Emission lifetimes were measured following excitation of the sample with a laser pulse at 450 nm as delivered by a Nd-YAG laser (B.M. Industries, 5021 DNS/DPS 10, λ = 1064 nm, harmonic generation of 532, 355 and 266 nm, respectively, laser pulse with $\tau_L \approx 6$ ns, beam diameter $d = 7$ mm and maximal repetition rate $f = 10$ Hz, laser pulse energy E_L at the location of the sample ≈ 1 mJ) coupled with an optical parametrical oscillator (OPO, B.M. Industries, OP 901) for generation of the excitation wavelength. Time-resolved detection of the luminescence of the sample after laser excitation was done with a photomultiplier tube in combination with a monochromator (λ_{em} = 630 nm, time resolution 250 ns and 20 ns). The signal of the photomultiplier was read out by a digital storage oscilloscope (DSO, Gould 4072) and transferred to a personal computer for processing, storage and output. All measurements were made with samples previously deoxygenated by purging with nitrogen. The complex concentration was 10 μM in all cases.

Cyclic voltammetry was performed with a PAR potentiostat 263 using a three-electrode cell with glassy carbon working, Ag/AgCl reference and Pt counter electrodes. Deoxygenated acetonitrile solutions of the complexes containing $TBABF_4$ (10^{-1} M) as supporting electrolyte were used. $E_{1/2}$ values were calculated from half the difference between E_P values for the anodic and cathodic waves from cyclic voltammograms. The ferrocene-ferrocenium couple was observed at 0.45 V (ΔE_P = 88 mV) in acetonitrile under the measurement conditions.

Construction of Various Supramolecules by π−π Interactions: Self-Assembly of Nickel(II) Macrocyclic Complexes Containing Pyridine Pendant Arms with Bidentate Ligands

Kil Sik Min[a] and Myunghyun Paik Suh*[a]

Keywords: Macrocyclic ligands / Nickel / Self-assembly / π−π interactions / Supramolecular chemistry

The supramolecular compounds, $[Ni(C_{20}H_{32}N_8)(en)](ClO_4)_2 \cdot 2\,H_2O$ (**1**), $[Ni(C_{20}H_{32}N_8)(isonicotinate)_2]$ (**2**), and $[Ni(C_{20}H_{32}N_8)(BQDC)] \cdot 3\,H_2O$ (**3**), have been constructed by the self-assembly of a nickel(II) macrocyclic complex containing pyridyl pendant rings, $[Ni(C_{20}H_{32}N_8)](ClO_4)_2 \cdot 2\,H_2O$, with ethylenediamine (hereafter noted en), isonicotinic acid, and potassium 2,2′-biquinoline-4,4′-dicarboxylate, ($K_2BQDC \cdot 3\,H_2O$), respectively, in $MeCN/H_2O$. The X-ray crystal structure of **1** indicates that one en coordinates a nickel(II) macrocyclic complex to form a folded macrocyclic complex, which ends up with a stacking dimer via C–H···π and offset face-to-face π–π interactions between the pyridine pendant groups. The X-ray crystal structure of **2** indicates that two isonicotinate ions coordinate a nickel(II) macrocyclic complex at the axial positions and the pyridine groups of the coordinated isonicotinates are involved in offset face-to-face π–π interactions, which gives rise to a 1D chain. The 1D chains are linked together via the offset face-to-face π–π interactions between the pyridine groups of the macrocycle to generate a 2D network. The X-ray crystal structure of **3** indicates that each $BQDC^{2-}$ ion coordinates two nickel(II) macrocyclic complexes and each nickel(II) macrocyclic unit binds two $BQDC^{2-}$ ions at the axial positions to form a 1D chain. The 1D chains experience the intramolecular hydrogen bonding as well as the interchain offset face-to-face π–π interactions between the pyridyl pendant rings of the macrocycle and the $BQDC^{2-}$ ions, which gives rise to a 2D sheet. Between the 2D sheets herringbone π–π interactions exist, which results in a 3D framework.

Introduction

Self-assembly of organic molecules and metal-ion building blocks may yield a new generation of multidimensional supramolecular networks. In the assembly of the supramolecules, hydrogen bonding,[1] π−π stacking interaction,[2] and C−H···π interaction[3], besides the metal−ligand coordination, are utilized to induce intermolecular interactions.[4] In particular, supramolecules built by noncovalent interactions between aromatic rings are of great importance because of the potential applications for molecular recognition,[5] catalysis,[6] stabilizing protein structure,[7] and molecular devices.[8] To become a new class of solid materials, the supramolecules should be insoluble and the frameworks should be maintained, even after the removal of the guest molecules or restored upon reintroduction of the guest molecules. For this purpose, extensive intermolecular interactions, hopefully multidimensional ones, should exist in the solid. In particular, the control of dimensionality of the supramolecules is a challenging subject in the self-assembly since the ancillary ligation by solvent or anion may result in low dimensionality.

To obtain insoluble supramolecules which are constructed by the extensive π−π stacking interactions as well as the metal−ligand coordination, we have employed in the self-assembly the nickel(II) macrocyclic complex containing pyridine pendants (**A**) as a metal building block and the bidentate ligands such as en, isonicotinate, and 2,2′-biquinoline-4,4′-dicarboxylate ($BQDC^{2-}$) as the organic building blocks (Figure 1). We have obtained a dimer $[Ni(C_{20}H_{32}N_8)(en)](ClO_4)_2 \cdot 2\,H_2O$ (**1**), a 2D sheet $[Ni(C_{20}H_{32}N_8)(isonicotinate)_2]$ (**2**), and a 3D network $[Ni(C_{20}H_{32}N_8)(BQDC)] \cdot 3\,H_2O$ (**3**), respectively, from the self-assembly. Here, we report X-ray crystal structures and properties of these supramolecules.

Results and Discussion

Properties and X-ray Crystal Structure of $[Ni(C_{20}H_{32}N_8)(en)](ClO_4)_2 \cdot 2\,H_2O$ (1)

Compound **1** was prepared in $MeCN/H_2O$ by the self-assembly of nickel(II) macrocyclic complex **A** with en. It is soluble in DMF, DMSO, and $MeNO_2$/MeOH. The infrared spectrum (Nujol mull) shows $\nu_{C=N}$ of pyridine pendant rings at 1605 cm^{-1}, ν_{NH} of the primary amines of en at 3335 and 3270 cm^{-1}, and ν_{NH} of the secondary amines of macrocycle at 3182 cm^{-1}. The value of molar conductance (Λ_M) measured in DMSO is 70 $\Omega^{-1}cm^2mol^{-1}$, which corresponds to a 1:2 electrolyte.[9] The electronic absorption spectrum shows a d−d transition band at 532 nm (ε = 9), which corresponds to the characteristic chromophore of a nickel(II) ion coordinated with an N_4 macrocycle and an N_2 bidentate ligand.[10]

An ORTEP drawing of **1** is shown in Figure 2a and the selected bond lengths and angles are listed in Table 1. The nickel(II) ion displays distorted octahedral coordination geometry by coordination with the four secondary amine nitrogen atoms of the macrocycle in a folded conformation and the two nitrogen atoms of en in the *cis* positions. The average Ni−N bond length is 2.136(1) Å, which is longer than that for octahedral nickel(II) complex coordinated with N_4O_2 donors.[11] In the structure, one pyridine pendant group of the macrocyclic complex experiences C−H···π interaction[3] as well as offset face-to-face π−π interaction[2,12] with a pyridine pendant group belonging to a neighboring macrocyclic complex, which leads to a stacked dimer (Figure 2b). For the C−H···π interaction, the distance between the centroid of the pyridine pendant ring and the nearest carbon atom of the pendant group is 3.579 Å (H11A···centroid 2.699 Å, C11−H11A···centroid 159.4°).[13] For the π−π stacking interaction, the interplanar separation of the aromatic rings is 3.63−3.65 Å (centroid···centroid 4.741 Å) and the dihedral angle between the ring planes is 0.0°. The lattice water molecules form hydrogen bonds with the nitrogen atoms of the pyridine pendant groups: O9···N9 2.875(5) Å, O10···N10 2.789(5) Å. In addition, the oxygen atoms of the perchlorate anion form hydrogen bonds with a secondary amine of the macrocycle [O8···N4($-x$ + 1, $-y$ + 1, $-z$ + 1) 3.172(5) Å, O8−H4−N4 171.2°] and the primary amines of en [O3···N7($-x$, $-y$ + 1, $-z$) 3.155(6) Å, O3−H7A−N7 162.1°; O1···N8(x, y − 1, z) 3.202(6) Å, O1−H8B−N8 170.2°].

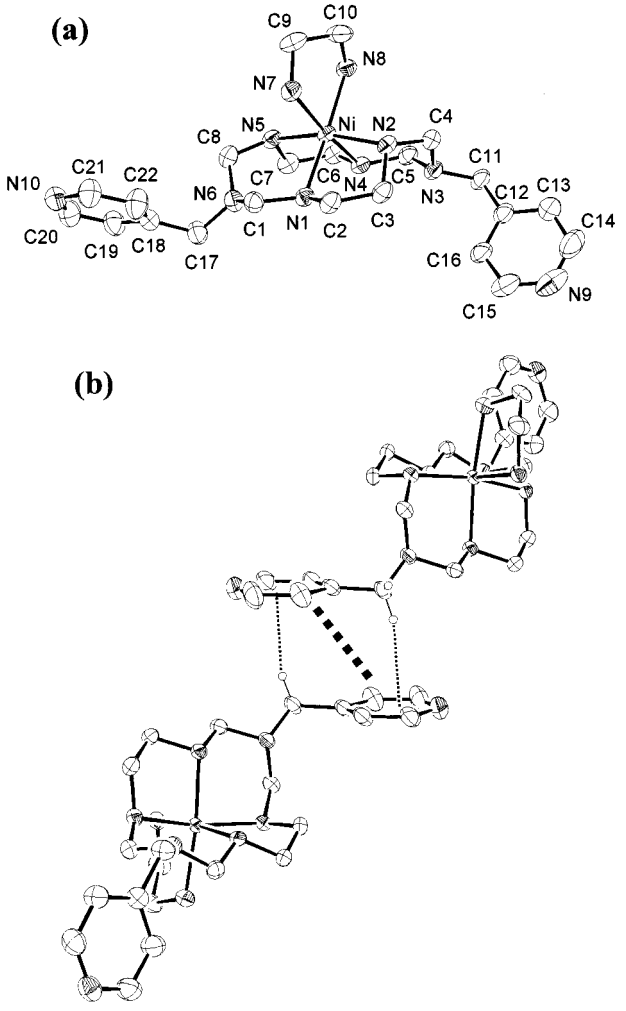

Figure 2. (a) ORTEP drawing of **1** with atomic numbering scheme; the atoms are represented by 40% probable thermal ellipsoids; (b) perspective view of **1**, showing a dimer; the C−H···π interactions are indicated as •••; the offset face-to-face π−π interaction between pyridine groups leading to a dimer is indicated as ■■■

Properties and X-ray Crystal Structure of [Ni($C_{20}H_{32}N_8$)(isonicotinate)$_2$] (2)

Compound **2** was prepared in MeCN/H_2O by the self-assembly of nickel(II) macrocyclic complex **A** with isonicotinate. It is insoluble in any solvents. The infrared spectrum (Nujol mull) shows $\nu_{C=N}$ of pyridine pendant groups at 1596 cm^{-1}, $\nu_{C=O}$ of the carboxylate groups coordinating the macrocyclic complex at 1547 cm^{-1}, and ν_{NH} of the secondary amines of macrocycle at 3213 and 3140 cm^{-1}. Two split secondary amine peaks of the nickel(II) complex indicate that the compound has two kinds of secondary amines, which is attributed to the hydrogen bonding interactions of the two secondary amines of the macrocycle as revealed by the X-ray crystal structure. The diffuse reflectance spectrum shows maximum absorption at 510 nm, which corresponds to the characteristic chromophore for the nickel(II) ion coordinated with N_4O_2 donors.[10]

An ORTEP drawing of **2** is shown in Figure 3a and the selected bond lengths and angles are listed in Table 1. The coordination geometry around the nickel(II) ion is a tetragonally distorted octahedron in which the nickel(II) ion is coordinated with the four secondary amine nitrogen atoms of the macrocycle in the square-planar fashion and two oxygen atoms from two isonicotinate ions at the axial sites. The average Ni−N and Ni−O bond lengths are 2.053(2) and 2.130(3) Å, respectively. All pyridine groups of the isonicotinate ions coordinating nickel(II) ions are involved in offset face-to-face π−π interactions by themselves (centroid···centroid 3.673 Å),[12] which leads to a supramolecular 1D polymer propagating along the *c* axis (Figure 3b). The interplanar separation and the offset angle between the ring planes of isonicotinate ions are 3.46−3.47 Å and 11.2°, respectively. Within a 1D chain, the free carbonyl oxygen atom of the coordinated carboxylate ion forms an intramolecular hydrogen bond with the secondary amine of the macrocycle [O2···N2 2.883(6) Å, O2−H2−N2 155.6°]. Therefore, two C−O bond lengths of the carboxylate group are not significantly different although one is coordinated [1.247(8) Å] and the other is uncoordinated [1.255(8) Å] to the nickel(II) ion. The 1D polymers are linked together via offset face-to-face π−π interactions between the pyridine rings of the macrocycle, which leads to a 2D network extending along the [1$\bar{1}$0] plane (Figure 3c). The pyridine rings are positioned completely parallel to each other with the dihedral angle of 0.0°. The intercentroid distance and the offset angle between the ring planes are 4.847 Å and 47.6°, respectively.

Properties and X-ray Crystal Structure of [Ni($C_{20}H_{32}N_8$)(BQDC)] · 3 H_2O (3)

Compound **3** was prepared in MeCN/H_2O by the self-assembly of nickel(II) macrocyclic complex **A** with 2,2′-biquinoline-4,4′-dicarboxylate ($BQDC^{2-}$). It is stable and does not loose guest water molecules upon exposure to the atmosphere. The compound is insoluble in any solvents. The infrared spectrum (Nujol mull) of **3** shows ν_{NH} of the secondary amines of macrocycle at 3276 and 3181 cm^{-1}, $\nu_{C=N}$ of pyridine pendant groups at 1600 cm^{-1}, and $\nu_{C=O}$ of the carboxylate groups of $BQDC^{2-}$ at 1579 cm^{-1}. Two split secondary amine peaks of the nickel(II) complex indicate that the macrocycle has two kinds of secondary amines due to the hydrogen bonding interactions, which is revealed by the X-ray crystal structure. The diffuse reflectance spectrum shows maximum absorption at 502 nm, which corresponds to the characteristic chromophore for the nickel(II) ion coordinated with N_4O_2 donors.[10] The TGA trace of **3** (Figure S1, Supporting Information) shows a weight loss of 5.65% at 80 °C, corresponding to the loss of three guest water molecules per unit formula. No chemical decomposition was observed up to 250 °C.

An ORTEP drawing of **3** is shown in Figure 4a and the selected bond lengths and angles are listed in Table 1. Each nickel(II) ion of macrocyclic complex **A** is coordinated by two carboxylate oxygen atoms of $BQDC^{2-}$ ion at the axial positions as well as the N_4 macrocycle to display a distorted octahedral coordination geometry. Since each $BQDC^{2-}$ ion binds two metal ions in an *exo*-bidentate mode, **3** becomes a linear coordination polymer (Figure 4b). The average Ni−N and Ni−O bond lengths are 2.064(3) and 2.110(3) Å, respectively. The aromatic ring of $BQDC^{2-}$ ion is tilted [dihedral angle = 67.5(2)°] with respect to the square coordination plane of the macrocycle. The $BQDC^{2-}$ bridging ligand is not planar since the dihedral angle between the carboxylate group and the aromatic ring of $BQDC^{2-}$ ion is 30.6(3)°. The dihedral angle between the carboxylate plane and the macrocyclic coordination plane involving nickel atom is 87.4(6)°. Within a 1D chain, intramolecular hydrogen bonding interactions exist between the uncoordinated oxygen atoms of carboxylate and the secondary amines of the macrocycle to form stable six-membered rings [O2···N1 2.915(7) Å, O2−H1−N1 150.7°]. Compound **3** has two kinds of 1D chains. The linear chains are linked by the offset face-to-face π−π interactions[12] between the aromatic groups of the $BQDC^{2-}$ ions belonging to a chain, and the pyridine pendant groups of the macrocycle belonging to the adjacent linear chains, which leads to a 2D network extending along the (002) plane (Figure 4c). The interplanar separation and the dihedral angle between the aromatic ring of $BQDC^{2-}$ ion and the pyridine pendant group of macrocyclic complex are 3.32−3.55 Å and 5.87°, respectively. Between the layers, there exist the herringbone π−π interactions between the $BQDC^{2-}$ ion and the pyridine pendant ring of macrocycle, which gives rise to a 3D network (Figure 4d). The distance between the centroids is 5.237 Å, and the dihedral angle between the pendant pyridine group and the aromatic ring of $BQDC^{2-}$ ion is 75.1(1)°. The separation between the layers is 10.697 Å. The shortest Ni···Ni distance within a linear chain is 13.451(5) Å and that between the linear chains is 12.968(4) Å. The lattice water molecules are located in the cavities created by the packed chains. The void volume of cavities per unit cell is 648 Å^3 (15.4%) as estimated by PLATON.[14] In addition, the lattice water molecules form hydrogen bonds with the uncoor-

dinated carboxylate oxygen atom [O2···O3($-1 + x$, y, z) = 2.757(8) Å], with the pyridine nitrogen atom of the macrocycle [O3···N4($1 + x$, $-0.5 - y$, $0.5 + z$) = 3.041(11) Å], and with the other lattice water molecule (O3···O4 = 2.754(7) Å).

Conclusion

We have constructed several supramolecules having structures of dimer, 2D sheet, and 3D framework by the self-assembly of a nickel(II) macrocyclic complex containing pyridyl pendant rings (**A**) with organic bidentate ligands such as en, isonicotinate, and 2,2′-biquinoline-4,4′-dicarboxylate, respectively. The supramolecules are assembled by the π−π stacking interactions involving aromatic rings of the organic ligand and the pyridine pendant groups attached to the macrocyclic ligand.

Experimental Section

General: All chemicals and solvents used in the synthesis were of reagent grade and used without further purification. − Infrared spectra were recorded with a Perkin−Elmer 2000 FT-IR spectrophotometer. − Elemental analyses were performed by the analytical laboratory of Seoul National University. − UV/Vis diffuse reflectance spectra were recorded with a Cary 300 Bio UV/Vis spectrophotometer. − Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) were performed at a scan rate of 5 °C/min using a DuPont TGA 2050 TA instrument and a DuPont DSC 2100 TA instrument, respectively.

Safety Note: *Although we have experienced no problem with the compounds reported in this work, perchlorate salts of metal complexes with organic ligands are often explosive and should be handled with great caution!*

$[Ni(C_{20}H_{32}N_8)](ClO_4)_2 \cdot 2\,H_2O$ (A):[15] To a stirred methanol solution (75 mL) of $Ni(OAc)_2 \cdot 4\,H_2O$ (12.4 g, 0.05 mol), were slowly added ethylenediamine (6.8 mL, 0.10 mol), paraformaldehyde (6.0 g, 0.20 mol), and 4-(aminomethyl)pyridine (10.8 g, 0.10 mol). The mixture was heated at reflux for 24 h. The solution was filtered while hot and the filtrate was concentrated to ca. 1/5 of the original volume. $HClO_4$ (60%, 20 mL) was added to the yellow-brown solution and the solution was allowed to stand in a refrigerator until yellow crystals of $[Ni(L + 2\,H)](ClO_4)_4 \cdot 2\,H_2O$ formed, these were filtered off, washed with methanol, and dried in air. Yield: 35%. To an MeCN suspension (40 mL) of $[Ni(L + 2\,H)](ClO_4)_4 \cdot 2\,H_2O$ (2.5 g), was added an excess amount of triethylamine (2 mL). The complex went into the solution and yellow crystals of $[Ni(L)](ClO_4)_2 \cdot 2\,H_2O$ (**A**) formed in a few minutes. The crystals were filtered off, washed with water, and dried in air. − FT IR (Nujol mull, cm^{-1}): $\tilde{\nu}$ = 3590 (s, br.), 3195 (s), 1650 (m), 1605 (s), 1565 (m), 1100 (s), 625 (s). − UV/Vis ($MeNO_2$): λ_{max} [nm] (ε [M^{-1} cm^{-1}]) = 450 (68). − $C_{20}H_{36}Cl_2N_8NiO_{10}$ (678.2): calcd. C 35.42, H 5.35, N 16.52; found C 35.24, H 4.93, N 16.59.

$[Ni(C_{20}H_{32}N_8)(en)](ClO_4)_2 \cdot 2\,H_2O$ (1): To an MeCN/H_2O (v/v; 1:1, 20 mL) solution of **A** (0.50 g, 0.74 mmol), was added dropwise an MeCN solution (5 mL) of ethylenediamine (0.044 g, 0.74 mmol) at room temperature. The color of the solution turned from yellow to purple. The solution was allowed to stand at room temperature. The purple crystals formed, which were filtered off, washed with MeOH, and dried in air. Yield: 83%. − FT IR (Nujol mull, cm^{-1}): $\tilde{\nu}$ = 3650 (s), 3335 (s), 3270 (s), 3182 (s), 1605 (s), 1565 (s), 1100 (s). − UV/Vis (DMSO): λ_{max} [nm] (ε [M^{-1} cm^{-1}]) = 339 (14), 532 (9). − Molar conductance (DMSO): Λ_M [Ω^{-1} cm^2 mol^{-1}] = 70. − $C_{22}H_{44}Cl_2N_{10}NiO_{10}$ (738.3): calcd. C 35.79, H 6.01, N 18.97; found C 35.38, H 5.62, N 19.27.

$[Ni(C_{20}H_{32}N_8)(isonicotinate)_2]$ (2): To an MeCN/H_2O (v/v; 1:1, 20 mL) solution of **A** (0.50 g, 0.74 mmol), was added dropwise an MeCN solution (10 mL) containing isonicotinic acid (0.18 g, 1.48 mmol) and excess triethylamine (0.30 g, 2.96 mmol) at room temperature. The color of the solution turned from yellow to pale pink. The solution was allowed to stand at room temperature. The pale pink crystals formed, which were filtered off, washed with water, and dried in air. Yield: 85%. − FT IR (Nujol mull, cm^{-1}): $\tilde{\nu}$ = 3213 (s), 3140 (s), 1596 (s), 1565 (s), 1547 (s). − UV/Vis (diffuse reflectance): λ_{max} [nm] = 260, 510, 650. − $C_{32}H_{40}N_{10}NiO_4$ (687.4): calcd. C 55.91, H 5.87, N 20.38; found C 55.24, H 5.87, N 20.58.

$[Ni(C_{20}H_{32}N_8)(BQDC)] \cdot 3\,H_2O$ (3): To an MeCN/H_2O (v/v; 1:1, 20 mL) solution of **A** (0.50 g, 0.74 mmol), was added dropwise an aqueous solution (10 mL) containing potassium 2,2′-biquinoline-4,4′-dicarboxylate ($K_2BQDC \cdot 3\,H_2O$) (0.35 g, 0.74 mmol) at room temperature. The color of the solution turned from yellow to pale yellow. The solution was allowed to stand at room temperature. The pale yellow crystals formed, which were filtered off, washed with water, and dried in air. Yield: 79%. − FT IR (Nujol mull, cm^{-1}): $\tilde{\nu}$ = 3392 (s), 3277 (s), 3183 (s), 3074 (m), 1600 (s), 1579 (s), 1546 (m), 1492 (m), 1026 (s). − UV/Vis (diffuse reflectance): λ_{max} [nm] = 257, 334, 502, 682. − $C_{40}H_{42}N_{10}NiO_7$ (833.5): calcd. C 57.22, H 5.76, N 16.68; found C 56.41, H 5.68, N 16.76.

X-ray Diffraction Measurements: Single crystals of **1** (0.5 × 0.5 × 0.2 mm), **2** (0.2 × 0.2 × 0.06 mm), and **3** (0.6 × 0.7 × 0.08 mm) were mounted on an Enraf−Nonius CAD4 diffractometer. The unit cell parameters were determined from 25 machine-centered reflections with 22° ≤ 2θ ≤ 28° for **1**, 19° ≤ 2θ ≤ 29° for **2**, and 22° ≤ 2θ ≤ 28° for **3**). Intensities were collected with graphite-monochromated Mo-K_α radiation, using the ω-2θ scan mode. For **1**, among 5835 reflections measured in the range 3.30° ≤ 2θ ≤ 49.96°, 4460 were assumed to be observed [$F > 4\sigma(F)$]. For **2**, among 2206 reflections measured in the range 3.84° ≤ 2θ ≤ 50.16°, 1278 were assumed to be observed [$F > 4\sigma(F)$]. For **3**, among 3404 reflections measured in the range 3.80° ≤ 2θ ≤ 49.90°, 1322 were assumed to be observed [$F > 4\sigma(F)$]. Three standard reflections were measured every 2 h as orientation and intensity control and no significant intensity decay was observed. Lorentz and polarization corrections were made. No absorption correction was made. The crystal structure was solved by direct methods[16] for **1** and **3** and by Patterson synthesis[16] for **2**, and refined by full-matrix least-squares methods using the SHELXL97 computer program.[17] For **1**−**3**, the positions of all non-hydrogen atoms were refined with anisotropic displacement factors. In **1**, all hydrogen atoms were located and refined with isotropic thermal parameters except those of the lattice water molecules. In **2** and **3**, all hydrogen atoms were allowed to ride on their bonded atoms with the isotropic displacement factors fixed with values of 1.2 times those of the bonded atoms, except those of the lattice water molecules. The crystallographic data of **1**−**3** are summarized in Table 2. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-143549 to -143551. Copies of the data can be obtained free of

An Accidental Discovery of a New Mixed-Valent Iodine Compound – Crystal Structure of Difluoroiodato(V) Iodine(III) Dichloride [$Cl_2IOI(O)F_2$]

Rolf Minkwitz*[a] and Michael Berkei[a]

Keywords: Iodine / Mixed-valent compounds / Vibrational spectroscopy / Structure elucidation / Halogens

The crystal structure of the novel iodine compound $Cl_2IOI(O)F_2$ is described. $Cl_2IOI(O)F_2$ contains iodine in two different oxidation states (III) and (V) and can formally be described as $ICl_2^+IF_2O_2^-$, linked by an unsymmetrical, nonlinear I–O–I bridge, with I–O bond lengths of 1.84(1) Å and 2.32(1) Å, and a bond angle of 122.5(5)°. It was accidentally obtained by the uncontrolled reaction between CF_3I, CF_3OCl, CF_2O, and Cl_2 at –70 °C over a period of about six months and finally two days at room temperature. $Cl_2IOI(O)F_2$ crystallises in the monoclinic space group $P2_1/c$ with four formula units per unit cell with the dimensions a = 12.910(1), b = 6.987(1), c = 7.550(1) Å, and β = 94.890(1)°. The molecule was additionally characterised by its Raman and IR spectra.

Introduction

Compounds containing iodine in different oxidation states are rather rare, and in most cases limited to polyiodide anions and cations. In neutral compounds, comproportionation to give the more stable oxidation state often takes place. An example of a stable mixed-valent iodine compound is $I(OSO_2F)_2I$.[1] It formally contains an iodine(III) and an iodide(−I). The I−I bond has a length of 2.676(1) Å and shows no ionic character, as might be expected.[1] Another example was reported by Kraft and Jansen in 1996.[2] The authors described the synthesis and characterisation of iodine trioxide I_4O_{12} which contains iodine in the oxidation states (V) and (VII).[2] In 1992, Rehr and Jansen determined the crystal structure of $(IO_2)_3HSO_4$ and reported a complex iodoxo polycation with iodine(III) and (V).[3] It seems that oxygen stabilises these compounds by secondary bonding, so that the tendency to comproportionation becomes negligible.

In this work we report the accidental preparation and crystal structure of difluoroiodato(V) iodine(III) dichloride [$Cl_2IOI(O)F_2$], a singular example of an iodine oxofluoride chloride with mixed-valent iodine atoms.

Results and Discussion

Formation of $Cl_2IOI(O)F_2$

$Cl_2IOI(O)F_2$ was accidentally obtained by the uncontrolled reaction between CF_3I, CF_3OCl, CF_2O, and Cl_2. These compounds were stored in a closed Pyrex ampoule at −70 °C over a period of about six months. After this time the formation of a yellow-orange solid beneath a yellow liquid was observed. The solid was thought to be I_2Cl_6 and so the ampoule was broken and introduced into an outlet at room temperature. Two days later, orange and red crystals were observed in the ampoule, which also contained a yellow gas. The ampoule was then stored under nitrogen at −70 °C, because on exposure to air the crystals were observed to decompose.

All solids were characterised by single crystal X-ray diffraction. The red solid was identified as α-ICl and the orange one as a mixture of I_2Cl_6 and $Cl_2IOI(O)F_2$. We think that the formation of $Cl_2IOI(O)F_2$ involves a complex mechanism, which is still unknown. Bearing in mind that the reaction between CF_3I and excess CF_3OCl yields IF_5, it is likely that IF_5 or a related iodine(V) oxofluoride is one possible intermediate in the formation of $Cl_2IOI(O)F_2$.[4−6] Attempts to repeat the synthesis of $Cl_2IOI(O)F_2$ failed. We decided to try to obtain an X-ray crystal structure and measure the Raman and IR spectra first, and used all the available material. Because of the small quantity of $Cl_2IOI(O)F_2$ obtained we were not able to perform further investigations.

Crystal Structure of $Cl_2IOI(O)F_2$

$Cl_2IOI(O)F_2$ crystallises in the monoclinic system in the space group $P2_1/c$ with a = 12.910(1) Å, b = 6.987(1) Å, c = 7.550(1) Å, β = 94.890(1)°, and four formula units per unit cell. The crystal structure was solved by direct methods and successive difference Fourier syntheses. For refinement full-matrix least-squares methods were applied. A final refinement with anisotropic thermal parameters gave values of $R1$ = 0.0558 and $wR2$ = 0.1297. For the data reduction, structure solution, and refinement, programs in the SHELXTL package, PLATON, MISSYM, and PARST were used.[7−11] The crystal data are summarised in Table 1.

$Cl_2IOI(O)F_2$ can be described as two pseudo-trigonal bipyramids linked by one edge over an unsymmetrical I−O−I bridge with lengths of I(1)−O(1) 1.84(1) Å, I(2)−O(1) 2.32(1) Å and an angle I(1)−O(1)−I(2) of 122.5(5)° (Figure 1). The bridging I(2)−O(1) bond is about 20% longer than the sum of the covalent radii (1.94 Å) and

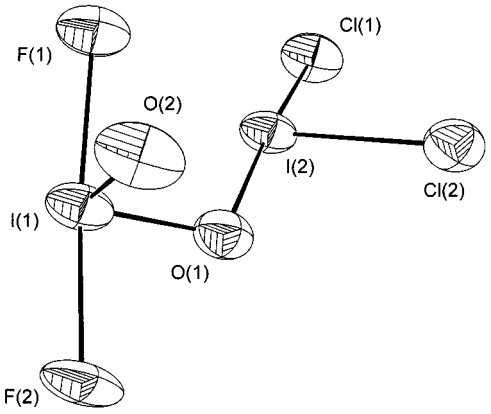

Figure 1. View of a $Cl_2IOI(O)F_2$ molecule; thermal ellipsoids are drawn at the 50% level

34% below the sum of the van der Waals radii (3.50 Å), as published by Bondi.[12] This secondary bond results in a distorted square planar environment around iodine.[13] We think that this description for $Cl_2IOI(O)F_2$ is more reasonable than formulating it as $ICl_2^+IO_2F_2^-$. The molecule contains iodine in two different oxidation states (III) and (V). The axial positions in the iodine(V) group are occupied by fluorine and the equatorial ones by a lone pair, a double bond oxygen, and the bridging oxygen.[14] In agreement with the Gillespie-Nyholm model of molecular geometry, the iodine(III) unit contains chlorine and oxygen in the apical positions, and one chlorine and two lone pairs in the equatorial plane.[15,16] Bond lengths and selected angles for $Cl_2IOI(O)F_2$ are listed in Table 2.

Table 2. Bond lengths [Å] and angles [°] of $Cl_2IOI(O)F_2$ and lengths [Å] and angles [°] of selected intermolecular contacts[a]

I(1)−O(1)	1.84(1)	O(1)−I(1)−O(2)	100.7(5)
I(1)−O(2)	1.81(1)	O(1)−I(1)−F(1)	90.1(4)
I(1)−F(1)	1.969(8)	O(1)−I(1)−F(2)	88.6(5)
I(1)−F(2)	1.917(8)	O(2)−I(1)−F(1)	85.2(4)
I(2)−Cl(1)	2.343(4)	O(2)−I(1)−F(2)	87.4(4)
I(2)−Cl(2)	2.352(5)	F(1)−I(1)−F(2)	172.2(4)
I(2)−O(1)	2.32(1)	Cl(1)−I(2)−Cl(2)	94.1(2)
		O(1)−I(1)−Cl(1)	175.5(3)
I(1)···F(1a)	3.038(8)	O(1)−I(1)−Cl(2)	84.2(3)

I(2)···O(1a)	3.36(1)	O(2)−I(1)−F(1a)	167.3(4)
I(2)···O(2a)	2.50(1)	O(2)−I(1)−F(1b)	117.7(4)
		O(2)−I(1)−F(2c)	115.9(5)
		Cl(2)−I(2)−O(1a)	127.1(2)
		Cl(2)−I(2)−O(2a)	166.0(3)

[a] Symmetry transformations: *a*: x, $1/2 - y$, $-1/2 + z$; *b*: $1 - x$, $1/2 + y$, $1/2 - z$; *c*: $1 - x$, $-1/2 + y$, $1/2 - z$; *d*: $1 - x$, $1 - y$, $1 - z$; *e*: x, $1/2 - y$, $1/2 + z$.

The I−F bonds have lengths of 1.969(8) and 1.917(8) Å and are comparable to those found in IF_3O [1.91(3) and 1.89(3) Å] and in $IF_2(O)OCH_3$ [1.929(3) and 1.964(3) Å].[17,18] The angle between iodine and the two fluorine atoms is 172.2(4)° and shows a difference from the ideal value of 180° due to the steric activity of the lone pair. In $Cl_2IOI(O)F_2$ there is an axial as well as an equatorial I−Cl bond, whose lengths of 2.343(4) and 2.352(5) Å are only slightly larger than the sum of the covalent radii (2.27 Å).[12] The I(2)−O(1) bond, with oxygen as the most electronegative ligand of I(2), has a length of 2.32 (1) Å and is significantly longer than the sum of the covalent radii of 1.94 Å, as published by Bondi.[12] This is in agreement with the principle reported by Varvoglis that, in iodine(III) compounds with axial ligands of different electronegativities, the distance between iodine and the more electronegative ligand is longer than the sum of the covalent radii, while the bond to the less electronegative ligand is comparable with the sum of covalent radii.[19] The bridging angle I(1)−O(1)−I(2) [122.5(5)°] is similar to those found in I_4O_{12} [102.1(4)−129.2(4)°] and $(IO_2)_3HSO_4$ [122.7(7)−133.4(9)°].[2,3]

The molecules are involved in a strong intermolecular linkage containing I−O and I−F contacts. Each I(1) of the iodine(V) unit has five intermolecular contacts, three I−F contacts with lengths between 3.038(8) and 3.259(9) Å, one I−O contact with a length of 3.32(1) Å, and one short I−O contact of 2.77(1) Å that shows along the I(1)−O(1) bond. A distorted octahedral environment for iodine results, similar to that in IF_5.[20] The lone pair occupies one position of the octahedron and four intermolecular contacts are arranged beside it, due to the tendency of the incoming lone pairs to avoid the domains of the other electrons in the valence shell of iodine. As expected, the iodine(III) atom I(2) undergoes only one very short intermolecular I−O contact with a length of 2.50(1) Å, about 1 Å below the sum of the van der Waals radii of 3.50 Å, which results in a

distorted square-planar environment around iodine.[12] The weak I(2)−O(1a) contact of 3.36(1) Å is probably caused by steric effects. All these contacts result in the formation of double layers stacked to the *a*-axis, with chlorine occupying the side positions (Figure 2). Between these layers no interactions below the sum of the van der Waals radii are found.

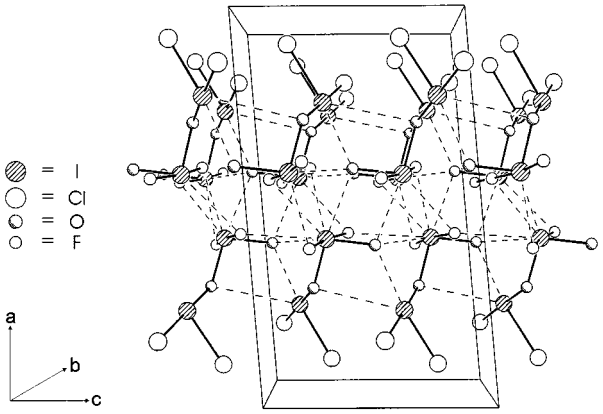

Figure 2. View of the unit cell of $Cl_2IOI(O)F_2$ in the *b*-orientation with a part of its environment; the molecules are arranged in double layers stacked on the *a*-axis and show a strong intermolecular linkage

Vibrational Spectra

The observed Raman and IR frequencies of $Cl_2IOI(O)F_2$ are summarised in Table 3 and the spectra are shown in Figure 3. The vibrational spectrum is assigned according to C_1 symmetry for $Cl_2IOI(O)F_2$, with 18 fundamental vibrations expected. The assignment has been made in comparison to known spectra of I_2Cl_6, ICl_2^+, IO_2F, IF_3O, $IO_2F_2^-$, and $(IO_2)_3HSO_4$.[21−23,3]

In the Raman spectrum, the ICl_2 stretching modes are the strongest lines and occur at 327 cm^{-1} (ν_{as} ICl_2) and 360 cm^{-1} (ν_s ICl_2). According to the relative intensities in the Raman and IR spectra, we have assigned the higher frequency to the symmetrical stretching mode. This is in agreement with the assignment for I_2Cl_6 (314 cm^{-1} ν_{as} ICl_2; 344 cm^{-1} ν_s ICl_2) and ICl_2^+ (364 cm^{-1} ν_{as} ICl_2; 371 cm^{-1} ν_s ICl_2).[21,22] The corresponding bending mode is observed at 144 cm^{-1}. The fundamental vibrations of the IF_2 group are assigned to the lines at 264 cm^{-1} (δ IF_2), 521 cm^{-1} (ν_s IF_2), and 537 cm^{-1} (ν_{as} IF_2). The stretching modes exhibit only weak intensities in the Raman spectrum, but they are observed in a typical range for axial IF_2 groups. For comparison, in KIO_2F_2 the I−F stretching modes are found at 472 and 434 cm^{-1} and in IF_3O at 515 and 550 cm^{-1}.[23] A similar behaviour is observed for the I−O stretching modes. In the Raman spectrum these have only low intensities but in the IR spectrum they are assigned to very strong bands. The stretching vibration of the I=O double bond is assigned to the bands at about 723−786 cm^{-1}, the stretching mode for the single bond I(1)−O(1) to the lines between 406 and 507 cm^{-1} and the secondary bond I(2)−O(1) to the line at 121 cm^{-1}. The complexity of the spectra in the range for the I−O stretching modes is typical for this kind of molecule and so the assignment can be made only tentatively.

Experimental Section

Caution! CF_3OCl is a highly reactive oxidising agent and potentially explosive when brought into contact with organic material. Avoid contact with CF_3OCl and the other compounds described in this paper because their hydrolysis leads to the formation of HF or HCl, which cause burns and in some cases irreparable damage. Safety precautions should be taken in using and handling these materials.

All synthetic work and sample handling was performed using a standard glass vacuum line and standard Schlenk techniques. Non-volatile materials were handled under dry nitrogen. $Cl_2IOI(O)F_2$ was obtained by the uncontrolled reaction between CF_3I, CF_3OCl, CF_2O, and Cl_2 as described above. We decided to obtain first X-ray, Raman and IR data and in the course of these studies the very small quantity of $Cl_2IOI(O)F_2$ was used up and we were not able to perform NMR spectroscopic or mass spectrometric measurements, or an elemental analysis.

The Raman spectra were recorded on a Jobin Yvon T64000 spectrometer using a Kr^+ laser (647.1 nm) from Spectra Physics. The spectra were obtained in a glass cell at room temperature.[24] Infrared spectra were recorded on a Bruker IFS 113v spectrophotometer. Spectra were obtained from a coated CsBr plate in a special IR cell.[25]

Single crystals were placed in Lindemann capillaries in a cooled stream of dry nitrogen at about −70 °C, and an X-ray diffraction study at −100 °C was carried out using a Nonius Kappa CCD diffractometer. 360 frames via ω-rotation and two times 100s per frame were measured. The crystal-to-detector distance was 3.1 cm. Crystal decay was monitored by repeating the initial frames at the end of data collection. Analysis of the duplicate reflections gave no indications of any decay.

Time-Dependent Solution Speciation of the Al^{III}–Citrate System: Potentiometric and NMR Studies

Andrea Lakatos,[a] István Bányai,[b] Patrick Decock,[c] and Tamás Kiss*[a]

Keywords: Aluminum / Citric acid / Oligomerizations / NMR spectroscopy

Time-dependent potentiometric and NMR spectroscopic measurements were carried out in the Al^{III}–citric acid system in an equimolar solution and at an excess of ligand in order to monitor the changes in speciation as a function of time. In fresh solutions, the mononuclear 1:1 species $[AlLH]^+$, $[AlL]$, $[AlLH_{-1}]^-$ and $[AlLH_{-2}]^{2-}$ and the 1:2 complexes $[AlL_2]^{3-}$, $[AlL_2H_{-1}]^{4-}$ and $[AlL_2H_{-2}]^{5-}$ are formed. In agreement with earlier findings (*Inorg. Chem.* **1988**, *27*, 2565), these complexes are converted to a large extent into a thermodynamically more stable trinuclear species as the solutions age. Depending on the composition of the initially formed mononuclear species, the formation of the trinuclear species is accompanied either by the consumption or by the liberation of hydroxide ions. NMR spectroscopy was used to confirm the considerable time dependence of the species distribution. The ^1H, ^{27}Al and ^{13}C NMR spectra indicated that at equilibrium the trinuclear species $[Al_3(LH_{-1})_3(OH)]^{4-}$ predominates in the pH range 4–7. Oligomerization of the mononuclear species takes place through at least one intermediate complex. At equilibrium, the ligand-exchange reactions between the trinuclear species, the mononuclear species and free citrate are slow on the NMR time scale.

Introduction

Citrate is one of the most extensively investigated ligands for Al^{III} in aqueous solution. The reason for this is that citrate is widely found in biological systems and in natural waters. As a powerful complexing agent, citrate may solubilize the neurotoxic Al^{III}, which prefers the coordination of oxygen donor containing ligands, thus permitting the absorption of Al^{III} from the environment to the human body.[1] Since citrate occurs at about 0.1 mM in blood plasma,[2] it can also be a good low molecular mass (l.m.m.) carrier of the absorbed Al^{III} in the blood stream.

Although the Al^{III}–citrate system has previously been studied by several techniques,[3–10] there are still contradictions in the proposed equilibrium model and binding modes of the complexes. The divergence is partly due to the numerous coordination possibilities and protonation states of the donor groups (citrate contains four potential donor groups, but only three can coordinate simultaneously to the same metal ion), and partly due to the rather slow oligomerization reactions that take place in solution. An early potentiometric study by Motekaitis and Martell led to a simple model involving only the mononuclear 1:1 species $[AlLH]^+$, $[AlL]$ and $[AlLH_{-1}]^-$, both in an equimolar solution and at an excess of citrate.[6] In contrast, Gregor and Powell suggested bis(complexes) as the predominant species at a ligand excess. Besides 1:1 complexes, they proposed the formation of $[AlL_2H]^{2-}$ and $[AlL_2]^{3-}$ in slightly acidic solutions and $[AlL_2H_{-1}]^{4-}$ and $[AlL_2H_{-2}]^{5-}$ in neutral and slightly alkaline solutions.[8] From these bis(complexes), $[AlL_2H_{-2}]^{5-}$ and $[AlL_2H_{-1}]^{4-}$ were recently isolated from slightly alkaline solutions as the first mononuclear Al^{III}–citrate complexes, and characterized by X-ray crystallography and NMR spectroscopy.[11,12] In a time-dependent potentiometric study, Öhman demonstrated that in an equimolar solution the monomeric species transform into trimeric complexes $[Al_3L_3H_{-4}]^{4-}$ and $[Al_3L_3H_{-7}]^{7-}$ in very slow processes.[10] One of these trimeric complexes was crystallized in the form of $[NH_4]_4[Al_3(LH_{-1})_3(OH)(H_2O)]$ from a neutral solution and was identified unambiguously and characterized in detail by ^1H, ^{13}C and ^{27}Al NMR spectroscopy and X-ray crystallography.[13]

Such time-dependent studies may furnish a more accurate speciation description of metal-ligand systems in biology, because thermodynamic equilibrium is never reached in biological fluids as a result of the continuous influx and efflux of the components. Thus, nonequilibrium models of metal–ligand interactions may provide more relevant information.[14]

In the present work, a time-dependent speciation study of the Al^{III}–citric acid system was made both under equimolar conditions and at an excess of citrate. The oligomerization reactions of the mononuclear species were followed by ^1H, ^{13}C and ^{27}Al NMR spectroscopy, and the formation of a trinuclear complex through intermediate species was clearly demonstrated.

Results and Discussion

Time-Dependent Potentiometric Measurements

Potentiometric titrations indicate an overlapping stepwise dissociation of three protons from the three carboxylic groups of the ligand. The protonation constants are reported in Table 1.

Table 1. Stability constants of proton (log K)and Al^{III} complexes (log β) of citric acid at 25 °C and I = 0.2 M (KCl)

	This work	log K[a] /log β Ref.[4] [b]	Ref.[8] [c]

[a] log K values are the logarithm of the stepwise protonation constants, which are numerically equal to the negative logarithm of the acidity constants, pK_a values, of the corresponding species; ±3 s.d. values are given in parentheses. – [b] I = 0.6 M (NaCl); T = 25 °C. – [c] I = 0.1 M (KCl); T = 25 °C. – [d] Average difference between the experimental and the calculated titration curves, expressed in mL of the titrant. – [e] See Experimental Section.

In the Al^{III}–citrate system data collection runs into difficulties because of a pronounced drift in pH due to the slow complexation reactions. Öhman and Sjöberg[4] reported equilibration requiring up to 6 h in slightly acidic solutions at low Al^{III}/citrate ratios. They demonstrated that this pH drift is due to the formation of the trinuclear species $[Al_3(LH_{-1})_3(OH)]^{4-}$ during the slow oligomerization process of the mononuclear complexes.[10] Gregor and Powel minimized this drift by working at Al^{III}/citrate ratios < 1:5. The equilibrium model found at such large excesses of ligand included only the mononuclear species $[AlLH]^{+}$, $[AlL]$, $[Al(HL)L]^{2-}$, $[AlL_2]^{3-}$, $[AlL_2H_{-1}]^{4-}$ and $[Al(LH_{-1})_2]^{5-}$. In earlier work,[19] a series of titrations were carried out at Al^{III}/citric acid ratios of 1:2, 1:3, 1:4 and 1:8. Evaluation of the titration curves obtained at high ligand excesses (ratios of 1:4 and 1:8) led to a model involving only mononuclear mono- and bis(complexes). However, when the titration curves for Al^{III}/citrate ratios > 1:4 were also included in the calculation, a much better fit was obtained if, besides the mononuclear complexes, the trinuclear species $[Al_3(LH_{-1})_3(OH)]^{4-}$ was also assumed. The stability constants obtained in this way, however, cannot be regarded as fully reliable, as equilibration was not definitely attained at each titration point in the pH range 5–7. Moreover, even a slight drift in the electrode response during the very long titration process (up to 4–6 h) may cause a significant error in pH, especially near the end of the titration, when the pH increases sharply (see Figure 2).

In order to acquire an accurate speciation description of the Al^{III}–citrate system in the equilibrium state even at a small ligand excess, and to obtain qualitative information concerning the kinetic route to true thermodynamic equilibrium, the "batch method" described in the Experimental Section was used instead of the normal titration procedure. Measurements were performed at Al^{III}/citrate ratios of 1:1 and 1:3 in the pH range 2.0–8.0 (Figure 1).

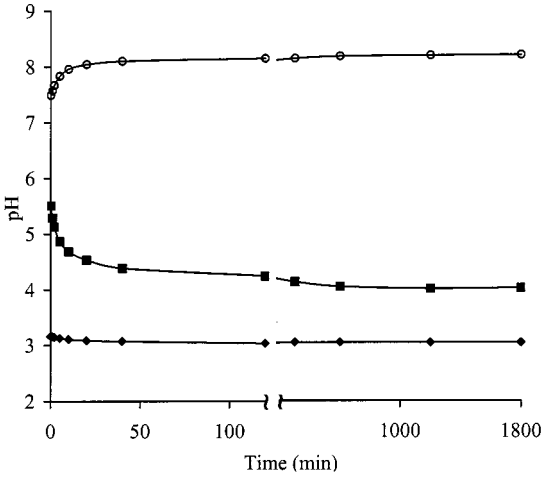

Figure 1. The change of pH as a function of time in solutions of the Al^{III}–citric acid system at a ratio 1:1, c_{Al} = 0.004 M, and at various starting pH values: (◆) 3.16, (■) 5.51, (○) 7.49

The time course of the pH changes of some selected batch solutions at different starting pH values is depicted in Figure 1. The pH changes are seen to be significant in the first 2 h; and complete equilibration can be attained in ca. 30 h. Interestingly, the direction of the pH change is dependent upon the starting pH; at pH < 6.5, the concentration of hydrogen ion increases with time, while above this pH it decreases. It has already been established[10] that this drift in pH is due to slow oligomerization reactions. Depending on the starting pH, the protonation state of the mononuclear complexes varies and their oligomerization may be accompanied by either the liberation or the consumption of protons (vide infra).

Titration curves created by using pH values relating to the same times are depicted in Figure 2. At a metal ion/ligand ratio of 1:1 the titration curves become steeper and steeper as the solution "ages". The differences between the consecutive curves are significant only in the early hours after mixing. At a metal/ligand ratio of 1:3, the differences between the titration curves are smaller than in equimolar solution, since the pH effect of the oligomerization processes is strongly buffered by the proton-dissociation reactions of the free citric acid. The 30-h titration curve represents the equilibrium state. On the basis of earlier literature reports,[4,8,10,15] the equilibrium titration data were evaluated by a speciation model including mononuclear mono- and bis(complexes) in different protonation states, i.e. $[AlLH]^{+}$, $[AlL]$, $[AlLH_{-1}]^{-}$, $[AlLH_{-2}]^{2-}$, $[AlL_2]^{3-}$,

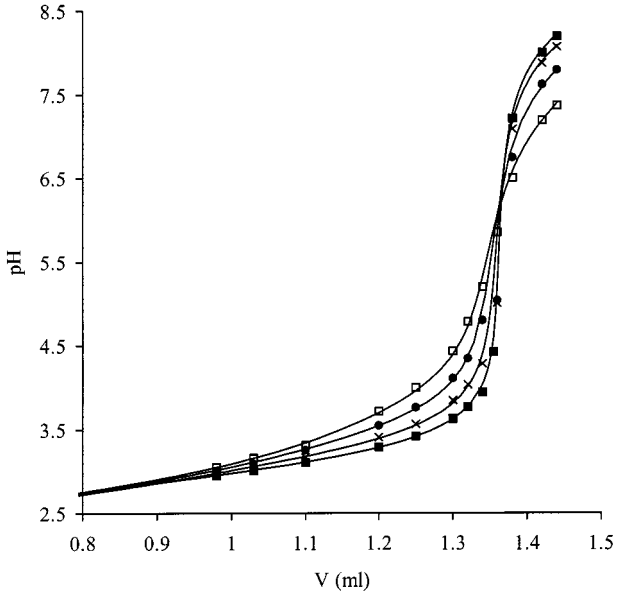

Figure 2. Titration curves (plotted as mL titrant KOH versus pH) of the Al^{III}−citric acid system at a ratio 1:1, $c_{Al} = 0.004$ M and at different times after mixing the reactants: (□) 1 min, (●) 10 min, (×) 40 min (■) at equilibrium (after 30 h)

$[AlL_2H_{-1}]^{4-}$ and $[AlL_2H_{-2}]^{5-}$, and the trinuclear complex $[Al_3L_3H_{-4}]^{4-}$, or more precisely $[Al_3(LH_{-1})_3(OH)]^{4-}$. The stability constants of the complexes, together with some literature data, are listed in Table 1. It can be seen from Table 1 that there is a better agreement in the stability constants of the mono(complexes) (especially the stepwise deprotonation data agree well), while there is a much higher uncertainty in the stability of bis(complexes). Our model is in reasonable good agreement with that proposed by Öhman,[4,10] except that he did not consider the species $[AlL_2H_{-1}]^{4-}$ and $[AlL_2H_{-2}]^{5-}$, and we did not find another trinuclear complex $[Al_3L_3H_{-7}]^{7-}$ or more precisely $[Al_3(LH_{-1})_3(OH)_4]^{7-}$. This latter species, however, is not formed in a significant quantity below pH ≈ 8, the upper limit of our studies. The differences in the stability constants can be explained by the rather large differences in the experimental conditions ($I = 0.6$ M, NaCl and 0.2 M, KCl). The agreement with the stability data of the mononuclear mono- and bis(complexes) reported by Gregor and Powell[8] is much better, as they used much closer experimental conditions ($I = 0.1$ M, KCl).

In order to obtain information about the complexation route of citric acid with Al^{III}, we evaluated the titration curves relating to the same times by using the same speciation model (vide supra). Species distribution curves at different times after the mixing of the components are depicted in Figure 3 and Figure 4. We are aware that the stability data calculated from the non-equilibrium titration points are not real thermodynamic constants (for this reason we do not report their values), but they can provide a roughly qualitative picture regarding the time course of the complex formation processes. Figure 3 clearly indicates that, shortly after mixing, mononuclear complexes predominate in the system, which then transform slowly to the trinuclear complex, $[Al_3(LH_{-1})_3(OH)]^{4-}$, probably through intermediate species. The concentration of the trinuclear species increases with time at the expense of the mononuclear mono(complexes) $[AlLH_{-1}]^{-}$ and $[AlLH_{-2}]^{2-}$, and also of the bis(complexes) $[AlL_2]^{3-}$, $[AlL_2H_{-1}]^{4-}$ and $[AlL_2H_{-2}]^{5-}$ in the case of an excess of ligand.

At pH ≈ 5, $[AlLH_{-1}]^{-}$, the predominating mononuclear complex, is formed in a fairly fast reaction and is in equilibrium with the trinuclear species. The pH of the solution decreases with time (see Figure 1), due to the slow equilibrium of Equation (1).

$$3\,[AlLH_{-1}]^{-} + H_2O \rightleftarrows [Al_3(LH_{-1})_3(OH)]^{4-} + H^{+} \quad (1)$$

At a ligand excess, bis(complexes) like $[AlL_2]^{3-}$ and $[AlL_2H_{-1}]^{4-}$ are also present and are also involved in the oligomerization processes. Several of the possible reactions are given in Equation (2), Equation (3) and Equation (4).

$$[AlL_2]^{3-} + 2\,[AlLH_{-1}]^{-} + H_2O \rightleftarrows [Al_3(LH_{-1})_3(OH)]^{4-} + HL^{2-} + H^{+} \quad (2)$$

$$[AlL(LH_{-1})]^{4-} + 2\,[AlLH_{-1}]^{-} + H_2O \rightleftarrows [Al_3(LH_{-1})_3(OH)]^{4-} + HL^{2-} \quad (3)$$

$$[AlL_2]^{3-} + [AlL(LH_{-1})]^{4-} + [AlLH_{-1}]^{-} + H_2O \rightleftarrows [Al_3(LH_{-1})_3(OH)]^{4-} + 2\,HL^{2-} \quad (4)$$

When the starting pH is ca. 7, the predominant mononuclear species is $[AlLH_{-2}]^{2-}$, and the pH increases with time according to the equilibrium of Equation (5).

$$3\,[Al(LH_{-1})(OH)]^{2-} \rightleftarrows [Al_3(LH_{-1})_3(OH)]^{4-} + 2\,OH^{-} \quad (5)$$

At a ligand excess the transformations of the species $[AlL_2H_{-1}]^{4-}$ and $[AlL_2H_{-2}]^{5-}$ should also be considered. As an illustration some of the possible oligomerization reactions are given in Equation (6) and Equation (7).

$$[AlL(LH_{-1})]^{4-} + 2\,[Al(LH_{-1})(OH)]^{2-} \rightleftarrows [Al_3(LH_{-1})_3(OH)]^{4-} + L^{3-} + OH^{-} \quad (6)$$

$$[Al(LH_{-1})_2]^{5-} + 2\,[Al(LH_{-1})(OH)]^{2-} + H_2O \rightleftarrows [Al_3(LH_{-1})_3(OH)]^{4-} + L^{3-} + 2\,OH^{-} \quad (7)$$

It must be mentioned here that these equilibria are written in the simplest way. During the oligomerization of the mononuclear complexes, one or more intermediate species are formed, as can be demonstrated by NMR spectroscopy (vide infra).

At pH ≈ 3, there is only a slight pH decrease with time. At this pH, the species [AlL] predominates in the fresh solution and only a small amount is transformed to the trinuclear complex at equilibrium. Thus, the changes in pH are not significant (see Figure 1).

NMR Spectroscopic Measurements in Equimolar Al^{III}−Citrate Solutions

^{1}H, ^{13}C and ^{27}Al NMR spectroscopic measurements were carried out to support the potentiometric results. The spectrum recorded at pH ≈ 2 in a 0.04 M solution (Figure 5a) reveals the AB quadruplet of the free citrate (×) at δ = 3.06, 3.03, 2.89 and 2.86 ($J_{AB} = 15.7$ Hz), two broad signals at δ = 2.95 and 2.92 and two sharper signals at δ = 2.83

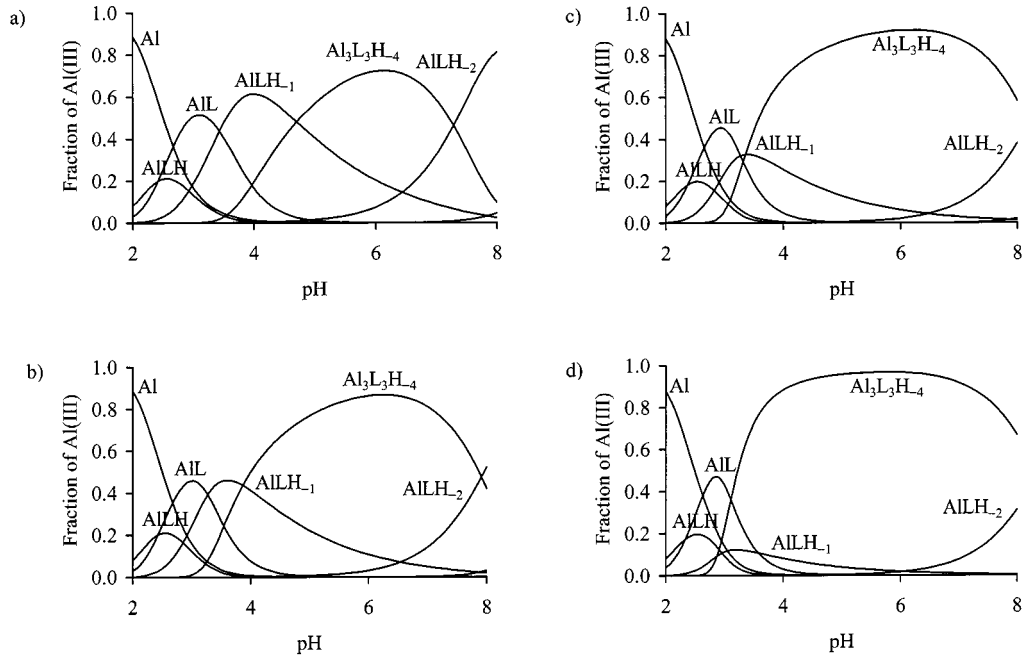

Figure 3. Species distribution curves as a function of pH in the Al^{III}–citric acid system at a ratio 1:1, c_{Al} = 0.004 M and at different times after sample preparation: (a) 1 min, (b) 10 min, (c) 40 min (d) at equilibrium (after 30 h)

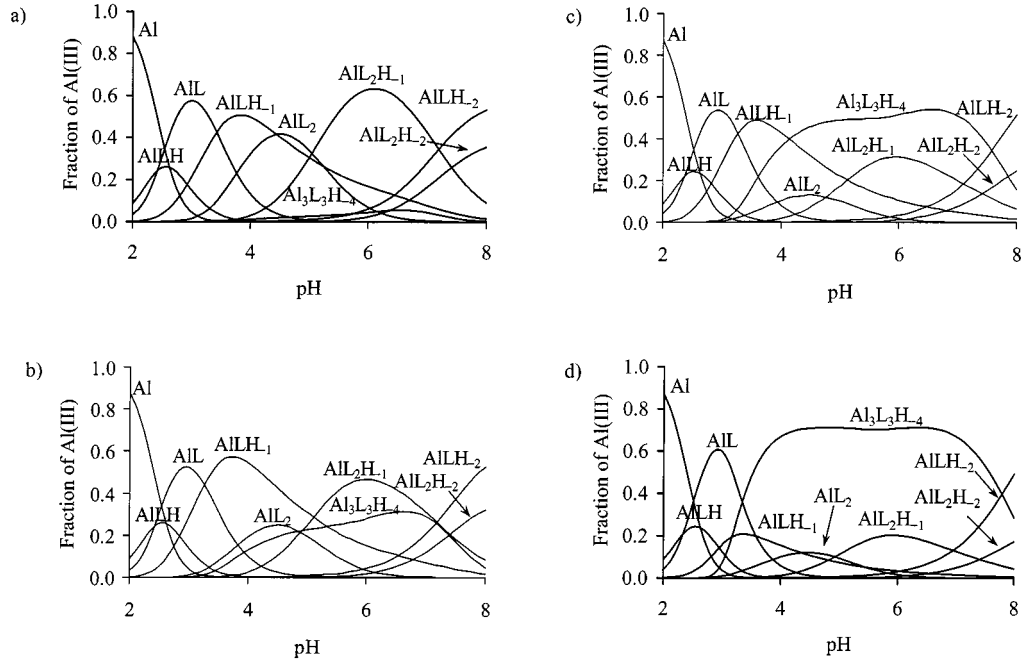

Figure 4. Species distribution curves as a function of pH in the Al^{III}–citric acid system at a ratio 1:3, c_{Al} = 0.004 M and at different times after sample preparation: (a) 1 min, (b) 10 min, (c) 40 min (d) at equilibrium (after 30 h)

and 2.80 which seem to be part of another AB quadruplet. Proton-proton correlation measurements confirm that these four signals form an AB quadruplet (•) with a coupling constant of 17.7 Hz. Potentiometry suggests that these signals belong to the mononuclear species $[AlLH]^+$.

On increasing of the pH to ca. 2.5, the ^1H NMR spectrum (Figure 5b) seems to be more complicated than expected from the speciation curves (Figure 3). From the signals appearing in the spectrum, the AB quadruplet of free citrate can unambiguously be assigned to δ = 3.03, 3.00, 2.87 and 2.84 (×), which is shifted upfield due to the deprotonation of one of the carboxyl groups. The AB quadruplet observed at pH ≈ 2 (•) is also shifted upfield. This indicates the equilibrium of two species, resulting in an average signal due to the fast proton exchange reactions between them. These two mononuclear species are probably $[AlLH]^+$ and [AlL]. The appearance of some low-intensity signals in the spectrum indicates that at 0.04 M, the oligomerization processes have already started at pH ≈ 2.5, while in more dilute solutions (e.g. at 0.004 M, under the conditions of our po-

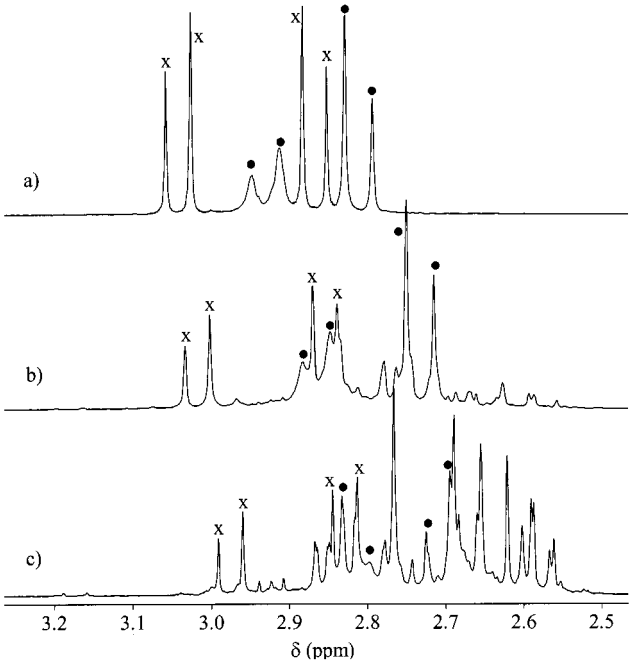

Figure 5. ^1H NMR spectra obtained in the Al^{III}−citric acid system at a ratio 1:1, c_{Al}=0.04 M and at different pH values: (a) pH ≈ 2, (b) pH ≈ 2.5, (c) pH ≈ 3; all spectra were recorded after the thermodynamic equilibrium was reached

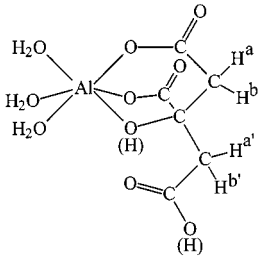
tentiometric studies) oligomerization starts only above pH ≈ 3 (Figure 3d). The ^1H COSY NMR spectrum obtained for the same solution (see Supporting Information) indicates that these minor signals form a series of AB quadruplets, suggesting a very asymmetric structure of the oligomeric complex formed at this pH. From these AB quadruplets, three can be clearly identified at δ = 2.86, 2.83, 2.66 and 2.63 (J_{AB} = 16.6 Hz); 2.88, 2.84, 2.63 and 2.59 (J_{AB} = 20.2 Hz) and 2.70, 2.67, 2.59 and 2.56 (J_{AB} = 14.6 Hz). The signal at δ = 2.76 does not couple with any other signal.

At pH ≈ 3, the oligomerization processes are more pronounced. The characteristic AB quadruplet of the mononuclear species that appears at lower concentrations is shifted to δ = 2.83, 2.80, 2.72 and 2.69 (•), and can be assigned to the species [AlL] and $[AlLH_{-1}]^-$ (Figure 5c).

A tridentate chelation of citric acid was assumed, involving the coordination of one of the deprotonated terminal carboxylates, the deprotonated central carboxylate group and the protonated alcoholic OH group in the case of the species $[AlLH]^+$; this latter group is deprotonated in the complex [AlL]. The other terminal carboxylic group is not bound, and protonated in the species $[AlLH]^+$ and [AlL], and deprotonated in the complex $[AlLH_{-1}]^-$. The fact that there is an AB quadruplet in the ^1H NMR spectrum can be explained by a relatively fast intramolecular exchange between the bound and unbound carboxylate moieties, i.e. the citrate molecule behaves fluxionally. A more likely explanation is that one of the methylene proton pairs (e.g. a and a′, see Scheme 1) probably has a spatial arrangement such that its chemical environment changes more than in the case of the protons b and b′ during fluxional motions. For this reason, the signals given by the protons a and a′ are broader than the signals for the protons b and b′. If the rate of fluxionality were lower, separate signals could be observed for the protons a and a′. In our opinion, only this proposed binding mode of the citrate molecule with a 5+6 joined (COO^-, OH, COO^-) chelate system (see Scheme 1) and their fluxional motion can explain the asymmetric pattern of the AB quadruplet assigned to the mononuclear species. Furthermore, participation of the protonated alcoholic OH group in the coordination in the species $[AlAH]^+$ is supported by the observed increase in the stability of this complex as compared with the corresponding complexes of malonic acid (H_2L) or succinic acid (H_2L).[16,17] The basicity adjusted stability constant [log K^* = log $K([AlLH]^+)$ − log $\beta(H_3L)$] characteristic for the equilibrium $Al^{3+} + H_3L \rightleftarrows [AlLH]^+ + 2\ H^+$ is log K^* = −2.53 for Al^{III}−citrate, while it is −5.57 for the corresponding 1:1 complex $[AlL]^+$ formed with succinic acid, which involves a seven-membered (COO^-, COO^-) chelate. The corresponding proton displacement constant for malonic acid, which forms a six-membered (COO^-, COO^-) chelate, is log K^* = −1.51.



$[AlLH]^+$—[AlL]—$[AlLH_{-1}]^-$

Scheme 1

Similar fluxional behavior was found in the case of the species $[AlL_2H_{-1}]^{4-}$ and $[AlL_2H_{-2}]^{5-}$ in aqueous solution. The solid-state structures of the isolated complexes $[AlL_2H_{-1}]^{4-}$ and $[AlL_2H_{-2}]^{5-}$, determined by X-ray crystallography, indicates asymmetric arrangements of the citrate molecules. Both citric acids bind to Al^{III} through one of the two terminal COO^- groups, the central COO^- group and the deprotonated alcoholate function, while the other terminal carboxylic functions are unbound (one of them is protonated in the species $[AlL_2H_{-1}]^{4-}$, while both are deprotonated in $[AlL_2H_{-2}]^{5-}$).[11,12]

The time-dependent changes in the species distribution in the pH range 3−8, i.e. the slow formation of the trinuclear species $[Al_3(LH_{-1})_3(OH)]^{4-}$ (Figure 3), is clearly demonstrated by NMR spectroscopy too. The required amounts of the stock solutions of Al^{III}, citrate and base were mixed at selected pH values (pH ≈ 5.0 and 7.0) and a series of spectra was taken at predetermined times until pH equilibrium was attained. Equilibrium was considered to be reached when two consecutive spectra coincided.

Figure 6 shows the time-dependence of the ^1H NMR spectra recorded at pH ≈ 5 (similar spectra obtained at pH ≈ 7 are included in the Supporting Information). The signals are initially poorly resolved, broad and merged, indicating dynamic changes in the system. The complexation

processes and/or ligand-exchange reactions between the initially formed mononuclear complexes and intermediate species seem to be fairly fast.

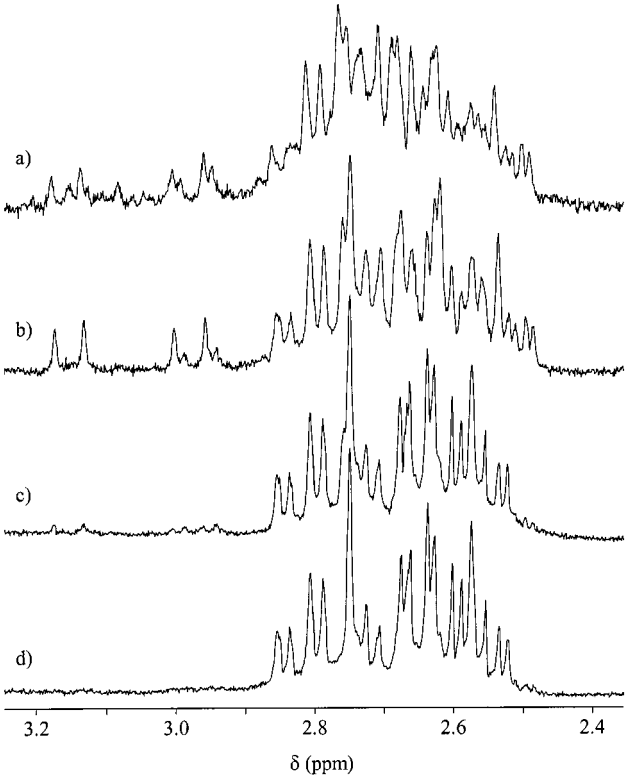


Figure 6. Time dependence of the ^{1}H NMR spectra of the Al^{III}–citric acid system at a ratio 1:1, c_{Al} = 0.04 M at starting pH ≈ 5; (a) 15 min, (b) 40 min, (c) 10 h, (d) 30 h after mixing of the components

At pH ≈ 5 in the equilibrium state, the characteristic but rather complicated spectrum of the trinuclear complex $[Al_3(LH_{-1})_3(OH)]^{4-}$ is obtained (see Figure 6d), as is expected from the potentiometric results. The speciation curves indicate that at this pH the trinuclear complex is the only species present (see Figure 3). The X-ray structure of the isolated trinuclear complex $[Al_3(LH_{-1})_3(OH)]^{4-}$ reveals an asymmetric arrangement of the carboxylate-bridged citrate molecules between the Al^{III} centers.[13] Accordingly, in the ^{13}C NMR spectrum 18 resonances appear: each carbon atom gives a separate signal. Similarly, the ^{1}H NMR spectrum is also complicated as all the methylene protons are chemically and magnetically unequivalent.[13,18] The characteristic ^{1}H resonances of the trinuclear complex are as follows: δ = 2.87, 2.85, 2.82, 2.80, 2.77, 2.74, 2.72, 2.69, 2.68, 2.65, 2.64, 2.62, 2.60, 2.58, 2.57, 2.55 and 2.54. A complete assignment of the signals was achieved by means of 2D carbon–proton correlation measurements and is under publication.[19] The appearance of the weak resonances between δ = 3.0 and 3.2 leads to the conclusion that the trinuclear complex is probably formed through at least one intermediate species. These "extra" resonances may belong to this/these intermediate species, since they reach a maximum intensity in time and are later almost completely absent from the spectrum obtained at equilibrium. It was demonstrated by ^{1}H COSY NMR measurements that they are half of the AB quadruplets, the other half lying under the signals of the trinuclear species.[12]

When the starting pH is ca. 7 (see Supporting Information), the pattern of the spectrum obtained in the equilibrium state clearly indicates the presence of the trinuclear species (the characteristic resonances are listed above), the free citrate (δ = 2.68, 2.63, 2.55 and 2.50; J_{AB} = 15.5 Hz) and a complex which gives broad resonances at δ = 2.49 and 2.45. These latter signals may be half of an AB quadruplet, the other part overlapping with signals of the trinuclear complex. According to potentiometry, this other complex is $[AlLH_{-2}]^{2-}$, which is a mixed hydroxo species with the same citrate binding mode as in the complex $[AlLH_{-1}]^-$. The broadening of the signals is probably due to the presence of the OH^- group in the coordination sphere of the Al^{III}. The appearance of free citrate can be explained by the change in the pH of the samples with time. As discussed above, at this pH the oligomerization is accompanied by a considerable release of OH^-. Thus, the pH at equilibrium is much higher than the starting value, reaching pH > 8.5. At this pH, OH^- starts to displace citric acid from the coordination sphere of Al^{III}, resulting in the parallel formation of $[Al(OH)_4]^-$.

The formation of intermediate complexes during oligomerization is clearly demonstrated by ^{13}C NMR spectroscopy too. To obtain a ^{13}C NMR spectrum of better quality, the concentration of citric acid was increased to 0.2 M and the Al^{III}/citric acid ratio was kept at 1:1. Figure 7 shows the methylene range of the spectra recorded at different times at pH ≈ 5. Spectrum (b) was obtained at equilibrium and the resonances of the six methylene carbon atoms of the asymmetric trinuclear complex are exhibited.[13] Due to the asymmetric structure and kinetically inert nature of the complex (vide extra), each methylene group yields separate signals. The upper spectrum (a) corresponds to a non-equilibrium state. Besides the signals of the trinuclear species, four new resonances can be recognized, at δ = 41.7, 43.6, 43.9 and 47.2. These signals are completely absent from the spectrum at equilibrium. The potentiometric results show that at pH ≈ 5 the complex $[AlLH_{-1}]^-$ oligomerizes to give $[Al_3(LH_{-1})_3(OH)]^{4-}$. This mononuclear complex may give at least 2 signals in the methylene range of the ^{13}C spectrum. Consequently, we cannot assign the "extra" signals in the above discussed spectrum to $[AlLH_{-1}]^-$. They are probably due to some intermediate species which forms during the oligomerization of the mononuclear complex to the final trinuclear species. These intermediate species are presumably oligonuclear complexes which contain at least two molecules of citric acid in an asymmetric arrangement. At pH ≈ 7, the same behavior is observed.

The changes in the Al^{III}–citrate system were also followed by ^{27}Al NMR spectroscopy (see Figure 8). The spectra recorded in a fresh equimolar Al^{III}–citrate solution at pH ≈ 5 and 7 consist of two components; a large peak at δ = 11.5 and a shoulder on the upfield side at about δ = 0. The intensity of the main signal increases with time, while that of the shoulder at δ = 0 initially increases and then undergoes a considerable decrease until equilibrium is re-

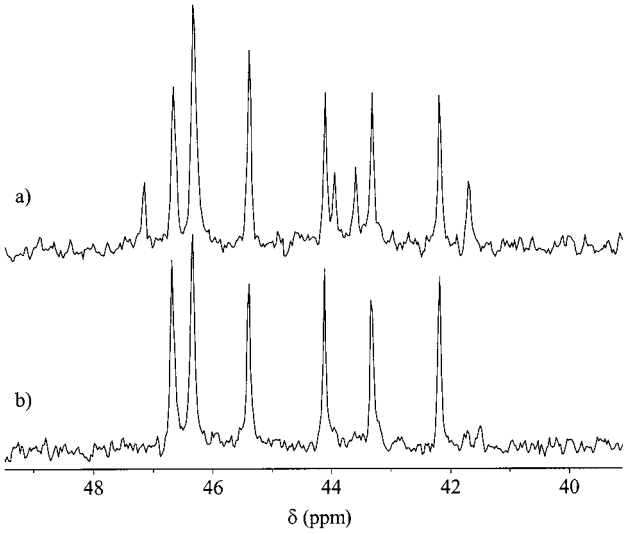

Figure 7. The methylene range of the time-dependent ^{13}C NMR spectra in the Al^{III}−citric acid system at a 1:1 ratio, c_{Al} = 0.2 M, at pH ≈ 5; (a) 12 h after mixing of the components, (b) at equilibrium

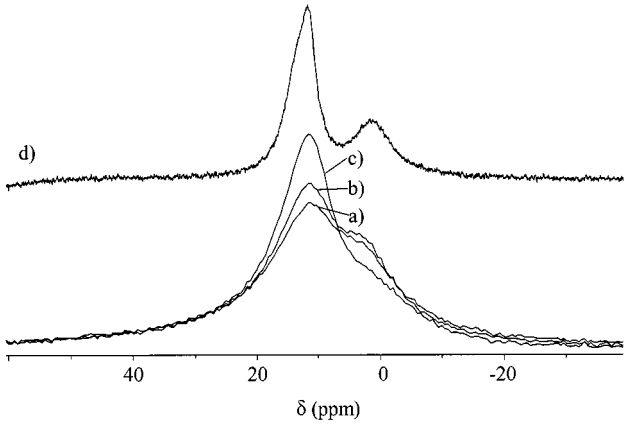

Figure 8. ^{27}Al NMR spectra (measured with a 200 MHz instrument) of the Al^{III}−citric acid system at a 1:1 ratio, c_{Al} = 0.1 M, at pH ≈ 7 and at different times after preparation of the sample; (a) 10 min, (b) 1 h, (c) 30 h, (d) the same spectra as (c) but measured with a 500 MHz instrument

ached. This behavior of the shoulder is probably related to the formation and decomposition of intermediate complexes. The fact that practically the same spectra were recorded at pH ≈ 5 and 7 suggests that a single species, formed fairly slowly, predominates in this pH range. Karlik et al.[5] assigned this spectrum to a mononuclear complex, probably $[AlLH_{-1}]^-$. It is now clear that this spectrum is that of the trinuclear species.

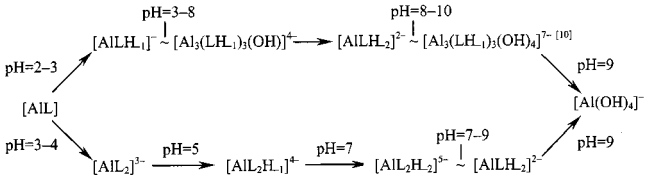
The ^{27}Al NMR spectrum of a sample recorded when the crystalline trinuclear complex was dissolved in water consisted of three signals: at δ = 0.2, at 10.7 and as a downfield shoulder on the latter, at 12.6.[13] In our case, as a result of the lower resolution of the instrument, the signals at δ = 10.7 and 12.6 are merged completely, giving a single broad peak with maximum at δ = 11.5 and the signal at δ = 0.2 becomes a shoulder. The spectral pattern described in the literature[13] was obtained when the same sample, as shown in Figure 8c, was measured with a 500 MHz instrument (see Figure 8d).

NMR Spectroscopic Measurements in the Al^{III}-Citrate System with Ligand Excess

The potentiometric results show that at an excess of ligand, besides the mononuclear 1:1 species, 1:2 complexes are also formed in freshly prepared solutions. These 1:2 and 1:1 complexes undergo slow oligomerization processes which, similarly as in equimolar solutions, result in the predominant formation of the trinuclear species $[Al_3(LH_{-1})_3(OH)]^{4-}$. The solid-state characterization and solution behavior of these 1:2 complexes have already been determined using ^1H and ^{13}C NMR spectroscopy.[11,12] The ^{13}C NMR measurements carried out by Gregor and Powell[8] in a Al^{III}−citrate solution at a 0.25 M Al^{III} and a metal ion/ligand ratio of 1:4, revealed the presence of the 1:2 species and free citrate only. The authors did not mention whether these spectra were taken in fresh solution or in the equilibrium state. In the ^1H NMR spectra measured by us at the same concentration at pH ≈ 5 and 7, but at an Al^{III}/citrate ratio of 1:3 (the ratio used in our potentiometric study), the signals of the trinuclear species could also be unambiguously recognized in the equilibrium state. It was further found that in concentrated solutions the oligomerization processes are slower than at 0.04 M or 0.004 M; equilibrium can be reached in about a week. These results lead to the conclusion that in ref.[8] the spectra were obtained using fresh solutions, and in the equilibrium state the trinuclear complex should also have formed, although in this case (because of the higher ligand excess) in a somewhat lower amount than at a ratio of 1:3. In less concentrated solutions and at higher metal/ligand ratios, the oligomerization processes may truly be negligible.

Conclusions

The time-dependent speciation study of the Al^{III}−citrate system indicates that in fresh solutions mononuclear mono- and bis(complexes) are the predominant species, although the trinuclear complex $[Al_3(LH_{-1})_3(OH)]^{4-}$ is also present, especially under equimolar conditions. However, the concentration of this complex is strongly reduced in the event of a ligand excess. The trinuclear species is formed in slow processes through the oligomerization of mononuclear complexes[10] (see the upper row of Scheme 2). An excess of



The species $[Al_3(LH_{-1})_3(OH)_4]^{7-}$ was proposed by Öhman at pH > 8[10]

Scheme 2

ligand favors the formation of the bis(complexes) (the reaction steps are indicated in the lower row of Scheme 2); under such conditions these are strongly competitive with the oligomerization processes indicated in the upper row.

These facts may be of importance when speciation model calculations on Al^{III} are performed for biological fluids, e.g. for blood serum, where citric acid may be present in a 100-fold excess as compared with Al^{III}. For the average concentrations of citrate and Al^{III} in serum, Harris[2] estimated 0.1 mM and 3 μM, respectively. However, ca. 80% of the total Al^{III} is bound to transferrin and only 20% is available for the l.m.m. binders.[2,14] As may be seen in Figure 9, under serum conditions the formation of the trinuclear species (even if the complex is very stable) is completely suppressed. In the event of an overload of Al^{III} in the organism, the metal concentration in the serum may increase to 10−100-fold, and this would increase the extent of the formation of the oligomeric species at equilibrium quite considerably. However, its formation is definitely a slow process and our calculations demonstrate that its concentration is still negligible 30 min after absorption.

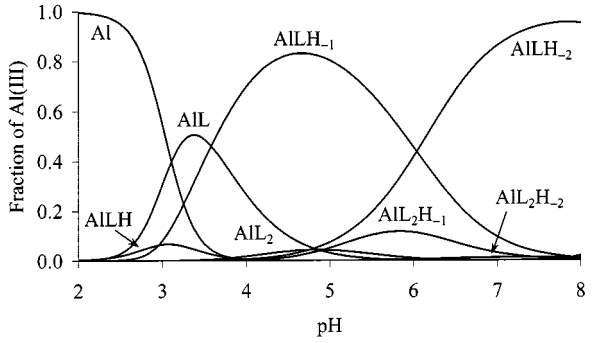


Figure 9. Speciation curves of the Al^{III}−citric acid system, at blood serum conditions, $c_{Al}{}^{III}$ = 0.6 μM, $c_{citrate}$ = 99 μM

As biological fluids are open systems, and by virtue of the continuous metabolic processes, Al^{III} may not spend enough time in the biological fluid for the equilibrium state to be reached. Accordingly, its speciation as calculated with the thermodynamic stability constants may not be totally relevant to the biological conditions. In such cases, only a complete equilibrium and kinetic description of the formation of all complexes can provide the exact biospeciation information. In such a complicated system, however, this can be achieved only in a very long and tedious way. A reasonable estimation of the speciation may be made by using stability constants calculated from measurements under non-equilibrium conditions.

Experimental Section

Reagents: Citric acid, of highest analytical purity (Sigma product), was used without further purification. The exact concentration of the ligand solution was determined by potentiometric titration using the Gran method.[20] The Al^{III} stock solution was prepared from recrystallized $AlCl_3{\cdot}6H_2O$, and its metal concentration was determined gravimetrically through its oxinate. The stock solution contained 0.1 M HCl to prevent hydrolysis of aluminium. The ionic strength of all solutions was adjusted to 0.2 M KCl and the temperature was 25.0±0.1 °C.

Potentiometric Measurements: The stability constants of the proton complexes of the ligands were determined by pH-potentiometric titrations of 10.0 mL samples. The ligand concentration was 0.004 M. The titrations were performed with a 0.2 M carbonate-free KOH solution of known concentration under purified argon. − The time-dependent speciation measurements were performed with the "batch" technique. After the appropriate amounts of stock solutions of Al^{III} were mixed with the ligand and the base, the pH of the solutions was recorded at given times until pH equilibrium was attained in the system (ca. 30 h). The procedure was repeated at different starting pH values, whereby titration curves relating to different times were obtained. The measurements were performed at metal/ligand ratios of 1:1 and 1:3, under intense stirring under argon. The pH range studied was 2−8. The time-dependent changes were monitored in this way for 39 different samples. However, in order to increase the reliability of the speciation description of the system in thermodynamic equilibrium twice as many samples were prepared, but half of them, i.e. every second was measured only 30 h after mixing, when pH equilibrium was surely attained. The stability constants listed in Table 1 were calculated from the total 78 "batch" points. The pH was measured with a Radiometer PHM 84 instrument with a CMAWL Russel combined glass electrode, which was calibrated for hydrogen ion concentration according to Irving et al.[21] − The concentration stability constants $\beta_{pqr} = [M_pL_qH_r]/[M]^p[L]^q[H]^r$ were calculated with the aid of the PSEQUAD computer program.[22] The stability constants used for the hydroxo species of Al^{III} were taken from ref.[23] and corrected to I = 0.2 using the Davies Equation: −5.49 for $[AlH_{-1}]^{2+}$, −13.54 for $[Al_3H_{-4}]^{5+}$, −97.2 for $[Al_{13}H_{-32}]^{7+}$ and −23.40 for $[AlH_{-4}]^{-}$.

NMR Spectroscopy: ^1H and ^{13}C NMR spectra were recorded at 25 °C with a Bruker AM360 spectrometer. In the ^1H and ^{13}C NMR spectra, chemical shifts were referenced to the signal of TMS as an external standard. The samples were prepared in D_2O; the pH was adjusted with concentrated NaOD and DCl, using the relation pH = pD + 0.4. The concentrations of the solutions were 0.04 M or 0.1 M for Al^{III}, and a metal ion/ligand ratio of 1:1 was usually applied. ^{27}Al NMR spectra were recorded with a Bruker AM200 instrument at 25 °C. Chemical shifts were recorded with respect to $[Al(H_2O)_6]^{3+}$. Solutions of 0.1 M Al^{III} and a metal ion/ligand ratio of 1:1 were prepared in water containing 10% of D_2O to provide an NMR lock signal.

Iron(III) Complexation by New Aminocarboxylate Chelators – Thermodynamic and Kinetic Studies

Guy Serratrice,*[a] Jean-Baptiste Galey,[c] Eric Saint Aman,[b] and Jacqueline Dumats[c]

Keywords: Iron / Chelates / Thermodynamics / Kinetics / N ligands

The complexation of Fe^{III} by new tetradentate and pentadentate aminocarboxylate chelators, designed to protect cells against iron-catalysed oxidative damage, was investigated. Ferric iron complexes of *N*,*N*′-bis(3,4,5-trimethoxybenzyl)-ethylenediamine-*N*,*N*′-diacetic acid (**L1**), *N*,*N*′-dibenzylethylenediamine-*N*,*N*′-diacetic acid (**L2**) and [*N*-(2-hydroxybenzyl)-*N*′-benzylethylenediamine-*N*,*N*′-diacetic acid] (**L3**) have been characterized in aqueous solution by potentiometric, UV/Vis spectrophotometric and cyclic voltammetric measurements. The parent ligand, ethylenediamine-*N*,*N*′-diacetic acid (**L4**), has also been studied. As expected, the presence of a hard phenolate donor group in **L3** significantly enhances the affinity for iron while decreasing the potential of the Fe^{III}/Fe^{II} redox couple compared to **L1** or **L2**. Kinetics studies have provided the kinetic rate constants related to the formation and the dissociation of the ferric complex with **L3**. The results reveal a fast Fe^{III} uptake, which is a favorable feature for a biological use of this type of ligand. Overall, these results demonstrate the pertinence of the use of such ligands to protect biological tissues against oxidative stress.

Introduction

In recent years there has been an intensive search for new iron ligands with medicinal applications. Several diseases are indeed associated with disturbance of iron homeostasis.[1] One major issue is the treatment of iron-overload-associated situations for people suffering from haematological defects such as β-thalassemia major. Indeed, because man is unable to actively excrete iron, systemic iron overload occurs rapidly when frequent blood transfusions are given.[2] In such situations, treatment with powerful iron chelators is the only effective way to remove excess iron. Currently, the hexadentate siderophore desferrioxamine (DFO) is by far the clinically most used iron chelator. However, DFO lacks oral activity and has a very short biological half life, which results in poor patient compliance.[3] Therefore, considerable effort has been focused on discovering new therapeutically useful iron chelators.

On the other hand, there are also other areas in which iron chelators could be useful. For instance, drugs able to specifically chelate iron from iron-containing enzymes such as ribonucleotide reductase or lipoxygenase could find important applications.[4] Moreover, in addition to systemic iron overload, local iron homeostasis disturbances can occur in several conditions associated with so-called ''oxidative stress'', i.e. when traces of iron are locally released from their normal storage sites and become available to catalyze Fenton chemistry, leading to oxidative damage to surrounding biological molecules.[5] However, there are few reports on the development of iron chelators specifically designed for the treatment of such oxidative stress-associated situations. The main reason is probably that the design of such systems is potentially problematic for medicinal chemists in terms of safety margins owing to the possible interaction of chelators with normal iron metabolism.[6]

We recently developed a new strategy based on the idea that an ''ideal'' iron chelator for use in oxidative stress-related conditions should effectively chelate iron only in pro-oxidant conditions. We therefore explored the possibility of generating pro-drugs that can be oxidatively activated into species with strong iron-binding capacity.[7] Of particular interest in such a strategy is the degree of control exercised by the oxidative stress conditions, whereby a dormant relatively inactive compound is transformed to an active species by the very conditions prevailing at sites where it is most needed.

N,*N*′-Bis(3,4,5-trimethoxybenzyl)ethylenediamine-*N*,*N*′-diacetic acid (**L1**) (Figure 1) is the most extensively studied ligand in this series. In aqueous solutions containing acetate and ferric salts, **L1** forms a μ-acetato μ-oxo diferric iron complex.[8] In the presence of ferrous salts in anaerobic conditions, a mononuclear ferrous complex is formed. Both complexes react with hydrogen peroxide or dioxygen in the presence of ascorbate to form a mononuclear (phenolato)-Fe^{III} complex resulting from the quantitative hydroxylation of **L1** into **L5** (Figure 2). Owing to the well-known affinity of phenolate ligands for ferric iron, **L1** appears to fit the aforementioned prerequisites regarding the generation of a strong iron chelator according to a local oxidative activation process.[9]

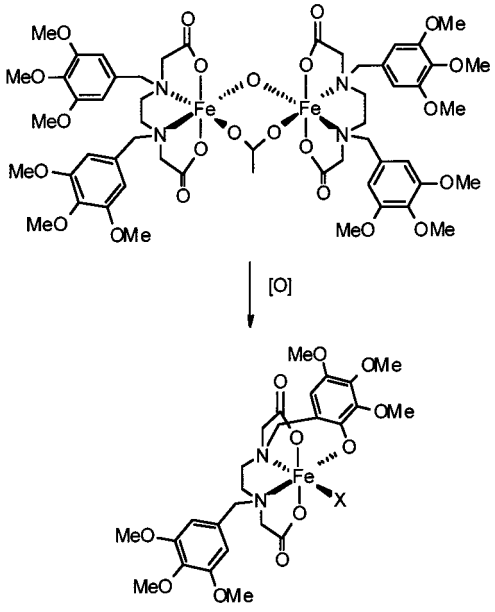

Figure 2. Reaction scheme for the oxidation of $Fe_2(\mathbf{L1})_2$

In the present paper, we extend our previous findings by accurately investigating the physicochemical parameters of Fe^{III} complexation by **L1** and analogs **L2** (*N*,*N*′-dibenzylethylenediamine-*N*,*N*′-diacetic acid) and **L3** [*N*-(2-hydroxybenzyl)-*N*′-benzylethylenediamine-*N*,*N*′-diacetic acid] (Figure 1), i.e. stability constants and redox potentials to demonstrate the pertinence of the use of such ligands to protect biological tissues against iron-catalyzed oxidative damage. The ligand ethylenediamine-*N*,*N*′-diacetic acid (**L4**) was also investigated for comparison and because the stability constants of the ferric complexes are unknown. A detailed kinetic study of the formation and of the dissociation of the ferric complex with **L3** is also described in order to (i) determine the reactivity patterns of this complex containing phenolate and aminoacetate donor groups and (ii) since few data are available in the literature for this type of ligand.

Results and Discussion

Ligand Deprotonation Constants

The deprotonation constants K_a of the ligands investigated in this research were studied by potentiometric titration. Analysis of the potentiometric titration curve (Figure 3a and Figure 3c as examples) by the SUPERQUAD program[10] yielded the pK_{an} values defined by Equation (1) and Equation (2) (charges omitted for clarity) and reported in Table 1.

$$LH_n \rightleftharpoons LH_{n-1} + H^+ \quad (1)$$

$$K_{an} = [LH_{n-1}]\cdot[H^+]/[LH_n] \quad (2)$$

Three pK_a values were determined and these correspond to one carboxylic acid group and the two ammonium groups. By comparison to EDTA the lowest pK_a value for each ligand is attributed to a carboxylic acid and the two highest ones to the ammonium nitrogen atoms. The pK_a values of **L4** are in good agreement with those determined by Harris and Martell [9.67, 6.57 and 2.36 (I = 0.1 M, KNO_3)].[11] The pK_a value of the other carboxylic acid is assumed to be significantly lower than 2.

A fourth pK_a value corresponding to the hydroxy group was determined for the ligand **L3** by spectrophotometric titration. This pK_a cannot be accurately determined by potentiometric titrations since deprotonation occurs at pH > 11. A spectrophotometric titration was carried out over the pH range 10−12. The corresponding UV spectra exhibit an isosbestic point at λ = 270 nm, indicating the presence of only two absorbing species. The data were processed by the LETAGROP SPEFO[12,13] program (absorbance values at 8 wavelengths). The best fit [$\Sigma(A_{exp} - A_{calc})^2 = 10^{-3}$] yielded a p$K_a$ value of 12.0 ± 0.1. The extinction coefficients were determined to be ε_{max} = 3500 $M^{-1}cm^{-1}$ (λ_{max} = 292 nm) and ε_{max} = 10000 $M^{-1}cm^{-1}$ (λ_{max} = 238 nm) for $\mathbf{L3}^{3-}$ and ε_{max} = 50 (λ_{max} = 292 nm) and ε_{max} = 1000 $M^{-1}cm^{-1}$ (λ_{max} = 238 nm) for $\mathbf{L3H}^{2-}$. The pK_a values for **L3** are close to those obtained for the ligands HBIDA [*N*-(2-hydroxybenzyl)iminodiacetic acid][14] and HBED [*N*,*N*′-bis(2-hydroxybenzyl)ethylenediamine-*N*,*N*′-diacetic acid][15] bearing similar donor groups, as indicated in Table 1. The high basicity of the hydroxy group reflects the presence of a hydro-

gen bond between the amino nitrogen atom and the hydroxy group.

Stability Constants of the Ferric Complexes

The stability constants β_{110} were determined by potentiometric titration for the ferric complexes of ligands **L1**, **L2** and **L4**. The titration curves for a 1:1 ratio of Fe^{III} to ligand (Figure 3d as an example) exhibit two breaks at a = 4 and a = 5, where a is equal to the number of moles of base added per mole of ligand. This clearly indicates the formation of hydroxo complexes Fe(OH)L and $Fe(OH)_2L$ at relatively low pH values. Analysis of the titration curves by the SUPERQUAD program[10] yielded the β_{110} and K^n_{OH} (n = 1 or 2) constants expressed as in Equation (3) and Equation (4).The values are given in Table 2.

$$\beta_{110} = [FeL]/[Fe^{3+}]\cdot[L] \quad (3)$$

$$K^n_{OH} = [Fe(OH)_nL]\cdot[H^+]/[Fe(OH)_{n-1}L] \quad (4)$$

Table 2. Fe^{III}−ligand stability constants and pFe values

Constants[a]	L1	L2	L3	L4
$\log \beta_{110}$	13.95(4)	15.20(9)	27.00(8)[b]	15.50(1)
pK^1_{OH} [c]	3.34(4)	3.52(9)	5.76(8)[b]	3.64(5)
pK^2_{OH} [d]	7.34(5)	7.27(5)		7.18(2)
pFe[e]	17.2	18.1	23.3	18.2

[a] All values were determined at 25 °C and I = 0.1 M ($NaClO_4$); values in parentheses are standard deviations in the last significant digit. − [b] Determined from spectrophotometric titration; K^1_{OH} = 6.02 from potentiometric titration. − [c] $K^1_{OH} = [Fe(OH)L][H^+]/[FeL]$ for the equilibrium $FeL + H_2O \rightleftarrows Fe(OH)L + H^+$. − [d] $K^2_{OH} = [Fe(OH)_2L][H^+]/[Fe(OH)L]$ for the equilibrium $FeLOH + H_2O \rightleftarrows Fe(OH)_2L + H^+$. − [e] Calculated for $[L]_{tot} = 10^{-5}$ M, $[Fe]_{tot} = 10^{-6}$ M at pH = 7.4.

For the tetraprotonated ligand **L3**, the breaks at a = 4 and a = 5 indicate the formation of the FeL and Fe(OH)L complexes (Figure 3b). However, it was not possible to determine the β_{110} value since the formation of the complex is complete at low pH values. Only the value of K^1_{OH} was determined from titration data and this is given in Table 2. The spectrophotometric titration was carried out over the range pH = 1−8 in order to determine the constants β_{110} and K^1_{OH}. The stoichiometric addition of Fe^{III} to a solution of **L3** over the pH range 1−2 led to the formation of a purple complex, the UV/Vis spectrum of which shows a maximum at 525 nm that is attributed to a phenolato-to-Fe^{III} charge transfer transition (Figure 4a). The absorbance data were processed with the LETAGROP-SPEFO program.[12,13] The best fit [$\Sigma(A_{exp} - A_{calc})^2 = 2 \times 10^{-3}$] was obtained by considering the formation of the [FeL] species and provides the values $\log \beta_{110}$ = 27.0 ± 0.08 and ε_{max} = 1950 $M^{-1}cm^{-1}$ (λ_{max} = 520 nm). No spectral change was observed over the pH range 2.5−4.5. As the pH value was increased from 5 to 7, the spectra showed isosbestic points at 394 and 491 nm, indicating that there are only two species with a different absorption in this pH range (Figure 4b). These absorbance data were also refined with the LETAGROP-SPEFO program.[12,13] The best fit [$\Sigma(A_{exp} - A_{calc})^2 = 3 \times 10^{-3}$] showed that deprotonation occurs through a one-proton step yielding a pK^1_{OH} value of 5.76 ± 0.08 and an absorption maximum at λ = 470 nm with ε = 1800 $M^{-1}cm^{-1}$ for the Fe(OH)L species. The value of pK^1_{OH} is in good agreement with the value 6.02 determined by potentiometric titration. The shift of the absorption

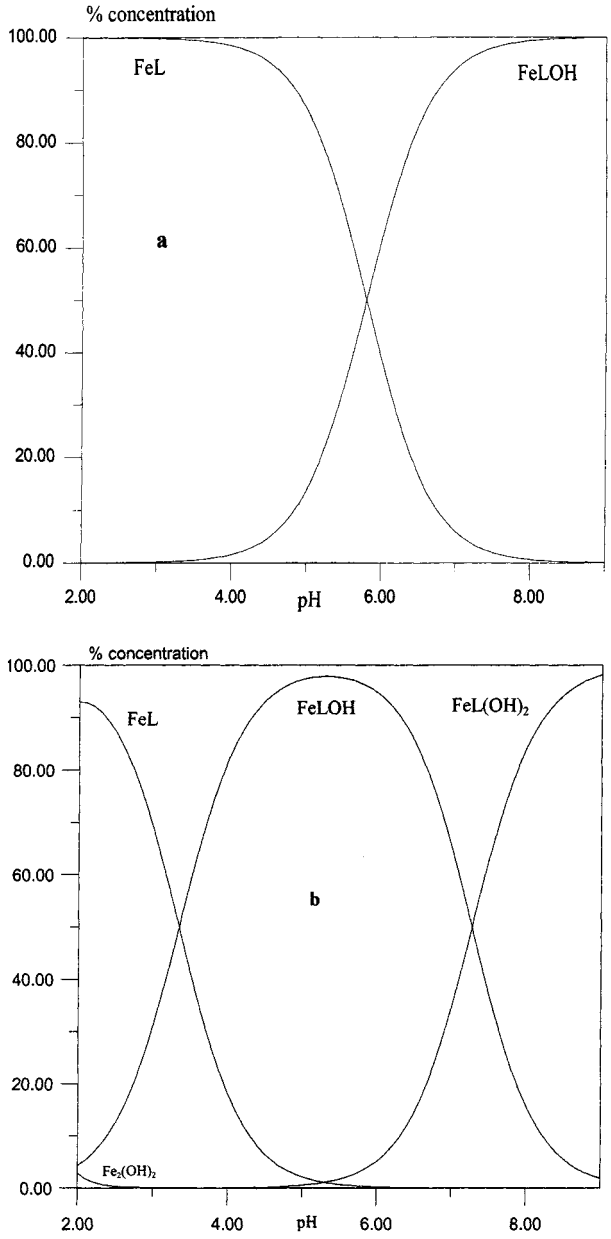

Figure 5. Distribution diagrams of the system Fe^{III}−**L3** (a) and Fe^{III}−**L1** (b) as a function of pH; $[Fe^{3+}]$ = 1 mM, [ligand] = 10 mM

maximum to lower wavelength reflects coordination with the more basic hydroxide ion. A similar spectral change has been observed for the ferric complex with HBIDA[14] [λ_{max} = 518 nm, ε_{max} = 1100 $M^{-1}cm^{-1}$ for FeL, λ_{max} = 460 nm, ε_{max} = 1010 $M^{-1}cm^{-1}$ for Fe(OH)L]. It is worth noting that the extinction coefficient is about half the value for Fe-HBED[15] (λ_{max} = 485 nm, ε_{max} = 3935 $M^{-1}cm^{-1}$), a system that has two phenolate donors and the same framework as **L3**. The distribution curves are shown in Figure 5 for ligands **L1** and **L3**.

The ferric complexes of the tetradentate ligands **L1**, **L2** and **L4** exhibit relatively low stability constants β_{110}, in agreement with those of tetradentate *N*,*N*′-diethylenediamine diacetic acid derivatives. Consequently, low values for pK^1_{OH} are observed (over the range 3.2−3.6). This reflects the high Lewis acid character of the ferric ion in FeL resulting from the low basicity of these ligands. A more reliable parameter for comparison of ligand effectiveness is the pFe^{III} value (= −log $[Fe^{3+}]$). The larger the pFe value, the more effective the ligand. The pFe^{III} values were calculated for $[L]_{tot} = 10^{-5}$ M, $[Fe]_{tot} = 10^{-6}$ M at pH = 7.4 and are reported in Table 2. The pFe values for **L2** and **L4** are very similar, indicating that substitution with benzyl groups does not influence the complexation. The lower ferric affinity of **L1** in comparison to **L2** and **L4** is probably due to steric effects of the methoxy substituents. A higher metal ion affinity is observed for **L3** and this fact is related to the

phenolate donor, as one would expect. An increase in the pFe value of 5.2 from **L2** (18.1) to **L3** (23.3) is observed. A comparison with the hexadentate ligand HBED (pFe = 26.97),[15] which contains two phenolate donors with an EDTA-type framework, shows that incorporation of one phenolate donor increases the pFe value by about 4−5 units. Furthermore, the pFe value for **L3** is higher than that of the tetradentate ligand HBIDA (19.95), which has one phenolate donor, one nitrogen donor and two carboxylate donors. The pK^1_{OH} values are very close, being 5.76 for **L3** and 5.75 for HBIDA. This indicates that the Lewis acidity of Fe^{III} is similar in both complexes.

Electrochemistry

The electrochemical behavior of the Fe^{III} + **L(1−3)** complexes was studied by cyclic voltammetry in an aqueous solution over the pH range 3−10.5 in order to investigate the ability of these complexes to undergo redox cycling under physiological conditions and to catalyze Fenton chemistry. In order to be able to catalyze the formation of hydroxyl radicals in the presence of hydrogen peroxide, an iron complex has to meet two conditions simultaneously: (i) the ferric chelate has to be reducible by physiological reductants, i.e. its standard redox potential must be higher than −0.534 V vs. Ag/AgCl (NADPH/$NADP^+$ redox couple) and (ii) single electron transfer from the ferrous chelate to hydrogen peroxide must be possible, i.e. its redox potential must lie below 0.25 V vs. Ag/AgCl (H_2O_2/HO˙, OH^-). The electrochemical response of the Fe^{III} + **L3** electrolytic solution is characterized in the 3−5 pH range by a quasi-reversible redox wave at $E_{1/2}$ = −0.21 V vs. Ag/AgCl (ΔE_p = 0.12 V, v = 0.1 V s^{-1}) corresponding to the Fe^{III}/Fe^{II} redox couple (Figure 6, curve 1). Increasing the pH value from 5 to 8 results in the progressive appearance of a new redox peak system at $E_{1/2}$ = −0.48 V (ΔE_p = 0.31 V), which grows at the expense of the original one at $E_{1/2}$ = −0.21 V (Figure 6, curves 2−4). Above pH = 8, the original wave disappears and the new peak system reaches full development (Figure 6, curves 5 and 6). This result is in agreement with the pK^1_{OH} value of 5.76 found for the Fe**L3**/Fe(OH)**L3** system and the distribution curve in Figure 5 (see above), i.e. the wave at $E_{1/2}$ = −0.48 V can be attributed to the Fe^{III}(OH)**L3**/Fe^{II}**L3** redox couple. Therefore, at pH = 7.4, the **L3** ferric chelate appears to be mainly in a form that is reducible by physiological reductants. However, the small difference between the $E_{1/2}$ values of NADPH and the **L3** ferric chelate could explain the fact that **L3**−iron is not a catalyst of reductant-driven Fenton reaction under physiological conditions.[7] In addition, a small proportion of the complex remains in the Fe**L3** form, which could be reduced by physiological reductants. This process would allow potential redox cycling of iron, especially during acidosis, which is generally associated with cell oxidative stress. Therefore, it is likely that additional parameters, such as the kinetics of complex formation, compensate for the thermodynamic factor that is favorable for the catalysis of Fenton chemistry.

In contrast, the electrochemical behavior of **L(1−2)** + Fe^{III} complexes appears more complicated, possibly due to the presence of several species in solution at basic pH values, including the μ-oxo binuclear species already characterized by ESI-MS.[8] At pH values above 8, an ill-behaved peak system is seen in the CV curves (Figure 7, curves 1 and 2) (E_{pc} = −0.80 and −0.72 V, E_{pa} = −0.15 and −0.04 V for the complexes **L2** + Fe^{III} and **L1** + Fe^{III}, respectively). For pH values lower than 4.5 (Figure 7,

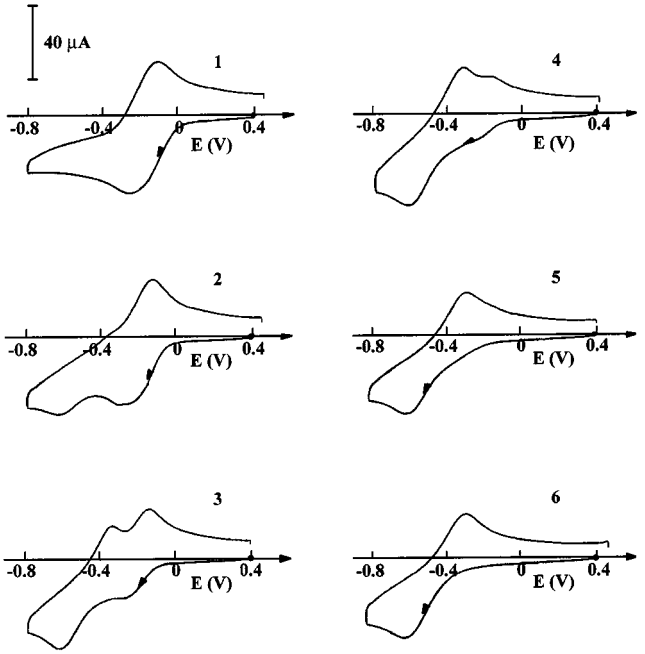

Figure 6. CV curves of Fe^{III} + **L3** (2.9 mM) in H_2O + $NaClO_4$ 0.1 M at a GC electrode (5 mm diameter); scan rate 0.1 Vs^{-1}; E vs. Ag/AgCl, aqueous NaCl (3 M) (+ 0.21 V vs. NHE); pH = 4.2 (1), 5.4 (2), 6.3 (3), 7.0 (4), 8.3 (5), 9.2 (6) (adjusted with $HClO_4$ or NaOH)

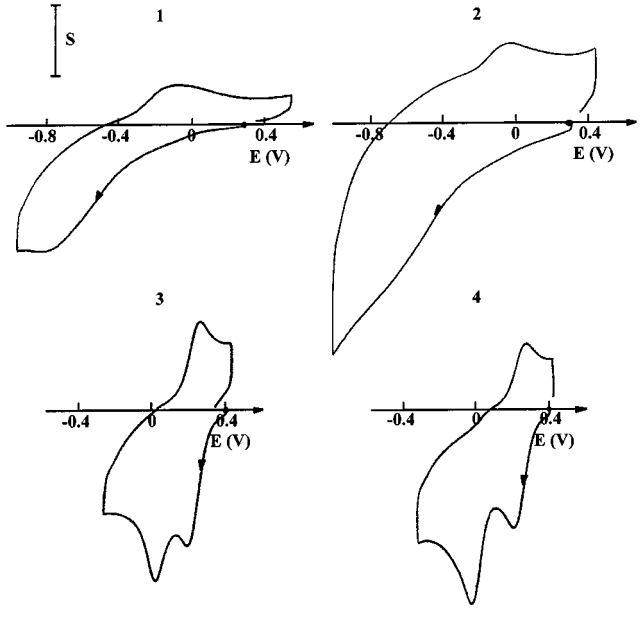

Figure 7. CV curves of Fe^{III} + **L2** (1, 3) and Fe^{III} + **L1** (2, 4), 0.5 mM in H_2O + $NaClO_4$ 0.1 M at a GC electrode (5 mm diameter); scan rate 0.1 V s^{-1}; E vs. Ag/AgCl, aqueous NaCl (3 M) (+0.222 V vs. NHE); pH = 8.3 (1, 2), 3.0 (3, 4) (adjusted with $HClO_4$ or NaOH); scale (S) = 10 μA (1, 2), 4 μA (3, 4)

curves 3 and 4), a reversible redox wave is seen at $E_{1/2}$ = 0.21 and 0.22 V (ΔE_p = 0.06 and 0.08 V, respectively) in the CV curves recorded in the presence of **L2** + Fe^{III} and **L1** + Fe^{III}, respectively. At lower potentials, a fully irreversible peak at 0 V (**L2** + Fe^{III}) or −0.04 V (**L1** + Fe^{III}) is observed, confirming the presence in solution of two different Fe^{III} species in a frozen equilibrium, i.e. the interconversion of these species is slow on the time scale of voltammetry. Between pH = 5 and 8, the CV curves consist of the overlapped electrochemical signals observed in basic and acidic media. These results are in agreement with pK^1_{OH} and pK^2_{OH} values of ca. 3 and 7 found for both **L2** + Fe^{III} and **L1** + Fe^{III} complexes, i.e. in basic media only the $Fe^{III}(OH)_2L$ complex is present in solution whereas in acidic media an equilibrium between $Fe^{III}L$ and $Fe^{III}(OH)L$ occurs. Taking into account the negative shift in potential for the redox couple $Fe^{III}(OH)L/Fe^{II}L$ in comparison to Fe^{III}**L3**/Fe^{II}**L3**, it can be assumed that the reversible wave at around 0.2 V is attributable to the $Fe^{III}L/Fe^{II}L$ redox couple (where L signifies **L1** or **L2**) when the irreversible electron transfer corresponds to the cathodic process characteristic of Fe^{III}(OH)**L3**. The irreversibility of the electron transfer is likely to be due to a change in the coordination sphere around the Fe center upon reduction. Comparing **L1** and **L2**, it must be noted that the substitution of **L1** with electron-donating methoxy groups does not influence significantly the potential characteristic of the iron-localized electron transfer. In addition, under the same experimental conditions, $E_{1/2}$ for the Fe^{III}EDTA/Fe^{II}EDTA redox couple is found at −0.10 V, showing that **L3** stabilizes the Fe^{III} form of the complex by ca. 0.12 V while **L1** and **L2** stabilize the Fe^{II} form of the complex by ca. 0.31 V. This is in agreement with the presence of the hard coordinating hydroxo site on **L3**.

Formation and Acid Hydrolysis Kinetics of the FeL3 Complex

The capacity of a chelator to protect against the formation of damaging oxidizing species is influenced not only by several thermodynamic factors, but also by kinetic factors. Therefore, the kinetics of formation of the Fe**L3** complex was investigated by a stopped-flow spectrophotometric method under pseudo-first-order conditions: [Fe^{III}] and [H^+] >> [L] and at ionic strength I = 2 M, 25 °C. The absorbance change vs. time of the phenolato-to-Fe^{III} charge transfer band at λ = 525 nm showed a single exponential curve indicating that the complex formation reaction proceeds through a single rate-limiting step. The spectra recorded with time using a diode array device were similar to those shown in Figure 4a. It was found that the pseudo first-order rate constants k_{obs} at a given acidity level ([H^+] varied from 0.05 to 0.15 M) have a linear variation as a function of [Fe^{3+}] with a significant intercept (Figure 8) that indicates a contribution of the reverse reaction. The slopes of these plots decrease as [H^+] increases. In addition, the intercepts of the plots increase as [H^+] increases.

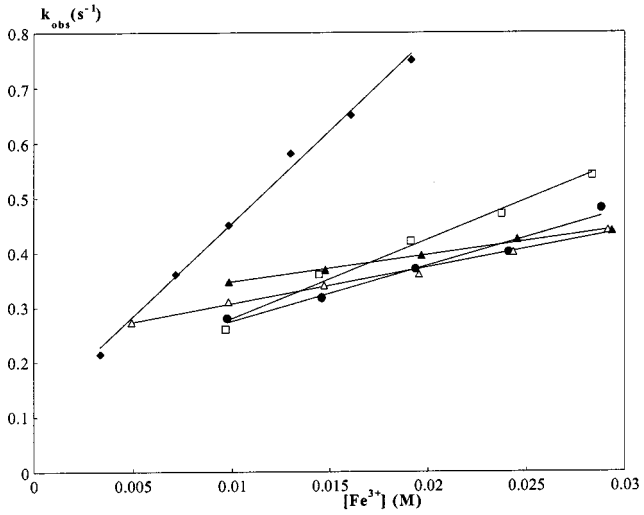

Figure 8. Variation of the experimental rate constant k_{obs} (s^{-1}) for the formation of the Fe^{III}−**L3** complex as a function of [Fe^{3+}] (M) at various [H^+] (M): (◆) 0.05, (□) 0.08, (●) 0.10, (Δ) 0.125, (▲) 0.15; [**L3**] = 0.4 mM; solvent: water, I = 2.0 M ($HClO_4$ + $NaClO_4$), T = 25 °C

The acid hydrolysis kinetics of the Fe−**L3** complex was studied in aqueous solution (ionic strength I = 2 M, 25 °C) by the pH jump method. The pH jump reactions were performed under pseudo-first-order conditions with respect to [H^+] (varying over the range 0.02−0.9 M) for solutions containing Fe^{III} and **L3** in a 1:1 molar ratio at an initial pH value of 4. The UV/Vis spectra recorded as a function of the time resemble the spectra recorded for the formation reaction study and for the equilibrium study at pH < 2 (Figure 4a) and indicate a total dechelation at the iron center. The exponential absorbance decay vs. time recorded at 520 nm indicates that the dissociation occurs through a single determining step. The plot of the k_{obs} rate constants vs. [H^+] is linear over the [H^+] range 0.2−1.0 M and slightly curved at low [H^+] (Figure 9).

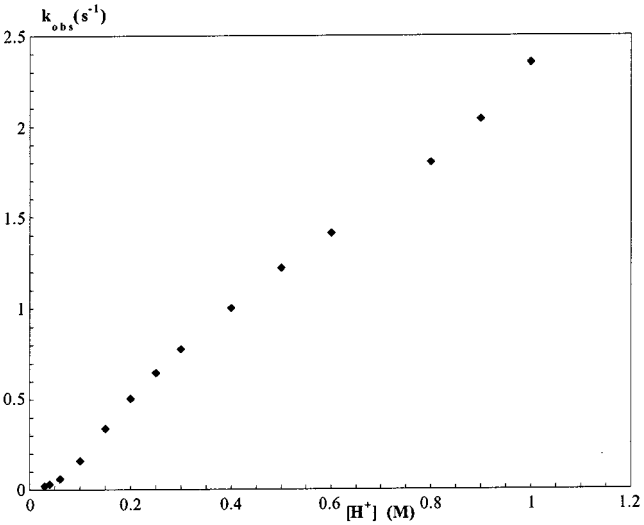

Figure 9. k_{obs} (s^{-1}) as a function of [H^+] (M) in the acid hydrolysis kinetics of the Fe^{III}−**L3** complex, [Fe**L3**] = 0.5 mM; solvent: water; I = 2.0 M ($HClO_4$ + $NaClO_4$), T = 25 °C

By taking into account the equilibria existing in solution under the experimental conditions and after analyzing the kinetics results from both the formation and the hydrolysis reactions, the reaction scheme shown in Equation (5) to Equation (14) can be proposed ($[FeOH]^{2+}$ for $[Fe(OH)(OH_2)_5]^{2+}$, Fe^{3+} for $[Fe(OH_2)_6]^{3+}$ and L for **L3**).

$$Fe^{3+} \rightleftharpoons FeOH^{2+} + H^+ \qquad K_{Fe} \qquad (5)$$

$$LH_5^{2+} \rightleftharpoons LH_4^+ + H^+ \qquad K_{a5} \qquad (6)$$

$$LH_4^+ \rightleftharpoons LH_3 + H^+ \qquad K_{a4} \qquad (7)$$

$$FeOH^{2+} + LH_4^+ \rightleftharpoons FeLH_2^{3+} + H^+ + H_2O \qquad k_3, k_{-3} \qquad (11)$$

$$Fe^{3+} + LH_3 \rightleftharpoons FeLH_2^{3+} + H^+ \qquad k_4, k_{-4} \qquad (12)$$

$$FeOH^{2+} + LH_3 \rightleftharpoons FeLH_2^{3+} + H_2O \qquad (13)$$

$$FeLH_2^{3+} \rightleftharpoons FeL^+ + 2\,H^+ \qquad K_{FeLH2} \qquad (14)$$

It was assumed that the rate-determining pathway involves the formation of the $[FeLH_2^{3+}]$ complex since the reaction proceeds through the coordination of Fe^{3+} with the phenolato oxygen atom and releases only one H^+ in the reaction according to Equation (12).

The pseudo-first-order kinetic according to Equation (15) can be obtained by neglecting terms from reactions according to Equation (8) to Equation (10), in agreement with the experimental results, where $[Fe^{3+}] = [Fe^{3+}]_{tot} - [FeOH^{2+}] - 2\,[Fe_2(OH)_2^{4+}]$ and $[H^+]$ takes into account the protons involved in formation of $[FeOH]^{2+}$ and $[Fe_2(OH)_2]^{4+}$ ($2\,Fe^{3+} \rightleftarrows [Fe_2(OH)_2]^{4+} + 2\,H^+$, K_{DFe}).

$$k_{obs} = \frac{[Fe^{3+}]}{[H^+]([H^+]^2 + [H^+]K_{a5} + K_{a4}K_{a5})}\{(k_3K_{Fe}K_{a5} + k_4K_{a4}K_{a5})[H^+] + k_5K_{Fe}K_{a4}K_{a5}\} + \{(k_{-3} + k_{-4})[H^+] + k_{-5}\}\left(\frac{[H^+]^2}{[H^+]^2 + K_{FeLH2}}\right) \qquad (15)$$

The values of K_{Fe} and K_{DFe} in 2.0 M $NaClO_4$ are 1.5×10^{-3} M and 2.4×10^{-3} M.[16] Since pK_{a5} was not determined, the fit of the data was performed using the value 1.17, which was obtained for the corresponding deprotonation of HBED.[15] The variation of the pseudo-first-order kinetic rate constant of the hydrolysis reaction is consistent with the last term of Equation 15.[17] The results of the nonlinear least-squares fit to Equation (15) of the combined formation and dissociation data are:

$(k_3K_{Fe}K_{a5} + k_4K_{a4}K_{a5}) = 0.078 \pm 0.018\ M^{-1}s^{-1}$ $k_5 = 13300 \pm 1400\ M^{-1}s^{-1}$

$(k_{-3} + k_{-4}) = 1.83 \pm 0.09\ M^{-1}s^{-1}$ $k_{-5} = 0.42 \pm 0.08\ s^{-1}$ $K_{FeLH2} = 0.026 \pm 0.005\ M^2$

The rate constants of the Fe^{3+} pathways have been found to be generally almost three orders of magnitude lower than those of the $[FeOH]^{2+}$ pathways.[18] So, if we assume a value of about $10\ M^{-1}s^{-1}$ for k_4, it seems reasonable to neglect the $k_4K_{a4}K_{a5}$ term with respect to $k_3K_{Fe}K_{a5}$. Thus, we can obtain $k_3 = 770 \pm 180\ M^{-1}s^{-1}$. From the values of k_5 and k_{-5}, $k_4/k_{-4} = K_{Fe}\,k_5/k_{-5}$ is calculated to be 47.5. An upper limit of k_{-4} is thus estimated to be 0.2 if $k_4 < 10$ and so we can obtain $k_{-3} = 1.6\ s^{-1}$.

In summary, we were able to determine the following rate constants:

$k_5 = 13300 \pm 1400\ M^{-1}s^{-1}$; $k_{-5} = 0.42 \pm 0.08\ s^{-1}$

$k_3 = 770 \pm 180\ M^{-1}s^{-1}$; $k_{-3} = 1.6 \pm 0.1\ s^{-1}$

Ligand substitution reactions at an iron center were assumed to be controlled by water exchange from the inner coordination shell. The rate constants may be described according to the Eigen−Wilkins mechanism[19] with a fast formation step of an outer-sphere complex (K_{os}) followed by a rate-limiting step involving the water substitution of the $[FeOH]^{2+}$ species (k_{ex}) according to Equation (16); k_f stands for k_3 or k_5, S is a statistical coefficient that accounts for the solvent shell composition and can be assigned an approximate value of 1/6.

$$k_f = K_{os} \cdot S \cdot k_{ex} \qquad (16)$$

Since k_{ex} does not change significantly with different ligands, variations in the rate constants are mainly due to the constant K_{os}. The charge of the ligand is one of the factors that influences the value of K_{os}. The constant can be estimated with the Fuoss equation[20] to be 0.2 for reactions of $[FeOH]^{2+}$ with a neutral ligand and ca. 0.02 for a ligand bearing a global positive charge. Accordingly, the value of k_5, which refers to the $[FeOH]^{2+} - LH_3$ pathway, is larger than the value of k_3, which refers to the $[FeOH]^{2+} - LH_4^+$ pathway ($k_5/k_3 \approx 17$). Furthermore, a comparison with the literature data indicates that k_5 is much higher than the rate constants determined for the $[FeOH]^{2+}$ − neutral ligand pathway for phenol, catechol and hydroxamate ligands (about 1×10^3 to $3 \times 10^3\ M^{-1}s^{-1}$). This finding can be explained by taking into account the zwitterionic character of the ligand **L3**. The two carboxylate anions are assumed to increase the K_{os} constant with respect to a ligand bearing no charges. The values of k_5 fall within the range for a ligand containing one or two aminoacetate donor groups,[21] such as H_4EDTA ($30000\ M^{-1}s^{-1}$) and H_3NTA ($15000\ M^{-1}s^{-1}$).

Kinetic data for the dissociation of ferric complexes with this type of ligand are not available in the literature. A comparison can be made with dissociation rate constants obtained for catecholate and hydroxamate ligands, which are the most widely reported in the literature. The dissociation rate of Fe**L3** by the $[FeOH]^{2+}$ pathway (1.6 and $0.42\ s^{-1}$) is close to that of the (monocatecholato)Fe−Tiron (1,2-dihydroxy-3,5-benzenedisulfonate) complex ($1.2\ s^{-1}$)[22] but significantly faster than those of the monohydroxamato

complexes (0.08 s^{-1} for acetohydroxamic acid and 0.0071 s^{-1} for *N*-methylacetohydroxamic acid).[23,24] A comparison with the last step of the dissociation of hexadentate chelates shows that **L3** releases Fe^{III} much faster than the tricatecholate TRENCAMS[25] (0.018 s^{-1}) and than the siderophores pyoverdin[26] ($> 6\ 10^{-5}\ s^{-1}$) and ferrioxamine B[27,28] (0.0021 s^{-1}).

Conclusion

In summary, this work has shown that the bis(aminocarboxylate)benzyl chelators of the present series have a relatively low affinity for Fe^{III}. It must be emphasized that these chelators (except **L3**) should be thermodynamically unable to compete for iron in most metalloproteins and especially for transferrin. For this reason side-effects can be expected to be limited, a situation in contrast to strong iron chelators, which can inhibit enzymes by removal of metal from active sites, by formation of a ternary complex or by depriving the apoenzyme of its normal source of iron. Under prooxidant conditions, e.g. in the presence of hydrogen peroxide, these chelators are hydroxylated to give species with strong iron affinity, as shown by the complexation stability constants and pFe value for **L3**, which are consistent with the presence of a hard phenolate donor group. Moreover, this dramatic increase of affinity for iron is associated with a large decrease in redox potential of Fe^{III}/Fe^{II}, which tends to inhibit iron reduction by physiological reductants thereby avoiding redox cycling of iron. However, it should be kept in mind that such a consideration refers to equilibrium conditions, which is generally not the case in biological systems, and these results agree with previous data showing that the **L3** iron complex is not a catalyst of reductant-driven Fenton reactions.[7] In addition, both the formation and dissociation kinetics of the ferric complex with **L3** were measured and were found to give consistent data. It should be emphasized that an interesting feature of **L3** is the fast uptake of Fe^{III} and its fast release under acidic conditions. The results presented here are in good agreement with biological data showing a very efficient protection of cultured cells by **L3** or **L1** prodrugs against hydrogen peroxide toxicity.[29,9]

Experimental Section

Materials and Equipment: Ligands **L1** and **L2** were prepared according to the procedure described previously.[8] All other compounds were of reagent grade and were used without further purification. Fe^{III} stock solutions were prepared by dissolving appropriate amounts of ferric perchlorate hydrate (Aldrich) in standardized $HClO_4$ and $NaClO_4$ solutions. The solutions were calibrated spectrophotometrically for ferric ions by using a molar extinction coefficient of 4160 $M^{-1}cm^{-1}$ at 240 nm.[30] Mass spectra were obtained by HPLC/MS with a Fisons Platform mass spectrometer equipped with an atmospheric pressure ion source in the electrospray ionization (ESI) mode. ^1H NMR spectra were recorded with a Bruker 500 MHz spectrometer.

Synthesis of L3

(a) *N*-(2-Hydroxybenzyl)-*N*′-benzylethylenediamine: A mixture of 8.05 g (66 mmol) of 2-hydroxybenzaldehyde and 10 g (66.6 mmol) of *N*-benzylethylenediamine was heated in 100 mL of MeOH at 50 °C for 30 min. The mixture was concentrated, the residue suspended in 150 mL of EtOH and 34 mmol of $NaBH_4$ was added. The reaction mixture was stirred at room temperature for 1 h and the solvent evaporated. 100 mL of water was added and concentrated HCl was used to acidify the solution to pH = 1−2. The crystalline dihydrochloride was collected by filtration, washed with cold ethanol and vacuum-dried over P_2O_5 to yield 13.85 g (81%) of *N*-(2-hydroxybenzyl)-*N*′-benzylethylenediamine. − MS (ESI^+); *m*/*z*: 256 $[M + H]^+$, 91 $[C_7H_7^+]$.

(b) *N*-(2-Hydroxybenzyl)-*N*′-benzylethylenediamine Diacetic Acid: A mixture of 12.8 g (50 mmol) of *N*-(2-hydroxybenzyl)-*N*′-benzylethylenediamine, 13.9 g (100 mmol) of bromoacetic acid, 2 g (50 mmol) of NaOH and 8.4 g (100 mmol) of $NaHCO_3$ in 150 mL of water was heated at 40 °C for 6 h while the pH value of the solution was maintained in the range of 11.5−12.5 by the addition of NaOH. Concentrated HCl was added to the reaction mixture until the pH value was lowered to 2. The white precipitate was filtered off and recrystallized from 2-propanol to yield 10 g of *N*-(2-hydroxybenzyl)-*N*′-benzylethylenediamine diacetic acid hydrochloride as a white powder (m.p. 190 °C, yield 46%). − ^1H NMR ([D$_6$]DMSO): δ = 3.14 (t, 2 H), 3.31 (t, 2 H), 3.42 (s, 2 H), 3.90 (2 × s, 4 H), 4.27 (s, 2 H), 6.85 (td, 1 H), 6.95 (d, 1 H), 7.23 (m, 7 H). − $C_{20}H_{25}ClN_2O_5$ (+ 0.05 NaCl) (411.8): calcd. C 58.33, H 6.08, Cl 9.06, N 6.80, O 19.45; found C 58.21, H 6.09, N 6.53, O 19.86, Cl 9.20.

Potentiometric Titrations: All the measurements were made at 25 °C and the solutions were prepared with deionized water that had been distilled twice. The ionic strength was fixed at $I = 0.1$ M with sodium perchlorate (PROLABO puriss). The potentiometric titrations were performed using an automatic titrator system, DMS 716 Titrino (Metrohm), equipped with a combined glass electrode (Metrohm, filled with saturated NaCl solution) and connected to an IBM Aptiva microcomputer. The electrodes were calibrated to read p[H] according to the classical method[31] (from titration of 0.1 M $HClO_4$ by 0.1 M NaOH). The ligand and its iron(III) complex of ca. 0.001 M were titrated with standardized 0.025 M sodium hydroxide. Argon was bubbled through the solutions to exclude CO_2 and O_2. Sodium hydroxide was prepared from 0.1 M NaOH (Prolabo) and was standardized. The titration data (120 points collected over the pH range 2.5−10.5 for the ligand solution and 100 points collected over the pH range 2.5−10 for the Fe^{III}−ligand solution) were refined by the nonlinear least-squares refinement program SUPERQUAD[10] to determine the deprotonation constants (σ_{fit} in the range 3−4). The pK_{an} values were calculated from the cumulative constants determined with the above program. The uncertainties in the pK_{an} values correspond to the standard deviations (1σ) in the cumulative constants.

Spectrophotometric Experiments: UV/Vis absorption spectra were recorded with a Perkin−Elmer Lambda 2 spectrometer using 1.000-cm path-length quartz cells and connected to a microcomputer; the acquisition was made with UV Winlab software (Perkin−Elmer). The temperature was maintained at 25 °C with a Perkin−Elmer PTP-1 variable temperature unit. The ferric complex with **L3** was studied by spectrophotometry. The UV/Vis spectrum of a solution containing equal amounts of ligand and Fe^{III} (10^{-4} M) was recorded as a function of pH over the range 1−8 (adjusted with $HClO_4$ or NaOH). An aliquot was taken from the solution

after each adjustment of the pH value and its spectrum was recorded. The pH measurements were made with a 713 Metrohm digital pH meter equipped with a microelectrode. The ionic strength was fixed at $I = 0.1$ M with $NaClO_4/HClO_4$. The spectrophotometric data were analyzed using the LETAGROP-SPEFO program.[12,13] The program uses a nonlinear least-squares method to calculate the thermodynamic constants of the absorbing species and their corresponding electronic spectra. The calculations were performed using absorbance values from about 6−8 wavelengths (between 400 and 600 nm). The range of values for the residual-squares sum $[\Sigma(A_{exp} - A_{calc})^2]$ of the fits was $10^{-2}-10^{-3}$.

Electrochemical Measurements: Electrochemical experiments were carried out using a PAR model 273 potentiostat equipped with a Kipp−Zonen x-y recorder. All experiments were run at room temperature under argon in a glove-box. A standard three-electrode cell was used. Potentials are referenced to Ag/AgCl, 3 M NaCl, aqueous reference electrode (+0.21 V vs. NHE). A glassy carbon disc electrode, used as a working electrode (5 mm diameter), was polished with 1 μm diamond paste. The electrochemical behavior of the Fe^{III}−ligand complex was studied by cyclic voltammetry (CV) in an aqueous solution containing 0.1 M $NaClO_4$ as a supporting electrolyte and buffered with tris-buffer for the experiments performed at pH = 7. For the experiments performed at pH ≠ 7, the pH value was adjusted following controlled additions of concentrated NaOH or $HClO_4$ aqueous stock solutions. The Fe^{III}−ligand solutions were prepared by dissolving stoichiometric amounts of ferric perchlorate and ligand in the electrolytic solutions.

Kinetics Studies: Kinetic measurements were performed with a KINSPEC UV (BIO-LOGIC Company, Claix, France) stopped-flow spectrophotometer equipped with a diode array detector (J & M) and connected to a TANDON microcomputer. The kinetic data were treated online with the commercial BIO-KINE program (BIO-LOGIC Company, Claix, France). The ionic strength was fixed at $I = 2$ M ($NaClO_4$, $HClO_4$) owing to the H^+ concentrations up to 1 M and allowing comparisons with literature data. − Formation kinetic studies were carried out under pseudo-first-order conditions at 25 °C with Fe^{III} in excess with respect to the ligand. The Fe^{III} concentration spanned the range $5 \times 10^{-3}-3 \times 10^{-2}$ M for each H^+ concentration, which was over the range 0.05−0.15 M. A solution containing Fe^{III} and H^+ and a solution containing the ligand **L3** (2×10^{-4} M) at the same ionic strength were mixed on the stopped-flow apparatus. In each case, first-order kinetics were observed. The reported rate constants are the average of about 8 replicate determinations (standard deviation in the range 1−2%). − The acid hydrolysis kinetics of the Fe^{III}−**L3** complex was studied under pseudo-first-order conditions in the presence of excess protons ($[H^+]$ range 0.02−1.0 M) at 25 °C. The initial pH value of the Fe^{III}−**L3** solution (7×10^{-4} M) was 4.

Acknowledgments

The authors thank Céline Carresi for performing the potentiometric measurements and Arnaud Pierra for performing the UV/Vis spectrophotometric and kinetic measurements with ligand **L3**. We are grateful to Dr. Alain Deronzier (LEOPR, Grenoble, France) for the use of the laboratory facilities, to Professor C. Béguin (LEDSS, Grenoble, France), Professor M. Fontecave and Dr. S. Ménage (CBCRB, CEA, Grenoble, France) for their interest in these studies.

Reaction of the (Dichloromethyl)oligosilanes $R(Me_3Si)_2Si-CHCl_2$ (R = Me, Ph, Me_3Si) with Organolithium Reagents and the Synthesis of Novel Kinetically Stabilized Silenes

Kathleen Schmohl,[a] Helmut Reinke,[a] and Hartmut Oehme*[a]

Keywords: Lithium / Silaethene / Silanes / Silenes / Silicon

The dichloromethyloligosilanes $R^1(Me_3Si)_2Si-CHCl_2$ (**1a**,**b**) (**1a**: R^1 = Me; **1b**: R^1 = Ph), prepared by treatment of methylbis(trimethylsilyl)silane or phenylbis(trimethylsilyl)silane respectively, with chloroform and potassium *tert*-butoxide, treated with the organolithium reagents R^2Li (R^2 = Me, Ph) to produce the intermediate organolithium derivatives $R^1R^2_2Si-CLi(SiMe_3)_2$ (**10**). Hydrolysis of **10** during the aqueous workup afforded the [bis(trimethylsilyl)methyl]silanes $R^1R^2_2Si-CH(SiMe_3)_2$ (**2**); quenching of the reaction mixture with chlorotrimethylsilane gave the [tris(trimethylsilyl)methyl]silanes $R^1R^2_2Si-C(SiMe_3)_3$ (**11**). The formation of **10** is discussed as proceeding through a remarkable series of isomerization processes involving the transient silenes $R^1R^2Si=C(SiMe_3)_2$ (**7**), which in the presence of an effective excess of R^2Li are immediately trapped to give **10**. By the use of sterically congested organolithium derivatives, the nucleophilic addition of R^2Li to the Si=C bond of **7** can be prevented and kinetically stabilized silenes obtained. Thus, Ph(2,4,6-iPr$_3$C$_6$H$_2$)Si=C(SiMe$_3$)$_2$ (**8b**) was synthesized by the reaction of **1b** with 2,4,6-triisopropylphenyllithium (molar ratio 1:2). Similarly, (Me$_3$Si)(2,4,6-iPr$_3$C$_6$H$_2$)Si=C(SiMe$_3$)$_2$ (**8c**) and (Me$_3$Si)(2-tBu-4,5,6-Me$_3$C$_6$H)Si=C(SiMe$_3$)$_2$ (**9c**) were prepared from (dichloromethyl)tris(trimethylsilyl)silane (**1c**) and 2,4,6-triisopropylphenyllithium or **1c** and 2-*tert*-butyl-4,5,6-trimethylphenyllithium (1:2), respectively, but due to difficulties in the separation of starting material and side products, **8b**, **8c**, and **9c** were obtained in impure form only. Despite the steric congestion, the compounds are reactive and exhibit the usual behavior of silenes. Thus **8b**, **8c**, and **9c** were chemically characterized by the reaction with water to give silanols, by the addition of methanol to give methoxysilanes and by formal [2+2] cycloadditions with benzaldehyde to afford stable 1,2-oxasiletanes. 1-Methyl-1-(2,4,6-triisopropylphenyl)-2,2-bis(trimethylsilyl)silene (**8a**), produced as intermediate from **1a** and 2,4,6-triisopropylphenyllithium (1:2), proved to be unstable in the presence of excess aryllithium compound. Thus, only the addition product Me(2,4,6-iPr$_3$C$_6$H$_2$)$_2$SiCH(SiMe$_3$)$_2$ (**14**) was isolated (after hydrolysis).

Introduction

Silenes are known to be extremely labile compounds which can be isolated and handled under normal conditions only in those cases where structural influences cause an efficient stabilization of the Si=C system.[1] In numerous reactions transient silenes occur as reactive intermediates, but until now the number of synthetic methods affording stable, isolable silenes is rather limited. Brook and co-workers introduced the photochemical isomerization of acyloligosilanes as a versatile method for the generation of silenes, and in 1982 they were the first to isolate a stable silene, $(Me_3Si)_2Si=C(OSiMe_3)Ad$ (Ad = 1-adamantyl), and to perform an X-ray analysis of the compound.[2] In 1983 Wiberg and his group succeeded in applying the classical 1,2 salt elimination to the synthesis of the stable silene $Me_2Si=C(SiMe$*t*$Bu_2)SiMe_3$ and provided the results of its X-ray analysis.[3] Elimination of lithium chloride after addition of *tert*-butyllithium to the carbon−carbon double bond of chloro(vinyl)silanes is also the crucial step in establishing Si=C bonds in a method developed by the groups of Jones and Auner, which was successfully used by Couret et al. in 1994 in the preparation of the stable 1,1-dimesityl-2-neopentylsilene.[4] A further method, which has proved to be an efficient general route to silenes, is the sila Peterson reaction. We were able to contribute to the development of the process and generated a number of transient silenes and studied their mode of dimerization,[5] and in 1996 Apeloig and co-workers succeeded in preparing the stable derivative (tBuMe$_2$Si)$_2$Si=CAd′ (Ad′ = 2-adamantylidene) by this method.[6] A few further stable silenes have been isolated by the groups mentioned.[1] Of course, the structures of these compounds are related to their methods of preparation, and extension of the substitution pattern by introducing new synthetic pathways is desirable.

Recently we reported the reaction of (dichloromethyl)-tris(trimethylsilyl)silane (**1c**) with organolithium reagents RLi (R = Me, *n*Bu, Ph, Mes).[7] As the result of a remarkable sequence of isomerization and addition steps, and a complete reorganization of the substitution pattern of the starting compound, [bis(trimethylsilyl)methyl]silanes **2** were formed as end products [Equation (1)].

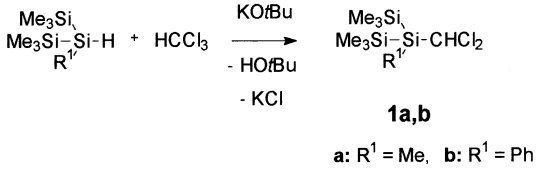
As outlined in Scheme 1 for the behavior of the (dichloromethyl)oligosilanes **1a−c** towards methyllithium or phenyllithium respectively, in the course of this reaction transient silenes occurred as intermediates, which in the presence of excess organolithium reagent were trapped to give the products mentioned. Increasing the bulkiness of the substituents of the organolithium derivatives used in this reaction is expected to afford kinetically stabilized silenes, sufficiently protected against the attack of excess lithium compound and stable with respect to dimerization. Thus, this paper describes the extension of the conversion depicted in Equation (1) for **1c** to (dichloromethyl)methylbis(trimethylsilyl)silane (**1a**) and (dichloromethyl)phenylbis(trimethylsilyl)silane (**1b**), as well as the generation of novel stable silenes along this new synthetic pathway.

Results and Discussion

Reaction of (Dichloromethyl)methylbis(trimethylsilyl)silane (1a) and (Dichloromethyl)phenylbis(trimethylsilyl)silane (1b) with Organolithium Derivatives

The dichloromethylsilanes **1a** and **1b** were prepared adapting a procedure reported by Weidenbruch et al. for the preparation of (dichloromethyl)tri-*tert*-butylsilane.[8] Thus, treatment of methylbis(trimethylsilyl)silane with chloroform in the presence of potassium *tert*-butoxide afforded **1a** in a yield of 36%. Compound **1b** was similarly obtained from phenylbis(trimethylsilyl)silane, $HCCl_3$ and KO*t*Bu (yield 41%) [Equation (2)]. The dichloromethylsilane **1a** has already been described by Sakurai et al., who obtained the compound from 2-chloroheptamethyltrisilane and dichloromethyllithium.[9]



In agreement with the described reaction of **1c** with organolithium compounds,[7] **1a** reacted with methyllithium at room temperature (molar ratio 1:3) to give, after hydrolytic workup, tris(trimethylsilyl)methane (**2ax**). Under the same conditions **1a** and phenyllithium afforded methyldiphenyl[bis(trimethylsilyl)methyl]silane (**2ay**). Similarly, reaction of **1b** with the same organolithium derivatives gave dimethylphenyl[bis(trimethylsilyl)methyl]silane (**2bx**) and triphenyl[bis(trimethylsilyl)methyl]silane (**2by**), respectively (Scheme 1). The structures of the compounds obtained were elucidated on the basis of NMR and MS data (see Experimental Section).

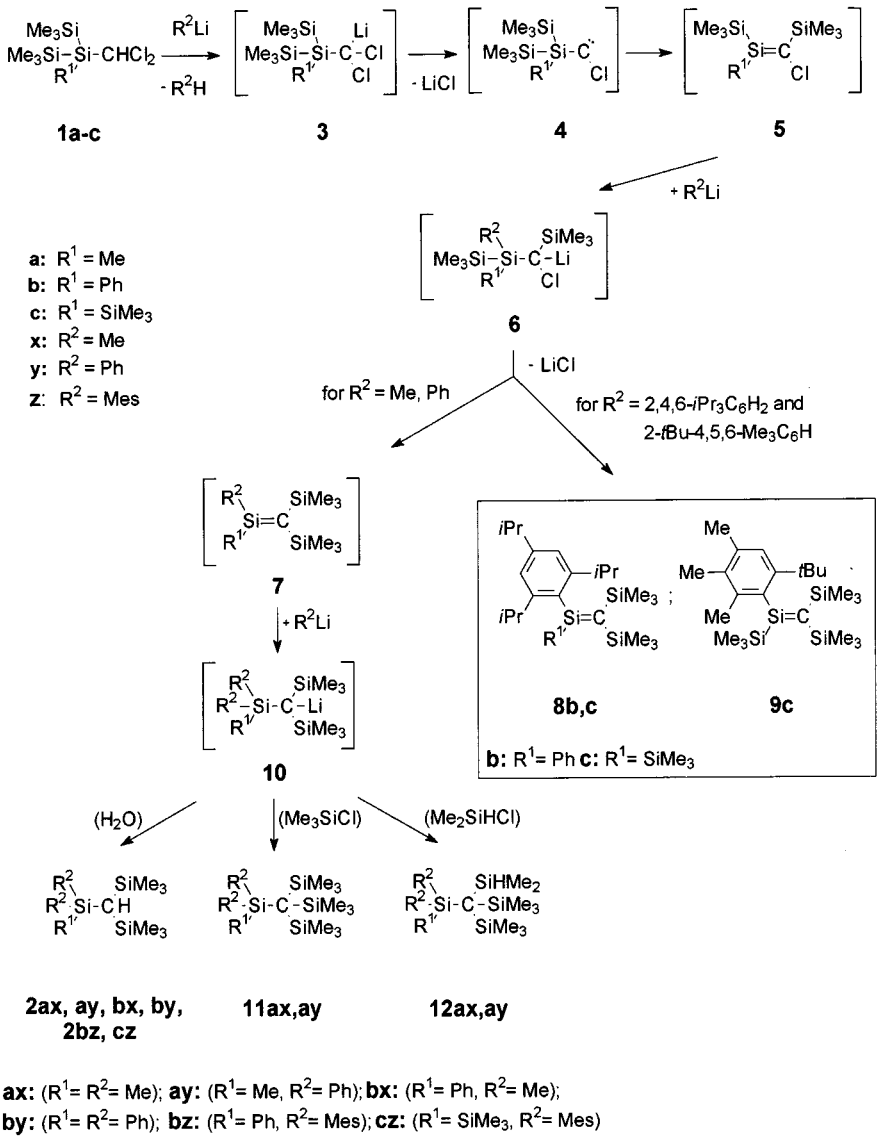
The conversion of **1a−c** to **2** by the means of organolithium compounds is a complex process. Two trimethylsilyl groups migrate from the central silicon atom to the neighboring carbon atom, formally replacing the two chlorine substituents, and the two organic groups introduced by the lithium derivatives occupy the former positions of the two trimethylsilyl substituents. Despite the unexpected outcome of the reaction, the conversion can be rationalized as a clear sequence of known steps. Our proposal for the reaction mechanism is outlined in Scheme 1, which also includes the formerly described conversion of **1c**.[7]

The dichloromethylsilanes **1a−c** are deprotonated by the organolithium reagents with generation of the silylcarbenoids **3**. Elimination of lithium chloride and migration of one trimethylsilyl group from the central silicon atom to the carbene carbon atom affords the intermediate silene **5**.

Rearrangements of silylcarbenes to silenes involving the shift of one substituent from the silicon atom to the neighboring carbene carbon atom are well-documented reactions and a standard method for the generation of transient silenes.[10] Hydrogen, alkyl, aryl, and silyl groups have been found to be suitable migrating substituents in this isomerization process; the migrating ability of the silyl groups exceeds that of the other groups mentioned.[11] In the presence of excess organolithium reagent the silenes **5** are immediately trapped to give the new carbenoids **6**. Repeated elimination of LiCl and a further 1,2-Si,C shift of one trimethylsilyl group affords the silenes **7**, which again undergo nucleophilic addition of a third equivalent of R^2Li, producing **10**. Hydrolysis during the aqueous workup affords **2**.

The intermediate existence of the chlorosilylcarbene **4** could not be proved and an intramolecular Me_3Si/Li exchange in **3**, followed by a 1,2 lithium chloride elimination, might be an alternative route to the silene **5**. Trapping experiments of the carbene **4** were abandoned, since it is well known that silylcarbenes, generated photochemically or thermally from the corresponding diazo compounds, very rapidly rearrange to the respective silenes, and in numerous experiments with different scavenger reagents only the silenes were detected.[11,12] The carbenoids **6** proved to be moderately stable at low temperatures. As described previously, we succeeded in trapping **6cy**, generated from **1c** and phenyllithium, with chlorotrimethylsilane to give $Ph(Me_3Si)_2Si-CCl(SiMe_3)_2$ and by quenching with water, affording $Ph(Me_3Si)_2Si-CHClSiMe_3$.[7] The intermediate organolithium compounds **10**, formed by addition of methyllithium or phenyllithium to the silene double bond of **7**, are suitable precursors for highly congested tris(silyl)-methyl-substituted silanes. Thus, addition of chlorotrimethylsilane to the product mixture obtained after the reaction of **1a**,**b** with MeLi or PhLi produced the [tris(trimethylsilyl)methyl]silanes **11**. Similarly, quenching of **10** with Me_2SiHCl gave the [dimethylsilylbis(trimethylsilyl)-methyl]silanes **12**.

Independent of the molar ratio **1a−c**/RLi, we found the reaction to proceed through all intermediates outlined in Scheme 1 to give the final products **2**, **11**, or **12**, respectively. Attempts to isolate dimers of the silenes **5** or **7** by reducing the ratio of the reactants to 1:2 or 1:1 were unsuccessful. We assume that the deprotonation of **1a−c**, producing the carbenoids **3**, is a slow process compared with the subsequent steps, and the transient silenes **5** and **7**, formed during the course of the reaction, always meet an effective ex-



Scheme 1. Reaction of the dichloromethyloligosilanes **1a−c** with organolithium reagents R^2Li

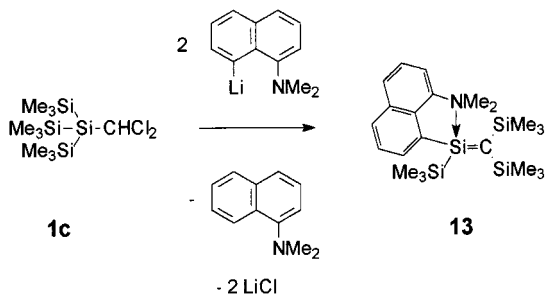
cess of the organolithium reagent, finally producing the congested silanes.

Reaction of the Dichloromethylsilanes 1a−c with 2,4,6-Triisopropylphenyllithium and of 1c with 2-*tert*-Butyl-4,5,6-trimethylphenyllithium − Synthesis and Behavior of the Stable Silenes 8b, 8c, and 9c

As discussed above, in the course of the reaction of the dichloromethylsilanes **1a−c** with methyllithium or phenyllithium, the transient silenes **5** and **7** occur as intermediates. As expected, in the presence of excess organolithium reagent, the almost unprotected, reactive silenes are immediately trapped to give the addition products **6** or **10**, respectively. However, if organolithium reagents are chosen with groups R^2, which, when introduced to the silene Si atom of **7**, provide sufficient stabilization of the silaethene by means of their steric bulk or by intramolecular donor-acceptor interactions, the reaction may stop at this stage and the resulting silenes may be expected to be stable. The high reactivity of silenes of type **5** also allows the addition of extremely congested organolithium derivatives to produce carbenoids **6**, which after loss of LiCl and subsequent isomerization may result in the formation of kinetically stabilized Si=C systems. Thus, we consider (dichloromethyl)oligosilanes and their reaction with organometallic bases as a promising tool in the synthesis of stable silenes.

Following this concept we studied the reaction of **1c** with 8-dimethylamino-1-naphthyllithium and obtained **13** in a straightforward one-pot reaction as a yellow, crystalline compound in a yield of 79% [Equation (3)].[13] The X-ray analysis of **13** confirmed the expected picture of an intramolecularly donor-stabilized silene with fourfold coordination at the silene silicon atom. Obviously, the 8-dimethylaminonaphthyl substituent dramatically decreases the electrophilic character of the silicon center and prevents further attack of organolithium reagent at the silene double bond. Thus, **13** is stable and can be isolated, and the reaction is highly recommended as an efficient and versatile method

for the synthesis of further intramolecularly donor-stabilized silenes.



For the synthesis of kinetically stabilized silenes of type **7** two options were taken into consideration. Firstly, bulky groups R^1 may be introduced at the silene Si atom by starting with appropriately substituted (dichloromethyl)silanes **1**, or secondly, space-demanding substituents R^2 may be introduced by the respective organolithium derivatives R^2Li in the reaction with **1a**−**c**. Concerning the first alternative, we tried to synthesize (dichloromethyl)mesitylbis(trimethylsilyl)silane following the standard method described above. Unfortunately, mesitylbis(trimethylsilyl)silane was recovered unchanged after treatment with chloroform and potassium *tert*-butoxide. No reaction between the H-silane and CCl_2 occurred, probably due to steric reasons. On the other hand, **1b** and **1c**, which were chosen for some preliminary experiments, reacted with mesityllithium (1:2) to give after hydrolysis the "normal" silene addition products $PhMes_2Si-CH(SiMe_3)_2$ (**2bz**) and $Me_3SiMes_2Si-CH(SiMe_3)_2$ (**2cz**),[7] respectively, (Scheme 1). Obviously, one *Si*-mesityl substituent and one *Si*-phenyl or *Si*-trimethylsilyl group at the silene silicon atom of **7** provides insufficient protection to the Si=C system against the attack of mesityllithium. Replacement of the mesityl group in **7** by a 2,4,6-tri-*tert*-butylphenyl substituent is expected to increase the kinetic stability of the silene. But 2,4,6-tri-*tert*-butylphenyllithium did not react with the (dichloromethyl)-silane **1c**. The components remained unchanged, i.e. no deprotonation of **1c** occurred, very likely due to the steric congestion in both the dichloromethylsilane and the organolithium compound. Also, the reaction of **1c** with *tert*-butyllithium in pentane gave unsatisfactory results. We obtained a complex mixture of products. Neither a silene, nor any product resulting from a silene, could identified.

However, treatment of **1b** and **1c** with 2,4,6-triisopropylphenyllithium (molar ratio 1:2) afforded in a clean reaction the indefinitely stable silenes **8b** and **8c**, respectively. Similarly, **1c** and 2-*tert*-butyl-4,5,6-trimethylphenyllithium (1:2) gave the silene **9c** (Scheme 1). The compounds were obtained by a straightforward one-pot reaction of the components in ether at room temperature. Unfortunately, we did not succeed in crystallizing the compounds, and in all cases complete separation of starting materials or side products from the oily silenes failed. In particular the quality of **8b** and **9c** did not allow an unambiguous assignment of e.g. their NMR signals, and therefore no spectroscopic data of the compounds are given. The silene **8c** was obtained as a pale yellow oil, only slightly contaminated with 1,3,5-triisopropylbenzene, after reaction of the components, removal of the solvent and extraction of the residue with pentane. Triisopropylbenzene, formed as by-product, was separated by repeated concentration of the pentane solution in vacuo, finally at 100 °C. Furthermore, under these conditions no silene dimerization or uncontrolled decomposition was observed. Compound **8c** could be characterized by its NMR and MS data (see Experimental Section). Indicative of the proposed structure is the ^{29}Si chemical shift of the silene silicon atom of **8c** (δ = 79.6). Silenes with comparable substitution patterns are unknown, but similarly structured derivatives, such as (*E*)-$(Me_3Si)TipSi=C(OSiMe_3)Ad$ ($\delta^{29}Si$ = 40.3; Ad = 1-adamantyl),[14] $Mes_2Si=CHCH_2tBu$ ($\delta^{29}Si$ = 77.6)[4] or $(Me_3Si)(tBuMe_2Si)Si=Ad'$ ($\delta^{29}Si$ = 51.7, Ad′ = 2-adamantylidene)[6] also show characteristic downfield shifts of the Si=C signals in their ^{29}Si NMR spectra. Unfortunately, the ^{13}C NMR signal of the silene carbon atom of **8c**, which is expected to appear with very low intensity, could not be assigned unambiguously.

To our surprise, the reaction of **1a** with 2,4,6-triisopropylphenyllithium (molar ratio 1:2) did not give the stable silene **8a**, but led after aqueous workup to methylbis(2,4,6-triisopropylphenyl)[bis(trimethylsilyl)methyl]silane (**14**) [Equation (4)]. Obviously, replacement of a phenyl group or a trimethylsilyl group in **8b** or **8c**, respectively, by the smaller methyl substituent, decreases the steric protection of the Si=C system and in the presence of excess organolithium reagent a second 2,4,6-triisopropylphenyl substituent is introduced at the silene silicon atom. Compound **14** is an extremely congested silane and structural data would be of particular interest. However, due to the poor crystal quality, the accuracy of the X-ray structural analysis was not very high. Thus, the connectivity of the structure proposed was

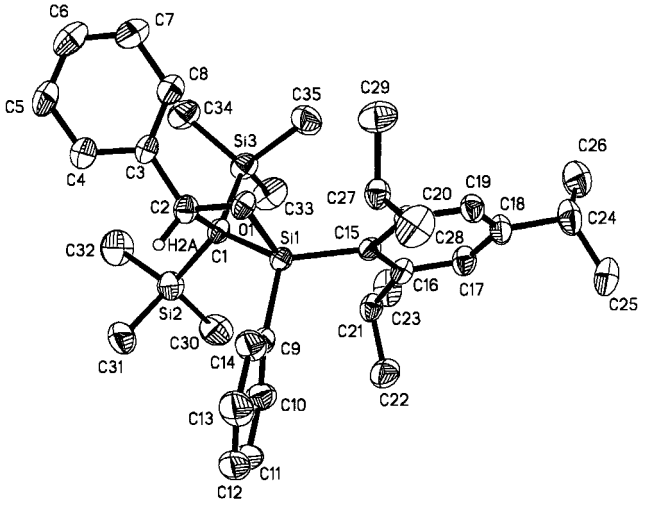


Figure 1. Molecular structure of **19b** in the crystal (H atoms omitted); selected bond lengths [Å] and angles [°]: Si1−O1 1.679(2), O1-C2 1.461(4), C2−C1 1.607(5), C1−Si1 1.924(3), Si1−C15 1.900(3), Si1−C9 1.890(3), C1−Si2 1.912(3), C1−Si3 1.915(4), C2−C3 1.495(5); Si1−O1−C2 112.6(2), O1−C2−C1 99.3(2), C2−C1−Si1 79.11(18), C1−Si1−O1 80.72(13), C9−Si1−C15 107.71(14), Si2−C1−Si3 111.86(17), torsion angle C1−C2−O1−Si1 25.9(2)

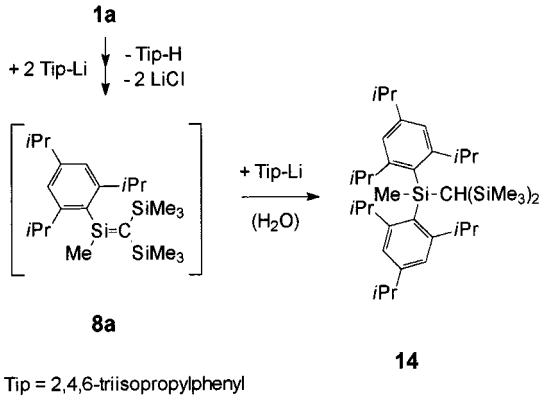
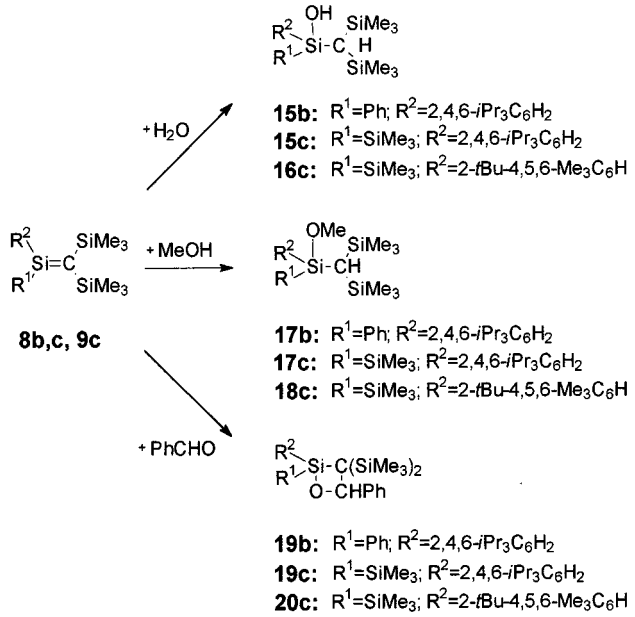
confirmed unambiguously, but a detailed discussion of bond parameters is excluded.



Despite the steric congestion, which prevents the dimerization of **8b**, **8c**, and **9c**, the compounds are reactive and exhibit the typical behavior of silenes. Thus, treatment with water led to the expected formation of the silanols **15b**, **15c**, and **16c** (Scheme 2). Similarly, methanol was added to the silene group to afford the methoxysilanes **17b**, **17c**, and **18c**. The results of the nucleophilic addition of methyllithium or phenyllithium to the Si=C unit, a reaction which we generally used for the characterization of transient silenes,[15] were unclear in case of **8b**, **8c**, and **9c**. We obtained complex mixtures of products, from which no compounds could be isolated. Further, reactions with 2,3-dimethyl-1,3-butadiene, which were intended to give [2+2] or [2+4] cycloadducts,[1] produced unsatisfactory results. The components were recovered unchanged. Both unsuccessful attempts at characterization are interpreted as an indication of the extreme steric shielding of the silene group.



Scheme 2. Conversion of the stable silenes **8b**, **8c**, and **9c** with water into the silanols **15b**, **15c**, and **16c**, with methanol into the methoxysilanes **17b**, **17c**, and **18c**, and with benzaldehyde into the 1,2-oxasiletanes **19b**, **19c**, and **20c**

Benzaldehyde adds to the Si=C functionality of **8b**, **8c**, and **9c** in a formal [2+2] reaction to afford the 1,2-oxasiletanes **19b**, **19c**, and **20c** (Scheme 2). 1,2-Oxasiletanes, generated as intermediates in the reaction of transient silenes with carbonyl compounds in most cases undergo rapid decyclizations to give oligomers of the respective silanones and an olefin.[16] But in case of relatively stable silenes of the "Brook-type",[1b] the formation of stable 1,2-oxasiletanes is common.[17] Compounds **19b**, **19c**, and **20c** were formed in low yields (besides large quantities of unidentified material), but could be isolated in crystalline form, and for all three compounds X-ray structural analyses were performed. The molecular structure of **19b**, which was chosen as an example of the comparable 1,2-oxasiletane systems, is shown in Figure 1. In all three structures the ring bonds are slightly longer than the usual acyclic values [Si−C: **19b**: 1.924(3), **19c**: 1.944(3), **20c**: 1.939(3); C−C: **19b**: 1.607(5), **19c**: 1.603(4), **20c**: 1.600(5); C−O: **19b**: 1.461(4), **19c**: 1.440(4), **20c**: 1.446(4); Si−O: **19b**: 1.679(2), **19c**: 1.684(2), **20c**: 1.680(2) Å]. These data are comparable with those reported for 1,2-oxasiletanes.[17] The four-membered rings in **19c** and **20c** are nearly planar, in **19b** the ring is folded, the torsion angle C1−C2−O1−Si1 being 25.9°.

Experimental Section

General: All reactions involving organometallic reagents were carried out under purified argon. − NMR: Bruker AC 250 or Bruker ARX 300, tetramethylsilane as internal standard. − IR: Nicolet 205 FT-IR. − MS: Intectra AMD 402. − $Me(Me_3Si)_2SiH$, $Ph(Me_3Si)_2SiH$, and $(Me_3Si)_3SiH$ were prepared using the method described by Marschner.[18] − The syntheses and structures of **1c**, **2cx**, **2cy**, and **2cz** were described previously.[7] − Due to the formation of SiC, the results of the elemental analyses of some compounds were unsatisfactory. In these cases HRMS data are given.

(Dichloromethyl)methylbis(trimethylsilyl)silane (1a):[9] At room temperature, KO*t*Bu (1.42 g, 12.6 mmol) and chloroform (1.51 g, 12.6 mmol) were added gradually to a solution of methylbis(trimethylsilyl)silane (2.2 g, 11.5 mmol) in pentane (30 mL). After stirring for 12 h, water was added, the organic layer separated and the aqueous phase extracted with pentane. The collected extracts were dried and concentrated and the residue purified by kugelrohr distillation (50 °C/1.4·10^{-2} mbar) to give 1.14 g (36%) of **1a**. Colorless oil. − ^{1}H NMR ([D$_6$]benzene): δ = 0.16 [s, Si(CH$_3$)$_3$; 18 H], 0.20 (s, SiCH$_3$; 3 H), 5.28 (s, CH; 1 H). − ^{13}C NMR ([D$_6$]benzene): δ = −0.7 [Si(CH$_3$)$_3$], −8.4 (SiCH$_3$), 64.8 (CH). − ^{29}Si NMR ([D$_6$]benzene): δ = −23.2 (*Si*SiMe$_3$), −15.8 (SiMe$_3$). − $C_8H_{22}Cl_2Si_3$ (273.4): calcd. C 35.14, H 8.11, Cl 25.93; found C 35.35, H 8.39, Cl 24.94.

(Dichloromethyl)phenylbis(trimethylsilyl)silane (1b): As described for **1a**, phenylbis(trimethylsilyl)silane (2.2 g, 8.71 mmol), KO*t*Bu (1.1 g, 9.81 mmol) and chloroform (1.17 g, 9.81 mmol) afforded after kugelrohr distillation at 110 °C/2.2·10^{-1} mbar 1.2 g (41%) of a colorless oil. − ^{1}H NMR ([D$_6$]benzene): δ = 0.24 (s, SiCH$_3$; 18 H), 5.63 (s, CH; 1 H), 7.11−7.45 (m, arom. CH; 5 H). − ^{13}C NMR ([D$_6$]benzene): δ = −0.0 (SiCH$_3$), 63.6 (CH), 128.3, 129.2, and 135.3 (arom. CH), 133.8 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −24.2 (*Si*SiMe$_3$), −15.2 (Si*Si*Me$_3$). − MS (70 eV); *m*/*z* (%): 334 (1) [M]$^+$, 319 (3) [M − CH$_3$]$^+$, 299 (100) [M − Cl]$^+$. − $C_{13}H_{24}Cl_2Si_3$ (335.5): calcd. C 46.54, H 7.20, Cl 21.13; found C 46.79, H 7.13, Cl 21.38.

Tris(trimethylsilyl)methane (2ax): To a solution of **1a** (0.5 g, 1.83 mmol) in ether (30 mL), a threefold molar quantity of methyllithium was gradually added at room temperature. After stirring for 12 h, the mixture was hydrolyzed and the organic layer separated, dried and concentrated. Compound **2ax** was separated by column chromatography (silica gel, heptane) as a colorless oil, yield 0.3 g (70%). The spectral data measured for **2ax** agree with those described in the literature.[19]

Methyldiphenyl[bis(trimethylsilyl)methyl]silane (2ay): Similarly, **1a** (0.5 g, 1.83 mmol) and ethereal phenyllithium solution (5.5 mmol) afforded 0.45 g (68%) of **2ay**. Colorless crystals, m.p. 66−69 °C. − ^{1}H NMR ([D$_6$]benzene): δ = 0.02 [s, Si(CH$_3$)$_3$, 18 H], 0.04 (s, CH, 1 H), 0.74 (s, SiCH$_3$, 3 H), 7.13−7.52 (m, arom. CH, 10 H). − ^{13}C NMR ([D$_6$]benzene): δ = −2.2 (CH), 1.3 (SiCH$_3$), 3.4 [Si(CH$_3$)$_3$], 128.3, 129.0, and 134.8 (arom. CH), 140.4 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −9.6 (SiMe$_3$), −0.1. −(SiMe). − MS (70 eV); *m/z* (%): 356 (2) [M]$^+$, 341 (100) [M − CH$_3$]$^+$, 279 (5) [M − Ph]$^+$. − C$_{20}$H$_{32}$Si$_3$ (356.7): calcd. C 67.34, H 9.04; found C 67.04, H 9.07.

Dimethylphenyl[bis(trimethylsilyl)methyl]silane (2bx): As described for **2ax**, **1b** (0.5 g, 1.49 mmol), and MeLi (4.50 mmol) gave after chromatographic separation (silica gel, heptane) 0.73 g (84%) of **2bx**. Colorless oil. − ^{1}H NMR ([D$_6$]benzene): δ = −0.38 (s, CH, 1 H), 0.08 [s, Si(CH$_3$)$_3$, 18 H], 0.38 [s, Si(CH$_3$)$_2$, 6 H], 7.18−7.49 (m, arom. CH, 5 H). − ^{13}C NMR ([D$_6$]benzene): δ = −1.0 (CH), 1.8 [Si(CH$_3$)$_3$], 3.4 [Si(CH$_3$)$_2$], 128.8, 133.7, and 134.7 (arom. CH), 142.5 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = − 16.2 (SiMe$_2$Ph), − 0.3 (SiMe$_3$). − MS (70 eV); *m/z* (%): 279 (100) [M − CH$_3$]$^+$. − C$_{15}$H$_{30}$Si$_3$ (294.7): calcd. C 61.14, H 10.26; found C 61.16, H 10.26.

Triphenyl[bis(trimethylsilyl)methyl]silane (2by): As described for **2ax**, **1b** (0.5 g, 1.49 mmol), and PhLi (4.50 mmol) gave after chromatographic separation (silica gel, heptane) and recrystallization from methanol 0.44 g (70%) of **2by**. Colorless crystals, m.p. 82−84 °C. − ^{1}H NMR ([D$_6$]benzene): δ = 0.07 (s, SiCH$_3$, 18 H), 0.31 (s, CH, 1 H), 7.15−7.71 (m, arom. CH, 15 H). − ^{13}C NMR ([D$_6$]benzene): δ = 1.3 (CH), 3.8 (SiCH$_3$), 127.9, 129.4, and 136.7 (arom. CH), 137.9 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −10.0 (SiPh$_3$), −0.0 (SiMe$_3$). − MS (70 eV); *m/z* (%): 419 (2) [M + H]$^+$, 403 (48) [M − CH$_3$]$^+$, 341 (100) [M − Ph]$^+$, 264 (6) [M − Ph$_2$]$^+$, 259 (11) [M − CH(SiMe$_3$)$_2$]$^+$. − C$_{25}$H$_{34}$Si$_3$ (418.8): calcd. C 71.70, H 8.18; found 70.84, 8.05. HRMS calcd. for C$_{24}$H$_{31}$Si$_3$ (M − CH$_3$): 403.17337; found 403.17013.

Dimesitylphenyl[bis(trimethylsilyl)methyl]silane (2bz): At room temperature, a twofold molar excess of mesityllithium was added to a solution of **1b** (0.56 g, 1.65 mmol) in ether (30 mL). After stirring for 12 h, water was added and the organic phase was separated, dried and concentrated. Column chromatography of the residue (silica gel, heptane) and recrystallization of the product from methanol gave 0.1 g (12%) colorless crystals, m.p. 45−50 °C. − ^{1}H NMR ([D$_6$]benzene): δ = −0.07 and 0.05 (2 s, SiCH$_3$, 2 × 9 H), 0.33 (s, CH, 1 H), 2.09 and 2.22 (2 s, Mes-CH$_3$, 2 × 6 H), 2.33 and 2.34 (2 s, Mes-CH$_3$, 2 × 3 H), 6.70−7.86 (m, arom. CH, 9 H). − ^{13}C NMR ([D$_6$]benzene): δ = −0.4 and 4.7 (SiMe$_3$), 4.7 (CH), 20.9, 21.0, 21.1, 25.8, and 26.1 (aryl-CH$_3$), 127.4, 128.2, 128.9, 129.2, 130.0, 130.6, 136.3, 138.1, 138.5, 143.8, and 144.5 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −16.0 (aryl$_3$Si), 0.3 and 1.1 (SiMe$_3$). − MS (70 eV); *m/z* (%): 502 (1) [M]$^+$, 487 (5) [M − CH$_3$]$^+$; HRMS calcd. for C$_{31}$H$_{46}$Si$_3$ 502.25965, found 502.29074.

1-(2,4,6-Triisopropylphenyl)-1,2,2-tris(trimethylsilyl)silene (8c): To a solution of **1c** (0.5 g, 1.5 mmol) in ether (30 mL) a twofold molar excess of 2,4,6-triisopropylphenyllithium was gradually added at room temperature. After stirring for 12 h, the mixture was concentrated and the residue extracted with pentane. After filtration, the solution was repeatedly concentrated (with further addition of pentane) in vacuo, finally at 100 °C/10^{-2} mbar, to give 0.4 g (58%) of a pale yellow oil, which proved to be a mixture of **8c** and 1,3,5-triisopropylbenzene. − **8c:** ^{1}H NMR ([D$_6$]benzene): δ = 0.17, 0.24, and 0.49 (3 s, SiCH$_3$, 3 × 9 H), 1.17, 1.25, and 1.38 (3 d, ^3J = 6.7 Hz, *i*Pr-CH$_3$, 3 × 6 H), 2.72 (sept, ^3J = 6.7 Hz, *i*Pr-CH, 1 H), 3.33 (sept, ^3J = 6.7 Hz, *i*Pr-CH, 2 H), 7.00 (s, arom. CH, 2 H). − ^{13}C NMR ([D$_6$]benzene): δ = 1.3, 4.8, and 6.3 (SiCH$_3$), 24.1, 24.2, and 24.7 (*i*Pr-CH$_3$), 34.7 and 38.1 (*i*Pr-CH), 121.0 (arom. CH), 136.0, 151.7, and 152.4 (arom. C), the signal of the Si=C atom could not be assigned unambiguously. − ^{29}Si NMR ([D$_6$]benzene): δ = −15.4 (Si*Si*Me$_3$), −6.8 and −5.7 (CSiMe$_3$), 79.6 (Si=C). − MS (70 eV); *m/z* (%): 463 (88) [M + H]$^+$, 390 (5) [M − SiMe$_3$]$^+$; HRMS calcd. for C$_{25}$H$_{50}$Si$_4$ 462.29285, found 462.29895. − 1,3,5-*i*Pr$_3$C$_6$H$_3$: ^{1}H NMR ([D$_6$]benzene): δ = 1.24 (d, ^3J = 7.5 Hz, CCH$_3$, 18 H), 2.82 (sept, ^3J = 7.5 Hz, CHMe$_2$, 3 H), 6.99 (s, arom. CH, 3 H). − ^{13}C NMR ([D$_6$]benzene): δ = 24.4 (CH$_3$), 34.8 (CH), 122.4 (arom. CH), 149.1 (arom. C).

Tetrakis(trimethylsilyl)methane (11ax): To a solution of **1a** (0.5 g, 1.83 mmol) in ether (30 mL), MeLi (5.5 mol) was added at room temperature. The mixture was stirred for 12 h and subsequently chlorotrimethylsilane (0.5 g, 4.5 mmol) was added. Stirring was continued for further 12 h. After the addition of water, separation of the organic layer and concentration, the residue was purified by column chromatography (silica gel, heptane). Colorless crystals, yield 0.46 g (82%), m.p. 129−135 °C. The spectral data obtained for **11ax** are identical with those of authentic material.[20]

Methyldiphenyl[tris(trimethylsilyl)methyl]silane (11ay): Following the procedure for the synthesis of **11ax**, **1a** (0.5 g, 1.83 mmol), PhLi (5.5 mmol) and chlorotrimethylsilane (0.5 g, 4.5 mmol) gave after chromatography (silica gel, heptane) and recrystallization from ethanol gave colorless crystals (0.44 g), which proved to be a mixture of **11ay** and approx. 10% of **2ay**. The two compounds could not be cleanly separated, therefore only the NMR and MS data of **11ay** are given. − ^{1}H NMR ([D$_6$]benzene): δ = 0.10 (s, SiCH$_3$, 27 H), 0.32 (s, SiCH$_3$, 3 H), 7.13−7.79 (m, arom. H). − ^{13}C NMR ([D$_6$]benzene): δ = 0.8 (SiCH$_3$), 3.5 [Si(CH$_3$)$_3$], Si$_4$C could not be assigned unambiguously, 128.3, 128.9, and 136.3 (m, arom. CH), 140.1 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −13.1 (SiMePh$_2$), 2.2 (SiMe$_3$). − MS (70 eV); *m/z* (%): 413 (2) [M − CH$_3$]$^+$, 351 (1) [M − Ph]$^+$, 192 (100) [M − C(SiMe$_3$)$_3$]$^+$.

Dimethyl[tris(trimethylsilyl)methyl]silane (12ax): The preparation of **12ax** followed the procedure given for **11ax**, but chlorodimethylsilane was used instead of chlorotrimethylsilane. Thus, **1a** (0.5 g, 1.83 mmol), MeLi (5.5 mmol) and Me$_2$SiHCl (0.5 g, 5.5 mmol) gave after purification by column chromatography (silica gel, heptane) colorless crystals, yield 0.43 g (82%), m.p. 97−103 °C. − IR (KBr): $\tilde{\nu}$ = 2099 cm^{-1} (SiH). − ^{1}H NMR ([D$_6$]benzene): δ = 0.25 (s, SiCH$_3$, 27 H), 0.21 (d, ^3J = 3.0 Hz, SiCH$_3$, 3 H), 0.30 (d, ^3J = 3.0 Hz, SiCH$_3$, 3 H), 4.31 (br. q, ^3J = 3.0 Hz, SiH, 1 H). − ^{13}C NMR ([D$_6$]benzene): δ = −4.1 (quat. C), 1.6 (HSiCH$_3$), 4.5 [Si(CH$_3$)$_3$]. − ^{29}Si NMR ([D$_6$]benzene): δ = −16.9 (SiH), −1.3 (SiMe$_3$). − MS (70 eV): *m/z* (%): 289 (1) [M − H]$^+$, 275 (100) [M − CH$_3$]$^+$. − C$_{12}$H$_{34}$Si$_4$ (290.7): calcd. C 49.57, H 11.79; found C 49.50, H 11.58.

Methyldiphenyl[(dimethylsilyl)bis(trimethylsilyl)methyl]silane (12ay): Similarly, **1a** (0.5 g, 1.83 mmol), PhLi (5.5 mmol), and Me$_2$SiHCl (0.5 g, 5.5 mmol) afforded 0.3 g (40%) of **12ay**. Colorless crystals, m.p. 93−97 °C. − IR (KBr): $\tilde{\nu}$ = 2122 cm^{-1} (SiH). − ^{1}H

NMR ([D$_6$]benzene): δ = 0.18 [d, ^3J = 3.8 Hz, Si(CH$_3$)$_2$, 6 H], 0.22 [s, Si(CH$_3$)$_3$, 18 H], 0.91 (s, PhSiCH$_3$, 3 H), 5.08 (sept, ^3J = 3.8 Hz, SiH, 1 H), 7.14−8.01 (m, arom. CH, 10 H). − ^{13}C NMR ([D$_6$]benzene): δ = −1.8 (quat. C), 1.8 [Si(CH$_3$)$_2$], 5.6 [Si(CH$_3$)$_3$], 127.5, 129.2, and 136.8 (arom. CH), 139.6 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −16.0 and −15.5 (SiPh$_2$ and SiH), −0.8 (SiMe$_3$). − MS (70 eV); *m/z* (%): 399 (1) [M − H]$^+$, 336 (50) [M − C$_6$H$_5$, − H]$^+$, 321 (100) [M − C$_6$H$_5$, − CH$_3$, − H]$^+$, 264 (10) [M − C$_6$H$_5$, − SiMe$_3$]$^+$. − $C_{22}H_{38}Si_4$ (414.9): calcd. C 63.69, H 9.23; found C 63.65, H 9.13.

Methylbis(2,4,6-triisopropylphenyl)[bis(trimethylsilyl)methyl]silane (14): At room temperature a threefold molar excess of 2,4,6-triisopropylphenyllithium was added to **1a** (0.5 g, 1.8 mmol) in ether (30 mL). After stirring for 12 h, water was added and the organic layer separated, dried and concentrated. Chromatographic separation of the residue (silica gel, heptane) gave 0.42 g (44%) of **14**. Single crystals were obtained by recrystallization from heptane, m.p. 151−156 °C. − ^{1}H NMR ([D$_6$]benzene): δ = 0.11 and 0.38 (2 s, SiCH$_3$, 2 × 9 H), 0.22 (br. s, SiCH$_3$, 3 H), 0.46 (s, CH, 1 H), 1.40 (br. signal) and 1.12−1.23 (m, *i*Pr-CH$_3$, 36 H), 2.73 (m, *i*Pr-CH, 2 H), 3.23, 3.32, 3.59, and 3.73 (4 br. signals, *i*Pr-CH, 4 × 1 H), 6.90−7.20 (2 m, arom. CH, 4 H). − ^{13}C NMR ([D$_6$]benzene): δ = 4.3 and 5.7 [Si(CH$_3$)$_3$], 8.2 (CH), 9.2 (SiCH$_3$), 22.3, 23.0, 23.7, 23.9, 24.9, 25.7, 26.5, and 27.0 (*i*Pr-CH$_3$), 31.7, 32.4, 33.2, 34.1, and 35.3 (*i*Pr-CH), 122.7 (arom. CH), 138.1, 148.8, and 149.4 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −13.0 (SiMe), −1.4 and 0.6 (SiMe$_3$). − MS (70 eV); *m/z* (%): 608 (1) [M]$^+$, 593 (16) [M − CH$_3$]$^+$, 535 (1) [M − SiMe$_3$]$^+$, 449 (9) [M − CH(SiMe$_3$)$_2$]$^+$, 404 (89) [M − Tip, − H]$^+$, 201 (100) [M − 2 Tip, − H]$^+$. − $C_{38}H_{68}Si_3$ (609.2): calcd. C 74.92, H 11.25; found C 74.10, H 11.01.

General Procedure for the Preparation of the Silanols 15b, 15c, and 16c: To an ethereal solution of the dichloromethylsilane **1b** or **1c** a 2.2-fold molar excess of the respective organolithium compound was added at room temperature. After stirring for 12 h, the product was hydrolyzed by addition of water. The resulting silanols were extracted with ether and the solutions dried and concentrated. The residues were purified by chromatography (silica gel, heptane).

15b: Compound **1b** (0.5 g, 1.5 mmol) and 2,4,6-triisopropylphenyllithium (3.3 mmol) gave 0.4 g (55%) of silanol **15b**. Colorless oil. − IR (cap.): $\tilde{\nu}$ = 3682 cm^{-1}(OH). − ^{1}H NMR ([D$_6$]benzene): δ = 0.17 and 0.20 (2 s, SiCH$_3$, 2 × 9 H), 0.31 (s, CH, 1 H), 1.20 (d, ^3J = 6.7 Hz, *i*Pr-CH$_3$, 12 H), 1.23 (d, ^3J = 6.7 Hz, *i*Pr-CH$_3$, 6 H), 1.89 (s, OH, 1 H), 2.75 (sept, ^3J = 6.7 Hz, *i*Pr-CH, 1 H), 3.65 (sept, ^3J = 6.7 Hz, *i*Pr-CH, 2 H), 7.10−7.70 (m, arom. CH, 7 H). − ^{13}C NMR ([D$_6$]benzene): δ = 3.5 and 3.7 (SiCH$_3$), 7.8 (CH), 24.0, 24.8, and 25.7 (*i*Pr-CH$_3$), 33.3 and 34.5 (*i*Pr-CH), 121.9, 127.4, 129.4, and 133.1 (arom. CH), 135.1, 142.5, 150.5, and 155.3 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −2.8 (SiOH), −0.4 and 0.7 (SiMe$_3$). − MS (70 eV); *m/z* (%): 469 (70) [M − CH$_3$]$^+$, 467 (100) [M − OH]$^+$, 407 (20) [M − SiMe$_3$]$^+$. − $C_{28}H_{48}Si_3O$ (484.9): calcd. C 69.35, H 9.98; found C 66.87, H 9.80; HRMS calcd. for $C_{27}H_{45}OSi_3$ [M − CH$_3$] 469.26051, found 469.27783.

15c: Compound **1c** (0.5 g, 1.5 mmol) and 2,4,6-triisopropylphenyllithium (3.3 mmol) afforded 0.35 g (49%) of **15c**, colorless crystals, m.p. 54−57 °C (heptane). − IR (KBr): $\tilde{\nu}$ = 3681 cm^{-1} (OH). − ^{1}H NMR ([D$_6$]benzene): δ = 0.02 (s, CH, 1 H), 0.06, 0.20 and 0.30 (3 s, SiCH$_3$, 3 × 9 H), 1.35 (s, OH, 1 H), 1.21, 1.32 and 1.37 (3 d, ^3J = 6.7 Hz, *i*Pr-CH$_3$, 3 × 6 H), 2.77 (sept, ^3J = 6.7 Hz, *i*Pr-CH, 1 H), 3.50 (sept, ^3J = 6.7 Hz, *i*Pr-CH, 2 H), 7.09 (s, arom. CH, 2 H). − ^{13}C NMR ([D$_6$]benzene): δ = 0.7, 3.4, and 3.7 (SiCH$_3$), 9.2 (CH), 24.1, 25.6, and 26.0 (*i*Pr-CH$_3$), 32.5 and 32.4 (*i*Pr-CH), 121.7 (arom. CH), 134.9, 149.9, and 154.5 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −19.3 (Si*Si*Me$_3$), −0.6 and 1.8 (CSiMe$_3$), 7.6 (SiOH). − MS (70 eV); *m/z* (%): 465 (3) [M − CH$_3$]$^+$, 390 (1) [M − SiMe$_3$, − OH, − H]$^+$, 203 (100) [M − Tip, − SiMe$_3$, − H]$^+$. − $C_{25}H_{52}OSi_4$ (481.6): calcd. C 62.42, H 10.89; found C 62.14, H 10.87.

16c: Compound **1c** (0.5 g, 1.5 mmol) and 2-*tert*-butyl-4,5,6-trimethylphenyllithium (3.3 mmol) gave 0.3 g (44%) **16c**, colorless crystals, m.p. 50−56 °C. − IR (nujol): $\tilde{\nu}$ = 3695 cm^{-1} (OH). − ^{1}H NMR ([D$_6$]benzene): δ = −0.03, 0.19, and 0.38 (3 s, SiCH$_3$, 3 × 9 H), 0.32 (s, CH, 1 H), 1.48 (s, *t*Bu-CH$_3$, 9 H), 1.62 (s, OH, 1 H), 1.93, 2.12, and 2.16 (3 s, aryl-CH$_3$, 3 × 3 H), 7.23 (s, arom. CH, 1 H). − ^{13}C NMR ([D$_6$]benzene): δ = 0.2, 3.6, and 4.4 (SiCH$_3$), 6.1 (CH), 15.1, 21.1, and 24.0 (aryl-CH$_3$), 34.2 (*t*Bu-CH$_3$), 36.6 (*t*Bu-C), 127.0 (arom. CH), 132.4, 135.9, 136.3, 141.2, and 153.7 (arom. C). − ^{29}Si NMR ([D$_6$]benzene): δ = −18.2 (Si*Si*Me$_3$), 0.5 (CSiMe$_3$), 1.5 (SiOH). − MS (70 eV); *m/z* (%): 437 (5) [M − CH$_3$]$^+$, 379 (37) [M − SiMe$_3$]$^+$; HRMS calcd. for $C_{23}H_{48}OSi_4$ 437.24907, found 437.25476.

General Procedure for the Preparation of the Methoxysilanes 17b, 17c, and 18c: At room temperature a 2.2-fold molar excess of the respective organolithium reagent was added to the ethereal solution of **1b** or **1c**, respectively After stirring for 12 h, excess methanol was added and stirring was continued for 2 h. The ethereal phases were separated and concentrated, and the residues were purified by chromatography (silica gel, heptane).

17b: Compound **1b** (0.5 g, 1.5 mmol) and 2,4,6-triisopropylphenyllithium (3.3 mmol) gave 0.45 g (60%) of **17b**, colorless oil. − IR (cap.): $\tilde{\nu}$ = 1103 cm^{-1} (SiOC). − ^{1}H NMR ([D$_6$]benzene): δ = 0.05 and 0.12 (2 s, SiCH$_3$, 2 × 9 H), 0.15 (s, CH, 1 H), 1.04, 1.07 and 1.13 (3 d, ^3J = 6.7 Hz, *i*Pr-CH$_3$, 3 × 6 H), 2.63 (sept, *i*Pr-CH, 1 H), 3.18 (s, OCH$_3$, 3 H), 3.45 (sept, *i*Pr-CH, 2 H), 7.04 (s, Tip-CH, 2 H), 6.95 and 7.54 (2 m, Ph-CH, 5 H). − ^{13}C NMR ([D$_6$]benzene): δ = 3.6 and 4.2 (SiCH$_3$), 8.4 (CH), 24.4, 24.6, and 26.3 (*i*Pr-CH$_3$), 32.3 and 34.5 (*i*PrCH), 51.8 (OCH$_3$), 121.9, 127.5, 129.6, and 132.3 (arom. X-ray Structure Determinations of 19b, 19c, and 20c: Suitable crystals of the compounds were selected under a microscope and sealed onto a glass fiber. Afterwards rotational photos were taken and 13 reflections chosen to find reasonable reduced cells for the data collections. These data collections were done with a Siemens P4 four-circle diffractometer equipped with a graphite monochromator and using Mo-K_α radiation in a routine ω-scan. The structures were solved by direct methods (*SHELXTL*, Siemens Analytical X-ray Inst. Inc., **1990**) and refined by the full-matrix least-squares method of SHELXL-97 (G. M. Sheldrick, Universität Göttingen, **1997**). All non-hydrogen atoms were refined anisotropically . The H atoms were put into theoretical positions and refined using the riding model. Further details see Table 1. Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-143201 (**19b**), -143202 (**19c**), and -143203 (**20c**). Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Tuning the Reversible Binding of NO to Iron(II) Aminocarboxylate and Related Complexes in Aqueous Solution

Thorsten Schneppensieper,[a] Stefan Finkler,[a] Almut Czap,[a] Rudi van Eldik,*[a] Martin Heus,[b] Peter Nieuwenhuizen,[b] Carel Wreesmann,[b] and Wiebe Abma[c]

Keywords: Iron / Chelates / Thermodynamics / Nitric oxide / Stability constants

Chelate complexes of Fe^{II} were investigated with respect to their reactivity against nitric oxide and dioxygen. Through a systematic variation of the structure of the polyaminocarboxylate EDTA, a series of 38 potential chelate ligands were selected for Fe^{II}. The nitrosyl complexes were prepared from the Fe^{II} chelates with NO gas and examined spectroscopically by UV/Vis and ATR-IR techniques, and themodynamically by determining the overall binding constants for NO. In addition, the reversibility of NO binding to these Fe^{II} chelates and the rate of the competing oxidation by dioxygen were studied qualitatively. Whereas the studied complexes all form more or less stable nitrosyl complexes with a characteristic band pattern in the UV/Vis spectra and only slightly diverging frequencies for the NO stretching vibration in the IR spectra, they differ considerably in the reversibility of NO binding, the overall NO binding constants and the sensitivity towards dioxygen. It was found that an increasing number of donor groups on the chelate ligand causes a stronger coordination to Fe^{II}, and increases the tendency of the Fe^{II} chelates to transfer electron density from iron to substrates like dioxygen or nitric oxide. This results in an accelerated oxidation of Fe^{II} to Fe^{III} by dioxygen and a more pronounced tendency of the corresponding nitrosyl complexes to slowly decompose to Fe^{III} and N_2O. In addition, the overall binding constant for NO (K_{NO}), which spans a range from $1 \cdot 10^3$ to $2 \cdot 10^7$ M^{-1}, increases in the same direction as a result of the inductive effect of the chelate ligand.

Introduction

Chelate complexes of Fe^{II} in aqueous solution have been suggested as homogeneous catalysts for the selective binding and subsequent reduction of NO to dinitrogen in denitrification processes.[1–9] An essential aspect of this process is the efficient binding of NO by a metal chelate in order to increase its solubility in aqueous solution. Although a number of studies have dealt with the binding of NO to chelate complexes of Fe^{II}, none have undertaken a systematic investigation of the chelate properties in order to optimize the efficiency and reversibility of the binding process.[1,10–14] In this study we undertook a systematic variation of the donor number and donor atoms of multidentate chelates, and determined the overall binding constants for NO to the corresponding Fe^{II} complexes. In addition, we studied the reversibility of the binding process, as well as the UV/Vis and IR spectral changes associated with these reactions. Parallel to this, the competing reaction with dioxygen was also investigated quantitatively. An interesting correlation between the binding ability for NO and the oxygen sensitivity of the Fe^{II} complexes was found. The observed trends are reported in a qualitative way, and the most important factors that control the efficiency and reversibility of the binding of NO to Fe^{II} chelates are discussed.

In order to establish an extended series of chelate ligands that are able to bind NO more or less reversibly in the form of Fe^{II} complexes, we used the polyaminocarboxylate EDTA as a reference and starting point for nearly all structural modifications. The seven-coordinate $[Fe^{II}(EDTA)(H_2O)]^{2-}$ complex[15] certainly belongs to the hitherto best examined systems for NO binding in aqueous solution, and detailed kinetic and thermodynamic data are available in the literature.[16–18] Furthermore, EDTA is an inexpensive industrial product and its structure offers nearly unlimited possibilities for modification. Through a systematic variation of the EDTA structure we obtained a set of altogether 38 chelate ligands summarized in Figure 1. Apart from direct EDTA derivatives (**Series 1**), we also studied a considerable number of MIDA analogues as indirect EDTA derivatives (**Series 2**) in order to investigate the influence of a reduction in the molecular size of the chelate ligand on the NO binding characteristics of the corresponding Fe^{II} complexes.

Since a systematic treatment enables more specific conclusions to be reached on the relation between structure and function of the examined systems, it was advantageous to further divide the EDTA and MIDA analogues in different subgroups. Within the series of EDTA analogues (**Series 1**), the ethylene spacer between the two EDTA nitrogens was varied through branching or elongation (**subgroup a**), or some or all of the four acetic acid end groups were replaced without

affecting the central ethylenediamine component (**subgroup b**). The MIDA analogues (**Series 2**) are divided into three subgroups. Whereas in **subgroup a** the methyl group of MIDA is exchanged by another non-coordinating group, it is exchanged in **subgroup b** by a further coordinating function. **Subgroup c** summarizes derivatives in which the nitrogen donor of MIDA is replaced by oxygen, sulfur, a methylene group, or an aromatic nitrogen.

Chelate ligands, which cannot be related directly to either MIDA or EDTA analogues, are compiled in a third main group (**Series 3**). These include the phosphonates ATMP, EDTMP, and DTPMP (derivatives of NTA, EDTA, and DTPA), nitrogen-free hydroxycarboxylic acids like TARTRATE and CITRATE, and the aromatic aminocarboxylate APTA.

Results and Discussion

Preliminary Observations

In the following sections, Fe^{II} chelate complexes and the corresponding nitrosyl complexes are indicated by the formulae $[Fe^{II}(L)_x]$ and $[Fe^{II}(L)_x(NO)]$, respectively, where L = chelate ligand. Although the number of bound chelate molecules are only precisely known in a few cases, especially for L = EDTA (x = 1) and MIDA (x = 1 and 2),[19] it is safe to assume that all EDTA analogues form 1:1, and MIDA analogues with three donor groups form either 1:1 or 1:2 complexes with Fe^{II}. In general, the 1:1 complexes are quite stable species in solution as judged from their stability constants reported in the literature.[19] Typical examples are

Figure 1. Survey of tested chelate ligands

In order to check these numbers, pH titrations were performed for the complexes $[Fe^{II}(L)_x]$ (L = MIDA, EDTA). Calculations relating to the determination of protonation and complex formation constants were performed using the computer program PSEQUAD.[20] The measured stability constants, $3.39 \cdot 10^{11}$ M^{-2} (L = MIDA) (see Table 1) and $2.29 \cdot 10^{14}$ M^{-1} (L = EDTA) are in good agreement with those reported in the literature.[21] Speciations (see Figure 2) were calculated with the computer program SPECIES.[22] The results for the Fe−MIDA system indicate that below pH 3 no complex formation occurs. Between pH 3 and 5, the 1:1 [Fe(MIDA)] complex is generated, and above pH 5 the 1:2 complex is partially present. At pH 8 the iron is totally complexed and at pH > 10 the 1:2 complex is the dominating species. This species distribution indicates that at pH 5, where most of the experiments were performed, mainly the 1:1 complex will exist. The 1:2 complex will only be present

as the major species when a large excess (ca. 20 fold) of MIDA is used. A similar conclusion was reached on the basis of ^{1}H NMR spectra recorded for the uncoordinated ligand in solution.

Net charges for these complexes are only given when the composition of the complex can be specified, e.g. $[Fe^{II}(EDTA)]^{2-}$. A coordinated water molecule was detected in the crystal structure of the EDTA complex,[15] which can therefore be presented by the formula $[Fe^{II}(EDTA)(H_2O)]^{2-}$. Preliminary water exchange studies on several $[Fe^{II}(L)_x]$ complexes using ^{17}O NMR techniques, indicated that they in general have at least one water molecules bound to the Fe^{II} center.[23] In the absence of further details and for reason of uniformity, water molecules will be omitted in all following formulae. However, it should be kept in mind that some of the complexes are seven-coordinate species, such that the reaction with NO is probably not a simple addition of NO to $[Fe^{II}(L)_x]$ but rather substitution of a labile bound water molecule by NO.

Whereas the coordination stoichiometry of $[Fe^{II}(MIDA)_x]^{(2x-2)-}$ and analogues can now be predicted for the selected experimental conditions in terms of pH and metal to ligand concentration ratio as outlined above, the composition of the corresponding NO complex, viz.

$[Fe^{II}(MIDA)_xNO]^{(2x-2)-}$, remains to be determined. For this purpose a potentiometric titration of the NO complex was done. From the speciation diagram it was possible to confirm that under the selected conditions the 1:1 complex is the dominating species in solution (see Figure 3).

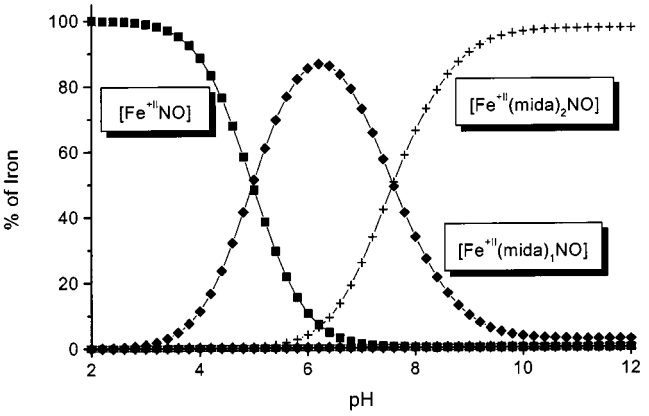

Figure 3. Species distribution curves for the $[Fe^{II}(MIDA)_xNO]^{(2x-2)-}$ complex [experimental conditions: $[Fe^{II}(MIDA)NO] = 4 \cdot 10^{-3}$ M, $T = 25$ °C, $I = 0.5$ M ($NaClO_4$)]

pH titrations of the $[Fe^{II}(MIDA)_xNO]$ complex resulted in a stability constant of $3.09 \cdot 10^{11}$ M^{-2} (Table 1) and show that there is nearly no change in the overall stability constant between $[Fe^{II}(MIDA)_x]$ and $[Fe^{II}(MIDA)_xNO]$. The addition of NO caused a small but significant change in the logK_1 and logK_2 values in favor of the 1:1 complex.

The species distribution (Figure 3) clearly indicates that the reaction with NO significantly stabilizes the 1:1 complex in a manner that at pH 5 more of the 1:1 [Fe(MIDA)NO] complex is generated than found for the speciation in the absence of NO. In fact, the increase in the 1:1 complex is approximately twice the decrease in the 1:2 complex concentration during the introduction of NO into the solution.

It can be concluded from the above described experiments that MIDA and analogous chelates mainly form 1:1 complexes with Fe^{II} and NO. $[Fe(MIDA)_2NO]^{2-}$ can only be prepared in solution in the presence of a large, at least 20 fold, excess of MIDA.

General Features in the UV/Vis and ATR-IR Spectra of Fe^{II} Nitrosyl Complexes

UV/Vis spectra

The identification and spectral characterization of metal−NO complexes has received much attention from researchers over the last few decades, and the results are summarized in some selected publications.[10,11,16,24−27] In the majority of cases, especially when the chelate ligand L is a polyaminocarboxylate, the UV/Vis spectra of the nitrosyl complexes $[Fe^{II}(L)_x(NO)]$ are characterized by three absorption bands: two strong *charge-transfer (C-T)* bands around 340 and 440 nm, respectively, and one weaker *d-d* band between 580 and 640 nm (data are summarized in Table 2). Whereas the position of the high energy *C-T* band at about 340 nm is almost not affected by the nature of the bound chelate ligand, the low energy *C-T* band around 440 nm shows a small, and the *d-d* band a strong dependence on the selected chelate. In addition, a correlation exists between the positions of the *C-T* and *d-d* bands: with decreasing wavelength of the low energy *C-T* band, the wavelength of the *d-d* band increases (see Figure 4).

The two extreme cases are on the one hand the non-chelated iron complex, $[Fe^{II}(H_2O)_5(NO)]^{2+}$, with absorption bands at 451 nm and 585 nm (similar values were also found in the presence of potential ligands such as ^{t}BIDA, EDTP, and glutaric acid which do not coordinate efficiently to Fe^{II}), and on the other hand complexes with coordinated EDTA, DTPA, or HEDTRA, which have absorption bands at about 434 ± 1 nm and 635 ± 2 nm. Most of the other nitrosyl complexes exhibit an intermediate position with respect to their UV/Vis spectra.

Some preliminary observations led us to believe that the shift in the C-T band to lower and that of the *d-d* band to higher wavelengths may be associated with a systematic displacement of electron density between the iron metal center and NO. This is particularly indicated by the chemical features of the corresponding $[Fe^{II}(L)_x]$ complexes

[a] Fe^{II}/Lig. indicates the ratio beween Fe^{II} and chelate ligand L which was used to prepare the $[Fe^{II}(L)_x(NO)]$ complexes for UV/Vis spectra and determination of K_{NO} values. − [b] Conditions (*if not otherwise indicated*): 1 mM Fe^{II} ($FeSO_4$); 100 mM acetic acid/acetate buffer, pH = 5.0; I = 0.5 (adjusted with $NaClO_4$); $T \approx 23$ °C; molar extinction coefficients are quoted in brackets in M^{-1} cm^{-1}. − [c] Conditions (only for IR): 200 mM Fe^{II}; excess of chelate ligand L: 10 to 25%; unbuffered solutions.

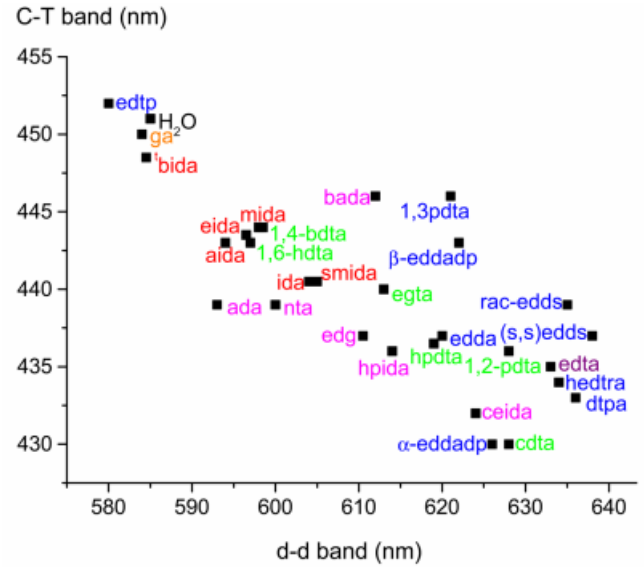

Figure 4. Correlation between the *C-T* and *d-d* band positions in the UV/Vis spectra of $[Fe^{II}(L)_x(NO)]$ complexes with L = polyaminecarboxylates.

which show, as described in detail below, in the direction from L = H_2O to L = EDTA, HEDTRA, or DTPA an increase in oxygen sensitivity accompanied by a decrease in the reversibility of the binding of NO·. Along these lines it could be favorable to consider the pentaaqua and MIDA nitrosyl complexes formally as $[Fe^{II}(H_2O)_5(NO^{\cdot})]^{2+}$ and $[Fe^{II}(MIDA)(NO^{\cdot})]$, respectively, compared to the EDTA nitrosyl complex as $[Fe^{III}(EDTA)(NO^{-})]^{2-}$.[27,28] This would indicate that in the former case the bound NO has more a radical, whereas in the latter case NO has more an anionic character. However, in the selected systems the difference in the distribution of electron density between Fe^{II} and NO seems to be very small, which is most evident from the ATR-IR spectra discussed in the following section.

Fe^{II} nitrosyl complexes which deviate in their UV/Vis data from the common features described above, were in general formed by chelate ligands other than polyaminocarboxylates (Figure 1, **Series 2 subgroup c** and **Series 3**). The most pronounced deviation in the UV/Vis spectrum is exhibited by the Fe^{II} complex of DIPIC. In contrast to all other studied $[Fe^{II}(L)_x]$ complexes, the complexes with L = DIPIC show strong bands associated with the aromatic ring at 459 nm (x = 1) or 482 nm (x = 2). Recently, several structures of iron(II/III) complexes with DIPIC have been reported, and structures with different stoichiometries could be characterized.[29−32] Even the seven-coordinate complex $[Fe^{II}(DIPIC)_2H_2O]^{2-}$ was characterized, which underlines our assumption that in the 1:2 complexes a water molecule can be coordinated in the seventh position.[31]

ATR-IR Spectroscopy

IR spectroscopy is considered to be an useful tool for the determination of the binding mode and oxidation state of NO in metal based complexes.[25,33] Efforts to distinguish between NO bound to the metal center in a linear mode as NO^+ or in a bent mode as NO^- on the basis of the NO stretching frequencies, revealed a considerable overlap in the range between 1600 and 1800 cm^{-1}.[33−35] It seems that there is a gradual change from the extreme NO^- form at lower frequency to the extreme NO^+ form at higher values. On this basis, changes in the electron delocalization for different $Fe^{II}(L)-NO$ complexes should be accompanied by characteristic shifts in the NO stretching frequencies.

Since only a few IR spectra of polyaminocarboxylate−Fe−NO complexes are known from the literature,[18] an extended series of $[Fe^{II}(L)_x]$ and $[Fe^{II}(L)_x(NO)]$ complexes were investigated by IR spectroscopy using the ATR technique.[36] The series was limited to those complexes which could be synthesized at a concentration level required to produce undistorted spectra with a satisfactory intensity and resolution (see Table 2). The values for example, obtained for $[Fe^{II}(EDTA)]^{2-}$ and $[Fe^{II}(EDTA)(NO)]^{2-}$, viz. ν(COO⁻, asym.) = 1588 cm^{-1}, ν(COO⁻, sym.) = 1406, 1325 cm^{-1}, and ν(COO⁻, asym.) = 1611 cm^{-1}, ν(COO⁻, sym.) = 1398, 1317 cm^{-1}, ν(NO) = 1777 cm^{-1}, respectively, are in good agreement with literature data.[37]

In the series of the complexes $[Fe^{II}(H_2O)_5(NO)]^{2+}$, $[Fe^{II}(MIDA)(NO)]$, and $[Fe^{II}(EDTA)(NO)]^{2-}$, the shift in the NO band from 1810 to 1783 to 1777 cm^{-1}, respectively, could suggest a gradual change from a partially more positive (NO^+) to a partially more negative (NO^-) binding character of NO. However, the frequencies of the NO vibrations for the MIDA and EDTA complexes hardly differ from each other, with the result that the deviation is too small to predict a significantly different binding mode. It follows that although the reported IR data do not reveal detailed information on the nature of the Fe-NO bond, the spectra do supplement the UV/Vis data and provide direct evidence for the reversible coordination of NO to the Fe^{II} centers.

Qualitative Characteristics of Fe^{II}-L Complexes During the Reactions with NO and O_2

The influence of the chelate ligand on the chemical features of the Fe^{II} complexes is clearly reflected by the reversibility of NO binding and the oxidation rate of $[Fe^{II}(L)_x]$. There are two extreme cases in which way both substrates (O_2 and NO) react with Fe^{II} chelates: in the first case they bind reversibly to the Fe^{II} center, whereas in the second case a shift of electron density from iron to the substrate, accompanied by the irreversible formation of the corresponding Fe^{III} complex, occurs. These opposite cases are illustrated on the one hand by iron complexes of water (aqua complexes) or several MIDA analogues (reversible substrate binding), and on the other hand by iron complexes of several EDTA analogues (irreversible substrate binding). In the following, MIDA and EDTA were selected as typical chelate ligands in order to examine the opposite features of both groups of complexes in more detail.

Reversibility of the Binding of NO to $[Fe^{II}(L)_x]$ Complexes

The main characteristic of $[Fe^{II}(MIDA)]$ is its ability to bind NO completely reversibly.

This is evident from the UV/Vis spectra in Figure 5, which show the mutual conversion between the $[Fe^{II}(MIDA)]$ complex (traces a, c, and e) and the corresponding nitrosyl complex $[Fe^{II}(MIDA)(NO)]$ (traces b, d, and f) by bubbling alternately NO or an inert gas through the complex solution. Obviously, the inert gases remove low concentrations of free NO from the solution, which are formed by a partial dissociation of the nitrosyl complex. In this way the equilibrium is driven back to the left side of Equation (1) to regenerate finally the pure starting complex $[Fe^{II}(MIDA)]$, from which the nitrosyl complex can be formed again.

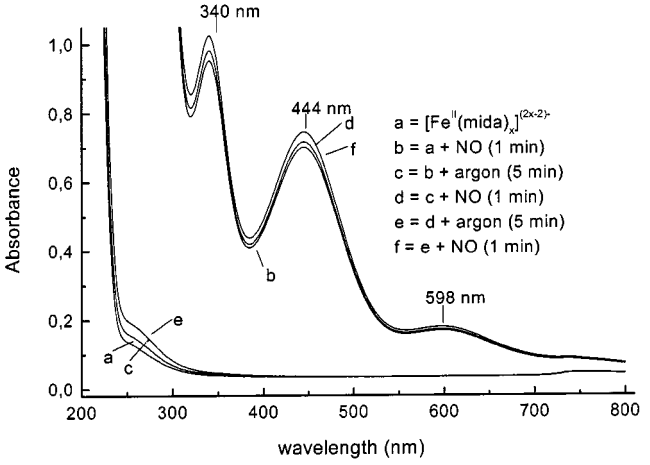

Figure 5. Reversibility of the NO binding to $[Fe^{II}(MIDA)]$ (exp. conditions: 1 mM $FeSO_4 \cdot 7\ H_2O$; 2.5 mM MIDA; 100 mM acetate buffer; pH = 5.0; T = 23 °C)

$$[Fe^{II}(MIDA)] + NO \rightleftharpoons [Fe^{II}(MIDA)(NO^{\cdot})] \quad (1)$$

The complete reversibility of the binding of NO to $[Fe^{II}(MIDA)]$ indicates that practically no electron transfer between Fe^{II} and NO occurs, which means that NO is presumably bound as radical to the Fe^{II} center. A similar behavior was found for the ligand free system (i.e. $[Fe^{II}(H_2O)_6]^{2+}$ species) and in the case of all MIDA analogues which are compiled in Figure 1, **Series 2** under **subgroups a** and **c**.

In comparison to the analogous MIDA complex, the NO chemistry of $[Fe^{II}(EDTA)]^{2-}$ is somewhat more complex.[16–18] As shown in Figure 6, there is to a certain extent a reversible binding of NO to $[Fe^{II}(EDTA)]^{2-}$ that can be observed when the whole experiment is performed within a time period of less than one hour. The fact that from the partially decomposed nitrosyl complex (trace d) the initial nitrosyl complex (trace e) can be restored completely, indicates that no irreversible electron transfer from Fe^{II} to NO occurred during the release of NO. Obviously, an equilibrium between $[Fe^{II}(EDTA)]^{2-}$ and the corresponding nitrosyl complex must exist [Equation (2)], which differs from the corresponding equilibrium for the MIDA system [see Equation (1)] only with respect to the position of the equilibrium, which lies more on the right side and leads to the observed poorer release of NO from the complex (Figure 6, traces c and d).

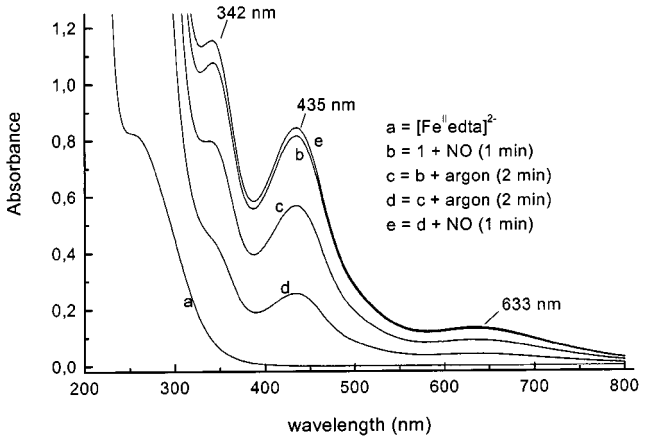

Figure 6. Reversibility of the NO binding to $[Fe^{II}(EDTA)]^{2-}$ (exp. conditions: 1 mM $FeSO_4 \cdot 7\ H_2O$; 1.25 mM EDTA; 100 mM acetate buffer; pH = 5.0; 23 °C)

$$[Fe^{II}(EDTA)]^{2-} + NO \rightleftharpoons [Fe^{II}(EDTA)(NO)]^{2-} \quad (2)$$

An irreversible electron transfer from Fe^{II} to NO occurs in the case of the EDTA system on a time scale of several hours, which is followed by the dissociation of the complex according to Equation (3) into $[Fe^{III}(EDTA)]^{-}$ and NO^{-} (nitroxyl anion). $[Fe^{III}(EDTA)]^{-}$ is identified in the UV/Vis spectrum (Figure 6) by its very intense absorption band below 400 nm,[38] whereas the unstable nitroxyl anion reacts immediately to nitrous oxide (N_2O). The latter product was detected mass spectrometrically in the form of N_2O in the gas phase.[39] As shown in Figure 7, the predominant part of $[Fe^{II}(EDTA)(NO)]^{2-}$ decomposes at room temperature within about 20 h.

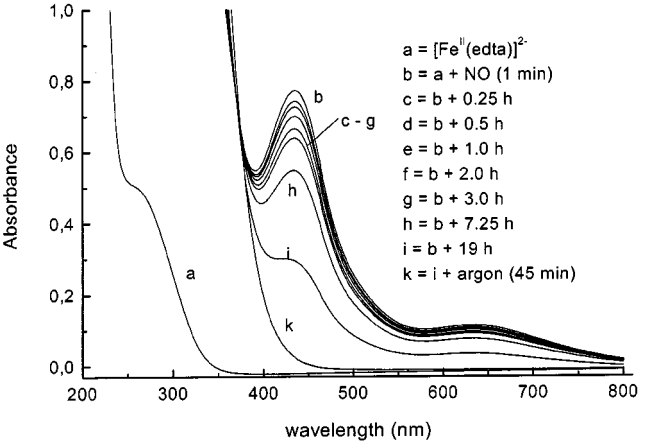

Figure 7. Thermal decomposition of $[Fe^{II}(EDTA)(NO)]^{2-}$ to $[Fe^{III}(EDTA)]^{-}$ and N_2O (exp. conditions: 1 mM $FeSO_4 \cdot 7\ H_2O$; 1 mM EDTA; 100 mM acetate buffer; pH = 5.0; T = 23 °C)

$$[Fe^{II}(EDTA)(NO)]^{2-} \xrightarrow{slow} \underset{(unstable)}{\{Fe^{III}(EDTA)(NO^{-})\}^{2-}} \rightarrow [Fe^{III}(EDTA)]^{-} + \underset{(unstable)}{\{NO^{-}\}} \quad (3)$$

In summary, for the $[Fe^{II}(EDTA)]^{2-}$/NO system a rapid equilibrium between $[Fe^{II}(EDTA)]^{2-}$ and $[Fe^{II}(EDTA)(NO)]^{2-}$

exists, which is followed by a slow and irreversible redox process accompanied by the dissociation of the complex to form $[Fe^{III}(EDTA)]^-$ and N_2O. The slow electron transfer process can be considerably accelerated when instead of EDTA, CDTA, or α-EDDADP are used as chelating ligands. In these cases the dissociation of the nitrosyl complexes to $[Fe^{III}(L)]^-$ and N_2O occurs on a time scale of some minutes. Obviously, small steric and electronic effects may control in a very sensitive way the rate of this irreversible electron transfer process.

