}N_{24}O_{12})\cdot 17H_2O$ (2): In an aqueous solution of KNO_3 (1 M) and Hpts (0.01 M) was dissolved cucurbituril to a concentration 6.7 mM of cucurbituril. The white lamellar crystals were separated after standing for one day and a fraction of them (0.22 g) were dissolved in HCl (16 mL, 3 M). $In(NO_3)_3\cdot 4.5H_2O$ (60 mg, 0.15 mmol) was dissolved in the solution (5 mL). Colorless prismatic crystals of **2** separated after one week. Yield − 0.015 g (7%). − $C_{72}H_{127}Cl_{12}In_3N_{48}O_{50}$: calcd. C 26.73, H 3.96, N 20.78, Cl 13.15; found C 26.18, H 3.67, N 20.41, Cl 12.15.

$[In(H_2O)_6](NO_3)_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot 9H_2O$ (3): In a solution of $In(NO_3)_3\cdot 4.5H_2O$ (3.94 g, 10.13 mmol) in water (10 mL), cucurbituril (0.10 g, 0.085 mmol) was dissolved after heating for 15 min on a hot plate. The solution was filtered and left in an open beaker for 1 day. Large colorless crystals of **3** separated, which, however, lost two water molecules. Yield − 0.081 g (19%). − $C_{36}H_{62}N_{27}O_{34}In$: calcd. C 28.23, H 4.08, N 24.69, NO_3^- 11.86, In 7.50; found C 28.00, H 4.07, N 24.85, NO_3^- 12.88, In 8.09.

$[Al(H_2O)_6]Cl_3\cdot(C_{36}H_{36}N_{24}O_{12})\cdot 18H_2O$ (4): In a solution of $AlCl_3\cdot 6H_2O$ (0.12 g, 0.5 mmol) in water (10 mL), cucurbituril (30 mg, 0.026 mmol) was dissolved after heating for 15 min on a hot plate. The solution was filtered and left in an open beaker for 4 days. Large colorless crystals of **4** separated, which, however, rapidly lost their water (1−2 minutes) and disintegrated when they were taken out of the mother liquor.

Synthesis and Structures of Aminoalkoxyalanes

Heinrich Nöth,*[a] Andreas Schlegel,[a] Bakthan Singaram,[b] Jörg Knizek,[a][+] Peter Mayer,[a][+] and Thomas Seifert[a][+]

Dedicated to Professor Hubert Schmidbaur on the occasion of his 65th birthday

Keywords: Aluminum / Amino alcohols / Hydrido complexes / NMR spectroscopy

Reactions of various amino alcohols with $AlH_3{\cdot}NMe_3$ in hydrocarbons or ethers yielded the corresponding aminoalkoxyalanes $R_2N(X)_nOAlH_2$ **1**–**4** which are dimeric in the solid state. The structures of **1**–**4** show a characteristic Al_2O_2 ring system with pentacoordinated Al atoms. Pentacoordination is also observed in bis(–)-*R*-ephedrinoalane **(5)** which is, however, monomeric. Reduction of acetophenone with (–)-*R*-ephedrinoalane **(3)** proceeded without any noticeable stereoselectivity. Temperature-dependent ^{27}Al NMR studies suggest that the well-defined structures found in the solid state are not retained in solution.

Introduction

Although $LiAlH_4$ and $NaBH_4$ are amongst the most widely used hydride reducing reagents,[1] their stereoselectivity is negligible.[2] Therefore, modifications of these hydrides by suitable substituents to achieve adequate stereo- and enantioselectivity have been investigated. Amongst these reagents is lithium binaphtholato-*tert*-butoxy hydrido aluminate, Noyori′s reagent, which shows very high enantioselectivity.[3] The factors which control the reaction mechanism, and consequently the stereoselectivity, are not yet fully understood. The main reason for this lies in the lack of knowledge concerning the composition of the active reducing species in solution. Recently, we have shown that the stability of alkoxyaluminum hydrides and alkali metal organyloxohydridoaluminates in solution depends on the nature of the substituents at the Al centers.[4] In principle, it should be possible to turn AlH_3 into a reagent with high stereo- and possibly enantioselectivity, for instance by introducing chiral substituents.[5] In this paper we describe new aminoalkoxoalanes, some of them with chiral centers, as well as some temperature-dependent ^{27}Al NMR studies, which provide information about their nature in solution.

Synthesis

The synthesis of aminoalkoxo alanes was performed by allowing the amino alcohols R*OH to react with $AlH_3{\cdot}NMe_3$ [see Equation (1) and (2)] particularly those leading to alanes of type R^*OAlH_2, because their hydride content is higher than that of the alanes $(R^*O)_2AlH$.

$$R^*OH + AlH_3{\cdot}NMe_3 \rightarrow R^*OAlH_2 + NMe_3 + H_2 \quad (1)$$

$$2R^*OH + AlH_3{\cdot}NMe_3 \rightarrow (R^*O)_2AlH + NMe_3 + 2\,H_2 \quad (2)$$

$$2\,R^*OAlH_2 \rightarrow (R^*O)_2AlH + AlH_3 \quad (3)$$

The reactions were performed in tetrahydrofuran or toluene with *N*,*N*-dimethylaminoethanol, *N*,*N*-dimethylaminopropanol, (−)-(*S*)-1-methylpyrrolidine-2-methanol, (*N*-methyl-L-prolinol) or (−)-*N*-methylephedrine. Common to all these amino alcohols is the tertiary amino group. Reactions in a 1:1 ratio led to the alane derivatives **1**−**4**, while the 2:1 reaction of the ephedrine with $AlH_3{\cdot}NMe_3$ yielded the bis(aminoalkoxo)alane **5**.

Compounds **1**−**4** proved to be dimeric in the solid state. Because no compounds of type $R^*OAlH_2{\cdot}NMe_3$ [R*O = $R_2N(CH_2)_nO$] were obtained, it is evident that the amino group of the amino alcohol has displaced the Me_3N ligand from the Al center. Taking this into account, several different structural units may result, as depicted by Formulae **A**−**G**.

Although the dimeric nature of these compounds is ascertained in the solid state to be of type **B**, it cannot be excluded that the compounds may adopt other structures in solution.

Reduction of acetophenone with the ephedrinoalane **3** resulted in practically no stereospecific induction; these experiments will therefore not be described.

Spectroscopic Properties

^{27}Al NMR spectroscopy should allow us to distinguish between **A** and **C**, with tetracoordinated Al centers, and types **B**, **D**, and **F**, with pentacoordinate Al atoms. A structure of type **G** should result in two ^{27}Al resonances with a quintet for the AlH_4 anion in the proton-coupled spectrum. For a structure of type **E**, a single broad resonance is be expected (exchange signal). The resonances for structures

with pentacoordinate Al centers should appear further upfield, indicating electronically better shielded atoms. Table 1 lists the ^{27}Al NMR shifts and IR spectroscopic data for the Al−H stretching vibrations.

Table 1. ^{27}Al chemical shifts of compounds **1**−**5** (main signal) in [D$_8$]toluene at 27 °C (δ in ppm, half-height width $h_{1/2}$ in Hz) and νAlH (in cm^{-1}) in the IR spectra

	δ^{27}Al	$h_{1/2}$	νAlH$_2$/AlH
1	91	1090	1755, 1716
2	91	1880	1767, 1730
3	96	4260	1811, 1776
4	92	1970	1749, 1715
5	83	3690	1777

With the exception of compound **5**, all ^{27}Al resonances lie in the narrow range of 91−96 ppm. All signals are quite broad, and it was not possible to resolve ^{27}Al,^{1}H-coupling. This is in agreement with the rather high asymmetry about the Al center which allows for rapid relaxation. The δ^{27}Al values are by themselves not necessarily a convincing argument for tetra- or pentacoordination because the observed chemical shifts are on the border of tetra- and pentacoordination.[6] However, by comparing these data with those of (ROAlH$_2$)$_2$ (R = alkyl, δ^{27}Al = 115−130),[4,7] featuring tetracoordination for Al, then the δ^{27}Al values for compounds **1**−**5** support pentacoordination in toluene solution (*vide infra*). This is particularly evident for compound **5** with δ^{27}Al = 83. The most striking difference between alkoxyalanes with small alkyl groups and the aminoalkoxyalanes is that, in solution, the latter are not subject to ligand exchange, which would lead to AlH$_3$ and bis(aminoalkoxy)alanes, as shown in Equation (3).

Although the dimeric nature of compounds **1**−**4** were ascertained by X-ray structure analysis, there are alternatives as depicted by formulae **D**−**F**.

A structure of type **E**, which might even become ionic as shown in **G**, can be excluded immediately because only a single ^{27}Al NMR signal is observed in toluene solution and none for AlH$_4^-$. This also excludes structures with two chemically and spectroscopically different Al centers. Isomers **D** and **F** should be discernible from structure **B** by IR spectroscopy: the absorptions for terminal AlH groups and for tetracoordinated Al atoms are expected in the range of 1800−1900 cm^{-1}, and for the bridging AlH$_2$Al groups at about 1650 cm^{-1}.[4,7,8] The presence of two IR absorptions in the range from 1703−1777 cm^{-1} can be assigned to antisymmetric and symmetric AlH$_2$ vibrations for pentacoordinated Al centers, and this rules out the presence of structures **D** and **F** in solution.

However, the temperature-dependent ^{27}Al NMR spectra of compound **1** in toluene reveal that the situation in toluene is more complex (see Figure 1). Firstly, the spectra show the presence of hexacoordinated species which seem to gain in concentration at low temperature. On warming the solution, the dominant signal at δ ≈ 60 (−70 °C) moves to δ ≈ 90 at higher temperature, indicating a rapid equilibrium between penta- and tetracoordinated species. However, with

increasing temperature the signal not only becomes sharper, as expected, but rather at 20 °C the δ = 91 signal represents a contribution of >90% by a pentacoordinated Al species. We assume that this signal represents a situation of a rapid equilibrium [see Equation (4)] between various molecules having penta- and tetracoordinated centers. $^{1}J(^{27}Al,^{1}H)$ could not be observed at any temperature owing to the considerable line widths (1090−4250 Hz). Similar ^{27}Al NMR spectra were observed for compounds **2**−**4**. Therefore, there is no single species present in solution, and this should be reflected in the reactions of these compounds. Equation (4) describes the state of these molecules in solution.

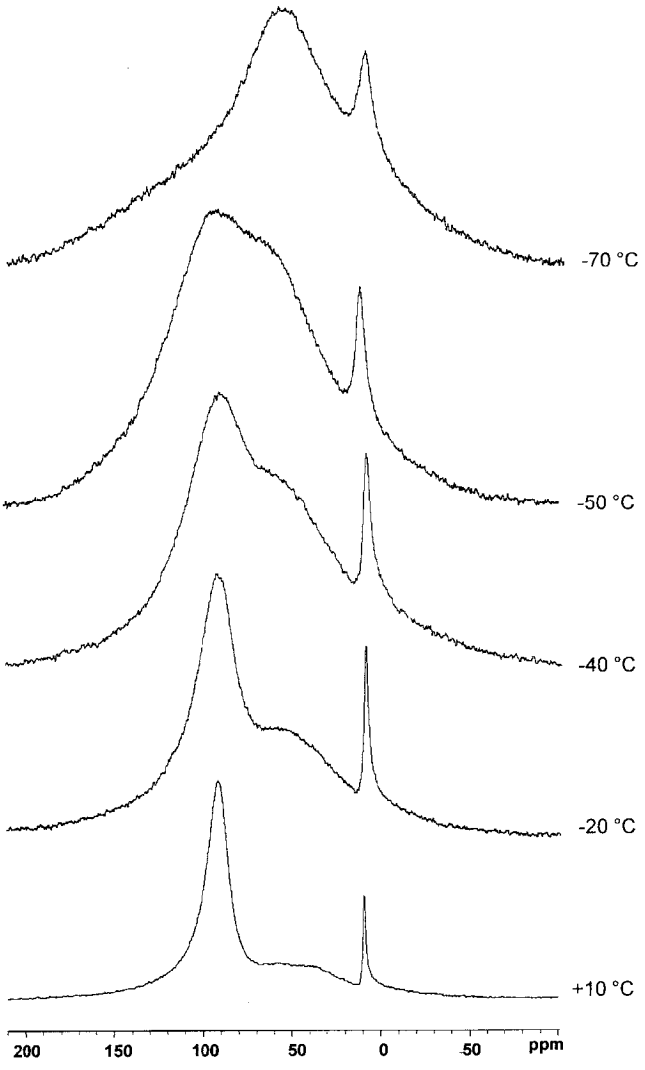

Figure 1. Temperature-dependent ^{27}Al NMR spectra of compound **1** in deuterated toluene

Evidence for the stability of the dimeric entities of compounds **1**−**4** comes from mass spectra. In all cases, the $[M_2 - 2\ H]^+$ ion has been detected, demonstrating that the compounds are volatile, but not as monomeric units; rather, they also retain their dimeric state of aggregation in the gas phase. Compound **5**, however, is monomeric in the gas phase in agreement with its structure in the crystal.

Molecular Structures

Compounds **1**−**5** were obtained as single crystals, and their structures were determined by X-ray methods. Figure 2−6 represent the molecular structures. The general features of these structures are: i) all compounds are dimeric in the solid state, except **5**, even though they all have pentacoordinated Al atoms, and ii) the presence of a central, planar, or almost planar, Al_2O_2 four-membered ring. Compounds **1**, **2**, and **3** contain aminoalkoxy groups forming a five-membered ring with the Al atom. This geometry induces a considerable distortion about the Al centers from a trigonal bipyramidal arrangement. As expected, the Al−O bond in the "trigonal plane" is shorter than the Al−O bond in the axial position. Except for compound **1**, where the sum of the bond angles for this plane is only 349.2°, almost perfect "planes" are present in compounds **2**−**5** (359 ± 1°).

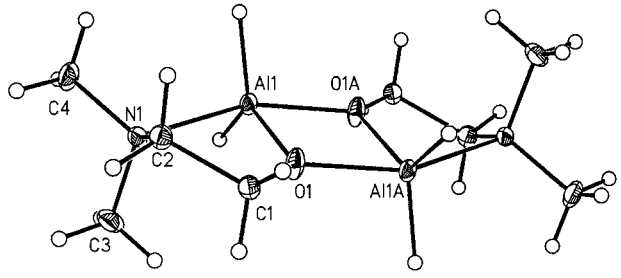

Figure 2. Molecular structure of dimeric *N*,*N*-dimethylaminoethoxyalane **(1)**; thermal ellipsoids are drawn on a 25% probability scale; selected bond lengths (in Å): Al1−O1 1.850(2), Al1−O1A 1.903(2), Al1−N1 2.133(2), Al1−H1 1.50(2), Al1−H2 1.54(3).; selected bond angles (in °): O1−Al−O1A 75.61(8), Al1−O1−C1 122.6(1), Al1A−O1−C1 132.4(1), Al1−O1−Al1A 104.39(8), N1−Al1−O1 79.71(7), N1−Al1−O1A 154.50(7), H1−Al1−H2 120(1), H1−Al−O1 125.4(9), H2−Al1−O1 114(1), N1−Al1−H1 92.9(9), N1−Al−H2 94(1)

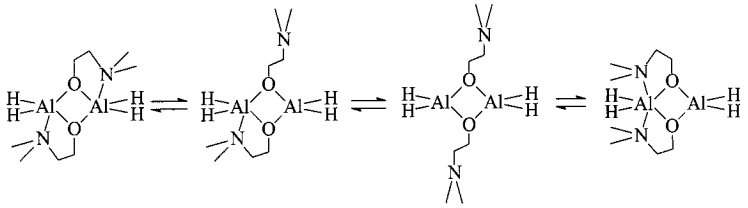
The axis N1−Al1−O1A in the centrosymmetric molecule **1** is bent towards the equatorial Al1−O1 bond (see Figure 2), and the deviations from the 90° angles (axial to equatorial) result from ring strain both of the Al_2O_2 four-membered ring [O1−Al1−O1A 75.61(8)°] as well as of the five-membered Al−O−C−C−N ring [distorted envelope configuration with N1−Al1−O1 = 79.71(7)°].

In contrast to **1**, which crystallizes in the centrosymmetric monoclinic space group $P2_1/n$, compounds **2** and **3**



(4)

crystallize in the acentric monoclinic space group $P2_1$, as expected for the presence of chiral aminoalkoxy ligands. There are two independent molecules of **2** in the unit cell, both having the same configuration but a different conformation (see Figure 3). The sum of bond angles for the atoms around the "trigonal plane" is 360°, and the H−Al−H bond angle is close to 120°. The Al−N coordination generates a new chiral center at the nitrogen atom, the absolute stereoconfiguration being of the *S*-type. The two "terminal" pyrrolidine rings are oriented towards the same side with respect to the Al_2O_2 ring, resulting in a "boat conformation", and the two molecules reveal an (*S,R*) and an (*R,R*) configuration. The CH_2O moiety of the prolinato group forms a shorter Al−O distance within the five-membered $AlNC_2O$ ring than to the Al atom of the next H_2Al-OR' unit [1.833(2) vs. 1.919(2) Å].

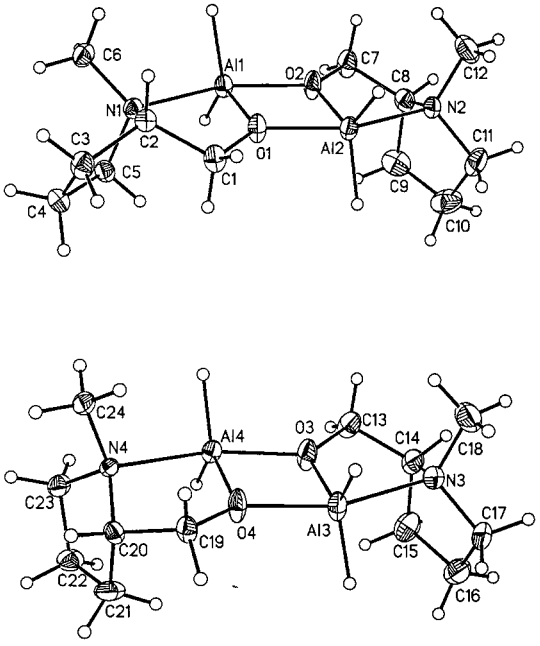


Figure 3. Molecular structure of dimeric *N*-methyl-L-prolinatoalane **(2)**; thermal ellipsoids represent a 25% probability; selected bond lengths (in Å): Al1−O1 1.833(2), Al1−O2 1.919(2), Al1−N1 2.141(2), Al2−O1 1.901(2), Al1−H1 1.51(3), Al1−H2 1.59(3), Al2−H3 1.51(3), Al2−H4 1.55(3); selected bond angles (in °): O1−Al1−O2 74.73(9), N1−Al1−O1 80.73(9), N1−Al1−O2 155.46(9), H1−Al1−H2 118(2), H1−Al1−O1 122(1), H2−Al1−O1 120(1), N1−Al1−H1 92(1), N1−Al1−H2 94(1), Al1−O1−Al2 105.4(1), Al1−O1−C1 122.0(2), Al2−O1−C1 132.5(2), O2−Al2−O1 75.20(9), O2−Al2−N2 80.33(9), O1−Al2−N2 155.5(1)

In compound **3** (Figure 4), we observe a slightly nonplanar Al_2O_2 ring [sum of bond angles = 354.98(8)°]. The geometry around the two Al atoms indicates a strongly distorted trigonal bipyramid, the axial N−Al−O bonds being 153.28(8)° and 150.57(8)°, respectively. However, there is a perfect "trigonal plane" as shown by the sum of the bond angles (360°). But we find the same sum of bond angles for atoms H1B, O1 and N2 around atom Al1. This indicates that the geometry at the Al atoms can also be considered as a distorted "tetragonal pyramid". This involves atoms H1A, O1, O2 and N2 as the base and H1B as the top of the pyramid. It is, of course, evident that the absolute stereoconfiguration at atoms C3 and C14, as well as at C2 and C13 (*R* or *S*), has not changed, as demonstrated by the analogous arrangement of the phenyl groups with respect to the Al_2O_2 ring.

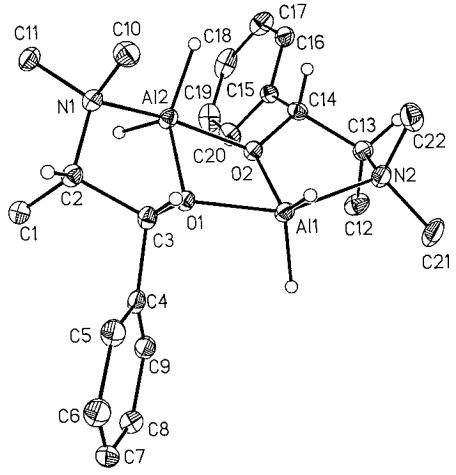

Figure 4. Molecular structure of dimeric (−)-*N*-methylephedrinatoalane **(3)**; thermal ellipsoids are depicted on a 25% probability scale; selected bond lengths (in Å): Al1−O1 1.940(2), Al1−O2 1.848(2), Al1−N2 2.145(2), Al2−O1 1.870(2), Al2−O2 1.920(2), Al2−N1 2.140(2), Al1−H1A 1.59(3), Al1−H1B 1.54(2); selected bond angles (in °): O1−Al1−O2 75.88(7), O1−Al1−N2 153.23(8), N2−Al1−O2 80.92(8), H1A−Al1−H1B 119(1), H1A−Al1−O2 127.1(9), H1B−Al1−O2 114.2(9), O1−Al1−H1A 92.7(9), O1−Al1−H1B 105.5(9), N2−Al1−H1A 90.7(9), N2−Al1−H1B 97(1), O1−Al2−O2 75.85(7), O1−Al2−N1 80.61(8), Al2−O1−C3 121.1(1), Al2−N1−C2 105.7(1)

Compound **4**, a derivative of *N*,*N*-dimethylaminopropanol, differs from the other dimeric aminoalkoxyalanes as the trigonal bipyramid is less distorted owing to the formation of a six-membered $AlOC_3N$ ring, which exerts less ring strain (Figure 5). Consequently, the axial N−Al−O bond is now 164.43(6)°, approximately 10° wider than in compounds **1**−**3**. Like compound **1**, compound **4** is also centrosymmetric. Nevertheless, due to the different Al−O bond lengths and the sharp bond angles O1−Al1−O1A [77.96(5)°] and Al1−O1−Al1A [102.04(6)°], the H−Al−O bond angles are quite different [128.6 and 113.1(7)°]. The six-membered rings are present in a chair conformation.

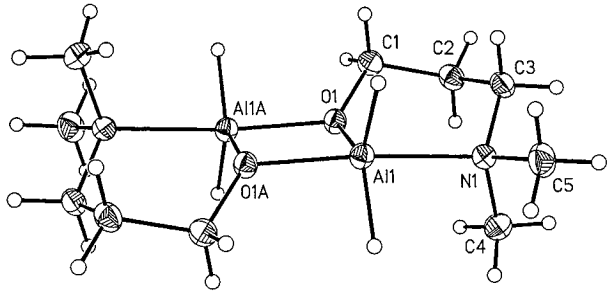

Figure 5. Molecular structure of dimeric (dimethylamino)propanolatoalane **(4)**; thermal ellipsoids depict a 25% probability; selected bond lengths (in Å): Al1−O1 1.834(1), Al1−O1A 1.930(1), Al1−N1 2.127(1), Al1−H1 1.53(2), Al1−H2 1.55(1); selected bond angles (in °): O1−Al1−O1A 77.96(5), Al1−O1−Al1A 102.04(5), Al1−O1−C1 125.8(1), Al1A−O1−C1 125.8(1), H1−Al1−H2 118(1), H1−Al1−O1 128.6(7), H2−Al1−O1 113.1(7), N1−Al1−O1A 164.43(6), N1−Al1−H1 87.3(6), N1−Al1−H2 91.7(7)

In contrast to the mono(aminoalkoxy)alane compound **5**, the bis(ephedrino)alane is monomeric but also features a pentacoordinated Al center (Figure 6). The molecule shows a twofold axis lying in the Al−H vector. While the axial positions of the slightly distorted pentagonal bipyramid are occupied by the nitrogen atoms [N−Al−N(0A) 174.3°] the trigonal plane is formed by the hydride hydrogen atom and two oxygen atoms, all bond angles for this plane being 120°. The Al−O bond lengths are shorter (1.760 Å) than in compounds **1**−**4**, while the Al−N bond lengths are almost the same as in the other compounds reported here.

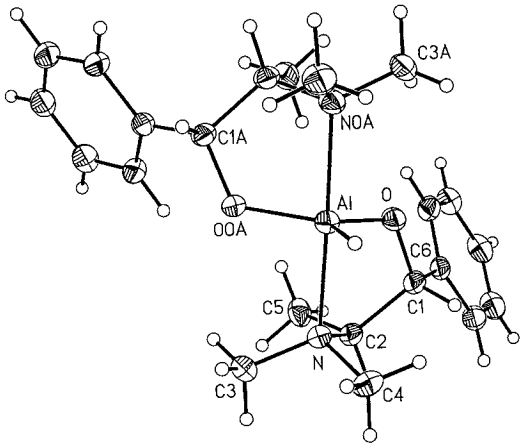

Figure 6. ORTEP plot of the molecular structure of bis(ephedrino)alane **(5)**; thermal ellipsoids represent a 25% probability; aromatic and methyl hydrogen atoms are omitted for clarity; selected bond lengths (in Å): Al−O 1.7603(2), Al−N 2.138(2), Al−H 1.83(2), O−C1 1.398(2), N−C3 1.478(3), N−C4 1.478(3); selected bond angles (in °): O−Al−O(0A) 119.9(1), O−Al−N 92.54(7), O−Al−N(0A) 84.61(7), O−Al−N 174.3(1), O−Al−H 120.0(1)N−Al−H 92.9(1). C1−O−Al 119.4(1), C3−N−C4 107.4(2), C2−N−Al 103.0(1)

Discussion

Amino alcohols react smoothly in a 1:1 molar ratio with $AlH_3{\cdot}NMe_3$, providing aminoalkoxyalanes $R_2N(CH_2)_nOAlH_2$ quantitatively. During the reaction, not only is H_2 formed but also the Me_3N coordinated to AlH_3 is displaced by the amino group of the amino alcohol, a displacement that is most likely entropy-driven owing to the formation of five- or six-membered rings in which the amino group coordinates to the Al center. It is typical for compounds **1**−**4** that the Al atoms are pentacoordinated, two monomeric $R_2N(CH_2)_nOAlH_2$ units form dimers by Al−O coordination which leads to a central Al_2O_4 four-membered ring with two significantly different Al−O bond lengths. The O−Al−O bond angles are rather acute (about 75°) while the Al−O−Al bond angles are quite wide (about 105°), with the oxygen atoms residing in a planar Al_2C environment. Similar structures have been found for aminoalkoxy-diorganylalanes $[R_2N(CH_2)_nOAlR_2']_2$-gallanes and $[R_2N(CH_2)_nOGaR_2]$.[9] These classes of compounds are also dimeric. However, they may become monomeric by increasing the size of the ligand. Thus, the Me_2Al and the Me_2Ga derivatives of the darvon alcohol [(+)-(2*S*,3*R*)-4-dimethylamino-1,2-diphenyl-2-butanol] are monomeric in the solid state.[10] Interestingly, reactions of R_2AlCl (R = Me, Et) with amino alcohols not only gives access to dimeric aminoalkoxy alkyl chloroalanes $[R^*OAl(R)Cl]_2$ but, in the case of Me_2AlCl and (*S*)-α,α-diphenyl-2-pyrrolidinyl methanol, an ionic complex $\{MeAl(R^*O)_2AlMe]^+[MeAlCl_3]^-$ is formed.[12] Although compounds **1**−**5** are the first structurally characterized aminoalkoxyalanes, one gallium homologue has been reported previously: *N*,*N*′′-dimethylaminoethoxydihydridogallane.[11] The bond lengths in the gallium compound are slightly longer than in the comparable aluminium compounds, and this holds also for the alane and gallane (E = Al, Ga) pairs of $[t\text{BuOEH}_2]_2$.[7b] Table 2 shows a comparison of the structural parameters of the dimeric compounds **1**−**4** with similar aminoalkoxydiorganylalanes.

First of all, it can be noted that the $Al-O_{ax}$ bond lengths are approximately up to 0.09 Å longer than the $Al-O_{eq}$ bonds. In general, the Al−O and particularly the Al−N bond lengths of the diorganylamine derivatives are longer than those of the alane derivatives, while the $N-Al-O_{ax}$ bond angles do not vary by more than 3.5°. Furthermore, a comparison of the only two closely related pairs of alane and gallane derivatives is also included in Table 2.

Bond lengths are generally somewhat longer for the gallium compounds,[6b] while the bond angles are almost identical.[7b] Although pentacoordination at Al is the structural feature for all aminoalkoxydihydridoalanes described here,

Table 2. Comparison of bond lengths (in Å) and bond angles (in °) in structurally related dimeric aminoalkoxyalanes and dimeric alkoxydialkylalanes; (−)MEP = (−)-*N*-methylephedrine, (−)NMP = *N*-methyl-L-proline

the situation in solution is different. At ambient temperature, the ^{27}Al NMR spectra demonstrate the dominating presence of a dimer. However, a temperature-dependent series of ^{27}Al NMR as well as ^{1}H and ^{13}C NMR spectra clearly show that the room-temperature spectrum represents an averaged dynamic situation. The line width is also indicative of this assumption. Furthermore, at low temperature a significant amount of hexacoordinated Al centers is present besides the pentacoordinated Al and possibly the tetracoordinated species. Therefore, a comparatively complex situation exists in solution. A more detailed study will be needed to evaluate the kinetics and energetics of the species involved in the equilibrium (4). Taking these equilibria into account, the practical absence of any stereoselective reduction of acetophenone with prolinolatodihydridoalane or (+)-*N*-methylephedrinodihydridoalane can be understood.

Experimental Section

All manipulations were carried out using Schlenk techniques under an N_2 atmosphere, using flame-dried glassware. $AlH_3{\cdot}NMe_3$ was prepared from $[Me_3NH]Cl$ and $LiAlH_4$.[15] The amino alcohols are commercially available and were used as supplied. NMR: Jeol GSX 270 and Jeol EX 400:TMS C_6D_6, $AlCl_3$ in H_2O, LiCl in D_2O as standards. Routine spectra were recorded at 24.5 °C. − IR: Nicolet FT, range 4000−400 cm^{-1}. − X-ray: Siemens P4 diffractometer, Mo-K_α-radiation, graphite monochromator, CCD area detector. − C,H,N analysis was performed with an automated analyzer. Al was determined by TEDA titration.

Dimeric *N,N*-Dimethylaminoethoxyalane (1): $AlH_3{\cdot}NMe_3$ (0.71 g, 7.9 mmol) was dissolved in toluene (25 mL). At −25 °C a solution of $Me_2NCH_2CH_2OH$ (0.71 g, 8 mmol) in toluene (10 mL) was added slowly with stirring. After the gas evolution had ceased, the solution was reduced in vacuo to about half of its volume. The crystals that separated at −20 °C were isolated. Toluene was then removed partially from the filtrate. Compound **1** (810 mg, 86.9%) was isolated; m.p. 184−186 °C (dec.). − ^{1}H NMR (C_6D_6): δ = 1.95 (s, 12 H, N*Me*$_2$), 1.96 [t,^{3}J(H,H) = 5.6 Hz, 4 H, NC*H*$_2$], 3.57 [t,^{3}J(H,H) = 5.6 Hz, 4 H, OC*H*$_2$], ca. 4 (broad, 4 H, Al*H*$_2$). − ^{13}C NMR (C_6D_6): δ = 44.3 (N*Me*$_2$), 55.4 (N*C*H$_2$), 58.4 (O*C*H$_2$). − ^{27}Al NMR (C_6D_6): δ = 91 ($h_{1/2}$ = 1090 Hz), 94 ($h_{1/2}$ = 900 Hz). − IR (Nujol, Hostaflon): ṽ: 3000 vs, 2978 vs, 2921 vs, 2885 vs, 2841 vs, 2808 sh, m, 2800 sh, m, 2794 m, 1755 vs/1719 vs [νAlH$_2$], 1496 m, 1459 vs, 1438 s, 1429 s, 1403 m, 1378 m, 1354 m, 1277 vs, 1254 vs, 1185 vs, 1089 vs, 1073 vs, 955 vs, 908 vs, 825 vs, 779 vs, 748 vs, 718 vs, 684 m, 556 vs, 550 vs cm^{-1}. − MS (70 eV): *m*/*z* = 233 [(**1**)$_2$ − H]$^+$, 203 [(**1**)$_2$ − 2 Me − H]$^+$. − $C_8H_{24}Al_2O_2N_2$ (234.3): calcd. C 41.02, H 10.33, Al 23.04, N 11.96; found C 40.58, H 9.85, Al 23.11, N 11.34.

Dimeric *N*-Methylprolinatoalane (2): To a stirred solution of $AlH_3{\cdot}NMe_3$ (0.84 g, 9.5 mmol) in toluene (10 mL) was added dropwise a solution of *N*-methylprolinol [(*S*)-2-hydroxymethyl-1-methylpyroline, 1.06 g, 9.5 mmol] in toluene (10 mL). After gas evolution had ceased, stirring was continued for one hour. Repeated crystallisations at −78 °C gave colorless needles (2.45 g, 90.4%), m.p. 134−151 °C (dec.). − ^{1}H NMR (C_6D_6): δ = 1.18−1.27 (m, 1 H), 1.34−1.42 (m, 1 H), 1.78−1.94 (m, 3 H), 1.99−2.03 (m, 1 H), 2.04 (s, 3, NC*H*$_3$), 3.18−3.24 (m, 1 H), 3.51 [dd, *J*(H,H) = 2.1 Hz, 11 Hz, 1 H], 3.63 [dd, *J*(H,H) = 4.7 Hz, 11 Hz, 1 H). − ^{13}C NMR: δ = 21.3 (*C*H$_2$), 27.6 (*C*H$_2$), 43.7 (N*C*H$_3$), 56.1 (N*C*H$_2$), 57.9 (N*C*H), 67.6 (O*C*H$_2$). − ^{27}Al NMR: δ = 91 ($h_{1/2}$ = 1880 Hz). − IR (Nujol, Hostaflon): ṽ: 2971 vs, 2939 vs, 2907 s, 2873 vs, 2813 w, 1767 vs/1730 vs, [νAlH$_2$], 1486 w, 1477 w, 1460 s, 1451 w, 1422 m, 1381 m, 1365 m, 1351 m, 1340 m, 1319 m, 1298 m, 1281 m, 1253 m, 1241 m, 1215 m, 1193 m, 1141 s, 1097 vs, 1060 s, 1043 s, 1029 vs, 996 vs, 920 vs, 897 m, 886 m, 831 vs, 810 vs, 773 vs, 737 vs,br, 633 vs, 577 vs, 560 vs, 537 vs cm^{-1}. − MS (70 eV): *m*/*z* = 286 [M$^+$], 285 [M$^+$ − H], 284 [M$^+$ − 2 H], 269 [M$^+$ − 2 H − CH$_3$], 256 [M$^+$ − 2 CH$_3$], 255 [M$^+$ − H − 2 CH$_3$]. − $C_{12}H_{28}Al_2N_2O_2$ (286.32): calcd. C 50.34, H 9.86, Al 9.42, N 9.78; found C 49.29, H 9.99, Al 9.15, N 9.35.

Dimeric (−)-Ephedrinoalane (3)$_2$: As described for **2**, $AlH_3{\cdot}NMe_3$ (1.73 g, 19.4 mmol) in toluene (17.1 mL) was treated with (−)-(1*R*,2*S*)-2-dimethylamino-1-phenyl-propanol (2.68 g, 15.0 mmol) dissolved in toluene (27.3 mL). Crystallisation at −20 °C yielded **3** (2.75 g, 88.8%) as colorless crystals, m.p. 166 °C (dec.), softening at ≈139 °C. − ^{1}H NMR (C_6D_6): δ = 0.69 [d, ^{3}J(H,H) = 7.2 Hz, 6 H, 3-*H*], 1.89 (s, 6 H, NC*H*$_3$), 2.15 (s, 6 H, NC*H*$_3$), 2.47 [dq, ^{3}J(H,H) = 5.4 Hz, 2 H, 2-*H*], 4.1 (s, br., 4 H, Al*H*$_2$), 5.41 [d, ^{3}J(H,H) = 5.4 Hz, 2 H, 1-*H*], 7.06 [dd, ^{3}J(H,H) = 7.5 Hz, 2 H, *p*-*H*(Ar)], 7.22 [dd, ^{3}J(H,H) = 7.5 Hz, 4 H, *m*-*H*(Ar)], 7.55 [d,^{3}J(H,H) = 7.5 Hz, 4 H, *o*-*H*(Ar)]. − ^{13}C NMR (C_6D_6): δ = 10.5 (*C*H$_3$), 40.6 (N*C*H$_3$), 46.2 (N*C*H$_3$), 65.5 (N*C*H), 72.9 (O*C*H), 127.3, 127.7, 127.9 (*C*−Ar), 140.9 [*i*-*C*(Ar)]. − ^{27}Al NMR (C_6D_6): δ = 96 ($h_{1/2}$ = 4260 Hz) − IR (Nujol, Hostaflon): ṽ: 3082 m, 3060 m, 3024 s, 3007 s, 2989 vs, 2925 s, 2901 vs, 2890 vs, 2869 vs, 2847 s, 2798 m, 1811 vs/1776 vs/1703 vs, br.(ν AlH$_2$), 1604 m, 1492 m, 1463 vs, 1449 vs, 1432 vs, 1406 vs, 1386 vs, 1364 m, 1349 m, 1302 m, 1243 m, 1217 m, 1196 m, 1177 m, 1129 m, 1109 vs, 1101 vs, 1070 vs, 1010 vs, 961 vs, 899 vs, 865 vs, 850 vs,sh, 824 s, 789 vs, 758 vs, 742 vs, 726 vs,sh, 716 vs, 703 vs, 661 vs, 591 vs, 574 vs; (toluene): ṽ = 1805 vs,sh, 1784 vs,br, 1748 vs,br cm^{-1}. − $C_{22}H_{36}Al_2N_2O_2$ (414.49): calcd. C 63.75, H 8.75, Al 13.02, N 6.76; found C 63.01, H 8.62, Al 12.85, N 6.40.

Dimeric *N,N*-Dimethylaminopropanolatoalane (4)$_2$: To $AlH_3{\cdot}NMe_3$ (0.84 g, 9.5 mmol) in toluene (10 mL) was added a solution of $Me_2N(CH_2)_3OH$ (0.97 g, 9.45 mmol) in toluene (10 mL) at −10 °C, while stirring. Stirring was continued for 30 minutes after gas evolution had ceased. Crystallisation at −20 °C gave **4** (1.09 g, 87.9%) as colorless prisms, melting in the range of 118−133 °C. − ^{1}H NMR (C_6D_6): δ = 1.19 [tt, ^{3}J(H,H) = 5.5 Hz, 4 H, 2-*H*], 2.00 (s, 12 H, N*Me*$_2$), 2.15 [t, ^{3}J(H,H) = 5.5 Hz, 4 H, NC*H*$_2$], 3.90 [t, ^{3}J(H,H) = 5.5 Hz, 4 H, OC*H*$_2$]. − ^{13}C NMR (C_6D_6): δ = 26.3 (C2), 45.6 (N*Me*$_2$), 59.4 (N*C*H$_2$), 64.0 (O*C*H$_2$). − ^{27}Al NMR (C_6D_6): δ = 92 ($h_{1/2}$ = 1970 Hz) − IR (Nujol, Hostaflon): ṽ = 3009 s, 3004 s, 2993 s, 2960 vs, 2926 vs, 2904 vs, 2876 vs, 2866 vs, 2840 s, 2806 m, 1749 vs/1715 vs (νAlH$_2$), 1475 vs, 1455 s, 1429 vs, 1398 w, 1385 w, 1377 w, 1356 w, 1301 m, 1269 s, 1252 m, 1234 s, 1184 s, 1170 s, 1098 vs, 1087 vs, 1049 vs, 1016 vs, 967 s, 900 vs, 862 vs, 772 vs, 748 vs, 721 vs, 598 vs, 558 vs, 545 vs cm^{-1}. − $C_{10}H_{28}O_2N_2Al_2$ (262.30): calcd. C 45.79, H 10.76, Al 20.57, N 10.68; found C 44.95, H 10.99, Al 20.43, N 10.09.

Bis(ephedrino)alane (5): To a stirred solution of $AlH_3{\cdot}NMe_3$ (0.49 g, 5.5 mmol) in diethyl ether (10 mL) was added a solution of (−)-(1*R*,2*S*)-2-dimethylamino-1-phenylpropanol (1.97 g, 11.0 mmol) in tetrahydrofuran (10 mL). After addition, stirring was continued for 1 hour. All volatile material was then removed from the solution in vacuo. Crystallisation of the solid residue at −20 °C from toluene/hexane (2:1, 15 mL) gave clear crystals (1.78 g, 84%), m.p. 86 °C, softening ≈70 °C. − ^{1}H NMR (C_6D_6): δ = 0.97 [d,^{3}J(H,H) = 7.2 Hz, 6 H, 3-*H*], 2.30 (s, 6 H, NC*H*$_3$), 2.38 (s, 6 H, NC*H*$_3$), 2.31−2.36 [m,^{3}J(H,H) ≈ 5 Hz, 2 H, 2-*H*], 5.34 [d,

X-ray Structure Determinations: Single crystals were transferred from the toluene suspensions onto precooled polyfluoroether oil (–30 °C) and the selected specimen was mounted on the tip of a glass fiber. This was transferred to the goniometer head which was cooled by a stream of N_2 gas to 193 K (LT2 device). After optically aligning the crystal, five different sets in χ of 15 frames each were collected (Δ = 0.3°), and the data were used to calculate the cell dimensions (SMART program).[16] Data collection was performed by using the hemisphere mode of the SMART program. Data for a total of 1290 frames were collected at two different χ-settings with Δ = 0.3°. The data was reduced with the program SAINT[17] and an empirical adsorption correction was applied (SADABS). The structures were solved (SHELXTL)[18] by direct methods and the non-hydrogen atoms were refined anisotropically. The positions of the H atoms bonded to Al were taken from the difference Fourier map; all others were either taken from the Fourier map or placed in calculated positions and included in the final refinement cycles. Compound **5** crystallized as **5**·0.5C_7H_8. The toluene molecule is disordered. Refinement was performed with SOF = 0.5 for two orientations. No hydrogen atoms were included for the toluene molecules. Relevant data referring to crystallography, data collection and refinement are summarized in Table 3.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Data Centre as supplementary publication no. CCDC-148492–148496 (**1**–**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge C32.1 EZ, UK [Fax: (internat.) +44-1223/336-033. E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the Fonds der Chemischen Industrie and particularly Chemetall GmbH for support of this study. Furthermore, we would like to acknowledge the cooperation of Dipl.-Chem. K. Knabel, Dr. Martina Vosteen and Dr. R. Waldhör for recording the NMR spectra, and Mrs. D. Ewald for measuring the mass spectra.

Alkylthiolatoalanes and Alkylthiolatohydridoaluminates

Jörg Knizek,[a] Heinrich Nöth,*[a] and Andreas Schlegel[a]

Dedicated to Prof. Dr. Drs. h. c. Rolf Huisgen on the occasion of his 80th birthday

Keywords: Aluminum / Lithium / S ligands / Hydrides / Structure elucidation

Reactions of thiols RSH (R = Et, *i*Pr, *t*Bu) with $AlH_3{\cdot}NMe_3$ lead to $RSAlH_2{\cdot}NMe_3$ or $(RS)_2AlH{\cdot}NMe_3$ compounds, depending on the stoichiometry. Similarly, the 1:1 reaction of $LiAlH_4$ with RSH (R = Et, *i*Pr) in ether produces $LiAlH_3SR$, however, in the case of $NaAlH_4$ and *i*PrSH in THF, ligand exchange of $NaAlH_3(SR)$ to $NaAlH_4$, $NaAlH_2(SR)_2$ and $NaAlH(SR)_3$ occurs. A byproduct of the formation of $LiAlH(StBu)_3$ (**6**), in ether is $[(Et_2O)LiAlH(StBu)_3{\cdot}LiStBu]_2$ (**7**). Reaction of a 1:1 mixture of $LiAlH_4$ with $AlH_3{\cdot}NMe_3$ and HS*t*Bu (1:1:5) leads to $LiAlH(StBu)_3{\cdot}AlH(StBu)_2NMe_3$ (**8**). Compounds **5**, **7** and **8** were characterized by X-ray structure determinations. All molecules contain tetracoordinated Al centers.

Introduction

Aluminum compounds containing aluminum−sulfur bonds are comparatively less well studied than the thermodynamically more stable compounds with Al−O bonds.[1] Therefore, most of them are hydrolytically unstable in spite of the fact that alkanethiols are more acidic than alcohols, even if sulfur is less electronegative than oxygen. This can be readily rationalized by the theory of the HSAB principle. In consonance with this well-known principle is the observation that in dimethylaluminum complexes of thiophene a C-bridging is preferred over an Al−S interaction.[2] However, Al−S bridging in thioalanes is a well-known feature.[3] For instance, Me_2AlSMe is dimeric both in the solution and gas phase, and dimerization occurs via Al−S bonds.[4] However, this compound forms a chain structure in the solid phase.[4] If bulky R groups are introduced as in $Al(SAr)_3$, $RAl(SR)_2$ and $R_2Al(SR)$ (R = *t*Bu, Ar = 2,4,6-$tBu_3C_6H_2$), monomeric arylthioalanes with three-coordinated Al atoms are kinetically stabilized.[5] Not surprisingly, this demonstrates the tendency of oligomerization. So far only a few studies have been concerned with the reaction of thiols with aluminum hydride.[6] For instance, thiomorpholine reacts with $AlH_3{\cdot}NMe_3$ to produce dimeric $H_2Al[\mu\text{-}N(CH_2)_4S]$, a nitrogen-bridged dimeric substituted alane;[6a] this unit, in the solid state, forms a two-dimensional network via Al−S interactions generating pentacoordinated Al centers.

The reaction of $LiAlH_4$ with $(Et_2HN{-}CH_2{-}CH_2{-}SH)Cl$ yields $AlH(SCH_2CH_2NEt_2)_2$ irrespective of a 1:1 or 1:2 stoichiometry. It is assumed that $H_2AlSCH_2CH_2NEt_2$ is formed in a first stage followed by ligand exchange to give AlH_3 and $AlH(SCH_2CH_2NEt_2)_2$.[6a] Moreover, a number of other thiolatoalanes, H_2AlSR, have been reported.[6b,6c] Alkylthiolatoalanes smell even worse than the thiols, a long-standing experience of the senior author,[7] and this may be a reason why these compounds have not been very attractive for a closer investigation. The purpose of the study reported here was to compare the formation and structures of some thiolatoalanes and thiolatohydridoaluminates with those of organyloxoalanes and alkali metal organyloxohydridoaluminates.[8,9]

Synthesis

Two routes have been employed to prepare alkylthiolatoalanes as depicted in Equation (1) to (3).

$$AlH_3{\cdot}NMe_3 + RSH \longrightarrow RSAlH_2{\cdot}NMe_3 + H_2 \quad (1)$$

R	Et	*i*Pr	*t*Bu
	1	2	3

$$AlH_3 + tBuSH \longrightarrow \underset{\mathbf{4}}{tBuSAlH_2} + H_2 \quad (2)$$

$$AlH_3{\cdot}NMe_3 + 2\,tBuSH \longrightarrow \underset{\mathbf{5}}{(tBuS)_2AlH{\cdot}NMe_3} + 2\,H_2 \quad (3)$$

Compound **1,** a liquid, fumed in contact with air, solidified at − 20 °C and decomposed on distillation under vacuum. This also holds for the liquid compounds **2** and **3**. Complexed trimethylamine was not released under vacuum; in contrast to alkoxyalane−trimethylamines (particularly with alkyl = Me, Et, *n*Pr)[8,10] which are prone to ligand exchange to give polymeric and insoluble products of various compositions. The alkylthiolatoalanes showed no tendency of this behavior. Solvent-free $tBuSAlH_2$ resulted according to Equation (2). However, the ^{27}Al NMR spectrum of the solution in ether suggests that the compound is present as $tBuSAlH_2{\cdot}OEt_2$. It looses the coordinated ether in vacuo readily, and the ether-free compound is a moisture-sensitive white powder.

When $LiAlH_4$ was allowed to react with thiols, the amount of H_2 liberated depended on the stoichiometry involved [Equation (4)].

$$MAlH_4 + n\,RSH \longrightarrow MAlH_{4-n}(SR)_n + nH_2 \quad (4)$$
$$M = Li, Na;\ R = Et, i\text{Pr}, t\text{Bu}$$

$$2\,NaAlH_2(S\text{-}i\text{Pr})_2 \leftrightarrow NaAlH_3(S\text{-}i\text{Pr}) + NaAlH(S\text{-}i\text{Pr})_3 \quad (5)$$

$$2\,NaAlH_3(S\text{-}i\text{Pr}) \rightarrow NaAlH_4 + NaAlH_2(S\text{-}i\text{Pr})_2 \quad (6)$$

1:1 reactions of $LiAlH_4$ with EtSH or *i*PrSH in ether gave a solution which shows only a single ^{27}Al NMR signal at $\delta = 115$; this demonstrates not only the formation of $LiAlH_3(SR)$ but also proves its stability against ligand exchange. For the analogous organyloxyhydridoaluminates this kind of ligand exchange is typical,[9−11] and all members of the series $LiAlH_{4-n}(OR)_n$ can be detected in solution. However, when *i*PrSH was allowed to react with $NaAlH_4$ in THF in a 1:1 ratio the ^{27}Al NMR spectrum reveals the presence of at least three species [$NaAlH_4$, $NaAlH_2(S\textit{i}Pr)_2$ and $NaAlH(S\textit{i}Pr)_3$] in solution, as shown in Equation (5).

Treatment of $LiAlH_4$ in ether with *t*BuSH in a 1:3 ratio yielded compound **6** which was isolated as $Et_2O{\cdot}LiAlH(S\textit{t}Bu)_3$. However, in addition to this main product small amounts of crystals separated from the solution, and an X-ray structure analysis proved them to be $(Et_2O){\cdot}LiAlH(S\textit{t}Bu)_3{\cdot}LiS\textit{t}Bu$ (**7·Et$_2$O**). Most likely this compound was formed in a reaction sequence described by Equation (7) to (9).

$$LiAlH_4 + 3\,{}^t\text{BuSH} \longrightarrow \underset{\mathbf{6}}{LiAlH(S^t\text{Bu})_3} + 3\,H_2 \quad (7)$$

$$LiAlH(S^t\text{Bu})_3 + Et_2O \rightarrow HAl(S^t\text{Bu})_2{\cdot}OEt_2 + LiS^t\text{Bu} \quad (8)$$

$$LiAlH(S^t\text{Bu})_3 + LiS^t\text{Bu} \rightarrow \underset{\mathbf{7}}{LiAlH(S\text{-}^t\text{Bu})_3\,LiS^t\text{Bu}} \quad (9)$$

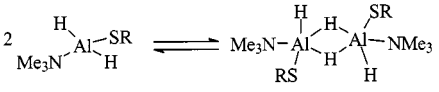
Obviously, $LiAlH(S\textit{t}Bu)_3$ behaves as a Lewis acid and adds $LiS\textit{t}Bu$ through its *t*BuS groups. In order to test whether $LiAlH(S\textit{t}Bu)_3$ would add an alane as a Lewis base, we employed $(t\text{BuS})_2AlH{\cdot}NMe_3$. As shown in Equation (10) a 1:1 mixture of $LiAlH_4$ and $AlH_3{\cdot}NMe_3$ reacted smoothly with *t*BuSH to produce the compound $LiAlH(S\textit{t}Bu)_3{\cdot}AlH(S\textit{t}Bu)_2{\cdot}NMe_3$ (**8**). However, the alane acted as a ligand only for the Li center with the formation of Li−S bonds, and no NMe_3 displacement from $(t\text{BuS})_2AlH{\cdot}NMe_3$ occurred.

$$LiAlH_4 + AlH_3{\cdot}NMe_3 + 5\,HS^t\text{Bu} \rightarrow \underset{\mathbf{8}}{LiAlH(S^t\text{Bu})_3{\cdot}\,AlH(S^t\text{Bu})_2{\cdot}\,NMe_3} + 5\,H_2 \quad (10)$$

NMR-Spectroscopic Data

As already indicated, only a single ^{27}Al NMR signal can be observed for the alkylthiolatoalanes **1**−**5**. Table 1 lists the relevant data.

Compounds **1**−**3** are tetracoordinated at the Al atom as shown by the low-field resonances. The signals are not very broad, nevertheless no Al−H coupling can be observed. Compound **4**, in ether solution, shows a better shielded Al center than compounds **1**−**3**. However, in benzene solution the Al nucleus of the ether-free compound **4** exhibits no change in shielding, but an enormous increase in the line width. This is an indication of the association of monomeric molecules in solution, probably through hydrogen bonds [Equation (11)]. If **4** were present in solution with pentacoordinated Al centers, the signal would then appear at an even higher field ($\delta \approx 110-120$). The ^{27}Al NMR spectrum of **4** in benzene solution also shows a low-intensity signal at $\delta = 9$ which points to the presence of a hexacoordinated species.



(11)

In contrast to alkoxyalanes, the shielding of the ^{27}Al nucleus is only marginally influenced by the number of RS substituents (compare **3** with **5**). However, this is not the case for the alkylthiolatohydridoaluminates; here, $\delta(^{27}Al)$ changes in the same manner as for the $AlH_{4-n}(OR)_n^-$ species.[9,11c] A higher degree of RS substitution leads to a successive deshielding of the ^{27}Al nucleus. The solution for the 1:1 reaction of $NaAlH_4$ with *i*PrSH shows three ^{27}Al NMR

Table 1. ^{27}Al NMR spectroscopic data of alkylthiolatoalanes and alkylthiolatohydridoaluminates (δ in ppm, $h_{1/2}$ in Hz)

	1	**2**	**3**	**4**	**5**	**6**	**7**
$\delta^{27}Al$	152	151	147	132	147	136	147
$h_{1/2}$	1053	1126	1103	1510	924	4390	1000
Solvent	C_6D_6	C_6D_6	C_6D_6	Et_2O	C_6D_6	C_6D_6	C_6D_6
δ (^7Li)	−	−	−	−	−	0.26	0.70
Solvent						Ether	C_6D_6
	$LiAlH_3SEt$	$LiAlH_3S\textit{i}Pr$	$LiAlH_2(S\textit{i}Pr)_2$	$LiAlH(S\textit{t}Bu)_3$			
$\delta^{27}Al$	115	115	128	131, 133			
Solvent	Ether	Ether	Ether	THF, Ether			

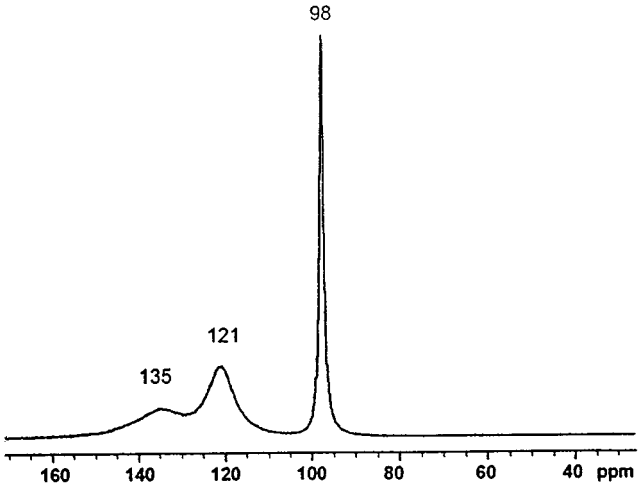


Figure 1. ^{27}Al NMR spectrum of a solution of "$NaAlH_2(SiPr)_2$" in THF to show the presence of various species; signals at δ = 98, 121 and 135 are assigned to $NaAlH_4$, $NaAlH_2(SiPr)_2$ and $NaAlH(SiPr)_3$

signals (see Figure 1). The sharp signal stems from $NaAlH_4$, the signal at δ = 135 is due to $NaAlH(SiPr)_3$ and the signal at δ = 121 due to $NaAlH_2(SiPr)_2$ (exchange). $NaAl(SiPr)_4$ is not present as this would give rise to a sharp and easily detectable signal.

IR Data

Table 2 contains a list of Al−H stretching bands. Compounds **2** and **3** exhibit a strong band in the narrow region 1805−1808 cm^{-1}, and compound **5** a strong and sharp band at 1840 cm^{-1}. Therefore, two electronegative RS groups strengthen the Al−H bond. This is in agreement with the series of compounds $AlH_{3-n}X_n{\cdot}OEt_2$ (X = Cl, Br).[12] Compound **4** shows a band for a terminal Al−H stretching vibration at 1846 cm^{-1}. In addition, there is a strong broad band ranging from 1750 to 1570 cm^{-1}, which is due to an Al−H−Al bridging mode. A band at 1699 cm^{-1} is observed for compound **2** (solid in Nujol mull) which also proves the presence of bridging hydrides. Consequently, this compound does not seem to be present as monomeric $iPrSAlH_2{\cdot}NMe_3$, but it is associated through Al−H−Al bridges. This is because the IR data exclude the presence of an Al−(SR)−Al bridge. The Al−H(terminal) stretching vibrations for the hydridoaluminates are found in the 1850-cm^{-1} region, which are associated with tetracoordinated Al centers.

Table 2. Al−H strechting bands (in cm^{-1}) for compounds **2**−**6** and **8**; for further data see Experimental Section

	2	**3**	**4**	**5**	**6**	**8**

Molecular Structures

The structural features deduced from IR- and NMR-spectroscopic data of compounds **1**−**5** are ascertained by the determination of the molecular structure of **5** by X-ray structure analysis. This compound crystallizes in space group $P2_1/c$. The Al center is surrounded by two S atoms, one N and one H atom in a distorted tetrahedral array (see Figure 2).

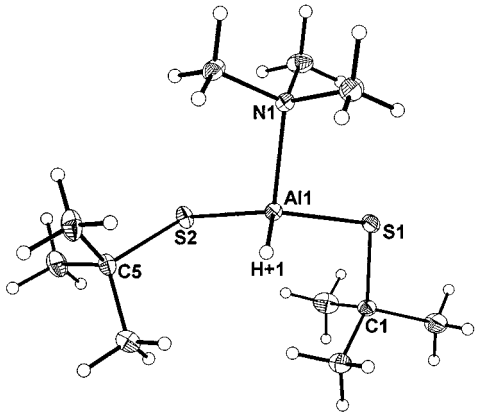

Figure 2. ORTEP plot of the molecular structure of the crystal of $HAl(StBu)_2{\cdot}NMe_3$ (**5**); thermal ellipsoids are shown on a 25% probability scale; selected bond lengths [Å] and angles [°] (esd values in parentheses): Al1−S1 2.2496(5), Al1−S2 2.2296(5), Al1−N1 2.020(1), Al1−H1 1.50(2), S1−C1 1.861(1), S2−C5 1.863(1); N1−Al1−S1 98.46(3), N1−Al1−S2 106.19(4), S1−Al1−C2 112.00(2), H1−Al1−N1 102.9(6), H1−Al1−S1 118.1(6), H1−Al1−S2 116.2(6), Al1−S1−C1 106.44(4), Al1−S2−C5 108.20(5), C10−N1−C9 109.2(1), C10−N1−C11 108.5(1), C9−N1−C11 107.6(1), C10−N1−Al1 112.70(8), C11−N1−Al1 110.09(8), C9−N1−Al1 108.6(9)

The Al−S bond lengths (average 2.240 Å) are shorter than the Al−S dative bond in $[tBuAl(\mu\text{-}OC_6H_4\text{-}2\text{-}SMe)]_2$ [2.778(1) Å].[13] The latter is comparable with the Al−S bond lengths in $AlH(SCH_2CH_2NEt_2)_2$ (average 2.725 Å)[14] with its pentacoordinated Al center. Thus, the difference in bond lengths between the tetracoordinated Al center in **5** and the pentacoordinated Al atom in $AlH(SCH_2CH_2NEt_2)_2$ is ca. 0.49 Å. It is also significantly longer than in the tricoordinated Al compound $Al(SC_6H_2tBu_3)_3$ [2.185(8) Å].[15] Al−S−C bond angles are wider than the H−S−C bond angles in thiols (96−101°).[16]

Crystals obtained from the 1:3 reaction of $LiAlH_4$ with *t*BuSH were suspected to be $LiAlH(StBu)_3$ but proved to be the ether adduct of dimeric $LiAlH(StBu)_3{\cdot}LiStBu$ (**7**) by X-ray structure analysis. The molecular structure as found for the solid state is represented in Figure 3.

The centrosymmetric dimer features a planar central Li_2S_2 ring with open S−Li−S bond angles [103.9(3)°] and rather sharp Li−S−Li angles [76.1(3)°]. Each lithium atom is tetracoordinated, atom Li1 is surrounded by three sulfur atoms and one oxygen atom, while atom Li2 coordinates to four sulfur atoms. It should be noted that the Li−S bonds to the tetracoordinated S4 atom (average 2.429 Å) are slightly shorter than the Li−S bonds to the tricoordinated

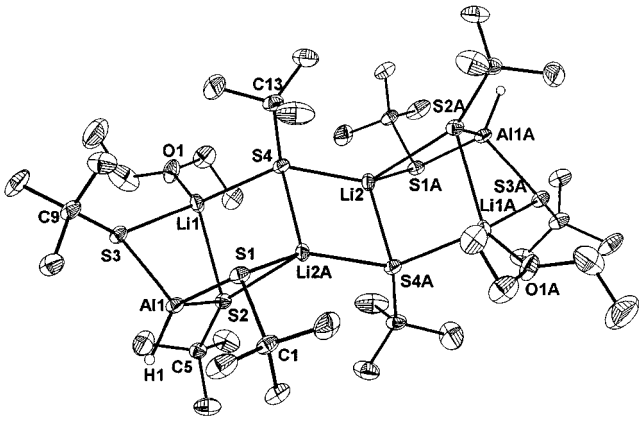

Figure 3. Molecular structure of the crystal of **7·OEt$_2$**; thermal ellipsoids are depicted on a 25% probability level; hydrogen atoms bonded to C atoms are not shown for clarity; selected atom distances [Å] and bond angles [°] (esd values in parentheses): Al1−H1 1.39(1), Al1−S1 2.259(2), Al1−S2 2.263(2), Al1−S3 2.242(2), Al1−S1 3.250(8), Li1−O1 1.889(9), Li1−S2 2.548(9), Li1−S3 2.563(9), Li1−S4 2.427(9), Li1−Li2A 3.39(1), Li2−Li2A 2.98(2), Li2A−S4 2.404(8), Li2−S1A 2.494(8), Li2−S4A 2.431(8), Li2−S2A 2.803(9), Li2A−S1 2.494(8), Li2A−S2 2.803(9), S1−C1 1.854(5), S2−C5 1.858(5), S3−C9 1.848(5), S4−C13 1.838(5); H1−Al1−S1 112(2), H1−Al1−S2 116(4), H1−Al1−S3 117(4), S1−Al1−S2 102.83(8), S1−Al1−S3 110.16(8), S2−Al1−S3 96.80(7), S1−Li2a−S4 137.6(3), S1−Li2A−S2 89.4(3), O1−Li1−S4 1o8.9(4), O1−Li1−S2 127.5(4), Al1−S1−Li2A 90.2(2), Al1−S2−Li2A 82.7(2), Al1−S2−Li1 84.8(2), Al1−S3−Li1 84.8(2), LI1−S4−Li2 139.1(3), Li1−S4−Li2A 88.4(3), Li2−S4−Li2A 76.1(3)

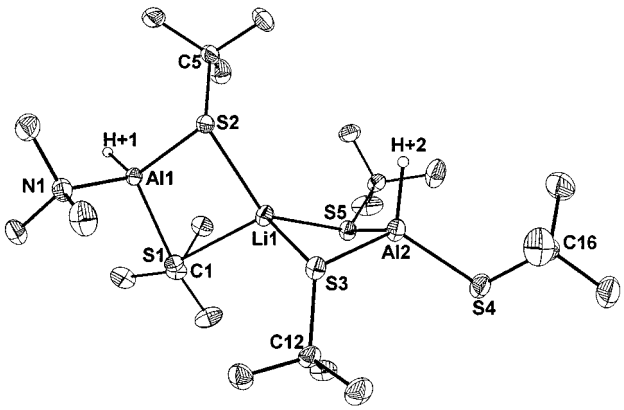

Figure 4. ORTEP presentation of the molecular structure of the crystal of **8**; thermal ellipsoids are drawn on a 25% probability level; H atoms bonded to carbon atoms are omitted for clarity; selected atom distances [Å] and bond angles [°] (esd values in parentheses): Al1−H1 1.48(4), Al1−N1 1.979(3), Al1−S1 2.246(1), Al1−S2 2.243(1), Al2−H2 1.58(4), Al2−S3 2.281(2), Al2−S4 2.237(2), Al2−S5 2.293(2), Li1−S1 2.489(6), Li1−S2 2.551(6), Li1−S3 2.491(6), Li1−S5 2.445(6), S1−C1 1.865(4), S2−C5 1.866(4), S3−C12 1.866(4), S4−C16 1.865(4), S5−C20 1.858(4); N1−Al1−S1 103−7(1), N1−Al1−S2 106.2(1), S1−Al1−S2 103−67(5). Al1−S−Li1 83.5(2), Al1−S2−Li1 82.2(2), S1−Li1−S2 88.8(2), S3−Li1−S5 88.5(2), S1−Li1−S3 109.8(2), S2−Li1−S5 136.5(3), S2−Li1−S3 108.7(2), DS1−Li1−S5 112.9(2), Li1−S5−C20 127.2(2)

S atoms. Atom Li1 binds to only two sulfur atoms of the $HAl(StBu)_3^-$ unit, and these bonds are the longest ones (2.548, 2.563 Å) while the bond Li1−S4 adopts an intermediate position (2.494 Å). The shortest Al−S bond is Al1−S2 [2.263(2) Å], atom S2 being tetracoordinated. It features a very large Li2A−S2−C5 bond angle of 155.1(2)°. All S−Al−S bond angles are rather sharp (96−103°), and, consequently, the H−Al−S bond angles are wide (112−117°). This asymmetry for a tetracoordinated Al atom with respect to a tetrahedral array is also present at the Li atoms.

A much simpler molecular structure is observed for compound **8**, $LiAlH(StBu)_3{\cdot}AlH(StBu)_2{\cdot}NMe_3$, as shown in Figure 4. One can readily note that it is an addition product of $HAl(StBu)_2{\cdot}NMe_3$ and $LiAlH(StBu)_3$. The metal ions are tetracoordinated and the skeleton of the molecule can be described as a spirocycle with the Li atom at the spiro center. This Li atom coordinates to four sulfur atoms with Li−S bond lengths ranging from 2.489(6) to 2.511(6) Å. There are two pairs of sharp S−Li−S bond angles (88°) and two wide ones (136°). The coordination geometry around both Al atoms is a strongly distorted tetrahedral geometry. The distortion is greater for Al1 than for Al2. At Al2, the S−Al−S bond angles are all different, the smallest one is S3−Al2−S5 with only 97.66(5)°, probably due to the coordination of these S atoms to Li1. In contrast, the angle S3−Al2−S4 is rather wide, 117.49(6)°, while the angle S5−Al2−S4 [109.19(6)°] is almost a perfect tetrahedral angle.

Discussion

Although the present study on the interaction of thiols with alane·trimethylamine, $LiAlH_4$ and $NaAlH_4$ is not as complete as analogous studies with alcohols,[8−11] some generalizations can be deduced. As expected, when the thiols, which are more acidic than alcohols, react, the amount of hydrogen evolved and the formation of the products are determined by the stochiometry involved. While AlH_3 in ether reacts with alcohols (ROH) having small R groups (R = Me, Et, Pr), to produce not very well defined products of composition $AlH_{3-n}(OR)_n$, only single-type species $AlH_2(SR){\cdot}NMe_3$ and $AlH_2(SR){\cdot}NMe_3$, which are stable against ligand exchange at ambient temperatures, are formed in the reaction of alane trimethylamine with thiols. Compound $AlH_2SEt{\cdot}NMe_3$ associates in the solid state through hydride bridges, and the IR spectra clearly show that there are no Al−S−Al bridging bonds. In contrast, compounds $ROAlH_2$ are characterized by Al−O−Al bridges.[17] This difference can readily be explained by the HASB theory. The softer base H^- is preferred as a bridging ligand over sulfur, and the IR spectra of the compounds $RSAlH_2{\cdot}NMe_3$ indeed show the presence of Al−H−Al bridges,[18] while in the case of alkoxyalanes the Al−O bonds are thermodynamically favored. No bands attributable to Al−H−Al vibrations are present for $(tBuS)_2AlH{\cdot}NMe_3$ (**5**) in agreement with its molecular structure.

Reactions of $MAlH_4$ with RSH have concentrated on the $LiAlH_4$/*t*BuSH and $NaAlH_4$/*i*PrSH systems, particularly on the former. For the first system, the product expected by

the stoichiometry of the reaction has been found to be $LiAlH(StBu)_3$ (**6**). However, in addition, a small amount of the dimeric compound $LiAlH(StBu)_2{\cdot}LiStBu$ (**7**) is also formed, demonstrating that $LiHAl(StBu)_3$, whose structure is still unknown, may act as a Lewis base through its RS groups. This has been verified by the addition of the alane $(tBuS)_2AlH{\cdot}NMe_3$ to $LiHAl{\cdot}(StBu)_3$ in compound **8**. This is a feature that needs further investigation; a similar behavior is, as yet, unknown in alkoxyaluminate chemistry. However, an investigation of Noyori's reagent[19,20] revealed many unexpected aspects showing that even hexacoordinated aluminates are readily formed.[21] We will report on these results shortly.

It is expected that the Al−S bond length would increase with increasing coordination number, and this can be demonstrated for the compounds investigated. All Al atoms of compounds **5**, **7** and **8** are tetracoordinated while the S atoms have coordination numbers 2, 3 and 4, respectively. Average Al−S bonds are as follows: $Al^{(4)}-S^{(2)}$ = 2.239 Å, $Al^{(4)}-S^{(3)}$ = 2.244 Å, and $Al^{(4)}-S^{(4)}$ = 2.457 Å. In addition, the average Al−S bond length $Al^{(6)}-S^{(2)}$ has been found to be 2.399 Å.[22] (Coordination numbers are set here in superscript). Therefore, we observe an increase in the Al−S bond lengths as the coordination number of sulfur increases. The $Al^{(4)}-S^{(2)}$ bond length is shorter than the $Al^{(6)}-S^{(2)}$ bond lengths by 0.016 Å. This trend was to be expected. Li−S bond lengths give no clear separation between $Li^{(4)}-S^{(3)}$ and $Li^{(4)}-S^{(4)}$, the former span the range from 2.489 to 2.566 Å, the latter from 2.457 to 2.548 Å. These data are in agreement with known structures of lithium thiolates,[23] the shortest being 2.39 Å found in $(Et_2O)_2Li(trip-S)_2In(S-trip)_2$ (trip = 2,4,6-triisopropylphenyl).

Experimental Section

All experiments were performed under anhydrous conditions and dinitrogen using Schlenk techniques. $LiAlH_4$ was supplied by Chemetall GmbH and $AlH_3{\cdot}NMe_3$ prepared form $LiAlH_4$ and $[Me_3NH]Cl$.[24] The thiols used were obtained commercially. − NMR: Jeol GSX 270 and EX 400; standards: $AlCl_3$ in H_2O (1 M), C_6D_6, $SiMe_3$. − IR: Nicolet 20 FT spectrometer (4000−400 cm^{-1}) as Nujol/Hostaflon mulls. − X-ray: Siemens P4 diffractometer with CCD area detector and LT2 low-temperature device. − Elemental analysis: C, H, N in the microanalytical laboratory of the institute; Al complexometrically. Partial hydrolysis was noted in weighing small samples for elemental analysis. This may be the reason for several significant deviations between calculated and found values.

Alkylthiolatoalanes and Lithium(alkylthiolato)hydridoaluminates. − General Procedure: The hydrides ($AlH_3{\cdot}NMe_3$, AlH_3 in ether, $LiAlH_4$ or $NaAlH_4$) were dissolved or suspended in toluene, ether or THF. While stirring, a solution of the thiol in the respective solvent was added (1:1, 1:2 ratio), and stirring was continued until gas evolution had ceased. No elemental analysis was performed when ^{27}Al NMR spectra proved that only a single compound was present.

Ethylthiolatoalane·Trimethylamine (1): Prepared from $AlH_3{\cdot}NMe_3$ (0.68 g, 7.63 mmol) in toluene (5 mL), and EtSH (0.47 g, 7.63 mmol) in toluene (4 mL). Addition at −4 °C, 2 h stirring at ambient temperature. An oil remained after stripping off all volatiles in vacuo. This oil solidified on standing to a waxy mass. − ^{27}Al NMR (70 MHz, C_6D_6): δ = 152 ($h_{1/2}$ = 1053 Hz). − ^1H NMR (270 MHz, C_6D_6): δ = 1.33 [t, ^3J(H,H) = 7.5 Hz, 3 H, CH_3CH_2S-], 2.00 (s, 9 H, NCH_3), 2.67 [q, ^3J(H,H) = 7.5 Hz, 2 H, CH_3CH_2S-], 4.0 (br, 2 H, AlH_2). − ^{13}C NMR (68 Hz, C_6D_6): δ = 20.9 (CH_3CH_2S-), 21.5 (br., CH_3CH_2S-), 46.9 (NCH_3).

Isopropylthiolatoalane·Trimethylamine (2): Prepared from $AlH_3{\cdot}NMe_3$ (560 mg, 6.28 mmol) in toluene (10 mL) and *i*PrSH (480 mg, 6.28 mmol) in toluene (5 mL) at 0 °C, 2 h stirring at ambient temperature. All volatiles were removed in vacuo. Yield: 950 mg (92.7%). − ^{27}Al NMR (104 MHz, C_6D_6): δ = 151 ($h_{1/2}$ = 1126 Hz). − ^1H NMR (400 MHz, C_6D_6): δ = 1.43 [d, ^3J(H,H) = 6.6 Hz, 6 H, CH_3(*i*Pr)], 1.97 (s, 9 H, NCH_3), 3.25 [qq, ^3J(H,H) = 6.6 Hz, 1 H, CH(*i*Pr)], 4.08 (br., AlH_2). − ^{13}C NMR (100 MHz, C_6D_6): δ = 29.7 [CH_3(*i*Pr)], 47.0 (NCH_3), 32.6 [br., CH(*i*Pr)]. − IR (CsBr): $\tilde{\nu}$ = 2975 (vs), 2953 (vs), 2916 (vs), 2857 (vs), 1808 (vs, νAlH_2), 1699 (m, br., νAlH_{br}), 1480 (vs), 1463 (vs), 1447 (vs), 1406 (m), 1379 (m), 1363 (s), 1244 (s), 1152 (s), 1102 (m), 1050 (m), 1015 (m), 994 (vs), 887 (m), 816 (s), 792 (vs), 746 (vs), 702 (vs), 650 (vs, br), 626 (vs), 552 (s), 501 (s) cm^{-1}.

***tert*-Butylthiolatoalane·Trimethylamine (3):** Prepared from $AlH_3{\cdot}NMe_3$ (1.18 g, 13.2 mmol) in toluene (10 mL) and Me_3CSH (1.19 g, 13.2 mmol) in toluene (10 mL) at −15 °C. The resulting solution was stirred for 1 h at 20 °C. After removal of all volatiles, 2.20 g (92.8%) of an oily liquid remained, m.p. 10−15 °C. − ^{27}Al NMR (70 MHz, C_6D_6): δ = 147 ($h_{1/2}$ = 1103 Hz). − ^1H NMR (270 MHz, C_6D_6): δ = 1.97 [s, 9 H, CH_3(*t*Bu)], 1.59 (s, 9 H, NCH_3). − ^{13}C NMR (68 MHz, C_6D_6): δ = 37.1 [CH_3(*t*Bu)], 42.4 [br., C_q(tBu)], 47.3 (NCH_3). − IR (CsBr): $\tilde{\nu}$ = 2972 (vs), 2957 (vs), 2937 (vs), 2921 (vs), 2894 (s), 2862 (s), 1805 (vs,νAlH_2), 1480 (vs), 1462 (vs), 1361 (vs), 1244 (m), 1164 (m), 1156 (m), 1103 (w), 995 (vs), 818 (m), 792 (m, sh), 754 (vs), 732 (s), 705 (vs), 659 (s, br.), 625 (s), 583 (m), 521 (m), 501 (m), 464 (m) cm^{-1}.

***tert*-Butylthiolatoalane (4):** $LiAlH_4$ (25.42 mmol) in Et_2O (20 mL) was converted into AlH_3 by reaction with $AlCl_3$ (1.17 g, 8.47 mmol), dissolved in ether (20 mL), followed by addition of Me_3CSH (3.06 g, 32.9 mmol) in ether (10 mL). After 2 h, the insoluble material was separated and ether removed from the filtrate in vacuo. An oil remained that proved to contain Et_2O by NMR spectroscopy. It was treated several times with small amounts of pentane and the residue was then kept in vacuo for several hours. This produced a white powder. Yield: 4.00 g (66.6%). −^{27}Al NMR (70 MHz, Et_2O): δ = 132 ($h_{1/2}$ = 1510 Hz), (C_6D_6): δ = 132 ($h_{1/2}$ = 6632 Hz), 9 ($h_{1/2}$ = 3061 Hz). − ^1H NMR (270 MHz, C_6D_6): δ = 1.58 [s, 9 H, CH_3(*t*Bu)], ca. 4.5 (br., AlH_2). − ^{13}C NMR (68 MHz, C_6D_6): δ = 14.7 (CH_3), 47.8 [C_q(*t*Bu)]. − IR (Nujol, Hostaflon): $\tilde{\nu}$ = 2962 (vs), 2937 (vs), 2925 (vs), 2900 (vs), 2862 (vs), 1846 (vs, br.)/ca.1750−1570 (s, br.) (νAlH_n), 1472 (vs), 1460 (vs), 1395 (s), 1369 (s, sh), 1364 (s), 1159 (m), 810 (vs, br.), 744 (vs, br), 688 (vs, br), 666−600 (vs, br), 576 (s, br) cm^{-1}. − $C_4H_{11}AlS$ (118.17): calcd. C 40.66, H 9.38; found C 37.62, H 8.50.

Bis(*tert*-butylthiolato)alane·Trimethylamine (5): Prepared from $AlH_3{\cdot}NMe_3$ (920 mg, 10.3 mmol) in toluene (15 mL) and Me_3CSH (1.86 g, 20.7 mmol) in toluene (8 mL) at −15 °C. The resulting solution was stirred for 1 h followed by reduction of the volume of the solution by ca. 50%. From this solution crystals separated at −20 °C. Yield: 2.41 g (93.4%), m.p. 62 °C. − ^{27}Al NMR (70 MHz, C_6D_6): δ = 147 ($h_{1/2}$ = 924 Hz). − ^1H NMR (270 MHz, C_6D_6): δ = 1.71 [s, 18 H, CH_3(*t*Bu)], 1.94 (s, 9 H, NCH_3). − ^{13}C NMR

(68 MHz, C_6D_6): δ = 37.1 [CH_3(tBu)], 47.3 (NCH_3). − IR (Nujol, Hostaflon): $\tilde{\nu}$ = 2975 (vs), 2957 (vs), 2938 (vs), 2900 (vs), 2733 (vs), 1840 (vs, νAlH_2), 1482 (vs), 1471 (s), 1458 (s), 1444 (m), 1423 (m), 1406 (s), 1390 (m), 1360 (s), 1245 (s), 1241 (s), 1212 (s), 1166 (vs), 1150 (vs), 1110 (s), 1105 (s), 1024 (m), 997 (vs), 988 (vs), 819 (vs), 657 (vs), 628 (vs), 580 (vs), 528 (vs), 493 (vs), 460 (s) cm^{-1}. − $C_{10}H_{25}AlNS_2$ (250.42): calcd. C 47.96, H 10.06, Al 10.78, N 5.59; found C 46.33, H 8.61, Al 10.45, N 5.31.

Lithium Tris(*tert*-butylthiolato)hydridoaluminate (6) and Its 1:1 Adduct with Lithium *tert*-Butylthiolate (7): A solution of Me_3CSH (4.81 g, 53.3 mmol) in ether (20 mL) was allowed to react with $LiAlH_4$ (17.76 mmol) in ether (20 mL). A slightly turbid solution formed. On keeping the clear solution at 0 °C for several days, a small amount of crystals of (**7**)$_2$ formed. This was confirmed by X-ray structure analysis. From the filtrate all volatile materials were removed in vacuo, and the residue washed several times with small amounts of pentane. On keeping the solid material under vacuum (10^{-3} Torr) all the ether could be removed from **6**. Yield: 4.75 g (71%), m.p. 136 °C (dec.). − ^{27}Al NMR (70 MHz, C_6D_6): δ = 136 ($h_{1/2}$ = 4392 Hz); (Et_2O): δ = 133 ($h_{1/2}$ = 1782 Hz); (THF): δ = 131 ($h_{1/2}$ = 1535 Hz). − ^{7}Li NMR (105 MHz, Et_2O): δ = 0.26 ($h_{1/2}$ = 64.9 Hz). − ^{1}H NMR (270 MHz, C_6D_6): δ = 1.10 [t, br., ^3J(H,H) = 7.0 Hz, 6 H, $CH_3(Et_2O)$], 1.70 [s, 27 H, CH_3(*t*Bu)], 3.33 [dd, br., ^3J(H,H) = 7.0 Hz, 4 H, $CH_2(Et_2O)$]. − ^{13}C NMR (68 MHz, C_6D_6): δ = 15.1 [$CH_3(Et_2O)$], 36.2 [CH_3(*t*Bu)], 45.1 (C_q), 65.7 [$CH_2(Et_2O)$]. − IR (Nujol, Hostaflon): $\tilde{\nu}$ = 2973 (vs), 2959 (vs), 2938 (vs), 2921 (vs), 2894 (vs), 2859 (vs), 1829 (vs, νAlH_2), 1472 (s), 1458 (s), 1389 (m), 1362 (vs), 1216 (m), 1187 (m), 1167 (vs), 1153 (vs), 1106 (m), 1097 (s), 1069 (s), 1027 (m), 839 (w), 820 (s), 657 (vs), 613 (vs), 578 (vs) cm^{-1}. − $C_{12}H_{38}AlLiS_3$ (302.47): calcd. C 47.65, H 9.33, Al 8.92; found C 47.16, H 9.30, Al 8.55.

Lithium Pentakis(*tert*-butylthiolato)dihydridodialuminate·Trimethylamine (8): A solution of $LiAlH_4$ (8.08 mmol) in ether (5 mL) was added to a solution of AlH_3·NMe_3 (720 mg, 8.08 mmol) in toluene (10 mL), followed by dropwise addition of Me_3CSH (3.64 g, 40.4 mmol), dissolved in toluene (5 mL), at −20 °C. Stirring was continued for 1 h, and ether removed at 10 Torr from the solution. On cooling to −20 °C needles of **8** separated. From the filtrate all volatiles were removed in vacuo giving **8**, m.p. 147−150 °C (dec.). − ^{27}Al NMR (104 MHz, C_6D_6): δ = 147 ($h_{1/2}$ = 998 Hz). − ^{7}Li NMR (105 MHz, C_6D_6): δ = 0.70 ($h_{1/2}$ = 11.0 Hz). − ^{1}H NMR (270 MHz, C_6D_6): δ = 1.72 [s, br., CH_3(*t*Bu)], 1.73 [s, br., CH_3(*t*Bu)], 1.92 (s, NCH_3). − ^{13}C NMR (68 MHz, C_6D_6): δ = 36.4 [br., CH_3(*t*Bu)], 37.1 [CH_3(*t*Bu)], 43.2 (C_q), 47.3 (NCH_3). − IR (Nujol, Hostaflon): $\tilde{\nu}$ = 2969 (vs), 2957 (vs), 2938 (vs), 2929 (vs), 2894 (vs), 2859 (vs), 1858 (vs)/1782 (vs, νAlH_2), 1481 (s), 1472 (s), 1459 (s), 1446 (w), 1406 (m), 1360 (vs), 1309 (m, br.), 1244 (s, br.), 1236 (vs), 1212 (m), 1166 (vs), 1152 (vs), 1111 (m), 1105 (m), 997 (m), 986 (vs), 815 (s), 653 (vs), 628 (s), 578 (m) cm^{-1}. − $C_{23}H_{56}Al_2S_5LiN$ (567.94): calcd. C 48.64, H 9.94, Al 9.50, N 2.47; found C 46.86, H 9.22, Al 9.13, N 1.86.

Crystal Structure Determinations: Single crystals of compounds **5**, **7**, and **8** were covered with perfluoroether oil, the selected crystal mounted on the tip of a glass fiber and placed on a goniometer head. The goniometer head was then fitted on the support of a Siemens P4 diffractometer equipped with a low-temperature device LTP2 and a CCD area detector. Graphite-monochromated Mo-K_α radiation was used for measurements. Preliminary unit-cell determinations were performed with the reflection data of a total of 75 frames taken in five different orientations of 15 frames each by changing φ by 0.3° increments. Data collection was performed with the program HEMISHERE and 5 s/frame exposure time with two

different χ settings. Data of a total of 1290 frames were collected and reduced using the program SAINT including absorption correction with the program SADABS. The structures were solved by direct methods (SHELXPLUS).[25] All non-hydrogen atoms were refined anisotropically, H atom positions at Al were taken from the difference Fourier data, and the H atom positions on C were calculated. These were included in the final refinement with a riding model, while the AlH hydrogen atoms were freely refined with fixed isotropic *U* values in the final cycles of refinement. All refinements proceeded normally. Relevant data are summarized in Table 3. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-143572 (**5**), -143573 (**7**·OEt_2), -143574 (**8**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank Fonds der Chemischen Industrie and Chemetall GmbH for their generous support for this study, Mrs. E. Kiesewetter for measuring the IR spectra and Mrs. D. Kaeser for performing the elemental analyses of the rather smelly substances.

Metal Assembly of Cyclodextrin Recognition Sites

Johanna M. Haider[a][+] and Zoe Pikramenou*[a][+]

Keywords: Cyclodextrins / Supramolecular chemistry / Receptors / Coordination chemistry / Molecular devices

Cyclodextrin recognition sites are assembled in macromolecular structures by using metal assembly principles. Methylated cyclodextrins are functionalised with bidentate bipyridine and tridentate terpyridine units to give versatile receptor ligands, β-CD–mbpy and β-CD–ttp, respectively, for metal complexation. Tris-cyclodextrin complexes are prepared by reaction of the β-CD–mbpy receptor with iron(II) and by reaction of β-CD–ttp with europium(III). The latter leads to a luminescent complex with three recognition sites around the luminescent metal core. Bis-cyclodextrin complexes are prepared by addition of iron(II) to β-CD–ttp. The characterisation of the compounds and their luminescent properties are reported.

Introduction

Receptors for small molecule recognition are popular building blocks in supramolecular design.[1] Artificial receptors have been developed from either multiple covalent bond synthesis or self-assembly principles for applications that range from biomedical research to the sensor field.[2] The design of optical molecular sensors based on recognition events has attracted much interest for the technological development of molecular devices.[3] Photoactive metal centres have been appended to calixarene[4] or cyclodextrin[5] receptor molecules for sensing ion or molecule recognition events. We are interested in employing cyclodextrins as rigid receptors that bind photoactive guests leading to the spatial organisation of energy or electron donor-acceptor arrays based on transition metals. Cyclodextrins are particularly attractive natural host molecules, water soluble, with a hydrophobic well-defined cavity.[6] Formation of transition metal arrays for photoinduced processes have been previously developed by using covalent bond bridges[7] or hydrogen-bond interfaces[8] to bring the metal centres together in one array. The importance of the cyclodextrin approach is that light-induced processes can be observed between two photoactive units held together by *non-covalent* interactions in aqueous solutions.[9]

The design of cyclodextrin-based organised arrays requires functionalisation of the cyclodextrin glucose units which can be achieved by modifying and using synthetic routes established in carbohydrate chemistry.[10] Metal centres have been attached to both discrete sugar units[11] and functionalised cyclodextrins,[12] primarily for developing models for enzymatic catalysis or sensors. In order to increase the number of guest interaction sites in cyclodextrin recognition systems the design of molecules with more than one cyclodextrin binding sites is attractive. Previous methods to link more than one cyclodextrin have employed covalent bond multi-step synthesis using bridges such as bipyridines,[13] porphyrins,[14] or organoselenium moieties.[15] Such bridged bis-cyclodextrin compounds have shown interesting catalytic properties for ditopic recognition of substrates.[13a] In this paper the assembly of cyclodextrins using coordination principles to yield complexes with multiple cyclodextrin recognition sites around a central metal core is reported. Our approach, using metal centres to assemble receptors, provides metal-directed spatial control of the receptors so that directional intramolecular energy or electron transfer processes between the central metal core and the guest species included in the receptor sites can take place when the metal core is photoactive. Metal centres have been previously employed to bring hydrogen-bonded recognition sites together.[16]

We wish to report the assembly of two or three functionalised cyclodextrins around a metal centre depending on the coordination preference of the metal core; octahedral metal centres and nine-coordinate lanthanide ions are used to spatially organise cyclodextrins functionalised with bidentate (β-CD−mbpy) and tridentate units (β-CD−ttp). Metal coordination properties allow the assembly of three cyclodextrins, which has not previously been investigated via covalent bond synthesis.

Results and Discussion

Synthesis

To incorporate a bidentate site on the cyclodextrin rim a new monosubstituted cyclodextrin 2,2′-bipyridine derivative was synthesised by attaching a monohydroxy permethylated cyclodextrin to the 4-position of a 2,2′-bipyridine to give β-CD−mbpy. Bipyridine functionalised cyclodextrins have been previously prepared either by William-

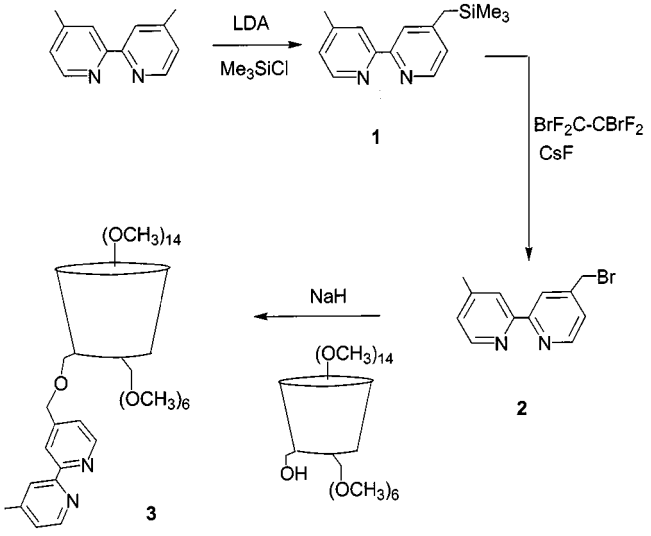
son ether synthesis at the 5,5′- or 6-positions of the bipyridine,[12c] thioether formation at 5,5′-disubstituted bipyridines[13a] or via "phosphinimine" type reactions of 5-methylamino bipyridines.[17] We employed the Williamson ether synthesis as a convenient route to attach the 4-position of a 4,4′-dimethyl 2,2′-bipyridine onto the cyclodextrin. We chose the 4-position both to avoid steric crowding around the metal (a problem with the 6-substituents) and to ensure good electronic coupling for communication of a redox active guest with the metal in photoinduced intramolecular processes. The functionalised cyclodextrin was prepared from the monohydroxy permethylated β-cyclodextrin[18] and 4-bromomethyl, 4′methyl-2,2′-bipyridine. The latter was prepared by modification of a procedure of monosilylation of the dimethyl 2,2′-bipyridine[19] followed by bromination with BrF_2CCF_2Br (Scheme 1).

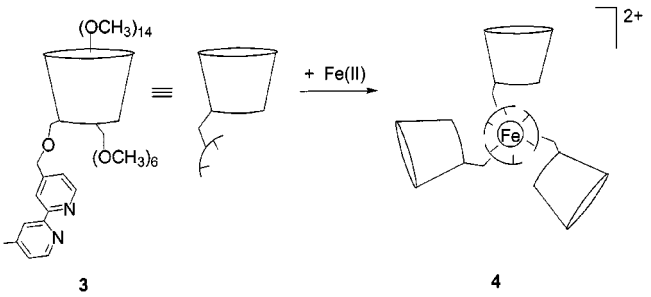


Scheme 1

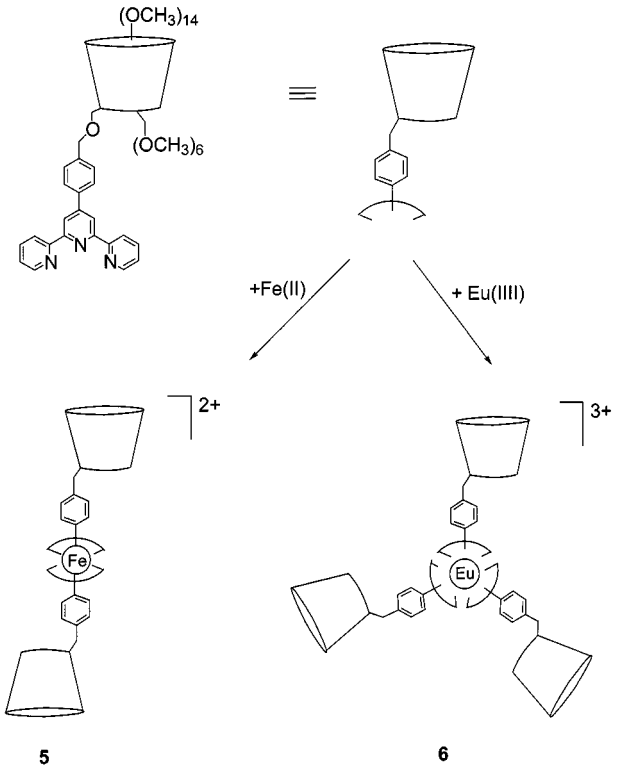
The 4-substituted bipyridine was shown to be more reactive towards the ether formation under similar conditions than the analogous 6- and 5- substituted bipyridines. The β-CD−mbpy is an attractive ligand due to its versatile solubility in both halogenated solvents and water which is important not only in the handling and purification of the compound but also in the metal complex formation.

Simple addition of Fe^{II} to a methanolic solution of β-CD−mbpy results in a deep red colour which is attributed to a complex with three cyclodextrins around the iron centre, $[Fe(\beta\text{-CD}-\text{mbpy})_3]^{2+}$ (Scheme 2). Solubility of the complex is enhanced by the presence of the methylated cyclodextrins and chromatographic methods have been more effective for isolation of the complex rather than recrystallization used in the analogous $[Fe(mbpy)_3][PF_6]_2$ complex.

Three cyclodextrins can potentially be assembled around a metal by using a tridentate binding site (such as a tolylterpyridine unit) attached on the cyclodextrin (β-CD−ttp) and a nine coordinate lanthanide, such as europium, (Scheme 3). We have previously reported such a functionalised cyclodextrin β-CD−ttp.[9] Europium(III) ions do not possess strong ligand field preference, adopting high coordination numbers in solution and they are known to form a tris-complex with 2,2′:6,′2′′ terpyridine. Upon addition of three equivalents of β-CD−ttp in an ethanolic solution of europium chloride the tris-cyclodextrin complex, $[Eu(\beta\text{-CD}-\text{ttp})_3]^{3+}$, is formed.[20]



Scheme 2



Scheme 3

When a metal with octahedral geometry is employed with the tridentate functionalised cyclodextrin two cyclodextrins are assembled around the metal; when Fe^{II} is reacted with β-CD−ttp a strong purple coloured complex of $[Fe(\beta\text{-CD}-\text{ttp})_2]^{2+}$ is formed.

Characterisation

NMR, UV/Vis spectroscopy together with mass spectrometric analysis were employed to confirm the identification of the compounds. Electrospray mass spectrometry has proven to be an important technique in the identification of self-assembled polymetallic systems.[21] In our case it has been successfully applied in cyclodextrin systems. In Table 1 the electrospray mass spectrometry data of the complexes

[a] CD_f = [6-monohydroxy permethylated β-cyclodextrin−H].

The H_{Glu}-6,6′ pair of the substituted glucose of the cyclodextrin also becomes diastereotopic, one proton is shifted to δ = 4.06 and shows a cross peak in the 2D TOCSY with the other one at δ = 3.71. Distinct from the cyclodextrin proton manifold are the six primary methoxy groups at δ = 3.34, 3.32, 3.31, 3.30, 3.28, 3.27 and the H_{Glu}-2 glucose protons at δ = 3.18−3.12. Full assignment of the cyclodextrin protons also agrees with previously detailed studies of permethylated cyclodextrins.[22]

The $[Fe(\beta\text{-CD}-mbpy)_3][PF_6]_2$ complex is diamagnetic which indicates that the cyclodextrin substitution does not induce any steric hindrance, which is known to be responsible for spin crossover phenomena in iron complexes.[23] In

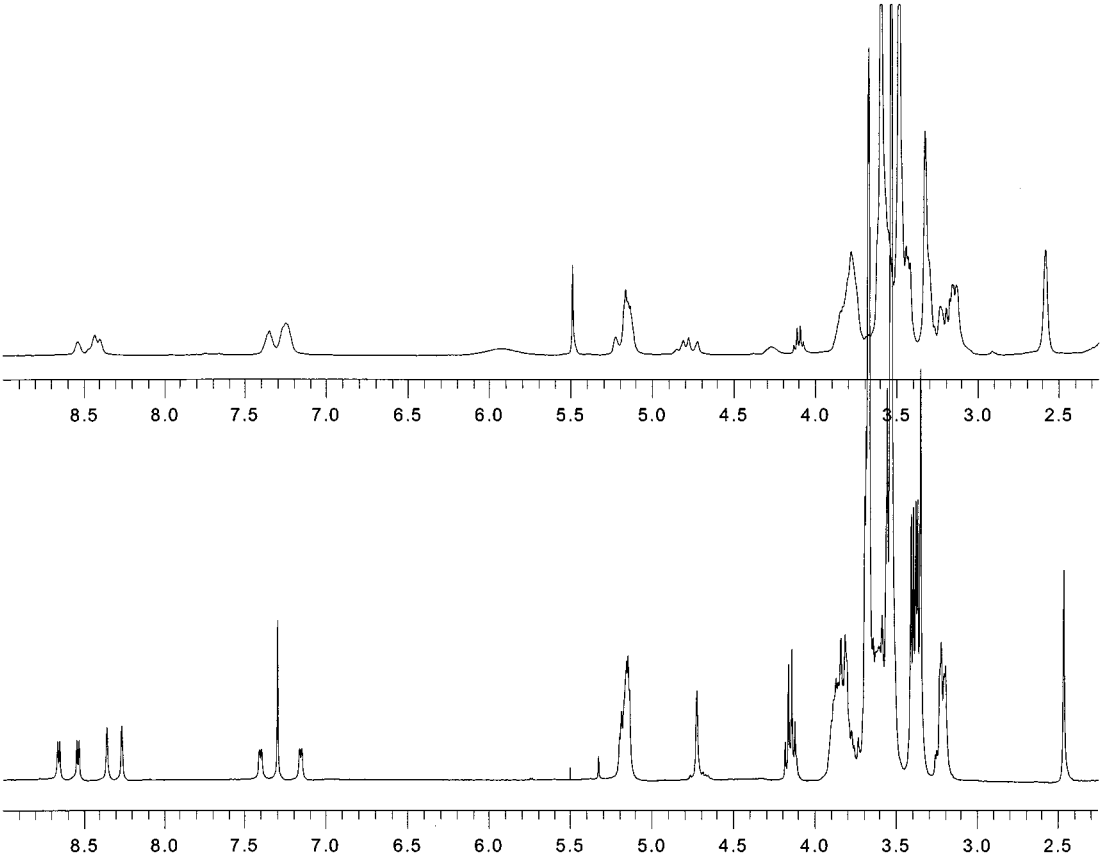

Figure 1. The 360 MHz ^1H NMR spectra of β-CD−mbpy (bottom) in $CDCl_3$ and $[Fe(\beta\text{-CD}-mbpy)_3][PF_6]_2$ (top) in CD_3CN

are presented. The data confirm the formulation of the bis- and tris-cyclodextrin complexes.

In the ^1H NMR spectrum of the β-CD−mbpy ligand, shown in Figure 1, the characteristic anomeric protons of the glucose units are non-equivalent due to the mono-substitution; five of them overlap (multiplet at δ = 5.4) while two separate doublets appear at δ = 5.12 and 5.10 (J = 4 Hz).

Substitution of the bipyridine unit is confirmed by the shift of the methylene group from δ = 4.43 in the bromide derivative to δ = 4.66 in β-CD−mbpy. The splitting of the signal as an AB pattern due to the diastereotopic protons upon attachment to the chiral cyclodextrin also confirms this. The rest of the aromatic protons appear as six signals. the ^1H NMR spectrum of the complex (Figure 1), the complexation with the β-CD−mbpy is confirmed by the shift, of the H-6,6′ protons of the bipyridine, to lower frequencies. The aromatic proton peaks are broader than are usually observed which may be due to the presence of the two *fac* and *mer* isomers[24] or to a very small impurity of iron(III)[25] which is difficult to exclude due to the high solubility of the complex. The complex UV/Vis absorption spectrum shows the characteristic MLCT absorption at 530 nm which agrees with the model compound which is a tris-bipyridine iron(II) complex without the cyclodextrin receptor.

The purple bis-cyclodextrin iron complex $[Fe(\beta\text{-CD}-ttp)_2][PF_6]_2$ was characterised by 600 MHz ^1H NMR

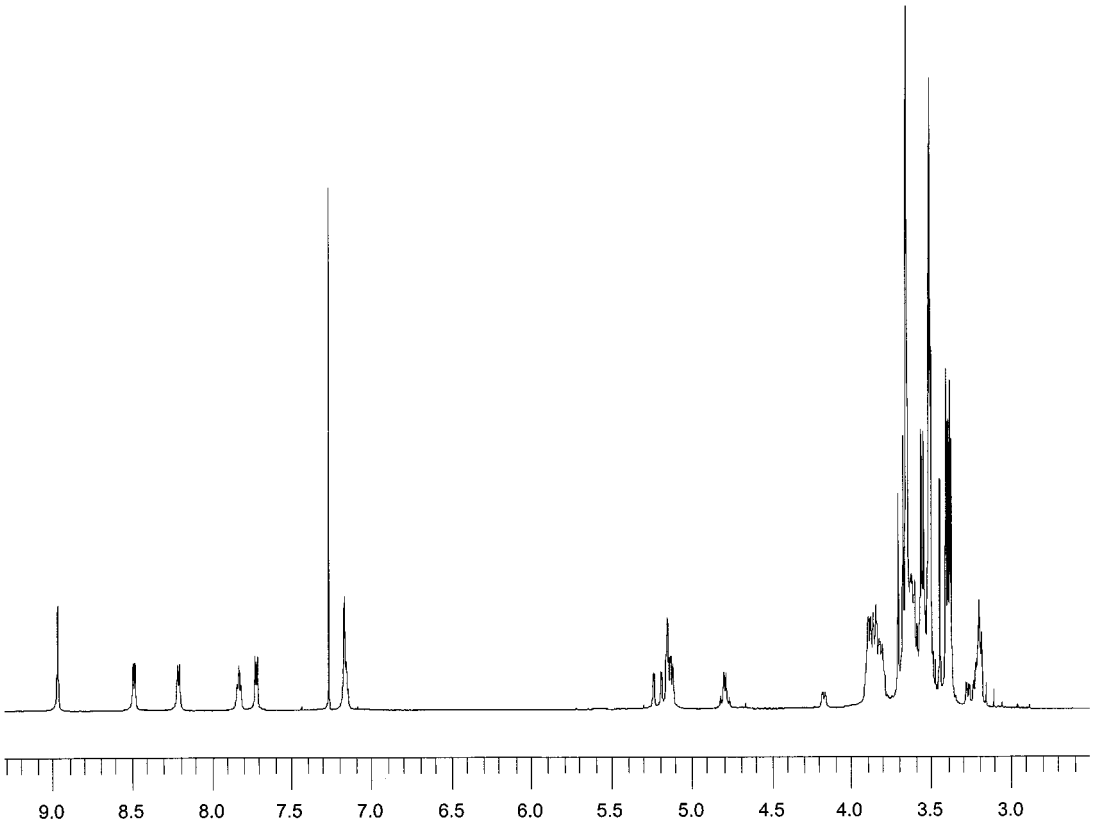

Figure 2. The 600 MHz ^{1}H NMR spectrum of $[Fe(\beta\text{-CD}-ttp)_2][PF_6]_2$ in $CDCl_3$

spectroscopy (Figure 2). The H-6 protons of the terpyridine unit show a 1.55 ppm shift at lower frequencies with respect of the chemical shift in the ligand spectrum attributed to metal coordination.[26] The methylene protons on the benzyl ring are diastereotopic appearing as a doublet of doublets at $\delta = 4.75$ where the methylene diastereotopic protons of the substituted glucose ring appear at $\delta = 4.15$ and 3.80, the latter is obscured by the rest of the cyclodextrin protons ($\delta = 3.15-3.90$). This was assigned from the ^{1}H-^{1}H COSY contour plot. Acetonitrile solutions of the iron complex display a typical MLCT absorption band at 569 nm. No luminescence was detected upon excitation to the MLCT band for either the bipyridine or the terpyridine cyclodextrin complexes. This is not surprising since both iron(II) bipyridine and terpyridine complexes bear low lying metal-centred states that provide radiationless pathways for luminescence quenching.[27]

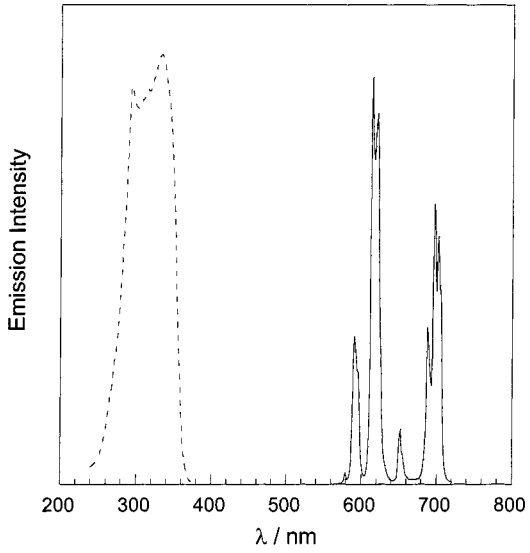

Figure 3. Emission ($\lambda_{exc} = 330$ nm, solid line) and excitation ($\lambda_{em} = 616$ nm, dashed curve) spectra of $[Eu(\beta\text{-CD}-ttp)_3]^{3+}$ in acetonitrile corrected for PMT and lamp response, respectively

Luminescence Spectroscopy

The europium complex was characterised by electrospray mass spectrometry and NMR spectroscopy. In the ^{1}H NMR spectrum of the perchlorate salt of the complex, the observed chemical shifts of the terpyridine protons are consistent with previously reported studies of europium terpyridine complexes.[28] The complex is stable in most organic solvents but dissociates in the presence of water as expected for lanthanide terpyridine complexes.[28] The europium ion was selected as a luminescent probe with well explored photophysical properties. Acetonitrile solutions of the complex exhibit strong red luminescence, characteristic of the europium ion upon excitation at the ligand band (Figure 3). The excitation spectrum upon monitoring the 616 nm europium emission shows a band centred at 320 nm corresponding to the ligand π-π^* transition which is in agreement with the absorption spectrum of the complex. The tolyl-terpyri-

dine units act as light-harvesting centres for collecting the energy and transferring it to the lanthanide centre.

Conclusions

Metal assembly of polypyridine functionalised cyclodextrins leads to the formation of complexes with two or three cyclodextrin receptor sites around the metal core. The employment of methylated cyclodextrins leads to versatile soluble ligands for metal complex formation. The metallo-receptors developed in this study can take part in photoactive processes occurring in more than one direction in space through the metal core and the guests. We are currently studying the ruthenium(II) analogues of these receptors because of their attractive photophysical properties for inducing energy or electron transfer processes.

Experimental Section

General Procedures and Materials: All starting materials were purchased from Aldrich unless otherwise indicated. β-Cyclodextrin (Acros) was recrystallized from water and dried under vacuum at 80 °C for 8 hours. $RuCl_3 \cdot xH_2O$ was provided from Johnson & Matthey as a loan. Solvents used in synthetic procedures were analytical grade apart from the ones used in size exclusion chromatography and spectroscopic studies where HPLC grade solvents were used. THF was freshly distilled from sodium under nitrogen. All ligand synthetic procedures were carried out under a nitrogen atmosphere. Thin layer chromatography (TLC) analyses were performed on either Merck silica gel 60 glass plates or Merck alumina gel 60 glass plates as indicated. Biobeads SX3 was used as a stationary phase for size exclusion chromatography. Cyclodextrins were detected by an oxidising solution consisting of anisaldehyde/acetic acid/methanol/sulfuric acid in a 2:45:430:22 ratio followed by heating at around 100 °C.

NMR spectra were recorded on Bruker DRX 360 and Varian Inova 600 spectrometers. The protons on the glucose units were indicated as H_{Glu} in the assignments. Fast atom bombardment mass spectrometry was performed on a Kratos MS-50 spectrometer and electrospray on a Quattro instrument at the EPSRC Mass Spectrometry Service Centre in Swansea.

Absorption spectra were recorded on a Perkin−Elmer Lambda 16 UV/Vis spectrometer. Emission and excitation spectra were recorded on a Photon Technology International QM-1 steady state spectrometer described elsewhere.[29]

4′-Methyl-{4-(trimethylsilyl)methyl}-2,2′-bipyridine (1): To a solution of LDA (Fluka, 1.05 g, 9.78 mmol) in freshly distilled THF (20 mL) a solution of 4,4′-dimethyl-2,2′-bipyridine (1.50 g, 8.15 mmol) in the same solvent (50 mL) was added dropwise at −78 °C. The dark brown mixture was kept stirring at that temperature for an hour. Trimethylsilyl chloride (1.06 g, 9.78 mmol) was added under vigorous stirring and after 20 s the reaction was quenched with absolute EtOH (10 mL), where upon the solution turned green. The cold reaction mixture was poured into an aqueous saturated $NaHCO_3$ solution and was left to reach room temperature. The mixture was extracted by dichloromethane (3 × 40 mL) and the combined organic phases were dried over anhydrous Na_2SO_4. After filtration and evaporation of the solvent TLC analysis of the mixture showed the presence of mono- and bis- silyl-substituted products (silica gel deactivated with NH_3, R_f = 0.68 and 0.86, respectively). Pure product was obtained after column chromatography (silica gel deactivated by addition of 10% triethylamine to the eluent system: EtOAc/cyclohexane 3:7) (yield: 1.5 g, 72%).

^{1}H NMR (360 MHz, $CDCl_3$): δ = 8.51 (d, J = 4.98 Hz, 1 H, H-6), 8.45 (d, J = 5.26 Hz, 1 H, H-6′), 8.21 (s, 1 H, H-3′), 8.04 (s,1 H, H-3), 7.09 (dd, J = 4.97 Hz, J = 1 Hz, 1 H, H-5′), 6.93 (dd, J = 5.01 Hz, J = 1 Hz, 1 H, H-5), 2.41 (s, 3 H, 4′-methyl), 2.19 (s, 2 H, 4-methylene), 0.02 (s, 9 H, CH_3-Si).

4-Bromomethyl-4′-methyl-2,2′-bipyridine (2): Caesium fluoride (0.475 g, 3.125 mmol) and $BrF_2C-CBrF_2$ (0.813 g, 3.125 mmol) were added to a solution of **(1)** (0.4 g, 1.56 mmol) in dry DMF (5 mL). The reaction was followed by TLC (deactivated silica, EtOAc/hexane 1:4) (R_f(product) = 0.43). The reaction reached completion after 4−5 h and the mixture was then poured into water (10 mL) and extracted by EtOAc (3 × 50 mL). The combined organic phases were washed with brine, dried over Na_2SO_4, filtered and the solvent evaporated. The brown oil was purified by column chromatography (deactivated silica ethyl acetate/cyclohexane 1:4) to give a slightly yellow oil (yield: 0.3 g, 73%).

^{1}H NMR (360 MHz, $CDCl_3$): δ = 8.60 (d, J = 4.99 Hz, 1 H, H-6), 8.49 (d, J = 4.96 Hz, 1 H, H-6′), 8.37 (s, 1 H, H-3), 8.19 (s, 1 H, H-3′), 7.29 (dd, J = 4.95 Hz, J = 1 Hz, 1 H, H-5), 7.11 (dd, J = 5.03 Hz, J = 1 Hz, 1 H, H-5′), 4.43 (s, 2 H, 4- methylene), 2.39 (s, 3 H, 4′-methyl).

6-Mono[4-methyl(4′-methyl-2,2′-bipyridyl)]-permethylated β-cyclodextrin (β-CD−mbpy) (3): 6-Monohydroxy permethylated β-cyclodextrin (0.8 g, 0.565 mmol) was dissolved in freshly distilled THF (15 mL). NaH (100 mg, 60% suspension in oil, 2.6 mmol) was added and a white precipitate was formed. A solution of (**2**) (208 mg, 0.789 mmol) in THF (5 mL) was added. The mixture was left to reflux for 12 h, quenched with brine (5 mL) and the solvent was evaporated. The residue was treated with brine (10 mL) and extracted with dichloromethane (3 × 40 mL). The combined organic phases were dried over Na_2SO_4, filtered and the solvent was evaporated. The compound was purified through column chromatography (Biobeads SX3, acetone). Yield 0.3 g, 33%.

^{1}H NMR (600 MHz, $CDCl_3$): δ = 8.58 (d, J = 5 Hz, 1 H, H-6), 8.46 (d, J = 5 Hz, 1 H, H-6′), 8.28 (s, 1 H, H-3), 8.19 (s, 1 H, H-3′), 7.33 (dd, J = 5 Hz, J = 1 Hz, 1 H, H-5), 7.09 (dd, J = 5 Hz, J = 1 Hz, 1 H, H-5′), 5.12 −5.07 (H_{Glu}-1, 7 H), 4.66 (dd, J = 13.5 Hz, J = 19.0 Hz, 2 H, CH_2 on C-4-bpy), 4.06 (dd, J = 6.8 Hz, J = 3.85 Hz, 1 H, H_{Glu}-6), 3.83−3.12 (m, H_{Glu}-2,3,4,5,6, $-OCH_{3Glu}$), 2.39 (s, 3 H, -CH_3 on C-4′).

[Fe(β-CD−mbpy)$_3$][PF$_6$]$_2$ (4): A solution of $[NH_4]_2Fe(SO_4)_2 \cdot 6H_2O$ (12 mg, 0.03 mmol) in water (1 mL) was added to a solution of (**3**) (150 mg, 0.09 mmol) in MeOH (2 mL). The mixture immediately turned dark purple and was left stirring for 30 min. The mixture was treated with a methanolic solution of NH_4PF_6, following extraction with dichloromethane (3 × 20 mL) and column chromatography (Biobeads SX3, acetone) the complex was obtained in 45% yield (70 mg).

^{1}H NMR (360 MHz, $CDCl_3$): δ = 8.55, 8.42 (2 H, H-3,-3′), 7.35, 7.25 (4 H, H-5,-5′, H-6,-6′), 5.25 −5.10 (7 H, H_{Glu}-1), 4.80 (2 H, CH_2 on C-4-bpy), 4.25 (1 H, H_{Glu}-6), 3.9−3.1 (m, H_{Glu}-2,3,4,5,6, $-OCH_{3Glu}$), 2.6 (3 H, $-CH_3$ on C-4′). − UV/Vis (MeOH) (ε/$M^{-1}cm^{-1}$): λ = 520 nm (9770), 351 (9700), 297 (83400), 289 (88100). − ESI MS (CH_3CN): m/z = 2422{M − 2[PF_6]}$^{2+}$.

$[Fe(\beta\text{-CD}-ttp)_2][PF_6]_2$ (5): To a solution of β-CD−ttp (50 mg, 0.029 mmol) in methanol (1 mL) a solution of $(NH_4)_2Fe(SO_4)_2$ in the same solvent (5.6 mg, 0.014 mmol) was added. The complex formed immediately giving a strong purple coloured solution. The mixture was heated for a few minutes to 50 °C, cooled to room temperature and a solution of ammonium hexafluorophosphate (4.8 mg, 0.028 mmol) in methanol (1 mL) was added. There was no precipitation due to the high solubility of the methylated cyclodextrin and the complex was isolated following extraction by dichloromethane (74 mg, yield: 73%).

^{1}H NMR (600 MHz, $CDCl_3$): δ = 8.98 (s, 4 H, H-3′), 8.48 (d, *J* = 7.9 Hz, 4 H, H-3), 8.19 (d, *J* = 7.7 Hz, 4 H, H_o), 7.80 (dd, *J* = 6.4, 6.8 Hz, 4 H, H-4), 7.71 (d, *J* = 7.7 Hz, 4 H, H_m), 7.19- 7.15 (m, 4 H, H-5,6), 5.24−5.10 (m, 7 H, H_{Glu}-1), 4.78 (dd, *J* = 7.6 Hz, 4 H, $-CH_2$-benzyl), 4.18 (dd, *J* = 10.7 Hz, *J* = 2.9 Hz, 2 H, H_{Glu}-6), 4.0−3.0 (m, H_{Glu}-2,3,4,5,6 $-OCH_{3Glu}$). − FAB-MS (nitrobenzyl alcohol matrix): *m*/*z* = 3674 $\{M - [PF_6]\}^+$, 3530 $\{M - 2[PF_6]\}^+$. − UV/Vis (MeOH) (ε/ $M^{-1}cm^{-1}$): λ = 568 nm (13800), 313 (37500) 286 (46000).

$[Eu(\beta\text{-CD}-ttp)_3][PF_6]_3$ (6): 6-Monotolylterpyridine permethylated β-cyclodextrin, β-CD−ttp (100 mg, 57 mmol) was dissolved in absolute EtOH (2 mL) and a hot solution of $Eu(NO_3)_3{\cdot}5H_2O$ (8.56 mg, 19 mmol) in the same solvent (1 mL) was added. The mixture was refluxed for 3 hours, the volume was reduced and NH_4PF_6 in EtOH (1 mL) was added. As no precipitate was formed, the mixture was extracted in dichloromethane (2 mL) following evaporation of the solvent. It was filtered through a Millipore column to remove the excess of NH_4PF_6, to yield 85 mg of the complex after solvent evaporation (yield 79%).

ESI-MS (MeOH/EtOH): *m*/*z* = 1788 $\{M - 3[PF_6]\}^{3+}$. − ^{1}H NMR (300 MHz, CD_3CN): δ = 16.14 (H-6), 7.18 ($H_{o/m}$), 6.95 (H-4), 6.6 ($H_{o/m}$), 6.3 (H-5), 5.1 (H_{Glu}-1), 4.6 ($-CH_2$-benzyl), 4.0−3.0 (rest of cyclodextrin protons), 2.5−2.4 (H3, 3′). − UV/Vis (CH_2Cl_2): λ = 280, 330 nm.

Acknowledgments

We are grateful to EPSRC for financial support to J. M. H. (GR/L91788), Drs. N. Spencer, C. M. Hewage and M. Chavarot for obtaining the NMR spectra and Dr. A. M. W. Cargill Thompson for helpful discussions. We also wish to thank Johnson & Matthey for a loan of ruthenium trichloride.

An Unusual Oxidation of 1,5-Dimethyl-2,4-bis(dialkylamino)-1,5-diaza-2,4-diphosphinan-6-one with Hexafluoroacetone

Igor V. Shevchenko,*[a] Rostislav N. Mikolenko,[a] Alexander N. Chernega,[b] Eduard B. Rusanov,[b] and Hansjoerg Grützmacher[c]

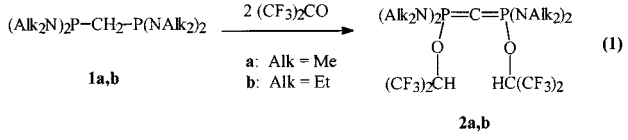
Dedicated to Professor Michael Lattman on the occasion of his 50th birthday

Keywords: Methylenediphosphane / Hexafluoroacetone / Carbodiphosphorane / Ylides / Wittig reaction / Oxidations

The oxidation of heterocycles **5a,b**, or **9** containing a methylenediphosphane unit, with hexafluoroacetone does not lead to the expected dioxaphospholane heterocycles, but yields unstable carbodiphosphoranes **6a,b** or ylide **10** respectively, which then react easily with HFA to give the stable intermediate products **7a,b** or **11** of the Wittig reaction.

Introduction

It is well-known that the oxidation of phosphanes with hexafluoroacetone (HFA) usually leads to the formation of 1,3- or 1,4-dioxaphospholane heterocycles.[1–4] Recently, however, we showed that this is not the only possible pathway for this reaction and that the presence of a methylene group in an α-position to the phosphorus atom may direct the reaction in an unusual way.[5,6] For example, bis[bis(dialkylamino)phosphinyl]methanes **1a,b** easily react with only two equivalents of HFA quantitatively, giving carbodiphosphoranes **2a,b** (Scheme 1).

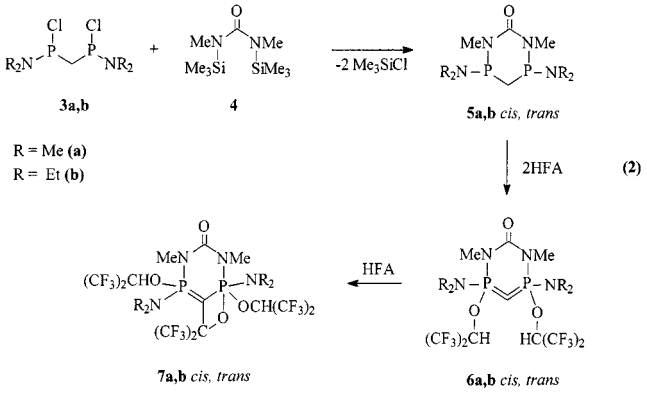


Scheme 1

Results and Discussion

In order to demonstrate the scope of this unusual reaction, we decided to employ other diphosphanes containing the structural fragment P–CH_2–P. It was interesting, for example, to investigate the reaction of HFA with compounds in which this fragment was a part of a heterocyclic system. As a model system we chose 1,5-dimethyl-2,4-bis(dialkylamino)-1,5-diaza-2,4-diphosphinan-6-one **5a,b**.[7]

The reactivity of **5a,b** in the reaction with HFA did not differ much from that of **1a,b**. The reaction proceeded smoothly at room temperature when gaseous HFA was slowly bubbled through a solution of **5a** or **5b** in dichloromethane at 20 °C. However, only small quantities of the expected cyclic carbodiphosphoranes **6a,b** could be detected in the reaction mixture by NMR spectroscopy. Unlike carbodiphosphoranes **2a,b**, compounds **6a,b** underwent addition of one more equivalent of HFA to give the heterocycles **7a,b**, which were the main product in this reaction (Scheme 2). The rate of addition of HFA to carbodiphosphoranes **6a,b** evidently exceeded the rate of their own formation; with HFA as limiting reagent, the content of **6a,b** did not grow and the starting material **5a,b** remained in the reaction mixture.



Scheme 2

These results are consistent with the only known example of the addition of HFA to hexaphenylcarbodiphosphorane.[8] Here, the same type of [1,2]oxaphosphetane was obtained by a cyclic addition. However the reaction required excess HFA and heating to 50 °C.

Starting heterocycles **5a,b** were obtained in high yield by the addition of silylated urea **4** to methylene-bis(diethylaminochlorophosphanes) **3a,b** and were used in the reaction with HFA without purification. They existed as *cis*- and *trans*-isomers, depending on the position of the substituents at the phosphorus atoms with respect to the cycle. The *cis*-isomer of **5** is kinetically more stable and its formation is favored. The *trans*-isomer **5-*trans*** is thermodynamically more stable and the *cis*/*trans* ratio after reaching equilibrium between the isomers is 1:9. The rate of transformation of **5-*cis*** into **5-*trans*** depends on the solvent used in the reaction.[7] This gave us the possibility to use varying *cis*/*trans* ratios from 1:1 to 1:9 when **5a,b** was reacted with HFA.

The products of this reaction, compounds **7a,b**, also formed *cis*- and *trans*-isomers. However, unlike the starting heterocycles **5a,b**, they exist independently of each other and do not show any tendency to interconvert one into the other. That is why the observed ratio between the isomers of product **7** reflects the isomer distribution of the starting compound **5** before reaction with HFA.

When compounds **5a,b** were prepared in diethyl ether, the initial ratio between the isomers was 1:1 and after reaction with HFA the products **7a,b** were obtained with the same ratio of isomers. Each isomer displays two characteristic doublets in the ^{31}P NMR spectrum. Compounds **7a,b** are stable crystalline products and were isolated as a mixture of *cis*- and *trans*-isomers. The ratio of the isolated material corresponded to the one seen in solution and since both have equal solubility, they could not be separated. Attempts to separate them by liquid chromatography led to their substantial decomposition on the surface of silica gel, even though compounds **7a,b** do not react with water in the absence of silica gel.

When **5a,b** were prepared in dichloromethane, the *cis*/*trans* equilibrium ratio (1:9) was rapidly reached. The addition of HFA to this isomeric mixture gave the same distribution of isomers in the reaction products **7a,b**. The predominant content of **7a,b-*trans*** allowed for their isolation as pure crystalline substances. The structures of **7a,b-*trans*** are consistent with their NMR spectra. For example, the ^{31}P NMR spectrum of **7a** shows two doublets at −42 ppm and 33 ppm, which are characteristic of the ylide and spirophosphorane phosphorus atoms respectively. The ^{1}H and ^{13}C NMR spectra showed the non-equivalence of dialkylamino groups. All CF_3 groups of **7a,b-*trans*** are nonequivalent and give rise to six independent multiplets in the ^{19}F NMR spectra. Two of them do not show FH coupling, as they belong to the CF_3 groups connected to the four-membered ring.

The structure of compound **7b-*trans*** was confirmed by a single-crystal X-ray diffraction study. The general view of the molecule is shown in Figure 1. It should be noted that heterocycles of this type have not been studied by structural methods yet.[9]

The central 6-membered ring P(1)P(2)N(1)N(2)C(1)C(2) in this compound is almost planar: deviations from the least-square plane do not exceed 0.070 Å. The 4-membered heterocycle P(2)O(3)C(1)C(12) is planar within 0.026 Å.

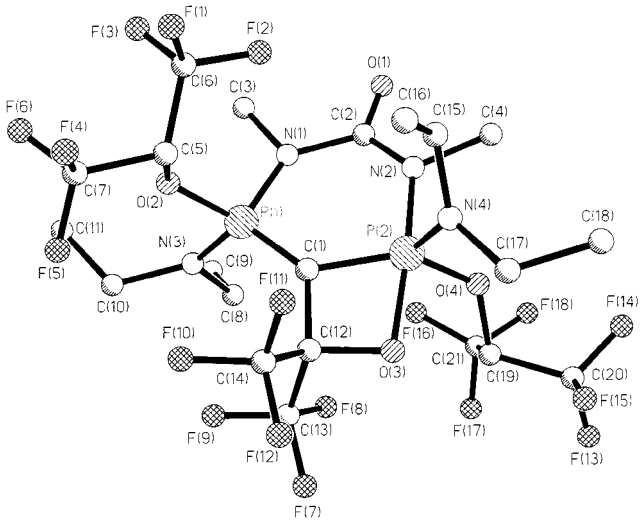

Figure 1. Perspective view and labelling scheme for the molecule **7b-*trans*** (H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: P(1)−N(1) 1.634(3), P(1)−C(1) 1.668(4), P(2)−C(1) 1.738(4), P(2)−N(2) 1.773(3), P(2)−O(3) 1.779(3), O(3)−C(12) 1.407(4), N(1)−C(2) 1.421(5), N(2)−C(2) 1.352(5), C(1)−C(12) 1.507(5); N(1)−P(1)−C(1) 105.8(2), C(1)−P(2)−N(2) 98.3(2), C(12)−O(3)−P(2) 94.9(2), C(2)−N(1)−P(1) 129.3(3), C(2)−N(2)−P(2) 132.3(3), C(12)−C(1)−P(2) 93.1(2), P(1)−C(1)−P(2) 132.2(2), N(2)−C(2)−N(1) 121.1(3), O(3)−C(12)−C(1) 95.9(3)

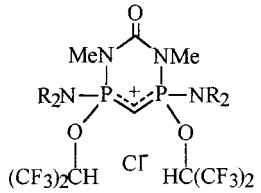
The dihedral angle between the planes of the 6- and 4-membered cycles is 11.63°. All nitrogen atoms have a trigonal coordination sphere (corresponding sums of bond angles lie within a narrow range: 358.6−360.0°). Atom P(1) has significantly distorted tetrahedral coordination whereas atom P(2) has a trigonal bipyramidal coordination, with atoms O(3) and N(2) being in axial and atoms C(1), N(4), O(4) in equatorial positions.

Together with **7a,b**, small quantities of the cyclic carbodiphosphoranes **6a,b** were detected in the reaction mixture (about 5−10% based on ^{31}P NMR spectrum). These compounds also exist as *cis*- and *trans*-isomers. Each of them displays a singlet in the range of 40−44 ppm. This value is consistent with the chemical shifts of acyclic carbodiphosphoranes **2a,b**. As a strong base, **6a,b** can react with ammonium hydrochlorides to give salts **8a,b**. Since chlorophosphanes **3a,b** were frequently contaminated with small amounts of dialkylammonium chloride, salts **8a,b** were found in the reaction mixture with a yield of about 3−4%. When the reaction was carried out in THF, **8b** crystallized from the reaction mixture as a colorless crystalline product. *A priori*, this compound should also give rise to two isomers. However, only one isomer of **8b** was formed, as is evident from the ^{31}P NMR spectrum where only one singlet



8a,b

at 44.05 ppm is observed. The X-ray analysis of a single crystal revealed that this is the *cis*-isomer (Figure 2). The hexafluoroisopropoxide groups form two chelating units, which embrace the chlorine anion forming the thermodynamically stable structure. The chlorine atom is kept by the two hydrogen bonds which is only possible for the *cis*- but not for the *trans*-isomer (Cl···C(5) 3.323(9), Cl···C(12) 3.377(9) Å).

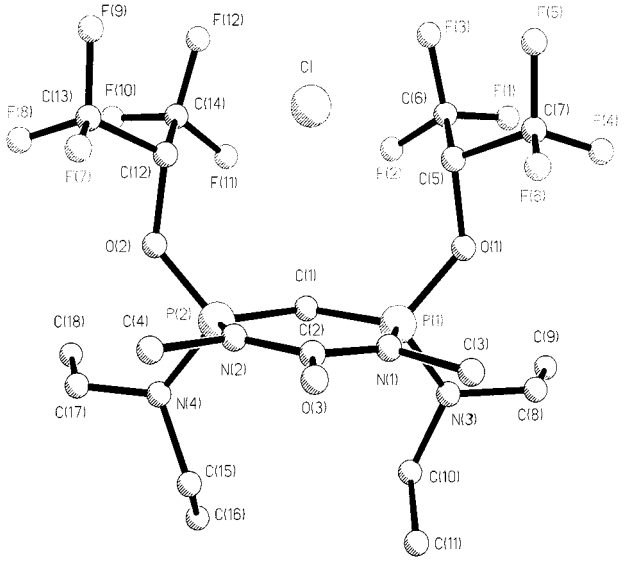


Figure 2. Perspective view and labelling scheme for the molecule **8b-*cis*** (H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: P(1)−N(1) 1.654(10), P(1)−C(1) 1.671(11), P(2)−C(1) 1.662(11), P(2)−N(2) 1.661(10), N(1)−C(2) 1.39(2), N(2)−C(2) 1.364(14); N(1)−P(1)−C(1) 107.4(5), C(1)−P(2)−N(2) 106.3(5), C(2)−N(1)−P(1) 129.5(9), C(2)−N(2)−P(2) 130.9(9), P(1)−C(1)−P(2) 125.5(7), N(2)−C(2)−N(1) 119.5(13)

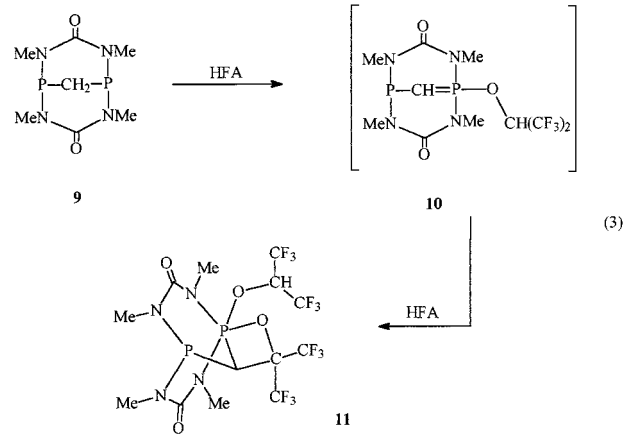
As in compound **7b-*trans***, the central 6-membered ring P(1)P(2)N(1)N(2)C(1)C(2) of **8b-*cis*** is almost planar: deviations do not exceed 0.060 Å. Atoms P(1) and P(2) have significantly distorted tetrahedral coordination. These data differ from the results of X-ray analyses, which we obtained earlier for the *cis*- and *trans*-isomers of the sulfur-derivative of heterocycle **5b**. These isomers showed noticeably distorted ring conformations, while the distortions at the phosphorus atoms were less pronounced than in **7b**-*trans* and **8b**-*cis*.[10] Owing to the $n_{N(1,2)}-\pi_{C=O}$ conjugation, the N(1)−C(2) and N(2)−C(2) bonds of **8b-*cis*** and **7b-*trans*** are noticeably shorter than the standard value of 1.45 Å for the $N(sp^2)-C(sp^2)$ single bond.[11] Comparison of the geometrical parameters of **8b-*cis*** and **7b-*trans*** with the corresponding values in related systems[10,12−14] shows delocalization of electron density over the N(1)−P(1)−C(1)−P(2)−N(2) bond system for the former molecules. It is noteworthy that unlike compound **7b-*trans***, in which the P(1)=C(1) double bond is localized as is indicated by the rather different bond lengths [P(1)−C(1) 1.668(4), P(2)−C(1) 1.738(4) Å], charge delocalization over the P(1)−C(1)−P(2) system [P(1)−C(1) 1.671(11), P(2)−C(1) 1.662(11) Å] is observed in **8b-*cis***.

For the further studies of the reactions of $P-CH_2-P$-containing heterocycles with HFA we used compound **9**. Its structure is rather close to that of **5a,b**, but instead of dialkylamino groups the two phosphorus atoms are bridged by one more urea unit. The reaction of compound **9** with HFA is slower and after 48 h in a sealed tube, a polymeric product of uncertain structure (82%) and compound **11** (18%) were obtained (Scheme 3). Since compound **11** is poorly soluble in dichloromethane, which was used as a solvent, it crystallized directly from the reaction mixture as colorless crystals.



Scheme 3

Unlike **5**, the phosphorus atoms of compound **9** are less nucleophilic, as they are bonded to two amide nitrogen atoms. That is why the reaction of **9** with HFA involves only one of the two phosphorus atoms. Although we could not detect it, we assumed that in this case the first reaction product, the ylide intermediate **10**, undergoes two simultaneous processes: polymerization and addition of HFA across the P=C bond to give **11**.

The structure of **11** was determined by NMR spectroscopic and analytical data. The ^1H NMR spectrum shows the non-equivalence of the all four methyl groups, the characteristic multiplet of the $(CF_3)_2CH$ unit at 5.48 ppm and doublet of doublets of the P−CH−P proton at 4.82 ppm. All CF_3 groups are also non-equivalent and display separate multiplets in the ^{19}F NMR spectrum. The interesting feature of this compound is that the two CF_3 groups at the four-membered cycle show a through-space coupling with the tricoordinated phosphorus atom. This phosphorus atom appears as a multiplet at 61 ppm in the ^{31}P NMR spectrum, whereas the other phosphorus atom gives rise to a doublet at −43 ppm.

Thus, the reaction of the $P-CH_2-P$ containing heterocycles **5** and **9** with hexafluoroacetone did not lead to the formation of the expected 1,3,2- or 1,4,2-dioxaphospholane heterocycles with a pentacoordinated phosphorus atom, but yielded derivatives of cyclic carbodiphosphoranes with tetracoordinated ylide phosphorus atoms.

Experimental Section

All operations were performed under nitrogen in a dry box. The solvents were dried by the usual procedures. The NMR spectra were recorded on JEOL FX-90Q and Varian 300 MHz spectro-

meters. The ^{1}H and ^{13}C NMR chemical shifts were referenced to tetramethylsilane (TMS). The ^{31}P NMR chemical shifts were measured using 85% aqueous orthophosphoric acid as an external standard. As usual, high frequency shifts were given positive signs. The digital resolutions were 0.25 Hz, 0.5 Hz and 1.25 Hz for ^{1}H-, ^{13}C- and ^{31}P NMR spectra respectively.

Synthesis of Compounds 3a,b: Compounds **3a,b** can be obtained with a 35−40% yield (after distillation) from methylene-bis(dichlorophosphane)[17] and dialkylamine. Use of silylated dialkylamine increases the yield to 50%. It is more convenient, however, to prepare fully substituted tetra(dialkylamino)methylenediphosphane **1a,b**, which can be isolated by distillation in 75−80% yield, and mix it subsequently with one equivalent of starting methylene-bis(dichlorophosphane) without solvent.

Synthesis of Compound 7a-*trans*: *N,N′*-Dimethyl-*N,N′*-bis(trimethylsilyl)urea[18] **4** (154 mg, 0.663 mmol) was added to a solution of methylene-bis(dimethylaminochlorophosphane) **3a** (150 mg, 0.638 mmol) in dichloromethane (1.5 mL), and the mixture was stirred at room temperature for 15 min. The reaction mixture was then placed in a 5-mm NMR tube and gaseous HFA (40 mL, 1.79 mmol) was slowly bubbled through it at room temperature using a syringe with a thin needle. The solvent was removed in vacuo 10 min after the addition of HFA and the residue was extracted with hexane (2 × 5 mL). The hexane solution was concentrated in vacuo to a volume of 5 mL and then cooled to −15 °C. In 48 h colorless crystals of **7a-*trans*** were separated and dried in vacuo. Yield 120 mg (25%), m.p. 101−102 °C. − ^{1}H NMR (89.56 MHz, $CDCl_3$): δ = 2.59 (d, $^{3}J_{PH}$ = 13.2 Hz, 6 H, N(CH_3)$_2$), 2.75 (d, $^{3}J_{PH}$ = 15.1 Hz, 6 H, N(CH_3)$_2$), 2.78 (d, $^{3}J_{PH}$ = 16.8 Hz, 3 H, NCH_3), 2.86 (d, $^{3}J_{PH}$ = 10.0 Hz, 3 H, NCH_3), 5.18 (m, 1 H, CHCF$_3$), 5.42 (m, 1 H, CHCF$_3$). − ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 28.6 (s, 1 C, NCH$_3$), 35.7 (s, 1 C, NCH$_3$), 36.8 (s, 2 C, N(CH$_3$)$_2$), 37.6 (d, $^{2}J_{PC}$ = 8.5 Hz, 2 C, N(CH$_3$)$_2$), 67.0−75.5 (m, 3 C, CH(CF$_3$)$_2$), 120.4 (q, $^{1}J_{FC}$ = 282.8 Hz, 2 C, CF$_3$), 121.3 (q, $^{1}J_{FC}$ = 279.2 Hz, 2C, CF$_3$), 123.5 (q, $^{1}J_{FC}$ = 289.0 Hz, 2C, CF$_3$), 153.8 (dd, $^{2}J_{PC}$ = 10.9 Hz, $^{2}J_{PC}$ = 11.2 Hz, C=O). − ^{19}F NMR (282.2 MHz, $CDCl_3$): δ = −72.99 (m, CF$_3$), −73.47 (m, CF$_3$), −74.08 (m, CF$_3$), −74.62 (m, CF$_3$), −76.17 (m, CF$_3$), −77.27 (m, CF$_3$). − ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = −42.0 (d, $^{2}J_{PP}$ = 75.6 Hz), 33.1 (d, $^{2}J_{PP}$ = 75.6 Hz). − $C_{17}H_{20}F_{18}N_4O_4P_2$ (748.29): calcd. C 27.29, H 2.69; found C 27.18, H 2.82.

Synthesis of Compound 7b-*trans*: *N,N′*-Dimethyl-*N,N′*-bis(trimethylsilyl)urea[18] **4** (128 mg, 0.550 mmol) was added to a solution of methylene-bis(dimethylaminochlorophosphane) **3b** (150 mg, 0.515 mmol) in dichloromethane (2 mL), and the mixture was stirred at room temperature for 45 min. The solvent was then removed in vacuo and the remaining oil was allowed to stay at 25 °C for 30 min in order for the *cis*- and *trans*-isomers of **3b** to reach equilibrium. Subsequently, the oil was dissolved in CH_2Cl_2 (1 mL), the solution was placed in a 5-mm NMR tube and gaseous HFA (32 mL, 1.44 mmol) was slowly bubbled through the solution using a syringe equipped with a thin needle. The solvent was removed in vacuo 10 min after the addition of HFA, and the residue was extracted with hexane (2 × 3 mL). The hexane solution was concentrated in vacuo to a volume of 1 mL and then cooled to −15 °C. The colorless crystals of **7b-*trans*** formed over 24 h were separated and dried in vacuo. Yield 116 mg (29%), m.p. 120−121 °C. − ^{1}H NMR (89.56 MHz, $CDCl_3$): δ = 1.04 (t, $^{3}J_{HH}$ = 7.1 Hz, 6 H, NCH$_2$CH_3), 1.17 (t, $^{3}J_{HH}$ = 7.1 Hz, 6 H, NCH$_2$CH_3), 2.84 (d, $^{3}J_{PH}$ = 7.3 Hz, 3 H, NCH_3), 2.91 (d, $^{3}J_{PH}$ = 10.3 Hz, 3 H, NCH_3), 3.09 (m, 8 H, NCH_2CH$_3$), 5.11 (m, 1 H, CHCF$_3$), 5.35 (m, 1 H, CHCF$_3$). − ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 11.97 (s, 1 C, NCH$_2$CH_3), 12.14 (s, 1 C, NCH$_2$CH_3), 14.0 (s, 2 C, NCH$_2$CH_3), 30.0 (s, 1 C, NCH$_3$), 36.1 (s, 1 C, NCH$_3$), 37.7 (d, $^{2}J_{PC}$ = 8.6 Hz, 2 C, NCH$_2$CH$_3$), 42.3 (s, 2 C, NCH$_2$CH$_3$), 65.0−76.2 (m, 3 C, CH(CF$_3$)$_2$), 120.5 (q, $^{1}J_{FC}$ = 286.5 Hz, 2 C, CF$_3$), 121.5 (q, $^{1}J_{FC}$ = 284.1 Hz, 2C, CF$_3$), 123.5 (q, $^{1}J_{FC}$ = 286.4 Hz, 2C, CF$_3$), 153.8 (dd, $^{2}J_{PC}$ = 10.9 Hz, $^{2}J_{PC}$ = 11.1 Hz, 1 C, C=O). − ^{19}F NMR (282.2 MHz, $CDCl_3$): δ = −72.29 (m, 3 F, CF_3), −72.86 (m, 3 F, CF_3), −74.10 (m, 3F, CF_3), −74.17 (m, 3 F, CF_3), −74.39 (m, 3 F, CF_3), −75.51 (m, 3 F, CF_3). − ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = −38.2 (d, $^{2}J_{PP}$ = 74.2 Hz), 36.0 (d, $^{2}J_{PP}$ = 74.2 Hz). − $C_{21}H_{28}F_{18}N_4O_4P_2$ (804.40): calcd. C 31.36, H 3.51; found C 31.69, H 3.58.