Oxygen Sensitivity of $[Fe^{II}(L)_x]$ Complexes

In analogy to the reaction of $[Fe^{II}(MIDA)]$ with nitric oxide, the chemical behavior in the presence of air oxygen indicates that almost no electron transfer reaction from Fe^{II} to O_2 occurs. Consequently, solutions of $[Fe^{II}(MIDA)]$ are not oxidized to $[Fe^{III}(MIDA)]^+$ by air [Equation (4)].

$$[Fe^{II}(MIDA)] + O_2 \not\longrightarrow [Fe^{III}(MIDA)]^+ \quad (4)$$

In contrast to this, $[Fe^{II}(EDTA)]^{2-}$ is highly oxygen sensitive. Its transformation to the corresponding $[Fe^{III}(EDTA)]^-$ complex [Equation (5)] is complete in less than 1 minute. This oxidation reaction proceeds according to a complex multistep mechanism which was extensively studied in the literature.[40−43]

$$2\,[Fe^{II}(EDTA)]^{2-} + {}^1/_2\,O_2 + 2\,H^+ \xrightarrow{\text{fast}} 2\,[Fe^{III}(EDTA)]^- + H_2O \quad (5)$$

Besides EDTA, a similarly high oxidation rate of Fe^{II} complexes is observed when the EDTA analogues 1,2-PDTA, CDTA, HEDTRA, EDDS, and α-EDDADP are used (see Figure 1, **Series 1**).

Comparison Between the Fe^{II} Complexes of MIDA and EDTA Analogues

A final comparison between the MIDA system, and the EDTA, CDTA, and α-EDDADP systems, show that the $[Fe^{II}(MIDA)]$ complex can reversibly bind NO and probably also O_2, but does not tend to undergo any electron transfer process, neither to NO, nor to O_2. In contrast, Fe^{II} complexes of the above mentioned EDTA analogues undergo electron transfer processes both to O_2 and NO. The final products of these reactions are $[Fe^{III}(L)]^-$ and either H_2O or N_2O. Whereas the electron transfer from $[Fe^{II}(L)]^{2-}$ to dioxygen is always very fast, the redox reaction with NO is much slower, especially in the case of EDTA.

Stability Constants (K_{NO}) for $[Fe^{II}(L)_x(NO)]$ Complexes

Measurement of the K_{NO} Values

Stability constants for nitrosyl complexes are based on the equilibrium between $[Fe^{II}(L)_x]$ and $[Fe^{II}(L)_x(NO)]$ complexes [Equation (6)] and are therefore defined by Equation (7).

$$[Fe^{II}(L)_x] + NO \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} [Fe^{II}(L)_x(NO)] \quad (6)$$

$$K_{NO} = k_{on} / k_{off} = \frac{[Fe^{II}(L)_x(NO)]}{[Fe^{II}(L)_x]\cdot[NO]} \quad (7)$$

In general, quite vague and rather divergent K_{NO} data for only a few Fe^{II}−polyamino−carboxylate complexes exist in the literature, especially for the chelating ligands EDTA, NTA, and DTPA and for aquated Fe^{II}, $[Fe^{II}(H_2O)_5(NO)]^{2+}$. A comprehensive survey of literature data is given in the review of Demmink et al.[16] These data were often determined indirectly, e.g. from kinetic measurements according to the relationship $K_{NO} = k_{on}/k_{off}$. The disadvantage of such indirect methods is especially the low degree of accuracy of the calculated values.

In our work, we successfully adopted a direct approach to obtain the equilibrium constant K_{NO} by utilizing the recently developed possibility to measure the concentration of free NO in solution with a NO electrode.[44] The remaining unknown equilibrium concentrations in Equation (7), viz. $[Fe^{II}(L)_x(NO)]$ and $[Fe^{II}(L)_x]$, could be easily determined by UV/Vis spectroscopy.

Influence of the Chelate Ligands on the Magnitude of the K_{NO} Values

The K_{NO} values for the $[Fe^{II}(L)_x(NO)]$ complexes are summarized on a logarithmic scale in Figure 8**a**, in which the different groups and subgroups of chelate ligands are presented in different colors (the corresponding numerical K_{NO} values with their relative error limits are given in Table 2). The scale in Figure 8**a** extends a range from $1\cdot10^3$ M^{-1} to $2\cdot10^7$ M^{-1}. In general, coordination of a chelate ligand to Fe^{II} considerably stabilizes the NO binding on the complex.

A detailed analysis of the magnitude of K_{NO} as a function of the chemical structure of the chelate ligand suggests that both electronic and steric effects have a pronounced influence. The highest K_{NO} values are found for ligands such as EDTA, DTPA, HEDTRA, EDDS, EDTMP, NTA, CEIDA, and ATMP, which have at least four strong donor groups and can bind effectively to the Fe^{II} center. A reduction in the number of strong chelating groups as well as an increased steric hindrance, or elongation of the distances between the chelate groups, lead to a remarkable decrease in the K_{NO} values.

Figure 9 shows a correlation between the K_{NO} values and the position of the *C-T* band for nearly the complete series of nitrosyl complexes. The shift in the *C-T* band to lower wavelengths is probably caused by a more pronounced ligand to metal charge transfer from NO to Fe. The synchronous increase in the band energy and the K_{NO} values in Figure 9 indicates that charge transfer seems to play an important role in the stabilization of the Fe−NO bond. For the very stable $[Fe(EDTA)NO]^{2-}$ complex, the Fe−NO bond is suggested to have significant $Fe^{III}-NO^-$ character and the *LMCT* band occurs at 435 nm, i.e. it has a high energy barrier. On the other hand, for the less stable $[Fe(H_2O)_5(NO)]^{2+}$ complex the *LMCT* band occurs at significantly lower energy (451 nm), with the result that the Fe−NO bond is suggested to have more of a $Fe^{II}-NO$

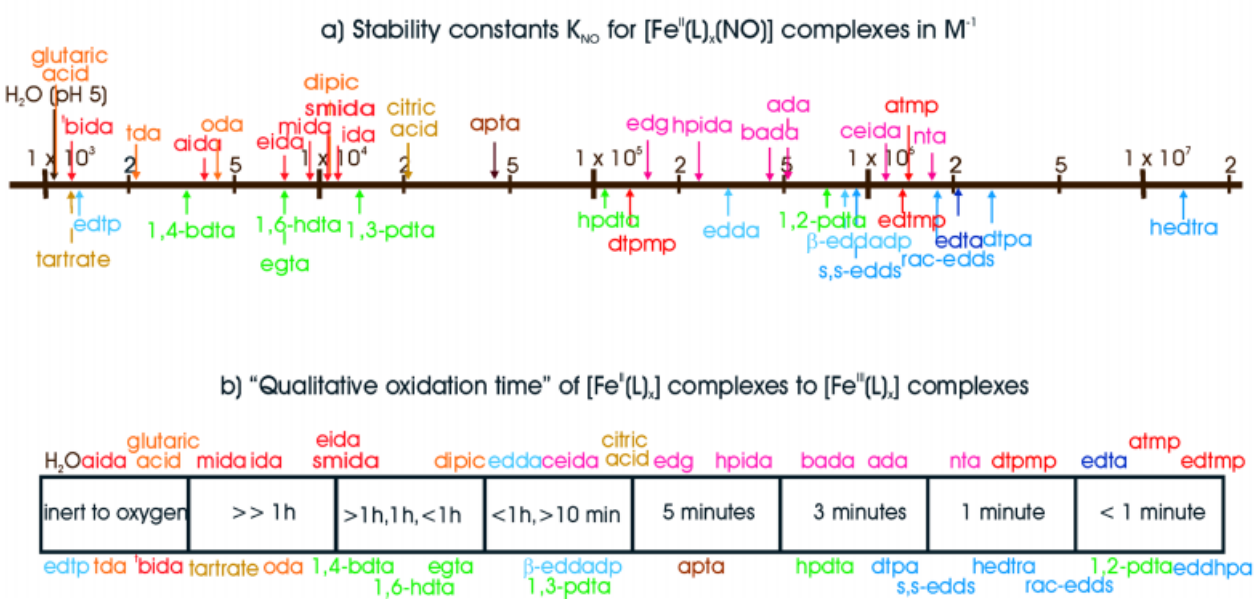

Figure 8. Correlation between K_{NO} and qualitative oxidation time of $[Fe^{II}(L)_x]$ complexes

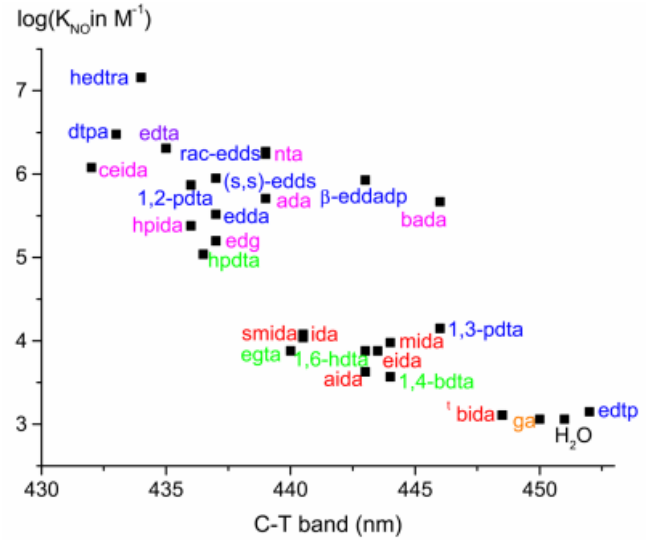

Figure 9. Correlation between the logarithmic K_{NO} values and the position of the *C-T* band in the UV/Vis spectra of $[Fe^{II}(L)_x(NO)]$ complexes with L = polyaminecarboxylates

character. Thus the position of the *LMCT* band is a measure of the charge distribution in the Fe−NO band and correlates directly with the stability of the Fe(L)NO complex.

Following this more general interpretation of the influence of the chelate ligand on the magnitude of K_{NO}, different types of ligands are discussed in more detail.

Stability Constants of $[Fe^{II}(L)(NO)]$ Complexes for EDTA Analogues

For the stability constant of the EDTA complex, $[Fe^{II}(EDTA)(NO)]^{2-}$, a value of approx. $2{\cdot}10^6$ M^{-1} was found, which lies far on the right end of the scale in Figure 8**a** and is in good agreement with literature data ranging between $1.5{\cdot}10^6$ and $3{\cdot}10^6$ M^{-1} at 20 to 25 °C.[14] The high formation constant of the EDTA complex is probably caused by the tailor-made structure of EDTA, which tightly binds all six donor groups to the Fe^{II} center forming five sterically favored five-member rings.

The tuning of the EDTA structure as outlined in Figure 1, **Series 1** (indicated by blue and green colours in Figure 8**a**), clearly demonstrates that the formation of such five-member rings between the donor groups of the ligand and the Fe^{II} center is the most crucial factor for the stabilization of the Fe^{II}−NO bond in the complex. Whereas in 1,2-PDTA the branching of the ethylene spacer of EDTA by a methyl group has only a quite minor influence on the K_{NO} value, both the elongation of the ethylene spacer in the ligands 1,3-PDTA, 1,4-BDTA, 1,6-HDTA, and EGTA, and the substitution of all acetate groups in EDTP by propionate cause a drastic decrease or even a complete loss in the tendency of the ligand to bind to the iron center. This is reflected by K_{NO} values that shift more and more to the value for the pentaaqua nitrosyl complex on the left end of the scale in Figure 8**a**. Obviously, the formation of higher than five-member chelate rings on Fe^{II} is very unfavorable. Therefore, it is not surprising that EDTP with its four elongated carboxylate arms completely looses its binding ability, whilst in 1,3-PDTA, 1,4-BDTA, 1,6-HDTA, and EGTA a coordination of one of both the aminodiacetate units of the ligand to Fe^{II} should still be possible. The exceptional position of the K_{NO} value for the HPDTA complex, which is about ten-fold higher than the value for the 1,3-PDTA complex, is probably caused by coordination of the hydroxyl group to the iron center.

In comparison to the above mentioned ligands, a less pronounced reduction in the K_{NO} constants was observed when only two acetate groups of EDTA were either omitted (EDDA) or substituted by propionate (β-EDDADP) groups. This indicates that in the EDTA structure, besides the ethylene spacer, only two of the four acetate groups are most essential to stabilize the binding of NO. In addition, the deviations between the K_{NO} values of the EDDA and β-ED-

DADP complexes suggest that the propionate groups do not completely loose their ability to bind to Fe^{II}.

The Fe^{II} complexes of EDDS and DTPA have similar K_{NO} values as the EDTA complex, indicating that neither the substitution of the four acetate groups by two succinate groups (EDDS) nor the elongation of the system by an additional ethyleneaminediacetate unit (DTPA) considerably affect the binding characteristics. From the three possible stereoisomers of EDDS, the (*s*,*s*)-form, a natural product synthesized by *Amycolatopsis orientalis*,[45] shows a two-fold lower K_{NO} value than the optical inactive "racemate". It is reasonable to expect that the content of the *meso*-form in the racemate is responsible for the higher K_{NO} value.

Among the EDTA analogues, HEDTRA forms a nitrosyl complex with the highest stability constant. K_{NO} ($1.45 \cdot 10^7$ M^{-1}) exceeds more than five times the value for the EDTA complex. It is not easy to account for this high value, since the molecular structure of the HEDTRA complex is unknown in solution. Probably the hydroxyl group is not (or only weakly) coordinated to the metal center, such that the change in geometry of the complex enhances the stability of the $Fe^{II}-NO$ bond. This suggestion is supported by preliminary kinetic data, which indicate that especially the dissociation rate of NO from the complex (k_{off}) is much slower than in the case of the EDTA complex.[46]

Stability Constants of $[Fe^{II}(L)_x(NO)]$ Complexes for MIDA Analogues

In comparision to $[Fe^{II}(H_2O)_5(NO)]^{2+}$, complexes of MIDA and other three-dentate MIDA analogues stabilize the binding of NO only by a maximum factor of 10, i.e. the K_{NO} values hardly exceed 10^4 M^{-1} (Figure 8**a**, red and orange colors). Under the assumption that, as it was shown in the case of L = MIDA, these ligands selectively form 1:1 nitrosyl complexes with Fe^{II}, the at least 200 times lower stabilization of the $Fe^{II}-NO$ bond in comparison to the EDTA complex can be accounted for in terms of the different coordination geometry of the donor groups. The crystal structure of $[Fe^{II}(EDTA)H_2O]^{2-}$ shows a labile coordinated water molecule as a seventh donor group which is bound nearly opposite to both nitrogens of the mono-capped trigonal-prismatic structure.[15] In the nitrosyl complex, NO most probably substitutes the labile water molecule and as a consequence the $Fe^{II}-NO$ bond is considerably polarized by the strong inductive effect of both opposite nitrogens, and therefore has a high stability.

For the series of three-dentate MIDA analogues, the lower stabilization of the $Fe^{II}-NO$ bond by coordinated ODA, TDA, and AIDA is obviously due to a reduced donor capacity of either the hetero atoms, oxygen (ODA) and sulfur (TDA), or the nitrogen lone pair of AIDA which is delocalized by the acetyl group.

Four-dentate MIDA analogues, which have an additional coordinating group bound to the IDA nitrogen (Figure 1, **Series 2**, **subgroup b**), show in comparison to the three-dentate ligands a strong increase in the K_{NO} values (Figure 8**a**, pink colour). Whereas a hydroxyl group (EDG, HPIDA) increases the stability constant by a factor of about 20, a third carboxylate group (NTA, BADA, CEIDA) can cause a larger than 100 fold enhancement. The most pronounced effect was found in the case of NTA ($K_{NO} = 1.75 \cdot 10^6$ M^{-1}), which likely coordinates to the iron center by creating three sterically favoured five-membered rings. As shown before, both the elongation of an acetate to a propionate group (BADA) and the amide delocalization of ADA, lower the ability to coordinate NO to Fe^{II} and decrease the K_{NO} value by a factor of about 3 in comparison to the NTA complex. The high K_{NO} value of the CEIDA complex ($1.2 \cdot 10^6$ M^{-1}) is probably caused by the fact that the third ligand arm of this chelate coordinates to the Fe^{II} center with both the sulfur and the carboxylate group by forming two five-member rings.

Stability Constants of $[Fe^{II}(L)_x(NO)]$ Complexes for L ≠ Polyaminocarboxylates

The phosphonates ATMP, EDTMP, and DTPMP represent derivatives of the polyaminocarboxylates NTA, EDTA, and DTPA, in which the carboxylate groups are substituted by phosphonate groups. Although the positions of the absorption bands in the UV/Vis spectra differ considerably for the $Fe^{II}-NO$ complexes of both groups (Table 2), the K_{NO} values are in the case of ATMP and EDTMP amazingly similar to the constants for the corresponding NTA and EDTA complexes. This demonstrates that phosphonate is comparable to carboxylate in coordinating to Fe^{II} and stabilizing the $Fe^{II}-NO$ bond. Of both the nitrogen-free compounds, L-tartrate and citrate, only citrate binds strongly to Fe^{II} and causes in comparison to $[Fe^{II}(H_2O)_5(NO)]^{2+}$ a considerably enhanced stability of the Fe^{II}-NO bond with a value of about $2 \cdot 10^4$ M^{-1}.

Correlation Between the Oxygen Sensitivity of $[Fe^{II}(L)_x]$ and the Stability Constants of the Corresponding Nitrosyl Complexes

By comparing the oxygen sensitivity of the $[Fe^{II}(L)_x]$ complexes with the stability constants of the nitrosyl complexes, an interesting correlation was found which enables a more detailed understanding of the chemical nature of these systems. In order to examine the oxygen sensitivity of $Fe^{II}-$ligand complexes, we preferred not to perform detailed quantitative kinetic measurements, due to the complex nature and demanding analysis of the multistep reactions between $[Fe^{II}(L)_x]$ and O_2.[43−46] However, it was as a first approximation sufficient to obtain a set of qualitative data, on which basis the different complexes could be compared. We could realize such a comparison by simply introducing air into solutions of $[Fe^{II}(L)_x]$ complexes and recording UV/Vis spectra before and during the bubbling period in time sequences of 1, 3, 5, 10, 15, 30, 60 ... minutes. The degree of oxidation could easily be followed by the increase in absorbance below 400 nm. The time in which more than approx. 80% of the $[Fe^{II}(L)_x]$ complex was converted into the $[Fe^{III}(L)_x]$ complex was taken as "qualitative oxidation time" and entered for comparison purposes in the qualitative time scale of Figure 8**b**. It can be seen from

Figure 8**b** that the range of "qualitative oxidation time" varies from the totally inert hexaaqua complex to the extremely oxygen sensitive complexes of EDTA, 1,2-PDTA, which are oxidized within a few seconds and can no more be determined accurately by this qualitative method.

A good correlation exists between the oxygen sensitivity of $[Fe^{II}(L)_x]$ complexes and the stability constants of their nitrosyl complexes, which is clearly seen from the comparison in Figure 8**a** and 8**b**. In general, the higher the K_{NO} value for the nitrosyl complex, the shorter the "qualitative oxidation time". Obviously, an increasing inductive effect of the chelate ligand causes both an increasing stability of the $Fe^{II}-NO$ bond in the nitrosyl complexes, and also an enhanced electron transfer from Fe^{II} to O_2 in the corresponding $[Fe^{II}(L)_x]$ complexes. The two extreme cases are on the one hand "naked" $[Fe^{II}(H_2O)_6]^{2+}$ with its very low affinity for both dioxygen and NO, and on the other hand the $[Fe^{II}(EDTA)]^{2-}$ complex with its very high affinity for both dioxygen and NO. Thus the stability of the Fe(L)NO complex directly correlates with the oxygen sensitivity of the $Fe^{II}(L)$ complex, i.e. with the ability to form $Fe^{III}-O_2^-$. This again suggests that the stability of the Fe(L)NO complex is also controlled by its ability to bind NO as $Fe^{III}-NO^-$, which correlates with the position of the *LMCT* band observed in Figure 9. These trends should then also correlate with the redox potentials of the $Fe^{II/III}(L)$ complexes (see Table 3).

Table 3. Redox potentials vs. NHE

$[Fe^{III}(H_2O)_6]^{3+}/[Fe^{II}(H_2O)_6]^{2+}$	$E_{1/2} = 0.771$ V	(ref.[47])
$[Fe^{III}(1,3\text{-PDTA})]^-/[Fe^{II}(1,3\text{-pdta})]^{2-}$	$E_{1/2} = 0.309$ V	(this work)
$[Fe^{III}(EDTA)]^-/[Fe^{II}(EDTA)]^{2-}$	$E_{1/2} = 0.129$ V	(this work)
$[Fe^{III}(DTPA)]^-/[Fe^{II}(DTPA)]^{2-}$	$E_{1/2} = 0.110$ V	(ref.[48])

It is seen from the quoted values that the tendency of $Fe^{II}(L)$ to be oxidized (as reflected by the lower redox potential) correlates directly with the oxygen sensitivity of $Fe^{II}(L)$ and its ability to bind NO. In these cases $Fe^{II}(L)$ is formally oxidized to effectively bind O_2 and NO as $Fe^{III}-O_2^-$ and $Fe^{III}-NO^-$, respectively.

Conclusion

The results reported in this study clearly demonstrate that the correlation found between the oxygen sensitivity and the K_{NO} values for the investigated complexes, makes it very difficult to find suitable $[Fe^{II}(L)_x]$ complexes that will show a low oxygen sensitivity and a high affinity to bind NO (i.e. $K_{NO} > 1\cdot10^6$ M^{-1}). The exceptionally high K_{NO} value for the HEDTRA complex and the more favorable relation between the oxygen sensitivity and K_{NO} values for the DTPA, CEIDA, and β-EDDADP complexes, suggest that these ligands are promising candidates for technical applications. However, so far no kinetic details are available, and the conclusions are based on thermodynamic stability constants for the binding of NO and qualitative observations on the oxygen sensitivity of the complexes. A detailed kinetic analysis of the "on" and "off" reactions for the interaction of $Fe^{II}(L)$ with NO is presently underway[46] and may reveal significant differences that will enable a kinetic control and further tuning of the overall process.

Experimental Section

General Remarks: All experiments were performed under strict exclusion of air oxygen. Buffer solutions were deaerated for extended periods (in general 1 minute per mL solution) with pure N_2 or Ar, or in some cases freeze-thaw cycles were performed under vacuum in order to completely remove the dissolved dioxygen in solution, before they were brought in contact with Fe^{II} salts or nitric oxide.

NO gas, purchased from Messer Griesheim or Rießner Gase in a purity of at least 99.5 vol%, was cleaned from trace amounts of higher nitrogen oxides like N_2O_3 and NO_2 by passing it through an Ascarite II column (NaOH on silica gel, Sigma–Aldrich). NO from a gas tank should not be used after six months following the date of its industrial preparation, since decomposition causes a drastic decrease in the purity of the gas. The decomposition is pressure dependent, which led us to only use bottles filled with a maximum pressure of 20 bar, and resulted in a longer life-time of the NO gas.

The chelate ligands AIDA, ATMP, BADA, 1,4-BDTA, ^{t}BIDA, DTPMP, *rac.* EDDS, (*s,s*)-EDDS,[49] EDG, EDTMP, EIDA, HPDTA, HPIDA, MIDA, NTA, 1,3-PDTA, and SMIDA were supplied by Akzo Nobel. All other ligands and chemicals were purchased from Arcos Chimica, Fluka, Lancaster Synthesis, or Sigma–Aldrich with the highest available purity (at least 97%). APTA was synthesized according to a procedure described in the literature.[50]

UV/Vis spectra were recorded on a Cary 1G UV/Vis spectrophotometer from Varian using a 1 cm quartz cuvette directly attached to a round flask with a sideway gas connection. This enabled the performance of different physical or chemical operations, like bubbling the solution with NO or N_2, and the measurement of spectra under exclusion of dioxygen in the same vessel.

IR spectra were recorded with the use of a two mirror ATR cell on a ATI Mattson FTIR *Infinity* spectrophotometer. The reflection instrument utilizes a Ge crystal as an internal reflection plate with a size of 50 × 20 × 2 mm and 45° angle of incidence. For each complex two independent measurements of 100 scans were performed under inert gas atmosphere.

The concentration of free nitric oxide in solution was determined with an ISO-NOP electrode connected to an ISO-NO Mark II nitric oxide sensor from World Precision Instruments. The NO electrode consists of a membrane covered anode which selectively oxidizes NO to NO_3^- ions. The resulting current is proportional to the concentration of NO in solution. The NO electrode was calibrated daily with fresh solutions of sodium nitrite and potassium iodide according to the method suggested by the manufacturers. The calibration factor nA/μM was determined with a linear fit program.

Potentiometric measurements were performed on a METROHM 702 SM Titrino in a jacketed, air-tight glass titration cell equipped with a combined pH glass electrode (METROHM 6.0203.100), N_2 inlet and outlet, and a graduated 10 mL microburet (METROHM 6.1518.210). The electrode was calibrated with strong acid and strong base so as to read directly in hydrogen ion concentration.

The ion product of water, i.e. $pK_W = -\log[H^+][OH^-] = 13.85$, was determined experimentally. A carbonate-free 0.10 M sodium hydroxide solution was prepared with boiled distilled water and was standardized by titrations with potassium hydrogen phthalate. Gran's method[51] was used to confirm the absence of carbonate in the sodium hydroxide standard solution. The NaOH solution was stored under nitrogen. All solutions were adjusted to an ionic strength of 0.5 M with $NaClO_4$. The temperature was maintained at 25.0 ± 0.1 °C by circulating thermostated water through the outer jacket of the cell. All measurements were carried out while bubbling N_2 through the solution.

pH measurements were performed with the aid of a Mettler Delta 340 pH-meter. The reference electrode was filled with NaCl instead of KCl to prevent precipitation of $KClO_4$.

Cyclic voltammogramms were recorded with an EG&G PARC potentiostat-galvanostat Model 263 controlled by a PC. The electrochemical cell was a conventional one with three electrodes. The reference electrode was Ag/AgCl, the counter electrode was a platinum sheet and a glassy carbon electrode was used as the working electrode (all from BAS). Solutions for cyclic voltammetry were fully deoxygenated with nitrogen for at least 1 h. Following deoxygenation, the behavior of the electrode was studied in the buffer solution and checked by measurements on the redox couple of $K_3[Fe(CN)_6]$. Reported $E_{1/2}$ values are corrected to the NHE scale. The concentration of the solutions was 5 mM for $[Fe^{II}(EDTA)]^{2-}$ and $[Fe^{II}(1,3\text{-PDTA})]^{2-}$. Solutions were prepared by dissolving the respective ligand and $Fe_2(SO_4)_3 \cdot 5\,H_2O$ in 0.1 M acetate buffer at pH 5. The ionic strength was adjusted to 0.5 M ($NaClO_4$).

In all UV/Vis experiments, solutions of 1 mM of Fe^{II} chelates in 100 mM acetate buffer at pH 5.0 were used. The Fe^{II} complexes were prepared from $FeSO_4 \cdot 7\,H_2O$ and the chelate in an excess of 10 to 50% over the required stoichiometric amount, i.e. between 1.1 and 1.5 mM in the case of the EDTA analogues, and between 2.2 and 3.0 mM in the case of the MIDA analogues. In each buffer solution the ionic strength was adjusted to a value of 0.5 M by addition of calculated amounts of sodium perchlorate. For ATR-IR measurements, unbuffered solutions of Fe^{II} chelates at a concentration of up to 200 mM were used.

Thermodynamic and Kinetic Studies on Complex-Formation Reactions of a Cobalt(II) Tripodal Tetraamine Complex

Zhong-Lin Lu,[a][‡] Mohamed S. A. Hamza,[a][‡‡] and Rudi van Eldik*[a]

Keywords: Cobalt / Thermodynamics / Kinetics / Tripodal ligands / N ligands

Complex-formation constants were determined for the reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with different pyridine- and imidazole-based nucleophiles, and the kinetics of these reactions was studied as a function of entering ligand concentration, temperature, and pressure. The steric hindrance associated with the methyl substituents on the trigonal-bipyramidal complex induces a sensitive control over the substitution mechanism from dissociative for the weaker and more bulky entering nucleophiles, to associative for the stronger and less bulky nucleophiles. A changeover in mechanism can be observed as a function of nucleophile concentration, in the case of 2-MeImH as the entering ligand. The mechanistic assignments are based on the observed rate laws, and the activation parameters determined under limiting concentration conditions.

Introduction

The thermodynamics and kinetics of complex-formation and ligand-substitution reactions of octahedral transition metal complexes have been studied in much detail by many groups, and a number of reviews have appeared on this topic, of which a few typical examples are referenced.[1a−1d] In contrast, the formation, stability, and mechanistic behaviour of five-coordinate square-pyramidal or trigonal-bipyramidal first-row transition metal complexes have received significantly less attention.[2] Such five-coordinate complexes can exhibit significantly different ligand substitution behaviour since they are, in principle, able to coordinate an additional nucleophile in the transition state. In contrast, six-coordinate complexes usually undergo dissociative ligand substitution reactions. Thus, the study of their behaviour is of fundamental importance to the understanding of complex-formation and ligand-substitution reactions in general.

By way of a typical example, the introduction of a tripodal tetraamine ligand such as tren [tris(2-aminoethyl)-amine] into the coordination sphere of copper(II) leads to the formation of a trigonal-bipyramidal complex, $[Cu(tren)(H_2O)]^{2+}$. This complex exhibits significantly slower water-exchange and complex-formation reactions than the parent $[Cu(H_2O)_6]^{2+}$ ion due to the absence of Jahn−Teller distortion.[3,4] Not only are the reactions much slower, their mechanism has also changed from the I_d to the I_a type as clearly indicated by the significantly different volumes of activation reported for these reactions.[3,4] Furthermore, the mechanistic behaviour of these complexes can be systematically tuned by the introduction of steric hindrance on the tripodal ligand, viz. tren, trimethylated (Me_3tren, i.e. one methylation per primary amine group of tren) and hexamethylated tren (Me_6tren, i.e. fully methylated primary amine groups).[5] The substitution reactions of $[Cu(Me_3tren)(H_2O)]^{2+}$ are more than two orders of magnitude slower than those of $[Cu(tren)(H_2O)]^{2+}$, but still follow an I_a mechanism. However, in the case of the $[Cu(Me_6tren)(H_2O)]^{2+}$ complex, a further decrease in the substitution rate and a changeover back to a dissociative reaction mechanism is observed. Only at high entering nucleophile concentrations, could evidence for a parallel associative reaction path be observed.[5] The introduction of steric hindrance on the tripodal tetraamine chelate controls the substitution behaviour of these complexes, and the extension of the chelate rings from ethyl to propyl causes a geometric changeover from trigonal-bipyramidal to square-pyramidal which is accompanied by a change in lability.[6]

Based on this experience, we have begun a study on the corresponding behaviour of cobalt(II) complexes. Our interest lies in the activation of dioxygen reported for the $[Co(tren)(H_2O)]^{2+}$ complex [7] and the details of the underlying reaction mechanism, which can then be compared with that previously found for an octahedral cobalt(II) complex.[8] However, since the activation of dioxygen in general involves the combination of ligand substitution and subsequent redox processes, it is at first essential to understand the ligand substitution behaviour of these systems. Due to the extreme oxygen sensitivity of the $[Co(tren)(H_2O)]^{2+}$ complex,[7] we first turned to the almost oxygen-insensitive $[Co(Me_6tren)(H_2O)]^{2+}$ complex and studied its complex-formation reactions in more detail. results of this study show that the ligand-substitution mechanism can be controlled by the concentration and nucleophilicity of the entering ligand.

Results and Discussion

Determination of Complex-Formation Constants

The stability constant (log K) of the cobalt(II) complex with the chelate Me_6tren is 8.53, which is smaller than that of the corresponding copper(II) complex (viz. 15.65), and the pK_a of the corresponding aqua complex, $[Co(Me_6tren)(H_2O)]^{2+}$, is 8.6.[9]

The complex-formation constants for substitution of water on $[Co(Me_6tren)(H_2O)]^{2+}$ by pyridine, 4-methylpyridine, and imidazole were determined in the following manner. The complex concentration was kept constant at $3.4 \cdot 10^{-3}$ M and different concentrations of the ligands L were added.

$$[Co(Me_6tren)(H_2O)]^{2+} + L \rightleftharpoons [Co(Me_6tren)(L)]^{2+} + H_2O \quad K$$

On increasing the ligand concentration, the characteristic peak at 470 nm is incrementally reduced and almost disappears completely at high ligand concentrations. A typical example of the spectral changes observed for the substitution reaction with ImH is shown in Figure 1. The spectra in general show clean isosbestic points at low entering nucleophile concentrations, but a shift in isosbestic points occur at high added nucleophile concentrations. In the case of the reaction with ImH this effect is not very strong, but in the case of the reaction with 4-Mepy the deviations in isosbestic points are very significant. This indicates that different substitution products, in which the Me_6tren ligand is displaced in a stepwise manner by the entering nucleophile, can be formed depending on the concentration and nature of the added nucleophile. In fact it was possible to isolate and characterise $[Co(L)_4(H_2O)_2](ClO_4)_2$ (L = 4-MePy) and $[Co(L)_6](ClO_4)_2$ (L = ImH) as reaction products at high concentrations of 4-Mepy and ImH (see Experimental Section). From the molar conductivity measurements it is clear that the two isolated complexes are 2:1 electrolytes. The plot of absorbance at 470 nm versus ligand concentration for the reaction with ImH is shown in Figure 2. The latter data were used to estimate the complex-formation constant (K) in the usual manner.[10] Plots of $\log\{(A_x - A_i)/(A_\infty - A_x)\}$ versus log[nucleophile] showed a linear dependence with unity slope at low nucleophile concentrations, but deviations occurred at higher concentrations due to the formation of 1:2 and higher substituted complexes.

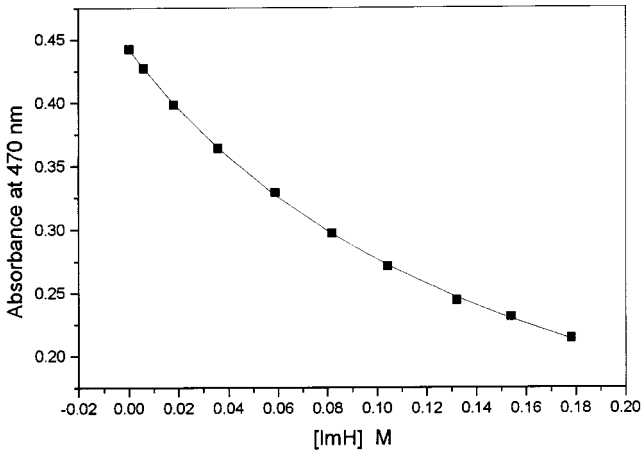

Figure 2. Absorbance at 470 nm versus concentration of ImH for the reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with ImH at 25.0 °C, pH = 7.92 ± 0.02, I = 1.0 M, 0.05 M Tris buffer, $[Co^{II}] = 3.21 \cdot 10^{-3}$ M

The 1:1 complex-formation constants for pyridine (py), 4-methylpyridine (4-Mepy), and imidazole (ImH) were found to be 1.0 ± 0.3 , 1.8 ± 0.4, and 7.4 ± 1.8 M^{-1} at 25 °C, respectively. A plot of the complex-formation constants (log K) versus the pK_a values of the ligands is shown in Figure 3. It can be seen that log K increases linearly with increasing pK_a, which is consistent with that expected in terms of the basicity of the entering nucleophiles. Such linear correlations between log K and pK_a have also been reported in the literature.[11]

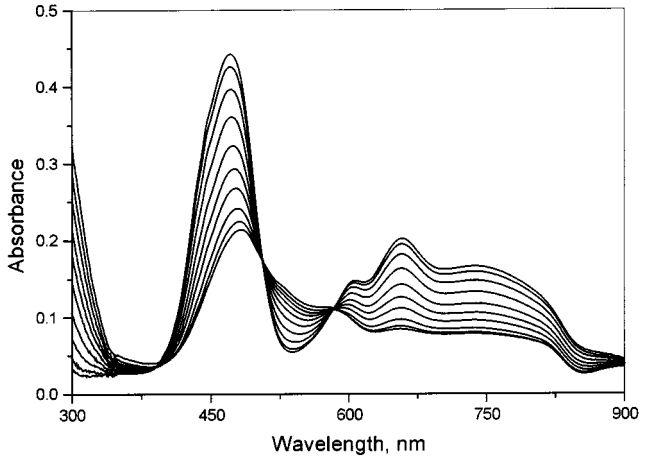

Figure 1. Absorption spectra for the complex formation between $[Co(Me_6tren)(H_2O)]^{2+}$ and ImH ([ImH] from 0.0 to 0.18 M) at 25.0 °C, pH = 7.92 ± 0.02, I = 0.2 M, 0.05 M Tris buffer, $[Co^{II}] = 3.21 \cdot 10^{-3}$ M

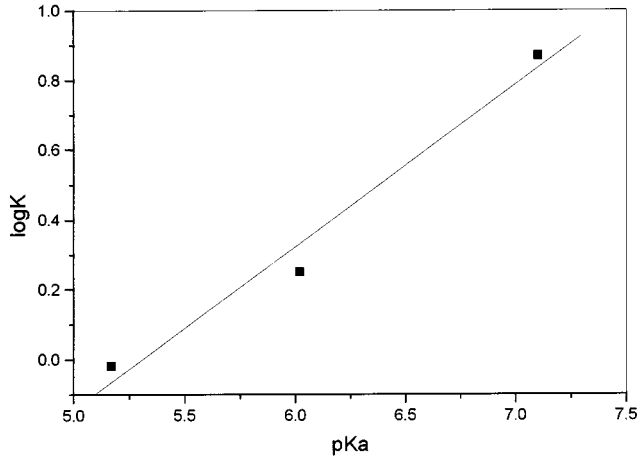

Figure 3. Plot of log K (from thermodynamic method) versus pK_a of the ligands for the reaction between $[Co(Me_6tren)(H_2O)]^{2+}$ and Py, 4-MePy, and ImH

A comparison of the K value for the formation of the pyridine complex, viz. 1.0 ± 0.3 M^{-1}, with that for the corresponding $[Cu(Me_6tren)(H_2O)]^{2+}$ complex, viz. 6.6 ± 0.3 M^{-1},[5] indicates that the copper(II) complex is more stable. This is in agreement with the higher stability constant (log K) reported for $[Cu(Me_6tren)(H_2O)]^{2+}$ as compared with that for $[Co(Me_6tren)(H_2O)]^{2+}$, viz. 15.65 and 8.53, respectively.[9]

Kinetic Analysis

Preliminary Observations

Preliminary kinetic experiments for the reaction of $[Co(Me_6tren)(H_2O)^{2+}]$ with the selected organic bases at a pH < 7.9, revealed kinetic traces in the absence of an added nucleophile as a result of the dilution of the complex solution in the stopped-flow instrument. This effect could be correlated with the dissociation of the complex on dilution. For this reason all kinetic measurements were performed at pH = 7.9 where this effect is negligible. Under this condition a small fraction of the complex exists in the inert hydroxo form due to the pK_a value of 8.6. Further experiments demonstrated that the observed pseudo first-order rate constants measured in the presence of an excess of the nucleophile also depended on the concentration of the cobalt(II) complex; the effect being much stronger at lower pH due to the partial dissociation of the complex under such conditions. All kinetic measurements were therefore performed at a fixed cobalt(II) concentration and a pH of 7.9.

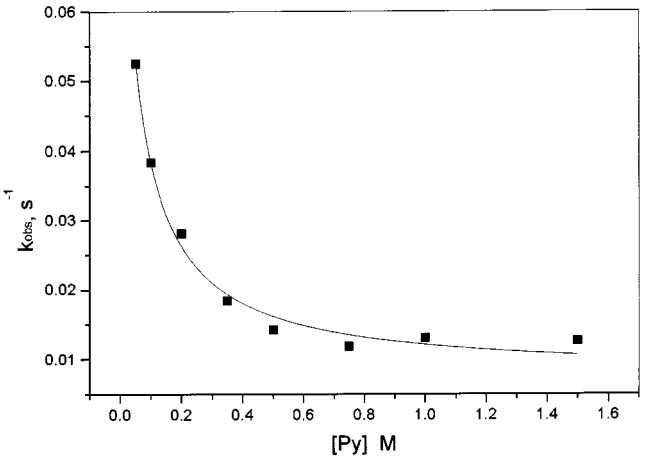

Figure 4. Kinetic data for the reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with pyridine at 25°C, pH = 7.92 ± 0.02, I = 1.0 M, 0.05 M Tris buffer, $[Co^{II}] = 3.61 \cdot 10^{-3}$ M

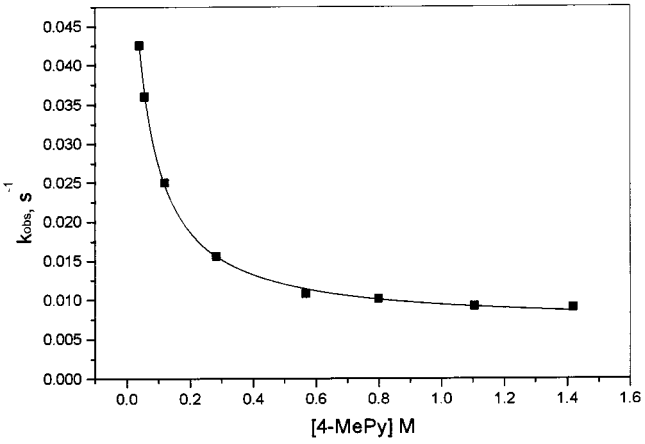

Figure 5. Kinetic data for the reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with 4-MePy at 25.0 °C, pH = 7.92 ± 0.02, I = 1.0 M, 0.05 M Tris buffer, $[Co^{II}] = 3.2 \cdot 10^{-3}$ M

Reactions of Pyridine and 4-Methylpyridine with $[Co(Me_6tren)(H_2O)]^{2+}$

The reactions of pyridine and 4-methylpyridine with $[Co(Me_6tren)(H_2O)]^{2+}$ are very similar. Kinetic measurements on the reaction were performed using total ligand concentrations in the range of 0.05−1.5 M at a pH = 7.92 and ionic strength of 1.0 M ($NaClO_4$), and thus always at least in 10-fold excess of the $[Co(Me_6tren)(H_2O)]^{2+}$ concentration. When k_{obs} is plotted versus the entering ligand concentration, k_{obs} decreases with increasing ligand concentration over the whole ligand concentration range (see Figure 4 and Figure 5). This is very characteristic for a dissociative mechanism involving an efficient back reaction. A similar nucleophile concentration dependence has been reported for several reversible dissociative ligand substitution reactions in the literature.[12a−12e] However, it should be noted that the observed trends differ significantly from that observed for the substitution reaction of $[Cu(Me_6tren)(H_2O)]^{2+}$ with pyridine [4] (see further Discussion).

On the basis of the observed kinetics, we propose the following reversible two-step mechanism [Equation (1) and Equation (2)].

$$[Co(Me_6tren)(H_2O)]^{2+} \rightleftharpoons [Co(Me_6tren)]^{2+} + H_2O \quad k_1, k_{-1} \qquad (1)$$

$$[Co(Me_6tren)]^{2+} + L \rightleftharpoons [Co(Me_6tren)(L)]^{2+} \quad k_2, k_{-2} \qquad (2)$$

(L = Py and 4-MePy) The rate law for this mechanism can be expressed as shown in Equation (3).

$$k_{obs} = (k_1k_2[L] + k_{-1}k_{-2})/(k_{-1} + k_2[L]) \qquad (3)$$

A non-linear least-squares fit of the data according to Equation (3) reveals that k_1 = 0.0076 ± 0.0025 s^{-1}, k_{-2} = 0.094 ± 0.015 s^{-1}, and k_2/k_{-1} = 18 ± 6 M^{-1} for pyridine, and those for 4-methylpyridine are k_1 = 0.0066 ± 0.0009 s^{-1}, k_{-2} = 0.077± 0.004 s^{-1}, and k_2/k_{-1} = 24 ± 2 M^{-1} at 25 °C. Thus the complex-formation constant K (= $k_1k_2/k_{-1}k_{-2}$) from the kinetic data for the reaction with pyridine is 1.5 ± 0.7 M^{-1} and that for 4-methylpyridine is 2.1 ± 0.3 M^{-1}, whereas the formation constant from the thermodynamic measurements are 1.0 ± 0.3 and 1.8 ± 0.4 M^{-1}, re-

spectively. It follows that the data from the two independent methods are similar within the experimental error limits.

The temperature dependence of the substitution reactions of $[Co(Me_6tren)(H_2O)]^{2+}$ with pyridine and 4-methylpyridine was studied under limiting conditions at pyridine and 4-methylpyridine concentrations of 1.0 and 1.105 M, respectively, i.e. where k_{obs} reaches a minimum and $k_{obs} \approx k_1$. The results are summarised in Table 1, from which it follows that the activation enthalpy and activation entropy are 74 ± 4 kJ mol^{-1} and -35 ± 12 J K^{-1} mol^{-1} for the reaction with pyridine, and 71 ± 2 kJ mol^{-1} and -47 ± 5 J K^{-1} mol^{-1}, respectively, for substitution by 4-methylpyridine. Both the activation entropies are negative and are not in line with the concept of a limiting dissociative mechanism as suggested by the observed rate law. This is not unusual since activation entropies are inherently subjected to large error limits as a result of the way in which they are determined, viz. by extrapolation of rate constants measured over a limited temperature range to $1/T = 0$. For this reason the effect of pressure on the reaction with 4-methylpyridine was studied under similar experimental conditions. It was, however, difficult to obtain accurate data due to turbidity problems that occurred during mixing in the high-pressure stopped-flow system (see Experimental Section). For this reason the ionic strength of the solutions was decreased to almost zero and the temperature was raised to 45.0 ± 0.1 °C, which significantly improved the quality of the data. The results indicate that the observed rate constant (practically k_1) decreases with increasing pressure. The average activation volume calculated from the slope of $\ln(k)$ versus pressure ($= -\Delta V^{\neq}/RT$) for four series of measurements is $+15 \pm 7$ cm^3 mol^{-1}. The large error limits is a result of the unfavourable time scale of the reaction and the small absorbance change associated with the reaction under these conditions. The value in principle supports the operation of a dissociative mechanism.

Reaction of Imidazole with $[Co(Me_6tren)(H_2O)]^{2+}$

The kinetics of the substitution reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with imidazole differed significantly from that reported above for pyridine and 4-methylpyridine. When k_{obs} is plotted versus the ligand concentration (see Figure 6), it is clear that k_{obs} increases linearly with increasing imidazole concentration in the lower concentration range, but increases almost exponentially in the higher concentration range. The data can be interpreted in terms of a two-step associative substitution mechanism in which imidazole first displaces the coordinated water molecule in Equation (4), followed by either the binding of a second imidazole molecule to form a six-coordinate complex, or the stepwise dechelation of the Me_6tren ligand to form a five-coordinate disubstituted product in Equation (5).

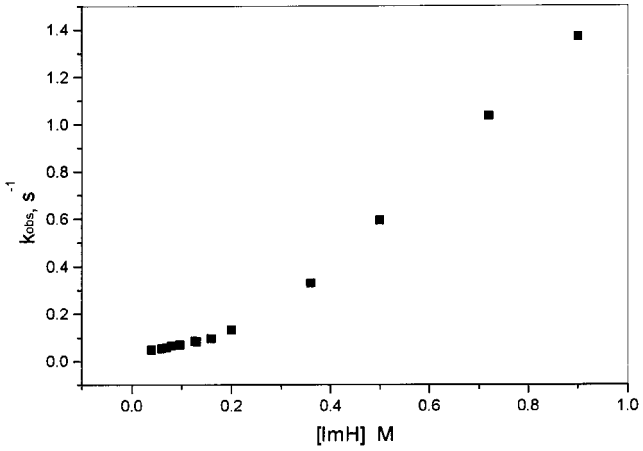

Figure 6. Kinetic data for the reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with ImH at 25.0 °C, pH = 7.92 ± 0.02, I = 0.2 M, 0.05 M Tris buffer, $[Co^{II}] = 3.21 \cdot 10^{-3}$ M

On the basis of these arguments we propose the following mechanism for the substitution of $[Co(Me_6tren)(H_2O)]^{2+}$ by imidazole (ImH).

Table 1. Kinetic data for the substitution of $[Co(Me_6tren)(H_2O)]^{2+}$ by an organic ligand L at pH = 7.92 ± 0.02, 0.05 M Tris buffer and I = 1.0 M

Ligand (L)	Temp. [°C]	k_{obs} [s^{-1}]	$\Delta H^{\neq}$ [kJ mol^{-1}] and $\Delta S^{\neq}$ [J mol^{-1} K^{-1}]

[a] I = 0.2 M.

$$[Co(Me_6tren)(H_2O)]^{2+} + ImH \rightleftharpoons [Co(Me_6tren)(ImH)]^{2+} + H_2O \quad k_3, k_{-3} \tag{4}$$

$$[Co(Me_6tren)(ImH)]^{2+} + ImH \rightarrow [Co(Me_6tren)(ImH)_2]^{2+} \quad k_4 \tag{5}$$

This leads to rate law (6) for the formation of the substitution products:

$$k_{obs} = k_{-3} + k_3[ImH] + (k_4k_3/k_{-3})[ImH]^2 \tag{6}$$

At lower concentrations of ImH, the rate law Equation (6) reduces to

$$k_{obs} = k_{-3} + k_3[ImH] \tag{7}$$

At higher concentrations of ImH, the rate law Equation (6) can be rewritten as

$$(k_{obs} - k_{-3})/[ImH] = k_3 + (k_4k_3/k_{-3})[ImH] \tag{8}$$

k_{-3} can be obtained directly from the plot of k_{obs} versus [ImH] at lower concentrations (Figure 6), and all other rate constants can then be obtained from the plot of $(k_{obs} - k_{-3})/[ImH]$ versus [ImH] for all the data points (see Figure 7). This results in $k_{-3} = 0.031 \pm 0.002$ s^{-1}, $k_3 = 0.27 \pm 0.03$ M^{-1} s^{-1}, and $k_4(k_3/k_{-3}) = 1.46 \pm 0.08$ M^{-2} s^{-1}, from which it follows that $k_4 \approx 0.17 \pm 0.02$ M^{-1} s^{-1}, i.e. ca. two times as slow as k_3. These data account for the initial linear dependence of k_{obs} on the imidazole concentration in the lower concentration range and the exponential behaviour due to the contribution of the second-order term in imidazole concentration at higher concentrations.

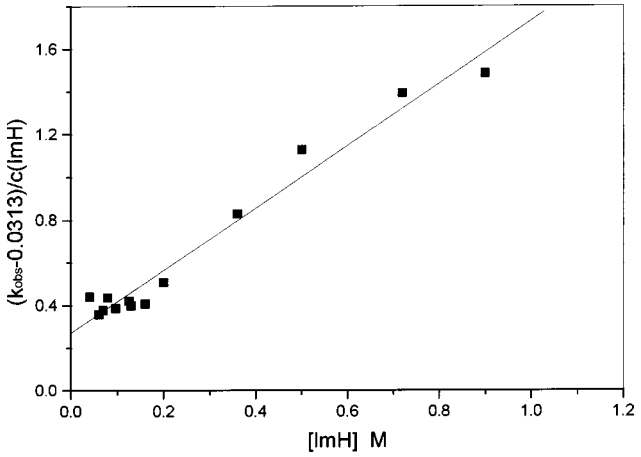

Figure 7. Fit of the kinetic data for the reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with ImH according to Equation (8) at 25.0 °C, pH = 7.92 ± 0.02, I = 0.2 M, 0.05 M Tris buffer, $[Co^{II}] = 3.21 \cdot 10^{-3}$ M

The temperature dependence of the reaction was studied at imidazole concentrations of 0.096 and 0.50 M, in order to cover the low and high concentration ranges, respectively. The results are included in Table 1 and the activation enthalpies are 48 ± 1 and 59 ± 1 kJ mol^{-1}, respectively. The significantly negative activation entropies of −87 ± 4 and −71 ± 4 J K^{-1} mol^{-1}, respectively, support the associative nature of the substitution process. The effect of pressure on the reaction was studied at an imidazole concentration of 0.16 M, and the pressure dependence of k_{obs} (see Figure 8) results in a $\Delta V^{\neq}$ value of −2.61 ± 0.07 cm^3 mol^{-1}. This small and negative value suggests that substitution by imidazole follows an associative interchange (I_a) mechanism.[3]

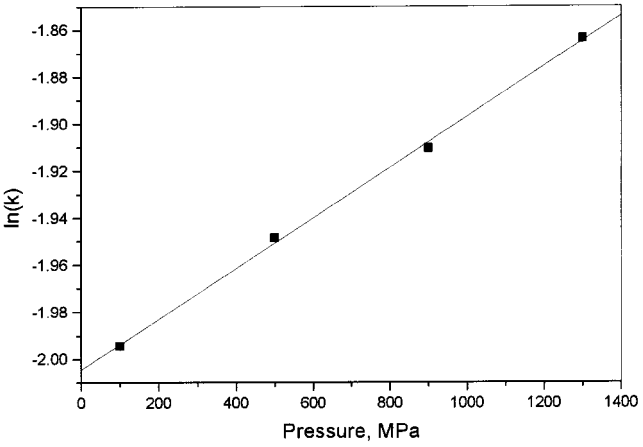

Figure 8. High pressure kinetic data for the reaction between $[Co(Me_6tren)(H_2O)]^{2+}$ and ImH at 25.0 °C, pH = 7.92 ± 0.02, I = 0.2 M, 0.05 M Tris buffer, $[Co^{II}] = 3.21 \cdot 10^{-3}$ M and [ImH] = 0.16 M

Reaction of 2-Methylimidazole with $[Co(Me_6tren)(H_2O)]^{2+}$

The reaction of 2-methylimidazole with $[Co(Me_6tren)(H_2O)]^{2+}$ is again different from that reported above for the reactions with pyridine, 4-methylpyridine and imidazole. In this case a combination of the dependencies reported in Figures 4 to 6 is observed. When k_{obs} is plotted versus the 2-methylimidazole concentration, it first decreases with increasing 2-methylimidazole concentration in the lower concentration range, and then increases with increasing concentration in the higher concentration range (see Figure 9). k_{obs} passes through a minimum at a 2-methylimidazole concentration of ca. 0.2 M and then depends linearly on the 2-methylimidazole concentration as shown in Figure 9. This concentration dependence is very similar to that reported for the substitution reaction of $[Cu(Me_6tren)(H_2O)]^{2+}$ with pyridine.[4] According to the literature and the results reported above, we propose the following mechanism for the substitution reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with 2-methylimidazole.

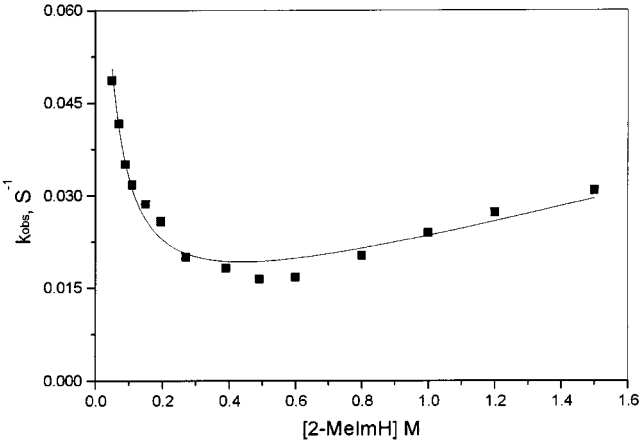

Figure 9. Kinetic data for the reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with 2-MeImH at 25.0 °C, pH = 7.92 ± 0.02, I = 1.0 M, 0.05 M Tris buffer, $[Co^{II}] = 3.23 \cdot 10^{-3}$ M

The mechanism consists of two parallel competing reaction paths. The displacement of coordinated water proceeds according to a dissociative mechanism that results in a rate law similar to Equation (3), and can account for the decrease in k_{obs} with increasing 2-methylimidazole concentration. The parallel dechelation reaction path can exhibit a linear dependence on the 2-methylimidazole concentration similar to Equation (7), with an intercept for the reverse reaction under conditions where dechelation is a pre-equilibrium step. The combination of these concentration dependencies will result in the curved dependence observed in Figure 9. At low 2-methylimidazole concentration the reaction will proceed mainly by the displacement of coordinated water, whereas at higher 2-methylimidazole concentration the parallel dechelation path will become more important since a linear concentration dependence is exhibited. The reactions can be summarised as described below.

At lower concentrations of 2-MeImH

$$[Co(Me_6tren)(H_2O)]^{2+} \rightleftharpoons [Co(Me_6tren)]^{2+} + H_2O \quad k_1, k_{-1} \qquad (1)$$

$$[Co(Me_6tren)]^{2+} + L \rightleftharpoons [Co(Me_6tren)(L)]^{2+} \quad k_2, k_{-2} \qquad (2)$$

(L = 2-MeImH)

The rate law is the same as given in Equation (3). At higher concentrations of 2-methylimidazole a significant contribution of the parallel associative displacement of the Me_6tren chelate, involving a dechelation pre-equilibrium, is suggested to account for the observed data [Equation (9) and Equation (10)].

$$[Co(Me_6tren)(H_2O)]^{2+} \rightleftharpoons [Co(Me_6tren')(H_2O)]^{2+} \quad K_5 \qquad (9)$$

$$[Co(Me_6tren')(H_2O)]^{2+} + L \rightarrow [Co(Me_6tren')(H_2O)(L)]^{2+} \quad k_6 \qquad (10)$$

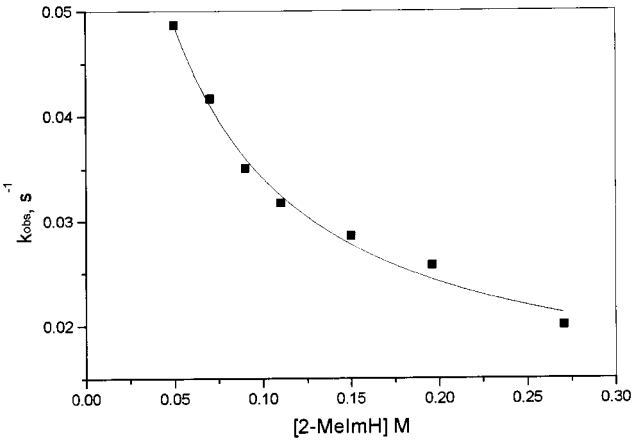
(Me_6tren′ represents 3-coordinated Me_6tren; L = 2-MeImH) This mechanism leads to the rate law $k_{obs} = k_6K_5[L]$, and combined with Equation (3) results in the combined rate law

$$k_{obs} = (k_1k_2[L] + k_{-1}k_{-2})/(k_{-1} + k_2[L]) + k_6K_5[L] \qquad (11)$$

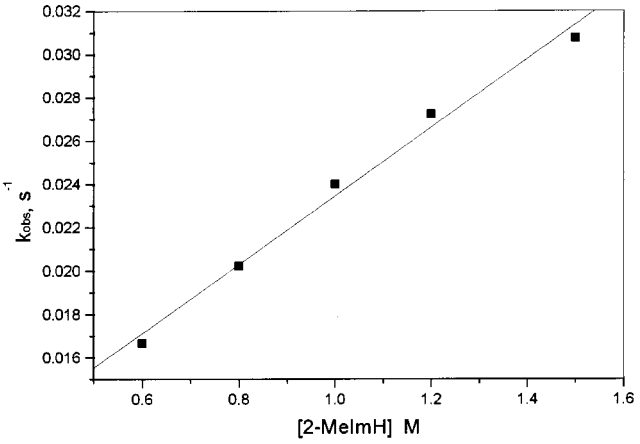
At high concentrations of 2-MeImH, Equation (11) reduces to

$$k_{obs} = k_1 + k_6K_5[L] \qquad (12)$$

From a fit of the data in Figure 10 (a) using Equation (3), $k_1 = 0.012 \pm 0.006$ s^{-1}, $k_{-2} = 0.12 \pm 0.04$ s^{-1} and $k_2/k_{-1} = 37 \pm 23$ M[4]$^{-1}$. With these values and using $k_1k_2/k_{-1} = 0.42$ M^{-1} s^{-1}, the experimental data in Figure 9 were fitted to Equation (11), which resulted in $k_1 = 0.007 \pm 0.001$ s^{-1}, $k_{-2} = 0.18 \pm 0.03$ M^{-1} s^{-1}, $k_2/k_{-1} = 60 \pm 10$ M^{-1}, and $k_6K_5 = 0.014 \pm 0.001$ M^{-1} s^{-1}. From a fit of the higher concentration data in Figure 10 (b) using Equation (12), $k_1 = 0.0076 \pm 0.0010$ s^{-1} and $k_6K_5 = 0.0158 \pm 0.001$ M^{-1} s^{-1}. It follows that the experimental data reported in Figure 9 is well described by the mechanism outlined in the reactions represented by Equations (1), (2), (9), and (10).



(a)



(b)

Figure 10. Fit of the kinetic data reported for the reaction of $[Co(Me_6tren)(H_2O)]^{2+}$ with 2-MeImH in Figure 9; (a) for data at [2-MeImH] < 0.3 M; (b) for data at [2-MeImH] from 0.5 to 1.6 M

Overall Comparison of Kinetic Data

According to the kinetic data for the substitution reaction of $[Co(Me_6tren)(H_2O)^{2+}]$ with pyridine and 4-methylpyridine, the reactions proceed according to a dissociative mechanism, which is controlled by the release of H_2O, i.e. k_1. The limiting rate constants reached at high nucleophile concentrations represent k_1 and are indeed close for the two ligands studied (0.0076 s^{-1} for pyridine as compared with 0.0066 s^{-1} for 4-methylpyridine). On increasing the nucleophilicity, the substitution reaction with imidazole shows an associative character, and a second imidazole ligand can enter the coordination sphere at high ligand concentration.

The steric hindrance associated with 2-methylimidazole prevents an associative reaction at low ligand concentration, and evidence for a dissociative reaction is observed. On increasing the ligand concentration further, a concentration range is reached where an associative process contributes to the overall reaction sequence. Again it can be seen that the limiting (minimum) value reached is that for k_1

(viz. 0.008 s^{-1}), which is close to that found for pyridine and 4-methylpyridine, and is consistent with the same rate-determining step.

For the substitution reaction with imidazole, k_3 (viz. 0.27 M^{-1} s^{-1}) is larger than k_4 (viz. 0.17 M^{-1} s^{-1}), which is in agreement with the difficulty of the second imidazole molecule in entering the coordination sphere. By way of comparison, the second-order rate constant for the reaction with 2-methylimidazole, viz. $k_6K_5 = 0.014$ M^{-1} s^{-1}, is significantly smaller presumably due to steric reasons.

Within the context of a limiting dissociative mechanism, the entering nucleophile must compete with the solvent for the intermediate [Co(Me_6tren)] species, as expressed by the ratio k_2/k_{-1}. This ratio increases from pyridine (18 M^{-1}), to 4-methylpyridine (24 M^{-1}), to 2-methylimidazole (60 M^{-1}), which follows the order of the increase in nucleophilicity of the ligands.

For the aquation of the substituted complex, it can be seen that k_{-2} for pyridine (viz. 0.09 s^{-1}) is similar to that for 4-methylpyridine (viz. 0.08 s^{-1}), and both are larger than the corresponding data (k_{-3}) for imidazole (viz. 0.031 s^{-1}), which is again consistent with the order of nucleophilicity of the ligands. These values are all smaller than that for 2-methylimidazole (viz. 0.18 s^{-1}), which can be ascribed to the steric hindrance associated with the 2-methylimidazole ligand which will accelerate the aquation of the complex.

For the complex-formation constants K, there is a small difference between the thermodynamically and kinetically determined values. For the ligands pyridine, 4-methylpyridine and imidazole, K_{td} is 1.0, 1.8, and 7.4 M^{-1}, respectively, whereas K_{kin} for these ligands is 1.5, 2.1, and 8.7 M^{-1}, respectively. It can be seen that the values of K from the thermodynamic analysis are slightly smaller than those from the kinetic treatment, but are in good agreement considering the error limits involved.

Conclusions

The results of this study have demonstrated how the nature and mechanism of ligand substitution reactions of [Co(Me_6tren)(H_2O)]$^{2+}$ can be controlled in a rather sensitive manner by the nature, concentration, and nucleophilicity of the entering ligand. We are presently in the process of extending this study systematically to the substitution behaviour of the sterically less hindered and more oxygen-sensitive [Co(Me_3tren)(H_2O)]$^{2+}$ and [Co(tren)(H_2O)]$^{2+}$ complexes. Finally, we plan to investigate the activation of dioxygen by both complexes in more detail.

Experimental Section

Materials: The compounds used were of commercially available reagent quality (Acros), except for the preparation reported below. Ultra pure water was used for the preparation of the aqueous solutions. *WARNING: Perchlorate salts are potentially explosive; they should be handled in small amounts and with caution!* − The ligand Me_6tren was prepared according to a literature method and characterised by ^{13}C and ^1H NMR spectroscopy.[13] The spectra were in agreement with those reported in the literature.[13] [Co(Me_6tren)]-(ClO_4)$_2$ was prepared according to the literature and characterised by elemental analysis and spectral data.[14] Solutions of the complex for the thermodynamic and kinetic studies were prepared by dissolving the solid product in the buffer (0.05 M Tris and pH ≈ 7.9) [I = 1.0 M for reactions with pyridine, 4-methylpyridine and 2-methylimidazole; and I = 0.2 M for imidazole ($NaClO_4$)], adding 50% excess of the Me_6tren chelate to stabilise the complex, and adjusting the final pH of the solution with 1.0 M $HClO_4$ to 7.92 ± 0.02.

Physical Measurements: Conductance measurements were made with a HANNA instrument HI1281 at room temperature. − Electronic spectra were measured with a Shimadzu 240 spectrophotometer. − IR spectra were recorded with an ATJ Mattson FT-IR 60 AR spectrophotometer in KBr pellets in the 4000−400 cm^{-1} range. − ESR spectra were recorded with a Bruker DXP 300 AVANCE spectrometer.

Characterisation of [Co(L)$_4$(H_2O)$_2$](ClO_4)$_2$ (L = 4-MePy) and [Co(L)$_6$](ClO_4)$_2$ (L = ImH): In the study of the complex-formation reactions in the presence of a large excess of entering nucleophile, precipitates were formed during the reaction of [Co(Me_6tren)(H_2O)]$^{2+}$ with 4-methylpyridine and imidazole. These were isolated and characterised.

[Co(4-MePy)$_4$(H_2O)$_2$](ClO_4)$_2$: $C_{24}H_{32}Cl_2CoN_4O_{10}$ (666.4): calcd. Methods

Thermodynamic Studies: Spectral and thermodynamic measurements were carried out at 25.0 ± 0.1 °C in 0.05 M Tris buffer and 1.0 M $NaClO_4$ for pyridine and 4-methylpyridine, and 0.2 M $NaClO_4$ for imidazole. UV/Vis spectra were recorded with a Varian Cary 5 spectrophotometer using a 1-cm quartz cuvette. The pH of the solutions was measured by employing a Mettler Delta pH meter with a Mettler Toledo Inlab 412 combined glass electrode. The electrode calibration for the H^+ concentration was such that pH is defined as −log[H^+]. All test solutions were kept under nitrogen. Details on the experimental method and treatment of the data have been reported before.[20,21]

Kinetic Studies: An Applied Photophysics, Model SX 18MV, stopped-flow spectrophotometer with an observation path length

of 1.0 cm was used to monitor the kinetics of the substitution reaction of $[Co(Me_6tren)](ClO_4)_2$ with organic bases at ambient pressure. In each case the pH values of the complex and ligand solutions were adjusted to 7.92 ± 0.02 using 0.05 M Tris and $HClO_4$. The ionic strength was kept constant at 1.0 M ($NaClO_4$) for the reactions with pyridine, 4-methylpyridine, and 2-methylimidazole, and at 0.2 M for the reaction with imidazole. Temperature control was achieved by circulation of a thermostated fluid (25.0 ± 0.1 °C). The substitution kinetics were monitored at 470 nm, and kinetic traces as a function of concentration and temperature were recorded with an online computer and subsequently processed to yield kinetic parameters using the OLIS KINFIT program (Bogart, GA). A minimum of at least five kinetic traces were recorded for each set of experimental conditions. The kinetic traces fitted well to a single exponential function. − Kinetic measurements at elevated pressure for the substitution reactions of $[Co(Me_6tren)(H_2O)]^{2+}$ with imidazole and 4-methylpyridine were performed with a home-built stopped-flow unit which can be immersed in a high-pressure chamber.[22] For the reaction with imidazole, the solutions were identical to those used in the ambient pressure experiments and the monitoring wavelength was 470 nm. The temperature was controlled by circulation of a thermostated fluid at 25.0 ± 0.1 °C. For the reaction with 4-methylpyridine, the ionic strength of the solutions was reduced to almost zero and the temperature was increased to 45.0 ± 0.1 °C in order to prevent turbidity problems encountered during the mixing of concentrated solutions. The kinetic data was also checked under ambient conditions at low ionic strength, in order to justify the selected conditions.

Synthesis, Characterisation and Electrochemical Behaviour of Rhodium(III) Complexes Containing 1,2-Naphthoquinone-2-oxime and Formation of Imine Complexes through N−O Bond Cleavage

Xiao-Xia Liu[a] and Wing-Tak Wong*[a]

Keywords: Rhodium / N ligands / Electrochemistry

The new rhodium(III) complexes [Rh(η^2-nqo)L_2Cl_2] **(1a–1d)** and [Rh(η^2-nqo)$_2$LCl] **(2b–2d)** [**1a**, L = PPh_3; **1b,2b**, L = pyridine (py); **1c,2c**, L = 4-phenylpyridine (ppy); **1d,2d**, L = 4-acetylpyridine (apy)] have been prepared by treatment of the reaction mixture of $RhCl_3 \cdot 3H_2O$ and 1,2-naphthoquinone-2-oxime (nqo) in ethanol by P or N donor ligands. Cyclic voltammetric studies show that the new complexes display an irreversible metal-localised two-electron reduction from Rh^{III} to Rh^{I}, accompanied by the loss of the chloride ligands. The 1,2-naphthoquinone-2-imine (nqi) complexes [Rh(η^2-nqo)(η^2-nqi)Cl_2]·L **(3b–3d)** (**3b**, L = py; **3c**, L = ppy; **3d**, L = apy), [Rh(η^2-nqo)(η^2-nqi)Cl_2] **(4)** and [Rh(η^2-nqo)$_2$(nqi)Cl] **(5)** were obtained by deoxygenation of the oxime group in which N–O bond cleavage is observed. The molecular structures of **1a**, **2b**, **4** and **5** were established by single crystal X-ray analyses.

Introduction

Rhodium(III) complexes containing chloride ligands have attracted much attention. They have been shown to be active in processes such as the photochemical[1] and the electrochemical[2−5] reduction of protons or water to dihydrogen, the electrocatalytic hydrogenation of organics,[2−4] and the electrochemical regeneration of NADH from NAD^+.[6,7] Most of the complexes mentioned above contain 2,2-bipyridine type ligands. 1,2-Naphthoquinone-monooximes are another kind of donor ligand with a π-accepting ability.[8,9] In ruthenium 1,2-naphthoquinone-1-oxime complexes, the MLCT from ruthenium(II) to the ligand occurs with comparatively low energy.[10] The existence and the number of this ligand in 2,2-bipyridine-containing ruthenium complexes influence the electrochemical property of the metal centre.[11] Metal complexes containing 1,2-naphthoquinone-monooximes are of interest as they are widely used for analytical purposes[12,13] and are potentially useful for the preparation of a wide variety of organic compounds.[14−17] However, most of the studies have been concerned with first-row transition metals.[14−20] Reports dealing with these ligands involving complexes of second-row transition metals are very limited.[9,11,21,22] As a continuation of our studies on 1,2-naphthoquinone-monooxime complexes of second row transition metals,[10,23−25] we herein present the formation of a series of chloro rhodium(III) complexes containing 1,2-naphthoquinone-2-oxime (abbreviated as nqoH).

Results and Discussion

Synthesis and Characterisation of Rhodium(III) Complexes [Rh(η^2-nqo)L_2Cl_2] (1a−1d) and [Rh(η^2-nqo)$_2$LCl] (2b−2d)

The new rhodium(III) complexes [Rh(η^2-nqo)L_2Cl_2] **(1a−1d)** and [Rh(η^2-nqo)$_2$LCl] **(2b−2d)** [**1a**, L = PPh_3; **1b,2b**, L = pyridine (py); **1c,2c**, L = 4-phenylpyridine (ppy); **1d,2d**, L = 4-acetylpyridine (apy)] were synthesised by the treatment of a reaction mixture of $RhCl_3 \cdot 3H_2O$ and 1,2-naphthoquinone-2-oxime in refluxing ethanol with PPh_3, pyridine, 4-phenylpyridine or 4-acetylpyridine (Scheme 1). Characterisation of the new complexes by spectroscopic methods (^{1}H NMR, FAB MS) reveals that **1a−1d** contain one nqo and two P or N donor ligands coordinated to the metal centre (Table 1). In order to establish the molecular structure of complex **1a**, a single-crystal X-ray diffraction analysis was carried out. The molecular structure of **1a** is depicted in Figure 1, while bond lengths and angles are available in the Supporting Information. The molecule of **1a** contains a pseudo octahedrally coordinated rhodium centre. The nqo ligand coordinates to the metal centre through its oximato N and naphthoquinonic O atoms to form a five-membered metallocyclic ring [O(1)−Rh−N(1) 81.3(2)°]. This coordination mode is very common for 1,2-naphthoquinone-monooxime ligands.[9,10,16,19−25] The molecule also contains two chloride atoms [Cl(1) and Cl(2)], which are *trans* to the oximato N and naphthoquinonic O atoms, respectively ([N(1)−Rh−Cl(1) 170.8(1)°], [O(1)−Rh−Cl(2) 176.5(1)°]), forming an equatorial plane with the nqo ligand. The two phosphane ligands occupy the perpendicular positions to complete the six coordination configuration of the Rh metal centre ([P(1)−Rh−P(2) 178.32(5)°]). The mean Rh−P distance is 2.3945(1)Å, which is similar to other Rh complexes with phosphane coordinated to their metal centre, such as in [Rh(Hdmg)(bdio)(PEt_3)]$^+$[Rh(Hdmg)$_2Cl_2$]$^-$·H_2O (dmg = dimethylglyoximato; bdio = 2,3-butanedione 2-imino 3-oxi-

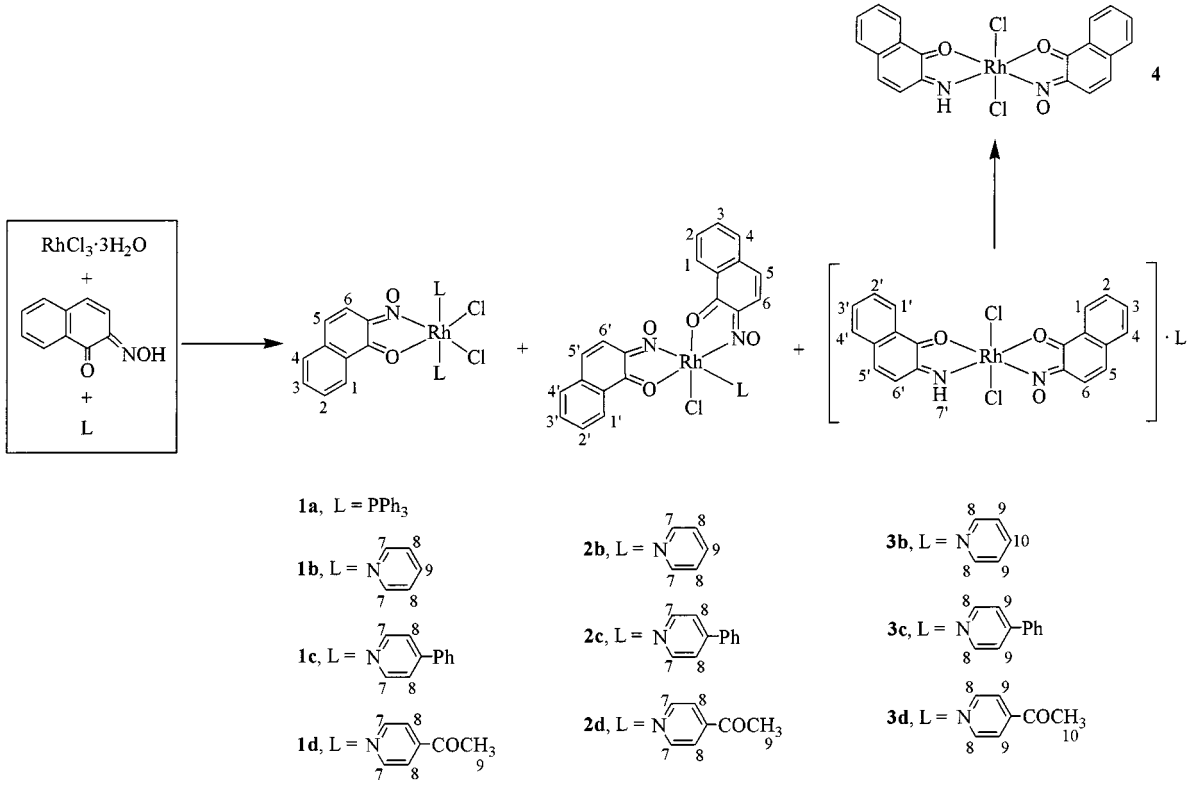

Scheme 1. Reaction of $RhCl_3 \cdot 3H_2O$ with nqoH followed by treatment with the pyridyl ligand

mato), where the corresponding bond length is 2.3817(8)Å.[26] In the ^{1}H NMR spectra of the pyridine complexes **1b**−**1d**, the chemical shifts of the nqo proton signals are very similar to those in **1a**, showing that the nqo ligands have very similar chemical environments. Thus, complexes **1b**−**1d** are proposed to have similar molecular structures to **1a**, with the bidentate nqo ligand and the two chloride atoms occupying the equatorial plane, and the two pyridyl ligands occupying the perpendicular sites.

Characterisation of complexes **2b**−**2d** by spectroscopic methods (Table 1) reveals that they contain two nqo ligands, one pyridyl ligand and one chloride atom. A single crystal X-ray analysis was conducted on **2b**. The molecular structure of [Rh(η^2-nqo)$_2$(py)Cl] **(2b)** is depicted in Figure 2, while the bond parameters can be obtained from the Supporting Information. A distorted octahedral coordination of the rhodium metal centre is observed. The nqo ligands chelate to the metal centre in a similar way as in **1a** [O(1)−Rh−N(1) = 81.3(2)° and O(3)−Rh−N(2) 81.8(2)°]. The oximato N and the naphthoquinonic O atoms adopt a mutually *cis* geometry as in the ruthenium 1,2-naphthoquinone-2-oxime complexes *cis*,*cis*-[Ru(η^2-nqo)$_2$L$_1$L$_2$] (L$_1$, L$_2$ = CO or pyridyl ligands).[10,24] Pyridine is coordinated to the Rh centre through its N atom and is *trans* to the oximato N of an nqo ligand, as in *cis*,*cis*-[Ru(η^2-nqo)$_2$(CO)L] (L = pyridyl ligands).[10,24] The chloride atom is *trans* to the naphthoquinonic O atom of another nqo ligand, with a Rh−Cl bond length of 2.332(2)Å. This is consistent with the Rh−Cl distance in other rhodium complexes such as [Rh(Hdmg)(bdio)(PEt$_3$)]$^+$[Rh(Hdmg)$_2$Cl$_2$]$^-\cdot$H$_2$O [2.3320(9) Å].[26] The nqo ligands of **2b**−**2d** exist in a similar chemical environment, since they display very similar chemical shifts in their ^{1}H NMR spectra. The spatial arrangement of the ligands in complexes **2b**−**2d** should be the same. The asymmetry of the nqo ligands gives rise to the possibility for the presence of structural isomers other than **2b**−**2d**; in fact, we observe some other minor bands in the reaction mixture from TLC. Unfortunately, we could not isolate or characterise these compounds.

Electrochemistry of Complexes 1a−1d and 2b−2d

Cyclic voltammetry of complexes **1a**−**1d** and **2b**−**2d** was performed at a standard scan rate of 100 mV s^{-1} in CH_2Cl_2/0.1 M tetrabutylammonium hexafluorophosphate (TBAH). The redox potentials are listed in Table 2 and the representative cyclic voltammogram of **1a** is shown in Figure 3.

The electrochemical behaviour of [Rh(η^2-nqo)(PPh$_3$)$_2$Cl$_2$] **(1a)** resembles that of other chloro rhodium(III) complexes with 2,2′-bipyridyl ligands, such as [RhL(P)$_2$(Cl)$_2$]$^+$ [2,27] and [RhL$_2$(Cl)$_2$]$^+$,[3,28,29] and some complexes containing π-coordinated ligands [Rh(C$_5$Me$_5$)LCl]$^+$ (P = PPh$_2$Et or PPh$_3$; L = 2,2-bipyridyl ligands).[1,4−6,30−32] This behaviour is characterised by an irreversible, metal-localised two-electron reduction at peak potential E_{c1}, which is associated with the loss of the two chloride ligands (EC mechanism) yielding the Rh^I complex [Scheme 2, Equation (1)]. A controlled-potential electrolysis at a potential slightly negative to this wave, consumes two electrons per molecule of com-

plex and leads to a purple-coloured solution. We failed to isolate the purple product as it was not stable enough under our experimental conditions. The colour of the solution slowly changed to red on removing the applied potential. The reverse process, the reoxidation of the Rh^I complex, is also a two-electron step (E_{a1}), with subsequent completion of the coordination sphere of the d^6 metal centre by addition of the chloride ligands [Equation (2)].

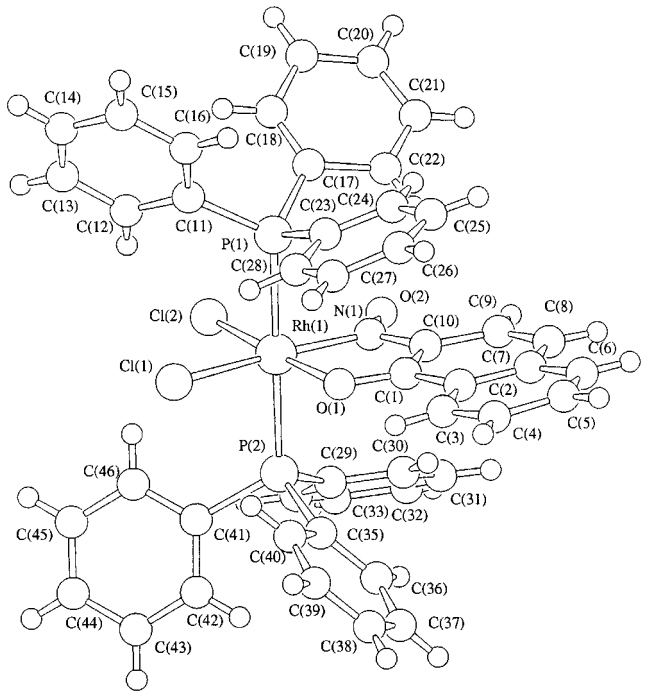

Figure 1. The molecular structure of $[Rh(\eta^2\text{-nqo})(PPh_3)_2Cl_2]$ **(1a)** with the atom numbering scheme

The Rh^I complex can be further reduced at a more negative potential with an apparently reversible (E_{c2}, E_{a2}) single-electron step. The 2,2-bipyridyl complexes displayed similar reversible redox couples, which have been attributed to the reduction of the pyridyl ligand, leading to the coordinated radical anion $L^{\cdot -}$. Lund reported the cyclic voltammetric study of fluorenone oxime (F1=NOH), which displayed a nearly reversible reduction at −1.67 V vs. SCE to its radical anion $F1{=}NOH^{\cdot -}$.[33] The reduction of the oxime group in a copper(II) complex $[Cu(H_2L)(H_2O)_2]Cl_2$ [L is a tripodal ligand containing an oxime group, such as *N*,*N*-(2-hydroxyacetophenyl)-(3-butane-2-oxime)-*N*′-(2-hydroxyacetophenyl)-1,2-diaminoethane] appeared around −1.5 V vs. SCE.[34] Similarly, the one-electron reduction of our nqo complex **1a** is oximato-ligand centred [Equation (3)] and leads to the radical anion. Compared with the free ligand (Table 2), the coordinated nqo is more difficult to reduce due to the π back-donation from the metal centre to the ligand.[30,35] This reduction process for complexes **1b**−**1d** appears at a more negative potential than that of **1a**. As the phosphane is a π-acceptor ligand, the degree of metal-to-nqo-ligand electron shift is smaller in **1a** than in **1b**−**1d**. This ligand-based reduction in complexes **1b**−**1d** is irreversible, and the reoxidation peak of Rh^I to Rh^{III} is not detected. In complexes **2b**−**2d**, apart from the irreversible metal-centred processes, two *quasi*-reversible one-electron reductions of the nqo ligands (E_{c2} for one nqo and E_{c3} for another) at less-negative potentials are observed. Since there are two nqo ligands in each of the **2b**−**2d** complexes,

the π back-donation from the metal centre to each nqo ligand will be less than that in complexes **1b**−**1d** with only one nqo ligand present.

Formation of 1,2-Naphthoquinone-2-imine Complexes

The orange-red complexes **3b**−**3d** are also afforded in the reactions with pyridyl ligands (Scheme 1). Their ^1H NMR spectra show the signals for the naphthalene ring and pyridyl protons with an integration ratio of 2:1, and also a broad peak near δ = 11.4, assigned to the NH proton, which disappears after D_2O exchange. In the $^1H,^1H$ COSY spectra of **3c** and **3d**, this peak is coupled with proton $H^{6'}$ of the nqo-derived ring. It can be assigned to the proton on the imino N atom. Slow evaporation of a $CHCl_3$ solution of complexes **3b**−**3d** gave a red crystalline product **4**. An X-ray diffraction analysis was carried out on a single crystal to elucidate the molecular structure. The molecular structure of **4** is shown in Figure 4, and the corresponding bond parameters are available from the supplementary material. The molecule contains two chloride atoms, one nqo ligand and one oximato deoxygenated nqo ligand. There is no pyridyl ligand. The central metal atom also adopts a distorted octahedral coordination mode, as in **1a** and **2b**. The two chloride atoms are *trans* to each other [Cl(1)−Rh−Cl(2) = 178.5(2)°] and the two naphthalene-derived rings occupy the equatorial plane. The nqo and the nqo-derived ligands adopt a chelate mode to the metal centre. The C−O bond length O(3)−C(11) in the nqo-derived ligand is 1.24(2)Å, which is comparable with the corresponding bond length for the quinonic group [C−O = 1.247(5)Å] in 3-hydroxy-2-methyl-1,4-benzoquinone 4-oxime,[36] and is smaller than the corresponding one [O(1)−C(1) = 1.32(1)Å] for the nqo ligand in the same molecule. The C−N bond length ([N(2)−C(20) = 1.27(1) Å]) is of a similar length to the imino C−N bond length [1.294(5)Å] in $[Rh(Hdmg)(bdio)(PEt_3)_2]^+[Rh(Hdmg)_2Cl_2]^-\cdot H_2O$[26] and also to that in $[TcCl(dmg)_2(bdio)BEt]$ [av. C−N = 1.29(1)Å].[37] This bond length is shorter than the corresponding one [N(1)−C(10) = 1.43(2)Å] for the nqo ligand, similar to the situation for the naphthoquinonic group. Complex **4** can be obtained from all three orange-red complexes **3b**−**3d** (based on X-ray single crystal analyses and FAB MS data) under very mild conditions (prolonged standing in $CHCl_3$ solution at room temperature for one day or at −20 °C for a few days). In addition, the pyridyl ligands in **3b**−**3d** can be exchanged with one another, provided that an excess of the pyridyl ligand of the desired complex is added (see below). We suggest that **3b**−**3d** are formed through interaction of the pyridyl ligands with part of a surrounding ligand in **4**. The nqo ligand is believed to undergo N−O bond cleavage of the oximato moiety to give the 1,2-naphthoquinone-2-imino (nqi) ligand, and complex **4** can be formulated as $[Rh(\eta^2\text{-nqo})(\eta^2\text{-nqi})Cl_2]$. Unfortunately, due to the extremely low solubility of **4** in common solvents, we failed to get satisfactory ^1H NMR spectroscopic data. The MS data of **3b**−**3d** conform to the stoichiometry of a molecule containing two chloride atoms, one nqo ligand, one nqi ligand and a pyridine or derived ligand. These complexes can be formulated as $[Rh(\eta^2\text{-nqo})(\eta^2\text{-nqi})Cl_2]\cdot L$ (**3b**, L = py; **3c**, L = ppy; **3d**, L = apy).

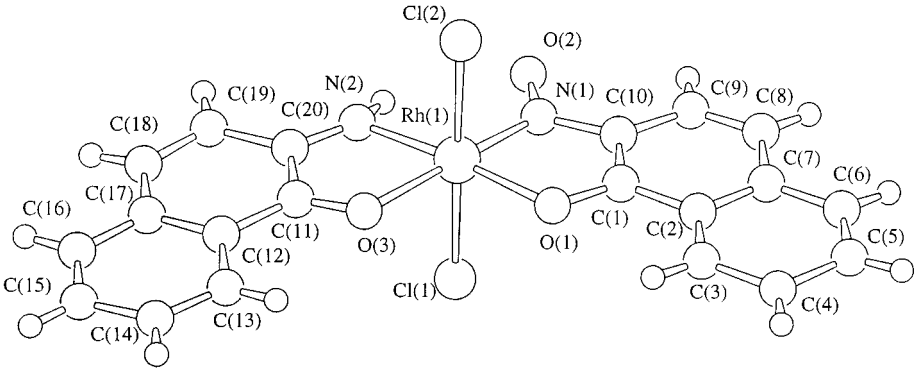

Figure 4. The molecular structure of $[Rh(\eta^2\text{-nqo})(\eta^2\text{-nqi})Cl_2]$ **(4)** with the atom numbering scheme

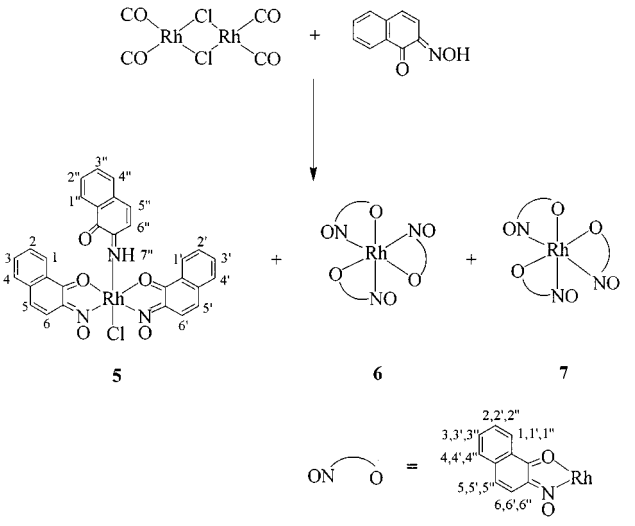
Conversion Among 3b−3d Through Pyridyl Ligand Exchange

Pyridyl ligand exchange of **3d** by a tenfold excess of pyridine or 4-phenylpyridine at 30 °C was conducted in $CDCl_3$. The reaction mixture was continuously monitored by ^1H NMR spectroscopy and a change in the spectrum observed after 1 h. The proton resonances due to **3d** gradually decrease, accompanied by an increase in the intensities of other proton signals. The proton resonances of **3d** completely disappear after one day. A single product **3b** or **3c** is formed in the two reaction mixtures. The identity of **3b** and **3c** are confirmed by both ^1H NMR spectroscopy and their chromatographic properties. Pyridyl ligand exchange of **3b** by a tenfold excess of 4-acetylpyridine similarly gives **3d** after one day at 30 °C. No crystals of **4** are obtained in these reaction mixtures, even when they stand at room temperature for a long time. This ligand-exchange reaction rate is found to be sensitive to the amount of pyridyl ligand added. A substantial increase in the amount of ligand added results in a faster ligand exchange. This result, along with the isolation of **4** from the $CHCl_3$ solution of **3b−3d**, supports the hypothesis that **3b−3d** are adducts of **4** and the corresponding pyridyl ligand through comparatively loose interaction.

Other Routes for N−O Bond Cleavage of the Oxime Group in 1,2-Naphthoquinone-2-oxime and the Formation of Tris(1,2-naphthoquinone-2-oximato)rhodium(III) Complexes

A low yield (10%) of the N−O bond cleavage product $[Rh(\eta^2\text{-nqo})_2(nqi)Cl]$ **(5)** was obtained from the reaction of nqoH with $[Rh^I(\mu\text{-Cl})(CO)_2]_2$ in benzene. The reaction also affords the tris(1,2-naphthoquinone-2-oximato)-rhodium(III) complexes, *fac*-$[Rh(\eta^2\text{-nqo})_3]$ **(6)** in a 40% yield and *mer*-$[Rh(\eta^2\text{-nqo})_3]$ **(7)** in a 10% yield (Scheme 3). The molecular structure of complex **5** was confirmed by X-ray single crystal analysis. The structure of **5** is shown in Figure 5, while the bond parameters are available from the Supporting Information. The central metal atom adopts an essentially octahedral geometry with three naphthalene-derived rings and one chloride atom. Two of the naphthalene rings are nqo ligands, which occupy the equatorial plane and chelate to the Rh centre in a similar way to other nqoH complexes[10,20,24] including **1a**, **2b** and **4**. The oximato groups, as well as the naphthoquinonic O atoms, adopt a *cis* geometry relative to each other. This differs from our previously determined ruthenium complex *trans,trans*-$[Ru\{\eta^2\text{-(1-nqo)}\}_2(PBu_3)_2]$ (1-nqo = 1,2-naphthoquinone-1-oximato), where both of the oximato N and the naphthoquinonic O atoms in the two equatorial 1-nqo ligands adopt a mutual *trans* geometry.[10] One of the perpendicular positions in **5** is occupied by a chloride atom and the other by an imino N atom of the 1,2-naphthoquinone-2-imino ligand, obtained through the deoxygenation of the oxime group in 1,2-naphthoquinone-2-oxime. The naphthoquinonic O atom of nqi is left pendant with a C−O bond length of 1.26(2)Å, which is comparable with the corresponding ones in complex **4** [1.24(2)Å] and 3-hydroxy-2-



Scheme 3. Reaction of $[Rh^I(\mu\text{-Cl})(CO)_2]_2$ and nqoH

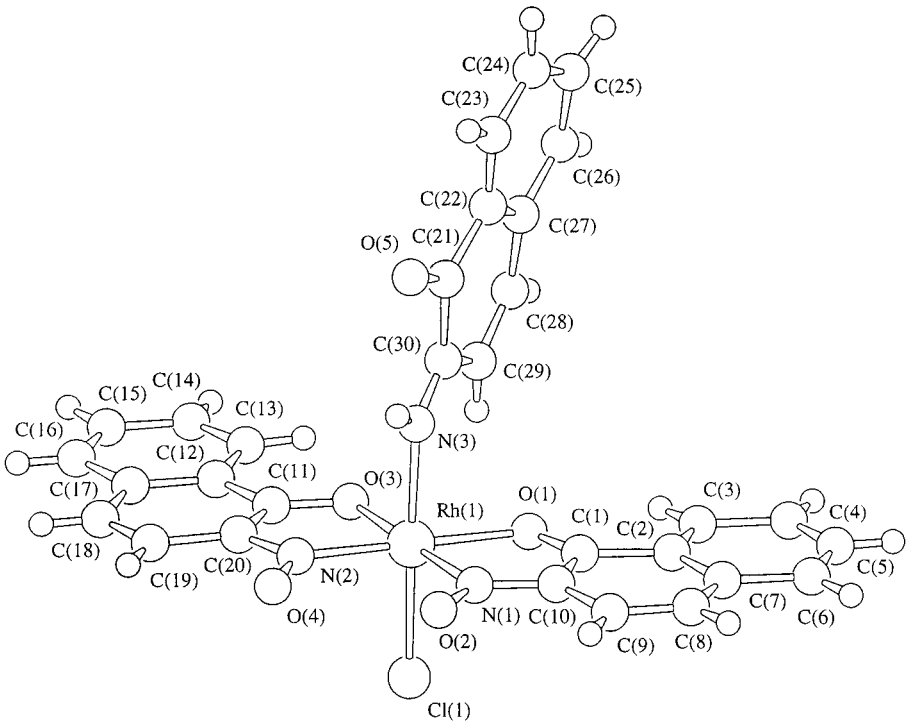


Figure 5. The molecular structure of $[Rh(\eta^2\text{-nqo})_2(nqi)Cl]$ **(5)** with the atom numbering scheme

methyl-1,4-benzoquinone-4-oxime [1.247(5)Å].[36] The C−N bond length of the nqi ligand is [N(3)−C(30) = 1.26(2)Å], which is in good agreement with that in the imino group [N(2)−C(20) = 1.27(1)Å] in **4**. The proton of the NH group appears as a broad peak at δ = 10.30 in the ^{1}H NMR spectrum (Table 1) and also disappears after D_2O exchange.

Previously, there were two other reports on the reduction of the oxime group to imine in rhodium complexes.[26,38] In both cases, $NaBH_4$ was used as the reducing agent. $[Rh^{III}(Hdmg)(H_2dmg)Cl_2]$[26] was first reduced to the Rh^I complex and, upon addition of phosphanes of small size and good donor ability, Rh^I was reoxidised to Rh^{III}, accompanied by the reduction of one of the equatorial oxime groups to imine. We have demonstrated a ruthenium carbonyl-induced deoxygenation of 1,2-naphthoquinone-1-oxime, leading to a coordinated 1,2-naphthoquinone-1-imine intermediate.[23] The ruthenium cluster with naphthoquinone-imino ligands was obtained in low yield through the following coupling reaction. The formation of 1,2-naphthoquinone-2-imine in complex **5** may be caused by the reduction of the oxime group by Rh^I to imine, which is stabilised towards hydrolysis by coordination to the Rh^{III} metal centre. However, in the reaction with $RhCl_3{\cdot}3H_2O$ as the starting material and in the presence of pyridine-type ligands, we have no reducing agent in the system. There are some other reports on the metal-induced deoxygenation of 1,2-naphthoquinone-mono-oxime,[14−18] however, they are all concerned with first-row transition metals. Treatment of the 1,2-naphthoquinone-2-oxime copper(II) complex with PPh_3 gave 2-amino-N^4-(1-hydroxy-2-naphthyl)-1,4-naphthoquinone 4-imine,[16] while 2-amino-1,4-naphthoquinone 4-*N*-phenylimine was obtained on treatment with aniline.[17] Both indicated the formation of nitrene/quinone imine intermediates obtained through the deoxygenation of the oximato group of the ligand. Direct evidence for the imine formation was given by the imine complexes $[Fe(qo{-}A)_2]$ (where qo−A = 4-phenylamino-1,2-naphthoquinone-mono-imine) obtained through the interaction of pentacarbonyl iron(0) with 1,2-naphthoquinone-mono-oxime in the presence of aniline.[18] The reaction between $[Cu\{\eta^2\text{-(1-nqo)}\}_2]$ and aniline gave an imine complex, bis(4-phenylimino-1,2-naphthoquinone-1-imino)bis(aniline)copper(II).[17] The mechanism for the formation of the nqi ligand in **3b**−**3d** and **4** is not certain at this point; however, we believe it occurs as a result of the modification of the coordinated nqo ligand as in the Cu^{II} analogue.[17]

The molecular formulae of **6** and **7**, as established by electrospray ionisation (ESI) mass spectrometry, are consistent with the calculated experimental isotopic patterns for $C_{30}H_{18}N_3O_6Rh$, and reveal their isomeric nature. The isomerism of **6** and **7** was confirmed by ^{1}H NMR spectroscopy in $CDCl_3$. Complex **6** gives rise to the same ^{1}H NMR signals for the three ligands showing that it has a highly symmetrical *fac* geometry as in a very recently structurally characterised ruthenium 1-nqo analogue $[Ru\{\eta^2\text{-(1-nqo)}\}_3]^-$, in which only one set of 1-nqo signals is present for the three ligands.[22] A nickel complex anion $[Ni(4\text{-Clqo})_3]^-$ (4-Clqo = 4-chloro-1,2-benzoquninone-2-oximato)[39] and a naturally occurring pigment ferroverdin[40] *fac*-$[Fe^{II}\{4\text{-}[p\text{-}(CH_2{=}CH)C_6H_4OC(=O)]\text{-1,2-benzoquninone-2-oximato}\}_3]^-$ are other examples of *fac* geometry based on X-ray evidence. Although without X-ray analysis, the geometry of $[Fe^{II}(RQ)_3]^-$ (RQ = 4-R-1,2-benzoquninone-2-ox-

imato, R = Me, *t*Bu, Cl, Br[41] and 3,4-benzo[42]) were also deduced to be *fac*, since the three ligands in the molecule are equivalent (shown by ^{1}H NMR spectroscopy). The three naphthalene rings of complex **7** give rise to different ^{1}H NMR signals, although some of them merge together to give intensified peaks. Thus, complex **7** is proposed to have *mer* geometry as in $[Mn^{III}L_3]$ (L = 4-chloro-1,2-benzoquinone-2-oximato)[43] and $[Ni^{III}(RQ)_3]$ (RQ = 4-R-1,2-benzoquninone-2-oximato, R = Me, *t*Bu and Cl).[44] However, when $[Mn^{III}L_3]$ is electrochemically reduced to anionic $[Mn^{II}L_3]^-$, it exists as a mixture of *fac* and *mer* isomers, both in solution (by ^{1}H NMR spectroscopy) and in the solid state (by X-ray analysis).[43] It was suggested that the favourable *mer* geometry for neutral complexes is partially due to a steric factor, the pendant oximato oxygen atoms are further apart than in the *fac* form. The origin of the *fac* form could be the effect of electrostatic stabilisation.[44] Nevertheless, the complexes are neutral in our system, the *fac* isomer is very favourable and there is no isomerisation observed after separation. This *fac* geometry is also favoured in the tris(arylazooximato)rhodium(III) complexes,[45] whereas the cobalt(III) analogues[46] exist exclusively in the *mer* form. This was explained by an increase in the facial area in going from the Co^{III} to the Rh^{III} chelate.[45]

Experimental Section

All manipulations were carried out under nitrogen with standard Schlenk techniques. Chemicals were purchased from commercial sources and used as received. Preparative thin-layer chromatographic (TLC) plates were prepared from silica (Merck Kieselgel 60 GF_{254}). – ^{1}H NMR spectra were obtained on a Bruker DPX-300 spectrometer using deuterated chloroform as the lock and reference. – Fast atom bombardment (FAB) mass spectra were recorded on a Finnigan MAT 95 mass spectrometer. Electrospray ionisation quadropole ion trap mass spectra were obtained on a Finnigan LCQ™ LC/MS^n system. – Electrochemical measurements were conducted on a PAR 273A potentiostat in CH_2Cl_2 containing 0.1 mol dm^{-3} *n*-tetrabutylammonium hexafluorophosphate (TBAH), using a conventional argon gas sealed three-electrode cell. The working electrode was a glassy carbon disc for cyclic voltammetry and a carbon plate for large-scale electrolysis. Potentials are reported vs. ferrocene internal standard ($Fc^{0/+}$).

Synthesis of $[Rh(\eta^2\text{-nqo})(PPh_3)_2Cl_2]$ (1a): Solid samples of $RhCl_3{\cdot}3H_2O$ (53 mg, 0.2 mmol) and 1,2-naphthoquinone-2-oxime (69 mg, 0.4 mmol) were dissolved in 100 mL ethanol and refluxed for 2 h. PPh_3 (105 mg, 0.4 mmol) in hot ethanol was then added and the solution refluxed for another 10 h. The solvent was then removed and the residue chromatographed by TLC, with a solvent mixture of *n*-hexane/CH_2Cl_2 (1:4, v/v) as the eluent to afford the complex $[Rh(\eta^2\text{-nqo})(PPh_3)_2Cl_2]$ (**1a**; 80%, 139 mg). Red crystals of **1a** were grown by slow evaporation of an *n*-hexane/$CHCl_3$ solution at room temperature. $C_{46}H_{36}Cl_2NO_2P_2Rh$ (870.56): calcd. C 63.5, H 4.2, N 1.6; found C 63.2, H 4.5, N 1.5.).

Synthesis of $[Rh(\eta^2\text{-nqo})L_2Cl_2]$ (1b–1d), $[Rh(\eta^2\text{-nqo})_2LCl]$ (2b–2d), $[Rh(\eta^2\text{-nqo})(\eta^2\text{-nqi})Cl_2]{\cdot}L$ (3b–3d) and the Formation of $[Rh(\eta^2\text{-nqo})(\eta^2\text{-nqi})Cl_2]$ (4): A procedure analogous to the above was followed, adding pyridine (py), 4-phenylpyridine (ppy) or 4-acetylpyridine (apy), respectively, instead of PPh_3. Upon TLC separation with a solvent mixture of *n*-hexane/CH_2Cl_2 (1:5–1:6, v/v), the complexes $[Rh(\eta^2\text{-nqo})L_2Cl_2]$ **(1b–1d)**, $[Rh(\eta^2\text{-nqo})_2LCl]$ **(2b–2d)** and $[Rh(\eta^2\text{-nqo})(\eta^2\text{-nqi})Cl_2]{\cdot}L$ **(3b–3d)** (**1b–3b**, L = py; **1c–3c**, L = ppy; **1d–3d**, L = apy) were isolated. Upon standing in a $CHCl_3$ solution of **3b–3d** at room temperature for one day, red crystals of $[Rh(\eta^2\text{-nqo})(\eta^2\text{-nqi})Cl_2]$ **4** were obtained. Red crystals of **2b** were grown by slow evaporation of *n*-hexane/$CHCl_3$ solution at –20 °C.
1b: $C_{20}H_{16}Cl_2N_3O_2Rh$ (504.1805): calcd. C 47.6, H 3.2, N 8.3; found C 47.8, H 3.1, N 8.1.
1c: $C_{32}H_{24}Cl_2N_3O_2Rh$ (656.3757): calcd. C 58.6, H 3.7, N 6.4; found C 58.3, H 3.9, N 6.3.
1d: $C_{24}H_{20}Cl_2N_3O_4Rh$ (588.2541): calcd. C 49.0, H 3.4, N 7.1; found C 48.7, H 3.2, N 7.3.
2b: $C_{25}H_{17}ClN_3O_4Rh$ (561.7884): calcd. C 53.4, H 3.1, N 7.5; found C 53.5, H 2.9, N 7.2.
2c: $C_{31}H_{21}ClN_3O_4Rh$ (637.8860): calcd. C 58.4, H 3.3, N 6.6; found C 58.7, H 3.4, N 6.4.
2d: $C_{27}H_{19}ClN_3O_5Rh$ (603.8252): calcd. C 53.7, H 3.2, N 7.0; found C, 53.6, H 2.9, N 7.2.
3b: $C_{25}H_{18}Cl_2N_3O_3Rh$ (582.2503): calcd. C 51.6, H 3.1, N 7.2; found C 51.8, H 2.9, N 7.5.
3c: $C_{31}H_{22}Cl_2N_3O_3Rh$ (658.3479): calcd. C 56.6, H 3.4, N 6.4; found C 56.7, H 3.4, N 6.4.
3d: $C_{27}H_{20}Cl_2N_3O_4Rh$ (624.2871): calcd. C 51.9, H 3.2, N 6.7; found C, 51.6, H 2.9, N 7.0.
4: $C_{20}H_{13}Cl_2N_2O_3Rh$ (503.1491): calcd. C 47.7, H 2.6, N 5.6; found C 47.8, H 2.4, H 5.5.

Pyridyl Ligand Exchange of 3d and 3b: Complex **3d** (6 mg, 0.01 mmol) and $CDCl_3$ (1 cm^3) were placed in an oven-dried NMR tube. A tenfold excess of pyridine was added. After warming the tube in a thermostat at 30 °C for 1 h, ^{1}H NMR spectra were recorded at time intervals of 1 h until no **3d** was detected. After 20 h, all **3d** had been converted into **3b** according to the ^{1}H NMR spectroscopic data. The single metal-containing product of **3b** was obtained by TLC separation with a solvent mixture of *n*-hexane/CH_2Cl_2 (1:10, v/v) as the eluent.

The single metal-containing products **3c** and **3d** were obtained by a similar procedure of ligand exchange with **3d** and **3b** and 4-phenylpyridine and 4-acetylpyridine, respectively.

Reaction Between $[Rh^I(\mu\text{-Cl})(CO)_2]_2$ and 1,2-Naphthoquinone-2-oxime: $[Rh^I(\mu\text{-Cl})(CO)_2]_2$ (39 mg, 0.1 mmol) and 1,2-naphthoquinone-2-oxime (104 mg, 0.6 mmol) was dissolved in benzene (50 mL) and stirred at room temperature for 3 h. The solvent was removed from the dark red solution and the residue chromatographed by TLC with *n*-hexane/CH_2Cl_2 (1:5, v/v) as the eluent. Three red products were isolated as $[Rh(\eta^2\text{-nqo})_2(nqi)Cl]$ (**5**; 10%, 13 mg), *fac*-$[Rh(\eta^2\text{-nqo})_3]$ (**6**; 40% yield, 49 mg) and *mer*-$[Rh(\eta^2\text{-nqo})_3]$ (**7**; 10% yield, 12 mg). Single crystals of **5** were grown by slow evaporation of a *n*-hexane/CH_2Cl_2 solution at –20 °C.
5: $C_{30}H_{19}ClN_3O_5Rh$ (639.86): calcd. C 56.3, H 3.0, N 6.6; found C 56.0, H 2.7, N 6.6.
6: $C_{30}H_{18}N_3O_6Rh$ (619.40): calcd. C 58.2, H 2.9, N 6.8; found C 58.0, H 2.6, N 6.8.
7: $C_{30}H_{18}N_3O_6Rh$ (619.40): calcd. C 58.2, H 2.9, N 6.8; found C 58.2, H 3.0, N 7.0.

Crystallography:
Single crystals of **1a**, **2b**, **4** and **5** were obtained as described above. A crystal of **1a** was mounted on a glass fibre by means of epoxy resin, while crystals of **2b**, **4** and **5** were sealed in Lindemann glass capillaries. Crystal intensity data were collected for **1a**, **2b** and **4** on

a Siemens Smart CCD and for **5** on a MAR research image-plate scanner, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) for unit-cell determination and data collection. Intensity data were corrected for Lorentz and polarisation effects. An approximation to absorption correction by inter-image scaling was also applied. Summaries of the crystallographic data, structure solution and refinement are given in Table 3. Scattering factors were taken from part a in ref.[47] and anomalous dispersion effects were included in *Fc* (part b). The structures were solved by direct methods (SIR 92[48] for **1a**, **4** and **5**; SHELXS 86[49] for **2b**). The remaining non-hydrogen atoms were determined by subsequent Fourier and Fourier-difference techniques. The structures were refined by full-matrix least-squares analysis on *F*, with all non-hydrogen atoms refined anisotropically until convergence was reached. The hydrogen atoms of the organic moieties were generated in their ideal positions (C−H, 0.95Å). They were included in the structure factor calculations on a Silicon-Graphics computer using the program package TEXSAN.[50]

Crystallographic data (excluding structure factors) for the structures **1a**, **2b**, **4** and **5** reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-144600 to -144603, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Monoanionic *N,N,O*-Scorpionate Ligands and their Iron(II) and Zinc(II) Complexes: Models for Mononuclear Active Sites of Non-Heme Iron Oxidases and Zinc Enzymes

Alexander Beck,[a] Bernhard Weibert,[a] and Nicolai Burzlaff*[a]

Keywords: Scorpionates / Zinc / Iron / Oxidases / Enzymes

The chemical behavior of two bis(3,5-dialkylpyrazol-1-yl)-acetic acids and their coordination properties towards $ZnCl_2$ and $FeCl_2$ was studied. Reaction of bis(3,5-dimethylpyrazol-1-yl)acetic acid (bdmpza) (**1**) with $ZnCl_2$ and $FeCl_2$ gave the 2:1 complexes [$(bdmpza)_2Zn$] (**4**) and [$(bdmpza)_2Fe$] (**5**). Crystal structures of both complexes were obtained. In contrast, the sterically more hindered ligand bis(3,5-di-*tert*-butylpyrazol-1-yl)acetic acid (bdtbpza) (**3**) coordinates only once to zinc(II) resulting in the complex [(bdtbpza)ZnCl] (**6**). This provides a structural model complex for the active sites of zinc enzymes such as thermolysin or carboxypeptidase. The good agreement with these active sites was demonstrated by a crystal structure of **6**. To the best of our knowledge, this is the first report of zinc complexes with a monoanionic *N,N,O*-tridentate ligand using a carboxylate *O*-donor. Substitution of benzylthiolate for the chloride ligand **6** yielded [(bdtbpza)Zn(SCH_2Ph)] (**8**) indicating that the bulky *tert*-butyl groups do not prevent access to the zinc atom. Reaction of bdtbpza (**3**) with $FeCl_2$ led to [(bdtbpza)FeCl] (**7**), which might serve as a structural model complex for the active sites of mononuclear non-heme iron oxidases and oxygenases such as IPNS, DAOCS or CAS.

Introduction

In recent years, there has been a significant progress in the structural characterization of mononuclear non-heme iron enzymes involved in dioxygen activation.[1] The facial motif of the three metal binding amino acids histidine, histidine and aspertate or glutamate is thought to be essential in many of these enzymes.[2] This has caused a growing interest in model complexes for the active sites of these enzymes. The so called facial 2-His-1-carboxylate triad, a term introduced by Que Jr.,[2] is found, for example, in enzymes such as tyrosine hydroxylase (TyrH),[3] 2,3-dihydroxy-biphenyl 1,2-dioxygenase (extradiol catechol dioxygenase) (BphC),[4] isopenicillin N synthase (IPNS)[5–7] or α-ketoglutarate-dependent enzymes such as deacetoxycephalosporine C synthase (DAOCS)[8] and clavaminic acid synthase (CAS).[9]

Due to the lack of suitable monoanionic *N,N,O* ligands that mimic this facial triad, model complexes with *N,N,N* tripod ligands were used to study these enzymatic reactions. The work of Que, Kitajima or Moro-oka often focused on tris(pyrazol-1-yl)borate (Tp) and tris(2-pyridylmethyl)amine (TPA) ligands.[10]

Furthermore, zinc complexes with such *N,N,O* ligands could serve as models for the active site of several zinc enzymes, binding the metal with two histidines and one glutamate. Examples are carboxypeptidase A and thermolysin.[11] Bioinorganic experiments with zinc complexes by Vahrenkamp, Moro-oka and Parkin are again often based on *N,N,N* ligands such as Tp and TPA.[12] Parkin accessed *N,N,O* model complexes indirectly by insertion of formaldehyde or carbon dioxide into a borohydride bond of zinc bis(pyrazol-1-yl)hydroborate complexes.[13,14] Recently, Carrano published the scorpionate ligand (3-*tert*-butyl-2-hydroxy-5-methylphenyl)-bis(3,5-dimethylpyrazol-1-yl)-methane to generate model complexes of zinc enzymes.[15,16] Instead of a carboxylate *O*-donor, this ligand contains a phenolate *O*-donor. Last year Otero et al. introduced for the first time with bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza, **1**) (Figure 1) and the resulting niobium complex [$NbCl_2$(bdmpza)(PhCCMe)], a scorpionate ligand with a carboxylate and two pyrazole donor groups.[17]

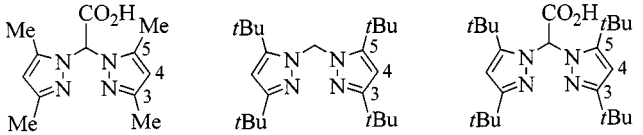

Figure 1. Bispyrazol-1-yl ligands

Herein we report on model complexes of zinc and iron with the scorpionate ligand bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza, **1**) and the new, sterically more hindered bis(3,5-di-*tert*-butylpyrazol-1-yl)acetate (bdtbpza, **3**).

Results

In our quest to find suitable *N,N,O* ligands as models for the active sites of the facial 2-His-1-carboxylate triad in iron- and zinc-containing enzymes, scorpionate ligands like bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza, **1**) seemed to be suitable as a mimic for this facial triad.

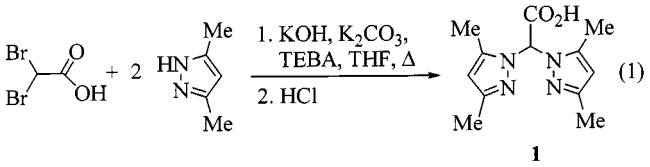
In addition to the multistep ligand synthesis published by Otero et al., we found a simple one-step synthesis for bdmpza (**1**) starting from commercially available reagents [Equation (1)].



1

Treatment of dibromoacetic acid with two equivalents of 3,5-dimethylpyrazole and an excess of potassium hydroxide, potassium carbonate and a small portion of phase-transfer catalyst gave bdmpza (**1**) in reasonable yield. Unreacted 3,5-dimethylpyrazole could be recycled by extraction with diethyl ether at neutral pH value. The ^{1}H and ^{13}C NMR spectra exhibit resonances similar to those reported by Otero et al. for 0.25 [{Li(H_2O)(bdmpza)}$_4$].[17] Compound **1** is slightly soluble in water. In D_2O a resonance $\delta(^{1}H) = 14.02$ was detected that disappeared after 30 minutes and was assigned to the carboxylate proton.

Reaction of bdmpza (**1**) with the biologically relevant metals iron and zinc afforded the 2:1 complexes **4** and **5**. The double coordination of bdmpza to the metals demonstrated too small a steric hindrance of the ligand bdmpza (**1**). Even equimolar amounts of bdmpza (**1**), base and water-free $ZnCl_2$ or $FeCl_2$ yielded only coordination compounds with two scorpionate ligands bound to the metals. The target compounds [(bdmpza)ZnCl] and [(bdmpza)-FeCl] could not be detected. The formation of small amounts of them should be detectable by MS from the typical isotopic fingerprint of the chlorine atom.

The infrared spectra of both complexes [(bdmpza)$_2$Zn] (**4**) and [(bdmpza)$_2$Fe] (**5**) show an intense $\nu_{as}(CO_2^-)$ absorption at 1659 cm^{-1} and medium intensity bands at 1558 cm^{-1} due to ν(C=N). These values fit those reported for the niobium complex [$NbCl_2$(bdmpza)(PhCCMe)].[17] Complex **4** was characterized spectroscopically. Due to four equivalent pyrazolyl rings, only one set of resonances was detected for these rings. For the paramagnetic complex **5** a ^{1}H NMR spectrum was recorded that shows four single signals at $\delta(^{1}H) = 1.2$, 7.0, 14.4 and 55.7. These resonances were assigned to H^4 of the pyrazolyl groups, the two methyl groups and the proton at the bridging carbon atom, respectively.

The iron compound **5** is stable and can be handled in solution for short periods of time in air. Attempts to exchange one of the bdmpza ligands in **5** with a thiolate ligand have not been successful. X-ray structure determinations of the complexes [(bdmpza)$_2$Zn] (**4**) and [(bdmpza)$_2$Fe] (**5**) finally confirmed their identity (Figure 2 and 3). Selected distances and angles are summarized in Table 1.

The coordination spheres around the zinc and iron atoms are almost octahedral with the scorpionate "clamp" causing a deviation of 4−6° from the 90° angle. The good correspondence of both structures in distances and angles emphasizes the similarity of zinc(II) and iron(II) according to their coordination reactions.

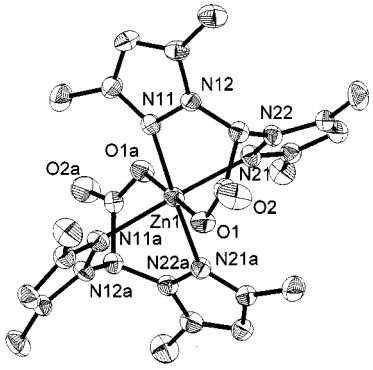


Figure 2. Molecular structure of [(bdmpza)$_2$Zn] (**4**); thermal ellipsoids are drawn at the 50% probability level

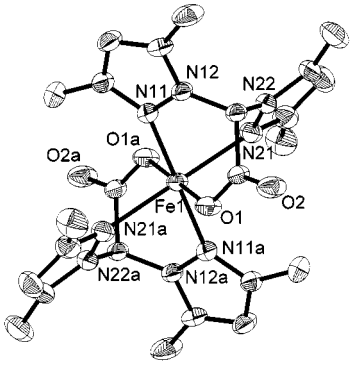

Figure 3. Molecular structure of [(bdmpza)$_2$Fe] (**5**); thermal ellipsoids are drawn at the 50% probability level

Table 1. Selected distances and angles of complexes 4 and 5

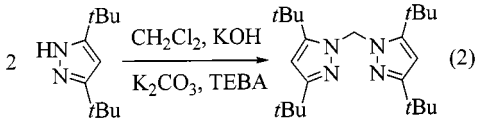
Distance [Å]	4	5	Angle [°]	4	5
M−N(11)	2.178(3)	2.169(3)	N(11)−M−N(21)	84.23(12)	84.05(10)
M−N(21)	2.180(3)	2.212(3)	O(1)−M−N(11)	84.42(11)	84.35(10)
M−O(1)	2.119(3)	2.080(3)	O(1)−M−N(21)	86.12(10)	86.36(11)

The chemical workup of iron(II) compounds under anaerobic conditions is much more difficult than with zinc complexes, and the NMR analyses are restricted to paramagnetic ^{1}H NMR spectroscopy because of the high-spin character. Therefore, the chemical similarity is useful to test possible synthetic routes firstly with zinc(II) and to later transfer this knowledge to reactions with iron(II). One might say that the zinc(II) serves as a "Trojan Horse".

The former studies of Moro-oka et al. with model complexes of the trispyrazolylborate ligands Tp^{tBu,iPr} und Tp$^{iPr}{}_2$ have already shown that sterically more hindered pyrazoles can prevent the Tp ligands from coordinating twice to the metal.[10b] We therefore tried to prevent double coordination by introducing substituents R larger than the methyl group at the pyrazole rings.

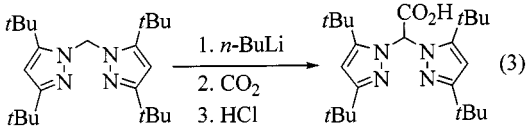
In analogy to the synthesis of bis(3,5-dimethylpyrazol-1-yl)methane,[18] 3,5-*tert*-butylpyrazole reacted with dichloromethane, base and phase-transfer catalyst to give bis(3,5-*tert*-butylpyrazol-1-yl)methane (bdtbpzm) (**2**). 5-*tert*-Butyl-

3-methylpyrazole proved to be unsuitable for this reaction because three inseparable isomers were obtained in the bis(pyrazol-1-yl)methane formation. Therefore, we used a pyrazole with two identical substituents, R, in positions 3 and 5 [Equation (2)].



2

As in the synthesis of bdmpza by Otero et al., the scorpionate ligand bis(3,5-di-*tert*-butylpyrazol-1-yl)acetate (bdtbpza) (**3**) could be synthesized from bis(3,5-*tert*-butylpyrazol-1-yl)methane (bdtbpzm) (**2**) by deprotonation with *n*-butyllithium and subsequent addition of carbon dioxide [(Equation (3)].



2 **3**

The spectroscopic properties of bdtbpza (**3**) are very similar to bdmpza (**1**), with two high-field signals in the ^{1}H NMR spectrum that are due to the *tert*-butyl groups. Compound **3** was also characterized by an X-ray structure determination (Figure 4 and Table 2).

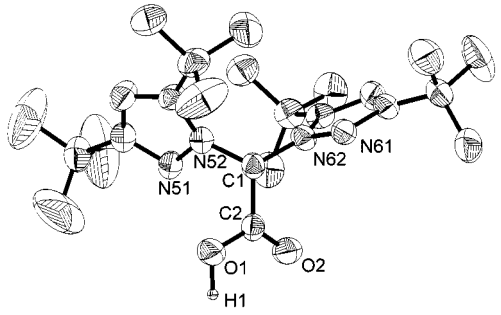


Figure 4. Molecular structure of the bdtbpza ligand (**3**); thermal ellipsoids are drawn at the 50% probability level

Table 2. Selected distances and angles of ligand **3**

Distance [Å]	**3**	Angle [°]	**3**
C(1)−C(2)	1.523(7)	O(1)−C(2)−O(2)	124.6(5)
C(2)−O(1)	1.334(5)	C(2)−C(1)−N(52)	112.5(4)
C(2)−O(2)	1.212(6)	C(2)−C(1)−N(62)	112.1(4)
C(1)−N(52)	1.448(7)	N(52)−C(1)−N(62)	116.0(4)
C(1)−N(62)	1.511(6)		

As in the previous reaction with bdmpza (**1**) the ligand bdtbpza (**3**) was treated with base and water-free $ZnCl_2$ or $FeCl_2$. Fortunately, bdtbpza (**3**) coordinates only once to zinc(II) and iron(II), so that compounds [(bdtbpza)ZnCl] (**6**) and [(bdtbpza)FeCl] (**7**) could be isolated, characterized and tested according to their chemical reactivity.

Both complexes display $\nu_{as}(CO_2^-)$ absorptions around 1680 cm^{-1}. The conformation of the complex [(bdtbpza)-ZnCl] (**6**) could be confirmed by X-ray structure determination (Figure 5). Selected distances and angles are summarized in Table 3.

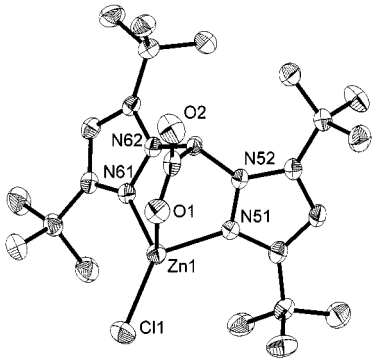

Figure 5. Molecular structure of [(bdtbpza)ZnCl] (**6**); thermal ellipsoids are drawn at the 50% probability level

Table 3. Selected distances and angles of complex **6**

Distance [Å]	**6**	Angle [°]	**6**
Zn−N(51)	2.067(3)	N(51)−Zn−N(61)	87.55(8)
Zn−N(61)	2.053(2)	O(1)−Zn−N(51)	93.85(9)
Zn−O(1)	1.990(2)	O(1)−Zn−N(61)	93.21(9)
Zn−Cl(1)	2.170(2)	N(51)−Zn−Cl(1)	130.62(7)
		N(61)−Zn−Cl(1)	127.18(7)
		O(1)−Zn−Cl(1)	114.64(7)

Compared with the structures of **4** and **5**, the angle O−Zn−N in **6** is widened by 8−9°. As expected, the distance Zn−Cl and the angles O−Zn−N and N−Zn−N are in good agreement with those in the structure of [η^3-$(HCO_2)Bp^{tBu,iPr}$]ZnCl published by Parkin.[14] Similar to this structure, the tetrahedral coordination at zinc is distorted, causing the zinc atom to stack only 0.45 Å out of the N(51)−N(61)−Cl(1) plane. Parkin observed a Zn−O distance of 2.065(4) Å. In **6** the equivalent distance is significantly shorter [1.990(2) Å], due to the fact that one of the donor groups is a carboxylate.

[(Bdtbpza)FeCl] (**7**), in contrast to [$(bdmpza)_2$Fe] (**5**), is not stable to air or moisture: it has to be handled under an atmosphere of argon or nitrogen. Although a dimer $[(bdtbpza)FeCl]_2$ cannot be ruled out completely by our data, an [M$^+$] peak for [(bdtbpza)FeCl] (**7**) can be detected by MS. This indicates that the product [(bdtbpza)FeCl] (**7**) might be isostructural to [(bdtbpza)ZnCl] (**6**). A final answer to this question has to be postponed until a structure determination of **7** is available.

[(Bdtbpza)ZnCl] (**6**) can be treated with benzylthiol and base to yield the benzylthiolate complex [(bdtbpza)-$ZnSCH_2Ph$] (**8**). This reaction is quantitative but it proved to be difficult to remove excess thiol. The spectroscopic properties of **8** are nearly the same as those of **6**, apart from

Table 4. Comparison of Zn−N and Zn−O distances in thermolysin and carboxypeptidase with [(bdmpza)$_2$Zn] (**4**) and [(bdtbpza)ZnCl] (**6**)

	Thermolysin [19]	Carboxypeptidase [20]	[(bdmpza)$_2$Zn]	[(bdtbpza)ZnCl]
d(Zn−N)/Å	2.08, 1.9	2.2	2.178(3)	2.067(3)
d(Zn−N)/Å	2.10, 2.0	2.2	2.180(3)	2.053(2)
d(Zn−O)/Å	2.08, 1.9	2.2	2.119(3)	1.990(2)

additional ^{1}H and ^{13}C NMR spectroscopic signals due to the benzylthiolate ligand. Particularly characteristic for this thiolate ligand is a single resonance at $\delta(^1H) = 3.93$, assigned to the methylene group. A $\nu_{as}(CO_2^-)$ absorption was found at 1677 cm^{-1} in the IR spectrum.

Discussion

The aim of the experiments was to create new structural model complexes for mononuclear non-heme iron oxidases and zinc enzymes. As shown in Table 4 and 5, the distances of the M−N and M−O bonds in [(bdmpza)$_2$Zn] (**4**) and [(bdmpza)$_2$Fe] (**5**) are in good agreement with those of the active sites of thermolysin,[19] carboxypeptidase,[20] IPNS,[5−7] DAOCS[8] and CAS.[9]

Table 5. Comparison of Fe−N and Fe−O distances in IPNS and DAOCS with [(bdmpza)$_2$Fe] (**5**)

	IPNS [6][7]	DAOCS [8]	CAS [9]	[(bdmpza)$_2$Fe]
d(Fe−N)/Å	2.19, 2.09	2.2	2.15, 2.14, 2.25	2.169(3)
d(Fe−N)/Å	2.20, 2.24	2.2	2.12, 2.12, 2.28	2.212(3)
d(Fe−O)/Å	2.06, 2.09	2.2	2.06, 2.07, 2.16	2.080(3)

These data already show that sterically more hindered derivatives of bispyrazolyl acetate should be suitable ligands for model complexes. By using the new ligand bdtbpza (**3**) we implemented this steric hindrance.

With [(bdtbpza)ZnCl] (**6**) a tetrahedral zinc complex with a monoanionic *N,N,O*-tridentate ligand using a carboxylate *O*-donor was synthesized for the first time. A comparison of the X-ray structure determination of **6** with the coordination environment of the enzymes, according to the distances Zn−N and Zn−O (Table 4) indicates their significance as structural models for these active sites. [(Bdtbpza)ZnCl] (**6**) might be the best structural analogue for the enzymes thermolysin and carboxypeptidase.

For future biomimetic studies, a coordination of possible enzymatic substrates to the bdmpza model complexes is essential. In the case of model complexes for the active site of thermolysin or carboxypeptidase, this could be a small peptide. For models of IPNS or α-ketoglutarate-dependent enzymes as CAS or DAOCS, this might be a thiolate or α-ketoglutarate or even a dioxygen. The reactivity of **6** towards an exchange of the chloro ligand by a thiolate clearly shows the potential of the chloro complexes **6** and **7** in the synthesis of zinc(II) and iron(II) model complexes. Therefore, our future work will focus on the synthesis of model complexes for non-heme iron enzymes activating dioxygen, such as IPNS, as well as their chemical reactivity.

As shown recently by Moro-oka et al., the steric hindrance of a Tp^{tBu,iPr} ligand might prevent access of substrates to the metal of the complexes.[10c] Thus, the model complex [Tp^{tBu,iPr}Fe^{II}(O$_2$CMe)] shows no affinity to O$_2$, in contrast to the sterically less-hindered [Tp$^{iPr}{}_2$Fe^{II}(O$_2$CMe)] complex. We propose that this affinity to dioxygen, essential for our further experiments with iron complexes, might be guaranteed by the much smaller carboxylate donor groups in future model complexes [(bdtbpza)FeR].

Conclusions

Two bis(3,5-dialkylpyrazol-1-yl)acetic acids **1** and **3** were introduced as new ligands for synthetic structural analogues of zinc or non-heme iron enzymes. The steric hindrance of bis(3,5-dimethylpyrazol-1-yl)acetic acid is too small, causing the ligand to coordinate twice to zinc(II) or iron(II). With bis(3,5-di-*tert*-butylpyrazol-1-yl)acetic acid the steric hindrance of this new *N,N,O* ligand was improved. The structural model complexes of zinc(II) and iron(II) obtained mimic the so called facial 2-His-1-carboxylate triad; this is especially important in mononuclear non-heme iron enzymes. We are sure that the obtained model complexes represent a good starting point to investigate the reactivity of such enzymes, especially with respect to dioxygen activation.

Experimental Section

All experiments involving iron(II) were carried out in Schlenk tubes under an atmosphere of argon using suitable purified solvents. Microcrystalline precipitates were separated by centrifugation with a Hettich Rotina 46 R Schlenk tube centrifuge. − IR: Biorad FTS 60, CaF_2 cuvets (0.5 mL). − ^{1}H NMR and ^{13}C NMR: Bruker WM 250, Bruker AC 250, JEOL GX 400, δ values relative to TMS; in some cases the ^{13}C NMR spectroscopic signals of quaternary carbon atoms were to weak to be detected. − EI-MS and FAB MS: modified Finnigan MAT 312. − Elemental analyses: Analytical Laboratory of the Fachbereich Chemie. − A modified Siemens P4 diffractometer was used for X-ray structure determinations.

3,5-Dimethylpyrazole, 2,2,6,6-tetramethyl-3,5-heptandione, dibromoacetic acid and $ZnCl_2$ were used as purchased. Water-free $FeCl_2$ was synthesized from $FeCl_3$.[21] 3,5-Di-*tert*-butylpyrazole was obtained by standard literature methods from 2,2,6,6-tetramethyl-3,5-heptandione and hydrazine hydroxide.[22]

Ligand Syntheses

Synthesis of Bis(3,5-dimethylpyrazol-1-yl)acetic Acid (bdmpza) (1): Dibromoacetic acid (5.45 g, 25.00 mmol), 3,5-dimethylpyrazole

(4.81 g, 50.00 mmol), KOH (5.05 g, 90.00 mmol), K_2CO_3 (12.44 g, 90.00 mmol) and benzyltriethylammonium chloride (1.00 g), serving as phase-transfer catalyst, were dissolved in tetrahydrofuran (100 mL) and heated under reflux for 5 to 6 hours. The solvent was removed in vacuo, the residue dissolved in water (100 mL) and acidified to a pH value of 7 with half-concentrated HCl. To remove excess pyrazole, the solution was extracted with diethyl ether (2 × 150 mL). The water phase was further acidified to a pH value of 1 and extracted again with diethyl ether (5 × 150 mL). To improve the extraction of the water-soluble bdmpza **1** tetrahydrofuran can be added. The organic layer was dried (Na_2SO_4) and the solvent was removed in vacuo. The residue was recrystallized from acetone yielding bdmpza (1) as colorless microcrystalline needles and dried in vacuo over SICAPENT©. In an analogous reaction of dichloroacetic acid chloride with three equivalents of 3,5-dimethylpyrazole, bdmpza (**1**) can be obtained in a slightly lower yield. Yield 2.79 g (45%); m.p. 171 °C (dec.). – ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 2.20 (s, 6 H, CH_3), 2.24 (s, 6 H, CH_3), 5.90 (s, 2 H, H_{pz}), 6.76 (s, 1 H, CH). – ^{1}H NMR (D_2O, 250 MHz): δ = 2.09 (s, 6 H, CH_3), 2.18 (s, 6 H, CH_3), 5.99 (s, 2 H, H_{pz}), 6.79 (s, 1 H, CH), 14.03 (s, CO_2H). – ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ = 11.0 (CH_3), 13.3 (CH_3), 69.9 (CH), 107.8 (C_{pz}), 141.7 (C_{pz}), 148.9 (C_{pz}), 165.1 (CO_2H). – EI MS (70 eV, 170 °C): *m*/*z* (%) = 248 (6) [M^+], 204 (20) [$M^+ - CO_2$], 109 (100) [$M^+ - CO_2 - C_5H_7N_2$], 96 (50) [$C_5H_8N_2$]. – IR (THF): $\tilde{\nu}$ = 1758 cm^{-1} (CO_2H), 1563 (C=N). – $C_{12}H_{16}N_4O_2$ (248.28): calcd. C 58.05, H 6.50, N 22.57; found C 58.38, H 6.54, N 22.09.

Synthesis of Bis(3,5-di-*tert*-butylpyrazol-1-yl)methane (bdtbpzm) (2): 3,5-Di-*tert*-butylpyrazole (3.00 g, 16.64 mmol), KOH (3.60 g, 64.16 mmol), K_2CO_3 (9.00 g, 65.12 mmol) and benzyltriethylammonium chloride (0.5 g) were dissolved in dichloromethane (100 mL) and heated under reflux for 5 hours. Salts were removed by filtration and the filtrate was concentrated in vacuo to dryness. The white residue was dissolved in water and extracted with pentane (2 × 150 mL). The organic layer was dried ($MgSO_4$) and the solvent removed in vacuo. The white residue was recrystallized from pentane to give bdtbpzm (**2**) as a white powder, which was dried in vacuo. Yield 2.40 g (77%), m.p. 132 °C. – ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 1.21 (s, 18 H, CH_3), 1.25 (s, 18 H, CH_3), 5.90 (s, 2 H, CH_2), 6.52 (s, 2 H, H_{pz}). – ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ = 29.8 (CH_3), 30.4 (CH_3), 31.9 (C-*t*Bu), 66.7 (CH_2), 101.9 (C_{pz}), 153.0 (C_{pz}), 159.1 (C_{pz}). – EI MS (70 eV, 125 °C): *m*/*z* (%) = 372 (10) [M^+], 315 (1) [$M^+ - C_4H_9$], 193 (100) [$M^+ - C_{11}H_{19}N_2$], 57 (18) [C_4H_9]. – IR (THF): $\tilde{\nu}$ = 1542 cm^{-1} (C=N). – $C_{23}H_{40}N_4$ (372.60): calcd. C 74.14, H 10.82, N 15.04; found C 74.12, H 10.79, N 14.90.

Synthesis of Bis(3,5-di-*tert*-butylpyrazol-1-yl)acetic Acid (bdtbpza) (3): A solution of bis(3,5-di-*tert*-butylpyrazol-1-yl)methane (bdtbpzm) (**2**) (2.30 g, 6.17 mmol) in tetrahydrofuran (50 mL) was treated with *n*BuLi (≈1.6 M solution in hexane, 4 mL, 6.40 mmol) at −70 °C. The solution is allowed to warm to −45 °C during a period of 4 h and finally poured onto 200 g of crushed dry ice. After reaching room temperature, the solvent was removed in vacuo and the white residue dissolved in water (100 mL). The aqueous solution was acidified with half concentrated HCl to a pH value of 1 and extracted with diethyl ether (3 × 100 mL). The combined organic layers were dried (Na_2SO_4) and concentrated in vacuo to give a honey-like yellow oil. The product crystallized within two days when stored at room temperature under air. The white crystalline substance was washed with pentane to remove unchanged bis(3,5-di-*tert*-butylpyrazol-1-yl)methane (bdtbpzm) (**2**), which gave bdtbpza (**3**) as a colorless powder. Upon recrystallization from acetone, cubic crystals suitable for an X-ray structure determination were obtained. Yield 2.25 g (88%), m.p. 92 °C. – ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 1.21 (s, 18 H, CH_3), 1.24 (s, 18 H, CH_3), 6.01 (s, 2 H, H_{pz}), 7.27 (s, 1 H, CH). – ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ = 30.0 (CH_3), 30.1 (CH_3), 31.9 (C-*t*Bu), 32.2 (C-*t*Bu), 72.7 (CH), 103.1 (C_{pz}), 154.0 (C_{pz}), 159.6 (C_{pz}), 166.2 (CO_2H). – EI MS (70 eV, 145 °C): *m*/*z* (%) = 372 (8) [$M^+ - CO_2$], 315 (1) [$M^+ - CO_2 - C_4H_9$], 193 (100) [$M^+ - C_{11}H_{19}N_2 - CO_2$], 57 (20) [$C_4H_9$]. – IR (THF): $\tilde{\nu}$ = 1767 cm^{-1} (CO_2H), 1542 (C=N). – $C_{24}H_{40}N_4O_2 \cdot 0.5\ C_4H_{10}O$ (453.67): calcd. C 68.84, H 10.00, N 12.35; found C 68.48, H 9.76, N 12.36.

Synthesis of Model Compounds

Synthesis of [(bdmpza)$_2$Zn] (4): A solution of bdmpza ligand (**1**) (500 mg, 2.01 mmol) in MeOH (20 mL) was deprotonated with the subsequent addition of NaOH (80 mg, 2.01 mmol). A solution of $ZnCl_2$ (137 mg, 1.01 mmol) in MeOH (10 mL) was then added. The initially clear solution was stirred at room temperature for 1 h. The white precipitate that formed was separated by centrifugation, washed with MeOH (15 mL) and dried in vacuo to afford **4** as a white powder. Colorless prism-like crystals suitable for an X-ray structure determination were obtained by recrystallization from MeOH/H_2O (20:1) at 4 °C. Treatment of bdmpza (**1**) with equimolar amounts of NaOH and $ZnCl_2$ yielded the identical compound. Yield 517 mg (92%), m.p. 280−300 °C (dec.). – ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 1.97 (s, 12 H, CH_3), 2.45 (s, 12 H, CH_3), 5.87 (s, 4 H, H_{pz}), 6.57 (s, 2 H, CH). – ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ = 10.9 (CH_3), 12.7 (CH_3), 67.1 (CH), 106.7 (C_{pz}), 139.7 (C_{pz}), 150.2 (C_{pz}), 166.3 (CO_2^-). – FAB MS (NBOH-matrix): *m*/*z* (%) = 873 (10) [2 M − bdmpza], 559 (20) [MH^+], 419 (40) [$MH^+ - CO_2 - C_5H_7N_2$], 375 (20) [$MH^+ - 2\ CO_2 - C_5H_7N_2$], 361 (20) [$MH^+ - 2\ CO_2 - (C_5H_7N_2)CH_2$], 203 (60) [$(C_5H_7N_2)_2CH^+$], 109 (100) [$(C_5H_7N_2)CH_2^+$], 95 (75) [$C_5H_7N_2$]. – IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1659 cm^{-1} (CO_2^-), 1558 (C=N). – $C_{24}H_{30}N_8O_4Zn$ (559.93): calcd. C 51.48, H 5.40, N 20.01; found C 51.23, H 5.36, N 19.25 or C 51.21, H 5.66, N 20.09.

Synthesis of [(bdmpza)$_2$Fe] (5): A solution of bdmpza ligand (**1**) (500 mg, 2.01 mmol) in MeOH (15 mL) was deprotonated with the subsequent addition of NaOH (80 mg, 2.01 mmol). A solution of water-free $FeCl_2$ (128 mg, 1.01 mmol) in MeOH (10 mL) was then added. The initially clear solution was stirred at room temperature for 2 h. The tan to white precipitate that formed was separated by centrifugation, washed with MeOH (15 mL) and dried in vacuo to yield **5** as a colorless crystal powder. Recrystallization from acetonitrile/dichloromethane (1:1) yielded greenish prism-like crystals suitable for an X-ray structure determination. [(Bdmpza)$_2$Fe] (**5**) was also obtained by treatment of bdmpza (**1**) with equimolar amounts of potassium *tert*-butoxide and $FeCl_2$ in dichloromethane. Yield 512 mg (92%), m.p. 305−315 °C (dec.). – ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 1.2 (s, 2 H, CH), 7.0 (s, 12 H, CH_3), 14.4 (s, 12 H, CH_3), 55.7 (s, 4 H, H_{pz}). – EI MS (70 eV, 340 °C): *m*/*z* (%) = 550 (8) [M^+], 398 (35) [$M^+ - CO_2 - (C_5H_7N_2)CH_2$], 204 (30) [$(C_5H_7N_2)_2CH_2^+$], 109 (78) [$(C_5H_7N_2)CH_2^+$], 96 (40) [$C_5H_8N_2$]. – IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1659 cm^{-1} (CO_2^-), 1558 (C=N). – $C_{24}H_{30}FeN_8O_4$ (550.40): calcd. C 52.35, H 5.50, N 20.36; found C 52.26, H 5.42, N 19.52.

Synthesis of [(bdtbpza)ZnCl] (6): To a solution of bis(3,5-di-*tert*-butylpyrazol-1-yl)acetic acid (bdtbpza) (**3**) (1.00 g, 2.40 mmol) in acetonitrile (30 mL) was added $ZnCl_2$ (380 mg, 2.79 mmol) and the solution stirred vigorously at ambient temperature. After 5 min potassium *tert*-butoxide (268 mg, 2.39 mmol) was added. Within 1 min a white precipitate was formed. After 2 h the solvent was removed in vacuo. The residue was dissolved in dichloromethane (25 mL) and

salts were separated by centrifugation. Dichloromethane was removed in vacuo, the residue washed with diethyl ether (2 × 10 mL) and dried in vacuo to afford [(bdtbpza)ZnCl] (**6**) as a white crystal powder. Recrystallization from acetone at room temperature yielded prism-like colorless crystals within 5 days that were suitable for an X-ray structure determination. Yield 1.06 g (86%), m.p. 239 °C. − ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 1.44 (s, 18 H, CH_3), 1.56 (s, 18 H, CH_3), 6.16 (s, 2 H, H_{pz}), 7.42 (s, 1 H, CH). − ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ = 30.2 (CH_3), 31.2 (CH_3), 32.2 (C-*t*Bu), 32.6 (C-*t*Bu), 72.3 (CH), 103.8 (C_{pz}), 156.4 (C_{pz}), 164.4 (C_{pz}), 165.3 (CO_2^-). − EI MS (70 eV, 240 °C): *m*/*z* (%) = 514 (1) [M^+], 470 (12) [$M^+ - CO_2$], 413 (100) [$M^+ - CO_2 - C_4H_9$], 279 (21) [$M^+ - CH_2 - C_{11}H_{19}N_2 - CO_2$], 193 (7) [$M^+ - Zn - Cl - C_{11}H_{19}N_2 - CO_2$], 57 (54) [$C_4H_9$]. − IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1681 cm^{-1} (CO_2^-), 1547 (C=N). − $C_{24}H_{39}ClN_4O_2Zn$ (516.43): calcd. C 55.82, H 7.61, N 10.85; found C 55.52, H 7.72, N 10.70.

Synthesis of [(bdtbpza)ZnSCH$_2$Ph] (8): A solution of [(bdtbpza)ZnCl] (**6**) (500 mg, 0.97 mmol) in acetonitrile (20 mL) was treated at ambient temperature with benzylthiol (158 mg, 2.79 mmol) and potassium *tert*-butoxide (109 mg, 0.97 mmol). After 3 h the solvent was evaporated, the residue dissolved in dichloromethane (25 mL) and salts removed by centrifugation. The solution was concentrated to dryness in vacuo and the residue was washed with pentane to yield [(bdtbpza)ZnSCH$_2$Ph] (**8**) as a colorless powder. Yield 550 mg (91%), m.p. 88 °C. − ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 1.38 (s, 18 H, CH_3), 1.56 (s, 18 H, CH_3), 3.93 (s, 2 H, SCH_2), 6.13 (s, 2 H, H_{pz}), 7.10−7.39 (m, 5 H, Ph), 7.42 (s, 1 H, CH). − ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ = 29.7 (SCH_2), 30.3 (CH_3), 31.2 (CH_3), 32.2 (C-*t*Bu), 32.5 (C-*t*Bu), 72.2 (CH), 103.6 (C_{pz}), 125.6 (CPh), 128.1 (CPh), 128.5 (CPh), 144.6 (CPh), 155.9 (C_{pz}), 164.0 (C_{pz}), 166.0 (CO_2^-). − EI MS (70 eV, 300 °C): *m*/*z* (%) = 602 (7) [M^+], 557 (2) [$M^+ - CO_2$], 501 (75) [$M^+ - CO_2 - C_4H_9$], 366 (20) [$M^+ - CH_2 - C_{11}H_{19}N_2 - CO_2$], 244 (20) [Zn + $C_{11}H_{19}N_2$], 194 (100) [$C_{11}H_{20}N_2 + CH_2$], 91 (90) [C_7H_7], 57 (30) [C_4H_9]. − IR (CH_2Cl_2): $\tilde{\nu}$ = 1677 cm^{-1} (CO_2^-), 1543 (C=N). − $C_{31}H_{46}N_4O_2SZn$ (604.17): calcd. C 61.63, H 7.67, N 9.27; found C 61.33, H 7.56, N 8.53.

Synthesis of [(bdtbpza)FeCl] (7): To a solution of bis(3,5-di-*tert*-butylpyrazol-1-yl)acetic acid (bdtbpza) (**3**) (500 mg, 1.20 mmol) in acetonitrile (20 mL) was added water-free $FeCl_2$ (150 mg, 1.18 mmol) and the reaction mixture stirred at ambient temperature for 10 min. Potassium *tert*-butoxide (135 mg, 1.20 mmol) was added and stirred for 3 h. The solvent was evaporated and the residue was dissolved in dichloromethane (25 mL). Salts were removed by centrifugation and the solution concentrated to dryness in vacuo. The residue was washed with diethyl ether (2 × 10 mL) and dried in vacuo to afford [(bdmpza)FeCl] (**7**) as a colorless powder. Yield 520 mg (87%), m.p. 203 °C (dec.). − ^{1}H NMR ($CDCl_3$, 250 MHz): δ = −21.4 (s, 18 H, CH_3), 3.2 (s, 2 H, H_{pz}), 11.3 (s, 18 H, CH_3). − EI MS (70 eV, 280 °C): *m*/*z* (%) = 506 (4) [M^+], 462 (11) [$M^+ - CO_2$], 405 (100) [$M^+ - CO_2 - C_4H_9$], 271 (12) [$M^+ - CH_2 - C_{11}H_{19}N_2 - CO_2$], 57 (44) [$C_4H_9$]. − IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1684 cm^{-1} (CO_2^-). − $C_{24}H_{39}ClFeN_4O_2$ (506.90): calcd. C 56.87, H 7.75, N 11.05; found C 56.57, H 7.86, N 10.91.

X-ray Structure Determinations: Single crystals of **3**, **4**, **5** and **6** were sealed in glass capillaries at room temperature. A modified Siemens P4-Diffractometer was used for data collection (Wyckhoff technique, graphite monochromator, Mo-K_α radiation, λ = 0.71073 Å, scan rate 4−30°min^{-1} in ω). Compound **4** was measured at room

temperature and the others at −30 °C. Structures were solved using direct methods {Siemens SHELXS-93 (VMS)[23]} and refined with full-matrix least-squares against F^2 {Siemens SHELXL-96 (VMS)[24]}. A weighting scheme was applied in the last steps of the refinement with $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ and $P = [2F_c^2 + \mathrm{Max}(F_o^2,0)]/3$. Hydrogen atoms were included in their calculated positions and refined in a riding model.

The metal atoms in structures of **4** and **5** are in special positions, causing the asymmetric unit to be filled by only half a molecule. Compound **4** crystallized as a solvate with 1.5 water molecules, one of which interacts with the carboxylate group. In the asymmetric unit of structure **5**, half a molecule of dichloromethane was found and refined in a special position.

Compound **3** crystallized with half a molecule of diethyl ether in the asymmetric unit in a special position. The proton of the carboxylic acid was found. The poor *R*-factors of compound **3** are caused by a weak diffraction of the crystal. So the θ-range of the measurement was only up to 23° causing a low reflection/parameter ratio. Nevertheless, anisotropic refinement was applied to all non-hydrogen atoms.

All details and parameters of the measurements are summarized in Table 6. Structure pictures were prepared with the program Diamond 2.1c.[25] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-145052 (**4**), CCDC-145053 (**5**), CCDC-145054 (**6**) and CCDC-145055 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Photochemically Induced Isomerisation of Ruthenium Polypyridyl Complexes

Stefano Fanni,[a] Frances M. Weldon,[a] Leif Hammarström,[b] Emad Mukhtar,[b] Wesley R. Browne,[a] Tia E. Keyes,[c] and Johannes G. Vos*[a]

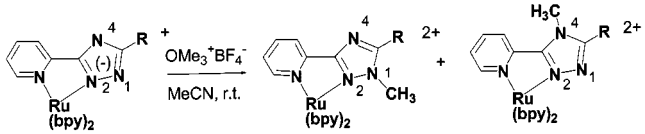
Keywords: Ruthenium / Coordination modes / Photochemistry / Electrochemistry / Heterocycles

The synthesis and characterisation of a series of ruthenium polypyridyl complexes containing pyridyltriazole ligands in different coordination modes are described. The electrochemical and electronic properties of the compounds with respect to the coordination mode of the pyridyltriazole ligand are reported. Upon photolysis of the complex containing the 1-methyl-3-(pyridin-2-yl)-1,2,4-triazole ligand, irreversible ligand isomerisation is observed.

Introduction

During the last number of years we have been actively involved in the study of ruthenium and osmium polypyridyl complexes containing ligands with 1,2,4-triazole moieties such as pyridyl-[1] and pyrazyltriazoles.[2] These studies have shown that for dinuclear compounds containing anionic triazolate bridges, strong intercomponent interactions are observed.[3] In addition, mononuclear complexes containing negatively charged triazole rings were found to be photostable.[4] Of further interest in these studies is the inherent asymmetry of the ligands. The nitrogen atoms of the pyridine or pyrazine rings have significantly different electronic properties to the triazole-based nitrogen atoms. In addition the N1 (or N2) and N4 atoms of the triazole ring are nonequivalent, as shown by differences between the acid−base properties of complexes containing N2- and N4-bonded ligands.[1,2] With *N*-substituted triazole ligands, either N2- or N4-coordination of the ligands is observed, depending on the position of the substituent.[5] Furthermore, it has been shown that for complexes containing neutral pyridyltriazole ligands, photochemically induced isomerisation of the pyridyltriazole ligand can occur.[4,6]

Recently we developed a new synthetic route towards complexes containing *N*-substituted triazole ligands as shown in Scheme 1.[7]



Scheme 1

In this method, the N2 isomer of a 3-(pyridin-2-yl)-1,2,4-triazole (L1) ruthenium polypyridyl precursor complex (**RuL1*N2***) was directly methylated yielding complexes which then contain the ligands 1-methyl-3-(pyridin-2-yl)-1,2,4-triazole (L2) and 4-methyl-3-(pyridin-2-yl)-1,2,4-triazole (L3). Surprisingly, the sterically least favoured complex, **RuL2*N2***, methylated at the N2 position; was obtained as the main product, with a yield of about 90%, whereas in the reaction between L2 and $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ only the N4 isomer of the complex, **RuL2*N4***, could be obtained in appreciable amounts. This new synthetic strategy provided us with the first opportunity to compare their photophysical and photochemical properties and to investigate the role played by steric hindrance. In this paper we report the photochemical and photophysical properties of ruthenium bis(bipyridyl) complexes with the *N*-substituted triazole ligands L2, L3 and 1,4-bis[1-methyl-3-(pyridin-2-yl)-1,2,4-triazol-5-yl]benzene (L4) (see Figure 1). In the latter ligand, both the N2 and N4 sites are sterically hindered. The effect of the benzene and the methyl groups on the composition of the compounds and on their photophysical and photochemical properties were investigated. Emission lifetime, UV/Vis and NMR studies indicate that an irreversible

photoisomerisation takes place, in which the sterically hindered N2-bonded L2 complex is transformed into the N4 species. For the mono- and dinuclear L4 complexes, a less clear picture was obtained, but photoinduced reactions were also observed. The results obtained are discussed with respect to the electronic properties of the compounds.

Results and Discussion

General

An important issue to be addressed first is the coordination mode of the triazole rings in the obtained products, in particular in the L4 complexes. For L2 and L3, the coordination of the triazole ring is known from earlier studies.[1,7] From the reaction mixture of the mononuclear L4 complex, two isomers were isolated by semi-preparative HPLC. In the dinuclear complex, coordination of the two metal units may occur to N2/N2′, N4/N4′ or N2/N4′ of the triazole ring. HPLC analysis of the reaction mixture showed the presence of different isomers. One main isomer was isolated in a pure form by recrystallisation.

^{1}H NMR Spectroscopy

The position of the methyl signals in the ^{1}H NMR spectra is diagnostic for the type of isomer obtained (see Table 1). For L2 and L4, the methyl substituent is expected to resonate significantly further upfield than in the free ligand when the ligand is bonded through the N2 atom. This is a consequence of the steric interaction between the methyl group and a neighbouring bpy ligand. For the N4 isomer a smaller shift is expected since no interaction between the methyl group and the bpy ligands is possible.[1,5,8] The methyl resonances recorded for the complexes fall clearly into two groups. The first set of signals at $\delta \approx 3.2$ is indicative of the presence of steric hindrance, since the values are shifted upfield by about 0.7 ppm, with respect to the free ligand. Such a shift indicates N2 coordination for L2 and L4 complexes. The resonances found at $\delta \approx 4$ point to coordination modes where the methyl group does not interact with the neighbouring bpy ligands and are indicative of N4 coordination in the L2 and L4 ligands and of N2 coordination in the L3 complex. For the dinuclear L4 complex, only one methyl signal was obtained at $\delta = 3.23$, clearly indicating that both centres are bonded in the same manner, namely through N2.

Table 1. Chemical shifts (ppm) for methyl groups; measurements were carried out in DMSO unless otherwise stated

Compound	CH_3
RuL2*N2*	3.15 (3.54[a])
RuL2*N4*	3.97 (4.17[a])
RuL3*N4*	4.21
RuL4*N4* (f)	4.07
(b)	3.82
RuL4*N2* (f)	4.10
(b)	3.27
RuRuL4*N2N2*	3.23
(in CD_3CN)	3.17

[a] Measured in acetone; (f) and (b) refer to the free and bound pyridyltriazole ring, respectively.

Redox Properties

All complexes show well-behaved electrochemistry (see Table 2). The redox processes are reversible, with peak-to-peak separations of 60−100 mV. **RuRuL4*N2N2′*** exhibits a single, two-electron, metal-based oxidation, without any sign of splitting, indicating that the interaction between the metal centres is at best very weak. The N4-coordinated complexes exhibit somewhat lower $Ru^{II/III}$ potentials than the N2 compounds possibly indicating improved π-acceptor properties of ligands coordinated in the N2 mode. The similarity of the reduction potentials of the compounds reported in this work and those observed for $[Ru(bpy)_3]^{2+}$ suggests that the first reduction process is bpy based. This is further confirmed by the first reduction potential observed for **$[Ru(L2N4)_3]^{2+}$** (L2 coordinated through N4) of −1.75 V vs. SCE,[9] approximately 400 mV more negative than that observed for $[Ru(bpy)_3]^{2+}$. This value suggests that the lowest unoccupied molecular orbital (LUMO) in the L2 complex is about 3300 cm^{-1} higher than in the homoleptic bpy complex.

Table 2. Electrochemical data for the triazole complexes; all measurements were carried out in acetonitrile with 0.1 M TEAP; all redox potentials measurements were performed using ferrocene as an internal reference

Complex	Oxidation potential [V vs. SCE]	Reduction potential [V vs. SCE]
RuL2*N2*	1.30	−1.36, −1.57
RuL2*N4*	1.20	−1.39, −1.61
RuL3*N2*	1.19	−1.39, −1.61
RuL4*N2*	1.31	−1.35, −1.56
RuL4*N4*	1.20	−1.35, −1.58
RuRuL4*N2N2′*	1.29	−1.38, −1.59
$[Ru(bpy)_3]^{2+}$	1.26	−1.35, −1.55, −1.80

Electronic Properties

The absorption spectra bands observed in the 400−460 nm region are associated with dπ−π* MLCT bands. The MLCT bands for complexes containing a *N*4-coordinated triazole ring are found at about the same energy as that of $[Ru(bpy)_3]^{2+}$. In agreement with the electrochemical data, the N2-bonded isomers have an MLCT band at higher energy suggesting that in this coordination mode the σ-donor properties of the L2 and L4 ligands are reduced.

All the compounds show emission at room temperature and at 77 K. The emission lifetimes of the complexes in acetonitrile, measured by time-correlated single-photon counting, are given in Table 3. For **RuL2*N4*** and **RuL4*N4***, the major decay component shows a lifetime of 9.0 ns and 35 ns, respectively. A minor (< 5%), faster component has a lifetime of approximately 1 ns. In contrast, for **RuL2*N2*** and **RuL4*N2*** the 1 ns component was dominant. In these samples, a second slower component was present, and its magnitude varied between 15% and 50% for different meas-

Table 3. UV/Vis absorption and emission data for the complexes; all measurements were carried out in acetonitrile unless otherwise stated

Complex	Absorption λ_{max} [nm] (ε [10^4 $M^{-1}cm^{-1}$])	Emission λ_{max} [nm] 300 K	77 K[a]	$\tau_{300\ K}$ [ns]
RuL2*N2*	435 (1.15)	615	566	1.0
RuL2*N4*	452 (1.07)[a]	600[a]	585	9.0
RuL3*N2*	440 (1.44)[a]	600[a]	584	14.0
RuL4*N2*	415 (1.33)	611	570	1
RuL4*N4*	453 (0.90)	614	584	35
RuRuL4*N2N2′*	414 (2.60)	603	573	1
$[Ru(bpy)_3]^{2+}$	452 (1.30)	615	582	950[b]

urements. The lifetime of this component matched that of the corresponding N4 isomer. The dimeric **RuRuL4*N2N2′*** also has a dominant 1 ns component, with a minor slower (32 ns) component that matches the lifetime of **RuL4*N4***.

The results obtained from the lifetime measurements for the N2 isomers of L2 and L4 were at first hard to explain, since an impurity level as high as 50% would certainly have been detected by the other characterisation techniques. The formation of a photoproduct seems a more likely explanation for the behaviour observed. For the compounds under investigation, the occurrence of photoinduced ligand processes is not unexpected. It is generally assumed that upon excitation of ruthenium polypyridyl complexes, an electron is transferred from the metal-based ground state to a singlet metal-to-ligand charge-transfer (^{1}MLCT) state. From this singlet state, the emitting ^{3}MLCT state is populated efficiently by intersystem crossing. Population of the nearby antibonding triplet metal-centred state (^{3}MC) then explains the photoinduced reactivity of the compounds, and in the literature both ligand exchange and rearrangements have been reported.[4,10,11]

To investigate this hypothesis further, a photolysis was carried out in which ^{1}H NMR spectra were taken after various irradiation times. After irradiating for 6 h in acetonitrile, analysis of the CH_3 resonance suggested that up to 70% of the complex underwent photoinduced isomerisation to the corresponding **RuL2*N4*** complex. Further irradiation (up to 12 h) resulted mainly in decomposition of the complex **RuL2*N2***. This decomposition probably occurs by the formation of a photoinduced intermediate where the pyridyltriazole ligand is coordinated in a monodentate fashion. Such behaviour in strongly coordinating solvents has been reported before for other complexes containing neutral pyridyltriazole ligands.[6b] Under the same conditions, **RuL2*N4*** shows a remarkable photostability and decomposition becomes noticeable only after 24 h of irradiation. The same experiment was carried out in a weakly coordinating solvent, namely acetone, in an effort to reduce the formation of secondary photoproducts (see Figure 2). Analysis of the methyl region of the spectra shows that the resonance originally obtained for the N2 isomer at $\delta = 3.54$ is replaced by a signal at $\delta = 4.17$ after photolysis. This is indicative of the formation of the N4 isomer, and in acetone typically a 100% photoisomerisation of **RuL2*N2*** to **RuL2*N4*** was obtained after irradiation for 30 h. No evidence for the formation of a solvated metal complex was observed. No changes were observed in the ^{1}H NMR spectra of **RuL2*N4*** after irradiating for 24 h. These results suggest that irreversible photoinduced isomerisation of **RuL2*N2*** to **RuL2*N4*** is taking place as shown in Scheme 2.

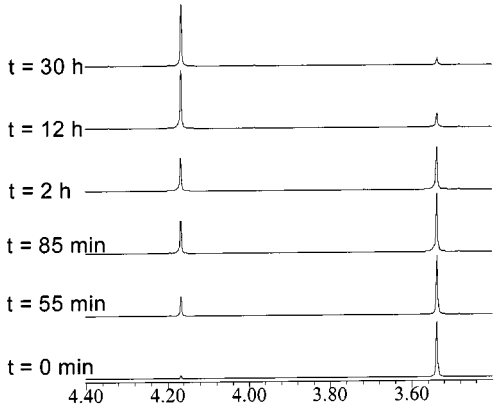

Figure 2. ^{1}H NMR spectra of the methyl region taken during photolysis of **RuL2*N2*** in [D_6]acetone

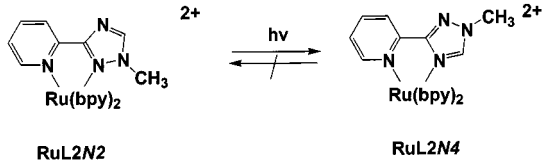

Scheme 2

This photoisomerisation process can also be observed using UV/Vis absorption spectroscopy. As can be seen in Figure 3, irradiation of **RuL2*N2*** in acetone causes a gradual decrease in intensity of the band at 415 nm and a concomitant growth of bands at 355 nm and 455 nm, which are associated with the **RuL2*N4*** complex (Table 3). The UV/Vis spectra show isosbestic points at 448 nm and 372 nm, indicating that photoproducts are formed directly without the production of long-lived intermediates. Upon complete photolysis, no further changes in the absorption spectrum occur, which further indicates the photostability of **RuL2*N4***.

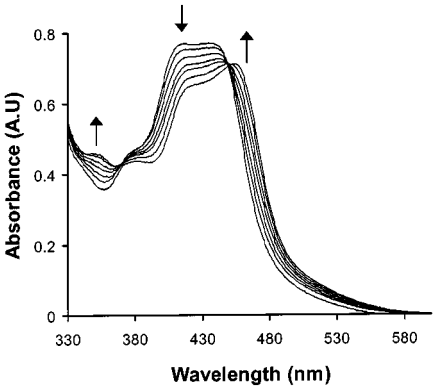

Figure 3. UV/Vis absorption spectra of **RuL2*N2*** in acetone upon irradiation for (a) 0 min, (b) 2.5 min, (c) 5 min, (d) 10 min, (e) 17.5 min, (f) 27.5 min, (g) 120 min

The conclusions drawn from the NMR and UV/Vis studies were further corroborated by emission lifetime measurements on **RuL2*N2*** in acetonitrile exposed to varying amounts of light. The results are shown in Figure 4. To minimise exposure of the sample to light during the lifetime measurements, these were continued for only 2−3 min (giving 1000 counts in the peak channel). In the first measurement, the contribution from the longer lived N4 isomer emission was only 15%. However, after only a few minutes of subsequent irradiation with a 450-W Xe lamp (using a water heat filter and a $\lambda > 385$ nm cut-off), this contribution had increased to 80%, indicating an almost complete conversion into the N4 isomer. When irradiation was continued, an instrument-response limited component ($\tau < 150$ ps) started to appear (not shown), and after 100 min of irradiation very little of the N4 isomer remained. We attribute the very short-lived component to the photolysed complex in which the L2 ligand had presumably been replaced by acetonitrile.

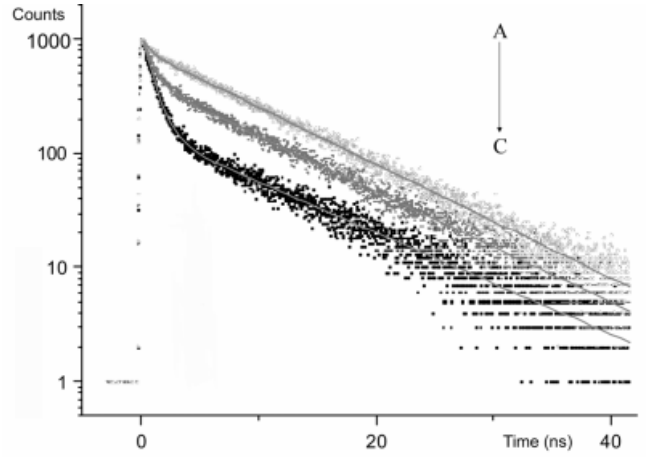

Figure 4. Emission decays for the same sample of **RuL2*N2*** in acetonitrile; curve A: sample prepared in the dark; curve B: after 1.5 min of irradiation with an Xe lamp; curve C: after 6.5 min of irradiation; the lines are double-exponential fits to the data, with lifetimes of 1.0 ns and 9.0 ns; the contribution from the slower component increased from 15% in A to 40% in B and 80% in C

Since **RuL4*N2* and RuRuL4*N2N2′*** also showed a double-exponential emission decay, NMR experiments were also carried out for the L4 compounds. For all three complexes, irradiation in acetone resulted in a complex mixture of products, which could be attributable to partial isomerisation and decomposition of the starting material and products. The results obtained from these experiments were not further analysed.

Concluding Remarks

The results obtained in this investigation demonstrate the importance of steric factors in the photochemical properties of ruthenium polypyridyl compounds. Earlier studies[4] have shown that for the protonated L1 complexes, a *reversible* N2/N4 photoinduced isomerisation is taking place. The results obtained for the L2 complex indicate that sterically hindered complexes (i.e. **RuL2*N2***), have the tendency to release the steric congestion upon photolysis by converting into the corresponding unhindered isomer (i.e. **RuL2*N4***). The presence of a steric constraint in the compound therefore leads to an *irreversible* photoisomerisation.

Pyridyltriazoles are mainly σ-donor ligands and have only limited π-acceptor properties. Therefore it seems likely that the small differences observed in the electronic spectra and in the $Ru^{II/III}$ redox potentials of the different isomers can be explained by a reduced σ-donor capability of the N2 isomer owing to steric hindrance. This leads to a lower excited-state ^{3}MC level in the N2 isomer than in the N4 isomer and facilitates the photochemically induced isomerisation of the N2 isomer by a photochemically driven process.

When substituents are present at both the N1 and C5 positions (as in the three L4 complexes), neither of the possible isomers is sterically unhindered. Hence, irradiation of these complexes results in a mixture of different isomers of similar stability (or, in other words, ''photochemical instability'').

Experimental Section

Materials: All synthetic reagents were of commercial grade and no further purification was employed, unless otherwise stated. All solvents employed in spectroscopic and electrochemical measurements were of HPLC or spectroscopic grade.

Experimental Methods: ^{1}H NMR spectra were recorded with a Bruker AC400 (400 MHz) instrument. For NMR-scale photochemical experiments, 5−10 mg of a given complex was dissolved in [D_3]acetonitrile or [D_6]acetone (0.5 mL), placed in a borosilicate NMR tube and irradiated using a 150-W halogen lamp. NMR spectra were taken at regular intervals and the degree of isomerisation checked by integration of the CH_3 resonance signals. − UV/Vis spectra (accuracy ± 2 nm) were obtained using a Shimadzu UV3100 UV/Vis−NIR spectrophotometer interfaced to an Elonex PC433 personal computer. The estimated error of the extinction coefficients is 5%. − Emission spectra (accuracy ± 5 nm) were obtained with a Perkin−Elmer LS50B luminescence spectrometer

equipped with a red-sensitive Hamamatsu R928 detector, interfaced with an Elonex PC466 personal computer employing Perkin−Elmer FL WinLab custom-built software. At room temperature, unless otherwise indicated, acetonitrile was the solvent used, and excitation and emission slit widths of 10 nm, were employed. At 77 K measurements were carried out in ethanol/methanol (4:1, v/v) using excitation and emission slit widths of 5 nm. The spectra were not corrected for the photomultiplier response. − For electrochemical measurements, HPLC grade acetonitrile dried with molecular sieves was employed. Potentials are ± 50 mV. The electrolyte used was 0.1 M tetraethylammonium perchlorate (TEAP). The electrochemical cell used was a conventional three-compartment cell with glass frits. The reference electrode used was a saturated calomel electrode. The working electrode was a 3-mm diameter teflon shrouded glassy carbon electrode and a platinum gauze was employed as the counter electrode. Prior to reduction measurements, the solutions were degassed for 15 min with nitrogen. Cyclic voltammetry (100 mVs^{-1}) was carried out using a CH instruments Model 660 electrochemical workstation interfaced to an Elonex 486 PC. Analytical HPLC experiments were carried out using a Waters HPLC system, consisting of a model 501 pump, a 20-μL injector loop, a Partisil SCX radial PAK cartridge mounted in a radial compression *Z* module and a Waters 990 photodiode array detector. An NEC APCIII computer controlled the system. The detection wavelength used was 280 nm and the flow rate was 2.0 mL/min. The mobile phase was CH_3CN/H_2O (80:20) containing 0.1 M $LiClO_4$. Semipreparative HPLC was carried out using an ACS pump, a 1-mL injection loop and a Waters Partisil SCX 10 μm cation exchange column (25 × 100 mm). The mobile phase used was $CH_3CN:H_2O$ (80:20) containing KNO_3 (0.12−0.20 M). The flow rate used varied between 1.50 and 2.0 mL/min.

Single-Photon Counting: Fluorescence lifetimes were determined using time-correlated single-photon counting. The excitation source had a tuneable output of a 200 kHz and a 120 femtosecond optical parametric amplifier (OPA, Coherent Radiation Inc). This device was pumped by a regenerative amplifier (700 μJ, 150 fs, 200 kHz) seeded by the 80 fs output of a Ti:Sapphire oscillator. The frequency-doubled fundamental generated in the OPA was used to excite the samples at 400 nm. A polariser was located before the sample to define the vertical polarisation of the excitation light and all fluorescence measurements were carried out with an analysing polariser before the detector was oriented at the magic angle (54.7°), relative to the excitation polarisation, to remove anisotropy effects. Fluorescence was observed through an interference filter centred at 600 nm (Oriel, USA) with a full-width at half-maximum of 10 nm. A microchannel plate multiplier (Hamamatsu) was used for the detection. Instrumental response curves were measured by exchanging the 600 nm interference filter after the sample with a 400 nm filter and recording the scattering from a scatter solution. The instrumental response (FWHM) was ca. 100 ps. The fluorescence decay data were analysed with a nonlinear least-squares program using a modified Levenberg−Marquardt algorithm with iterative reconvolution. The reduced χ^2 and residual plots were used to judge the quality of the fits. The samples for emission lifetime measurements were dissolved in spectroscopic grade acetonitrile (Merck) to an optical density of ca. 0.3 at the excitation wavelength. The solvents were not degassed since quenching by O_2 had negligible effect on the short lifetimes measured. Lifetimes are ± 10%.

Ligand Synthesis

Synthesis of 1,4-Bis[1-methyl-3-(2-pyridyl)-1,2,4-triazol-5-yl]benzene (L4)

Step 1. Synthesis of *N2*-methyl-2-pyridylamidrazone: 2-Cyanopyridine (36 g, 0.35 mol) and excess methylhydrazine (18.43 g, 0.40 mol) were mixed in a minimum amount of ethanol and allowed to stir overnight. The pale yellow crystalline product was filtered, washed with diethyl ether and air dried. Yield 26.7 g (50%). − M.p. 108−110 °C (ref.[12] 109−110 °C). − ^{1}H NMR ($CDCl_3$): δ = 7.24 (1 H, dd, pyridyl H^5), 7.67 (1 H, dd, pyridyl H^4), 8.08 (1 H, d, pyridyl H^3), 8.50 (1 H, d, pyridyl H^6), 5.24 (2 H, br. s, NH), 2.98 (3 H, s, CH_3). − ^{13}C NMR ($CDCl_3$): δ = 38.48, 119.60, 123.32, 136.02, 146.41, 147.77, 150.72.

Step 2. Synthesis of *N*,*N*′-Terephthaloylbis[(*N2*-methyl-2-pyridyl)hydrazidine]: This intermediate was prepared by the dropwise addition of a THF solution (30 cm^3) of terephthaloyl dichoride (5.08 g, 0.025 mol) to a solution of *N2*-methyl-2-pyridylamidrazone (7.50 g, 0.05 mol) and triethylamine (10 cm^3) in THF while maintaining the reaction mixture at 0°C. The reaction mixture was then reduced to approximately 25 mL and an equal volume of water was added. The yellow product was filtered, washed with water, hot methanol and diethyl ether, dried under vacuum and then left in an oven at 60 °C for 24 h. Yield 7.00 g (65%). − M.p. 178−180 °C. − ^{1}H NMR ($CDCl_3$): δ = 8.15 (2 H, s, phenyl), 8.10 (1 H, d, pyridyl H^3), 7.65 (1 H, dd, pyridyl H^4), 7.43 (1 H, dd, pyridyl H^5), 8.60 (1 H, d, pyridyl H^6), 10.30 (1 H, br. s, NH), 4.11 (3 H, s, CH_3). − ^{13}C NMR ($CDCl_3$): δ = 38.50, 120.82, 124.67, 128.85, 129.10, 136.89, 148.24, 150.26, 153.79, 161.2.

Step 3. Cyclization of *N*,*N*′-Terephthaloylbis[(*N2*-methyl-2-pyridyl)hydrazidine] to Form L3: *N*,*N*′-Terephthaloylbis[(*N2*-methyl-2-pyridyl)hydrazidine] (7.00 g, 0.017 mol) was suspended in a minimum volume (ca. 30 mL) of ethylene glycol and heated at reflux for 2 h. A white crystalline precipitate was obtained upon cooling of the solution. Further precipitation of the product was induced by the addition of a small amount of water to the mother liquor. The ligand was recrystallised from boiling methanol, filtered and dried under vacuum overnight. Yield 4.20 g (66%). − M.p. 278−280 °C. − ^{1}H NMR ($CDCl_3$): δ = 8.07 (2 H, s, phenyl), 8.10 (1 H, d, pyridyl H^3), 7.92 (1 H, dd, pyridyl H^4), 7.45 (1 H, dd, pyridyl H^5), 8.67 (1 H, d, pyridyl H^6), 4.12 (3 H, s, CH_3). − ^{13}C NMR ($CDCl_3$): δ = 37.65, 121.58, 124.15, 129.00, 129.13, 137.16, 149.45, 149.71, 154.26, 159.88. − MS; *m*/*z*: 395 $[M + 1]^+$. − $C_{22}H_{18}N_8$: calcd. C 66.98, H 4.60, N 28.41; found C 66.69, H 4.61, N 27.95.

Synthesis of Metal Complexes: *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$[13] was prepared as reported in the literature. **RuL2*N4*** and **RuL3*N2*** were prepared as reported before.[1] **RuL2*N2*** was prepared by direct methylation[7] of **RuL1*N2***.[1]

Synthesis of $[Ru(bpy)_2L4](PF_6)_2$: L4 (0.789 g, 2 mmol) was dissolved in hot methanol/water (2:1, v/v). To the solution was added *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (0.312 g, 0.6 mmol) and the mixture was heated at reflux for 6 h. Following the removal of most of the solvent by rotary evaporation and the addition of saturated aqueous NH_4PF_6 solution, the resulting precipitate was filtered and dried. HPLC analysis revealed the presence of two isomers in a 30:70 ratio (isomer 1/isomer 2). These were obtained in a pure form by semipreparative HPLC using acetonitrile/water (80:20) containing 0.11 M KNO_3 as the mobile phase and a flow rate of 1.7 mL/min. Total yield after purification (isomer 1 + isomer 2): 0.20 g (30%).

Isomer 1 (RuL4*N4*): $C_{42}H_{34}F_{12}N_{12}P_2Ru\cdot 3H_2O$: calcd. C 45.78, H 3.50, N 14.58; found C 45.24, H 3.12, N 14.14.

Isomer 2 (RuL4*N2*): $C_{42}H_{34}F_{12}N_{12}P_2Ru\cdot H_2O$: calcd. C 45.19, H 3.23, N 15.06; found C 45.41, H 3.15, N 14.93.

Synthesis of [(Ru(bpy)$_2$)$_2$L4](PF$_6$)$_4$·3H$_2$O (RuRuL4*N2N2′*): *cis*-[Ru(bpy)$_2$Cl$_2$]·2H$_2$O (0.624 g, 1.2 mmol) and L4 (0.197 g, 0.5 mmol) were heated at reflux in ethanol/water (2:1, v/v) for 6 h. Upon cooling of the reaction mixture, a few drops of a saturated aqueous solution of ammonium hexafluorophosphate were added, whereupon a bright orange precipitate was obtained. This was filtered and recrystallised from acetone/water (2:1, v/v). HPLC analysis of the product showed the presence of only one isomer. Yield 0.30 g (33%). − $C_{62}H_{50}F_{24}N_{16}P_4Ru_2$·3H$_2$O: calcd. C 40.11, H 3.04, N 12.07; found C 40.27, H 3.08, N 12.02.

Protonation of the Heterocyclic Cp-Anion Equivalent [Pyrrolyl-B(C_6F_5)$_3$]Li − Formation of a Useful Neutral Brønsted Acid for the Generation of Homogeneous Metallocene Ziegler Catalysts

Gerald Kehr,[a] Rolf Roesmann,[a] Roland Fröhlich,[a][‡] Christiane Holst,[a][‡] and Gerhard Erker*[a]

Keywords: Protonations / Heterocycles / Homogeneous catalysis / Brønsted acids / Zirconium

N-pyrrolyllithium (**1**) adds to B(C_6F_5)$_3$ to yield [(C_4H_4N)B(C_6F_5)$_3$]Li (**3**). The corresponding monoetherate (**3**·OEt_2) was characterized by X-ray diffraction and shows an η^5 coordination of the pyrrolyl moiety to the lithium cation. Treatment of **3** with HCl in ether leads to H^+ addition at a pyrrolyl α-position to yield the neutral dipolar Brønsted acid system [(C_4H_5N)B(C_6F_5)$_3$] (**4**). The reagent **4** can be used to protonate $Cp_2Zr(CH_3)_3$ to yield [$Cp_2Zr(CH_3)^+$(C_4H_4N)B(C_6F_5)$_3^-$] (**6**) and methane. H^+ transfer from **4** to (butadiene)-zirconocene results in the formation of the (π-allyl)metallocene salt [(C_4H_7)ZrCp_2^+(C_4H_4N)B(C_6F_5)$_3^-$] **(8)**. In analogous reactions, the neutral Brønsted acid was employed as a protonating activator component for the generation of homogeneous Ziegler catalysts derived from a variety of (butadiene)- or (dimethyl)*ansa*-metallocenes. The systems generated by treatment with **4** show comparable activities in ethene or propene polymerization reactions as conventionally generated Group 4 metallocene Ziegler catalysts.

Introduction

The generation of homogeneous Group 4 metallocene Ziegler catalysts and related early and late transition metal catalyst systems is mostly carried out by treatment of the respective metal complex catalyst precursors with methylaluminoxane.[1] Alternatively, alkyl anion abstraction from, for example, ^{R}Cp$_2$MR$_2$ species, with the trityl cation[2] or with B(C_6F_5)$_3$ has also been reported,[3] as has the use of single component catalysts derived from ^{R}Cp$_2$M(butadiene) complexes by addition of B(C_6F_5)$_3$ or the related (pyrrolyl)B(C_6F_5)$_2$ Lewis acids.[4,5] In principle, formation of the active [^{R}CpMR$^+$] catalyst species by protonation with a suitable Brønsted acid would be an alternative, provided sufficiently non-nucleophilic conditions could be maintained throughout the reaction. Ammonium salts have been successfully employed for this purpose, especially dimethylanilinium reagents such as [PhNMe$_2$H$^+$] with [BPh$_4^-$] or [B(C_6F_5)$_4^-$] anions.[6] Sometimes low solubilities and the stoichiometric formation of a tertiary amine have complicated this protonation route for the generation of active homogeneous Ziegler catalysts. We here report the formation and some features of a neutral dipolar Brønsted acid reagent that may make the protonation route in some cases an attractive alternative to the activation methods presently used in homogeneous organometallic Ziegler catalyst formation and the chemistry of reactive organometallic cation systems.[7]

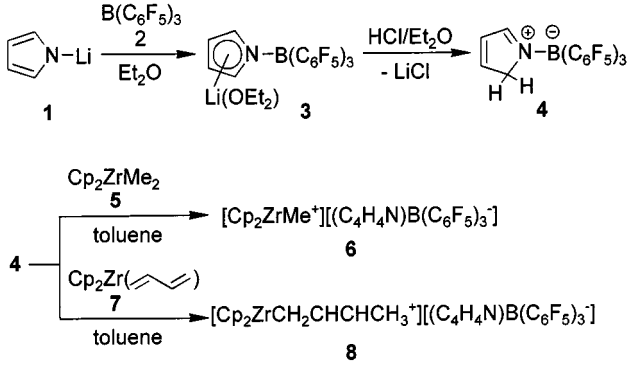
Results and Discussion

N-pyrrolyllithium (**1**) was treated with B(C_6F_5)$_3$ (**2**)[8] to yield the [(*N*-pyrrolyl)B(C_6F_5)$_3$]Li reagent **3** (Scheme 1). Complex **3** shows symmetrical pyrrolyl ^{1}H/^{13}C NMR resonances at δ = 6.72 (2,5-H) and 5.84 (3,4-H)/125.0 (C2,5) and 108.9 (C3,4), and a ^{11}B NMR signal at δ = −8.2 (in [D_6]benzene) indicating tetracoordinated boron. A ^{7}Li NMR resonance (in [D_8]THF) at δ = −2.6 points to a mononuclear geometry of the lithium compound **3** in this coordinating solvent.[9] Single crystals of **3**·OEt_2 were obtained from pentane/ether solution at 8 °C that allowed for characterization by an X-ray crystal structure analysis.

The structure shows that the pyrrolyl unit is bonded to a tetravalent boron atom [N1−B: 1.576(4) Å]. The pyrrolyl moiety of the [(C_4H_4N)−B(C_6F_5)$_3^-$] anion exhibits a distorted η^5 coordination to the lithium atom.[10] The Li−N1 bond is short at 2.281(7) Å, the Li−C5 [2.350(8) Å]/Li−C2 [2.423(8) Å], and Li−C4 [2.492(9) Å]/Li−C3 [2.533(9) Å] linkages become increasingly longer, but all heavy atoms of the planar pyrrolyl framework are clearly within bonding



Scheme 1

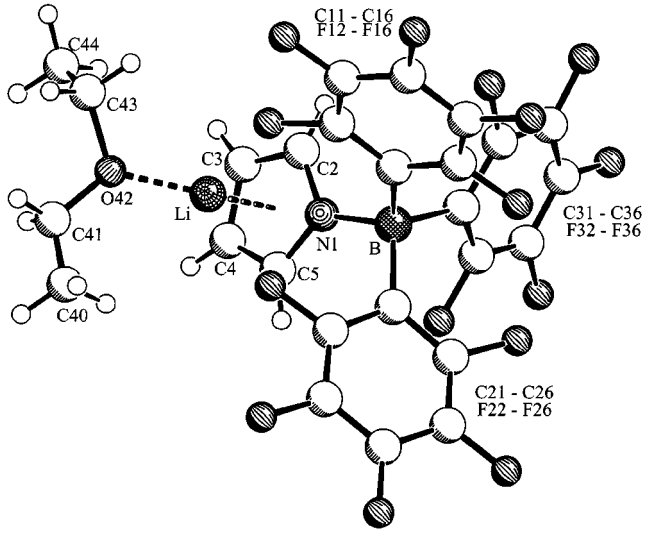
distance of the lithium atom. Extensive bond delocalization is observed inside the C_4H_4N moiety (see Figure 1). The lithium atom in **3** is further coordinated to an ether molecule [O42−Li: 1.830(7) Å] and, remarkably, to two fluorine atoms from the *ortho* F−C bonds of two of the boron bound -C_6F_5 substituents [Li−F16: 2.041(7) Å, Li−F26: 2.467(8) Å]. This additional lithium-fluorine interaction,[11] which is in the same range of bond lengths as the Li−C(pyrrolyl) unit, makes the coordination geometry of the lithium atom in complex **3** distorted tetrahedral [bond angles O42−Li−pyrrolyl (centroid): 136.0°; O42−Li−F16: 105.4(3)°; O42−Li−F26: 118.5(4)°; F16−Li−F26: 81.2(3)°].



Fjgure 1. Molecular structure of complex **3**; selected bond lengths (Å) and angles (°): B−C21 1.637(5), B−C31 1.647(5), B−C11 1.656(5); C16−F16−Li 136.4(3), C26−F26−Li 136.4(2), N1−B−C21 109.4(3), N1−B−C31 102.5(2), N1−B−C11 112.6(3), C21−B−C31 115.8(3), C21−B−C11 104.1(3), C31−B−C11 112.7(3), C2−N1−B 125.0(3), C2−N1−C5 106.8(3), C5−N1−B 127.1(3); for additional values see text

Treatment of **3** with anhydrous HCl in ether resulted in protonation at an α-carbon atom of the pyrrol ring with formation of **4**. The neutral dipolar product was isolated in 57% yield after recrystallization from toluene. It shows four characteristic ^{1}H NMR resonances of the *N*-borylated pyrrolium ring system at δ = 7.35, 6.34, 5.45 and 3.53 in a 1:1:1:2 ratio {^{13}C NMR signals at δ = 171.1 (C2), 155.5 (C4), 127.2 (C3), 65.3 (C5) in [D_6]benzene; ^{15}N NMR resonance at δ = −145; ^{11}B NMR signal at δ = −7.6 in [D_8]toluene}.

The X-ray crystal structure analysis of **4** (single crystals from toluene at −18 °C; Figure 2) shows a planar pyrrolium ring system bonded to boron [N1−B6: 1.608(2) Å] that exhibits alternating double and single bonds [N1−C2: 1.298(2) Å; C2−C3: 1.431(3) Å; C3−C4: 1.318(3) Å; C4−C5: 1.474(3) Å; N1−C5: 1.449(2) Å; hydrogen atoms at the C_4H_5N ring were located from difference Fourier maps].

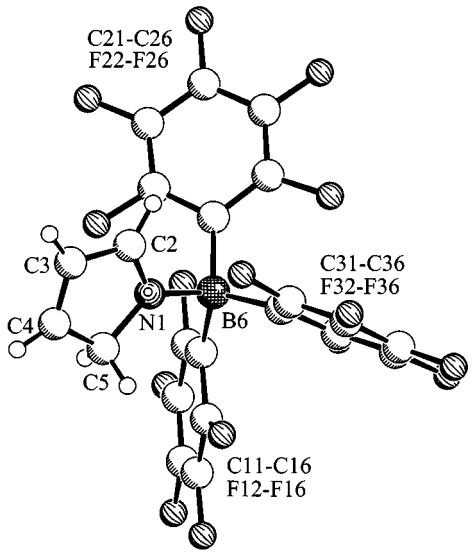


Figure 2. Molecular structure of **4**; selected bond lengths (Å) and angles (°): B6−C21 1.640(2), B6−C31 1.647(2), B6−C11 1.653(2); N1−B6−C21 105.13(12), N1−B6−C31 109.01(12), N1−B6−C11 106.37(12), C21−B6−C31 112.79(13), C21−B6−C11 114.36(13), C31−B6−C11 108.83(12), C2−N1−C5 107.61(14), C2−N1−B6 126.36(14), C5−N1−B6 125.98(13), N1−C2−C3 112.22(17), C4−C3−C2 106.83(18), C3−C4−C5 109.18(18), N1−C5−C4 104.05(16); for additional values see text

The neutral Brønsted acid **4** turns out to be well suited for the generation of group 4 metallocene cation complexes by protonation reactions of a variety of organometallic precursors. Two typical examples are the proton transfer reactions of **4** with dimethylzirconocene (**5**) and (η^4-butadiene)-zirconocene (**7**, see Scheme 1). Compound **4** reacts with $Cp_2Zr(CH_3)_2$ (**5**) in toluene at ambient temperature during 1 h to yield cleanly the organometallic salt [$Cp_2ZrCH_3^+$][$(C_4H_4N)B(C_6F_5)_3^-$] (**6**). The proton transfer reaction in this case results in the liberation of one equivalent of methane. Compound **4** rapidly transfers a proton to the butadiene ligand of **7** to yield a single [Cp_2Zr(*trans*-crotyl)$^+$][$(C_4H_4N)B(C_6F_5)_3^-$] isomer (**8**).

Both reactions were used for the generation of active homogeneous metallocene Ziegler catalysts for ethene polymerization in situ. In addition, the Brønsted acid **4** was employed in the generation of active ethene and propene polymerization catalysts from dimethyl- or η^4-butadiene complexes of a series of *ansa*-metallocene frameworks (see Scheme 2).[12,13] The resulting catalysts were compared with their conventionally generated analogues [i.e. obtained by MAO treatment of the respective metallocene dichlorides, or $B(C_6F_5)_3$ treatment of the respective metallocene dimethyl complexes or -η^4-butadiene complexes], and found to be comparable in activity and selectivity with these established procedures (see Table 1).[13] These reactions demonstrate that H^+ transfer from this new, readily available neutral proton source [$(C_4H_5N)B(C_6F_5)_3$] (**4**) provides an attractive alternative for the formation of reactive organometallic cations and related active catalyst systems, with concurrent generation of the essentially non-nucleophilic counter anion [$(C_4H_4N)B(C_6F_5)_3^-$]. A variety of interesting applications of the neutral Brønsted acid **4** and related sys-

tems in organometallic chemistry and catalysis can be envisioned. Further examples are being actively investigated in our laboratory.

[a] Reactions at 20 °C, 1 bar, if not otherwise noted. – [b] In g polymer/mmol[Zr]·bar·h. – [c] 40 °C, 2 bar. – [d] From ref. 13. – [e] Not determined. – [f] From ^{13}C NMR pentade analysis. – [g] These reactions were not carried out under completely isothermal conditions because of their high exothermicities; that is probably the cause of the slightly different isotacticities observed.

Experimental Section

All reactions were carried out in an inert atmosphere (argon) using Schlenk-type glassware or in a glovebox. Solvents were dried and distilled under argon prior to use. For additional general information including a description of the instrumentation used for physical characterization of the compounds see refs. 5 and 11a.

Preparation of $[(C_4H_4N)B(C_6F_5)_3]Li$ (3): Solid *N*-pyrrolyllithium[14] (0.53 g, 7.27 mmol) was mixed with solid $B(C_6F_5)_3$ (3.72 g, 7.27 mmol). Then, 50 mL of diethyl ether was added and the suspension stirred for 3 h at ambient temperature. Solvent was removed in vacuo and the residue suspended in pentane. The solid product was collected by filtration, washed with pentane (3 × 20 mL) and dried in vacuo to yield **3**·Et_2O (4.5 g, 91%), m.p. 137 °C, decomp. at 204 °C. – ^1H NMR (600 MHz, [D$_6$]benzene, 298 K): δ = 6.72 (m, 2 H, 2,5-H), 5.84 (m, 2 H, 3,4-H), 2.80 (q, 4 H, CH_2 of Et_2O), 0.68 (t, 6 H, CH_3 of Et_2O). – ^{13}C NMR (150.7 MHz, [D$_6$]benzene, 298 K): δ = 148.2 ($^1J_{FC}$ = 234 Hz), 139.8 ($^1J_{FC}$ = 250 Hz), 137.6 ($^1J_{FC}$ = 249 Hz), 121.3 (br., *o*-, *p*-, *m*-, *ipso*-C of C_6F_5), 125.0 (C2,5), 108.9 (C3,4), 65.9, 14.0 (Et_2O). – ^{11}B NMR (64.2 MHz, [D$_6$]benzene, 300 K): δ = −8.2 ($\nu_{1/2} \approx 50$ Hz). – ^7Li NMR (77.8 MHz, [D$_8$]THF, 300 K): δ = −2.6 ($\nu_{1/2} \approx 2$ Hz). – ^{19}F NMR (282 MHz, [D$_6$]benzene, 300 K): δ = −134.9, −157.5, −162.7 (*o*-, *p*-, *m*-F of C_6F_5). – $C_{26}H_{14}BF_{15}LiNO$ (659.1): calcd. C 47.38, H 2.14, N 2.13; found C 47.63, H 2.95, N 1.90.

X-ray Crystal Structure Analysis of 3: $C_{26}H_{14}BF_{15}LiNO$, M = 659.13, yellow crystal 0.20 × 0.20 × 0.10 mm, a = 11.478(2), b = 15.266(6), c = 15.539(2) Å, β = 93.66(1)°, V = 2717.2(12) Å^3, $\rho_{calcd.}$ = 1.611 g cm^{-3}, μ = 15.22 cm^{-1}, empirical absorption correction by ψ scan data ($0.751 \le T \le 0.863$), Z = 4, monoclinic, space group $P2_1/n$ (No. 14), λ = 1.54178 Å, T = 223 K, ω/2θ scans, 5820 reflections collected ($+h$, $-k$, $\pm l$), [(sinθ)/λ] = 0.62 Å^{-1}, 5540 independent (R_{int} = 0.029) and 2856 observed reflections [$I \ge 2\sigma(I)$], 408 refined parameters, R = 0.062, $wR2$ = 0.166, max. residual electron density 0.40 (−0.35) e Å^{-3}, hydrogens calculated and refined as riding atoms.

Preparation of $[(C_4H_5N)B(C_6F_5)_3]$ (4): A 1 M solution of HCl in diethyl ether (3.00 mL, 3.00 mmol) was added dropwise with rapid stirring to a solution of **3**·Et_2O (1.50 g, 2.56 mmol) in 60 mL of ether. Volatiles were removed in vacuo after 30 min. and the residue stirred with pentane (20 mL). The solid was collected by filtration and extracted three times with toluene. Solvent was removed from the combined toluene phases in vacuo. The residue was recrystallized from toluene at -18 °C to yield **4** (852 mg, 57%), m.p. 178 °C. – ^1H NMR (600 MHz, [D$_6$]benzene, 298 K): δ = 7.35 (br., $^1J_{CH}$ = 184 Hz, 1 H, 2-H), 6.34 (m, $^1J_{CH}$ = 180 Hz, 1 H, 4-H), 5.45 (m, $^1J_{CH}$ = 182 Hz, 1 H, 3-H), 3.53 (br., $^1J_{CH}$ = 143 Hz, 2 H, 5-H). – ^{13}C NMR (150.7 MHz, [D$_6$]benzene, 298 K): δ = 171.1 (C2), 155.5 (C4), 148.2 ($^1J_{FC}$ = 241 Hz), 140.6 ($^1J_{FC}$ = 253 Hz), 137.6 ($^1J_{FC}$ = 249 Hz), 118.5 (br., *o*-, *p*-, *m*-, *ipso*-C of C_6F_5), 127.2 (C3), 65.5 (C5). – ^{11}B NMR (192.2 MHz, [D$_6$]benzene, 298 K): δ = −7.6 ($\nu_{1/2} \approx 90$ Hz). – ^{19}F NMR (563.7 MHz, [D$_8$]toluene, 298 K): δ = −132.3, 155.7, −162.6 (*o*-, *p*-, *m*-F of C_6F_5). – ^1H,^{15}N-GHMBC (600/60.7 MHz, [D$_8$]toluene, 213 K): δ = 6.93, 6.07, 5.20/−145 (2-, 4-, 3-H/N). – $C_{22}H_5BF_{15}N$ (579.1): calcd. C 45.63, H 0.87, N 2.42; found C 45.50, H 1.11, N 2.27.

X-ray Crystal Structure Analysis of 4: $C_{22}H_5BF_{15}N$, M = 579.08, light yellow crystal 0.30 × 0.10 × 0.10 mm, a = 10.415(1), b = 11.079(1), c = 18.160(1) Å, β = 98.54(1)°, V = 2072.2(3) Å^3, $\rho_{calcd.}$ = 1.856 g cm^{-3}, μ = 2.04 cm^{-1}, empirical absorption correction by SORTAV ($0.941 \le T \le 0.980$), Z = 4, monoclinic, space group $P2_1/n$ (No. 14), λ = 0.71073 Å, T = 198 K, ω and φ scans, 8760 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sinθ)/λ] = 0.65 Å^{-1}, 4722 independent (R_{int} = 0.022) and 3772 observed reflections [$I \ge 2\sigma(I)$], 367 refined parameters, R = 0.042, $wR2$ = 0.091, max. residual electron density 0.30 (−0.21) e Å^{-3}, hydrogens from difference Fourier maps and refined as riding atoms.

Data sets were collected with Enraf−Nonius CAD4 and Nonius Kappa-CCD diffractometers, the latter one equipped with a rotating anode generator Nonius FR591. Programs used: data collection EXPRESS (Nonius B.V., **1994**) and COLLECT (Nonius B.V., **1998**), data reduction MolEN (K. Fair, Enraf−Nonius B.V., **1990**) and Denzo-SMN (Z. Otwinowski, W. Minor, *Methods in Enzymology* **1997**, *276*, 307−326), absorption correction for CCD data SORTAV (R. H. Blessing, *Acta Cryst.* **1995**, *A51*, 33−37; R.H.

Blessing, *J. Appl. Cryst.* **1997**, *30*, 421−426), structure solution SHELXS-97 (G. M. Sheldrick, *Acta Cryst.* **1990**, *A46*, 467−473), structure refinement SHELXL-97 (G. M. Sheldrick, Universität Göttingen, 1997), graphics SCHAKAL (E. Keller, Universität Freiburg, 1997).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications CCDC-144532 (**3**) and CCDC-144533 (**4**). Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Reaction of $Cp_2Zr(CH_3)_2$ (5) with $[(C_4H_5N)B(C_6F_5)_3]$ (4); Generation of 6: Toluene (5 mL) was added to a solid mixture of **5** (101 mg, 0.40 mmol) and **4** (233 mg, 0.40 mmol). Pentane (80 mL) was added to the reaction mixture after 1 h to precipitate the product **6**, which was collected by filtration, washed with pentane (10 mL) and dried in vacuo. Yield of **6**: 210 mg, 64%. − ^{1}H NMR (600 MHz, [D$_8$]toluene, 298 K): δ = 6.98 (br., 2 H, pyrrolyl 2-H, 5-H), 5.27 (s, 10 H, Cp), 5.06 (m, 2 H, pyrrolyl 3-H, 4-H), -0.02 (s, 3 H, Zr−CH$_3$). − ^{13}C NMR (150.7 MHz, [D$_8$]toluene, 223 K): δ = 148.1 ($^1J_{CF}$ = 242 Hz), 139.7 ($^1J_{CF}$ = 249 Hz), 137.3 ($^1J_{CF}$ = 248 Hz), 120.7 (br., *o*-, *p*-, *m*-, *ipso*-C of C$_6$F$_5$), 137.2 ($^1J_{CH}$ = 189 Hz) and 101.8 ($^1J_{CH}$ = 166 Hz, pyrrolyl C2,5 and C3,4), 113.0 ($^1J_{CH}$ = 176 Hz, Cp), 40.2 ($^1J_{CH}$ = 120 Hz, ZrCH$_3$) (assignments confirmed by ^{1}H,^{1}H-GCOSY, ^{1}H,^{13}C-GHSQC and ^{1}H,^{13}C-GHMBC experiments). − ^{11}B NMR (64.2 MHz, [D$_8$]toluene, 298 K): δ = −8.7 ($\nu_{1/2}$ = 110 Hz). − ^{19}F NMR (563.7 MHz, [D$_8$]toluene, 223 K): δ = −130.9, −157.3, −163.2 (*o*-, *p*-, *m*-F of C$_6$F$_5$).

Reaction of (Butadiene)zirconocene (7) with 4; Generation of 8: Toluene (5 mL) was added at ambient temperature to a solid mixture of (*s-cis*-/*s-trans*-η^4-butadiene)ZrCp$_2$ (1:1) (**7**, 51 mg, 0.19 mmol) and **4** (107 mg, 0.19 mmol). The mixture was stirred for 30 min., then the solvent was removed in vacuo. The viscous residue was solidified by stirring with 50 mL of pentane. The product was collected by filtration, washed with pentane (2 × 10 mL) and dried in vacuo, yield of **8**: 106 mg (67%). − ^{1}H NMR (600 MHz, [D$_8$]toluene, 253 K): δ = 7.24, 4.87 (br., each 2 H, pyrrolyl), 4.66 (s, 10 H, Cp), 4.30 (dt, ^3J = 11 Hz, ^3J = 16 Hz, 1 H, =CH−), 3.37 (dq, ^3J = 6 Hz, ^3J = 16 Hz, 1 H, =C*H*−CH$_3$), 1.52 (d, ^3J = 11 Hz, 2 H, =CH$_2$), 1.28 (d, ^3J = 6 Hz, 3 H, CH$_3$). − ^{13}C NMR (150.7 MHz, [D$_8$]toluene, 253 K): δ = 148.3 ($^1J_{CF}$ = 244 Hz), 139.7 ($^1J_{CF}$ = 256 Hz), 137.4 ($^1J_{CF}$ = 249 Hz, *o*-, *p*-, *m*-C of C$_6$F$_5$), *ipso*-C of −C$_6$F$_5$ and pyrrolyl-C not observed, 123.2 ($^1J_{CH}$ = 150 Hz, =CH−), 108.0 ($^1J_{CH}$ = 177 Hz, Cp), 104.1 ($^1J_{CH}$ = 152 Hz, =*C*H−CH$_3$), 47.0 ($^1J_{CH}$ = 155 Hz, =CH$_2$), 18.6 ($^1J_{CH}$ = 126 Hz, CH$_3$) (assignment supported by ^{1}H,^{13}C-GHSQC). − ^{11}B NMR (64.2 MHz, [D$_8$]toluene, 298 K): δ = −8.8 ($\nu_{1/2}$ = 130 Hz). − ^{19}F NMR (563.7 MHz, [D$_8$]toluene, 223 K): δ = −130.8, −157.9, −163.5 (*o-, p-, m*-F of C$_6$F$_5$).

Polymerization Reactions with 4 as an Activator

a) Ethene Polymerization: A glass autoclave was charged with 300 mL of toluene and 2 mL of triisobutylaluminum, then thermostated for 1 h and the solution saturated with ethene (at 1 or 2 bar, see Table 1) for another hour. The catalyst was generated by treatment of the respective metallocene precursor with **4** in toluene, and this toluene solution was injected into the autoclave. The polymerization reaction was stopped by quenching with 50 mL aqueous HCl/methanol (1:5 v/v). The resulting polymer was washed subsequently with HCl, water, methanol and acetone and dried.

b) Propene Polymerization: Reactions were carried out analogously (at 2 bar). After quenching with HCl/CH$_3$OH, water (100 mL) was added. Stereoregular polypropylene samples were then collected by filtration and washed with HCl, water, methanol and acetone. Atactic polypropylene was extracted twice with toluene (200 mL); solvent was removed from the combined organic phases and the polymer dried in vacuo.

Characterization of Calcined and Reduced Multi-Component Co−Ni−Mg−Al-Layered Double Hydroxides

Didier Tichit,*[a] Solange Ribet,[a] and Bernard Coq[a]

Keywords: Clays / Cobalt / Nickel / Reductions / Spinel phases

Several Co–Ni–Mg–Al-layered double hydroxides (LDH) have been synthesized by coprecipitation at constant pH = 9. All samples present well crystallized, layered structures, no excess phases were detected by X-ray diffraction, and the lattice *a* parameter followed the Vegard correlation. The cations thus belong to the same, brucite-like, lattice. Calcined samples exhibit XRD patterns of the crystallographic phase preferentially adopted by the major cation in the LDH: i.e., a mixed oxide of the rock salt type in the case of Ni or Mg, and a spinel-like structure for Co. Surface areas reached maximum values in the range of 200–300 m^2g^{-1} after calcination at 573 K. They were stabilized with increasing Ni or Mg content, as higher amounts of mixed oxide phase were formed. Programmed temperature reduction showed two domains of H_2 consumption, assigned to reduction of $Co_{3-x}Ni_xO_4$ species below 720 K, and to NiMg(Al)O and $Co_{3-x-y}Ni_xMg_yAlO_6$, of rock salt type and spinel-like structures respectively, above this temperature. These assignments are in agreement with the XRD patterns and show that Ni and Co are associated in the same crystallographic phases.

Introduction

Layered double hydroxides (LDHs) or anionic clays of the general formula $[M_{1-x}^{2+}M_x^{3+}(OH)_2]^{x+}[A^{m-}]_{x/m}\cdot n\,H_2O$ are increasingly used as precursors of catalysts with varying divalent and trivalent cations in their layers.[1] These two cations are distributed inside brucite-like sheets in an octahedral environment. The structure is based on the stacking of these positively charged layers, with hydrated compensating anions in the interlamellar domain.[1,2] Interest in LDHs is undoubtedly increasing because not only two but, more frequently, several cations may be accommodated in the structure, thus leading to a wide variety of multi-component catalyst precursors. Therefore, the intrinsic properties of the resulting catalysts − like acido-basicity and hydrogenating or oxidizing capabilities − might be tuned through the nature and the relative quantities of the cations and the activation conditions. We previously reported that highly active and selective catalysts for the hydrogenation of acetonitrile into ethylamine were obtained when using Co/Ni/Mg/Al LDH precursors.[3] Improvements of these catalysts, which require Ni or Co metals deposited on poorly acidic supports, resulted from adjustment of the Mg content and of alloying Ni, the active metal, with Co.[3,4]

This work is aimed at the study of the synthesis and activation of quaternary Co−Ni−Mg−Al LDHs. Their decomposition has been followed under oxidizing and reducing atmospheres. Special attention has been paid to temperature programmed reduction (TPR) experiments to support XRD in the identification of the nature of phases present in the precursor.

Results

Synthesis of the LDH Precursors

Cationic contents of the synthesis solutions and formula of the solids as deduced from their chemical analysis are given in Table 1. It is assumed that all cobalt is in the form of Co^{2+}. The water content is evaluated from TG analysis. As can be seen, Co and Ni content in the layers is close to the corresponding levels in solution. In contrast, the Mg content is always slightly lower than expected. This behavior is in accordance with the respective precipitation pHs of Co, Ni, and Mg in their hydroxide forms, occurring from pH = 9 for the first two elements, but at pH above 10 for the last.

The slight variations described above obviously dictate that the layer charges of the different samples are not strictly identical, since $x = Al^{3+}/(\Sigma M^{2+}+Al^{3+})$ is in the range of 0.25−0.28.

Both nitrate and carbonate anions are present in the structures, always with an excess of anionic charge. This probably results from the presence not only of CO_3^{2-} but also of HCO_3^-, very often formed at pH ≈ 9. The presence of CO_3^{2-} is consistent with contamination by air during synthesis.

XRD profiles of the samples, dried at 353 K, are reported in Figure 1. They show that a single hydrotalcite-like phase is present in all cases, with several (00*l*) reflections. The (003) reflection is usually sharp; in contrast, the (006) and higher reflections are broad in the samples containing Co, Ni, and Mg concomitantly. Such features provide evidence of structures poorly ordered along the *c* axis.

Ni(2)Mg(1)Al	0.00	0.50	0.25	0.25	$[Ni_{0.53}Mg_{0.19}Al_{0.28}(OH)_2](CO_3^{2-})_{0.05}(NO_3^-)_{0.22}$, 0.6 H_2O	0.304(1)	2.520(6)
Co(1.5)Ni(1.5)Al	0.38	0.37	0.00	0.25	$[Co_{0.36}Ni_{0.36}Al_{0.28}(OH)_2](CO_3^{2-})_{0.04}(NO_3^-)_{0.23}$, 0.5 H_2O	0.305(3)	2.620(0)
Co(0.8)Ni(0.8)Mg(1.4)Al	0.30	0.30	0.15	0.25	$[Co_{0.32}Ni_{0.33}Mg_{0.10}Al_{0.26}(OH)_2](CO_3^{2-})_{0.12}(NO_3^-)_{0.21}$, 0.6 H_2O	0.305(9)	2.428(5)
Co(1.2)Ni(1.2)Mg(0.6)Al	0.20	0.20	0.35	0.25	$[Co_{0.20}Ni_{0.20}Mg_{0.31}Al_{0.28}(OH)_2](CO_3^{2-})_{0.10}(NO_3^-)_{0.12}$, 0.6 H_2O	0.305(9)	2.530(2)

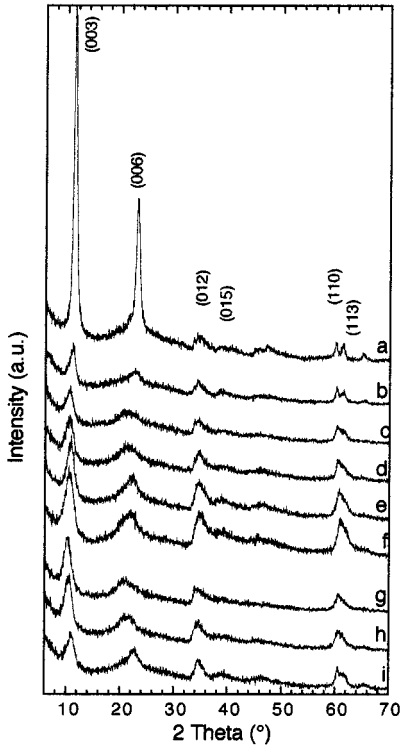

Figure 1. X-ray diffraction patterns of the different samples: (a): Co(3)Al, (b): Co(2)Mg(1)Al, (c): Co(1.5)Ni(0.5)Mg(1)Al, (d): Co(1)Ni(1)Mg(1)Al, (e): Co(0.5)Ni(1.5)Mg(1)Al, (f): Ni(2) Mg(1)Al, (g): Co(1.5)Ni(1.5)Al, (h): Co(1.2)Ni(1.2)Mg(0.6)Al, (i): Co(0.8)Ni(0.8)Mg(1.4)Al

Some peculiar characteristics can otherwise be quoted:

(1) for the series of materials of identical Mg content ($Mg^{2+}/\Sigma M^{2+}$ = 1:3), the (003) and (006) peaks become progressively sharper and the (11*l*) peaks vanish as the Ni content increases. Stacking order between the layers thus increases at the expense of that within the layers.

(2) Mg content has a lesser influence on the shape of the XRD patterns. Its smaller ionic size (0.065 nm) compared to Ni (0.069 nm) or Co (0.074 nm) induces less distortion of the layers.

Therefore, the orders along the *a* and *c* crystallographic directions of the multi-component LDHs mainly depend on their Co and Ni content. Accordingly, the lattice *a* parameter follows the Vegard correlation with the Co or Ni content (Figure 2), but is independent of the Mg content (Table 1). No clear relationship exists between the lattice *c* parameter and Co and Ni content, while a small decrease is noted with Mg content at similar Ni/(Co+Ni) ratio (Table 1). This could not reasonably be assigned to a variation of the layer charge. To sum up, the existence of a unique (003) line and the evolution of the lattice *a* parameter, in agreement with the Vegard correlation, show that all cations belong to the same brucite-like lattice class. Moreover, a low crystallinity of the samples is in line with this assumption, if one considers that up to four cations are accommodated in the layers.

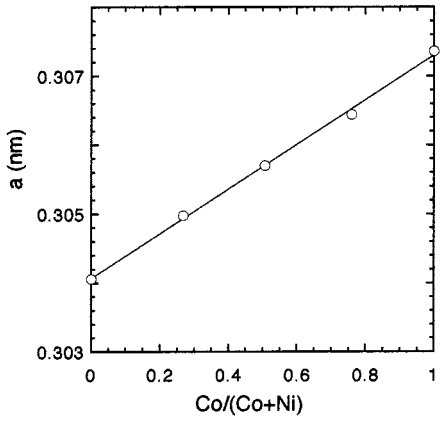

Figure 2. Variation of the lattice *a* parameter of the Co−Ni−Mg−Al samples as a function of Co/(Co+Ni) ratio for $Mg^{2+}/\Sigma M^{2+}$ = 1:3

Results of TG-DTG analysis are given in Table 2. Mass losses occur in two steps up to 973 K, as classically found with Mg−Al and M−Mg−Al samples (M = Ni, Co).[5−10] The low-temperature weight loss originates from the removal of water molecules in the interlayer space and weakly bonded CO_3^{2-} species.[5,7] Dehydroxylation of the layers with concomitant H_2O release, and decomposition of the anions result in the weight loss at 540−600 K. Total weight losses, in the range of 33−39 wt%, increase significantly with Mg content. This is due to the greater water release at ca 350 K in the Mg-containing samples, owing to the higher hydration ability of Mg compared to Ni and Co.

The first peak is at about 393 K in all cases, while there is a systematic shift of the second peak from 543 to 623 K when the Ni/(Co+Ni) molar ratio increases with similar Mg content.

Table 2. Weight losses and temperatures of maximum rates in the thermogravimetric analysis of the various samples

Samples	Total weight loss (%)	1st weight loss T_1 (K)	wt (%)	2nd weight loss T_2 (K)	wt (%)
Co(3)Al	28	463	10	503	18
Co(2)Mg(1)Al	35	393	11	543	24
Co(1.5)Ni(0.5)Mg(1)Al	37	393	10	563	27
Co(1)Ni(1)Mg(1)Al	37	393	10	583	27
Co(0.5)Ni(1.5)Mg(1)Al	38	403	11	603	27
Ni(2)Mg(1)Al	39	383	10	623	29
Co(1.5)Ni(1.5)Al	33	383	8	583	25
Co(1.2)Ni(1.2)Mg(0.6)Al	35	393	9	583	26
Co(0.8)Ni(0.8)Mg(1.4)Al	38	383	13	583	25

Calcination of the LDH Precursors

Calcination of LDH precursors leads to one or several phases. Their number and nature depend on the cations involved in the structure and on the temperature. However, some general tendencies can be expected, considering that below 1100 K, Ni and Mg probably form mixed oxides of NiO and MgO type on the one hand,[9,11,12] while, on the other hand, Co easily forms spinel-like structures.[7,8] The results from TG experiments prompted us to study the samples calcined at 573 and 773 K, since the main structural transformations of LDHs occur in this temperature range.

XRD patterns of the materials calcined at 773 K (Figure 3) look very different, depending on cation composition. For a given sample, the only change observed when the calcination temperature increases from 573 to 773 K is a better crystallinity.

For Ni(2)Mg(1)Al, the (111), (200), and (220) reflections of the NiO-like structure are recorded at 0.2422, 0.2087, and 0.1473 nm. These values are slightly shifted toward lower values than in the pure rock salt type single oxide (04-0835 ICDD data file), due to the presence of smaller ionic radius Al^{3+} within the lattice. For Co(2)Mg(1)Al, reflections at 0.4679, 0.2875, 0.2448, 0.2025, 0.1647, 0.1561, and 0.1432 nm can be assigned to the (111), (220), (311), (400), (422), (511), and (440) planes, respectively, of $CoAl_2O_4$ or Co_3O_4 spinel phases, which are indistinguishable. Such an assignment assumes that Co_3O_4 is thermodyamically more stable under air than CoO.[13] Moving now to quaternary LDHs, the case of Co(1)Ni(1)Mg(1)Al is archetypal, since the most intense peaks both of the rock salt type and of the spinel-like phases are detected. Actually, calcined LDHs exhibit XRD patterns of the crystallographic phases preferentially adopted by the major cation in the structure. Accordingly, Co(0.5)Ni(1.5)Mg(1)Al, Co(0.8)Ni(0.8)Mg(1.4)Al, on the one hand, and Co(1.5)-Ni(0.5)Mg(1)Al, Co(1.2)Ni(1.2)Mg(0.6)Al, on the other hand, present profiles of mixed oxide and spinel-like phases, respectively.

Several relevant features concern the textural properties of the different samples, either non-calcined, or calcined at 573 and 773 K (Table 3). Specific surface areas are generally low, from 20 to 90 m^2g^{-1} for the non-calcined samples, only outgassed at 473 K. This is due to still remaining compensating anions, as shown by the temperatures of the second

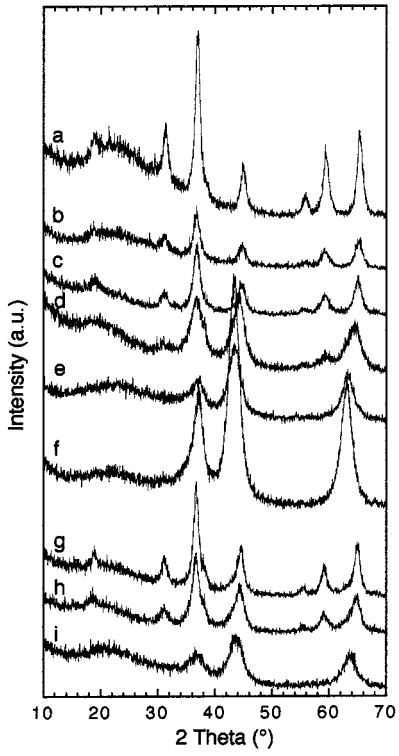

Figure 3. X-ray diffraction patterns of the samples calcined at 773 K: (a): Co(3)Al, (b): Co(2)Mg(1)Al, (c): Co(1.5)Ni-(0.5)Mg(1)Al, (d): Co(1)Ni(1)Mg(1)Al, (e): Co(0.5)Ni(1.5)-Mg(1)Al, (f): Ni(2)Mg(1)Al, (g): Co(1.5)Ni(1.5)Al, (h): Co(1.2)Ni-(1.2)Mg(0.6)Al, (i): Co(0.8)Ni(0.8)Mg(1.4)Al

DTG peaks in the range 540−620 K, except for Co(2)-Mg(1)Al. The adsorption isotherms of the calcined samples are of type II (Figure 4) and the full adsorption−desorption isotherms exhibit type H3 hysteresis loops. Nonetheless, although a hysteresis loop is observed, the isotherms are classified as type IIb (according to Rouquerol et al.[14]) rather than as type IV, because no plateau is observed at high P/P_0. Such adsorption−desorption isotherms are characteristic of aggregates of plate-like particles, classically found with clays. Specific surface areas go through maximum values after calcination at 573 K (Table 3). Their decrease above this temperature is in line with the enhancement of crystallinity shown by XRD. It should be pointed out that, after calcination at 773 K, the specific surface area is higher when Ni

progressively substitutes for Co in samples of similar Mg content, or when Mg content increases in samples of similar Co/(Co+Ni) ratio. Indeed well crystallized spinel-like phases result in lower specific surface areas than rock salt-like structures. Microporosity increases with Mg content: i.e., when mixed oxide becomes the major phase. A limited degree of microporosity sometimes appears even though a type II isotherm is found.[14] A slightly higher microporous volume in Mg-containing samples than in Ni-containing counterparts is in agreement with the results reported for Mg(Al)O and Ni(Al)O mixed oxides.[10]

Reduction of the Calcined Materials

TPRs have been performed on the calcined samples. Some profiles are presented in Figure 5, and H_2 uptakes listed in Table 4. Two distinct domains of H_2 consumption – at low (LT) and high (HT) temperature – always appear as previously reported for Co–Al and Co–Mg–Al LDHs.[3] In the LT domain, one can observe a shoulder at about 473 K, then a highly intense peak with its maximum increasing with Co content, going from 533 K for Co(0.5)Ni(1.5)Mg(1)Al to 638 K for Co(2)Mg(1)Al. Both peaks may be assigned to the reduction of Co species, since they are not detected on Ni(2)Mg(1)Al; moreover, their intensities regularly increase with the Co content of Co–Ni–Mg–Al LDHs. For Co–Al and Co–Mg–Al samples, the shoulder at about 473 K in the LT domain was not identified so unequivocally, and was assigned to reduction of Co_3O_4.[6] These propositions will be discussed more extensively later for Co–Ni–Mg–Al LDHs.

In the HT domain, TPR profiles of the ternary LDHs containing only one reducible cation are very distinct. They differ in a narrow and intense peak extending over 100 K

for Co(2)Mg(1)Al, and a large and broad feature extending over 400 K for Ni(2)Mg(1)Al. For Co(1.5)Ni(1.5)Al, with two reducible cations, maxima at 820 and 960 K reflect the presence of Co and Ni reducible phases respectively.

Finally, in the quaternary LDHs, several remarks may be made concerning the influence of Co/(Co+Ni) ratio:

(1) The shape of the TPR peak moves progressively from that characteristic of Co(2)Mg(1)Al to that characteristic of Ni(2)Mg(1)Al upon Ni substitution.

(2) Compared to the Ni free sample [Co(2)Mg(1)Al], a shift of 30 K toward higher temperature is noted when Ni is introduced in low amount [Co(1.5)Ni(0.5)Mg(1)Al]; after that the temperature of maximum H_2 consumption rate is shifted toward lower values when the Ni content becomes higher.

(3) The temperatures of maximum H_2 consumption rates are rather insensitive to the Mg content.

(4) The TPR profiles of samples at identical Co and Ni content [Co/(Co+Ni) = 0.5] are not the simple averaging of those of Co(2)Mg(1)Al and Ni(2)Mg(1)Al samples.

This last remark demands a more detailed discussion, which is emphasized when looking carefully at the H_2 consumption values of samples calcined at 773 K (Table 4). For Co(2)Mg(1)Al, H_2 consumption in the LT and HT domains represents 30 and 70% of the total, respectively. The total H_2/Co molar ratio of 1.11 for this sample is thus consistent with the presence of Co^{3+} in Co_3O_4; this is normally reduced to Co^0 at low temperature, as proposed by Arnoldy and Moulijn.[13] In the TPR of Ni(2)Mg(1)Al, all H_2 was taken up above 600 K; this was previously assigned to NiO-type phase reduction to Ni^0 in similar materials.[5] On the basis of simple combination of the H_2 consumption values for Ni and Co, one might expect that the H_2 taken up in the LT and HT domains for Co(1.5)Ni(1.5)Al would be 15% and 85%, respectively. However, the actual distribution is 22% and 78%. This is a general behavioral pattern, and significantly higher values for H_2 consumption in the LT range persist when Mg is present and/or the Co/(Co+Ni) ratio modulated.

Discussion

The goal when preparing these LDHs was to develop new bimetallic hydrogenation catalyst precursors, particularly active and selective for the hydrogenation of acetonitrile into ethylamine.[3] In this respect it was of utmost importance to identify the kind of intimate vicinity and of interaction between Ni and Co at the different stages of catalyst elaboration. On that account, we will pay special attention in the following discussion to the nature of the phases obtained upon calcination and their evolution during TPR experiments.

As a first step, TG and XRD analysis of the "as-prepared" materials have shown that a unique LDH phase exists. This is, moreover, clearly highlighted in Figure 6, which shows a correlation appearing between the temperature of maximum weight loss from DTG plots (Table 2) and the *a* parameter (Table 1) for samples of various Co/(Co+Ni) ratios and similar Mg content. The temperature of anion decomposition derived from DTG plots reflects the strength of electrostatic interaction between the layers and the anions. When Ni is substituted for Co, the lattice *a* parameter decreases and the positive charges thus become more localized, enhancing the electrostatic attraction with the anions.

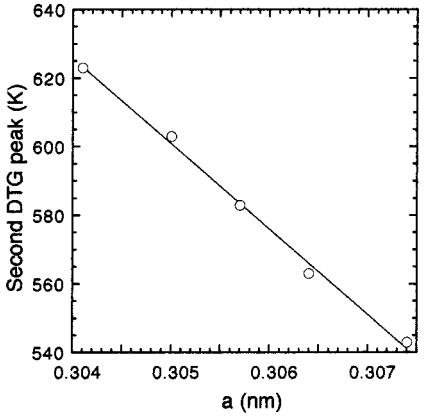

Figure 6. Correlation between the temperature of the second DTG peak and the *a* parameter for the Co−Ni−Mg−Al samples with $Mg^{2+}/\Sigma M^{2+}$ = 1:3

Upon calcination of LDH precursors, one obtains Ni- and Co-containing oxide phases of complex nature and composition. Co-containing LDHs give rise to a crystalline Co_3O_4 phase after calcination at 573 K. In the case of multi-component Co−Ni−Mg−Al LDHs, this behavior might be clarified by examination of the chemical compositions, XRD patterns, and reduction processes in TPR experiments. The reduction of calcined supported Ni catalysts has shown that the prevailing species belong to the NiO-type phase.[15−17]

In contrast, several studies on cobalt or cobalt-magnesium silica gels,[18,19] CoO/Al_2O_3,[13] or Co/SiO_2[20] catalysts reveal the complexity of the reduction process and the multiplicity of phases involved. For example, reduction of Co species, belonging to up to eight sub-phases, occurs within four different temperature domains for Co/Al_2O_3 materials.[13]

As far as the reduction processes in Co−Ni−Mg−Al LDHs are concerned, the main difficulties come from the multiplicity of possible occurring phases. A first remarkable

feature is that the shapes of the reduction profiles above 723 K are unchanged for Co−Mg−Al and Co−Ni−Mg-Al LDHs calcined at 573 or 773 K. This is consistent with the invariance in this temperature range of the crystalline phases detected by XRD. Hence, probably only weak diffusion of the cations is taking place during calcination or reduction processes.

We shall first discuss the reduction processes occurring in the LT domain (< 720 K). There is no peak of hydrogen consumption in the LT domain for the Co-free sample. On that account, the group of peaks appearing at LT for Co-containing materials must correspond to reduction of Co species. This peak was generally a broad feature arising from unresolved contributions. Compared to Co(3)Al, the reduction of Co is made easier in ternary or quaternary compounds containing Co and Ni. At variance with this, reduction of Co is more difficult in Co(2)Mg(1)Al than in Co(3)Al. The hydrogen consumption peak maxima at LT coincide with those generally found for reduction of bulk Co_3O_4[13] in the sequence $Co_3O_4 \rightarrow CoO \rightarrow Co$. Two reduction peaks have indeed been reported for bulk Co_3O_4, silica-supported Co catalysts[20] and promoted cobalt-Kieselguhr Fischer−Tropsch catalysts.[21] However, the reduction of Co_3O_4 to Co^0 on alumina-supported catalyst exhibits only one broad reduction peak,[13] which looks like that observed for reduction of Co(3)Al (Figure 5). The decrease of reducibility of Co upon addition of Mg can be discussed in parallel with the effect of MgO addition, which delayed the reduction of CoO in Kieselguhr-supported Co catalysts.[21] This behavior was ascribed to the formation of CoO−MgO solid solution. On the other hand, a better reducibility of CoO species has been reported upon Ni addition, and accounted for a decrease in their particle sizes.[22] This process may be initiated by formation of a solid solution of CoO and NiO, both exhibiting a rock salt-like structure. According to this proposal, it is a little puzzling why Ni acts as a diluent but Mg does not. For this reason, another process may be postulated, assuming that Ni^{2+} would substitute tetrahedral Co^{2+} in the Co_3O_4 spinel lattice. This would lead to $Co(Co_{2-x}Ni_x)O_4$ phases.[23] The broad peak of H_2 consumption at LT on Co−Ni−Mg−Al materials is very probably composed of two contributions (Figure 5), corresponding to the reduction of these phases in two steps. We previously pointed out the increase in reducibility of Co_3O_4 species with Co loading in Co−Ni−Mg−Al LDHs. A similar phenomenon has, in the case of Co/Al_2O_3, been assigned to a better nucleation process of the metallic nuclei.[24]

In the reduction processes in the HT domain (> 720 K) of the catalysts, several relevant features can be highlighted:

(1) The XRD patterns of the calcined Co- and Ni-rich samples exhibit characteristic lines of spinel and rock salt-like structures, respectively.

(2) Unlike in the LT domain, the reducibility of Co in samples in which Mg and/or Ni are present is higher than in Co(3)Al.

(3) Reduction of the spinel $CoAl_2O_4$ phase, giving rise to a straight and intense peak, was previously reported at least 100 K above the HT reduction peak of Co(3)Al.[13]

(4) Finally, the total H_2 consumption, not exceeding 1.17 [H_2/(Co+Ni)], shows that in multi-cationic samples the cations are not fully reduced. However, it is worth noting that the H_2 consumption relative to that observed for Co(3)Al, increases only slightly upon Mg addition, but more significantly upon Ni addition,.

We can tentatively estimate the H_2 consumption in the LT and HT domains for Co(3)Al, assuming that it would be decomposed into Co_3O_4 and $CoAl_2O_4$ spinel phases upon calcination at 773 K:

$$[Co_{0.75}Al_{0.25}(OH)_2][(CO_3^{2-})_{0.07}(NO_3^-)_{0.12}] \cdot 0.63\ H_2O \rightarrow 0.21\ Co_3O_4 + 0.125\ CoAl_2O_4 + 0.07\ CO_2 + 0.12\ NO + 1.63\ H_2O + 1.15\ O_2 \quad (1)$$

Theoretical H_2 consumption of 1.33 and 1 (H_2/Co) corresponds to the reduction of Co_3O_4 and $CoAl_2O_4$, respectively: close to the experimental values of 1.39 and 1.06 found when these phases are deposited on alumina.[13] This will result in H_2 consumption in the LT and HT domains of 1.11 and 0.17 for Co(3)Al. A large discrepancy is thus noted with the experimental values of 0.29 and 0.71 H_2/Co. Therefore, one should consider that Co_3O_4, reduced in the LT domain, exists in much lower quantities than would be expected from Equation (1). In contrast, a larger amount of a second phase more easily reducible than $CoAl_2O_4$ is formed in the HT domain; this phase might be Co_3AlO_6, as proposed by Arnoldy and Moulijn.[13] It could not be differentiated from $CoAl_2O_4$ by XRD, thanks to their similar patterns. When considering Co(2)Mg(1)Al, we might hypothesize that a $Co_{3-x}Mg_xAlO_6$ phase could probably exist.

When Co, Ni, Mg, and Al are present simultaneously, several phases are involved, because different mixed oxides and spinel-like structures could be formed. Anyway, the reduction profile is clearly modified when Ni content increases: i) the reduction starts at a lower temperature than in the Ni-free sample, ii) the peak becomes less asymmetric, with a progressive increase in intensity of the shoulder observed on the lower temperature side, iii) H_2 consumption increases. In contrast, the reducibility of Ni and Co seems almost insensitive to Mg content. However, as the reducibility of Co increases while that of Ni decreases with Mg content,[5] a compensating effect cannot be ruled out. Therefore, the presence of Ni(Mg)AlO- and $Co_{3-x-y}Ni_xMg_yAlO_6$-type phases can be postulated, with, of course, several other minor phases like, for example, alumina, depending of the nominal compositions of the samples.

To sum up: in Co−Ni−Mg−Al LDHs, the species reduced below 723 K (LT domain) would be a $Co_{3-x}Ni_xO_4$ mixed oxide with a spinel structure. Above 723 K (HT domain), mixed oxides of the NiMg(Al)O type, and a spinel phase containing both Co and Ni − tentatively assigned to $Co_{3-x-y}Ni_xMg_yAlO_6$ − can be proposed. The XRD pat-

tern has the aspect of the rock salt-like structure of the major NiMg(Al)O phase. The existence of a phase containing both Co and Ni is supported by recent results obtained in the hydrogenation of acetonitrile, in which the catalysts obtained from reduction of Co−Ni−Mg−Al LDHs were most active and selective for ethylamine than the catalysts prepared from Ni−Mg−Al and Co−Mg−Al LDHs.[3]

Conclusion

It was possible to obtain multi-component LDHs, accommodating Co, Ni, Mg, and Al cations in the same brucite-like sheet, without identifiable excess phase, in a wide range of compositions. The progressive substitution of Ni for Co decreases the lattice *a* parameter, inducing a stronger electrostatic attraction with the anions, the decomposition of which is thus shifted toward higher temperatures. The thermally decomposed samples are a mixture of Ni- and Mg-containing rock salt-type, and Co-containing spinel-like phases. Accordingly, the surface areas increase with the Ni or Mg content, accounting for the decreasing proportion of spinel-like phase in the mixture. The two distinct temperature domains observed in TPR are in agreement with the well known behavior of Co, giving spinel phases reduced below 720 K, while complex phases containing Co, Ni, and Mg are reduced above this temperature. The two maxima observed in the first domain and the enhancement of reducibility with Ni content suggest that a $Co_{3-x}Ni_xO_4$ phase is formed. H_2 consumption, shapes of the reduction profiles, and also XRD patterns make it plausible to propose that NiMg(Al)O and $Co_{3-x-y}Ni_xMg_yAlO_6$ phases are reduced above 720 K, in relative amounts depending on the stoichiometry of the LDHs. It is worth noting that the reducible Co and Ni cations are in close interaction in these phases, resulting in interesting properties when these materials are used as catalyst precursors.

Experimental Section

Preparation of the LDH Precursors: A solution containing the appropriate amounts of cobalt, nickel, magnesium, and aluminium nitrates (Aldrich) dissolved in 250 cm^3 of deionized water was delivered into a polypropylene reactor by a chromatography-type pump at a constant flow of 1 cm^3min^{-1} at room temperature and ambient atmosphere. A second aqueous solution of 1 M NaOH (SdS) was fed by a pH-stat apparatus (718 Stat Titrino, Metrohm) at a constant pH value of ca. 9.0 ± 0.2. After precipitation, the suspension was aged at 373 ± 5 K for 15 h with stirring. The solid product was isolated by centrifugation, washed thoroughly with deionized water, and dried overnight at 353 K in an oven. Nine samples were synthesized following this procedure, varying the ratio between the divalent cations and maintaining the ratio $M^{2+}/Al^{3+} \approx 3$ (Table 1).

These samples belong to two different families, with molar ratios in solution corresponding on the one hand to $Mg^{2+}/\Sigma M^{2+} = 1:3$ and variable $Ni^{2+}/\Sigma M^{2+}$ and, on the other hand to $Ni^{2+}/(Co^{2+}+Ni^{2+}) = 1:2$ and variable $Mg^{2+}/\Sigma M^{2+}$.

As an example, the multi-component Co−Ni−Mg−Al sample labeled Co(1.5)Ni(0.5)Mg(1)Al corresponds to a compound prepared from $M^{2+}/\Sigma M^{2+} = 1.5:3$, 0.5:3 and 1:3 for Co^{2+}, Ni^{2+}, and Mg^{2+}, respectively.

Characterization of the Solids: Chemical analyses of the samples were performed at the Service Central d'Analyse du C.N.R.S. (Solaize, France). Powder X-ray diffraction (XRD) patterns were recorded on a Philips instrument (40 kV, 20 mA) using Cu*K*α radiation (λ = 0.154 nm). The 2θ angle ranged from 6° to 70°. A monochromator was applied, to avoid fluorescence phenomena. Thermogravimetric experiments (TG) were carried out on a Setaram TG 85 1000 °C microbalance in air (80 cm^3min^{-1}) from 293 to 973 K (ramp: 2 K min^{-1}). Specific surface areas were determined by N_2 adsorption at 77 K with a Micromeritics ASAP 2000 instrument and using the BET equation. The samples were outgassed in vacuum ($2\cdot10^{-4}$ Pa) at 523 K overnight before N_2 adsorption. The calcination of the samples was carried out in an air flow at 573 or 773 K (ramp 2 K min^{-1}). The final temperature was maintained for 5 h.

The reducibility of the samples was examined by temperature programmed reduction by hydrogen (TPR). The experimental setup was derived from that proposed classically.[25] Detection was carried out with the thermal conductivity detector of a Shimadzu GC8 chromatograph. The experimental parameters were carefully selected to meet the recommendations of Monti and Baiker.[26] An aliquot of the catalyst (20−30 mg) was activated first at 623 K or 773 K for 4 h in air (ramp: 2 K min^{-1}, flow: 50 cm^3min^{-1}) and then cooled to room temperature. After flushing with He, the TPR was started in H_2/Ar gas (3:97 vol/vol, purity of both gases > 99.995%) from 293 to 1293 K (ramp: 10 K min^{-1}, flow: 20 cm^3min^{-1}).

Copper(II)- and Proton-Assisted Condensation Reactions of a Tetrapodal Pentaamine with Acetone: Formation of "Podand-cum-Macrocycle" Copper Complexes and a Protonated Bis(aminal)

Christopher Zimmermann,[a] Frank W. Heinemann,[a] and Andreas Grohmann*[a]

Dedicated to Professor Dieter Sellmann on the occasion of his 60th birthday

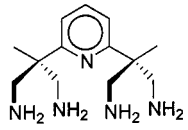
Keywords: N ligands / Copper / Template synthesis / Schiff bases / Macrocycles

The tetrapodal pentaamine 2,6-$C_5H_3N[CMe(CH_2NH_2)_2]_2$ (pyN_4, **1**) forms mononuclear complexes with Cu^{II}, as shown for a series of compounds of the type $[(\mathbf{1})Cu]X_2$ (X = Br, SCN, PF_6, ClO_4). The coordination environment of the copper ion is square-pyramidal, with the pyridine nitrogen atom of **1** in the apical position. The axial bond $Cu–N_{py}$ is significantly longer than the four Cu–N bonds at the base of the pyramid, average values being 2.16 Å and 2.03 Å, respectively. When $[(\mathbf{1})Cu]X_2$ (X = PF_6, ClO_4) is refluxed with an excess of acetone in methanol in the absence of base, the corresponding bis(isopropylideneimine) complexes $[\{(nac)_2pyN_4\}Cu]X_2$ are obtained, in which two diametrically opposite primary amino groups of **1** have condensed with the ketone. The complex cations, which are now chiral, again have square-pyramidal coordinated Cu^{II}. In the presence of sodium methoxide, the condensation of $[(\mathbf{1})Cu]X_2$ with acetone proceeds further, leading to the formation of one diacetone-amine-imine linkage in the product. A 12-membered 1,5,9-triazamacrocycle, incorporating the 2,6-disubstituted pyridine unit, is thus formed. Two podand nitrogen donors of the NN_4 set (which retains its square pyramidal topology) remain: a primary amine and an isopropylidene imine group. The product forms as a mixture of both conceivable isomers (azomethine groups at the base of the pyramid *cis* or *trans*), which were separated and structurally characterised as the tribromocuprate(I) and hexafluorophosphate salts, respectively. The condensation of metal-free **1** with acetone in the presence of two equivalents of HBr yields the bis(aminal) salt (2,6-$C_5H_3N\{CMe[cyclo\text{-}CH_2NH_2C(CH_3)_2NHCH_2\text{-}]\}_2)Br_2$, in which one of the secondary amino groups in each diazacyclohexane ring is protonated, as ascertained by X-ray crystallography. The aminal is a metal-free tautomer of the bis(isopropylideneimine) ligand $(nac)_2pyN_4$, to which it converts upon reaction with Cu^{II} under suitable conditions, providing an alternative synthetic route to complexes of the type $[\{(nac)_2pyN_4\}Cu]X_2$.

Introduction

The tetrapodal pentaamine **1** (pyN_4) forms mononuclear complexes with cobalt(III), nickel(II), and iron(II/III) in which all four arms of the ligand as well as the apical donor atom are coordinated to the metal centre.[1,2] A monodentate additional ligand completes the coordination octahedron. We are currently exploring ways to introduce a functional periphery into such complexes,[3,4] appended to the basal donor atoms of **1**, that will engage in secondary interactions with the monodentate ligand, so as to control its binding and reactivity. Ligand derivatives with: (a) one, (b) two, or (c) four modified sidearms have been obtained by Schiff base condensation with carbonyl compounds, such as: (a) salicylaldehyde, (b) acetone, or (c) cinnamaldehyde, and isolated in the form of their nickel(II) complexes, which are mononuclear.[4]

The spatial orientation of the secondary donor groups in the ligand periphery has to enable noncovalent interactions



1

with the monodentate ligand; at the same time, the coordination of peripheral groups to the apical site (which would hinder the binding of an exogenous ligand) is to be precluded, and the periphery should not interfere with mononuclear NN_4 complex formation. These difficulties are illustrated by two derivatives of **1**: 1) the mono(salicylaldehyde) derivative, as obtained under (a), above, is hexadentate, its NN_4O donor set occupying all coordination sites in an octahedral complex;[4] 2) a related symmetrical ligand, with four uniformly modified sidearms and a potential NN_4O_4 donor set, adopts a dinucleating coordination mode in the case of nickel(II) and copper(II): each metal ion uses a square-planar disposed N_2O_2 donor subset, and the pyridine nitrogen atom remains uncoordinated.[5]

A strategy to enforce a mononucleating NN_4 donor set in derivatives of **1** irrespective of the nature of the ligand periphery is to increase the rigidity ("juxtapositional fixedness"[6,7]) of the coordination cap. One possibility is to tie

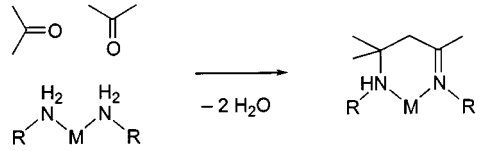
the 1,3-diaminoprop-2-yl sidearms together by bridges between equatorial amino groups, to give a macrocyclic ring "capped" by a pyridine unit. At a later stage, the bridges could carry donor groups pointing towards the sixth coordination site. In order to probe the viability of this approach, we chose a reaction known to furnish acetone-derived C_3 linkages between adjacent NH_2 groups in transition metal amine complexes (the Curtis reaction, Scheme 1).[8,9] In this contribution, we describe the copper(II) complex of **1**, and its reactivity, and that of partially protonated **1**, towards acetone.



Scheme 1. Condensation of adjacent primary amino groups in a metal complex with acetone to produce a diacetone-amine-imine linkage (Curtis reaction)

Results and Discussion

[(1)Cu]X_2 (X = Br, SCN, PF_6, ClO_4)

The bromide salt [(**1**)Cu]Br_2 formed in good yield as a microcrystalline purple solid upon refluxing a methanolic solution of equivalent amounts of the pentaamine **1**, prepared by neutralisation of **1**·4HBr·MeOH with four equivalents of LiOMe, and $CuCl_2·2H_2O$. Recrystallisation from methanol or methanol/water yielded the solvates [(**1**)Cu]Br_2·0.5MeOH (**2**), [(**1**)Cu]Br_2·2MeOH (**3**), and [(**1**)Cu]Br_2·$3H_2O$ (**4**), and recrystallisation in the presence of NH_4SCN or NH_4PF_6 gave the thiocyanate and hexafluorophosphate salts [(**1**)Cu]$(SCN)_2$·H_2O (**5**) and [(**1**)Cu]$(PF_6)_2$ (**7**). The perchlorate [(**1**)Cu]$(ClO_4)_2$ (**8**), which is soluble in acetone, was obtained directly from the reaction of **1** and $[Cu(DMF)_6](ClO_4)_2$ in methanol (see Experimental Section). The magnetic moment determined for **2** (Gouy balance, 1.7 μB) conforms to one unpaired electron, as expected for Cu^{II}, and a quasi-reversible redox wave in the cyclic voltammogram of this compound at $E_{1/2} = -0.62$ V (vs. NHE) is assigned to the [Cu^{II}/Cu^{I}] couple.[10]

X-ray structural data have been obtained for several compounds of composition [(**1**)Cu]X_2, showing the copper(II) ion to be present in a square-pyramidal coordination environment in all cases. The pyridine nitrogen atom of the pentaamine ligand occupies the axial position, while the primary amino groups are at the base of the pyramid. Without exception, the axial bond Cu−N_{py} is significantly longer than the basal copper−nitrogen bonds, average values being 2.16 Å and 2.03 Å, respectively. While pentacoordinate Cu^{II} is not susceptible to first-order Jahn−Teller effects, such differences, which have been ascribed to a "plasticity effect", are a common feature in the structural chemistry of this ion.[11,12] The following discussion pertains to the cation in [(**1**)Cu]$(SCN)_2$·H_2O (**5**), whose structure is shown in Figure 1. The complex has crystallographic C_1 symmetry. The basal Cu−N bond lengths are similar (Table 1), averaging 2.039(3) Å, while the axial Cu−N bond length is 2.207(2) Å. These values are similar to those determined for the corresponding bonds in the pentaammine copper(II) complex $K[Cu(NH_3)_5](PF_6)_3$.[13] All N_{ax}−Cu−N_{bas} angles in **5** are close to 90°. A distortion of the ligand framework from ideal square-pyramidal geometry, which is probably due, in large measure, to crystal packing effects,[2] causes the pyridine ring to be tilted from the normal on the basal CuN_4 plane by 27.3(1)°, and the nonbonded distances C16···C21 and C17···C20 to be lengthened and shortened

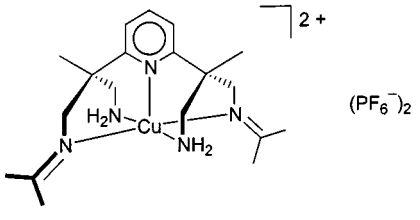
[{(nac)$_2$pyN$_4$}Cu](PF$_6$)$_2$

When a suspension of [(**1**)Cu](PF$_6$)$_2$ (**7**) in methanol is refluxed with a large excess of acetone in the absence of base, a mononuclear copper(II) complex is obtained cleanly and in good yield as a blue-violet solid which contains the bis(acetoneimine) derivative of the ligand, as verified by an X-ray structure analysis, i.e. [{(nac)$_2$pyN$_4$}Cu](PF$_6$)$_2$·Me$_2$(C=O) (**9**).[15] Heating the mixture to reflux is essential for the reaction to take place; in a separate experiment under otherwise identical conditions, stirring a solution of **7** in acetone at room temperature led to quantitative re-isolation of the starting material upon workup.



9

The IR spectrum of **9** has absorptions between 3400 and 3000 cm^{-1} (ν_{N-H} str) and at 1582 cm^{-1} (ν_{N-H} def), characteristic of coordinated primary amine groups, and a new strong absorption at 1658 cm^{-1} assigned to the C=N stretching vibration. The spectrum is similar to that of a nickel(II) complex of the same ligand previously isolated from *basic* mixtures of **1** and acetone upon addition of a suitable nickel(II) salt.[4] In the same manner as has been observed for the nickel(II) complex, reacting [(**1**)Cu](PF$_6$)$_2$ (**7**) in neat acetone does not lead to more highly condensed products. The generation of **9** parallels the formation of a copper(II) bis(isopropylideneimine) complex from bis(1,3-propanediamine)copper(II) perchlorate and acetone under base-free conditions, as reported by Curtis and House.[16] A *trans* arrangement of the coordinated *N*-isopropylidene groups was inferred on the basis of circumstantial evidence for this complex, whose hydrolytic instability, however, precluded structural characterisation. The complex was isolated as an intermediate from a reaction which, upon prolonged standing and without added base, produced a square planar 16-membered macrocyclic copper(II) species. Contrary to these observations, compound **9**, which is remarkably stable towards hydrolysis, shows no further reaction with acetone in the absence of base.

The structure of the cation in **9** is shown in Figure 2. The molecule is C_2-symmetrical, with the metal ion, the pyridine nitrogen atom N11, and the pyridine carbon atom C13 lying on the rotation axis. The pyridine, primary amine, and isopropylidene-imine nitrogen atoms define a square pyramid, which is distorted slightly in the sense that, while one basal *trans* N–Cu–N unit is strictly linear [∠(N13–Cu1–N13A) = 179.6(3)°], the other is bent at an angle of ∠(N12–Cu1–N12A) = 170.3(2)° (Table 1). Of the basal Cu–N bonds, those involving the sp^2 nitrogen atoms are shorter [d(Cu1–N12) = 2.008(2) Å], as expected, than those involving the primary amine groups [d(Cu1–N13) = 2.046(2) Å]. Again, the axial Cu–N bond is longer [d(Cu1–N11) = 2.105(4) Å] than the bonds at the base of the pyramid. Overall, the structure resembles that of a related pentacoordinate nickel(II) complex of the same ligand, except that in the latter the M–N_{ax} bond is the shortest of all metal–nitrogen bonds.[4] Complexes of this topology are chiral, the aliphatic quaternary carbon atoms being stereogenic centres as a consequence of asymmetric substitution of the basal N_4 donor set. Compound **9** crystallises in the noncentrosymmetric space group *C*2, which indicates spontaneous resolution of enantiomers upon crystallisation.[17]

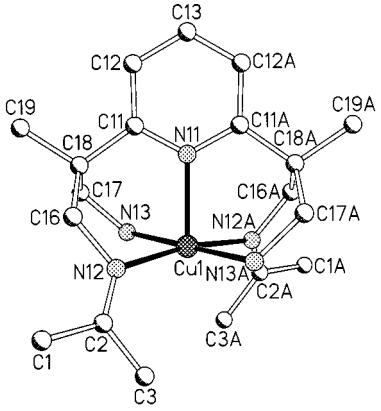


Figure 2. Molecular structure of the cation in **9**; for clarity, ball-and-stick representations have been chosen, and hydrogen atoms have been omitted

Copper(II) Pentaamine Complexes Containing an Acetone-Derived C_3 Bridge and an Isopropylidene-Imine Unit

Whereas refluxing mixtures of [(**1**)Cu]X_2 and acetone in methanol, in the absence of base, yield the *trans*-bis(isopropylideneimine) derivative (compounds **9** and **10**, above), an excess of sodium methoxide in such solutions causes the condensation to proceed further, leading to the formation of one diacetone-amine-imine linkage. A 12-membered 1,5,9-triazamacrocycle, incorporating the pyridine nitrogen atom, is thus formed. Two "podand" nitrogen donors remain of the NN_4 set, viz. a primary amine and an isopropylidene imine group (podand-cum-macrocycle). The condensation parallels the formation of an isolable intermediate in the Ni^{II}/ethylenediamine system, which also contains one diacetone-amine-imine bridge beside an isopropylideneimine and an NH_2 group.[16] In our case, with Cu^{II}, complete cyclisation involving all basal N donors, in a manner similar to the formation of a 16-membered tetraazamacrocycle from the Cu^{II} complex of 1,3-diaminopropane,[8] has so far not been observed. Two regioisomeric forms are possible for the condensation product of **1**, depending on whether the C=N double bonds are *cis* or *trans* with respect to the pyridine ring plane. Indeed, the product initially forms as a mixture of both isomers, which have been separately obtained as the hexafluorophosphate (*trans*, **11**) and tribromocuprate(I) salts (*cis*, **12**), by a combination of fractional crystallisation and temperature-induced isomerisation (see Experimental Section). In the case of **12**, the reducing agent responsible for the formation of $[Cu^{I}Br_3]^{2-}$ is as yet unidentified. However, the pentaamine **1** has been shown to act partially as a reducing agent in the case of some cobalt(III) complexes.[1]

Figure 3 shows the crystal structures of the cations in **11** and **12**. Both complexes, which are chiral, crystallise in centrosymmetric space groups (Table 3). The coordination geometry of the Cu^{II} ion is square-pyramidal in both cases, with a similar tilt of the pyridine ring (Table 2). The Cu−N_{ax} and Cu−N_{bas} bond lengths do not differ markedly from those determined for the bis(isopropylideneimine) complex **9** (Table 1). The diacetone-amine-imine linkage runs alongside the pyridine ring, spanning a pair of *cis*-positioned nitrogen atoms of both 1,3-diaminoprop-2-yl sidearms. The conformation of the bridge is the same in both structures, only its orientation is inverted on going from **11** (C=N *trans*) to **12** (C=N *cis*). Isomerism at the secondary amine centres due to restricted inversion is not observed. Neither structure is significantly strained, as judged from the bond lengths and angles in the ligand framework; in particular, the bond angles in the 12-membered triazamacrocycle incorporating the acetone-derived bridge and the *ortho*-disubstituted pyridine unit are within the range for sp^2- and sp^3-hybridised carbon and nitrogen atoms. The conformation of the triazamacrocycle in **11** and **12** is similar to that found in Cu^{II} and Ni^{II} complexes of 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene, which may be obtained by the metal-templated condensation of dipropylenetriamine with acetone.[18,19] It therefore seems unlikely that the formation of a second diacetone-amine-imine linkage in **11** or **12** is inhibited purely for reasons of ring strain that would otherwise ensue; rather, the nucleophilicity of the last remaining primary amino group appears to be significantly reduced, and a stronger base may be required to produce an amido ligand in sufficient concentration to allow the second ring closure to proceed.[20]

A Bis(aminal) Derivative From the Reaction of 1·2HBr with Acetone

Beside transition metal ions such as Ni^{II} and Cu^{II}, protons have also been used as a templating agent (and acid catalyst) in macrocyclisations involving C=N bond formation.[3,21] Metal-free condensation products are attractive as they provide indirect access to macrocyclic complexes not otherwise accessible, either by a metal-template reaction or by transmetallation. In the case of 1,2-diaminoethane, with acetone as the carbonyl component, the formation of a macrocyclic product is observed only when the diamine is employed in its monoprotonated form, $H_2NCH_2CH_2NH_2{\cdot}HX$.[22,23] The macrocycle, which separates as the diprotonated salt, is assembled from two equivalents of diamine and four equivalents of acetone, containing two diacetone-amine-imine bridges. The same product forms when mesityloxide (4-methyl-3-pentene-2-one) is used as the carbonyl component. In the case of monoprotonated 1,3-diaminopropane, instead of macrocycle formation, the reaction with acetone may lead preferentially to the aminal derivative, which is a six-membered hexahydropyrimidine ring.[24−27] The intermediate formation of aminals has been invoked as the controlling process in the assembly of a Schiff base tetramacrocycle from **1** and a difunctional aldehyde in the presence of protons,[3] and a bis(aminal) product has been isolated from the reaction of **1** with two equivalents of ferrocenecarbaldehyde.[5] In view

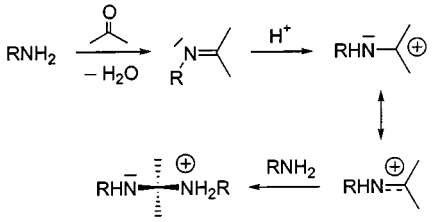
of the fact that the pentaamine **1** contains two 1,3-diaminopropyl residues in close proximity, thereby perhaps favouring macrocyclisation, we studied the reactivity of **1** towards acetone in the presence of two equivalents of hydrogen bromide.

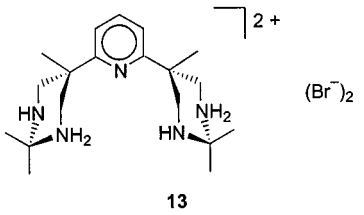
When a methanolic solution of **1**·2 HBr, prepared in situ from the pentaamine tetrahydrobromide by addition of the required amount of LiOMe, is refluxed with an excess of acetone, the mixture soon deposits a colourless precipitate (52% isolated yield). Bands characteristic of a C=N stretching vibration are absent in the IR spectrum of this product, ruling out Schiff base formation. Instead, the combined elemental analysis, NMR and mass spectroscopic data show the material to be a bis(aminal) dihydrobromide/methanol solvate (**13**), formed by condensation of **1**·2HBr with two equivalents of acetone, by the classical mechanism shown in Scheme 2. The same product is obtained, again exclusively, when reacting **1**·2HBr with mesityloxide (4-methyl-3-

pentene-2-one), H^+ apparently catalysing hydrolysis of the latter after its carbonyl group has formed the Schiff base, with concomitant liberation of water.



Scheme 2. Formation of the protonated aminal moiety in **13**, involving acetone and two equivalents of primary amine

Single crystals of **13** were of sufficient quality to allow the determination of its solid-state structure, and in particular the hydrogen atom positions, all of which could be deduced from a difference Fourier synthesis. The structure of the dication, which has crystallographic C_1 symmetry, is shown in Figure 4. Each diazacyclohexane ring contains one nitrogen atom carrying two protons and hence a formal positive charge (N13, N15), and one nitrogen atom with a single proton (N12, N14). The diazacyclohexane rings both have a chair conformation, and are held in relative proximity by weak intramolecular/interionic hydrogen bonded contacts between aminal NH/NH_2 groups and one bromide counterion [Figure 4; d(N13−H13B···N14) = 3.230(5) Å, ∠(NHN) = 141.3(4)°, van der Waals radius of N: 1.55 Å;[14] d(N13−H13A···Br1) = 3.223(3) Å, ∠(NHBr) = 160.1(4)°; d(N14−H14B···Br1) = 3.587(3) Å, ∠(NHBr) = 150.8(4)°, sum of van der Waals radii of N and Br: 3.4 Å[14]]. As a consequence of the intramolecular contacts, the "single" proton H14B adopts an equatorial position, while H12B is in an axial position. The nitrogen−carbon bonds involving the NH_2^+ groups are slightly but significantly longer than the corresponding bonds involving NH (see the legend to Figure 4), as has been found for other amine/ammonium pairs.[28] The nitrogen atom N12 has a hydrogen-bonded contact with the OH group of the solvate methanol molecule. Bond lengths and angles in the diazacyclohexane and pyridine rings are in the normal range.



13

The bis(aminal) **13**, when deprotonated, is a metal-free tautomer of the bis(isopropylideneimine) ligand as found in complexes **9** or **10**. Indeed, the reaction of **13** with $[Cu(DMF)_6](ClO_4)_2$, after addition of two equivalents of LiOMe, yields **10** as the exclusive product, as identified by elemental analysis and IR spectroscopy. Compound **13** may thus serve as a metal-free equivalent of this chiral ligand, and work is currently under way to extend its coordination chemistry to other transition metals.

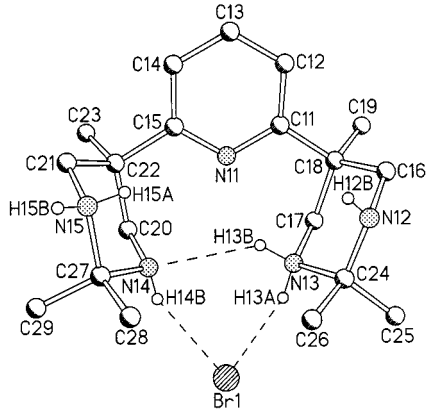


Figure 4. Molecular structure of the doubly protonated bis(aminal) which forms as the dibromide salt **13** when condensing **1**·2HBr with acetone. The positions of all hydrogen atoms have been located in a difference Fourier synthesis, but only the nitrogen-bonded protons are shown for clarity; some structural parameters are: N12−C16 = 1.468(6) Å, N12−C24 = 1.461(6) Å, N13−C17 = 1.501(5) Å, N13−C24 = 1.533(6) Å; C16−N12−C24 = 114.9(4)°, C17−N13−C24 = 114.0(3)°, N12−C24−N13 = 109.2(3)°

Conclusion

Reaction of the copper(II) template $[(\mathbf{1})Cu]^{2+}$ with acetone does not furnish a symmetrical condensation product in which all basal N donors have been incorporated into a macrocyclic ring, spanned by a 2,6-disubstituted pyridine unit, to give a reinforced coordination cap as outlined in the Introduction. The $[(\mathbf{1})Cu]^{2+}$/acetone system may, however, be controlled to provide the chiral bis(isopropylideneimine) ligand $\{(nac)_2pyN_4\}$ exclusively, and other transition metal complexes of this ligand should be accessible by an indirect route, via the diprotonated bis(aminal) of **1** formed in the reaction of **1**·2HBr with acetone. Current work addresses the question whether the metal-free condensation reaction can be extended to other carbonyl compounds, to give a series of chiral square pyramidal coordination caps derived from **1** with two substituted sidearms.

Experimental Section

CAUTION! Although no problems were encountered in this work, transition metal perchlorate complexes with organic ligands are potentially explosive and should be handled with due precautions.

Materials and Instrumentation: Manipulations were performed under dinitrogen using standard Schlenk techniques and freshly dried solvents. Reagents were AR grade or better and were purchased from Merck, Fluka, and Aldrich. **1**·4HBr·MeOH and $[Cu(DMF)_6](ClO_4)_2$ were prepared as described previously.[29,30] IR (KBr discs) and UV/Vis spectra (solvent: DMSO) were recorded on Perkin−Elmer 16PC FT-IR and Shimadzu UV-3101 PC instruments. Cyclic voltammograms were recorded using an EG & G potentiostat PAR model 264A and a conventional three-electrode configuration consisting of a glassy carbon working electrode, a platinum auxiliary electrode and a Ag/AgCl reference electrode (room temperature; solvent: DMSO; scan rate: 50 mV s^{-1}; supporting electrolyte: NBu_4PF_6 [10^{-1} M]; internal standard: ferrocene,

$E(Fc/Fc^+)$ = +0.4 V vs. NHE[31]). NMR spectra were measured on a JEOL JNM-EX 270 spectrometer, and mass spectra were obtained on JEOL MSTATION 700 and Micromass ZABSpecE spectrometers. Magnetic moments were measured using a Johnson-Matthey Gouy balance, with diamagnetic corrections calculated from Pascal's constants.[32] Elemental analyses were performed using Carlo Erba Elemental Analysers 1106 and 1108.

X-ray Crystallography: Crystal data for compounds **5**, **9**, **11**, **12** and **13** are given in Table 3, and selected distances and angles are listed in Table 1 and 2. Cation structures are presented in Figure 1−4. Structural data for other compounds containing the copper complex $[Cu(\mathbf{1})]^{2+}$ have been deposited with the Cambridge Crystallographic Data Centre {$[Cu(\mathbf{1})](Br)_2\cdot 2MeOH$ (**3**), $[Cu(\mathbf{1})](Br)_2\cdot 3H_2O$ (**4**), $[Cu(\mathbf{1})](Br)(PF_6)\cdot MeOH$ (**6**), $[Cu(\mathbf{1})](ClO_4)_2$ (**8**), $[\{(nac)_2pyN_4\}Cu](ClO_4)_2$ (**10**)}; the cation parameters resemble those determined for **5**. All structures discussed in this contribution were solved by direct methods and refined by full-matrix least-squares procedures on F^2 using SHELXTL NT 5.10 (Bruker AXS, 1998). All non-hydrogen atoms were refined anisotropically.

Treatment of Hydrogen Atoms: All hydrogen atom positions in compounds **5**, **11**, **13** were obtained from a difference Fourier synthesis. For the structure of **5**, the positional H atom parameters were refined while a common isotropic displacement parameter was kept constant. In the case of the solvate water molecule in **5** and for the entire structures of **11** and **13**, both positional and common isotropic displacement parameters were kept constant during refinement.

The hydrogen atoms in compounds **9**, **12** were geometrically positioned and allowed to ride on their carrier atoms during refinement; their isotropic displacement parameters were tied to those of the adjacent atoms by a factor of 1.2 or 1.5.

Other Remarks: The disorder of the hexafluorophosphate anions in compound **9** could be resolved into two preferred orientations [occupancy factors 0.86(2) and 0.14(2)].

The maximum of the residual electron density in compound **11** is located within the ligand framework, indicating that a small percentage of the other isomer is present in the crystal structure. In preliminary X-ray structural analyses of product used "as-obtained" (no treatment subsequent to synthesis; see details below), the presence of both isomers in approximately equal amounts led to the determination of identical C−N single and C=N double bond lengths. In the structure of **11**, these distances are distinctly different [N12−C7: 1.473(5) Å, N15−C5: 1.290(5) Å]; for this reason, no allowance was made for the possible presence of the other isomer.

The structure of **12** is unremarkable in this respect, the maximum of the residual electron density being located at the copper atom.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-149662−149665 (**3**−**6**) and CCDC-149666−149671 (**8**−**13**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$[(\mathbf{1})Cu](X)_2\cdot$solv (X = Br, solv = 0.5MeOH; 2): To a stirred suspension of **1**·4HBr·MeOH (1.24 g, 2.04 mmol) in methanol (20 mL) was added a solution of LiOMe (0.310 g, 8.16 mmol) in MeOH (5 mL) in one portion, to give a clear solution after ca. 15 min. at room temperature. To this was added a solution of $CuCl_2\cdot 2H_2O$ (0.347 g, 2.04 mmol) in methanol (15 mL), and the mixture refluxed overnight. The solution changed colour from brown through blue to purple, and deposited a purple microcrystalline precipitate, which was collected on a glass frit, washed with methanol (3 × 10 mL), and dried in vacuo (0.65 g, 65%). Recrystallisation from methanol or methanol/water, with or without an added anion source (NH_4SCN, NH_4PF_6) and/or diethyl ether, yielded the compounds $[(\mathbf{1})Cu](Br)_2\cdot 2MeOH$ (**3**), $[(\mathbf{1})Cu](Br)_2\cdot 3H_2O$ (**4**), $[(\mathbf{1})Cu](SCN)_2\cdot H_2O$ (**5**), $[(\mathbf{1})Cu](Br)(PF_6)\cdot MeOH$ (**6**), and $[(\mathbf{1})Cu](PF_6)_2$ (**7**), in most cases as single crystals. All compounds are purple, with the exception of compound **5**, which is blue. The following analytical data were obtained for compound **2**: $C_{13}H_{25}Br_2CuN_5\cdot 0.5CH_4O$ (490.8): calcd. C 33.04, H 5.55, N 14.27; found C 33.14, H 5.95, N 14.53. − IR (KBr): $\tilde{\nu}$ = 3442 cm^{-1}, 3432, 3303, 3213, 2982, 2926, 1600, 1584, 1470, 1455, 1250, 1088, 1011, 822, 768, 624. − MS (FAB, *p*-NBA): *m/z* (%) = 314 $[(\mathbf{1})Cu]^+$ (100), 395 $\{[(\mathbf{1})Cu]Br\}^+$ (65). − μ_{Eff} (spin only) = 1.71 BM. − Cyclic voltammetry (room temp., 10^{-3} M soln. in abs. DMSO): $E_{1/2}$ (Cu^{II}/Cu^{I}) = −0.62 V. − UV/Vis: λ_{max} (ε) = 530 nm (61 $dm^3\cdot mol^{-1}\cdot cm^{-1}$).

$[(\mathbf{1})Cu](ClO_4)_2$ (8): In contrast to the bromide salts **2**, **3** and **4**, the perchlorate salt **8** is soluble in acetone. It was prepared from the free pentaamine ligand **1** as follows: A suspension of **1**·4 HBr·MeOH (1.20 g, 1.98 mmol) in MeOH was neutralised by addition of 4 equiv. LiOMe. The resulting solution was taken to dryness, extracted with CH_2Cl_2 to remove LiBr, and the dichloromethane extract taken to dryness to leave **1** as a pale yellow oil. Addition of MeOH (15 mL) gave a clear solution, to which was added in one portion a faint blue solution of $[Cu(DMF)_6](ClO_4)_2$ in MeOH (15 mL). A purple solution formed immediately, which was refluxed for 1 h and subsequently reduced in volume to ca. 20 mL by applying a stream of dry dinitrogen. When crystallisation set in, the mixture was filtered, and diethyl ether allowed to diffuse into the filtrate. The single crystals obtained in this manner were separated by filtration, washed with MeOH, and dried in a stream of dinitrogen (0.21 g, 21%). Additional crops of **8** were obtained by allowing the mother liquor to stand in air. − $C_{13}H_{25}Cl_2CuN_5O_8$ (513.8): calcd. C 30.39, H 4.90, N 13.63; found C 30.68, H 4.96, N 13.75. − IR (KBr): $\tilde{\nu}$ = 3303 cm^{-1}, 3216, 3137, 2963, 2927, 2881, 1601, 1585, 1471, 1456, 1399, 1261, 1084 (br), 1012, 822, 802, 769, 625. − MS (FD): *m/z* (%) = 315 $[(\mathbf{1})Cu]^+$ (100), 413 $\{[(\mathbf{1})Cu](ClO_4)\}^+$ (80).

$[\{(nac)_2pyN_4\}Cu](X)_2$ (X = PF_6: 9): To a suspension of $[(\mathbf{1})Cu](PF_6)_2$ (0.20 g, 0.33 mmol) in methanol (30 mL) was added acetone in large excess (1 mL), and the mixture refluxed overnight to give a purple solution. Diffusion of diethyl ether into this solution produced single crystals of the acetone solvate $[\{(nac)_2pyN_4\}Cu](PF_6)_2\cdot H_3C(C=O)CH_3$ (0.15 g, 62%). − $C_{19}H_{33}CuF_{12}N_5P_2\cdot C_3H_6O$ (743.1): calcd. C 35.56, H 5.29, N 9.43; found C 35.26, H 5.64, N 9.32. − IR (KBr): $\tilde{\nu}$ = 3371 cm^{-1}, 3316, 3214, 3113, 2958, 1729 (acetone), 1658 (C=N), 1582, 1469, 1374, 1265, 1122, 1014, 836 (PF_6), 557. − MS (FAB, *p*-NBA): *m/z* (%) = 394 $[\{(nac)_2\text{-}pyN_4\}Cu]^+$ (100), 475 $\{[\{(nac)_2\text{-}pyN_4\}Cu]Br\}^+$ (35). − μ_{Eff} (spin only) = 1.60(3) BM. − UV/Vis: λ_{max} (ε) = 528 nm (125 $dm^3\cdot mol^{-1}\cdot cm^{-1}$).

X = ClO_4 (10): The perchlorate salt $[(\mathbf{1})Cu](ClO_4)_2$ (**8**), when treated in a similar manner with an excess of acetone in MeOH/acetone at reflux under base-free conditions, gave the corresponding bis(isopropylideneimine) complex **10** as an unsolvated solid. − $C_{19}H_{33}Cl_2CuN_5O_8$ (594.0): calcd. C 38.42, H 5.60, N 11.79; found C 37.92, H 5.95, N 11.70. − IR (KBr): $\tilde{\nu}$ = 3321 cm^{-1}, 3273, 3214, 3113, 2981, 1661 (C=N), 1592, 1469, 1374, 1266, 1088 (br, ClO_4), 818, 624. − MS (FD): *m/z* (%) = 395 $[\{(nac)_2\text{-}pyN_4\}Cu]^+$ (20), 494 $\{[\{(nac)_2\text{-}pyN_4\}Cu]ClO_4\}^+$ (100). Compound **10** may also be

obtained by first reacting a methanolic solution of **1** with acetone under reflux, followed by addition of $[Cu(DMF)_6](ClO_4)_2$ in MeOH. Finally, **10** was obtained from the diprotonated bis(aminal) **13** (see below) as follows: To a solution of **13** in methanol was first added LiOMe (2 equiv.), then $[Cu(DMF)_6](ClO_4)_2$ (1 equiv.) in MeOH, and the mixture refluxed overnight to give a purple solution. Isothermal diffusion of ether into this solution produced a purple crystalline precipitate identified as **10** by IR spectroscopy and elemental analysis.

Preparation of Copper(II) Complexes of 1 Containing an Acetone-Derived C_3 Bridge and an Isopropylidene-Imine Unit: To a stirred suspension of **1**·4HBr·MeOH (0.766 g, 1.26 mmol) in methanol (20 mL) was added a slight excess of sodium metal (0.125 g, 5.23 mmol). After the evolution of H_2 had ceased, acetone (5 mL) was added to the clear solution, and the mixture refluxed for 1 h. After cooling to room temperature, $CuCl_2·2H_2O$ (0.215 g, 1.26 mmol) was added as a solid in one portion, and the mixture refluxed overnight to give a purple solution. To this was added solid $NaPF_6$ to produce a purple precipitate, which was isolated and dried in vacuo (A). Preliminary X-ray data of this material indicated a mixture of two structural isomers (see text and X-ray Crystallography, above) originating from the condensation of $[(\mathbf{1})Cu]^{2+}$ with three equivalents of acetone. Elemental analysis data are in agreement with this formulation: $C_{22}H_{37}CuF_{12}N_5P_2$ (725.0): calcd. C 36.45, H 5.14, N 9.66; found C 36.50, H 5.33, N 9.62. The mother liquor of this preparation was taken to dryness, leaving a reddish-brown solid (B). Both isomers were obtained separately as follows:

Isomer with *trans*-Oriented C=N Double Bonds (11): The crystalline solid obtained under (A), above, was taken up in an acetone/methanol mixture (1:1, 20 mL), and the mixture refluxed overnight to give an intensely coloured purple solution. Cooling to room temperature produced a purple precipitate of single crystals and a faintly pink supernatant. Elemental analysis, although as yet unsatisfactory, and mass spectrometric data indicate a compound of composition $C_{22}H_{37}CuF_{12}N_5P_2$ [bis(hexafluorophosphate) salt, 725.0]: calcd. C 36.45, H 5.14, N 9.66; found C 35.57, H 5.04, N 8.92. − ESI: *m/z* (%) = 434 $[C_{22}H_{37}N_5Cu]^+$ (100). − IR (KBr): $\tilde{\nu}$ = 3356 cm^{-1}, 3307, 3270, 2983, 2939, 2357, 2338, 1660 (C=N), 1589, 1471, 1375, 1243, 1127, 1020, 984, 843 (PF_6), 556.

Isomer with *cis*-Oriented C=N Double Bonds (12): The solid obtained under (B) above was likewise taken up in an acetone/methanol mixture (1:1, 20 mL), and the mixture refluxed overnight. The purple solution, upon cooling to room temperature, deposited reddish-purple single crystals, leaving a strongly coloured purple supernatant. Elemental analysis data best agree with the solid being a monomethanol solvate of composition $C_{22}H_{37}Br_3Cu_2N_5·CH_4O$ (tribromocuprate salt, 770.4): calcd. C 35.86, H 5.36, N 9.09; found C 34.60, H 6.11, N 8.73. − FAB: *m/z* (%) = 434 $[C_{22}H_{37}N_5Cu]^+$ (100). − IR (KBr): $\tilde{\nu}$ = 3442 cm^{-1}, 3212, 3136, 2969, 2368, 2344, 1645 (C=N), 1585, 1572, 1466, 1446, 1420, 1372, 1356, 1241, 1219, 1152, 1095, 1012, 834, 821, 764, 659, 597, 416.

Preparation of the Bis(aminal)dihydrobromide 13: Solid **1**·4HBr·MeOH (0.67 g, 1.1 mmol) was treated with 2 equivalents of LiOMe (1 M solution in methanol, 2.2 mL, 2.2 mmol), giving a clear solution after stirring at room temperature for 5 min. To this was added a large excess of anhydrous acetone (30 mL), and the mixture heated to reflux. A colourless precipitate began to form after a few minutes. Refluxing was continued for 1 h; the mixture was then allowed to cool to room temperature, filtered (G4 glass frit), the obtained solid washed with acetone (2 × 8 mL), and dried in vacuo overnight (0.30 g, 52%). Single crystals of **13** (methanol solvate) were obtained by allowing diethyl ether to diffuse into a methanolic solution of the salt at room temperature. − $C_{19}H_{35}Br_2N_5·CH_4O$ (525.4): calcd. C 45.72, H 7.48, N 13.33; found C 45.92, H 7.30, N 13.25. − ^{1}H NMR ([D$_6$]DMSO, room temp.): δ = 8.35 (br. s, 6 H, NH), 7.84 [AB_2, 3 lines, ^3J(HH) = 7.9 Hz, 1 H, py-H^4], 7.45 [AB_2, 2 lines, ^3J(HH) = 7.9 Hz, 2 H, py-H^{3,5}], 4.12 [br. s, 1 H, OH (methanol)], 3.47 (br. m, 4 H, −C*H*H−), 3.15 [s, 3 H, CH_3 (methanol)], 3.11 (br. m, 4 H, −CH*H*−), 1.52 [s, 6 H, $C(CH_3)_2$], 1.42 [s, 6 H, $C(CH_3)_2$], 1.37 (s, 6 H, py−C−CH_3). − ^{13}C NMR ([D$_6$]DMSO, room temp.): δ = 161.86 (s, C2/6), 138.19 (s, C4), 119.23 (s, C3/5), 69.63 (s, aminal *C*Me$_2$), 48.58 (s, CH_3OH), 46.94 (s, $-CH_2-$), 37.00 (s, py-*C*−Me), 25 [br, aminal C(*C*H$_3$)$_2$], 23.01 (py−C-*C*H$_3$). − FD: *m/z* (%) = 253 $[py(NH_2)_2(NH_3)_2]^+$ (25), 293 $[py(NH_2)(NH_3)(NHC(CH_3)_2NH_2)]^+$ (30), 333 $[py\{NHC(CH_3)_2NH_2\}_2]^+$ (50). − IR (KBr): $\tilde{\nu}$ = 3244 cm^{-1}, 2961, 1585, 1566, 1500, 1470, 1390, 1238, 1123, 1034, 983, 944, 914, 900, 883, 813, 761, 715, 643, 632, 525, 496, 484, 442. A similar reaction of **1**·2HBr in methanol with two equivalents of mesityloxide (4-methyl-3-pentene-2-one, $C_6H_{10}O$), after stirring at room temperature for 3 days, produced **13** as the exclusive product, as identified by elemental analysis and mass spectrometry. Further, mass spectra show the bis(aminal) (*m/z* = 333) to form also when reacting unprotonated **1**, prepared by addition of 4 equiv. of LiOMe to a suspension of **1**·4HBr·MeOH in methanol, with acetone or mesityloxide (3 days, room temperature).

Acknowledgments

We thank Professor D. Sellmann for generous support of this work and Mr. W. Donaubauer and Mr. H.-G. Köhler for mass spectral measurements. Financial support from the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

Recent Developments in the Reactivity of Allenylidene and Cumulenylidene Complexes

Victorio Cadierno,[a] M. Pilar Gamasa,[a] and José Gimeno*[a]

Dedicated to Prof. Dr. José Barluenga on the occasion of his 60th birthday

Keywords: Allenylidene complexes / Cumulenylidene complexes / Carbene complexes / Vinylidene complexes / Alkynyl complexes

Allenylidene and higher cumulenylidene complexes [M]=C(=C)$_n$=CR^{1}R^2 (n = 1, 2, 3) have continuously gained significance in the context of transition metal carbene chemistry. Important developments which have been disclosed during the last two years are reviewed. These include a variety of stoichiometric and catalytic reactions of allenylidene complexes and their utility in organic synthesis. The related chemistry of butatrienylidene (n = 2) and pentatetraenylidene (n = 3) complexes as well as theoretical studies are also reviewed.

I. Introduction

The chemistry of transition metal carbene complexes has reached such a state of development so as to allow its wide use as one of the most powerful tools in modern organic synthesis.[1] Allenylidene (propadienylidene) complexes [ML$_n$]=C=C=CR^{1}R^2, which belong to the series of unsaturated carbene derivatives [ML$_n$]=C(=C)$_n$=CR^{1}R^2 ($n > 0$; cumulenylidene complexes), have received increasing interest during the last few years. Although the utility of these carbene complexes is still not comparable to that of the classical Fischer-type, both experimental and theoretical studies have been the subject of special attention.

The continuous growth of this chemistry stems mainly from:

a) The presence of an unsaturated carbon chain. Similar to the analogous polyinyl derivatives [ML$_n$]−(C≡C)$_n$−R, cumulenylidenes are potentially useful as precursors of molecular wires or polymers related to polyacetylene of interest in the field of novel materials with opto-electronic properties.[2]

b) The search for novel carbene complexes bearing unsaturated carbon moieties and/or other types of functional groups which can provide multifaceted reactive sites of interest in organic synthesis.

Victorio Cadierno, born in Oviedo (Spain) in 1969, studied chemistry at the University of Oviedo and received his Ph.D. in 1996 working under the supervision of Prof. J. Gimeno. He then joined the group of Prof. J. P. Majoral at the Laboratoire de Chimie de Coordination du CNRS (Toulouse, France) for a two-year postdoctoral stay. Thereafter, he returned to the University of Oviedo where he is currently "Profesor Asociado". His research interests cover the activation of alkynes by transition metal complexes as well as the coordination chemistry of hemilabile phosphane ligands.

M. Pilar Gamasa, born in Pamplona (Spain), studied chemistry at the University of Zaragoza (Spain) and received her Ph.D. under the supervision of Prof. R. Usón. After two years of postdoctoral studies at the Georgia Institute of Technology (Atlanta, U.S.A.) with Prof. E. C. Ashby, she moved to the University of Oviedo (Spain) and became Associate Professor in 1985. Her research has been focused on the chemistry of transition metal carbonyl complexes and on the activation of alkynes and polyynes by transition metal complexes.

José Gimeno studied chemistry at the University of Zaragoza where he received his Ph.D. in 1973 and was promoted to Assistant Professor of Inorganic Chemistry in 1978. He has spent postdoctoral periods at the University of Athens, Georgia (1975−1977) and University of Regensburg (1981), working with Prof. R. B. King and Prof. W. A. Herrmann, respectively. In 1982 he became Professor of Inorganic Chemistry at the University of Oviedo. Since then his research work has been devoted to the study of the activation of terminal alkynes by transition metal complexes mainly of Group 8, including stoichiometric and catalytic processes of alkynyl, vinylidene, allenylidene and other unsaturated carbene complexes.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

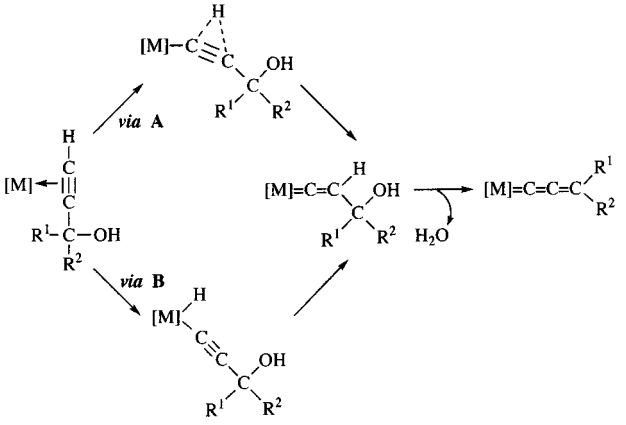
c) The recent discovery of the catalytic activity of allenylidene ruthenium(II) complexes in ring-closing metathesis (RCM) of olefins. These are more accessible catalysts than the classical Schrock-type and Grubbs' alkylidene derivatives.[3]

d) The synthetic accessibility of the cumulenylidene complexes $[ML_n]=C(=C)_n=CR^1R^2$ with higher unsaturation (n = 2, 3) which have also provided further reactivity patterns, albeit in a limited number.

The chemistry of allenylidene complexes and related species have been the subject of two general reviews[4a][4b] which cover the literature up to June 1998 including other specific surveys on rhodium, iridium[4c] and ruthenium complexes.[4d−4f] Brief accounts of the particular aspects of dinuclear and cluster species containing bridging allenylidene moieties have also appeared.[4g−4i] Since the discovery of the first allenylidene complexes $[M\{=C=C=CPh(NEt_2)\}(CO)_5]$ (M = Cr, W)[5a] and $[Mn(=C=C=Ct Bu_2)(\eta^5\text{-}C_5H_5)(CO)_2]$[5b] in 1976 several synthetic approaches have been reported.[4a,4b] Those with the greatest use follow essentially the strategy first used by Selegue for the preparation of $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(PMe_3)_2][PF_6]$ which is based on the spontaneous dehydration of the hydroxyvinylidene species formed, either via **A** or via **B** (see Scheme 1), after the coordination of 2-propyn-1-ols at the metal center.[6]



Scheme 1. Mechanism of the isomerization of 2-propyn-1-ols into allenylidene ligands

Large series of mono- and dinuclear derivatives containing half-sandwich (**A**) as well as octahedral (**B**) or square-planar (**C**) electron-rich metal fragments of Groups 6, 7, 8, and 9 have now been isolated (see Figure 1).[7] They are obtained in generally good yields as stable solids and have been fully characterized through the usual spectroscopic and/or diffractometric techniques. Octahedral Group 6 metal carbonyl derivatives $[M(=C=C=CR^1R^2)(CO)_5]$ are generally thermally unstable and the stabilization of the carbene moiety requires the presence of electron-releasing substituents ($R^1 = R^2 = p\text{-}NR'_2C_6H_4$, $p\text{-}OR'C_6H_4$, etc.). Furthermore, a short number of dinuclear and cluster complexes containing bridging allenylidene groups $[(M_nL_m)(\mu\text{-}\eta^x=C=C=CR^1R^2)_y]$ are also known.[4] More recently, cumulenylidene complexes of the type: (*i*) buta-1,2,3-trienylidenes $[ML_n]=C(=C)_2=CR^1R^2$ with $[ML_n]$ = *trans*-$[RuClL_2]^+$ [L_2 = bis(diphenylphosphanyl)methane (DPPM), bis(diethylphosphanyl)methane (DEPM), 1,2-bis(diphenylphosphanyl)ethane (DPPE)}, $[Ru(\eta^5\text{-}C_5H_5)L_2]^+$ {L = PPh_3, $P(OMe)_3$}, $[Fe(\eta^5\text{-}C_5Me_5)L_2]^+$ [L_2 = DPPE, 1,2-bis(diisopropylphosphanyl)ethane (DIPPE)], and (*ii*) penta-1,2,3,4-tetraenylidenes$[ML_n]=C(=C)_3=CR^1R^2$ with $[ML_n]$ = *trans*-$[RuCl(DPPE)_2]^+$, *trans*-$[RhCl(PiPr_3)_2]$, *trans*-$[IrCl(PiPr_3)_2]$, $[Cr(CO)_5]$, $[W(CO)_5]$ have also been described, the latter being prepared through the intermediate formation of $[M\{=C(=C)_5=CR^1R^2\}(CO)_5]$ (M = Cr, W).[4b]

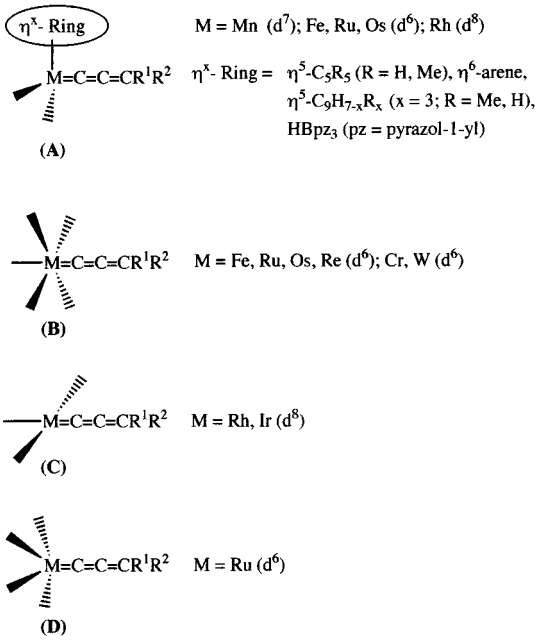


Figure 1. Stereochemistry of mononuclear allenylidenes

Although the first reactivity studies of allenylidene and higher cumulenylidene derivatives emerged simultaneously to their synthesis, their chemistry has grown rapidly and important developments have been disclosed after the period covered in the above-mentioned reviews. The present review will focus mainly on the reactivity studies of allenylidene complexes including stoichiometric and catalytic processes. Special attention will be devoted to the regioselective nucleophilic additions and the utility of these species in organic synthesis. It is worth mentioning the first coordinatively unsaturated Group 8 allenylidene complexes **D** (see Figure 1), some of them showing catalytic activity in RCM (ring-closing metathesis) of olefins.[8] Furthermore, recent advances in theoretical studies which shed light on the chemical behavior as well as a short account of novel structural and spectroscopic properties will be also discussed. Recent developments in the chemistry of related cumulenylidene complexes are also mentioned. This review covers the literature up to May 2000.

II. Structural and Spectroscopic Properties

II.1 X-ray Diffraction Studies

Structural parameters of novel allenylidene complexes studied by X-ray diffraction confirm the previously known features of the metal−allenylidene bonding. Thus, metal−carbon, $C_\alpha-C_\beta$, and $C_\beta-C_\gamma$ bond lengths are in accordance with the well-known description of the bonding as a resonance of metal−carbene and metal−alkynyl mesomers, the latter being the dominant contribution to the observed structures (zwitterionic species $[M]^- - C{\equiv}C-C^+R^1R^2$ for neutral allenylidene complexes):

$$[M]^+{=}C{=}C{=}CR^1R^2 \rightleftarrows [M]-C{\equiv}C-C^+R^1R^2$$

The first coordinatively unsaturated 16-electron allenylideneruthenium complexes, namely $[RuCl_2(=C=C=CPh_2)(PCy_3)_2]$ and $[RuCl_2(=C=C=CPh_2)(PCy_3)(IMes)]$ [IMes = 1,3-bis(2,4,6-trimethylphenyl)imidazol-2-ylidene], have now been described.[8] The crystal structures show that the allenylidene moiety is located at the apex and the ruthenium atom at the bottom of a square pyramid. The most relevant structural feature in both structures is the almost equal bond lengths Ru−C_α (ca. 1.79 Å) which are in the usual range found in other 16-electron carbeneruthenium complexes (1.76−1.84 Å).[9] These values contrast with the larger bond lengths shown by cationic 18-electron species $[Ru]^+{=}C{=}C{=}CR^1R^2$ (see below) indicating that the metal−allenylidene bond is stronger for the former complexes. This structural property is related to the lower catalytic activity of these complexes relative to that observed in the cationic 18-electron (arene)ruthenium complexes in ring-closing metathesis (RCM) reactions (see below). The bond lengths along the allenylidene chain are in the usual range for ruthenium complexes (see below). The allenylidene chain in $[RuCl_2(=C=C=CPh_2)(PCy_3)_2]$ shows an unusual bending [$C_\alpha-C_\beta-C_\gamma$ = 167.20(18)°] which is attributed to a C−H interaction with hydrogen atoms of the PCy_3 ligands.

The rest of the structures reported show M−C_α bond lengths in the 1.858(7)−1.943(8) Å range and $C_\alpha-C_\beta$ in the 1.221(9)−1.267(3) Å range, which compare well with those found previously (1.84−1.94 and 1.24−1.27 Å, respectively).[4a,4b] The allenylidene chain also shows the expected slightly bent linear arrangement (ca. 170−176°).[4a,4b] It should be noted that the *trans*-$[Ru(C{\equiv}CPh)(=C=C=CPh_2)(DPPE)_2][PF_6]$ complex shows bond lengths Ru−C_α [2.11(1) Å] and $C_\alpha-C_\beta$ [1.14(2) Å], unusually larger and shorter, respectively, than those found in analogous mononuclear ruthenium(II) complexes.[10]

Other X-ray crystal-structure determinations include:

A) Mononuclear Derivatives

a) Cationic complexes: (*i*) hexacoordinated ruthenium(II) complexes $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5Me_5)(PEt_3)_2][BF_4]$,[11] $[Ru\{=C=C=C(Me)(C_4H_3NMe\text{-}2)\}(\eta^5\text{-}C_5H_5)(PPh_3)_2][PF_6]$,[12] $[RuCl(=C=C=CPh_2)(\eta^6\text{-}p\text{-cymene})(IMes)][PF_6]$,[13] $[Ru(=C=C=CPh_2)(\eta^5\text{-TRIPOD})][PF_6]$ (TRIPOD = $CH_3C(CH_2\text{-}\eta^5\text{-}C_5H_4)(CH_2\text{-}\eta^1\text{-}PPh_2)_2$),[14] $[Ru(=C=C=CPh_2)\{HB(pz)_3\}(PPh_3)_2][PF_6]$ (pz = pyrazol-1-yl)[15] and $[RuCl(=C=C=CPh_2)(PPh_3)\{\kappa^3\text{-}N,N,N\text{-}(S,S)\text{-}i\text{Pr-PYBOX}\}][PF_6]$ {(*S,S*)-*i*Pr-PYBOX = 2,6-bis[4′-(*S*)-isopropyloxazolin-2′-yl]pyridine},[16] and (*ii*) the tetra-coordinated rhodium(I) complex *trans*-$[Rh(=C=C=CPh_2)(O=CMe_2)(P\textit{i}Pr_3)_2][PF_6]$.[17]

b) Neutral octahedral ruthenium(II) *fac,cis*-$[RuCl_2(=C=C=CPh_2)(PNP)]$ {PNP= $MeCH_2CH_2N(CH_2CH_2PPh_2)_2$},[18] $[RuCl_2(=C=C=CPh_2)(CO)(Sb\textit{i}Pr_3)_2]$[19] and square-planar iridium(I) *trans*-$[IrF(=C=C=CPh_2)(P\textit{i}Pr_3)_2]$[20] complexes.

B) Polynuclear Derivatives

a) Dinuclear cationic complexes of three types (Figure 2): (*i*) the osmium(II) derivative $[(\eta^5\text{-}C_5H_5)(PPh_3)_2Os\{=C=C=C(H)-C{\equiv}C-Os(\eta^5\text{-}C_5H_5)(PPh_3)_2\}][BF_4]$ (**A**);[21] (*ii*) the mixed-valence ruthenium(II)−ruthenium(III) complex $[Ru(=C=C=Rc)(\eta^5\text{-}C_5H_5)(DPPE)][BF_4]_2$ [Rc = $(\mu^2\text{-}\eta^6\text{:}\eta^5\text{-}C_5Me_4)Ru(\eta^5\text{-}C_5H_5)$] containing a half-sandwich ruthenium(III) fragment bonded to a (cyclopentadienylidene)ethylidene group which acts as the bridging chain to the (η^5-C_5H_5)Ru moiety (**B**).[22] Another example of this type is the dimetallic iron(II)−chromium(0) complex $[(CO)_2(\eta^5\text{-}C_5H_5)Fe(\mu\text{-}\eta^1\text{:}\eta^7\text{-}C_2C_7H_6)Cr(CO)_3][BF_4]$ (**C**) although structural parameters of the Fe−$C_\alpha-C_\beta-C_\gamma$ chain indicate that the bridging moiety can be better described as a substituted tropylium alkynyl group;[23] and (*iii*) the bis(allenylidene)dirhodium(I) complex $\{[(P\textit{i}Pr_3)_2\{Ph(o\text{-Tol})C=C=C=\}Rh]_2(\mu\text{-}1,3\text{-}N_3)\}^+$ (**D**) in which the two allenylidene groups, both rhodium atoms and the bridging azide ligand form an unusual eleven-membered chain.[24]

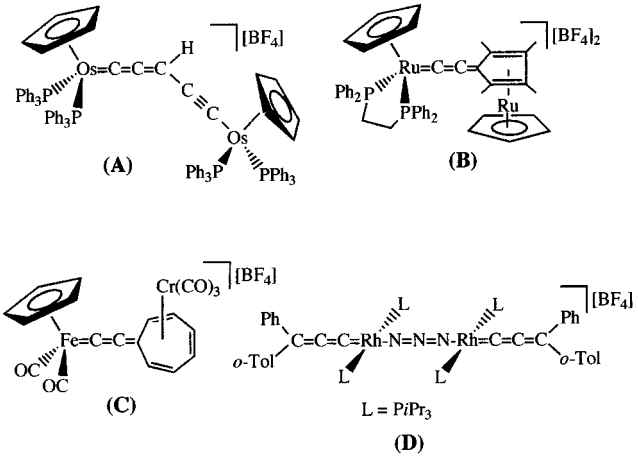

Figure 2. Some structures of dinuclear allenylidene complexes

b) Bridging cumulenylidene complexes (Figure 3): (*i*) The polynuclear complex $[Re(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)(CCC)Os_3(CO)_9(\mu\text{-OMe})]$ (**A**) showing a bridging moiety Re=C=C−C in which the terminal carbon atom is bonded to the three osmium atoms and the center carbon atom binds to the osmium atom that is not methoxide-bridged. The ReCCC chain is highly distorted;[25] (*ii*) bridging butatrien-

ylidene pentanuclear ruthenium complexes $[Ru_5(\mu_5\text{-}CCCCH_2)(\mu_3\text{-}SMe)(\mu\text{-}SMe)(\mu\text{-}PPh_2)_2(CO)_{10}]$ (**B**) and $[Ru_5(\mu_5\text{-}CCCCH_2)(\mu\text{-}SMe)_2(\mu\text{-}PPh_2)_2(CO)_{11}]$ (**C**) in which the cumulenylidene ligand is attached to the cluster by three of its four carbon atoms;[26] (*iii*) trinuclear ruthenium clusters containing bridging μ_3-allenylidene ligands of the type **D**.[27] The X-ray crystal structures of a series of analogous derivatives containing Ru_3 and Ru_3Au cores have been also reported;[27] (*iv*) the Fe,Co mixed metal cluster of composition $[(\eta^5\text{-}C_5Me_5)Fe_2Co_4(\mu\text{-}C_4H)(CO)_{17}]$ (**E**) which consists of two triangular Fe_2Co and Co_3 cluster fragments linked by a C_4H bridge.[28] This moiety acts as a bridging allenylidene interacting with the Fe_2Co fragment as a μ_3-η^1(Fe):η^1(Fe):η^2(Co) ligand.

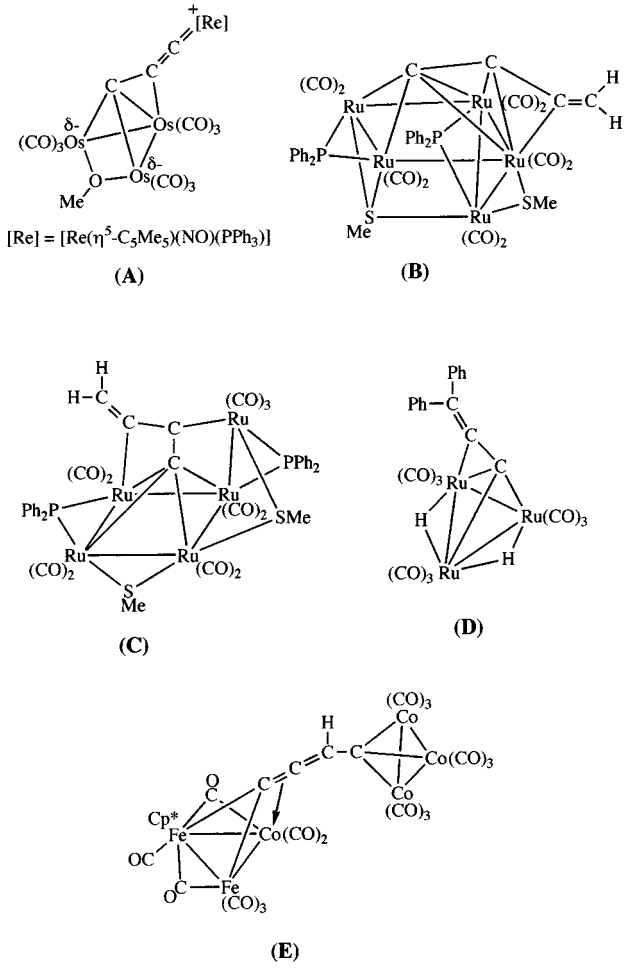

Figure 3. Some structures of polynuclear cumulenylidene complexes

Furthermore, the structures of the dinuclear complexes $[(DMPE)_2IMn{=}C{=}C{=}C{=}C{=}MnI(DMPE)_2][BPh_4]$ [DMPE = 1,2-bis(dimethylphosphanyl)ethane],[29a] $[(\eta^5\text{-}C_5Me_5)(DIPPE)Fe{=}C{=}C{=}C{=}C{=}Fe(DIPPE)(\eta^5\text{-}C_5Me_5)][PF_6]_3$[29b] and $[(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)Re{=}C{=}C{=}C{=}Mn(CO)_2(\eta^5\text{-}C_5H_5)][BF_4]$[30] have also been determined by X-ray diffraction. They consist of a linear arrangement of the bridging cumulenylidene ligand with almost equal C=C distances (ca. 1.27−1.33 Å).

II.2 Spectroscopic Properties

II.2.1 IR and ^{13}C NMR

The infrared spectra of novel allenylidene complexes show the characteristic ν(C=C=C) strong absorption in the 1870−1971 cm^{-1} region. A lower frequency is observed (1803−1825 cm^{-1}) for the dinuclear $Ru^{III}-Ru^{II}$ complexes $[Ru(=C=C=Rc)(\eta^5\text{-}C_5H_5)L^1L^2][BF_4]_2$ [Rc = $(\mu^2\text{-}\eta^6{:}\eta^5\text{-}C_5Me_4)Ru(\eta^5\text{-}C_5H_5)$; $L^1 = L^2 = PPh_3$, L^1L^2 = DPPE] which seems to indicate that the unsaturated chain is intermediate between that of a vinylidene and an allenylidene moiety.[22] C_α chemical shifts and coupling constants *J*(CP) in the ^{13}C NMR spectra have been widely reported and generally used as one of the most relevant data to support the existence of the metal−carbene bond. As expected, typical low field signals are found in the range $\delta \approx 255-320$. The following features deserve to be mentioned: a) although the resonance for the dinuclear iron(II) complex $[(\eta^5\text{-}C_5H_5)(PPh_3)_2Fe\{=C=C=CH-C\equiv C-Fe(PPh_3)_2(\eta^5\text{-}C_5H_5)\}][BF_4]$ appears as usual ($\delta_{C\alpha}$ = 223.3), an high field chemical shift is shown by the corresponding resonance in the analogous osmium derivative ($\delta_{C\alpha}$ = 196.2);[21] b) a significant shielding effect on the C_α nucleus is observed in allenylidenes containing donor groups of the type *trans*-$[RuX\{=C=C=CR^1R^2\}(DPPE)_2][PF_6]$, i.e. X = Cl; R^1 = H; R^2 = *p*-$NMe_2C_6H_4$ ($\delta_{C\alpha}$ = 265.7) vs. X = Cl; R^1 = H; R^2 = Ph ($\delta_{C\alpha}$ = 321.07), X = Cl; $R^1 = R^2$ = *p*-$OMeC_6H_4$ ($\delta_{C\alpha}$ = 288.4) vs. X = Cl; $R^1 = R^2$ = Ph ($\delta_{C\alpha}$ = 308.58), and R^1 = H; R^2 = CH=CH(*p*-$NO_2C_6H_4$) ($\delta_{C\alpha}$ = 322.77);[10] c) although the order $\delta_{C\alpha} > \delta_{C\beta} > \delta_{C\gamma}$ is usually found for most of the allenylidene complexes, an inversion of the sequence of the chemical shifts has been reported in several cases, i.e. *trans*-$[IrX(P\mathit{i}Pr_3)_2]$ (X = OH, OPh, F; $\delta_{C\alpha}$ = 202.7−205.8, $\delta_{C\beta}$ = 252.8−273.9).[20]

II.2.2 Mössbauer Spectroscopy

^{57}Fe Mössbauer spectroscopic studies have been performed for mono- and dinuclear iron−allenylidene complexes by Lapinte et al.[31] The spectrum of the complex $[Fe\{=C=C=C(OMe)Me\}(\eta^5\text{-}C_5Me_5)(DPPE)][BPh_4]$ displays a quadrupole doublet at δ = 0.160 mm s^{-1} with a quadrupole splitting of ΔE_Q= 1.451 mm s^{-1}. These parameters are well-differentiated from those of analogous complexes containing iron−carbon single bonds with the conclusion that by using this spectroscopic technique, it is possible to identify the metal−carbon bonding order. The spectra of the bridging butatrienylidene complexes $[(\eta^5\text{-}C_5Me_5)L^1L^2Fe\{=C=C=C=C(H)Fe(\eta^5\text{-}C_5Me_5)(CO)_2\}][BF_4]$ (L^1L^2 = DPPE, DIPPE) at 80 K show two quadrupole doublets δ = 0.161−0.257 and 0.029 mm s^{-1} (ΔE_Q= 1.973−1.264 and 1.974−1.778 mm s^{-1}, respectively) which are characteristic of iron dinuclear species with two different coordination environments around the metal atoms.[32] The doublet with the larger isomeric shift was assigned to the $[(\eta^5\text{-}C_5Me_5)L^1L^2Fe]$ fragment. These values are consistent with a weak Fe=C π-bond which is in agreement with the electron delocalization along the cumulenylidene chains

in which significant contributions of the mesomers [Fe]−C^+=C=C=C(R)−[Fe] and [Fe]−C≡C−C^+=C(R)−[Fe] are present.

III. Theoretical Studies

Since the early studies by Hoffman[33] using the half-sandwich complex [Mn(=C=C=CH_2)(η^5-C_5H_5)(CO)$_2$] as a model, a series of theoretical calculations on allenylidene complexes involving several metallic fragments have now been reported. These studies, performed using the Extended Hückel Molecular Orbital (EHMO) methodology, generally confirm the initial results obtained on the electronic structure[33] and on the reactivity[34] which establish: (*i*) the most stable conformation of the allenylidene group =C=C=CR^1R^2 is that contained in the molecular plane, (*ii*) the allenylidene fragment is a σ-donor π-acceptor ligand with a dominant contribution to the bonding of the latter component, and (*iii*) the carbon atoms of the unsaturated chain are alternatively electron-poor and electron-rich, starting from the metal center. Hence, electrophilic centers are located at the C_α and C_γ atoms while the C_β atom is a nucleophilic site.

Table 1 collects quantitative data of the LUMO and HOMO distribution, as well as net charges at the carbon atoms of the allenylidene chain on a series of cationic ruthenium and osmium(II) as well as the neutral [OsCl(=C=C=CH_2)(η^5-C_5H_5)(PH_3)] models. On the basis of these data, the following points deserve to be highlighted: (*i*) the LUMO distribution along the C_3 chain (20−28% C_α; 30−37% C_γ) is similar, regardless of the nature of the metal (Ru or Os) and the auxiliary ligands, (*ii*) total charge transfer from the metallic fragments [OsCl(η^5-C_5H_5)(PH_3)] and [Os(η^5-C_5H_5)(PH_3)$_2$]$^+$ is similar and higher (ca. 57−60%) than that of [Os(η^5-C_5H_5)(CO)(PH_3)]$^+$, (*iii*) the fragment [Ru(η^5-C_9H_7)(PH_3)$_2$]$^+$ shows total charge-transfer values which are notably higher (ca. 69−86%) than those of [Ru(η^5-C_9H_7)(CO)(PH_3)]$^+$ and [Ru(η^5-1,2,3-$Me_3C_9H_4$)(CO)(PH_3)]$^+$, respectively.

These results allow the rationalization of the reactivity of these species which can be classified, depending on the type of addition, as electrophilic and nucleophilic allenylidenes. It is worth mentioning the versatile chemical behavior of [Os(=C=C=CPh_2)(η^5-C_5H_5)(P*i*Pr$_3$)$_2$][PF_6], which probably arises from the particular total charge-transfer value and its cationic character which is able to undergo both electrophilic and nucleophilic additions (see below).[38] As a general trend, it can be observed that the cationic complexes undergo orbitally controlled nucleophilic additions at either C_α and C_γ atoms, and that the regioselectivity depends on the steric and/or electronic properties of the ancillary ligands (see below).

EHMO calculations have also been performed for a bridging (allenylidene)dirhodium(I) complex, using [Rh_2(μ-OOCH)(μ-σ,σ-C=C=CH_2)(CO)$_2$(PH_3)$_2$]$^+$ as a model, showing that the allenylidene ligand also behaves as a good π-acceptor ligand, the highest negative charge being located at the C_α atom.[39] This charge is found to decrease towards the C_γ atom. Brief accounts of theoretical calculations on the dinuclear complexes [(η^5-C_5H_5)(PH_3)$_2$Ru{=C=C=C(H)−C≡C−Ru(PH_3)$_2$(η^5-C_5H_5)}]$^+$ [21] and [(PH_3)$_4$IMn=C=C=C=C=MnI(PH_3)$_4$][29a] have also been reported. More recently,[40] density-functional calculations have been performed on the metallacumulenylidene complexes [Cr{(=C)$_n$$H_2$}(CO)$_5$] ($n$ = 2−9) showing, as for the above-mentioned examples, that the electrophilic and nucleophilic attacks are frontier orbital controlled. Dissociation energies have been calculated and found to be essentially independent of the chain length.

IV. Reactivity of Cationic Allenylidene Complexes

As shown in previous theoretical and experimental studies,[4a,4b] the reactivity of novel cationic transition-metal allenylidene derivatives is mainly governed by the electron-deficient character of the C_α and C_γ carbon atoms in the cumulene chain, which are therefore subject to nucleophilic attacks. The regioselectivity of the nucleophilic additions seems to be controlled by the electronic and steric properties both of the substituents on the unsaturated hydrocarbon chain and the ancillary ligands on the metal atom and the nucleophile used (see below). Additions of electrophiles at the nucleophilic C_β atom of neutral allenylidene derivatives are scarce,[4a−4b] the protonation of the diphenylallenylidene osmium(II) complex [Os(=C=C=CPh_2)(η^5-C_5H_5)(P*i*Pr$_3$)$_2$][PF_6] with HPF_6 to give the alkenylcarbyne [Os{≡C−C(H)=CPh_2}(η^5-C_5H_5)(P*i*Pr$_3$)$_2$][PF_6]$_2$ being the only example of an electrophilic addition in a cationic complex reported to date.[38]

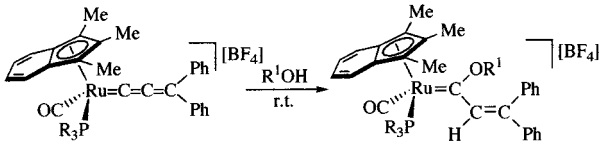
IV.1 Additions of Neutral Nucleophiles

IV.1.1 Alcohols

One of the most remarkable reactions of cationic allenylidene complexes is the nucleophilic addition of alcohols to afford Fischer-type α,β-unsaturated alkoxycarbene derivatives of general formula $[M]^+=C(OR^1)-C(H)=CR^2R^3$.[4a−4b] The regioselectivity of the addition is in agreement with the formation of allenyl species $[M]-C(HO^+R^1)=C=CR^2R^3$ as intermediates or transition states. This oxygen−C_α interaction labilizes the O−H bond, favoring the migration of the hydrogen atom to C_β. The ability of the allenylidene ligand to undergo these nucleophilic attacks is clearly dependent on the electronic and steric nature of the ancillary ligands on the metal atom.[4a−4b] This is nicely illustrated by the behavior of indenylruthenium(II)−allenylidene complexes. Thus, while the disubstituted derivatives $[Ru(=C=C=CR^2R^3)(\eta^5\text{-}1,2,3\text{-}R^1_3C_9H_4)L^1L^2]^+$ (R^1 = H, $L^1 = L_2 = PPh_3$, L^1L^2 = DPPE, DPPM, $R^2 = R^3$ = Ph, $R^2R^3 = C_{12}H_8$; R^1 = Me, L^1L^2 = DPPM, $R^2 = R^3$ = Ph) are unreactive towards alcohols,[41,42] the diphenylallenylidene complexes $[Ru(=C=C=CPh_2)(\eta^5\text{-}1,2,3\text{-}Me_3C_9H_4)(CO)(PR_3)]^+$ (PR_3 = PPh_3, P*i*Pr$_3$, PCy_3) containing the less sterically demanding and more π-accepting CO/PR_3 combination react with methanol or ethanol to yield the alkenyl(alkoxy)carbene derivatives $[Ru\{=C(OR^1)-C(H)=CPh_2\}(\eta^5\text{-}1,2,3\text{-}Me_3C_9H_4)(CO)(PR_3)][BF_4]$ (**1**) (Scheme 2).[42,43] It should be noted that the diphenylallenylidenes $[RuCl(=C=C=CPh_2)(\eta^6\text{-}p\text{-cymene})(PR_3)][PF_6]$ (PR_3 = PCy_3, P*i*Pr$_3$, PPh_3), used recently by Dixneuf and co-workers as active catalysts for the RCM of olefins, are also unreactive towards alcohols.[44]



R^1 = Me, PR_3 = PPh_3, P*i*Pr$_3$, PCy_3 **1**
R^1 = Et, PR_3 = PPh_3, P*i*Pr$_3$

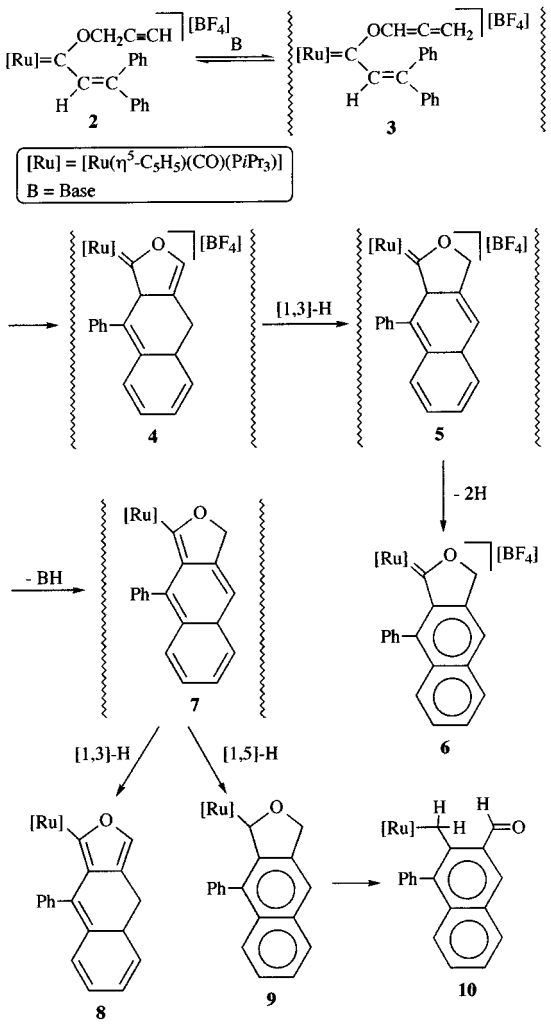
Scheme 2. Synthesis of (1,2,3-trimethylindenyl)ruthenium(II)−(alkenyl)(alkoxy)carbene complexes

There is also an influence of the allenylidene substituents in the reactivity of the corresponding complexes towards alcohols. This fact is clearly shown in the formation of the Fischer-type carbene complexes $[Ru\{=C(OMe)-C(H)=C(H)R\}(\eta^5\text{-}C_9H_7)L^1L^2][PF_6]$ (R = Ph, L^1L^2 = DPPE, DPPM; R = H, L^1L^2 = DPPM) which are readily obtained by the reaction of $[RuCl(\eta^5\text{-}C_9H_7)L^1L^2]$ with HC≡CCH(OH)R and $NaPF_6$ in methanol by nucleophilic attack of the alcohol on the unstable allenylidene intermediates $[Ru\{=C=C=C(H)R\}(\eta^5\text{-}C_9H_7)L^1L^2][PF_6]$.[41] The related methoxycarbene derivatives $[Ru\{=C(OMe)-C(H)=CMe_2\}(\eta^6\text{-}C_6Me_6)(MDMPP\text{-}P,O)][PF_6]$[MDMPP-*P*,*O* = P(2-*O*-6-MeOC$_6$H$_3$)Ph$_2$],[45] $[RuCl\{=C(OMe)-C(H)=CPh_2\}(PPh_3)\{\kappa^3\text{-}N,N,N(PYBOX)\}][PF_6]$ [PYBOX = 2,6-bis(dihydrooxazolin-2′-yl)pyridine],[16] and $[Re\{=C(OMe)-C(H)=C(H)Me\}(TRIPHOS)(CO)_2][CF_3SO_3]$ [TRIPHOS = 1,1,1-tris(diphenylphosphanylmethyl)ethane][46] have recently been obtained following this simple synthetic procedure. In addition, the methoxy(methoxyethyl)carbene complex $[Re\{=C(OMe)CH_2CH_2(OMe)\}(TRIPHOS)(CO)_2][CF_3SO_3]$ has been prepared by treatment of hydroxyvinylidene $[Re\{=C=C(H)CH_2(OH)\}(TRIPHOS)(CO)_2][CF_3SO_3]$ with methanol, through a concerted dehydration followed by a double addition of MeOH to the C_α and C_γ atoms of the transient allenylidene $[Re(=C=C=CH_2)(TRIPHOS)(CO)_2][CF_3SO_3]$.[46]

The reaction of $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(P\text{-}iPr_3)][BF_4]$ with propargyl alcohol is of particular interest. The addition gives the α,β-unsaturated (propargyloxy)carbene complex $[Ru\{=C(OCH_2C{\equiv}CH)-C(H)=CPh_2\}(\eta^5\text{-}C_5H_5)(CO)(PiPr_3)][BF_4]$ (**2**) which reacts with bases to afford a mixture of rare cycloaddition products including **6**, **8**, **9**, and **10** (Scheme 3),[47] the main components of the mixture being dependent on the nature of the base used. The following mechanism is proposed: (*i*) formation in the first step of the (allenyloxy)carbene intermediate **3** by a base-catalyzed isomerization of the propargylic unit into an allenic moiety, (*ii*) an intramolecular Diels−Alder reaction within complex **3** to give the unstable tricyclic alkoxycarbene **4** (the $C_\beta-C_\gamma$ double bond and one of the phenyl groups of the alkenyl unit act as an inner-outer ring diene and the $C=CH_2$ fragment of the alkoxy group acts as a dienophile) and (*iii*) subsequent 1,3-hydrogen shift from the methylene group of the central ring to the OCH= carbon atom on **4** would give carbene intermediate **5** which by aromatization should yield the stable complex **6**. Formation of **8** and **9** has been explained by taking into account that a deprotonation process occurs on **5** to produce the tricyclic alkenyl derivative **7**, which could evolve both by a 1,3- or 1,5-hydrogen shift, respectively. Complex **10** seems to be the result of a concerted intramolecular proton-transfer reaction within the heterocycle of **9**.

IV.1.2 Amines

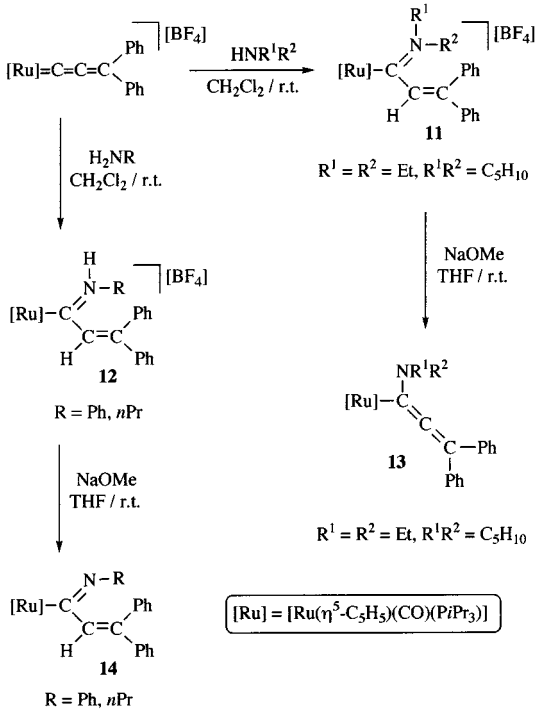
By analogy with the above-mentioned reactions, the addition of primary or secondary amines to a cationic allenylidene ligand should afford aminocarbene complexes $[M]^+=C(NR^1R^2)-C(H)=CR^3R^4$. In this context, Esteruelas and co-workers have recently described the reactivity of $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(PiPr_3)][BF_4]$ towards secondary and primary amines.[48] As expected, addition of the N−H bond of the amines to the $C_\alpha-C_\beta$ double bond of the allenylidene group takes place, yielding complexes **11** and **12** (Scheme 4). Nevertheless, structural studies as well as theoretical calculations seem to indicate that these complexes are better described as azoniabutadienyl species, where the contribution of the aminocarbene resonance form is not relevant. Once again, the regioselectivity of these nucleophilic attacks seems to be governed by the steric bulk of the ligands present at the metal center, since the cationic alkynyl derivative $[Ru\{C{\equiv}CCPh_2(NHMe_2)\}(\eta^5\text{-}C_5H_5)(PPh_3)_2][PF_6]$ was quantitatively obtained when



Scheme 3. Synthesis of polycyclic ruthenium(II) complexes starting from $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(P\mathit{i}Pr_3)][BF_4]$

$[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(PPh_3)_2][PF_6]$ was dissolved in neat dimethylamine.[49] The marked difference in behavior between the tertiary and secondary azoniabutadienyl complexes **11** and **12** should be noted. Thus, while deprotonation of **11** takes place on the $CH{=}CPh_2$ group to yield aminoallenyl derivatives **13**, deprotonation of **12** occurs selectively at the nitrogen atom affording azabutadienyl complexes **14** (Scheme 4).[48]

The reactivity of the cationic Rh^I−diphenylallenylidene derivative *trans*-$[Rh(=C=C=CPh_2)(O=CMe_2)(P\mathit{i}Pr_3)_2][PF_6]$ towards pyridine and ammonia has also been explored.[17] Surprisingly, in this case no addition of the amine on the allenylidene chain was observed, giving instead acetone substitution products i.e. *trans*-$[Rh(=C=C=CPh_2)(Py)(P\mathit{i}Pr_3)_2][PF_6]$ and *trans*-$[Rh(=C=C=CPh_2)(NH_3)(P\mathit{i}Pr_3)_2][PF_6]$. In addition, treatment of complexes *trans*-$[RuCl\{=C=C=C(OMe)CH_2Ph\}(DPPE)_2][PF_6]$[50] and $[Re\{=C=C=C(Me)Ph\}(TRIPHOS)(CO)_2][CF_3SO_3]$,[46] containing an acidic hydrogen atom at C_δ, with triethylamine exclusively yields neutral enynyl derivatives *trans*-$[RuCl\{C{\equiv}C{-}C(OMe){=}C(H)Ph\}(DPPE)_2]$ and $[Re\{C{\equiv}C{-}C(Ph){=}CH_2\}(TRIPHOS)(CO)_2]$, respectively, as the result of a deprotonation process.

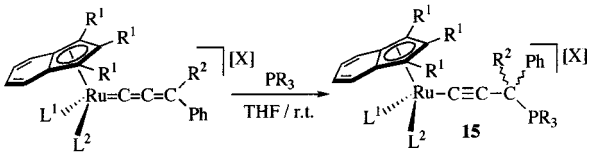


Scheme 4. Preparation of (azoniabutadienyl)-, (aminoallenyl)- and (azabutadienyl)Ru^{II} complexes

IV.1.3 Phosphanes

a) Phosphonioalkynyl and -allenyl Complexes: The nucleophilic attack of phosphanes on allenylidene complexes is a well-documented reaction.[4a−4b] Thus, we have found that indenylruthenium(II)−allenylidene complexes $[Ru\{=C=C=C(R^2)Ph\}(\eta^5\text{-}1,2,3\text{-}R'_3C_9H_4)L^1L^2]^+$ (R^1 = H, R^2 = Ph, $L^1 = L^2 = PPh_3$, L^1L^2 = DPPE, DPPM, L^1 = CO, $L^2 = P\mathit{i}Pr_3$; R^1 = H, R^2 = H, $L^1 = L^2 = PPh_3$; R^1 = Me, R^2 = Ph, L^1 = CO, $L^2 = PPh_3$, $P\mathit{i}Pr_3$) undergo regioselective additions of tertiary phosphanes at the C_γ atom, affording cationic phosphonioalkynyl complexes **15** in excellent yields (Scheme 5).[43,51] The related phosphonioalkynyl derivatives $[Ru\{C{\equiv}CCR^1R^2(PPh_3)\}(\eta^5\text{-}C_9H_7)(PPh_3)_2][PF_6]$ (R^1 = R^2 = H; CR^1R^2 = cyclopentyl, cyclohexyl) and $[Ru\{C{\equiv}CC(H)Ph(PPh_3)\}(\eta^5\text{-}1,2,3\text{-}Me_3C_9H_4(CO)(PPh_3)][BF_4]$ were obtained in a one-pot synthesis by reaction of halide complexes $[RuCl(\eta^5\text{-}C_9H_7)(PPh_3)_2]$ and $[RuBr(\eta^5\text{-}1,2,3\text{-}Me_3C_9H_4)(CO)(PPh_3)]$ with the corresponding propargyl alcohol in the presence of $NaPF_6$ or $AgBF_4$ and a large excess of PPh_3.[43,52,53] These nucleophilic additions seem to be controlled not only by the steric properties of the metallic fragments but also both by the cone angle of the phosphane and the size of the allenylidene substituents. Thus, complexes $[Ru\{C{\equiv}CCPh_2(PMe_3)\}(\eta^5\text{-}C_9H_7)(DPPM)][PF_6]$ and $[Ru\{C{\equiv}CCPh_2(PMe_3)\}(\eta^5\text{-}1,2,3\text{-}Me_3C_9H_4)(CO)(PPh_3)][BF_4]$ slowly isomerize at room temperature to give the thermodynamically more stable phosphonioallenyl derivatives $[Ru\{C(PMe_3){=}C{=}CPh_2\}(\eta^5\text{-}C_9H_7)(DPPM)][PF_6]$[51] and

[Ru{C(PMe$_3$)=C=CPh$_2$}(η^5-1,2,3-Me$_3$C$_9$H$_4$)(CO)(PPh$_3$)][BF$_4$],[43] respectively, while [Ru{C(PMe$_2$Ph)=C=CPh$_2$}(η^5-C$_9$H$_7$)(DPPM)][PF$_6$][51] and [Ru{C(PR$_3$)=C=CPh$_2$}(η^5-C$_5$H$_5$)(CO)(P*i*Pr$_3$)][BF$_4$] (PR$_3$ = PPh$_3$, PMePh$_2$, PHPh$_2$)[54] were obtained regioselectively when allenylidenes [Ru(=C=C=CPh$_2$)(η^5-C$_9$H$_7$)(DPPM)][PF$_6$] and [Ru(=C=C=CPh$_2$)(η^5-C$_5$H$_5$)(CO)(P*i*Pr$_3$)][BF$_4$] were treated with the appropriate phosphane. Related phosphanylalkynyl complexes [Ru{C≡CCR^{1}R^2(PEt$_3$)}(η^5-C$_5$Me$_5$)(PEt$_3$)$_2$][BPh$_4$] (R^1 = R^2 = Me; CR^{1}R^2 = cyclohexyl) were recently synthesized in low yields, by the direct activation of HC≡CC(OH)R^{1}R^2 by [RuCl(η^5-C$_5$Me$_5$)(PEt$_3$)$_2$] without an external source of PEt$_3$.[11] Apparently, phosphane dissociation occurs to some extent in solution, reacting with transient [Ru(=C=C=CR^{1}R^2)(η^5-C$_5$Me$_5$)(PEt$_3$)$_2$][BPh$_4$] species.



R^1 = H, R^2 = H, L^1 = L^2 = PPh$_3$, PR$_3$ = PMe$_3$, PMe$_2$Ph, PMePh$_2$, PPh$_3$, X = PF$_6^-$

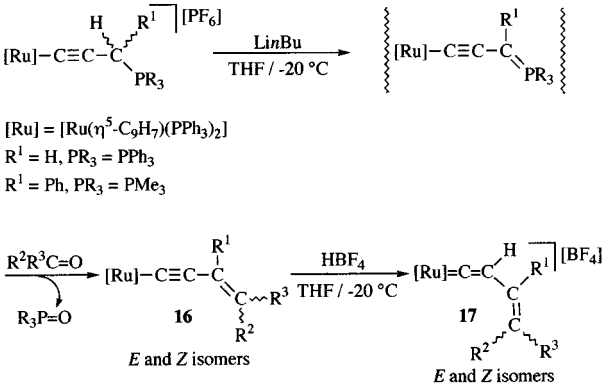
Scheme 5. Synthesis of indenylruthenium(II)−phosphanylalkynyl complexes

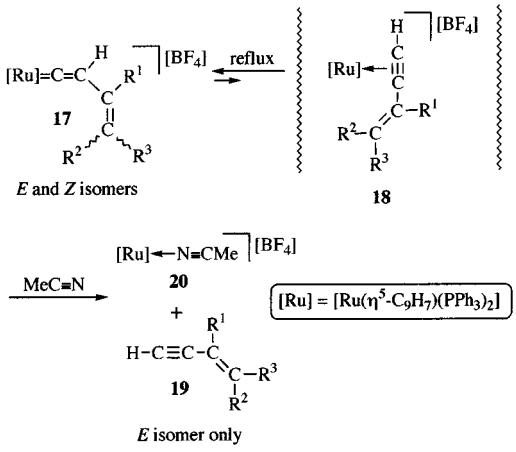
b) Synthetic Utility of Phosphonioalkynyl Complexes: We have exploited the synthetic utility of the readily available indenylruthenium(II)−phosphonioalkynyl complexes [Ru{C≡CC(R^1)H(PR$_3$)}(η^5-C$_9$H$_7$)(PPh$_3$)$_2$][PF$_6$] (R^1 = H, PR$_3$ = PPh$_3$; R = Ph, PR$_3$ = PMe$_3$) containing an acidic hydrogen atom at C$_\gamma$. These complexes are suitable precursors for the high-yield preparation of a wide series of neutral enynyl and polyenynyl complexes **16** (Scheme 6) by means of Wittig-type processes with carbonyl compounds.[55,56] When aldehydes are used, inseparable mixtures of the corresponding (*E*) and (*Z*) stereoisomers are obtained. The polyenynyl skeleton in complexes **16** should be an excellent pathway for electron delocalization between the electron-rich metal fragment [Ru(η^5-C$_9$H$_7$)(PPh$_3$)$_2$] and terminal functional groups. We therefore carried out a series of Wittig reactions using unsaturated aldehydes and ketones bearing strong electron-accepting end groups (e.g. *p*-NO$_2$C$_6$H$_4$, *p*-CNC$_6$H$_4$) or efficient bridging groups (e.g. C≡N, pyridine), capable of coordinating metallic acceptor fragments [e.g. Cr(CO)$_5$, W(CO)$_5$]. As expected, the resulting donor−acceptor enynyl and polyenynyl complexes are of interest as materials with good second-order nonlinear optical (NLO) properties exhibiting high values of the molecular quadratic hyperpolarizability coefficient (β).[52]

We have also shown that protonation of these polyunsaturated alkynyl derivatives proceeds regioselectively at the C$_\beta$ atom of the alkynyl group affording unprecedented cationic



Scheme 6. Synthesis of indenylruthenium(II)−enynyl, −polyenynyl, −vinylvinylidene, and −polyenylvinylidene complexes

vinylvinylidene and polyenylvinylidene species **17** (Scheme 6).[55,56] Vinylvinylidene complexes **17** are of interest in organic synthesis. Heating at reflux in acetonitrile stereoselectively generates the corresponding terminal (*E*)-1,3-enynes **19** and the cationic nitrile complex [Ru(η^5-C$_9$H$_7$)(N≡CMe)(PPh$_3$)$_2$][BF$_4$] (**20**) (Scheme 7).[56] This reaction can be explained taking into account that vinylvinylidenes **17** are in equilibrium with their η^2-coordinated 1,3-enyne tautomers [Ru{η^2-HC≡CC(R^1)=CR^{2}R^3}(η^5-C$_9$H$_7$)(PH$_3$)$_2$][BF$_4$] (**18**). The rapid substitution of the labile coordinated enyne by the more basic acetonitrile ligand favors the displacement of the equilibrium to afford the final species **19** and **20**. Ab initio molecular orbital (MO) calculations on the model [Ru(=C=CH$_2$)(η^5-C$_9$H$_7$)(PH$_3$)$_2$]$^+$ are consistent with the experimental results.



Scheme 7. Synthesis of terminal (*E*)-1,3-enynes starting from indenylruthenium(II)−vinylvinylidene complexes

In summary, it was shown that indenylruthenium(II)−allenylidene complexes are useful precursors for the syn-

thesis of functionalized terminal alkynes. Schemes 6 and 7 show a systematic synthetic approach which allows the isolation of free alkynes in good yields, recovering the metallic fragment quantitatively.

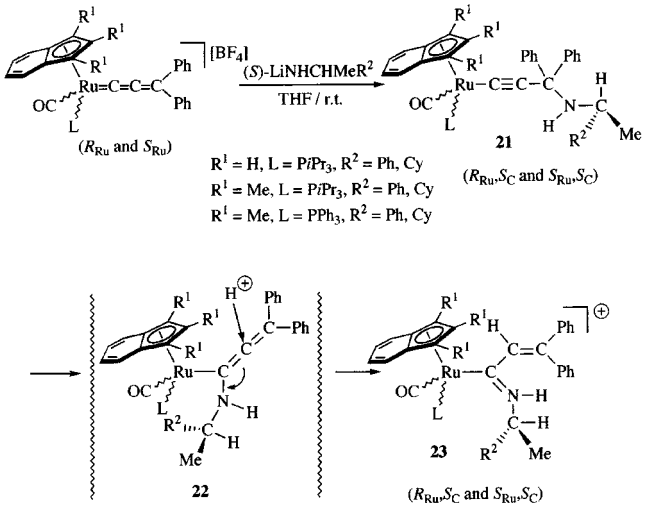
IV.2 Additions of Anionic Nucleophiles: Synthesis of Neutral Alkynyl Complexes [M]−C≡C−C(Nu)R^1R^2

IV.2.1 Heteroanions

In marked contrast to alcohols, alcoholates $[R^1O]^-$ add regioselectively at the C_γ atom of cationic allenylidene complexes to afford neutral alkynyl derivatives of general formula [M]−C≡C−C(OR^1)R^2R^3.[4a−4b] Complexes [Ru{C≡CC(OR)Ph_2}(η^5-C_5H_5)L^1L^2] [L^1 = L^2 = PPh_3, R = Me; L^1 = PPh_3, L^2 = $PPh_2CH_2C(=O)tBu$, R = Me, Et; L^1 = CO, L^2 = P*i*Pr_3, R = Me],[49,54,57] [Ru{C≡CC(OMe)Ph_2}(η^5-C_9H_7)L^1L^2] [L^1 = L^2 = PPh_3; L^1L^2 = DPPE, DPPM; L^1 = CO, L^2 = P*i*Pr_3; L^1 = PPh_3, L^2 = $PPh_2CH_2C(=O)t$-Bu],[43,51,57] [Ru{C≡CC(OMe)Ph_2}(η^5−1,2,3-$Me_3C_9H_4$)(CO)(PPh_3)],[42] [Ru{C≡CC(OMe)$C_{13}H_{20}$}(η^5-C_9H_7)(PPh_3)$_2$],[58] [Ru{C≡CC(OMe)Ph_2} {HB(pz)$_3$}(PPh_3)$_2$],[15] *trans*-[Ru{C≡CC(OMe)Ph_2}(C≡CR)(DPPE)$_2$] (R = Ph, *p*-$OMeC_6H_4$)[10] and [Os{C≡CC(OMe)Ph_2}(η^5-C_5H_5)(P*i*Pr_3)$_2$][38] have recently been synthesized in high yields by treatment of the appropriate allenylidene complex with the corresponding sodium or potassium alkoxide. No isomerization of these alkynyl derivatives into alkoxyallenyl species [M]−C(OR^1)=C=CR^2R^3 has been reported. The inverse regioselectivity observed with these hard nucleophiles seems to be charge-controlled (see Table 1). In agreement with this, theoretical calculations carried out by Esteruelas and co-workers on the model complexes [Ru{C≡CC(OMe)H_2}(η^5-C_5H_5)(CO)(PH_3)] and [Ru{C(OMe)=C=CH_2}(η^5-C_5H_5)(CO)(PH_3)] indicate that the former is approximately 9.29 kcal/mol more stable than the latter.[54] Although neutral alkynyl derivatives usually react with electrophiles at the β-position to produce cationic vinylidene complexes,[4a] protonation of these methoxyalkynyl species regenerates the starting allenylidenes in almost quantitative yields.

The related alkynyl complexes [Ru{C≡CC(OH)Ph_2}(η^5-C_5H_5)(CO)(P*i*Pr_3)] and *trans*-[Ru{C≡CC(H)Ph_2}(C≡CPh)(DPPE)$_2$] have also been regioselectively obtained by the reaction of [Ru(=C=C=CPh_2)(η^5-C_5H_5)(CO)(P*i*Pr_3)][BF_4] and *trans*-[Ru(C≡CPh){=C=C=CPh_2}(DPPE)$_2$][PF_6] with KOH and $NaBH_4$, respectively.[10,54] The cationic (diphenylallenylidene)rhodium(I) derivative *trans*-[Rh(=C=C=CPh_2)(O=CMe_2)(P*i*Pr_3)$_2$][PF_6] also undergoes substitution of the labile acetone ligand when treated with sodium acetate or potassium hydroxide, yielding neutral allenylidenes *trans*-[Rh(=C=C=CPh_2){κ^1(*O*)-COOMe}(P*i*Pr_3)$_2$] and *trans*-[Rh(=C=C=CPh_2)(OH)(P*i*Pr_3)$_2$], respectively.[17]

In our laboratory we have explored the reactivity of indenylruthenium(II)−allenylidene compounds towards N-donor hard nucleophiles such as amides or azides and we have found that complexes [Ru(=C=C=CPh_2)(η^5-1,2,3-$R^1_3C_9H_4$)(CO)L][BF_4] (R^1 = H, L = P*i*Pr_3; R^1 = Me, L = PPh_3, P*i*Pr_3) react with lithium (*S*)-α-methylbenzylamide or lithium (*S*)-1-cyclohexylethylamide to afford alkynyl derivatives **21** in a regioselective manner (Scheme 8).[43] These complexes were obtained as equimolecular mixtures of diastereoisomers. It should be noted that, in marked contrast to the above-mentioned methoxyalkynyl derivatives, complexes **21** are thermodynamically unstable and slowly generate azoniabutadienyl compounds **23** both in solution and in the solid state. Formation of **23** probably involves an initial migration of the amide group from the C_γ to C_α to yield allenyl complexes **22**, followed by protonation on the central carbon atom of the allenic moiety.

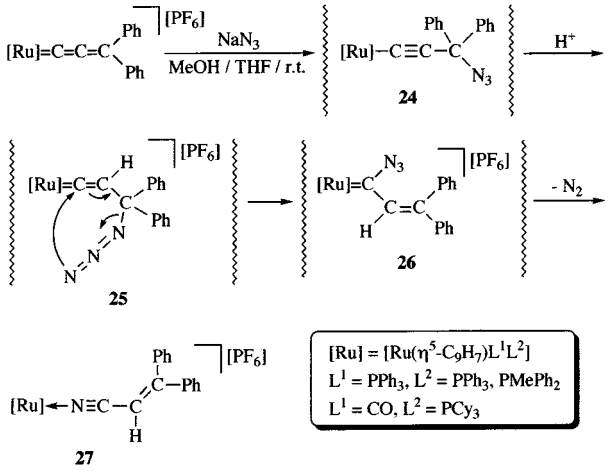


Scheme 8. Reactivity of indenylruthenium(II)−allenylidene complexes towards chiral amides

Treatment of indenyl complexes [Ru(=C=C=CPh_2)(η^5-C_9H_7)L^1L^2][PF_6] (L^1 = PPh_3, L^2 = PPh_3, $PMePh_2$; L^1 = CO, L^2 = PCy_3) with sodium azide in methanol does not afford stable alkynyl species. Instead, the reaction gives the cationic nitrile complexes **27** (Scheme 9).[59] We propose that, although initially the expected alkynyl derivatives **24** are formed, they are readily protonated by the protic solvent (we note that no reaction was observed in the absence of methanol) to generate vinylidene intermediates **25**. Intramolecular attack of the terminal nitrogen atom of the azide group at the electrophilic C_α atom on vinylidenes **25**[4a] and subsequent rearrangement gives the α,β-unsaturated carbene complexes **26**. The reaction ends with the extrusion of N_2 and the migration of the metallic fragment to the nitrogen atom to give the observed products. Complexes **27** can be easily demetalated by treatment with a second equivalent of NaN_3 to yield free diphenylacrylonitrile and the azide complexes [Ru(N_3)(η^5-C_9H_7)L^1L^2].

IV.2.2 Carbanions

Cationic allenylidene complexes can be used as suitable starting materials for carbon−carbon coupling reactions through the nucleophilic addition of carbanions to the unsaturated hydrocarbon chain. In this context we have reported that complexes [Ru(=C=C=CR^1R^2)(η^5-C_9H_7)-



Scheme 9. Reactivity of (indenyl)Ru^{II}−allenylidene complexes towards sodium azide

$L^1L^2][PF_6]$ ($L^1 = L^2 = PPh_3$, $R^1 = R^2 = Ph$, $R^1R^2 = C_{13}H_{20}$; L^1L^2 = DPPE, $R^1 = R^2 = Ph$) regioselectively react with alkyllithium reagents or sodium cyanide under mild conditions to yield $[Ru\{C{\equiv}CC(R^3)R^1R^2\}(\eta^5\text{-}C_9H_7)L^1L^2]$ ($L^1 = L^2 = PPh_3$, $R^1 = R^2 = Ph$, R^3 = Me, *n*Bu, C≡N; $L^1 = L^2 = PPh_3$, $R^1R^2 = C_{13}H_{20}$, R^3 = C≡N; L^1L^2 = DPPE, $R^1 = R^2 = Ph$, R^3 = Me, *n*Bu).[51,58,60] Related cyclopentadienyl complexes $[Ru\{C{\equiv}CC(R)Ph_2\}(\eta^5\text{-}C_5H_5)(PPh_3)_2]$ (R = Me, C≡N, C_5H_5)[49] and $[Os\{C{\equiv}CC(Me)Ph_2\}(\eta^5\text{-}C_5H_5)(P\textit{i}Pr_3)_2]$[38] have recently been obtained using this synthetic methodology. Highly functionalized alkynyl complexes $[Ru\{C{\equiv}CC(C{\equiv}CR^4)R^2R^3\}(\eta^5\text{-}1,2,3\text{-}R^1_3C_9H_4)L^1L^2]$ (R^1 = H, $L^1 = L^2 = PPh_3$, $R^2 = R^3 = Ph$, R^4 = H, Ph, *n*Pr; R^1 = H, L^1L^2 = DPPE, $R^2 = R^3 = Ph$, R^4 = H, Ph, *n*Pr; R^1 = H, $L^1 = L^2 = PPh_3$, $R^2R^3 = C_{13}H_{20}$, R^4 = H; R^1 = H, L^1 = CO, $L^2 = P\textit{i}Pr_3$, $R^2 = R^3 = Ph$, R^4 = H; R^1 = Me, L^1 = CO, $L^2 = PPh_3$, $R^2 = R^3 = Ph$, $R^4 = Ph$) have been prepared in our group using acetylides as nucleophiles.[42,43,51,56]

Some of these alkynyl species have proved to be of interest in both organometallic and organic synthesis. Using $[Ru\{C{\equiv}CC(C{\equiv}CH)Ph_2\}(\eta^5\text{-}C_9H_7)(PPh_3)_2]$ as starting material, and taking advantage of the presence of a triple bond functionality at the end of the alkynyl chain, we carried out a series of Pauson-Khand cyclization reactions.[61] For instance, the unprecedented alkynyl and vinylidene derivatives **28** and **29** containing tricyclic cyclopentenone fragments (Figure 4) have been isolated from the strained cyclic alkenes norbornadiene and norbornene.

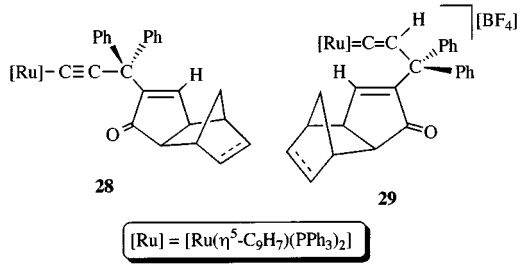


Figure 4. Structure of organometallic cyclopentenones

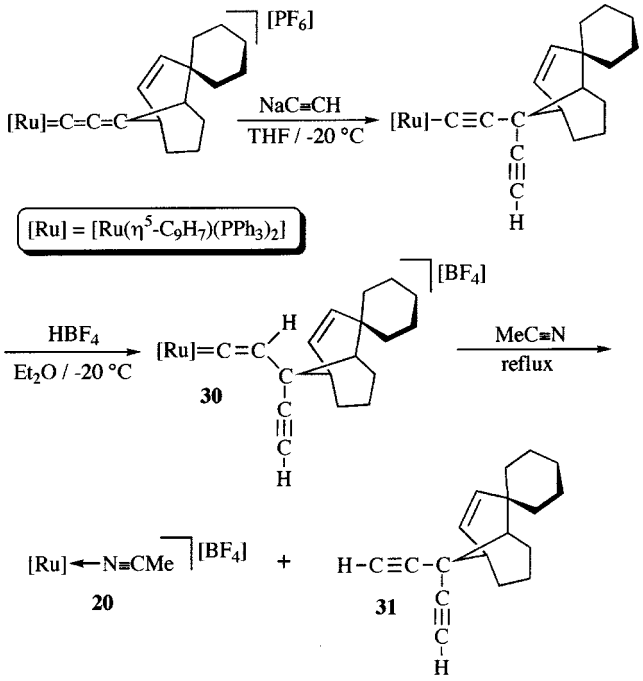
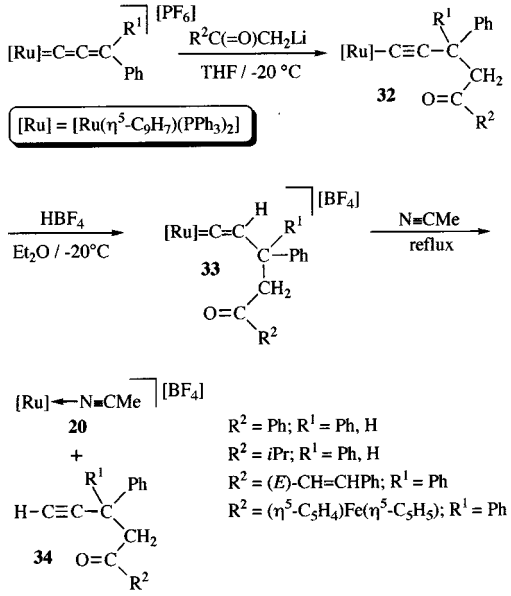
In addition, using the demetalation approach shown in Scheme 7, the unprecedented diyne $(HC{\equiv}C)_2CC_{13}H_{20}$ (**31**) can be easily prepared by demetalation of vinylidene $[Ru\{{=}C{=}C(H)C(C{\equiv}CH)C_{13}H_{20}\}(\eta^5\text{-}C_9H_7)(PPh_3)_2][BF_4]$ (**30**) with acetonitrile (Scheme 10).[56]



Scheme 10. Demetalation of allenylidene complex $[Ru\{{=}C{=}C{=}C(C_{13}H_{20})\}(\eta^5\text{-}C_9H_7)(PPh_3)_2][PF_6]$

The utility of transition metal allenylidenes in organic synthesis is also demonstrated in the synthesis of terminal oxoalkynes $HC{\equiv}CC(R^1)Ph(CH_2COR^2)$ (**34**), starting from $[Ru\{{=}C{=}C{=}C(R^1)Ph\}(\eta^5\text{-}C_9H_7)(PPh_3)_2][PF_6]$ (R^1 = H, Ph) and lithium enolates ($LiCH_2COR^2$) (Scheme 11).[62] The process is based on the regioselective nucleophilic attack of the enolate moiety at the C_γ atom of the cumulene chain to afford neutral oxo-functionalized alkynyl derivatives **32**. These derivatives are subsequently transformed into vinylidenes **33** and demetalated[62b] with MeC≡N as previously described. Regio- and diastereoselective nucleophilic additions of lithium enolates derived from the chiral ketones (−)-carvone and (+)-pulegone to $[Ru(={C=C=}CPh_2)(\eta^5\text{-}C_9H_7)(PPh_3)_2][PF_6]$ allowed us to prepare chiral alkynyl complexes (*R*,*R*)-**35** and (*R*,*R*)-**36** (see Figure 5).[62a] We note that the related osmium(II)−oxoalkynyl complex $[Os\{C{\equiv}CC(CH_2COMe)Ph_2\}(\eta^5\text{-}C_5H_5)(P\textit{i}Pr_3)_2]$ has recently been obtained by Esteruelas and co-workers.[38]

Chiral oxoalkynes **40** have been obtained by the same methodology from the optically active allenylidene **37** (Scheme 12).[59] The initial formation of alkynyl derivatives **38**, which involves the generation of a new stereogenic center at C_γ, is diastereoselective since only one diastereoisomer is detected by NMR spectroscopy. The configuration of this new chiral carbon atom in both alkynyl (**38**), vinylidene (**39**), or free alkyne (**40**) derivatives is presently unknown.



Scheme 11. Synthesis of terminal oxoalkynes from alkynylruthenium(II) complexes

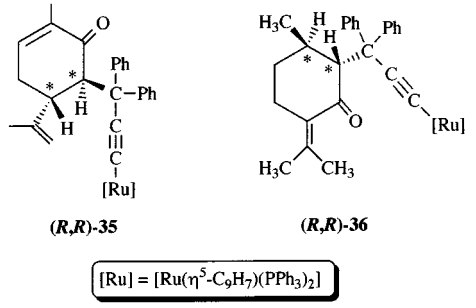


Figure 5. Structure of optically active alkynylruthenium(II) complexes

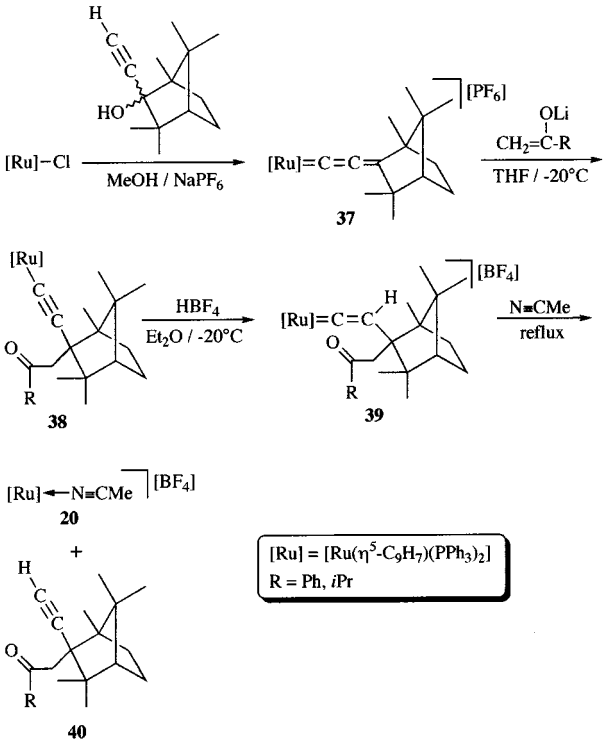
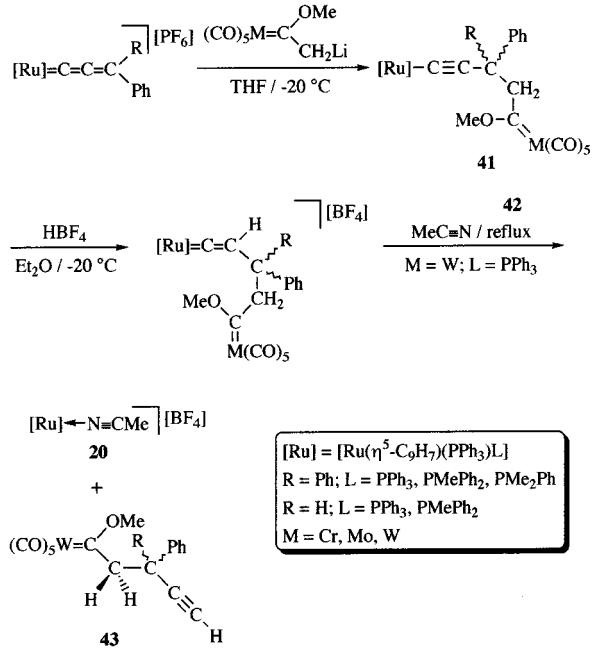
Cationic indenylruthenium(II)−allenylidene derivatives are also suitable starting materials for the preparation of dimetallic species containing hydrocarbon bridges through carbon−carbon coupling reactions with organometallic anionic nucleophiles. We have reported that [Ru{=C=C=C(R)Ph}(η^5-C_9H_7)(PPh_3)L][PF_6] (R = Ph, L = PPh_3, $PMePh_2$, PMe_2Ph; R = H, L = PPh_3, $PMePh_2$) reacts regioselectively with anionic Fischer-type methoxycarbene derivatives [$(CO)_5M${=C(OMe)CH_2}]$^-$ (M= Cr, Mo, W) to yield unprecedented neutral alkynylcarbene complexes **41** (Scheme 13).[60] Protonation of these compounds leads to the formation of **42**, which represent the first examples of dimetallic complexes containing a vinylidenecarbene type hydrocarbon bridge. In addition, the novel tungsten−methoxycarbenes **43**, bearing a terminal alkyne functionality, could be prepared by selective demetalation of the ruthenium fragment in refluxing acetonitrile.

Nucleophilic additions of carbanions at C_α of cationic allenylidenes to afford neutral allenyl species are also known.[4a−4b] As an example, we have described the synthesis of allenylmetallacyclic derivatives **44** and **45** (Scheme 14) by deprotonation of an auxiliary phosphane



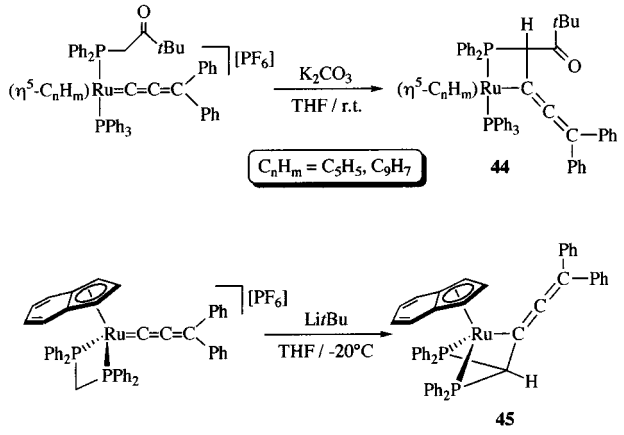
Scheme 12. Synthesis of optically active alkynyl and vinylidene complexes, and terminal alkynes derived from (−)-fenchone



Scheme 13. Preparation of dimetallic complexes containing alkynylcarbene and vinylidenecarbene bridges

ligand and subsequent carbon−carbon coupling between the electrophilic C_α and the initially generated carbanion.[51,57] We note that formation of **44** is diastereoselective since only one pair of enantiomers S_{Ru},R_C/R_{Ru},S_C is

obtained as confirmed by X-ray crystal structure determinations.[57]



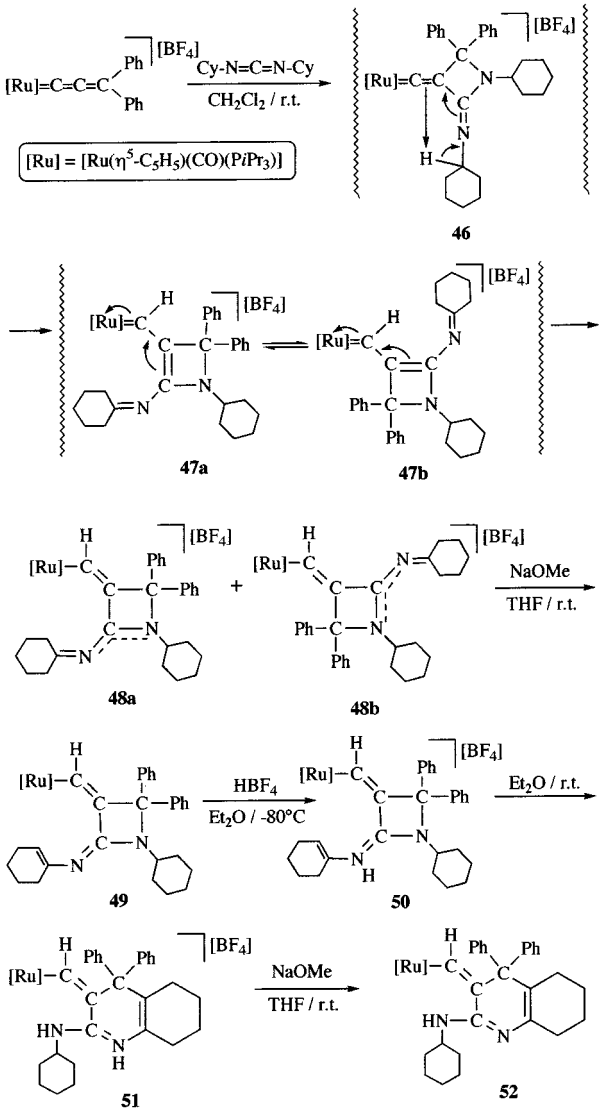
Scheme 14. Intramolecular C−C coupling reactions between allenylidene and phosphane ligands

IV.3 Cyclization Reactions

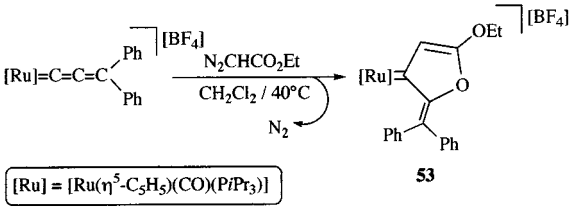
Cationic transition metal allenylidene complexes are useful starting materials to generate unsaturated cyclic structures by the reaction of their highly polarized unsaturated chain with organic substrates.[4a−4b] In this context, Esteruelas and co-workers have recently reported[63] that $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(P\textit{i}Pr_3)][BF_4]$ reacted with dicyclohexylcarbodiimide to afford the unprecedented iminium azetidinylidenemethyl complex **48** which was isolated as a mixture of the corresponding (*Z*) (**48a**) and (*E*) (**48b**) stereoisomers (Scheme 15). Formation of **48** can be rationalized as the result of a [2+2] cycloaddition between the $C_\beta-C_\gamma$ double bond of the allenylidene ligand and one of the two carbon−nitrogen double bonds of the carbodiimide group. Thus, intermediate **46** was formed and rapidly evolved into carbene **47**, probably as a mixture of isomers, through an Alder-ene type process. A final charge redistribution within **47** gave the observed species **48**. Complex **48** was used as a suitable precursor for the preparation of other heterocyclic species such as **49−52** (Scheme 15).

The doubly α,β-unsaturated oxygen-containing cyclic carbene complex **53** has been prepared by the addition of ethyl diazoacetate to $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(P\textit{i}Pr_3)][BF_4]$ (Scheme 16).[64] In this case, a formal 1,3-addition of the organic reagent at the $C_\alpha-C_\beta$ double bond takes place.

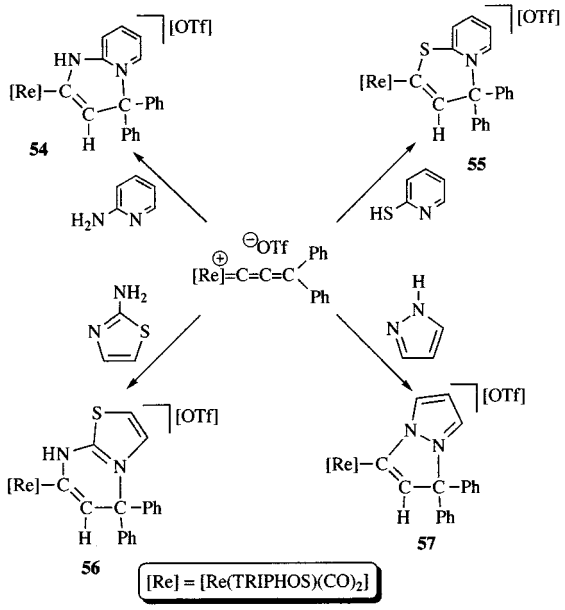
Since allenylidenes have two electrophilic and one nucleophilic centers, the reactions of these compounds with organic molecules containing two nucleophilic heteroatoms and one electrophilic hydrogen atom give rise to 1,2,3-diheterocyclization processes. Following the previously reported reactions with the allenylidene complex $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(P\textit{i}Pr_3)][BF_4]$,[65a] Bianchini and coworkers have similarly found that the cationic (diphenylallenylidene)rhenium(I) complex $[Re(=C=C=CPh_2)(TRIPHOS)(CO)_2][CF_3SO_3]$ reacts with N,S- and N,N-heterocycles to generate heterobicyclic compounds **54−57** (Scheme 17).[65b] All these species are formed by the initial addition of the heteroatom−H bond to the $C_\alpha-C_\beta$ double bond of the allenylidene ligand, to produce intermediate α,β-unsaturated carbenes which undergo a further nucleophilic attack of the second heteroatom at C_γ of the unsaturated chain.[65c]



Scheme 15. Reactivity of $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(P\textit{i}Pr_3)][BF_4]$ towards dicyclohexylcarbodiimide

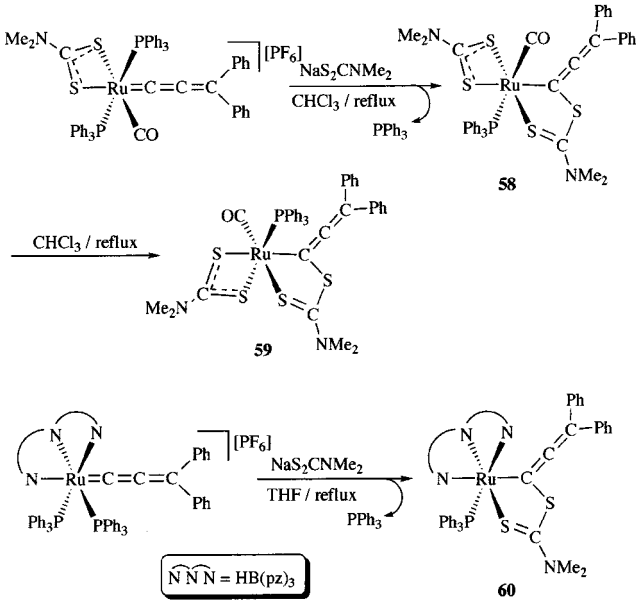


Scheme 16. Cyclization of $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(P\textit{i}Pr_3)][BF_4]$ with ethyl diazoacetate



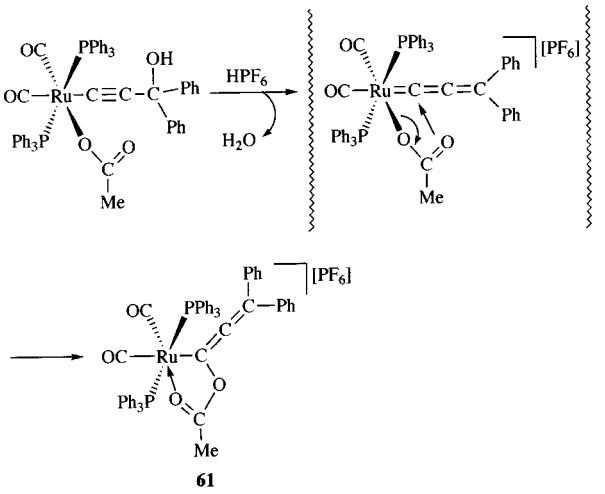
Scheme 17. 1,2,3-diheterocyclizations on [Ru(=C=C=CPh$_2$)(TRIPHOS)(CO)$_2$][OTf]

Other cyclization processes involving direct metal−carbon double-bond additions are also known. Hill and co-workers have recently reported the preparation of metallacyclic allenyl complexes **58** and **60** by the addition of sodium dimethyldithiocarbamate to diphenylallenylidenes [Ru(=C=C=CPh$_2$)(S$_2$CNMe$_2$)(CO)(PPh$_3$)$_2$][PF$_6$] and [Ru(=C=C=CPh$_2$){HB(pz)$_3$}(PPh$_3$)$_2$][PF$_6$], respectively (Scheme 18).[66] Complex **58** is not stable and slowly generates the thermodynamically stable isomer **59**. A plausible mechanism to explain the formation of **58** and **60** may involve the initial attack of dimethyldithiocarbamate at C_α, followed by the substitution of a triphenylphosphane ligand with the C=S group.



Scheme 18. Coupling of allenylidene ligands with dithiocarbamate

A related intramolecular coupling between an acetate ligand and a transient diphenylallenylidene moiety also occurs when hydroxyalkynyl complex [Ru{C≡CC(OH)Ph$_2$}{κ^1-(*O*)-COOMe}(CO)$_2$(PPh$_3$)$_2$] is treated with HPF$_6$, affording metallacycle **61** (Scheme 19).[67]

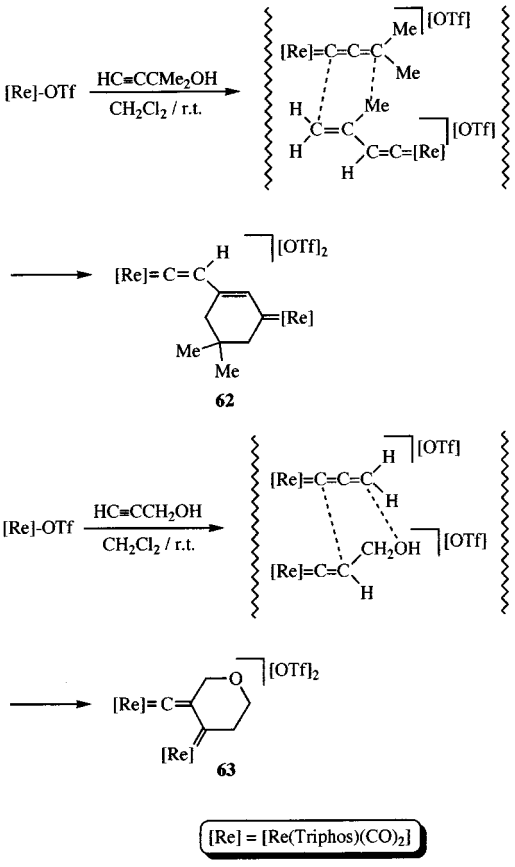


Scheme 19. Intramolecular coupling of an allenylidene ligand with acetate

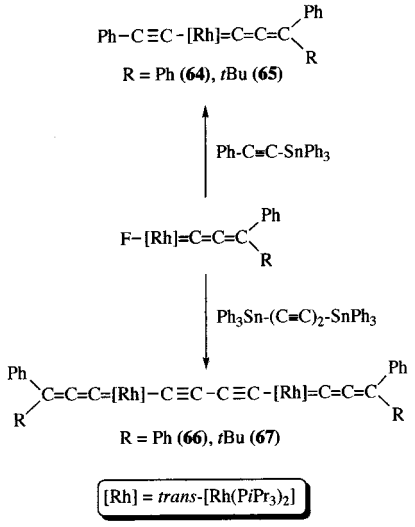
Finally, dinuclear cyclic complexes **62** and **63** (Scheme 20) have been prepared by Bianchini and co-workers through direct activation of 2-methyl-3-butyn-2-ol or propargyl alcohol by [Re(OTf)(TRIPHOS)(CO)$_2$].[46] In the first case, carbene vinylidene complex **62** seems to be formed by the coupling of transient allenylidene [Re(=C=C=CMe$_2$)(TRIPHOS)(CO)$_2$][CF$_3$SO$_3$] and alkenylvinylidene [Re{=C=C(H)−C(Me)=CH$_2$}(TRIPHOS)(CO)$_2$][CF$_3$SO$_3$] species which are simultaneously generated in the initial dehydration process.[68] An unprecedented coupling between the allenylidene [Re(=C=C=CH$_2$)(TRIPHOS)(CO)$_2$][CF$_3$SO$_3$] and its hydroxyvinylidene precursor [Re{=C=C(H)CH$_2$(OH)}(TRIPHOS)(CO)$_2$][CF$_3$SO$_3$] was proposed in the formation of complex **63**.

V. Reactivity of Neutral Allenylidene Complexes

The reactions of several square-planar (allenylidene)rhodium(I) and -iridium(I) chloride complexes with nucleophiles do not proceed through the typical addition, but instead result in substitution products. For instance, the iridium complex *trans*-[IrCl(=C=C=CPh$_2$)(P*i*Pr$_3$)$_2$] reacts with KOH to give the hydroxo derivative *trans*-[Ir(OH)(=C=C=CPh$_2$)(P*i*Pr$_3$)$_2$].[20] The rhodium complexes *trans*-[RhX{=C=C=CPh(R)}(P*i*Pr$_3$)$_2$] (X = OH, NCO, N$_3$) have been prepared in a similar fashion.[24][69] The fluoride complexes obtained by the treatment of the hydroxo complexes with NEt$_3$·3HF have been used as appropriate starting materials for the preparation of mononuclear (**64**, **65**) and dinuclear (**66**, **67**) alkynyl derivatives (Scheme 21).[70] Alternatively, complexes **66** and **67** can be prepared directly by treatment of the hydroxo derivatives with (Ph$_3$Sn)$_2$C$_4$.



Scheme 20. Couplings between allenylidene and alkenylvinylidene or hydroxyvinylidene ligands



Scheme 21. Substitution reactions on square-planar (allenylidene)-rhodium(I) complexes

The reactions of rhodium azide complexes with CO lead either to the formation of the azidoalkynyl complex **68** or of the cyanoalkenyl derivatives **70** and **71** (Scheme 22).[24] A formal addition of the azide anion to C_α or C_γ is postulated as a possible route to the intermediates which give **70** and **71** by elimination of nitrogen. The azidoalkynyl complex **69** was characterized by NMR at low temperature. No electrophilic addition product was observed in the reaction of the rhodium azide derivatives with $[Me_3O][BF_4]$ leading instead to the formation of the dinuclear bis(allenylidene) complexes **72−75** (Scheme 22).[24]

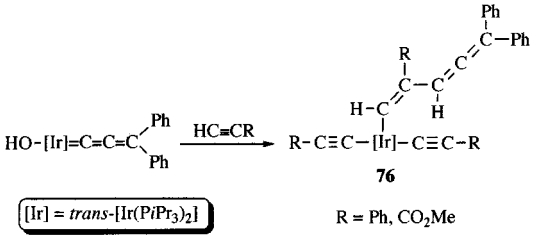
71,75	An	An
73	Ph	*o*-MeC$_6$H$_4$

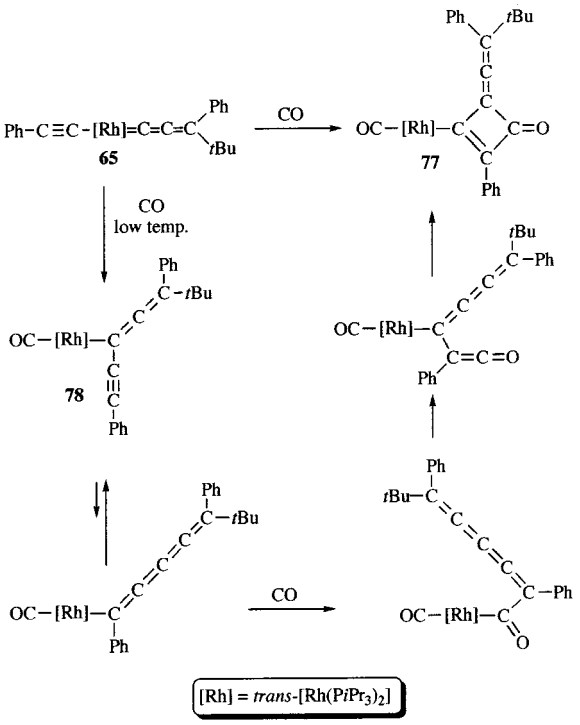
Scheme 22. Reactivity of (allenylidene)rhodium(I) azide complexes

New metal-assisted C−C coupling reactions have been described. *trans*-[Ir(OH)(=C=C=CPh$_2$)(P*i*Pr$_3$)$_2$] reacts with an excess of the terminal alkynes RC≡CH (R = Ph, CO_2Me) to give complexes **76** (Scheme 23). The formation of **76** presumably involves the substitution of OH by C_2R, followed by the oxidative addition of a second molecule of the alkyne to give the iridium hydride intermediate [IrH(C≡CR)$_2$(=C=C=CPh$_2$)(P*i*Pr$_3$)$_2$]. This intermediate could undergo a rearrangement to form a metal−allenyl species followed by a C−C coupling process with a third molecule of alkyne.[20]

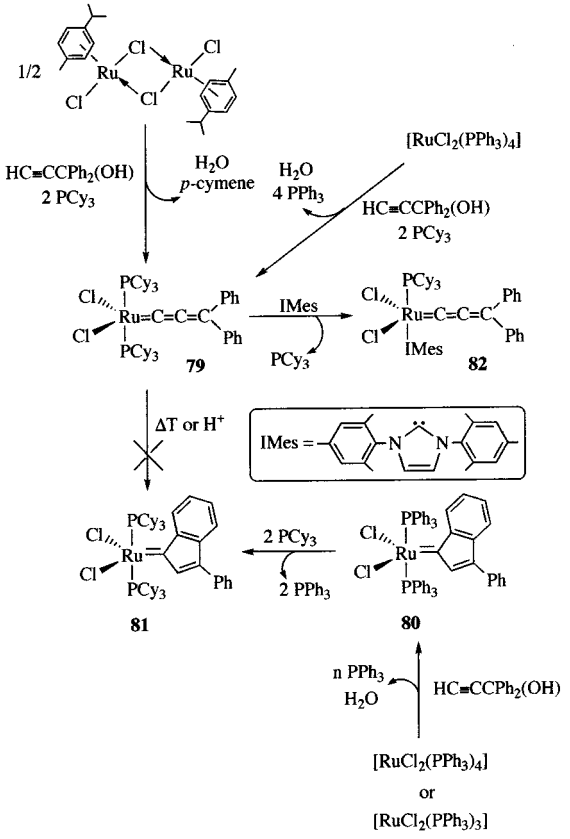


Scheme 23. C−C coupling reactions promoted by *trans*-[Ir(OH)-(=C=C=CPh$_2$)(P*i*Pr$_3$)$_2$]

An unprecedented triple coupling [C_2+C_1+C_1] of alkynyl, allenylidene, and carbonyl groups has been described by Werner and co-workers.[70] This coupling involves the reaction of complex **65** with CO leading to the formation of **77**, a complex containing a highly unsaturated cyclobutenone ligand in the coordinating sphere of the rhodium atom. A possible mechanism for this conversion is shown in the Scheme 24. The proposed intermediate complex **78** was isolated as a thermally unstable solid.



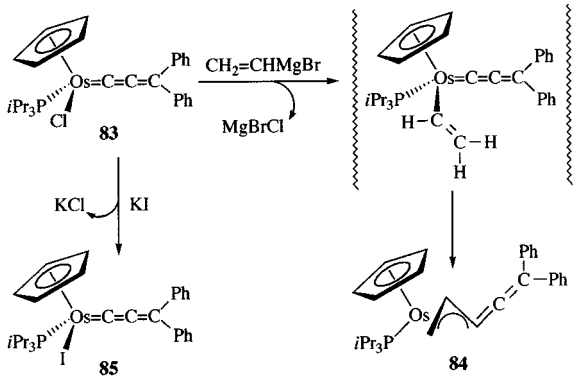
Scheme 24. Unprecedented [C_2+C_1+C_1] coupling of an allenylidene, an alkynyl and a CO ligand



Scheme 25. Synthesis and reactivity of 16-electron ruthenium(II)−allenylidene complexes

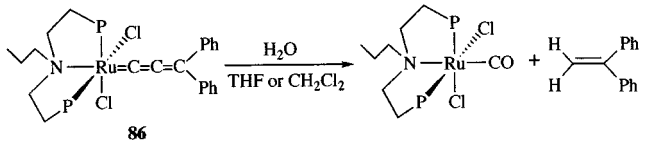
A series of 16-electron ruthenium(II)−allenylidene species have been described as the first unsaturated allenylidene complexes (Scheme 25). The parent complex [$RuCl_2$(=C=C=CPh_2)(PCy_3)$_2$] (**79**) is obtained in good yield from the reaction of [$RuCl_2(PPh_3)_4$] or 0.5 equiv. of [$RuCl_2(\eta^6$-*p*-cymene)]$_2$ with 1,1-diphenyl-2-propyn-1-ol and 2 equiv. of PCy_3. However, the reaction of either [$RuCl_2(PPh_3)_3$] or [$RuCl_2(PPh_3)_4$] with HC≡CC(OH)Ph_2 leads only to the 3-phenyl-1-indenylidene complex **80** which then undergoes phosphane exchange with PCy_3 to provide complex **81**. The allenylidene complex **79** is stable at elevated temperatures and towards protic acids, and no conversion into 3-phenyl-1-indenylidene complex **81** was observed.[8,71] The exchange of one PCy_3 ligand for IMes affords the allenylidene complex **82** in high yield (Scheme 25). The similar 16-electron complex [$OsCl_2$(=C=C=CPh_2)(PPh_3)$_2$] has been isolated and is stable in methanol at room temperature.[72]

An intramolecular nucleophilic addition at the allenylidene chain has been described[15][66] in the reaction of the trispyrazolylborate neutral complex [RuCl(=C=C=CPh_2){HB(pz)$_3$}(PPh_3)] with Na[S_2CNMe_2] resulting in the metallacyclic allenyl complex **60** (see Scheme 18). Another type of intramolecular addition was observed in the reaction of [OsCl(=C=C=CPh_2)(η^5-C_5H_5)(P*i*Pr_3)] (**83**) with CH_2=CHMgBr which gives the pentatrienyl complex [Os(η^3-CH_2CHC=C=CPh_2)(η^5-C_5H_5)(P*i*Pr_3)] (**84**) (Scheme 26).[73] This complex is formed by migratory insertion of the allenylidene ligand into the Os−CH=CH_2 bond of the vinylosmium intermediate which cannot be isolated. Complex **83** also reacts with KI to give the iodo derivative **85**.



Scheme 26. Reactivity of the neutral allenylidene [OsCl(=C=C=CPh_2)(η^5-C_5H_5)(P*i*Pr_3)]

Nucleophilic addition of water to the allenylidene chain in the complex *fac*,*cis*-[$RuCl_2$(=C=C=CPh_2)(PNP)] (**86**) has been reported to occur both in THF or CH_2Cl_2 at room temperature, to give the carbonyl derivative *fac*,*cis*-[$RuCl_2$(CO)(PNP)] and the corresponding free alkene H_2C=CPh_2 (Scheme 27).[18] The reaction proceeds by regioselective cleavage of the $C_\alpha-C_\beta$ bond. The use of D_2O gives the corresponding deuterated alkene D_2C=CPh_2.



Scheme 27. Selective $C_\alpha-C_\beta$ bond cleavage by water in a ruthenium(II)−allenylidene complex

Dötz and co-workers[74] have reported the synthesis of a series of sugar-derived or (disaccharide)metal−(alkenyl)-(methoxy)carbene complexes obtained from the reactions of sugar-based propargylic alcohols and $[W(CO)_5(THF)]$. The formation of these carbene species is rationalized through the typical addition of alcohols to the transient allenylidene species generated from the propargylic alcohols.

A series of neutral carbonylruthenium trinuclear clusters containing bridging allenylidene groups of type **D** shown in Figure 3 have been reported.[27] These derivatives undergo substitution reactions of the carbonyl groups by phosphane ligands. The formation of a tetranuclear Ru_3Au cluster is also described. Furthermore, a C−C coupling between an allenylidene bridging moiety and a phenyl group of a coordinated dppm ligand in a related Ru_3 cluster to give a 1,3-diphenylindenyl ligand has been also reported.[75]

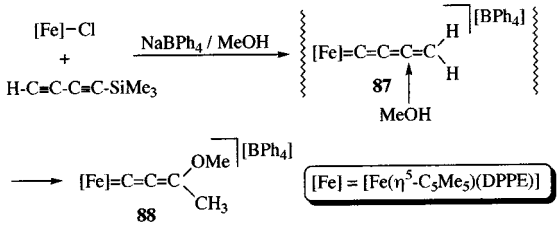
VI. Reactivity of Complexes Containing Higher Cumulenylidene Ligands

Although the chemistry of higher cumulenylidene complexes $[M]=C(=C)_n=CR^1R^2$ ($n > 1$) has not received as much attention as that of allenylidenes ($n = 1$), theoretical[40] and experimental[4b,4e] evidence point also to the alternating electron deficiency and richness of the carbon atoms of the unsaturated chain as one moves along the chain from the metal atom. Therefore nucleophilic additions at the odd-numbered carbon atoms and electrophilic additions at the even-numbered carbon atoms can be expected.

VI.1 Butatrienylidene Complexes

Mononuclear transition metal complexes containing butatrienylidene ligands $[M]=C(=C)_2=CR^1R^2$ have usually been reported as highly reactive intermediates in different reactions.[4b][4e] Indeed, complexes $[(\eta^5\text{-}C_5Me_5)L^1L^2Fe\{=C=C=C=C(R)Fe(CO)_2(\eta^5\text{-}C_5Me_5)\}]^+$ (L^1L^2 = DPPE, DIPPE; R = H, Me), obtained by protonation or methylation at C_δ of neutral dimetallic butadiynes $[(\eta^5\text{-}C_5Me_5)L^1L^2Fe\{C\equiv CC\equiv CFe(CO)_2(\eta^5\text{-}C_5Me_5)\}]$, are the only butatrienylidene complexes stable enough to be isolated and spectroscopically characterized to date.[32] These stable species have been studied by cyclic voltammetry (CV). Thus, while tertiary butatrienylidenes $[(\eta^5\text{-}C_5Me_5)L^1L^2Fe\{=C=C=C=C(Me)Fe(CO)_2(\eta^5\text{-}C_5Me_5)\}][CF_3SO_3]$ display a reversible one-electron oxidation process and an irreversible reduction process, complexes $[(\eta^5\text{-}C_5Me_5)L^1L^2Fe\{=C=C=C=C(H)Fe(CO)_2(\eta^5\text{-}C_5Me_5)\}][BF_4]$ show a more complicated pattern, owing to the acidic character of the hydrogen atom on C_δ, and signals assigned to $[(\eta^5\text{-}C_5Me_5)L^1L^2Fe\{C\equiv CC\equiv CFe(CO)_2(\eta^5\text{-}C_5Me_5)\}]$ are also observed in the voltammograms. In fact, these monosubstituted complexes can be readily deprotonated with DBU or traces of water to afford the starting butadiynes $[(\eta^5\text{-}C_5Me_5)L^1L^2Fe\{C\equiv CC\equiv CFe(CO)_2(\eta^5\text{-}C_5Me_5)\}]$.

Activation of trimethylsilyl-1,3-butadiyne $HC\equiv CC\equiv CSiMe_3$ by $[FeCl(\eta^5\text{-}C_5Me_5)(DPPE)]$ in methanol has been reported to yield the methoxyallenylidene $[Fe\{=C=C=C(OMe)CH_3\}(\eta^5\text{-}C_5Me_5)(DPPE)][BPh_4]$ (**88**) (Scheme 28).[31] Formation of **88** involves the generation of the unstable butatrienylidene derivative $[Fe(=C=C=C=CH_2)(\eta^5\text{-}C_5Me_5)(DPPE)][BPh_4]$ (**87**), by an initial 1,4-H shift and subsequent desilylation of the intermediate $[Fe\{=C=C=C=C(H)SiMe_3\}(\eta^5\text{-}C_5Me_5)(DPPE)][BPh_4]$, which readily undergoes addition of methanol to the $C_\gamma-C_\delta$ double bond.

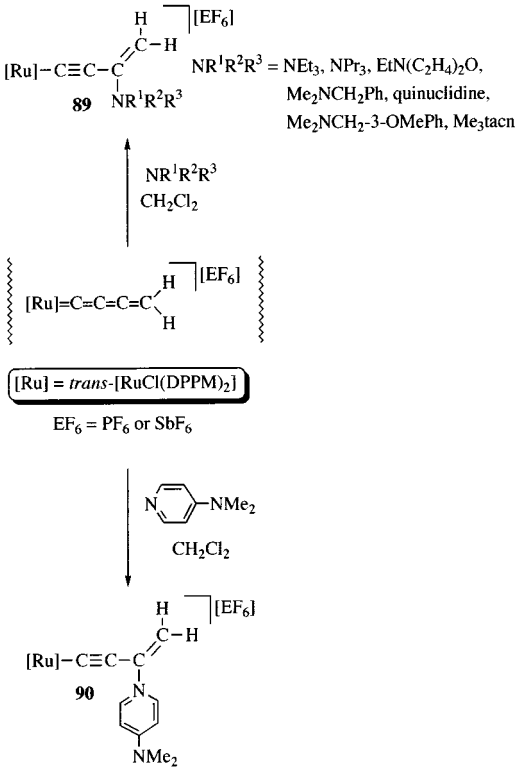


Scheme 28. Synthesis of the iron(II)−allenylidene $[Fe\{=C=C=C(OMe)CH_3\}(\eta^5\text{-}C_5Me_5)(DPPE)][BPh_4]$

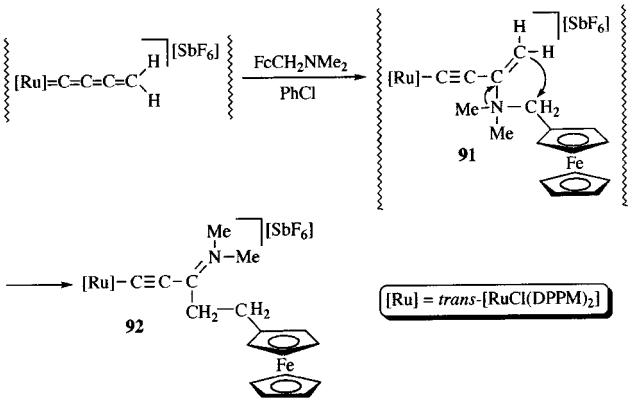
Protonation of the neutral diynylruthenium(II) complex *trans*-$[RuCl(C\equiv CC\equiv CPh)(DPPE)_2]$ or direct activation of 1,3-butadiyne $HC\equiv CC\equiv CPh$ by *cis*-$[RuCl_2(DPPE)_2]$ allows the formation of the cationic buta-1,2,3-trienylidene derivative *trans*-$[RuCl\{=C=C=C=C(H)Ph\}(DPPE)_2]^+$.[50] This complex is a very reactive species which cannot be isolated since it adds water or methanol from the reaction media to the electrophilic C_γ atom to yield the acylvinylidene *trans*-$[RuCl\{=C=C(H)C(=O)CH_2Ph\}(DPPE)_2]^+$ or the methoxyallenylidene *trans*-$[RuCl\{=C=C=C(OMe)CH_2Ph\}(DPPE)_2]^+$, respectively.[50]

Treatment of *cis*-$[RuCl_2(DPPM)_2]$ with an excess of butadiyne ($HC\equiv CC\equiv CH$) in the presence of a halide-abstracting reagent ($NaPF_6$ or $NaSbF_6$), allows the generation of *trans*-$[RuCl(=C=C=C=CH_2)(DPPM)_2]^+$, which can be trapped in situ by the addition of tertiary amines to C_γ, to yield stable 2-ammoniobutenynyl complexes **89** (Scheme 29).[76] When 4-(dimethylamino)pyridine is used, this ambident nucleophile binds regioselectively to the unsaturated carbon chain through the pyridine nitrogen atom to give **90**.[76] The reaction of *trans*-$[RuCl(=C=C=C=CH_2)(DPPM)_2]^+$ with (ferrocenylmethyl)dimethylamine has been also reported.[77] In this case the initially generated 2-ammoniobutenynyl derivative **91** evolves into the iminium alkynyl complex **92** by migration of the resonance-stabilized

ferrocenylcarbenium ion from the quaternary nitrogen atom to the neighboring nucleophilic C_δ atom (Scheme 30).

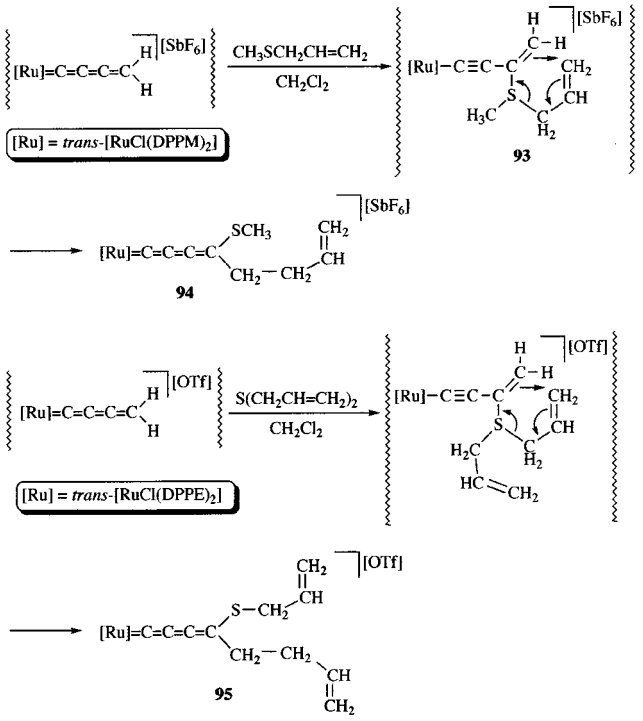


Scheme 29. Reactivity of *trans*-[RuCl(=C=C=C=CH_2)$(DPPM)_2$][EF_6] towards tertiary amines



Scheme 30. Reactivity of *trans*-[RuCl(=C=C=C=CH_2)-$(DPPM)_2$][SbF_6] towards (ferrocenylmethyl)dimethylamine

Addition of sulfur nucleophiles at *trans*-[RuCl(=C=C=C=CH_2)$(DPPM)_2$][SbF_6] has been reported to yield thioallenylidene derivatives.[78] Thus, while the reaction with ethanethiol produces *trans*-[RuCl{=C=C=C(SEt)CH_3}-$(DPPM)_2$][SbF_6], by addition of the S−H bond to the $C_\gamma-C_\delta$ double bond of the cumulene chain, thioallenylidene **94** is obtained when allyl methyl sulfide is used (Scheme 31). Formation of **94** involves the initial nucleophilic attack of the sulfide at the electrophilic C_γ atom to generate the unstable enynyl derivative **93** which undergoes a [3,3] thia-Claisen-type rearrangement. In a similar way, thioallenylidene **95** has been prepared from the butatrienylidene *trans*-[RuCl(=C=C=C=CH_2)$(DPPE)_2$][CF_3SO_3] generated in situ and diallyl sulfide (Scheme 31).



Scheme 31. Synthesis of thioallenylidene complexes from ruthenium(II)−buta-1,2,3-trienylidene intermediates

Full details on the reactivity of the highly reactive butatrienylidene[Ru(=C=C=C=CH_2)(η^5-C_5H_5)$(PPh_3)_2$][PF_6], formed from butadiyne and [Ru(η^5-C_5H_5)(THF)$(PPh_3)_2$]-[PF_6], have recently been reported.[12][79] Complexes [Ru{C≡CC(PPh_3)=CH_2}(η^5-C_5H_5)$(PPh_3)_2$][PF_6], [Ru-{=C=C=C(NPh_2)Me}(η^5-C_5H_5)$(PPh_3)_2$][PF_6], [Ru{C≡CC-(=O)Me}(η^5-C_5H_5)$(PPh_3)_2$], and [Ru{=C=C=C(C_4H_3NMe-2)Me}(η^5-C_5H_5)$(PPh_3)_2$][PF_6] were prepared by trapping this cumulenylidene derivative with triphenylphosphane, diphenylamine, water, and *N*-methylpyrrole, respectively.[12] In addition, a wide series of functionalized alkynyl derivatives containing either quinoline **96** or 1-aza-buta-1,3-diene fragments **97** (Figure 6) can be obtained when complexes [Ru(=C=C=C=CH_2)(η^5-C_5H_5)-L^1L^2][PF_6] [L^1 = L^2 = PPh_3, $P(OMe)_3$] are treated with an excess of aromatic imines.[79]

The synthesis and reactivity of Ru_4−butatrienylidene clusters of type **B−C** (Figure 3) have also been reported.[26]

VI.2 Pentatetraenylidene Complexes

The dimetallic complex $[(\eta^5\text{-}C_5Me_5)(PPh_3)(NO)Re{=}C{=}C{=}C{=}C{=}Mn(CO)_2(\eta^5\text{-}C_5Cl_5)][BF_4]$, obtained by treatment of $[(\eta^5\text{-}C_5Me_5)(PPh_3)(NO)Re{-}C{\equiv}C{-}C{\equiv}C{-}C(OMe){=}Mn(CO)_2(\eta^5\text{-}C_5Cl_5)]$ with an excess of BF_3 gas, is the only pentatetraenylidene derivative reported during the period covered by this review.[30] This cumulenylidene complex is stable towards dimethyl sulfide, ethylene or tetracyanoethylene, but readily reacts with trimethylphosphane, even at −80 °C, to afford complicated mixtures of products which have not been identified.

VII. Catalytic Studies

The role of allenylidene species in catalytic processes has been previously described for ruthenium(II) complexes, albeit in a small number of organic transformations.[80] Remarkably, Fürstner, Dixneuf and co-workers have reported for the first time the catalytic activity of an allenylidene complex, namely $[RuCl(=C=C=CPh_2)(\eta^6\text{-}p\text{-cymene})(PR_3)][PF_6]$ (PR_3 = PCy_3, $PiPr_3$), in ring-closing metathesis of olefins which proves to be comparable in efficiency to the alkylidene derivatives developed by Grubbs.[44] Similarly, the allenylidene complex $[RuCl(=C=C=CPh_2)(\eta^6\text{-}p\text{-cymene})(PCy_3)][PF_6]$ is also a good catalyst for the yne-ene ring-closing metathesis of the mixed propargylic allyl ethers $HC{\equiv}C{-}CR^1R^2OCH_2{-}CH{=}CH_2$ into 3-vinyl-2,5-dihydrofurans.[81] It was shown that an initial photochemical irradiation of the catalyst efficiently promotes the catalytic activity. Following these pioneering works, Dixneuf and co-workers studied the scope of these catalytic transformations.[82] It was demonstrated that the efficiency of these cationic 18-electron allenylidene precatalysts depends on the nature of the counter-anion. The use of $[CF_3SO_3]^-$ improves the activity, which leads to high-yield transformations of *N*,*N*-diallyltosylamine into *N*-tosyldihydropyrrole at room temperature, while the metathesis of the ene-yne ether $HC{\equiv}C{-}C(Me)(Ph)OCH_2{-}CH{=}CH_2$ was completed in a shorter time. New catalytic reactions are produced by using $[BF_4]^-$. Although mechanistic studies have not yet been explored, these preliminary results seem to suggest that the dissociation of the *p*-cymene ligand takes place in the precatalyst complex (either thermally or photochemically), generating a 14-electron allenylidene species $[RuCl(=C=C=CPh_2)(PR_3)]^+$ which effectively acts as the active catalyst.

The catalytic activity of the novel 16-electron allenylidene complexes $[RuCl_2(=C=C=CPh_2)L^1L^2]$ (L^1 = PCy_3, L^2 = PCy_3, IMes) in RCM reactions involving diethyl allylmalonate and *N*,*N*-diallyltosylamine has been investigated[8] showing that the catalytic activity is much poorer than that shown by the above-mentioned cationic 18-electron (allenylidene)ruthenium(II) complexes.[44] This behavior probably arises from the significantly higher bonding energy of the allenylidene moiety at the metal center (see X-ray discussion above). Catalytic studies by Fürstner, Hill, and co-workers in the RCM of α,ω-dienes and -dienynes using mononuclear and dinuclear (allenylidene)ruthenium(II) complexes as catalysts have been also reported.[83] However, the actual nature of the catalysts was recently revisited and reformulated as indenylidene species after full characterization (see complexes **80**−**81** in Scheme 25).[71,84] The first example of a water-soluble allenylidene complex, the dinuclear salt $[(TPPMS)_4Ru_2Cl_4(=C=C=CPh_2)_2]$ (TPPMS = $[Na][Ph_2P\text{-}\{2\text{-}OSO_2C_6H_4\}]$) which shows catalytic activity in ROM and ROMP of olefins, was recently prepared.[85]

Concluding Remarks

Studies on the reactivity of allenylidene and higher cumulenylidene complexes have been widely developed since the discovery of the first derivatives by Fischer and Berke. Both experimental and theoretical studies on allenylidene complexes $[M]{=}C{=}C{=}CR^1R^2$ are now well established, indicating that the electrophilic centers are located at C_α and C_γ, while the C_β atom is a nucleophile site. Nucleophilic attacks dominate the reactivity of allenylidene complexes relative to the electrophilic additions which usually occur in neutral complexes. Recently, an unusual protonation of the cationic complex $[Os(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(PiPr_3)_2][PF_6]$ with HPF_6 to give the alkenylcarbyne $[Os\{{\equiv}C{-}C(H){=}CPh_2\}(\eta^5\text{-}C_5H_5)(PiPr_3)_2][PF_6]_2$ was reported. Recent theoretical calculations on higher cumulenylidene chains $=C(=C)_n{=}CH_2$ (n = 0−7) also confirm that the electrophilic and nucleophilic attacks are frontier orbital controlled, showing that the carbon atoms are alternatively electron-poor and electron-rich, starting from the metal. Reactivity studies on butatrienylidene and pentatetraenylidene complexes, which are now emerging, seem to agree with these expectations.

Most of the results on the reactivity of allenylidene complexes continue to reveal the potential utility in selective C−C and C−heteroatom bond formation. Relevant developments which have been disclosed are: (*i*) regio- and stereoselective additions at the C_γ atom which provide a valuable methodology for the synthesis of functionalized alkynyl complexes, some of them being of interest for the synthesis of polyen(yn)yl chains; (*ii*) inter- and intramolecular cyclization reactions involving $C_\alpha{-}C_\beta$ and $C_\beta{-}C_\gamma$ double bonds; (*iii*) intramolecular C−C coupling reactions with alkynes, alkenyl and alkynyl groups, leading to the selective formation of highly unsaturated hydrocarbon moieties.

Although the utility of allenylidene complexes in catalytic processes are still scarce, studies of the catalytic activity in ring-closing metathesis (RCM) of olefins have been reported for the first time. Provided that the efficiency is comparable to that of Grubbs' alkylidene complexes, it is apparent that this achievement would enhance the rapid progress of this field in the near future.

Acknowledgments

The authors wish to thank to Profs. M. I. Bruce, M. A. Esteruelas, H. Fischer, S. P. Nolan, M. Peruzzini, H. Werner, and R. F. Winter for kindly providing information on their unpublished work. Financial support of the authors' research provided by the Dirección General de Investigación Científica y Técnica of Spain (DGICYT, Project PB96-0558) and the EU (Human Capital Mobility programme, Project ERBCHRXCT 940501) is also gratefully acknowledged.

Note Added in Proof: (i) Novel examples of catalytic ring-closing olefin metathesis using the 18-electron allenylidene complexes $[RuCl(=C=C=CR_2)(\eta^6\text{-}p\text{-cymene})(PR_3)]_+$ (PR_3 = PPh_3, PCy_3, $PiPr_3$) have been described.[86] – (ii) The allenylidene derivative $[Ru(=C=C=CPh_2)(\eta^5\text{-}C_5H_5)(CO)(PiPr_3)][BF_4]$ reacts with 2-aminopyridine and thioisonicotinamide to afford unprecedented pyrido-[1,2-*a*]pyrimidinyl and 1,3-thiazinyl complexes, respectively, which are formed through 1,2,3-diheterocyclization processes.[87]. In addition, novel functionalised [alkenyl(methoxy)carbene]Ru^{II}, -Cr^0 and -W^0 derivatives have been synthesized by addition of methanol on unstable allenylidene complexes.[88]. – (iii) The isolation and structural characterization of the butatrienylidene complex *trans*-$[IrCl(=C=C=C=CPh_2)(PiPr_3)_2]$,[89] as well as the preparation of pentatetraenylidene derivatives of general formula $[Re(=C=C=C=CAr_2)(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)][BF_4]$ (CAr_2 = 9-fluorenylidene moieties),[90]) have been described. – (iv) The zwitterionic μ-but-2-yn-1-ylidene-4-ylidyne complex $[Ru_3(CO)_{10}(\mu_3\text{-}C\text{-}C{\equiv}C\text{-}\mu\text{-}C)\text{-}Fe_2(\eta^5\text{-}C_5Me_5)_2(CO)_3]$ and its dimerized product containing a cumulenic μ-C_8 ligand $[\{(\eta^5\text{-}C_5Me_5)Fe\}_4\{\mu\text{-}C_8\text{-}C(=O)\}\text{-}\{Ru_2(CO)_{13}\}]$ have been prepared.[91]

Metal-Assisted P−H Bond Formation: A Step towards the Hydrogenation of White Phosphorus

Maurizio Peruzzini,*[a] Isaac de los Rios,[a] Antonio Romerosa,[b] and Francesco Vizza[a]

Dedicated to the memory of our unforgettable friend Professor José Antonio Ramírez (1957−2000)

Keywords: P−H bond formation / Phosphanes / Phosphorus / Transition metals

An overview of the chemistry of transition metal complexes containing P–H bonds is presented. Central to this microreview are those compounds in which the P–H bond is assembled by reactions entailing the transfer of one or more hydrogen atoms to white phosphorus or to P_x fragments resulting from P_4 activation and degradation within the coordination sphere of a transition metal complex. The relevance of these processes to the as yet unaccomplished hydrogenation of white phosphorus is briefly discussed.

Contents

1. Introduction
2. Formation of P−H Bonds from Naked P Atoms and Units Bonded to Transition Metal Complexes
2.1 A Survey of Transition Metal Complexes Incorporating P−H Bonds

Maurizio Peruzzini (second from left) was born in Florence, Italy, in 1955. After his "Laurea" cum laude at the University of Florence in 1979 under the supervision of Luigi Sacconi and Piero Stoppioni, he joined the team led by Claudio Bianchini at ISSECC-CNR in 1986, where he is currently Senior Research Associate. He obtained the "Raffaele Nasini" gold medal prize awarded by the Inorganic Chemistry Division of the Societá Chimica Italiana in 1993 in recognition of his contribution to the chemistry of non-classical hydrides. His research interests are primarily in the field of organometallic chemistry and catalysis, as well as the activation and functionalization of pnicogen and chalcogen elements, mediated by transition metals. He has authored over 160 papers and patents and made more than 120 presentations at national and international meetings.

Isaac de los Rios (second from right) was born in Jerez de la Frontera, Spain, in 1970. He received his PhD from the University of Cadiz in 1997 under the guidance of M. Carmen Puerta. He is currently working on the activation and functionalization of white phosphorus in Florence at ISSECC-CNR in the group of Maurizio Peruzzini, with a Spanish Government grant. He has published about 15 papers in organometallic chemistry.

Antonio Romerosa (first from right) was born in Granada, Spain, in 1964. He graduated from the Universidad de Granada with a B.S. in Coordination Chemistry in 1987, and received his Ph.D. in organometallic borane chemistry from the Universidad Autónoma de Barcelona in January 1992. In the same year he undertook a postdoctoral research with Claudio Bianchini and Maurizio Peruzzini at ISSECC-CNR, Florence (Italy), before becoming Assistant Professor and then Associate Professor (1996) at the Universidad de Almería (Spain). He has performed postdoctoral research at ISSECC-CNR (Florence, Italy), Queen's University of Belfast (UK), the Instituto de Química (UNAM, México-DF), and Durham University (UK). His research interests cover fundamental aspects of both organometallic and bioinorganic chemistry. He has authored over 50 papers.

Francesco Vizza (first from left) was born in Cirò (KR), Italy, in 1957 and received his "laurea" in Biology from the University of Florence in 1982 under the supervision of Mario Ciampolini. He was then assistant researcher at the Department of Chemistry of the University of Florence, working in the field of macrocycle complexes. In 1986 he joined ISSECC-CNR, where he is presently Researcher and responsible for a catalysis laboratory. His current research interests are in the fields of homogeneous and heterogeneous catalysis (HDS, HDN, polymerization and copolymerization of olefins), chemistry of white phosphorus, transition metal complexes in therapy and diagnostics, and high-pressure NMR spectroscopy. He has authored about 85 papers and patents.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

1. Introduction

During the second part of the twentieth century there has been a spectacular renaissance of phosphorus chemistry, which has had a profound impact on a broad range of disciplines.[1] Few other branches of chemistry have had a greater influence on chemistry, biology, and material sciences, nor offer greater potential for addressing future needs and opportunities in far-reaching areas of science and engineering.

In keeping with the renowned interest of phosphorus chemistry, the coordination chemistry of elemental phosphorus, which was virtually unexplored until 1970, has now become a mature province of inorganic chemistry and has contributed important results to the resurgence of main group chemistry.[2] It begins from the reporting of $[(PPh_3)_2ClRh(\eta^2\text{-}P_4)]$ by Ginsberg and Lindsell in 1971,[3] and proceeds through an as yet unfinished string of key discoveries. Milestones in this story include, among others, Sacconi's reporting of $[(NP_3)Ni(\eta^1\text{-}P_4)]$ [$NP_3 = N(CH_2CH_2PPh_2)_3$], the first coordination compound exhibiting an intact *tetrahedro*-tetraphosphorus ligand,[4] and the spectacular complexes $[\{Cp^*Mo\}_2(\mu,\eta^6\text{:}\eta^6\text{-}P_6)]$[5] and $[Cp^*Fe(\eta^5\text{-}P_5)]$[6] prepared by Scherer and co-workers. These compounds, respectively containing the unprecedented hexaphosphabenzene and pentaphosphacyclopentadienyl ligands, bolstered confidence in the hypothesized approach based on building up polyphosphorus ligands through the well-known isolobal relationship between P atoms and CH groups.[7] Of course, there were many other breakthroughs in the coordination chemistry of naked phosphorus atoms and units, and dozens of other relevant contributions from the groups led by Sacconi,[8] Scherer,[9] Scheer,[10] Dahl,[11] Markó,[11a,12] Goh,[13] Wachter,[14] Huttner,[15] Stoppioni,[16] Schrock,[17] Cummins,[18] and others[19] have contributed to the rapid metamorphosis of white phosphorus coordination chemistry. Outstanding reviews describing the coordination chemistry of white phosphorus have also appeared in recent literature.[20]

In contrast, studies addressing the reactivity of these complexes have until recently seldom been considered, and remain quite rare in the literature. In addition, many of these early studies have been limited to the straightforward addition of electrophilic metal fragments − generally $M(CO)_5$ (M = Cr, Mo, W) − to the residual electron pair of the unsubstituted phosphorus atom.[21] An excellent recent survey by Whitmire deals with the chemistry of main group/transition metal cluster compounds, but addresses the reactivity of these complexes only to a limited extent,[20b] and does not cover the chemistry related to the metal-mediated hydrogenation of white phosphorus. This microreview is intended to fill this gap and focuses on the metal-mediated formation of P−H bonds, with particular emphasis on those reactions in which the P−H bond is produced starting from the P_4 molecule or fragments thereof.

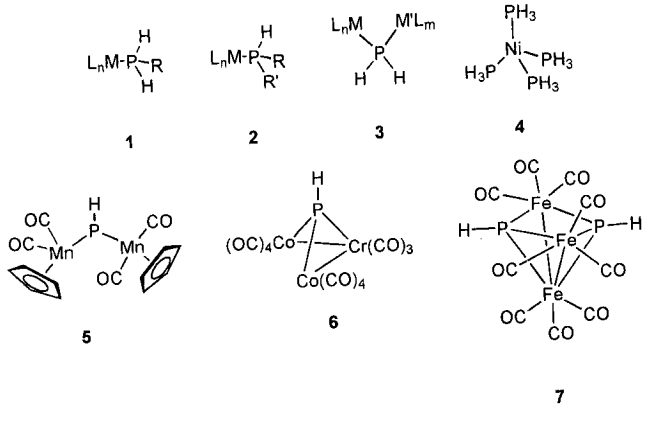
2. Formation of P−H Bonds from Naked P Atoms and Units Bonded to Transition Metal Complexes

2.1. A Survey of Transition Metal Complexes Incorporating P−H Bonds

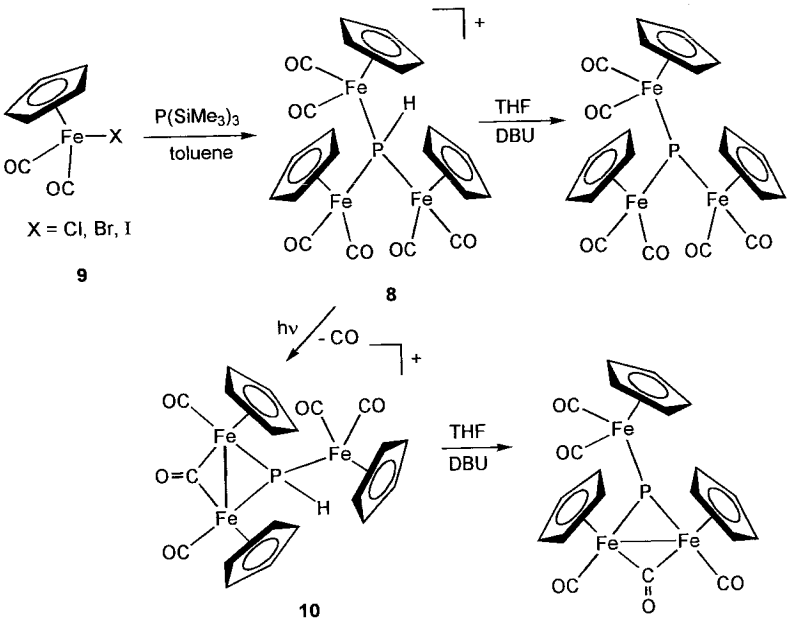
Unlike that of nitrogen, the reaction of white phosphorus with hydrogen has received comparably little attention, and the possibility that H_2 might directly react with P_4 is still a matter of debate.[22] Thus, the sparse reports on this subject, indicating that a reaction could take place only under high H_2 pressure at elevated temperature (> 360 °C), should be carefully considered.[23]

Although a bewildering variety of binary phosphorus-hydrogen compounds (phosphanes) have been described in the last thirty years,[24−26] transition metal complexes containing phosphorus hydrides are practically limited to the numerous complexes containing primary (**1**) and secondary (**2**) phosphanes (or phosphites) or their simple derivatives, particularly bridging phosphido species (**3**).[27,28] There also exist a small number of transition metal complexes incorporating one or more PH_3 ligands,[29] but homoleptic species, such as $[Ni(PH_3)_4]$ (**4**), are extremely rare.[30] PH_3 complexes are in turn a suitable starting point for the preparation of terminal and bridging phosphido (PH_2) complexes,[31] and some μ-phosphinidene derivatives, such as $[\{Cp^*Mn(CO)_2\}_2(\mu\text{-}PH)]$ (**5**)[32] and $[\{Co(CO)_4\}_2\{Cr(CO)_3\}(\mu_3\text{-}PH)]$ (**6**)[33] have also been prepared from PH_3 precursors.

Clusters featuring μ_3-PH or μ_4-PH capping phosphinidene ligand are also well known.[33,34] Such compounds can be prepared by direct interaction of PH_3 with polymetallic clusters[34c] or by treating a preformed PH_3 metal complex with a carbonyl cluster.[33] However, the best synthetic approach to phosphinidene clusters is the hydrolysis of silylphosphinidene clusters. A neat application of this preparative methodology has recently been reported by Schauer and co-workers, who synthesized the biphosphinidene cluster $[Fe_3(CO)_9(\mu_3\text{-}PH)_2]$ (**7**) by controlled hydrolysis of P−Si bonds.[35] The reactivity of **7**, which is largely centered on the P−H functionality, has been investigated thoroughly. Remarkably, the reaction chemistry at one P−H functional site is effectively transferred to the second P−H site through the trimetallic $Fe_3(CO)_9$ core.

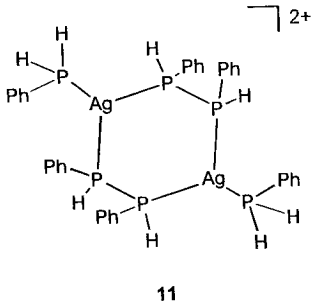


Stable triorganometallic phosphonium salts of formula $[\{Cp(CO)_2Fe\}_3(\mu_3\text{-}PH)]_n$ X (**8**) (n = 1, X = halide; n = 2, X = $FeCl_4$) have been prepared by Lorenz and co-workers by in situ methanolysis of P−Si bonds. Thus, **8** has readily been obtained as reddish brown microcrystals by treatment of $[CpFe(CO)_2X]$ (**9**) with $P(SiMe_3)_3$ at room temperature in toluene followed by crystallization in the presence of methanol.[36] UV irradiation induced the transformation of the tetrachloroferrate salt $[\{Cp(CO)_2Fe\}_3(\mu_3\text{-}PH)]_2[FeCl_4]$ into the *closed-Fe,Fe*-triferriophosphonium derivative $[\{Cp(CO)_2Fe\}\{(\mu\text{-}CO)[Cp(CO)_2Fe]_2\}(\mu_3\text{-}PH)]_2[FeCl_4]$ (**10**) by means of elimination of one CO ligand and formation of an Fe−Fe bond supporting a bridging carbonyl ligand.[37] Notably, the PH protons in both the triferriophosphonium derivatives **8** and **10** can easily be removed with DBU (1,8-diazabicyclo[5.4.0]undecene) in THF. Scheme 1 summarizes these transformations.

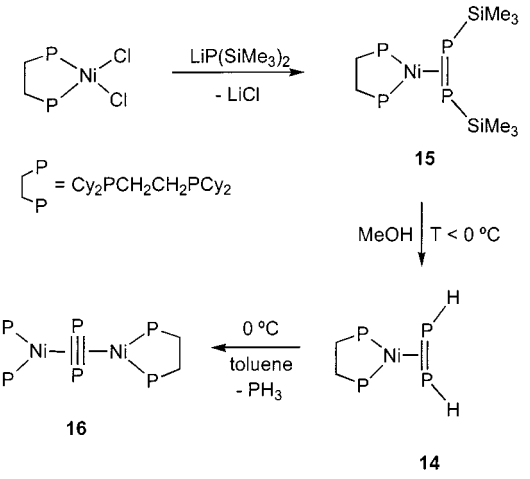


Scheme 1

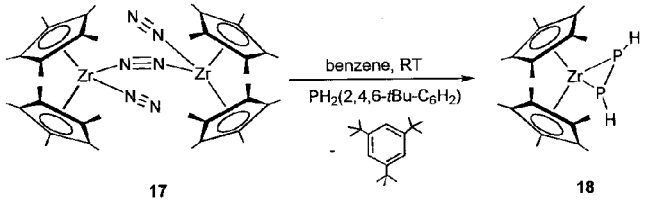
Of the other phosphanes, including the long-known P_2H_4, no transition metal derivative has yet been reported; unsurprising in view of the hyperreactivity of these molecules and their marked tendency to disproportionate.[24−26] However, complexes of substituted diphosphanes are known, and some of them, such as the dinuclear silver complex $[\{(PH_2Ph)Ag\}_2(\mu,\eta^1\text{:}\eta^1\text{-}P,P'\text{-}P(H)PhP(H)Ph)_2](AsF_6)_2$ (**11**), featuring two bridging diphenyldiphosphane ligands, have been authenticated by X-ray methods.[38] The coordination chemistry of substituted diphosphenes (P_2R_2) has also been studied, but the stabilization of diphosphene complexes usually requires bulky substituents. An outstanding review by Weber highlights the coordination chemistry of these ligands, also including the very few compounds containing P−H bonds.[39] At present, four complexes containing the parent diphosphene ligand (P_2H_2) have been reported. Two of these, $[Cp_2Mo(\eta^2\text{-}P_2H_2)]$ (**12**) and $[Cp_2TaH(\eta^2\text{-}P_2H_2)]$ (**13**), were prepared from direct treatment of metal hydrides with white phosphorus[40,41] and will be discussed in detail in the next section. The formation of the kinetic intermediate $[(dcpe)Ni(\eta^2\text{-}P_2H_2)]$ (**14**) (dcpe = $Cy_2PCH_2CH_2PCy_2$) during the methanolysis of $[(dcpe)Ni(\eta^2\text{-}P_2(SiMe_3)_2)]$ (**15**) en route to the formation of the diphosphorus dimetallic species $[\{(dcpe)Ni\}_2\text{-}(\mu,\eta^2\text{:}\eta^2\text{-}P_2)]$ (**16**) (Scheme 2) was briefly mentioned by Schäfer and co-workers.[42] Although **14** was not stable enough to be isolated, it was observed at low temperature and its ^{31}P and ^1H NMR spectra were recorded. At 0 °C in toluene, it slowly decomposed, yielding **16** and phosphane (PH_3). However, no details about this intriguing decomposition reaction, in which both P−P and P−H bonds were broken and reassembled, were provided.



The only other known diphosphene complex was prepared by Stephan and co-workers by treatment of $[\{Cp^*_2Zr(N_2)\}_2(\mu\text{-}N_2)]$ (**17**) with the primary phosphane $PH_2(2,4,6\text{-}t\text{Bu-}C_6H_2)$.[43] The reaction proceeded smoothly in benzene at room temperature to afford the diphosphene complex $[Cp^*_2Zr(\eta^2\text{-}P_2H_2)]$ (**18**) and 2,4,6-tBu$_3$-C_6H_3 in excellent yield (Scheme 3). The formation of **18** was associated with a P−C bond activation reaction at the sterically congested Zr−P system, which forms in the presence of a bulky primary phosphane. Such P−C bond activation



Scheme 2

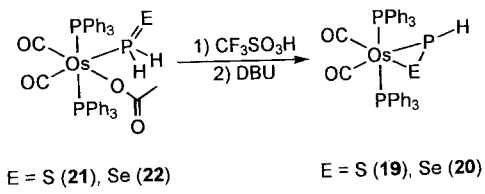


Scheme 3

methodology has successfully been used to synthesize several substituent-free P_x complexes of zirconium.[43]

It is worth mentioning that the parent diphosphene (P_2H_2) molecule, which in the four derivatives mentioned above was stabilized by complexation with low-valent organometallic metallocenes, has never been isolated in the free state. Such a molecule represents the lightest member of the P_nH_n family of phosphorus hydrides, the heavier members of which ($n > 2$) are known in the form of monocyclic phosphanes,[24−26,44] or, for $n = 2$, have been isolated by stabilization with bulky organic substituents. Theoretical investigations of P_2H_2 model complexes, such as $[(PH_3)_2Pd(P_2H_2)]$[45] and $[(CO)_5Cr(P_2H_2)]$[46] predict that the side-on η^2-coordination mode is the preferred one, with a short elongation of the diphosphene ligand P−P bond relative to that in the free molecule.[47]

Also relevant to this survey are the thioxophosphane and selenoxophosphane osmium complexes [Os(η^2-PHE)(CO)$_2$(PPh$_3$)$_2$] (E = S, **19**; Se, **20**), which were elegantly prepared by Roper and co-workers by stepwise addition of triflic acid and DBU to the thiophosphido and selenophosphido derivatives [Os{PH$_2$(E)}(η^1-*O*-OOCCH$_3$)(CO)$_2$(PPh$_3$)$_2$] (E = S, **21**; Se, **22**) (Scheme 4).[48]



Scheme 4

Apart from these sparse examples, there does not exist any other homogeneous group of low-valent phosphorus transition metal complexes hosting the P−H functionality. This is particularly surprising if one considers that the number of known phosphorus hydrides is only exceeded by that of hydrocarbons[25] and that, notwithstanding the difficulties of directly utilizing higher phosphorus hydrides as starting reagents for preparative purposes, there should be at least three reliable synthetic strategies for incorporation of P−H bonds within the coordination polyhedron of a transition metal complex:

(a) the direct reaction of white phosphorus with transition metal hydrides,

(b) the electrophilic hydrogenation (addition of protic acids) of neutral transition metal species incorporating P_x units,

(c) the nucleophilic hydrogenation (addition of hydride reagents) of transition metal complexes incorporating P_x units.

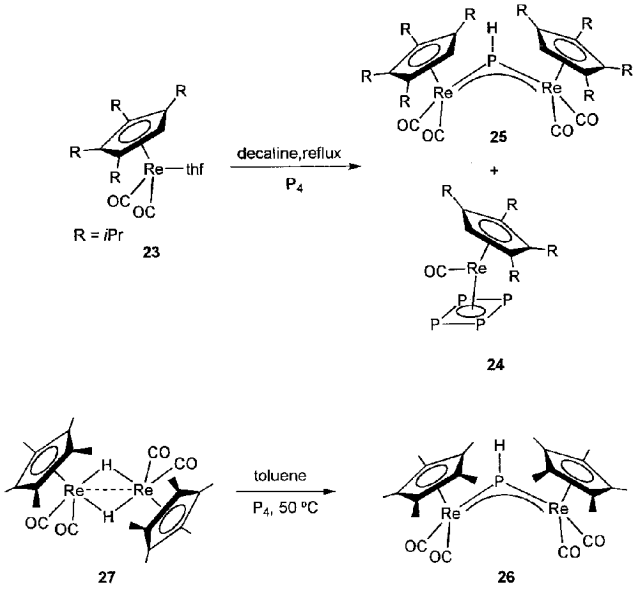
Although the above strategies should be broadly useful for the synthesis of transition metal complexes with P−H ligands in several preparative contexts, these methods have only been exploited to a very limited extent.

Treatment of white phosphorus with organometallic complexes may sometime result in the direct formation of P−H species even in the absence of suitable hydrogen donor sources. Adventitious water is generally considered to be responsible for the formation in these unpredictable reactions of species containing P−H. A pleasing example of this chemistry is provided by the study of the reaction of the sterically demanding rhenium metallocene [(1,2,3,4-*i*Pr$_4$C$_5$H)Re(CO)$_2$(thf)] (**23**) with excess P_4.[49a] After prolonged reflux in decalin and chromatographic workup, a mixture was obtained, from which the tetraphosphacyclobutane [(1,2,3,4-*i*Pr$_4$C$_5$H)Re(CO)(η^4-P$_4$)] (**24**) and μ-phosphinidene [{(1,2,3,4-*i*Pr$_4$C$_5$H)Re(CO)$_2$}$_2$(μ-PH)] (**25**) complexes were separated (Scheme 5). A similar phosphinidene complex [{Cp*Re(CO)$_2$}$_2$(μ-PH)] (**26**) was obtained by treatment of [{Cp*Re(CO)$_2$}$_2$(μ−H)$_2$] (**27**) with P_4 in toluene. However, no details of the mechanism leading to **26** were given.[49b] The two dirhenium phosphinidenes exhibit NMR resonances shifted strongly to low field (^{31}P: δ = 505/512, and ^{1}H: δ = 15.5/14.8), with direct P−H coupling constants (191/187 Hz) typical of $^1J_{PH}$ couplings.[50]

2.2. Reaction of White Phosphorus with Transition Metal Hydrides

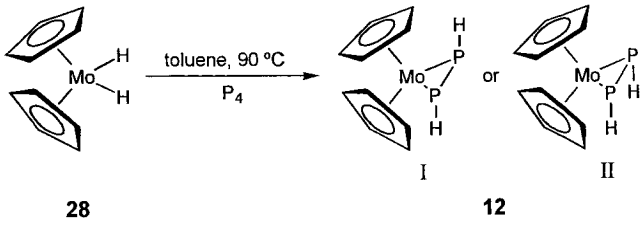
2.2.1. Reactions of White Phosphorus with Hydrido-Metallocenes

The reaction of white phosphorus with a transition metal complex was first described as early as 1974, by Green and co-workers. In a short note it was reported that the molybdenum dihydride [Cp$_2$MoH$_2$] (**28**) reacted smoothly with P_4 in hot toluene at 90 °C to yield, after chromatographic workup on alumina, deep red crystals; these were assigned the stoichiometry [Cp$_2$Mo(η^2-P$_2$H$_2$)] (**12**) on the basis of MS analysis, molecular mass determination, and ^{1}H and



Scheme 5

^{31}P NMR spectroscopy (Scheme 6).[40] However, spectroscopic methods alone were not capable of distinguishing between the two possible stereoisomers of the diphosphene ligand in **12** [*trans* (I) or *cis* (II)], which were preferred to the planar arrangement because of stereochemical arguments. The P_2H_2 ligand in **12** is believed to supply two electrons to the Mo^{II} complex, thus paralleling the bonding behavior of ethene in the related $[Cp_2Mo(C_2H_4)]$.



Scheme 6

Confirmation of Green's formulation of **12**, was provided soon after by Cannillo et al., who determined the molecular structure of **12** using X-ray methods. A view of the structure of Green's complex is presented in Figure 1.[51]

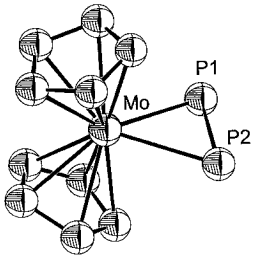


Figure 1. Crystal structure of $[Cp_2Mo(\eta^2\text{-}P_2H_2)]$ (**12**)

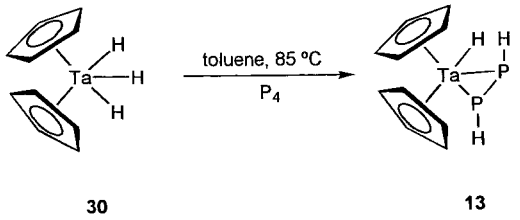
The most intriguing feature of the structure is the presence of a *quasi*-isosceles, triangular MoP_2 moiety, featuring a P−P separation of 2.146 Å, shorter than that found in black or white allotropes of phosphorus and in the diphosphane P_2H_4, but longer than the P=P bond length measured for P_2 molecules in the gas phase by electron diffraction.[52] The two P−H hydrogen atoms could not be located in the electron density map, but their presence was confidently inferred from spectroscopic measurements. In particular, the ^{1}H NMR spectrum exhibited an AA′XX′ multiplet at $\delta = 0.19$ with a $J_{PH} + J_{PH'}$ separation of ca. 160 Hz, while the corresponding multiplet in the proton-coupled ^{31}P NMR spectrum appeared at $\delta \approx 203$.[53] A sharp band at 2240 cm^{-1} in the IR spectrum was assigned to the stretching mode of the P−H bond.

No convincing information about the process which results in the assembling of the $Mo(P_2H_2)$ moiety from MoH_2 and excess P_4 has been provided, and the whole mechanism transforming the MoH_2 unit into the $Mo(P_2H_2)$ unit remains obscure. In situ monitoring of the originally reported "one-pot synthesis" of **12** by $^{31}P\{^1H\}$ and ^{1}H NMR spectroscopy was not informative in retrospect.[54] The initial formation of **12** was already observed at 40 °C, but the transformation of **28** into the diphosphene complex was completed within a reasonable time only at temperatures higher than 60 °C. No intermediate species en route to the diphosphene was observed. In our hands, the formation of **12** was confirmed by the appearance in the $^{31}P\{^1H\}$ NMR spectrum ([D$_8$]toluene) of a singlet resonance at $\delta = -194.6$, paralleled by the rising in the proton spectrum of a doublet of doublets at $\delta \approx 0.44$ [^1J(H,P) = 91.5 Hz, ^2J(H,P) = 67.7 Hz].[53] These NMR spectroscopic data, which confirm those given by Green with a lower field instrument, differ from those reported by Stephan and coworkers for $[Cp^*_2Zr(\eta^2\text{-}P_2H_2)]$,[55] but are in line with the NMR spectroscopic data given by Schäfer et al. for the thermally unstable $[(Cy_2PCH_2CH_2PCy_2)Ni(\eta^2\text{-}P_2H_2)]$.[56]

The reaction of primary phosphanes with $[Cp_2MH_3]$ (M = Nb, **29**; Ta, **30**) was thoroughly studied by Stephan and co-workers, who synthesized a variety of hydrido-diphosphene complexes $[Cp_2MH(\eta^2\text{-}P_2R_2)]$ (R = Ph, Cy) using this procedure.[41] In order to prepare unsubstituted diphosphene species, the reaction of white phosphorus with the tantalum trihydride **30** was successfully investigated. Thus, **30** and white phosphorus reacted in toluene at 85 °C to yield colorless crystals of $[Cp_2TaH(\eta^2\text{-}P_2H_2)]$ (**13**) after workup (Scheme 7).



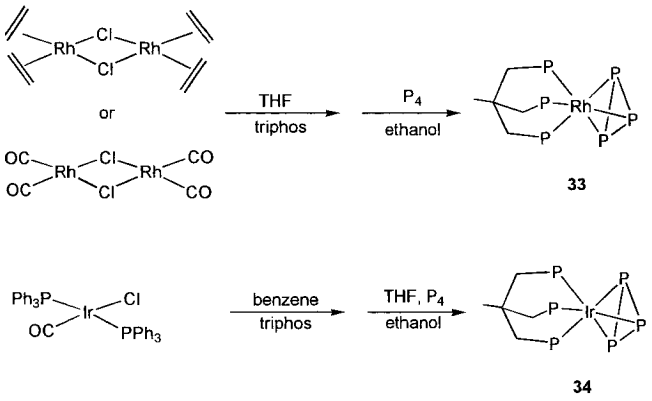
Scheme 7

Compound **13** was characterized by NMR spectroscopy and X-ray crystallography; the structural data revealed geometric features similar to those of **12**, with two cyclopentadienyl rings and a diphosphene ligand coordinated to the metal center. The three-membered MP_2 ring is tightly bonded to tantalum, with P−Ta−P angles ranging from 47.6 to 48.4°. A crystallographically located, but stereo-

chemically inactive, hydride ligand completes the coordination sphere about the metal center. As for **12**, the two diphosphene hydrogen atoms were not located by X-ray methods and their disposition in the complex remains unclear. Theoretical calculations and analogy with the *transoid* disposition adopted by other crystallographically characterized disubstituted diphosphenes of formula $[Cp_2MH(\eta^2\text{-}P_2R_2)]$ (M = Nb, Ta; R = Ph, Cy), gave credence to the view that the P_2H_2 ligand in **13** also adopts a *transoid* disposition. In particular, an energy difference of only 1−2 kcal mol^{-1} for the two optimized structures was computed by EHMO methods. A series of variable-temperature NMR experiments were consistent with the *transoid* structural assignment. Particularly informative was the analysis of the NOE enhancements observed at 193 K between the two P_2H_2 protons and the protons of the two inequivalent Cp rings. Compound **13** is stereochemically non-rigid, but the occurrence of a fluxional process exchanging *cisoid* and *transoid* isomers by inversion of both diphosphene ligand PH moieties could not be confirmed from analysis of the low-temperature NMR spectra. As with the molybdenum derivative **12**, no mechanism for the formation of **13** was provided.

2.2.2 Reactions of White Phosphorus with Hydrido-Polyphosphanes

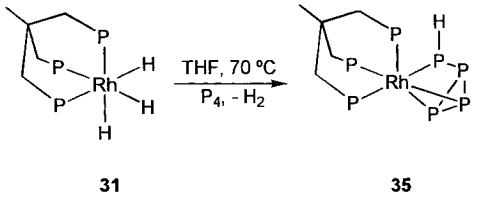
Notwithstanding Green's breakthrough in metal-assisted P−H chemistry and the continuous and impressive burgeoning of P_4-coordination chemistry during the last two decades,[57] studies dealing with the reactivity of transition metal hydrides with white phosphorus remained almost ignored until a couple of years ago, when we decided to investigate the reactivity of white phosphorus with transition metal hydrides stabilized by tripodal polyphosphanes. Our attention focused first on the known trihydrides [(triphos)RhH_3] (**31**)[58] and [(triphos)IrH_3] (**32**),[59] which had been successfully used by Bianchini and co-workers as hydrogenating catalysts for a variety of organic unsaturated substrates such as alkenes,[60] alkynes,[61] and thiophene derivatives,[62] including the highly HDS-resistant dibenzothiophene.[63] One of the most important reasons for choosing these hydrides at the very beginning of our investigation, apart from the general knowledge of their chemistry and the effectiveness of their catalytic performances in hydrogenation processes, was that the reactivity of both (triphos)Rh and (triphos)Ir systems towards white phosphorus was well known from Sacconi's studies, dating back to 1979.[64] Indeed, irrespective of the rhodium(I) or iridium(I) precursor,[65] the combination of triphos, M^I and white phosphorus resulted in the formation of the air- and moisture-stable complexes [(triphos)M(η^3-P_3)] as lemon yellow (M = Rh, **33**) or off-white (M = Ir, **34**), crystalline materials in moderate yields (Scheme 8).[64][66] Complexes **33** and **34** belong to the extensively studied family of *cyclo*-triphosphorus complexes $[(triphos)M(\eta^3\text{-}P_3)]^{n+}$ (n = 0, M = Co, Rh, Ir; n = 1, M = Ni, Pd, Pt) containing the P_3 unit *trihapto*-coordinated to the transition metal center.[67] The reactivity of these complexes has been widely investigated.[21,68]



Scheme 8

The generally accepted mechanism that governs the chemistry of both **31** and **32** involves the thermal reductive elimination of dihydrogen to produce the highly reactive species [(triphos)MH]. Once formed, the 16-electron fragment may be blocked by two-electron donor ligands, such as CO, or may reform an M^{III} complex by promoting the oxidative addition of different addends. In no case was removal of the residual hydride observed, although in a few instances it might selectively be delivered onto one of the oxidatively added atoms.[69] On all of these premises, it was of interest to see how the thermally generated fragments [(triphos)MH] would react with white phosphorus.

In keeping with our expectations, treatment of **31** with white phosphorus in THF at about 70 °C under nitrogen did not produce, at least directly, the *cyclo*-triphosphorus species **33**, but afforded an orange solution from which dark yellow microcrystals of the novel complex [(triphos)Rh(η^1:η^2-HP_4)] (**35**) were obtained after solvent removal under reduced pressure (Scheme 9).[70]



Scheme 9

Although the solid structure of **35** has not yet been verified by X-ray crystallography, the solution structure of the complex was substantiated by intensive multinuclear and multidimensional NMR experiments, which unequivocally demonstrated the presence of the rhodium-bonded η^1:η^2-HP_4 ligand, acting as a six-electron donor towards the (triphos)Rh fragment.