Synthesis of Compound 8b-*cis*: *N,N′*-Dimethyl-*N,N′*-bis(trimethylsilyl)urea[18] **4** (134 mg, 0.578 mmol) was added to a solution of methylene-bis(dimethylaminochlorophosphane) **3b** (160 mg, 0.550 mmol) in THF (4 mL), and the mixture was stirred at room temperature for 15 min. The solvent and all volatiles were then removed in vacuo (0.05 Torr) for 15 min, and the remaining oil was dissolved again in THF (4 mL). The solution was then placed in a 10-mm NMR tube and gaseous HFA (17 mL, 0.755 mmol) was slowly bubbled through the solution using a syringe equipped with a thin needle. The reaction mixture was allowed to stay at −15 °C. Colorless crystals of **8b-*cis*** formed over 24 h were separated and dried in vacuo. Yield 13 mg (3.6%). − ^{1}H NMR (89.56 MHz, $CDCl_3$): δ = 1.22 (t, $^{3}J_{HH}$ = 7.1 Hz, 12 H, NCH$_2$CH_3), 3.04 (d, $^{3}J_{PH}$ = 6.2 Hz, 6 H, NCH_3), 3.25 (m, 8 H, NCH_2CH$_3$, 1 H, PCHP), 7.46 (m, 2 H, CHCF$_3$). − ^{19}F NMR (84.26 MHz, $CDCl_3$): δ = −72.98 (d, $^{3}J_{FH}$ = 41.0 Hz, 12 F, CF_3). − ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 44.0 (s, 2 P).

Synthesis of Compound 11: Gaseous hexafluoroacetone (20.5 ml; 0.914 mmol) was condensed into a solution of bicyclic compound **9** (113 mg; 0.456 mmol) in dichloromethane (1 mL) in a glass tube. The tube was sealed and kept at room temperature for 3 d. The colorless crystalline product formed in the reaction mixture was then filtered off, washed with dichloromethane (0.3 mL) and dried in vacuo (0.05 mm). Yield 49 mg (18.5%), m.p. 120−121 °C. − ^{1}H NMR ($CDCl_3$): δ = 2.93 (d, $^{3}J_{HP}$ = 9.4 Hz, 3 H, NCH_3), 2.99 (d, $^{3}J_{HP}$ = 10.2 Hz, 3 H, NCH_3), 3.14 (d, $^{3}J_{HP}$ = 9.4 Hz, 3 H, NCH_3), 3.18 (d, $^{3}J_{HP}$ = 12.6 Hz, 3 H, NCH_3), 4.82 (dd, $^{2}J_{HP}$ = 6.1 Hz, $^{2}J_{HP}$ = 26.1 Hz, 1 H, P−CH−P), 5.48 (d of hept., $^{3}J_{HP}$ = 14.9 Hz, $^{3}J_{HF}$ = 5.6 Hz, 1 H, HC(CF$_3$)$_2$). − ^{19}F NMR (84.26 MHz, $CDCl_3$): δ = −77.93 (m, CF$_3$), −74.11 (m, CF$_3$), −73.18 (m, CF$_3$), −70.98 (m, CF$_3$). − ^{31}P NMR ($CDCl_3$): δ = −43.3 (d, $^{2}J_{PP}$ = 65.0 Hz, 1 P), 61.3 (m, $^{2}J_{PP}$ = 65.0 Hz, 1 P). − $C_{13}H_{14}F_{12}N_4O_4P_2$ (580.21): calcd. X-ray Crystal Structure Determination of Compounds 7b-*trans* and 8b-*cis*: Crystal data, data collection and processing parameters are given in Table 1. All crystallographic measurements were performed at 20 °C on a CAD-4-Enraf−Nonius diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) and ω-2θ scan mode (the ratio of the scanning rates ω/2θ = 1.2). Unit-cell parameters were calculated from the setting angles of 22 strong, high-angle carefully centered reflections with $13 > \theta > 12°$ for **7b-*trans*** and $11 > \theta > 10°$ for **8b-*cis***. Three reflections were chosen as intensity standards and were measured every 3600 s of X-ray exposure time, and three orientation control reflections were measured every 147 reflection. Correction for crystal decay (ca. 13% for **7b-*trans*** and 8% for **8b-*cis***) was applied during the processing of data sets. All data were corrected for Lorentz and polarization effects but not for absorption. Both structures were solved by direct methods.[15] Non-hydrogen atoms were refined against F by the full-matrix least-squares technique[16] in the anisotropic approxi-

Diastereoselective Homochiral Self-Assembly Between Anions and Cation in Solution

Olivier Maury,*[a] Jérôme Lacour,[b] and Hubert Le Bozec*[a]

Keywords: Chiral recognition / NMR spectroscopy / Ruthenium / Self-assembly / Supramolecular chemistry

Diastereoselective homochiral self-assembly occurs in solution by mixing the propeller-like racemic tris(DEAS-bpy) ruthenium(II) cation **B** [DEAS-bpy = 4,4′-bis(diethylaminostyryl)-[2,2′]-bipyridine)] and the racemic TRISPHAT anion **A** [TRISPHAT = tris(tetrachlorobenzenediolato)phosphate(V)]. This phenomenon is clearly shown by ^{1}H NMR spectroscopic studies which reveal: (i) the existence of a rapid equilibrium between their homochiral and heterochiral associations, (ii) at room temperature, the preferential formation of the homochiral ion pairs with a ratio homochiral/heterochiral = 72:28, and (iii) at 243 K, the almost pure homochiral associations ($\mathbf{B}^{\Lambda}$,$\mathbf{A}^{\Lambda}{}_2$) and ($\mathbf{B}^{\Delta}$,$\mathbf{A}^{\Delta}{}_2$).

Introduction

Propeller-like molecules are potential candidates for diastereoselective self-assembly, where chiral supramolecules are spontaneously formed from a mixture of racemic components. Such types of chiral recognition have generally been observed in the solid state.[1] The recognition driving force is mainly due to the formation of intermolecular hydrogen bonds, the helicity of both compounds ensuring the spatial compatibility of the H-donor and acceptor groups.[2] Moreover, a few examples of self-assembly have also been observed for propeller-like H-bond-free molecules: spontaneous homochiral segregation occurred during the formation of columnar liquid crystals[3] or during gel crystallization,[4] the homochiral association of the propellers ensuring the optimal packing. Chiral recognition phenomena have also been observed among guest tris(diimine) metal complexes when intercalated into host mineral clays.[5]

D_3-symmetric propeller-like molecules are particularly interesting as a new class of octupolar chromophores for nonlinear optics (NLO).[6] Coordination chemistry is a powerful tool to design such compounds,[7] and recently we[8] and others[9] have reported the large molecular hyperpolarisability of octahedral ruthenium(II) complexes [Ru(bpy′)$_3$][PF$_6$]$_2$, where bpy′ is a functionalized 2,2′-bipyridine. With the aim of increasing the NLO activity of such systems, we became interested in the association of Ru^{II} cationic octupoles with counter anions also having a D_3 propeller-like topology. We sought to use the propeller-like tris(tetrachlorobenzenediolato)phosphate(V) anion [TRISPHAT] **A** (Figure 1) which was recently described as a chiral shift agent,[10] a chiral inducer onto Fe^{II} complexes[11] and for its ion-pair chromatographic-resolution properties.[12]

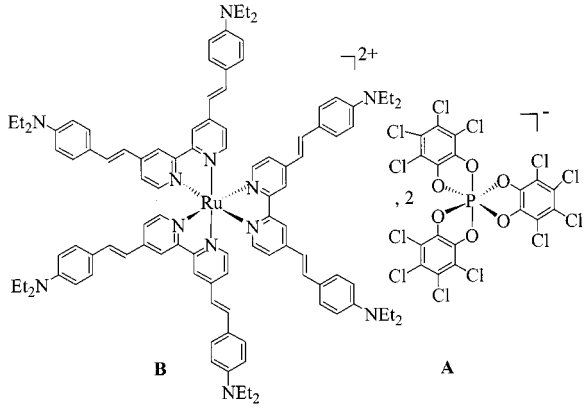

Figure 1. TRISPHAT anion **A** (Δ) and [Ru(DEAS-bpy)$_3$]$^{2+}$ cation **B** (Δ) (DEAS-bpy = 4,4′-bis(diethylaminostyryl)-[2,2′]-bipyridine)

In this article, we wish to describe the synthesis and ^{1}H NMR spectroscopic studies of the association between a racemic D_3-symmetric ruthenium tris(DEAS-bpy) dication {where DEAS-bpy represents 4,4′-bis(diethylaminostyryl)-[2,2′]-bipyridine} and the racemic TRISPHAT anion which reveals a remarkable diastereoselective, homochiral self-assembly phenomenon in solution.

Results and Discussion

The tris(bipyridyl) ruthenium complex (**B**,[PF$_6$]$_2$) is classically prepared by reacting [RuCl$_2$(DMSO)$_4$] with DEAS-bpy (three equivalents) in refluxing DMF, followed by an anionic exchange with NaPF$_6$. The TRISPHAT salt (**B**,**A**$_2$) is obtained either from the chloride or the hexafluorophosphate salts by anion metathesis with [HNBu$_3$][TRISPHAT] (Scheme 1). This new complex is much more soluble than the corresponding PF$_6$ salt in chlorinated solvents allowing its purification by using silica-gel column chromatography with dichloromethane as eluent. The spectroscopic and

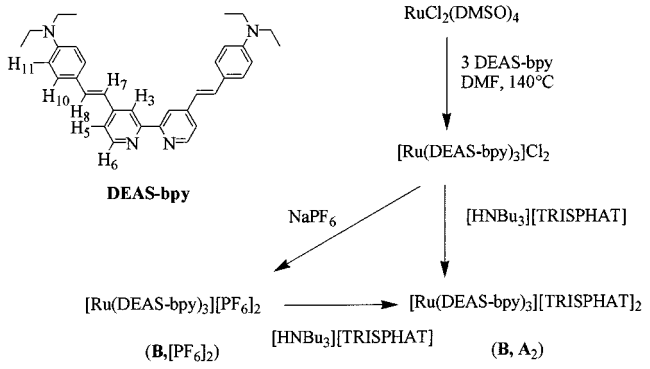
analytical data are given in the Experimental Section. The aromatic parts of the ^{1}H NMR spectra of (**B**,[PF_6]$_2$) and (**B**,**A**$_2$) are displayed in Figure 2. For the TRISPHAT salt, a strong deshielding of the H_6 proton is observed ($\Delta\delta$ = +0.5 ppm) while the bipyridyl protons H_3 and H_5, as well as the protons of the styryl substituents (H_7-H_{11}), are displaced to higher field when compared to those of the corresponding hexafluorophosphate salt. A similar, but weaker, effect can be observed in the corresponding ^{13}C NMR spectra (see Experimental Section), with the C_6 carbons being shifted downfield ($\Delta\delta$ = +1.0 ppm).



Scheme 1. Synthesis of (**B**,**A**$_2$) and indexation of DEAS-bpy

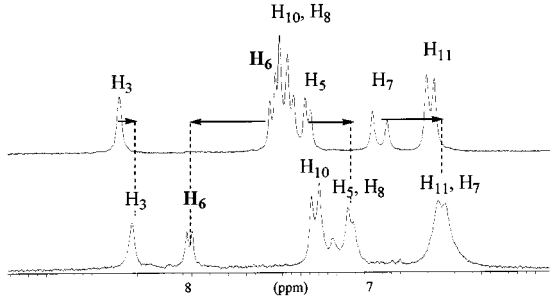


Figure 2. Effect of the counter-anion on the aromatic region of the ^{1}H NMR spectra of (**B**,[PF_6]$_2$) (up) and (**B**,**A**$_2$)

It is worth noting that the TRISPHAT anion **A** and the Ru^{II} complex **B** exist as two configurationally stable Λ and Δ enantiomers.[13] Their association should afford a mixture of diastereoisomeric complexes consisting of two couples of enantiomeric homochiral (**B**$^{\Lambda}$,**A**$^{\Lambda}_2$), (**B**$^{\Delta}$,**A**$^{\Delta}_2$) and heterochiral (**B**$^{\Lambda}$,**A**$^{\Delta}_2$), (**B**$^{\Delta}$,**A**$^{\Lambda}_2$) derivatives. Surprisingly, the ^{1}H NMR spectrum of the racemic mixture (CD_2Cl_2, 293 K) shows only one set of signals for the bipyridyl ligands (Figure 2) suggesting either a dynamic phenomenon or the selective formation of one diastereoisomer. Lowering the temperature to 243 K results in a slight shift and broadening of the signals, but no splitting of the ^{1}H NMR signals is observed (Figure 3). On the other hand, a direct observation of diastereoisomers by NMR spectroscopy should be possible through exchange between *rac* (**B**,[PF_6]$_2$) and the partially resolved chiral cinchonidinium−Δ TRISPHAT salt **A**$^{\Delta}$ ([α]$_D$ = −320, *de* = 86%).[14] The ^{1}H NMR spectrum of this mixture (298 K), shows two sets of signals for the bipyridyl ligands, corresponding to the expected mixture of homochiral and heterochiral diastereoisomers (Figure 4a).[15] The H_6 and $H_{6'}$ protons give signals of equal intensity at δ = 8.17 and 7.54, values which are notably different from that observed for the racemic mixture (unique signal, δ = 7.98, Figure 4f or Figure 2). At this stage no direct explanation could be given; since the TRISPHAT enantiomeric excess seems to have a large influence on the NMR spectra, two other experiments were carried out.

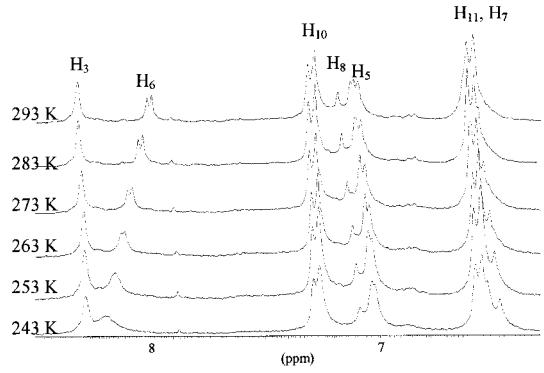

Figure 3. Variable temperature ^{1}H NMR spectra of *rac* (**B**,**A**$_2$) complexes (CD_2Cl_2, 300 MHz)

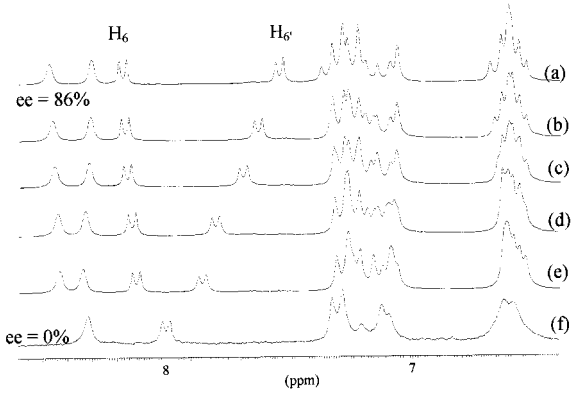

Figure 4. Aromatic part of the ^{1}H NMR spectra (CD_2Cl_2, 200 MHz, 293 K)of (**B**,**A**$_2$) (**A**$^{\Delta}$, *ee* = 86%) (a); *rac* (**B**,**A**$_2$) (f); during the addition of *rac* ([$HNBu_3$],**A**) to the solution of (**B**,**A**$_2$) (**A**$^{\Delta}$, *ee* = 86%) (b-e)

In order to decrease the TRISPHAT enantiomeric excess, *rac* (**B**,**A**$_2$) was incrementally added to the solution obtained with partially resolved TRISPHAT, containing mainly the (**B**$^{\Delta}$,**A**$^{\Delta}_2$) and (**B**$^{\Lambda}$,**A**$^{\Delta}_2$) diastereoisomers (Figure 4a). The convergence of the H_6 and $H_{6'}$ proton NMR probes is observed whereas their relative intensities remain equal, clearly indicating that these two signals are due to Δ−[Ru(DEAS-bpy)$_3$]$^{2+}$ and Λ−[Ru(DEAS-bpy)$_3$]$^{2+}$ propellers in a TRISPHAT-oriented medium. The dependence of the H_6 and $H_{6'}$ chemical shifts on TRISPHAT's *ee* is due to rapid equilibria involving the homochiral and heterochiral associations. For the two rapid equilibria, the position of the H_6 and $H_{6'}$ coalescence signals δ_{obs} is given by the equation: $\delta_{obs} = x\delta_{HOMO} + (1 - x)\delta_{HETERO}$ [Equation (a)] where x represents the relative amount of the homochiral species and δ_{HOMO} and δ_{HETERO} the chemical shift of the pure diastereoisomers. This equation allows the de-

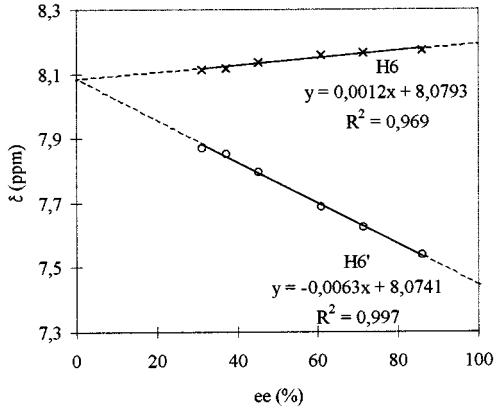
termination of the relative amount of both homochiral and heterochiral diastereoisomers.

Finally, in order to quantify the role of the TRISPHAT enantiomeric excess, small amounts of *rac* ([$HNBu_3$],**A**) were successively added to a solution of (**B**,$\mathbf{A_2}$) ($\mathbf{A^{\Delta}}$, *ee* = 86%, Figure 4a). The evolution of the ^1H NMR spectra (Figure 4b−e) also shows that, for both family of protons, the intensity is retained, whereas their chemical shifts converge. For each **B** enantiomer, the positions of H_6 and $H_{6'}$ traduce the homochiral/heterochiral composition of the equilibria in Equations (1) and (2), respectively (vide supra).

$$(\mathbf{B^{\Delta}},\mathbf{A^{\Delta}_2}) + 2\,[HNBu_3][\mathbf{A^{\Lambda}}] \rightleftharpoons (\mathbf{B^{\Delta}},\mathbf{A^{\Lambda}_2}) + 2\,[HNBu_3][\mathbf{A^{\Delta}}] \quad (1)$$

$$(\mathbf{B^{\Lambda}},\mathbf{A^{\Delta}_2}) + 2\,[HNBu_3][\mathbf{A^{\Lambda}}] \rightleftharpoons (\mathbf{B^{\Lambda}},\mathbf{A^{\Lambda}_2}) + 2\,[HNBu_3][\mathbf{A^{\Delta}}] \quad (2)$$

As shown in Scheme 2, the chemical shifts of H_6 and $H_{6'}$ vary linearly with the TRISPHAT enantiomeric excess. The validity of Equation (a) is enforced by the fact that the straight lines intercept the Y-axis at the same point (δ = 8.07) corresponding to the racemic mixture *rac* (**B**,$\mathbf{A_2}$), experimentally recorded at δ = 7.98 (Figure 4f). Of particular interest, the slopes of the straight lines are very different, showing a different evolution of the two equilibria in Equations (1) and (2) during the addition of *rac* **A** (and especially the isomer $\mathbf{A^{\Lambda}}$). Both equilibria are displaced to the right but the shift of the equilibrium in Equation (2) is about five times[16] more pronounced than that of the equilibrium in Equation (1), clearly showing that, under these experimental conditions,[17] the homochiral association is spontaneously preferred to the heterochiral one.



Scheme 2. H_6 and $H_{6'}$ chemical shift vs. TRISPHAT's *ee*

Extrapolation of the straight lines to *ee* = 100% allows the determination of the theoretical chemical shift for the pure homochiral (H_6, δ_{HOMO} = 8.19) and heterochiral ($H_{6'}$, δ_{HETERO} = 7.44) isomers. Thus, according to equation (a), the unique $H_6/H_{6'}$ signal of the racemic mixture (**B**,$\mathbf{A_2}$) at δ = 7.98 allows the determination of x = 0.72. This traduces for each $[Ru(DEAS\text{-}bpy)_3]^{2+}$ enantiomer, the rapid equilibrium between the 72% homochiral [($\mathbf{B^{\Lambda}}$,$\mathbf{A^{\Lambda}_2}$) or ($\mathbf{B^{\Delta}}$,$\mathbf{A^{\Delta}_2}$)] and 28% heterochiral [($\mathbf{B^{\Lambda}}$,$\mathbf{A^{\Delta}_2}$) and ($\mathbf{B^{\Delta}}$,$\mathbf{A^{\Lambda}_2}$)] diastereoisomers. In other words, the homochiral isomer is 0.56 kcal·mol^{-1} more stable than the heterochiral one at 298 K in CH_2Cl_2.

This result can also be used to explain the variable-temperature ^1H NMR experiment of *rac* (**B**,$\mathbf{A_2}$) in CD_2Cl_2 (Figure 3), where the ratio of homochiral/heterochiral diastereoisomers linearly increases with the lowering of the temperature leading toward the formation of the thermodynamically favored homochiral form.

Conclusion

As previously noticed, tris(bipyridyl) metal complexes (M = Fe, Ru) have already been associated with the TRISPHAT anion but only in its enantiopure form,[10−12] the same association with racemic TRISPHAT giving rise to insoluble salts.[11] In contrast, the use of functionalized DEAS-bpy, which leads to an enhanced solubility of the corresponding ruthenium salt, allows the study of the association with racemic TRISPHAT. The enantiopure TRISPHAT anion is known to form a diastereoselective, homochiral ion-pair with the labile tris(4,4′-dimethyl-[2,2′]-bipyridine) iron(II) dication.[11] In the present work, we show that the same homochiral association occurs between racemic TRISPHAT and the nonlabile propeller-like ruthenium complex. Moreover, this recognition is temperature dependant, leading to the almost pure homochiral associations ($\mathbf{B^{\Lambda}}$,$\mathbf{A^{\Lambda}_2}$) or ($\mathbf{B^{\Delta}}$,$\mathbf{A^{\Delta}_2}$) at 243 K. Such diastereoselective self-assembly has already been observed by Swager et al. for neutral, propeller-like metal complexes during the formation of columnar liquid crystals, the homochiral segregation being driven by the optimization of the packing.[3] In this paper, the self-assembly occurs in solution between charged propeller-like compounds. The driving force is thought to be the minimization of the electrostatic interactions, the anion/cation distance being shorter in the homochiral association (Figure 5).

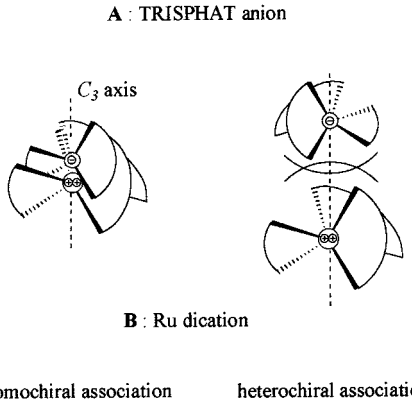


Figure 5. Schematic representation of both homochiral and heterochiral interactions

Finally, the assembly of octupolar anions and cations opens the way towards the design of supramolecular materials for nonlinear optics. Studies are now in progress to examine the NLO activity of such multi-octupolar compounds.

Experimental Section

General: All reactions were routinely performed under argon using Schlenk techniques. − NMR spectra (^{1}H, ^{13}C, ^{31}P) were recorded on a BRUKER DPX 200 (operating at 200.12 MHz for ^{1}H, 50.32 MHz for ^{13}C and 81.91 MHz for ^{31}P) or on a BRUKER AC 300 (operating at 300.13 MHz for ^{1}H) spectrometers. NMR spectroscopic data are listed in parts per million (ppm) and are reported relative to 85% H_3PO_4 (^{31}P) or to tetramethylsilane (^{1}H, ^{13}C), residual solvent peaks being used as internal standard (CD_2Cl_2: ^{1}H: δ = 5.25; ^{13}C: δ = 53.45). Complete attribution of the ^{1}H and ^{13}C spectra required 2D experiments [COSY, H−C correlation (hmqc and hmbc sequences)]. − UV/Vis spectra were recorded on a BIO-TEK/KONTRON UVIKON 941 spectrophotometer in dichloromethane solution. − High resolution mass spectrometry measurements (FAB) were performed by the Centre Regional de Mesures Physiques de l'Ouest (Rennes, France) and elemental analysis by the Service Central d'Analyse du CNRS (Solaize, France). Solvents are simply distilled prior to use. $[RuCl_2(DMSO)_4]$[18] and the ligand 4,4′-bis(diethylaminostyryl)-[2,2′]-bipyridine[19] were prepared using published methods. The complex (**B**,$[PF_6]_2$) has already been published[9] but its NMR spectroscopic data are completed for comparison.

Characterization of (B,$[PF_6]_2$): ^{1}H NMR (CD_2Cl_2, 298 K): δ = 8.32 (br. s, 6 H, H_3), 7.5 (d, ^1J = 6 Hz, 6 H, H_6), 7.44 (d, ^1J = 8 Hz, 12 H, H_{10}), 7.35 (d, ^1J = 16 Hz, 6 H, H_8), 7.31 (d, ^1J = 6 Hz, 6 H, H_5), 6.89 (d, ^1J = 16 Hz, 6 H, H_7), 6.6 (d, J = 8 Hz, 12H, H_{11}), 3.3 (br. m, 24 H, H_{12}), 1.1 (t, ^1J = 6.5 Hz, 36H, H_{13}). − ^{13}C NMR (CD_2Cl_2, 298 K): δ = 157.0 (C_2), 150.0 (C_6), 149.1 (C_{12}), 147.6 (C_4), 137.2 (C_8), 129.5 (C_{10}), 122.8 (C_5), 122.3 (C_9), 120.1 (C_3), 117.6 (C_7), 111.6 (C_{11}), 44.6 (C_{13}), 12.4 (C_{14}). − ^{31}P NMR (CD_2Cl_2, 298 K): δ = −144 (hept, J = 712 Hz). − UV/Vis (CH_2Cl_2): λ_{max} = 520 (150000), 446 nm (142000). − HRMS-FAB ($C_{102}H_{114}F_6N_{12}PRu$, {[B][$PF_6$]}$^+$): calcd. 1753.8004; found1753.7971.

Preparation of (B,[TRISPHAT]$_2$): $[RuCl_2(DMSO)_4]$ (250 mg, 51.6 mmol, 1 equiv.) and 4,4′-bis(diethyl-aminostyryl)-2,2′-bipyridine (777 mg, 1.55 mmol, 3 equiv.) were dissolved in dimethylformamide (10 mL). The dark red solution was stirred overnight in refluxing DMF. After cooling to room temperature, [$HNBu_3$][TRISPHAT] (986 mg, 1.03 10^{-3} mol, 2 equiv.) was added. After stirring for 30 min. at room temperature, a dark red solid was precipitated out by addition of water (100 mL). The complex was filtered off and purified by column chromatography (silica gel, CH_2Cl_2). The solvent was removed under vacuum to afford a dark red microcrystalline powder (1.22 g, 67% yield). − ^{1}H NMR (CD_2Cl_2, 298 K): δ = 8.29 (br. s, 6 H, H_3), 7.98 (d, ^1J = 6 Hz, 6 H, H_6), 7.3 (d, ^1J = 8 Hz, 12 H, H_{10}), 7.1 (d, ^1J = 16 Hz, 6 H, H_8), 7.09 (d, ^1J = 6 Hz, 6 H, H_5), 6.62 (d, ^1J = 16 Hz, 6 H, H_7), 6.6 (d, ^1J = 8 Hz, 12 H, H_{11}), 3.3 (br. m, 24 H, H_{12}), 1.1 (t, ^1J = 6.5 Hz, 36 H, H_{13}). − ^{13}C NMR (CD_2Cl_2, 298 K): δ = 156.9 (C_2), 151.0 (C_6), 149.0 (C_{12}), 147.0 (C_4), 136.3 (C_8), 129.4 (C_{10}), 122.5 (C_5), 122.2 (C_9), 119.9 (C_3), 117.3 (C_7), 111.4 (C_{11}), 44.5 (C_{13}), 12.4 (C_{14}), 141.6 (d, J = 6 Hz, TRISPHAT), 122.66 (TRISPHAT), 114.0 (d, J = 20 Hz, TRISPHAT). − ^{31}P NMR (CD_2Cl_2, 298 K): δ = −80.5 (s). − UV/Vis (CH_2Cl_2): λ_{max} = 520 (146000), 447 nm (143000). − HRMS-FA) ($C_{120}H_{114}Cl_{12}N_{12}O_6PRu$, {**B**,[TRISPHAT]}$^+$): calcd. 2377.3995; found 2377.3927. − $C_{138}H_{114}Cl_{24}N_{12}O_{12}P_2Ru$: calcd. Copper Complexes as Functional Models for Dopamine β-Hydroxylase – Mechanistic Study of Oxygen Atom Transfer from Cu/O Species to Benzylic C−H Bonds[‡]

Ingrid Blain,[a] Michel Giorgi,[a] Innocenzo De Riggi,[b] and Marius Réglier*[a]

Keywords: Copper / Enzymes / Radicals / RPY2 ligand / Oxygen atom transfer / O-O activation

The mechanism of the oxygen atom transfer reaction mediated by copper-oxygen species has been studied through a substrate-binding ligand approach. Oxidations of copper 5-X-IndPY2 type complexes in which an electron donating (X = OMe) or withdrawing group (X = CN) substitutes the aromatic nucleus in position 5, lead to compounds **2b,c** and **3b,c** resulting from benzylic hydroxylations. With these complexes, where one of the benzylic positions is influenced by a *para* substituent (leading to **2b,c**) while the other suffers influence from the *meta* group (leading to **3b,c**), we observe that the ratio **2**:**3** > 1 is in favor of a certain electrophilicity of the copper/oxygen species responsible for the hydroxylations. While a concerted mechanism cannot be excluded, the results are in favor of a two-step mechanism involving radical species.

Introduction

The mechanism of O_2 activation by copper-containing mono-oxygenases such as dopamine β-hydroxylase (DBH; benzylic hydroxylation of dopamine into noradrenaline) is of current interest.[1] Given that this enzymatic process involves the formation of highly reactive Cu/O radical species, which are responsible for hydrogen atom abstraction from the substrate, the Cu/O_2 chemistry has been the subject of recent investigations and considerable progress in the understanding of structural and spectroscopic aspects was made through biomimetic studies using copper complexes as active site models.[2,3] Recently, using the substrate-binding ligand approach,[4] Itoh and co-workers have described the first benzylic hydroxylation at the β-position of a tertiary amino group similarly to that of DBH.[5] This approach involved the study of copper complexes derived from RPY2-type ligands, in which a phenethylamine "substrate" is covalently bound to the tertiary amino group of the ligand, favoring conditions for an intramolecular oxygen atom transfer. An important feature of Itoh's hydroxylation is that not only does it occur during the reaction of the [PhenPY2]Cu^{I} complex with O_2 (condition I) but also under conditions close to the enzymatic reaction where the [PhenPY2]Cu^{II} complex is reduced first by benzoin before the reaction with O_2 (condition II). A detailed study of intermediates formed under condition I showed that upon reaction with O_2 the first step is the formation of the side-on $[L_2Cu_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)]^{2+}$ species.[6] A detailed kinetic study including solvent, *p*-substituent and the kinetic deuterium isotope effects suggested the rate-determining step of the benzylic hydroxylation of the ligand to be the O−O bond homolysis of the μ-η^2:η^2-peroxodicopper(II) intermediate to give a bis(μ-oxo)dicopper species $[Cu_2^{III}(\mu\text{-}O)_2]^{2+}$ (Scheme 1: **A** → **B**).[7]

In order to get more information on the Oxygen Atom Transfer to the Ligand (OATL) involved in these reactions (Scheme 1: **B** → **C**), we studied the reaction of copper complexes derived from a RPY2 ligand in which a 2-aminoindane "substrate" is used.[8] Due to a five-membered ring structure fused to an aromatic nucleus, 2-aminoindane is a very promising substrate for studying the stereochemistry of the transfer of an oxygen atom. Indeed, 2-aminoindane possesses two benzylic stereogenic centers, each bearing two hydrogen atoms and the stereochemistry of aminoindanols obtained after hydroxylation (*cis* vs. *trans*) can be regarded as an indicator for the stereoselectivity of the oxygen atom transfer.[9] On the other hand, the two equivalent benzylic positions in 2-aminoindane can be differentiated by benzylic mono substitution with a deuterium atom (Scheme 2: **1a**). In this way, the process involving an insertion into a C−H bond competes with a process involving an insertion into a C−D bond. The ratio of compounds **2**:**3** (Scheme 2) resulting from these two processes is related to the deuterium kinetic isotope effect (DKIE) of the reaction.

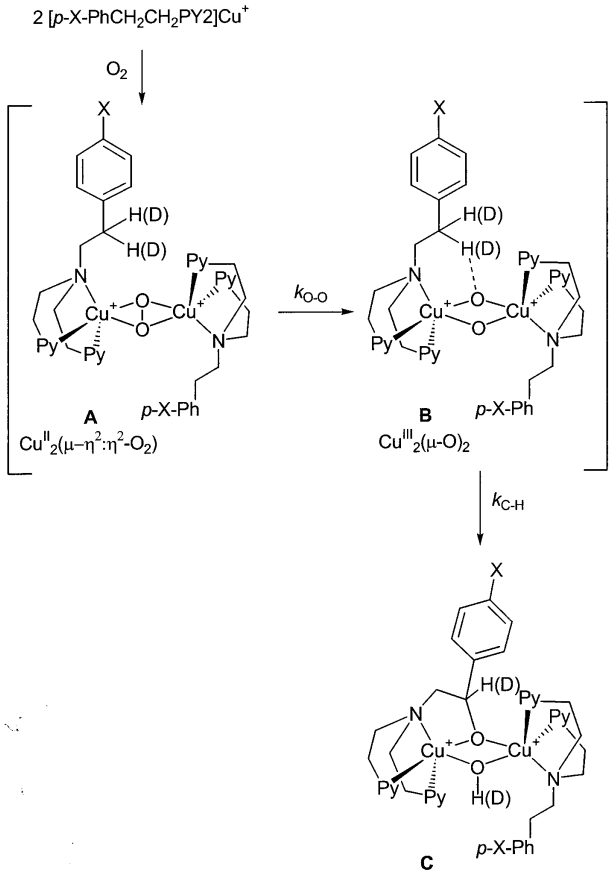
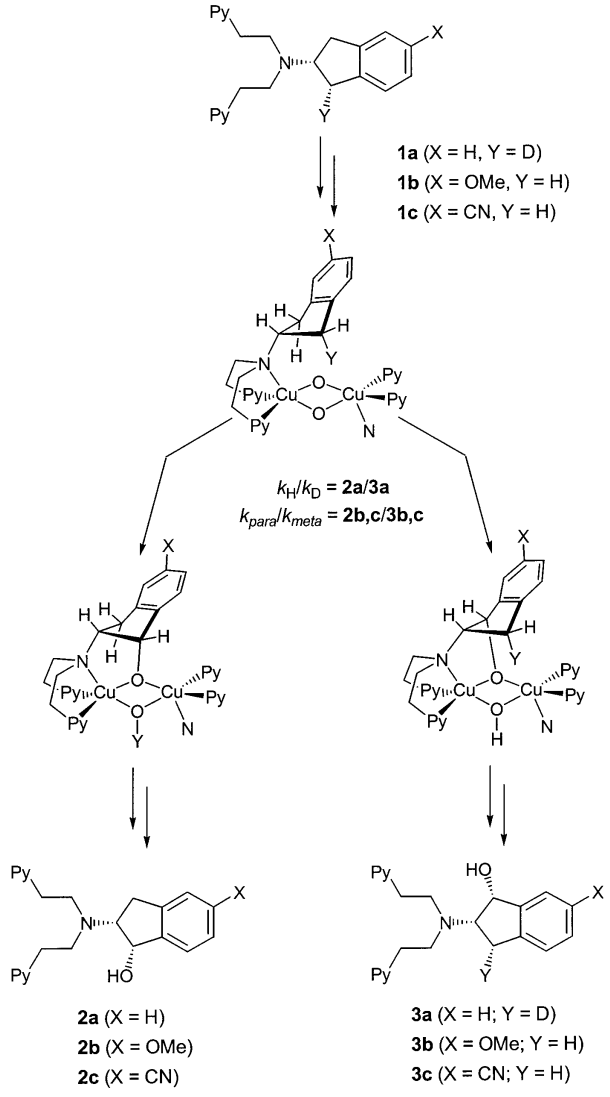


Scheme 1. Substrate-binding ligand approach

With copper complexes derived from ligand **1a** (Table 1, runs 1−2), we demonstrated that the oxygen atom transfer occurs with retention of configuration and we determined a DKIE of 11 and 7.6 for conditions I and II, respectively. In order to study the substituent effect on the oxygen atom transfer reaction and using the same strategy, we describe now the elaboration of new ligands **1b,c** in which an electron donating (OMe) or withdrawing group (CN) substitutes the aromatic nucleus in position 5. With these ligands, where one of the benzylic positions is influenced by a *para* substituent while the other suffers influence from the *meta* group, the oxygen atom transfer should be influenced by various electronic factors and the ratio of compounds **2**:**3** resulting from this transformation should give information on the k_{para}/k_{meta} ratio as well as the mechanism of the OATL process.

Results and Discussion

The ligands 5-X-IndPY2 **(1b,c)** and 7-X-TetralPY2 **(1d,e)** were synthesized by Michael addition of the corresponding primary amines to freshly distilled 2-vinyl pyridine in a methanol/acetic acid mixture. The copper(I) complexes [5-X-IndPY2]$CuPF_6$ and [7-X-TetralPY2]$CuPF_6$ were prepared by reaction of $[CH_3CN]_4CuPF_6$ and the corresponding ligands in dichloromethane. The corresponding copper(II) complexes [5-X-IndPY2]$Cu(CF_3SO_3)_2$ and [7-X-TetralPY2]$Cu(CF_3SO_3)_2$ were obtained in nearly quantitative yields by complexation of the ligands with $Cu(CF_3SO_3)_2$ in methanol. Recrystallization from dichloromethane using the diethyl ether vapor diffusion technique afforded blue crystals of [7-OMe-TetralPY2]$Cu(CF_3SO_3)_2$ which were suitable for X-ray diffraction analysis (Table 2, Figure 1).



Scheme 2. 2-Aminoindane in substrate-binding ligand approach

The oxidation of copper complexes derived from 5-X-IndPY2 ligands **1b,c** was performed in dichloromethane under conditions I and II. After demetallation of the resulting copper(II) complexes with 35% aqueous ammonia the oxidation products were analyzed by NMR spectroscopy. Under condition I, the oxidation led to a 1:1 mixture of the recovered ligands **1b,c** and the two hydroxylated ligands **2b,c** and **3b,c** (Table 1, runs 3 and 5). Under condition II, these two compounds **2b,c** and **3b,c** were also obtained but in quantitative yields (Table 1, runs 4 and 6). Because it was impossible to separate them by chromatography, their structure and the ratios were determined by NMR spectroscopic analysis of the mixture. To achieve this, the first task was the complete assignment of all protons and carbons by

[a] We could not obtain a very good R value during the structure refinement because the diffracted intensities (high mosaicity and anisotropic shape of the samples) and the resolution (few intensities could be measured until 2θ = 48°) were low. As the absorption corrections did not give better results, we did not use them in the last refinement cycles.

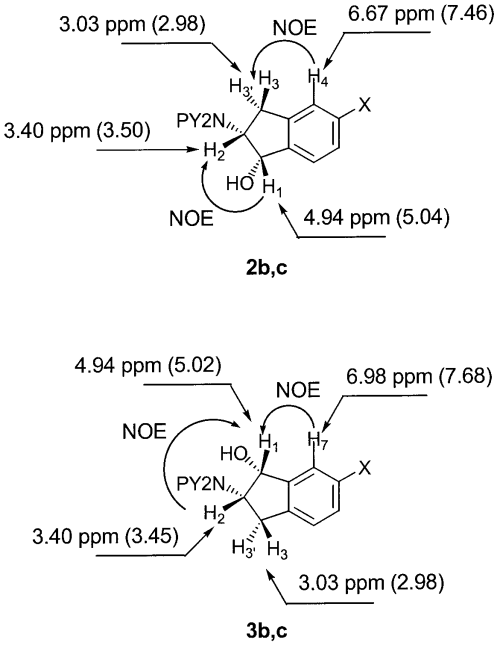
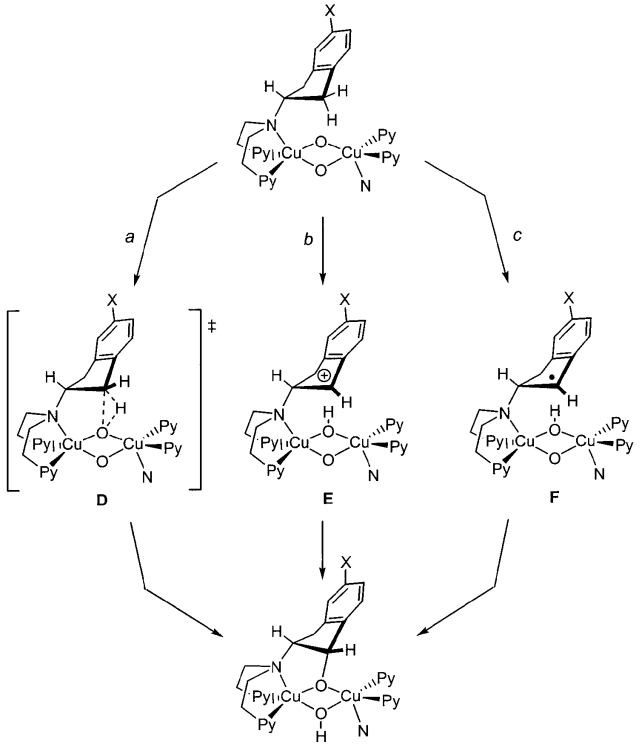
homo- and heteronuclear correlation experiments (COSY gradient, HMQC and HMBC). Then two dimensional NOESY sequences revealing several interesting Nuclear Overhauser Effects (NOE) allowed us to attribute the fine structure of compounds **2b,c** and **3b,c** (Scheme 3). First of all, an NOE between protons H_1 and H_2 allowed the assignment of the *cis* stereochemistry of the 1,2-amino alcohol. In order to attribute the structure of the major compound, we first localized on the ^{1}H NMR spectra protons in the *ortho* position of the X substituent (numbered H_4 for **2b,c** and H_7 for **3b,c**). In both cases these protons show an NOE with the two benzylic protons H_3 for the major isomers, while the minor isomers show an NOE with proton H_1. These results indicate unambiguously that the major isomers correspond to the *para*-hydroxy compounds **2b,c**, and the minor isomer to the *meta*-hydroxy compounds **3b,c**. Integration of protons corresponding to **2b,c** and **3b,c** gave the *para*/*meta* ratios reported in Table 1.

In compounds **1b,c**, whatever the nature of the substituent (OMe vs. CN) and under reaction conditions I or II, hydroxylation preferentially occurs in the *para* position. The effects are more important for the electron donating OMe group (**2b**/**3b** = 3.3 and 4.3) than for the electron-withdrawing CN (**2c**/**3c** = 1.5 and 2.3). This is in favor of a certain electrophilicity of the copper/oxygen species responsible for the hydroxylations. In one of our previous studies, the higher DKIE observed under condition I compared to that of condition II (11 vs. 7.6) was rationalized as the occurrence of two different copper-oxygen intermediates.[10] Though being low, the differences observed in the **2**:**3** ratios confirm once again this former interpretation. Under condition I, the occurrence of a bis(μ-oxo)dicopper



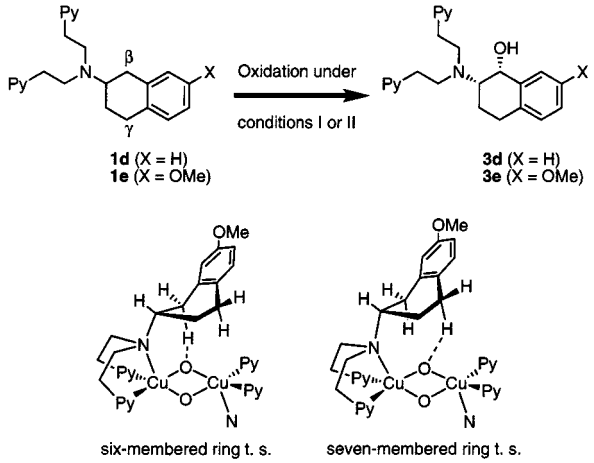
Scheme 3. Some Nuclear Overhauser Effects observed with compounds **2b,c** and **3b,c**. Chemical shifts are reported for X = MeO and in parenthesis for X = CN



Scheme 4. Possible mechanisms for the oxygen atom transfer

species $[Cu_2^{III}(\mu\text{-}O)_2]^{2+}$ is now well accepted as the principal active species in oxygen atom transfer. But in the presence of benzoin (condition II), the structure of the active copper/oxygen species is less clear and several structures can be proposed. Among them, species involving the mixed valence $[Cu^{II}Cu^{III}(\mu\text{-}O)_2]^{2+}$ intermediates or the oxygen radical species $[Cu^{II}-O^{\bullet}]^{+}$ ($\equiv [Cu^{III}-O^{-}]^{+}$) are very attractive.[10] Possible pathways consistent with these structures and an intramolecular oxygen atom insertion into the benzylic C−H bond are presented in Scheme 4. The high **2**:**3** ratios observed with 5-OMe-IndPY2 ligand (Table 1, runs 3 and 4) could be in favor of a hydride abstraction (Scheme 4, pathway *b*) and a carbocation intermediate **E**. Although these values indicate transition-state stabilization by an electron donating group, they are small compared with values normally observed in reactions involving benzylic carbocation intermediates. Moreover, with the 5-CN-IndPY2 ligand, we would expect a more marked effect in favor of the *meta* product **3c**. Indeed, according to the Hammet equation $\log(k/k_0) = \sigma\rho$,[11] values of $\log(k_{para}/k_{meta})$ can be estimated by the expression $\rho(\sigma_p-\sigma_m)$. Considering that for reactions involving benzylic carbocation intermediates, the ρ value is less than −2, we would expect a k_{para}/k_{meta} ratio of 6 and 0.6 for MeO and CN groups, respectively.[12] These results, which seem to be unfavorable to the intermediacy of **E**, could be in favor of a concerted mechanism (Scheme 4: pathway *a*) where a positive minimal charge development in the transition state may be envisaged. However, initial radical formation (Scheme 4: pathway *c*) by a hydrogen atom abstraction by the Cu−O core seems to be more reasonable, since Mayer has recently shown that metal-oxo complexes can oxidize hydrocarbons by a hydrogen-atom abstraction mechanism which is attributed to their thermodynamic affinity for a hydrogen atom ($\equiv H^+ + e^-$).[13] This proposal is all the more reasonable as similar values of the k_{para}/k_{meta} ratio are often seen in radical-generating systems. Indeed, for benzylic H abstraction of *p*- or *m*-substituted toluenes by *t*BuOO$^{\bullet}$ (*t*BuO$^{\bullet}$) radical the ratios k_{para}/k_{meta} were found to be 3.14[14] and 1.3[14] (1.0[15]) for OMe and CN groups, respectively.[16]

All of our results and those described in the literature, concern hydroxylation occurring in the β position of a tertiary amino group of the ligand. In order to study the factors that govern the oxygen atom transfer, we decided to examine the hydroxylation of ligands derived from 2-aminotetralin compounds. Like 2-aminoindane, 2-aminotetralin possesses two benzylic carbons but one is in the β position while the second is in the γ position with respect to the amino group. Moreover, the γ position can be activated by a OMe substituent in position 7 of the aromatic ring and it would be interesting to know whether this activation would be enough for directing the hydroxylation towards this benzylic position. Under both oxidation conditions, hydroxylation takes place at the β benzylic carbon even when an OMe substituent is present in position 7 of the aromatic ring (Table 1, runs 7−10). This is evident from the ^{1}H NMR spectrum, which shows a doublet at δ = 4.65 (**3d**) and 4.60 (**3e**) with coupling constants ^3J = 3.4 Hz characteristic for a *cis* stereochemistry.[17] Our results demonstrate that the six-membered transition state is more favorable than the seven-membered one even when an OMe



Scheme 5. 7-X-TetralPY2 ligands **1d,e** in oxygen atom transfer reaction

substituent activates the γ benzylic position (Scheme 5). It might be hazardous to consider the Cu−O core as an oxygen centered radical, however, we can see here a similarity to Barton's reaction where an intramolecular δ C−H bond activation by an alkoxy radical takes place.[18]

Conclusion

Several examples of OATL are described in the literature demonstrating that the substrate binding ligand approach gives valuable information about the active species involved in the copper−dioxygen activation. However, two problems remain. The first one concerns the mechanism of the oxygen atom transfer. The question is to determine whether the oxygen atom transfer occurs in a concerted pathway or in a two step process involving radical intermediates. For the moment, it is difficult to answer this fundamental question. More experiments are needed, notably using a radical clock fixed on the tertiary amino group of the ligand. The second problem concerns the catalytic aspect of the oxygen atom transfer. Few examples of oxygen atom transfer from a copper center to an exogenous substrate are known.[19,20] To achieve this, the substrate association in the copper coordination sphere still remains to be solved.[21] We think this will be an exciting challenge for the organic chemist.

Experimental Section

General: Solvents were freshly distilled under Ar (MeOH/Mg, Et_2O/Na-benzophenone ketyl, CH_3CN/CaH_2 and CH_2Cl_2/P_2O_5). Deoxygenation of solvents and solutions was carried out by 3 vacuum/purge cycles. Preparations and handling of air sensitive compounds were carried out using standard Schlenk techniques. Commercial starting materials were used without further purification, except for 2-vinylpyridine, which was distilled prior to use. 2-Amino-5-methoxyindane was prepared in two steps from 5-methoxy-1-indanone by a procedure described in the literature.[22] 2-Amino-5-cyanoindane was prepared in six steps from 5-bromo-1-indanone.[23] 2-Aminotetralin and 2-amino-7-methoxytetralin were obtained by reductive amination of the corresponding 2-tetralones.[24] NMR spectra were recorded at 25 °C on Bruker AC-200 or AMX-400 spectrometers. Chemical shifts are reported in ppm as δ values downfield from an internal standard of TMS. Homo- and heteronuclear correlations were obtained by COSY gradient, HMQC and HMBC techniques with a 5 mm reverse probehead using a *z* field gradient. 2D-NOESY experiments were performed with a 5 mm $^1H/^{13}C$ DUAL probehead.

Ligands 1b−e: To absolute MeOH were added 2-vinylpyridine, primary amine and acetic acid. After refluxing for several days, MeOH was evaporated and 15% NaOH was added. The product was extracted with CH_2Cl_2 and the organic layer dried over Na_2SO_4. Evaporation of CH_2Cl_2 under reduced pressure (18 Torr) left the crude product. Flash chromatography (SiO_2, CH_2Cl_2/MeOH 95:5) afforded the pure ligands (Table 3).

1b: ^1H NMR (200 MHz, $CDCl_3$): δ = 2.65−2.85 (m, 2 H), 2.90−3.10 (m, 10 H), 3.65−3.80 (m, 1 H), 3.75 (s, 3 H), 6.60−6.75 (m, 2 H), 7.00−7.20 (m, 5 H), 7.55 (td, *J* = 7.5 and 1.7 Hz, 2 H), 8.50 (ddd, *J* = 4.8, 1.7 and 1 Hz, 2 H). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 36.1 (CH_2-ind), 36.2 (2 CH_2), 37.3 (CH_2-ind), 51.5 (2 CH_2), 55.4 (CH_3O), 63.6 (CHN), 110.0 (CH-aryl), 112.2 (CH-aryl), 121.1 (2 CH-pyr), 123.4 (2 CH-pyr), 125.0 (CH-aryl), 133.8 (C-aryl), 136.2 (2 CH-pyr), 143.2 (C-aryl), 149.3 (2 CH-pyr), 158.7 (C-aryl), 160.7 (2 C-pyr).

1c: ^1H NMR (200 MHz, $CDCl_3$): δ = 2.70−3.10 (m, 12 H), 3.75 (m, 1 H), 7.20 (d, *J* = 8.2 Hz, 1 H), 7.30−7.40 (m, 6 H), 7.55 (td, *J* = 7.5 and 1.7 Hz, 2 H), 8.50 (ddd, *J* = 5.5, 1.7 and 1 Hz, 2 H). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 35.8 (2 CH_2), 36.4 (CH_2-ind), 40.0 (CH_2-ind), 51.2 (2 CH_2), 62.7 (CHN), 109.9 (C-aryl), 119.4 (CN), 121.2 (2 CH-pyr), 123.4 (2 CH-pyr), 125.2 (CH-aryl), 127.9 (CH-aryl), 130.5 (CH-aryl), 136.3 (2 CH-pyr), 143.0 (C-aryl), 147.6 (C-aryl), 149.2 (2 CH-pyr), 160.2 (2 C-pyr).

1d: ^1H NMR (200 MHz, $CDCl_3$): δ = 1.50−1.70 (m, 1H), 2.00−1.85 (m, 1H), 2.95−3.05 (m, 13 H), 6.96−7.10 (m, 8H), 7.54 (td, *J* = 7.5 and 1.7 Hz, 2 H), 8.51 (ddd, *J* = 4, 1.7 and 1 Hz, 2 H). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 25.0 (CH_2-tetral), 29.7 (CH_2-tetral), 32.3 (CH_2-tetral), 38.0 (2 CH_2), 50.9 (2 CH_2), 56.9 (CHN), 121.1 (2 CH-pyr), 123.6 (2 CH-pyr), 125.5 (CH-aryl), 125.6 (CH-aryl), 128.5 (CH-aryl), 129.4 (CH-aryl), 136.1 (2 CH-pyr), 136.3 (2 C-aryl), 149.1 (2 CH-pyr), 160.7 (2 C-pyr).

1e: ^1H NMR (200 MHz $CDCl_3$): δ = 1.55 (qd, *J* = 11.7 and 6.5 Hz, 1 H), 1.85−2.00 (m, 1 H), 2.65−2.76 (m, 4 H), 2.90−3.07 (m, 9 H), 3.72 (s, CH_3O), 6.53 (d, *J* = 2.7 Hz, 1 H), 6.62 (dd, *J* = 8.2 and 2.7 Hz, 1 H), 6.92 (d, *J* = 8.2 Hz, 1 H), 7.03−7.12 (m, 4 H), 7.52 (td, *J* = 7.6 and 1.7 Hz, 2 H), 8.48 (ddd, *J* = 5.8, 1.7 and 1 Hz, 2 H). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 26.0 (CH_2-tetral), 28.9 (CH_2-tetral), 32.5 (CH_2-tetral), 38.0 (2 CH_2), 50.9 (2 CH_2), 55.2 (CH_3O), 57.0 (CHN), 112.0 (CH-aryl), 113.9 (CH-aryl), 121.1 (2 CH-pyr), 123.6 (2 CH-pyr), 128.4 (C-aryl), 129.4 (CH-aryl), 136.1 (2 CH-pyr), 137.4 (C-aryl), 149.2 (2 CH-pyr), 157.4 (C-aryl), 160.6 (2 C-pyr).

Copper(II) Complexes: To a solution of $Cu(CF_3SO_3)_2$ in MeOH was added dropwise a solution of the ligand in MeOH. This mixture was then stirred for 30 min. MeOH was evaporated in vacuo and Et_2O was added. The precipitate was filtered off, washed with Et_2O and dried in vacuo to give the copper(II) complexes as blue solids (Table 4).

General Procedure for the Oxidation of Copper(I) Complexes by O_2 (Condition I): To a solution of $[CH_3CN]_4CuPF_6$ (100 μmol) in degassed CH_2Cl_2 (50 mL) was added dropwise a solution of ligand **1b−e** (100 μmol) in CH_2Cl_2 (50 mL). The mixture was allowed to stir under Ar for 1 h, and then exposed to O_2 atmosphere for 24

h. Then, CH_2Cl_2 was evaporated in vacuo and Et_2O was added and the precipitate obtained was centrifuged, washed with Et_2O and dried in vacuo to give a mixture of copper(II) complexes. This mixture was dissolved in CH_2Cl_2 (20 mL), washed with 35% NH_4OH (5 mL), brine (3 × 5 mL) and dried over Na_2SO_4. Evaporation of CH_2Cl_2 under reduced pressure (18 Torr) gave the crude product. Flash chromatography (SiO_2, CH_2Cl_2/MeOH 90:10) afforded the recovered ligands **1b−e** and a mixture of compounds **2b,c** and **3b,c** (**3d,e**).

General Procedure for the Oxidation of Copper(II) Complexes by O_2 in the Presence of Benzoin (Condition II): To a solution of copper(II) complex (100 µmol) in degassed CH_2Cl_2 (6 mL) were added benzoin (200 µmol) and NEt_3 (200 µmol). This mixture was stirred under Ar for 2 h and then exposed to O_2 atmosphere for 24 h. CH_2Cl_2 was evaporated in vacuo and Et_2O was added. The precipitate obtained was centrifuged, washed with Et_2O and dried in vacuo to give a mixture of copper(II) complexes. This mixture was dissolved in CH_2Cl_2 (20 mL), washed with 35% NH_4OH (5 mL), brine (3 × 5 mL) and dried over Na_2SO_4. Evaporation of CH_2Cl_2 under reduced pressure (18 Torr) gave the crude product. Flash chromatography (SiO_2, CH_2Cl_2/MeOH 90:10) afforded compounds **2b,c** and **3b,c** (**3d,e**).

2b: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.95 (dd, *J* = 15 and 7 Hz, 1 H), 2.98−3.09 (m, 5 H), 3.10−3.25 (m, 4 H), 3.40 (m, 1 H), 3.75 (s, CH_3O), 4.94 (d, *J* = 5 Hz, 1 H), 6.71−6.75 (m, 2 H), 7.08 (ddd, *J* = 7, 5 and 1 Hz, 2 H), 7.12 (d, *J* = 8 Hz, 2 H), 7.33 (d, *J* = 9 Hz, 1 H), 7.55 (td, *J* = 8 and 2 Hz, 2 H), 8.50 (bd, *J* = 5 Hz, 2 H). − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 34.3 (CH_2-Ind), 34.4 (2 CH_2), 49.9 (2 CH_2), 55.4 (CH_3O), 67.0 (CHN), 72.7 (CHOH), 110.3 (CH-aryl), 112.9 (CH-aryl), 121.5 (2 CH-pyr), 123.7 (2 CH-pyr), 126.5 (CH-aryl), 135.6 (C-aryl), 136.6 (2 CH-pyr), 143.4 (C-aryl), 149.4 (2 CH-pyr), 160.0 (2 C-pyr), 160.5 (C-aryl).

2c: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.95−3.00 (m, 5 H), 3.02 (m, 1 H), 3.08−3.20 (m, 4 H), 3.50 (m, 1 H), 5.04 (d, *J* = 5.4 Hz, 1 H), 7.05−7.10 (m, 4 H), 7.45−7.50 (m, 3 H), 7.53 (td, *J* = 8 and 2 Hz, 2 H), 8.46 (dd, *J* = 5 and 1.6 Hz, 2 H). − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 34.4 (CH_2-Ind), 34.5 (2 CH_2), 49.6 (2 CH_2), 66.3 (CHN), 73.4 (CHOH), 119.2 (CN), 123.6 (2 CH-pyr), 112.1 (C-aryl), 121.4 (2 CH-pyr), 126.1 (CH-aryl), 128.4 (CH-aryl), 131.2 (CH-aryl), 136.5 (2 CH-pyr), 142.8 (C-aryl), 148.7 (C-aryl), 149.1 (2 CH-pyr), 159.6 (2 C-pyr).

3b: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.95 (dd, *J* = 15 and 7 Hz, 1 H), 2.98−3.09 (m, 5 H), 3.10−3.25 (m, 4 H), 3.40 (m, 1 H), 3.76 (s, CH_3O), 4.94 (d, *J* = 5 Hz, 1 H), 6.88 (dd, *J* = 8 and 2 Hz, 1 H), 6.98 (d, *J* = 2 Hz, 1 H), 7.20−7.00 (m, 1 H), 7.08 (ddd, *J* = 7, 5 and 1 Hz, 2 H), 7.12 (d, *J* = 8 Hz, 2 H), 7.55 (td, *J* = 8 and 2 Hz, 2 H), 8.50 (bd, *J* = 5 Hz, 2 H). − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 33.1 (CH_2-Ind), 34.4 (2 CH_2), 49.9 (2 CH_2), 55.5 (CH_3O), 66.9 (CHN), 73.7 (CHOH), 110.3 (CH-aryl), 115.5 (CH-aryl), 121.5 (2 CH-pyr), 123.7 (2 CH-pyr), 125.6 (CH-aryl), 135.6 (C-aryl), 136.6 (2 CH-pyr), 143.4 (CH-aryl), 149.4 (2 CH-pyr), 159.2 (C-aryl), 160.0 (2 C-pyr).

3c: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.95−3.00 (m, 5 H), 3.02 (m, 1 H), 3.08−3.20 (m, 4 H), 3.45 (m, 1 H), 5.02 (d, *J* = 5.8 Hz, 1 H), 7.05−7.10 (m, 4 H), 7.28 (d, *J* = 8 Hz, 1H), 7.45−7.50 (m, 1 H), 7.53 (td, *J* = 8 and 2 Hz, 2 H), 7.68 (d, *J* = 1 Hz, 1 H), 8.46 (dd, *J* = 5 and 1.6 Hz, 2 H). − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 34.0 (CH_2-Ind), 34.5 (2 CH_2), 49.6 (2 CH_2), 66.4 (CHN), 73.2 (CHOH), 110.6 (CH-aryl), 119.2 (CN), 121.4 (2 CH-pyr), 123.6 (2 CH-pyr), 125.6 (CH-aryl), 129.1 (CH-aryl), 132.6 (CH-aryl), 136.5 (2 CH-pyr), 144.8 (C-aryl), 147.4 (C-aryl), 149.1 (2 CH-pyr), 159.6 (2 C-pyr).

3d: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.00 (m, 1 H), 2.62−3.10 (m, 10 H), 3.10−3.30 (m, 1 H), 4.65 (d, *J* = 3.4 Hz, 1 H), 6.98−7.10 (m, 5 H), 7.10−7.20 (m, 2 H), 7.35 (m, 1 H), 7.50 (td, *J* = 7.5 and 2 Hz, 2 H), 8.48 (dd, *J* = 5 and 1 Hz, 2 H). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 19.9 (CH_2-tetral), 29.5 (CH_2-tetral), 35.8 (2 CH_2), 49.7 (2 CH_2), 61.6 (CHN), 68.34 (CHOH), 121.2 (2 CH-pyr), 123.6 (2 CH-pyr), 126.0 (CH-aryl), 127.6 (CH-aryl), 128.2 (CH-aryl), 130.6 (CH-aryl), 136.3 (2 CH-pyr), 137.4 (2 C-aryl), 149.0 (2 CH-pyr), 160.0 (2 C-pyr).

3e: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.95 (m, 2 H), 2.60−3.30 (m, 11 H), 3.80 (s, CH_3O), 4.60 (d, *J* = 3.4 Hz, 1 H), 6.75 (dd, *J* = 8.6 and 2.8 Hz, 1 H), 6.90 (d, *J* = 2.8 Hz, 1 H), 7.10−6.95 (m, 5 H), 7.50 (td, *J* = 7.5 and 2 Hz, 2 H), 8.50 (dd, *J* = 5, 2 and 1 Hz, 2 H). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 20.2 (CH_2-tetral), 28.7 (CH_2-tetral), 35.9 (2 CH_2), 49.8 (2 CH_2), 55.4 (CH_3O), 61.6 (CHN), 68.5 (CHN), 114.2 (C-aryl), 114.8 (CH-aryl), 121.2 (2 CH-pyr), 123.6 (2 CH-pyr), 128.5 (C-aryl), 129.2 (C-aryl), 136.3 (2 CH-pyr), 138.5 (C-aryl), 149.1 (2 CH-pyr), 157.9 (C-aryl), 160.2 (2 C-pyr).

X-ray Structure Analysis: Crystal data for [7-OMe-TetralPY2]-$Cu(CF_3SO_3)_2$ together with details of the X-ray diffraction experiment, are reported in Table 4.

Crystallographic data for the structure reported in this paper has been deposited at the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-137161. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033, E-mail: deposit@chemcrys.cam.ac.uk].

Keywords: Ferrocene / Molybdenum / Multiple bonds / Oligomers / Rhodium

The tetranuclear compounds $Mo_2(O_2CCF_3)_4(FPA)_2$ (**1**), $Rh_2(O_2CCH_3)_4(FPA)_2$ (**2**), and $Rh_2(O_2CCF_3)_4(FPA)_2$ (**3**) (FPA = ferrocenyl-4-pyridylacetylene) have been synthesized by the reaction of bimetallic tetraacetates with FPA in a 1:2 stoichiometry. They have been investigated as models of oligomeric and polymeric complexes of analogous composition. UV/Vis absorption spectroscopy and cyclic voltammetry indicate that $Rh_2(O_2CCF_3)_4$ possesses the strongest inductive effect of the three bimetallic tetracarboxylates examined in this study. Complex **1** was additionally characterized by single crystal X-ray analysis, revealing a Mo–Mo distance of 214.22(3) pm, which is elongated in comparison to $Mo_2(O_2CCF_3)_4$ [209.0(4) pm], and a Mo–N distance of 250.4(2) pm. Oligomers with backbones consisting of 1,1′-bis(4-pyridylethynyl)ferrocene (BPEF) and bimetallic tetracarboxylates, $[M_2(O_2CR)_4(BPEF)]_n$ (M = Mo, R = CF_3, **4**; M = Rh, R = CH_3, **5**; M = Rh, R = CF_3, **6**), have been prepared by treating the bimetallic tetracarboxylates with BPEF in a 1:1 molar ratio. The terminal groups and the number of repeating units have been estimated by elemental analyses. The oligomeric complexes **5** and **6** are insoluble in all common solvents. Complex **4** dissolves in strongly coordinating donor solvents due to replacement of the BPEF ligands by solvent molecules.

Introduction

Polymers and oligomers containing metal-metal bonds in the backbone may display novel conductive, optical, and magnetic properties.[1] A number of bimetallic carboxylates[1f,2a] have been linked by bidentate axial ligands, resulting in one-dimensional polymeric species. Pyrazine has been used to link $Cr_2(O_2CCH_3)_4$,[2b] $Mo_2(O_2CCH_3)_4$,[3a] $Cu_2(O_2CCH_3)_4$,[3b] and $Ru_2\{O_2C(CH_2)_6CH_3\}_4$.[3c] $Mo_2(O_2CCF_3)_4$ units have been linked by 9,10-anthraquinone, 2,6-dimethyl-1,4-benzoquinone, 1,4-naphthoquinone,[3d] and 2,5-dimethyl-*N*,*N*′-dicyanoquinone diimine (2,5-DM-DCNQI).[3e] $Mo_2(O_2CCH_3)_4$ units have been bridged by 4,4′-bipyridine,[3a] 1,2-bis(dimethylphosphanyl)ethane (dmpe) and tetramethylethylenediamine (tmed).[3f] $Rh_2(O_2CC_2H_5)_4$ units have been linked by phenazine and durenediamine ligands, respectively.[2c] Phenazine has also been employed to connect cationic $Ru_2(O_2CC_2H_5)_4^+$ complexes to afford polymers.[2d] However, to the best of our knowledge, examples of oligomers and polymers based on bimetallic monomers with organometallic spacing groups are not yet known in the literature.[1f] This paper describes the first representatives of bimetallic oligomers bridged by π-conjugated ferrocene derivatives. $Mo_2(O_2CCF_3)_4$ is feasible as a building block because, in principle, the quadruple bond allows a delocalization of electrons along the oligomer chain. Dirhodium tetracarboxylates $Rh_2(O_2CCH_3)_4$ and $Rh_2(O_2CCF_3)_4$ are also employed, taking advantage of their air- and moisture-stability. The replacement of CH_3 by CF_3 is recommended for increasing the solubility and the metal-axial ligand interaction in the oligomer.

Ferrocene-containing complexes are currently receiving much attention due to their increasing role in the rapidly growing area of materials science. They have been of use as charge-transfer complexes and polymers,[4] molecular sensors,[5] and in nonlinear optics.[6] The favorable electrochemical properties of ferrocene make this molecule a particularly promising candidate for incorporation into polymer chains. It is quite obvious that ferrocene polymers are more likely to display exceptional properties when the different metal centers are intimately coupled through suitable unsaturated bridging units.[7] We therefore explore an oligomer system containing both ferrocene and metal-metal bonds in the backbone. Introduction of bimetallic complexes into the ferrocene-based oligomers combines the advantages of both the ferrocene and the metal-metal bonds. Additionally, it allows the use of a wider diversity of metals (Mo, Rh, Re, Cu, Cr, W, Pt, Ru, etc.) and equatorial ligands which may be helpful in fine-tuning the oligomer properties.

Results and Discussion

Tetranuclear Complexes

Preparation and Characterization

In order to better understand the electronic and electrochemical properties of oligomeric complexes of analogous composition, complexes **1**–**3** were synthesized as models by the reaction of dirhodium- or dimolybdenum-tetracarboxylate with the monodentate FPA ligand in a 1:2 molar ratio as shown in Equation (1).

(1)

The dimolybdenum compound **1** decomposes when exposed to air within a couple of hours in the solid state and within 10 minutes in solution. The dirhodium complexes **2** and **3** are air stable. Compounds **1** and **3** are soluble in most polar organic solvents, e.g. CH_2Cl_2, $CHCl_3$, MeCN, THF, etc., but **2** is only soluble in CH_2Cl_2 and $CHCl_3$, due to the commonly lower solubility of acetyl complexes in comparison to trifluoroacetyl compounds.[2a]

The IR active C≡C stretching vibration gives rise to bands at 2207, 2205, and 2206 cm^{-1} respectively for compounds **1**–**3**. This vibration is slightly lower in energy in all cases than in the free FPA ligand (2210 cm^{-1}). The pyridyl ring stretching vibration appears at 1601, 1603, and 1604 cm^{-1}, the corresponding signal of FPA at 1594 cm^{-1}.

The pyridyl protons of **2** [$\delta(H_\alpha)$ = 9.11, $\delta(H_\beta)$ = 7.72] show their resonances at lower field than the free ligand FPA (δ = 8.53 and 7.32, respectively). In contrast, up-field shifts of the α-ring pyridyl protons are observed in compounds **1** (δ = 8.03) and **3** (δ = 8.27), possibly due to the strong electron-withdrawing effect of the trifluoroacetyl ligands, which diminish backbonding effects from the bimetallic cores. The ferrocene proton resonances are comparable for compounds **1**–**3** and the free ligand. The proton NMR signal of the CH_3CO_2 group is shifted downfield in CD_2Cl_2 from δ = 1.76 [axial ligand free $Rh_2(O_2CCH_3)_4$] to δ = 1.88 in the case of complex **2**, demonstrating that electron density must be shifted back to the ferrocenyl unit in the latter molecule. The ^{13}C NMR spectroscopic data of the CH_3 moiety shows the same trend [δ = 23.5 in the starting material $Rh_2(O_2CCH_3)_4$ and δ = 30.1 in the axially ligated product compound].

Attempts to prepare mixed-valence complexes by chemical oxidation have not yet been successful. Treatment of $Rh_2(O_2CCH_3)_4(FPA)_2$ with I_2 in dichloromethane at room temperature resulted in no reaction, while the same treatment carried out on $Mo(O_2CCF_3)_4(FPA)_2$ led to immediate decomposition.

Structural Investigation

The molecular structure of compound **1** together with selected interatomic distances, angles and torsion angles are shown in Figure 1. The neutral complex crystallizes in the space group *P*1(bar) (No. 2). Quadruply bonded dimolybdenum complexes with four bridging $(O_2CCF_3)^-$ ligands usually exhibit a crystallographic center of inversion in the solid state, as does compound **1**. The two pyridyl ligands coordinate to the molybdenum atoms in the axial positions and are slightly bent [Mo_a–Mo–N 165.85(5)°]. Compound **1** and all other 11 crystallographically characterized compounds with a $[Mo_2(\mu\text{-}O_2CCF_3)_4]$ building block exhibit a very similar core geometry.[8] As expected the $[Mo_2(\mu\text{-}O_2CCF_3)_4]$ unit has a nearly idealized D_{4h} symmetry. The observed Mo–Mo bond length of 214.22(3) pm in **1** is found at the upper end of the known range for Mo–Mo quadruple bonds. The elongation of the Mo–Mo bond in comparison to the starting material {$[Mo_2(\mu\text{-}O_2CCF_3)_4]$, *d*(MoMo) = 209.0(4) pm} is clearly due to the electron donor capability of the axial ligands. Donation of additional electron density to a quadruple bond leads to a weakening of the Mo–Mo interaction, caused by the involvement of antibonding orbitals. The Mo–O distances do not vary significantly. The Mo-pyridyl bond is comparatively long [Mo–N 250.4(2) pm], indicating relatively weak molybdenum–nitrogen interactions. However, the Mo–N distance is shorter than expected from the sum of the van der Waals radii (Mo–N: 382 pm) but longer than the sum of the covalent radii (Mo–N: 215 pm).[8] The NMR and IR data described above are in good agreement with all these observations.

Electronic Absorption Spectra

Any perturbation of the electronic structure of the ferrocenes should lead to a bathochromic shift of the respective UV/Vis transitions. Figure 2 presents a comparison of the UV/Vis spectra of complex **2** and FPA. A peak at 365 nm (13600 M^{-1} cm^{-1}) and a broad band around 451 nm (3040 M^{-1} cm^{-1}) in **2** are assigned to d-d transitions in the ferrocene unit.[9] FPA shows similar absorptions at 352 nm (2320 M^{-1} cm^{-1}) and 449 nm (760 M^{-1} cm^{-1}) but significantly lower extinction coefficients. The higher energy d-d transition bands in the spectra of complexes **1** and **3** are probably shoulders of π-π* absorptions. As shown in Table 1, the lower energy absorptions appear around 451 nm (2340 M^{-1} cm^{-1}) and 466 nm (6310 M^{-1} cm^{-1}) in the derivatives **1** and **3**. In addition to the d-d transitions, the spectra show a strong peak assigned to a π-π* transition at about 310 nm: FPA, 304 nm (12800 M^{-1} cm^{-1}); **1**, 305 (37499); **2**, 308 (32800); **3**, 316 (47500). The shift to longer wavelength absorptions in the case of derivatives **1**–**3** compared to unco-

Figure 1. ordinated FPA is probably due to the inductive effects of the dimetallic moieties. The degree of deviation of the bathochromic shifts of both d-d and π-π* transitions of complex **3** vs. FPA are bigger than in the case of compound **2**, due to the strong electron-withdrawing effect of the trifluoroacetyl groups. Complexes **1** and **3** bear the same carboxylato ligand, but the shifts of both d-d and π-π* bands in **3** vs. FPA are more pronounced than in derivative **1**. This reflects the fact that the Lewis acidity of $Rh_2(O_2CCF_3)_4$ is higher than that of $Mo_2(O_2CCF_3)_4$.

Electrochemical Properties

As depicted in Figure 3, the cyclic voltammogram of complex **2** in CH_2Cl_2 exhibits two subsequently reversible anodic couples. The first oxidation with $E_{1/2} = 0.18$ V is assigned to the oxidation of the two ferrocene units, whereas the second with $E_{1/2} = 0.52$ V is due to the oxidation process $[Rh_2]^{5+/4+}$. The coordination of dirhodium(II) by FPA results in a pronounced cathodic shift of $[Rh_2]^{5+/4+}$ from the parent $Rh_2(O_2CCH_3)_4$ (0.90 V), probably due to the strong electron-donating ability of FPA. The weak anodic shift of $Fe^{3+/2+}$ in complex **2** compared to FPA (0.12 V) is probably caused by the inductive effect of the acetate ligands in $Rh_2(O_2CCH_3)_4$. This effect compensates at least partially the electron deficiency of the Rh centers. As presented in Table 1, the $Fe^{3+/2+}$ oxidation potentials of **1** and **3** are also anodically shifted to 0.17 V and 0.27 V respectively from the parent FPA. Moreover, the shift of compound **3** vs. free FPA is more remarkable than the one in **1** and **2**, reflecting the negative inductive effect of the trifluoroacetate ligands of $Rh_2(O_2CCF_3)$. This result is consistent with the results obtained from electron absorption spectroscopy (see above).

FPA gives a half-peak width $W_{1/2}$ of 237 mV, whereas complex **1** displays a $W_{1/2}$ of 297 mV. Although the $Fe^{3+/2+}$ oxidation peak width of **1** is 60 mV broader than that of

FPA, both DPV and SQW measurements reveal a single process. A single $Fe^{3+/2+}$ oxidation wave as narrow as that of FPA is observed for both compounds **2** and **3**. The apparent lack of interaction between the ferrocene units in the tetranuclear complexes might be due to the less favorable energetic positions of the available orbitals in the complexes, the relatively weak Mo-axial ligand interactions and the presence of the rather long conjugating units between the ferrocene fragments.

Thermogravimetry

The complexes **1**−**3** and their precursor complexes $Mo_2(O_2CCF_3)_4$, $Rh_2(O_2CCF_3)_4$, $Rh_2(O_2CCH_3)_4$, and FPA have been examined by thermogravimetry (TG). While the bimetallic starting materials sublime with onset temperatures of 226 °C [$Mo_2(O_2CCF_3)_4$], 278 °C [$Rh_2(O_2CCH_3)_4$], and 312 °C [$Rh_2(O_2CCF_3)_4$], FPA starts to decompose at 229 °C, the tetrameric product complexes **1** and **2** are more stable than both their precursor complexes, with decomposition onset temperatures of 247 °C and 296 °C. However, compound **3** decomposes with a lower onset temperature (275 °C) than its bimetallic precursor $Rh_2(O_2CCF_3)_4$. The product complexes **1**−**3** are therefore in general significantly more stable than the least stable starting material, two of them are even more thermally stable than both precursors. This clearly proves the formation of product compounds of significant stability.

Oligomeric and Polymeric Complexes

Preparation and Characterization

The one-dimensional organometallic oligomer $[Mo_2(O_2CCF_3)_4(BPEF)]_n$ (**4**) with alternating ferrocene units and dimolybdenum quadruple bonds in the π-conjugated chain is obtained by the reaction of $Mo_2(O_2CCF_3)_4$ with one equivalent of BPEF [BPEF = 1,1′-bis(4-pyridylethynyl-)ferrocene] as shown in Equation 2. The orange solid is readily soluble in THF, moderately soluble in CH_3CN, and insoluble in all other common organic solvents. The solid state IR spectrum exhibits the characteristic C≡C stretching vibration at 2211 cm^{-1} and the C−F stretching vibration at 1193 cm^{-1}. These bands are nearly identical in energy to those in free BPEF [ν(C≡C) = 2208 cm^{-1}] and $Mo_2(O_2CCF_3)_4$ [ν(C−F) = 1192 cm^{-1}]. The strong band at 1592 cm^{-1} attributed to the pyridyl ring shifts to 1603 cm^{-1} after ligation.

Elemental analyses are consistent with an oligomer or polymer having the stoichiometry $Mo_2(O_2CCF_3)_4$/BPEF = 1:1. The ^1H NMR spectroscopic data of δ($H_α$-pyridyl) (δ = 8.42) and δ($H_β$-pyridyl) (δ = 7.21) in **4** ([D_8]THF) are nearly identical with those of BPEF (δ = 8.46 and 7.19, respectively), and it is impossible to estimate the number of repeating units n in **4** from the ^1H NMR spectroscopic data. Besides the pyridyl protons, the ferrocene protons (δ($H_α$-C_5H_4) = 4.61, δ($H_β$-C_5H_4) = 4.42) also display a similar chemical shift compared to those of free BPEF (δ = 4.57 and 4.37, respectively). The major difference is that the pyridyl protons in **4** show broad signals at room temperature. They become broader and shift to lower field [δ($H_α$) = 8.78, δ($H_β$) = 7.31] at +55 °C, but split to a doublet with peaks

	M	R	m	n	p
4	Mo	CF_3	0	unknown	0
5	Rh	CH_3	1	ca. 3	0
6	Rh	CF_3	0	9-14	1

at δ = 8.38 and 7.20, respectively, at −80 °C. This behavior is probably due to a temperature-dependent fluxionality in the system. At lower temperatures the whole structure is more rigid. Increasing the temperature leads to significant thermal movements, causing a broadening of the signals. Free BPEF does not show temperature dependence in its NMR spectrum. The ^{13}C NMR chemical shift of the R−CO_2 carbon atom in complex **4** (δ = 166.7, [D_8]THF) is not significantly different from that in $Mo_2(O_2CCF_3)_4$ (δ = 167.0). Therefore it is assumed that the oligomer chain of complex **4** may be broken due to the combined effects of weak metal-axial ligand interactions and the relatively strong coordinating ability of the solvent THF which is present in high excess. It is known that the strong σ component found in Mo−Mo quadruple bonds ($\sigma^2\pi^4\delta^2$) prevents stronger binding of any low-lying orbitals at the axial positions.[2a] A huge excess of the coordinating solvent THF is therefore very likely to break the oligomer chain. It was reported that the dissolution of $[Ru_2(O_2C(CH_2)_6CH_3)_4(pyrazine)]_n$ in coordinating solvents such as THF and MeOH also resulted in breaking of the polymer chain.[3c] We have reported the preparation of $[Mo_2(\mu\text{-}O_2CCH_3)_2(\mu\text{-}dppma)_2(NC_5H_4\text{-}R)_2]^{2+}$ recently. A mixture of nitrile and pyridine ligated complexes is obtained if the reaction is conducted in acetonitrile instead of dichloromethane.[11] Chemical ionization mass spectrometry (CI-MS) measurements of oligomer **4** also indicate that the metal-axial ligand interaction is weak, showing two major peaks corresponding to $BPEF^+$ and $[Mo_2(O_2CCF_3)_4]^+$ but no parent oligomer ion.

At an onset temperature of ca. 273 °C the oligomer **4** breaks down, producing sublimed $Mo_2(O_2CCF_3)_4$ units. Further heating results in gradual decomposition of the residue and gives a residual weight of 30% at 800 °C under He atmosphere as shown by TGA analysis (Figure 4). It is to be noted, however, that the onset of sublimation for the starting material $[Mo_2(O_2CCH_3)_4]$ is more than 45 °C below the onset of the first decomposition step of compound **4** (226 °C). Derivative **4** is also significantly more stable than the analogous tetrameric complex **1** (see above). This not only proves that complex **4** is not merely a mixture of starting materials, but also explains why all the $[Mo_2(O_2CCH_3)_4]$ incorporated in derivative **4** does not sublime when the oligomeric structure breaks down. The temperature is already significantly above the sublimation temperature of the dimolybdenum precursor so that only part of it is still able to sublime; the remaining residue decomposes gradually.

In the solid state, compound **4** is stable in air for a couple of hours, but in solution it decomposes within 10 min when exposed to air. In order to obtain air stable organometallic oligomers of this type, $Rh_2(O_2CCH_3)_4$ and $Rh_2(O_2CCF_3)_4$ were employed to yield oligomers **5** and **6** as shown in Equation (2). It is additionally anticipated that $Rh_2(O_2CCF_3)_4$ leads to stronger metal-axial ligand interactions because it is a stronger Lewis acid than $Rh_2(O_2CCH_3)_4$. Accordingly, neither compound **5** nor complex **6** are soluble in any common solvents. THF and acetonitrile are unable to break the axial interactions between the dirhodium core and the BPEF ligands, in contrast to the case of compound **4**.

The IR spectra of **5** and **6** exhibit characteristic C≡C stretching vibrations at 2208 and 2210 cm^{-1}, respectively. Derivative **6** additionally shows the C−F stretching vibration at 1194 cm^{-1}. These data are comparable with those of free BPEF [ν(C≡C) = 2208 cm^{-1}] and free $Rh_2(O_2CCF_3)_4$ [ν(C−F) = 1190 cm^{-1}].

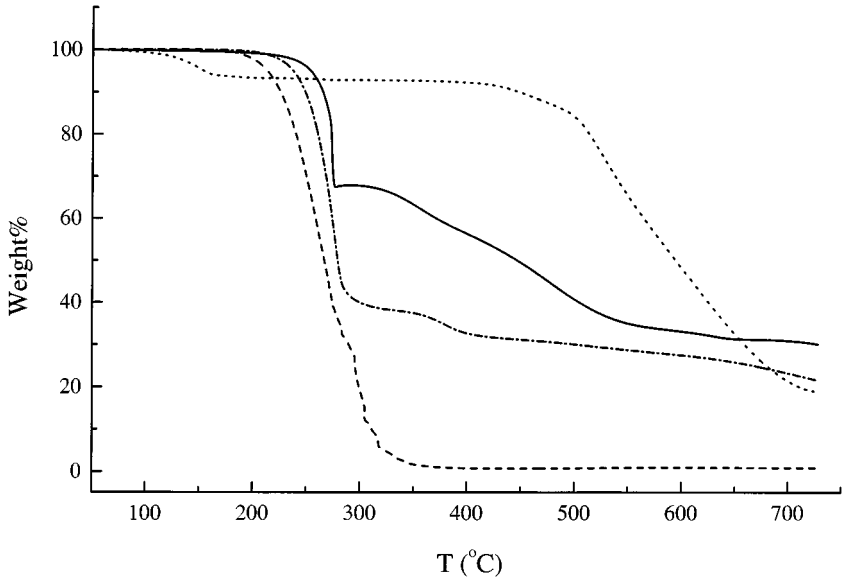

Figure 4. Plot of percent weight loss versus temperature for the thermal decomposition of $[Mo_2(O_2CCF_3)_4(BPEF)]_n$ (**4**, solid line), $Mo_2(O_2CCF_3)_4$ (dashed line), BPEF (dotted line), and $Mo_2(O_2CCF_3)_4(FPA)_2$ (**1**) (dashed-dotted line)

The poor solubility of complexes **5** and **6** prevents successful measurements of NMR spectra and the determination of the molecular mass in solution. However, the elemental analyses provide a rough way of estimating the number of repeating units and the terminal groups of the oligomers. The analytical results for complex **5** suggest the terminal groups are $Rh_2(O_2CCH_3)_4$ because the carbon content is much lower than that assumed for a stoichiometry $Rh_2(O_2CCH_3)_4$/BPEF = 1:1. The calculated elemental percentages are compared to the experimental data in Table 2. The percentages of H, N, and Fe are not sensitive enough to the extension of the oligomer chain, but those of C and Rh are quite informative. Taking the absolute error of the C analyses as 0.3%, and of the Rh analyses of 1%, the oligomer **5** has the composition of $[Rh_2(O_2CCH_3)_4]_{n+1}(BPEF)_n$ (n is around 3, most likely a mixture of oligomers with different lengths) and the average molecular mass is 2933. In the same manner, the composition of oligomer **6** is assumed to be $[Rh_2(O_2CCF_3)_4]_n(BPEF)_{n+1}$ (n = 9−14), the terminal groups are BPEF, and the molecular mass is in the range of 9803 to 15034 (Table 2). Considering the well-defined onset of sublimation for the complexes **4**−**6** (see below) it is unlikely that these derivatives still contain a significant amount of the starting materials (which can be removed easily by washing − see Experimental Section). Therefore the results obtained from elemental analysis should at least give a reliable estimation of the size of the oligomers.

The TGA profiles of complexes **5** and **6** are in principle similar to that of compound **4**. Oligomer **5** is thermally stable under a He atmosphere until the temperature reaches ca. 300 °C. Then the polymer structure breaks down and $Rh_2(O_2CCH_3)_4$ starts to sublime. Again, the longer chain of compound **5** is somewhat more stable than the tetranuclear model compound **2** (see above). Further heating results in gradual decomposition of the residue and gives a residual weight of 53% at 730 ° C. $Rh_2(O_2CCH_3)_4$ without any axial ligands has a sublimation onset temperature of about 20 °C (278 °C) below that of the oligomer **5**. Compound **6** is thermally stable under He below 320 °C. The residual weight is 28% at 730 °C. Despite the fact that the tetranuclear complex **3** is less stable than $Rh_2(O_2CCF_3)_4$, its oligomeric analogue **6** is more stable than this precursor (decomposition onset at 312 °C, see above). These data are additional proof of the significant interactions in the bimetallic complexes with the axial BPEF ligands.

Electrochemical Properties

The insolubility of oligomers **5** and **6** prevents investigation of their electrochemical properties in solution, but the properties of complex **4** were investigated by cyclic voltammetry. The usual solvent for the oxidation of ferrocene is dichloromethane due to its inertness towards ferrocenium-type ions. However, we employed acetonitrile and tetrahydrofuran for the measurements because complex **4** is much more soluble in these solvents. It is to be noted, however, that the data obtained are probably not representative of the oligomeric compound **4** but only of fragments of it and therefore have to be regarded with great caution. Dissolved complex **4** displays an irreversible $Fe^{3+/2+}$ oxidation at −0.20 V in THF, which is comparable to the parent BPEF (−0.22 V). The $Fe^{3+/2+}$ oxidation wave of BPEF (0.43 V) is still irreversible in MeCN. However, when the scan rate reaches 200 mV/s, a reversible curve with $E_{1/2}$ = 0.41 V is observed for compound **4** dissolved in acetonitrile. The fact that the oxidation potential for the dissolved derivative **4** is very close to that of free starting material supports the view of a breakdown of the oligomeric structure in solution.

Electronic Absorption Spectra

BPEF shows d-d transitions at 350 nm (3550 M^{-1} cm^{-1}) and 458 nm (870 M^{-1} cm^{-1}), as well as π-π* transition at 308 nm (16900 M^{-1} cm^{-1}) in CH_3CN. It is anticipated that

these absorption bands move to longer wavelengths and exhibit stronger extinction coefficients when BPEF forms an oligomer with $Mo_2(O_2CCF_3)_4$ in complex **4** for the same reasons as in the tetranuclear model complex **1**. However, the UV/Vis spectrum of dissolved complex **4** in CH_3CN does not show these features. The d-d and π-π* transitions of the dissolved derivative **4** are comparable to BPEF both in energy and in intensity, except that the d-d absorption around 350 nm appears as a shoulder of the π-π* absorption band of dissolved **4**. This behavior again supports the view that destruction of the oligomeric structure of **4** by the donor solvents occurs.

Conclusions

A new type of organometallic oligomer with the backbone consisting of bimetallic tetracarboxylates and a π-conjugated ferrocene derivative is easily generated by mixing the precursor compounds in solution at room temperature. The terminal groups and the number of repeating units are estimated by elemental analysis. The poor solubility of $[Rh_2(O_2CCH_3)_4]_{n+1}(BPEF)_n$ ($n \approx 3$) (**5**) and $[Rh_2(O_2CCF_3)_4]_n(BPEF)_{n+1}$ (n = 9–14) (**6**) prevents investigation of their electronic and electrochemical properties. The properties of dissolved $[Mo_2(O_2CCF_3)_4(BPEF)]_n$ (**4**) in MeCN and THF solutions are not related to the behavior of the real oligomer due to coordination competition between BPEF and the donor solvents. TGA studies prove the strength of the metal-axial interactions in the oligomeric complexes **4**–**6**. The electronic and electrochemical investigations of the tetranuclear model compounds indicate that the ferrocene units are electronically noncommunicating. Further research in this field will include modification of the tetracarboxylate ligands, bimetallic centers and ferrocene bridges in order to enhance the solubility of the oligomers and increase the electronic coupling within the oligomeric chains. Work in this direction is currently under way in our laboratory.

Experimental Section

General: All preparations and manipulations were carried out under an oxygen- and water-free argon atmosphere using standard Schlenk techniques. Solvents were dried by standard procedures, distilled, and stored under argon over 4-Å molecular sieves. $Mo_2(O_2CCF_3)_4$,[2e] $Rh_2(O_2CCH_3)_4$,[11] and $Rh_2(O_2CCF_3)_4$[12] were prepared according to the literature methods. – Elemental analyses were performed at the Mikroanalytisches Labor of the TU München in Garching. – ^1H and ^{13}C NMR were recorded by a Jeol JNM GX-400 spectrometer. – IR spectra were obtained on a Perkin–Elmer FT-IR spectrometer using KBr pellets as IR matrix. – Electronic absorption spectra were recorded using a Perkin–Elmer Lambda 2 UV/Vis spectrometer. – Cyclic voltammograms were recorded with a computer-controlled Model 173 Potentiostat/galvanostat (EG&G Princeton Applied Research) in argon-saturated and dry solutions with tetrabutylammonium hexafluorophosphate (TBAH, 0.1 M) as supporting electrolyte. The working electrode was platinum and the reference electrode silver wire. Potentials are quoted vs. the ferrocene/ferrocenium couple as internal standard. – TGA was performed using a Perkin–Elmer TGA 7 Thermogravimetric Analyzer with a heating rate of 15 °C/min.

Ferrocenyl-4-pyridylacetylene (FPA): Synthesized from ferrocenylacetylene[13] and 4-bromopyridine hydrochloride using a modified literature procedure.[14] Decomposes at 154 °C. – $C_{17}H_{13}FeN$ (287.14): calcd. C 71.11, H 4.56, N 4.88; found C 71.25, H 4.47, N 4.59. – Positive FAB-MS: m/z = 288 $[FPA + H^+]^+$. – Selected IR (KBr): $\tilde{\nu}$ = 2210 s (C≡C), 1636 m, 1594 vs, 1536 m, 1455 m, 1411 m, 1103 m, 1040 m, 1023 m, 1004 m, 987 m, 927 m, 817 vs, 538 m, 499 s, 483 s cm^{-1}. – ^1H NMR (CD_2Cl_2, room temp.): δ = 4.25 (s, 5 H, C_5H_5), 4.31 (t, 2 H, H_β-C_5H_4), 4.54 (t, 2 H, H_α-C_5H_4), 7.32 (d, 2 H, H_β-C_5H_4N), 8.53 (d, 2 H, H_α-C_5H_4N). – ^{13}C NMR

(CD_2Cl_2, room temp.): δ = 69.9, 70.4, 72.1 (C_5H_5 & C_5H_4), 83.6 (C_5H_4CC), 94.3 (CCC_5H_4N), 125.5 (C_β-C_5H_4N), 132.3 (C_γ-C_5H_4N), 150.1 (C_α-C_5H_4N).

1,1′-Bis(4-pyridylethynyl)ferrocene (BPEF): Synthesized by a modified literature procedure for 1,1′-bis(phenylethynyl)ferrocene.[10] A mixture of 1,1′-diiodoferrocene[15] (1.0 g, 2.3 mmol), 4-ethynylpyridine[16] (0.60 g, 5.8 mmol), $Pd(PPh_3)_4$ (0.10 g, 0.090 mmol), CuI (0.018 g, 0.090 mmol), and (iPr)$_2$NH (40 mL) was heated at reflux for 24 h. The solvent was removed under vacuum, and the residue extracted with H_2O/CH_2Cl_2. The organic layer was washed with H_2O, dried with $MgSO_4$, and chromatographed on a SiO_2 (70−220 mesh) column. Successive elution with CH_2Cl_2 and CH_2Cl_2/THF (1:1) led to the development of three bands. The third band in reddish-orange color afforded 0.70 g (89%) of the product. Decomposes at 155 °C. − $C_{24}H_{16}FeN_2$ (387.85): calcd. C 74.26, H 4.13, N 7.22; found C 73.98, H 4.37, N 7.01. − positive FAB-MS: *m/z*: 389 [BPEF + H^+]$^+$. − selected IR (KBr): $\tilde{\nu}$ = 2208 s (C≡C), 1633 m, 1592 vs, 1536 m, 1405 m, 1261 s, 1097 s, 1030 s, 997 m, 932 m, 817 vs, 801 vs, 540 m, 498 s cm^{-1}. − ^{1}H NMR ($CDCl_3$, room temp.): δ = 4.37 (t, 4 H, H_β-C_5H_4), 4.57 (t, 4 H, H_α-C_5H_4), 7.19 (d, 4 H, H_β-C_5H_4N), 8.46 (d, 4 H, H_α-C_5H_4N). − ^{13}C NMR ($CDCl_3$, room temp.): δ = 68.0, 71.4, 73.4 (C_5H_4), 84.5 (C_5H_4CC), 92.4 (CCC_5H_4N), 125.2 (C_β-C_5H_4N), 131.8 (C_γ-C_5H_4N), 149.6 (C_α-C_5H_4N).

$Mo_2(O_2CCF_3)_4(FPA)_2$ (1): A CH_2Cl_2 solution (25 mL) containing $Mo_2(O_2CCF_3)_4$ (0.10 g, 0.16 mmol) and FPA (0.10 g, 0.35 mmol) was stirred at room temperature for 2 h. The solvent was removed under oil pump vacuum and the residue was washed with *n*-hexane. Yield: 0.16 g, 82%. Slow evaporation of the diethyl ether solution of **1** gave crystals suitable for single crystal X-ray analysis. − $C_{42}H_{26}F_{12}Fe_2Mo_2N_2O_8$ (1218.23): calcd. C 41.41, H 2.15, N 2.30; found C 41.16, H 2.24, N 2.19. − Selected IR (KBr): $\tilde{\nu}$ = 2207 s (C≡C), 1601 vs, 1421 m, 1220 vs, 1193 vs. (C−F), 1170 vs, 1155 vs, 1004 s, 925 m, 856 m, 816 s, 779 m, 730 s, 596 m, 538 m, 499 m cm^{-1}. − ^{1}H NMR (CD_2Cl_2, room temp.): δ = 4.23 (s, 10 H, C_5H_5), 4.33 (t, 4 H, H_β-C_5H_4), 4.53 (t, 4 H, H_α-C_5H_4), 7.24 (d, 4 H, H_β-C_5H_4N), 8.03 (d, 4 H, H_α-C_5H_4N). − ^{13}C NMR (CD_2Cl_2, room temp.): δ = 70.2, 70.5, 72.3 (C_5H_5 & C_5H_4), 83.2 (C_5H_4CC), 126.0 (C_β-C_5H_4N), 149.2 (C_α-C_5H_4N), 166.6 (CO_2).

$Rh_2(O_2CCH_3)_4(FPA)_2$ (2): A solution of FPA (0.14 g, 0.50 mmol) in THF (10 mL) was added to a THF solution (30 mL) of $Rh_2(O_2CCH_3)_4$ (0.10 g, 0.23 mmol). The orange precipitate was collected and washed with Et_2O after being stirred at room temperature for 2 h. Yield: 0.18 g, 78%. − $C_{42}H_{38}Fe_2N_2O_8Rh_2$ (1016.28): calcd. C 49.64, H 3.77, N 2.76; found C 49.51, H 3.79, N 2.46. − Selected IR (KBr): $\tilde{\nu}$ = 2205 vs (C≡C), 1593 vs, 1450 m, 1429 vs, 1344 m, 1217 m, 1171 m, 1107 m, 1061 m, 1012 m, 925 m, 826 s, 694 s, 628 m, 600 m, 541 m, 500 s, 483 m, 446 m cm^{-1}. − ^{1}H NMR (CD_2Cl_2, room temp.): δ = 1.88 (s, 12 H, CH_3), 4.31 (s, 10 H, C_5H_5), 4.38 (t, 4 H, H_β-C_5H_4), 4.63 (t, 4 H, H_α-C_5H_4), 7.72 (d, 4 H, H_β-C_5H_4N), 9.11 (s, br, 4 H, H_α-C_5H_4N). − ^{13}C NMR (CD_2Cl_2, room temp.): δ = 30.1 (CH_3), 70.2, 70.6, 72.4 (C_5H_5 & C_5H_4), 126.9 (C_β-C_5H_4N), 150.6 (C_α-C_5H_4N), 191.4 (CO_2).

$Rh_2(O_2CCF_3)_4(FPA)_2$ (3): A solution of FPA (0.096 g, 0.33 mmol) in Et_2O (20 mL) was added to a solution of $Rh_2(O_2CCF_3)_4$ (0.10 g, 0.15 mmol) in Et_2O (10 mL). The orange precipitate was collected and washed with Et_2O after being stirred at room temperature for 2 h. Yield: 0.090 g, 49%. − $C_{42}H_{26}F_{12}Fe_2N_2O_8Rh_2$ (1232.16): calcd. C 40.94, H 2.13, N 2.27; found C 40.50, H 1.98, N 2.16. − selected IR (KBr): $\tilde{\nu}$ = 2206 vs (C≡C), 1662 vs, 1604 vs, 1456 m, 1424 m, 1223 vs, 1193 vs (C−F), 1172 vs, 1016 m, 925 m, 858 m, 818 s, 786 m, 738 s, 603 m, 540 m, 501 m cm^{-1}. − ^{1}H NMR ([D$_8$]THF, room temp.): δ = 4.26 (s, 10 H, C_5H_5), 4.39 (s, 4 H, H_β-C_5H_4), 4.61 (s, 4 H, H_α-C_5H_4), 7.46 (d, 4 H, H_β-C_5H_4N), 8.27 (d, 4 H, H_α-C_5H_4N). − ^{13}C NMR ([D$_8$]THF, room temp.): δ = 70.1, 72.8 (C_5H_5 & C_5H_4), 83.5 (C_5H_4CC), 99.6 (CCC_5H_4N), 113.3 (CF_3), 126.6 (C_β-C_5H_4N), 135.6 (C_γ-C_5H_4N), 152.3 (C_α-C_5H_4N), 175.7 (CO_2).

$[Mo_2(O_2CCF_3)_4(BPEF)]_n$ (4): A CH_2Cl_2 solution (10 mL) of BPEF (0.050 g, 0.13 mmol) was added to a CH_2Cl_2 solution (10 mL) of $Mo_2(O_2CCF_3)_4$ (0.071 g, 0.11 mmol), immediately giving an orange precipitate. After being stirred at room temperature for 2 h, the precipitate was collected and washed with Et_2O. Yield: 0.095 g (84%). − $(C_{32}H_{16}F_{12}FeN_2Mo_2O_8)_n$ ($n \times$ 1032.2): calcd. C 37.24, H 1.56, F 22.09, Fe 5.41, Mo 18.90, N 2.71; found C 37.56, H 1.50, F 23.51, Fe 3.88, Mo 19.24, N 2.67. − Selected IR (KBr): $\tilde{\nu}$ = 2211 m (C≡C), 1633 m, 1603 vs, 1424 m, 1222 vs, 1193 vs (C−F), 1159 vs, 1002 m, 856 m, 824 m, 780 m, 731 vs, 595 s, 502 m cm^{-1}. − ^{1}H NMR ([D$_8$]THF, room temp.): δ = 4.42 (s, 4 H, H_β-C_5H_4), 4.61 (s, 4 H, H_α-C_5H_4), 7.21 (s, 4 H, H_β-C_5H_4N), 8.42 (s, br, 4 H, H_α-C_5H_4N). − ^{13}C NMR ([D$_8$]THF, room temp.): δ = 72.3, 74.2 (C_5H_4), 85.2 (C_5H_4CC), 93.0 (CCC_5H_4N), 114.6 (CF_3), 126.0 (C_β-C_5H_4N), 132.5 (C_γ-C_5H_4N), 150.6 (C_α-C_5H_4N), 166.7 (CO_2).

$[Rh_2(O_2CCH_3)_4]_{n+1}(BPEF)_n$ ($n \approx$ 3) (5): A THF solution (15 mL) of $Rh_2(O_2CCH_3)_4$ (0.057 g, 0.13 mmol) was added to a THF solution (5 mL) of BPEF (0.050 g, 0.13 mmol). The orange precipitate was collected and washed with THF after being stirred at room temperature for 2 h. Yield: 0.10 g, 93%. − $C_{104}H_{96}Fe_3N_6O_{32}Rh_8$ (2932.71): calcd. C 42.59, H 3.30, Fe 5.71, N 2.87, Rh 28.07; found C 42.74, H 3.54, Fe 6.03, N 2.94, Rh 27.6. − selected IR (KBr): $\tilde{\nu}$ = 2208 m (C≡C), 1592 vs, 1500 m, 1429 vs, 1346 m, 1216 m, 1046 m, 1027 m, 1010 m, 827 m, 696 s, 628 m, 555 m, 478 m cm^{-1}.

$[Rh_2(O_2CCF_3)_4]_n(BPEF)_{n+1}$ (n = 9−14) (6): A CH_2Cl_2 solution (10 mL) of $Rh_2(O_2CCF_3)_4$ (0.039 g, 0.059 mmol) was quickly added to a CH_2Cl_2 solution (10 mL) of BPEF (0.023 g, 0.059 mmol). The reddish-orange precipitate was collected after 1 h and washed with Et_2O. Yield: 0.055 g, 86%. − For calculated analytical data refer to Table 2; found C 38.00, H 1.66, F 20.52, Fe 5.35, N 2.85, Rh 19.4. − Selected IR (KBr): $\tilde{\nu}$ = 2210 m (C≡C), 1666 vs, 1606 s, 1426 m, 1222 vs, 1194 vs (C−F), 1169 vs, 1016 m, 858 m, 828 m, 786 m, 738 s, 540 m, 503 m cm^{-1}.

X-ray Crystallography: Crystal data and details of the structure determination are presented in Table 3. A clear red-brown plate (0.25 × 0.15 × 0.05 mm) was employed for the analysis. Preliminary examination and data collection were carried out on a Kappa CCD area detecting diffraction system (NONIUS; MACH^3) equipped with a rotating anode and graphite monochromated Mo-K_α radiation (NONIUS; FR 591). The unit cell parameters were obtained by full-matrix least-squares refinements of 31046 reflections. Data collection were performed at 153 K (exposure time: 60 s per frame; 9 sets, and Ω-scans, Δ/ΔΩ: 1°; *d*x: 40.0 mm). A total number of 19385 reflections were collected. Raw data were corrected for Lorentz and polarization effects, corrected for absorption and decay effects and scaled with the program DENZO-SMN. After merging (R_{int} = 0.0184) a sum of 4089 independent reflections remained and were used for all calculations. All "heavy atoms" of the asymmetric unit were refined anisotropically. All hydrogen atoms were located in the difference Fourier map and refined with individual isotropic temperature parameters. Full-matrix least-squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with SHELX-97 weighting scheme and stopped at shift/err < 0.001. Neutral atom scattering factors for all atoms and anomalous dispersion

corrections for the non-hydrogen atoms were taken from *International Tables for Crystallography.* All calculations were performed on a DEC 3000 AXP workstation and an Intel Pentium II PC, with the STRUX system, including the programs PLATON, SIR92, and SHELX-97.[17]

Theoretical Studies of $[Os_3(CO)_{10}(\alpha\text{-Diimine})]$: Structures, Frontier Orbitals and Bonding

Maria José Calhorda,*[a,b] Elke Hunstock,[a] Luís F. Veiros,[c] and František Hartl[d]

Keywords: Osmium / Cluster compounds / DFT calculations / Charge transfer / Molecular orbitals / Diimines

DFT calculations were performed on $Os_3(CO)_{10}$(α-diimine) clusters, for α-diimine = DAB (1,4-diaza-1,3-butadiene), PYCA (σ-*N*,σ-*N*′-pyridine-2-carbaldehyde-imine), and BIPY (2,2′-bipyridine). Geometry optimizations were performed for several models of the possible isomers under different conditions. Axial isomers were always found to be the most stable, in agreement with the available X-ray determined structures. A full optimization of the geometry was required in order to improve the quality of the results, but the distances tended to be longer than the experimental ones. In spite of these shortcomings, the nature of the frontier orbitals, showing the increasing localization of the cluster LUMO in the α-diimine ligand as this is expanded (45, 65, 76% for DAB, PYCA, and BIPY, respectively), was consistent with the increasing MLCT character of the HOMO–LUMO transition along the series. Extended Hückel calculations were able to reproduce these trends qualitatively.

Introduction

There is a significant number of theoretical studies dealing with binary carbonyl transition metal clusters. The $M_3(CO)_{12}$ triad (M = Fe, Ru, Os) has been the object of a very important fraction of such studies, the relevant issue being that the iron derivative exhibits C_{2v} symmetry and has two bridging carbonyls over one edge, while both the ruthenium and the osmium clusters only possess terminal carbonyls. Several levels of theory have been used, starting from semiempirical extended Hückel (EH) and INDO calculations, up to HF and MP2 calculations, and more recently DFT methods.[1] Semiempirical methods can be applied to all clusters, independently of their size and symmetry, and this is their main advantage. On the other hand, more sophisticated methods can give a better answer to specific problems and become more reliable when trying to predict structures of molecules. From our previous experience, it is known that DFT methods are very adequate for dealing with first-row transition-metal clusters, while MP2 becomes the best choice for third-row derivatives. On the other hand, MP2 takes considerable time and requires extensive computer capabilities when studying large systems.[2]

Theoretical studies of mixed clusters containing other ligands besides carbonyls are less common, although they involve much chemistry.[3] The influence of the nature of the ligands on carbonyl bridge formation has been studied and it was found that coordination of π-donors can increase the tendency to form carbonyl bridges in clusters of second-row transition metals, such as ruthenium or rhodium, when they are absent in the binary carbonyl parent cluster.[4] Some publications address the triosmium clusters in detail. Morokuma and co-workers studied the bonding in $Os_3(CO)_9(C_6H_6)$ using single-point MP2 energy calculations on HF-optimized structures, and EH for orbital analysis.[5] Some of us qualitatively analyzed the bonding of *ortho*-metallated α-diimines to $HOs_3(CO)_9$.[6a]

In this work, DFT calculations[7] performed under different conditions and on models of three $Os_3(CO)_{10}$(α-diimine) clusters are described, and the reliability of extended Hückel[8] calculations on these systems is discussed. This study was prompted by the rich photochemistry[9] and intriguing electrochemistry[6] exhibited by these clusters. Di- and trinuclear transition-metal carbonyls with the α-diimine ligand have been found to undergo a photochemical metal−metal bond homolysis from a low-lying σπ* excited state, in which σ represents the metal−metal bonding orbital and π* represents the lowest unoccupied orbital of the α-diimine. This excited state is either directly optically available or can be occupied by surface crossing from the metal-to-α-diimine (MLCT) states.[10] Experimental results indicate that a similar situation also applies to the $Os_3(CO)_{10}$(α-diimine) clusters which produce diradicals in non-coordinating or weakly coordinating solvents upon irradiation with visible light.[9] This knowledge can be used to check the accuracy of our model compounds, as will be discussed later.

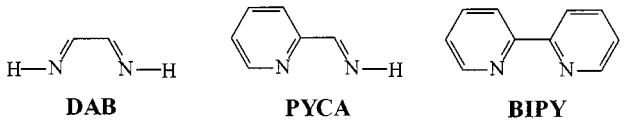
Results and Discussion

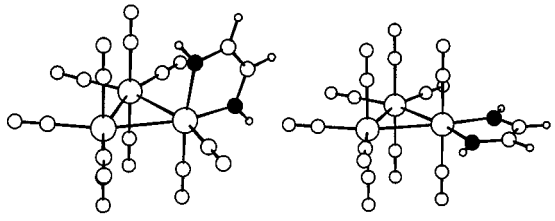
Molecular Structures

Three model α-diimine ligands were considered in this work, namely DAB (1,4-diaza-1,3-butadiene), PYCA (σ-*N*,σ-*N*′-pyridine-2-carbaldehyde-imine), and BIPY (2,2′-bipyridine), as depicted in Scheme 1. They differ by the progressive replacement of the imine C=N bonds by pyridine rings.



Scheme 1

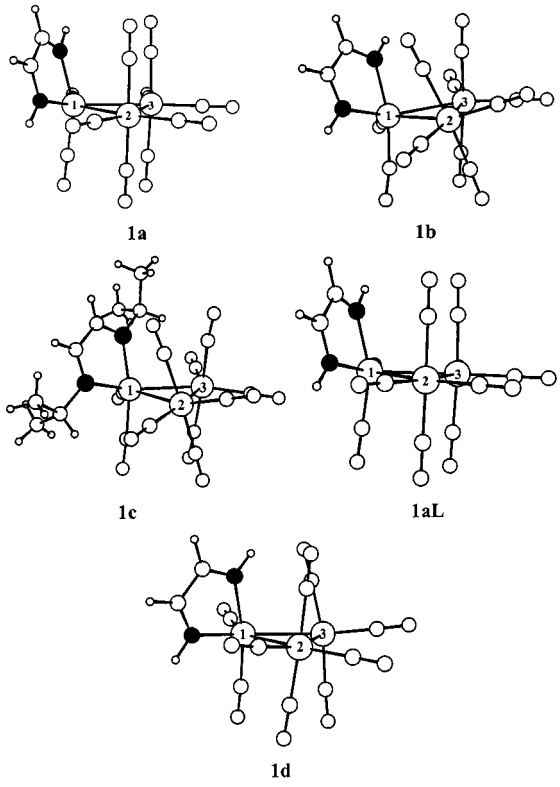
The $Os_3(CO)_{10}$(DAB) cluster (**1**) was the first to be studied (see Experimental Section for details) and the availability of the X-ray structure of the related $Os_3(CO)_{10}$(*i*Pr-DAB)[11] provided a good starting point for the calculations. In principle, two alternative structures are possible for this cluster with the α-diimine σ-*N*,σ-*N*′-chelated to a single osmium atom, namely the axial and the equatorial one, as depicted in Scheme 2, left and right.



Scheme 2

The axial isomer (left) has no symmetry (C_1), while the equatorial isomer has two mirror planes and a twofold rotation axis. The first model was very similar to what can be seen in Scheme 2, since the terminal carbonyl groups were forced to lie on the Os3 plane or to be perpendicular to it. The other variables were optimized. The axial isomer (**1aL**) was found by DFT calculations to be more stable by 0.83 eV. A relatively large basis set (see basis set L in Experimental Section) was used for these two initial calculations. A reduced basis set (see Experimental Section) was used afterwards (**1a**) because the size of the other ligands (PYCA and BIPY) prevented the use of the larger one. Obviously, the same conditions must be used in order to compare results for the three α-diimine ligands. Extended Hückel calculations[8] led to a similar result, namely that the axial isomer was more stable by 0.75 eV.

The features of the rigid models **1aL** and **1a** significantly deviated from those of the available crystal structure of $Os_3(CO)_{10}$(*i*Pr-DAB). Besides the distances, to which we shall come back, the angles were totally different. Therefore, the model for the more stable axial isomer was improved, making it more flexible by allowing all the torsion angles to vary (**1b**). The calculated DFT energy dropped by 0.71 eV. A single-point calculation was also performed using the coordinates of the experimental structure (**1c**). The energies cannot be compared, as there are two isopropyl substituents on the DAB nitrogen atoms. However the nature of the frontier orbitals should be similar if the model is reliable, and calculated and experimental bond lengths can therefore be compared. The geometry of the axial isomer, with C_1 symmetry, was also optimized using *Gaussian 94*[12] (**1d**; HF; see Experimental for details). A general idea of the structural differences between the five calculations of the axial isomer can be inferred from the drawings in Scheme 3, showing the rigid model (**1a**), the more flexible model (**1b**), the experimental structure on the top right (**1c**), the rigid model (basis set L; **1aL**), and the flexible model (Gaussian; **1d**).



Scheme 3

The most relevant distances (Os−Os and Os−N) are listed in Table 1, and while the main features of the observed structure are reproduced in the calculations, the distances tend to be too long when DFT methods are used (**1a, 1b**). Although only the HF approach could be used owing to the size of the cluster, the distances (**1d**) are in

Table 1. Selected distances (pm) in several models and calculation levels of $Os_3(CO)_{10}$(DAB) (**1a, 1aL, 1b, 1d**) and in $Os_3(CO)_{10}$(*i*Pr-DAB) (**1c**)

Bond/Model	**1a**	**1aL**	**1b**	**1c** (exp.)	**1d**[a]
Os1−Os2	305.0	303.2	297.9	287.7	292.3
Os1−Os3	301.6	301.3	300.6	288.0	292.5
Os2−Os3	303.7	304.6	299.9	286.7	296.9
Os1−N1	212.0	210.9	213.7	211.4	215.5
Os1−N2	212.0	210.9	209.3	206.6	207.3

[a] HF calculations.

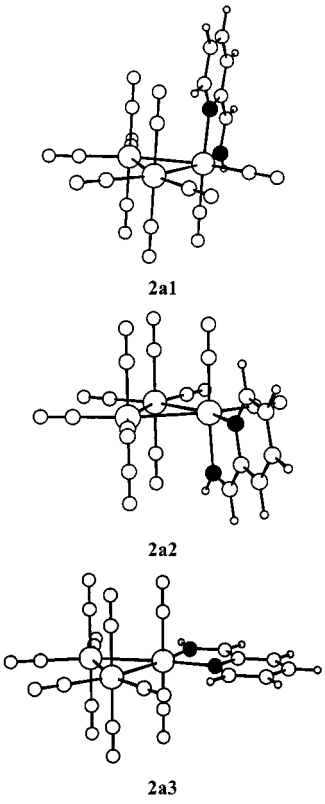
better agreement with the experimental ones (**1c**), especially with respect to the Os−Os bonds.

The first two columns in Table 1 demonstrate the effect of the basis set. The larger one (**1aL**) leads to shorter distances, but exceeded our computing capabilities when we moved to the larger α-diimine ligands. A comparison of the values in columns **1a** and **1b** shows, however, that the effect of using a better model is more important. Indeed, the full geometry optimization is more effective in reducing bond lengths than increasing the basis set. For instance, Os1−Os2 drops from 305.0 pm in **1a** to 303.2 in **1aL** with the better basis set, but to 297.9 pm in **1b**, with a better model and a small basis set, getting closer to the experimental value of 287.7 pm (**1c**).When the same model is used and one compares DFT and HF, it can be seen that this last method leads to shorter Os−Os bond lengths. The computation time is increased, though, and one of the Os−N bonds is even longer. The size and lack of symmetry of compound **1** precluded an MP2 calculation, although recent calculations on the more symmetric $Os_3(CO)_{12}$ showed MP2 to reproduce distances better.[2]

Another interesting aspect of the experimental structure, also reproduced by the full optimization procedure, concerns the torsion angles around the carbonyl groups. Although a list of their values is of limited value, it can be noted that some of them move away from the perpendicular to the Os3 plane by up to 25°, as clearly seen in Scheme 3. The HF structure (**1d**) has bond lengths in good agreement with the experimental structure (**1c**), but the torsion angles are very different, and the carbonyls bend in the wrong direction, revealing the limitations of this approach. The overall picture provided by the DFT-optimized structure is more realistic, despite the long bond lengths.

The introduction of the first pyridine ring changes DAB into PYCA (Scheme 1). As the ligand is asymmetric, there are more possible isomers for the model compound $Os_3(CO)_{10}$(PYCA) (**2**), as the two axial isomers (**2a1, 2a2**) shown in Scheme 4 (top and center) are not equivalent. The equatorial isomer (**2a3**) is the more symmetric one, with a mirror plane (C_s).

There is no X-ray structure available for compound **2** or a related one. DFT calculations with the standard basis set, keeping the carbonyls perpendicular to or on the Os_3 plane, were performed for the three isomers. The most stable is the axial isomer **2a1**. The other axial isomer **2a2** has a higher energy (0.18 eV), while the equatorial **2a3**, with an energy 0.31 eV higher than **2a1**, is the least stable. For this $Os_3(CO)_{10}$(PYCA) cluster, EH calculations showed the axial species **2a2** to be the most stable, followed by **2a3** (0.28 eV) and **2a1** (2.23 eV). This result can be traced to steric repulsion between the pyridine ring of the ligand and the carbonyls perpendicular to the Os_3 plane, as no geometry optimization was made. The DFT calculations, allowing for these repulsions to be relieved during the geometry-optimization process, led to a more likely order of stability, with **2a1** being the most stable isomer.[13] Also, since the carbonyl groups are much stronger π-acceptors than the α-diimines, *cis*-$Os_3(CO)_2$ geometries (as in the axial isomers) are more stable than structures with carbonyls in *trans* positions (the equatorial isomer) competing for π back donation from the same metal orbitals.



Scheme 4

A full optimization of the axial isomer (**2b**), taking all the degrees of freedom into account, resulted in a more stable cluster (0.94 eV), as expected from the study of the DAB derivatives. A complete geometry optimization using Gaussian94 HF, was also performed (**2d**). The representation of the geometries clarify the changes in the carbonyl positions which take place as the model improves (Scheme 5). The relevant distances are given in Table 2.

These distances can be compared with those of $Os_3(CO)_{10}$(*i*Pr-DAB) given in Table 1. The conclusions are similar to those drawn above, namely that DFT methods give too long distances. The HF calculation leads to shorter Os−Os bonds, but on the other hand one of the Os−N bonds is the largest. Interestingly, for this system, the carbonyls occupy the same positions as in the DFT-optimized structures and in $Os_3(CO)_{10}$(*i*Pr-DAB), in opposition to what was found for the model DAB cluster.

The third cluster studied was $Os_3(CO)_{10}$(BIPY) (**3**). There are two isomers, an axial and an equatorial one, similar to those in Scheme 2. A complete optimization of both isomers was performed using DFT calculations, and the axial isomer was found to be more stable by 0.52 eV. The drawings of the optimized structures of the (**3b1**) axial and equatorial (**3b2**) isomers and the X-ray structure of $Os_3(CO)_{10}$(BIPY) (**3c**)[14] are represented in Scheme 6. Both the calculated Os−Os and Os−N distances are too long compared with the observed ones (Table 3).

Os1−N1	217.3	222.5	226.3
Os1−N2	217.3	211.9	211.7

[a] HF calculations.

Since the geometry of the two isomers of $Os_3(CO)_{10}$(BIPY) was fully optimized, they can be compared more reliably. From the two drawings in Scheme 6, it can be seen that the carbonyls do not need to distort so much away from directions perpendicular to the Os3 plane in the case of the equatorial isomer. This reflects a smaller number of steric repulsive interactions in the axial isomer of the cluster. This steric constraints are reflected in the EH relative energies of the two isomers (idealized geometries with carbonyls perpendicular or in the plane of Os_3): the axial isomer is less stable by 2.07 eV. If the carbonyls are allowed to bend back, away from the α-diimine ligand, the energy immediately starts to drop. It is worth noting that in the DAB cluster, where steric repulsions are negligible, the axial

Os1−N1	219.8	219.4	217.9
Os1−N2	220.3	220.3	209.0

isomer was found to be the most stable by EH calculations. The introduction of the pyridine rings reverses this pattern and demands further optimization of the geometry (as done in the DFT calculations).

The Os−Os distances are the same in $Os_3(CO)_{10}$(BIPY) and in $Os_3(CO)_{10}$(*i*Pr-DAB) within experimental error, so that any of them can be used to check the calculations on $Os_3(CO)_{10}$(PYCA).

A Qualitative View of the Bonding

The three α-diimine ligands DAB, PYCA, and BIPY have an increasingly large π-system. The bonding of DAB to the cluster is achieved by σ-donation from the two equivalent nitrogen lone-pair orbitals, as the symmetric and antisymmetric combinations, to empty cluster orbitals localized in Os1. There is also a back-donation component from the cluster to the second π* (DAB), LUMO. The set of π orbitals of DAB is very similar to that of 1,3-butadiene, taking into account the different electronegativities of carbon

and nitrogen. The interaction between DAB and $Os_3(CO)_{10}$ is depicted on the right hand side of Figure 1 (EH calculations). The corresponding interaction with PYCA is shown on the left hand side.

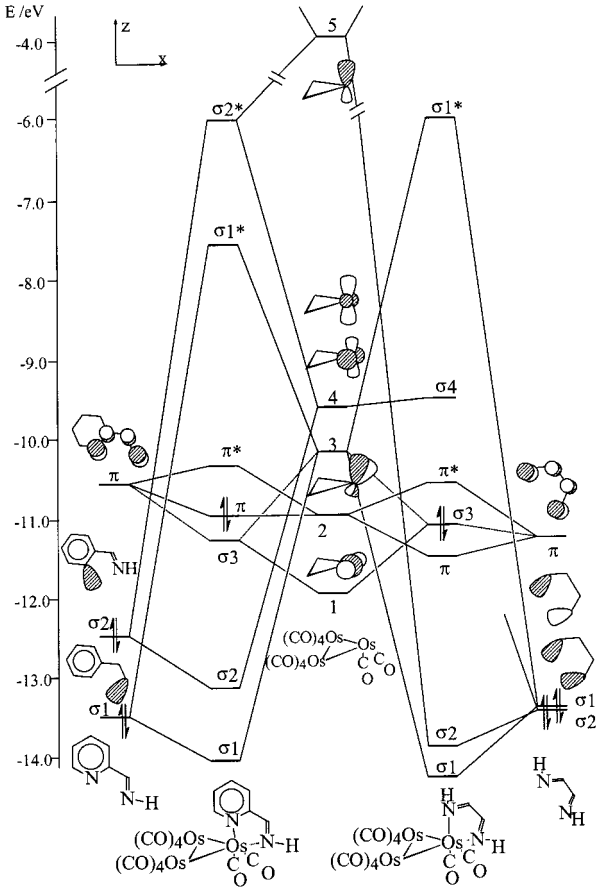

Figure 1. Molecular orbital diagram between the cluster fragment $Os_3(CO)_{10}$ (center) and DAB (right) or PYCA (left), showing the most relevant interactions

The presence of the pyridine ring lifts the degeneracy between the two nitrogen lone pairs. The π* (PYCA) LUMO, the acceptor orbital, is largely localized on the same atoms as in DAB, but lies at higher energy owing to the larger number of nodes (not shown). As a consequence, the LUMO of the triosmium clusters, which is the antibonding combination arising from this back-donation component involving π* (PYCA), is expected to possess different a character in the two clusters. In $Os_3(CO)_{10}$DAB, the energy match is better, the interaction stronger, the covalent character more pronounced, and the levels are delocalized between the carbonyl−osmium fragment and the DAB ligand. For $Os_3(CO)_{10}$PYCA, the energy match is not as good, and the cluster LUMO is much more located on the π* (PYCA) orbital (closer in energy) than on the cluster core. The trend is qualitatively the same as one moves to BIPY. The corresponding π* (BIPY) LUMO lies at a higher energy than that of PYCA, and the cluster LUMO becomes even more localized on the BIPY ligand. We come back to these features in the next section.

The Frontier Orbitals (DFT) and the MLCT Transition

As was discussed above, the agreement between experimental and calculated structures using DFT methods improves when the model is improved and a full optimization is performed. The other feature associated with the different models which changes significantly is the composition of the frontier orbitals. This is of great importance because one of the aims of the present study is to understand and compare the character of the lowest-energy electronic transition in the three investigated clusters, and a reliable way of determining that orbital composition is essential.

The results for the $Os_3(CO)_{10}$(DAB) models compared with those of the experimental structure are given in Table 4.

Table 4. Composition of the frontier orbitals (%) of two models of $Os_3(CO)_{10}$(DAB) (**1a, b**) and of $Os_3(CO)_{10}$(*i*Pr-DAB) (**1c**)

[a] LUMO. − [b]HOMO.

There is a striking difference in the composition of the LUMO, as one moves from the more primitive (**1a**), to the better model (**1b**), and to the real structure (**1c**). The LUMO becomes much more localized on the DAB ligand, going from only 21%, to 45%, and 53%, the last two numbers being comparable. The HOMO is not as sensitive to the type of model.

Table 5. Composition of the frontier orbitals (%) of two models of $Os_3(CO)_{10}$(PYCA) (**2a1, 2b**)

	2a1			**2b**		
m.o.	Os1	Os2,3	PYCA	Os1	Os2,3	PYCA

[a] LUMO. − [b] HOMO.

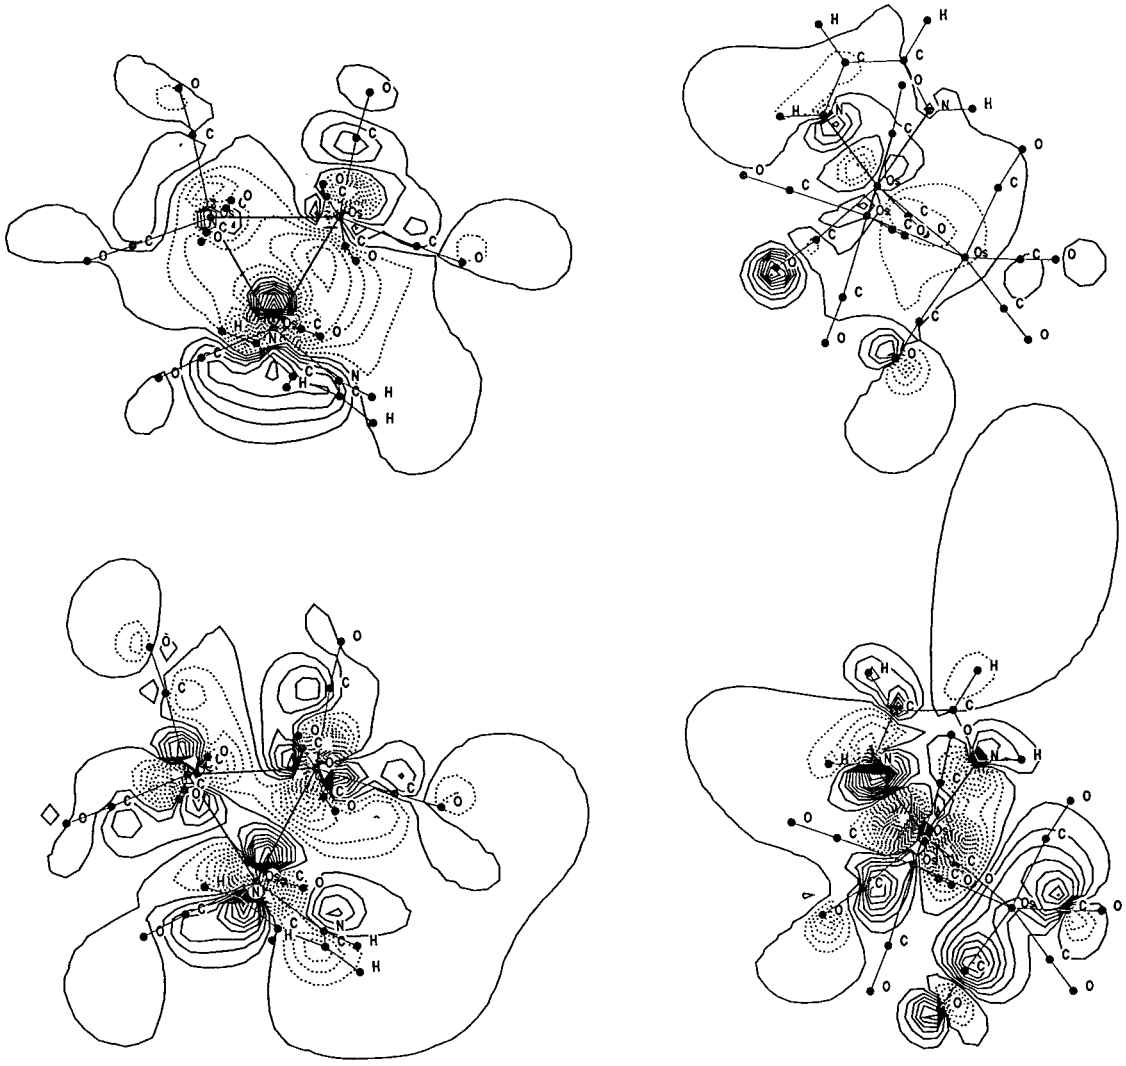

Figure 2. Wavefunction contour plots of the HOMO (top) and LUMO (bottom) of $Os_3(CO)_{10}$(DAB) (**1b**), in the Os_3 plane (left) and in the N−Os−N plane (right)

The same behavior has been found for the $Os_3(CO)_{10}$-(PYCA) cluster (Table 5).

It can be seen that the LUMO has only a contribution of 40% of the ligand in the primitive model, which increases to 65% in **2b**. Conversely, the ligand contribution to the HOMO drops. There is no structure of the cluster, so these values cannot be checked. For $Os_3(CO)_{10}$(BIPY) (Table 6) only the best model (**3b1**) was calculated (full optimization) and there is an experimental structure (**3c**).

There is a good agreement between the composition of the orbitals of the model and of the observed structure, suggesting that our model, in spite of its limitations with regard to the reproduction of bond lengths, describes accurately the nature of the frontier orbitals.

The character of the frontier orbitals can be seen in a better way in the two-dimensional wavefunction plots of Figure 2. In two-dimensional plots, a convenient plane to plot the wavefunction contours must be chosen. In the $Os_3(CO)_{10}$(α-diimine) clusters, the relevant planes are those defined by N−Os−N and by Os_3. We show in Figure 2 both the HOMO and the LUMO for $Os_3(CO)_{10}$(DAB) (**1b**), as two-dimensional plots in the Os_3 plane (left) and in the N−Os−N plane (right).

The same representation is given for $Os_3(CO)_{10}$(BIPY) (**3b1**), in order to compare the character of the orbitals (Figure 3).

The relative energies of the molecular orbitals are also important for the analysis of the electronic transitions. They also depend on the model used to describe the cluster, as can be seen from the selection given in Table 7, for models of $Os_3(CO)_{10}$(DAB) (**1a, 1b**) and $Os_3(CO)_{10}$(*i*Pr-DAB) (**1c**). The HOMO−LUMO gap is 1.76 eV for $Os_3(CO)_{10}$(*i*Pr-DAB) (**1a**), close to the value obtained for the flexible model **1b** (1.66 eV), but much larger than the result obtained with the rigid model **1a** (1.46 eV).

Finally, in Table 8 we give the relative energies of the frontier orbitals for the flexible models of the axial isomers of the three clusters (**1b, 2b, 3b1**) and $Os_3(CO)_{10}$(BIPY). The HOMO−LUMO gap varies with the α-diimine ligand, going from 1.66 eV for the DAB cluster, to 1.50 eV for the

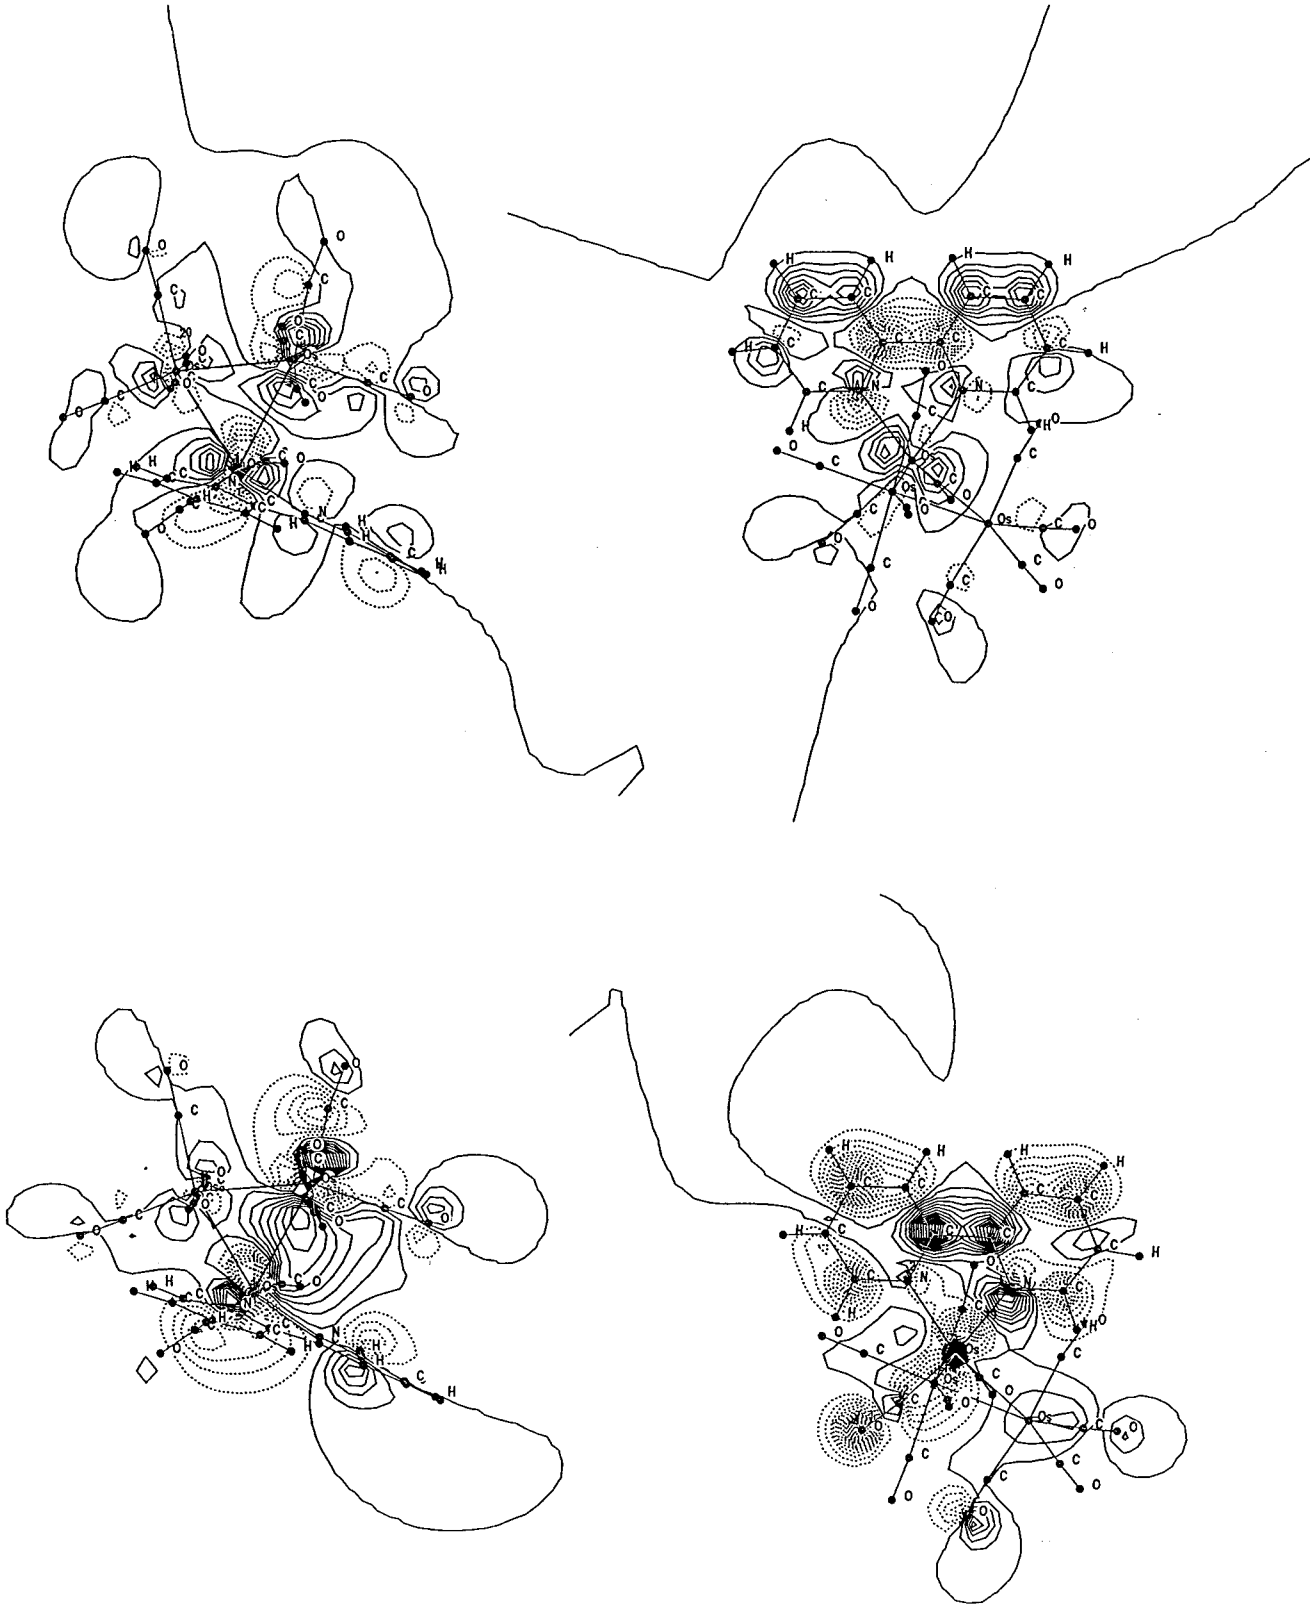

Figure 3. Wavefunction contour plots of the HOMO (top) and LUMO (bottom) of $Os_3(CO)_{10}$(BIPY) (**3b1**), in the Os_3 plane (left) and in the N−Os−N plane (right)

PYCA cluster, and 1.41 eV for the BIPY cluster. It becomes smaller as the HOMO becomes more localized in the metals and the LUMO in the diimine.

Final Remarks

As discussed above, the LUMO becomes progressively more localized on the α-diimine ligand as one moves from

[a] LUMO. – [b] HOMO.

DAB, to PYCA, to BIPY in $Os_3(CO)_{10}$(α-diimine) (45, 65, 76% from **1b, 2b, 3b1**, respectively) and the HOMO on the metal-carbonyl core (32, 39, 44%), indicating that the cluster core-to-ligand charge-transfer character of the HOMO−LUMO transition increases along the series. This trend agrees well with the previously published resonance Raman spectra of the clusters $Os_3(CO)_{10}$(α-diimine) (α-diimine = *i*Pr-DAB, *i*Pr-PYCA, BIPY).[9a][9b] The spectra document that in the case of the *i*Pr-DAB-derivative, the HOMO−LUMO transition possesses a pronounced metal−ligand bonding-to-antibonding rather than charge-transfer character, in agreement with its negligible solvatochromism.[15] For the *i*Pr-PYCA and BIPY-derivatives, the resonance Raman spectra and negative solvatochromism[9b] manifest a significant charge transfer character of this first electronic transition. This difference is also reflected in the limited tendency of the clusters $Os_3(CO)_{10}$(R-DAB) (R = alkyl) to produce charge-separated zwitterions from the diradical intermediates photogenerated upon the HOMO−LUMO excitation, in sharp contrast to the photochemistry of the R-PYCA and, in particular, BIPY-derivatives.[9a] Such conversion demands localization of the excited electron mainly in the π* orbital of the α-diimine ligand, which is not the case in the strongly π-delocalized Os−DAB metallacycle (see Table 4, model **1b**).