Key points of the NMR spectroscopic characterization lending credence to the proposed structure for **35** were the temperature-invariant $^{31}P\{^1H\}$ NMR spectrum, exhibiting a well-resolved ABCDEFGX spin system (confirmed by computer simulation and fitting), and the ^{31}P,^{31}P-2D COSY NMR spectrum. In particular, it was possible to disentangle the not trivial pattern of P,P connectivities from an analysis

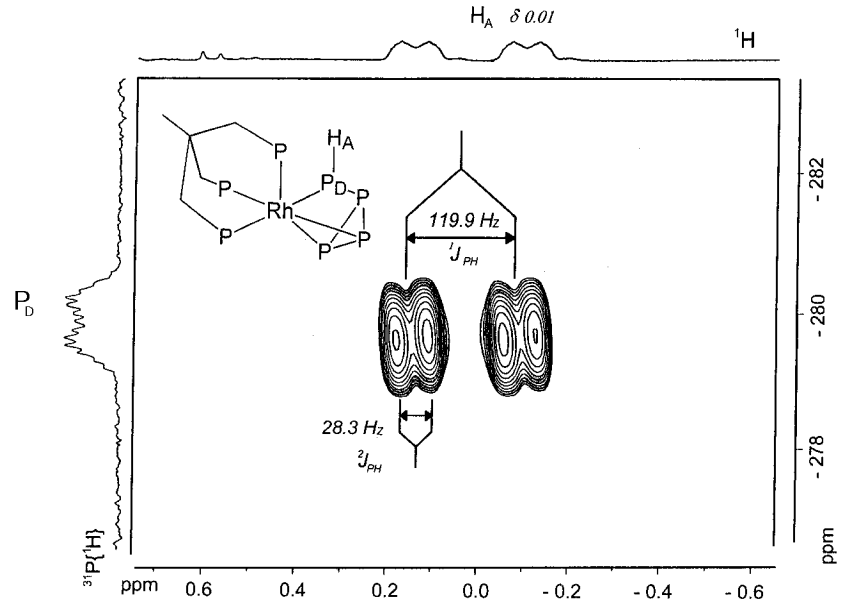


Figure 2. Contour plot of a section of the $^{1}H,^{31}P$-2D NMR spectrum of [(triphos)Rh(η^1:η^2-HP_4)] (**35**), showing the relevant cross peak between the P_D atom and the P−H hydrogen atom

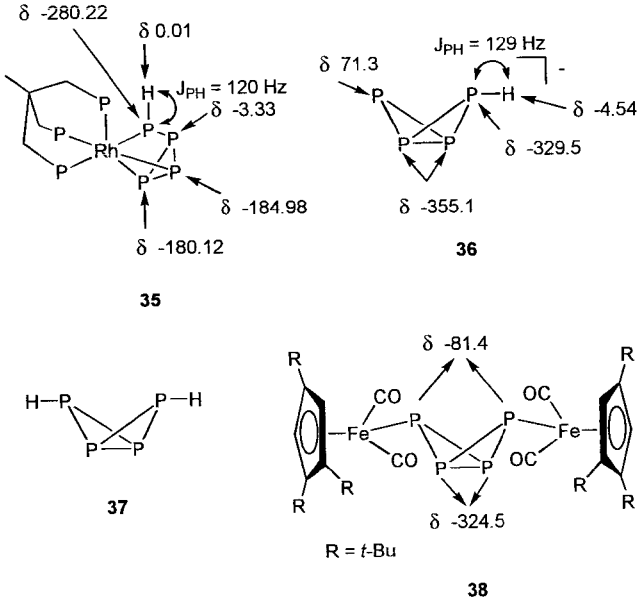
of the homonuclear correlation spectrum, and eventually to confirm the proposed structure for the phosphorus skeleton originating from the P_4 tetrahedron. The presence of the P−H ligand was underscored by a weak absorption at 2213 cm^{-1} in the IR spectrum (disappearing in the deuterated isotopomer [D_1]-**35**), by ^{31}P-DEPT NMR polarization transfer experiments (DEPT-90 and DEPT-135), and by $^{1}H,^{31}P$-HMQC heteronuclear correlation NMR experiments. Inspection of the heterocorrelated spectrum made evident the presence of a cross-peak signal correlating the phosphorus multiplet centered at $\delta = -280.22$ and a doublet of broad doublets resonating at $\delta \approx 0.01$ in the ^{1}H NMR spectrum. A relevant section of the contour-plot diagram, illustrating the one-bond P−H correlation, is presented in Figure 2.

Although the assemblage of the HP_4 ligand from white phosphorus and a transition metal hydride and its incorporation into a metal complex framework is unprecedented, the existence of an HP_4 anion had previously been demonstrated by Baudler and co-workers, who in 1988 prepared the alkaline salts M(HP_4) (**36**: M = Li, Na, K) by treatment of white phosphorus with metal naphthalenide as reducing reagent in 1,2-dimethoxyethane at −78 °C.[71] Unlike **35**, which is stable at room temperature under nitrogen or argon in both solid state and in solution, Baudler's derivatives could not be stored even at low temperature, decomposing in a few days at −78 °C, thus indicating that stabilization of highly reactive intermediates, even in phosphorus hydrido chemistry, can be achieved by means of metal coordination. A comparison of the NMR parameters of **35** with those of Baudler's salt reflects the substantial spectroscopic differences occurring upon stabilization of the tetraphosphorus monohydrido anion by metal coordination, but, noticeably, shows an almost identical value for the two one-bond P−H coupling constants [119.9 Hz for **35** vs. 129 Hz for K(HP_4)]. The P_4H units in both **35** and **36** can be formally considered as monodeprotonated anions derived from the known tetraphosphorus dihydride P_4H_2. This phosphane, which has been identified by mass spectrometry, is the simplest member of the low-hydrogen phosphanes of formula P_nH_{n-2}.[72] These exhibit structural motifs based on condensed polyphosphorus ring systems, and in the case of P_4H_2 a bicyclo[1.1.0]tetraphosphane structure (**37**) has been proposed.[24−26,72] In terms of their structural layouts, both the tetraphosphane **37** and the derivatives **35** and **36** can be traced back to the few known derivatives containing the tetraphosphabicyclobutane skeleton (P_4^{2-}). Complexes of



this class, featuring a butterfly MP_4M array, have been directly obtained either by cothermolysis of P_4 with $[\{Cp'(CO)_2Fe\}_2]$ − one example is $[\{Cp'(CO)_2Fe\}_2(\mu,\eta^1{:}\eta^1\text{-}P_4)]$ (**38**) (Cp' = 1,2,4-tBu$_3$-C_5H_2)[73] − or by reaction of the diphosphene complex $[Cp^*(CO)_2Fe(P{=}PCp^*)]$ with $[\{Cp^*(CO)_2Fe\}_2]$ − one example is $[\{Cp^*(CO)_2Fe\}_2\text{-}(\mu,\eta^1{:}\eta^1\text{-}P_4)]$ (**39**).[74]

Now the task at hand was to understand the mechanism leading to **35** and to explore the chemical reactivity of the HP_4 ligand. To address the first point, we decided to follow the reaction of P_4 and **31** by in situ NMR spectroscopy in order to observe some intermediates preceding the formation of the HP_4 ligand. Thus, when a 5-mm NMR tube (sealed under nitrogen) containing a [D$_8$]THF solution of **31** and white phosphorus (1:2) was heated in the NMR probe, a slow reaction took place at ca. 40 °C, selectively producing **35** as the only phosphorus-containing complex, without providing any evidence for intermediate species. The transformation was very slow at this temperature; after 4 h, less than 25% of **31** had been converted into the HP_4 compound. Inspection of the ^{1}H NMR spectrum revealed that dihydrogen had also been released (singlet at $\delta \approx 4.75$). Heating the probe-head to ca. 70 °C resulted in the fast (2 h) disappearance both of the **31** doublet at $\delta \approx 29$ and of the set of resonances due to **35**, and led to the formation of a doublet of quadruplets at $\delta \approx -269$, which was attributed to the *cyclo*-triphosphorus complex **33** by comparison with an authentic specimen.[64] The formation of **33**, which is almost quantitative after 2 h at 70 °C, was accompanied by the disappearance of the H_2 resonance in the proton spectrum and by the progressive development in the $^{31}P\{^1H\}$ NMR spectrum of a singlet resonance at $\delta = -244.77$, which was attributed to the formation of PH_3. In agreement with this assignment, this singlet transformed into a narrow quadruplet, with $^1J(H,P) = 186.9$ Hz, in the proton-coupled NMR spectrum. Figure 3 illustrates these transformations and highlights these experiments.

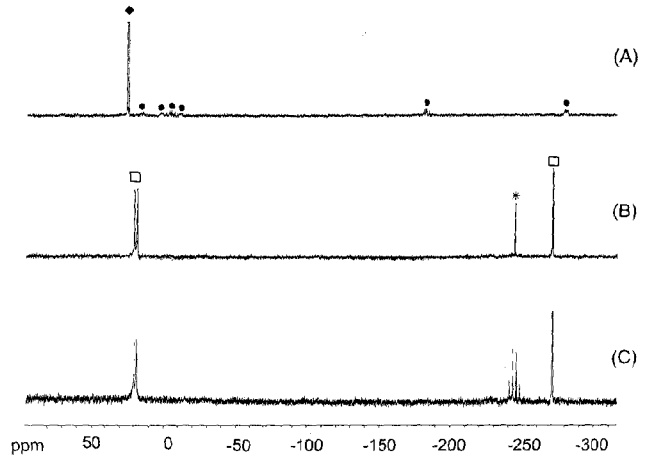


Figure 3. Monitoring of the reaction of $[(triphos)RhH_3]$ (**31**) with P_4 (2:1) in [D$_8$]THF: (A) $^{31}P\{^1H\}$ spectrum after 1 h heating at 40 °C; (B) $^{31}P\{^1H\}$ spectrum after 2 h heating at 70 °C; (C) ^{31}P spectrum after 2 h heating at 70 °C; (◆) $[(triphos)RhH_3]$ (**31**); (•) $[(triphos)Rh(\eta^1{:}\eta^2\text{-}HP_4)]$ (**35**); (□) $[(triphos)Rh(\eta^3\text{-}P_3)]$ (**33**); (*) PH_3

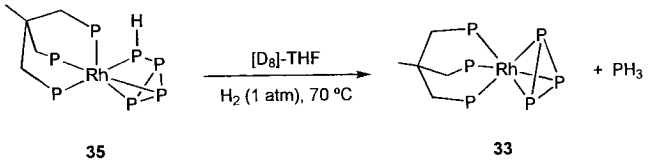
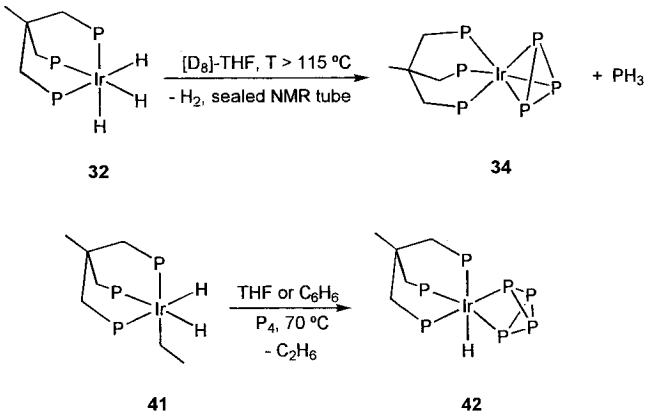
The reaction described above is remarkable because it provides the first evidence that *at least one of the four P atoms of white phosphorus can be hydrogenated to phosphane by a metal-assisted reaction*. It is also worth mentioning that all of the three hydride ligands in **31** are selectively transferred to the same phosphorus atom, while the three remaining phosphorus units in the P_4 molecule are efficiently scavenged in the form of the thermally robust *cyclo*-triphosphorus moiety in complex **33**. A separate NMR experiment carried out with the perdeuterated trihydride [D$_3$]-**31** confirmed the total incorporation of deuterium into the phosphane molecule, thus indicating that the three hydrogen atoms were transferred from the rhodium center to the same phosphorus atom. Addition of H_2 (1 atm) to a [D$_8$]THF solution of **35** at 70 °C transformed the HP_4 species into PH_3 and **33** (Scheme 10), but under N_2 the thermal reaction was difficult to control and the formation of **33** (< 70%) was accompanied by extensive decomposition. No compound arising from the formally produced "phosphinidene" (PH) species was identified and, because of the complexity of the reaction mixture, no experiment aimed at trapping this highly reactive fragment was attempted.



Scheme 10

As NMR monitoring of the reaction of **31** with P_4 did not provide definitive mechanistic information, we turned our attention to the kinetically more inert and thermally more robust iridium complex **32.** As expected, and in keeping with the general behavior of **32**, the reaction of the iridium trihydride with P_4 did not differ from that of its rhodium congener. However, the reaction needed a greater degree of activation to start, taking place only at temperatures higher than 115 °C. At this temperature, the formation of PH_3 and **34** from the undetected complex $[(triphos)Ir(\eta^1{:}\eta^2\text{-}HP_4)]$ (**40**) should occur very rapidly, and thus did not allow for the detection of any intermediate species during an in situ NMR experiment (sealed NMR tube) (Scheme 11). However, having established that the [(triphos)IrH] fragment is well suited as a platform for carrying out the hydrogenation reaction of P_4 to PH_3 and *cyclo*-P_3, it was an obvious step to look through the variety of organometallic complexes available in our laboratory and therefore to turn our attention to the cognate iridium complex $[(triphos)Ir(H)_2Et]$ (**41**).[75] Compound **41** thermally eliminates ethane, rather than H_2, under milder conditions (ca. 70 °C) and, irrespective of the solvent medium (benzene, THF, acetone, acetonitrile, etc), gives the fragment [(triphos)IrH]. This, in the absence of any external reagent, brings about C−H bond activation of the solvent, yielding octahedral Ir^{III} complexes of formula $[(triphos)Ir(H)_2R]$ [R = C_6H_5, C_4H_7O, $CH_2C(O)CH_3$, CH_2CN, etc.]. However, when a solution of **41** in THF or benzene was brought to reflux in the presence

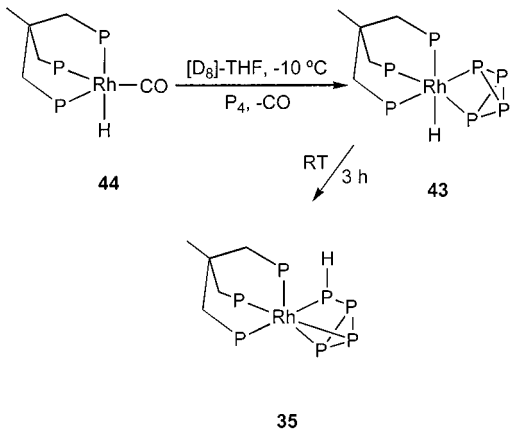
of elemental phosphorus (Ir/P_4 = 1:2), no solvent activation took place, and a bright yellow solution was obtained, from which pale yellow microcrystals of the novel compound [(triphos)IrH(η^2-P_4)] (**42**) separated.[76] Compound **42** was characterized by elemental analysis, mass spectrometry and IR spectroscopy [IR: medium-intensity ν(Ir−H) band at 2061 cm^{-1}], as well as by multinuclear NMR spectroscopy.



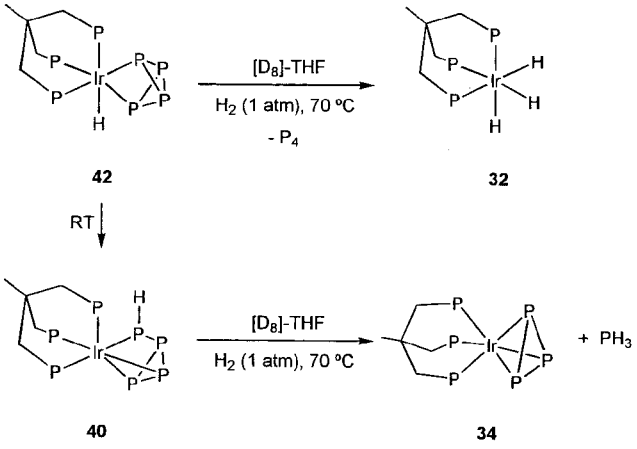
Scheme 11

Complex **42** is a member of the well-known family of transition metal complexes containing the bicyclotetraphosphane ligand[77] and, in keeping with this hypothesized structure, it shows in the $^{31}P\{^1H\}$ NMR spectrum a slightly second-order-perturbed ABB′CDEE′ spin system. Probably, **42** forms by oxidative addition of P_4 to the unsaturated [(triphos)IrH] fragment. This can reasonably be assumed as the first basic step of the reaction of P_4 with both **31** and **32**. In contrast to the easy synthesis of **42**, no analogous rhodium compound could be detected in the reaction of **31** with P_4. However, a species showing NMR parameters in line with that of the anticipated [(triphos)RhH(η^2-P_4)] (**43**) was generated in a 5-mm NMR tube by treating a cold [D_8]THF solution of the hydrido-carbonyl complex [(triphos)RhH(CO)] (**44**)[58] with one equivalent of P_4, dissolved in the same solvent. At room temperature, the transformation of **43** into **35** is sufficiently slow to allow the hydrido-bicyclotetraphosphane complex to be isolated. On standing of the solution at room temperature, **43** was transformed quantitatively into **35** within 3 h (Scheme 12).[78] On the basis of this finding, it is quite probable that **43**, which initially forms at the temperature required to eliminate H_2 thermally from **31**, undergoes a quick transformation into **35** without being observable by NMR experiments.

Compound **42** is kinetically stable and could be isolated in the solid state in pure form. Nevertheless, in a THF solution standing at room temperature in a sealed NMR tube, it spontaneously tautomerized within days into the HP_4 derivative [(triphos)Ir(η^1:η^2-HP_4)] (**40**) (Scheme 13). The reaction was not selective and a number of unknown iridium species and some decomposition products accompanied the formation of **40**, which could not be obtained in a yield higher than 25%. Hydrogenation of **40**, in a [D_8]THF solution heated at about 70 °C, cleanly produced PH_3 and the iridium *cyclo*-P_3 complex **34**. Remarkably, when pressurized with dihydrogen, **42** did not produce PH_3 and **34**, because the reductive elimination of P_4 became competitive with the hydrogenation reaction of the activated P_4 ligand. Thus, after exposure of **42** to H_2 and heating at ca. 70 °C, the trihydride **32** was quantitatively recovered (Scheme 13). Nevertheless, this result is valuable from a mechanistic viewpoint as it underlines that *the functionalization of the activated P_4 ligand by selective delivery of one hydride from the metal center to the phosphorus atom is mandatory for accomplishing the complete hydrogenation of one P atom to PH_3*.



Scheme 12



Scheme 13

A perusal of the large body of collected experimental information about the reaction with white phosphorus of **31** and **32** provides convincing evidence with which to propose a plausible mechanism for the hydrogenation of one phosphorus atom in white phosphorus to phosphane. Fundamental key points of the proposed mechanism, which is depicted in Scheme 14 are:

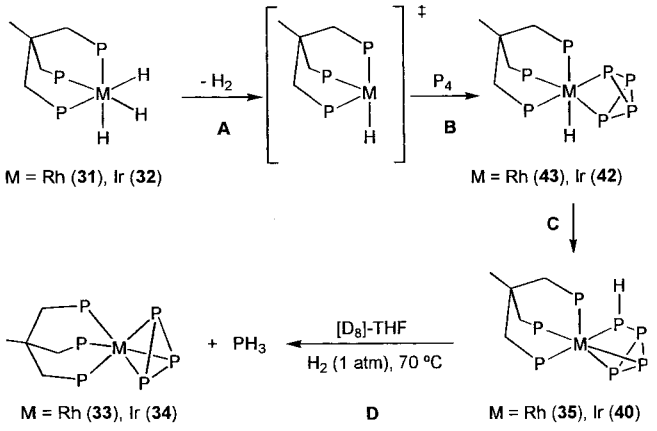
(**A**) the thermal elimination of H_2 from the rhodium or iridium trihydride is the preparative step necessary to generate the highly reactive fragment [(triphos)MH],

(**B**) the P_4 oxidative addition occurs by P−P bond activation and results in the formation of the octahedral hydrido-bicyclotetraphosphanes **42** and **43**. The iridium complex **42** is endowed with enough stability to be isolated in the solid state, but the rhodium analogue **43** could not be intercepted

under the experimental conditions used. It has been synthesized at lower temperature by alternative routes,[78]

(**C**) the unprecedented HP_4 complexes **35** and **40** are obtained from the irreversible intramolecular tautomerization $M(H)(\eta^2\text{-}P_4) \rightarrow M(\eta^1{:}\eta^2\text{-}HP_4)$ by hydride migration from the metal to one of the proximal P atoms of the η^2-P_4 ligand. This step is a prerequisite for the following hydrogenation reaction,

(**D**) in the absence of H_2, the reaction stops at the HP_4 complex, but when dihydrogen is added, or when the reaction is carried out in a closed system, complete hydrogenation of the hydrogenated phosphorus atom in the HP_4 ligand takes place. Notably, the hydrogenation step is accompanied by concomitant P−P bond cleavage with release of PH_3.



Scheme 14

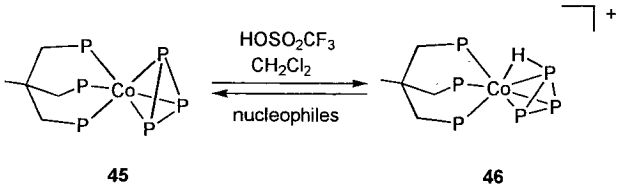
The final hydrogenation step, conveying two hydrogen atoms to the PH group in the HP_4 ligand, is currently under study. A possible mechanism accounting for the formation of PH_3 involves the metal-mediated, heterolytic splitting of a molecular hydrogen ligand, followed by stepwise addition of H^+ and H^- to the hydridotetraphosphorus ligand. Convincing chemical evidence supporting the heterolytic mechanism comes from the observation that electrophiles like H^+ and Me^+ selectively attack the hydrogen-substituted P atom in **35** (vide infra),[79] and that both (triphos)Rh and (triphos)Ir systems are capable of coordinating H_2, forming the highly fluxional, nonclassical hydrides $[(triphos)Rh(\eta^2\text{-}H_2)(H)_2]^+$ [80] and $[(triphos)Ir(\eta^2\text{-}H_2)(H)_2]^+$.[81]

Now there remains the crucial point of turning the stoichiometric hydrogenation of white phosphorus into a catalytic process. In this regard, we think that the formation of **33**, which accompanies the assemblage of PH_3 from **35** and H_2, represents a dead-end, because the triphos *cyclo*-triphosphorus complexes are extremely robust and cannot return the rhodium precursor to the reaction system under any realistic conditions. Experimentally, we have not yet been able to observe any catalytic reaction, and only a stoichiometric amount of phosphane was produced when a solution of **31** and white phosphorus (Rh/P_4 = 1:10) in $[D_8]$THF was pressurized with up to 30 atm of H_2 in a sapphire NMR tube and heated up to 90 °C (high-pressure NMR experiment). Harsher reaction conditions caused extensive decomposition of the rhodium complexes without increasing the PH_3 yield.[82]

Nonetheless, we think it possible to accomplish the catalytic hydrogenation of P_4, providing that hydrogen transfer from the transition metal hydride to phosphorus is carried out using a metal hydride capable of coordinating and activating P_4, but unable to form stable complexes with the released P_x fragment (i.e. *cyclo*-P_3 in the case at hand). In order to verify this hypothesis, we are currently expanding the range of transition metal hydrides to be treated with white phosphorus. Particularly, we are looking at hydrides stabilized by polydentate ligands capable of easily dissociating one arm (hemilabile ligands), which should make coordination of H_2 to the intermediate P_4-activated complexes possible.[82]

2.3. Electrophilic Hydrogenation of P_x Units Incorporated into Transition Metal Complexes

Electrophilic hydrogenation (addition of protic acids) of neutral transition metal species incorporating P_x units is a simple method for generating the P−H bond functionality in a metal-stabilized polyphosphorus P_x unit. However, this synthetic procedure has scarcely been used and the only well-documented literature example related to such reaction was reported by Stoppioni and co-workers in 1991.[83] By straightforward addition of two equivalents of triflic acid to a suspension of $[(triphos)Co(\eta^3\text{-}P_3)]$ (**45**) in dichloromethane, a rapid dissolution of the starting compound occurred, giving an orange solution from which orange crystals of composition $[(triphos)Co(\eta^3\text{-}HP_3)](OSO_2CF_3)_2\cdot(H_5O_2)$ (**46**) were obtained after layering with benzene at room temperature (Scheme 15).



Scheme 15

The reaction is reversible, and even mild nucleophiles such as acetone, ether and ethanol can deprotonate **46**, giving back the *cyclo*-triphosphorus complex **45**. NMR analysis of the complex did not clarify the solution structure of the $[(triphos)Co(\eta^3\text{-}HP_3)]^+$ cation. However, the observation in the ^1H NMR spectrum of a temperature-invariant broad hump at $\delta \approx -13.7$ points to the presence of a hydrogen atom with a rather prominent hydride character.[84] The solid-state structure of **46** consists of triflate anions, $H_5O_2^+$ and $[(triphos)Co(\eta^3\text{-}HP_3)]^+$ cations in a 2:1:1 ratio. Noticeably, the co-crystallized molecules of triflic acid and adventitious water found by the X-ray diffraction analysis do not show any short contacts with the complex cation. The addition of a proton to the tetrahedral array of the parent CoP_3 cluster causes only moderate distortions, resulting in a slight lengthening of the Co−P bonds from 2.301 Å in **45**

to 2.396 Å [d(Co−P)$_{ave}$ = 2.343 Å] in **46** (Figure 4). A rationale for the location of the crystallographically undetected proton was obtained, in view of the distorted solid-state geometry, by theoretical analysis using both a semiempirical extended Hückel approach and ab initio DFT calculations.[85]

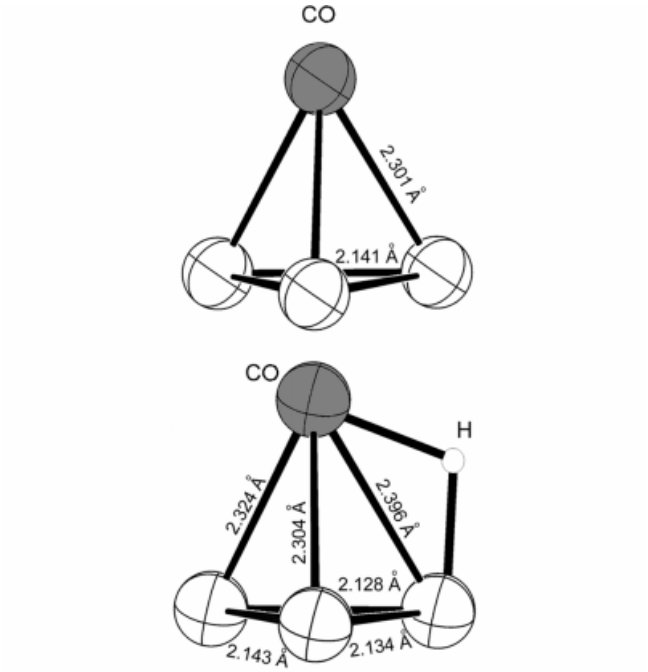


Figure 4. Comparison of the inner cores of [(triphos)Co(η^3-P_3)] (**45**) (top) and [(triphos)Co(η^3-HP_3)]$^+$ (**46**) (bottom); the H atom in **46** has been inserted in a calculated position

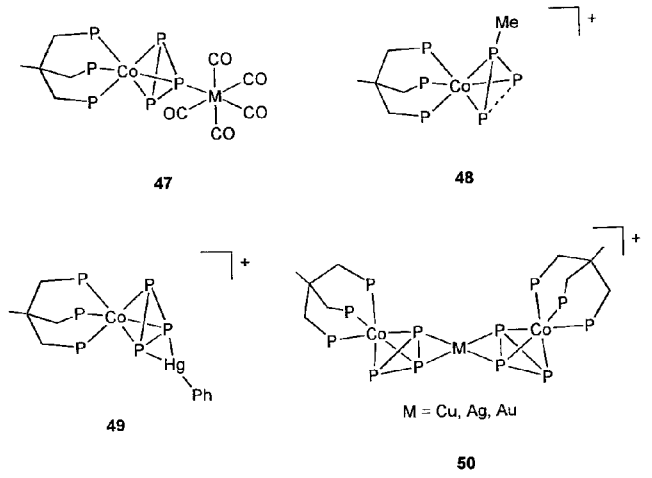
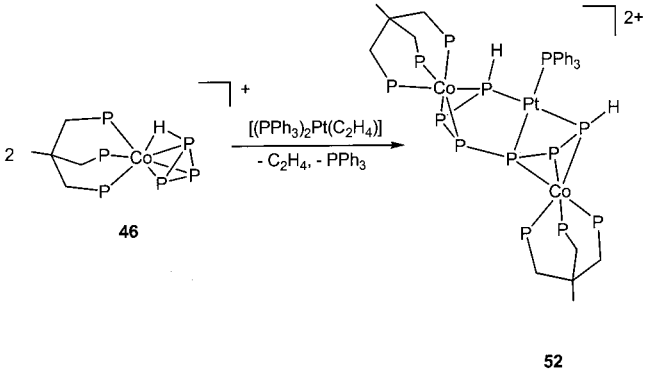
Among the four different preferential sites of attack of the H^+ to the CoP_3 moiety, the optimized structure for the $CoHP_3^+$ cation entails the added H atom forming a bridge between one of the phosphorus atoms of the P_3 ring and cobalt. The calculated minimized geometry was found to be in very good agreement with that proposed on the basis of the experimentally observed crystallographic distortions for **46** and has been attributed to the minimal steric requirements of the H^+. In keeping with the existence of slightly higher minima in the energy profile associated with the electrophilic alkylation of **45**,[85] the electrophilic addition of sterically more demanding fragments to **45** results in the formation of geometrically distinct Co(η^3-P_3R)$^{n+}$ (n = 0, 1) adducts, in which the added electrophile may bind one CoP_3 core phosphorus atom as an exocyclic ligand, such as in [(triphos)Co(η^3-P_3{M(CO)$_5$})] (**47**),[21b,86] and [(triphos)-Co(η^3-P_3Me)]PF_6 (**48**),[87] or may be bound to a pair of phosphorus atoms of a slightly elongated P−P edge, such as in the mononuclear mercury adduct [(triphos)Co(η^3-P_3{HgPh})]PF_6 (**49**),[68e] or in the binuclear species with a coinage metal cation bridging two CoP_3 fragments, [{(triphos)Co(η^3-P_3)}$_2$(μ_4-M)]PF_6 (M = Cu, Ag, Au) (**50**).[68d,68g]

The protonated complex **46** was successfully used by Di Vaira and Stoppioni as the starting material for the construction of an unprecedented open-chain P_6H_2 ligand by reaction with [$(PPh_3)_2Pt(C_2H_4)$] (**51**).[88] Thus, addition of **51** to a dichloromethane solution of **46** gave dark brown crystals of [{(triphos)Co}$_2$(η^3,η^3,η^3-P_6H_2){Pt(PPh_3)}]-$(OSO_2CF_3)_2$·$2C_6H_6$ (**52**), authenticated by X-ray methods (Scheme 16).

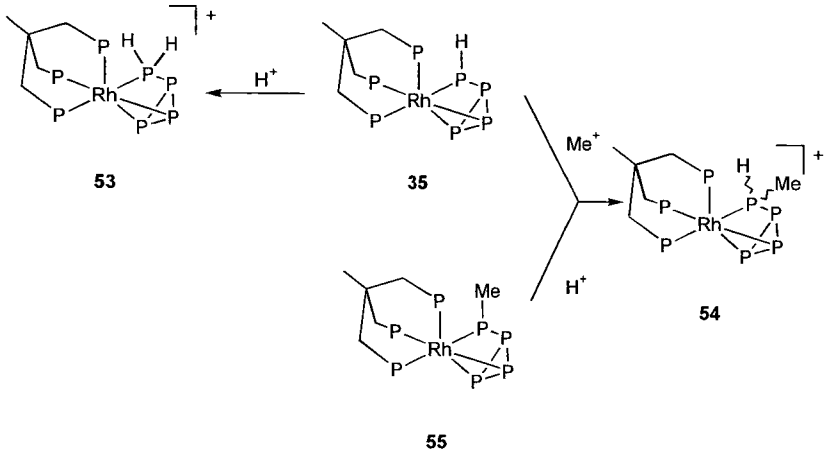




Scheme 16

The cationic complex **52** results from the coming together of two [(triphos)Co(η^3-HP_3)]$^+$ cations and a Pt(PPh_3) moiety. The P_6H_2 fragment is generated by P−P bond formation from two different Co(HP_3)$^+$ units, while during the reaction the labile ethene and one triphenylphosphane ligand are removed from the platinum center. This metal center exhibits the usual square-planar geometry, formed by the residual PPh_3 ligand and by three phosphorus atoms of the assembled P_6H_2 fragment. Although the presence of two triflate anions implies the existence of two protons, as required for charge balance, these could not be located either by structural investigation, or by spectroscopic techniques (IR and ^{1}H NMR). However, the narrow distribution of the six Co−P bonds in **52** [d(Co−P)$_{ave}$ = 2.305 Å] would rule out a bridging Co−H−P location for the skeletal hydrogen atoms in **52**. Similarly, theoretical EH calculations do not indicate any electrophilic privileged target between the six P atoms of the P_6H_2 ligand, but rather point to an appreciable amount of negative charge spread over the six positions in the hexaphosphorus chain.[88]

Addition of electrophiles to [(triphos)Rh(η^1:η^2-HP_4)] (**35**) was briefly considered in order to shed some light on



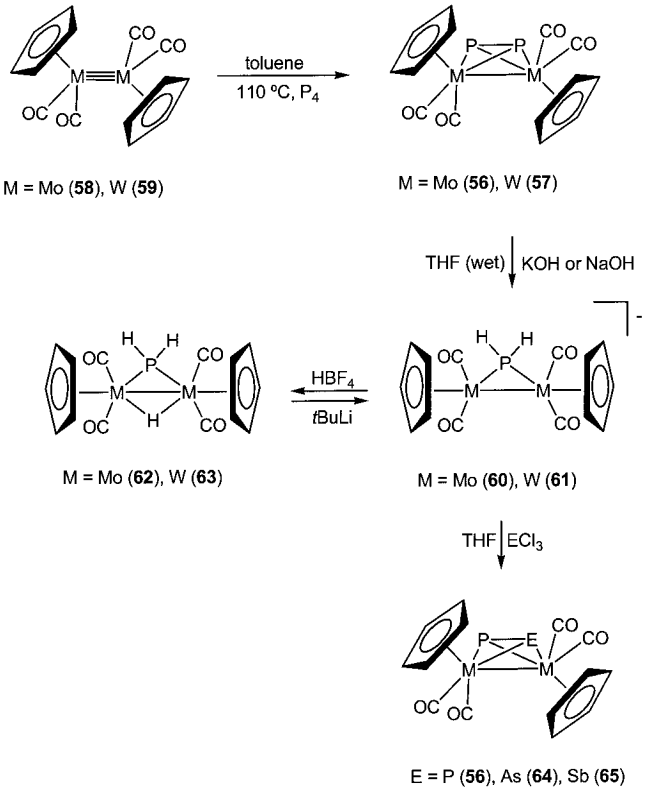
Scheme 17

the reaction mechanism that transforms **35** into PH_3 and **33** (vide supra).[79] Thus, in a series of dedicated in situ experiments, it was demonstrated that the phosphorus atom bearing the P−H functionality is the selected target of electrophilic reagents H^+ or Me^+. As a result, the cationic derivatives [(triphos)Rh(η^1:η^2-H_2P_4)](BF_4) (**53**) and [(triphos)Rh(η^1:η^2-H(Me)P_4)](OSO_2CF_3) (**54**), which were characterized by NMR spectroscopy, were synthesized. Notably, the signal of the phosphorus atom, that underwent the addition of the second substituent, experienced a significant downfield shift, moving − for example − from $\delta = -280.22$ in **35** to -172.83 in **54**. Conclusive evidence confirming the regioselectivity of the electrophilic attack on the RP_4 ligands was obtained by comparing the reaction of **35** with $MeOSO_2CF_3$ and the cross reaction in which one equivalent of HBF_4 or $HOSO_2CF_3$ was added to a solution of the methylated complex [(triphos)Rh(η^1:η^2-MeP_4)] (**55**).[78,79] Irrespective of the starting [(triphos)Rh(RP_4)] substrate and the electrophile used, the final products of the cross reactions exhibited identical NMR properties, and may therefore be assigned as the cationic [(triphos)Rh(η^1:η^2-H(R)P_4)]Y (R = H, **53**; R = Me, **54**). Scheme 17 summarizes these reactions.

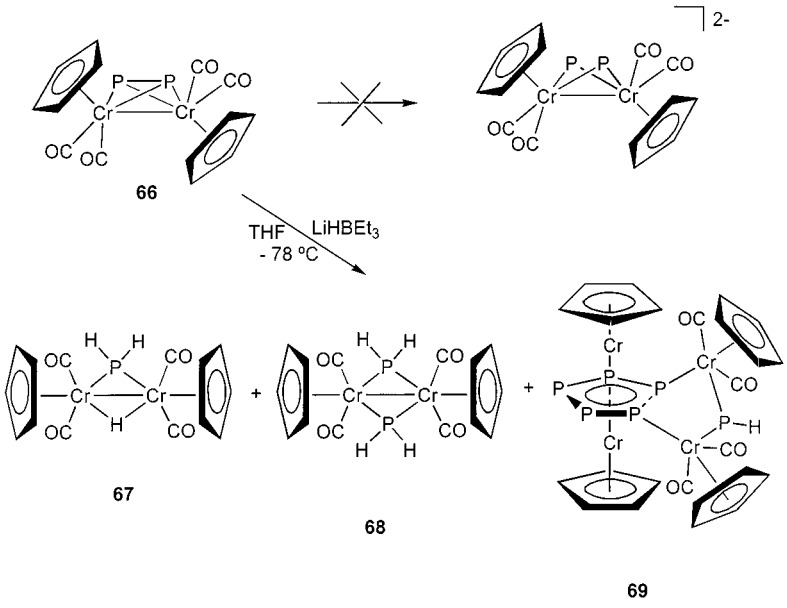
2.4 Nucleophilic Hydrogenation of P_x Units Incorporated into Transition Metal Complexes

The "nucleophilic hydrogenation"[89] of transition metal complexes incorporating P_x units is a synthetic methodology that can be successfully used to introduce a P−H functionality into the framework of a transition metal complex. This route to species containing P−H was first adopted by Mays and co-workers, who have recently undertaken a thorough investigation of the reactivity of transition metal complexes featuring a bridging diphosphorus ligand. As a provisional result of these ongoing studies, it has been demonstrated that transition metal species with bridging P_2 ligands have a high synthetic potential as precursors to very unusual and frequently otherwise inaccessible organophosphorus ligands.[90]

As a key contribution to this chemistry, the Cambridge team investigated the reactivity of the easily accessible M_2P_2 tetrahedranes [{$CpM(CO)_2$}$_2$(μ,η^2,η^2-P_2)] [M = Mo (**56**); W (**57**)], originally prepared by Scherer et al., by cothermolysis of white phosphorus and [$CpM(CO)_2$]$_2$ [M = Mo (**58**); W (**59**)] in refluxing toluene.[91] Thus, treatment of **56** (or **57**) with a large excess of NaOH or KOH in wet THF afforded the new anionic phosphido complexes [{$CpM(CO)_2$}$_2$(μ-PH_2)]$^-$ [M = Mo (**60**); W (**61**)] as air-sensitive, purple solutions.[92] The two complexes were not isolated as solids, but after addition of a slight excess of HBF_4·OEt_2, orange crystals of the new neutral derivatives



Scheme 18



Scheme 19

[{CpM(CO)$_2$}$_2$(μ-PH$_2$)(μ-H)] [M = Mo (**62**); W (**63**)] were obtained in fairly good yield (Scheme 18). As well as by straightforward spectroscopic and FABMS characterization, the molybdenum derivative **62** was authenticated by X-ray diffraction analysis, confirming the presence of an essentially planar MoHMoP core.

The formation of **62** was reversible and the purple color of **60** could be restored by adding one equivalent of *t*BuLi in THF. Solutions of **60** were extremely reactive towards halogenated compounds.[93] Quite remarkable is the reaction with ECl$_3$ (E = P, As, Sb), which immediately produced orange solutions from which the air-stable tetrahedranes [{CpMo(CO)$_2$}$_2$(μ,η^2,η^2-PE)] [E = P (**56**); As (**64**); Sb (**65**)] were obtained. Crystallographic analysis of **64** and **65** confirmed the presence of rare examples of hetero-μ,η^2:η^2-PAs and -μ,η^2:η^2-PSb ligands.

A relevant breakthrough in this chemistry has recently been provided by the German group led by Scheer, which has studied the reactivity of the chromium derivative [{CpCr(CO)$_2$}$_2$(μ,η^2:η^2-P$_2$)] (**66**) towards main-group hydrides.[94] The work of Scheer et al. was aimed at breaking the P−P bond of the Cr$_2$P$_2$ tetrahedrane to generate a dianionic moiety (Cr$_2$P$_2^{2-}$) suitable for use as building block for the formation of new metal-bridged oligomers (a P atom is isolobal with a CH group[7]) (Scheme 19). Surprisingly, the addition of two equivalents of "superhydride" to a THF solution of **66** did not afford the expected dianion,[95] but yielded a mixture of P−H compounds which were separated by column chromatography on silica gel.[96]

The major product was the dichromium complex [{CpCr(CO)$_2$}$_2$(μ-H)(μ-PH$_2$)] (**67**), which shares most of its spectroscopic and structural parameters with Mays' derivatives **62** and **63**. The chromium dimer [{CpCr(CO)$_2$}$_2$(μ-PH$_2$)$_2$] (**68**) and a singular tetrachromium derivative [{CpCr(CO)$_2$}$_2$(μ-PH)}{(CpCr)$_2$(μ,η^1:η^1:η^5:η^5-P$_5$)}] (**69**) were also formed as minor products. Complex **68** consists of two CpCr(CO)$_2$ units held together by two phosphido (μ-PH$_2$) bridges, while the paramagnetic complex **69** exhibits a unique triple-decker sandwich structure in which the middle *cyclo*-P$_5$ ligand additionally coordinates the chromium metal center of an external [{CpCr(CO)$_2$}$_2$(μ-PH)] moiety with two contiguous P atoms. The *cyclo*-P$_5$ ligand is unusually distorted in comparison to other triple-decker complexes with the *cyclo*-P$_5$ ligand,[97] and its bonding properties have been interpreted by supposing a partition of the P$_5$ ligand into a allylic P$_3$ and a P$_2$ subunit.[98]

3. Concluding Remarks

This review summarizes the chemistry of transition metal complexes containing P−H bonds, and specifically highlights the possibility of establishing one or more P−H bonds in a transition metal center by hydrogenation of white phosphorus or polyphosphorus ligands. In examining the wealth of knowledge so far collected about reactions involved in the metal-assisted formation of P−H bonds from P$_4$ or P$_x$ ligands, it has become evident that a first step has been made in the direction of metal-assisted P$_4$ hydrogenation, but it is also evident that there remain many unresolved questions requiring additional synthetic efforts in order to accomplish a second, more important and probably definitive, step in such a direction. Clearly, further studies aimed at unraveling the intimate mechanism of the stoichiometric hydrogenation reactions of white phosphorus described here would be highly desirable in view of the industrial relevance associated with the as yet unaccomplished hydrogenation of the P$_4$ molecule.

The first industrial production of synthetic ammonia from nitrogen and hydrogen was begun at BASF in Ludwigshafen, Germany, in 1913, using a revolutionary catalytic process combining N$_2$ and H$_2$ at high pressure. At present,

we do not yet know when the catalytic production of PH_3 from white phosphorus and hydrogen will be written about in future chemical textbooks, but certainly we now know that transition metal complexes can bring about such intriguing processes.

Acknowledgments

This work was supported by the EU through the inco Copernicus project ERB IC15CT960746 and COSTD17 Action. The authors wish to express their gratitude to their colleagues, H. Butenschön (Hannover, Germany), L. Y. Goh (Singapore), H. Grützmacher (ETH, Zürich, Switzerland), O. J. Scherer (Kaiserslautern, Germany), R. R. Schrock (MIT, MA, USA), D. W. Stephan (Windsor, Canada) and P. Stoppioni (Florence, Italy) for preprints of unpublished results or for answering specific questions about their researches in this area. The authors are indebted to colleagues H. M. Lee (Hong Kong) and M. Ehses (INM, Saarbrücken, Germany) for reading the manuscript and for the helpful suggestions and P. Barbaro (Florence, Italy) for running ^{2}D-NMR spectra. I. R. thanks the Spanish "Ministerio de Educacion y Cultura" for the postdoctoral fellowship granted.

[53] Because of a misunderstanding of the reference scale in the original literature,[40] the resonance due to the P_2H_2 ligand in **12** was erroneously reported to be positioned at lower field with respect to H_3PO_4.[39,40] Correctly, it resonates at $\delta = -194.60$, and therefore at higher field with respect to 85% H_3PO_4.[54]

[54] I. de los Rios, M. Peruzzini, unpublished observations.

[55] $[Cp^*_2Zr(\eta^2\text{-}P_2H_2)]$ (**18**) exhibits a singlet resonance at δ = 134.3 in the $^{31}P\{^1H\}$ NMR spectrum and a PH proton signal at δ = 4.68 [dd, J(H,P) = 310.0 and 21.3 Hz].[43]

[56] The signal of the P_2H_2 ligand in $[(dcpe)Ni(\eta^2\text{-}P_2H_2)]$ (**14**) appears as a singlet at $\delta = -120$.[42]

[57] Curiously, Green's report on P_4 functionalization mediated by $[Cp_2MoH_2]$ was published shortly after the first report on metal-mediated P_4 activation by Lindsell and Ginsberg.[3]

Metal-Mediated Self-Assembly of Molecular Squares of Porphyrins Rimmed with Coordination Compounds

Elisabetta Iengo,[a] Romina Minatel,[a] Barbara Milani,[a] Luigi G. Marzilli,[b] and Enzo Alessio*[a]

Keywords: Porphyrinoids / Supramolecular chemistry / N ligands / Self-assembly / Ruthenium

Partially coordinated *meso*-tetra(4′-pyridyl)porphyrin, in which two out of four peripheral 4′-(N)py sites are bound to inert Ru^{II} complexes, self assembles with cationic square-planar Pd^{II} or neutral octahedral Ru^{II} 90° angular units to yield a new family of molecular squares, in which the periphery of the porphyrins is rimmed with coordination compounds.

Introduction

The metal-mediated self-assembly of bi- and polydentate *N*-donor ligands is a widely used approach to the efficient construction of discrete two- and three dimensional supramolecular architectures.[1] The same self-assembly principle has been applied to the construction of multiporphyrin assemblies[2] which can either mimic naturally occurring multichromophore aggregates, such as the photosynthetic reaction center and the light harvesting complex of purple bacteria,[3] or can be used as electron- and/or energy-transfer molecular devices for advanced technological tasks.[1a,2] In such supramolecular architectures the position and relative orientation of the chromophores is essentially dictated by the nature and geometry of the metal auxiliaries.[4] In particular, there has been substantial recent interest in the construction of cyclic multiporphyrin assemblies (molecular squares) which lock the chromophores in a mutually coplanar geometry.[1a,5]

In general, the relatively few examples of molecular squares of porphyrins based on homonuclear metal corners or edges have been prepared by coordination of *meso*-di(4′-pyridyl)porphyrins *basic* building blocks,[6] either *cis* (90° angular, A_b) or *trans* (180° linear, L_b), with suitable coordination compounds, precursors for angular (90°, A_a) or linear (180°, L_a) *acidic* building blocks.[7,8] Recently, we described an efficient approach to heterobimetallic cyclic porphyrin assemblies featuring different diagonally opposed metal ions.[9]

Here we report the stepwise construction of a new class of molecular squares of porphyrins comprising two types of metal centers: the nuclei of one metal have a structural role (corners of the square, either Pd or Ru), while those of the other metal (Ru) rim the periphery of the chromophores.

Results and Discussion

In the first step of this synthetic approach two out of four peripheral 4′-(N)py sites of 4′-TPyP[6] were coordinated to metal centers. We reported that treatment of *meso*-(4′-pyridyl)porphyrins with the Ru^{II} complex *cis,fac*-$[RuCl_2(DMSO)_3(CO)]$ (**1**) leads to the selective coordination of *cis,cis,cis*-$[RuCl_2(DMSO\text{-}S)_2(CO)]$ fragments ([**Ru**]) to the peripheral basic sites of the chromophores.[10] The 4′-(N)py−[**Ru**] bonds are both stable and inert. Thus, reaction of 4′-TPyP with two equivalents of **1** yielded a mixture of the five possible adducts (plus unchanged 4′-TPyP):[11] the two bis-ruthenated isomeric products, *cis*-4′-TPyP([**Ru**])$_2$ (**2**) and *trans*-4′-TPyP([**Ru**])$_2$ (**3**), were obtained in pure form by chromatography. The nature and geometry of **2** and **3** were unambiguously established from a combination of ^{1}H NMR spectroscopy (Figure 1) and mass spectrometry. The number of NMR signals for the eight pyrrole protons (β-H) proved to be particularly important in distinguishing between the *cis* and *trans* isomers, since the other resonances are only marginally different: *trans*-4′-TPyP([**Ru**])$_2$ (**3**) gives two doublets of the same intensity (4β-H each), while *cis*-4′-TPyP([**Ru**])$_2$ (**2**) shows two doublets plus two singlets of the same intensity (2β-H each).

The sulfoxide resonances (four equally intense singlets in the region for *S*-bonded DMSO which may overlap partially or completely in pairs) confirm through integration that two [**Ru**] fragments are bound to each 4′-TPyP and are always consistent with the *cis,cis,cis* geometry of each ruthenium unit.[13] Electrospray mass spectrometry (ES-MS) analysis of **2** and **3** gave peaks corresponding to MH^+ (m/z = 1332.0, calculated 1332.2) and MH_2^{2+} (m/z = 667.4, calculated 666.6), plus fragmentation peaks deriving from the loss of one or both [**Ru**] units; the isotopic distribution

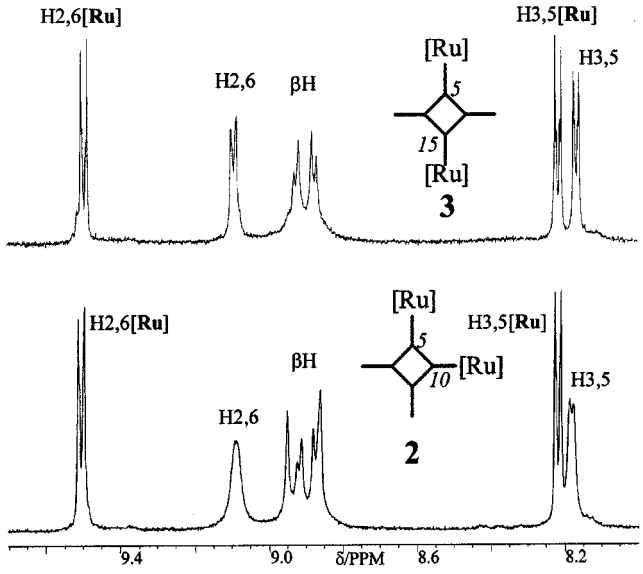

Figure 1. Downfield region of the ^{1}H NMR spectrum of *cis*-4′-TPyP([**Ru**])$_2$ (**2**)[12] (bottom) and *trans*-4′-TPyP([**Ru**])$_2$ (**3**) (top) with the corresponding schematic building block representations; see Figure 2 for labeling scheme; [**Ru**] = *cis,cis,cis*-[RuCl$_2$(DMSO-*S*)$_2$(CO)]

patterns were also consistent with the calculated isotopic envelope expected for such isomers.

We demonstrated that coordination of one (or more) [**Ru**] unit(s) to 4′-PyPs[6] does not affect significantly the further reactivity of the uncoordinated 4′-(N)py ring(s).[11] Compounds **2** and **3**, with two residual unbound 4′-(N)py rings either at 90° or 180°, are thus described as A_b and L_b building blocks, respectively, and are suitable for the construction of molecular squares. As examples, we investigated the reactivity of **2** towards [Pd(dppp)(OTf)$_2$] (**4**) [dppp = 1,3-bis(diphenylphosphanyl)propane, OTf = triflate] and *trans*-[Ru^{II}Cl$_2$(DMSO-*S*)$_4$] (**5**), which are precursors for the double-charged square-planar [Pd(dppp)]$^{2+}$,[7,8] and for the neutral octahedral *trans,cis*-[RuCl$_2$(DMSO-*S*)$_2$] (***t*Ru**) A_a units,[9−11] respectively. The reaction of **2** with **4** or **5** was monitored by ^{1}H NMR spectroscopy in CDCl$_3$ solution, which established that titration of **4** into a CDCl$_3$ solution of **2** led readily to the quantitative formation of [Pd(dppp){*cis*-4′-TPyP([**Ru**])$_2$}]$_2$(OTf)$_4$ (**6**) (Figure 2).

Complex **6** is an example of a new type of heterobimetallic [2+2] molecular square of porphyrins in which the Pd^{II} ions form two corners of the square, while the four Ru^{II} complexes rim the outside of the assembly. Integration of the NMR resonances confirmed the 2:1:1 ratio between [**Ru**], 4′-TPyP, and dppp expected for **6**. ES-MS analysis of **6** gave an [M − 3OTf] peak of *m/z* = 1240.0 (calculated 1240.3) resulting from a loss of three triflate anions from a total of four (and also a series of fragmentation peaks corresponding to the loss of [**Ru**] units and neutral ligands). Coordination of the Pd−bisphosphane fragment to **2** induced characteristic shifts of NMR signals; these included mainly the ^{1}H NMR resonances of the previously unbound 4′-N(py) rings (Figure 3) and the proton-decoupled ^{31}P NMR signal (upfield shift of ca 10 ppm relative to **4**, as is

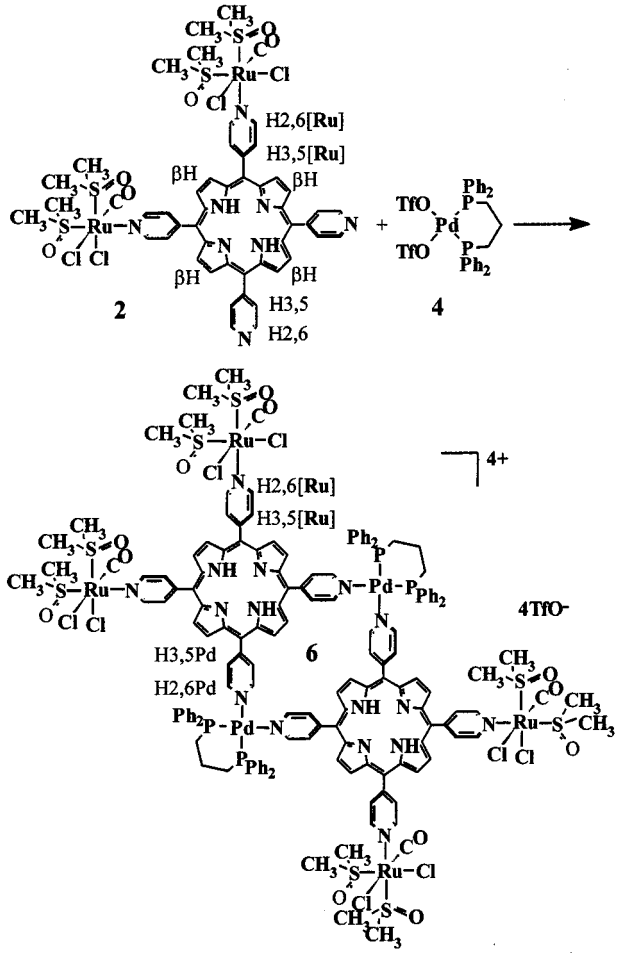

Figure 2. Schematic synthesis of [Pd(dppp){*cis*-4′-TPyP([**Ru**])$_2$}]$_2$(OTf)$_4$ (**6**) with labeling scheme

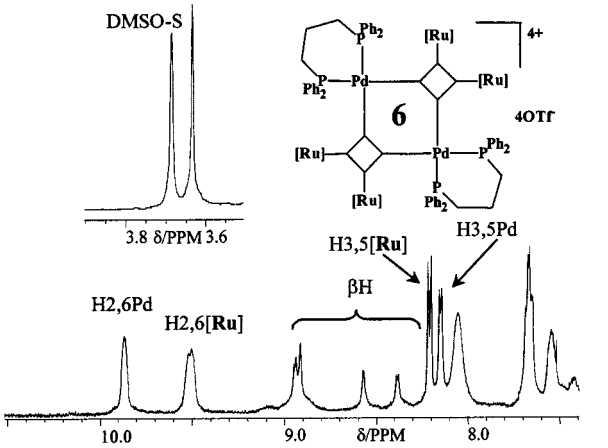

Figure 3. Downfield region, and DSMO-*S* region (insert), of the ^{1}H NMR spectrum of [Pd(dppp){*cis*-4′-TPyP([**Ru**])$_2$}]$_2$(OTf)$_4$ (**6**) with its schematic representation; see Figure 2 for labeling scheme

the case in similar compounds[7,9]). In **6** the resonances of the 4′(N)py−Pd rings are well resolved from those of the 4′(N)py−[**Ru**] rings, which were almost unshifted upon formation of the square. The most downfield H2,6 and the most upfield H3,5 signals (correlated in the COSY spec-

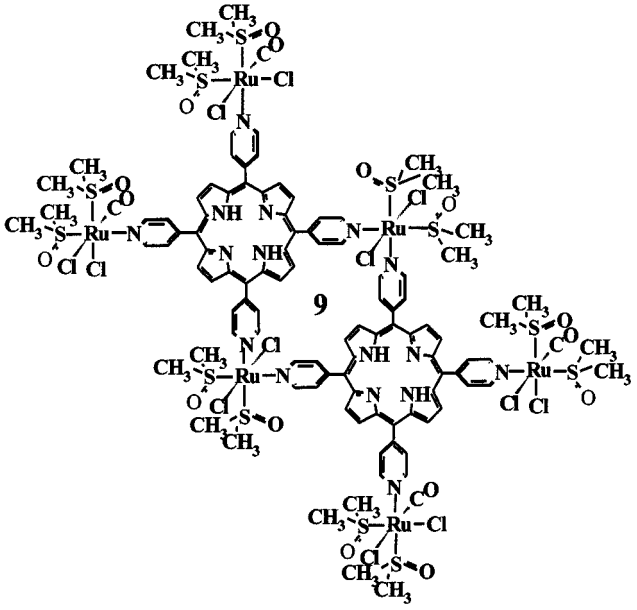

Figure 4. Schematic representation of *trans,cis,cis*-[$RuCl_2$(DMSO-*S*)$_2${*cis*-4′-TPyP([**Ru**])$_2$}]$_2$ (**9**)

trum) were thus attributed to the 4′(N)py−Pd rings; these assignments also agree well with those reported by Stang and co-workers for the corresponding [2+2] molecular square, [Pd(dppp)(4′-*cis*DPyP)]$_2$(OTf)$_4$] (**7**), prepared by reaction of equimolar amounts of 4′-*cis*DPyP and **4**.[7] It should be noted that formation of [Pd(dppp){*cis*-4′-TPyP([**Ru**])$_2$}]$_2$(OTf)$_4$ (**6**) involves a slight upfield shift of the H3,5 resonance of the previously unbound 4′(N)py rings in **2**. Moreover, in **6** one singlet and, in particular, one doublet of the β-H resonances on each porphyrin are remarkably upfield shifted also; these signals are correlated by clear NOE cross-peaks to the H3,5 4′(N)py−Pd signal in the NOESY spectrum. Similar anomalously upfield resonances for the protons closest to Pd were found in the ^{1}H NMR spectra of **7**[7] and of the heterobimetallic Ru^{II}−Pd^{II} cyclic assemblies [Pd(dppp){*trans,cis,cis*-$RuCl_2$(X)(Y)(4′-*cis*DPyP)$_2$}](OTf)$_2$ (X, Y = DMSO-*S*, CO)[9] and were attributed by us to the shielding cone of the phenyl rings of the dppp ligand rather than to the Pd^{II} center.[9] This hypothesis is confirmed here by the NMR spectrum of the [2+2] square of rimmed porphyrins [Pd(PEt_3)$_2${*cis*-4′-TPyP([**Ru**])$_2$}]$_2$(OTf)$_4$ (**8**), closely related to **6** and prepared by treatment of **2** with one equivalent of *cis*-[Pd(PEt_3)$_2$(OTf)$_2$]. In **8**, which lacks the shielding phenyl rings on the phosphanes, the resonances of the pyrrole protons closest to Pd and those of the 4′(N)py−Pd rings are remarkably more downfield-shifted than in **6** (e.g. δ H3,5 = 8.62 in **8** vs. 8.16 in **6**).

Finally, the neutral molecular square of porphyrins rimmed with ruthenium coordination compounds *trans,cis,cis*-[$RuCl_2$(DMSO-*S*)$_2${*cis*-4′-TPyP([**Ru**])$_2$}]$_2$ (**9**, Figure 4) was prepared by treatment of **2** with one equivalent of *trans*-[$Ru^{II}Cl_2$(DMSO-*S*)$_4$] (**5**). Metallacycle **9** features two types of Ru^{II} centers with different coordination environments and roles: ***t*Ru** moieties are located at the two corners of the square, while four [**Ru**] units rim the periphery of the square. Coordination of **2** to the ***t*Ru** moiety affected mainly the H2,6 and H3,5 resonances of the 4′-N(py) ring involved in the new bonds, which experienced downfield shifts similar to those found in the corresponding *trans,cis,cis*-[$RuCl_2$(DMSO-*S*)$_2$(4′-MPyP)$_2$] complexes.[9−11]

Conclusion

In conclusion, we have demonstrated that new families of cationic and neutral multiporphyrin metallacycles, in which the porphyrins are externally decorated with Ru^{II} complexes, are readily assembled through the formation of coordination bonds between partially ruthenated 4′-TPyP and either square planar Pd^{II} or octahedral Ru^{II} auxiliaries, respectively.

The higher degree of complexity of the new molecular squares of porphyrins rimmed with coordination compounds compared to the previously known multichromophore cyclic assemblies requires a more demanding synthetic approach (mainly in terms of purification of the partially metalated porphyrins) but also offers exciting perspectives: in future a proper choice of the external and of the structural metal centers (corners of the square) might favor electron and/or charge transfer from one site to another within the assembly. Moreover, the external metal centers might be exploited for incorporating special properties (e.g. chirality, luminescence, ...) into the multiporphyrin cyclic assembly and for its further functionalization. For the time being, since the main focus of the present work was directed towards the establishment of a synthetic approach for such novel cyclic assemblies, only metal compounds with a well-known and tested chemistry were used both as structural and rimming units.

Experimental Section

^{1}H and ^{31}P{^{1}H} NMR spectra were recorded on a Jeol EX400 spectrometer at 400 and 161.9 MHz, respectively. The ^{1}H NMR signals were referenced to the signal of residual $CHCl_3$ (δ = 7.26) and assignments were made with the aid of 2D COSY experiments, as detailed in the text; ^{31}P NMR spectra were referenced to external H_3PO_4. ES-MS data were obtained on a Perkin−Elmer AP1 spectrometer. Samples were dissolved in chloroform; the spectra were recorded in the positive ion mode at 5.6 kV accelerating potential; 2% trifluoroacetic acid was added to the solutions of **2** and **3**. The UV/Vis spectra were obtained on a Jasco V−550 spectrophotometer. All reagents were analytical grade.

Preparation of *cis*-4′-TPyP([Ru])$_2$ (2) and *trans*-4′-TPyP([Ru])$_2$ (3): The reaction between 4′-TPyP and *cis,fac*-$RuCl_2$(DMSO)$_3$(CO) (**1**) was performed as reported in ref.[11] Components of the mixture were separated by column chromatography on silica gel;[11] the two bis-ruthenated isomeric products, *cis*-4′-TPyP([**Ru**])$_2$ (**2**) and *trans*-4′-TPyP([**Ru**])$_2$ (**3**), were obtained as a mixture from the column and their separation required further preparative-scale TLC on silica gel plates (CH_2Cl_2/EtOH mixture 90:10; R_f **2** = 0.81, R_f **3** = 0.84). The products were extracted from the silica with an acetone/MeOH mixture (80:20). 100 mg of 4′-TPyP yielded, on average, 11 mg each of isolated **2** and **3** (5%). Elemental analyses for **2** and

3 were not reliable because they were affected by the presence of variable amounts of solvent molecules of crystallization.

Selected data for **2:** ^{1}H NMR ($CDCl_3$): δ = −2.96 (s, 2 H, NH), 3.62 (s, 6 H, DMSO-*S*), 3.64 (s, 6 H, DMSO-*S*), 3.69 (s,12 H, DMSO-*S*), 8.19 [m, 4 H, H3,5(py)], 8.22 (m, 4 H, H3,5[**Ru**]), 8.86 (s, 2 H, β-H), 8.88 (d, ^3J = 8 Hz, 2 H, β-H), 8.91 (d, ^3J = 8 Hz, 2 H, β-H), 8.95 (s, 2 H, β-H), 9.09 [m, 4 H, H2,6(py)], 9.51 (m, 4 H, H2,6[**Ru**]). − UV/Vis (CH_2Cl_2): λ (ε × 10^4/M^{-1} cm^{-1}) = 419 (28), 514 (1.5), 549 (0.6), 589 (0.5), 645 (0.2) nm.

Selected data for **3:** ^{1}H NMR ($CDCl_3$): δ = −2.97 (s, 2 H, NH), 3.62 (s, 6 H, DMSO-*S*), 3.64 (s, 6 H, DMSO-*S*), 3.69 (s, 12 H, DMSO-*S*), 8.17 [m, 4 H, H3,5(py)], 8.22 (m, 4 H, H3,5[**Ru**]), 8.88 (d, ^3J = 4 Hz, 4 H, β-H), 8.92 (d, ^3J = 4 Hz, 4 H, β-H), 9.09 [m, 4 H, H2,6(py)], 9.50 (m, 4 H, H2,6[**Ru**]). − UV/Vis (CH_2Cl_2): λ (ε × 10^4/M^{-1} cm^{-1}) = 419 (38.5), 515 (2.2), 549 (0.8), 589 (0.7), 645 (0.3) nm.

Preparation of [Pd(dppp){*cis*-4′-TPyP([Ru])$_2$}]$_2$(OTf)$_4$ (6), [Pd(PEt$_3$)$_2${*cis*-4′-TPyP([Ru])$_2$}]$_2$(OTf)$_4$ (8), and *trans,cis,cis*-[RuCl$_2$(DMSO-*S*)$_2${*cis*-4′-TPyP([Ru])$_2$}]$_2$ (9): Owing to the very low amounts of precursor **2** (few mg), reactions leading to molecular squares **6**, **8**, and **9** were performed exclusively in an NMR tube. The formation of **6** and **8** occurred rapidly, while the formation of **9** required three hours at ambient temperature. The electronic spectra of **8** and **9** are qualitatively very similar to that of **6** (see below) in terms of the shape and position of the absorption bands, but the purity of the products isolated from the NMR solutions upon removal of the solvent (established by NMR spectroscopy) was not deemed high enough for quantitative measurements (determination of absorption coefficients).

Selected data for **6:** ^{1}H NMR ($CDCl_3$): δ = −3.16 (s, 4 H, NH), 3.63 (s, 12 H, DMSO-*S*), 3.69 (s,12 H, DMSO-*S*), 8.16 (m, 8 H, H3,5Pd), 8.21 (m, 8 H, H3,5[**Ru**]), 8.38 (d, ^3J = 4 Hz, 4 H, β-H), 8.58 (s, 4 H, β-H), 8.92 (s, 4 H, β-H), 8.94 (d, ^3J = 4 Hz, 4 H, β-H), 9.52 (m, 8 H, H2,6[**Ru**]), 9.86 (m, 8 H, H2,6Pd). − ^{31}P NMR ($CDCl_3$): δ = 6.1. − UV/Vis (CH_2Cl_2): λ (ε × 10^4/ M^{-1} cm^{-1})= 424 (52.0), 518 (3), 553 (1), 592 (0.6), 646 (0.1) nm.

Selected data for **8:** ^{1}H NMR ($CDCl_3$): δ = −2.98 (s, 4 H, NH), 3.65 (s, 12 H, DMSO-*S*), 3.70 (s, 6 H, DMSO-*S*), 3.71 (s, 6 H, DMSO-*S*), 8.22 (m, 8 H, H3,5[**Ru**]), 8.56 (d, ^3J = 4 Hz, 4 H, β-H), 8.62 (m, 8 H, H3,5Pd), 8.87 (s, 4 H, β-H), 8.94 (d, ^3J = 4 Hz, 4 H, β-H), 9.01 (s, 4 H, β-H), 9.52 (m, 8 H, H2,6[**Ru**]), 10.18 (m, 8 H, H2,6Pd). − ^{31}P NMR ($CDCl_3$): δ = 21.5.

Selected data for **9:** ^{1}H NMR ($CDCl_3$): δ = −2.89 (s, 4 H, NH), 3.71, 3.70, 3.66, 3.64 (s, 72 H, DMSO-*S*), 8.25 (m, 8 H, H3,5[**Ru**]), 8.39 (m, 8 H, H3,5*t***Ru**), 8.96 (m, 8 H, H-β), 9.00 (m, 4 H, H-β), 9.03 (s, 4 H, H-β), 9.55 (m, 8 H, H2,6[**Ru**]), 10.10 (m, 8 H, H2,6*t***Ru**).

[12] As it is often the case with pyridylporphyrins, the broadening of the H2,6 and H3,5 resonances in the ^{1}H NMR spectrum of compound **2** is due to the presence in solution of small amounts of Lewis acids, in this case very likely silica from the chromatographic purification of **2**. The weak and labile interaction between the uncoordinated pyridyl rings of compound **2** and the Lewis acid induces a broadening (and a very small shift) of the proton resonances of such rings.

[13] Since the [**Ru**] moiety is chiral, both **2** and **3** must exist as mixtures of stereoisomers (with *C* or *A* [**Ru**] units), with potentially different NMR signals. However, at the field used, the ^{1}H NMR signals were not distinct for the diastereoisomers.

A Novel Organometallic Polymer of Osmium(0), $[Os(2,2'\text{-bipyridine})(CO)_2]_n$: Its Electrosynthesis and Electrocatalytic Properties Towards CO_2 Reduction

Sylvie Chardon-Noblat,*[a] Alain Deronzier,*[a] František Hartl,*[b] Joris van Slageren,[b] and Taasje Mahabiersing[b]

Keywords: Osmium / Electrochemistry / Polymers / Carbon dioxide / Reductions

A new kind of organometallic polymer of osmium(0) $[Os^0(bpy)(CO)_2]_n$ (bpy = 2,2′-bipyridine) has been prepared as a thin film on an electrode surface by electrochemical reduction of the mononuclear *trans*(Cl)-$[Os^{II}(bpy)(CO)_2Cl_2]$ precursor complex. This modified electrode proves to be a good electrocatalyst for the reduction of CO_2 in aqueous media.

Introduction

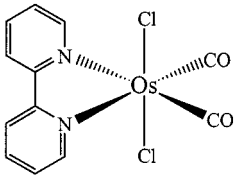
It is now well established that the two-electron reduction of a mononuclear ruthenium(II) complex precursor such as *trans*(Cl)-$[Ru(bpy)(CO)_2Cl_2]$ (bpy = 2,2′-bipyridine) leads to the facile formation of thin films of $[Ru(bpy)(CO)_2]_n$ on conductive electrode surfaces.[1,2] This new kind of organometallic polymer, containing Ru−Ru chains, proved to be a highly selective and efficient catalyst for the electroreduction of carbon dioxide in aqueous media[3,4] and for the water-gas shift (WGS) reaction.[5] It also exhibits interesting photochemical properties.[6] We could reasonably expect formation of an analogous Os^0 organometallic polymer by the electrochemical reduction of the parent mononuclear osmium(II) complex *trans*(Cl)-$[Os(bpy)(CO)_2Cl_2]$ (**1**), which has recently been synthesized but only superficially characterized.[7]

We present here a preliminary electrochemical study of **1** which confirms that films of the $[Os(bpy)(CO)_2]_n$ polymer can indeed be prepared effectively. Their capability to act as an electrocatalyst for CO_2 reduction has been briefly evaluated.

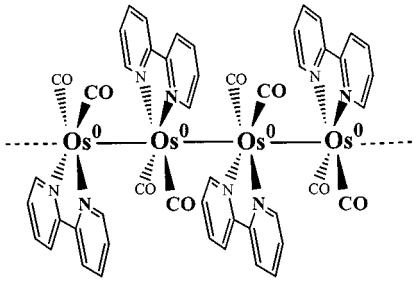
Results and Discussion

Synthesis of Complex 1

The complex *trans*(Cl)-$[Os(bpy)(CO)_2Cl_2]$ (**1**) was synthesized in two steps according to a modified literature procedure[7] (see Experimental Section). The ^1H NMR spectroscopic data reveal that the bpy ligand coordinates in a symmetrical environment, with the chloride ligands occupying the axial positions as schematically depicted in Figure 1.



1



2

Figure 1. Schematic molecular structures of **1** and **2**

The IR spectrum of **1** displays two intense CO-stretching bands (2022 and 1943 cm^{-1}) shifted to lower frequencies relative to the corresponding *trans*(Cl)-$[Ru(bpy)(CO)_2Cl_2]$ complex.[8] It is noteworthy that the ν(CO) band shifts of 41/56 cm^{-1} in the solid state (CsI pellet or nujol) are much larger than the values of 23/31 cm^{-1} in CH_3CN and 24/33 cm^{-1} in THF. The lower ν(CO) frequencies for **1** reflect a stronger Cl→Os σ- and, in particular, π-donation inducing a stronger Os→CO π-back-donation. At the same time the Os−Cl bonds in **1** are stronger and less readily split upon electrochemical reduction than in the Ru derivative, as shown by the radical anion $[Os(bpy^{\cdot-})(CO)_2Cl_2]^-$ detectable by cyclic voltammetry (CV) in THF at moderate scan rates (see below). A similar difference in ν(CO) frequencies and stability of the M−Cl bond was observed, for example,

in the [M(bpy)(CO)$_3$Cl] complex series (M = Re[9] and Mn[10]).

Electrochemical Behaviour of Complex 1

The CV of **1** in CH_3CN (with added 0.1 M TBAP) exhibits an irreversible nearly two-electron cathodic peak at $E_{pc} = -1.61$ V[11] along with small anodic peaks between -0.80 V and 0 V on the reverse scan [Figure 2(a)]. This behaviour is typical of an electrodeposition-redissolution phenomenon, as previously observed for the parent mononuclear Ru^{II} complex.[1,2]

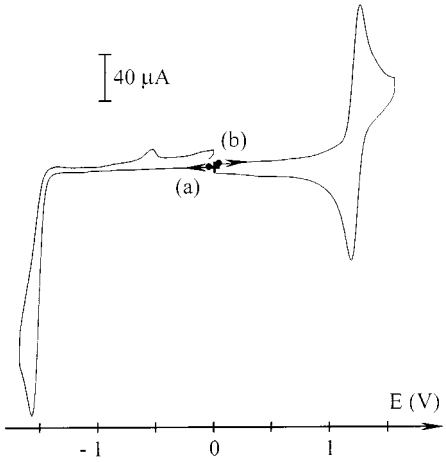

Figure 2. Cyclic voltammograms (ν = 100 mV s^{-1}) of **1** (2.2 mM) in CH_3CN + 0.1 M TBAP at a Pt disc electrode (r = 2.5 mm) recorded between: (a) 0 V and -1.70 V, and (b) 0 V and 1.60 V vs. Ag/Ag$^+$

The negative potential shift observed for the reduction of **1** compared to the corresponding Ru^{II} complex ($\Delta E_{pc} = -0.11$ V)[8] is in agreement with the stronger Os→bpy π-back-donation induced by the Cl→Os donation along with the increased Os→CO π-back-donation, as revealed by the IR ν(CO) data (see above).

The reductive electrochemical polymerization of **1**, monitored by iterative CV or by applied potential electrolysis, leads to a dark green-blue coloured electroactive polymer [Os^0(bpy)(CO)$_2$]$_n$ (**2**) adherent to the working electrode surface. Equation (1) summarizes the overall process of electropolymerization.

$$n\,[Os^{II}(bpy)(CO)_2Cl_2] + 2n\,e^- \rightarrow [Os^0(bpy)(CO)_2]_n + 2n\,Cl^- \quad (1)$$

The electroactivity and electropolymerization properties of the osmium complex **1** are consistent with the mechanism proposed for the electropolymerization of *trans*(Cl)-Ru(bpy) equivalent complex in acetonitrile.[12] The electroreduction of **1** produces ultimately the polymer **2** by an electrochemical propagation process [Equation (2)−(5)]. The initial formation of the one-electron reduced [Os(bpy$^{\bullet-}$)(CO)$_2$Cl$_2$]$^-$ (**1**$^-$) species containing the 2,2′-bipyridine radical anion [Equation (2)] is followed by rapid loss of one chloride ligand to give an Os^I complex [Equation (3)]. This formally 17e$^-$ species readily dimerizes [Equation (4)]. Details of this step will be published in a forthcoming article. The similar or even more facile reducibility of the dimer, and further tetramer and oligomer intermediates compared to that of **1**, allows the growth of a polymeric chain [Equation (5)].

$$[Os^{II}(bpy)(CO)_2Cl_2] + e^- \rightarrow [Os^{II}(bpy^{\bullet-})(CO)_2Cl_2]^- \quad (2)$$

$$[Os^{II}(bpy^{\bullet-})(CO)_2Cl_2]^- \rightarrow [Os^{I}(bpy)(CO)_2Cl] + Cl^- \quad (3)$$

$$2\,[Os^{I}(bpy)(CO)_2Cl] \rightarrow [Os^{I}(bpy)(CO)_2Cl]_2 \quad (4)$$

$$n/2\,[Os^{I}(bpy)(CO)_2Cl]_2 + n\,e^- \rightarrow \text{dimers} \rightarrow \text{oligomers} \rightarrow [Os^0(bpy)(CO)_2]_n + n\,Cl^- \quad (5)$$

Experiments conducted in a less dissociating and coordinating solvent like THF support this overall mechanism. In this solvent the electrogenerated radical anion [Os(bpy$^{\bullet-}$)(CO)$_2$Cl$_2$]$^-$ is remarkably stable, the cyclic voltammogram exhibiting now a nearly reversible one-electron couple at $E_{1/2} = -1.64$ V ($\Delta E_p = 0.17$ V; $I_{pa}/I_{pc} = 0.93$) at a scan rate of 100 mVs^{-1} (Figure 3). However, decreasing the scan rate to 20 mVs^{-1} turns the reduction of **1** almost totally irreversible; an exhaustive electrolysis carried out at -1.80 V then furnished the polymer **2** after two electrons per precursor **1** had been passed (see below). In addition, some UV/Vis, IR and EPR spectroelectrochemical experiments, conducted at low temperatures, are in progress and confirm the localization of the odd electron in the radical anion of **1** on the bpy ligand.

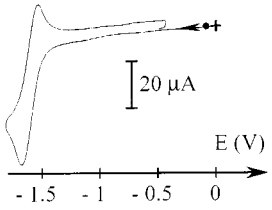

Figure 3. Cyclic voltammogram (ν = 100 mV s^{-1}) of **1** (1.6 mM) in THF + 0.2 M TBAP at a Pt disc electrode (r = 2.5 mm) recorded between 0 V and -1.85 V vs. Ag/Ag$^+$

The growth of the electroactive Os^0 polymeric film **2** can be more conveniently documented by iterative CV carried out in CH_3CN (+ 0.1 M TBAP). Two clear reversible redox systems, characteristic of the polymer electroactivity, appear at $E_{1/2} = -0.80$ V (anodic) and -1.55 V (cathodic) and increase in size continuously as the potential is repeatedly scanned from -0.60 to -1.75 V (Figure 4A). When the resulting modified electrode is transferred into a fresh electrolyte solution in the absence of **1** [Figure 4B(a)], the electroactivity persists and remains unaffected, provided the potential scan is limited to -0.60 V.

The redox properties of **2**, immobilized on the electrode surface, strongly resemble those of [Ru(bpy)(CO)$_2$]$_n$.[2] Their comparison allows us to attribute the reversible anodic system to oxidation of the osmium centre ($Os^{I/0}$) and the reversible cathodic system to the reduction of the bpy ligand (bpy$^{0/\bullet-}$) in the polymer **2**. The complete electropolymerization of **1** (2 mM) can be achieved by its exhaustive controlled-potential electrolysis at a large-surface working electrode at -1.60 V. A quantitative electrical yield (two mol of electron are needed for one mol of precursor complex) is obtained. During this electropolymerization experiment

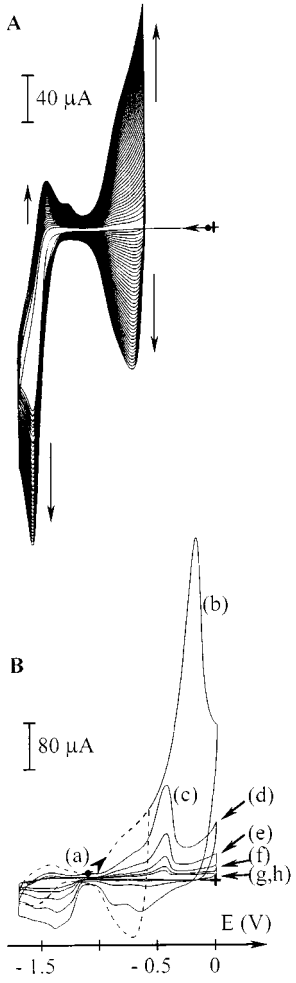

Figure 4. (A) Cyclic voltammograms (ν = 100 mV s^{-1}) of **1** (2.2 mM) in CH_3CN + 0.1 M TBAP at a Pt disc electrode (r = 2.5 mm) from the 1st to the 40th successive scans between −0.60 V and −1.75 V; (B) cyclic voltammograms recorded with the same Pt working electrode modified with surface-deposited **2**, transferred into neat CH_3CN +0.1 M TBAP; scan range: (a) −0.6 V and −1.75 V; (b) − (h) 0 V and −1.75 V vs. Ag/Ag^+

two molar equivalents of chloride ligand were liberated in solution, as revealed by voltammetry on a rotating disk electrode.[13] A comparison of the intensity of the wave at $E_{1/2}$ = 0.60 V (Cl^- oxidation system) with that of a standard solution of chloride confirms the overall stoichiometry of the polymerization process [Equation (1)]. It should be noted that a large anodic peak located at −0.21 V is observed when the potential is scanned back to 0 V [Figure 4B(b)]. This peak corresponds to the oxidation-desorption of the polymer **2** that induces cleavage of the Os−Os bonds, as was also demonstrated for the corresponding Ru^0(bpy) polymer.[8] In fact, successive potential scans in this range of potentials induce the complete disappearance of the polymer film electroactivity [Figure 4B(b)-(h)].

A full physicochemical characterization of the $[Os(bpy)(CO)_2]_n$ polymeric film is not easy to achieve since it is unstable at potentials higher than −0.40 V and cannot be handled in air. However, the molecular structure of **2** presented in Figure 1 is strongly supported by the close resemblance of the physicochemical properties of **2** with those of the corresponding Ru^0 polymer as well as by the following arguments:[2] (a) The insolubility of **2** is in favour of a polymeric structure; (b) The electronic absorption spectrum of the film deposited on optically transparent electrode (OTE) doped with indium tin oxide (ITO) exhibits two broad and intense absorption bands in the visible region (λ_{max} = 554 and 664 nm), consistent with a polymeric structure containing metal−metal bonds and possessing an Os→bpy charge transfer transition;[4] (c) Electropolymerization of **1** consumes exactly two electrons per Os(bpy) moiety and results in decoordination of both Cl^- ligands; (d) The ν(CO) wavenumbers and band pattern of **2** [1958 (vs), 1900 (m) and 1872 (s) cm^{-1}], recorded in THF at 293 K during in situ IR spectroelectrochemical experiments, are close to those of the Ru^0 polymer [1966 (vs), 1908 (s) and 1885 (vs)]. The smaller difference in the ν(CO) wavenumbers between the Os and Ru polymers observed for the parent dichloro complexes (see above), is understandable, as the Cl^- ligands are already dissociated and the metal→CO π-back-donation is therefore not affected.

In the positive potential region, the CV of **1** exhibits a reversible one-electron anodic wave (I_{pa}/I_{pc} = 1) formally corresponding to the Os^{II}/Os^{III} redox couple [Figure 2(b)]. The lower oxidation potential of **1** ($E_{1/2}$ = 1.23 V) than for the corresponding Ru^{II} dichloro complex ($E_{1/2}$ = 1.45 V),[14] again reflects the stronger Cl→Os σ/π-donation. The absence of any associated peak on the reverse cathodic scan on the scale of the CV indicates the stability of the oxidized osmium(III) cationic complex. However, bulk electrolysis at 1.30 V, consuming one electron per mol of **1**, produces a new species which is soluble in the electrolyte and reversibly reducible at a lower potential ($E_{1/2}$ = 0.47 V). Investigation of this novel complex is in progress.

Electrocatalytic Reduction of CO_2 with $[Os(bpy)(CO)_2]_n$ (2)

The electrocatalytic properties of the $[Os(bpy)(CO)_2]_n$ polymer, deposited on the cathode surface as described above, were investigated with CV experiments carried out in CO_2-saturated organic solvents containing ca. 10% water, and pure aqueous media. The initial electroactivity of the polymer in pure CO_2-saturated organic electrolyte [Figure 5(a)] completely changed after addition of 5% water [Figure 5(b)]. In particular, a strong enhancement of the cathodic current at −1.30 V was observed. In addition, repeated voltammetric scanning between −0.70 V and −1.50 V shows that this catalytic effect is persistent. Preparative scale electrolyses, using carbon felt electrodes (10 × 10 × 4 mm^3) modified with electrodeposited $[Os(bpy)(CO)_2]_n$ ($\tau_{Os} = 5 \times 10^{-7}$ mol cm^{-2}), confirm the catalytic activity of this molecular cathode towards CO_2 electroreduction. For instance, preliminary experiments have revealed that electrolysis conducted at −1.23 V vs. SCE in pure aqueous electrolyte (H_2O + 0.1 M $LiClO_4$) produces $HCOO^-$ and CO with 10% and 60% current efficiency, respectively, after 60 C had been consumed. The difference between the $[M(bpy)(CO)_2]_n$ (M = Ru^0 or Os^0) catalysts in the selectivity of the product formation towards formate is noteworthy. It should be recalled that under the same elec-

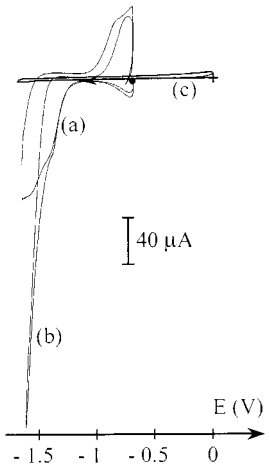

Figure 5. Cyclic voltammograms (ν = 100 mV s^{-1}) in CO_2-saturated CH_3CN + 0.1 M TBAP recorded with a vitreous carbon working electrode (r = 1.5 mm) pre-modified with **2**, deposited during electrolysis of **1** (1.2 mM) at −1.60 V (Q = 5 mC), conditions: (a) before addition of water; (b) after addition of 5% water; (c) zero electroactivity of the naked VC electrode after addition of 5% water

trocatalytic conditions the Ru(bpy) polymer conducts almost quantitative transformation of CO_2 into CO with a current efficiency higher than 97%, whereas the yield of $HCOO^-$ is less than 1%.[3] These results nicely correspond with the different electrocatalytic properties of related mononuclear $[M(bpy)_2(CO)H]^+$ complexes (M = Os^{II} [15] and M = Ru^{II}).[16] In CO_2-saturated CH_3CN with added water the latter Os and Ru complexes act as homogeneous catalysts for the electrochemical reduction of CO_2 to formate with 22% and 17% yield, and to CO with 46% and 57% yield, respectively. Further research to improve the stability and catalytic performance of **2** is in progress.

Conclusion

The strong Cl→Os σ/π-donation makes the axial Os−Cl bonds in *trans*(Cl)-[Os(bpy)$(CO)_2Cl_2$] (**1**) less prone to cleavage upon reduction than the Ru−Cl bonds in the corresponding Ru^{II} complex. Nevertheless, dissociation of the Cl^- ligands is still rapid and produces ultimately the same kind of insoluble, redox-active polymer $[Os^0(bpy)(CO)_2]_n$ (**2**) as reported for Ru. Electrocatalytic reduction of CO_2 in aqueous media, initiated by reduction of **2** deposited on the cathode surface, results in a higher yield of formate production than achieved previously with $[Ru^0(bpy)(CO)_2]_n$. Further investigation of **1**, **2** and closely related complexes is in progress to understand the catalytic mechanism and to improve the catalyst performance.

Experimental Section

General Remarks: K_2OsCl_6 (Alfa) and NH_4Cl (Fluka), formaldehyde and formic acid (both Acros) were used as received. Acetone, hexane, 2-propanol, THF and dichloromethane (all purchased from Acros) were dried by conventional procedures. All syntheses and measurements were performed under an atmosphere of dry nitrogen or argon, using standard Schlenk techniques. Silica gel (kieselgel 60, Merck, 70−230 mesh) for column chromatography was dried and activated by heating in vacuo at 160 °C overnight. The solutions of slightly light-sensitive *trans*(Cl)-[Os(bpy)$(CO)_2Cl_2$] were kept in the dark to avoid photochemical decomposition.

Electrochemical measurements were carried out using an EG & G Princeton Applied Research Model 173 potentiostat-galvanostat equipped with a Sefram TGM 164 X-Y recorder. The cyclic voltammograms were obtained in a conventional three-electrode cell under an argon atmosphere in a dry box (Jaram). The working electrodes for cyclic voltammetry were platinum or vitreous carbon discs (0.19 or 0.07 cm^2) polished with a 2 μm diamond paste (Mecaprex Presi). All potentials are reported relative to Ag|10 mM Ag^+ in CH_3CN + 0.1 M nBu_4NClO_4 (TBAP).[11] The supporting electrolyte, from Fluka, was dried under vacuum at 80° C for 3 days before use. Acetonitrile from Rathburn (HPLC grade) was used as received. THF was freshly distilled from Na/benzophenone.

All preparative-scale electrocatalytic experiments were run under a CO_2 atmosphere on carbon felt pieces (RVC 2000 from Le Carbone Lorraine) modified by a polymer film in a conventional three-electrode cell made air-tight with vacuum grease (M. Apiezon). All experiments were stopped after a predetermined number of coulombs had been passed. The current efficiency corresponds to the theoretical number of mol calculated from the experimental number of coulombs (100% yield)/calculated number of mol after analysis (CO_2 reduction into CO or $HCOO^-$ is a two-electron reduction process). CO was analysed on a Delsi Model 30 gas chromatograph with a FID, with a 120-cm long 5 Å molecular sieve column, followed by a catalytic oven. H_2 was used as carrier gas. Formate ions were analysed on a Waters Associate HPLC with a Bio-Rad HPX-87H cation exchange resin column eluted with 10^{-2} M H_2SO_4 solution. A UV detector at 224 nm was used.

Electronic absorption spectra were recorded with a Hewlett-Packard HP 8452 A diode array spectrophotometer controlled with a Compaq 286 computer. UV/Vis spectroelectrochemical experiments were conducted in a dry box under an argon atmosphere. The cells were inserted into an optical translator connected to the spectrophotometer by an optical fibre system (Photonetics spectrofip system). The optical fibres pass through the wall of the dry box by means of seals. UV/Vis spectroelectrochemical measurements on polymer films were made by using a conventional sandwich-type cell.[17] The optical transparent electrode (OTE) (1.1 cm diameter) was doped with indium tin oxide (ITO) (Balthracon Z 20 from Balzers).

IR spectra were recorded with Perkin−Elmer Spectrum GX FTIR or Bio-Rad FTS-7 FTIR spectrometers. IR spectroelectrochemical experiments at room temperature were carried out with a previously described OTTLE cell equipped with a Pt minigrid working electrode (32 wires/cm) and with CaF_2 windows.[18]

^1H NMR spectra were recorded at room temperature on Bruker AMX 300 or AC-250 spectrometers; the chemical shifts (in ppm) are relative to the solvent $CDCl_3$ (δ = 7.25) or CD_3CN (δ = 1.96).

Synthesis of *trans*(Cl)-[Os(bpy)$(CO)_2Cl_2$] (1) $[Os(CO)_2Cl_2]_n$: K_2OsCl_6 (1 g; 2.1 mmol) was added to an N_2-purged (20 min.) mixture of formaldehyde (15 mL) and formic acid (90%, 50 mL) and refluxed for 3 days. The colour changed from red to green within 3 h and ultimately to light yellow (NB: further reflux produces a brownish solution presumably due to organic decomposition products). Next, the solution was cooled to room temperature and the solvents evaporated. The brownish residue was

extracted with acetone to remove KCl. After evaporation of the acetone the solid was washed with CH_2Cl_2/hexane (1:1) to remove any organic side products. The product was obtained with a yield in the range of 800−900 mg and is a white, occasionally pinkish/yellowish powder. − IR (THF): ν(CO) = 2116 cm^{-1} (m) and 2022 (vs).

***trans*(Cl)-[Os(bpy)(CO)$_2$Cl$_2$] (1):** Polymeric $[Os(CO)_2Cl_2]_n$ (200 mg) and an excess of bpy (5 equiv.) were dissolved in 2-propanol (50 mL) and heated at reflux temperature until the IR spectra showed complete conversion [two intense ν(CO) bands arose at 2040 and 1972 cm^{-1}]. In order to obtain exclusively the desired dichloro complex, the crude product was redissolved in NH_4Cl-saturated CH_2Cl_2 and stirred overnight. The solution was filtered and the resulting complex **1** was purified by column chromatography (activated silica, using CH_2Cl_2/hexane gradient elution) to yield a light yellow powder. Yield: 100 mg (50%). The use of *n*-propanol instead of 2-propanol should be avoided, as it results in significantly lower yields (ca 20%). − IR (THF): ν(CO) = 2032 cm^{-1}(vs), 1962 (vs); in *n*PrOH: ν(CO) = 2041 (vs), 1972 (vs); in CH_2Cl_2: ν(CO) = 2040 (vs), 1971 (vs); in CH_3CN: ν(CO) = 2038 (vs), 1968 (vs); in CsI pellet: ν(CO) = 2022 (vs), 1943 (vs), ν(Os−Cl) 317 (w). − ^{1}H NMR ($CDCl_3$): δ = 9.13 (d, ^3J = 7.2 Hz, 2 H, $H_{6,6'}$), 8.23 (d, ^3J = 10.8 Hz, 2 H, $H_{3,3'}$), 8.13 (t, ^3J = 10.8 Hz, 2 H, $H_{4,4'}$), 7.67 (t, ^3J = 8.0 Hz, 2 H, $H_{5,5'}$). − UV/Vis (THF): λ_{max} = 362 nm; in CH_3CN: λ = 350. − MS (FD^+): *m*/*z* = 474 [M + H]$^+$; (FAB^+): *m*/*z* = 474 [M + H]$^+$, 446 [M + H − CO]$^+$, 439 [M + H − Cl]$^+$, 418 [M + H − 2CO]$^+$, 411 [M + H − 2Cl]$^+$, 383 [M + H − CO − 2Cl]$^+$.

Synthesis and Solid-State Structure of $(Li_4Am_3)^+\cdot\{Li[(\mu\text{-}Me)_2Al(Me)tBu]_2\}^-$ {Am = [PhNC(Ph)NPh]$^-$}: A Polymeric Species Incorporating a Lithium-Nitrogen Cluster Cation

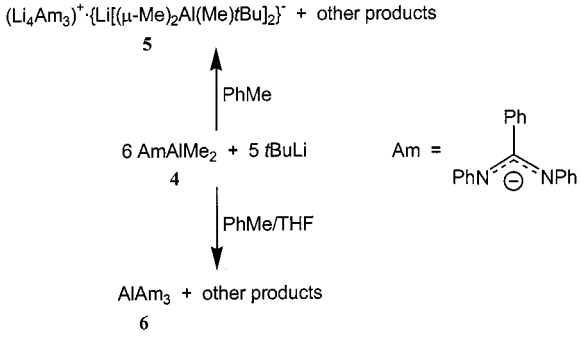
Robert P. Davies,[a] David J. Linton,[b] Paul Schooler,[b] Ronald Snaith,[b][†] and Andrew E. H. Wheatley*[b]

Keywords: Aluminum / Cluster compounds / Cations / Lithium

The sequential reaction of PhN(H)C(Ph)NPh (AmH) with $AlMe_3$ and *t*BuLi leads to the isolation of both the cluster $(Li_4Am_3)^+\cdot\{Li[(\mu\text{-}Me)_2Al(Me)tBu]_2\}^-$ **(5)** and the aluminium tris(amidinate) $AlAm_3$ **(6)**. In the solid state, **5** has a polymeric structure based on tetranuclear Li_4-cluster cations and lithium bis(aluminate) anions which associate by the formation of weak Li···MeAl bonds.

Introduction

The current interest being shown in the structures and reactivities of synthetically useful[1] lithium-containing heterobimetallic species[2] led us to synthesise lithium aluminate monomers $Me_2Al(\mu_2\text{-}OAr)_2Li$ (Ar = aryl), species which may play a role in conjugate additions to α,β-unsaturated ketones.[3] Moreover, it has recently been shown that *t*BuLi reacts with $Me_2AlN(Me)C(O)Ph$ to give a lithium aluminate which, in turn, yields a unique heterobimetallic mixed-anion ladder upon introduction of oxygen to the reaction mixture.[4] Whereas this chemistry utilised a reagent containing the $Me_2AlN(R)C(=X)$ fragment (X = O), the use of species in which X = N has also been fruitful. Accordingly, whereas the 1:1 lithium[5] and sodium[6] salts of 2-pyridylamine reagents [(2-Pyr)N(H)R] have been characterised, it has lately been reported that BuLi isomers react with the amidoalane $Me_2AlN(2\text{-}Pyr)Ph$ **(1)** to afford the hydride-containing compounds[7] $[Li(Me_2AltBu_2)_2]^-\{Li_8(H)[N(2\text{-}Pyr)Ph]_6\}^+$ **(2)** and $Li_7(H)[N(2\text{-}Pyr)Ph]_6$ **(3)** both of which incorporate cationic lithium-nitrogen clusters. In seeking to extend this new type of chemistry we have tested the reactivity of BuLi reagents towards Group 13 amidinates — species which have been extensively studied in both neutral[8] and cationic[9] contexts. Accordingly, we have employed $AmAlMe_2$ **(4)** {Am = [PhNC(Ph)NPh]$^-$}. Although simple lithiation[2b,10] has been reported for amidine reagents, as indeed have the syntheses of sodium[10c] and potassium[11] derivatives, we report here the isolation and characterisation of a more complex intermetallic amidinate compound. Reaction of *t*BuLi with **4** affords the tetralithium cluster $(Li_4Am_3)^+\cdot\{Li[(\mu\text{-}Me)_2Al(Me)tBu]_2\}^-$ **(5)** and also the aluminium tris(amidinate) $AlAm_3$ **(6)** (Scheme 1).



Scheme 1

Results and Discussion

Reaction of a solution of *N*,*N*′-diphenylbenzamidine[12] in toluene with $AlMe_3$ yields the aluminium amidinate $AmAlMe_2$ **(4)**, the treatment of which with *t*BuLi affords a solution from which crystals of **5** can be obtained (see Experimental Section). X-ray crystallography shows that in the solid state **5** is a mixed aggregate composed of an unusual lithium bis(aluminate) anion weakly bonded to a superlithiated cluster cation (Figure 1). The $\{Li[Me_2Al(Me)tBu]_2\}^-$ ion contains two Al centres arranged such that two methyl substituents on each are disposed tetrahedrally about Li(1). The resulting $Li[(\mu\text{-}C)_2Al]_2$ motif indicates some generality for the single previous report of this unit in a molecular context.[7] To the best of our knowledge the only close relative of this anion is present in the solvent-separated ion pair $[Li(DME)_3]^+\{Li[(\mu\text{-}OPh)_2AlEt_2]_2\}^-$.[13] Furthermore, the $\{Li[Me_2Al(Me)tBu]_2\}^-$ ion also constitutes part of a group of only a few characterised Group 1 metal-containing anions.[13,14] The mean M−(μ-C) distances (2.234 and 2.034 Å for M = Li and Al, respectively)

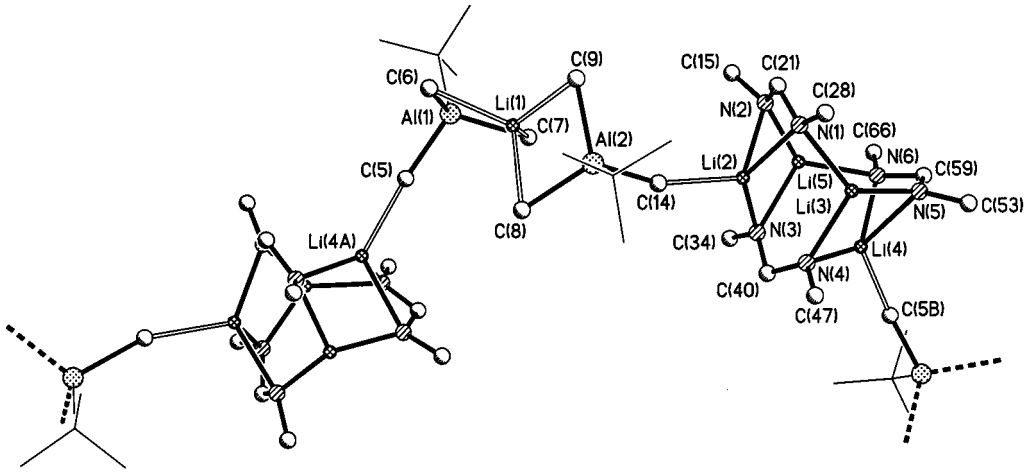

Figure 1. Polymeric structure of **5**; hydrogen atoms, phenyl rings (except the *ipso* atoms of the *N*-bonded rings) omitted for clarity; selected bond lengths (Å) and angles (°): N(1)−Li(3) 2.016(6), Li(3)−N(5) 1.992(6), N(6)−Li(5) 2.016(6), Li(5)−N(2) 1.996(6), N(2)−Li(2) 2.191(6), N(1)−Li(2) 2.089(7), N(4)−Li(3) 2.109(6), N(5)−Li(4) 2.199(6), N(6)−Li(4) 2.064(7), N(3)−Li(5) 2.124(6), Li(2)−N(2) 2.191(6), Li(4)−N(4) 2.130(6); N(2)−Li(5)−N(6) 127.0(3), N(1)−Li(3)−N(5) 125.5(3), N(1)−Li(2)−N(2) 63.7(2), Li(2)−N(2)−Li(5) 75.8(2), N(2)−Li(2)−N(3) 98.5(3), N(2)−Li(5)−N(3) 104.7(3), Li(2)−N(3)−Li(5) 74.9(2), N(5)−Li(4)−N(6) 64.0(2), N(5)−Li(3)−N(4) 105.2(3), N(5)−Li(4)−N(4) 97.7(3), Li(3)−N(5)−Li(4) 76.0(2), Li(3)−N(4)−Li(4) 75.2(2)

correlate accurately with those reported previously both in the molecular anion $[Li(Me_2Al\textit{t}Bu_2)_2]^-$ (2.25 and 2.07 Å)[7] and also in $LiAlEt_4$ (2.30 and 2.02 Å),[15] the polymeric structure of which is based on the same motif.

The cationic fragment of **5**, $(Li_4Am_3)^+$, takes the form of a lithium-nitrogen cluster. Whereas the lithium amide dication cluster recently reported to encapsulate a hydride ion exhibits $Li_8(amide)_6$ stoichiometry,[7] that of the monocationic moiety in **5** is $Li_4(amidinate)_3$. Thus the Li:organic ratio is retained, with the steric requirements of the *N*,*N*′-diphenylbenzamidinate ligand apparently requiring the formation of a smaller aggregate. The cationic component of **5** contains two types of charge-delocalised amidinate ligand, each of which interacts with the alkali metal centres through both of its sp^2-hybridised *N*-centres [C⩬N⩬C(Ph) = 121.6(3)−124.3(3)°]. Two amidinate ions, one on either side of the cluster, incorporate N(1)⩬C(21)⩬N(2) and N(5)⩬C(59)⩬N(6). These ligands both bond to Li(3) and Li(5), affording a concave eight-membered $(NCNLi)_2$ ring.[5e][6b,16] The Li−N interactions within this ring are short [1.992(6)−2.016(6) Å] in comparison to those between these nitrogen atoms and the remaining two lithium centres in the cluster cation [Li(2) and Li(4), 2.064(7)−2.199(6) Å]. Each of the two ligands which form this upper eight-membered ring interact individually with the Group 1 metal centres in the lower tier in an asymmetrically bidentate fashion. Thus, Li(2)−N(1) and Li(4)−N(6) average to 2.077 Å, while Li(2)−N(2) and Li(4)−N(5) average to 2.195 Å. This lengthening of the latter Li−N interactions is consistent with the bonding pattern observed in the eight-membered $(NCNLi)_2$ ring: N(1) and N(6) form relatively short bonds to Li(2) and Li(4) (mean Li−N = 2.016 Å) but interact more weakly with both Li and C centres within the ring [mean N⩬C(Ph) = 1.342 Å]. Conversely, N(2) and N(5) form stronger bonds with both Li and C centres in this ring [mean Li−N = 1.994 Å; mean N⩬C(Ph) = 1.325 Å] at the expense of short interactions with the two basal cations. These last two Li^+ centres are straddled by the third ligand [Li(2)−N(3) and Li(4)−N(4) = 2.113(6) and 2.130(4) Å, respectively]. However, this basal anion is orientated such that both Li(2)···N(4) and Li(4)···N(3) are extended (mean 2.583 Å) so as to be of no bonding significance. Thus, the basal tier of the cluster can be viewed as a four-membered $(LiN)_2$ ring which has undergone the fracture of two *trans*-edges to afford a pair of LiN fragments.[17] The remaining interactions between cluster base and upper $(NCNLi)_2$ ring involve the stabilisation of Li(3) and Li(5) by N(4) and N(3), respectively (mean Li−N = 2.117 Å).

The solid-state structure of **5** reveals a polymer by virtue of weak interactions between Li(2) and the terminal Me group [C(14)] in the anion and between C(5) in this anion and the analogous alkali metal centre [Li(4A)] in the adjoining cationic unit [mean Li···C(Me) = 2.295 Å] (Figure 1). These interactions raise the coordination of the otherwise low-valent Li centres in the cleaved $(LiN)_2$ ring (see above) at the base of the cluster cation. This positively charged component of **5** contrasts with normally observed ion-separated species in which otherwise isolated Li^+ centres are coordinated by a neutral Lewis base,[18] and with the recent observation of $(Li_2)^{2+}$ clusters.[19] Aggregated and charged lithium-containing clusters have also been reported in the lithium "ate" complex $(Li{\cdot}HMPA)^+{\cdot}[Li_5(N{=}CPh_2){\cdot}HMPA]^-$ $[HMPA = O{=}P(NMe_2)_3]$[14b] and $Ta(4\text{-}Me\text{-}C_6H_4)_6^-$ $[Li_4Br_3(Et_2O)_7]^+$,[20] as well as in both **2** and **3**.[7]

Attempts to understand the mechanism of formation of **5** are ongoing. The observation that the amorphous solid obtained by removing the solvent from a 1:1 mixture of *N*,*N*′-diphenylbenzamidine and $AlMe_3$ is $AmAlMe_2$ **(4)**[21] points to the first stage intermediate in the synthesis of **5** being the aluminium mono(amidinate). However, the treatment of this species with *t*BuLi initiates a complex reaction which requires further elucidation. The isolation (see Ex-

perimental Section) and structural characterisation of the aluminium tris(amidinate) $AlAm_3$ **(6)** may also be instructive — attempts to recrystallise THF-solvated (i.e. oligomerised) **5** afforded only a co-crystalline mixture which ^1H NMR spectroscopy suggests contains **5** (or its solvated and deaggregated analogue) and **6**. Mechanical separation of the crystals allows the characterisation of pure $AlAm_3$, for which formulation the solid-state structure (Figure 2) revealed one molecule of lattice toluene.

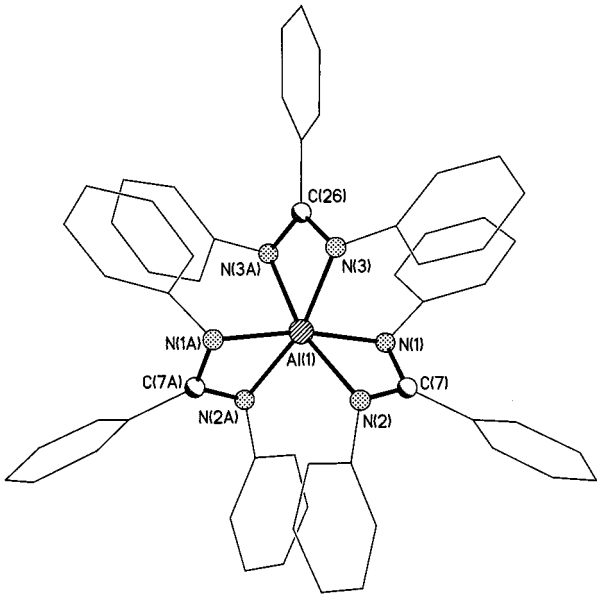

Figure 2. Molecular structure of monomeric **6**·PhMe; hydrogen atoms and lattice toluene molecule omitted for clarity; selected bond lengths (Å) and angles (°): Al(1)−N(1) 1.997(3), Al(1)−N(2) 1.981(3), Al(1)−N(3) 1.985(3); N(1)−Al(1)−N(2) 66.7(1), N(3)−Al(1)−N(3A) 66.8(2)

While the isolation and characterisation of **4**, the novel polymer **5** and also of **6** cast some light on the complex processes occurring in systems of the type discussed here, further mechanistic investigations are clearly required and will be reported subsequently. More generally, we are seeking to vary the choice of *N*-centred organic residue and organoaluminium reagent in an attempt to generate new compounds related to **5**, and so investigate the extent of this chemistry.

Experimental Section

General: All operations were carried out using standard Schlenk techniques. *N*,*N*′-diphenylbenzamidine was used as received from Lancaster. Toluene (freshly distilled from sodium), hexane and THF (freshly distilled from sodium-potassium alloy) and trimethylaluminium and *tert*-butyllithium were added direct to the nitrogen-filled Schlenk tube using standard syringe techniques. − NMR spectroscopy: Bruker DRX 400 (400.137 MHz for ^1H). For ^1H NMR spectroscopy, [D_6]benzene and [D_8]THF as solvents, TMS at 25 °C as external standard.

Dimethylaluminium *N*,*N*′-Diphenylbenzamidinate, 4·$^1/_3$PhMe: *N*,*N*′-diphenylbenzamidine (0.272 g, 1 mmol) was dissolved in toluene (2 mL) and cooled to −78 °C, whereupon $AlMe_3$ (0.5 mL, 1 mmol, 2 M in toluene) was added. The resultant mixture was warmed to room temperature and stirred for 30 minutes. Reflux afforded a yellow solution from which **4**·$^1/_3$PhMe was deposited as an amorphous solid upon removal of the solvent. Yield 73%, m.p. 176−178 °C. − $C_{70}H_{71}Al_3N_6$ (1076): calcd. C 78.07, H 6.60, N 7.81; found C 76.53, H 6.43, N, 8.35. − ^1H NMR (400 MHz, C_6D_6): δ = 7.19−6.49 (m, 16 H, Ph + $^1/_3$*Ph*Me), 2.15 (s, 1 H, $^1/_3$Ph*Me*), −0.01, −0.28 (m, 6 H, AlMe).

Compound 5: As for **4** but after stirring at room temperature for 30 minutes the solution was returned to −78 °C and treated with *t*BuLi (0.49 mL, $^5/_6$ mmol, 1.7 M in pentane). The resultant suspension was warmed to room temperature and dissolved at reflux with the addition of toluene (20 mL). The yellow solution was stored at +70 °C for two days whereupon colourless cubes of **5** were deposited. Yield 35% (based on *t*BuLi consumed), m.p. decomp. from 220 °C. − $C_{71}H_{81}Al_2Li_5N_6$ (1107): calcd. C 76.96, H 7.32, N 7.59; found C 77.95, H 6.69, N, 7.18. − ^1H NMR (400 MHz, [D_8]THF): δ = 7.05, 7.02 (br. m, 18 H, Ph), 6.83 (br. s, 12 H, Ph), 6.48 (br. s, 15 H, Ph), 0.70 (m, $^3J_{H-Al}$ = 5.0 Hz, 18 H, *t*Bu), −1.33 (sext., $^2J_{H-Al}$ = 5.7 Hz, 18 H, AlMe).

Aluminium Tris(*N*,*N*′-diphenylbenzamidinate), 6·PhMe: As for **5** utilising an initial solvent mixture of 5:1 toluene/THF (1:0.2 mL). The suspension produced after *t*BuLi addition and reflux was filtered and the resultant solution stored at room temperature for 1 week, whereupon a complex co-crystalline mixture was obtained. Mechanical separation allowed the characterisation of **6**·PhMe. M.p. 298−300 °C. − $C_{64}H_{53}Al_3N_6$ (933): calcd. C 82.31, H 5.68, N 9.00; found C 80.29, H 5.55, N 9.27. − ^1H NMR (400 MHz, C_6D_6): δ = 7.34−6.89 (m, 16 H, Ph + $^1/_3$*Ph*Me), 2.32 (s, 1 H, $^1/_3$Ph*Me*).

Crystal Data for 5: $C_{71}H_{81}Al_2Li_5N_6$, M = 1107.08, monoclinic, space group *Cc*, a = 13.7160(3), b = 23.9360(7), c = 20.6990(6) Å, β = 90.5220(19)°, U = 6795.3(3) Å^3, Z = 4, D_c = 1.082 g cm^{-3}, Mo-K_α (λ = 0.71070 Å), μ = 0.086 mm^{-1}, T = 180(2) K. 26396 reflections (10837 unique, θ < 50.10°, R_{int} = 0.0481). Refinement on F^2 values of all data gave $wR2$ = 0.1453, conventional R = 0.0547 on F values of 8799 reflections with $F^2 > 2\sigma(F^2)$, 754 parameters. Residual electron density extrema 0.49 and −0.28 e Å^{-3}.

Crystal Data for 6·PhMe: $C_{64}H_{53}AlN_6$, M = 933.10, monoclinic, space group *C*2/*c*, a = 18.2750(12), b = 18.7770(11), c = 16.2890(9) Å, β = 112.547(3)°, U = 5162.3(5) Å^3, Z = 4, D_c = 1.201 g cm^{-3}, Mo-K_α (λ = 0.71070 Å), μ = 0.086 mm^{-1}, T = 180(2) K. 8348 reflections (4517 unique, θ < 49.94°, R_{int} = 0.0358). Refinement on F^2 values of all data gave $wR2$ = 0.2166, conventional R = 0.0707 on F values of 3185 reflections with $F^2 > 2\sigma(F^2)$, 307 parameters. Residual electron density extrema 0.69 and −0.64 e Å^{-3}.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-145946 (**5**) and -145945 (**6**·PhMe). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and X-ray Structures of $[Os_3Pt(CO)_9(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(\eta^1\text{-}C{\equiv}CPh)(L)]$ (L = 4,4′-Dimethyl-2,2′-bipyridine, 4,4′-bis(*tert*-butyl)-2,2′-bipyridine): New Heterometallic Clusters with a μ_4-η^2- and an η^1-Acetylide Group on a Spiked-Triangular Metal Core

Wai-Yeung Wong,*[a] Fai-Lung Ting,[a] and Wai-Lim Lam[a]

Keywords: Osmium / Platinum / Alkyne ligands / Cluster compounds

Treatment of $[Os_3(CO)_{10}(NCMe)_2]$ with platinum bis(alkynyl) complexes *cis*-$[Pt(C{\equiv}CPh)_2(L)]$ [L = 4,4′-dimethyl-2,2′-bipyridine (Me_2bipy), 4,4′-bis(*tert*-butyl)-2,2′-bipyridine (tBu$_2$bipy)] at room temperature readily affords the novel, spiked-triangular heterometallic cluster complexes $[Os_3Pt(CO)_9(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(\eta^1\text{-}C{\equiv}CPh)(L)]$ (L = Me_2bipy **1**, tBu$_2$bipy **2**) in moderate yields. X-ray analysis of both complexes reveals that one alkynyl moiety is coordinated to the metal atoms in a μ_4-η^2(⊥) mode, accompanied by a concomitant transfer of an η^1-C≡CPh group from the platinum centre to the osmium atom to give a metal framework with an osmium atom apically bonded to an Os_2Pt triangle.

Introduction

There is continuing interest in transition metal σ-alkynyl complexes and polymers stemming from their possible applications in materials science.[1,2] Within this field, rigid-rod polymers based on metals linked by alkynyl groups in a *trans*-configuration have proved particularly fruitful, and a number of new materials with novel electronic properties have been prepared, the nature of which depends on the metals, the ancillary ligands and the spacer units.[3−10] Likewise, *cis*-platinum bis(alkynyl) complexes have recently been exploited as novel precursors for the synthesis of a series of homo- or heterobimetallic complexes in which the second metal is linked to the bis(alkynyl) molecule by coordination to the alkynyl C≡C triple bonds.[11−16] The use of alkynyl platinum species as alkynylating agents is also known.[15] These bimetallic complexes have been shown to exhibit a range of interesting chemical and physical properties.[17] In an effort to extend this chemistry to other multimetallic systems, we have studied the reactions of some *cis*-$[Pt(C{\equiv}CPh)_2$(diimine)] complexes with $[Os_3(CO)_{10}(NCMe)_2]$. To our surprise, we have discovered that this leads to new heterometallic complexes formed by transformations involving η^1-acetylide transfer, opening of the Os_3 triangle and formation of two Pt−Os bonds. We describe herein the characterization of two new compounds $[Os_3Pt(CO)_9(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(\eta^1\text{-}C{\equiv}CPh)(L)]$ [L = 4,4′-dimethyl-2,2′-bipyridine (Me_2bipy), 4,4′-bis(*tert*-butyl)-2,2′-bipyridine (tBu$_2$bipy)] showing two distinct bonding modes for the alkynyl fragment.

Results and Discussion

The mixed-metal cluster compounds $[Os_3Pt(CO)_9(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(\eta^1\text{-}C{\equiv}CPh)(L)]$ (L = Me_2bipy **1**, tBu$_2$bipy **2**) were readily prepared by the room temperature reactions of the molecular tweezers *cis*-$[Pt(C{\equiv}CPh)_2(L)]$ with one molar equivalent of $[Os_3(CO)_{10}(NCMe)_2]$ in CH_2Cl_2 (Scheme 1). Complexes **1** and **2** were isolated by preparative TLC as stable red solids in moderate yields and characterized by satisfactory IR and NMR spectroscopy and FAB mass spectrometry. X-ray crystallography established the full details of their molecular structures and the coordination modes of the alkynyl moiety.

Crystals of **1** and **2** were grown from hexane/CH_2Cl_2 at room temperature. Complex **1** crystallized in an asymmetric unit possessing two crystallographically independent molecules. Perspective drawings of **1** and **2** are depicted in Figure 1 and 2, respectively. The structural features of both **1** and **2** are very similar and they will not be discussed separately. The molecular structures of **1** and **2** reveal that the Os_3 triangle has opened out with Os−Os−Os angles of 112.31(2) and 111.41(3)° in **1** and **2**, respectively. This is accompanied by the formation of two Pt−Os bonds. Three carbonyl groups are bound to each osmium atom. The metal core of **1** and **2** consists of an essentially isosceles Os_2Pt triangle, with a third osmium atom, Os(2), apically bonded to Os(1) to give an "out-of-plane" spiked-triangular metal framework. The Pt centre adopts a pseudo square planar geometry. Although there are several known examples of Os_3Pt clusters containing a closed Os_3 triangle with a spiked Pt atom,[18,19] complexes comprising an open triangular cluster of three osmium atoms with a Pt(diimine) moiety spanning one of the two Os−Os bonds are very rare. To the best of our knowledge, structurally characterized examples of such a metal core have only been encountered in $[Os_3Pt(CO)_{11-n}(L)_n(\mu_3\text{-}S)_2]$ (n = 1, 2; L = PPh_3, PMe_2Ph) with phosphane ligands on the Pt atom.[20,21] The Pt−Os distances range from 2.6397(6) to 2.6770(6) Å in **1** and **2**, and are somewhat shorter than those in previously reported Os_3Pt clusters {2.712(1) Å in $[Os_3Pt(\mu\text{-}H)(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(CO)_{10}(PCy_3)]$,[18] 2.714(1)−2.811(1) Å in

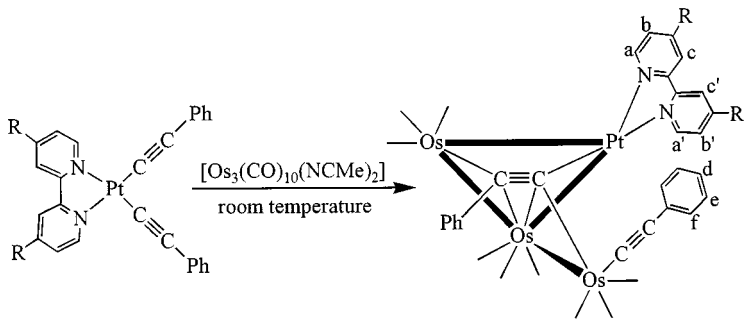

Scheme 1. Synthesis of complexes **1** and **2**

$[Os_3Pt(\mu\text{-}H)_2(\mu\text{-}CO)(CO)_9(COD)]$,[22] 2.764(1) Å in $[Os_3Pt(\mu\text{-}H)_2(\mu_4\text{-}C)(CO)_{10}\{P(cyclo\text{-}C_6H_{11})_3\}]$,[19] 2.789(1)-2.936(1) Å in $[Os_3Pt(CO)_9(PMe_2Ph)_2(\mu_3\text{-}S)_2]$[20]}. The spiked Os(1)−Os(2) edge [2.8909(6) Å in **1**, 2.914(1) Å in **2**] is notably longer than the other Os(1)−Os(3) bond [2.8032(7) Å in **1**, 2.810(1) Å in **2**] in both cases. The Pt−N bond [2.148(7)−2.174(7) Å] is also lengthened after coordination to the cluster motif relative to those observed in other *cis*-platinum bis(alkynyl) diimine complexes [2.04−2.07 Å],[13,14] probably due to the electron-withdrawing nature of the Os_3 fragment.

Another remarkable feature in the formation of **1** and **2** is the activation of a phenylacetylide unit in the starting platinum complex and its facile transfer from the platinum centre to the spiked osmium atom, resulting in a terminal alkynyl group on the Os(2) atom. The −C≡CPh group is σ-bonded to Os(2) in an η^1 mode with the C≡C bond length [average 1.21(2) Å] and Os(2)−C−C bond angle [average 175(1)°] typical of a metal−acetylide bond. The presence of an η^1-acetylide ligand is a relatively rare phenomenon in osmium cluster chemistry, although terminal acetylides are common in mononuclear osmium complexes.[23−25] A similar feature is only found in the homometallic $[Os_3(CO)_6(\mu\text{-}\eta^2\text{-}C{\equiv}CPh)(\eta^1\text{-}C{\equiv}CPh)(\mu\text{-}PPh_2)_2(NH_2Et)_2]$[26] and the heterometallic $[(\eta^5\text{-}C_5Me_5)W(O)(\mu\text{-}O)Os_3(\eta^1\text{-}C{\equiv}CPh)(CO)_{11}]$[27] complexes.

The remaining Pt-alkynyl unit is coordinated to the Os_3 chain with a $\mu_4\text{-}\eta^2(\|)$-C≡CPh moiety (Figure 3), in a manner similar to $[CpWOs_3(CO)_{11}(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)]$ involving an alkynyl transfer and formation of two W−Os bonds.[28] The

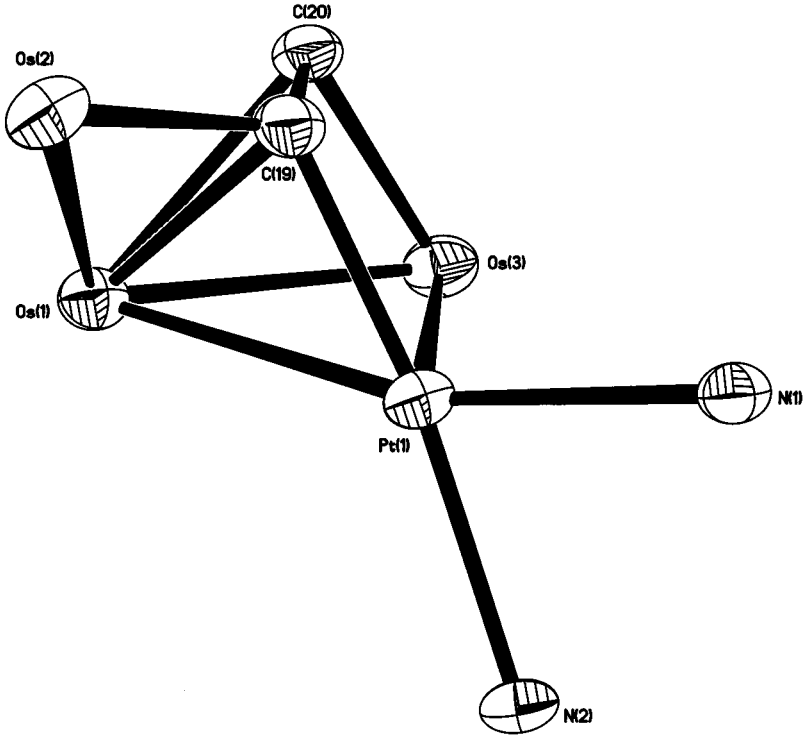

Figure 3. A perspective view of **1** showing the metal core and alkynyl coordination

vectors Pt(1)−Os(3) and C(19)−C(20) in **1** as well as Pt(1)−Os(3) and C(10)−C(11) in **2** are nearly parallel. Although $\mu_4\text{-}\eta^2(\perp)$ bonding modes have been documented for acetylides in spiked tetrametallic systems such as $[Os_3Pt(\mu\text{-}H)(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(CO)_{10}(PCy_3)]$,[18] $[(\eta^5\text{-}C_5H_5)FeRuCo_2(CO)_9(\mu\text{-}CO)(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)]$,[29] $[(\eta^5\text{-}C_5H_5)_2Ni_2Fe_2(CO)_5(\mu\text{-}PPh_2)(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)]$[30] and $[Ru_3Pt(\mu\text{-}H)\{\mu_4\text{-}\eta^2\text{-}C{\equiv}C(t\text{Bu})\}(CO)_9(COD)]$,[31] clusters with a $\mu_4\text{-}\eta^2(\parallel)$-C≡CPh group are, to the best of our knowledge, not common. The C(19)−C(20)−Os(3)−Pt(1) mean plane makes a

dihedral angle of 57.2° with the triangular Os_2Pt plane in **1** [58.2° in **2**]. Formally, the μ_4-η^2-C≡CPh ligand forms a π bond with Os(1) and three separate σ bonds to Os(2), Os(3) and Pt(1) in each case. Assuming that the μ_4-η^2-C≡CPh and η^1-C≡CPh moieties act as a five- and one-electron donor, respectively, each of the complexes **1** and **2** has 62 cluster valence electrons (CVE) which is consistent with a 16-electron Pt centre. This apparent low CVE count is commonly observed in clusters containing Pt atoms.[32]

Experimental Section

Preparation of $[Os_3Pt(CO)_9(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(\eta^1\text{-}C{\equiv}CPh)(Me_2bipy)]$ (1): A CH_2Cl_2 solution of $[Os_3(CO)_{10}(NCMe)_2]$ (0.050 g, 0.054 mmol) was stirred at room temperature with *cis*-$[Pt(C{\equiv}CPh)_2(Me_2bipy)]$[14,33] (0.031 g, 0.054 mmol) under nitrogen. After 30 min. the solvent was evaporated under vacuum, and the crude product was purified by preparative TLC, eluting with *n*-hexane/CH_2Cl_2 (3:2, v/v) to afford an orange band (R_f = 0.30) which was identified as complex **1** (0.023 g, 30%). – IR (CH_2Cl_2): ν(CO) = 2084 w, 2065 w, 2048 vs, 2012 s, 1998 m, 1973 m and 1960 sh cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 2.33 (s, 3 H, Me), 2.49 (s, 3 H, Me), 6.08 (d, J = 7.3 Hz, 2 H, H_f), 6.58 (t, J = 7.3 Hz, 2 H, H_e), 6.79 (t, J = 7.3 Hz, 1 H, H_d), 7.16–7.49 (m, 9 H, H_b, $H_{b'}$, H_c, $H_{c'}$ and Ph), 8.67 (d, J = 6.8 Hz, 1 H, H_a or $H_{a'}$), 8.85 (d, J = 5.4 Hz, 1 H, H_a or $H_{a'}$). – FAB MS: m/z = 1404 [M^+]. – $C_{37}H_{22}N_2O_9Os_3Pt$ (1404.27): calcd. C 31.51, H 1.57, N 1.99; found C 31.40, H 1.45, N 1.78.

Preparation of $[Os_3Pt(CO)_9(\mu_4\text{-}\eta^2\text{-}C{\equiv}CPh)(\eta^1\text{-}C{\equiv}CPh)(t\text{Bu}_2bipy)]$ (2): A mixture of $[Os_3(CO)_{10}(NCMe)_2]$ (0.050 g, 0.054 mmol) and $[Pt(C{\equiv}CPh)_2(t\text{Bu}_2bipy)]$ (0.036 g, 0.054 mmol) was stirred at room temperature under nitrogen for 30 min. The resulting orange-red solution was evaporated to dryness and the residue was subjected to TLC with *n*-hexane/CH_2Cl_2 (3:2, v/v) as eluent to give complex **2** as an orange band (R_f = 0.50) in 28% yield (0.022 g). – IR (CH_2Cl_2): ν(CO) = 2083 w, 2064 w, 2048 vs, 2011 s, 1998 m, 1972 m and 1958 sh cm^{-1}. – ^1H NMR ($CDCl_3$): δ = 1.30 (s, 9 H, *t*Bu), 1.43 (s, 9 H, *t*Bu), 6.02 (d, J = 7.6 Hz, 2 H, H_f), 6.53 (t, J = 7.6 Hz, 2 H, H_e), 6.78 (t, J = 7.6 Hz, 1 H, H_d), 7.18–7.60 (m, 9 H, H_b, $H_{b'}$, H_c, $H_{c'}$ and Ph), 8.74 (d, J = 5.4 Hz, 1 H, H_a or $H_{a'}$), 8.91 (d, J = 5.7 Hz, 1 H, H_a or $H_{a'}$). – FAB MS: m/z = 1488 [M^+]. – $C_{43}H_{34}N_2O_9Os_3Pt$ (1488.43): calcd. C 34.70, H 2.30, N 1.88; found C 34.49, H 2.20, N 1.75.

Crystallographic Data for $1{\cdot}CH_2Cl_2$: $C_{38}H_{24}Cl_2N_2O_9Os_3Pt$, M = 1489.18, triclinic, space group $P\bar{1}$, a = 9.317(1), b = 17.843(2), c = 25.672(3) Å, α = 73.857(2), β = 87.260(2), γ = 86.020(2)°, U = 4087.8(8) $Å^3$, Z = 4, T = 293 K, μ(Mo-K_α) = 128.91 cm^{-1}, 24218 reflections measured, 17554 unique, R(int) = 0.0370, final $R1$ = 0.0408, w$R2$ = 0.0894 (based on F^2) for 17554 [$I > 2\sigma(I)$] observed reflections.

Crystallographic Data for $2{\cdot}CH_2Cl_2$: $C_{44}H_{36}Cl_2N_2O_9Os_3Pt$, M = 1573.34, triclinic, space group $P\bar{1}$, a = 11.420(2), b = 13.972(3), c = 16.438(3) Å, α = 111.92(3), β = 101.84(3), γ = 90.69(3)°, U = 2370.1(8) $Å^3$, Z = 2, T = 293 K, μ(Mo-K_α) = 111.23 cm^{-1}, 13770 reflections measured, 10007 unique, R(int) = 0.0484, final $R1$ = 0.0553, w$R2$ = 0.1639 (based on F^2) for 10007 [$I > 2\sigma(I)$] observed reflections.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-151605 (**1**) and CCDC-151606 (**2**). Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supramolecular Assembling of Dizinc Macrocyclic Complexes with Thymine and Uracil — The Role of Intra- and Intermolecular Hydrogen Bonding

Carla Bazzicalupi,[a] Andrea Bencini,*[a] Emanuela Berni,[a] Antonio Bianchi,*[a] Samuele Ciattini,[a] Claudia Giorgi,[a] Piero Paoletti,*[a] and Barbara Valtancoli*[a]

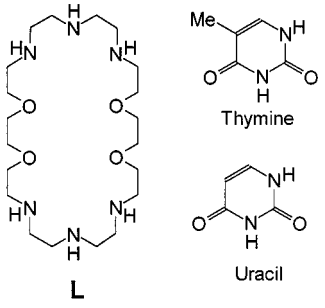
Keywords: Macrocycles / Supramolecular chemistry / Zinc / Nucleobases / Hydrogen bonds

A binuclear Zn^{II} complex with an oxa-aza macrocyclic ligand can bind two deprotonated thymine or uracil moieties, giving versatile building blocks for the assembly of supramolecolar structures, by hydrogen bond pairing of the nucleobases.

Introduction

In the last few years a great deal of interest has been devoted to the recognition of nucleobases, nucleosides and nucleotides by synthetic receptors in aqueous solutions,[1−11] due both to their use as mimic systems for enzymes and to their potential medical application. Particular attention has been focused on the role of nucleobases in the recognition process, since these molecules possess several functions which can be used for hydrogen bonding and/or metal binding. Metal complexes are often chosen as receptors for these substrates. Recent work by Kimura[8−11] has shown that thymine derivatives containing an imide CO−NH−CO moiety (such as AZT or thymidine), are strongly bound by Zn^{II} complexes with cyclen-based macrocycles (cyclen = 1,4,7,10-tetraazacyclododecane), through a recognition process which involves deprotonation of the imide function, metal binding by the deprotonated nitrogen and hydrogen bonding between the CO functions and two complementary amine groups of the macrocyclic unit. This "three-point" binding mode accounts for the selective binding of thymine derivatives with respect to cytosine ones, which don't contain an "imide" moiety.

Several zinc enzymes, however, contain two Zn^{II} ions in their active site. At the same time, binuclear metal complexes with macrocyclic ligands are potential receptors for nucleobases.[10] The particular topology of these ligands, in fact, may force the two metal centres into close proximity where they can act as multipoint binding sites for substrate molecules or anions.[12,13] Ligand **L** presents two almost independent binding moieties — the two triamine chains — separated by two weakly coordinating polyoxa chains.[14] In its dizinc complex each metal is bound by a triamine unit and presents an unsaturated coordination sphere. This complex, therefore, may be a promising receptor for nucleobases, such as thymine (TH) or uracil (UH).



Results and Discussion

Thymine and uracil binding to the dizinc complex $[Zn_2\mathbf{L}]^{4+}$ was studied by means of potentiometric measurements in aqueous solutions. This complex displays similar binding features towards thymine and uracil. We found, in fact, that it forms stable 1:1 and 1:2 complexes with both deprotonated thymine and uracil at neutral or slightly alkaline pH's. Deprotonation and simultaneous binding of thymine and uracil to the $[Zn_2\mathbf{L}]^{4+}$ complex takes place at neutral pH, to give the 1:1 complexes $[Zn_2\mathbf{LT}]^{3+}$ or $[Zn_2\mathbf{LU}]^{3+}$ {log K = 5.3(1) and 5.0(1) for the equilibria $[Zn_2\mathbf{L}]^{4+}$ + T^- = $[Zn_2\mathbf{LT}]^{3+}$ and $[Zn_2\mathbf{L}]^{4+}$ + U^- = $[Zn_2\mathbf{LU}]^{3+}$, respectively}. These complexes are formed in the pH range 6.5−9, with a maximum percentage of ca. 20% at pH 7.5 in solutions containing $[Zn_2\mathbf{L}]^{4+}$ and TH or UH in a 1:1 molar ratio. This process is followed at slightly alkaline pH's by deprotonation and binding of a second nucleobase, leading to the assembly of the $[Zn_2\mathbf{LT}_2]^{2+}$ and $[Zn_2\mathbf{LU}_2]^{2+}$ complexes {log K = 5.0(1) and 4.7(1) for the equilibria $[Zn_2\mathbf{LT}]^{3+}$ + T^- = $[Zn_2\mathbf{LT}_2]^{2+}$ and $[Zn_2\mathbf{LU}]^{3+}$ + U^- = $[Zn_2\mathbf{LU}_2]^{2+}$, respectively}, which contain two deprotonated nucleobases. These species are formed in the pH range 7−10.5 (maximum percentage ca. 60% at pH 9). It is of interest to note that, for both thymine and uracil, the constant for the addition of the first deprotonated nucleobase is almost equal to that for the addition of the second one, suggesting that each nucleobase is coordinated, almost independently, by one Zn^{II} ion of the $[Zn_2\mathbf{L}]^{4+}$ complex.

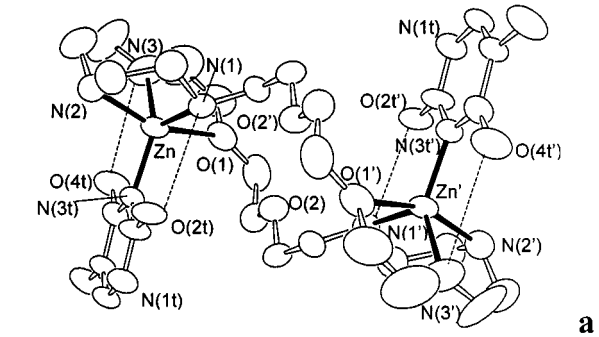
The crystal structure of the $[Zn_2\mathbf{L}T_2]^{2+}$ cation (Figure 1a) shows that two deprotonated thymine units are coordinated to the two metal centers and lie on opposite sides with respect to an ideal plane containing the macrocycle oxygen atoms. The metals are symmetry related [Zn···Zn′ = 7.667(5) Å] and present a distorted trigonal bipyramidal coordination geometry, with the equatorial plane defined by the "lateral" N(1) and N(3) amine groups of the macrocycle and the deprotonated N(3t) nitrogen of thymine, with a rather short Zn−N(3t) bond length [1.948(6) Å], due to the anionic nature of this donor. The "central" nitrogen N(2) of the triamine unit and an oxygen [O(1)] of the polyoxa chain occupy the apical positions and are bound at longer distances [Zn(1)−N(2) = 2.143(9) Å, Zn(1)−O(1) = 2.398(7) Å] than the other three coordinated nitrogens. The Zn^{II} ion and the two lateral amine groups lie on the plane of the thymine ring [max. deviation 0.325(7) Å for N(1)]. Such a complementary disposition allows the formation of two rather strong hydrogen bonds between the two carbonyl oxygens of thymine and the coordinated N(1) and N(3) amine groups of the macrocycle [N(1)···O(2t) = 3.02(1) Å; N(3)···O(4t) = 3.39(2) Å]. Furthermore, deprotonation of the imide nitrogen develops negative charges at the carbonyl functions, which become better acceptors for the N−H hydrogens. The match of the complementary binding sites of receptor and substrate allows the formation of a tight $(CO)_2N(3t)-ZnN(1)N(3)$ unit and may account for the remarkably high stability in aqueous solution of the present dizinc complex with deprotonated thymine.

Thymine, however, possesses another binding site, the N(1t) nitrogen, which can be used for hydrogen bonding. Besides intramolecular hydrogen bonding, inspection of the crystal packing revealed the formation of hydrogen-bond pairing between the thymine units of different $[Zn_2\mathbf{L}T_2]^{2+}$ complexes. The ORTEP drawing of the crystal packing for the $[Zn_2\mathbf{L}T_2]^{2+}$ complex (Figure 1b) clearly shows that each thymine unit is associated through two symmetry-related strong hydrogen bonds [N(1t)···O(2t) 2.769(9) Å] with a thymine moiety of a different binuclear complex. Consequently, the $[Zn_2\mathbf{L}T_2](ClO_4)_2$ complexes are assembled into infinite pillars of $[Zn_2\mathbf{L}T_2]^{2+}$ units, joined together through a centrosymmetrical hydrogen bond network.

The assembly of this supramolecular architecture can also be ascribed to the macrocyclic structure of **L**, which keeps two Zn-thymine units at rather close distance. At the same time, the well-known ability of thymine to give hydrogen bonds with other nucleobases (a different thymine unit in the present case) allows the formation of the pillared structure presented by the $[Zn_2\mathbf{L}T_2](ClO_4)_2$ complex.

The crucial role played by both intra- and intermolecular hydrogen bonding in this assembling process is confirmed by the crystal structure of the dinuclear Zn^{II} complex with uracil, which presents the same binding sites as with thymine (Figure 2).

In the $[Zn_2\mathbf{L}U_2]^{2+}$ complex, each metal displays a trigonal bipyramidal coordination geometry, very similar to that found in the thymine complex. The N(3u), N(1) and N(3) nitrogens define the basal plane, while the N(2) and



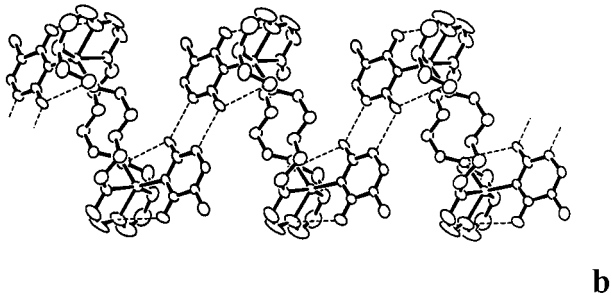


Figure 1. (a) ORTEP drawing of the $[Zn_2\mathbf{L}T_2]^{2+}$ cation; (b) crystal packing for $[Zn_2\mathbf{L}T_2](ClO_4)_2$ displaying the intramolecular hydrogen bonds and the hydrogen bond pairing between thymine units of different $[Zn_2\mathbf{L}T_2]^{2+}$ complexes (perchlorate anions are omitted for clarity); selected bond lengths (Å) and angles (°): Zn−N(3t) 1.948(6), Zn−N(3) 2.034(9), Zn−N(1) 2.070(7), Zn−N(2) 2.143(9), Zn−O(1) 2.398(7); N(3t)−Zn−N(3) 129.0(4), N(3t)−Zn−N(1) 119.2(3), N(3)−Zn−N(1) 111.5(4), N(3t)−Zn−N(2) 105.0(3), N(3)−Zn−N(2) 83.6(4), N(1)−Zn−N(2) 84.7(3), N(3t)−Zn−O(1) 94.5(3), N(3)−Zn−O(1) 74.5(4), N(1)−Zn−O(1) 96.5(3), N(2)−Zn−O(1) 156.9(3), Zn···Zn′ 7.667(5)

O(1) donors, at the apical positions, are coordinated at longer distances. Figure 2 clearly shows the optimal matching between the N(1)−Zn−N(3) unit of the receptor and the $CO-N(3u)^{-}-CO$ imide function, leading, once again, to an enhanced receptor-substrate interaction through the formation of a strong Zn−N(3u) bond [1.93(1) Å] and two N(1)···O(2u) and N(3)···O(4u) hydrogen bonds [3.05(2) and 3.16(2) Å, respectively]. As in the case of thymine, intermolecular hydrogen bond pairing between two symmetry related uracil units of two different dizinc clusters [N(1u)···O(2u), 2.84(2) Å] leads to the formation of infinite pillars of $[Zn_2\mathbf{L}U_2]^{2+}$ complexes (Figure 2b).

To the best of our knowledge, the $[Zn_2\mathbf{L}T_2](ClO_4)_2$ and $[Zn_2\mathbf{L}U_2](ClO_4)_2$ complexes are the first structurally characterized dizinc assemblies containing two thymine or uracil units.

The present structures suggest that binuclear Zn^{II} macrocyclic complexes with nucleobases may be used as building blocks for supramolecular structures, due to the versatile hydrogen bonding ability of these molecules. Intramolecular hydrogen bonds, in fact, give a significant contribution to the stability of the binuclear dithymine or diuracil adducts. At the same time, intermolecular hydrogen bonding of different binuclear complexes contributes to generate the as-

sembly of supramolecular architectures based on infinite pillars of $[Zn_2\mathbf{L}T_2]^{2+}$ or $[Zn_2\mathbf{L}U_2]^{2+}$ units.

Further investigations on different nucleobases are in progress.

Experimental Section

General Remarks: Compound **L** and $[Zn_2\mathbf{L}](ClO_4)_4$ were prepared as previously described.[14]

$[Zn_2LT_2](ClO_4)_2$: Crystals of the $[Zn_2\mathbf{L}T_2](ClO_4)_2$ complex were obtained in 82% yield by slow evaporation of an aqueous solution containing $[Zn_2\mathbf{L}](ClO_4)_4$ (0.001 M) and TH (0.002 M) at pH 8. − $C_{30}H_{56}Cl_2N_{10}O_{16}Zn_2$ (1014.49): C 35.52, H 5.56, N 13.81; found C 35.7, H 5.7, N 14.0.

$[Zn_2LU_2](ClO_4)_2$: This compound was prepared in 87% yield in a similar manner as already described for $[Zn_2\mathbf{L}T_2](ClO_4)_2$. − $C_{28}H_{52}Cl_2N_{10}O_{16}Zn_2$ (986.44): C 34.09, H 5.31, N 14.20; found C 34.2,H 5.3, N 14.1.

Potentiometric Measurements: All potentiometric measurements (pH = −log[H^+]) were carried out in 0.1 M NMe_4NO_3 (pK_w = 13.83 at 298.1 K) at 298.1 K, by using the method and procedure from ref.[14] The nucleobase:[Zn^{II} complex] molar ratio was varied from 0.3 to 5 in order to better ascertain the stoichiometry of the adducts. The computer program HYPERQUAD[15] was used to calculate the addition constants from e.m.f. data.

X-ray Crystallographic Study: $[Zn_2\mathbf{L}T_2](ClO_4)_2$: $C_{30}H_{56}Cl_2N_{10}O_{16}Zn_2$, M = 1014.48, triclinic, $P\bar{1}$, a = 9.305(6) Å, b = 9.612(4) Å, c = 13.170(5) Å, α = 103.17(3)°, β = 100.94(4)°, γ = 100.53(4)°, V = 1094.2(9) Å^3, T = 298 K, Z = 1, calculated density 1.540 Mg/m^3. Data collection with an Enraf Nonius CAD4 diffractometer, graphite-monochromated Mo-K_α radiation, crystal size 0.3 × 0.25 × 0.1 mm, θ-2θ scan, $2\theta_{max}$ = 50°, μ = 1.295 mm^{-1}, 4500 reflections collected, 3719 unique (R_{int} = 0.1355) which were used in all calculations, absorption correction by psi-scan method, transmission factors 0.72−0.82, data/parameters 3719/272, final R indices $R1$ = 0.0838 [$I > 2\sigma(I)$], $wR2$ = 0.2711. All hydrogen atoms were introduced in calculated positions.

$[Zn_2\mathbf{L}U_2](ClO_4)_2$: $C_{28}H_{52}Cl_2N_{10}O_{16}Zn_2$, M = 986.44, triclinic, $P\bar{1}$, a = 9.405(1) Å, b = 9.443(1) Å, c = 12.457(2) Å, α = 103.46(1)°, β = 96.81(1)°, γ = 100.53(1)°, V = 1042.7(2) Å^3, T = 298 K, Z = 1, calculated density 1.571 Mg/m^3. Data collection with a Siemens P4 diffractometer equipped with a rotating anode, graphite-monochromated Cu-K_α radiation, crystal size 0.15 × 0.1 × 0.1 mm, θ-2θ scan, $2\theta_{max}$ = 110°, μ = 3.280 mm^{-1}, 2688 reflections collected, 2173 unique (R_{int} = 0.0684) which were used in all calculations, absorption correction by psi-scan method, transmission factors 0.61−0.72, data/parameters 2173/261, final R indices $R1$ = 0.0810 [$I > 2\sigma(I)$], $wR2$ = 0.2278. All hydrogen atoms were introduced in calculated positions.

Both structures were solved using the direct methods of the SIR97 program[16] and refined by full-matrix least-squares on F^2 by means of the SHELXL-97 program.[17]

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-149822 {$[Zn_2LT_2](ClO_4)_2$} and -149823 {$[Zn_2LU_2](ClO_4)_2$}. Self-Assembly of Fourteen Components into a Soluble, Neutral, Metalloprismatic Cage

Bala Manimaran,[a] T. Rajendran,[a,c] Yi-Long Lu,[a] Gene-Hsiang Lee,[b] Shie-Ming Peng,[b] and Kuang-Lieh Lu*[a]

Keywords: Cage compounds / Rhenium / Solvatochromism / Self assembly / N ligands

A novel one-pot synthesis of rhenium-based triangular prismatic cages has been accomplished in excellent yields by a self-assembly strategy. Reaction of $Re_2(CO)_{10}$ with 2,4,6-tri-4-pyridyl-1,3,5-triazine (tpt) in the presence of an aliphatic alcohol (1-butanol, 1-octanol or 1-dodecanol) afforded molecular prisms, $[\{(CO)_3Re(\mu_2\text{-}OR)_2Re(CO)_3\}_3(\mu_3\text{-}tpt)_2]$ (**1**, R = C_4H_9; **2**, R = C_8H_{17}; **3**, R = $C_{12}H_{25}$) by solvothermal methods. Fine tuning of the solubility is achieved by tailoring the length of the alkyl chain of the alcohol. Compounds **1**–**3** reported here are the first Re-containing molecular prisms of the $M_6L_2L'_6$ type. In addition, they are the first neutral, prismatic cages without counterions that are highly air and moisture stable. Compounds **2** and **3** are soluble in most common organic solvents and they exhibit a large solvatochromism: the value of λ^{ab}_{max} could be tuned over 125 nm simply by changing the polarity of the solvent.

Introduction

The fabrication of nanometer-scale macrocycles by metal-directed, self-assembled cage compounds is an important component of supramolecular chemistry.[1] There is an upsurge of interest in this area due to the potential applications of these molecules in host-guest chemistry and molecular recognition.[2] Since the construction of larger cages by conventional covalent synthetic procedures is a tedious process, self-assembly techniques have been employed by several groups to obtain the metal-directed assembly of cage compounds.[3−5] The nanosized, spherical-cage Pd^{II} complexes constructed by the metal-induced self-assembly strategy using an exotridentate ligand 2,4,6-tri-4-pyridyl-1,3,5-triazine (tpt) exhibit remarkable thermodynamic stability with a large spherical void.[6] Recently, we have initiated a systematic approach for the design of rhenium-containing, neutral, cage-like supramolecules to explore their applications. In this communication we report the synthesis and characterization of the prismatic cages of the type $M_6L_2L'_6$, $[\{(CO)_3Re(\mu_2\text{-}OR)_2Re(CO)_3\}_3(\mu_3\text{-}tpt)_2]$ (**1**, R = C_4H_9; **2**, R = C_8H_{17}; **3**, R = $C_{12}H_{25}$) made from fourteen components, including the octahedrally coordinated Re metal center, the tpt ligand and an aliphatic alcohol. The advantage here is that the product is obtained in excellent yield in a one-pot synthesis by a self-assembly strategy using solvothermal methods, where the alcohol that is used as solvent also serves as one of the reagents. It is noteworthy that the currently known prismatic supramolecules are either highly charged or encapsulated with counterions.[1h,1i,4d,5d] On the other hand, compounds **1**−**3** are the first neutral, prismatic cages without counterions that are highly air and moisture stable. Compounds **2** and **3** are soluble in most common organic solvents and they show a large solvatochromism.

Results and Discussion

Treatment of $Re_2(CO)_{10}$ with tpt in $CH_3(CH_2)_nOH$ (n = 3, 7, 11) using solvothermal methods at elevated temperatures leads to the formation of the thermodynamically stable cage structures **1**, **2**, and **3**, respectively, in excellent yields (Scheme 1). Compound **1** has been spectroscopically and crystallographically characterized. The ORTEP drawing of **1** (Figure 1) reveals a prismatic cage architecture, where two planar tpt ligands coordinate to six rhenium atoms, which are themselves connected by six butoxy bridges, thereby forming a triangular prismatic cage. Each rhenium atom occupies a corner of the triangular prism and is bonded to one nitrogen atom of the pyridyl group of the tpt ligand, two butoxy groups and three carbonyl groups, maintaining a distorted octahedral geometry. The maximum and minimum rhenium−rhenium distances in the molecule are 13.5 and 3.4 Å, respectively. The three pyridyl rings of the tpt moiety are canted slightly (ca. 15°) from the plane containing the triazine ring. Some groups of researchers have experienced difficulty in growing X-ray quality single crystals of metallomacromolecules containing two to twelve metal centers.[7] In contrast, our synthetic strategy has led to the formation of single crystals of good quality. The electroneutrality of the cage compounds **1**−**3** mitigates

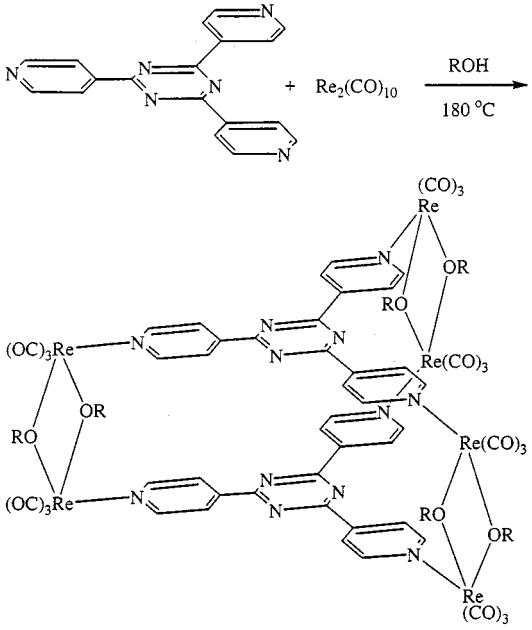
interference of the counterions inside the cavity, which creates problem in most of the sensor studies. The extraordinary affinity of oxygen with rhenium is capitalized in this synthetic approach by utilizing oxo-bridges bearing long, hydrophobic tails. The ^1H and ^{13}C NMR spectral measurements and the FAB-MS data of the cage compounds are in agreement with the proposed structures.



Scheme 1

It has been a challenge to synthesize highly soluble multimetal supramolecules and it is obvious that the solubility of such molecules is of paramount importance for their potential applications. Lees and co-workers have recently reported that complexes with more metal centers have lower solubility; a square complex with four metal components displayed lower solubility than a related triangular complex with three metal components.[7b] Interestingly the solubility of compounds **1**−**3** has been improved enormously by changing the length of the alkyl moiety from butyl to octyl and then to dodecyl. An increase in the chain length of the alkoxo moiety increases the hydrophobicity of the cage, thereby increasing the solubility of the compound in organic solvents. Compounds **2** and **3** are readily soluble in CH_2Cl_2, $(CH_3)_2CO$ and other common organic solvents, whereas **1** is much less soluble. Because of the greater solubility of compounds **2** and **3** they were used for further studies.

Compounds **2** and **3** display an identical CO stretching pattern in their infrared spectra which is similar to that observed for previously reported compounds.[8] The UV/Vis spectra of **2** and **3** in CH_2Cl_2 show an intense, high-energy band at 243 nm and a broad low-energy band at 488 nm. In agreement with previous reports on related systems, the former absorption is assigned to the intraligand $\pi-\pi^*$ transition and the low energy absorption to a metal-to-ligand charge transfer (MLCT) transition.[9] In addition, there is a shoulder at about 265 nm, which may be assigned

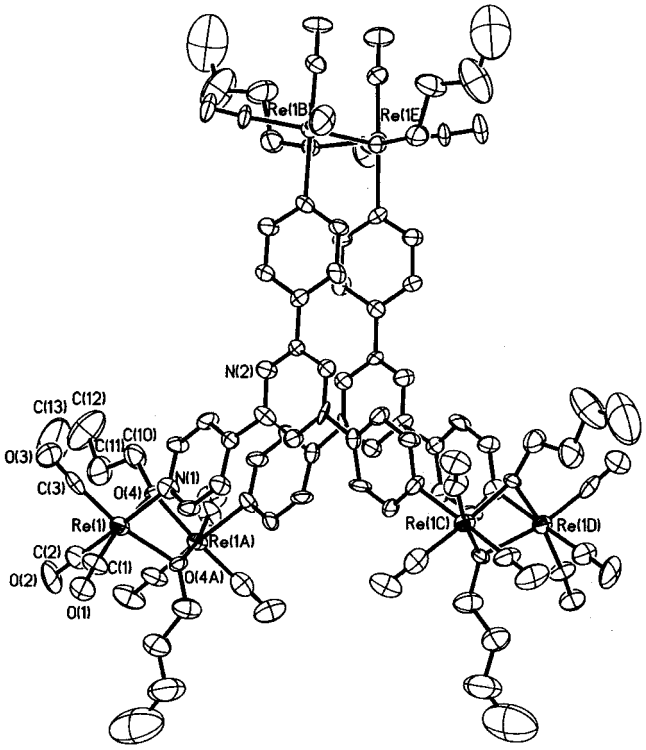


Figure 1. ORTEP diagram of $[\{(CO)_3Re(\mu_2\text{-}OC_4H_9)_2Re(CO)_3\}_3(\mu_3\text{-}tpt)_2]$ (**1**); selected bond lengths (Å) and angles (°): Re(1)−N(1) 2.216(12), Re(1)−O(4) 2.122(10), Re(1)−O(4A) 2.144(9), Re(1)−C(1) 1.98(2), Re(1)−C(2) 1.91(2), Re(1)−C(3) 1.89(2), O(4)−C(10) 1.44(2); O(4)−Re(1)−N(1) 83.1(4), O(4A)−Re(1)−N(1) 82.0(4), Re(1)−O(4)−Re(1A) 105.5(4), O(4)−Re(1)−O(4A) 71.7(4), C(10)−O(4)−Re(1) 124.8(10), C(10)−O(4)−Re(1A) 122.6(10)

to another $\pi-\pi^*$ transition as suggested by Tapolsky et al.[10] The interesting feature that deserves further attention is the observation of the MLCT at a comparatively long wavelength (488 nm), indicating the readily reducible nature of the ligand.[11] We have recorded the absorption spectra of **2** and **3** in a large number of solvents and it is interesting to point out that they show substantial solvatochromism: the value of λ^{ab}_{max} could be tuned over 125 nm, with a corresponding change in the color of the solution from yellow to red, simply by changing the polarity of the solvent (λ^{ab}_{max} values for **2** in DMSO and CCl_4 are 424 and 549 nm, respectively).[12]

In summary we have succeeded in the one-pot, high yield synthesis and characterization of neutral prismatic cages containing hexanuclear rhenium centers linked by six alkoxy bridges bearing lengthy alkyl chains. The presence of the lengthy alkyl chain dramatically increases the hydrophobic nature of the cage-like compounds and hence the solubility, which is a major problem in many of the supramolecular motifs. The interesting photophysical properties and solvatochromism of these supramolecular cage-like structures promise many applications. We are currently extending the metal-induced, self-assembly by solvothermal methods to the synthesis of molecular cages of new architecture from different sets of molecular components, and these results will be reported in a future publication.

Experimental Section

A suspension consisting of a mixture of $Re_2(CO)_{10}$ (98 mg, 0.15 mmol) and tpt (32 mg, 0.10 mmol) in 1-butanol (10 mL) in a 30 mL Teflon flask was placed in a steel bomb. The bomb was placed in an oven maintained at 180 °C for 48 h and then cooled to 25 °C. Good quality, maroon-colored, single crystals of **1** were obtained. The crystals were separated by filtration and washed with 1-butanol. Compounds **2** and **3** were also synthesized by following a similar procedure. The solvent from the reaction mixture was removed by vacuum distillation and the residue was redissolved in CH_2Cl_2 and passed through a short silica gel column to get pure **2** and **3**. Yield: **1**, 109 mg, 81%; **2**, 124 mg, 82%; **3**, 142 mg, 85%.

Oxa- and Azacalixarenes as Ligands for Uranyl Ions − Evidence for Two Different Complexation Modes

Pierre Thuéry,*[a] Martine Nierlich,[a] Jacques Vicens,[b] Bernardo Masci,[c] and Hiroyuki Takemura[d]

Keywords: Uranium / Calixarenes / Zwitterion / Crystal structure

The first crystal structures are reported for uncomplexed parent tetrahomodioxa- and tetrahomodiazacalix[4]arene compounds and their 1:1 uranyl complexes. A 1:1 uranyl complex is also reported for a hexahomotriazacalix[3]arene. While analogous features are observed for the uncomplexed dioxa- and diazacalixarenes, completely different coordination modes are observed in their uranyl complexes. The complex of *p-tert*-butyltetrahomodioxacalix[4]arene is obtained in the presence of triethylamine and consists of an anionic core in which the cation is located at the centre of the lower rim, as is frequently observed. Both *p*-chloro-*N*-benzyl-hexahomotriazacalix[3]arene and *p*-methyl-*N*-benzyl-tetrahomodiazacalix[4]arene react with uranyl nitrate without adding a basic agent. The resulting 1:1 complexes are neutral, the cation being located outside the macrocycle and bound to two phenoxide groups of its zwitterionic form and to the nitrate counter-ions. The difference in coordination mode between homooxa- and homoazacalixarene complexes is attributed to the electrostatic repulsion between the uranyl ions and the ammonium groups located around the lower rim in the latter case, which prevents a close approach of the complexed cation.

Introduction

The work of Shinkai et al., who demonstrated about ten years ago the "uranophile" potential of water-soluble calixarenes, generated an interest that led to the investigation of uranyl complexes of calixarenes.[1] Unfortunately, the crystal structures of the complexes involved have never been elucidated due to the difficulties encountered in growing single crystals. However, since then a lot of structural information has been gathered about the uranyl complexes of parent calix[*n*]arenes (*n* between 5 and 9 and *n* = 12) and homooxacalixarenes,[2] whereas only one crystal structure involving coordinating pendent arms grafted on a calix[4]arene has been reported.[3] Parent calixarenes and homooxacalixarenes readily form uranyl complexes in a basic medium. These are either mononuclear with the smallest calixarenes in cone conformation (*p-tert*-butyldihomooxacalix[4]arene,[2a] *p-tert*-butylhexahomotrioxacalix[3]arene,[2i] *p-tert*-butylcalix[5]arene[2e]) or polynuclear with larger, flattened calixarenes (*p-tert*-butylcalix[8]arene,[2b,2c,2k] *p-tert*-butylcalix[9]arene,[2k] *p-tert*-butylcalix[12]arene[2j]). *p-tert*-Butylcalix[6]arene gives only external complexes with a 2:1,[2g] 2:2[2d] or 3:3[2k] metal:ligand stoichiometry. Calix[7]arene is another peculiar case, being able to engage in complexation only one of its two (trimeric and tetrameric) subunits,[2f] or both.[2h] The complex formed by *p-tert*-butylhexahomotrioxacalix[3]arene (ligand **1** in Scheme 1) is of particular interest since it constitutes the first and, up to now, the only example of a pseudo-trigonal equatorial coordination for the uranyl ion.[2i]

The homooxa- and homoazacalixarenes are less rigid than calixarenes, as shown by ^{1}H NMR spectroscopic measurements in the case of the former.[4] Furthermore, they possess two different kinds of potential binding sites, and homoazacalixarenes, which were first synthesized some years ago,[5] can bear various substituents on the amine nitrogen atom. The metal-ion complexes of homooxacalixarenes thus far reported have been obtained classically in a basic medium.[2a,2i,6] In order to further investigate the complexing properties of these ligands, we synthesized, in the presence of triethylamine, the uranyl complex of another oxacalixarene, *p-tert*-butyltetrahomodioxacalix[4]arene (**2**), the structure of which is reported herein as well as that of the uncomplexed ligand. We have recently begun the investigation of azacalixarenes as ligands and reported the crystal structures of *p*-chloro-*N*-benzylhexahomotriazacalix[3]arene (**3**) and of its mononuclear complex with neodymium nitrate.[7] This work demonstrated a peculiarity of the homoazacalixarenes as ligands in that they are able to com-

plex lanthanide ions without the addition of a basic agent such as the commonly used triethylamine or 1,4-diazabicyclo[2.2.2]octane (DABCO), owing to the displacement of the protons from oxygen to nitrogen atoms (zwitterionic or amphiionic form) upon complexation. We report herein the synthesis in a neutral medium as well as the crystal structures of the uranyl complexes of two azacalixarenes, **3** and *p*-methyl-*N*-benzyltetrahomodiazacalix[4]arene (**4**), and the crystal structure of the uncomplexed molecule **4**. Unfortunately, we have not succeeded in growing single crystals of the complex species obtained with **3** and **4** in a basic medium, for comparative purposes. To the best of our knowledge, the crystal structures reported herein are the first ones for parent tetrahomodioxa- and tetrahomodiazacalix[4]arenes and their complexes.

Results and Discussion

Uncomplexed Calixarenes

The asymmetric unit in **2**·2CH_3CN (**5**) is composed of half a molecule, located around a binary axis perpendicular to its mean plane (Figure 1). The overall shape is that of a very distorted cone, and is determined by an intramolecular hydrogen bonding array which links both phenolic and ether groups (Table 1). The two ether links, which give the molecule its high flexibility, are positioned so as to bring the ether atom O(2) and its symmetry-related equivalent O(2′) close to the protons of the phenolic atoms O(3) and O(3′). However, the macrocycle is not large enough to prevent the formation of a cyclic hydrogen bonding array link-

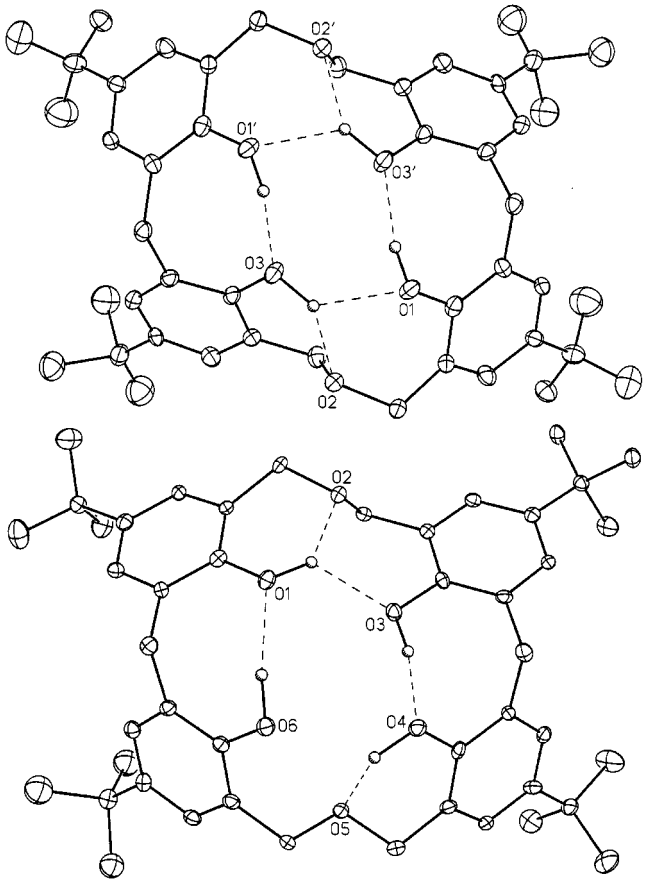

Figure 1. View of *p-tert*-butyltetrahomodioxacalix[4]arene **2** in **5** (top) and in **6** (bottom), showing the difference in hydrogen bonding patterns; hydrogen bonds in dashed lines; hydroxyl protons represented as small spheres of arbitrary radii; other hydrogen atoms and solvent molecules omitted for clarity; symmetry code: ′ = *y*, *x*, −*z*

ing the four phenolic oxygen atoms, with O(3) and O(3′) giving a bifurcated hydrogen bond, the O(3)···O(2) bond being stronger than O(3)···O(1). The calixarene shape can be characterized by the values of the dihedral angles between the phenolic rings and the mean plane defined [± 0.339(4) Å] by the phenolic oxygen atoms, which are 38.8(2) and 47.2(2)° [mean value 43(6)°]. The cup shape is sufficiently deep for the two acetonitrile molecules (not involved in hydrogen bonding) to be included in the cavity: such a situation has already been observed in the case of *p-tert*-butylcalix[6]arene,[8] which confirms the similarity between the two ligands in terms of cavity size.[9]

The asymmetric unit in **2**·2.5C_5H_5N (**6**) is composed of one molecule, represented in Figure 1, the overall features of which are analogous to those in **5**. However, the calixarene conformation is different in the surroundings of atom O(5), which results in a slight enlargement of the macrocycle and the breaking of one of the hydrogen bonds. The interest of this structure is to show that, depending upon the solvent, it is possible to observe conformations of the ether bridge which do not allow bifurcate hydrogen bonds. The values of the dihedral angles between the phenolic rings and the mean plane defined [± 0.188(2) Å] by the phenolic

[a] Symmetry code: $' = y, x, -z$.

oxygen atoms are 38.5(2), 22.7(2), 46.8 (2) and 70.6(1)°, which indicate a strong deviance with respect to a regular cone shape. Two pyridine molecules, roughly orthogonal to each other and not involved in hydrogen bonding, are located in the calixarene cavity.

The asymmetric unit in **4**·CH_3CN (**7**) comprises one molecule, without any crystallographic symmetry (Figure 2). The conformation of the calixarene is strikingly similar to that observed in **5**, with a similar hydrogen bonding pattern. The hydrogen bonds linking the phenolic oxygen atoms between them [O(1)···O(2) and O(3)···O(4)] are however much weaker than their counterparts in **5**: such a predominance of OH···N bonds over OH···O ones has already been encountered in **3**, but was less pronounced.[7] The values of the dihedral angles between the four phenolic rings and the mean plane defined [± 0.321(1) Å] by the phenolic oxygen atoms are 41.1(1), 43.0(1), 30.0(1) and 41.1(1)°, [mean value 39(6)°] comparable to those in **5**. However, in the present case, the cavity, which is not as deep as in **5** and **6**, due to the replacement of *tert*-butyl by methyl substituents, is empty. The benzyl substituents are directed towards the exterior of the macrocycle, on the lower rim side.

If the uncomplexed oxa- and azacalixarenes present closely related features, the basic nature of the nitrogen atoms in the latter results in different complexing behaviours, exemplified hereafter in the case of uranyl ions.

Uranyl Ion Complexes

The complexation of one uranyl ion by **2** in the presence of NEt_3 to give $[UO_2(\mathbf{2} - 4H)]^{2-}(HNEt_3^+)_2$·$CHCl_3$·

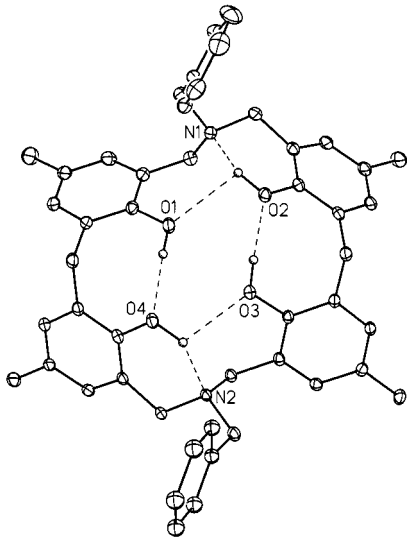

Figure 2. View of *p*-methyl-*N*-benzyltetrahomodiazacalix[4]arene **4** in **7**; hydrogen bonds in dashed lines; hydroxyl protons represented as small spheres of arbitrary radii; other hydrogen atoms and solvent molecule omitted for clarity; only the main component of disordered atoms is represented

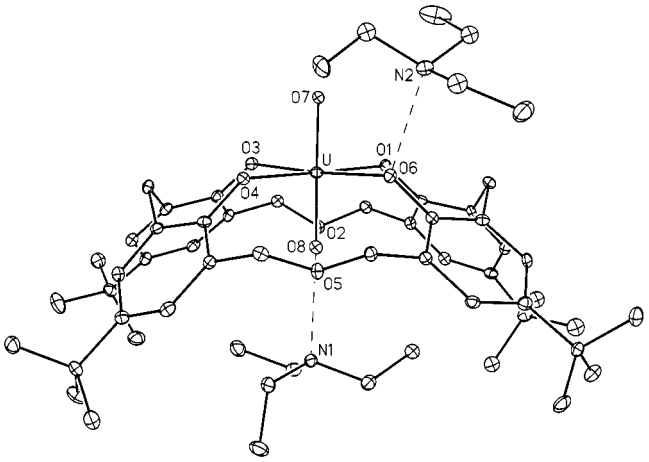

Figure 3. View of the "internal" uranyl ion complex of *p-tert*-butyltetrahomodioxacalix[4]arene **8**; hydrogen bonds in dashed lines; hydrogen atoms and solvent molecules omitted for clarity; only the main component of disordered atoms is represented

CH_3CN (**8**) is accompanied by a conformational change of the macrocycle. As illustrated in Figure 3, the cation is located at the centre of the lower rim, with its main axis perpendicular to it, and bound to the four deprotonated oxygen atoms [mean U−O distance 2.28(3) Å, as observed previously for phenoxide groups[2]]. The molecule presents two orthogonal non-crystallographic symmetry planes with the uranyl axis at their intersection and passing through either the methylene or the ether bridges. Such a square planar equatorial geometry is rather common in calixarene complexes, having been observed in the complexes of *p-tert*-butyldihomooxacalix[4]arene,[2a] *p-tert*-butylcalix[7]arene[2f] and *p*-benzylcalix[7]arene,[2h] but it is rarely so regular [mean $O_{phenol}-U-O_{phenol}$ angle between adjacent phenolic units 90(5)°, mean $O_{uranyl}-U-O_{phenol}$ angle 90(2)°]. In particular, with respect to *p-tert*-butyldihomooxacalix[4]arene, the presence of a second ether link in **2** permits a more symmetrical geometry around the cation. The ether oxygen atoms were not coordinated in the two other uranyl complexes of oxacalixarenes reported.[2a,2i] Also, in the present case, the two ether oxygen atoms are clearly non bonding, being at distances of 3.832(4) and 3.820(4) Å from the uranium atom [values larger than in the previous cases: 3.534(8)[2a] and 3.1(1)[2i] Å] and at distances of 1.812(6) and 1.893(6) Å from the mean plane defined [± 0.027(2) Å] by the four coordinating oxygen atoms. The disruption of the hydrogen bonding pattern of **2** and the location of the four phenolic oxygen atoms in a plane result in a conformation different from those observed in **5** and **6**. The values of the dihedral angles between the four phenolic rings and the mean plane defined by the phenolic oxygen atoms are 47.9(2), 40.0(1), 48.3(1) and 42.9(2)° [mean value 45(4)°]. The two triethylammonium counter-ions in **8** are located as frequently observed, one of them hydrogen bonded to an uranyl oxo atom and included in the calixarene cavity and the other hydrogen bonded to a phenoxide group. We have mentioned above the similarity in size between *p-tert*-butyltetrahomodioxacalix[4]arene and *p-tert*-butylcalix[6]arene; however, these ligands appear very different from equivalent towards uranyl complexation, since the latter gives "external" complexes only.[2d,2g,2k]

Whereas the uranyl ion is located at the centre of the lower rim in the three complexes of oxacalixarenes presently reported, the coordination mode in the complex of the azacalixarene **3**, obtained without a basic agent being added, is completely different. The asymmetric unit in $[UO_2(NO_3)_2\mathbf{3}]\cdot C_5H_5N\cdot CHCl_3$ (**9**) comprises one molecule (Figure 4), which does not possess any true symmetry element, but presents a pseudo symmetry plane containing the atom O(2) and the uranyl ion. The cation is located outside the lower rim array and is bound to two phenoxide ions

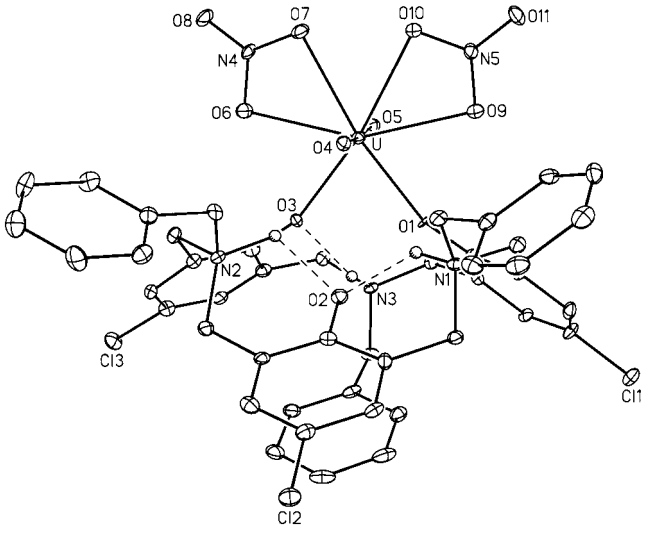

Figure 4. View of the "external" uranyl ion complex of *p*-chloro-*N*-benzylhexahomotriazacalix[3]arene **9**; hydrogen bonds in dashed lines; protons of the ammonium groups represented as small spheres of arbitrary radii; other hydrogen atoms and solvent molecules omitted for clarity

only, with its axis roughly parallel to the mean plane of the molecule. The coordination sphere is completed by two bidentate nitrate ions. Such a six-coordinate environment is unusual in uranyl complexes of calixarenes and is due to the small-bite nature of nitrate ions. The uranium atom is located at 1.556(7) Å from the mean plane defined by the three phenoxide oxygen atoms, a value comparable to that of the neodymium(III) complex of **3** [1.591(2) Å][7] which presents many similarities with **9** (an obvious difference being that the neodymium ion is bound to the three phenoxide oxygen atoms). In both complexes, the three phenolic protons have been transferred to the amine groups upon complexation. An asymmetric array of hydrogen bonds links the ammonium and phenoxide groups in **9**, as in the Nd^{3+} complex. The values of the three dihedral angles between the phenolic rings and the mean plane defined by the three phenolic oxygen atoms are 64.6(3), 2.23(9) and 60.2(3)°: those values are different from those in both the uncomplexed molecule **3** and its Nd^{3+} complex. In the latter case, one of the rings was nearly parallel to the mean plane, as the one corresponding to the non-coordinated phenolic group in **9**, but the two other rings are much more "vertical" in **9**. Two benzyl substituents are located on the lower rim side and directed towards the exterior of the macrocycle whereas the third one is on the upper rim side and directed towards the cavity, in which it occupies a position nearly parallel to that of the uncomplexed phenolic ring.

The question arises as to the role of the acid-enhancing *p*-chlorine substituent in the auto-deprotonation process leading to complex **9** as well as to the Nd^{3+} complex of **3**. Complex **10** brings an answer as well as an interesting point of comparison with complex **8**. The complexation by ligand **4** occurs also without a basic agent being added, giving $[UO_2(NO_3)_2\mathbf{4}]\cdot 0.5CH_3OH\cdot H_2O$ (**10**) in which the complex molecule is neutral. This reaction indicates that the presence of chlorine atoms is not necessary to promote the protons transfer. The asymmetric unit in **10** comprises one complex molecule lacking any symmetry element (Figure 5). The uranyl ion is bound to two phenoxide groups, as in **9**, and its distance from the mean plane defined [± 0.030(5) Å] by the four calixarene oxygen atoms is 1.543(8) Å. The two nitrate counter-ions behave differently: one is bidentate and the other monodentate. This difference with **9** may be ascribed to an $O_{phenol}-U-O_{phenol}$ angle slightly larger in **10** [78.9(3)° to be compared with 75.1(3)° in **9**], which could make the available space insufficient for two bidentate nitrate ions. The two coordinated phenolic groups are deprotonated and the two amine groups are turned into ammonium cations. Hydrogen bonds are formed between each ammonium group and its two neighbouring oxygen atoms, and also between the two non-coordinated, protonated, oxygen atoms O(3) and O(4) and the two phenoxide groups. The modification of the hydrogen bonding pattern with respect to **7** results in a different calixarene conformation. The values of the dihedral angles between the four phenolic rings and the mean oxygen atoms plane are 61.7(3), 59.1(3), 21.0(4) and 16.1(5)°, the two uncomplexed phenolic moieties being closer to the mean plane. Two half-cones are defined on each side of the N(1)···N(2) axis, but their junction does not give an overall cone conformation: the usual terms defining the conformation of classical small calixarenes are of no practical use in the present case, which is reminiscent of larger, flattened calixarenes.

The question arises of the origins of the difference in coordination mode between the uranyl complex of *p*-*tert*-butylhexahomotrioxacalix[3]arene and **8** on the one hand and **9** and **10** on the other. The main reason is likely to be the electrostatic repulsion between the uranyl cation and the two or three ammonium groups in the latter cases, which prevents the cation from being located in the mean plane

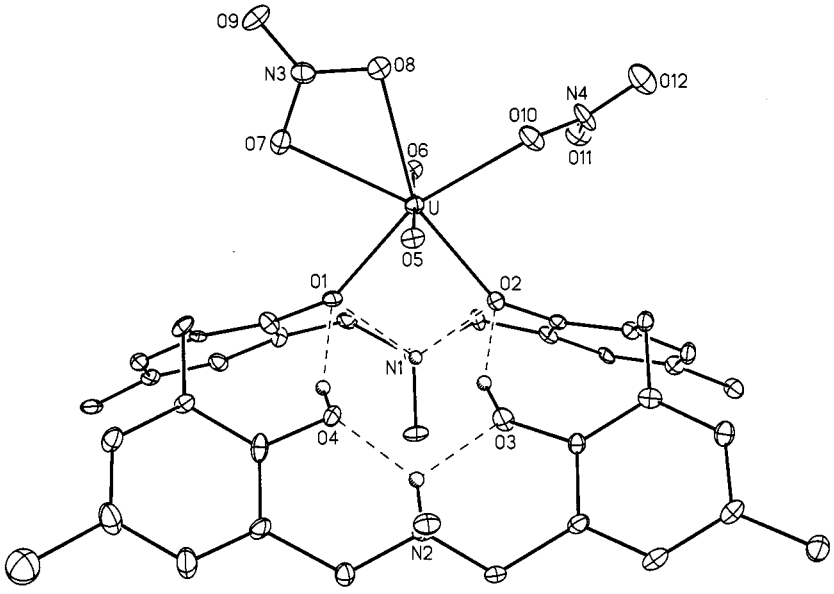

Figure 5. View of the "external" uranyl ion complex of *p*-methyl-*N*-benzyltetrahomodiazacalix[4]arene **10**; hydrogen bonds in dashed lines; protons of the hydroxyl and ammonium groups represented as small spheres of arbitrary radii; other hydrogen atoms, benzyl groups and solvent molecules omitted for clarity

defined by the lower rim. An influence of the steric hindrance associated with the benzyl groups occupying the cavity is not likely, due to the high flexibility of these substituents and the high affinity of phenoxide groups for uranyl ions. In spite of repeated attempts, we did not succeed in growing single crystals of the complex species obtained with azacalixarenes in a basic medium (NEt_3 or DABCO), for comparative purposes. It may be assumed that the deprotonation of the ligand by the base could lead to an anionic complex with a coordination mode closer to that observed with other calixarenes. It must be noted that, by contrast with all the uranyl complexes of calixarenes reported up to now, the azacalixarene complexes **9** and **10** are neutral and not anionic, since the ligand itself is neutral and the metal cation is bound to its counter-ions.

The interest of zwitterions for the simultaneous solvent extraction of cations and anions has recently been pointed out and exemplified by a Schiff base bearing morpholine groups.[10] In this case, the Schiff base with deprotonated hydroxyl groups complexes the metal ion while the protonated morpholine groups complex the counter-ion. The situation is somewhat different in the case of azacalixarenes since the cationic part of the ligand is not directly involved in complexation, but simply pushes the cation into an "external" position in which it cannot reach its usual coordination number from the calixarene and must remain bound to its counter-ions.

Experimental Section

Synthesis

***p-tert*-Butyltetrahomodioxacalix[4]arene (2):** This compound was synthesized as previously reported.[11] Slow evaporation of a solution of **2** in $CHCl_3/CH_3CN$ (1:1) gave colourless single crystals of **2**·$2CH_3CN$ (**5**) suitable for X-ray crystallography, whereas slow evaporation of a solution in pyridine gave colourless single crystals of **2**·$2.5C_5H_5N$ (**6**) of lower quality.

***p*-Methyl-*N*-benzyl-tetrahomodiazacalix[4]arene (4):** A solution of 2,2′-methylenebis(4-methyl-6-hydroxymethyl)phenol (8.00 g, 27.8 mmol) and benzylamine (3.4 g, 31.7 mmol) in 100 mL of xylene was heated under reflux for 34 h. After removal of the solvent under reduced pressure, the resultant oily material was subjected to silica-gel column chromatography with CH_2Cl_2 as an eluent. **4** was obtained as a colourless powder (5.81 g, yield 58.3%). The analytical sample was recrystallized from CH_2Cl_2/C_2H_5OH. M.p. 146−148 °C. − ^1H NMR (270 MHz, $CDCl_3$): δ = 2.17 (s, 12 H, Ar−CH_3), 3.43, 3.60, 4.25 (3bs, 16 H, Ar−CH_2−), 6.69 (d, *J* = 2 Hz, 4 H, Ar−H), 7.03 (d, *J* = 2 Hz, 4 H, Ar−H), 7.34 (br. s, 10 H, side arm Ar−H), 10.6 (br. s, 4 H, Ar−OH). − $C_{48}H_{50}N_2O_4$·$0.5C_2H_5OH$ (741.93): calcd. C 79.32, H 7.20, N 3.78; found C 79.11, H 7.35, N 3.67. Concentration of the mother liquor also afforded 0.31 g (3.3%) of *p*-methyl-*N*-benzyldihomoazacalix-[4]arene. Slow evaporation of a solution of **4** in $CHCl_3/CH_3CN$ (1:1) gave colourless single crystals of **4**·CH_3CN (**7**) suitable for X-ray crystallography.

$[UO_2(2-4H)]^{2-}(HNEt_3^+)_2$·$CHCl_3$·$CH_3CN$ (8): Compound **2** (0.02 g, 0.03 mmol) was dissolved in 6 mL of $CH_3CN/CHCl_3$ (1:1) and 1 mL of NEt_3; a solution of $UO_2(NO_3)_2$·$6H_2O$ (0.03 g, 0.06 mmol) in 2 mL of CH_3CN was then added dropwise, immediately giving an orange solution, which was allowed to slowly evaporate. A few orange single-crystals suitable for X-ray crystallography deposited in three days together with a microcrystalline powder. Microanalysis results including both crystals and powder were unsatisfactory due to the heterogeneous nature of the latter.

$[UO_2(NO_3)_2 3]$·C_5H_5N·$CHCl_3$ (9): Compound **3** (0.15 g, 0.19 mmol) was dissolved in 30 mL of $CH_3CN/CHCl_3$ (1:1) and a solution of $UO_2(NO_3)_2$·$6H_2O$ (0.3 g, 0.6 mmol) in 30 mL of CH_3CN was added dropwise, immediately giving an orange solution. Orange single crystals, unstable out of their mother solution but suitable for X-ray crystallography, were obtained upon recrystallization from pyridine. − $[UO_2(NO_3)_2 3]$·$CHCl_3$·H_2O, $UC_{46}H_{45}Cl_6N_5O_{12}$ (1310.60): calcd. C 42.16, H 3.46; found C 42.06, H 3.35. − FAB-MS $[UO_2$·$C_{45}H_{42}Cl_3N_3O_3]$: *m*/*z* = calcd. 1047.26; found 1048.2.

$[UO_2(NO_3)_2 4]$·$0.5CH_3OH$·H_2O (10): Compound **4** (0.04 g, 0.055 mmol) was dissolved in 3 mL of $CHCl_3$ and a solution of $UO_2(NO_3)_2$·$6H_2O$ (0.04 g, 0.08 mmol) in 5 mL of CH_3OH was added dropwise, immediately giving an orange solution. Orange single crystals suitable for X-ray crystallography were obtained in a few hours. − $UC_{48.5}H_{54}N_4O_{13.5}$ (1146.99): calcd. C 50.79, H 4.75; found C 50.28, H 4.28.

Crystallography

The data were collected on a Nonius Kappa-CCD area detector diffractometer[12] using graphite-monochromated Mo-K_α radiation (0.71073 Å). The crystals were introduced in Lindemann glass capillaries with a protecting "Paratone" oil (Exxon Chemical Ltd.) coating. The data were processed with DENZO-SMN.[13] The structures were solved by direct methods with SHELXS-97[14] and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL-97.[15] No absorption correction was done for **5**, **6** and **7**, the product μ<d> being lower than 0.1. Absorption effects in **8**, **9** and **10** were corrected empirically with the program MULABS from PLATON.[16] Hydroxyl and ammonium protons, as well as those of chloroform molecules, were introduced as found on the Fourier difference maps whereas all other hydrogen atoms in all compounds were introduced at calculated positions (except in the disordered parts). All hydrogen atoms were treated as riding atoms with a displacement parameter equal to 1.2 (OH, NH, CH, CH_2) or 1.5 (CH_3) times that of the parent atom. All non-hydrogen atoms were refined anisotropically, except the disordered ones. Special features for each compound are indicated in the following.

2·$2CH_3CN$ (5): The data were recorded at ambient temperature since the crystals deteriorate at low temperature, which is seemingly due to a phase transition phenomenon. Some soft restraints have been applied on the badly resolved acetonitrile molecules. The absolute structure could not be determined from the value of the Flack parameter.[17]

2·$2.5C_5H_5N$ (6): One *tert*-butyl substituent was found disordered over two positions, which have been refined with occupation factors constrained to sum to unity. The nitrogen atoms were not located in the pyridine molecules (one of them disordered around a symmetry centre).

4·CH_3CN (7): One of the two benzyl substituents was disordered over two positions sharing two carbon atoms, which have been refined with occupation factors constrained to sum to unity.

$[UO_2(2-4H)]^{2-}(HNEt_3^+)_2$·$CHCl_3$·$CH_3CN$ (8): Some disorder was present on one *tert*-butyl group and one triethylammonium

ion, which was modelled with two positions refined with occupation factors constrained to sum to unity. The absolute structure was determined from the value of the Flack parameter [−0.015(6)].

$[UO_2(NO_3)_2]\cdot C_5H_5N\cdot CHCl_3$ (9): The absolute structure was determined from the value of the Flack parameter [−0.013(7)].

$[UO_2(NO_3)_2]\cdot 0.5CH_3OH\cdot H_2O$ (10): The two benzyl substituents were found disordered over two positions each. These four positions, which have been refined with occupation factors constrained to sum to unity for each benzyl moiety, overlap between neighbouring molecules and share one or two atomic positions. The occupation parameters have been chosen so as to take into account the impossibility of a simultaneous occupation of overlapping positions. The methanol solvent molecule was also found disordered over two sites symmetrically related, each affected with a 0.5 occupation. The structure was refined as corresponding to a racemic twin, the fractional contribution of the two components being x and $(1 - x)$, with $x = 0.504(14)$.

Crystal data and structure refinement parameters are given in Table 2. The molecular plots were drawn with SHELXTL.[18] All calculations were performed on a Silicon Graphics R5000 workstation.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-144187−144192 (**5**−**10**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Nickel(II) Tetraazamacrocyclic Complexes with Two Pendant Amino Groups: Electrochemical and Kinetic Studies

Bohdan Korybut-Daszkiewicz,*[a] Joanna Taraszewska,[b] and Bohdan Kamieński[a]

Keywords: Electrochemistry / Kinetics / Macrocyclic ligands / N ligands / Nickel

Isomeric 2,9-bis(amionmethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecanenickel(II) and -4,11-dienenickel(II) complexes (**1**–**4**) were studied by cyclic voltammetry. The thermodynamic stability of Ni^{III} was the greatest in complex **4** with a *trans* configuration of the pendant amino groups. On acidification, the Ni^{II}/Ni^{III} redox process was not observed. After alkalisation the redox process was only recovered in complex **4**. The kinetics of the two-step macrocyclic ring isomerisation in 1 M HCl and DCl was studied, as a function of temperature, by UV/Vis and ^1H NMR techniques. The energies of activation for the isomerisation of the cyclam ring from *trans*-V (**5α**) to *trans*-II (**5β**) and from *trans*-II to *trans*-I (**5γ**) were equal to 22.6 and 26.9 kcal mol^{-1}, respectively.

Introduction

Tetraazamacrocyclic polyamines bearing pendant amine groups are especially interesting for studying the influence of axial coordination on the properties of the coordinated metal ion. It was found that such intramolecular donors can profoundly alter the properties of the complexed metal ions.[1,2] The first examples of such ligands were synthesised by Kaden.[1] Complexes of this type found application in the electrocatalysis of processes such as the reduction of CO_2 to CO[3] and hydrogen evolution.[4] They can be also linked to monoclonal antibodies, allowing the specific labelling of macrocycle-conjugated antibodies with radioisotopes,[5,6] and their consequent use as targeting agents in the diagnosis and therapy of cancers and other diseases.

The behaviour of metal complexes with such ligands is spectacular due to the internal pH-dependent equilibrium between the open and chelated forms of the pendant arm. When the pendant amine group is protonated, the diamagnetic, square-planar Ni^{II} complexes are formed. However, at higher pH values, coordination of the amine group leads to the paramagnetic, octahedral complexes. Such a change of structure gives a colour variation that may find analytical application. Due to the active role of the flexible side-chain, the above class of molecules was named scorpiands.[7] The pH-dependent electrochemical behaviour of Ni^{II} tetraazamacrocyclic complexes containing one pendant amino group was studied by Fabbrizzi et al.,[7] by Kimura et al.,[3] and by us.[8]

Nickel(II) complexes of cyclam derivatives substituted with two pendant amino groups are also the subjects of the pH-dependent equilibria. Cyclam dienes functionalised with two pendant arms – *trans*-2,9-bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-dienenickel(II) diperchlorate and its folded *cis* analogue were first synthesised by Korybut-Daszkiewicz,[9,10] and their crystallographic structure determined.[10,11] Recently, Korybut-Daszkiewicz et al.[12] synthesised and characterised isomeric Ni^{II} complexes of *cis*-2,9-bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane. The coordination of the two pendant amino groups located on the same side of the tetraazamacrocyclic ring forces the ring to adopt a folded conformation. Protonation of the pendant amino groups resulted in the change of the macrocyclic conformation from folded to planar, and further isomerisation.

This paper is devoted to the study of the pH-dependent electrochemical behaviour of both groups of complexes, and the kinetics of their isomerisation by UV/Vis and ^1H NMR spectroscopy. The schematic structures of studied complexes and their protonated forms are presented in Figure 1.

Results and Discussion

Redox Properties of Complexes

The voltammetric behaviour of complexes **1**–**4** was studied in aqueous solutions containing 0.1 M NaCl as supporting electrolyte. In the negative potential range, reduction of Ni^{II} to Ni^{I} was not observed. The cyclic voltammograms recorded in the positive potential range on the glassy carbon (GC) electrode are shown in Figure 2. In each complex, Ni^{II} was oxidised to Ni^{III} at a potential corresponding to peak *a* and Ni^{III} was reduced to Ni^{II} at a potential corresponding to peak *b*. The redox process Ni^{II}/Ni^{III} in all complexes was reversible. The values of formal potentials E_f, calculated as midpoints between corresponding anodic and cathodic peaks, were 0.70V, 0.66V, 0.60V, and 0.43V for complexes **1**, **2**, **3**, and **4**, respectively.

The voltammetric behaviour of complex **1** at various pH values is shown in Figure 3A. After addition of HCl (pH = 2, curve 2) the current diminished about 25%, in comparison with that in neutral solution, and did not change with time (measurements up to 40 min). The value of E_f shifted

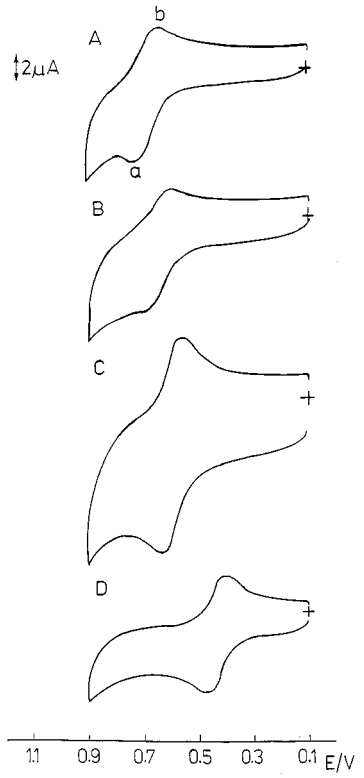

Figure 2. Cyclic voltammograms of $5\cdot10^{-4}$ M complexes **1** (A), **2** (B), **3** (C), and **4** (D) at a GC electrode in aqueous 0.1 M NaCl solution; scan rate 0.05 Vs^{-1}

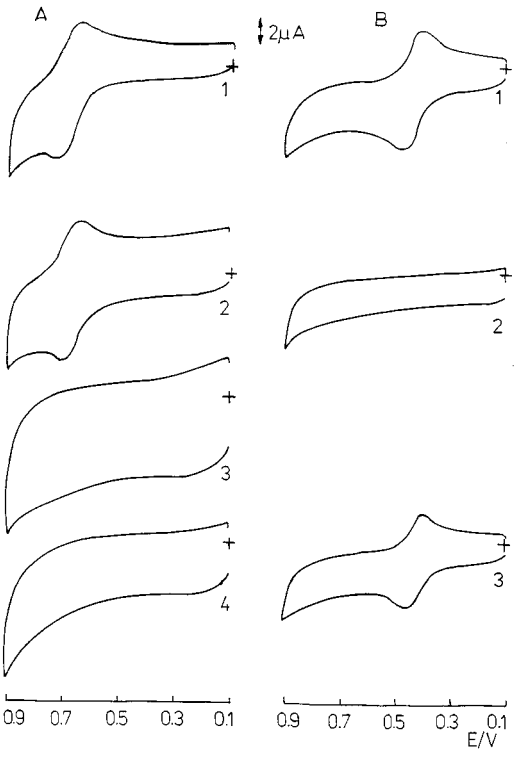

Figure 3. Cyclic voltammograms of $5\cdot10^{-4}$ M complexes **1** (A) and **4** (B) in 0.1 M NaCl as a function of the pH; (A) curve 1: pH = 7; curve 2: pH = 2; curve 3: pH = 1; curve 4: pH = 7; (B) curve 1: pH = 7; curve 2: pH = 3; curve 3: pH = 7

to 0.67 V. Further acidification (pH = 1) caused a rapid decrease of current with time, ultimately resulting in the disappearance of the redox process (curve 3). A subsequent alkalisation of solution did not change the picture even after 2 d (curve 4). The same behaviour was observed for complex **3**. In complex **2** the redox process Ni^{II}/Ni^{III} disappeared already at pH = 3, and did not recover after alkalisation. In complex **4** (Figure 3B) the redox process Ni^{II}/Ni^{III} disappeared at pH = 3, (curve 2) however, it was recovered after the subsequent alkalisation of solution (curve 3).

A comparison of E_f values for the redox process Ni^{II}/Ni^{III} in tetraazamacrocyclic complexes with one and with two pendant amino groups in neutral solutions is presented in Table 1. In tetraazamacrocyclic complexes with one pendant amino group, the most favourable access to the trivalent state was in 6-aminocyclam and the relative stabilization of Ni^{III} was the lowest in *N*-(aminomethyl)cyclam. This is based on the fact that the secondary amines are intrinsically more basic than the tertiary amines, and the interactions of tertiary nitrogen atoms with the metal ion are weaker than those of the secondary amine nitrogen atoms.[13,14]

Table 1. Formal potentials E_f of Ni^{II} tetraazamacrocyclic complexes with one and two pendant amino groups

Complex	E_f ([V] vs.MCE)	Ref.
Ni^{II}-5-AmMe-5,12-diMe-cyclam	0.655	[8]
Ni^{II}-1-AmEt-cyclam	0.740	[7]
Ni^{II}-6-Am-cyclam	0.560	[3]
1	0.700	this work
2	0.660	this work
3	0.600	this work
4	0.430	this work

In complexes **1**−**3**, with two pendant amino groups that are in a folded conformation, the potential of the Ni^{II}/Ni^{III} couple (Table 1) was similar to that in *N*-(aminoethyl)cyclam and 5-aminomethyl-5,12-dimethylcyclam. However, in complex **4**, which is in the *trans* conformation, it was much less positive. From the point of view of the structure of the coordination sphere one can conclude that the thermodynamic stabilization of Ni^{III} is more effective in the *trans* complex, where the macrocycle surrounds the metal ion in a square-planar manner, than in the *cis* analogues with a folded conformation of the amine. A similar effect has been observed by Taraszewska et al.[15] for other nickel azamacrocyclic complexes.

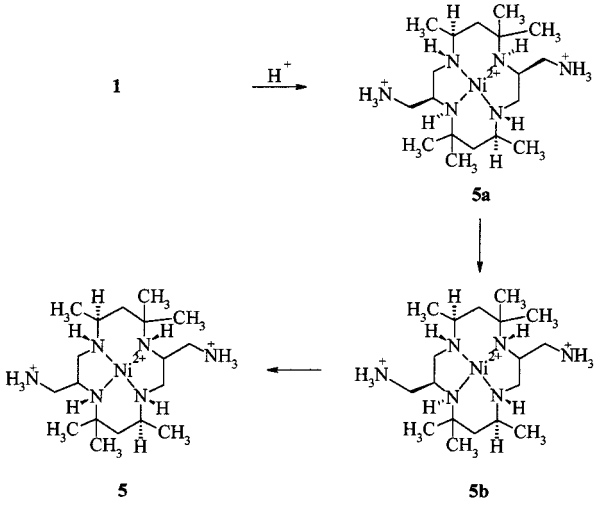
In acidic solutions the behaviour of complexes with two pendant amino groups was different to those with one pendant group. For 5-aminomethyl-5,12-dimethylcyclam studied by us previously[8] at pH = 0.8 we recorded two anodic peaks at potentials 0.65 V and at 0.85 V corresponding to the Ni^{II} oxidation from the complex with a deprotonated and with a protonated amino group, respectively. In more acidic solutions, only a peak at 0.85 V was recorded. Similar behaviour has been described by Fabbrizzi et al.[7] Applying CV with fast scan rates we could record the reduction peak of Ni^{III} from the square-planar complex.[8] In this way we proved experimentally for the first time the existence of Ni^{III} in tetraazamacrocyclic complex in the square-planar form, which is unusual for this type of complex, and has only been observed in some anionic tetraazamacrocyclic complexes.[16] On the basis of the stop-flow experiments we estimated the rate constant of the decoordination of the pendant amino group as equal to 815 s^{-1} (at 25 °C). We observed the reduction of Ni^{II} to Ni^{I}, but the complex of Ni^{I} was not stable.

In complexes with two pendant amino groups studied here, the oxidation of Ni^{II} from the protonated forms was not observed. It may be connected with the presence of many methyl groups in the macrocyclic rings, which forbid the access of axial substituents (solvent or anions), therefore Ni^{III} cannot be formed.

The lack of the redox couple Ni^{II}/Ni^{III} after alkalisation of solutions containing protonated forms of complexes **1**−**3** highlights the fact that the macrocyclic ring cannot be refolded, and coordination of the pendant NH_2 groups to Ni^{II} ion is impossible. It was only possible in complex **4**, which in deprotonated and protonated forms has a planar conformation of the macrocyclic ring with pendant arms in the *trans* configuration. Nevertheless, the octahedral folded complexes **1**−**3** could be regenerated in a basic sodium perchlorate solution.[9,11,12]

Kinetic Studies

As has been described in a previous paper,[12] protonated complex **1** undergoes isomerisation connected with inversion of configuration of N(1) and N(8) nitrogen atoms and simultaneous conformation changes of the six-membered chelate rings. The isomerisation pathway is shown in Scheme 1. The kinetics of isomerisation was followed by UV/Vis and ^1H NMR spectroscopy.



Scheme 1

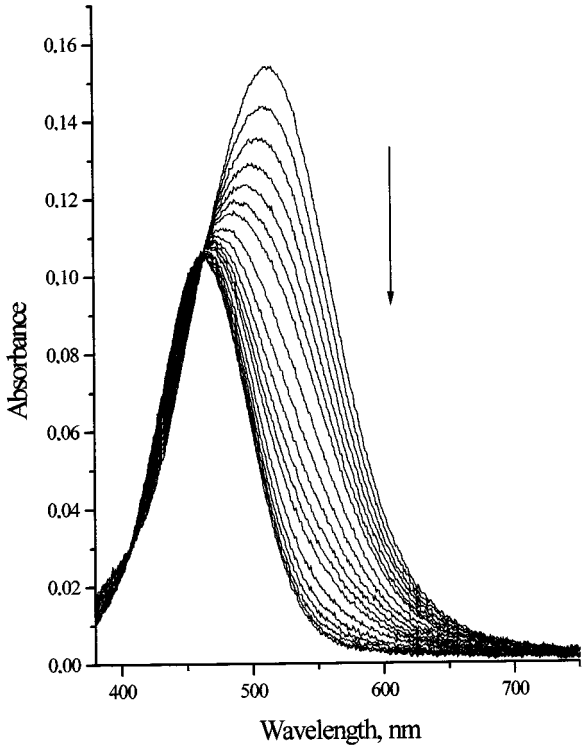


Figure 4. Monitoring of the isomerisation of **5α** into **5β** by UV/Vis spectroscopy; changes of absorption with time recorded for $1 \cdot 10^{-3}$ M complex **1** dissolved in 1 M HCl at 35°C

UV/Vis Studies

Measurements were carried out in solutions of $1 \cdot 10^{-3}$ M of complex **1** dissolved in 1 M HCl in the temperature range 20−45 °C. Changes of absorption with time at 35 °C are shown in Figure 4. The absorption maximum gradually changed from 515 nm, characteristic for complex **5α** (formed from **1** upon protonation) to 462 nm, which is characteristic for isomer **5β**. The steady state was reached after 2.5 h. Absorption changes connected with this isomerisation process were monitored at the wavelength 580 nm. Plots of the absorbance changes vs. time were approximated by the relationship $A(t)/A_o = \exp(-kt)$ for up to 3 half-times, which means that this isomerisation process followed a first-order kinetics. The same procedure was adopted at other temperatures.

Kinetics of isomerisation depended on the acid concentration. A similar experiment carried out in solution acidified with 2 M HCl showed that the kinetics of isomerisation was three times slower ($k = 0.38\ h^{-1}$, 35 °C). In 0.1 M HCl a fast isomerisation to the isomer **5γ** was observed. Such dependence on the acid concentration suggests that the proton dissociation at N(1) and N(8) is the rate determining step in these isomerisation processes. At 35 °C in 0.1 M HCl the inversion of configuration at N(1) and N(8) is fast, and isomer **5γ** is formed in a short time. In 1 M HCl the inversion at the first nitrogen atom is much faster than at second one, therefore we were able to follow the pathway **5α** to **5β**. The isomerisation of **5β** to **5γ** in this medium was followed at higher temperatures by ^{1}H NMR technique (Figure 5).

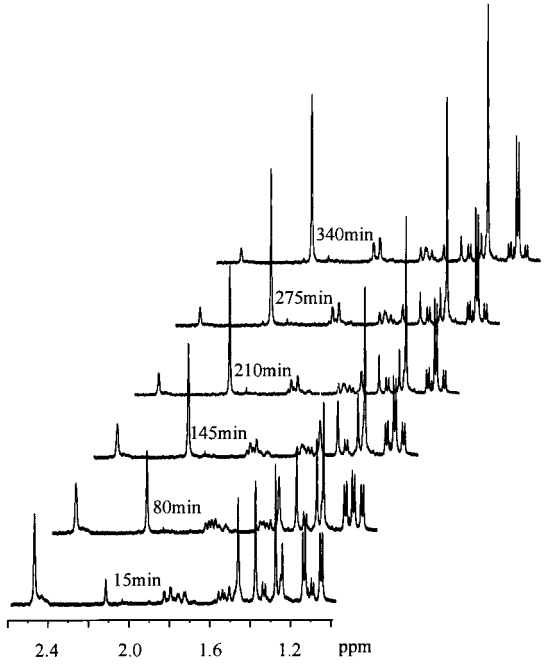

Figure 5. Monitoring of the isomerisation of **5β** into **5γ** by ^{1}H NMR spectroscopy; the methyl group absorption region of the 500 MHz spectra in 1 M DCl solution at 55°C

^{1}H NMR Measurements

The ^{1}H NMR measurements were carried out in $1 \cdot 10^{-3}$ M solutions of complex **5β** in 1 M DCl in the temperature range 40−60 °C. The first spectrum was collected 15 min after dissolution of the sample and the following spectra were measured every 62.5, 32.5, 42.5, 32.5, and 18 min up to 3 half-times at 40, 45, 50, 55, and 60 °C, respectively. The concentrations of the isomer **5β** was followed by integration of 4 proton signal at δ = 2.40−2.53 (overlapping 1 proton multiplet and methyl group singlet) (I_β), and that of the isomer **5γ** by integration of 6 proton methyl group singlet at δ = 2.09−2.16 (I_γ). Plots of the concentration changes vs. time followed a first-order kinetics approximated by the relationship $c(t)/c_0 = \exp(-kt)$ where $c(t)/c_0 = 3I_\beta/(3I_\beta + 2I_\gamma)$.

The values of rate constant k as a function of temperature for both processes are collected in Table 2. The activation energies E_a calculated from this relationship (Figure 6)

Table 2. Dependence of the rate constants of isomerisation on temperature for pathways **5α**−**5β** and **5β**−**5γ** in 1 M HCl and DCl solutions, respectively

Temp. [°C]	**5α**−**5β** k [h^{-1}][a]	**5β**−**5γ** k [h^{-1}][b]
20	0.164	
25	0.336	
30	0.531	
35	1.031	
40	1.785	0.050

50		0.204
55		0.359
60		0.651

[a] UV/Vis. − [b] ^{1}H NMR.

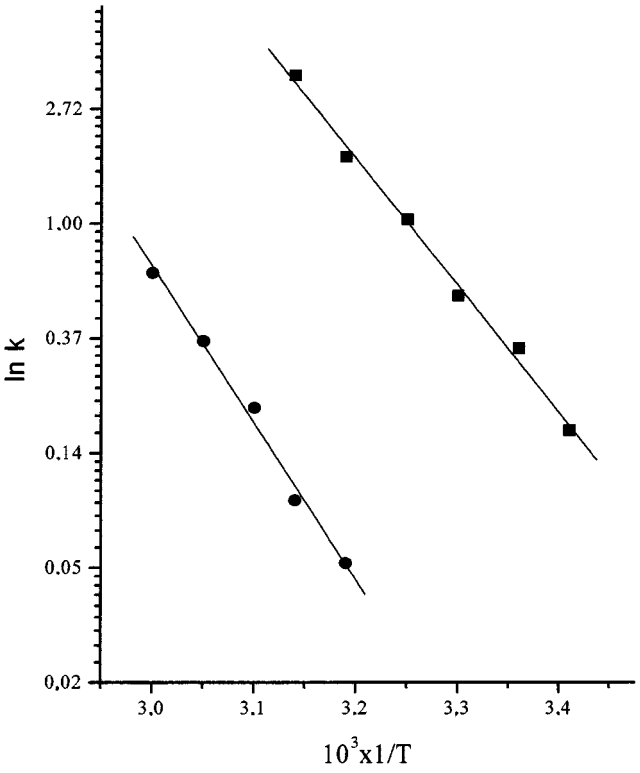

Figure 6. Plots of ln k vs $10^3 \times 1/T$ for the isomerisation of **5α** into **5β** (■) and **5β** into **5γ** (•)

are equal to 22.6 ± 0.7 and 26.9 ± 1.0 kcal mol^{-1} for isomerisation of **5α** into **5β** and **5β** into **5γ**, respectively.

Conclusion

The redox potentials of the Ni^{II}/Ni^{III} couple in complexes **1**−**3**, which are in a folded conformation, were similar to those of complexes with one pendant amino group. However, the thermodynamic stability of Ni^{III} was significantly higher in complex **4**, which exists in a *trans* configuration with a planar conformation of macrocyclic ring. This observation seems to be a general one. The redox process Ni^{II}/Ni^{III} disappeared in acidic solutions and after subsequent alkalisation was recovered only in complex **4** in *trans* configuration.

Protonation of folded complex **1** led to the formation of thermodynamically unstable complex **5α** with a *trans*-V conformation of the macrocyclic ring. Studies in 1 M HCl enabled us to follow the kinetics of stepwise isomerisation of the ring from **5α** through **5β** (*trans*-II) to **5γ** (*trans*-I). The kinetics of isomerisation was followed by UV/Vis and ^{1}H NMR techniques as a function of temperature. The rate constants of the pathway **5α**−**5β** were much higher than those of **5β**−**5γ**. The corresponding activation energies are 22.6 and 26.9 kcal·mol^{-1}, respectively.

Experimental Section

Materials: Complexes **1**−**4** and **5β** were synthesized as described in ref.[12,9,10], respectively. All chemicals were p.a. grade reagents. Triply distilled water was used. The third distillation was carried out from an all-quartz still.

Instrumentation: Cyclic voltammograms of complexes **1**−**4** were measured at a glassy carbon (GC-20) electrode. The counter electrode was a Pt plate. A 1 M aqueous calomel electrode (MCE) was used as the reference electrode. It was connected to the electrolytic cell via an intermediate vessel filled with the solution under investigation. Solutions were deaerated by flushing with pure argon. A measuring system consisting of EPA-20A potentiostat, an EG-20 functions generator (ELPAN Poland) and an *x*,*y* recorder. − The UV/Vis spectra were measured by a Cary 1E (Varian) spectrophotometer. − The 500 MHz ^{1}H NMR spectra were measured in 1 M DCl solutions with a Bruker DRX500 Avance spectrometer.

Acknowledgments

The authors are grateful to Mrs. S. Pawłowska for her great help in electrochemical and UV/Vis measurements. We are indebted to Prof. P. Sobota from Wrocław University for help in estimation of rate constant of de-coordination of a pendant arm by stop-flow method.

A Novel Redox-Active Conjugated Palladium Homobimetallic Complex

Toshiyuki Moriuchi,[a] Seiji Bandoh,[a] Manabu Miyaishi,[a] and Toshikazu Hirao*[a]

Keywords: Coordination modes / Molecular dynamics / N ligands / Palladium / Redox chemistry

The π-conjugated molecule *N,N′*-bis(4′-dimethylaminophenyl)-1,4-benzoquinone diimine (L^2) was incorporated into the palladium(II) complex **1** bearing the *N,N′*-bis(2-phenylethyl)-2,6-pyridinedicarboxamide ligand, to afford the redox-active conjugated palladium(II) homobimetallic complex **2**. An X-ray crystal structure determination of **2** reveals that two palladium complex units are bridged by the quinone diimine moiety to form the C_2-symmetrical 2:1 complex with an *anti* configuration, and that the bridging π-conjugated spacer moieties are aligned along a straight line almost parallel to the *a* axis, to form the columns of the π-conjugated molecules in the molecular packing. Variable temperature ^{1}H NMR studies of the conjugated complex **2** indicate that the *syn* configuration is enthalpically more favorable than the *anti* configuration in CD_2Cl_2 by 1.0 kcal/mol, but entropically less favorable by 4.5 cal/mol from the van't Hoff plot. The redox function of the quinone diimine moiety is modulated by complexation with the palladium complex **1**. The conjugated complex **2** shows three separate redox waves assignable to the successive one-electron reduction of the quinone diimine moiety and one-electron oxidation process of the two terminal dimethylamino groups. Chemical reduction of **2** in THF with $CoCp_2$ resulted in the appearance of ESR signals with weak ^{105}Pd coupling centered around g = 2.0041. The added electrons are considered to be delocalized over the Pd^{II}-quinone diimine d-π* system in the complex.

Introduction

Quinone diimines can exist in three redox forms: the reduced phenylenediamide dianions, the partially reduced semiquinone diimine radical anions, and the oxidized neutral quinone diimines. The combination of this redox behavior and complexation with transition metals provides an efficient redox system. *o*-Benzoquinone diimines have attracted much attention as a redox-active compound in this context.[1] However, transition metal complexes with *p*-benzoquinone diimine ligands have been investigated in only a few cases and the coordination behavior of *p*-benzoquinone diimine has hitherto remained unexplored.[2] In a previous paper, the emeraldine base form of polyanilines as π-conjugated polymers, which contains a *p*-benzoquinone diimine unit, has been revealed to coordinate to transition metals, affording conjugated complex systems.[3] The polymer complex can effectively serve as an oxidation catalyst,[4] in which the quinone diimine moiety is considered to contribute to a reversible redox process in the catalytic cycle of a transition metal. These results prompted us to investigate the redox properties of the transition metal complexes with *p*-benzoquinone diimines and to characterize the complexes structurally. We herein report the synthesis of the palladium(II) homobimetallic complex with a bridging π-conjugated *p*-benzoquinone diimine.

Results and Discussion

The construction of a conjugated complex system was demonstrated by use of a redox-active π-conjugated molecule, *N,N′*-bis(4′-dimethylaminophenyl)-1,4-benzoquinone diimine (L^2).[5] Complexation with a palladium complex bearing a tridentate ligand, which has one open coordination site, is expected to provide the bimetallic conjugated complex. In this context, the palladium(II) complex [(L^1)Pd(MeCN)] (**1**) bearing one interchangeable coordination site was prepared by treatment of $Pd(OAc)_2$ with the *N*-heterocyclic tridentate podand ligand, *N,N′*-bis(2-phenylethyl)-2,6-pyridinedicarboxamide (L^1H_2),[6] in acetonitrile. The X-ray crystal structure of **1**[7] indicates that the open coordination site is occupied by an ancillary acetonitrile, presenting the complex **1** with one labile ligand.[8] Treatment of the palladium(II) complex **1** with L^2 in acetonitrile led to the formation of the 2:1 complex [(L^1)Pd(L^2)Pd(L^1)] (**2**, Scheme 1).

The structure of the conjugated complex **2** was confirmed by X-ray crystallography. The solid-state molecular structure reveals that the two [(L^1)Pd] units are bridged by the quinone diimine moiety of L^2 to form the C_2-symmetrical 2:1 complex ***anti*-2** with a Pd−Pd separation 8.17 Å, as depicted in Figure 1. Crystallographic data for ***anti*-2** can be found in Table 1, with selected bond lengths and bond angles listed Table 2. Each nitrogen atom of the quinone diimine moiety of L^2 is deviated from the least-squares plane of C(37)−C(38)−C(39*)−C(37*)−C(38*)−C(39) by 4.7° in the same direction, probably due to coordination to a palladium atom which is deviated from the plane by 10.7°. One phenyl ring of the podand moiety of [(L^1)Pd] is oriented in a near face-to-face arrangement at a distance of ca. 3.9 Å with the phenyl ring of another [(L^1)Pd], suggesting a weak π-stacking interaction. This interaction might cause

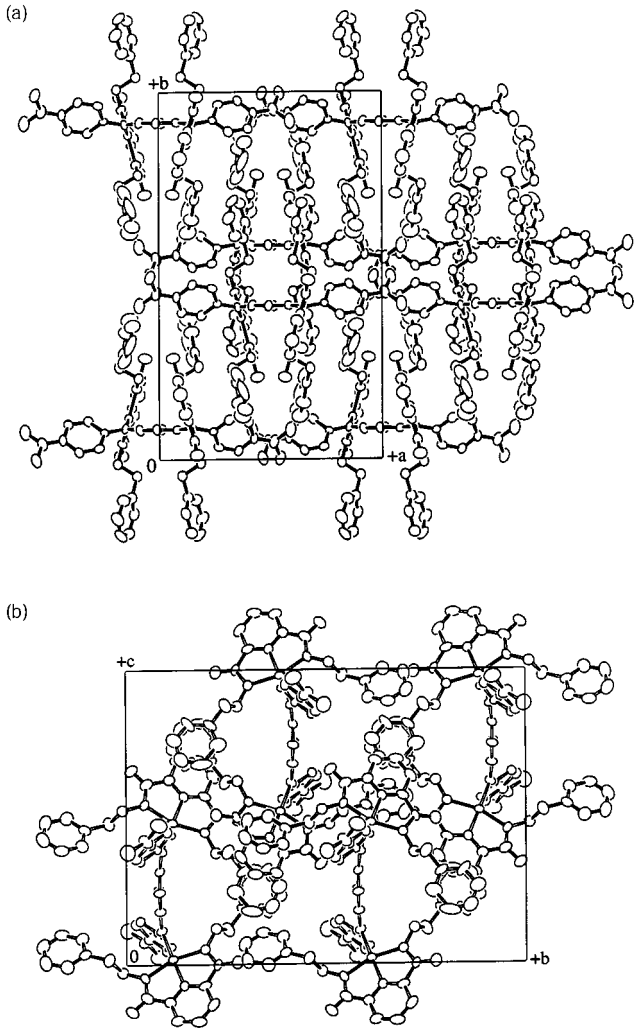

Figure 2. (a) Projection down the *c* axis and (b) projection down the *a* axis of the molecular packing of ***anti*-2**

the above-mentioned deviation of the palladium atoms. Due to π-conjugation of L^2, the orientation of each phenylene ring should be within a limited range of locations parallel to the quinone diimine moiety. The steric interaction between the hydrogen atom at C(32) and the hydrogen atom at C(38), however, causes the phenylene ring of L^2 to rotate away from this orientation, resulting in a conformation with a dihedral angle of 50.1° between the phenylene and quinone planes. Each phenylene ring of L^2 has an opposite dihedral angle with respect to the quinone plane, causing a propeller twist of 79.8° between the planes of the two phenylene rings. The least-squares plane of N(1)–N(2)–N(3)–Pd is at an angle of 109.7° instead of 90° from the plane of C(31)–N(4)–C(37) as a result of the twist of the π-conjugated plane of L^2. Another interesting feature is that the bridging π-conjugated molecules L^2 are aligned along a straight line almost parallel to the *a* axis in the molecular packing (Figure 2a). The coordination planes of palladium composed of the pyridyl and two amide moieties occupy nearly the *bc* plane (Figure 2b).

Variable temperature ^{1}H NMR studies of the conjugated complex **2** indicated interesting molecular dynamics in solution (Figure 3). As the temperature was lowered, the peaks of the *syn* conformer ***syn*-2** appeared and increased gradually. It should be noted that the conjugated complex **2** prefers the *anti* configuration at temperatures above 220 K and the *syn* configuration below this temperature. The equilibrium constant K_{eq} between ***anti*-2** and ***syn*-2** was calculated from variable temperature ^{1}H NMR spectra (Scheme 2). The temperature dependence of K_{eq} is used to construct the van't Hoff plot of $\ln K_{eq}$ vs. T^{-1} (Figure 4). The *syn* configuration is enthalpically more favorable than the *anti* configuration in CD_2Cl_2 by 1.0 kcal/mol, but entropically less favorable by 4.5 cal/mol from the van't Hoff plot.

The interesting redox properties of **2** were disclosed by cyclic voltammetry. The conjugated complex **2** in CH_2Cl_2 shows three separate redox waves ($E_{1/2}$ = –1.49 V, –0.85 V, and 0.20 V vs. Fc/Fc^+) as depicted in Figure 5. The waves at –1.49 V and –0.85 V are assigned to the successive one-electron reduction of the quinone diimine moiety to give

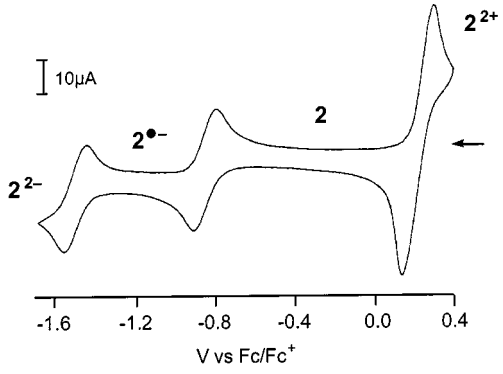

Figure 5. Cyclic voltammogram of **2** (1.0×10^{-3} M) in CH_2Cl_2 (0.1 M nBu$_4$NClO$_4$) at a glassy carbon working electrode with scan rate = 100 mV/s under Ar

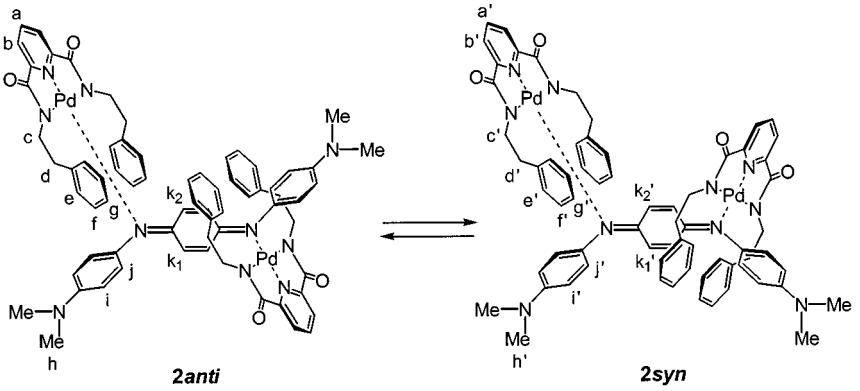
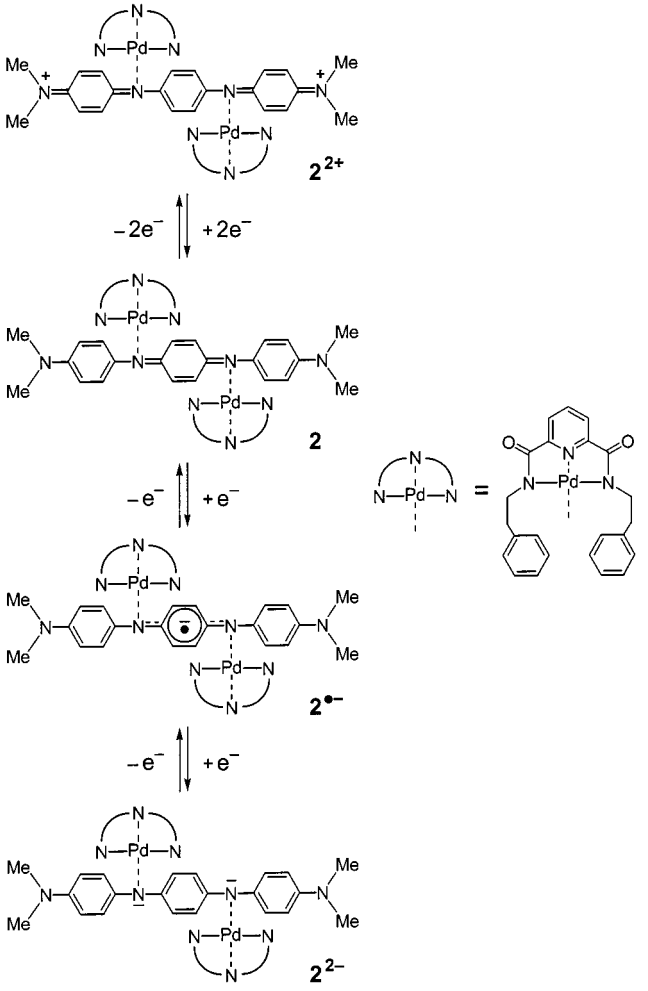
the corresponding reduced species. This result is in sharp contrast to the redox behavior of L^2 in CH_2Cl_2, in which an irreversible reduction wave is observed at −1.67 V. Generally, the generated radical anion appears to be unstable, although this depends on the availability of a proton source.[9] In the case of reduction of the complex **2**, the added electrons are considered to be delocalized over the Pd^{II}-quinone diimine d-π* system. Compared with the uncomplexed one, the complexed quinone diimine becomes stabilized as an electron sink. Accordingly, the redox properties of the quinone diimine moiety are modulated by complexation with the palladium complex **1**, affording a multiredox complex system. Furthermore, the most positive anodic peak with twice height ($E_{1/2}$ = 0.20 V) is attributable to a one-electron oxidation process of the two terminal dimethylamino groups.[10] A substantial positive shift of this



Scheme 2. Numbering of carbon atoms of the conjugated complex **2**; the left palladium complex moiety in each isomer is moved for labelling



Scheme 3. Schematic representation of the redox behavior of the conjugated complex **2**

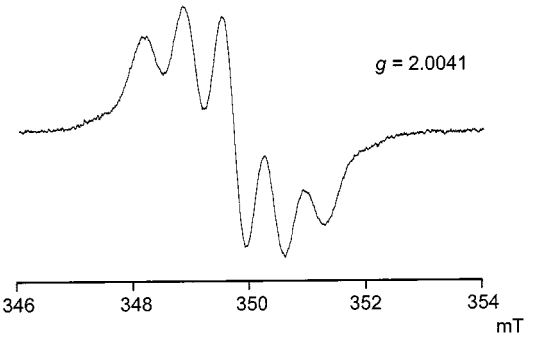


Figure 6. ESR spectrum of $\mathbf{2}^{\bullet-}$ in THF at 290 K

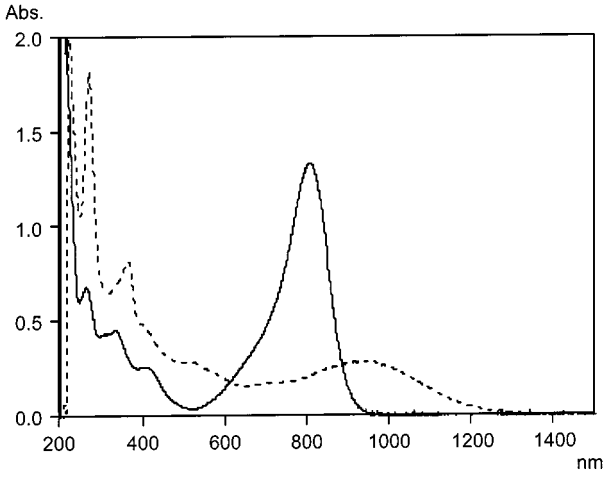

Figure 7. Electronic spectra of **2** (−) and $\mathbf{2}^{\bullet-}$ (− −) (2.0×10^{-5} M) in THF

oxidation wave compared with the free quinone diimine L^2 ($E_{1/2} = -0.08$ V) is consistent with the coordination of L^2 to palladium. The redox behavior of the conjugated complex **2** is depicted schematically in Scheme 3.

To gain insight into the redox properties of the conjugated complex **2**, the redox behavior was investigated spectroscopically. The chemical reduction of **2** in THF with $CoCp_2$ resulted in the appearance of the ESR signals centered around $g = 2.0041$, with hyperfine coupling to two equivalent nitrogen nuclei and four equivalent protons and weak coupling to the ^{105}Pd nucleus (natural abundance 22.2%, $I = 5/2$) as shown in Figure 6, indicating that the unpaired electron is located mostly on the quinone diimine moiety. Some delocalization onto the metal is revealed by the weak satellite lines due to ^{105}Pd coupling. The ESR signal could be approximately simulated by assuming the following parameters: $A_N = 6.6$ G; $A_H = 1.6$ G; $A_{Pd} = 3.4$ G.

The electronic spectrum of a solution of **2** in THF exhibits a strong broad absorption around 806 nm ($\log \varepsilon = 4.82$), probably assignable to a low-energy charge-transfer transition with significant Pd content (Figure 7). The generated semiquinone diimine complex $\mathbf{2}^{\bullet-}$ could be characterized by a broad absorption around 931 nm ($\log \varepsilon = 4.16$) as illustrated in Figure 7. This broad absorption, the assignment of which is not yet clear, might be a charge-transfer transition or an internal transition with significant Pd content.

Conclusion

Two palladium atoms were demonstrated to be bridged by the quinone diimine moiety of the π-conjugated molecule L^2 to afford the novel redox-active conjugated homobimetallic complex system, in which the complexed quinone diimine becomes stabilized as an electron sink. The *syn* configuration of the conjugated complex **2** is enthalpically more favorable than the *anti* one in CD_2Cl_2, but entropically less favorable. These results are related to the conjugated complexes with polyanilines. Bimetallic complexes composed of π-conjugated bridging spacers and terminal redox-active transition metals have currently received much attention as functional materials.[11] From this point of view, the potential use of the present bimetallic complex characterized by the redox-active π-conjugated bridging spacer appears to be promising.

Experimental Section

General Methods: All reagents and solvents were purchased from commercial sources and were further purified by the standard

methods, if necessary. Melting points were determined on a Yanagimoto Micromelting Point Apparatus and were uncorrected. Infrared spectra were obtained with a Perkin−Elmer Model 1605 FT-IR. ^{1}H NMR spectra were recorded on a JEOL JNM-GSX-400 (400 MHz) spectrometer with tetramethylsilane as an internal standard. Mass spectra were run on a JEOL JMS-DX303HF mass spectrometer. Electronic spectra were obtained using a Hitachi U-3500 spectrophotometer.

N,N′-Bis(2-phenylethyl)-2,6-pyridinedicarboxamide (L^1H_2) was prepared according to the method reported in a previous paper.[6b] *N,N′*-Bis(4′-dimethylaminophenyl)-1,4-benzoquinone diimine (L^2) was prepared by the literature method.[5]

Preparation of [(L^1)Pd(MeCN)] (1): A mixture of L^1H_2 (18.7 mg, 0.05 mmol) and $Pd(OAc)_2$ (11.2 mg, 0.05 mmol) in acetonitrile (5 mL) was stirred under argon at room temperature for 2 h. After evaporation of the solvent, the palladium complex **1** was isolated in 96% yield (24.9 mg) as yellow crystals by recrystallization from acetonitrile. M.p. 165−167 °C (uncorrected). − IR (KBr): $\tilde{\nu}$ = 1590, 1388 cm^{-1}. − ^{1}H NMR (400 MHz, CD_3CN, 298 K): δ = 2.78 (t, *J* = 7.3 Hz, 4 H), 3.40 (t, *J* = 7.3 Hz, 4 H), 7.19−7.33 (m, 10 H), 7.56 (d, *J* = 7.7 Hz, 2 H), 8.01 (t, *J* = 7.7 Hz, 1 H). − MS (FAB): *m*/*z* = 478 [(M − CH_3CN)$^+$ + 1]. − $C_{25}H_{24}N_4O_2Pd$ (518.91): calcd. C 57.87, H 4.66, N 10.80; found C 57.83, H 4.75, N 10.76.

Preparation of [(L^1)Pd(L^2)Pd(L^1)] (2): A mixture of **1** (20.8 mg, 0.04 mmol) and L^2 (6.9 mg, 0.02 mmol) was stirred in acetonitrile (20 mL) under argon at room temperature for 2 h. After evaporation of the solution, the conjugated palladium complex **2** was isolated in 73% yield as dark green crystals by recrystallization from chloroform/hexane. M.p. 227−229 °C (decomp.). − IR (KBr): $\tilde{\nu}$ = 1588, 1359, 1161 cm^{-1}. − UV/Vis (THF): λ_{max} (log ε) = 806 (4.82) nm. − ^{1}H NMR (400 MHz, CD_2Cl_2, 220 K, *anti*/*syn* = 1:1): δ = 2.15−2.30 (m, 8 H, *syn* and *anti*), 2.38−2.50 (m, 8 H, *syn* and *anti*), 2.76−2.90 (m, 8 H, *syn* and *anti*), 3.00−3.10 (m, 8 H, *syn* and *anti*), 3.13 (s, 12 H, *anti*), 3.20 (s, 12 H, *syn*), 6.75−6.92 (m, 24 H, *syn* and *anti*), 6.97−7.10 (m, 24 H, *syn* and *anti*), 7.38 (s, 2 H, *syn*), 7.62 (dd, *J* = 10.3, 2.2 Hz, 2 H, *anti*), 7.70 (d, *J* = 8.1 Hz, 4 H, *syn*), 7.76 (d, *J* = 8.1 Hz, 4 H, *anti*), 7.95 (d, *J* = 8.8 Hz, 4 H, *syn*), 7.99 (d, *J* = 8.8 Hz, 4 H, *anti*), 8.10 (t, *J* = 8.1 Hz, 2 H, *syn*), 8.15 (t, *J* = 8.1 Hz, 2 H, *anti*), 8.95 (dd, *J* = 10.3, 2.2 Hz, 2 H, *anti*), 9.08 (s, 2 H, *syn*). − MS (FAB): *m*/*z* = 1301 [M$^+$ + 1]. − $C_{68}H_{66}N_{10}O_4Pd_2$ (1300.18): calcd. C 62.82, H 5.12, N 10.77; found C 62.50, H 5.11, N 10.60.

Generation of [(L^1)Pd(L^2)$^{\bullet-}$Pd(L^1)] (2$^{\bullet-}$): For spectroscopic purposes, **2**$^{\bullet-}$ was generated by treatment of **2** with 1 equiv. of cobaltocene in THF. The cobaltocene and cobaltocenium ion present in the reaction mixture did not significantly interfere with the electronic spectrum because of their low extinction coefficient below 400 nm.

Equilibrium Measurement for 2: Measurement of the equilibrium constants at various temperatures was carried out by integration of the appropriate peaks during ^{1}H NMR spectroscopy. Spectra were taken in CD_2Cl_2 at 15 K intervals from 198 to 273 K. The thermodynamic parameters were determined from the van't Hoff plot of $\ln K_{eq}$ vs. T^{-1}.

Electrochemical Experiments: The cyclic voltammetry measurements were performed on a BAS CV-50 W voltammetry analyzer in deaerated acetonitrile containing 0.1 M *n*Bu_4NClO_4 as a supporting electrolyte at 298 K with a three-electrode system consisting of a highly polished glassy carbon working electrode (BAS), a platinum auxiliary electrode (BAS), and an Ag/AgCl (0.01 M) reference electrode (BAS) at 100 mV/s scan rate. Potentials are given vs. Fc/Fc^+.

X-ray Crystal Structure Determination of *anti*-2: A dark green crystal of the conjugated palladium complex ***anti*-2** with approximate dimensions of 0.20 × 0.20 × 0.30 mm was mounted on a glass fiber. The measurement was made on a Rigaku AFC5R diffractometer with graphite monochromated Mo-K_α radiation and a rotating anode generator. The cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections in the range 22.81 < 2θ < 27.12°. The data were collected at a temperature of 23 ± 1 °C using the ω-2θ scan technique to a maximum 2θ value of 55.1°. Totals of 8202 independent reflections were obtained and 7912 were unique. The structure was solved by heavy-atom Patterson methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was based on 2875 observed reflections [$I > 3\sigma(I)$] and 379 variable parameters. R = 0.081, R_w = 0.112. Crystallographic details are given in Table 1. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-152467 for *anti*-**2**. Copies of the data can be obtained free of charge on application to CCDC. 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank Professor M. Haga at Chuo University for helpful discussions. We are indebted to Professor Y. Wei for the preparation of L^2. This work was financially supported in part by a Grant-in-Aid for Scientific Research on Priority Areas from the Ministry of Education, Science, and Culture, Japan. Thanks are also due to the Analytical Center, Faculty of Engineering, Osaka University for the use of their facilities.

A First Series of Dimeric Porphyrins Electrochemically Linked with Diphosphonium Bridges

Laurent Ruhlmann[b] and Alain Giraudeau*[a]

Keywords: Electrochemistry / Oxidation / Phosphorus / Synthetic methods / Porphyrins

The synthesis of dimeric porphyrins with a diphosphonium bridge in a direct one-pot electrochemical reaction is reported. The variation in the yields of this coupling reaction depends on the conditions of the electrolysis, and was examined mainly with respect to the detected by-products. An interpretation of this selective formation of dimers is proposed. Monomers and trimers were also obtained. These new compounds were characterized by ^{1}H NMR, ^{31}P NMR, UV/Vis spectroscopy and microanalysis. Important excitonic interactions were observed when the two porphyrin chromophores were linked with a short diphosphonium bridge. The NMR-spectroscopic data suggest that isomers are present in solution. Electrochemical data indicate that the two phosphonium groups of the bridge are not electrochemically independent in the zinc dimers.

Introduction

The synthesis of porphyrin dimers is being extensively pursued as these compounds provide models for the study of electron-transfer processes. Over the years, many models with various extended porphyrin structures have been prepared and studied with a particular interest in the dependence of the geometric factors on their physical properties.[1−8] The structural flexibility of the models is largely determined by the nature of the bridge. The totally rigid, covalently linked bis(porphyrins)[9−13] have chromophores fixed at well-defined distances and orientations, whereas conformational effects can be observed with less rigid systems.[14−16] To observe efficient interactions between the different chromophores, a large variety of bridging chains have been used as spacers in the building of dimers, but only a few reports[17−20] have been devoted to phosphanylporphyrins. Electrochemistry has been shown to be an appropriate synthetic tool in the coupling of porphyrins.[21−25] Recently, we reported a dimeric porphyrin,[23] with a diphosphonium bridge, which was synthesized by controlled potential electrolysis, a method that readily provides a convenient access to a large variety of new homometallated porphyrin dimers and trimers in a direct one-pot electrochemical reaction. This paper demonstrates the power of this approach and describes the efficient synthesis of various diphosphonium-bridged porphyrins using more or less rigid diphosphanes with variable length (Figure 1).

Physical characteristics of the synthesized porphyrins have been analyzed to identify the interactions between the different moieties in the dimers and the trimers.

Results

Electrosynthesis

The starting point for the synthesis is the electrochemical oxidation of (*meso*-tetraphenylporphyrin)zinc (ZnTPP) in the presence of various di- and triphosphanes. The oxidation waves of ZnTPP are reversible one-electron reactions in CH_3CN/1,2-$Cl_2C_2H_4$ (1:4).[26−28] In the presence of diphosphanes or ARPHOS, the second oxidation step became irreversible (Figure 2) and a new cathodic peak appeared, as observed in the reduction of electrochemically generated isoporphyrins.[28−31] Only the first oxidation step of ZnTPP was taken into account in this work.

In a typical experiment, a solution of the metalloporphyrin ZnTPP (1 equiv.) and bis(diphenylphosphanyl)methane (0.5 equiv.) was oxidized in the presence of 2,6-lutidine (2,6-Lut). 2,6-Lut was used to trap protons liberated during the course of porphyrin oxidation[23] and to prevent diphosphane-induced demetallation of ZnTPP before electrolysis. After maintaining the working potential at +0.85 V vs. SCE for 3 h, the initial violet solution turned green. The decrease in the oxidation current was not exponential with time. When this current reached the residual current measured in the absence of electroactive moieties, the electrolysis was stopped. The number of Coulombs consumed calculated from the recorded current−time curve $i = f(t)$ indicated that 2 Faradays per mol of ZnTPP were consumed in the reaction. After extraction and purification (see Exp. Sect.) the dimer **1-Zn-Zn** was characterized as the only new bis(porphyrin), obtained in 81% yield.

Increasing the diphosphane concentration caused a drastic decrease in the yield of the dimer, even in the presence

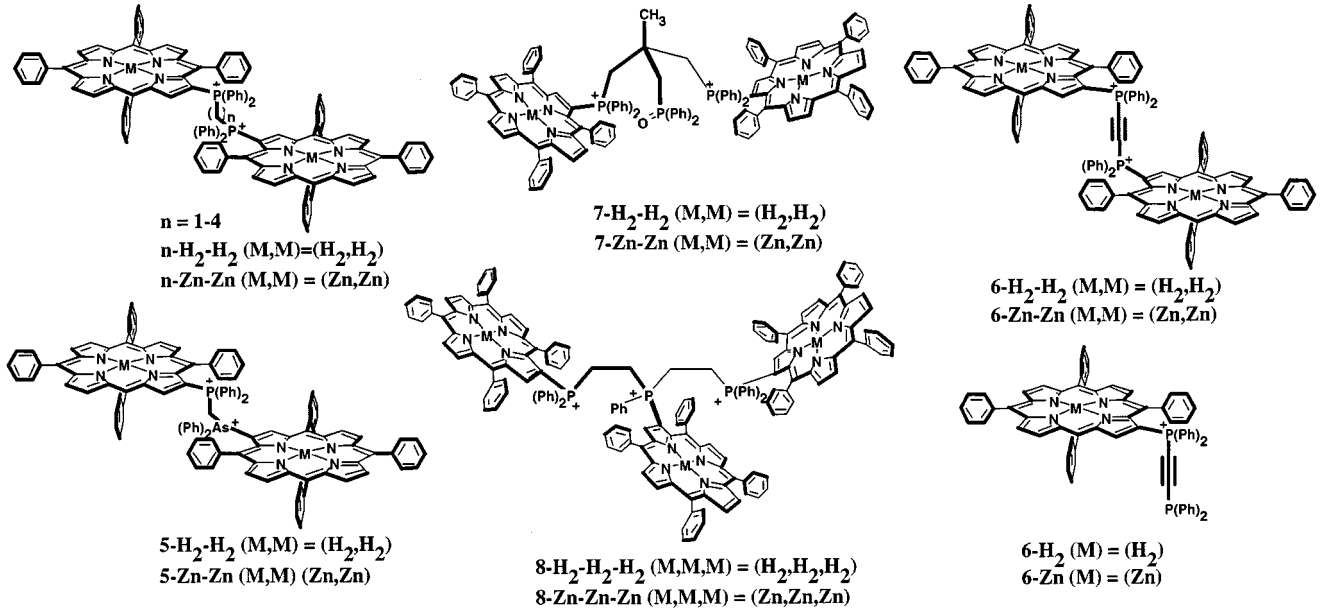

Figure 1. Porphyrins synthesized in this study

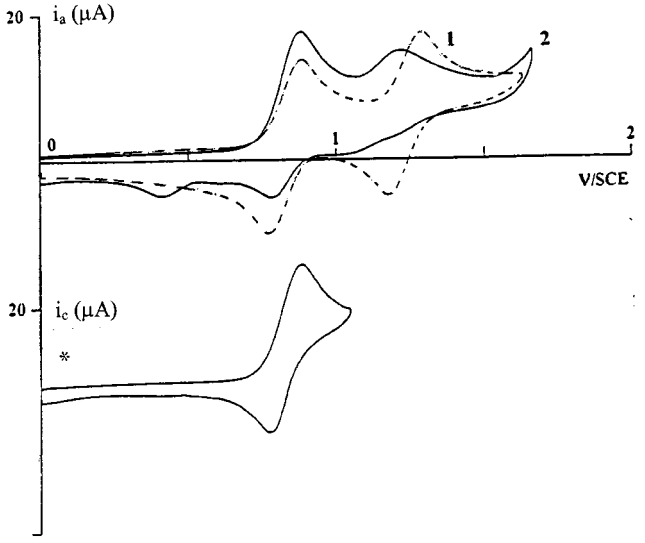

Figure 2. Cyclic voltammetry of ZnTPP in the absence of [1) dotted line] and in the presence of [2) full line] 1,2-bis(diphenylphosphanyl-ethane) (10 equiv.); *: first oxidation step only, in both cases; $CH_3CN/1,2\text{-}Cl_2C_2H_4$ (1:4) + T.E.A.PF_6 (0.1 M); working electrode Pt (v = 100 mV·s^{-1})

of a large excess of 2,6-Lut. No dimer was obtained when more than 10 equiv. of diphosphanes were used. This unexpected feature is interpreted in the discussion on the analysis of the side-products of the reaction. Diphosphane oxide and/or violin were recovered in these experiments; the overall yields of these compounds were high when using high concentrations of diphosphane and 2,6-lutidine.

By using 0.5 mol-equiv. of diphosphane (0.33 mol-equiv. of triphosphane in the case of the trimer **8-Zn-Zn-Zn**), only the desired dimers (or trimer) were produced in good yield.

In the present electrosynthesis, the formation of the dimers is described by Equation (1).

$$2\ P + Nu\text{-}\square\text{-}Nu \xrightarrow{E^1_{ox}} (P\text{-}\beta\text{-}Nu\text{-}\square\text{-}Nu\text{-}\beta\text{-}P)^{2+} + 4\ e^- + 2\ H^+ \quad (1)$$

(P = ZnTPP, Nu-□-Nu = diphosphane)

β-Monosubstituted porphyrin was also formed during the synthesis of the dimer **6-Zn-Zn**, in the presence of more than 0.5 equiv. of bis(diphenylphosphanyl)acetylene, as already described.[23]

UV/Vis Absorption Spectra

All the synthesized porphyrins exhibit a red shift of the Soret (B) and visible (Q) bands relative to the porphyrin subunits ZnTPP and H_2TPP. Complete UV/Vis data are reported in the Exp. Sect. for the electrosynthesized porphyrins. This bathochromic shift results from the electron-withdrawing effect of the positive charge located on the phosphonium cation(s). In the case of the metallated dimers, the Soret band shows significant broadening and its extinction coefficient is less intense than expected. These results suggest the presence of excitonic interactions between the two porphyrin rings in the dimers. These effects are greatly enhanced in the short-bridged **1-M-M** dimers (M = Zn and Cu) as shown in Figure 3 by the large red shift and by the splitting of the Q bands associated with a broad Soret band, with an extinction coefficient that is the lowest of those observed in the case of the **1-Zn-Zn** dimer.

This is clearly the result of exciton coupling which has been reported to become important when two porphyrin moieties are brought into close proximity[32−34] and/or when going from the nonmetallated porphyrin to the metallated parent.[34]

^{1}H NMR Spectra

The ^{1}H NMR spectra of the monomers, dimers and trimers show the well-known downfield shift of the aro-

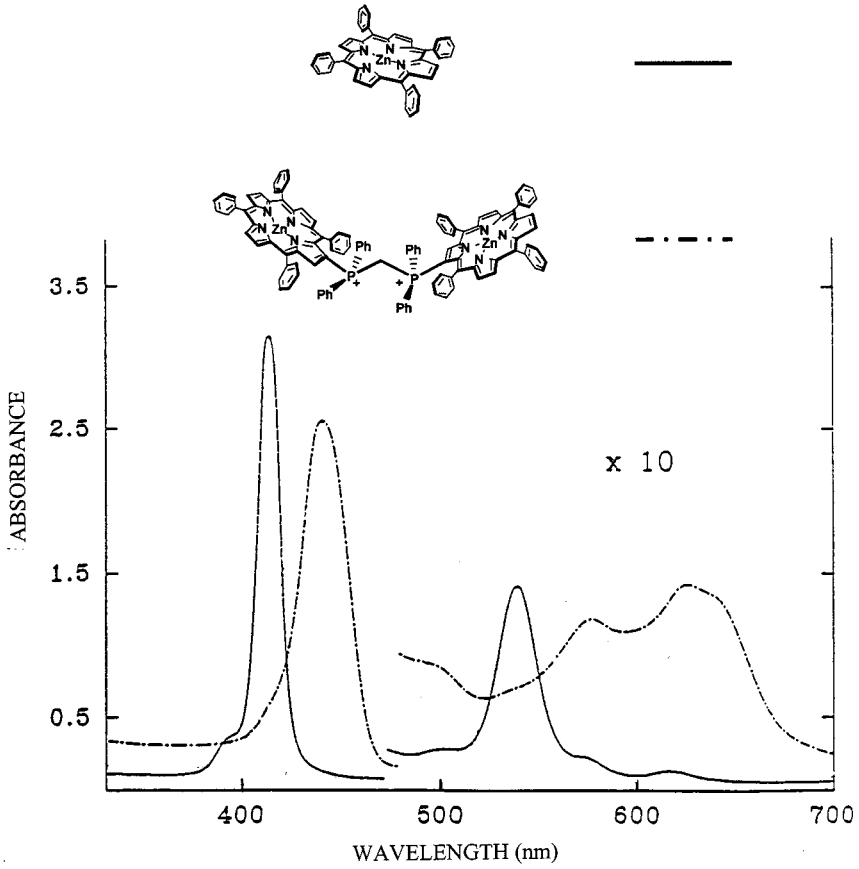

Figure 3. UV/Vis absorption spectra of the bis(porphyrin) **1-Zn-Zn** and of its monomeric subunit in CH_2Cl_2

matic proton signals of the porphyrin ring which characterizes the β-substitutions.[35] In the porphyrin rings of the dimers, the two β-H protons adjacent to the spacer give two distinct well-separated singlets, whereas the other β-proton signals appear as six doublets. The signals for the alkyl protons of the spacers are further downfield than those of the neutral ligands as owing to the presence of a positive charge on the phosphonium group. (For a full assignment, see Exp. Sect.) These protons coalesce into broadened signals or complex multiplets, with a splitting of the signal for the protons of the $-CH_2-$ groups bearing the phosphonium cations. A typical spectrum,[36] illustrated for the dimer **3-H_2-H_2** (Figure 4) shows a broad peak at $\delta \approx 2.42$, corresponding to the internal $-CH_2-$ of the linker and two distinct multiplets at $\delta = 2.80$ and 3.00, corresponding to the external $-CH_2-$ groups.

Such a distinct pair of multiplets is not observed in the corresponding neutral diphosphane which gives a triplet at $\delta = 2.25$. The appearance of two sets of resonances for the protons of the CH_2 groups bearing the phosphorus atoms as well as for the adjacent β-H protons, whose corresponding resonance signals are separated by $\Delta\delta = 0.03$ in the synthesized dimers and trimers, indicates the presence of a mixture of two isomers (Table 1). This is in agreement with previous studies of dimeric porphyrin systems[32,37–39] which connect two rings through their β-pyrrole positions. In particular, conformational analysis predicts a great conformational freedom when the two phenyl groups of the porphyrin unit are not substituted.[39] Furthermore, one of the β-H resonance doublets is shifted significantly downfield from the others. This could suggest that it experiences more shielding than the others, and may indicate the position of the phosphorus-linked phenyl groups.

The signals for the inner N−H protons of all the free-base porphyrins appear upfield as singlets and ruled out a cofacial conformation of the dimers which would induce a large upfield shift of the internal N−H protons[40] that is not observed.

^{31}P NMR Spectra

In the different neutral diphosphanes, the two phosphorus atoms are equivalent and their signals appear upfield as a singlet. In the bis(2-diphenylphosphanylethyl)-phenylphosphane, the signals of the two lateral phosphorus atoms appear as a doublet at $\delta = -13.15$, whereas the central atom gives a triplet at $\delta = -17.15$.

As expected, the two phosphonium cations of the dimers give rise to signals further downfield. Two well-separated signals are observed. A clear-cut evolution of these signals is depicted by the increase in the relative chemical shift $\Delta\delta$ (Table 1) between the two phosphonium groups which correlates with the increase in the length of the bridge linking the porphyrin subunits. These two signals indicate that the two phosphonium cations are in different environments. This result is not surprising because it is energetically not

favorable to have a dimer when the two phosphorus atoms are in identical environments.

There is clear evidence that this is the case: Both the $(Ph)_2P(CH_2)P(Ph)_2$ and $(Ph)_2P(CH_2)_2P(Ph)_2$ linkages show doublets in the ^{31}P spectra (see Exp. Sect.) indicating the coupling of the phosphorus atoms in different environments. It is quite likely that this is true for the longer congeners, but that the coupling is too small to show it.

Electrochemistry

All electrochemical data are collated in Table 2. Owing to adsorption phenomena that occurred at the Pt electrode and inhibited the reduction signals, the cathode redox behavior of the different synthesized porphyrins was examined on an Hg electrode. The number of exchanged electrons for each system was determined by exhaustive coulometry, and by comparing the limiting currents of the different waves characterizing a given system.

The observed electron transfers were assigned to the π-systems of the porphyrins[41–42] or to the phosphonium cations,[43] based on their known general redox characteristics. This assignment was also achieved by the use of the recorded spectroelectrochemical data. All the spectra show typical features of porphyrin π-cation or π-anion radical complexes: broad α,β bands and a Soret band with decreased intensity as illustrated in Figure 5.

Redox behavior of the substituted monomers has previously been reported.[23] The dimers and trimers exhibit three distinct electroactive sites, namely the spacer and the two or three lateral porphyrin units. The electrochemical ring oxidations and reductions of the porphyrin subunits occur on both sides of the electroactivity range of the spacer. The oxidation potentials of the porphyrins in the dimers and trimers are more positive than the corresponding ones in the unsubstituted subunits. This positive shift may be ascribed to the electron-withdrawing effect of the positively charged spacer.[44] The close values observed between the reduction potentials of the dimers and trimers, and those of the corresponding porphyrin subunits were expected because this reduction occurred in neutral molecules,

Table 2. All potentials in V/SCE obtained from stationary (RDE) or cyclic voltammetry in $CH_3CN/1,2\text{-}Cl_2C_2H_4$ (1:4), T.E.A.PF_6 (0.1 M) medium; transfers are reversible one-electron steps, except when noted; working electrode: Pt

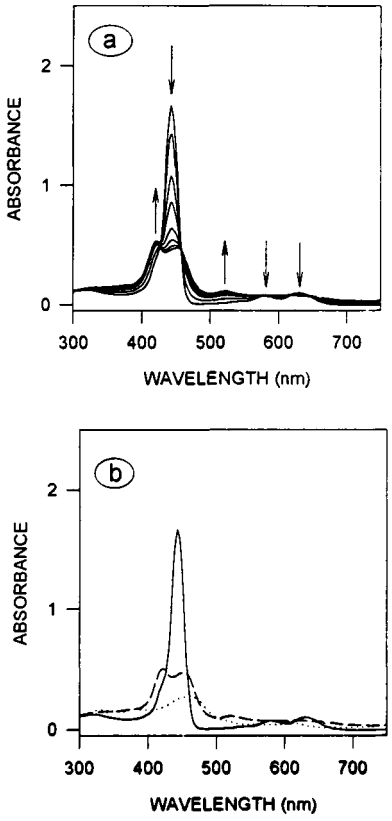

Figure 5. a) UV/Vis absorption spectra recorded during the oxidation of **4-Zn-Zn** in $CH_3CN/1,2\text{-}Cl_2C_2H_4$ (1:4) + T.E.A.PF_6 (0.1 M) at 1.0 V vs. SCE; b) UV/Vis absorption spectra of **4-Zn-Zn**: (− − − −) unoxidized form, (------) two-electron oxidized species (first wave, 1.00 V), and (·····) four-electron oxidized species (second wave, 1.27 V)

and the positively charged spacers become neutral before the reduction of the side porphyrin rings. In the synthesized porphyrins, each of the different oxidation and reduction steps observed appears as reversible or quasi-reversible, with an exchange of one electron per porphyrin subunit, except for the oxidation step of the nonmetallated complexes. The irreversible two-electron transfer observed in the free-base porphyrins may be explained by the instability of the radical cation.[24]

The reduction signal of the phosphonium cations appeared in CV at −0.70 V vs. SCE for the free bases and −1.1 V vs. SCE for the zinc complexes. This cathode signal corresponds to a two-electron reduction step. Two distinct reduction peaks are observed in all the zinc dimers and in the **6-H_2-H_2** dimer, each corresponding to a reversible electron transfer. This feature indicates that the two phosphonium cations are not independent.

By analyzing both the redox and UV/Vis results of the synthesized dimers, a common behavior appeared that depended on the nature (metallated or not) of these compounds. While the free-base dimers showed only minimal excitonic effects, the corresponding metallated dimers showed significant interactions between the chromophores. Similarly, the two phosphonium cations appeared as independent electroactive centers in the free-base dimers, but showed an interaction in their metallated homologs. This behavior could be analyzed as a consequence of δ−π interactions present in the metalloporphyrins. These interactions would thus favor a coupling between the different subunits (spacer, porphyrin). Consequences of these δ−π interactions have already been reported with the redox behavior of substituted metalloporphyrins.[44]

Discussion

Previous results on the electrochemical preparation of porphyrin dimers with a viologen as a spacer have established that the synthesis is achieved by means of a two-electron reaction per mol of porphyrin.[24] This sequence was also validated in the synthesis of the above porphyrins.

Nevertheless, a large increase in the diphosphane present in solution somewhat limits the range of the experiments. When a large excess of diphosphanes is added, the concentration of the 2,6-lutidine has to be increased to prevent the diphosphane-induced demetallation of ZnTPP. Owing to the lengthy electrolysis and the hygroscopic nature of 2,6-lutidine, an increase in its concentration leads to the introduction of significant amounts of water in the coulometric solution. Thus, if the hydroxide ions become the main nucleophile present in solution and if they react with the generated π-cation radical of the porphyrin, then, hydroxyisotetraphenylporphyrin is produced. Further α-attack of the OH^- ions would lead to violin formation, as already described by Dolphin et al.[45] The final purple complex isolated as a by-product exhibited electronic and ^1H NMR spectra similar to violins, in which only three of the pyrrole rings are conjugated. When phosphanes are the main nucleophiles in solution, phosphonium isoporphyrin would be formed before further α-attack of the OH^- ions would take place. This α-attack would give betaine and a four-membered ring transition state[46] (intermediate in the Wittig reaction), leading to the formation of (*meso*-tetraphenylporphyrin)zinc and phosphane oxide. This reaction would explain the drastic decrease in the yield of the dimers and of the characterized side-products collected when the concentration of 2,6-lutidine and/or of the diphosphanes was increased.

The most intriguing feature in this synthesis is the selective formation of dimers even with excess nucleophile. This was not observed with the rigid linear 4,4′-bipyridine linker. This result may be explained if one considers that the phosphorous atoms act as more efficient nucleophiles than the nitrogen atoms in these experiments, and that the phosphorus ligands used as linkers are flexible chains. The fact that both monomers and dimers are formed when the more rigid acetylene chain is used agrees with this hypothesis. This is also supported by the higher yield of desired dimer observed in the case of the long flexible diphosphane: 1,4-bis(diphenylphosphanyl)butane chain. Steric hindrance is most probably the reason why only two porphyrin units are linked with 1,1,1-tris(diphenylphosphanylmethyl)ethane, while the trimer **8-Zn-Zn-Zn** is formed when using the stretched bis(2-diphenylphosphanylethyl)phenylphosphane chain.

Conclusion

The results presented in this paper clearly illustrate that phosphorus ligands act as powerful nucleophiles which allow electrochemical β-substitutions on *meso*-tetraphenylporphyrins. When 0.5 mol-equiv. of diphosphanes is used, only the dimers are produced in good yields (> 60%). Selective dimer formation in a one-pot electrochemical step is particularly noteworthy when considering that only the monomer was generated in the case of the 4,4′-bipyridine nucleophiles.

Evidence for excitonic coupling is observed in the dimers. This effect is particularly enhanced in the metallated **1-M-M** dimers and demonstrates that bridging with the short 1,2-bis(diphenylphosphonium)methane chain keeps the two porphyrin chromophores in an interactive proximity. Isomers are therefore possible because of the two different electrophilic β-sites. Both ^1H NMR and ^{31}P NMR spectroscopy results suggest that geometric factors modulate the mutual interactions of the two porphyrin units in the dimers. The preparation of the trimer further validates this electrochemical method as a direct route to oligomeric porphyrins linked by phosphonium bridges.

Experimental Section

I. Materials: All solvents and chemicals were of reagent-grade quality, purchased commercially and used without further purification unless otherwise stated. CH_2Cl_2, for use in exhaustive electrolysis or UV/Vis spectrophotometry, was heated at reflux in the presence of CaH_2 and then distilled off. The supporting electrolyte tetraethylammonium hexafluorophosphate (T.E.A.PF_6) was used without further purification. All the diphosphanes and triphosphanes were purchased from Strem Chemical Inc. Thin-layer chromatography (TLC) was performed on commercially prepared alumina or silica gel plates purchased from Roth Sochiel.

II. Apparatus: All electrochemical measurements were carried out under argon at 25 °C on a dropping mercury electrode or on a disk electrode. Voltammetric data were obtained with a standard three-electrode system using a Bruker E 130 M potentiostat and a high-impedance millivoltmeter (minisis 6000, Tacussel). Current−potential curves were obtained from an Ifelec If 3802 X-Y recorder. The working electrode was a platinum disk (E.D.I. type, Solea Tacussel) with a surface area of 3.14 mm^2. A platinum wire was used as the auxiliary electrode. The reference electrode was a saturated calomel electrode (SCE) that was electrically connected to the studied solution by a junction bridge filled with the corresponding solvent/supporting electrolyte solution. − For polarographic and differential pulse polarographic experiments, a signal generator (GSATP from Solea-Tacussel) was associated with a potentiostatic device (Solea-Tacussel), comprising of a potentiostat (PRT 20−2X) and a voltage pilot unit (Servovit 2). − Coulometric measurements and quantitative electrochemical synthesis were performed either in a standard 50-mL cell or in a large 300-mL cell. In the standard cell, the working electrode was a platinum wire (Ø = 0.8 mm) with a length of 60 cm. In the large cell, the working electrode was a cylindrical platinum grid (Ø = 5 cm, h = 7 cm). For the controlled-potential electrolysis, the anodic and cathodic compartments were separated by a fritted glass disk to prevent diffusion of the electrogenerated species. − The spectrophotometric analyses were performed with a Hewlett−Packard 8452 A diode array spectrometer. The thin-layer spectroelectrochemical cell has been described previously.[47] − UV/Vis spectra were recorded with a Shimazu UV-260 spectrophotometer and a Hewlett−Packard 8452 A diode array spectrometer. − ^1H and ^{31}P NMR spectra were

obtained in [D_6]acetone with a Bruker AC 300 spectrometer (300 MHz and 120 MHz, respectively). − Elemental analyses were performed by the microanalysis services of the Chemical Department of I.U.T. Sud (Strasbourg).

III. Synthesis: Compounds H_2TPP, ZnTPP and CuTPP were prepared and purified by known procedures.[48,49]

Electrochemical Synthesis. − General Procedure: Prior to electrolysis, the corresponding mixtures were stirred and degassed by bubbling argon through the solution for 10 min. The desired working potential was then applied. During anodic oxidation, the electrolyzed solution was continuously stirred and maintained under argon. The course of the reaction was monitored by TLC (silica gel/1% CH_3OH in CH_2Cl_2) and UV/Vis spectrophotometry. Electrolysis was stopped when the current reached the residual current measured in the absence of electroactive material (i.e., 0.1 M solution of T.E.A.PF_6). After electrolysis, the solvents were removed in a rotary evaporator. The residue was dissolved in a minimum amount of CH_2Cl_2; the mixture was then poured into water, and the organic layer was washed three times. The organic solution was dried with $CaSO_4$, concentrated (to 5 mL), and then purified by chromatography. Typical preparation and characterization of a dimer **1-Zn-Zn**, **1-H_2-H_2** and **1-Cu-Cu** are reported below.

1-Zn-Zn: ZnTPP (200 mg, 2.95×10^{-4} mol), 2,6-Lut (50 μL, 4.30 10^{-4} mol) and $(Ph)_2P-CH_2-P(Ph)_2$ (57 mg, 1.475×10^{-4} mol) were dissolved in a solution of T.E.A.PF_6 (0.1 M, 300 mL) in 1,2-$Cl_2C_2H_4$/CH_3CN (4:1). The electrolysis was carried out for 6 h at +0.85 V vs. SCE. After the workup, as described above, the organic extract (5 mL) was purified by chromatography on silica gel. The first fraction (eluted with CH_2Cl_2) was unchanged ZnTPP (32 mg, 0.47×10^{-4} mol). The desired product was eluted with a mixture of CH_2Cl_2/CH_3OH (99:1). After evaporation of the solvent, **1-Zn-Zn** was recrystallized from CH_2Cl_2/*n*-hexane to afford the product as green crystals (242 mg, 1.19×10^{-4} mol, 81%). − UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$): = 442 (186900), 580 (9100), 624 (10800), 644 nm (10700). − ^{1}H NMR [300 MHz, $(CD_3)_2CO$, 25 °C]: δ = 9.08 [s, 1 H, β-H adj. to $-P(Ph)_2-^+$], 9.05 [s, 1 H, β-H adj. to $-P(Ph)_2-^+$], 8.85 (d, J_{cis} = 4.77 Hz, 2 H, β-H), 8.83 (d, J_{cis} = 4.80 Hz, 4 H, β-H), 8.79 (d, J_{cis} = 4.77 Hz, 2 H, β-H), 8.64 (d, J_{cis} = 4.77 Hz, 2 H, β-H), 8.17 [dt, J_o = 7.71 Hz, J_m= 1.47 Hz, 4 H, *o*-H of $-P(Ph)_2-^+$], 8.15 (d, J_{cis} = 4.77 Hz, 2 H, β-H), 8.13 [dt, J_o= 7.71 Hz, J_m = 1.47 Hz, 4 H, *o*-H of $-P(Ph)_2-^+$], 8.02 [dt, J_o = 7.71 Hz, J_m = 1.47 Hz, 4 H, *o*-H of Ph adj. to $-P(Ph)_2^+$], 7.84−7.49 (m, 36 H, H of Ph), 7.40 (t, J_o = 7.71 Hz, 3 H, *p*-H of Ph), 7.39 [t, J_o = 7.71 Hz, 3 H, *p*-H of Ph], 7.13 [t, J_o = 7.71 Hz, 2 H, *p*-H of Ph adj. to $-P(Ph)_2^+$], 7.00 [t, J_o = 7.71 Hz, 4 H, *p*-H of $-P(Ph)_2-^+$], 3.71 (d, ^1J = 12.12 Hz, 1 H, $-CH_2$), 3.65 (d, ^1J = 12.12 Hz, 1 H, $-CH_2-$). − ^{31}P NMR [120 MHz, $(CD_3)_2CO$, 25 °C]: δ = 20.02 [d, $^2J_{P-P}$ = 15.01 Hz, $-P(Ph)_2^+$], 18.64 [d, $^2J_{P-P}$ = 15.01 Hz, $-P(Ph)_2-^+$], −145.44 (sept, $^1J_{P-F}$ = 700.80 Hz, PF_6^-). − $C_{113}H_{76}F_{12}N_8P_4Zn_2$ (2028.54): calcd. C 66.91, H 3.77, N 5.52, P 6.11; found C 66.80, H 3.87, N 5.61, P 6.08. − M.p. > 300 °C.

1-H_2-H_2: Hydrochloric acid (25%, 100 mL) was added to a solution of **1-Zn-Zn** in acetone, and the mixture was stirred for 30 min at room temperature. After the addition of water (200 mL), the organic layer was separated, washed with water and neutralized with saturated sodium acetate solution. The solution was again washed with water, dried with $CaSO_4$ and concentrated. Recrystallization of the residue with CH_2Cl_2/*n*-hexane gave **1-H_2-H_2** in almost quantitative yield. − UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 432 (461600), 530 (22600), 560 (8200), 604 (8300), 670 nm (16000). − ^{1}H NMR [300 MHz, $(CD_3)_2CO$, 25 °C]: δ = 9.08 [s, 1 H, β-H adj. to $-P(Ph)_2-^+$], 9.04 [s, 1 H, β-H adj. to $-P(Ph)_2-^+$), 9.04 (d, J_{cis} = 4.41 Hz, 2 H, β-H), 9.02 (d, J_{cis} = 4.41 Hz, 2 H, β-H), 8.82 (d, J_{cis} = 4.41 Hz, 2 H, β-H), 8.76 (d, J_{cis} = 4.41 Hz, 2 H, β-H), 8.71 (d, J_{cis} = 4.41 Hz, 2 H, β-H), 8.40 (d, J_{cis} = 4.41 Hz, 2 H, β-H), 8.24 [d, J_o = 7.35 Hz, 4 H, *o*-H of $-P(Ph)_2-^+$], 8.18 [d, J_o = 7.35 Hz, 4 H, *o*-H of $-P(Ph)_2-^+$], 8.11 [d, J_o = 7.35 Hz, 4 H, *o*-H of Ph adj. to $-P(Ph)_2-^+$], 7.85−7.39 (m, 42 H, H of Ph), 7.21 [t, J_o = 6.99 Hz, 2 H, *p*-H of Ph adj. to $-P(Ph)_2-^+$], 7.05 (t, J_o = 6.99 Hz, 4 H, *p*-H of Ph), 3.72 (d, ^1J = 12.12 Hz, 1 H, $-CH_2-$), 3.67 (d, ^1J = 12.12 Hz, 1 H, $-CH_2-$), −2.47 (s, 4 H, N−H). − ^{31}P NMR [120 MHz, $(CD_3)_2CO$, 25 °C]: δ = 19.83 [d, $^1J_{P-C}$ = 14.18 Hz, $-P(Ph)_2^+$], 18.08 [d, $^2J_{P-P}$ = 14.18 Hz, $-P(Ph)_2$]. − $C_{113}H_{80}Cl_2N_8P_2$ (1682.80): calcd. C 80.65, H 4.79, N 6.66, P 3.68; found C 80.81, H 4.83, N 6.52, P 3.60. − M.p. > 300 °C.

1-Cu-Cu: 1-H_2-H_2 was dissolved in a CH_2Cl_2/CH_3OH (1:1) mixture with an excess of $Cu^{II}(CH_3COO)_2 \cdot H_2O$ (10 equiv.). The mixture was heated at reflux for 3 h, and after cooling, was treated with tetraethylammonium hexafluorophosphate (100 equiv.). After evaporation of the solvent, the residue was dissolved in a minimum amount of CH_2Cl_2, washed with water (4 times) and dried with $CaSO_4$ for 6 h. The solution was concentrated to 5 mL in a rotary evaporator and then purified on a silica gel column (CH_2Cl_2) to afford black−violet crystals of **1-Cu-Cu** in more than 90% yield. − UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 440 (246500), 576 (13600), 625 (16500), 643 nm (15000). − $C_{113}H_{76}Cu_2F_{12}N_8P_4$ (2024.89): calcd. C 66.97, H 3.78, N 5.53, P 6.11; found C 66.81, H 3.82, N 5.48, P 6.01. − M.p. > 300 °C.

2-Zn-Zn: The same procedure as described for **1-Zn-Zn** was applied using ZnTPP (200 mg, 29.5 mmol, 1 equiv.), 2,6-Lut (50μL, 43 mmol) and $(Ph)_2P-CH_2-CH_2-P(Ph)_2$ (57 mg, 14.8 mmol, 0.5 equiv.). 5-H_2-H_2: Compound **5-H_2-H_2** was obtained quantitatively as described for **1-H_2-H_2**. – UV/Vis (CH_2Cl_2), λ_{max} (ε, $M^{-1}cm^{-1}$) = 432 (370000), 500 (21100), 566 (7400), 612 (6700), 670 nm (12800). – ^1H NMR [300 MHz, $(CD_3)_2CO$, 25 °C]: δ = 9.13 [s, 1 H, β-H adj. to $-P^+(Ph)_2-$], 9.10 [s, 1 H, β-H adj. to $-P^+(Ph)_2-$], 9.08 (d, J_{cis} = 5.16 Hz, 2 H, β-H), 9.05 (d, J_{cis} = 5.16 Hz, 2 H, β-H), 8.97 (d, J_{cis} = 5.1 Hz, 2 H, β-H), 8.79 (d, J_{cis} = 4.80 Hz, 2 H, β-H), 8.74 (d, J_{cis} = 4.80 Hz, 2 H, β-H), 8.47 (d, J_{cis} = 5.16 Hz, 1 H, β-H), 8.46 (d, J_{cis} = 5.16 Hz, 1 H, β-H), 8.28–8.12 [m, 12 H, *o*-H of $-P^+(Ph)_2-$ and *o*-H of Ph adj. to $-P^+(Ph)_2$], 7.92–7.20 (m, 48 H, H of Ph), 2.75 (m, 2 H, $-CH_2-$), 2.42 (m, 2 H, $-CH_2$), −2.44 (s, 4 H, N–H internal). – ^{31}P NMR [120 MHz, $(CD_3)_2CO$, 25 °C]: δ = 22.54 [s, $-P^+(Ph)_2-$]. – $C_{114}H_{82}AsCl_2N_8P_3$ (2030.72): calcd. C 75.95, H 4.59, N 6.22; found C 76.11, H 4.64, N 6.20.

6-Zn and 6-Zn-Zn: ZnTPP (20 mg, 29.5 mmol), 2,6-Lut (20 μL, 17.20 × 10^{-5} mol) and $(Ph)_2P-C\equiv C-P(Ph)_2$ (11.6 mg, 2.95 × 10^{-5} mol) were dissolved in a solution of T.E.A.PF_6 (0.1 M) in 1,2-$Cl_2C_2H_4$/CH_3CN (4:1). The stirred reaction mixture was electrolyzed for 3 h at 0.80 V vs. SCE. After workup, the unchanged ZnTPP was separated from the monomeric (**6-Zn**) and dimeric (**6-Zn-Zn**) porphyrins by column chromatography (silica gel), eluting with CH_2Cl_2/0.1% CH_3OH. Further elution did not allow for the effective separation of the two porphyrins (**6-Zn** and **6-Zn-Zn**). Pure monomer and dimer were obtained only after demetallation of the mixture and chromatography as described below. After coulometry, the solvents were evaporated. The residue was dissolved in a minimum amount of CH_2Cl_2/CH_3COCH_3 (1:1) and dilute HCl (25%, 100 mL) was added. This mixture was stirred for 30 min at room temperature. After the addition of water (200 mL), the organic layer was collected, washed again and neutralized with sodium acetate. The porphyrins **6-H_2** and **6-H_2-H_2** were then separ-

ated by column chromatography (CH_2Cl_2/0.1% CH_3OH) to give, after recrystallization from CH_2Cl_2/*n*-hexane, brown powders: **6-H$_2$** (6.8 mg, 22%) and **6-H$_2$-H$_2$** (16.7 mg, 66%).

6-H$_2$: H$_2$TPP-β-P$^+$(Ph)$_2$−C≡C−P(Ph)$_2$, Cl$^-$: UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 426 (269200), 522 (17400), 558 (8400), 598 (7800), 655 nm (8300). − ^{1}H NMR [300 MHz, $(CD_3)_2CO$, 25 °C]: δ = 8.93 (s, 1 H, β-H), 8.77 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.76 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.73 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.56 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.42 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.25−8.18 [m, 5 H, 4 *o*-H of −P$^+$(Ph)$_2$ − and 1 β-H], 8.06 [dt, J_o = 6.6 Hz, J_m = 1.7 Hz, 2 H, *o*-H of Ph adj. to −P$^+$(Ph)$_2$−], 7.86−7.76 (m, 10 H, *o*-H of Ph), 7.72−7.42 (m, 16 H, H of Ph), 7.36 (t, J_o = 7.7 Hz, 3 H, *p*-H of Ph), 7.35 [t, J_o = 7.0 Hz, 2 H, *p*-H of P(Ph)$_2$], 7.23 [t, J_o = 7.7 Hz, 1 H, *p*-H of Ph adj. to P$^+$(Ph)$_2$], 7.16 [t, J_o = 7.7 Hz, 2 H, *p*-H of −P$^+$(Ph)$_2$−], −2.57 (s, 2 H, N−H). − ^{31}P NMR [120 MHz, $(CD_3)_2CO$, 25 °C]: δ = 18.95 [s, −P$^+$(Ph)$_2$−], 3.51 [s, −P(Ph)$_2$−]. − $C_{70}H_{49}ClN_4P_2$ (1043.60): calcd. 6-H$_2$-H$_2$: H$_2$TPP-β-P$^+$(Ph)$_2$−C≡C−P$^+$(Ph)$_2$-β-H$_2$TPP, 2 Cl$^-$: UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 430 (214200), 527 (16600), 564 (4900), 607 (7300), 666 nm (10900). − ^{1}H NMR [300 MHz, $(CD_3)_2CO$, 25 °C]: δ =9.06 (d, J_{cis} = 5.5 Hz, 2 H, β-H), 9.02 (d, J_{cis} = 5.5 Hz, 2 H, β-H), 8.87 (d, J_{cis} = 5.5 Hz, 1 H, β -H), 8.85 (d, J_{cis} = 5.5 Hz, 1 H, β-H), 8.76 [s, 1 H, -H adj. to −P$^+$(Ph)$_2$−], 8.71 [s, 1 H, β-H adj. to −P$^+$(Ph)$_2$−], 8.67 (s, 1 H, β-H), 8.64 (s, 1 H, β-H), 8.46 (d, J_{cis} = 5.5 Hz, 1 H, β-H), 8.41 (d, J_{cis} = 5.5 Hz, 1 H, β-H), 8.26−8.19 [m, 10 H, 8 *o*-H of −P$^+$(Ph)$_2$− and 2 β-H], 8.14−8.05 [m, 4 H, *o*-H of Ph adj. to −P$^+$(Ph)$_2$−], 7.93−7.14 (m, 48 H, H of Ph), −2.48 (s, 2 H, N−H), −2.51 (s, 2 H, N−H). − ^{31}P NMR [120 MHz, $(CD_3)_2CO$, 25 °C]: δ = 24.80 [s, −P$^+$(Ph)$_2$−], 16.51 [s, −P$^+$(Ph)$_2$−]. − $C_{114}H_{78}Cl_2N_8P_2$ (1692.80): calcd. C 80.89, H 4.64, Cl 4.19, N 6.62, P 3.66; found C 80.75, H 4.78, Cl 4.34, N 6.70, P 3.81.

6-Zn: Compound **6-H$_2$** was dissolved in a solution of $(CH_3COO)_2Zn^{II}$ (10 equiv.) in CH_2Cl_2/CH_3OH (1:1). The mixture was maintained at reflux for 3 h. After cooling at room temperature, the mixture was treated with an excess of tetraethylammonium hexafluorophosphate (100 equiv.). After evaporation of the solvent, the residue was dissolved in a minimum amount of CH_2Cl_2. The mixture was then poured into water, and the organic layer was washed (4 times) and dried with $CaSO_4$ for 6 h. The solution was then concentrated (to 5 mL) and purified by chromatography on a silica gel column (elution with CH_2Cl_2/CH_3OH, 99:1) to give a dark green powder of **6-Zn** in 90% yield. − UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 428 (209200), 560 (9400), 603 nm (5000). − ^{1}H NMR [300 MHz, $(CD_3)_2CO$, 25 °C]: δ = 8.84 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.800 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.798 [s, 1 H, β-H adj. to −P$^+$(Ph)$_2$−], 8.77 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.768 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.63 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.17 (d, J_{cis} = 4.8 Hz, 1 H, β-H), 8.11 [dd, J_o = 8.8 Hz, J_m = 1.8 Hz, 4 H, *o*-H of −P$^+$(Ph)$_2$−], 8.01 [dd, J_o = 8.1 Hz, J_m = 1.5 Hz, 2 H, *o*-H of Ph adj. to −P$^+$(Ph)$_2$−], 7.94−7.55 (m, 26 H, *o*-H and *m*-H of Ph), 7.49 [t, J_o = 7.4 Hz, 2 H, *p*-H of P(Ph)$_2$], 7.41 (t, J_o = 7.4 Hz, 3 H, *p*-H of Ph), 7.31 [t, J_o = 7.4 Hz, 1 H, *p*-H of Ph adj. to −P$^+$(Ph)$_2$], 7.03 [t, J_o = 7.4 Hz, 2 H, *p*-H of −P$^+$(Ph)$_2$], − ^{31}P NMR [120 MHz, $(CD_3)_2CO$, 25 °C]: δ = 4.64 [s, −P$^+$(Ph)$_2$−], 3.51 [s, −P$^+$(Ph)$_2$−], −145.44 (sept, $^1J_{P-F}$ = 700.8 Hz, PF_6^-). − $C_{70}H_{47}F_6N_4P_3Zn$ (1216.47): calcd. C 69.12, H 3.89, N 4.61, P 7.64, Zn 5.37; found C 69.31, H 4.05, N 4.74, P 7.75, Zn 5.56.

6-Zn-Zn: The same procedure described for **6-Zn** was used to obtain **6-Zn-Zn** from **6-H$_2$-H$_2$** in 90% yield. − UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 438 (215600), 569 (10600), 623 nm (11800). − ^{1}H NMR [300 MHz, $(CD_3)_2CO$, 25 °C]: δ= 8.87 (d, J_{cis} = 4.8 Hz, 2 H, β-H), 8.82 (d, J_{cis} = 4.8 Hz, 4 H, β-H), 8.80 [s, 1 H, β-H adj. to −P$^+$(Ph)$_2$−], 8.79 [s, 1 H, β-H adj. to −P$^+$(Ph)$_2$−], 8.78 (d, J_{cis} = 4.8 Hz, 2 H, β-H), 8.65 (d, J_{cis} = 4.8 Hz, 2 H, β-H), 8.18 (d, J_{cis} = 4.8 Hz, 2 H, β-H), 8.16 [d, J_o = 7.7 Hz, 4 H, *o*-H of −P$^+$(Ph)$_2$ −], 8.12 [d, J_o = 7.7 Hz, 4 H, *o*-H of −P$^+$(Ph)$_2$−], 8.03 [d, J_o = 7.7 Hz, 4 H, *o*-H of Ph adj. to −P$^+$(Ph)$_2$−], 7.90−7.10 (m, 48 H, H of Ph), − ^{31}P NMR [120 MHz, $(CD_3)_2CO$, 25 °C]: δ = 14.03 [s, −P$^+$(Ph)$_2$−], 13.62 [s, −P$^+$(Ph)$_2$−], 145.44 (sept, $^1J_{P-F}$ = 700.8 Hz, PF_6^-). − $C_{114}H_{74}F_{12}N_8P_4Zn_2$ (2038.54): calcd. C 67.17, H 3.66, N 5.50, P 6.08, Zn 6.41; found C 67.32, H 3.74, N 5.42, P 6.22, Zn 6.52.

7-Zn-Zn: This was prepared by the same method as **1-Zn-Zn**, using ZnTPP (200 mg, 2.95×10^{-4} mol, 1 equiv.), 2,6-Lut (50 μL, 4.3×10^{-4} mol) and 1,1,1-tris(diphenylphosphanylmethyl)ethane (61 mg, 0.98×10^{-4} mol. 0.33 equiv.). Product **7-ZnZn** was recovered (184 mg, 0.88×10^{-4} mol, 75%). − UV/Vis (CH_2Cl_2): λ_{max} (ε, $M^{-1}cm^{-1}$) = 446 (298000), 582 (12100), 640 nm (19900). − ^{1}H NMR [300 MHz, $(CD_3)_2CO$, 25 °C]: δ = 9.71 [s, 1 H, β-H adj. to −P$^+$(Ph)$_2$−], 9.68 [s, 1 H, β-H adj. to −P$^+$(Ph)$_2$−], 8.90 [d, J_{cis} = 4.80 Hz, 4 H, β-H adj. to −P$^+$(Ph)$_2$−], 8.82 (d, J_{cis} = 4.80 Hz, 2 H, β-H), 8.80 (d, J_{cis} = 4.80 Hz, 2 H, β-H), 8.76 (d, J_{cis} = 4.77 Hz, 2 H, β-H), 8.51 (d, J_{cis} = 4.77 Hz, 2 H, β-H), 8.24 [dt, 4 H, J_m = 1.83 Hz, J_o = 6.99 Hz, *o*-H of Ph adj. to −P$^+$(Ph)$_2$−], 8.20−8.13 [m, 12 H, *o*-H of −P$^+$(Ph)$_2$− and PO(Ph)$_2$], 7.99−6.67 (m, 54 H, H of Ph), 4.60 [d, ^3J = 13.30 Hz, 2 H, −CH$_2$−PO(Ph)$_2$], 2.69 [d, ^1J = 13.30 Hz, 1 H, −CH$_2$−P$^+$(Ph)$_2$−], 2.62 [d, ^1J = 13.30 Hz, 1 H, −CH$_2$−P$^+$(Ph)$_2$−], 1.92 [d, ^1J = 13.30 Hz, 1 H, −CH$_2$−P$^+$(Ph)$_2$−], 1.86 (d, ^1J = 13.30 Hz,1 H, −CH$_2$−), 0.80 (s, 3 H, −CH$_3$−). − ^{31}P NMR (120 MHz, $(CD_3)_2CO$, 25 °C): δ = 26.43 [s,PO(Ph)$_2$- and −P$^+$(Ph)$_2$−], 15.88 [s, −P$^+$(Ph)$_2$−], −143.35 (sept, $^1J_{P-F}$ = 700.7 Hz, PF_6^-). − $C_{129}H_{93}F_{12}N_8OP_5Zn_2$ (2284.83): calcd. 2-(4′,4′-Dimethyl-3′,4′-dihydrooxazol-2′-yl)phenol: Some First-Row Transition Metal Complexes of This Naturally Occurring Binding Group

Govindasamy Mugesh,[a] Harkesh B. Singh,*[a] and Ray J. Butcher[b]

Dedicated to Prof. B. L. Khandelwal on the occasion of his 63rd birthday

Keywords: Oxazolines / Metal assisted hydrolysis / Hydrogen bonds / Chirality / Siderophores

The synthesis and characterization of monomeric Mn^{III}, Co^{II}, Ni^{II}, Cu^{II}, and Zn^{II} phenolates derived from a biologically relevant ligand, 2-(4′,4′-dimethyl-3′,4′-dihydrooxazol-2′-yl)-phenol (**1**), are described. The addition of $Mn(OAc)_2 \cdot 4\,H_2O$ to an ethanolic solution of **1** affords an unexpected 1:3 complex $[Mn(OR)\{O(Ox)\}_2]$ (**2**) [R = $C_6H_4CONHC(Me_2)CH_2OH$, Ox = 2-(4,4-dimethyl-2-oxazolinyl)phenyl] in which one of the five-membered oxazoline rings is partially hydrolyzed. The complexes $[M\{O(Ox)\}_2]$ [M = Co (**3**), Ni (**4**), Cu (**6**), or Zn (**7**)] were prepared in good yield by the reactions of **1** with the corresponding metal acetates. Novel formation of the six-coordinate Ni^{II} complex **5** with neutral acetic acid was observed during the crystallization process. The complexes were characterized by elemental analysis, magnetic susceptibility, as well as EPR, ^1H NMR, electronic, and mass spectral techniques. Complexes **2**, **3**, **5**, **6**, and **7** were characterized by single crystal X-ray diffraction studies. Complex **2** is six-coordinate whereas complexes **3**, **6**, and **7** are four-coordinate with two oxazoline bidentate ligands. The geometry around the metal center is found to be distorted tetrahedral for all of the four-coordinate complexes. Complex **5** is octahedral with four coordination sites occupied by the two bidentate oxazoline ligands and the other two are occupied by two neutral acetic acid molecules. The hydroxy groups of the coordinated acetic acid are hydrogen-bonded to the phenolate oxygen atoms of the oxazoline ligands. The variable-temperature ^1H NMR spectroscopic studies of complex **7** indicate that the interconversion between the (*M*) and (*P*) helix is slow at low temperatures.

Introduction

Interest in the biochemistry of 2-(2-hydroxyphenyl)-2-oxazoline started with the finding that this ligating moiety is present as a naturally occurring iron chelator in some classes of siderophores such as mycobactine, parabactin, and vibriobactin.[1]

Owing to the strong chelating ability of the oxazoline ligand and its high affinity for Fe^{III}, the siderophores have been shown to be highly potent in the deferration of mammalian cell lines and are potentially useful for chelation therapy.[2] The use of oxazoline ligands in a wide range of catalytic reactions has also been reported in recent years.[3] In this regard much effort has been directed towards the synthesis and catalytic applications of metal complexes containing 2-(2′-hydroxyphenyl)-2-oxazoline ligands.[4] Recently, Ti^{IV} and Zr^{IV} complexes of 2-(2′-hydroxyphenyl)-2-oxazolines have been used for some homogeneous catalytic reactions such as Mukaiyama reaction, allylations, hydrocyanations, Diels–Alder reactions.[4b] In these cases, the bis-(oxazoline)-ligated transition metal Lewis acids displayed activity for almost all commonly encountered Lewis acid promoted reactions. More recently, Ni^{II}, Pd^{II}, and Mn^{III} complexes of chiral oxazoline ligands containing N,O and N,P moieties and Mn^{III} complex of 2-(2′-hydroxyphenyl)-2-oxazoline have been used for the catalytic epoxidation of styrene.[5]

Although a few complexes of 2-(2′-hydroxyphenyl)-2-oxazolines with trivalent and divalent metal ions are known,[6–8] very little information is available about their structural chemistry. As part of our work on intramolecularly coordinated organochalcogens,[9] we have recently described the synthesis and characterization of Group 12 metal chalcogenolates (S, Se, Te) with bidentate oxazoline ligands.[10] Interestingly, the (thiolato)-[10a] and (selenolato)-zinc[10b] complexes were found to be chiral at room temperature and interconversion between the (*M*) and (*P*) helix was slow at room temperature. Replacement of the S or Se by Te led to the faster interconversion between the (*M*) and (*P*) forms. A similar trend was observed when the central metal ion was varied. It was observed that the interconversion of enantiomers at small metal ions, such as zinc, was slower whereas at the larger metal ions, such as mercury, it was much faster even at low temperature. Since the isolation of "helically" chiral metal complexes of zinc with lighter chalcogens (S, Se) was found to be more facile than the complexes with the heavier chalcogen (Te), it was thought worthwhile to extend our approach to the lightest chalcogen (oxygen) as well. Also, in order to generalize our observations, we extended our approach to other transition metals where the isolation of the tetrahedral complexes was

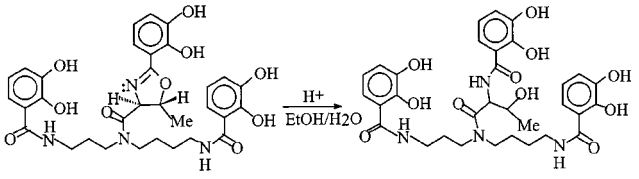
feasible. In this paper we describe the synthesis and characterization of Mn^{III}, Co^{II}, Ni^{II}, Cu^{II}, and Zn^{II} complexes with the naturally occurring 2-(2′-hydroxyphenyl)-2-oxazoline ligating moiety.

Results and Discussion

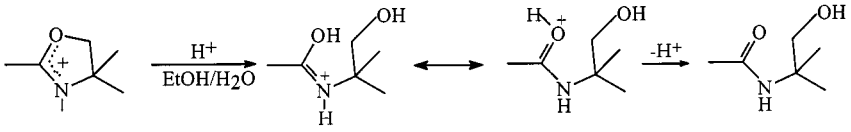
Synthesis

The ligand 2-(4′,4′-dimethyl-3′,4′-dihydrooxazol-2′-yl)-phenol (**1**) was prepared in a one-pot synthesis by following the published procedure with minor modifications.[5] Since the proton of the hydroxy group in the oxazoline was acidic enough to react with the metal salts containing basic anion acetate, the ligand was treated with various metal acetates in absolute ethanol to obtain the corresponding metal complexes (Scheme 1). The addition of $Mn(OAc)_2 \cdot 4\,H_2O$ to an ethanolic solution of **1** afforded a black-green solution of complex **2**. Elemental analysis of the black-green crystals obtained upon slow evaporation of the solvent did not match with the expected 1:2 complex. Instead, it indicated the formation of a 1:3 complex where manganese was in a +3 oxidation state. Interestingly, one of the oxazoline rings undergoes a metal-assisted hydrolysis (vide infra) in the presence of acetic acid produced during the reaction. However, no hydrolysis of the oxazoline ring was observed with the other metal ions.

The partial hydrolysis of the oxazoline ring in complex **2** is similar to the hydrolysis of the active site of Agrobactin, a siderophore from *Agrobacterium tumefaciens*. The oxazoline ring of the siderophore hydrolyzes in the presence of an acid to give the open-chain form, Agrobactin A (Scheme 2).[1a] It has been further reported by Neilands et al. that the replacement of the −OH group in the 2-position of the benzene ring with −OMe or −OBz groups in Agrobactin led to a facile opening of the oxazoline ring.[1c] Similarly, in ligand **1** the coordination of the nitrogen atom to the metal center probably disturbs the co-planarity of the oxazoline ring leading to hydrolysis of the five-membered ring in the presence of acetic acid. The partial hydrolysis of the oxazoline ring is also noteworthy since acid hydrolysis of the oxazoline ring in complex **2** leads to the formation of an amide instead of the expected acid (−COOH). The mechanism of the hydrolysis involves the formation of the oxazolium ion. The oxazolium ion so formed presumably then



Scheme 2. Acid-catalyzed hydrolysis of the oxazoline ring present in the active site of Acrobactin to the open-chain from, Agrobactin A



Scheme 3. Proposed mechanism of the hydrolysis of oxazoline ring in complex **2**

opens to afford the cleaved product which then undergoes tautomerization to give the open-chain amide (Scheme 3).[1a]

In order to determine whether the presence of air plays an important role in the ligand hydrolysis, the synthesis of complex **2** was attempted under nitrogen. In this case, a very air-sensitive green-colored gummy solid, presumably the expected Mn^{II} complex, was obtained. All efforts to obtain crystals of the Mn^{II} complex were unsuccessful. Isolation of the Mn^{III} complex under aerobic conditions further demonstrates that both the stability of the Mn^{III} oxidation state and its oxophilicity promote the ligand hydrolysis.

The addition of $Co(OAc)_2 \cdot 4\,H_2O$ to an ethanolic solution of **1** resulted in an immediate formation of Co^{II} complex **3** as a pink-colored solid. The crystals of the complex were obtained from a CH_2Cl_2/methanol (1:1) solution. When an ethanolic solution of **1** was added to a solution of $Ni(OAc)_2 \cdot 4\,H_2O$, an immediate formation of a green precipitate was observed. After 12 h of stirring at room temperature, the pale green solid obtained was filtered and washed with ethanol. Interestingly, the slow concentration of the filtrate afforded dark green crystals which were different from the compound obtained by filtration of the reaction mixture. Elemental analyses of both the products indicated that the pale green solid was the expected 1:2 complex **4** whereas the dark green crystalline solid (**5**) obtained from the filtrate was an acetic acid [produced in the reaction mixture during the reaction of $Ni(OAc)_2 \cdot 4\,H_2O$ with **1**] adduct of **4** (vide infra). The addition of acetic acid to an ethanolic solution of complex **4** also afforded complex **5**. Although four-coordinate Ni^{II} complexes are known to coordinate extra ligands in solution to set up equilibria between four-, five-, and six-coordinate complexes,[11] the strong bonding of the acetic acid molecules in this case is surprising since the recrystallization from methanol did not lead to the expected exchange.[11b] The Cu^{II} and Zn^{II} complexes **6** and **7** were prepared in good yields by the reaction of **1** with the corresponding metal acetates. All the complexes are quite soluble in common organic solvents such as CH_2Cl_2, $CHCl_3$, benzene, etc.

NMR Spectroscopy

Complex **7** was studied in solution by NMR spectroscopy. The ^1H NMR spectrum of **7** in $CDCl_3$ showed only small chemical shift differences compared with the spectrum of **1**. We have recently observed an AB spin behavior of the methylene protons in the corresponding zinc thiolate and selenolate complexes, and used it as a diagnostic probe for their chirality.[10a,10b] For complex **7**, no such behavior was observed at room temperature and the signals for the methyl and methylene protons were observed as singlets. However, the signals due to the methyl and methylene protons were slightly broad and this showed that the complex was probably not rigid at room temperature. At −55 °C, the $-CH_3$ protons gave rise to two singlets and the $-CH_2-$ protons gave an AB quadruplet (Figure 1). When the solution was heated to 50 °C, the two signals observed for the methyl protons and the AB quadruplet for the methylene protons became sharp singlets. This clearly indicates that the interconversion of the (*M*) and (*P*) helix is fast at room temperature and becomes slow at a low temperature on the NMR spectoscopic time scale. A similar behavior was observed at low temperatures for the cadmium thiolate, selenolate, and tellurolate complexes derived from 4,4-dimethyl-2-phenyloxazoline.[10] The ^{13}C NMR spectrum of **7** was re-

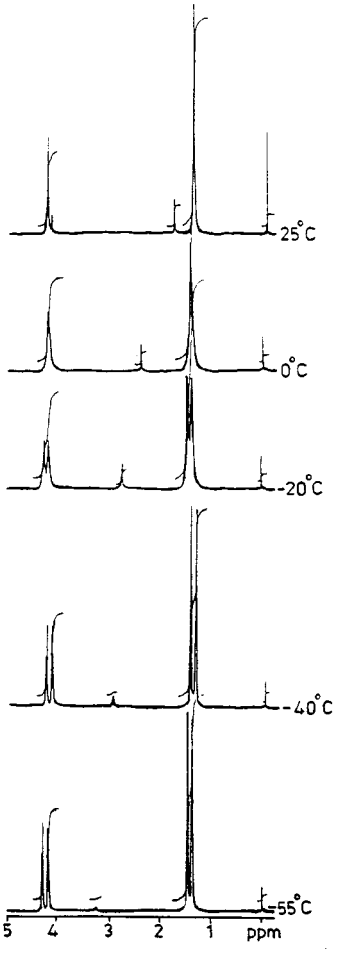


Figure 1. Variable-temperature ^1H NMR ($CDCl_3$, 300 MHz) spectra (in part only) of **7** at −55°C, the signals due to the $-CH_2-$ and $-CH_3$ protons split into an AB quadruplet and two singlets, respectively

corded in $CDCl_3$. The methyl and methylene carbon signal were shifted upfield with respect to those of **1**. The signals for the oxygen-bearing aromatic carbon atom and C(2) of the heterocycle were significantly shifted downfield (δ = 160.2 and 165.3 for **1**, δ = 170.0 and 170.5 for **7**).

Magnetic Properties

The room-temperature magnetic moment of the black-green manganese(III) complex **2** is 3.33 BM which indicates that the complex is low-spin (S = 1). The observed magnetic moment of **2** is considerably larger than the spin-only value of 2.83 BM for two unpaired electrons. This result is attributable to the presence of the orbital angular momentum for the ground term ion. Mn^{III} is known to form low-spin octahedral complexes only with strong donors like cyanides, oximes, or porphyrins. Complex **2** provides a rare example of a low-spin Mn^{III} complex with N and O donors from the oxazoline ligand. Although the effective magnetic moments for the tetrahedral Co^{II} complexes are normally observed close to the spin-only values, the observed magnetic moment for the Co^{II} complex **3** (μ_{eff} = 4.57 BM) is much higher than the spin-only magnetic moment (μ = 3.87 BM) for three unpaired electrons. This discrepancy may again be caused by angular momentum introduced to the ground state (A_2) by mixing of higher T states. The magnetic moment of 3.05 BM determined for the octahedral Ni^{II} complex **5** is very close to the spin-only value for two unpaired electrons, whereas the magnetic moment observed for tetrahedral Ni^{II} complex **4** (3.42 BM) is much higher than the spin-only value. This is in agreement with the general observation that octahedral Ni^{II} complexes have less orbital momentum than the tetrahedral complexes. It is known that the magnetic moment of truly tetrahedral Ni^{II} complexes should be about 4.2 BM because of the ground state, $^3T_1(F)$, which has much inherent orbital angular momentum. However, it is also reported that even slight distortion in the geometry reduces this markedly by splitting the orbital degeneracy. Thus, fairly regular tetrahedral complexes have moments of 3.5−4.0 BM, while for the more distorted ones the moments are 3.0−3.5 BM, i.e. in the same range as for six-coordinate complexes. The magnetic moment observed for **4**, therefore, suggests that the geometry around the metal ion is highly distorted. The magnetic moment of complex **6** (1.76 BM) is very close to the spin only value (1.73 BM) for one unpaired electron. The geometry around the metal center is, therefore, predicated as planar since a higher orbital contribution to the magnetic moment is expected for a tetrahedral Cu^{II} complex than for a planar one.[12]

Electronic Spectra

The solution-phase electronic spectrum (> 200 nm) of the ligand **1** consists of two relatively intense bands centered at 255 nm (ε_{max} = 47500 $M^{-1}cm^{-1}$) and 303 (ε_{max} = 36600 $M^{-1}cm^{-1}$), involving $\pi\rightarrow\pi^*$ transitions, and a low-intensity feature (ε_{max} = 2500 $M^{-1}cm^{-1}$) in the 350−360 nm region, responsible for the yellow color, and presumably involving $n\rightarrow\pi^*$ excitation. The electronic spectrum of **2** is dominated by a peak with medium intensity centering at 303 nm (ε_{max} = 7480 $M^{-1}cm^{-1}$), attributable to the $\sigma(N)\rightarrow Mn^{III}$ ligand-to-metal charge-transfer (LMCT) transition. One broad band at 658 nm (ε_{max} = 191 $M^{-1}cm^{-1}$) may be attributed to the ligand field transition. A broad peak centered at 500 nm (ε_{max} = 357 $M^{-1}cm^{-1}$) is also attributed to d-d transition. Four-coordinate tetrahedral and pseudo-tetrahedral Co^{II} complexes are commonly intense blue or green in color. Complex **3** shows pink color in the solid state as well as in solution. However, this is not surprising since a few complexes with dipivaloylmethane are known to give a pink color in solution.[13,14] In the tetrahedral Co^{II} case, there are three regions of absorption and, therefore, three spin-allowed electronic transitions are expected. Three d-d transition bands were observed as weak features at 501 nm (ε_{max} = 110 $M^{-1}cm^{-1}$), 563 (ε_{max} = 90 $M^{-1}cm^{-1}$), and 619 (ε_{max} = 30 $M^{-1}cm^{-1}$). The splitting of the middle band is probably due to spin-orbit coupling. There are four strong absorption bands in the high-energy region, 244 nm (ε_{max} = 33850 $M^{-1}cm^{-1}$), 281 nm (ε_{max} = 12070 $M^{-1}cm^{-1}$), 312 nm (ε_{max} = 10000 $M^{-1}cm^{-1}$), and 344 nm (ε_{max} = 11750 $M^{-1}cm^{-1}$), which can be assigned to the ligand transitions and charge-transfer transitions. For **4**, two bands, observed at 689 nm (ε_{max} = 15 $M^{-1}cm^{-1}$) and 591 nm (ε_{max} = 12 $M^{-1}cm^{-1}$), can be attributed to d-d transitions. There are three strong absorption bands in the high-energy region, 246 nm (ε_{max} = 12900 $M^{-1}cm^{-1}$), 309 nm (ε_{max} = 4730 $M^{-1}cm^{-1}$), and 336 nm (ε_{max} = 2590 $M^{-1}cm^{-1}$), which may be assigned to charge transfer and intra-ligand transitions. For **5**, there are two intense bands in the region between 200 and 340 nm that may be assigned to the intra-ligand $\pi\rightarrow\pi^*$ transitions. The band at 340 nm (ε_{max} = 1500 $M^{-1}cm^{-1}$) with medium intensity indicates the charge-transfer (CT) character. Finally, a weak feature (ε_{max} = 12 $M^{-1}cm^{-1}$) assigned to d-d transition, is present in the 500−600 nm range. For the Cu^{II} complex **6**, the ligand field transition occurs as a single broad band centering at 653 nm with an ε_{max} of 105 $M^{-1}cm^{-1}$. In addition two intense bands appear at higher energies. The peak that appears at 244 nm (ε_{max} = 30600 $M^{-1}cm^{-1}$) is assigned to the $\sigma(N)\rightarrow Cu^{II}$ LMCT transition.[15−17] The peak with medium intensity at 343 nm (ε_{max} = 11600 $M^{-1}cm^{-1}$) is too low for a charge-transfer transition involving an N donor. For tetrahedral Cu^{II} complexes with phenolate coordination, the $Cu^{II}\rightarrow$phenolate MLCT absorption occurs near 300 nm.[18,19] Therefore, the band at 309 nm (ε_{max} = 10600 $M^{-1}cm^{-1}$) is assigned as the higher energy $Cu^{II}\rightarrow\pi^*$-phenolate transition.

Electrochemistry

The cyclic voltammograms of **2−6** were recorded at room temperature in acetonitrile in the potential range −1.5 to +2.0 V vs. Ag/AgCl reference electrode. Complex **2** exhibits a quasi-reversible one-electron oxidation-reduction corresponding to the Mn^{IV}/Mn^{III} redox process ($E_{1/2}$ = 1.59 V; ΔE_p = 130 mV vs. Fc/Fc^+, $E_{1/2}$ = 0.38 V; ΔE_p = 100 mV at scan rate 50 mVs^{-1}). The Mn^{III}/Mn^{II} couple was not

observed up to −2.2 V, showing high stability of the Mn^{III} state in the present environment. Other complexes do not show any well-defined response in this potential range.

X-ray Crystallography

Crystal Structure of 2

Complex **2** crystallizes in the triclinic space group $P\bar{1}$. As can be seen in Figure 2, one of the five-membered oxazoline rings is partially hydrolyzed to give the open-chain form. The Mn^{III} ion present in the complex is six-coordinate where two nitrogen donor atoms of oxazoline rings and one carbonyl oxygen atom of the hydrolyzed oxazoline are coordinated to the central metal ion in addition to the aryloxo groups. Selected bond lengths and angles are summarized in Table 1. The three Mn−O−(Ar) bond lengths are close to each other but differ significantly from the distance between Mn and the carbonyl oxygen atom. The Mn−O and Mn−N bond lengths are comparable with the corresponding bond lengths reported for other related Mn^{III} pseudo-octahedral complexes.[19] The bond lengths and angles for the oxazoline ring reflect many similarities with the Agrobactin (Table 2).[1c] The intramolecular hydrogen bonds which are very similar to the ones observed in Agrobactin efficiently stabilize the molecular structure in the crystalline state. There are several weak interactions between the atoms in the crystal structure. Of these interactions, the hydrogen bonding between the NH proton and oxygen atom of the hydrolyzed oxazoline ring [O(33)···H−N(3) 2.266(6) Å; O(33)···N(3) 2.697(4) Å] is found to be much stronger than the others.

Crystal Structure of 3

A perspective view of the molecule with an atom numbering scheme is shown in Figure 3. Compound **3** crystallizes as a neutral monomer in the $P\bar{1}$ space group of a triclinic system. The geometry around the Co^{II} center is tetrahedral with two bidentate oxazoline ligands. Selected bond lengths and angles are given in Table 3. The average Co−O bond length 1.9052 Å is significantly shorter than those reported for $Co(OAc)_2(imid)_2$ [1.984(1) Å][20] and $Co(OAc)_2$(2-Me-imid)$_2$ [2.098(1) Å].[21] The average Co−N bond lengths 1.9885 Å is also shorter than those observed for $Co(OAc)_2(imid)_2$ [2.0135(1) Å] $Co(OAc)_2$(2-Me-imid)$_2$ [2.062(3) Å]. The average chelate bite angle of O−Co−N is 94.57°. The larger bite angle leads to relatively smaller O−Co−O and N−Co−N angles of 119.23(7)° and 121.25(7)°, respectively. The O−Co−O angle of 119.23(7)° is higher than the corresponding value reported for Co-

Crystal Structure of 5

The molecular structure of complex **5** is shown in Figure 4. Selected bond lengths and angles are presented in Table 4. The unit cell of **5** contains two nonsymmetric equivalent molecules. No significant differences between these two molecules are observed. The structure of complex **5** is found to be quite interesting. The Ni atom is six-coordinate and the geometry around the metal center is distorted octahedral. The Ni ion is bonded to two nitrogen and two oxygen atoms [both pairs are in the *cis* position (O−Ni−N angles 88.22−98.37°)] as well as two oxygen atoms of neutral acetic acid molecules. Interestingly, the acidic protons form strong hydrogen bonds with the aryloxo function of the ligand. This observation is similar to the one reported for a binuclear nickel(II) complex in which the neutral acidic acid molecule is involved in a hydrogen bonding with the alkoxo function.[11b] The C−O bond lengths of the coordinated oxygen atoms [C(12a)−O(3a) 1.223(3) Å, C(12b)−O(3b) 1.223(3) Å] are quite short while the distance of the noncoordinated oxygen atoms [C(12a)−O(4a) 1.302(4) Å, C(12b)−O(4b) 1.298(3) Å] are rather long. The bonding situation of the acetic acid molecules then allows for assuming double-bond-coordinated carbonyl groups C(12a)−O(3a) and C(12b)−O(3b) and C−O single bonds C(12a)−O(4a) and C(12b)−O(4b). The molecule has eight rings: two phenyl groups, two oxazoline groups, and four six-membered chelate rings; the latter are connected by the metal atom. The Ni(1)−N(1a) [2.075(2) Å] and Ni(1)−N(1b) [2.074(2) Å] distances are larger than those reported for four-coordinate Ni^{II} complexes with similar oxazoline ligands.[6] From the bond angle values it is observed that the two nitrogen atoms of the oxazoline five-membered rings and the two oxygen atoms of neutral acetic acid molecules form a square planar arrangement and the two phenolate oxygen atoms lie above and below the plane. The O(1a)−Ni(1)−O(1b) bond angle of 169.98(7)° indicates that these two atoms lie in the axial positions. The geometrical isomer isolated is, therefore, defined as the *cis* isomer.

Crystal Structure of 6

An ORTEP view of the copper complex **6** is shown in Figure 5. Complex **6** crystallizes in the monoclinic space group $P2_1/c$. The N atoms of the oxazoline five-membered ring and phenolato O atoms gave a distorted tetrahedral arrangement. Both tetrahedral and planar configurations have been reported for the related bis[*N*-alkylsalicylaldiminato(*O*−*N*)]copper(II) complexes, depending upon the nature of the alkyl groups.[22] For comparison with **6**, the complexes with α-branched *N*-alkyl groups should be considered. In the case of *i*Pr or *t*Bu groups, they were found to be pseudo-tetrahedral in the solid state. For example, bis[*N*-isopropylsalicylaldiminato(*O*−*N*)]copper(II) has a tetrahedral structure with an angle of 60° between the salicylaldiminato planes, whereas, *N*-Ph and *N*-Me substituted complexes are almost planar.[23,24] Lehn and co-workers have reported the crystal structure of a chiral bis(dihydrooxazole)copper(II) complex,[25] with a dihedral angle of 52° between the two N−Cu−N planes. Similar to the salicylaldiminato complexes, the oxazoline complexes also form both tetrahedral and square planar complexes depending upon the nature of the alkyl groups present on the five-membered ring. Bolm et al. have reported a Cu^{II} complex with a chiral oxazoline ligand in which the geometry around the metal center was found to be almost square planar.[6] However, the geometry around the metal center in complex **6** tends more towards tetrahedral which is probably due to the presence of the two methyl groups on the oxazoline ring. Bolm et al. have also reported that there is an interaction between the Cu atom of one molecule and the phenolate O atom of the neighboring molecule which make the Cu atoms pentacoordinate.[6] However, in complex **6** no such interactions were observed. In **6**, the angle between O(11)−Cu−N(1) and O(21)−Cu−N(2) planes is 30.8°, which indicates a distortion from planar geometry. The Cu−O distances [1.880(2) Å and 1.885(2) Å] and the Cu−N distances [1.985(2) Å, 1.986(2) Å] are similar to those reported for the chiral Cu^{II} complex[6] and bis(*N*-alkylsalicylaldiminato)copper(II) complexes.[24] In **6**, the angles of 91.76(7)° and 91.99(7)° for O(11)−Cu−N(1) and O(21)−Cu−N(2) are slightly smaller than the corresponding angles in bis(*N*-alkylsalicylaldiminato)copper(II) (94.4 and 95.0°). Significant bond lengths and angles for **6** are given in Table 3.

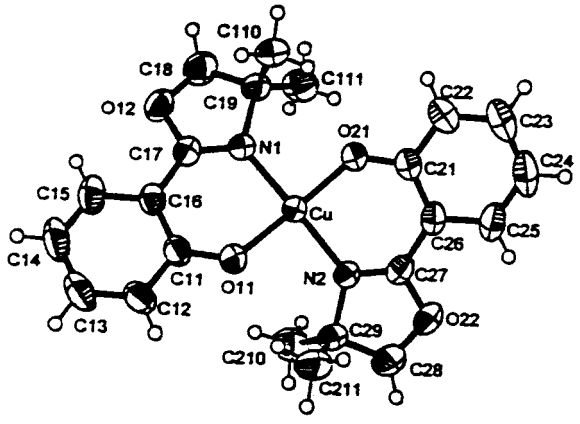

Figure 5. Crystal structure of complex **6**

Crystal Structure of 7

The colorless crystals of Zn^{II} complex **7** belong to the space group $P\bar{1}$ of the triclinic system. An ORTEP view of the structure is shown in Figure 6. Selected bond lengths and angles for **6** are given in Table 3. The Zn atom has a distorted tetrahedral coordination configuration. The interplanar angle between Zn−O(11)−N(1) and Zn−O(21)−N(2) is 86.2°. The planes between the phenyl ring and the heterocyclic ring are only slightly twisted. The dihedral angle between C(15)−C(16)−C(17)−O(12) is −0.9(3)°, that of C(15)−C(16)−C(17)−N(1) is −179.8(2)°. The Zn−O(11), Zn−O(21), Zn−N(1), and Zn−N(2) bond lengths are 1.9026(18), 1.9187(18), 1.9866(19), and 1.992(2) Å. Whereas the Zn−O distances do not differ substantially from values reported for similar Schiff base complexes,[26] the Zn−N distances are relatively short. However, the Zn−N bond lengths are slightly longer than the values reported for a similar oxazoline complex.[6]

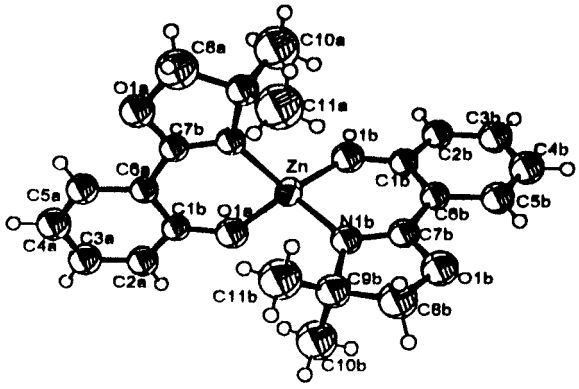

Figure 6. Crystal structure of complex **7**

Conclusion

In conclusion, we have shown that the 2-(4′,4′-dimethyl-3′,4′-dihydrooxazol-2′-yl)phenol ligand can be conveniently used to synthesize tetrahedral complexes of the late first row transition metals. Complexes **3**, **6**, and **7** crystallize as racemates in achiral space group, however, for complex **7**, the interconversion between the (*M*) and (*P*) helix is slow at low temperatures. Since the other complexes (Co, Ni, Cu) are found to be paramagnetic, the variable-temperature NMR spectroscopy of these complexes, which is used to study their low-temperature behavior, could not be attempted. The solid-state structures show that none of these complexes are chiral. Similar to the behavior of Agrobactin, the ligand 2-(4′,4′-dimethyl-3′,4′-dihydrooxazol-2′-yl)-phenol undergoes metal-assisted hydrolysis/oxidation in the presence of oxophilic Mn^{III} ions to give the partially hydrolyzed oxazoline ring as found in Agrobactin A, forming a novel mononuclear complex. The ability of Ni^{II} to form six-coordinate complexes with neutral ligands allows the

isolation of a novel octahedral Ni^{II} complex with a neutral acetic acid ligand.

Experimental Section

General Procedures: Solvents were purified by standard procedures[27] and were freshly distilled prior to use. 2-Amino-1-methyl-1-propanol (Merck) and $ZnCl_2$ were also purified prior to use.[27] 2-Hydroxybenzonitrile (Merck) was used as received. − Melting points were recorded in capillary tubes and are uncorrected. − IR spectra were recorded as KBr pellets with a Nicolet Impact 400 FT-IR spectrometer. − For **1** and **7**, the ^1H, and ^{13}C spectra were obtained at 300 and 75.42 MHz in $CDCl_3$ with a Varian VXR 300S spectrometer. Chemical shifts are cited with respect to $SiMe_4$ as an internal standard. − Elemental analyses were performed with a Carlo−Erba model 1106 elemental analyzer. − Fast atom bombardment (FAB) mass spectra were recorded at room temperature with a JEOL SX 102 DA-6000 mass spectrometer/data system using xenon (6 kV, 10 mV) as the bombarding gas. − Cyclic Voltammetry (CV) experiments were performed with an EPΣG Princeton Applied Research Potentiostat/Galvanostat Model 273A which consisted of a one-compartment cell with platinum working and counter electrodes and an Ag−AgCl electrode (reference electrode). Tetraethylammonium perchlorate was used as the supporting electrolyte. All solutions were purged with argon or nitrogen and retained under these gases while the CV data were recorded. − The EPR spectra of the complexes in chloroform or ethanol were recorded with a Varian E-112 EPR spectrometer using tetracyanoethylene as *g* marker ($g = 2.00277$) at room temperature and liquid-nitrogen temperatures. − Magnetic susceptibilities of powdered samples were determined at room temperature with a Faraday balance, standardized with mercury tetracyanocobaltate(II) [$\chi = 16.44 \cdot 10^{-6}$ cm^3 mol^{-1}]. The molar susceptibilities were corrected for ligand diamagnetism using Pascal's constants. The effective magnetic moments were calculated using the expression $\mu_{eff} = 2.83(\chi_m \times T)^{1/2}$. − Electronic absorption spectra were obtained in $CHCl_3$ at 25 °C in a 1-cm quartz cuvette with a Shimadzu UV-2100 apparatus.

Synthesis of 2-(4′,4′-Dimethyl-3′,4′-dihydrooxazol-2′-yl)phenol (1): This compound was synthesized by following the published procedure with minor modifications.[5] 2-Amino-1-methyl-1-propanol (5.99 g, 6.41 mL, 67.20 mmol), 2-hydroxybenzonitrile (5.35 g, 44.91 mmol), and $ZnCl_2$ (0.31 g, 2.24 mmol) were dissolved in chlorobenzene (90 mL) and refluxed for 24 h under nitrogen. The resulting reaction mixture was filtered to remove the undissolved impurities. The filtrate was concentrated under reduced pressure to give a brown oil which was dissolved in 50 mL of CH_2Cl_2 and washed with water. The organic layer was separated, dried with anhydrous Na_2SO_4, filtered, and concentrated to give the desired compound as a light brown oil.

Synthesis of [Mn(OR){O(Ox)}$_2$] (2): To a solution of $Mn(OAc)_2 \cdot 4\,H_2O$ (0.25 g, 1.02 mmol) in absolute ethanol (20 mL) was added a solution of **1** (0.38 g, 1.99 mmol) in ethanol (10 mL). The reaction mixture was stirred for 24 h at room temperature. The resulting dark green solution was concentrated under reduced pressure to give a dark oil. This was dissolved in dry ether (20 mL) and filtered through Celite to remove the undissolved impurities. Addition of hexane (20 mL) to the ethereal solution followed by cooling of the solution overnight afforded a black-green solid. The solid was filtered off, washed with hexane and dried under reduced pressure to give **2** as a black-green crystalline solid. Compound **2** was recrystallized by slow concentration of a solution of **2** in 1:1 mixture of CH_2Cl_2 (5 mL)/CH_3OH (5 mL) at room temperature to give black-green crystals. Yield: 0.31 g (48%). − M.p. 180−182°C. − $C_{33}H_{38}MnN_3O_7$ (643.6): calcd. C 61.58, H 5.95, N 6.53; found C 61.52, H 5.10, N 6.13. − MS; *m/z*: 453 $[C_{22}H_{26}N_2O_5Mn]^+$, 435 $[C_{22}H_{24}N_2O_4Mn]^+$, 293 $[C_{11}H_{14}NO_5Mn]^+$, 244 $[C_{11}H_{12}NO_2Mn]^+$, 191 $[C_{11}H_{12}NO_2]^+$, 173 $[C_{11}H_{12}NO]^+$. − IR (KBr): $\tilde{\nu}$ = 1580 cm^{-1}(C=O), 1609 cm^{-1}(C=N). − EPR (Solid & $CDCl_3$, 298 K): Silent.

Synthesis of [Co{O(Ox)}$_2$] (3): To a solution of $Co(OAc)_2 \cdot 4\,H_2O$ (0.25 g, 1.01 mmol) in absolute ethanol (20 mL) was added a solution of **1** (0.38 g, 1.99 mmol) in ethanol (10 mL). A pink-colored compound precipitated immediately. The stirring was continued for 12 h at room temperature. The resulting crude solid was filtered and dried under vacuum. Pink-colored needle-shaped crystals of the desired compound **3** were obtained by slow concentration of a CH_2Cl_2(5 mL)/methanol(5 mL) solution of the crude product at room temperature. Yield: 0.37g (85%). − M.p. 234−236°C. − $C_{22}H_{24}CoN_2O_4$ (439.4): calcd. X-ray Crystallographic Studies: The diffraction measurements for compounds **2**, **3**, **5**, **6**, and **7** were performed at room temperature (293 K) with a Siemens R3m/V diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The unit cell was determined from 25 randomly selected reflections using the automatic search index and least-squares routine. For **2**, the θ range for data collection was from 2.25 to 27.50° whereas for **3**, **5**, **6**, and **7** the ranges were 2.58−27.50°, 1.29−27.50°, 2.40−27.50°, and 2.58−50.59°. The index range for **2** was $-13 \le h \le 0$, $-13 \le k \le 13$, $-19 \le l \le 20$ while for **3**, **5**, **6**, and **7** the ranges were $0 \le h \le 10$, $-13 \le k \le 13$, $-16 \le l \le 17$; $0 \le h \le 41$, $-20 \le k \le 0$, $-21 \le l \le 21$; $-14 \le h \le 0$, $0 \le k \le 12$, $-25 \le l \le 25$, and $0 \le h \le 11$, $-14 \le k \le 14$, $-18 \le l \le 18$. The data for **3**, **6**, and **7** were corrected for Lorentz, polarization, and absorption effects. The maximum and minimum transmission values of the correction factors for compounds **3** (dimensions 0.48 × 0.50 × 0.49 mm), **6** (0.19 × 0.88 × 0.38 mm), and **7** (0.28 × 0.64 × 0.32 mm) were 0.4733 and 0.3904, 0.2873 and 0.2187, and 0.9181 and 0.8319. The data were monitored by measuring two standard reflections every 60 min of X-ray exposure time. The structures were solved by routine heavy-atom (using SHELXS 86[28]) and Fourier methods and refined by full-matrix least squares with the non-hydrogen atoms anisotropic and hydrogen atoms with fixed isotropic thermal parameters of 0.07 Å^2 using the SHELXL 93 program.[29] The hydrogen atoms were partially located from difference electron-density maps and the rest were fixed at calculated positions. Scattering factors were from common sources.[30] Some details of data collection and refinement are given in Table 5 and Table 6. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-134052 (**2**), -134053 (**3**), -134054 (**5**), -134055 (**6**), -134056 (**7**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structural Investigations of Oligomeric Axially Bridged Ruthenium Phthalocyanines by EXAFS Spectroscopy

Achim Weber,[a] Teja S. Ertel,[a] Ulrich Reinöhl,[a] Martin Feth,[a] Helmut Bertagnolli,*[a] Meret Leuze,[b] and Michael Hanack*[b]

Keywords: EXAFS spectroscopy / Ruthenium / Phthalocyanines / Structure elucidation

To obtain more information about the structure of phthalocyaninatoruthenium compounds an EXAFS investigation was carried out on amorphous bisaxially bridged phthalocyaninatoruthenium(II) oligomers, $[PcRu(tz)]_n$ (**1**), $[PcRu(pyz)]_n$ (**2**) and $[PcRu(dib)]_n$ (**3**). Detailed structural models for the three compounds were deduced from the determined atomic distances around the metal center. A bisaxial structure of the ligands could be proven for all compounds and additionally, the structure parameters could be determined.

Introduction

In recent years phthalocyaninatoruthenium(II) complexes have been investigated with particular regard to their preparation, chemistry, and structure.[1−3] Some years ago we reported the first synthesis of pure phthalocyaninatoruthenium(II) $(PcRu)_2$.[4] Later, we developed a convenient method for obtaining $(PcRu)_2$ by thermal decomposition of the corresponding bisisoquinoline or bis-3-chloropyridine complex $PcRu(L)_2$ (L = iqnl; 3-Clpy) at 250 or 270 °C,[5,6] respectively. This provides the basis for the preparation of axially bridged $[PcRu(L)]_n$ oligomers with bidentate bridging ligands L [e.g. L = pyrazine (pyz), *s*-tetrazine (tz), 1,4-diisocyanobenzene (dib)] as a new class of intrinsic semiconductors.[2,4]

An important condition for achieving electrical conductivity in phthalocyaninato compounds is the stacked arrangement of the macrocycles. Assuming a suitably small distance between cofacially arranged planar macrocycles possessing an extended π-electron system, electron delocalization by π-π overlap of the perpendicular orbitals in a stacked arrangement is possible. In particular, oxidation (or less frequently reductive doping) of the macrocycles generates charge carriers leading to semiconducting or conducting quasi-one-dimensional materials.

Phthalocyaninato compounds, however, do not crystallize in this stacked arrangement, except phthalocyaninatolead(II) (PcPb) in its monoclinic modification.[7] Metallophthalocyanines in general crystallize in an α- or β-modification (inclined stacked), which is not favorable for π-orbital overlap and thus for the formation of a conducting band.

Some years ago a route was developed to stacked arrangements of phthalocyaninato transition metal compounds which lead to coordination oligomers and polymers where the macrocycle, the central metal atom and the bridging ligand can be varied systematically. The stacking is achieved by connecting the central transition metal atoms of the macrocycle with bidentate bridging ligands L bisaxially. Such bridged macrocyclic transition metal compounds $[MacM(L)]_n$ have been synthesized and investigated in detail with respect to their physical properties.[8,9] The bridging ligands L are linear π-electron-containing organic molecules, for example pyrazine, 1,4-diisocyanobenzene or substituted 1,4-diisocyanobenzenes, *s*-tetrazine or substituted tetrazines, and others. Many of the bridged macrocyclic metal complexes $[MacM(L)]_n$ (“shish-kebab polymers”) can be prepared in high yields and high purity by treating the metallomacrocycle MacM with the pure ligand or with the ligand in an appropriate solvent. The bridged structure has been confirmed for many compounds using a variety of physical methods[8] including detailed IR investigations,[10] Mössbauer spectroscopy,[11] ^1H and ^{13}C NMR spectroscopy[12] and scanning tunneling microscopy (STM).[13]

$(PcRu)_2$ reacts easily with ligands L such as pyrazine, *s*-tetrazine, 1,4-diisocyanobenzene and others to form the corresponding monomers $PcRu(L)_2$, and under somewhat different conditions to form the bridged systems $[PcRu(L)]_n$.[4,14] Although the monomeric complexes $PcM(L)_2$ (L = pyz, tz, dib; M = Fe, Ru, Os) are all insulators, it can be seen that the ligand (L) has a significant effect on the conductivity of the bridged complexes $[PcM(L)]_n$: as 1,4-diazabicyclo[2.2.2]octane (dabco) is a ligand containing no π-orbitals to interact with the metallomacrocycle the $[PcM(dabco)]_n$ complexes are also insulators,[2] whereas an increase in electrical conductivity is observed for the pyrazine- and 1,4-diisocyanobenzene-bridged compounds. $[PcRu(pyz)]_n$ (**2**) and $[PcRu(dib)]_n$ (**3**) exhibit electrical conductivities ($\sigma_{RT} = 1 \times 10^{-7}$ S cm^{-1} and σ_{RT} =

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0303−0679 $ 17.50+.50/0

2×10^{-6} S cm^{-1})[4,15] in the low semiconducting region. However, by changing the bridging ligand to *s*-tetrazine or its derivatives the conductivity increases by three to five orders of magnitude without external oxidative doping.[2,16] With *s*-tetrazine as the ligand in $[PcRu(tz)]_n$ (**3**), a powder conductivity of 0.01 S cm^{-1} can be achieved.

Structural investigations on oligomeric phthalocyaninatoruthenium(II) compounds with EXAFS or LAXS spectroscopy have only been performed on oxygen-containing materials up to now.[3] Extended X-ray absorption fine structure (EXAFS) has been considered to be a powerful technique for determining the local atomic environment of a specific atom without regard to the state of the sample. An analysis of the EXAFS provides information on the bond length, the coordination number, the "Debye−Waller"-like factor, and the nature of the scattering atoms surrounding an excited atom.[17,18] In this paper, we have studied (μ-*s*-tetrazine)phthalocyaninatoruthenium(II) (**1**), (μ-pyrazine)phthalocyaninatoruthenium(II) (**2**) and (μ-1,4-diisocyanobenzene)phthalocyaninatoruthenium(II) (**3**) as amorphous solids by transmission EXAFS spectroscopy.

Results and Discussion

(μ-*s*-Tetrazine)phthalocyaninatoruthenium(II) (1)

In the Fourier transforms (see Figure 1b and 1d), several coordination shells are visible. In fitting the EXAFS function to the experiment we fixed the coordination numbers to the known values of the phthalocyanine molecule. Furthermore, the four shells of the phthalocyanine macrocycle were only fitted independently in such a way that the determined distances led to meaningful interatomic distances in the macrocycle itself. Taking these considerations into account the number of parameters decreases from 12 to 9 and is clearly less than the number of independent data points (22).[19]

Five backscatterers are necessary for a good fit of the EXAFS function (see Figure 1c, 1d and Table 1). These are the four backscatterers of the phthalocyanine macrocycle and one nitrogen backscatterer, which can be traced back to the bridging ligand *s*-tetrazine at a distance of 2.22 Å. Without this backscatterer the fit worsens significantly to

Table 1. EXAFS-determined structural data of **1**[a]

[a] Absorber−backscatterer distance *r*, coordination number *N* and Debye−Waller factor σ with their calculated standard deviation. The simulations with four and five backscatterers are marked by the superscripts 4 and 5. The ΔE_0 shift of **1** of EXCURV92 is 19.03 eV and the *R*-factors are 35.8[4] and 28.2[5].

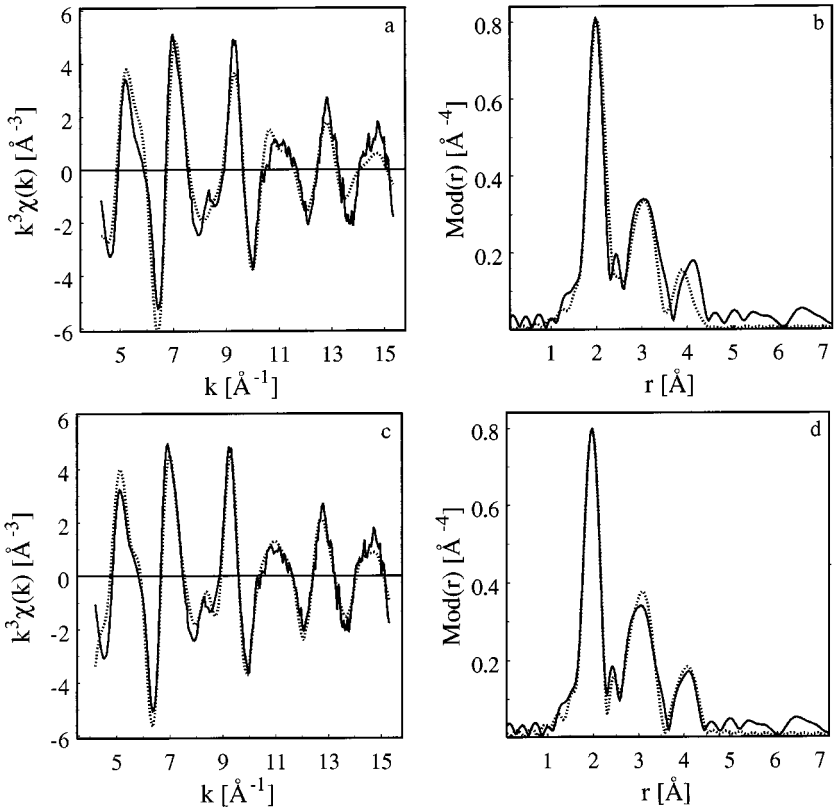

Figure 1. Experimental (solid line) and calculated (dotted line) Ru−K $k^3 \cdot \chi(k)$ functions (a, c) and their corresponding Fourier transforms without phase correction (b, d) of **1** (*k* range: 3.45−15.45 Å^{-1}); simulation with four (a, b) and five (c, d) backscatterers; the corresponding structural data are given in Table 1

about 21%. The difference of the fit with four and five backscatterers can be compared in Figure 1a and 1b (four backscatterers) and Figure 1c and 1d (five backscatterers). The resulting model of **1** with the determined distances can be seen in Figure 2a.

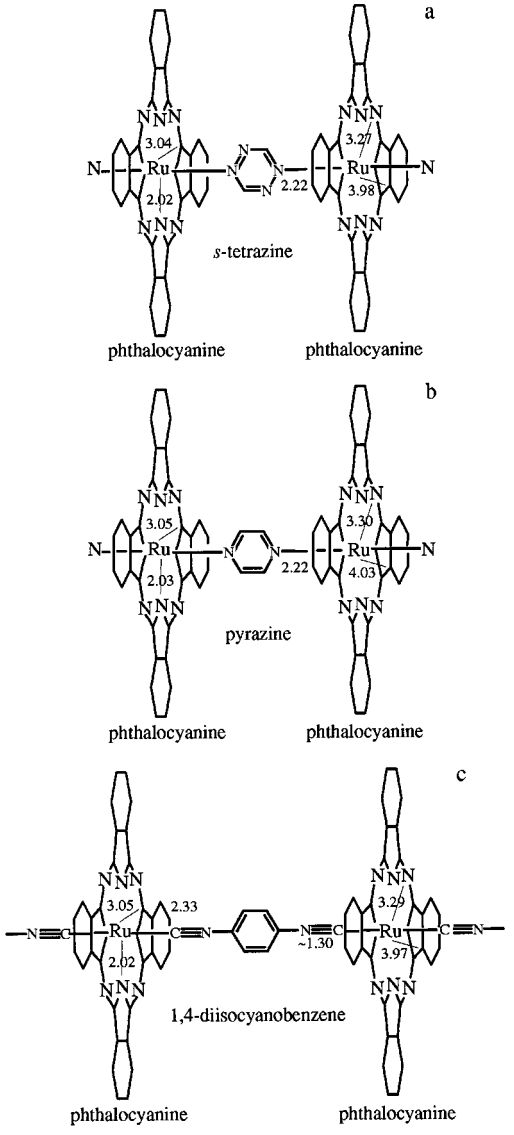

Figure 2. Determined distances and proposed structures of **1** (a), **2** (b) and **3** (c)

Without any knowledge of the structure, one would expect the ruthenium atom to be located in the plane of the phthalocyanine ring. A planar arrangement of the atoms should give rise to a considerable contribution of multiple scattering to the EXAFS spectrum. Defining the multiple scattering unit shown in Figure 3, we found in several calculations that for this geometrical arrangement the relevant maximum order of multiple scattering is three. But in all fits we could not describe the experimental spectrum satisfactorily.

Since only single scattering contributes to the EXAFS function, we are forced to assume that the ruthenium atom

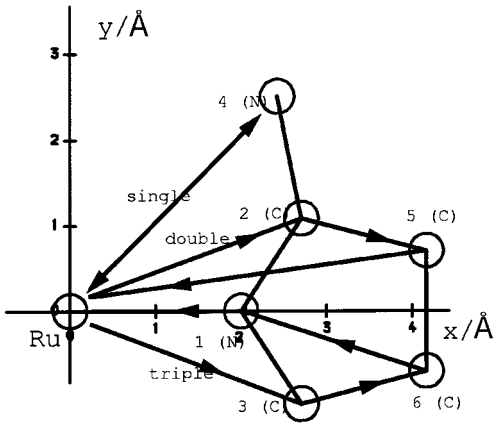

Figure 3. Defined multiple scattering unit illustrating single, double and triple scattering paths; for reasons of clarity the axially coordinated ligand atom is not drawn, but included in our calculations

is not positioned in the plane of the ring, the ring itself is not planar, or both. In order to check the dependence of the amount of multiple scattering from the out-of-plane displacement of the ruthenium atom in an idealized planar macrocycle, we performed systematic calculations. We found the astonishing result that the amount of multiple scattering does not depend very strongly on the out-of-plane position of the ruthenium atom. The contribution of the multiple scattering almost vanishes only when the displacement amounts to 1.75 Å. Since such a large displacement of the ruthenium atom is quite unlikely, we have to conclude that the nonplanarity of the macrocycle is the main cause of the absence of any multiple scattering and that the possible displacement of the ruthenium atom — if it exists — plays only a minor role. From the determined distances, it is not possible to make any structural statements concerning the nonplanarity of the macrocycle.

(μ-Pyrazine)phthalocyaninatoruthenium(II) (2)

For a good simulation of the EXAFS function of compound **2**, at least five shells are necessary (see Table 2 and Figure 4). These are the four shells of the phthalocyanine macrocycle and an additional nitrogen backscatterer at 2.22 Å, which can only be assigned to the ligand pyrazine as there are no ring atoms located in that distance range. The fit index decreases to about 9% if we take five shells of

[a] Absorber−backscatterer distance r, coordination number N and Debye−Waller factor σ with their calculated standard deviation. The simulations with four and five backscatterers are marked by the superscripts 4 and 5. The ΔE_0 shift of **2** is 19.60 eV and the R-factors are 38.9[4] and 35.4[5].

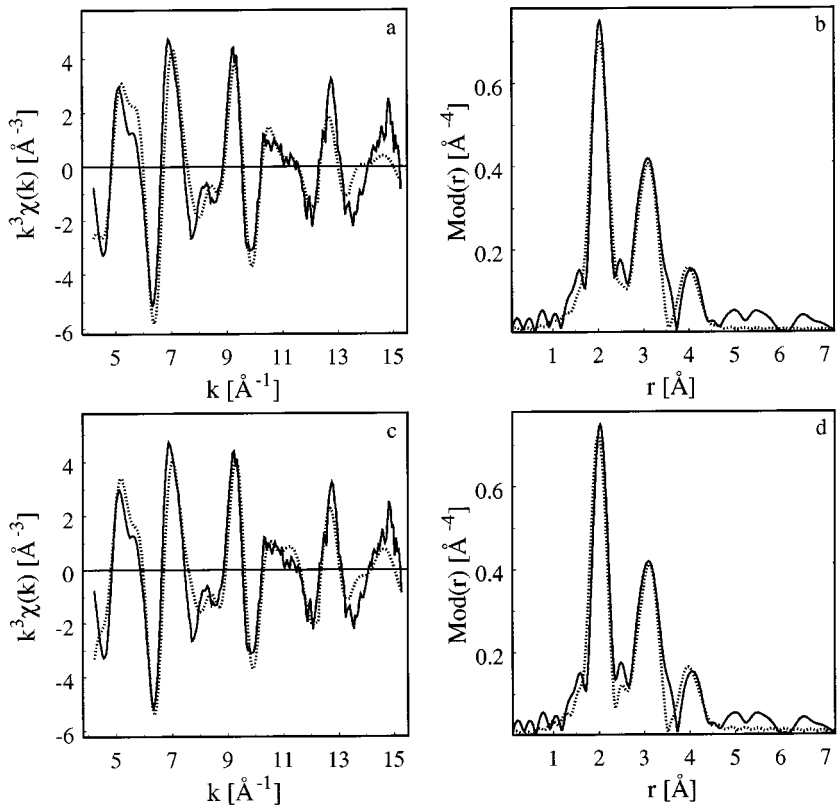

Figure 4. Experimental (solid line) and calculated (dotted line) Ru−K $k^3 \cdot \chi(k)$ functions (a, c) and their corresponding Fourier transforms without phase correction (b, d) of **2** (k range: 3.45−15.45 Å^{-1}); simulation with four (a, b) and five (c, d) backscatterers; the corresponding structural data are given in Table 2

the phthalocyanine macrocycle instead of four into account (compare Figure 4a, 4b and 4c, 4d).

If we make the simplified assumption that the four nitrogen atoms of the phthalocyanine macrocycle that form the first coordination shell lie in a plane, the displacement of the ruthenium atom can be explained in the following way. From crystallographic data we know that the metal−nitrogen distance of planar systems, for example in phthalocyaninatomanganese(tetracyanoethenide), is typically 1.97 ± 0.3 Å.[20−22] As a N−N diagonal distance of 3.94 ± 0.6 Å follows from this value, we can calculate that the ruthenium atom is located 0.4 ± 0.3 Å outside the plane of the macrocycle (see Figure 2). It should be noted that this triangulation depends critically on both the measured Ru−N distance and the assumed N-center distance. It is only given here to get a rough estimation of the amount of the possible displacement. The resulting model of **2** with the determined distances can be seen in Figure 2b.

(μ-1,4-Diisocyanobenzene)phthalocyaninatoruthenium(II) (3)

As in **1**, five shells are required to describe the EXAFS function (see Table 3 and Figure 5). Again, these are the four shells of the phthalocyanine macrocycle and one additional carbon backscatterer at 2.33 Å, which can only be assigned to the ligand 1,4-diisocyanobenzene as in that distance range no ring atoms are located. The fit worsens drastically (nearly 40%) if we do not take this fifth carbon backscatterer into account (compare Figure 5a and 5b with 5c and 5d). Further backscatterers could not be found by EXAFS spectroscopy. The next distance to the nitrogen from the 1,4-diisocyanobenzene should be about 1.3 Å further away than the carbon backscatterer (at about 3.6 Å). A fitting with this backscatterer in this distance range does not increase the agreement of the experimental EXAFS function compared to the fitted function. The resulting model of **3** with the determined distances can be seen in Figure 2c.

Conclusion

It was possible to deduce detailed structural models for (μ-*s*-tetrazine)phthalocyaninatoruthenium(II) (**1**), (μ-pyraz-

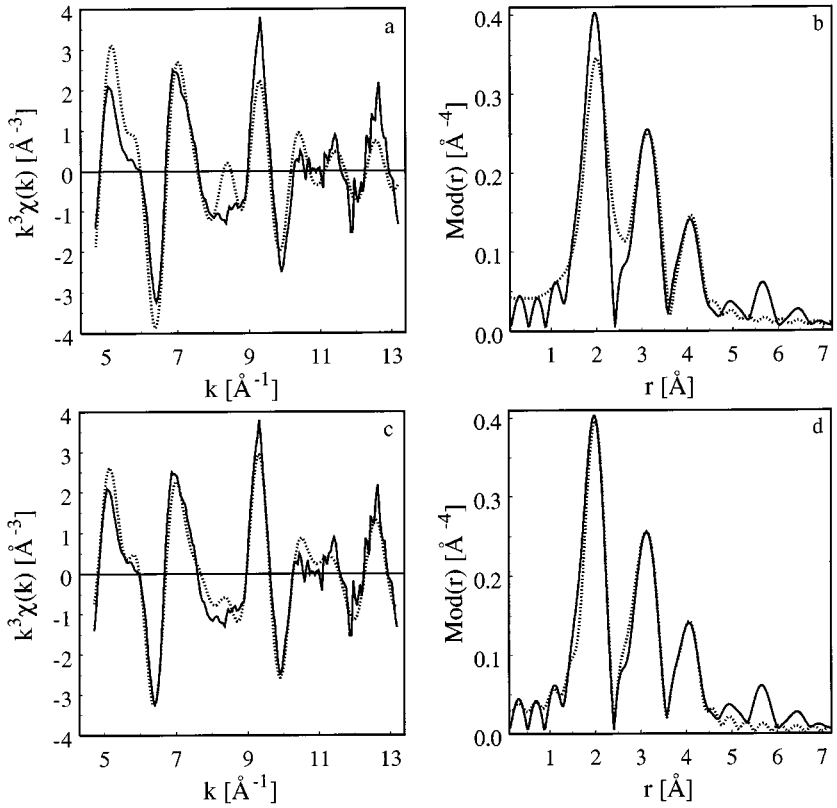

Figure 5. Experimental (solid line) and calculated (dotted line) Ru−K k^3·$\chi(k)$-functions (a, c) and their corresponding Fourier transforms without phase correction (b, d) of **3** (k range: 3.45−13.25 Å^{-1}); simulation with four (a, b) and five (c, d) backscatterers; the corresponding structural data are given in Table 3

ine)phthalocyaninatoruthenium(II) (**2**) and (μ-1,4-diisocyanobenzene)phthalocyaninatoruthenium(II) (**3**) by EXAFS spectroscopy. A sixfold coordination of the ruthenium atom exists in the investigated compounds, where the bridging ligands are located axially in an octahedral arrangement on both sides of the phthalocyanine macrocycle. The differences in the environment around the ruthenium center between the compounds **1**, **2** and **3** are not significant.

Experimental Section

^{1}H NMR: Bruker ARX 250 (250.133 MHz), as internal standard [D$_5$]pyridine was used. − UV/Vis Shimadzu UV−365. − Elemental analyses: Carlo Erba Elemental Analyzer 1104, 1106. Due to the formation of ruthenium nitride and carbide, only hydrogen values were determined by elemental analysis for the oligomeric phthalocyaninatoruthenium complexes **1**−**3**.

Starting Materials and General Methods: Pyrazine was commercially available. 1,4-Diisocyanobenzene[23] and *s*-tetrazine[24] were prepared according to known procedures. Phthalocyaninatoruthenium was prepared according to the method described previously.[5]

(μ-*s*-Tetrazine)phthalocyaninatoruthenium(II) (1): A mixture of phthalocyaninatoruthenium (**1**) (100 mg, 0.16 mmol), *s*-tetrazine (15 mg, 0.18 mmol), and dry tetrahydrofuran (10 mL) was refluxed under an inert gas atmosphere for 6 days. After cooling to room temperature, the reaction mixture was centrifuged. The collected solid was washed several times with acetone and then dried in vacuo at 70 °C. Yield: 87 mg (78%), blue-black powder.

$[C_{34}H_{18}N_{12}Ru]_n$ ($[695.67]_n$): calcd. H 3.1; found H 3.1. − ^{1}H NMR (250 MHz, [D$_5$]pyridine, 25 °C): δ = 7.78−8.13 (m, 1 H, Pc-H$_a$), 8.75−9.44 (m, 1 H, Pc-H$_b$). − UV/Vis (chlorobenzene): λ_{max} = 642, 583 nm.

(μ-Pyrazine)phthalocyaninatoruthenium(II) (2): A mixture of phthalocyaninatoruthenium (100 mg, 0.16 mmol), pyrazine (15 mg, 0.19 mmol), and dry tetrahydrofuran (10 mL) was refluxed under an inert gas atmosphere for 6 days. After cooling to room temperature, the reaction mixture was centrifuged. The collected solid was washed several times with acetone and dried in vacuo at 70 °C. Yield: 67 mg (60%), dark blue powder.

$[C_{36}H_{20}N_{10}Ru]_n$ ($[693.69]_n$): calcd. H 2.9; found H 2.9. − ^{1}H NMR(250 MHz, [D$_5$]pyridine, 25 °C): δ = 5.67 (m, 1H; pyrazine), 7.86−8.01 (m, 4 H, Pc-H$_a$), 9.44−9.55 (m, 4 H, Pc-H$_b$). − UV/Vis (chlorobenzene): λ_{max} = 639, 585 nm.

(μ-1,4-Diisocyanobenzene)phthalocyaninatoruthenium(II) (3): A mixture of phthalocyaninatoruthenium (**1**) (100 mg, 0.16 mmol), 1,4-diisocyanobenzene (22 mg, 0.17 mmol), and dry tetrahydrofuran (10 mL) was refluxed under an inert gas atmosphere for 6 days. After cooling to room temperature, the reaction mixture was centrifuged. The collected solid was washed several times with acetone and then dried in vacuo at 70 °C. Yield: 91 mg (75%), blue-black powder.

$[C_{40}H_{20}N_{10}Ru]_n$ ($[742.09]_n$): calcd. H 2.8; found H 2.8. − ^{1}H NMR (250 MHz, [D$_5$]pyridine, 25 °C): δ = 3.6−3.7 (m, 4 H, 1,4-diisocyanobenzene), 7.88−8.06 (m, 8 H, Pc-H$_a$), 9.36−9.57 (m, 8 H, Pc-H$_b$). − UV/Vis (chlorobenzene): λ_{max} = 640, 582 nm.

EXAFS Measurements: The EXAFS measurements of the oligomeric phthalocyaninatoruthenium complexes **1**−**3** were performed

at the ruthenium K edge at 22118 eV, at the beamline A1, at the Hamburger Synchrotronstrahlungslabor (HASYLAB) at DESY, Hamburg, with a Si<311> double crystal monochromator under ambient conditions (5.4 GeV, beam current 100 mA). The tilt of the second monochromator crystal was set to 30% harmonic rejection. Energy resolution was estimated to be about 10 eV at the ruthenium K edge. Data were collected in transmission mode with ion chambers which were continuously flushed with argon. Energy calibration was monitored with a 20 μm thick ruthenium metal foil. All measurements were performed under an inert gas atmosphere. The samples were embedded in a polyethylene matrix, whose thickness was adjusted to an absorption jump of $\mu = 1.5$. First, background absorption was removed from the experimental absorption spectrum by subtraction of a Victoreen-type polynomial. Then, the spectrum with background subtracted was convoluted with a series of increasingly broader Gaussian functions and the common intersection point of the convoluted spectra was taken as energy E_0.[25,26] To determine the smooth part of the spectrum, corrected for pre-edge absorption, a piecewise polynomial was used. It was adjusted in such a manner that the low-R components of the resulting Fourier transform were minimal. After division of the background-subtracted spectrum by its smooth part, the photon energy was converted into a photoelectron wavenumber scale. The resulting EXAFS function was weighted with k^3. Data analysis in k space was performed according to the curved-wave multiple scattering formalism of the program EXCURV92 with the XALPHA phase and amplitude functions.[27] The mean free path of the scattered electrons was calculated from the imaginary part of the potential (VPI was set to −4.00), the amplitude reduction factor AFAC was fixed at 0.8 and an overall energy shift (E_0) was assumed.

Acknowledgments

We wish to thank HASYLAB (Hamburg) for kind support of synchrotron radiation and the Fonds der Chemischen Industrie for generous financial support. This work has been supported by the DFG (Grant No. Li 154/41−4).

Half-Sandwich Chloro Complexes as Ligands for $RuCl_2L_2$ (L = PR_3, alkene): Syntheses, Structures, and Catalytic Activity of New Homo- and Heterobimetallic Complexes

Ana C. da Silva,[a] Holger Piotrowski,[a] Peter Mayer,[a] Kurt Polborn,[a] and Kay Severin*[a]

Keywords: Halides / Catalysis / Heterobimetallic complexes / Oxidations / Ruthenium / Rhodium / Iridium

Homo- and heterobimetallic complexes, in which half-sandwich complexes of ruthenium(II), rhodium(III), and iridium(III) are connected via three chloro bridges to $RuCl_2(PPh_3)_2$, have been synthesized. The complexes were obtained in quantitative yields by reaction of $[(cymene)RuCl(\mu\text{-}Cl)]_2$ or $[Cp^*MCl(\mu\text{-}Cl)]_2$ (M = Rh, Ir) with $[(PPh_3)_2ClRu(\mu\text{-}Cl)_3Ru(Me_2CO)(PPh_3)_2]$ (**2**). The crystal structure of **2** has been determined by X-ray analysis. Evidence that half-sandwich chloro complexes are generally suited for stabilizing $RuCl_2L_2$ fragments is provided by the synthesis of complexes $[(cymene)Ru(\mu\text{-}Cl)_3RuCl(dppb)]$ [dppb = 1,4-bis(diphenylphosphanyl)butane] and $[(cymene)Ru(\mu\text{-}Cl)_3RuCl(cod)]$ (cod = 1,5-cyclooctadiene), both of which have been structurally characterized. The abilities of all the complexes to catalyze the oxidation of secondary alcohols with 2-butanone have been investigated. The complex $[Cp^*Rh(\mu\text{-}Cl)_3RuCl(PPh_3)_2]$ has proved to be highly active, displaying a performance superior to that of previously known catalysts such as $[RuCl_2(PPh_3)_3]$. Using a substrate/catalyst ratio of 500:1, initial turnover frequencies of up to 3400 h^{-1} were observed. The potential of these types of bimetallic complexes to act as catalysts for other reactions is discussed.

Introduction

Inspired by Nature, specifically by the high efficiencies and selectivities of bimetallic metalloenzymes, chemists have tried hard to design polynuclear complexes showing superior performances in catalytic reactions. Despite numerous efforts, often accompanied with elaborate syntheses of suitable ligands, success has hitherto been rare, especially in relation to catalysts with relevance in organic synthesis.[1] Prominent exceptions are the heterometallic lanthanide complexes developed by Shibasaki et al., which are excellent catalysts for asymmetric aldol and nitro-Mannich-type reactions,[2] and a dinuclear rhodium complex that has been used in hydroformylation reactions.[3]

We have investigated the syntheses, structures, and reactivities of dinuclear complexes in which two different metal fragments are connected by halo bridges.[4] A major advantage of this kind of compound is that the synthesis is generally fast and easy. Consequently, a variety of different complexes can be obtained in a short time, allowing an efficient screening of their catalytic properties.

The first convincing evidence that highly active catalysts can be found within this class of compounds was recently provided by the groups of Grubbs and Herrmann. Studying metathesis reactions with well-defined (carbene)ruthenium complexes, they discovered that dinuclear complexes in which ruthenium, osmium, and rhodium complexes are connected by chloro bridges to a ruthenium fragment are exceptionally active.[5] Importantly, the catalytic activity of the carbene complex is modulated by the second metal fragment, which itself does not participate directly in the catalytic reaction.

We describe herein the synthesis and structures of new homo- and heterobimetallic complexes containing $RuCl_2L_2$ fragments (L = PR_3, alkene). The formally unsaturated 14-electron species are coordinated to half-sandwich complexes of ruthenium, rhodium, and iridium via three chloro bridges. The catalytic oxidation of secondary alcohols by 2-butanone with these types of bimetallic complexes is reported.

Results and Discussion

Synthesis of Dinuclear Complexes with $RuCl_2(PR_3)_2$ Fragments

$[RuCl_2(PPh_3)_3]$ is a remarkably versatile catalyst precursor. Catalytic reactions such as hydrogenations, isomerizations, oxidations, and hydrosilylations have been carried out with this complex, in some cases with remarkable efficiency.[6] A major drawback of $[RuCl_2(PPh_3)_3]$, however, is its low solubility in organic solvents. For several reactions, the loss of one triphenylphosphane ligand is assumed to occur prior to catalysis. We were thus interested in ascertaining whether organometallic chloro complexes of the late transition metals could be used to stabilize and solubilize the active $RuCl_2(PPh_3)_2$ fragment. In a first experiment, we investigated the reaction of $[(cymene)RuCl(\mu\text{-}Cl)]_2$ with $[RuCl_2(PPh_3)_3]$ in dichloromethane (Scheme 1).

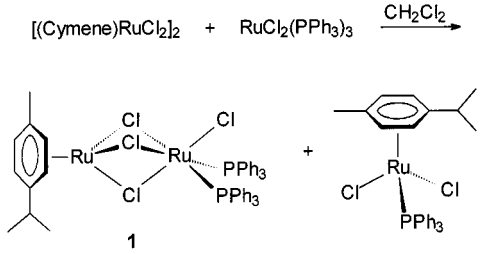

Scheme 1. Synthesis of complex **1**

Equimolar amounts of two products were formed, one of which was identified as [(cymene)$RuCl_2(PPh_3)$] by NMR (^1H, ^{31}P). The second product (**1**) was isolated in pure form by washing the mixture with acetone. Spectroscopic as well as analytical data pointed to a complex of the empirical formula [Ru_2Cl_4(cymene)$(PPh_3)_2$]. The geometry of **1** was established by a single-crystal X-ray analysis, which revealed a structure with three bridging chloro ligands. This geometry is what was expected in view of the high tendency of (arene)-[7] as well as (phosphane)ruthenium(II) complexes[6c] to form (μ-Cl)$_3$ structures. Unfortunately, despite numerous attempts, we were unable to obtain crystallographic data of satisfactory quality and therefore a more detailed analysis of the structure of **1** is not presented.

In a quest for a more suitable source of the $RuCl_2(PPh_3)_2$ fragment, we turned our attention to a complex of the stoichiometry [$RuCl_2(PPh_3)_2(Me_2CO)]_n$ (**2**). Wilkinson first synthesized this compound by heating [$RuCl_2(PPh_3)_3$] in acetone under reflux.[8] Later, a dimeric structure with two bridging chloro ligands was suggested,[9] but problems in reproducing the reaction were also reported.[10] We have found that a complex of this formula can be obtained if [$RuCl_2(PPh_3)_3$] is treated with acetone at room temperature. The heterogeneous reaction is best carried out without stirring. Under these conditions, dark-red crystals of **2** are formed in good yield after several days. The crystals, which can be stored without the need for an inert gas, display very low solubility in all common organic solvents. The molecular structure of **2** in the crystal is shown in Figure 1. The complex is dimeric but, contrary to previous suggestions, three and not two chloro bridges are observed. Consequently, the second molecule of acetone is not coordinated to the ruthenium center. Therefore, complex **2** should be formulated as [$(PPh_3)_2$ClRu(μ-Cl)$_3$Ru(Me_2CO)-$(PPh_3)_2$]Me_2CO.

The geometry about the ruthenium atoms can be described as distorted octahedral. The distortion is mainly due to the sterically demanding phosphane ligands and is manifested in large P−Ru−P angles (98.2 and 99.7°). In agreement with general theoretical investigations,[11] the acetone ligand shows an η^1 and not an η^2 coordination mode. The C−O bond length in the coordinated acetone molecule is slightly longer (1.20 Å) than the C−O bond length in the co-crystallized "free" acetone molecule (1.17 Å). The structural motif found for **2** is common in (phosphane)ruthenium chemistry. Several other complexes of the

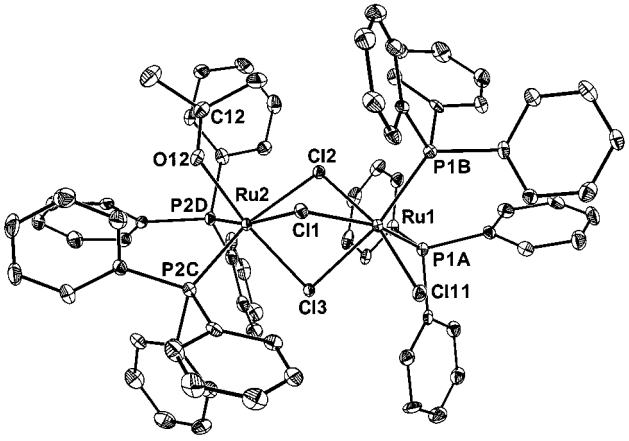

Figure 1. Molecular structure of **2** in the crystal; the solvent molecule and hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Ru1−Cl1 2.540(2), Ru1−Cl2 2.395(2), Ru1−Cl3 2.450(2), Ru2−Cl1 2.446(2), Ru2−Cl2 2.470(2), Ru2−Cl3 2.368(2), Ru1−Cl11 2.400(2), Ru1−P1A 2.268(2), Ru1−P1B 2.293(2), Ru2−P2C 2.300(2), Ru2−P2D 2.316(2), Ru2−O12 2.121(4), O12−C12 1.201(8); Ru1−Cl3−Ru2 83.19(5), P1A−Ru1−P1B 98.23(6), Cl2−Ru1−Cl11 165.04(5), P2C−Ru2−P2D 99.71(6)

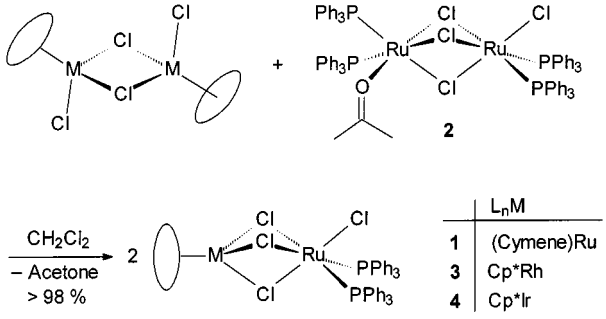
general formula [$(PR_3)_2$ClRu(μ-Cl)$_3$Ru(L)$(PR_3)_2$] (L = neutral or anionic ligand) have been described.[6c,12] Structural data for the closely related [$(PPh_3)_2$ClRu(μ-Cl)$_3$Ru(CS)$(PPh_3)_2$] are available.[13]

Complex **2** proved to be an ideal starting material for the synthesis of **1** and the heterobimetallic complexes **3** and **4**. Upon reaction of **2** with [(cymene)RuCl(μ-Cl)]$_2$ or [Cp*MCl(μ-Cl)]$_2$ (M = Rh, Ir) in dichloromethane, the dinuclear compounds were obtained in quantitative yields (Scheme 2).

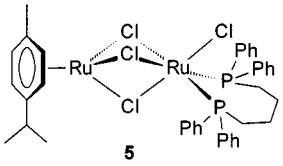


Scheme 2. Synthesis of the homo- and heterobimetallic complexes **1**, **3**, and **4**

Compounds **3** and **4** are among the first heterobimetallic complexes with three chloro bridges to be synthesized.[14] Heterobimetallic $Rh^{III}-Ru^{II}$ complexes with bridging hydrido and carboxylato ligands have been described by Süss-Fink.[15] In contrast to [$RuCl_2(PPh_3)_3$], the new complexes show good solubility in a variety of organic solvents, such as dichloromethane, tetrahydrofuran, and benzene, a prerequisite for applications in homogeneous catalysis. Although they are not very sensitive towards oxygen in the solid state, solutions of **1**, **3**, and **4** readily turn brown upon exposure to air.

For catalytic applications, ruthenium complexes with chelating phosphane ligands are especially interesting since the

accessibility of the active site can be controlled by the bite angle of the chelate. Furthermore, stereochemical information can be introduced using chiral ligands. To demonstrate that half-sandwich chloro complexes are suited for stabilizing $RuCl_2(L-L)$ complexes [L−L = bis(phosphane)], we have synthesized complex **5** by reaction of $[RuCl_2(PPh_3)(dppb)]$ with $[(cymene)RuCl(\mu\text{-}Cl)]_2$; $[(cymene)RuCl_2(PPh_3)]$, which is formed as a side product, can be separated by crystallization from acetone.



5

The structure of complex **5** in the crystal is shown in Figure 2. As expected, the (η^6-arene)Ru fragment is coordinated via three chloro bridges to the second ruthenium atom, the geometry about which can be described as distorted octahedral. The Ru−Cl bond length to the terminal chloro ligand (2.39 Å) is smaller than the Ru−Cl distances of the bridging chloro ligands (2.41−2.53 Å). The P−Ru−P bond angle (94.2°) is comparable to those found in other Ru(dppb) complexes.[16]

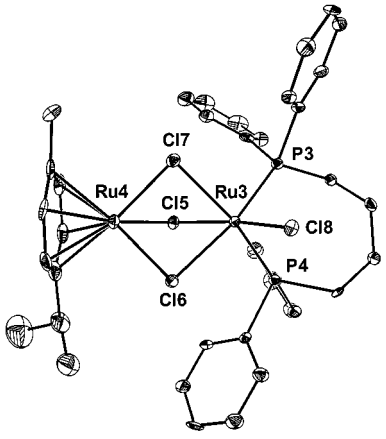


Figure 2. Molecular structure of **5** in the crystal; hydrogen atoms and solvent molecules are omitted for clarity; selected bond lengths [Å] and angles [°]: Ru4−Cl5 2.425(2), Ru4−Cl6 2.410(2), Ru3−Cl6 2.535(2), Ru4−Cl7 2.438(2), Ru3−Cl5 2.407(2), Ru3−Cl7 2.534(2), Ru3−P3 2.240(2), Ru3−P4 2.249(2), Ru3−Cl8 2.387(2); Ru3−Cl5−Ru4 86.17(6), P3−Ru3−P4 94.24(7), Cl8−Ru3−Cl5 166.99(7), P4−Ru3−Cl5 94.63(6)

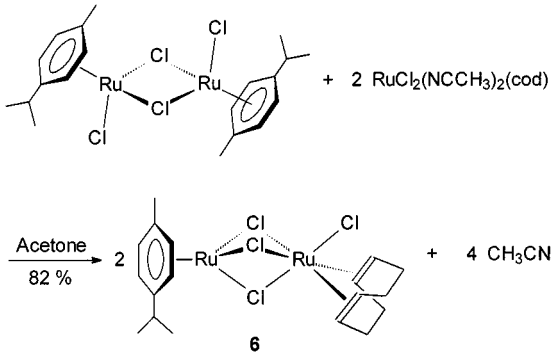
Synthesis of a Dinuclear Complex with an $RuCl_2(cod)$ Fragment

To investigate whether half-sandwich chloro complexes can form dinuclear complexes with other $RuCl_2L_2$ fragments (L ≠ PR_3), we studied the reaction of $[(cymene)RuCl(\mu\text{-}Cl)]_2$ with $[RuCl_2(cod)(NCCH_3)_2]$. This complex was chosen because the acetonitrile ligands could be expected to be labile. After reaction in refluxing acetone and crystallization from CH_2Cl_2/pentane, we were able to isolate the dimeric complex **6** (Scheme 3).



6

Scheme 3. Synthesis of complex **6**

Due to the reduced symmetry of **6** as compared to $[RuCl_2(cod)(NCCH_3)_2]$, four discrete signals due to the C atoms of the cyclooctadiene ligand are observed in its ^{13}C NMR spectrum ($CDCl_3$). Accordingly, two groups of signals are observed for the olefinic protons in the ^1H NMR spectrum. X-ray analysis of **6** reveals a structure similar to that of **5**, with the dppb ligand being substituted by a cod ligand (Figure 3). Again, the Ru−Cl bond length to the terminal chloro ligand (2.39 Å) is shorter than the Ru−Cl distances of the bridging chloro ligands (2.42−2.49 Å). The cyclooctadiene ligand shows the normal tub conformation with Ru−C bond lengths in the expected range.[17]

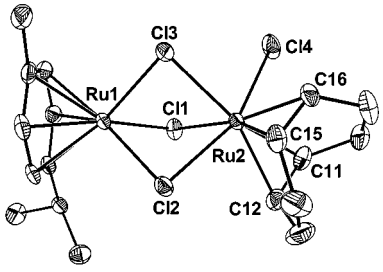


Figure 3. Molecular structure of **6** in the crystal; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Ru1−Cl1 2.441(1), Ru1−Cl2 2.422(1), Ru1−Cl3 2.441(1), Ru2−Cl1 2.482(1), Ru2−Cl2 2.454(1), Ru2−Cl3 2.485(1), Ru2−Cl4 2.388(1), Ru2−C11 2.177(4), Ru2−C12 2.185(4), Ru2−C15 2.174(4), Ru2−C16 2.181(4); Cl2−Ru1−Cl1 79.02(4), Cl4−Ru2−Cl2 158.06(4), Cl4−Ru2−Cl3 84.31(5), Cl2−Ru2−Cl3 78.54(4), Cl1−Ru2−Cl3 82.00(4), Ru1−Cl3−Ru2 83.53(3)

Catalytic Oxidations of Secondary Alcohols

Various methods are available for the oxidation of alcohols to carbonyl compounds. Especially appealing − both from an economic as well as environmental point of view − are transition metal catalyzed oxidations in which ketones act as both the solvent and the oxidant for the process. One of the most successful catalyst precursors for this Oppenauer-type[18] reaction is $[RuCl_2(PPh_3)_3]$. This was demonstrated by the group of Bäckvall. In the presence of K_2CO_3, hydrogen is catalytically transferred from secondary alcohols to acetone with high efficiency.[19] We have investigated the ability of the aforementioned dinuclear complexes to catalytically oxidize alcohols under conditions similar to those employed by Bäckvall. In a first series of

experiments, we screened the reactivities of **1** and **3−6** in the oxidation of diphenylmethanol. Using 0.2 mol-% of the catalyst precursor, 2-butanone as the hydrogen acceptor, and K_2CO_3 as the base, we were able to obtain benzophenone in 22−94% yield (Table 1, Entries 1−5, Scheme 4). The heterobimetallic Cp*Rh^{III} complex **3** displayed the highest activity. Subsequently, we tested the activities of the metal complexes used in our synthesis. All the half-sandwich complexes displayed activities comparable to that of $[RuCl_2(PPh_3)_3]$, but significantly lower than that of **3** (Table 1, Entries 6−10). The phosphane complexes **1** and **3−5** were also employed in the oxidation of 1-phenylethanol (Table 1, Entries 11−14). Again, the highest yield was obtained with complex **3**, followed by the (cymene)Ru^{II} complex **4**. With acetophenone as the substrate, initial turnover frequencies were determined. For all the dinuclear complexes, values in excess of 1000 h^{-1} were obtained, with a maximum of 3400 h^{-1} for the reactions with complex **3**.

Table 1. Catalytic oxidation of diphenylmethanol and 2-phenylethanol by 2-butanone; the reactions were performed in refluxing 2-butanone (2.00 mL) with 0.40 mmol of the substrate, the appropriate catalyst (0.80 μmol), and K_2CO_3 (0.40 mmol)

Entry	Complex	R	Time [h]	Yield [%][a]

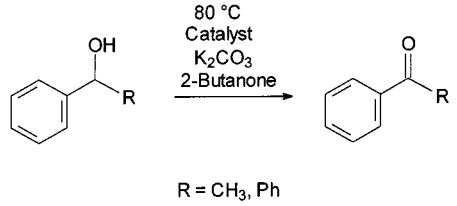
[a] Determined by GC analysis. − [b] Substrate/metal = 500:1.



Scheme 4

In order to test the scope of the catalyst precursor **3**, oxidations of several other aromatic and aliphatic (cyclic and linear) alcohols have been carried out. With just 0.2 mol-% of **3**, good to excellent yields were obtained after 1 h (Table 2). Remarkably, even cyclohexanol, a substrate which is known to be problematic,[19] was converted into cyclohexanone in 85% yield within 1 h. With $[RuCl_2(PPh_3)_3]$ under otherwise identical conditions, only 5% of the product was obtained. Oxidation of the primary alcohol $PhCH_2OH$ was not possible with our catalyst system. Deactivation of the catalyst through the formation of carbonyl complexes is a possible explanation. In the oxidation of the unsaturated alcohol cyclohexenol, the isomer cyclohexanone was observed as a side product. Contrary to previous reports concerning reactions with $[RuCl_2(PPh_3)_3]$,[19a] the presence of a small amount of water (0.5%) reduces the activity of **3**. Although catalytic amounts of base are sufficient to initiate the reaction, larger quantities of K_2CO_3 are favorable because the base can bind residual water. No reaction was observed in the absence of base.

Table 2. Oxidation of secondary alcohols by 2-butanone in the presence of the heterobimetallic complex **3**; the reactions were performed as described in the Exp. Sect. with a substrate/catalyst ratio of 500:1

Entry	Substrate	Product	Yield [%][a]
1	1-indanol	1-indanone	> 99
2	1-tetralol	1-tetralone	97
3	cyclopentanol	cyclopentanone	95
4	cyclohexanol	cyclohexanone	85
5	cycloheptanol	cycloheptanone	99
6	2-octanol	2-octanone	86

[a] The yield was determined by GC analysis after 1 h.

The mechanism of this potentially very complicated reaction has still to be elucidated. Most probably, one or more hydrido complexes are formed through reaction of **3** with the deprotonated substrate. This kind of reaction has been described for $[Cp^*RhCl(\mu\text{-}Cl)]_2$[20] as well as for $[RuCl_2(PPh_3)_3]$.[6c] The hydrido complex(es) represent(s) the catalytically active species, being able to transfer hydrogen from the substrate to 2-butanone. Based on the results of our control experiments, which show that $[Cp^*RhCl(\mu\text{-}Cl)]_2$ and $[RuCl_2(PPh_3)_3]$ on their own are less active (Table 1, Entries 7 and 9), and the fact that $RuHX(PPh_3)_2$ (X = Cl, H) is electronically unsaturated,[21] it is reasonable to predict that di- or polynuclear complexes with chloro and/or hydrido bridges play an important role in the catalytic cycle.

Conclusions

We have shown that half-sandwich complexes of ruthenium, rhodium, and iridium can be used to stabilize $RuCl_2(PPh_3)_2$, a metal fragment with special importance in homogeneous catalysis. In the dinuclear complexes formed, the two metal centers are connected by three chloro bridges. With regard to future applications in organic synthesis, it should be emphasized that the synthesis of these complexes is fast and easy: they can be obtained in virtually 100% yield by reaction of commercially available half-sandwich complexes with **2**, which itself can be prepared in crystalline form simply by mixing $[RuCl_2(PPh_3)_3]$ with acetone. Half-sandwich complexes are also suited for stabilizing other $RuCl_2L_2$ fragments. This has been demonstrated by synthesizing complex **5** with a chelating phosphane ligand and complex **6** with a cyclooctadiene ligand. We assume that related complexes can be obtained in a similar fashion.

The heterobimetallic $Rh^{III}-Ru^{II}$ complex **3** represents one of the best catalyst precursors for the Oppenauer-type oxidation of simple secondary alcohols yet found. In the presence of 0.2 mol-% of **3** and a weak base, aromatic and

aliphatic alcohols are converted into the corresponding ketones in good to excellent yield within 1 h. Side reactions are not generally observed.

We are currently exploring the potential of these types of bimetallic complexes to act as catalyst precursors for other reactions. Both metal fragments − the organometallic π-complex[22] as well as the $RuCl_2L_2$ fragment − are known to be essential constituents of catalysts for hydrogenations, the metathesis of olefins, and isomerization reactions, among others. We think that the combination of these two fragments within one molecule can give rise to new catalyst systems with superior characteristics (solubility, activity, selectivity). Further results will be presented in the near future.

Experimental Section

General Remarks: All reactions were performed under dry dinitrogen. The solvents were distilled from appropriate drying agents and stored under dinitrogen. 2-Butanone (> 99.7%) was obtained from Riedel-de Häen and degassed prior to use. The complexes $[RuCl_2(PPh_3)_3]$,[23] $[RuCl_2(PPh_3)(dppb)]$,[24] $[(cymene)RuCl(\mu\text{-}Cl)]_2$,[25] $[Cp^*MCl(\mu\text{-}Cl)]_2$ (M = Rh, Ir),[26] and $[RuCl_2(cod)(NCCH_3)_2]$[27] were prepared according to literature procedures. − NMR spectra were recorded with JEOL EX 400 or GSX 270 spectrometers using the residual protonated solvents as internal standards. − GC-MS analyses were performed with a CP-cyclodextrin-B-2,3,6-M-19 column (50 m) coupled to a Varian 3800 spectrometer.

2: $[RuCl_2(PPh_3)_3]$ (959 mg, 1.00 mmol) was suspended in acetone (60−500 mL) without stirring. After several days, red crystals had formed, which were isolated, washed with acetone (4 × 100 mL), and dried in a stream of dinitrogen. The yields (53−90%) and the reaction times (2−14 d) were found to depend on the amount of acetone. Large amounts of acetone give short reaction times but also reduce the yields. − $C_{39}H_{36}Cl_2OP_2Ru$ (754.6): calcd. C 62.07, H 4.81; found C 61.95, H 4.88.

Synthesis of Complexes 1, 3, and 4: A mixture of **2** (75.5 mg, 0.10 mmol) and the appropriate chloro-bridged complex (0.05 mmol) in CH_2Cl_2 (15 mL) was stirred until a clear solution had been obtained (1−2 h). After removal of the solvent under reduced pressure and drying in vacuo, the products were obtained in quantitative yields.

1: Red powder. − ^{1}H NMR (270 MHz, CD_2Cl_2): δ = 1.19 [d, ^3J = 7 Hz, 6 H, $CH(CH_3)_2$], 2.12 (s, 3 H, CH_3, cymene), 2.75 [s, ^3J = 7 Hz, 1 H, $CH(CH_3)_2$], 5.15 (d, ^3J = 11 Hz, 1 H, $CH{=}CH_2$), 5.22 (d, ^3J = 5 Hz, 2 H, CH, cymene), 5.38 (d, ^3J = 5 Hz, 2 H, CH, cymene), 7.00−7.30 (m, 30 H, Ph). − ^{13}C NMR (68 MHz, CD_2Cl_2): δ = 18.4, 22.0 (CH_3, cymene), 30.9 (CH, cymene), 78.4, 78.5 (CH, cymene), 95.3, 101.4 (C, cymene), 126.8−136.1 (Ph). − ^{31}P NMR (109 MHz, CD_2Cl_2): δ = 50.3. − $C_{46}H_{44}Cl_4P_2Ru_2 \cdot 1/2CH_2Cl_2$ (1045.2): calcd. C 53.43, H 4.34; found C 53.59, H 4.25.

3: Red powder. − ^{1}H NMR (270 MHz, CD_2Cl_2): δ = 1.60 (s, 15 H, Cp*), 7.01−7.32 (m, 30 H, Ph). − ^{13}C NMR (68 MHz, CD_2Cl_2): δ = 9.1 (CH_3, Cp*), 93.7 (d, ^1J = 9 Hz, C, Cp*), 126.6−135.2 (Ph). − ^{31}P NMR (109 MHz, CD_2Cl_2): δ = 50.1. − $C_{46}H_{45}Cl_4P_2RhRu \cdot 1/4CH_2Cl_2$ (1026.8): calcd. C 54.10, H 4.47; found C 54.00, H 4.53.

4: Red powder. − ^{1}H NMR (270 MHz, CD_2Cl_2): δ = 1.56 (s, 15 H, Cp*), 7.02−7.35 (m, 30 H, Ph). − ^{13}C NMR (68 MHz, CD_2Cl_2): δ = 8.9 (CH_3, Cp*), 85.3 (C, Cp*), 126.5−136.1 (Ph). − ^{31}P NMR (109 MHz, CD_2Cl_2): δ = 52.1. − $C_{46}H_{45}Cl_4P_2RhRu \cdot 2/3CH_2Cl_2$ (1151.5): calcd. C 48.68, H 4.06; found C 48.50, H 4.15.

5: A solution of $RuCl_2(dppb)(PPh_3)$ (172 mg, 0.20 mmol) and $[(cymene)RuCl_2]_2$ (122 mg, 0.20 mmol) in acetone (25 mL) was heated under reflux. After 30 min, the heating was stopped and the solution was placed in a freezer (−20 °C). After 7 d, red crystals had formed, which were isolated and dried in a stream of dinitrogen. Yield: 109 mg (60%). − ^{1}H NMR (270 MHz, CD_2Cl_2): δ = 1.17 [d, ^3J = 7 Hz, 6 H, $CH(CH_3)_2$], 1.21−1.32 (m, 2 H, CH_2), 1.75−1.87 (m, 2 H, CH_2), 2.00−2.09 (m, 2 H, CH_2), 2.12 (s, 3 H, CH_3, cymene), 2.71 [s, ^3J = 7 Hz, 1 H, $CH(CH_3)_2$], 3.11−3.20 (m, 2 H, CH_2), 5.18 (d, ^3J = 6 Hz, 2 H, CH, cymene), 5.31 (d, ^3J = 6 Hz, 2 H, CH, cymene), 7.21−7.65 (m, 20 H, Ph). − ^{13}C NMR (68 MHz, CD_2Cl_2): δ = 18.4, 22.0, 22.6 (CH_2, dppb; CH_3, cymene), 29.8, 30.0, 30.3 (m, PCH_2), 30.9 (CH, cymene), 78.3, 78.5 (CH, cymene), 95.0, 101.0 (C, cymene), 127.0−140.7 (Ph). − ^{31}P NMR (109 MHz, CD_2Cl_2): δ = 54.4. − $C_{38}H_{42}Cl_4P_2Ru_2CH_3COCH_3$ (962.7): calcd. C 51.15, H 5.03; found C 51.20, H 5.05.

6: A mixture of $[RuCl_2(cod)(NCCH_3)_2]$ (38.0 mg, 0.10 mmol) and $[(cymene)RuCl(\mu\text{-}Cl)]_2$ (30.6 mg, 0.05 mmol) in acetone (10 mL) was heated under reflux for 1 h. After removal of the solvent under reduced pressure, the product was crystallized from CH_2Cl_2/hexane. Orange crystals, yield 49 mg (82%). − ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.39 [d, ^3J = 7 Hz, 6 H, $CH(CH_3)_2$], 1.72−1.81 (m, 4 H, CH_2, cod), 2.23−2.31 (m, 2 H, CH_2, cod), 2.32 (s, 3 H, CH_3, cymene), 2.44−2.50 (m, 2 H, CH_2, cod), 2.96 [s, ^3J = 7 Hz, 1 H, $CH(CH_3)_2$], 4.33−4.39 (m, 2 H, CH, cod), 4.44−4.50 (m, 2 H, CH, cod), 5.44 (d, ^3J = 6 Hz, 2 H, CH, cymene), 5.66 (d, ^3J = 6 Hz, 2 H, CH, cymene). − ^{13}C NMR (68 MHz, CD_2Cl_2): δ = 18.8, 22.5, 29.6, 29.9, 31.3 (CH_2, cod; CH, CH_3, cymene), 78.1, 79.6, 84.5, 84.9 (CH, cod + cymene), 97.2, 101.0 (C, cymene). − $C_{18}H_{26}Cl_4Ru_2$ (586.4): calcd. C 36.87, H 4.47; found C 36.87, H 4.43.

Crystal Structure Analyses: The structures of complexes **2** and **5** were determined with a Stoe IPDS. The structure of complex **6** was determined with an Enraf−Nonius diffractometer. Structure solution was performed by direct methods using SHELXS-97 or SHELXS-86.[28] The structures were refined by full-matrix least-squares techniques on F^2 (SHELXL-97, SHELXL-93).[28] For the hydrogen atoms, a riding model was employed. Complex **5** co-crystallized with pentane and dichloromethane. There are three molecules of CH_2CH_2 in the unit cell, the positions of two of which are only partially occupied (Table 3). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-144081 (**5**), -144082 (**2**), -144083 (**6**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-(0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

General Procedure for the Catalytic Oxidation of Secondary Alcohols: A suspension of K_2CO_3 (55.3 mg, 0.40 mmol) and the substrate (0.40 mmol) in 2-butanone (2.00 mL) was heated under reflux under dry dinitrogen. The reaction was initiated by addition of the catalyst (0.8 μmol), dissolved in CH_2Cl_2 (0.40 mL). After the time indicated, a sample (50 μL) was removed from the reaction vessel, quenched with acetone/acetic acid (3.5:1, 450 μL), and analyzed by capillary GC. The initial turnover frequency for the reduc-

Paramagnetic Bis(amidinate) Iron(II) Complexes and their Diamagnetic Dicarbonyl Derivatives[‡]

Beatrice Vendemiati,[a] Giansiro Prini,[b] Auke Meetsma,[a] Bart Hessen,*[a] Jan H. Teuben,[a] and Orazio Traverso[b]

Keywords: Iron / N ligands / Magnetic properties / X-ray diffraction / Carbonyl complexes

Reactions of two equivalents of the lithium amidinate salts Li[*t*BuC(NR)$_2$] (R = *i*Pr, cyclohexyl) with $FeCl_2$ have been found to yield paramagnetic bis(amidinate) iron(II) compounds of the type [*t*BuC(NR)$_2$]$_2$Fe. In the case of R = cyclohexyl, the product has been characterized by single-crystal X-ray diffraction analysis as having a distorted tetrahedral geometry. The derivative with R = *i*Pr is an oil, but its ^{1}H and ^{13}C NMR spectra indicate a similar monomeric structure. Both species have been found to react readily with CO to give the new diamagnetic Fe^{II} dicarbonyls [*t*BuC(NR)$_2$]$_2$Fe(CO)$_2$. The compound with R = *i*Pr has been structurally characterized, which showed it to have a strongly distorted octahedral structure with the carbonyls in a *cis* arrangement.

Introduction

The amidinates [RC(NR′)$_2$]$^-$ (R = H, alkyl, aryl; R′ = alkyl, aryl, $SiMe_3$) constitute a class of versatile monoanionic ancillary ligands for transition metals.[1] They can bind in a chelating *N*,*N*′-η^2 fashion to a single metal center, or form *N*,*N*′-μ bridges between two metals. In the latter case, "lantern" complexes of the type {[μ-RC(NR′)$_2$]$_2$M}$_2$ can be formed that may contain very short M−M bonding contacts.[2,3] Amidinates have also found extensive use as ancillary ligands in catalytically active metal complexes, e.g. in Group 4 metal mono- and bis(amidinate) complexes, which can be activated with methylalumoxane (MAO) to give active olefin polymerization catalysts,[4] in cationic aluminum amidinate alkyls,[5] and in neutral (alkyl)bis(amidinate)vanadium ethene oligomerization catalysts.[6] To date, the chemistry of amidinate complexes of iron has yielded only a few well-defined complexes. For Fe^{II}, one type of dimeric bis(amidinate) complex has been reported, {[RC(NPh)$_2$]$_2$Fe}$_2$ (R = H, Ph), which has a "twisted" A-frame structure with two bridging and two dihapto amidinate ligands.[7] In addition, one example of a monomeric bis(amidinate) Fe^{II} complex is known, which contains amidinate ligands bearing ferrocenyl substituents on their backbone carbons, i.e. {[FcC(NCy)$_2$]$_2$Fe} (Fc = ferrocenyl).[8] As yet, no details of the reactivities of these complexes have been reported.

We are interested in the chemistry of iron(II) amidinates, especially with respect to their Lewis acidic behavior, their redox chemistry, and their potential as catalyst precursors. We describe herein the synthesis and characterization of paramagnetic monomeric iron(II) complexes of the highly substituted amidinate ligands [*t*BuC(NR)$_2$]$^-$ (R = *i*Pr, cyclohexyl).[9] The bis(amidinate) species [*t*BuC(NR)$_2$]$_2$Fe has been structurally characterized for R = Cy. These complexes appear to be quite light-sensitive. They react with CO to give the new distorted octahedral dicarbonyls *cis*-[*t*BuC(NR)$_2$]$_2$Fe(CO)$_2$, of which the derivative with R = *i*Pr has also been structurally characterized.

Results and Discussion

The lithium amidinates Li[*t*BuC(NR)$_2$] (R = *i*Pr, Cy) used in this study were readily available from the reaction of the corresponding carbodiimides with *t*BuLi.[9] Reaction of two equivalents of Li[*t*BuC(NCy)$_2$] with $FeCl_2$ in THF solution produced a brown-yellow colored solution, which gradually turned red-brown on exposure to ambient light. When the reaction mixture was worked-up under these conditions, a significant amount of a red-brown oil was recovered, which hampered isolation of the desired product. However, when the reaction and subsequent workup were performed with the exclusion of light, extraction with and crystallization from pentane yielded the bis(amidinate) Fe^{II} complex [*t*BuC(NCy)$_2$]$_2$Fe (**1a**) as yellow crystals in 54% isolated yield (Scheme 1). An analogous procedure with Li[*t*BuC(N*i*Pr)$_2$] resulted in a relatively low yield of a deep-brown/yellow oil that resisted all attempts to crystallize it. NMR spectroscopy (vide infra) indicated that this oil consisted mainly of [*t*BuC(N*i*Pr)$_2$]$_2$Fe (**1b**), although some impurities were present.

Scheme 1. Formation of the bis(amidinate) iron(II) complexes

A crystal structure determination of **1a** was performed (Figure 1; selected interatomic distances and angles are listed in Table 1). It showed the compound to be monomeric, with two dihapto amidinate ligands and the iron in a distorted tetrahedral environment. The geometry of the two Fe−N−C−N four-membered rings is essentially planar [largest deviation seen in the Fe−N(3)−C(30)−N(4) dihedral angle of 10.3(2)°, Fe−N(1)−C(13)−N(2) = −4.9(2)°]. The angle between these two least-squares planes is 86.4(1)°. The structure is similar to that of the only other known monomeric bis(amidinate) Fe^{II} complex, {[FcC(NCy)$_2$]$_2$Fe},[8] although in the latter the average Fe−N distance is longer (2.037 Å vs. 2.020 Å in **1a**) and the dihapto amidinates are less symmetrically bound (the largest difference between the Fe−N distances for one amidinate ligand is 0.025 Å vs. 0.011 Å in **1a**).

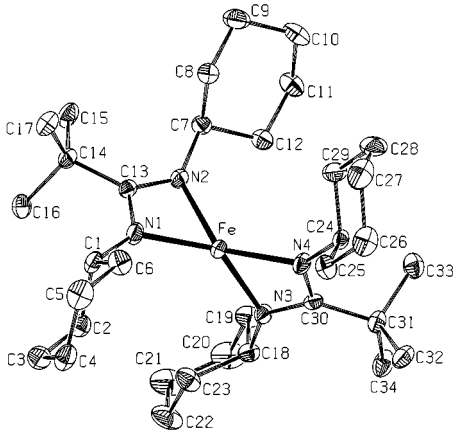

Figure 1. Molecular structure of **1a**; hydrogen atoms are omitted for clarity

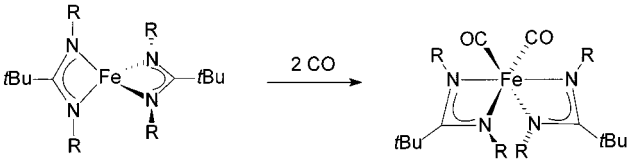
Table 1. Selected interatomic distances (Å) and bond angles (°) in **1a**

Fe−N(1)	2.014(2)	N(1)−C(13)	1.336(3)
Fe−N(2)	2.025(2)	N(2)−C(13)	1.340(3)
Fe−N(3)	2.026(2)	N(3)−C(30)	1.328(3)
Fe−N(4)	2.015(2)	N(4)−C(30)	1.347(3)
N(1)−Fe−N(2)	65.38(8)	N(1)−Fe−N(4)	143.41(8)
N(3)−Fe−N(4)	65.15(8)	N(2)−Fe−N(3)	124.71(8)
N(1)−Fe−N(3)	137.38(8)	N(2)−Fe−N(4)	132.90(8)
N(1)−C(13)−N(2)	109.2(2)	N(3)−C(30)−N(4)	108.9(2)
Fe−N(1)−C(1)	135.8(2)	Fe−N(2)−C(7)	133.8(2)
Fe−N(3)−C(18)	133.8(2)	Fe−N(4)−C(24)	137.3(2)

The bis(amidinate) Fe^{II} compounds **1** are paramagnetic. Magnetic susceptibility measurements on solid **1a** showed Curie−Weiss behavior over the temperature range 5−300 K with μ_{eff} = 4.82 and θ = −1.36 K, consistent with a magnetically dilute solid with tetrahedral d^6 ions (S = 2). ^{1}H NMR spectra of the compounds **1** in C_6D_6 (25 °C) consequently show broad resonances, but nevertheless allow assignments to be made. For **1b**, three resonances are observed at δ = 190.4, 8.8, and −2.2 (in a 2:9:12 ratio) which can be attributed to the *i*Pr CH, *t*Bu CH_3, and *i*Pr CH_3 groups, respectively. For **1a**, the first two resonances are also present (at δ = 188.6 and 9.0), but these are accompanied by additional resonances (at δ = 11.9 and 10.7, as well as a group of less-well-resolved resonances in the δ = 4−0 region of the spectrum) that can be attributed to the cyclohexyl methylene protons. NMR spectroscopy thus suggests that complexes **1a** and **1b** have a similar structure in solution. The ^{13}C NMR spectrum of **1b** (C_6D_6, 25 °C) consists of two broad resonances at δ = 336 and 310, most probably attributable to the *t*Bu and *i*Pr methyl groups, respectively, and a third broad feature at δ = 661. The assignment of the latter resonance is ambiguous, as it could feasibly be attributed to the *i*Pr CH group or the *t*Bu quaternary carbon. The ^{13}C NMR spectrum of **1a** shows similar resonances (at δ = 628, 335, and 304), with two additional narrower resonances at δ = 27.9 and 20.1, associated with the δ- and γ-CH_2 groups, respectively, of the cyclohexyl moiety.

Both 14-electron bis(amidinate) Fe^{II} complexes **1** react with CO in hexane solution in the absence of light to give the diamagnetic carbonyl derivatives [*t*BuC(NR)$_2$]$_2$Fe(CO)$_2$ (R = Cy, **2a**; *i*Pr, **2b**), which were obtained in the form of orange crystals (Scheme 2). The IR spectra of these compounds show two carbonyl vibrations [**2a**: ν(CO) = 1999 and 1929 cm^{-1}], indicative of a *cis*-dicarbonyl structure. The ^{1}H and ^{13}C NMR spectra of the derivative with R = *i*Pr (**2b**) show the resonances of one *t*Bu group and two nonequivalent *i*Pr groups, each with two diastereotopic methyl groups. This, together with the IR data, suggests a C_2-symmetric octahedral *cis*-bis(η^2-amidinate)Fe(CO)$_2$ structure for **2b** that is nonfluxional on the NMR time scale at ambient temperature. The ^{1}H NMR spectrum of **2a** is less-well-resolved, but is consistent with the same structure type. For both complexes, the carbonyl ^{13}C NMR resonance is found at δ = 219.



1a [R]=[Cy]
1b [R]=[*i*Pr]

2a [R]=[Cy]
2b [R]=[*i*Pr]

Scheme 2. Formation of the bis(amidinate) iron(II) dicarbonyl complexes

An X-ray crystal structure determination of **2b** corroborated the conclusions drawn from the spectroscopic studies.

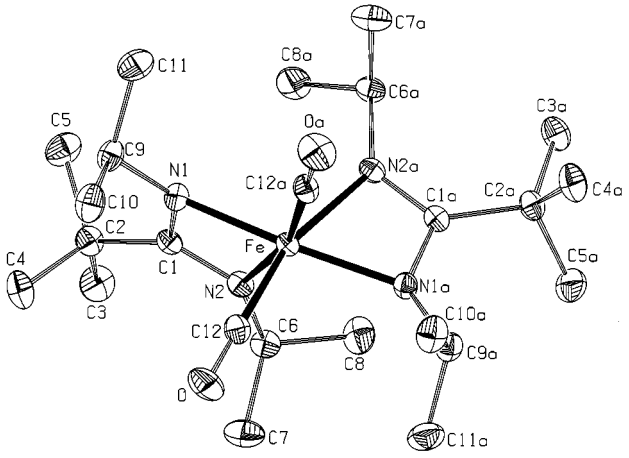


Figure 2. Molecular structure of **2b**; hydrogen atoms are omitted for clarity

Table 2. Selected interatomic distances (Å) and bond angles (°) in **2b**

Fe−N(1)	1.986(1)	N(1)−C(1)	1.342(2)
Fe−N(2)	2.031(1)	N(2)−C(1)	1.324(2)
Fe−C(12)	1.771(2)	O−C(12)	1.143(2)
N(1)−Fe−N(2)s	62.53(5)	N(1)−Fe−N(2a)	104.21(5)

N(1)−Fe−C(12a)	99.85(6)	N(2)−Fe−C(12a)	163.99(6)
N(1)−Fe−N(1a)	165.01(5)	N(2)−Fe−N(2a)	90.01(5)
C(12)−Fe−C(12a)	93.09(7)	Fe−C(12)−O	179.1(1)

The structure is shown in Figure 2, while pertinent interatomic distances and angles are listed in Table 2. The compound crystallizes in the space group C_2/c, with a C_2 symmetry axis passing through the Fe atom. The amidinate ligands are again bound in a dihapto fashion with the FeNCN ring having a planar geometry [the dihedral angle Fe−N(1)−C(1)−N(2) is −4.6(1)°]. The two Fe-amidinate planes, related by C_2 symmetry, are essentially orthogonal [87.49(8)°]. The Fe−N(2) distance is 0.045 Å longer than the Fe−N(1) distance, as a consequence of the *trans*-position of N(2) in relation to the CO ligand. Compared to the two known Fe^{II} *cis*-dicarbonyl complexes with bidentate monoanionic ligands — the phosphanyl-enolate and phosphanyl-carboxylate derivatives $[Ph_2PCHC(Ph)O]_2Fe(CO)_2$ [10] and $[Ph_2PCH_2C(O)O]_2Fe(CO)_2$[11] — complex **2b** has a much more strongly distorted octahedral geometry. This is due to the very small "bite angle" of the dihapto amidinate ligand, i.e. N(1)−Fe−N(2) is just 64.53(5)°, as compared to O−Fe−P angles of 82−86° in the other two complexes. In all three complexes, the C−Fe−C angle is about 93°, and hence this feature would appear to be quite insensitive to changes in the ligand. In the IR spectra, the carbonyl vibrations for **2** are found at noticeably lower wavenumbers than for the phosphanyl-carboxylate and -enolate complexes (2048, 1998 cm^{-1} and 2023, 1969 cm^{-1}, respectively), indicating that the amidinate ligands are better donors.

In conclusion, we have prepared two paramagnetic 14-electron bis(amidinate) iron(II) complexes and their diamagnetic 18-electron dicarbonyl derivatives. ^1H and ^{13}C NMR spectroscopy of the paramagnetic complexes proved helpful in establishing their structural relationship, which was especially useful as **1b** could not be crystallized. We are presently studying the Lewis acidities, electrochemistry, and photochemistry of the new complexes. Preliminary results suggest that the binding of the two CO molecules to the $(amidinate)_2Fe$ moiety can be readily reversed upon irradiation.

Experimental Section

General: All experiments were performed under a nitrogen atmosphere using standard Schlenk, glove-box, and vacuum line techniques. All manipulations involving compounds **1** were performed in the absence of light, the samples being protected by enveloping glassware in a black plastic bag whenever possible. Solvents (pentane, hexane, THF) were distilled from Na/K alloy prior to use. Deuterated benzene was dried over Na/K alloy and vacuum transferred before use. The Li salts Li[*t*BuC(NR)$_2$] (R = Cy, *i*Pr)[9] and anhydrous $FeCl_2$ [12] were prepared according to literature procedures. − NMR spectra were recorded on Varian VXR-300 or Unity 500 spectrometers. The ^1H NMR spectra were referenced to the resonances of residual protons in the deuterated solvent. Chemical shifts (δ) are given relative to tetramethylsilane (downfield shifts are positive). − IR spectra were recorded on a Mattson 4020 Galaxy FT-IR spectrophotometer. − Elemental analyses were performed at the Microanalytical Department of the University of Groningen; all data are the average of at least two independent determinations. − Magnetic susceptibility measurements on solid **1a** were performed on an MPMS-7 Quantum Design instrument under zero-field cooled conditions (1000 T field, 5−300 K temperature range). The EMU and temperature data are the average of three independent determinations; μ_{eff} was calculated from the total spin quantum number $S = 1.96$ obtained from the Curie−Weiss law ($C = 2.90$, $\theta = -1.35$ K).

Preparation of [*t*BuC(NCy)$_2$]$_2$Fe (1a): All manipulations were performed under the exclusion of light (vide supra). To a stirred suspension of $FeCl_2$ (0.653 g, 5.51 mmol) in THF (40 mL), solid Li[*t*-BuC(NCy)$_2$] (2.843 g, 10.5 mmol) was added at ambient temperature. After stirring for 2 h, the solvent was removed in vacuo, and then any residual THF was removed by stirring the mixture with pentane (20 mL) and subsequently pumping off the volatiles. Extraction of the residue with pentane (30 mL), concentration of the extract, and cooling it to −25 °C afforded 1.640 g (2.81 mmol, 54%) of **1a** as analytically pure yellow crystals. − ^1H NMR ([D$_6$]benzene, 25 °C): δ = 188 ($\Delta\nu_{1/2}$ = 280 Hz, 4 H, *i*Pr CH), 11.9 ($\Delta\nu_{1/2}$ = 40 Hz, 8 H, Cy CH$_2$), 10.7 ($\Delta\nu_{1/2}$ = 60 Hz, 8 H, Cy CH$_2$), 9.0 ($\Delta\nu_{1/2}$ = 60 Hz, 18 H, *t*Bu Me), 2.7 ($\Delta\nu_{1/2}$ = 470 Hz, 8 H, Cy CH$_2$), 1.5 ($\Delta\nu_{1/2}$ = 73 Hz, 4 H, Cy CH$_2$), 1.1 ($\Delta\nu_{1/2}$ = 33 Hz, 4 H, Cy CH$_2$), 0.5 ($\Delta\nu_{1/2}$ = 785 Hz, 8 H, Cy CH$_2$). − $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 25 °C): δ = 628 (assignment uncertain), 335 (*t*Bu Me), 304 (Cy β-CH$_2$), 27.9 (Cy δ-CH$_2$), 20.1 (Cy γ-CH$_2$). − $C_{34}H_{62}N_4Fe$ (582.7): calcd. C 70.08, H 10.72, N 9.61, Fe 9.58; found C 69.74, H 10.79, N 9.39, Fe 9.75.

Preparation of [*t*BuC(N*i*Pr)$_2$]$_2$Fe (1b): Following a similar procedure as described above for **1a**, but using Li[*t*BuC(N*i*Pr)$_2$] (0.934 g, 4.91 mmol) and $FeCl_2$ (0.308 g, 2.43 mmol), 0.26 g (0.61 mmol, 25%) of crude **1b** was obtained as a brown-yellow oil upon evaporation of the solvent from the pentane extract. − ^1H NMR ([D$_6$]ben-

zene, 25 °C): δ = 190 ($\Delta\nu_{1/2}$ = 240 Hz, 4 H, *i*Pr CH), 8.8 ($\Delta\nu_{1/2}$ = 55 Hz, 18 H, *t*Bu Me), −2.2 ($\Delta\nu_{1/2}$ = 305 Hz, 24 H, *i*Pr Me). Resonances attributable to a diamagnetic impurity (probably derived from the ligand) are visible in the NMR spectrum at around δ = 3−4 and 0.6−1.6. − $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 25 °C): δ = 661 (assignment uncertain), 336 (*t*Bu Me), 310 (*i*Pr Me).

Preparation of [*t*BuC(NCy)$_2$]$_2$Fe(CO)$_2$ (2a): A 50 mL flask was charged with **1a** (0.323 g, 0.55 mmol) and hexane (10 mL). The flask was attached to a vacuum line, the solution was degassed by several freeze-pump-thaw cycles, and then CO (140 Torr, 1.2 mmol) was admitted. The mixture was allowed to stand (protected from light) for two days at ambient temperature. It was then concentrated and cooled to −25 °C, whereupon orange bar-shaped crystals were deposited. Yield: 0.244 g (0.38 mmol, 69%) of analytically pure **2a**. − ^{1}H NMR ([D$_6$]benzene, 25 °C): δ = 4.19 (m, 2 H, Cy CH), 3.53 (m, 2 H, Cy CH), 2.2−1.5 (m, 32 H, Cy CH$_2$), 1.26 (s, 18 H, *t*Bu Me), 1.20 (m, 8 H, Cy CH$_2$). − ^{13}C (APT) NMR ([D$_6$]benzene, 25 °C): δ = 219.4 (CO), 176.6 (NCN), 57.4 and 58.0 (NCH), 40.9 [*C*(CH$_3$)], 38.6, 36.3, 35.1, and 32.3 (CH$_2$), 30.5 [C(*C*H$_3$)$_3$], 26.5 (2×), 26.2, 26.1, 25.9, and 25.8 (CH$_2$). − IR (Nujol, KBr): $\tilde{\nu}$ = 1999, 1929 cm^{-1} [ν(CO)]. − $C_{36}H_{62}FeN_4O_2$ (638.8): calcd. C 67.69, H 9.78, N 8.77, Fe 8.74; found C 67.56, H 9.67, N 8.58, Fe 8.60.

Preparation of [*t*BuC(N*i*Pr)$_2$]$_2$Fe(CO)$_2$ (2b): For this preparation, compound **1b** was first generated by reaction of $FeCl_2$ (0.150 g, 1.18 mmol) with Li[*t*BuC(N*i*Pr)$_2$] (0.450 g, 2.36 mmol) in THF (15 mL) as described above, and the product was extracted with hexane (20 mL). A flask charged with this hexane extract was attached to a vacuum line and the solution was degassed; thereafter CO (1 bar) was admitted. After allowing the solution to stand for two days (protected from light), it was filtered, concentrated, and cooled to −25 °C. This led to the deposition of 0.158 g (0.33 mmol, 28% overall) of orange crystalline **2b**; m.p. 112−113 °C. − ^{1}H NMR ([D$_6$]benzene, 25 °C): δ = 4.58 (quint., $^3J_{HH}$ = 5.8 Hz, 2 H, *i*Pr CH), 3.95 (quint., $^3J_{HH}$ = 6.3 Hz, 2 H, *i*Pr CH), 1.50 and 1.19 (d, $^3J_{HH}$ = 5.8 Hz, 6 H each, *i*Pr Me), 1.27 and 1.15 (d, $^3J_{HH}$ = 6.3 Hz, 6 H each, *i*Pr Me), 1.17 (s, 18 H, *t*Bu). − ^{13}C (APT) NMR ([D$_6$]benzene, 25 °C): δ = 219.4 (CO), 177.1 (NCN), 49.6 and 48.5 (NCH), 41.1 [*C*(CH$_3$)], 30.7 [C(*C*H$_3$)$_3$], 27.5, 26.3, 24.7, and 22.8 [CH(*C*H$_3$)$_2$]. − IR (Nujol, KBr): $\tilde{\nu}$ = 2009, 1942 cm^{-1} [ν(CO)].

X-ray Crystal Structure Determinations: Diffraction data were collected on an Enraf−Nonius CAD4-F diffractometer. Pertinent crystallographic data and information concerning the data collection and residuals can be found in Table 3. For **1a**, the cell parameters were derived from the setting angles of 22 reflections in the range 16.37° ≤ θ ≤ 21.54°; for **2b** from 22 reflections in the range 17.95° ≤ θ ≤ 20.39°. Intensity data were corrected for Lorentz and polarization effects, but not for absorption. The structures were solved by Patterson methods and the models were extended by direct methods applied to difference structure factors using the program *DIRDIF*.[13] In both structures, all hydrogen atoms were located and refined with isotropic displacement parameters. Final refinement on F^2 was carried out by full-matrix least-squares techniques. Calculations were performed with the program packages *SHELXL*[14] (least-squares refinement) and *PLATON*[15] (geometric data). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-147087 for **1a** and -147086 for **2b**. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors wish to thank J. Baas for performing the solid-state susceptibility measurements on **1a**, and Montell Italia S.p.A. and the University of Ferrara for grants (to G.P. and B.V.).

Intercalates of Vanadyl Phosphate with Unsaturated Alcohols

Ludvík Beneš,*[a] Klára Melánová,[a] Vítězslav Zima,[a] Miroslava Trchová,[b] Eva Uhlířová,[b] and Pavel Matějka[c]

Keywords: Vanadium / Phosphorus / Alcohols / Intercalations / Vibrational spectroscopy / X-ray scattering

Intercalates of $VOPO_4$ with several linear unsaturated alcohols (2-propen-1-ol, 2-buten-1-ol, 2-propyn-1-ol, 2-butyn-1-ol, 3-butyn-1-ol 2-pentyn-1-ol, 3-pentyn-1-ol, 4-pentyn-1-ol, 5-hexyn-1-ol, 2-octyn-1-ol, and 10-undecyn-1-ol) have been prepared and characterized by powder X-ray diffractometry, IR and Raman spectrometry, and thermogravimetry. The arrangement of the alcohol molecules with respect to the type and position of the multiple bonds in the carbon chain is proposed. Alcohols with terminal triple bonds form very stable intercalates. It is presumed that these alcohols are anchored to the host layers by donor-acceptor bonds between their oxygen atoms and the vanadium atoms of the host, and by H-bonding between the acetylenic hydrogen of the terminal carbon and the oxygen atoms of the host.

Introduction

The tetragonal layer structure of $VOPO_4$ is made up of distorted VO_6 octahedra and PO_4 tetrahedra which are linked by corner-sharing oxygen atoms (O_{host}).[1−3] Each octahedron is joined to four tetrahedra and the layers are connected along the *c* axis by the sharing of the remaining two trans vertices of the octahedron. One of these two vanadium−oxygen bonds is short indicating the presence of a V=O bond, while the other is much longer and can be ascribed to the coordination of the oxygen atom from the V=O group of an adjacent $(VOPO_4)_\infty$ layer. Interlayer interactions are therefore established through V=O···V bonds in anhydrous $VOPO_4$. In $VOPO_4{\cdot}2H_2O$, the sixth position in the VO_6 octahedron is complemented by the oxygen atom of one water molecule which is then *trans* to the oxygen atom of the V=O bond. The second water molecule is located in the interlayer space and is H-bonded to O_{host} atoms and to the water molecules of the first type. The formation reaction of $VOPO_4{\cdot}2H_2O$ from $VOPO_4$ can be considered as a kind of intercalation reaction, in which the coordination of the guest species to the metal center provides the driving force.[3] Similar reactions have been described for other donor ligands containing oxygen or nitrogen containing functional groups, leading to new materials with interesting properties and structures.[4] Vanadyl phosphate forms a number of intercalation compounds with molecular guests having a Lewis base character.[5] Intercalations of aliphatic and aromatic amines,[6−10] heterocycles,[10−14] carboxylic acids[15] and their derivatives,[16] amino acids,[17] metallocenes,[18,19] alcohols,[20,21] diols,[20,22,23] and poly(oxyethylene) compounds[24] have been studied.

The reaction of solid $VOPO_4{\cdot}2H_2O$ with liquid or melted solid 1-alkanols in a microwave field leads to intercalation compounds with the composition $VOPO_4{\cdot}2C_nH_{2n+1}OH$ (n = 2−18). All the polycrystalline layer complexes retain the structure of the original $(VOPO_4)_\infty$ layers. The alcohol molecules are placed between the host layers in a bimolecular arrangement, that is, in two layers. The guest molecules are anchored to the host layers by donor−acceptor bonds between the oxygen atom of the OH group of the guest (O_{guest}) and the vanadium atom (V_{host}), and also by hydrogen bonds between the OH group and O_{host}. The aliphatic chains of the intercalated alcohol molecules possess an all-*trans* configuration and their axes are perpendicular to the plane of the host layers.[20] In the intercalates of $VOPO_4$ with 1,ω-diols and 1,2-diols, the guest molecules are bonded to the host layers in a similar way as in the alkanol intercalates.[20,22]

Intercalates of vanadyl phosphate with *cis*-2-butene-1,4-diol and 2-butyne-1,4-diol have been prepared. It was presumed from the values found for the basal spacing that the molecules of *cis*-2-butene-1,4-diol and 2-butyne-1,4-diol are arranged in a similar manner to those of 1,4-butanediol in the interlayer space. The observed differences in the basal spacings confirm this proposal because the distances between the terminal oxygen atoms calculated from the bond lengths and bond angles decrease in the order 1,4-butanediol (6.20 Å) > 2-butyne-1,4-diol (5.75 Å) > *cis*-2-butene-1,4-diol (5.62 Å).[23]

The influence of the multiple bond and its position in the alcohol chain on the arrangement of the guest molecules in the interlayer space of the host, and on the properties of the intercalate formed is reported.

Results and Discussion

In contrast to ethanol, propanol and butyl alcohol,[25] no unsaturated alcohol can be intercalated into anhydrous vanadyl phosphate. Only 2-propen-1-ol, 2-buten-1-ol and 2-propyn-1-ol can replace the water molecules in $VOPO_4 \cdot 2H_2O$. The intercalates with longer unsaturated alcohols had to be prepared by reintercalation of propanol-intercalated vanadyl phosphate. The intercalates prepared were yellow, crystalline solids, indicating that the vanadium(V) had not been significantly reduced.

The diffractograms of all intercalates show a series of relatively sharp (00*l*) reflections (see Figure 1 and 2). The *a* parameters of their tetragonal lattices were determined from the (200) and (*h*0*l*) lines, provided they were observed. The values found for the lattice parameters *a* and *c* are presented in Table 1. The number of alcohol molecules per formula unit in $VOPO_4 \cdot x$ROH is hereafter referred to as the stoichiometric quotient *x*. The experimental stoichiometric quotients x_{exp} obtained by the thermogravimetric analyses, and by the elemental analyses for the carbon and hydrogen content are given in Table 1. For comparison, the values of x_{calc}, calculated as a ratio of the volume of the alcohol intercalated and the molar volume of the free alcohol, which was calculated from its density, are also given in this table. The volume of the alcohol intercalated was calculated as the difference between the unit cell volume of the intercalate and anhydrous $VOPO_4$. It is obvious from Table 1 that the packing of the guest molecules is closer in the intercalate than in the free alcohol.

Table 1. Lattice parameters and the guest contents in $VOPO_4$ intercalated with unsaturated alcohols

Alcohol	*a* [Å]	*c* [Å]	x_{exp}	x_{calc}
2-propen-1-ol	6.22	14.76	1.90	1.82
2-buten-1-ol	6.20	18.51	2.05	1.96
2-propyn-1-ol	6.22	10.15	1.60	1.20
2-butyn-1-ol	6.22	15.07	1.93	1.71
3-butyn-1-ol	6.21	16.15	1.95	1.84
	6.20	9.83	0.91	0.87
2-pentyn-1-ol	6.21	18.80	–	1.84
3-pentyn-1-ol	6.20	18.64	1.92	1.83
	6.21	11.10	1.11	0.89
4-pentyn-1-ol	6.22	11.23	1.08	0.89
5-hexyn-1-ol	6.16	12.76	1.10	0.90
2-octyn-1-ol	6.20	22.26	–	1.47
10-undecyn-1-ol	6.21	19.90	1.05	0.96

The alcohols with a terminal triple bond (4-pentyn-1-ol, 5-hexyn-1-ol and 10-undecyn-1-ol) form intercalates containing one molecule of alcohol per formula unit; they are stable in air at ambient conditions (relative humidity 40–60%). 3-Butyn-1-ol forms an intercalate containing two alcohol molecules per formula unit at room temperature. This intercalate is unstable and slowly loses one molecule of alcohol to form a phase with a lower basal spacing. This transformation is irreversible. The same phase, which is stable at room temperature, is formed when $VOPO_4 \cdot 2C_3H_8OH$ is heated with 3-butyn-1-ol. The transformation is also observed at 38 °C during temperature XRD measurements of the $VOPO_4 \cdot 2$(3-butyn-1-ol) intercal-

ate. 2-Propyn-1-ol forms an intercalate, containing about 1.6 molecules of alcohol per formula unit, which is stable in air.

Alcohols with a triple bond at the second carbon atom (2-butyn-1-ol, 2-pentyn-1-ol and 2-octyn-1-ol) form unstable intercalates which rapidly decompose to $VOPO_4{\cdot}2H_2O$ in air at ambient conditions (relative humidity 40−60%). Therefore, it was not possible to determine the composition for 2-pentyn-1-ol- and 2-octyn-1-ol-intercalated vanadyl phosphate. Phases with lower basal spacing ($d = 10.56$ Å at 74−111 °C for 2-butyn-1-ol, and $d = 15.9$ Å at around 77 °C and 11.6 Å at 87−115 °C for 2-pentyn-1-ol) were found by XRD measurements in situ at the given temperatures. These phases cannot be synthesized by the method described in the Experimental Section at the given temperatures. The number of guest molecules probably increases during the cooling of the reaction mixture after the synthesis; compounds containing two guest molecules are then formed.

3-Pentyn-1-ol forms an intercalate with two alcohol molecules at room temperature. This intercalate slowly loses one molecule of alcohol and transforms to a phase with a lower basal spacing in air (relative humidity ≈ 40−60%). This then slowly decomposes to $VOPO_4{\cdot}2H_2O$. The intercalate with a basal spacing of 11.10 Å can be prepared by heating $VOPO_4{\cdot}2C_3H_7OH$ with 3-pentyn-1-ol at 80 °C. The phase with a higher alcohol content and a higher basal spacing is not formed, which indicates that the high-temperature phase is very stable. The same transformation was observed at about 50 °C during temperature XRD measurements of the $VOPO_4{\cdot}2$(3-pentyn-1-ol) intercalate.

Both alcohols with a double bond (2-propen-1-ol and 2-buten-1-ol) form intercalates with a similar composition and stability as the corresponding saturated alcohols.[20]

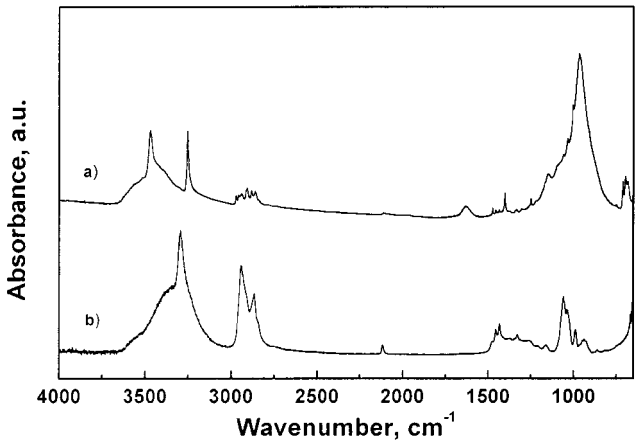

Figure 3. FTIR spectra: (a) 5-hexyn-1-ol-intercalated vanadyl phosphate (in KBr pellet); (b) liquid 5-hexyn-1-ol (ATR on ZnSe crystal)

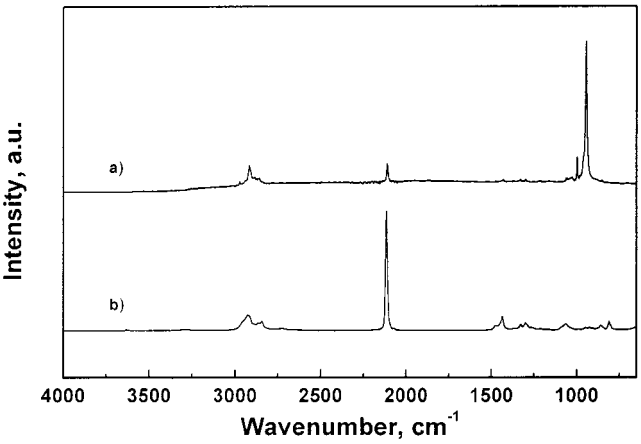

Figure 4. Raman spectra: (a) 5-hexyn-1-ol-intercalated vanadyl phosphate; (b) liquid 5-hexyn-1-ol

Infrared and Raman Spectra

The infrared spectra of 2-propen-1-ol, 2-propyn-1-ol, 4-pentyn-1-ol, 5-hexyn-1-ol and their $VOPO_4$ intercalates were measured in KBr pellets in the transmission mode. The spectra of the corresponding alkynols in the liquid state were measured by the ATR technique on ZnSe crystal.

The infrared spectra of liquid 5-hexyn-1-ol and its $VOPO_4$ intercalate are given in Figure 3. The Raman spectra of these compounds are given in Figure 4. The results for 4-pentyn-1-ol are very similar to that obtained for 5-hexyn-1-ol, and they are not presented here. The positions of the main spectral bands of the host structure in the spectrum of $VOPO_4$ intercalated with 5-hexyn-1-ol differ only slightly from those of anhydrous vanadyl phosphate or its hydrated form.[26] This confirms that the structure of the original $VOPO_4$ layers remains unchanged after the intercalation reaction. The intense band at 948 cm^{-1} in the Raman spectrum corresponds to the symmetric $\nu(PO_4)$ stretching vibration of the phosphate tetrahedron in the $(VOPO_4)_\infty$ layers, and is observed at 966 cm^{-1} in the infrared spectrum. The position of the vanadyl stretching vibration V=O at 1004 cm^{-1} in the Raman spectrum indicates coordination of O_{guest} to V_{host}. This band is observed at 1007 cm^{-1} in the infrared spectrum, allowing us to distinguish this band from other bands belonging to the intercalated alcohol molecules.

The infrared and Raman spectra of pure and intercalated 5-hexyn-1-ol differ in the position, shape and intensity of the corresponding bands as a consequence of the intercalation reaction in the interlayer space. The O−H stretching vibration must be sensitive to a phase change as in the case of 2-propyn-1-ol.[27] The infrared spectrum of liquid 5-hexyn-1-ol shows that the alcohol is completely associated. The ν(O−H) frequencies occur at about 3575 and 3392 cm^{-1}. The higher frequency band results from ν(O−H) of the terminal OH group, where the oxygen atom is hydrogen-bonded to the hydrogen atom of the O−H group of the adjacent guest molecule in the intermolecularly hydrogen-bonded chain. The lower frequency of the ν(O−H) band results from the intermolecularly hydrogen-bonded OH groups within the chain.[27] Remarkable changes are observed in this region upon intercalation into $VOPO_4$. A new sharp band at 3474 cm^{-1} occurs in the intercalated compound. Such bands are usually observed for unassociated hydroxyl groups, absorbing strongly in the region 3670−3580 cm^{-1}.[28] The presence of this new band is likely

to be related to the steric hindrance resulting from the hydrogen bonds. We suggest that it arises as a result of the anchoring of the oxygen atom from the OH group to the vanadium atom by donor−acceptor bonds. The shoulder on the higher frequency side of this band probably results from an association with other alcohol molecules, or from the formation of hydrogen bonds to the oxygen atoms from the layers. A sharp band at about 1404 cm^{-1} corresponds to the O−H bending vibration and strongly supports the assignment of the hindered hydroxyl stretching vibration. The band observed at about 1630 cm^{-1} is probably due to the association of the hydroxyl groups and the water molecules in KBr pellet.

The acetylenic C−H stretching vibration is observed at 3295 cm^{-1} for liquid 5-hexyn-1-ol. This vibration is remarkably constant with respect to the variation of the chemical structure of the rest of the molecule, but is sensitive to its physical state.[29] The acetylenic hydrogen is able to associate freely with proton-accepting groups, which leads to the shift of the vibration up to 120 cm^{-1} in extreme cases.[30] The position of this vibration is shifted to 3254 cm^{-1} after intercalation in $VOPO_4$, reflecting the association with the hydroxyl group of the second alcohol molecule or the formation of hydrogen bonds to the oxygen atoms from the layers. The ≡C−H bending vibration results in one or two strong absorption bands in the 610−680 cm^{-1} region.[29]

The remarkable change in the C−H vibrations is observed when going from liquid 5-hexyn-1-ol to its intercalated form. During the fixation of the intercalated molecules in the interlayer space some new bands arise in the region of the stretching vibrations, where only two bands at 2945 and 2867 cm^{-1} are observed in the infrared spectrum of the liquid alcohol. The interaction of the alcohol molecules with the host in the intercalate leads to the splitting of the bands in the 1150−1490 cm^{-1} region. The four fundamental bands expected to occur in this region are: CH_2 bending δ(C−H), CH_2 wagging ω(C−H), O−H bending δ(O−H) and CH_2 twisting γ(C−H).[27] The C≡C stretching absorption band has appreciable intensity only in hydrocarbons with terminal triple bonds.[30] This band occurs at 2121 cm^{-1} both in the infrared and Raman spectra of the liquid alcohol, and is very intense in the latter. It is shifted to 2114 cm^{-1} in the intercalate.

The infrared spectra of liquid 2-propyn-1-ol and its intercalate in $VOPO_4$ are given in Figure 5. The Raman spectra of these compounds are given in Figure 6. These spectra differ from those of 5-hexyn-1-ol and 4-pentyn-1-ol intercalated in $VOPO_4$. The Raman spectrum of the intercalate with 2-propyn-1-ol is strongly influenced by baseline radiation. The intense broad band centered at about 915 cm^{-1} in this spectrum probably corresponds to the symmetric ν(PO_4) stretching vibration of the phosphate tetrahedron,[26] overlapped by the strong band of 5-hexyn-1-ol. The sharp band at 996 cm^{-1} corresponds to the V=O stretching vibration. Interpretation of this region in the infrared spectrum is rather complicated. The ν(PO_4) stretching vibration, the V=O stretching vibration and the C−O_{guest}H stretching vibration overlap in this part of the spectrum. With the help

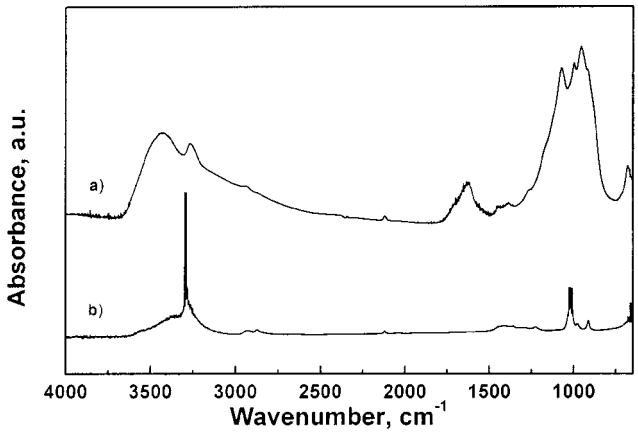

Figure 5. FTIR spectra: (a) 2-propyn-1-ol-intercalated vanadyl phosphate (in KBr pellet); (b) liquid 2-propyn-1-ol (ATR on ZnSe crystal)

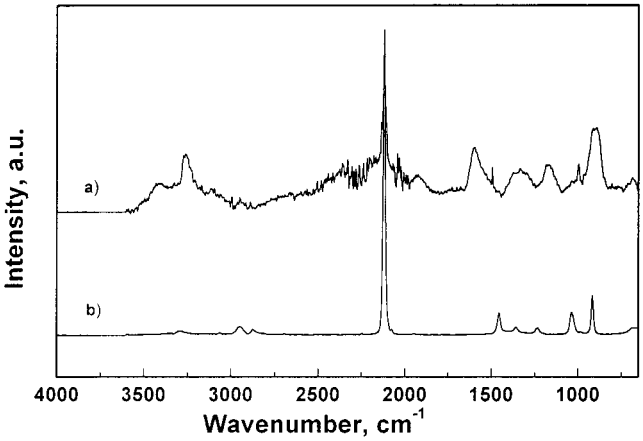

Figure 6. Raman spectra: (a) 2-propyn-1-ol-intercalated vanadyl phosphate; (b) liquid 2-propyn-1-ol

of the Raman spectrum, the band at 959 cm^{-1} in the infrared spectrum is assigned to the symmetric ν(PO_4) stretching vibration which is infrared active due to the distortion of the phosphate tetrahedron in the intercalate. The band at about 1004 cm^{-1} is probably due to the vanadyl V=O stretching vibration corresponding to the anchoring of the hydroxyl oxygen of 2-propyn-1-ol to V_{host}. The C−O_{guest}H stretching band of the alcohol is likely to be overlapped by other bands. The intense band at about 1074 cm^{-1} may be an asymmetric stretching vibration ν(PO_4) of the phosphate tetrahedron. This band is due to the strong interaction between the alcohol hydroxyl and acetylenic groups, and the phosphate oxygen through hydrogen-bonds.

Changes are also observed in the high frequency region of the spectrum of the intercalate relative to that of liquid 2-propyn-1-ol. The strong hydrogen bonding of the alcohol in the intercalate leads to a broad band for the OH stretching vibration centered at about 3434 cm^{-1}. The band at about 1630 cm^{-1} with a shoulder at about 1719 cm^{-1} corresponds to the bending vibrations of the hydrogen-bonded OH groups and of the water molecules in the KBr pellet. The sharp and intense band of the acetylenic CH vibration observed in the spectrum of the liquid alcohol at 3295 cm^{-1}

is shifted to 3270 cm^{-1} in the spectrum of the intercalate. In the Raman spectrum, this band is broadened and observed at 3265 cm^{-1}, which corresponds to the hydrogen bonding of the acetylenic CH group with O_{host}. The position of the C≡C stretching absorption band both in liquid 2-propyn-1-ol and in the intercalate occurs at 2121 cm^{-1} in the infrared spectrum and is very intense in the Raman spectrum at about 2125 cm^{-1}.

The infrared spectra of liquid 2-propen-1-ol and its $VOPO_4$ intercalate are given in Figure 7. The Raman spectra of these compounds are given in Figure 8. The Raman spectrum of the intercalate is only slightly influenced by baseline radiation. The intense band at about 944 cm^{-1} in the Raman spectrum probably corresponds most to the symmetric $\nu(PO_4)$ stretching vibration of the phosphate tetrahedron, and the sharp band at 1000 cm^{-1} to the V=O stretching vibration. The bands of 2-propen-1-ol in the Raman spectrum are at the same positions in the intercalate and in liquid 2-propen-1-ol. With the help of the Raman spectrum, the band at 948 cm^{-1} in the infrared spectrum was assigned to the symmetric $\nu(PO_4)$ stretching vibration. The band at about 996 cm^{-1} is probably the $C-O_{guest}H$ stretching band of the intercalated alcohol. Its position is also not changed in the intercalate as a consequence of the weak interaction between the alcohol and the host layers. The intense band at about 1104 cm^{-1} in the spectrum of the intercalate is assigned to the asymmetric stretching vibration $\nu(PO_4)$ of the phosphate tetrahedron. This band is due to the hydrogen bonds between the alcohol hydroxyl and the phosphate oxygen, analogous to the saturated 1-alkanols.[31] The strong hydrogen bonding of the alcohol in the intercalate leads to broad OH stretching vibration bands centered at about 3403 and 3582 cm^{-1}. The band at about 1630 cm^{-1} is assigned to the bending vibration of the hydrogen-bonded OH groups and the water molecules in the KBr pellet, and is overlapped by the C=C stretching vibration band in 2-propen-1-ol. This band is very strong in the Raman spectra.

Suggested Structures

Alcohols with a double bond in their aliphatic chain are placed in the interlayer space of the host in a way similar to that of saturated alcohols with the same chain length (i.e. the distance from C_1 to C_n).[20,31] This means that they are arranged in two layers and the angle, α, at which they are tilted to the plane of the host sheets, increases with an increasing number of carbon atoms, as in the homologous series of ethanol, 1-propanol and 1-butanol intercalates.[31] Half of the guest molecules are anchored to V_{host} by donor−acceptor bonds with O_{guest}. The rest of the guest molecules forms hydrogen bonds between their OH groups and O_{host} or between these OH groups and the guest oxygen atoms coordinated to V_{host}.

The intercalates containing about two molecules of alcohols with a triple bond (2-butyn-1-ol, less stable phase of 3-butyn-1-ol with a higher basal spacing, 2-pentyn-1-ol, and 3-pentyn-1-ol) per formula unit have distinctly lower basal spacings than the intercalates with saturated alcohols with the same chain length.[20] The shortening of the chain length by the triple bond is insignificant irrespective of its position. This means that in the presumed bimolecular arrangement of the guest molecules, the carbon chain must be tilted towards the host layers more (it must have a smaller α value) than the intercalates with saturated alcohols, in which the chains are perpendicular to the host layers.[20,31] With respect to other aspects, it can be presumed that the guest molecules are bonded in a manner similar to that found for the alken-1-ol and 1-alkanol intercalates discussed previously.

Alcohols with terminal triple bonds (except 2-propyn-1-ol) form intercalates which are very stable in air and which contain one guest molecule per formula unit ($x = 1$). Elongating their carbon chain by one atom increases the basal spacing of the intercalate by 1.4 Å, which is more than the value corresponding to adding one carbon atom to a chain perpendicular to the host layer (1.279 Å).[20] On the other hand, the basal spacing of the 3-butyn-1-ol intercalate (9.83 Å) excludes a bimolecular arrangement with slanted alcohol chains, as two alkyl chains placed parallel with $(VOPO_4)_\infty$ sheets in the interlayer space require a basal spacing of 12 Å.[24] An alcohol with a terminal triple bond

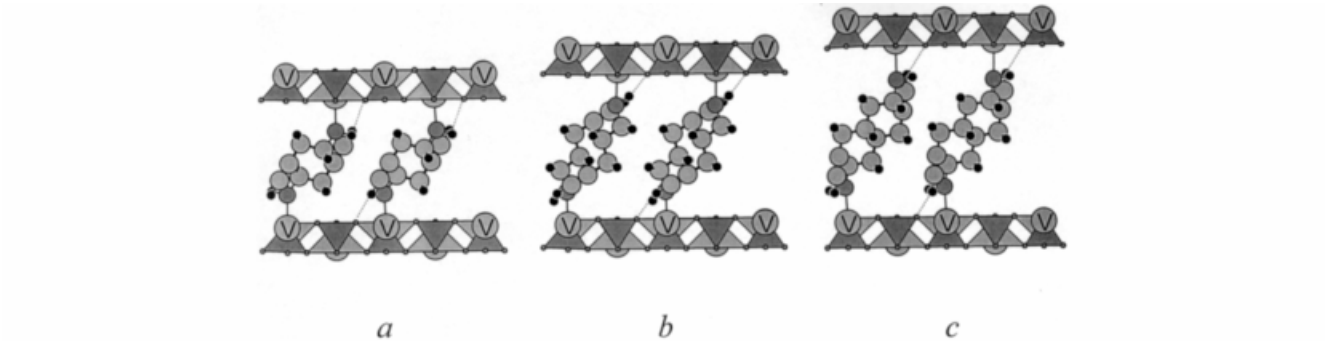

Figure 9. Proposed arrangement of 3-butyn-1-ol (a), 4-pentyn-1-ol (b) and 5-hexyn-1-ol (c) molecules between the host layers; the hydrogen bonds between the acetylenic hydrogen of the guest and O_{host} are depicted as dotted lines

must therefore be arranged in the monomolecular manner depicted in Figure 9. The alcohols with terminal triple bonds are anchored to the $(VOPO_4)_\infty$ layers in two ways. Firstly, by coordination of their O_{guest} from the OH group to V_{host}, and secondly by forming a hydrogen bond between the acidic hydrogen of the guest H−C≡C− group and O_{host} in such a way that the guest molecules generate a pillared structure similar to that found in the 1,ω-diol intercalates,[17] thus increasing the stability of the intercalate. As can be seen in Figure 9 for the 3-butyn-1-ol, 4-pentyn-1-ol and 5-hexyn-1-ol series, α increases with increasing length of the alkyl chain. This increase can be attributed to the increase of guest−guest hydrophobic interactions between the carbon chains. In the case of the 10-undecyn-1-ol intercalate, the alkyl chains are almost perpendicular ($\alpha \approx 90°$) to the host layers (see Figure 10), and the basal spacing of the intercalate is accordingly about 1 Å more than that of the 1,10-decandiol intercalate with a chain that is one carbon atom shorter. In the arrangement described above, the O_{guest} atoms are placed so that they cause a mutual shift of the neighboring host layers. This shift leads to the formation of a turbostratic structure in the intercalate, which explains the absence of (*hkl*) reflections in the diffractograms.