The extended Hückel method does not give a good result for predicting relative energies of isomers, in the absence of a geometry optimization, but leads to a good description of the nature of the frontier orbitals, reflecting the progressive contribution of the α-diimine ligand to the LUMO and of the three osmium atoms to the HOMO in the $Os_3(CO)_{10}$(α-diimine) clusters.

Experimental Section

All Density Functional Theory calculations were performed using the Amsterdam Density Functional program package (ADF).[17,18] The Local Spin Density (LSD) exchange correlation potential was used with the Local Density Approximation of the correlation energy (Vosko−Wilk-Nusair).[19] Gradient-corrected geometry optimizations were performed using Becke's[20] exchange and Perdew's[21] correlation functionals, and included relativistic effects, treated by a quasi-relativistic method where Darwin and mass-velocity terms are incorporated.[23]

The inner shells of Os (1s−5p) were frozen, for both the large (L) and reduced basis sets. A triple-ζ STO basis set was used for the valence part of Os (5d−6s), additionally augmented by one diffuse 6p function. For C and N, the 2s and 2p valence shells were described by a triple-ζ STO basis, augmented by one 3d polarization function. For O and H a double-ζ STO basis was used. In the large (L) case, the 2s and 2p shells of C, O and N and the 1s shell of H are triply split and augmented by two polarization functions (3d+4f for C, O, N; 2p+3d for H).

The Hartree−Fock (HF) geometry optimizations were performed using Gaussian94.[12] For Os, the inner shells (1s−4f) were replaced by relativistic effective core potentials of Hay and Wadt,[24] thus including the outermost core orbitals into the SCF procedure. These orbitals were fully contracted while the valence shells were described by a double-ζ STO basis completed by two additional diffuse 6p functions.[25] For the ligand atoms C, O, N and H, standard basis sets (6−31G) were used. The geometry optimizations were performed without any symmetry constraints, except for the equatorial isomers (C_s symmetry).

The extended Hückel method with modified H_{ij} values was used.[26] The basis set for the metal atoms consisted of *n*s, *n*p and (*n-1*)d orbitals. The s and p orbitals were described by single Slater-type wavefunctions, and the d orbitals were taken as contracted linear combinations of two Slater-type wavefunctions. The parameters used for Os were (H_{ii}/eV, ζ): 6s −8.17, 2.452; 6p −4.81, 2.429; 5d −11.84, 5.571, 2.416 (ζ_2), 0.6372 (C_1), 0.5598 (C_2). Standard parameters were used for other atoms. The calculations were performed on model clusters with idealized structures based on the real structures quoted throughout the text. The results were compared with the real structures, when available, producing qualitatively similar results. The bond lengths (Å) were as follows: Os−Os 2.90, Os−C(CO) 1.95, Os−N 2.15, Os−C 2.15, C−O 1.15, C−N 1.40, C−C 1.40, C−H 1.08, N−H 1.08.

Chromium and Tungsten Carbene Complexes of Thieno[3,2-*b*]thiophene

Marilé Landman,[a] Helmar Görls,[b] and Simon Lotz*[c]

Keywords: Carbene complexes / Dinuclear complexes / Chromium / Tungsten / Sulfur heterocycles

Dinuclear carbene complexes with 3,6-dimethylthieno[3,2-*b*]thienylene (T′T′) and thieno[3,2-*b*]thienylene (TT) spacers were prepared using the classical Fischer method. Their reactivity in solution towards oxygen, as well as their structural features were investigated. Chromium and tungsten carbene complexes were synthesized via dilithiation of the thienothiophene, followed by the addition of the appropriate metal carbonyl complex and subsequent alkylation with triethyloxonium tetrafluoroborate. Monocarbene [M{C(OEt)T′T′H}$(CO)_5$], (M = Cr, **1**; W, **4**), biscarbene [$(CO)_5$M{C(OEt)T′T′C(OEt)}M$(CO)_5$], (M = Cr, **2**; W, **5**), and the products [M{C(OEt)T′T′C(O)OEt} $(CO)_5$], (M = Cr, **3**; W, **6**), where a metal moiety of **2** and **5** has been replaced by an ester functionality, were isolated. The reaction product afforded in the reaction of $Cr(CO)_6$ with lithiated thieno[3,2-*b*]thiophene, [Cr{C(OEt)TTC(O)Bu}$(CO)_5$], **7**, did not resemble any of the products isolated in the similar reaction of $Cr(CO)_6$ with lithiated 3,6-dimethylthieno[3,2-*b*]thiophene.

Introduction

The current interest in thiophenes as molecules with potential electro-optical properties for use as molecular devices[1] was recently extended to include thieno[3,2-*b*]thiophenes.[2] Research in this area has unfortunately been impeded by the lack of convenient synthetic methods. Since the discovery of the first stable transition metal carbene complex by Fischer and Maasböl in 1964,[3] research in this field has been extensive with wide application possibilities. Several mononuclear, as well as dinuclear[4] biscarbene complexes with various spacers have been prepared. The first biscarbene complex containing two different metal moieties, contains a 2,2′-bithienylene (T−T) spacer and was published in 1995,[5] however, the synthetic method was unsatisfactory. In this paper the syntheses of carbene complexes containing thieno[3,2-*b*]thiophene and 3,6-dimethylthieno[3,2-*b*]thiophene as bridging units in dinuclear biscarbene complexes are reported. This work represents an extension of previously published dinuclear biscarbene complexes with thienylene (T) spacers, [$(CO)_2$ L_3M{C(OEt)TC(OEt)}M$L_3(CO)_2$], (M = Cr, L = CO; M = W, L = CO; M = Mn, L = Cp, MeCp).[6]

In an attempt to enhance the electron density and transmission properties of thieno[3,2-*b*]thiophene for potential application in non-linear optics, the synthesis of 2-arylthieno[3,2-*b*]thiophene was planned.[7] Various synthetic routes were proposed for this synthesis and intermediates containing metal fragments as substituents such as 2-tributylstannylthieno[3,2-*b*]thiophene, (thieno[3,2-*b*]thiophen-2-yl)boronic acid, and 2-thieno[3,2-*b*]thienylzinc chloride were prepared from lithio precursors. A number of α-substituted thienothiophene compounds have been synthesized in a similar manner via the monolithiated derivative e.g. selenium and tellurium compounds.[8] Several silyl compounds[9] were synthesized via the use of 2,5-disubstituted thieno[3,2-*b*]thiophenes, prepared by dilithiation of thieno[3,2-*b*]thiophene and followed by the subsequent reaction with electrophiles.

Results and Discussion

Examples of compounds containing thienothiophenes as bridging spacers are limited in the literature and mostly confined to main group metal compounds. The synthesis of thieno[3,2-*b*]thiophene was based on the work of Goldfarb and co-workers,[10] but several of the reaction steps were revised to obtain higher yields.[11,12,13] Since no practical short-step synthesis for thieno[3,2-*b*]thiophene, or substituted derivatives thereof, was available in the literature, the utilization of thienothiophenes in coordination chemistry with transition metals has been neglected. However, in 1994, Choi and co-workers[14] reported a one-pot synthesis of 3,6-dimethylthieno[3,2-*b*]thiophene, which promoted investigation of the properties of these molecules in coordination chemistry. This synthesis was based on the discovery made by Teste and Lozac'h[15] that the reaction of 2,5-dimethyl-3-hexyne-2,5-diol with elemental sulfur afforded 3,6-dimethylthieno[3,2-*b*]thiophene, although the yield was low. Choi re-examined this reaction and varied the reaction conditions until 3,6-dimethylthieno[3,2-*b*]thiophene was obtained in a reasonable yield.

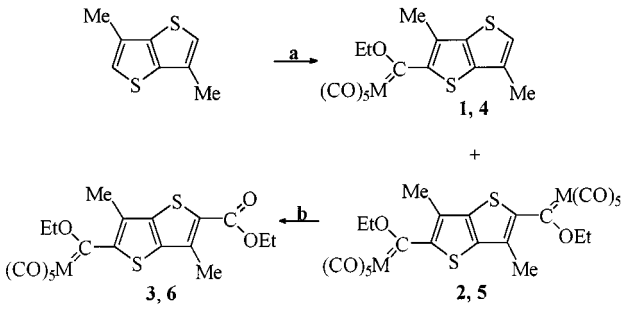
The novel carbene complexes **2** and **5** were synthesized using the classical Fischer method. The dimetallation of thieno[3,2-*b*]thiophene and 3,6-dimethylthieno[3,2-*b*]thiophene was based on the method described by Bugge.[13] The reactions were carried out in hexane and TMEDA was introduced together with butyllithium to form 2,7-dilithio species at elevated temperatures. Formation of biscarbene complexes followed after addition of the metal hexacarbonyl and subsequent quenching with the alkylating agent $Et_3O{\cdot}BF_4$. The synthetic procedure for the preparation of these complexes is outlined in Scheme 1.



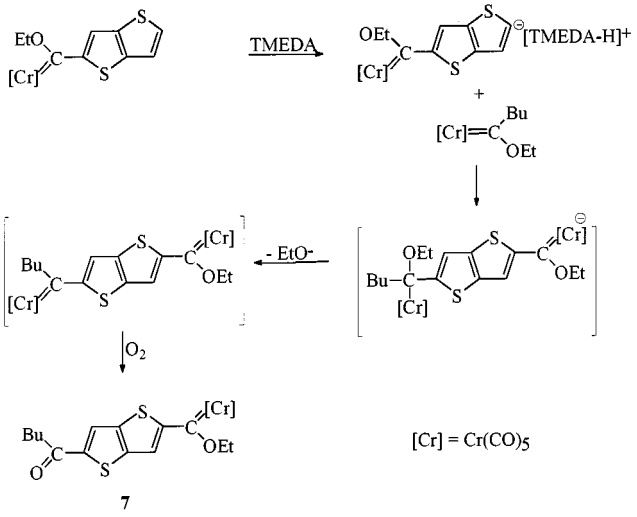
M = Cr, **1-3**
M = W, **4-6**

Scheme 1. Synthesis of the novel carbene complexes **1**−**6**; reagents: (a) 2 equiv. *n*BuLi, $M(CO)_6$, $Et_3O{\cdot}BF_4$; (b) O_2

Carbene complexes of chromium, complexes **1** and **2**, were crystallized from hexane/dichloromethane (1:1) solutions to affording red-orange needles for the monocarbene complex and purple-black crystals for the biscarbene complex. X-ray diffraction studies confirmed the structures of these compounds. Similar products, complexes **3** and **4**, were obtained for tungsten and characterized spectroscopically. Complexes **3** and **6** are suggested to have formed in solution by oxidation of the air-sensitive biscarbene complexes, involving trace amounts of oxygen.[6]

Complex **7** was isolated from the reaction between $Cr(CO)_6$ and thieno[3,2-*b*]thiophene and did not resemble any of the products obtained from the similar reaction with 3,6-dimethylthieno[3,2-*b*]thiophene. Although the synthetic procedure followed was identical, only complex **7** was isolated instead of the expected monocarbene and biscarbene complexes. The yield of **7** was low and implies the formation of other unstable compounds. The structural elucidation of this complex was based on the data collected with the use of NMR spectroscopy, infrared data, and mass spectrometry.

A possible reaction route to **7** is attributed to the enhanced acidity exhibited by the protons of the unsubstituted thienothiophene. Hence, the suggested formation of product **7**, as is illustrated in Scheme 2, can be explained by reaction of a deprotonated thienothiophene monocarbene complex and a metal butyl carbene to give a dinuclear ylide intermediate. Elimination of an ethoxy group follows and after subsequent oxidation of the more reactive metal butyl carbene end of the biscarbene, the final product, complex **7**, is afforded. TMEDA acts as a base and deprotonates the ring at the 7-position of the monocarbene complex, while its conjugated acid assists in the removal of the ethoxy group from the ylide.



Scheme 2. Suggested formation of complex **7**

The complexes were fully characterized and their NMR spectra recorded in deuterated chloroform. The monocarbene complexes, **1** and **4**, display a quadruplet signal for the H7 proton due to coupling with the methyl group on C6. This methyl signal is observed as a doublet and a coupling constant of ca. 1 Hz is determined for this four-bond coupling. It is interesting to note the significant difference in chemical shift values of the methylene resonance of the carbene ethoxy substituent on the spectra of the three tungsten complexes compared with the same signal on the spectra of the chromium complexes. The chemical shift is observed significantly more upfield for the tungsten complexes than for the chromium complexes, denoting that these resonance values are fairly characteristic for a specific metal and unaffected by the substituent on the 7-position of the 3,6-dimethylthieno[3,2-*b*]thiophene unit. Also characteristic is the position of the methylene resonances of the ester groups at $\delta \approx 4.35$ for both complexes **3** and **6**, which shows that the influence of the different metals is not transferred through the ligand to the other side of the thienothiophene rings. This was also observed for the corresponding thiophene complexes.[6] On the proton, as well as on the carbon NMR spectra of complexes **3** and **6** evidence for the further decomposition of these products to the 2,7-bis(ethyl ester) of 3,6-dimethylthieno[3,2-*b*]thiophene is observed and signifies the reactivity in solution towards oxygen of not only the biscarbene but also of the resulting monocarbene-ester complexes over prolonged periods of time.

Carbene carbon chemical shifts are found at characteristic values for the different metals on the ^{13}C NMR spectra. The values fall within the range of $\delta = 317-319$ for the chromium complexes, while these resonances are observed at $\delta = 292-297$ on the tungsten spectra. This same sequence is noted for the position of the $M(CO)_5$ peaks on the different spectra. The difference in chemical shift value ($\Delta\delta$) of the carbonyl resonances is approximately 10 ppm,

with tungsten upfield from chromium. The methylene carbons of the carbene ethoxy group of the different metal spectra reveal the opposite trend, with the resonances of the chromium complexes observed upfield from those of the tungsten complexes.

The lower wavenumbers observed on the infrared spectra of the monocarbene complexes **1** and **4** compared with those of the biscarbene complexes, and the decomposition products, indicate stronger metal-carbonyl back bonding and thus a decrease in C−O bond order. This implies weaker metal to carbene carbon π-bonding. Alternatively, the substituents on the carbene carbon may play a greater role in stabilizing the electrophilic carbene carbon. The values reported for the monocarbene complexes of chromium and tungsten containing a phenyl substituent, $[Cr(CO)_5C(OEt)Ph]$[16] and $[W(CO)_5C(OMe)Ph]$,[17] are even higher than for the thiophene complexes, implying that the phenyl unit is a poorer donor of electron density relative to the thienyl or, consequently, the thienothienyl substituent.

From the structures of complexes **1** and **2**, as shown in Figure 1 and Figure 2, it is noted that the heteroaromatic spacer, the carbene carbon and the metal atom are all coplanar for both structures. The metal fragment is orientated towards the sulfur atom and away from the methyl substituent on the ring in complex **1**. For complex **2**, the two $Cr(CO)_5$ metal fragments are found on opposite sides of the spacer ligand, positioned towards the sulfur atom and away from the methyl substituent on the ring. This is in contrast with the structure of the biscarbene complex of chromium pentacarbonyl, constituting a thienylene.[6] In this complex, the metal fragments are found on the same side of the thiophene ring and on the side opposite to the sulfur atom in the ring. However, for the biscarbene complex of chromium pentacarbonyl with biphenylene as the bridging ligand, the metal moieties are again on opposite sides of the axis connecting the two carbene carbon atoms.[4b] The Cr metal is approximately octahedrally arranged, with two of the *cis*-carbonyl ligands bending away from the carbene carbon. This is indicated by the bond angles of 94.5(1)° for both the C(12)−Cr(1)−C(1) and C(12A)−Cr(1)−C(1) angles in **1** and 93.1(1)° for both the angles C(7)−Cr−C(1) and C(9)−Cr(1)−C(1) in **2**. On considering the positions of the ethyl group of the ethoxy substituent relative to the metal fragment in the solid state, the (*Z*)-isomer of this complex along the carbene−O bond is observed. This is in accordance with the observation in the literature that the (*Z*)-isomer is by far the most popular arrangement in the crystal structures of ethoxy- or methoxy-substituted carbene complexes of octahedrally coordinated metals.[18] Suggested delocalization in the ring system is promoted by the observed bond lengths, which are all very similar and correspond to distances between characteristic $C(sp^2)$ single bonds and $C(sp^2)$ double bonds.[19] In contrast to the observation made for complex **1** where only the one thiophene unit is affected, delocalization in complex **2** occurs throughout the whole heteroarene system, aided by the influence of the second metal fragment, which is absent in complex **1**.

Conclusion

Transition metal biscarbene complexes with conjugated spacers are still limited in the literature. In this paper, we have reported the syntheses of biscarbene complexes with thienothiophene spacers, comprising two fused thiophene units. On comparing the relative stabilities in solution of these novel complexes with those of biscarbene complexes of thiophene, as described in the literature,[6] it was found that by increasing the number of thiophene units in the spacer, the stability of the complexes improves. However, formal stability studies were not conducted but the rate of decomposition of the individual complexes in solution was taken as a criterion. Biscarbene complexes convert into monocarbene-ester products within minutes after being dissolved in acetone or THF.

Experimental Section

General Remarks: All NMR spectra were recorded in deuterated chloroform, unless stated otherwise, using TMS as an internal

standard on a Bruker ARX-300 spectrometer. − Infrared spectra were recorded on a BOMEM FT-IR spectrophotometer using dichloromethane as solvent unless otherwise specified. − Mass spectra were recorded at ca. 70 eV on a Finnigan Mat 8200 instrument, using the electron impact method.

All reactions were performed in an inert atmosphere of either nitrogen or argon by using standard Schlenk techniques and vacuum-line methods. Solvents were dried and distilled under nitrogen prior to use. − Column chromatography was carried out under nitrogen using either silica gel (particle size 0.063−0.200 nm) or neutral aluminium oxide as resin. − Most chemicals were used directly without prior purification. The following compounds were prepared using known literature methods: 3,6-dimethylthieno[3,2-*b*]thiophene,[14] 2,3,5-tribromothiophene,[11] 3-bromothiophene,[12] ethyl (3-thienylthio)acetate,[10] ethyl (2-formyl-3-thienylthio)acetate,[13] thieno[3,2-*b*]thiophene carboxylic acid, thieno[3,2-*b*]thiophene[12], and triethyloxonium tetrafluoroborate.[20]

Revised Synthesis of Thieno[3,2-*b*]thiophene: Synthesis of 2,3,5-tribromothiophene was effected according to the method described by Brandsma and Verkruijsse,[11] and involved the reaction of bromine (180.00 mL; 3.50 mol) and thiophene (80.00 mL, 1.00 mol) in a 48% aqueous HBr/diethyl ether solution (400 mL/100 mL) at elevated temperatures (75°C). The target product (97%) and HBr were formed. Reduction of 2,3,5-tribromothiophene (321.00 g, 1.00 mol) to obtain 3-bromothiophene (55%),[12] was performed using zinc dust (196.00 g, 3.00 mol) in 175 mL of acetic acid. Reaction of 3-bromothiophene (90.50 g, 0.55 mol) with elemental sulfur (17.60 g, 0.55 mol), followed by the addition of ethyl bromoacetate (61.4 mL, 0.55 mol), afforded ethyl (3-thienothio)acetate (73%). On reacting this acetate-substituted thiophene (26.60 g, 0.13 mol) with phosphorus oxychloride (30.00 g, 0.19 mol) in *N*,*N*-dimethylformamide (14.00 g, 0.19 mol) afforded ethyl(2-formyl-3-thienothio)acetate (85%) in a Vilsmeier formylation reaction.[13] Cyclization and the subsequent decarboxylation of this compound yielded thieno[3,2-*b*]thiophene.[10]

Chromium Carbene Complexes 1, 2, and 3: 3,6-Dimethylthieno[3,2-*b*]thiophene (0.67 g, 4.00 mmol) was dissolved in 50 mL of hexane. TMEDA (1.20 mL, 8.00 mmol) and *n*-butyl lithium (5.5 mL, 8.8 mmol) were added at room temperature. The mixture was refluxed for 45 minutes and then cooled to 0 °C. After the addition of 50 mL of THF, $Cr(CO)_6$ (1.76 g, 8.00 mmol) was added and the suspension stirred for an hour. The color of the reaction changed to dark brown. After completion of the reaction, the solvent was removed in vacuo. The residue was dissolved in 20 mL of dichloromethane. Triethyloxonium tetrafluoroborate (1.50 g, 8.10 mmol) was dissolved in 20 mL of dichloromethane and this was added to the cooled reaction mixture (−20 °C). An immediate color change to a purple solution was observed. Stirring was maintained for a further hour while the temperature was allowed to reach room temperature. The mixture was then filtered, the solvent removed, and the remainder purified on a silica gel column. Three products were isolated, starting with pure hexane as eluent and gradually increasing the polarity of the solvent by adding dichloromethane. The first was the orange monocarbene complex **1**. The second purple complex was the biscarbene complex **2**, while the third red-orange compound was characterized as **3**. This complex was isolated using a hexane/dichloromethane mixture (1:1) as eluent.

Tungsten Carbene Complexes 4, 5, and 6: 3,6-Dimethylthieno[3,2-*b*]thiophene (0.34 g, 2.00 mmol) was dissolved in 30 mL of hexane. TMEDA (0.60 mL, 4.00 mmol) and *n*-butyl lithium (2.80 mL, 4.40 mmol) were added to this solution at room temperature. The same procedure was followed as for the chromium analog with the addition of $W(CO)_6$ (1.40 g, 4.00 mmol). For alkylation triethyloxonium tetrafluoroborate (0.74 g, 4.00 mmol) was used. On purification using column chromatography, three bands separated. The eluent used involved hexane/dichloromethane mixtures of various compositions. While the first product was isolated using pure hexane as eluent, a 1:1 mixture was used to isolate the third product. The first monocarbene complex **4** was isolated as an orange solid. The second purple complex was characterized as the biscarbene complex **5**, while the third red-orange band was identified as **6**.

Chromium Carbene Complex 7: Thieno[3,2-*b*]thiophene (0.56 g, 4.00 mmol) was dissolved in 30 mL of hexane. THF (100 mL) was added together with TMEDA (1.20 mL, 8.00 mmol) and *n*-butyllithium (5.50 mL, 8.80 mmol). The mixture was refluxed for 45 minutes and cooled to 0 °C, after which 100 mL of THF was added. $Cr(CO)_6$ (1.70 g, 8.00 mmol) was introduced and the mixture was stirred for an hour at room temperature. The solvent was evaporated and triethyloxonium tetrafluoroborate (1.50 g, 8.00 mmol), dissolved in 30 mL of dichloromethane, was added at −30 °C. The mixture was stirred for 15 minutes in the cold and for a further 45 minutes at room temperature, after which it was filtered and the solvent evaporated. The residue was column chromatographed with a hexane/dichloromethane (1:1) solution to yield the purple-pink product **7**.

7: Yield 0.79 g (42%), $C_{19}H_{16}O_7S_2Cr$ (472.5): calcd. C 48.30, H 3.42; found C 48.51, H 3.59. − IR (ν_{CO}; CH_2Cl_2) = 2058 (m), 1978 (w), 1943 (vs) cm^{-1}. − ^1H NMR ($CDCl_3$, 300.135 MHz): δ = 8.33 (s, 1 H, H^3), 7.82 (s, 1 H, H^6), 5.21 (q, ^3J = 7.0 Hz, 2 H, OCH_2CH$_3$−M), 2.93 [t, ^3J = 7.5 Hz, 2 H, C(O)CH_2CH$_2$CH$_2$CH$_3$], 1.74 [t, ^3J = 7.5 Hz, 2 H, C(O)CH$_2$$CH_2CH_2CH_3$], 1.69 (t, ^3J = 7.0 Hz, 3 H, OCH$_2$$CH_3$−M), 1.42 [t, ^3J = 7.5 Hz, 2 H, C(O)CH$_2$CH$_2$$CH_2CH_3$], 0.95 [t, *J* = 7.5 Hz, 3 H, C(O)CH$_2$CH$_2$CH$_2$$CH_3$]. − ^{13}C NMR ($CDCl_3$, 75.1 MHz): δ = 317.0 (carbene carbon), 223.5, 217.5 (CO), 194.5 (C=O), 164.0 (C^2), 155.1 (C^7), 146.8, 139.4, 134.4 (C^3, C^4, C^5, C^6, C^{10}, C^{11}), 75.7 (OCH_2CH$_3$−M), 43.0 [C(O)CH_2CH$_2$CH$_2$CH$_3$], 25.5 [C(O)CH$_2$$CH_2CH_2CH_3$], 22.8 [C(O)CH$_2CH_2$$CH_2CH_3$], 15.1 (OCH$_2$$CH_3$−M), 13.9 [C(O)CH$_2CH_2CH_2$$CH_3$]. − MS (EI); *m*/*z*: 472 [M^+], 444 [M^+ − CO], 416 [M^+ − 2 CO], 388 [M^+ − 3 CO], 360 [M^+ − 4 CO], 332 [M^+ − 5 CO].

X-ray Crystallographic Study: The intensity data for the compounds were collected at −90 °C on a Nonius−Kappa CCD diffractometer, using graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarization effects, but not for absorption.[21,22] The structures were solved by direct methods (SHELXS)[23] and refined by full-matrix least squares techniques against F_o^2 (SHELXL-97)[24]. The hydrogen atoms of the structures were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically. XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations. One molecule of chromium hexacarbonyl co-crystallized with two molecules of the monocarbene complex **1**. Other experimental details are given in Table 1. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary material publication nos. CCDC-142023 (**1**) and CCDC-142024 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [Fax: (internat.) +44 1223/336-033; E-mail: deposite@ccdc.cam.ac.uk].

Acknowledgments

We wish to thank Mr E. Palmer for the NMR measurements and the University of Pretoria and the Foundation for Research and Development, Pretoria, for financial assistance.

Redox Characteristics and Anion Association Behaviour of Stereoisomeric Forms of Mono- and Oligonuclear Metal Complexes Using High Pressure Electrochemistry

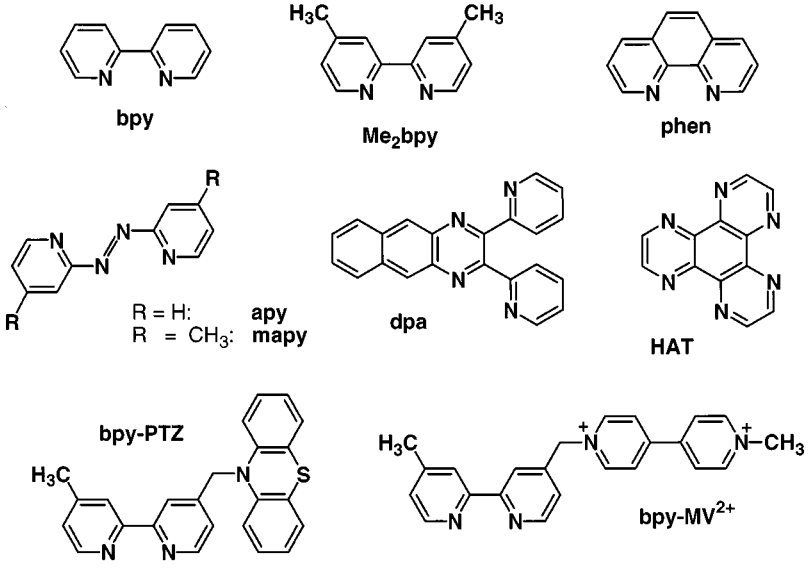
Brett D. Yeomans,[a] Laurence S. Kelso,[a] Peter A. Tregloan,[b] and F. Richard Keene*[a]

Keywords: Anion association / Stereochemistry / High-pressure electrochemistry / Mixed-valence / Ruthenium polypyridyl

The effect of the presence of the anions PF_6^-, BF_4^-, ClO_4^-, and tosylate$^-$ on the potentials of the $Ru^{III/II}$ redox processes in a series of mono-, di-, and trinuclear complexes involving polypyridyl ligands are reported. The anions gives rise to a cathodic shift in the respective redox potentials in the sequence $PF_6^- < BF_4^- \approx ClO_4^- <$ tos$^-$, with the magnitude of the shifts being largest for the tri-nuclear and smallest for the mononuclear species. In one dinuclear complex, a variation of anion was also observed to affect the difference in potentials between the [6+/5+] and [5+/4+] couples. These effects are consistent with known specific association of the anions with metal complexes of this type. In the presence of PF_6^-, high-pressure electrochemical studies revealed the molar volume changes for successive redox couples in di- and trinuclear complexes were almost invariant ($\Delta V_{complex}$ = 24 ± 2 cm^3 mol^{-1}) and consistent with the value for mononuclear species. This constancy is interpreted in terms of isolated $Ru^{III/II}$ processes in all complexes and implies that the electrostrictive effects on solvent are limited to a very short range.

Introduction

We have recently established that the stereochemical relationship of the components in mono- and oligonuclear species influences intramolecular electron and energy transfer processes between them. These studies have included the variation in lifetimes of the charge-separated excited states in the four geometric isomers of the chromophore-quencher complex $[Ru(Me_2bpy)(bpy\text{-}A)(bpy\text{-}D)]^{4+}$ {Me_2bpy = 4,4′-dimethyl-2,2′-bipyridine; bpy-A = bpy-MV^{2+} = (4′-methyl-2,2′-bipyridin-4-yl)methyl-1′-methyl-4,4′-bipyrinediium cation (MV^{2+} is an acceptor quencher); bpy-D = bpy-PTZ = 4′-methyl-2′,2-bipyridin-4-yl)methyl]phenothiazine (PTZ is a donor quencher)},[1,2] the variation in redox characteristics of the diastereoisomers of the two dimetallic systems $[\{Ru(pp)_2\}_2(\mu\text{-azo})]^{4+}$ {azo = azobis(2-pyridine),



apy, or azobis(4-methyl-2-pyridine), mapy; pp = 2,2′-bipyridine (bpy) or Me_2bpy} and $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{4+}$ {dpa = 2,3-bis(2-pyridyl)-1,4-diaazaanthracene},[3,4] and the variation of excited state lifetimes for the diastereoisomers of the dinuclear $[\{Ru(pp)_2\}_2(\mu\text{-HAT})]^{4+}$ and trinuclear

$[\{Ru(pp)_2\}_3(\mu\text{-HAT})]^{6+}$ complexes involving the bridging ligand HAT {pp = bpy or phen (1,10-phenanthroline); HAT = 1,4,5,8,9,12-hexaazatriphenylene}.[5]

At this stage, because of the limited number of examples available, the factors which give rise to dependence of such physical characteristics on the stereochemistry are not yet clear.

As part of our stereochemical studies, we have also established a general cation-exchange chromatographic procedure which allows the separation of stereoisomers of mono- and oligonuclear complexes.[3−10] The mechanism of the separation involves differential association of the anion of the eluent with the stereoisomers of the substrate cation, and NMR titration studies reveal the association has π-stacking and hydrophobic components.[4,7,8] More detailed studies of complex−anion (and probably complex−solvent) interactions will complete our understanding of the more intimate mechanistic details of the factors which contribute to the discrimination.

Recent reports have shown that electrochemical techniques such as cyclic voltammetry and differential pulse voltammetry performed at high pressure may be used to measure redox reaction volume changes (ΔV_{cell}) for electrochemical cells involving reactions of transition metal complexes.[11] Further, the experimental ΔV_{cell} can be resolved into reference electrode and working electrode contributions and the latter in turn broken into electrostrictive and intrinsic components, so that the technique can provide otherwise inaccessible information on the solvational and structural changes which accompany metal complex reduction processes − in both aqueous and non-aqueous solutions.

For systems such as those listed above, the technique therefore had immediate appeal in probing the nature of differences in the redox characteristics of stereoisomeric forms of the same complex, and in investigating the differences in anion/solvent interactions between similar structures. The present paper reports the first such investigations.

Results and Discussion

Syntheses

Synthesis and Separation. The synthesis of $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})](PF_6)_4$ was achieved by heating a 2:1 mixture of $[Ru(bpy)_2Cl_2]$ and the dpa ligand in methanol/water for 24 h. An alternative procedure involved heating an ethylene glycol solution of the reactants in a microwave oven: however, this method produced a lower yield of the dinuclear complex, with an increase in the production of mononuclear $[Ru(bpy)_2(dpa)]^{2+}$.

The dinuclear species $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{4+}$ exists in two diastereoisomeric forms, one *racemic* (consisting of the ΔΔ/ΛΛ enantiomeric pairs) and the other *meso* (ΔΛ). The diastereoisomers were separated by cation-exchange chromatography: the *rac* diastereoisomer appeared to be less stable than the *meso*, and underwent slow decomposition in the solid form.

For diastereoisomer characterisation, the resolution of one of the diastereoisomers unequivocally establishes its identity as *rac*. We have developed chromatographic methods for separation of enantiomers by ion-exchange chromatography, using chiral eluents.[5,7,12] Cation-exchange chromatography of the two separated diastereoisomers of $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{4+}$ (isolated from Bands 1 and 2 of the their chromatographic separation) using an aqueous solution of sodium (−)-*O*,*O*′-dibenzoyl-L-tartrate as the eluent showed that the product from Band 2 separated further into two bands (designated 2A and 2B), therefore unambiguously identifying it as the *rac* form. The isolated cations from this resolution had equal and opposite CD spectra (Figure 1).

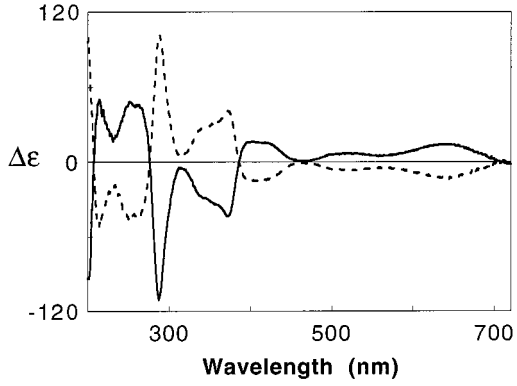

Figure 1. CD spectra (CH_3CN solution) of the ΔΔ (- - - - -) and ΛΛ (——) enantiomers of *rac*-$[\{Ru(bpy)_2\}_2(\mu\text{-dpa})](PF_6)_4$

On the basis of Exciton Theory and by comparison with previous resolutions of similar species,[5] Band 2A was assigned as ΔΔ and Band 2B as ΛΛ.

Electrochemistry

Redox potentials were determined by cyclic and differential pulse voltammetry in CH_3CN solution containing 0.1 M supporting electrolyte. The anion of the electrolyte was observed to affect the redox potentials associated with the $Ru^{III/II}$ couples in mono-, di-, and trinuclear complexes, and the separation between the formally [5+/4+] and [6+/5+] processes in dinuclear systems.

The $[FeCp_2]^{+/0}$ couple was employed as the reference in these studies, and this couple itself is known to be solvent and electrolyte dependent.[13,14] Consequently, the $[FeCp^*_2]^{+/0}$ redox couple (Cp* = pentamethylcyclopentadienyl anion), which is less susceptible to anion and solvent interactions,[14] was also used as a reference; however, we found little difference for $[FeCp_2]^{+/0}$ vs. $[FeCp^*_2]^{+/0}$ in the range of electrolytes employed {$E_{1/2}$ values of $[FeCp_2]^{+/0}$ vs. $[FeCp^*_2]^{+/0}$ in acetonitrile/0.1 M $[(n\text{-}C_4H_9)_4N]X$ solution were 520 mV (X = BF_4^-), 512 mV (PF_6^-), 510 mV (ClO_4^-), and 507 mV (tos^-; tosylate ion}. On this basis, the reasonable assumption is made that the data reported reflect only the changes in potential associated with working electrode half-cell of the particular complex involved.

Table 1. Electrolyte-anion dependence of redox potentials of complexes vs. $[FeCp_2]^{+/0}$ in CH_3CN/0.1 M $[(n\text{-}C_4H_9)_4N]X$

	Anion X^-	$E_{1/2}$ (mV) [3+/2+]	$E_{1/2(1)}$ (mV) [5+/4+]	$E_{1/2(2)}$ (mV) [6+/5+]	$\Delta E_{1/2}$ (mV)

$[Ru(phen)_3]^{n+}$	PF_6^-	892			
	tos^-	860			
$[Ru(phen)_2(HAT)]^{n+}$	PF_6^-	1172			
	BF_4^-	1140			
	ClO_4^-	1184			
	tos^-	1072			
$\Delta\Lambda$(*meso*)-$[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{n+}$	PF_6^-		1160	1384	224
	BF_4^-		1160	1356	196
	ClO_4^-		1106	1310	204
	tos^-		972	1054	86
$\Delta\Lambda$(*meso*)-$[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{n+}$	PF_6^-		1069	1262	193
	BF_4^-		1008	1200	192
	ClO_4^-		1025	1200	175
	tos^-		962	1082	120
$\Delta\Delta/\Lambda\Lambda$(*rac*)-$[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{n+}$	PF_6^-		1088	1263	175
	BF_4^-		1048	1203	155
	ClO_4^-		1049	1202	153
	tos^-		990	1094	104

The dependencies of redox potentials of complexes studied in this work on the anion of the electrolyte are listed in Table 1. There is a cathodic shift of potentials in solutions containing certain electrolyte anions, with tos^- having the greatest effect. The induced shifts are less for $Ru^{III/II}$ couples in monouclear complexes (50 mV for complexes containing only bpy and phen ligands and their derivatives; 100 mV for mononuclear complexes containing the ligand HAT) than those) in dinuclear systems for the formally [5+/4+] (100−200 mV) and [6+/5+] processes (150−300 mV.

For the mononuclear complex couples $[Ru(bpy)_3]^{3+/2+}$, $[Ru(Me_4bpy)_3]^{3+/2+}$, and $[Ru(phen)_3]^{3+/2+}$, a cathodic shift in the redox potential was observed in the order $PF_6^- < BF_4^- < ClO_4^- < tos^-$, with the same trend being observed for $[Ru(phen)_2(HAT)]^{3+/2+}$ but of larger magnitude. Ion-pairing between the cationic complex and electrolyte anion would be expected to result in a cathodic shift in the redox potential due to the lesser net charge of the ion-pair,[13,14] so the shift of potentials to less positive values in solutions with different electrolyte anions can be correlated with differential ion-pairing;[4,8] i.e. the tos^- anion interacts with the complex to a greater extent than does PF_6^-. The effect observed for $[Ru(phen)_2(HAT)]^{3+/2+}$ suggests an even greater interaction.

For dinuclear complexes, the electrochemistry of $[\{Ru(Me_2bpy)_2\}_2(\mu\text{-mapy})]^{4+}$,[3] $[Ru(phen)_2(HAT)]^{2+}$, $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$, and $[\{Ru(phen)_2\}_3(HAT)]^{6+}$ [5] have been reported elsewhere. In the present study, in CH_3CN/0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$ solution the diastereoisomers of $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{4+}$ each exhibited two reversible one-electron oxidations corresponding to successive oxidation of the metal centres, and multiple reversible ligand-based reductions. However, the *meso* and *rac* forms differed (Figure 2); in the *meso* complex the first oxidation ($E_{1/2(1)}$) occurred at a less positive potential than the *rac* form, resulting in a greater separation of the two oxidations ($\Delta E_{1/2}$). The separation between such oxidations in a dinuclear species is used as an indication of the degree of M−M interaction.[15]

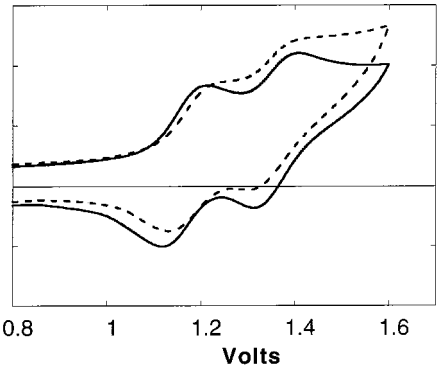

Figure 2. Cyclic voltammograms (CH_3CN/0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$ solution) of the *meso*- (——) and *rac*- (- - - - -) diastereoisomers of $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{n+}$ {[5+/4+] and [6+/5+] couples only}

In dinuclear systems, the anions also affect this separation between [5+/4+] $\{E_{1/2(1)}\}$ and [6+/5+] $\{E_{1/2(2)}\}$ redox couples. For example, $\Delta E_{1/2}$ for $\Delta\Lambda$-$[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{4+}$ ranged from 193 mV $\{[(n\text{-}C_4H_9)_4N]PF_6\}$ to 120 mV $\{[(n\text{-}C_4H_9)_4N]tos\}$, with $\Delta E_{1/2}$ decreasing in the order $PF_6^- > BF_4^- > ClO_4^- > tos^-$. Even more dramatic effects were observed for $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ (Table 1). The effects were always in the order that the separation for $PF_6^- > BF_4^- > tos^-$: the effect of ClO_4^- was more variable, but generally comparable with that of BF_4^-. In all cases, the absolute potentials of both couples shifted, and the greater negative shift of the [6+/5+] couple leads to the decrease in separation. Changing the electrolyte cation {e.g.

$[(C_2H_5)_4N]ClO_4$ cf. $[(n\text{-}C_4H_9)_4N]ClO_4$} made no difference to the voltammetry.

For dinuclear species, ion-pairing offers one possible explanation for the remarkable observations of the dependence of $\Delta E_{1/2}$ on the identity of the anion in the electrolytes. For these dinuclear complexes, on purely electrostatic grounds ion-pairing would be stronger for the [6+]/[5+] couple (cf. [5+]/[4+]) because of the larger charges involved, resulting in $E_{1/2(2)}$ ([6+]/[5+]) shifting more cathodically than $E_{1/2(1)}$.

An alternative rationalization of the effect is more speculative. Recent work has shown specific interactions between a variety of aliphatic and aromatic anions with ruthenium(II) complexes containing polypyridyl ligands,[8] and in the case of dinuclear species, specific interactions have been identified in the region between the metal centres. The presence of the anion(s) in that region might result in an increased metal−metal separation, with the resultant decrease in metal−metal interaction manifested in a smaller separation between the two metal-based oxidations ($\Delta E_{1/2}$), as observed for tos^- (for which the association would be strongest) with $[\{Ru(bpy)_2\}(\mu\text{-dpa})]^{4+}$ and $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$.

Spectroelectrochemistry

Detailed spectroelectrochemical studies of the dinuclear complexes bridged by apy and mapy have previously been reported.[3] Similar studies were undertaken in the present work for the complexes $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$, $[\{Ru(phen)_2\}_3(\mu\text{-HAT})]^{6+}$, and $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{4+}$, and the absorption data for the resulting electrogenerated species are collated and presented as Supporting Information (Table S1). All three compounds showed clear isosbestic points for the first oxidation process, and reversibility was demonstrated by coincidence of the various isosbestic points during the reverse reduction step, which led to ultimate recovery of the starting compound.

For the dinuclear complexes the first oxidation was a one-electron process, producing the mixed-valence species $[(pp)_2Ru^{III}(\mu\text{-L})Ru^{II}(pp)_2]^{5+}$ (pp = bpy or phen) which possess intense intervalence charge transfer or metal-to-metal charge transfer (MMCT) bands in the near infrared (NIR) region of the spectrum. The formation of such a band in a spectroelectrochemical experiment is shown for the oxidation of *meso*-$[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ in Figure 3. Additionally, the overlayed spectra of $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{4+}$ and its electrogenerated [5+] and [6+] analogues are shown in Figure 4. The first oxidation of both these dinuclear complexes was accompanied by a 50% decrease in the intensity of their respective MLCT absorptions (at 15600 cm^{-1} and 18200 cm^{-1}, respectively). This is consistent with the notional conversion of one of the d^6 metal centres in each dimer to a d^5 entity. The band attributed to the $d\pi(Ru^{II})\rightarrow\pi^*$(bridge) MLCT absorption collapsed completely following removal of a second electron.

An analysis of the NIR absorbances using Hush theory[16,17] reveals a large discrepancy between calculated and experimentally derived values of $\Delta\nu_{1/2}$ (Table 2). While a strong solvent dependency may account for this (our measurements were primarily carried out in CH_3CN solution), the non-applicability of the theory suggests a large degree of delocalisation and thus strongly interacting (Robin and Day "Class III") behaviour.[18−20] This is further supported by the unsymmetrical (non-gaussian) appearence of the bands and the apparent fine structure within the NIR region absorbances. No differences in band energy, intensity or shape were observed between the diastereoisomeric pairs of the dinuclear species investigated.

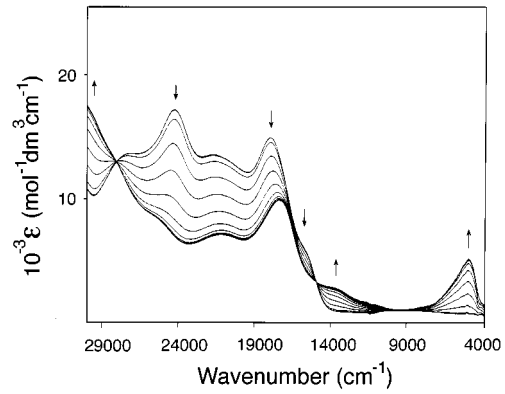

Figure 3. Spectroelectrochemical study of one-electron oxidation of *meso*-$[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ (CH_3CN/0.1 M $[(n\text{-}C_4H_9)_4N]ClO_4$ solution)

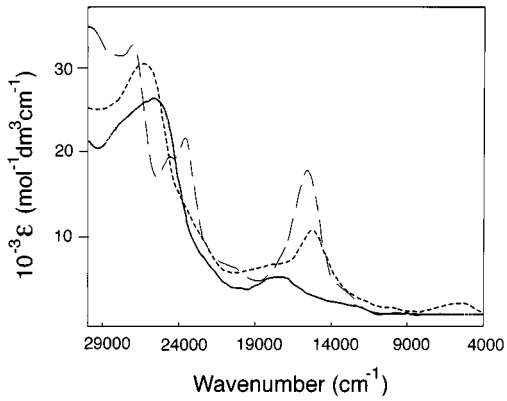

Figure 4. UV/Visible spectra of $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{4+}$ (− − − −) and the electrogenerated 5+ (- - - - -) and 6+ (——) analogues (CH_3CN/0.1 M $[(n\text{-}C_4H_9)_4N]ClO_4$ solution)

Table 2. MMCT band analysis of mixed-valence dinuclear species in CH_3CN solution at −32 °C

Dinuclear Complex	$\tilde{\nu}_{max}$ [cm^{-1}]	$\Delta\tilde{\nu}_{1/2}$ (calcd.) [cm^{-1}]	$\Delta\tilde{\nu}_{1/2}$ (exp.) [cm^{-1}]
$[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{5+}$	5600	3600	2800
$[\{Ru(bpy)_2\}_2(\mu\text{-mapy})]^{5+}$ [3]	6900	3990	1600
$[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{5+}$	5200	3470	1700
$[\{Ru(*phen*)_2\}_2(\mu\text{-HAT})]^{5+}$	8200	4350	1900

For the dinuclear complexes, some problems were encountered when attempts were made to fully oxidize both metal centres to the trivalent state. A spectrum of $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{6+}$ was obtained at −32 °C, however the compound was only metastable when held at a high anodic potential for extended periods of time. A gradual

reduction in the absorption intensity was observed across the entire spectral region and following regeneration the original [4+] cation also exhibited a reduced intensity.

We were unable to observe the $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{6+}$ cation. Subjecting the [5+] species to high anodic potentials over a 3 h period led to a new unidentified [6+] compound in which one or more of the phenanthroline ligands appeared to have undergone oxidation. The product species is characterised by an intense absorption at 11300 cm^{-1} which can tentatively be assigned as a $\sigma(\text{ligand})\rightarrow d^5(Ru^{III})$ (LMCT) transition. The oxidation of phenanthroline to 1,10-phenanthroline-5,6-dione while coordinated to a ruthenium or cobalt(III) centre is a well-documented phenomenon: the reaction is known to proceed readily (and at much lower potentials) relative to the oxidation of an uncoordinated ligand.[21,22] This oxidative conversion was completely irreversible, however the new species was itself very stable and displayed its own completely reversible spectroelectrochemistry. Upon reduction to the 5+ state, this new complex exhibited a unique MMCT band which predictably collapsed upon further reduction to a [4+] species (Figure 5). Repeated oxidations and reductions via bulk electrolysis gave reproducible isosbestic points and uniform absorption intensities.

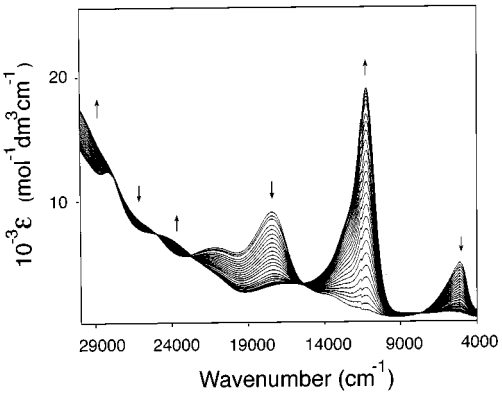

Figure 5. Spectroelectrochemical trace of the reduction of $[\{Ru(*phen*)_2\}_2(\mu\text{-HAT})]^{5+}$ (CH_3CN/0.1 M $[(n\text{-}C_4H_9)_4N]ClO_4$ solution)

Reduction of the dinuclear complexes bridged by dpa or HAT led to rapid decomposition of the original [4+] species. Re-oxidation of the dpa species produced a compound whose visible spectrum was very similar to that of $[Ru(bpy)_2(dpa)]^{2+}$. This is consistent with a previous spectroelectrochemical investigation of $[\{Ru(bpy)_2\}_2(\mu\text{-dpp})]^{4+}$ where it was determined that mononuclear $[Ru(bpy)_2(dpp)]^{2+}$ was produced via de-chelation of dinuclear starting material subjected to large cathodic potentials.[18]

The spectroelectrochemistry of the $[\{Ru(phen)_2\}_3(\mu\text{-HAT})]^{6+}$ trinuclear complex presented none of the problems associated with the dinuclear species. Two successive oxidations {[6+]→[7+] and [7+]→[8+]} and two reversible reductions {[6+]→[5+] and [5+]→[4+]} were easily achieved. The starting compound was also regenerated without any appreciable degradation. No NIR absorption bands were observed for the potentially mixed-valent [5+] or [6+] species. The absence of a MMCT transition implies that electron density is totally delocalised across the entire molecule and hence removal of an electron from the system only results in a small change in the effective charge on all three metal centres. This is borne out by the relatively small differences between the visible absorption spectra following each successive redox event.

High-Pressure Electrochemistry

High-pressure voltammetry techniques enable the measurement of molar volume changes of electron-transfer reactions.[11] The standard molar volume change ($\Delta V°_{cell}$) for a redox reaction is given by $\Delta V°_{cell} = (d\Delta G°/dP)$, or $\Delta V°_{cell} = -nF(dE°/dP)$, where n is the number of electrons transferred and F is the Faraday constant. The cell reaction volume (ΔV_{cell}) of a redox couple can therefore be determined by measuring the pressure dependence of $E_{1/2}$ for the redox couple. ΔV_{cell} is the sum of the two half-cell components, $\Delta V_{complex}$ and ΔV_{ref}, arising from the molar volume changes of the reference and working electrodes, respectively. The same reference {Ag/Ag^+ (0.01 M in CH_3CN)} was employed for all experiments; ΔV_{ref} for this system has been determined to be -20.7 cm^3 mol^{-1}.[11] Using this value for ΔV_{ref}, molar volumes changes for the reduction processes of the complexes, $\Delta V_{complex}$, were then calculated and are listed with the measured ΔV_{cell} values in Table 3.

The $\Delta V_{complex}$ will be made up of two components, ΔV_{elec} and ΔV_{intr}: the former is an electrostrictive contribution arising from interaction of solvent molecules and counterions with the ionic charge of the complex, and the latter is an intrinsic contribution arising from bond length and structural changes within the molecule. For the ruthenium complexes containing polypyridyl ligand studied here, minimal structural changes occur within the $Ru^{III/II}$ redox process,[23] so that the major component of $\Delta V_{complex}$ will be ΔV_{elec}, reflecting the interaction of solvent and electrolyte with the complex cation.

While there is little influence of the anion on the value of $\Delta V_{complex}$ for the mononuclear species $[Ru(phen)_2(HAT)]^{3+/2+}$ {$\Delta V_{complex} = 22.2$ cm^3 mol^{-1} in $[(n\text{-}C_4H_9)_4N]PF_6$ and 20.0 cm^3 mol^{-1} in $[(C_2H_5)_4N]ClO_4$}, in all other complexes studied there appears to be a significant effect, which is noticably more positive (by 7−12 cm^3 mol^{-1}) in PF_6^- than in ClO_4^- media. This effect is presumably related to the specific interactions/association of some anions: it is consistent with a greater release of solvent in the presence of the less strongly associated anion PF_6^- because the effective complex charge is higher, and $\Delta V_{complex}$ is proportional to Δz^2 (see below). The discrimination of the anions in dinuclear complexes indicates that the region between the metal centres is additionally important.[8]

For all species except the monomer, shifts in $E_{1/2}$ at 1 bar indicate that ClO_4^- associates more strongly than PF_6^-, and the differences in ΔV values seem to parallel the differences (or lack thereof) in $E_{1/2}$ measured in the respective media. However, leaving aside the data for the $[Ru(phen)_2(HAT)]^{3+/2+}$ couple in perchlorate media, the values of $\Delta V_{complex}$ are remarkably constant across charge

Table 3. ΔV_{cell} and corresponding molar volume changes ($\Delta V_{complex}$) for reduction of mono-, di-, and trinuclear complexes in CH_3CN/0.1 M $[(n\text{-}C_4H_9)_4N]X$ ($X = PF_6^-$, ClO_4^-) solution

[a] $\Delta V_{complex} = \Delta V_{cell} - \Delta V_{ref}$ ($\Delta V_{ref} = -20.7\ cm^3\ mol^{-1}$); ref.[11]

changes and across complexes within each charge change group ($\Delta V_{complex} = 24 \pm 2\ cm^3\ mol^{-1}$). Furthermore, there does not appear to be any significant difference in $\Delta V_{complex}$ between the diastereoisomers within the $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})]^{n+}$ and $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{n+}$ species: the values of $\Delta V_{complex}$ for the *meso* isomers of both dinuclear complexes are generally within $2\ cm^3\ mol^{-1}$ of the *rac* form, which is not significantly greater than experimental error.

This is a surprising result. Previous studies have discussed the correlation between electrostrictive changes ΔV_{elec} and $\Delta z^2/r$ $\{\Delta z^2 = (z_{ox})^2 - (z_{red})^2$; r = radius of species$\}$.[24] Calculated van der Waal's volumes for the mono-, di-, and trinuclear complexes $\{[Ru(phen)_2(HAT)]^{n+}$, $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{n+}$, and $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{n+}\}$ were 518, 847, and 1177 Å^3, respectively: even allowing for the approximation incurred because of the non-spherical nature of the di- and trinuclear species, the constancy of $\Delta V_{complex}$ cannot be accounted for by this simple $\Delta z^2/r$ relationship.

A rationalization for the effect may be found in ion association, which is known to occur between the cationic mono-, di-, and trinuclear complexes used in this study and a variety of anions.[8] Indeed, NMR titration studies of the interaction of a number of mononuclear (2+) and dinuclear (4+) complexes with strongly associating anions were interpreted to indicate a 2:1 and 4:1 ratio of anions/cation, respectively.[8] Accordingly, the "effective charge" would be expected to be less than the formal charge in these species. Furthermore, if in di- and trinuclear species there were differences in the extent of association between the oxidized and reduced forms, then their effective charges would also be less than the formal charges, and actually closer to the charges applying to the mononuclear situation. Thus for each redox couple in the systems studied, the measured values of $\Delta V_{complex}$ could be similar. This situation is represented by the Equation (1).

$$[M^{n+} \ldots pX^-]^{(n-p)+} + e^- \rightarrow [M^{(n-1)+} \ldots (p-q)X^-]^{(n-p-1+q)+} + qX^- \quad (1)$$

However, consideration of the Nernst equation would a require a linear relationship between $E_{1/2}$ and $\ln[X^-]$ with a slope of $-0.059q$ (q is the number of anions released from association on a one-electron reduction of the substrate).[25] Our studies of the dependence of $E_{1/2}$ on the concentration of the anion indicated that there was no significant release of associated anions on reduction within any nuclearity regime.

Another rationale has its basis within the nature of the redox changes. Regardless of the nuclearity, each redox process involves a change at one ruthenium centre from oxidation state III to II. The observed consistency of $\Delta V_{complex}$ values may indicate that the effects on solvent are localised around individual ruthenium centres. In other words, the system behaves as a sequence of localised 3+/2+ charge changes and that in all cases Δz^2 is effectively 5, regardless of the overall charge. The consistent value of ca. $20-26\ cm^3\ mol^{-1}$ is in agreement with the [3+/2+] couples measured both in this work, and in other independent observations of [3+/2+] reductions: e.g. $\Delta V_{complex} = 22.2\ cm^3\ mol^{-1}$ (acetonitrile/0.1 M $[(C_2H_5)_4]ClO_4$) for $[Fe(phen)_3]^{3+/2+}$.[11] The interpretation that all centres are acting as independent $Ru^{III/II}$ couples appears to be in conflict with the communication between the metal centres in the di- and trinuclear species, as evidenced by our observation of MMCT bands in such complexes (discussed above). However, in 1,4-pyrazine-bridged dinuclear ruthenium complexes, in which there is also strong communication between the metal centres, reaction entropies ($\Delta S°$) for successive redox changes are independent of the oxidation state of the second Ru centre, and correspond to the $\Delta S°$ values for the corresponding mononuclear moieties. This was interpreted to demonstrate that the entropy change upon reduction of the Ru was caused by short-range effects not reaching further than two solvent molecules.[26] It is not unreasonable to conclude that the constancy of the values of $\Delta V_{complex}$ across successive redox changes and across complexes within each charge

group observed in the present work reflects isolated events where the solvent effect is limited to a short range.

Experimental Section

Physical Measurements: Electronic spectra were recorded using a Cary 5E UV/Vis/NIR spectrophotometer. NMR spectra were recorded on Bruker AM300 or Varian Mercury 300 MHz spectrometers. Electrochemical measurements at atmospheric pressure were performed in an argon-filled drybox using a Bioanalytical Systems (BAS) 100A electrochemical analyzer. Cyclic voltammetry in acetonitrile employed a platinum disk (1 mm diameter) working electrode, platinum wire counter electrode and Ag/Ag^+ (0.01 M) reference electrode. Solutions contained 0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$ or $[(C_2H_5)_4N]ClO_4$ as electrolyte. Typically, scan rates were 100−200 mV s^{-1}. Ferrocene ($[FeCp_2]$ was added as an internal standard after each experiment (oxidation at +0.095 V vs. Ag/Ag^+). For differential pulse voltammetry (DPV) measurements the conditions used were scan rate 4 mV/s, pulse amplitude 50 mV, pulse width 60 msec and pulse period 1 s. Spectra of oxidized and reduced species were obtained at 240 K by electrogeneration within a cryostatted optical semi-thin-layer electrochemical (OSTLE) cell, utilizing a Perkin−Elmer Lambda 9 UV/Vis/NIR spectrophotometer, as described previously.[27] High resolution mass spectra were obtained at the Australian Institute of Marine Science (Townsville) on a Bruker BioApex 47e ICR Mass Spectrometer with an electrospray source, using solutions ca. 2 μg/mL in acetonitrile.

The high pressure electrochemical cell is a development of our earlier design[24,28] and has a sample volume of ca. 1 mL, uses a 1 mm Pt disk working electrode, 2 mm Pt disk counter electrode and a Ag/Ag^+ (0.01 M in 0.1 M supporting electrolyte) reference electrode separated from the working solution by a Vycor™ frit mounted in a flexible Teflon™ sleeve.[11] The high-pressure electrochemical experiments were performed in acetonitrile solution containing 0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$ or $[(C_2H_5)_4N]ClO_4$ as supporting electrolyte: samples were prepared in air, then purged with N_2 before closing the cell and mounting it in the high pressure bomb, thermostatted at 298 K. Cyclic voltammetry and differential pulse experiments were carried out using a MacLab potentiostat and data acquisition system with E-Chem software (AD Instruments). Data were recorded at intervals of about 500 psi (34 bar) up to the maximum pressure, allowing the cell to thermally equilibrate for about 20 mins between measurements, and then at intermediate pressures as the pressure was lowered, to check the integrity of measurements over the period of the measurements, typically 4 h.

Materials: Ammonium hexafluorophosphate (Aldrich), potassium hexafluorophosphate (Aldrich), 2,3-diaminonaphthalene (Fluka), sodium toluene-4-sulfonate (sodium tosylate; Aldrich), tetra-*n*-butylammonium hexafluorophosphate {$[(n\text{-}C_4H_9)_4N]PF_6$; Aldrich}, tetra-*n*-butylammonium perchlorate {$[(n\text{-}C_4H_9)_4N]ClO_4$; Fluka}, tetra-*n*-butylammonium tosylate {$[(n\text{-}C_4H_9)_4N]$tos; Fluka}, tetraethylammonium perchlorate {$[(C_2H_5)_4N]PF_6$; Kodak Eastman}, and decamethylferrocene (Aldrich) were used as supplied. SP Sephadex C-25 (Pharmacia) was used for chromatographic separation of ruthenium complexes.[4] HPLC grade acetonitrile (BDH) was used for electrochemical measurements; all other solvents were of reagent grade and used without purification. The ruthenium complexes $[Ru(bpy)_2Cl_2]\cdot 2\,H_2O$,[29] $[Ru(pp)_3](PF_6)_2$ {pp = bpy, phen, or Me_4bpy (4,4′,5,5′-tetramethyl-2,2′-bipyridine)},[12] $[Ru(phen)_2(HAT)](PF_6)_2$,[5] $[\{Ru(phen)_2\}_2(\mu\text{-HAT})](PF_6)_4$,[5] $[\{Ru(phen)_2\}_3(\mu\text{-HAT})](PF_6)_6$,[5] and $[\{Ru(bpy)_2\}_2(\mu\text{-mapy})](PF_6)_4$ and $[\{Ru(Me_2bpy)_2\}_2(\mu\text{-mapy})](PF_6)_4$[3] were prepared and purified by literature methods.

2,3-Bis(2-pyridyl)-1,4-diazaanthracene (dpa): Preparation by a modified procedure of Goodwin and Lions[30] for 2,3-bis(2-pyridyl)quinoxaline. 2,3-Diaminonaphthalene (1.0 g, 6.3 mmol) and 2,2′-pyridil (= di-2-pyridylglyoxal; 1.34 g, 6.3 mmol) were refluxed in ethanol (20 cm^3) for 0.5 h. The volume of the reaction mixture was reduced to half via rotary evaporation. The yellow crystalline solid was collected by filtration and recrystallised from ethanol. Yield: 1.53 g (77%); m.p. 184−185 °C. ^{13}C NMR ($CDCl_3$): δ = 123.0, 124.0, 126.9, 127.8, 128.6, 134.2, 136.6, 137.6, 148.3, 153.0, 157.5.

$[\{Ru(bpy)_2\}_2(\mu\text{-dpa})](PF_6)_4$. − Method A: 2,3-Bis(2-pyridyl)-1,4-diazaanthracene (dpa; 31.7 mg, 0.095 mmol) was dissolved in nitrogen-purged 50% aqueous methanol (20 cm^3). $[Ru(bpy)_2Cl_2]\cdot 2\,H_2O$ (105 mg; 0.202 mmol) was added and the mixture heated at reflux for 24 h. Methanol was removed via rotary evaporation and the crude product precipated from the aqueous solution by addition of a saturated solution of KPF_6. A dark green solid was isolated by vacuum filtration and washed sparingly with water. Purification was achieved by cation-exchange chromatography (SP-Sephadex C-25; eluent 0.5 M NaCl). A claret band of mononuclear material eluted first, followed by the desired dark green product, which was isolated as the PF_6^- salt. Yield: 117 mg (71%). ESMS (accurate mass): observed *m/z* 1597.1009 (most abundant isotope peak within cluster); $[C_{62}H_{46}N_{12}Ru_2](PF_6)_3^+$ requires 1597.1005.

Method B: A mixture of $[Ru(bpy)_2Cl_2]\cdot 2\,H_2O$ (170 mg, 0.33 mmol) and dpa (50 mg; 0.15 mmol) in ethylene glycol (3 cm^3) was heated in a modified microwave oven[31] (Sharp model R-2V55; 600 W, 2450 MHz) on medium-high power for 5 min. The green solution was poured into distilled water (50 cm^3) and a saturated solution of KPF_6 added dropwise yielding a dark green solid, which was collected and washed with distilled water. Purification of the crude product was achieved as above. Yield: 85 mg (33%).

Column Conditions for Separation/Resolution of $[\{Ru(bpy)_2\}_2(\mu\text{-dpa})](PF_6)_4$: Separation of the diastereoisomers and resolution of the enantiomers of the *rac* form were achieved by cation exhange chromatography on SP Sephadex C-25 support using 0.25 M sodium toluene-4-sulfonate and 0.075 M sodium (−)-*O*,*O*′-dibenzoyl-L-tartrate as eluents, respectively.[7] The diastereoisomers separated after passing through an effective column length (ECL) of 150 cm (the *meso* band eluting first). Resolution to give the two enantiomers (ΔΔ and ΛΛ) of the *rac* form was achieved over an ECL of 80 cm. All products were precipitated as the PF_6^- salts by addition of a saturated solution of KPF_6 to each green band after elution. Diastereoisomeric ratio (*rac*/*meso*): 44:56. Enantiomeric ratio (ΔΔ/ΛΛ): 49:51.

Acknowledgments

This work was supported by the Australian Research Council, James Cook University and the University of Melbourne. The authors would like the thank Dr. Graham Heath (Australian National University) for use of the OSTLE facilities, Dr Len Barbour (University of Alabama) for the van der Waal's volume calculations, and Professors Royce Murray (University of North Carolina, Chapel Hill, USA) and Joseph Hupp (Northwestern University, Evanston, USA) for valuable discussions.

Formation of Metallamacrocycles from Palladium(II), Platinum(II) and Copper(I) Complexes and the Ditopic Ligands [{*p*-(Ph_2PO)C_6H_4}$_2$$CMe_2$], [{2-$Ph_2PO$-3,5-($Me_3C$)$_2$$C_6H_2$}$_2$S], [{*p*-[($C_{10}H_6O$)$_2$PO]$C_6H_4$}$_2$$CMe_2$]

Carmela Grazia Arena,[a] Dario Drommi,[a] Felice Faraone,*[a] Claudia Graiff,[b] and Antonio Tiripicchio[b]

Keywords: Macrocycles / Metallacycles / Palladium / Platinum / Copper

The new ligands bis(phosphinito) [{2-Ph_2PO-3,5-(Me_3C)$_2$$C_6H_2$}$_2$S] (**4**) and chiral bis(phosphite) [{*p*-[($C_{10}H_6O$)$_2$PO]C_6H_4}$_2$$CMe_2$] (**5**) were synthesised and their reactions with palladium(II), platinum(II), copper(I) substrates were studied. The ligand **3** [{*p*-(Ph_2PO)C_6H_4}$_2$$CMe_2$], previously reported by us, was also used in the same reactions. Ligands **3** and **5** formed 28-membered metallamacrocycles while ligand **4** afforded the analogous compound only in the reaction with the copper(I) substrate. In the reaction of **3** with [Pd(PhCN)$_2$Cl$_2$] the metallamacrocycle [PdCl$_2$(μ-**3**)]$_2$ (**6**) or the oligomer [Pd$_2$Cl$_4$(μ-**3**)]$_n$ (**7**) were formed, depending on the molar ratio used. The reaction of **3** with [Pd(η^3-C_3H_5)Cl]$_2$ afforded compound {[Pd(η^3-C_3H_5)Cl]$_2$(μ-**3**)} (**8**). The allylpalladium macrocycle [Pd(η^3-C_3H_5)(μ-**3**)]$_2$[OTf]$_2$ (**9**) was obtained by treating a solution of **8** in THF with $AgCF_3SO_3$. The reactions of ligand **3** with [Pt(COD)I$_2$] or [Cu(NCCH$_3$)$_4$]BF$_4$ led to the formation of metallamacrocycles [PtI$_2$(μ-**3**)]$_2$ (**10**) and [Cu$_2$(μ-**3**)$_2$][BF$_4$]$_2$·2CH$_3$CN (**11**), respectively. The structure of **10** was also elucidated by X-ray analysis. Reactions of **4** with palladium(II) and platinum(II) complexes afforded a mixture of two very different compounds in almost an equimolar ratio. An X-ray analysis established that one is a mononuclear compound, formed by modification of the ligand **4**, containing a P,S-chelate, namely {PdCl$_2${[2-Ph_2PO-3,5(Me_3C)$_2$$C_6H_2$][3,5-($Me_3C$)$_2$$C_6H_2$OH]S}] (**12**). The reaction between [Cu(NCCH$_3$)$_4$]BF$_4$ and **4** afforded the ionic metallamacrocycle [Cu(μ-**4**)][BF$_4$]$_2$·2CH$_3$CN (**14**). In compound **10**, the size of the central cavity formed by the bridging ligand **3** was determined.

Introduction

In the last twenty years a number of studies have indicated that hydrogen bond formation is not the unique mode through which the supramolecular self-assembly of molecules can occur and coordination bond formation was found to be a very useful tool to promote supramolecular self-assembly processes.[1a,2] In fact the preferred coordination numbers, the geometry of transition metal complexes and the shape of the bi- and polydentate ligands drives a spontaneous supramolecular self-assembly process to give metallamacrocycles with trigonal, square-planar, and tetrahedral coordinated metal ions.[2] In this context, a renewed interest in metallamacrocycles has recently been observed. Additionally, they can potentially act as host molecules in the generation of supramolecular architectures.[3] Several bi- or polydentate rigid aromatic nitrogen ligands have been used in reactions with transition metal complexes, generally in a square-planar configuration, to induce metallamacrocyclic structure formation.[1,4] Recently,[5] "flexible" non-chelating proligands HE-EH [HE-EH = 1,4-($HOCH_2$)$_2$$C_6H_4$, 1,3-($HOCH_2$)$_2$$C_6H_4$, (4-$HOC_6H_4$)$_2$$CH_2$] have been used in the reaction with [Mo(NO)(tp*)I$_2$]$_2$ {tp* = HB(3,5-$Me_2C_3HN_2$)$_3$} in the presence of NEt_3, to afford the dinuclear metallacyclophanes [Mo(NO)(tp*)(E-E)]$_2$ as the major product. In these reactions, kinetic control in the formation of the dinuclear metallamacrocycles was observed.

Lately,[6] we have synthesized the large valence angle bis(*p*-phosphinito) ligands [*p*-(Ph_2PO)C_6H_4]$_2$X (X = O, **1**; S, **2**; CMe_2, **3**), designed to induce a bridging coordination in transition metal complexes. The reactions of **1**−**3** with [Ru(*p*-cymene)Cl$_2$]$_2$, [Rh(C_5Me_5)Cl$_2$]$_2$, [Rh(C_5H_5)(CO)$_2$]$_2$ gave dinuclear complexes in which the two metal centres are bridged by only one phosphinito ligand.[6]

In this paper we report the synthesis of the new ligands bis(phosphinito) [{2-Ph_2PO-3,5-(Me_3C)$_2$$C_6H_2$}$_2$S] (**4**) and chiral bis(phosphite) [{*p*-[($C_{10}H_6O$)$_2$PO]C_6H_4}$_2$$CMe_2$] (**5**), and the reactions of **3**, **4** and **5** with palladium(II), platinum(II), and copper(I) substrates. The crystal structures of the dichloromethane solvates of the macrocyclic dinuclear complex [Pt{[*p*-(Ph_2PO)C_6H_4]$_2$$CMe_2$}I$_2$]$_2$ (**10**) and of [PdCl$_2${[2-Ph_2PO-3,5-(CMe_3)$_2$$C_6H_2$][3,5-($CMe_3$)$_2$-$C_6H_2$OH]S}] (**12**) are also reported.

Results and Discussion

Synthesis of Ligands 4 and 5

In order to synthesise a bis(phosphinito) ligand with a bigger steric requirement than ligands **1**−**3**, we prepared

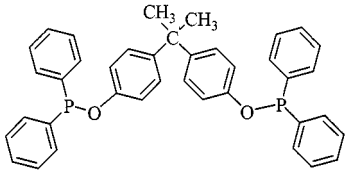
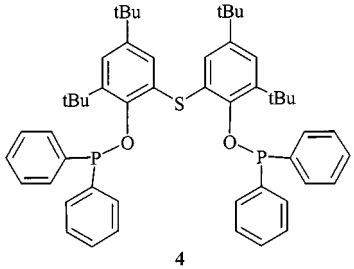
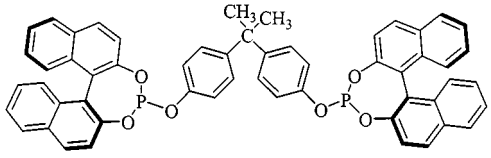
ligand **4** which has sulfur as the bridging atom, two phosphinito groups at the 2-position, and four *tert*-butyl groups as substituents in the aromatic moieties.



3



4



5

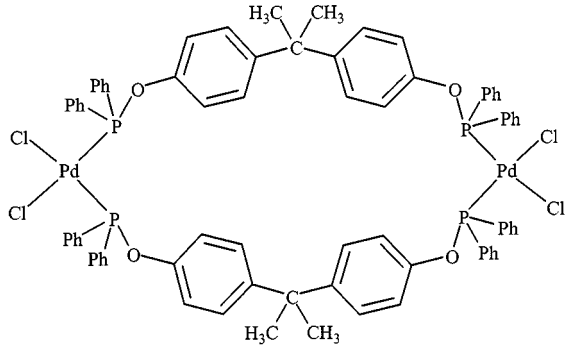
Ligand **4** was synthesised by treating 4,4′,6,6′-di-*tert*-butyl-2,2′-thiobisphenol[7] with PPh_2Cl and an excess of NEt_3 in toluene at room temperature. Several recrystallisations from hexane gave the pure product **4** as a white moderately air-stable powder, which was analysed by $^{31}P\{^1H\}$, ^1H NMR spectroscopy and GCMAS. In the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$ solution), a singlet appears at $\delta = 117.1$ and in the ^1H NMR two singlets at $\delta = 1.26$ and 1.31 due to *tert*-butyl groups as well as signals due to aromatic groups are seen. In the mass spectrum, a molecular peak at 810 was observed.

Ligand **5** has the same backbone as **3**, but it is chiral owing to the presence of two chiral configurationally resolved binaphthol groups. It was prepared by lithiation of 2,2-bis(4-hydroxyphenyl)propane in THF and subsequent addition of the lithium derivative to a solution of (*S*)-(1,1′-binaphthalene-2,2′-dioxy)chlorophosphane[8] in the same solvent at room temperature. The pure product was isolated as a white, air-sensitive powder and characterised by NMR spectroscopy. The $^{31}P\{^1H\}$ NMR spectrum (C_6D_6 solution), shows a singlet at $\delta = 144.79$ while the ^1H NMR exhibits a signal at $\delta = 1.47$ due to the CH_3 groups as well as two doublets at $\delta = 6.96$ and 7.0 ($J = 3$ Hz) due to the *p*-substituted phenyl groups. Multiplets in the range $\delta = 7.45-7.64$ due to the binaphthyl protons are also observed.

Ligands **3**−**5** were designed to induce a bridging coordination to transition metal centres. Structural determination of dinuclear Ru^{II} complexes containing ligand **3** proved that the P−P distance is longer than 9 Å[6] and therefore a *cis* or *trans* chelating bonding mode for ligands **3** and **5** is not expected.

Reactions of Ligands 3−5 with Palladium(II), Platinum(II) and Copper(I) Complexes

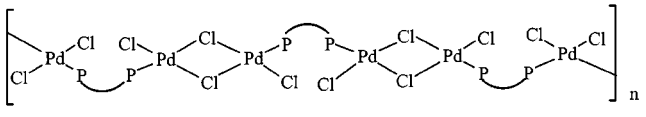
The reaction of **3** with $[Pd(PhCN)_2Cl_2]$ in a 1:1 molar ratio in toluene produced a yellow precipitate which was analysed as metallamacrocycle $[PdCl_2(\mu\text{-}\mathbf{3})]_2$ (**6**).



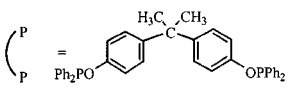
6

It is air-stable, soluble in chlorinated solvents and proved to be non-conducting in acetone solution. In agreement with the proposed structure, the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$), shows a singlet at $\delta = 109.0$ while the ^1H NMR spectrum features a singlet at $\delta = 1.46$ due to the $C(CH_3)_2$ group together with the characteristic resonances of phenyl rings.

When a solution of **3** in toluene was added to a solution of $[Pd(PhCN)_2Cl_2]$ in the same solvent in a 1:2 molar ratio, an orange-brown precipitate quickly formed which was insoluble in common organic solvents and analysed as $[Pd_2Cl_4(\mathbf{3})]$ (**7**). Compound **7** dissolves moderately only in coordinating solvents such as CH_3CN and DMF.

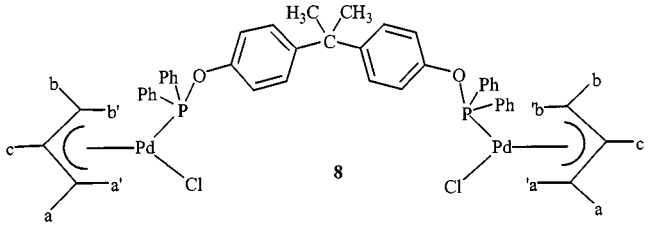


7



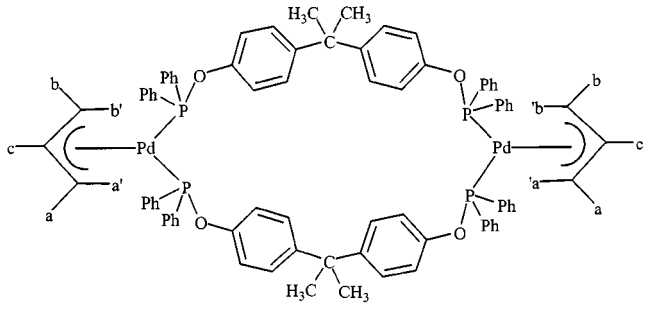
The $^{31}P\{^1H\}$ NMR spectrum of **7** in CD_3CN shows a resonance at $\delta = 106.3$ as a sharp singlet which is consistent with a symmetric geometry. The ^1H NMR spectrum shows a singlet at $\delta = 1.37$ due to the isopropyl group, together with the signals of the aromatic rings in the correct integration ratio. Although it was not possible to obtain useful information from the mass spectrum because of the wide fragmentation of the compound **7**, on the basis of NMR spectroscopic data and the observed chemical properties, we

deduced that **7** was an oligomer, $[Pd_2Cl_4(\mu\text{-}\mathbf{3})]_n$, in which the chloride and the phosphinito ligands alternately coordinate as bridges to palladium(II) centres. In coordinating solvents such as CH_3CN and DMF, a break of the chloro bridge probably occurs but the oligomeric structure is maintained. Furthermore, the ^1H NMR spectra of **7** (CD_3CN solution) shows features which indicate that scrambling processes take place. The proposed structure of **7** is in agreement with the trend of the palladium(II) to give bi- and polynuclear chloro-bridged compounds.[9] Reaction of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ with **3** in a 1:1 molar ratio afforded the expected dinuclear compound $\{[Pd(\eta^3\text{-}C_3H_5)Cl]_2(\mu\text{-}\mathbf{3})\}$ (**8**) in which the two metal atoms are bridged by only one phosphinito ligand.



8

This is corroborated by the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$ solution), which shows a sharp singlet at δ = 123.29, indicating a plane of symmetry in the molecule. In the ^1H NMR spectrum, the singlet at δ = 1.55 was assigned to the isopropyl group. A ^1H NOESY experiment made the assignment of each allylic proton signal possible: two broad multiplets at δ = 2.20 (^3J = 12 Hz, $H_{b'}$) and at δ = 3.13 (J = 6 Hz, H_b), two doublets of doublets at δ = 3.57 (^3J = 11 Hz, J_{PH} = 15 Hz, Ha′) and at δ = 4.67 (J_{PH} = 7 Hz, H_a), one multiplet at δ = 5.22 (H_c). Phase-sensitive 2D-^1H NOESY spectrum shows NOE peaks between H_c and its vicinal H_a and H_b protons. The analysis of the NMR spectroscopic data led us to conclude that a dynamic process, fast on the NMR time scale, was taking place and that it involved all the allylic protons in the molecule. This process is due to two concurrent $\eta^3-\eta^1-\eta^3$ rearrangements of the allylic fragment.[10]

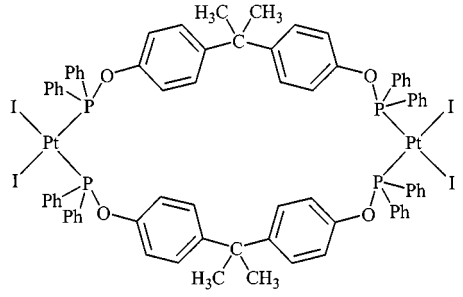


9

In order to prepare an allylpalladium macrocycle, a solution of $\{Pd(\eta^3\text{-}C_3H_5)Cl]_2(\mu\text{-}\mathbf{3})\}$ (**8**) in THF was initially treated with $AgCF_3SO_3$ in a 1:2 molar ratio, and after filtration of the AgCl precipitate, was further treated with 1 equivalent of **3**. The white dinuclear allylpalladium macrocycle $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}\mathbf{3})]_2[OTf]_2$ (**9**) was obtained in good yield and was characterised by microanalysis, NMR spectroscopy and conductivity measurements.

The presence of a broad signal at δ = 120.6 in the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$), revealed a complex fluxional process in the complex. This was further supported by the broadness of the signals observed in the ^1H NMR spectra recorded over a wide range of temperatures.

Reaction of $[Pt(COD)I_2]$ with ligand **3** in an equimolar ratio proceed in a similar way to that with $[Pd(PhCN)_2Cl_2]$. Addition of ligand **3** to a toluene solution of $[Pt(COD)I_2]$ led to the formation of metallamacrocycle $[PtI_2(\mu\text{-}\mathbf{3})]_2$ (**10**) as a yellow precipitate which was characterized by NMR spectroscopy and X-ray analysis. As expected, the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$) displays a peak at δ = 81.81, together with satellites due to $^{195}Pt-P$ coupling (J_{PtP} = 3968 Hz), and the ^1H NMR spectrum features all ligand signals in the correct integration ratio.



10

Crystal Structure of $[PtI_2(\mu\text{-}3)]_2\cdot 2CH_2Cl_2$ ($\mathbf{10}\cdot 2CH_2Cl_2$)

A view of the structure of complex **10** is shown in Figure 1, together with the numbering system. Selected bond lengths and angles are given in Table 1. The metallamacrocycle has an imposed crystallographic C_2 symmetry.

The coordination at Pt is square-planar and involves two P atoms mutually in *cis* position and two I atoms. The two Pt−I [2.6523(11) and 2.6562(9) Å] and Pt−P [both 2.259(2) Å] bond lengths are equal. The most interesting feature is the 28-membered metallacycle; the conformation of the ring is shown in Figure 2. The central cavity seems to be too small to bind even small guest molecules. Critical cross-ring interatomic distances are C23···C23′ (3.983 Å), C23−C24′ and C23′−C24 (4.078 Å). The apex indicates an atom related by the twofold axis. The Pt−Pt′ and C7−C7′ separations are 13.071 and 8.974 Å, respectively. Furthermore, two phenyl groups at P2 point to the same side of the ring, facing one another, the shortest contacts involving C31···C31′ (3.690 Å), C31−C32′ and C31′−C32 (3.983 Å). It is worth noting that the O2 atom is involved in an intermolecular hydrogen bond with the Cl2 atom [O2···Cl2 = 3.048(5), Cl2···H2 = 2.32(5) Å; 02−H2−Cl2 = 157(5)°].

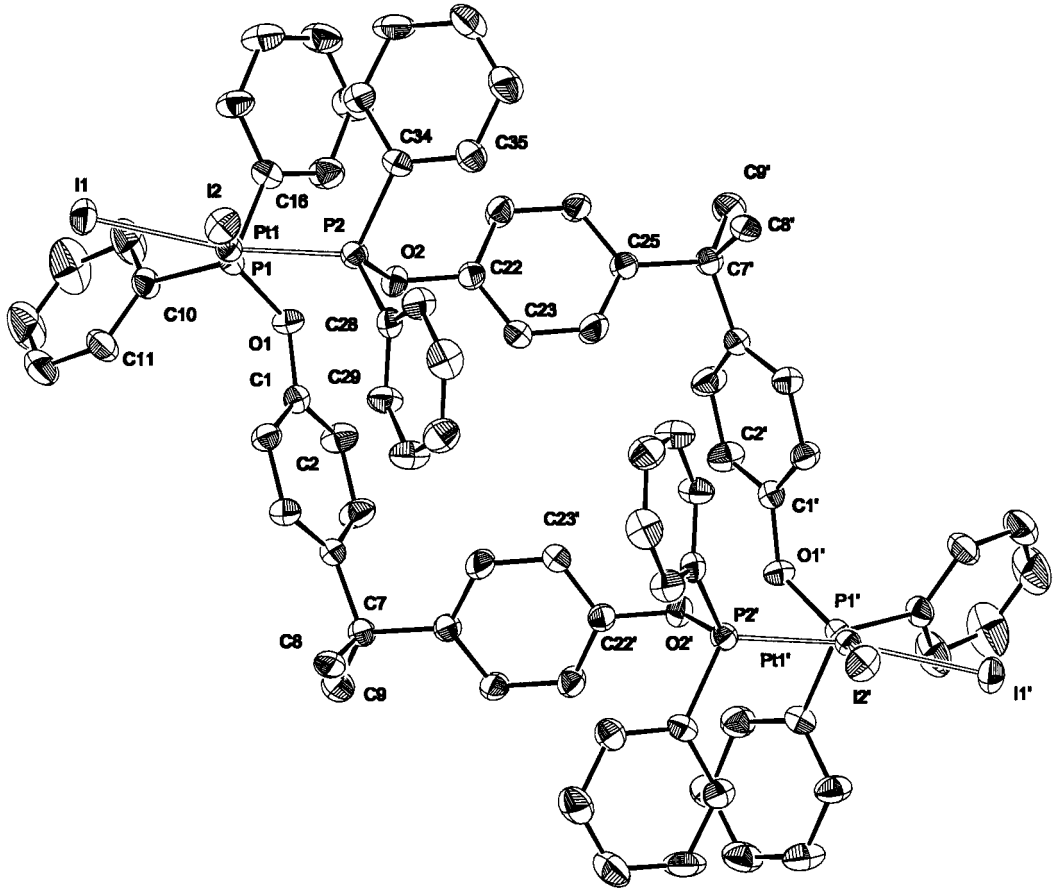


Figure 1. ORTEP view of the structure of the complex **10** together with the numbering scheme; the ellipsoids for the atoms are drawn at the 30% probability level

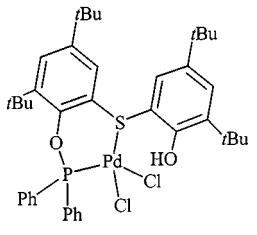
The reaction between $[Cu(NCCH_3)_4]BF_4$ and ligand **3** in a 1:1 molar ratio in dichloromethane solution, afforded the metallamacrocycle $[Cu_2(\mu\text{-}\mathbf{3})_2][BF_4]_2{\cdot}2CH_3CN$ (**11**) as a white solid. Conductivity measurements in methanol solution proved that compound **11** is a 2:1 electrolyte. The $^{31}P\{^1H\}$ NMR spectrum displays a singlet at $\delta = 99.06$, while the ^1H NMR spectrum ($CDCl_3$ solution) in addition to the expected signals, also shows a singlet at $\delta = 1.55$ due to the CH_3CN molecule of crystallisation. The coordination of acetonitrile to the metal centre can be excluded, since the observed chemical shift is the same as that of the free CH_3CN.

Reactions of **4** with Pd^{II} and Pt^{II} complexes gave different results from those reported for ligands **3**. Addition of one equivalent of **4** to a solution of $[Pd(PhCN)_2Cl_2]$ in toluene afforded a mixture of two very different compounds, **12** and **13**, in a 42:58 ratio, each giving rise to a singlet at $\delta = 135.66$ and 78.79, respectively, in the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$).



12

Fractional crystallisation from CH_2Cl_2/hexane allowed us to separate the two compounds. Thus, **12** was obtained as yellow crystals which exhibit only a signal at $\delta = 135.66$ in the $^{31}P\{^1H\}$ NMR in $CDCl_3$. An X-ray analysis carried out on these crystals established that it has formula $[PdCl_2\{[2\text{-}Ph_2PO\text{-}3,5\text{-}(CMe_3)_2C_6H_2][3,5\text{-}(CMe_3)_2\text{-}C_6H_2OH]S\}]$.

Crystal Structure of $[PdCl_2\{[2\text{-}Ph_2PO\text{-}3,5\text{-}(CMe_3)_2C_6H_2]\text{-}[3,5\text{-}(CMe_3)_2\text{-}C_6H_2OH]S\}]{\cdot}2CH_2Cl_2$ (**12**·2CH_2Cl_2)

A view of the structure of complex **12** is shown in Figure 3 together with the numbering system. Selected bond lengths and angles are given in Table 2. The coordination at Pd is square-planar and involves two Cl atoms and the P1 and S1 from the chelating ligand, obtained by fragmentation of **4**. The six-membered chelating ligand is in a boat conformation with the two near-planar S1PdP101 and 01C13C18S1 moieties forming a dihedral angle of 41.1(1)°. The Pd−P1 and Pd−S1 bond lengths are 2.1985(15) and 2.2770(13) Å, respectively. The Pd−Cl1 and Pd−Cl2 bond lengths, 2.3149(14) and 2.3769(15) Å respectively, are rather different; the bond *trans* to the P atom is longer.

In light of the structure determined for **12**, we may consider two hypotheses based on this result. One could explain the hydrolysis of one P−O bond in the pure ligand as being due to the presence of water in the solvent. However, this can be excluded since the reaction was repeated several

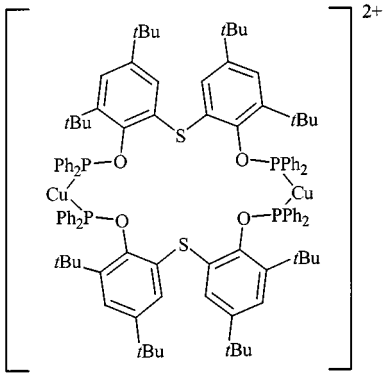
times under rigorously anhydrous conditions and the same result was obtained. Furthermore, the reaction between the Cu complex and the same sample of ligand **4** used in the reaction with [Pd(PhCN)$_2$Cl$_2$] in toluene, gave a product (see below) which does not arise from P−O bond hydrolysis in ligand **4**. Another possibility is that a very complicated reaction takes place which could involve sulfur coordination to the palladium centre. In this case, a lengthening and breaking of one P−O bond can occur by a probable, but not experimentally proven, contribution of the solvent. Undoubtedly, the characterization of **13** is fundamental to the understanding of this reaction. Unfortunately, several attempts to obtain suitable crystals for X-ray analysis of **13** failed so far. However, other studies have to be conducted to give insight into this reaction.

Reaction of [Pt(COD)I$_2$] with 1 equivalent of ligand **4** produced a mixture of compounds, as could be inferred by the presence of several peaks in the $^{31}P\{^1H\}$ NMR spectrum. It is also likely that a product similar to **12** can be formed in this reaction. Differently from palladium, reaction between [Cu(NCCH$_3$)$_4$]BF$_4$ and ligand **4** in a 1:1 molar ratio in toluene afforded the white ionic metallamacrocycle [Cu(μ-**4**)][BF$_4$]$_2$·2CH$_3$CN (**14**), which was soluble in chlorinated solvents, acetone and methanol. Compound **14** was found to be a 1:2 electrolyte in methanol solution.



14

Complex **14** presents elemental analysis and NMR spectroscopic data fully consistent with the proposed structure. Indeed, only two sharp singlets are present for *tert*-butyl groups in the ^1H NMR spectrum, consistent with the proposed symmetric structure. Furthermore, a sharp singlet at $\delta = 108.81$ is present in the $^{31}P\{^1H\}$ NMR spectrum.

On the basis of the similar structural features of ligands **3** and **5**, we expect a similar behaviour in the reactions between **5** and Pd, Pt and Cu complexes. Only in the case of the reaction with the Cu complex, was it not possible synthesise a product in pure form. A rapid degradation of the initially formed macrocycle probably occurs in solution.

The reaction of [Pd(PhCN)$_2$Cl$_2$] with ligand **5** in toluene and in a 1:1 molar ratio, led to the formation of an orange-brown precipitate, which shows a singlet at $\delta = 107.68$ together with two signals of very low intensity at $\delta = 86.6$ and 85.7 in the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$). However, several recrystallisations from toluene/hexane made it possible to obtain the pure chiral metallamacrocycle [Pd(μ-**5**)Cl$_2$]$_2$ (**15**).

Its $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$) features only the signal at $\delta = 107.68$, while all expected signals in the correct integration ratio are present in the ^1H NMR spectrum. By adding ligand **5** to a solution of [Pt(COD)I$_2$] in toluene, the metallamacrocycle [Pt(μ-**5**)I$_2$]$_2$ (**16**) precipitated as a yellow solid. The resulting compound was not in a pure form, but

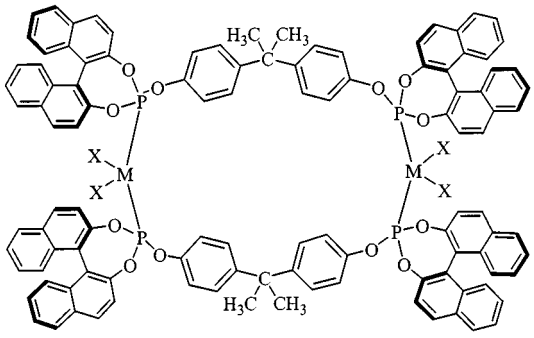
repeated recrystallisations from toluene/hexane allowed us to obtain the pure compound **16**. It was characterised by elemental analyses, $^{31}P\{^1H\}$ and ^1H NMR spectroscopy. In the $^{31}P\{^1H\}$ NMR spectrum, a singlet at δ = 84.06 (J_{PtP} 5543) is present.



M = Pd, X = Cl, **15** M = Pt, X = I, **16**

Conclusion

A new class of dinuclear metallamacrocycles [M(μ-**L**)X$_2$]$_2$ [M = Pd^{II}, Pt^{II}, Cu^{I}] characterised by a 28-membered ring was obtained using the ditopic ligands **3** and **5**. In the case of **4**, only the Cu^{I}-based dinuclear macrocycle was formed with this ligand. Different results were achieved with Pd^{II} and Pt^{II} complexes on account of sulfur being involving in the course of the reaction. The lack of formation of cyclic tri- and tetranuclear species in the reaction of **3** with Pd^{II}, Pt^{II} and Cu^{I} substrates is a consequence both of the geometry of ligand **3** and of thermodynamic factors owing to the very strong metal−phosphorus bond. Another consequence of the ligand geometry is that when ligand **3** was used in the reaction with [Ru(η^6-*p*-cymene)Cl$_2$]$_2$, only the dinuclear complex {[Ru(η^6-*p*-cymene)Cl$_2$]$_2$[μ-(*p*-Ph$_2$POC$_6$H$_4$)$_2$C(Me)$_2$]} was obtained[6] and attempts to ob-

tain bi- and tetranuclear metallamacrocycles were unsuccessful. The formation of the dinuclear metallamacrocycles $[M(\mu\text{-}L)X_2]_2$ (M = Pd^{II}, Pt^{II}, Cu^{I}, L = **3**, **5**) was promoted by the presence of *cis*-coordinated labile ligands in the starting complexes. Thus, the reaction of $[M(PPh_3)_4]$ (M = Pt, Pd) with dihalobenzophenone afforded the dinuclear complex $\{[MX(PPh_3)_2]_2[(\mu\text{-}(C_6H_4)_2CO]\}$ (M = Pt, X = I, M = Pd, X = Br, I) and failed to give $\{[MX_2(PPh_3)]_2[(\mu\text{-}(C_6H_4)_2CO]_2\}$.[11]

A very interesting aspect connected with the formation of metallamacrocycles is the introduction of chirality by suitable self-assembly building blocks. At least five different ways of rationally designed chiral supramolecular species have been indicated.[12] Stang successfully used an appropriate metal complex bearing (*R*)-(+)-BINAP as the chiral ancillary ligand for the synthesis of chiral palladium(II) and platinum(II) supramolecular square-planar species.[12] The use of the ditopic chiral ligand **5** made the synthesis of chiral palladium(II)- and platinum(II)-based macrocycles possible.

From this work we conclude that chiral dinuclear square-planar metallamacrocycles can be obtained by spontaneous self-assembly of building units of palladium(II) and platinum(II) complexes containing labile ligands and the chiral bidentate ligand **5**. This methodology can be extensively used owing to the great number of chiral ligands, with different geometric properties, which should prove to be bi- and tridentate functional building blocks for the synthesis of chiral supramolecular squares. Up to now, the use of chiral dinuclear square-planar metallamacrocycles as organometallic reagents is an unexplored topic.

The ability for molecular recognition of these new metallamacrocycles depends on the size of the cavity formed. On the basis of the X-ray crystal structure of the complex **10·2CH$_2$Cl$_2$** the cavity determined by meaningful cross-ring interatomic distances seems to be too small to bind guest molecules. We are actually trying to synthesize different types of bis(phosphinito) ligands with the aim of obtaining metallamacrocycles that can act as host molecules in the formation of supramolecular species.

Experimental Section

All syntheses were performed under argon or nitrogen using standard Schlenk-tube techniques. Freshly distilled, dry, and oxygen-free solvents were used throughout. [D_6]Benzene (99.5+%) and [D_3]chloroform (99.8+%) were used as received from Aldrich Chemical Co. All other reagents were of the highest purity grade commercially available and were used without further purification. Redox Analytical Laboratories, Milan, performed microanalyses. ^{1}H, ^{31}P and ^{13}C NMR spectra were obtained with a Bruker AMX R-300 spectrometer equipped with a broad-band probe operating at 300.13, 121.49 and 75.46 MHz, respectively [δ (ppm) relative to Me_4Si, *J* (Hz)]. $^{31}P\{^1H\}$ spectra were run using an aqueous H_3PO_4 sample (85%) as external reference (δ = 0). Standard pulse sequences were employed for ^{1}H-2D-NOESY. Mixing times of 0.8 s were used for the phase-sensitive NOESY experiments. $[Cu(NCCH_3)_4]BF_4$[13], $[\{p\text{-}(Ph_2PO)C_6H_4\}_2CMe_2]$,[6] and 4,4′,6,6′-di-*tert*-butyl-2,2′-thiobisphenol[7] were prepared by standard methods. IR spectra of KBr pellets were recorded with a Perkin−Elmer FT-IR 1720 spectrometer. GLC analyses were performed with a Carlo Erba HRGC 5160 series Mega instrument using a 25-m Mega OV1 column.

[{2-Ph$_2$PO-3,5-(CMe$_3$)$_2$C$_6$H$_2$}$_2$S] (4): The synthetic procedure was essentially the same as previous described for **1**, using a solution of PPh_2Cl (1.98 g, 9.00 mmol) and a solution of 4,4′,6,6′-di-*tert*-butyl-2,2′-thiobisphenol (2.00 g, 4.50 mmol) and NEt_3 (1.45 g, 14.3 mmol) in toluene (40 mL each). The reaction mixture was warmed to room temperature and then kept under continuous stirring for 72 h. The ligand **4** was obtained as a white solid by filtration of the resulting mixture and crystallisation from toluene/hexane (1:3, v/v). Yield 87% (3.17 g, 3.90 mmol). − $C_{52}H_{60}O_2P_2S$ (811.0): calcd. C 77.01, H 7.46, S 3.95; found C 76.97, H 7.49, S 3.91. − ^{1}H NMR ($CDCl_3$): δ = 1.26 [s, 18 H, $C(CH_3)_3$], 1.31 [s, 18 H, $C(CH_3)_3$], 7−7.12 (m, 12 H, CH), 7.28 (d, ^3J = 2.5 Hz, 2 H, CH), 7.39 (d, ^3J = 2.5 Hz, 2 H, CH), 7.61−7.67(m, 8 H, CH). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 117.21 (s).

[{*p*-[(C$_{10}$H$_6$O)$_2$PO]C$_6$H$_4$}$_2$CMe$_2$] (5): *n*BuLi solution in hexanes (1.6 M, 1.09 mL, 0.112 g, 1.75 mmol) was added dropwise to a solution of 2,2-bis(4-hydroxyphenyl)propane (0.200 g, 0.876 mmol) in THF (20 mL) at −78 °C. The white mixture was added to a solution of (*S*)-(1,1′-binaphthalene-2,2′-dioxy)chlorophosphane in THF (3 mL) at 0 °C. The resulting pale yellow solution was allowed to reach room temperature and stirred for ca. 2 h. The solution was then dried under vacuum and extracted with toluene (3 × 5 mL). Decreasing the solution volume followed by the addition of hexane led to the formation of a white solid. The pure ligand **3** was isolated, washed with small volumes of hexane and finally dried under vacuum with a yield of 70% (0.525 g, 0.613 mmol). − $C_{55}H_{38}O_6P_2$ (856.8): calcd. C 77.10, H 4.47; found C 77.3, H 4.49. − ^{1}H NMR (C_6D_6): δ = 1.47 [s, 6 H, $C(CH_3)_2$], 6.96−7.65 (m, 24 H, CH). − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 144.79 (s).

[PdCl$_2$(μ-3)]$_2$ (6): Ligand **3** (0.165 g, 0.260 mmol), dissolved in toluene (5 mL), was treated with a solution of $[Pd(PhCN)_2Cl_2]$ (0.100 g, 0.260 mmol) in toluene (30 mL). A yellow solid precipitated immediately and was separated from the mother solution after ca. 1 h, washed with toluene (3 × 1 mL), diethyl ether (1 × 1 mL) and then dried under vacuum. Yield 82% (0.166 g, 0.107 mmol). − $C_{78}H_{68}Cl_4O_4P_4Pd_2$ (1548): calcd. C 60.52, H 4.43; Cl, 9.16; found C 60.16, H 4.34; Cl, 8.93. − ^{1}H NMR ($CDCl_3$): δ = 1.46 [s, 6 H, $C(CH_3)_2$], 6.45 (d, ^3J = 8.4 Hz, 4 H, CH), 6.70 (d, ^3J = 8.7 Hz, 4 H, CH), 7.28−7.46 (m, 12 H, CH), 7.66−7.69 (m, 8 H, CH). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 109.03 (s).

[Pd$_2$Cl$_4$(μ-3)]$_n$ (7): The orange compound **7** was prepared from $[Pd(PhCN)_2Cl_2]$ (0.080 g, 0.208 mmol) and **3** (0.062 g, 0.104 mmol) as described above for compound **6**. Yield 75% (0.074 g, 0.078 mmol). − $C_{39}H_{34}Cl_4O_2P_2Pd_2$ (951.3): C. 49,24; H. 3,60; Cl. 14,91; found C. 49,20; H. 3,63; Cl. 14,87. − ^{1}H NMR (CD_3CN): δ = 1.37 [s, 6 H, $C(CH_3)_2$], 6.25 (d, ^3J = 8.7 Hz, 4 H, CH), 6.52 (d, ^3J = 8.9 Hz, 4 H, CH), 6.86−7.69 (m, 20 H, CH). − $^{31}P\{^1H\}$ NMR (CD_3CN): δ = 106.32 (s).

{[Pd(η^3-C$_3$H$_5$)Cl]$_2$(μ-3)} (8): To a solution of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (0.05 g, 0.137 mmol) in dichloromethane (10 mL) was added ligand **3** (0.082 g, 0.137 mmol). The resulting yellow solution was stirred for 1 h and then reduced to 3 mL in vacuo. Addition of hexane (10 mL) led to the formation of a yellow precipitate. Yield 72% (0.048 g, 0.050 mmol). − $C_{45}H_{44}Cl_2O_2P_2Pd_2$(962.5): calcd. C 56.15, H 4.61; Cl, 7.37; found C 56.25, H 4.53; Cl, 6.99. − ^{1}H NMR ($CDCl_3$): δ = 1.55 [s, 6 H, $C(CH_3)_2$], 2.20 [d (br.), ^3J = 12 Hz, 2

H, $H_{b'}$], 3.13 [d (br.), ^3J = 6 Hz, 2 H, H_b], 3.57 [dd (br.), ^3J = 11 Hz, J_{HP} 15 Hz, 2 H, $H_{a'}$], 4,67 [dd (br.), J_{HP} 7 Hz, 2 H, H_a], 5.22 [m (br.), 2 H, H_c], 6.99 (d, ^3J = 5 Hz, 4 H, H_e), 7.01 (d, ^3J = 5 Hz, 4 H, H_d), 7.43−7.45 (m, 12 H, $H_{m,p}$), 7.85−7.93 (m, 8 H, H_o). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 123.29 (s).

[Pd(η³-C_3H_5)(μ-3)]$_2$[OTf]$_2$ (9): The bridge complex **8** (0.077 g, 0.080 mmol) was dissolved in dichloromethane (10 mL) and $AgCF_3SO_3$ (0.041 g, 0.16 mmol) was added with continuous stirring. After 5 min, ligand **3** (0.048 g, 0.080 mmol), dissolved in THF (2 mL), was added to the suspension and the mixture stirred for a further 1 h. The mixture was filtered through Celite, and the solution was concentrated to a small volume; addition of hexane and vigorous shaking led to the formation of **9** as a white solid. Yield 65% (0.093 g, 0.050 mmol). − $C_{86}H_{78}F_6O_{10}P_4S_2Pd_2$ (1786): calcd. C 57.82, H 4.40, S 3.59; found C 57.3, H 4.20, S 3.74. − ^1H NMR ($CDCl_3$): δ = 1.53 [s, 12 H, $C(CH_3)_2$], 3.33 [s (br.), 2H, $H_{b'}$], 3.48 [s (br.), 2 H, H_b], 3.87 [s (br.), 2 H, $H_{a'}$], 3.95 [s (br.), 2 H, H_a], 5.32 [m (br.), 2 H, H_c], 6,48 [d (br.), ^3J = 8 Hz, 8 H, H_e], 7,02 [d (br.), ^3J = 10 Hz, 4 H, H_d], 7,41−7.46 [m (br.), $H_{m,p}$, 24 H], 7,83−7.86 [m (br.), 16 H, H_o]. − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 120,6 [s (br.)].

[PtI_2(μ-3)]$_2$ (10): The dinuclear complex was prepared by reaction of ligand **3** (0.089 mg, 0.143 mmol) with a solution of [Pt(COD)I_2] (0.080 g, 0.143 mmol) in toluene (30 mL). A yellow precipitate was immediately obtained. The reaction mixture was stirred for 1 h and then the solvent was removed. The precipitate was washed with toluene (3 × 1 mL) and finally dried in vacuo. Yield 78% (0.117 g, 0.056 mmol). − $C_{78}H_{68}I_4O_4P_4Pt_2$ (2091): calcd. C 44.8, H 3.28, I 24.28; found C 45.15, H 3.39, I 24.60. − ^1H NMR ($CDCl_3$): δ = 1.51 [s, 6 H, $C(CH_3)_2$], 6.35 (d, ^3J = 8.4 Hz, 4 H, CH), 6.72 (d, ^3J = 8.3 Hz, 4 H, CH), 7.16−7.41 (m, 12 H, CH), 7.63−7.70 (m, 8H, CH). − $^{31}P\{^1H\}$ ($CDCl_3$): δ = 81.81 (s, J_{PtP} = 3968 Hz).

[Cu(μ-3)]$_2$[BF_4]$_2$·2CH_3CN (11): A dichloromethane solution containing ligand **3** (0.095 g, 0.159 mmol) was added dropwise to a solution of [Cu(CH_3CN)$_4$]BF_4 (0.050 g, 0.159 mmol) in CH_2Cl_2 (10 mL). The colourless solution was kept under continuous stirring for ca. 1 h, filtered through Celite and concentrated under vacuum until a volume of 1 mL was achieved. Further addition of hexane (10 mL) led to the formation of a white solid which was isolated, washed several times with hexane and dried. Yield 87% (0.109 g, 0.069 mmol). − $C_{82}H_{74}B_2Cu_2F_8N_2O_4P_4$ (1576): calcd. C 62.49, H 4.73, N 1.78; found C 62.29, H 4.93, N 1.59. − ^1H NMR ($CDCl_3$): δ = 1.49 [s, 6 H, $C(CH_3)_2$], 1.98 (s, 6 H, CH_3), 6.7 (d, ^3J = 8.4 Hz, 4 H, CH), 6.93 (d, ^3J = 8.3 Hz, 4 H, CH), 7.35−7.43 (m, 20 H, CH). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 99.06 (s). − Λ [ohm^{-1} cm^2 mol^{-1}] (5 10^{-4} − 10^{-3} M CH_3OH) = 182.

[$PdCl_2$\{[2-Ph_2PO-3,5-$(MeC)_2C_6H_2$][3,5-$(Me_3Cl_2C_6H_2OH]S$\}] (12): A solution of [Pd($PhCN$)$_2$$Cl_2$] (0.050 g, 0.130 mmol) in toluene (10 mL) was treated with a toluene solution of ligand **4** (0.105 g, 0.130 mmol). The yellow solution was stirred for ca. 30 min and then reduced to a small volume (1 mL). By crystallization from a toluene/hexane mixture, a yellow solid was obtained. Yield 78% (0.081 g, 0.101 mmol). − $C_{40}H_{51}Cl_2O_2PSPd$ (804.2): calcd. C 59.74, H 6.39, Cl 8.82, S 3.99; found C 59.37, H 6.31, Cl 8.26, S 4.23. − ^1H NMR ($CDCl_3$): δ = 0.99 [s, 9 H, $C(CH_3)_3$], 1.03 [s, 9 H, $C(CH_3)_3$], 1.30 [s, 9 H, $C(CH_3)_3$], 1.31 [s, 9 H, $C(CH_3)_3$], 6.34 (d, ^3J = 2.1 Hz, 1 H, CH_{Ar}), 7.21−7.71 (m, 14 H, CH). − $^{31}P\{^1H\}$ ($CDCl_3$): δ = 135.66 (s).

[Cu(μ-4)]$_2$[BF_4]$_2$·CH_3CN (14): The white compound **13** was prepared from [Cu(CH_3CN)$_4$]BF_4 (0.080 g, 0.254 mmol) and the ligand **4** (0.206 g, 0.254 mmol) as described above for the compound **11**. Yield 89% (0.222 g, 0.113 mmol). − $C_{106}H_{123}B_2Cu_2F_8NO_4P_4S_2$ (1963): calcd. C 64.83, H 6.31, N 0.71, S 3.26; found C 64.48, H 6.42, N 0.80, S 2.95. − ^1H NMR ($CDCl_3$): δ = 0.87 [s, 18 H, $C(CH_3)_3$], 1.24 [s, 18 H, $C(CH_3)_3$], 2.26 (s, 3 H, CH_3), 7.01−7.40 (m, 24 H, CH). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 108.81 (s). − Λ [ohm^{-1} cm^2 mol^{-1}] (5 10^{-4} − 10^{-3} M CH_3OH) = 183.

[$PdCl_2$(μ-5)]$_2$ (15): Ligand **5** (0.110 g, 0.128 mmol), dissolved in toluene (5 mL), was added dropwise with continuous stirring to a solution of [Pd($PhCN$)$_2$$Cl_2$] (0.05 g, 0.128 mmol) in toluene (10 mL). A yellow-orange solid began to precipitate. After 2 h, the solid was isolated from the reaction mixture, washed with toluene (3 × 1 mL), and dried under vacuum. Yield 73% (0.097 g, 0.046 mmol). − $C_{110}H_{76}Cl_4O_{12}P_4Pd_2$ (2068): calcd. C 63.88, H 3.70, Cl 6.86; found C 63.56, H 4.04, Cl 6.93. − ^1H NMR ($CDCl_3$): δ = 1.27 [s, 6 H, $C(CH_3)_2$], 6.25 (d, ^3J = 6.6 Hz, CH, 4 H), 5.5 (d, ^3J = 6.6 Hz, 4 H, CH), 7.27−7.65 (m, 12 H, CH), 7.89−8.01 (m, 8 H, CH). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 107.68 (s).

[PtI_2(μ-5)]$_2$ (16): The yellow bridge species was synthesized by the reaction of a solution of [Pt(COD)I_2] (0.050 g, 0.089 mmol) in toluene (10 mL) with a toluene solution of ligand **5** (0.076 mg, 0.089 mmol), using the same procedure for the synthesis of **16**. Yield 78% (0.116 g, 0.045 mmol). − $C_{110}H_{76}I_4O_{12}P_4Pt_2$ (2611): calcd. C 50.59, H 2.93, I 19.44; found C 50.28, H 2.59, I 19,60. − ^1H NMR ($CDCl_3$): δ = 1.27 [s, 6 H, $C(CH_3)_2$], 6.36 (d, ^3J = 8.8 Hz, 4 H, CH), 6.63 (d, ^3J = 8.3 Hz, 4 H, CH), 7.16−7.88 (m, 20 H, CH). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 84.06 (s, J_{PtP} 5543 Hz).

X-ray Structure Determination of 10·2CH_2Cl_2 and 12·2CH_2Cl_2: The crystals of both complexes were obtained by crystallization from dichloromethane solutions and molecules of solvent were found in them. The intensity data of both complexes were collected at room temperature with a Siemens AED (**10·2CH_2Cl_2**) and with an Enraf−Nonius CAD 4 (**12·2CH_2Cl_2**) single-crystal diffractometer using graphite-monochromated Mo-K_α (**10·2CH_2Cl_2**) and Cu-K_α (**12·2CH_2Cl_2**) radiation and the θ/2θ scan technique. Crystallographic and experimental details for both structures are summarized in Table 3. A correction for absorption was made for both complexes [maximum and minimum value for the transmission coefficient was 1.000 and 0.487 (**10·2CH_2Cl_2**), 1.000 and 0.697 (**12·2CH_2Cl_2**).[14] The structures were solved by Patterson and Fourier methods and refined by full-matrix least-squares procedures (based on F_o^2) with anisotropic thermal parameters in the last cycles of refinement for all the non-hydrogen atoms, except for the carbon and chlorine atoms of the solvent molecules (**10·2CH_2Cl_2**) and except for the carbon atoms of the two isobutyl groups which were found disordered in two positions with an occupancy factor of 0.5 (**12·2CH_2Cl_2**). In both structures, the hydrogen atoms were introduced into the geometrically calculated positions and refined riding on the corresponding parent atoms. In the final cycles of refinement a weighting scheme $w = 1/[\sigma^2F_o^2 + (0.0533\ P)^2]$ (**10·2CH_2Cl_2**) and $w = 1/[\sigma^2F_o^2 + (0.1271\ P)^2]$ (**12·2CH_2Cl_2**) where $P = (F_o^2 + 2\ F_c^2)/3$ was used. All calculations were carried out with the DIGITAL AlphaStation 255 computers of the "Centro di Studio per la Strutturistica Diffrattometrica" del CNR, Parma, using the SHELX-97 systems of crystallographic computer programs.[15] The supplementary material for the structures includes the lists of atomic coordinates for the non-H atoms, of calculated coordinates for the hydrogen atoms, of anisotropic thermal parameters and complete lists of bond lengths and angles. The details of the crystal structure investigations have been deposited in the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-143608 (**10·2CH_2Cl_2**) and -143609 (**12·2CH_2Cl_2**). Copies of the data can be obtained free of charge on application to CCDC,

Table 3. Crystal data and structure refinement for **10·2CH$_2$Cl$_2$** and **12·2CH$_2$Cl$_2$**; $R1 = \Sigma|F_o - F_c|/|\Sigma(F_o)$ $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$

Enthalpies of Sublimation of $M(\eta^5\text{-}C_5H_5)_2Cl_2$ (M = Ti, Zr, Hf, V, Nb, W) Complexes

Hermínio P. Diogo,[a] Manuel E. Minas da Piedade,*[a] Jorge M. Gonçalves,[b] Manuel J. S. Monte,[b] and Manuel A. V. Ribeiro da Silva[b]

Keywords: Transition metals / Metallocenes / Knudsen effusion / Thermochemistry

The standard molar enthalpies of sublimation of $M(\eta^5\text{-}C_5H_5)Cl_2$ (M = Ti, V, Zr, Nb, Hf, and W) compounds, at 298.15 K, were determined by the Knudsen effusion method to be: 124.4±2.9 kJmol^{-1} (M = Ti), 108.5±4.6 kJmol^{-1} (M = Zr), 110.2±2.9 kJmol^{-1} (M = Hf), 140.1±7.4 kJmol^{-1} (M = V), 127.4±4.4 kJmol^{-1} (M = Nb), and 120.7±8.6 kJmol^{-1} (M = W). The results obtained show a tendency to linearly decrease with increasing metal atomic radius.

Introduction

The study of bent metallocenes has generated a wealth of fundamental chemistry and some major commercial applications (e.g. new Ziegler-Natta catalysts for the production of polyethylene and polypropylene).[1] These studies have also raised an increasing number of questions about the energetics of reactivity and bonding in these complexes as one tries to rationalise the observed reactions and molecular structures.[2]

The enthalpies of sublimation of $M(\eta^5\text{-}C_5H_5)_2Cl_2$ (M = Ti, Zr, Hf, V, Nb, Ta, Mo, W) complexes are of considerable importance in the study of the energetics of transition metal-ligand bonds. Bis(cyclopentadienyl) compounds, $M(\eta^5\text{-}C_5H_5)_2L_n$ (M = Ti, Zr, Hf, V, Nb, Ta, Mo, W; L = H, halogen, CO, alkyl, alkene, aryl, alkoxide, thiolate, phosphane, etc.; n = 1−3), have been extensively used as models for investigating the general trends of M−L bond dissociation enthalpies in group 4−6 transition metals.[3−9] Absolute M−L bond dissociation enthalpies in these complexes can, in principle, be obtained by calculating the enthalpy of reaction (1) from the gas phase enthalpies of formation of $M(\eta^5\text{-}C_5H_5)_2L_n$, $M(\eta^5\text{-}C_5H_5)_2$, and L:

$$M(\eta^5\text{-}C_5H_5)_2L_n\,(g) \rightarrow M(\eta^5\text{-}C_5H_5)_2\,(g) + nL\,(g) \quad (1)$$

$$DH^o(M-L) = \Delta_fH^o[M(\eta^5\text{-}C_5H_5)_2, g]/n + \Delta_fH^o(L, g) - \Delta_fH^o[M(\eta^5\text{-}C_5H_5)_2L_n, g]/n \quad (2)$$

where $DH^o(M-L)$ denotes a bond dissociation enthalpy for n = 1 and a mean bond dissociation enthalpy for n = 2 or 3.

Unfortunately, although many $\Delta_fH^o[M(\eta^5\text{-}C_5H_5)_2L_n, g]$ and $\Delta_fH^o(L, g)$ values are available,[3−9] the enthalpies of formation of the $M(\eta^5\text{-}C_5H_5)_2$ fragments are not known. In order to overcome this problem, all $DH^o(M-L)$ values reported up to now for $M(\eta^5\text{-}C_5H_5)_2L_n$ compounds have been anchored in the mean M−Cl bond dissociation enthalpies of the corresponding dichlorides. This has been done by considering reaction (3) and Equation 4:

$$M(\eta^5\text{-}C_5H_5)_2L_n\,(g) + 2\,Cl\,(g) \rightarrow M(\eta^5\text{-}C_5H_5)_2Cl_2\,(g) + nL\,(g) \quad (3)$$

$$DH^o(M-L) = 2\,DH^o(M-Cl)/n + \Delta_fH^o[M(\eta^5\text{-}C_5H_5)_2Cl_2, g]/n + \Delta_fH^o(L_n, g) - \Delta_fH^o[M(\eta^5\text{-}C_5H_5)_2L_n, g]/n - 2\Delta_fH^o(Cl, g)/n \quad (4)$$

The calculation of $DH^o(M-L)$ from Equation 4 requires knowledge of the values of $DH^o(M-Cl)$ and $\Delta_fH^o[M(\eta^5\text{-}C_5H_5)_2Cl_2, g]$. The M−Cl bond dissociation enthalpies in $M(\eta^5\text{-}C_5H_5)Cl_2$ have been estimated from the corresponding values in the homoleptic molecules MCl_x.[3−5,8] The enthalpies of formation of $M(\eta^5\text{-}C_5H_5)_2Cl_2$ in the gaseous state can be derived from Equation 5.

$$\Delta_fH^o[M(\eta^5\text{-}C_5H_5)_2Cl_2, g] = \Delta_fH^o[M(\eta^5\text{-}C_5H_5)_2Cl_2, cr] + \Delta_{sub}H^o[M(\eta^5\text{-}C_5H_5)_2Cl_2] \quad (5)$$

The enthalpies of sublimation of $M(\eta^5\text{-}C_5H_5)_2Cl_2$ are therefore needed to calculate $DH^o(M-L)$ from Equation 4.

The $\Delta_{sub}H^o[M(\eta^5\text{-}C_5H_5)_2Cl_2]$ values are also interesting since they are directly related to the intermolecular forces that dictate the solid state structures of the $M(\eta^5\text{-}C_5H_5)_2Cl_2$ compounds. They can therefore be useful in the development of methods for predicting crystal structures or enthalpies of sublimation of organometallic compounds based on atom-atom potential calculations.[10] The ability to predict crystal structures has of course a major impact in areas of great current chemical research activity, such as crystal engineering,[11] while the enthalpy of sublimation and vapour pressures of organometallic compounds are important in, for example, the design of chemical vapour deposition (CVD) processes.[12]

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0101−0257 $ 17.50+.50/0

Only the enthalpies of sublimation of $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$, $Zr(\eta^5\text{-}C_5H_5)_2Cl_2$, and $Hf(\eta^5\text{-}C_5H_5)_2Cl_2$ have been measured up to now,[8,9,13,14] and some discrepancies exist in cases where more than one independent result has been reported. The importance of $\Delta_{sub}H^o[M(\eta^5\text{-}C_5H_5)_2Cl_2]$ for the research topics mentioned above led us to undertake their systematic determination for group 4−6 transition metals.

Results and Discussion

The enthalpies of sublimation of the $M(\eta^5\text{-}C_5H_5)_2Cl_2$, compounds were derived from vapour pressure versus temperature measurements, using three different Knudsen effusion apparatuses.[15−18] For M = Ti, Zr, Hf, V, and W, the vapour pressures, p (Table 1), were determined as a function of the temperature, T, from the mass of sample, m, lost by the cell during the time t, according to:[19]

$$p = \frac{m}{AtK_C}\sqrt{\frac{2\pi RT}{M}} \quad (6)$$

where M is the molar mass of the effusing vapour, A is the area of the effusion hole, R is the gas constant, and K_C is the Clausing factor given by Equation 7.[19]

$$K_C = \frac{8r}{3l + 8r} \quad (7)$$

In Equation 7, l and r represent the thickness and the radius of the effusion hole, respectively. The vapour pressure data in Table 1 were fitted to the Clausius−Clapeyron Equation 8.[20]

$$\ln p = -\frac{a}{T} + b \quad (8)$$

and the enthalpies of sublimation of the dichloride complexes at the mean temperature, T_m, of the experiments were obtained as $\Delta_{sub}H^o(T_m) = aR$, where R is the gas constant. The values of $\Delta_{sub}H^o(T_m)$, and of the constants a and b in Equation 8 are indicated in Table 2. The uncertainties quoted correspond to σt_s, where σ is the standard error and t_s the Student's factor for a 95% confidence level.[21] Plots of Equation 8 for $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$, $Zr(\eta^5\text{-}C_5H_5)_2Cl_2$, $Hf(\eta^5\text{-}C_5H_5)_2Cl_2$, $V(\eta^5\text{-}C_5H_5)_2Cl_2$, and $W(\eta^5\text{-}C_5H_5)_2Cl_2$ are shown in Figure 1. The lines for the titanium, zirconium and hafnium complexes are based on the values of the corresponding a and b constants for the global results in Table 2.

In the case of $Nb(\eta^5\text{-}C_5H_5)_2Cl_2$, the mass of compound effusing from the Knudsen cell was monitored with a quartz crystal resonator detector.[17,18] If a thin film of any substance is deposited on the surface of a quartz crystal resonator, a shift Δf, of the main resonance frequency, f, is observed, which is a function of the mass of the coating, m.[22] Under the conditions of our experiment, the rate of change of the resonance frequency of the quartz crystal, v, with the time, t, is proportional to the rate of effusion of the compound from the cell, m/t:[17,18]

$$v = \frac{\Delta f}{t} = C_f\frac{m}{t} \quad (9)$$

where C_f is a proportionality constant. Equations 6 and 9 lead to:

$$p = \frac{v}{C_f AK_C}\sqrt{\frac{2\pi RT}{M}} \quad (10)$$

and, therefore, according to Equations 8 and 10, a plot of $\ln(vT^{1/2})$ against $1/T$ should give a straight line:

$$\ln(vT^{1/2}) = -\frac{a}{T} + b' \quad (11)$$

of slope $a = \Delta_{sub}H^o(T_m)/R$, and ordinate b. By fitting Equation 11 to the v and T data given in Table 1 for $Nb(\eta^5\text{-}C_5H_5)_2Cl_2$ it was possible to derive the values of a, b', and

[a] See Equation 8, for M = Ti, Zr, Hf, V, W. – [b] See Equation 11, for M = Nb.

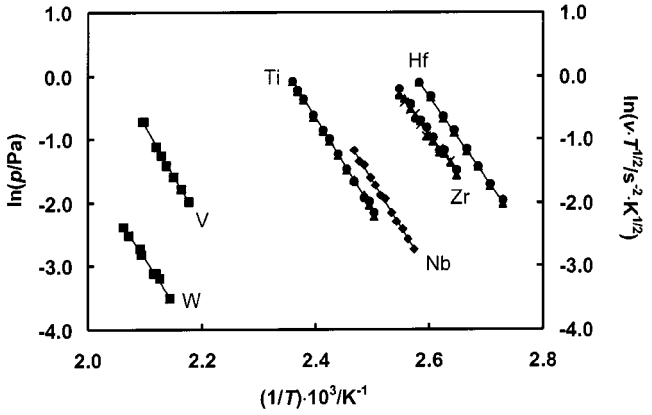

Figure 1. Plots of the Clausius–Clapeyron equation for the $M(\eta^5\text{-}C_5H_5)_2Cl_2$ (M = Ti, Zr, Hf, V, W) compounds and of $\ln(vT^{1/2})$ versus $1/T$ for $Nb(\eta^5\text{-}C_5H_5)_2Cl_2$ (see text). (•) – hole 1, (×) – hole 2, (▲) – hole 3, (■) – hole 4, (◆) – hole 5

$\Delta_{sub}H^o(T_m)$ indicated in Table 2. The uncertainties quoted were calculated as described above for the other complexes. A representation of $\ln(vT^{1/2})$ versus $1/T$ for $Nb(\eta^5\text{-}C_5H_5)_2Cl_2$, based on the a and b constants in Table 2, is also shown in Figure 1.

The enthalpies of sublimation of the $M(\eta^5\text{-}C_5H_5)_2Cl_2$ compounds, at 298.15 K, were derived from:

$$\Delta_{sub}H^o(298.15\ K) = \Delta_{sub}H^o(T_m) + \Delta_{sub}C_p^o(298.15 - T_m) \quad (12)$$

by using the $\Delta_{sub}H^o(T_m)$ data in Table 2 and an estimated value $\Delta_{sub}C_p^o = -(50\pm20)$ JK^{-1}mol^{-1}.[23] The results obtained are shown in Table 3.

As mentioned in the Introduction, only the enthalpies of sublimation of $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$,[8,9,13,14] $Zr(\eta^5\text{-}C_5H_5)_2Cl_2$,[8,9,13,14] and $Hf(\eta^5\text{-}C_5H_5)_2Cl_2$[8,9,13] had been previously measured. Correction of the reported values from their reference temperatures to 298.15 K, using Equation 12 and $\Delta_{sub}C_p^o = -(50\pm20)$ JK^{-}·^{1}mol^{-1}, led to the results in Table 3. Note, however, that the information needed to recalculate the corresponding uncertainties using the Student's factor is lacking in the literature. The errors in the published data included in Table 3 may, therefore, be underestimated relative to those quoted for our values.

Table 3 shows that the standard molar enthalpies of sublimation of $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$, $Zr(\eta^5\text{-}C_5H_5)_2Cl_2$, and $Hf(\eta^5\text{-}C_5H_5)_2Cl_2$ proposed in this paper agree, within the experimental error, with those obtained by Balducci et al.[13] and by Rabinovich et al.,[8,9] using effusion methods. Our value for $\Delta_{sub}H^o[Zr(\eta^5\text{-}C_5H_5)_2Cl_2]$ is also in good agreement with a mass spectrometric result published by Kiser et al.[14] A large discrepancy exists, however, between the $\Delta_{sub}H^o[Ti(\eta^5\text{-}C_5H_5)_2Cl_2]$ value reported by Kiser et al.[14] and those obtained by us and other authors. The enthalpy of sublimation of $\Delta_{sub}H^o[W(\eta^5\text{-}C_5H_5)_2Cl_2]$ in Table 3 is also ca. 16 kJmol^{-1} higher than an estimate of 104.6±4.2 kJmol^{-1} reported by Tel'noi et al.[8]

Finally, it is interesting to note that a linear least squares analysis of a representation of the $\Delta_{sub}H^o[M(\eta^5\text{-}C_5H_5)_2Cl_2]$ (M = Ti, Zr, Hf, V, Nb, W) values reported in this paper versus the atomic radii of the metals, r_M,[24] (Table 3), leads to (Figure 2):

$$\Delta_{sub}H^o[M(\eta^5\text{-}C_5H_5)_2Cl_2]/kJmol^{-1} = -0.972(r_M/pm) + 263.3 \quad (13)$$

with a regression coefficient of 0.9. Equation 13 reproduces the experimental $\Delta_{sub}H^o[M(\eta^5\text{-}C_5H_5)_2Cl_2]$ values with a maximum error of 10 kJmol^{-1}, and predicts that $\Delta_{sub}H^o[Ta(\eta^5\text{-}C_5H_5)_2Cl_2] = 124\pm10$ kJmol^{-1}, and $\Delta_{sub}H^o[Mo(\eta^5\text{-}C_5H_5)_2Cl_2] = 131\pm10$ kJmol^{-1}. Attempts to measure the enthalpies of sublimation of $Ta(\eta^5\text{-}C_5H_5)_2Cl_2$, and $Mo(\eta^5\text{-}C_5H_5)_2Cl_2$ in the Lisbon laboratory failed due to decomposition of the samples before a measurable mass loss from the Knudsen cell could be obtained.

Conclusion

The enthalpies of sublimation of the $M(\eta^5\text{-}C_5H_5)_2Cl_2$ compounds reported in this paper (*i*) decrease from the first to the second transition series, (*ii*) remain almost constant from the second to the third transition series, and (*iii*) decrease across a transition series. This trend shows a remarkably good linear correlation with the atomic radii of the metals. The significance of this correlation to the nature of the intermolecular potentials in these molecules needs to

be investigated. The obtained $\Delta_{sub}H°[M(\eta^5\text{-}C_5H_5)_2Cl_2]$ data will also enable an improvement in the reliability of bond dissociation enthalpies derived for bis(cyclopentadienyl) compounds, which are one of the most important model systems used to study the systematics of bonding energetics in transition metal compounds.

Experimental Section

General: All syntheses were carried out under argon atmosphere, by standard Schlenk techniques. Solvents were dried as recommended by Perrin et al.[25] and distilled and stored under argon atmosphere. The $W(\eta^5\text{-}C_5H_5)_2H_2$ used in the preparation of $W(\eta^5\text{-}C_5H_5)_2Cl_2$ was synthesised as described by Green and Knowles[26] and purified by sublimation at 353 K and 0.13 Pa.

C, H, N elemental analysis were performed with a Carlo Erba 1106 elemental analyser. Infrared spectra were obtained with a Perkin–Elmer 683 spectrophotometer calibrated with polystyrene film. Band intensities are referred to as following: vs, very strong; s, strong; m, medium; w, weak.

Materials: $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$ was prepared as recommended by Samuel[27] and purified by sublimation at 333 K and 0.13 Pa. – $C_{10}H_{10}Cl_2Ti$: calcd. C 48.24, H 4.05; found C 48.20, H 4.03. – IR (KBr, cm^{-1}): 3120 m, 1445 s, 1375 w, 1028 m, 1015 s, 874 m, 820 vs.

$Zr(\eta^5\text{-}C_5H_5)_2Cl_2$ was synthesised as described in the literature[27–29] and purified by sublimation at 363 K and 1.3 Pa. – $C_{10}H_{10}Cl_2Zr$: calcd. C 41.09, H 3.45; found C 41.03, H 3.47. – IR (KBr, cm^{-1}): 3100 m, 1865 w, 1760 w, 1660–1640 w, 1435 s, 1360 m, 1115 m, 1065 w, 1020–1015 vs, 935–920 w, 860–840 vs, 815 vs.

$Hf(\eta^5\text{-}C_5H_5)_2Cl_2$ (Aldrich, 98%) was purified by sublimation at 390 K and 0.13 Pa. – $C_{10}H_{10}Cl_2Hf$: calcd. C 31.64, H 2.65; found C 31.59, H 2.62. – IR (KBr, cm^{-1}): 3115 m, 1440 s, 1367 w, 1023 s, 1013 s, 855–840s, 814 vs.

$V(\eta^5\text{-}C_5H_5)_2Cl_2$ (Aldrich, 95%) was purified by sublimation at 463 K and 0.13 Pa. – $C_{10}H_{10}Cl_2V$: calcd. C 47.65, H 4.00; found C 47.59, H 3.94. – IR (KBr, cm^{-1}): 3100 m, 1450 m, 1370 w, 1015–1025 w, 1013 s, 890 w, 830 vs.

$Nb(\eta^5\text{-}C_5H_5)_2Cl_2$ was synthesised as described in the literature[30] and purified by sublimation at 363 K and 1.3 Pa. – $C_{10}H_{10}Cl_2Nb$: calcd. C 40.85, H 3.43; found C 40.60, H 3.68. – IR (KBr, cm^{-1}): 3100 m, 1435 m, 1360 w, 1260 w, 1120 w, 1070 w, 1020 s, 870 m, 820 vs.

The method of preparing $W(\eta^5\text{-}C_5H_5)_2Cl_2$ [31] was adapted from that given by Cooper and Green.[32] Dropwise addition of chloroform to a solution of $W(\eta^5\text{-}C_5H_5)_2H_2$ in toluene, under argon atmosphere, at room temperature, gave green crystals of $W(\eta^5\text{-}C_5H_5)_2Cl_2$. These were washed with diethyl ether and dried at room temperature in a filter funnel connected to a water aspirator pump. The product obtained was washed with dichloromethane in a Soxhlet apparatus for 24 h, until colourless extracts were observed, and dried under vacuum (318 K, 1.3 Pa). – $C_{10}H_{10}Cl_2W$: calcd. C 31.20, H 2.62; found C 31.40, H 2.60. – IR (KBr, cm^{-1}): 3110 m, 1430 m, 1360 w, 1265 vw, 1110 vw, 1010 m, 875 m, 835 s, 800 m, 585 w.

Apparatus: The Knudsen effusion apparatus used in the Porto laboratory to measure the vapour pressures of the complexes $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$, $Zr(\eta^5\text{-}C_5H_5)_2Cl_2$, and $Hf(\eta^5\text{-}C_5H_5)_2Cl_2$ has been reported.[15] This apparatus enables the simultaneous operation of three Knudsen cells. In the present work, the effusion holes had a thickness of 0.049 mm, and the areas were 0.596 mm^2 (hole 1), 0.754 mm^2 (hole 2), and 0.862 mm^2 (hole 3). The cells were immersed in a silicone oil bath whose temperature was controlled to within ±0.001 K using a Tronac PTC 40 thermostat. The temperature of the sample was assumed to be identical to the temperature

of the bath, which was measured to ±0.01 K with an Amarell calibrated mercury thermometer. In a typical experiment, each cell was charged with ca. 300 mg of sample and the observed mass loss was determined to $\pm 10^{-5}$ g with a Mettler H54 balance. The duration of the runs varied from 3 h to 6 h and the corresponding mass losses from the cell varied between 10 mg and 30 mg.

In the Lisbon laboratory, the vapour pressures of V(η^5-$C_5H_5)_2Cl_2$ and W(η^5-$C_5H_5)_2Cl_2$ were measured with the Knudsen effusion setup previously described.[16] The temperature range of the apparatus was, however, extended up to ca. 650 K by replacement of the water bath with a Termolab tubular furnace surrounding the brass block containing the effusion cell. The temperature of the furnace was controlled to ±0.1 K by a Eurotherm 902P thermostatic unit and a K type thermocouple placed in contact with the inner wall of the furnace. The equilibrium temperature inside the cell was assumed to be identical to the temperature of the brass block. This temperature was measured with a Tecnisis 100 Ω platinum resistance thermometer embedded in the block and connected in a four wire configuration to a Keithley 2000 multimeter. The average of all temperature readings acquired during a constant 10 s interval was stored in the buffer memory of the multimeter. The mean value of the total number of readings accumulated by the multimeter during a run was taken as the corresponding sample temperature. The bronze cell used in the experiments[16a][16b] had an effusion hole with an area of 0.440 mm^2, and a thickness of 0.0209 mm. In a typical run, the cell was charged with ca. 250 mg of sample and the observed mass loss was determined to $\pm 10^{-5}$ g with a Sartorius 2474 balance. The duration of the experiments varied between ca. 21 h and 23 h for V(η^5-$C_5H_5)_2Cl_2$, and 18 h and 25 h for W(η^5-$C_5H_5)_2Cl_2$. The corresponding sample mass losses from the cell were in the ranges ca. 15 mg − 56 mg and 4 mg − 13 mg, respectively.

The compound Nb(η^5-$C_5H_5)_2Cl_2$ was studied using an improved version[18] of the Knudsen effusion apparatus with a quartz crystal microbalance detector, described by Burkinshaw and Mortimer.[17] The cylindrical Knudsen cell with an external diameter of 13 mm, an internal diameter of 6 mm, and a depth of 8 mm, was made of steel. The cell was closed by screwing on a steel lid containing a central effusion hole. The hole has the shape of diverging conical orifice with the smaller section (0.8 mm diameter) facing the interior of the cell. The complete cell was screwed into an electrically heated cylindrical steel block, inside the vacuum chamber of an Edwards 306 vacuum coating unit, equipped with a Edwards FTM3 film thickness monitor incorporating a water cooled quartz crystal resonator (6 MHz). The temperature of the block was controlled to ±0.1 K by an Eurotherm 815 unit. The temperature of the sample was measured by a Labfacility P100/0620 platinum resistance thermometer screwed to the bottom of the effusion cell. The vapour effusing from the Knudsen cell condensed on the quartz crystal resonator which was positioned above the effusion hole. The changes in the oscillation frequency of the crystal were monitored as a function of time by a Philips Frequency Counter PM. The pressure inside the vacuum chamber was maintained at ca. $6 \cdot 10^{-5}$ Pa by an Edwards system consisting of an E2M12 rotary pump and a E04 diffusion pump with a liquid nitrogen trap. In the study of Nb(η^5-$C_5H_5)_2Cl_2$ the cell was initially charged with ca. 200 mg of compound, and the temperature of the furnace was raised until the rate of sublimation corresponded to a rate of frequency change, *v*, greater than ca. 10 Hz min^{-1}. When equilibrium was established the frequency counter readings were acquired as a function of time for 45−60 min. The experiment was repeated at successively higher temperatures separated by ca. 2 K.

Acknowledgments

This work was supported by the PRAXIS XXI and SAPIENS programmes (Projects PRAXIS/PCEX/QUI/62/96 and SAPIENS/35406/99). We also thank Ana L. F. Pires for assistance in the measurements of the vapour pressures of Ti(η^5-$C_5H_5)_2Cl_2$ and Zr(η^5-$C_5H_5)_2Cl_2$, and Dr. Jay Labinger (Beckman Institute, California Institute of Technology) for providing the Ta(η^5-$C_5H_5)_2Cl_2$ sample used in attempts to measure its enthalpy of sublimation.

Further Investigation into the Platinum-Activated Addition of Diphenylsulfimide to Acetonitrile; the X-ray Crystal Structure of $[PPh_4][PtCl_2(Ph_2SNC(Me)NH)]_2Cl$

Paul F. Kelly*[a] and Alexandra M. Z. Slawin[b]

Keywords: Sulfur / Nitrogen / Platinum / Sulfimides / Nitriles

Reaction of Ph_2SNH (**1**) with $[PtCl_2(MeCN)_2]$ (1:1 ratio) in MeCN at 50 °C results in the formation of $[PtCl_2\{Ph_2SNC(Me)NH\}]$ (**3**); without heating $[Pt(Ph_2SNH)\{Ph_2SNC(Me)NH\}Cl]Cl$ (**2**) is the primary product. Attempts to grow X-ray quality crystals of **3** have not succeeded; it does, however, form a crystalline 2:1 adduct with $[PPh_4]Cl$ (**3a**), the structure of which confirms the presence of the bidentate $Ph_2SNC(Me)NH$ ligand hydrogen-bonded to the chloride anion. Reaction of **3** with three equivalents of **1** and two of $Tl[PF_6]$ results in the formation of $[Pt(Ph_2SNH)_2\{Ph_2SNC(Me)NH\}_2][PF_6]_2$ (**4**), the first example of a complex containing the $[Ph_2SNC(Me)N(H)]$ unit acting as a monodentate ligand, bound through the nitrogen atom.

Introduction

As part of our continuing interest in the coordination chemistry of sulfur−nitrogen species[1] we have recently reported on the reactivity of *S*,*S*′-diphenylsulfimide, Ph_2SNH (**1**), towards a number of metal centres, including copper (resulting in *trans*-$[CuCl_2(Ph_2SNH_2)]$ which, uniquely for a neutral Cu^{II} species exhibits square-planar and pseudo-tetrahedral allogons),[2] cobalt,[3] and platinum.[4] During investigations into reactions involving the latter metal we discovered that the reaction of two equivalents of **1** with $PtCl_2(MeCN)_2$ resulted in the formation of $[Pt(Ph_2SNH)\{Ph_2SNC(Me)NH\}Cl]Cl$ (**2**) rather than the expected simple substitution product. In effect one of the incoming sulfimide units had added to a metal-bound acetonitrile − an addition that does not take place in the absence of the metal centre (or indeed in the presence of a metal other than platinum, at least amongst those we have investigated so far). The resulting nitrile/sulfimide ligand binds in a bidentate fashion through a nitrogen and a sulfur atom; indeed, one of the most interesting aspects of this reaction was the fact that **2** constitutes the first example of a sulfimide unit binding to a metal centre through a sulfur atom. Here we present the results of further investigations into this reaction.

Results and Discussion

Upon first isolating **2** from the 2:1 reaction of **1** with $PtCl_2(MeCN)_2$ we made preliminary, tentative assumptions about the reaction mechanism. Given that nucleophilic attack upon coordinated nitriles is well known[5] we anticipated that this would be the first stage, with the resulting *N*-bound monodenate ligand then chelating by removal of the other nitrile (and S−Pt bond formation). Then the second sulfimide would displace a chloride to give the final product. In order to go some way to confirming this suggestion we have now analysed the analogous equimolar reaction, which should, on the basis of the latter mechanism, generate $[PtCl_2\{Ph_2SNC(Me)NH\}]$ (**3**). The latter does indeed form, though not in as straightforward a manner as we had anticipated. Within a short time of complete addition of the reagents a crystalline material starts to form; rather than being **3**, however, IR spectroscopy indicates that this material is in fact **2**. If, however, the crude mixture at this stage is heated to ca. 50 °C for two hours any solids present redissolve and the colour of the solution gradually changes from pale yellow to a bright lemon colour. After precipitation of a small amount of impurity with Et_2O, the main reaction product can be retrieved by evaporation of the solvent and trituration of the oily residue with cold ether. Although, unfortunately, we have yet to grow crystals suitable for single crystal diffraction, the resulting bright yellow material may be formulated as **3** by a combination of IR, NMR, and microanalysis.

Further confirmation of its nature comes when crystallisation is attempted in the presence of $[PPh_4]Cl$. We initially performed this in the hope that the chloride would break the Pt−S bond thus giving a monodentate $[Ph_2SNC(Me)NH]$ ligand. In fact this does not happen (though, as we will see, we can achieve this in other ways); rather, the chloride binds through hydrogen bonds to two units of **3** to give the adduct **3a** (Figure 1).

Within the Pt−S−N−C−N metallacycle of **3a** there appears to be minimal difference in geometry between the two independent units and indeed between them and the previously reported values for **2**. While the planes of the two metallacycles are inclined at an angle of 53° to each other,

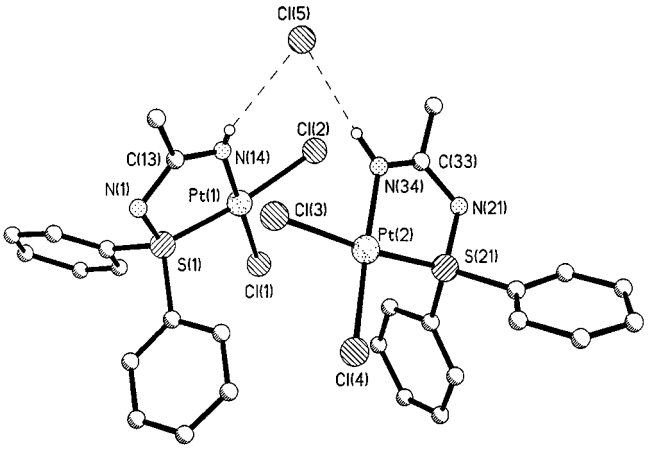

Figure 1. The X-ray crystal structure of **3a** (omitting the $[PPh_4]^+$ cation)

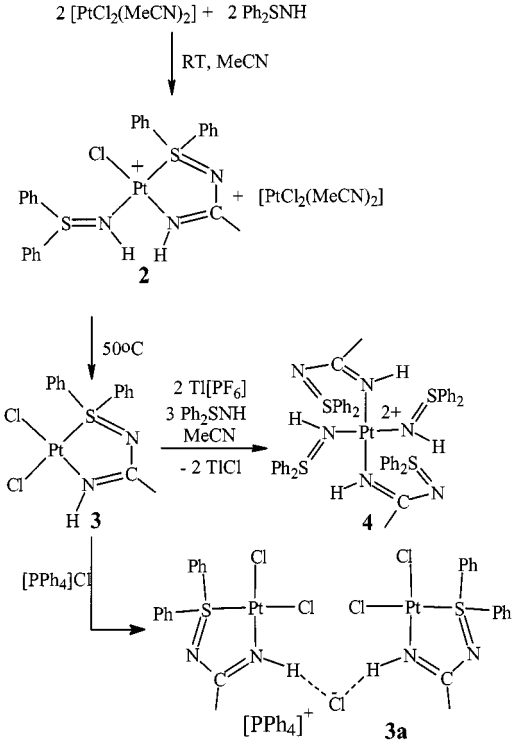
the average H···Cl interaction distance is 2.33 Å, and the average N−H−Cl angle 160°. The resulting structure is interesting for a number of reasons. Firstly it confirms the tendency of the N−H bonds of coordinated sulfimide units to get involved in significant hydrogen bonding interactions. In the case of previously noted examples, the formation of such bonds was undoubtedly aided by the fact that they were part of cation−anion interactions;[3,6] here this is obviously not the case, though the significant interactions are present nonetheless.

In addition, of course, it confirms the basic structure of **3**; further confirmation, and of the original mechanism we put forward, comes when **3** is treated with **1**. Within a few minutes of addition in MeCN crystals of **2** (confirmed by IR) begin to form. We can thus be confident that the kind of mechanism shown in Scheme 1 applies to the system as a whole. As **1** is slowly added to the system during the 1:1 reaction **3** starts to form; once formed it then acts as a competitor to the $PtCl_2(MeCN)_2$. Unreacted **1** can thus either undergo nitrile addition to give more **3** or substitution on the **3** that has been formed in order to give **2**. The latter appears to be preferred, meaning that by the end of addition of **1** the mixture consists of **2** and, presumably, unchanged $PtCl_2(MeCN)_2$. This mixture can, however, be driven through to **3** by heating, suggesting that the unchanged sulfimide ligand in **2** is actually quite labile.



Scheme 1. Summary of the reactions to form **2**, **3**, **3a**, and **4**

An important feature of **3** is its obvious potential as a reagent with which to probe the properties of the bidentate ligand − in particular its lability. A significant result in this area is obtained when **3** (formed in situ) is treated with $Tl[PF_6]$ and three equivalents of **1**. The thallium salt displaces chloride from **3** with, presumably, MeCN taking up the vacant site. This intermediate then reacts with three equivalents of **1** to produce a new species, **4**, which may be isolated in crude form by centrifugation of the mixture (in order to separate the bulk of the finely divided TlCl generated in the reaction) followed by filtration and removal of the solvent. Trituration of the oily product with Et_2O yields an off-white solid from which crystalline material may be grown by slow diffusion of Et_2O into a solution in MeCN.

We can formulate **4** as $[Pt(Ph_2SNH)_2\{Ph_2SNC(Me)NH\}_2][PF_6]_2$ by a combination of microanalysis, IR, NMR. X-ray crystallography also backs this up, though we do not formally present the results here as the structure suffers from poor quality [unit cell: triclinic, space group $P\bar{1}$; a = 10.4943(2), b = 11.0252(3), c = 14.1772(4) Å; α = 107.45(1), β = 100.295(1), γ = 110.441(1)°]. Its does, however, confirm that the Pt centre now exhibits two unchanged sulfimide ligands and two sulfimide/nitrile addition ligands both bound in monodentate fashion as shown in Scheme 1. As for the mechanism of formation of **4**, we can reasonably assume that the initial reaction of $Tl[PF_6]$ with **3** replaces at least one of the halides with MeCN which can then react with **1**, possibly giving $[Pt(Ph_2SNC(Me)NH)_2]$ as an intermediate. Additional molecules of **1** then substitute into this by breaking Pt−S bonds.

In conclusion, the isolation of **3** in good yield will allow us to probe the substitution properties of this new class of chelating ligand. The isolation of **4** is important insofar as it indicates that the new ligands formed in the platinum-assisted sulfimide/nitrile reactions are not constrained to chelation and thus may ultimately prove to be labile. The displacement and isolation of such addition products as free species would provide us with interesting new (and undoubtedly reactive) systems that cannot be generated by direct sulfimide/nitrile reactions. It would also raise the intriguing possibility of adjusting the reaction system to allow the platinum to act catalytically. Work towards this end is currently underway.

Experimental Section

All reactions were carried out under dry nitrogen; MeCN was dried and distilled from calcium hydride, diethyl ether from sodium. −

IR spectra were run with a Perkin−Elmer PE2000 spectrometer; NMR with a Bruker AC250 spectrometer; microanalysis was performed by Loughborough's Departmental service. − Ph_2SNH (**1**) was prepared by our previously reported variation upon the literature route.[6]

3: A solution of $[PtCl_2(MeCN)_2]$ (61 mg, 0.18 mmol) in MeCN (10 mL) was treated with a solution of **1** (36 mg, 0.18 mmol) in the same solvent (10 mL) added over a period of 1 min, with stirring. The resulting mixture was then heated to 50 °C and stirred at this temperature for 2 h during which time the solution colour changed from pale yellow to a bright lemon. At this point the volume of the solvent was reduced to ca. 5 mL in vacuo and Et_2O (50 mL) added with stirring. This resulted in the formation of a small amount of a flocculant white precipitate which was filtered off and the solution reduced to dryness in vacuo then triturated with Et_2O to give a bright yellow product. Yield 60 mg, 67%. − IR (key bands, i.e. non-phenyl): $\tilde{\nu}$ = 3296 cm^{-1} (ms, νN−H), 1529 (s, νC−N), 808 (m, νN−S), 356 (mw, νPt−Cl), 331 (m, νPt−Cl). − ^1H NMR ($CDCl_3$): δ = 8.13 (m, 4 H, phenyl), 7.65 (m, 6 H, phenyl), 2.43 (s, 3 H, CH_3). − $C_{14}H_{14}Cl_2N_2PtS$ (508.3): calcd. C 33.1, H 2.8, N 5.5; found C 32.9, H 2.8, N 5.7. − Crystallisation by slow diffusion of Et_2O into a CH_2Cl_2 solution to which $[PPh_4]Cl$ had been added resulted in well-formed yellow crystals of the adduct $[PPh_4][PtCl_2(Ph_2SNC(Me)NH)]_2Cl$ (**3a**).

4: A crude solution of **3** in MeCN was generated as above from $[PtCl_2(MeCN)_2]$ (43 mg, 0.12 mmol) and **1** (25 mg, 0.12 mmol) (with heating for2 h followed by cooling to room temperature) and treated with $Tl[PF_6]$ (86 mg, 0.25 mmol). This resulted in the immediate production of a finely divided white solid within a pale brown/red solution; the mixture thus formed was stirred for 1 min then solid **1** (73 mg, 0.36 mmol) added. After stirring for 1 h at 60 °C, the mixture was cooled to room temperature and stirred overnight. At this stage it was centrifuged to separate out the bulk of the very finely divided solid present and then filtered through Celite, the solvent volume reduced to a few mL and Et_2O (50 mL) added with stirring. The resulting brown/orange oil was triturated with Et_2O to give the crude product as an off-white solid. Yield 116 mg. Microanalysis reveals this material to be contaminated with variable amounts of a CHN-free impurity, presumably TlCl, which proves surprisingly difficult to remove; the IR spectrum is, however, identical to that of pure crystalline material generated by slow diffusion of Et_2O into an MeCN solution. Yield of the crystalline material is typically half that of the crude material; however, we believe that the bulk of this shortfall reflects decomposition in solution over the time taken for crystallisation (the solution darkens appreciably over a period of days, even in an inert atmosphere) rather than there being a high impurity level in the crude material. − IR (key bands, i.e. non-phenyl): 3366 cm^{-1} (ms), 3320 (m) (both ν N−H), 1542 (s,ν C−N), 918 (m, ν N−S), 842 (vs, br., ν P−F). − ^1H NMR (CD_3CN): δ = 7.74 (m, 2 H, phenyl), 7.62 (m, 4 H, phenyl), 7.36 (m, 14 H, phenyl), 2.41 (s, 3 H, CH_3). − $C_{52}H_{50}F_{12}N_6P_2PtS_4$ (1372.3): C 45.5, H 3.7, N 6.1; found C 45.3, H 3.9, N 6.2.

Crystal Data for 3a: $C_{52}H_{48}Cl_5N_4PPt_2S_2$, M = 1391; triclinic, space group $P\bar{1}$; a = 11.96(1), b = 22.83(1), c = 10.703(6) Å, α = 92.00(5), β = 111.51(6) γ = 77.48(6)°; V = 2651(3) $Å^3$, Z = 2, calculated density: 1.743 gcm^{-3}. Yellow prism, dimensions 0.3 × 0.1 × 0.08 mm, μ (Mo-K_α) = 56.50 cm^{-1}, λ = 0.71069 Å, F(000) = 1352. − Data were collected (using a Rigaku AFC7S diffractometer with graphite-monochromated Mo-K_α radiation) by the ω-2θ scan technique to a maximum 2θ value of 50.0°. Of 9820 measured reflections 9333 were unique. An empirical absorption correction was applied resulting in transmission factors ranging from 0.66 to 1.00. − Structure analysis and refinement: The structure was solved by direct methods and refined by full-matrix least squares against F. Non-hydrogen atoms were refined anisotropically; hydrogen atoms were included but not refined. Refinement against F led to R = 0.042 [$R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$], Rw = 0.045. The maximum/minimum residual electron densities in the final ΔF map were 1.33 and −1.96 $e^-/Å^3$; calculations were performed using the teXsan crystallographic software package of Molecular Structure Corporation.[7] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-143676. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

New Alkyl−Cobalt(III) Complexes with Tridentate Amino−Oxime Ligands: Synthesis, Structure, and Reactivity

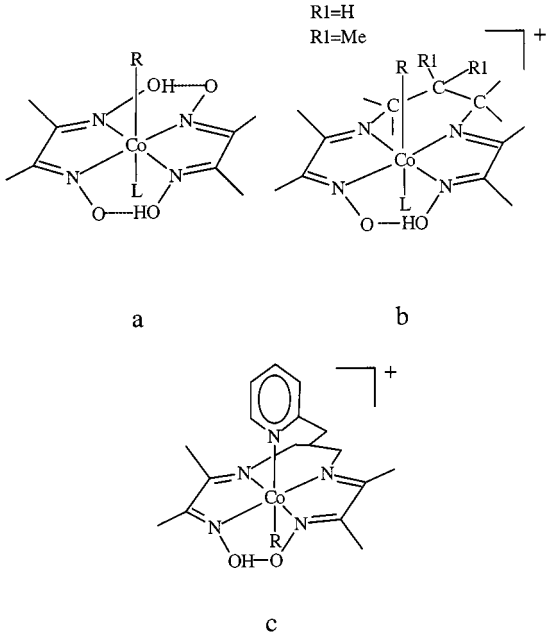
Renata Dreos,[a] Alessandro Felluga,[a] Giorgio Nardin,[a] Lucio Randaccio,*[a] Patrizia Siega,[a] and Giovanni Tauzher*[a]

Keywords: Cobalt / Tridentate ligands / Alkylations / Vitamins / N ligands

The oxidative addition of alkyl halides to the Co^{I} species generated by the reduction of $[Co^{III}(LNHpy)(HLNHpy)](ClO_4)_2$ (**1**), where HLNHpy is the tridentate 2-(2-pyridylethyl)amino-3-butanone oxime ligand and LNHpy is its conjugate base, led to the formation of a new class of organocobalt complexes of general formula $[RCo^{III}(LNHpy)(HLNHpy)](ClO_4)$ [R = Me (**2a**), Et (**2b**), CH_2CF_3 (**2c**), *n*Bu (**2d**), and CH_2Cl (**2e**)]. All the complexes were characterised by ^1H and ^{13}C NMR spectroscopy. The X-ray structures of **2a**, **2b** and **2c** provide evidence for a pseudo-octahedral configuration, where HLNHpy and LNHpy act as bi- and tridentate ligands, respectively. The axial geometry in **2a** is closer to that found in methylcobalamin than that reported for other models, suggesting steric and electronic *cis* influences of the equatorial ligands close to those of the corrin nucleus. The solution properties and the reactivity show strong analogies with those of the previously known Vitamin B_{12} models.

Introduction

Previous studies on classical models for coenzyme B_{12}, such as alkylcobaloximes $LCo(DH)_2R$ (Scheme 1a, DH = monoanion of dimethylglyoxime, R = alkyl, L = neutral Lewis base), have been aimed at elucidating the factors that affect the properties of the Co−C bond. Experimental evidence shows that steric and electronic factors are both important in this context.[1] The recent structural results on B_{12} enzymes have shown that in some of the enzyme-bound B_{12} coenzymes, the benzimidazole residue is replaced in the coordination to Co by the imidazole moiety of a histidine of the protein chain.[2] This finding has renewed interest in the nature of the Co−L bond in simple models.[3,4,5] The early hypothesis[1] that the Co−L distance is influenced by the orientation of the planar L ligand, measured by the torsional angle φ around that bond, has been confirmed.[6−8] In orientation A (Scheme 2), when φ is close to 0, the Co−L distance is found to be shorter by about 0.03 Å than in orientation B (Scheme 2), corresponding to φ close to 90°. Typically, orientation A is found in cobaloximes, whereas orientation B is found in iminocobaloxime analogues (Scheme 1b). However, in the lariat-type complexes[8] (Scheme 1c), derived from iminocobaloximes, the values of φ and of the Co−py distance are similar to those in the cobaloxime analogues. In fact, in the lariat-type complexes, although derived from iminocobaloximes, orientation A is imposed by the conformational rigidity of the pentadentate ligand.



Scheme 1

Less definitive indications about the influence of the L orientation on the Co−C bond in the ground state has been found so far. In fact, structural (Co−R distance) and spectroscopic (ν_{Co-Me}) evidences have suggested that orientation B may correspond to a weaker Co−C bond than in orientation A.[7] On the other hand, FT-Raman studies did not detect any change in the Co−C force constants even in base-on and base-off cobalamins.[9] Furthermore, recent studies[10] on the interaction of adenosylcobinamides with hindered bases, (1,2-Me_2Im, 2-Mepy and 2,6-Me_2py) have provided evidence for a dominant effect of the axial base on the transition state of the Co−C bond-cleavage process.

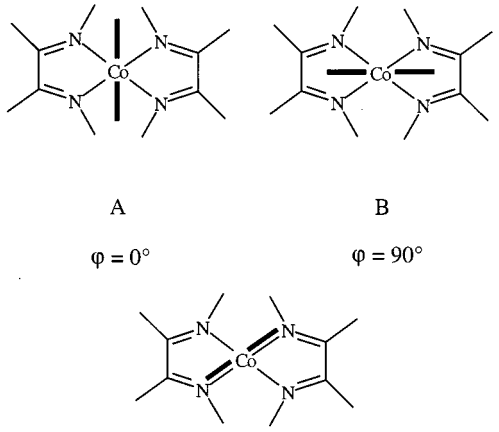
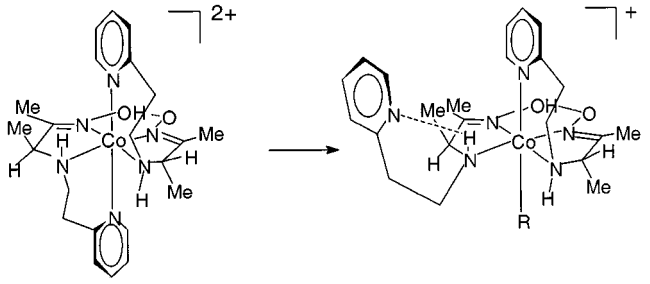


Scheme 2

In order to obtain further insight into the above points, we have synthesised a new class of organocobalt derivatives $[RCo(LNHpy)(HLNHpy)]ClO_4$, (**2**) (HLNHpy = 2-(2-pyridylethyl)amino-3-butanone oxime) derived from $[Co(LNHpy)(HLNHpy)](ClO_4)_2$ (**1**),[11] (Scheme 3). The geometry of **2** is reminiscent of the lariat-type complexes,[8] which combine the corrin-like features of the iminocobaloximes with an appended axial base. However, they differ from the latter by having a more crowded equatorial moiety, owing to the side substituents at the amino C−N fragments. Therefore, complexes **2** could potentially mimic the interactions between axial and equatorial moieties in cobalamins better than previous models.



1 **2**

Scheme 3

The synthesis and NMR characterisation of a series of complexes of type **2** [R= Me (**2a**), Et (**2b**), CH_2CF_3 (**2c**), *n*Bu (**2d**), CH_2Cl (**2e**)], the crystal structure of **2a**, **2b**, **2c** as well as the reactivity of the Me derivative are reported and their ability to model the B_{12} system is discussed.

Results

Synthesis

The organometallic complexes of type **2** were obtained according to Equation (1).

$$[Co^{III}(LNHpy)(HLNHpy)]^{2+} \xrightarrow{NaBH_4, PdCl_2} [Co^{I}(LNHpy)(HLNHpy)]$$
$$[Co^{I}(LNHpy)(HLNHpy)] \xrightarrow{RX} [R\text{-}Co^{III}(LNHpy)(HLNHpy)]^{+} + X^{-} \quad (1)$$

The process involves the oxidative addition of the appropriate alkyl halide to the nucleophilic Co^I species, which may be generated in situ by the reduction of **1** with $NaBH_4$/$PdCl_2$. Similar synthetic routes have been extensively exploited to obtain cobalt complexes containing highly unsaturated equatorial ligands. Generally, the Co^I species are obtained from Co^{III} by the use of $NaBH_4$.[12] We observed[11] that although the reduction of **1** with $NaBH_4$ does not proceed beyond the formation of a Co^{II} species, the complete reduction to Co^I could be achieved by the addition of a catalytic amount of $PdCl_2$ to the reaction mixture. The formation of Co^I is recognisable by its nucleophilic reactivity toward alkyl halides, but the dark brown solutions are extremely sensitive to oxygen and this prevented further characterisation. It is noteworthy that the Co^{II} complex obtained by reduction with $NaBH_4$ is unreactive toward alkyl iodides (see Discussion). Several attempts to synthesise organometallic derivatives with bulky alkyl groups such as iC_3F_7, iC_3H_7, and adamantyl were carried out, but the Co^I species failed to react with the corresponding alkyl halide. Even after several hours, Co^I was unchanged and its presence could be verified by the addition of CH_3I to the reaction mixture, which rapidly led to the formation of the methyl derivative.

Reactivity of the Methyl Derivative 2a

Like alkylcobalamins[13] and synthetic alkylcobalt(III) chelates,[14] complex **2a** is light-sensitive. The photolysis of an aqueous solution of the complex in the presence of oxygen produced formaldehyde and complex **1**. This result may be rationalised by the assumption that the initial step is the homolysis of the Co−C bond, which produces a Co^{II} species and methyl radicals. In the presence of oxygen they are oxidised, giving **1** and formaldehyde, which are the expected products of aerobic photolysis.[13]

The methyl-transfer reaction occurs from complex **2a** to $Co^{II}(DH)_2(H_2O)_2$. The reaction was carried out in the dark under nitrogen. After exposure to air, complex **1** and $CH_3Co^{III}(DH)_2H_2O$ were isolated and identified [Equation (2)].

$$[CH_3Co^{III}(LNHpy)(HLNHpy)]^{+} + [Co^{II}(DH)_2] \longrightarrow$$
$$[Co^{II}(LNHpy)(HLNHpy)]^{+} + [CH_3Co^{III}(DH)_2H_2O] \quad (2)$$
$$[Co^{II}(LNHpy)(HLNHpy)]^{+} \xrightarrow{O_2} [Co^{III}(LNHpy)(HLNHpy)]^{2+}$$

Since the process occurs in the absence of light, it can be formulated as a direct transfer of the methyl radical to the acceptor. The Co^{II} species arising from the dealkylation gives **1** after oxidation in the air. The complex **2a** also

methylates Vitamin B_{12r} under the experimental conditions described above [Equation (3)].

$$[CH_3Co^{III}(LNHpy)(HLNHpy)]^+ + \text{Vit. } B_{12r} \longrightarrow CH_3B_{12} + [Co^{II}(LNHpy)(HLNHpy)]^+ \quad (3)$$

The exchange reaction of the chelate moiety of **2a** has been successfully carried out in one case: A methanolic solution of **2a**, dimethylglyoxime, and pyridine (allowed to stand overnight) produced $CH_3Co^{III}(DH)_2py$ as a product. It seems likely that the reaction proceeds by the stepwise replacement of the two amino oxime ligands by dimethylglyoxime.

X-ray Structures

The ORTEP[15] drawings of **2a**−**2c** are given in Figure 1, crystal data in Table 1. For **2a**, only the ORTEP drawing of one of the two crystallographically nonequivalent molecules (A) is shown. Complexes **2** can formally be described as being derived from parent compound **1**, by substitution of one axial pyridyl moiety with the R group. Complex **1** can

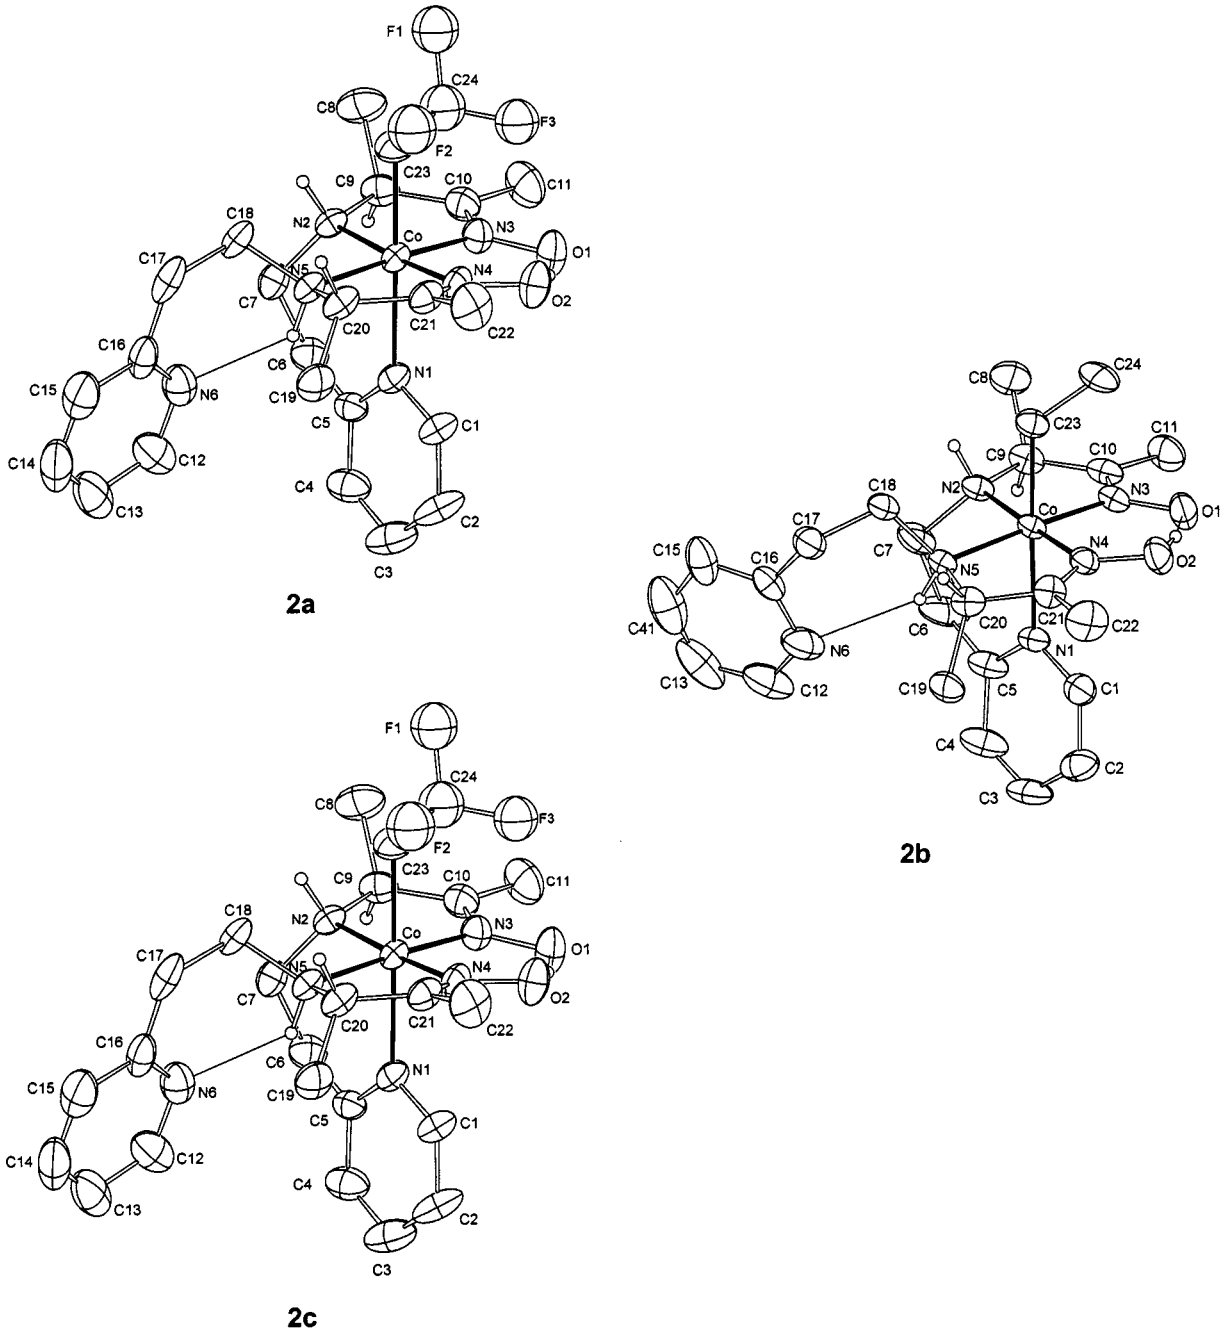


Figure 1. ORTEP diagram with the numbering scheme for the non-hydrogen atoms of one of the two crystallographic independent molecules of **2a**, **2b**, and **2c**

therefore, to a good approximation, be considered as a structural reference for complexes **2** (Scheme 3). The pendant pyridyl group in complexes **2** is anchored through N6 to the N5 amino atom by a short intramolecular hydrogen bond in the range of 2.861(8)−3.020(8) Å (Table 2). The two oximic O atoms of LNHpy and HLNHpy are hydrogen-bonded, with O···O distances ranging from 2.401(7) to 2.432(7) Å (Table 2). The average of the values is shorter by about 0.07 Å than that of 2.487(2) Å, obtained by averaging 140 values found in cobaloximes.[1b] Analysis of the N−O bonds in the three complexes and of the Fourier difference maps did not allow for location of the H oxime bridge, which was assumed to be bonded to O2 (see below), so that LNHpy acts as a tridentate and HLNHpy as a bidentate ligand.

The coordination around N1 is such that the two Co−N1−C angles differ by up to about 10°, the largest value being on the side of the 2-ethylene chain (Table 2). Such an asymmetric coordination of the axial N donor is typical of lopsided ligands, such as Me_3Bzm,[1] and of lariat-type complexes of Scheme 1c.[8]

The axial distances, together with the torsion angle around the Co−N1 bond, φ, are given in Table 3. The Co−N1 distances reflect the notable *trans* influence of the alkyl group in complexes **2**, relative to that of the pyridyl group in **1**. The Co−C bond length in complexes **2** appears to increase with the bulk and to decrease with the electron-withdrawing ability of R, in agreement with previous findings in cobaloximes.[19]

The bending angle, α, between the two equatorial five-membered rings and the displacement, d, of Co out of the four N equatorial donor plane are given in Table 3. The displacement occurs towards the axial pyridyl group in A and B molecules of **2a** and towards R in **2b** and **2c**, and reflects the difference in bulk between R and the *trans*-pyridyl group.[16] In all the complexes, the pyridyl ligand is tilted out of the axial direction and the tilt can be measured by the dihedral angle, γ, between the mean planes of the pyridyl ligand and of the four equatorial N donors. The values of γ in **1** and **2**, (Table 3), are close to those observed in py (82.3°) and 1,5,6-trimethylbenzimidazole (Me_3Bzm) (81.0°) iminocobaloximes with methyl substituents on the propylene bridge (Scheme 1b, R1 = Me).[17]

Equatorial coordination distances and angles in complexes **2** are given in Table 2 together with those of **1**. In complexes **2**, the Co−N4 distances are slightly shorter than those of Co−N3. This supports the previous assignment of the oxime bridge H atom.[18]

NMR Characterisation

The characterisation in solution was performed by ^{1}H and ^{13}C NMR spectroscopy in [D_6]DMSO. The (LNHpy)(HLNHpy) moiety gives rise to strikingly similar ^{1}H NMR spectra for all five complexes. The spectrum of **2c** is described as an example. The CH_3 protons give rise to two doublets at δ_H = 0.66 and 1.32 (CH_3CH) and two singlets at δ_H = 1.78 and 2.05 ($CH_3C{=}N$), each signal integrating for three protons. Ethylenic CH_2 protons generate four partially overlapped multiplets in the range δ_H = 2.88−3.44, the total integration corresponding to eight protons. The signals for the CH protons at δ_H = 3.75 and 3.82 appear as broad multiplets, and those for the NH protons at δ_H = 4.75 and 5.47 as a broad doublet and a broad singlet, respectively; each of these signals integrates for one proton. On addition of D_2O to the DMSO solution, the NH signals did not disappear, indicating a slow exchange on the NMR time scale. In $CDCl_3$ solution, the NH doub-

let (belonging to the bidentate ligand) shifts downfield to δ_H = 5.74, whereas the NH singlet shifts upfield to δ_H = 4.60; the different behaviour could be due to the formation of an intramolecular hydrogen bond between the proton of the NH doublet and the nitrogen atom of the noncoordinated pyridine, as found in the solid state. Aromatic protons generate two series of partially overlapped signals, of correct multiplicity and intensity, in the δ_H range 8.41−7.30. The oxime proton resonates at δ_H = 19.6. This value, very close to that found in the lariat-type complexes[8] and shifted remarkably downfield with respect to that of cobaloximes[20] and imino cobaloximes,[21] suggests a strong hydrogen bond.

The main difficulty in the assignment of ^{1}H and ^{13}C NMR spectra of the (LNHpy)(HLNHpy) moiety lied in distinguishing between the resonances of the tridentate and of the bidentate ligands. An almost complete assignment of ^{1}H and ^{13} C signals was performed for **2c** using homonuclear and heteronuclear shift correlation 2D NMR (H,H- and H,C-COSY), HMBC and DIFNOE spectroscopy. Shift assignments for the other alkyl complexes were made according to those of **2c** (Table 4 and 5).

The protons bonded to the α-carbon atom of the axial alkyl groups show a remarkable downfield shift with respect to those of the corresponding cobaloximes (+1.07 ppm for Me, +1.25 ppm for Et, and +1.14 ppm for CH_2CF_3)[20] although a direct comparison is not thoroughly meaningful, because the spectra of the latter were recorded in $CDCl_3$ and the solvent significantly influences the chemical shift of the Cα protons in complexes **2**. The effect is much weaker for protons that are more distant from the metal centre. For R = Et and *n*Bu, the CH_2 resonances in the ^{1}H NMR spectrum are partially buried; for R = CH_2CF_3, the CH_2 protons give rise to a quadruplet owing to coupling with fluorine ($^3J_{HF}$ = 15 Hz). It is noteworthy that in the CH_2Cl derivative, these protons generate an AB spectrum ($^2J_{HH}$ = 5 Hz) owing to the coupling between diastereotopic geminal protons.

Discussion

Complexes **2** are structurally similar to lariat-type complexes, but with some additional features. In fact, the equatorial moiety is more crowded with respect to the latter model, because of the side substituents on the amino C−N, pointing above and below the equatorial plane. Furthermore, the values of φ, found in complexes **1** and **2**, make them "representatives" of the orientation C of Scheme 2, as compared with cobaloximes and lariat complexes, which exhibit orientation A, and iminocobaloximes, which exhibit orientation B. However, the relative flexibility of the ethylene chain bearing the coordinated pyridyl group allows for a rotation, even if limited, of the axial py residue around the Co−N1 bond. This rotation is somewhat less restricted than in lariat-type complexes.[8] In fact, there is clear evid-

ence that the orientation of the py moiety also appreciably influences the length of the Co−N1 bond, so that the expected trend in the *trans* influence with R is modified (see below). Thus, for the same ligand *trans* to N1 (and N6 in **1**) larger φ values correspond to longer Co−N1 distances. In fact, the values of φ and of the Co−N1 distance in mole-

[a] Resonances not assigned separately. − [b] Data in the upper line refer to the tridentate ligand, data in the lower line refer to the bidentate ligand.

cule A are smaller than those in molecule B of **2a**. Analogously, the Co−N1 bond is longer than the Co−N6 bond and φ is larger than φ′ in both molecules A and B of **1** (Table 3). This suggests that the φ values of 36° in **2b** and of 44° in **2c** should correspond to a short- and a long-type Co−N1 bond, respectively. Therefore, it appears that the Co−N(py) distance *trans* to the same donor reaches the largest value when φ approaches 50°, which corresponds to orientation C in Scheme 2. That this conformation is the most strained, is also suggested by the increase in the bending α angle when φ approaches 50°, as shown in Figure 2, where the α/φ plot is reported for complexes **1** and **2**.

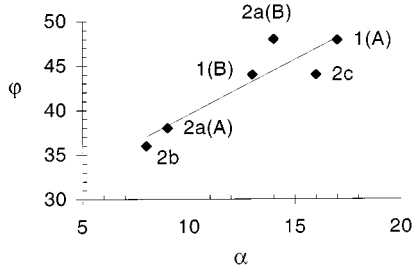

Figure 2. Dependence of the torsion angle φ around the Co−N1 bond on the bending angle α between the two equivalent five-membered rings in complexes **1** and **2**; A and B refer to the two independent molecules of **1** and **2a**

Taking these observations into account, it is of interest to compare the geometry of the axial fragment in complexes **2** with that in the analogous alkylcobaloximes and other related B_{12} models. In the latter series, the Co−N(ax) distance increases with an increase in the σ-donating ability of R, for L ligands with very similar φ values. Thus, in cobaloximes and iminocobaloximes, for which φ ≈ 0 and 90°, respectively, the order of increasing Co−py distances is Cl << CH_2CF_3 < Me < Et. Furthermore, for a given R, the Co−py bond is lengthened, when φ ≈ 90° (in complexes of Scheme 1, b) with respect to that observed when φ ≈ 0° (in complexes of Scheme 1, a and c), irrespective of the type of equatorial moiety. For complexes **2**, the apparently anomalous trends in Co−N(ax) distances with R as well as the differences between the A and B molecules of **2a** (and in the same molecule of **1**) can easily be interpreted if both contributions are considered. In fact, the distance Co−N1 of 2.134(5) Å (R = Me, φ = 38°) in molecule A of **2a**, is shorter than in **2b** [2.168(5) Å] (R = Et, φ = 36°), as is the case with the other B_{12} models. Analogously, the distance of 2.185(5) Å (R = Me φ = 48°) in molecule B of **2a** is longer than in **2c** [2.160(6) Å] (R = CH_2CF_3, φ = 44°). The influence of the torsion angle on the Co−N1 distance can be evaluated in **1**, where the two axial Co−N1 distances (φ ≈ 45°) are longer that those of Co−N6 (φ ≈ 30°). Therefore, the Co−N1 distance is the result of a compromise between the energies involved in the torsion around N1 and in the Co−N1 stretching. These structural features are in agreement with recent molecular mechanics calculations for $LCo(DH)_2Me$ (L is a planar N donor ligand) based on a new approach which also takes the contribution of the electronic *trans* influence into account.[5] These calculations have furnished profiles of the strain energy against the φ angle, which is characterised by a large maximum centred at φ = 90° and a minimum at φ = 0°, the difference in height ranging from 8 to 40 kJ/mol and increasing with the L bulk.[5] In addition, the large maximum at approximately φ = 90° has a fine structure, consisting of two nearly equal maxima at about 55° and 145°, separated by a relative minimum at φ = 90°. This suggested that orientation C (Scheme 2) is energetically even less favoured than orientation B. The corresponding plot of calculated Co−N(ax) distances against φ shows a profile very similar to that of the strain energy with a Co−N bond lengthening at φ = 50° which increases from 0.03 to 0.06 Å depending on the bulk of L. The Co−R distances follow the same trend in all the series of Table 3, reflecting the effects of the bulk and the σ-donating ability of R.[19]

Recent accurate Co−Me and Co−N axial distances of 1.979(4) and 2.162(4) Å, respectively, have been reported in MeCbl.[22] Hence, one of the most interesting structural features of model **2** is that the geometry of the axial N−Co−Me fragment is much closer to that of MeCbl (where the axial N ligand is a benzimidazole residue) than any other previously proposed B_{12} model, as shown by a comparison of the axial distances in several B_{12} models and MeCbl (Table 6).

The present complexes also show many solution properties characteristic of cobalamins and of their synthetic models. Significant parallels include the observation of the

Co^{III}/Co^{II} and Co^{II}/Co^{I} redox series, the reactions of the Co^{I} species with alkylating agents to give organocobalt derivatives, the photochemically induced Co−C cleavage and the alkyl-transfer reactions to radical acceptors. On the other hand, there are some distinctive aspects in the chemical behaviour of these novel models which deserve attention. One is the appreciable influence of the steric factors, which is clearly indicated by the anomalous trend in the *trans* influence (see structural results) and by the fact that it is apparently impossible to prepare derivatives with bulky alkyl groups, such as isopropyl, adamantyl and perfluoroisopropyl, which have been reported for previously known models.[1,23] The observed methyl transfer from **2a** to $Co^{II}(DH)_2$ and Vitamin B_{12r} may also be interpreted in terms of steric factors that lower the stability of Co−C bond in these amino−oximato complexes.

The electronic factors appear to be less important in determining the stability of the Co−C bond. In this regard, it should be noted that both alkylcobalamines and their simple models, contain highly unsaturated ligands that allow for an extensive electronic delocalisation over the equatorial plane, while the alkyl−cobalt complexes **2** contain only two unconjugated C=N bonds in their chelating system. It follows that a high extent of unsaturation of the equatorial ligand is not a necessary prerequisite for the formation of stable alkyl−cobalt complexes. This result is not unexpected; at least in a few cases, the synthesis of alkyl−cobalt compounds containing completely saturated polyamine (N4) macrocycles has been successfully achieved.[24−26] On the contrary, electronic factors play a relevant role in stabilising the lowest oxidation state of the metal ion. Thus, both the higher lability of the Co^{I} derivative of the complex (**1**) and the more drastic conditions required for its formation, relative to the formation of the corresponding cobal(I)oximes, may be ascribed to the lower extent of unsaturation present in the equatorial ligand. In at least one case it was unequivocally proved that the Co^{II}/Co^{I} reduction is responsive to the extent of unsaturation present in the ligand; a greater unsaturation causes an anodic shift in the half-wave potentials.[27] This trend justifies, at least qualitatively, the experimental observations reported above.

The last point to stress is the inability of the Co^{II} species derived from **1** to react with alkyl halides to give the corresponding alkyl−cobalt species by means of a free radical process. This behaviour is somewhat unexpected because both photochemical and alkyl-transfer processes involve homolytic cleavage of the Co−C bond, thereby providing clear evidence for the tendency of these complexes to react through radical processes. In addition, the majority of the Co^{II} forms of the Vitamin B_{12} models and Vitamin B_{12r} itself have been found to be reactive toward alkyl halides. On the basis of kinetic studies[28] the following stepwise free-radical mechanism [Equation (4)] has been proposed for these series of compounds:

$$LCo^{II} + RX \longrightarrow LCo^{III}X + R \quad \text{(slow)}$$

$$LCo^{II} + R \longrightarrow LCo^{III}R \quad \text{(fast)} \qquad (4)$$

$$2LCo^{II} + RX \longrightarrow LCo^{III}X + LCo^{III}R$$

Likewise, the lack in reactivity of the Co^{II} form of **1** can be attributed to its inability to abstract the halogen from the alkyl halide in the slow step rather than to its low tendency to trap free alkyl radicals.

Conclusions

Tridentate amino−oxime ligands are effective in stabilising the Co^{III}−C bond, as the analogous tridentate imino−oxime ligands.[29,30] The methyl derivative undergoes photolytic homolysis and is a better methyl donor than methylcobaloxime. These organometallic complexes can therefore be considered as suitable models for the B_{12} system (alkylcobalamin), such as the well-known alkylcobaloximes and other related models.[1] A distinctive feature of this new model is the appreciable influence of steric factors on their chemical behaviour. This is clearly indicated by the anomalous trend in the *trans* influence and by the fact that it is apparently impossible to prepare derivatives with bulky alkyl groups, such as *i*Pr, adamantyl and perfluoroisopropyl, which, on the contrary, have been reported for previously known models. In this respect, they more closely parallel the alkylcobalamin chemistry. Furthermore, the axial distances in the methyl derivative, very close to those recently reported for methylcobalamin, make them a better B_{12} structural model than any other previously reported.[22] Structural evidence is given that this behaviour can be related to the crowded equatorial moiety, which interacts with

the axial ligands more strongly than in cobaloximes. A recent comparison[22] of the structural, spectroscopic and electrochemical properties of alkylcobalamins with those of alkylcobaloximes suggests that the corrin ligand makes more electronic charge available on Co than on the $(DH)_2$ ligand (electronic *cis* influence), and that the longer Co−N axial distances in cobalamins are also due to ring electronic influence. Both the longer Co−N1 bonds and the increased difficulty in the Co^{III}/Co^{I} reduction, relative to alkylcobaloximes, suggests a higher charge density on Co in complexes **2**. The present models are possibly also electronically closer to cobalamins. These compounds therefore seem to offer a better opportunity to study the influence of steric factors on the formation and cleavage of the Co−C bond, than that provided by previous B_{12} models. Finally, the easy substitution of the chelating ligand, which occurs without cleavage of the Co−Me bond, suggests the possibility of preparing new series of otherwise inaccessible organometallic compounds.

Experimental Section

Vitamin B_{12a} and methylcobalamin were purchased from Aldrich. $CH_3Co(DH)_2H_2O$, $CH_3Co(DH)_2py$, and $Co(DH)_2(H_2O)_2$ were prepared by previously reported methods.[12] All other reagents and chemicals were commercial products and were used without further purification. − ^1H and ^{13}C NMR spectra were recorded with a Jeol EX-400 (^1H at 400 MHz and ^{13}C at 100.4 MHz) from [D_6]DMSO solutions with TMS as internal standard. Two-dimensional homonuclear and heteronuclear correlated spectra (H,H and H,C COSY) were obtained using the instrument's automatic programme. The HMBC spectrum of $[CF_3CH_2Co(LNHpy)(HLNHpy)]ClO_4$ in [D_6]DMSO was obtained as a 2048 × 256 data matrix with 64 scans (preceded by 4 dummy scans) per t_1 value and a PDBS (pulse delay between scans) of 1.00 s. An 8.7 μs 90° PW (pulse width) of ^{13}C was used. Values of Δ_1 (the delay between the first 90° proton pulse and the first 90° ^{13}C pulse) and Δ_2 (the delay between the first and the second 90° ^{13}C pulse) were 3.6 and 62.5 ms, respectively.

Syntheses: The same synthetic procedure was followed for all the $[RCo(LNHpy)(HLNHpy)]ClO_4$ complexes (R = Me, Et, *n*Bu, CH_2Cl, CH_2CF_3). − ***CAUTION:*** *Although no problems were encountered in the present study, perchlorate salts are potentially explosive and should only be handled in small quantities!* − The reactions were performed at room temperature, under an inert atmosphere and in the dark. In a typical experiment, a solution of NaOH (0.20 g, 5.00 mmol) in water (2 mL) was added to a suspension of complex **1** (1.00 g, 1.49 mmol) in methanol (150 mL). The resulting clear solution was treated with $NaBH_4$ (0.12 g, 4.70 mmol), dissolved in a minimum volume of water, followed by three drops of $PdCl_2$ solution, prepared by the addition of conc. HCl to a suspension of $PdCl_2$ (1.00 g) in water (20 mL) until complete dissolution had occurred. When the solution assumed a dark brown colour (after 15 min), a solution of the appropriate alkyl iodide (7.45 mmol, i.e. 5 equiv. with respect to the complex) in methanol (10 mL) was added. After about 30 min, the dark brown solution turned to bright orange. At this point, the flow of N_2 was suspended and the methanol was removed in a rotary evaporator at 40 °C. The aqueous suspension was extracted with CH_2Cl_2 (2 × 50 mL) and the residual water removed from the organic phase by treatment with anhydrous Na_2SO_4. After filtration, the solution was concentrated to 10 mL, passed through a chromatographic column of Al_2O_3 and eluted with CH_2Cl_2. A solution of the pure product was obtained (50 mL). The by-products, which were most strongly bound, could eventually be eluted with methanol. Diisopropyl ether was then added until the solution became turbid, and the suspension was allowed to stand overnight. Crystals of the desired product were recovered by filtration and air-dried. In order to obtain crystals suitable for X-ray analysis or for a better purification, the products were treated as follows.

$[CH_3Co(LNHpy)(HLNHpy)]ClO_4·0.5CH_3COCH_3$ (2a): Some drops of water were added to a saturated solution of the complex in acetone, followed by diisopropyl ether, until the solution became turbid. After standing in the dark in a stoppered vessel for 2 d, orange crystals were collected by filtration and air-dried. Yield: 0.31 g (34%). − $C_{24.5}H_{39}ClCoN_6O_{6.5}$ (616.0): calcd. C 47.8, H 6.4, N 13.6; found C 47.9, H 6.4, N 13.6.

$[C_2H_5Co(LNHpy)(HLNHpy)]ClO_4$ (2b): Recrystallised as above; red crystals were obtained. Yield: 0.28 g (31%). − $C_{24}H_{38}ClCoN_6O_6$ (610.0): calcd. C 47.9, H 6.4, N 14.0; found C 48.0, H 6.3, N 13.7.

$[CF_3CH_2Co(LNHpy)(HLNHpy)]ClO_4·0.5CH_2Cl_2$ (2c): Recrystallised by the diffusion of diisopropyl ether stratified over a saturated solution of the complex in dichloromethane. Yellow crystals were collected by filtration and air-dried. Yield: 0.37 g (36%). − $C_{24.5}H_{36}Cl_2CoF_3N_6O_6$ (697.4): calcd. C 42.2, H 5.2, N 12.1; found C 42.5, H 5.2, N 12.2.

[*n*-C_4H_9Co[(LNHpy)(HLNHpy)]ClO_4 (2d): Recrystallised as above; red crystals were obtained. Yield: 0.25 g (27%). − $C_{26}H_{42}ClCoN_6O_6$ (629.1): calcd. C 49.6, H 6.75, N 13.4; found C 49.4, H 6.7, N 12.8.

$[ClCH_2Co(LNHpy)(HLNHpy)]ClO_4$(2e): Recrystallised as above; yellow crystals were obtained. Yield: 0.42 g (45%). − $C_{23}H_{35}Cl_2CoN_6O_6$ (621.4): calcd. C 44.5, H 5.7, N 13.5; found C 44.4, H 5.7, N 13.3.

Substitution of the Chelating System by Dimethylglyoxime: Dimethylglyoxime (0.114 g, 0.98 mmol) and pyridine (0.5 mL) were added to a solution of complex **2a** (0.300 g, 0.49 mmol) in methanol (20 mL). The solution was allowed to stand for 5 h at room temperature in the dark. Water (5 mL) was then added to the solution. After evaporation of the methanol, orange crystals of $CH_3Co(DH)_2py$ were collected by filtration (0.154 g, 82%) and identified by ^1H NMR ($CDCl_3$): δ_H = 0.82 (3 H, CH_3−Co), 2.13 (12 H, CH_3−C), 7.33, 7.73, 8.62 (5 H, C_5H_5N). Following the same procedure, but with exclusion of pyridine, no reaction was observed and the starting complex was recovered. After recrystallisation, the complex was identified by elemental analysis. − $C_{24.5}H_{39}ClCoN_6O_{6.5}$ (616.0): calcd. C 47.8, H 6.4, N 13.6; found C47.6, H 6.3, N 13.3.

Transmethylation Reaction on $Co(DH)_2(H_2O)_2$: A solution of complex **2a** (0.100 g, 0.17 mmol) in methanol (20 mL) was treated with $Co^{II}(DH)_2(H_2O)_2$ (0.055 g, 0.17 mmol, 1 equiv.) under N_2, in the dark at room temperature. After 5 h, the solution was allowed to stand in air, water (5 mL) was added and the methanol was removed in a rotary evaporator. The aqueous residue was extracted with CH_2Cl_2. By evaporation of the solvent, the complex **1** was obtained and identified by ^1H NMR spectroscopy. The aqueous phase, concentrated in air with exclusion of light, gave red crystals of $CH_3(DH)_2H_2O$ identified by ^1H NMR (CD_3OD): δ_H = 0.67 (3 H, CH_3−Co), 2.24 (12 H, CH_3−C).

Transmethylation of Complex 2a on Vitamin B_{12r}: The reaction was carried out under nitrogen, in the dark and at room temperature. A solution of Vitamin B_{12a} (0.050 g) in water (25 mL) was reduced to Vitamin B_{12r} as described in the literature.[14] A solution of the complex **2a** (0.100 g) in methanol (25 mL) was then added and the reaction mixture was allowed to stand overnight. After the evaporation of methanol and the addition of acetone (30 mL), a red microcrystalline precipitate formed slowly. The product (0.030 g, 70%) was collected by filtration, air-dried, and identified as methylcobalamin by comparison of its UV/Vis and ^{1}H NMR spectra in D_2O with those of an authentic sample.

Photolysis of Complex 2a: A solution of $[CH_3Co(LNHpy)(HLNHpy)]ClO_4$ (0.100 g, 0.17 mmol) in water (50 mL) was exposed to sunlight for 1 h. It was then concentrated in air after the addition of a few drops of a saturated solution of $NaClO_4$. Red crystals of complex **1** were collected by filtration and identified by ^{1}H NMR spectroscopy. A solution of **2** (2 mg) in water (1 mL) was photolysed; the formaldehyde present in the filtrate was detected by the chromotropic acid test.[31]

Structure Determination: Single crystals, suitable for X-ray data collection of **2**, were grown as already reported in syntheses. Single-crystal X-ray data were collected at room temperature with a CAD4 Enraf−Nonius diffractometer using graphite-monochromated Mo-K_α radiation (λ= 0.71073 Å). Cell parameters were determined from 25 carefully selected reflections. Data were corrected for Lorentz polarisation effects and for absorption by the ψ-scan technique. Detailed crystallographic data are presented in Table 1. − The structures were solved by Patterson methods followed by Fourier syntheses and refined by full-matrix least-squares cycles. All the calculations were carried out with SHELXS (solution of structures) and SHELXL (refinement of structures) programs.[32] The hydrogen atoms were set in calculated positions and allowed to ride on the atoms to which they are linked. One water molecule at 0.25 occupancy and one acetone molecule at 0.5 occupancy were located in the unit cell of **2b** and **2c**, respectively. Other refinement conditions are given in Table 1. Crystallographic data (excluding structure factors) reported in this paper have been deposited at the Cambridge Crystallographic Data Centre and allocated the deposition numbers CCDC-145122 (**2a**), -145123 (**2b**), and -145124 (**2c**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1IZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Quinone Oxygen-Coordinated Palladium(II) Complexes with Anthraquinone Ligands Bearing *N*-Heterocyclic Coordination Sites

Toshiyuki Moriuchi,[a] Takuo Watanabe,[a] Isao Ikeda,[a] Akiya Ogawa,[b] and Toshikazu Hirao*[a]

Keywords: Coordination modes / Quinones / Crystal engineering / Palladium / Redox chemistry

The coordination properties of anthraquinone ligands bearing *N*-heterocyclic coordination sites to divalent palladium, and structural characterization of the quinone oxygen-coordinated palladium(II) complexes are described. The intramolecular NH···O (quinone) hydrogen bond [N(1)···O(2), 2.617 Å] was observed in the crystal structure of 1-chloro-8-[2-(2-pyridyl)ethylamino]-9,10-anthraquinone (**1a**). The anthraquinone moieties of **1a** are oriented in a face-to-face manner to form π-stacks in the crystal, with an interplanar distance of ca. 3.5 Å between the neighboring anthraquinone moieties. Complexation of **1a** with $Pd(OAc)_2$ afforded the palladium(II) complex **2a**. The quinone oxygen, which is bent out of the anthraquinone plane, is coordinated to the palladium(II) center, which is substituted by the amino nitrogen in a position *trans* to the pyridyl nitrogen in the crystal structure **2a**. 1-(2-Phenylethylamino)-8-[2-(2-pyridyl)ethylamino]-9,10-anthraquinone (**1b**) was also found to form the 1:1 quinone oxygen-coordinated palladium(II) complex **2b**. The single-crystal X-ray structure determination of **2b** shows the existence of two independent molecules in the asymmetric unit. These two molecules are present in a good mirror image relationship, indicating conformational enantiomers. Furthermore, they are overlapped in a face-to-face manner to form the π-stack dimer, which arranges in a herringbone motif with the virtues of offset stacking and edge-to-face contacts in the crystal packing. Starting from 1,5-bis[2-(2-pyridyl)ethylamino]-9,10-anthraquinone (**1c**) bearing two *N*-heterocyclic coordination sites, the conjugated palladium(II) homobimetallic complex **2c** was obtained. Two palladium atoms are bridged by the quinone moiety to afford a redox-active conjugated homobimetallic complex system. The crystal structure of **2c** reveals that two palladium atoms are disposed on opposite faces of the anthraquinone plane, accompanied by the bend of the quinone oxygens out of the anthraquinone plane. The anthraquinone moieties of **2c** are arranged in an edge-to-face orientation in the crystal packing. In the palladium(II) complexes **2b**–**c**, the d,π-conjugated system is interconnected through a π-π interaction between the π-conjugated systems. The cyclic voltammograms of these quinone oxygen-coordinated palladium(II) complexes **2a**–**c** show two redox couples based on the quinone moiety, which are positively shifted relative to the free quinone ligands.

Introduction

Efficient redox processes of transition metal complexes are one of the key factors in developing versatile systems for new materials and catalytic redox reactions. Since ligand coordination greatly contributes to redox processes, ligand design is often crucial for the construction of an efficient redox system. From this point of view, the redox-active quinone ligands, which are present in three redox forms (the reduced hydroquinone dianions, the partially reduced semiquinone radical anions, and the oxidized neutral quinones) are considered to permit an efficient redox system. A variety of transition metal complexes with *o*-quinones or their reduced forms have been prepared and studied extensively.[1] For *p*-quinone ligands, Bäckvall has demonstrated the involvement of the π-coordination of *p*-quinone to a Pd^0 center in the Pd-catalyzed oxidation of olefins and conjugated dienes.[2] The redox properties of the Pd^0 complexes with π-bound *p*-quinone ligands have also been investigated.[3] However, the *p*-quinone complexes, in which a quinone oxygen coordinates to a high valent transition metal, have not been investigated extensively,[4] despite the elucidation of their coordination and redox properties in catalysis. In our previous papers,[5] the π-conjugated molecule, *N,N′*-bis(4′-dimethylaminophenyl)-1,4-benzoquinone diimine, was introduced to the palladium(II) complex bearing the *N*-heterocyclic tridentate podand ligand, affording a redox-active π-conjugated palladium(II) homobimetallic complex, in which the redox properties of the quinone diimine moiety are modulated by complexation. These results prompted us to investigate the redox properties of the transition metal complexes with *p*-quinones and to characterize the complexes structurally. Another interesting feature depends on the π-π interactions between the anthraquinone aromatic rings in the crystal packing.[6] This interaction could induce architecturally controlled self-assembly, leading to molecular aggregates in the solid state. The π-π interaction between the π-conjugated moieties of the conjugated complexes is considered to be one of the most convenient approaches for the assembly of the conjugated complexes. In this context, we herein report the coordination properties of anthraquinone ligands bearing *N*-heterocyclic coordination sites to

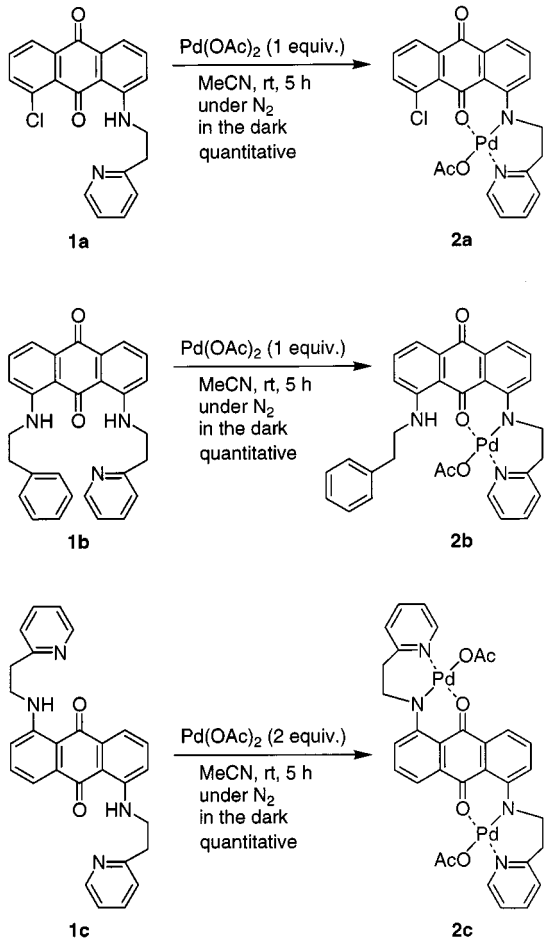
divalent palladium, and the structural characterization of the quinone oxygen-coordinated palladium(II) complexes.



Scheme 1

Results and Discussion

The anthraquinone ligands **1a–c** were prepared from the corresponding chloroanthraquinones and 2-(2-aminoethyl)-pyridine (Scheme 1). These anthraquinone ligands were fully characterized by spectroscopic techniques and elemental analysis. The FT-IR spectra of the anthraquinone ligands **1a–c** show hydrogen-bonded NH and C=O stretching bands (**1a**: 3286 and 1635 cm^{-1}, **1b**: 3263 and 1620 cm^{-1}, **1c**: 3255 and 1620 cm^{-1}, Table 1). The crystal structure of **1a** supports the presence of an intramolecular hydrogen bond between NH and C=O (quinone) [N(1)···O(2), 2.617 Å; H···O(2), 1.88 Å, Figure 1 and Table 2], indicating a slightly longer carbonyl bond [O(2)–C(13), 1.224 Å] than the non-hydrogen bonded carbonyl bond [O(1)–C(6), 1.216 Å]. Selected bond lengths and bond angles are listed in Table 3. It is notable that the anthraquinone moieties of **1a** are oriented in a face-to-face

manner with an interplanar distance of ca. 3.5 Å between the neighboring anthraquinone moieties, which form π-stacks in the crystal as shown in Figure 2. The arrangement of π-stacks represents an offset π-stacked geometry which places one carbonyl oxygen atom directly above the carbonyl carbon atom of the neighboring molecule.

Complexation of **1a** with $Pd(OAc)_2$ in acetonitrile afforded the 1:1 palladium(II) complex **2a** (Scheme 1). The formation of **2a** was followed by spectrophotometric titration. Thus, the absorption around 647 nm due to **2a** appeared and increased until the ratio of [**1a**]/[$Pd(OAc)_2$] was 1:1, with concomitant disappearance of the absorption of

[a] Two independent molecules exist in the asymmetric unit.

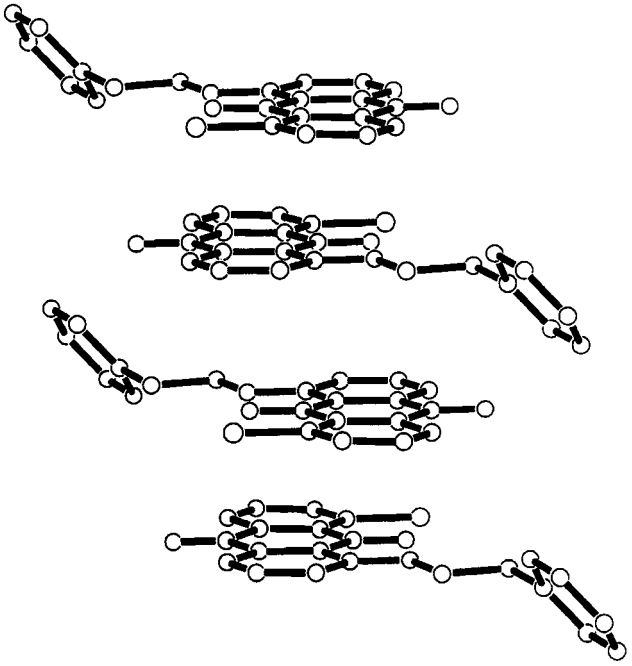

Figure 2. Crystal packing diagram of **1a** showing extended π-stacking

1a around 505 nm (Figure 3). This result supports the formation of the 1:1 complex **2a**. The structure of the isolated complex **2a** was elucidated by ^{1}H NMR spectroscopy. The absence of an amine proton in the ^{1}H NMR spectrum indicates the displacement of the acetate ligands of $Pd(OAc)_2$ by the amino nitrogen of **1a**. The down-field shift

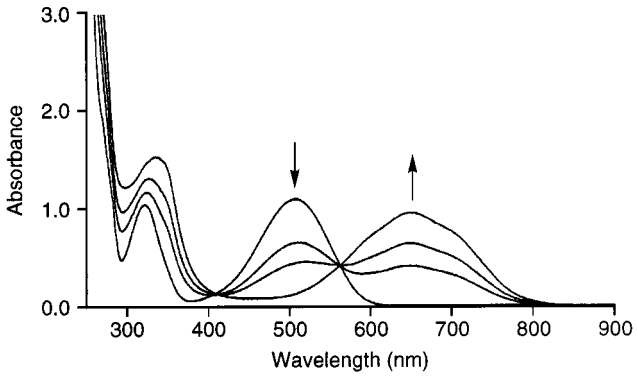

Figure 3. UV/Vis spectra on successive treatment of **1a** (1.0×10^{-4} M) with $Pd(OAc)_2$ (0, 0.4, 0.6, 1.0×10^{-4} M) in MeCN under argon

of the pyridyl protons implies the coordination of the pyridyl nitrogen to palladium.

Further structural information for **2a** was obtained by an X-ray crystal structure determination (Figure 4 and Table 2). The quinone oxygen and pyridyl nitrogen atoms coordinate to palladium in a *trans* fashion. The coordinated quinone carbonyl bond [O(2)−C(13), 1.266 Å] is longer than the uncoordinated one [O(1)−C(6), 1.217 Å], which is consistent with the observation of two kinds of C=O stretching bands (1651 and 1620 cm^{-1}) in the FT-IR spectrum of **2a**. The bond lengths of both N(1)−C(11) and C(12)−C(13) are shortened upon complexation [**1a**: N(1)−C(11), 1.365 Å; C(12)−C(13), 1.474 Å; **2a**: N(1)−C(11), 1.327 Å; C(12)−C(13), 1.414 Å]. The O(2)−C(13)−C(12) and C(12)−C(11)−N(1) angles increase slightly to accommodate the palladium atom [**1a**: O(2)−C(13)−C(12), 121.5°; C(12)−C(11)−N(1), 122.2°; **2a**: O(2)−C(13)−C(12), 125.2°; C(12)−C(11)−N(1), 124.9°]. Additionally, the palladium center deviates considerably from the anthraquinone plane. The coordination

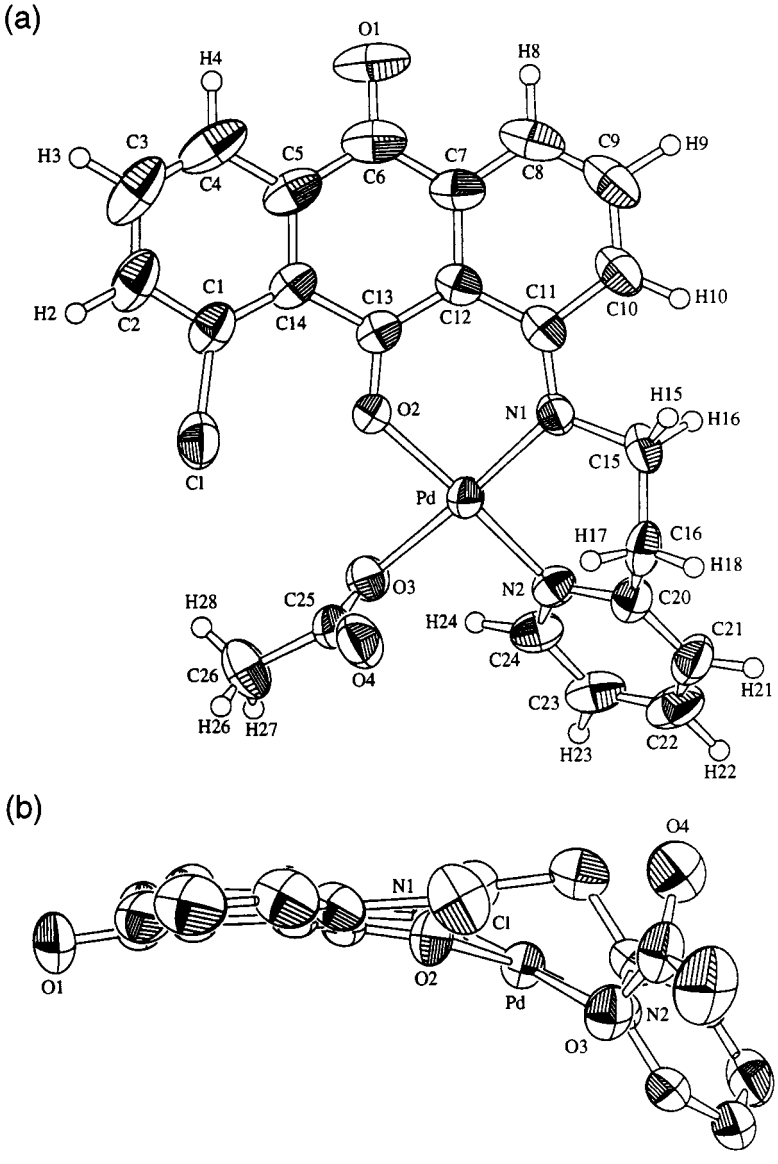

Figure 4. (a) Top view and (b) side view of the molecular structure of **2a** (40% probability ellipsoids. Hydrogen atoms are omitted for clarity)

geometry is almost square planar with the palladium-bonded amino nitrogen in a position *trans* to the acetoxy group. Another interesting feature lies in the nonplanar anthraquinone skeleton of **2a**, which is in sharp contrast to the planar one of **1a**. The two phenyl rings in the anthraquinone moiety form a V shape intersecting at C(6) and C(13) with a dihedral angle of 15.2°, where O(1) and O(2) are bent slightly out of the anthraquinone plane, as shown in Figure 4b. The π-stacks observed for **1a** are not observed in the crystal packing of **2a**, possibly due to the nonplanar anthraquinone skeleton (Figure 5).

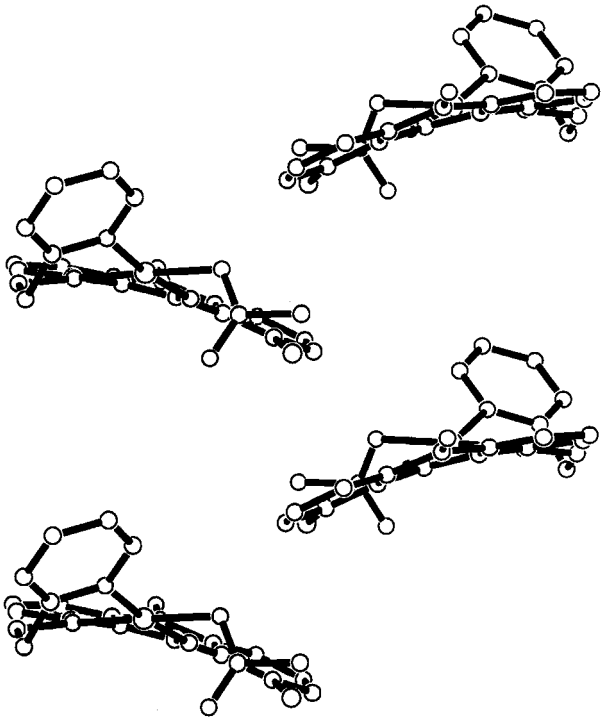

Figure 5. Crystal packing diagram obtained for **2a**

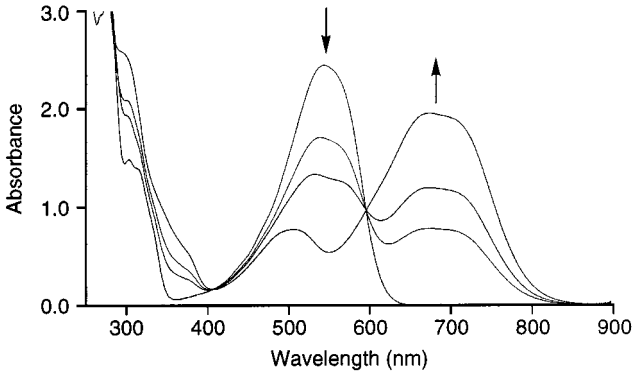

Figure 6. UV/Vis spectra on successive treatment of **1b** (1.0×10^{-4} M) with $Pd(OAc)_2$ (0, 0.4, 0.6, 1.0×10^{-4} M) in MeCN under argon

On the basis of these observations, the complexation behavior and molecular arrangement of the unsymmetrical anthraquinone ligand **1b** was studied to gain insight into the effect of the pendant group at the 8-position. Treatment of **1b** with $Pd(OAc)_2$ in acetonitrile afforded the 1:1 complex **2b** (Scheme 1). A similar spectral change was observed to support the formation of the palladium(II) complex **2b**, which exhibited a broad band around 675 nm (Figure 6). In the ^{1}H NMR spectrum of the isolated complex **2b**, the down-field shift of the pyridyl protons, and no shift of the phenylethyl group indicate that the nitrogen of the phenylethylamino group does not coordinate.

The crystal structure of **2b** is also characterized by a quinone oxygen-coordinated square planar geometry, in which the palladium atom is deviated from the anthraquinone plane, as observed in **2a** (Figure 7 and Table 2). As **2b** crystallized in the space group $P\bar{1}$ with $Z = 4$, two independent molecules exist in the asymmetric unit. Noteworthy, they are present in a good mirror image relationship as depicted in Figure 8. However, the barrier of interconversion of these

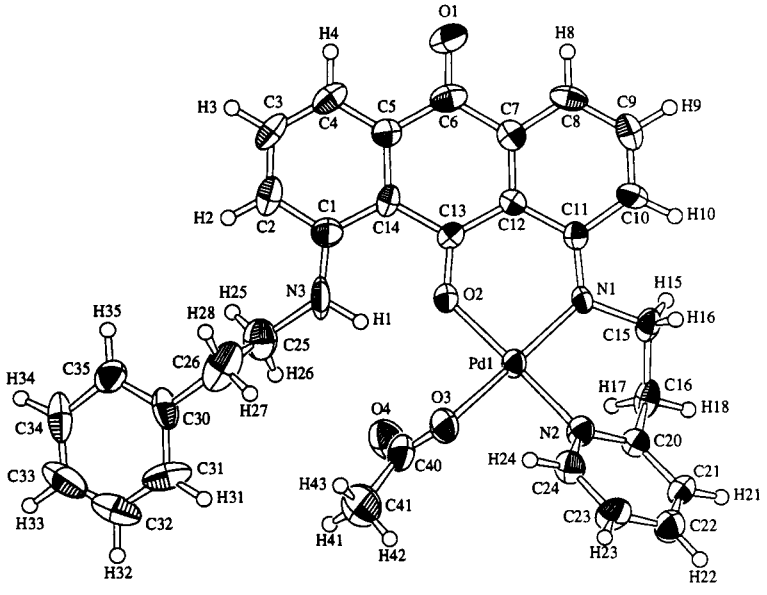

Figure 7. Molecular structure of **2b** (40% probability ellipsoids)

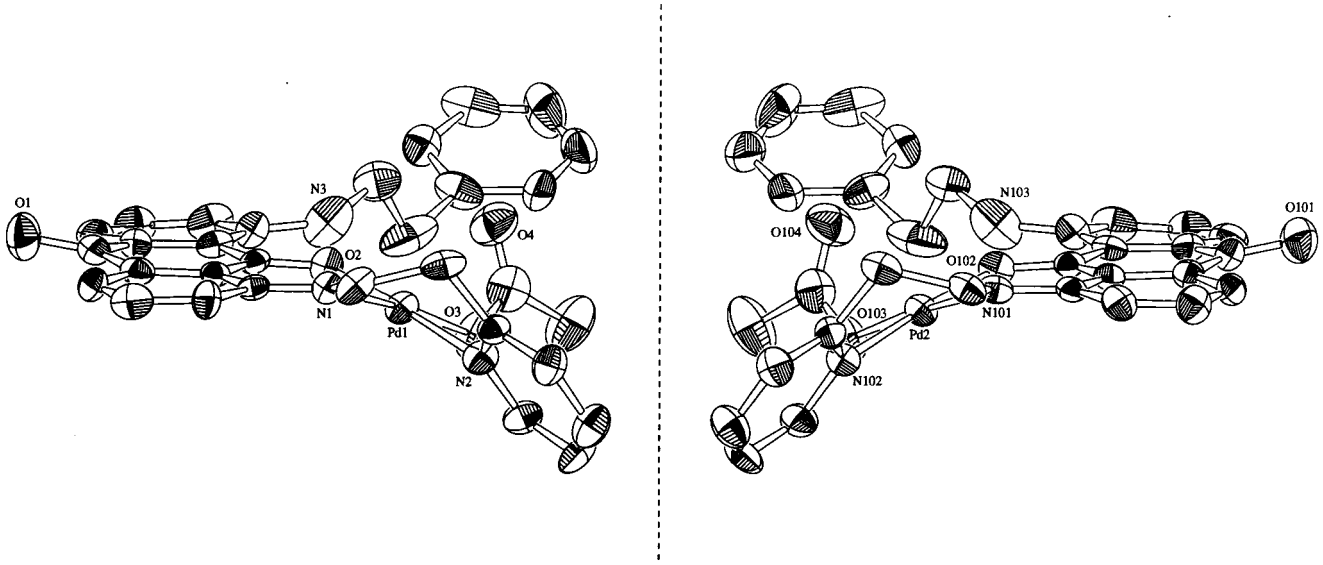

Figure 8. Conformational enantiomers of **2b** (40% probability ellipsoids); the enantiomorphs are related by the mirror plane

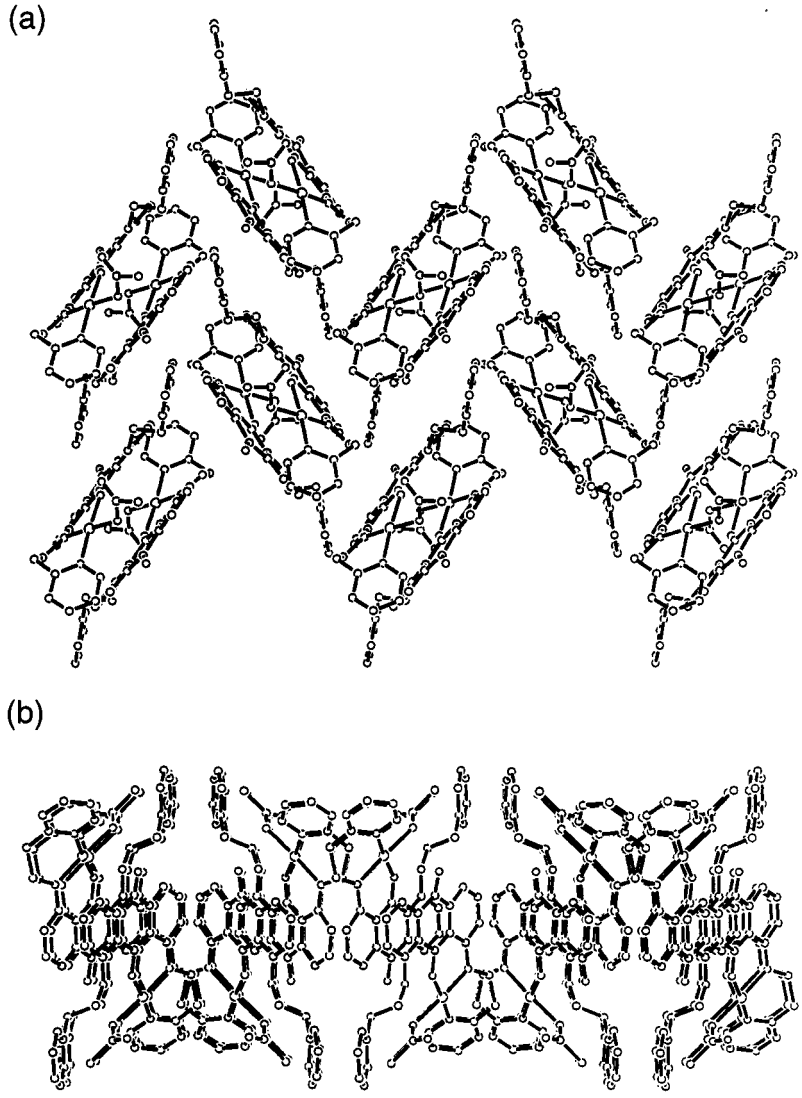

Figure 9. (a) Top view and (b) side view of the herringbone packing of the π-stack dimer in the crystal packing of **2b**

conformational enantiomers is low in solution. In the crystal packing (Figure 9), these enantiomers are present in a face-to-face manner with an interplanar distance of ca. 3.5 Å between the anthraquinone moieties, which form a π-

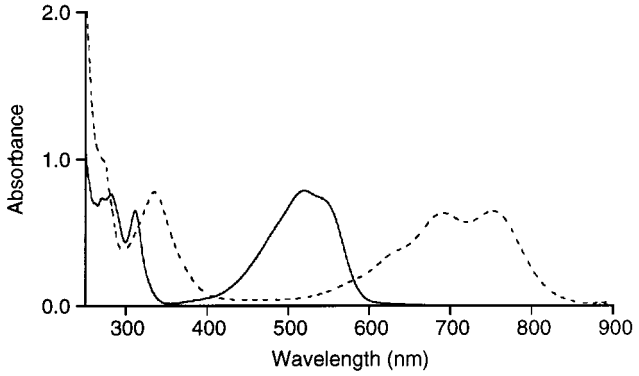

Figure 10. UV/Vis spectra of **1c** (−) (5.0×10^{-5} M) and **2c** (− −) (5.0×10^{-5} M) in CH_2Cl_2 under argon

stacked dimer that arranges in a herringbone motif with the virtues of offset stacking and edge-to-face contacts. Additionally, intramolecular hydrogen bonding between NH and C=O (quinone) [N(3)···O(2), 2.60 Å; H···O(2), 1.8 Å; N(103)···O(102), 2.60 Å; H···O(102), 1.8 Å] remains upon complexation.

Terminal bimetallic complexes with π-conjugated bridging spacers have recently received much attention as functional materials.[7] From this point of view, the construction of a conjugated bimetallic complex system with the 1,5-disubstituted anthraquinone ligand **1c** was examined. Treatment of **1c** with two equivalents of $Pd(OAc)_2$ in acetonitrile led to the formation of the conjugated palladium(II) homobimetallic complex **2c** as shown in Scheme 1. Only one kind of proton signal in ^1H NMR spectrum and only one C=O stretching

[a] Two independent molecules exist in the asymmetric unit.

band (1620 cm^{-1}) in the FT-IR spectrum were detected, indicating the symmetrical coordination of two quinone oxygens to each palladium. Two low-energy bands with maxima around 753 and 691 nm were observed in the UV/Vis spectrum (Figure 10). The structure of **2c** was confirmed by an X-ray crystal structure determination (Figure 11 and Table 2). In the asymmetric unit, there are two independent molecules with almost the same conformation since **2c** crystallized in the space group $P\bar{1}$ with $Z = 4$. Selected bond lengths and bond angles are summarized in Table 4. Both quinone oxygens participate in the coordination to each palladium. The coordination geometry around both palladium centers is almost the same. Two palladium atoms are disposed on opposite faces of the anthraquinone plane, accompanied by the

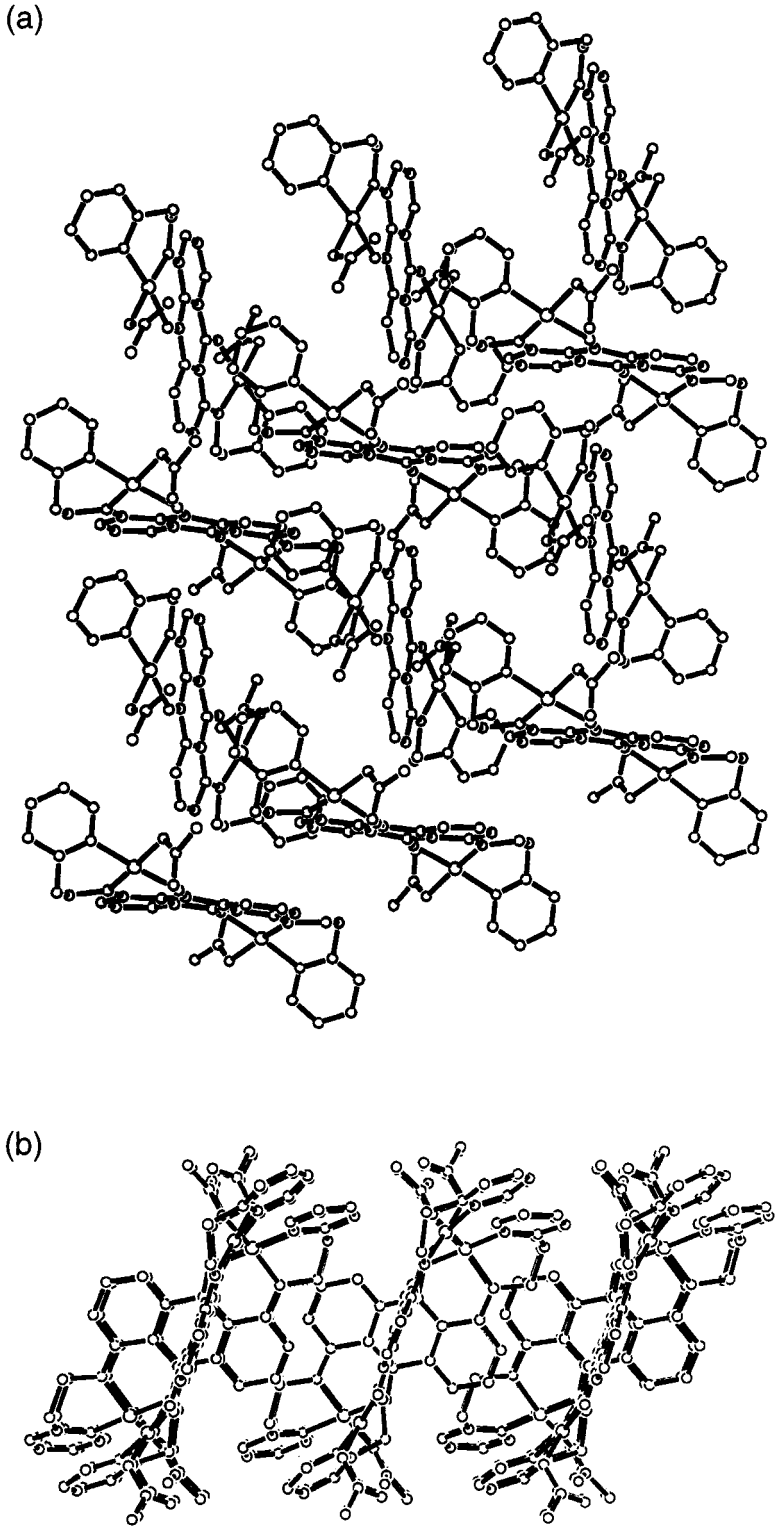

Figure 12. (a) Top view and (b) side view of the crystal packing diagram of **2c** showing edge-to-face π-π interactions

bend of quinone oxygens which lie out of the anthraquinone plane. Two palladium atoms are bridged by the quinone moiety to afford a redox-active conjugated homobimetallic complex. Two independent molecules are interconnected by an edge-to-face interaction between the anthraquinone rings in the crystal packing, as shown in Figure 12.

The redox properties of **1** and **2** were investigated by cyclic voltammetry in CH_2Cl_2. Electrochemical interest in the palladium(II) complexes in this study lies in the redox properties of the anthraquinone ligands because the complexation contributes to the electronic state. The redox potentials as listed in Table 1 are given vs. the standard Fc/Fc^+ redox couple. The quinone oxygen-coordinated palladium(II) complex **2a** shows two redox couples ($E_{1/2}$ = −1.73 V and −1.32 V vs. Fc/Fc^+) assignable to stepwise one-electron reductions of the anthraquinone moiety to give the corresponding reduced species. These redox couples are positively shifted relative to the free anthraquinone ligand **1a** ($E_{1/2}$ = −1.94 V and −1.44 V vs. Fc/Fc^+) as illustrated in Figure 13. As expected, the palladium(II) homobimetallic complex **2c** exhibits a more anodic shift due to the binding of two divalent palladium. Compared with the uncomplexed one, the complexed quinone is considered to be stabilized as an electron sink.

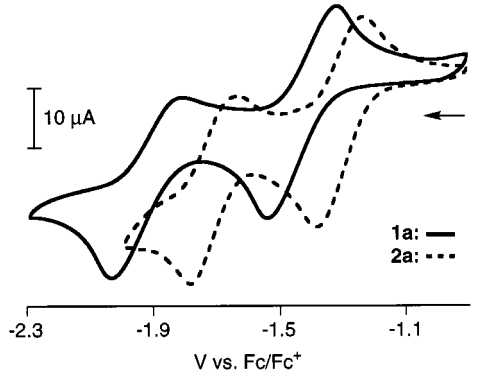

Figure 13. Cyclic voltammograms of **1a** (1.0×10^{-3} M) and **2a** (1.0×10^{-3} M) in CH_2Cl_2 (0.1 M nBu_4NClO_4) at a glassy carbon working electrode with scan rate = 100 mV/s under Ar

Conclusion

The anthraquinone ligands **1** bearing *N*-heterocyclic coordination sites have been shown to form the quinone oxygen-coordinated palladium(II) complexes. The X-ray crystal structure determination of the palladium(II) complex **2** indicates the coordination of the quinone oxygen to palladium. The conjugated palladium(II) homobimetallic complex **2c** was obtained in the case of the anthraquinone ligand bearing two *N*-heterocyclic coordination sites. The results reported in this paper reveal the aggregation properties of anthraquinone derivatives in a solid state. The anthraquinone ring plays an important role in the arrangement through the π-π interactions in the crystal packing. The quinone oxygen-coordinated palladium(II) complexes **2** exhibit two redox couples based on the quinone moiety, suggesting that the complexed quinones can be considered to be stabilized as an electron sink. In the palladium(II) complexes **2b−c**, the d,π-conjugated system is revealed to interconnect through π-π interactions between the π-conjugated systems. The controlled assembly of the redox-active conjugated complexes is envisaged to permit potential applications as functioning components of molecular devices.

Experimental Section

General Methods: All reagents and solvents were purchased from commercial sources and were further purified by standard methods, if necessary. Melting points were determined on a Yanagimoto Micromelting Point apparatus and were uncorrected. Infrared spectra were obtained with a Perkin−Elmer model 1605 FT-IR. ^1H NMR spectra were recorded on a Bruker AM-600 (600 MHz) or a JEOL JNM-GSX-400 (400 MHz) spectrometer with tetramethylsilane as an internal standard. Mass spectra were run on a JEOL JMS-DX303HF mass spectrometer. Electronic spectra were obtained using a Hitachi U-3000 spectrophotometer.

Synthesis of 1-Chloro-8-[2-(2-pyridyl)ethylamino]-9,10-anthraquinone (1a): A mixture of 1,8-dichloroanthraquinone (0.554 g, 2.0 mmol), 2-(2-aminoethyl)pyridine (1.22 g, 10.0 mmol), 4-dimethylaminopyridine (0.020 g, 0.16 mmol), and triethylamine (2.05 g, 20 mmol) in toluene (30 mL) was stirred under argon at reflux temperature for 7 days. After evaporation of the toluene in vacuo, the resulting mixture was dissolved in chloroform, washed with saturated $NaHCO_3$ aqueous solution and brine, and dried over $MgSO_4$. The anthraquinone ligand **1a** (reddish brown needles) was isolated in 68% yield by silica-gel column chromatography and purified by recrystallization from chloroform/hexane. − M.p. 168−170 °C (uncorrected). − R_f = 0.45 (ethyl acetate). − IR (KBr): $\tilde{\nu}$ = 3286 (NH), 1658 (C=O), 1635 (C=O) cm^{-1}. − ^1H NMR (400 MHz, CD_3CN): δ = 3.19 (t, J = 6.8 Hz, 2 H), 3.79 (q, J = 6.8 Hz, 2 H), 7.20 (ddd, J = 7.8, 4.9, 1.1 Hz, 1 H), 7.28 (dd, J = 8.7, 1.1 Hz, 1 H), 7.31 (ddd, J = 7.8, 1.1, 0.9 Hz, 1 H), 7.46 (dd, J = 7.4, 1.1 Hz, 1 H), 7.59 (dd, J = 8.7, 7.4 Hz, 1 H), 7.66 (dd, J = 8.0, 7.7 Hz, 1 H), 7.68 (td, J = 7.8, 1.9 Hz, 1 H), 7.82 (dd, J = 8.0, 1.4 Hz, 1 H), 8.18 (dd, J = 7.7, 1.4 Hz, 1 H), 8.56 (ddd, J = 4.9, 1.9, 0.9 Hz, 1 H), 9.60 (br, 1 H). − MS (EI): m/z = 362 [M^+]. − $C_{21}H_{15}N_2ClO_2$ (362.81): calcd. C 69.52, H 4.17, N 7.72, Cl 9.77; found C 69.26, H 4.09, N 7.64, Cl 9.86.

Synthesis of 1-(2-Phenylethylamino)-8-[2-(2-pyridyl)ethylamino]-9,10-anthraquinone (1b): A mixture of **1a** (0.36 g, 1.0 mmol), 2-phenylethylamine (0.30 g, 2.5 mmol), 4-dimethylaminopyridine (0.010 g, 0.10 mmol), and tripropylamine (1.43 g, 10 mmol) in xylene (20 mL) was stirred under argon at reflux temperature for 7 days. After evaporation of the xylene in vacuo, the resulting mixture was dissolved in chloroform, washed with saturated $NaHCO_3$ aqueous solution and brine, and dried over $MgSO_4$. The anthraquinone ligand **1b** (purple needles) was isolated in 53% yield by silica-gel column chromatography and purified by recrystallization from chloroform/hexane. − M.p. 183−184 °C (uncorrected). − R_f = 0.44 (ethyl acetate/chloroform 1:1 v/v). − IR (KBr): $\tilde{\nu}$ = 3263 (NH), 1658 (C=O), 1620 (C=O) cm^{-1}. − ^1H NMR (600 MHz, $CDCl_3$): δ = 3.08 (t, J = 7.4 Hz, 2 H), 3.24 (t, J = 7.1 Hz, 2 H), 3.59 (q, J = 7.4 Hz, 2 H), 3.77 (q, J = 7.1 Hz, 2 H), 7.04 (d, J = 8.5 Hz, 1 H), 7.10 (d, J = 8.5 Hz, 1 H), 7.18 (dd, J = 7.6, 4.7 Hz, 1 H), 7.26−7.29 (m, 2 H), 7.31−7.37 (m, 4 H), 7.48 (dd, J = 8.5, 7.6 Hz, 2 H), 7.55 (d, J = 7.6 Hz, 2 H), 7.62 (td, J = 7.6, 1.7 Hz, 1 H), 8.62 (dd, J = 4.7, 1.7 Hz, 1 H), 9.69 (br, 1 H), 9.73 (br, 1 H).

− MS (EI): m/z = 447 [M^+]. − $C_{29}H_{25}N_3O_2 \cdot 0.25H_2O$ (452.04): calcd. C 77.06, H 5.69, N 9.30; found C 77.04, H 5.57, N 9.29.

Synthesis of 1,5-Bis[2-(2-pyridyl)ethylamino]-9,10-anthraquinone (1c): A mixture of 1,5-dichloroanthraquinone (1.39 g, 5.0 mmol), 2-(2-aminoethyl)pyridine (3.05 g, 25 mmol), 4-dimethylaminopyridine (0.050 g, 0.40 mmol), and tripropylamine (7.16 g, 50 mmol) in toluene (70 mL) was stirred under argon at reflux temperature for 7 days. After evaporation of the toluene in vacuo, the resulting mixture was dissolved in chloroform, washed with saturated $NaHCO_3$ aqueous solution and brine, and dried over $MgSO_4$. The anthraquinone ligand **1c** (red brown needles) was isolated in 12% yield by silica-gel column chromatography and purified by recrystallization from chloroform/hexane. − M.p. 169−170 °C (uncorrected). − R_f = 0.30 (ethyl acetate). − IR (KBr): $\tilde{\nu}$ = 3255 (NH), 1620 (C=O) cm^{-1}. − ^1H NMR (400 MHz, CD_3CN): δ = 3.17 (t, J = 6.9 Hz, 4 H), 3.76 (q, J = 6.9 Hz, 4 H), 7.15 (dd, J = 8.5, 1.0 Hz, 2 H), 7.21 (ddd, J = 7.7, 4.9, 1.0 Hz, 2 H), 7.32 (ddd, J = 7.7, 1.0, 0.8 Hz, 2 H), 7.45 (dd, J = 7.5, 1.0 Hz, 2 H), 7.55 (dd, J = 8.5, 7.5 Hz, 2 H), 7.69 (td, J = 7.7, 1.9 Hz, 2 H), 8.54 (ddd, J = 4.9, 1.9, 0.8 Hz, 2 H), 9.70 (br, 2 H). − MS (EI): m/z = 448 (M^+). − $C_{28}H_{24}N_4O_2 \cdot 0.5H_2O$ (457.53): calcd. General Procedure for the Preparation of the Palladium(II) Complex 2: To anthraquinone ligand **1** (0.20 mmol) in acetonitrile (40 mL) was added an acetonitrile solution (10 mL) of $Pd(OAc)_2$ (44.9 mg, 0.20 mmol) under argon. For the preparation of **2c**, two equiv. of $Pd(OAc)_2$ were used. Stirring at room temperature for 5 h in the dark afforded a blue solution. After evaporation of the solvent in vacuo, the palladium(II) complex **2** was quantitatively isolated by recrystallization from acetonitrile.

Electrochemical Experiments: The cyclic voltammetry measurements were performed on a BAS CV-50 W voltammetry analyzer in deaerated CH_2Cl_2, containing 0.1 M nBu_4NClO_4 as a supporting electrolyte, at 298 K, with a three-electrode system consisting of a highly polished glassy carbon working electrode (BAS), a platinum auxiliary electrode (BAS), and an Ag/AgCl (0.01 M) reference electrode (BAS), at 100 mV/s scan rate. Potentials are given vs. Fc/Fc^+ as an internal standard.

X-ray Crystal Structure Determination: All measurements for **1a**, **2a**, **2b**, and **2c** were made on a Rigaku AFC5R diffractometer with graphite monochromated Mo-K_α radiation and a rotating anode generator. The structures of **1a**, **2a**, and **2b** were solved by direct methods and expanded using Fourier techniques. The structure of **2c** was solved by heavy-atom Patterson methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. The H atoms involved in hydrogen bonding were located in electron density maps. The remainder of the H atoms were placed in idealized positions and allowed to ride with the C atoms to which each is bonded. Crystallographic details are given in Table 2. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-146561 for **1a**, -146562 for **2a**, -146563 for **2b**, and -146564 for **2c**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Rhodium(I) Complexes with $OPPy_2Ph$ and $OPPy_3$ (Py = 2-Pyridyl), and Their Behavior in Hydrogenation Reactions

Juan A. Casares,[a] Pablo Espinet,*[a] José M. Martín-Alvarez,[a] Gustavo Espino,[b] Mercedes Pérez-Manrique,[b] and Florencia Vattier[b]

Dedicated to Professor Angel Alberola on the occasion of his 70th birthday

Keywords: Alkenes / Hydrogenations / N ligands / Phosphanes / Rhodium

The reaction of $[Rh_2(\mu\text{-}Cl)_2(COD)_2]$ (COD = 1,5-cyclooctadiene) or $[Rh_2(\mu\text{-}Cl)_2(TFB)_2]$ (TFB = tetrafluorobenzobicyclo[2.2.2]octatriene) with the N-donor chelating ligand $OPPy_2Ph$ (Py = 2-pyridyl) in the presence of $TlBF_4$ affords cationic complexes $[Rh(diene)(OPPy_2Ph)](BF_4)$ (**1**, diene: COD; **2**, diene: TFB). Compounds **1** or **2** react with CO to give $[Rh(CO)_2(OPPy_2Ph)](BF_4)$ (**4**), which is also obtained by treatment of $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ with $OPPy_2Ph$ and $TlBF_4$. In a similar way, the complexes $[Rh(diene)(OPPy_3)](BF_4)$ (**5**, diene: COD; **6**, diene: TFB) are obtained when using $OPPy_3$; they react with CO to give $[Rh_2(\mu\text{-}CO)_3(OPPy_3)_2](BF_4)_2$ (**9**). The behavior of the complexes in solution is reported. The complexes with $OPPy_3$, **5** and **6**, show equivalence of the three Py groups in their NMR spectra. Complex **5** is square-planar in the solid state, and in solution, and the uncoordinated and coordinated Py groups undergo fast exchange in solution. Complex **6** is pentacoordinated in the solid state and in solution, and its Py groups exchange their coordination sites in a fast topomerization process. The single-crystal X-ray structures of **5** and **6** have been solved. The behavior of **1** and **5** as catalysts in hydrogenation reactions of cyclohexene, acetone, and cyclohexanone is also reported.

Introduction

Recent years have seen a renascence of interest in the study of multidentate nitrogen-donor ligands and their use in homogeneous catalysis.[1] N-donor ligands have some advantages over P-donors: mainly their higher stability towards oxidation, allowing a longer life for the catalysts. Because of this, cationic complexes of rhodium(I) with diolefins and N-donor ligands have been studied in catalyzed reduction processes of unsaturated organic compounds,[2] and the scope of these reactions has successfully been extended to the synthesis of chiral products, with fairly good enantiomeric excess.[1,3] Amongst the N-donor ligands, the most widely used are anionic substituted pyrazolylborates, because they can stabilize both rhodium(I) and rhodium(III) complexes, and it is possible to modulate the steric hindrance around the metal by properly choosing the substituents on the Pz rings.[4] The most important electronic variation that can be introduced onto ligands is a change in overall charge, and neutral tris-chelate ligands have indeed been tested in parallel with anionic pyrazolates $[HB(^RPz)_3]^-$. Good results have been obtained with substituted 1,4,7-triazacyclononane,[5] while other neutral *fac*-terdentate ligands, such as trispyrazolylmethane or trispyridylmethane have been less intensely studied in comparison.[6] Terdentate planar ligands such as *terpy* cannot be compared with the previous ones because of their very different geometrical restrictions and electronic properties.[7]

We have shown previously that, in Pd chemistry, $OPPy_2Ph$ (Py = 2-pyridyl) coordinates through the N atoms, in such a way that the two pyridyl rings are disposed obliquely respective to the coordination plane of the metal, giving rise to a six-membered ring in a "boat" conformation, with the Ph group lying above the metal.[8] $OPPy_3$ behaves similarly, but the third Py group can pentacoordinate the metal (as happens in some fluxional process intermediates), enabling $OPPy_3$ to act either as a bidentate or as a tridentate ligand. Pentacoordination might be more accessible for Rh than for in Pd. We report here the synthesis of complexes of rhodium(I) with these ligands and diolefins (COD = 1,5 cyclooctadiene and TFB = tetrafluorobenzobicyclo[2.2.2]octatriene) or carbon monoxide, as well as the behavior of the cationic diolefin complexes in catalytic hydrogenation of ketones and olefins.

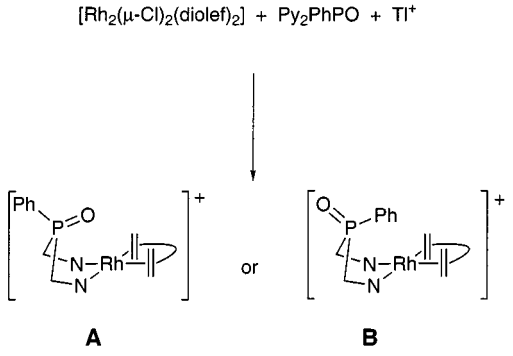
Results and Discussion

a) Complexes with $OPPy_2Ph$

The complexes $[Rh(COD)(OPPy_2Ph)](BF_4)$ (**1**) and $[Rh(TFB)(OPPy_2Ph)](BF_4)$ (**2**) were prepared as yellow, crystalline solids by treatment of $OPPy_2Ph$ with the corresponding $[Rh_2(\mu\text{-}Cl)_2(diene)_2]$ in the presence of $TlBF_4$. Their IR spectra in the solid state show the expected ν(P=O) band at wavelengths similar to those of the free ligands, which rules out coordination of the oxygen in the complexes .

Compounds **1** and **2** can adopt two conformations: with either the oxygen (**A**) or the aromatic free ring (**B**) towards the metal. In any case, the coordination plane of the metal is not a symmetry plane (Scheme 1). Their ^1H NMR spectra in $CDCl_3$ show signals for only one conformer in each case: six nonequivalent nuclei for the 1,5-COD ligand in **1**; and two aliphatic and two olefinic signals for **2**. In order to determine which conformer is present in solution, a NOESY spectrum of **1** was recorded. As shown in Figure 1, both olefinic protons give NOEs with the pyridine H-6, while one of them gives a clear NOE cross peak with the phenyl group. This supports conformer **B**, with the phenyl ring towards the metal; in line with the situation found for Pd[8] and analogous tris(pyrazolyl)borate complexes of rhodium(I).[4k−4m]



Scheme 1. Diolefin: COD (**1**); TFB (**2**)

In deuterated acetone, however, complexes **1** and **2** are fluxional and exhibit exchange between the upper and lower halves of the COD or TFB, respectively. Both feature olefinic protons in coalescence at room temperature, while at −60 °C these have split into two well defined signals. For **2**, this exchange is also observable in the ^{19}F NMR spectrum, which changes from an ABCD spin system pattern at −40 °C to an AA′BB′ one at room temperature (Figure 2). The ^{31}P NMR spectra are not affected by the exchange, showing only one doublet for each compound in all the temperature range studied. This suggests that the fluxionality observed in the ^1H and ^{19}F spectra is not associated with any conformational change in the coordinated ligand $OPPy_2Ph$. On the contrary, the solvent-dependence of the process strongly points to a pentacoordinated intermediate in which either the Py groups, the double bonds, or both, exchange their coordination sites. These fluxional processes are common in $[Rh(diene)(L-L)]^+$ complexes, and it has been shown that the exchange rate in noncoordinating solvents is increased by the presence of traces of Cl^- anions, or by adventitious acetone.[7,9,10]

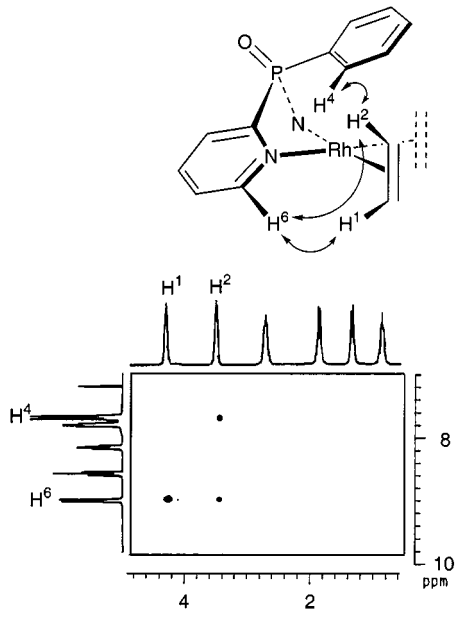


Figure 1. NOESY spectrum of **1** in $CDCl_3$ at 273 K

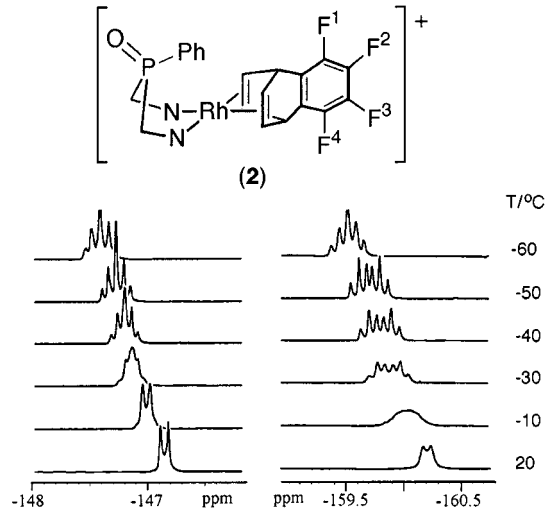

Figure 2. ^{19}F NMR spectra of **2** in $[D_6]$acetone at different temperatures. F^1 and F^4 (ca. −147) become equivalent at room temperature, due to diolefin rotation. The same is observed for F^2 and F^3 (ca. −160)

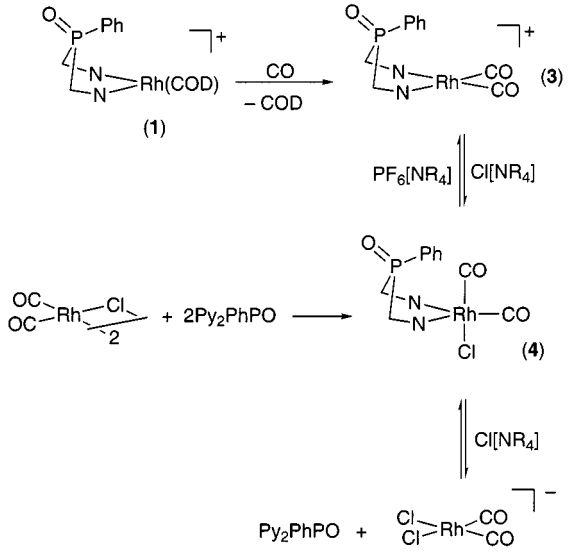
By bubbling CO through a dichloromethane solution of **1**, it is easy to obtain a dicarbonyl complex $[Rh(CO)_2(OPPy_2Ph)]BF_4$ (**3a**), which shows ν(CO) at 2104 and 2047 cm^{-1} [(Equation (1)].

$$[Rh(COD)(OPPy_2Ph)] + CO \rightarrow [Rh(CO)_2(OPPy_2Ph)]BF_4 + COD \quad (1)$$

Attempts at isolating neutral carbonyl complexes with $OPPy_2Ph$ were unsuccessful. The reaction of $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ with $OPPy_2Ph$ (1:1) was monitored in deuterated chloroform by NMR techniques. The ^{31}P and ^1H



Scheme 2

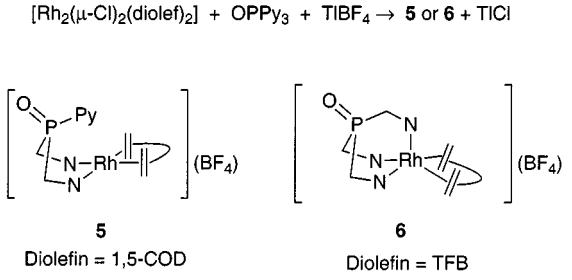
NMR spectra at room temperature show a mixture of the cation in complex **3** (9%, presumably with Cl^- as the counter-anion), the desired chlorocarbonyl compound $[RhCl(CO)_2(OPPy_2Ph)]$ **4** (70%) and free ligand $OPPy_2Ph$ (21%) (Scheme 2). In agreement with the NMR results, the Infrared spectrum of a comparable solution in CH_2Cl_2 at room temperature shows six carbonyl bands, corresponding to a mixture of the three *cis* dicarbonyl complexes in equilibrium: two from the cationic compound **3**, two from the neutral chlorodicarbonyl complex **4** (at 2035 and 2095 cm^{-1}), and two corresponding to the anion $[Rh(Cl)_2(CO)_2]^-$ (at 2071 and 1995 cm^{-1}).[11] At −60 °C, there is a small change in the ratio of products, but no new signals appear. The addition of an excess of $[Et_3BzN]Cl$ to the solution shifts the equilibrium completely, displacing the $OPPy_2Ph$ ligand, and only $[Rh(Cl)_2(CO)_2]^-$ is observed in the IR spectrum. In contrast, the addition of a large amount of $[Bu_4N][PF_6]$ shifts the equilibrium toward **3**, and the other two complexes disappear.

The donor ability of the $OPPy_2Ph$-N,N ligand can be evaluated from the stretching bands of the carbonyl groups in the IR spectra of the complexes. For all of these, the ν(CO) values are shifted to higher frequency, not only relative to the analogous complexes with bipyridine, but also relative to the complexes with monodentate pyridine or other nonplanar chelating ligands like bispyrazolylmethane or bidentate imidazolyl ligands like $(mim)_2CH_2$ (mim = *N*-methylimidazol-2-yl).[12] Since the geometry of the ligand does not permit a good π interaction with the metal, this has to be attributed more to a poorer donor ability in the $OPPy_2Ph$-N,N ligand than to a higher π acceptor character. This is reinforced by the electron-withdrawing ability of the P=O group, compared to geometrically similar ligands such $(Py)_2S$.[12c] The overall effect is that $OPPy_2Ph$-N,N behaves as a rather labile N-donor ligand, which can easily be removed from the rhodium (I) complexes.

b) Complexes with $OPPy_3$

Diolefin Complexes

The diolefin complexes $[Rh(COD)(OPPy_3)](BF_4)$ (**5**) and $[Rh(TFB)(OPPy_3)](BF_4)$ (**6**) were prepared as yellow, crystalline solids by treatment of $OPPy_3$ with the corresponding $[Rh_2(\mu\text{-}Cl)_2(diene)_2]$ in the presence of $TlBF_4$ (Scheme 3). In these compounds, the $OPPy_3$ ligand can act either in bidentate or in tridentate fashion, giving tetracoordinated or pentacoordinated complexes, respectively. For ligands containing pyridyl groups, the values of $\nu(CN)_{Py}$ indicate whether they are coordinated or not:[9,13] the uncoordinated Py groups exhibit this band at 1574 cm^{-1}, but it moves to higher frequency when coordinated. The IR spectrum of **5** in the solid state shows two bands at 1587 and 1572 cm^{-1}, one of coordinated and one of free Py; thus the compound seems to be square-planar with only two coordinated Py groups. In contrast, the IR spectra of **6** in the solid state shows just one $\nu(CN)_{Py}$ absorption at 1586 cm^{-1}; hence the three Py groups are coordinated and the compound is pentacoordinated in the solid state. In agreement with this interpretation, the ν(P=O) bands in **5** (1206 cm^{-1}) appear at almost the same value as in the free ligand, while the coordination of the third Py group shifts this stretching band to 1230 cm^{-1} in **6**. This shift has previously been observed in other complexes in which the $OPPy_3$ ligand coordinates in a tridentate mode,[14] and is related to the decrease in the CPC angle around the phosphorus, which is accompanied by an increase in the P=O strength, as also observed, for instance, in strained cyclic ketones.[15−17]



Scheme 3. Diolefin: COD (**5**); TFB (**6**)

In order to evaluate these structural hypotheses and other structural features, the structures of **5** and **6** were deter-

mined by X-ray diffraction methods, and their corresponding ORTEP diagrams are shown in Figure 3 and Figure 4, respectively. Selected bond lengths and angles for both structures are listed in Table 1.

Molecular Structure of [Rh(COD)(OPPy$_3$)](BF$_4$)·Acetone (5·Acetone)

The rhodium atom has an essentially square-planar geometry. Its deviation from the plane defined by N1, N2, and the midpoints of the olefinic bonds is 0.038 Å. The neutral ligand is acting as an *N,N*-chelate, as expected, and the six-membered chelate ring shows a boat conformation. The Rh−N bond lengths (2.125 and 2.112 Å) are within the normal range for pyridine ligands bonded to Rh^I. The distance from the third nitrogen atom to the rhodium (3.975 Å) is clearly out of the bonding interaction range (sum of the van der Waals radii: 3.15 Å). The coordinated pyridyl rings are inclined relative to the coordination plane, making angles of 126.3° and 122.8°. The conformer found is the one that places the uncoordinated pyridyl ring above the coordination plane: similar to conformer **B** in Scheme 1. This structure should render the olefinic moieties above and below the coordination plane nonequivalent in the NMR.

Molecular Structure of [Rh(TFB)(OPPy$_3$)](BF$_4$)·xAcetone (6·xAcetone)

Its geometry can be described as distorted trigonal bipyramidal, with one of the nitrogen atoms (N1) and the midpoints of one olefinic bond (M2) in axial positions (angle N1−Rh1−M2 = 167.51°). The equatorial plane is defined by the other two nitrogen atoms (N2 and N3) and M1 (the midpoint between carbon atoms C41 and C42), with the rhodium atom lying 0.039 Å above this plane. From the rhodium, the distance to the axial nitrogen is shorter than those to the equatorial nitrogen atoms (2.126 vs. 2.279 and 2.269 Å), as found in other *tbp* structures.[18] The olefinic bond in the equatorial plane is longer than the one in the axial position, as a consequence of stronger π backbonding in the equatorial position. This effect also explains the shorter distances from rhodium to the carbon atoms in the equatorial double bond than to those in the axial double bond. Other interatomic distances in the TFB ligand are similar to the values obtained in other rhodium-TFB complexes. [19]

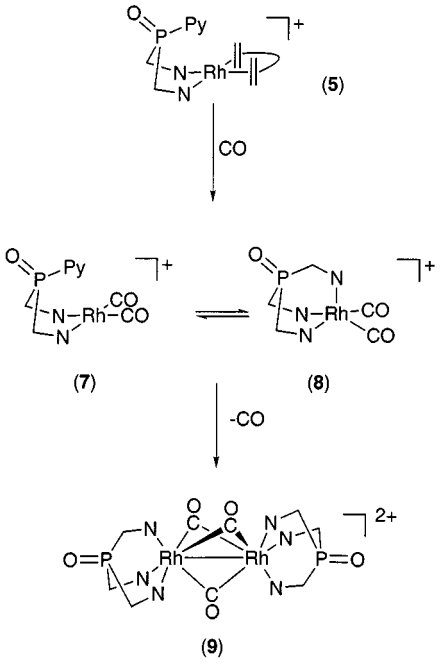
The hapticity of the $OPPy_3$ ligand (κ^2 or κ^3) depends on the diene coordinated to the rhodium. This dependence has been reported and studied for poly(pyrazolyl)borato complexes.[4i−4n] It has been proposed that dienes with a larger bite angle, such as COD, favor a κ^2 structure, while dienes with a smaller bite angle favor the κ^3 coordination mode. In complex **6**, the bite angle of the TFB ligand is 69.71°, resulting in a pentacoordinated structure with the three pyridyl rings bonded to the rhodium.

Behavior in Solution of Diolefin Complexes with OPPy$_3$

In spite of this solid state structural difference for **5** and **6**, in solution they behave more similarly. Their ^1H NMR spectra both show only one signal for all the olefinic protons, and the three Py rings are equivalent, while $J^{103}_{Rh-}{}^{31}_{P}$ is maintained even at high temperature (50 °C). The ^{19}F NMR spectrum of **6** corresponds to an AA′BB′ spin system, even at −60 °C. These data reveal the existence of fast intramolecular fluxional processes for both complexes; however, these are not the same in each case. In fact, their IR spectra in Cl_2CH_2 solution and in the solid state are almost identical. Hence, **5** remains square-planar [$\nu(CN)_{Py}$ at 1574 and 1589 cm^{-1}], with the free and the coordinated Py groups exchanging rapidly in solution. On the other hand, **6** remains pentacoordinated in solution [$\nu(CN)_{Py}$ at 1590 and 1586 cm^{-1}], and the observed equivalence of the Py groups and the fluorine nuclei is due to the fast exchange of coordination sites in the pentacoordinated complex.

Carbonyl Complexes

The carbonylation of **5** in dichloromethane gives a mixture of *cis*-dicarbonyls [ν(CO) at 2105 and 2049 cm^{-1}, and



Scheme 4

at 2085 and 2021 cm^{-1}], corresponding to the formation of square-planar (**7**) and pentacoordinated (**8**) complexes (Scheme 4). This process is followed by the precipitation of an insoluble product with only one ν(CO) absorption at 1836 cm^{-1}, elemental analysis of which agrees with the formulation $[Rh_2(\mu\text{-}CO)_3(OPPy_3)_2](BF_4)_2$ (**9**). Analogous products are obtained when using triazacyclononane,[5a] $HCPz_3$,[6b] $MeGaPz_3$,[6c] or $[HBPz_3]^-$ [4k] as ligands. By removing the solvent and washing the resulting oil with n-hexane, it is possible to obtain a mixture of **7**, **8**, and **9a**, but if the oil is then redissolved in tetrahydrofuran and refluxed for 30 min, all the monomeric dicarbonyls are transformed into **9a**.

The carbonylation process was monitored by ^1H and ^{31}P NMR spectroscopy. A solution of **5** was prepared under nitrogen and cooled in an ice bath at 0 °C. After bubbling CO through for 10 min, the solution was placed in the NMR probe, previously thermostated at 0 °C. The spectrum showed that all the starting compound **5** had reacted, giving free cyclooctadiene, only one group of pyridyl signals in the ^1H NMR, and one doublet at 13.2 ($^3J_{Rh\text{-}P}$ = 7.12 Hz) in the ^{31}P NMR. The spectrum did not change on cooling to −60 °C, showing that the exchange between the square-planar and pentacoordinated isomers is very fast. After warming the sample to 0 °C, nitrogen was bubbled through the solution until **9** started to precipitate; the spectra recorded at this point showed a decrease in intensity of the aromatic signals assigned to (**7** + **8**) relative to the signals of the residual 1,5-COD, reflecting the insolubility of **9a**. After the NMR experiment, the solution was left at room temp. for one hour, and a yellow-green solid was formed. The solution was filtered and the solid was characterized as **9a** by its IR spectrum. A GC of the solution showed that 1,5-cyclooctadiene was the only organic product of the reaction.

The reaction of $OPPy_3$ with $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ in dichloromethane proceeds with CO evolution, to give $[Rh_2(\mu\text{-}CO)_3(OPPy_3)_2][RhCl_2(CO)_2]_2$ (**9b**) as a dark red, insoluble compound [ν(CO) = 2066, 1989, and 1834 cm^{-1}]. Attempts at obtaining a neutral chlorocarbonyl complex were unsuccessful.

c) Catalytic Experiments

The hydrogenation of cyclohexene, acetone, and cyclohexanone, using the cationic complexes **1** and **5** as catalysts, was examined. Significant hydrogenation rates were only observed above 50 °C. An almost linear increase of the rate of hydrogenation with pressure was found. Hydrogenation of a 1:1 mixture of cyclohexene and cyclohexanone showed a clear preference for the hydrogenation of cyclohexene. Representative catalytic experiments are summarized in Table 2.

Table 2. Results of the catalysis experiments

Complex	Time[a] [min]	Cyclohexanone	Acetone	Cyclohexene[b]
1[c]	30	4.6	2.1	27 (30)
1[c]	60	18	7.5	55 (57)
1[c]	120	43	18	78 (80)
5[c]	30	12	6.0	47 (40)
5[c]	60	20	10	67 (61)
5[c]	120	48	20	78 (64)
1[d]	30	3.1		30
1[d]	60	13		54
1[d]	120	29		72
5[d]	30	8.5		11
5[d]	60	19		47
5[d]	120	36		56

[a] Reaction conditions: Catalyst 0.014 mmol; Substrate 28 mmol; solvent: 18 mL of a solution of NaOH 0.04 mol dm^{-3} in methanol; $P(H_2)$ 10 bar; T: 80 °C. – [b] The data in parentheses have been obtained using pure methanol as solvent, without base. – [c] The substrate was only cyclohexanone, only acetone or only cyclohexene in each case. – [d] The substrate was a mixture of cyclohexanone (1.4 mmol) and cyclohexene (1.4 mmol).

The behavior of the two catalysts is very similar. The conversion rates obtained with **5** are slightly higher than with **1**, while the selectivity follows the opposite trend. In the light of the very different chemical behavior found for the complexes with $OPPy_3$ and $OPPy_2Ph$, a greater difference had been expected for the catalytic experiments. The similarity in catalytic behavior suggests that probably, thanks to the poor donor ability of the ligands under catalytic conditions (low concentration of complex, large excess of substrates, and high pressure of hydrogen), there is decoordination of the nitrogen ligand to give the active compound, the complexes with $OPPy_3$ and $OPPy_2Ph$ being the resting state for the catalyst. This hypothesis is further supported by the observation that addition of an excess of ligand to the solution (complex: ligand ratio = 1:1) leads to a nearly 50% decrease in catalytic activity.

Conclusion

The $OPPy_3$ and $OPPy_2Ph$ ligands are nitrogen-based ligands containing sp^2-hybridized nitrogen donors. Com-

pared with geometrically analogous anionic pyrazolylborates, both similarities and differences are found. They are very similar in coordination and dynamic behavior. However, 2-pyridylphosphane oxides are weaker ligands than pyrazolylborates. Because of this they are unable to withstand working conditions currently used in catalytic reactions.

Experimental Section

General Remarks: All manipulations were conducted with rigorous exclusion of air. Solvents were dried by known procedures and distilled under nitrogen prior to use. − ^{1}H NMR (300.16 MHz), ^{19}F NMR (282.4 MHz), and ^{31}P NMR (121.4 MHz) spectra were recorded on a Bruker ARX 300 instrument equipped with a VT-100 variable-temperature probe. Chemical shifts are reported from tetramethylsilane (^{1} H), CCl_3F (^{19}F), or H_3PO_4 (85%) (^{31}P), with positive shifts downfield, and at ambient probe temperature unless otherwise stated. NOESY experiments were carried out with a standard program, operating in phase-sensitive mode, with a 5% random variation in the evolution time, to avoid COSY cross-peaks, and with a mixing time equal to T_1 of the olefinic signals as measured by inversion recovery. − Combustion CHN analyses were made on a Perkin−Elmer 2400 CHN microanalyzer. − Infrared spectra were recorded on a Perkin−Elmer 843 (range 4000−200 cm^{-1}) with Nujol mulls between polyethylene sheets, or in dichloromethane solution between NaCl plates. − The catalytic reactions were monitored by GLC on a Hewlett−Packard II 5890, using an HP-FFAP column and with mesitylene as internal standard. The precursors $[Rh_2(\mu\text{-}Cl)_2(1,5\text{-}COD)_2]$,[20] $[Rh_2(\mu\text{-}Cl)_2(TFB)_2]$,[21] $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ and the ligands $OPPy_2Ph$ and $OPPy_3$ were prepared by published methods.[22]

$[Rh(OPPy_2Ph)(COD)]BF_4$ (1): A suspension of $[Rh_2(\mu\text{-}Cl)_2(COD)_2]$ (200 mg, 0.41 mmol) in acetone (20 mL) was treated with $TlBF_4$ (236 mg, 0.81 mmol) and $OPPy_2Ph$ (238 mg, 0.85 mmol). After 30 min stirring at room temperature, the TlCl was filtered off and the yellow solution was concentrated to dryness in vacuum. The yellow residue was recrystallized from dichloromethane-diethyl ether, washed with diethyl ether and vacuum dried. Yield 409 mg (87%). − $C_{24}H_{25}BF_4N_2OPRh$ (578.16): calcd. C 49.86, H 4.36, N 4.82; found C 49.68, H 4.16, N 4.57. − ^{1}H NMR ($CDCl_3$): δ = 8.93 (m, 2 H), 8.56 (m, 2 H), 8.11 (m, 2 H), 7.82 (m, 3 H), 7.63 (m, 4 H), 4.14 (m, 2 H), 3.44 (m, 2 H), 2.64 (m, 2 H), 1.82 (m, 2 H), 1.22 (m, 2 H), 0.85 (m, 2 H). − ^{31}P NMR: δ = 18.7 (d, $^3J_{Rh\text{-}P}$ = 7.56 Hz). − IR (Nujol mull): $\nu(CN)_{Py}$ 1587 cm^{-1}; ν(P=O) 1203 cm^{-1}.

$[Rh(TFB)(OPPy_2Ph)]BF_4$ (2): A suspension of $[Rh_2(\mu\text{-}Cl)_2(TFB)_2]$ (100 mg, 0.14 mmol) in acetone (15 mL) was treated with $TlBF_4$ (80 mg, 0.28 mmol) and $OPPy_2Ph$ (77 mg, 0.28 mmol). After 30 min stirring at room temperature, the TlCl was filtered off and the yellow solution was concentrated to dryness in vacuum. The yellow residue was recrystallized from dichloromethane-diethyl ether, washed with diethyl ether and vacuum dried. Yield 139 mg (73%). − $C_{28}H_{19}BF_8N_2OPRh$ (696.2): calcd. C 48.31, H 2.75, N 4.02; found C 48.71, H 2.90, N 4.03. . − ^{1}H NMR ([D$_6$]acetone): δ = 9.04 (m, 2 H), 8.36 (m, 2 H), 8.14 (m, 2 H), 3.94 (m, 4 H), 1.65 (m, 4 H), 1.83 (m, 4 H). − ^{31}P NMR: δ = 18.6 (d, $^3J_{Rh\text{-}P}$ = 6.8 Hz). − ^{19}F NMR: δ = −147.15 (m, 2 F), −150.1 (4 F, BF_4^-), −160.20 (m, 2 F). − IR (Nujol mull): $\nu(CN)_{Py}$ 1589 cm^{-1}; ν(P=O) 1214 cm^{-1}.

$[Rh(CO)_2(OPPy_2Ph)]BF_4$ (3a): Carbon monoxide was bubbled through a solution of **1** (130 mg 0.225 mmol) in dichloromethane (20 mL) for 2 h. The resulting pale yellow solution was concentrated to 5 mL and diethyl ether was added. The yellow solid formed was filtered off, washed with diethyl ether and vacuum dried. Yield 80 mg (67%). − $C_{18}H_{13}BF_4N_2O_3PRh$ (525.9): calcd. C 41.09, H 2.47, N 5.34; found C 41.22, H 2.53, N 5.22. − ^{31}P NMR: δ = 19.6 (d, $^3J_{Rh\text{-}P}$ = 9.6 Hz). − ^{1}H NMR ($CDCl_3$): δ = 9.23 (m, Py), 8.58 (m), 8.22 (m), 7.82 (m), 7.64 (m, Ph). − IR (Nujol mull): ν(CO) 2092, 2035 cm^{-1}; $\nu(CN)_{Py}$ 1594 cm^{-1}; ν(P=O) 1212 cm^{-1}.

Reaction of $[Rh_2(\mu\text{-}Cl)_2(CO)_2]$ with $OPPy_2Ph$: $Rh_2(\mu\text{-}Cl)_2(CO)_4$ (220 mg, 0.55 mmol) and $OPPy_2Ph$ (320 mg, 1.1 mmol) were dissolved in 20 mL of dichloromethane. The solution was split into three aliquots; one was used as reference, another was used to study by IR the effect of adding $[Et_3BzN]Cl$, and the third was used to study by IR the reactivity with $[Bu_4N][PF_6]$.

$[Rh(CO)_2(OPPy_2Ph)][RhCl_2(CO)_2]$ (3b): $Rh_2(\mu\text{-}Cl)_2(CO)_4$ (110 mg, 0.27 mmol) and $OPPy_2Ph$ (80 mg, 0.27 mmol) were dissolved in 10 mL of dichloromethane. The solution was filtered and 5 mL of ethanol were added. After concentration to 5 mL, **3b** crystallized as yellow plates. Yield 135 mg (73%). − $C_{20}H_{13}Cl_2N_2O_5PRh_2$ (669.00): calcd. C 35.70, H 1.93, N 4.16; found C 35.91, H 2.00, N 4.11. − ^{31}P NMR ([D$_6$]acetone): δ = 19.97 (d, $^3J_{Rh\text{-}P}$ = 7.4 Hz). − ^{1}H NMR ([D$_6$]acetone): δ = 9.49 (m, Py), 8.68 (m), 8.56 (m), 8.01 (m), 7.86 (m, Ph), 7.78 (m), 7.51 (m). − IR: ν(CO) 2098, 2065, 2038, 1991 cm^{-1}; $\nu(CN)_{Py}$ 1590 cm^{-1}; ν(PO) 1213 cm^{-1}.

$[Rh(COD)(OPPy_3)]BF_4$ (5): The procedure was as described for **1**, but $OPPy_3$ (237 mg, 0.85 mmol) was added instead of $OPPy_2Ph$. Yield 790 mg (84%). − $C_{23}H_{24}BF_4N_3OPRh$ (579.2): calcd. C 47.70, H 4.18, N 7.26; found C 47.55, H 4.15, N 7.12. − ^{31}P NMR: δ = 14.7 (d, $^3J_{Rh\text{-}P}$ = 5.56 Hz). − ^{1}H NMR: δ = 9.00 (m, Py), 8.33 (m), 8.13 (m); 3.91, 1.65 and 1.86 (br. signals, COD). − IR (Nujol mull): $\nu(CN)_{Py}$ 1587 and 1572 cm^{-1}, ν(P=O) 1206 cm^{-1}. Single crystals of $5{\cdot}Me_2CO$ suitable for X-ray diffraction were formed by slow diffusion of a solution of the complex in acetone-ethanol (2:1) and *n*-hexane at room temperature.

$[Rh(TFB)(OPPy_3)]BF_4$ (6): The procedure was as described for **2**, but $OPPy_3$ (77 mg, 0.14 mmol) was used instead of $OPPy_2Ph$. Yield 135 mg (70%). − $C_{27}H_{18}BF_8N_3OPRh$ (697.1): calcd. C 46.52, H 2.60, N 6.03, found C 46.58, H 2.73, N 5.98. − ^{31}P NMR ([D$_6$]acetone): δ = 3.0 (d, $^3J_{Rh\text{-}P}$ = 6.8 Hz). − ^{19}F NMR: δ = −147.2 (m, 2 F), −150.3 (4 F, BF_4^-), −160.5 (m, 2 F). − ^{1}H NMR: δ = 9.64 (m, Py), 8.65 (m), 8.43 (m) and 7.96 (m), 6.13 (m, TFB) and 3.94 (m). − IR (Nujol mull): ν_{Py}(CN) 1586 cm^{-1}, νP=O 1230 cm^{-1}. Single crystals of $\mathbf{6}{\cdot}x Me_2CO$ suitable for X-ray diffraction were formed by slow diffusion of a solution of the complex in acetone-ethanol (2:1) into *n*-hexane at room temperature.

$[Rh_2(\mu\text{-}CO)_3(OPPy_3)_2](BF_4)_2$ (9a): Carbon monoxide was bubbled through a solution of **2** (150 mg 0.235 mmol) in dichloromethane (20 mL) for 2 h. The solvent was evaporated and the residue was dissolved in THF (10 mL) and refluxed for 30 min. The insoluble green solid formed was filtered off, washed with diethyl ether and vacuum dried. Yield 72 mg (60%). − $C_{33}H_{24}B_2F_8N_6O_5P_2Rh_2$ (1026.0): calcd. C 38.63, H 2.34, N 8.22; found C 38.70, H 2.41, N 8.17. − IR (Nujol mull): ν(CO) 1836 cm^{-1}; $\nu(CN)_{Py}$ 1593 cm^{-1}; ν(PO) 1236 cm^{-1}.

$[Rh_2(\mu\text{-}CO)_3(OPPy_3)_2][RhCl_2(CO)_2]_2$ (9b): $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ (100 mg, 0.25 mmol) and Py_3PO (155 mg, 0.55 mmol) were dissolved in 10 mL of dichloromethane; the solution was stirred until the CO evolution ceased (two hours). The insoluble dark red solid

formed, $[Rh_2(\mu\text{-}CO)_3(OPPy_3)_2][RhCl_2(CO)_2]_2$ was filtered, washed with dichloromethane and vacuum dried. Yield 145 mg (80%). − $C_{37}H_{24}Cl_4N_6O_9P_2Rh_4$ (1312.2): calcd. C 33.90, H 1.85, N 6.40; found C 33.91, H 1.80, N 6.42.

X-ray Crystallography: Suitable single crystals were mounted on glass fibers, and diffraction measurements were made using a Bruker SMART CCD area-detector diffractometer with Mo-K_α radiation (λ = 0.71073 Å).[23] Intensities were integrated from several series of exposures, each exposure covering 0.3° in ω, the total data set being a hemisphere.[24] Absorption corrections were applied, based on multiple and symmetry-equivalent measurements.[25] The structure was solved by Patterson synthesis or direct methods and refined by least-squares on weighted F^2 values for all reflections (see Table 3).[26] All nonhydrogen atoms were assigned anisotropic displacement parameters and refined without positional constraints. Hydrogen atoms were taken into account at calculated positions and their positional parameters were refined. Refinement proceeded smoothly to give R_1 = 0.0419 for **5**·acetone and R_1 = 0.0621 for **6**, based on the reflections with $I > 2\sigma(I)$. Further refinement for **6**, including a molecule of acetone with one carbon in a special position led to a final R_1 value of 0.0505 for **6**·$C_{2.5}O$. Hydrogen atoms of the acetone in **6**·$C_{2.5}O$ were not included in the calculations. Complex neutral-atom scattering factors were used.[27] Crystallographic data (excluding structure factors) for the structures **5**·acetone and **6**·$C_{2.5}O$ reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as Supplementary Publication numbers CCDC-144233 (**5**·Me_2CO) and CCDC-144234 (**6**·$C_{2.5}O$). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Catalytic Experiments. − Hydrogenation with Molecular Hydrogen: In each experiment, 0.014 mmol of the rhodium complex and 28 mmol of the substrate were dissolved in 18 mL of a 0.04 M solution of sodium hydroxide in methanol. After stirring for some minutes in order to dissolve the complex completely, the solution was transferred to a previously deaerated high pressure reactor containing a magnetic bar for stirring the solution; the reactor was then filled with the desired pressure of hydrogen and connected to a thermostated oil bath. The course of the reaction was followed by taking a sample of the solution at different times and refilling the reactor to the previous pressure. The solutions were analyzed by GC. The homogeneity of the catalysis was tested by adding a large excess of mercury to the reaction vessel (Hg:catalyst = 100:1).

The First Example of a True "Turnbull's Blue" Family Compound with Trapped Iron Oxidation States

Vitaly V. Pavlishchuk,*[a] Iryna A. Koval,[a] Eugeny Goreshnik,[b] Anthony W. Addison,*[c] Gerard A. van Albada,[d] and Jan Reedijk[d]

Keywords: Prussian blue / Magnetic susceptibility / Valence trapping / Iron / Macrocycles

The first compound of a true Turnbull's Blue family [i.e. an iron(II) hexacyanoferrate(III)] complex with valence-trapped states of iron – $[Fe([9]ane\text{-}S_3)_2]_3[Fe(CN)_6]_2\cdot 2H_2O$ (Ukrainian Red, UR) was synthesized. It crystallizes in the trigonal space group P3, a = 12.038(8) Å, b = 12.038(8) Å, c = 14.342(7) Å, α = 90.00°, β = 90.00°, γ = 120.00°. The unit cell of UR consists of separate $[Fe([9]ane\text{-}S_3)_2]^{2+}$ cations, $[Fe(CN)_6]^{3-}$ anions and 5.3 molecules of water. Encapsulation of the Fe^{II} in the homoleptic thioether environment plays the dual role of stabilizing Fe^{II} and protecting the central metal ion from direct bridging with hexacyanoferrate(III) anions. The absence of such interactions and trapping of iron oxidation states in the cations and anions was demonstrated by X-ray diffraction and magnetic susceptometry. Magnetic measurements are consistent with diamagnetic Fe^{II} inside the macrocyclic moieties and S = 1/2 for Fe^{III} in the hexacyanoferrate(III) anions.

Introduction

Until the 1960's Turnbull's Blue was believed to be iron(II) hexacyanoferrate(III), $Fe_3[Fe(CN)_6]_2$. This saga began 300 years ago when Berlin and Diesbach prepared Prussian Blue, also called Berlin Blue. The Prussian Blue synthesis heralded not only the discovery of a new family of cyanides, but initiated a whole field of coordination chemistry. Prussian Blue was ascribed as being the iron(III) hexacyanoferrate(II), $Fe_4[Fe(CN)_6]_3$, in contrast to the similarly intense blue pigment Turnbull's Blue. Recently[1–3] all these various iron cyanides have been consolidated into a single family of Prussian Blues (PB's). In this paper we use this name solely in reference to iron-containing cyanoferrates. Only since the 1960s have the identities of Prussian ($Fe_4[Fe(CN)_6]_3$) and Turnbull's Blues ("$Fe_3[Fe(CN)_6]_2$") been elucidated by magnetochemistry and Mössbauer spectroscopy.[2,4–10] These methods, as well as subsequent X-ray examination[11] revealed that Prussian Blue and Turnbull's Blue are both iron(III) hexacyanoferrates(II), containing high spin Fe^{3+} cations and $[Fe(CN)_6]^{4-}$ with low-spin Fe^{II}, linked by cyanide bridges. Thus, a real "Turnbull's Blue" simultaneously containing Fe^{II} and $[Fe(CN)_6]^{3-}$ has never been reported. Detailed examination of PB's molecular and electronic structures suggest a significant exchange interaction between ions, and valence delocalization[1,10,12,13] along the Fe–C≡N–Fe bonds. All PB′s have been assigned as Robin and Day Class II mixed-valence systems.[14] In such systems partial valence delocalization occurs, and two oxidation states are still distinguishable by physical methods. Until now, only polymeric PB's with magnetic interaction or valence delocalization between iron atoms have been described in the literature.[1,10,12,13,16–18] The detection of high-temperature ferromagnetic ordering in a number of PB-family complexes containing different metal ions connected by CN^- bridges has stimulated the design and study of new magnetic materials based on these compounds.[1,15–21] The recent discovery of photoinduced magnetization in a cobalt-containing PB analog may be of practical interest for the development of photochemically tunable molecular magnets.[22] From this point of view, the synthesis of true Turnbull's Blue complexes with trapped oxidation states is still a challenge and is of significant fundamental interest. Blocking of such iron-iron interactions may be achieved by shielding the iron cations with homoleptic macrocyclic ligands, generating around them a coordinatively saturated environment which precludes any bridging by anions. Comparison of the magnetic and electronic properties of complexes containing cyano bridges with those that do not can reveal the details of the roles of such bridging groups in superexchange interactions between the metal centers. In this paper we report the synthesis and properties of the first

example of a true Turnbull's Blue (i.e. iron(II) hexacyanoferrate(III)) complex with valence-trapped states of iron − $[Fe([9]ane\text{-}S_3)_2]_3[Fe(CN)_6]_2\cdot 2H_2O$, which we refer to as Ukrainian Red (UR).