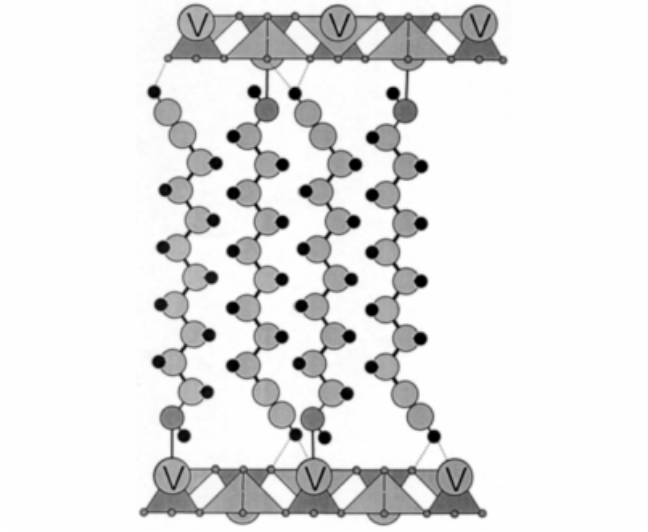

Figure 10. Proposed arrangement of 10-undecyn-1-ol molecules between the $VOPO_4$ layers; the hydrogen bonds between the acetylenic hydrogen of the guest and O_{host} are depicted as dotted lines

The intercalate with 2-propyn-1-ol has a different arrangement of the guest molecules. The number of guest molecules in the intercalate is about 1.6 molecules per vanadium atom. Accordingly, we can propose that one molecule of alcohol is anchored to the host layer by a $V_{host}-O_{guest}$ donor-acceptor bond. The guest molecules are bonded to the adjacent host layer by the hydrogen bond between the H−C≡C− group and O_{host}, as in other alcohols with terminal triple bonds.. The diffractograms of the intercalate correspond to a turbostratic structure, this means that the host layers are mutually shifted. Such an arrangement forms cavities in the interlayer space, in which other alcohol molecules can be placed (Figure 11). These molecules are bonded by hydrogen bonds both to the host layers and to neighboring coordinated alcohol molecules.

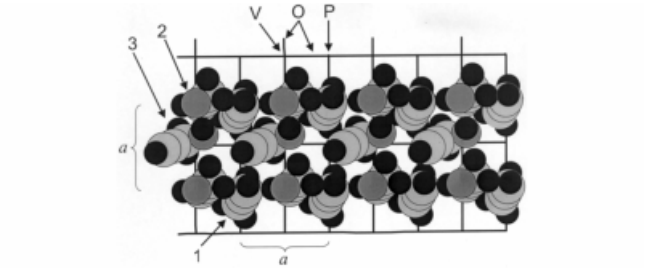

Figure 11. Arrangement of 2-propyne-1-ol molecules between the $VOPO_4$ layers viewed down the *c* axis; the upper $VOPO_4$ layer is not depicted; 1 = guest molecules coordinated to the lower host layer; 2 = guest molecules coordinated to the upper host layer; 3 = H-bonded guest molecules

Experimental Section

Preparation: Intercalates of 2-propen-1-ol, 2-propyn-1-ol and 2-buten-1-ol were prepared by suspending $VOPO_4 \cdot 2H_2O$ (0.3 g) in dry alcohol (7 mL), and subsequent short exposure (0.5−2 min) to a microwave field. Intercalates of the other unsaturated 1-alcohols were obtained by the following reintercalation reaction. The solid propanol-intercalated host ($VOPO_4 \cdot 2C_3H_7OH$) was prepared first and used as the starting material.[20] The reintercalation reactions were carried out by shaking $VOPO_4 \cdot 2C_3H_7OH$ (0.4 g) in the corresponding alcohol (5 mL) for two days. The solid product formed was filtered off. All samples for the X-ray diffraction analyses were left with a small residue of the respective alcohol. The samples for the TG-DTA and elemental analyses were washed with dry ether and dried under dry nitrogen at room temperature.

Analyses: The TGAs of the intercalates were performed with a Derivatograph MOM (Hungary), the measurements were carried out in the temperature range of 30−600 °C in air, at a heating rate of 5 °C/min. The weight of the samples was 100 mg. In some cases the composition was checked by elemental analysis (C, H).

Diffraction Measurements: The powder data of the intercalates with a minor surplus of the guest alcohol were obtained with an X-ray diffractometer (HZG-4, Freiberger Präzisionsmechanik, Germany) using Cu-$K_{\alpha 1}$ radiation (λ = 1.54051 Å) with discrimination of the Cu-K_{β} by a Ni filter. The Cu-$K_{\alpha 2}$ intensities were removed from the original data. Silicon (a = 5.43055 Å) was used as an internal standard. Diffraction angles were measured from 1.5° to 37° (2Θ). The polycrystalline sample containing an excess of the liquid guest was placed in a flat sample holder and protected against moisture by a polyethylene foil. The stability of the intercalate in air was tested by exposing it to air with ambient humidity, on a glass plate. Temperature measurements (from 22 to 240 °C) were carried out on a heated corundum plate with a thermocouple.[32] Each diffractogram was measured at constant temperature and a cycle of heating and measuring lasted about 20 min.

IR Spectra Measurements: Infrared measurements in the range 400−4000 cm^{-1} were made with a fully computerized Nicolet IMPACT 400 FTIR spectrometer (300 scans per spectrum at 2 cm^{-1} resolution). Measurements were performed in the transmission mode as KBr pellets and by the ATR technique on ZnSe crystal.[33] The spectra were corrected for the H_2O and CO_2 content in the optical path.

Raman Spectra Measurements: FT Raman spectra were collected using a Fourier transform near-infrared (FT-NIR) spectrometer Equinox 55/S (Bruker) equipped with an FT Raman module FRA 106/S (Bruker) (128 interferograms were co-added per spectrum in the range 4000−(−1000) cm^{-1} at 4 cm^{-1} resolution).

Multiple Oxidative Addition of $Ph_2(C_5H_4N)PSe$ to $[Ru_3(CO)_{12}]$ − Structural Characterization of $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)_2(\mu\text{-}C_5H_4N)(\mu_3\text{-}C_5H_4N)(CO)_6]$ Containing Two Differently Metalated 2-Pyridyl Fragments

Daniele Cauzzi,[a] Claudia Graiff,[a] Chiara Massera,[a] Giovanni Predieri,*[a] and Antonio Tiripicchio[a]

Keywords: Ruthenium / Selenium / Bridging ligands / N ligands / Carbonyl complexes / Cluster compounds

The ligand $Ph_2(2\text{-}C_5H_4N)PSe$ undergoes multiple fragmentation by reaction with $[Ru_3(CO)_{12}]$ affording the 54-electron trinuclear complex $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)_2(\mu\text{-}C_5H_4N)(\mu_3\text{-}C_5H_4N)(CO)_6]$ (**1**) which does not contain any Ru–Ru bond and is built up by a unique synergism of five bridging ligands. Complex **1** contains two bridging pyridyl groups: the first one connects two ruthenium atoms through σ bonds and lies on the plane defined by the three metals; the second one is also σ-bound to two ruthenium atoms, and is nearly perpendicular to the metal plane in such a way that it appears to be involved in a weak π interaction with the third metal.

Introduction

The chemistry of chalcogenido-carbonyl metal compounds comprises a variety of molecular architectures spanning from dinuclear metal species to giant molecular clusters.[1,2] In this context, systematic investigations carried out by our group on the reactivity of tertiary phosphane and diphosphane selenides, such as Ph_3PSe and $(Ph_2PSe)_2CH_2$ (dppmSe$_2$) towards $[M_3(CO)_{12}]$ (M = Fe or Ru) have shown that these reactions provide simple, sometimes selective synthetic routes to phosphane-substituted, selenido-carbonyl clusters.[3−5] Moreover, these processes lead in some instances to the formation of species not easily achievable by other paths, such as $[Ru_4(\mu_3\text{-}Se)_4(CO)_{10}(dppm)]$, which is the first reported 72-electrons Ru−Se cubane-like cage complex.[6]

As a natural extension of these studies, we have considered the reactions of group-8 carbonyl clusters with tertiary phosphane selenides bearing heterocyclic moieties, such as the 2-pyridyl and 2-thienyl rings. The presence of these groups was expected to lead to new reactivity patterns in cluster growing processes, owing to the coordinating ability of the heteroatoms and to the possible release of heterocyclic fragments. In fact, we have recently found that the reaction of $Ph_2(C_4H_3S)PSe$ with $[Ru_3(CO)_{12}]$ affords the open triangular 50-electron cluster $[Ru_3(\mu_3\text{-}Se)_2(CO)_7\{P(C_4H_3S)Ph_2\}_2]$ and the 48-electron cluster $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)(\mu\text{-}C_4H_3S)(CO)_6\{P(C_4H_3S)Ph_2\}]$ derived from the multiple fragmentation of one phosphane ligand on the metal triangle.[7]

Regarding the pyridyl derivative $Ph_2(2\text{-}C_5H_4N)PSe$, its parent compound $Ph_2(2\text{-}C_5H_4N)P$ (and related ligands) has been extensively used to bridge metal centres in dinuclear and cluster species.[8−10] However, faced with $[Ru_3(CO)_{12}]$ it undergoes a P−C cleavage expelling a phenyl ring,[11] the P−C(Py) bond remaining intact. On the other hand, pyridyl fragments on ruthenium and osmium clusters have been obtained by direct reactions with pyridine and related molecules.[12−15] The organometallic chemistry of nitrogen and sulfur heterocycles is further motivated by its relevance to the hydrodenitrogenation and hydrodesulfurization processes.[16]

Results and Discussion

The reaction between $Ph_2(2\text{-}C_5H_4N)PSe$ and $[Ru_3(CO)_{12}]$ affords the products shown in Scheme 1 (carbonyls omitted), whose distribution depends on the reaction conditions. Cluster **2** [*nido* core, seven skeletal electron pairs (sep)] should be regarded as the primary product of the oxidative attack of two selenide molecules to the metal triangle, whereas cluster **3** (*closo*, 7 sep) should derive from **2** through thermal condensation and ligand exchange processes. Clusters of these two families are generally the main

products in the reactions of iron and ruthenium carbonyls with phosphane selenides.[3]

In addition, the starting triruthenium triangle undergoes multiple oxidative attack by two P−C(Py) groups, resulting in the formation of the unprecedented compound $[Ru_3(\mu_3\text{-}Se)(\mu\text{-}PPh_2)_2(\mu\text{-}C_5H_4N)(\mu_3\text{-}C_5H_4N)(CO)_6]$ (**1**), whose molecular structure is shown in Figure 1.

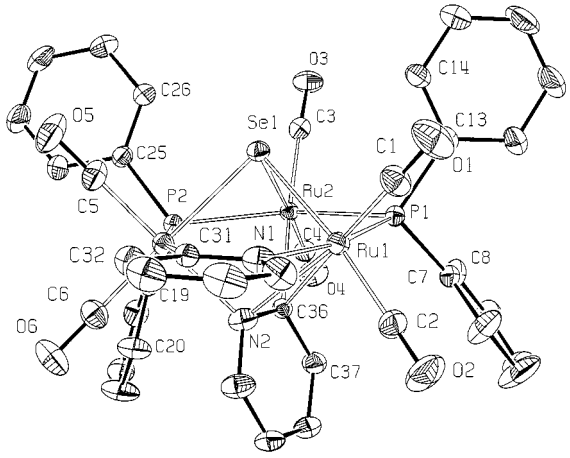

Figure 1. ORTEP diagram (30% probability level) of the molecular structure of **1** showing the atom numbering scheme; selected interatomic distances (Å): Ru(1)−Se(1) 2.515(1), Ru(1)−P(1) 2.433(1), Ru(1)−N(1) 2.173(2), Ru(1)−N(2) 2.619(3), Ru(1)−C(36) 2.822(3), Ru(2)−Se(1) 2.599(1), Ru(2)−P(1) 2.395(1), Ru(2)−P(2) 2.404(1), Ru(2)−C(36) 2.147(2), Ru(3)−Se(1) 2.550(1), Ru(3)−P(2) 2.416(1), Ru(3)−N(2) 2.171(2) Ru(3)−C(31) 2.128(2), N(1)−C(31) 1.348(3), N(2)−C(36) 1.353(3), Ru(1)···Ru(2) 3.351(1), Ru(1)···Ru(3) 3.442(1), Ru(2)···Ru(3) 3.476(1)

The structure of this polynuclear species is characterized by the presence of a nearly planar array of eleven atoms forming two roughly coplanar fused rings, i.e. the heptaatomic RuPRuPRuCN cycle and one pyridyl ring [dihedral angle 6.9(1)°]. The selenido ligand bridges three noninteracting ruthenium(II) atoms, and is elevated over the mean plane defined by the heptaatomic ring by 1.62 Å. This value is significantly lower than the mean distance of the selenium atoms from the Ru_4 plane (1.82 Å) observed in the Ru_4Se_2 octahedral clusters,[3] as a consequence of the rather large Ru···Ru spans (average 3.42 Å). This μ_3-Se bridging mode, connecting three noninteracting metal atoms, has two precedents in another trinuclear ruthenium compound containing a phosphazene ligand[17] and in a triosmium derivative.[18]

Another peculiarity of the structure of **1** is the presence of two different bridging fashions of the 2-pyridyl group. The first one [μ_2-η^1:η^1, concerning the N(1) ring] differs from those usually observed in the triangular Ru or Os clusters containing *N*-heterocyclic fragments, as these ligands currently occupy edge-bridging diaxial sites;[14] the present mode (coplanarity with the Ru_3 ensemble) is rather rare, being paralleled only by that observed in the bridged butterfly cluster $[HRu_5C(CO)_{14}(C_5H_4N)]$.[19] The second bridging mode is adopted by the N(2) ring capping the trimetallic plane opposite to the selenium atom. N(2) and C(36) are σ-bound to Ru(3) and Ru(2), respectively, in such a way that the pyridine ring is nearly perpendicular to the plane defined by the three metal atoms (74°), and seems involved in a weak π interaction with the third metal. Although this interaction with Ru(1) appears quite weak [Ru(1)−N(2) 2.619(3), Ru(1)−C(36) 2.822(3) Å], it could be required to complete the coordination sphere of Ru(1) and is suggested by the orientation of the pyridine ring. In fact, the pyridine plane is inclined towards Ru(1) with respect to the Ru(2)−Ru(3) axis by 11.0°. Moreover, if we consider that the capping pyridyl group donates two π electrons to Ru(1), the whole set of ligands contributes 30 electrons to the structure, attaining the expected count of 54 electrons. This would be an unprecedented type of bridging mode for the pyridyl group, although it has been observed with the piperidyl ligand.[20] There is one other structure where the pyridyl fragment adopts a μ_3-bridging mode, but in a η^1:η^1:η^1 fashion.[21]

As a final remark, it should be emphasized that complex **1** is built up by a unique structural synergism of five bridging ligands. It has been obtained from $Ph_2(2\text{-}C_5H_4N)PSe$ through P=Se and P−C(Py) bond cleavages, the latter process contrasting with the reactivity of $Ph_2(2\text{-}C_5H_4N)P$ towards $[Ru_3(CO)_{12}]$, which undergoes P−C(Ph) rupture,[11] as mentioned in the introduction. The different behaviour observed in this work could be due to the presence of capping selenido ligands, as observed in the case of diphenylthienylphosphane selenide.[7]

Experimental Section

General Remarks: The starting reagents $[Ru_3(CO)_{12}]$, KNCSe, $Ph_2(2\text{-}C_5H_4N)P$ and Me_3NO are pure commercial products (Aldrich and Fluka) and were used as received. The solvents (C. Erba) were dried and distilled by standard techniques before use. All manipulations (prior to the TLC separations) were carried out under dry nitrogen by means of standard Schlenk techniques. Elemental (C, H, N) analyses were performed with a Carlo Erba EA 1108 automated analyzer. IR spectra (KBr discs or CH_2Cl_2 solutions) were recorded on a Nicolet 5PC FT spectrometer. ^1H (300 MHz), ^{31}P (81.0 MHz, 85% H_3PO_4 as external reference) NMR spectra ($CDCl_3$ solutions) were recorded on Bruker instruments, AC 300 (^1H) and CXP 200 (^{31}P).

Synthesis of $Ph_2(2\text{-}C_5H_4N)PSe$: A large excess of KNCSe (1.50 g, 10.4 mmol) was added to an acetonitrile (150 mL) solution of diphenyl-2-pyridylphosphane (0.70 g, 2.7 mmol); the solution was stirred at room temperature for 3 h, then the solvent was removed in vacuo and the residue was washed with water. The rough powder was recrystallized from ethanol, obtaining a white microcrystalline product (yield 85%). $C_{17}H_{14}PNSe$ (342.24): calcd. C 56.7, H 4.1, N 4.1; found C 57.2, H 3.9, N 4.0. − FTIR (KBr): $\tilde{\nu}$ = 569 cm^{-1} (PSe). − ^{31}P NMR ($CDCl_3$): δ = 31.5 [s, ^1J(P,Se) = 720 Hz]. − ^1H NMR ($CDCl_3$): δ = 8.71 [d, ^3J(H,H) = 4 Hz, 1 H, 6-Py], 8.61 [t, ^3J(H,H) = ^3J(H,P) = 6 Hz, 1 H, 3-Py], 7.92−7.34 (mm, 12 H, 2Ph, Py).

Reactions of $Ph_2(C_5H_4N)PSe$ with $[Ru_3(CO)_{12}]$: $[Ru_3(CO)_{12}]$ (150 mg, 0.235 mmol) was reacted 1:2 with $Ph_2(C_5H_4N)PSe$ (161 mg, 0.469 mmol) in toluene at 70 °C for 1 h until the solution turned deep reddish brown. The mixture was evaporated to dryness and the residue was redissolved in a small amount of dichloromethane. TLC separation on silica, with a 1:1 dichloromethane/hexane as

eluent mixture, yielded three products: a red band, a light orange one and a reddish orange one, in order of elution. Two trace products and some decomposition were also observed. The first product was identified as **1** after the solution of its crystal structure (yield 12%). The third reddish orange derivative was identified as $[Ru_3Se_2(CO)_7\{P\text{-}P(C_5H_4N)Ph_2\}_2]$ (**2**) by comparison of its ^{31}P NMR and FT-IR spectra with those of the related cluster $[Ru_3Se_2(CO)_7(PPh_3)_2]$[22] (yield 32%). The identity of the second product is under investigation. Compound **1**: FTIR (CH_2Cl_2): $\tilde{\nu}$ = 2021 s (CO), 2013 sh, 1964 s cm^{-1}. – $^{31}P\{^1H\}$ NMR ($CDCl_3$, 25 °C): δ = 49.0 (d), −18.6 [d, ^2J(P,P) = 166 Hz]. – ^1H NMR ($CDCl_3$, 25 °C): δ = 8.52 [d, ^3J(H,H) = 6 Hz, 1 H Py], 7.91−6.62 (m, 13 H, 2Ph, Py).

The same 1:2 reaction was carried in the presence of Me_3NO (18 mg, 0.24 mmol) and gave a deep red solution; it was processed as in the previous case, yielding, in order of elution, **1** (10%), $[Ru_4Se_2(CO)_9(\mu\text{-}P,N\text{-}Ph_2(C_5H_4N)P)]$ (**3**) (light orange 22%) and **2** (7%), along with an unidentified species and some decomposition. Cluster **3** was identified by comparison of its IR spectral data with those of the analogous dppm derivative.[4] Purification by crystallization (from a CH_2Cl_2/MeOH mixture at 5 °C for some days) gave well-formed crystals of **1** suitable for X-ray analysis.

X-ray Structural Analysis: Cluster **1**, $C_{40}H_{28}N_2O_6P_2Ru_3Se$, M = 1076.75 triclinic, space group $P\bar{1}$, a = 16.619(4) Å, b = 12.494(3) Å, c = 10.214(5) Å, α = 98.49(4)°, β = 111.28(6)°, γ = 106.70(2)°, V = 2000(1) Å^3, Z = 2, D_c = 1.788 g·cm^{-3}, F(000) = 1052, graphite monochromated Mo-K_α radiation, λ = 0.71073 Å, μ = 21.56 cm^{-1}. Philips PW 1100 diffractometer, θ−2θ scan technique at room temperature. 11672 Unique reflections measured (with θ in the range 3−30°) and used in the refinement. The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares procedures (based on F_o^2), using the SHELX-97 system of crystallographic computer programs.[23] All non-hydrogen atoms were refined anisotropically; all hydrogen atoms were placed at their geometrically calculated positions and refined riding on their parent atoms; final wR_2 = 0.0688 and R_1 [for 8871 reflections with $I > 2\sigma(I)$] 0.0272; weighting scheme used in the last cycles of refinement $w = 1/[\sigma^2F_o^2 + (0.0365\ P)^2]$, where $P = (F_o^2+2F_c^2)/3$. Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-147775. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Symmetric and Non-Symmetric Dinuclear Alkenyl-Bridged Carbene Complexes of Chromium and Tungsten

Karine Ulrich,[a] Véronique Guerchais,[a] Karl-Heinz Dötz,[b] Loic Toupet,[c] and Hubert Le Bozec*[a]

Keywords: Binuclear complexes / Carbenes / Bridging ligands / Chromium / Tungsten

Treatment of $(CO)_5W{=}C(NMe_2)CH{=}CH{-}Ar{-}(OH)(H)C{\equiv}CH$ (**1a–b**) [**a**: $-Ar-$ =1,4-C_6H_4–; **b**: $-Ar-$ = 2,5-C_4H_2S–] with $W(CO)_5$(THF) in methanol yields the nonsymmetrical bis(alkenylcarbene)-bridged ditungsten complexes $(CO)_5W{=}C(NMe_2)CH{=}CH{-}Ar{-}CH{=}CH(OMe)C{=}W(CO)_5$ (**3a–b**). Similarly, the symmetrical bis(methoxycarbene)ditungsten derivative $[(CO)_5W{=}C(OMe)CH{=}CH{-}]_2$(1,4-$C_6H_4$–) (**4a**) is obtained in a low yield from the precursor $(CO)_5W{=}C(OMe)$-$CH{=}CH{-}C_6H_4{-}(OH)(H)C{\equiv}CH$ (**2a**). Complexes **3a** and **3b** undergo aminolysis reactions with diamines such as piperazine and ethylenediamine to produce the corresponding bis[alkenyl(amino)carbene]ditungsten complexes **5a–b** and **6a–b**. The reaction of **1a** with $Cr(CO)_5$(THF) affords the heterobimetallic (W–Cr) bis(carbene) complex $(CO)_5W{=}C(NMe_2)CH{=}CH{-}Ar{-}CH{=}CH(OMe)C{=}Cr(CO)_5$ (**3′a**). This complex, as well as the bis(methoxycarbene) derivative **4′a**, can also be obtained by treatment of $(CO)_5W{=}C(XR)CH{=}CH{-}C_6H_4{-}CHO$ [**1c**: XR = NMe_2; **2c**: XR = OMe] with $(CO)_5Cr{=}C(OMe)CH_2^-Li^+$. All the new compounds have been characterized by analytical and spectroscopic methods, and the single-crystal structures of **3a**, **4a–b**, and **4′a** have been established.

Introduction

During the last decade, binuclear transition-metal complexes with unsaturated organic spacers such as polyynes have been the subject of considerable investigations due to their potential applications in molecular electronics or nonlinear optics.[1,2] A wide range of bis(carbene) complexes have also been reported. Thus, symmetrical bis(carbene) complexes of Groups 6 and 7 metals containing aryl[3,4] and thienyl[5,6] bridges are accessible from dilithiated aromatic precursors by the classic Fischer method. A series of alkenyl- or polyenyl-bridged bis(carbene) complexes have been prepared either by condensation reactions of dialdehydes with the methyl group of (alkoxy)methylcarbene complexes,[7,8,9] or by oxidative coupling of $[M]{=}C(OR)CH_2Li$.[10,11] The synthesis of a symmetrical bis(carbene) complex with an ammonium pentadienide bridge has also been described.[12] The formation of bis(aminocarbene)-dichromium complexes[13] has been achieved by reaction of arylbis(amides) with $Cr(CO)_5^{2-}$. Recently, H. Fischer et al. reported an efficient synthesis of symmetrically substituted alkynediyl-bridged aminocarbene complexes by Pd coupling of two $(CO)_5M{=}C(NR_2)(C{\equiv}C)_n$ units (n = 1,2,3).[14] The same precursors were also used to prepare polynuclear complexes of the type $[(CO)_5M{=}C(NR_2)(C{\equiv}C)]_xM'L_n$.[15] By contrast, nonsymmetrical bis(carbene) complexes are scarce. A bis(aminocarbene)chromium−iron complex has been prepared in two steps by the reaction of a diamide with $Cr(CO)_5^{2-}$and $Fe(CO)_4^{2-}$.[13] An ethyne-bridged (alkoxycarbene)(aminocarbene)ditungsten complex was also recently obtained by the Fischer route starting from an ethynylcarbene complex.[14] We have previously described a convenient route to alkenyl(alkoxy)- and -(amino)carbene complexes of Groups 6 and 8 metals, by activation of propargyl alcohol derivatives.[16,17] With the use of dialkynols, this procedure was recently applied to the synthesis of alkenylcarbene complexes **I** containing a free propargyl alcohol substituent (Scheme 1).[18] In this paper we report a new synthetic route to a series of dinuclear π-conjugated bridged carbenechromium(0) and -tungsten(0) complexes. We show that this methodology, which is based on the sequential activation of dialkynols, opens the route to nonsymmetrical bis(carbene) complexes **II**. Preliminary results of this work have already been reported.[19]

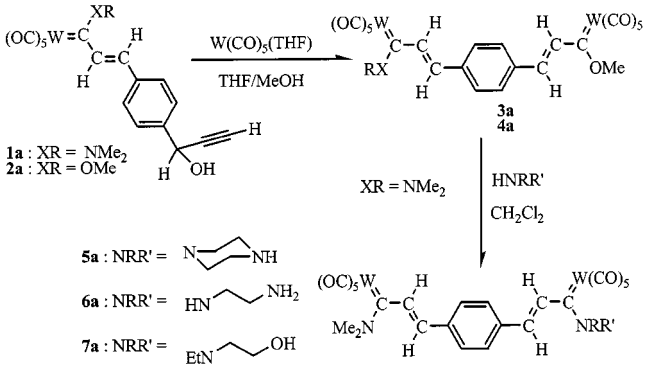
Results and Discussion

Synthesis of Bis(carbene)-Bridged Ditungsten Complexes

When solutions of the [alkenyl(dimethylamino)carbene]-tungsten complex **1a** and of the photogenerated $W(CO)_5(THF)$ adduct in methanol/tetrahydrofuran were combined at room temperature, the color gradually changed from red to dark red. The reaction proceeded rather slowly and required 3 d for completion. The bimetallic complex **3a** was obtained in a 60% yield after chromatographic workup (Scheme 2). Under similar conditions, the symmetrical binuclear bis(methoxycarbene) derivative **4a** was isolated from **2a** in a lower yield (30%) as violet microcrystals. This latter complex was already obtained as a by-product (9%) during the synthesis of **2a** from the dialkynol 1,4-[H−C≡CH(OH)]C_6H_4.[18]



Scheme 2

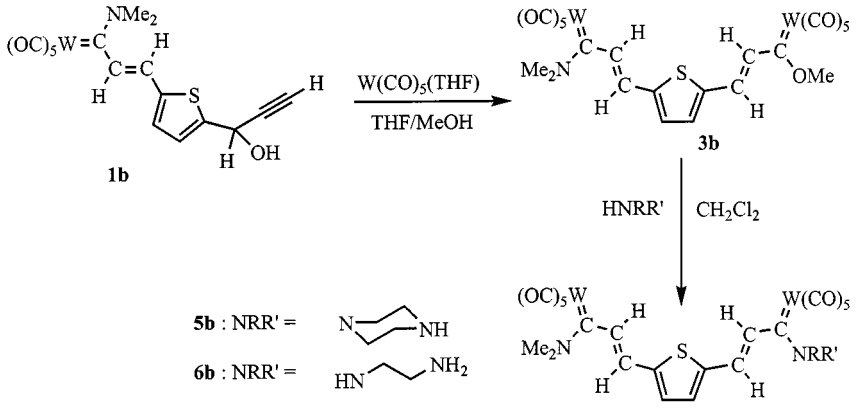
The same protocol was applied to **1b** to prepare the thienyl-bridged bimetallic complex **3b** in a 61% yield (Scheme 3). The new complexes **3a** and **3b** were unequivocally characterized by means of standard spectroscopic techniques (IR, ^1H and $^{13}C\{^1H\}$ NMR). The structures of **3a**, the symmetrical bis(methoxycarbene) derivative **4a** and its thienyl analog **4b**[18] were also confirmed by X-ray diffraction studies (vide supra). The stereoselective formation of the new CH=CH bond was easily deduced by the coupling constants, $^3J_{H\text{-}H} \approx 16-17$ Hz, which is indicative of an (*E*) configuration. For each alkenyl fragment, the ^1H and ^{13}C shifts of the β-proton and β-carbon atom appear upfield from the shift of the α-proton and α-carbon atom, respectively (Table 1). This trend was previously observed for monometallic alkenyl(alkoxy)- and -(amino)carbene complexes.[16,20] The ^1H and ^{13}C NMR spectra show two N*Me* signals as expected by the restricted rotation around the C(carbene)−NMe_2 bond. The ^{13}C NMR spectra also display two carbene resonances at $\delta \approx 300$ and 250, in the range characteristic for (alkoxycarbene)- and (aminocarbene)tungsten complexes, respectively. Thus, these data suggest that there is apparently no π delocalization occurring along the alkenyl bridges, in contrast to the recently described π-conjugated ethyne-bridged bis(carbene) complex $(CO)_5W{=}C(NMe_2){-}C{\equiv}C{-}(OMe){=}W(CO)_5$ where the carbene resonances were found shifted upfield by more than 60 ppm [δ = 235.9 and 181.7].[14]

Complexes **3a** and **3b** could be easily transformed into bis(aminocarbene) complexes by the classical aminolysis route. For example, addition of excess of piperazine, ethylenediamine or 2-(ethylamino)ethanol (3−5 equiv.) in dichloromethane at room temperature led to the isolation of the bis(aminocarbene) complexes **5a−b**, **6a−b** [(*E*)/(*Z*) ≈ 9:1], or **7a** in good yields (Scheme 2 and Scheme 3).

Spectroscopic data clearly reveal the presence of two alkenyl(amino)carbene fragments (see Table 1 and Exp. Sect.). We note in particular the presence of two characteristic low-field singlet resonances for the carbene carbon atoms (δ ≈ 250). As these complexes contain a free amine site, a second aminolysis reaction was attempted in order to prepare tetrametallic tetrakis(aminocarbene) complexes. However, after stirring a 1:1 mixture of **6b** and **3a** in dichloromethane at room temperature, no reaction occurred, even after 1 d. The starting complexes were recovered.

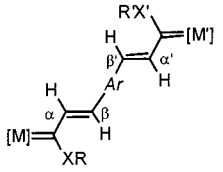
Synthesis of Bis(carbene)-Bridged Tungsten−Chromium Complexes

Treatment of **1a** with $Cr(CO)_5(THF)$ at room temperature, and after 18 h of stirring, afforded the new heterobimetallic (W−Cr) bis(carbene) complex **3′a** in a modest yield, up to 30% (Scheme 4). Prolonged reaction times were found to decrease the yield. This observation reflects the reduced thermal stability of both $Cr(CO)_5(THF)$ and **3′a**, which slowly decompose in solution. Efforts to prepare the analogous bis(methoxycarbene) complex **4′a** starting from the less reactive compound **2a** failed.



Scheme 3

Table 1. Selected ^1H and ^{13}C NMR spectroscopic data for the bimetallic complexes in $CDCl_3$



Complex	M	XR	M′	X′R′	−*Ar*−	M=C	M′=C	$C_{\alpha,\alpha'}$ ($H_{\alpha,\alpha'}$)	$C_{\beta,\beta'}$ ($H_{\beta,\beta'}$)

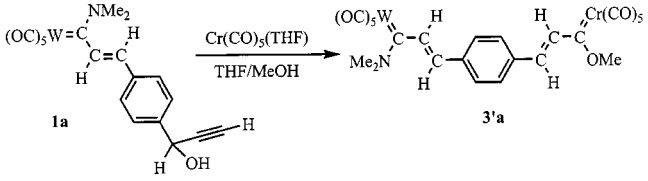
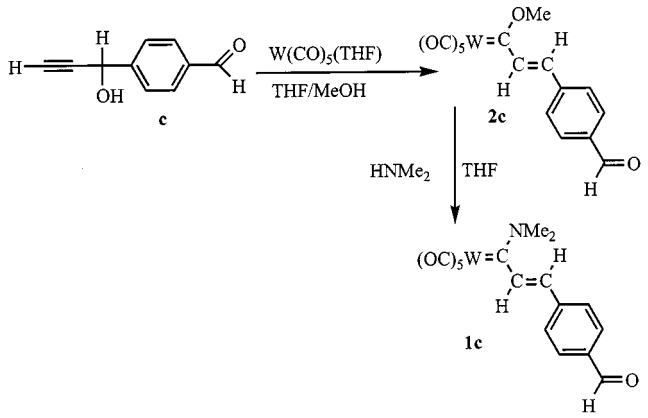
[a] Ref.[18]



Scheme 4

An alternative synthetic approach to **3′a** and **4′a** is the use of the Aumann's procedure which allows the condensation of aldehydes with the Fischer-type (methoxy)methylcarbene derivative $(CO)_5Cr{=}C(OMe)Me$.[7] The [alkenyl(methoxy)carbene]tungsten complex **2c**, containing a *p*-phenylaldehyde group, was generated in a 40% yield on activation of the propargyl alcohol derivative **c** with $W(CO)_5(THF)$. Subsequent addition of dimethylamine afforded, almost quantitatively, the corresponding (dimethylamino)carbene complex **1c** (Scheme 5).



Scheme 5

When complex **2c** was combined with $(CO)_5Cr{=}C(OMe)Me$ and treated with Et_3N/Me_3SiCl the heterobimetallic complex **4′a** was obtained in a 33% yield after chromatographic workup (Scheme 6). The same route was also employed for the synthesis of **3′a**, but the isolated yield was lower (20%).

Spectroscopic data are in agreement with the proposed nonsymmetric structures. The ^1H NMR spectrum of **4′a** exhibits two singlets for the two nonequivalent O*Me* groups, and two AB systems for the α,β- and α′,β′-alkenyl protons, respectively. The ^{13}C NMR spectrum consists of distinct signals for the two alkenyl and methoxy carbon atoms, and the carbene resonances are found in the range typical for [(methoxy)carbene]chromium and -tungsten. The unsymmetrical alkenyl-bridged [(dimethylamino)carbene](methoxycarbene) complex **3′a** also exhibits two distinct sets of proton and carbon atom resonances (Table 1 and Exp. Sect.).

Molecular Structures of 3a, 4a, 4b, and 4′a

The structures of the carbene complexes **3a**, **4a**, **4b**, and **4′a** were determined by single-crystal X-ray diffraction. The molecular structures are displayed in Figures 1−4. Selected bond lengths and angles are listed in Table 2. In all cases, the environment about the metal atoms is octahedral. The (*E*) configuration of the alkenyl double bond in these molecules was confirmed. Moreover, in all cases the carbon chain adopts a *s-trans* stereochemistry with respect to the $C_{carb}-C_\alpha$ bond.

Structure of 4b

The two "$W(CO)_5$" fragments are on the same side of the thiophene bridge, a feature already observed for the dinuclear chromium complex $[Cr(CO)_5(=C(OEt)-]_2(C_4H_2S)$ (Figure 1).[5] However, by contrast to the latter species, the sulfur atom of the ring in **4b** is directed towards the metal units. The W=C bond length [2.166(9) Å] is similar to that found in other W−(alkoxycarbene) complexes.[21] The C−C and S−C bond lengths of the thiophene ring [1.360(12), 1.365(12), 1.368(12); 1.713(9), and 1.719(9) Å] compare well with those of thiophene-containing complexes.[5,22,23] The

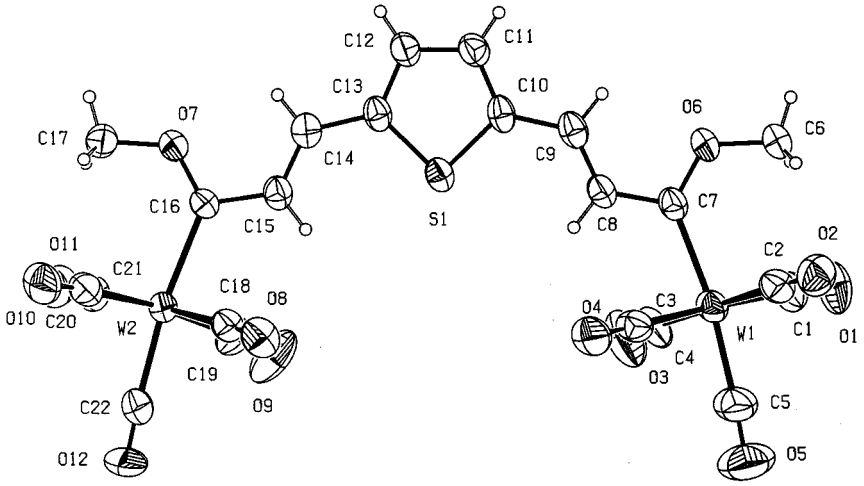

Figure 1. Molecular structure of $(CO)_5W{=}C(OMe)CH{=}CH{-}C_4H_2S{-}CH{=}CH(OMe)C{=}W(CO)_5$ (**4b**)

pattern of bond lengths in **4b** [W−C7 2.166(9), C7−C8 1.435(11), C8−C9 1.336(13), C9−C10 1.453(11) Å], indicates a limited π delocalization in the ground state.[24] Remarkably, the thiophene ring, the alkenyl, the carbene carbon and the tungsten atoms are in a plane (mean deviation from the plane 0.06 Å).

Structure of Complexes 4a, 3a, and 4′a

As observed in **4b**, in all cases the two metal units are in a *cis* configuration with respect to the benzene ring. The W=C(O) bond length [2.165(6) Å] in **4a** (Figure 2) is normal. The alkenyl portion in **4a** exhibits an alternating C−C single-bond, double-bond, and single-bond sequence [1.464(7), 1.320(7), 1.433(7) Å].

Complex **3a** (Figure 3) exhibits a W=C(N) distance of 2.256(7) Å, which is rather long relative to that of typical aminocarbene complexes [W−C 2.186(22) Å in $(CO)_5W{=}C(NHMe)Ph)$].[25,26] The C(carbene)−N bond [1.315(9) Å] is somewhat short indicating a double-bond character.[14] These values compare well with those reported for

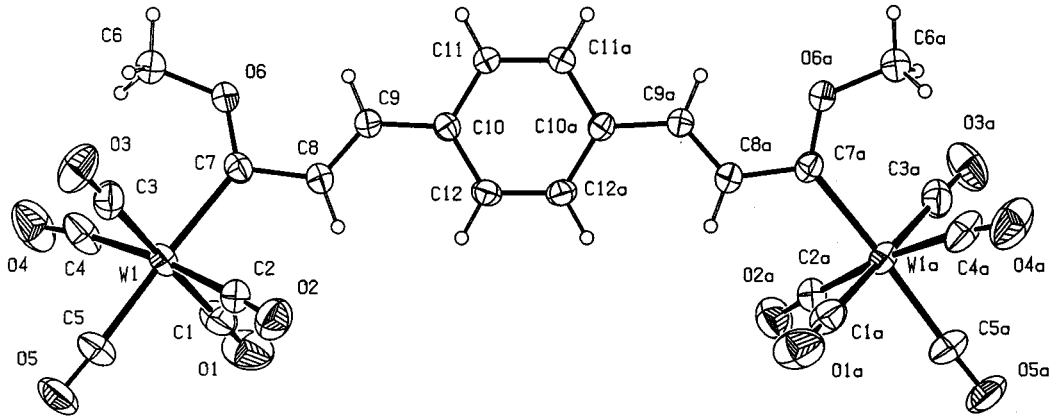

Figure 2. Molecular structure of $(CO)_5W{=}C(OMe)CH{=}CH{-}C_6H_4{-}CH{=}CH(OMe)C{=}W(CO)_5$ (**4a**)

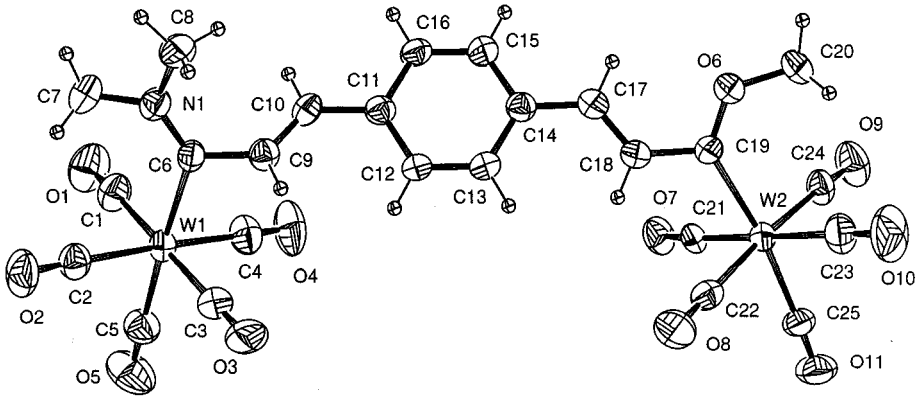

Figure 3. Molecular structure of $(CO)_5W{=}C(NMe_2)CH{=}CH{-}C_6H_4{-}CH{=}CH(OMe)C{=}W(CO)_5$ (**3a**)

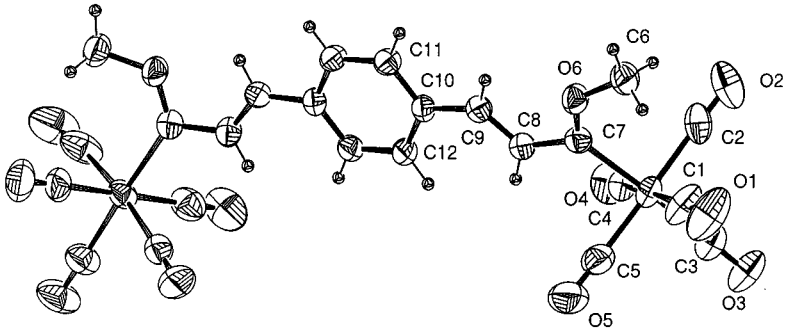

Figure 4. Molecular structure of $(CO)_5W{=}C(OMe)CH{=}CH{-}C_6H_4{-}CH{=}CH(OMe)C{=}Cr(CO)_5$ (**4′a**)

$(CO)_5W{=}C(NMe_2){-}(NMe_2)C{=}W(CO)_5$ [W=C 2.295(7), 2.281(7); C_{carb}–N 1.310(8), 1.314(9) Å],[14] $[(CO)_5W{=}C(NMe_2)C{\equiv}C{-}Hg{-}C{\equiv}CC(NMe_2){=}W(CO)_5]$, and $[(CO)_5W{=}C(NMe_2)C{\equiv}C{-}TiCp_2{-}C{\equiv}CC(NMe_2){=}W(CO)_5]$.[15] This is consistent with the magnetically nonequivalent methyl substituents in the NMR spectra. The W–C(O) distance [2.181(7) Å] is in the range of that of the above structures. As for **4a**, the C–C bond chain is alternated [1.489(10), 1.315(10), 1.463(10); 1.472(10), 1.315(10), 1.444(10) Å]. The bridging carbon chain is planar (mean deviation from the plane 0.087 Å); however, the two metal units deviate from this plane by 23° and 65° for the C(alkoxy)- and C(amino)carbene parts, respectively.

The molecular structure of the heterodimetal (Cr–W) complex **4′a** (Figure 4) is disordered for the metal positions (W,Cr), a feature which is also observed for $(CO)_5Cr\{{=}C(COMe)CH_2CH_2C(OMe)C{=}\}W(CO)_5$.[27] It is worth noting that the orientation of the aromatic ring contrasts with that in the (Cr–Fe) complex $[(CO)_5Cr\{{=}C(NMe_2)(m\text{-}C_6H_4)C(NMe_2){=}\}Fe(CO)_4]$ in which the phenyl bridge is perpendicular to the plane of the metal–carbene bond.[13]

Conclusion

This study shows that binuclear alkenylcarbene-bridged complexes can be conveniently prepared by sequential activation of bis(propargyl alcohol) derivatives. This route allows the synthesis of nonsymmetrical bis(carbene) complexes containing either two different tungsten–carbene fragments (amino- and alkoxycarbene) or two different me-

tallic centers (Cr and W). This opens up an entry to novel "push-pull" heterobimetallic bis(carbene) compounds, for instance with Groups 6 and 8 metals since they are both known to activate propargyl alcohols. Moreover, the reactivity of alkenylcarbene complexes is known to depend on the nature of the metal (Cr vs. W) and the substituent (alkoxy vs. amino) in typical reactions such as annulations and Diels−Alder cycloadditions. Studies on the reactivity of our nonsymmetric complexes, particularly with regard to the ability to discriminate the two metal−carbene fragments, are in progress.

Experimental Section

General: All manipulations were carried out under argon with Schlenk techniques. Solvents were dried and distilled before use by standard techniques. − NMR spectra were recorded with Bruker DPX-200 and Bruker AM-300 spectrometers. − Infrared spectra were obtained with a Nicolet FT-IR spectrometer. − High resolution mass spectra were obtained with Varian MAT 311 and Micromass ZABSpec TOF spectrometers at the C.R.M.P.O., University of Rennes 1. − Microanalyses were performed by the "Centre de Microanalyse du CNRS" at Vernaison, France.

Procedures for the Preparation of Bis(carbene)-Bridged Ditungsten Complexes

$(CO)_5W{=}C(NMe_2)CH{=}CH{-}C_6H_4{-}CH{=}CH(MeO)C{=}W(CO)_5$ (3a): A solution of $W(CO)_6$ (0.421 g, 1.2 mmol) in 60 mL of THF was irradiated for 6 h at room temperature by using a Rayonet and a Pyrex photochemical reactor. The yellow solution of $W(CO)_5$(THF) was then transferred into a Schlenk flask containing a solution of **1a** (0.537 g, 1 mmol) in 30 mL of methanol. The reaction mixture was stirred for 3 d at room temperature. After evaporation of the solvent under vacuum, the red residue was chromatographed on silica gel. Elution with dichloromethane/pentane (1:3) gave the bimetallic complex **3a** as a red solid in a 60% yield (0.525 g). − IR (CH_2Cl_2): ν_{CO} = 2059 (m), 1905 (s); $\nu_{C=C}$ = 1581 (w), 1546 (w) cm^{-1}. − ^1H NMR (300.133 MHz, $CDCl_3$): δ = 7.81 (d, 1 H, $^3J_{HH}$ = 15.4 Hz, C*H*=), 7.54 (d, 2 H, $^3J_{HH}$ = 8.3 Hz, C_6H_4-), 7.36 (d, 2 H, $^3J_{HH}$ = 8.3 Hz, C_6H_4-), 7.12 (d, 1 H, $^3J_{HH}$ = 15.4 Hz, C*H*=), 7.05 (d, 1 H, $^3J_{HH}$ = 16.7 Hz, C*H*=), 5.86 (d, 1 H, $^3J_{HH}$ = 16.7 Hz, C*H*=), 4.57 (s, 3 H, O*Me*), 3.77 [s, 3 H, N*Me* (*Z*)], 3.36 [s, 3 H, N*Me* (*E*)]. − ^{13}C {^1H} NMR (75.469 MHz, $CDCl_3$): δ = 306.5 (W=*C*), 252.1 (W=*C*), 203.9, 203.4 (*C*O), 198.3, 197.6 (*C*O), 143.3 (*C*H=), 139.6 (*C*H=), 138.6, 134.3 (C_6H_4−), 133.3 (*C*H=), 129.9, 127.3 (C_6H_4−), 122.0 (*C*H=), 69.05 (O*Me*), 53.5 [N*Me* (*Z*)], 44.5 [N*Me* (*E*)]. − $C_{27}H_{17}NO_{11}W_2$ (874.98): C 34.31, H 1.96, N 1.60; found C 34.97, H 2.19, N 1.61. − HRMS (FAB^+): calcd. for $C_{27}H_{17}NO_{11}{}^{184}W_2$ 874.9821; found 874.9834.

$(CO)_5W{=}C(OMe)CH{=}CH{-}C_6H_4{-}CH{=}CH(MeO)C{=}W(CO)_5$ (4a): The synthesis followed the method outlined for the synthesis of **3a**. Compound **4a** was obtained from $W(CO)_6$ (0.417 g, 1.1 mmol) and **2a** (0.520 g, 0.99 mmol) as a red dark powder in a 30% yield (0.250 g). − IR (CH_2Cl_2): ν_{CO} = 2065 (m), 1941 (s) cm^{-1}. − ^1H NMR (300.133 MHz, $CDCl_3$): δ = 7.85 (d, 2 H, $^3J_{HH}$ = 15.5 Hz, C*H*=), 7.50 (s, 4 H, C_6H_4−), 7.10 (d, 1 H, $^3J_{HH}$ = 15.5 Hz, C*H*=), 4.55 (s, 6 H, OCH_3). − ^{13}C {^1H} NMR (200.131, $CDCl_3$): δ = 307.0 (W=*C*), 203.8, 197.4 (*C*O), 144.2 (*C*H=), 137.1 (C_6H_4-), 131.8 (*C*H=), 129.0 (C_6H_4−), 69.1 (OCH_3).

$(CO)_5W{=}C(NMe_2)CH{=}CH{-}C_4H_2S{-}CH{=}CH(OMe)C{=}W(CO)_5$ (3b): The synthesis followed the method outlined for the synthesis of **3a**. Compound **3b** was obtained from $W(CO)_6$ (0.320 g, 0.91 mmol) and **1b** (0.370 g, 0.68 mmol)as a red dark oil in a 61% yield (0.370 g). − IR (CH_2Cl_2): ν_{CO} = 2064 (m), 1931 (s) cm^{-1}. − ^1H NMR (200.131 MHz, $CDCl_3$): δ = 7.56 (d, 1 H, $^3J_{HH}$ = 15.0 Hz, C*H*=), 7.28 (d, 1 H, $^3J_{HH}$ = 15.0 Hz, C*H*=), 6.90 (d, 1 H, $^3J_{HH}$ = 16.3 Hz, C*H*=), 7.28 (d, 1 H, $^3J_{HH}$ = 3.7 Hz, C_4H_2S), 6.95 (d, 1 H, $^3J_{HH}$ = 3.7 Hz, C_4H_2S), 6.11 (d, 1 H, $^3J_{HH}$ = 16.3 Hz, C*H*=), 4.57 (s, 3 H, O*Me*), 3.81 [s, 3 H, N*Me* (*Z*)], 3.40 [s, 3 H, N*Me* (*E*)]. − ^{13}C {^1H} NMR (50.322 MHz, $CDCl_3$): δ = 303.1 (W=*C*), 250.9 (W=*C*), 203.8, 203.1 (*C*O), 198.1, 197.5 (*C*O), 146.2, 142.3 (C_4H_2S), 139.8 (*C*H=), 139.4 (*C*H=), 135.4 (*C*H=), 129.0, 126.8 (C_4H_2S), 117.3 (*C*H=), 68.7 (O*Me*), 53.4 [N*Me* (*Z*)], 44.7 [N*Me* (*E*)]. − HRMS (FAB^+): calcd. for $C_{23}H_{15}NO_{11}S^{184}W_2$ 880.9385; found 880.9411.

$(CO)_5W{=}C(NMe_2)CH{=}CH{-}C_6H_4{-}CH{=}CH(MeO)C{=}Cr(CO)_5$ (3′a): In a procedure analogous to the synthesis of **3a**, $Cr(CO)_6$ (0.2 g, 0.9 mmol) was irradiated in THF at −10 °C for 6 h. The yellow solution of $Cr(CO)_5$(THF) was then transferred into a Schlenk flask containing a solution of **1a** (0.3 g, 0.6 mmol) in 30 mL of methanol. The reaction mixture was stirred for 18 h at room temperature. After evaporation of the solvent under vacuum, the red residue was chromatographed on a silica gel column. Elution with dichloromethane/pentane (1:3) gave the bimetallic complex **3′a** as a red oil in a 30% yield (0.132 g). − IR (CH_2Cl_2): ν_{CO} = 2056 (m), 1944 (s), 1928 (s) cm^{-1}. − ^1H NMR (250 MHz, $CDCl_3$): δ = 7.93 (d, 1 H, $^3J_{HH}$ = 15.3 Hz, C*H*=), 7.57 (d, 2 H, $^3J_{HH}$ = 8.3 Hz, C_6H_4−), 7.42 (d, 2 H, $^3J_{HH}$ = 8.3 Hz, C_6H_4−), 7.09 (d, 1 H, $^3J_{HH}$ = 16.7 Hz, C*H*=), 6.92 (d, 1 H, $^3J_{HH}$ = 15.3 Hz, C*H*=), 5.93 (d, 1 H, $^3J_{HH}$ = 16.7 Hz, C*H*=), 4.80 (s, 3 H, O*Me*), 3.83 [s, 3 H, N*Me* (*Z*)], 3.42 [s, 3 H, N*Me* (*E*)]. − ^{13}C {^1H} NMR (75.469 MHz, $CDCl_3$): δ = 332.7 (Cr=*C*′), 252.3 (W=*C*), 216.9, 203.4 (*C*O), 216.6, 197.6 (*C*O), 139.5 (*C*H=), 139.3 (*C*H=), 138.6, 134.1 (C_6H_4-), 129.9 (*C*H=), 128.6, 127.1 (C_6H_4-), 121.9 (*C*H=′), 53.4 (O*Me*), 49.5 [N*Me* (*Z*)], 44.4 [N*Me* (*E*)]. − HRMS (FAB^+): calcd. for $C_{25}H_{17}NO_{11}CrW$ 743; found 742.97.

$(CO)_5W{=}C(OMe)CH{=}CH{-}C_6H_4{-}CHO$ (2c): A solution of $W(CO)_6$ (2.6 g, 7.4 mmol) in 60 mL of THF was irradiated for 6 h at room temperature by using a Rayonet and a Pyrex photochemical reactor. The yellow solution of $W(CO)_5$(THF) was then transferred into a Schlenk flask containing a solution of the dialkynol derivative **c** (1 g, 6.2 mmol) in 30 mL of methanol. The reaction mixture was then stirred for 18 h at room temperature. After evaporation of the solvent under vacuum, the red residue was chromatographed on a silica gel column. Elution with dichloromethane/pentane (1:3) gave the red monometallic complex **2c** as a red oil in a 38% yield (1.19 g). − IR (CH_2Cl_2): ν_{CO} = 2066 (m), 1939 (s) cm^{-1}. − ^1H NMR (200.131 MHz, $CDCl_3$): δ = 10.0 (s, 1 H, C*H*O), 7.91 (d, 1 H, $^3J_{HH}$ = 15.5 Hz, C*H*=), 7.65 (m, 4 H, C_6H_4−) 7.11 (d, 1 H, $^3J_{HH}$ = 15.5 Hz, C*H*=), 4.65 (s, 3 H, O*Me*). − ^{13}C {^1H} NMR (75.46 MHz, $CDCl_3$): δ = 307.8 (W=*C*), 203.7, 197.2 (*C*O), 145.4 (*C*H=), 140.6 (*C*H=), 137.2, 130.5 (C_6H_4−), 129.4 (C_6H_4−), 69.3 (O*Me*). − HRMS (FAB^+): calcd. for $C_{16}H_{10}O_7{}^{182}W$ 497.9939; found 497.9937.

$(CO)_5W{=}C(OMe)CH{=}CH{-}C_6H_4{-}CH{=}CH(MeO)C{=}Cr(CO)_5$ (4′a): Equimolar quantities of **2c** (0.252 g, 0.5 mmol) and the complex $(CO)_5Cr(OCH_3)(CH_3)$ (0.126 g, 0.5 mmol) were dissolved in ether (30 mL) with triethylamine (0.280 mL, 2 mmol) and trimethylsilyl chloride (0.250 mL, 1.5 mmol), and the resulting mixture was stirred for 6 h at room temperature. The solvent was removed under vacuum, and the red-brown residue was chromatographed on a silica gel column. Elution with dichloromethane/pentane (1:3) gave the bimetallic complex **4′a** in a 33% yield (0.012 g). − IR

(CH_2Cl_2): ν_{CO} = 2067, 2057 (m), 1943 (s) cm^{-1}. – ^1H NMR (200.131 MHz, $CDCl_3$): δ = 7.97 (d, 1 H, $^3J_{HH}$ = 15.3 Hz, C*H*=), 7.89 (d, 1 H, $^3J_{HH}$ = 15.3 Hz, C*H*=), 7.59 (m, 4 H, C_6H_4–), 7.12 (d, 1 H, $^3J_{HH}$ = 15.3 Hz, C*H*=), 6.85 (d, 1 H, $^3J_{HH}$ = 15.3 Hz, C*H*=), 4.81 (s, 3 H, O*Me*), 4.63 (s, 3 H, O*Me*). – $^{13}C\{^1H\}$ NMR (50.32 MHz, $CDCl_3$): δ = 333.4 (Cr=*C*), 306.9 (W=*C*), 224.3, 216.5 (*C*O), 203.4, 197.3 (*C*O), 144.2 (*C*H=), 140.0 (*C*H=), 138.6, 134.1 (C_6H_4–), 129.9 (*C*H=), 128.6, 127.1 (C_6H_4–), 121.9 (*C*H=), 69.1 (O*Me*), 66.6 (O*Me*). – HRMS (FAB^+): calcd. for $C_{24}H_{14}O_{12}Cr^{182}W$ 730.21; found 729.8.

General Procedure for the Preparation of Bis[alkenyl(amino)carbene]-ditungsten Complexes: To a solution of **3a** (0.874 g, 1 mmol) in 20 mL of dichloromethane at room temperature was added 3–5 equiv. of amine. The color rapidly changed from red to orange. After stirring for 20 min, the solvent was removed in vacuo and the crude product was chromatographed on a silica gel column using pentane/dichloromethane (1:2) as the eluent. Evaporation of the solvent gave the bis(aminocarbene) complexes as orange solids in good yields.

$(CO)_5W=C[N(-CH_2CH_2-)_2NH]CH=CH-C_6H_4-CH=CH-(Me_2N)C=W(CO)_5$ (5a): Yield 54% (0.501 g). – IR (paraffin): ν_{CO} = 2061 (m), 1894 (s); $\nu_{C=C}$ = 1530 (f) cm^{-1}. – ^1H NMR (300.135 MHz, $[D_6]$acetone): δ = 7.54 (s, 4 H, C_6H_4–), 7.32 (d, 2 H, $^3J_{HH}$ = 16.7 Hz, C*H*=), 6.15 (d, 1 H, $^3J_{HH}$ = 16.7 Hz, C*H*=), 6.10 (d, 1 H, $^3J_{HH}$ = 16.8 Hz, C*H*=), 4.36 and 4.10 (m, 4 H, CH_2), 3.94 [s, 3 H, N*Me* (*Z*)], 3.59 [s, 3 H, N*Me* (*E*)], 3.20 and 3.01 (m, 4 H, CH_2). – $^{13}C\{^1H\}$ NMR (75.469 MHz, $[D_6]$acetone): δ = 248.3, 245.0 (W=*C*), 204.7, 204.5 (*C*O), 199.5, 199.3 (*C*O), 140.3, 139.4 (*C*H=), 136.9, 136.8, 127.9 (C_6H_4–), 124.3, 122.9 (*C*H=), 65.2 and 56.7 (CH_2), 54.3 [N*Me* (*Z*)], 48.5 and 48.2 (CH_2), 44.92 [N*Me* (*E*)]. – $C_{28}H_{23}N_3O_{10}W_2$ (929): C 36.17, H 2.50, N 4.52; found C 36.41, H 2.62, N 4.48. – HRMS (FAB^+): calcd. for $C_{28}H_{23}N_3O_{10}{}^{184}W_2$ 929.0399; found 929.0400.

$(CO)_5W=C[N(-CH_2CH_2-)_2NH]CH=CH-C_4H_2S-CH=CH-(Me_2N)C=W(CO)_5$ (5b): Yield 50% (0.440 g). – IR (CH_2Cl_2): ν_{CO} = 2061 (m), 1925 (s) cm^{-1}. – ^1H NMR (200.135 MHz, $[D_6]$-acetone): δ = 7.02 (d, 2 H, $^3J_{HH}$ = 16.4 Hz, C*H*=), 7.0 (m, 2 H, C_4H_2S), 6.20 (d, 2 H, $^3J_{HH}$ = 16.4 Hz, C*H*=), 4.39 and 4.14 (m, 4 H, CH_2), 3.86 [s, 3 H, N*Me* (*Z*)], 3.52 [s, 3 H, N*Me* (*E*)], 2.94 and 2.88 (m, 4 H, CH_2).

$(CO)_5W=C[N(H)(CH_2-CH_2NH_2)]CH=CHC_6H_4CH=CH-(Me_2N)C=W(CO)_5$ (6a): Yield 75% (0.677 g). – IR (KBr): ν_{CO} = 2062 (m), 1895 (s) cm^{-1}. – ^1H NMR (300.134 MHz, CD_2Cl_2): δ = 7.38 (d, 2 H, $^3J_{HH}$ = 8.2 Hz, C_6H_4–), 7.21 (d, 2 H, $^3J_{HH}$ = 8.2 Hz, C_6H_4–), 7.03 (d, 2 H, $^3J_{HH}$ = 16.7 Hz, C*H*=), 5.95 (d, 2 H, $^3J_{HH}$ = 16.7 Hz, C*H*=), 3.80 [s, 3 H, N*Me* (*Z*)], 3.36 [s, 3 H, N*Me* (*E*)], 2.88 (m, 2 H, CH_2), 2.73 (t, 2 H, CH_2). – $^{13}C\{^1H\}$ NMR (75.469 MHz, $[D_6]$acetone): δ = 248.4 (W=*C*), 204.4, 202.5 (*C*O), 199.3, 199.1 (*C*O), 140.8 (C_6H_4–), 139.8 (*C*H=), 135.4, 129.4, 127.7 (C_6H_4–), 124.7 (*C*H=), 65.2 (NH*C*H_2), 54.3 [N*Me* (*Z*)], 44.9 [N*Me* (*E*)], 33.1 (*C*H_2NH_2). – $C_{26}H_{21}N_3O_{10}W_2$ (903): C 34.55, H 2.34, N 4.65; found C 30.09, H 1.96, N 3.83. – HRMS (FAB^+): calcd. for $C_{26}H_{21}N_3O_{10}{}^{184}W_2$ 903.0246; found 903.0240.

$(CO)_5W=C[N(H)(CH_2-CH_2-NH_2]CH=CH-C_4H_2S-CH=CH(Me_2N)C=W(CO)_5$ (6b): Yield 70% (0.636 g). – IR (CH_2Cl_2): ν_{CO} = 2061 (m), 1924 (s) cm^{-1}. – ^1H NMR (200.131 MHz, $CDCl_3$): δ = 6.84 (d, 1 H, $^3J_{HH}$ = 3.5 Hz, C_4H_2S), 6.74 (d, 1 H, $^3J_{HH}$ = 3.5 Hz, C_4H_2S), 6.67 (d, 2 H, $^3J_{HH}$ = 15.3 Hz, C*H*=), 6.14 (d, 2 H, $^3J_{HH}$ = 15.3 Hz, C*H*=), 3.80 [s, 3 H, N*Me* (*Z*)], 3.40 [s, 3 H, N*Me* (*E*)], 3.09 (m, 2 H, CH_2), 2.82 (m, 2 H, CH_2). – $^{13}C\{^1H\}$ NMR (75.469 MHz, CD_2Cl_2): δ = 204.19, 202.07 (*C*O), 198.8, 198.2 (*C*O), 54.5 [N*Me* (*Z*)], 49.1 [N*Me* (*E*)]. – HRMS (FAB^+): calcd. for $C_{24}H_{19}N_3O_{10}S^{184}W_2$ 908.9810; found 908.9815.

$(CO)_5W=C[N(CH_2CH_2OH)CH_2CH_3]CH=CH-C_6H_4-CH=CH(Me_2N)C=W(CO)_5$ (7a): Yield 81% (0.755 g). – IR (CH_2Cl_2):

X-ray Crystal Structure Analysis: Crystals, data collection, and refinement parameters for complexes **3a**, **4a**, **4b**, and **4′a** are given in Table 3. Crystals were obtained by slow concentration of a dichloromethane solution. All X-ray data were collected with an automatic diffractometer CAD4 NONIUS (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å). After Lorentz and polarization corrections, the structures were solved with SIR-97,[27] which reveals the non-hydrogen atoms of the structure and a statistical disorder between Cr and W atoms (complex **4′a**). After anisotropic refinement, a Fourier difference map reveals all the hydrogen atoms. The whole structures were refined with SHELXL97 by the full-matrix least-squares technique (use of *F* square magnitude; *x*, *y*, *z*, β_{ij} for Cr, W, C, and O atoms, *x*, *y*, *z* in riding mode for H atoms).[28] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-146553 (**4b**), -146554 (**4a**), -146555 (**3a**), -146556 (**4′a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mössbauer, Crystallographic, and Density Functional Theoretical Investigation of the Electronic Structure of Bis-Ligated Low-Spin Iron(II) Phthalocyanines

Victor N. Nemykin,[a] Nagao Kobayashi,*[a] Victor Y. Chernii,[b] and Vitaly K. Belsky[c]

Keywords: Iron / Phthalocyanines / Mössbauer spectroscopy / Density functional calculations

We present the crystal structure of pcFe(4-methylpiperidine)$_2$ as a first example of a low-spin iron(II) phthalocyanine (pc) complex bis-axially coordinated by aliphatic amines. It is shown that electronic rather than steric effects are responsible for the elongation of the Fe–N(axial) bond in pcFeL$_2$ complexes. Using density functional theory, the electronic structures as well as Mössbauer isomer shifts and quadrupole splittings have been investigated for a large number of pcFeL$_2$ and pcFeL^{1}L^2 complexes, in which the axial ligands have varying electronic and steric properties. The electron charge densities and electric field gradients at the iron ion were evaluated using a locally dense basis approach with Wachters' all-electron basis set for the iron ion, the 6-311++G(2d) basis set for atoms directly bonded to the iron ion, the 6-31G(d) basis set for atoms two bonds away from the iron ion, and the 3-21G* basis set for all other atoms. A good correlation between the theoretical and experimental isomer shifts and quadrupole splittings has been observed for all the complexes tested. It has also been shown that the proposed model for the calculation of Mössbauer spectral parameters is adequate for the evaluation of the axial ligand conformation in cases of conformational flexibility in pcFeL$_2$ complexes.

Introduction

Iron-containing tetrapyrrole macrocycles and their analogues have been found to be capable of mimicking the active sites of a wide variety of biological enzymes.[1] Tetrabenzotetraazaporphyrin, i.e. phthalocyanine (pc), iron complexes have been the subject of widespread interest, both as homogeneous and heterogeneous catalytic systems with high oxygenating activity,[2] and have also been extensively studied as heme protein models[3] by virtue of their high thermal and chemical stability. The possibility of axial coordination and the stability of iron−axial ligand bonds are key features of these systems that play an important role in catalytic and model biological processes.[1−3] The nature of the central metal−axial ligand bonding in phthalocyanine iron complexes has been qualitatively discussed over the past 30 years. A large number of bis-axially coordinated low-spin iron(II) pcs (pcFeL$_2$ or pcFeL^{1}L^2) with aliphatic and heterocyclic nitrogen bases, isonitriles, phosphanes, and phosphites have been studied.[4−6] In principle, Mössbauer spectroscopy represents one of the most powerful methods for assessing the metal−axial ligand interaction in these systems. However, despite a large amount of experimental data concerning the Mössbauer spectra of iron pcs,[5,6] publications on the theoretical analysis of ^{57}Fe Mössbauer spectral parameters of these complexes are scarce, especially for bis-axially coordinated low-spin iron(II) pcs. This can be mainly attributed to two factors.[6] Firstly, only a few good X-ray crystallographic structures are available for pcFeL$_2$ or pcFeL^{1}L^2 complexes that can be used as initial structures for quantum mechanical calculations.[7] With a view to rectifying this situation, we present herein the first crystal structure of a low-spin iron(II) pc bis-axially coordinated by aliphatic amines. Secondly, the computation of energies, electronic structures, and properties of transition metal complexes requires consideration of electronic correlation effects.[8] However, for calculations of the electronic structures on systems of the size of pcFeL$_2$ or pcFeL^{1}L^2 (containing up to 97 atoms), all the usual electron correlation methods, based, for example, on multiconfigurational interaction, Möller−Plesset perturbation theory, or other algorithms, would require speeds typically as high as ca. N^5 (where N is the number of basis functions) and are still expensive. Fortunately, computational methods based on density functional theory (DFT) can be used as an alternative to conventional ab initio methods for large systems of this type because they include electron correlation effects in the exchange-correlation functional and are computationally very inexpensive. As has recently been shown, the simplest local density approximation (LDA) as well as the more precise B3LYP exchange-correlation functional generally give much better results for the ground-state properties of transition metal compounds, including porphyrins having structures that closely resemble those of pcs, than those obtained at the semiempirical or conventional ab initio Hartree−Fock levels.[9] In this paper, we present Mössbauer

spectra and the results of DFT calculations for a large number of bis-axially coordinated iron(II) pcs. In addition, X-ray crystallographic data are presented for a low-spin iron(II) pc coordinated by two aliphatic amines. In order to find the best computational method for the prediction of Mössbauer spectral parameters and to understand the origin of the differences in the spectroscopic data, comparative semiempirical, conventional ab initio, and DFT calculations have also been performed. In particular, we wanted to ascertain whether it is possible to reproduce a large difference in quadrupole splitting (ΔE_Q) among the complexes (from 0.56 to 2.28 mm s^{-1}), and to rationalize the influence of specific effects, such as the conformation of the axial ligands, on the Mössbauer spectral parameters. For these purposes, we chose the following pcs, in which the axial ligands have varying electronic and steric properties: pcFe(14en)$_2$ (**1**), pcFe(mepip)$_2$ (**2**), pcFe($BuNH_2$)$_2$ (**3**), pcFe(mim)$_2$ (**4**), pcFe(mepy)$_2$ (**5**), pcFe(*cyclo*-$C_6H_{11}NC$)$_2$ (**6**), pcFe(CO)(dmf) (**7**), and [pcFe$(CN)_2$]$^{2-}$ (**8**), where 14en, mepip, mim, and mepy are 1,4-diaminobutane, 4-methylpiperidine, *N*-methylimidazole, and 4-methylpyridine, respectively. As described below, the results represent the first successful theoretical analysis and prediction of Mössbauer spectral parameters in bis-axially coordinated low-spin iron(II) pcs.

Results and Discussion

Structural Aspects and Rotational Barriers

The SHELXTL-93 structure of pcFe(mepip)$_2$ (**2**) is shown in Figure 1. Atomic coordinates, as well as selected intramolecular distances and angles for this complex, are summarized in the Supporting Information (Tables 2 and 3) with the numbering scheme indicated in Figure 1. The structure of pcFe(mepip)$_2$ (**2**) is the first X-ray structure of an iron(II) pc to provide unprecedented stereochemical data on the coordination of aliphatic amines to iron pcs. In the recently reported X-ray structure of turnip cytochrome *f*, one of the axial ligands was found to be the α-NH_2 group of *Tyr*-1, and thus pcFe(mepip)$_2$ (**2**) may provide a useful starting point for delineating the role of aliphatic amino acids in biologically relevant amine complexes of iron porphyrins. In the unit cell of pcFe(mepip)$_2$ (**2**), four solvated mepip molecules are present in a chair conformation. The iron ion is coordinated by six nitrogen atoms that form an approximately square-bipyramidal structure. The essentially uniform Fe−N(pc) distance (1.93 Å) is consistent with a low-spin iron(II) configuration and is close to the corresponding distances found in other known bis(amino)-ligated iron(II) pcs such as pcFe(mim)$_2$ (**4**) and pcFe(mepy)$_2$ (**5**) (Table 1).[7a,7b] The Fe−N(mepip) distance (2.12 Å) is longer than that in any of the known iron(II) pcs bis-axially coordinated through the N, C, or O atoms of the ligands.[7] Two factors may be invoked to account for this bond elongation, namely steric interactions between protons of the axial ligand and the pc core, and electronic effects. Both of these are discussed below. The N(pc)−Fe−N(mepip) angles are close to 90° (the largest deviation is 1.85°). The phthalocyanine core is almost planar, keeping the interatomic distances close to those in pcFe(mim)$_2$ (**4**) and pcFe(mepy)$_2$ (**5**).[7] The axial ligands adopt a chair conformation with the intramolecular distances and angles close to those in solvated molecules present in the unit cell. The dihedral planes between the axial ligands are close to zero. This orientation of the axially coordinated mepip planes relative to the phthalocyanine core in the structure of **2** is fixed by the steric requirements imposed by the conformation of the solvated, as well as neighboring, axially coordinated mepip molecules. Any rotation of the axially coordinated ligands about the Fe−N(mepip) axis leads to a reduction in the non-bonding interactions between the carbon or hydrogen atoms of the axial ligands and the axially coordinated ligands of neighboring molecules of pcFe(mepip)$_2$ (**2**) and/or solvated mepip molecules. For example, rotation of the axial ligand about the *z* axis by 90° would result in unacceptably close non-bonding contacts (less that 2 Å) between the carbon atoms of the axial ligand and a nitrogen atom of a solvated mepip molecule. Such steric hindrance to the rotation of axial ligands in the crystal structure of pcFe(mepip)$_2$ (**2**) is well reproduced by rotational barrier calculations at the molecular mechanical and semiempirical levels. The results of calculations at the molecular mechanical level are summarized in Figure 2. Similarly qualitative results were obtained from semiempirical PM3 level calculations. Thus, the procedure described in the Experimental Section leads to estimated barriers for rotation of the axial ligands of 1.92 kcal mol^{-1}, 1.20 kcal mol^{-1}, and 2.54 kcal mol^{-1} at the MM+ level and of 2.07 kcal mol^{-1}, 1.71 kcal mol^{-1}, and 2.95 kcal mol^{-1} at the PM3 level for pcFe(mepip)$_2$ (**2**), pcFe(mim)$_2$ (**4**), and pcFe(mepy)$_2$ (**5**), respectively. Similar results have recently been reported for the barriers to rotation of axial ligands in predominantly planar or slightly distorted bis-axially coordinated iron(II) and iron(III) porphyrins.[9a,10] Thus, it is clear that in the gas phase, or in solution in the absence of any specific interactions between bis-axially coordinated iron(II) pcs and solvent molecules, the rotational barrier for rotations of axial ligands is invariably very small, in agreement with the room-temperature ^{1}H NMR spectral data.[4a−4e] On the other hand, for solvated mepip molecules the height of the rotational barrier of the axial ligand increases by more than two orders of magnitude according to both MM+ and PM3 calculations (Figure 2). Finally, it is important to delineate the factors that are responsible for the elongation of the Fe−N(axial) bond in pcFe(mepip)$_2$ (**2**) as compared with the corresponding distances in the complexes pcFe(mim)$_2$ (**4**) and pcFe(mepy)$_2$ (**5**). If steric interactions were to play a major role, as discussed previously[11] for tppFe(pip)$_2$, which contains an almost planar porphyrin core, the decrease in the Fe−N(axial) bond length would lead to a dramatic increase in the barrier to rotation of the axial ligand in pcFe(mepip)$_2$ (**2**). In order to reproduce this effect, model calculations on pcFe(mepip)$_2$ (**2**) were carried out in which the Fe−N(axial) bond length was shortened to 2.04 Å [as in pcFe(mepy)$_2$ (**5**)]. The results

showed that, in fact, the barrier to rotation of the axial ligand increases by less than 1.0 kcal mol^{-1} and that the total energies differ by less than 7 kcal mol^{-1}, both at the molecular mechanical and semiempirical levels. These results clearly indicate that the elongation of the Fe−N(axial) bond in pcFe(mepip)$_2$ (**2**) must stem from a difference in the electronic structure of the axial ligands in pcFe(mepip)$_2$ (**2**) compared to the situation in other pcFeL$_2$ and pcFeL^{1}L^2 complexes, in particular complexes pcFe(mim)$_2$ (**4**) and pcFe(mepy)$_2$ (**5**). Indeed, the Fe−N(axial) distances are roughly paralleled by the order of the magnitude of the sum of σ-donor and π-acceptor properties of the axial ligands: mepip > mepy > *cyclo*-$C_6H_{11}NC$ > CO.[5b,12]

Mössbauer Spectra of Bis-axially Coordinated Iron(II) Phthalocyanines

As for other low-spin ($S = 0$) iron(II) inorganic and organometallic compounds,[13] the Mössbauer spectra of bis-axially coordinated iron(II) phthalocyanines consist of one doublet,[5] the example shown in Figure 3 being typical. The quadrupole splitting, ΔE_Q, varies significantly from 0.56 mm s^{-1} in the complex [pcFe(CN)$_2$]$^{2-}$ (**8**) to 2.89 mm s^{-1} in pcFe(dabco)$_2$.[5d] The valence contribution (q_{val}) to ΔE_Q is approximately related to the anisotropy of the Fe(3d) and Fe(4p) shell occupations, as expressed by the Townes−Dailey approximation:[9a,13−16] $q_{val} =$

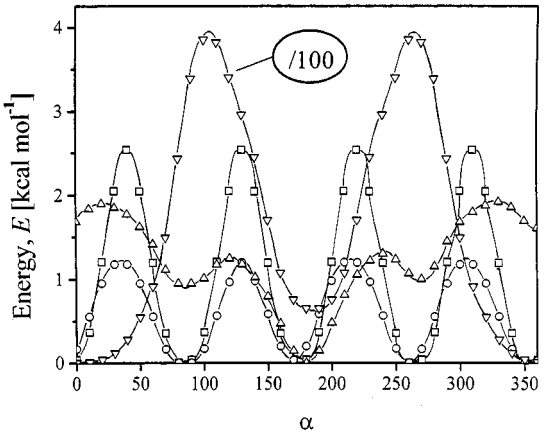

Figure 2. Barriers to axial ligand rotation in **2** (upward triangles), in **2** with solvated mepip molecules (inverted triangles), in **4** (circles), and **5** (squares), computed by a molecular mechanics (MM+) method

$^4/_7(1 - R)\langle r^{-3}\rangle_{3d}\{n(d_{xy}) + n(d_{x^2-y^2}) - n(d_{z^2}) - [n(d_{xz}) + n(d_{yz})]/2\} + {}^4/_5(1 - R)\langle r^{-3}\rangle_{4p}\{[n(p_x) + n(p_y)]/2 - n(p_z)\}$, where n(d) and n(p) are the effective populations of the respective iron orbitals, and $\langle r^{-3}\rangle$ is the expectation value of $1/r^3$ taken over the appropriate iron radial functions. For most bis-axially coordinated low-spin iron(II) macrocyclic complexes, such as pcs, porphyrins, and substituted dioximates, the valence contribution to ΔE_Q dominates[5,6a,9a] and hence the large (> 2.0 mm s^{-1}) quadrupole splitting seen in many pcFeL$_2$ complexes having a formal $(d_{xy})^2(d_{xz},d_{yz})^4$ electronic configuration is difficult to understand. Accordingly, in order to understand this phenomenon and to reproduce the large ΔE_Q values, comparative quantum chemical calculations were performed on the various pcFeL$_2$ and pcFeL^{1}L^2 complexes, as described in the next section.

Density Functional Theory Calculations

Despite the large amount of experimental data on Mössbauer spectra of low-spin iron(II) pcs, only one theoretical study of quadrupole splittings on the basis of INDO semiempirical calculations has been published, although the parameters were not given.[6a] Moreover, to the best of our knowledge, there has been no report of a successful theoretical analysis of Mössbauer spectral parameters for low-spin

iron(II) pcs. In view of this, the Mössbauer spectral parameters for the complexes $pcFe(mepip)_2$ (**2**) and $pcFe(mim)_2$ (**4**), for which relatively large quadrupole splittings were observed compared to other low-spin iron(II) pcs, have been analyzed theoretically, and the results have been compared by quantum chemical calculations at the following levels of theory: (i) semiempirical ZINDO/S,[17] (ii) conventional ab initio [with the same basis set as discussed for DFT methods, as well as with Wachters' all-electron basis set for iron and 6-311+G(2d) for all other atoms], (iii) DFT methods with B3LYP, LDA, and LSDA EC functionals. As can be seen from the results presented in Table 2, the electric field gradients obtained from both semiempirical and conventional ab initio methods show a marked deviation from the experimental values, while those obtained from the DFT methods are much closer. As a consequence, in the following we will discuss and compare only the results of the DFT calculations.

Orbital Energies

The order of the orbital energies is shown in Table 3, in the Supporting Information (Tables 4 and 5), and Figure 4 and Figure 5. In general, the order of metal-centered orbitals reflects the splitting pattern of distorted octahedral coordination of the central ion. The "t_{2g}" manifold of the Fe(3d) orbitals is split into an almost degenerate d_{xz} and d_{yz} pair and a d_{xy} orbital, except in the case of $[pcFe(CN)_2]^{2-}$ (**8**), while the "e_g" manifold is split into d_{z^2} and $d_{x^2-y^2}$ orbitals. Furthermore, in all cases the LUMO "e_g" orbitals are pc-centered as in other metal-containing pcs.[21] However, the relative energies of the metal-centered orbitals as well as the pc-centered orbitals were found to be strongly dependent on the EC functional used. Thus, when the B3LYP EC hybrid functional was used (Figure 4), the pc "a_{1u}" (in D_{4h} notation) orbital was found to be the HOMO for all the complexes, except in the case of

Table 3. Calculated orbital energies (eV) for complexes **1−8** using the B3LYP hybrid EC functional

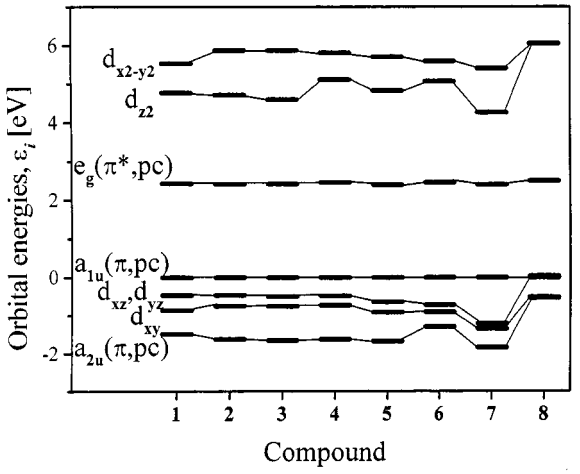

Figure 4. The ground-state MOs of complexes **1**−**8** [relative to "a_{1u}" (pc) orbital] with predominant Fe(3d) character, as well as the most important pc-centered MOs, as obtained by B3LYP DFT calculations

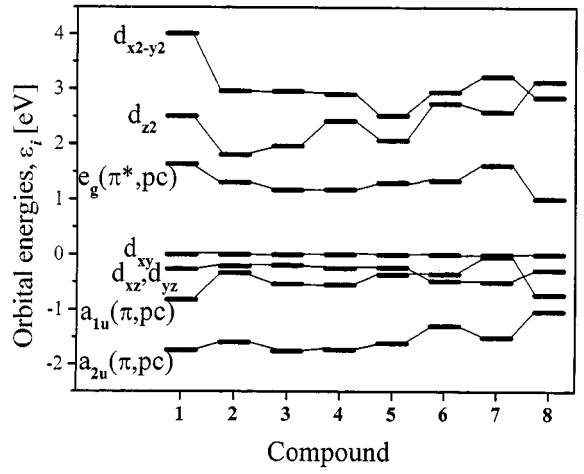

Figure 5. The ground-state MOs of complexes **1**−**8** (relative to d_{xy} orbital) with predominant Fe(3d) character, as well as the most important pc-centered MOs, as obtained by LSDA DFT calculations

$[pcFe(CN)_2]^{2-}$ (**8**) where the d_π orbitals are slightly higher in energy and are thus the HOMOs. For **1**−**8**, the d_{xz} and d_{yz} orbitals are higher in energy compared to d_{xy}, while the $d_{x^2-y^2}$ orbital is always higher in energy than d_{z^2}. When LDA and LSDA EC functionals were employed (Figure 5), the order of the orbital energies was found to be roughly similar, but differed in a few respects. Thus, the near-degenerate "d_π" orbitals are always lower in energy than the d_{xy} orbital, which is the HOMO. The $d_{x^2-y^2}$ orbital is higher in energy than the d_{z^2} orbital for **1**−**7**, while in the case of $[pcFe(CN)_2]^{2-}$ (**8**) the order of these orbitals is reversed. As can be seen in Figure 4 and 5, the splitting between the $d_{x^2-y^2}$ and d_{z^2} orbitals is considerably smaller for the complexes pcFe(*cyclo*-$C_6H_{11}NC)_2$ (**6**) and $[pcFe(CN)_2]^{2-}$ (**8**). The main reason for this is the destabilization of the iron d_{z^2} orbital due to the shorter iron−axial ligand distances as compared to those in the other tested complexes. In the case of $[pcFe(CN)_2]^{2-}$ (**8**), strong electron donation from the negatively charged cyano groups also serves to destabilize the d_{z^2} orbital. In the case of complexes pcFe(*cyclo*-$C_6H_{11}NC)_2$ (**6**) and pcFe(CO)(dmf) (**7**), which contain at least one axial ligand with strong π-back-donating properties, the d_{xz} and d_{yz} orbitals are significantly stabilized and have lower energies than the pc-centered "a_{1u}" orbital.

It is interesting to compare the calculated iron 2p and 3s orbital energies with the experimentally determined ionization potentials (IPs) (XPS experiments) for the $pcFe(im)_2$ ($Fe_{2p3/2}$: 708.0 eV; Fe_{3s}: 92.5 eV) and $pcFe(3mepy)_2$ ($Fe_{2p3/2}$: 708.1 eV; Fe_{3s}: 92.3 eV) complexes.[19] The reverse-signed 2p and 3s iron orbital energies computed for complexes **1**−**8** [Table 3 and Supporting Information (Tables 4 and 5)] parallel the IP values obtained from the XPS data. In particular, the closest values were obtained using the B3LYP EC functional.

The crystal field splittings, Δ_{cf}, defined as the differences between the orbital energies of d_π (average value) and d_{z^2} for the B3LYP EC functional (Figure 4) or d_{xy} and d_{z^2} {$d_{x^2-y^2}$ for $[pcFe(CN)_2]^{2-}$ (**8**)} for the LDA and LSDA EC functionals (Figure 5) are larger than 1.8 eV, in agreement with the observed low-spin ground state for **1**−**8** (in general, the value of Δ_{cf} parallels the values in the spectrochemical series).[20] It is well known that in the electronic spectra of $pcFeL_2$ and $pcFeL^1L^2$ complexes, the band at around 2.95 eV can be assigned as a metal-to-ligand charge transfer (MLCT) band [d_{xz}, d_{yz} → "b_{1u}" (π*, pc)] since it is sensitive to the nature of the axial ligand.[4f,21] Using the LDA and LSDA EC functionals, the estimated energies of the MLCT bands were in qualitative agreement with the available experimental data, while with the B3LYP EC functional, the obtained values reflected a strong overestimation of the MLCT band energies, which is typical of ground-state calculations with hybrid DFT EC functionals.[22] For all the tested EC functionals, the pc "a_{1u}" orbital was found to be higher in energy than the pc "a_{2u}" orbital and the orbital separation was of the order of 1 eV or more {except for complex $[pcFe(CN)_2]^{2-}$ (**8**)}, consistent with the fact that the lowest energy π-π* transition has an essentially pure "a_{1u}" (π, pc) → "e_g"(π*, pc) configuration.[21]

Isomer Shifts and Electric Field Gradients

The following five quantities can be derived from Mössbauer experiments, as well as theoretical calculations using SCF wavefunctions:[13] isomer shift (δ), quadrupole splitting (ΔE_Q), the sign of the principal component, V_{zz}, of the EFG tensor, the direction of V_{zz}, and the asymmetry parameter (η). The isomer shift in Mössbauer spectroscopy depends on the electron charge density, ρ(0), at the nucleus and is proportional to changes in ρ(0) with respect to reference compounds. Thus, $\delta = \alpha[\rho(0) - \rho_r(0)]$, where α is a calibration constant and ρ(0) and $\rho_r(0)$ are the electron charge densities at the nuclei in the sample and reference compounds, respectively.[13] For quantum chemical calculations, the $\rho_r(0)$ value is usually replaced by a constant, β, and thus δ is calculated as $\delta = \alpha[\rho(0) - \beta]$. In the ideal case, β corresponds to the electron charge density at the Mössbauer nucleus in the reference compound.[13,23] A good correlation was found when plotting the isomer shift

values against the calculated total electron charge densities on the iron atoms for complexes **1−8** (Figure 6). The calibration constant, α, was evaluated as −0.192 a_o^3 mm s^{-1} for the eight points, with a correlation coefficient r^2 of 0.980 and an r.m.s. error of 0.016 mm s^{-1}. This obtained value of α is close to that recently published and used for CASSCF ab initio calculations of Mössbauer spectral parameters for iron porphyrins (−0.166 a_o^3 mm s^{-1})[23a] and other iron-containing inorganic and organometallic compounds.[24] Moreover, the value obtained for constant β (Figure 6) is close to the calculated total electron charge density at the iron atom in sodium nitroprusside (11617.77 a_o^{-3}). When the calculated value for sodium nitroprusside ρ(0) was included in the ρ(0)/δ correlation analysis, the correlation coefficient did not change ($r^2 = 0.981$), but α changed significantly from −0.19 to −0.26 a_o^3 mm s^{-1}. The latter value of α is closer to that found by Trautwein et al. for some iron-containing inorganic compounds (−0.31 to −0.38 a_o^3 mm s^{-1}).[25] The calibration constant α can also be written as $\alpha = (4Ze^2R^2c/5E_\gamma)\cdot(\delta R/R) = C\cdot(\delta R/R)$,[13] where R is the average nuclear radius and δR is the change in radius on going from the ground to the excited state. Having estimated α from a ρ(0)/δ correlation analysis and calculated the total electron charge density for sodium nitroprusside, which is used as a reference compound, it is possible to estimate the value of $\delta R/R$ in order to support our isomer shift calculations on $pcFeL_2$ and $pcFeL^1L^2$ complexes. Using the value of $C = 0.3083\cdot10^3$ a_o^3 mm s^{-1} obtained by Alton and Swift,[24c] the $\delta R/R$ values were estimated (average for **1−8**) as $-6.16\cdot10^{-4}$ and $-8.43\cdot10^{-4}$ when α is −0.19 and −0.26 a_o^3 mm s^{-1}, respectively. Both these values are in reasonable agreement with previously published results.[24] Although the computed values of α and $\delta R/R$ estimated from the correlation analysis are different, the present results are very promising because they suggest that Mössbauer isomer shifts in iron pcs, and probably in other iron-containing compounds as well, can be calculated with high accuracy using modern DFT methods.

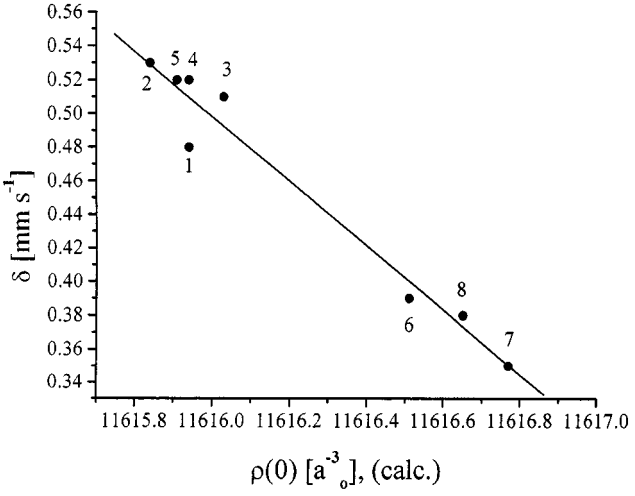

Figure 6. Correlation between the observed Mössbauer isomer shifts and the calculated total electron densities at the ^{57}Fe nucleus by the B3LYP DFT method; numerical values are given in Table 2

The Mössbauer quadrupole splittings and asymmetry parameters, η, for compounds **1−8**, calculated using the locally dense basis set approach in conjunction with the B3LYP, LSDA, and LDA EC functionals are presented in Table 2, while those calculated with the B3LYP EC functional are shown graphically in Figure 7. The results of our DFT calculations using the B3LYP EC functional demonstrate that the magnitude of the ΔE_Q values, the sign and orientation of the principal component of the EFG tensor, and the η values, are all in agreement with the experimental data. A correlation coefficient of $r^2 = 0.982$, with an r.m.s. error of 0.14 mm s^{-1}, has been found between the predicted and experimental ΔE_Q values for complexes **1−8**. These results are very promising, since they suggest that DFT methods can now be applied with some reliability to predicting both Mössbauer quadrupole splittings and Mössbauer isomer shifts in large systems such as phthalocyanines, for which other methods based on semiempirical and conventional ab initio quantum mechanical levels have hitherto proved inadequate. For example, for the complex $pcFe(mepip)_2$ (**2**), we have computed ΔE_Q and δ values of 2.18 and 0.52 mm s^{-1}, respectively, which can be quite favorably compared with the experimental values of 2.28 and 0.53 mm s^{-1}. Similarly, for complex $pcFe(cyclo\text{-}C_6H_{11}NC)_2$ (**6**), even though the EFG is much smaller, there is likewise good accord between the computed (0.55 and 0.35 mm s^{-1}) and experimental (0.69 and 0.39 mm s^{-1})[5d] values. Among complexes **1−8**, the computed and experimental ΔE_Q values only differ significantly in the case of the complex $[pcFe(CN)_2]^{2-}$ (**8**) (marked as **8a** in Table 2 and indicated by an unfilled circle in Figure 7); this large deviation could originate from the uncompensated lattice effects of two positively charged counterions, as well as from deficiencies in the basis sets and the functional used. Indeed, when, for example, two sodium ions were placed in the positions of the cationic nitrogen atoms of PNP counterions, as determined experimentally for $(PNP)_2[pcFe(CN)_2]$,[7c] the calculated ΔE_Q value was found to be in excellent agreement with the experimental data (marked as case **8b** in Table 2). The large η value calculated in the case of **8b** can easily be explained by taking into consideration the fact that in the actual crystal of $(PNP)_2[pcFe(CN)_2]$, the iron pc is symmetrically surrounded by four PNP cations,[7c] whereas in our model calculation only two sodium ions were used in order to compensate for the negative charge of the $[pcFe(CN)_2]^{2-}$ moiety. The observation that V_{zz} is directed along the Na−Na axis supports this explanation. As pointed out in the literature,[4a][5a][5b] the axial ligand in the complex $pcFe(14en)_2$ (**1**) is probably stabilized through intramolecular hydrogen bond formation. It is thus interesting to compare the experimental Mössbauer spectral parameters with those calculated for the open-chain (**1a**) and intramolecularly hydrogen-bonded conformations (**1b**). The calculated Mössbauer spectral parameters for **1a** are close to those calculated for the complex $pcFe(BuNH_2)_2$ (**3**), for which only an open-chain conformation is possible. On the other hand, the calculated Mössbauer spectral parameters for **1b** are in close agreement with the experimental data, sup-

porting the previously proposed hypothesis concerning the possibility of intramolecular hydrogen bonding in this complex. Additional evidence concerning the axial ligand conformation in pcFe(14en)$_2$ (**1**) can be obtained from a comparison of the experimental ^{1}H NMR spectra of pcFe(14en)$_2$ (**1**) and pcFe(BuNH$_2$)$_2$ (**3**) and the computed isotropic shifts for the protons of the axial ligands. It is well known that in the ^{1}H NMR spectra of pcFeL$_2$ complexes the protons of the axial ligands are strongly shielded by the ring current of the pc ring, this effect depending on the electronic structures of the axial ligands and their positions in relation to the pc plane.[4a−4e] The experimental chemical shifts for the coordinated NH$_2$ protons in pcFe(14en)$_2$ (**1**) and pcFe(BuNH$_2$)$_2$ (**3**), as well as the calculated chemical shifts and shieldings are summarized in Table 4, together with the calculated NMR parameters for ^{57}Fe. Again, the calculated chemical shifts for **1a** and pcFe(BuNH$_2$)$_2$ (**3**) are close, while the values for **1b** differ significantly in accord with the experimental data. Finally, the computed ^{57}Fe chemical shifts have reasonable values, as judged on the basis of the available experimental and calculated data for bis-axially coordinated iron(II) porphyrins.[9c,26] Since the calculated η values for complexes **1**−**8** are small, and the direction of V_{zz} corresponds almost exactly with the molecular z axis, in agreement with the experimental data,[4c,4d] the V_{zz} components of the EFG can be divided into the so-called valence, covalence, and lattice contributions.[9a,14,15] The valence contribution is approximately proportional to the anisotropy of the Fe(3d) and Fe(4p) shell occupations. The covalence contribution is almost proportional to the Fe−ligand overlap population, while the ligand contribution arising from the cores and valence electrons of all ligand atoms is roughly proportional to the charge on the atom of the ligand directly coordinated to the iron and the Fe−ligand distance as Z/r^3. Taking all these factors into consideration, it appears possible to discuss the influence of each contribution on the EFG in complexes **1**−**8**. Unfortunately, however, as discussed in the literature,[27,28] the Mulliken population and charge distribution analysis are completely inappropriate for systems containing a large number of diffuse Gaussian-like functions. Thus, considering the fact that for bis-axially coordinated iron pcs and porphyrins, particularly for those with experimentally large ΔE_Q values, the valence contribution usually dominates over the covalent and ligand contributions,[9a] the anisotropy of the Fe(3d) and Fe(4p) shell occupations can be expected to be around 0.3−0.5 electrons for complexes **1**−**5** and **7**. However, a Mulliken population analysis gave an anisotropy of Fe(3d) shell occupation of no more than 0.23 electrons. The covalent contribution, which is based on the Mulliken population analysis, is also inappropriate because the overlap populations have negative (!) values for all the Fe−ligand bonds in all the cases tested and, of course, do not have any physical meaning. The most attractive alternative to the Mulliken population analysis is based on the use of Natural Bond Orbital (NBO) population and charge distribution analysis.[28] However, the NBO package, as implemented in the Gaussian-98 program family and GAMESS (USA) software, is unable to operate with such large and highly covalent systems as found in phthalocyanines. Since the Gaussian-98W program is based on Gaussian-type basis functions, the next questions to be addressed are the influence of various basis sets, particularly on the iron atom, and of the functionals on the calculated EFG components and thus the ΔE_Q values. From our comparative calculations of the EFG components for the complexes pcFe(mepip)$_2$ (**2**) and [pcFe(CN)$_2$]$^{2-}$ (**8**) using the Wachters−Hay all-electron basis set (611111111/51111/311) for the iron ion, with and without the inclusion of diffuse functions, and using the original Wachters' all-electron basis set for the iron ion,[16,17] with and without the inclusion of polarization functions, it can be concluded that the influence of diffuse and polarization functions is small, and that the ΔE_Q values computed with the Wachters−Hay all-electron basis set are in better agreement with the experimental data [Supporting Information (Table 6)]. The ΔE_Q values calculated with pure DFT functionals (LDA and LSDA), as well as those estimated from Gaussian-98W calculations of ρ(0), are presented in Table 2. Inspection of these results reveals that the estimated values of ρ(0) are in good agreement with the expected values, while both functionals are systematically overestimated with respect to the experimentally observed ΔE_Q values for complexes **1**−**7**. However, in both cases, a good correlation between calculated and experimental ΔE_Q values is observed, with correlation coefficients r^2 of 0.957 and 0.993 and r.m.s. errors of 0.18 and 0.09 mm s^{-1} for the LDA and LSDA EC functionals, respectively. One of the advantages of the hybrid DFT B3LYP EC functional is that it is not necessary to take Sternheimer corrections into consideration when ΔE_Q values are computed from the EFG tensor components. On the other hand, for pure DFT methods, Sternheimer corrections must be applied when ΔE_Q values are computed, at least for the LDA functional, as pointed out by the authors.[9a,14,15] Since it is impossible to separate valence, covalence, and lattice contributions to the EFG using the Gaussian-98W

[a] The isotropic shifts are obtained from the computed absolute shielding as: $\delta = -2912 - \sigma$, where the value of $\delta = -2912$ refers to the computed absolute shielding in $Fe(CO)_5$. − [b] The isotropic shifts are obtained from the computed absolute shielding as: $\delta = 31.9197 - \sigma$, where the value of $\delta = 31.9197$ refers to the computed absolute shielding of the protons in TMS at the B3LYP/6−31G(d) level.

and GAMESS (USA) programs, we were unable to accurately calculate ΔE_Q values for complexes **1**−**8** applying Sternheimer corrections, even at the limits of the simple Townes−Dailey approximation.[16,29]

Thus, it is concluded that DFT methods, particularly employing the B3LYP EC functional, are now able to reproduce and predict the Mössbauer spectral parameters of bis-axially coordinated iron(II) pcs with high accuracy, in contrast to semiempirical and conventional ab initio methods. The hybrid B3LYP EC functional can be recommended as the best approximation for the evaluation of total electron charge density and electric field gradient on a Mössbauer nucleus using the Gaussian-98W program, while the LDA and LSDA EC functionals are only useful with software implementing an alternative to Mulliken population analysis algorithms.[9a,14,15]

Conclusions

In this paper, we have discussed the relationship between the nature of the axial ligands in bis-axially coordinated iron(II) phthalocyanines and their electronic structures, structural, and Mössbauer spectral parameters. The first example of a crystal structure of a low-spin iron(II) pc bis-axially coordinated by aliphatic amines has been presented, and the reasons for the observed elongation of the Fe−N(ax) bond length have been discussed. The electronic structures of numerous $pcFeL_2$ and $pcFeL^1L^2$ complexes have been assessed on the basis of density functional theory calculations. The results constitute the first accurate calculations of Mössbauer quadrupole splittings and isomer shifts for bis-axially coordinated low-spin iron(II) phthalocyanine complexes by means of density functional theory methods. A good correlation between the experimental and theoretical values has been obtained using the hybrid B3LYP EC functional, while with the pure DFT LDA and LSDA functionals, it has been found that Sternheimer corrections need to be taken into consideration when quadrupole splittings are computed. Of particular interest is the reproduction of the Mössbauer spectral parameters of complexes with conformationally flexible axial ligands.

Experimental Section

Synthesis: Compounds **1**−**4** were synthesized according to standard methods.[4a−4c][5a−5c] All the complexes were characterized by their UV/Vis, ^{1}H NMR, and Mössbauer spectra, as well as by elemental analysis [Supporting Information (Table 1)]. In addition, an experimental geometry for $pcFe(mepip)_2$ (**2**) was determined by an X-ray crystallographic analysis.

X-ray Crystallography: A single crystal of $pcFe(mepip)_2$ (**2**) was obtained by slowly evaporating the solvents from a benzene/heptane (1:3, v/v) solution of the complex over a period of a week. Diffraction data were collected with a CAD-4 diffractometer using Mo-K_α radiation ($\lambda = 0.71073$ Å). The structure was solved by full-matrix least-squares techniques on F^2 for all data, with anisotropic thermal parameters for non-hydrogen atoms and isotropic parameters for hydrogen atoms. All calculations were performed using the SHELXTL-93 software.[30] General information concerning the crystal structural determination is given in Table 5. Crystallographic data (excluding structural factors) for **2** have been deposited at the Cambridge Crystallographic Data Centre (CCDC) as supplementary publication no. CCDC-145879. Copies of the data

Mössbauer Spectroscopy: Mössbauer spectra were recorded using a GRS-4M spectrometer in constant acceleration mode. The source was ^{57}Co in a chromium matrix with an initial activity of 50 mCi. Isomer shifts were referenced to sodium nitroprusside at 298 K (the conversion factor from sodium nitroprusside to iron foil is -0.257 mm s^{-1}).

Computational Aspects: Total electron charge density and electric field gradient calculations were carried out using Gaussian-98W software.[31] In order to negate convergence problems, the following procedures were used for the energy convergence and electric field gradient calculations: Step 1: All atoms were represented by a 3-21G* basis set at the Hartree−Fock level. Step 2: As Step 1, but iron was represented by a Wachters−Hay all-electron basis set (611111111/51111/311) using the scaling factors of Raghavachari and Trucks,[32] and the 6-31G* basis set was used for all atoms directly attached to or two bonds away from iron. Step 3: As Step 2, but using the respective exchange-correlation functional. The following exchange-correlation (EC) functionals were used for the DFT calculations: Becke's three-parameter exchange functional with the Lee, Parr, and Yang correlation functional (B3LYP),[33] the Local Density Approximation (LDA) functional,[34] and the Local Spin Density exchange functional with the Vosko, Wilk, and Nusair correlation functional (LSDA).[35] Step 4: As Step 3, but a 6-311++G(2d) basis set was used for all atoms directly attached to iron. Since Raghavachari and Trucks recommended both scaling and the inclusion of diffuse functions when using a Wachters−Hay basis set for the first transition row elements,[32] we compared electric field gradient calculations on the complexes pcFe(mepip)$_2$ (**2**) and [pcFe(CN)$_2$]$^{2-}$ (**8**) using a Wachters−Hay basis set for iron with and without diffuse functions. Moreover, since the Wachters−Hay basis set implemented in the Gaussian-98W program and the set originally reported by Wachters[36] are different, we also compared electric field gradient calculations on the complexes pcFe(mepip)$_2$ (**2**) and [pcFe(CN)$_2$]$^{2-}$ (**8**) using the original Wachters' all-electron basis set for iron (62111111/331211/3111), with and without the inclusion of polarization functions.[37] A more detailed discussion concerning the influence of different Wachters' basis sets at the iron atom on the electric field gradient tensor elements in the complexes pcFe(mepip)$_2$ (**2**) and [pcFe(CN)$_2$]$^{2-}$ (**8**) is given in the Results and Discussion section. The total electron charge densities on the iron atoms were estimated using Gaussian-98W software with the help of the atoms-in-molecules (AIM) algorithm.[21] Since the current codes of AIM included in the Gaussian-98W program can only operate up to five digits when total electron densities are computed (this leads to an error of 0.1−0.2 mm s^{-1} in the isomer shift calculations), the total electron charge densities on the iron atoms were calculated more precisely using GAMESS (USA) software[38] with the help of converged wavefunctions obtained from the previous DFT calculations [DFT is not currently included in GAMESS (USA)]. The components of the electric field gradient tensor (EFG), V_{ii}, were directly calculated using a Gaussian-98W program based on the following expression: $V_{ij} = \partial^2/\partial_{xi}\partial_{xj}[\Sigma Z_A e/(|r_A - r_{Fe}|) - \int e\rho(r)/(|r - r_{Fe}|)dr]$, where r_{Fe} is the position vector of the iron nucleus, ρ(r) is the first-order density matrix of electrons, and r_A and Z_A are the position vector of the nucleus of atom A and the nuclear charge, respectively. The measured ΔE_Q is related to the major component, V_{zz}, of the EFG tensor according to the following expression[33] where e is the electron charge, Q is the quadrupole moment of the $I^* = 3/2$ 14.4 keV excited state, and η is the asymmetry parameter [$\eta = |V_{xx} - V_{yy}|/|V_{zz}|$ ($V_{zz} > V_{yy} > V_{xx}$)].

$$\Delta E_Q = (1/2)eQV_{zz}(1 + \eta^2/3)^{1/2}$$

The magnitude of the nuclear quadrupole moment Q was chosen as 0.16 barn on the basis of the most recently determined value.[9b,39] This value is also close to that used by Trautwein's group (0.15 barn) for calculations of Mössbauer spectral parameters using an LDA EC functional.[9a,14,15] As recently shown[9b−9d] for DFT calculations with a B3LYP hybrid EC functional, Sternheimer corrections do not have to be taken into account when ΔE_Q is predicted on the basis of the DFT calculations. Experimentally determined geometries for pcFe(mepip)$_2$ (**2**), pcFe(mim)$_2$ (**4**), pcFe(mepy)$_2$ (**5**), pcFe(*cyclo*-C$_6$H$_{11}$NC)$_2$ (**6**), pcFe(CO)(dmf) (**7**), and [pcFe(CN)$_2$]$^{2-}$ (**8**) were used,[7] with the modification that C−H and N−H bond lengths were extended to typical values (1.05−1.09 Å); the most important structural parameters are given in Table 1. Since X-ray crystal data are not available for the complexes pcFe(14en)$_2$ (**1**) and pcFe(BuNH$_2$)$_2$ (**3**), the pc core was reproduced from the experimental geometry of pcFe(mepip)$_2$ (**2**), while in each case the axial ligands were placed at an Fe−N distance of 2.08 Å and their geometries were optimized at the semiempirical PM3 level[40] using the Polack−Ribiere algorithm[41] with help of the HyperChem 5.1Pro software.[42] Since the experimental geometries for pcFe(mepip)$_2$ (**2**) and pcFe(mepy)$_2$ (**5**) are quite similar, in spite of the pronounced difference between the axial ligands (mepip is a pure and strong σ-donor, while mepy is a moderate σ-donor and π-acceptor),[5b,12] the structural parameters of the pc core were considered to be representative of those of pcFe(14en)$_2$ (**1**) and pcFe(BuNH$_2$)$_2$ (**3**) as well. The choice of structural parameters for the axial ligands in pcFe(14en)$_2$ (**1**) and pcFe(BuNH$_2$)$_2$ (**3**) was not so straightforward. However, our electronic structural calculations on pcFe(14en)$_2$ (**1**) and pcFe(BuNH$_2$)$_2$ (**3**) showed the geometry of the axial ligands as obtained by optimization at the semiempirical PM3 level to be adequate for the prediction of Mössbauer and ^{1}H NMR spectral parameters. The molecular z axis was defined by the iron atom and the two atoms of the axial ligands directly coordinated to it. The rotation barriers of the axial ligands were calculated using the HyperChem 5.1Pro software at the molecular mechanics (MM+ force field) and semiempirical (PM3) levels. In all such model calculations, the phthalocyanine core and one axial ligand were kept fixed, while the other axial ligand was rotated in steps of 10° about the molecular z axis. The height of rotation barrier was then derived from the variation of the total energy as a function of the rotation angle. The NMR shielding tensor elements were calculated using the gauge-including atomic orbital (GIAO) method[43] with the help of the Gaussian-98W program. The aforementioned basis set with the hybrid B3LYP EC functional (Step 4) was used for the calculations of the NMR isotropic shifts.

Supporting Information Available: Spectroscopic and analytical data for the pcs used in this study. Atomic coordinates, equivalent isotropic displacement parameters, bond lengths and angles for **2**. Calculated orbital energies for complexes **1**−**8** using the LSDA and LDA EC functionals. Calculated, using the B3LYP hybrid EC functional and different basis sets for iron, Mössbauer quadrupole splittings in complexes **2** and **8** (see the note on the first page of this article).

ε-Caprolactam as a Donor Ligand for Lanthanide Halides: Formation of Cationic $[Ln(C_6H_{11}NO)_6Cl]^{2+}$ and $[Ln(C_6H_{11}NO)_4Cl_2]^{+}$ Complexes

William J. Evans,*[a] Cy H. Fujimoto,[a] Michael A. Greci,[a] and Joseph W. Ziller[a]

Keywords: Lanthanides / Cations / ε-Caprolactam / Halides / O ligands

Examination of the coordination chemistry of ε-caprolactam with lanthanide trichlorides reveals that cationic ε-caprolactam-solvated complexes of two types can be obtained from acetonitrile depending on the size of the metal. The larger lanthanides Ce, Nd, Pr, and Sm form capped octahedral dications, $[Ln(C_6H_{11}NO)_6Cl]^{+2}$, with the chloride ligand in the capping position. The smaller metals Eu, Gd, and Ho form *trans*-octahedral monocations $[Ln(C_6H_{11}NO)_4Cl_2]^{+}$. Chloride ions are the counteranions in both cases.

Introduction

To define the first step in lanthanide-based ring opening polymerization of ε-caprolactone,[1] the coordination chemistry of this substrate with lanthanide trichlorides was previously studied.[2] These investigations showed that this monomer enhances the solubility of the lanthanide trichlorides in THF and generates a wide range of structures. $[YbCl_3(C_6H_{10}O_2)(THF)_2]$ and $[YCl_3(C_6H_{10}O_2)_3]$ were observed as well as ion pairs such as $[TbCl_4(THF)_2]^-[TbCl_2(THF)_5]^+$ and $[Cl_3Ln(\mu\text{-}Cl)_3LnCl_3]^{3-}$-$[Ln(C_6H_{10}O_2)_8]^{3+}$ (Ln = Sm and Nd).[2] This is in contrast to the usual coordination chemistry of yttrium and the lanthanide trichlorides in the presence of oxygen donors, which typically involves formation of seven coordinate pentagonal bipyramidal species of the general formula $LnCl_3L_4$ (L = oxygen donor ligand).[3]

Since metal trichlorides are important starting materials in the chemistry of yttrium and the lanthanides,[4] and since the presence of bridging or nonbridging ligands can have a significant effect on the chemistry of these metals,[5] it was of interest to determine if other neutral ligands similar to ε-caprolactone could likewise modify the chemistry of the lanthanide halides. Accordingly, we have studied the coordination chemistry of the lanthanide chlorides with a nylon-6 precursor, ε-caprolactam, since it is structurally similar to ε-caprolactone (Figure 1).

Since ε-caprolactam is more basic than ε-caprolactone, it has the potential to provide enhanced effects. To the best of our knowledge there is only one structural report of a lanthanide ε-caprolactam complex in the literature, $[Pr(C_6H_{11}NO)_8]^{3+}[OSO_2CF_3^-]_3$, a complex formed from hydrated praseodymium triflate and ε-caprolactam in triethylorthoformate.[6] We report here our synthetic and structural studies on the $LnCl_3$/ε-caprolactam system and the series of cationic complexes which resulted.

Results

ε-Caprolactam differs from ε-caprolactone[2] in that addition of this compound to slurries of the lanthanide trichlorides in THF does not bring the solids into solution. In fact, addition of ε-caprolactam to slurries of the lanthanide trichlorides in THF led to little visible change, except for the metals, neodymium, gadolinium, and holmium which had slight color changes. However, removal of solvent from these $LnCl_3$/ε-caprolactam mixtures, followed by washing with toluene to remove excess ε-caprolactam, gave solids whose IR spectra indicated the presence of coordinated ε-caprolactam. Crystallization from hot THF of the $PrCl_3$/ε-caprolactam product generated the dicationic ε-caprolactam complex $[Pr(C_6H_{11}NO)_6Cl]^{2+}$ as its chloride salt $[Pr(C_6H_{11}NO)_6Cl]Cl_2$ (Figure 2).

Single crystals of $[Ce(C_6H_{11}NO)_6Cl]Cl_2$ and $[Nd(C_6H_{11}NO)_6Cl]Cl_2$ were also obtained in this way, but the approach was not general for the remainder of the lanthanides.

Since THF was not a viable solvent for exploring the coordination chemistry of ε-caprolactam with the entire series of lanthanide trichlorides, an alternative solvent was examined. Acetonitrile proved to be suitable, even though it could have led to acetonitrile-solvated complexes. As with THF, addition of ε-caprolactam to slurries of lanthanide trichlorides in acetonitrile led to only small visible changes except for the Nd, Gd, and Ho systems. Although no obvious changes occurred, ε-caprolactam did become incorporated into the metal-containing solids isolated from these

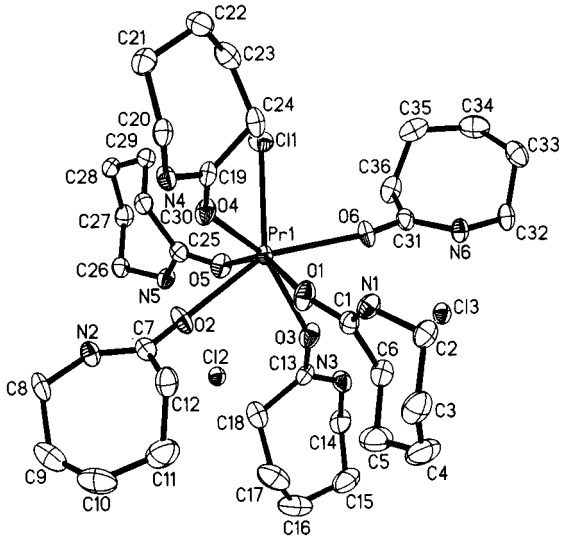

Figure 2. Thermal ellipsoid plot of $[Pr(C_6H_{11}NO)_6Cl)]Cl_2$ **(2)** with the probability ellipsoids drawn at the 50% level; complexes **1**, **3**, and **4** are isomorphous with **2**

systems. Recrystallization of these materials from hot acetonitrile gave single crystals suitable for X-ray diffraction for seven lanthanides ranging in size from Ce to Ho.

Two types of complexes crystallized, neither of which contained acetonitrile. Complexes of the formula $[Ln(C_6H_{11}NO)_6Cl]Cl_2$ (Figure 2) were found for the larger metals Ce **(1)**, Pr **(2)**, Nd **(3)**, and Sm **(4)**. Complexes **1, 2,** and **3** were identical to the ε-caprolactam complexes obtained from THF. Complexes of formula $[Ln(C_6H_{11}NO)_4Cl_2]Cl$ (Figure 3) were found for Eu **(5)**, Gd **(6)**, and Ho **(7)**.

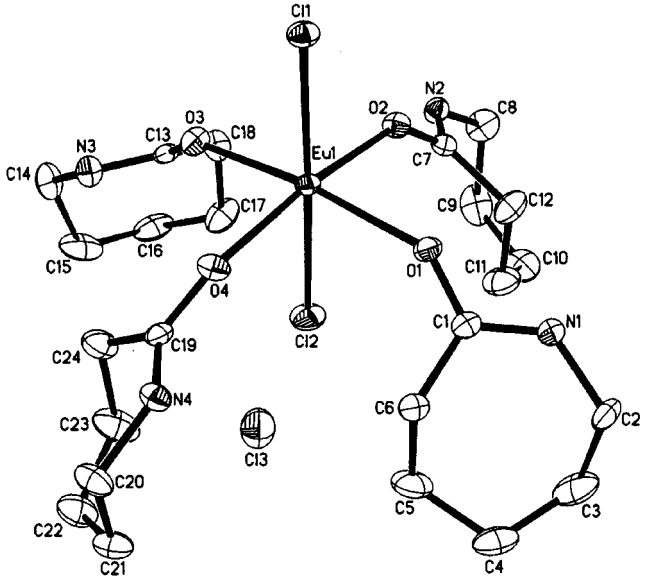

Figure 3. Thermal ellipsoid plot of $[Eu(C_6H_{11}NO)_4Cl_2)]Cl$ **(5)** with the probability ellipsoids drawn at the 50% level; complexes **6** and **7** are structurally similar to **5**

The complexes were characterized by infrared spectroscopy and elemental analysis and were definitively identified by X-ray crystallography. The IR spectra of **5−7** were similar to those of **1−4,** but the two types of spectra could be distinguished from each other in the fingerprint region. Single crystals were not obtained in the lanthanum case, **8**, but the white solid isolated from the analogous synthesis had an infrared spectrum identical to those of **1−4**.

Complexes **1−4** crystallize in the same space group and their unit cell parameters decrease from Ce to Sm, as is consistent with the decreasing size of the metals.[7] Each lanthanide in **1−4** is seven coordinate with a capped octahedral geometry arising from coordination of the carbonyl oxygen atoms of six ε-caprolactam molecules and one chloride, which is in the capping position. The two remaining chloride ions in the structure are separated from the metal at distances over 6 Å. The bond lengths in **1−3** and **5** vary as expected based on the changes in metal size (Table 1).

Only the praseodymium complex **2** will be described in detail since it can be directly compared to the only other lanthanide ε-caprolactam complex in the literature, $[Pr(C_6H_{11}NO)_8]^{3+}[OSO_2CF_3^-]_3$ **(9)**.[6] The degree of distortion in the capped octahedral geometry of **2** can be evaluated from the O−Pr−O angles between the *trans* oxygen atoms of the distorted octahedron, which range from 150.4−153.1(10)° and the adjacent O−Pr−O angles which range from 72.2(2)° to 117.8(2)° with an average angle of 87.6(2)°. The Pr−Cl distance [2.757(2) Å] can be compared to that in the six coordinate analog $PrCl_3(HMPA)_3$ [2.72(1) Å].[8] The average Pr−O bond length in **2** [2.418(3) Å] is comparable to that in **9** [2.449(12) Å] which has a higher coordination number and a higher charge on the cation. Both of these Pr−O(ε-caprolactam) distances are comparable to the Pr−O(HMPA) distance in $PrCl_3(HMPA)_3$ [2.353(2) Å],[8] a complex that also contains a strongly coordinating ligand.

The late metal complexes of formula $[Ln(C_6H_{11}NO)_4Cl_2]Cl$ [Ln = Eu **(5)**; Gd **(6)**; Ho **(7)**] have a six coordinate octahedral geometry with the chloride ligands in the *trans* positions. Complexes **6** and **7** are structurally similar to **5**, but they are not isomorphous. Unfortunately, only connectivity could be determined for both **6** and **7**, so **5** will be described in detail. The structure of **5** is only slightly distorted from a regular octahedral geometry with O−Eu−O *trans* angles of 172.42(7)−177.63(2)° and O−Eu−O *cis* angles of 85.17(5)−94.99(5)°. The Eu−Cl bond length in **5** [2.6505(8) Å] is comparable to the analogous bond length in seven coordinate $EuCl_3(THF)_4$,[3c] [2.628(3) Å]. The Eu−O bond in **5** [2.315(2) Å], is significantly shorter than the Eu−O(THF) distance in $EuCl_3(THF)_4$ [2.435(7) Å],[3c] even when the difference in coordination number is taken into account.[7]

Discussion

ε-Caprolactam differs considerably in its coordination chemistry with the lanthanide trichlorides compared to ε-caprolactone. Although its size and coordination mode, through the carbonyl group, are similar to those of ε-caprolactone, ε-caprolactam does not enhance the solubility of

Table 1. Bond lengths in $[Ln(C_6H_{11}NO)_6Cl]^{2+}$ and $[Ln(C_6H_{11}NO)_4Cl_2]^+$

Compound	Ln	Ln−O	$Ln-Cl_{coordinated}$	(Ln−O) − (Ln radius)[7]	(Ln−Cl) − (Ln radius)[7]
1	Ce	2.437(3)	2.7798(9)	1.37	1.71
2	Pr	2.418(3)	2.757(2)	1.36	1.70
3	Nd	2.407(3)	2.7412(12)	1.36	1.70
5	Eu	2.315(18)	2.6505(8)	1.37	1.71

the metal trichlorides and does not generate a variety of different structures upon coordination. Instead, the greater basicity of ε-caprolactam makes it such a powerful ligand that it displaces one or two chloride ligands from the metal and forms cationic complexes. The formation of these cations explains why ε-caprolactam does not increase solubility in solvents of moderate polarity.

The displacement of chloride ligands by ε-caprolactam leads to two types of crystalline cations, dicationic $[Ln(C_6H_{11}NO)_6Cl]^{2+}$ complexes for the larger metals and monocationic $[Ln(C_6H_{11}NO)_4Cl_2]^+$ compounds for the smaller metals. The existence of just two classes of compounds is typical of many types of lanthanide complexes in which the structural type with a high coordination number is found early in the series and a smaller coordinate variation forms with the later metals.[9]

Conclusion

Although ε-caprolactam is not useful in solubilizing lanthanide trichlorides, it is a powerful coordinating ligand which can displace anionic ligands and stabilize cationic complexes of these large metals.

Experimental Section

All of the compounds described below were handled under nitrogen with rigorous exclusion of air and water using standard Schlenk, vacuum line, and glovebox techniques. Solvents were prepared and physical measurements obtained as previously described.[10] All solvents were dried by distillation from sodium/benzophenone ketyl, except acetonitrile which was purchased anhydrous from Aldrich. ε-Caprolactam was purchased from Aldrich and sublimed before use. The lanthanide trichlorides were dried as previously described.[11] IR spectra were obtained as thin films using an ASI ReactIR 1000 spectrometer. Complete elemental analyses were performed by Desert Analytics, Tucson, Arizona. Complexometric analyses were obtained as previously described.[12]

General Procedures for the Synthesis of $[Ln(C_6H_{11}NO)_6Cl]Cl_2$ and $[Ln(C_6H_{11}NO)_4Cl_2]Cl$. Preparation of $[Ce(C_6H_{11}NO)_6Cl]Cl_2$ (1): In a glovebox, ε-caprolactam (0.36 g, 3.2 mmol) was added to a 15 mL slurry of THF and $CeCl_3$ (0.10 g, 0.41 mmol). After stirring overnight, volatiles were removed by rotary evaporation and the solids were washed with hot toluene (3 × 5.0 mL) to remove any excess ε-caprolactam. The resultant solid was dried under vacuum and was isolated as a white powder (0.20 g, 53%). X-ray quality crystals were grown from a concentrated THF solution. − $Ce(C_6H_{11}NO)_6Cl_3$ (925.43): calcd. C 46.72, H 7.19, N 9.08, Cl 11.49; found C 46.88, H 7.19, N 9.16, Cl 11.28. − IR: $\tilde{\nu}$ = 3177 vs, 2922 s, 2853 s, 1613 vs, 1490 s, 1440 s, 1351 s, 1293 s, 1258 s, 1200 s, 1119 s, 1079 s, 980 s, 822 s, 791 s, 690 s cm^{-1}. Complex **1** was also obtained using an analogous procedure with acetonitrile in place of THF. The composition of the product obtained from acetonitrile was determined by comparing IR spectra and unit cell parameters of single crystals.

$[Ln(C_6H_{11}NO)_6Cl]Cl_2$ [Ln = Pr (2); Nd (3); Sm (4)] and $[Ln(C_6H_{11}NO)_4Cl_2]Cl$ [Ln = Eu (5); Gd (6); Ho (7)]: Compounds **2**−**7** were prepared as described for **1**. Complexes **1**, **2** and **3** gave single crystals in THF and acetonitrile. Complexes **4**−**7** gave single crystals only from acetonitrile. Solvents, reagents, yields and spectroscopic data for individual samples are given below.

$[Pr(C_6H_{11}NO)_6Cl]Cl_2$ (2): In THF, $PrCl_3$ (0.09 g, 0.4 mmol) and ε-caprolactam (0.30 g, 2.7 mmol) were combined and a green solid (0.26, 77%) was isolated. − $Pr(C_6H_{11}NO)_6Cl_3$ (926.23): calcd. Pr 15.21, found Pr 15.0. − IR: $\tilde{\nu}$ = 3177 vs, 2922 s, 2853 s, 1613 vs, 1490 s, 1440 s, 1417 w, 1366 s, 1293 w, 1258 w, 1200 s, 1119 s, 1092 w, 1073 w, 980 s, 868 w, 826 s, 775 s, 690 s cm^{-1}.

$[Nd(C_6H_{11}NO)_6Cl]Cl_2$ (3): ε-Caprolactam (0.60 g, 5.3 mmol) was added to a pale blue-green slurry of $NdCl_3$ (0.17 g, 0.67 mmol) in THF and a light blue solid was isolated (0.42, 67%). − $Nd(C_6H_{11}NO)_6Cl_3$ (929.56): calcd. Nd 15.51, found Nd 15.2. − IR: $\tilde{\nu}$ = 3181 vs, 2922 s, 2853 s, 1610 vs, 1490 s, 1440 s, 1366 s, 1289 s, 1258 s, 1200 s, 1119 s, 1092 w, 1073 w, 980 w, 891 w, 868 w, 826 s, 772 s, 690 s cm^{-1}.

$[Sm(C_6H_{11}NO)_6Cl]Cl_2$ (4): $SmCl_3$ (0.1 g, 0.4 mmol) and ε-caprolactam (0.31 g, 2.7 mmol) were combined in acetonitrile. A white solid (0.29, 80%) was isolated. − $Sm(C_6H_{11}NO)_6Cl_3$ (935.68): calcd. Sm 16.07, found Sm 15.8. − IR: $\tilde{\nu}$ = 3176 vs, 2912 s, 2850 s, 1610 vs, 1487 s, 1438 s, 1417 w, 1366 s, 1293 w, 1258 w, 1200 s, 1119 s, 1092 w, 1073 w, 980 s, 868 w, 826 s, 775 s, 690 s cm^{-1}.

$[Eu(C_6H_{11}NO)_4Cl]Cl_2$ (5): ε-Caprolactam (0.50 g, 4.4 mmol) was added to a slurry of $EuCl_3$ (0.23 g, 0.89 mmol) in acetonitrile . The slurry was stirred overnight and was worked up as described above (0.35 g, 55%). − $Eu(C_6H_{11}NO)_4Cl_3$ (710.96): calcd. Eu 21.37, found Eu 21.5. − IR: $\tilde{\nu}$ = 3177 vs, 2922 s, 2853 s, 1617 vs, 1490 s, 1436 vs, 1200 s, 1119 s, 1089 s, 980 s, 961 s, 822 s, 791 s, 691 s cm^{-1}.

$[Gd(C_6H_{11}NO)_4Cl]Cl_2$ (6): ε-Caprolactam (0.51 g, 4.5 mmol) was added to a white slurry of $GdCl_3$ (0.22 g, 0.83 mmol) in acetonitrile. Immediately after mixing the reagents, a clear solution formed. After approximately 30 min., the mixture deposited a white precipitate. The resultant white solid was isolated as described above and dried under vacuum (0.51 g, 85%). − $Gd(C_6H_{11}NO)_4Cl_3$ (716.25): calcd. Gd 21.96; found Gd 21.4. − IR: $\tilde{\nu}$ = 3165 vs, 2930 s, 2860 s, 1606 vs, 1494 s, 1370 s, 1324 s, 1289 s, 1204 s, 1166 w, 1123 s, 1092 s, 984 s, 961 s, 892 w, 869 s, 826 s, 799 s, 691 s cm^{-1}.

$[Ho(C_6H_{11}NO)_4Cl_2]Cl$ (7): ε-Caprolactam (1.0 g, 8.9 mmol) was added to a pink slurry of $HoCl_3$ (0.44 g, 1.6 mmol) in acetonitrile. A white solid resulted (1.0 g, 85%). − $Ho(C_6H_{11}NO)_4Cl_3$ (723.93):

calcd. Ho 22.78; found Ho 22.0. − IR: $\tilde{\nu}$ = 3165 vs, 2926 s, 2860 s, 1606 vs, 1494 s, 1432 s, 1355 s, 1289 s, 1262 w, 1166 w, 1119 s, 1092 w, 1027 w, 984 w, 961 w, 891 w, 868 w, 822 s, 787 s, 687 s cm^{-1}.

$[La(C_6H_{11}NO)_6Cl]Cl_2$ (8): ε-Caprolactam (1.2 g, 11 mmol) was added to a white slurry of $LaCl_3$ (0.38 g, 1.6 mmol) in acetonitrile and the mixture was stirred overnight. The resultant solid was isolated following the procedures described above (0.53 g, 37%). − $La(C_6H_{11}NO)_6Cl_3$ (924.22): calcd. La 15.03; found La 15.4. − IR: $\tilde{\nu}$ = 3177 vs, 2922 s, 2853 s, 1602 vs, 1490 s, 1440 s, 1351 s, 1293 s, 1258 s, 1200 s, 1119 s, 1092 w, 1073 w, 980 s, 826 s, 776 s, 691 s cm^{-1}.

X-ray Data Collection, Structure Determination, and Refinement for $[Ce(C_6H_{11}NO)_6Cl]Cl_2$ (1): A colorless crystal of approximate dimensions 0.15 × 0.14 × 0.13 mm obtained from a solution of acetonitrile was mounted on a glass fiber and transferred to a Bruker CCD platform diffractometer. The SMART[13] program package was used to determine the unit-cell parameters and for data collection (40 sec/frame scan time for a hemisphere of diffraction data). The raw frame data was processed using SAINT[14] and SADABS[15] to yield the reflection data file. Details are in Table 2.

Subsequent calculations were carried out using the SHELXTL[16] program. The space group was the centrosymmetric monoclinic space group *Cc*. The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. The analytical scattering factors[17] for neutral atoms were used throughout the analysis. Hydrogen atoms were included using a riding model. At convergence, *wR2* = 0.0630 and GOF = 1.147 for 469 variables refined against 7697 unique data. As a comparison for refinement on *F*, *R1* = 0.0291 for those 7416 data with $I > 2\sigma(I)$. The absolute structure was assigned by refinement of the Flack parameter.[18]

$[Pr(C_6H_{11}NO)_6Cl]Cl_2$ (2): All data were collected on a Siemens P4 diffractometer from a crystal of dimensions 0.43 × 0.43 × 0.40 mm. The determination of Laue symmetry, crystal class, unit cell parameters and the crystal's orientation matrix were carried out according to standard procedures. Intensity data were collected at 163 K using a 2θ/ω scan technique with Mo-K_α radiation. The raw data were processed with a local version of CARESS[19] which employs a modified version of the Lehman−Larsen algorithm to obtain intensities and standard deviations from the measured 96-step peak profiles. Subsequent calculations were carried out using the SHELXTL[16] program. All data were corrected for absorption and for Lorentz and polarization effects and were placed on an approximately absolute scale. The space group was the noncentrosymmetric *Cc*. At convergence, *wR2* = 0.0517 and GOF = 1.148 for 470 variables refined against all 5393 unique data. As a comparison for refinement of *F*, *R1* = 0.0218 for those 5152 data with $I > 2\sigma(I)$.

$[Nd(C_6H_{11}NO)_6Cl]Cl_2$ (3): From a solution of THF, a pale violet crystal of approximate dimensions 0.14 × 0.26 × 0.37 mm was mounted on a glass fiber and transferred to the Siemens P4 diffractometer. A total of 3995 intensity data within a limiting Bragg angle of 28.00° were measured. Structure solution and refinement were based upon all 3995 unique reflections. Solution of the structure was accomplished by a combination of direct and heavy-atom methods. Final full-matrix least-squares refinement of 469 structure parameters included anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were included in idealized positions (C−H = 0.96 Å) and refined by use of the riding model. Computer programs utilized included CARESS[19] for data processing and SHELXTL,[16] Version 5.02, for all other computations.

$[Eu(C_6H_{11}NO)_4Cl_2]Cl$ (5): A colorless crystal of approximate dimensions 0.07 × 0.25 × 0.31 mm was mounted on a glass fiber and handled as described above for **1**. The space group was the centrosymmetric monoclinic $P2_1/n$. At convergence, *wR2* = 0.0700 and GOF = 1.006 for 325 variables refined against 7304 unique data. As a comparison for refinement on F, *R1* = 0.0309 for those 5532 data with $I > 2\sigma(I)$.

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-147969 (**3**), -147970 (**1**), -147971 (**2**), -147972 (**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Assembly of Zinc Ions by the New ON_2S_2 Ligand BMIBIP

Claas Sudbrake[a] and Heinrich Vahrenkamp*[a]

Dedicated to Professor Dieter Sellmann on the occasion of his 60th birthday

Keywords: N ligands / S ligands / O ligands / Zinc / Ligand design / Enzyme models

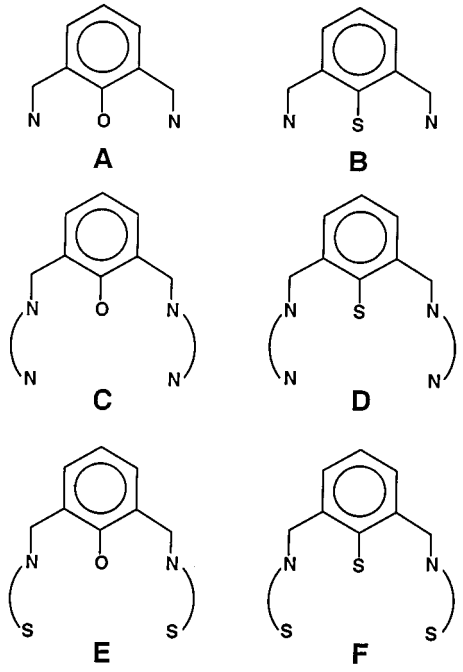
The new ON_2S_2 ligand bis(iminomethyl)-2-6-bis(mercaptoisobutyl)-4-methylphenol (H_3BMIBIP) has been synthesized from 2,6-diformyl-4-methylphenol and 2-mercaptoisobutylamine. Its reaction with diethylzinc in the presence of alcohols yields complexes of composition [(BMIBIP)Zn_2(OR)] (R = CH_3, C_2H_5 and $CH_2C_6H_4CF_3$). A structure determination of the trifluoromethylbenzylate compound has shown it to be a tetranuclear complex consisting of two (BMIBIP)Zn_2 units linked by triply bridging alkoxide ligands to form a double norcubane with a $Zn_4O_4S_2$ framework.

Introduction

The phenomenon of cooperativity in conventional catalysis and the fact that many metalloenzymes have binuclear reaction centers[1] have spurred the investigations of binuclear coordination compounds in recent years. Out of this has emerged a new class of polydentate ligands, the so-called binucleating ligands.[2] A simple construction principle for these consists in the use of a central bridging unit (phenolate, thiophenolate, bipyridine, pyrazole, etc.) to which two polydentate side groups are attached. The functionalization of the binuclear reaction centers that can be achieved with such ligands has been impressively demonstrated recently by modelling iron[3] and copper[4] containing enzymes.

The most common type of binucleating ligand is derived from the basic framework **A** which itself is a variation of the classical salicylic aldimine type. Its thiophenolate analogue **B** is much less developed in coordination chemistry. This is repeated when the hapticity of the ligands is increased: while the Cambridge Crystallographic Database yields more than 130 entries for complexes derived from type **C**, there are just 9 for type **D**, including two zinc complexes.[5] Finally the sulfur-rich type **E** is represented by only four copper complexes containing the sulfur as a thioether donor,[6] while N_2S_3 ligands of type **F**, or complexes thereof, seem to be unknown so far.

As was shown by the pioneering work of Sellmann and co-workers,[7] sulfur-rich polydentate ligands have a high versatility for bioinorganic and catalytic model complex chemistry. We have tried to apply this in the field of zinc chemistry by the design and use of N_2S,[8,9] NS_2,[10] and N_3S_2 [11] ligands which contain sulfur as thiolate. Like others, we soon found that it is difficult to control oligothiolates because the bridging tendency of the thiolate sulfur causes a rich, but unpredictable, chemistry of oligonuclear complexes. However, we were also able to show that the application of multiply chelating ligands reduces the aggregation tendency and allows the formation of mononuclear zinc-bis(thiolate) complexes.[11]



Along these lines we started working on binucleating ligands of type **E**. This paper describes the new ligand H_3BMIBIP and some zinc complexes thereof.

Results and Discussion

Ligand H_3BMIBIP

The ligand synthesis was easy, as both its components 2,6-diformyl-4-methylphenol (**1**) and 2-mercaptoisobutylamine (**2**) are commercially available. Compound **2** was chosen in order to introduce a moderate amount of steric hindrance in the vicinity of sulfur in order to reduce the bridging tendency of the thiolate functions. Schiff base condensation of the two components was straightforward and yielded H_3BMIBIP in moderate yields. The ligand exists as a pale yellow crystalline solid which is easily identified by its simple ^{1}H NMR spectrum (see Experimental Section).

2

Zinc Complexes

In its deprotonated state the ligand BMIBIP is trianionic. Its combination with two divalent metal ions therefore calls for the binding of one additional monoanionic ligand. Ideally, this ligand should have the tendency for bridging, thereby completing the square configuration of both metal ions. In simple cases this might be a halide or thiolate ligand, whereas for bioinorganic model studies it might be, for example, an organophosphate. In the case of zinc binding one would envisage the attachment of additional monodentate ligands to complete a square pyramidal or octahedral coordination.

We tried to verify this for zinc complexes by treating the ligand with base and subsequently with zinc salts. The resulting, probably oligomeric or polymeric, complexes could not be obtained in a pure state. However, using diethylzinc both as the base and as the source of zinc yielded crystalline products in good yields. When alcohols were present, either as a solvent or as a co-reagent, these products had the composition L·Zn(OR). Thus, reaction with methanol, ethanol, or 4-trifluoromethylbenzyl alcohol gave the complexes **3a**, **3b**, and **3c**, respectively. Complexes **3** are soluble in polar aprotic organic solvents and crystallize as yellow solvates from chloroform or dichloromethane. Their ^{1}H NMR spectroscopic data (see Experimental Section) are in accordance with the composition [(BMIBIP)Zn_2(OR)] (**3a**: R = Me, **3b**: R = Et, **3c**: R = 4-$CF_3C_6H_4CH_2$).

Structure of 3c

Triclinic crystals of **3c** were obtained from chloroform. They contain four formula units and four solvent molecules per unit cell, the latter disordered over six positions. The four formula units of **3c** make up two crystallographically independent tetranuclear molecular units. These are quite similar and can both be represented by the simplified drawing of Figure 1. Table 1 lists the relevant bond lengths in the tetranuclear dimers.

Table 1. Zinc-ligand bond lengths (Å) in **3c**

	Molecule 1	Molecule 2
Zn1−O1	2.076(4)	2.088(4)
Zn1−N1	2.001(5)	1.999(5)

Zn2−O1	2.160(4)	2.156(4)
Zn2−N2	2.079(5)	2.084(5)
Zn2−S2	2.295(2)	2.291(2)
Zn2−O2	2.151(4)	2.172(4)
Zn2−S1′[a]	2.377(2)	2.383(2)

[a] Bonds linking the two dinuclear units.

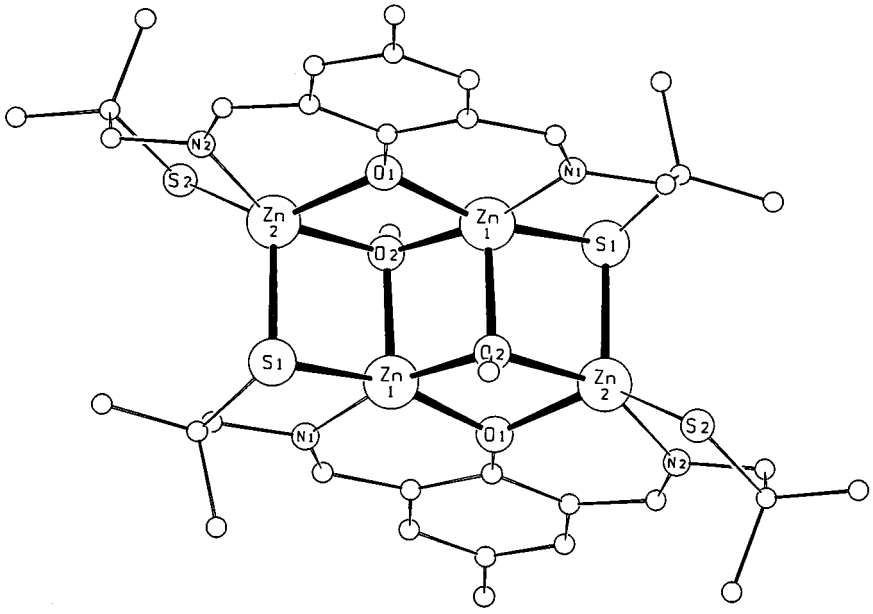

Figure 1. Molecular structure of **3c** (*p*-trifluorobenzylate units at O2 omitted for clarity)

The molecular constitution found for **3c** represents a new type of tetranuclear aggregate which is assembled from two pentadentate ligands. In each of the two dinuclear units, the BMIBIP ligand exerts its expected ligation pattern by giving both zinc ions a square environment. The dimerization of the two dinuclear units is brought about by placing them face to face across a center of symmetry and linking them through the unshared electron pairs of O2 and S1. Thereby the linkage is represented by four rungs of a ladder, and the resulting $Zn_4O_4S_2$ core has the shape of two open cubes sharing a common face.

The coordination of all four zinc ions is square-pyramidal. Both Zn1 and Zn2 have a basal ZnO_2NS coordination, but the apical donor is oxygen for Zn1 and sulfur for Zn2. Accordingly, the BMIBIP ligand uses one of its thiolate functions as a terminal and the other as a bridging ligand. Thus, although the whole tetranuclear complex has inversion symmetry it contains no other symmetry elements.

The observed bond lengths (Table 1) are in their normal ranges (cf. the chemistry of zinc alkoxides or zinc thiolates). The Zn−N bonds are the shortest, corresponding to the fact that N is only terminal. The Zn−S bonds underline this by the clear distinction of the Zn−S2 and Zn−S1 distances. Among the Zn−O bonds it is noticeable that those from Zn1 are significantly shorter than those from Zn2; this may reflect the presence of the very good donor S2 as a terminal ligand on Zn2.

Conclusions

This work has shown that H_3BMIBIP is a good candidate for the assembly of metal ions. It is easy to synthesize, it provides a biorelevant ON_2S_2 donor set able to surround two metal ions in a square-planar fashion, and it can position the two metal ions such that both can coordinate to one and the same additional ligand, i.e. a substrate for a catalytic process. When zinc is present as the divalent metal ion, its tendency to be five-coordinate in the given donor set can easily be met by dimerization of the LZn_2X complexes. It should be worthwhile to find out how other divalent metals, for example with preference for square-planar or octahedral coordination, make use of the donor capacity of BMIBIP.

Experimental Section

General: For general working and measuring procedures, see ref.[12] All reactions were performed under an inert atmosphere. Starting materials were obtained commercially.

H_3BMIBIP: A solution of 2,6-diformyl-4-methylphenol (1.01 g, 6.18 mmol) in methanol (25 mL) was added to a solution of 2-mercaptoisobutylamine hydrochloride (1.75 g, 12.35 mmol) also in methanol (25 mL). Upon stirring and addition of anhydrous sodium acetate (1.02 g, 12.35 mmol) a cloudy precipitate started forming. After refluxing for 30 min. and cooling to room temp. the solvent was removed in vacuo. The residue was redissolved in 20 mL of dichloromethane, filtered and evaporated to dryness again. Crystallization of the residue from 10 mL of methanol at 4 °C yielded H_3BMIBIP (0.84 g, 40%) as a yellow powder, m.p. 99 °C. − $C_{17}H_{26}N_2OS_2$ (338.5): calcd. C 60.31, H 7.74, N 8.27; found C 60.27, H 7.67, N 8.13. − ^{1}H NMR (CD_3COOD): δ = 1.55 (s, 12 H, CH_3), 2.19 (s, 3 H, CH_3), 3.43 (s, 4 H, CH_2), 6.22 (d, J = 6.8 Hz, 2 H, CH=N), 7.28 (d, J = 6.4 Hz, 2 H, Ph).

3a: A 1 M solution of diethylzinc in *n*-hexane (5.00 mL, 5.00 mmol) was slowly dropped with stirring into a solution of H_3BMIBIP (0.84 g, 2.49 mmol) in a mixture of absolute methanol (10 mL) and absolute dichloromethane (30 mL). After stirring for 1 h the volume was reduced in vacuo to 20 mL upon which the product precipitated. After filtration, washing with a small amount of diethyl ether and drying in vacuo **3a** (0.68 g, 51%) was obtained as a pale yellow microcrystalline solid. M.p. 165 °C. − $C_{18}H_{26}N_2O_2S_2Zn_2{\cdot}0.5CH_2Cl_2$ (457.3 + 42.5): calcd. C 41.16, H 5.04, N 5.19, Zn 24.23; found C 41.33, H 4.93, N 5.52, Zn 24.25. − ^{1}H NMR ($CDCl_3$): δ = 1.12 (s, 12 H, CH_3), 1.76 (s, 3 H, CH_3), 2.20 (s, 3 H, CH_3), 3.41 (s, 4 H, CH_2), 5.32 (s, 1 H, CH_2Cl_2), 7.09 (s, 2 H, CH=N), 8.15 (s, 2 H, Ph).

3b: A 1 M solution of diethylzinc in *n*-hexane (2.66 mL, 2.66 mmol) was slowly dropped with stirring into a solution of H_3BMIBIP (0.45 g, 1.33 mmol) in a mixture of absolute ethanol (2 mL) and absolute chloroform (15 mL). After stirring for 30 min. the solvent was removed in vacuo. The residue was redissolved in a few milliliters of chloroform and layered with diethyl ether. After 4 days at 4 °C the resulting precipitate was filtered off, washed with a few milliliters of diethyl ether and dried in vacuo to give **3b** (0.39 g, 47%) as a pale yellow powder. M.p. 195 °C. − $C_{19}H_{28}N_2O_2S_2Zn_2{\cdot}CHCl_3$ (511.4 + 119.4): calcd. C 38.09, H 4.63, N 4.44, Zn 20.73; found C 38.09, H 4.70, N 4.70, Zn 21.25. − ^{1}H NMR ([D_6]DMSO): δ = 1.07 (t, J = 7.0 Hz, 3 H, CH_3), 1.45 (s, 12 H, CH_3), 2.13 (s, 3 H, CH_3), 3.30 (s, 4 H, CH_2), 3.58 (q, J = 7.0 Hz, 2 H, OCH_2), 7.10 (s, 2 H, CH=N), 7.26 (s, 1 H, $CHCl_3$), 8.10 (s, 2 H, Ph).

3c: A 1 M solution of diethylzinc in *n*-hexane (4.03 mL. 4.03 mmol) was dropped slowly with stirring into a solution of H_3BMIBIP (0.68 g, 2.02 mmol) and 4-trifluoromethylbenzyl alcohol (0.53 g, 3.00 mmol) in absolute chloroform (25 mL). After stirring for 1 h the solution was filtered, the filtrate reduced to half its volume in vacuo and layered with diethyl ether. After 1 day at 4 °C the precipitate was filtered off and washed with a few milliliters of hexane to give **3c** (0.56 g, 40%) as a colorless powder. M.p. 188 °C. − $C_{25}H_{29}F_3N_2O_2S_2Zn_2{\cdot}0.5CHCl_3$ (641.4 + 59.7): calcd. C 43.69, H 4.24, N 4.00; found C 43.80, H 4.75, N 4.15. − ^{1}H NMR ($CDCl_3$): δ = 1.47 (s, 12 H, CH_3), 1.66 (s, 2 H, OCH_2), 2.20 (s, 3 H, CH_3), 3.57 (s, 4 H, CH_2), 7.19 (m, 6 H, Ph), 7.24 (s, 0.5 H, $CHCl_3$), 8.08 (s, 2 H, CH=N).

Structure Determination:[13] From a chloroform solution of **3c** layered with diethyl ether crystals of composition $(\mathbf{3c})_2{\cdot}2CHCl_3$ were obtained. Diffraction data were recorded at room temp. with the ω/2θ technique on a Nonius CAD4 diffractometer fitted with a molybdenum tube (K_α, λ = 0.7107 Å) and a graphite monochromator. No absorption corrections were applied. The structures were solved by direct methods and refined anisotropically with the SHELX program suite.[14] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[15] Table 2 lists the crystallographic data.

Methylated Derivatives of Hydrazinium Azide

Anton Hammerl,[a] Gerhard Holl,[b] Klaus Hübler,[c][‡] Manfred Kaiser,[b] Thomas M. Klapötke,*[a] and Peter Mayer[a][‡]

Keywords: Azides / Hydrazine / Hydrazinium azide / Nitrogen

The synthesis and characterization of polymethylated hydrazinium azide species is reported. The crystal structure of methylhydrazinium azide and *N,N′*-dimethylhydrazinium azide was determined. The thermal, shock and friction sensitivity as well as the explosion products of some of the compounds were investigated.

Introduction

Hydrazinium azide, first reported by Curtius in 1891,[1] is a powerful explosive. The explosion of hydrazinium azide produces nitrogen, hydrogen and ammonia.[2]

$$[N_2H_5]^+[N_3]^- \xrightarrow[30\ bar]{\Delta} 2.18\ N_2 + 1.52\ H_2 + 0.65\ NH \quad (1)$$

This encouraged us to investigate hydrazinium azide for use as a nitrogen rich, highly energetic material.[3−8] We replaced the hydrogen atoms in hydrazinium azide step-by-step with methyl groups, characterized these compounds and tested the explosive characteristics of the most promising compounds.

Results and Discussion

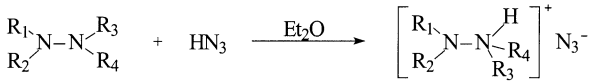
Of all possible methyl-substituted hydrazine azide compounds, *N,N*-dimethylhydrazinium azide **(1)** and *N,N,N*-trimethylhydrazinium azide **(2)** have been reported previously.[4,7] Here, we report the syntheses and characterization of methylhydrazinium azide **(3)**, *N,N′*-dimethylhydrazinium azide **(4)**, *N,N,N′*-trimethylhydrazinium azide **(5)**, *N,N,N′,N′*-tetramethylhydrazinium azide tetramethylhydrazinate **(6)**, *N,N,N,N′*-tetramethylhydrazinium azide **(7)** and pentamethylhydrazinium azide **(8)**.

Azides **3**,**4**,**5** and **6** (Table 1) were prepared by adding a solution of HN_3 in ether to the anhydrous hydrazine at 0 °C. Methylhydrazinium azide **(3)** was isolated as a colorless solid and purified by sublimation. *N,N′*-dimethylhydrazinium azide **(4)** and *N,N,N′*-trimethylhydrazinium azide **(5)** were isolated as ether insoluble liquids that were purified by low temperature sublimation.

Table 1. Numbering scheme for methylated hydrazinium derivatives

	R_1	R_2	R_3	R_4
3	CH_3	H	H	H
1	CH_3	CH_3	H	H
4	CH_3	H	CH_3	H
5	CH_3	CH_3	CH_3	H
6	CH_3	CH_3	CH_3	CH_3

The reaction of tetramethylhydrazine with HN_3 is different from the other reactions since a clear solution forms after the addition of HN_3. After distilling off ether and HN_3, it was possible to isolate a yellowish oil that was purified by low temperature sublimation.



(2)

Compounds **3**−**6** are all sensitive to oxidation. The oxidation is faster in compounds where more methyl groups are present. Methylhydrazinium azide **(3)** is hygroscopic but can be stored in air for several minutes before a color change occurs, while the liquid HN_3 salts turn brown immediately and form black residues in minutes. The HN_3 salts **3**−**6** are very volatile. TG analysis of **3** showed that the compound sublimes at ambient temperature and a drastic increase of sublimation rate occurs at temperatures higher than 50 °C.

Compounds **7** and **8** (Table 2) were made by halogen exchange of the respective iodide salts with silver azide. They were purified by recrystallization from methanol. Compounds **7** and **8** are hygroscopic but not sensitive to oxidation.

(3)

The vibrational spectra (Table 3) show the characteristic absorptions of the azide anion around 2030 cm^{-1} [$\nu_{as}(N_3^-)$, IR] and around 1330 cm^{-1} [$\nu_s(N_3^-)$, Raman] for all the compounds. *N,N,N′,N′*-tetramethylhydrazinium azide tetramethylhydrazinate **(6)** also shows an absorption at 2131 cm^{-1} (IR) and 2129 cm^{-1} (Raman) that is assigned to the HN_3 moiety. We believe that this band is due to the dissociation of the tetramethylhydrazine−HN_3 adduct, explaining the fierce explosions observed with this compound.

Table 3. Characteristic analytical data for hydrazinium azide derivatives

	N*H* (^{1}H)	^{14}N NMR	$\nu_{as}(N_3^-)$	$\nu_s(N_3^-)$	m.p.
3	6.89	−134 −278 −323	2037	1340	68 °C
4	7.33	−134 −275	2034	1339	−8 °C
5	7.54	−134 −275	−	1336	10 °C
6	6.22	−130 −255	2131 (HN_3) 2018	1331	−20 °C
7	6.49	−131 −278 −301	2037	1332	174 °C
8	−	−132 −278 −291	2009	1321	180 °C

The ^{14}N NMR spectra for **3**,**4**,**5**,**7** and **8** (Table 3) show two signals around δ = −134 and −277, the first corresponding to the terminal nitrogen atoms, and the second to the central nitrogen atom. Compound **6** has two signals at δ = −130 and −258. The shift of δ = −258 suggests that the azide ion is bound differently from that of the other compounds. A similar ^{14}N NMR shift is observed for phenylhydrazinium azide phenylhydrazinate at δ = −255.[9] This compound consists of two phenylhydrazine units that are bridged by a proton via hydrogen bonds. The azide anion is connected through weaker hydrogen bonds to the two phenylhydrazine units. Azide **6** seems to be a similar compound because of the ^{14}N NMR shifts, the easy elimination of HN_3 and because hydrazinium azide salts, in general, are not soluble in ether. Tetramethylhydrazine is the weakest base of the hydrazines[10] used here, which explains this behavior. Hydrogen diazide shows a similar structure with two azide ions being bridged by a proton via hydrogen bonds.[11] This is not possible here because tetramethylhydrazine is more basic than an azide ion. In solution no third signal in the ^{14}N NMR around δ = −320 for HN_3 was detected for **6**. We believe that the bands for HN_3 that were detected in the vibrational spectra display belong to only trace amounts of HN_3 due to their high intensity. Elemental analysis for **4**, **5** and **6** was not performed because of serious security hazards. Compounds **7** and **8** show a third, broad signal at δ = −301 and −306, respectively, for the nitrogen atoms of the hydrazinium ions. The ^{1}H NMR spectra in [D_6]DMSO show signals for the NH protons at around δ = 7. The signals for the CH protons and their ^{13}C NMR resonances are in similar ranges to that of the starting materials.

Crystal Structure of 3

Crystals of **3** are orthorhombic, space group *Pnma* with $Z = 8$ molecules in the unit cell. The bond lengths and angles of the methylhydrazinium ion as indicated in Figure 1 are in good agreement with methylhydrazinium trifluoroacetate.[12] Two pairs of hydrogen bonds connect the methylhydrazinium ion to four adjacent azide ions. The shorter pair connects the protonated central nitrogen atom N4 with two N3 atoms of an azide ion, the longer pair of hydrogen bonds connects the terminal hydrazine nitrogen atom with two N1 atoms of an azide atom. The azide atoms show a small difference in N−N bond lengths. The N1−N2 bond is 1.167(1) Å long, slightly shorter than the N2−N3 bond which is 1.184(1) Å. This is caused by stronger hydrogen bonding of N3 [N4−H4−N3 contact distance 2.8815(7) Å] than N1 [N5−H5−N1 contact distance 3.1018(9) Å].

Crystal Structure of 4

The crystals used for the structure determination of **4** were twinned, monoclinic, with space group *Cc* and $Z = 4$. The bond lengths and angles of the dimethylhydrazinium ion (Figure 2) are in good agreement with the bond lengths of other hydrazinium ions. The torsion angles of the hydrazinium ion are 175.2(3)° and 176.6(3)°, i.e. almost 180°. This conformation is stabilized with hydrogen bonds. The N−N bond lengths of both independent azide ions are different in length, as is the case with the azide ion in **3**. The longer N−N bond length in the azide ion corresponds to two shorter hydrogen bonds to adjacent hydrazinium ions; the shorter N−N bond length corresponds to a longer hydrogen bond to the next hydrazinium ion, as in **3**.

The hydrogen-bonded hydrazinium and azide ions form layers (Figure 3). The methyl groups of the hydrazinium ions are above and below these layers, so that two methyl groups are between each layer. The weak interactions between the layers explain the low melting point of the compound. The structure of compound **5**, which also has a melting point below room temperature, should be similar.

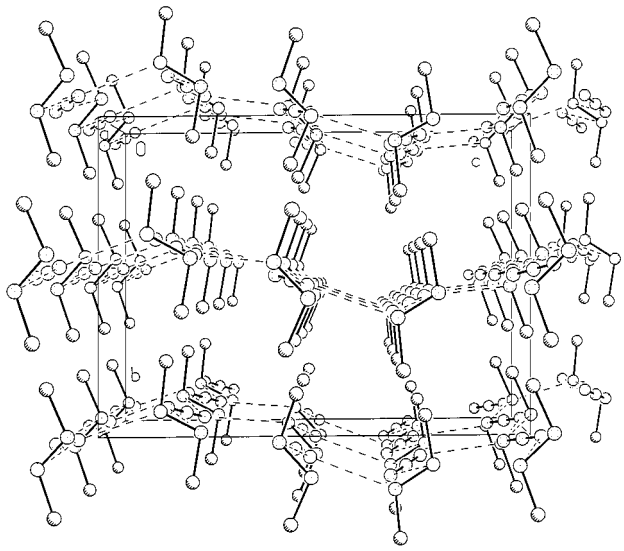

Figure 3. Layers in the crystal structure of **4**

Sensitivity Towards Shock, Friction and Electric Charge, and Thermal Sensitivity

All reported compounds show almost no sensitivity towards shock or friction. No detonation was observed after dropping a weight of 5 kg from 50 cm onto the compounds, nor was any detonation observed when grinding the compounds in a mortar. When exposing the compounds to an electric discharge of about 20 kV from a high frequency brush electrode, all compounds showed no sensitivity. The thermal sensitivity of the HN_3 salts differs from compounds with trimethylated nitrogen atoms. The HN_3 salts **1**, **3**, **4, 5** and **6** do not explode when heated with a heating rate of about 10 °C/min.; they sublime away from the heat source. An explosion can only be started by a strong heat source, for example a hot metal plate or a Bunsen burner. The more methyl groups that are attached to the hydrazinium ion, the fiercer the explosion gets. Methylhydrazinium azide **(3)** and the *N,N*-dimethylhydrazinium azide **(1)** show the same properties, while *N,N′*-dimethylhydrazinium azide **(4)** and compounds **5** and **6** give a much bigger explosion. *N,N′*-

dimethylhydrazinium azide **(4)** exploded in the microanalyser, damaging the glass tubing. In general one would expect less-fierce explosions with an increasing number of methyl groups. In our studies the compounds with more methyl groups are liquids and the bonding of HN_3 to the hydrazine unit is therefore weaker.

The trimethylated compounds **2**, **7** and **8** are less sensitive. While *N,N,N*-trimethylhydrazinium azide **(2)** gives a weak explosion on heating with a Bunsen flame, *N,N,N,N′*-tetramethylhydrazinium azide **(7)** only burns, and pentamethylhydrazinium azide **(8)** burns more sluggishly than **7**.

For methylhydrazinium azide **(3)**, *N,N*−dimethylhydrazinium azide **(1)**, *N,N′*-dimethylhydrazinium azide **(4)**, *N,N,N*-trimethylhydrazinium azide **(2)** and *N,N,N,N′*-tetramethylhydrazinium azide **(7)** the gaseous products were determined after their explosions. The appropriate azide (100 mg) was loaded into a 150 mL evacuated steel vessel. The explosion was started with a red hot metal wire and the gaseous products were analyzed by mass spectrometry and IR spectroscopy.

Explosion Products

After the explosion of methylhydrazinium azide **(3)**, H_2, N_2 and methane were detected. The IR spectrum also showed trace amounts of HN_3. *N,N*-Dimethylhydrazinium azide **(1)** produced dinitrogen as the main product. Small amounts of dihydrogen, methane and methylated amines were also detected.

N,N′-dimethylhydrazinium azide **(4)** produced dinitrogen, dihydrogen and methane as well as trace amounts of methylated amines. *N,N,N*-Trimethylhydrazinium azide **(2)** exploded to dinitrogen, dihydrogen, trimethylamine and trace amounts of methane. *N,N,N,N′*-Tetramethylhydrazinium azide gave dinitrogen, trimethylamine, trace amounts of dihydrogen, and other methylated amines. For all compounds no carbon soot was found after the explosion.

Conclusion

We substituted the hydrogen atoms of hydrazinium azide with methyl groups and the products formed during the explosion of methylhydrazinium azide **(3)**, *N,N′*-dimethylhydrazinium azide **(1)**, *N,N′*-dimethylhydrazinium azide and *N,N,N*-trimethylhydrazinium azide **(2)** include hydrogen.

N,N′-Dimethylhydrazine, *N,N,N′*-trimethylhydrazine and *N,N,N′,N′*-tetramethylhydrazine give salts with HN_3 that are liquid at room temperature and give rise to fiercer explosions than solid compounds.

Hydrazinium azides with a trimethylated nitrogen atom are not sensitive to oxidation and are not volatile, but are very hygroscopic. Due to the increased number of methyl groups the compounds explode only sluggishly.

Experimental Section

General Remarks: *CAUTION: Silver azide, hydrazoic acid and all the reported compounds are explosives. Safety equipment like leather gloves, face-shields and ear-plugs are recommended.* All syntheses were carried out using standard Schlenk techniques under dry nitrogen or argon. Ether was purified by distillation over Na/benzophenone, and methanol by distillation over Na. The distilled solvents were stored under nitrogen. Methylhydrazine and *N,N*-dimethylhydrazine were used as provided by Aldrich, *N,N′*-dimethylhydrazine was prepared by reacting *N,N′*-dimethylhydrazinium chloride from Fluka with sodium hydroxide and was dried over BaO and CaH_2. *N,N,N′*-trimethylhydrazine,[13] *N,N,N′,N′*-tetramethylhydrazine,[14] *N,N,N,N′*-tetramethylhydrazinium iodide[15] and pentamethylhydrazinium iodide[13] were prepared according to known procedures. − NMR: Jeol EX 400, ^1H (400.0 MHz), ^{13}C (100.0 MHz): chemical shifts refer to $\delta_{TMS} = 0.00$; ^{14}N (28.6 MHz): shifts refer to CH_3NO_2. − IR: Nicolet 520 FT-IR (solid compounds as KBr pellets, liquid compounds as film between KBr plates). − Raman: Perkin−Elmer FTIR-2000 spectrometer (Nd-Yag Laser: 1064 nm, Laser power: 100 mW). − CHN analysis: Elementar Vario EL analyzer. − Melting points: Büchi B450. − DSC: Setaram DSC 141. − TG: Setaram DTA-TG 92. − MS: Balzers QMS 420.

Methylhydrazinium Azide (3): A 2 M solution of HN_3 in ether (25 mL) was slowly added to anhydrous methylhydrazine (0.55 g, 12.0 mmol). During the addition a colorless precipitate was formed. After the addition the reaction mixture was stirred for an hour. The precipitate was separated, washed with ether and pentane. Methylhydrazinium azide was sublimed to give colorless crystals. − Yield: 0.91 g (86%). − m.p.: 68 °C. − IR: $\tilde{\nu}$ = 3355 m, 3290 m, 3202 s, 3121 s, 3033 m, 2974s, 2864 m, 2776 m, 2505 m, 2037 s(ν_{as}, N_3), 1605 m, 1591 m, 1486 m, 1454 w, 1402 w, 1339 m, 1333 m, 1112 s, 1009 s, 934 s, 890 m, 802 w, 649 m, 642 m, 515 m, 427 m cm^{-1}. − Raman: $\tilde{\nu}$ = 3167 w, 3018 m, 2953 s, 2795 w, 1459 w, 1340 vs(ν_s N_3), 1290 w, 1013 w, 877 w, 253 w, 181 m, 122 m cm^{-1}. − ^1H NMR ([D$_6$]DMSO): δ = 2.50 (s, 3 H, CH_3), 6.89 (s, 4 H, NH). − ^{13}C NMR ([D$_6$]DMSO): δ = 37.6 (CH_3). − ^{14}N NMR ([D$_6$]DMSO): δ = −134 (*N*N*N*), −278 (N*N*N), −323 (Me*N*H_2*N*H_2). − DSC: 69.3 °C (m.p.), 151.5 °C. − CH_7N_5 (89.10): calcd. ***N,N,N′*-Trimethylhydrazinium Azide (5):** A 2 M solution of hydrazoic acid in ether (15 mL) was slowly added to anhydrous *N,N,N′*-trimethylhydrazine (0.50 g, 6.8 mmol). After the addition of 3 mL of the solution the reaction mixture became turbid. After all of the HN_3 had been added to the reaction mixture, two liquid phases formed. The bottom phase was separated and stored at −30 °C. After several days colorless crystals sublimed onto the walls of the reaction vessel. − Yield: 0.36 g (46%). − M.p.: 10 °C. − Raman: $\tilde{\nu}$ = 3152 w, 3026 w, 2964 m, 1580 w, 1456 w, 1336 s(ν_s N_3), 1247 vw, 1181 vw, 1139 vw, 999 vw, 889 vw, 818 m, 474 m, 220 s, 155 s, 99 s cm^{-1}. − ^1H NMR ([D$_6$]DMSO): δ = 2.50 (s, 3 H, CH_3),

2.63 (s, 6 H, $(CH_3)_2$), 7.54 (s, 2 H, NH). − ^{13}C NMR ([D$_6$]DMSO): δ = 34.3 ($NHCH_3$), 46.6 [$N(CH_3)_2$]. − ^{14}N NMR ([D$_6$]DMSO): δ= −134 (*N*N*N*), −275 (N*N*N).

***N,N,N′,N′*-Tetramethylhydrazinium Azide Tetramethylhydrazinate(6):** A 2 M solution of hydrazoic acid in ether (10 mL) was slowly added to anhydrous tetramethylhydrazine (0.77 g, 8.8 mmol). After the addition of 3 mL of the HN_3 solution the reaction mixture became turbid. After all of the HN_3 solution had been added, a clear solution was obtained. HN_3 and ether were distilled off and a syrupy yellow liquid remained. At −78 °C a colorless solid was isolated by fractional sublimation at 10^{-3} Torr. − Yield: 0.57 g (55%) − M.p.: − 22 °C − IR: $\tilde{\nu}$ = 3319 m, 2969 s, 2669 m, 2594 m, 2497 m, 2451 m, 2131 s (HN_3), 2018 s(ν_{as} N_3), 1645 w, 1469 m, 1443 w, 1412 w, 1326 w, 1244 w, 1215 m, 1182 m, 1146 w, 1134 m, 1097 m, 1059 m, 1026 m, 989 w, 962 w, 880 w, 729 w, 639 w, 623 vw, 548 m, 500 m, 439 vw. cm^{-1} − Raman: $\tilde{\nu}$ = 3006 m, 2967 s, 2800 m, 2129 w (ν_{as} N_3, HN_3), 1475 m, 1445 m, 1331 (ν_s N_3), 989 vw, 963 w, 882 w, 732 m, 550 w, 502 w, 97 s cm^{-1}. − ^{1}H NMR ([D$_6$]DMSO): δ = 2.28 (s, 12 H, C*H*$_3$), 7.33 (s, 3 H, N*H*). − ^{13}C NMR ([D$_6$]DMSO): δ = 38.5 (*C*H$_3$). − ^{14}N NMR ([D$_6$]DMSO): δ= −135 (*N*N*N*), −258 (N*N*N).

***N,N,N,N′*-Tetramethylhydrazinium Azide (7):** Silver azide was prepared by adding a solution of silver nitrate (1.60 g, 9.4 mmol) in 20 mL of water to a solution of sodium azide (0.80 g, 12.3 mmol) in 20 mL of water. Silver azide was filtered off and washed with water. The wet product was then added to a solution of *N,N,N,N′*-tetramethylhydrazinium iodide (1.00 g, 4.6 mmol) in water. Yellow silver iodide immediately precipitated. The reaction mixture was stirred overnight and the water removed under vacuum. The product was recrystallized from methanol. − Yield: 0.35 g (58%) − M.p.: 174 °C (decomposition). − IR: $\tilde{\nu}$ = 3429 s, 3194 s, 3055 s, 2989 s, 2037 s(ν_{as}, N_3), 1730 w, 1635 m, 1541 w, 1485 m, 1456 m, 1385 m, 1278 w, 1268 w, 1186 w, 1121 w, 1049 w, 977 w, 939 w, 838 w, 712 w, 649 w, 642 w, 522 w, 451 w cm^{-1}. − Raman: $\tilde{\nu}$ = 3031 m, 2940 m, 2789 w, 1465 w, 1441 w, 1398 w, 1332 s(ν_s N_3), 1247 vw, 947 vw, 847 w, 715 w, 102 s cm^{-1}. − ^{1}H NMR ([D$_6$]DMSO): δ = 2.57 (d, *J* = 3.0 Hz, 3 H, NHC*H*$_3$), 3.21 [s, 9 H, N(C*H*$_3$)$_3$], 6.61 (q, *J* = 6.2 Hz, 1 H, N*H*CH$_3$). − ^{13}C NMR ([D$_6$]DMSO): δ = 30.5 (NCH_3), 53.4 [$N(CH_3)_3$]. − ^{14}N NMR ([D$_6$]DMSO): δ= −131 (*N*N*N*), −278 (N*N*N), −301 [$CH_3NHN(CH_3)_3$]. − $C_4H_{13}N_5$ (131.18): calcd. X-ray Crystallographic Study: Single crystals of **3** and **4** were submerged in dried perfluoropolyether oil under anaerobic conditions. Suitable crystals were mounted on a glass fiber, transferred to the diffractometer and cooled in the cold gas stream derived from liquid nitrogen. The measurement for **3** was performed on a Stoe IPDS diffractometer equipped with an image-plate area detector and for that of **4** on a Siemens P4 diffractometer, both with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). All calculations were performed using SIR-97[16] and SHELXL-97. Crystallographic data are reported in Table 4.[17]

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-149154 (**3**) and CCDC-149571 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Lipophilic Metal−Salicylideneimine−Crown Ether Hybrids — Ditopic Carriers in the Facilitated Transport of Amphiphilic Molecules Across Bulk Liquid Membranes

Jay D. Pike,[a] Dell T. Rosa,[a] and Dimitri Coucouvanis*[a]

Keywords: Supramolecular chemistry / Molecular recognition / Manganese / Macrocyclic ligands / Facilitated transport

The crown ether-functionalized Mn^{III} salicylaldimine complexes manganese(III) 4,5-bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6-X [X = Cl^-, I^-, CH_3COO^-, $(CH_3)_3CCOO^-$, $B(Ph)_4^-$] have recently been synthesized and studied as effective ditopic transport carriers of hydrophobic amino acids and neurotransmitters through $CHCl_3$ bulk liquid membranes (BLMs). A detailed analysis of the BLM transport of tryptophan and serotonin with these complexes, along with various derivatives, shows the ditopic nature of the mechanism of transport and reveals the importance of the role of both the crown ether function and the metal center. Kinetic data on the BLM transport of tryptophan follow Michaelis–Menten behavior with K_m = 25 mM and $V_m = 6.75 \times 10^{-3} h^{-1}$. Variable temperature studies on the rate of transport of tryptophan (and serotonin) were conducted. From Arrhenius plots, the activation energies, E_a, and pre-exponential factors, A, were determined to be 20 ± 1 (17 ± 5) kJ mol^{-1} and 8200 (947) $M^{-1}h^{-1}$, respectively. From these parameters, values for the thermodynamic activation energies, $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ were calculated to be 26 ± 4 (32 ± 1) kJ mol^{-1}, 17 ± 1 (14 ± 5) kJ mol^{-1}, and –30 ± 9 (–60 ± 14) J K^{-1} mol^{-1}, respectively. Similar studies with serotonin are reported.

Introduction

Cell membranes that protect the cell and at the same time allow for the transport of solutes across the cell boundary consist of lipid bilayers that contain a hydrophobic interior flanked by hydrophilic surfaces. The transport of biologically important small molecules through cell membranes is an essential process for living organisms.[1] The vast majority of such molecules are water-soluble species that by themselves are insoluble in lipid membranes.

In the absence of sufficient hydrophobicity, facilitated transport by specific carriers is necessary to allow for appreciable partitioning for the transport of hydrophilic molecules.[2] A great number of naturally occurring carriers are known for the transport of amino acids, neurotransmitters, nucleosides, sugars, etc. Often these carriers are proteins of mostly unknown structures that exhibit high specificity in the recognition of substrates.[3] The transporter proteins are difficult to isolate, although several have been obtained from various systems including the *E. coli* glucose transport system,[4] the *E. coli* β-galactoside transport system,[5] the baker's yeast galactose transport system,[6] the *E. coli* leucine binding membrane component,[7] and the *E. coli* arginine transport system.[8]

Other hydrophilic molecules, including most drugs, cannot readily cross lipid bilayer membranes unassisted. Carriers for the facilitated transport of hydrophilic drugs across cell membranes are rare and the design and synthesis of such molecules are of vital concern to pharmacology.

The transport of particles across membranes may be either by simple passive permeation (free diffusion) or by facilitated diffusion. Facilitated transport may be "active" or "passive." In the former, the transport process is coupled with the free energy of a chemical reaction that takes place in the transport region and is converted into "pumping" work. In the latter, the driving force is derived from the concentration gradient across the membrane (electrochemical potential gradient) and is at times assisted by "counterflow". This occurs when concentration gradients of two substances at opposite sites of the membrane accelerate the rate of transport of both substances.[9] An example of this type of amino acid transport is the transport of the essential extracellular serine, glycine, and threonine in *Streptococcus faecium*. The transport of these amino acids into the cell is coupled with the outward transport of alanine, which is synthesized in large quantities inside the cells.[10]

Numerous artificial transport systems with varying degrees of success have been developed, including: a) the effective transport of amino acid derivatives by metal complex carriers across CH_2Cl_2 or $CHCl_3$ bulk liquid membranes (BLMs) using hydrophobic, neutral $LM(Cl)_2$ complexes (M= Co^{2+}, Cu^{2+}, L = a macrocyclic polyamine ligand) in basic aqueous solutions assisted by the concomitant transport of antiport halide ions[11]; b) the pH-gradient driven transport of amino acids by positively or negatively charged hydrophobic carriers;[12] c) the transport of hydrophobic amino acids from aqueous solution at the isoelectric point by Kemp's triacid-acridine 2:1 condensate;[13] d) the transport of phenylalanine in a neutral pH transport system

facilitated by cooperative ditopic interactions between the amino acid and unbound arylboronic acid and crown ethers;[14] e) the simultaneous transport of anions and cations by a neutral bifunctional receptor that contains calix[4] phosphate and an appended uranyl salophene unit;[15] f) the ditopic fixation and transport of amino acids with a bifunctional metalloporphyrin receptor;[16] g) the proposed ditopic transport of amino acids by lanthanide(III) tris(β-diketonate) complexes,[17] and; h) the use of phenylboronic acid/trioctylmethylammonium bromide as a carrier of amino acids through a dichloroethane BLM.[18] The enantioselective transport of amino acid derivatives also has been reported with chiral organic agents,[19] and several other metal complexes[20] have shown the ability to transport certain amino acids.

Our interest in supramolecules containing individual subunits with unique structural and reactivity properties[21] has led us to the synthesis of crown-functionalized salicylaldimine ligands. These compounds are readily obtained by Schiff-base coupling reactions between an appropriate salicylaldehyde and 1,2-diaminobenzo-crown ethers or 1,2,1′,2′-tetraaminodibenzo-crown ethers. The products that have been obtained thus far contain one tBu$_4$-salphen unit per 18-crown-6 unit (Figure 1A) and, more recently, 15-crown-5 and 12-crown-4 units.[22] With dibenzo-crown ethers, 2:1 tBu$_4$-salphen:crown ether molecules have been obtained with 18-crown-6 (Figure 1B), 24-crown-8, and 30-crown-10 units.[22b] The supramolecular coordination chemistry of crown ether-functionalized complexes[23] has been studied to a considerable extent and includes derivatives of salicylaldimines,[24] porphyrins,[25] and phthalocyanines.[26] The synthesis of derivatives of salphen ligands with 15-crown-5 ethers fused to the salicylidene rings has been reported.[27] The structures of these compounds[28] have not been determined, although their reactions with metal ions and elementary characterization have been reported.[29]

Metal complexes of the dinucleating ligands reported herein can be obtained readily by the incorporation of transition metal ions into the salicylaldimine portion of the ligand and, when available, alkali metal ions into the crown ether subunit. The presence of both electron pair accepting sites (the salicylaldimine-bound metal) and hydrogen bond accepting sites (the crown ether cavity) makes these molecules ideally suited for the recognition of zwitterions and amphiphilic molecules in general.

In previous communications,[30] we reported our studies on tryptophan and serotonin transport across a $CHCl_3$ BLM using crown ether-functionalized Mn^{III} and Ni^{II} complexes. In this paper we report in detail the synthesis and structures of these ditopic receptor molecules and our detailed studies of their use in the passive transport of tryptophan and serotonin across BLMs (Figure 2).

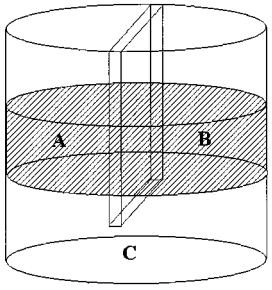

Figure 2. Bulk Liquid Membrane, BLM, transport cell: (A) and (B) source and receiving compartments; (C) $CHCl_3$ BLM

The active uptake of tryptophan is the first step in the synthesis of serotonin in the brain and is facilitated by a carrier that also transports other neutral and branched-chain amino acids. Serotonin is a very important neurotransmitter and influences a multitude of brain functions including sleep, cognition, sensory perception, motor activity, temperature regulation, appetite, sexual behavior, and hormone excretion.[31] Efficient synthetic carriers that facilitate the transport of both tryptophan and serotonin are not known.

Results and Discussion

Synthesis

The synthesis of *N*,*N*′-4,5-dimethoxybenzenebis(3,5-di-*tert*-butylsalicylideneimine) **(4)** and 4,5-bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6 **(9)** (Scheme 1) involves

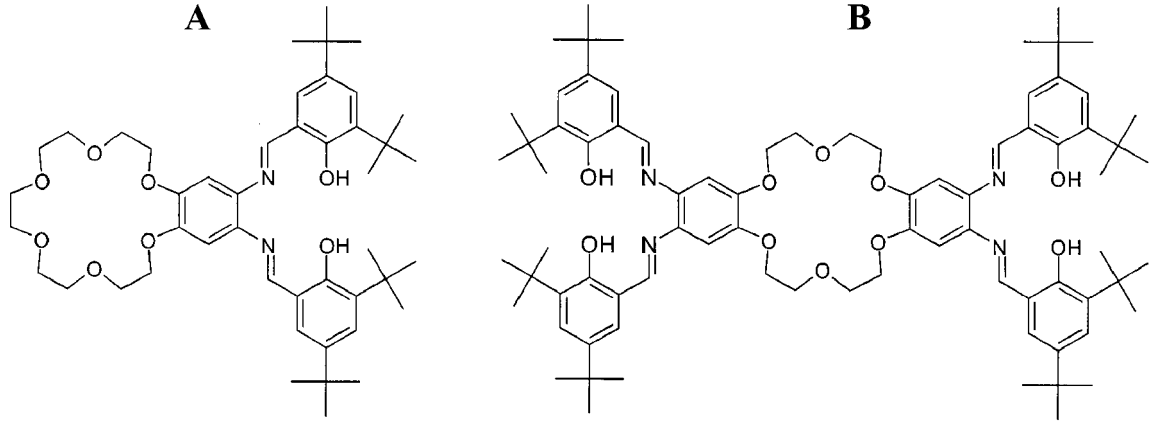

Figure 1. Ditopic Receptor Ligands: (A) tBu$_4$18-C-6; (B) (tBu$_4$)$_2$18-C-6

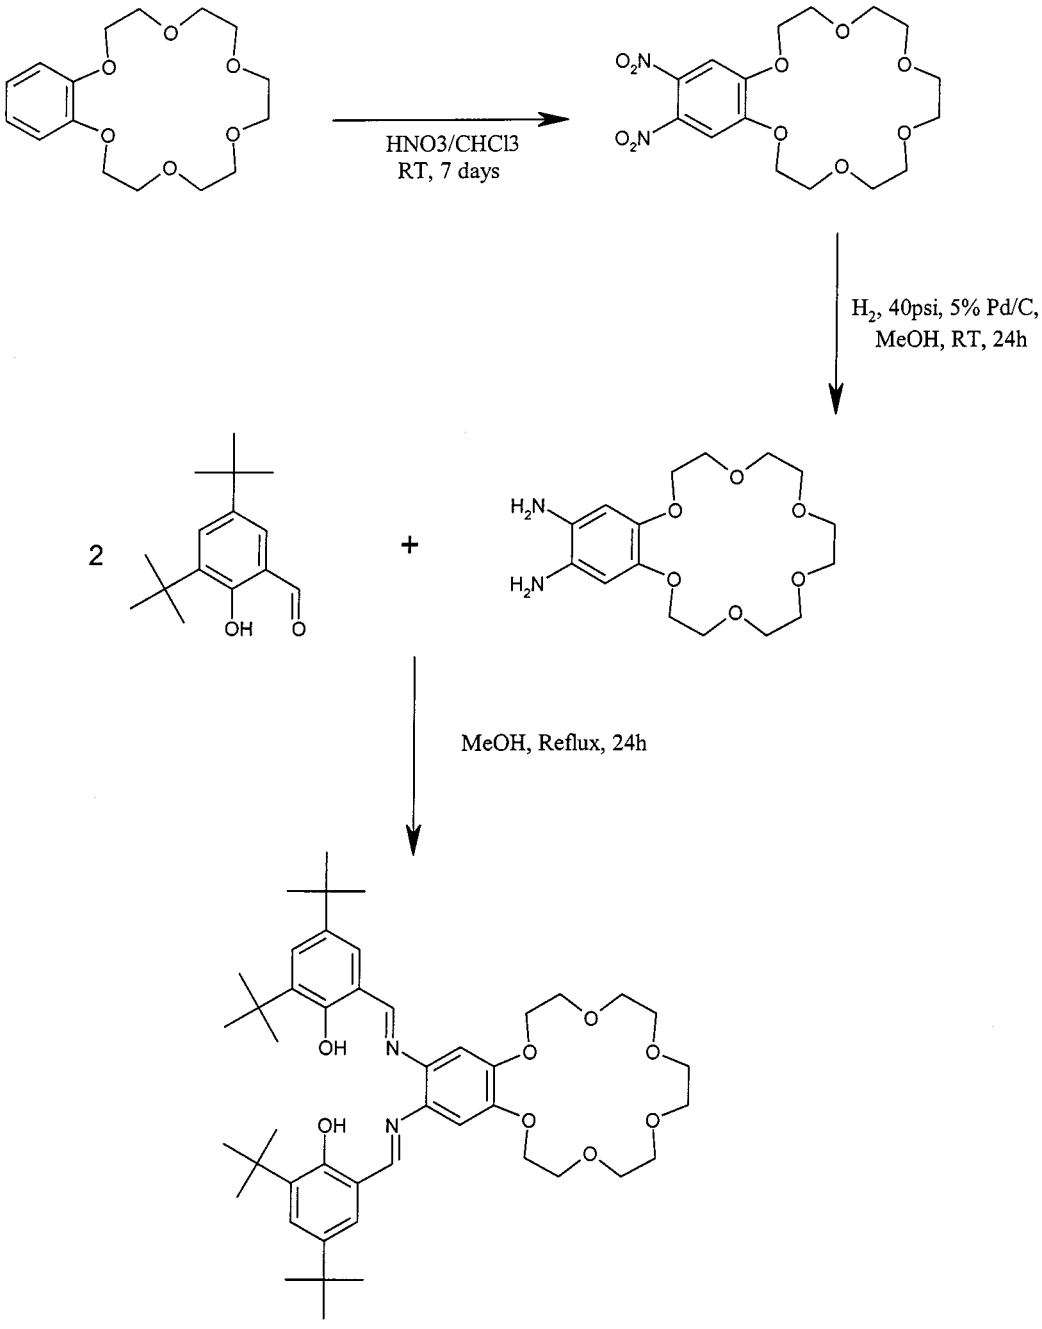
nitration of benzo-18-crown-6 followed by catalytic hydrogen reduction and Schiff-base condensation with the appropriate salicylaldehyde. The metal complexes of **4** (tBu$_4$M-Veratrole) and **9** (tBu$_4$M18-C-6) are obtained by addition of a methanolic solution of the metal salt to a chloroform solution of the ligand. Addition of "wet" methanolic solutions of alkali metal salts (KI, KCl, CsI, CsCl) to the chloroform solutions of the crown ether complexes allows for the introduction of alkali metal ions to the empty crown ether cavities. Complexes with two different Cs:M ratios were obtained by simply adjusting the CsI:M complex stoichiometry (M = Ni^{2+}, Mn^{3+}). An excess of salt usually yields the 1:1 (Cs^+ or K^+):tBu$_4$M18-C-6 complex.

The 1:2 (Cs^+):tBu$_4$M18-C-6 complexes are obtained when a 2:1 tBu$_4$M18-C-6:CsI ratio is used in the synthesis. The counterions that accompany the cationic Mn^{III} complexes can be exchanged readily with anions of the alkali metal salts. This often presents analytical problems and therefore the use of reagents with different anions is avoided.

Spectroscopic Characterization

The infrared spectra of the tBu$_4$M18-C-6 complexes in the region between 3500 cm^{-1} to 450 cm^{-1} are similar for different metal ions and dominated by the characteristic vibrations of the ligand. The spectra have been previously



Scheme 1. Synthesis of tBu$_4$H$_2$18-C-6 **(9)**

assigned for the ligand as well as for the complexes. In the spectra of all the tBu$_4$M18-C-6 complexes the C=C stretching vibration occurs between 1595 and 1470 cm^{-1}, and the C=C out-of-plane bending at about 750 cm^{-1}. The C−H stretching of the *tert*-butyl groups is observed at 2960, 2910, and 2868 cm^{-1} and the imine stretch −C=N− is observed between 1620 and 1606 cm^{-1}. A C−O stretch for the phenolic oxygens of the salicylidene subunit is observed at about 1180 cm^{-1}. The out-of-plane C−H bending for the aromatic ring protons is observed at 820 to 846 cm^{-1}. The manganese complexes **5**, **6**, **15−28,** and **33** show the metal−oxygen stretch coupled with ring distortions around 540 cm^{-1}. Only very weak vibrations are observed in the far-IR region of the spectrum with features around 380 cm^{-1} and at times near 340 cm^{-1}.

Electronic Spectra

The electronic spectrum of ligand **9** shows two strong absorptions at 390 nm and 280 nm. The former is associated with an n−π* transition of the C=N group and the latter with a π−π* transition.[32] A shoulder at 239 nm is also due to a π−π* transition.[32] The spectra of the metal derivatives of **9** (tBu$_4$M18-C-6) (Table 1) are quite similar for different metal ions, even when alkali metal ions occasionally occupy the ether cavity. Generally, addition of transition metal ions to the salphen unit produces a change in color from the pale yellow color of the metal-free ligand to a deep red or brown color. In the Ni^{II} complex **10**, a sharp new band appears in the electronic spectrum at 496 nm, assigned to a charge-transfer transition from the ligand to the metal d orbitals (for Ni^{II}Salphen, the absorptions observed at 380−480 nm have previously been assigned[33] as charge transfer bands). The π−π* band at 266 nm in the free ligand also increases in intensity. Solutions of the Mn^{III} complexes **15−28,** and **33** in CH_2Cl_2 (Table 1) show broad bands at 490, 380, and 320 nm, and a sharper π−π* band at 260 nm [in the Mn(salen)X complexes, absorptions have been reported[34] at 588, 481, and 400 nm but only the visible region was scanned from 667−400 nm]. The electronic spectra of the tBu$_4$M18-C-6 complexes and the tBu$_4$MVeratrole complexes are similar.

Magnetic Susceptibility

The magnetic moments for the Mn^{III} complexes (Table 2) are all consistent with $S = 2$ ground states where variations from the spin only value (4.9 BM) may be due to spin-orbit coupling or inter/intramolecular interactions in the solid state. The complex **27**, with a structure similar to **14**, shows a magnetic moment (6.80 BM at 300 K and 6.26 BM at 4 K) less than that expected for two independent Mn^{III} centers (≈9.8 BM for 2 Mn^{III}) and indicative of antiferromagnetic coupling.

Table 2. Magnetics susceptibilities (μ_{eff}^{corr}/mol, in BM) for selected complexes at 300 and 4 K

	5[a]	**15**	**20**	**22**	**27**
300K	5.06	4.41	5.08	5.38	6.80
4K	4.88	4.38	4.84	4.95	6.26

[a] See Table 1 for the numbering scheme of complexes.

^{1}H NMR Spectroscopic Studies

The compounds, **3** and **9**,and their diamagnetic Ni^{II} derivatives, **4**, **10,** and **12−14**, could be characterized by ^{1}H NMR in a satisfactory manner in CD_2Cl_2 using the solvent as a reference. In the spectrum of **3**, the aromatic proton resonances appear at δ = 7.44, 7.28, and 6.87. The resonance for the imine proton is found at δ = 8.71 and for the *tert*-butyl protons at δ = 1.43 and 1.33. The Ni^{II} derivative **4** also shows a similar pattern with a large shift observable

for the imine proton found at δ = 7.99. The remaining proton resonances are only slightly changed.

The ^{1}H NMR resonances of the salphen unit in **9** and its Ni^{II} derivative **10** are similar to those of their salen-veratrole counterparts. The assignment of the resonance peaks (Table 3) follow the numbering in Scheme 2. The protons of the phenol oxygen atoms in **9** readily exchange with water protons present in the solvent. The *tert*-butyl groups in all spectra are found at about δ = 1.3 to 1.4. The salphen unit of **9** shows the aromatic proton resonances at δ = 6.86, 7.22, and 7.44. These resonances, upon Ni^{II} coordination, shift to δ = 7.08, 7.13, and 7.38. The imine proton again shows the greatest shift upon metal complexation from δ = 8.66 to 7.96. The resonances due to the crown ether protons are unaffected by Ni^{II} coordination and are found at δ = 3.62, 3.66, 3.71, 3.90, and 4.23 in both **9** and **10**.

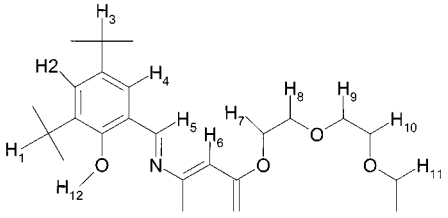

Scheme 2. Proton numbering for NMR spectra of the *t*Bu_4Ni18-C-6 complexes

When an alkali metal ion coordinates to the crown ether cavity, shifts can readily be seen in a non-coordinating solvent such as CD_2Cl_2. The alkali metal complexes show a remarkably different pattern in the crown ether proton resonances compared to those observed for **9** and **10.** Complexes **12**, **13**, and **14** show only three inequivalent sets of protons at around δ = 3.5, 3.6, and 4.3 with the resonance at δ = 3.6 accounting for twelve protons by integration of the areas. In the 1:2 Cs^+:complex **14** twice as many ^{1}H resonances are found as with the monomer **13**. This doubling of resonances reflects the loss of symmetry as a result of dimerization. The protons that point inside the pocket occupied by the Cs^+ ion are differentiated from the protons residing on the same carbon but oriented outside the pocket. This proton inequivalency shows that the "sandwich" complex (Figure 3D) that forms in the solid state stays intact in a noncoordinating environment.

In a coordinating solvent such as [D_6]DMSO, the spectra of the CsI derivatives **13** and **14** are identical and indicate dissociation of the alkali metal ions as a result of competition with the coordinating solvent. A common ^{1}H NMR pattern also is seen when CD_2Cl_2 solutions of the complexes **12**−**14** are saturated with D_2O. The resulting spectra are similar to that of **10**. An equilibrium between the complex **10** and CsI is evident when a saturated aqueous solution of CsI is extracted by a CD_2Cl_2 solution of **10**. The ^{1}H NMR spectrum of this solution of **10** exhibits resonance shifts that are similar to the 1:1 Cs^+:complex **13**. The same experiment with KI does not show any changes and perhaps reflects the insignificant partitioning of KI in CD_2Cl_2.

Description of Structures

[Nickel(II) 4,5-bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6] *n*-hexylammonium chloride (11)

The structure of **11** (Figure 3A) shows the benzo-18-crown-6 unit covalently attached to the Ni^{II}-*t*Bu_4Salphen unit. The Ni−O and Ni−N bond lengths (Table 4) are unexceptional and similar to those reported previously for other similar square planar complexes.[35] The *n*-hexylammonium cation that co-crystallizes with the ditopic receptor molecule in **11** shows the aliphatic chain oriented parallel to the *t*Bu_4Salphen unit at a distance of approximately 3.8 Å. The $-NH_3^+$ end is coordinated to the crown ether unit with the N atom nearly equidistant from the six ether oxygen donors. The average N−O distance of 2.92(4) Å is indicative of strong H-bonding interactions [N−O range 2.848(4)−3.032(4) Å]. This distance is slightly longer than the corresponding distance reported for the ammonium bromide "adduct" of 18-crown-6.[36] In **11** the nitrogen of the hexylammonium cation lies 0.901 Å above the plane formed by the crown ether oxygen atoms. The dihedral angle between the best plane defined by the six crown ether oxygen atoms and the NiO_2N_2 Ni^{II}-Salphen plane is 150°. This orientation places the Ni^{II} center approximately 8.5 Å from the crown ether O_6 centroid. In the lattice, pairs of individual **11** units are found nearly parallel to one another with the closest intermolecular Ni^{II}-18-crown-6 distance at 3.507 Å. The hexylammonium cations are located between the loosely held dimers and the Cl^- counterion is located 6.454 Å from the Ni^{II} ion.

[Nickel(II) 4,5-bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6]Cl (12-Cl)

In the structure of **12** (Figure 3B) the Ni^{II} coordination is also square planar and nearly identical to that found in **11** (Table 4). The Ni^{II} ion is located 0.0062(1) Å above the plane formed by the salicylidene oxygen and nitrogen donor atoms. A potassium cation resides in the crown ether pocket

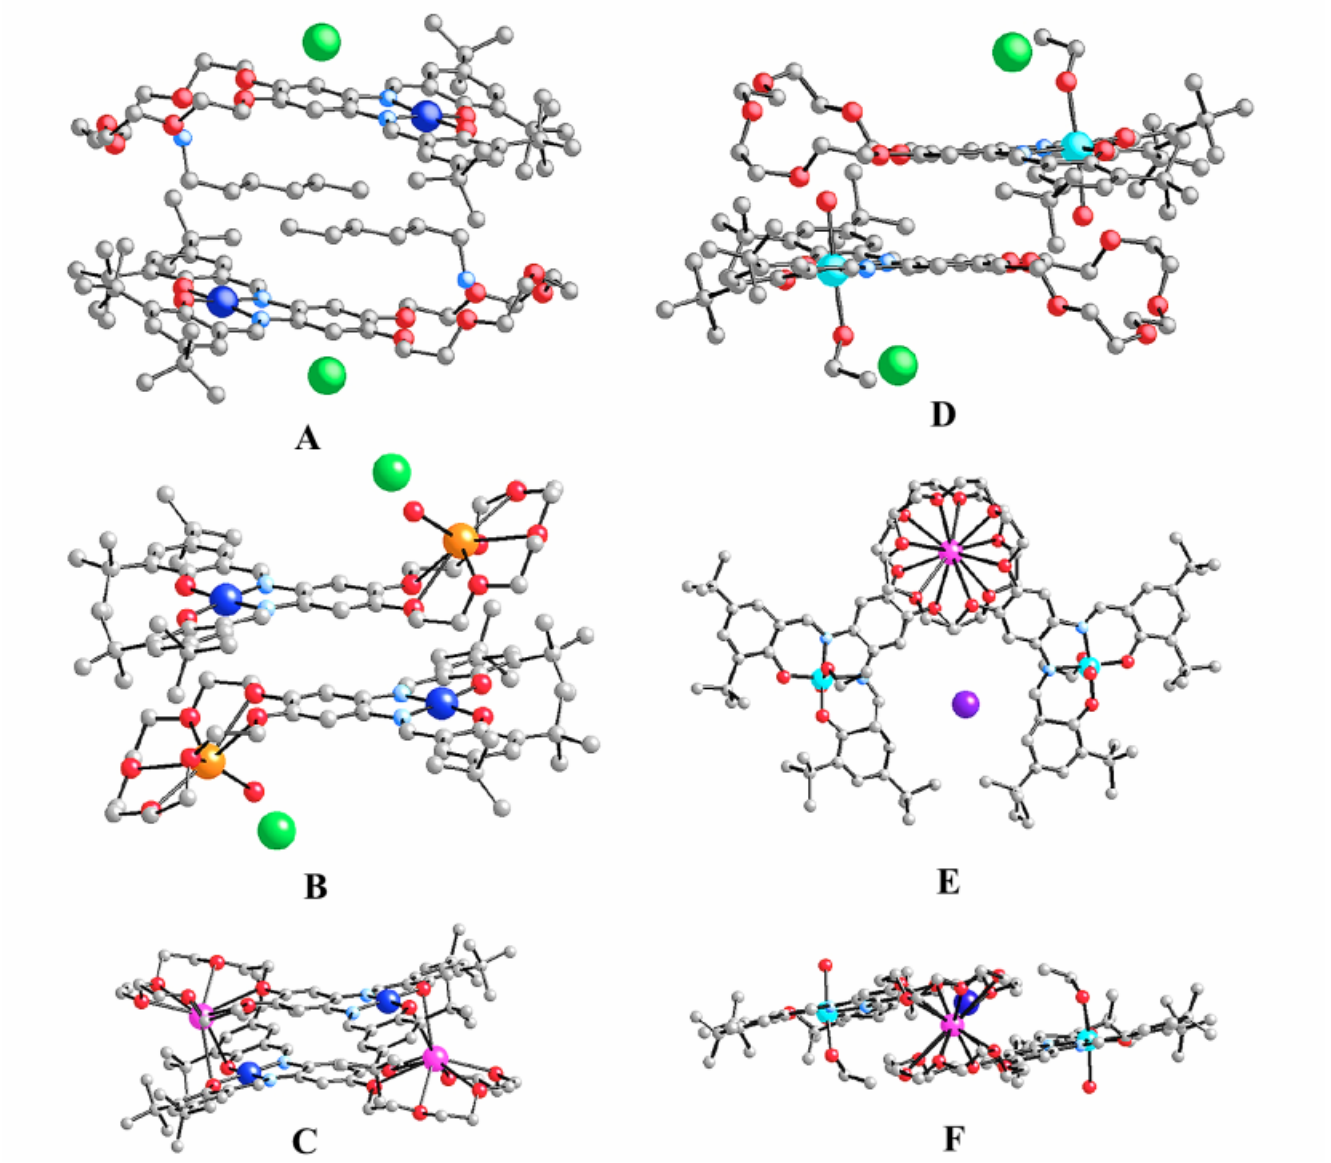

Figure 3. Molecular rendering obtained from Crystal Maker (color scheme: Ni blue; C grey; N light blue; O red; Mn aquamarine blue; K orange; Cs pink) using crystallographic coordinates of: (A) tBu$_4$Ni18-C-6[HexNH$_3$Cl] (**11**); (B) tBu$_4$Ni18-C-6(KI) (**12**); (C) the dimeric complex of tBu$_4$Ni18-C-6(CsI) complex (**13**); (D) tBu$_4$Mn18-C-6Cl (**15**), showing the hydrogen bonding between the H$_2$O ligand and the crown ether; (E) tBu$_4$uMn18-C-6I(1/2 CsI) (**28**); and (F) side view of the sandwich complex tBu$_4$Mn18-C-6I(1/2 CsI) (**28**)

C−O(ether)	1.42(3)	1.41(3)	1.42(4)	1.38(4)	1.41(3)	1.42(7)
A−O(ether)[b]		2.83(5)	3.05(9)	3.29(8)		3.34(12)

[a] See Table 1 for the numbering scheme of complexes. − [b] A represents the alkali metal coordinated to the cavity of the crown ether.

at a distance of 7.102(1) Å from the Ni^{II} ion. The K^+ ion is seven coordinate bound to the six oxygen atoms of the crown ether [avg. K−O = 2.83(2) Å; range 2.751(4)−2.899(4) Å] and a water molecule [$K-O_{H_2O}$ = 2.687(4) Å]. The potassium cation in **12** is located 0.747(4) Å above the best plane defined by the six crown ether oxygen atoms. The crown ether−K^+ bonding in **12** is similar to that reported for the potassium thiocyanate complex of 18-crown-6[37] (avg. K−O = 2.805 Å; range 2.770−2.833 Å). The chloride anion is found 3.478(1) Å from the K^+ ion, 7.102(1) Å from the Ni^{2+} ion and is hydrogen bonded to the K^+ bound water molecule at 3.409(3) Å. In the lattice, the closest Ni−Ni distance is 8.098(1) Å and the closest intermolecular contact is between Ni^{II} and O(8) at 3.507(3) Å.

[Nickel(II) 4,5-bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6]CsI (13)

In the structure of **13** (Figure 3C) the eight coordinate cesium ion is bound to the crown ether (Table 4) [avg. Cs−O = 3.08(3) Å; range 3.021(4)−3.177(4) Å] and two salicylidene oxygen atoms of another molecule at 3.298(4) Å and 3.266(4) Å. The dimeric arrangement is a consequence of the large ionic radius of Cs^+, which accommodates coordination numbers higher than six when associated with oxygen ligands. The coordination of the cesium in **13** is similar to that reported[38] for cesium thiocyanate with 18-crown-6 (avg. Cs−O = 3.146 Å; range 3.04−3.27 Å). Two nitrogen atoms (ordered thiocyanate anions) at 3.30 and 3.32 Å complete the eightfold coordination. The iodide anion for **13** is found 7.246 Å from the cesium ion and close to five carbon atoms at distances that range from 3.762(4) Å to 3.984(4) Å.

[Nickel(II) 4,5-bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6](1/2 CsI) (14)

In **14**, the cationic dimer (Figure 3D) contains two $C_{46}H_{64}N_2NiO_8$ units bound to a single cesium ion "sandwiched" between the two crown ether units. The cesium ion is twelve coordinate [avg. Cs−O = 3.30(3) Å; range 3.168(4)−3.445(4) Å]. In the structure, the two Cs^+-coordinated 18-crown-6 units are nearly parallel (dihedral angle between the two best O_6 planes is 3.1°) and staggered relative to each other. The distance of the cesium ion from the two planes is 1.832(4) Å and 1.741(4) Å. This arrangement is similar to a stack of 18-crown-6 units with cesium ions reported by Domasevitch, et al.[39] [avg. Cs−O = 3.265(8) Å; range 3.152(7)−3.431(8) Å]. In **14**, the iodide counterion is situated nearly equidistant from the two Ni^{2+} ions [6.867(2) Å and 6.952(2) Å] and the cesium ion [7.265(4) Å]. The Ni − Ni distance is 13.137(9) Å. Six solvent molecules are found in the lattice, a water molecule and five methanol molecules. All solvents are found at their sites at half occupancy.

Manganese(III) 4,5-bis(3,5-di-*tert*-butylsalicylideneimine)-benzo-18-crown-6-Cl (15)

In the structure of **15** the Mn^{III} ion occupies the tBu_4-Salphen unit and is octahedral, with the axial positions occupied by a water molecule [$Mn-O_{H_2O}$ = 2.289(3) Å] and an ethanol molecule ($Mn-O_{EtOH}$ = 2.214 Å). Both of these Mn−O bond lengths are in the range 2.21−2.29 Å so the ligands cannot be hydroxide or ethoxide (Figure 3E). The Mn^{III}−L distances, both axial and equatorial, are similar to that reported for the Mn(salen) acetate structure[40] [$Mn-O_{acetate}$ = 2.201(5) Å]. In **15**, the Mn^{III} ion is located 0.012(4) Å above the plane of the salicylidene oxygen and nitrogen atoms toward the ethanol ligand [in Mn(salen)-acetate[40] the Mn^{III} ion is found 0.017(4) Å out of the equatorial plane towards the acetate ligand]. Also found in the asymmetric unit were an additional ethanol molecule of solvation and the chloride anion [Mn−Cl = 4.541(1) Å]. The chloride anion is hydrogen bonded to the hydroxyl proton of the coordinated ethanol ligand [$Cl-O_{EtOH}$ = 3.085(4) Å] and the additional ethanol molecule of crystallization [$Cl-O_{EtOH}$ = 3.025(4) Å]. Short intermolecular hydrogen bonds in the crystal are observed between the Mn-bound H_2O ligand and the 18-crown-6 unit of another molecule. The dimeric arrangement (Figure 3E) again demonstrates the hydrogen bonding abilities of the crown ether units. The distance between the centroid of the crown ether and the manganese is 8.570(1) Å, and indicates that for effective direct crown ether-to-metal ditopic interactions the optimum donor-acceptor site separation within a zwitterionic guest should be around 8 ± 1 Å.

Bis[Manganese(III) 4,5-bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6 chloride]CsI (27)

The twelve coordinate Cs^+ cation in the dimeric **27** is located on a crystallographic twofold axis at 0, *y*, 1/4 in the space group *C*2/*c*. The general structure of the dimeric trication in **27** (Figure 3F) is very similar to that found in the structure of **14** (Table 4) and to a previously reported CsCl:benzo-18-crown-6 1:2 complex.[41] The iodide anion in the asymmetric unit is found in two positions with occupancies of 0.20 and 0.30 at 7.038(2) Å and 7.114(2) Å from the Mn^{III} ions and at 7.801(4) Å and 7.526(4) Å from the Cs^+ ion. The Mn−Mn distance at 13.113(9) Å is quite similar to the Ni−Ni distance in **14** of 13.137(9) Å. The chloride ion is also located at a position equidistant from the two Mn^{III} ions [8.14(1) Å]. In a manner similar to that described for **15**, each of the two Mn^{III} ions in **27** are axially coordinated by an ethanol and water molecules with M−O bond lengths of 2.33(2) Å and 2.22(2) Å, respectively.

Transport Properties of the Ditopic Receptors

The salphen-crown ether ditopic receptors are characterized by the availability of both an electron accepting site and an electron donating site within the same molecule. This availability allows the salphen-crown ether ditopic receptors to recognize and interact with amphiphilic guest

molecules. Important molecules of this type include amino acid zwitterions, or bifunctional molecules that contain acidic ammonium or basic carboxylate or hydroxo groups. The effective relative stability of 1:1 host-guest complexes is subject to size "matching" and is expected to be important in determining the selectivity features of host-guest interactions. The relative importance of a particular pair of interactions is difficult to evaluate when multiple interactive sites are present within the host and guest molecules. Generally, the sum of the $\Delta\Delta G$ values for the interactions involving host-guest complexation (following desolvation and/or reorganization events) will determine the thermodynamic feasibility of a given process.

In addition to the thermodynamic driving force required for transport ($\Delta\Delta G < 0$), favorable kinetics must allow for the association or dissociation of a guest molecule with a host carrier. An analysis of tryptophan and serotonin transport data obtained with various carriers leads to certain elementary conclusions and hypotheses regarding the transport properties of the salphen-crown ether ditopic receptors.

Tryptophan was chosen initially for transport experiments due to its hydrophobic nature relative to other amino acids and also its convenient electronic spectrum. It absorbs at 278 nm with an extinction coefficient of 5000 $M^{-1}cm^{-1}$, which permits sensitive detection in the millimolar range. In addition to the ammonium and carboxylate functional groups, tryptophan has additional sites for interaction, principally a phenyl ring that may $\pi-\pi$ stack with the aromatic rings of the salphen crown and the indole N−H group which may hydrogen bond to axial ligands on the metal center. The rate of tryptophan transport by numerous carriers was determined to evaluate the relative importance of the different sites. The benzo-18-crown-6 system was used as a benchmark against which all results could be compared. Transport studies with serotonin were carried out to determine the importance of size compatibility in the transport process.

An analysis of the fluxes[42] for the transport of tryptophan with various carriers (Table 5) shows a wide variation in the abilities of the salphen-crown ether hybrids to serve as carriers. The differences are associated mainly with the type of metal ion coordinated by the salphen ligand and also the type of alkali metal ion that may occupy the crown ether cavity. The role of the salphen-bound metal centers in the transport properties of the ditopic receptor carriers becomes apparent when the rate of tryptophan transport with the positively charged Mn^{III} complex **16** is compared to that of the free ligand **9**, the Ni^{II} complex **10**, the Cu^{II} complex **29**, and the corresponding $Fe^{III}-O-Fe^{III}$ dimeric complex[43] (Figure 4). In **9**, **10**, and **29**, the carrier is neutral and is not subject to significant electrostatic interactions with the tryptophan zwitterion. Furthermore, the ligand field stabilizations of the square Ni^{II} and Cu^{II} centers in **10** and **29** preclude any strong axial interactions with the carboxylate functional group on the amino acid. As a result, **9, 10,** and **29** are inferior carriers relative to **16** and their transport properties are similar to those exhibited by simple crown ethers. The transport of tryptophan by the neutral $Fe^{III}-O-Fe^{III}$ complex, however, is significant and proceeds at approximately 70% the rate observed for the Mn^{III} cation. In **16,** the best carrier in the group, the Mn^{III} ion not only carries a net positive charge but also has a propensity to bind axially coordinated ligands. The superior transporting character of **16** relative to the $Fe^{III}-O-Fe^{III}$ dimer may be due to the electrostatic interactions, which are significant for the former but weak or absent for the latter.

Table 5. Calculated fluxes of the selected complexes (based on 24 h measurement)

[a] The unit for flux is (mol/second/mol Carrier/m^2) $\times 10^{-4}$ – [b] The abbreviated name for this compound can be found in Table 1.

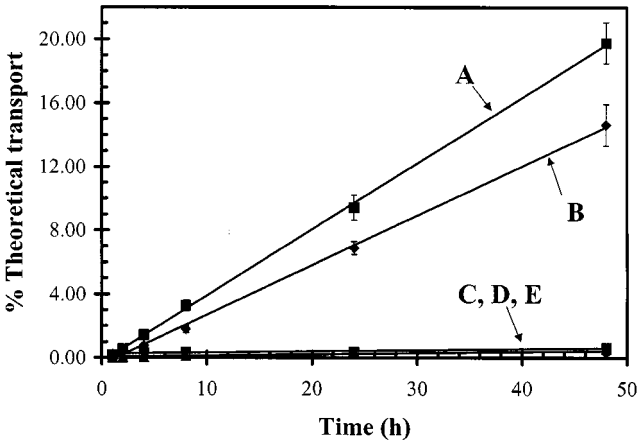

Figure 4. $CHCl_3$ BLM transport of tryptophan by 0.9 mM solutions of the carriers: (A) tBu$_4$Mn18-C-6I **(16)**; (B) [tBu$_4$Fe18-C-6]O, Fe−O−Fe dimer; (C) tBu$_4$Ni18-C-6 **(10)**; (D) tBu$_4$Cu18-C-6 **(29)**; (E) tBu$_4$H$_2$18-C-6 **(9)**; the initial concentration of tryptophan in the source phase was 50 mM

The initial transport rates of tryptophan and serotonin by tBu$_4$Mn18-C-6X (X = I, Cl) were determined as a function of carrier concentration (Figure 5) and showed first order dependence. In this concentration-gradient driven process, the concentrations of tryptophan or serotonin in the source and receiving compartments of the transport cell eventually become equal as the system asymptotically approaches equilibrium. First order rate constants obtained from these plots by linear fits of the data (Figure 5) show a slower rate of transport for serotonin (Figure 5C) than for tryptophan (Figure 5A).

For the facilitated transport of a given solute through a membrane by a membrane-residing carrier, C_m, the flux, J_{solute}, is defined as[44]:

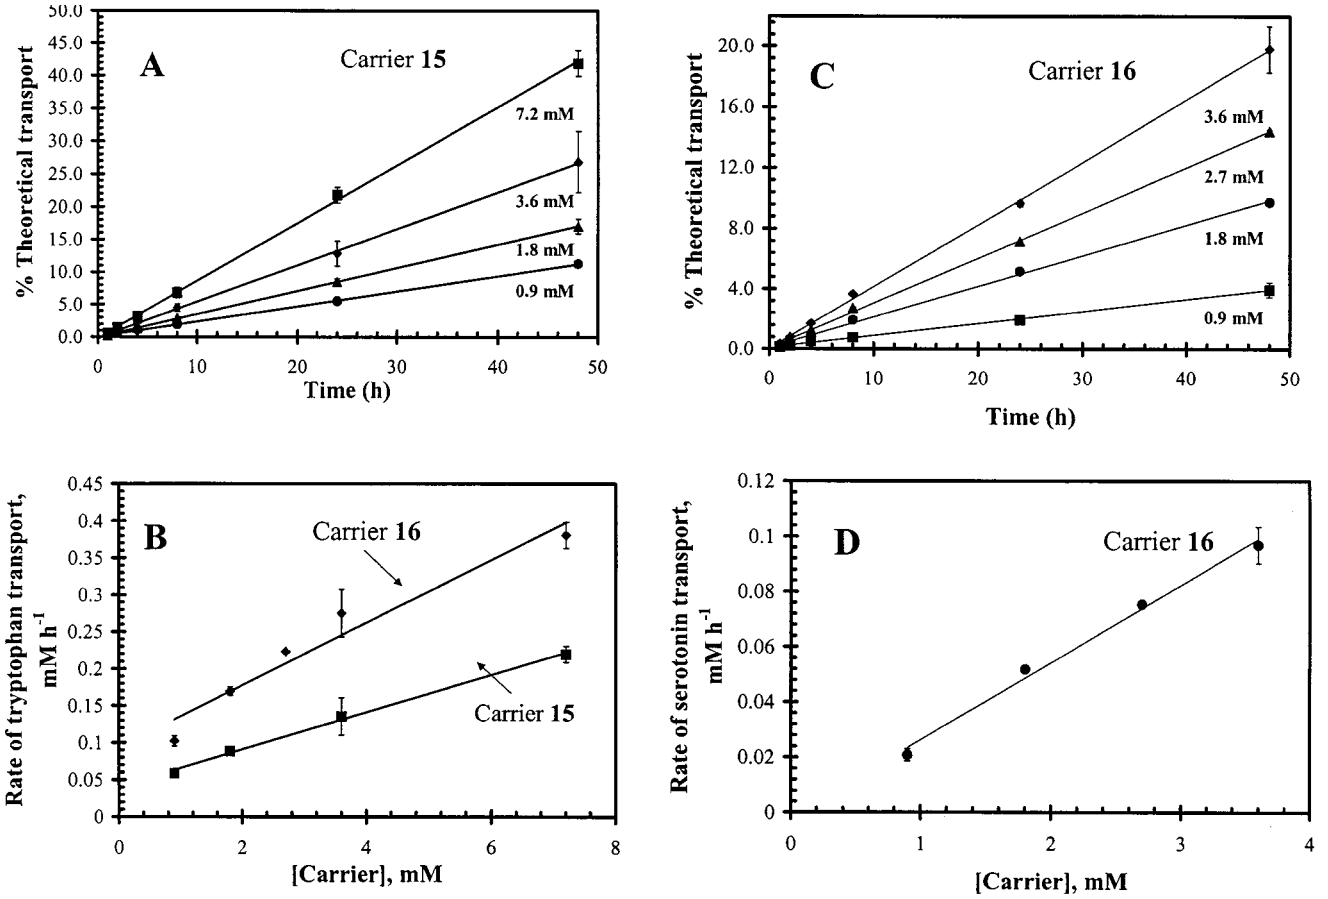

Figure 5. (A) $CHCl_3$ BLM transport of tryptophan as a function of tBu$_4$Mn18-C-6Cl **(15)** carrier concentration; the concentration of carrier varied from 0.9−7.2 mM; (B) plots of the rate of tryptophan transport vs. carrier concentration for tBu$_4$Mn18-C-6I **(16)** and tBu$_4$Mn18-C-6Cl **(15)**; (C) $CHCl_3$ BLM transport of serotonin as a function of tBu$_4$Mn18-C-6I **(16)** carrier concentration; the concentration of carrier varied from 0.9−7.2 mM; (D) plot of the rate of serotonin transport vs. concentration of tBu$_4$Mn18-C-6I; the initial concentration of tryptophan in the source phase was 50 mM

$$J_{solute} = \frac{D_{cs}C_oK_{ex}}{L}\frac{S_s - S_r}{(1+K_{ex}S_s)(1+K_{ex}S_r)}$$

where D_{cs} = carrier−solute diffusion constant, C_0 = total concentration of carrier, S_s = concentration of solute at source interface, S_r = concentration of solute at receiving interface, L = membrane thickness, and $K_{ex} = [CS_m]/[S_s][C_m]$. When K_{ex} is not very small and/or S_s is reasonably large (such as early in the transport process), then $K_{ex}S_r << 1$ and the flux is given by:

$$J_{solute} = \frac{D_{cs}C_oK_{ex}S_s}{L}\frac{S_s}{(1+K_{ex}S_s)}$$

which is of the form of the Michaelis−Menten equation for the process:

$$C_m + S_s \xleftrightarrow{Kex} [CS_m] \rightarrow C_m + S_r$$

The Michaelis−Menten constant K_m ($K_m = [S_s][C_m]/[CS_m] = 1/K_{ex}$) can be obtained from double-reciprocal Lineweaver−Burk plots. The transport of tryptophan and serotonin were followed as a function of substrate concentration and found to follow Michaelis−Menten kinetics. From Lineweaver−Burk plots (Figure 6), K_m values of 25 mM and 245 mM were determined for tryptophan and serotonin transport, respectively. From these apparent Michaelis constants carrier-permeant extraction constants ($K_{ex} = 1/K_m$) of 40 M^{-1} and 4 M^{-1} were determined for the tryptophan and serotonin carrier complexes, respectively. The origin of this difference in K_m and K_{ex} values is difficult to ascertain considering the multitude of interactions that contribute to various extents to the overall free energy of carrier-guest complexation. Practical difficulties in maintaining control of pH and their effects in the transport process also make comparisons difficult. Phenomenologically, one may expect weaker Mn−O bonding with the protonated phenolic oxygen donor of serotonin than with the carboxylate group of tryptophan. In such a case, and considering other events energetically similar, one may attribute the differences to differences in Mn−O interactions.