Results and Discussion

Synthesis

The reaction of $[Fe([9]ane\text{-}S_3)_2](ClO_4)_2$ with $K_3[Fe(CN)_6]$ in aqueous solution in molar ratio 3:2 results in precipitation of shiny ruby colored crystals of product, while the color of the solution changes to dull yellow. If the reaction mixture is allowed to stand for several days an additional amount of product forms, along with a minor amount of classic PB colloid. The analytical data agree with the formula $[Fe([9]ane\text{-}S_3)_2]_3[Fe(CN)_6]_2\cdot 2H_2O$ for the bulk product, while an X-ray diffraction study proves the constitution of a single crystal to be $[Fe([9]ane\text{-}S_3)_2]_3[Fe(CN)_6]_2\cdot 5.3H_2O$ (vide infra). Ukrainian Red shows no sign of redox exchange between its cations and anions during crystallization, so in contrast to classical PB's, the Fe^{III} ions in UR remain as hexacyanoferrate(III) anions, and the Fe^{II} ions are muffled by two trithiamacrocyclic ligands. Its composition thus matches formally the *virtual* classic Turnbull's Blue composition ($Fe_3[Fe(CN)_6]_2$), but with iron(II) in macrocyclic moieties. The hexathiamacrocyclic environment around Fe lends significant relative stabilization to the Fe^{2+} oxidation state[23] and because of the consequently high $E_{1/2}$ value[23] for the $[Fe([9]ane\text{-}S_3)_2]^{3+/2+}$ couple, the hexacyanoferrate(III) ions cannot oxidize $[Fe([9]ane\text{-}S_3)_2]^{2+}$ to $[Fe([9]ane\text{-}S_3)_2]^{3+}$. In addition, the macrocyclic shielding in UR prevents the formation of cyanide bridges between Fe^{II} and Fe^{III} and thus is also crucial for preventing electron delocalization between these two iron atoms in different oxidation states. $[Fe([9]ane\text{-}S_3)_2]_3[Fe(CN)_6]_2\cdot 2H_2O$ is insoluble in most common solvents. In order to confirm the integrity of the iron centers during the reaction and the absence of interactions between them in the complex salt, we investigated the crystal and molecular structure of UR as well as its IR and optical spectra and magnetochemical behavior.

[a] Standard deviations in parentheses.

The unit cell of UR consists of separate $[Fe([9]ane\text{-}S_3)_2]^{2+}$cations, $[Fe(CN)_6]^{3-}$ anions and 5.3 molecules of water (Figure 2). The macrocyclic cations are arranged in UR in such a way that the macrocyclic ligands form an unusual linear tube, along whose central axis the iron(II) ions are situated (Figure 3). Two nonequivalent $[Fe(CN)_6]^{3-}$ anions balance the positive charge of the cations, while water molecules occur in the unit cell in two

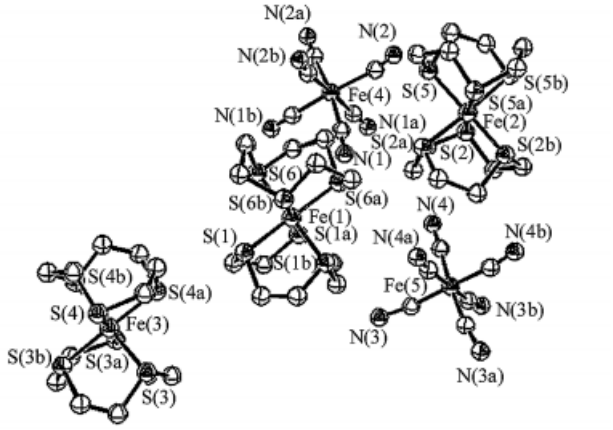

Figure 1. Molecular structure of Ukrainian Red. For clarity of presentation, water molecules and hydrogen atoms are not shown

independent positions with occupancies 1 and 0.77 (the multiplicity of each position is 3, thus $3+3 \times 0.77$ gives 5.3 water molecules in unit cell). The cations and anions are not connected by CN^- bridges, as is evident from Figure 1. There is no evidence for the existence of hydrogen bonding inside the unit cell.

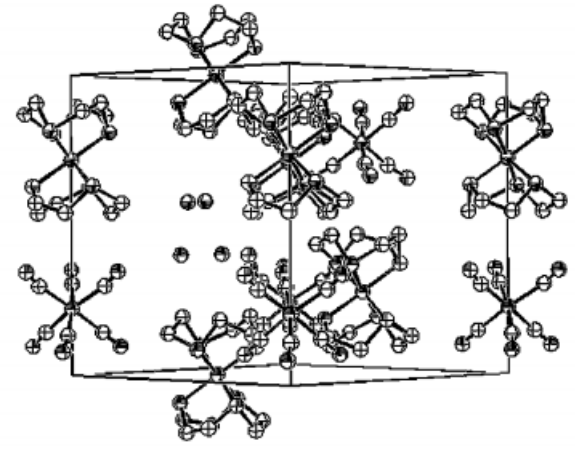

Figure 2. Unit cell content of Ukrainian Red

Similarities between the lattice building blocks in UR and in the starting reagents might be anticipated. Indeed, comparison of the Fe−C bond lengths in UR with those in $K_3[Fe(CN)_6]$[25] shows no significant differences. In the potassium salt, all the Fe−C distances are approximately equal (1.93−1.95 Å), whereas in UR these values vary within slightly larger limits (1.91 and 1.95 Å). These differences between the Fe−C distances are not significant relative to their standard deviations (Table 2) and thus may reveal that the equivalence of the Fe−C bonds is inherited by UR. In the potassium salt, the cyanide ligand $C\equiv N^-$ bond lengths are practically constant (1.14−1.16 Å).[24] In UR, they are also within these limits and the mean $[Fe(CN)_6]^{3-}$ radius (the distance between Fe and N) in UR is close to that in $K_3[Fe(CN)_6]$.[25] Previously, a dynamic Jahn−Teller effect in $K_3[Fe(CN)_6]$ was detected by magnetic circular dichroism[26] and Mössbauer spectroscopy,[27] while a static Jahn−Teller distortion was demonstrated for $[Fe([9]ane\text{-}S_3)_2](PF_6)_3$ by Mössbauer spectroscopy.[28] The bond lengths in UR offer no clear evidence in favor of a Jahn−Teller distortion in $[Fe(CN)_6]^{3-}$. Nonetheless, deviations of the C−Fe−C angles from 90° (Table 2) along with nonlinearity of the Fe−C≡N units in UR (Figure 1, Table 2) leave room for speculation about the existence of a Jahn−Teller distortion in this compound.

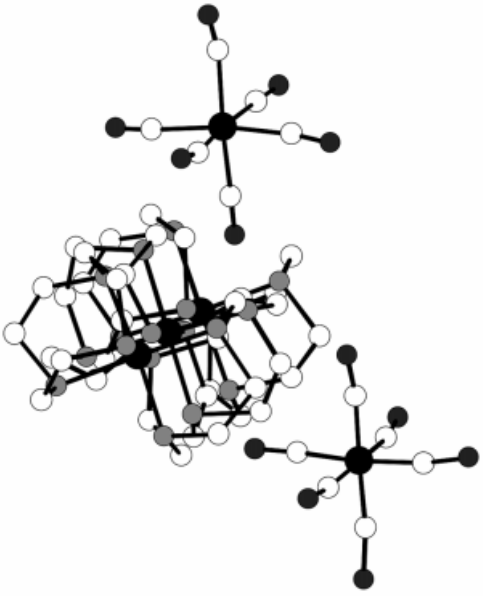

Figure 3. A perspective view of UR

The structural parameters for two of the three $[Fe([9]ane\text{-}S_3)_2]^{2+}$ cations in the UR unit cell (Table 2) also differ slightly from those described earlier in the literature.[23] The angles around Fe(1) of the central macrocycle (Table 2) coincide with those found in $[Fe([9]ane\text{-}S_3)_2](ClO_4)_2$. However, the corresponding angles in the two terminal macrocyclic cations are different (Table 2).[23] The Fe−S distances in UR vary between 2.23 and 2.27 Å, while in the parent $[Fe([9]ane\text{-}S_3)_2](ClO_4)_2$ these values are within 0.01 Å of 2.25 Å.[23] The terminal $[Fe([9]ane\text{-}S_3)_2]^{2+}$ in UR show slightly distorted octahedra as shown by some bond angle deviations from 90° (Table 2). These minor distortions in the cation structure in UR can be attributed to the influence of lattice packing in this compound.

The IR spectrum of UR contains a sharp band at 2100 cm^{-1} with a weaker satellite at 2113 cm^{-1} and a broad shoulder at lower frequency. These absorptions are attributed to the $\nu_{C\equiv N}$ mode of the nonbridging cyanide groups. The splitting of this mode and its broadening at lower frequencies may be attributed to the presence of the different types of cyanide anions in UR.

The reflectance spectrum of UR (Figure 4) shows two strong absorptions at 23,641 and 18,587 cm^{-1}, which originate from the individual ions. The band at 18,587 cm^{-1} is attributed to the $A_{1g} \rightarrow T_{1g}$ d-d transition in the octahedral low-spin d^6 $[Fe([9]ane\text{-}S_3)_2]^{2+}$ cations, as observed in $[Fe([9]ane\text{-}S_3)_2](ClO_4)_2$.[23] The second $A_{1g} \rightarrow T_{2g}$ d-d transition normally observed in $[Fe([9]ane\text{-}S_3)_2]^{2+}$ at 25,316 cm^{-1} is obscured in UR by the broad charge transfer band,

π t_{2u} (CN^-) $\rightarrow$ t_{2g} (Fe^{III}). The band at 23,641 cm^{-1} in UR also arises from hexacyanoferrate(III) and is attributed to σ t_{1u} (CN^-) $\rightarrow$ t_{2g} (Fe^{III}) charge transfer.[29] In contrast to PB, and as expected for this structure, there is no sign of an intervalence charge transfer band in UR in the region 6,600−30,300 cm^{-1}. Unfortunately, the insolubility of UR in common solvents prevents measurements of its optical spectrum in solution.

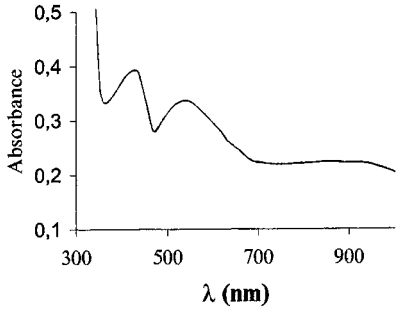

Figure 4. Electronic spectrum of UR in $BaSO_4$ matrices

The magnetochemical results for UR are consistent with the structural and spectral data. The temperature dependence of χT for UR was fitted in agreement with a $^2T_{2g}$ $[Fe(CN)_6]^{3-}$ ground state split under the influence of spin-orbit coupling in the magnetic field model[30,31] (Figure 5):

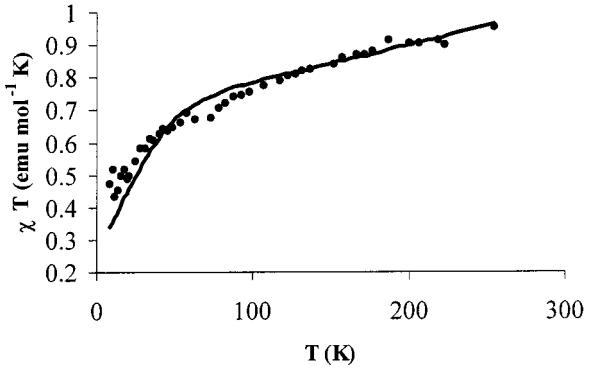

Figure 5. Variable-temperature magnetic data for UR. The solid line was calculated from Equation 1 with $\lambda = -72 \pm 6$ cm^{-1}, $\kappa = 0.75 \pm 0.03$, $TIP = 0.0015 \pm 0.0001$ emu; experimental data. ($R = [\Sigma(\chi_{obs} - \chi_{calc})^2/\Sigma\chi^2_{obs}]^{1/2}$) = 0.029

$$\chi_M = \frac{N\beta^2}{3kT}\left[\frac{3x(1+k)^2 - 8(2+k)^2 + \{30x(1-k)^2 + 8(2+k)^2\}e^{3x/2}}{9x\{1+2e^{3x/2}\}}\right] + TIP$$

κ is the orbital reduction factor, and $x = \kappa\lambda/3$ while the other symbols have their usual meanings. The additional term for temperature independent paramagnetism was introduced in order to reflect coupling between the singlet ground state and nonthermally populated excited states for the low-spin Fe^{2+} cations in the macrocyclic moieties.[31]

The susceptibility data for UR fit well to the above model under the assumption that significant magnetic exchange interactions between ions in the salt are absent. κ-Values for $[Fe(CN)_6]^{3-}$ in previous work[32−37] were also derived without consideration of magnetic exchange at even very low temperatures in $K_3[Fe(CN)_6]$.[38] The calculated κ = 0.75 for the $[Fe(CN)_6]^{3-}$ ion in UR reflects considerable covalency in this anion. The literature values for κ vary between 0.56 and 0.90; however, our value is close to that reported by Figgis.[37] The substantial reduction of λ (ref. between −250[37] and −400[35] cm^{-1}) also might be considered as evidence for the existence of a Jahn−Teller effect[34,35] in the hexacyanoferrate ions in UR. The separation of the $[Fe(CN)_6]^{3-}$ anions from each other is too great (9.5 Å) for significant magnetic exchange between iron(III) atoms.

Conclusion

Summarizing the results of this study, we would like to emphasize that almost three centuries have passed before a compound having a composition consistent with the original Turnbull's Blue formulation was synthesized. Success was achieved mainly due to the chosen synthetic strategy of encapsulating the Fe^{II} inside the homoleptic thioether environment. Such coordination plays the dual role of stabilizing Fe^{II} and protecting the central metal ion from direct bridging with hexacyanoferrate(III) anions. The absence of such interactions and trapping of iron oxidation states in the cations and anions was demonstrated by X-ray diffraction and magnetic susceptibility. In contrast to the classical PB's, assigned as Class II mixed valence systems,[14] UR is a Robin and Day Class I compound which shows no sign of valence delocalization in its spectroscopic and magnetic properties. This study also confirms the significant role of CN^- bridges in the magnetic interactions normally found in PB complexes. Shielding by the macrocyclic ligands prevents magnetic interactions between metal centers, so that UR shows no magnetic exchange between iron atoms. Further work is underway, involving coordinatively unsaturated $[M[9]ane-S_3]^{n+}$ building blocks and hexacyanoferrate/chromate(III) as potential sources of ferromagnetic materials.

Experimental Section

General Remarks: All reactants and solvents were of reagent grade and used as purchased; $[Fe([9]aneS_3)_2](ClO_4)_2$ was prepared according to the procedure reported by Wieghardt and co-workers.[23]

Physical Measurements: Infrared spectra were measured on a Carl Zeiss-Jena Specord M 75IR spectrometer using KBr pellets. Electronic spectra were recorded by the diffuse reflectance technique using $BaSO_4$ matrices on a Carl Zeiss-Jena Specord M-40 spectrophotometer. The magnetochemical behavior of the complex in the 5−278 K temperature range was studied using a fully automated Manics DSM-8 susceptometer. Data were corrected for diamagnetic contributions, estimated from the Pascal constants.[30]

$[Fe([9]aneS_3)_2]_3[Fe(CN)_6]_2 \cdot 2H_2O$ (Ukrainian Red): An aqueous solution of $K_3[Fe(CN)_6]$ (0.088 g, 0.27 mmol) was slowly added to an aqueous solution of $[Fe([9]ane-S_3)_2](ClO_4)_2$ (0.246 g, 0.40 mmol).

After half an hour, dark ruby colored prisms formed, which were filtered off, washed with water and ethanol and dried in air. Yield: 0.20 g, 63%. Elemental analysis; calcd. for $C_{48}H_{76}Fe_5N_{12}O_2S_{18}$: calcd. C 33.7, H, 4.48, N, 9.83, S, 33.8, Fe, 16.3; found calcd. C 33.6, H, 4.41, N, 9.89, S, 33.6, Fe, 16.0%. IR (cm^{-1}, KBr disc): 3386 (ν_{O-H}), 2113, 2101 ($\nu_{C\equiv N}$). Optical spectrum (solid state) : $\tilde{\nu}_{max}$, cm^{-1}: 23,641, 18,587.

X-ray Crystallographic Study: For X-ray diffraction, the selected crystal was mounted in a glass capillary, set on the goniometer head and carefully centered. X-ray intensity data were measured on an automated four-circle Dartch diffractometer with graphite-monochromated Mo-K_α radiation in the θ-2θ scan mode. Rotation and Weissenberg photographs gave preliminary parameters for the trigonal unit cell and Laue class 3 was defined. Any systematic absences were found and space group $P3$ was assigned to the unit cell. The cell parameters were least-squares refined using 24 reflections in the range: $25° \leq 2\theta \leq 30°$. The structure was solved using the CSD program package[20]. Iron and sulfur atoms were found by direct methods, the positions of other non-hydrogen atoms being derived from Fourier synthesis. All H atoms were found by difference Fourier synthesis, and their positional and overall thermal parameters were refined isotropically. Crystallographic data for Ukrainian Red are presented in Table 1. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-138604. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(1223)336−033; E-mail: deposit@ccdc.cam.ac.uk].

Intramolecular Dynamics of Asymmetric Lanthanide(III) Porphyrin Sandwich Complexes in Solution

Sergey P. Babailov,*[a] Athanassios G. Coutsolelos,[b] Alexander Dikiy,[c] and Georgios A. Spyroulias[d]

Keywords: NMR spectroscopy / Lanthanides / Phenyl ring rotation / Metalloporphyrins

Temperature dependencies of the ^{1}H NMR spectra of asymmetric double-decker complexes of DyH(oep)(tpp) (**I**) and LuH(oep)(tpp) (**II**), where tpp is tetraphenylporphyrin and oep is octaethylporphyrin, have been analyzed. The kinetic and thermodynamic parameters for intramolecular phenyl ring rotations have been determined. The rotation in (**I**) is characterized by k(298 K) = 11.4 s^{-1}, $\Delta H^{\ddagger}$ = 48.0±6.0 kJ mol^{-1}, while in (**II**) the derived parameters are found to be k(298 K) = 14.0 s^{-1}, $\Delta H^{\ddagger}$ = 65.5±7.1 kJ mol^{-1}. The possible reasons for the different characteristics of these complexes are discussed. The structural parameters calculated for **I** and YbH(oep)(tpp) (**III**), indicate close similarities between the complexes. Nevertheless, it appears that the principal values of the molar paramagnetic susceptibility tensor (χ_i) differ significantly in these complexes.

Introduction

A number of physico-chemical studies on sandwich-complexes containing lanthanide metal(III) or metal(IV) ions and porphyrin ligands have been reported in the literature. These studies have been carried out using techniques such as UV/Vis, CD[1a−1g], low-temperature NIR spectroscopy[2c,2d], NMR,[1a−1c,2b−2e,3b−3d] resonance Raman (RR),[4c,4d,5a−5d] and electron spin resonance[1c,3c,4d] spectroscopies, as well as electrochemistry,[1d,2,3a] photophysics,[4a,4b] and X-ray crystal structure studies[1b,1c,2d,6]. Presently, the thermodynamic, structural, and electronic properties of these complexes are well known, both in solution and in the solid state. Recently, a new phenomenon, involving intramolecular rotation of the decker rings about each other in symmetrical sandwich complexes has been discovered and studied using CD and NMR spectroscopies.[1f,1g] The investigation of the dynamic properties of double-decker complexes represents an interesting area in metalloporphyrin chemistry and attracts the interest of researchers.

Although intramolecular dynamic processes involving motions, like phenyl ring rotation, in lanthanide porphyrin sandwich complexes were partially investigated, this motion was not sufficiently elucidated and described. The phenyl rings rotation-rate has been determined for the symmetric YbH(tpp)$_2$ complex at room temperature by the analysis of NOESY cross-peaks intensities.[3e] However, the activation parameters of the phenyl ring rotation were not measured. In this report we use the dynamic NMR approach[7a−7d] to obtain the phenyl rings rotation rate and the activation enthalpy for this process in solution on the asymmetric double-decker complexes DyH(oep)(tpp) (**I**) and LuH(oep)(tpp) (**II**).[3d,3e] The schematic representation of the complexes structure is illustrated in Figure 1. In addition, the results obtained by using pseudo-contact shifts and lanthanide-induced enhancements of longitudinal relaxation rates experienced by some protons of paramagnetic DyH(oep)(tpp) and YbH(oep)(tpp) (**III**) reveal that the structures of the complexes are very similar, with only a slight decrease in distances between the planes of porphyrin ligands upon increase in the atomic number of the lanthanide ions. This result has been interpreted as being due to so-called lanthanide contraction.

Results and Discussion

We have already reported the complete ^{1}H NMR signal assignment of complexes **I-III**.[3d,3e] The signal assignment was based on 1D NOE technique as well as on 2D NOESY, ROESY, TOCSY, and COSY experiments.

The intramolecular phenyl ring rotation rate for complex **II** was determined from the measurements of the temperature dependence of its ^{1}H NMR spectrum. ^{1}H NMR spectra of complex **II** at different temperatures are shown in Figure 2. ^{1}H NMR signals corresponding to *endo-ortho*,

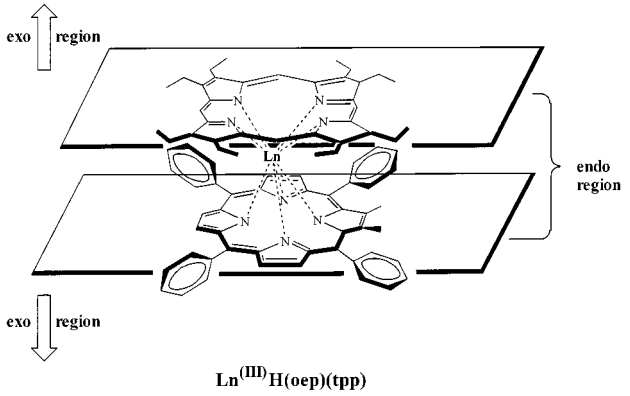

Figure 1. Schematic representation of the asymmetric LnH(oep)(tpp) complexes

exo-ortho, *endo-meta*, *exo-meta* protons are broadened with an increase in temperature, which is consistent with pairwise exchange between the sites: (*endo-ortho*) ⇄ (*exo-ortho*), and (*endo-meta*) ⇄ (*exo-meta*) (see Table 1). The first-order rate constant, k, for the intramolecular exchange processes was determined by comparison of calculated and observed temperature dependent linewidths of (*endo-ortho*), (*exo-ortho*), (*endo-meta*), and (*exo-meta*) ^{1}H NMR signals, according to a procedure reported for the uncoupled two-site exchange case.[7a,7e] Activation parameters were determined using the Eyring Kinetic Equation (1) from weighted least squares {$\ln[k(T)/T]$ versus $1/T$}[7a,7b,7e] where R is the gas constant, k_B is the Boltzmann constant and h is the Planck constant.

$$\ln[k(T)/T] = -\Delta H^{\ddagger}/RT + \Delta S^{\ddagger}/R + \ln(k_B/h) \quad (1)$$

The activation enthalpy of the phenyl rings rotation for **II** was found to be $\Delta H^{\ddagger} = 65.5 \pm 7.1$ kJ mol^{-1} with k(298 K) = 14.0 s^{-1}. We have also calculated the free energy of activation $\Delta G^{\ddagger} = 67.7 \pm 7.1$ kJ mol^{-1} at 95° C in order to compare it with data previously reported. The value obtained for the phenyl ring-flip activation free en-

ergy in **II** is in good agreement with that found for the Ru(CO)(*i*Pr tpp) complex ($\Delta G^{\ddagger}$ = 77.8 kJ mol^{-1} at 95° C).[7e]

In order to compare the thermodynamic parameters of the phenyl ring flipping in LnH(oep)(tpp) complexes across the lanthanide series, including the activation enthalpy in the Lu complex, which is the last member of the series, the analogous parameters were determined for the Dy^{III} complex (**I**). The temperature dependence of ^{1}H NMR spectra of **I** within the temperature range 288 K to 306 K (data not shown) was investigated. No significant temperature dependent changes of the ^{1}H NMR linewidth were observed in addition to the Curie−Weiss dependence of the hyperfine shifts.[7b] This phenomenon can be explained by considering that the exchange rates between the sites (*endo-ortho*) ⇄ (*exo-ortho*), and (*endo-meta*) ⇄ (*exo-meta*) are smaller with respect to broadening of these signals due to lanthanide-induced enhancements of the relaxation rates (Table 1).

In order to determine the phenyl ring rotation rate constants for **I**, the temperature dependence of the 1D NOE spectra was investigated. The temperature variation of 1D NOE spectra of **I** is shown in Figure 3. The 1D NOE spectra were obtained by saturating *endo-ortho* and *endo-meta* signals. Upon saturation of *endo-ortho* and *endo-meta* signals, strong negative connectivities with signals *exo-ortho* and *exo-meta,* respectively, are observed. A temperature decrease results in a decrease of intensities of these negative peaks. This is consistent with the observed negative peaks being due to saturation transfer. We used these experimental data to evaluate the rate constants for the rotation of the phenyl rings. The time dependence of the longitudinal magnetization in an observed site at a transfer of saturated spins from the irradiated site is well known.[7a] During the irradiation the absorption intensity in the observed site [$v(t)$] falls off exponentially to a new steady state level [$v(\infty)$] due to transfer of saturated spins from the irradiated site. The rate of attainment of the new steady state, as well as its intensity, is determined by T_1 and the pre-exchange lifetime ($1/k$) of the observed site. Therefore, the rate constants were obtained using the following ratio [Equation (2)][7a] where $v(0)$ is the absorption intensity in the observed site without irradiation of another site.

$$k = [v(0) - v(\infty))/(v(\infty)\ T_1] \quad (2)$$

The measured intensities of the saturation transfer spectra (Figure 3) allowed us to determine the phenyl ring-flip rate constant [k(298 K) = 11.4 s^{-1}] and the activation enthalpy for this process ($\Delta H^{\ddagger}$ = 48.0±6.0 kJ mol^{-1}).

An increase of the activation enthalpy along the series of lanthanide oep-tpp sandwich complexes reflects a larger steric barrier. Therefore, the differences in activation enthalpy of complexes **II** with respect to **I** may be related to a slight decrease of the porphyrin inter-plane distance. This is consistent with the ionic radius decrease along the series of lanthanide metals, known as *"lanthanide contraction"*.

In order to access this possibility, we have analyzed the available NMR and structural data on these complexes using Equation (3). It was assumed that the dipolar term dominates in the lanthanide-induced enhancements of spin-lattice relaxation rates on the ligand nuclei for **I** and **III**. The comparison of the calculated values of the structural parameter [$r(i)/r(CH_3)$], where r is distance between the lanthanide cation and the resonated proton,[10a−10c] (Table 1) for **I** and **III** reveals that the corresponding values in both complexes are rather similar although not identical.

$$r(i)/r(CH_3) = [T_1(i)/T_1(CH_3)]^{1/6} \quad (3)$$

The observed small differences between two complexes can be due either to an error in determination of $T_1(i)$ values or to minor structural differences.

A theoretical ratio has been previously reported for the variation of the pseudo-contact shifts in a series of isostructural Ln complexes.[11a,11b] In order to compare the hyperfine shifts of **I** with corresponding values of **II** (Table 1),

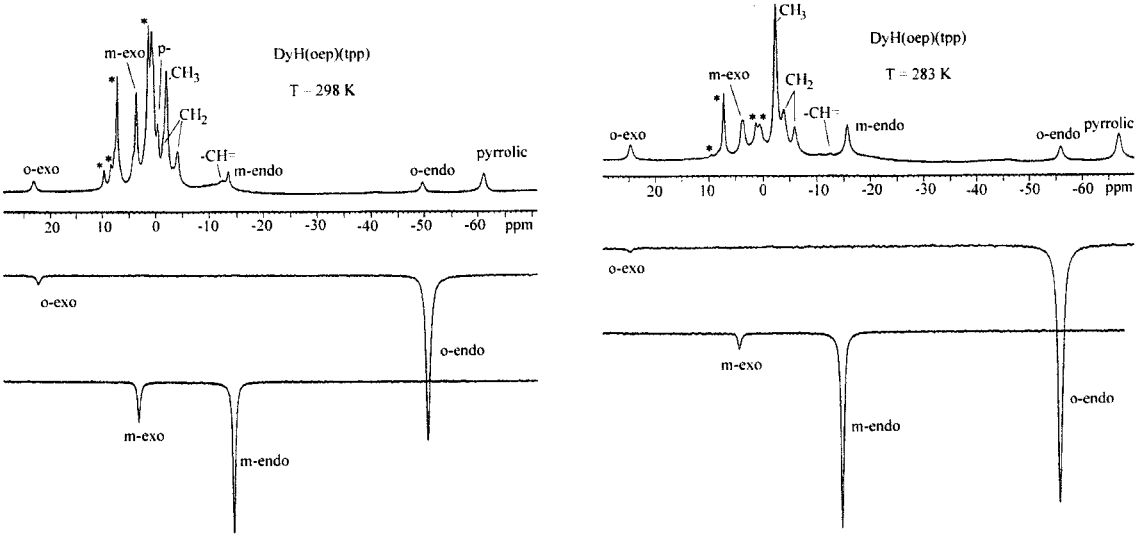

Figure 3. 500-MHz ^{1}H NMR 1D NOE difference spectra of DyH(oep)(tpp) (complex **I**) in $CDCl_3$ solution at various temperatures; assignment of diastereotopic phenyl proton peaks is reported; the asterisks indicate solvent or/and impurities

the parameters $\Delta\delta/B(\mathrm{Ln})$, where $\Delta\delta$ is the hyperfine shift and $B(\mathrm{Ln})$ is the Bleaney's constant,[11a,11b] were calculated. The analysis of Table 1 indicates that there is no correlation between the corresponding values of these parameters for complexes **I** and **III**. This means that the principal values (χ_i) of the molar paramagnetic susceptibility tensor change drastically from **I** to **III**, while only minor structural differences between these complexes occur. This behavior can be rationalized as due both to the effect of lanthanide contraction and to the macrocyclic nature (as basicity, planarity, etc.) of the ligand. These results are in rather good agreement with the study of complexes of macrocyclic polyether 18-crown-6 with paramagnetic lanthanide cations.[11b] The values of $(\chi_z - \chi_{av})/B(\mathrm{Ln})$ parameter are found to change monotonically three times with increase in the atomic number of Ln for Ln = Ce, Nd, and Pr with minor changes in the effective angle H−(18-crown-6)−Ln with C_2 axis of symmetry of the complexes. Therefore, the significant variation of molar paramagnetic susceptibility between complexes **I** and **III** are proposed to be related to a slight decrease of the distance between the planes of porphyrin ligands. This distance decreasing is relative to the increase in the number of lanthanide *f* electrons, which consequently results to lanthanide ionic radius contraction.

Experimental Section

Complexes **I**−**III** were synthesized according to the methods previously described.[1e,3d] Samples for NMR spectroscopy were prepared by dissolving **I**−**III** in deuterated chloroform. NMR spectra were recorded using MSL 200 and DRX 500 Bruker spectrometers operating at 200.13 and 500.13 MHz Larmor frequencies, respectively. Recycle delays and irradiation times ranged from 50 to 350 ms and from 20 to 200 ms, respectively. The spectra were calibrated by assigning the residual chloroform signal at 298 K to a shift from TMS of $\delta = 7.23$. 1D NOE spectra were recorded in difference mode using acquisition schemes previously described.[8a,8b] The chemical shift values of the diamagnetic LuH(oep)(tpp) complex[3d,3e] were used to calculate the hyperfine shifts for paramagnetic complexes **I** and **III**.

Longitudinal relaxation times were measured using a nonselective inversion recovery pulse sequence.[9a] The T_1 values were obtained from a two-parameter fit of the data to an exponential recovery function. In all cases the magnetization recovery was found to be exponential within the accuracy of the experiment, as expected for fast relaxing nuclei with little cross relaxation and favorable chemical exchange conditions.[9b]

Solution temperature was controlled using a Bruker B-VT 1000 temperature controller. Fourier-transformed spectra were subjected to complete line shape analysis[7a,7b,7d] on a Pentium-166 computer to obtain rate data for complexes **II**.

Boron-Bridged Group-4 *ansa*-Metallocene Complexes

Pamela J. Shapiro[a]

Keywords: Group-4 elements / Metallocenes / Boron bridge / Lewis acids / Alkene polymerization

Boron-bridged group-4 *ansa*-metallocene complexes are newcomers to the field of metallocene-mediated olefin polymerization catalysis. Because of the Lewis acidity of the boron bridge, it is more reactive than the more common carbon and silicon bridges. It is also more vulnerable to cleavage from the ligand framework by nucleophilic agents. A primary goal of our work is to involve the boron bridge more actively in the reaction chemistry of the metallocene while keeping the bridge intact.

Introduction

Metallocenophanes and *ansa*-Metallocenes

The earliest examples of interannular-bridged metallocenes are ferrocene derivatives and are called ferrocenophanes in association with the nomenclature system for bridged, aromatic, organic compounds.[1−3] The first examples of interannular-bridged metallocene complexes of the group-4 transition metals were synthesized by Katz and by Bernal;[4,5] however, Brintzinger is responsible for popularizing these systems and for popularizing the term "*ansa*-metallocene".[6] The latin prefix *ansa* (for bent handle, attached at both ends) was also borrowed from the organic nomenclature for bridged aromatic compounds. The term *ansa*-metallocene has generally been applied to bridged, bent-metallocene complexes of main-group metals,[7−10] the early transition metals (groups 3−7)[11−22] and the lanthanide metals,[23−27] whereas the term metallocenophane continues to be used for the bridged sandwich compounds of iron and ruthenium.[28−30]

Group-4 *ansa*-metallocene complexes are currently favored for the stereocontrol that they afford in Ziegler−Natta-type olefin polymerization catalysis.[31−33] These complexes are also popular as catalysts for various asymmetric organic transformations.[34] Although a number of different bridging groups have been introduced, carbon and silicon moieties are most common and have served a primarily structural role, that of fixing the cyclopentadienyl, indenyl, or fluorenyl rings of the metallocene in a specific orientation with respect to the active site. The bridge has also been designed to direct the stereochemistry of ring addition during metallocene formation;[11] however, to date, there has been little *chemical* participation of the *ansa* moiety in the reactions occurring at the transition metal center.[25]

This chemical participation has been one of the goals of our research. To this effect we have incorporated an electrophilic borylidene moiety in the *ansa* position of the metallocene. One of our objectives is the activation of the transition metal center by the boron bridge in a manner currently accomplished by external Lewis acid coactivators. The potential to couple geometry changes at the boron bridge with chemistry occurring at the transition metal center is another attractive feature of this new class of *ansa*-metallocenes.

Although related to the boron-bridged systems described herein, group-4 metallocenes with dangling boryl groups will not be covered in this review article. Participation of the dangling boryl group in the chemistry of the transition metal has been demonstrated by Piers and co-workers.[35] Bochmann and co-workers have modeled intramolecular activation of ligands on the metal center by boron.[36] Their examples indicate that the ability of the Lewis-acidic boryl

The author was born in Boston, Massachusetts (USA) in 1962. Her interest in transition metal mediated catalysis was inspired by her undergraduate research experience in the laboratories of Professor K. B. Sharpless while she was earning her Bachelor of Science degree at MIT. She received her training in synthetic and mechanistic organometallic chemistry as a Ph.D. student in the research group of Professor J. E. Bercaw at Caltech in Pasadena, CA. After a postdoctoral year at DuPont's Experimental Station in Wilmington, DE, in 1991 she joined the chemistry faculty at the University of Idaho where she is currently Associate Professor of Inorganic Chemistry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

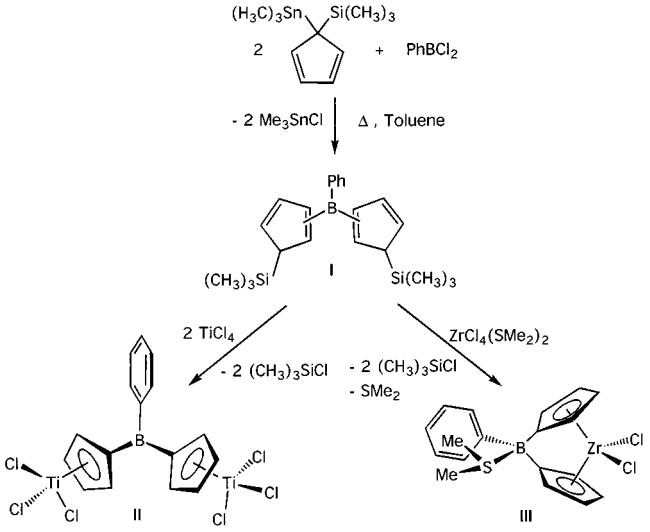
group to activate the metal complexes intramoleculary by σ-ligand abstraction is very sensitive to the proximity of the boryl group to the ligands. In this respect, dangling the boryl group over the active site of the metal center is more effective than including it within the interannular bridge of the metallocene. Nevertheless, *inter*molecular activation of the metal center of another complex by the boron bridge is still possible and does occur. Additional examples of group-4 metallocene complexes with dangling boryl groups are found in ref.[37−40,41b]

Syntheses of Boron-Bridged *ansa*-Metallocenes

Manners and co-workers reported the first example of a [1]borylidene-bridged metallocene, which was prepared by treating 1,1′-dilithioferrocene with an aminodichloroborane.[30] Unfortunately, a similar approach for introducing a boron atom between the cyclopentadienyl rings of metallocene complexes of the more reactive group-4 metals is not possible since further metallation of the cyclopentadienyl ring is unlikely in the presence of the electrophilic group-4 metal center. Instead, the boron-bridged dicyclopentadienyl ligand framework must be assembled prior to its attachment to the group-4 metal center.

In 1979, Jutzi and Seufert reported a method for the synthesis of cyclopentadienylboranes involving the reaction of haloboranes with cyclopentadienyltrimethylsilanes and -trimethylstannanes.[41a] The presence of an additional trimethylsilyl substituent on the cyclopentadienyl ring allows the further attachment of a titanium trichloride fragment by reaction with $TiCl_4$.[41b] The avoidance of salt-metathesis reactions in these synthetic steps is attractive due to the vulnerability of the boron−cyclopentadienyl linkage to cleavage by strong nucleophiles.[42] In 1995, Reetz and co-workers reported using this chemistry to form boron-substituted zirconocenes.[37] We have also employed this chemistry for the synthesis of the boron-bridged titanium homobimetallic complex **II** and the *ansa*-zirconocene complex **III** shown in Scheme 1.[43]



Scheme 1. Syntheses of boron-bridged titanium homobimetallic complex **II** and *ansa*-zirconocene complex **III**

The more labile trimethylstannyl substituents on the cyclopentadienyl rings are required for the ring borylation step. Formation of an *ansa*-metallocene was not expected from the reaction of ligand **I** with $TiCl_4$ since it has been shown that the attachment of only *one* cyclopentadienyl ligand to the titanium center is possible by this dehalodesilation route.[44] On the other hand, although zirconium tetrachloride has been shown to readily metallate two trimethylsilylcyclopentadiene rings by this route, it is completely unreactive toward ligand **I**, as are $[ZrCl_4(THF)_2]$ and $[ZrCl_4(THT)_2]$ (THT = tetrahydrothiophene). Fortunately, $[ZrCl_4(SMe_2)_2]$ does react with **I** to form the *ansa*-metallocene **III**, in which one of the dimethyl sulfide ligands is retained as an adduct on the phenylborylidene bridge. The attachment of an electropositive boron atom to the ring system apparently deactivates the silyl substituents toward electrophilic substitution by Zr^{IV} such that only a non-oligomeric, weakly solvated source of $ZrCl_4$ is suitable. Even when **I** is treated with two equivalents of $[ZrCl_4(SMe_2)_2]$, the *ansa*-metallocene is formed preferentially. We have used this same reaction to generate various other boryl-cyclopentadienylzirconium complexes, including $[\{Ph_2(SMe_2)B(C_5H_4)\}ZrCl_3]$ and $[\{(C_6F_5)_2(SMe_2)B(C_5H_4)\}ZrCl_3]$,[45] in which the boryl group is pendant to but not bridging between the cyclopentadienyl rings.

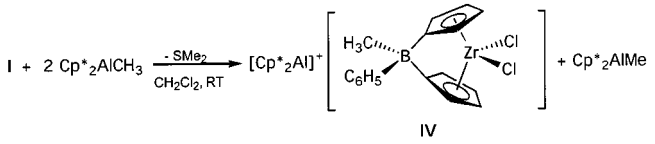
We believe that the dimethyl sulfide assists in the formation of the *ansa* complex since its coordination to the boron rehybridizes the single-atom bridge from an sp^2 to an sp^3 geometry which can better accommodate the bent-metallocene structure. As we were preparing to publish our findings, we discovered a report on the synthesis of the base-free version of **III** by Rufanov and co-workers.[46] These authors employed bis(trimethylstannyl)cyclopentadiene as the precursor to their boron-bridged ligand, forming the stannylated analog of **I**, which was treated directly with $ZrCl_4$. A mononuclear, *ansa*-metallocene structure was proposed for the base-free species, although an X-ray crystal structure was not obtained, and the molecular weight of the complex was not determined. The validity of this assignment is still in question, and we have not yet successfully prepared the base-free *ansa*-metallocene either by the Rufanov method or by complete removal the dimethyl sulfide adduct from **III**.

Lewis Aciditiy of Phenylborylidene Bridge

Efforts to abstract the Lewis base adduct from **III** with a stronger Lewis acid have been, so far, unsuccessful. Surprisingly, when either **III** or the related *tert*-butyl isocyanide complex are combined with an equimolar amount of $B(C_6F_5)_3$ in CD_2Cl_2, only partial abstraction of the Lewis base adduct (30−37%) by $B(C_6F_5)_3$ from the phenylborylidene bridge is observed by ^1H and ^{19}F NMR spectroscopy at 273 K.[47] We expected the boron atom of the phenylborylidene bridge to have an electrophilicity more comparable to that of BPh_3 based on its substitution. Indeed, ν(CN) for the *tert*-butyl isocyanide analog of **III**, $[\{(Ph)(tBuNC)B(\eta^5\text{-}C_5H_4)_2\}ZrCl_2]$, is identical to that of $Ph_3B(CN-tBu)$ (2272 cm^{-1})[48] and substantially lower than that of

$(C_6F_5)_3B(CN-tBu)$ (2310 cm^{-1}).[49] Thus, we surmise that the greater affinity of **III** for its Lewis base adducts arises from the relief of the internal strain which would exist in the sp^2-hybridized boron bridge.

The reactivity of the borylidene bridge in **III** also reveals a Lewis acidity more comparable to that of $B(C_6F_5)_3$ than BPh_3, since **III** is able to accomplish methide abstraction in a manner similar to that of $B(C_6F_5)_3$. For example, reaction of **III** with Cp^*_2AlMe ($Cp^* = C_5Me_5$) affords the pentamethylaluminocenium cation $[Cp^*_2Al]^+$ with $[(Ph)(Me)B(\eta^5\text{-}C_5H_4)_2ZrCl_2]^-$ as the counteranion [Equation (1)]. $B(C_6F_5)_3$, but not BPh_3, reacts in a similar manner with Cp^*_2AlMe.[47]



IV

The formation of **IV** is important as it indicates the possibility of stabilizing a borate-bridged *ansa*-zirconocene complex as a zwitterion (Figure 1).

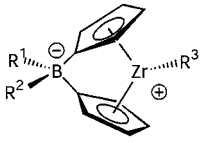


Figure 1. Hypothetical borate-bridged *ansa*-zirconocene zwitterion

It is clear, however, that the countercation plays a role in the stability of the borate bridge. The stability of **IV**, with its permethylaluminocenium countercation, suggests that a sterically hindered, non-intrusive countercation is desirable. This is further supported by the synthesis of a variety of stable borate-bridged *ansa*-zirconocene salts by treating **III** with $[Bu_4N]X$ (X = Cl, Br, I, BF_4, BH_4) and $[(Ph_3P)_2N]Cl$.[45] The borylidene bridge in **III**, like $B(C_6F_5)_3$, also abstracts a methyl anion from Cp_2ZrMe_2, as indicated by ^1H and ^{11}B NMR spectra of the reaction. We are currently trying to isolate and fully characterize the product of this reaction.

Alkylation of Boron-Bridged *ansa*-Zirconocene Complexes

Alkylation of the transition metal center is an essential step in forming an active catalyst center for olefin polymerization and other applications in catalysis. The vulnerability of the electrophilic boron bridge to nucleophilic attack and subsequent cleavage from the cyclopentadienyl ring is probably responsible for our unsuccessful efforts to alkylate complex **III** using conventional organometallic alkylating reagents such as alkyllithium, Grignard, alkylzinc, and alkylaluminum reagents. Such cleavage of the boryl group from the cyclopentadienyl ligand has been encountered in other cases.[43,49]

Dynamic behavior observed in the variable-temperature ^1H NMR spectra of **III** revealed that the dimethyl sulfide adduct is only weakly coordinated to the boron. It is readily replaced by more tightly coordinating ligands, such as PMe_3, to form $[\{Ph(PMe_3)B(\eta^5\text{-}C_5H_4)_2\}ZrCl_2]$ (**V**) which, unlike **III**, is non-labile on the NMR time scale [Equation (2)].[43]

III V

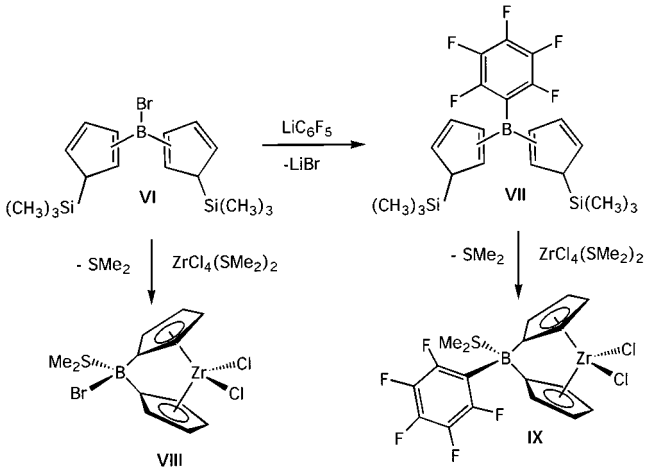
This substitution protects the boron sufficiently to allow alkylation of the zirconium center by alkyllithium and Grignard reagents to form complexes of the type $[\{Ph(PMe_3)B(\eta^5\text{-}C_5H_4)_2\}ZrR_2]$ (R = CH_2SiMe_3, $CH_2C_6H_5$), which can be activated with either $B(C_6F_5)_3$ or $[PhMeNH]^+[B(C_6F_5)_4]^-$ toward ethylene and propene polymerization.[45] A related phenylborylidene-bridged bis(indenyl)zirconium dichloride complex was recently reported by Reetz and co-workers.[50] The trimethylphosphane adduct of this complex, upon activation with MAO (MAO = methylalumoxane), was found to be a better catalyst for the polymerization of propene than the diethyl ether adduct, presumably due to stronger complexation of the boron by PMe_3. Similarly, complex **V**, with its tightly coordinating PMe_3, is activated by MAO toward olefin polymerization. Complex **III**, however, with its weakly coordinating SMe_2, is completely inactive under the same reaction conditions. Complex **IV** and other borate-bridged complexes such as $[NEt_4]^+[\{Ph(Cl)B(\eta^5\text{-}C_5H_4)_2\}ZrCl_2]^-$ and $[(Ph_3P)_2N]^+[\{Ph(Cl)B(\eta^5\text{-}C_5H_4)_2\}ZrCl_2]^-$ are also activated by MAO toward olefin polymerization, although their activities in the polymerization of ethylene were found to be lower than that of **V**.[47]

Other Boron-Bridged Group-4 Metallocene Complexes

The phenyl group on the borylidene bridge may be replaced with other substituents for the purpose of fine-tuning the electrophilicity of the boron. By using BBr_3 instead of $PhBCl_2$ in the ligand synthesis shown in Scheme 1, we are able to prepare ligand **VI**, in which the bromine is readily replaced by other moieties, such as the pentafluorophenyl group in ligand **VII**. These ligands were used to prepare complexes **VIII** and **IX** (Scheme 2). A variable-temperature ^1H NMR study shows that, in contrast to complex **III**, the dimethyl sulfide adduct in complex **IX** is non-labile on the NMR time scale.[45]

An X-ray crystal structure of complex **IX** confirmed its formulation but the structure is highly disordered with an unidentified solvent molecule. A preliminary ORTEP drawing of the molecule is shown in Figure 2.[51]

Introduction of an amido group onto the boron bridge allows the isolation of base-free group-4 *ansa*-metallocenes complexes, examples of which have been reported by Braunschweig and by Ashe (Figure 3).[52,53] π-Electron donation from the nitrogen to the boron is evident in the X-ray crystal structures of these complexes and is presumably responsible for the greater stability of the base-free boron



Scheme 2. Variations on the substitution of the boron bridge

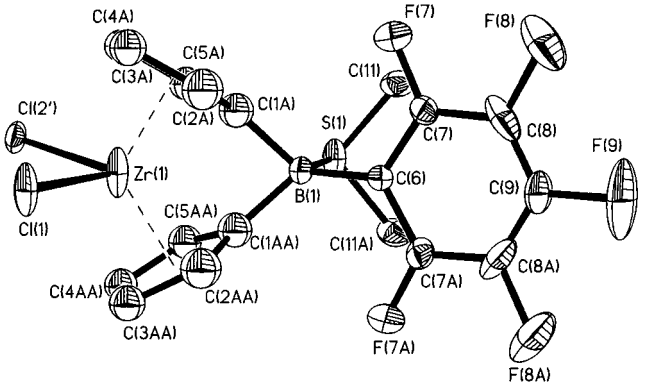


Figure 2. Preliminatry ORTEP drawing of the molecular structure of **IX**; thermal ellipsoids are drawn at 30% probability

bridges. Complex **XI**, upon activation with MAO, exhibits polymerization activities in the range exhibited by Me_2Si-bridged zirconocenes.

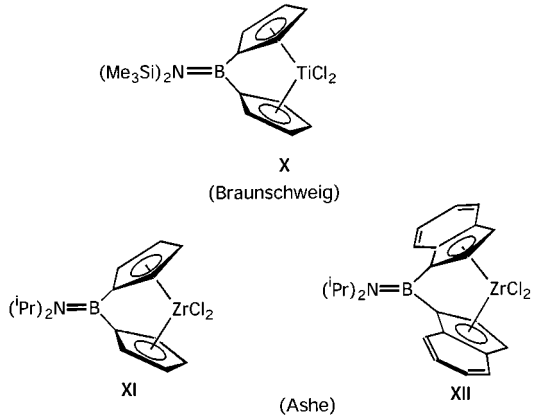

Figure 3. Amidoborylidene-bridged *ansa*-metallocene complexes of Ti^{IV} and Zr^{IV}

As mentioned above, Reetz and co-workers have recently reported the synthesis of a bis(indenyl)zirconium dichloride complex with different Lewis bases coordinated to the phenylborylidene bridge (**XIII**, Figure 4).[50] Reaction of the dianionic indenyl ligand with $ZrCl_4$ affords a 1:1 mixture of *rac*- and *meso*-metallocene isomers, from which the *rac* isomer can be selectively crystallized in 12% yield. The PMe_3 adduct of this system exhibits high propene polymerization activity as well as high selectivity for an isotactic polymer. Base-free, methylborylidene- and tris(trimethylsilyl)borylidene-bridged analogs of C_2-symmetric bis(indenyl)zirconium complexes were reported separately by Rufanov and co-workers, although no X-ray crystallographic data confirming the structures are available.[54]

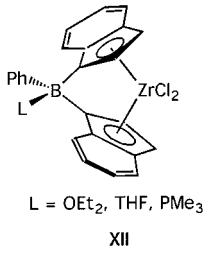

Figure 4. Phenylborylidene-bridged *rac*-bis(indenyl)zirconium complex prepared by Reetz and co-workers

A new paradigm for the synthesis of interannularly bridged metallocenes involving the formation of a donor/acceptor linkage between a Lewis-acidic boryl substituent on one ring of the metallocene and a Lewis-basic substituent on the opposite ring was introduced by Starzewski and co-workers (**XIV**, Figure 5).[55] This self-assembly approach to bridge formation affords enormous synthetic control and versatility in the design of the *ansa*-metallocene complexes since the electronic and steric properties of the donor and acceptor components are easily varied and the final stereochemistry of the metallocene, i.e. the relative orienation of asymmetrically substituted cyclopentadienyl rings or indenyl rings, is more easily controlled.

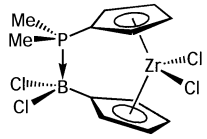

Figure 5. Donor/acceptor *ansa*-zirconocene complex introduced by Starzewski and co-workers

Structural Features of Boron-Bridged *ansa*-Zirconocene and -Titanocene Complexes

Table 1 lists selected geometric features of crystallographically characterized boron-, silicon-, and 1-, 2-, and 3-carbon-bridged metallocenes. The bite angle ε of the bridge, the dihedral angle α between the ring planes, and the angle γ formed by the metal center and the ring centroids are defined in Figure 6.

The narrowing of γ and the widening of α relative to the two-carbon- and three-carbon-bridged complexes reflects the distortion of the *ansa*-metallocenes from a "normal" geometry. The degree of distortion caused by a boron bridge is much larger than that of a silicon bridge but not quite as large as the distortion in a carbon-bridged *ansa*-metallocene.

Large changes in the size of the bridge bite angle ε produce relatively small changes in γ and α. For instance, despite a difference of over 5° in the bridge bite angles for the

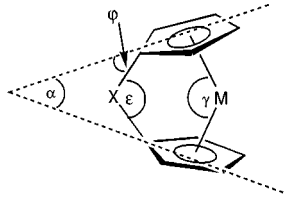

Figure 6. Illustration of *ansa*-metallocene angles listed in Table 1

final two entries of Table 1, the magnitudes of γ and α for the two complexes are nearly identical. This is due to a compensating distortion, represented by angle φ, in which the bridging atom bends away from the plane of the cyclopentadienyl or indenyl rings. The bending distortion of the bridge for the final complex (φ =18° and 20°) is greater than that of the preceding complex (φ =16° and 16.5°).

The bite angles of the base-free amidoborylidene-bridged species, complexes **II**, **XI**, and **XII**, are quite narrow for sp^2-hybridized boron atoms (cf. the 127° bridge angle for the bimetallic titanium complex **II** shown in Scheme 1[39]), illustrating the considerable strain experienced by an sp^2-hybridized boron atom in the *ansa* position.

Increasing the reaction space about the transition metal center by reducing the size of the bridge has been found to improve metallocene catalyst activity in some instances[56–58] and diminish it in others.[59][60] The effect of ring tilt on the olefin polymerization activity of metallocene catalysts is somewhat unpredictable because it depends on the type of rings comprising the ligand framework as well as on their substitution.[61–63] For example, [$Me_2Si(Ind)_2ZrCl_2$] generates a better catalyst for propene polymerization than [$Me_2C(Ind)_2ZrCl_2$] upon activation with MAO;[61] however, the reverse is true when the indenyl rings are substituted with *tert*-butyl groups at the 3-position.[63]

We have already noted from the data in Table 1 that the boron-bridged metallocenes are more distorted from a relaxed metallocene geometry than the silicon-bridged complexes but less distorted than the carbon-bridged complexes. Polymerization studies to date have shown that, with suitable protection of the boron, the activity and isospecificity of the boron-bridged complexes can be comparable to that of silicon-bridged analogs.[50,53] Furthermore, the potential to tune the electronic properties of the boron bridge, and consequently the transition metal center,[64] expands the range of ligand modification opportunities available for controlling the activity and selectivity of the metallocene catalyst.

Summary

The viability of boron-bridged goup-4 *ansa*-metallocene complexes as olefin polymerization catalysts that are competitive with the more common carbon- and silicon-bridged systems has been demonstrated. Although the boron bridge tends to be more vulnerable to nucleophilic attack and subsequent cleavage from the metallocene rings, tightly coordinating Lewis bases can protect it from this type of degradation. Furthermore, anionic borate bridges remain intact when accompanied by a suitable countercation.

Base-free, boron-bridged species have been prepared by introducing substituents that can donate additional π-electrons to the empty p orbital on the boron. In the absence of such stabilization, the sp^2-hybridized boron bridge behaves as a strong Lewis acid because of the internal strain it experiences in the *ansa* position, strain which can be somewhat relieved by rehybridization of the boron to sp^3 through the coordination of a Lewis base. This property, together with the ability of the boron to coordinate a wide variety Lewis bases, expands the potential functionality of the *ansa* bridge well beyond the structural role that it normally plays.

Acknowledgments

I thank my talented co-workers listed in the references for their contributions to this chemistry, and I am grateful to the National Science Foundation and the University of Idaho for their support. I am also grateful to Dr. Brendan Twamley (University of Idaho) for calculating many of the angles in Table 1 from the original crystal structure data and for proof-reading this manuscript.

The Effect of Internal Hydroxy Groups in Chiral Diphosphane Rhodium(I) Catalysts on the Asymmetric Hydrogenation of Functionalized Olefins

Armin Börner[a]

Keywords: Asymmetric synthesis / Cooperative effects / Hydrogenation / Phosphanes / Rhodium

The unique effects of internal hydroxy groups in chiral rhodium(I) diphosphane catalysts on the asymmetric hydrogenation of functionalized olefins are summarized. In the first part, effects caused by the additional functional group on the rate and enantioselectivity of the catalytic reaction with Rh^I-diphosphane complexes are shown. For comparison, the results obtained with relevant parent catalysts or complexes bearing alkoxy groups are also considered. Subsequently, mechanistic studies which may explain the rate-reducing as well as the *ee*-enhancing effect of hydroxy groups are discussed in detail. Furthermore, the subtle competitive interplay between the hemilabile behaviour of hydroxy groups and their ability to establish hydrogen bonding within the framework of the ligand or between the ligand and the substrate is shown. Proof is given that conformationally flexible ligands bearing hydroxy groups can respond to varying electronic features of the catalytic centre and the substrate. Finally, the beneficial effect of hydroxy groups on the fine-tuning of diphosphane catalysts of low performance is demonstrated for some examples. This modification resulted in catalysts which afforded the chiral hydrogenation product in up to 99% *ee*.

Introduction

The effective control of stereoselective transformations is at the centre of modern organic chemistry research.[1] In stereodifferentiating catalysis employing transition metal complexes, two principal interactions between the catalyst and the prochiral substrate can be identified and these interactions enable chiral recognition: stereodiscriminating bond formation and diastereoselective repulsive interactions. These factors lead to diastereomeric intermediates with different thermodynamic stabilities and consequently in different concentration ratios. The diastereomeric intermediates in turn react to form the enantiomeric products. Owing to the energy differences of the intermediates, the rates are more or less different. For most catalytic reactions, the thermodynamic stabilities of the intermediates as well as the rate constants of the pre-equilibrium and the rate-determining steps are not available and cannot be predicted by theoretic methods. Consequently, the design of asymmetric catalysts is mainly based on trial and error.

To optimize chiral catalysts of low performance, several approaches have been envisaged. The most common way is to increase the bulkiness of selected parts of the ligand or to ensure rigid or restrained conformations of the catalyst.[2,3] Achiwa[4] and RajanBabu[5] showed that in some cases electronic effects can be advantageously employed for the fine-tuning of chiral catalysts. Most of these approaches consider the chiral catalyst as being static and focus on the construction of conformationally fixed molecules and do not take the varying steric and electronic features of catalytic intermediates or different substrates into consideration.[6]

Armin Börner received his Ph.D. in 1984 from the University of Rostock (Germany) with Prof. H. Kristen, working in the field of carbohydrate chemistry. He moved to the Department of Complex Catalysis of the Academy of Sciences of the former GDR, at that time led by Prof. H. Pracejus. After some research stays in the pharmaceutical industry and abroad (1981, Debrecen, Hungary; 1987, Hyderabad, India), he joined the group of Prof. H. B. Kagan at the Laboratoire Synthèse Asymétrique at Orsay (France) in 1991 for a postdoctoral position. In 1992 he joined the "Asymmetric Catalysis" group at the Max-Planck-Gesellschaft (leader Prof. R. Selke), where he finished his habilitation in 1994. In 1993/94 he was a guest lecturer at the University of Würzburg. Currently, he is working as head of department at the Institut für Organische Katalyseforschung (IfOK). In 2000 he was appointed a C3-professor for "Asymmetric Catalysis" at the university of Rostock. His main research is focused on basic research in asymmetric catalysis with transition metals and its application in industry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

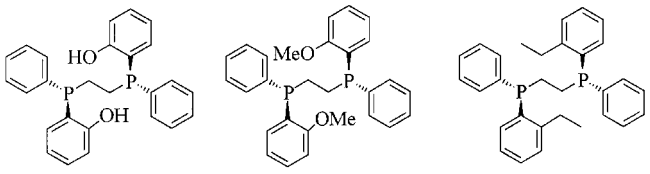
In 1992 Sawamura and Ito addressed the question of the benefit of secondary interactions in asymmetric metal catalysis.[7] Since that time, we and several other groups have elaborated the synthesis and application of chiral ligands containing additional functional groups. The aim was to control the conformational fluxionality within diastereomeric catalyst−substrate assemblies by electrostatic interactions,[8] π,π-interactions,[9] charge-transfer interactions,[10] hydrogen bonding,[11] Lewis acid/base interactions[12] or by inclusion in crown ethers.[13]

In particular, we were interested in investigating the influence of hydroxy groups in the backbone of conventional chiral diphosphane Rh^I-catalysts on the asymmetric hydrogenation. This reaction is of pivotal importance from an academic point of view[14] as well as for practical applications.[15] In the beginning of the research, we focused our attention on the synthesis of chiral hydroxy phosphanes and developed main strategies for their preparation. This work has recently been reviewed.[16] In this paper we will concentrate on the effects caused by hydroxy groups in diphosphane metal catalyst on the asymmetric hydrogenation. Simultaneously, reasons for these peculiar effects will be discussed. It should be noted that the effect of other "active" functional groups like amino or carboxylate groups are also worth being elaborated on, but are not considered here in detail.[7] Other typical features of phosphane ligands bearing hydroxy groups, such as the improvement of the solubility of the catalyst in water,[17] transformations into other functional groups[18] or the construction of heterobimetallic catalysts[12d,12e] have been discussed elsewhere.

In order to illustrate the distinct behaviour of the hydroxy group in the hydrogenation catalysts, comparison with closely related catalysts acting under the same conditions is necessary. From this point of view, valuable information can be derived particularly by comparison with analogous catalysts bearing alkoxy groups. The beneficial effect of alkoxy functionalities, especially that of the OMe group in asymmetric hydrogenation, has been more thoroughly investigated and employed in the past.[19] Principally, the OMe and the OH groups have some common features in catalysis, e.g. both can act as hemilabile ligands[20] and show a "windshield wiper effect" if properly placed,[21] but only the latter is able to serve as a hydrogen-bond donor. In this review, similarities between both are analyzed, but evidence will be also provided to show that the structural differences can have a significant influence on the course of the rhodium-catalyzed asymmetric hydrogenation.

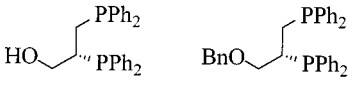
Effects and Preliminary Results

As far back as 1982, Knowles et al. briefly noted that by substitution of the methoxy groups in the industrially applied DiPAMP[22] ligand (**1-OMe)** by OH groups (**1-OH**), a hydrogenation catalyst was obtained which exhibited good enantioselectivity but rather poor reactivity.[23] This sporadic observation indicated for the first time that the hydroxy group may be used for enantiocontrol. Furthermore, a relationship between the additional functional group and the lowered rate of the asymmetric hydrogenation was found.



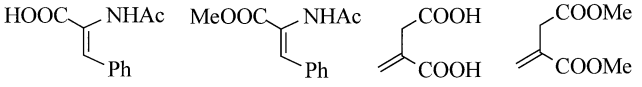
1-OH **1-OMe (DiPAMP)** **1-Et**

In the same year, Amma and Stille reported the synthesis of (*R*)-1,2-bis(diphenylphosphanyl)propan-3-ol (**2-OH**).[24]



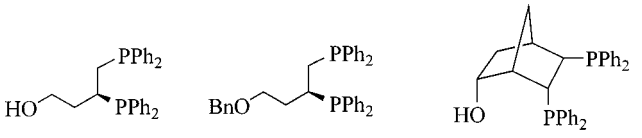
2-OH **2-OBn**

Attempts to utilize this ligand in the asymmetric hydrogenation of (*Z*)-*N*-acetylamino acrylic and (*Z*)-*N*-acetylamino cinnamic acid (AH), which are commonly used as standard substrates,[25] failed owing to the poor activity of the relevant Rh^I complex. Interestingly, by benzylation of the OH group (ligand **2-OBn**) an active catalyst was obtained.



AH **AMe** **ItH_2** **$ItMe_2$**

We explored the same catalytic reaction with the homologous ligand **3-OH**.[26] The corresponding Rh-catalyst hydrogenated AH and its methyl ester (AMe) very slowly. This negative effect could be overcome by protection of the OH-group as the benzyl ether (**3-OBn**).

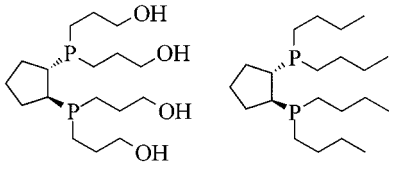


3-OH **3-OBn** **4 (HO-NorPHOS)**

At this time we concluded that an attractive interaction between the OH group and other parts of the catalyst−substrate complexes could be responsible for the observed decelerating effect. It is worth mentioning that the hydrogenations described above were performed in a large excess of methanol. In general, with parent catalysts no rate-reducing effects were observed in this solvent. That means that the effect of the hydroxy group could unambiguously be attributed to intramolecular and not to intermolecular interactions. In a ligand based on a rigid carbon skeleton such as **4**, this interaction should be disturbed. Indeed, **HO-NorpHOS** gave a hydrogenation catalyst with an activity similar to Brunner's **NorPHOS**, in spite of the fact that

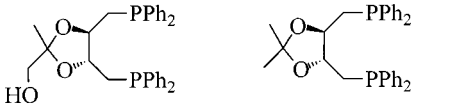
the former was also based on the 4-hydroxy-1,2-bis(diphenylphosphanyl)butane moiety like **3-OH**.[27]

In the meantime, other groups also reported interesting catalytic effects observed after functionalization of phosphane catalysts. Thus, Dahlenburg and Kurth found that by incorporation of hydroxy groups, bis-trialkylphosphanes such as **5-H** may get profit in the Rh^I-catalyzed asymmetric hydrogenation of AH.[28] **5-OH** showed a 12% higher enantioselectivity than was observed with the parent ligand.

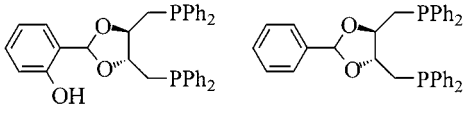


5-OH **5-H**

All the 1,2-diphosphanes described above form five-membered chelates with rhodium(I). Owing to the low conformational flexibility of this chelate size, attractive interactions of the additional functional group may be hindered or even overridden by steric effects. For example, Imamoto et al. found similarly high *ee*'s by application of a rhodium(I) complex with the DiPAMP analogous ligand **1-Et**.[29] Based on this result, they advocated the idea that the effect of the methoxy group in the DiPAMP−Rh-catalyst is based preferentially on steric reasons. A change of the reaction rate owing to the nonpolar ethyl group was not reported. Prompted by this result, we next turned our attention to the synthesis and application of conformationally flexible seven-membered chelates of the DIOP type like **6-OH** and **7-OH**.[30]



6-OH **6-H (DIOP)**



7-OH **7-H**

Surprisingly, under reduced H_2 pressure, Rh^I catalysts based upon these hydroxy phosphanes reduced the standard substrates more slowly than their parent catalysts derived from **DIOP** and **7-H**.[31] These results gave evidence that a remote OH group may also influence the rate and thus the mechanism of the asymmetric reaction. In several instances, improved enantioselectivities were also noted owing to the effect of the hydroxy group, but this correlation was not generally valid for all pairs of ligands tested. Interestingly, the X-ray structural analysis of the precatalyst [Rh(**6-OH**)(COD)]BF_4 gave no evidence that the OH group interfered with the rhodium centre. In contrast the hydroxy group was found to be situated far away from the metal. This fact indicated that the decisive interaction of the functional group with the catalytic centre is of low energy and may first come into play during the catalytic cycle or at least after coordination of the prochiral substrate.

Recently, Kagan et al. noted a striking enhancement of the enantioselectivity from 45% *ee* to more than 85% *ee* in the hydrogenation of AH, when the isopropylidene-protected bis-ferrocene ligand **8-Isoprop** was replaced by the corresponding diols **8-OH**.[32] It is noteworthy, that the increase in the *ee* found with these OH substituted nine-membered chelates was almost independent of the configurations at the 2,3-positions (**8(a-c)-OH**).

Mechanistic Studies

To better elaborate the dual effect of the OH group, we required a suitable model catalyst. As discussed above, conformers of 1,2-diphosphane chelates might be too rigid to permit a clear differentiation between attractive interactions within the catalyst−substrate assembly and sterically driven effects due to the 5-membered ring. Furthermore, because of the conformational rigidity, low hydrogenation rates are generally characteristic for these hydrogenation catalysts. Therefore, decelerating effects caused by additional functional groups may entirely block the catalytic reaction (vide supra). Conformationally flexible seven-membered chelates and therefore more active catalysts based on 1,4-bis(diphenylphosphanyl)butane ligands bearing one or two hydroxy groups in the carbon chain seemed to be much better suited. In addition, since other stabilizing groups are not present in these model complexes, catalytic effects can clearly be traced to the effect of the oxygen functionalities.

In a first study, we compared the Rh^I complexes of (*S*)-1,4-bis(diphenylphosphanyl)butan-2-ol (**9-OH**) and its methyl ether (**9-OMe**) in the asymmetric hydrogenation of AH, itaconic acid (ItH_2) and their corresponding methyl esters (AMe, $ItMe_2$).[33] The results are listed in Table 1. For comparison, results obtained with the Rh-complex of 1,4-bis(diphenylphosphanyl)butane (DPPB) are also included, representing a seven-membered chelate ring without any additional coordinating groups.[34a]

Table 1. Hydrogenations with [Rh(ligand)(COD)]BF_4

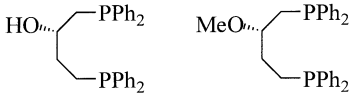
[a] Molar ratio catalyst/substrate = 1:100, 1 bar H_2 in methanol, room temp.; substrates: **AH**, **AMe**, **ItH_2**, **$ItMe_2$**. – [b] Corresponds to the time when 100% consumption of hydrogen was observed. – [c] In the original publication (ref.[34a]) times for 50% consumption of hydrogen were given. – [d] D. Heller, A. Börner, unpublished results. – [e] Hydrogenation proceeded only under elevated pressure.

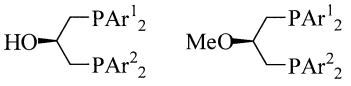


9-OH **9-OMe**

The latter is the most active catalyst in this series. It is remarkable that in comparison to the unfunctionalized catalyst, the incorporation of the methoxy as well as the hydroxy group diminished the rate of the reaction. This comparison nicely illustrates that the decelerating effect is not only restricted to the hydroxy but also to the methoxy group bearing catalysts.[35] In our opinion, this effect of the OMe group has been underestimated in the past.[36]

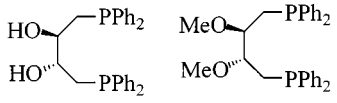
It is clear that the hydroxy group bearing catalyst gave generally superior enantioselectivities. In some cases, improvement of the selectivity by more than 35% *ee* was achieved relative to the catalyst based on **9-OMe**. In particular, the hydrogenation of substrate acids profits from this effect. Simultaneously with the enhancement of the enantioselectivity, a serious decrease in the activity was observed. In general, no change in the sense of the induced chirality was observed when **9-OH** was used instead of **9-OMe**. Interestingly, X-ray structural analysis and $^{31}P\{^1H\}$ NMR spectroscopic studies of the relevant precatalysts gave no evidence of a close proximity of the oxygen functional groups to the metal centre. This result again implicated that the decisive interaction takes place more in certain catalytic species rather than in the precatalyst.

Of relevance to this discussion are results by Huttner et al. with cationic Rh^I complexes based on chiral 1,3-bis(diarylphosphanyl)propan-2-ol (**10-OH**).[37] In the hydrogenation of standard substrates, no reduced rate was found relative to the corresponding OMe substituted catalyst (**10-OMe**). The OH group bearing catalyst was even more active than its OMe counterpart. No significant difference in the stereodiscriminating abilities of both ligands was observed. NMR spectroscopic investigations of the precatalysts in solution revealed that among different twist and chair conformations present in a dynamic equilibrium, no species was found with the oxygen group coordinated at the rhodium centre. Apparently, the absence of catalytic effects in this system commonly attributed to the OH group can be described as being a result of the high stability of the relevant conformations of the six-membered chelate which does not allow the OH group to play an active role in the chirality transfer.



10-OH **10-OMe**

In order to enhance the tendency of the hydroxy group to approach the catalytic centre, we incorporated in the butane chain of **9-OH** a second hydroxy group in a *threo* position in order to create **11-OH**.[34] For comparison, the corresponding dimethoxy ligand (**11-OMe**) was synthesized in a similar way.

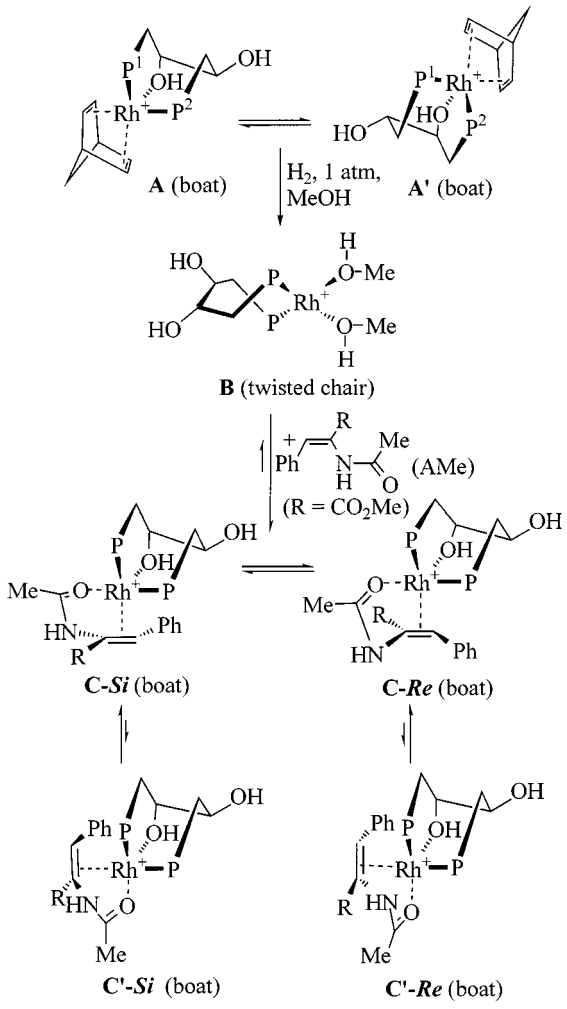


11-OH **11-OMe**

Rh^I complexes of these ligands were proofed for the asymmetric hydrogenation of standard substrates in methanol.[34a] Results are also shown in Table 1. In comparison to catalysts with only one oxygen group (**9-OMe**, **9-OH**) the incorporation of the second oxygen group further diminished the rate. As was also found with single oxygen-substituted ligands, exchange of the methoxy by hydroxy groups resulted in a significant increase in selectivity by up to 35% *ee*.

The X-ray structural analyses of the precatalysts based on **9-OH** and **9-OMe** showed some agreements but also striking differences. Neither structure was C_2 symmetric as the structures of the ligands imply. In the former, the phosphorus atoms are bonded to the rhodium with different interatomic distances (2.283 Å and 2.377 Å). Furthermore, one of the enantiotopic hydroxy groups interacts with the metal (2.396 Å) to a degree never before observed in related methoxyphosphane complexes derived from DiPAMP[38] or Nagel's PyrPHOS.[39] Owing to this interaction the seven-membered chelate is forced to adopt a boat conformation (see Scheme 1, **A**). As anticipated, one important driving force for the formation of the five-membered O–Rh–P

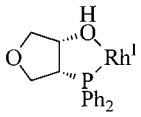
cycle is the pseudo-equatorial arrangement of the hydroxy group in the fused six-membered ring which is fixed in a distorted chair conformation.



Scheme 1. The counter-ligand-dependent O−Rh-interactions at different stages of the asymmetric hydrogenation of AMe (*P*−Ph groups are omitted)

For the structure of [Rh(COD)(**11-OMe**)]BF_4, different features were noted. Both phosphorus atoms are thus bonded at approximately equal distances to the metal. The most important difference in comparison to the hydroxy complex is the distance between rhodium and the oxygen of the neighbouring ether group (3.282 Å). This is a difference of more than 0.9 Å.

The occurrence of the five-membered O−Rh−P chelate should be also confirmed in solution. To have a model compound for this investigation, *cis*-3-diphenylphosphanyl-4-hydroxytetrahydrofuran[40] was synthesized and its cationic Rh^I complex **12** was spectroscopically characterized in solution.[41] Particularly valuable for this discussion was the observation in the $^{31}P\{^1H\}$ NMR spectrum of the downfield shift of the phosphorus signal at δ = 40.1 owing to the formation of the five-membered chelate.[42]



12

With this result in hand, we analyzed the $^{31}P\{^1H\}$ NMR spectra of the precatalyst [Rh(NBD)(**11-OH**)]BF_4 in CD_3OD, since CH_3OH was the solvent of the hydrogenation. (Figure 1a). The complex was characterized at ambient temperature by a doublet at δ = 18.1 which showed a coalescence at 243 K when the temperature was lowered. The spectrum at 189 K displayed two sets of well-separated double doublets at δ = 44.0 (J_{Rh-P} = 141.5 Hz, J_{P-P} = 41.4 Hz) and δ = −2.7 (J_{Rh-P} = 129.1 Hz, J_{P-P} = 41.4 Hz) produced by two nonequivalent phosphorus atoms. Keeping the typical downfield resonance of the five-membered hydroxy phosphane rhodium chelate **12** in mind, the resonance at δ = 44.0 could be unambiguously assigned to this ring size. The coordination of the oxygen causes the seven-membered ring to adopt the boat conformation **A** (Scheme 1) as concluded from the X-ray structural analysis. The typical change of the band shapes with decreasing temperature gave clear evidence that the doublet observed at room temperature was characteristic of a rapid exchange of the phosphane signals. This interchange of upfield with downfield and downfield with upfield phosphorus resonances caused by the alternate coordination of the two hydroxy groups was not distinguishable on the NMR time scale at ambient temperatures. Due to the C_2-symmetry of the ligand boat structures **A** and **A′** are identical.

The methoxy complex [Rh(COD)(**11-OMe**)]BF_4 showed a different behaviour with decreasing temperature (Figure 1b). The coalescence temperature was 35 K lower than in the hydroxy complex. Even at 177 K the doublets of doublets were less separated. Additionally, at δ = 17.2 a doublet was observed which corresponds in shift and coupling to that of the cationic Rh(DPPB)-complex. The signal could therefore clearly be assigned to a C_2-symmetric complex and proved that at low temperatures this complex also existed in a conformation where the oxygen atoms did not interact with the metal (Scheme 2, twisted chair-conformation **B**). Owing to these measurements, considerable differences in the populations of the conformers **A** and **B** of the hydroxy and methoxy complexes were concluded. This difference was explained by repulsive interactions between the oxygen group and the phenyl rings of the phosphanyl moiety. Increasing size of the oxygen substituent prevented the ligand from binding in the η^3-coordination mode. Further proof for this assumption came from the comparison with the corresponding bis-*O*-Ph_3Si-substituted complex. No Rh−O interaction was found owing to the bulky silyl groups.

The precatalyst in turn was converted into the catalytically active species by hydrogenation of the stabilizing diolefin (Scheme 1).[34b] The $^{31}P\{^1H\}$ NMR spectrum of the bis-methanol complex **B** at room temperature showed a doublet at δ = 47.5. In comparison to the bis-olefin com-

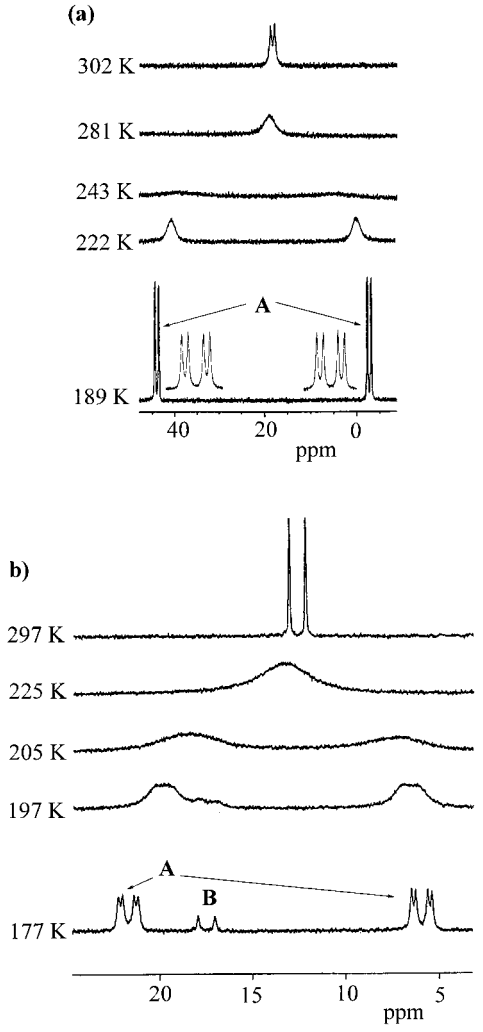


Figure 1. $^{31}P\{^1H\}$ NMR spectra of the complexes [Rh(NBD)(**11-OH**)]BF_4 (a) and [Rh(COD)(**11-OMe**)]BF_4 (b) in CD_3OD at different temperatures; the relevant equilibrium of the conformers is depicted in Scheme 1 (top) and Scheme 2, respectively

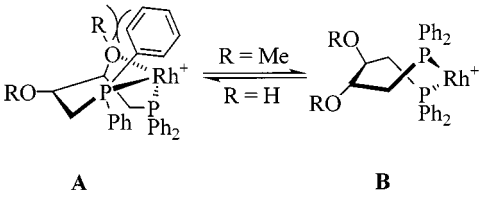


Scheme 2. Influence of the size of the *O*-substituent on the equilibrium of metal-coordinated and uncoordinated conformers

plex, the downfield shift was caused by the strong π-donor, but weak π-acceptor properties of the *O*-coordinated solvent.[43] However, no dynamic phenomenon was observed at all accessible temperatures. This was a clear indication that in contrast to the precatalyst in the catalytically active species, the interaction of the hydroxy groups with the metal was fully suspended. The complex existed exclusively in the relaxed C_2-symmetric twisted chair conformation **B**. This behaviour was rationalized by the decrease in the Lewis-acidity of rhodium(I) caused by the coordination of methanol, hence the interaction of the metal with the OH group (Lewis-base) is disfavoured.

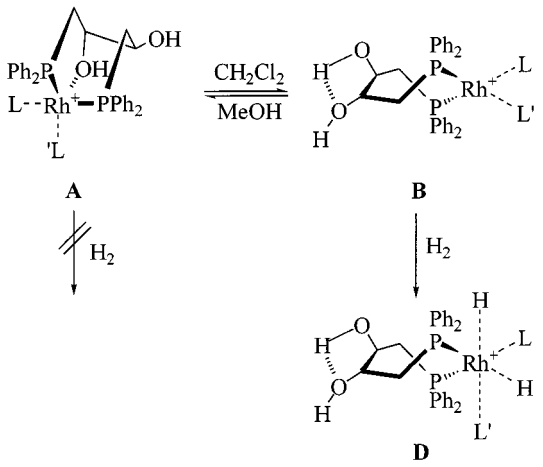
This finding clearly illustrated that in the precatalyst not only steric interactions assisted by the second hydroxy group forces the hydroxy group to approach the metal, but also attractive interactions come into play. This result was additionally confirmed by a combined ^{103}Rh NMR density-functional study.[44] It was calculated that the "pure electronic" effect of the coordinated OH group causes an upfield shift of more than 150 ppm in the ^{103}Rh NMR spectrum relative to the resonance of the same conformation of the non-functionalized complex.

By addition of a non-symmetric prochiral substrate such as AMe, catalyst−substrate complexes were formed from the solvent complex (Scheme 1, **C**).[34b] In contrast to corresponding complexes of related 1,4-diphosphanes like DPPB, the solvent−complex was fully consumed by the substrate. This result agrees well with the small Michaelis constant measured in the hydrogenation of AMe with [Rh(**11-OH**)$(MeOH)_2$]BF_4. The peculiar pattern of the spectrum was rationalized by the assumption of a tripodal coordination of the hydroxy phosphane ligand. In principle, because of the stereofacial coordination of prochiral AMe to rhodium, the alternate coordination of both hemilabile OH ligands should produce a spectrum characterising four diastereomeric substrate complexes (**C-*Si***, **C-*Re***, **C′-*Si***, **C′-*Re***). But the only complexes found were those where the phosphane *trans* to the carbonyl oxygen was involved in the six-membered O−P−Rh chelate (**C-*Si***, **C−R*e***). Up to now there is no rationale for this preference.

In general, these results showed that electronically different counter-ligands can significantly influence the "arm-off arm-on"-mechanism between the hydroxy group and the metal and consequently the conformation of the chiral catalyst. Furthermore, these results provided evidence that the coordination of the OH group takes place stereoselectively in catalyst−substrate complexes with electronically non-symmetric substrates.

Basically, the tripodal coordination mode of the ligand and the bidentate coordination of the prochiral dehydroamino acid produces 18-electron Rh^I complexes. For the subsequent oxidative addition of hydrogen, which is considered as the rate-determining step in the asymmetric hydrogenation,[45] prior decomplexation of the hemilabile ligand is necessary (Scheme 3, **A** → **B** → **D**). Obviously, this feature is responsible for the lowering of the hydrogenation rate observed in the presence of hemilabile OH and OMe ligands. In other words, the concentration of the inactive 18-electron complexes and the rate of decomplexation determines the rate of the hydrogenation.

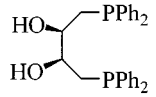
Unexpected proof for this assumption derived from the hydrogenation in a non-polar solvent.[34b] In contrast to the reaction in methanol in CH_2Cl_2 the hydrogenation proceeded approximately fivefold faster without affecting the enantioselectivity. The temperature-dependent $^{31}P\{^1H\}$ NMR spectra of the precatalyst in $CD_2Cl_2/CHCl_2F$ strikingly differed from those observed in CD_3OD. Thus at low temperature, a C_2-symmetric complex featuring no Rh−O interactions was preferentially found. The corresponding complex with tripodal coordination of the chiral ligand was



Scheme 3. HO/Rh- and HO/HO-interactions of **11-OH** complexes and their influence on the reactivity towards H_2 (L,L′ = diolefin, MeOH, bidentate substrate)

observed only in a small quantity. In the IR spectrum in solution the formation of intramolecular hydrogen bonding between the OH groups was observed (**B**, Scheme 3). Evidently, in a nonpolar solvent this strong intramolecular hydrogen bonding is more favoured than the (weak) interaction of one of the hydroxy groups with rhodium (**A**). When the Rh−O interaction is suspended, the hydrogenation can operate unhindered. In methanol the intramolecular hydrogen bonding is cleaved and the Rh−O interaction dominates. The complex is converted into an inactive state. Macroscopically, the decrease in the concentration of the active catalyst−substrate complex is expressed in the deceleration of the hydrogenation.

In the model system discussed above, the formation of the η^3-coordinated species was assisted by the *threo* arrangement of the hydroxy groups, which in the chelate cycle caused the pseudo-equatorial orientation of the uncoordinated OH group. We therefore anticipated that by changing the geometry of the *threo* 2,3-diol moiety to *erythro*, the Rh−O interaction should be disfavoured. Simultaneously, the tendency for the formation of the intramolecular hydrogen bonding should be improved.[46] In order to give evidence for this hypothesis, the required (achiral) (2*R*,3*S*)-1,4-bis(diphenylphosphanyl)butane-2,3-diol (**13-OH**) was synthesized.[47]



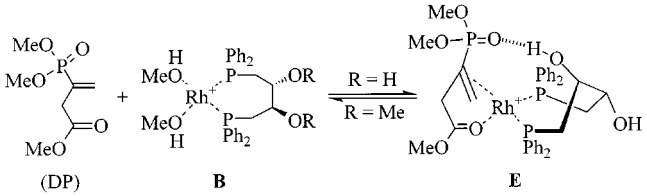
13-OH

IR solid state spectra and $^{31}P\{^1H\}$ NMR of [Rh(**13-OH**)(COD)]BF_4 in CD_3OD revealed also for this precatalyst an intramolecular interaction between the OH group and the Rh centre. However, the small difference in the chemical shift of $\delta = 21.9$ is in remarkable contrast to the value observed for the relevant *threo*-complex ($\Delta\nu = 46.7$ ppm), but corresponds to the difference found with [Rh(**11-OMe**)(COD)]BF_4 ($\Delta\nu = 16.1$ ppm). As discussed above for the latter, a higher dominance of the bidentate coordination mode in methanol was concluded. Obviously, in addition to η^3-coordinated species, the *erythro*-complex also showed considerable amounts of η^2-coordinated conformations at ambient temperature. Interestingly, in the $^{31}P\{^1H\}$ NMR spectra of relevant catalyst−substrate complexes, no significant differences between catalyst−substrate complexes of **11-OH** and **13-OH** at low temperature could be found, which is in contrast to observations made with precatalysts.

Results of hydrogenation experiments with (achiral) [Rh(**13-OH**)(COD)]BF_4 are also given in Table 1. Inspection of all the values clearly shows that hydrogenations with this complex were superior. The hydrogenation times measured with this catalyst were even shorter than with the catalyst bearing only a single hydroxy group (**9-OH**). Its activity was similar to that of the Rh(DPPB) catalyst. This result showed that the typical decelerating effect of the OH group can be fully suspended by a second OH group.

It should be reminded that an accelerating effect on the hydrogenation of dehydroamino acid derivatives has been already achieved with the **11-OH** catalyst when the reaction was carried out in a non-polar solvent. The change from methanol to CH_2Cl_2 facilitated the formation of an intramolecular hydrogen bond and shifted the equilibrium from η^3- to η^2-coordination.

Recently, it could be shown that this hydrogen bonding between the *threo* OH groups was easily disrupted by the addition of triphenylphosphane oxide owing to the favoured intermolecular hydrogen bonding between P=O and one of the OH groups.[47] The other hydroxy group coordinated to the rhodium. This cleavage reaction could be also initiated when the P=O fragment was incorporated in an appropriate prochiral substrate like 3-dimethylphosphono-butenoate (DP), a phosphonate analogue of dimethyl itaconate (Scheme 4). $^{31}P\{^1H\}$ NMR spectroscopic studies in deuterated methanol showed that in a mixture of [Rh(**11-OMe**)$(MeOH)_2$]BF_4 and a fivefold excess of the prochiral substrate, the bis-solvent complex (**B**) was exclusively present. The observation of this complex gave proof of the low stability of the diastereomeric catalyst−substrate complexes.



Scheme 4. Shift of the equilibrium between solvent complex and catalyst−substrate complex in dependence on the substituent R in CD_3OD as solvent

In contrast, by addition of DP to [Rh(**11-OH**)$(MeOH)_2$]$^+$ predominantly the resonances of a catalyst−substrate complex (**E**) were observed, revealing its high thermodynamic stability. The typical shift of the signals indicated that, surprisingly, no interaction between one of the OH groups and the metal centre took place. It was assumed that the Rh−O interaction is suspended owing to

an intramolecular hydrogen bonding between the OH group and the P=O functionality.

Results of the asymmetric hydrogenation are listed in Table 2. As can be clearly seen, with [Rh(**11-OMe**)(COD)]BF_4 very poor conversion occurred. The hydrogenation product was obtained in 24% *ee*. In striking contrast, the rhodium complex based on **11-OH** reduced the prochiral substrate much faster, to give the saturated product with 83% *ee*. This is an increase of approximately 60%.

11-OH	methanol	220	83 (*S*)
11-OH	CH_2Cl_2	no conversion	–

[a] For conditions of the hydrogenation compare Table 1. – [b] Time required for 50% consumption of hydrogen.

It is remarkable that by application of [Rh(**11-OH**)(COD)]BF_4 in dichloromethane as solvent, no conversion was observed. As discussed above, it can be concluded that an intramolecular hydrogen bonding between one of the OH groups and the P=O group of the substrate is established in both solvents. While in MeOH the remaining OH group is engaged by the solvent affording a 16-electron species and therefore allowing the oxidative addition of hydrogen to proceed, in dichloromethane this OH group couples to the rhodium centre. The η^3-coordinated complexes produced are catalytically inactive and therefore hinder the hydrogenation. This assumption also explains the dramatic reversal of the hydrogenation activity by changing from AMe which is a poor hydrogen-bond acceptor to the strong hydrogen-bond acceptor DP in MeOH and dichloromethane, respectively. With the former substrate, the catalytically inactive η^3-complexes are dominant in MeOH, whereas in case of the latter, η^3-complexes dominate in dichloromethane.

The previously reviewed studies illustrate the high mobility of the internal hydroxy groups in appropriate metal complexes and their decisive role in the establishment of pre-equilibria between catalyst and catalyst–substrate complexes. In some cases, relationships between structure and catalytic properties could be deduced. Simultaneously, gradual (size) and fundamental (H-bonding) differences in the behaviour of OH and OMe groups became obvious. Clearly, the characterization of precatalysts or individual stable catalyst–substrate complexes alone does not allow for a reliable conclusion on macroscopically observed overall rates and enantioselectivities. The rate constants of the pre-equilibrium steps and of the rate-determining steps are required in order to determine the special role of the catalytically unreactive η^3-coordinated catalyst–substrate complexes on the enantioselectivity. Unfortunately, up to now the complete set of data under hydrogenation conditions has not been accessible owing to the great complexity of relevant model systems. Several features remain speculative. For example, this holds for the stabilization of hydrido alkyl rhodium complexes by the OH group beyond the oxidative addition of H_2, as was found by Brown et al. in relevant DiPAMP substrate complexes.[48] Furthermore, the question of the effect of potential attractive interactions between the proton of the functional group and metal-bonded hydride[49] has up to now not been addressed at all.

In summary, results observed with tailored model catalysts and model substrates clearly illustrates that the negative effect on the rate, frequently observed with Rh^I hydrogenation catalysts bearing hydroxy phosphanes as ligands, can be entirely overcome by the co-operative effect of an appropriately placed second hydroxy group or a strong hydrogen-bond accepting group such as P=O incorporated in the substrate. As a result we can take full advantage of the positive effect on the enantioselectivity. It has to be verified that the superior enantioselectivities in the asymmetric hydrogenation of standard substrates such as AH and ItH_2 as outlined above can also be explained by a (weak) intramolecular hydrogen bonding between the hydroxy groups of the ligand and the carboxylic group of the substrate during the catalytic cycle.

First Applications in Highly Enantioselective Asymmetric Hydrogenations

As seen above, the incorporation of hydroxy groups can dramatically improve the stereodiscriminating properties of

Table 3. Asymmetric hydrogenation with cationic Rh^I complexes based on RoPHOS-ligands

chiral hydrogenation catalysts. Recently, we[50] and later, the groups of Zhang[51] and RajanBabu[52] found access to a new class of functionalized DuPHOS ligands derived from D-mannitol called RoPHOS (**14**). As shown in Table 3, benzyloxy,[50b] methoxy[53] and hydroxy groups[51] at the 3- and 4-positions of the phospholane moiety have a different effect on the enantioselectivity. Thus, with the OH bearing ligand **14-OH**, more than 99% *ee* could be achieved in the hydrogenation of AH and AMe. Although the increase is small, a significant gain in the enantioselectivity was achieved.

More dramatic effects were recently reported by Brown et al. in the hydrogenation of methyl *N*-acyl cinnamates with BPE-RoPHOS hybrid ligands.[54] The most striking results are listed in Table 4. Thus, by utilization of the ligand **15-H**, a hybrid of the well-known and individually efficient ligands BPE and DiPAMP, poor enantioselectivity was achieved. Incorporation of remote methoxy groups (**15-OMe**) in the phospholane increased the *ee*. The highest enhancement was obtained because of the assistance of the hydroxy groups (ligand **15-OH**). In some cases, in comparison to the parent ligand **15-H**, a difference of up to 90% resulted owing to the remote hydroxy groups.

Concluding Remarks

Results summarised herein show the great academic challenge, but also the high potential associated with the use of internal hydroxy groups in chiral rhodium diphosphane catalysts for tuning the reactivity and the enantioselectivity of asymmetric hydrogenations. The crucial issue lies in the large number and variety of competing binding sites in relevant polyfunctionalized catalyst−substrate complexes. These features are related to the action of enzymes. Modelling of individual interactions, studies of equilibria and evaluation of their effect on the rate and the enantioselectivity are therefore of great importance for the proper placement of additional functional groups within the catalyst. The effective control of such secondary interactions opens new perspectives for the enantiodiscrimination of prochiral substrates and gives access to a new generation of biomimetic catalysts.

There are an increasing number of reports in the literature indicating that hydroxy groups in phosphorus ligands may also influence other metal-catalyzed transformations, such as hydroformylations,[55] transfer hydrogenations[56]or Baylis−Hillman reactions.[51b] In some of these reports, the reduced rate of the catalytic reaction was problematic. The progress achieved over the last years in asymmetric hydrogenation with Rh^I hydroxy phosphane catalysts is an encouraging sign that the decelerating effect of the hydroxy group can also be overcome in these reactions by the employment of suitable substrates and/or appropriate reaction conditions.

Acknowledgments

The author is grateful for the financial support provided by the Max-Planck-Gesellschaft, BASF AG (Ludwigshafen), Bmbf (Förderkennzeichen 03C0304A), NATO and the Fonds der Chemischen Industrie. [35] Frequently, the decelerating effect of the alkoxy group may be suspended owing to the engagement of the ligating oxygen atom in a conformationally rigid heterocycle in the backbone of the ligand. A prominent example is DIOP (H. B. Kagan, T.-P. Dang, *J. Am. Chem. Soc.* **1972**, *94*, 6429−6433). Relevant rhodium catalysts exhibit extremely high hydrogenation activities for the substrates considered herein.

[36] Ref.[19c], footnote 49; ref.[19d]; Reduced hydrogenation activities were also reported for some diphosphanes catalysts bearing amino groups: K. Achiwa. Y. Ohga, Y. Iitaka, *Chem. Lett.* **1979**, 865−868; Y. Ohga, Y. Iitaka, K. Achiwa, *Chem. Lett.* **1980**, 861−864; K. Achiwa, P. A. Chaloner, D. Parker, *J. Organomet. Chem.* **1981**, *218*, 249−260; W. Hu, C.-C. Chen, G. Xue, A. S. C. Chan, *Tetrahedron: Asymmetry* **1998**, *9*, 4183−4192 and references therein. In some cases the decelerating effect of the amino group could be overcome by *N*-acylation.

Second-Order Optical Nonlinearities in Coordination Chemistry: The Case of Bis(salicylaldiminato)metal Schiff Base Complexes

Pascal G. Lacroix[a]

In memory of my greatly respected mentor Professor Olivier Kahn

Keywords: Nonlinear optics / Metal complexes / Schiff bases / Molecular devices

Since the mid-1980s, there has been a growth of interest in the search and development of molecular second-order nonlinear optical (NLO) materials that possess various device applications. Beside the most traditional donor-acceptor ("push-pull") organic chromophores (e.g. the stilbene family), chemists have increasingly extended their field of investigations to newer generations of organic molecules of greater complexity. In recent years, coordination complexes through their unique characteristics such as various redox and magnetic properties, in addition to their great diversity of geometries, have introduced a new dimension to the area. This review attempts to summarize the NLO capabilities of bis(salicylaldiminato)metal Schiff base complexes: (*i*) chromophores with enhanced hyperpolarizabilities (β) can be obtained by virtue of the coordinated metal center; (*ii*) the use of chiral substituents allows the engineering of the chromophores into various non-centrosymmetric environments and efficiencies of about 10 times that of urea in second-harmonic generation; (*iii*) the general trend observed for the high temperature stability in this family of chromophores, while combined with the large β×μ products, makes these systems interesting candidates for their incorporation into poled polymers with high glass transition temperatures (*Tg*); (*iv*) the possibility for β modulation induced by magnetic transition is also seen with respect to the concept of molecular switching.

1. Introduction

Materials which exhibit highly nonlinear optical (NLO) responses are currently of great scientific and technological interest.[1] While inorganic solids such as $LiNbO_3$ and KH_2PO_4 have traditionally attracted the widest attention,[2] it is now recognized that molecular-based materials possess many superior NLO characteristics: ultrafast response times, lower dielectric constants, better processability as thin-film devices, and enhanced non-resonant NLO responses relative to the traditional inorganic solids.[3] When a molecule is subjected to laser light [i.e. very high intensity electric field (*E*)], the polarization of the molecule is expressed by Equation (1).[4]

$$\mu(E) = \mu_0 + \alpha E + \beta E^2 + \ldots \quad (1)$$

In this expression, μ_0 is the permanent dipole moment, α the linear polarizability, and β the quadratic hyperpolarizability (origin of the NLO response). According to the widely used two-level model,[5] β can be described in terms of a ground and first excited state, having a charge-transfer character, and is related to the energy of the optical transition (ΔE), its oscillator strength (*f*), and the difference between the ground and excited state dipole moments ($\Delta\mu$) through Equation 2).

$$\beta = \frac{3e^2\hbar f \Delta\mu}{2m(\Delta E)^3} \times \frac{(\Delta E)^4}{\left((\Delta E)^2 - (2\hbar\omega)^2\right)\left((\Delta E)^2 - (\hbar\omega)^2\right)} \quad (2)$$

The author was born in Dole, France. He received his PhD under the supervision of Prof. Olivier Kahn, at the university of Orsay (France) in 1989. He entered the field of nonlinear optics as a postdoctoral fellow, with Prof. Tobin J. Marks, at Northwestern University (Evanston, USA) from 1989 to 1991. He then returned to Orsay, where he pursued in the field of hybrid magnetic-NLO materials designed by intercalation chemistry. He moved to the Laboratoire de Chimie de Coordination (Toulouse, France) in 1994. His current research interest concerns multi-property materials with nonlinear optical, magnetic, and conducting properties.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

The largest β values are obtained when the molecules contain π-electronic systems with charge asymmetry arising from contributions from the substituents-induced asymmetry. This situation is optimized with "push-pull" molecules, in which the magnitude of β can be correlated with the electron-donating and -accepting strength of the substituent,[6] but can also be enhanced by increasing the path of conjugation between the substituents.[7] The most traditional experimental determination of β is the Electric-Field-Induced-Second-Harmonic (EFISH) method,[8] which requires the molecules to be aligned by a strong electric field by means of their static dipole moments (μ). Therefore, the EFISH signal is proportional to β×μ. Measurements of β can also be carried out with the Hyper-Raleigh Scattering (HRS) method,[9] which does not require electric fields, and therefore is suitable for nonpolar and ionic chromophores.

The polarization of a macroscopic material is again given by an expression analogous to Equation (1), where the macroscopic polarization (P) is expressed by Equation (3).

$$P = \chi^{(1)}E + \chi^{(2)}E^2 + \ldots \quad (3)$$

$\chi^{(2)}$ is the quadratic susceptibility and is related to the underlying β. An important point to note is that for $\chi^{(2)}$ to be non-zero, the material needs to be non-centrosymmetric. This can be explained by the fact that $P(-E) = -P(E)$ in a centrosymmetric material. Therefore, $\chi^{(2)}(-E)(-E) = -(\chi^{(2)}E^2)$, and $\chi^{(2)} = 0$. Consequently, the search for materials with efficient quadratic nonlinearities has to be conducted in two steps which include: (*i*) the designing of molecular structures with a large β value, and (*ii*) the engineering of the chromophores into non-centrosymmetric environments.

Several examples of chromophores are shown in Table 1. They all have been successfully embodied into non-centrosymmetric environments in the solid state following various methodologies. The oldest strategy in crystal engineering for $\chi^{(2)}$ NLO materials is chirality, which ensures the crystallization of a pure enantiomer in a non-centrosymmetric space group. Methyl 2-[(2,4-dinitrophenyl)amino]propanoate (MAP, **1**) was the first $\chi^{(2)}$ NLO material studied in depth, which exploited this strategy.[10] Among several alternative attempts, we have previously reported on the intercalation of cationic chromophores such as 4′-dimethylamino-1-methylstilbazolium (DAMS, **2**) into lamellar matrices as a possible route towards highly efficient $\chi^{(2)}$ NLO materials.[11] However, the method which has been widely adopted since the late 1980s requires poling the chromophores at high temperatures in polymers with high glass transition temperatures (*Tg*).[12] Disperse Red One (DR1, **3**) is an example of an organic chromophore which has widely been investigated in poled polymers for fifteen years.[13] High *Tg* NLO polymers have recently been reviewed.[14]

The macroscopic NLO properties are usually measured by Second-Harmonic Generation (SHG), and the results are expressed as the d_{33} tensor component of $\chi^{(2)}$ in poled polymer materials,[14] or as the SHG efficiency versus that of urea in the Kurtz−Perry powder test[15] for microcrystalline solids. However, it has to be emphasized that this test, which has a modest reliability, is not sufficient to fully understand the origin and extent of the NLO response.

Table 1. Examples of chromophores for which non-centrosymmetric solid-state environments have been obtained by crystal growth (**1**), intercalation into layered host matrices (**2**) or as functionalized poled polymers (**3**)

2. Organometallic and Inorganic Chromophores

2.1. "Push-pull" Organometallic Chromophores

Besides organic molecules, which up to now have been the most widely investigated systems, organometallic structures should be intriguing candidates as second-order NLO chromophores by virtue of their low-energy electronic charge-transfer excitations. The report in 1987 that *cis*-1-ferrocenyl-2-(4-nitrophenyl)ethylene[16] exhibited an SHG efficiency 62 times that of urea has motivated many organometallic chemists to enter the field. As a result, a number of reports of organotransition metal systems with NLO properties have appeared in the literature.[17] Nevertheless, in the late 1980s, despite many synthetic efforts, the measured NLO responses of organometallic chromophores were almost invariably lower than those of π-organic chromophores of comparable molecular dimensions. Understanding the reasons for such modest NLO responses became possible when the Zerner Intermediate Neglect of Differential Overlap (ZINDO) method in conjunction with the Sum Over States (SOS) formalism made the NLO response−electronic structure relationships available.[18] It was pointed out that many organometallics possess pseudo-centrosymmetric electronic environments and, therefore, lack the extreme electronic asymmetry required for large second-order NLO responses.[19] This tendency is illustrated

in Table 2 where the calculated hyperpolarizabilities of organometallics are compared with a stilbene analogue.[18]

Table 2. Comparison of calculated molecular hyperpolarizabilities for organometallic chromophores and a prototypical organic structures (ref.[18])

Compound	β ($\times 10^{-30}$ cm^5 esu^{-1})
 **4**	65.9
 **5**	30.8
 **6**	23.5

Our interest in the field of coordination complexes based NLO chromophores started at this point, by examination of $(CO)_5W-L$ (where L represents an extended π-organic system).[20] The reason for this choice is related to the topological similarity to the conventional push-pull organic chromophores which could offer attracting alternatives to the aforementioned η^5-ferrocenyl complexes and (η^6-arene)chromium structures. Our study pointed out the versatility of the pyridine$-W(CO)_5$ based chromophores (Table 3) in which $-W(CO)_5$ usually acts as a donor,[21] in compounds **7**−**9**, and by contrast with the withdrawing effect of the pyridine$-W(CO)_5$ moiety evidenced in **10**. The molecular orbital analysis indicates that the carbonylmetal fragment acts as σ-acceptor, forcing the adjacent pyridine ring to become the molecular LUMO. As a consequence, the seemingly innocent pyridine becomes a strong acceptor.[20] Since the early 1990s, the interest in using a metal center for converting a pyridine into a strong acceptor for NLO purposes has grown with respect to the concept of octupolar chromophores,[22] which are non-centrosymmetric and nonpolar molecules (e.g. point groups T_d, and D_{3d}). NLO (pyridine)metal complexes, including intriguing new octupolar architectures, have recently been reviewed by Le Bozec.[23]

2.2. A New Approach in the Search of Inorganic NLO Candidates

Until the early 1990s, the main strategy in the design of metal-organic NLO chromophores was to simply mimic organic molecules by using metal centers instead of organic donors[16,17a,17b]. The ferrocene derivative **5** is probably the best example that illustrates this methodology. However, the fact that the NLO response of such chromophores was almost invariably lower than that of π-organics gave rise to the idea that copying organic NLO structures by means of organometallic substituents might not have been the best guideline towards coordination compounds with enhanced optical nonlinearities. This idea becomes more relevant in the case of inorganic complexes, where the d-electrons are more strongly held by the metal atom than in the case of organometallic compounds. This difference can raise difficulties in the designing of classical push-pull chromophores, within the framework of a two-level model built up in the realm of organic chemistry with extended π-conjugated electronic structures.

Table 3. Comparison of experimental (EFISH) molecular hyperpolarizabilities for a series of $(CO)_5W-$pyridine derivatives and for stilbazole-based chromophores at 1.907 μm (**7**−**9**) and 1.064 μm (**10**−**11**)

 **11**	28	[20]

Our interest in inorganic chromophores started in 1990 by a short theoretical investigation of (pentammine)ruthenium derivatives. A lot of work had been devoted to mixed-valence Ru^{II}/Ru^{III} complexes[24] since the initial report on the mixed-valence $[Ru(NH_3)_5]_2pz^{5+}$ (**12**, Figure 1) by Creutz and Taube.[25] In this compound an electron is almost fully delocalized with $(Ru^{II})^{1/2}/(Ru^{III})^{1/2}$ centers (class III in the Robin−Day classification of mixed-valence systems[26]). Consequently, the $(NH_3)_5Ru^{II}$ fragment can formally be seen as a very strong electron donor. However, although ruthenium-based complexes have exhibited sizeable NLO responses as push-pull chromophores in some cases (e.g. $\beta = 70 \times 10^{-30}$ cm^3 esu^{-1} for compound **13**[27]), the

largest NLO responses were reported in compounds in which the pyridine−Ru^{II} fragments act as electron acceptors and not donors (e.g. $\beta = 2200 \times 10^{-30}$ cm^3 esu^{-1} for the octupolar systems **14**[28]). This versatility prompted us to greatly modify our approach to inorganic chromophores in the early 1990s. It became increasingly clear that the traditional donor/acceptor chemical guidelines would probably no longer be fully sufficient in finding the best candidates in chromophore design.

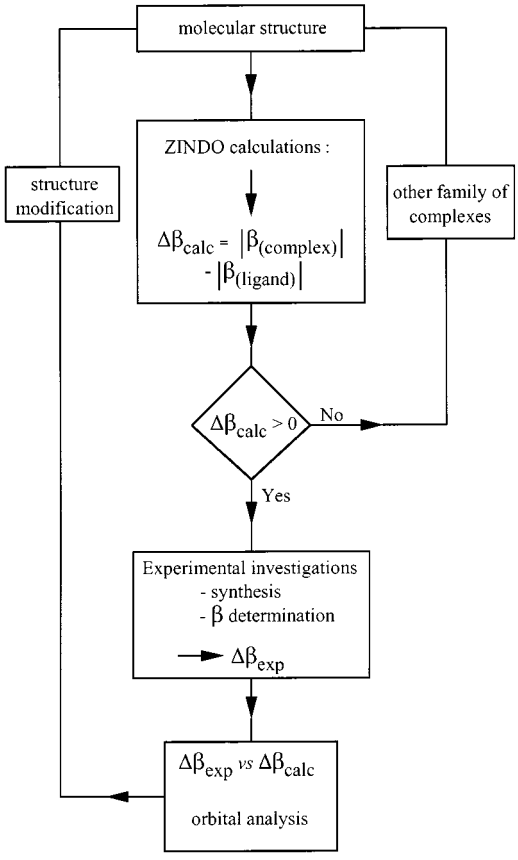
Figure 1. Ruthenium-based charge-transfers in mixed valence complexes **12** and NLO chromophores **13**, and **14**; the five NH_3 of $Ru(NH_3)_5$ are omitted for clarity in **12**

To avoid tedious synthetic programs, with the outcome of uncertain NLO properties, theoretical quantum procedures have been very helpful in the last decade.[18] We became convinced that the search for new families of inorganic chromophores should require preliminary calculations conducted on idealized molecular structures for selecting new inorganic candidates with sizeable nonlinearities. The criteria for the selection is as follows: $\beta_{complex} > \beta_{ligand}$, the comparison between experimental and calculated data being the test to prove the relevance of the quantum description of the properties. Our methodology is summarized in Scheme 1. Besides the gain in synthesis time, this approach is an attempt to fully understand what orbitals are actually involved in the NLO response, and finally to provide chemical guidelines for designing molecules with enhanced capabilities. In conclusion to this section, it is worth noting the tetrahedral cobalt(II) complex with two 1-(*p*-dimethylaminophenylhydrazono)-2-(*p*-nitrophenylimino)ethane ligands reported in 1992 by Simon et al.[29] Although the complex did not follow the traditional push-pull structures, the authors provided evidence for enhanced nonlinearities after metal complexation. The reasons for such behavior are probably related to a better conjugation within the donor−acceptor chromophore by virtue of the metal center. This example also illustrates the fact that pure chemical intuition may no longer be fully appropriate in predicting the extent of the NLO response, and emphasizes the need for efficient screening methods for selecting inorganic NLO materials. This approach has been successfully used in the design of bis(salicylaldiminato)metal Schiff base complexes with NLO capabilities.



Scheme 1

3. Bis(salicylaldiminato)metal Schiff Base Complexes

3.1. Complexes with NLO Responses Larger than that of the Related Ligands

The first report of an NLO metal complex of the tetradentate salen [*N*,*N*′-bis(salicyleneaminato)ethylene] ligand

was that of Thompson et al. in 1991.[30] The authors observed second-harmonic generation in M^{III}-(salen)Py−$NHCH_2X$ derivatives. However, in these systems, the metal−salen core was probably not directly involved in the charge-transfer process responsible for the NLO response, but was rather used to enhance the NLO response of an apical substituted pyridine ligand, in a way similar to that observed in **10** or **14**. The report by Di Bella et al.[31] on various Ni(salen) (**15**, Table 4) derivatives with experimental sizeable NLO responses opened interesting perspectives for metal complexes. In contrast with the widely investigated push-pull organic chromophores, such complexes offer a large variety of structures that allows to locate the metal atom in a more strategic position at the center of the charge-transfer system, making better use of the metal d-orbital hybridization schemes in an organic environment. Importantly, it was proven by a ZINDO theoretical analysis that the NLO response of Ni(salen) complexes is dominated by the HOMO → LUMO transition, in which the nickel atom acts as a donor. This result indicates that this family of derivatives can offer suitable candidates for the strategy introduced in the preceding section.

The best result, which successfully applied this methodology was obtained in the investigation of the NLO properties of ligand **16**, compared with that of the corresponding nickel(II) complex **17** (Table 4).[32] It was shown that the complex exhibits an enlarged NLO response relative to that of the free ligand, with experimental β values of 109 and 235×10^{-30} cm^5 esu^{-1} for **16** and **17**, respectively. In this family, a slight red shift of about 15 nm upon metal complexation provides a modest β enhancement. Moreover, the intrinsic role of the metal center can be understood from a comparative analysis of the calculated data for **16** and **17**. In contrast to the two-level description of the NLO properties of push-pull organic chromophores, the data indicate that two transitions (1→2 and 1→3) are involved in the NLO response for both ligand and metal complex. The differences in electronic populations between the ground state and the two excited states are shown in Figure 2 for **16** and **17**. The picture clearly reveals the enhancement of the intramolecular charge transfer, once the metal atom has been introduced in the molecular structure. This suggests that the metal center, which acts as a donor, favors the conjugation of the chromophore, and hence allows a larger charge transfer in the excited states. One may expect various NLO responses by simply changing the nature of the metal center in this family of inorganic chromophores, a situation that would provide a possibility for optimizing β, once a suitable ligand has been selected. This has been achieved for the Zn^{II} derivative, with a β value of 400×10^{-30} cm^5 esu^{-1}, roughly twice that of the Ni^{II} complex. However, the orbital origin of this difference was not clarified, because of the different geometries between Zn^{II} and Ni^{II} complexes. The search for bis(salicylaldiminato)metal Schiff base complexes with NLO capabilities has been further optimized with the design of compound **18**.[33] However, the β enhancement upon complexation is modest and the metal center itself behaves as a weak donor, in contrast to the situation encountered in **17**, and depicted in Figure 2.

Besides the large β value, it has to be emphasized here that this family of derivatives exhibits excellent thermal stabilities (e.g. 360, 400, and 300 °C for **15**, **17**, and **18**, respectively). It is now generally believed that molecular second-order NLO materials will enter the marketplace, depending on the ability of the chromophores to be poled in

Table 4. Experimental (EFISH) NLO responses of various bis(salicylaldiminato)metal Schiff base complexes (ref.[31,32])

Compounds		β ($\times10^{-30}$ cm^5 esu) 1.34 μm	1.9 μm	Compounds		β ($\times10^{-30}$ cm^5 esu) 1.34 μm	1.9 μm
	**15**	-20.5			**17**	235	800 ($\beta\times\mu$)
	**16**	109			**18**		1530 ($\beta\times\mu$)

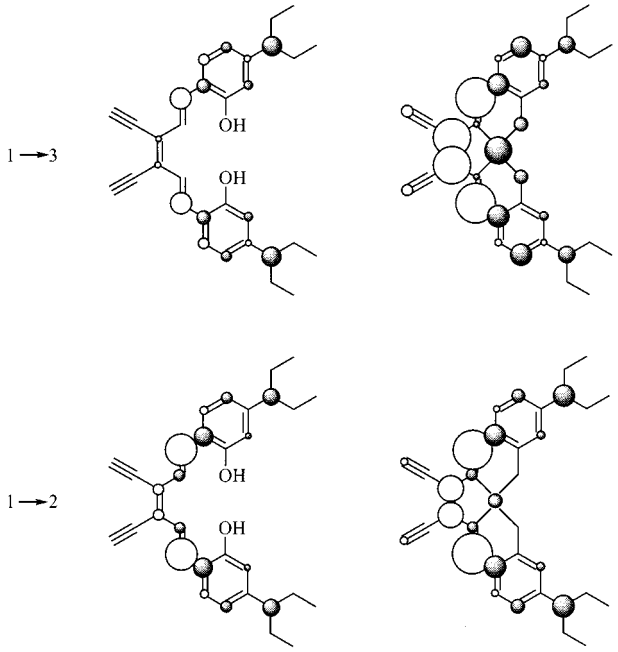


Figure 2. Difference in electronic populations between the ground state and the two excited states for **16** (left) and **17** (right); the black (white) contributions indicate a decrease (increase) in electron density in the charge-transfer process

polymers with very high glass transition temperatures.[12a] The rationale is that if *Tg* is far above the device's operating temperature, the alignment will not decay significantly over the life-time of the device. For stable and efficient poling, it has been realized that polymers with *Tg* higher than 250 °C have to be used and consequently, a good thermal stability has become an important prerequisite for $\chi^{(2)}$ NLO materials. This is undoubtedly one of the major characteristics of metal−salen derivatives. An important point to note is that the poling process requires the use of external electric fields. Therefore although β is the origin of the NLO effect, $\beta\times\mu$ is the molecular figure of merit for poled polymer films. The NLO response of **18** ($\beta\times\mu = 1530\times10^{-48}$ cm^5 D esu^{-1} at 1.907 μm, which corresponds to a static $\beta_0\times\mu = 968\times10^{-48}$ cm^5 D esu^{-1} at zero frequency) can be compared with that of the best organic candidates of similar molecular size.[3a] Although μ enhancement rather than β enhancement is mostly responsible for the large $\beta\times\mu$ value, this large NLO response definitely establishes the potential of these derivatives in the poled polymer approach.

Several metal−salen-based polymers have already been reported,[34] one of them using NLO monomers (polymer **19**, Figure 3).[35] On the other hand, the compounds were found to be rather insoluble, and no NLO effects have been reported. The crystal structure of a chain made of Mn^{III}(salen)(4-pyridylglycinate) blocks (**20**) has also been reported.[36] The structure reveals head-to-tail alignment of adjacent dipoles, but adjacent polymer chains are antiparallel, so no NLO effects are observed. To the best of our knowledge, the only report of NLO properties for an amorphous polymer containing metal Schiff base complexes has been that of poled polyhydroxystyrene doped with chromophore **18** (5% w/w). It exhibits a d_{33} value of 0.65 pm V^{-1} at 1.907 μm, and retains 85% of its NLO response after one week.[33] Although this value is a sizable NLO response for host-guest systems, larger d_{33} values (ca. 10 pm V^{-1}) would require functionalized polymers with chromophores covalently bonded. This has not been achieved yet.

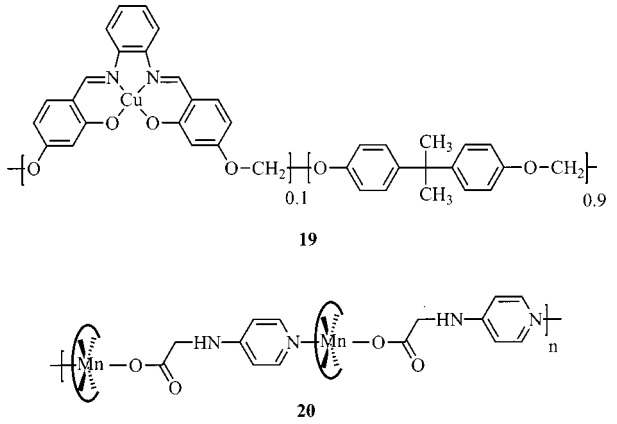

Figure 3. Chains containing bis(salicylaldiminato)metal Schiff base, with NLO capabilities; the ellipse represents a salen ligand in **20**

3.2. Chiral Complexes Efficient in Second-Harmonic Generation

In 1996, Chiang reported on an Fe^{III} derivative **21** (Figure 4), which was found to crystallize in the non-centrosymmetric $P6_5$ space group, with a powder efficiency twice that of urea.[37] The origin of the quadratic NLO response was attributed to both the pyridine−Fe π-system and the salen ligand, the first component most likely being dominant. In contrast to **21**, the Cambridge data base reveals that most of the crystal structures of bis(salicylaldiminato)metal complexes reported to date exhibit centrosymmetric space groups. In particular, bis(salicylaldiminato)nickel(II) complexes all possess centrosymmetric crystal structures, except those made with a chiral diamine (pure enantiomer). This observation strongly supports the idea that derivatives such as **15**−**18** will most likely exhibit vanishing NLO properties due to crystal centrosymmetry.

As is well known, chirality provides the chemist with a means of guaranteeing that crystallization of a pure enantiomer will occur in a non-centrosymmetric space group. In order to promote SHG efficiencies in the solid state, careful examination of Figure 2 provides interesting chemical

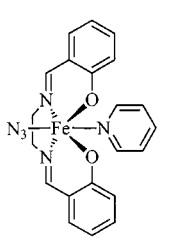

Figure 4. Fe^{III} complex exhibiting two charge-transfer transitions in the salen ligand and in the pyridine−Fe^{III} π-system

guidelines. It appears that the "C=N−C" linkage plays an important role as the withdrawing counterpart of the chromophore, in terms of charge transfer, whereas the contribution of the nitrile substituent is weak. Thus, complexes such as **22**−**24** (Table 5) are preferred in which the "C=N−C" linkage is present, with the addition of two asymmetric carbon atoms to force the crystallization into a non-centrosymmetric space group for the pure (1*R*−2*R* or 1*S*−2*S*) enantiomers. Complex **22** is the first bis(salicylaldiminato)-based metal complex on which this methodology was successfully applied for NLO purposes.[38] However, an unexpectedly low SHG efficiency, < 0.25 times that of urea was observed, arising from a pseudo-centrosymmetric crystal structure.

Table 5. SHG powder efficiencies (vs. urea) of chiral bis(salicylaldiminato)metal Schiff base complexes at 1.907 μm

Compounds		Efficiencies	[ref.]
	**22**	< 0.25	[38]
	**23**	13	[39]
	**24**	8	[38]

This strategy was further optimized in complex **23**, which crystallizes in the non-centrosymmetric $P2_1$ space group, and to date exhibits the highest SHG efficiency (13 × that of urea) in this class of materials.[39] The structure−NLO property relationships established by Zyss lead to the *d* component of $\chi^{(2)}$ given in Equation (4) where θ is defined as the angle between β and the 2_1 two-fold axis of the crystal, and *N*, the concentration of chromophores per volume unit.[40]

$$d_{ZXX} = N\beta\cos\theta\sin^2\theta \quad (4)$$

θ is equal to 57.8° for **23** and corresponds to an angular factor of 0.381. This value must be compared with the $2/\sqrt{3} = 0.385$ theoretical value which maximizes the angular factor for the most favorable crystal structure.[40] Consequently, the molecular orientation of **23** is optimized in the solid, and an efficiency 13 times that of urea is probably close to the upper limit for bis(salicylaldiminato)nickel(II) Schiff base complexes based on this π-electronic structure.

The deleterious effect of pseudo-centrosymmetry on the bulk SHG efficiency of molecules such as **22** can tentatively be related to the fact that the chiral substituent lies near the mean plane of the chromophore. Therefore, two isomers made from (1*R*,2*R*)-cyclohexanediyl or (1*S*,2*S*)-cyclohexanediyl, placed on top of each other almost coincide. Indeed, a calculation indicates that an average distance between the carbon atoms of the cyclohexanediyl and the NiO_2N_2 plane of **22** is to 0.31 Å. In other words, the molecule is "weakly chiral" in the sense of the quantification of chirality developed by Mislow.[41] By contrast, the out-of-plane displacement of the chiral substituents is large in **23**, in which the centroids of the phenyl substituents are located about 3.2 Å apart from the NiO_2N_2 plane. This difference can account for an enhanced "degree of chirality" for **23** relative to that of **22**.

To encourage out-of-plane displacements, alternative chromophores were envisioned such as **24**. Beside an SHG efficiency 8 times that of urea, **24** exhibits a different optical spectrum with a red shift, strongly indicative of reduced transition energy [Δ*E* in Equation (2)], and hence an enhanced β value.[38] It is worth mentioning that **24** brings about NLO chromophores with additional magnetic ($S = 2$) capabilities. The possibilities for interplay between magnetic and NLO behaviors will be discussed in the next section.

3.3. A Possibility for NLO Switching in Metal Schiff Base Complexes

Coordination complexes offer a large variety of magnetic properties by virtue of the coordination metal center,[42] that could bring about NLO chromophores with unique characteristics as multi-property building blocks. However, the possibility for direct interplay between both properties remains a challenging question. Di Bella et al. have shown that, on passing from close-shell Ni^{II}(salophen) to open-shell Cu^{II} or Co^{II} analogues **25** (Figure 5), experimental β values could increase from −20 to −50, and −170 $\times 10^{-30}$ cm^5 esu^{-1}, respectively.[43] This effect has been ascribed to the different natures of the electronic excited states. By contrast, we have investigated the paramagnetic complex **26**, which is the Cu^{II} analogue of **17**.[32] EFISH measurements revealed a β value of 200×10^{-30} cm^5 esu^{-1}, which is comparable with the 235×10^{-30} cm^5 esu^{-1} value measured for **17** within the range of uncertainty of the EFISH method.

However, various recent investigations have pointed out the possibility of β enhancement in organic radicals.[44,45] Such observations open interesting perspectives towards a possible interplay between magnetic and NLO behaviors.

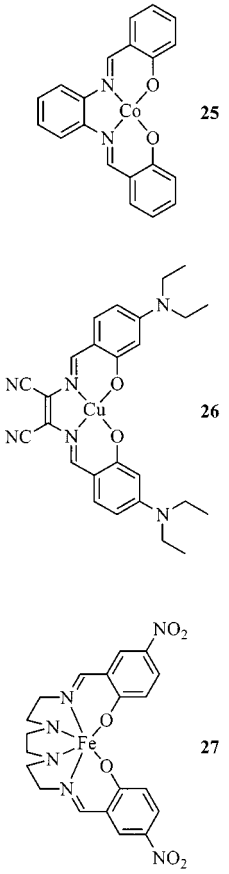

Figure 5. Paramagnetic bis(salicylaldiminato)metal Schiff base complexes with NLO capabilities

The possibility of bulk NLO modulation occurring upon ferromagnetic phase transition in a material containing NLO chromophores can be theoretically envisioned. It has long been known that a rotation of the axis of linearly polarized light occurs on passage through a magnetized material. This is commonly called the Faraday rotation.[46] This effect, which modifies the angle between *E* (the electric field component of the light) and β, should therefore modulate the NLO behavior of the solid. Nevertheless, the β value of the chromophores would not be affected by such a magnetic transition. By contrast, in bis(salicylaldiminato) Schiff base complexes, the spin carrier is the NLO chromophore itself. Therefore, one might wonder if this unique characteristic could encourage a relationship between both properties at the molecular level.

The first evidence for β modulation occurring upon magnetic phase transition has recently been reported in compound **27** (Figure 5).[47] Compound **27** is an iron(II) derivative, which reveals metal-to-ligand charge-transfer capabilities. The frontier orbitals of **27** are shown in Figure 6. By virtue of the two nitro substituents, the compound exhibits the push-pull character required for a sizable β value. At high temperatures, the two chromophores present in the crystal unit cell are equivalent (spin state, $S = 2$), and therefore possess the same β. Interestingly, the compound undergoes a spin transition ($S = 2 \rightarrow S = 0$) in two steps upon cooling down. A phase at intermediate temperature (around 150 K) has been observed in which one half of the chromophores are $S = 0$, and one half are $S = 2$.[48] This unique characteristic allows us to calculate the hyperpolarizability for both spin states in nearly identical solid-state environments. It is found that an enhancement of the static hyperpolarizability (β_0) of about 25% (36.9 to 45.9 $\times 10^{-30}$ cm^5 esu^{-1}) occurs on passing from $S = 0$ to $S = 2$. The main origin of this effect is likely to be related to geometry modifications occurring in the coordination sphere of the metal center.

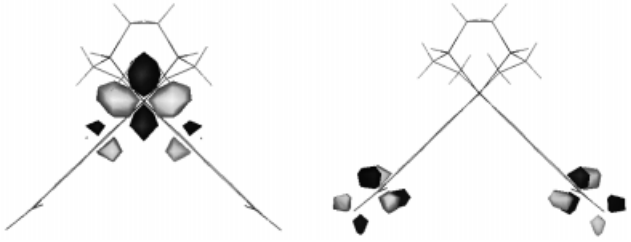

Figure 6. HOMO (left) and LUMO (right) for **27**

In these last few years, the intriguing concept of molecular switches has attracted great interest from a variety of perspectives.[49,50] These molecular NLO materials have recently been reviewed.[51] The switch is usually achieved by isomerization or redox/proton transfer. For example, Coe et al. have reported on an efficient redox switching in ruthenium(II) complexes.[52] By contrast, **27** is the first example of a new class of molecules in which a β switch could be envisioned from a magnetic phenomenon. However, in order to be fully convincing, a switch should be attached to an "on and off" behavior, which has not yet been observed.

4. Concluding Remarks

Until the late 1980s the push-pull one-dimensional electronic model has been the basis of almost every NLO chromophore such as the typical benchmark *p*-nitroaniline molecule. We have reported on various examples of ferrocene-, $W(CO)_5$-, or $Ru(NH_3)_5$-based organometallic and inorganic molecules for which an unexpectedly low NLO response has suggested, in the early 1990s, that the design of chromophores could be reconsidered aside from the traditional push-pull framework in coordination chemistry. Owing to the ability of computational models to provide efficient screening methods of selection, a new family of bis(salicylaldiminato) Schiff base complexes has finally emerged. It is worth noting that, in most reports on these materials, a large part of the work was invariably devoted to theoretical investigations of the properties.

Various Schiff-base complexes have now been reported to exhibit significant β enhancement upon metal complexation. For instance, Espinet et al. have recently ob-

tained Pd^{II} and Pt^{II} complexes in which β_0 enhancements as high as 80% of those of the corresponding ligands were measured.[53] In the present paper, we have presented a class of bis(salicylaldiminato) Schiff base complexes, which appear to be thermally robust NLO materials possessing large $\beta\times\mu$ products. Therefore, they provide interesting candidates for incorporation into high *Tg* polymer matrices. The next challenging goal for this research program would be to be able to covalently link the best of the bis(salicylaldiminato) Schiff base complexes (e.g. **17** and **18**) into polymers, such as polyimides. Beside the poled polymers approach, versatile synthetic methodologies allow for the design of chiral derivatives, with solid-state SHG efficiencies or paramagnetic multifunctional building blocks, in which the properties are expected to be related in some way to the concept of molecular switches. As the NLO field matures, it can be anticipated that materials with switchable NLO responses will find various novel applications.

Acknowledgments

The experimental work reported from our group was performed by F. Averseng, G. Lenoble, I. Malfant, C. Lepetit, and J. C. Daran. NLO measurements were performed by K. Nakatani (ENS Cachan), and early ZINDO calculations by S. Di Bella (University of Catania). The author is grateful to all of them.

Dynamic Behaviour, Solution and Crystal Structure of an Allylmolybdenum/Oxo/Hydroxo Heterocubane

Cornelia Borgmann,[a] Christian Limberg,*[a] Sven Cunskis,[a] and Peter Kircher[a]

Dedicated to Prof. Dr. Günter Helmchen on the occasion of his 60th birthday

Keywords: Allyl complexes / Cubanes / Molybdenum / NMR spectroscopy / Rearrangements

The synthesis of a highly unsymmetrical, chiral oxometallocubane anion $[\{(\pi\text{-}C_3H_5)Mo(CO)_2\}_4(\mu_3\text{-}OH)_3(\mu_3\text{-}O)]^-$ built up from organometallic moieties and oxo ligands is described. Its structure was investigated not only in the solid state (X-ray diffraction analysis) but also in solution applying modern sophisticated NMR techniques. It was thereby possible to identify a trigonal twist rearrangement as the process responsible for the fluxional behaviour of this compound in solution: the (π-allyl)Mo moieties are highly mobile, rotating on the "oxo surface" even at –65 °C. This complex can be regarded as a suitable model for (π-allyl)Mo units incorporated into molybdenum oxide surfaces.

Introduction

Organotransition metal oxide complexes are noteworthy in representing a link between solid, more or less ionic metal oxides and low-valent molecular organometallic systems. Despite their potential model character with respect to oxidation intermediates[1,2] — for instance in processes where organic substrates are converted catalytically on metal oxide surfaces — there are as yet surprisingly few known representatives with organic ligands other than Cp.[1–4] One example of heterogeneous catalysis, where organometallic oxo moieties might play a significant role, entails the oxidation of propene at bismuthmolybdates by O_2 to yield acrolein:[5,6] the rate determining step is proposed to lead to surface intermediates with π-allyl Mo units embedded in an oxidic environment, and this stimulates research with the aim of preparing molecular complexes being modelled on this situation.

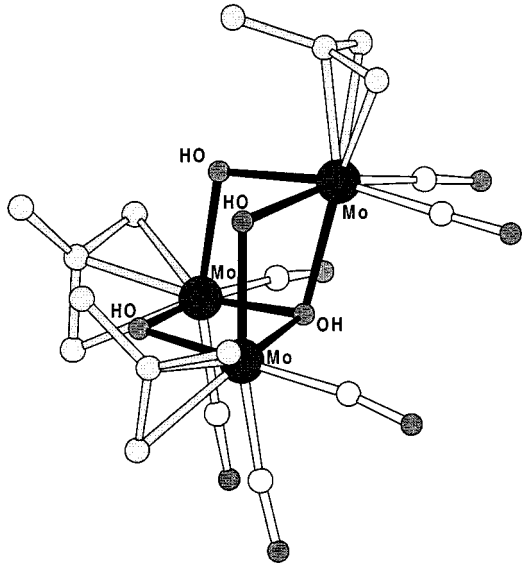

Figure 1. Molecular structure of **1**;[7] hydrogen atoms are omitted for clarity

Results and Discussion

In a recent study[7] we were able to prepare a complex anion $[\{(C_4H_7)Mo(CO)_2\}_3(\mu\text{-}OH)_3(\mu_3\text{-}OH)]^-$ **(1)** with (π-methallyl)Mo units in a *hydroxide* ligand sphere by treatment of $[Mo(\pi\text{-methallyl})(CO)_2(NCCH_3)_2(THF)]O_3SCF_3$ **(2)** with KOH/18-crown-6. Methallyl ligands were chosen instead of allyl ligands as they often facilitate the interpretation of NMR spectra and, additionally, provide a kinetic stabilisation for labile compounds. However, looking at the crystal structure of **1** (Figure 1), it occurred to us that the methyl substituents at the allyl groups also have an influence on the product formation: the structure can be considered as being derived from a neutral cubane-like arrangement, where one corner, a $[(\pi\text{-}C_4H_7)Mo(CO)_2]^+$ unit, is missing because the methyl groups occupy the corresponding space. This suggested analogous experiments with the allyl-derivative of **2**, **2′**.[7] Reacting this compound with KOH/18-crown-6 (Scheme 1) provided, after appropriate

work up, compound **3** as red crystals, one of which was analysed by X-ray diffraction (Figure 2).

The Solid-State Structure of 3

Indeed, the sterically less demanding allyl ligands allow a fourth $[(\pi\text{-}C_3H_5)Mo(CO)_2]^+$ unit to complete the cubane-like geometry. This, however, further polarises the OH ligands thereby enhancing their acidity. Accordingly, after the formation of the neutral product $[\{(\pi\text{-}C_3H_5)Mo(CO)_2\}_4(\mu_3\text{-}OH)_4]$ one proton is abstracted by excess [(18-crown-6)K]OH leading to **3** which possesses a highly unsymmetrical (chiral) anion $[\{(\pi\text{-}C_3H_5)Mo(CO)_2\}_4(\mu_3\text{-}OH)_3(\mu_3\text{-}O)]^-$. Two of these anions can be found within the unit cell, each of them being connected through a carbonyl oxygen atom [(O(41) in Figure 2] to a K^+ cation coordinated by a crown ether and a THF molecule [O(400)]. The two resulting ion pairs **3** in the cell are enantiomers. None of the hydroxylic protons could be located in the structure analysis, so it is not immediately obvious which of the O atoms corresponds to the oxo ligand. However, this can be inferred from a comparison of the Mo−O bond lengths within **3**. Most of them can be assigned to one of two relatively narrow distance ranges i.e. **I:** Mo(3)−O(234/123) 2.237(7)/2.261(7), Mo(1)−O(123/134) 2.327(6)/2.253(7), Mo(2)−O(123) 2.261(7), Mo(4)−O(134/234) 2.306(8)/2.259(7) Å; **II:** Mo(3)−O(134) 2.143(8), Mo(2)−O(234) 2.195(7) Å. The group **I** bonds all have CO ligands bound *trans* to them, while group **II** bonds are located *trans* to allyl ligands and are somewhat shorter as the *trans* influence of the allyl group is weaker than that of CO. Only the bonds of O(124) do not fit into these groups: Mo(2)−O(124) [2.118(7) Å] with a CO ligand in the *trans* position clearly lies out of the region defined by the group **I** bonds, which are considerably longer. Furthermore, Mo(4)−O(124) and Mo(1)−O(124) (*trans* to allyl) are, at 2.050(7) and 2.093(7) Å, significantly shorter than the group **II** bonds. It is therefore reasonable to assign O(124) to the O^{2-} ligand within the complex.[8]

Compound **3** can thus be considered as a suitable, *soluble* model for (π-allyl)Mo units incorporated in molybdenum oxide surfaces, and a detailed NMR spectroscopic analysis of its dynamics promised to provide valuable information. The determination of the solution structure of **3** formed the basis for such an investigation.

The Solution Structure of 3

When dissolved in [D_8]THF, compound **3** shows, at room temp. (apart from the signals due to the crown ether), only three broad signals corresponding to averaged resonances of all H_{syn}, H_{anti}, and H_{meso} protons, i.e. **3** is highly fluxional in solution. No OH signals can be seen. On cooling of the sample, the spectrum dramatically changes in a continuous fashion until a stationary situation is reached at −65 °C. At this point a geometry of the anionic framework corresponding to the one in the crystal structure is frozen out on the ^{1}H NMR time scale, as shown by HSQC, HMBC,

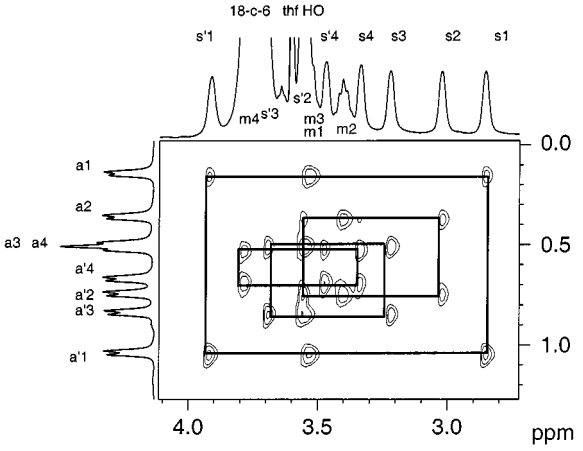

Figure 3. TOCSY NMR spectrum of **3** (500 MHz, [D_8]THF, −65 °C)

	^{13}C			^{1}H				
Allyl group	C^1	C^2	C^3	H$_a$	H$_{a'}$	H$_m$	H$_s$	H$_{s'}$
1	49.8	64.7	77.7	0.14	1.04	3.54	2.85	3.91
2	53.3	60.5	81.0	0.36	0.74	3.39	3.02	3.55
3	55.0	59.3	79.1	0.50	0.84	3.55	3.22	3.64
4	53.5	58.3	79.4	0.52	0.67	3.78	3.34	3.47

TOCSY and NOESY NMR experiments: Each proton belonging to the anion of **3** now shows an individual signal (see Figure 3, where the absorptions of all the allylic protons and their correlations in the TOCSY spectrum are shown), and applying the above-mentioned methods it was possible to assign[9] all of them to a certain position in one of four allyl groups, as indicated in Table 1. The structure frozen out at that temperature thus has to belong to the C_1 point group. Furthermore, the signals of the OH protons can now be observed: A resonance at $\delta = -1.1$ with an integral of one proton should be assigned[10] to the HO(123) ligand, and a second one appearing at $\delta = 4.4$ must belong to HO(134).[12] Moreover, the NOESY spectrum reveals that the signal of HO(234) is hidden by the overlapping resonances of H$_{s'}$ belonging to allyl group 2, H$_m$ of allyl group 3 and H$_m$ of allyl group 1. All other features can also be interpreted in terms of the structure shown in Figure 2, but assignments other than the ones mentioned would be less unambiguous.