Kinetic studies as a function of temperature for tryptophan and serotonin transport and Arrhenius plots (Figure 7) yielded activation parameters (Table 6). The energies of activation E_a of 20 ± 1 and 17 ± 5 kJ mol^{-1} indicate diffusion-controlled processes.[44]

Studies were conducted to determine the relative transport efficiency of the ditopic receptors by comparison to

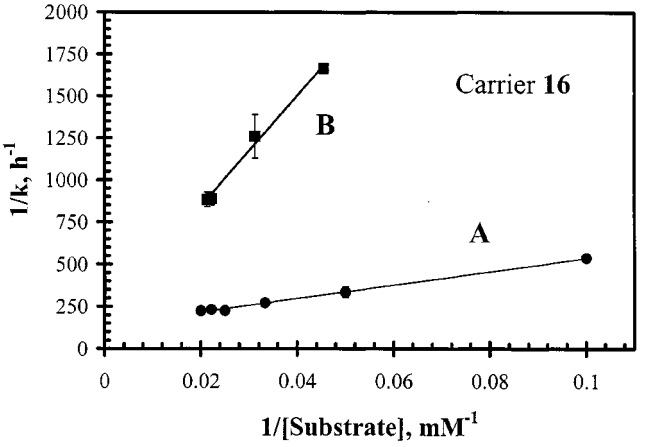

Figure 6. Lineweaver−Burk plots for: (A) tryptophan transport, and (B) serotonin transport with *t*Bu$_4$Mn18-C-6I **(16)** as the carrier; concentrations of tryptophan and serotonin were 10−50 mM and 22−47 mM, respectively

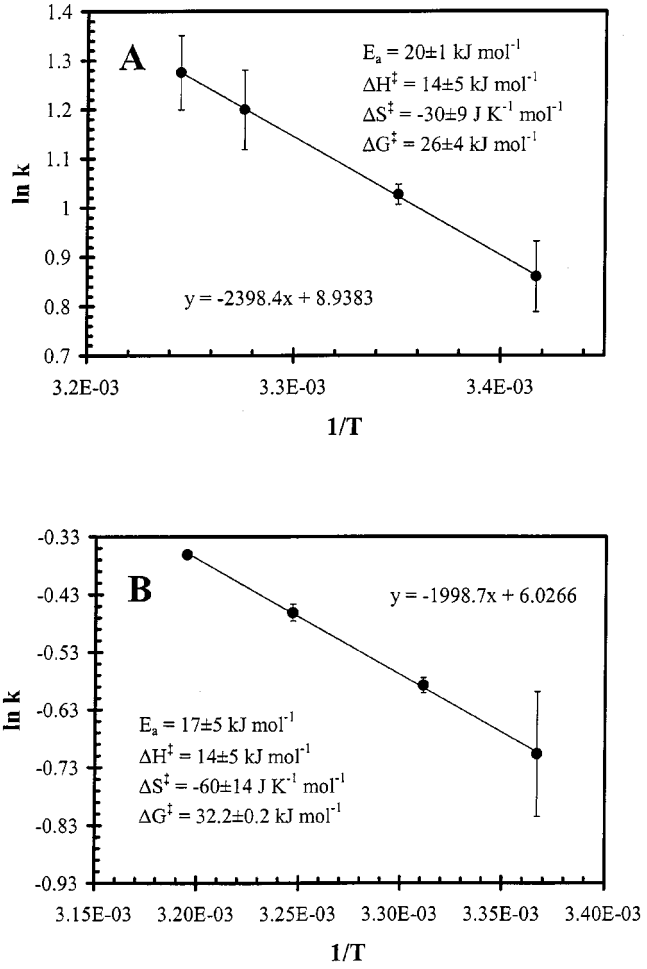

Figure 7. Arrhenius plots for: (A) tryptophan, and (B) serotonin transport with *t*Bu$_4$Mn18-C-6I **(16)** as the carrier; temperature range: 297−315 K

that of an equimolar mixture of two closely related monotopic half-receptors. The transport of tryptophan by a 1:1 mixture of Mn^{III} *N*,*N*′-dimethoxybenzenebis(3,5-di-*tert*-butylsalicylideneimine) iodide **(6)** and benzo-18-crown-6 were compared to those of **16** and also of **6** and benzo-18-crown-6 individually. The results show (Figure 8A) that in an equimolar mixture the two carrier components of **16** function synergistically. The rate of transport observed with **16**, however, is still 30% faster and indicative of moderate ditopic cooperativity. The same experiments carried out with serotonin (Figure 8B) show greater ditopic cooperativity and can be attributed to a better spatial matching between the donor-acceptor pairs within the serotonin-**16** complex. The synergism displayed by the mixture of the two carrier components of **16** in the transport of tryptophan and serotonin (Figure 8) has been reported previously for equimolar mixtures of arylboronic acids and crown ethers in the transport of L-phenylalanine through $CHCl_3$. Similarly, the ditopic cooperativity shown by **16** in the transport of tryptophan, which is more pronounced in the transport of serotonin, has been reported previously for crown ether-functionalized boronic acids in the facilitated transport of catecholamines.[45] The synergism observed in the tryptophan transport by a 1:1 mixture of benzo-18-crown-6 and **6** suggests that the transport of tryptophan by **16** may proceed simultaneously by first and second order reactions. A plot of the tryptophan transport rate as a function of carrier concentration (Figure 5) and an attempted fit with a second degree polynomial did not show evidence for a second order process, where two molecules of **16** act in tandem in the transport process.

The Role of the Crown Ether Unit

The salphen-crown ether ditopic receptors are capable of lowering the kinetic barrier associated with the $H_2O-CHCl_3$ interface transport of the carrier-guest complex. This is due to the ability of the relatively hydrophilic crown ether to "invade" the water solution across the interface. The covalently bound highly hydrophobic salphen unit precludes the partitioning of the carrier into the water. The importance of the crown ether in the transport of tryptophan is apparent when **16** is compared to the *t*Bu$_4$MnVeratrole complex **6** (Figure 9). The latter is a complex similar in most aspects to **16** except that it lacks the crown ether appendage. The electronic structural similarities[46] between **6** and **16** notwithstanding, the rates of tryptophan transport between **6** and **16** differ significantly and indicate that the crown ether unit plays an important role in transport. This undoubtedly derives from the hydrogen-bond-accepting nature of the crown ether cavity and its ability to interact with $-NH_3^+$ groups. This type of interaction has been previously established in various structure determinations[47] and also in the structure of **11** (Figure 3A).

The importance of an unhindered crown ether group in the transport of tryptophan is further demonstrated in the difference in transport rates between the salphen-crown, such as **16**, and the salphen-crown-salphen carriers, such as **33** (Figure 1B). The former shows transport rates (Figure 9) far superior to those observed with the latter with two metal-salphen units. A reason for this counter-intuitive difference may be the additional hydrophobic unit in **33** that effectively blocks the crown ether from penetrating across the interface. Nevertheless, the possibility that this differ-

ence still may be partly due to the differences in donor properties between the benzo-18-crown-6 and dibenzo-18-crown-6 units should not be overlooked. In the dibenzo-18-crown-6 units, weaker donor properties may be displayed due to the presence of only two aliphatic ether oxygen donors.[48]

An examination of the transport properties of the tBu$_4$Mn18-C-6X (**15** and **16**) and tBu$_4$MnVeratroleX (**5** and **6**) carriers (X = Cl and I; Figure 10) shows the I^- salt of the former to be better than the Cl^- salt. The opposite is observed with the latter, where **5** shows a faster transport rate than the corresponding I^- salt, **6**. The crown ether unit

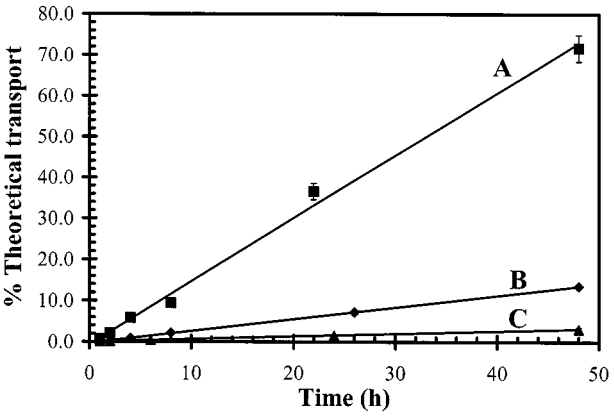

Figure 9. $CHCl_3$ BLM transport of tryptophan by 7.2 mM solutions of: (A) tBu$_4$Mn18-C-6I, (B) (tBu$_4$Mn)$_2$18-C-6I, and (C) tBu$_4$MnVeratroleI; the initial concentration of tryptophan in the source phase was 50 mM

common to **15** and **16** allows the penetration of these carriers across the interface and the higher transport rate of the I^- carrier **16** is very likely due to its higher ionic nature relative to the Cl^- analog, **15** (vide infra). In **5** and **6**, the absence of the crown ether appendix underscores the need for a different kinetic factor for facilitating interface crossing. A possible explanation for the halide effects in the transport properties of **5** and **6** is that the less hydrophobic Cl^- salt is more likely to effectively approach the interface than the I^- salt. It appears that, in transport with the tBu$_4$MnVeratroleX carriers, the ability to approach the interface becomes the rate-determining step.

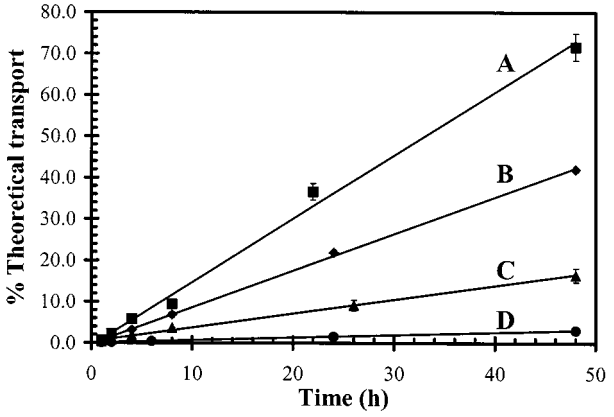

Figure 10. $CHCl_3$ BLM transport of tryptophan by 7.2 mM solutions o: (A) tBu$_4$Mn18-C-6I, (B) tBu$_4$Mn18-C-6Cl, (C) tBu$_4$MnVeratroleCl, and (D) tBu$_4$MnVeratroleI; the initial concentration of tryptophan in the source phase was 50 mM

The Effects of Alkali Metal Ions

The beneficial contributions of the crown ether units in the transport of tryptophan are diminished when alkali metal ions are introduced to the crown ether cavities of **15**

and **16**. Alkali metal ions are well-known to bind strongly to crown ethers in interactions that depend greatly on size matching between the ionic radius of the cation and the crown ether cavity.[49] The effects on the rate of tryptophan transport when alkali metal ions are competing with the $-NH_3^+$ moiety of the amino acid are as expected, and show a decrease in the rate of tryptophan transport when K^+ or CsCl salts are present at various concentrations. With CsI, the rate of transport depends on the concentration of Cs^+ in the $CHCl_3$ phase. With both **26** and **28**, the rate of transport slightly increases relative to that in the absence of the Cs^+ ion. Once a saturated aqueous solution of CsI is used in both the source and receiving compartments, the rate decreases following the behavior of the other alkali metal salts. The alkali metal salt-effect has been studied in the transport of amino acids into cells of *Streptomyces hydrogenans*, where K^+ or Rb^+ salts were introduced into a solution of the amino acid and an increase in the transport rate into the cell was observed.[50] In the present systems, the aqueous source and receiving compartments in transport experiments using carriers **20**−**28** were analyzed for the appropriate alkali metal salt by both conductivity experiments and HPLC analyses. These analyses showed that at least 95% of all K^+ salts and CsCl leached into the aqueous solutions after the first hour of transport. These results support the contention that the alkali metal-induced decrease in the tryptophan transport rate is due to the competition of the alkali metal cations with the $-NH_3^+$ group of tryptophan for the crown ether "tail" of the carrier as it penetrates the interphase. This is not the case with the CsI "adducts" **26** and **28**. The concentration of CsI in the aqueous phases in contact with $CHCl_3$ solutions of **26** and **28** tended to be consistently lower and, at equilibrium, only 75% of the total amount of CsI had leached out. The hydrophobicity of the CsI and its association with the carriers **26** and **28** in $CHCl_3$ solution may be the reason for the transport-rate enhancement found with the complexes **26** and **28**. However, the specific host-guest interactions involved in tryptophan transport with **26** and **28** are not clear and may have their origin in the unique structure of **28**, which persists in $CHCl_3$ solution. The ^1H NMR spectrum of the Ni^{II} complex **10** in CD_2Cl_2 (saturated with CsI) exhibits resonances reminiscent of the spectrum of tBu$_4$Ni18-C-6(CsI) **(13)**. This behavior demonstrates a significant tendency of CsI to partition into the organic phase and interact with the carrier.

Axial Interactions with the Mn^{III} Center

Numerous positively charged Mn^{III} salen complexes are known with the counterions bound to the metal (in noncoordinating solvents), forming square pyramidal complexes.[51] In coordinating solvents, the cationic Mn^{III} complexes form 2:1 solvent adducts with an octahedral geometry. This is also demonstrated in the crystal structures of **15,** which show that when **15** is crystallized from a methanol solution, the metal accepts two axially coordinated solvent molecules, whereas crystallization from ethyl acetate gives a derivative with the chloride counterion coordinated to one of the two axial sites on the metal.[52] The electronic spectra of the complexes **15**−**19** in CH_2Cl_2 solution are all unique and show varying magnitudes of axial ligand−metal ion interactions, as evidenced by the location of an electronic absorption band between 470 and 500 nm (Table 1). The tetraphenylborate salt **17** shows this absorption at the shortest wavelength (470 nm). Taking into account the noncoordinating properties of this anion, the absorbance is probably due to coordination of the MeOH present in the CH_2Cl_2. Indeed, a common band is observed at 460 nm for all complexe **15**−**19**, in MeOH solution (Table 7). The bathochromic shifts of the 470 nm band, caused by coordination of electron donors to the Mn^{III} center in **15**−**19**, indicate that this electronic absorption is very likely due to a metal-to-ligand charge transfer (MLCT) process. The relative substrate transport rates are slower for carriers that show the larger bathochromic shifts of the MLCT band (Table 1). The differences in the bathochromic shift of the CT absorption reflect differences in strength of the Mn^{III}-axial ligand interactions. Generally, the transport data indicate that the less coordinating anions do not compete effectively with the amino acids for the Mn^{III} site. As a result, the efficiency of tryptophan transport follows the order: $B(Ph)_4^- > I^- = Piv^- > Cl^- > Ac^-$ (Figure 11). This is also the order by which Λ_m, the molar conductivity, increases (Table 7). The conductance measurements indicate that hydrophobic $CHCl_3$−ion interactions promote ionic dissociation in $CHCl_3$ solution.

As a consequence, the greater donor properties of the pivalate anion, with an expected superior solubility in nonaqueous media and anticipated stronger interactions with the Mn^{III} center, are not reflected in the transport rate of tryptophan by it; the latter shows a higher transport rate than the acetate salt **18**.

With tetraphenylborate as a counterion for the Mn^{III} carrier, compound **17** shows a considerable increase in the rate of tryptophan transport. This is noteworthy considering the limited solubility of **17** in $CHCl_3$. Indeed, the solubility of **17** is considerably less than that of the other carriers. The origin of this reduced solubility of **17** in nonaqueous media may be due to extensive charge localization in the carrier ion-pair. The bulky tetraphenylborate anion, which is unable to coordinate to the metal ion, leaves a full positive charge on the metal. Similar arguments may be made for the iodide salt **16**, which also shows fast transport rates. In addition to hydrophobicity, another reason for the increase in the rate of transport observed with the tetraphenylborate and iodide salts may be that these weakly interacting anions allow the salphen-bound metal to interact with the aqueous phase and coordinate axial H_2O ligands (vide infra).

Host−Guest Interactions

In the zwitterionic form, amino acids can interact either with the RNH_3^+ group (with the crown ether site in the carrier) or with the $R-COO^-$ group (with the Mn^{III} site). With hosts such as **16**, the host-guest interactions cannot be ditopic due to the short span of the amino acid functional groups relative to the separation between the Mn^{III}

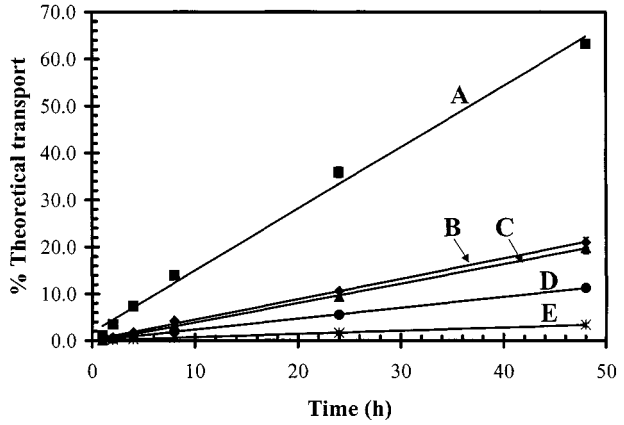

Figure 11. Effect of the anion, X, in the transport of tryptophan by 0.9 mM solutions of the tBu$_4$Mn18-C-6X carriers: (A) tBu$_4$Mn18-C-6(BPh$_4$) **(17)**, (B) tBu$_4$Mn18-C-6(Piv) **(19)**, (C) tBu$_4$Mn18-C-6I **(16)**, (D) tBu$_4$Mn18-C-6Cl **(15)**, and (E) tBu$_4$Mn18-C-6(OAc) **(18)**; the initial concentration of tryptophan in the source phase was 50 mM

center and the crown ether cavity. This distance becomes shorter when H_2O is added axially to the Mn^{III} center and should make it possible for the zwitterionic amino acid guest to hydrogen-bond to the water molecules through the carboxylate group and simultaneously to the crown ether cavity through the ammonium group. The observed ditopic behavior (Figure 8) very likely reflects transport with a water-coordinated Mn^{III} center. Molecular mechanics calculations[53] on the tryptophan-tBu$_4$Mn18-C-6 complex support this suggestion and show (see Figure 12) that, when tryptophan is placed in the pocket of the carrier that contains a water molecule axially coordinated to the Mn^{III} center, the relative energy of the host-guest complex decreases.[53] In the energy-minimized structure, in addition to RNH_3^+ hydrogen bonding with the crown ether appendix ($RNH_3^+\cdots O$, 2.69 Å), short hydrogen bonds are found between the amino acid carboxylate group and the Mn^{III}-bound water molecule($COO^-\cdots H_2O-Mn$, 2.51 Å). In the energy-minimized structure without the Mn^{III}-bound water molecule, the only hydrogen bonding interaction is between the RNH_3^+ unit and the crown ether unit ($RNH_3^+\cdots O$, 2.69 Å; $COO^-\cdots Mn$, 3.79 Å). The same type of calculations was performed with serotonin. With a water molecule axially bound to the Mn^{III} ion in **16** the energy minimized structures (Figure 13) show the relative energy of the serotonin-**16** complex[53] much higher than that of the complex without an axially bound water molecule. The lower energy of the latter is not unexpected considering the favorable spatial disposition of the donor (OH group) and acceptor (NH_3^+ group) sites in the serotonin molecule at a distance of 8.35 Å. This distance is comparable to the Mn^{III}-crown ether centroid distance of 8.72 Å and allows for an optimal host-guest interaction. This interaction accounts for the superior ditopic effect shown in the serotonin transport by **16** (Figure 8B) relative to the transport of tryptophan by the same carrier (Figure 8A).

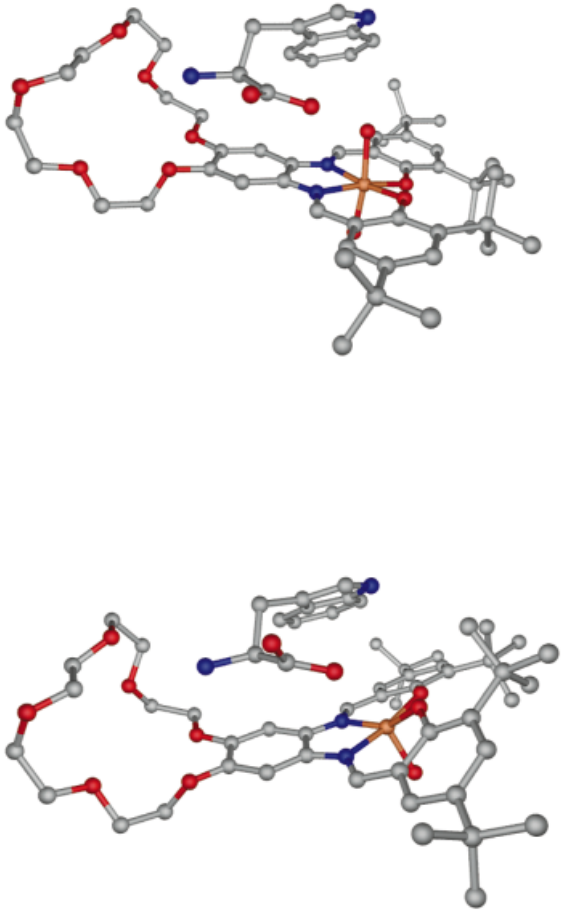

Figure 12. Optimized structures of the tryptophan-tBu$_4$Mn18-C-6 complex: (A) with, and (B) without an Mn-coordinated H_2O ligand

Other modes of interaction are possible with tryptophan and the ditopic carriers. These include a contact between

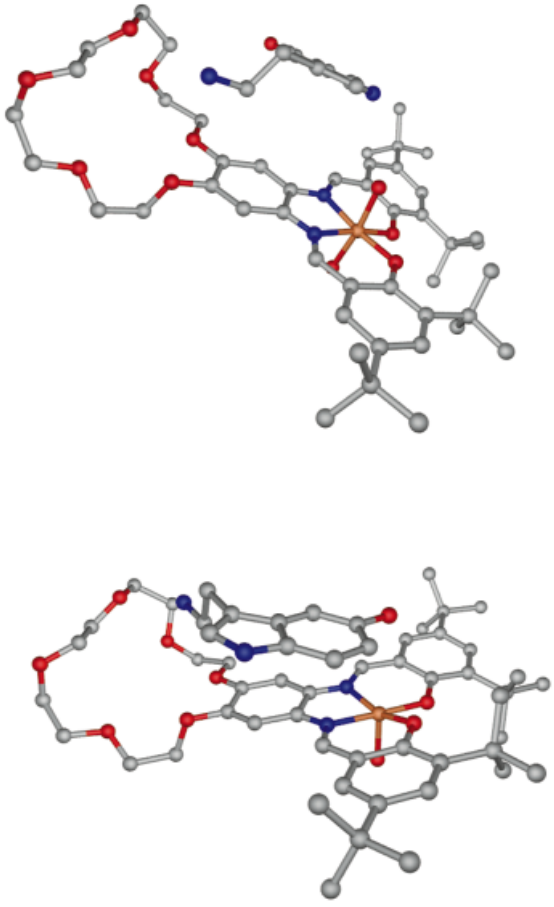

Figure 13. Optimized structure of the serotonin-tBu$_4$Mn18-C-6 complex: (A) with, and (B) without an Mn-coordinated H_2O ligand

the aromatic ring of tryptophan and the "bridging" aromatic ring of the carrier through π-stacking and also simple hydrophobic interactions of tryptophan with the organic phase. The use of leucine and phenylalanine in transport experiments was undertaken to explore the possible importance of these modes of interaction. Solubility data indicate that both are slightly less hydrophobic than tryptophan (11.4 mg TRP/mL H_2O at 23 °C, 24.3 mg LEU/mL H_2O at 25 °C, and 29.7 mg PHE/mL H_2O at 23 °C[54]). The rates of transport of the three amino acids show a dependence on hydrophobicity but not on aromaticity and suggest that the rates depend on the ability of the amino acids to approach and enter the organic solvent-water interface.

Conclusion

A new class of ditopic receptor molecules has been synthesized and structurally characterized. The unique structural features of these molecules are: a) a very lipophilic unit that consists of two 3,5-di-*tert*-butylsalicylideneimine moieties that form a square O_2N_2 coordination site, and b) a relatively hydrophilic benzo-18-crown-6 ether unit capable of binding to alkali metal ions and hydrogen bonding with ammonium functional groups. These molecules, which are totally insoluble in water but very soluble in nonpolar solvents, have been found to be effective in the facilitated transport of hydrophobic amino acids and serotonin across $CHCl_3$ bulk liquid membranes.

The metal ion within the O_2N_2 coordination site, and its affinity for axial ligands, determines transport efficiency. The neutral Ni^{II} derivatives of the ditopic receptors, with little affinity for axial ligands, are poor carriers and their efficiency in the transport of tryptophan is roughly equal to the unmetallated ligands or benzo-18-crown-6 ether. In contrast, the monocationic Mn^{III} derivatives are very efficient carriers in the facilitated transport of tryptophan and serotonin. In these carriers the counterions that can also coordinate to the Mn^{III} ion inhibit transport and the inhibition is roughly correlated to the magnitude of interaction, which is also reflected in the extent of ionic dissociation as determined by equivalent conductance measurements.

The kinetics of tryptophan and serotonin transport are first order in both substrate and carrier. The transport by equimolar mixtures of the individual interacting units (the Mn^{III} complex of the tetra-*tert*-butylsalphenveratrole tetradentate ligand and the benzo-18-crown-6 cyclic ether) shows some synergism. The two units, when covalently bound in the ditopic receptors, are considerably more effective and show ditopic cooperativity, which is moderate for tryptophan and considerably better for serotonin. The results correlate with molecular mechanics calculations and the relative energies associated with the optimized host-guest structures. The slower rate of serotonin transport is attributed to its greater hydrophilicity relative to tryptophan. Tritopic carriers that consist of two hydrophobic salphen units on either side of a dibenzo-18-crown-6 ether bridging unit are not efficient in the transport of tryptophan. This result, and the poor transport properties of the Mn-veratrole complex, have been rationalized in terms of either the blocking or unavailability of the crown ether unit in both of these ineffective carriers.

It is suggested that the interface-invading ability of the sterically unencumbered crown ether in the ditopic carriers lowers the kinetic barrier to interphase transport. The latter is thermodynamically driven by the concentration gradient between the source and receiving phase. The catalytic effect of the crown ether appendage is also apparent in the transport properties of ditopic carriers when alkali metal ions are present. In the latter case, transport is inhibited as the RNH_3^+ group of the tryptophan zwitterion competes with the alkali metal cations and does not have free access to the water-invading crown ether.

Experimental Section

General Remarks: Chemicals/Instrumentation

Details regarding the acquisition and purification of the solvents and reagents used, along with details regarding instruments used and spectroscopic techniques and methods can be found in the Supporting Information.

Synthesis

1,2-Dimethoxy-4,5-dinitrobenzene (1): A modified procedure of Frisch and Bogert[55] for the nitration of 1,2-dimethoxybenzene was carried out and the compound was obtained in 80% yield.[56]

1,2-Diamino-4,5-dimethoxybenzene (2): The reduction of 1,2-dimethoxy-4,5-dinitrobenzene was performed as reported by Weinberger and Day[57] and the product was obtained in 75% yield.

***N,N′*-4,5-Dimethoxybenzenebis(3,5-di-*tert*-butylsalicylideneimine), *t*Bu$_4$Veratrole (3):** Under an inert atmosphere, compound **2** (1.70 g, 10 mmol) was dissolved in MeOH (70 mL) to give a colorless solution. A solution of 3,5-di-*tert*-butylsalicylaldehyde (4.77 g, 20 mmol) in MeOH (50 mL) was added and the resulting bright yellow solution was refluxed for 18 hours. Upon cooling the product precipitated as a yellow crystalline material. The solid was collected by filtration in air and dried overnight under vacuum. Yield 4.2 g (70%).[56]

Nickel(II) *N,N′*-4,5-Dimethoxybenzenebis(3,5-di-*tert*-butylsalicylideneimine), *t*Bu$_4$NiVeratrole (4): Ligand **3** (3.00 g, 5 mmol) was dissolved in $CHCl_3$ (100 mL). Nickel acetate tetrahydrate (1.25 g, 5 mmol) was dissolved in 40 mL of methanol. This solution was slowly added to the solution of **3**. A bright red or orange powder precipitated immediately. Stirring was continued for one hour. The precipitate was collected by filtration, washed with EtOH (10 mL), and dried under vacuum overnight to yield an orange-red powder. Yield 2.96 g (90%). − $C_{38}H_{52}N_2NiO_4$ (659.55): calcd. C 69.41, H 7.66, N 4.26, Ni 8.93; found C 69.65, H 7.57, N 4.17, Ni 8.04. − UV/Vis (CH_2Cl_2): λ (ε × 10^{-3} м$^{-1}$ cm^{-1}) = 496 nm (br, 14.6), 466 (sh, 12.1), 404 (sh, 27.0), 386 (42.1), 371 (sh, 29.1), 298 (25.2), 266 (55.5). − IR (CsI): $\tilde{\nu}$ = 1614 cm^{-1} (vs, C=N), 383 (s). − ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 7.99 (s, 2 H), 7.39 (d, 2 H), 7.26 (d, 2 H), 7.11 (d, 2 H), 4.00 (s, 6 H), 1.47 (s, 18 H), 1.32 (s, 18 H). − ^{13}C NMR (300 MHz, CD_2Cl_2): δ = 97.7, 120, 127, 131, 137, 138, 141, 150, 154, 164.

Manganese(III) *N,N′*-4,5-Dimethoxybenzenebis(3,5-di-*tert*-butylsalicylideneimine)X, *t*Bu$_4$MnVeratroleX [X = Cl (5) or I (6)]: A procedure similar to that described for the synthesis of **4** above was followed for the synthesis of **5** and **6**.[56]

4,5-Dinitrobenzo-18-crown-6 (7): Solid benzo-18-crown-6 (5 g, 16.0 mmol) was added slowly over thirty minutes to concentrated nitric acid (150 mL) with stirring. $CHCl_3$ (100 mL) was added to the yellow solution and the two layers were stirred for seven days. After this time the acid was diluted with an equal volume of distilled water. The product was extracted with chloroform (3 × 100 mL). The chloroform was evaporated to dryness leaving a yellow waxy residue. The product was used without further purification. Yield 5.5 g (85%). − ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 7.76 (s, 2 H), 4.30 (m, 4 H), 3.76 (m, 4 H), 3.58 (m, 8 H), 3.50 (s, 4 H).

4,5-Diaminobenzo-18-crown-6 (8): Compound **7** (2 g, 4.95 mmol), 5% palladium on activated carbon (1 g), and methanol (100 mL) were placed into a hydrogenation vessel. The mixture was degassed and allowed to react with hydrogen gas at 40 p.s.i. with agitation for 18 hours. The solution was filtered under Schlenk conditions through a minimal pad of celite and the clear solution was reduced to dryness by removing the solvent under reduced pressure. A pale off-white powder was obtained that readily decomposed in solution when exposed to air but was moderately stable as a solid. The solid was stored under inert atmosphere conditions. Yield 0.85 g (50%).

4,5-Bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6, *t*Bu$_4$H$_2$18-C-6 (9): Under an inert atmosphere, compound **8** (1 g, 2.91 mmol) and 3,5-di-*tert*-butylsalicylaldehyde (1.36 g, 5.82 mmol) were dissolved in methanol (50 mL). The resulting solution was refluxed under N_2 for 48 hours. The product precipitated from solution upon cooling as a yellow powder and was isolated by filtration in air. Yield 3.25 g (72%).[56]

Nickel(II) 4,5-Bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6, *t*Bu$_4$Ni18-C-6 (10): An amount of nickel acetate tetrahydrate (0.16 g, 0.65 mmol) was dissolved in MeOH (50 mL) and added to a solution of **9** (0.5 g, 0.65 mmol) in CH_2Cl_2 (50 mL) resulting in an intense red solution. The solvent was slowly evaporated to afford fibrous red crystals. Yield 0.38 g (70%).[56]

Nickel(II) 4,5-Bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6·*n*-hexylammonium chloride, *t*Bu$_4$Ni18-C-6[HexNH$_3$Cl] (11): This compound was obtained in 40% yield in a manner analogous to that used for the synthesis of **10** in the presence of hexylammonium chloride.[56] The complex crystallized from a dark red MeOH/acetone solution upon slow evaporation of acetone.

[Nickel(II) 4,5-Bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6]AX, *t*Bu$_4$Ni18-C-6(AX) [AX = KI (12); CsI (13); 1/2 CsI (14)]: AX (0.60 mmol or 0.30 mmol in the case of **14**) was dissolved in MeOH (50 mL) and added to a solution of **10** (0.5 g, 0.60 mmol) dissolved in acetone (50 mL). The intense red color remained unchanged. The compounds **12**, **13** and **14** were obtained in yields of 80%, 85% and 85%, respectively.[56]

Manganese(III) 4,5-Bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6-X, *t*Bu$_4$Mn18-C-6X [X = Cl (15); I (16); B(Ph)$_4$ (17); Acetate (18); Pivalate (19)]: Manganese(II) acetate (0.16 g, 0.65 mmol) was dissolved in MeOH (50 mL) and added to a solution of **9** (0.5 g, 0.65 mmol) in $CHCl_3$ (50 mL), resulting in a dark brown solution. An excess amount of the sodium salt of the anion (2.6 mmol) was added to provide an anionic source for the Mn^{III} center. The ethanol solution of the compound was stirred in air overnight and the solvent removed. The residue was redissolved in chloroform (50 mL) and washed with deionized water (10 × 100 mL) to remove the excess salt and any sodium coordinated by the crown ether. The complex was isolated by evaporation of the remaining solvent. Crystals of **15** were obtained by slow evaporation of an ethanol or ethyl acetate solution of the complex.[56]

15: Yield 0.74 g (80%). − $C_{46}H_{64}MnN_2O_8Cl{\cdot}CH_3CH_2OH{\cdot}H_2O$: calcd. C 62.15, H 7.82, Mn 5.92, N 3.02; found C 61.88, H 8.14, Mn 5.87, N 3.09. − UV/Vis (CH_2Cl_2): λ (ε × 10^{-3} м$^{-1}$ cm^{-1}) = 483 nm (br, 12.2), 380 (20.5), 364 (sh, 19.7), 319 (20.9), 263 (30.4); UV/Vis (MeOH): λ (ε × 10^{-3} м$^{-1}$ cm^{-1}) = 459 nm (br, 12.1), 378 (29.7), 313 (24.0), 258 (35.5). − FAB-MS (3-nitrobenzyl alcohol): *m*/*z* = 827 [M − CH_3CH_2OH − H_2O − Cl]. − IR (CsI): $\tilde{\nu}$ = 1605 (vs, C=N) cm^{-1}, 393, 359. − Magnetic moment, μ_{eff}^{corr} = 4.41 BM/mole (300 K); 4.38 (4 K).

The syntheses and spectroscopic and physical properties of **16**, **17**, **18** and **19**, obtained in 95%, 87%, 95% and 94%, respectively, were similar to those of **15**.[56]

[Manganese(III) 4,5-Bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6 chloride]AX, *t*Bu$_4$Mn18-C-6Cl(AX) [AX = K, (20); KCl (21); CsI (22); CsCl (23); 1/2 CsCl (24)]: AX (0.60 mmol or 0.30 mmol in the case of **24**) was dissolved in methanol (50 mL) and added to a methanolic solution of **15** (0.61 g, 0.60 mmol). The compounds were isolated in 90%, 92%, 85% and 88%, respectively for **20**, **21**, **22** and **23**, by slow solvent evaporation.

[Manganese(III) 4,5-Bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6 iodide]AX, *t*Bu$_4$Mn18-C-6I(AX) [AX = KI (25); CsI (26);

[a] See Table 1 for the numbering scheme of complexes. − [b] $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. − [c] $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2\}^{1/2}$, $w = 1/[\sigma^2(F_o^2) + (0.0186P)^2 + 17.3751P]$, where $P = [\mathrm{Max}(F_o^2, 0) + 2F_c^2]/3$.

1/2 CsCl (27); 1/2 CsI (28)]: The synthesis of these iodo derivatives, in high yields, was also similar to that of **20**−**24**.[56]

Copper(II) 4,5-Bis(3,5-di-*tert*-butylsalicylideneimine)benzo-18-crown-6, *t*Bu$_4$Cu18-C-6 (29): This compound was obtained from copper acetate in a manner similar to that described for the synthesis of **10**.

4,4′,5,5′-Tetranitrodibenzo-18-crown-6 (30): Solid dibenzo-18-crown-6 (5 g, 13.9 mmol) was added slowly over thirty minutes to 150 mL of concentrated nitric acid and the mixture was stirred until all remaining solids dissolved. The orange solution was then poured over one liter of ice and a yellow solid precipitated. The solid was collected by filtration, washed with deionized water (100 mL), saturated sodium bicarbonate solution until there was no further CO_2 evolution, and then deionized water (3 × 100 mL). The yellow powder was allowed to air dry. Yield 7.2 g (96%). − ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 7.73 (s, 4 H), 4.29 (unresolved, 8 H), 3.83 (unresolved, 8 H). − ^{13}C NMR (300 MHz, [D$_6$]DMSO): δ = 150.9 (4 C), 135.8 (4 C), 108.2 (4 C) 69.1 (4 C), 68.2 (4 C).

4,4′,5,5′-Tetraaminodibenzo-18-crown-6, (31): Compound **30** (2 g, 3.70 mmol) was ground to a fine powder and placed into a hydrogenation vessel along with one gram of palladium on activated carbon and distilled methanol (100 mL). The mixture was deoxygenated and allowed to react with hydrogen gas at about 40 p.s.i. with agitation for 18 hours. The solution was filtered under Schlenk conditions through a minimal pad of celite and the pale off-white filtrate was reduced to dryness with a cold trap. Compound **30** was obtained as a pale off white powder. The compound readily decomposed in solution when exposed to air, and was moderately stable as a solid. The material was handled under nitrogen and used immediately. Yield ≈50%.

4,4′,5,5′-Tetra(3,5-di-*tert*-butylsalicylideneimine)dibenzo-18-crown-6, (*t*Bu$_4$H$_2$)$_2$18-C-6 (32): Under an inert atmosphere, compound **31** (1 g, 2.38 mmol) and 3,5-di-*tert*-butylsalicylaldehyde (2.23 g, 9.52 mmol) were dissolved in methanol (50 mL). The solution was refluxed with stirring under N_2 overnight. The product precipitated from solution upon cooling as a yellow powder and was isolated by filtration in air. Yield 2.52 g (53%); m.p. 266−268 °C.

Bis[Manganese(III) 4,4′,5,5′-tetra(3,5-di-*tert*-butylsalicylideneimine)chloride] Dibenzo-18-crown-6, (*t*Bu$_4$Mn)$_2$18-C-6 (33): Manganese(II) chloride (0.10 g, 0.80 mmol) was dissolved in methanol (50 mL) and added to a solution of **32** (0.5 g, 0.39 mmol) in dichloromethane (50 mL). The resulting yellowish-brown solution was refluxed for eighteen hours with stirring under air. The solution was evaporated to dryness and the remaining dark brown residue was dissolved in acetone (50 mL). The brown solution was filtered and methanol (30 mL) was added to the filtrate. The resulting solution was allowed to evaporate to dryness to yield dark brown crystals of **33**. These were collected by filtration and dried under vacuum. Yield 70%.[56]

X-ray Crystallographic Study

Collection and Reduction of X-ray Data: Single crystal, X-ray diffraction data were collected for complexes **11**−**15** and **27**. For structures **11**, **12**, **13**, **15**, and **27** a selected crystal was attached to a glass fiber and mounted on the Siemens SMART system for data collection at 173(2)K (Mo-K_α radiation: λ = 0.71073 Å). Data collection and analysis procedures are described in the Supporting Information for each of the structures. Crystal and refinement data are listed in Table 8. Details concerning structure solution and refinement for each of the structures reported herein have been deposited as Supporting Information.

[42] The flux values (Table) used for comparison purposes was calculated using the 24 h measurement and is expressed in mol or equivalents and dividing by: the time (in seconds), number of mol of carrier, and the area of $2.2 \times 10^{-3} m^2$. This value was then multiplied by 10^4 to give a reasonably scaled number.

[53] The program Hyperchem was used for performing mm+ calculations. We feel that the absolute values of the energies obtained for the optimized structures are rather unreliable given the lack of sophistication in these calculations. The relative values of the energies, however, can be used for comparative purposes. These are as follows: carrier with tryptophan interacting with the H_2O, 59.67 kcal/mol; carrier with tryptophan interacting with the metal, 73.3 kcal/mol; carrier with serotonin interacting with H_2O, 31.4 kcal/mol; carrier with serotonin interacting with the metal, 27.2 kcal/mol.

Dioxo- and Oxovanadium(V) Complexes of Biomimetic Hydrazone *ONO* Donor Ligands: Synthesis, Characterisation, and Reactivity

Mannar R. Maurya,*[a] Shilpa Khurana,[a] Carola Schulzke,[b] and Dieter Rehder[b]

Keywords: Vanadium / Oxo complexes / NMR spectroscopy / Hydrazones / N ligands / O ligands

The dioxovanadium(V) complexes M[VO_2(L)*solv*] (**2**, **5**, **6**) have been isolated along with dimeric, oxo-bridged monooxovanadium complexes with the formula [{VOL}$_2$μ-O] (**1**, **4**), and characterised by their spectral and thermogravimetric properties and reactivity patterns. H_2L is the hydrazone H_2{(R-sal)-iNH} [sal derives from salicylaldehyde (R = H) or *p*-Cl-salicylaldehyde (R = Cl)] or H_2hap-iNH, where hap is the *o*-hydroxyacetophenone moiety, and iNH stands for isonicotinic acid hydrazide. In the isolated potassium (M = K) complexes **2a**, **5** and **6**, *solv* is a water molecule, which was exchanged for methanol or DMSO in the respective solutions as shown by ^{51}V NMR. Treatment of the dimeric (**1** and **4**) or anionic complexes (**2a** and **5**) with H_2O_2 yielded (unstable) oxoperoxovanadium complexes K[$VO(O_2)$L] (**7**, **8**). Acidification of **1** and **4** afforded oxohydroxo complexes. When compound **2a** is dissolved in methanol, it is partly deoxygenated to form [VO(OMe)(HOMe)L] (**9**), the crystal and molecular structures of which have been determined, confirming the *ONO* binding mode of L in its enolate form.

Introduction

The coordination chemistry of vanadium with multidentate ligands has achieved a special status in the last decade because of its catalytic[1,2] and medicinal[3−5] input. Structural and/or functional models for vanadate-dependent haloperoxidases, for vanadium nitrogenases and other biologically active vanadium compounds have further stimulated vanadium coordination chemistry.[6,7] The active site structures of the vanadate-dependent haloperoxidases have been revealed by X-ray diffraction studies. Accordingly, the vanadate ion is distorted towards a trigonal pyramid, thus providing a fifth coordination site which is occupied by N^{ε} of a histidine, covalently linking the vanadate ion to the protein.[8−10] These enzymes lose their activity upon reduction or removal of vanadium; re-oxidation or reconstitution with vanadate fully restores their activity,[11] demonstrating that V^V (VO^{3+} or VO_2^+) is essential for catalytic activity. Various types of oxovanadium(V) complexes such as [VO(OR)(HOR)L],[12−16] [VO(OR)L][17,18] [{VOL}$_2$μ-O],[19−22] [VOL(DD)],[23−30] [VO_2L][29,31−42] [H_2L is an *ONO* (hydrazone, azo or Schiff base) ligand, and DD a monobasic, bidentate *OO* or *ON* donor], [VO_2-(picolinate)$_2$]$^-$,[43] and [VO_2(nitrilotriacetate)]$^{2-}$[44] have been studied in this context.

Dioxovanadium(V) complexes are commonly synthesised by the reaction of (i) vanadates with *ONO*-functional ligands in aqueous solution,[33−38] or (ii) [VO(acac)$_2$] (acacH = acetylacetone) or $VOSO_4$ with the ligands in non-aqueous or mixed solvent media followed by oxidation with O_2.[37−40] Pecoraro et al. have prepared dioxovanadium(V) complexes by the reaction of [$VO(OEt)_3$] with appropriate ligands[41] or by oxidation of oxovanadium(IV) complexes with KNO_2 in H_2O/MeOH.[42] The present series of dioxovanadium complexes containing *ONO*-functional ligands[37−42,45] is comparatively limited. We present here the preparation and characterisation of VO_2^+ complexes of *N*-isonicotinamidosalicylaldimines (aroylhydrazones; Scheme 1). These ligands possess five potential donor sites, three of which are used, namely the phenolate and enolate oxygen atoms, and the imine nitrogen atom originating from the condensation of the hydrazine and salicylaldehyde. Coordination compounds of aroylhydrazones have been reported to act as inhibitors of enzymes,[46a] and antifungal/antibacterial agents.[46b] Spectral and structural aspects, reactivity patterns of the compounds, and the crystal structure of a deoxygenation product are reported.

Results and Discussion

Synthesis and Solid-State Characteristics of Dioxovanadium Complexes

Structures of the dioxovanadium complexes **2**, **5** and **6**, based on spectroscopic data, thermogravimetric studies, elemental analyses and the X-ray diffraction analysis of **9** (the deoxygenation product of **5**) are shown in Scheme 2. The structures are formulated for the solid samples isolated as described in the Exp. Sect. As shown by ^{51}V NMR spectro-

R' = Me, R = H: **6(H_2O)**

Scheme 2

A solution of potassium vanadate(V), generated in situ by dissolving V_2O_5 in aqueous KOH, reacts with the potassium salt of the ligands H_2Rsal-iNH (Scheme 1) at pH = 7.5 to give two types of vanadium(V) complexes, namely the neutral, oxo-bridged dimeric monooxovanadium complexes [{VO(Rsal-iNH}$_2$μ-O] (**1**: R = H; **4**: R = Cl), and potassium salts of the anionic dioxovanadium complexes K[VO_2(Rsal-iNH)H_2O)] [**2a(H_2O)**: R = H; **5(H_2O)**: R = Cl]. Using $NH_4[VO_3]$ and the sodium salt of the ligands results in the formation of the corresponding ammonium salts NH_4[VO_2(Rsal-iNH)H_2O)] [**2b(H_2O)**: R = H] along with the dimers. The final pH value of the reaction mixture plays an important role in that a decrease (to pH = 6.5) increases the yield of the dimeric complex. Neutral dimeric and anionic complexes can be separated by fractional crystallisation from methanol, where the dimers crystallise first. The ligand H_2hap-iNH only yields the dioxovanadium complex K[VO_2(hap-iNH)H_2O] [**6(H_2O)**]. Complex **1** was also synthesised by allowing equimolar amounts of [$VO(acac)_2$] and H_2sal-iNH to react in acetone, followed by aerial oxidation [Equations (1) and (2)].

$$[VO(acac)_2] + H_2\text{sal-iNH} \rightarrow \underset{\mathbf{3}}{[VO(\text{sal-iNH})]} + 2\text{acacH} \quad (1)$$

$$2\underset{\mathbf{3}}{[VO(\text{sal-iNH})]} + 1/2O_2 \rightarrow \underset{\mathbf{1}}{[\{VO(\text{sal-iNH})\}_2\mu\text{-O}]} \quad (2)$$

The intermediate complex **3** can be isolated as a stable solid. Furthermore, **1** is obtained from the reaction of $VO(OEt)_3$ with H_2sal-iNH in absolute ethanol under aerobic conditions. The most probable reaction pathways for this reaction are given by Equations (3) and (4), based on the analogy of the formation of the dimeric complex [{VO(sal-L-pheala)}$_2$μ-O] (H_2sal-L-pheala = *N*-salicylidene-L-phenylalaninato) by exposure of CH_2Cl_2 solutions of [VO(OMe)(MeOH)(sal-L-pheala)] to air.[21] The underlying reaction is probably an exchange of OR by OH (from moisture), followed by condensation to form the dimeric compound.

$$VO(OEt)_3 + H_2\text{sal-iNH} \xrightarrow{\text{EtOH}} [VO(OEt)(EtOH)(\text{sal-iNH})] \quad (3)$$

$$[VO(OEt)(EtOH)(\text{sal-iNH})] \xrightarrow{(H_2O)} [\{VO(\text{sal-iNH})\}_2\mu\text{-O}] \quad (4)$$

The brown, dimeric complexes **1** and **4** are poorly soluble in methanol, ethanol, DMF and DMSO, while the yellow to yellow-orange dioxo complexes **2, 5** and **6** are soluble in all these solvents.

As shown by, inter alia, thermogravimetric analysis, **2**, **5** and **6** contain one molecule of water. Thermogravimetric data are collated in Table 1. The dioxo complexes lose water in the temperature range 90−200 °C, indicative of covalently, though not particularly strongly bonded water. This is expected if the water is coordinated in the *trans* position to one of the doubly bonded oxygen atoms (cf. Scheme 2). The remaining anhydrous complexes **2a**, **5** and **6** decompose at higher temperatures (loss of the ligand less one oxygen atom) to form potassium metavanadate $K[VO_3]$. The decomposition pattern is different for the anhydrous ammonium salt **2b**: Between 205 and 330 °C, a weight loss of 7.5% corresponding to the loss of NH_3 and H_2O occurs, possibly by the reaction sequence represented by Equations (5) and (6).

$$NH_4[VO_2(\text{sal-iNH})] \rightarrow H[VO_2(\text{sal-iNH})] + NH_3 \quad (5)$$

$$2H[VO_2(\text{sal-iNH})] \rightarrow [\{VO(\text{sal-iNH})\}_2\mu\text{-O}] + H_2O \quad (6)$$

On further heating, [{VO(sal-iNH)}$_2$μ-O] decomposes to yield V_2O_5 as the final product. The decomposition pattern of **4** is interesting because it undergoes elimination of oxy-

Table 1. Thermogravimetric analyses

Compound	Temperature range (°C)	% Weight loss obs. (calcd.)	Group lost	(Expected) residue	% Residue obs. (calcd.)
2a	100-200	5.2 (4.8)	H_2O	K[VO_2(sal-iNH)]

	255-730	71.5 (71.4)	2L − 3O	V_2O_5	26.0 (26.0)
5	90-185	4.5 (4.4)	H_2O	K[VO_2(Clsal-iNH)]	
	63.0 (62.3)		L − 1O	K[VO_3]	33.5 (33.4)
6	4.5 (4.6)		H_2O	K[VO_2(hap-iNH)]	
	61.0 (60.3)		L − 1O	K[VO_3]	34.5 (35.1)

[a] See text for additional details.

gen by the rupture of the μ-$O(VO)_2$ fragment with the concomitant thermally induced reduction of V^V to V^{IV} and the formation of **3** [Equation (7)].

$$\underset{\mathbf{1}}{[\{VO(sal\text{-}iNH)\}_2\mu\text{-}O]} \rightarrow 2\underset{\mathbf{3}}{[VO(sal\text{-}iNH)]} + 1/2O_2 \quad (7)$$

The poor stability of **3** did not allow for its isolation, in contrast to the corresponding Mo and W systems, where the intermediately formed species have been isolated and characterised.[47]

The IR spectra of the ligands exhibit bands in the regions 1678−1680 and 3100−3180 cm^{-1} due to ν(C=O) and ν(NH) stretches, respectively. These bands disappear on complexation, indicating the transformation of the carbonyl moiety owing to enolisation and consequent replacement of H by the metal ion. A new band appearing in the 1210−1250 cm^{-1} region was assigned to the ν(C−O) (enolato) mode. The ν(C=N) (azomethine) stretch of the ligands appears at 1609−1629 cm^{-1}, and this band is shifted to a lower wavenumber by 10−15 cm^{-1} in the complexes, thereby indicating the coordination of the azomethine nitrogen atom. In the dimeric complexes **1** and **4**, this band is doubled, suggesting a nonequivalence of the two halves of the molecule, e.g. because of an asymmetric bridge. A ligand band at 900−1000 cm^{-1} due to the ν(N−N) stretch undergoes a 10−40 cm^{-1} shift to a higher wavenumber upon complexation. The high frequency shift of the ν(N−N) band is expected because of diminished repulsion between the lone pairs of adjacent nitrogen atoms.[48] A broad band for the ligands at approximately 2800 cm^{-1} was assigned to intramolecular hydrogen bonds involving the phenolic OH group; the absence of this band in the dioxo complexes indicates the deprotonation of the phenol and subsequent coordination of the oxygen atom to the metal centre. However, the presence of a broad band at approximately 3400 cm^{-1} is possibly due to coordinated water in these complexes. The dimeric complexes exhibit weak combination bands covering the region 2300−2700 cm^{-1}. This again suggests extensive intermolecular hydrogen bonding in the complexes.

All dioxovanadium(V) complexes exhibit two sharp bands in the 900−950 cm^{-1} region, indicative of the *cis*-$\{VO_2\}^+$ structural unit. In the dimeric complexes, two sharp bands arise at ca. 960 cm^{-1}, assigned to ν(V=O), and a broad band is observed at ca. 860 cm^{-1} due to ν[V−(μ-O)−V]. The presence of two ν(V=O) in the dimers **1** and **4** supports the nonequivalence of the two oxo-bridged halves[22] already noted above.

Solution Studies

The electronic absorption spectra of all the ligands and complexes were recorded in methanol, and the absorption maxima with their extinction coefficients (wherever possible) are listed in Table 2. The UV spectra of the ligands exhibit three spectral bands at 214.5−219.5, 284−289.5 and 330−342 nm. The most probable assignments for these bands are $\Phi \rightarrow \Phi^*$, $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions, respectively. A weak shoulder associated with the second band, due to hydrogen bonding and association, is absent in the dioxo complexes. This indicates that the hydrogen bonds are broken after complex formation. In dimeric complexes, however, this band is still present, therefore indicating the existence of hydrogen bonding in solution as well. Other intra-ligand bands are still present in the complexes, with significant shifts in the band positions towards lower wavelengths. Dioxovanadium(V) complexes have a $3d^0$ configuration, and d−d bands are therefore not expected. All the complexes display an intense to medium electronic spectral band in the visible region at 403−410 nm. This was assigned to a ligand-to-metal charge-transfer (LMCT) transition from the phenolate oxygen atom to an empty d-orbital of the vanadium atom.

Table 2. Electron absorption spectra

Further evidence for the coordination mode of the ligands was obtained from the ^1H and ^{13}C NMR spectra. The relevant spectral data are collected in Tables 3 and 4. They confirm the IR and UV/Vis evidence. A significant downfield shift of the azomethine (−CH=N−) proton signal in the complexes relative to the corresponding free ligands demonstrates the coordination of the azomethine nitrogen atom. In the ^1H NMR spectrum of the complexes, the absence of the ligand signals arising from the phenolic −OH and the hydrazone −NH protons in the δ = 11.08−13.19 region further indicates that bonding occurs through the phenolate and enolate groups. The methyl protons of H_2hap-iNH resonate at δ = 3.36, and this signal

[a] Letters given in parentheses indicate the signal structure: s = singlet, d = doublet, t = triplet, dd = doublet of doublets, td = triplet of doublets, m = multiplet, br = broad (unresolved). – [b] ($\Delta\delta$) = δ(complex) – δ(ligand). – [c] Methyl proton signals at δ = 3.36. – [d] Methyl proton signals at δ = 3.14 and 3.16.

appears as two independent signals of equal intensity at δ = 3.14 and 3.16 for complex **6**. Aromatic protons appear in the expected regions in spectra of the ligands as well as of the complexes, with slight shifts in their positions. All these data are consistent with what has previously been observed in dioxo molybdenum(VI)[49] and dioxotungsten(VI)[50] complexes with these ligands, and supports their dibasic tridentate *ONO* coordination mode.

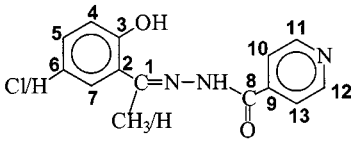
^{13}C NMR spectra (Table 4 and Figure 1) also provide useful diagnostic tools for the elucidation of the structures of the complexes. Assignments were based on the chemical shift and intensity patterns, and on the coordination-induced shifts $\Delta\delta$ = [δ(complex) – δ(free ligand)] of the signals for carbon atoms in the vicinity of the coordinating functions.[51] Large coordination shifts were observed for the carbon atoms bearing the phenolate and enolate oxygen atoms (C3 and C8) and for the azomethine carbon atom (C1). The ^{13}C NMR spectra of the dimeric, neutral complexes are nearly identical to those of the anionic dioxo complexes. The nonequivalence of the two halves of the molecules in solutions of dimers **1** and **4** is reflected in a broadening of the respective resonances. The solubility of the ammonium complex **2b** is too low to obtain high quality spectra. The spectral pattern of **2b** is, however, identical to that of the potassium salts **2a** and **5**. Heating the solutions to improve the solubility, causes slow demetallation of the complexes.

To further characterise the complexes, we recorded ^{51}V NMR spectra; δ(^{51}V) values of specific compounds are presented in the Exp. Sect. Owing to the quadrupole moment (spin 7/2) of the ^{51}V nucleus, the resonances are somewhat broadened; the line widths at half-height are typically approximately 200 Hz, which is still relatively narrow in ^{51}V NMR spectroscopy.[52] The dioxovanadium complexes **2**, **5** and **6** all show one strong resonance between δ = –530 and –550, which is what one would expect for a dioxovanadium complex containing a mixed *O*/*N* donor set.[52,53] For **2** and **5**, there is a distinct solvent dependence: In [D_6]DMSO, the signal appears at δ = –532, in methanol between δ = –539 and –541, and in deuterated methanol (CD_3OD) at δ = –549, hinting at participation of the solvent in coordination. The solvent dependence is less pronounced for **6** (δ = –533 and –538 in [D_6]DMSO and CD_3OD, respectively), which may be explained by steric hindrance imparted by the methyl group on the azomethine carbon atom, preventing effective binding of the solvent to the sixth coordination site. The approximately 10 ppm upfield shift of the signals in deuterated with respect to nondeuterated methanol can be traced back to a deuterium isotope effect $^n\Delta^D$ through two bonds ($DOCD_3$) plus three bonds ($DOCD_3$), [($^2\Delta$ + $3^3\Delta$)^D]: The heavier isotope gives rise to a more pronounced shielding of the metal nucleus as a consequence of a diminished paramagnetic deshielding term in the overall shielding.[52a]

Reactivity Patterns of 1 to 6, and the Structure of 9

cis-Dioxovanadium(V) complexes commonly generate oxomonoperoxo species in solution on treatment with

Table 4. ^{13}C NMR chemical shifts; for atom labelling see scheme below



Compound	C1	C8	C3	C9	C11, C12	C10, C13	C2, C4, C5, C6, C7

[a] Δδ = δ(complex) − δ(free ligand). − [b] Methyl carbon signal at δ = 14.30. − [c] Methyl carbon signal at δ = 16.95.

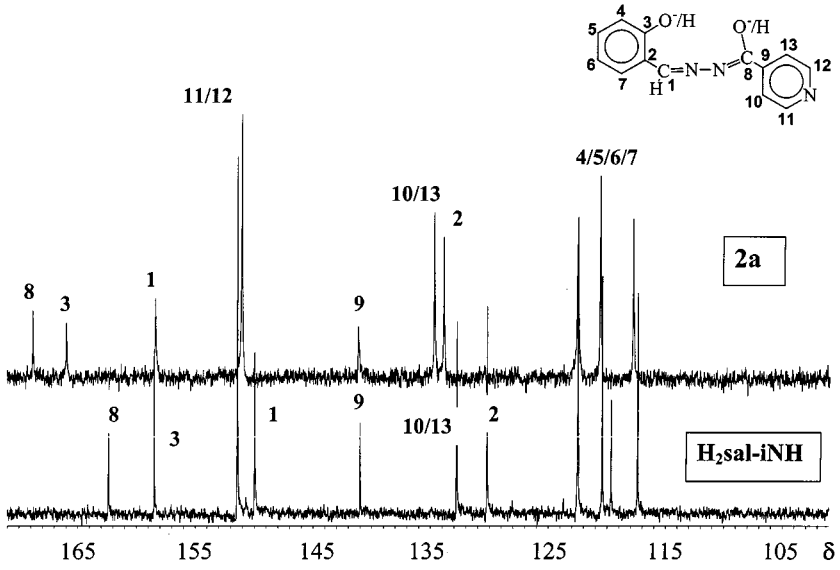

Figure 1. 90.56 MHz $^{13}C\{^1H\}$ NMR spectra of H_2sal-iNH (below) and its dioxovanadium complex **2a** in [D_6]DMSO (above); the inset shows the enol(ate) form of the ligand

H_2O_2,[14,54,55] and a corresponding reaction was also accomplished with **2a** and **5** with 30% H_2O_2 in methanol in an ice bath to yield **7** and **8** [cf. Equations (8) and (9)], which can also be obtained from the dimeric compounds **1** and **4.** The reaction, as monitored by electron absorption spectroscopy (Figure 2), exhibits an increase in intensity and shift of the band at 402.5 nm for **1** to 412 nm for **7**. Correspondingly, the 403.5 nm band of **2a** is shifted to 410 nm. This new band remains constant for several hours at approximately 10 °C. The rate at which peroxo complex formation occurs, seems to be dependent on the amount of H_2O_2 added. In both cases, the bands of the starting products at 322 and 226 nm remain almost unchanged, while the band at 279 nm gradually disappears. A similar spectral pattern was observed for **8**, in which these bands appear at 410, 322 and 225 nm. The relative stability of the peroxo

species at approximately 10 °C in the presence of excess of H_2O_2 enabled us to isolate complexes **7** and **8** (see Exp. Sect.), which showed a UV/Vis spectrum similar to that observed during spectroscopic studies. The peroxo complexes **7** and **8** show three IR-active modes associated with the $\{V(O_2)\}^{2+}$ moiety, namely the symmetric $V(O_2)$ stretch (ν_2) at ca. 580 cm^{-1}, the antisymmetric $V(O_2)$ (ν_3) at ca. 740 cm^{-1}, and the O−O (ν_1) stretch at ca. 895 cm^{-1}, characteristic of η^2-coordination of the peroxo group.[56] In addition, complexes **7** and **8** display the ν(V=O) mode at 950 (**7**) and 954 cm^{-1} (**8**). The isolated peroxo complexes are unstable and lose oxygen even at ambient temperature within a day. The species obtained in this way have spectral patterns (IR as well as electronic) similar to those of the dimers. The overall reaction may thus be represented as shown by the coupled (through **7**) [Equations (8) and (9)].

$$\underset{\mathbf{2a}}{[VO_2(\text{sal-iNH})]^-} + H_2O_2 \leftrightarrows \underset{\mathbf{7}}{[VO(O_2)(\text{sal-iNH})]^-} + H_2O \quad (8)$$

$$2\underset{\mathbf{7}}{[VO(O_2)(\text{sal-iNH})]^-} + 2H^+ \leftrightarrows \underset{\mathbf{1}}{[\{VO(\text{sal-iNH})\}_2\mu\text{-O}]} + H_2O_2 + \tfrac{1}{2}\,O_2 \quad (9)$$

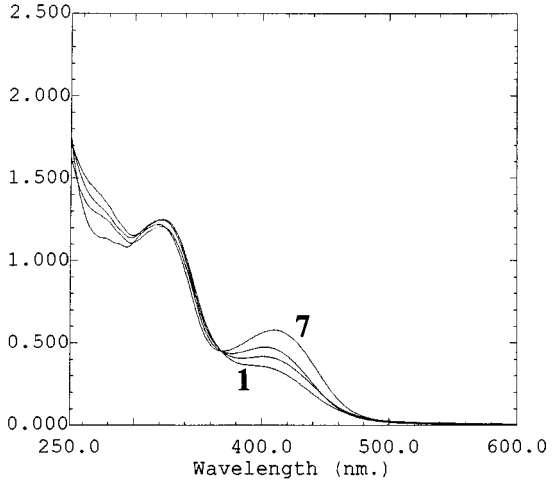

Figure 2. Titration of $[\{VO(\text{sal-iNH})\}_2\mu\text{-O}]$ (**1**) with 30% H_2O_2; the spectra were recorded after the successive addition of 2-drop portions of H_2O_2 to 5 mL of ca. 10^{-4} M solutions of **1** in MeOH

At ambient temperature, the ^{51}V NMR spectrum of **1** after addition of H_2O_2 in CD_3OD showed five resonances at δ = −616, −658, −678, −687 and −692. All these resonances are further upfield than those of the starting products and should indicate the formation of peroxo species.[57] The signal at δ = −692 corresponds to the diperoxovanadate $[VO(O_2)_2OH]^{2-}$, which is formed by partial decomposition of the peroxo complex.[58]

A solution of dimers **1** and **4** in methanol was treated with methanolic KOH at pH ≈ 8.5 and stirred for 1−2 h to provide $K[VO_2L(H_2O)]$-type complexes. The reaction is reversible, i.e. treatment of the monomeric complexes **2a** and **5** with HCl in methanol at pH ≈ 6.5 provides $[\{VOL\}_2\mu\text{-O}]$.

Addition of methanol *saturated* with HCl gas to a methanolic solution of **4** results in a colour change from orange-red to dark red with a gradual shift of the bands at 321.5 and 408.5 nm to 337 and 428 nm, respectively, as illustrated in Figure 3a. A similar behaviour has also been observed for **1**; the bands at 322 and 402.5 nm gradually shifted to 341 and 425 nm on acidification. Based on literature reports[42,59] on similar reactions, the species formed on acidification is most probably $[VO(OH)(\text{Clsal-iNH})H_2O]$. A hydroxooxo complex, viz. $[VO(OH)(HL)]^+$, H_2L = *N*-[(*o*-hydroxyphenyl)methyl]-*N*′-(2-hydroxyethyl)ethylenediamine, has been generated by Pecoraro et al.[33] in solution from the respective dioxovanadium(V) dimer, and the hydroxovanadium(IV) complex $[TpVO(OH)(H_2O)]$ [Tp = tris(pyrazolyl)borate] has recently been structurally characterised.[60] The formation of a hydroxo complex is further corroborated by an upfield shift of the ^{51}V NMR resonance from $\delta(^{51}V) = -533$ for **4** to δ = −554 for the species formed on acidification. The dependence of the ^{51}V shielding on protonation is well documented for vanadates(V)[57] and peroxovanadates.[57a,61] IR and electronic spectra of the compound isolated from the solution under study match well with those of **4**, indicating that on isolation, deprotonation and recovery of the starting material occurs. The reversibility of the reaction is also pertinent in solution (Figure 3b), when the acidified solution is treated with KOH dissolved in methanol. These results are of some interest in the context of the active-site structure and the function of vanadate-dependent haloperoxidases, for which a hydroxo ligand in an apical position has been noted on the basis of X-ray diffraction data[8−10] and proposed as an intermediate on the basis of kinetic studies.[42] Interestingly, no isosbestic points were observed during the progress of the reaction, which indicates complete conversion of $[(VOL)_2\mu\text{-O}]$ into the new species. A further increase in the HCl concentration does not cause changes in the LMCT band positions; excess HCl finally results in decomposition.

The formation of the neutral, monomeric monooxovanadium complex $[VO(OMe)(HOMe)(\text{Clsal-iNH})]$ (**9**) from the dioxo complex **5** by exposing methanolic solutions to low temperatures for a couple of weeks is of interest in the context of oxovanadium complexes used as oxo-transfer reagents both in catalytic and stoichiometric oxygenation reactions.[62,63] We have not been able to isolate bulk amounts of **9**; the predominant species in the mother liquor remains **5**, suggesting an equilibrium of the kind shown in Equation (10), from which **9** is gradually removed by crystallisation. The presence of small amounts of **9** in solution is also indicated by ^{51}V NMR (minor signal at −543).

$$\underset{\mathbf{5}}{K[VO_2(\text{Clsal-iNH})]} + 2\text{MeOH} \leftrightarrows \underset{\mathbf{9}}{[VO(OMe)(HOMe)(\text{Clsal-iNH})]} + \text{KOH} \quad (10)$$

Figure 4 shows an ORTEP drawing of the molecule, and a section from the unit cell of **9**, and Table 5 contains selected structure parameters. The basic structure is that of a tetragonal pyramid with the doubly bonded oxygen atom in the apex, and the phenolate and enolate oxygen atoms O2 and O3, the methoxide oxygen atom O4 and the imine nitrogen atom N1 in the plane. The vanadium atom devi-

N2-C8	1.309(3)	N1-N2-C8	108.0(2)

ates from this plane by 0.23 Å. The position *trans* to the oxo group is occupied by a weakly bonded methanol molecule [V−O5 = 2.327(2) Å]. The elongation of this bond is due to the strong *trans* influence of the oxo group and has previously been observed in other complexes containing the {VO(*ONO*)HOR}[12−16,29] or {VO(*ONO*)H_2O}[64] moieties. The other bond lengths *d* are similar to those observed in similar complexes;[12,25,28,29] the distances *d*(O3−C8) [1.300(3) Å] and *d*(N2−C8) [1.309(3) Å] support the enolate mode of coordination. With 175.84(9)°, the O=V−(HOMe) axis is almost linear. In the tetragonal plane, the two "open" angles O2−V−O4 and O3−V−O4 amount to 101.7 and 95.4°, while the bite angles of the tridentate ligand are 74.2° for the 5-membered ring, and 83.3° for the 6-membered ring. The ligand system is practically planar. The only angle that deviates significantly from sp^2 planarity is the angle of 108.0(2)° at the (noncoordinating) N2. This nitrogen atom is involved in intermolecular hydrogen bonding to the proton of the coordinated methanol, as shown in Figure 4, bottom; the N2···H−O5 distance amounts to 2.87 Å.

Conclusion

Oxovanadium(V) complexes show in vitro and in vivo activity in oxidation and oxygen-transfer reactions.[62,65] In the native systems (vanadate-dependent haloperoxidases) which have also been shown to exhibit oxo-transferase activity,[66] vanadium is in an O_4N-coordination environment. Intermediates formed during catalytic turnover, containing protonated {VO_2} [{VO(OH)}, {VO(H_2O)}] and {VO(O_2)}

cores have been postulated.[42,62,67,68] The dioxovanadium compounds described here model the active site in vanadate-dependent haloperoxidases in that they contain an O_4N-donor set (as well as a weakly bonded water molecule), including a doubly bonded oxo group which can be protonated to form a hydroxooxo complex, or replaced by peroxide to form an oxoperoxo complex. Furthermore, the ability of vanadium compounds to transfer oxo groups is modelled by the formation of a structurally characterised monooxo complex [VO(OMe)(HOMe)L] (**9**) by deoxygenation of the dioxo complex K[VO_2L(HOMe)] [**2a(MeOH)**].

Experimental Section

General Remarks: V_2O_5, NH_4VO_3, salicylaldehyde (sal), isonicotinic acid hydrazide (iNH) and *o*-hydroxyacetophenone (hap) were purchased from Loba Chemie, India. 5-Chlorosalicylaldehyde was prepared according to a literature procedure.[69] H_2sal-iNH,[70a] H_2Clsal-iNH,[70a] H_2hap-iNH[70b] (cf. Scheme 1) and [VO(acac)$_2$][71] were prepared as described previously. − Elemental analyses were carried out by the Central Drug Research Institute, Lucknow, India. − IR spectra were recorded as KBr pellets with a Perkin−Elmer model 1600 FT-IR. − UV/Vis spectra (in methanol) were recorded with a UV-1601 PC UV/Vis spectrophotometer. − ^{1}H NMR spectra were obtained with a Bruker 200 MHz spectrometer, ^{13}C and ^{51}V NMR spectra with a Bruker AM 360 spectrometer at 90.56 and 94.73 MHz, respectively, in rotating 10-mm diameter vials with the common parameter settings. All δ(^{51}V) values are quoted relative to $VOCl_3$ as external standard. − Thermogravimetric analyses of the complexes were carried out on a simple manually operated thermobalance constructed in our laboratory. The instrument was calibrated using crystallised $CuSO_4 \cdot 5H_2O$. Samples were run under a dynamic air atmosphere, with a heating rate of 3 to 5 °C min^{-1}.

Crystal Structure Determination: Data were collected with a Syntex $P2_1$ diffractometer in the 2θ-scan mode using a graphite monochromator and Cu-K_α radiation. Crystal data and details of the data collection and refinement are collated in Table 6. The program systems SHELXS 86 and SHELXL 93 were used throughout.[72] The methanolic hydrogen atom (H5O on O5) was found explicitly; all other hydrogen atoms were placed into calculated positions and included with common thermal parameters in the last cycles of refinement. An absorption correction (DIFABS) was carried out. Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data centre as supplementary publication no. CCDC-148428. Copies of the data can be obtained free of charge on application to CCDC,12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.)+ 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of Complexes: For thermogravimetric analyses and UV/Vis, ^{1}H and ^{13}C NMR spectroscopic data, cf. Tables 1−4 in the Discussion; IR and ^{51}V NMR spectroscopic data are included in the Exp. Sect.

[{VO(sal-iNH)}$_2$μ-O] (1), K[VO_2(sal-iNH)H_2O] (2a) and [VO(sal-iNH)] (3): Vanadium(V) oxide (0.50 g, 5 mmol) was dissolved in aqueous KOH (0.30 g, 5 mmol in 10 mL) and stirred for 2 h. The resulting solution was filtered. A filtered solution of H_2sal-iNH (1.20 g, 5 mmol), dissolved in aqueous KOH (0.60 g, 10 mmol in 20 mL), was added to the above solution with stirring, and the pH value of the reaction mixture was slowly adjusted to 7.5 with HCl (4 M). After 2 h of stirring, the precipitated orange solid was filtered, washed with cold water followed by acetone, and dried. On recrystallisation from methanol (ca. 40 mL), **1** precipitated as a brown solid, which was filtered off and dried in vacuo over silica gel. After reducing the volume of the filtrate to ca. 10 mL and keeping it at ca. 10 °C, yellow crystalline **2a** separated within 2−4 d. This was filtered off, washed with acetone and dried as above. Yield of **1**: 256 mg (15%); **2a**: 820 mg (40%). − **Data for 1:** $C_{26}H_{18}N_6O_7V_2$ (628.4): calcd. C 49.69, H 2.87, N 13.38; found C 49.79, H 3.12, N 13.11. − IR (KBr): $\tilde{\nu}_{max}$ = 1635 cm^{-1}, 1605 (C=N), 1212 (C−O, enolic), 1045(N−N), 970, 955(V=O), 864 [V-(μ-O)−V], 477, 461, 406(V−O, V−N). − ^{51}V NMR: δ = −541 ([D$_6$]DMSO), −549 and a minor signal at −541 (CD_3OD/CH_3OH). − **Data for 2a:** $C_{13}H_{11}KN_3O_5V$ (379.3) calcd. C 41.17, H 2.90, N 11.08; found C 41.00, H 3.13, N 10.86. − IR (KBr): $\tilde{\nu}_{max}$ = 1603 (C=N) cm^{-1}, 1213 (C−O, enolic), 1025 (N−N), 928, 907 (sym and asym VO_2), 595, 405 (V−O, V−N). − ^{51}V NMR: δ = −532 ([D$_6$]DMSO), −541 and minor signal at −549 (CH_3OH/CD_3OD).

Alternative Preparation of 1: A solution of H_2sal-iNH (1.20 g, 5 mmol) in acetone (20 mL) was added with stirring to an equimolar amount of [VO(acac)$_2$], dissolved in acetone (10 mL), and the resulting yellowish green suspension was heated at reflux in a water bath for 4 h. After cooling to room temperature, a green precipitate of [VO(sal-iNH)] (**3**) was filtered off, washed with acetone and dried. Compound **3** was suspended in acetone (30 mL), and air was slowly passed through the suspension at ca. 40 °C for ca. 20 h with occasional shaking, or until the yellowish green suspension had completely disappeared and crystalline orange-red solid **1** separated instead. This was filtered, washed with acetone, recrystallised from methanol and dried. Yield (based on [VO(acac)$_2$]) 60%. For the preparation of **1**, it is not necessary to isolate intermediate **3**. − **Data for 3:** $C_{13}H_9N_3O_4V$ (322.2): calcd. C 50.99, H 2.94, N 13.73; found C 50.68, H 3.08, N 13.60. − IR (KBr): $\tilde{\nu}_{max}$ = 1606(C=N) cm^{-1}, 994(V=O). − Complex **1** was also prepared in almost the same yield from the reaction of VO(OEt)$_3$ and H_2sal-iNH in absolute ethanol under aerobic conditions: A solution of H_2sal-iNH (1.20 g, 5 mmol) in absolute ethanol (20 mL) was added to VO(OEt)$_3$ (equiv. to 5 mmol, prepared[41] in situ) in absolute ethanol (10 mL), and the reaction mixture was heated at reflux for

6 h. After reducing the volume to ca. 10 mL, the flask was kept open to air at room temp., yielding orange-red **1** within 24 h. This was filtered, washed with ethanol and dried in vacuo.

$NH_4[VO_2(sal\text{-}iNH)H_2O]$ (2b): $NH_4[VO_3]$ (0.59 g, 5 mmol) was dissolved in water (10 mL) by heating in a water bath. This solution was added to a filtered solution of H_2sal-iNH (1.20 g, 5 mmol), dissolved in aqueous NaOH (0.40 g, 10 mmol), with stirring, and the pH value was adjusted to 7.5 with HCl (4 M). After 2 h, stirring was stopped, and the orange solid, which had separated, was filtered off, washed with water, followed by acetone, and dried. The crude mass was dissolved by heating in a minimum amount of methanol, and filtered. On standing overnight at ambient temperature, brown solid **1** precipitated. This was filtered off and dried in vacuo. After reducing the filtrate to ca. 10 mL, it was kept at 10 °C for a few days, whereupon yellow crystals of **2b** separated. These were filtered off and dried in vacuo at ambient temperature. Yield of **1**: 317 mg (20%); **2b**: 808 mg (45%). − **Data for 2b:** $C_{13}H_{13}N_4O_5V$ (356.2): calcd. C 43.82, H 3.65, N 15.73; found C 43.61, H 3.83, N 15.56. − IR (KBr): $\tilde{\nu}_{max}$ = 1605 cm^{-1} (C=N), 1225 (C−O, enolic), 1063 (N−N), 946, 927 (sym and asym VO_2), 477, 463, 420 (V−O, V−N).

$[\{VO(Clsal\text{-}iNH)\}_2\mu\text{-}O]$ (4) and $K[VO_2(Clsal\text{-}iNH)H_2O]$ (5): Complexes **4** (25% yield) and **5** (40% yield) were prepared analogously to **1** and **2a**, replacing H_2sal-iNH with H_2Clsal-iNH. − **Data for 4:** $C_{26}H_{16}Cl_2N_6O_7V_2$ (646.30): calcd. C 44.77, H 2.30, N 12.05; found C 44.47, H 2.51, N 11.83. − IR (KBr): $\tilde{\nu}_{max}$ = 1625 cm^{-1}, 1602 (C=N), 1288 (C−O, enolic), 1087 (N−N), 952 (V=O), 846 [V−(μ-O)−V], 462, 427 (V−O, V−N). − ^{51}V NMR: δ = −539 ([D_6]DMSO), −548 and a minor signal at −543 (CD_3OD/CH_3OH). − **Data for 5:** $C_{13}H_{10}ClKN_3O_5V$ (413.7): calcd. C 37.73, H 2.42, N 10.16; found C 37.85, H 2.61, N 10.04. − IR (KBr): $\tilde{\nu}$ = 1607 cm^{-1} (C=N), 1288 (C−O, enolic), 1038 (N−N), 938, 904 (sym and asym VO_2), 462, 416 (V−O, V−N). − ^{51}V NMR: δ = −532 ([D_6]DMSO), −541 (CH_3OH/CD_3OD).

$K[VO_2(hap\text{-}iNH)H_2O]$ (6): The potassium salt of the ligand H_2hap-iNH was prepared in situ by treating H_2hap-iNH (1.27 g, 5 mmol) with KOH (0.60 g, 10 mmol) in water (15 mL). This solution was added dropwise to stirred aqueous potassium vanadate (5 mmol, prepared from V_2O_5 and KOH). The pH value of the reaction mixture was adjusted to 7.5 by slow addition of HCl (4 M). After 2 h, the yellow solid, which had separated, was filtered off, washed with acetone and dried in vacuo. Yield 1080 mg (55%). $-C_{14}H_{13}KN_3O_5V$ (393.3): calcd. C 42.75, H 3.30, N 10.68; found C 42.55, H, 3.63, N 10.74. − IR (KBr): $\tilde{\nu}_{max}$ = 1587 cm^{-1} (C=N), 1248 (C−O, enolic), 1058 (N−N), 943, 907 (sym and asym VO_2), 473 (V−O, V−N). − ^{51}V NMR: δ = −533 ([D_6]DMSO), −538 and a minor signal at −547 (CH_3OH/CD_3OD).

$K[VO(O_2)(sal\text{-}iNH)H_2O]$ (7) and $K[VO(O_2)(Clsal\text{-}iNH)H_2O]$ (8): $K[VO_2(sal\text{-}iNH)\cdot H_2O]$ (**2a**, 0.150 g) was dissolved in methanol (10 mL) and the clear, yellow solution was cooled with ice. H_2O_2 (30%, 4 mL) was added dropwise to the stirred solution. The resulting orange-red solution was stirred for 2 h, and the red solid **7**, which separated was filtered off, washed with cold methanol and dried in vacuo. Additional, impure peroxo complex **7** was obtained from the filtrate on cooling it overnight to 5 °C. Complex **8** was prepared similarly, using $K[VO_2(Clsal\text{-}iNH)\cdot H_2O]$ (**5**, 0.150 g) and H_2O_2 (30%, 4 mL). Satisfactory elemental analyses were not obtained owing to the instability of the peroxo complexes. Further characteristics are discussed in the text.

[VO(OMe)(HOMe)(Clsal-iNH)] (9): Crystals of **9** suitable for X-ray analysis were grown in a saturated solution of **5** in methanol, standing at 4 °C for a few weeks.

Antimony-Substituted Keggin-Type Polyoxomolybdates: Polar Crystals and Catalytic Oxidative Dehydrogenation of Alcohols

Alexander M. Khenkin,[a] Linda J. W. Shimon,[b] and Ronny Neumann*[a]

Keywords: Antimony / Polyoxometalates / Alcohols / Molybdenum / Dehydrogenations

An antimony-substituted polyoxomolybdate, $[PSb^{III}(H_2O)Mo_{11}O_{39}]^{4-}$, of the α-Keggin structure, has been synthesized. Although the molecular structure is typical, we have found from the analysis of the X-ray diffraction data that the crystal is anisotropic with alignment of the molecular units so that the substituted antimony atoms are all directed along the polar *c* axis and on the same side of the molecular unit. UV/Vis, ESR and magnetic susceptibility data support a formulation of $[PSb^{III}(H_2O)Mo_{11}O_{39}]^{4-}$ whereby there is partial electron delocalization with some formation (10–20%) of Mo^{V}. Oxidation of $[PSb^{III}(H_2O)Mo_{11}O_{39}]^{4-}$ with ozone or bromine yields the oxidized species $[PSb^{V}(O)Mo_{11}O_{39}]^{4-}$ and $[PSb^{V}(Br)Mo_{11}O_{39}]^{3-}$. In the anaerobic oxydehydrogenation of alcohols, $[PSb^{V}(O)Mo_{11}O_{39}]^{4-}$ is more active than $[PSb^{V}(Br)Mo_{11}O_{39}]^{3-}$. Catalytic aerobic oxidation of benzylic alcohols to aldehydes was also possible with no over-oxidation and formation of carboxylic acids.

Introduction

Mixtures of metal oxides containing both main group and transition metal elements are very important materials used as catalysts for heterogeneous, gas phase oxidative transformations. Such oxidative transformations include oxydehydrogenation, oxygenation and ammonoxidation reactions. Conceptually, polyoxometalates or heteropolyanions may be considered to be soluble analogs of such metal oxides and have been shown to be of general interest as catalysts for low temperature, homogeneous, liquid phase oxidation reactions.[1−6] Essentially, research carried out to date in this context can be divided into two main groups. In one research area, transition metal-substituted polyoxotungstates are used as catalysts. Here, it has been convenient to picture the catalytic process by proposing the activation of an oxidant such as iodosobenzene,[7−9] hydroperoxide,[10−18] periodate,[19−22] *N*-oxide,[23] or molecular oxygen[24−26] at the transition metal center which is "ligated" by a lacunary polyoxotungstate. In the second set of investigations, polyoxomolybdates and polyoxovanadomolybdates of the Keggin structure with high redox potentials, almost invariably $[PV_xMo_{12-x}O_{40}]^{q-}$ ($x = 0, 1, 2$), are used as catalysts. Significant applications of these compounds include their use in place of copper salts in Wacker-type reactions,[27−28] in oxydehydrogenation reactions[29−33] and most recently in the oxygenation of hydrocarbons.[34]

Since mixed metal oxides containing antimony oxide often play an important role in heterogeneous oxidation catalysis, we sought to prepare and characterize the first polyoxomolybdates of the Keggin structure substituted in the addenda position by Sb^{III} and Sb^{V} atoms. The catalytic activity of these polyoxoantinomatomolybdates was investigated and compared to the well-known polyoxovanadomolybdates. The literature that describes antimony-containing polyoxometalates is rather scant. Originally little was known about the compositions and structures of Sb^{III}-containing polyoxotungstates.[35−37] More recently, large clusters of polyoxotungstates containing Sb^{III} in the heteroatom but not addenda positions have been prepared and structurally determined.[38−39] Also, it has been shown that antimony *counter cations* have a stabilizing effect on polyoxometalates at high (>400 °C) temperatures.[40−42]

Results and Discussion

Synthesis, Structure Determination and Characterization of $[PSb^{III}(H_2O)Mo_{11}O_{39}]^{4-}$

The first approach taken to prepare phosphomolybdates with antimony substitution in the addenda position was by the classical synthesis whereby an acidified solution of molybdate, antimonate, and phosphate is extracted with diethyl ether. For example, Sb_2O_5 (5 mmol) in 50 mL concentrated HCl was refluxed until dissolution, followed by addition of Na_2HPO_4 (5 mmol in 10 mL H_2O), $Na_2MoO_4{\cdot}2H_2O$ (55 mmol in 40 mL H_2O) and 2.5 mL concentrated H_2SO_4 and heating at 90 °C for 1 h. The isolated polyoxometalate was shown by ICP-MS to contain only a very small amount of antimony with a P/Sb/Mo ratio of 1:0.04:12. Increasing the amount of Sb_2O_5 was to no avail. However, preparation of the antimony(III)- and antimony(V)-substituted phosphomolybdate is straightforward in nonaqueous media by insertion of $Sb(OAc)_3$ into the lacunary position of $[Q_4H_3PMo_{11}O_{39}]$ [$Q = (n\text{-}C_4H_9)_4N^+$], Equation (1).[43]

$$Q_4H_3PMo_{11}O_{39} + Sb(OAc)_3 \xrightarrow[CH_3CN]{} Q_4Sb(L)^{III}PMo_{11}O_{39}$$

The reaction yielded, after recrystallization, dark green prisms of $Q_4PSb^{III}(H_2O)Mo_{11}O_{39}$ which were used for X-ray diffraction measurements. The compound crystallizes in the monoclinic space group C_c (No. 9) with two molecular formula units per asymmetric unit. For details of the structural analysis, see the Experimental Section, Table 1 and Supporting Information. The polyoxoanion itself has the usual α-Keggin-type structure. For one molecule of the asymmetric unit, the central phosphate moiety was well defined whereas for the other phosphate there was disordered oxygen coordination. Also there is coordination of a simple oxygen-containing ligand (assumed to be water) at the antimony position. Generally, in most monosubstituted Keggin structures, XMW_{11}, the substituted metal atom positions are fully disordered due to the cubic crystal structure.[44] Here, the lower monoclinic symmetry has allowed us to determine that the compound crystallizes anisotropically with the antimony atoms aligned along the polar *c* axis (Figure 1). The anisotropic antimony positions originally determined from the Patterson solution were confirmed by the observation that isotropic substitution into the structure at other positions, or assuming positional disorder of the antimony atom, led to statistically significantly poorer *R* values without the addition of extra parameters. Inspection of the packing revealed the anisotropic arrangement of the molecule with respect to the polar *c* axis. Importantly, this anisotropy is observed despite the fact that the larger Sb^{III} cation (0.80 Å vs. 0.60 Å for Mo^{VI})[45] is well accommodated in the addenda position of the Keggin compound without significantly distorting the molecular structure. The average bond lengths are $Mo-O_t$ = 1.686 (range 1.65−1.74, s = 0.038), $Mo-O_c$ = 1.992 (range 1.76−2.08, s = 0.104) and $Mo-O_e$ = 1.926 (range 1.81−2.09, s = 0.091). The average bond lengths for the antimony position are $Sb-O_t$ = 1.72, $Sb-O_c$ = 1.86 and $Sb-O_e$ = 1.85 and are not statistically different from those associated with molybdenum: that is, the Sb−O bonds lengths are within one standard deviation of those of the respective Mo−O bond lengths. In the past in mono-substituted Keggin compounds, such anisotropy has been observed only in two cases. In the first example, it was observed for the $[GaPbW_{11}O_{39}]^{7-}$ compound.[46] This Keggin species has a significantly distorted structure because of the much larger size of the Pb^{2+} cation[45] (W^{VI} = 0.58 Å vs. Pb^{II} = 1.18 Å), which might explain the anisotropic crystals formed. In the second instance, alignment is attained by formation of chains in manganese- and cobalt-substituted phosphotungstates. Bonds are formed due to displacement of the labile aquo ligand of the transition metal leading to chainlike polymeric structures with molecular units bridging oxo moieties, WO_t-M.[47−48] To reiterate, in this case the structure is not distorted, nor is there indication of intermolecular bonding.

Several additional lines of evidence support the substitution of Sb^{III} into the lacunary position of the polyoxomolybdate. First, the IR spectrum of $[PSb^{III}(H_2O)Mo_{11}O_{39}]^{4-}$ (Figure 2b) is similar to that of $[PMo_{12}O_{40}]^{3-}$ and significantly different from the spectrum of the lacunary species

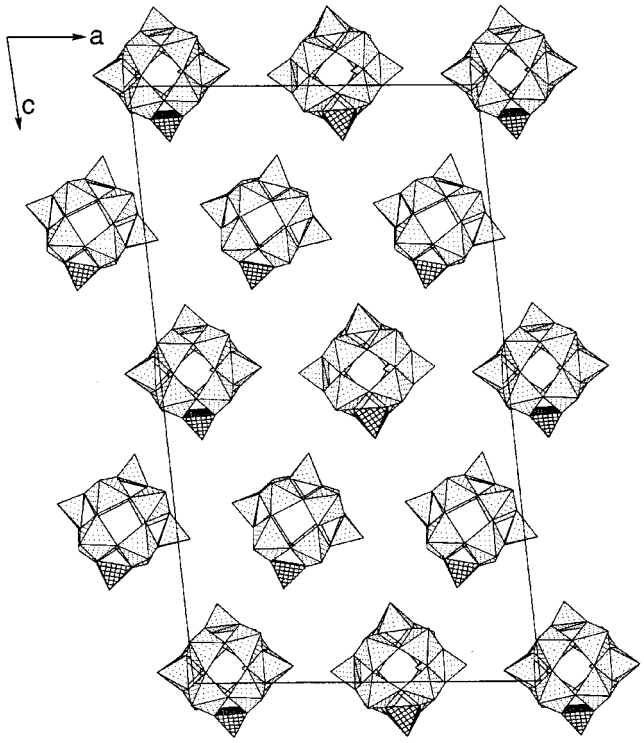

Figure 1. Structure of the inorganic sub-lattice in the *ac* plane; the Sb-containing polyhedra are hashed and the Mo-containing polyhedra are dotted

(Figure 2a). The four peak spectrum of the complete polyoxometalate is typical for Keggin structures of T_d symmetry. Second, the ^{31}P NMR spectrum of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ has a single peak at δ = −1.20, whereas the peak for the lacunary $[Q_4H_3PMo_{11}O_{39}]$ is at δ = −4.82. The cyclic voltammogram of $[PSb^{III}(H_2O)Mo_{11}O_{39}]^{4-}$ {0.5 mM $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$, 1 M QBF_4 in CH_3CN} shows a well-defined one- or two-electron Mo (VI → V) process that is very similar to that of $[PMo_{12}O_{40}]^{3-}$. No oxidation of antimony(III) to antimony(V) or reduction of antimony(V) to antimony(III) in the polyoxomolybdate was observed in the cyclic voltammograms in the interval +1.1 to −0.3 V.

We have formulated the Sb^{III}-substituted species as $[PSb^{III}(H_2O)Mo_{11}O_{39}]^{4-}$ indicating localization of the valence electrons on the antimony atom. This formulation is worthy of further comment. Thus, it is important to stress that upon addition of $Sb(OAc)_3$ to the lacunary substrate

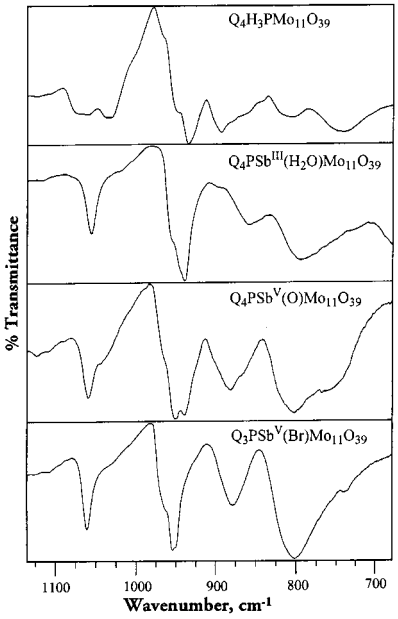

Figure 2. IR spectra of the various phosphoantimonatomolybdates

the solution became deep green, indicating reduction of the polyoxomolybdate and electron transfer (delocalization) from Sb^{III} (5s electrons) to Mo^{VI} (4d). In the UV/Vis spectrum of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ in acetonitrile the typical absorbance at ≈750 nm is observed. Importantly, however, the molar extinction coefficient ($\varepsilon = 0.17\ mM^{-1}cm^{-1}$) is one order of magnitude less than a one-electron-reduced $[PMo_{12}O_{40}]^{4-}$ ion prepared by addition of one equivalent of hydrazine to $[PMo_{12}O_{40}]^{3-}$. The intensity of the peak at ≈750 nm is a well-known measure of the degree of reduction of polyoxometalates.[49] Second, the ESR spectrum of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ in CH_3CN at 25 °C showed only a weak isotropic signal at the expected field,[50] $g = 1.937$, $A = 75$ G, which had about ≈5−10% of the intensity of $[PMo_{12}O_{40}]^{4-}$. Finally, the magnetic susceptibility was measured and found to be approximately 0.45 μ_B. A value of ≈1.8 μ_B for a d^1 state is to be expected. Our interpretation of the UV/Vis, ESR and magnetic susceptibility spectroscopic data is that upon addition of $Sb(OAc)_3$ to the lacunary species there is no electron transfer from Sb^{III} to Mo^{VI} with formation of Sb^{IV} or Sb^{V} and one or more Mo^{V} centers; rather, there is only partial electron delocalization with some formation of Mo^{V}.[51] Complete transfer of one electron and localization of an electron at a molybdenum center, i.e. formation (formally) of $[PSb^{IV}Mo^{V}Mo^{VI}_{10}O_{39}]^{4-}$, should have yielded both more intense UV/Vis and ESR spectra, and a magnetic susceptibility for a d^1 state of ≈1.8 μ_B. Since Sb^{IV} is an uncommon oxidation state, a transfer of two electrons could be contemplated to form $[PSb^{V}Mo^{V}_2Mo^{VI}_9O_{39}]^{4-}$; this, however, should have yielded a yet more intense absorbance at 750 nm and no or a weak ESR signal due to antiferromagnetic coupling.

Oxidation of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$

The Sb^{III}-substituted polyoxomolybdate can conveniently be oxidized to a Sb^{V} analog by either molecular bromine or ozone. Addition of one equivalent of Br_2 to $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ immediately forms a yellow compound. Similarly, bubbling ozone though a CH_3CN solution of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ for five minutes also yielded a yellow solution with a slight greenish tint. Both treatments gave ESR-silent compounds and appeared to be diamagnetic from the magnetic susceptibility measurements, suggesting that all the Sb^{III} atoms were oxidized to Sb^{V}. The IR spectra of the products resulting from the two treatments were somewhat different. The oxidation with bromine gave a compound whose IR spectrum (Figure 2d) was essentially unchanged from that of the original Sb^{III} compound(Figure 2b). On the other hand, treatment with ozone gave a product whose IR spectrum was slightly different (Figure 2c). Most notable is the split peak at 951 and 939 cm^{-1}. The ^{31}P NMR spectra of the two compounds are also different: treatment with Br_2 gave a compound with a peak at $\delta = -5.00$, whereas with ozone a peak at $\delta = -5.25$ was obtained. As will be discussed below, the resulting Sb^{V}-containing compounds can also be differentiated based on their activity in the stoichiometric oxidation of alcohols (Table 2). Based on the IR spectra and elementary analysis, we assume that oxidation by bromine yielded $[Q_3PSb^{V}(Br)Mo_{11}O_{39}]$while with ozone $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$was obtained according to the reaction pathways in Equation (2) and Equation (3).

$$Q_4PSb^{III}Mo_{11}O_{39} + Br_2 \longrightarrow Q_3PSb^{V}(Br)Mo_{11}O_{33} + QBr$$

$$Q_4PSb^{III}Mo_{11}O_{39} + O_3 \longrightarrow Q_4PSb^{V}(O)Mo_{11}O_{39} + O_2$$

The appearance of an additional peak in the IR spectra of $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$ at 939 cm^{-1} is most likely explained by the Sb = O_t vibration — a Sb−Br absorption would be expected at lower out-of-range energies (<400 cm^{-1}).

Anaerobic and Catalytic Aerobic Oxidation of Alcohols by Sb-POM

In Table 2 we have summarized the results for the anaerobic oxidation (under argon) of various alcohols by phosphoantimonato(V)molybdates in benzonitrile at 135 °C: primary alcohols are oxidized selectively to aldehydes and secondary alcohols to the corresponding ketones. From these results it is easy to determine that $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$ is a more active oxidant than $[Q_3PSb^{V}(Br)Mo_{11}O_{39}]$. The order of activity is benzylic > allylic ≈ cycloaliphatic > secondary aliphatic > primary aliphatic alcohols. These results indicate that the C−H bond strength determines the reactivity of the alcohol. During the reaction the yellow color of $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$ and $[Q_3PSb^{V}(Br)Mo_{11}O_{39}]$ was changed to the deep-green color of a reduced polyoxometalate. The reaction stoichiometry and the extinction coefficient measured at 750 nm indicate that a two-electron-reduced polyoxometalate was formed.

Aerobic catalytic oxidation of alcohols and other substrates by $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$ as catalyst was also invest-

Table 2. Anaerobic oxidation of alcohols by phosphoantimonato(V) molybdates

Substrate	Product	Yield of polyoxometalate[a] $[Sb(O)PMo_{11}O_{39}]^{4-}$	$[SbBrPMo_{11}O_{39}]^{3-}$
Benzyl alcohol	benzaldehyde	100 (100)[b]	100 (80)[b]
1-Phenylethanol	acetophenone	100	100
Cinnamyl alcohol	cinnamaldehyde	100	100
1-Hexanol	1-hexanal	70	0
2-Hexanol	2-hexanone	98	50
Cyclohexanol	cyclohexanonone	100 (38)[b]	85 (0)[b]
cis-2-Hexanol	*cis*-2-hexanal	100	45
trans-2-Hexanol	*trans*-2-hexanal	100	40
cis-3-Hexanol	*cis*-3-hexanal	80	15

[a] Reaction conditions: alcohol (40 mM) and polyoxometalate (5 mM) were treated with 1 mL of PhCN at 135 °C under Ar for 20 h. – [b] In acetonitrile at 80 °C.

Table 3. Aerobic oxidation catalyzed by $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$

Substrate	Product	Conversion, mol-%[a]
Benzyl alcohol	benzaldehyde	76 (5)[b]
1-Phenylethanol	acetophenone	80 (9)[c]
Cinnamyl alcohol	cinnamaldehyde	100
4-Methoxybenzyl alcohol	4-methoxybenzaldehyde	62
4-Methylbenzyl alcohol	4-methylbenzaldehyde	78
4-Nitrobenzyl alcohol	4-nitrobenzaldehyde	100 (62)[d]
Benzylamine	$PhCH_2N{=}CHPh$	40
Dihydroanthracene	anthracene	7 (62)[c]

[a] Reaction conditions: substrate (100 mM) and $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$ (1 mM) were reacted in 1 mL of PhCN at 135 °C under 2 atm. O_2 for 20 h. – [b] Catalyst: $Q_4PSb^{III}(H_2O)Mo_{11}O_{39}$. – [c] Catalyst: $Q_5PV_2Mo_{10}O_{40}$. – [d] 4-Nitrobenzyl alcohol, 300 mM.

igated (Table 3) in pressure tubes at 135 °C under two atmospheres of oxygen with PhCN as solvent. Of the alcohols tested only benzylic alcohols were oxidized in appreciable yields. Cyclohexanol, 2-hexanol, and *cis*-2-hexenol all gave less than 5 mol-% conversion in this catalytic system with $[Q_4Sb(O)PMo_{11}O_{39}]$ as catalyst. Interestingly, the electron-donating methoxy substituent reduced the yield whereas the electron-withdrawing nitro substituent increased the yield significantly (up to 186 turnovers were measured). It is notable that benzoic acids as overoxidation products were not detected under the reaction conditions. Benzylamine was also oxidatively dehydrogenated to the corresponding Schiff base imine, $PhCH{=}NCH_2Ph$, in a reaction that has been observed in the past for $[PV_2Mo_{10}O_{40}]^{5-}$. In fact, the use of the better known oxidation catalyst $[Q_5PV_2Mo_{10}O_{40}]$ gave an activity about one order of magnitude less than for the oxidation of benzylic alcohols. On the other hand, in the oxydehydrogenation of dihydroanthracene to anthracene, $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$ was significantly less active than $[Q_5PV_2Mo_{10}O_{40}]$ (7 mol-% conversion vs. 65 mol-%). Also interesting is to note that the antimony(III) compound $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ showed little catalytic activity. Finally, in a competitive oxidation of benzyl alcohol and [D_7]benzyl alcohol a kinetic isotope effect of 2.8 ± 0.1 was measured. It would be premature and presumptuous to present a mechanistic pathway for oxydehydrogenation catalyzed by $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$. However, the low kinetic isotope effect, the higher activity of 4-nitrobenzyl alcohol vs. 4-methoxybenzyl alcohol and the relative inactivity compared to $[Q_5PV_2Mo_{10}O_{40}]$ for dihydroanthracene oxidation, where mechanistic research has indicated an electron-transfer-initiated process,[33–34] all indicate that for $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$ a different mechanism is to be expected.

Experimental Section

Synthesis of $Q_4PSb^{III}(H_2O)Mo_{11}O_{39}$: $[Q_4H_3PMo_{11}O_{39}]$ (Q^+ = tetra-*n*-butylammonium cation) was prepared by the literature procedure,[43] and its purity ≈99% was determined by ^{31}P NMR, infrared and UV/Visible spectroscopic analysis. $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ was synthesized as follows: antimony(III) acetate (0.116 g, 0.39 mmol, 1.5 equiv.) was added to a solution of $Q_4H_3PMo_{11}O_{39}$ (0.7 g, 0.26 mmol) in acetonitrile (30 mL). The color slowly changed from yellow-green to deep-green. After 2 hours of stirring the reaction mixture was filtered. The solution was placed in a crystallizing dish and allowed to evaporate slowly at room temperature. The crude, deep green crystalline product was separated by filtration and recrystallized from acetonitrile to give green crystals of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ (0.6 g, 84%). $C_{64}H_{146}Mo_{11}N_6O_{40}PSb$ (2819.91): calcd. C 27.26, H 5.15, N 1.99; found C 27.45, H 5.36, N 1.72. ICP-MS ratio P:Sb:Mo = 1:1:11. The UV/Vis spectrum was measured on an HP 8452 diode array instrument. – λ_{max} (CH_3CN) = 218 nm (ε = 830 mM^{-1} cm^{-1}), 316 (ε = 18), 750 (ε = 0.17). The ^{31}P NMR was measured on a Bruker DPX 250 spectrometer at 101.254 MHz with H_3PO_4 as external standard, a single peak at δ = −1.20 was observed. The IR spectrum was measured on a Nicolet Protégé 460 with a sample deposited on a KBr disk by evaporation of an CH_3CN solution. Peaks at $\tilde{\nu}$ = 1061, 955, 862, 802 cm^{-1} were observed. Cyclic voltammetry was measured on a BAS −1 instrument fitted with a glass carbon working electrode. A 0.5 mM solution of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ in acetonitrile with 1 M QBF_4 was used for the measurements. $E_{1/2}$ = −0.14, +0.2 and an irreversible anodic wave at +0.9 V vs. SCE (similar to $Q_3PMo_{12}O_{40}$). The ESR spectra were

measured at room temperature on a Bruker ER-200 spectrometer with DPPH as reference. The spectrum of 1 mM $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ in CH_3CN at 25 °C showed a weak isotropic signal at $g = 1.937$, width 75 G. The average magnetic susceptibility was measured on a Sherwood Scientific Magnetic Susceptibility Balance as a neat powder at 22 °C. Pascal's constants were used to obtain the final diamagnetic correction. To avoid errors in our estimates of the diamagnetic correction the susceptibility of the lacunary $[Q_4H_3PMo_{11}O_{39}]$ was measured as reference. The difference between the magnetic susceptibility of $[Q_4H_3PMo_{11}O_{39}]$ and $[Q_4H_3PMo_{11}O_{39}]$ allowed us to calculate the effective magnetic moment of the delocalized blue electron[52] which was 0.45 μ_B. Slow concentration of the acetonitrile solution gave emerald-green prisms which were used for the single-crystal X-ray diffraction investigation.

Crystal Structure Determination of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$: Data were collected on dark-green prisms 0.2 × 0.2 × 0.1 mm using a Nonius−Kappa CCD diffractometer with Mo-K_α ($\lambda = 0.71073$ Å) radiation. 43215 reflections and 10857 independent reflections were collected with $-40 \le h \le 39$, $0 \le k \le 12$, $-23 \le l \le 24$, frame scan width of 1.0°, scan speed 1° per 20 sec and a typical mosaicity of 0.5°. Data were processed with Denzo−Scalepack.[53] The crystallographic data are presented in Table 1. The structure was solved by Patterson methods with SHELXS-97. Full-matrix least-squares refinement was based on F^2 with SHELX-97. Refinement proceeded to convergence by minimizing $\Sigma||F_o| - |F_c||/\Sigma|F_o|$. 1229 parameters with 580 restraints yielded a final $R = 0.0651$ for data with $I > 2\sigma(I)$ and $R = 0.0673$ for all 10857 reflections. A final difference-Fourier synthesis map showed several peaks less than 2.008 e/Å^3 scattered about the unit cell without significant features. The goodness-of-fit on F^2 was 1.062. As is common for these polyoxometalate structures the counter cations were mostly disordered and therefore also incomplete but are equally distributed throughout the cell.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149090. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Oxidation of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$: A solution of $[Q_4PSb^{V}(O)Mo_{11}O_{39}]$ was prepared by bubbling an oxygen stream (250 mL/min) containing 9 μg/mL of ozone through a 1.6 mM solution of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ in acetonitrile. After 5 min the color changed from green to yellow. UV (CH_3CN): $\lambda_{max} = 218$ nm, 302 (sh). − ^{31}P NMR: $\delta = -5.25$. − IR: $\tilde{\nu} = 1059$, 951, 939, 881 and 804 cm^{-1}. A solution of $[Q_3PSb^{V}(Br)Mo_{11}O_{39}]$ was prepared by addition of one equivalent Br_2 as a 0.4 mM solution of Br_2 in acetonitrile to a 1.6 mM solution of $[Q_4PSb^{III}(H_2O)Mo_{11}O_{39}]$ in acetonitrile. The color immediately changed from green to yellow. UV: $\lambda_{max} = 270$ nm. − ^{31}P NMR: $\delta = -5.00$. − IR: $\tilde{\nu} = 1061$, 954, 879 and 802 cm^{-1}.

Oxidation Reactions with Phosphoantimonato(V) Molybdates: Typically, oxidation reactions were carried out in 13 mL glass pressure tubes by loading the vial with the appropriate amounts of substrate, polyoxometalate and solvent. The tube was purged and loaded with the desired gas (argon or oxygen) by using three freeze, pump and thaw cycles. The reaction tube was placed in a thermostated oil bath and the mixture stirred magnetically. Aliquots were removed at the appropriate time intervals for analysis by gas chromatography. Oxidation reaction products were characterized using reference compounds, when available, by use of GLC (HP-6890 gas chromatograph) with a flame ionization detector and a 15 m × 0.32 mm 5% phenylmethylsilicone (0.25 μm coating) capillary column and helium carrier gas. Products whose initial identity was questionable were unambiguously identified using a gas chromatograph equipped with a mass-selective detector (GC-MS HP 5973) equipped with the same column.

Photochemically Induced Silicon−Carbon Bond Cleavage in a Dimethylsilyl-Bridged Dicyclopentadienyl Diruthenium Complex

Thomas Fox[a] and Peter Burger*[a]

Keywords: Cyclopentadienes / Ruthenium / IR spectroscopy / Photochemistry / Rearrangements / Thermodynamics / Density functional calculations

The synthesis and X-ray crystal structure of the novel permethylated dimethylsilyl-bridged diruthenium complex $Me_2Si[(C_5Me_4)Ru(CO)_2]_2$ **(1)** is reported. The molecular structure displays a metal–metal bond of 2.7121(4) Å, which is supported by two symmetrical μ-bridging CO groups and, in addition, two terminal carbonyl ligands. In solution, exchange of these carbonyl groups is observed, as shown by ^{13}C NMR EXSY and VT IR-measurements. It is suggested that the exchange process proceeds via the energetically disfavoured intermediate **1a**, which displays four terminal CO ligands. This view is supported by density functional calculations, which indicate a C_2-symmetrical structure for **1a**. Photochemically induced cleavage of the silicon–carbon and Ru–Ru bonds in **1** results in complex **3**, which is thermodynamically uphill from **1** according to our DFT calculations. The molecular structure of complex **3** was unambiguously confirmed by X-ray crystallography.

Introduction

Thermal or photochemical skeletal rearrangements of dicyclopentadienyl ligands in dinuclear complexes with bridging cyclopentadienyl groups have recently received significant attention.[1−5] Perhaps the most exciting result in this area is the fulvalenediyl diruthenium system recently reported by Vollhardt and co-workers.[5] These complexes undergo photochemically induced C−C bond cleavage to give *energetically less-stable* products. Since this process can be thermally reversed, it has been anticipated that these systems might be potential light energy storage systems. As part of our research into oxidation catalysis, we have considered dicyclopentadienyl-bridged ditungsten complexes with metal−metal multiple bonds.[6] Recently, we have extended our research program to include the group 8 transition metals ruthenium and osmium. In the course of these studies, we observed facile, and quantitative, photochemically induced Si−C bond cleavage in the dimethylsilyl-bridged permethylated complex $Me_2Si[(C_5Me_4)Ru(CO)_2]_2$ (**1**). While this work was in progress, Bitterwolf et al. reported similar results in the parent complex $Me_2Si[(C_5H_4)Ru(CO)_2]_2$ (**2**),[7] which was shortly followed by an alternative synthesis for **2** and a short discussion on fluxionality in the parent compound by Zhou and coworkers.[8] In this paper, we will focus on kinetic and thermodynamic aspects of the fluxional processes in the metal−metal bonded complex **1** and its photochemical Si−C bond cleavage product **3**.'

Results and Discussion

In analogy to the parent complex **2** and the methano-bridged congener $CH_2[(C_5Me_4)Ru(CO)_2]_2$ (**4**), the dinuclear complex **1** was obtained from the treatment of the permethylated dimethylsilyl-bridged ligand with 0.66 equiv. $Ru_3(CO)_{12}$ in refluxing octane [Equation (1)].[8,9]

When the reaction according to Equation (1) was carried out under rigorously oxygen-free conditions, the ^1H NMR spectrum of the crude reaction mixture displayed, along with the signals of the major product **1**, additional peaks for a C_{2v} symmetrical minor product. The most prominent resonance of the minor product was a singlet at $\delta = -10.0$ in [D$_6$]benzene, indicative of a ruthenium hydride complex. In analogy with the hydride resonance in the unbridged pentamethyl cyclopentadienyl (Cp*) compound Cp*Ru(CO)$_2$H, which displays a singlet for the Ru hydride at $\delta = -10$,[10] we tentatively assigned these resonances to the presumed initial dihydride product $SiMe_2[(C_5Me_4)Ru(CO)_2H]_2$ (**5**). Complex **5** could then convert into the final product **1** with concomitant H_2 loss. Attempts to isolate the presumed dihydride complex **5**, either exclusively or as a major product, failed. We therefore carried out the reaction with few measures to exclude O_2 (see Experimental Section for details).[11]

Initial attempts to isolate the dinuclear product **1** from the reaction mixture by chromatography proved to be cumbersome, since, on alumina (Al_2O_3, neutral, act II−III), partial decomposition to give $[(C_5Me_4H)Ru(CO)_2]_2$ (**6**), by reaction of **1** with the alumina support, was observed. The identification of complex **6** was facilitated through its diagnostic ^1H NMR resonance of the unique Cp ring proton ($C_5Me_4\mathit{H}$), observed as singlet at $\delta = 4.46$ in [D$_6$]benzene. Formation of compound **6** from **1** during this workup procedure was later confirmed when pure complex **1** was subjected to column chromatography on alumina. The isolation of **1** was, however, accomplished by sublimation at 190 °C in high vacuum, after which compound **1** was obtained as an analytically pure, orange, air-stable solid in ca. 50% yield.

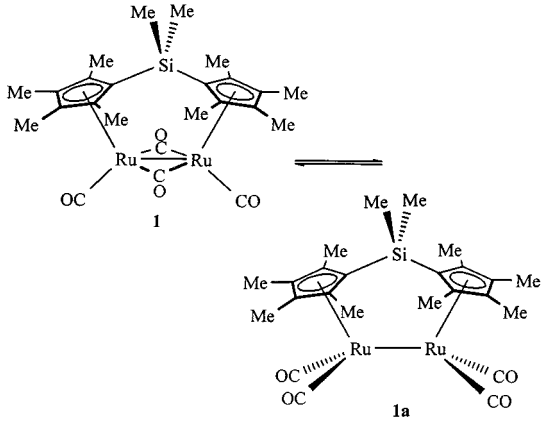
It should be noted at this point that in the X-ray crystal structure of the related parent complex $Me_2Si[(C_5H_4)Ru(CO)_2]_2$ (**2**), two bridging and two terminal CO groups were observed.[8] Differences in the solution and the IR spectra of **2** in KBr, however, suggested an equilibrium between the structure found in the solid state and another isomer, with four terminal CO groups, in solution. These results contrasted with the findings for the related methano-bridged diruthenium complex $CH_2[(C_5H_4)Ru(CO)_2]_2$ (**4**), for which four terminal CO groups were observed in the X-ray crystal structure, with just minor amounts of the corresponding bridged carbonyl complex $CH_2[(C_5H_4)Ru(\mu\text{-}CO)(CO)]_2$ in solution.[9]

The latter findings for the parent complex **2**, together with investigations by Angelici et al. into analogous CH_2- and C_2H_4-bridged complexes,[12] as well as a number of experimental and theoretical studies dedicated to the structural isomerism of CO ligands in the unbridged ruthenium and iron complexes $[CpFe,Ru(CO)_2]_2$, prompted us to look in detail at the solution structure of complex **1** and, in particular, consider the fluxional processes shown in Equation (2).[13–16] Before we address the solution behaviour of **1**, we will discuss the solid-state structure of compound **1** as observed in the single-crystal X-ray structure.



X-ray Crystal Structure of 1

The molecular structure of **1**, presented in Figure 1, illustrates that there are two types of carbonyl groups: i.e., two bridging and two terminal carbon monoxide ligands. This parallels findings from the X-ray crystal structure of the parent complex **2**. Details of data collection are summarized in Table 4; selected distances and angles are given in Table 1.

The molecule is located on a crystallographic C_2 axis passing through the Si atom and the midpoint of the Ru–Ru vector. A Ru–Ru single bond is indicated by a metal–metal distance of 2.7121(4) Å, with two symmetrical μ-bridging carbonyl groups [Ru1–C10 2.031(3), Ru1–C10A 2.032(3) Å] supporting the metal–metal bond. The metal–metal bond length is thus in the usual range observed for other cyclopentadienyl-bridged ruthenium complexes with μ-bridging carbonyl groups.[4,7,8,12] The remaining terminal CO groups [Ru1–C11 1.869(3) Å] are contained within the plane of the Ru metal centres and the centroids of the cyclopentadienyl rings. The ruthenium centres and the bridging carbonyl groups form a puckered four-membered ring, with a pucker angle of ca. 29°. A similar observation has been made for the ethano-bridged complex $C_2H_4[(C_5H_4)Ru(\mu\text{-}CO)(CO)]_2$ by Angelici et al.,[12] and has been rationalized on electronic grounds in a study by Hoffmann and co-workers.[16] From the top view of the molecular structure of complex **1** presented in Figure 1, it becomes immediately apparent that the molecular symmetry is close to idealized C_{2v} symmetry.

IR Data

In the IR spectrum of **1** in CH_2Cl_2 at room temperature, three absorptions in the ν(CO) range were detected: at 1980 (vs, terminal), 1940 (w, terminal), and 1757 (s, bridging) cm^{-1}. The band at 1757 cm^{-1} clearly demonstrates the presence of a μ-bridging carbonyl ligand consistent with the molecular structure of complex **1** observed in the solid state. Since we could detect just *two* terminal CO stretches in the terminal IR range, as would have been predicted for the μ-CO bridged complex **1**, there was initially no evidence for an additional isomer, such as the unbridged complex **1a**.

However, in the less polar solvent pentane, an additional *third* band could be observed in the terminal CO range [1992(vs), 1966(w), 1942(w)] in the IR spectrum. The presence of this additional vibration provided strong evidence for the presence of a further species, which was tentatively assigned as the isomer **1a**. In order to obtain further evidence for an exchange equilibrium between the bridging and presumed nonbridging complexes **1** and **1a**, we attempted variable temperature (VT) FT-IR measurements on **1** in pentane. Due to the quite low solubility of **1** in this solvent, however, these experiments proved to be difficult. While changes in the relative intensities of the absorptions consistent with a change in equilibrium concentrations were observed, no quantitative interpretation of the data was possible. We have therefore turned to VT NMR spectroscopic measurements on complex **1**; these are described in the following sections.

NMR Spectroscopic Analysis

The ^1H NMR spectrum of **1** in CD_2Cl_2 solution is temperature-*independent* (−95 °C to 35 °C) and displays three

sharp, well-resolved singlets for the ring methyl and dimethylsilyl groups, with a 2:2:1 integration ratio consistent with a C_{2v} symmetrical structure. In sharp contrast to this, we observed a strong temperature dependence for the ^{13}C NMR resonances of the CO ligands in **1**. At −95 °C, the 75.3 MHz ^{13}C NMR spectrum of **1** in CD_2Cl_2 solution displays two well-resolved resonances for two chemically inequivalent carbon monoxide ligands: at δ = 201.5 and 259.9, respectively. Upon warming, the ^{13}CO NMR resonances start to broaden at −85 °C and shift towards each other, until they completely disappear at −50 °C. For the Cp and dimethylsilyl groups, on the other hand, only sharp resonances with small temperature shifts were observed, which corresponds with the temperature independence of the ^1H NMR spectrum. Overall, the process was found to be completely reversible, which suggested an equilibrium between an *energetically preferred structure*, with two terminal and two bridging CO ligands (at lower temperature) as observed in the X-ray crystal structure, and an energetically *less favourable* complex with four terminal CO groups. This scenario is identical to the proposed exchange in the unsubstituted parent complex **2**.[8] In the fast-exchange regime, at higher temperatures, just one ^{13}C NMR CO resonance was therefore predicted in the time-averaged ^{13}C NMR spectrum. This was confirmed through ^{13}C NMR in $[D_{18}]$decahydronaphthalene at 100 °C and 50.3 MHz, with a single, sharp resonance at δ = 223.6 observed for the CO groups.

In order to provide unambiguous evidence for an equilibrium exchange between the terminal and bridging CO groups in complex **1**, through the intermediacy of isomer **1a** [Equation (2)], we resorted to 2D-^{13}C EXSY experiments. Thanks to the excellent solubility of **1** in CD_2Cl_2 even at low temperatures, this experiment appeared feasible for natural ^{13}C abundance in the CO ligands. From inspection of the line widths of the two chemically inequivalent ^{13}CO resonances at 75.3 MHz in the temperature range between −95 and −50 °C, a temperature of −65 °C was deemed a reasonable compromise between the line shape and exchange rate. The measurement was performed using a standard 2D EXSY pulse sequence over two days. The 2D EXSY spectrum is presented in Figure 2.

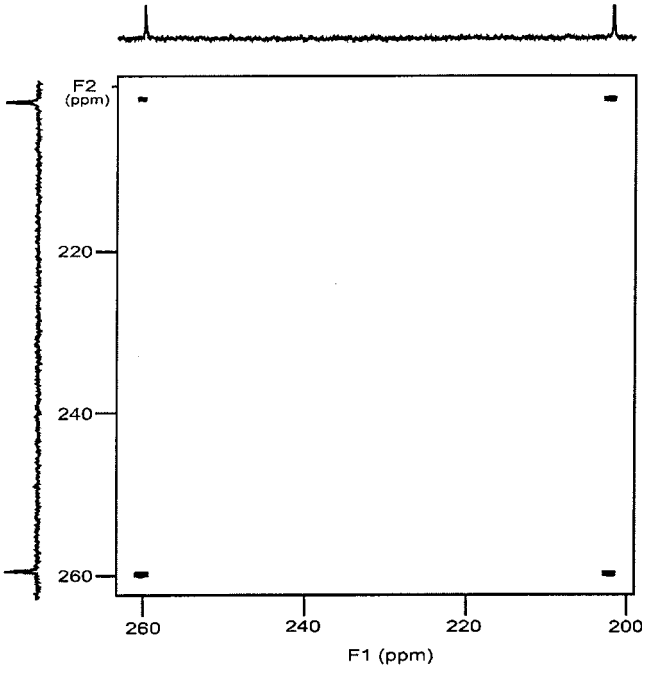

Figure 2. EXSY ^{13}C NMR spectrum (carbonyl range)

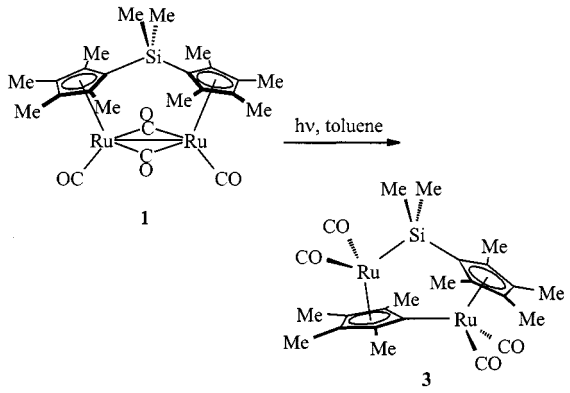
The substantial cross peaks between the two chemically inequivalent ^{13}CO resonances in the 2D EXSY spectrum provide excellent supporting evidence for the exchange of the bridging and terminal carbonyl groups, and clearly substantiate the exchange mechanism presented in Equation (2).

Subsequently, the determination of the activation parameters for the exchange process was attempted from a lineshape analysis of the temperature-dependent natural abundance ^{13}C NMR CO resonances. Unfortunately, this procedure turned out to be unreliable because of the strong dependence of the derived activation parameters on the natural line width in the slow-exchange regime, which could not be determined with sufficient accuracy. While the experimental and simulated ^{13}C NMR spectra were in excellent agreement, fits of the Eyring plot showed a large dependence on this parameter with derived $\Delta H^{\ddagger}$ values, varying by as much as 14 ± 4 kcal/mol. Further attempts to determine the rate of exchange by coalescence measurements were thwarted by difficulties in detecting the coalesced ^{13}C NMR carbonyl resonance, due to its extreme broadness. Further support for the observed exchange was therefore sought from DFT calculations, which are presented below. Prior to the discussion of these results, however, we will discuss a further reaction that was observed in the course of our investigations.

Photochemical Reaction of 1

In the course of studying photochemical CO ligand substitution reactions in **1**, we noticed the formation of a new compound in which the CO ligands had *not* been substituted. We hence studied the UV irradiation (medium pressure Hg lamp) of complex **1** by itself; i.e, in the absence of any added ligand [Equation (3)]. Conversion into the novel photochemical product **3** was also observed under these conditions and appeared to be clean (95% isolated yield) and fast. Essentially identical rates for the photochemical conversion were observed when a 1 M $NaNO_2$ solution as a UV/Vis cutoff filter (400 nm cutoff) was used in the photolysis experiments, implying that the lowest energy transition at 460 nm (broad band) in the UV/Vis spectrum of **1** in toluene is crucial to the photochemical process(es). The ^1H and ^{13}C NMR spectra of this product displayed five singlets (1:1:1:1:1 ^1H NMR integration ratio) for the methyl resonances of the Cp-methyl and the $SiMe_2$ groups and suggested a significant structural change compared to complex **1**. In the IR spectrum, the absence of bands in the expected range for μ-bridging CO groups was particularly noteworthy, and *four* bands for terminal CO groups at 2009 (vs), 1983 (vs), 1948 (vs), and 1922 (vs) cm^{-1} were observed in CH_2Cl_2 solution. The aforementioned spectroscopic data were consistent with the proposed structure for complex **3** shown in Equation (3), in which Si−C bond cleavage has occurred.



The structural assignment was unambiguously confirmed by the results of an X-ray crystal structure analysis (Figure 3). Details of data collection and selected distances and angles are summarized in Table 2 and 4.

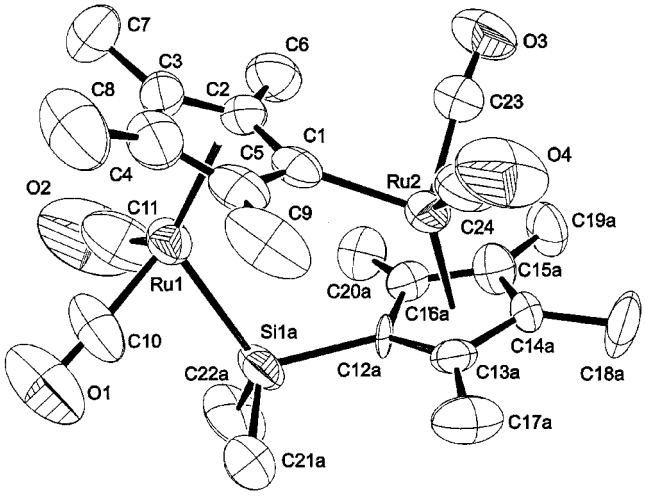


Figure 3. Ortep plot of the photochemical Si−C cleavage product, complex **3**; thermal ellipsoids are shown at the 50% probability level; only one of the disordered cyclopentadienyl rings (denoted by affix a) is shown

Since disordering of the $SiMe_2$ group and one of the attached Cp rings caused severe problems in the refinement, we will refrain from the discussion of bond angles and distances and instead briefly inspect the bond topology in complex **3**. In addition to the cleavage of the Si−C bond in the starting material, the Ru−Ru single bond observed in the starting material (complex **1**) is no longer present in the product, and new ruthenium−carbon and ruthenium−silicon bonds have been formed. There are four terminal carbonyl ligands, which explains the absence of bands in the μ-CO bridging ligand range in the IR spectrum.

Photochemical silicon-carbon cleavage in **1** parallels observations by Bitterwolf et al. in the unsubstituted parent complex **2**.[1] In the latter case, however, the reaction has been found to be more complicated, and competition between Si−C and, in addition, C−H activation of the cyclopentadienyl ring C−H group in the position *ortho* to the bridgehead atom was noticed. The apparent difference be-

tween the outcome of the photochemical reactions of complexes **1** and its unsubstituted congener **2** is best explained with a more difficult C−H activation step (higher activation barrier) at the sp^3-hybridized methyl group in **1**, as compared to the aromatic C−H group in **2**; there is ample evidence for this in the literature.[17,18] The higher barrier would thus lead to a preference for the Si−C activation step over its C−H counterpart. In an attempt to shed some light on the mechanism of this transformation, we have attempted to investigate this reaction thermally in a kinetic study. However, even under very harsh conditions (i.e. at temperatures of 180 °C and after an extended period of time), we could not detect thermal formation of the Si−C cleavage product **3**, and only unchanged starting material **1** was recovered, quantitatively. Prior to our DFT-calculations, which are detailed in the next section, we anticipated that complex **3** might not be obtained from **1** under thermal control, due to a thermally inaccessible barrier for the thermal transformation ($\Delta G^{\ddagger} > 40$ kcal/mol).

DFT Calculations

In view of the fact that complexes **1** and **3** might be interesting systems for light energy storage, we turned to DFT calculations to establish the thermodynamic preferences of this system. In addition, we wanted to assess the relative thermodynamic stabilities of the μ-CO bridged complex **1**, and its isomer **1a** with four terminal CO groups.

The molecular geometries found in the X-ray crystal structures of **1** and **3** were used as starting points for the geometry optimizations. A Becke−Perdew (BP86) functional[19,20] and TZVP basis-sets including a relativistic pseudopotential (Stuttgart−Dresden, ecp-28-mwb)[21] for the Ru centres and an SVP basis for the residual atoms were used at the initial stage in these calculations (basis I). After convergence of the optimizations at this level, TZVP-basis sets were applied for all atoms and the optimizations pursued further (basis II). Typically, this procedure required just a few optimization cycles to converge with the larger basis sets. An excellent agreement of the optimized geometries for complexes **1** and **3** with their X-ray crystal structures, with few deviations, was observed. As previously noticed in metal carbonyl complexes by others,[22,23] the unscaled calculated ν(CO) vibrational data were also in good agreement with the observed experimental IR data. The final calculated total energies are depicted graphically in Figure 4; selected calculated angles and ν(CO) vibrations of the optimized geometries, along with their experimentally determined values, are given in Table 3.

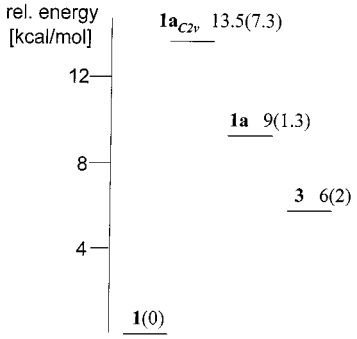

Figure 4. Relative energies of complexes **1**, **1a**, **1a$_{C2v}$**, and **3** as determined by DFT calculations using the BP86 functional; relative energies (kcal/mol) for B3LYP optimized geometries are included in parentheses (not on scale)

The results of the DFT calculations for complexes **1** and **1a** clearly provide supporting evidence for the higher thermodynamic stability of the μ-bridged carbonyl isomer **1**, with a preference of ca. 9 kcal/mol for **1**. However, on the basis of the fact that both isomers are present in comparable concentrations in pentane, as determined by IR spectroscopy, the theoretically predicted energy difference between the isomers **1** and **1a** is deemed to be too large. In view of this consideration, we have also included entropic contributions to this equilibrium; these are quite likely to be in favour of the unbridged isomer **1a**. This apparent unsatisfactory agreement may be attributed to solvation effects, which are not included in the (gas phase) calculations. It deserves special mention that strongly polar solvents were found to have a remarkable influence on the equilibrium position of such isomers.[13] However, since both isomers **1**

and **1a** are present even in the low-polarity solvent pentane, which can be quite confidently deemed compatible with the DFT calculations in the gas phase, it is suspected that the energetics of this system might not be appropriately represented by the applied BP86 functional. In addition, we have therefore performed calculations with the B3LYP hybrid functional,[24] which has been deemed to give excellent thermodynamic data not only for organic compounds but also for organometallic species. These calculations were performed with the large basis set (basis II) and the BP86-optimized geometries for the geometry optimizations. In general, the B3LYP-calculated relative energy differences (Figure 4) are appreciably smaller, while the energetic order of the isomers is unchanged. On the basis of the calculated difference of 1.3 kcal/mol between **1** and **1a**, a ca. 1:10 mixture in favour of the bridged isomer **1** would be predicted. Note that this is in good agreement with our temperature-dependent ^{13}C NMR and IR spectroscopic data.

It is worth mentioning that the geometry of the unbridged complex with four terminal CO groups (i.e. **1a**), converged at a structure that displays approximate C_2 symmetry, rather than C_{2v}. This can easily be seen from a plot along the metal-metal bond of **1a**, which is presented in Figure 5.

When the geometry optimizations were performed with C_{2v} symmetry constraints (complex $\mathbf{1a_{C2v}}$), the energy was found to lie 4.5 (BP86, 6 kcal/mol B3LYP) kcal/mol above that of **1a**. The presence of several imaginary frequencies in the range from −500 to $-64\ cm^{-1}$ nevertheless clearly showed that the optimized geometry for $\mathbf{1a_{C2v}}$ is not a stationary point (local minimum). Analysis of the latter frequencies showed that the major driving force behind the distortion to **1a** is due to the fact that it allows elongation of the $Si-C_{bridgehead}$ bond and shortening of the Ru−Ru bond. While we have no conclusive explanation for the energy differences between the two functionals, it should be noted that, in high level calculations on a nickel olefin system, an excellent agreement between these two functionals was observed, and also with calculations performed at the CASPT2 level.[25] It is noteworthy that we also observed negligible energy differences between B3LYP and BP86 functional in a related dicyclopentadienyl-bridged diruthenium system containing a CMe_2 rather than a dimethylsilyl

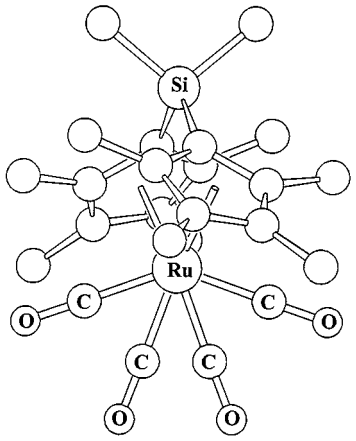

Figure 5. View along the metal−metal bond of the DFT-optimized structure of complex **1a**

bridge {i.e., $Me_2C[(C_5H_4)Ru(CO)_2]_2$}.[26] Furthermore, an inspection of the deviations between experimental and theoretical enthalpies for silicon-containing neutral compounds of the G2 test set[27] revealed large errors for both the BP86 (−7, +11 kcal/mol) and the B3LYP (−20, +3 kcal/mol) functionals, with the latter being more accurate for less-polar compounds. Hence, on the basis of these data, no clear judgement can be made as to either the appropriateness or the accuracy of these two widely applied functionals. Nevertheless, it is thought that despite the heavy usage of the B3LYP functional as the "ultima ratio" for DFT-derived energies in organometallic systems, some doubts seem appropriate and further calibration studies are definitely required.

Nevertheless, the most interesting result from the DFT calculations is the fact that the photochemically rearranged product **3** is estimated to be *6 kcal/mol less thermodynamically stable* (BP-86-functional, 2 kcal/mol for the B3LYP functional) than the metal-metal bonded starting material **1**. This view is further supported by single-point MP2 calculations (for details see Experimental Section) of the BP-86 optimized geometries **1** and **3**, which also showed a pronounced thermodynamic preference of 7 kcal/mol for complex **1** over **3**. For the unsubstituted parent complex $Me_2Si[(C_5H_4)Ru(CO)_2]_2$ (**2**), and its Si−C cleavage product **6** (the unsubstituted analogue of complex **3**), we calculate a similar thermodynamic situation, with compound **2** being energetically favoured by 6 kcal/mol (BP-86 functional, basis II). This sparked the idea that the photochemical transformation might be *reversed* thermally (**3** → **1**). We have therefore studied the thermolysis of **3** in toluene, which is described in the next section.

Thermolysis Experiments on Complex 3

The thermolysis experiments involving **3** were performed at temperatures up to 170 °C in sealed NMR tubes in [D_8]toluene and monitored by ^{1}H NMR spectroscopy. However, under these conditions thermal reconversion of complex **3** into **1** was *not* observed, even after extended reaction times (2 weeks) and at the highest possible temperatures. At present, it is therefore unclear whether large kinetic barriers account for the absence of a thermal reaction or whether the applied DFT methodology might not be accurate enough to make such predictions. However, it is especially noteworthy that we have observed an excellent agreement between experimentally determined (by DSC) energy differences and DFT calculations (within 1 kcal/mol) between constitutional isomers in the aforementioned, closely related C_1-bridged diruthenium system, $Me_2C[(C_5H_4)Ru_2(CO)_2]_2$.[26] At present, we therefore favour the notion that thermally unaccessible kinetic barriers (> 40 kcal/mol) prevent thermal reconversion of **3** to **1**.

Conclusion

The DFT calculations suggest that, in analogy to Vollhardt's fulvalenediyl diruthenium system,[5] rather inert, energetically disfavoured, photochemically rearranged products can also be obtained with other X-bridged (e.g., X = $SiMe_2$ here) dicyclopentadienyl systems. While the photochemical reaction could not be reversed for complexes **1** and **1a**, we will report on related functional systems in due course.

Experimental Section

The dimethylsilyl-bridged dicyclopentadiene ligand $Me_2Si(C_5Me_4H)_2$ was prepared according to published methods.[28] $Ru_3(CO)_{12}$ was used as received from Alfa. − ^{1}H NMR and ^{13}C NMR spectra were recorded on Varian Gemini 200 and 300 spectrometers operating at 200, 300 and 50.1, 75.4 MHz respectively. Chemical shifts are given in ppm and are referenced to the residual H solvent shift or ^{13}C NMR solvent shift. The assignment of ^{1}H NMR and ^{13}C NMR resonances is based on NOE and DEPT experiments. − IR spectra were measured on a Biorad-FTS 45 Fourier IR-spectrometer. − X-ray crystal structure analyses were performed on a STOE-IPDS image plate system with monochromated Mo-K_α (0.70713 Å) beam. − Elemental analysis were performed with a LECO CHNS-900 analyzer in our institute.

Synthesis of $SiMe_2[C_5Me_4Ru(CO)_2]_2$ (1): $SiMe_2(C_5Me_4H)_2$ (1 g, 3.33 mmol) and $Ru_3(CO)_{12}$ (1.4 g, 2.22 mmol) were refluxed for 5 days in 80 mL of *non-deoxygenated* octane. After this period, the resulting dark brown mixture was allowed to come to room temperature and the solvent removed in high vacuum. The solid residue was then sublimed at 190 °C and 10^{-2} Torr, with the product collected as an orange solid at the water-cooled sublimation finger, and finally recrystallized from CH_2Cl_2/ether at −30 °C. ***Caution:*** *The solid remainder of the sublimation is highly pyrophoric.* Yield: 1.04 g, 1.67 mmol, 50%. − ^{1}H NMR (25 °C, C_6D_6): δ = 1.93 (s, 12 H, $SiMe_2[\alpha$-$C_5Me_4]$), 1.80 (s, 12 H, $SiMe_2[\beta$-$C_5Me_4]$), 0.28 (s, 6 H, $SiMe_2[C_5Me_4]$). − ^{13}C{^{1}H} NMR (CD_2Cl_2, −65 °C): δ = 260.3(s, *C*O), 202.1 (s, *C*O) 110.6 (s, C_5Me_4), 103.8 (s, C_5Me_4), 78.9 (s, bridgehead C_5Me_4), 13.1 (s, C_5Me_4), 11.3 (s, C_5Me_4), 2.8 (s, $SiMe_2$). − $C_{10}D_{14}$, 100 °C: δ = 223.6 (s, *C*O), 110.1 (s, C_5Me_4), 105.1 (s, C_5Me_4), 79.1 (s, bridgehead C_5Me_4), 14.8 (s, C_5Me_4), 12.5 (s, C_5Me_4), 5.5 (s, $SiMe_2$). − IR (carbonyl range, CH_2Cl_2): $\tilde{\nu}$ = 1980(vs), 1940(w), 1757(s) cm^{-1}; IR (carbonyl range, KBr): $\tilde{\nu}$ = 1978(vs), 1934(w), 1768(s) cm^{-1}. − MS(EI, 70 eV): *m*/*z* (%) = 612 (100) [$M^{+\cdot}$], 584 (30) [$M^{+\cdot}$ − CO], 556 (100) [$M^{+\cdot}$ − 2 CO], 528 (100) [$M^{+\cdot}$ − 3 CO]. − $C_{24}H_{30}O_4Ru_2Si$ (612.7): calcd: C 47.05, H 4.94; found C 46.79, H 4.81.

Synthesis of Complex 3: Compound **1** (100 mg, 0.295 mmol) was dissolved in a Teflon-tap-sealed Pyrex Schlenk tube in 100 mL dry, thoroughly deoxygenated toluene, to give an orange solution. The Schlenk tube was immersed in a water bath kept at 10 °C and with the tube placed in close proximity to a medium pressure Hg lamp (HPK 125 W). An almost colourless (faintly yellowish) solution indicated the end of the photolysis reaction (usually 6 h). The solvent was removed in high vacuum and the product recrystallized from a toluene/pentane (1:1) mixture at −35 °C to give a colourless microcrystalline solid. Yield: 95 mg, 0.28 mmol, 95%. − ^{1}H NMR (25 °C, C_6D_6): δ = 2.14 (s, 6 H, C_5Me_4), 2.00 (s, 6 H, C_5Me_4), 1.88 (s, 46 H, C_5Me_4), 1.53 (s, 6 H, C_5Me_4), 0.78 (s, 6 H, $SiMe_2$). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 205.9, 203.1 (*C*O), 129.4, 110.8, 105.3 104.7, 101.1, 76.4 ($Me_2SiC_5Me_4$, RuC_5Me_4), 16.4, 12.9, 11.9, 10.4, 8.3(s, C_5Me_4, $SiMe_2$). − MS (EI, 70 eV): *m*/*z* (%) = 612 (15) [$M^{+\cdot}$],

DFT and MP2 Calculations: The applied methodology is described in the text. The DFT calculations were performed with the Turbomole program suite[29] and using the RI-J-DFT (BP-86 functional) implementation (RIDFT) for the geometry optimizations and the calculation of the second derivatives.[30] Essentially identical energy differences were obtained with the BP-86 functional using the *pure* DFT rather than the RI-J-DFT method. The parallelized version of the Turbomole program package was used on our 12 CPU Linux cluster in all cases.[31] The single-point MP2 calculations on **1** and **3** were carried out using the geometry optimized with the BP-86 functional using the basis set described below. The RI implementation of MP2 available in Turbomole was used for these calculations (RIMP2),[32] with molecular orbitals possessing eigenvalues lower than −3 Hartrees treated as frozen core (MOs 1−35 for both **1** and **1a**). Final total energies in Hartree with unscaled zero-point energies in parentheses (in kJ/mol) for the optimized geometries using a Becke−Perdew (BP86) functional (RI-DFT method), TZVP basis sets[33] for all atoms and a Stuttgart−Dresden pseudopotential (ECP-28-mwb)[21] for the ruthenium centres are: **1**: −1713.84199(1232); **1a**: −1713.83043(1232); $\mathbf{1a_{C2v}}$: −1713.82021; **3**: −1713.83285(1236). Second derivatives were obtained numerically from finite differences. Using the same basis sets and ECPs, but the hybrid functional B3LYP instead, the following total energies were obtained for optimized geometries (cartesian gradients < 10^{-3} Hartree/Bohr): **1:** −1712.59622; **1a**: −1712.59412; $\mathbf{1a_{C2v}}$: −1712.58449; **3:** −1712.59309 [Hartree]. In the latter case, the BP86 optimized geometries were used as starting geometries. The MP2 total single point energies for compounds **1** and **3** with the HF energies and MP2 energy corrections in parentheses are: **1**: −1708.47894 [−1703.30867 (HF), −5.17028 (MP2)]; **3** −1708.46803 [−1703.33175 (HF), −5.13628 (MP2)]. The total energies in Hartrees for the optimized geometries (cartesian gradients < $2{\cdot}10^{-4}$ Hartree/Bohr) using the BP-86 functional with its RI-implementation in Turbomole, TZVP basis sets for all atoms and a Stuttgart−Dresden pseudopotential for Ru (ECP-28-mwb) of the unsubstituted parent complex **2** and the Si−C cleavage product **6** derived from it (the analogue of **3**), are: **2**: −1399.21427; **6**: −1399.20464.

X-ray Crystal Structure Analyses. − General Remarks: Suitable single crystals of complexes **1** and **3** were mounted on glass fibres in Paratone-N (oil) and were transferred on the goniometer head to the diffractometer and the crystal cooled to −80 °C in a N_2 cryostream. The data sets were collected with graphite monochromated Mo-K_α radiation (0.707173 Å) on a Stoe IPDS image plate diffractometer. Intensities were corrected for Lorentz and polarization effects and absorption corrections performed numerically with the faces and corresponding crystal dimensions determined using the STOE Faceit-Video CCD camera microscope system. The structures were solved using direct methods with the SHELXS-86 program package.[34] The refinements were carried out with SHELXL-93 using all unique F_o^2.[35] Except for complex **3**, all non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were calculated in idealized positions (C−H bonds fixed at 0.96 Å) and refined as a riding model with a fixed isotropic displacement factor of U = 0.08 Å^2. The details of the data collection and refinement, including R-values, are summarized in Table 4.

Complex 3: The cyclopentadienyl ring connected to the $SiMe_2$ unit and the dimethylsilyl group itself (atoms C12A,B−C22A,B, Si1A,B) were found to be disordered and were refined with two split positions (labelled A and B) and refined with occupation factors of 0.57 and 0.43. Carbon atoms C12−C22 were refined isotropically and all other non-hydrogen atoms anisotropically.

Crystallographic data for complexes **1** and **3** (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication numbers CCDC-140425 (**1**) and -140426 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Properties of Dimetallic Complexes Based on a New Oxalamidine-Derived Ligand System with Pendant Pyridine Functionality

Jörg Wuckelt,[a] Manfred Döring,*[a] Helmar Görls,[a] and Peter Langer*[b]

Keywords: Molybdenum / Cobalt / Hydrogen bonds / Chelates / N ligands

Reaction of sterically hindered bis(imidoyl)chlorides of oxalic acid with picolylamine afforded conformationally locked oxalic acid-derived amidines with pendant pyridine functionalities. Based on this new multivalent ligand system, dimetallic complexes were efficiently prepared.

Introduction

The synthesis of dimetallic complexes, particularly those containing two different transition metals "communicating" with each other, is of considerable current interest for both theoretical and practical reasons.[1] Important properties have been postulated for these compounds, such as cooperative effects in catalysis, intramolecular electron-transfer reactions, molecular-based ferromagnetic and antiferromagnetic interactions and self-organization processes. However, the synthesis of heterodimetallic complexes is associated with severe problems, since two metals exhibiting different demands in terms of their coordination sphere have to be brought close together. Very recently, the preparation of heterodimetallic complexes has been realized using aminopyridines as bridging ligands.[2] Herein, we report an efficient synthesis of heterodimetallic complexes which relies on the use of a new multivalent ligating system.

The ability of amidinates to act as four-electron-donating, bidentate ligands for main group elements, transition metals, and the lanthanides is well established.[3] We and others have studied the coordination chemistry of oxalic acid-derived amidines which can act as four-electron-donor ligands (to give five-membered rings) or as bridging ligands.[4] Very recently, the coordination chemistry of ancillary amidinate ligands with a pendant pyridine functionality has been described by Arnold and co-workers. The metal complexes (Mg, Al, Zr, La) prepared were shown to be monomeric, with the pendant pyridine coordinated intramolecularly.[5] In most cases, the tridentate ligands coordinated meridionally to the metal centre. This work prompted us to disclose our results related to the coordination chemistry of oxalic acid-derived amidines containing pendant pyridine functionalities. The use of this new ligand system allowed the efficient synthesis of a variety of heterodimetallic diazadiene complexes.

Results and Discussion

Unfortunately, our initial attempts to prepare the desired ligands **3** by condensation of 2-aminomethylpyridine with the oxalic acid bis(imidoyl)chlorides **1a–c** (R = Tol, Ph, $MeOC_6H_4$)[4e] in the presence of triethylamine were unsuccessful, since cyclization products were exclusively obtained.[4f] The use of oxalic acid bis(imidoyl)esters, prepared by reaction of the corresponding bis(imidoyl)chlorides with ethanol, was equally disappointing and resulted in formation of complex reaction mixtures. Fortunately, the problem could be eventually solved by the use of the sterically hindered bis(imidoyl)chlorides **1d–f** [R = 2,4,6-$Me_3C_6H_2$, 2,6-$Me_2C_6H_3$, 2,6-(iPr)$_2C_6H_3$] which allowed the preparation of the desired oxalamidines **3a–c**, respectively, in good yields (Scheme 1). During the synthesis of **3c**, the cyclization product **2** was obtained as a side-product in 15% yield. The use of sterically undemanding bis(imidoyl)chlorides was possible in the reaction of 2-aminoethylpyridine with

bis(imidoyl)chlorides to give the amidines **4** (**4a**: R = Tol, **4b**: R = Ph) in good yields.

Amidines represent flexible molecules which usually undergo *E*/*Z* isomerization by a tautomeric rotation mechanism.[6a] In the case of oxalamidines, *two* imino-groups are present and rotation of the central C−C bond can give rise to *s-trans* or *s-cis* conformations.[6b] Therefore, very complex or coalescent ^{1}H NMR spectra are normally observed at room temperature due to the highly flexible structure. Interestingly, *sharp* signals and a low-field NH resonance were observed for compounds **3** which suggested that the latter are conformationally restricted by the presence of intramolecular hydrogen bonds and by the high steric demand of the substituents. Moderately broad signals were observed only for the CH_2 and the NH groups. The location of the NH group was proven by low-temperature ^{1}H NMR measurements: upon cooling to 0 °C, formation of a doublet is observed for the CH_2 groups due to a ^3J coupling of the latter with the adjacent NH group.

The structure of amidine **3a** was independently confirmed by X-ray crystallography (Figure 1). The amidine moiety is planar and shows an *s-trans*-(*Z*/*Z*) configuration. The bulky mesityl groups are twisted out-of-plane by 104.9°. It is noteworthy that the oxalamidines **3** represent rare examples of systems containing intramolecular three-centre ("bifurcated") hydrogen bonds.[7] Two hydrogen bonds (to the amidine nitrogen N1A and to the pyridine nitrogen N3) are observed for the hydrogen atom located at nitrogen N2 (N1A−H 2.18 Å, N3−H 2.41 Å). Bifurcated hydrogen bonds are of great current interest since they play an important role in DNA conformation[8] and in protein hydration.[9] Two types of three-centre interaction can be distinguished, one involving two donors and one acceptor ("HXH"), and the other involving one donor and two acceptors ("XHY"). Very recently, computational studies of a depsipeptide model have shown that addition of a second acceptor (Y) to a hydrogen bond XH has no enthalpic benefit, while addition of a second donor (H) to XH is modestly favourable enthalpically.[10]

Two conformations are, in principle, possible for oxalamidine ligands coordinated to the metal. The ligand can posses an *s-trans*- or an *s-cis* conformation. We have found that oxalamidinate complexes of molybdenum posses the *s-cis* conformation.[4c−4d,12] These compounds are thus 1,4-diazadiene complexes.[11] The reaction of dibenzyldiphenyloxalamidine with $Mo(CO)_4$(nor) resulted in rotation of the central C−C bond and coordination of the aromatic (rather than the aliphatic) imino groups to the metal to give an *s-cis*-configured DAD complex (Scheme 2).[12] The chemoselectivity can be explained by the fact that protonation of the nitrogen atom would result in interruption of the conjugation of the phenyl and the imino group. Interestingly, formation of the *s-trans*-configured complex **5** was observed in the reaction of ligand **3a** with $Mo(CO)_4$(nor) (Scheme 2). The structure of complex **5** was determined by spectroscopic means: whereas only two carbonyl absorptions (IR) are observed for $Mo(CO)_4$(nor), four absorptions are observed for complex **5**. In addition, two sets of signals are

Figure 1. Scheme 2. Synthesis of hetero-dimetallic complexes **5**−**8**

observed in the ^{1}H NMR spectrum. In the ^{13}C NMR spectrum of **5**, separate signals are detected for all carbon atoms which could be assigned to the proposed structure. All spectroscopic data indicate that complex **5** adopts an unsymmetrical structure containing an *s-trans*-configured oxalamidine unit rather than a symmetrical structure containing a *cis*-configured oxalamidine unit. The *s-trans* selectivity can be explained by the assumption that the hydrogen bond involving the pyridine nitrogen is more stable than the hydrogen bond located within the oxalamidine substructure. The 2-aminomethylpyridine subunit is planar due to intramolecular hydrogen bonding. Therefore, coordination of *two aromatic* imino groups to the metal would result in severe steric interactions. Coordination of *two* aliphatic imino groups to the metal would result in cleavage of two relatively stable pyridine hydrogen bonds. In contrast, formation of complex

5 involves a prototropic shift, cleavage of a weak hydrogen bond and formation of a strong one.

To support our hypothesis, compound **3a** was deprotonated with $NaN(SiMe_3)_2$: reaction of the sodium salt of **3a** with $Mo(CO)_4$(nor) gave the *s-cis*-configured heterodimetallic complex **6** (Scheme 2). The structure of complex **6** was independently confirmed by an X-ray structure analysis (Figure 2). The pyridine moieties are located above and below the plane of the chelate system. The mesityl substituents of the ligand are located orthogonal to each other due to steric interactions. The sodium atom is coordinated by two pyridine nitrogens, by an amidinate-derived nitrogen atom and by an oxygen atom of a neighbouring molecule. These atoms define the equatorial square plane of a distorted octahedron. The oxygen atoms of two THF molecules are located at the axial positions. The Mo−C33 bond is shorter than the other Mo−C distances due to the *trans* effect of the nitrogen N1 and the polarizing influence of the sodium ion. The C35−O3 bond is elongated (1.189 Å) and lies in the same range as normal C−O double bonds.[13]

Deprotonation of the NH group of complex **6** and subsequent reaction with one equivalent of $CoBr_2$ or $PdCl_2$ resulted in formation of the heterodimetallic complexes **7** (Mo/Co) and **8** (Mo/Pd). The spectroscopic properties of these products are very similar to those of complex **6**, which suggests that the same type of structure is adopted. For compound **8** only two signals (^{1}H NMR) are observed for the CH_3 groups and only one signal is observed for the CH_2 groups. The chemical shifts are almost identical to those observed for complex **6**. Due to the anionic character of the ligands, bathochromic shifts (IR) are observed for the equatorial carbonyl ligands of complexes **6**−**8**. Whereas examples are known where hydrogen bonding influences the selectivity or the rate of organic transformations, such effects are rare in complexation reactions. However, such processes should play an important role in the binding of transition metals to biomolecules.

The synthesis and properties of *homo*dimetallic complexes were next studied. Reaction of $Cu(OAc)_2$ with the pyridyloxalamidines **3** and **4** resulted in formation of the deeply green to black coloured (Cu/Cu) complexes **9** and **10** (Scheme 3). Reaction of ligands **3** with $PdCl_2(CH_3CN)_2$ resulted in formation of the orange coloured (Pd/Pd) complexes **11**.

1:1 solution of MeOH and water. The ligand shows an *s-trans*-(*E*/*E*) configuration. The square-planar coordination spheres of the Cu^{II} atoms are distorted. The amidine moiety is planar. In contrast, the tolyl groups are twisted out of plane by ca. 90°. The bond lengths C1−N1 and C1−N2 are almost identical, due to delocalization of the π-electrons (N1−C1−N2). Whereas intense (C=N) absorptions (IR) were observed for the free ligands, no respective absorptions were present for the metal complexes **9−11**, again due to delocalization of the π-electrons. In the electron paramagnetic resonance (EPR) spectrum of complex **10b** a signal was detected at $g = 2.082$. Although the hyperfine structure could not be resolved, the value and the anisotropy of the resonance line were typical for the $g_\perp$ signal of Cu^{II}. An antiferromagnetic interaction between the Cu atoms can be anticipated.[14] Quantitative EPR measurements showed that only ca. 15% of Cu^{II} with $s = 0.5$ was present. The magnetic moment of complex **10b** ($\mu_{eff} = 1.55$ BM, T = 296 K) was lower than the spin-only value of the Cu^{II} ion ($\mu_{eff} = 1.73$ BM).

In conclusion, we have reported the synthesis of conformationally locked oxalic acid-derived amidines with pendant pyridine functionalities. Based on this multivalent ligand system, new hetero- and homodimetallic complexes were efficiently prepared.

Experimental Section

General: All solvents were dried by standard methods and all reactions were carried out under an inert atmosphere. Petroleum ether (PE, b.p. 40−70 °C), diethyl ether (E), *tert*-butyl methyl ether (MTBE), toluene and acetone were distilled prior to use. The solvents that were used for the reactions (THF and ether), were distilled from sodium/benzophenone immediately prior to use. The oxalic acid bis(imidoyl)chlorides were prepared according to literature procedures.[4e] NMR: 200 MHz and 50 MHz (for ^1H and ^{13}C, respectively), if not quoted otherwise, on an AC 200 F (Bruker) apparatus. The solvents $CDCl_3$, CD_2Cl_2 and [D_8]THF were used as received. The multiplicity of the carbon atoms was determined by the DEPT 135 technique and quoted as: CH_3, CH_2, CH and C for primary, secondary, tertiary and quaternary carbon atoms. MS: EI, 70 eV; CI, H_2O: chemical ionization with water. Preparative scale chromatography: J. T. Baker silica gel (60−200 mesh). For the EPR measurements, an ESP 300 E apparatus (Bruker, ν = 9.4 GHz, internal standard: diphenylpicrylhydrazyl). Melting points, uncorrected, were measured using a Büchi apparatus. Elemental analyses: Microanalytical laboratory of the Universities of Hannover and Jena.

General Procedure for the Preparation of Oxalic Acid Amidines (3): A THF solution of **1** (2.0 mmol), 2-picolylamine (0.44 mL) and NEt_3 (0.63 mL, 4.5 mmol) was refluxed for 48 h. After cooling, the precipitated $HNEt_3Cl$ was filtered and the solvent of the filtrate was removed in vacuo. The residue was purified by chromatography (toluene → toluene/acetone = 1:1).

Synthesis of Bis(tetrahydrofuran)sodium Tetracarbonyl[*N*,*N*′-bis(2-pyridylmethyl)-1,2-bis(2,4,6-trimethylphenylimino)ethane-1,2-diaminato]molybdate (6): To a THF solution (25 mL) of **3a** (0.51 g, 1.0 mmol) was slowly added a THF solution of $NaN(SiMe_3)_2$ (1 mL, 1 M). After stirring for 30 min the solution was warmed to 20 °C and a THF solution (30 mL) of $Mo(CO)_4$(nor) (0.30 g, 1.0 mmol) was added. After stirring for 2 h, the precipitated yellow solid was filtered, washed three times with THF (10 mL) and dried in vacuo to give 0.45 g of yellow crystals (52%). ^{1}H NMR (200 MHz, [D$_6$]DMSO): δ = 2.00, 2.13 (2 × s, 2 × 9 H, CH_3), 5.32, 4.12 (2 × s, 2 × 2 H, CH_2), 6.55−8.27 (m, 12 H, Ar). − IR (Nujol): $\tilde{\nu}$ = 1991, 1877, 1863, 1812, 1769, 1754 (s, $\nu_{C\equiv O}$), 1593 (m), 1566 (m), 1537 (s) cm^{-1}. − $C_{44}H_{51}N_6MoNaO_6$ (878.9): calcd. C 60.13, H 5.85, N 9.56; found C 59.59, H 5.65, N 9.26.

Synthesis of Metal Complexes (7a−b): To a THF solution (25 mL) of **6** (0.51 g, 1.0 mmol) was added a THF solution of $NaN(SiMe_3)_2$ (2 mL, 1 M). After stirring for 30 min a THF solution (30 mL) of $Mo(CO)_4$(nor) (0.30 g, 1.0 mmol) was added. The solution was stirred for 30 min and subsequently a THF solution (25 mL) of $CoBr_2(THF)_2$ or $PdCl_2(CH_3CN)_2$ (1 mmol) was added. After stirring for 4 h the solution was filtered (celite) and the filtrate was concentrated in vacuo. An ether layer was added on the top of the THF solution which resulted in precipitation of the product as greenish crystals.

Cobalt(II) Bis(tetrahydrofuran)[*N*,*N*′-bis(2-pyridylmethyl)-1,2-bis(2,4,6-trimethylphenylimino)ethane-1,2-diaminato]molybdate (7a): Yield: 0.52 g (68%). − IR (Nujol): $\tilde{\nu}$ = 1983, 1929, 1854, 1838, 1805 (s, $\nu_{C\equiv O}$), 1610 (s, $\nu_{C=N}$), 1579 (s), 1558 (s) cm^{-1}. − $C_{44}H_{50}CoMoN_6O_6$ (913.78): calcd. C 57.83, H 5.52, N 9.20, Co 6.45; found C 57.19, H 5.93, N 9.42, Co 6.55.

Palladium(II) Bis(tetrahydrofuran)[*N*,*N*′-bis(2-pyridylmethyl)-1,2-bis(2,4,6-trimethylphenylimino)ethane-1,2-diaminato]molybdate (7b): Yield: 0.71 g (74%). − ^{1}H NMR (200 MHz, [D$_6$]DMSO): δ = 2.04, 2.14 (2 × s, 18 H, CH_3), 4.16 (br, 4 H, CH_2), 6.64, 8.54 (m, 12 H, Ar, Pyr). − IR (Nujol): $\tilde{\nu}$ = 1995, 1914, 1883, 1822, 1745 (s, $\nu_{C\equiv O}$), 1611 (s, $\nu_{C=N}$), 1586 (s), 1562 (s) cm^{-1}. − $C_{44}H_{50}MoN_6O_6Pd$ (961.3): calcd. C 54.98, H 5.24, N 8.74; found C 54.43, H 5.13, N 9.00.

Synthesis of the Dimetallic Cu Complexes (9a−c) and (10a−b): A MeOH solution (25 mL) of $Cu(OAc)_2(H_2O)$ (0.36 g, 2.0 mmol) and of the ligand **3** or **4** (1 mmol) was stirred for 2 h at 50 °C. The deep green solution was filtered and the solvent of the filtrate was removed in vacuo. To the residue was added ether and the precipitate was filtered and dried in vacuo. The crude product was recrystallized from MeOH or H_2O/MeOH (1:1).

Bis(acetato)[*N*,*N*′-bis(2-pyridylmethyl)-1,2-bis(2,4,6-trimethylphenylimino)ethane-1,2-diaminato]dicuprate(II) (9a): Yield: 0.25 g of deep green to black crystals (34%). − IR (Nujol): $\tilde{\nu}$ = 1613 (s), 1595 (s), 1566 (s) cm^{-1}. − $C_{36}H_{40}Cu_2N_6O_4$ (747.8): calcd. C 57.82, H 5.39, N 11.24, Cu 16.99; found C 57.80, H 5.38, N 11.19, Cu 16.41.

Bis(methanol)bis(acetato)[1,2-bis(2,6-dimethylphenylimino)-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diaminato]dicuprate(II) (9b): Yield: 0.40 g of deep green to black crystals (50%). − IR (Nujol): $\tilde{\nu}$ = 3370 (br, $\nu_{OH(MeOH)}$), 1611 (s), 1582 (s), 1567 (s) cm^{-1}. − $C_{36}H_{42}Cu_2N_6O_6$ (781.9): calcd. C 55.30, H 5.41, N 10.75, Cu 16.26; found C 55.06, H 5.38, N 10.87, Cu 15.95.

Bis(acetato)[1,2-bis(2,6-diisopropylphenylimino)-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diaminato]dicuprate(II) (9c): Yield: 0.57 g of deep green to black crystals (69%). − IR (Nujol): $\tilde{\nu}$ = 1625 (s), 1599 (s), 1582 (s), 1567 (s) cm^{-1}. − $C_{42}H_{52}Cu_2N_6O_4$ (832.0): calcd. C 60.63, H 6.30, N 10.10, Cu 15.28; found C 60.71, H 6.42, N 10.11, Cu 14.87.

Bis(methanol)bis(acetato){*N*,*N*′-bis[(2-aminoethyl)-2-pyridyl]-1,2-bis(4-tolylimino)ethane-1,2-diaminato}dicuprate(II) (10a): Yield: 0.49 g of deeply green to black coloured crystals (62%). − IR (Nujol): $\tilde{\nu}$ = 3265 (br, $\nu_{OH(MeOH)}$), 1607 (s), 1571 (s), 1505 (s), 1485 (s) cm^{-1}. − $C_{36}H_{42}Cu_2N_6O_6$ (781.9): calcd. C 55.30, H 5.41, N 10.75, Cu 16.26; found C 55.37, H 5.58, N 10.67, Cu 15.74.

Bis(methanol)bis(acetato){*N*,*N*′-bis[(2-aminoethyl)-2-pyridyl]-1,2-bis(4-methoxyphenylimino)ethane-1,2-diaminato}dicuprate(II) (10b): Yield: 0.53 g of deep green to black crystals (68%). − IR (Nujol): $\tilde{\nu}$ = 3390 (br, ν_{OH}, MeOH), 1606 (s), 1586 (s), 1502 (s), 1486 (s) cm^{-1}. − μ_{eff} = 1.5 BM. − EPR (296 K, solid): $g_\perp$ = 2.0036. − $C_{35}H_{40}Cu_2N_6O_7$ (783.8): calcd. C 53.70, H 5.15, N 10.74, Cu 16.09; found C 53.36, H 5.01, N 10.88, Cu 15.87.

Synthesis of the Dimetallic Pd Complexes (11a−c): A THF solution (30 mL) of $PdCl_2(CH_3CN)_2$ (0.52 g, 2.0 mmol) and of the ligand **3** or **4** (1.0 mmol) was stirred for 24 h at 20 °C. The product, which precipitated as an orange solid, was filtered, washed with THF and dried in vacuo.

Dichloro[*N*,*N*′-bis(2-pyridylmethyl)-1,2-bis(2,4,6-trimethylphenylimino)ethane-1,2-diaminato]dipalladate(II) (11a): Yield: 0.36 g of an

orange solid (41%). − IR (Nujol): $\tilde{\nu}$ = 1633 (s), 1610 (m), 1593 (s), 1577 (s), 1568 (s), 1515 cm^{-1}. − $C_{38}H_{46}Cl_2N_6Pd_2$ (870.6): calcd. C 52.43, H 5.33, N 9.65, Cl 8.14; found C 51.88, H 5.35, N 10.45, Cl 8.12.

Dichloro[1,2-bis(2,6-diisopropylphenylimino)-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diaminato]dipalladate(II) (11b): Yield: 0.50 g of an orange solid (58%). − IR (Nujol): $\tilde{\nu}$ = 1610 (m), 1593 (s), 1577 (s), 1564 (s) cm^{-1}. − $C_{38}H_{46}Cl_2N_6Pd_2$ (870.6): calcd. C 52.43, H 5.33, N 9.65, Cl 8.14; found C 51.88, H 5.35, N 10.04, Cl 8.45.

Dichloro{*N*,*N*′-bis[(2-aminoethyl)-2-pyridyl]-1,2-bis(4-tolylimino)-ethane-1,2-diaminato}dipalladate(II) (11c): Yield: 0.39 g of an orange solid (52%). − ^{1}H NMR (200 MHz, [D$_6$]DMSO): δ = 2.18 (s, 6 H, CH_3), 2.97, 3.31 (2 × br, 2 × 4 H, CH_2), 6.93 (m, 4 H, Ar), 6.85 (t, J = 7.6 Hz, 1 h, Pyr), 6.93 (d, J = 6.9 Hz, 1 H, Pyr), 7.41 (t, J = 8.4 Hz, 1 H, Pyr), 8.40 (d, J = 5.4 Hz, 1 H, Pyr). − IR (Nujol): $\tilde{\nu}$ = 1673 (s), 1605 (m), 1579 (s), 1504 (m) cm^{-1}. − $C_{30}H_{30}N_6Cl_2Pd_2$ (758.4): calcd. C 47.51, H 3.99, N 11.08, Cl 9.35; found C 47.39, H 4.38, N 11.53, Cl 9.51.

Crystal Structure Determinations: The intensity data for the compound were collected on a Nonius Kappa CCD diffractometer, using graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarization effects, but not for absorption.[15,16]

The structures were solved by direct methods (SHELXS [17]) and refined by full-matrix least-squares techniques against F_o^2 (SHELXL-97[18]). The hydrogen atoms of the structures were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[18] XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

Crystal Data for 3a:[19] $C_{32}H_{36}N_6$, M_r = 504.67 g mol^{-1}, colourless prism, size 0.40 × 0.38 × 0.32 mm^3, monoclinic, space group $P2_1/n$, a = 6.4164(5), b = 21.157(2), c = 10.3108(6) Å, β = 94.085(2)°, V = 1396.2(2) $Å^3$, T = 183 K, Z = 2, $\rho_{calcd.}$ = 1.200 gcm^{-3}, μ (Mo-K_α) = 0.73 cm^{-1}, F(000) = 540, 3067 reflections, Θ_{max} = 26.27°, 2815 independent reflections, 1724 reflections with $F_o > 4\sigma(F_o)$, 208 parameters, R = 0.0568, R_w = 0.1645, largest difference peak and hole: 0.369 e $Å^{-3}$.

Crystal Data for 6:[19] $C_{44}H_{51}MoN_6NaO_6$, M_r = 878.84 g mol^{-1}, colourless prism, size 0.30 × 0.25 × 0.15 mm^3, monoclinic, space group $P2_1/n$, a = 12.3530(6), b = 20.6111(5), c = 17.2796(8) Å, β = 94.755(1)°, V = 4384.4(3) $Å^3$, T= −90 °C, Z = 4, $\rho_{calcd.}$ = 1.331 gcm^{-3}, μ(Mo-K_α) = 3.62 cm^{-1}, F(000) = 1832, 11681 reflections in h(−13/0), k(−22/21), l(−19/19), measured in the range 3.95° ≤ Θ ≤ 23.31°, completeness Θ_{max} = 98.6%, 6126 independent reflections, R_{int} = 0.036, 5706 reflections with $F_o > 4\sigma(F_o)$, 527 parameters, 0 restraints, $R1_{obs}$ = 0.047, wR^2_{obs} = 0.121, $R1_{all}$ = 0.066, wR^2_{all} = 1.134, GOOF = 1.084, largest difference peak and hole: 0.485/−0.555 e $Å^{-3}$.

Formation and Dissociation Kinetics of the Complexes $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^{-}$

László Burai,[a] Róbert Király,[a] István Lázár,[a] and Ernő Brücher*[a]

Keywords: Gadolinium / Imaging agents / Kinetics / Macrocyclic ligands / Phosphonate complexes

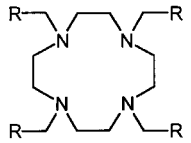
The monobutyl ester of H_8DOTP, the ligand $H_4DOTPMB$, was synthesized, and the protonation constants (K_i^H) and the stability constant of Gd(DOTPMB) were determined by pH-potentiometry (25 °C, 0.1 M Me_4NCl): $\log K_i^H$, (i = 1, 2, and 3) = 10.34(0.02), 7.72(0.025), and 2.42(0.030), respectively, and $\log K_{GdL}$ = 12.19(0.05). The rates of formation of Gd(DOTPMB) and Gd(DOTP) were studied by ^1H relaxometry in the pH range 5.4–7, and also by spectrophotometry in the case of Gd(DOTP) (7 < pH < 8). For both reactions, first-order rate constants were obtained at different concentration ratios of the reactants, which indicated the rapid formation of a reaction intermediate. The compositions of the intermediates are $Gd(H_iDOTPMB)$ (i = 1, 2) and $H_nGd(H_2DOTP)$ (n = 0–4), respectively, where one or two protons are attached to the nitrogen atoms of the ligand. The rate of rearrangement (k_r) of the intermediate $Gd(H_iDOTPMB)$ to the product Gd(DOTPMB) increases with increasing $[OH^-]$: $k_r = k_{OH}[OH^-] + k_{2OH}[OH^-]^2$, where k_{OH} = (1.3±0.25) $\times 10^3$ $M^{-1}s^{-1}$ and k_{2OH} = (7.8±0.2) $\times 10^{11}$ $M^{-2}s^{-1}$. For the formation reaction of Gd(DOTP), only the first term exists and k_{OH} = (7.2±0.1) $\times 10^3$ $M^{-1}s^{-1}$. For the complexation reactions, similar mechanisms were proposed in which deprotonation of the species Gd(HDOTPMB) and $H_nGd(HDOTP)$ plays the rate-determining role. For the deprotonation, general base catalysis was found to be satisfactory. The rate of dissociation of Gd(DOTPMB) in 0.025–1.0 M HCl solution ([HCl] + $[Me_4NCl]$ = 1.0 M) was lower than that of Gd(DOTP) and the first-order rate constants exhibited saturation curves with increasing $[H^+]$. Based on the assumption that the protonated species HGd(DOTPMB) and $H_5Gd(DOTP)$ dissociate, the rate constants (and protonation constants) were found to be (5.4±0.2) $\times 10^{-4}$ $M^{-1}s^{-1}$ (K_{GdL}^H = 1.7±0.1) and (2.1±0.1) $\times 10^{-4}$ $M^{-1}s^{-1}$ (K_{H4GdL}^H = 1.9±0.1), respectively.

Introduction

Complexes of lanthanides with the tri- and tetraacetate derivatives of cyclen (e.g. DOTA; H_4DOTA = 1,4,7,10-tetraazacyclododecanetetraacetic acid) are finding wide-ranging applications in medical diagnosis and therapy. $Gd(DOTA)^-$ is a clinically used contrast agent in magnetic resonance imaging (MRI).[1−5] The radioactive $^{90}Y(DOTA)^-$ attached to proteins or monoclonal antibodies is a potential drug in the therapy of cancer.[4,6] The success of the cyclic tetraazapolycarboxylates in practical use, and also their interesting chemistry, initiated the synthesis and study of the phosphonate analogues. The ligand 1,4,7,10-tetraazacyclododecanetetrakis(methylenephosphonic acid), H_8DOTP, an analogue of H_4DOTA, has also been synthesized.[7−9] The protonation constants of $DOTP^{8-}$ are unusually high because of the large negative charge of the ligand, and the first protonation constant could be determined only by ^1H NMR spectroscopy.[10] The stability constants of the complexes $Ln(DOTP)^{5-}$ [Ln^{3+} = lanthanide(III) ion] are somewhat higher than those of $Ln(DOTA)^-$.[10−12] However, the species $Ln(DOTP)^{5-}$ predominates only at pH > ca. 9, while in the pH range 4−9, protonated complexes are formed: $H_iLn(DOTP)^{(5-i)-}$ (i = 1−4). The successive protonation equilibria have been characterized by determining the protonation constants.[12]

The complex $Gd(DOTP)^{5-}$ cannot be used as a contrasting agent in MRI because of its high negative charge [at physiological pH values, the monoprotonated $GdH(DOTP)^{4-}$ predominates[12]]. However, some complexes $Ln(DOTP)^{5-}$ are used as shift and relaxation reagents in biology.[6,13−16]

The complexes of lanthanides with the monoesters of DOTP are similar to the complexes of DOTA in that they possess a single negative charge, and can be regarded as potential contrast agents in MRI. (The charges of the ligands DOTP and DOTPMB as well as those of the complexes will be written only when absolutely necessary.) The complex formed between Gd^{3+} and the monobutyl ester of



R = COOH	H_4DOTA
R = $PO(OH)_2$	H_8DOTP
R = PO(OBu)OH	$H_4DOTPMB$

Scheme 1

DOTP (= DOTPMB; see Scheme 1) interacts strongly with human serum albumin and is partly excreted through the hepatobiliary system. $Gd(DOTPMB)^-$ can therefore be regarded as a potential liver contrast agent.[17]

It is important for lanthanide complexes used in biological systems to be thermodynamically stable and in particular they should be kinetically inert. Whereas the stability constant of $Gd(DOTP)^{5-}$ is known,[12] that of

$Gd(DOTPMB)^-$ has not been reported.[17] Practically no quantitative data are available on the formation and dissociation rates of the Ln^{3+} complexes of DOTP and its esters. Kim et al. found that both the formation and dissociation of La(F-DOTPME) {F-DOTPME = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrakis[methylenephosphonic acid mono-(2′,2′,2′-trifluoroethyl) ester]} were very slow, and that the stability constant of the complex ($\log K_{LaL}$ = 14.9[18]) was much lower than that of $La(DOTP)^{5-}$ ($\log K_{LaL}$ = 27.6[12]). Both this finding and the much lower protonation constants of the ligand F-$DOTPME^{4-}$ indicate that the basicity of the oxygen donors in the phosphonate ester functional groups, −PO(OR)OH, is much lower than that in the phosphonate groups, $-PO(OH)_2$. The values of the protonation constants indicate that the phosphonate ester groups, −PO(OR)OH, similarly to the phosphinate groups, −PO(R)OH, are strongly acidic.[18,19] In spite of the low basicity of the phosphinate oxygen atoms, the kinetic stability of the lanthanide complexes of the tetraazatetraphosphinate derivative ligand is very high. The proton-assisted dissociation rates of the phosphinate complexes in 0.1 M HCl are comparable with those of $Ln(DOTA)^-$.[4,5,19−23] Thus, a high kinetic stability can be expected for the complex $Gd(DOTPMB)^-$.

The rates of formation and dissociation of the complexes Gd(DOTP) and Gd(DOTPMB) were studied in order to obtain useful information about the biological application of the ligands DOTP and DOTPMB, and for a comparison of the kinetic behaviour of complexes formed with DOTP, DOTPMB, and DOTA, which have similar donor atoms but different functional groups and charges.

Results and Discussion

Protonation and Stability Constants

In order to control the purity of the DOTP sample, we re-determined the protonation constants of $DOTP^{8-}$. The K_1^H value was too high to be determined by pH-potentiometry.[10] The log K_i^H values (i = 2−7) obtained were 12.45(0.005), 9.18(0.007), 7.95(0.008), 6.08(0.008), 5.20(0.007), and 1.85(0.15), respectively, which agree well with the data reported earlier by Delgado et al.[10] and Geraldes et al.[8]

Three protonation constants could be determined by pH-potentiometry for the ligand $DOTPMB^{4-}$: $\log K_1^H$ = 10.34(0.020), $\log K_2^H$ = 7.72(0.025) and $\log K_3^H$ = 2.42(0.030). The completely deprotonated $DOTPMB^{4-}$ has only four negative charges, and its first two protonation constants are therefore significantly lower than those of $DOTP^{8-}$. The oxygen donor atoms of the $P(O)(OBu)O^-$ groups are weakly basic, and therefore we obtained only one protonation constant in the low pH range (2 < pH < 5). For the protonation sequence of the 12-membered tetraaza macrocyclic derivatives, which possess methylenephosphonate pendant arms, it was demonstrated that the first two protonations take place on two opposite nitrogen atoms of the ring.[8]

The stability constant of $Gd(DOTPMB)^-$, calculated from the titration data obtained with the "out-of-cell" technique, was found to be $\log K_{GdL}$ = 12.19(0.05). The formation of protonated or dinuclear complexes was not detected

The stability constant of $Gd(DOTPMB)^-$ is much lower than that of $Gd(DOTP)^{5-}$ ($\log K_{GdL}$ = 28.8[12]), because the charge of the $DOTPMB^{4-}$ and the basicity of its donor atoms are much lower than those of $DOTP^{8-}$.

Formation Kinetics of $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^-$

The reactions between Gd^{3+} and DOTP or DOTPMB in the pH range 5.4−7 are relatively slow and can be studied by measuring the longitudinal relaxation rates of the water protons. The relaxivities of Gd^{3+}·aq and the complexes $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^-$ differ sufficiently to furnish reliable rate data. In the presence of excess ligand, the formation rates can be expressed as Equation (1), where k_{obs} is a pseudo-first-order rate constant, and $[GdL]_t$ is the total concentration of the complex formed.

$$\frac{d[GdL]_t}{dt} = k_{obs}[Gd^{3+}] \quad (1)$$

Similarly to the results obtained in the study of the formation of the complexes $Ln(DOTA)^-$,[20−23] first-order rate constants were obtained even at comparable concentrations of the reactants. These findings were interpreted by assuming that there is a rapid formation of a reaction intermediate which rearranges to the product in the rate-determining step, characterized by the rate constant, k_r in Equation (2).

$$Gd^{3+} + H_xL \rightleftharpoons (x\text{-}y)H^+ + Gd(H_yL) \xrightarrow{k_r} GdL + yH^+ \quad (2)$$

The values of the rate constants, k_{obs}, increase with increasing ligand concentration, and at a ligand to Gd^{3+} ratio of approximately 2−3 give rise to a saturation value, k_r. In the presence of a 10-fold excess of ligand, we obtained such values (i.e., $k_{obs} = k_r$), which characterize the rate of rearrangement of the intermediate.

In the formation reactions of $Gd(DOTPMB)^-$, the ligand is present in the form of the species $H_2DOTPMB^{2-}$ and $HDOTPMB^{3-}$ (5.4 < pH < 7), since the protonation constants of $DOTPMB^{4-}$ ($\log K_i^H$) are 10.34, 7.72, and 2.42. The reaction intermediates formed by mixing solutions of Gd^{3+} and DOTPMB are probably mono- and diprotonated species, Gd(HDOTPMB) and $Gd(H_2DOTPMB)^+$, since there is practically no pH change at the start of the reaction. The structures of the intermediates are probably not similar to those of $Ce(H_2DOTA)^+$, Ce(HDOTA), and $Eu(H_2DOTA)^+$,[22,23] in which four carboxylate oxygens are coordinated to the Ln^{3+}, which occupies an "out-of-cage" position, while the protons protonate one or two nitrogen atoms. The structure of the ligand DOTPMB is not known and probably only two phosphonate ester groups of the mono- or diprotonated ligand can be coordinated to the Gd^{3+} in the intermediates.

The rate constants k_r are presented in Figure 1 and display a second-order dependence on the OH^- concentration.

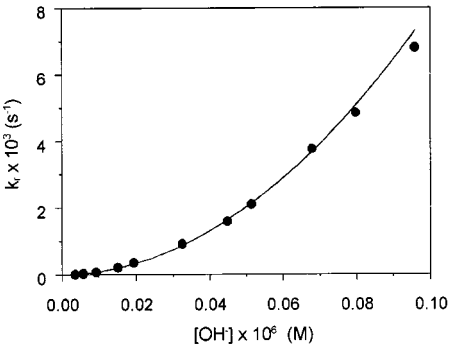

Figure 1. First-order rate constants (k_r) obtained for the formation reaction of $Gd(DOTPMB)^{-}$ {25 °C, 0.1 M $(CH_3)_4NCl$, $[Gd^{3+}]_t = 5\cdot10^{-4}$ M, $[L]_t = 5\cdot10^{-3}$ M}

$$k_r = k_{OH}[OH^-] + k_{2OH}[OH^-]^2 \quad (3)$$

The fit of the k_r data to Equation (3) gave the rate constants k_{OH} and k_{2OH}, presented in Table 1.

[a] Ref.[26] – [b] Obtained for the formation of Ce(DOTA).[24]

The mechanism of formation of $Gd(DOTPMB)^{-}$ is presumably similar to those of the complexes $Ln(DOTA)^{-}$.[22–24] It is assumed that the diprotonated intermediate is involved in a dissociation equilibrium with the kinetically active monoprotonated intermediate [Equation (4)].

$$Gd(H_2DOTPMB)^+ \rightleftharpoons Gd(HDOTPMB) + H^+ \quad (4)$$

The extent of dissociation is characterized by the protonation constant, $K^H_{GdHL} = [GdH_2L]/([GdHL][H^+])$. With an increase in the pH, the monoprotonated intermediate is produced in increasing amounts in a direct reaction, since $\log K^H_2 = 7.72$. This intermediate undergoes deprotonation in a slow, rate-determining process, presumably with the assistance of an H_2O molecule [Equation (5)] or an OH^- ion [Equation (6)].[24]

$$Gd(HDOTPMB) + H_2O \xrightarrow{k_{GdHL}} Gd(DOTPMB)^- + H_3O^+ \quad (5)$$

$$Gd(HDOTPMB) + OH^- \xrightarrow{k^{OH}_{GdHL}} Gd(DOTPMB)^- + H_2O \quad (6)$$

The slow transfer of a proton is followed by a fast rearrangement of the deprotonated intermediate to furnish the product.

On the basis of the equilibrium reaction [Equation (4)], the concentration of the monoprotonated intermediate is directly proportional to the OH^- concentration, which explains the direct proportionality between the rate constant k_r and the OH^- concentration. The second-order dependence of the k_r values on the OH^- concentration can be interpreted in terms of the OH^--catalyzed deprotonation of the monoprotonated intermediate Gd(HDOTPMB) [Equation (6)].

When Equations (5) and (6) are taken into account, the rate of formation of $Gd(DOTPMB)^{-}$ can be given as in Equation (7).

$$\frac{d[GdL]_t}{dt} = k_{GdHL}[GdHL] + k^{OH}_{GdHL}[GdHL][OH^-] \quad (7)$$

Comparing Equation (1) and Equation (7), and bearing in mind that the formation of the intermediates is practically complete in the presence of excess ligand ($[Gd^{3+}] = [GdHL] + [GdH_2L]$), the concentration of GdH_2L can be expressed in terms of the protonation constant K^H_{GdHL}, when Equation (8) is obtained[24], where K_W ($= 1.66\cdot10^{-14}$) is the ionic product of water. From the fit of the experimental k_r values (Figure 1) to Equation (8), the rate constants k_{GdHL} and k^{OH}_{GdHL}, and the protonation constant K^H_{GdHL} were calculated and are presented in Table 1.

$$k_r = \frac{k_{GdHL}[H^+] + k^{OH}_{GdHL}K_W}{[H^+] + K^H_{GdHL}[H^+]^2} \quad (8)$$

In the postulated reaction mechanisms expressed by Equations (4)–(6), the deprotonation of the monoprotonated intermediate Gd(HDOTPMB) plays an important role. If the reactions according to Equations (5) and (6) are rate-controlling, then general base catalysis must occur in the formation reactions. In this case, deprotonation of the intermediate will take place with the transfer of a proton to any Brönsted base, e.g. to the basic form of the buffer. The rate constants $k_{obs} = k_r$ presented in Figure 2 increase with increasing concentration of the buffer MES, which indicates the validity of the Brönsted equation and the occurrence of general base catalysis.[25] These results demonstrate that the rate-determining step in the formation of $Gd(DOTPMB)^{-}$ is the transfer of a proton from the intermediate Gd(HDOTPMB) to a Brönsted base (H_2O, OH^- or the basic form of the buffer), followed by a fast rearrangement of the deprotonated intermediate, in which the Gd^{3+} enters the coordination cage formed by the four nitrogen and oxygen atoms of the ligand.

The formation kinetics of $Gd(DOTP)^{5-}$ seems simpler than in the case of $Gd(DOTPMB)^{-}$, since the rate of formation is directly proportional to the OH^- concentration in the pH range 5.4–8, as shown in Figure 3. On the basis of the rate constants in Figure 3, the rate law is also simple for the formation of $Gd(DOTP)^{5-}$, since $k_r = k_{OH}[OH^-]$, where $k_{OH} = (7.2\pm0.1)\times10^3$ $M^{-1}s^{-1}$. The k_{OH} values obtained for the formation of Gd(DOTP), Gd(DOTPMB), and Gd(DOTA)[20] are compared in Table 1. It can be seen that the rates of formation of Gd(DOTA) and of some other complexes Ln(DOTA)[20–23] are significantly higher than those of the phosphonate com-

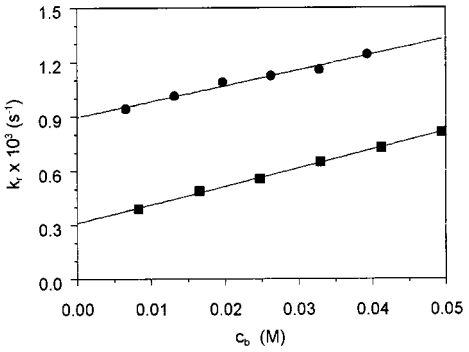

Figure 2. First-order rate constants (k_r) obtained for the formation reaction of $Gd(DOTP)^{5-}$ at pH = 6.82 (■) and of $Gd(DOTPMB)^{-}$ at pH = 6.43 (●) as a function of the concentration of the buffer MES {25 °C, 0.1 M $(CH_3)_4NCl$, $[Gd^{3+}]_t = 5\cdot10^{-4}$ M, $[L]_t = 5\cdot10^{-3}$ M}

plexes, and Gd(DOTP) is formed somewhat faster than Gd(DOTPMB) in this pathway. The simple rate law characterising the formation of Gd(DOTP) is surprising, because the ligand is present in the form of the species H_2L^{6-}, H_3L^{5-}, H_4L^{4-}, H_5L^{3-}, and H_6L^{2-} in the pH range investigated, in which several differently protonated intermediates can be formed in the first stage of the formation reaction.

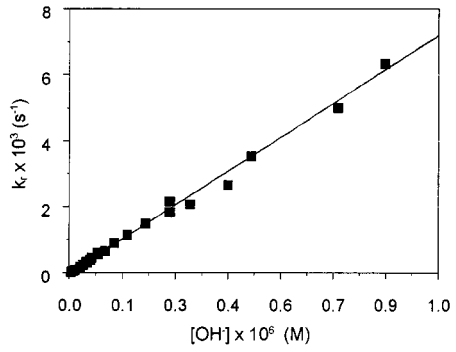

Figure 3. First-order rate constants (k_r) obtained for the formation reaction of $Gd(DOTP)^{5-}$ {25 °C, 0.1 M $(CH_3)_4NCl$, $[Gd^{3+}]_t = 5\cdot10^{-4}$ M, $[L]_t = 5\cdot10^{-3}$ M}

In the reactions of formation of the similar complexes $Ln(DOTA)^{-}$ in the pH range 4−6, a pronounced pH drop was observed at the start of the reactions, which was followed by a slow decrease in the pH value.[20,22] This finding was explained in terms of the formation of the intermediate $Ln(H_2DOTA)^{+}$, which slowly lost the protons.[22,23] In contrast, we did not observe any drop in the pH value when solutions of Gd^{3+} and $H_xDOTP^{(8-x)-}$ were mixed. This indicates that the composition of the intermediate formed is $Gd(H_xDOTP)$, where x is the average number of protons on DOTP at the given pH value. Taking the protonation constants of DOTP into consideration, in the pH range 5.3−8 the average number of protons decreases from $x = 5.7$ to $x = 3.5$. Since two of these protons are attached to two diagonally located nitrogen atoms of the ligand in the pH range investigated, an average of between $n = 3.7$ and 1.5 protons protonate the eight phosphonate oxygen atoms, and thus there are always at least four nonprotonated oxygen atoms $-O^-$ which coordinate to Gd^{3+} in the intermediates $H_nGd(H_2DOTP)$. However, it is not likely that the protonated $H_xDOTP^{(8-x)-}$ is preorganized in a similar way as the ligand $H_xDOTA^{(4-x)-}$. The X-ray crystal structure of H_8DOTP indicates that two diagonally located phosphonate groups are positioned above the plane of the ring nitrogen atoms, while the other two phosphonate groups are orientated away from the ring.[9] It thus seems more probable that only two methylenephosphonate groups are coordinated to Gd^{3+} in the protonated intermediates $H_nGd(H_2DOTP)$. This difference in the structures of the intermediates $H_nGd(H_2DOTP)$ and $Gd(H_2DOTA)$ partly explains the significantly lower rates of formation of the complexes $Ln(DOTP)^{5-}$.

The rearrangement of the intermediate to the product occurs with the loss of protons. The complexes Gd(DOTP) formed are protonated on the noncoordinated oxygen atoms at pH < 9.[12] The protonation constants[12] indicate that the average composition of the protonated complex at pH = 8 is $H_{0.6}Gd(DOTP)$, while at pH = 5.3 it is $H_{2.5}Gd(DOTP)$, i.e. the rearrangement of the intermediate and the entry of Gd^{3+} into the coordination cage occurs with the liberation of 1−2 protons.

The data presented in Figure 2 indicate that the rate constants k_r increase with increasing concentration of the basic form of the buffer, MES, pointing to the validity of general base catalysis. This can be interpreted by assuming the formation of kinetically active intermediates with the dissociation of one of the two protons attached to the nitrogen atoms [Equation (9)] where $n = 0-4$.

$$H_nGd(H_2L) \rightleftharpoons H_nGd(HL) + H^+ \quad (9)$$

The rate-controlling step is presumably the transfer of the proton from the nitrogen atom of $H_nGd(HL)$ to a Brönsted base, e.g. H_2O or the basic form of the buffer. It may be expected that the catalytic effect of OH^- occurs at pH > 8. However, in the formation of $Ce(DOTA)^{-}$, the effect of OH^- catalysis was observed at pH > ca. 7.5.[24] The direct dependence of the formation rates on $[OH^-]$ (Figure 3) is a consequence of the equilibrium according to Equation (9). The concentration of the intermediate $H_nGd(HL)$, which plays a crucial role in the rate-determining step, is directly proportional to $[OH^-]$.

On the basis of the direct proportionality between the rates of formation (k_r) and the concentration of OH^-, it can be assumed that the rate-controlling proton transfer is not influenced by the presence of various numbers of protons attached to the phosphonate oxygen atoms in the intermediates $H_nGd(HL)$. Based on this assumption, the rate of formation of Gd(DOTP) can be expressed as $\Sigma k_{H_nGd(HL)}[H_nGd(HL)]$. To calculate of the rate constants $k_{H_nGd(HL)}$, it is necessary to know the stability constants of the intermediates $H_nGd(H_2L)$. Unfortunately, these stability constants are not available and their pH-potentiometric determination would be difficult, because of the very low solubilities of some protonated species. The rate of

formation of $Gd(DOTP)^{5-}$ can thus be characterized by the rate constant k_{OH} presented in Table 1.

Table 2. Rate constants and protonation constants characterizing the dissociation and protonation of the complexes {25 °C, 1.0 M $(CH_3)_4NCl$ − HCl}

	Gd(DOTP)	Gd(DOTPMB)	Gd(DOTA)[a]
$k_{HGdL} \times 10^4$ [$M^{-1}s^{-1}$]	5.4±0.2	2.1±0.1	0.006
K^H_{HiGdL}[b]	1.7±0.1	1.9±0.1	14[c]

[a] Ref.[20] − [b] $i = 4$ for Gd(DOTP) and $i = 0$ for Gd(DOTPMB) and Gd(DOTA). − [c] Determined by pH-potentiometry.[22]

The k_{OH} values obtained for the formation of $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^{-}$ are significantly lower than the value of the rate of formation of Gd(DOTA) (Table 1). These differences can be interpreted by assuming a more preorganised structure of the ligand DOTA than of DOTP and DOTPMB. The structures of the intermediates $Gd(H_2DOTPMB)$ and $H_nGd(H_2DOTP)$ probably differ more significantly from the structures of the products $Gd(DOTPMB)^{-}$ and $Gd(DOTP)^{5-}$ than in the case of the complexes of DOTA. The deprotonation and rearrangement of Gd(HDOTPMB) with the assistance of an H_2O molecule are particularly slow if we take into account that this intermediate is present in a macroscopic concentration, owing to the low value of $\log K_2^H$. The extremely slow formation of $Gd(DOTPMB)^{-}$ through this pathway is particularly evident if the $k_{Ln(HL)}$ value ($3.3 \cdot 10^{-4}$ s^{-1}) is compared with that obtained for $Ce(DOTA)^{-}$ ($k_{Ln(HL)} = 18.5$ s^{-1}). This large difference in the rate constants is indicative of the difficulties connected with the deprotonation and rearrangement of the intermediate Gd(HDOTPMB).

Kinetic Stability of $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^{-}$

It is known from the literature that the dissociation of the Ln^{III} complexes of tetraaza macrocyclic derivative ligands is very slow, because of their rigid structures.[19−22,26] ^1H, ^{13}C and ^{31}P NMR spectroscopic studies indicate that the structures of the complexes $Ln(DOTP)^{5-}$ are even more rigid than that of $Ln(DOTA)^{-}$.[27] The kinetic stability of $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^{-}$ was therefore studied in the presence of a large excess of HCl. The reaction according to Equation (10) was observed.

$$GdL + xH^+ \rightleftharpoons Gd^{3+} + H_xL \quad (10)$$

The progress of the dissociation was monitored by measuring the changes in the longitudinal relaxation rates of water protons in solutions with different HCl concentrations. The rate of the dissociation reaction is as shown in Equation (11) where $[GdL]_t$ is the total concentration of the Gd^{3+} complex.

$$-\frac{d[GdL]_t}{dt} = k_d[GdL]_t \quad (11)$$

The first-order rate constants (k_d) are shown in Figure 4. The k_d values increase with increasing $[H^+]$, showing saturation curves. Similar results were obtained in the study of the rates of dissociation of some DOTA and DOTA-derivative complexes.[20,22,26] This led us to assume that rapid formation of protonated complexes occurs at the beginning of the reaction. The protonation occurs on the phosphonate oxygen atom(s), but the resulting protonated complex cannot dissociate directly because the Gd^{3+} is in the "coordination cage". For dissociation, at least one proton must be transferred to a ring nitrogen atom, after which the metal ion moves out from the "in-cage" position and the dissociation may take place. Either the transfer of the proton(s) or the structural rearrangement or both processes occur slowly. The protonation equilibria of $Gd(DOTP)^{5-}$, which forms the thermodynamically stable protonated species $HGd(DOTP)^{4-}$, $H_2Gd(DOTP)^{3-}$, $H_3Gd(DOTP)^{2-}$, and $H_4Gd(DOTP)^{-}$ in the pH range 4−8,[12] suggest that species that can dissociate [e.g. $H_5Gd(DOTP)$, etc.] are formed at lower pH values, as a consequence of further protonation. This assumption was supported by the ^1H NMR spectra of $La(DOTP)^{5-}$ solutions, recorded after the addition of increasing amounts of DCl. When 1−4 equiv. of DCl had been added to the solution, the spectrum was similar to that shown in Figure 5C, even after a few weeks. After the addition of 5 equiv. of DCl, the spectrum slowly changed, as shown in Figure 6. The multiplet pattern of the spectrum at the beginning of the reaction (Figure 5C and Figure 6A) was transformed into two broad bands, characteristic of the ligand (Figure 5A). The conversion was almost complete after 4 months. This reveals that the attachment of the fifth proton plays a crucial role in the kinetic stability of the complex. This proton must be attached to a binding $P-O^-$ oxygen atom since the four noncoordinated oxygen atoms are protonated when the rigid, symmetrical structure of the complex is no longer evident. When a noncoordinated phosphonate group is formed, one of the protons can be transferred to the nitrogen atom, after which the Ln^{3+} ion moves out of the coordination cage, and dissociation occurs.

Since the complex $Gd(DOTPMB)^{-}$ involves only four coordinated P−O donor groups, formation of the monoprotonated complex HGd(DOTPMB) results in the breaking

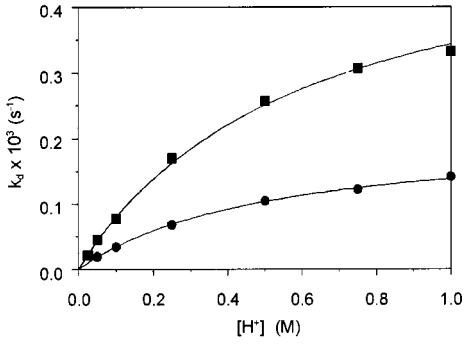

Figure 4. Rate constants of dissociation (k_d) of $Gd(DOTP)^{5-}$ (■) and of $Gd(DOTPMB)^{-}$ (●) as a function of the H^+ concentration {25 °C, 1.0 M $(CH_3)_4NCl$ − HCl, $[GdL]_t = 1 \times 10^{-3}$ M}

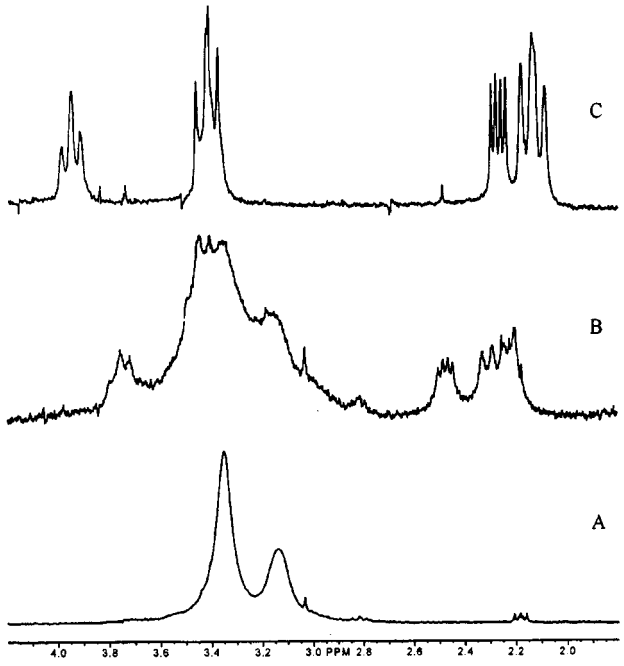

Figure 5. ^{1}H NMR spectra of DOTP at pD = 6 (A), and of La(DOTP)$^{5-}$ at pD = 4.5 (B) and at pD = 10.2 (C)

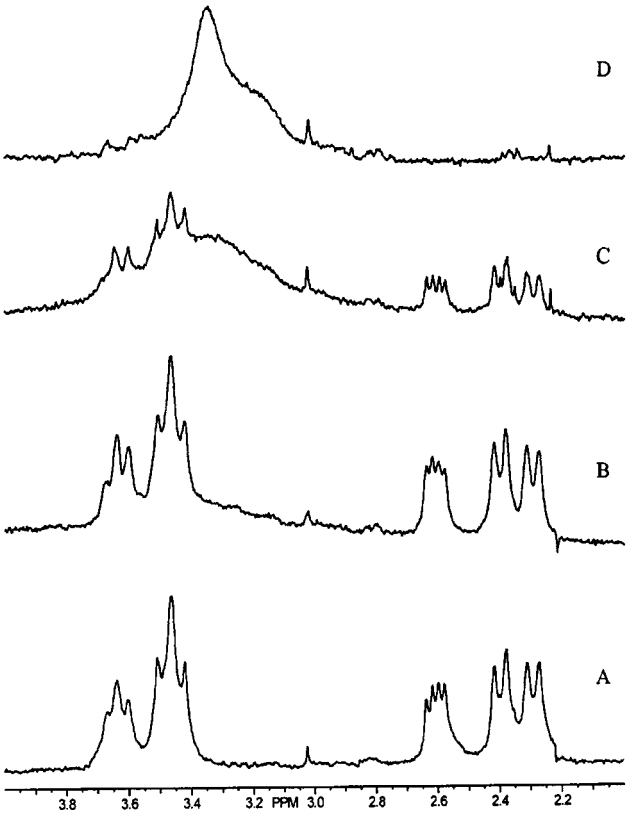

Figure 6. ^{1}H NMR spectra of La(DOTP)$^{5-}$ immediately after the addition of 5 equiv. of DCl (A), 1 d later (B), 1 week later (C), and 4 months later (D)

of a Gd^{3+}−O−P bond, after which a nitrogen atom can be protonated and the complex dissociates.

If dissociation of the protonated species HGd(DOTPMB) and H_5Gd(DOTP) is assumed, the rate of dissociation can be given as Equation (12) where $i = 1$ for Gd(DOTPMB) and $i = 5$ for Gd(DOTP).

$$-\frac{d[GdL]_t}{dt} = k_{HiGdL}[H_iGdL] \quad (12)$$

The total concentration of the complexes is $[GdL]_t = [H_{i-1}GdL] + [H_iGdL]$, since formation of the tetraprotonated H_4Gd(DOTP)$^-$ is practically complete at pH < 3. From Equations (11) and (12), and by using the expression for the total concentration of the complexes, we obtain Equation (13) where K^H_{HiGdL} is the first protonation constant of Gd(DOTPMB) ($i = 0$) and the fifth protonation constant ($i = 4$) of Gd(DOTP): $K^H_{HiGdL} = [H_{i+1}GdL)]/([H_iGdL][H^+])$.

$$k_d = \frac{k_{HiGdL}K^H_{HiGdL}[H^+]}{1 + K^H_{HiGdL}[H^+]} \quad (13)$$

The experimental k_d data (Figure 4) were fitted to Equation (13), and the rate constants k_{HiGdL} and protonation constants K^H_{HiGdL} were calculated (Table 2). The low value of K^H_{H4GdL} for Gd(DOTP)$^{5-}$ indicates that further protonation of H_4Gd(DOTP)$^-$, in which all the oxygen donors are bonded or protonated, is much more difficult than the protonation of e.g. H_3Gd(DOTP)$^{2-}$ ($\log K^H_{H3GdL} = 4.0$[12]). It is surprising that the kinetic stability of Gd(DOTP) is somewhat lower than that of Gd(DOTPMB) (Table 2) in spite of the much higher thermodynamic stability of Gd(DOTP)$^{5-}$ ($\log K_{Gd(DOTP)} = 28.8$[12] and $\log K_{Gd(DOTPMB)} = 12.19$). This unexpected result is probably a consequence of the practical unavailability of protonation sites in Gd(DOTPMB)$^-$. The negatively charged phosphonate oxygen atoms are coordinated to Gd^{3+}, while the oxygen atoms of the ester cannot be protonated under such conditions. Furthermore, the basicity of the P−O$^-$ oxygen atoms is very low; the third protonation constant of DOTPMB is $\log K^H_3 = 2.42$.

These results permit some general conclusions to be made about the kinetic stability of the Gd^{3+} complexes. The kinetic stability depends on the availability of basic protonation sites on the complex. The complex is appreciably inert against proton-assisted dissociation if the basicity of the donor atoms of some functional groups is low. In this case, the stability constant is also low, but the low ligand basicity means that the extent of protonation of the complex is very low, and thus the proton-assisted dissociation occurs slowly. Similar findings on the kinetic stabilities of the complexes of phosphinate and amide derivatives of DOTA and DTPA were reported earlier.[19,28,29]

Owing to its high kinetic stability, Gd(DOTPMB)$^-$ can be regarded as a safe contrast agent (it is more inert than Gd(DTPA)$^{2-}$), in spite of its relatively low stability constant.

Table 2 gives the rate constant k_{HGdL} which characterizes the proton-assisted dissociation of Gd(DOTA)$^-$.[20] On the basis of Equation (13), at low [H$^+$] $k_d = k_{HiGdL}K^H_{HiGdL}[H^+] = k_1[H^+]$. Wang et al.[20] reported the k_1 value and k_{HGdL} was calculated with the use of the protonation constant of Gd(DOTA)$^-$.[22] A comparison of the

data reveals that the rates of dissociation of the Gd^{3+} complexes with the phosphonate and phosphonate ester ligands are larger by about three orders of magnitude. The protonation constant of $Gd(DOTA)^{-}$ is about ten times larger than that of $H_4Gd(DOTP)$ or Gd(DOTPMB). However, $Gd(DOTA)^{-}$ is known to be protonated on a non-coordinated carboxylate oxygen atom[30] and thus even the protonated complex is relatively inert.[30] The formation of $HGd(DOTPMB)$ or $H_5Gd(DOTP)$ occurs at low pH values where the complex is thermodynamically unstable and protonation results in decoordination of a functional group and gradual dissociation of the complex.

Conclusions

The ligand DOTP and its monobutyl ester, DOTPMB, are significantly more sluggish than their tetraacetate analogue, DOTA, in their reactions with Gd^{3+}. However, the proton-assisted dissociation of the complexes $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^{-}$ is approximately one thousand times faster than that of $Gd(DOTA)^{-}$.

The basicities of the nitrogen and particularly of the oxygen donor atoms and the charge of $DOTPMB^{4-}$ are much lower than those of $DOTP^{8-}$, and the stability constants of $Gd(DOTPMB)^{-}$ and $Gd(DOTP)^{5-}$ are $\log K_{GdL} = 12.19$ and $\log K_{GdL} = 28.8$, respectively. In spite of this large difference in stability, the proton-assisted dissociation of $Gd(DOTP)^{5-}$ is somewhat faster than the similar reaction of $Gd(DOTPMB)^{-}$. The high inertness of $Gd(DOTPMB)^{-}$ is a result of the low basicities of the donor atoms. $Gd(DOTP)^{5-}$ forms protonated complexes in neutral media, while $Gd(DOTPMB)^{-}$ is protonated only in acidic solutions.

The complexes $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^{-}$ are formed slowly through the formation of protonated intermediates, $H_nGd(H_2DOTP)$ and $Gd(H_2DOTPMB)$, in which presumably only two functional groups are coordinated to the Gd^{3+} and two nitrogen atoms are protonated. The rearrangement of the intermediates to the product is a general base-catalyzed process, with the release of the last proton from the ring nitrogen atoms as the rate-determining step.

Experimental Section

Synthesis of H_8DOTP: The ligand H_8DOTP was synthesized according to a published method.[9] The purity of the ligand was checked by ^{1}H NMR spectroscopy and was found to be higher than 99.5%.

Synthesis of Na_4DOTPMB: Into a 100-mL round-bottomed flask were placed cyclen (2.66 g, 15.41 mmol), benzene (15 mL), glacial acetic acid (6 mL), paraformaldehyde (3.20 g), and dibutyl phosphite (13.0 g), dissolved in benzene (15 mL), and the mixture was stirred at room temperature for 3 d. From the reaction mixture, an azeotropic mixture of benzene and water (20 mL) was distilled off, then benzene (30 mL) was added to the residue and distilled off again. This latter procedure was repeated once more, and the solution was then concentrated under reduced pressure to give a dark brown viscous oil. This oil was redissolved in diethyl ether (150 mL), and water (50 mL) was added. Solid sodium bicarbonate was added until the evolution of gas had ceased. The organic phase was separated and dried with anhydrous sodium sulfate for 8 h. The drying agent was filtered off and the filtrate was concentrated under reduced pressure, furnishing the dibutyl ester DOTPDB as a viscous, dark brown oil. DOTPDB was suspended in water (50 mL), sodium hydroxide pellets (14 g) were added and the two-phase mixture was vigorously stirred and boiled for 30 min, and then left to stand at room temperature for 2 d. The aqueous layer was removed, water (50 mL) and sodium hydroxide (10 g) were added, and the mixture was boiled with vigorous stirring for 30 min. The mixture was then cooled to room temperature, and the aqueous layer was separated. The semisolid residue was redissolved in boiling water (approx. 28 mL), sodium hydroxide solution (4.8 M, 3 mL) was added and the clear solution was heated at reflux for 3 h. NaOH pellets were then added until a significant amount of solid had precipitated. Additional NaOH (2 g) was added and, after cooling, the precipitate was filtered off, washed thoroughly with acetone and dried to constant weight under reduced pressure, resulting in a brownish hygroscopic powder, which proved to be pure Na_4DOTPMB (8.69 g). – ^{1}H NMR (D_2O, DSS): δ = 3.88 (q, 8 H, O–CH_2), 2.89 (d, 8 H, N–CH_2–P), 2.75 (s, 16 H, ring CH_2), 1.63 (m, 8 H, CH_2), 1.38 (m, 8 H, CH_2), 0.92 (t, 12 H, CH_3).

Equilibrium Measurements: The concentrations of ligand solutions were determined by pH-potentiometry, from the titration curves obtained in the absence and in the presence of excess $CaCl_2$. – $LnCl_3$ (Ln = Gd and La) solutions were prepared by dissolving Ln_2O_3 (99.9%, Fluka) in 6 M HCl, after which the excess HCl was evaporated. The concentrations of $LnCl_3$ solutions were determined by complexometry with standardized K_2H_2EDTA, and xylenol orange was used as indicator. – The pH-potentiometric titrations were carried out in jacketed vessels kept at a constant temperature of 25 °C (thermostat), with a Radiometer PHM85 pH-meter, an ABU80 autoburette and PHG211 glass and K401 calomel electrodes. The ionic strength of the solutions was maintained constant (0.1 M Me_4NCl, $pK_W = 13.90$). For the titrations, an Me_4NOH solution (0.1 M) was used. Hydrogen ion concentrations were calculated from the measured pH values by a known procedure.[24,31] For the determination of the protonation constants of the ligands, the concentrations of the samples were 0.010 M for DOTP and 0.0038 M for DOTPMB. Three parallel titrations (60–90 points) were performed for each ligand in the pH range 2.0–12.2. The protonation constants are defined as $K_i^H = [H_iL]/([H_{i-1}L][H^+])$. – The compositions of the intermediates formed in the reaction between Gd^{3+} and H_xDOTP were studied by measuring the pH changes that occurred after the reactants were mixed. The concentrations of Gd^{3+} and H_xDOTP in the samples were $3\cdot10^{-4}$ M and $5\cdot10^{-3}$ M, respectively. The initial pH values of the samples (which were slightly buffered owing to the presence of a small excess of ligand) were 5.37, 6.07, 6.88, and 7.82. The decrease in the pH value was measured until equilibrium was reached. For the determination of the amount of protons released in the reactions, similar samples containing only H_xDOTP (0.1 M KCl) were titrated with HCl of known concentration until the equilibrium pH was established. – The stability constant of $Gd(DOTPMB)^{-}$ was determined by an "out-of-cell" technique. In the pH range 2.7–5.0, 15 solution samples (5 mL) were prepared in which the concentrations of DOTPMB and $GdCl_3$ were 0.0038 M each. The equilibrium pH values were measured three weeks after the preparation of the samples.

Kinetic Measurements: The rates of formation of the complexes were studied by relaxometry in the pH range 5.4−7.0. The formation of $Gd(DOTP)^{5-}$ was also investigated by spectrophotometry ($7.0 < pH < 8.0$). For the formation reactions, pseudo-first-order conditions were maintained with a 10-fold ligand excess, while the concentration of Gd^{3+} was $5\cdot10^{-4}$ M. All measurements were performed at constant temperature (25±0.2 °C) and constant ionic strength (0.1 M Me_4NCl). − The rates of formation reactions at $pH < 7.0$ were studied by measuring the longitudinal relaxation rates ($1/T_1$) of water protons. The pseudo-first-order rate constants (k_{obs}), were calculated from the values of the proton relaxation rates measured at the start, at time t and at equilibrium of the reactions. The proton relaxation times were measured at 9 MHz with an MRS-4 NMR spectrometer (Institute Jozef Stefan, Ljubljana, Slovenia). The temperature of the sample holder was kept constant with the use of an air stream. The T_1 values were measured by using the inversion recovery method (180° − τ − 90°), with an average of 4−6 measurements at 6−8 different τ values. A constant pH value was maintained by using 0.05 M MES as a buffer. − In the spectrophotometric measurements, the indicator method[32] was applied. In slightly buffered solutions (0.01 M HEPES, pH = 7.0−8.0), an approximate decrease of 0.1 in the pH value was monitored at 573 nm by using cresol red as indicator ($c_{ind} = 2.5\cdot10^{-5}$ M). The measurements were carried out with a Cary 1E UV/Vis spectrophotometer, using tandem cells for mixing the reagents. − The rates of dissociation of the complexes were studied by relaxometry (25 °C) in 0.025−1.0 M HCl. The ionic strength of the solutions was kept constant. The sum of the concentrations of HCl and Me_4NCl was 1.0 M. The concentrations of $Gd(DOTP)^{5-}$ and $Gd(DOTPMB)^{-}$ were each 0.001 M. For calculation of the first-order rate constant, k_d, the relaxation rates were used, measured at the start, at time t and at equilibrium of the reaction. − The ^1H NMR spectra were recorded in D_2O with a Bruker AM 360 spectrometer, DSS being used as internal standard. The pD values were calculated from the measured pH values by using the known equation[33] pD = pH + 0.4. − The protonation constants and the stability constants were calculated from the equilibrium measurement data through the use of the PSEQUAD program.[34] All calculations with kinetic data were made with least-squares fitting by the program SCIENTIST® for WINDOWS™ by MICROMATH®, version 2.0. The reported errors correspond to the standard deviation calculated by the programs.