Dynamics of 3

Considering **3** as a model, and having identified the solution structure of its anion as being equivalent to the one in the solid state structure, the most important remaining question concerns the type of dynamic process responsible for the changes of the spectrum observed on annealing of the sample. Recently, we have been able to show[13] that in [(π-allyl)(CO)$_2$Mo(OR)$_3$] complex metal fragments the allyl ligands themselves are comparatively rigid (i.e. they are not involved in π-σ-π rearrangements or other processes involving Mo−C bond breaking), but that the (allyl)Mo(CO)$_2$ moiety is capable of "rotating" on the trigonal sphere formed by the three alkoxide ligands by a trigonal twist rearrangement[14−16] (see Figure 4). This process, which has been proved only for a few examples in the literature,[13−17] is also important in the case of **3**: in the NOESY spectrum, where the time scale is different from that of a "normal" ^{1}H NMR spectrum due to the long mixing times, exchange cross peaks with characteristic phases can be found between the signals within each of the proton groups (*syn*, *anti*, *meso*, OH), indicating that even at −65 °C there is a motion by which, for instance, not only the *anti* protons belonging to *one* allyl group but also those belonging to *different* allyl ligands become equivalent. This finding can only be understood if trigonal twist arrangements are operative. If, for instance, the (allyl)Mo(2)(CO)$_2$ unit of **3** as shown in Figure 2 is rotated (viewing this unit as shown in Figure 4) anticlockwise by 120° on the O(123/124/234) surface, the enantiomer of the structure shown in Figure 2 is obtained, which of course has identical NMR properties, but the ligands on Mo(4) now correspond to those of Mo(1) (and vice versa), while H$_2$C(22) has turned into H$_2$C(24). This causes typical exchange peaks in the NOESY spectrum, for instance, between the two H$_a$ signals, the two H$_s$ signals, the two H$_{a'}$ signals etc. belonging to C(22) and C(24). On further annealing this process becomes faster until the protons of the allyl groups on Mo(4) and Mo(1) [as well as those of C(22) and C(24)] become indistinguishable also on the time scale of the ^{1}H NMR spectrum showing coalescence. Similar effects occur when two or even three (allyl)Mo units rotate simultaneously, so that the dramatic changes of the spectra with temperature are understandable (the case becomes even more complicated if allowance for shifts of the hydroxylic protons is made at higher temperatures, which is not unreasonable).

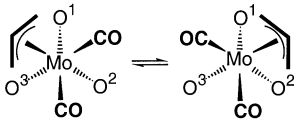

Figure 4. Trigonal twist rearrangement of a (π-allyl)Mo moiety on an oxo surface

In conclusion a novel organometallic oxomolydocubane **3** has been synthesised in a controlled fashion and analysed structurally. There is only one other compound known with a soft π-allyl and a hard oxo ligand being connected to one and the same Mo centre: [{(C$_4$H$_7$)Mo(CO)$_2$(bipy)}$_2$(μ-MoO$_4$-κ*O*,κ*O*′)], which is insoluble in all common solvents.[18] For **3**, however, it could be unequivocally proved that on dissolution not only does its constitution remain intact but the chiral structure it adopts in the crystal is thermodynamically favoured also in solution. Even at −65 °C the (π-allyl)Mo moieties are mobile, rotating an the "oxo surface". From the latter finding, conclusions can also be drawn concerning the dynamics of molybdenum oxide-supported (π-allyl)Mo fragments, as, for instance, those poten-

tially formed as intermediates during the oxidation of propene with bismuthmolybdates.

Experimental Section

Synthesis of 3: A solution of AgO_3SCF_3 (0.51 g, 2.0 mmol) in 8 mL THF was added to a solution of **2′**[7] (0.62 g, 2.0 mmol) with a cannula. Immediately, AgCl precipitated as a greyish solid. The filtrate was added to a suspension of KOH (0.18 g, 3.0 mmol) and 18-crown-6 (0.79 g. 3.0 mmol) in 10 mL THF. After stirring for 3 h the precipitated white K(18-crown-6)O_3SCF_3 was filtered off from the red-orange solution, which was subsequently layered with 100 mL of light petroleum. Storing at −20 °C for 6 days yielded 0.41 g (0.3 mmol) of analytically pure, crystalline **3·3.75THF** corresponding to a yield of 55%. ^{1}H and ^{13}C NMR (500 MHz, [D$_8$]THF): see Table 1. − IR (KBr): $\tilde{\nu}$ = 1915 (br, s)/1821 (br, s) [ν(CO)], 3606 (m)/3563 (m) [ν(OH)] cm^{-1}. − $C_{39}H_{61}KMo_4O_{19.75}$ (1267.78) [**3·1.75 THF**; 2 molecules of THF per molecule of **3** are lost on drying]: calcd. C 36.95, H 4.85; found C 36.59, H 5.11.

X-ray Crystallography

3·3.75THF: $C_{32}H_{47}KMo_4O_{18}\cdot C_{15}H_{30}O_{3.75}$, M_r = 14.12, monoclinic, space group *Cc*, Z = 4, a = 13.756(3), b = 28.077(6), c = 33.650(7) Å, β = 101.72(3), V = 12725.00 Å^3, 3.4 < 2θ < 52.0°, ω-scan, T = 200 K, δ_{cald} = 1.547 g cm^{-3}, measured 31925, independent 24490, and observed reflections 20526 with $I > 2\sigma(I)$, Lp correction, 1472 refined parameters with R = 0.070, residual electron density (max./min.): 1.244/−0.911 eÅ^{-3}; Mo-K_α radiation, λ = 0.71073 Å, was used and the structures were solved by direct methods (program: SHELXS-97) and refined versus F^2 (program: SHELXL-97) with anisotropic temperature factors for all non-hydrogen atoms, apart from C(22) and some of the atoms belonging to the THF molecules, which could only be refined isotropically.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-146570. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

[8] Repeated crystallisations of **3** applying various techniques and solvent mixtures yielded crystals differing in their space groups and the numbers of THF molecules within the unit cells; the structure of the anion, however, always remained identical to the one depicted in Figure 2 (within the frames given by the errors). In one case the protons at the O(134) and O(234) atoms could even be located.
[9] The signals of the *syn* and *anti* protons connected to a certain terminal C atom were identified by means of HSQC and HMBC NMR spectra, while the two terminal CH_2 groups belonging to one and the same allyl group (i.e. $C^1H_aH_s$ and $C^3H_{a'}H_{s'}$ connected through C^2H_m, compare the designations in Table 1) were correlated by TOCSY NMR spectra (Figure 3).
[10] NMR studies concerning the anion **1**[7] and other carbonyl(hydroxo)molybdenum complexes[11] showed that μ_x-OH resonances are increasingly shifted to higher field, the more CO ligands can be found *trans* to the *x* Mo−OH bonds, and HO(123) bears the maximum of three CO ligands in *trans* position to it.
[11] J. T. Lin, S. K. Yeh, G. H. Lee, Y. Wang, *J. Organomet. Chem.* **1989**, *361*, 89.
[12] In a NOESY NMR spectrum this signal shows intense cross peaks to only two of the eight *anti* protons ($H_{a'}$ of the allyl groups designated as 2 and 4 in Table 1), and it is therefore reasonable to assign it to HO(134) as, unlike HO(234), it is exactly in such a situation where it is close only to the *anti* protons at C(44) and C(12).

Self-Assembly of Nickel(II) Complexes of New Bis-Bidentate Schiff Base Ligands[‡]

Laura Carbonaro,[a] Mauro Isola,*[a] Vincenzo Liuzzo,[a] Fabio Marchetti,[b] Federica Balzano,[c] Christian Silvio Pomelli,[a] and Andrea Raffaelli[c]

Keywords: Nickel / Schiff bases / Self assembly / N ligands / Supramolecular chemistry

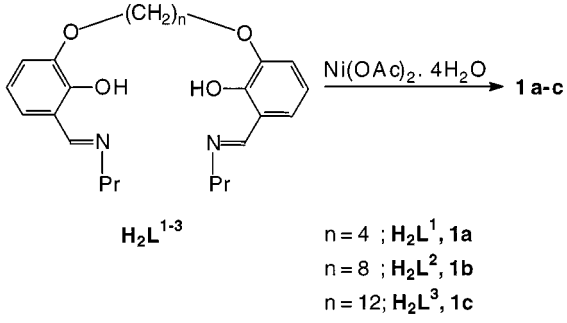
Nickel(II) complexes derived from three new bis-bidentate Schiff bases, H_2L^{1-3}, having two *N*-*n*-propyl-salicylaldiminate units linked by an O–$(CH_2)_n$–O spacer (n = 4, 8, 12, respectively) at the 3-position of the salicyl moieties, are described. The pyridine adduct of the complex with the shorter spacer forms a cyclic trinuclear structure, $[Ni_3(L^1)_3(py)_6]$ (**2**), in the solid state, where each Ni^{II} ion is octahedrally coordinated by two N,O-bidentate arms of two different ligands and two pyridine nitrogens. The base with n = 8 leads to the double-helical dinuclear complex, $[Ni_2(L^2)_2]$·THF (**3**), which is the first example of a structurally characterised helicate based on a square-planar N_2O_2 coordination geometry. In $CHCl_3$ solution, **3** undergoes a disassembly process which results in an equilibrium mixture where the mononuclear species is largely predominant.

In recent years there has been increasing interest in the dinuclear and polynuclear coordination complexes of relatively simple ligands which exhibit, in solution and/or in the solid state, unusual, in some cases unexpected, structural complexity.[1] Helicates,[2] grids,[3] boxes and rings[4] are examples of supramolecular structures generated by the complexation of multidentate ligands with metal ions.

Interesting studies have been devoted to the development of synthetic procedures in order to prepare new multidentate ligands exhibiting the potential ability to give bridged polynuclear species. In particular, a number of attractive ligands with bidentate, chelating binding sites with flexible spacers between them have recently been reported.[5]

Here we describe a general procedure for the facile preparation of new tetradentate Schiff base ligands containing two N,O-bidentate chelating moieties linked through flexible polymethylene dioxo spacers, and their coordination behaviour with nickel(II).

The ligands H_2L^1, H_2L^2 and H_2L^3 were prepared in good yields (ca. 50%) by reaction of the dianion of 2,3-dihydroxybenzaldehyde with the appropriate alkyl α,ω-dibromide in dimethyl sulfoxide,[6] followed by the treatment of the resulting dialdehydes with *n*-propylamine. Reaction of the ligands with $Ni(OAc)_2·4H_2O$ in a 1:1 molar ratio in ethanol afforded the complexes **1a–c** as light-green solids (Scheme 1).



Scheme 1

Elemental analyses suggest the formation of 1:1 complexes for all three systems; however, **1a** exhibits quite different properties from those of both **1b** and **1c**. While the latter complexes have relatively low melting points (190–192 °C and 120–122 °C, respectively) and are moderately (Et_2O, dioxane) or very soluble (chloroform, THF, toluene) in organic solvents, **1a** has a melting point >320 °C and is insoluble in most common organic solvents, suggesting a higher structural complexity. However, **1a** is soluble in pyridine (py), and on addition of Et_2O to the pyridine solution the crystalline green solid **2**, analysing as **1a·2py**, precipitates; this material is paramagnetic, while **1a** is diamagnetic, similar to **1b** and **1c**. These data suggest that nickel(II) adopts a square-planar (SP) coordination geometry in **1a–c** and a nonplanar geometry in the pyridine adduct **2**, at least in the solid state.

Electrospray ionization mass spectroscopy (ESI-MS) of acetonitrile solutions of **1b**, **1c** and **2** indicates the presence of Ni^{II}/ligand 1:1 complexes, but higher mass peaks, corresponding to 2:2 aggregates or species resulting from their fragmentation, suggest the existence in solution of dinuclear complexes, in substantial amounts for **2**, and in small amounts for **1b** and **1c**. The spectrum of **2** also shows a very weak peak corresponding to a trinuclear species.

The ^{1}H NMR spectrum of **2** in $CDCl_3$ shows broad signals whose chemical shift depends on the concentration (mainly for the imine and aromatic protons and for the *ortho* protons of the complexed pyridine) suggesting the presence of an equilibrium involving Ni^{II} ions in a nonplanar environment. Single crystals of **2** were grown from pyridine/diethyl ether and studied by X-ray diffraction. The complex is the cyclic trimer $[Ni_3(L^1)_3(py)_6]$ shown in Figure 1. Each nickel(II) ion is octahedrally coordinated by two pairs of O,N coordination sites of two different ligands and two pyridine nitrogens. The molecule posses a pseudo threefold axis (C_3), that in the Figure points out of the page. As the ligands turn around as a helix fragment, the molecule is chiral, but forms racemic crystals because helices of opposite chirality regularly alternate in the centrosymmetric $P2_1/c$ space group.

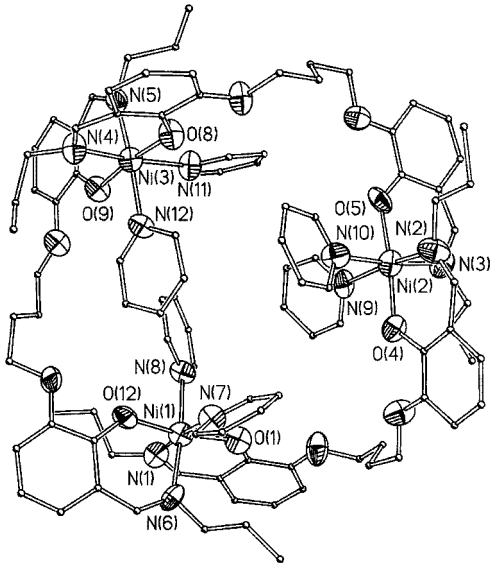

Figure 1. Crystal structure of **$[Ni_3(L^1)_3(py)_6]$** (**2**); Ni, O and N atoms are represented by 30% probability thermal ellipsoids; C atoms are represented by small spheres and H atoms are omitted for clarity; relevant bond lengths (Å) and angles (°): Ni(1)−O(1) 2.007(12), Ni(1)−O(12) 2.02(1), Ni(1)−N(1) 2.11(1), Ni(1)−N(6) 2.11(1), Ni(1)−N(8) 2.15(1), Ni(1)−N(7) 2.16(1), Ni(2)−O(4) 2.00 (1), Ni(2)−O(5) 2.02(1), Ni(2)−N(2) 2.12(1), Ni(2)−N(3) 2.14(2), Ni(2)−N(9) 2.16(1), Ni(2)−N(10) 2.22(1), Ni(3)−O(9) 1.988(9), Ni(3)−O(8) 2.013(9), Ni(3)−N(4) 2.10(1), Ni(3)−N(5) 2.11(1), Ni(3)−N(12) 2.17(1), Ni(3)−N(11) 2.20(1); O(1)−Ni(1)−O(12) 169.6(4), O(1)−Ni(1)−N(1) 89.4(5), O(12)−Ni(1)−N(1) 97.7(5), O(1)−Ni(1)−N(6) 98.5(5), O(12)−Ni(1)−N(6) 89.5(4), N(1)−Ni(1)−N(6) 86.9(5), O(1)−Ni(1)−N(8) 86.3(5), O(12)−Ni(1)−N (8) 86.2(5), N(1)−Ni(1)−N(8) 89.5(5), N(6)−Ni(1)−N(8) 174.0(5), O(1)−Ni(1)−N(7) 86.8(4), O(12)−Ni(1)−N(7) 86.8(5), N(1)−Ni(1)−N(7) 173.3(5), N(6)−Ni(1)−N(7) 88.2(5), N(8)−Ni(1)−N(7) 95.7(5), O(4)−Ni(2)−O(5) 173.9(4), O(4)−Ni(2)−N(2) 89.0(5), O(5)−Ni(2)−N(2) 96.4(5), O(4)−Ni(2)−N(3) 94.4(5), O(5)−Ni(2)−N(3) 88.0(5), N(2)−Ni(2)−N(3) 93.9(6), O(4)−Ni(2)−N(9) 83.2(5), O(5)−Ni(2)−N(9) 91.1(5), N(2)−Ni(2)−N(9) 170.1(5), N(3)−Ni(2)−N(9) 92.8(5), O(4)−Ni(2)−N(10) 90.4(5), O(5)−Ni(2)−N(10) 87.5(5), N(2)−Ni(2)−N(10) 83.4(6), N(3)−Ni(2)−N(10) 174.5(6), N(9)−Ni(2)−N(10) 90.4(5), O(9)−Ni(3)−O(8) 173.0(4), O(9)−Ni(3)−N(4) 95.3(5), O(8)−Ni(3)−N(4) 89.4(5), O(9)−Ni(3)−N(5) 88.4(5), O(8)−Ni(3)−N(5) 96.9(5), N(4)−Ni(3)−N(5) 88.3(5), O(9)−Ni(3)−N(12) 84.1(4), O(8)−Ni(3)−N(12) 90.5(5), N(4)−Ni(3)−N(12) 93.3(5), N(5)−Ni(3)−N(12) 172.5(5), O(9)−Ni(3)−N(11) 90.2(5), O(8)−Ni(3)−N(11) 85.3(4), N(4)−Ni(3)−N(11) 174.2(5), N(5)−Ni(3)−N(11) 89.9(5), N(12)−Ni(3)−N(11) 89.2(5)

Single crystals of the complex **$[Ni_2(L^2)_2]\cdot$THF** (**3**) were obtained by slow evaporation of a solution of **1b** in THF/Et_2O. X-ray diffraction analysis shows that dinuclear molecules (Figure 2) result from the coordination of two $(L^2)^{2-}$ ligands to two nickel centres. Each metal atom is linked in a *trans*-square-planar (*trans*-SP) geometry by two N,O-coordination sites of different ligands. The nickel atoms and chelating groups lie approximately on parallel planes (max. deviations 0.31 and 0.22 Å, respectively) spaced by 3.46 Å. The planes are bonded by two octyl chains which are twisted forming a double helix. On going from Ni(1) to Ni(2) the chains twist by a quarter of a turn. The whole molecule possesses a *pseudo* D_2 symmetry, one of the two-fold axes passing through the nickel atoms.

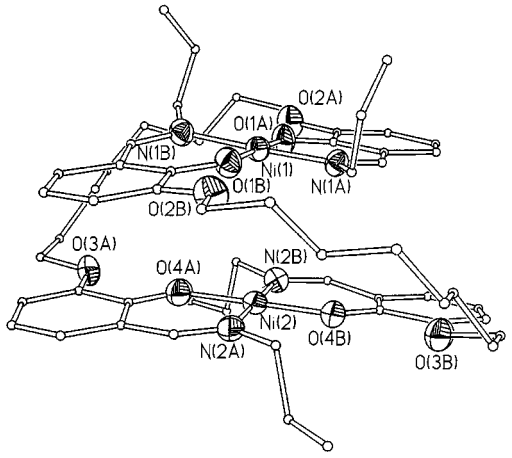

Figure 2. Perspective view of the molecular structure of **$[Ni_2(L^2)_2]\cdot$THF** (**3**); Ni, O and N atoms are represented by 30% probability thermal ellipsoids; C atoms are represented by small spheres, and H atoms and clathrated THF are omitted for clarity; only the most populated positions of the disordered propyl groups are shown; relevant bond lengths (Å) and angles (°): Ni(1)−O(1A) 1.844(8), Ni(1)−O(1B) 1.852(8), Ni(1)−N(1A) 1.908(8), Ni(1)−N(1B) 1.925(9), Ni(2)−O(4A) 1.858(7), Ni(2)−O(4B) 1.859(7), Ni(2)−N(2B) 1.892(11), Ni(2)−N(2A) 1.909(10); O(1A)−Ni(1)−O(1B) 177.4(49), O(1A)−Ni(1)−N(1A) 92.9(4), O(1B)−Ni(1)−N(1A) 87.9(4), O(1A)−Ni(1)−N(1B) 86.4(4), O(1B)−Ni(1)−N(1B) 92.9(4), N(1A)−Ni(1)−N(1B) 178.0(4), O(4A)−Ni(2)−O(4B) 179.6(4), O(4A)−Ni(2)−N(2B) 86.6(4), O(4B)−Ni(2)−N(2B) 93.4(4), O(4A)−Ni(2)−N(2A) 92.8(4), O(4B)−Ni(2)−N(2A) 87.2(4), N(2B)−Ni(2)−N(2A) 179.4(4)

The square-planar geometry found for **3** is rather unusual[7] for double-stranded helical complexes, but not surprising in this case. In fact it is known[8] that in bis(*N*-alkylsalicylaldiminato)nickel(II) complexes, in the absence of space-demanding alkyl substituents, the nickel atom exhibits planar geometry.

The ^{1}H NMR spectra of a $CDCl_3$ solution of microcrystalline **1b** and **1c** show a major set (>90%) of resonances and some signals of very low intensity. The major reson-

ances, corresponding to a largely predominant species, and the minor set of signals can be assigned, according to the ESI-MS data, to the mononuclear and dinuclear complexes, respectively. The mononuclear complexes have been characterized by ROESY analysis (see Experimental Section). As far as the set of minor resonances is concerned, it can be unambiguously assigned, at least in the case of **1b**, to the dinuclear species interconverting with the mononuclear complex in solution. In fact, the ^{1}H NMR spectra of a $CDCl_3$ solution of **3** recorded at different times after dissolution of the solid sample shows a decrease of the intensity of the signals corresponding to the dinuclear species and a concomitant increase of the intensity of the resonances due to the mononuclear complex (Figure 3a and Figure 3b). When equilibrium is reached (>29 h), the spectrum is identical to that of the mononuclear complex **1b** (Figure 3b and Figure 3c).

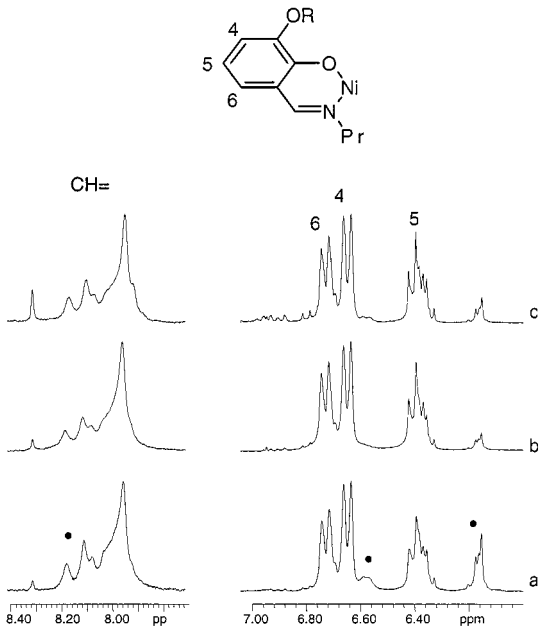

Figure 3. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C) spectral regions corresponding to aromatic and imine protons of: (a) the dinuclear complex **3** after 10 min, (b) the dinuclear complex **3** after 29 h and (c) complex **1b**; a filled circle denotes resonances corresponding to the dinuclear species

The existence of an interconversion equilibrium between dinuclear and mononuclear species is also demonstrated by a ^{1}H NMR saturation transfer experiment. In fact, the selective irradiation of the resonance at $\delta = 6.16$, corresponding to the dinuclear species, produces saturation transfer at $\delta = 6.38$, corresponding to the resonance of the H_5 proton of the mononuclear species (Figure 4).

Thus, while in the solid state the ligand $(\mathbf{L^2})^{2-}$ is able to coordinate each chelating arm to a different metal centre to give a bridged dinuclear species, in solution it prefers to act as a tetradentate chelate to a single Ni^{II} ion, presumably in a *cis*-SP geometry; in fact, a space filling representation[9] of **1b** indicates that the spacer appears not to be long enough to make accessible to Ni^{II} ion the sterically preferred *trans*-SP coordination geometry. Moreover, molecular mechanics calculations[9] suggest that the system consisting of two mononuclear units of **1b** with the Ni^{II} ion adopting a *cis*-SP coordination geometry is more stable (ca. 4 kcal/mol in vacuo, ca. 9 kcal/mol in THF solution) than the calculated minimum-energy dinuclear structure, whose distances and angles are in good agreement with those found by X-ray analysis. These results indicate that the octamethylene bridging unit supplies the ligand $(\mathbf{L^2})^{2-}$ with optimal geometric requirements to easily wrap about the Ni^{II} ions to produce both mono- and dinuclear complexes with a small energetic difference, and that the solvation energy and crystal packing forces must play a fundamental role in the stabilisation of either species.

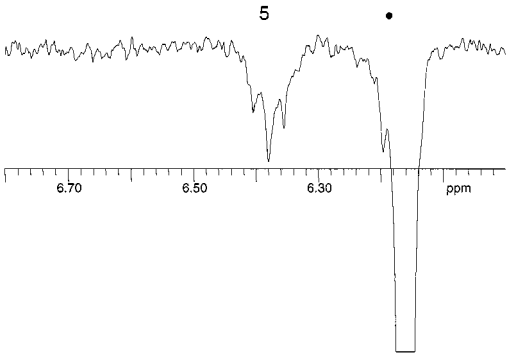

Figure 4. Saturation transfer difference spectrum (300 MHz, $CDCl_3$, 25 °C) of equilibrium mixture **3/1b** corresponding to the irradiation of the resonance at $\delta = 6.16$

Finally, it can be envisaged that structural modifications of the spacer (length and flexibility) and of the steric hindrance of the substituents on the imine nitrogen atoms, combined with the stereoelectronic preference of the metal ion, could easily modulate the coordination geometry of this new class of bis-bidentate ligands, in order to favour the self-assembly process of high-nuclearity species. Work along these lines is in progress.

Experimental Section

IR spectra were collected on a Perkin−Elmer Paragon 500 FTIR spectrophotometer and electronic absorption spectra with a Perkin−Elmer Lambda 9 spectrophotometer in chloroform; λ_{max} in nm and ε in $M^{-1}\,cm^{-1}$. ESI mass spectra were recorded on a PE Sciex API III plus triple quadrupole mass spectrometer equipped with an Atmospheric Pressure Ionization source and an articulated Ionspray interface. The sample was dissolved in chloroform (1 mg/mL) and diluted 1:100 with acetonitrile. Experimental conditions included: IS voltage, 5.5 kV; OR voltage, 90 V.

NMR measurements were performed on a Varian VXR-300 spectrometer in $CDCl_3$ as solvent; the temperature was controlled by the Varian control unit (±0.1 °C). ^{1}H NMR chemical shifts are referenced to TMS as external standard. The 2D NMR spectra were obtained by using standard sequences. The phase-sensitive ROESY spectra were acquired with a spectral width of 3000 Hz in 2 K data points using 8 scans for each of the 256 t_1 increments, with a mixing time ranging from 200−600 ms. A Gaussian function was applied for processing in both dimensions.

In the saturation transfer experiments, selective irradiation was applied for up to 2 s immediately prior to the observation pulse (with a 1-ms interval to allow for electronic recovery), and a total pulse interval of 3 s was used. The spectra were acquired in an interleaved fashion, first by saturating the resonance of interest and then by applying the decoupler significantly off-resonance. The difference spectra were obtained by subtracting the transformed off-resonance spectrum from the on-resonance spectrum.

Preparation of the Dialdehydes: To a solution of 2,3-dihydroxybenzaldehyde (6.5 g, 47 mmol) in anhydrous DMSO (100 mL) was added NaH (2.5 g, 104 mmol) under nitrogen. After stirring for 1 h at room temperature, 23 mmol of the appropriate dibromide was added and the resulting solution was allowed to stir for 24 h. The reaction mixture was poured into water (300 mL) and washed with chloroform. The aqueous layer was subsequently acidified with 6 M HCl and extracted with chloroform (3 × 50 mL). The combined chloroform extracts were dried over anhydrous Na_2SO_4, filtered, concentrated under reduced pressure, and methanol (20 mL) added. A colourless solid was obtained, which was filtered off and dried. Yields: from 60% to 65%.

1,4-Bis(3-formyl-2-hydroxy)phenoxybutane: m.p. 153−155 °C. − IR (Nujol): $\tilde{\nu}$ = 1646 cm^{-1} (C=O). − ^1H NMR ($CDCl_3$): δ = 11.07 (s, 2 H, OH), 9.93 (s, 2 H, CHO), 7.18−6.96 (m, 6 H, C_6H_3), 4.18 (t, 4 H, CH_2O), 2.11 [t, 4 H, $(CH_2)_2$]. − $C_{18}H_{18}O_6$ (330.33): calcd. C 65.45, H 5.49; found C 65.19, H 5.63.

1,8-Bis(3-formyl-2-hydroxy)phenoxyoctane: m.p. 116−119 °C. − IR (Nujol): $\tilde{\nu}$ = 1646 cm^{-1} (C=O). − ^1H NMR ($CDCl_3$): δ = 11.02 (s, 2 H, OH), 9.91 (s, 2 H, CHO), 7.18−6.96 (m, 6 H, C_6H_3), 4.04 (t, 4 H, CH_2O), 1.89−1.42 [m, 12 H, $(CH_2)_6$]. − $C_{22}H_{26}O_6$ (386.44): calcd. C 68.38, H 6.78; found C 68.89, H 7.10.

1,12-Bis(3-formyl-2-hydroxy)phenoxydodecane: m.p. 92 °C. − IR (Nujol): $\tilde{\nu}$ = 1646 cm^{-1} (C=O). − ^1H NMR ($CDCl_3$): δ = 11.03 (s, 2 H, OH), 9.94 (s, 2 H, CHO), 6.96−7.18 (m, 6 H, C_6H_3), 4.07 (t, 4 H, CH_2O), 1.89−1.31 [m, 20 H, $(CH_2)_{10}$]. − $C_{26}H_{34}O_6$ (442.55): calcd. C 70.56, H 7.74; found C 70.32, H 7.53.

Preparation of the Ligands H_2L^{1-3} and Their Ni^{II} Complexes: The Schiff bases were synthesised following standard procedures. A mixture of dialdehyde (2.2 mmol) and *n*-propylamine (12 mmol) in ethanol (20 mL) was heated to reflux for 2 h. After cooling, a yellow solid precipitated out on addition of water. Recrystallisation from $CHCl_3$/hexane afforded yellow crystalline material. Yields: 80−90%.

H_2L^1: m.p. 108−110 °C. − IR (Nujol): $\tilde{\nu}$ = 1628 cm^{-1} (C=N). − ^1H NMR ($CDCl_3$): δ = 14.19 (s, 2 H, OH), 8.33 (s, 2 H, CH=N), 6.99−6.74 (m, 6 H, C_6H_3), 4.16 (t, 4 H, CH_2O), 3.58 (t, 4 H, CH_2N), 2.16 [t, 4 H, $(CH_2)_2$], 1.74 (m, 4 H, CH_2), 1.01 (t, 6 H, CH_3). − $C_{24}H_{32}N_2O_4$ (412.52): calcd. C 69.88, H 7.82, N 6.79; found C 69.74, H 7.94, N 6.67. − UV/Vis: λ_{max} (10^{-3} ε) = 243 (sh) (17), 262 (23), 305 (sh) (4.1), 330 (5.4), 425 (0.92).

H_2L^2: m.p. 84−86 °C. − IR (Nujol): $\tilde{\nu}$ = 1627 cm^{-1} (C=N). − ^1H NMR ($CDCl_3$): δ = 14.22 (s, 2 H, OH), 8.33 (s, 2 H, CH=N), 6.95−6.74 (m, 6 H, C_6H_3), 4.04 (t, 4 H, CH_2O), 3.57 (t, 4 H, CH_2N), 1.92−1.44 (m, 16 H, CH_2), 1.00 (t, 6 H, CH_3). − $C_{28}H_{40}N_2O_4$ (468.63): calcd. C 71.76, H 8.60, N 5.98; found C 71.24, H 8.88, N 5.60. − UV/Vis: λ_{max} (10^{-3} ε) = 243 (sh) (18), 262 (25), 305 (sh) (4.6), 330 (5.8), 425 (1.0).

H_2L^3: m.p. 73−75 °C. − IR (Nujol): $\tilde{\nu}$ = 1629 cm^{-1} (C=N). − ^1H NMR ($CDCl_3$): δ = 14.19 (s, 2 H, OH), 8.32 (s, 2 H, CH=N), 6.95−6.74 (m, 6 H, C_6H_3), 4.04 (t, 4 H, CH_2O), 3.58 (t, 4 H, CH_2N), 1.95−1.31 (m, 24 H, CH_2), 1.00 (t, 6 H, CH_3). − $C_{32}H_{48}N_2O_4$ (524.74): calcd. C 73.25, H 9.22, N 5.34; found C 72.92, H 9.22, N 5.03. − UV/Vis: λ_{max} (10^{-3} ε) = 243 (sh) (19), 262 (26), 305 (sh) (4.8), 330 (6.0), 425 (1.0).

The reaction of H_2L^{1-3} with Ni^{II} acetate tetrahydrate in a 1:1 molar ratio in ethanol at room temperature gave light green solids. A solution of H_2L^{1-3} (2 mmol) in EtOH (20 mL) was added dropwise to a solution of $Ni(CH_3COO)_2{\cdot}4H_2O$ (2 mmol) in EtOH (20 mL). After stirring at room temperature for 2 h, green microcrystalline **1a**,**1b** and **1c,** respectively**,** were collected by filtration, washed with diethyl ether and dried in vacuo. Yields: 90%. The adduct **2** was obtained by addition of Et_2O to a pyridine solution of **1a.**

$[Ni_x(L^1)_x]$ (1a): m.p. >320 °C. − IR (Nujol): $\tilde{\nu}$ = 1612 cm^{-1} (C=N). − $C_{24}H_{30}N_2NiO_4$ (469.20): calcd. C 61.44, H 6.44, N 5.97; found C 61.57, H 6.70, N 5.42.

$[Ni_3(L^1)_3(py)_6]$ (2): m.p. 120−125 °C (dec.). − IR (Nujol): $\tilde{\nu}$ = 1617 cm^{-1} (C=N). − ESI-MS: *m*/*z* (%) = 413 (100) $[H_2L^1 + H]^+$, 469 (90) $[NiL^1 + H]^+$, 881 (50) $[Ni(L^1)_2 + 3H]^+$, 938 (traces) $[(NiL^1)_2 + H]^+$, 1426 (traces) $[(NiL^1)_3 + Na]^+$. − ^1H NMR ($CDCl_3$): δ = 9.16 (4 H, Py), 7.73 (2 H, Py), 7.45 (4 H, Py), 6.85 (2 H, Ph), 6.69 (2 H, Ph), 6.32 (2 H, Ph), 4.43 (2 H, CH=N), 3.87 (4 H, CH_2), 1.87 (8 H, CH_2), 1.60 (4 H, CH_2), 0.99 (6 H, CH_3). − $C_{102}H_{120}N_{12}Ni_3O_{12}$ (1872.2): calcd. $[NiL^3]$ (1c): m.p. 120−122 °C ($CHCl_3$/hexanes). − IR (Nujol): $\tilde{\nu}$ = 1611 cm^{-1} (C=N). − ESI-MS: *m*/*z* (%) = 525 (100) $[H_2L^3 + H]^+$, 581 (95) $[NiL^3 + H]^+$, 1106 (traces) $[Ni(L^3)_2 + 3H]^+$, 1161 (traces) $[(NiL^3)_2 + H]^+$. − ^1H NMR ($CDCl_3$): δ = 7.59 (s, 2 H, CH=N), 6.71 (dd, 2 H, H_6), 6.62 (dd, 2 H, H_4), 6.38 (dd, 2 H, H_5), 3.81 (t, 4 H, CH_2O), 3.51 (t, 4 H, CH_2N), 1.96 (m, 4 H, CH_2CH_2N), 1.73 (m, 4 H, CH_2CH_2O), 1.41 (m, 4 H, $CH_2CH_2CH_2O$), 1.40−1.20 (m, 12 H, CH_2), 1.00 (t, 6 H, CH_3). − $C_{32}H_{46}N_2NiO_4$ (581.41): calcd. C 66.11, H 7.97, N 4.82; found C 66.16, H 8.25, N 4.66. − UV/Vis: λ_{max} (10^{-3} ε) = 251 (45), 268 (54), 335 (8.4), 420 (4.0), 625 (0.09).

X-ray Crystallographic Study: X-ray diffraction measurements were carried out with a Siemens P4 diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Compound **2**, green square-section needle-like crystals, in part hollow as square tubes, $C_{102}H_{120}N_{12}Ni_3O_{12}$; M = 1882.23; T = 293(2) K, monoclinic, space group $P2_1/c$ (No. 14); a = 9.078(4), b = 34.150(14), c = 32.815(9) Å, U = 10173(7) $Å^3$; Z = 4; μ = 0.613 mm^{-1}; crystal size (mm) 0.92 × 0.23 × 0.22. 12353 reflections collected, 9455 independent, R_{int} = 0.1514. The structure was solved by the automatic direct methods of the SIR97 programme.[10] The structure was refined by full-matrix least-squares methods with the SHELX97 program.[11] Owing to the relatively high internal R value, calculated on the equivalent reflections, anisotropic thermal factors were used only for Ni, N and O atoms. The hydrogen atoms were introduced in calculated positions and allowed to ride on the connected heavy atoms. Final reliability factors for 652 parameters,

refined with no restraints: R_1 = 0.1158 calculated for 4893 reflections with $I > 2\sigma(I)$, wR_2 = 0.2201 for all 9455 reflections in the refinement; *GOF* = 1.187.

Compound **3**, deep olive green prismatic crystals, $C_{60}H_{88}N_4Ni_2O_9$; M = 1126.76; T = 293(2) K, Orthorhombic, space group $Pna2_1$ (No. 33); a = 14.813(2), b = 21.540(2), c = 18.277(2) Å, U = 5831.7(11) Å^3; Z = 4; μ = 0.703 mm^{-1}; crystal size (mm) 0.58 × 0.38 × 0.19. 4911 reflections collected, 4245 independent, R_{int} = 0.0282. The structure was solved by standard automatic direct methods and refined by least-squares methods. Abnormally high values of thermal factors and inconsistent geometry revealed a conformational disorder in two of the terminal propyl groups and in the clathrated THF. The two propyl groups were refined as distributed in two different conformations with a constrained geometry, while the THF molecule was refined with a fixed conformation taken from a well-refined structure in the literature.[11] At the end of the refinement, residual peaks and holes of 0.403 and −0.339 e·Å^{-3} were present around the disordered solvent molecule of the difference Fourier map. The solution and constrained refinement were done by means of the SHELX97 programme.[12] Final reliability factors for 632 parameters, refined with five restraints: R_1 = 0.0583 calculated for 3020 reflections with $I > 2\sigma(I)$, wR_2 = 0.0904 for all 4245 reflections in the refinement; *GOF* = 1.023.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-147138 (**2**) and -147139 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$(C_7H_{13}N_2)_3Al$ – The First Tris(diketiminato)metal Complex[‡]

Norbert Kuhn,*[a] Stefan Fuchs,[a] and Manfred Steimann[a]

Dedicated to Professor Max Schmidt on the occasion of his 75th birthday

Keywords: Aluminum / Chelates / N ligands / Vinamidines / Coordination chemistry

The stable tris(diketiminato)metal complex $(C_7H_{13}N_2)_3Al$ (**4**) is obtained from $Me_3N{\cdot}AlH_3$ and the vinamidine $C_7H_{14}N_2$ (**1**). The X-ray structure analysis of the complex **4** reveals a distorted octahedral coordination of the nitrogen atoms at the aluminum centre.

Introduction

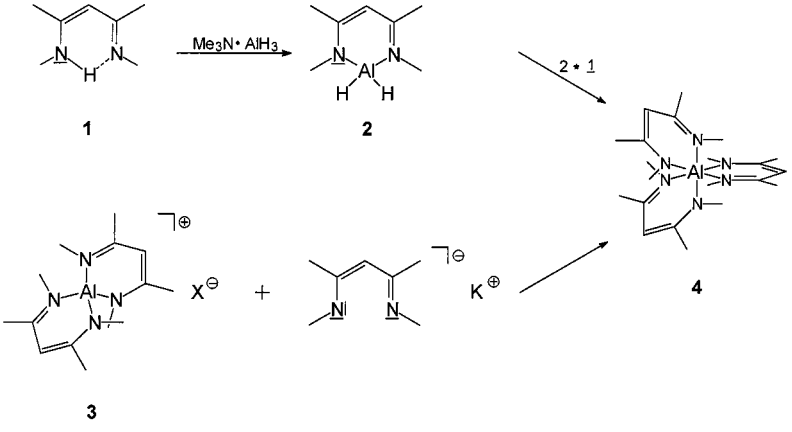
(β-Diketiminato)metal complexes of main group[1–12] and transition[13–18] elements, including compounds of the types $VinMX_2$, $VinMX_3$ and Vin_2M (Vin = η^2-diketiminato), have drawn increasing interest in the past years. In contrast to their ketiminato and diketonato analogues, complexes of the type Vin_3M are unknown, as yet. In the course of our investigations on vinamidine[19,20] aluminum chelates[1,2,21,22] we have tried to fill this gap, and present now the first tris(diketiminato)metal complex.

Results and Discussion

The title compound **4** is obtained from the vinamidine **1**[23] and $Me_3N{\cdot}AlH_3$ as colourless crystals in moderate yield, the isolable alane **2**[21] being the intermediate (Scheme 1). The compound is also formed by reacting the cationic complex **3**[22] (X = Cl, Br) with alkali metal vinamidinates, as confirmed by NMR spectroscopy.

The X-ray structure analysis of **4** (Figure 1) reveals a distorted octahedral coordination geometry at the metal centre. Owing to the increased coordination number, the geometry of the VinAl fragments exhibits a significant difference to that found for **2** and **3** (X = BPh_4) due to a lengthening of the Al–N bonds and a decrease in the N–Al–N bond angles [Al–N 2.002(18) to 2.0626(17) Å, N–Al–N 86.19(7) to 91.39(7) °]. There is no indication of steric overcrowding, for example by distortion of the near planar ring fragments or by unusual lengthening of bonds.

The NMR spectroscopic data of **4** are in the expected range (see Exp. Sect.). The ^{27}Al NMR signal (δ = 15.5) is shifted to high field in relation to **2**[21] and **3**;[22] this is caused by the increase of the coordination number at the metal centre.[24,25] Although it is present as its molecular ion in the mass spectrum (EI), we have not succeeded in subliming this compound without decomposition. As expected, compound **4** is less sensitive towards nucleophilic attack (e.g. towards hydrolysis) than **3**, apparently due to its lower charge density.



Scheme 1

There are only a moderate number of examples involving a sixfold nitrogen coordination at Al. Apparently, these

compounds are stabilised by the low steric demand of the ligands (see, for example, $[Al(NH_3)_6]^{3+}$,[26] $[Al(MeCN)_6]^{3+}$,[27,28] $[Al(N_3)_3py_3]$[29]) and by chelate effects as observed for pyrazolylborato,[30] amidinato[31] and triazenido[32−34] complexes. In addition, some cage compounds are known.[35−38]

In summary, the surprising absence of Vin_3M complexes from the literature in the case of the *N*-methylated ligand may be a consequence of synthetic reasons rather than low stability. In fact, we have not been able to prepare **4** starting from aluminum halides and vinamidines or their alkali metal derivatives, as yet. We are continuing our efforts to find a general route, especially to transition metal Vin_3M complexes, which are of interest as chiral counterparts of the well-known diketonato complexes $(acac)_3M$.[39]

Experimental Section

General Remarks: All synthetic experiments were routinely carried out in purified solvents under argon. *N*-methyl-4-(methylimino)-2-penten-2-amine (**1**)[23] and $Me_3N{\cdot}AlH_3$ [40] were prepared according to published procedures. NMR: Bruker AC 250; MS: Finnigan MAT 311A; X-ray: Siemens P4.

Preparation of Tris{η²-*N*-methyl-4-(methylimino)-2-penten-2-aminato}alane (4): A solution of $Me_3N{\cdot}AlH_3$ (0.18 g, 2.0 mmol) in toluene (10 mL) was added slowly to a solution of **1** (0.76 g, 6.0 mmol) in toluene (20 mL). After stirring for 24 h, the solvent was removed in vacuo and the residue dissolved again in 20 mL toluene. The filtered solution was evaporated to dryness and the remaining solid recrystallised from toluene/pentane to give **4** (0.32 g, 40%) as colourless crystals. − ^{1}H NMR ([D$_6$]benzene): δ = 1.81 (s, 18 H, 4,6-Me), 2.79 (s, 18 H, 1,3-Me), 4.63 (s, 3 H, 5-H). − ^{13}C NMR ([D$_6$]benzene): δ = 22.6 (4,6-Me), 37.1 (1,3-Me), 95.1 (C5), 166.4 (C4,6). − ^{27}Al NMR ([D$_6$]benzene, $[Al(H_2O)_6]^{3+}$ ext.): δ = 15.5. − MS (EI, 70 eV, Vin = $C_7H_{13}N_2$): *m*/*z* (%) = 401 (5) [M^+ − H], 277 (20) [M^+ − Vin], 126 (70) [Vin^+], 111 (78) [Vin^+ − Me], 96 (100) [Vin^+ − 2Me] and further fragments. − $C_{21}H_{39}AlN_6$ (402.56): calcd. C 62.66, H 9.76 N 20.88; found C 62.27, H 10.04, N 20.49.

X-ray Crystallographic Study: $C_{21}H_{39}AlN_6$, triclinic, M = 402.56 g cm^{-3}, space group = $P\bar{1}$ (No. 2), T = 293 K, Mo-K_α, a = 8.687(2), b = 8.904(3), c = 17.004(2) Å, α = 87.314(19), β = 78.230(17), γ = 63.99(2) °, Z = 2, D = 1.157 g cm^{-3}, μ = 0.106 mm^{-1}, crystal size 0.25 × 0.25 × 0.35 mm^3, θ range for data collection 2.45 to 27.50°, 8048 reflections collected, 5227 independent reflections [R(int) = 0.0363], direct methods, no adsorption correction; final R indices [$I > 2\sigma(I)$]: $R1(wR2)$ = 0.0496 (0.1268); R indices (all data): $R1(wR2)$ = 0.0748 (0.1488); GooF = 1.911. Hydrogen atoms calculated, not refined. − Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-151144. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Versatility of the Nature of the Magnetic Gadolinium(III)−Vanadium(IV) Interaction − Structure and Magnetic Properties of Two Heterobinuclear [Gd, V(O)] Complexes

Jean-Pierre Costes,*[a] Françoise Dahan,[a] Bruno Donnadieu,[a] Javier Garcia-Tojal,[a] and Jean-Pierre Laurent[a]

Keywords: Schiff bases / Vanadium / Lanthanides / Magnetic properties

It has been known for a long time that the magnetic exchange interaction between copper and gadolinium ions is always ferromagnetic. Very recently, three exceptions to this general trend were revealed. They involve complexes associating a gadolinium(III) ion with a copper(II) ion or with radicals of the nitroxide or semiquinone types. We want to show that this trend is more general than expected, for such a behavior can also be observed in heterobinuclear vanadyl-gadolinium complexes.

Introduction

The interest given to magnetic interactions between rare earth ions and other types of spin carriers has been focused mainly on gadolinium(III) derivatives containing free radicals[1−4] or copper(II)[5−11] complexes. Very few examples involving nickel(II), cobalt(II), iron(III) and vanadium(IV)[12] ions have been reported. In all these species the interaction between gadolinium(III) and the other paramagnetic center was found to be ferromagnetic. Recently three exceptions to this general trend were revealed; they involve radicals of the nitroxide and semiquinone types[13,14] and a copper(II) complex.[15] Preliminary studies show that an antiferromagnetic behavior is also observed in new trinuclear(Gd, Cu_2) complexes. In search of original examples of antiferromagnetic coupling we have considered the systems consisting of the gadolinium(III) and vanadium(IV) ions and several ligands H_2L^i derived from 2-hydroxy-3-methoxybenzaldehyde.

Results and Discussion

In two instances we succeeded in obtaining well-defined, crystalline complexes by very slow and careful addition of the suitable mononuclear precursors $L^iV(O)$ to $Gd(NO_3)_3{\cdot}6H_2O$, in acetone.[16] Chemical analysis data lead to the following formulae: $[L^1V(O)Gd(H_2O)(NO_3)_3]{\cdot}H_2O$ (**1**) and $[L^2V(O)\{(CH_3)_2CO\}Gd(NO_3)_3]$ (**2**) [H_2L^1 and H_2L^2 stand for *N*,*N*′bis(3-methoxysalicylidene)-1,2-diamino-2-methylpropane and *N*,*N*′-bis(3-methoxysalicylidene)-1,3-diamino-2,2′-dimethyl-propane, respectively].

The heterobinuclear nature of **1** and **2** is supported by the molecular structures[17] shown in Figure 1 and 2. In each compound the metallic ions are doubly bridged by two phenolato oxygen atoms [O(1) and O(2)] of the ligand L^i. The most pertinent difference between the two complexes concerns the GdO_2V bridging core, which is almost planar in **1** with a dihedral angle α between the [O(1)−Gd−O(2)] and [O(1)−V−O(2)] planes of 3.5(7)°, while in compound **2** the value is 20.7(l)°. The related Gd···V separations are equal to 3.5191(5) and 3.5043(4) Å in **1** and **2**, respectively. In both compounds, gadolinium(III) is decacoordinated, although in **2** the coordination sphere comprises four oxygens from L^2 and six from three chelating NO_3, while in **1** one chelating NO_3 is replaced by one monodentate (NO_3) and a water molecule. This water molecule is involved in a hydrogen bonding network through an uncoordinated H_2O and a bound NO_3. Nevertheless, the intermolecular Gd···Gd distance is large [7.7512(2) Å] and slightly shorter than in **2** [8.3816(4) Å], where hydrogen bonds are absent. The vanadium(IV) ion is pentacoordinated in **1** and hexacoordinated in **2** due to the presence of an additional acetone molecule which is loosely bound in an axial position. The vanadium-oxo bond has the same length in both complexes, while the basal bonds are slightly shorter in **1** than in **2**. The metal ions are displaced from the mean basal planes by 0.6183(5) and 0.3418(4) Å in **1** and **2**, respectively. All the intermolecular metal contacts are large (≥7.47 Å) with the exception of a V···V separation of 5.7665(7) Å in **2**. The analogous value in **1** is 7.475(l) Å. However, the lack of bridging pathway between the two V^{IV} ions militates against the possibility of a discernible interaction. Finally, the magnetic data for both complexes may be analyzed on the basis of isolated binuclear species.

From our previous work,[12a] compound **1** has a ferromagnetic ($S_T = 4$) ground state with a coupling constant J of 1.5 cm^{-1}. As for **2**, the profile of the $\chi_M T$ vs. T curve (Figure 3) differs significantly from that of **1** and suggests an antiferromagnetic ($S_T = 3$) ground state. In the 2−300 K

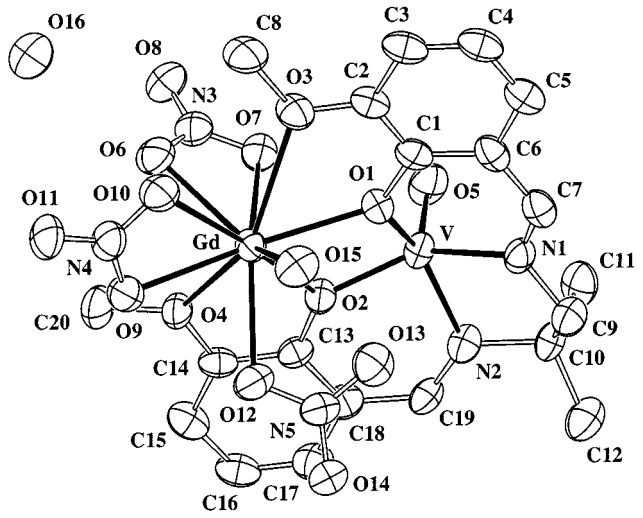

Figure 1. Zortep drawing of **1** with thermal ellipsoids at the 50% probability level; hydrogen atoms are omitted; selected bond lengths [Å] and angles [°]: V−O(l) 1.942(2), V−O(2) 1.937(2), V−O(5) 1.588(3), Gd−O(1) 2.376(2), Gd−O(2) 2.424(2), O(l)−V−O(2) 80.82(9), O(l)−Gd−O(2) 63.19(7), Gd−O(1)−V 108.76(9), Gd−O(2)−V 107.08(9), V···Gd 3.5191(5)

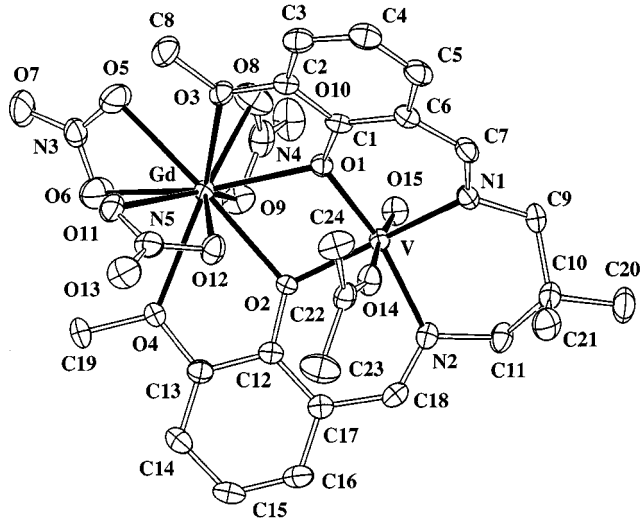

Figure 2. Zortep drawing of **2** with thermal ellipsoids at the 50% probability level; hydrogen atoms are omitted; selected bond lengths [Å] and angles [°]: V−O(l) 1.988(2), V−O(2) 1.986(1), V−O(15) 1.588(2), Gd−O(l) 2.405(2), Gd−O(2) 2.414(2), O(1)−V−O(2) 80.25(6), O(1)−Gd−O(2) 64.20(5), Gd−O(l)−V 105.42(6), Gd−O(2)−V 105.14(6), V···Gd 3.5043(4)

range, fitting the experimental data to the expression[18] derived from the Hamiltonian $H = -JS_{Gd}\cdot S_V$ yields $J = -2.6$ cm^{-1}, $g_{Gd} = 2.0$ and $g_V = 2.1$, the agreement factor R $[(\chi_M T_{calcd.} - \chi_M T_{obs})^2/(\chi_M T_{obs})^2]$ being equal to 3.8×10^{-5}. There is no sign of secondary effects (intermolecular coupling, zero field splitting, ...). The nature of the ground state is definitely substantiated by field-dependent magnetization measurements. Up to 5×10^4 G, the data comply with the values calculated from the Brillouin function for an $S_T = 3$, $g = 2.1$ spin system.

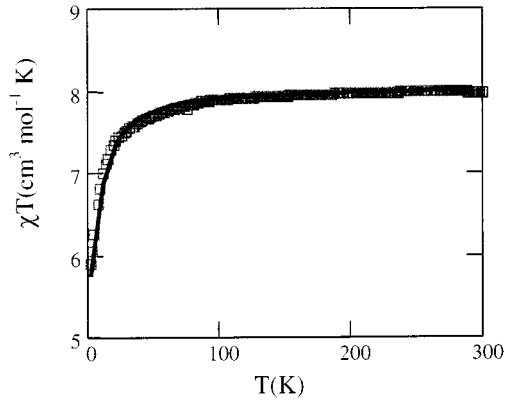

Figure 3. Plot of $\chi_M T$ vs. T for **2** (1000 G); the solid line represents the best data fit

Finally, the present work shows that the magnetic changeability which has so far been observed for (Gd, radical)[13,14] and (Gd, Cu)[15] complexes is also a property of the [Gd, V(O)] compounds. In the two series of bimetallic complexes, a lengthening of the diimino chain of the ligand (from N−C−C−N to N−C−C−C−N) is responsible for a spin-state reversal (from $S = 4$ to $S = 3$). Concurrently there is a significant increase in the bending of the bridging core. The present data reinforce the suggestion[13−15] that the nature and magnitude of the (Gd, M) [M = organic radical, copper(II), vanadium(IV)] interactions result from a sensitive balance between two opposite contributions. The available interaction models[7,18−21] stress the importance of charge transfer (CT) excited states in stabilizing selectively either a low-spin or a high-spin state. The former case corresponds to a CT between two singly occupied orbitals (from $3d_{Cu}$ or $3d_{VO}$ to $4f_{Gd}$) while the second originates from a CT from a singly occupied orbital ($3d_{Cu}$ or $3d_{VO}$) to an empty orbital ($6s_{Gd}$ or more probably $5d_{Gd}$) . These CT-based mechanisms do not seemingly conflict with the observation that the spin states of the binuclear complexes are little affected by the symmetry change of the magnetic orbitals of the second spin carrier (d_{xy} vs. $d_{x^2-y^2}$ type) but are significantly dependent on the planarity of the bridging network.

Experimental Section

Starting materials were purchased from Acros and Aldrich (*o*-vanillin, 1,3-diamino-2,2′-dimethylpropane, 1,2-diamino-2-methylpropane, vanadyl sulfate and gadolinium nitrate hexahydrate), and used without further purification. The compounds were synthesized as follows.

Vanadyl Complexes: The monomeric vanadyl entities were prepared by addition of an aqueous solution of vanadyl sulfate (10 mmol, 1.63 g) to a mixture of *o*-vanillin (20 mmol, 3.04 g) and the corresponding diamine (10 mmol; 0.88 and 1.02 g, for **1** and **2** respectively) in boiling methanol. The precipitates were filtered off, washed with methanol and diethyl ether, and dried under vacuum.

$L^1VO(H_2O)$: Moss green powder, yield 52%. − $C_{20}H_{24}N_2O_6V$ (439.36): calcd. C 54.7, H 5.5, N 6.4; found C 54.5, H 5.3, N 6.0.

− Selected IR bands: $\tilde{\nu}$ = 3481, 2930, 1617, 1552, 1470, 1443, 1401, 1297, 1248, 1225, 1083, 975, 855, 748, 734 cm^{-1}.

$L^2VO(H_2O)$: Light green powder, yield 58%. − $C_{21}H_{26}N_2O_6V$ (453.39): calcd. C 55.6, H 5.8, N 6.2; found C 55.5, H 5.9, N 6.1. − Selected IR bands: $\tilde{\nu}$ = 3435, 2954, 1652, 1618, 1555, 1471, 1453, 1432, 1412, 1392, 1326, 1297, 1248, 1224, 1086, 1066, 958, 859, 733 cm^{-1}.

Vanadyl-Gadolinium Complexes. The vanadyl precursors (1 mmol) were dissolved in acetone and equimolar amounts of the corresponding lanthanide nitrates (1 mmol) were added. Stirring for 90 minutes at room temperature [$L^1VO(H_2O)$ precursor] or stirring and boiling for 40 minutes [$L^2VO(H_2O)$ precursor] yielded green precipitates that were filtered off, washed with acetone and diethyl ether, and dried under vacuum. Dark green crystals of the gadolinium derivatives suitable for X-ray studies were obtained by slow diffusion in a cell device. In the case of **2**, solutions of both gadolinium nitrate and the corresponding precursor in acetone were allowed to react for 10 days at room temperature. Compound **1** required a dichloromethane/acetone (5:2) solution in the compartment occupied by the vanadyl monomer, and the diffusion was carried out at 255 K during nine days.

$[L^1VOGd(NO_3)_3(H_2O)](H_2O)$ (1): Green precipitate, yield 69%. − $C_{20}H_{26}GdN_5O_{16}V$ (800.63): calcd. C 30.0, H 3.3, N 8.8; found C 30.1, H 3.0, N 8.8. − Selected IR bands: $\tilde{\nu}$ = 3470, 2977, 1615, 1560, 1521, 1462, 1437, 1400, 1384, 1306, 1281, 1249, 1226, 1078, 1005, 859, 746 cm^{-1}.

$[L^2VO(C_3H_6O)Gd(NO_3)_3]$ 2. Green precipitate, yield 56%. − $C_{24}H_{30}GdN_5O_{15}V$ (836.71): calcd. C 34.4, H 3.6, N 8.4; found C 34.5, H 3.3, N 8.3. − Selected IR bands: $\tilde{\nu}$ = 3391, 2962, 1703, 1630, 1609, 1567, 1521, 1489, 1473, 1435, 1311, 1283, 1245, 1230, 1064, 995, 857, 741, 735 cm^{-1}.

$Fe_9O_3(OC_2H_5)_{21}\cdot C_2H_5OH$ – A New Structure Type of an Uncharged Iron(III) Oxide–Alkoxide Cluster

Michael Veith,*[a] Frank Grätz,[a] and Volker Huch[a]

Keywords: Iron / Oxo compounds / Alkoxides / Cluster compounds / Magnetic properties

A new nona iron(III) oxide-alkoxide cluster has been prepared by the treatment of $FeCl_3$ with three equivalents of sodium ethoxide. The molecule is the first example of a neutral iron(III) alkoxide cluster based on OEt ligands and shows a paramagnetic moment of 13.4(1) μ_B at 293 K in the solid state.

Introduction

Iron(III) oxides, alkoxides and hydroxides show a great structural diversity, the most remarkable feature being the formation of charged and uncharged clusters by formal condensation.[1] The iron atoms in such compounds are often linked by oxygen atoms. The remaining ligands on the iron atoms may be hydroxide,[2–5] carboxylate,[4–7] alkoxide,[6,8,9] multipodal amino-organic,[10] or amino hydroxyorganic[2] groups, to mention just a few possibilities. The structural building blocks of such iron oxide clusters are often FeO_6 octahedra (less frequently FeO_5 bipyramids or square pyramids) linked by oxygen atoms, which show twofold to sixfold coordination. The new cluster $Fe_9O_3(OEt)_{21}\cdot EtOH$ described here is the first example of such an aggregate containing, apart from bridging oxygens, only the alkoxide group OEt as ligand.

Results and Discussion

In our attempt to synthesise the alkoxide[11–13] $Fe(OC_2H_5)_3$[14] by reaction of iron(III) chloride with sodium ethoxide following established routes, we noticed that a solid brown compound could be isolated in about 60% yield. The X-ray crystal structure analysis of this molecular compound revealed a new structure type within iron(III) alkoxide clusters (see Figure 1). It also showed that the compound is made up of three oxygen atoms, nine iron(III) atoms, twenty-one alkoxide ligands and an alcohol molecule coordinated to one of the Fe centres. The molecular formulation $Fe_9O_3(OC_2H_5)_{21}\cdot C_2H_5OH$ **(1)** has been confirmed by elemental analysis. The oxygen atoms in the cluster presumably come from the residual water in C_2H_5OH.[15] The molecule has the lowest point symmetry C_1 which is due to asymmetric adduct formation of a neutral ethanol molecule.

Leaving this extra ligand apart an almost *mm*2 (C_{2v}) symmetry can be attributed to the rest of the molecule (neglecting the orientations of the ethyl groups). A pseudo-twofold axis runs through the iron atom Fe(1) and the central oxygen atom O(6) which connects three metal atoms in a trigonal planar coordination sphere. The other two oxygen atoms are in the centres of very distorted Fe_4 tetrahedra, the distortion being due to an important elongation of one of the edges [Fe(2)···Fe(4) and Fe(3)···Fe(5)]. These elongated edges are the only ones which are not bridged by μ_2-OC_2H_5. While most of the iron atoms have one terminal OC_2H_5 ligand, Fe(1), Fe(2) and Fe(3) are completely integrated in the oxygen bridge network, and Fe(6) has an additional C_2H_5OH neutral ligand. At Fe(1) there are four μ_2-OC_2H_5 terminal bridges, while at Fe(2) and Fe(3) there are three. Fe(4), Fe(5) and Fe(6) are almost octahedrally coordinated by oxygen atoms, while all other iron atoms are in distorted trigonal bipyramidal oxygen coordination spheres. The largest deviation from trigonal bipyramidal geometry is found for Fe(1), which is better described as square pyramidal with respect to the nearest oxygen atoms. Altogether there are six terminal OC_2H_5 ligands, fifteen bridging μ_2-OC_2H_5 groups and an additional neutral C_2H_5OH ligand. There is a neat dependence of Fe–O distances and coordination numbers on the atoms involved in the bond as well as on the site of the coordination polyhedron (axial versus equatorial): Fe–λ^4O = 201.1(7) pm, Fe–λ^3O = 191.1(1)

pm and Fe−OC_2H_5 (μ_2) = 200.9(0) pm; Fe−OC_2H_5 (terminal) = 178.7(3) pm (mean values). As anticipated, the neutral alcohol ligand at Fe(6) has the longest Fe−O bond [219.0(5) pm]. Interestingly, all μ_2-OC_2H_5 bridges are found at the equatorial sites of the trigonal bipyramidally coordinated iron atoms. The proton of the alcohol ligand can be located and serves as a bridging atom (hydrogen bond) between O(25) and O(4), O(5) and O(6).

The magnetic moment[16−19] of $Fe_9O_3(OC_2H_5)_{21}\cdot C_2H_5OH$ in the solid state is μ_{eff} = 13.4(1) B.M. at 293 K.[20]

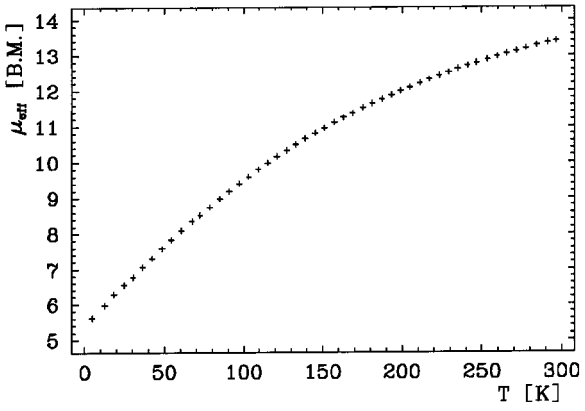

Figure 2. Plot of the magnetic moment (μ_{eff} [B.M.]) of solid **1** versus temperature [K] (see ref.[20])

From the steady shortening of the magnetic moment of crystalline cluster **1** with decreasing temperature (Figure 2) an antiferromagnetic exchange interaction within the molecule can be deduced.[20]

The values found have to be compared to a calculated value for one independent high spin Fe^{3+} ion of μ_{eff} = 5.92 B.M. The crystals seem to be ferrimagnetic, and this is currently being investigated further.[21] Interestingly, the cluster **1** when dissolved in benzene shows a tendency to dissociate. Cryoscopic measurements in the same solvent give a molecular weight of about 510 g/mol. This corresponds to a fragmentation into several species from the original cluster (molecular weight, 1543.0 g/mol) and is more than the simple release of the neutral ethanol ligand. As a solid residue from the benzene solution of cluster **1** we have isolated a compound which analysed as "$Fe_5O(OC_2H_5)_{13}$". We are currently investigating the structural and physical consequences of this decomposition which is driven by simple change of the solvent. Further studies on this system are underway.[21]

Experimental Section

$Fe_9O_3(OC_2H_5)_{21}\cdot C_2H_5OH$ (1): The solvent C_2H_5OH was distilled from sodium and kept over molecular sieves. Under a dry nitrogen atmosphere anhydrous $FeCl_3$ (4.428 g, 27.3 mmol) was added to a solution of sodium ethoxide [formed in situ from sodium (1.886 g, 82.0 mmol) and C_2H_5OH (20 mL)] in ethanol. The mixture was stirred under reflux for 100 h. After removing the solvent under reduced pressure the residue was distilled at 200 °C/0.01 Torr; the product crystallizes on cooling as a brown solid. Yield 2.735 g (60%). − $C_{44}H_{111}Fe_9O_{25}$: calcd. C 34.3, H 7.3, Fe 32.6; found C 34.2, H 7.3, Fe 32.1. − M..p.: 90 °C.

X-ray Crystallography

A crystal suitable for X-ray crystallography was isolated from an ethanol solution of **1**. Stoe IPDS diffractometer, Mo-K_α radiation (λ = 71.073 pm), 293 K, crystal size 0.2 × 0.18 × 0.12 mm, triclinic, space group $P\bar{1}$ with a = 1247.4(2) pm, b = 1746.2(3) pm, c = 1814.1(4) pm, α = 68.02(3)°, β = 84.58(3)°, γ = 88.45(3)°, V = 3647.7(12) × 10^6 pm^3, Z = 2, ρ = 1.405 Mg·m^{-3}, μ = 1.798 mm^{-1}, 2.07° ≤ θ ≤ 24.08°, −14 ≤ h ≤ 13, −19 ≤ k ≤ 20, −20 ≤ l ≤ 20, 23099 measured reflections, 10729 independent, $R1$ = 0.0627, $wR2$ = 0.1553, GOF = 0.928, no restraints, 483 parameters, remaining electron density max. 0.717 × 10^{-6} min. −0.652 × 10^{-6} e·pm^{-3}.

The structure described in this paper was solved with the heavy-atom method and refined towards F^2 for all observed reflections (solution and refinement with SHELXS-97 and SHELXL-97, hydrogen atoms were calculated in an ideal tetrahedral geometry and optimised).

Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication CCDC-149596. Ruthenium(III) Coordination to the Exocyclic Nitrogen of 9-Methyladenine and Stabilisation of the Rare Imine Tautomer by Intramolecular Hydrogen Bonding

Aldrik H. Velders,[a] Bart van der Geest,[a] Huub Kooijman,[b] Anthony L. Spek,[b] Jaap G. Haasnoot,[a] and Jan Reedijk*[a]

Keywords: Ruthenium / Bioinorganic chemistry / N ligands / Crystal structure / Hydrogen bonds

The X-ray structure of *trans*-[$RuCl_3(dmtp)_2$(9-MeAde)] shows that this compound is the first crystallographic example of a ruthenium(III) complex with an adenine derivative coordinated as a monodentate ligand through the exocyclic *N*6 nitrogen; two intramolecular hydrogen bonds stabilise the coordination of the adenine, which is present as a neutral ligand in the rare tautomeric imine form with a unique short C6–N6 distance of 1.293(3) Å.

Introduction

In the search for new antitumour-active metal compounds, several chlororuthenium complexes have proven to be promising candidates for clinical studies.[1] In particular, complexes of the type *trans*-$[RuCl_4(L)_2]^-$, with L a heterocyclic ligand like imidazole or indazole, have shown good activity against platinum-resistant tumours.[2,3] The hydrolysis properties[4] of these complexes, and their binding to biologically available ligands present in proteins[5] and nucleic acids,[6] appear to be important factors in the study of a structure-activity relationship. The anionic tetrachlororuthenium(III) complexes are to be considered as prodrugs that hydrolyse rapidly in vivo to form relatively stable neutral *trans*-$[RuCl_3(H_2O)(L)_2]$ complexes.[7] By using the bicyclic nitrogen heterocycle 5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine, dmtp, we have directly synthesised the first hydrolysis product of such antitumour complexes, *trans*-$[RuCl_3(H_2O)(dmtp)_2]\cdot H_2O$, in which intramolecular hydrogen-bonding interactions of the two dmtp ligands stabilise the coordinated water molecule.[8] This monoaquabis(dmtp)ruthenium(III) complex appears to be a very useful compound for the investigation of the binding properties of this type of ruthenium(III) antitumour complex with biological molecules, such as the heterocyclic nitrogen ligands present in nucleic acids (purines and pyrimidines). In this paper the synthesis and characterisation of the reaction product of *trans*-$[RuCl_3(H_2O)(dmtp)_2]\cdot H_2O$ with the DNA model base 9-methyladenine, 9-MeAde (Figure 1), *trans*-$[RuCl_3(dmtp)_2$(9-MeAde)] (**1**) is presented. The adenine is present in the rare imine tautomer and coordinates to the ruthenium through the exocyclic N6 nitrogen.

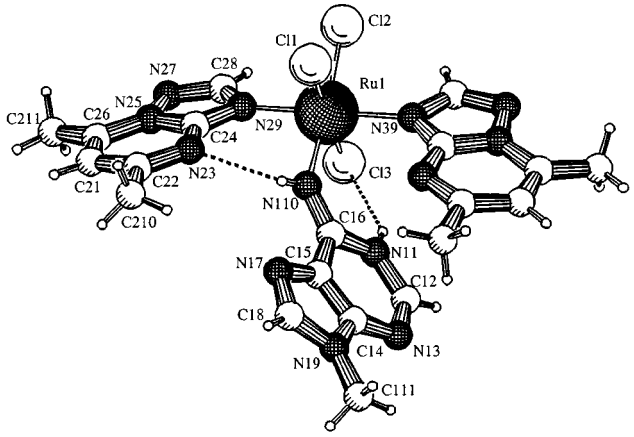

Figure 1. Molecular structure of **1**; intramolecular hydrogen bonding is indicated with dotted lines; the co-crystallised solvent molecule is omitted for clarity; selected metal-ligand bond lengths (Å) and angles (°): Ru(1)−Cl(1) 2.3329(8), Ru(1)−Cl(2) 2.3852(8), Ru(1)−Cl(3), 2.3772(8), Ru(1)−N(29) 2.083(2), Ru(1)−N(39) 2.090(2), Ru(1)−N(110) 2.035(2); Cl(1)−Ru(1)−Cl(3) 178.64(3), N(29)−Ru(1)−N(39) 178.00(8), Cl(2)−Ru(1)−N(110) 175.82(7); donor···acceptor (D···A) distances (Å) and donor−hydrogen···acceptor (D−H···A) angles (°) of the intramolecular hydrogen bonds: N(11)−H···Cl(3) 3.22(9) and 144(3); N(11)−H···N(23) 2.936(3) and 140(3).

Coordination of metal ions to the exocyclic N6 of adenine is difficult, but can occur after deprotonation of the amine.[9] Crystallographic evidence for coordination to the exocyclic nitrogen of deprotonated adenine derivatives has been observed with molybdenum complexes,[10] in a dinuclear platinum complex,[11] and in trinuclear rhodium[12] and ruthenium(II) arene complexes.[13] Crystallographic reports of exocyclic coordination of adenine derivatives in the imine form are even less well-known and have been reported only for a mercury compound,[14] a dimolybdenum complex,[15] and a platinum adduct.[16,17] In DNA, adenine is mainly present in the amine form (Scheme 1) with the N6 and N1 nitrogens acting as hydrogen donor and acceptor atoms, respectively, involved in base pairing with thymine. The imine form of adenine can result in nucleobase mispairing and therefore it is of great biological importance to get a de-

tailed understanding of the factors influencing the formation and properties of such metal complexes.[18−20]

The crystal structure of *trans*-[$RuCl_3(dmtp)_2$(9-MeAde)] (Figure 1) shows a neutral six-coordinated ruthenium(III) complex with three chloride ions in a *mer* configuration, the two dmtp ligands are coordinated through the triazole N9 nitrogens in a mutual *trans* head-to-head orientation. The Ru−N(9) and Ru−Cl bond distances and angles are comparable to those found in related complexes, such as, for example,[8] *trans*-[$RuCl_3(H_2O)(dmtp)_2$]·H_2O and[21] *trans*-[$RuCl_3(H_2O)(admtp)_2$]·H_2O which also display a quasi-octahedral stereochemistry with two *trans*-located triazolopyrimidine ligands. The 9-MeAde is coordinated to the ruthenium through the exocyclic N6 atom, completing the coordination sphere. In the difference density map a hydrogen atom is clearly visible at the N1 site, indicating that the 9-MeAde is neutral and present in the imine form. Also, the short C6−N6 distance of 1.293(3) Å is typical for the imine form of adenine. The average C−N distance for amine groups coordinated to transition metals is 1.39 Å (596 entries in the Cambridge Structural Database, version April 1999).

The N3 site of triazolopyrimidine ligands is known to form intramolecular hydrogen bonds easily with other coordinated ligands like water molecules or amines.[8,21,22] Also, in **1** the N3 atom of one of the two dmtp ligands is involved in an intramolecular hydrogen bond, in this case with the imine proton of the 9-MeAde. The tautomeric imine form of 9-MeAde in **1** is furthermore stabilised by an intramolecular hydrogen bond between the proton on the endocyclic nitrogen N1 and one of the *cis*-coordinated chloride ions. Both hydrogen bonds constrain the 9-MeAde to orient in a *syn* orientation with respect to the N(1) site.

The crystal structure of [$Ru(NH_3)_5$(1-$MeCyt^-$)]$(PF_6)_2$, where 1-$MeCyt^-$ stands for the anion of the pyrimidine 1-methylcytosine,[23] was the first crystallographic report of a DNA base coordinating through the exocyclic nitrogen to a ruthenium(III) complex. More recently, a trinuclear ruthenium-arene complex[13] has been reported in which a deprotonated adenine coordinates contemporaneously through the N1, N7 and N6 nitrogens. The present 9-MeAde complex **1** is the first crystallographic evidence of a purine coordinated to a ruthenium ion though its exocyclic amine as a monodentate ligand in the rare tautomeric imine form. The Ru−N(110) bond length of 2.035(2) Å is significantly shorter than the Ru−N(29) and Ru−N(39) distances [2.083(2) and 2.090(2) Å, respectively] and suggests a considerable π-bonding between the ruthenium and the 9-MeAde ligand.

Ruthenium complexes are known to coordinate preferentially to the N7 nitrogens of oxopurines;[24−27] the N7 is, however, not necessarily the most likely binding site of aminopurines. In fact, in the late seventies it was suggested on the basis of DNA binding studies with single- and double-stranded DNA that ruthenium(III) ammine complexes do not preferentially bind to the N7 of adenine, but possibly coordinate to adenine through the exocyclic nitrogen N6.[28] The absorption spectrum of **1** in the near-UV and visible part of the electromagnetic spectrum shows two main absorption bands at 360 and 500 nm, which have also been observed in several ruthenium(III) ammine complexes with adenine-like ligands.[29,30] The present study unambiguously confirms these absorptions to be characteristic for a ruthenium(III) ion coordinated to the exocyclic, imine group of a nucleobase.

In the solid-state structure of **1**, the two dmtp ligands are not equivalent, but it is likely that in solution all three heterocyclic ligands are to some extent flexible and can rotate around their Ru−N axes. This, in fact, can be concluded from the ^1H NMR spectroscopic data of **1**, in which the two dmtp ligands are indistinguishable. The ^1H NMR spectrum of **1** (Figure 2) shows largely shifted and broadened resonances which is caused by the presence of the paramagnetic ruthenium(III) centre. On the basis of the relative intensities of the peaks, and by comparison with related complexes, the dmtp[8,21,31] and adenine[32,33] proton resonances have been assigned. The dipolar contribution to the isotropic shifts in a ruthenium(III) adenine-κ^{N6} complex are relatively small and the shifts of the H2 and H8 protons can be attributed mainly to the contact contributions;[33] the large shifts of the 9-MeAde ring protons are therefore consistent with a strong π-overlap.

In conclusion, the structure of complex **1** indicates that the use of the triazolopyrimidine dmtp offers the possibility to stabilise, isolate and study the interaction of potential ruthenium antitumour complexes with biological targets like the DNA bases. The intramolecular hydrogen bonds between the dmtp and the 9-MeAde in **1** are not likely to be a prerequisite for N6 coordination, but do play an important role in facilitating the isolation and characterisation of this mode of coordination. The hydrogen-bond interac-

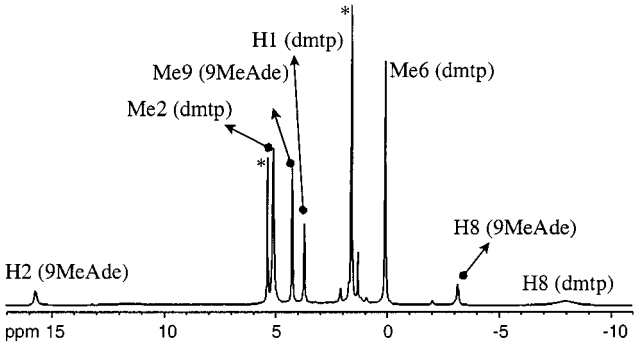

Figure 2. ^1H NMR spectrum of **1** in CD_2Cl_2; the proton numbering is as given in Figure 1; the asterisks indicate residual solvent signals

tion of the N1(H) with a coordinated chloride, on the other hand, is likely to be of influence on the coordination to the adenine N6, also in other (antitumour-active) chlororuthenium complexes. Such a stabilisation of the imine form through (hydrogen) bonding with the N(1) and N(6) of the adenine would inhibit the formation of a normal base pair with thymine; instead, mispairing with guanine or adenine bases might be favoured which eventually can lead to mutations.[18,34,35] The interaction of *trans*-$[RuCl_3(H_2O)(dmtp)_2]\cdot H_2O$ with other nucleobases, as well as the subsequent reactions of the formed adducts, are current subjects of investigation.

Experimental Section

General Remarks: NMR: Data were obtained at 300.13 MHz on a Bruker DPX 300 MHz spectrometer (for CD_2Cl_2 as solvent, δ_H = 5.33 at 295 K). The ^1H NMR signals of **1** could be identified as the paramagnetically shifted and broadened signals with relatively fast relaxation times (on the order of milliseconds). The magnetic moment of **1** was determined on a Johnson Matthey Alfa Product Magnetic Susceptability Balance MK I. Elemental analyses were performed by the Microanalytical Laboratory, University College, Dublin (Ireland). UV/Vis spectra were obtained on a Perkin−Elmer Lambda 900 spectrophotometer. The ligand 5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine (dmtp) and *trans*-$[RuCl_3(H_2O)(dmtp)_2]\cdot H_2O$ were prepared as described previously.[8] 9-Methyladenine was prepared by methylation of adenine with methyl iodide.[36]

***trans*-[$RuCl_3$(9-MeAde-*N*6)$(dmtp)_2$] (1):** A mixture of *trans*-$[RuCl_3(H_2O)(dmtp)_2]\cdot H_2O$ (0.10 g, 0.2 mmol) and 9-MeAde (0.10 g, 0.7 mmol) was heated in 20 mL ethanol (98%) at 75 °C, without stirring. After 15 minutes, the colour of the initially yellowish suspension turned to dark red and after 30 minutes a red microcrystalline powder precipitated, which was isolated by filtration and washed with ethanol and diethyl ether. Yield, 60 mg (50%). The compound was dissolved in a dichloromethane/ethanol mixture (3:1) and red crystals were obtained by diethyl ether diffusion into this solution. The crystals obtained in this way were not stable in air for long periods of time, most likely because of evaporation of co-crystallised solvent molecules; the X-ray data analyses were done on crystals freshly taken out of the mother liquor. $C_{20}H_{23}Cl_3N_{13}$ (652): calcd. C 36.8, H 3.58, Cl 16.3, N 27.9; found C 35.5, H 3.52, Cl 16.5, N 26.4. − The effective magnetic moment, μ_{eff}, of the complex was determined to be 1.9 Bohr magneton at 20 °C, which is in the range of that expected for a single-electron system like a low-spin ruthenium(III) ion.[37] $-^1H$ NMR ([CD_2Cl_2, at 25 °C): δ = −8.0 [2 H, H8 (dmtp)], −3.1 [1 H, H8 (9-MeAde)], 0.1 [6 H, Me6 (dmtp)], 3.7 [2 H, H1 (dmtp)], 4.2 [3 H, Me9 (9-MeAde)], 5.1 [6 H, Me2 (dmtp)], 15.7 [1 H, H2 (9-MeAde)]. − UV/Vis (CH_2Cl_2): λ = 362 nm (ε = $7.12\cdot10^3$ м$^{-1}$ cm^{-1}), 500 (ε = $2.48\cdot10^3$ м$^{-1}$ cm^{-1}).

X-ray Crystallographic Study: $C_{20}H_{23}Cl_3N_{13}Ru\cdot1/2CH_2Cl_2$, M_r = 695.39, red, plate-shaped crystal (0.02 × 0.20 × 0.40 mm), triclinic, space group *P*1(bar) with *a* = 9.7336(12), *b* = 11.2417(15), *c* = 13.924(2) Å, α = 80.922(7), β = 74.505(8) and γ = 75.410(8)°, *V* = 1414.2(3) Å^3, *Z* = 2, D_x = 1.633 g cm^{-3}, μ(Mo-K_α) = 0.96 mm^{-1}. All data, where relevant, are given with disordered solvent contribution. 15167 Reflections were measured (6389 independent, R_{int} = 0.0461, 1.6° < θ < 27.5°, T = 150 K, Mo-K_α radiation, graphite monochromator, λ = 0.71073 Å) on a Nonius KappaCCD diffractometer with rotating anode; no absorption correction was applied. The structure was solved by automated direct methods (SHELXS-86,[38]). Full-matrix least-squares refinement of 345 parameters on F^2 (SHELXL-97,[38]) resulted in a final *R*1 value of 0.0356 (*wR*2 = 0.0789, GoF = 1.021). H atoms were introduced at calculated positions and included riding on their carrier atoms except for the N−H hydrogens which were located on a difference Fourier map and whose positions were refined. A cavity (1/2,1/2,1/2) with a volume of 206 Å^3 per unit cell was filled with disordered solvent (most likely dichloromethane); the associated electron density was taken into account with the PLATON/SQUEEZE procedure.[39] A total of 42 e per unit cell was found (consistent with the presence of one CH_2Cl_2 molecule) and corrected for. Final residual density was in the range −0.81 to 0.50 e Å^{-3}.

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149915. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Reactivity of Monoborylacetylene Derivatives

Yiqun Gu,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

Dedicated to Prof. Ulrich Müller on the occasion of his 60th birthday

Keywords: Alkynes / Boranes / Boron / Hydroboration / Phenols

The catechol-substituted monoborylacetylenes **1a**–**d** are obtained from the reaction of bis(diisopropylamino)borylacetylene with catechol derivatives and 2,2′-biphenol. The catalytic trimerization of **1a**–**d** with $[(\eta^5\text{-}C_5H_5)Co(CO)_2]$ yields isomeric mixtures of the triborylbenzene derivatives **2a,2a′**, **2b,2b′**, and **2c,2c′**. The reaction of **2a,2a′** with mesitylllithium provides the hexamesityl-substituted 1,3,5-triborylbenzene **2e**. Hydroboration of **1a** with catecholborane affords a mixture of 1,1-bis(1,3,2-benzodioxaborol-2-yl)ethene (**3a**) and *trans*-1,2-bis(1,3,2-benzodioxaborol-2-yl)ethene (**4a**). Hydroboration of **1a** and **3a** with one or two mol of $HBCl_2$ and subsequent substitution of the chlorine atoms of the product with catechol leads in each case to the 1,1,1-trisborylmethane derivative **5a** in 83 and 78% yield, respectively, which forms the tris(THF) adduct **5a**$(thf)_3$. Treatment of **5a** with *t*BuLi yields 1,1,1-tris[di(*tert*-butyl)boryl]ethane **6a**. $[Co_2(CO)_8]$ reacts with **1a** to give 3-(1,3,2-benzodioxaborol-2-yl)-1,2-bis(tricarbonylcobalta)tetrahedrane **(9a)**. The new compounds have been characterized by NMR spectroscopy and mass spectrometry as well as by X-ray structure analyses for **1a**, **3a**, **5a**, **5a**$(thf)_3$, and **9a**.

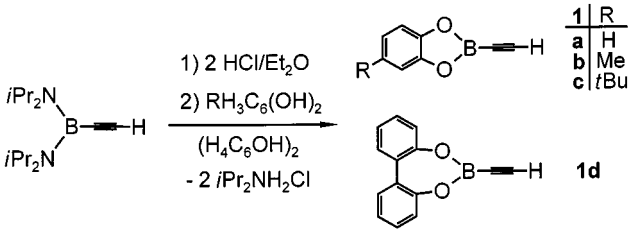
Introduction

Alkynylboranes are interesting synthons for a variety of compounds. Köster et al.[1] prepared monoborylacetylenes by reacting amine-stabilized dialkylchloroboranes with metal acetylides. The addition of diethyl ether-trifluoroborane to the formed adducts leads to donor-free borylacetylenes. Thermally stable monoborylacetylenes[2,3] are obtained with electron-donating groups such as dialkylamino or alkoxy, which reduce the Lewis acidity at the boron center. Dialkoxyborylacetylenes[4,5] may be formed from the corresponding aminoacetylenes. In the reaction of metal acetylides with dialkoxyhaloboranes the halogen atom as well as the alkoxy substituents are replaced. In contrast, the reaction of diaminohaloboranes with metal acetylides leads to the expected compounds in good yields. Here we report on the synthesis and properties of the catechol-substituted monoborylacetylene derivatives **1a−c**.

Results and Discussion

Synthesis and Properties of Monoborylacetylenes (1)

For the preparation of catechol-substituted monoborylacetylenes bis(diisopropylamino)borylacetylene[6] is reacted in THF with two equivalents of HCl and one equivalent of catechol or biphenol, leading to the monoborylacetylenes **1a−d** in 46 to 68% yield (Scheme 1). The colorless solids may be sublimed in vacuo (**1a−c**) or recrystallized (**1d**); the melting points of the products are between 45 °C (**1c**) and 115 °C (**1d**). Compounds **1a−c** are soluble in common organic solvents whereas **1d** dissolves only in toluene and THF and forms a stable THF adduct.



Scheme 1

The ^1H NMR spectra of **1a−d** exhibit a singlet for the acetylenic proton between δ = 2.77 (**1a**) and 2.37 (**1d**). In the ^{13}C NMR spectra the signals of the α carbon atoms (bound to boron) were not observed; the signals for the β carbon atoms (δ = 94−86) are shifted to lower field relative to alkylacetylenes (δ = 70−80),[7] which may indicate an interaction of the empty orbital at boron with the π system of the triple bond. Also, the oxygen atoms in **1a−c** may compete for the empty orbital at boron. In **1d** the boron atom is in bonding contact with the oxygen atom of one THF molecule. The ^{11}B NMR signal for **1d** is shifted to higher field (δ = 15.9) relative to the values for **1a** (δ = 24.1), **1b**, and **1c** (both δ = 24.3). The X-ray structure analysis of **1a** (Figure 1) reveals an almost linear B−C−C−H moiety. The boron atom is trigonal coordinated, and the heterocycle is almost planar. Compound **1a** has approximately C_{2v} symmetry, the C≡C distance [1.195(3) Å] is slightly widened relative to other R−C≡C−R compounds[8] (1.183 Å) and the B−C bond [1.520(4) Å] is short

for a B−C single bond. This is in agreement with structural data for oxygen-substituted diborylacetylenes.[6,9]

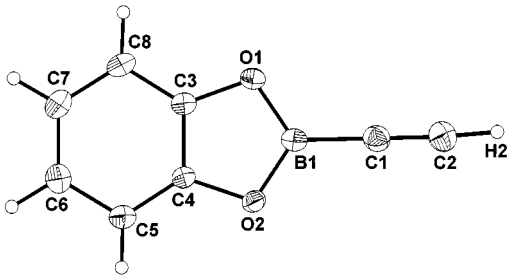

Figure 1. Molecular structure of **1a** in the crystal; selected bond length [Å] and angles [°]: B1−O1 1.387(3), B1−O2 1.372(3), B1−C1 1.520(4), C1−C2 1.195(3), C2−H2 1.00(3); O1−B1−O2 112.3(2), O1−B1−C1 123.2(2), O2−B1−C1 124.4(2), B1−C1−C2 178.7(2), C1−C2−H2 176(1)

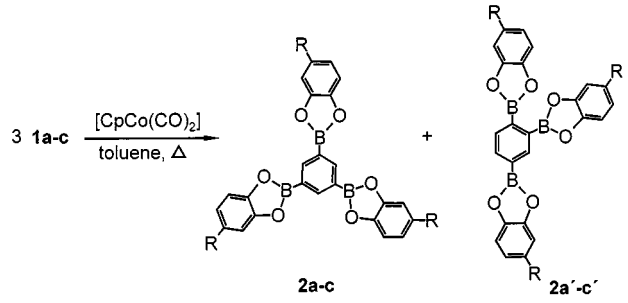
Trimerization of 1 to Triborylbenzene Derivatives (2)

Only a few triborylbenzene derivatives are known;[10,11] these have been prepared in low yields by Grignard reactions. The synthesis of substituted arenes by cobalt-catalyzed trimerization of alkynes is well established and has led to a broad application in organic synthesis.[12] Very recently we obtained hexaborylbenzene derivatives by cyclotrimerization of diborylacetylenes in the presence of catalytic amounts of (η^5-cyclopentadienyl)dicarbonylcobalt.[13,14] Analogously, in refluxing toluene the monoborylacetylenes **1a−c** form isomeric mixtures of the triborylbenzene derivatives **2a,2a′**, **2b,2b′**, and **2c,2c′** in good yields (>50%; Scheme 2). The 1,3,5- and 1,2,4-isomers could not be separated.

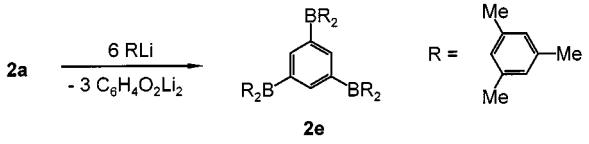


Scheme 2

The mixtures of **2a−c,2a′−c′** are light brown, air-stable solids. The product **2a,2a′** is not soluble in most organic solvents; it partially dissolves in methanol, however, with slow decomposition and formation of catBOMe ($\delta^{11}B$ = 18). In contrast, **2b,2b′** and **2c,2c′** easily dissolve in THF and CH_2Cl_2.

The ^{11}B NMR spectra exhibit broad signals at δ = 30.1 for **2a,2a′** (in [D_4]MeOH), δ = 29.6 for **2b,2b′**, and δ = 33.9 for **2c,2c′** (in CD_2Cl_2). In the ^1H NMR spectrum of **2a,2a′** several signals appear in the arene region. The pattern for *ortho* substitution of the catechol group is found between δ = 6.60 and 6.76. A multiplet between δ = 8.1 and 7.5 is assigned to the central rings of **2a,a′**. In the ^{13}C NMR spectrum, three signals at δ = 146.2, 120.9, and 116.3 are found for the carbon atoms of the catechol groups. A signal at δ = 131.6 is assigned to the hydrogen-substituted carbon atoms of the central aromatic ring of the symmetrical isomer **2a**. Resonances at δ = 141.6, 137.9, and 134.7 are due to the central aromatic carbon atoms (CH) of the unsymmetrical derivative **2a′**. The ^1H NMR spectra of **2b,2b′** and **2c,2c′** indicate that the unsymmetrical derivatives are the main products. In the aromatic region, these compounds exhibit multiplets for the substituted catechol groups at δ = 6.44−6.66 for **2b,2b′** (in [D_4]MeOH) and δ = 7.17−7.43 for **2c,2c′** (in CD_2Cl_2). A second multiplet at δ = 7.50−7.77 in the spectrum of **2b,b′** is generated by the three unsymmetrical protons of the central arene ring. The corresponding signals for **2c′** can be fully assigned: the two adjacent protons give rise to two doublets of doublets at δ = 8.31 ($^3J_{HH}$ = 7.5 Hz, $^4J_{HH}$ = 1.3 Hz) and δ = 8.14 ($^3J_{HH}$ = 7.5 Hz, $^5J_{HH}$ = 0.8 Hz), the resonance for the remaining proton appears as a pseudo triplet at δ = 8.74 (averaged $J_{HH} \approx 1$ Hz). In addition, the nine methyl groups of the three *tert*-butyl substituents of **2c′** result in two signals at δ = 1.37 and 1.35, integrating for nine and eighteen protons respectively, which belong to the groups in the 2- and 1,4-positions. The ^{13}C NMR spectra also indicate the predominant formation of the unsymmetrical structures **2b′** and **2c′**. In the aromatic region of the ^{13}C NMR spectra of **2c,2c′** 19 of the expected 21 signals for the nonboron-bound carbon atoms can be distinguished. A signal for the central C(H) carbon atoms in the symmetrical structure is not found, which means either that **2c** is not present or that its concentration is very low. In the spectra of the products **2a,2a′** and **2b,2b′**, however, the presence of small amounts of the isomers **2a** and **2b** is clearly seen. Beside the aromatic ^{13}C resonances for **2a′/2b′**, signals at δ = 131.6 and 130.7 are assigned to the central C(H) atoms in **2a** and **2b**, respectively.

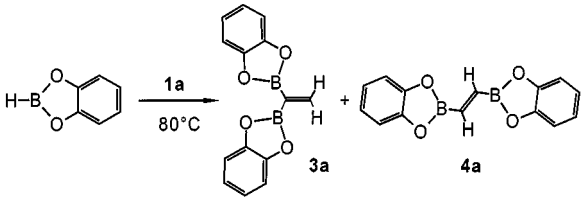
The reaction of **2a,2a′** with mesityllithium provides the hexamesityl-substituted triborylbenzene derivative **2e** in 49% yield (Scheme 3). Its spectroscopic data and the X-ray structure analysis confirm that the symmetric isomer 1,3,5-tris(dimesitylboryl)benzene (**2e**) has been formed. This compound was first prepared in 2% yield from 1,3,5-tribromobenzene Grignard reagent and fluorodimesitylborane.[11]



Scheme 3

Hydroboration of 1a to Yield 1,1-Bis(1,3,2-benzodioxaborol-2-yl)ethene (3a), *trans*-1,2-Bis(1,3,2-benzodioxa-borol-2-yl)ethene (4a), and 1,1,1-Tris(1,3,2-benzodioxaborol-2-yl)ethane (5a)

Alkynes and alkenes are hydroborated regioselectively by 1,3,2-benzodioxaborole (catecholborane).[15] The reaction of the monoborylacetylene **1a** with catecholborane at 80 °C leads to a mixture of 1,1-bis(1,3,2-benzodioxa-borol-2-yl)ethene (**3a**) and a small amount of *trans*-1,2-bis(1,3,2-benzo-



Scheme 4

dioxaborol-2-yl)ethene (**4a**) in 86% yield (Scheme 4).[16] The *cis*-addition of catecholborane proceeds regioselectively favoring the formation of the 1,1-isomer **3a**. Only a minor amount of the 1,2-isomer **4a** is obtained. Related 1,2-derivatives with a *cis*-arrangement have been reported by Marder and Norman,[17] and isomeric 1,1-diborylethene derivatives have been synthesized by Matteson.[18] Colorless **3a** melts at 105 °C with decomposition, it is soluble in toluene, benzene, and THF.

In the NMR spectra only signals for **3a** were found, indicating that the amount of the 1,2-derivative **4a** is rather small. However, its formation was unambiguously proven by X-ray structure analysis (see below). The ^{1}H NMR spectrum of **3a** exhibits a multiplet signal between δ = 6.60−6.93 for the aromatic protons and for the alkene hydrogen atoms. In the ^{13}C NMR spectrum one finds three signals at δ = 148.8, 123.1, and 112.9 for the aromatic carbon atoms. One sharp signal for the CH_2 carbon atom of the ethene unit at δ = 154.9 proves the presence of the 1,1-isomer, its chemical shift is similar to that of comparable compounds.[19,20] In the ^{11}B NMR spectrum one signal appears at δ = 32.2.

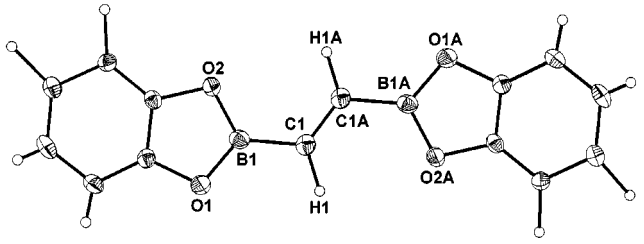


Figure 2. Molecular structure of **4a** in the crystal; selected bond lengths [Å] and angles [°]: C1−C1a 1.348(10), C1−B1 1.554(8), B1−O1 1.386(7), B1−O2 1.386(7), C1−H1 1.12(5); C1a−C1−B1 122.3(6), C1−B1−O1 125.8(5), C1−B1−O2 122.8(5), O1−B1−O2 111.4(5)

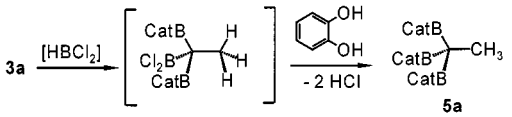
In the solid state the molecule **4a** (Figure 2) has a crystallographic inversion center at the midpoint of the C=C double bond and is almost planar (max. dev. 0.04 Å) resulting in C_{2h} symmetry. Both the B and C atoms of the ethene unit are planar coordinated. The heterocycles are almost planar and they are in a coplanar arrangement (dihedral angle: 0°). The length of the C1−C1a bond [1.348(10) Å] is that of a double bond and the B−C bonds [1.554(8) Å] are a bit shorter than single bonds.

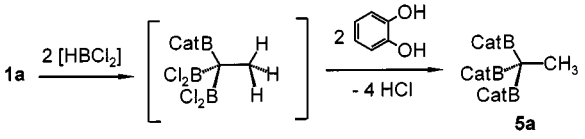
As indicated above, the hydroboration of **1a** with catecholborane stops after the first *cis*-addition. However, **3a** reacts with $HBCl_2$,[21,22] and subsequent substitution of the Cl atoms by catechol leads to 1,1,1-triborylethane **(5a)** in



Scheme 5

78% yield (Scheme 5). It is a colorless solid, which is soluble in toluene, THF, and dichloromethane. The spectroscopic data of **5a** are discussed below.

The hydroboration of **1a** with $[HBCl_2]$ and subsequent substitution of the chlorine atoms by catechol groups leads to 1,1,1-triborylethane **(5a)** in 83% yield (Scheme 6). The solid is recrystallized from THF to yield the THF adduct **5a**$(thf)_3$; in toluene it loses THF and forms crystalline **5a**. Both compounds have been studied by X-ray structure analyses (see below). The related compound $[(MeO)_2B]_3CCH_3$ has been reported previously.[18]



Scheme 6

The ^{1}H NMR spectrum of **5a** indicates a C_3 symmetry with three boryl substituents bonded to one carbon atom. The *ortho* substitution pattern for the aromatic region is observed between δ = 6.67−6.97, and a singlet appears at δ = 2.04 for the methyl group. The ^{13}C NMR spectroscopic data confirm the assignments from the ^{1}H NMR spectrum. The ^{11}B NMR spectrum shows one broad signal at δ = 35.

The X-ray diffraction study reveals that **5a**$(thf)_3$ has approximately C_{3v} symmetry (Figure 3 and 4). The heterocycles are almost planar. The boron-bound carbon atom is almost tetrahedral, and the C1−C2 bond is 1.556(5) Å. All B−C and B−O bond lengths in **5a**$(thf)_3$ are normal. The distances from the boron to the oxygen atoms of the THF molecules (2.72−2.91 Å) are relatively short. This, and the geometrical arrangement of the THF molecules, suggests a very weak interaction between these atoms. A similar arrangement was found in 1,1,2,2-tetrakis(1,3,2-benzodioxaborol-2-yl)ethane·2THF.[9] The THF-free solid-state structure of **5a** is almost identical to that of **5a**$(thf)_3$. No significant changes in bond lengths and angles are observed, which means that the influence of the THF molecules in **5a**$(thf)_3$ on its structural parameters is negligible.

1,1,1-Tris[di(*tert*-butyl)boryl]ethane (6a)

Treatment of **5a** with *t*BuLi results in the formation of 1,1,1-tris[di(*tert*-butyl)boryl]ethane (**6a**) in 12% yield (Scheme 7). Compound **6a** is a colorless, thermally stable liquid, which does not form any *closo*-C_2B_3 carborane by elimination of trisorganoboranes. In the mass spectrum of **6a** the molecular ion M^+ is absent; however, M^+ patterns for the C_2B_3 carborane derivative **7a** (m/z = 258) and for the C_2B_4 carborane derivative **8a** [m/z = 325, $(M - H)^+$] appear. These carboranes are most likely formed in the mass spectrometer. The ^{11}B NMR spectrum does not show

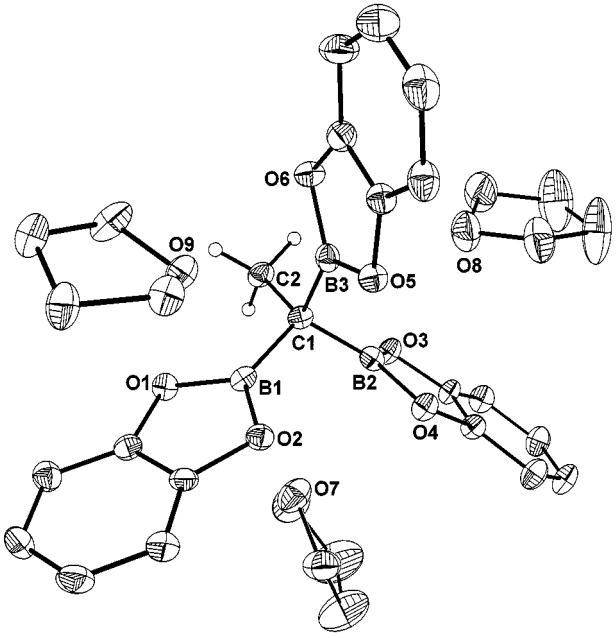


Figure 3. Molecular structure of **5a(thf)$_3$** in the crystal; selected bond lengths [Å] and angles [°]: C1−C2 1.556(5), C1−B1 1.544(6), C1−B2 1.564(6), C1−B3 1.569(6), B1−O1 1.407(5), B1−O2 1.395(5), B2−O3 1.397(5), B2−O4 1.385(5), B3−O5 1.387(6), B3−O6 1.395(6); B1−C1−C2 110.8(3), B1−C1−B2 110.2(3), B1−C1−B3 105.9(3), B2−C1−B3 108.5(3), C2−C1−B2 110.5(3), C2−C1−B3 110.9(3). Selected bond lengths [Å] and angles [°] for **5a**: C−C 1.556 [1.554−1.557(3)], C−B 1.568 [1.560−1.581(3)], B−O 1.385 [1.380−1.398(3)], B−C−C 110.4−113.1(2), B−C−B 103.3−113.1(2)

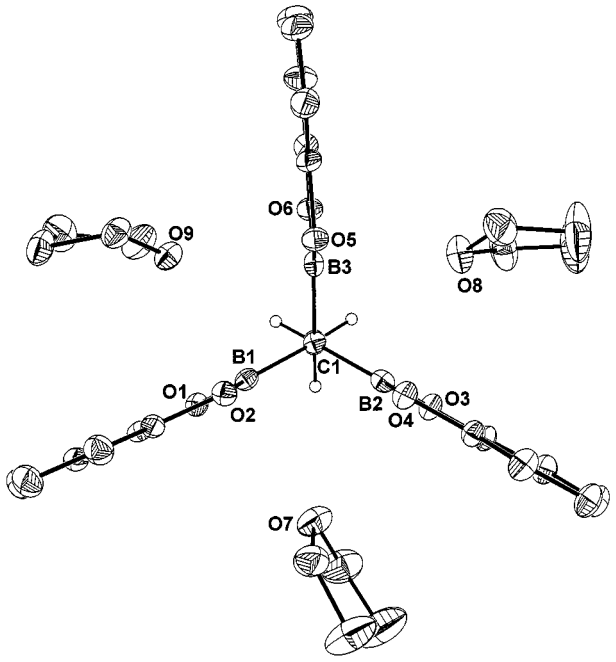

Figure 4. Molecular structure of **5a(thf)$_3$** as viewed along the C1−C2 vector

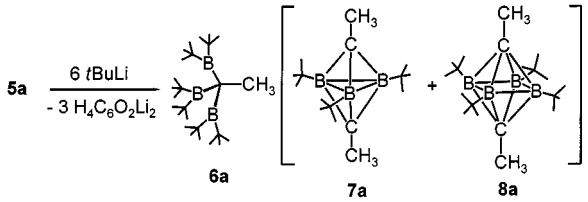
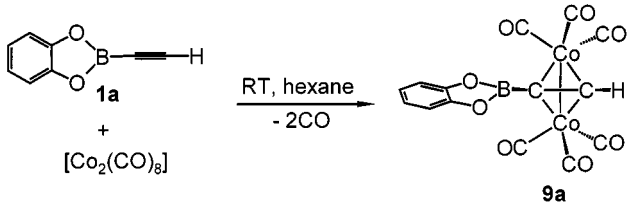
any signal for the carboranes, it contains only the signal for **6a** at δ = 83.4. The ^{1}H NMR spectrum exhibits two singlets at δ = 1.92 and 1.11 in the ratio 1:18, the ^{13}C NMR spectrum shows two signals at δ = 14.1 and 30.3, the carbon atoms adjacent to boron are not detected.



Scheme 7

3-(1,3,2-Benzodioxaborol-2-yl)-1,2-bis(tricarbonylcobalta)-tetrahedrane (9a)

Dicobaltahexacarbonyl-η^2-alkyne complexes are obtained by reacting alkynes with $Co_2(CO)_8$.[23] Analogously, the monoborylacetylene **1a** reacts with [$Co_2(CO)_8$] in hexane with elimination of CO to give complex **9a** (Scheme 8).



Scheme 8

Chromatographic workup of the dark brown solution and crystallization from toluene gives dark crystals of **9a** in 42 % yield. It is soluble in hexane, toluene, THF, or CH_2Cl_2, although it decomposes when exposed to light or heat. In the ^{1}H NMR spectrum the aromatic protons appear as an *ortho* pattern between δ = 6.70−6.94, the aliphatic proton gives a singlet at δ = 5.83 and is thus shifted downfield by more than 3 ppm relative to **1a** (δ = 2.77). This has been explained in related compounds by the electronegativity of the Co_2C_2 unit and the anisotropy effect of the C≡O groups. In the ^{13}C NMR spectrum three signals appear at δ = 149.0, 123.2, and 112.8 for the aromatic carbon atoms. The signal for CO at δ = 200 is broadened by intramolecular CO exchange. A broad signal at δ = 71 is found for the boron-bonded carbon, whereas the signal for the other carbon atoms appears at δ = 81.9. The ^{11}B NMR signal at δ = 32.6 is shifted downfield by 8 ppm with respect to that of **1a** (δ = 24.1).

The X-ray diffraction study confirms the structure of **9a** as that of a tetrahedrane (Figure 5). The almost linear B−C−C−H moiety in **1a** has been altered by the complexation, the angles are decreased to 151.0(2)° (B1−C2−C1) and 141(1)° (C2−C1−H1). The atoms C1−C2−Co1−Co2 form a distorted tetrahedrane, the dihedral angle O1−B1−C2−C1 is 11.9°. The Co−Co bond length of 2.48 Å is comparable with other data,[24] the distance between the carbon atoms of the tetrahedrane [1.334(3) Å] is 0.14 Å longer than the C−C bond in **1a**, and is of the same magnitude as a double bond.[24b,24c]

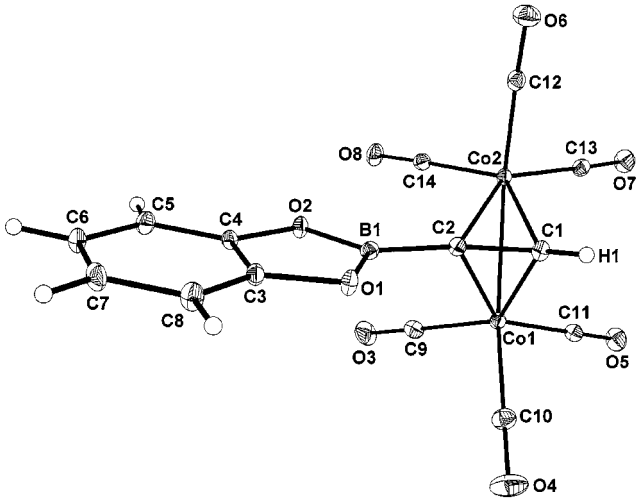


Figure 5. Molecular structure of **9a** in the crystal; selected bond lengths [A] and angles [°]: C1−C2 1.334(3), C1−Co1 1.956(2), C1−Co2 1.957(2), C2−Co1 1.991(2), C2−Co2 1.976(2), Co1−Co2 2.480(1), C2−B1 1.528(3); H1−C1−C2 141(1), C1−C2−B1 151.0(2), Co1−C1−Co2 78.67(7), Co1−C2−Co2 77.41(7), C1−C2−Co1 68.9(1), C1−C2−Co2 69.4(1), C2−C1−Co1 71.7(1), C2−C1−Co2 70.9(1), C1−Co1−C2 39.51(8), C1−Co2−C2 39.66(8), C1−Co1−Co2 50.68(6), C2−Co1−Co2 51.03(5)

Experimental Section

General: All reactions were carried out under a purified nitrogen atmosphere. The solvents were dried according to published procedures. − NMR: Bruker AC 200 or DRX 200 and Jeol FX-90 Q (^{11}B, external standard, $BF_3{\cdot}OEt_2$; ^{1}H, ^{13}C, standards were the signals of the residual protons in the deuterated solvents, calculated relative to TMS). − MS: Finnigan MAT 8230, ZAB-2F VG-Micromass and Jeol MS station JMS 700. − The following compounds were prepared according to literature procedures: bis(diisopropylamino)borylacetylene,[6] catecholborane.[15] * Boron carbide formation often reduces the found values.

1,3,2-Benzodioxaborol-2-yl-acetylene (1a), 1,3,2-(5-Methylbenzo)-dioxaborol-2-yl-acetylene (1b), 1,3,2-(5-*tert*-Butyl-benzo)dioxaborol-2-yl-acetylene (1c), and 2-Ethinyldibenzo[d.f]-1,3,2-dioxaborepine·THF (1d·thf): To a stirred solution of bis(diisopropylamino)borylacetylene (3.307 g, 14.0 mmol) in 50 mL of THF at −78 °C was added $HCl{\cdot}OEt_2$ (3.12 M; 10 mL, 31.2 mmol) within 30 min. Stirring was continued for 30 min., and NH_2iPr_2Cl formed as a white solid. Then, 14.0 mmol of the corresponding aromatic diol (**1a:** 1.540 g of catechol; **1b:** 1.744 g of 4-methylcatechol; **1c:** 2.330 g of 4-*tert*-butylcatechol; **1d:** 2.644 g of 2,2′-biphenol) dissolved in 10 mL of THF was added and the reaction mixture was allowed to warm overnight to room temperature. After filtration of the solid the solution was reduced almost to dryness. The products **1a**, **1b**, and **1c** were sublimed, **1d** was crystallized from THF.

1a: 1.227 g (61%), m.p. 53 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.77 (s, 1 H, C≡CH), 7.24−7.14 (m, 4 H, C_6H_4). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 93.7 (br., C≡*C*H), 113.7, 124.3, 148.5 (C_6H_4), B*C* not observed. − ^{11}B NMR (64 MHz, $CDCl_3$): δ = 24.1. − EI-MS: *m*/*z* (%) = 144 (100) [M^+]. − HR-EIMS: *m*/*z* = 144.0382 [M^+], calcd. for $^{12}C_8{}^1H_5{}^{11}B^{16}O_2$: 144.0383 (Δ = 0.1 mmu).

1b: 1.009 g (46%), m.p. 48 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.36 (s, 3 H, CH_3), 2.75 (s, 1 H, C≡CH), 7.12−6.88 (m, 3 H, C_6H_3). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 21.3 (CH_3), 93 (br., C≡*C*H), 112.0, 113.3, 123.8, 133.4, 145.4, 147.6 (C_6H_3), B*C* not observed. − ^{11}B NMR (64 MHz, $CDCl_3$): δ = 24.3. − EI-MS: *m*/*z* (%) = 158 (100) [M^+]. − $C_9H_7BO_2$ (158.0): calcd. C 68.43, H 4.47; found C 67.24, H 4.64.

1c: 1.915 g (68%), m.p. 45 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.31 (s, 9 H, CH_3), 2.75 (s, 1 H, C≡CH), 7.28−7.14 (m, 3 H, C_6H_3). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 31.7 (CH_3), 34.9 [*C*(CH_3)$_3$], 93 (br., C≡*C*H), 110.0, 111.7, 120.1, 144.3, 145.2, 147.4 (C_{ar}), B*C* not observed. − ^{11}B NMR (64 MHz, $CDCl_3$): δ = 24.3. − EI-MS: *m*/*z* (%) = 200 (24.6) [M^+], 185 (100) [$M^+ - CH_3$]. − $C_{12}H_{13}BO_2$ (200.0): calcd. C 72.05, H 6.55; found C 71.38, H 6.51.

1d·THF: 2.715 g (66%), m.p. 115 °C (dec.). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.94 (quint, 4 H, THF), 2.37 (s, 1 H, C≡CH), 4.00 (t, 4 H, THF), 7.45−7.02 (m, 8 H, H_{ar}). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 25.3 (THF), 69.5, 86 (br., C≡*C*H), 121.3, 124.1, 128.7, 129.2, 129.7, 153.1 (C_{ar}), B*C* not observed. − ^{11}B NMR (64 MHz, $CDCl_3$): δ = 15.9. − EI-MS: *m*/*z* (%) = 220 (100) [M^+]. − HR-EIMS: *m*/*z* = 220.0698 [M^+], calcd. for $^{12}C_{14}{}^1H_9{}^{11}B^{16}O_2$: 220.0696 (Δ = 0.2 mmu).

Tris(1,3,2-benzodioxaborol-2-yl)benzene Isomers (2a,2a′), Tris[1,3,2-(5-methylbenzo)dioxaborol-2-yl]benzene Isomers (2b,2b′), and Tris[1,3,2-(5-*tert*-butylbenzo)dioxaborol-2-yl]benzene Isomers (2c,2c′): Monoborylacetylene (**1a:** 0.865 g; **1b:** 0.956 g; **1c:** 1.209 g; 6.0 mmol) and (η^5-cyclopentadienyl)dicarbonylcobalt (0.055 g, 0.3 mmol, 5 mol-%) were heated in 15 mL of toluene for 24 h under reflux. The solid was separated and washed several times with small amounts of solvent (**2a,2a′:** THF and CH_2Cl_2; **2b,2b′:** toluene and CH_2Cl_2; **2c,2c′:** hexane) and dried in vacuum.

2a,2a′: 1.345 g (52%), m.p. 237 °C. − ^{1}H NMR (200 MHz, [D$_4$]MeOH): δ = 6.76−6.60 (m, 12 H, C_6H_4), 8.10−7.50 (m, 3 H, C_6H_3). − ^{13}C NMR (50 MHz, [D$_4$]MeOH): δ = 116.3, 120.9 (C_6H_4), 131.6 (C_6H_3, central, symm.), 134.7, 137.9, 141.7 (C_6H_3, central, unsymm.), 146.2 (C_6H_4). − ^{11}B NMR (64 MHz, [D$_4$]MeOH): δ = 30.1. − EI-MS: *m*/*z* (%) = 432 (100) [M^+]. − HR-EIMS: *m*/*z* = 432.1183 [M^+], calcd. for $^{12}C_{24}{}^1H_{15}{}^{11}B_3{}^{16}O_6$: 432.1148 (Δ = 3.6 mmu). − $C_{24}H_{15}B_3O_6$ (431.8): calcd. C 66.76, H 3.50; found C 65.28*, H 3.72.

2b,2b′: 1.550 g (55%), m.p. 220 °C. − ^{1}H NMR (200 MHz, [D$_4$]MeOH): δ = 2.18 (s, 9 H, CH_3), 6.66−6.44 (m, 9 H, C_6H_3, terminal), 7.64−7.50, 7.77 (each br., 3 H, C_6H_3, central). − ^{13}C NMR (50 MHz, [D$_4$]MeOH): δ = 21.0 (CH_3), 116.5, 117.4, 121.4 (C_6H_3, terminal), 130.7 (C_6H_3, central, symm.), 132.1 (C_6H_3, central, unsymm.), 134.5 (C_6H_3, terminal), 137.9, 141.1 (C_6H_3, central, unsymm.), 144.1, 146.3 (C_6H_3, terminal). − ^{11}B NMR (64 MHz, [D$_4$]MeOH): δ = 29.6. − EI-MS: *m*/*z* (%) = 474 (100) [M^+]. − HR-EIMS: *m*/*z* = 474.1643 [M^+], calcd. for $^{12}C_{27}{}^1H_{21}{}^{11}B_3{}^{16}O_6$: 474.1617 (Δ = 2.6 mmu). − $C_{27}H_{21}B_3O_6$ (473.9): calcd. C 68.43, H 4.47; found C 67.39, H 4.71.

2c′: 1.858 g (52%), m.p. 190 °C. − ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 1.35 (s, 18 H, CH_3), 1.37 (s, 9 H, CH_3), 7.43−7.17 (m, 9 H, C_6H_3, terminal), 8.14 (dd, 3 H, $^3J_{HH}$ = 7.5 Hz, $^5J_{HH}$ = 0.8 Hz), 8.31 (dd, 3 H, $^3J_{HH}$ = 7.5 Hz, $^4J_{HH}$ = 1.3 Hz, H adj.), 8.74 (pseudo triplet, 3 H, averaged $J_{HH} \approx$ 1 Hz). − ^{13}C NMR (50 MHz, CD_2Cl_2): δ = 31.9 (CH_3), 35.2 [*C*(CH_3)$_3$], 110.32, 110.36, 110.40, 111.87, 111.93, 111.95 [C(H) catechol, adj. to C(O)] 120.06, 120.13, 120.21 [C(H) catechol, adj. to C(CH_3)$_3$], 146.58, 146.62 [*C*(CH_3)$_3$], 147.25, 147.33, 147.42, 148.80, 148.84 [C(O)], BC not observed. − ^{11}B NMR (64 MHz, CD_2Cl_2): δ = 33.9. − EI-MS: *m*/*z* (%) = 600 (90) [M^+], 585 (100) [$M^+ - CH_3$]. − HR-EIMS: *m*/*z* = 600.2994

[M^+], calcd. for $^{12}C_{36}{}^{1}H_{39}{}^{11}B_3{}^{16}O_6$: 600.3026 (Δ = 3.2 mmu). − $C_{36}H_{39}B_3O_6$ (600.1): calcd. C 72.05, H 6.55; found C 70.44*, H 6.53.

1,3,5-Tris(dimesitylboryl)benzene (2e): To a suspension of **2a,2a′** (0.210 g, 0.44 mmol) in toluene (30 mL) was added a solution of MesLi·OEt_2 (1.191 g) in Et_2O (10 mL) at −20 °C. The mixture was then heated for 3 h under reflux. After removal of the solvents the reaction mixture was worked-up by column chromatography (SiO_2/THF). Recrystallization from toluene yielded 0.330 g of **2e** (49%), m.p. 235 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.88 (s, 36 H, *o*-CH_3), 2.23 (s, 18 H, *p*-CH_3), 6.70 (s, 12 H, C_6H_2), 7.50 (s, 3 H, C_6H_3). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 21.2 (CH_3), 23.4, 128.0, 138.4, 140.5 (C_6H_2), 145.1 (C_6H_3), B*C* not observed. − ^{11}B NMR (29 MHz, [D_8]toluene): δ = 88. − EI-MS: *m*/*z* (%) = 822 (2) [M^+ − H], 703 (6) [M^+ − Mes − H], 574 (12) [M^+ − $BMes_2$], 324 (54) [M^+ − 2$BMes_2$ − H], 249 (91) [$BMes_2$]$^+$, 120 (100) [MesH]$^+$, 105 (75) [$MesH^+$ − Me].

Bis(1,3,2-benzodioxaborol-2-yl)ethenes (3a and **4a):** A solution of **1a** (0.800 g, 5.6 mmol) and CatBH·THF (1.067 g, 5.6 mmol) in 20 mL of THF was heated at 80 °C under reflux for 4 h. Then the solvent was partially removed in vacuum and a white solid (1.267 g, 86%, m.p. 105 °C dec.) separated. It contained **3a** and a small amount of **4a**, which was not detected by NMR spectroscopy but obtained by crystallization from toluene.
3a: ^{1}H NMR (200 MHz, C_6D_6): δ = 6.93−6.60 (m, 8 H, C_6H_4), 6.99 (s, 2 H, BCH). − ^{13}C NMR (50 MHz, C_6D_6): δ = 112.8, 123.0, 148.8 (C_6H_4), 154.9 (CH_2). − ^{11}B NMR (64 MHz, C_6D_6): δ = 32.2. − EI-MS: *m*/*z* (%) = 264 (30) [M^+]. − $C_{14}H_{10}B_2O_4$ (263.8): calcd. C 63.73, H 3.82; found C 63.18, H 4.13.

1,1,1-Tris(1,3,2-benzodioxaborol-2-yl)ethane (5a): Procedure A: To a solution of **1a** (1.941 g, 13.5 mmol) in 50 mL of pentane was added BCl_3 (6 mL, 69.1 mmol) at −20 °C. Then triethylsilane (4.00 g, 34.4 mmol) in 10 mL of pentane was added very slowly at −20 °C. After 2 h of stirring at room temperature the solution was cooled to −20 °C and catechol (3.053 g, 27.7 mmol) in 10 mL of THF was added within 40 min. After 18 h of stirring at room temperature the solid was isolated by filtration, washed several times with hexane and dried in vacuum. Recrystallization from toluene yielded **5a** (4.282 g, 83%).
Procedure B: To a suspension of **3a** (1.543 g, 5.8 mmol) in 30 mL of pentane was added BCl_3 (2 mL, 23.0 mmol) at −20 °C. Then, triethylsilane (0.900 g, 7.7 mmol) in 20 mL of pentane was very slowly added. After 2 h of stirring at room temperature the solution was cooled to −20 °C and catechol (0.644 g, 5.8 mmol) in 5 mL of THF was added within 30 min. The reaction mixture was stirred for 18 h at −20 °C. Thereafter the solid was separated, washed several times with hexane, and dried in vacuum. Recrystallization from toluene yielded **5a** (1.731 g, 78%), m.p. 155 °C (dec.) − ^{1}H NMR (200 MHz, C_6D_6): δ = 2.04 (s, 3 H, CH_3), 6.97−6.67 (m, 12 H, C_6H_4). − ^{13}C NMR (50 MHz, C_6D_6): δ = 12.2 (CH_3), 112.8, 122.9, 149.0 (C_6H_4). − ^{11}B NMR (64 MHz, C_6D_6): δ = 35.4. − EI-MS: *m*/*z* (%) = 384 (100) [M^+]. − HR-EIMS: *m*/*z* = 384.1169 [M^+], calcd. for $^{12}C_{20}{}^{1}H_{15}{}^{11}B_3{}^{16}O_6$: 384.1147 (Δ = 2.1 mmu). − $C_{20}H_{15}B_3O_6$ (383.8): calcd. C 62.59, H 3.94; found C 61.01*, H 4.27.

1,1,1-Tris[di(*tert*-butyl)boryl]ethane (6a): A suspension of **5a** (1.00 g, 2.6 mmol) in 70 mL of hexane was reacted at −70 °C with 9 mL of *t*BuLi. After stirring at −20 °C the mixture was heated for 5 h under reflux. Separation of the solid resulted in a yellow solution, which was slowly concentrated under reduced pressure (50 Torr). The yellow, oily residue was distilled at 80 °C/0.4 Torr to yield **6a** (0.122 g, 12%). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.11 [s, 54 H, $C(CH_3)_3$], 1.92 (s, 3 H, CH_3). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.1 (CH_3), 30.3 [$C(CH_3)_3$], B*C* not observed. − ^{11}B NMR (29 MHz, $CDCl_3$): δ = 83.4. − EI-MS: *m*/*z* (%) = 325 (0.8) [M^+(**8a**) − H], 258 (1.2) [M^+(**7a**)], 243 (1.9) [M^+(**7a**) − Me], 41 (100).

3-(1,3,2-Benzodioxaborol-2-yl-1,2-bis(tricarbonylcobalta)tetrahedrane (9a): To a solution of $Co_2(CO)_8$ (2.034 g, 5.9 mmol) in 30 mL of hexane at −20 °C was slowly added **1a** (0.856 g,

5.9 mmol) in 20 mL of hexane. After stirring for 3 days at 20 °C the solvent was removed and the reaction mixture separated by column chromatography (florisil): with n-hexane red-brown $Co_2(CO)_8$, and with toluene brown **9a** was eluted (1.082 g, 42%), m.p. 125 °C (dec.). – ^{1}H NMR (200 MHz, C_6D_6): δ = 5.83 (s, 1 H, CH), 6.94–6.70 (m, 4 H, H_{ar}),. – ^{13}C NMR (50 MHz, C_6D_6): δ = 71 (br., CB), 81.9 (CH), 112.8, 123.2, 149.0 (C_{ar}), 200 (br., CO). – ^{11}B NMR (64 MHz, C_6D_6): δ = 32.6. – EI-MS: *m/z* (%) = 430 (12) [M^+], 402 (39) [M^+ – CO], 374 (6) [M^+ – 2CO], 346 (16) [M^+ – 3CO], 318 (36) [M^+ – 4CO], 290 (91) [M^+ – 5CO], 262 (46) [M^+ – 6CO], 118 (100) [Bcat – H]$^+$. – HR-EIMS: *m/z* = 429.8763 [M^+], calcd. for $^{12}C_{14}{}^1H_5{}^{11}B^{16}O_8{}^{59}Co_2$: 429.8741 (Δ = 2.2 mmu).

X-ray Crystal Structure Analyses of 1a, 4a, 5a, 5a(thf)$_3$ and 9a: Table 1 contains details of the structures. The intensities for **1a**, **4a**, and **5a(thf)$_3$** were measured with a four-circle diffractometer, and for **9a** and **5a** with a CCD area detector (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, ω-scans). The structures were solved by direct methods (SHELXS-86)[25] and refined by least-square methods based on F^2 with all measured reflections (SHELXL-97)[26]. For **1a**, **4a**, **5a** and **9a** the hydrogen atoms were located by difference Fourier synthesis and refined isotropically; for **5a(thf)$_3$** the hydrogen atoms were inserted in calculated positions. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-148514 (**1a**), -148515 (**4a**), -148516 [**5a(thf)$_3$**], -150265 (**5a**), and -148517 (**9a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Support of this work by the Deutsche Forschungsgemeinschaft (SFB 247), the Fonds der Chemischen Industrie, and the BASF AG is gratefully acknowledged. We thank Dr. Peter Greiwe for helpful discussions.

Syntheses and Reactivity of Exocyclic Unsaturated Heterodiborolanes and Their Diborylhexadiene Precursors − Formation of 2-Aza-4,5-dicarba-*nido*-hexaboranes(6)

Peter Greiwe,[a] Volker Beez,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

Dedicated to Prof. Dr. Herbert Schumann on the occasion of his 65th birthday

Keywords: Heterocarboranes / Heterocycles / Hydroborations / Heteroboranes / Boron

The aryl-substituted 3,4-diboryl-2,4-hexadienes **4c–e** are generated when 3,4-bis(dimethoxyboryl)-2,5-dimethyl-2,4-hexadiene (**4a**) and 3,4-bis(dichloroboryl)-2,5-dimethyl-2,4-hexadiene (**4b**) react with two equivalents of xylyllithium or duryllithium. Cyclization reactions of **4b** with heptamethyldisilazane and of **4c** with $MeN(SiMe_3)_2$, $S(SiMe_3)_2$, and $O(SiMe_3)_2$ lead to the corresponding 2,5-diaryl-3,4-diisopropylidene-1-hetero-2,5-diborolanes **5a,b**, **6**, and **7** in excellent yields. 1-Aza-2,5-di-*tert*-butyl-3,4-diisopropylidene-1-methyl-2,5-diborolane (**5c**) is obtained from the reaction of **5a** with two equivalents of *tert*-butyllithium. When the azadichlorodiborolane **5a** is reacted with $Li[BH_4]$ or $Li[DurBH_3]$ the Cl atoms are replaced by hydrogen or duryl and the liberated BH_3 hydroborates the isopropylidene groups to form the 2-aza-4,5-dicarba-4,5-diisopropyl-2-methyl-*nido*-hexaboranes **10a,b**. The new compounds are characterized by MS and ^1H, ^{11}B and ^{13}C NMR spectroscopy. X-ray structure analyses of **4c** and **4e** show that the two halves of the hexadienes are rotated by 80 to 90°. The solid state structures of the three duryl-substituted heterodiborolanes **5b**, **6**, and **7** reveal twist conformations of the C_2B_2X rings.

Introduction

A number of larger azacarboranes with 10−12 vertices are known,[1] but, to the best of our knowledge, examples of smaller clusters with C,B,N framework atoms have not been published. Recently, we reported the hydroboration of appropriate heterocycles to produce carborane[2a] and heterocarborane[2b] compounds. In particular a combined substitution/hydroboration reaction of the thiadiborolane **1** with $Li[RBH_3]$ produces the 4,5-dicarba-2-thia-*nido*-hexaborane(5) derivatives **2a−d** and the thiadicarbanonaborane(8) **3**.[2b]

Analogously, it should be possible to synthesize other heterocarboranes as well. We describe here corresponding reactions of the 1-aza-1-methyl-2,5-diborolane **5a** to give derivatives of the new class of 2-aza-4,5-dicarba-*nido*-hexaboranes(6) (**10**). In addition, the syntheses of some boron-alkyl-substituted 1-aza-, 1-thia-, and 1-oxa-2,5-diborolanes are reported. They are potential precursors for heterodicarba-*nido*-hexaboranes.

Results and Discussion

3,4-Diboryl-2,4-hexadienes

Attempts to replace the chlorine atoms in **1** by alkyl groups using organometallic reagents were not successful, as cleavage of B−S bonds occurred. However, as will be demonstrated, such chlorine substitution is possible in the case of the azadiborolane **5a**. Because of this limitation, a generally applicable approach to substituted heterodiborolanes was developed. The key compounds are 3,4-bis(monoorganoboryl)-substituted 2,4-hexadienes of type **4**, which can be transformed into heterodiborolanes.

3

In the bis(dimethoxy)- and bis(dichloroboryl)hexadienes **4a,b**, each of the boryl groups may be monosubstituted when bulky xylyllithium or duryllithium are used, to give the compounds **4c−e**. Whereas **4d** is isolated in 70% yield by distillation, the yield of the crystalline duryl compound **4e** was considerably less (13%). The chlorine derivative **4c** was obtained by recrystallization from hexane in 40% yield. When the sterically less demanding *tert*-butyllithium was reacted with **4a,b**, mixtures of alkylated species with different substitution patterns were obtained (Scheme 1).

The derivatives **4d,e** are not suitable for cyclization reactions because the methoxy groups are unreactive toward trimethylsilyl reagents. Also, attempts to exchange OMe for Cl in **4d** using an excess of BCl_3 or PCl_5 did not lead to

the desired chlorine compound. Either **4d** did not react or decomposition occurred.

Heterodiborolanes

Cyclization reactions of 1,2-bis(dichloroboryl)- or 1,2-bis[chloro(organo)boryl]arenes, -alkenes, and -alkanes with reagents carrying trimethylsilyl as leaving groups have been successfully employed in the syntheses of various five and six-membered heterocycles.[3] Accordingly, compound **4b** reacts with one equivalent of $MeN(SiMe_3)_2$ to give the azadiborolane **5a** in 90% yield as a pale-yellow, air-sensitive liquid. In spite of the bulky duryl groups, compound **4c** yields the corresponding azadiborolane **5b** almost quantitatively when allowed to react with equimolar amounts of $MeN(SiMe_3)_2$. The formation of the duryl-substituted thia- and oxadiborolanes **6** and **7**, on the other hand, requires an excess of $O(SiMe_3)_2$ or $S(SiMe_3)_2$, the absence of solvent, and higher temperatures (120 °C). Under these conditions, **6** and **7** are obtained in very good yields (Scheme 2).

Scheme 2

As shown above, monosubstitution of the boryl groups in the hexadienes **4a,b** can only be carried out when bulky substituents are used thus blocking a second substitution. A possible way to introduce smaller groups is the replacement of Cl in chloro-heterodiborolanes by alkyl groups; however, this was not successful for **1**. Only the azadiborolane **5a** is readily derivatized by this method. When treated with two equivalents of *tert*-butyllithium, compound **5a** generates the alkylated azadiborolane **5c** as a colorless, thermally labile liquid in 63% yield.

Azadicarba-*nido*-hexaboranes(6)

The only product of the reaction of **5a** with $Li[DurBH_3]$ is the 2-aza-4,5-dicarba-3-duryl-4,5-diisopropyl-2-methyl-*nido*-hexaborane (**10a**) carrying a duryl group in an equatorial position. This result is in agreement with the analogous reaction of the sulfur compound **1** with $Li[DurBH_3]$, whereas the reaction of **1** with $Li[PhBH_3]$ gives two isomers.[2b] This different behavior has been explained[2b] by a different reactivity of the lithium borates. In the first case, a duryl group would initially be transferred to the five-membered ring, which is then hydroborated by BH_3 to form the thiacarborane **2d**. In the second case, $Li[PhBH_3]$ would substitute the chlorine atoms by either hydrogen *or* a phenyl group and a mixture of two compounds (**2b,c**) is obtained. Such reasoning is not necessary if one assumes that the aryl group is always transferred first to give intermediates of type **5e,f** (if the starting material is **5a**) or the corresponding thia derivative (if the starting material is **1**), followed by hydroboration of the double bonds. This leads to a bicyclic organoborane of type **9** (and its thia analog) in which the boryl groups can easily change places by a rearrangement process prior to formation of the cluster structure (Scheme 3). Thus the finding of a mixture of two products (**2b,c**) having the phenyl group in either the apex *or* equatorial position and of only one product with an equatorial duryl substituent (**2d**, **10a**) can be explained by steric reasons. A duryl group in the apex position is strongly disfavored because the *ortho*-methyl groups would come very close to the isopropyl groups and the equatorial boron atoms.[4] For a phenyl group there is no such steric restriction, and both positions are possible.

Scheme 3

When **5a** is allowed to react with $Li[BH_4]$, a complex mixture of BH-substituted products is formed (Scheme 3). Three of them can be separated by GC/MS analysis. The compound with the shortest retention time is easily identified as the 2-aza-4,5-dicarba-4,5-diisopropyl-2-methyl-*nido*-hexaborane(6) (**10b**) by MS. The molecular peak is found at $m/z = 175$ and its *nido* structure is inferred from the ^{11}B NMR spectroscopic data. The two other compounds with longer retention times show MS peaks at $m/z = 189$ and 349, respectively. The first peak may be assigned to a product which is formed by hydroboration of **5f** with two equivalents of BH_3; the isotopic distribution pattern supports the presence of an additional BH_3 relative to **10b**. The isotopic pattern of the compound with $m/z = 349$ is in agreement with a molecular formula of $(i\text{PrC})_4(BH)_6(NMe)_2$ suggesting "dimerization" of the azacarborane **10b** or its precursors **8b** or **9b**. Since several structural isomers are possible, a geometry is not proposed at this point.

Spectroscopic and Structural Characterization

Both, the ^1H and ^{13}C NMR spectra of the diborylhexadienes **4c–e** exhibit two signals for the isopropylidene methyl groups. For the aryl ring C atoms in **4d** not adjacent to boron, three resonances are found consistent with freely rotating xylyl groups. The *ortho*-methyl groups of the aryl substituents in **4d,e** produce a strongly broadened signal which shows that ring rotation is somewhat restricted. The NMR spectra of the chlorine derivative **4c** show four singlets for the duryl-methyl protons, and all six aromatic carbon atoms can be distinguished, implying a fully restricted rotation about the B–C bond at ambient temperature. Surprisingly, only one slightly broadened signal for the methyl carbon atoms of the duryl groups is found.

The ^{11}B NMR shifts of the aza- and oxadiborolanes **5b** and **6** are almost identical ($\delta = 55$ and 54, respectively) and the *tert*-butyl derivative **5c** gives a signal at $\delta = 58$, whereas the value for the thiadiborolane **7** is $\delta = 72$. Although the ^1H and ^{13}C NMR spectroscopic data suggest that the duryl groups can rotate freely in **5b** and **6**, the data for **7** are consistent with a restricted rotation, which might be explained by the larger B–S distances compared to B–N and B–O, and the accompanying geometrical changes (see below).

The composition of **10a** follows from the ^1H and ^{11}B NMR and the mass spectra. Although **10a** could not be separated fully from by-products, most of the ^1H NMR signals were assigned. Four doublets are observed for the isopropyl groups and four singlets for the duryl substituents, as expected for the *nido* structure shown in Scheme 3. This is supported by the ^{11}B NMR spectroscopic data showing one doublet at $\delta = -41.5$ ($^1J_{BH} = 202$ Hz) for the apex BH, a second doublet at $\delta = 13.5$ ($^1J_{BH} = 130$ Hz, equatorial BH), and a singlet at $\delta = 23.1$ (equatorial B-duryl). Among the signals of the product mixture obtained from the reaction of **5a** with $Li[BH_4]$, the ^{11}B NMR spectroscopic data of **10b** can be identified when compared to those of **10a**. The equatorial boron atoms give a doublet at $\delta = 13.6$ ($^1J_{BH} = 155$ Hz) and for the apical boron a signal at $\delta = -45.2$ ($^1J_{BH} = 202$ Hz) is found. These data are very similar to those measured for the closely related thiacarborane **1d**, and calculated values[2b] and are in line with the proposed *nido*-6-⟨V⟩ clusters with a pentagonal aperture derived from a pentagonal bipyramid by removal of one apical vertex. This geometry was found for the solid state structure of **1d**. Both azacarboranes show NMR signals for one five-connected boron atom in the high-field region having large B–H coupling constants which are typical of apical bonding situations.[5] At lower field resonances for two three-connected boron atoms are found exhibiting coupling constants in the normal range for equatorial bonding.[5] The alternative *nido*-6-⟨IV⟩ structure established for $N_2B_4H_6$ derivatives which represents a fragment of a pentagonal bipyramid with a missing vertex at the base[6] can thus be excluded. Such a geometry has two kinds of four-connected boron atoms and would give rise to NMR signals in the region between the values found for **10a,b**.

Single crystal X-ray diffraction studies showed that the unit cell of the crystals of **4e** contained two independent molecules with crystallographic C_2 symmetry. The solid state structures of **4c** (Figure 1) and **4e** exhibit, as expected, similar features. The $Me_2C{=}C{-}B(OMe)/Cl$ units are

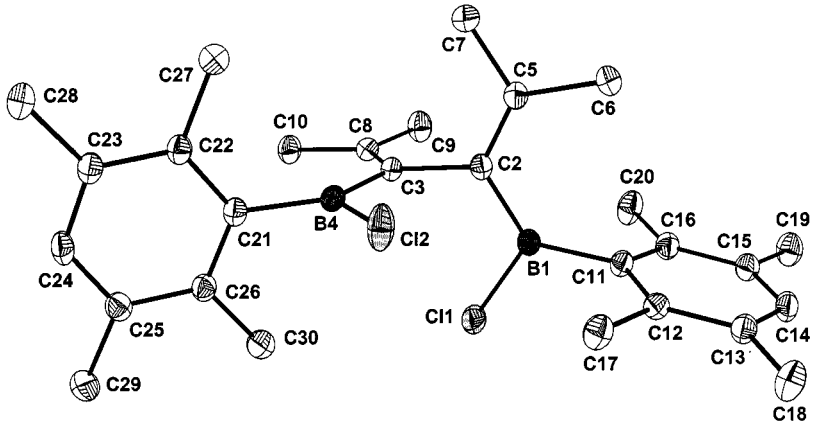

Figure 1. Molecular structure of **4c**; selected bond lengths [Å] (corresponding data for **4e** in square brackets): C3–C8 1.355(3) [1.328(8)], C2–C5 1.360(3) [1.355(8)], C2–C3 1.529(3) [1.520(10), 1.510(11)], C3–B4 1.540(4) [1.574(9)], C2–B1 1.541(4) [1.560(10)], B4–Cl2 1.799(3) [B–O 1.374(8)] B1–Cl1 1.802(3) [B–O 1.377(8)], B4–C21 1.582(4) [1.589(9)], B1–C11 1.581(4) [1.590(8)]

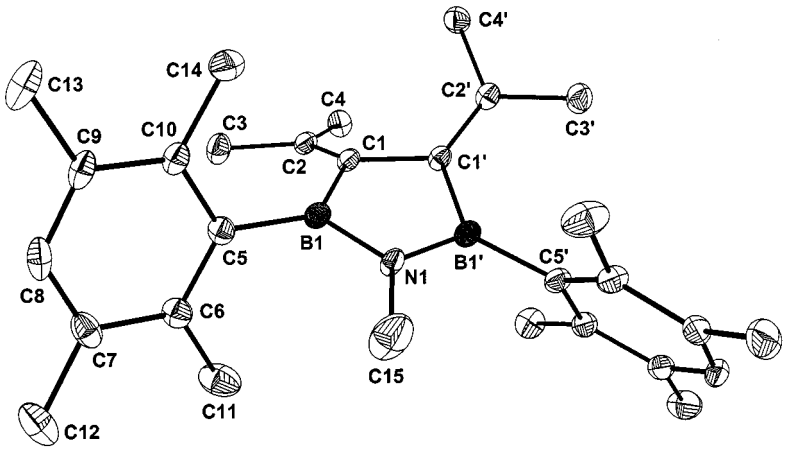

Figure 2. Molecular structure of **5b**; selected bond lengths [Å] and angles [°]: C1−C1′ 1.501(6), C1−C2 1.353(4), C1−B1 1.567(5), B1−C5 1.575(5), B1−N1 1.425(4), N1−C15 1.462(7); C2−C1−C1′−C2′ 51.0

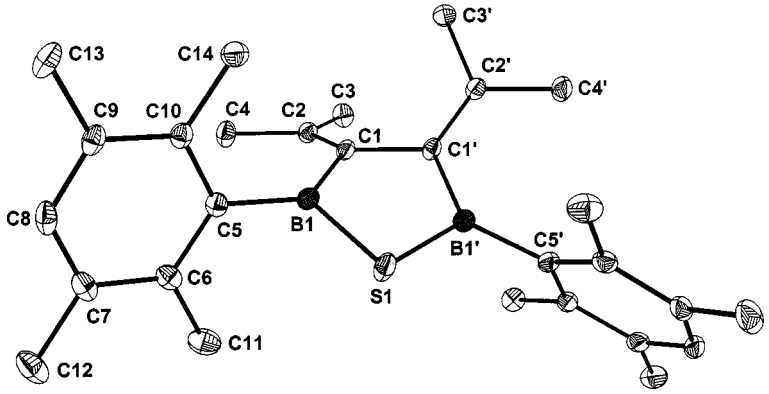

Figure 3. Molecular structure of **7**; selected bond lengths [Å] and angles [°] (corresponding data for **6** in square brackets): C1−C1′ 1.508(3) [1.500(4)], C1−C2 1.359(2) [1.358(3)], C1−B1 1.552(2) [1.571(3)], B1−C5 1.572(2) [1.570(5)], B1−S1 1.824(2) [B1−O1 1.400(2)]; C2−C1−C1′−C2′ 53.8 [50.2]

planar and the two halves of the molecules are rotated by 90° (**4c**) and by 78 and 82° in the two independent molecules of **4e**. This difference is most probably due to crystal packing effects. The duryl groups are positioned almost perpendicular to the $Me_2C{=}C{-}B(OMe)/Cl$ plane (85/89° in **4c** and 88/87° in **4e**).

The molecular structures of **5b** (Figure 2), **6** and **7** (Figure 3) exhibit C_2 symmetry, the axis bisects the C1−C1′ bond and runs through the heteroatom. The five-membered rings are twisted about the C1−C1′ bond by 17.9° (**5b**), 16.0° (**6**) and 22.3° (**7**), respectively (B1−C1−C1′−B1′ torsion angles). Because of the steric bulk, the two neighboring isopropylidene groups are twisted about the double bonds by 18.5° (**5b**), 19.0° (**6**), and 18.1° (**7**) as determined from the [C1′−C1−B1]/[C4−C3−C2] interplanar angles. The duryl groups adopt angles of 67° (**5b**), 66° (**6**), and 69° (**7**) with the corresponding C1−B1−X planes.

Conclusion

In this paper we report a route to transform the azaorganoborane heterocycle **5a** into the 2-aza-4,5-dicarba-*nido*-hexaboranes **10a,b**. The synthetic strategy involves a substitution/hydroboration reaction of **5a** with $Li[RBH_3]$ (R = H, Dur) to give the hydrido-1-aza-2,5-diborolanes **5e,f** which are hydroborated by the freed BH_3. Presumably, the final products **10a,b** are formed via the intermediates **8a,b** and **9a,b**. This reaction sequence allows the formation of other heterodicarbahexaboranes.

Experimental Section

All reactions and manipulations were performed in dry glassware under argon or nitrogen using standard Schlenk techniques. Solvents were distilled from appropriate drying agents under inert gas before use. − $Et_2O{\cdot}BF_3$ was used as the external standard for ^{11}B NMR. As internal references for ^1H and ^{13}C NMR spectra the signals of the deuterated solvents were used and calculated for TMS. NMR: Bruker AC 200 and Bruker DRX 200. − MS: Varian MAT CH7 and GCMS HP 5971. − The following starting materials were prepared by literature methods: lithium durylborate,[7] xylyllithium,[8] duryllithium.[8] Hexamethyldisilathiane, hexamethyldisiloxane, and heptamethyldisilazane were commercially obtained.

3,4-Bis[(chloro)durylboryl]-2,5-dimethyl-2,4-hexadiene (4c): A sample of duryllithium ($DurLi{\cdot}OEt_2$; 5.14 g, 24.8 mmol), obtained from DurBr and LiBu, was suspended in 150 mL of hexane, cooled to 0 °C, and **4b** (3.35 g, 12.4 mmol), dissolved in 20 mL of hexane, was added. The mixture was refluxed for 2.5 h and the precipitate

filtered off and washed twice with 20 mL of hexane. The filtrates were concentrated and cooled to −30 °C. Colorless **4c** (2.31 g, 5 mmol, 40%) precipitated from the solution. − ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.77, 1.82 (2 s, 2 × 6 H, $(CH_3)_2C$), 2.09, 2.10 (2 s, 2 × 6 H, *m*-aryl-CH_3), 2.24, 2.42 (2 s, 2 × 6 H, *o*-aryl-CH_3), 6.88 (s, 2 H, aryl). − ^{11}B NMR (C_6D_6, 64 MHz): δ = 61. − ^{13}C NMR (C_6D_6, 50 MHz): δ = 19.4 (aryl-CH_3), 26.7, 23.7 [2 × C(*C*H_3)$_2$], 131.5, 131.8, 132.5, 133.8, 134.2 (5 × C_{aryl}), 145, 147 [both br, B*C*C$(CH_3)_2$ and BC_{aryl}], 164.1 [*C*$(CH_3)_2$]. − EI-MS: *m*/*z* (%) = 467 [M^+], (19), 432 [M^+ − Cl] (100), 413 (71), 332 [M^+ − Dur] (23).

3,4-Bis[(2,6-dimethylphenyl)methoxyboryl]-2,5-dimethyl-2,4-hexadiene (4d) and 3,4-bis[(duryl)methoxyboryl]-2,5-dimethyl-2,4-hexadiene (4e): The same procedure as described for **4c** was used. Instead of recrystallization the solvent was stripped off and the remaining viscous product was distilled under high vacuum. Yields: 790 mg (2 mmol, 70%) of **4d** and 100 mg (0.2 mmol, 13%) of **4e**. Compound **4e** crystallizes at room temp. after a few hours, whereas **4d** becomes a glass-like solid

4d: ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.65, 1.69 [2 s, 2 × 6 H, C$(CH_3)_2$], 2.15 (s, broad, 12 H, aryl-CH_3), 3.38 (O−CH_3), 6.91 (d, $^3J_{HH}$ = 7.5 Hz, 4 H, aryl), 7.08 (t, $^3J_{HH}$ = 7.5 Hz, 2 H, aryl). − ^{11}B NMR ($CDCl_3$, 64 MHz): δ = 47. − ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 21.3 (aryl-CH_3), 22.4, 24.0 [C(*C*H_3)$_2$], 53.5 (O−CH_3), 126.1, 127.1, 137.9 (3 × C_{aryl}), 141, 143 [both br, B*C*C$(CH_3)_2$ and BC_{aryl}], 147.3 [*C*$(CH_3)_2$]. − EI-MS: *m*/*z* (%) = 402 (22) [M^+], 298 (8) [M^+ − xylyl], 224 (66) [M^+ − (BXylOMe) − OMe], 209 (58) [M^+ − (BXylOMe) − OMe − Me], 147 (100) [XylBOMe$^+$].

4e: ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.84, 1.86 [2 s, 2 × 6 H, $(CH_3)_2$C], 2.17 (s, 12 H, *m*-aryl-CH_3), 2.22 (s, br, 12 H, *o*-aryl-CH_3), 3.32 (s, 6 H, O−CH_3), 6.90 (s, 2 H, duryl). − ^{11}B NMR (C_6D_6, 64 MHz): δ = 49. − ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 18.3, 19.6 (aryl-CH_3), 22.7, 24.4 [2 × C(*C*H_3)$_2$], 53.4 (O−CH_3), 131.1, 133.3, 133.7 (3 × C_{aryl}), 147.6 [*C*$(CH_3)_2$]. − EI-MS: *m*/*z* (%) = 458 (12) [M^+], 325 (9) [M^+ − duryl], 309 (4), 252 (37) [M^+ − DurB$(OMe)_2$], 237 (31), 175 (100) [DurBOMe$^+$].

1-Aza-2,5-dichloro-3,4-diisopropylidene-1-methyl-2,5-diborolane (5a): Heptamethyldisilazane (1.52 g, 8.69 mmol) was added at room temp. to a solution of **4b** (2.36 g, 8.69 mmol) in 50 mL of hexane. The mixture was refluxed for 4 h, the solvent evaporated and the residue distilled at 58 °C/8 × 10^{-3} mbar to give 1.80 g (7.8 mmol, 90%) of colorless, air-sensitive **5a**. − ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.71, 2.15 [2 s, 2 × 6 H, $(CH_3)_2$C, *exo* and *endo*], 2.89 (s, 3 H, N−CH_3). − ^{11}B NMR (C_6D_6, 64 MHz): δ = 44. − ^{13}C NMR (C_6D_6, 50 MHz): δ = 23.1, 26.4 [2 × C(*C*H_3)$_2$, *exo* and *endo*], 29.7 (N−CH_3), 137 [br, B*C*−C$(CH_3)_2$], 146.0 [*C*$(CH_3)_2$]. − EI-MS: *m*/*z* (%) = 229 (51) [M^+], 214 (100) [M^+ − CH_3], 200 (7) [M^+ − C_2H_5], 122 (25) [M^+ − C_8H_{11}].

1-Aza-2,5-diduryl-3,4-diisopropylidene-1-methyl-2,5-diborolane (5b): Heptamethyldisilazane (325 mg, 1.85 mmol) was added to a solution of **4c** (650 mg, 1.4 mmol) in 25 mL of hexane. The mixture was stirred for 15 h, filtered and the solvent removed in vacuo. According to the ^{1}H NMR spectrum the reaction was almost quantitative. Recrystallization from hexane at −80 °C gave 425 mg (1 mmol, 70%) of colorless **5b**. − ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.81, 1.84 [2 s, 2 × 6 H, $(CH_3)_2$C], 2.16, 2.26 [2 s, 2×12 H, aryl-CH_3], 2.56 (N−CH_3), 6.94 (s, 2 H, duryl). − ^{11}B NMR (C_6D_6, 64 MHz): δ = 55. − ^{13}C NMR (C_6D_6, 50 MHz): δ = 19.0, 19.6 (aryl-CH_3), 25.9, 23.2 [C(*C*H_3)$_2$], 31.6 (N−CH_3), 131.3, 133.5 (2 × C_{aryl}), 142.5 (C_{aryl}H), 143, 144 [both br, B*C*C$(CH_3)_2$ and BC_{Aryl}]. − EI-MS: *m*/*z* (%) = 425 (100) [M^+], 382 (17) [M^+ − C$(CH_3)_2$], 356 (12), 291 (17) [M^+ − Dur].

1-Aza-2,5-di-*tert*-butyl-3,4-diisopropylidene-1-methyl-2,5-diborolane (5c): *tert*-Butyllithium (24 mmol, 1.7 M in pentane) was added to a solution of **5a** (2.74 g, 12 mmol) in hexane at −50 °C. The mixture was stirred for 15 h at room temp., the liquid separated from the precipitate and the solvent removed in vacuo. The remaining oil was distilled at 10^{-2} mbar and a bath temperature of 50−90 °C yielding 2.06 g (7.5 mmol, 63%) of **5c**. Part of the product decomposed under these conditions to a dark brown solid. − ^{1}H NMR ($CDCl_3$, 200 MHz): δ =1.19 (s, 18 H, *t*Bu), 1.66, 1.82 [2 s, 2×6 H, $(CH_3)_2$C], 2.88 (s, 3 H, N−CH_3). − ^{11}B NMR (C_6D_6, 64 MHz): δ = 58. − ^{13}C NMR (C_6D_6, 50 MHz): δ = 21.4 [*C*$(CH_3)_2$], 22.9, 26.9 [2 × C(*C*H_3)$_2$], 28.6 [C(*C*H_3)$_3$], 32.9 (N−CH_3), 126.0 [*C*$(CH_3)_2$], 150 [br, B*C*C$(CH_3)_2$]. − EI-MS: *m*/*z* (%) = 273 (28) [M^+], 216 (24) [M^+ − *t*Bu], 174 (10) [M^+ − C$(CH_3)_2$], 160 (16), 41 (100) [$C_3H_5^+$].

2,5-Diduryl-3,4-diisopropylidene-1-oxa-2,5-diborolane (6): A sample of **4c** (400 mg) was refluxed for six hours in 10 mL of hexamethyldisiloxane. After removal of all volatile components, pure **6** remained as a colorless solid. − ^{1}H NMR (C_6D_6, 200 MHz): δ = 1.69, 1.86 [2 s, 2×6 H, $(CH_3)_2$C], 2.12, 2.33 (2 s, 2×12 H, aryl-CH_3), 6.94 (s, 2 H, duryl). − ^{11}B NMR (C_6D_6, 64 MHz): δ = 54. − ^{13}C NMR (C_6D_6, 50 MHz): δ = 19.5, 19.3 (2 × aryl-CH_3), 23.5, 25.6 [2 × C(*C*H_3)$_2$], 132.1, 133.5, 134.5 (C_{aryl}H), 147.5 [*C*$(CH_3)_2$]. − m.p. 190 °C (dec.). − EI-MS: *m*/*z* (%) = 412 (100) [M^+], 278 (25) [M^+ − Dur], 252 (38) [M^+ − DurBO].

2,5-Diduryl-3,4-diisopropylidene-1-thia-2,5-diborolane (7): A sample of **4c** (800 mg, 1.71 mmol) was heated for 4 h to 120 °C in 5 mL of hexamethyldisilathiane. The yellow solution was cooled to room temp. which caused the product to precipitate. The colorless solid **7** (610 mg, 1.4 mmol, 83%) was separated and washed with cold hexane. − ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.77, 1.82 [2 s, 2 × 6 H, $(CH_3)_2$C], 2.07 (s, 6 H, aryl-CH_3), 2.21 (s, 18 H, aryl-CH_3), 6.92 (s, 2 H, duryl). − ^{11}B NMR ($CDCl_3$, 64 MHz): δ = 72. − ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 18.9, 19.3 (2 × *m*-aryl-CH_3), 19.5, 19.8 (2 × *o*-aryl-CH_3), 22.8, 25.4 [2 × C(*C*H_3)$_2$], 131.2, 132.3, 132.5, 133.1, 133.5 (5 × C_{aryl}), 145 [br, B*C*−C$(CH_3)_2$ or BC_{aryl}], 145.5 [*C*$(CH_3)_2$], 148 [br, B*C*−*C*$(CH_3)_2$ or BC_{aryl}]. − EI-MS: *m*/*z* (%) = 428 (100) [M^+], 294 (20) [M^+ − Dur], 253 (69) [M^+ − C$(CH_3)_2$ − Dur].

2-Aza-4,5-dicarba-3-duryl-4,5-diisopropyl-2-methyl-*nido*-hexaborane(6) (10a): Lithium durylborate (990 mg, 6.2 mmol) was suspended in 60 mL of hexane. Compound **5a** (720 mg, 3.1 mmol) was added at room temp. and the mixture was stirred for 48 h. The solution was separated from the precipitate, the solvent evaporated and the residue distilled at 90−100 °C/8 × 10^{-3} mbar to yield 142 mg of a colorless oil consisting mostly of **10a**. − ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 0.95, 0.99, 1.17, 1.20 [4 d, 4×3 H, CH(C*H*$_3$)$_2$, $^3J_{HH}$ = 8 Hz], 2.16, 2.19 (2 s, 2 × 3 H, *m*-methyl), 2.21, 2.23 (2 s, 2 × 3 H, *o*-methyl), 2.62 (s, 3 H, *N*-methyl), 6.88 (s, 1 H, *p*-aryl-CH). − ^{11}B NMR (C_6D_6, 64 MHz): δ = 23.1 (s, B-duryl), 13.5 (d, B_{eq}H, $^1J_{BH}$ = 130 Hz), −41.5 (d, B_{apical}H, $^1J_{BH}$ = 202 Hz). − EI-MS: *m*/*z* (%) = 295 (20) [M^+ − B], 280 (3) [M^+ − B − CH_3], 252 (10) [M^+ − B − C_3H_7], 43 (100) [$C_3H_7^+$], 41 [$C_3H_5^+$].

2-Aza-4,5-dicarba-4,5-diisopropyl-2-methyl-*nido*-hexaborane(6) (10b): Li[BH_4] (155 mg, 5.75 mmol) was suspended in 50 mL of hexane and **5a** (660 mg, 2.88 mmol) was added at room temp. After 5 h of stirring at 40 °C, the solvent was removed at 1 mbar and the remaining colorless oil condensed into a dry-ice cooled trap. − ^{11}B NMR (C_6D_6, 64 MHz): δ = −45.2 (d, B_{apical}, $^1J_{BH}$ = 202 Hz), 13.6 (d, B_{eq}, $^1J_{BH}$ = 155 Hz). − EI-MS: *m*/*z* (%) = 175 (22) [M^+], 160 (10) [M^+ − Me], 146 (11) [M^+ − NMe], 132 (45) [M^+ − *i*Pr], 41 (100) [$C_3H_5^+$].

Crystal Structure Determinations: Crystal data and details of the structure determinations are presented in Table 1. Data collection for **4c**, **4e**, **5b**, and **6**: Siemens Stoe AED2 diffractometer (Mo-K_α radiation, ω-scans) at −70 °C; for **7**: Bruker AXS Smart 1000 area detector (Mo-K_α, ω-scans) at −100 °C. The structures were solved by direct methods (SHELXS 86)[9] and refined by least-squares based on F^2 with all measured reflections (SHELXL 97)[9] using anisotropic temperature factors for non-hydrogen atoms. Hydrogen atoms were located and refined isotropically (**6**, **7**) or inserted in calculated positions (**4c**, **4e**, **5b**). The structure refinement of **7** revealed that sulfur was partially replaced by oxygen (ca. 9%).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-146539 (**4c**), -146540 (**4e**), -146541 (**5b**), -146542 (**6**), and -146543 (**7**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[4] As simple modeling of such a carborane shows the only possible orientation for an apical duryl group is parallel to the basal B−B and C−C vectors. Even in this position the *ortho*-methyl groups are very close to the isopropyl substituents and the equatorial boron atoms, but these steric interactions do not seem to be severe enough that one would completely exclude the possibility of a duryl group in the apical position. There are only two feasible ways from which such a carborane could originate: by an exchange of two boryl groups in **9a** or by a hydroboration with 1,2-diduryldiborane(6). Both reactions would involve intermediates with even shorter duryl−isopropyl contacts, too short for nonbonding interactions. Thus a carborane with a duryl group in an apical position should be stable but in the above discussed cases duryl−isopropyl interactions make the bicyclic intermediates energetically inaccessible so that a carborane cannot form this way.

Reactions of Diboratetrahalides(4) with Boriranylideneboranes − Formation, Reactivity, and Structures of Cyclic Tetraborylmethanes and Isomeric Diborylmethyleneborane Derivatives

Andreas Ziegler,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

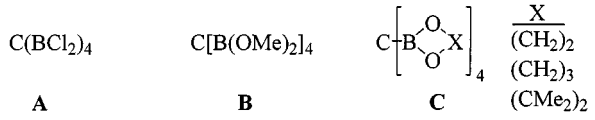
Dedicated to Prof. Dr. Günter Helmchen on the occasion of his 60th birthday

Keywords: Boranes / Diboration / Hyperconjugation / Cyclizations

Reaction of the boriranylideneboranes **1a**,**b**,**c** with tetrahalogenodiboranes(4) leads to two types of products. In the case of **1a** the cyclic tetraborylmethane derivatives **2a**,**a′** are formed in high yield, whereas **1b**,**c** yield the isomeric linear diborylmethyleneboranes **3b**,**c**. Compound **2a** reacts with diethylamine, (dimethylamino)trimethylsilane, and lithium pyrrolidinide to give the 1,3-diboretanes **4a**,**b**,**c**. The composition of the products was determined from spectroscopic data and X-ray structure analyses of **2a**, **3c**, **4a**, and **4c**.

Introduction

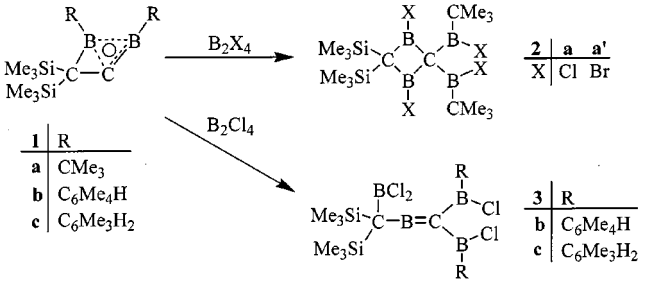
In 1969 the first synthesis of tetraborylmethane derivatives was reported. Stone et al.[1] obtained the tetrakis(dichloroboryl)methane (**A**), which was characterized by mass spectrometry, in a co-condensation reaction of carbon and borontrichloride. At the same time, Matteson et al. synthesized the oxygen-substituted derivatives **B** and **C**.[2−5] These compounds are widely used in organic synthesis.



A **B** **C**

Tetraborylmethane [$C(BH_2)_4$] has been the subject of theoretical studies. Schleyer et al. calculated the energy differences between the tetrahedral and the planar structure of methane derivatives.[6] It was found that electropositive substituents like lithium or boron should stabilize the planar tetracoordinate configuration by reducing the energy difference of 630 kJ/mol between tetrahedral and planar methane. For nonclassical (planar) methane, boron and lithium should act as σ-donor and π-acceptor substituents. The formation of a three-center, two-electron bond means that all substituents must lie in the same plane. Recently, the X-ray structure analysis of $C[B(OMe)_2]_4$ revealed, as expected, that it has the classical tetrahedral structure.[7]

We present here reactions of the nonclassical boriranylideneboranes **1a**,**b**,**c**, first prepared by Berndt et al. in the early 1980s,[8,9] with tetrahalogenodiboranes(4). In the case of the *tert*-butyl-substituted compound **1a**, the addition of B_2X_4 (X = Cl, Br) leads to **2a**,**a′**, which are the first tetraborylmethane derivatives with two different substituents at the central carbon atom (Scheme 1). In contrast, **1b**,**c** and B_2Cl_4 form the linear products **3b**,**c** in good yields. To our surprise the reactivity of **2a**,**a′** is rather weak. Substitutions to form definite products occur with amines to give **4a**,**b**,**c**.



Scheme 1

Results and Discussion

Synthesis and Reactivity

The tetraborylmethanes **2a** and **2a′** are formed in excellent yields upon addition of B_2X_4 (X = Cl, Br) to a solution of **1a** in hexane at low temperature. The spectroscopic data of **2a**,**a′** are similar; **2a** is a colorless, low melting, crystalline solid, which shows only one ^{11}B NMR signal at δ = 69 for all boron atoms. In the ^1H NMR spectrum the expected signals for $SiMe_3$ and CMe_3 are observed. The ^{13}C NMR spectrum of **2a** exhibits the resonances of the methyl groups of the trimethylsilyl and *tert*-butyl substituents at δ = 3.7 and 29.6, respectively. The quaternary carbon atoms of CMe_3 and Si_2CB_2 give broad signals at δ = 31 and 58, respectively. A low-field temperature-dependent signal at δ = 79 is detected for the central carbon atom of CB_4.

Compound **2a′** is less stable than **2a**. Decomposition of freshly prepared, colorless **2a′** is visible by the increase of a

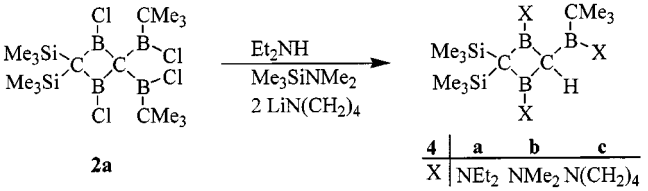
brown color. The CI mass spectra of **2a′** exhibits the molecular ion peak [M^+] at $m/z = 648$ with an intensity of 2%.

The reaction of B_2Cl_4 with the aryl-substituted compounds **1b**,**c** yields slightly yellow crystals of **3b**,**c** with a molecular mass of 622 and 594, respectively. The ^{11}B NMR spectra show, for both compounds, one broad signal, which splits at higher temperature into two peaks with a 1:1 intensity. The signal at lower field belongs to the two equivalent boron atoms, the second signal is formed by superposition of signals for the remaining boron centers. The expected signals appear in the ^1H and the ^{13}C NMR spectra of **3b**,**c**, the signals for CB_3 are broad and located at $\delta = 95$ and 96, respectively.

In an attempt to substitute the four chlorine atoms at boron by amino substituents, compound **4a** was synthesized by treating **2a** with an excess of diethylamine in hexane (Scheme 2). This type of compound is already known in the literature and was first prepared by Berndt et al.[10,11] It is obtained as a colorless solid in good yield. During the reaction, one of the carbon−boron bonds is cleaved with protonation of the carbon atom by the amine. The ^{11}B NMR spectrum of **4a** shows only one signal at $\delta = 45$ for all three boron atoms. For the methylene protons of the diethylamine groups of the ring, an ABX_3 system appears due to the prochiral carbon ring atom. The resonance for the proton at HCB_3 is located at $\delta = 0.37$, as indicated by a two-dimensional ^1H, ^{13}C NMR study. The remaining signals of **4a** are in the expected areas. In the ^{13}C NMR spectrum the CB_3 signal is located at $\delta = 28$.



Scheme 2

In another attempt to synthesize a tetraborylmethane derivative with four amino groups, compound **2a** was treated with four equivalents of (dimethylamino)trimethylsilane. The only product isolated in this reaction is **4b**, an analog of **4a**. The origin of the hydrogen in **4b** is not known, although it might come from the *tert*-butyl group of the cleaved boryl group. However, the expected cleavage product, a (dimethylamino)boracyclopropane, was not detected. Compound **4b** was characterized by ^1H, ^{13}C and ^{11}B NMR spectroscopy. A CI mass spectrum of **4b** shows the molecular ion peak [$M^+ + 1$] at $m/z = 394$ as the base peak.

To obtain further information on the reactivity of **2a**, attempts were made to substitute only two of the four chlorine atoms at boron by amino substituents. When **2a** is treated with two equivalents of lithium pyrrolidinide, the formation of **4c** is observed. Its composition was determined by NMR and MS spectroscopy and an X-ray structure analysis.

Crystal Structures

Single crystals of **2a** were grown from a hexane solution at −20 °C. Figure 1 shows a molecule of **2a**. The torsion angle C1−B1−B2−C2 is very small (4.5°) so that the four-membered ring is almost planar. The bond lengths C1−B1 and C1−B2 are 1.555 and 1.547 Å, which are shortened in comparison to C2−B1 and C2−B2 (1.605 and 1.606 Å). The bond lengths C1−Si1 and C1−Si2 (1.912 and 1.914 Å) are longer than the corresponding distances in **4a** and **4c**. We explain these data by C−Si hyperconjugation of the ring boron atoms with the C1−Si1 and C1−Si2 bonds in **2a**. Tetracoordinate C2 is not a planar carbon center, it has a normal tetrahedral environment of four boron atoms.

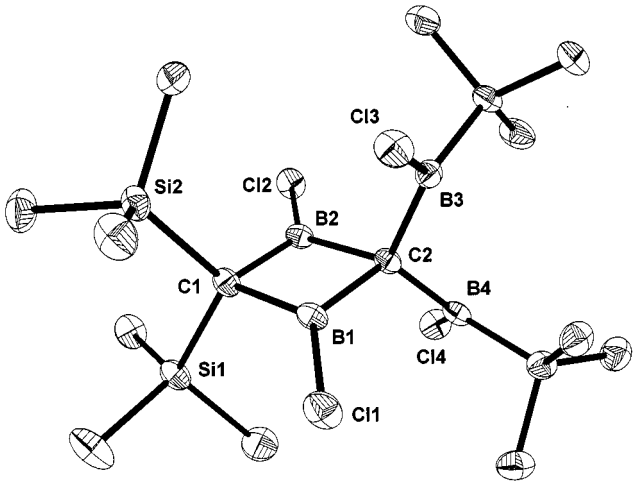


Figure 1. Structure of **2a** in the crystal; selected bond lengths [Å] and angles [°]: B1−C1 1.555(3), B1−C2 1.605(3), B2−C1 1.547(3), B2−C2 1.606(3), C2−B3 1.575(2), C2−B4 1.573(3), C1−Si1 1.912(2), C1−Si2 1.914(2); B1−C1−B2 80.4(1), B1−C2−B2 77.2(1), C1−B1−C2 101.0(1), C1−B2−C2 101.2(1), B3−C2−B4 113.4(1), torsion angle C1−B1−B2−C2 4.5(2)

Crystals of the compounds **3b**,**c** suitable for X-ray structure analyses were obtained from hexane at −20 °C. Both structures are disordered in the crystal. Only the structure of **3c** (Figure 2) will be discussed here because of its better crystallographic data. The most prominent feature is the linear C1−B1=C2 unit. The short B1−C2 bond length of 1.416 Å is in the range of a C=B double bond, the bond length C1−B1 (1.472 Å) is in between that of a single and a double bond. The C1−B3 bond is, at 1.732 Å, very long. Most surprising is the small B1−C1−B3 angle of 101.0°, which is a large deviation from the normal tetrahedral angle. The observed lengthening of the C1−B3 bond length in connection with the decreased bond angle and the short C1−B1 bond is explained by hyperconjugation of the C1−B3 sigma bond with the empty orbital at B1.[8]

Crystals of **4a** were obtained from hexane, whereas **4c** formed crystals in a solution of toluene. Only the structure of **4a** is discussed here. Selected bond lengths and angles of both molecules are listed in the legend of Figure 3. The four-membered ring of **4a** is slightly folded (8.7°). The B−N distances (1.397−1.414 Å) are in the range of those in other aminoboranes. The angles in the ring are very similar to those of **2a**.

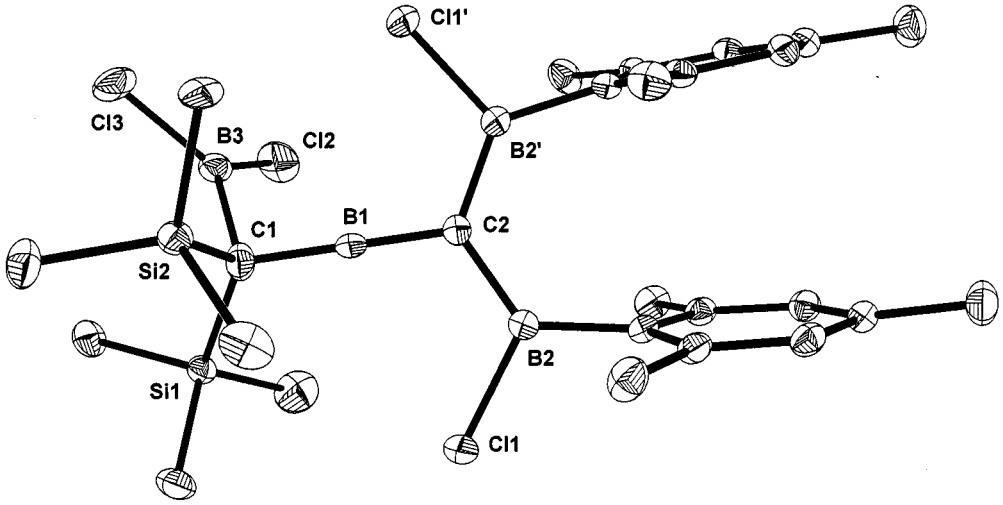

Figure 2. Structure of **3c** in the crystal; selected bond lengths [Å] and angles [°]: B1−C2 1.416(4), B1−C1 1.472(4), B2−C2 1.523(2), B3−C1 1.732(4), C1−Si1 1.878(1), C1−Si2 1.905(1); B1−C2−B2 117.5(1), B1−C1−B3 101.0(1), B1−C1−Si1 105.6(1), B1−C1−Si2 117.4(1), C2−B1−C1 180.00

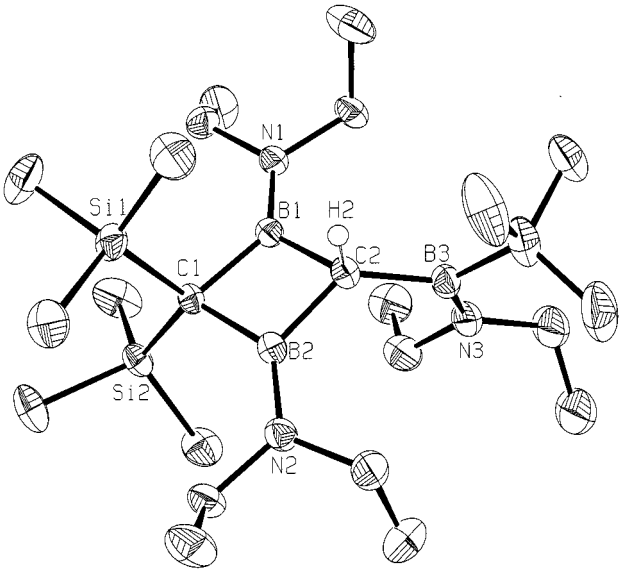

Figure 3. Structure of **4a** in the crystal; selected bond lengths [Å] and angles [°]: B1−C1 1.622(2), B1−C2 1.600(2), B2−C1 1.621(2), B2−C2 1.599(2), C2−B3 1.581(2), C1−Si1 1.881(1), C1−Si2 1.882(1), B1−N1 1.400(2), B2−N2 1.397(2), B3−N3 1.414(2);B1−C1−B2 79.5(1), B1−C2−B2 80.8(1), C1−B1−C2 99.2(1), C1−B2−C2 99.3(1), B2−C2−B3 129.6(1), B1−C2−B3 129.8(1), torsion angle C1−B1−B2−C2 8.7(2). − Selected bond lengths [Å] and angles [°] for **4c**: B1−C1 1.622(3), B1−C2 1.593(3), B2−C1 1.614(3), B2−C2 1.597(3), C2−B3 1.568(3), C1−Si1 1.879(2), C1−Si2 1.875(2), B1−N1 1.387(3), B2−N2 1.389(3), B3−N3 1.405(3); B1−C1−B2 78.1(2), B1−C2−B2 79.4(2), C1−B1−C2 99.2(2), C1−B2−C2 99.4(2), B2−C2−B3 129.7(2), B1−C2−B3 129.7(2), torsion angle C1−B1−B2−C2 14.8(2)

Conclusion

Reaction of the boriranylideneboranes **1a**,**b**,**c** with tetrahalogenodiboranes(4) leads to the cyclic tetraborylmethane derivatives **2a**,**a′** or to the isomeric diborylmethyleneboranes **3b**,**c**. The substitution of the chlorine atoms of **2a** by amino groups yields the triamino derivatives **4a**,**b**,**c**, with unexpected cleavage of one of the exocyclic C−B bonds.

Experimental Section

General: Reactions were carried out under dry argon or nitrogen, using standard Schlenk techniques. Solvents were dried, distilled, and saturated with nitrogen. Glassware was dried with a heat-gun under high vacuum. − ^{1}H and ^{13}C NMR: Bruker DRX 200 spectrometer and Bruker AC 500, ^{11}B NMR: Bruker DRX 200 spectrometer, NMR references are $(CH_3)_4Si$ and $BF_3{\cdot}Et_2O$. − Mass spectra were obtained with a ZAB-2F VH Micromass CTD spectrometer and high resolution mass spectra with a Joel MS Station JMS-700 spectrometer. − Melting points (uncorrected) were measured with a Büchi apparatus using capillaries which were filled under argon or nitrogen, and sealed.

4,4-Bis(*tert*-butylchloroboryl)-1,3-dichloro-2,2-bis(trimethylsilyl)-1,3-diboretane (2a): B_2Cl_4 (0.74 g, 4.50 mmol) was condensed into a solution of **1a** (1.33 g, 4.34 mmol) in 10 mL of hexane at −85 °C. The mixture was allowed to warm to room temperature. The solvent and all volatile components were removed under vacuum, and the colorless solid obtained was crystallized from hexane at −20 °C. Yield: 1.88 g (92%), m.p.: 78−81 °C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.22 [s, 18 H, $Si(CH_3)_3$], 1.07 [s, 18 H, $C(CH_3)_3$]. − ^{11}B NMR (64 MHz, $CDCl_3$): δ = 69. − ^{13}C NMR (125 MHz, $CDCl_3$, 223 K): δ = 3.7 [q, $Si(CH_3)_3$], 29.6 [q, $C(CH_3)_3$], 31 [br. s, $C(CH_3)_3$], 58 (br. s, CB_2), 79 (br. s, CB_4). − CI-MS: *m*/*z* (%) = 470 (6) [M^+], 455 (13) [$M^+ - CH_3$], 433 (100) [M^+ − Cl]. − HR-MS (CI): *m*/*z* = 433.1790 [M^+ − Cl]; calcd. $^{12}C_{16}{}^1H_{36}{}^{35}Cl_3{}^{29}Si_2{}^{11}B_4$: 433.1794 (Δ*mm*: 0.4).

1,3-Dibromo-4,4-bis(bromo-*tert*-butylboryl)-2,2-bis(trimethylsilyl)-1,3-diboretane (2a′): B_2Br_4 (0.16 g, 0.31 mmol) was condensed into a solution of **1a** (0.10 g, 0.31 mmol) in 10 mL of hexane at −85 °C. The mixture was allowed to warm to room temperature. The solvent and all volatile components were removed under vacuum, and a colorless solid was obtained. Yield: 0.16 g (82%). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.32 [s, 18 H, $Si(CH_3)_3$], 1.21 [s, 18 H, $C(CH_3)_3$]. − ^{11}B NMR (64 MHz, $CDCl_3$): δ = 70. − ^{13}C NMR (125 MHz, C_6D_6): δ = 3.2 [q, $Si(CH_3)_3$], 29.4 [q, $C(CH_3)_3$], 32 [br. s, $C(CH_3)_3$], 61 (br. s, CB_2), 86 (br. s, CB_4). − CI-MS: *m*/*z* (%) = 648 (2) [M^+], 633 (3) [$M^+ - CH_3$], 567 (100) [M^+ − Br].

[Bis(trimethylsilyl)(dichloroboryl)methyl]-1,1-bis(chlorodurylboryl)-methyleneborane (3b): B_2Cl_4 (1.11 g, 6.80 mmol) was condensed

into a solution of **1b** (3.36 g, 6.80 mmol) in 45 mL of hexane at −85 °C. The mixture was allowed to warm to room temperature. The product was filtered and the colorless solid obtained was crystallized from hexane at −80 °C. Yield: 2.27 g (50%), m.p.: 189−191 °C (dec.). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.65 [s, 18 H, $Si(CH_3)_3$], 1.91 (s, 12 H, *o*- and *m*-CH_3), 1.94 (s, 12 H, *o*- and *m*-CH_3), 6.54 (s, 2 H, *p*-H). − ^{11}B NMR (96 MHz, $CDCl_3$): δ = 54, 62 (1:1). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 2.7 [q, $Si(CH_3)_3$], 18.9 (q, *o*- or *m*-CH_3), 19.5 (q, *o*- or *m*-CH_3), 130.8 (d, *p*-C), 131.4 (s, *o*- or *m*-C), 132.2 (s, *o*- or *m*-C), 142 (br. s, *i*-C). − ^{13}C NMR(125 MHz, CD_2Cl_2, 183 K, additional signals): δ = 44 (br. s, CB_2), 95 (br. s, CB_3). − EI-MS: *m*/*z* (%) = 622 (44) [M^+], 512 (76) [$M^+ - Me_3SiCl$]. − HR-MS (EI): *m*/*z* = 620.2135 [M^+]; calcd. $^{12}C_{28}{}^1H_{44}{}^{35}Cl_4{}^{29}Si_2{}^{11}B_4$: 620.2162 (Δ*mm*: 2.7).

[Bis(trimethylsilyl)(dichloroboryl)methyl]-1,1-bis(chloromesitylboryl)methyleneborane (3c): B_2Cl_4 (1.22 g, 7.47 mmol) was condensed into a solution of **1c** (2.07 g,4.81 mmol) in 45 mL of hexane at −85 °C. The mixture was allowed to warm to room temperature, and then kept for 15 h at −20 °C to yield yellow crystals of **3c**. Yield: 0.94 g (33%), m.p.: 146−148 °C (dec.). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.61 [s, 18 H, $Si(CH_3)_3$], 2.03 (s, 12 H, *o*-CH_3), 2.11 (s, 6 H, *p*-CH_3), 6.35 (s, 4 H, *m*-H). − ^{11}B NMR (64 MHz, $CDCl_3$, 298 K): δ = 60. − ^{11}B NMR (64 MHz, toluene, 333 K): δ = 57, 65. − ^{13}C NMR (125 MHz, $CDCl_3$, 223 K): δ = 3.2 [q, $Si(CH_3)_3$], 22.0 (q, *p*-CH_3), 23.2 (q, *o*-CH_3), 45 (br. s, CB_2), 96 (br. s, CB_3), 126.8 (d, *m*-C), 136.5 (s, *o*-C), 137.5 (s, *p*-C), 140 (s, *i*-C). − CI-MS: *m*/*z* (%) = 594 (20) [M^+], 558 (60) [M^+ − Cl]. − HR-MS (EI): *m*/*z* = 592.1803 [M^+]; calcd. $^{12}C_{26}{}^1H_{40}{}^{35}Cl_4{}^{29}Si_2{}^{11}B_4$: 592.1811 (Δ*mm*: 0.8).

4-(*tert*-Butyldiethylaminoboryl)-1,3-bis(diethylamino)-2,2-bis(trimethylsilyl)-1,3-diboretane (4a): Compound **2a** (0.10 g, 0.21 mmol) was dissolved in 8 mL of hexane and diethylamine (0.12 g, 1.70 mmol) was added at −30 °C. The mixture was allowed to warm to room temperature and then was refluxed for three days. After filtration, part of the solvent was removed under vacuum, and the solution was cooled to −80 °C to give colorless crystals, m.p.: 230−233 °C. Yield: 0.04 g (42%). − ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.03 [s, 9 H, $Si(CH_3)_3$], 0.10 [s, 9 H, $Si(CH_3)_3$], 0.37 (s, 1 H, B_3CH), 0.89 (t, 3 H, NCH_2CH_3), 0.97 (t, 9 H, NCH_2CH_3), 0.98 [s, 9 H, $C(CH_3)_3$], 1.04 (t, 6 H, NCH_2CH_3), 2.71 (q, 2 H, NCH_2CH_3), 2.95 (dq, 2 H, NCH_2CH_3), 3.05−3.25 (m, 4 H, NCH_2CH_3), 2.22 (q, 2 H, NCH_2CH_3), 3.34 (dq, 2 H, NCH_2CH_3). − ^{11}B NMR (64 MHz, $CDCl_3$): δ = 45. − ^{13}C NMR (125 MHz, $CDCl_3$, 223 K): δ = 3.2 [q, $Si(CH_3)_3$], 4.9 [q, $Si(CH_3)_3$], 13.2 (q, NCH_2CH_3), 14.2 (q, NCH_2CH_3), 14.3 (q, NCH_2CH_3), 18 (br. s, CB_2), 22 [br. s, $C(CH_3)_3$], 28 (br. s, CB_3), 31.2 [q, $C(CH_3)_3$], 39.3 (t, NCH_2CH_3), 40.9 (t, NCH_2CH_3), 41.0 (t, NCH_2CH_3), 44.5 (t, NCH_2CH_3). − CI-MS: *m*/*z* (%) = 477 (5) [M^+], 420 (100) [$M^+ - C(CH_3)_3$]. − HR-MS (EI): *m*/*z* = 477.4482 [M^+]; calcd. $^{12}C_{24}{}^1H_{58}{}^{11}B_3{}^{14}N_3{}^{29}Si_2$: 477.4449 (Δ*mm*: 3.3).

4-(*tert*-Butyldimethylaminoboryl)-1,3-bis(dimethylamino)-2,2-bis(trimethylsilyl)-1,3-diboretane (4b): Compound **2a** (0.22 g, 0.47 mmol) was dissolved in 10 mL of toluene and (dimethylamino)trimethylsilane (0.22 g, 1.87 mmol) was added at −25 °C. The mixture was allowed to warm to room temperature and was then refluxed for two days. The solvent and volatile compounds were removed under vacuum to yield an orange solid. The crude product was sublimed to give 0.06 g (32%) of **4b**. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.02 [s, 9 H, $Si(CH_3)_3$], 0.06 [s, 9 H, $Si(CH_3)_3$], 0.30 (s, 1 H, B_3CH), 0.97 [s, 9 H, $C(CH_3)_3$], 2.41 (s, 3 H, NCH_3), 2.64 (s, 6 H, NCH_3), 2.77 (s, 6 H, NCH_3), 2.80 (s, 3 H, NCH_3). − ^{11}B NMR (64 MHz, $CDCl_3$): δ = 45. − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 3.1 [q, $Si(CH_3)_3$], 4.7 [q, $Si(CH_3)_3$], 21 (br. s, CB_2), 23 [br. s, $C(CH_3)_3$], 28 (br. s, CB_3), 31.2 [q, $C(CH_3)_3$], 40.4 (q, NCH_3), 40.5 (q, NCH_3), 41.7 (q, NCH_3), 44.5 (q, NCH_3). − CI-MS: *m*/*z* (%) = 394 (100) [$M^+ + 1$]. − HR-MS (EI): *m*/*z* = 336.2820 [$M^+ - C(CH_3)_3$]; calcd. $^{12}C_{14}{}^1H_{37}{}^{11}B_3{}^{14}N_3{}^{29}Si_2$: 336.2835 (Δ*mm*: 1.5).

4-(*tert*-Butylpyrrolidylboryl)-1,3-dipyrrolidyl-2,2-bis(trimethylsilyl)-1,3-diboretane (4c): A suspension of lithium pyrrolidinide (0.09 g, 1.20 mmol) in 20mL of hexane was added dropwise to a solution

of **2a** (0.28 g, 0.60 mmol) in 10 mL of hexane at −55 °C. The mixture was allowed to warm to room temperature and then was refluxed overnight. The solvent and volatile compounds were removed under vacuum, and the crude orange product was crystallized from toluene to give orange **4c**. Yield: 0.14 g (48%). − ^{1}H NMR (200 MHz, C_6D_6): δ = 0.28 [s, 9 H, $Si(CH_3)_3$], 0.34 [s, 9 H, $Si(CH_3)_3$], 1.24 [s, 9 H, $C(CH_3)_3$], 1.52 (m, 12 H, NCH_2CH_2), 2.76−3.52 (m, 12 H, NCH_2), signal for B_3CH was not observed. − ^{11}B NMR (64 MHz, C_6D_6): δ = 44. − ^{13}C NMR (50 MHz, C_6D_6): δ = 3.7 [q, $Si(CH_3)_3$], 5.0 [q, $Si(CH_3)_3$], 24.1 (t, NCH_2CH_2), 25.7 (t, NCH_2CH_2), 27.0 (t, NCH_2CH_2), 28.9 (t, NCH_2CH_2), 31.0 [q, $C(CH_3)_3$], 44.3 (t, NCH_2), 48.8 (t, NCH_2), 50.0 (t, NCH_2), 52.3 (t, NCH_2), CB signals were not observed. − EI-MS: *m/z* (%) = 471 (1) [M^+], 414 (100) [$M^+ - C(CH_3)_3$]. − HR-MS (EI): *m/z* = 471.4000 [M^+]; calcd. $^{12}C_{24}{}^1H_{52}{}^{11}B_3{}^{14}N_3{}^{29}Si_2$: 471.3979 (Δ*mm*: 2.1).

X-ray Structure Determinations of 2a, 3c, 4a, and 4c: Crystal data and details of the structure determinations are listed in Table 1. Intensity data for **3c**, **4a**, and **4c** were collected at 173 K with a Bruker AXS Smart 1000 and for **2a** at 210 K with a Siemens Stoe AED2 diffractometer (Mo-K_α radiation, λ = 0.7107 Å, graphite monochromator, ω-scan). The structures were solved by direct methods and refined by least-squares methods based on F^2 with all measured reflections (SHELXTL NT5.1).[12] All non-hydrogen atoms were refined anisotropically. One of the two independent molecules in **4c** is disordered.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-147172 (**2a**), CCDC-147173 (**3c**), CCDC-147174 (**4a**), CCDC-147175 (**4c**). Copies of the data can be obtained free of charge upon application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Molecular "Floppyness" and the Lewis Acidity of Silanes: A Density Functional Theory Study

Holger Fleischer[a]

This paper is dedicated to Prof. Dr. Karl Hensen on the occasion of his 65th birthday

Keywords: Coordination chemistry / Density functional calculations / Lewis acids / Silanes

A comprehensive set of Lewis acid-base adducts of silanes was investigated by means of the density functional theory geometry optimization [B3LYP/6–31G(d)], and thermochemical calculations, [B3LYP/6–311+G(2d,p)//B3LYP/6–31G(d)]. Complex formation was found to weaken Si–Cl and Si–Br bonds more than Si–F or Si–H bonds. Comparable distances between Si and a Lewis base L (L = NH_3, OH_2, F^-) are shorter in hexa- than in pentacoordinated complexes. The molecular structures of the pentacoordinated Si complexes allowed for a mapping of an S_N2 reaction pathway by correlating the lengths of the Si–X and Si–L bonds. Complex formation was found to be exothermic for most of the coordination compounds, and the analysis of the natural atomic charges revealed a high ionic character of the dative bonds. Formation of the anionic complexes and of $SiH_2X_2(py)_2$ is most exothermic with X = Cl or Br and otherwise most exothermic with X = F. Only small enthalpy differences were found between the *trans* and *cis* configurations of $SiF_4(py)_2$. The standard free enthalpy of complex formation is negative only for complexes between halosilanes and F^-, i.e. all other silane Lewis base adducts are thermodynamically unstable under standard conditions with respect to dissociation. It is inferred that the existence of some of the silicon complexes in the solid state or in solution is caused by stabilizing intermolecular forces, and silanes are classified as very weak Lewis acids. The thermochemistry of complex formation was analyzed in terms of molecular "floppyness" of the silanes and the energy of interaction between the deformed silane and the Lewis base. The enhanced complex stability of $SiCl_4(py)_2$ compared to $SiH_4(py)_2$ and of $GeF_4(NH_3)$, $[GeF_5]^-$ and $[GeF_6]^{2-}$ compared to the analogues silane adducts does not result from a stronger Lewis acid base interaction but from an increased "floppyness" of $SiCl_4$ and GeF_4 compared to SiH_4 and SiF_4, respectively.

Introduction

While many compounds of group 13 elements act as Lewis acids due to their electron deficiency, the driving force for the formation of hypervalent silanes must be different. Many adducts of silanes with Lewis bases have been characterized,[1] and hypervalent compounds have long since been the subject of many experimental[2] and theoretical[3] investigations; some are even of pharmaceutical interest.[4] Several review articles have been published in this field.[5] Hence, since Si atoms can participate in donor acceptor interactions, the corresponding silanes were said to be Lewis acids.

But does the Lewis acidity of, for example, $SiCl_4$ follow from the existence of $SiCl_4(py)_2$ *in the solid state*? And why does $SiCl_4(py)_2$ exist and $SiH_4(py)_2$ does not?[1f] Most complexes between silanes and typical Lewis bases are hitherto found only in the solid state or in polar solvents, some exist at very low temperatures only with matrix isolation,[6] and $SiF_4(NH_3)$ is the only example of a silane adduct known to the author, that has been detected in the gas phase, but at very low temperatures.[7]

Thus two questions arise: first, how does the Lewis acidity of silanes depend on their molecular properties, and second, is the existence of adducts between silanes and Lewis bases at room temperature at all enabled by intermolecular forces, in contrast to group 13 Lewis acids like BX_3, AlX_3 and GaX_3 (X = H, alkyl, halogen) whose adducts with Lewis bases are known to exist in the gas phase under normal conditions (see e.g. reference 8)? $SiH_2Cl_2(py)_2$ was recently calculated to be thermodynamically unstable under normal conditions with respect to dissociation into SiH_2Cl_2 and pyridine.[9] It is thus of interest to look at the thermodynamic stability of a more comprehensive set of silicon complexes, including different coordination numbers, donor atoms and substitution patterns of the silicon atom. Some of the molecules investigated exist in the solid state, i.e. $SiH_3Cl(OMe_2)$,[10] $SiH_2Cl_2(py)_2$,[1f,9] $SiH_2Br_2(py)_2$,[1f] $SiF_4(py)_2$,[11] $SiCl_4(py)_2$,[12] $SiF_4(NH_3)_2$,[13], $SiF_4(NH_3)$,[6] SiF_5^-,[14] and SiF_6^{2-},[15] the others are model compounds, i.e. $SiH_3X(NH_3)$, $SiX_4(NH_3)$ and $SiH_3X(OH_2)$, $SiH_2F_2(py)_2$, $SiH_4(py)_2$, $[SiH_3XF]^-$, $[SiH_4F]^-$, $[SiCl_4F]^-$, $[SiH_4F_2]^{2-}$ and $[SiCl_4F_2]^{2-}$ (X = F, Cl, Br for complexes of SiH_3X and SiH_2X_2 and X = H, F, Cl for complexes of SiX_4, py = pyridine).[16,18] To investigate the matter of "genuine" Lewis acidity of silanes, no molecules such as silatranes or 1-sila-8-dimethylaminonaphthalene, whose potential donor and acceptor sites are forced into close proximity, and where an interaction is favored by molecular steric strains, were considered. Furthermore, no chelating or macrocyclic

Lewis bases were included in the study to avoid their stabilizing effect on complexes.

Geometry optimizations for molecules as large as $SiCl_4(py)_2$ (27 atoms, 166 electrons), with a full-electron Hartree-Fock (HF) method using a reasonable basis set [e.g. 6−31G(d)], followed by CI (configuration interaction) or MP*n* (n-th order Møller Plesset perturbation) calculations to account for electron correlation exceeded the limits of the available computational resources. Hence a DFT (density functional theory) approach[19,20] was chosen which includes dynamic electron correlation effects without requiring as many computational resources as the above quoted methods do. In the present paper, the results of DFT geometry optimizations and thermochemical calculations on coordination compounds of different silanes will be presented, and molecular factors influencing the Lewis acidity of and dative bonds[21,22] to silanes will be discussed

Results and Discussion

Molecular Structures

Selected structural parameters are given in Table 1 to 3 (See Figure 1 for a graphical overview of the complexes).

[a] See text for definition of x and l. x is not given for equatorial Si−X bonds in SiX_4(L). − [b] The first of the two values refers to the equatorial, the second to the apical Si−X bond.

The molecular geometry of the complexes may give an indication of the strength of the Lewis acid/base interaction in terms of atomic distances and distortion of silane and Lewis base from their ground state geometries. According to Pauling,[34] the bond length is an indication of the bond strength, i.e. the shorter Si−L bond (L = O for OH_2, OMe_2; L = N for NH_3, NMe_3 and py; L = F for F^-) should be the stronger one.[35] As different X and L are to be compared with each other, relative lengths are used instead of r_e(Si−X) and r_e(Si−L). Accordingly, r_e(Si−X) is divided by r_e(Si−X) of the parent silane to give the relative length $x = r_e(Si-X)/r_e(Si-X)_{silane}$ and r_e(Si−L) is divided by the sum of the covalent radii of Si and L to give the relative length $l = r_e(Si-L)/[r_{cov}(Si) + r_{cov}(L)]$. (Covalent radii are taken from reference 36 and are 122, 118, 75, 73 and 71 pm for Ge, Si, N, O and F, respectively). In the complex anions, in $SiH_3X(L)$ and in $SiH_2X_2(py)_2$, r_e(Si−L) decreases for a given complex with X in the order H > F > Cl > Br, and, for a given L, the relative lengths of the Si−X bond, x, increases in the same order, the only excep-

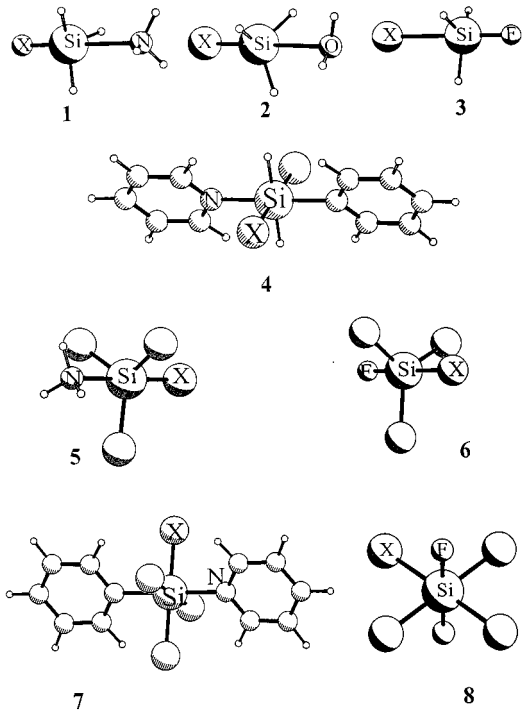

Figure 1. Molecular graphics of the hypervalent compounds investigated (only those systems are shown, in which X is varied) $SiH_3X(NH_3)$ **1**, $SiH_3X(OH_2)$ **2**, $[SiH_3XF]^-$ **3**, $SiH_2X_2(py)_2$ **4** (X = F, Cl, Br); $SiX_4(NH_3)$ **5**, $[SiX_4F]^-$ **6**, $SiX_4(py)_2$ **7**, $[SiX_4F_2]^{2-}$ **8** (X = H, F, Cl)

tions being $[SiH_4F]^-$ and $[SiH_3F_2]^-$. For the other complexes, $SiX_4(NH_3)$ and $SiX_4(py)_2$, Si−N is shortest with X = F.

The relative length *x* increases with L in the order L = O < N << F^- and the relative length *l* decreases in the same order. Thus, *l* and *x* suppose F^- to be the strongest of all Lewis bases studied in the present work.

Considering the electrically neutral amine-silane complexes, r_e(Si−N) is smaller in the hexacoordinated compounds $SiX_4(py)_2$, $SiH_2X_2(py)_2$ and $SiF_4(NH_3)_2$ than in the pentacoordinated $SiX_4(NH_3)$, $SiH_3X(NH_3)$, $SiH_3F(NMe_3)$ and $SiF_4(NMe_3)$, and smaller in $SiX_4(NH_3)$ and $SiF_4(NMe_3)$ than in $SiH_3X(NH_3)$ and $SiH_3F(NMe_3)$. The difference in r_e(Si−N) between $SiF_4(py)_2$ and $SiF_4(NH_3)_2$, and between $SiF_4(NMe_3)$ and $SiF_4(NH_3)$, is marginal, while r_e(Si−N) is shorter in $SiH_3F(NMe_3)$ than in $SiH_3F(NH_3)$. These results suppose that the Si−N distance is mainly determined by electronic and not by steric factors. The nature of the Si−L bond in $SiH_3X(L)$ and $SiX_4(L)$ was analyzed in terms of second order perturbation in a natural orbital basis (see Table 4). It is not the absolute values of these energies that are of interest, but, for comparable complexes, their relative orders. In complexes $SiH_3X(L)$, the interaction of the lone pair of L with the anti-bonding orbital of the apical Si−X bond, n(L)−σ*(Si−X), was found to play the major role, a result that rationalizes the considerable lengthening of the Si−X bond due to interaction of L with Si. Compared to n(L)−σ*(Si−X), the interaction between the lone pair of L and the anti-bonding orbitals of the equatorial Si−H bonds, n(L)−σ*(Si−H), is rather small. In $SiX_4(L)$, the apical Si−X bond is only slightly longer than the equatorial ones, and in $GeF_4(NH_3)$, $r_e(Ge-F^a)$ is even smaller than $r_e(Ge-F^e)$, a relation well reflected by the NBO interaction energies (see Table 4).

Structure Correlation

Interpreting the pentacoordinated complexes in terms of structure correlation[37] as "snapshots" of an S_N2 reaction path, with the nucleophile and the nucleofuge occupying the apical positions of a trigonal bipyramid, a smaller *l* requires a bigger *x* and vice versa. As can be seen from Figure 2a, the pentacoordinated complexes give a reasonably good correlation between *x* and *l*, in contrast to the hexacoordinated ones (see Figure 2b). The deformations of SiH_3X and SiX_4, as measured by the difference of *a*(HSiX) and

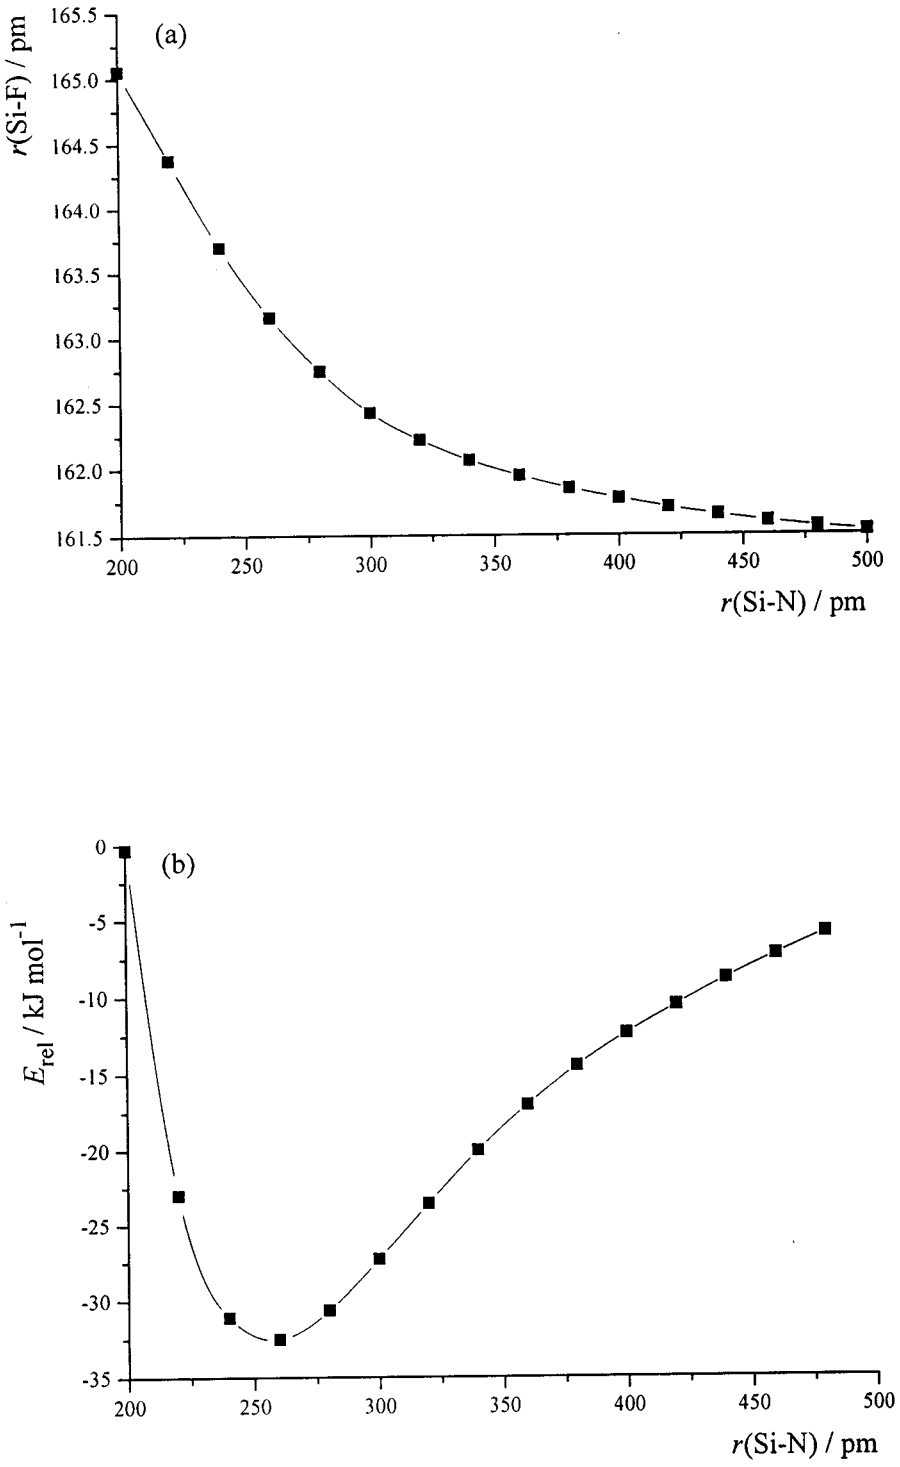

Figure 3. (a) Correlation between r(Si−N) and r(Si−F) in $SiH_3F(NH_3)$; (b) Relaxed potential energy scan (B3LYP/6−31G(d)) for r(Si−N) of $SiH_3F(NH_3)$; $E_{rel} = 0$ represents complete dissociation

$a(X^aSiX^e)$ between the complex and the silane, corroborate the structure correlation, as the approaching nucleophile L pushes the H and X^e atoms away towards X^a and narrows a(HSiX) and $a(X^aSiX^e)$. For $SiH_3F(NH_3)$, a relaxed potential energy scan was performed by changing r(Si−N) in a stepwise manner and optimization of the remaining parameters. The potential energy as a function of r(Si−N) (b) and a correlation of r(Si−N) with r(Si−F) (a) are given in Figure 3. The latter shows a typical pattern for a correlation with mutual weakening of the bonds as it occurs in an S_N2 mechanism, analogous to Figure 2a.

Comparison to Solid State Structures

$SiH_3Cl(OMe)_2$ presents a striking example of a dative bond to Si that is shorter in the solid state than in the isolated molecule (see Table 1). This difference is attributed to

stabilizing intermolecular contacts in the solid state.[10] The shorter Si−O bond in the solid state corresponds to a longer Si−Cl bond, an example for structure correlation within different "phases". The considerable shift of the Si−O distance by changes in the molecular environment implies that the curvature of the potential energy surface, $\partial^2 V/\partial r_e(Si-O)^2$, at its minimum is small, i.e. the bond is weak. This weakness applies also for the Si−N bond in $SiH_3F(NH_3)$ (see Figure 3). r(Si−N) can be varied around the equilibrium distance over a range of 75 pm without increasing the energy by more than 5 kJ mol^{-1}.

Thermochemistry of Complex Formation: Structural "Stiffness" vs. Energy of Interaction

Since the energy, enthalpy and free enthalpy of complex formation are state functions, their values do not depend on the way in which the complex is formed. It is useful to divide the complex formation from silane (S) and Lewis base (L) into two steps. First, the molecules of the silane and the Lewis base are deformed from their ground state geometries, S(GS) and L(GS), to their complex geometry, S(CG) and L(CG), the energy required being ΔE_{def}(S) [Equation (1a)] and ΔE_{def}(L) [Equation (1b)].

$$S(GS) \rightarrow S(CG) \quad (1a)$$

$$L(GS) \rightarrow L(CG) \quad (1b)$$

In all complexes, ΔE_{def}(L) proved to be only a small fraction of ΔE_{def}(S), and only ΔE_{def}(S) is further considered.

The deformed silane and Lewis base then interact and form the complex [Equation (2)].

$$S(CG) + n\ L(CG) \rightarrow SL_n \quad (2)$$

The energy of the process shown in Equation (2), V, represents the strength of interaction. Since the energy required for Equation (1a) may even vary for the same silane and the same coordination number, a study of ΔE_{def}(S) from the ground state geometry to a well defined distorted geometry was performed. For hexacoordinated complexes of SiH_2X_2 and SiX_4, the silane molecules were "flattened", i.e. the geometry optimization was performed with the symmetry restricted to D_{2h} for SiH_2X_2 and D_{4h} for SiX_4. To account for the pentacoordinated complexes of SiH_3X and SiX_4, the molecules were optimized with a trigonal pyramidal structure, which means that the HSiX angles in SiH_3X and the XSiX angles in SiX_4 between the unique X atom and the other X atoms were fixed to 90°. This symmetry is designated as "C_{3v}(tp)". The energy necessary for these kinds of deformations is a measure of the "floppyness" of the silane to adopt the geometry in a given complex. Values for ΔE_{def}(S) are given in Table 7.

The standard enthalpy of complex formation, ΔH_c^{298}, and the standard free enthalpy of complex formation, ΔG_c^{298}, obtained in the present study exhibit partially very small absolute values (see Table 5a and 5b), hence counterpoise calculations are essential to correct them for the basis set superposition error (bsse).[31,32,38] Counterpoise-corrected

Table 5. (a) Enthalpies of complex formation, ΔH_c^{298}; (b) free enthalpies of complex formation, ΔG_c^{298}; (c) basis set superposition errors for the thermochemistry of complex formation; for details see text

values are indicated by the superscript "cc". Differences in ΔH_c^{298} between different complexes can subsequently be analyzed in terms of ΔE_{def}(S) vs. V^{cc}.

Lewis Bases with N or O Donor Atoms

The formation of $SiH_3X(L)$ from SiH_3X and L is more exothermic for L = NH_3 than for L = OH_2, a result that is in accordance with the n(L)−σ*(Si−X) energies already presented (vide infra), and reflects the enhanced Lewis basicity of NH_3 compared to H_2O. ΔH_c^{298} of $SiH_3X(L)$ is more negative for X = F than for X = Cl or X = Br, and Table 6 reveals that this is due to the small ΔE_{def}, despite V^{cc} being smaller for $SiH_3F(L)$ than for $SiH_3Cl(L)$ or $SiH_3Br(L)$.

With $SiX_4(NH_3)$ on the other side, complex formation is exothermic only for X = F and even more endothermic for X = Cl than for X = H, and the differences in ΔH_c^{298} between different X groups are much bigger than for $SiH_3X(NH_3)$. Both, ΔE_{def} and V^{cc}, are very small for SiH_4, in accordance with the long Si−N bond in $SiH_4(NH_3)$ (see Table 3). The reduced stability of $SiCl_4(NH_3)$ relative to $SiF_4(NH_3)$ can be attributed entirely to the stronger interaction between SiF_4 and NH_3 (see Table 6), with ΔE_{def} being about equal for the two complexes. As with $SiF_4(NH_3)$/$SiCl_4(NH_3)$, the increased stability of $SiF_4(py)_2$ relative to $SiCl_4(py)_2$ is due to the difference in V^{cc} and not in ΔE_{def}. It is striking that one of the "classical" silicon complexes, $SiCl_4(py)_2$,[1b] exhibits a positive ΔH_c^{298}, in contrast to the formation of *solid* $SiCl_4(py)_2$ from $SiCl_4$ and pyridine, which is distinctly exothermic. Formation of $SiH_4(py)_2$ is even less favored, but this is caused by $\Delta E_{def}(SiH_4)$ being bigger than $\Delta E_{def}(SiCl_4)$, while V^{cc} of $SiH_4(D_{4h})$ and $SiCl_4(D_{4h})$ with pyridine are nearly equal. This means that the different Lewis acidities of SiH_4 and $SiCl_4$ are not caused by different electron-withdrawing forces of the ligands, but are due to different ΔE_{def}.

The variable differences in ΔH_c^{298} for penta- and hexacoordinated complexes of SiH_4 on one hand and of SiF_4/$SiCl_4$ on the other have their cause in different trends of $\Delta E_{def}[SiX_4,C_{3v}(tp)]$ and $\Delta E_{def}[SiX_4(D_{4h})]$ and in the different degrees of deformation of SiX_4 in $SiX_4(L)$. ΔE_{def} $[SiH_4,C_{3v}(tp)]$ is about 100 kJ mol^{-1} smaller and $\Delta E_{def}[SiH_4(D_{4h})]$ about 100 kJ mol^{-1} bigger than the respective values for SiF_4 and $SiCl_4$.

Only recently, and also by means of DFT calculations, Gillespie and co-workers related the weaker Lewis acidity of BF_3 relative to BCl_3 to the higher energy that is necessary to achieve a pyramidalization of the former.[8] The authors take the greater strength of the B−F bond relative to the B−Cl bond, and ligand close-packing effects as the causes for this effect and favor them over the "classical" explanation in terms of an n(X)−p_π(B) interaction. In the present work, a second order perturbation analysis of $SiX_4(D_{4h})$ in an NBO basis reveals substantial stabilization for X = F and Cl (440 and 436 kJ mol^{-1} for each molecule, respectively) through an n(X)−3p_π(Si) interaction. In $SiF_4(py)_2$, and $SiCl_4(py)_2$, this kind of interaction is reduced to 232 and 204 kJ mol^{-1}, respectively, but is still considerably high. Due to the absence of lone pairs, this interaction cannot operate with X = H. The significantly lower $\Delta E_{def}(D_{4h})$ for SiF_4 and $SiCl_4$ compared to SiH_4 cannot be due to bond

strengths, as the Si−H bond is weaker than the Si−F and Si−Cl bonds, nor due to a stronger repulsion between X atoms, as H atoms are smaller and less charged than F atoms. Instead, the above mentioned $n(X)-3p_{\pi}(Si)$ interaction (see Table 4), which stabilizes the deformed states of SiF_4 and $SiCl_4$, is seen to be responsible for the results outlined in Table 7.

Comparing $SiH_2X_2(py)_2$ and $SiX_4(py)_2$, ΔH_c^{298} of $SiF_4(py)_2$ is much more negative than ΔH_c^{298} of $SiH_2F_2(py)_2$, whereas ΔH_c^{298} of $SiCl_4(py)_2$ is slightly positive and ΔH_c^{298} of $SiH_2Cl_2(py)_2$ is negative (see Table 5a). Similar relations are found for $SiH_3X(NH_3)/SiX_4(NH_3)$ (X = F, Cl), where the formation of $SiF_4(NH_3)$ and $SiH_3Cl(NH_3)$, is much more exothermic than that of $SiH_3F(NH_3)$ and $SiCl_4(NH_3)$. Hence, SiH_2Cl_2 and SiF_4 are more Lewis acidic than SiH_2F_2 and $SiCl_4$, and SiH_3Cl and SiF_4, more acidic than $SiCl_4$ and SiH_3F. For the pyridine complexes, this order is due to $\Delta E_{def}(SiH_2X_2)$ being smaller than $\Delta E_{def}(SiX_4)$ and V^{cc} of $SiH_2Cl_2(py)_2$ bigger than that of $SiH_2F_2(py)_2$.

Considering the N and O donor complexes, V^{cc} is bigger in the hexacoordinated than in the pentacoordinated ones, which reflects the different $r_e(Si-L)$, i.e. short Si−L bonds correspond to strong interactions and vice versa. These differences can be explained in terms of second order NBO interactions (see Table 4). In the pentacoordinated complexes, the Si−L bonds result mainly from $n(L)-\sigma^*(Si-X)$ interactions, while in hexacoordinated complexes, $n(L)-3p_z(Si)$ interactions dominate. Due to a smaller difference in the NBO energies and a bigger overlap integral of n(L) and $3p_z(Si)$, compared to n(L) and $\sigma^*(Si-X)$, the second order $n(L)-3p_z(Si)$ energy is considerably bigger than the $n(L)-\sigma^*(Si-X)$ energy.

In terms of ΔG_c^{298} (see Table 5b), none of the neutral Lewis bases NH_3, NMe_3, py, OH_2 and OMe_2 forms complexes with silanes that are thermodynamically stable under normal conditions. This is in accordance with results on some SiF_4-amine adducts which are completely dissociated in the gas phase under normal conditions.[39]

Figure 3b shows the results of a relaxed potential energy scan for $SiH_3F(NH_3)$ in which the potential energy is given as a function of $r(Si-N)$. The curve represents a typical Morse-type potential. No barrier of activation occurs that could kinetically stabilize any thermodynamically labile complex towards dissociation or would prevent complex formation. The existence or nonexistence of this type of complex thus depends on thermodynamic factors only, with the solid state or polar environments providing additional stabilization.

A comparison of $SiF_4(NH_3)$ with $GeF_4(NH_3)$ reveals a higher thermodynamic stability of the latter (see Table 5). Approximately the same values of ΔE_{def} allow for a more enhanced distortion of GeF_4 (see Table 3), which, in turn, gives a stronger interaction with NH_3, as can be seen from V^{cc}.

F^- as Lewis Base

While NH_3, OH_2, their methyl derivatives and pyridine cannot substitute a halide or hydride from an Si center without charge separation, substitution reactions of silanes with F^- according to Equations (3a)−(3c) do not generate electric charges.

$$SiH_3X + F^- \rightarrow SiH_3F + X^- \quad (3a)$$

$$SiX_4 + F^- \rightarrow SiX_3F + X^- \quad (3b)$$

$$SiX_4 + 2\,F^- \rightarrow SiX_2F_2 + 2\,X^- \quad (3c)$$

For X = F, these reactions proceed in a thermochemically neutral manner, they are exothermic for X = Cl, Br and endothermic for X = H, in accordance with results of Gronert et al.[40]

The absolute value of ΔH_c^{298} as a function of the Lewis bases in complexes $SiH_3X(L)$, $SiX_4(L)$ and $SiX_4(L)_2$ is much bigger for $L = F^-$ than for the neutral ligands (see Table 5). The heavier the atom X is, the more exothermic becomes the complex formation with $L = F^-$, $[SiH_4F_2]^{2-}$ being the only complex exhibiting positive ΔH_c^{298} and ΔG_c^{298}. All other F^- complexes are thermodynamically stable with respect to dissociation into silane and F^-.

Gutsev calculated $[SiF_6]^{2-}$ to be unstable towards dissociation into $[SiF_5]^-$ and F^-, and to exhibit a metastable octahedral geometry with respect to ionization ($[SiF_6]^{2-} \rightarrow [SiF_6]^- + e^-$, see also reference 18).[41] The thermodynamic instability of $[SiF_6]^{2-}$ is confirmed in the present study, with $\Delta H^{298} = -206.9$ and $\Delta G^{298} = -248.7$ kJ mol^{-1} for the reaction $[SiF_6]^{2-} \rightarrow [SiF_5]^- + F^-$ [B3LYP/6−311+(2d,p)//B3LYP/6−31G(d)]. Furthermore, formation of SiF_6^{2-} is not much more exothermic than that of $SiF_4(py)_2$ or $SiF_4(NH_3)_2$. The existence of SiF_6^{2-}must thus be due to intermolecular stabilization, either in the solid state or in solution.

As with $GeF_4(NH_3)$, $[GeF_5]^-$ and $[GeF_6]^{2-}$ are thermodynamically more stable than their silicon analogues. In contrast to $SiF_4(NH_3)$ and $GeF_4(NH_3)$, the degree of deformation of SiF_4 and GeF_4 in $[EF_5]^-$ and $[EF_6]^{2-}$ (E = Si, Ge) is the same. It is hence striking, that V^{cc} for $[EF_5]^-$ and $[EF_6]^{2-}$ is even more negative for E = Si, and the overall increased thermodynamic stability of $[GeF_5]^-$ and $[GeF_6]^{2-}$ results from significantly smaller values of $\Delta E_{def}(GeF_4)$ compared to $\Delta E_{def}(SiF_4)$ (see Table 6 and 7).

Table 8. ΔH^{298} for reactions according to Equations 3a−c

X =	H	Cl	Br
reaction 3a		−195.9	−241.1
3b	93.8	−212.9	
3c	162.0	−426.8	

The more negative ΔH^{298} (see Table 8) for a given reaction, the more negative is the corresponding ΔH_c^{298} (see Table 5). Notably, ΔH_c^{298} is always more negative than the corresponding ΔH^{298}, i.e. in contrast to anions with pentacoordinated carbon atoms, which represent transition states in S_N2 reactions, silanes form complexes, that are thermodynamically stable toward decomposition either into SiH_3X/SiX_4 and F^- or $SiH_3F/SiFX_3$ and X^-. With the anionic complexes, Haaland's distinction between covalent

and dative bonds (see reference 22) comes to its limits. For example, the two Si−F bonds in $[SiH_3F_2]^-$ (D_{3h}) are equivalent by symmetry and the criterion of least-energy bond cleavage defines the Si−F bond that is broken first as dative, since dissociation would favorably be heterolytic, giving SiH_3F and F^-. The other one is subsequently defined as covalent, since least-energy cleavage will give SiH_3 and F instead of SiH_3^+ and F^-. Distinction between a covalent and a dative Si−F bond would thus be arbitrary. Taking $[SiH_3ClF]^-$, the first bond to be broken is either Si−F or Si−Cl, which would be defined as dative, giving either SiH_3Cl and F^- or SiH_3F and Cl^-, and leaving the other as covalent. This is an arbitrary distinction as well, but here between two nonequivalent bonds and this cannot be justified. It is suggested for such cases to extend Haaland's definition, and to define the dative bond as that whose heterolytic cleavage costs less energy, which in the present case is the Si−Cl bond. Thus, in contrast to the complexes with N/O donors, where the Si−L bond formed is the dative bond, in complexes with F^- as Lewis base, Si−Cl and Si−Br bonds become dative, as can be seen from ΔH^{298} in Table 8, which represent the enthalpy differences of the heterolytic bond cleavage [see Equations (3a)−(3c)]. It is this qualitative difference between F^- and N/O donors which is seen as the cause of the different trends of Lewis acidity outlined above.

Natural Atomic Charges

Atomic charges should indicate the ionic character of bonds in hypervalent Si compounds and its dependence on X and L. Natural atomic charges[28,29] are directly related to the eigenvalues of the density matrix expressed in terms of natural atomic orbitals and are thus more reliable than Mulliken atomic charges.[28]

The highest values for q_{Si} are always with X = F (see Table 9). q_{Si} varies little with L, if X = F and *decreases* in this case on coordination in all cases except $[SiH_3F_2]^-$. For X ≠ F, q_{Si} *increases* on coordination in most cases, and is most positive in the complex anions. An increase of charge of the central atom on coordination was previously found for $SiH_2Cl_2(py)_2$, $[SiH_4F]^-$ and $[SiH_5]^-$, but also for $[GeH_5]^-$ and $[SnH_5]^-$.[9,40] A similar relationship holds for q_X. It varies little for X = F, for which it is most negative (except for $[SiH_3XF]^-$) and it is more negative in the hypervalent than in the tetravalent silanes. Comparing $[SiX_4F]^-$ to $[SiX_4F_2]^{2-}$ and $SiF_4(NH_3)$ to $SiF_4(NH_3)_2$, q_X is more

Table 9. Natural atomic charges (a) of the Si atom, (b) of X and (c) of L (L = N for NH_3, NMe_3, py; L = O for H_2O, Me_2O; L = F for F^-).

negative in the hexacoordinated complexes. In $SiX_4[C_{3v}(tp)]$, $SiX_4(NH_3)$ and $[SiX_4F]^-$, q_X is more negative for the apical than for the equatorial X. It is interesting to note that the reduced negative charge on the donor atom in NMe_3 compared to NH_3 (and as well in OMe_2 compared to OH_2) has little influence on q_{Si}.

For SiH_3X, SiH_2X_2 and their complexes, $q_{H(Si)}$ (not given in Table 9) becomes more negative in the order X = Br < Cl < F.

The increase in the charge difference between Si and X on complex formation in most cases gives a hint of a pronounced ionic nature of the interaction between Si and L, increasing in the order X = H < Br < Cl < F and, consequently, $SiH_3X < SiH_2X_2 < SiX_4$. In the course of the complex formation, electron density is shifted from and to the periphery of the molecule, i.e. X becomes more negatively and the H atoms of the ligands more positively charged. This shift will certainly favor intermolecular coulombic and charge-dipole interactions and hence gives a reasonable explanation for the stabilization of the otherwise unstable silane-amine complexes in polar solutions and in the solid state.

Alternative Complex Configurations: *cis* vs. *trans*

It has already been established [3d,22,42,43] that in pentacoordinated Si complexes with a trigonal bipyramidal configuration, the most stable structure has the Lewis base, i.e. the dative bond, in an apical rather than an equatorial position [*cf.* $SiF_4(NMe_3)$ vs. PF_4NMe_2 in ref.[22]]. In the present paper, $SiF_4(py)_2$ was chosen to investigate the case of *cis* (C_2) vs. *trans* (D_{2h}) configuration in distorted octahedral complexes. All known XRD structures of hexacoordinated Si complexes of the SiA_4B_2 type that are not configurationally strained, i.e. that do not contain chelating Lewis bases or the Si atom as a member of a ring system, exhibit a *trans*- rather than a *cis* configuration.[9,11–13,44,45]

Since the Si–N bond is longer in the *cis*- than in the *trans* complex, and, regarding the *cis* complex, the Si–F bonds *trans* to the Si–N bonds are shorter than the two Si–F bonds in mutual *trans* position (see Figure 4), the *trans*-effect of F is obviously stronger than that of N. The bond angles around the Si atom in *cis*-$SiF_4(py)_2$ are: *a*(F^bSiF^b) 101.5, *a*(F^aSiF^a) 161.7, *a*(F^aSiF^b) 95.3 and 96.3, *a*(NSiN) 84.5, *a*($NSiF^a$) 82.9 and 83.5, *a*($NSiF^b$) 87.0 and 171.5° ("a" denotes the two F atoms *trans* to each other, "b" denotes the other two). In spite of the huge differences in their molecular structures, ΔH_c^{298} is surprisingly very similar for the two configurations, with a difference of only 7.6 kJ mol^{-1} in favor of the *trans* complex. The much stronger interaction due to a shorter contact distance between py and SiF_4(CG) in the *trans* complex is nearly entirely compensated by the energy of deformation, which is much bigger for the *trans* complex (285.6 kJ mol^{-1}) than for the *cis* complex (216.6 kJ mol^{-1}). Since the energy difference between the *cis* and *trans* configurations is rather small, the domination of the *trans* configuration in all SiA_2B_4 complexes in the solid state is assumed to be mainly a crystal packing effect.

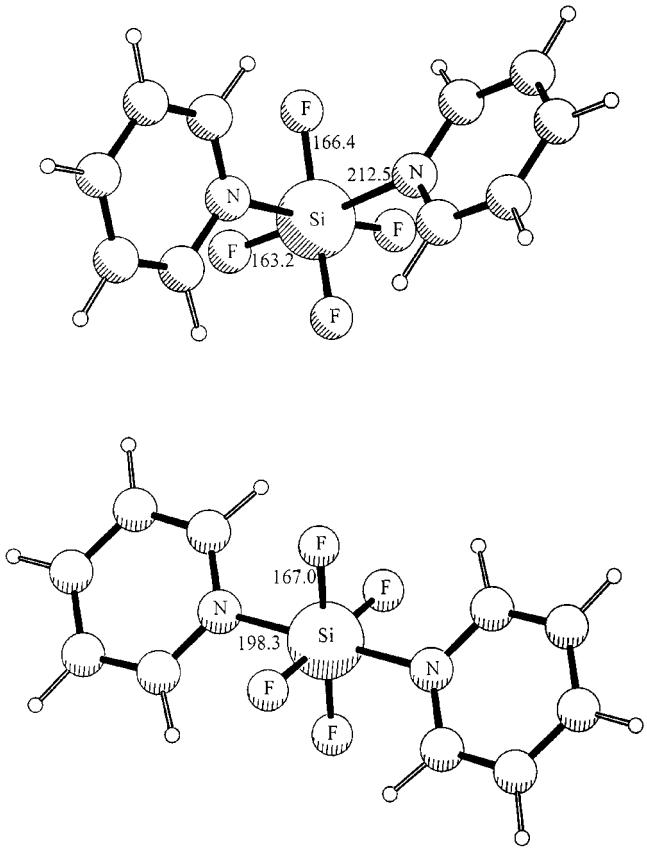

Figure 4. Molecular graphics of *cis*- (above) and *trans*-$SiF_4(py)_2$ with selected interatomic distances

Comparison of the B3LYP/6–311+G(2d,p)//B3LYP/6–31G(d) Approach to More Sophisticated Models and Experimental Results

$SiF_4(NH_3)$ is the only silane adduct with a known gas-phase structure, and it was taken as a probe for the reliability of the B3LYP/6–31G(d) geometry optimizations for the present subject.[46] Since the N and F atoms exhibit large negative charges according to NBO analyses (see Table 9), the geometry of $SiF_4(NH_3)$ was optimized with the B3LYP/6–311+G(2d,p) model to reveal the influence of diffuse functions on the molecular structure. Additionally, an MP2/6–311+G(2d,p) geometry optimization was performed to compare the MP2 and the B3LYP level. Furthermore, with $SiH_3F(NH_3)$, another comparison of the B3LYP and the MP2 model was performed.

The data in Table 10a demonstrate that *r*(Si–F) and *a*(F^aSiF^e) agree very well between all theoretical models and the experiment. The Si–N bond is too long with all model chemistries, MP2/6–311+G(2d,p) giving the closest value. A good agreement between DFT- and MP2-optimized covalent bond lengths and angles is also achieved for $SiH_3F(NH_3)$.

The dative bond is far more sensitive to the chosen method of geometry optimization and the basis set than the covalent bonds are. Complex formation is estimated to be more exothermic with the MP2 method of electron correla-

tion than with B3LYP, while diffuse functions have a minor influence.

Conclusion

The aim of the present work was to give a comprehensive study of the Lewis acidity of silanes and to have a closer look at its molecular origins. The method of partitioning the energy of complex formation into a deformation energy, ΔE_{def}, and an interaction energy, V, together with an analysis of the nature of the dative bond in terms of natural bond orbitals and natural atomic charges proved to be very useful for this purpose. Silanes were shown to be weak Lewis acids towards neutral N and O donor Lewis bases. The energy gained by interaction with these donor atoms is, in many cases, not much bigger, and in quite a few cases even smaller, than the energy necessary to change the geometry of the silane from the ground state to that in the complex, leading to comparably small values of ΔH_c^{298}. Since the formation of the complex reduces the number of molecules, ΔS_c^{298} of the system is negative. This fact leads to a positive value of ΔG_c^{298} for all complexes with N and O donor atoms. Only complexes of silanes with the very strong Lewis base F^- exhibit a negative standard free enthalpy of formation. A comparison of SiF_4 and GeF_4 shows that the latter is a stronger Lewis acid than SiF_4, but not due to a stronger interaction with Lewis bases, but due to a more floppy ground-state geometry, resulting in smaller ΔE_{def}. The DFT calculations in the present paper rationalize why complexes between silanes and N/O donating Lewis bases were never observed in the gas phase under standard conditions. The atomic charges, the changes in bond lengths during complex formation and, compared to N and O donors, the significantly more exothermic reactions of halosilanes with F^- suggest that the interaction between Si and the donor atoms exhibit an highly ionic character, increasing from SiH_3X to SiH_2X_2 to SiX_4 and from X = Br to Cl to F. Silanes are classified as very weak Lewis acids due to the "stiffness" of their molecular structure and only with very strong Lewis bases or stabilized by intermolecular forces in solution of the solid state, Lewis base adducts of silanes can exist at room temperature.

Experimental Section

Theoretical Methods

All calculations were performed on various servers of the Zentrum für Datenverarbeitung, Universität Mainz, using the GAUSSIAN94 software package.[23] The geometries of all molecules were fully optimized under the respective symmetry constraints using a 6−31G(d) basis set and density functional theory (DFT)[19] employing a combination of local, gradient-corrected, and exact exchange functionals according to the prescription of Becke[24] and the gradient-corrected correlation functional of Lee, Yang and Parr[25] [B3LYP/6−31G(d)] (for basis set terminology see e.g. reference 26). All stationary points were characterized by calculation of analytic force constants. With the same model chemistry, natural atomic charges were calculated and second order perturbation energies in a natural orbital basis were calculated.[27−29] Taking the B3LYP/6−31G(d) optimized geometries, single-point energies were calculated at the B3LYP level using Pople's 6−311+G(2d,p) basis set.[30] H^{298} and G^{298} were obtained from B3LYP/6−311+G(2d,p)//B3LYP/6−31G(d) energies and unscaled B3LYP/6−31G(d) thermal corrections. Using the B3LYP/6−31G(d) optimized geometries of the complexes, B3LYP/6−311+G(2d,p) counterpoise calculations were performed to correct the energy of interaction between Si and the donor atoms for the basis set superposition error (bsse).[31,32]

All thermochemical quantities (i.e. ΔE, ΔH, ΔG and V) are given in kJ mol^{-1}, all atomic distances in pm, all bond and torsional angles in degree and all charges in fractions of the elemental charge (1.609×10^{-19} C).

[16] Due to the presence of protic hydrogen atoms, $SiH_3X(NH_3)$, $SiH_3X(OH_2)$ (X = Cl, Br) and $SiCl_4(NH_3)$ are thermodynamically unstable with respect to the formation of di-/oligosilazanes and NH_4X (L = NH_3), or disiloxanes and HX (L = H_2O).[17] Since this reaction channel does not interfer with the subject studied, these compounds can still serve as models for dative Si−N and Si−O interactions.

Open-Chain Polyamine Ligands Bearing an Anthracene Unit − Chemosensors for Logic Operations at the Molecular Level

Sérgio Alves,[a] Fernando Pina,*[a] M. Teresa Albelda,[b] Enrique García-España,*[b] Conxa Soriano,[c] and Santiago V. Luis*[d]

Keywords: Polyamines / Nickel / Copper / Zinc / Cadmium / Sensors / Logic gates

In this work the absorption and the fluorescence emission properties as well as the protonation sequence of three open chain polyamine ligands of different dimensions bearing an anthracene unit were studied. The protonation and stability constants with Ni^{2+}, Cu^{2+}, Zn^{2+}, and Cd^{2+} have been determined in 0.15 mol·dm^{-3} NaCl at 298.1 ± 0.1 K. The values of both protonation and stability constants follow the expected trends according to the number of nitrogen donors, sequence of chelate rings and hydrophilic–hydrophobic balance. Chelation enhancement of the fluorescence emission (CHEF) was observed for some complexes of these ligands with Zn^{2+} and Cd^{2+}. In contrast the analog complexes containing $Cu^{2+}$and Ni^{2+} exhibit a chelation enhancement of the quenching (CHEQ) except for the complexes with the largest chain where some protonated metal complexes are emissive. These systems are explored from the point of view of chemosensors for logic operations at the molecular level.

Introduction

The tendency towards miniaturization has been a constant objective in many scientific applications, in particular those related to the construction of electronic components. The smaller size is associated with better performance and greater speed.[1,2] However, miniaturization based on top-down approaches, like lithographic techniques, seems to have reached its lower limits.[3,4] One possible alternative to overcome this drawback is the use of the bottom up approach. In this strategy molecules are viewed as elementary components performing a single act, and an assembly of molecular components as a device capable of executing a given function.[4,5]

Molecular analogs of electronic devices are important research tools. There is also a possibility of their future application in a chemical computer.[4−8] In order to mimic semiconductor logic gates, switches based on systems operating in liquid solutions (liquid logic) have been described.[8−13] De Silva and co-workers reported several examples of these systems constituted by a receptor and a fluorophore separated by a spacer.[8,10−13] The input signal (1,0) is obtained through the binding of metal ions or protons to the receptor, while the output signal (0,1) is generally detected by the presence of light emission. In a different approach, based on a pseudo rotaxane, the groups of Balzani and Stoddart were able to describe a conceptual XOR logic gate.[14]

In recent years our groups have been involved in the synthesis and photochemical characterization of chemosensors containing an aromatic hydrocarbon unit and bearing a polyamine receptor unit.[15−19] These molecules are capable of sensing not only cations,[15−18] but also anions.[19] In the case of H^+, Zn^{2+}, and Cd^{2+} we observed an enhancement of the fluorescence emission upon chelation (CHEF), while a quenching effect (CHEQ) can be detected for chelation of ATP, Cu^{2+}, and Ni^{2+}.[8,18,19]

In this work we explore the potential of a series of compounds containing one anthracene moiety, linked to a polyamine chain by an anthrylic carbon atom and their metal complexes. The purpose of this is for mimicking the electronic logic gates.

The systems reported here show a high versatility, because depending on pH, different logic gates, based on metal ion coordination (exhibiting CHEQ and CHEF effects), can be designed.

Results and Discussion

Protonation and Stability Constants

The protonation constants of **L3** and **L4** (Scheme 1) and the stability constants for their interaction with the metal ions Ni^{2+}, Cu^{2+}, Zn^{2+}, and Cd^{2+} are shown in Tables 1, 2,

and 3 respectively. All constants were determined in 0.15 mol·dm^{-3} NaCl at 298.1 ± 0.1 K.

The trend of the protonation constants (Table 1) can be largely interpreted in terms of minimization of coulombic repulsion between same sign charges.[20] **L3** presents three large constants [log K_1 − log K_3 = 2.4 or $\Delta(\log K_1/K_3)$ = 2.4] and two much lower constants for the fourth and fifth protonation steps [$\Delta(\log K_3/K_4)$ = 2.87, $\Delta(\log K_4/K_5)$ = 2.06]. **L4** displays even higher constants than **L3** in its first three protonation steps [$\Delta(\log K_1/K_3)$ = 1.63] an intermediate value for the fourth protonation step [$\Delta(\log K_3/K_4)$ = 1.75] and a group of two lower constants for the fifth and sixth protonation steps [$\Delta(\log K_5/K_6)$ = 1.9]. The first three protons binding the free polyamine **L3** can bind non-adjacent nitrogen atoms and therefore electrostatic repulsion will not be very large at this stage. The fourth protonation has to occur, however, adjacent to two already protonated nitrogen atoms yielding an important basicity decrease.

For **L4**, the situation is slightly different. The first three protons can bind the receptor through distant enough nitrogen atoms to yield even higher constants than **L3** (see Figure 1). The fourth protonation, however, will have to take place close to only one protonated centre yielding a smaller basicity reduction than that observed for the fourth step of **L3**.

Another point of interest is to compare these protonation constants with those reported in the literature for the polyamines, 1,4,7,10,13-pentaazatridecane (tetren, **L5**) and 1,4,7,10,13,16-hexaazahexadecane (penten, **L6**). The larger hydrophilicity of **L5** and **L6** is denoted in their higher protonation constants. This fact can be ascribed to the greater stabilisation by hydrogen bonding of **L5** and **L6,** containing primary nitrogen atoms at both ends, to the solvent water molecules.

The stability constants of the metal complexes of **L3** and **L4**, presented in Table 2 and Table 3, fulfil some of the general aspects of the coordination chemistry of polyamine ligands. Firstly, the Cu^{2+} complexes of both ligands are the ones displaying the largest stabilities; the stability trend observed $Cu^{2+} > Ni^{2+} > Zn^{2+}$ follows the expected tendency

Table 2. Stability constants for the interaction of **L3** with Cu^{2+}, Zn^{2+}, and Cd^{2+} determined in NaCl 0.15 mol·dm^{-3} at 298.1 ± 0.1 K

according to the general Irving−Williams order of stability for octahedral complexes. The stability of the Cd^{2+} complexes is, for the two ligands, slightly lower than that found for the Zn^{2+} complexes. It is interesting to note that, particularly for Cu^{2+}, the stability constants of the different complexes do not increase much from **L3** to **L4**. Although deriving coordination numbers from values of the free energy terms alone can often be misleading, comparison of the values of the stability constants with those presented by analogous complexes can provide useful information with respect to this. The stability of the $[CuL]^{2+}$ complexes of **L3** and **L4** (see Table 2 and Table 3) is clearly lower than those presented by the $[CuL]^{2+}$ complexes of **L5**, log K_{CuL} = 22.8, and **L6**, log K_{CuL} = 22.40(5),[21] and even slightly lower than that presented by the open-chain tetraamine 1,4,7,10-tetraazadecane, log K_{CuL} = 20.05. Therefore, all of this data, together with the presence of different protonated complex species seem to suggest that four nitrogen atoms are involved in the coordination sphere of the Cu^{2+} complexes of both polyamines. This point is further supported by comparison with the tetraamine **L2**, that also contains an anthracene fragment. The complex $[Cu\mathbf{L2}]^{2+}$ whose crystal structure denoted a 4-coordination of the Cu^{2+} by the nitrogen donors of the ligand,[18] presents a slightly higher stability than $[Cu\mathbf{L3}]^{2+}$ and $[Cu\mathbf{L4}]^{2+}$, again suggesting the same number of co-ordinated nitrogens. The higher stability of $[Cu\mathbf{L2}]^{2+}$ (log K_{CuL2} = 19.45) with respect to $[Cu\mathbf{L3}]^{2+}$ and $[Cu\mathbf{L4}]^{2+}$ can be ascribed to the better bite produced by an alternated sequence of five and six-membered chelate rings. For the other metal ions studied, Ni^{2+}, Zn^{2+}, and Cd^{2+}, similar comparisons with related polyamines also suggest four as the most likely number of nitrogen donors involved in the first co-ordination sphere of the metals (log K_{NiL2} = 11.61, log K_{ZnL2} = 8.62, log K_{CdL2} = 8.20, ref.[18]).

Electronic Absorption and Fluorescence Emission Studies

For all systems the molar fraction distribution of the different species in solution was calculated with the constants determined by potentiometry, and used to fit the absorption and the fluorescence emission titration curves.

Protonation Effects

The electronic absorption spectra of the free ligands reported in Scheme 1 do not change significantly with pH, in contrast with the fluorescence emission intensities which are dramatically dependent on the protonation state of the compounds (see Figure 1). In previous work carried out with the smaller ligands **L1** and **L2**, we reported that their fully protonated forms exhibit the highest emission intensity.[18] According to the NMR spectroscopic data, the first and second deprotonation steps occur on the two central

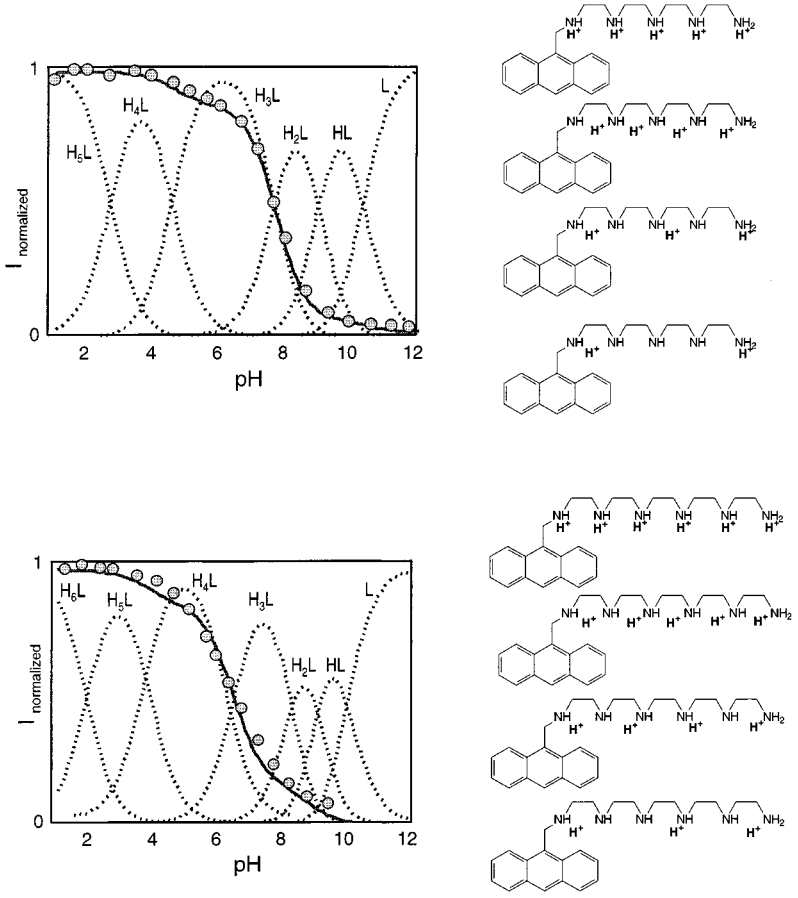

Figure 1. Fluorescence emission titration curves and molar fraction distributions of the ligands in the absence of metal ions; **L3**: λ_{exc} = 387 nm, λ_{em} = 420 nm; **L4**: λ_{exc} = 378 nm, λ_{em} = 418 nm

nitrogens of the chain. However, while the first deprotonation has only a small effect in the intensity of the fluorescence emission, the second one gives rise to its complete disappearance. The quenching effect can be accounted for by the thermodynamically favourable intramolecular photo-induced electron transfer from the lone pairs of the amine to the excited anthracene unit. This process is prevented by the protonation of the nitrogens, because protonation increases the oxidation potential by amounts of the order of 2 eV, changing the process from exergonic to endergonic. In the case of the macrocycle **L1** and its open-chain analog compound **L2**, the existence of one proton shared by the two central nitrogen atoms seems to be sufficient to prevent the quenching process. For this reason the complete quenching effect is only observed when both central nitrogens 2 and 3 are not protonated.

This pattern is repeated in the case of the compounds **L3** and **L4**.

A large quenching effect is observed only for the forms in which nitrogens 2 and 3 are completely deprotonated. It is worthwhile noting that deprotonations occurring on nitrogen atoms located at large distances from the anthracene ($n \geq 4$) do not produce significant quenching effects. This result can be explained by the well-known decrease of the electron transfer efficiency with the distance. According to CPK models the most suited nitrogen atoms for such a transfer seem to be those located at positions 2 and 3.

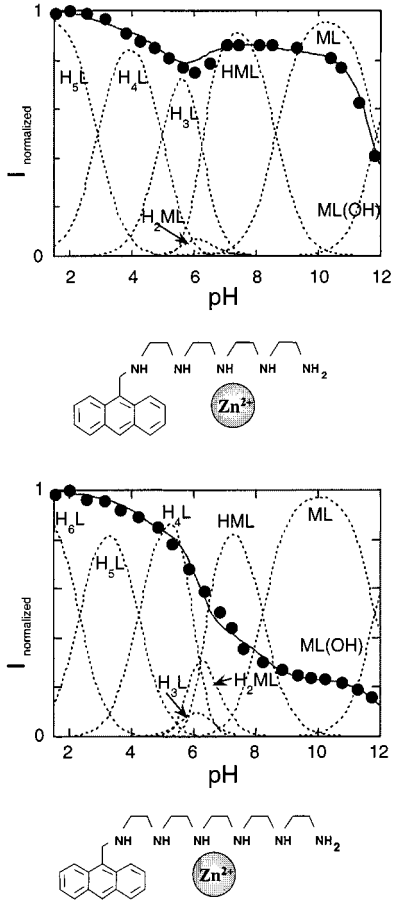

Figure 2. Fluorescence emission titration curves and molar fraction distributions of the ligands in the presence of Zn^{2+}; **L3**: λ_{exc} = 388 nm, λ_{em} = 420 nm; **L4**: λ_{exc} = 379 nm, λ_{em} = 418 nm

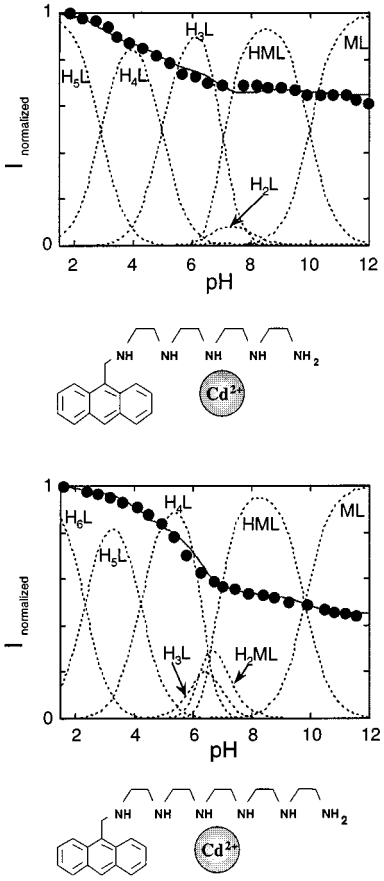

Figure 3. Fluorescence emission titration curves and molar fraction distributions of the ligands in the presence of Cd^{2+}; **L3**: λ_{exc} = 380 nm, λ_{em} = 419 nm; **L4**: λ_{exc} = 382 nm, λ_{em} = 418 nm

Chelation Enhancement of the Fluorescence Emission (CHEF)

It is well documented that metal cations like Zn^{2+} and Cd^{2+}, can give rise to complexes exhibiting fluorescence emission.[18,22,23] Figure 2 and Figure 3 show the fluorescence emission titration curves of the compounds **L3** and **L4**, in the presence of equimolar quantities of Zn^{2+} and Cd^{2+}, respectively. As reported in previous work, the zinc complexes of ligands containing a polyamine chain linked to an aromatic hydrocarbon unit are generally emissive except for the hydroxo species.[17,18] In principle, any positively charged substrate capable of binding to the nitrogen lone pairs could prevent the electron transfer. However, the interaction with metal cations can also give rise to other non-emissive excited states (charge transfer) or promote the quenching by energy transfer involving the metal. This is not the case for Zn^{2+} and Cd^{2+}, because these metal cations posses a d^{10} electronic configuration and, thus no charge transfer process (except metal-ligand CT when low energy empty ligand orbitals are available) or energy transfer is expected to occur. Therefore, for ligands **L2**−**L4** coordination of Zn^{2+} and Cd^{2+} produce a chelation enhancement of the fluorescence emission (CHEF effect).

On this basis, the species $[ZnL4]^{2+}$ showing a lower emission intensity than its analogous $[ZnL2]^{2+}$ [18] and $[ZnL3]^{2+}$ is an exception. This behaviour can be explained by the fact that Zn^{2+} is coordinated by only four nitrogen atoms. In the case of the species $[ZnL4]^{2+}$ there would be two non-coordinated deprotonated nitrogens (one more than in **L3**), and probably one of these nitrogens can get closer to the anthracene. Attempts to obtain suitable crystals of these complexes for X-ray diffraction in order to support our interpretation have unfortunately been unsuccessful.

In general, there is an important difference between Zn^{2+} and Cd^{2+} complexes in the basic pH region, because Cd^{2+}, differently from Zn^{2+}, does not easily form the non-emissive hydroxo complexes. This fact permits the existence of strong emissions, for example at pH = 12, which can be explored for practical purposes, vide infra. Finally, the species $[CdL4]^{2+}$ is also less emissive than its analogs $[CdL3]^{2+}$ and $[CdL2]^{2+}$, probably by the same reason pointed out for the Zn^{2+} complexes.

Chelation Enhancement of the Quenching (CHEQ)

Contrarily to Zn^{2+} and Cd^{2+}, many other metal cations are able to quench the emission when forming the corresponding complexes giving rise to the appearance of CHEQ effects. Cu^{2+} and Ni^{2+} are representative examples (see Figure 4 and Figure 5, respectively). This quenching effect can be explained by the existence of deactivation channels involving the metal orbitals. Energy transfer for both metal ions as well as electron transfer in the case of Cu^{2+}, have been claimed as possible mechanisms of deactivation.

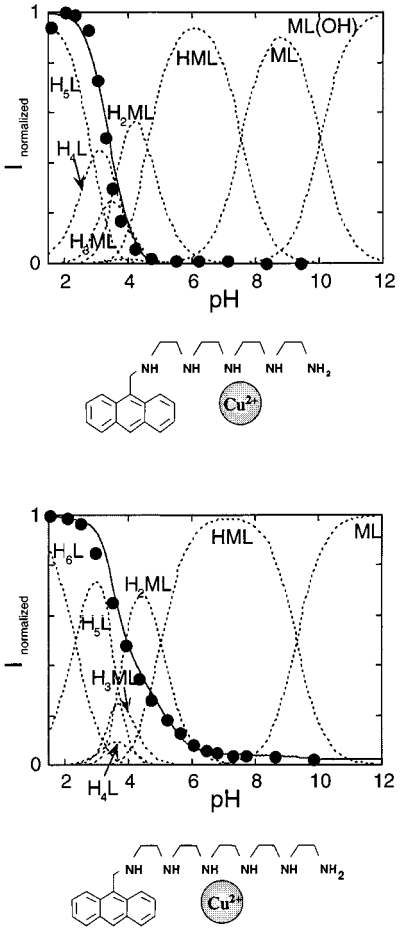

Figure 4. Fluorescence emission titration curves and molar fraction distributions of the ligands in the presence of Cu^{2+}; **L3**: λ_{exc} = 391 nm, λ_{em} = 418 nm; **L4**: λ_{exc} = 379 nm, λ_{em} = 418 nm

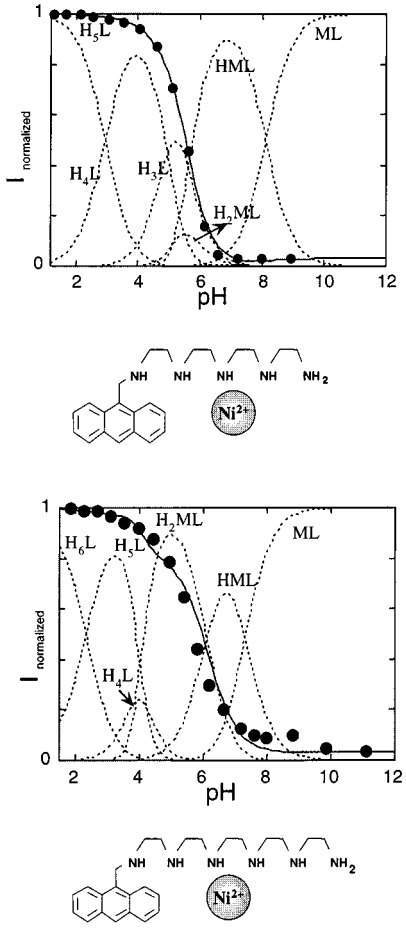

Figure 5. Fluorescence emission titration curves and molar fraction distributions of the ligands in the presence of Ni^{2+}; **L3**: λ_{exc} = 378 nm, λ_{em} = 418 nm; **L4**: λ_{exc} = 379 nm, λ_{em} = 418 nm

In Figure 4, the fluorescence emission titration curves of the ligands in the presence of Cu^{2+} are shown. As in the previous examples the dimension of the chain affects the emissive properties of the complexes. Comparing the Cu^{2+} complexes of these ligands, the most interesting feature is the existence of a slightly emissive $[CuH_2L4]^{4+}$ species, and a relatively strong emissive species, $[CuH_3L4]^{5+}$. In this case, we can expect that the metal ion to be coordinated by nitrogens 4, 5 and 6, is far enough away from the anthracene so as to decrease the metal-chromophore interaction.

Inspection of Figure 5, shows that while the $[NiL]^{2+}$ complexes are not emissive, strong emissions can be detected for some of the protonated complexes. Once more the most intense emission is observed for the ligand possessing the largest chain, $[NiH_2L4]^{4+}$. This behaviour can be explained as follows: i) by increasing the length of the chain, metal adducts containing protonated nitrogens are allowed to be formed ii) in these species the metal is more

distant from the fluorophore making their interactions difficult.

Logic Gates

In Figure 6 we represent the fluorescence emission titration curves of the complexes formed between **L3** and equimolar quantities of the metal cations Zn^{2+}, Cd^{2+},Cu^{2+}, and Ni^{2+}. This figure constitutes the basis for the following discussion.

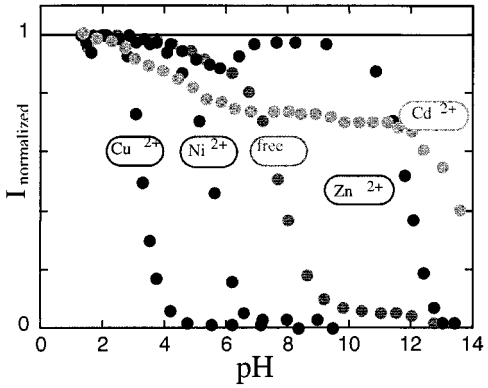

Figure 6. Comparison of the fluorescence emission of **L3** at 420 nm for the various metal ions; excitation wavelengths: Free − 387 nm; Zn^{2+} − 388 nm; Cd^{2+} − 380 nm; Cu^{2+} − 391 nm; Ni^{2+} − 378 nm

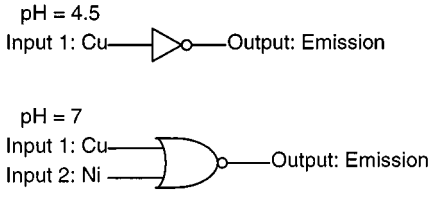
As reported previously by other authors[8,14] switching systems based on external impulses can be designed. In the present system we consider the impulses as the addition of a metal (symbol 1), or non addition, (symbol 0). Fluorescence emission intensity was used as an output signal as follows: i) if the emission reaches more than 60% of the maximum emission intensity of the free ligand at the considered wavelength the output is considered (1); ii) if the emission lies below 10% of the maximum emission intensity, the output is considered (0). It should be noted that this treatment is similar to the one used in electronics: for example in the case of the TTL family of logic gates the 1 level is considered approximately between 2 and 5 V, and the 0 level is between 0 and 0.8 V.[24]

Logic Gates Based on a CHEQ-CHEQ Pair

The first example concerns the use of a pair of metal ions both giving rise to CHEQ effects (Scheme 2).



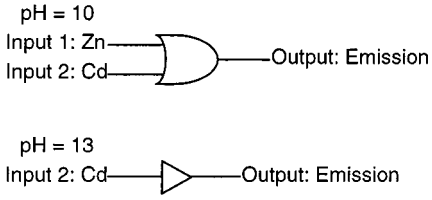
Cu^{2+}	Ni^{2+}	pH = 4.5	pH = 7
0	0	1	1
0	1	1	0
1	0	0	0
1	1	0	0
		NOT Cu^{2+}	NOR

Scheme 2

At pH = 1 the ligand is completely protonated and thus the system behaves independently of the metals giving in all case an output of 1. In terms of the electrical circuit analogy it means that the current flows in all circumstances and the output is 1 (third column in the table of Scheme 2). At pH = 4.5 (fourth column in the table), the situation is different. When neither Cu^{2+} nor Ni^{2+} are added to the solution of **L3** (inputs 0 in first and second column), the emission from the free ligand is observed, and the output is 1 (see Figure 6). Exclusive addition of Ni^{2+} at this pH value (input 0 for Cu^{2+}, input 1 for Ni^{2+}) gives rise to an emissive situation (output 1), while exclusive addition of Cu^{2+} leads to a quenching effect (output 0). When both metals are added (inputs 1 for Cu^{2+} and Ni^{2+}) it can be noted that the binding constant of Cu^{2+} is much higher than that of Ni^{2+}, resulting in a quenching effect (output 0). In terms of the logic table it can be considered as **NOT Cu^{2+}** since this column shows a positive answer (output 1) only when Cu^{2+} is absent. At pH = 7.0, both metal ions give rise to a quenching effect and the result is a **NOR** logic gate. The addition of any metal ion separately or both simultaneously gives an output of 0. Finally at pH = 10.0 the emission is quenched by electron transfer even in the absence of metal ions (output 0 in all cases). This means that no current can flow through the electrical circuit.

Logic Gates Based on a CHEF-CHEF Pair

When Zn^{2+} and Cd^{2+}, both exhibiting CHEF effects are used, a different set of logical gates is obtained, Scheme 3. At pH < 7 the situation is similar to that observed for $Ni^{2+}$and Cu^{2+} at pH = 1 and the output is always 1. At pH = 10.0, however, both metals compete for binding to the chemosensor and the two adducts show fluorescence emission, a situation that leads to an **OR** logic gate. At pH = 12.7 the response of the system is equal to the input of Cd^{2+}, because the association constant of $[CdL]^{2+}$ is much higher than the non emissive $[ZnL(OH)]^{+}$.

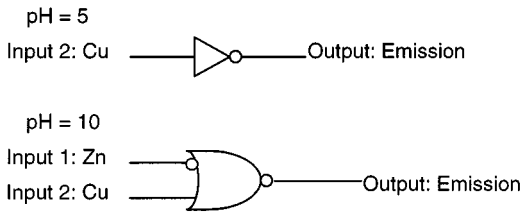


Zn^{2+}	Cd^{2+}	pH = 10	pH = 13
0	0	0	0
0	1	1	1
1	0	1	0
1	1	1	1
		OR	Cd^{2+}

Scheme 3

Logic Gates Based on a CHEF-CHEQ Pair

Another possibility is to combine metal ions that show CHEF and CHEQ effects (Scheme 4). In the case of Zn^{2+} and Cu^{2+}, the logic gates at pH = 1.0 (output 1 in all cases) and 5.0 (**NOT Cu^{2+}**) are similar to those described for Cu^{2+} and Ni^{2+} at pH = 1.0 and 4.5, respectively. However, in the



Zn^{2+}	Cu^{2+}	pH = 5	pH = 10
0	0	1	0
0	1	0	0
1	0	1	1
1	1	0	0
		NOT Cu^{2+}	NOT($Zn^{2+} \Rightarrow Cu^{2+}$)

Scheme 4

case of the logic gate at pH = 10, the complexes with Cu^{2+} are stronger than those of Zn^{2+} leading to a set of outputs which are equivalent to a negation of the implication $\mathbf{Zn^{2+} \Rightarrow Cu^{2+}}$. In this case an output 1 is obtained only when Zn^{2+} is present but Cu^{2+} is absent.

Experimental Section

Materials: Synthesis of receptors **L1**−**L2** has been accomplished as described in ref.[18]

***N*¹-(2-Aminoethyl)-N²[2-{[2-(anthrylmethyl)aminoethyl]amino}-ethyl]ethane-1,2-diamine:** Compound L3 was synthesised by an alternative procedure consisting of the reaction of a five-fold excess of the free amine tetraethylenepentaamine (3.76 g 20 mmol) with anthracene-9-carbaldehyde (0.82 g 4 mmol) to give the imine. To the solution in ethanol (75 mL) sodium borohydride (0.33 g 8.6 mmol) was added and the mixture was stirred at room temperature for 24 hours. The ethanol was removed at reduced pressure. The resulting residue was treated with water and the functionalised amine was extracted with dichloromethane (3 × 30 mL). The organic phase was washed with water and dried with anhydrous sodium sulfate and the solvent evaporated to yield the free amine, which was dissolved in ethanol and precipitated as a hydrochloride salt. (Yield 62%; 1.4 g). mp: 219−222 °C. − ^{1}H NMR (D_2O): δ_H = 3.15−3.32 (m, 14 H); 3.51 (t, 2 H), 5.19 (s, 2 H); 7.45 (t, 2 H); 7.56 (t, 2 H); 8.00 (d, 2 H); 8.12 (d, 2 H); 8.55 (s, 1 H). − ^{13}C NMR (D_2O): δ_C = 35.6, 43.7, 44.0, 44.7, 122.8, 125.9, 128.2, 129.8, 130.7, 131.2. − $C_{23}N_5H_{38}Cl_5$ (561.85): calcd. C 49.17, N 12.47, H 6.82; found C, 49.3, N, 12.6, H, 7.0.

***N*¹-[2-{(2-Aminoethyl)amino}ethyl]-*N*²-[{2-[{2-(anthrylmethyl)-amino}ethyl]amino}ethyl]ethane-1,2-diamine:** Compound **L4** was prepared as **L3**, by reaction of penthaethylenehexaamine and anthracene-9-carbaldehyde. (Yield 63%; 1.61 g) m.p. 189−192 °C. − ^{1}H NMR (D_2O) δ_H = 3.34−3.44 (m, 20 H); 4.94 (s, 2 H); 7.42 (t, 2 H); 7.53 (t, 2 H); 7.86 (d, 2 H); 7.97 (d, 2 H); 8.29 (s, 1 H). − ^{13}C NMR (D_2O): δ_C = 35.5, 43.5, 43.6, 44.8, 119.7, 122.5, 125.6, 127.9, 129.5, 130.2, 130.7. − $C_{25}N_6H_{44}Cl_6$ (641.38): calcd. C 46.7, N 13.09, H 6.9; found C, 47.1, N, 13.3, H, 7.2.

NaCl used as a background electrolyte, was a Merck suprapur product. CO_2-free NaOH and HCl solutions were prepared following the procedure reported in ref.[20]

Spectrophotometric and Spectrofluorimetric Titrations: Absorption spectra were recorded on a Perkin−Elmer Lambda 6 spectrophotometer and fluorescence emission on a SPEX F111 Fluorolog spectrofluorimeter. HCl and NaOH were used to adjust the pH values that were measured on a Metrohm 713 pH meter. Linearity of the fluorescence emission was checked in the concentration range 10^{-5} mol·dm^{-3} to 10^{-6} mol·dm^{-3}. The absorbance of the excitation wavelength was maintained lower than ca. 0.15. When excitation was carried out at wavelengths different from the isosbestic points, a correction for the absorbed light was performed.

Emf Measurements: The potentiometric titrations were carried out at 298.1 ± 0.1 K in NaCl 0.15 mol·dm^{-3}. The experimental procedure (burette, potentiometer, cell, stirrer, microcomputer, etc.) have been fully described elsewhere.[25] The acquisition of the emf data was performed with the computer program PASAT.[26] The reference electrode was an Ag/AgCl electrode in saturated KCl solution. The glass electrode was calibrated as an hydrogen-ion concentration probe by titration of previously standardized amounts of HCl with CO_2-free NaOH solutions and the equivalent point was determined by the Gran's method,[27] which gives the standard potential, $E°'$, and the ionic product of water [pK_w = 13.73(1)]. The concentrations of the different metal ions employed were determined gravimetrically by standard methods. NaCl was used as the supporting electrolyte instead of the more usual $NaClO_4$, due to the slightly higher solubility of the receptors in this medium.

The computer program HYPERQUAD,[28] was used to calculate the protonation and stability constants. The titration curves for each system (ca. 100 experimental points corresponding to at least three measurements, pH range investigated 2−10, concentration of metals and L ranging from $1{\cdot}10^{-3}$ to $5{\cdot}10^{-3}$ mol·dm^{-3}) were treated either as a single set or as separate curves without significant variations in the values of the stability constants. Finally, the data sets were merged together to give the final stability constants. Moreover, in the case of Ni^{2+}, measurements were made both in formation and in dissociation (from acid to alkaline pH and vice versa) to check the reversibility of the reactions.

NMR Measurements: The ^{1}H and ^{13}C NMR spectra were recorded on Varian UNITY 300 and UNITY 400 spectrometers, operating at 299.95 and 399.95 MHz for ^{1}H and at 75.43 and 100.58 MHz for ^{13}C. The spectra were obtained at room temperature in D_2O or $CDCl_3$ solutions. For the ^{13}C NMR spectra dioxane was used as a reference standard (δ = 67.4) and the solvent signal for the ^{1}H spectra. The probe temperature was regulated with a variable temperature accessory. Adjustments to the desired pH were made using drops of DCl or NaOD solutions The pH was calculated from the measured pD values using the correlation, pH = pD − 0.4.[29]

Heteroleptic Rare Earth Double-Decker Complexes with Porphyrinato and 2,3-Naphthalocyaninato Ligands − Preparation, Spectroscopic Characterization, and Electrochemical Studies

Jianzhuang Jiang,*[a] Wei Liu,[a,b] Ka-Lok Cheng,[b] Ka-Wo Poon,[b] and Dennis K. P. Ng*[b]

Keywords: Lanthanides / Actinides / Porphyrins / Phthalocyanines / Sandwich complexes

A series of RE(Nc)(TBPP) (**1**–**12**) complexes [RE = La, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Y, Ho, Er, Tm; Nc = 2,3-naphthalocyaninate; TBPP = *meso*-tetrakis(4-*tert*-butylphenyl)porphyrinate] and Eu[Nc(*t*Bu)$_4$](TClPP) [Nc(*t*Bu)$_4$ = tetra(*tert*-butyl)-2,3-naphthalocyaninate; TClPP = *meso*-tetrakis(4-chlorophenyl)-porphyrinate] (**13**) have been prepared by a one-pot procedure which involves the treatment of RE(acac)$_3$·*n*H$_2$O (acac = acetylacetonate) with the corresponding metal-free porphyrins and naphthalonitriles in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in *n*-octanol. These novel double-deckers have been spectroscopically characterized. A one-electron reduction and three one-electron oxidations have been revealed by electrochemical methods. The potentials of all these processes depend linearly on the ionic radii of the central metal ions, giving a relatively large potential difference (0.50–0.57 V) between the first oxidation and the first reduction processes.

Introduction

Tetrapyrrole derivatives such as porphyrins and phthalocyanines are able to form sandwich complexes with a range of metal ions including rare earths, actinides, group 4 transition metals, and some main group elements (e.g. Bi, In, Sn).[1] The resulting double- and triple-decker complexes possess intriguing and unique electronic and optical properties which render them useful in materials science. Bis(phthalocyaninato) rare earth complexes RE(Pc)$_2$,[2] for example, can be used in electrochromic devices,[3] field-effect transistors,[4] gas and herbicide sensors,[5] and optically addressed spatial light modulators.[6] While the chemistry and properties of both homoleptic and heteroleptic complexes with these two types of ligands have been extensively studied, little is known about the naphthalocyanine analogues which contain a more delocalized π system. It is expected that sandwich complexes containing these larger macrocyclic ligands should have distinct properties compared with the Pc counterparts owing to the narrower energy gap between the highest occupied and the lowest unoccupied molecular orbitals (HOMO and LUMO).[7,8]

A number of naphthalocyanine-containing double-[8,9] and triple-decker[8b,10] complexes have been reported, but virtually all of them are confined to lutetium complexes. Sandwich-type Nc[2] complexes of other metals have only appeared very recently.[11] It has been well documented that the electronic properties of these sandwich complexes depend on the ring-to-ring separation, which can be altered by the size of the metal center.[12] Studies of a whole series of analogous complexes with different metal centers are therefore of special importance.

We have recently developed an efficient synthetic pathway for heteroleptic sandwich complexes which involves a cyclic tetramerization of dicyanobenzenes using RE(ring)(acac) [RE = Eu, Y; ring = Pc, Por] as the template.[2,13] This method has been utilized to prepare the first hetereoleptic Nc and Por complexes Eu(Nc)(TPyP) and Eu[Nc(SC$_{12}$H$_{25}$)$_8$](TPyP).[2,14] We report herein an extension of this work which involves a simplified one-pot procedure leading to a series of (naphthalocyaninato)(porphyrinato) rare earth double-decker complexes. The spectroscopic and electrochemical properties of these novel sandwich compounds are also described herein.

Results and Discussion

The preparation of the mixed double-deckers RE(Nc)(TBPP) (RE = La, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Y, Ho, Er, Tm) (**1**−**12**) was mainly based on our previously described procedure,[2,13,14] but the prior generation of the half-sandwich complexes RE(TBPP)(acac) was found to be not necessary. Thus a one-pot procedure involving the metal-free porphyrin H$_2$(TBPP), RE(acac)$_3$·*n*H$_2$O, naphthalonitrile, and DBU in *n*-octanol could also lead to the desired products (Scheme 1). Similar to the RE(Por)$_2$ [Por = TPP or OEP][2,12b,15] and RE[Nc(*t*Bu)$_4$]$_2$ series,[2,11b] the yield of these mixed sandwiches decreases gradually with the size of the central metal ion (Table 1), showing that, for all these double-deckers, complexes with a smaller metal center are more difficult to obtain, probably due to

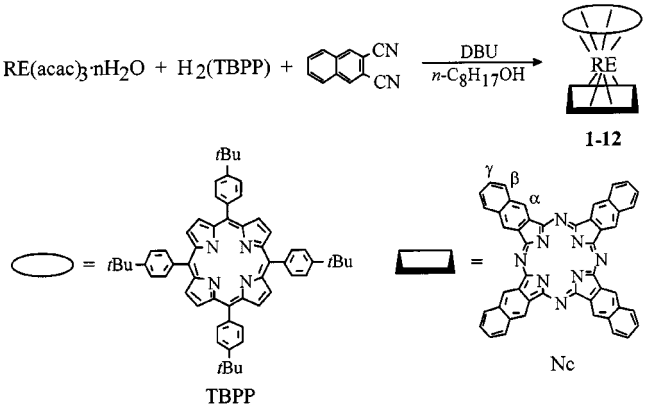
an increase in steric compression of the two macrocyclic ligands. The europium analogue Eu[Nc(*t*Bu)$_4$](TClPP) (**13**) was prepared similarly using the metal-free porphyrin H$_2$(TClPP)[2] and 6-*tert*-butylnaphthalonitrile.



Scheme 1. Synthesis of heteroleptic rare earth double-deckers

All these double-deckers, after being purified by column chromatography and recrystallization, were essentially pure as shown by thin-layer chromatography. However, satisfactory analytical data could not be obtained. This might be due to the presence of traces of impurities which could not be completely removed by conventional purification methods.[16] The compounds, however, were unambiguously characterized with a range of spectroscopic methods. The matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectra of all these compounds showed prominent signals attributed to the molecular ions, of which the isotopic patterns were in good agreement with the respective simulated spectra (Table 1).

Figure 1 shows the absorption spectrum of Pr(Nc)(TBPP) (**2**), which is representative for the spectra of this series of compounds. The spectral features resembled those of the Pc counterparts RE^{III}(Pc)(Por)[12c,13b,13c,17] and the previously reported Nc complexes Eu(Nc)(TPyP) and Eu[Nc(SC$_{12}$H$_{25}$)$_8$](TPyP),[14] and thus could be assigned in a similar manner. As shown in Table 1, the Nc B band (323−329 nm) and the TBPP B band (414−424 nm) are rather insensitive to the metal center. By analogy with the Pc analogues RE^{III}(Pc)(Por), the weak absorption at 479−482 nm and the near-IR band at 1025−1146 nm may arise from a hole localized on the Nc ring. The latter signal shifts gradually to the red as the size of the tervalent metal center decreases from La to Tm, which was also seen for the Pc counterparts.[12c] This observation suggests that this near-IR absorption should not be due to an intramolecular ring-to-ring charge-transfer transition as proposed previously.[14,18] For such a transition, a reverse trend should be observed because the π-π interactions between the rings will become stronger when the ring-to-ring separation decreases along the series.[12b,12c,19] This charge-transfer transition band, however, could not be detected for these complexes up to 2400 nm and the reason remains unclear at this stage. Another remarkable feature for these Nc double-deckers is the relatively intense Q bands at 549−583 and 612−635 nm, which are almost invisible in the Pc analogues.[12c,13b,13c,17] Both of these signals experience a hypsochromic shift when the size of the metal center decreases.

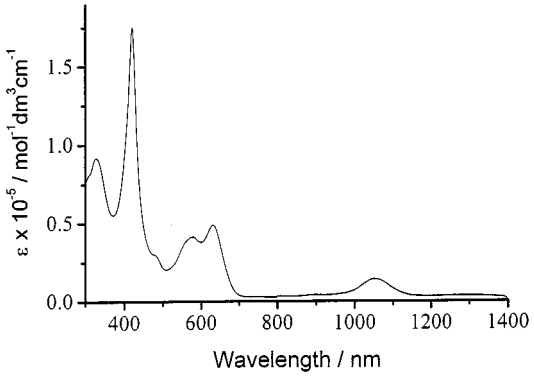


Figure 1. Electronic absorption spectrum of Pr(Nc)(TBPP) (**2**) in CHCl$_3$

The presence of Nc π radical anion (Nc$^{\bullet-}$) in these single-hole complexes was also corroborated by the strong IR marker band at 1319−1325 cm^{-1} (Table 1),[11b,11c] which is also a diagnostic band for the Pc π radical anion (Pc$^{\bullet-}$).[20] Due to the presence of this unpaired electron, these complexes, like other single-hole analogues, are usually NMR

[a] Given as: chemical shift (δ) (multiplicity, relative intensity and assignment) where s = singlet, br s = broad signal, d = doublet, m = multiplet. − [b] Recorded in the presence of $NaBH_4$. − [c] Recorded in the presence of hydrazine hydrate.

silent. We employed the strategy developed by L'Her[8a,21] using hydrazine hydrate or $NaBH_4$ as the reducing agent to generate the monoanionic $[RE^{III}(ring\text{-}1)(ring\text{-}2)]^-$ or protonated $RE^{III}H(ring\text{-}1)(ring\text{-}2)$ species, in which both the macrocycles become diamagnetic. We were able to obtain satisfactory ^{1}H NMR spectroscopic data for the reduced form of the La, Nd, Sm, and Eu double-deckers (Table 2). The spectra for the Pr, Dy, and Tm analogues, however, were hard to interpret which could be related to the different magnetic properties of the metal ions. It is worth noting that NMR spectroscopic data for such sandwich-type complexes having a paramagnetic metal center are rare indeed.[1]

Figure 2 shows the ^{1}H NMR spectra of the two Eu^{III} double-deckers **5** and **13** in the presence of hydrazine hydrate. It can be seen that the Nc α protons of the reduced form of **5** resonate as a singlet at δ = 10.95 because of the symmetrical Nc ring. The corresponding signal for **13** appears as a multiplet at δ = 10.79−11.17 due to the presence of a mixture of constitutional isomers and the non-equivalence of these α protons. The assignment for the Nc β and γ protons' signals (at ca. δ = 9.3 and 8.4, respectively) for these two compounds is supported by the smaller integration observed for the latter for **13**. Similar to other sandwiches containing a TPP ligand or its derivatives,[1b,17b,22] four distinct broad signals appear for the *ortho* and *meta* aryl protons in both cases, suggesting that there is a restricted rotation about the C(*meso*)−C(aryl) bonds.

The electrochemical behavior of all the double-deckers **1**−**13** in CH_2Cl_2 was investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV). The voltammograms generally displayed four quasi-reversible couples assignable to the first three one-electron oxidations and the first one-electron reduction of the sandwich compounds (Table 3); all of them are ligand-based processes. Figure 3 shows the cyclic voltammogram of Sm(Nc)(TBPP) (**4**), which is typical. The second one-electron reduction process, which was commonly seen in related double-deckers, could not be revealed for these complexes under the present conditions due to a solvent breakdown. As shown in Figure 4, the potentials of all these processes are linearly dependent on the ionic radius of the metal center,

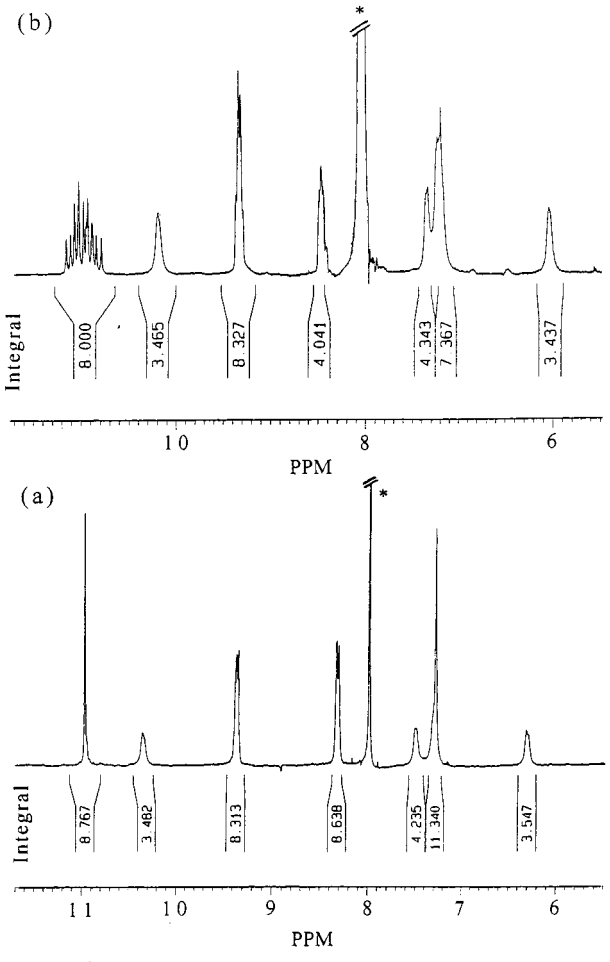

Figure 2. ^{1}H NMR spectra of (a) Eu(Nc)(TBPP) (**5**) and (b) Eu[Nc(*t*Bu)$_4$](TClPP) (**13**) in the presence of a small amount of hydrazine hydrate in $CDCl_3$/[D_6]DMSO (1:1); * indicates the signal for hydrazine hydrate

with a positive gradient for the first oxidation and the first reduction processes and a negative gradient for the second and third oxidation processes. The linear correlation observed between these potentials and the ionic radii of the central metals indicates that π-π interactions are probably present in these heteroleptic double-deckers. The potential difference between the first oxidation and the first reduction

is rather insensitive to the metal center with a value ranging from 0.50 to 0.57 V. These values, which can reflect the HOMO−LUMO gap of the complexes, are slightly larger than those of the Pc counterparts RE^{III}(Pc)(TPP) (0.45−0.48 V)[12c] and are significantly larger than those of the bis(naphthalocyaninato) analogues (0.29−0.37 V).[8,11b,11c]

In summary, we have prepared a series of rare heteroleptic rare-earth double-decker complexes containing porphyrinato and 2,3-naphthalocyaninato ligands by a simple one-pot procedure. It is envisaged that this methodology can be extended readily to other heteroleptic sandwich systems. Having a more delocalized macrocyclic ligand, these complexes have been found to exhibit distinct spectroscopic and electrochemical properties compared with those of the Pc counterparts.

Experimental Section

n-Octanol was distilled from sodium. The electrolyte [Bu$_4$N][PF$_6$] was recrystallized twice from tetrahydrofuran prior to use. All other reagents and solvents were of reagent grade and used as received. Naphthalonitrile,[23] 6-*tert*-butylnaphthalonitrile,[23] H$_2$(TBPP),[24] H$_2$(TClPP),[24] and RE(acac)$_3$·*n*H$_2$O[25] were prepared by previously described methods. − UV/Vis: Hitachi U-3300. − Near-IR: Hitachi U-3100. − IR: Perkin−Elmer 1600. − MALDI-TOF-MS: Bruker BIFLEX III, α-cyano-4-hydroxycinnamic acid as matrix. − Electrochemical measurements were carried out with a BAS CV-50 W voltammetric analyzer. The cell comprised inlets for a platinum-sphere working electrode, a silver-wire counter electrode and an Ag/AgNO$_3$ (0.1 M in MeCN) reference electrode which was connected to the solution by a Luggin capillary whose tip was placed close to the working electrode.[26] Typically, a 0.1 M solution of [Bu$_4$N][PF$_6$] in CH_2Cl_2 containing the sample was purged with nitrogen for 20 min, then the voltammograms were recorded at ambient temp. Potentials were referenced to the Ag/Ag$^+$ couple in MeCN, which was taken as +0.31 V vs. the saturated calomel electrode (SCE) as determined for this system previously using ferrocene as an internal standard.[27]

General Procedure for the Preparation of RE(Nc)(TBPP) (1−12) and Eu[Nc(*t*Bu)$_4$](TClPP) (13): A mixture of RE(acac)$_3$·*n*H$_2$O (0.10 mmol), H$_2$(TBPP) or H$_2$(TClPP) (0.05 mmol), naphthalonitrile or 6-*tert*-butylnaphthalonitrile (0.40 mmol), and DBU (50 mg, 0.33 mmol) in *n*-octanol (4 mL) was refluxed overnight (>18 h) under nitrogen to give a dark green solution. The volatiles were then removed under reduced pressure and the residue was chromatographed on a silica gel column with CH_2Cl_2/hexane (1:2) as eluent to remove the unchanged metal-free porphyrin as the first fraction. The column was further eluted with $CHCl_3$ to give a greenish blue band containing the desired double-decker. The crude product was further purified by the same chromatographic procedure followed

by recrystallization from a mixture of $CHCl_3$ and MeOH to give a dark blue powder. The yields together with the characterizing data for these complexes are given collectively in Table 1.

[18] There is now substantial evidence that the hole in this class of complexes is delocalized over both macrocycles at least to a certain extent. On this basis, this characteristic near-IR band should be more correctly assigned to an electronic transition from a bonding orbital constructed from the HOMO of each ring to a half-occupied antibonding orbital (see ref.[1b]).

Olefins Coordinated at a Highly Electrophilic Site − Dicationic Palladium(II) Complexes and Their Equilibrium Reactions with Nucleophiles

Christine Hahn,[a] Pasquale Morvillo,[a] and Aldo Vitagliano*[a]

Dedicated to Professor Paolo Corradini on the occasion of his 70th birthday

Keywords: Palladium / Alkene complexes / Nucleophilic additions / Tridentate ligands / Aminations

Dicationic olefin palladium(II) complexes [Pd(PNP)(olefin)]$(BF_4)_2$ [olefin = ethylene, propene, styrene, (*Z*)-2-butene, (*E*)-2-butene, norbornene; PNP = 2,6-bis(diphenylphosphanylmethyl)pyridine] have been prepared and characterized by ^1H, ^{13}C, and ^{31}P NMR spectroscopy. The coordinated double bond in these complexes is strongly electrophilic, and easily adds a variety of nucleophiles NuH (H_2O, MeOH, aliphatic and aromatic amines). This reaction competes with olefin displacement in a rapidly reversible equilibrium process, as a result of which the addition products can also be obtained starting from the substituted compounds [Pd(PNP)(NuH)]$(BF_4)_2$ and the appropriate olefin. Equilibrium constants for the addition and substitution reactions have been determined in a number of cases. Proton abstraction from [Pd(PNP)(CHRCHR′NuH)]$^{2+}$ by $NaHCO_3$ quantitatively drives the equilibrium to β-functionalized alkyl complexes of the general formula [Pd(PNP)(CHRCHR′Nu)](BF_4), which are unusually stable to β-H elimination.

Introduction

(Olefin)palladium(II) complexes are important intermediates in organic syntheses and catalytic processes,[1] where the addition of nucleophiles to the C=C double bond is the crucial step. This offers numerous possibilities for the functionalization of simple olefins.[2] Among these, the hydroamination process, which was first investigated in the early 1970s, has recently attracted renewed attention.[3] The electrophilic character of the coordinated olefin is enhanced by an increase in the positive charge on the metal center,[4] as also shown by the ability of cationic Pd^{II} complexes to promote olefin polymerization[5] and copolymerization[6] reactions. Accordingly, very high reactivity would, in principle, be expected for complexes where the metal center bears a net (+2) charge, thus making such species appealing targets for investigation. On the other hand, a net (+2) charge would also enhance the electrophilic character and hardness of the metal center, and in such species the soft olefinic ligand can be expected to be readily displaceable, even by weak ligands and/or nucleophiles. Consequently, dicationic alkene complexes are expected to be accessible only within a rather narrow range of conditions and their reactivity is not readily predictable in advance. In line with the above considerations, no dicationic Pd^{II} complex of a simple monoolefin had been described in the literature[7] until we reported[8] the synthesis and characterization of two compounds of the formula [Pd(PNP)(CH_2=CHR)]$(BF_4)_2$ [PNP = 2,6-bis(diphenylphosphanylmethyl)-pyridine;[9] R = H, Ph], together with their reactions with secondary aliphatic amines. A number of questions arose from the above study, e.g. concerning the range of accessible (+2) charged complexes, their reactivity with nucleophiles weaker than aliphatic amines, and the nature (kinetic or thermodynamic) and extent of the competition between nucleophilic addition and displacement. In the present paper, we address these issues, presenting some quantitative evidence for the high electrophilicity of the olefin and for the interplay between addition and substitution reactions in these species. We also report the generation of a rare class of non-chelating β-functionalized (alkyl)Pd^{II} derivatives that are thermally stable and do not undergo β-H elimination.[10−13]

Results and Discussion

Synthesis and Characterization of [Pd(PNP)(olefin)]$^{2+}$ Complexes

The dicationic (olefin)palladium(II) complexes [Pd(PNP)(olefin)]$(BF_4)_2$ [olefin: CH_2=CH_2 (**1**), CH_2=CHMe (**2**), CH_2=CHPh (**3**), (*Z*)-MeCH=CHMe (**4**), (*E*)-

MeCH=CHMe (**5**), norbornene (**6**)] were prepared by reaction of the chloro complex [Pd(PNP)Cl]Cl[14] with two equivalents of silver tetrafluoroborate in the presence of an excess of the olefin according to Equation (1). The preparation of complexes **1** and **3** by the same procedure has been described previously.[8] In an alternative synthetic route, the norbornene complex **6** could be prepared by displacement of ethylene with an excess of norbornene [Equation (2)] and was obtained in high yield in an analytically pure state.

$$\underset{\mathbf{1}}{[Pd(PNP)(CH_2{=}CH_2)](BF_4)_2} \xrightarrow[-\ CH_2{=}CH_2]{\text{norbornene/ } CH_2Cl_2} \underset{\mathbf{6}}{[Pd(PNP)(\text{norbornene})](BF_4)_2} \quad (2)$$

The complexes **2** and **4**−**6** were characterized by ^{31}P, ^{1}H, and ^{13}C NMR spectroscopy. They were found to be moderately stable in dichloromethane and nitromethane solution at room temperature and may be stored for months under a dry atmosphere. They slowly decompose in moist air, as was also observed for the ethylene and styrene complexes **1** and **3**.[8] The ^{1}H and ^{31}P NMR spectra of the complexes (see Experimental Section) indicate an averaged C_2 symmetry for the propene complex **2** and an averaged C_{2v} symmetry for the complexes **4** and **6** and hence a fast rotation of the olefin about the Pd−double bond axis in each case. The spectrum of the propene complex **2** does not show substantial changes on cooling down to 203 K, indicating that at this temperature olefin rotation is still fast on the NMR time scale. The pattern observed for the propene complex **2** also indicates that at room temperature the exchange (dissociation−reassociation) of the olefin is slow on the NMR time scale. This was confirmed for all the complexes examined by the appearance of well-separated signals for the protons of free and coordinated olefin when a small amount of free olefin was added to each sample.

The ^{13}C chemical shifts of the olefinic carbon atoms in the complexes **1**−**6** are listed in Table 1, together with the corresponding coordination-induced shifts Δδ. A rather uniform albeit modest upfield shift is observed: The average Δδ is −15 ppm for the methine carbon atoms (except in the case of norbornene) and −33 ppm for the methylene carbon atoms, confirming previous observations for complexes **1** and **3**.[8] As pointed out previously,[8] the small values of Δδ are consistent with the high positive charge present on the central ion (as compared with the isoelectronic Rh^{I} complexes[15]) and with a consequent presumably low contribution of π-back-donation to the metal−olefin bond.[16]

Table 1. ^{13}C NMR chemical shifts of the coordinated olefins in **1**−**6** ($\Delta\delta = \delta_{coord} - \delta_{free}$)

Olefin	δ(=CH_2)	Δδ(=CH_2)	δ(=CH)	Δδ(=CH)
$CH_2{=}CH_2$ [8]	88.0	−35.3		
MeCH=CH_2	86.4	−29.6	118.1	−16.5
PhCH=CH_2 [8]	77.2	−34.8	120.2	−15.3
(*Z*)-MeCH=CHMe			110.9	−14.4
(*E*)-MeCH=CHMe			107.8	−17.6
Norbornene			105.2	−30.5

Olefin Displacement

As mentioned in the previous section, in complexes **1**−**6** at room temperature the olefin exchange is slow on the NMR time scale, which seems to be a rather unusual feature for coordinatively unsaturated Pd^{II} complexes.[17] However, the exchange is fast on the laboratory time scale, as shown by an experiment in which free ethylene was added to an NMR sample of the propene complex **2** at room temperature. The ^{1}H NMR spectrum of the mixture, recorded within 3 min of mixing, showed the presence of both species **1** and **2**, the relative abundances of which remained unchanged with time, indicating a rapid equilibration of the olefin complexes. The equilibrium constant for the exchange [Equation (3)] of ethylene for propene was estimated as $K = 1.4$ by integration of the NMR signals of the four species involved. Similar experiments were performed on complexes **3**−**5**, allowing estimation of the respective equilibrium constants [Equation (3)].

$$\underset{\mathbf{2\text{-}5}}{[Pd(PNP)(\text{olefin})](BF_4)_2} + CH_2{=}CH_2 \quad \Big\Vert K\,(CD_2Cl_2) \quad (3)$$

olefin	*K*
propene	1.4
E-2-butene	3
Z-2-butene	6
styrene	26

$$\underset{\mathbf{1}}{[Pd(PNP)(CH_2{=}CH_2)](BF_4)_2} + \text{olefin}$$

The relative stabilities of the olefin complexes seem to be determined essentially by steric factors. It is worth noting that (*E*)-2-butene gives a more stable complex than (*Z*)-2-butene, in contrast to the sequence typically found for (2-butene)metal complexes.[16,18] This most likely arises from the C_2 symmetry of the "pocket" created by the PNP ligand, which is better suited for hosting the (*E*)- as compared to the (*Z*)-olefin. The substantially lower stability of the styrene complex **3** can be ascribed to a steric interaction between the phenyl groups, which was revealed by its X-ray structure.[8]

As anticipated in the introduction, the olefin in complexes **1**−**6** is easily displaced, even by ligands that are usually weakly coordinative towards d^8 ions. Dissolution in acetone led to loss of the olefin from all of the complexes, while saturation of dichloromethane solutions of **1**, **2**, or **3** with water followed by evaporation of the solvent furnished the aqua complex **7** [Equation (4)]. The displacement of ethylene by acetonitrile, giving complex **8**, proved to be even more favorable. In the latter two cases, the equilibrium constants for the exchange [Equation (4)] were determined by

^{1}H NMR measurements in CD_2Cl_2/CD_3NO_2 (4:1) and were found to be $K = 5{\cdot}10^{-2}$ and $K = 9{\cdot}10^{2}$ for **7** and **8**, respectively.

$$[Pd(PNP)(CH_2{=}CH_2)](BF_4)_2 + L \quad \mathbf{1}$$

L	K (CD_2Cl_2/CD_3NO_2)
H_2O	$5 \cdot 10^{-2}$
CH_3CN	$9 \cdot 10^{2}$

$$[Pd(PNP)(L)](BF_4)_2 + CH_2{=}CH_2 \qquad (4)$$

L = H_2O **7**; CH_3CN **8**

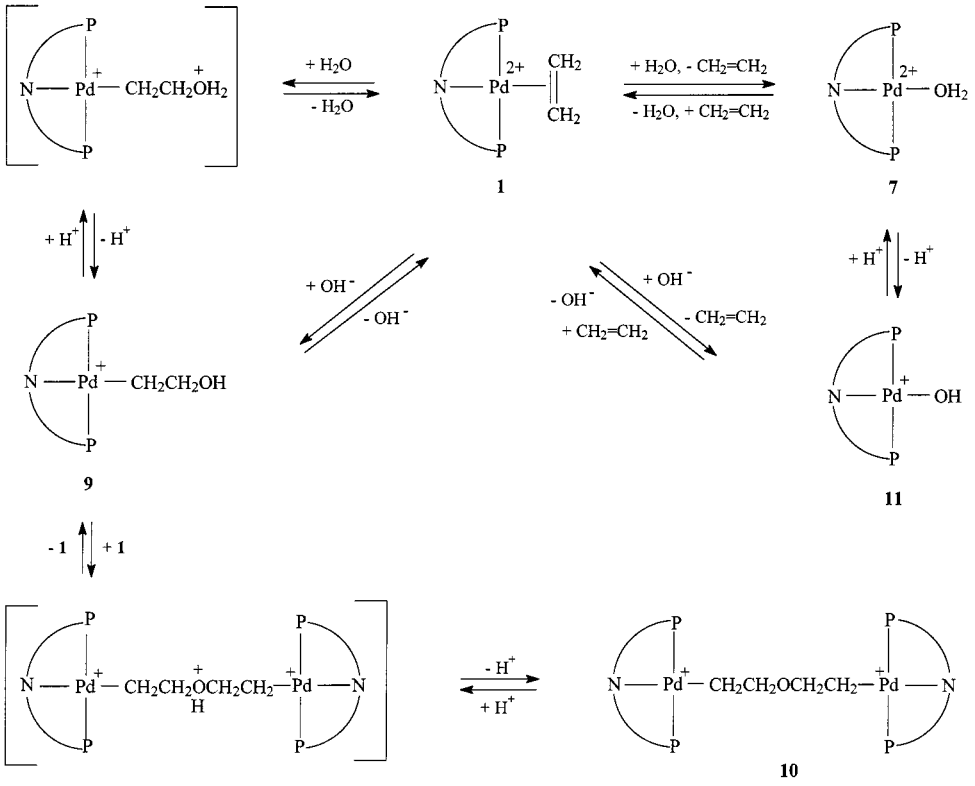
Reactions with Nucleophiles

Complexes **1**−**6** were treated with a number of nucleophiles, including water, methanol, and aliphatic and aromatic amines. In many cases, the reaction mixtures were directly analyzed by ^{1}H NMR, which revealed details that would have remained undetected in normal preparative experiments and hence provided a quantitative estimation of the factors controlling the behaviour of the system.

Reactions with H_2O

As mentioned above, treatment of the ethylene complex **1** with an excess of H_2O resulted in the displacement of the olefin with production of the aqua complex $[Pd(PNP)(H_2O)](BF_4)_2$ (**7**) [Equation (4)], which was isolated and characterized by ^{1}H NMR. However, when the reaction was performed in an NMR tube using an excess of ethylene and a drop of water (resulting in a biphasic mixture), signals appeared in the spectrum indicative of a partial conversion of **1** to addition products (see below). These addition products were almost undetectable in the absence of an excess of heterogeneous water. This qualitatively indicated the occurrence of an overall equilibrium, in which the nucleophilic attack on the coordinated olefin was followed by proton transfer to the water phase (see Scheme 1). Indeed, when the reaction was performed in the presence of solid $NaHCO_3$ (ca. 2 equiv.), the equilibrium was seen to be quantitatively shifted towards the addition products, which could be isolated as a solid mixture and were assigned the mono- and dialkylated structures **9** and **10** (Scheme 1). In the ^{1}H NMR spectrum of the mixture, two sets of signals are seen for the $[PdCH_2CH_2O]$ moiety at $\delta = 2.02$ and 3.44 for **9** and at $\delta = 1.79$ and 2.79 for **10**. Integration of these signals reveals a ratio of ca. 1:3. Correspondingly, two different signals are observed for the PCH_2 group of the coordinated PNP ligand, at $\delta = 4.38$ and $\delta = 4.44$, respectively, in the same 1:3 ratio. Reductive degradation of the product mixture with $NaBH_4$ in $[D_8]$THF gave a solution in which the ^{1}H NMR signals of ethanol and diethyl ether were found in the same 1:3 ratio as observed for **9** and **10** (corresponding to a molar ratio of 1:1.5), thus independently confirming the above assignments.

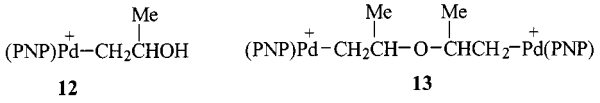
Both the substitution reaction and the nucleophilic attack were found to be readily reversible. Indeed, addition of 5 equiv. of concentrated HBF_4 to a sample of the alkyl derivatives **9** and **10** in the presence of free ethylene resulted in the formation of **1**. Also, treatment of the aqua complex



Scheme 1

7 with $NaHCO_3$ in dichloromethane saturated with ethylene likewise produced the same mixture of alkyl derivatives **9** and **10**. The formation of **10** was also performed in a stepwise manner, i.e. by first abstracting a proton from the coordinated water in **7** with an excess of $NaHCO_3$, giving the hydroxo complex $[Pd(PNP)(OH)]BF_4$ (**11**), and then treating the isolated complex **11** with ethylene. The latter reaction was monitored by ^1H NMR, which revealed the initial formation of the monoalkylated species **9** followed by partial conversion to **10**.

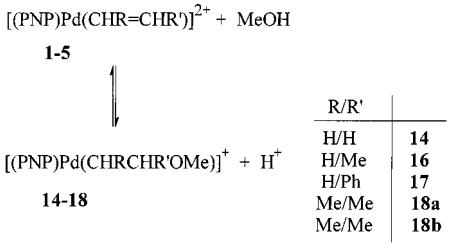
A similar set of equilibria were revealed in the case of the propene complex **2**. The major observed addition product (80% based on Pd) was the mononuclear primary alkyl derivative **12**, corresponding to a Markovnikov addition. Two pertinent differences from the ethylene case were qualitatively apparent. Firstly, the addition products were barely detectable in the absence of added $NaHCO_3$, indicating that the addition reaction is appreciably less favored than in the case of ethylene. Secondly, the binuclear species **13** was only produced as a minor product (20% based on Pd), probably reflecting the steric repulsion between two secondary carbon atoms linked to the same oxygen atom.



12 **13**

Reactions with MeOH

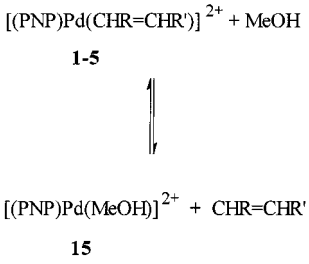
Dissolution of the ethylene complex **1** in CD_3OD produced a strongly acidic solution, the ^1H NMR spectrum of which revealed the presence of the addition product $[D_3]$**14**, a substitution product $[D_3]$**15**, and free ethylene in a molar ratio of 1:1:1. In the case of the propene complex **2**, the addition product $[D_3]$**16** was formed to a lesser extent (corresponding ratio 1:4:4), while for the styrene complex **3**, only the substitution product $[D_3]$**15** and free styrene were detectable in solution. Small amounts of the addition products were also detectable in the case of the 2-butene complexes **4** and **5**. Addition of an excess of free olefin to the solutions of **1** and **2** led to an increase in the relative amounts of the corresponding addition products **14** and **16**, respectively. These results indicate that in methanol solution two fast equilibrium reactions are operative [Equation (5) and Equation (6)].



R/R'	
H/H	**14**
H/Me	**16**
H/Ph	**17**
Me/Me	**18a**
Me/Me	**18b**

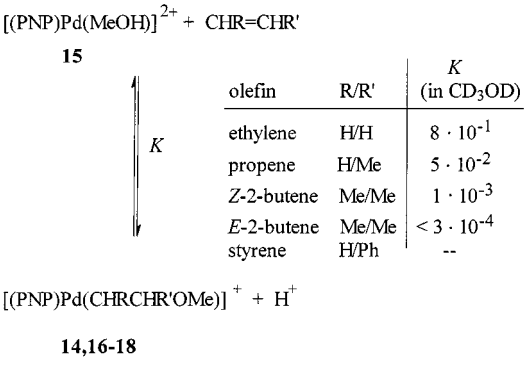
(5)

The equilibrium constants for the overall reaction [Equation (7)] were estimated for ethylene, propene, and the two



(6)

2-butenes, giving a relative measure of the stabilities of the (β-methoxyalkyl)palladium species compared with the respective free olefins.



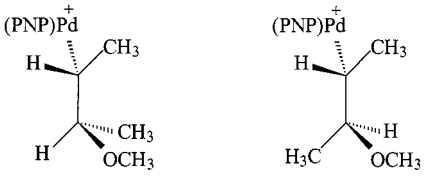
olefin	R/R'	K (in CD_3OD)
ethylene	H/H	$8 \cdot 10^{-1}$
propene	H/Me	$5 \cdot 10^{-2}$
Z-2-butene	Me/Me	$1 \cdot 10^{-3}$
E-2-butene	Me/Me	$< 3 \cdot 10^{-4}$
styrene	H/Ph	--

(7)

In the case of the ethylene complex **1**, the equilibrium represented by Equation (7) also results in a site exchange of the α- and β-protons of the alkyl chain. This exchange was actually revealed at room temperature by a ^1H NMR saturation transfer experiment, in which irradiation of either of the CH_2 groups caused a partial transfer of magnetization to the other CH_2 unit as well as to the free $CH_2=CH_2$ molecules, indicating that the overall exchange [Equation (7)] takes place at a rate comparable to the relaxation rates ($1-10\ s^{-1}$).

In line with our expectations, when the complexes **1**–**5** were treated with 2 equiv. of $NaHCO_3$ in methanol in the presence of an excess of free olefin, the equilibrium represented by Equation (7) was driven to completion leading to quantitative formation of the corresponding β-methoxyalkyl complexes **14** and **16**–**18**, which could be isolated. In the case of the ethylene complex **1**, the nucleophilic attack was also performed in a CH_2Cl_2 solution using 4 equiv. of MeOH, which led to the same result. High regioselectivity was achieved in the reactions of the propene and styrene complexes **2** and **3**, which gave **16** and **17**, respectively, in better than 97% abundances.[19] The structures of **16** and **17** were independently confirmed by reductive cleavage of the complexes with $NaBH_4$ in CD_3OD, which gave $CH_3CH(Me)OMe$ and $CH_3CH(Ph)OMe$, respectively. Addition of methanol to the (*Z*)- and (*E*)-2-butene complexes **4** and **5** furnished the diastereomers **18a** and **18b**, respectively, which could be distinguished by virtue of the slight but significant differences in their ^1H NMR spectra (see Experimental Section). The structures of **18a** and **18b** were

assigned assuming *trans* attack on the respective olefin complexes **4** and **5**. Although at present we are unable to provide any *direct* evidence for this assumption,[20] the alternative possibility of a *cis* addition (i.e. a true migratory insertion) seems unlikely in the light of previous knowledge on the stereochemistry of nucleophilic addition.[21] However, *circumstantial* evidence regarding this matter comes from the fact that although cationic (alkyl)(olefin) complexes of palladium(II) with bidentate ligands undergo rather fast insertion,[5] the isolated methyl derivative $[Pd(PNP)(CH_3)]BF_4$ is totally unreactive towards ethylene.[22]



18a **18b**

The obtained β-methoxyalkyl complexes are quite stable as solids and in solution, both when the σ-bonded carbon atom is primary (as in **14**, **16**, and **17**) and when it is secondary (as in **18a**,**b**). No interconversion between the two diastereomers **18a** and **18b** was observed in dichloromethane solution over a period of one week.

In spite of the commonly encountered high reactivity of norbornene, no addition product of methanol could be obtained from complex **6**, possibly because of steric instability of the σ-alkyl derivative that would be produced by the nucleophilic attack, or (as suggested by a referee) because of inertness of *exo*-η^2-norbornene towards *trans* addition.

In an attempt to cleave the Pd−C σ-bond protolytically, the β-methoxyalkyl complexes were treated with gaseous HCl in CD_2Cl_2 solution, allowing direct monitoring of the reaction by NMR. However, this led to an immediate reversion of the nucleophilic addition through heterolytic fragmentation. The respective olefin was liberated, along with MeOH and $[Pd(PNP)Cl]BF_4$.

$$\underset{\textbf{14, 16-18}}{[(PNP)Pd(CHRCHR'OMe)]BF_4} \xrightarrow{\substack{HCl\ (g)/\\ CD_2Cl_2}} [Pd(PNP)Cl]BF_4 + CHR{=}CHR' + MeOH \qquad (8)$$

For the complexes **18a** and **18b**, the reversion of the addition led almost exclusively to the formation of (*Z*)- and (*E*)-2-butene, respectively, which provides evidence for the microscopic reversibility of this reaction.

Reactions with Amines

The reactions of the secondary alkylamines piperidine and dimethylamine with the ethylene and styrene complexes **1** and **3** were recently reported from a purely preparative point of view.[8] We have now investigated the process in more detail and have extended the studies to less basic aromatic amines. After adding an excess of ethylene to a solution (0.007 mol L^{-1}) of the isolated dimethylamine complex **19**,[8] an equilibrium was attained within about 1 h at 283 K. The final solution contained the addition product **20**−H^+ together with very small but measurable amounts of the starting complex **19**. The ratio **20**−H^+/**19** was found to be proportional to the concentration of free ethylene, confirming the existence of the equilibrium and allowing estimation of the equilibrium constant for the formal "insertion"[23] reaction represented by Equation (9) ($K = 3 \cdot 10^4$ L mol^{-1}).

$$\underset{\textbf{19}}{[(PNP)Pd(Me_2NH)]^{2+}} + CH_2{=}CHR \quad \Big\Vert K_{ins}(CD_2Cl_2)$$

olefin	K_{ins} [L mol^{-1}]
ethylene	$3 \cdot 10^4$
propene	10^2

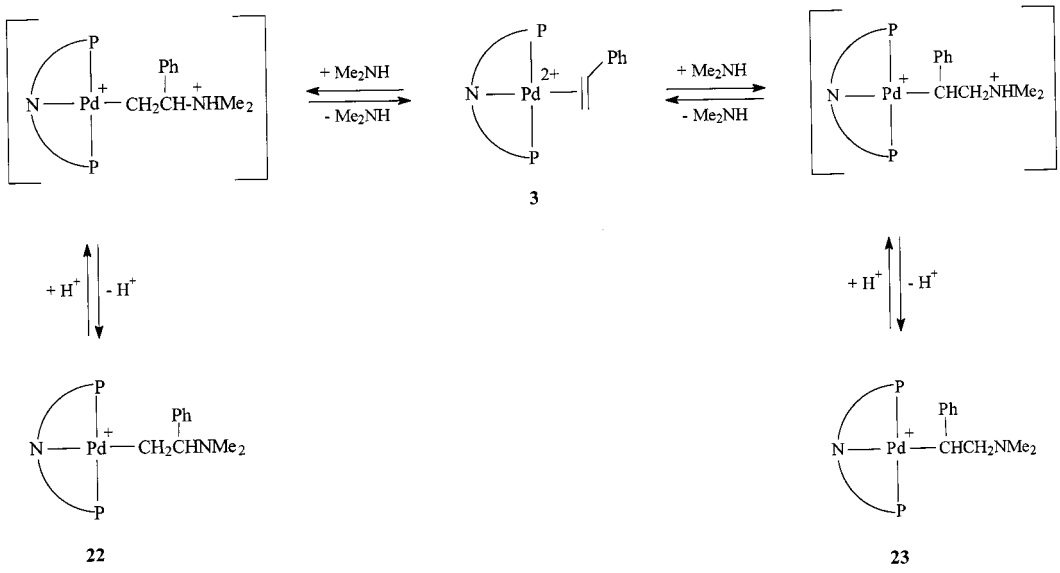
$$[(PNP)Pd(CH_2CHRNHMe_2)]^{2+} \qquad (9)$$

R = H, **20**-H^+,
R = Me, **21**-H^+

Similar experiments were performed using propene and styrene as the olefins. In the case of propene, the addition product **21**−H^+ was formed in an equilibrium reaction, the estimated constant for which was $K = 10^2$ L mol^{-1}. In the case of styrene, no addition product could be detected. However, when the reaction was performed starting from the styrene complex **3** and an excess (4 equiv.) of Me_2NH was added, the primary alkyl derivative **22** was formed immediately and completely isomerized within 1 h to the secondary (anti-Markovnikov) alkyl derivative **23** (Scheme 2). The same reaction with excess Me_2NH was also performed with the propene complex **2**, resulting in a mixture of **21** (82%) and the anti-Markovnikov product **24** (18%). The regiochemical assignments of the products **21**−**24** were confirmed by in situ reduction with sodium borohydride and ^1H NMR identification of the resulting amines. The higher stability of the secondary (anti-Markovnikov) alkyl derivative **23** compared to **22** is in contrast to the common trend shown by alkylmetal complexes (primary > secondary >> tertiary), but seems to reflect a common outcome in amination reactions of styrene.[3a]

21 **24**

Experiments similar to those described above were performed using aniline as a nucleophile. Starting from a solution (0.015 mol L^{-1}) of the isolated aniline complex **25** containing 0.1 mol L^{-1} of free ethylene, an equilibrium distribution of 10:1 between the starting complex and the addition product **26**−H^+ was attained within a few minutes. The estimated equilibrium constant for the formal "insertion"[23] reaction [Equation (10)] is $K = 1$ L mol^{-1}. Upon addition of $NaHCO_3$ (2 equiv.), the equilibrium was quantitatively driven towards the addition product **26**, which was



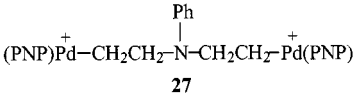
Scheme 2

formed together with small amounts of the dialkylated product **27**.[24]

$$[(PNP)Pd(PhNH_2)]^{2+} + CH_2{=}CH_2 \quad (\mathbf{25})$$

$$\Big\Vert \; K_{ins} = 1\ L\ mol^{-1}\ (CD_2Cl_2/CD_3NO_2) \qquad (10)$$

$$[(PNP)Pd(CH_2CH_2NH_2Ph)]^{2+} \quad (\mathbf{26}\text{-}H^+)$$



27

In the above experiments, the equilibrium concentration of the ethylene complex **1** was below the limit of detection, hence the equilibrium constants for the substitution and addition reactions could not be directly evaluated. In order to estimate their individual values, the equilibrium constants of two auxiliary substitution reactions [Equation (11) and Equation (12)] were determined by ^{1}H NMR.

$$[(PNP)Pd(PhNH_2)]^{2+} + MeCN \quad (\mathbf{25})$$

$$\Big\Vert \; K = 4 \cdot 10^{-3}\ (CD_2Cl_2/CD_3NO_2) \qquad (11)$$

$$[(PNP)Pd(MeCN)]^{2+} + PhNH_2 \quad (\mathbf{8})$$

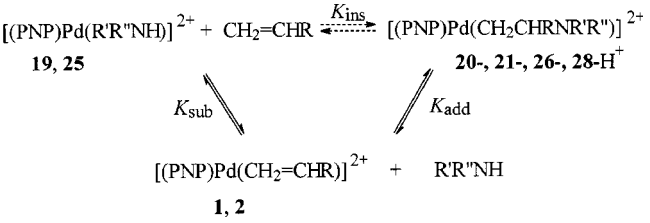
By combining these values with that for the ethylene displacement by acetonitrile [$K = 9{\cdot}10^2$, see Equation (4)], the equilibrium constants for the substitution (K_{sub}) and addition (K_{add}) reactions with aniline and dimethylamine were estimated. The values are reported in Table 2, together with the corresponding values for the propene complex **2**.

$$[(PNP)Pd(Me_2NH)]^{2+} + PhNH_2 \quad (\mathbf{19})$$

$$\Big\Vert \; K = 4 \cdot 10^{-4} \qquad (12)$$

$$[(PNP)Pd(PhNH_2)]^{2+} + Me_2NH \quad (\mathbf{25})$$

Table 2. Approximate values of the equilibrium constants for the addition (K_{add}), substitution (K_{sub}), and "insertion" (see ref.[23]) ($K_{ins} = K_{add}/K_{sub}$) reactions of **1** and **2** with amines



((Scan 19)) Amine	Me_2NH			$PhNH_2$		
Olefin	K_{ins} [L·mol^{-1}]	K_{add} [L·mol^{-1}]	K_{sub}	K_{ins} [L·mol^{-1}]	K_{add} [L·mol^{-1}]	K_{sub}
$CH_2{=}CH_2$	$3{\cdot}10^4$	10^{13}	$6{\cdot}10^8$	1	$2{\cdot}10^5$	$2{\cdot}10^5$
$CH_2{=}CHMe$	$1{\cdot}10^2$	10^{11}	$1{\cdot}10^9$	$5{\cdot}10^{-2}$	$1.5{\cdot}10^4$	$3{\cdot}10^5$

The K_{add} values given in Table 2 show that nucleophilic attack on the coordinated olefin is a quite favorable process in the dicationic complex, even when the nucleophile is a poorly basic aromatic amine. Moreover, the acidic β-ammonioalkyl derivative generated in the reaction can be further converted into the more stable β-aminoalkyl species through proton abstraction by an auxiliary base. When the basicity of the amine decreases, the nucleophilic attack is less favored, but at the same time the β-ammonioalkyl derivative is more acidic, and a successive proton abstraction becomes more favored. Therefore, the overall reaction in the presence of an auxiliary base is expected to be driven to a similar extent towards the (β-aminoalkyl)palladium derivative. In view of these considerations, we treated complexes **1** and **2** with primary aromatic amines of varying basicity (ranging from 4-methoxyaniline, pK_a = 5.3 to 2-chloroaniline, pK_a = 2.6) and $NaHCO_3$ (2 equiv.) in the presence of an excess of the respective gaseous olefins. The (β-aminoethyl)Pd^{II} compounds **26** and **28−34** were indeed obtained in good yields (Scheme 3) as cream-colored solids and were characterized by ^1H NMR.

Scheme 3

The structures of the propene derivatives **28**, **33**, and **34** were assigned essentially as in the case of the water and methanol adducts, and indicated selective attack at the secondary carbon atom (Markovnikov addition). As in the case of the corresponding β-methoxyalkyl species **14** and **16−18**, the complexes **26** and **28−34** can be stored indefinitely as solids and are also stable in solution; no evidence for β-H elimination was observed after a week in dichloromethane. This stability towards β-H elimination is quite exceptional in (alkyl)Pd species that are not stabilized by four- or five-membered ring formation.[11] It most likely arises from the impossibility of the putative hydride ligand to access either of the *cis* positions, both of them being firmly bound by the two phosphane "arms" of the PNP ligand. It is noteworthy in this respect that the only β-functionalized open-chain alkyl Pd^{II} derivatives hitherto isolated are *trans*-$[Pd(PMe_3)_2(CH_2CH_2Y)Br]$ (Y = CO_2Me, CN).[13]

Conclusions

The use of the tridentate "pincer" ligand PNP has allowed the unprecedented isolation of stable dicationic (olefin)Pd^{II} complexes, and the subject of nucleophilic addition to Pd^{II}-coordinated olefins has been re-examined using these dicationic complexes as substrates. The σ-alkyl derivatives resulting from the nucleophilic attack are remarkably stable towards β-H elimination, as a consequence of the unavailability of the adjacent coordination sites. Since side-reactions arising from β-H elimination do not take place, for the first time approximate equilibrium data could be obtained for the nucleophilic addition and for the competitive substitution reaction. The results indicate that in a dicationic Pd^{II} complex the olefin is highly activated towards nucleophilic addition (much more so than in neutral species[25]), both kinetically and thermodynamically. It is relevant to note in this respect that in monocationic complexes containing a ligand isoelectronic and isostructural with PNP (i.e. PCP), no nucleophilic attack on a coordinated olefin is observed.[26] The coordinated double bond actually acts as a strong electrophile, as indicated by its ability to capture a lone pair from methanol and to successively protonate a base as weak as methanol itself. Viewed from another perspective, the σ-alkyl derivatives resulting from the nucleophilic attack are strongly stabilized by the residual positive charge on the metal ion, and it appears that the C−Pd σ-bond is *more* stabilized by the positive charge than the Pd−N bond of a coordinated amine. Thus, the formal "insertion"[23] of the olefin into the Pd−N bond is thermodynamically favored (Table 2), while it was found to be *disfavored* in the case of neutral species.[27] This finding could be relevant for the development of synthetically useful hydroaminations, because olefin displacement, which is considered to be a serious obstacle to achieving such processes,[3a] might become a minor concern or even be of no consequence in the case of dicationic species.

Experimental Section

General: All reactions were carried out under dry nitrogen. CH_2Cl_2 was refluxed with CaH_2, MeOH with $Mg/Mg(OMe)_2$, and diethyl ether with Na/benzophenone. The solvents were distilled prior to use. CD_2Cl_2, CD_3NO_3, and $CDCl_3$ were dried with 4-Å molecular sieves. $AgBF_4$ was obtained from ABCR and was used without further purification. The aromatic amines RNH_2 were obtained from Aldrich and were distilled prior to use. − NMR spectra were recorded with Varian Gemini 200, Bruker AC-200, Bruker AC-250, and Bruker WH-400 instruments. ^1H NMR shifts were referenced to the resonances of the residual protons in the solvents and the ^{13}C NMR shifts to the solvent resonances (δ = 53.8, CD_2Cl_2; δ = 62.8, CD_3NO_2). For the ^{31}P NMR spectra, H_3PO_4 (85%) was used as an external standard.

Syntheses: The complexes [Pd(PNP)Cl]Cl,[14] $[Pd(PNP)(CH_2=CHR)](BF_4)_2$ [R = H (**1**), Ph (**3**)], and $[Pd(PNP)(L)](BF_4)_2$ [L = MeCN (**8**), Me_2NH (**19**), pyridine (**35**)][8] were prepared according to previously described procedures.

[Pd(PNP)(olefin)](BF$_4$)$_2$ (2, 4−6). − General Procedure: A mixture of [Pd(PNP)Cl]Cl (200 mg, 0.306 mmol) and $AgBF_4$ (121 mg, 0.620 mmol) in CH_2Cl_2 (10 mL) was saturated with the appropriate gaseous olefin (in the case of norbornene 10 equiv. of the olefin was added). After stirring the mixture for 10 min, the precipitate was filtered off. In the case of 2-butenes and norbornene, the precipitate (containing the product) was washed with nitromethane (1 mL, free from any nitrile!). The product was precipitated from the solution by the dropwise addition of diethyl ether. The solid was collected by filtration, washed with diethyl ether, and dried in vacuo.

2: Yield 191 mg (0.243 mmol, 78%); ivory-colored solid; m.p. 181 °C (dec.). − $C_{34}H_{33}B_2F_8NP_2Pd$ (797.62): calcd. 6. − Method A: According to the general procedure: yield 235 mg (0.251 mmol, 82%), ivory-colored solid. − **Method B:** To a solution of **1** (150 mg, 0.191 mmol) in CH_2Cl_2 (5 mL) was added ca. 10 equiv. of norbornene (2 mmol). After stirring the mixture for 1 h, the product was precipitated by the dropwise addition of diethyl ether. The solid was filtered off, washed three times with diethyl ether, and dried in vacuo. Yield 175 mg (0.187 mmol, 98%). − $C_{38}H_{37}B_2F_8NP_2Pd{\cdot}CH_2Cl_2$ (934.63): calcd. C 50.12, H 4.21, N 1.50; found C 49.80, H 4.03, N 1.39. − ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 0.77 (m, 1 H, norbornene), 1.34 (m, 1 H, norbornene), 1.55 (br, 4 H, norbornene), 1.94 (br, norbornene), 4.92 (t, J_{HP} = 4.2 Hz, 2 H, =CH, norbornene), 4.95 (pseudo t, N_{HP} = 5.0 Hz, 4 H, PCH_2), 7.57 (d, J_{HH} = 7.4 Hz, 2 H, py-3,5), 7.69−7.73 (m, 12 H, Ph), 7.86−7.98 (m, 9 H, Ph, py). − ^{13}C NMR (50 MHz, CD_3NO_2): δ = 23.6 (s, norbornene), 43.9 (s, norbornene), 46.0 (pseudo t, N_{CP} = 14.6 Hz), 54.5 (s, norbornene), 105.2 (s, =CH, norbornene), 124.6 (pseudo t, N_{CP} = 5.6 Hz, py-3,5), 125.4 (pseudo t, N_{CP} = 27.3 Hz, Ph$_i$), 130.7 (pseudo t, N_{CP} = 5.6 Hz, Ph$_m$), 134.1 (pseudo t, N_{CP} = 7.4 Hz, Ph$_o$), 134.7 (s, Ph$_p$), 144.2 (s, py-4), 159.9 (s, py-2,6). − ^{31}P NMR (81 MHz, CH_2Cl_2): δ = 50.4 (s).

[Pd(PNP)(H$_2$O)](BF$_4$)$_2$ (7): To a solution of **1** (100 mg, 0.127 mmol) in CH_2Cl_2 (6 mL) was added ca. 50 equiv. of H_2O (100 μL). After stirring for a few minutes, a yellow crystalline solid precipitated, which was collected by filtration, washed several times with diethyl ether, and dried in vacuo. Yield 90%. − ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 3.0 (v br, H_2O), 4.45 (br, 4 H, PCH_2), 7.54−8.05 (m, 23 H, Ph, py).

Reactions of 1 and 2 with H$_2$O: To a solution of **1** or **2** (100 mg) in CH_2Cl_2 (6 mL), saturated with ethylene or propene, respectively, 2 equiv. of $NaHCO_3$ and 50 equiv. of H_2O were added. The mixture was then stirred for 3 h, the solid was filtered off, and the solvent was removed under reduced pressure. A solid was obtained, which was recrystallized from CH_2Cl_2/diethyl ether.

9/10: Yield 87 mg (97% based on Pd); pale-yellow solid. − ^{1}H NMR (200 MHz, $CDCl_3$): **9**: δ = 2.02 (m, 2 H, $PdCH_2$), 3.44 (m, 2 H, CH_2), 4.44 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 7.35−7.73 (m, 23 H, Ph, py). − **10**: δ = 1.79 (m, 2 H, $PdCH_2$), 2.78 (m, 2 H, CH_2), 4.38 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 7.35−7.73 (m, 23 H, Ph, py). − ^{31}P NMR (81 MHz, CH_2Cl_2): **9/10**: δ = 24.1 (s).

12/13: Yield 82 mg (92% based on Pd); orange-yellow solid. − ^{1}H NMR (200 MHz, $CDCl_3$): **12**: δ = 0.81 (d, J_{HH} = 6.0 Hz, 3 H, CH_3), 2.01 (m, 2 H, $PdCH_2$), 3.66 (m, 1 H, CH), 4.44 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 7.15−7.75 (m, 23 H, Ph, py). − **13**: δ = 1.17 (d, J_{HH} = 4 Hz, 3 H, CH_3), 2.01 (m, 2 H, $PdCH_2$), 3.65 (m, 1 H, CH), 4.44 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 7.15−7.75 (m, 23 H, Ph, py). − ^{31}P NMR (81 MHz, CH_2Cl_2): **12/13**: δ = 22.3 (s), 23.7 (s).

Reductive Degradation with NaBH$_4$: To a suspension of 20 mg of the appropriate product mixture (**9/10** or **12/13**) in [D$_8$]THF (0.7 mL), cooled in an ice-bath, was added excess $NaBH_4$. After stirring for 1 h at room temperature, the dark-brown solution was filtered and the filtrate was analyzed by ^{1}H NMR spectroscopy.

[Pd(PNP)(OH)]BF$_4$ (11): A mixture of **7** (100 mg, 0.129 mmol) and 2 equiv. of $NaHCO_3$ in CH_2Cl_2 (5 mL) was stirred for 1.5 h. The mixture was then filtered and the product was precipitated from the filtrate by the dropwise addition of diethyl ether. The orange-yellow solid was collected by filtration, washed with diethyl ether, and dried in vacuo. Yield 85 mg (124 mmol, 96%). − ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 4.21 (pseudo t, N_{HP} = 4.4 Hz, 4 H, PCH_2), 7.15−7.75 (m, 23 H, Ph, py). − ^{31}P NMR (81 MHz, CH_2Cl_2): δ = 22.3 (s).

Reactions of [Pd(PNP)(CHRCHR′)](BF$_4$)$_2$ (1−5) with MeOH. − General Procedure: To a solution of **1−5** (100 mg) in MeOH (2 mL) cooled to 0 °C were added an excess of the appropriate olefin and 2 equiv. of $NaHCO_3$. The mixture was stirred for 3 h, the precipitate was filtered off, and the solvent was removed under reduced pressure. A beige solid was obtained in each case, which was recrystallized from CH_2Cl_2/diethyl ether.

[Pd(PNP)(CH$_2$CH$_2$OMe)]BF$_4$ (14): Yield 85%. − $C_{34}H_{34}BF_4NOP_2Pd$ (727.82): calcd. C 56.11, H 4.71, N 1.93; found

C 52.30, H 4.63, N 1.69; found C 51.26, H 4.46, N 1.62. – ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 0.68 (d, J_{HH} = 5.9 Hz, 3 H, CH_3), 1.67 (m, 1 H, $PdCH_2$), 2.20 (m, 1 H, $PdCH_2$), 2.74 (s, 3 H, OCH_3), 3.05 (m, 1 H, CH), 4.28–4.40 (m, 4 H, PCH_2), 7.50–7.68 (m, 22 H, Ph, py), 7.91 (t, J_{HH} = 7.8 Hz, 1 H, py-4).

[Pd(PNP){$CH_2CH(Ph)OMe$}]BF_4 (17): Yield 80%. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 2.00 (m, 1 H, PCH_2), 2.19 (m, 1 H, $PdCH_2$), 2.65 (s, 3 H, OCH_3), 3.78 (m, 1 H, CH), 4.41 (m, PCH_2), 6.84 (m, 2 H, CPh), 7.12 (m, 3 H, CPh), 7.49–7.95 (m, 23 H, PPh, py). – ^{31}P NMR (81 MHz, CH_2Cl_2): δ = 24.7 (s).

[Pd(PNP){CH(Me)CH(Me)OMe}]BF_4 [18a, obtained from (*Z*)-2-butene]: Yield 83%. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 0.82 (d, J_{HH} = 5.6 Hz, 3 H, CH_3), 0.92 (m, 3 H, CH_3), 2.74 (m, 2 H, CH–CH), 2.92 (s, 3 H, OCH_3), 4.31 (pseudo t, N_{HP} = 4.2 Hz, 4 H, PCH_2), 7.44–7.95 (m, 23 H, Ph, py). – ^{31}P NMR (81 MHz, CH_2Cl_2): δ = 21.8 (s).

[Pd(PNP){CH(Me)CH(Me)OMe}]BF_4 [18b, obtained from (*E*)-2-butene]: Yield 81%. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 0.93 (d, J_{HH} = 5.4 Hz, 3 H, CH_3), 1.04 (m, 3 H, CH_3), 2.72 (s, 3 H, OCH_3), 2.74 (m, 2 H, CH–CH), 4.35 (m, 4 H, PCH_2), 7.45–7.93 (m, 23 H, Ph, py).

Reductive Degradation of 16 and 17 with $NaBH_4$: To a solution of 20 mg of compound **16** or **17** in CD_3OD (0.7 mL), cooled in an ice-bath, was added excess $NaBH_4$. After stirring for 1 h at room temperature, the dark-brown solution was filtered and the filtrate was analyzed by ^{1}H NMR spectroscopy. – ^{1}H NMR: $CH_3CH(Me)OCD_3$: δ = 1.14 (d, J_{HH} = 6.2 Hz, 6 H, CH_3), 3.50 (sept, J_{HH} = 6.2 Hz, 1 H, CH).; $CH_3CH(Ph)OCD_3$: δ = 1.41 (d, J_{HH} = 6.1 Hz, 3 H, CH_3), 4.34 (q, J_{HH} = 6.1 Hz, 1 H, CH), 7.28 (m, 5 H, Ph).

Treatment of 14, 16–18a,b with HCl: Gaseous HCl was bubbled through solutions of **14**, **16–18a,b** in CD_2Cl_2, which led to a color change from orange to yellow. The ^{1}H NMR spectra of these solutions were found to feature signals attributable to both the free olefin and $[Pd(PNP)Cl]^+$.

[Pd(PNP)(MeOH)]$(BF_4)_2$ (15): Compound **1** (100 mg) was dissolved in MeOH (5 mL) and the solvent was removed under reduced pressure. This procedure was repeated twice more. Finally, the yellow solid was washed with diethyl ether and dried in vacuo. Yield 95%. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 3.17 (br, 1 H, OH), 3.38 (s, 3 H, CH_3), 4.49 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 7.48–8.01 (m, 23 H, Ph, py).

Reactions of 19 with Ethylene and Propene: Solutions of **19** (3 mg) in CD_2Cl_2 (0.6 mL) were saturated with ethylene and propene, respectively.

[(PNP)$PdCH_2CH_2NHMe_2$]$^{2+}$ (20–H^+): NMR: δ = 1.82 (m, 2 H, $PdCH_2$), 2.28 (s, 6 H, NMe_2), 2.79 (m, 2 H, NCH_2), 4.52 (pseudo t, N_{HP} = 5.0 Hz, 4 H, PCH_2), 7.48–8.02 (m, 23 H, Ph, py).

[(PNP)$PdCH_2CH(Me)NHMe_2$]$^{2+}$ (21–H^+): NMR: δ = 0.82 (d, J_{HH} = 6.2 Hz, 3 H, CH_3), 1.79 (m, 1 H, $PdCH_2$), 1.92 (m, 1 H, $PdCH_2$), 2.15 (s, 3 H, NCH_3), 2.22 (s, 3 H, NCH_3), 2.89 (m, 1 H, CH), 4.56 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 7.55–8.02 (m, 23 H, Ph, py).

Reaction of 3 with Me_2NH: Two NMR tubes were prepared, each containing a solution of **3** (8 mg) in CD_2Cl_2 (0.6 mL) with 4 equiv. of gaseous Me_2NH. A ^{1}H NMR spectrum was recorded immediately after the addition of the amine.

[(PNP)$PdCH_2CH(Ph)NMe_2$]$^+$ (22): NMR: δ = 1.68 [s, 6 H, $N(CH_3)_2$], 2.28 (m, 1 H, $PdCH_2$), 2.48 (m, 1 H, $PdCH_2$), 3.44 (m, 1 H, CH), 4.37 (pseudo t, 4 H, N_{HP} = 4.4 Hz, PCH_2), 6.55 (d, 2 H, J_{HH} = 8.2 Hz, Ph), 7.06 (m, 3 H, Ph), 7.53–7.98 (m, 23 H, PPh, py). – For the reductive degradation, an excess of $NaBH_4$ (dissolved in a drop of CD_3OD) was added instantly to one of the two solutions. After 20 min, its ^{1}H NMR spectrum was recorded again, which now featured signals due to $CH_3CH(Ph)NMe_2$. – The second sample was again analyzed by ^{1}H NMR after 1 h.

[(PNP)$PdCH(Ph)CH_2NMe_2$]$^+$ (23): NMR: δ = 1.89 [s, 6 H, $N(CH_3)_2$], 2.48 (m, 1 H, NCH_2), 2.68 (m, 1 H, PdCH), 3.98 (m, 1 H, NCH_2), 4.26 (d pseudo t, N_{HP} = 4.6 Hz, J_{HH} = 17 Hz, 2 H, PCH_aH_b), 4.40 (d pseudo t, N_{HP} = 4.4 Hz, J_{HH} = 17 Hz, 2 H, PCH_aH_b), 6.41 (d, J_{HH} = 7 Hz, 2 H, Ph), 6.87 (m, 3 H, Ph), 7.50–7.92 (m, 23 H, PPh, py). – After treatment of the solution with $NaBH_4$ (CD_3OD) as described above, the signals of $PhCH_2CH_2NMe_2$ were detectable.

Reaction of 2 with 4 Equiv. of Me_2NH: The reaction was carried out in an NMR tube in a similar manner as described for the reaction of **3** with Me_2NH.

[(PNP)$PdCH_2CH(Me)NMe_2$]$^+$ (21): ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 0.70 (d, J_{HH} = 6.2 Hz, 3 H, CH_3), 1.85 (m, 1 H, $PdCH_2$), 1.97 (s, 6 H, NCH_3), 2.05 (m, 1 H, $PdCH_2$), 2.62 (m, 1 H, CH), 4.48 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 7.57–7.98 (m, 23 H, Ph, py).

[(PNP)$PdCH(Me)CH_2NMe_2$]$^+$ (24): ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 1.02 (d pseudo t, J_{HH} = 7.0 Hz, N_{HP} = 3 Hz, 3 H, CH_3), 1.84 (s, 6 H, NCH_3), 4.36 (pseudo t, N_{HP} = 4.4 Hz, 4 H, PCH_2), 7.55–8.02 (m, 23 H, Ph, py). The remaining signals for CH and CH_2 are overlapped with the signals due to **21**.

[Pd(PNP)($PhNH_2$)]$(BF_4)_2$ (25): To a solution of **1** (100 mg) in CH_2Cl_2 (3 mL) was added aniline (0.5 mL). After stirring for a few minutes, an ivory-colored solid crystallized, which was collected by filtration, washed three times with diethyl ether, and dried in vacuo. Yield 85%. – $C_{37}H_{34}B_2F_8N_2P_2Pd \cdot 0.75CH_2Cl_2$ (912.27): calcd. C 49.70, H 3.92, N 3.07; found C 49.79, H 3.91, N 3.14. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 4.59 (pseudo t, N_{HP} = 4.8 Hz, 4 H, PCH_2), 5.70 (br, 2 H, NH_2), 6.67 (d, J_{HH} = 7.6 Hz, 2 H, NPh), 6.89 (m, 3 H, NPh), 7.55–7.80 (m, 22 H, Ph, py), 7.88 (t, J_{HH} = 7.6 Hz, 1 H, py-4).

Reactions of 25 with Ethylene and Propene: A solution of **24** (8 mg) in CD_2Cl_2/CD_3NO_2 (6:1) (0.6 mL) was saturated with either ethylene or propene. Since the signals of the addition products appear in the spectra at relatively low intensity and are partly overlapped by the signals of **25**, the full set of signals could not be detected.

[(PNP)$PdCH_2CH_2NH_2Ph$]$^{2+}$ (25–H^+): NMR: δ = 2.12 (m, 1 H, $PdCH_2$), 3.28 (m, 1 H, NCH_2), 4.47 (pseudo t, N_{HP} = 4.8 Hz, 4 H, PCH_2).

[(PNP)$PdCH_2CH(Me)NH_2Ph$]$^{2+}$ (26–H^+): NMR: δ = 0.92 (d, J_{HH} = 6.0 Hz, 3 H, CH_3).

Preparation of [Pd(PNP)($CH_2CHRNHAr$)]$(BF_4)_2$ (26, 28–34) – General Procedure: A solution of **1** or **2** (100 mg) in CH_2Cl_2 (2 mL) was cooled to 0 °C and saturated with the appropriate olefin; 2

equiv. of $NaHCO_3$ and 4 equiv. of $ArNH_2$ were then added. After stirring the mixture for 3 h, the precipitate was filtered off and the filtrate was concentrated to dryness under reduced pressure. A beige solid was obtained, which was recrystallized from CH_2Cl_2/diethyl ether.

[Pd(PNP)(CH_2CH_2NHPh)]BF_4 (26): Yield 87%. – $C_{39}H_{37}BF_4N_2P_2Pd{\cdot}0.5CH_2Cl_2$ (831.31): calcd. C 57.07, H 4.60, N 3.37; found C 56.72, H 4.58, N 3.26. – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 2.09 (m, 2 H, $PdCH_2$), 2.93 (br, 2 H, CH_2N), 3.41 (br, 1 H, NHPh), 4.43 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 5.98 (d, J_{HH} = 7.6 Hz, 2 H, NPh_o), 6.54 (t, J_{HH} = 7.4 Hz, 1 H, NPh_p), 6.92 (t, J_{HH} = 7.4 Hz, 2 H, NPh_m), 7.53–7.88 (m, 22 H, Ph, py), 7.94 (t, J_{HH} = 7.2 Hz, 1 H, py-4). – ^{31}P NMR (81 MHz, CH_2Cl_2): δ = 23.8 (s).

[Pd(PNP)($CH_2CH_2NHC_6H_4OMe$-*p*)]BF_4 (29): Yield 80%. – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.05 (m, 2 H, $PdCH_2$), 2.86 (br, 2 H, NCH_2), 3.07 (br, 1 H, NH), 3.68 (s, 3 H, CH_3) 4.45 (pseudo t, N_{HP} = 4.8 Hz, 4 H, PCH_2), 5.95 (d, J_{HH} = 9.2 Hz, 2 H, NC_6H_4), 6.54 (d, J_{HH} = 9.2 Hz, 2 H, NC_6H_4), 7.50–7.82 (m, 23 H, Ph, py). – ^{31}P NMR (81 MHz, CH_2Cl_2): δ = 23.6 (s).

[Pd(PNP)($CH_2CH_2NHC_6H_4Me$-*p*)]BF_4 (30): Yield 84%. – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.05 (m, 2 H, $PdCH_2$), 2.15 (s, 3 H, CH_3), 2.89 (br, 2 H, NCH_2), 3.19 (br, 1 H, NH), 4.44 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 5.80 (d, J_{HH} = 8.2 Hz, 2 H, NC_6H_4), 6.73 (d, J_{HH} = 8.2 Hz, 2 H, NC_6H_4), 7.49–7.74 (m, 23 H, Ph, py). – ^{31}P NMR (81 MHz, CH_2Cl_2): δ = 23.6 (s).

[Pd(PNP)($CH_2CH_2NHC_6H_4Cl$-*m*)]BF_4 (31): Yield 81%. – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.03 (m, 2 H, $PdCH_2$), 2.79 (br, 2 H, CH_2N), 3.50 (br, 1 H, NH), 4.45 (pseudo t, N_{HP} = 4.2 Hz, 4 H, PCH_2), 5.88 (m, 2 H, NC_6H_4Cl), 6.48 (d, J_{HH} = 8.2 Hz, 1 H, NC_6H_4Cl), 6.81 (t, J_{HH} = 8.4 Hz, 1 H, NC_6H_4Cl), 7.52–7.72 (m, 23 H, Ph, py). – ^{31}P NMR (81 MHz, CH_2Cl_2): δ = 23.6 (s).

[Pd(PNP)($CH_2CH_2NHC_6H_4Cl$-*o*)]BF_4 (32): Yield 81%. – $C_{39}H_{36}BF_4N_2P_2Pd \cdot 1.5\,CH_2Cl_2$ (950.68): calcd. C 51.11, H 4.13, N 2.94; found C 50.76, H 4.01, N 2.86. – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.09 (m, 2 H, $PdCH_2$), 2.94 (br, 2 H, CH_2N), 4.03 (br t, J_{HH} = 5.0 Hz, 1 H, NH), 4.46 (pseudo t, N_{HP} = 4.8 Hz, 4 H, PCH_2), 5.78 (d, J_{HH} = 8.0 Hz, 1 H, NC_6H_4Cl), 6.48 (d, J_{HH} = 7.8 Hz, 1 H, NC_6H_4Cl), 6.78 (t, J_{HH} = 8.0 Hz, 1 H, NC_6H_4Cl), 7.11 (d, J_{HH} = 7.8 Hz, 1 H, NC_6H_4Cl), 7.46–7.83 (m, 23 H, Ph, py).

[Pd(PNP){$CH_2CH(Me)NHPh$}]BF_4 (28): Yield 83%. – ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 0.84 (d, J_{HH} = 6.3 Hz, 3 H, CH_3), 1.94 (m, 1 H, CH_2), 2.20 (m, 1 H, CH_2), 3.12 (d, J_{HH} = 9.1 Hz, 1 H, NH), 3.27 (m, 1 H, CH), 4.39 (pseudo t, N_{HP} = 4.7 Hz, 4 H, PCH_2), 5.87 (d, J_{HH} = 7.8 Hz, 2 H, NPh), 6.53 (t, J_{HH} = 7.5 Hz, 1 H, NPh), 6.87 (t, J_{HH} = 7.8 Hz, 2 H, NPh), 7.48–7.75 (m, 22 H, PPh, py-3,5), 7.95 (t, 1 H, py-4).

[Pd(PNP){$CH_2CH(Me)NHC_6H_4Me$-*p*}]BF_4 (33): Yield 86%. – ^{1}H NMR (200 MHz, CD_2Cl_3): δ = 0.83 (d, J_{HH} = 7.0 Hz, 3 H, CH_3), 1.92 (m, 1 H, CH_2), 2.15 (s, 3 H, CH_3) 2.20 (m, 1 H, CH_2), 2.96 (d, J_{HH} = 9.0 Hz, 1 H, NH), 3.24 (m, 1 H, CH), 4.38 (pseudo-t, N_{HP} = 4.5 Hz, 4 H, PCH_2), 5.82 (d, J_{HH} = 7.1 Hz, 2 H, NC_6H_4), 6.71 (d, J_{HH} = 7.1 Hz, 2 H, NC_6H_4), 7.50–7.95 (m, 23 H, PPh, py).

[Pd(PNP)($CH_2CH(Me)NHC_6H_4Cl$-*o*)]BF_4 (34): Yield 81%. – ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.85 (d, J_{HH} = 6.2 Hz, 3 H, CH_3), 1.89 (m, 1 H, CH_2), 2.21 (m, 1 H, CH_2), 3.27 (m, 1 H, CH), 3.93 (d, J_{HH} = 9.0 Hz, 1 H, NH), 4.46 (pseudo t, N_{HP} = 4.6 Hz, 4 H, PCH_2), 5.74 (d, J_{HH} = 7.4 Hz, 1 H, NC_6H_4Cl), 6.46 (t, J_{HH} = 7.0 Hz, 1 H, NC_6H_4Cl), 6.73 (t, J_{HH} = 7.8 Hz, 1 H, NC_6H_4Cl), 7.09 (d, J_{HH} = 8 Hz, 1 H, NC_6H_4Cl), 7.44–7.85 (m, 23 H, PPh, py).

Reaction of 26 with 1: To a solution of **26** (7 mg) in CD_2Cl_2 (0.6 mL) saturated with ethylene, **1** (8 mg) was added, which led to a color change to reddish. An excess of $NaHCO_3$ was added and the mixture was stirred overnight, after which it had become yellow.

27: ^{1}H NMR (200 MHz): δ = 1.74 (m, 4 H, $PdCH_2$), 2.78 (t br, J = 7.8 Hz, 4 H, CH_2N), 4.35 (pseudo-t, N_{HP} = 4.8 Hz, 8 H, PCH_2), 5.73 (d, J_{HH} = 8.0 Hz, 2 H, NPh_o), 6.33 (t, J_{HH} = 7.2 Hz, 1 H, NPh_p), 6.62 (t, J_{HH} = 7.2 Hz, 1 H, NPh_m), 7.41–7.96 (m, 46 H, Ph, py).

Equilibrium Constant Determinations: The equilibrium constants for the exchange and addition reactions were determined by ^{1}H NMR analysis of equilibrium mixtures at 298 K (methanol addition reactions) or 283 K (all other cases) in CD_2Cl_2 or CD_2Cl_2/CD_3NO_2 (4:1) solution (c = 7–15 mM). With one exception (addition of Me_2NH to propene complex **2**), the reported values are the average result of three measurements run at different olefin or ligand concentrations. Very unbalanced exchange equilibria [e.g. Equation (11)] were handled by treating a solution of the most stable complex with a large excess of the exchanging ligand. The amine addition equilibria (olefin "insertion"[23]) were handled by treating a solution of the pure [Pd(PNP)(amine)]$(BF_4)_2$ complex (**19** or **25**) with an excess of the olefin. In this approach, the amount of free amine in the solution was made negligible and hence the simultaneous occurrence of proton-transfer equilibria to the free base could also be neglected. For the ligand-exchange reactions solutions (0.015 M) of **2**–**5** [Equation (3)], **1** [Equation (4), L = H_2O], and **25** [Equation (11)] were prepared and treated with an excess of the appropriate substituting ligand. In the case of the ethylene/MeCN exchange [Equation (4)], a solution of **8** was treated with a large excess of ethylene. The equilibrium constant for the $PhNH_2/Me_2NH$ exchange [Equation (12)] could not be determined directly because of an overlapping of all the relevant signals of the four species. Therefore, the constants of two further auxiliary equilibria were measured, involving the exchanges pyridine/Me_2NH (K = 1 in CD_2Cl_2) and $PhNH_2$/pyridine ($K = 4{\cdot}10^{-4}$ in CD_2Cl_2/CD_3NO_2).

Acknowledgments

We thank the Deutsche Akademie der Naturforscher Leopoldina (BMBF-LPD 9801-4) (C. H.) and the MURST (PRIN 9803243241) for financial support. We also thank the CIMCF, Università di Napoli "Federico II" for providing access to NMR facilities. We are grateful to Prof. D. Steinborn for helpful discussions.

[19] The ^1H NMR spectrum of **16** shows three multiplets (1 H each) at δ = 3.05, 2.20, and 1.67, and a doublet (3 H) at δ = 0.68, which can be assigned to the $-CH_2CH(Me)-$ fragment, the most downfield signal being attributable to a −CH−O fragment. In a homodecoupling experiment, irradiation of the signal at δ = 3.05 led to decoupling of the methyl doublet at δ = 0.68, thus unambiguously assigning the former to the C*H*Me proton and thereby pointing to a structure corresponding to a Markovnikov addition (**16**). In the ^1H NMR spectrum of **17**, two multiplets at δ = 2.00 and 2.19 are seen for the $Pd-CH_2$ moiety, while a multiplet at δ = 3.78 (1 H) can be assigned to the C*H*Ph fragment to which the methoxy group is bound.

[20] The best way of establishing the stereochemistry of the addition would be an X-ray structure determination of either **18a** or **18b**, but as yet we have been unable to obtain suitable crystals of the complexes. The methine H−H coupling constants (7.1 and 9.1 Hz, respectively, in CD_3OD) could also be useful for this purpose, but only in conjunction with a detailed theoretical study aimed at establishing the conformational distribution of the species. To be reliable, such a QM/MM investigation should take in account the interactions with the solvent and the counterion, which is beyond the scope of the present paper and might be worthy of a separate study.

Keywords: Alkenes / Polymerizations / Iron / N ligands

The synthesis and characterisation of iron(II) dichloro complexes containing neutral tridentate nitrogen ligands of the type 2-arylaminoalkyl-6-aryliminoalkylpyridine [2-ArNHCR(Me)-6-ArN=CR]C_5H_3N (R = H, Ar = 2,6-*i*$Pr_2C_6H_3$ or 2,4,6-$Me_3C_6H_2$; R = Me, Ar = 2,6-*i*$Pr_2C_6H_3$)] and 2,6-bis(arylaminomethyl)pyridine [2,6-$(ArNHCH_2)_2$]C_5H_3N (Ar = 2,6-*i*$Pr_2C_6H_3$) are described and their activity in ethylene polymerisation is compared with their 2,6-bis(aryliminoalkyl)pyridine analogues.

Introduction

Transition metal-catalyzed olefin polymerisation is currently a subject of intense academic and industrial interest. The need for greater control over the products of olefin polymerisation, combined with advances in the understanding of homogeneous polymerisation systems, have resulted in the development of highly active single-site olefin polymerisation catalysts such as Group 4 metallocenes and the ''constrained geometry'' catalysts'.[1−5] The development of non-metallocene early transition metal catalysts, and in particular the discovery of highly active late transition metal based systems, have signposted the way forward for further developments in catalytic olefin polymerisation.[6,7] The discovery by Brookhart and co-workers in 1995 of highly active nickel and palladium olefin polymerisation catalysts containing the α-diimine ligand frame[8] has been followed by extensive studies on variations of the α-diimine ligand.[9−11] In addition, many other non-diimine neutral bidentate ligands have been screened for olefin polymerisation activity, a large number by in situ methods.[7,12] However, to date, no other donor combinations have matched the high activities obtained with α-diimine ligands, suggesting a special feature of these systems that has yet to be fully understood.

A second family of highly active late transition metal polymerisation catalysts based on 2,6-bis(imino)pyridine complexes of iron and cobalt, was reported independently by ourselves,[13] Bennett and Brookhart in 1998.[14] The effects of ligand changes, especially at the aryl (Ar) and imino carbon (R) substituents, on the activity and product selectivity of these bis(imino)pyridine iron and cobalt catalysts (**I**) have been studied in detail,[15−17] as well as the polymerisation of propene[18−20] and applications in reactor blending.[21,22] Only a few variations on the core bis(imino)-pyridine skeleton have been reported; for example, a neutral tridentate bis(oxazolinyl)pyridine ligand[23] and monoanionic tridentate bis(imino)pyrollide,[24] bis(amino)phenyl and bis(phosphanyl)amide ligands.[25] These variations have resulted in very low catalyst activities. With a view to obtaining a greater understanding of structure-activity relationships in the [N,N,N]Fe catalyst system, we have targeted alternative tridentate [N,N,N] chelate ligands. A relatively straightforward modification to the ligand frame is to replace one, or both, of the imine groups by amine donors, examples being 2-aminoalkyl-6-iminoalkylpyridine complexes of type **II** and the 2,6-bis(aminoalkyl)pyridine species of type **III** (see Figure 1). The synthesis and characterisation of complexes of type **II** and **III** are described and their ethylene polymerisation activity is discussed and compared to the parent bis(imino)pyridine system **I**.

Results and Discussion

Synthesis of ligands and complexes

A convenient method of preparing 2-aminoalkyl-6-iminoalkylpyridines is by exploiting attack by nucleophilic reagents at the imine carbon atoms.[26] We have recently shown that $AlMe_3$ reacts with bis(imino)pyridines to give products of the type {[2-ArNCR(Me)-6-ArN=CR]-C_5H_3N}$AlMe_2$ (**1a−c**, Scheme 1) in which only one of the imino functionalities is attacked to generate an amide donor.[27] Hydrolysis of these complexes, followed by extraction with pentane and workup, affords ligands **2a−c** as pale yellow crystalline solids.

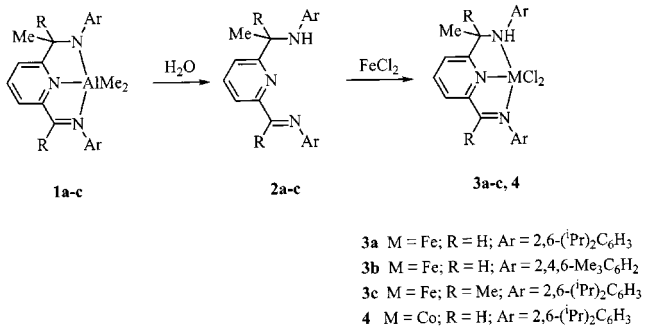

Scheme 1

The ^{1}H NMR spectra of **2a**−**c** confirm the presence of the amine protons as broad resonances in the range δ = 4.3−4.5, and the infrared spectra show N−H stretches in the region 3355−3365 cm^{-1}. A single crystal X-ray structure of **2a** shows the molecule to possess a *transoid* relationship between the imine and amine groups (Figure 2), a geometry that is different to the *cisoid* conformation in the metal complexes (see **3a**, Figure 3). There is only a small (ca. 7°) out-of-plane rotation of the C=N double bond relative to the pyridyl ring, whereas the 2,6-diisopropylphenyl ring system is oriented essentially orthogonally (ca. 87°). The *transoid* conformation observed here for the pyridyl imine unit is typical for such species in the solid state,[18,28,29] i.e. there has to be an approximate 180° rotation about the C(2)−C(9) bond for chelation of the pyridyl and imino nitrogen atoms to a metal centre. In contrast to the in-plane conformation of the conjugated imine group, there is a marked deviation of the saturated "amine arm" from co-planarity with the pyridyl ring, the N(1)−C(6)−C(7)−N(7) torsion angle being 65°. Centrosymmetrically related pairs of molecules pack such that the edge of ring **A** of one molecule is directed into the face of ring **B** of another; the centroid···centroid distance is 4.94 Å, and is consistent with an aromatic···aromatic edge-to-face interaction.

Treatment of **2a**−**c** with $FeCl_2$ in *n*BuOH at elevated temperature gives complexes **3a**−**c** as pale blue solids. Analogous to the bis(imino)pyridine systems, these complexes are

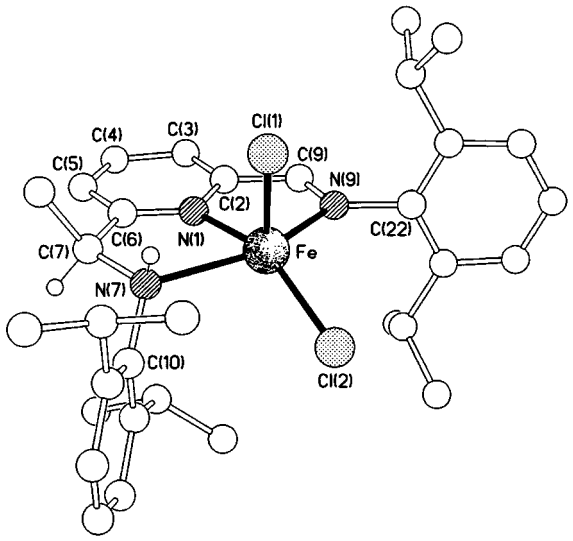

Figure 3. The molecular structure of **3a**; selected bond lengths (Å) and angles (°): Fe−N(1) 2.115(7), Fe−N(7) 2.310(8), Fe−N(9) 2.217(8), Fe−Cl(1) 2.311(3), Fe−Cl(2) 2.243(2), C(7)−N(7) 1.489(12), C(9)−N(9) 1.281(12); N(1)−Fe−N(9) 75.4(3), N(1)−Fe−Cl(2) 148.0(2), N(9)−Fe−Cl(2) 102.9(2), N(1)−Fe−N(7) 73.5(3), N(9)−Fe−N(7) 148.5(3), Cl(2)−Fe−N(7) 101.2(2), N(1)−Fe−Cl(1) 102.8(2), N(9)−Fe−Cl(1) 102.3(2), Cl(2)−Fe−Cl(1) 108.6(1), N(7)−Fe−Cl(1) 88.8(2)

paramagnetic, with μ_{eff} typically between 5.4 and 5.6 BM, indicating four unpaired electrons; they were further characterized by IR, MS and microanalysis. The IR spectra of **3a**−**c** show ν(N−H) stretches at ca. 3300 cm^{-1}. Crystals of **3a** suitable for a single crystal structure determination were grown from a concentrated acetonitrile solution. The X-ray analysis of **3a** shows[30] (Figure 3) that the partially saturated ligand (**2a**) complexes to the iron(II) centre in a similar way to its unsaturated analogue,[13,14] the N(7)−C(7)−py−C(9)−N(9) component being co-planar to within 0.07 Å, with the iron atom lying 0.07 Å out of this plane. The five-membered chelate ring containing the amino nitrogen atom N(7) is also almost planar, the torsional twist about the C(6)−C(7) bond being only ca. 6°. The geometry at iron is distorted square pyramidal with *cis* angles in the range 73.5(3) to 108.6(1)°, the iron atom lying 0.43

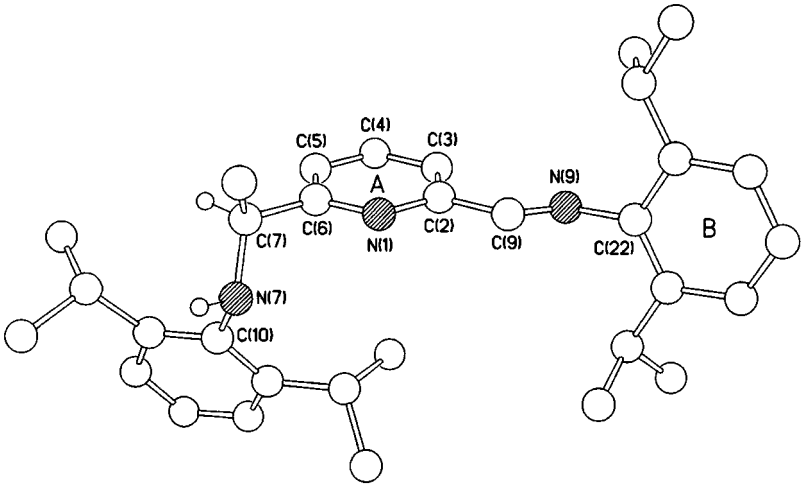

Figure 2. The molecular structure of **2a**; selected bond lengths (Å): C(7)−N(7) 1.473(8), C(9)−N(9) 1.255(8)

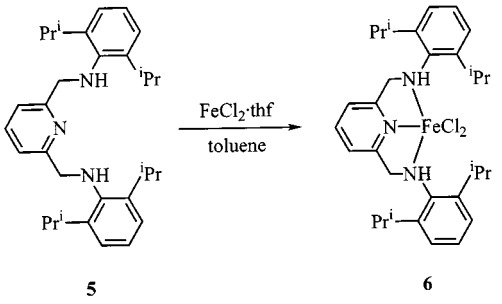
Å out of the basal plane in the direction of the apical atom Cl(1). The most noticeable feature in the pattern of bonding is the weak nature of the Fe−N(7) linkage [2.310(8) Å] — a distance equal to that to the apical chlorine centre Cl(1) [2.311(3) Å] — and a consequent shortening of the Fe−N(9) bond to 2.217(8) Å {*cf.* 2.238(4) and 2.250(4) Å in the related bis(imino)pyridine iron dichloride species[13−15]}. The Fe−N(1) bond length is, as expected, shorter at 2.115(7) Å, as is the distance to the basal chlorine [2.243(2) Å]. Both of the 2,6-diisopropylphenyl substituents are oriented approximately orthogonally to the basal coordination plane, the ca. 81° twist about the N(9)−C(22) bond facilitating characteristic C−H···N(pπ) interactions[31] between the isopropyl methine hydrogen atoms and the imine nitrogen [N(9)]; the H···N distances are 2.41 and 2.44 Å. The amine nature (i.e. sp^3 hybridisation) of the N(7) nitrogen precludes any such interaction here, and results in a distinct folding of the C(10) aryl substituent out of the N(7)−C(7)−py−C(9)−N(9) plane — the C(22) phenyl carbon atom is virtually coplanar with this plane (deviation ca. 0.03 Å) whilst C(10) lies 1.06 Å below it, such that the N−Ar bond is inclined by ca. 42° to this plane. This deviation will strongly affect the steric influence of the ligand on the remaining metal coordination sites. Finally, there are no dominant intermolecular interactions of note, although there is evidence for a weak C−H···Cl hydrogen bond between the imine C−H group [C(9)] in one molecule and the apical chorine [Cl(1)] in another; the C···Cl and H···Cl distances are 3.34 and 2.57 Å, respectively, with a C−H···Cl angle of 137°.

2,6-Bis(2,6-diisopropylphenylaminomethyl)pyridine **(5)** (see Scheme 2) was readily prepared according to a procedure by McConville and co-workers, from the reaction of 2,6-bis(bromomethyl)pyridine with LiNHAr (Ar = 2,6-diisopropylphenyl).[32] However, this potentially tridentate chelate does not react with anhydrous $FeCl_2$ in *n*BuOH, nor in THF; there is no colour change on mixing and warming to 80 °C, and after workup, only starting materials are recovered. In case this outcome may have been a consequence of the modified disposition of the large aryl groups imposed by the sp^3-hybridised nitrogen centres, we also attempted a similar reaction between 2,6-bis(diphenylaminomethyl)pyridine and $FeCl_2$ but again complexation did not occur. An alternative method, recently described by Calderazzo et al.,[33] was investigated by refluxing a mixture of pyridyldiamine ligand **5** and $FeCl_2$·thf in toluene overnight. This route leads to the desired complex **6** in high yield as blue/green crystals (Scheme 2). The compound is air stable and readily soluble in polar solvents such as dichloromethane or THF, but decomposes in acetone. Satisfactory microanalysis, IR and magnetic data (μ_{eff} = 5.08 BM) as well as X-ray crystallographic analysis confirm the structure of **6** to be the expected five-coordinate [N,N,N]$FeCl_2$ complex.

Depending upon the method of crystallization, two different crystalline forms are produced, one monoclinic (**6a**, Figure 4), obtained from a hot saturated toluene solution and the other orthorhombic (**6b**, Figure 5), grown from cold (−30 °C) toluene. In the monoclinic form, the ligand is tridentate, binding to the iron centre through the pyridyl and the two amine nitrogen atoms in a fashion analogous to that seen in the imine/amine complex **3a**. The geometry at iron is still distorted square pyramidal, but with the iron atom lying 0.61 Å out of the basal plane; the *cis* angles are in the range 74.2(1) to 115.6(1)°. The two five-membered chelate rings are nonplanar, there being torsional twists of ca. 26 and 18° about the C(2)−C(7) and C(6)−C(8) bonds, respectively. Interestingly, these twists are in opposite senses, thus producing δ and λ conformations, respectively, for the two rings, whereas the configurations at the two amino centres are the same. As expected, the Fe−N(1) distance [2.118(4) Å] is significantly shorter than that to the two amine nitrogens, which are the same at 2.313(4) and 2.328(4) Å for N(7) and N(8), respectively, values essentially the same as that to the amino nitrogen in **3a**. Similarly, the Fe−Cl(axial) distance [2.313(2) Å] is longer than its basal counterpart [2.269(2) Å]. In common with **3a**, the two 2,6-diisopropylphenyl ring systems are oriented approximately orthogonally to the basal coordination plane. Although both the amine nitrogen atoms N(7) and N(8) are pyramidal, as a consequence of the different folds of the five-membered chelate rings only one of the 2,6-diisopropylphenyl rings is folded out of the basal coordination plane, the other having its N(7)−C(9) linkage virtually in plane. This results in an overall geometry very similar to that seen in the imine-amine structure **3a**. The only intermolecular packing interaction of note is a weak π-π stacking of pairs of C(21) containing 2,6-diisopropylphenyl rings of adjacent molecules; the mean interplanar separation is 3.85 Å.



5 **6**

Scheme 2

The orthorhombic form of the complex **(6b)** has crystallographic C_2 symmetry about an axis passing along the Fe···N(1)···C(4) vector. The conformations of the two five-membered chelate rings are both λ relative to the *S* configurations at the amino centres (Figure 5); the torsional twists about the C(2)−C(5) bonds are ca. 17°. Accompanying this difference in the conformational/configurational relationship (*cf.* that in **6a**) is a change from a square pyramidal to a trigonal bipyramidal coordination geometry for the iron with N(1), Cl and ClA forming the equatorial plane. The angles subtended at iron by these three atoms are all, within statistical significance, 120°; the axial bonds [Fe−N(5)] subtend an angle of 153.8(2)°. The Fe−N(1) and Fe−N(5) bond lengths [2.095(5) and 2.322(4) Å, respectively] do not differ significantly from those in **6a**. In contrast to the asymmetric Fe−Cl bond lengths in **3a** and **6a**, here they are

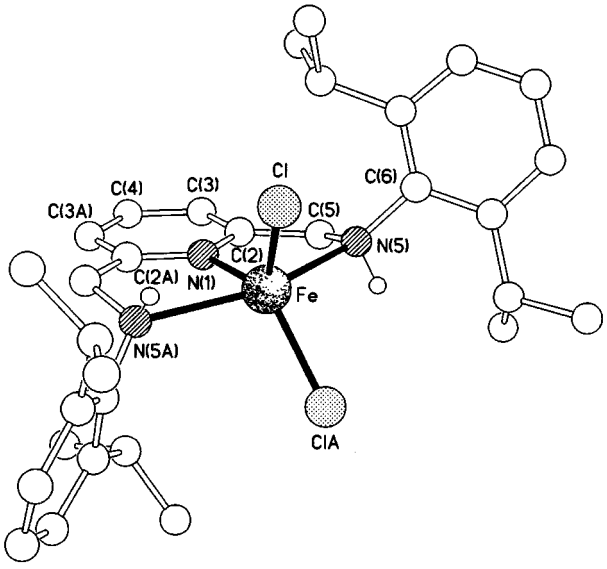

Figure 5. The molecular structure of the orthorhombic form of **6** (**6b**) showing also the trigonal bipyramidal geometry at iron; selected bond lengths (Å) and angles (°): Fe−N(1) 2.095(5), Fe−N(5) 2.322(4), Fe−Cl 2.277(2), C(5)−N(5) 1.479(6); N(1)−Fe−Cl 120.03(5), N(1)−Fe−ClA 120.03(5), Cl−Fe−ClA 119.94(9), N(1)−Fe−N(5A) 76.91(10), Cl−Fe−N(5A) 90.80(12), ClA−Fe−N(5A) 102.29(12), N(1)−Fe−N(5) 76.91(10), Cl−Fe−N(5) 102.29(12), ClA−Fe−N(5) 90.80(12), N(5A)−Fe−N(5) 153.8(2)

symmetric at 2.277(2) Å, there being no axial/basal distinction. The essentially orthogonal relationship between the 2,6-diisopropylphenyl ring systems and the N_3Fe coordination plane is retained, but in contrast to **6a**, because of the C_2 symmetry and the pyramidalisation at the amine nitrogens, one of the 2,6-diisopropylphenyl is directed "up" and the other "down". There are no intermolecular packing interactions of consequence.

For bis(imino)pyridine iron complexes we have shown previously that, depending on the aryl substituents of the ligand (e.g. 2,6-diisopropylphenyl versus mesityl), either square based pyramidal or trigonal bipyramidal geometries are observed in the solid state.[15] Here we see that, in the case of complex **6**, different geometries (**6a** and **6b**) are obtained depending on the method of crystallisation. These results suggest a small energy difference between the two geometries, indicating stereochemical nonrigidity of $[N,N,N]FeCl_2$ complexes, a behaviour that is not uncommon for five-coordinate complexes.[34]

Ethylene Polymerisation Results

The results of ethylene polymerization tests at 1 bar and 10 bar with precatalysts **3a−c**, **4** and **6** with methylaluminoxane (MAO) as activator are collected in Table 1. For comparison, the polymerisation results of the previously reported pyridyldiimine iron precatalysts **7** and **8** are also included (Figure 6). Two sets of polymerisation tests are shown in Table 1. Tests at 1 bar were carried out in a Schlenk flask at room temperature, with no scavenger and toluene as the solvent. High pressure tests (10 bar) were performed in a 1 litre autoclave at 35 °C, with triisobutylaluminium as a scavenger and isobutane as the solvent.

The results collected in Table 1 show that all of the new pyridylimine amine (**3a−c**) and pyridyldiamine (**6**) iron complexes are active ethylene polymerisation catalysts under these conditions. However, it is also apparent that the activities of these new precatalysts are dramatically reduced relative to the pyridyldiimine catalysts **7** and **8** (run 10 and 11). The highest activities of 90−110 g/mmol·h·bar are obtained with complex **3c**, which is derived from the pyridyldiketimine ligand (as in complex **8**). The precatalysts **3a** and **3b**, derived from aldimine precursors, generally show lower activities, around 20 g/mmol·h·bar. This difference in activity parallels the trends observed for aldimine (**7**) versus ketimine (**8**) precatalysts based on pyridyldiimine ligands (runs 10 and 11).[15] The very low activity observed for the pyridylimine amine cobalt precursor **4** (run 7) compared to the iron analogue **3a** (run 1) is equally not surprising, bearing in mind that, in general, for pyridyldiimine systems, cobalt precatalysts are an order of magnitude less active than their iron counterparts. Substitution of both imine donors for amine donors as in precatalyst **6** leads to a further decrease in activity, typically to around 10 g/mmol·h·bar. A similar behaviour of diimine versus diamine donors is observed in nickel ethylene polymerisation systems, where the saturated bis(2,6-diisopropylphenyl)ethylene diamine ligand showed only very low activity relative to the α-diimine analogue.[12]

Previously we have shown for pyridyldiimine iron polymerisation catalyst **8**, that the rate of propagation is first order in ethylene, resulting in a linear increase of the yield of polyethylene with pressure.[15] Although we have not carried out a systematic study of the effect of pressure on these new pyridylimine amine systems, the results in Table 1 show

Table 1. Results of ethylene polymerization runs using precatalysts **3a−c**, **4**, **6−8**

Run	Precatalyst (μmol)	Activator (mmol/equiv.)	T (C)	P (bar)	Yield (g)	Activity (g mmol^{-1} h^{-1} bar^{-1})	M_n	M_w	M_w/M_n

the difference between 1 bar and 10 bar tests. With a tenfold increase in pressure (similar amount of catalyst in each case) an approximate tenfold increase in polymer yield is observed, suggesting that for these systems the rate of propagation is also first order in ethylene.

Molecular weight data have only been obtained for the pyridyl imine amine systems which showed moderate activity (Table 1). The M_w value for the polyethylene obtained with the ketimine-derived imine amine catalyst **3c** is comparable to the parent pyridyl diimine catalyst **8**. The aldimine-derived analogue **3a** gives a lower value for M_n and M_w than for **3c**, but follows the same trend as seen for pyridyl diimine systems (cf. Runs 2 and 6 versus 10 and 11), including a negligible difference between 2,6-diisopropyl and mesityl substituents (**3a** versus **3b**, runs 2 and 4).

In conclusion, we have synthesized and characterized a series of complexes containing neutral tridentate [N,N,N] ligands. The 2-aminoalkyl-6-iminoalkyl-pyridine iron complexes of type **II** (Figure 1) show moderate activity in ethylene polymerisation, whereas a 2,6-bis(alkylamino)pyridyl iron complex of type **III** shows only low activity. Interestingly, although the activities are significantly lower than the related pyridyldiimine catalysts, similar trends upon ligand variation, both in activity as well as in polymer properties, are observed. A possible reason for the lower activity relative to bis(imino)pyridine systems is the weakness of the amino-iron interaction, which may lead to dissociation of the amine arm in these catalysts. However, the lack of conjugation through the ligand backbone may also be significant, as may the orientation of the amino aryl substituent in hindering access of monomer to the active site or growth of the polymer chain.

Experimental Section

General: All manipulations were carried out under an atmosphere of nitrogen using standard Schlenk and cannula techniques or in a conventional nitrogen-filled glove-box. Solvents were refluxed over an appropriate drying agent, and distilled and degassed prior to use. Elemental analyses were performed by the microanalytical services of the Department of Chemistry at Imperial College, Medac Ltd. or SACS at the University of North London. NMR spectra were recorded on a Bruker spectrometer at 250 MHz (^{1}H), and 62.9 MHz (^{13}C) at 293 K; chemical shifts are referenced to the residual protio impurity of the deuterated solvent; coupling constants are quoted in Hz. Mass spectra were obtained using either Fast Atom Bombardment (FAB), Electron Impact (EI) or Chemical Ionization (CI). Magnetic susceptibility studies were performed using an Evans balance or the Evans NMR method (solvent CD_2Cl_2; reference: cyclohexane).

Materials: The ligands 2,6-bis[(2,6-diisopropylphenylimino)methyl-]pyridine,[15] and 2,6-bis[(2,6-diisopropylphenylamino)methyl]pyridine (**5**),[32] as well as pyridinedicarboxaldehyde,[35] $FeCl_2$·thf[33] and the aluminium complexes **1a−c**[27] were prepared according to established procedures while 2,6-diacetylpyridine, MAO (10% solution in toluene) and all anilines were purchased from Aldrich Chemical Co. All other chemicals were obtained commercially and used as received unless stated otherwise.

Synthesis of Ligands and Complexes

6-[(2,6-Diisopropylphenylamino)-1-ethyl]-2-[(2,6-diisopropylphenylimino)methyl]pyridine (2a): Pentane (40 mL) was added to [C_5NH_3{CH=N(2,6-*i*Pr$_2$-C$_6$H$_3$)}{CHMeN(2,6-*i*Pr$_2$-C$_6$H$_3$)}]AlMe$_2$ (**1a**; 5.79 g, 11.0 mmol) followed by slow addition of an equal volume of water. After stirring for a further 3 h the pentane was stripped off. The aqueous phase was then extracted into chloroform (3 × 30 mL), filtered, dried over $MgSO_4$ and taken to dryness to give analytically pure [C_5NH_3{CH=N(2,6-*i*Pr$_2$-C$_6$H$_3$)}-{CHMeNH(2,6-*i*Pr$_2$-C$_6$H$_3$)}] (**2a**; 4.14 g, 80%). − ^{1}H NMR ($CDCl_3$, 293 K): δ = 8.38 (s, 1 H, N=CH), 8.17 [d, ^3J(HH) = 7.7, 1 H, Py-H$_m$], 7.73 [app. t, ^3J(HH) = 7.7, 1 H, Py-H$_p$], 7.3−7.0 (m, 7 H, Ar-H, Py-H$_m$), 4.48 [d, ^3J(HH) = 10.4, 1 H, N-H], 4.3−4.4 (m, 1 H, N−CHMe), 3.31 [sept, ^3J(HH) = 6.8, 2 H, CHMe$_2$], 3.02 [sept, ^3J(HH) = 6.8, 2 H, CHMe$_2$], 1.49 [d, ^3J(HH) = 6.6, 3 H,

N−CHMe], 1.3−1.2 (m, 18 H, $CHMe_2$), 1.09 (d, 6 H, $CHMe_2$). − CI MS: m/z = 470 [$(M + H)^+$]. − IR (Nujol mull): $\tilde{\nu}$ = 3356 cm^{-1} [ν(N−H)]. − $C_{32}H_{43}N_3$ (469.71): calcd. C 81.88, H 9.17, N 8.96; found C 82.21, H 9.30, N 8.71.

Crystal Data for 2a: $C_{32}H_{43}N_3$, M = 469.7, monoclinic, space group $P2_1/c$ (no. 14), a = 16.208(2), b = 10.364(1), c = 17.664(3) Å, β = 100.67(1)°, V = 2916.1(6) $Å^3$, Z = 4, D_c = 1.070 g cm^{-3}, μ(Cu-K_α) = 4.70 cm^{-1}, F(000) = 1024, T = 293 K; clear plates, 0.23 × 0.07 × 0.02 mm, Siemens P4/RA diffractometer, ω-scans, 4065 independent reflections. The structure was solved by direct methods and the non-hydrogen atoms were refined anisotropically using full-matrix least-squares based on F^2 to give R_1 = 0.096, wR_2 = 0.191 for 1619 independent observed reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 116°$] and 317 parameters.
Crystallographic data (excluding structure factors) for this structure have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149266. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

6-[(2,4,6-Trimethylphenylamino)-1-ethyl]-2-[(2,4,6-trimethylphenylimino)methyl]pyridine (2b): Prepared in the same way as described for compound **2a**, from Al complex **1b**. Yield 75%. − ^{1}H NMR ($CDCl_3$, 293 K): δ = 8.28 (s, 1 H, N=CH), 8.07 [d, ^3J(HH) = 7.8, 1 H, Py-H_m], 7.64 [app. t, ^3J(HH) = 7.8, 1 H, Py-H_p], 7.14 (d, 1 H, Py-H_m), 6.84 (s, 2 H, Ar-H), 6.70 (s, 2 H, Ar-H), 4.43 [br, q, ^3J(HH) = 6.5, 1 H, N−CHMe], 4.31 (s, br, 1 H, N−H), 2.23 (s, 3 H, Ar-Me_p), 2.18 (s, 6 H, Ar-Me_o), 2.13 (s, 3 H, Ar-Me_p), 2.07 (s, 6 H, Ar-Me_o), 1.36 (d, 3 H, NCHMe). − CI MS: m/z = 385 [$(M + H)^+$]. − IR (Nujol mull): $\tilde{\nu}$ = 3359 cm^{-1} [ν(N−H)]. − $C_{26}H_{31}N_3$ (385.55): calcd. C 81.04, H 8.05, N 10.91; found C 81.44, H 8.39, N 10.79.

6-[2-(2,6-Diisopropylphenylamino)-2-isopropyl]-2-[(2,6-diisopropylphenylimino)ethyl]pyridine (2c): Prepared in the same way as described for compound **2a**, from Al complex **1c**. Yield 71%. − ^{1}H NMR ($CDCl_3$, 293 K): δ = 8.25 [d, ^3J(HH) = 7.7, 1 H, Py−H_m], 7.79 (app. t, ^3J(HH) = 7.7, 1 H, Py-H_p), 7.59 (d, 1 H, Py-H_m), 7.2−7.0 (m, 6 H, Ar-H), 4.47 (s, br, 1 H, N−H), 3.31 [sept, ^3J(HH) = 6.7, 2 H, $CHMe_2$], 2.77 [sept, ^3J(HH) = 6.7, 2 H, $CHMe_2$], 2.24 (s, 3 H, N=CMe), 1.51 (s, 6 H, N−CMe_2), 1.17 (d, 12 H, $CHMe_2$), 1.07 (d, 12 H, $CHMe_2$). − EI MS: m/z = 497 [M^+]. − IR (Nujol mull): $\tilde{\nu}$ = 3362 cm^{-1} [ν(N−H)]. − $C_{34}H_{47}N_3$ (497.77): calcd. C 82.09, H 9.46, N 8.45; found C 82.39, H 9.71, N 8.30.

{6-[(2,6-Diisopropylphenylamino)-1-ethyl]-2-[(2,6-diisopropylphenylimino)methyl]pyridine}iron(II) Dichloride (3a): $FeCl_2$ (0.20 g, 1.57 mmol) was dissolved in hot *n*-butyl alcohol (10 mL) at 80 °C. A suspension of **2a** (0.72 g, 1.62 mmol) in *n*-butyl alcohol was added dropwise at 80 °C. The reaction mixture turned blue. After stirring at 80 °C for 15 minutes the reaction was allowed to cool to room temperature. The reaction volume was then reduced to a few millilitres and diethyl ether added to precipitate [C_5NH_3{CH=N(2,6-iPr_2-C_6H_3)}{CHMeNH(2,6-iPr_2-C_6H_3)}]$FeCl_2$ (**3a**; 0.76 g, 83%) as a blue powder, which was subsequently washed three times with diethyl ether (10 mL). − μ_{eff} (Evans Balance): 5.6 BM. − IR (Nujol): $\tilde{\nu}$ = 3303 cm^{-1} [ν(N−H)]. − FAB MS: m/z = 596 [M^+], 560 [M^+ − Cl]. − $C_{32}H_{43}N_3FeCl_2$ (596.46): calcd. C 64.43, H 7.21, N 7.05; found C 64.70, H 7.19, N 6.99.

Crystal Data for 3a: $C_{32}H_{43}Cl_2N_3Fe$, M = 596.4, orthorhombic, space group $P2_12_12_1$ (no. 19), a = 13.433(2), b = 13.449(3), c = 18.624(3) Å, V = 3365(1) $Å^3$, Z = 4, D_c = 1.177 g cm^{-3}, μ(Mo-K_α) = 6.30 cm^{-1}, F(000) = 1264, T = 293 K; deep red blocks, 0.57 × 0.40 × 0.23 mm, Siemens P4/PC diffractometer, ω-scans, 3302 independent reflections. The structure was solved by direct methods and the non-hydrogen atoms were refined anisotropically using full-matrix least-squares based on F^2 to give R_1 = 0.065, wR_2 = 0.113 for 1968 independent observed absorption corrected reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 50°$] and 347 parameters. The absolute chirality of **3a** (which undergoes spontaneous resolution upon crystallisation) was determined by an R-factor test [R_1^+ = 0.0648, R_1^- = 0.0666].
Crystallographic data (excluding structure factors) for this structure have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149267. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

{6-[(2,4,6-Trimethylphenylamino)-1-ethyl]-2-[(2,4,6-trimethylphenylimino)methyl]pyridine}iron(II) Dichloride (3b): Complex **3b** was prepared by an analogous route to that outlined for complex **3a** from $FeCl_2$ (0.15 g, 1.18 mmol) and ligand **2b** (0.44 g, 1.18 mmol). Yield: 0.46 g, 80%. − μ_{eff} (Evans Balance): 5.4 BM. − IR (Nujol): $\tilde{\nu}$ = 3307 cm^{-1} [ν(N−H)]. − FAB MS: m/z = 511 [M^+], 476 [M^+ − Cl]. − $C_{26}H_{31}Cl_2N_3Fe$ (512.30): calcd. C 60.94, H 6.05, N 8.20; found C 60.11, H 6.12, N 7.98.

{6-[2-(2,6-Diisopropylphenylamino)-2-isopropyl]-2-[(2,6-diisopropylphenylimino)ethyl]pyridine}iron(II) Dichloride (3c): Complex **3c** was prepared by an analogous route to that outlined for **3a** from $FeCl_2$ (0.15 g, 1.18 mmol) and **2c** (0.59 g, 1.18 mmol). Yield: 0.46 g, 62%. − μ_{eff} (Evans Balance): 5.6 BM. − IR (Nujol): $\tilde{\nu}$ = 3301 cm^{-1} [ν(N−H)]. − FAB MS: m/z = 623 [M^+], 588 [M^+ − Cl]. − $C_{34}H_{47}Cl_2N_3Fe$ (624.52): calcd. C 65.38, H 7.53, N 6.73; found C 65.31, H 7.89, N 7.31.

{6-[(2,6-Diisopropylphenylamino)-1-ethyl]-2-[(2,6-diisopropylphenylimino)methyl]pyridine}cobalt(II) Dichloride (4): Complex **4**[30] was prepared by an analogous route to that outlined for **3a** from $CoCl_2$ (0.15 g, 1.15 mmol) and **2a** (0.54 g, 1.15 mmol). Yield: 0.48 g, 70%. − μ_{eff}(Evans Balance): 4.6 BM. − IR (Nujol mull): $\tilde{\nu}$ = 3304 cm^{-1} [ν(N−H)]. − FAB MS: m/z = 599 [M^+], 563 [M^+ − Cl], 528 [M^+ −2Cl].

[2,6-Bis(2,6-diisopropylphenylaminomethyl)pyridine]iron(II) Dichloride (6): A suspension of the pyridyldiamine ligand **5** (0.45 g; 1.0 mmol) and $FeCl_2$·thf (1 equiv.) in toluene (50 mL) was refluxed overnight. Upon cooling to room temperature, the product precipitated as blue/green crystals (**6a**), which were washed with toluene and pentane and dried in vacuo. Another batch of crystals were grown from a saturated toluene solution at −30 °C (**6b**). Yield: 0.51 g (87%). − μ_{eff} (Evans NMR method): 5.08 BM. − $C_{31}H_{43}N_3FeCl_2$·0.5thf (620.51): calcd. C 63.88, H 7.63, N 6.77; found C 64.07, H 7.77, N 6.52.

Crystal Data for 6a (monoclinic form): $C_{31}H_{43}N_3Cl_2Fe$·0.5C_7H_8, M = 630.5, monoclinic, space group $P2_1/n$ (no. 14), a = 9.789(2), b = 14.750(4), c = 24.757(3) Å, β = 95.79(1)°, V = 3556(1) $Å^3$, Z = 4, D_c = 1.178 g cm^{-3}, μ(Mo-K_α) = 6.00 cm^{-1}, F(000) = 1340, T = 293 K; blue/straw dichroic needles, 0.77 × 0.17 × 0.17 mm, Siemens P4/PC diffractometer, ω-scans, 6268 independent reflections. The structure was solved by the heavy atom method and all the major occupancy non-hydrogen atoms were refined anisotropically using full-matrix least-squares based on F^2 to give R_1 = 0.066, wR_2 = 0.137 for 3276 independent observed reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 50°$] and 438 parameters.

Crystallographic data (excluding structure factors) for this structure have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149268. Crystal Data for 6b (orthorhombic form): $C_{31}H_{43}N_3Cl_2Fe{\cdot}3C_7H_8$, M = 860.8, orthorhombic, space group *Pccn* (no. 56), a = 25.815(2), b = 10.106(1), c = 18.516(1) Å, V = 4830.6(5) Å^3, Z = 4 (the complex has crystallographic C_2 symmetry), D_c = 1.184 g cm^{-3}, μ(Cu-K_α) = 37.9 cm^{-1}, F(000) = 1840, T = 183 K; pale yellow plates, 0.53 × 0.47 × 0.07 mm, Siemens P4/RA diffractometer, ω-scans, 3564 independent reflections. The structure was solved by direct methods and all the major occupancy non-hydrogen atoms were refined anisotropically using full-matrix least-squares based on F^2 to give R_1 = 0.068, wR_2 = 0.168 for 2253 independent observed absorption corrected reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 124°$] and 288 parameters.
Crystallographic data (excluding structure factors) for this structure have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149269. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

General Polymerization Procedures: (a) *High Pressure Tests*: A 1 litre stainless steel reactor was baked out under a nitrogen flow for at least 1 h at >85 °C and subsequently cooled to the temperature of polymerization. Isobutane (0.5 L) and trialkylaluminum (triisobutylaluminum) were introduced into the reactor and stirred at the reaction temperature for at least 1 hour. Ethylene was introduced by over-pressure and the difference between the total pressure and the initial pressure (isobutane and nitrogen: ca. 10 bar) is the pressure quoted in Table 1. The catalyst solution in toluene was then injected under nitrogen. The reactor pressure was maintained constant throughout the polymerization run by computer controlled addition of ethylene. The polymerization time was 60 minutes. Runs were terminated by venting off volatiles and the reactor contents were isolated, washed with aqueous HCl, methanol and dried in a vacuum oven at 50 °C.

(b) *Schlenk-line 1 bar ethylene Tests*: The precatalyst was dissolved in toluene (40 mL) and MAO (10 wt% in toluene) added to produce an orange solution. The Schlenk tube was placed in a water bath, purged with ethylene and the contents magnetically stirred and maintained under ethylene (1 bar) for the duration of the polymerization (60 minutes). The polymerization was terminated by the addition of aqueous hydrogen chloride. The solid PE was recovered by filtration, washed with methanol (50 mL) and dried (vacuum oven at 50 °C).

Acknowledgments

bp Chemicals Ltd and the Engineering and Physical Sciences Research Council are thanked for financial support. Drs J. Boyle and G. Audley are thanked for NMR and GPC measurements, respectively.

Inductive Effects in Ruthenium-Modified Amino Acids

Bernd Geißer,[a] Thomas Skrivanek,[b] Ute Zimmermann,[b] Derk J. Stufkens,[c] and Ralf Alsfasser*[a]

Keywords: Bioinorganic chemistry / Amino acids / Luminescence / Ruthenium

Emission spectroscopy has been used to probe and quantify electronic interactions mediated by alkyl side chains in a homologous series of amino acids. The ω-amine functions of diaminopropionic acid (DAPA), diaminobutyric acid (DABA), ornithine, and lysine were covalently labeled with a luminescent $[Ru(bipy)_3]^{2+}$ fragment. Protonation of the α-amine function results in a significant dependence of nonradiative excited-state decay rates on the number of methylene groups, *n*, in the respective side chain. Two analogous series of compounds in which the α-amino acid moiety was replaced by $R–NH_2$ or $R–NMe_3^+$ have been studied for comparison. It was found that the emission energies of the chromophore and the pK_A values of the remote amine functional groups in our complexes are both affected by inductive effects which can be described by a Hammett–Taft type relationship. We were able to show that the induction decays with $1/n$, where n = the number of methylene groups separating the chromophore from the amine and ammonium functions. A qualitative description of the phenomenon is given in terms of acid base theory.

Introduction

Peptides and peptide analogues are among the most versatile components for the biomimetic development of new compounds and materials. Examples include pharmaceuticals,[1] enzyme mimetics,[2–4] building blocks for combinatorial catalyst screenings,[5–7] light-harvesting peptides[8,9] and model compounds for electron-transfer proteins.[10–13] The unsurpassed adaptability of peptide scaffolds is achieved by a surprisingly simple building-block design. It remains a fascinating practical and intellectual challenge for chemists to study and understand the subtle interactions between individual amino acid functions which as a whole determine the function of the assembly.

The basic starting point for investigations of electronic interactions between side-chain functional groups and their microenvironment is amino acids and small peptides. Absorption[14,15] and resonance Raman spectra[16] and the characterization of photodegradation products[17] provide evidence for charge transfer processes involving the amide backbone and aromatic side chains. These processes can be modulated by inductive effects imposed by additional functional groups. An *N*-terminal ammonium ion has been shown to induce higher rates of photoinduced electron transfer reactions in phenylalanine containing peptides.[18]

A related effect is also responsible for the unusual photophysical properties of the ruthenium-substituted amino acids **1a–4a** shown in Figure 1. We have recently shown[19] that the ruthenium-based emission is quenched by protonation of the remote amino acid NH_2 group. Nonradiative decay rates increase as the number of methylene groups, *n*, decreases. Questions concerning the origin of this be-

havior have prompted us to study the amine and tetraalkylammonium derivatives **1b−4b** and **1c−4c**, respectively (Figure 1). Our results now enable us to propose a model which explains our observations.

The inductive effect of an ammonium functional group is interpreted in terms of acid-base interactions as defined by the ECT concept developed by Drago et al.[20,21] A semiquantitative analysis is possible by the introduction of a distance dependent Hammett−Taft σ-parameter.[22,23] This conceptual framework may contribute to a better understanding of inductive effects and serve as a starting point for more detailed quantitative analyses of electronic interactions in peptides and proteins.

Results

Synthesis and Characterization

The amine derivatives **1b−4b** were prepared analogously to the amino acids **1a−4a** starting from the succinimide ester $[Ru(bipy)_2(m\text{-OSu})](PF_6)_2$ [9] and the respective mono-*t*Boc protected diamine. Reaction of **1b−4b** with an excess of methyl iodide afforded the trimethylammonium complexes **1c−4c**. All compounds were purified by ion-exchange column chromatography and isolated as hexafluorophosphate salts. The products were characterized and their purity checked by ^{1}H NMR spectroscopy, FAB-MS, and C,H,N-elemental analysis.

NMR Titrations

Ground state pK_A values of the amine groups in **1b−4b** were determined by the same method as described recently for the amino acid complexes **1a−4a**.[19] The respective α-CH resonances were plotted as a function of pH (D_2O) and the curves were fit to a two-state acid base equilibrium.[24,25] Table 1 summarizes the pK_A values determined for the amine functions of our complexes together with some literature data.

Table 1. pK_A(NH_2/NH_3^+) values of **1a−4a**[19] and **1b−4b** as determined by NMR- (pK_A) and luminescence spectroscopy (pK_A*), respectively

Compound	pK_A	pK_A*

The pK_A values of the respective amine functions in **1a−4a** and **1b−4b** are strongly affected by the presence of the ruthenium chromophore. The α-NH_3^+ groups of our ruthenium-substituted amino acids are considerably less acidic than those of the respective parent compounds diaminopropionic acid (DAPA), diaminobutyric acid (DABA), ornithine, and lysine.[26] Similarly, the pK_A values of the ammonium groups in **1b−4b** are higher than those reported for the second protonation of the respective diamine.[27] It is interesting to note that the pK_A values obtained for **1a** and **2a** compare well with those reported for the two ω-amido-α-amino acids asparagine and glutamine. This suggests that the amino acid groups are more strongly affected by the amide function than by the ruthenium complex fragment.

Absorption and Resonance Raman Spectra

The UV/Visible spectra of the twelve complexes **1(a-c)−4(a-c)** are indistinguishable within experimental error and are typical for polypyridyl ruthenium complexes. No significant spectral changes are observable at pH values ranging from 0 to 14. A characteristic broad band at 457 nm with a shoulder at 430 nm is assigned to the MLCT transitions involving the unsubstituted and amide-substituted bipyridine ligands.

Resonance Raman spectra for **1a** were collected in order to evaluate further the contributions of the different bipyridine ligands to the absorption bands. Excitation wavelengths (λ_{exc}) of 433, 457.9, and 488 nm, respectively, were used which cover the MLCT band of the complex. Measurements at three different pH values (1, 7, and 12) show that the spectra do not vary significantly with pH.

The strongest bands are summarized in Table 2. They are found above 1000 cm^{-1} and belong to stretching vibrations of the ligands. No vibration of the amino acid moiety is resonance enhanced. The relative signal intensities significantly depend on the excitation wavelength. A comparison with $[Ru(bipy)_3]^{2+}$ shows that bands at 1608, 1563, 1320, and 1176 cm^{-1} can be assigned to vibrations involving the unsubstituted bipyridine rings in **1a**. They are strongest at λ_{exc} = 433 nm indicating that the shoulder at the high-energy end of the MLCT band is due to a Ru → bipy charge transfer. Transitions involving the amide-substituted ligand occur at lower energy, which is evident from the Raman bands at 1622, 1547, 1277, and 1214 cm^{-1} which increase as λ_{exc} is raised to 488 nm. Finally, the strongest Raman band is located at 1491 cm^{-1} and reveals a shoulder at its low-energy end (ca. 1483 cm^{-1}) when λ_{exc} = 488 nm.

1c	1.31 (100)	−1.33 (80)	−1.54 (80)	−1.83 (110)
2c	1.32 (90)	−1.34 (80)	−1.54 (80)	−1.83 (110)
3c	1.32 (90)	−1.34 (80)	−1.54 (80)	−1.77 (100)
4c	1.32 (90)	−1.34 (80)	−1.53 (90)	−1.73 (90)

Our data compare well with time-resolved resonance Raman studies reported by Meyer et al[28] for the lysine derivative **4a** in acetonitrile. The assignment of the low-energy transitions to charge-transfer processes involving the amide-substituted pyridine ring is consistent with a lower reduction potential of this ligand. It is important for the arguments presented in the following discussion that the MLCT transition involving the amino acid ligand bpy-DAPA is largely obscured by transitions to the unsubstituted bipyridines. This prevents an accurate determination of λ_{max} for the Ru → bpy-DAPA transition.

Cyclic Voltammetry

The cyclic voltammogram of each complex in acetonitrile is characterized by four reversible waves. Table 3 summarizes these data. Oxidation of the respective ruthenium(II) center is observed at a potential of ca. +1.32 V (vs. Ag/AgCl). The first ligand reduction occurs at a potential of ca. −1.3 V. Consistent with literature data of related complexes,[29] and our resonance Raman studies, we assign this wave to the reduction to the amide-substituted pyridine ring.

Whereas the oxidation waves are clearly independent of the bipyridine substituents, small differences are observed for the ligand reduction potentials. The amine complexes **1b−4b** appear to be more easily reducible than their amino acid and tetraalkylammonium analogues **1a,c-4a,c**. However, considering the broad waves which are typical for the class of complexes investigated this difference may not be significant.

Emission Spectra

The emission spectra of **1a−4a** and **1b−4b** are strongly pH dependent. In Figure 2, the uncorrected maximum emission intensities are plotted as a function of pH. Two protonation steps are clearly separated in each case. The inflection point at ca. pH 0.5 is assigned to protonation of the amide link.[19] The second inflection is due to protonation/deprotonation of the respective amine functions. The magnitude of the observed change in luminescence intensity depends on the number of methylene spacers separating the amide link from the α-C atom. The spectra of the amino acids and the ethylenediamine derivatives show very similar pH dependences except for a significant difference in the observed pK_A values. All luminescence titration curves yield pK_A values for the amine groups which are very similar to those obtained by NMR spectroscopy, suggesting similar acid-base properties of the ground and excited states. The results obtained from emission spectroscopy are also summarized in Table 1.

Lifetime measurements performed for all complexes at pH 0, 4.8, and 12 confirm our findings from steady state measurements. We have repeated and reproduced all lifetime experiments reported earlier[19] in order to assure that all data were obtained under the same conditions. These results are presented in Table 4. Amide protonation at low pH values results in large nonradiative decay rates (τ = ca. 60 ns) for all compounds. In the pH range between the two inflections shown in Figure 2, lifetimes increase with the number of methylene spacers, *n*. The values obtained for **1a** (τ = 345 ns) and **1b** (τ = 355 ns) at pH 4.8 compare well. At pH 12 we find very similar values of ca. 420 ns for all four amino acids. In the case of the amine derivatives **1b−4b** this number is slightly smaller (396 ns). We think that this difference is significant and may be due to medium effects associated with the high base concentration. As will be shown in the Discussion section, high pH values also

affect the lifetimes of the trimethylammonium complexes **1c−4c**.

The trimethylammonium complexes **1c−4c** were prepared in order to evaluate possible contributions of NH bonds to nonradiative decay processes.[30] The compounds exhibit lifetimes of 352 ns (**1c**), 399 ns (**2c**), 423 ns (**3c**), and 422 ns (**4 c**) at pH 4.8. These numbers also compare well with the data obtained for our series of amino acids, indicating that NH bonds are not involved in energy dissipation pathways. Slightly smaller values are observed at pH 12, indicating a small contribution of the basic medium to excited-state decay processes. In summary, our results demonstrate that a zwitterionic amino acid function, an ammonium ion, and a tetraalkylammonium ion have the same effects on the excited state properties of a $[Ru(bipy)_3]^{2+}$ chromophore.

Discussion

Our data demonstrate that the luminescence properties of the $[Ru(bipy)_3]^{2+}$ chromophores in **1(a-c)−4(a-c)** are affected by protonation of the amide link at very low pH, as well as by the presence of NR_4^+ functions in (i) the zwitterionic amino acid groups of **1a−4a**, (ii) the ammonium ions in **1b−4b**, and (iii) the trimethylalkylammonium groups in **1c−4c**. Two conclusions can be drawn from a comparison of the three series of compounds investigated: (i) the reduced lifetimes of the compounds with short alkyl spacers originate from the intramolecular presence of an NR_4^+ function and do not require a zwitterionic amino acid structure, and (ii) a direct participation of NH units in energy dissipation pathways is ruled out since the $RNMe_3^+$ compounds **1c−4c** do not differ significantly from the RNH_3^+ derivatives **1a,b−4a,b**. The latter conclusion is particularly important since hydrogen bonding to the solvent[31] and high energy NH vibrations are known to significantly effect nonradiative decay rates in other systems.[30]

It is evident from the emission spectra shown in Figure 3 that decreasing intensities are associated with a small but significant band-shift to lower energies. This observation suggests that the energy gap between the excited state and the ground state is affected. A contribution to the nonradiative decay rate constants according to the energy gap law is therefore evident. However, the differences between the emission maxima are very small making a quantitative analysis difficult. Figure 4 contains a plot of ln*k* versus emission energies which includes literature data reported for $[Ru(bipy)_3]^{2+}$.[32] The comparison in Figure 4b clearly shows that, in fact, the very small shift in energies observed for our compounds is sufficient to account for the observed differences in nonradiative decay rates. It should be noted that $[Ru(bipy)_3]^{2+}$ cannot be included without caution since linear energy-gap relationships are only expected within a series of closely related complexes. In addition, it has been reported that solvent effects in hydroxylic solutions may result in significant deviations from a simple linear energy-gap dependence.[33,34] As is shown in Figure 4b the linear fit obtained for our complexes alone is slightly steeper than that obtained if $[Ru(bipy)_3]^{2+}$ is included. However, we think the data show that the structure and pH-dependent nonradiative decay rates of our complexes can conveniently be explained in terms of the energy-gap law. This is important since we do not have any evidence for other well-known effects such as the participation of low lying d-d excited states,[35] solvent reorganization,[36] or different geometric displacements in the excited state.[37,38] These phenomena should manifest themselves in ligand loss or emission band shapes.

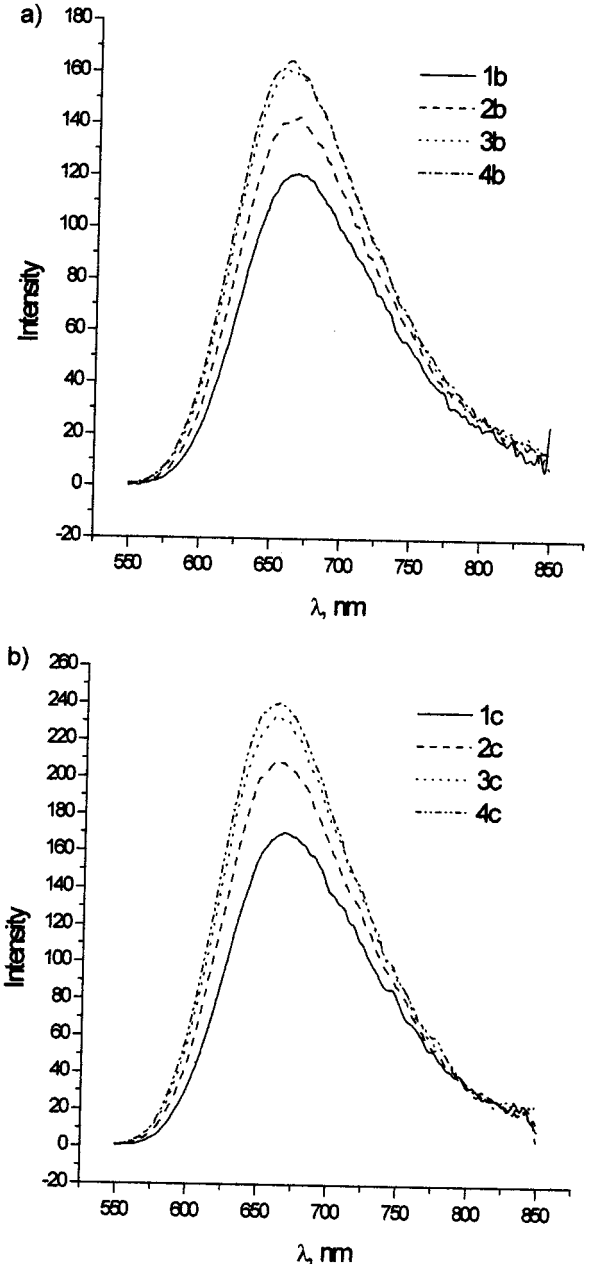

Figure 3. Corrected luminescence spectra measured at pH 4.8: a) **1b−4b**, b) **1c−4c**

The origin of the decreasing emission energies is most likely an inductive effect caused by the ammonium groups in our complexes. An electronic interaction between the ruthenium chromophore and the remote amine functions is evident from the ground state pK_A values given in Table 1. The NH_3^+ groups in **1a−4a** and **1b−4b** become more acidic as the number of methylene groups decreases. Similarly, the electron affinity of the ruthenium chromophore must increase in the presence of an ammonium group. This results in a lower HOMO−LUMO energy gap and explains our observations. A similar effect has been described by Seidel et al., who reported the influence of *N*-terminal ammonium groups on photoinduced electron transfer rates in tyrosine peptides.[18]

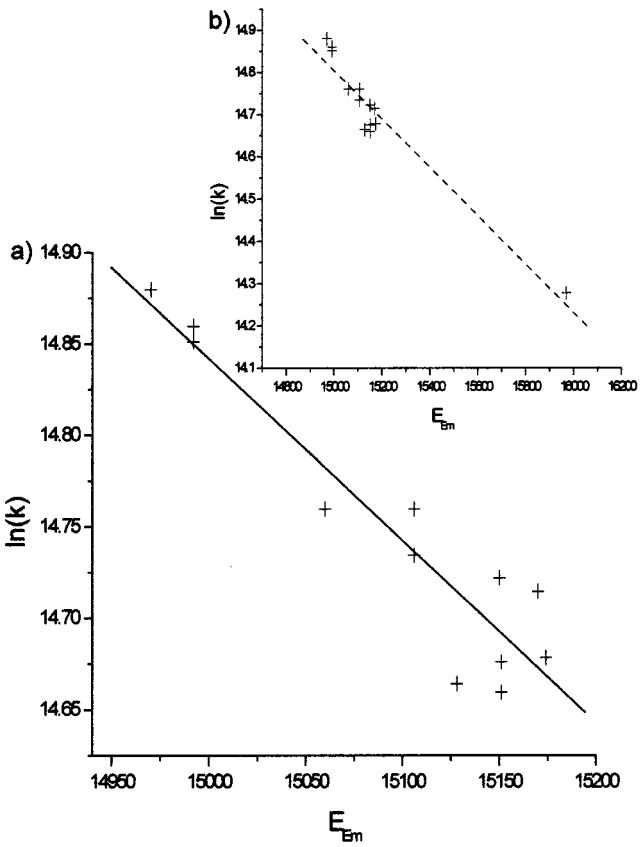

Figure 4. (a) Plot of ln k vs. E_{em} (pH = 4.8) for all compounds reported in this work; (b) comparison with the literature value reported for $[Ru(bipy)_3]^{2+}$ (see ref. [49])

Further support for an explanation which only involves an energy gap law relationship comes from the behavior of our complexes at low pH values. We have shown in a previous article[19] that protonation of the amide oxygen atom in **1a−4a** is associated with a large red shift of the emission energies. Resonance structures of the excited state can be drawn with the negative charge localized at the amide functional group and it is evident that protonation of this group will result in a lower reduction potential of the substituted bipyridine ligand.

We suggest that a qualitative description of the observed phenomena can be given in terms of acid-base interactions between the Lewis acid NR_4^+ and the Lewis basic amide link. Drago et al.[20,21] have developed the ECT-concept which splits acid-base interactions into three contributions. The first one, $C_{acid}C_{Base}$, describes covalent interactions and is irrelevant here since acid and base are separated by an alkyl chain in our complexes. The second one, $E_{Acid}E_{Base}$, originates in electrostatic interactions and may be the most important in determining the pK_A(NH_2/NH_3^+) values in **1b−4b**. The third contribution, $R_{Acid}T_{Base}$, (R: Receptance, T: Transmission) refers to an exchange of electron density between the acid and the base. The ECT parameters are closely related to the physical parameters electron affinity (EA), ionization energy (IE), and electronegativity as defined by the Jaffé scale.[39−41] Consideration of the electron transfer interaction $R_{Acid}T_{Base}$ may explain why a zwitter-

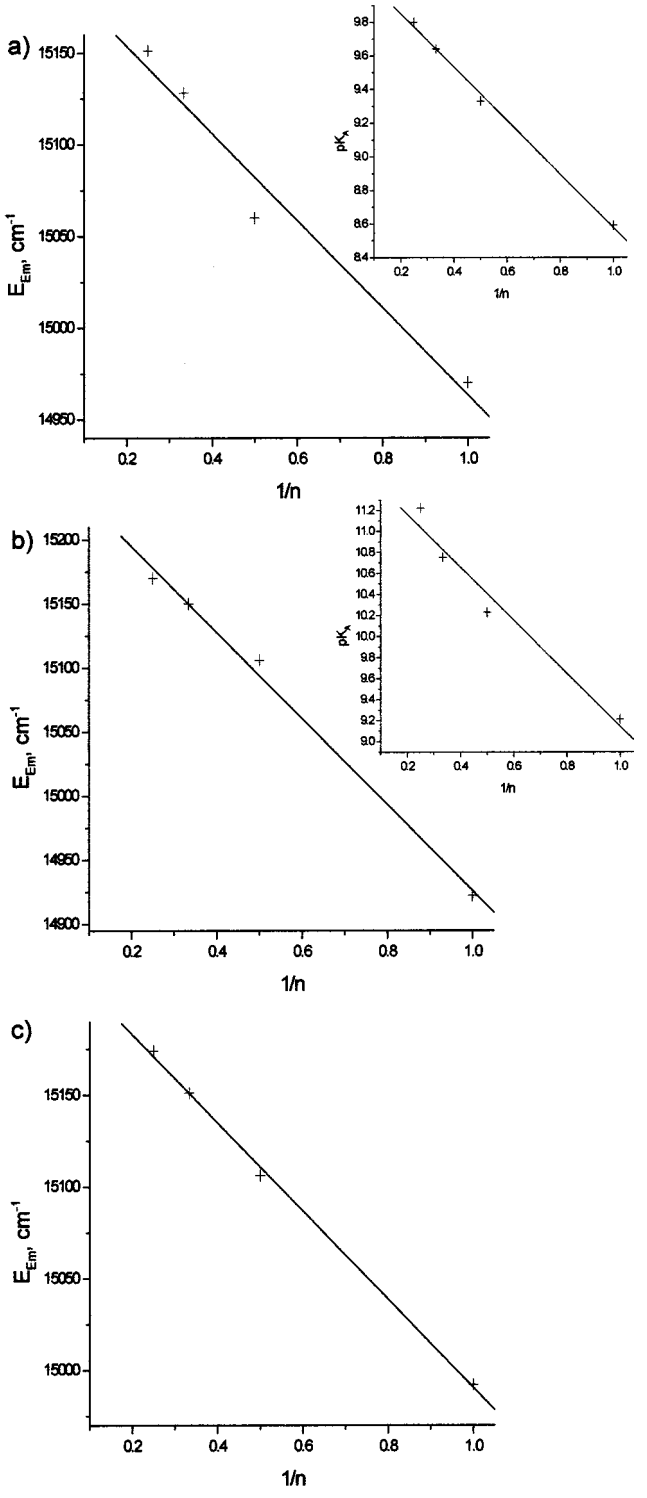

Figure 5. Plots of pK_A values (NH_2/NH_3^+) and emission energies (pH 4.8), respectively, vs. 1/*n*: (a) **1a−4a**, (b) **1b−4b**; (c) plot of the emission energies of **1c−4c** at pH 4.8 vs. 1/*n*

ionic amino acid (0 charge) and an ammonium function (+1 charge) can have the same effect on the LUMO energy of a conjugated chromophore.

The significant changes in pK_A(NH_2/NH_3^+) values observed for our amino acid (**1a−4a**) and amine (**1b−4b**) complexes indicate that inductive effects have to be relevant not only in the excited states, but also in the ground states of the molecules. It must therefore be explained why the decreased HOMO−LUMO gap is not manifest in changes of the absorption spectra and reduction potentials. The differences in emission energies, ΔE_{em}, are on the order of 2 kJ/mol between the two extremes within each series (**1a/4a**, **1b/4b**, **1c/4c**). This would correspond to an estimated change in redox potentials of ca. 20 mV, a value which is not significant within the experimental error of our cyclic voltammograms. As has been discussed above, the same is true for the absorption spectra of our complexes, which are largely obscured by overlapping MLCT bands. The resonance Raman spectra show that the MLCT transition to the substituted bipy ligand is covered by the Ru → bipy transition, which is more intense due to the presence of two unsubstituted bipyridine ligands. This makes a determination of the absorption energy corresponding to the Ru → substituted bipy transition impossible. It is evident that effects which are readily observable by emission spectroscopy cannot be determined by either absorption spectroscopy or cyclic voltammetry.

Inductive effects are usually described semi-quantitatively by linear free-energy relationships such as the Hammett[22] and Taft[23] equations. In a correlation analysis, rate constants or physical properties such as chemical shifts or IR frequencies[42] are plotted as a function of a parameter, σ, which is a measure of the magnitude of the electron-donating or -withdrawing effect imposed by a functional group. In our study the functional groups do not vary and the inductive effect is only a function of the number of methylene groups separating the chromophore from the ammonium function. As is shown in Figure 5, both pK_A values and emission energies give reasonably good straight lines when they are plotted against 1/*n*, where *n* is the number of methylene spacers as defined by Figure 1. Consequently, ln*k* also shows a linear dependence on 1/*n* and pK_A, respectively. This is shown in Figure 6. Thus, 1/*n* describes the decrease of σ with increasing alkyl chains separating a Lewis acid from a Lewis base. This relationship holds for zwitterionic amino acids as well as for ammonium ions and should therefore be a measure of similar effects in a large variety of different compounds including peptides and proteins.

Though four data points are a small basis for a quantitative correlation all the series behave similarly, thus supporting our interpretation. An interesting aspect is revealed by the ln*k* vs. 1/*n* plots obtained for the trimethylammonium complexes **1c−4c** at pH 4.8 and pH 12. The two lines are parallel with slightly higher nonradiative decay rates observed at high base concentration. This observation can be assigned to a medium effect which is comparable to the small ionic-strength contributions observed for nonradiative decay rates of the $[Ru(bipy)_3]^{2+}$ excited state.[43]

A few problems should finally be noted. Due to their inherent flexibility, alkyl chains prevent a quantitative analysis of distance effects between two functional groups. The number of bonds or the number of methylene groups, *n*, has to be used instead. In addition, the amide link applied in our study may result in the formation of *syn* and *anti*

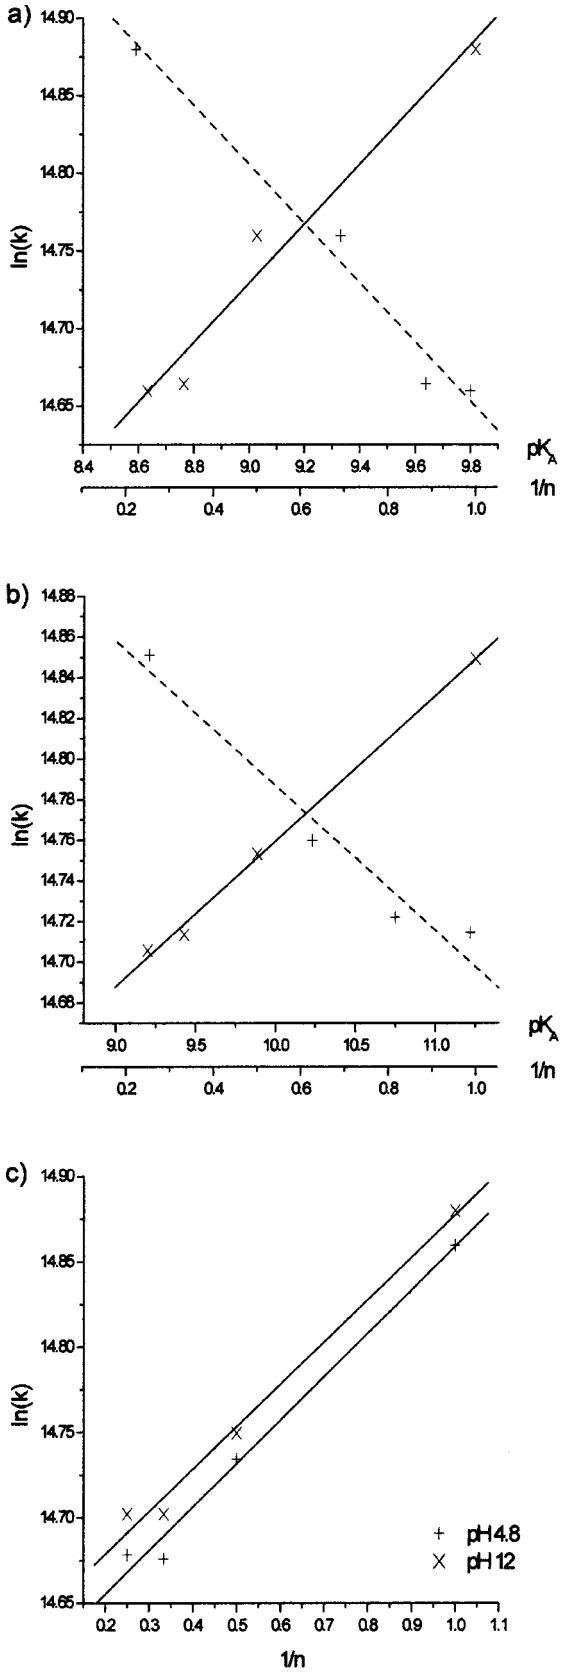

Figure 6. Plots of ln k vs. 1/n (solid lines, x) and pK_A values (dashed lines, +), respectively: (a) **1a−4a**, (b) **1b−4b**; (c) Plot of ln k vs. 1/n for **1c−4c** at pH 4.8 and pH 12, respectively

isomers which is a known complication in the quantitative analysis of photoinduced electron-transfer reactions involving amide-bridged donor-acceptor dyads.[44] Furthermore, alkyl bridges are known to effect electrostatic interactions since they modify the microscopic dielectric constant between the two relevant functional groups.[45] As a consequence, our empirical correlations are not suitable for a quantitative evaluation of different contributions such as the magnitude of electrostatic ($E_{Acid}E_{Base}$) or electron transfer ($R_{Acid}T_{Base}$) interactions. Detailed theoretical studies will be required to tackle these problems. However, with our proposed model we provide a starting point for such investigations.

Conclusions

Our studies concerning the photophysical properties of chromophore-substituted amino acids have lead us to propose a model for the interpretation of inductive effects in amino acids and peptides. Two observations are particularly important:
(1) The pK_A value of a remote functional group and the HOMO−LUMO gap of a chromophore are linearly related. This may be relevant for the interpretation of pH titration curves particularly in small molecular assemblies were meaningful assignments of pK_A values can be made.
(2) 1/n can be used to describe the decay of the electronic Hammett−Taft parameter, σ, when an increasing alkyl bridge separates two functional groups. Our data show that σ/n is significant in **1a** but very small in the lysine derivative **4a**. This may help to define the limiting case for "through-bond" interactions mediated by amino acid side chains in small peptide assemblies[13,28,29,46] and proteins.[47]

Experimental Section

Materials: $[Ru(bipy)_2Cl_2]$[48], $[Ru(bipy)_2(m\text{-OH})](PF_6)_2$ [9] and $[Ru(bipy)_2(m\text{-OSu})](PF_6)_2$ (m = 4-carbonyl-4′-methyl-2,2′-bipyridine, m-OSu = 4-carboxysuccinimidoester-4′-methyl-2,2′-bipyridine) were prepared according to the method reported by Erickson et al.[9] $RuCl_3$ was a donation from Degussa. Reagent grade solvents were obtained from Roth, NMR solvents from Aldrich and all other chemicals from Fluka. Water for preparations was demineralized. All reactions were carried out under argon.

Spectra were recorded with the following instruments: UV/Vis: Shimadzu UV-2101PC. − IR (KBr pellets): Mattson Polaris FT IR. − ^{1}H NMR: Bruker Avance DPX 300. All chemical shifts are referenced to residual solvent signals as internal standards previously referenced to TMS, with high-frequency shifts recorded as positive. Pyridine resonances are labelled "b" for the bipy, and "m" for the substituted bipy ligands, respectively. − Elemental analysis: Carlo Erba EA 1106. − FAB: Micromass ZabSpec mass spectrometer.

$[Ru(bipy)_2\{m\text{-}CONH(CH_2)_nNH_3^+\}](PF_6)_3$ (n = 2: 1b, 3: 2b, 4: 3b, 5: 4b). − General Procedure: $[Ru(bipy)_2(m\text{-OH})](PF_6)_2$ and HOSu (1.1 equiv.) were dissolved in acetonitrile (5 mL) and the solution was cooled to 0 °C. Dicyclohexylcarbodiimide (DCC, 2.5 equiv.) was added and the red suspension was stirred at 0 °C for 5 h. The

precipitated urea was filtered off and washed several times with small amounts of acetonitrile. The *N*-Boc-monoprotected diamine (1.2 equiv.) was added to the filtrate and the reaction mixture was stirred for 1.5 h at 41 °C. After removal of all the acetonitrile by rotary evaporation, the residue was suspended in a mixture of dioxane (20 mL) and 4 N HCl (6 mL) and stirred for 1 h at 0 °C. All solvent was removed by rotary evaporation and the residue dried under vacuum. The obtained solid was dissolved in water (100 mL), neutralized with 2 M NaOH and purified by ion exchange chromatography (Sephadex CM-50) with an NaCl gradient in aqueous phosphate buffer (0.6 mM, pH = 7.2). A first band was obtained at 10 mM NaCl which contained traces of $[Ru(bipy)_2(m\text{-}OH)]^{2+}$. The product was eluted with 80 mM NaCl. Rotary evaporation to dryness afforded an orange solid which was suspended in a minimum volume of methanol. The suspension was filtered to remove insoluble salts, all methanol stripped by rotary evaporation and the resulting red solid dried in vacuo.

The crude products were dissolved in water (20 mL), precipitated with a 1.5-fold excess of NH_4PF_6 in water (1 mL) and stirred for 1 h at room temp. HPF_6 (60%, 1.5 equiv.) was added to yield the compounds in their fully protonated form. After 10 min. the brown-orange precipitate was isolated by filtration, washed with cold 0.1 M HPF_6 (3 × 5 mL) and dried in a vacuum desiccator over silica gel.

1b: Yield: 890 mg (74%). − ^{1}H NMR (300 MHz, CD_3OD): δ = 2.58 (s, 3 H, m4′-CH_3), 3.22 (t, 2 H, $CH_2CH_2NH_3^+$), 3.73 (t, 2 H, $CH_2CH_2NH_3^+$), 7.34 (d, 1 H, m5′), 7.47 (m, 4 H, b5), 7.62 (d, 1 H, m5), 7.79 (m, 5 H, 4 × b6, m6′), 7.94 (d, 1 H, m6), 8.09 (m, 4 H, b4), 8.64 (m, 5 H, 4 ×b3, m3′), 8.95 (s, 1 H, m3). − IR (KBr pellets, cm^{-1}): $\tilde{\nu}$ = 3080 (m), 2926 (m), 1657 (m), 1543 (m), 1466 (m), 1449 (m), 1311 (m), 842 (vs, PF_6^-), 765 (s), 559 (s). − UV/Vis (H_2O): λ_{max} (lg ε, M^{-1} cm^{-1}) = 456 (4.24), 288 (4.95), 245 nm (4.44). − FAB$^+$ (*m*-NBA): *m*/*z* = 961 [$M^+ - PF_6^-$], 815 [$M^+ - 2\ PF_6^-$]. − $C_{34}H_{33}F_{18}N_8OP_3Ru{\cdot}H_2O$ (1105.6 + 18): calcd. Methods: Steady state luminescence spectra were recorded in deoxygenated demineralized water with a Perkin−Elmer LS 50B spectrofluorimeter equipped with a red-sensitive Hamamatsu R928 photomultiplier tube. 10 μM solutions of the complexes at different pH values were used and the emission spectra were corrected for imperfections of the instrument.

The emission and NMR titration curves for $[Ru(bipy)_2\{m\text{-}CONH(CH_2)_nNH_3^+\}](PF_6)_3$ **1b−4b** were obtained as described previously.[19]