Effect of Ion Coordination on the Conformational and Electronic Structure of 3,4-Bis(alkylthio)thiophenes

Fransesca Goldoni,[a] Luciano Antolini,[b] Geoffrey Pourtois,[c] Albertus P. H. J. Schenning,[a] René A. J. Janssen,[a] Roberto Lazzaroni,[c] Jean-Luc Brédas,[c] and E. W. Meijer*[a]

Keywords: Sulfur heterocycles / S ligands / Transition metals / Density functional calculations

A joint experimental and theoretical approach is used to study the coordination of soft transition metal ions with 3,4-bis(alkylthio)thiophenes. The synthesis of [$PdCl_2${3,4-bis(3-methylbutylthio)thiophene}], [$PtCl_2${3,4-bis(3-methylbutylthio)thiophene}] and [$PdCl_2${3′,4′-bis[2-(*S*)-methylbutylthio]-2,2′:5′,2′′-terthiophene}] by exchange of the benzonitrile ligands in [$PdCl_2(PhCN)_2$] and [$PtCl_2(PhCN)_2$] for the thiophene derivatives with thioether side chains is described. Changes in the conformational and electronic structure of the molecules were studied by X-ray diffraction, cyclic voltammetry, and optical and NMR spectroscopy; these experimental data are interpreted with the help of quantum mechanical calculations based on density functional theory. The complexes crystallize in a mixture of diastereoisomers, these stereoisomers are in equilibrium in solution, as observed by variable-temperature NMR spectroscopy. The complexation diminishes the electron-donor ability of the sulfur to the thiophene ring, as observed from the blueshift of the absorption maximum and from the absence of an oxidation wave in the positive potential regime for monomeric 3,4-bis(alkylthio)thiophenes. In this way it is possible to tune the properties of thiophene derivatives by ion coordination.

Introduction

Over the past two decades, thiophenes have attracted strong interest, because of the possible applications of the corresponding polymers in secondary batteries, sensors, photo- and electroluminescent devices, etc.[1−4] In particular, the development of side chain-substituted conjugated derivatives has led to the discovery of a number of interesting phenomena that are not observed in the unsubstituted parent polymers. For instance, the introduction of groups that could act as ligands opens possibilities for application in areas such as chemosensors and catalysis, as reported by Swager et al.[5,6] and Reynolds et al.,[7] respectively.

Because complexes with transition metal ions are of general use in fields such as catalysis, we are investigating the synthesis and properties of new conjugated polymers with alkylthio side groups, since thioether ligands are well known for their ability to complex soft transition metal ions.[8,9] Such conjugated polymers could act as probes or modulators of the activity of the catalytic centre. Furthermore, these systems could be used to anchor biomolecules in a reversible fashion by metal coordination. Similarly, Leclerc et al.[10] reported the possibility of fixing avidin to polythiophene through acid-base complexes. Finally, ion coordination can also be envisioned as an interesting approach to modulate the properties of the conjugated polymer in a noncovalent way.

In this paper we describe the synthesis of [$PdCl_2${3,4-bis(3-methylbutylthio)thiophene}] (**5**), [$PtCl_2${3,4-bis(3-methylbutylthio)thiophene}] (**6**) and [$PdCl_2${3′,4′-bis[2-(*S*)-methylbutylthio]-2,2′:5′,2′′-terthiophene}] (**7**) by exchange of the benzonitrile ligands in [$PdCl_2(PhCN)_2$] and *cis*-[$PtCl_2(PhCN)_2$] for the thiophene derivatives with thioether side chains. The complexes **5** and **6** crystallize in a mixture of diastereoisomers and these stereoisomers are in equilibrium in solution, as observed by variable temperature NMR spectrosocpy. The optical and electrochemical properties of the thiophene derivatives are strongly modified by the presence of the transition metal ions. To account for these properties, this paper also reports theoretical calculations on the geometries of the molecules and on their corresponding energies, together with the interpretation of the optical spectra.

Results and Discussion

Synthesis of the Complexes

The 3,4-bis(3-methylbutylthio)thiophenes **2** and 3,4-bis[2-(*S*)-methylbutylthio]thiophene **3** were conveniently synthesized by transetherification of 3,4-dimethoxythiophene (**1**) with the corresponding thiols, as we reported

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0303−0821 $ 17.50+.50/0

previously.[11] Stille coupling of the diiodo derivative of **3** with two equivalents of 2-trimethyltinthiophene in the presence of catalytic amounts of Pd^0 produced the desired terthiophene **4**.[12]

The chelate Pd complexes **5** and **7** were obtained by the reaction of an equimolar amount of the dithioether in dichloromethane with $[PdCl_2(PhCN)_2]$, as shown in Scheme 1. The complexes were separated as orange-red solids upon addition of 2-propanol. Using the same conditions as for complex **5**, the corresponding Pt derivative *cis*-$[PtCl_2(PhCN)_2]$ did not react with the ligand at room temperature, as reported for other thioether ligands.[8] However, under UV irradiation in $CHCl_3$, chelate complexation of the dithioether ligand to the platinum centre took place and was completed in a few hours. Addition of hexane led to precipitation of complex **6** as a pale yellow solid. All new compounds **2**−**7** were fully analysed, including NMR spectroscopy and elemental analysis.

Crystal Structure

Both compounds **5** and **6** crystallize in the monoclinic $P2_1/c$ space group, in quasi-identical cells (the axes or

angles do not differ by more than 0.45%, see Table 1).[13] In both compounds the asymmetric unit contains two crystallographically independent *syn* and *anti* isomeric molecules, which are shown in Figure 1 and 2 along with the atom numbering. Selected bond lengths and angles are reported in Table 2.2

A comparison between all structural features of both isomers of complexes **5** and **6**, starting from atomic fractional coordinates, reveals such a close resemblance that the same description can be indifferently applied to either the Pd (**5**) or Pt (**6**) derivative. Most of the corresponding bond lengths, bond angles, and torsion angles in compounds **5** and **6** are equal within one or two standard deviations; moreover, this is equally true for their nonbonded intermolecular contacts. In both complexes, the metal atoms of the two independent molecules display nearly ideal square-planar four-coordination, with the two *cis* Cl atoms and the two sulfanyl S atoms from the substituted thiophene molecule binding in a chelating fashion. As expected, the thiophene rings are nearly coplanar with respect to the coordination planes. The metal atoms are coplanar with their donor atoms in A-labelled molecules, and slightly displaced from the plane in B-labelled ones (Table 2).

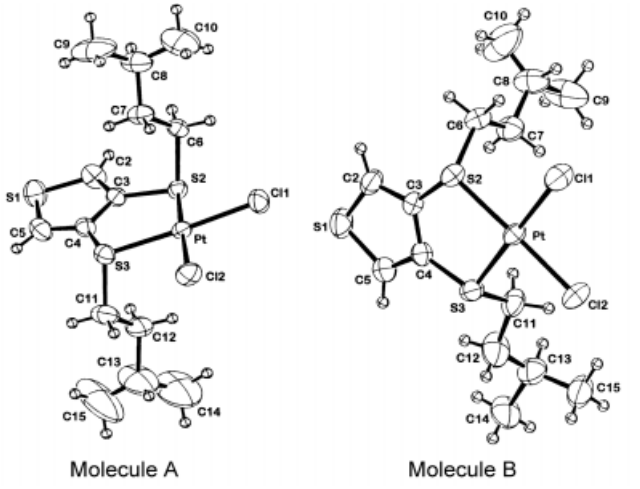

Figure 2. ORTEP drawing of the two independent molecules of compound **6**; thermal ellipsoids for non-H atoms enclose 30% probability

In order to estimate the relative energy of the different structures and to gain information on changes in the electronic density due to complexation, calculations were performed on representative models using a Density Functional Theory (DFT) approach. To keep the computational effort to a reasonable level, the alkylthio side chains were represented by methylthio groups. The theoretical description of the geometry obtained for [$PdCl_2${3,4-bis(methylthio)thiophene}] is fully consistent with the X-ray data of compound **5**. The largest difference between theoretical and experimental data is only about 0.02 Å and 3° for the bond lengths and bond angles, respectively. A comparison between the theoretical structures of 3,4-bis(methylthio)thiophene (Figure 3a) and [$PdCl_2${3,4-bis(methylthio)thiophene}] (Figure 3b,c) is reported in Table 3. These data indicate that the complexation does not lead to significant bond length or angle modifications in the thiophene moiety. The changes are large on the thioether groups where the complexation leads to an increase (0.03 Å) of the bond lengths between the C_β of the thiophene ring and the sulfur atoms.

The nature of the bonds between the thioether groups and the Pd atom is clearly covalent: the calculated Pd−S distances (2.292 Å) are indeed slightly lower than the sum

of the covalent radii (2.330 Å).[14] The quasi-equivalent bond lengths to the two Cl atoms (2.304 Å) and to the two sulfanyl S atoms (2.292 Å) and their respective angles (about 90°) form a nearly square planar configuration around the Pd centre, as also observed in the X-ray structure.

From the calculations it is possible to evaluate the stability of the complex, i.e., the binding energy of $PdCl_2$ to 3,4-bis(methylthio)thiophene; this is obtained from the difference in total energy between the complex and the separate partners. The value calculated with a nonlocal-gradient-corrected DFT approach is -181 kJ mol^{-1} and -171 kJ mol^{-1} for the *syn* and *anti* isomers, respectively. We also checked that alternative bonding sites for the Pd atom (the sulfur atom of the thiophene ring and the π system of the thiophene ring) lead to complexes with much lower binding energies (-83 and -52 kJ mol^{-1}, respectively).

In both complexes, the two independent molecules in the crystallographic unit differ only by the absolute configuration around the metal-bonded S atoms, which are stereocentres. Both crystals contain all the diastereoisomeric

Table 3. Comparison of theoretical bond lengths and angles of {3,4-bis(methylthio)thiophene} (**a**) and [$PdCl_2${3,4-bis(methylthio)thiophene}] (**b**) with the experimental data for compound **5** (isomer B)

forms. The S atoms of the A- and B-labelled molecules display *R,R* and *R,S* configurations, respectively. Due to the presence of an inversion centre (and of a glide plane), the inverted *S,S* and *R,S* configurations are also present, and hence the compounds crystallise in a racemic form. There are no significant differences between the corresponding bond lengths and angles of the two independent molecules, and their values compare well with the mean bond lengths retrieved from the Cambridge Structural Database.[15,16] It is of interest to note that the strong similarities between the two structures also apply to probable disorder problems, which involve, in particular, two terminal methyl groups of the alkyl chains. In both crystals, and in both independent molecules, the C(9) and C(10) atoms are affected by extremely high temperature factors, and, as a consequence, by extremely short (and unrealistic) bond lengths. Nevertheless, to observe this effect in both independent molecules and in both complexes could be of some significance with regard to their molecular packing mode. As reported above, both complexes exhibit the same molecular packing, characterised by only three nonbonded distances lower than 3.60 Å (two C···S and one C···C contacts). These interactions occur only between racemic pairs (A- or B-labelled) of molecules.

Variable Temperature NMR Spectroscopy

The variable temperature ^{1}H NMR spectrum of the palladium complex **5** in chloroform solution is shown in Figure 4. At room temperature the compound shows a singlet for the α-proton of the thiophene, and broad peaks in the aliphatic region, corresponding to the thioether side chains, all deshielded relative to the values for uncomplexed com-

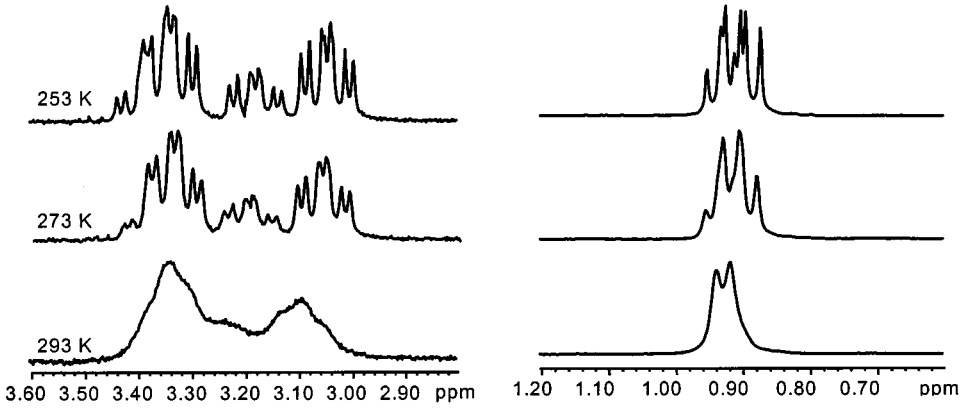

Figure 4. Variable temperature ^{1}H NMR spectrum of compound **5** in $CDCl_3$ in the regions corresponding to the signals of the SCH_2 and CH_3 protons

pound **2**. In the ^{13}C NMR spectrum at room temperature, there are two peaks in the aromatic region at $\delta = 128$ and 135, corresponding to the two α- and β-carbons of the thiophene ring, respectively, while five peaks for the aliphatic region are recorded, including two at $\delta = 21.9$ and 22.2 corresponding to the two methyl end groups, indicating that these groups have a reduced motional freedom. At −20 °C, the thioether side chains resolve into several multiplets. The diastereotopic $SCH_2(\alpha)$ is resolved into two groups of signals, each consisting of two double triplets, as shown in Figure 4. At lower temperatures, we also observe the presence of two doublets of doublets for the CH_3 group at the end of the chain, confirming the presence of two isomers.

The two *syn* and *anti* isomers are in equilibrium in solution, and from the coalescence temperature and the ratio of the integrated signals, we can deduce that one is preferred over the other in a 2:1 ratio. An approximate energy barrier of 68 kJ mol^{-1} can be calculated for the interconversion between the two isomers, and the difference in energy between the two forms is approximately 1.7 kJ mol^{-1}. The theoretical calculations on the corresponding [$PdCl_2${3,4-bis(methylthio)thiophene}] isomers (Figure 3) indicate that the *syn* form is more stable than the *anti* form by about 10 kJ mol^{-1}. Such an overestimation, relative to the experimental value, may be due to the fact that the calculations are performed on single isolated molecules, thereby neglecting the influence of the solvent. The two isomers can be identified with the two couples of diastereoisomeric molecules A and B observed in the crystal.

UV/Vis Spectroscopy

With respect to uncomplexed compound **2**, which presents an absorption maximum at 286 nm, the absorption maximum in complex **5** is blue-shifted by 29 nm, to 257 nm (Figure 5). The spectrum also shows two smaller bands at 315 nm ($\varepsilon = 2800$ dm^3 mol^{-1} cm^{-1}) and 412 nm ($\varepsilon = 1000$ dm^3 mol^{-1} cm^{-1}). INDO/SCI calculations on [$PdCl_2${3,4-bis(methylthio)thiophene}] indicate that the maximum at 257 nm is a HOMO to LUMO+1 transition localised on the thiophene moiety, and that the two bands at 315 nm and 412 nm are due to transitions involving the Pd atoms.

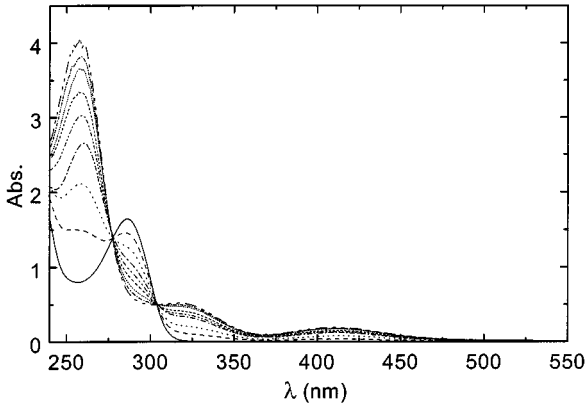

Figure 5. UV/Vis spectra of the titration of 3,4-bis(3-methylbutylthio)thiophene **(2)** with [$Pd(CH_3CN)_2Cl_2$] in acetonitrile

The blue shift of 29 nm found for the main absorption is related to the stabilization of the HOMO due to the diminished electron-donating ability of the S atoms; as a result, the absorption maximum gets closer to that of thiophene itself (231 nm). The absorption coefficient is significantly increased from $\varepsilon = 4800$ dm^3 mol^{-1} cm^{-1} at 286 nm in the uncomplexed compound to 11100 dm^3 mol^{-1} cm^{-1} at 257 nm in compound **5**.

From the titration experiment, we can observe the presence of two clear isosbestic points, indicating the presence of the two species (complexed and uncomplexed) in solution (see Figure 5).

Cyclic Voltammetry and Electropolymerisation.

The electrochemical characterisation of **5** reveals one reversible reduction wave at −0.71 V, while **2** just presents an irreversible oxidation wave at 1.7 V. No oxidation wave is observed for **5** in the positive potential regime ($E \leq 1.8$ V), which is in contrast to what is found in electron-donor-substituted thiophenes.[17−19] Therefore compound **5** cannot be oxidatively electropolymerised.

In order to explain this behaviour, we computed the electronic properties of 3,4-bis(methylthio)thiophene and its $PdCl_2$ complex. The electrophilic character of $PdCl_2$ is

clearly illustrated through the Mulliken charge-transfer analysis (Table 4).

Table 4. Mulliken charge analysis for [$PdCl_2${3,4-bis(methylthio)thiophene}]; the charge variation is defined as the difference between the DFT-calculated electronic charges in the complex and in the isolated compounds; a negative value corresponds to a gain of electronic density

Atoms	Charge variation |e|
Cl(1)	−0.16
Cl(2)	−0.16
Pd	−0.29
C(6)H_3 group	+.008
C(11)H_3 group	+.008
S(3)	+0.11
S(2)	+0.11
C(3)	−0.04
C(4)	−0.04
C(2)H	+0.10
C(5)H	+0.10
S(1)	+0.07

As a consequence of complexation, a partial charge transfer (−0.6 |e|) takes place from 3,4-bis(methylthio)thiophene to $PdCl_2$. The sulfur atoms of the thioether groups and the C_α atoms of the thiophene ring are the most depleted sites, while the alkyl side chains and the C_β atoms of the ring remain almost untouched. Globally, the decrease in electron density on the organic molecule upon complexation is consistent with the fact that oxidation becomes more difficult. Along the same lines, the redox properties can be qualitatively interpreted on the basis of the one-electron electronic structure of the molecule. Indeed, the oxidation process corresponds to the removal of one electron and can thus be roughly connected to the energy of the HOMO.[20] Similarly, the reduction process induces the addition of one electron that must be deposited on the LUMO.

The analysis of the electronic structure of 3,4-bis(methylthio)thiophene (**a**) and its $PdCl_2$ complex (Figure 6) shows two important points. Firstly, the HOMO of [$PdCl_2${3,4-bis(methylthio)thiophene}] is similar to that of 3,4-bis(methylthio)thiophene but is strongly stabilized (Table 5). This implies that oxidation becomes more difficult when going from 3,4-bis(methylthio)thiophene to its $PdCl_2$ complex. Secondly, the complexation leads to the localization of the LUMO on the Pd atom and to a strong energetic stabilization (Table 5). This is fully consistent with the appearance of a reduction peak at −0.71 V.

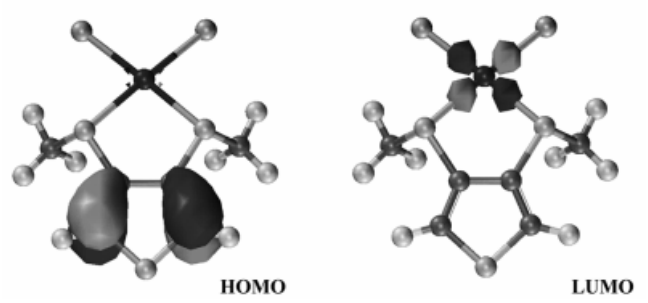

Figure 6. INDO-calculated HOMO and LUMO patterns of [$PdCl_2${3,4-bis(methylthio) thiophene}]

Table 5. Comparison of the INDO energies of the LUMO, and HOMO for 3,4-bis(methylthio)thiophene (**a**), {$PdCl_2$[3,4-bis(methylthio) thiophene]} (**b**), [3′,4′-bis(methylbutylthio)-2,2′:5′,2′′-terthiophene] (**4**), and {$PdCl_2$[3′,4′-bis(methylthio)-2,2′:5′,2′′-terthiophene} (**7**); the energies are in electron volts (eV)

	a	**b**	**4**	**7**
LUMO	0.34	−1.32	−0.88	−1.88
HOMO	−8.17	−9.70	−6.77	−7.75

Since complexation diminishes the electronic density on the α-positions of the thiophene ring (Table 4), electrochemical oxidation and monomer coupling at these positions become more difficult. This explains why the electropolymerisation of compound **5** was not successful. To overcome this problem, we therefore synthesized compound **7**, which possesses both a complexed Pd atom and two pristine C_α sites. This compound also has a reversible redox wave at −0.71 V and, most importantly, shows a highly irreversible oxidation wave at 1.7 V. This behaviour is consistent with the electronic structure of [$PdCl_2${3,4-bis(methylthio)thiophene}] and [$PdCl_2${3′,4′-bis(methylthio)-2,2′:5′,2′′-terthiophene}] (Table 5). The energetic values and the nature of the frontier molecular orbitals are modified when going from the thiophene complex to the terthiophene complex (Figure 7 and Table 5). In the terthiophene complex, both the HOMO and LUMO are mostly localized on the organic backbone, with strong similarities to those of the uncomplexed molecule. The HOMO of [$PdCl_2${3′,4′-bis(methylthio)-2,2′:5′,2′′-terthiophene}] is strongly destabilized (1.95 eV) relative to that of [$PdCl_2${3,4-bis(methylthio)thiophene}]. This destabilization of the HOMO implies that the oxidation process is much easier for [$PdCl_2${3′,4′-bis(methylthio)-2,2′:5′,2′′-terthiophene}] than for [$PdCl_2${3,4-bis(methylthio)thiophene}]. As for [$PdCl_2${3,4-bis(methylthio)thiophene}], complexation leads to the stabilization (1 eV) of the LUMO. However, the LUMO is no longer localized on the Pd atom but on the terthiophene part while the LUMO+1 is found on the Pd atom.

Based on these considerations, it is most likely that the oxidation wave at 1.7 V is due to the oxidation of the terthiophene moiety. Red films of electrochemically active, polymeric material can be grown on the Pt electrode by repetitive cycling, but the polymer is no longer soluble in organic solvents. The results of the electropolymerisation and of the complexation of the preformed polymers will be reported in a forthcoming paper.[21]

Conclusion

Complexes between thiophenes substituted with thioether ligands and transition metal ions were successfully synthesized. We have shown that complexation leads to the freezing of the rotation of the side chains, as the complexes

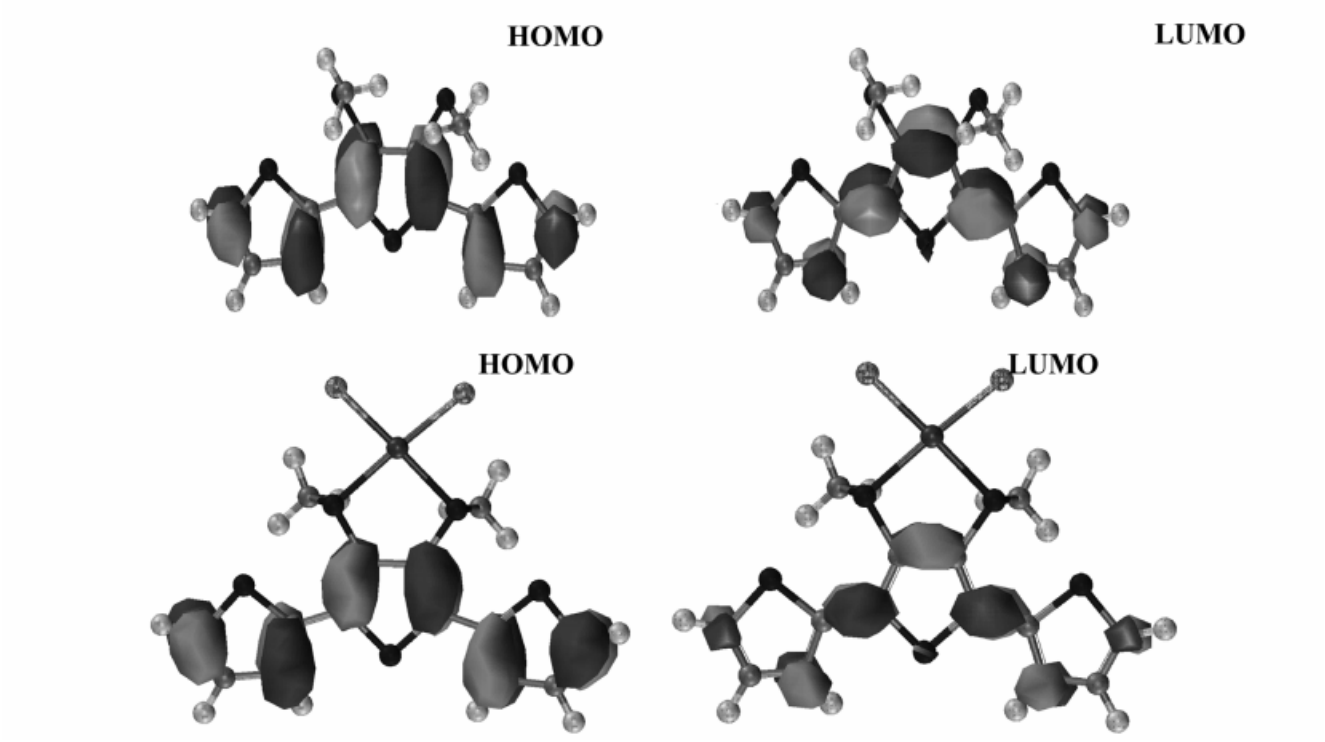

Figure 7. INDO-calculated HOMO and LUMO patterns of [$PdCl_2${3′,4′-bis(methylthio)-2,2′:5′,2′′-terthiophene} and -{3′,4′-bis(methylbutylthio)-2,2′:5′,2′′-terthiophene}]

are crystalline at room temperature. Furthermore, the reversible linkage with the metal ions modifies the optical and electrochemical properties of the thiophene derivatives. Thus, metal complexation can be used as a reversible tool for the modification of the properties in π-conjugated polymers.

Experimental Section

General Remarks: The IR spectra were recorded on a Perkin−Elmer 1600 series FT-IR spectrometer. NMR spectra were recorded on a Varian Gemini 300 spectrometer. Chemical shifts are reported in ppm downfield from TMS. The UV/Vis spectra were recorded on a Perkin−Elmer Lambda 900 spectrophotometer. Cyclic voltammograms were recorded with 0.1 M tetrabutylammonium hexafluorophosphate as supporting electrolyte using a Potentioscan Wenking POS73 potentiostat. The working electrode was a platinum disc (0.2 cm^2), the counterelectrode was a platinum plate (0.5 cm^2) and the reference electrode was a saturated calomel electrode calibrated against a Fc/Fc^+ couple. Electrospray-MS (ESI/MS) measurements were performed on a Perkin−Elmer/Sciex API300 mass spectrometer. Elemental analysis (C, H, N) was obtained by combustion analysis using a Perkin−Elmer 2400. 3,4-Bis(3-methylbutylthio)thiophene (**2**)[11] and 3′,4′-bis[2-(*S*)-methylbutylthio]-2,2′:5′,2′′-terthiophene (**4**)[12] were prepared as previously reported. All other reagents were commercial products and were used as received. Solvents were dried by standard procedures.

[$PdCl_2${3,4-Bis(3-methylbutylthio)thiophene}] (5): The ligand 3,4-bis(3-methyl-butylthio)thiophene[11] (**2**; 75 mg, 0.26 mmol) was added to a solution of [$PdCl_2(PhCN)_2$] (100 mg, 0.26 mmol) in dry dichloromethane (5 mL). After stirring at room temperature for 20 min., 2-propanol was added to give an orange precipitate of **5** which was filtered off and dried in vacuo (115 mg, 95%). − ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C, TMS): δ = 7.6 (s, 2 H, 2-H and 5-H), 3.3 (broad, 4 H, α-H), 2.06 (broad, 2 H, γ-H), 1.8−1.4 (broad, 4 H, β-H), 0.87 (broad, 6 H, CH_3). − ^{13}C NMR (75 MHz, $CDCl_3$, 20 °C): δ = 134 (C_4 and C_5), 128 (C_2 and C_3), 43 (α-C), 38 (δ-C), 27 (β-C), 22.2 (CH_3) and 21.9 (CH_3). − ES-MS; *m/z*: 395 [M − 2Cl]. − $C_{14}H_{24}Cl_2PdS_3$ (465.7): calcd. C 36.11, H 5.15; found C 36.11, H 5.24.

[$PtCl_2${3,4-Bis(3-methylbutylthio)thiophene}] (6): The ligand 3,4-bis(3-methyl-butylthio)thiophene[11] (**2**; 30.5 mg, 0.13 mmol) was added to a solution of [$PtCl_2(PhCN)_2$] (50 mg, 0.13 mmol) in chloroform (10 mL). The solution was irradiated (about 300 nm) at 35 °C for 11 h. The chloroform was evaporated and hexane was added. The solid was stirred in hot hexane, then the solvent was removed by decantation. The solid was then recrystallized from 2-propanol to give **6** (23.6 mg, 48%). − ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C, TMS): δ = 7.56 and 7.54 (s, 2 H, 2-H and 5-H), 3.28 and 3.15 (two multiplets, 4 H, α-H), 2.00 (multiplet, 2 H, γ-H), 1.8−1.4 (three multiplets, 4 H, β-H), 0.95, 0.94, 0.91 and 0.89 (four doublets, 6 H, 2 CH_3). − ^{13}C NMR (75 MHz, $CDCl_3$, 20 °C): δ = 125 (C_2 and C_3), 43 (α-C), 37.7 and 37.6 (δ-C), 27.3 and 27.2 (β-C), 22.4, 22.3 and 22.0 (CH_3). − $C_{14}H_{24}Cl_2PtS_3$ (554.3): calcd. C 30.33, H 4.32; found C 30.70, H 3.99. Probably due to a broadening of the signals, the peaks of the C_4 and C_5 could not be detected, even after an overnight acquisition.

[$PdCl_2${3′,4′-Bis[2-(*S*)-methylbutylthio]-2,2′:5′,2′′-terthiophene}] (7): The ligand 3′,4′-bis[2-(*S*)-methylbutylthio]-2,2′:5′,2′′-terthiophene[12] (**4**; 100 mg, 0.22 mmol) was added to a solution of [$PdCl_2(PhCN)_2$] (84 mg, 0.22 mmol) in dichloromethane (10 mL). After stirring at room temperature for 20 min., the solvent was removed to give **7** (115 mg, 83%). − ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C, TMS): δ = 7.54 (dd, J_{35} = 0.98 Hz, J_{45} = 5 Hz, 2 H, 5-H and 5"-H), 7.40 (broad dd, 2 H, 3-H and 3"-H), 7.16 (dd, J_{34} = 3.7 Hz,

J_{45} = 5 Hz, 2 H, 4-H and 4"-H), 3.4−2.8 (broad multiplets, 4 H, α-H), 2.1−1.6 (broad, 2 H, β-H), 1.4−1.0 (broad, 4 H, γ-H), 0.9−0.6 (broad, 6 H, δ- and ε-CH_3). − ^{13}C NMR (75 MHz, $CDCl_3$, 20 °C): δ = 130.6 (2C, 2-C and 2′′-C), 129.7 (2C, CH), 129.1 (2C, CH), 128.8 (2C, CH), 53.4, 52.8, 50.8, 50.2 [2C, CH_2(α)], 35.7, 34.3 [2C, CH(β)], 29.3, 29.2 [2C, CH_2 (γ)], 19.8, 18.9 [2C, CH_2(ε)], 11.3, 11.2 [2C, CH_2(δ)]. − $C_{22}H_{28}Cl_2PdS_5$ (629.9): calcd. C 41.95, H 4.47; found C 41.01, H 4.51. Probably due to a broadening of the signals, the peaks of the quaternary carbons could not be detected, even after an overnight acquisition.

Crystal Structure Determination for Compounds 5 and 6: Diffraction data for compound **5** were collected on a Enraf−Nonius CAD4 diffractometer, whereas those for compound **6** were obtained with a Siemens P4RA-M18X diffractometer equipped with a rotating anode (52 kV, 130 mA). In both cases, the ω-2θ scan mode was chosen. Crystal data and details of data collections and refinements are summarised in Table 1. The structures were solved by direct methods (SHELXS-86) and were refined by full-matrix least-square calculations based on F^2 (SHELXL-93). All non-hydrogen atoms were refined anisotropically, and H atoms were constrained to remain in ideal positions on the C atoms to which they are bonded. In both compounds, two methyl groups (C_9 and C_{10} in Figure 1 and 2) display unusually high thermal motion parameters and extremely short bond lengths, perhaps indicative of light disorder.

Theoretical Methodology: 3,4-Bis(methylthio)thiophene and [3′,4′-bis(methylthio)-2,2′:5′,2′′-terthiophene] were used as representative models for the 3,4-bis(3-methylbutylthio)thiophene (**2**) and [3′,4′-bis(methylbutylthio)-2,2′:5′,2′′-terthiophene] (**4**), respectively. The geometries of the isolated molecules as well as those of the complexes with $PdCl_2$ were fully optimized at the density functional level of calculation. The main advantage of Density Functional Theory (DFT) with respect to Hartree−Fock is that it allowed us to take electron correlation explicitly into account, which is of the utmost importance in the description of metal-organic interactions. The Vosko-Wilk-Nusair[22] function for the exchange-correlation potential in the local density approximation was used, along with a double numerical precision basis set (DNP) of 6−311 G* quality.[23] A frozen-core approximation equivalent to the use of a pseudopotential was used for the palladium and chlorine atoms. The binding energies and charge distributions calculations were carried out at the nonlocal level of DFT using the Becke-Lee-Yang-Parr gradient-corrected functional[24,25] for the exchange-correlation potential. This methodology has already been successfully applied to metal-organic systems containing aluminum, nickel, copper, and iron.[26,27] The interpretation of the optical spectra of [{$PdCl_2$(3,4-bis(methylthio) thiophene}] (**5**) was performed on the basis of Hartree−Fock INDO semiempirical calculations, coupled to a Single Configuration Interaction description (SCI).[28]

Transition Metal (^{53}Cr, ^{59}Co, ^{91}Zr, and ^{95}Mo) and ^{14}N NMR Spectroscopy of Coordination Compounds Containing Nitrogen Donor Ligands in Low-Viscosity Fluids

Sander Gaemers,[a] Jeroen Groenevelt,[a] and Cornelis J. Elsevier*[a]

Keywords: High-pressure NMR / Low-viscosity solvents / NMR spectroscopy / Quadrupole nuclei / Supercritical fluids / Subcritical fluids / Transition-metal NMR

Appreciable decreases of the line widths of NMR resonances of the quadrupolar nuclei ^{14}N, ^{53}Cr, ^{59}Co, ^{91}Zr, and ^{95}Mo have been obtained in supercritical solvents and in low-viscosity liquefied gases. Several α-diimines $R^1N{=}C(R^2){-}C(R^2){=}NR^1$ and their coordination compounds have been studied. Regarding the solubility of two α-diimines and some Cr, Zr, and Mo complexes it appears that the addition of small amounts of a modifier (acetone, CH_2Cl_2, THF) results in enhanced solubility of compounds without detrimental effects on the line widths. The use of HP NMR tubes (with and without pressure sensor) is very appropriate for measurements of NMR spectra under high pressure in supercritical fluids and liquefied gases of low viscosity. In several cases it appeared that the use of liquefied gases is more straightforward than the use of supercritical fluids, and gives similar or better results in terms of reduction of line widths.

Introduction

Nuclear magnetic resonance in solution plays an essential role in structure elucidation in chemistry, particularly the characterization of organometallic and coordination compounds. The development of transition metal NMR spectroscopy has greatly increased the knowledge of the relation between chemical shift and structure[1,2] in metal-containing compounds, and can help in solving structures and elucidating reaction mechanisms involving transition metal complexes.[3] Unfortunately, approximately 75% of the metal nuclei have a nuclear spin $I > {}^1/_2$, i.e. these nuclei possess a nuclear quadrupole moment. Obtaining NMR spectra of such nuclei can be troublesome due to their short T_1 and T_2, caused by the (extremely) efficient quadrupolar relaxation mechanism, which results in broadened resonance lines.[4,5] Accordingly, the application of nitrogen NMR spectroscopy for the analysis of nitrogen-containing compounds is difficult due to the low natural abundance of ^{15}N (0.36%), and the quadrupole moment of ^{14}N.

If line widths of quadrupolar nuclei could be considerably reduced, their acquisition and analysis would be greatly facilitated.[6,7] The quadrupolar relaxation[4] of a nucleus with $I > {}^1/_2$ is given in Equation (1), where I denotes the nuclear spin, η_s is the asymmetry parameter of the complex, χ is the nuclear quadrupole coupling constant, and τ_c is the rotational correlation time of the molecule in solution.

$$\Delta\nu_{1/2} = \frac{1}{\pi T_1} = \frac{1}{\pi T_2} = \frac{3\pi}{10}\left(\frac{2I+3}{I^2(2I-1)}\right)\left(1+\frac{\eta_s}{3}\right)(\chi)^2\,\tau_c$$

[a] Institute of Molecular Chemistry, Coordination and Organometallic Chemistry, University of Amsterdam, Nieuwe Achtergracht 166, 1018 WV Amsterdam, The Netherlands
E-mail: else4@anorg.chem.uva.nl

The expression for the rotational correlation time is presented in Equation (2), where V is the molecular volume, η_v is the bulk solvent viscosity, k is Boltzmann's constant, and T the temperature.

$$\tau_c = \frac{V\eta_v}{kT}$$

From Equation (1) and Equation (2) it appears that the quadrupolar relaxation rates can be reduced by employing solvents with a low bulk viscosity. For instance, supercritical fluids (SCFs) possess very low viscosities, which is one to two orders of magnitude lower than that of organic solvents,[6] enabling significant reductions of the line widths of quadrupolar broadened resonance lines.[7] Fortunately, the critical temperature and pressure of numerous compounds (see Table 1) are readily accessible by employing versatile yet simple devices like sapphire high-pressure NMR tubes in commercial NMR spectrometers.[8] This fact greatly facilitates the semi-routine acquisition of NMR spectra in supercritical fluids.

The recent and rapid growth in the use of SCFs as reaction media, particularly in catalysis involving transition metal compounds in homogeneous solution, is clearly evident.[9] A major problem is the low solvating power of these

fluids. Apolar compounds usually dissolve sufficiently in SCFs for catalysis and NMR spectroscopy (e.g. small organic molecules[6a,6c] or metal-carbonyl complexes[6b,6d]). For more polar compounds, there are several options: (i) modification with fluorinated anions[10] or with apolar side chains;[11] (ii) addition of small amounts of a co-solvent to a supercritical fluid;[12] (iii) application of polarizable SCFs, e.g., CHF_3, $CClF_3$, $CHClF_2$. In this study, we have taken recourse to the latter two options.

We have studied a number of nitrogen donor ligands (α-diimines) and transition metal complexes in liquefied gases and supercritical fluids by ^{14}N and transition metal (^{59}Co, ^{91}Zr, ^{95}Mo, ^{53}Cr) NMR spectroscopy. Several of these low-viscosity (supercritical) solvents were used to try to reduce their resonance line width. The solubility of α-diimines in several supercritical solvents has also been assessed. The data have been compared to those in common organic solvents.

Results and Discussion

A. ^{14}N NMR Spectroscopy of α-Diimines

Solubility

The solubility of the α-diimine $Me_3CCH_2N{=}C(Me){-}C(Me){=}NCH_2CMe_3$ [*neo*Pe−DAB(Me)] has been determined in $CDCl_3$, CO_2, CHF_3, and $CClF_3$ at 293 K and 323 K by comparison of the relative integrals of the proton signal of the $CH_2C(CH_3)_3$ moiety in their ^1H NMR spectra in the respective solvents. The sample volume of the HP NMR tube[8] was reduced to 1.7 mL employing an aluminum plug inserted in the high pressure NMR tube in order to reduce convection in the HP NMR tube and to ensure proper thermostatization of the samples during NMR experiments. The relative solubilities, the line widths at half height $\Delta\nu_{1/2}(^{14}N)$ and the ^{14}N and ^1H chemical shifts have been compiled in Table 2.

In liquefied gases and supercritical fluids, saturated solutions of *neo*Pe-DAB(Me) were employed at concentrations ranging from 0.004 to 0.072 M. The maximum achievable concentration in the compressed gasses amounted to 0.072 M in CO_2(l) at 293 K and 55.5 bar; the concentration employed in $CDCl_3$ was 0.091 M. The solubilities at 293 K and at 323 K are graphically shown in Figure 1.

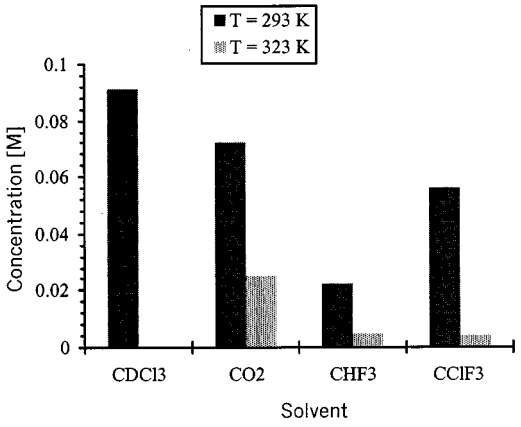

Figure 1. Solubility of $Me_3CCH_2N{=}C(Me){-}C(Me){=}NCH_2CMe_3$ [*neo*Pe-DAB(Me)] in various liquid and supercritical solvents

The solubility of *neo*Pe-DAB(Me) decreases by a factor of about 5 going from $CDCl_3$ to liquefied CHF_3 (293 K), but not very much for liquefied CO_2 or $CClF_3$. Its solubility is much lower (by a factor of between 4 and 20) in the supercritical state for the solvents studied (CO_2, $CClF_3$, CHF_3). This is the result of the low density of the SCFs compared to the density of the liquid state, which leads to a decrease of the solvent−solute interactions. The highest solubility of *neo*Pe-DAB(Me) in the series of pressurized gases studied was observed for CO_2 and $CClF_3$ in the liquid state. Its solubility in CHF_3, either in the liquid or supercritical state, is approximately a factor 4 or 5 lower than its solubility in liquid or supercritical CO_2. The higher solubility of *neo*Pe-DAB(Me) in liquid $CClF_3$ compared to liquid CHF_3 is due to the higher polarizability of the former. The higher solubility of *neo*Pe-DAB(Me) in CO_2 compared to CHF_3 is surprising as the dipole moment of the latter is higher than that of CO_2 [$\mu(CHF_3)$ = 1.65 Debye; $\mu(CHCl_3)$ = 1.01 Debye][13] and the polarizability of CHF_3

is slightly higher than that of CO_2 [$\alpha(CHF_3) = 2.80$ Å^3; $\alpha(CO_2) = 2.63$ Å^3].[14]

Chemical Shift

The ^{14}N chemical shifts of *neo*Pe-DAB(Me) vary between $\delta = -39$ and -42 (Table 2), the ^{14}N NMR resonances shift by 1 ppm upon heating the solutions from 293 K to 323 K. The change in ^{14}N chemical shift observed when heating liquefied gases is similar to the change observed when heating a $CDCl_3$ solution. In the case of the compressed gases, the effect of temperature on the chemical shift of the ^{14}N NMR resonance of *neo*Pe-DAB(Me) is not caused by a decrease of the fluid density, but is due to variations in the shielding tensor.

The variation in the ^1H chemical shift is more striking. The proton signals are shifted by approximately -1.5 ppm upon changing the solvent from $CDCl_3$ to the liquefied gases. In $CDCl_3$ no change is observed for the ^1H chemical shift, when heating the solution from 293 K to 323 K, whereas the chemical shift increases by 1 ppm in the case of the liquefied gases. This is explained by the variation of the diamagnetic volume susceptibility of the compressed gases changing from the liquid to the supercritical state.[15]

Line Widths

Line widths of the ^{14}N NMR resonances of *t*Bu-DAB and *neo*Pe-DAB(Me) in CO_2, $CClF_3$, CHF_3, SF_6, and acetone/[D_6]acetone (3:1) have been determined at various temperatures in the range 293−323 K. These data are graphically shown in Figure 2.

The reduction of the ^{14}N line widths in supercritical solvents compared to acetone and $CDCl_3$ is appreciable. [The ^{14}N line width of *neo*Pe-DAB(Me) has also been compared to $CDCl_3$ at 293 K; 1100 ± 25 Hz and at 323 K: 670 ± 20 Hz, see above, Table 2.] This clearly demonstrates the advantageous effect of the low-viscosity fluids on quadrupolar relaxation rates: Indeed much sharper lines are observed in the liquefied gases and supercritical fluids. Although the line widths of the ^{14}N resonances of *t*Bu-DAB (Figure 2, A) and *neo*Pe-DAB(Me) (Figure 2, B) are very different, the variation in line width for each compound spans a similar range, indicating that the values of τ_c in the various liquefied gases and SCFs are comparable. Furthermore, as expected, the observed ^{14}N NMR line widths are lower in the SCFs (at 323 K) than in the liquefied gases (at 293 K). Reduction factors[16] of the line widths of the ^{14}N NMR resonances in liquefied gases at 293 K and in the SCFs at 323 K relative to $CDCl_3$ at 293 K, as well as at 323 K, have been compiled in Table 3.

Not withstanding the fact that acetone has a much lower viscosity than chloroform, the line widths of the ^{14}N resonances in the liquefied gases and SCFs are considerably reduced with respect to acetone solutions. The line widths of the ^{14}N resonances observed in the liquefied gases range from 280 to 300 Hz, the line widths in the SCFs range from 140 to 160 Hz. This indicates similar viscosities of the solvents used (CO_2, $CClF_3$, CHF_3) for each of the domains (liquid and supercritical state, respectively).

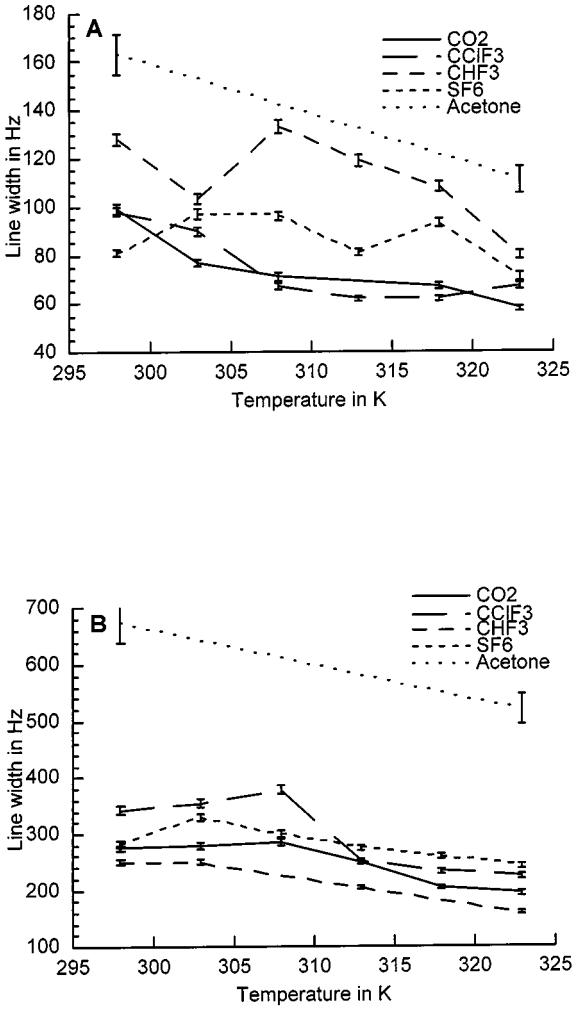

Figure 2. ^{14}N line widths at half height of (A) $Me_3CN{=}C(H){-}C(H){=}NCMe_3$ (*t*Bu-DAB) and (B) $Me_3CCH_2N{=}C(Me){-}C(Me){=}NCH_2CMe_3$ [*neo*Pe-DAB(Me)] in various compressed gasses and acetone; estimated error for the line widths (2%) indicated

Table 3. Reduction factors ($F_{1/2}$) of the ^{14}N line width for *neo*Pe-DAB(Me) in liquefied gases and supercritical fluids

$CDCl_3$[a]	CO_2		CHF_3		$CClF_3$	
T (K)	293	323	293	323	293	323
293	3.7	6.9	3.9	6.9	3.7	7.8
323	2.3	4.2	2.4	4.2	2.2	4.8

[a] Reduction factors [$F_{1/2} = \Delta\nu_{1/2}$(organic solvent)/$\Delta\nu_{1/2}$(compressed gas)] are reported relative to $CDCl_3$ at 293 K and 323 K.

Heating solutions in liquefied gases to above the critical temperature results in a reduction of the ^{14}N line width. The reduction factors associated with these changes range from 1.8 to 2.1. For $CDCl_3$ a reduction factor of 1.6 is observed when heating a solution from 293 K to 323 K. This indicates that the additional line narrowing resulting from the reduced viscosity of the supercritical fluid compared to the liquefied gas is small. The combined temper-

ature and viscosity effect of $CDCl_3$ is similar to that observed for the compressed gases. The fact that only a small viscosity effect is observed points to a significant "free rotor" contribution to the overall rotational correlation time, as has been described for tertiary amines.[17] For *neo*Pe-DAB(Me) the highest reduction of the ^{14}N resonance line width is found in supercritical $CClF_3$ (7.8 and 4.8 relative to $CDCl_3$ at 293 K and 323 K, respectively). The $F_{1/2}$ values found for supercritical CO_2 and CHF_3 are equal: 6.9 and 4.2 relative to $CDCl_3$ at 293 K and 323 K, respectively. This finding indicates that in CO_2 and CHF_3, the values of τ_c are similar under the conditions used.

In some cases the ^{14}N resonances were found to broaden upon heating the solutions from room temperature to the supercritical state, further heating resulted in a decrease of the ^{14}N line width. The initial (inhomogeneous) broadening of the ^{14}N resonances is attributed to the precipitation of solid material and convection.

Finally, we note that the reduction factors within a given solvent increase with temperature, as is seen for the ^{14}N resonances of *t*Bu-DAB and *neo*Pe-DAB(Me) (Table 2, Figure 2). When going from a liquefied gas at 298 K to the supercritical fluid at 323 K, the same or slightly larger reduction factors are observed when compared to the reduction factors for the acetone solutions in the same temperature range. This indicates that the reduced viscosity of the supercritical fluid compared to the liquefied gas contributes only slightly to the reduction of line widths.

B. Transition Metal and ^{14}N NMR Spectroscopy of Selected Coordination Compounds

^{59}Co NMR Spectroscopy

As an initial test of the appropriateness of our HP NMR system for transition metal NMR spectroscopy in SCFs, we have repeated an experiment performed by Rathke et al. in a static probe.[9a] The ^{59}Co NMR spectrum of $Co_2(CO)_8$ has been recorded in $[D_6]$benzene and CO_2(sc) and line widths of 10.4 kHz in $[D_6]$benzene at 296 K and 5.5 kHz in supercritical CO_2 at 310 K were observed. The ^{59}Co resonance recorded in supercritical CO_2 is well in agreement with the previously reported value of 5.1 kHz. The line width observed in $[D_6]$benzene is a factor of three smaller than the line width of 30 kHz reported previously.[9a] Possibly, the much larger line width in that case is due to poor homogeneity.

Further, we investigated the line widths of the ^{59}Co NMR resonances of $Co_4(CO)_{12}$ in $CDCl_3$ and CO_2. Due to its low solubility, the ^{59}Co NMR spectrum could only be recorded in liquid CO_2. The line widths for the apical ^{59}Co resonance of $Co_4(CO)_{12}$ are 4.0 kHz in $CDCl_3$ (296 K) and 3.6 kHz in CO_2 (296 K). The resonances of the cobalt atoms at the basal position were broader: 12.0 kHz in $CDCl_3$ (296 K) and 5.2 kHz in CO_2 (296 K). The variation in line width is the result of differences in the electric field gradient, experienced at the two sites of the cluster. This explanation is in agreement with previous reports concerning substituted cobalt clusters[18] and mixed cobalt−ruthenium clusters.[19] Upon changing from $CDCl_3$ solution to CO_2 solution, the reduction of the line width of the apical resonance is only 10%, whereas the line width of the basal resonance is reduced by more than a factor of two. The reduction of the rotational correlation time upon reducing the solvent viscosity from $CDCl_3$ to liquid CO_2 applies to the whole cluster, therefore one would expect the reduction factors of the line widths of the basal and apical ^{59}Co NMR resonances to be equal. However, it is documented that, due to differences in solvent polarity, the ratio of the line widths of the basal and the apical cobalt nuclei in various solvents varies between 1.9 in pentane and 3.2 in $CDCl_3$.[6] Here, we obtained a calculated ratio of 1.4 which, in agreement with the more apolar character of CO_2, is smaller but close to that observed for pentane.

^{53}Cr and ^{14}N NMR Spectroscopy

The application of supercritical solvents for the reduction of the resonance line width of quadrupolar transition metal nuclei has been further demonstrated for ^{53}Cr NMR spectroscopy. Two chromium isonitrile complexes $Cr(CO)_{6-x}(t\text{BuNC})_x$ (x = 1, 2) were studied by means of ^{14}N and ^{53}Cr NMR. The results have been compiled in Table 4.

Table 4. ^{14}N and ^{53}Cr NMR chemical shifts and line widths of two chromium isocyanide complexes of type $Cr(CO)_{6-x}(t\text{BuNC})_x$ in $[D_6]$acetone and CO_2

	^{53}Cr	90 Hz δ = 17.9	35 Hz δ = 15.7	35 Hz δ = 36.1	2.6
2	^{14}N	7 Hz δ = −174.5	7.5 Hz δ = −178.6	−	0.9
	^{53}Cr	44 Hz δ = 60.4	34 Hz δ = 52.4	−	1.3

[a] Number of *t*BuNC groups. − [b] Nucleus studied. − [c] Line width in Hz and chemical shift in ppm at T = 295 K. − [d] Line width in Hz and chemical shift in ppm at T = 343 K. − [e] Reduction factor [$F_{1/2} = \Delta\nu_{1/2}$(organic solvent)/$\Delta\nu_{1/2}$(compressed gas)].

The ^{14}N NMR resonances of the chromium complexes are sharp and broadened slightly with respect to uncoordinated *t*BuNC [$\Delta\nu_{1/2}(^{14}N)$ = 0.6 Hz[8]], indicating a small increase in the electric field gradient at the nitrogen atom upon coordination of the isocyanide group to the chromium center. The in this special case already very narrow ^{14}N line widths are found to increase slightly, changing from a $[D_6]$acetone solution to a liquid or supercritical CO_2 solution. This is most likely the result of inhomogeneous broadening as the experiment was performed on an unlocked and non-spinning sample. In addition, the precipitation of some solid material might have occurred in supercritical CO_2. The spectrum of $Cr(CO)_4(t\text{BuNC})_2$ could not be recorded in supercritical CO_2 due to its poor solubility in this medium.

The line widths of the chromium resonances for $Cr(CO)_{6-x}(t\text{BuNC})_x$ were found to decrease by a factor of

2.6 ($x = 1$) and 1.3 ($x = 2$) when changing the solvent from [D_6]acetone to supercritical ($x = 1$) and liquid ($x = 2$) CO_2. The reduction of the line widths of the already narrow ^{53}Cr resonances is relatively modest, especially when compared to ^{53}Cr line widths of many other chromium compounds[5c,20] and to the reduction of the ^{59}Co resonances described above.

To demonstrate the advantageous effect of the use of modifiers, the ^{53}Cr NMR spectrum of a 0.05 M solution of $(CO)_5Cr{=}C(NH_2)(Ph)$ was recorded in CO_2(sc) (critical density: 0.48 g/mL) with the addition of 5% (v/v) [D_6]acetone. This resulted in a ^{53}Cr NMR line width of 432 Hz ±5 Hz at δ = 170 (T = 323 K) after 14 h measuring time. This signal was found to be slightly broadened with respect to the signal recorded in the same mixture at 293 K, which had a line width of 402 ±5 Hz at δ = 169. The addition of a small amount of [D_6]acetone was used to dissolve the otherwise insoluble (in CO_2) chromium complex. Importantly, at the same sample concentration (0.05 M) no signal could be observed in pure [D_6]acetone after 14 h. A line width of $\Delta\nu_{1/2}$ = 1150 Hz at δ = 159 was reported for a highly concentrated sample (0.4 M in [D_6]acetone).[20] The signal observed by us for a 0.05 M sample after 48 h at 298 K in [D_6]acetone had a line width of 1340 Hz at δ = 151, thus a reduction factor $F_{1/2}$ = 3.3 applies.

^{95}Mo and ^{14}N NMR Spectroscopy

Complexes of type $Mo(CO)_4$(R-DAB) [R = *t*Bu, *c*Hex; R-DAB = R−N=C(H)−C(H)=N−R] are virtually insoluble in liquid and supercritical CO_2. The addition of a small amount of a modifier ([D_6]acetone) increases the solubility of these complexes in the low-viscosity liquid and supercritical fluid mixtures to such an extent that their ^{14}N and ^{95}Mo NMR spectra can be recorded. The results for $Mo(CO)_4$(R-DAB) complexes, which readily dissolve in [D_6]acetone and moderately so in CO_2/[D_6]acetone mixtures, have been compiled in Table 5 and Table 6.

Table 5. ^{14}N and ^{95}Mo line widths and chemical shifts of $Mo(CO)_4$(*t*Bu-DAB) in [D_6]acetone and CO_2/[D_6]acetone mixtures (critical density 0.48 ±0.02 g/mL)

[a] Amount of acetone v/v in the supercritical state; volume of the HP NMR tube: 6.9 mL. − [b] Line width in Hz. − [c] Chemical shift in ppm.

In the CO_2/[D_6]acetone mixtures, the line width of the ^{14}N and ^{95}Mo resonances decreases relative to the line width observed in [D_6]acetone, and decreases slightly with decreasing acetone concentration in the CO_2. This was expected, based on the concomitant decrease of the viscosity of the mixture. The line width of the ^{14}N resonance of $Mo(CO)_4$(*t*Bu-DAB) is lower than that of $Mo(CO)_4$(*c*Hex-DAB), and is found at higher frequencies. The smallest line width for $Mo(CO)_4$(*t*Bu-DAB) was 390 Hz, observed in supercritical CO_2/7% [D_6]acetone, for $Mo(CO)_4$(*c*Hex-DAB) 417 Hz in supercritical CO_2/11% [D_6]acetone. Only modest reduction factors are thus obtained for these compounds. A solution of (*t*Bu-DAB)$Mo(CO)_4$ in liquid CCl_2F_2 at 323 K resulted in a ^{14}N line width of 450 Hz. The same compound measured in a $CClF_3/CH_2Cl_2$ (89:11; v/v) mixture at 323 K resulted in a ^{14}N-resonance line-width of 370 Hz, the complex was insoluble in pure $CClF_3$.

[a] Amount of acetone v/v in the supercritical state; volume of the tube 6.9 mL. − [b] Line width in Hz. − [c] Chemical shift in ppm. − [d] Not determined due to low solubility.

The ^{95}Mo resonances are found at lower frequencies for (*t*Bu-DAB)$Mo(CO)_4$ than for the (*c*Hex-DAB)$Mo(CO)_4$ complex. Raising the temperature of the solutions of the complexes (R-DAB)$Mo(CO)_4$ (R = *t*Bu, *c*Hex) results in an increase of both the ^{14}N and ^{95}Mo chemical shifts. The chemical shifts of the ^{14}N and ^{95}Mo resonances are found to be lowest in the solutions containing a low percentage of [D_6]acetone. Increasing the amount of acetone results in a shift to higher ppm values. These findings are in agreement with a decrease of the metal-centered excitation energy ΔE_{av} at higher temperatures and higher solvent polarity, resulting in a high frequency shift.[5c,21]

Only very small reductions of the line widths (or none at all) of the already narrow ^{95}Mo NMR resonance were observed when changing from [D_6]acetone to low-viscosity CO_2/[D_6]acetone mixtures. This might be due to the coupling of the ^{14}N to the ^{95}Mo, resulting in broadened signals due to unresolved coupling. However, at low viscosity and high temperatures, no resolved couplings between ^{14}N and ^{95}Mo could be observed. Further studies at various magnetic field strengths may shed light on this conjecture.

^{91}Zr NMR Spectroscopy

The generally polar Zr^{IV} compounds are insoluble in liquid or supercritical CO_2, but these complexes can be solubilized in the apolar CO_2 by the addition of a small amount of THF (CO_2/THF = 93:7; v/v), similar to the cases described above. The solubility of Cp_2ZrCl_2 in CO_2/THF mixtures can be increased to such levels that it is possible to

observe the ^{91}Zr resonance in the supercritical mixture at 323 K. The line width of Cp_2ZrCl_2 is reduced from 375 Hz in THF at 296 K to 210 Hz in the supercritical mixture.[22a] However, the acquisition of the ^{91}Zr resonance in the CO_2/THF mixture took 14 h, whereas the ^{91}Zr signal can be acquired in 10 min in pure THF solution. Many ^{91}Zr resonances reported[5b][22b] are much broader, however. For such Zr species there may be an advantage of measuring ^{91}Zr NMR in CO_2/THF mixtures.

Conclusions

The employed HP NMR tubes with[8] and without[23] a pressure sensor are very appropriate and safe to use for measurements of NMR spectra under high pressure in supercritical fluids and liquefied gases of low viscosity. It has been shown that in order to increase the solubility of poorly soluble compounds in liquid or supercritical CO_2, small amounts of a modifier (an organic solvent) may be added, which further enables better shimming and acquisition in the locked mode.

The ^{14}N line widths follow the trend of the solvent viscosities, and are thus considerably reduced (by a factor of up to 7 or 8), even when compared to the line width observed in low-viscosity organic solvents like $CDCl_3$ and acetone. In view of the low solvating power of low-density SCFs, the use of liquefied gases, i.e. liquid CO_2 and $CClF_3$, might be preferred for the reduction of quadrupolar broadened NMR lines, since these combine a relatively high solvating power with large reduction factors. Moreover, the experimental procedure for NMR spectroscopy in liquefied gases is more straightforward than in SCFs and fewer problems with phase separation and precipitation of solid material are expected during NMR experiments.

NMR of quadrupolar transition metal ions in low-viscosity liquefied gases or in supercritical solvents with and without the addition of modifiers results in some cases in an appreciable decrease of their resonance line widths. Enhanced solubilities without detrimental effects on the line widths can easily be achieved by the addition of small amounts of a modifier (acetone, CH_2Cl_2, THF).

Experimental Section

General: All spectra were recorded with a Bruker DRX300 NMR spectrometer, employing a 10-mm broadband probe (^{103}Rh-^{91}Zr)-{^1H}. The solubility experiments were carried out in a 10-mm o.d., 8-mm i.d. sapphire HP NMR tube with pressure sensor as described previously.[8] The HP NMR tube was modified with an aluminum plug to reduce the sample volume to 1.7 mL. Some experiments were performed in a modified HP NMR tube similar to the one described by Roe.[23a] The volume of this 10-mm o.d., 8-mm i.d. tube is 6.0 mL.[23b] – The complexes $Co_4(CO)_{12}$,[24] $(t\text{BuNC})_x\text{Cr}(CO)_{6-x}$ (x = 1,2)[25] (R-DAB)Mo(CO)$_4$ (R = *t*Bu, *c*Hex, DAB = diazabutadiene;[26] and Cp_2ZrBr_2)[27] were synthesized according to literature procedures. A sample of $(CO)_5Cr{=}C(NH_2)(Ph)$ was kindly provided by Prof. Dr. K.-H. Dötz (Universität Bonn). Cp_2ZrCl_2 was obtained from Alfa and used as received.

Sample Preparation: The NMR samples were prepared by charging the HP NMR tube described previously[8] with the appropriate α-diimine, typically 50 mg. The HP NMR tube was flushed three times with the appropriate gas (to suppress the N_2 signal) and filled with the liquefied gas using either the hand driven pump for CO_2, or by condensation of the solvent gas with liquid nitrogen for $CClF_3$, CHF_3, and SF_6. The critical density used varied between ρ_c and ρ_c + 0.1 g/mL. – For the determinations of the solubility in liquefied gases, the HP NMR tube was charged with the appropriate amount of *neo*Pe-DAB(Me). The concentration of *neo*Pe-DAB(Me) amounted to 0.091 M in $CDCl_3$. In other solvents, saturated solutions were obtained with concentrations varying between 0.004 M and 0.071 M (see Table 2). Prior to dissolution of the α-diimines, the tube was flushed three times with the solvent gas. The gas was introduced using the methods described previously,[8] after warming to room temperature the excess solvent was carefully evaporated until the desired level was reached. For the determinations of the solubility in supercritical fluids, the aluminum plug was placed in the HP NMR tube after introduction of the desired compound. The tube was charged with the appropriate liquefied gas and the density of the supercritical state was determined by weight. All of the solutions studied were supercritical at 323 K, except for $CDCl_3$. – Samples for NMR experiments (determinations of line widths) were also prepared as described above[8] for the experiments with diimines. For NMR of metal complexes: A sample of (*t*Bu-DAB)Mo(CO)$_4$ (0.23 g, 0.6 mmol) was dissolved in the appropriate amount of [D_6]acetone (see Table 5 and Table 6), the HP NMR tube was filled with CO_2 employing a hand driven pump;[8] similarly, solutions of (*c*Hex-DAB)Mo(CO)$_4$ were prepared by dissolving a 0.10 g sample (0.25 mmol) in the appropriate amount of [D_6]acetone and filling the HP NMR tube with CO_2. A solution of (*t*Bu-DAB)Mo(CO)$_4$ in CCl_2F_2 was prepared by condensing CCl_2F_2 in an HP NMR tube containing a 0.10 g sample of the complex (0.26 mmol). Similarly $CClF_3$ was condensed in an HP NMR tube containing a solution of 0.10 g (*t*Bu-DAB)Mo(CO)$_4$ (0.26 mmol) in 0.5 mL CH_2Cl_2. A 0.05 M solution of $(CO)_5Cr{=}C(NH_2)(Ph)$ was prepared in CO_2/acetone, 95:5 (v/v). The samples of other metal compounds were prepared as concentrated solutions.

NMR Experiments: All spectra were recorded in the unlocked and non-spinning mode, except for the spectra recorded in $CDCl_3$ or acetone, these were recorded in the locked mode. The NMR experiments at 293 K were performed by cooling the samples with a stream of cold nitrogen using the spectrometers variable-temperature unit. The ^1H NMR spectra were recorded using the decoupler coil of the 10-mm broadband probe. A total of 20 transients were recorded for every spectrum. For each spectrum 32k complex points were sampled over a spectral width of 7585 Hz. An acquisition time of 2.2 s, a pre-acquisition delay of 10 s, and pulse duration of 5 μs were used (ca. 30). Before integration of the ^1H signals, the base line was corrected for small offsets using the spectrometer software in the automatic mode. In the proton spectrum, typically line widths of 2–3 Hz at half-height were found. The ^{14}N NMR spectra were recorded using the broad-band observe coil of the 10-mm broad band probe. An *anti*-ring sequence was used to reduce probe ringing. The number of transients recorded for the ^{14}N NMR experiments was 2000, and 4096 complex points were sampled over a spectral width of 10823 Hz, resulting in an acquisition time of 0.2 s, a pre-acquisition delay of 5 ms and a π/2 pulse duration of 27 μs were used. – The ^{95}Mo π/2 pulse duration was 34 μs, ^{53}Cr

$\pi/2$ pulse duration was 32 μs, and an *anti*-ring sequence was used to reduce rolling base lines. An exponential multiplication one tenth of the natural line width was applied prior to Fourier transformation. The ^{14}N resonances are reported relative to $MeNO_2$, ^{95}Mo relative to 2 M MoO_4Na_2 in D_2O, ^{59}Co relative to a saturated $K_3Co(CN)_6$ solution in D_2O, ^{53}Cr relative to a $Cr(CO)_6$ solution in $CDCl_3$ and ^{91}Zr relative to Cp_2ZrBr_2 in $CDCl_3$.[22b]

Acknowledgments

The authors wish to thank Ing. J. M. Ernsting for skillful technical assistance with the NMR spectrometer and H. Luyten for the construction and maintenance of the high-pressure NMR tube. We thank the Council for Chemical Sciences of the Netherlands Organization for Scientific Research (CW-NWO) and the John van Geuns Foundation for financial support with acquiring the spectrometer and probe.

On the Influence of the Bite Angle on the Allylic Alkylation of (*E*) and (*Z*) Substrates: Loss and Retention of Double Bond Stereochemistry

Richard J. van Haaren,[a] Gino P. F. van Strijdonck,[a] Henk Oevering,[b] Joost N. H. Reek,[a] Paul C. J. Kamer,[a] and Piet W. N. M. van Leeuwen*[a]

Keywords: Allyl complexes / Homogeneous catalysis / P ligands / Palladium

The bite angle of bidentate phosphane ligands has a pronounced influence on the degree of retention of the double bond geometry of the allylic substrate in the allylic alkylation reaction. To study the effect of the ligand on the regioselectivity, (*Z*)- and (*E*)-pent-2-enyl acetate were used as substrates. The alkylation of substrates with an (*E*) conformation of the double bond results in the preferential formation of the linear (*E*) product. A larger bite angle of the ligand results in an increase of the regioselectivity to >98% for the Sixantphos ligand. Analogously, the alkylation of (*Z*) substrates results in the formation of the linear (*Z*) product. Remarkably, for (*Z*) substrates, a larger bite angle of the ligand leads to an increased regioselectivity for the formation of the branched product instead of the linear product, up to 47.5% for Sixantphos. The observed regioselectivities are rationalized in terms of: a) a competition between *syn-anti* isomerization and alkylation, and b) a combination of steric and electronic effects in the transition state of the reaction. For all ligands tested, the reaction is faster for the (*E*) than for the (*Z*) substrate. However, competition experiments using the Sixantphos ligand show a relatively fast reaction rate for the (*Z*) substrate, which indicates that the coordination of the substrate to palladium is the discriminating, but not the rate-determining, step when both substrates are present.

Introduction

Transition metal-catalyzed allylic alkylation is a useful tool in synthetic organic chemistry.[1] A total control of the stereoselectivity and regioselectivity is required for most applications of this reaction. Whereas the enantioselective alkylation of symmetrically disubstituted allyl moieties (derived from, for example, cyclohexenyl acetate) has received much attention in the literature,[1] the regioselectivity of the reaction with other types of allylic substrates has been studied less extensively.[2−6]

When nonsymmetrically substituted allylic substrates are used,[2−6] regiocontrol is required prior to enantiocontrol (Figure 1). So far, palladium catalysts are the most widely studied, and generally show for such substrates a preference for the formation of the linear product.[1a,2] With bidentate P-N ligands, however, it is possible to obtain a high regioselectivity for the chiral branched product.[3] Catalysts based on other metals,[4] such as tungsten or iridium, also show a preference for the branched product, but the rate of the reaction is much lower than that found for palladium.

Relatively few studies have been reported concerning the influence of the geometry of the starting allylic substrate on the regioselectivity of the palladium catalyzed reaction.[5] Some years ago, Åkermark et al. reported such a study in which phenanthroline-type ligands were used in the allylic alkylation reaction with sodium diethyl 2-methylmalonate as the nucleophile.[5a] It was found that the regioselectivity of the reaction is dependent on the geometry of the double bond [(*E*) or (*Z*)] of the substrate. The (*E*) substrate reacts with the Pd(ligand) fragment to form an allylic complex having a *syn* geometry, which, after reaction with the nucleophile, mainly yields the linear (*E*) product. Analogously, the (*Z*) substrate reacts to form a (ligand)Pd(allyl) complex with an *anti* geometry (see Figure 1), which results in the formation of the linear (*Z*) and the branched product. They also reported that in the catalytic reactions, the regioselectivity is determined by competition between *syn-anti* isomerization and alkylation.

Recently, we have reported on the effect of the bite angle of bidentate *phosphane* ligands on the *syn*/*anti* ratio of cationic (P-P)Pd(crotyl) complexes.[6] It was found that a large bite angle leads to a low *syn*/*anti* ratio as a result of increased steric interactions. *Stoichiometric* alkylation of these complexes showed a correlation between the bite angle and the regioselectivity: the complexes were present as *syn*/*anti* mixtures, which complicated interpretation of the data. Moreover, apart from the C1 to C3 selectivity, the regioselectivity of the *catalytic* reaction was also determined by the competition between *syn-anti* isomerization and alkylation, which obscured structure-selectivity relations.

The *syn-anti* isomerization of the allyl moiety involves a π-σ rearrangement during which the allyl moiety is temporarily σ-bonded to the palladium through the substituted terminal allylic carbon atom (see Figure 2).[7] Rotation about the Pd−C bond and the adjacent C−C bond, followed by σ-π rearrangement then yields the other (*syn* or *anti*) isomer. As a result of increased steric hindrance, this process is slower when the substituent is larger. In order to explore the influence of the size of the allyl substituent on

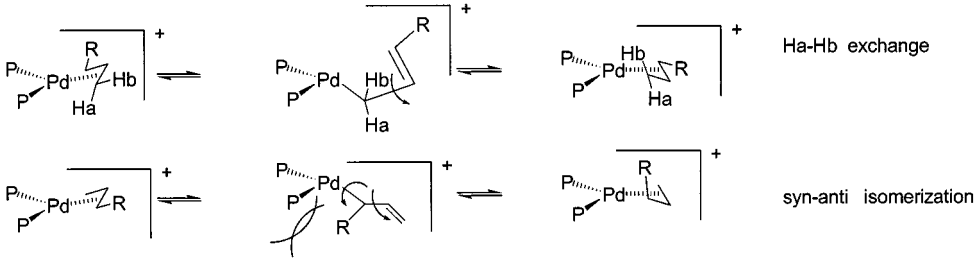

Figure 2. The π-σ rearrangement on different terminal sites of the allyl moiety (top: H_a-H_b exchange does not involve *syn-anti* isomerization of substituent R; bottom: *syn-anti* isomerization of substituent R is hampered by steric hindrance)

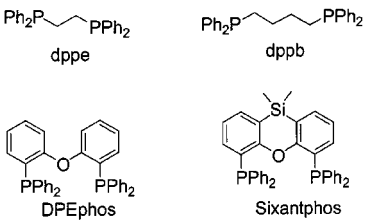
the regioselectivity, we have also performed the reaction with methyl-, ethyl- and propyl-substituted allylic substrates. By using (*Z*)- and (*E*)-pent-2-enyl acetate as substrates instead of (*E*)-but-2-enyl acetate, it appeared that a small change in steric size resulted in a relatively slow *syn-anti* isomerization rate (see below). This way, we have been able to study the effects of the ligands on the alkylation of the transient *syn* and *anti* isomeric complexes.

Results

All experiments were carried out with cationic (crotyl)Pd(ligand) complexes as catalyst precursors using four ligands that differ significantly in the calculated bite angle[6] (dppe, dppb, DPEphos and Sixantphos, see Figure 3).



ligand	calculated bite angle[a] (°)
dppe	85
dppb	99
DPEphos	108
Sixantphos	110

Figure 3. The ligands {[a]: the bite angle has been determined by pm3(tm) geometry optimization of the cationic (crotyl)Pd(ligand) complexes that have been employed in the catalytic experiments[6]}

(*Z*) *and* (*E*) *Allylic Substrates*

To study the effect of the double bond geometry of the substrate we performed the allylic alkylation of (*Z*)- and (*E*)-pent-2-enyl acetate with sodium diethyl 2-methylmalonate as the nucleophile (Table 1). Starting from the (*E*) substrate, the linear (*E*) product is formed primarily. When the bite angle of the ligand is larger, the regioselectivity for the formation of this product increases. In contrast, the (*Z*) substrate reacts to form both the linear (*Z*) and the branched product. In this case, a larger bite angle of the ligand results in an increase of the regioselectivity to the branched product. With dppe, the reaction rate is low compared to the other ligands and, remarkably, the linear (*E*) product is formed in high regioselectivity, even starting from the (*Z*) substrate. The fastest reactions are observed using the relatively flexible ligands dppb and DPEphos. For all ligands, the alkylation of the (*Z*) allylic substrate is slower than that of the (*E*) allylic substrate.

Competition Experiments

To gain more insight into the different courses the reaction takes for the (*E*)- and (*Z*)-pent-2-enyl acetate, competition experiments were carried out with the ligands dppb and Sixantphos (Table 2). It was found that in the separate experiments the alkylation of the (*Z*) substrate is much slower than that of the (*E*) substrate. With dppb in the com-

petition experiments, however, a much smaller difference in conversion rate is observed between the (*E*) and (*Z*) substrates. Furthermore, when Sixantphos is used as the ligand, the (*Z*) substrate is consumed at a higher rate than the (*E*) substrate. The initially predominating consumption of the (*Z*) substrate results in the formation of primarily the linear (*Z*) and the branched product. The regioselectivity of the reaction is dependent on the conversion and, as the reaction proceeds, the fraction of linear (*E*) product increases.

Influence of the Size of the Allyl Substituent

The results with (*E*)-pent-2-enyl acetate show a different regioselectivity than previously found for (*E*)-but-2-enyl acetate.[6] The results of the allylic alkylation of (*E*)-substituted allylic substrates bearing substituents of different size (methyl, ethyl and propyl) are compared in Table 3. In all cases there is a preference for the formation of the linear (*E*) product. The selectivity for the formation of the (*E*)

product increases when ligands with a larger bite angle are used. As expected, the regioselectivity is also influenced by the size of the substituent. The selectivity increases when the substituent is larger, leading to 99.3% linear (*E*) product in the alkylation of (*E*)-hex-2-enyl acetate (R = propyl) by a Sixantphos-ligated palladium complex. The size of the substituent also has a pronounced effect on the rate of the reaction: the larger the substituent, the slower the reaction.

Discussion

Several studies have been devoted to the origin of regioselectivity in the palladium-catalyzed allylic alkylation.[1a,2−6,8−10] Two different effects have been reported: 1) in the case of an *early* transition state, the regioselectivity is determined by the relative electrophilicity of the terminal allylic carbon atoms and steric hindrance is of minor importance;[8] 2) in the case of a *late* transition state, the degree steric hindrance encountered during the nucleophilic attack and the subsequent rotation of the allyl moiety becomes important.[2a,9] The route to the formation of the linear product is then favored over that of the branched product.

From theoretical[10] and experimental studies it is known that the allylic alkylation reaction proceeds by attack of the nucleophile on the cationic (π-allyl)Pd(ligand) species (Figure 4). This results in the formation of a single bond between the attacked allylic carbon atom and the nucleophile (stage **a**). A C=C double bond is then formed between the other two allylic carbon atoms (stage **b**). During these processes, the allyl moiety rotates, forming a transient neutral (olefin)Pd(P-P) complex (stage **b**).

In a recent theoretical study, a combined explanation is presented for the apparent occurrence of either an early or a late transition state.[10c] The nucleophilic attack at the most electrophilic terminal allylic carbon atom (early transition state) results in a lowering of the energy barrier of stage **b** of the reaction.

Influence of the Alkene Geometry

The alkylation of (*E*)-pent-2-enyl acetate does not yield more than 4% of the linear (*Z*) product and 2% of the branched product (Table 1), thus giving almost complete retention of alkene geometry. The linear (*E*) product can only be formed from the *syn* isomer (see Figure 1), indicating that for each of the tested palladium(ligand) complexes, oxidative addition of the (*E*) substrate yields mainly the *syn* isomer. Analogously, the results obtained for (*Z*)-pent-2-enyl acetate (Table 1) indicate that after its oxidative addition to palladium, the *anti* isomer is formed, which then reacts to form the linear (*Z*) product. However, reaction of the (*Z*) substrate leads to the formation of a relatively large amount of the linear (*E*) product. These mixtures of products can only be formed after isomerization from *anti* to *syn* (or vice versa) has occurred. Thus, the regioselectivity is a result of: (i) the *syn*/*anti* equilibrium, (ii) the competition between isomerization and alkylation, and (iii) the C1 to C3 regioselectivity for attack on the *syn* and the *anti* isomer.[5a] These points will be discussed individually below.

Concerning the *syn*/*anti* ratio, we have shown before that for cationic (crotyl)Pd(ligand) complexes (ligand = dppe, dppb, DPEphos and Sixantphos), the *syn* isomer is more stable than the *anti* isomer.[6] The crotyl substrate yields an allyl group with a relatively small methyl substituent. After oxidative addition of a pentenyl substrate, an allyl moiety bearing a larger ethyl group (*syn* or *anti*) is formed which will show more steric interaction of both the *syn* and the *anti* isomer with the ligand. The data obtained from the catalytic experiments (Table 1) indicate that the relatively small difference in size between a methyl and an ethyl substituent has a large effect on the *syn*/*anti* ratio of the transient allyl complexes. Because the results indicate that the *anti*-to-*syn* isomerization prevails over the *syn*-to-*anti* isomerization (Table 1), it is concluded that for larger substituents on the allyl group, the preferred *syn*/*anti* ratio is higher than that previously observed for the methyl substituent.

The occurrence of a competition between *syn*-*anti* isomerization and alkylation is supported by the concurrence

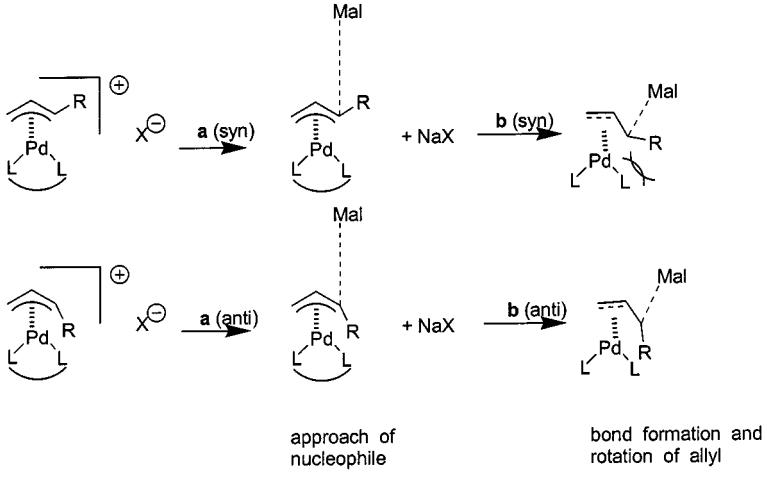

Figure 4. *Syn* and *anti* complexes: comparison of the consecutive steps of the reaction

of a low reaction rate and a low regioselectivity. Thus, the alkylation of the (*Z*) substrate occurs at a lower rate than that of the (*E*) substrate, allowing *anti*-to-*syn* isomerization to take place prior to nucleophilic attack, which lowers the overall regioselectivity. The rate of isomerization is especially fast for dppe relative to the rate of alkylation; the reaction of the (*Z*) substrate leads almost exclusively to the formation of the (*E*) product.

The effect of the bite angle on the C1 to C3 regioselectivity of the alkylation is different for the *syn* and the *anti* isomer. The selectivity of the *syn* isomer to the formation of the linear (*E*) product increases when the bite angle is larger. This can be explained in terms of steric hindrance during both stages **a** and **b** of the reaction. The linear C1 position is more accessible for the approaching nucleophile than the branched C3 position. Furthermore, during the bond formation the substituent has to bend away from the nucleophile in the direction of the sterically crowded Pd(ligand) fragment. Nucleophilic attack on the allyl moiety results in the formation of a transient palladium-olefin complex,[9c] in which the C=C double bond is located in the P−Pd−P plane and the malonate-substituted C3 atom below this plane (see Figure 4). When the branched product has been formed, the substituted C3 site, bearing the ethyl group and the malonate, is rotated out of the P−Pd−P plane (stage **b**). In a *syn*-substituted allyl moiety, the ethyl group points in the direction of the phenyl rings of the ligand. The steric interactions thus encountered are more pronounced when the bite angle of the ligand is larger. So, during both stages **a** and **b** of the reaction, steric hindrance directs the regioselectivity to the formation of the linear (*E*) product.

In contrast, the effect of the bite angle on the regioselectivity of the alkylation of the *anti* isomer shows the opposite trend. It is known that in palladium complexes of disubstituted allylic substrates, the branched *anti* position is relatively electrophilic and consequently more reactive than the branched *syn* position.[5b] The geometrical distortion resulting from steric interactions with the ligand are relatively large for the *anti* compared to the *syn* isomer. An increase of the bite angle will enhance the geometrical distortion of the allyl moiety and thereby[2c][10c] enhance the relative electrophilicity of the allylic carbon atom at the branched C3 position compared to the C1 position. Thus, during the approach of the nucleophile (stage **a** of the reaction) the electronic effects may prevail over the steric hindrance giving the branched product. During the rotation of the allyl moiety after the nucleophilic attack has taken place (stage **b**), the ethyl group of the *anti* isomer will point downward, i.e. not in the direction of the phenyl rings of the ligand, and steric hindrance will be less than in the case of the *syn* isomer (stage **b**). So also for the *anti* isomer, in both stage **a** and **b** of the reaction, the regioselectivity is directed to the formation of the same regioisomer, i.e. the branched product for the *anti* isomer and the linear (*E*) product for the *syn* isomer.

Competition Experiments

The competition experiments carried out to gain more mechanistic insight in the reaction course of the (*E*) and the (*Z*) substrate showed a relatively high reaction rate for the latter. Because the overall reaction rate in the separate experiments is higher for the (*E*) substrate than for the (*Z*) substrate, the discrimination in the competition experiments has to take place in an early stage of the catalytic cycle of the reaction. As a result of the better accessibility of the (*Z*) double bond relative to the (*E*) double bond, the coordination of the substrate to palladium will be faster for the (*Z*) than for the (*E*) substrate. As the (*E*) substrate is found to react faster, we conclude that the next steps of the reaction proceed at a higher rate for the (*E*) substrate than for the (*Z*) substrate (Figure 5).

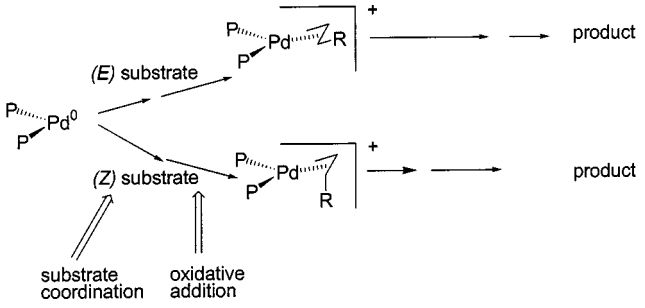

Figure 5. Schematic representation of the origin of kinetic resolution (the size of the arrows indicates the relative rate)

The change in rate difference in the competition experiments compared to the separate experiments is larger for Sixantphos, the ligand with the largest bite angle (Table 2). Upon coordination of the substrate to a Pd^0(Sixantphos) complex, the steric hindrance will be larger than for the analogous complex with the dppb ligand, and therefore the discrimination between the (*E*) and (*Z*) substrate will be more pronounced for Sixantphos. It is possible that, for dppb, the substrate discrimination does take place at this stage, but its effect may be compensated by a rate difference in the next steps of the reaction.

It can be argued that the discriminating step, coordination of the olefin, is not the rate determining step of the reaction. If the coordination of the (*E*) substrate were rate limiting, and thus slower than the coordination of the (*Z*) substrate, the (*E*) substrate would not react faster in the *separate* experiments. Analogously, if the coordination to palladium were the rate determining step for the (*Z*) substrate, it would not be found to react faster in the *competition* experiments.

On the other hand, if the rate determining step for the *E* substrate is indeed the substrate coordination and for the *Z* substrate, the subsequent oxidative addition would be rate determining and the latter being slower than the substrate coordination of the (*E*) substrate, the above arguments are not true. Unfortunately, the coordination of the substrate and the subsequent oxidative addition cannot be distinguished in kinetic experiments.

Effect of the Size of the Substituent

The alkylation of the (*E*) substrates with different substituents all show the same trend (Table 3). Both a larger bite angle of the ligand and a larger substituent on the allyl moiety result in an increase of the regioselectivity to the formation of the linear (*E*) product. As has been described above, the *syn*/*anti* isomer ratio will be lower for small groups, which accounts for the relatively large amount of linear (*Z*) product formed from alkylation of (*E*) but-2-enyl acetate. Furthermore, the relatively large size of the ethyl and propyl groups relative to the methyl group, hinders the attack of the nucleophile on the branched position. This explains the smaller amounts of branched product formed when either the substituent or the bite angle of the ligand is larger.

The rate of the reaction is also affected by the size of the substituent. The lower rate of reaction when larger substrates are used can be explained in terms of steric hindrance. During the oxidative addition and the nucleophilic attack, a larger allylic substrate will experience more steric hindrance than a small allylic substrate and the reaction may therefore proceed at a lower rate. The product dissociation will probably not be rate limiting, but, nevertheless, the coordination of a larger product will be more hindered than that of a small one, and therefore it may dissociate faster than a small product. Which of these effects prevails depends on the nature of the rate limiting step of the reaction, which may be determined by the size and orientation of the substituent and the bite angle of the ligand.

In the absence of significant steric interactions, a larger bite angle of the ligand results in an increase of the rate of reaction. Thus, the alkylation of (*E*)-but-2-enyl acetate occurs at the highest rate when the Sixantphos ligand is used. The rate of alkylation of the larger substrates is the highest for catalysts bearing a flexible ligand favoring a relatively large bite angle, such as dppb or DPEphos.

Conclusion

We separated the effect of the bite angle on the regioselectivity resulting from the *syn* and the *anti* isomeric complex. The regioselectivity of the reaction of the *syn* isomer is determined by steric effects in both the first and the second stage of the reaction, resulting in almost exclusive formation of the linear (*E*) product. The geometry of the allyl moiety in the *anti* isomer is presumably distorted to a large extent and the electrophilicity of the branched position is large relative to the linear position. The regioselectivity of its alkylation is, in the first stage of the reaction, mainly governed by electronic factors, and in the second stage by steric effects. For *syn* complexes of ligands with a large bite angle, the *linear* product is favored both in the first and the second stage of the reaction, whereas for the *anti* isomer, the *branched* product becomes the favored regioisomer in both stages of the reaction.

In competition experiments between the (*E*) and (*Z*) substrates, the (*Z*) substrate is found to react at a rate that is similar to or faster than that of the (*E*) substrate, whereas in separate experiments the reaction with the (*E*) substrate is faster. This effect is more pronounced for Sixantphos than for dppb. The substrate discrimination presumably takes place in the stage of coordination of the olefin to the metal center, prior to oxidative addition and prior to the rate determining step. Therefore, in a system in which both the (*E*) and (*Z*) substrate are present, the latter dominates the reaction rate.

Experimental Section

^{1}H NMR (300 MHz, TMS, $CDCl_3$), $^{31}P\{^1H\}$ (121.5 MHz external 85% H_3PO_4, $CDCl_3$), ^{13}C NMR (75.4 MHz, TMS, $CDCl_3$) were recorded on a Bruker AMX-300 spectrometer. The product distribution of the alkylation experiments was measured on an Interscience Mega2 GC apparatus, equipped with a DB1 column (length 30 m, inner diameter 0.32 mm, film thickness 3.0 μm) and an F.I.D. detector.

All experiments were carried out using standard Schlenk techniques. All solvents and allylic substrates were freshly distilled prior to use. Diethyl 2-methylmalonate, NaH, and (*E*)-hex-2-enyl acetate were obtained from Aldrich.

General Synthetic Procedures: Sodium diethyl 2-methylmalonate (0.5 M in THF) was prepared from diethyl 2-methylmalonate (20 mmol, 3.48 g) and NaH (20 mmol, 0.48 g) in THF at 273 K. The synthesis and characterization of all complexes,[6] crotyl acetate,[6] and the alkylation products of the coupling of crotyl acetate and (*E*)-hex-2-enyl acetate to sodium diethyl 2-methylmalonate are described elsewhere.[5a]

Alkylation Reactions: The *catalytic* reactions were performed at 292 K in THF (5 mL), using 0.05 mol-% of catalyst (0.25 μmol), 0.5 mmol of substrate (0.064 g) and 1.0 mmol of sodium diethyl 2-methylmalonate (0.20 g). All reagents were added from stock solutions. The reaction was monitored by taking samples from the reaction mixture which, after aqueous work up, were analyzed by GC using decane (0.0142 g) as the internal standard. − NMR spectroscopic data were obtained in $CDCl_3$ (δ in ppm).

On the Stabilisation of a Singlet Nitrene by the Phosphaniminato and Related Imine-Type Substituents, a Quantum Chemical Investigation

W. Schoeller*[a] and A. B. Rozhenko[a]

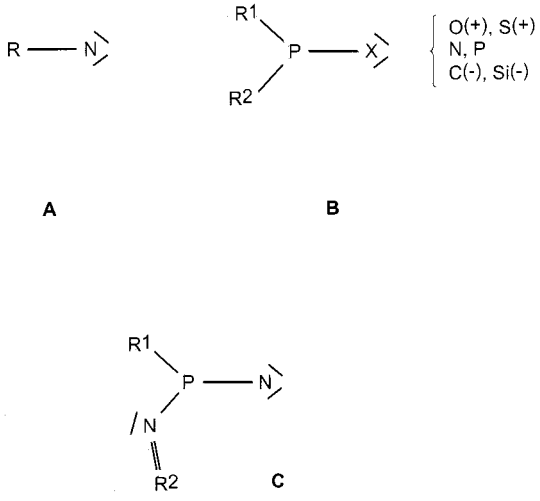
Dedicated to Prof. K. Dehniche on the occasion of his 70th birthday

Keywords: Density functional calculations / Nitrenes / Substituent effects / Radicals

The substituent effects on the singlet–triplet energy separations are explored for phosphanylnitrenes and related congeners from the Group 14 to Group 16 elements. Imine-type substituents (e.g. phosphaniminato, methyleneimine etc.) are more effective than amino groups in lowering the energy of a singlet below that of a triplet state. It is due to an effective stabilisation of the singlet and a destabilisation of the triplet.

Introduction

Nitrenes **A** are highly unstable species.[1−3] They become more stable in the case of phosphanylnitrenes **B** (X = N) that are substituted with bulky amino groups at the phosphorus atom (R^1,R^2 = NR'_2, R′= alkyl) (Scheme 1). It opens a wide field for the syntheses of new types of structures in low-coordination phosphorus chemistry.[4−9] Similarly, amino-substituted phosphanylphosphinidenes are considered as useful intermediates.[10−12] Consequently, the particular role of the amino group as a stabilising factor on a singlet ground state of a nitrene has been addressed by a variety of quantum chemical investigations.[13−21]



Scheme 1

These investigations indicate that nitrenes and especially phosphinidenes possess small energy separations between the singlet and the lowest-energy triplet state. On this basis, nitrenes are reminiscent of carbenes[22] as was recently summarised.[23,24]

Despite the wealth of investigations into nitrenes, important aspects that have hitherto not been investigated remain open: (1) The electronic structures of valence isoelectronic nitrene homologues of type **B**, with X originating from Group 16 ($X = O^{(+)}$, $S^{(+)}$) or from Group 14 ($X = C^{(-)}$, $Si^{(-)}$). In the present quantum chemical study, it will be shown that the Group 16 homologues possess singlet ground states and that the Group 14 homologues possess triplet ground states. (2) The effect of an imino function of type **C** in which a lone-pair is adjacent to the phosphorus atom. Evidence is given that these types of substituents [R^2= PH_3, $C(NH_2)_2$, CH_2, PH] are essentially more effective than amino groups in moving the energy of the singlet below that of the triplet, thus making it the ground state. A peculiar π-donating effect of methyleneimine-substituted iminophosphanes has been found.[25,26] The status of oxo- and thioxophosphonium ions has also been summarised recently.[6] The details of the calculations are given in the Theoretical Section at the end of this publication.

Results and Discussion

a. Qualitative Considerations

According to EH calculations,[27] the relevant molecular-orbital system of the parent phosphanylnitrene (C_{2v} symmetry imposed) is as follows (Figure 1).

The frontier orbitals are the p-orbital of the nitrogen atom (HOMO), in plane with the residual atoms, and the π* molecular orbital (LUMO) of the P−N bond. Phosphorus is much less electronegative than nitrogen,[28] hence the larger coefficient in the π* molecular orbital is at the phosphorus atom. In the π molecular orbital (HOMO-1), the opposite is true: the larger coefficient is located at the more electronegative nitrogen atom.

The two relevant lowest-energy electronic states (singlet and triplet) are constructed from these orbitals. The re-

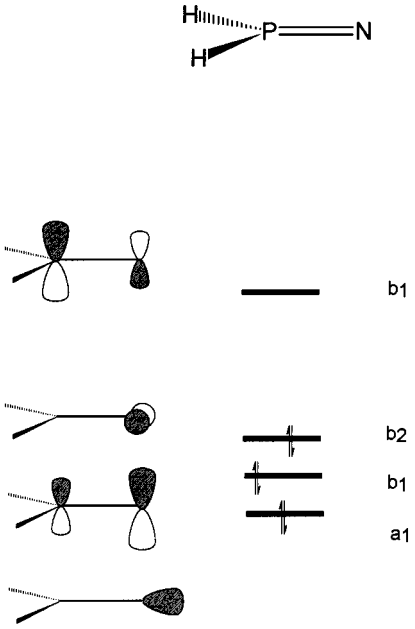

Figure 1. Frontier orbital system of the parent phosphanylnitrene

sulting Slater determinants for these states (C_{2v} symmetry) are as follows:

$\Psi\ (^1A_1) = ...(a_1)^2(b_1)^2(b_2)^2>$

$\Psi\ (^3A_2) = ...(a_1)^2(b_1)^2(b_2)^1(b_1)^1>$

MCSCF calculations[29] on the parent phosphanyl nitrene indicate that the given Slater determinants describe both states well. Geometry optimisation results in a planar structure (C_{2v} symmetry) for the singlet, while the triplet adopts a pyramidal structure at the phosphorus atom (C_s symmetry). The equilibrium structures are illustrated in Molden plots[30] shown in Figure 2 for the equilibrium singlet (top) and triplet (bottom) structures. The findings agree with the previous considerations of phosphanyl nitrenes.[14]

From the one-electron considerations, the following tendencies of the stabilities of the nitrenes and their valence isoelectronic homologues are observed: (a) π-Donating substituents raise the energy of the LUMO (π*), owing to conjugation with this molecular orbital. The HOMO (p) is generally not affected by substituents at the phosphorus atom.

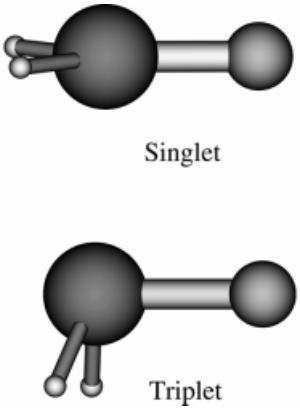

Figure 2. Molden plots of equilibrium singlet ($^1A_1$, C_{2v} symmetry) and triplet states ($^3A''$, C_s symmetry) of the parent phosphanylnitrene

Consequently, π-donating substituents increase the energy difference between the HOMO and the LUMO, and a singlet ground state is pronounced. (b) On the other hand, π-electron-attracting substituents favour a triplet ground state. The ability to enhance a singlet ground state should become more pronounced with increasing polarity of the P−X π-bond, i.e., in the order $X = O^{(+)} > N > C^{(-)}$. (c) When the terminal main group element X is less electronegative, the energy of the HOMO raises stronger than the energy of the LUMO. In other words the energy gap between these orbitals decreases and a triplet ground state is facilitated. It corresponds to the hypothesis that a singlet ground state is expected for these species in the order $X = C^{(-)} < N < O^{(+)}$. As will be shown below, a further effect is important for the strength of the resulting P−N π-bond in the singlet state of the nitrene. Strong σ-electron-withdrawing substituents at the phosphorus atom strengthen the P−N bond.

b. Phosphanylnitrene and Substituent Effects

We first investigated the parent systems, i.e., the phosphanylnitrene and its related valence isoelectronic homologues. The corresponding Group 14 and Group 16 congeners of various elements X were considered. The most relevant bonding parameters for the investigated species in their lowest-energy singlet and triplet states are collected in Table 1. The various electronic states were evaluated at the density functional level [B3LYP/6-31+g(d)] and at the more sophisticated CCSD(t) level. For the latter, a valence triple-zeta basis set augmented by diffuse functions was used. The more elaborate CCSD(t) calculations parallel the trends already observed at the density functional level. However, in general they tend to enhance more the stabilities of the singlet species. In the case of the nitrenes, the results also agree

Table 1. Relevant bonding parameters (bond lengths in Å, bond angles in degrees) and singlet−triplet energy differences (in kcal/mol) of phosphanylnitrenes and element homologues H_2PX; the first entry is the singlet ($^1A_1$, C_{2v} symmetry), the second entry is the triplet ($^3A''$, C_s symmetry), electron affinities and/or ionisation potentials (in eV) are given in parentheses

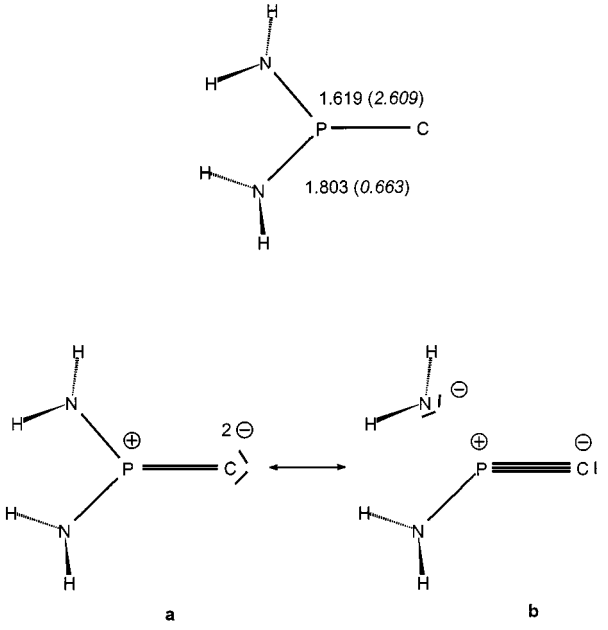
with the quantum chemical investigations already presented (see ref.[21] and cited work).

On the contrary, the species with X = $C^{(-)}$ or $Si^{(-)}$ are most likely to be found in a triplet ground state. At the very least, the singlet−triplet energy separations are fairly small. When X is more electronegative than nitrogen, a strong preference for a singlet ground state is observed. One may of course question whether the carbide or silicide analogues may exist at all, in the sense that in the corresponding singlet state, the negative charge will be kept in the structure or it undergoes spontaneous ionisation with the loss of an electron. In order to obtain a deeper insight into this aspect, we have also examined the corresponding lowest-energy doublet states ($^2B_2$, C_{2v} symmetry). The corresponding energy quantities (energy values obtained at the density functional level, in eV) are shown in the table in parentheses. Accordingly, the corresponding radicals have only a small tendency to add a further electron in the formation of a carbide or a silicide, but alternatively a rather large electron affinity is obtained for the Group 15 and Group 16 congeners.

Next we studied the effect of a typical π-donor (R^1, R^2 = NH_2) or π-acceptor (SiH_3) on the phosphanylnitrene and its valence isoelectronic homologues. The results of these investigations are collected in Table 2. Since the more elaborate CCSD(t) calculations parallel those at the density functional level, the following discussion will be based on the results calculated at the density functional level.

In accordance with the qualitative considerations, amino groups at the phosphorus atom tend to stabilise a singlet rather than a triplet ground state. Silyl groups do the opposite. The π-donation is most effective for the Group 16 congeners (X = $O^{(+)}$ > $S^{(+)}$) and least effective for X = $C^{(-)}$ and $Si^{(-)}$. For the latter species the ground state is a triplet.

In all cases, the resulting P−X bonds are shorter than those of corresponding double bond systems, for example, in iminophosphanes (ca. 1.54 Å)[31] or methylenephosphanes (ca. 1.64 Å).[32,33] Simultaneously, the bonds towards the trigonal phosphorus atom are significantly elongated. The most striking example is the diaminophosphanyl carbide, in which the P−N bonds become 1.803 Å, which is longer than a P−N single bond (1.76 Å).[28] An NBO population analysis[34] (Wiberg bond orders in italics) gives the results shown in Scheme 2.



Scheme 2

The weakening of the P−N (amino) bonds is compensated by the strengthening of the P−C bond. It can be attributed to the participation of the limiting structures **b** versus **a**, because the negative charge is shifted from the less electronegative carbon atom to the more electronegative nitrogen atoms.

We have also probed the effect of push-pull substitution at the phosphorus atom, i.e., R^1 = NH_2, R^2 = SiH_3. The effect on the singlet−triplet energy separation (17.4 kcal/mol) is similar to the effect of the monoamino-substituted nitrene (17.5 kcal/mol). In addition, we have investigated the case where the two amino groups are incorporated into a five-membered ring system *cyclo*-[N(H)CH=CHN(H)PN]. The singlet−triplet energy separation (18.0 kcal/mol) is similar to that found with monoamino substitution, but less than with diamino substitution (21.8 kcal/mol).

Table 2. Substituent effects on the singlet−triplet energy separations (in kcal/mol) in nitrene homologues R^1R^2PX, at the B3LYP/6-31+g(d) level

[a] Singlet states.

c. Amine- versus Imine-Type Substituents

A significant shortening of the P−X bond is observed for the nitrenes (X = N), in cases where strongly electronegative substituents are attached to the phosphorus atom

Table 3. Singlet−triplet energy separations (in kcal/mol) in various substituted nitrenes R^1R^2PN, at the B3LYP/6-31+g(d) level

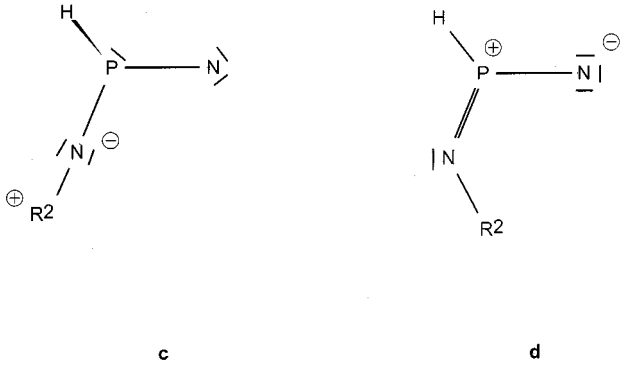
[a] Singlet states.

(Table 3), for R^1, R^2 = F or OH. These substituents are capable of polarising the phosphorus atom, i.e., to withdraw p-electron density from it. As a consequence, the σ-bond of P−N experiences more s-character and is shortened. In essence, it increases the stability of the P−N multiple bond.

At first glance, one would expect an increased singlet−triplet energy separation. However, electronegative substituents at the phosphorus atom have another effect, too. It is known that electronegative substituents increase the inversion barrier at a phosphane group.[35,36] Thus, electronegative substituents also favour a pyramidal triplet state. The calculated data (see Table 3) confirm this assertion. Fluorine, which is a poor π-donor but a strong electron-withdrawing σ-acceptor, tends to shorten the P−N bond (relative to the parent phosphanylnitrene). One fluorine atom (R^1/R^2 = F/H) shortens the P−N bond and increases the singlet-triplet energy separation, but the introduction of a second fluorine atom (R^1/R^2 = F/F) further reduces the P−N distance and simultaneously decreases the singlet−triplet energy difference. The special effect of fluorine substitution on the P−N bond length in the phosphanylnitrene is in agreement with the analogous limiting structure **a** and **b**, as has previously been noted[21].

The amino group is a strong π-donor (p-orbital) but on the other hand is also a strong σ-acceptor (sp^2-orbital). It is thus not the most suitable substituent for singlet stabilisation. A more appropriate substituent for singlet stabilisation should be a stronger π-donor as well as weaker σ-acceptor than the amino group. The latter aspect is of importance, otherwise the pyramidal triplet is equally well stabilised. A substituent that is more suitable for this purpose was therefore sought.

It has been well established that a phosphaniminato ligand can coordinate to a transition-metal fragment with a strong variation of the valence angle at the nitrogen atom.[37] More generally, it indicates that an imino function exerts σ-effects which are *dynamically* operative. This means that the σ-inductive effect of the same substituent can act differently in the lowest-energy singlet or triplet state. The two extreme bonding features (Scheme 3), **c** versus **d** are considered.



Scheme 3

In **c**, the nitrogen atom is sp-hybridised, while in the bent structure **d** it is sp^2-hybridised (PNP = 120°) [or sp^3 (109°)]. In **c** two lone pairs at the imino nitrogen atom are present, thus destabilising the triplet (with a pyramidal phosphorus atom, see Figure 2) by lone-pair repulsion (N vs. P). On the other hand, π-conjugation of the imino nitrogen atom with the phosphorus atom is present in **d**, and a singlet ground state is favoured. It should be noted that in the case of an amino group, lone-pair repulsion can be avoided in the triplet state by rotation of the amino group. Based on the present considerations, one can predict that substituents at the phosphorus atom that have an imino rather than an amino functional group are more likely to stabilise singlet ground states in the nitrenes and related species.

In order to strengthen these arguments, quantum chemical calculations [at the B3LYP/6-31+g(d) level] were performed on a variety of substituents with imino functions in the α-position to the phosphorus atom, namely, the phosphaniminato (H_3P-N), phosphanephosphinato (H_3P-P), methyleneimino (H_2C-N), diamino(methyleneimino) [$(H_2N)_2C-N$], and iminophosphane (HP=N) substituents (Table 3). Corresponding Molden plots of the equilibrium lowest-energy singlet and triplet states are shown representatively for the phosphaniminato ligand in Figure 3.

The structures preferentially adopt (*Z*) conformations. The P−N multiple bonds are significantly longer than in

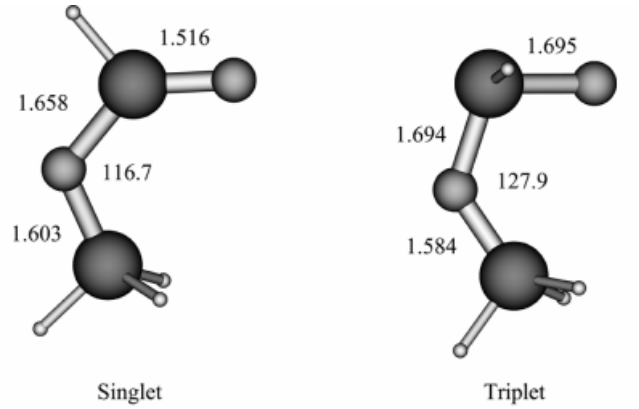


Figure 3. Molden plots of monosubstituted phosphaniminatonitrene; singlet state (left), lowest-energy triplet state (right)

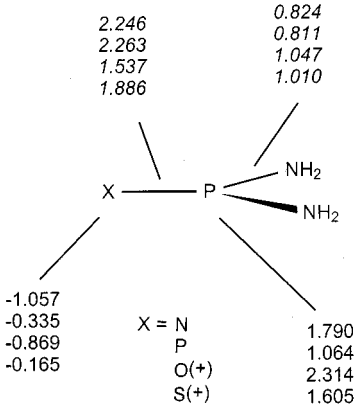

Scheme 4

the amino-substituted nitrenes (see Table 2), and the singlet−triplet separations are enlarged. Similar trends, shown here only for the phosphaniminato ligand, were observed for the other imino-type substituents, type **C**. For the phosphaniminato ligand we have also probed the case of disubstitution. The trend in mono- vs. disubstitution is not additive. It is worth noting the peculiar role of the phosphaniminato ligand which has also recently been shown to stabilise the singlet of phosphanylcarbenes.[38] Imine-type functional groups are also predicted to lengthen the strained P−P bond in 1,2-diphosphacyclobutene.[39]

Based on the singlet−triplet energy separations (see Table 1) the diamino-substituted oxo- and thioxophosphonium species should be fairly stable. In their planar singlets, the central phosphorus atom is surrounded by electronegative substituents. Results from the NBO population analysis for the case of **B** ($R^1 = R^2 = NH_2$ and X = , N, P, $O^{(+)}$, $S^{(+)}$) are shown in Scheme 4 (Wiberg bond orders are italicised).

The central atom (P) gains a large positive charge in the cations since the electron density is withdrawn to the peripheral atoms which are more electronegative than the central phosphorus atom. It is known that the thioxophosphonium cations and the nitrenes spontaneously dimerise to form four-membered ring systems.[6]

Conclusion

The results of our investigations can be summarised as follows:

(1) Singlet nitrenes are stabilised by π-donors. The stabilisation effects increase for the Group 16 and decrease for the Group 14 congeners. The opposite is true for π-attracting substituents. The carbides and silicides possess triplet ground states.

(2) Substituents which bear an imino function in an α-position to the phosphorus atom, e.g., the phosphaniminato ligand, promote a singlet ground state even more strongly than an amino group. Our investigations have thus revealed a new type of substituent for the stabilisation of species which were hitherto considered as being short-lived intermediates. In the experiment, however, the structures are encumbered by bulky substituent effects which in addition affect the kinetic stabilities of these species.

Theoretical Section

All calculations were performed with the Gaussian-98 set of programs.[40] The various structures were fully optimised at the B3LYP level by using the 6-31+g(d) basis set.[41−43] The density functional is built with Becke's three-parameter exchange functional[44,45] and the nonlocal correlation functional of Lee, Yang, and Parr.[46] The energy optimisations were conducted by analytically determined nuclear coordinate gradients. All the investigated structures were characterised by vibrational analysis within the harmonic approximation. The population analysis at the given optimised geometries were carried out according to the Weinhold−Reed partitioning scheme.[34] Further correlation corrections were obtained at the CCSD(t) level[47−49] by using triple-zeta valence basis sets[50,51] augmented with diffuse functions. One may note that the singlet−triplet energy separations within density functional theory depend on the shape of the chosen functional.[52] Nevertheless, the chosen density functional method is expected to predict correct trends for the substituent effects.

The Metalation of (*tert*-Butyldimethylsilyl)(2-pyridylmethyl)amine with Dimethylzinc and Subsequent Zinc-Mediated Carbon−Carbon Coupling Reaction

Matthias Westerhausen,*[a] Tobias Bollwein,[a] Nikolaos Makropoulos,[a] Thomas M. Rotter,[a] Tassilo Habereder,[a] Max Suter,[a] and Heinrich Nöth[a]

Keywords: Amides / Zinc / C−C coupling / Metalations / Metallacycles / N ligands

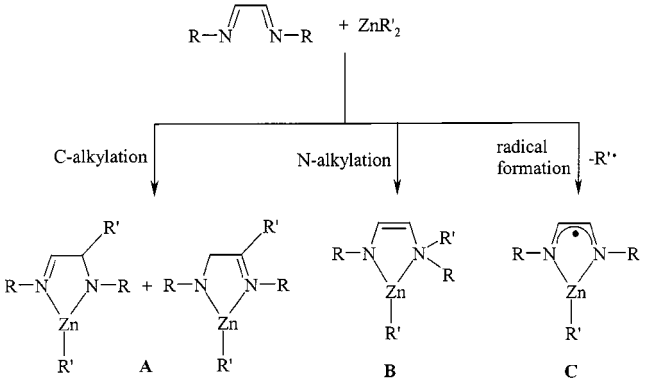
The lithiation of 2-(aminomethyl)pyridine and the subsequent reaction with $ClSiMe_2tBu$ yields (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**). The metalation of **1** with dimethylzinc gives colorless dimeric methylzinc 2-pyridylmethyl(*tert*-butyldimethylsilyl)amide (**2**), which crystallizes in the triclinic space group $P\bar{1}$. The solvent-free thermal decomposition of **2** at 150 °C leads to the evolution of methane, the precipitation of zinc metal and the formation of amine **1**, bis(methylzinc)—1,2-dipyridyl-1,2-bis(*tert*-butyldimethylsilylamido)ethane (**3**), and bis[(*tert*-butyldimethylsilyl)(2-pyridylmethyl)amido]zinc (**4**). Compound **3** can be obtained in good yield by reacting **2** with dimethylzinc at elevated temperatures in toluene. During this reaction, zinc metal precipitates and methane is evolved. The C–C coupling product **3** crystallizes in the tetragonal space group $I4_1cd$. The lithiation of **1** and the subsequent metathesis reaction with anhydrous $ZnCl_2$ yields complex **4** almost quantitatively.

Introduction

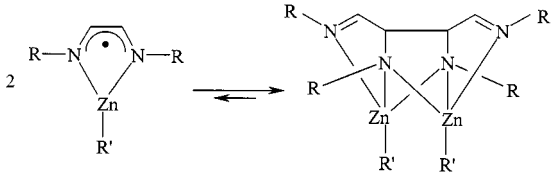
Pyridine complexes of zinc compounds are a well-known class of substance. On the one hand pyridine, as well as its derivatives such as 2,2′-bipyridine, are able to stabilize dialkylzinc[1−3] or even a geminal biszincated alkane but,[4] on the other hand, these coligands support homolytic Zn−C bond cleavage upon irradiation.[5] Furthermore, multi-dentate azaligands such as, for example, trispyrazolylborate anions enable reactions at the metal centers that can serve as model systems for enzymes.[6]

The reaction of dialkylzinc with 1,4-di(*tert*-butyl)-1,4-diazabutadiene (DAB) or *N*-*tert*-butylpyridine-2-carbaldimine (PYCA) yields the corresponding 1:1 complexes, which are red in color.[7] Subsequent to the adduct formation these compounds have three possible reaction pathways depending on the zinc-bonded alkyl substituent and on the reaction conditions: *C*-alkylation (**A**), *N*-alkylation (**B**) and homolytic Zn−C bond cleavage (**C**) (Scheme 1).[7,8,9] During all these reactions, one alkylzinc moiety remains unchanged and can be regarded as a spectator because the coordination of this metal fragment to the nitrogen atoms of the chelating ligand remains unchanged. Precipitation of zinc metal was not reported to occur during the course of the reactions.

Complex **C** shows a monomer-dimer equilibrium. The dimerization occurs through C−C bond formation as shown in Scheme 2. The newly formed C−C bond is longer than a C−C single bond, as exemplified by [Et−Zn(PYCA)]$_2$ with 156.9(8) pm and [Me_3SiCH_2−Zn(DAB)]$_2$ with a longer distance of 162 pm.[10]



Scheme 1. Possible reaction pathways of dialkylzinc with 1,4-di(*tert*-butyl)-1,4-diazabutadiene.



Scheme 2. Monomer-dimer equilibrium through C−C bond cleavage and formation.

The reduction of 1,4-di(*tert*-butyl)-1,4-diazabutadiene with lithium and the subsequent metathesis reaction with (DAB)$ZnCl_2$ yields $Zn(DAB)_2$, which can easily be reduced with potassium or oxidized in a comproportionation with (DAB)$Zn(O_3S-CF_3)_2$.[11] During all these reaction sequences, which were reported by van Koten and co-workers, the oxidation state of +2 for zinc remains unchanged.

Here we report on the synthesis of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine, which can easily be metalated

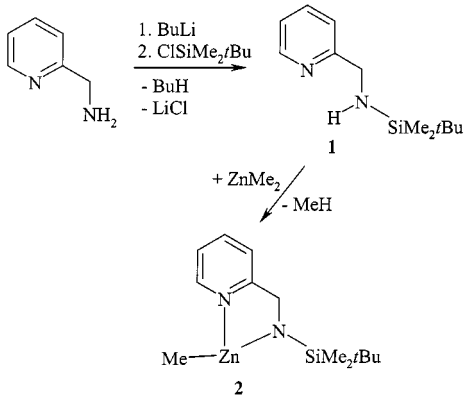
by dimethylzinc. The thermal decomposition as well as the reaction of this product with excess dimethylzinc leads to C−C bond formation and the precipitation of an equimolar amount of zinc metal. This unusual oxidative carbon−carbon coupling under formation of Zn^0 is irreversible and evidence for a monomer−dimer equilibrium by homolytic C−C bond cleavage was not found. The zincation of 2-(*N*-*tert*-butylaminomethyl)-1-methylbenzimidazole also uses the chelate effect and a zinc atom with a coordination number of 3 can be stabilized.[12] However, C−C bond formation was not observed during this reaction.

Results and Discussion

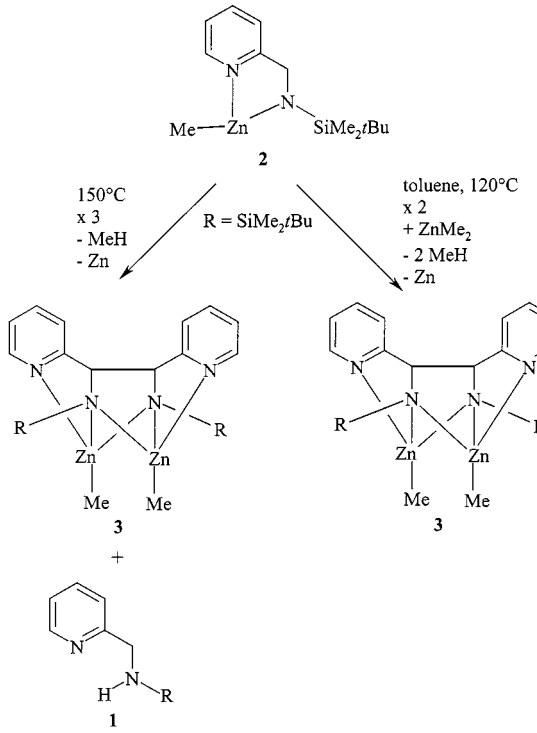
Synthesis

The lithiation of 2-pyridylmethylamine and the subsequent metathesis reaction with *tert*-butyldimethylsilyl chloride quantitatively yields (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**). Zincation of **1** with dimethylzinc in toluene gives colorless dimeric methylzinc—(*tert*-butyldimethylsilyl)(2-pyridylmethyl)amide (**2**) according to Scheme 3.

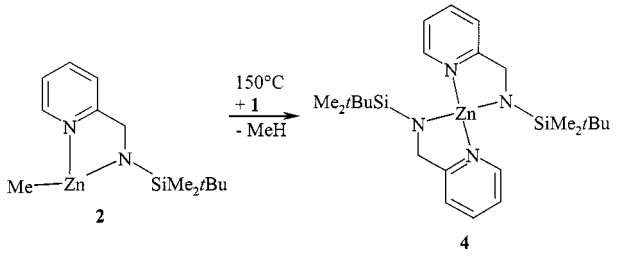


Scheme 3. Synthesis of **1** and **2**

The thermal decomposition of molten **2** at approximately 150 °C (Scheme 4) leads to the evolution of methane, as confirmed by mass spectrometry. During the course of this reaction the precipitation of zinc metal is observed and the NMR spectroscopic data also indicate the formation of **1**. In addition to these substances two new compounds are formed, namely the C−C coupling product bis(methylzinc)—1,2-bis(*tert*-butyldimethylsilylamido)-1,2-dipyridylethane (**3**) and bis[(*tert*-butyldimethylsilyl)(2-pyridylmethyl)-amido]zinc (**4**). Complex **4** forms due to zincation of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**) by derivative **2** under elimination of methane, as shown in Scheme 5. The C−C coupling product and the elemental zinc are formed in an equimolar ratio. Scheme 4 represents the reaction sequence of this thermolysis of **2** and the ^1H NMR spectrum of the thermolysis reaction is presented in Figure 1. The subsequent addition of dimethylzinc leads to the metalation of **1** and to dismutation reactions with **4**, both of which lead to **2**. The isolation of analytically pure **4** by fractional crystallization was not possible due to co-precipitation of minor amounts of **2** and/or **3** in the sample. For the sake of comparison, compound **4** was prepared by the metathesis reaction of anhydrous $ZnBr_2$ with lithium 2-pyridylmethyl-(*tert*-butyldimethylsilyl)amide, which was generated in situ by lithiation of **1**.



Scheme 4. Synthesis of the C−C coupling product **3** by reaction of **2** with dimethylzinc and as a result of thermal decomposition of **2** at 150 °C, which also gives complex **4** due to the metalation of **1** with **2** in the melt.



Scheme 5

In order to avoid the formation of bis[2-pyridylmethyl-(*tert*-butyldimethylsilyl)amido]zinc (**4**) and to obtain quantitatively the C−C coupling product **3**, dimethylzinc is added prior to the thermolysis of **2** in refluxing toluene. In this case neither amine **1** nor complex **4** are detectable by NMR spectroscopy, as shown in Figure 1. The zincation of the CH_2 group and the oxidative C−C coupling reaction lead to the precipitation of zinc metal, as confirmed by X-ray powder diffraction methods (Figure 2). The use of a molar ratio of 3:2 for dimethylzinc and (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**) gives **3** and elemental zinc in a 1:1 molar ratio.

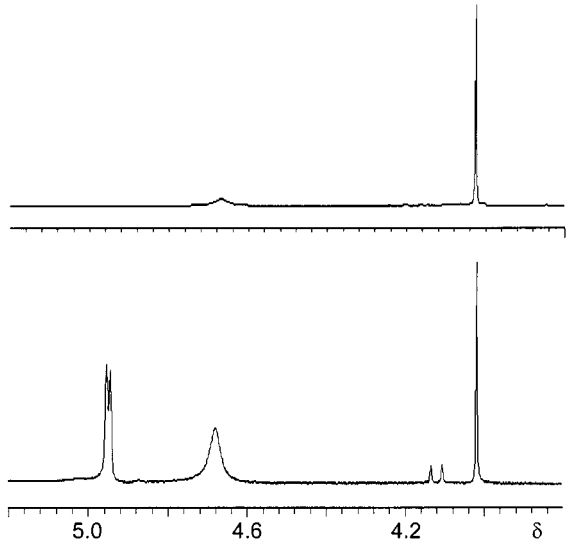


Figure 1. ^{1}H NMR spectroscopic monitoring of the progress of the C−C coupling reaction shown in the region of δ = 4.0 to 5.1 at 30 °C. Upper spectrum: Reaction of **2** with dimethylzinc in toluene; only compounds **2** and **3** are observed. Lower spectrum: Spectrum after thermal decomposition of **2** at 150 °C for 2 hours; after dissolving the residue in toluene compounds **1**, **3**, and **4** are detected (see also Table 2).

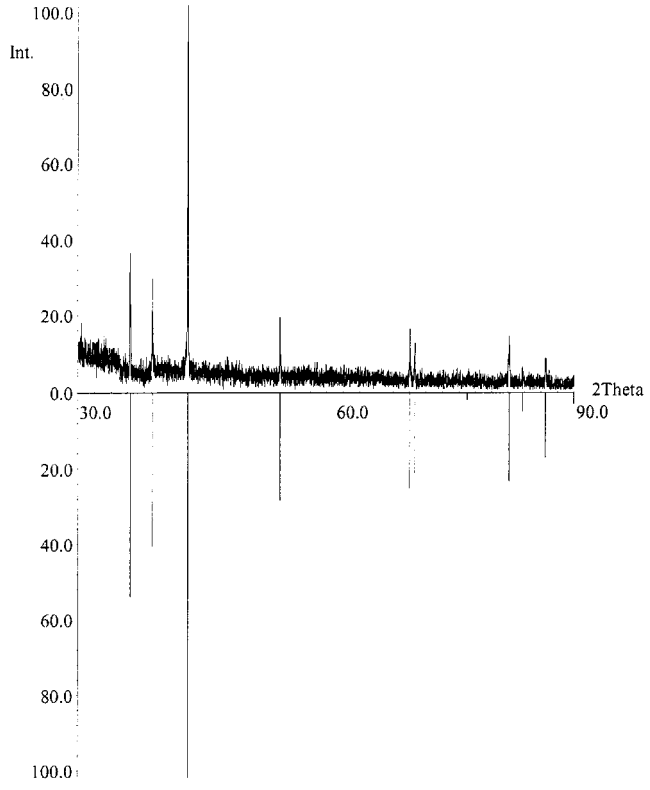

Figure 2. X-ray powder diffractogram of zinc that precipitated during the C−C coupling reactions (upper spectrum) and the reference line spectrum (below).

The stereoselective C−C coupling reaction leads to the formation of the *R*,*R* and *S*,*S* enantiomers, whereas a *meso*-diastereomer was not observed. A similar product with *tert*-butyl substituents at the nitrogen atoms was obtained by metalation of the corresponding amine and was already reported by van Koten and co-workers.[10] However, this complex dissociates into monomeric radicals through a homolytic C−C bond cleavage, as shown in Scheme 2. The presence of trialkylsilyl substituents seems to prevent this monomerization process. The colorless C−C coupling product **3** is EPR silent and its solution is colorless. In order to investigate the influence of the C−C coupling reaction on the coordination spheres of zinc and the amide nitrogen atoms the crystal structure determinations of **2** and **3** were performed.

Molecular Structures of 2 and 3

The molecular structure of **2** is shown in Figure 3 along with the numbering scheme. The second half of the molecule is generated by inversion symmetry and these atoms are marked with apostrophes. The zinc atom Zn1 is coordinated tetrahedrally by three nitrogen atoms and a methyl group. Selected bond lengths and angles are given in Table 1.

Due to the inversion symmetry the central Zn_2N_2 cycle is planar with an N1−Zn1−N1′ angle of 94°. The Zn−C distances lie within a characteristic range and there is no sign of steric strain in this dimer, although the Zn−N bonds are slightly longer than those in the aminomethylpyridine complexes of the zinc dihalides[13] and much longer than those in homoleptic zinc bis(amides).[14]

Figure 4 shows the molecular structure and the numbering scheme of the C−C coupling product **3**. The second half of the molecule is generated by crystallographic C_2 symmetry and the generated atoms are marked with apostrophes. Selected structural data are presented in Table 2. For the sake of comparison the numbering schemes of **2** and **3** are alike.

A tetradentate aza ligand is formed in the C−C coupling. Therefore, the methyl groups at the zinc atoms are at the same side of the Zn_2N_2 cycle. The C7 atom is chiral. Due to the molecular C_2 symmetry and the noncentrosymmetric

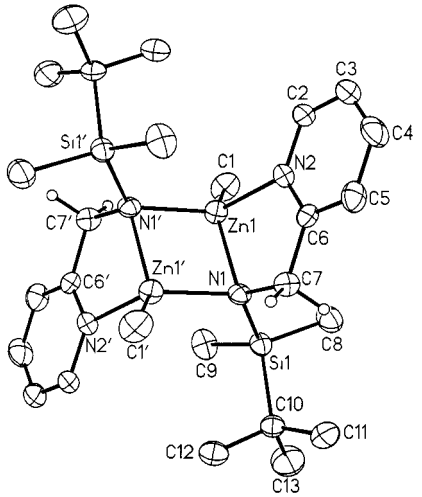

Figure 3. Molecular structure of **2**. The ellipsoids represent a probability of 40%. Atoms generated by the crystallographic inversion symmetry (−*x*, −*y*, −*z* + 1) are marked with apostrophes. The hydrogen atoms are omitted for clarity (with the exception of those at C7/C7′).

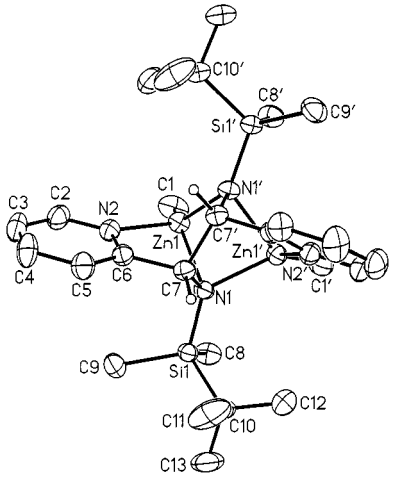

Figure 4. Molecular structure and numbering scheme of **3**. The ellipsoids represent a probability of 40%. Atoms generated by the crystallographic C_2 symmetry ($-x + 1 - 1$, $-y + 1$, $z + 1 - 1$) are marked with apostrophes. The hydrogen atoms are omitted for clarity (with the exception of those at C7/C7′).

tetragonal space group $I4_1cd$, the crystalline compound of this material consists of the *R*,*R* enantiomer. The arrangement of the molecules in the solid state is shown in Figure 5 and it can be seen that the molecules are orientated in the same direction.

The newly formed C7−C7′ bond of **3** is rather long, a situation also observed for $[Et-Zn(PYCA)]_2$ and $[Me_3SiCH_2-Zn(DAB)]_2$.[10] The tetradentate aza ligand enforces strong deviations from planarity in the Zn_2N_2 cycle. The angle between the normals of the planes N1/Zn1/N1′ and N1/Zn1′/N1′ amounts to 72.1°. This leads to short transannular Zn1Zn1′ contacts [287.5(2) pm for **2** and 272.11(5) pm for **3**] and small endocyclic angles at Zn1 and N1 (Table 1). The environment of C7 shows only insignificant deviations from the tetrahedral geometry.

Table 2. Selected NMR spectroscopic data of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**), the metalation product **2**, the C−C coupling product **3**, and bis[2-pyridylmethyl(*tert*-butyldimethylsilyl)amido]zinc (**4**).

NMR Spectroscopy

The NMR parameters of these compounds are listed in Table 2. The numbering scheme is taken from the X-ray structures presented in Figure 3 and 4 for **2** and **3**, respectively. The hydrogen atoms carry the same numbers as the corresponding carbon atoms. A similar numbering scheme is applied to **1** and **4**.

The C−C coupling and the resulting higher steric strain on the zinc centers lead to a high-field shift of the signals due to the zinc-bonded methyl groups in both the ^{1}H and the ^{13}C{^{1}H} NMR spectra. The signals due to the silicon-bonded methyl substituents of **2** are shifted to higher field compared to **1**, whereas the methyl groups of **3** are more deshielded. Furthermore, two singlets are observed for the methyl groups at the Si atoms for **3** and **4**. Compounds **2** and **4**, which both contain the bidentate (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amide substituent, are easily identified by their δ(^{29}Si{^{1}H}) values.

The most sensitive NMR probe for these molecules is the C7/H7 moiety and therefore this region was chosen to monitor the thermal decomposition of **2** (Figure 1). The AB spin system for the methylene group in **4** results from the tetrahedral geometry at the zinc atom: One hydrogen atom at C7 is at the same side as the pyridyl group of the opposite ligand, whereas the other H atom is oriented to the side of the trialkylsilyl group. The geminal coupling constant has a

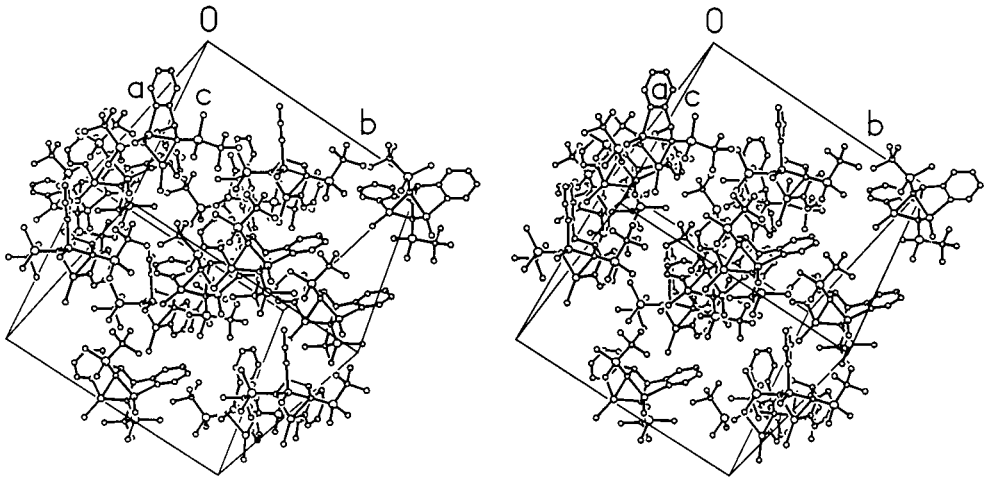

Figure 5. Stereoscopic view of the arrangement of the molecules of **3** in the elementary cell. All atoms are drawn with arbitrary radii, the H-atoms are omitted for clarity.

value of approximately 20 Hz and lies in the expected range. The ^{13}C chemical shifts of C7 vary between $\delta = 48.2$ for (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**) and $\delta = 67.3$ for the C−C coupling product **3**.

Conclusion and Prospects

The zincation of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)-amine (**1**) quantitatively yields **2**. The thermolysis of this compound, as well as the reaction of **2** with dimethylzinc, leads to oxidative C−C bond formation and yields **3**. At the same time the precipitation of an equimolar amount of zinc metal is observed. The synthetic approach to compound **3** is different to the synthesis of (PYCA)ZnEt reported by van Koten and co-workers. In contrast to bis(alkylzinc)—1,2-bis(*tert*-butylamido)-1,2-dipyridylethane, a monomer-dimer equilibrium is not observed for **3**. This allows the investigation of the reactivity of two zinc atoms that are in close contact with each other without considering the chemistry of radicals, which would form due to the homolytic C−C bond cleavage.

Experimental Section

General Remarks: All experiments and manipulations were carried out under an argon atmosphere. Reactions were performed using standard Schlenk techniques and the solvents were dried and thoroughly deoxygenated prior to use. − NMR spectra were recorded on Jeol GSX270 and EX400 spectrometers. − A Nicolet 520 FT-IR spectrophotometer was used to record the IR spectra; solid substances were analysed in nujol between KBr plates (vs very strong, s strong, m medium strong, w weak, vw very weak, sh shoulder). − The low carbon and nitrogen values in the elemental analyses result from the presence of carbide and carbonate as well as nitride formation during combustion of the compounds.

(*tert*-Butyldimethylsilyl)(2-pyridylmethyl)amine (1): A 2.5 M solution of *n*-butyllithium in hexane (40 mL, 100 mmol) was added slowly to a precooled solution (−78 °C) of 10.8 g of 2-aminomethylpyridine (100 mmol) in 100 mL of tetrahydrofuran. After 5 minutes of stirring, a solution of 15.1 g of *tert*-butyldimethylsilyl chloride (100 mmol) in 25 mL of tetrahydrofuran was added at −78 °C. The reaction solution was allowed to warm up and stirred at room temperature for an additional 2 h. The solvent was removed in vacuo at room temperature. The residue was dissolved in pentane and any insoluble materials were filtered off. The volatile components were removed at 120 °C to leave **1** as an oil which is an only slightly air-sensitive oil; yield: 19.54 g (87.9 mmol), 88%. − NMR spectroscopic data are listed in Table 2. − IR: $\tilde{\nu} = 3370$ cm^{-1} br, 3084 sh, 3069 w, 3010 w, 2953 s, 2928 s, 2896 s, 2883 s, 2855 s, 1593 s, 1571 m, 1471 s, 1463 s, 1434 s, 1406 s, 1388 s, 1360 m, 1344 w, 1254 s, 1216 w, 1145 sh, 1125 s, 1093 m, 1085 m, 1047 m, 1006 m, 995 m, 955 w, 938 m, 884 sh, 832 s, 812 m, 776 s, 752 m, 726 w, 680 w, 662 m, 628 w, 595 w, 565 w, 456 w, 403 w, 374 br, 358 br. − $C_{12}H_{22}N_2Si$ (222.406): calcd. C 64.80, H 9.97, N 12.59; found C 63.88, H 9.62, N 12.56.

Methylzinc—2-Pyridylmethyl(*tert*-butyldimethylsilyl)amide (2): A 2.0 M solution of dimethylzinc in toluene (4.8 mL, 9.6 mmol) was added slowly at 0 °C to a solution of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**) (2.12 g, 9.53 mmol) in 10 mL of toluene. After 15 h stirring at room temperature the volume of the dark solution was reduced to a few milliliters. Storage at 5 °C led to the precipitation of colorless crystals of **2**; yield: 2.13 g (3.53 mmol of dimeric **2**), 74%. − M.p. 136 °C. − NMR spectroscopic data are listed in Table 2. − IR: $\tilde{\nu} = 1641$ cm^{-1} vw, 1606 vs, 1593 s, 1572 vs, 1553 sh, 1485 vs, 1474 s, 1431 vs, 1408 vs, 1387 s, 1355 s, 1320 w, 1283 s, 1253 vs, 1208 m, 1154 s, 1148 s, 1125 s, 1105 m, 1084 m, 1059 s, 1045 vs, 1022 s, 1007 s, 994 s, 960 s, 936 m, 886 sh, 829 vs, 814 sh, 771 vs, 719 s, 675 sh, 661 vs, 637 s, 617 s, 564 m, 499 s, 460 s, 446 s, 415 s, 403 m, 389 s, 364 m, 327 w, 286 vw. − $[C_{13}H_{24}N_2SiZn]_2$ (603.624): calcd. C 51.73, H 8.02, N 9.28; found C 51.09, H 7.90, N 9.34.

Zinc Complex 3. − Method A (Thermal Decomposition of 2): Compound **2** was heated without a solvent for 2 h at 150 °C. The evolving gas was collected and identified as methane by mass spectrometry. During the thermal decomposition reaction zinc metal precipitated. The NMR spectroscopic investigation confirmed the formation of **1**, **3**, and **4**, and small amounts of unchanged **2** were still

present. Compounds **1** to **4** were dissolved in hydrocarbons and separated from the insoluble materials. X-ray powder diffraction analysis of the residue verified the elimination of zinc metal, which was formed in an equimolar amount to the C−C coupling product **3**.

Method B (C−C Coupling Reaction): To a solution of 3.57 g of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**) (16.1 mmol) in 20 mL of toluene was added 12.0 mL of a 2.0 M solution of dimethylzinc in toluene. The quantitative formation of **2** was confirmed by ^{1}H NMR measurements. The reaction mixture was heated under reflux for 5 h. During this time zinc metal precipitated. The solution was filtered and the volume of was reduced to a few milliliters. On cooling the solution to −18 °C colorless crystals of **3** precipitated in the shape of small grains of rice; yield: 6.49 g (10.79 mmol), 67%. − Physical data: M.p. 191 °C. − NMR spectroscopic data are listed in Table 2. − IR: $\tilde{\nu}$ = 1642 cm^{-1} vw, 1631 vw, 1602 vs, 1495 vw, 1474 vs, 1463 s, 1441 vs, 1408 m, 1386 m, 1357 m, 1348 m, 1331 w, 1290 m, 1279 m, 1249 vs, 1229 sh, 1212 w, 1186 vw, 1154 vs, 1106 m, 1060 vs, 1045 vs, 1020 vs, 1007 s, 936 vs, 890 m, 870 m, 844 s, 827 vs, 807 vs, 771 vs, 753 vs, 730 sh, 675 vs, 664 vs, 641 vs, 606 s, 573 vw, 557 sh, 544 m, 528 vs, 462 s, 437 s, 410 m, 378 w, 314 vw, 292 w, 274 w. − $C_{26}H_{46}N_4Si_2Zn_2$ (601.608): calcd. C 51.90, H 7.71, N 9.32; found C 52.01, H 7.81, N 9.32.

Zinc Complex 4: A 1.6 M solution of *n*-butyllithium (4.89 mL) in diethyl ether was added slowly at −78 °C to a solution of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**1**) (1.74 g, 7.82 mmol) in 10 mL of tetrahydrofuran. A solution of zinc dibromide (0.88 g, 3.91 mmol) in 5 mL of tetrahydrofuran was added to the reaction solution at 0 °C. The mixture was stirred for 10 h, the solvent was removed and the residue was extracted with pentane. Recrystallization yielded colorless **4**; yield: 0.70 g (1.37 mmol), 35%. − M.p. 114 °C. − NMR spectroscopic data are listed in Table 2. − IR: $\tilde{\nu}$ = 3414 cm^{-1} w, 3377 w, 1636 vw, 1604 s, 1594 sh, 1570 m, 1481 s, 1471s 1433 s, 1406 m, 1386 w, 1348 m, 1280 s, 1246 s, 1220 sh, 1211 w, 1151 m, 1122 vs, 1102 s, 1045 s, 1018 m, 1005 m, 994 sh, 982 sh, 927 s, 830 vs, 813 sh, 777 sh, 764 vs, 754 sh, 721 m, 671 sh, 657 m, 645 w, 614 w, 566 vw, 513 w, 486 vw, 469 vw, 454 vw, 429 sh, 407 w, 375 w, 351 w, 297 vw. − $C_{24}H_{42}N_4Si_2Zn$ (508.176): calcd. C 56.72, H 8.33, N 11.03; found C 56.72, H 8.33, N 11.03.

X-ray Structure Determinations of 2 and 3: Data were collected on a Siemens P4 diffractometer with a Siemens SMART−CCD area detector with graphite monochromated Mo-K_α radiation (λ = 71.073 pm) using oil-coated, rapidly cooled single crystals.[15] Crystallographic parameters and details of data collection and refinement procedures are summarized in Table 3.

The structures were solved by direct methods and refined with the software packages SHELXL-93 and SHELXL-97.[17] Neutral scattering factors were taken from Cromer and Mann[18] and for the hydrogen atoms from Stewart et al.[19] The non-hydrogen atoms were refined anisotropically. The H-atoms were considered with a riding model under restriction of ideal symmetry at the corresponding carbon atoms. Crystallographic data (excluding structure factors) for the structures of **2** and **3** has been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-147824 for **2** and -147825 for **3**. Copies of the data can be obtained on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [E-mail: deposit@ccdc.cam.ac.uk].

Dinuclear Zinc(II) Complexes of *N*,*N*′-Bis[2-(hydroxyphenyl)methyl]-*N*,*N*′-bis(2-pyridylmethyl)-1,*n*-alkanediamines

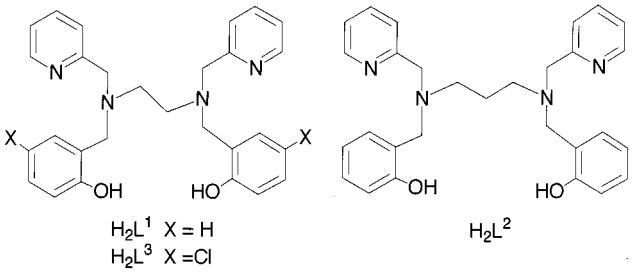
Harry Adams,[a] Darren Bradshaw,[a] and David E. Fenton*[a]

Keywords: Zinc / N ligands / O ligands / Structure elucidation

Neutral homodinuclear zinc(II) complexes [ZnL]·$ZnCl_2$ have been obtained from the reactions of the proligands *N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)-1,2-ethanediamine (H_2L^1) and *N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)-1,3-propanediamine (H_2L^2) with zinc chloride. Crystals of [ZnL^1]·$ZnCl_2$ (**3**) are triclinic, of space group *P*1(bar), with *a* = 9.2240(7), *b* = 10.4005(9), and *c* = 15.6418(13) Å, α = 91.634(2), β = 91.566(2), γ = 112.625(2)° and *Z* = 2, and those of [ZnL^2]·$ZnCl_2$ (**2**) are monoclinic, of space group $P2_1/c$, with *a* = 19.249(4), *b* = 17.275(4), and *c* = 16.546(3) Å, β = 92.742(5)° and *Z* = 8. The structures were refined by full-matrix least-squares procedures to R_1 = 0.0589 for **3** and R_1 = 0.085 for **2** for 4080 and 3786 independent reflections with $I \geq 4\sigma(I)$ respectively. The Zn in the [ZnL] moiety is coordinated in a distorted octahedral geometry [$N_2N'_2O_2$] and this unit serves as a chelating ligand, through the pair of phenolic O atoms, towards the $ZnCl_2$. The second zinc atom is in a distorted tetrahedral geometry. The structure of **2** shows a racemic mixture of two enantiomers, in which the pendant pyridinyl N atoms are *trans* to each other, whereas the structure of **3** reveals a new stereoisomer in which the pendant pyridinyl N atoms are *cis* to each. ^{1}H NMR spectroscopic data for the complexes shows a rigid solution structure for **2** and fluxional behaviour for **3**.

Introduction

An interest in generating models for manganese-containing metallobiosites led Neves et al. to synthesise mononuclear manganese(III) complexes of the *N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)-1,*n*-alkanediamine ligands H_2L^1 (*n* = 2) and H_2L^2 (*n* = 3).[1] The crystal structure of [MnL^1]PF_6 revealed that the manganese(III) is present in a pseudo-octahedral geometry with each of the two halves of the hexadentate ligand providing a facial N_2O donor set. The phenolic O-atoms were found to be *cis* to each other and, with the N-atoms of the ethylenic spacer, provided the equatorial donor array.



The pyridinyl N-atoms are in the apical sites and so are *trans* to each other. Similar pseudo-octahedral geometries and ligand dispositions have been found for gallium(III) and indium(III) in the closely related mononuclear complexes [ML^3]ClO_4 (M = Ga, In),[2] and for vanadium(III) in the complex [VL^1]PF_6.[3] The hexadentate ligands [O^(N^N_{pyr})^(N^N_{pyr})^O] have the capability to produce stereoisomers (Figure 1) but only (**1a**) has been crystallographically characterised in the above-mentioned complexes.

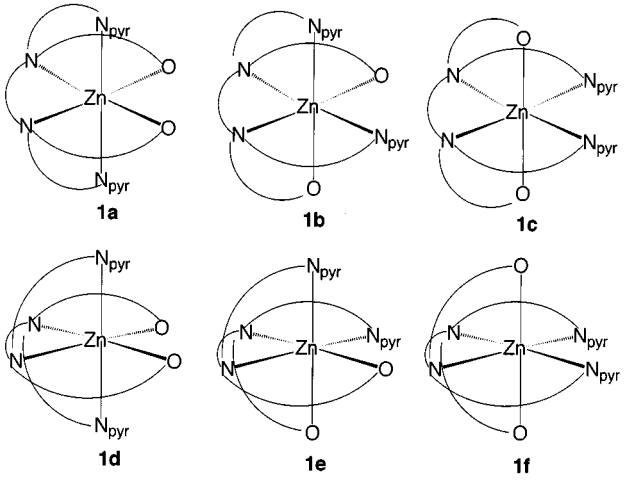


Figure 1. Octahedral stereoisomers derived from the ligands [O^(N^N_{pyr})^(N^N_{pyr})^O]

During the course of an investigation into the complexation of zinc(II) by tripodal and linked polypodal ligands bearing phenolic and pyridinyl groups[4–6] we have found that, in contrast to the above generation of mononuclear trivalent metal complexes, the reaction of zinc(II) chloride with H_2L^2 and H_2L^1 gives the homodinuclear complexes **2** and **3**, respectively, in which the anticipated neutral hexadentate zinc(II) complexes are not isolated but act as ligands towards a zinc chloride entity. In this paper we report this reactivity together with the crystal structures of

the resulting complexes. Prior to this report, studies of H_2L^1 and H_2L^2 with divalent metals have been restricted to those on the application of H_2L^1 in the extraction of divalent first row transition metals into $CHCl_3$ in which the speciation revealed that the ligand could act not only in a hexadentate mode but also in tri- and tetradentate modes to give positively charged species.[7]

Results and Discussion

The Complex $[ZnL^2]\cdot ZnCl_2$ (2)

Reaction of the ligand H_2L^2 with two equivalents of $ZnCl_2$ in acetonitrile solution in the presence of NEt_3 gave colourless crystals suitable for X-ray analysis. The analytical data suggested that a complex with a molecular formula $[Zn_2L^2Cl_2]$ had formed and it was noted that changing the ratio of the starting materials from 1:2 to 1:1 did not change the stoichiometry of the reaction product. As a dinuclear product had not been expected the crystal structure was determined in order to establish the bond connectivity. There are two enantiomeric molecules in the asymmetric unit. The molecular structure of each, depicted in Figure 2, revealed that one Zn atom is completely encapsulated by the deprotonated ligand in a pseudo-octahedral coordination environment similar to that found in $[MnL^1]PF_6$, and in contrast to the structure found for $Zn(L^4)_2\cdot 2H_2O$, in which there is no steric constraint imposed by an alkane linker joining the secondary amines and the phenolate-O atoms are *trans* to each other, as are the pyridinyl-N atoms.[8] This octahedral complex $[ZnL^2]$ acts as a ligand with the *cis*-phenolate O-atoms chelating to the second zinc atom to give the product $[ZnL^2]\cdot ZnCl_2$ (**2**).

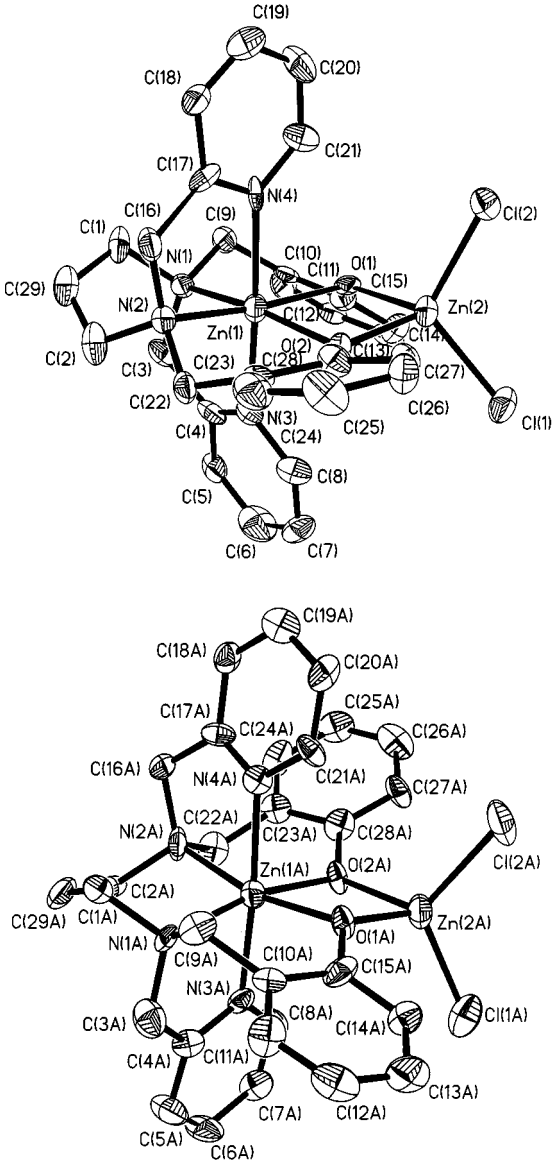

Figure 2. ORTEP drawings of the enantiomers of $[ZnL^2]\cdot ZnCl_2$ [Δ-**2** (a) and Λ-**2** (b)] showing the crystallographic labelling; thermal ellipsoids for the non-hydrogen atoms are drawn at the 50% probability level

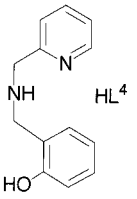

HL^4

The reaction of H_2L^2 with zinc(II) acetate yields the related complex $[ZnL^2]\cdot Zn(OAc)_2]$ in which the octahedral $[ZnL^2]$ unit, derived from stereoisomer **1a**, coordinates to the $Zn(OAc)_2$ through the *cis*-phenolato O atoms. The two acetato groups are monodentate and the second Zn atom is in a distorted T_d environment.[9]

The second zinc atom has a distorted tetrahedral coordination environment with two Cl atoms completing the coordination sphere. The Δ enantiomer (**1d**) is that containing Zn(1) and Zn(2), and the Λ enantiomer (**1a**) is that containing Zn(1A) and Zn(2A) (Figure 3); the designations Λ and Δ have been assigned assuming the species are tris-chelates with atom sequences O(1)Zn(2)O(2), N(2)C(16)C(17)N(4), and N(1)C(3)C(4)N(3) serving as chelating ligands.

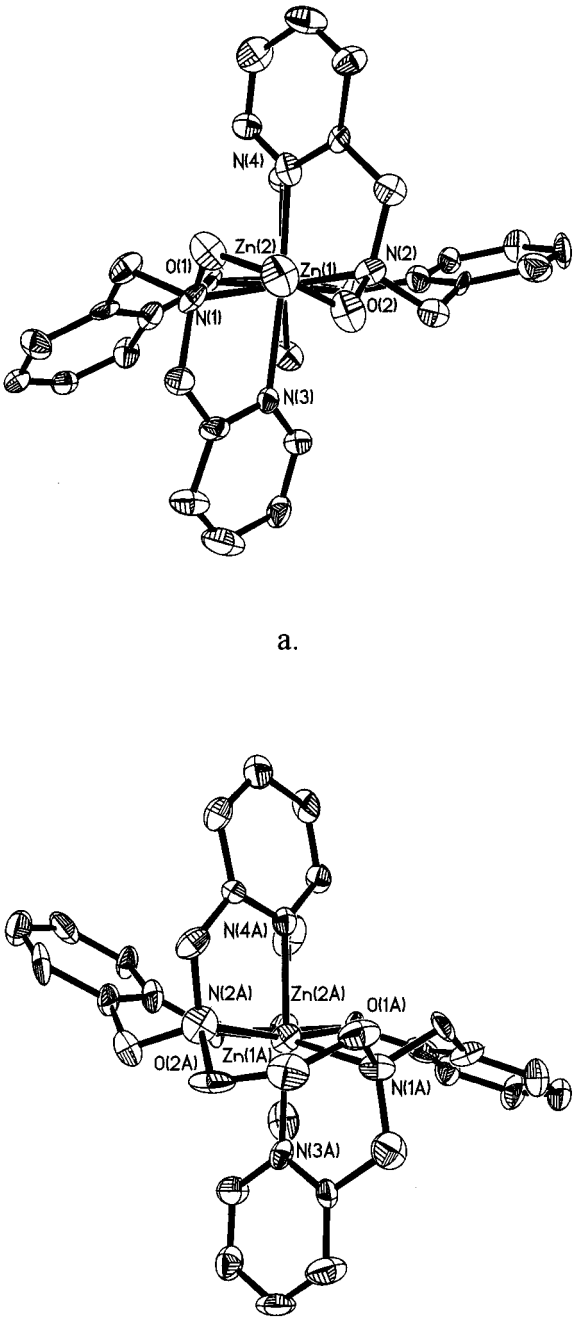

Figure 3. ORTEP drawings of the enantiomers of $[ZnL^2]\cdot ZnCl_2$ [Δ-**2** (a) and Λ-**2** (b)] viewed along the equatorial plane [(N(1)−N(2)−O(1)−O(2)]; thermal ellipsoids for the non-hydrogen atoms are drawn at the 50% probability level

Bond lengths and angles relating to the coordination at the metals are given in Table 1. The three *trans* angles in the octahedral sector of the Δ enantiomer, N(3)−Zn(1)−N(4), N(1)−Zn(1)−O(2), and N(2)−Zn(1)−O(1) are 175.2(3), 168.6(3), and 169.2(3)° respectively, and those in the Λ enantiomer, N(4A)−Zn(1A)−N(3A), N(1A)−Zn(1A)−O(2A), and N(2A)−Zn(1A)−O(1A) are 174.8(3), 167.6(3), and 167.1(3)° respectively, indicating some distortion from a pure octahedral geometry. The Zn−O bond lengths for Zn-phenolate interactions average 2.08 Å and are shorter than those for the Zn-amine interactions (average length = 2.17 Å) and those for the Zn−pyridyl interactions (average length = 2.14 Å).

Table 1. Selected bond lengths[Å] and bond angles [deg] for complexes **2** and **3**

	Δ-2	**Λ-2**[a]	**3**

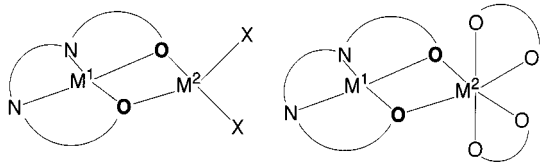
[a] The atomic labelling sequence for **Λ-2** in Figures 2 and 3 is 1A, 2A, 3A etc. corresponding directly to that for **Δ-2** of 1, 2, 3 etc.

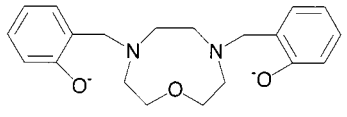
The coordination environment of the second zinc atom in each enantiomer is a distorted tetrahedron. The bond angles for the chelated O−Zn−O are 85.0(2)° [O(1)−Zn(2)−O(2)] and 84.6(3)° [O(1A)−Zn(2A)−O(2A)], and 113.98(11)° and 117.22(13)° for the Cl−Zn−Cl angles Cl(1)−Zn(2)−Cl(2) and Cl(1A)−Zn(2A)−Cl(2A) respectively. The remaining O−Zn−Cl angles are closer to the expected tetrahedral values. The Zn−O bonds (average length = 1.99 Å) are shorter than those at Zn(1) and Zn(1A) and the Zn−Cl bond lengths average 2.23 Å. The

intermetallic separations are 3.0540(18) [Zn(1)···Zn(2)] and 3.0474(18) Å [Zn(1A)···Zn(2A)].

Although the role of transition metal complexes as ligands has been well established for complexes of tetradentate salicylaldimines such as salen (salen = *N*,*N*′-ethylenebis(salicylideneimine)[2,2′-{1,2-ethanediylbis(nitrilomethylidyne)phenol}])[10] the above complex is a novel example of a hexadentate metal complex acting as a donor ligand towards a second metal atom. Previously, dinuclear zinc(II) complexes of the type $Zn(TSB)ZnX_2$ (X = Cl, ClO_4; TSB = tetradentate Schiff base), in which both zinc atoms were regarded as four-coordinate with a square coplanar Zn atom from the Schiff base adjacent to a tetrahedral Zn atom in the inorganic salt (Type 1), have been reported but no X-ray structural characterisation was made.[11,12] Homo- and heterodinuclear complexes in which a square coplanar Schiff base complex acts as a bidentate ligand towards a coordinatively unsaturated bis(1,1,1,5,5,5-hexafluoropentane-2,4-dionato)metal(II) (Type 2) have also been reported.[13–18]



In contrast the current compounds have a six-coordinated metal complex acting as a ligand towards an inorganic salt and resemble the coordination pattern found in the complex $[L^5Zn(OH_2)ZnCl_2]\cdot 0.5\,CH_3CN$.[19] In this compound one of the zinc atoms is octahedrally coordinated by the pentadentate dianionic macrocyclic ligand (L^5) and a water molecule, whilst the second zinc atom is tetrahedrally coordinated to two bridging phenolate oxygen atoms and to two chloride ions. The Zn···Zn separation was given as 3.08 Å but further details on bonds and angles were not released as the poor crystallinity of the crystals inhibited an accurate structure determination.



L^5

The Complex $[ZnL^1]\cdot ZnCl_2$ (3)

The reaction of $ZnCl_2$ with H_2L^1 gave the complex $[ZnL^1]\cdot ZnCl_2$ (**3**). Intriguingly the crystal structure revealed that a different spatial arrangement of donor atoms was present (Figure 4). Instead of the pyridine N-atoms being *trans* to each other they are now *cis* [N(3)–Zn(1)–N(4), 90.47(15)°, **1b**] and so give rise to a previously unreported stereoisomer for this class of compounds. There are two molecules, an enantiomeric pair, in the triclinic unit cell, with only one molecule in the asymmetric unit; the opposite enantiomer is generated by the inversion centre of the *P*1(bar) space group.

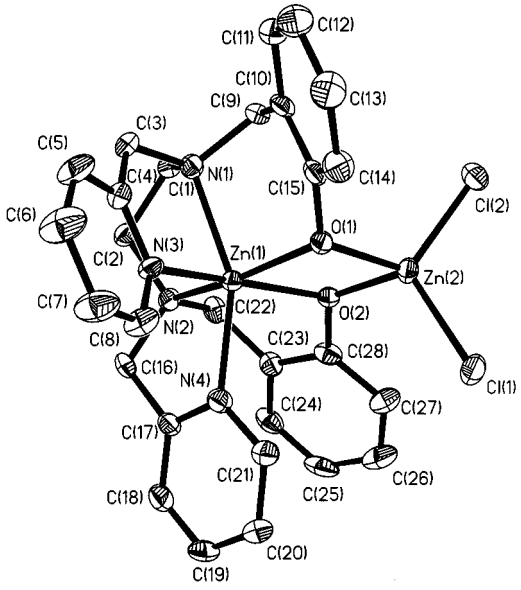


Figure 4. ORTEP drawing of $[ZnL^1]\cdot ZnCl_2$ (**3**) showing the crystallographic labelling; thermal ellipsoids for the non-hydrogen atoms are drawn at the 50% probability level

Bond lengths and angles relating to the coordination at the metals are given in Table 1. The three *trans* angles in the octahedral sector of the molecule, N(1)–Zn(1)–N(4), N(3)–Zn(1)–O(2), and N(2)–Zn(1)–O(1) are 154.04(15), 163.52(13), and 160.50(14)°, respectively, and are indicative of a larger distortion of the octahedral coordination geometry at Zn(1). The Zn–O bond lengths for Zn–phenolate interactions are 2.084(3) [(Zn(1)–O(1)] and 2.172(3) Å [Zn(1)–O(2)], and are again shorter than those for the Zn–amine interactions, 2.181(4) [Zn(1)–N(1)] and 2.200(4) Å [Zn(1)–N(2)], and those for the Zn–pyridyl interactions of 2.169(4) [Zn(1)–N(3)] and 2.122(4) Å [Zn(1)–N(4)]. The five-membered ring ($ZnNC_2N$) formed by the ethylenediamine linker has a skew conformation with a torsion angle N(1)–C(1)–C(2)–N(2) of −59.4° and the two carbon atoms of the linker, C(1) and C(2), are displaced by 0.43 and −0.30 Å on opposite sides of the ZnNN plane.

The second zinc atom is again in a tetrahedrally distorted coordination environment. The bond angle for the chelated O–Zn–O is 84.63(13)° [O(1)–Zn(2)–O(2)] and 113.63(5)° for the Cl–Zn–Cl angle [Cl(1)–Zn(2)–Cl(2)]. The remaining O–Zn–Cl angles are slightly more divergent [106.66(10)–116.92(10)°] from the expected tetrahedral values than in **2**. The Zn–O bonds (average length = 1.98 Å) are shorter than those at Zn(1) and the Zn–Cl bond lengths average 2.23 Å introducing further asymmetry to the tetrahedral site. The intermetallic separation of 3.1171(8) Å [Zn(1)···Zn(2)] is longer than that found in **2**.

Solution Studies

The ^{1}H NMR spectra of the metal complexes were recorded in [D$_6$]DMSO. The spectrum of **2** was sharp, as had been noted for the spectra of the closely related mononuclear gallium(III) and indium(III) complexes [ML]ClO$_4$ (L = L^1, L^3).[2] The spectra of these complexes did not undergo significant changes on raising the temperature from room temperature to 120 °C, indicating the intact and rigid nature of the octahedral complexes in solution. The structure is possibly stabilised by the presence of six-membered chelate rings, formed by the phenolic arms, in their preferred equatorial configuration.[1,20] The minor shifts of the ^{1}H resonance signals and slight broadenings of the signals were attributed to thermal vibrations of the coordinated ligands at elevated temperatures.[2] In contrast, although the resonances of **3** are close in value to those reported for the corresponding gallium and indium complexes some of them showed significant broadening at room temperature. An enhancement of the broadening and changes in chemical shifts occurred as the temperature was raised to 100 °C. This suggests that there are dynamic processes occurring over this temperature range. It was not possible to freeze any molecular motions due to the solution range of [D$_6$]DMSO, nor was it possible to obtain a limiting high temperature spectrum. It is proposed that the stereoisomer found in the solid state (**1b**), in which one of the six-membered chelate rings formed by the phenolic arms is in an equatorial configuration and the other is in an axial configuration, is less rigid than the stereoisomer **1a** in which both six-membered chelate rings formed by the phenolic arms are equatorial. Interconversion of the arms together with accompanying movement of the ethane linker would lead to the resonance broadening that is observed.

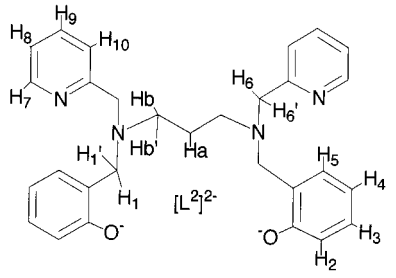
Conclusions

In contrast to the reactions of H$_2$L^1 and H$_2$L^2 with trivalent metals, which gave discrete mononuclear complex cations, zinc chloride reacts with H$_2$L^2 and H$_2$L^1 to give the dinuclear zinc(II) complexes **2** and **3**. In these complexes one zinc(II) atom is fully encapsulated by the deprotonated hexadentate ligand in a pseudo-octahedral geometry and this moiety then acts as a ligand towards ZnCl$_2$ through the *cis*-phenolato-O atoms. The second zinc(II) atom is in a distorted tetrahedral coordination environment. The structure of **2**, in which the pyridinyl N donors are *trans* to each other, is similar to those found for the trivalent metal complexes of L^1 in which the stereoisomer **1a** is found, but the structure of **2** further showed the presence in the asymmetric unit of a racemic mixture of the two enantiomers Λ (**1a**) and Δ (**1d**). The structure of **3** revealed a previously unreported second stereoisomer **1b** in which the pyridinyl N donors are *cis* to each other; in this case only one enantiomer was present in the asymmetric unit with the opposite enantiomer being generated from an inversion centre [$P\bar{1}$ space group].

Experimental Section

Measurements: Elemental analyses were carried out by the University of Sheffield microanalytical service. ^{1}H NMR spectra were recorded using a Bruker WH-400 spectrometer. Positive ion fast atom bombardment (FAB) mass spectra were recorded using a VG PROSPEC spectrometer (the matrix used was 4-nitrobenzyl alcohol).

Materials: Reagent or AR grade chemicals were used in this study. *N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)-1,2-ethanediamine (H$_2$L^1) and the *N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)-1,3-propanediamine (H$_2$L^2) were prepared by the published methods.[1,2]



Synthesis of Complexes

[Zn(L^2)·ZnCl$_2$] (2): *N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)-1,3-propanediamine (100 mg, 0.21 mmol) was dissolved in warm acetonitrile (10 mL) containing a trace amount of NEt$_3$. ZnCl$_2$ (60 mg; 0.44 mmol) was added and the solution was gently refluxed for 1 hour. After cooling and standing the solution afforded colourless crystals suitable for X-ray analysis. Yield: 84 mg, 60%. − ^{1}H NMR ([D$_6$]DMSO): δ = 8.85 (d, 2 H, 7-H), 7.71 (t, 2 H, 8-H), 7.27 (t, 2 H, 9-H), 7.04 (d, 2 H, 10-H), 6.95 (d, 2 H, 5-H), 6.81 (t, 2 H, 4-H), 6.64 (d, 2 H, 2-H), 6.45 (t, 2 H, 3-H), 4.33 (d, 2 H, 6′-H), 4.15 (d, 2 H, 1′-H), 3.73 (d, 2 H, 6-H), 3.36 (d, 2 H, 1-H), 2.79 (m, 2 H, b′-H), 2.64 (m, 2 H, b-H), 2.21 (bd, 2H, a-H). − MS (FAB; *m*NBA): *m*/*z* = 531 [Zn(L^2) + H]$^+$. − C$_{29}$H$_{30}$Cl$_2$N$_4$O$_2$Zn$_2$ (668.2): calcd. C 52.12, H 4.52, N 8.38, Cl 10.61; found C 52.03, H 4.56, N 8.23, Cl 10.90.

Investigation of the Cu^{II}/NCS^{-}/dpk Reaction System in CH_3OH [dpk = Di(2-pyridyl) Ketone]: Isolation, Structural Analysis and Magnetic Properties of a Dimer and a 1D Polymer with the Same Empirical Formula $[Cu(NCS)_2(dpk{\cdot}CH_3OH)]$

Zurine E. Serna,[a] Roberto Cortés,*[b] M. Karmele Urtiaga,[c] M. Gotzone Barandika,[b] Luis Lezama,[a] M. Isabel Arriortua,[c] and Teófilo Rojo*[a]

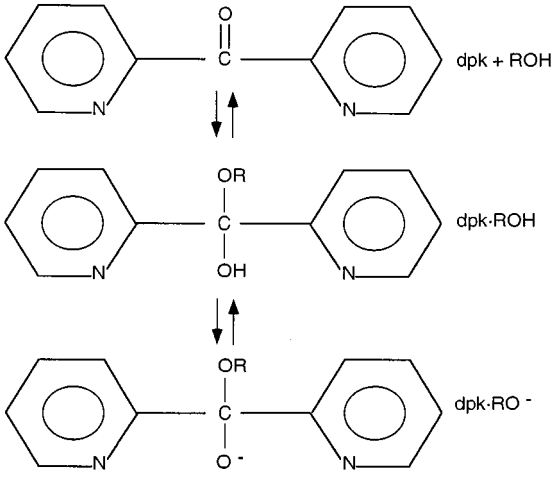
Keywords: N ligands / Copper / Coordination chemistry / EPR spectroscopy / Magnetic properties

Two polymorphous compounds with the general formula $[Cu(NCS)_2(dpk{\cdot}CH_3OH)]_n$ (dpk = di-2-pyridyl-ketone) have been synthesised and have been characterised both structurally and magnetically. The $dpk{\cdot}CH_3OH$ ligand is the result of the metal-promoted solvolysis of dpk in methanol and acts as a neutral donor. X-ray analysis carried out on single crystals for both compounds revealed that compound **1** is dimeric exhibiting double (*N*,*S*)-thiocyanate bridges, while compound **2** is 1D consisting of chains in which the metallic centres are connected through single *end-to-end* NCS^- groups. Magnetic susceptibility data showed that both compounds are antiferromagnetic, the values for the exchange constant *J* are –0.9 (**1**) and –0.3 cm^{-1} (**2**). The low values of *J* are consistent with the (N_{eq},S_{ax})-disposition of the thiocyanate bridges in the octahedral coordination sphere.

Introduction

High-dimensional arrangements exhibit potential applications in a great number of fields from heavy constructions to micro-circuitry.[1] Coordination polymers, in particular, have been the focus of attention of a great number of works devoted to the correlation between structural features and magnetic properties.[2] In this context, it is worth mentioning that the *N*,*N*′-type voluminous organic ligands have been extensively used, either as spacers or as coordination-site blockers.

Among the *N*,*N*′-donors, the di(2-pyridyl) ketone (dpk) ligand can be pointed out. This ligand exhibits certain singularities that explain its tendency to give rise to clusters[3] rather than infinite extended lattices when polynuclear systems are formed. The ligand dpk has three potential donor sites, however, when the ketocarbonyl group of dpk undergoes metal-promoted solvation (Scheme 1), four donor sites are exhibited. The resulting hydrated ($dpk{\cdot}H_2O$) or "alcoholated" (dpk·ROH) derivative can chelate either in a protonated or deprotonated state. As a consequence, the coordination possibilities of dpk are multiple and have been widely reported in the literature.[3,4] For instance, Tsohos et al.[3d] have reported a nonanuclear Co^{II}-dpk compound that clearly illustrates the capabilities of dpk. In this nonamer, the hydrated dpk derivative acts as a tetradentate ligand that is bonded to five different atoms of cobalt. This concentration of metallic ions around an organic molecule is obviously due to the proximity of the four potential donor atoms.



Scheme 1

The versatility of dpk could also be useful for the preparation of infinite arrays. To prevent cluster formation, pseudohalides could be used in combination with the organic ligand (as commonly carried out for other *N*,*N*′-

groups). With this aim, we have been working on Ni^{II}-dpk-L systems (L = N_3, NCO, NCS). However, our first results have confirmed the tendency of dpk to concentrate metallic ions around it, through the characterisation of some tetramers.[4j,4k]

In order to explore the possibility of obtaining infinite polynuclear systems with other metals, this work was focused on Cu^{II}-systems. For this metallic cation a 1D arrangement has been synthesised. In particular, the results herein reported concern the magnetic and structural characterisation of two polymorphs with the general formula $[Cu(NCS)_2(dpk{\cdot}CH_3OH)]_n$. Compound **1** is a dimer exhibiting double (*N*,*S*)-thiocyanate bridges, while compound **2** consists of chains in which the metallic centres are connected through single *end-to-end* NCS^- groups. In both cases, the alcoholated dpk-derivative, dpk·CH_3OH, acts as a tridentate ligand and bonds to a single copper atom.

Results and Discussion

Structural Analysis

The structures of **1** and **2** are shown in Figure 1 and Figure 2, respectively. As observed, compound **1** consists of Cu^{II} dimers in which the metallic cations are connected through di-μ-(1,3)-NCS bridges, while compound **2** consists of chains in which the metallic cations are connected through single *end-to-end* thiocyanate bridges. The intermetallic distances through the thiocyanate bridges are 5.393 (**1**) and 5.994 (**2**) Å.

The octahedral coordination sphere around the Cu^{II} cations is similar for both polymorphous compounds. Thus, in both compounds the axial positions are occupied by S and O atoms: S1 corresponding to a bridging thiocyanate group and O1 belonging to the dpk·CH_3OH group. The formation of the dpk·CH_3OH is as a result of the solvolysis of the original dpk in methanol. At the equatorial positions, four N-atoms can be found, N3 and N4 atoms corresponding to a bridging and a terminal thiocyanate, respectively, and N1 and N2 belonging to the organic ligand. Thus, the main difference between **1** and **2** lies in the fact that in **1** each copper centre is connected to another copper centre through the S1 and N3 atoms, while in **2** each copper centre is connected to two other copper centres, one through the S1 atom and the other through the N3 atom. In this way, Cu^{II}-chains extend along the y direction for **2**.

The coordination sphere around the Cu^{II} cations in both compounds is noticeably distorted. This distortion can be attributed to the *N*,*O*,*N*′-terdentate coordination of dpk·CH_3OH and the long Cu−S distances. As can be seen in Table 1, the axial distances [Cu−S1 = 2.852(2) Å and Cu−O1 = 2.487(4) Å for **1**, and Cu−S1 = 2.837(1) Å and Cu−O1 = 2.503(2) Å for **2**] are remarkably higher than the equatorial ones [Cu−N average distances are 1.987 (**1**) and 1.991(**2**) Å]. The terdentate chelation of dpk·CH_3OH results in an angle of 109.8° (**1**) and 115.5° (**2**) between both pyridyl rings, as well as in important deviations from the ideal octahedral angles.

[a] *i* for this compound = 1 − *x*, −*y*, 1 − *z*. − [b] *i* for this compound = −*x*, 1/2 + *y*, 1/2 − *z*.

The structural features concerning the intermetallic connections are typical for thiocyanate bridges in octahedral systems.[5] Thus, both compounds exhibit the common $Cu-N_{eq}-C-S_{ax}-Cu$ coordination for the *end-to-end* thiocyanate bridge. On the other hand, the bridge-angles (N−C−S = 178.4°, C−S−Cu = 91.4°, S−Cu−N = 95.5° and Cu−N−C = 169.5° for **1**, and N−C−S = 179.3°, C−S−Cu = 91.4 °, S−Cu−N = 92.9° and Cu−N−C = 159.5° for **2**) show a slight deviation from the ideal ones.

It is worth mentioning that a great number of intermolecular and intramolecular H-bonds are present for both compounds (Table 2). As a result, the dimers (**1**) and the chains (**2**) are packed as displayed in Figure 3 and 4, respectively. As observed in Figure 3, there are magnetically nonequivalent ions which are related by the following operation of symmetry: x, $1/2 - y$, $1/2 + z$. The distance between these Cu atoms is 8.644(2) Å and the angle formed by the normals to their equatorial planes is 70.7(1)°. The presence of magnetically nonequivalent atoms in the unit cell will be used below in the EPR discussion. On the other hand, as seen in Figure 4, the packing of the chains in **2** allows π-π interactions between the pyridyl rings [inter-ring distance is 3.96(5) Å].

In summary, even if the dpk derivative in **2** acts as a tridentate ligand, the preparation of an extended dpk system has been possible as the organic ligand does not act as a bridging group but as a coordination-site blocker. In this sense, the role played by thiocyanate as the only intermetallic linker seems to be crucial to prevent the formation of clusters, as desired.

IR Spectroscopy

A summary of the most important IR bands corresponding to compounds **1** and **2**, together with their tentative assignments[6] are given in Table 3. As can be seen, both compounds exhibit a split absorption at about 2100 cm^{-1} that corresponds to the asymmetric stretching mode of the C=N bond for the *N*,*S*-bonded thiocyanate.

In relation to the absorptions caused by the organic ligand, it is worth mentioning that the band at 1680 cm^{-1}, assigned to the C=O bond in conjugation with the pyridyl rings in dpk, is shifted to lower frequencies after solvolysis due to the presence of the C−O bond.[7] The bands assigned to the pyridyl ring stretching modes in **1** and **2** are also remarkably shifted, relative to the free dpk ligand, due to the loss of coplanarity between the pyridyl rings after rehybridisation from sp^2 to sp^3. The IR spectra also revealed the bands corresponding to the skeleton vibrations of the coordinated dpk·CH_3OH, which appear at slightly shifted frequencies relative to the free dpk.

EPR Spectroscopy

X- and Q-band powdered EPR spectra for **1** were recorded at room temp. down to 4.2 K. The spectra do not significantly change with temperature; a slight narrowing of the linewidth with decreasing temperature is observed. Q-band spectra, however, are better resolved than X-band ones. Figure 5 shows the Q-band spectrum for **1** at room temp. The signal seems to be rhombic, as is usually related to an exchange *g*-tensor. Additionally, there is a weak, broad signal at about 10750 G that must also be considered.

In order to interpret the spectrum in Figure 5 some structural features should be taken into account. The Cu^{II} octahedra in **1** are axially elongated suggesting that the molecular *g*-tensor is axial. However, it is also worth noting that compound **1** exhibits magnetically nonequivalent ions (Figure 3) that could involve interdimeric interactions. If the exchange interaction between nonequivalent centres were higher than the difference between the relative Zeeman energies, the EPR spectrum would not reveal the characteristics of the molecular *g*-tensor, but would show the ones corresponding to an average exchange *g*-tensor, g^{ex}. In that case, the components of the g^{ex} tensor could be expressed as a function of the components of the molecular *g*-tensor and the angles between them:[8] $(g_1^{ex})^2 = g_{\parallel}^2\cos^2\alpha + g_{\perp}^2\mathrm{sen}^2\alpha$ $(g_2^{ex})^2 = g_{\parallel}^2\mathrm{sen}^2\alpha + g_{\perp}^2\cos^2\alpha$ $g_3^{ex} = g_{\perp}$

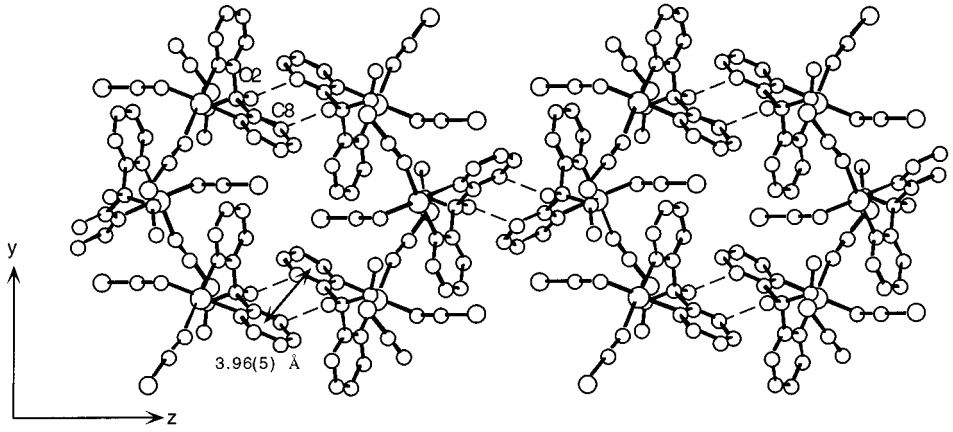

Figure 4. Packing of the dimers for **2** on the yz plane showing the H-bonds as discontinuous lines (see Table 2); the distance between parallel pyridyl rings is 3.96(5) Å

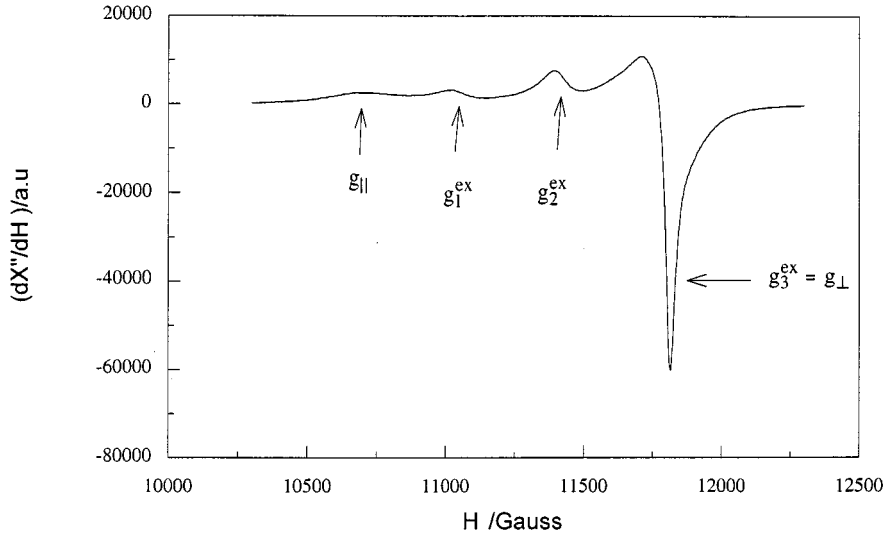

Figure 5. Q-band EPR powder spectrum at room temp. for **1**

where 2α is the angle formed by the magnetically non-equivalent chromophores; i.e. the canting angle between the normals to the equatorial planes of two interacting polyhedra [Equation (1)]:

$$\cos 2\alpha = \frac{g_1^{ex} - g_2^{ex}}{g_1^{ex} + g_2^{ex} - 2g_3^{ex}} \quad (1)$$

The observed values are $g_1^{ex} = 2.214$, $g_2^{ex} = 2.133$, $g_3^{ex} = 2.063$. Accordingly, $g_{\|} = 2.280$ and $g_{\perp} = 2.063$ have been calculated. The sequence $g_{\|} = 2.280 > g_{\perp} = 2.063 > 2.04$[8] agrees with the topology of the elongated [CuN_4SO] chromophores for **1**, as it corresponds to an ideal D_{4h} symmetry (d_x^2-$_y^2$ ground state). A calculated value of $2\alpha = 68°$ compares excellently with the crystallographic value of 70.7(1)°.

At this point, it is worth noting that the weak, broad signal on the spectrum that does not correspond to the rhombic tensor (ca. 10750 Gauss), but completely coincides with the $g_{\|}$ value deduced from g^{ex}. In other words, the spectrum seems to be the sum of two signals: those corresponding to the exchange and the molecular *g*-tensors. This unusual fact which has already been reported for two other

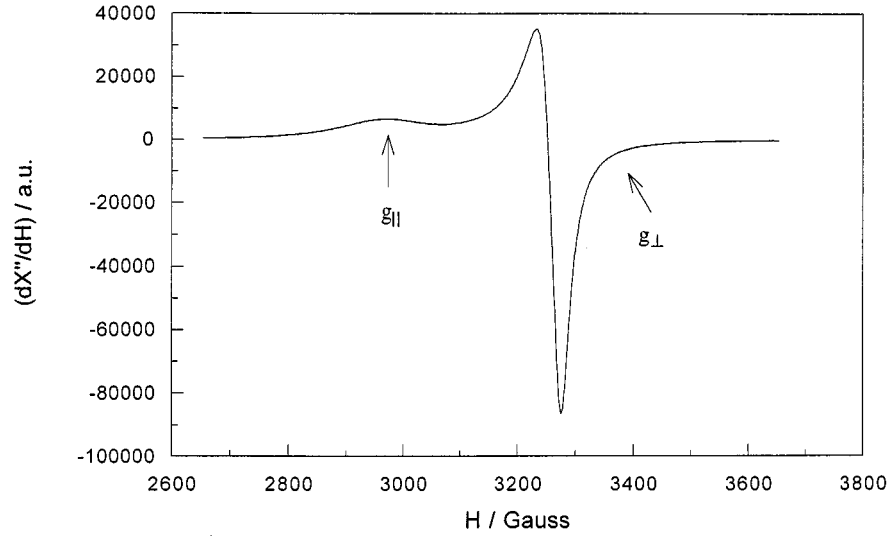

Figure 6. X-band EPR powder spectrum at room temp. for **2**

Cu^{II} compounds,[9] can only take place if the value of the exchange constant for the intermolecular coupling is similar to the Q-band energy-gap.

Figure 6 displays the X-band powdered EPR spectrum at room temp. for compound **2**. As observed, the signal is characteristic of an axial *g*-tensor with $g_{\|} = 2.258$ and $g_{\perp} = 2.052$. As for **1**, a slight narrowing of the linewidth is observed when the temperature is lowered from room temp. to 4.2 K. The *g* values account for a $d_{x^2-y^2}$ ground state, with an elongated octahedral copper(II) centre. They are in accordance with the $[CuN_4SO]$ chromophore corresponding to **2**.

Magnetic Properties

Compounds **1** and **2** were magnetically characterised through measurements of the thermal variation of the magnetic susceptibility, χ_m. Both polymorphous compounds exhibit similar magnetic behaviour. Thus, for both, χ_m continuously increases upon cooling (from 2.03×10^{-3} and 1.31×10^{-3} cm^3mol^{-1} at room temp. for **1** and **2**, respectively), the increase becoming exponential at temperatures tending to zero.

Figure 7 and 8 show the thermal variation of the $\chi_m T$ product and χ_m^{-1} for **1** and **2,** respectively. As can be seen, the $\chi_m T$ magnitude remains practically constant down to 25 K (**1**) and 50 K (**2**), temperatures below which the $\chi_m T$ values rapidly decrease towards zero. On the other hand, the Curie−Weiss law is followed over the whole measured temperature range in both cases. The calculated values of C_m and *g* (0.432 (**1**) and 0.429 (**2**) cm^3 K mol^{-1} and 2.146 (**1**) and 2.138 (**2**), respectively) are typical for an octahedrally-coordinated Cu^{II}.[10] The Weiss temperature, θ, has been observed to be −0.71 and −0.40 K, for **1** and **2**, respectively.

The above-mentioned aspects are indicative of the occurrence of antiferromagnetic exchange coupling which should take place through the thiocyanate intermetallic bridges. In order to evaluate the extension of these magnetic interactions, Equation (2) and (3) were used for **1** and **2**, respectively.

$$\chi_m = \frac{Ng^2\beta^2}{3kT}\frac{1}{1+\frac{exp(-2J/kT)}{3}} \quad (2)$$

$$\chi_m = \frac{Ng^2\beta^2}{kT}\frac{A+Bx+Cx^2}{1+Dx+Ex^2+Fx^3} \quad (3)$$

$A = 0.25,\quad B = 0.14995,\quad C = 0.30094,\quad D = 1.9862,\quad E = 0.68854,\quad F = 6.0626$

$x = J/kT$

where *N* and *k* are the Avogadro and Boltzmann constants, respectively, and β is the Bohr magneton.

The first of the expressions [Equation (2)][11] evaluates χ_m as a function of the exchange constant *J* for dimers with $S = 1/2$. The best fit parameters for **1** have been observed to be $J = -0.9$ cm^{-1} and $g = 2.145$. As observed in Figure 7, where the calculated $\chi_m T$ curve is displayed, there is an excellent agreement between both the theoretical and experimental data. On the other hand, the second expression [Equation (3)][12] accounts for the antiferromagnetic coupling for a Heisenberg chain with $S = 1/2$. Thus, the best fit parameters for **2** have been calculated to be $J = -0.3$ cm^{-1} and $g = 2.142$. As observed in Figure 8, the theoretical $\chi_m T$ curve reproduces the experimental data quite well.

Magnetic and Structural Correlations

Table 4 summarises the *J* values found in the literature for other (*N*,*S*)−NCS-bridged octahedral systems.[5,13] As observed, all but one exhibit low values for the magnetic

$\{[Cu(NCS)_2(Hmtpo)\text{-}(H_2O)]_2\}_n$	N_e-S_a $+N_e-S_e$	−148	[13]

exchange constant. It is worth noting that the common feature for the majority is the $N_{eq}-S_{ax}$ disposition of the bridge, while for the strongly antiferromagnetic compound[13] the "rare" $N_{eq}-S_{eq}$ bridge-mode can also be found. As discussed below this is in total agreement with the theoretical predictions.

On theoretical bases,[14] the $N_{eq}-S_{ax}$ disposition leads to the accidental orthogonality of the MO arising from the e_g metallic orbitals, minimising the antiferromagnetic component of the global J constant (as experimentally confirmed for octahedral systems). Therefore, the fact that the strongly antiferromagnetic compound in Table 4 cannot be described by this disposition confirms this theoretical analysis (which is obviously valid for both single and double *end-to-end* thiocyanate bridges).

Conclusions

The use of the pseudohalide thiocyanate in combination with the blocking ligand dpk has led to the preparation of two polymorphous Cu^{II}-compounds: a 1D polymer and a

dimer. In both cases, the metallic cations are coordinated in a similar way to dpk·CH_3OH as well as to terminal and *end-to-end* thiocyanate groups. The dpk·CH_3OH is the result of the metal-promoted solvolysis of dpk in methanol. Both compounds are weakly antiferromagnetic as expected for the (N_{eq},S_{ax})-type intermetallic bridges.

Experimental Section

Synthesis

The synthesis of the title compounds was carried out by mixing an aqueous solution of $CuCl_2·2H_2O$ (0.5 mmol, 10 mL) with an aqueous solution of NaNCS (1 mmol, 10 mL). After stirring for one hour, a solution of dpk (15 mmol, 50 mL) in methanol was added. A green precipitate immediately appeared. Methanol was then added until this precipitate dissolved. The resulting solution was left to stand at room temperature. After several days, two types of green X-ray quality single crystals were obtained: (**1**) elongated prismatic crystals (yield 17%) and (**2**) regular prismatic crystals (yield 23%). Elemental analysis and ICP results were in good agreement with the $C_{14}H_{12}CuN_4O_2S_2$ stoichiometry for both compounds. – **1:** calcd. C 42.47, H 3.05, Cu 16.05, N 14.15, S 16.19; found C 42.5, H 3.1, Cu 15.9, N 14.2, S 16.1. – **2:** calcd. C 42.47, H 3.05, Cu 16.05, N 14.15, S 16.19; found C 42.4, H 3.0, Cu 16.0, N 14.1, S 16.1.

Physical Measurements

Microanalyses were performed with a LECO CHNS-932 analyser. Analytical measurements were carried out in an ARL 3410 + ICP with a Minitorch equipment. IR spectroscopy was performed on a Nicolet 520 FTIR spectrophotometer in the 400−4000 cm^{-1} region. EPR spectra were recorded on powdered samples at X- and Q-band frequencies, with a Bruker ESP300 spectrometer equipped with a standard OXFORD low-temperature device calibrated by the NMR probe for the magnetic field, the frequency measured by using a Hewlett−Packard 5352B microwave frequency computer. Magnetic susceptibilities of powdered samples were carried out in the temperature range 1.8−300 K (at a value of 1000 Gauss of the magnetic field) using a Quantum Design Squid MPM5−7 magnetometer, equipped with a helium continuous-flow cryostat. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal tables).

Crystal Structure Determination

Single-crystal X-ray measurements for compounds **1** and **2** were carried out at room temperature on an Enraf−Nonius CAD-4 diffractometer with graphite-monochromated Mo-K_α radiation, operating in ω/2θ scanning mode using suitable crystals for data collection. Accurate lattice parameters were determined from least-squares refinement of 25 well-centred reflections. Intensity data were collected in the θ range 1−30°. During data collection, two standard reflections periodically observed showed no significant variation. Corrections for Lorentz and polarisation factors were applied to the intensity values.

The structures were solved by heavy-atom Patterson methods using the program SHELXS-97[15] and refined by a full-matrix least-squares procedure on F^2 using SHELXL-97.[16] Non-hydrogen atom scattering factors were taken from the International Tables of X-ray Crystallography.[17] In Table 5, crystallographic data and processing parameters for compounds **1** and **2** are shown.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-143208 (**1**) and CCDC-143207 (**2**). Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2 + 4PPh_3$ and $[(\eta^3\text{-}C_3H_5)PdCl(PPh_3)] + 1PPh_3$ do not produce the cationic (π-allyl)palladium(II) complex $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+Cl^-$ but a neutral (σ-allyl)palladium(II) chloride complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ in DMF and THF. This latter complex is also formed when one equivalent of chloride ion is added to $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^-$, leading to the conclusion that $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2 + 4PPh_3$ and $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^-$ are not equivalent precursors for the palladium-catalyzed allylic substitutions when they are performed in the absence of added chloride ions. The (σ-allyl)palladium(II) chloride complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ is also formed instead of $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(AcO)^-$ when the oxidative addition of allylic acetate to palladium(0) complexes, such as $[Pd^0(dba)_2] + 2PPh_3$, is performed in the presence of chloride anions. A cationic (π-allyl)palladium(II) complex is thus not formed in the presence of chloride ions, which are either delivered by the catalytic precursor or deliberately added.

Introduction

Palladium(0) complexes catalyze nucleophilic substitutions of allylic acetates (Tsuji−Trost reaction, Equation (1)).[1]

(1)

The main precursors of the palladium(0) catalyst are: **A**: $[Pd^0L_4]$; **B**: $[Pd^0(dba)_2]$ (or $[Pd^0_2(dba)_3] + nL$); **C**: $[(\eta^3\text{-}C_3H_5)PdL_2]^+(BF_4)^-$, a cationic (π-allyl)palladium(II) complex which provides a palladium(0) complex in situ after reaction with the nucleophile; or **D**: $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2 + 4$ L, a dimeric (π-allyl)palladium(II) chloride whose reaction with phosphane ligands is supposed to afford $[(\eta^3\text{-}C_3H_5)PdL_2]^+Cl^-$ and eventually a palladium(0) complex after reaction with the nucleophile.[1] These four different catalytic precursors are often considered to be equivalent, leading to the same active $[Pd^0L_2]$ catalyst and to the same cationic (π-allyl)palladium(II) complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+(AcO)^-$ formed through oxidative addition of $[Pd^0L_2]$ to the allylic acetate. However, recent papers point out that Pd-catalyzed nucleophilic allylic substitutions strongly depend on the precursor of the palladium(0) catalyst in terms of reactivity, regioselectivity and enantioselectivity.[2]

We have already established that $[Pd^0L_4]$ or $[Pd^0(dba)_2]$ associated with phosphane ligands effectively provide the same species $[Pd^0L_2]$, which is active in oxidative additions but is present in low and nonidentical concentrations relative to the precursor concentration because of its endergonic equilibrium with the nonreactive $[Pd^0L_3]$ or $[Pd^0(dba)L_2]$ complexes, respectively.[3] Consequently, $[Pd^0(PPh_3)_4]$ was found to be more efficient than $\{[Pd^0(dba)_2] + 2PPh_3\}$ in allylic nucleophilic substitutions.[4] Conversely, the nucleophilic attack on precursor **C**, the cationic (π-allyl)palladium(II) complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+(BF_4)^-$ is expected to provide $[Pd^0L_2]$ in stoichiometric amounts relative to the precursor. Therefore, the three precursors **A**, **B** and **C** should behave differently in terms of the kinetics of their oxidative addition to an allylic acetate, but should give the same cationic complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+(AcO)^-$, the key intermediate prone to react with the nucleophile.

When considering precursor **D**, i.e., $\{[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2 + 4L\}$, one equivalent of chloride ion is now present although its role is very often neglected. However, this chloride ion may introduce a change in the mechanism. Indeed, we have already established the influence of anions, chloride or acetate, delivered by the precursors of the Pd^0 catalyst on the mechanism of palladium-catalyzed cross-coupling[5a−5c] and Heck reactions.[5b−5d] In this context, it has been observed that deliberately added chloride ions induce stereocontrol in palladium-catalyzed substitutions of cyclic allylic acetates.[6] Recent papers report the beneficial effect of added halides on the regioselectivity of the allylic nucleophilic substitution,[7] as well as on its enantioselectivity.[7b,8] In other cases, a negative effect of added chloride ions on the enantioselectivity has been reported and interpreted as a partial destruction of the memory effect due to the formation of asymmetric ion-pairs between the cationic (π-allyl)palladium(II) complex and acetate anion.[2]

We report here an investigation on the effect of chloride ions on the first steps in the mechanism of palladium-catalyzed allylic substitution, leading to the conclusion that pre-

cursor **D** behaves quite differently from precursors **A**, **B**, and **C**. Cationic (π-allyl)palladium intermediates are not formed from **D** or when chloride anions are voluntary added to any catalytic system **A**, **B** or **C**.

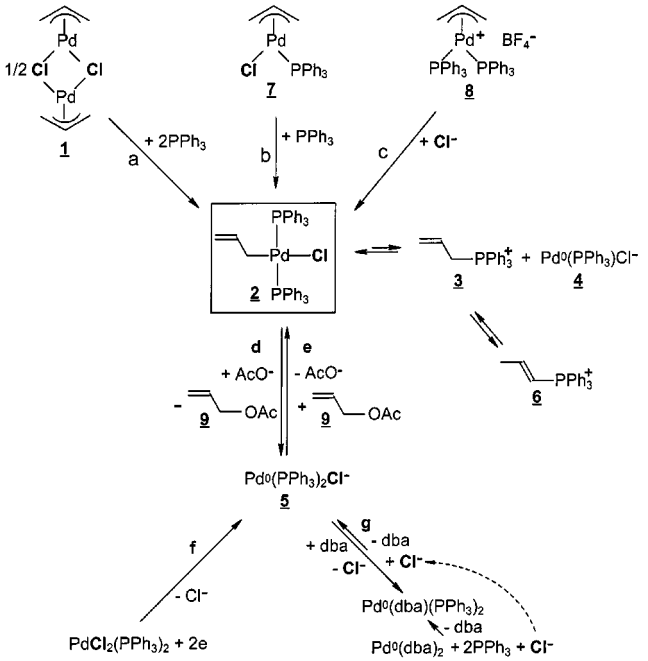
Results and Discussion

Reaction of $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2$ (1) with $4PPh_3$ in DMF

When four equivalents of PPh_3 (2 equiv. of L per Pd) were added to a solution of the dimeric (π-allyl)palladium(II) chloride **1** in $CDCl_3$, the three ^1H NMR signals observed for the free complex **1** (Table 1) totally disappeared.

Neither the five signals of $[(\eta^3\text{-}C_3H_5)PdCl(PPh_3)]$ **(7)** (Table 1) nor the three signals of a cationic (π-allyl)palladium(II) $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+Cl^-$ (Table 1) were detected. Instead, a main set of two signals was observed: a quintet (1 H, J = 10 Hz) and a broad doublet (4 H, J = 10 Hz). They are characteristic of the (σ-allyl)palladium chloride complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)** (Table 1, Scheme 1, route a) as already observed by Shaw et al.[9] Such an NMR pattern is characteristic of a fast equilibrium between two σ forms of **2** [Equation (2)] responsible for the magnetic equivalence of the four CH_2 protons.[9,10]

$$CH_2{=}CH\text{-}C^*H_2\text{-}Pd\text{-}Cl(PPh_3)_2 \rightleftharpoons C^*H_2{=}CH\text{-}CH_2\text{-}Pd\text{-}Cl(PPh_3)_2 \quad (2)$$



Scheme 1. Formation of a (σ-allyl)palladium chloride complex

The ^{31}P NMR spectrum exhibits a single, broad major signal at δ = 20.75 ($\Delta\nu_{1/2}$ = 50 Hz) in DMF and δ = 19.85 ($\Delta\nu_{1/2}$ = 67 Hz) in $CDCl_3$, which is characteristic of the (σ-allyl)palladium chloride complex **2**.

Extra ^1H NMR signals were also observed and assigned to the allytriphenylphosphonium cation **3** (Table 1, Scheme 1) by comparison with an authentic sample of the

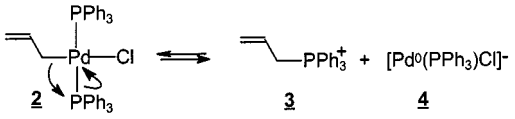
chloride salt **3**·Cl.[12] However, a slight shift of the CH_2-P^+ signal to higher field suggested that chloride was not the counter anion of **3**.[13] Considering that the phosphonium cation **3** was generated from the (σ-allyl)palladium complex **2** by a kind of reductive elimination [Equation (3)], this implies that a palladium(0) complex **4** is also formed concomitantly.



(3)

This interpretation is confirmed by voltammetric data. Indeed, performing cyclic voltammetry in DMF on a solution of **1** (2 mM) and 4 equivalents of PPh_3, revealed the presence of an oxidation peak at −0.03 V which characterizes a palladium(0) complex: it disappeared in the presence of PhI. Moreover, Equation (3) has to be an equilibrium since the ratio **2:3**, (initially equal to 3, as determined from the ^1H NMR spectroscopic data) decreases in the presence of increasing amounts of PPh_3 or dba. The effect of extra PPh_3 or dba is to stabilize the low ligated palladium(0) complex formed in Equation (3) as a more stable complex $[Pd^0(PPh_3)_nCl]^-$ (n = 2, 3)[14] or $[Pd(dba)(PPh_3)_2]$[3] inducing then a shift of the equilibrium in Equation (3) towards its right-hand side.

The conductivity of a solution of **1** (2 mM) and 4 equivalents of PPh_3 was measured in DMF at 20 °C and found to be 78 μS. This shows the formation of ionic species in DMF in agreement with the formulation in Equation (3). The conductivity increases upon successive additions of PPh_3 because of the shift of the equilibrium towards its right hand-side by stabilization of the palladium(0) complex **4** (vide supra). A conductivity of only 2 μS was measured for the same solution in $CDCl_3$, indicating that **4** and **3** (whose ^1H NMR signals are detected in $CDCl_3$) are ion-paired in this less polar solvent.

After two hours, a set of three ^1H NMR signals appeared and were assigned to the 3-propenyltriphenylphosphonium cation **6** by comparison with an authentic sample of **6**·Cl[12] (Table 1, Scheme 1). This cation was formed by the slow isomerization of **3**. The ^{31}P NMR signals of **6** and **3** were also detected in DMF (Table 1) and $CDCl_3$. The stability of **2** strongly depends on the phosphane ligand. The thermodynamic ability of **2** to form phosphonium salts is higher when the phosphane is more basic, consequently the stability of **2** follows the order:

$(p\text{-}CF_3C_6H_4)_3P > (p\text{-}ClC_6H_4)_3P > (p\text{-}HC_6H_4)_3P > (p\text{-}CH_3C_6H_4)_3P$

This set of experiments establishes that addition of four equivalents of PPh_3 per mol of **1** (precursor **D**) does not lead to the expected cationic π-allylpalladium complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+Cl^-$ but to the σ-allylpalladium complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)** (Scheme 1, route a). This main complex is involved in an equilibrium with a palladium(0) complex, an allylphosphonium salt and a 3-propenylphosphonium salt at longer times (1 h).

The mechanism of the formation of the (σ-allyl)palladium complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)** cannot be established since no intermediate was observed as its formation from **1** and $4PPh_3$ is too fast. It is known, however, that when only two equivalents of PPh_3 are added to **1**, a neutral (π-allyl)palladium chloride complex $[(\eta^3\text{-}C_3H_5)PdCl(PPh_3)]$ **(7)** is formed.[9] Compound **7** is thus a possible intermediate in the formation of **2**. We have therefore investigated the reaction of **7** with one equivalent of added PPh_3.

Reaction of $[(\eta^3\text{-}C_3H_5)PdCl(PPh_3)]$ (7) with PPh_3 in DMF

Analysis of a solution of **7** containing one equivalent of PPh_3 in $CDCl_3$ or DMF by ^1H and ^{31}P NMR spectroscopy and conductivity measurements showed the same chemical behavior as for the mixture {**1** + $4PPh_3$} (Table 1), i.e., no formation of the cationic (π-allyl)palladium complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+Cl^-$ but formation of the (σ-allyl)palladium chloride complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)** involved in the equilibrium in Equation (3) (Scheme 1, route b).

Since the cationic (π-allyl)palladium complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+Cl^-$ was not generated, it was of interest to test the reactivity of chloride ions with the cationic (π-allyl)palladium complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+(BF_4)^-$ **(8)**.

Reaction of $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^-$ 8 with Chloride Ions in DMF

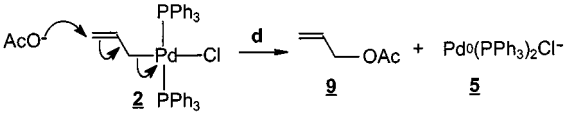
Addition of one equivalent of nBu$_4$NCl to a solution of the cationic (π-allyl)palladium complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+(BF_4)^-$ **(8)** in $CDCl_3$ or DMF induced the complete disappearance of **8** with formation of the (σ-allyl)palladium chloride complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)** by attack of the chloride ion at the cationic Pd^{II} center (Scheme 1, route c; Table 1). In agreement with the above results, the allyltriphenylphosphonium cation **3** was also formed in this process [Equation (3)].

When less than one equivalent of chloride ion (0.2 equiv.) was added to **8**, the three signals of **8** became broad and overlapped the two signals of **2**. This suggests that the reaction c in Scheme 1 is a dynamic equilibrium lying towards **2** so that it is totally shifted towards the (σ-allyl)palladium chloride **2** as soon as one equivalent of chloride ions are added to **8**.

Reaction of $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ (2) with Acetate Ions in DMF

Acetate anions are continuously released in a palladium-catalyzed substitution at allylic acetates [Equation (1)]. These released acetate ions may conceivably compete with chloride ions for the stabilization of Pd^{II} complexes. We have thus investigated the reaction of acetate ions with the σ-allylpalladium chloride, $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)**. When one equivalent of nBu$_4$NOAc was added to **2** (preliminarily formed by reaction of **8** with one equiva-

lent of nBu$_4$NCl), the allylic acetate **9** (19%) was observed on the ^{1}H NMR spectrum performed in $CDCl_3$. It was checked independently that nBu$_4$NOAc did not react with commercial **3**·Cl to produce the allylic acetate by a direct nucleophilic substitution. Note, however, that AcO^- catalyzes the isomerization of **3**·Cl to **6**·Cl, but without formation of **9**. This shows that the (σ-allyl)palladium chloride complex **2** is attacked by the acetate ion to produce allylic acetate (Scheme 1, route d), probably by reaction of the acetate anion at the allyl ligand by an S_N2' reaction [Equation (4)].



(4)

This reaction affords an anionic species $[Pd^0(PPh_3)_2Cl]^-$ **(5)**.[14] Such an anionic Pd^0 complex can be generated by reduction of $[PdCl_2(PPh_3)_2]$ (Scheme 1, route f).[14] It was thus of interest to investigate the oxidative addition of **5** to allylic acetate **9**, which is the backward reaction of Equation (4).

Oxidative Addition of $[Pd^0(PPh_3)_2Cl]^-$ to Allylic Acetate in DMF

The electrochemical bielectronic reduction of $[PdCl_2(PPh_3)_2]$ (2 mM in DMF) at −0.88 V produced $[Pd^0(PPh_3)_2Cl]^-$ **(5)** characterized by its oxidation peak at +0.10 V. In the presence of the allylic acetate **9** (4 mM) the oxidation peak current of the electrogenerated palladium(0) decreased, showing a partial reaction of **5** with **9**. This also released AcO^- in solution as characterized by the observation of its oxidation peak at +0.68 V. If the cationic $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(AcO)^-$ **(10)** complex were formed in the oxidative addition, its reduction should be observed at around −1.25 V, which is the reduction potential of an authentic sample of $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^-$ **(8)**. Such a reduction peak was not observed, but instead, two reduction peaks were present at more negative potentials, −1.53 V and −2.04 V, showing that the formation of **10** was bypassed. The same couple of reduction peaks was also observed when two equivalents of chloride ions were added to $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^-$ **(8)**, a reaction which affords the (σ-allyl)palladium chloride **2** and the phosphonium cation **3** with $Pd^0(PPh_3)Cl^-$ as the counter-anion [Equation (3]. The reduction peak at −1.53 V was then assigned to the reduction of **3** by comparison with an authentic sample of **3**·Cl, whereas the reduction peak at −2.02 V was assigned to the reduction peak of the (σ-allyl)palladium chloride complex **2**.

This establishes that the oxidative addition of $[Pd^0(PPh_3)_2Cl]^-$ to allylic acetate takes place (backward reaction of Equation (4), route e in Scheme 1) and does not afford the cationic (π-allyl)palladium complex $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(AcO)^-$ **(10)** but the (σ-allyl)palladium chloride $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)** by the reversible overall reaction shown in Equation (5) (Scheme 1, route f,e,d).[15]

$$Pd^0(PPh_3)_2Cl^- + CH_2{=}CH\text{-}CH_2\text{-}OAc \rightleftharpoons (\eta^1\text{-}C_3H_5)PdCl(PPh_3)_2 + AcO^- \quad (5)$$

However, $[PdCl_2(PPh_3)_2]$ is not often used as a precursor of Pd^0 in allylic substitutions because most nucleophiles active in the allylic substitutions are not able to reduce the Pd^{II} precursor to Pd^0. We have thus investigated the effect of chloride ions on the oxidative addition to allylic acetate starting from another catalytic system: $\{[Pd^0(dba)_2] + 2PPh_3\}$ often used as a precursor of Pd^0 catalysts.[1,16]

Oxidative Addition of $\{[Pd^0(dba)_2] + 2PPh_3\}$ to Allylic Acetate in the Presence of Chloride Ions in DMF

We have established that the oxidative addition of $[Pd^0(dba)_2] + 2PPh_3$ to the allylic acetate **9** is reversible and provides a cationic (π-allyl)palladium complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+(AcO)^-$ **(10)** in DMF (free ions) and in THF (ion pairs) (Equations 6−8).[17] This gives rise to the overall equilibrium in Equation (9) which may be monitored by UV spectroscopy.[17]

$$Pd^0(dba)_2 + 2\,PPh_3 \longrightarrow Pd^0(dba)(PPh_3)_2 + dba \quad (6)$$

$$Pd^0(dba)(PPh_3)_2 \rightleftharpoons Pd^0(PPh_3)_2 + dba \quad (7)$$

$$Pd^0(PPh_3)_2 + CH_2{=}CH\text{-}CH_2\text{-}OAc \rightleftharpoons (\eta^3\text{-}C_3H_5)Pd(PPh_3)_2^+ + AcO^- \quad (8)$$

$$Pd^0(dba)(PPh_3)_2 + CH_2{=}CH\text{-}CH_2\text{-}OAc \rightleftharpoons (\eta^3\text{-}C_3H_5)Pd(PPh_3)_2^+ + AcO^- + dba \quad (9)$$

When nBu$_4$NCl (750 equiv.) was added to a solution of $[Pd^0(dba)_2]$ (1 mM) and $2PPh_3$ in DMF, the absorbance of $[Pd^0(dba)(PPh_3)_2]$ at 396 nm decreased and reached a limiting value (70% of the initial absorbance) establishing the interference of chloride ions in the equilibrium in Equation (7), which is in agreement with the known stability of the anionic complex $Pd^0(PPh_3)_2Cl^-$ [14] [Equation (10)]. It is worthwhile to note that a large amount of nBu$_4$NCl is required to observe a significant decrease of the $[Pd^0(dba)(PPh_3)_2]$ concentration. This indicates that dba is a better ligand for $[Pd^0(PPh_3)_2]$ than Cl^-, and that at low chloride concentration, $[Pd^0(PPh_3)_2Cl]^-$ is only present at trace levels.

$$Pd^0(dba)(PPh_3)_2 + Cl^- \rightleftharpoons Pd^0(PPh_3)_2Cl^- + dba \quad (10)$$

When 60 equivalents of $CH_2{=}CH{-}CH_2{-}OAc$ were added to a solution of $[Pd^0(dba)_2] + 2PPh_3$ in DMF, the absorbance of $[Pd^0(dba)(PPh_3)_2]$ at 396 nm decreased and reached a limiting value corresponding to the thermodynamic

concentration of $[Pd^0(dba)(PPh_3)_2]$ imposed by the equilibrium in Equation (9) (Figure 1a, $t < 70$ s).

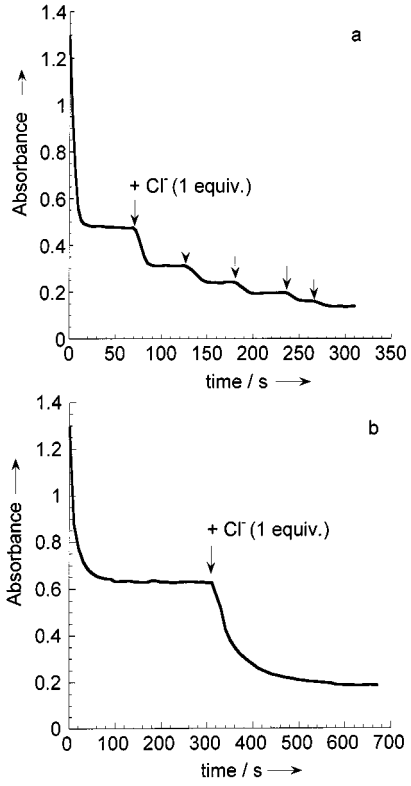


Figure 1. a) Variation of the absorbance ($\lambda = 396$ nm) of the UV spectrum performed in DMF at 20 °C in a 1 mm path cell of a solution of $[Pd^0(dba)_2]$ (1 mmol dm^{-3}) and PPh_3 (2 mmol dm^{-3}) after addition of 60 equivalents of $CH_2{=}CH{-}CH_2{-}OAc$ ($t < 70$ s), followed by successive additions of nBu$_4$NCl (one equivalent at each addition as indicated by the arrows; b) same experiment performed in THF ($\lambda = 394$ nm) after addition of 72 equivalents of $CH_2{=}CH{-}CH_2{-}OAc$ ($t < 300$ s), followed by addition of one equivalent of nBu$_4$NCl as indicated by the arrow

When one equivalent of nBu$_4$NCl was added, the limiting absorbance decreased to a lower value; it again decreased by successive additions of one equivalent of nBu$_4$NCl (Figure 1a). This shows that the chloride anion reacts with $[(\eta^3\text{-}C_3H_5)PdL_2]^+(AcO)^-$ **(10)** formed in the oxidative addition [Equation (9)], shifting this equilibrium to give the total disappearance of $[Pd^0(dba)(PPh_3)_2]$. This reaction gave the (σ-allyl)palladium complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)** [Equation (11)], which was characterized by performing ^{1}H NMR spectroscopy on a solution of $[Pd^0(dba)_2] + 2PPh_3$ in $CDCl_3$ after addition of **9** (3 equiv.) followed by nBu$_4$NCl (3 equiv.).

$$[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(AcO)^- + Cl^- \longrightarrow (\eta^1\text{-}C_3H_5)PdCl(PPh_3)_2 + AcO^- \quad (11)$$

However, AcO^- anions are released in reaction (11), so that a reaction similar to route d of Scheme 1 should operate, giving rise to the formation of $[Pd^0(dba)(PPh_3)_2]$ as the main Pd^0 complex [Equation (12)] instead of $[Pd^0(PPh_3)_2Cl]^-$.

$$(\eta^1\text{-}C_3H_5)PdCl(PPh_3)_2 + AcO^- + dba \longrightarrow Pd^0(dba)(PPh_3)_2 + CH_2{=}CH\text{-}CH_2\text{-}OAc + Cl^- \quad (12)$$

This has been checked independently by addition of nBu$_4$NOAc (1 equiv.) and dba (2 equiv.) to complex **2** (preliminary formed by reaction of **8** and one equivalent of nBu$_4$NCl). The formation of 19% of allylic acetate was then observed in the ^{1}H NMR spectrum performed in $CDCl_3$, together with $[Pd^0(dba)(PPh_3)_2]$, characterized by its two ^{31}P NMR signals in $CDCl_3$ and DMF[18] [Equation (12)].

Therefore, the oxidative addition of allylic acetate to the palladium(0) generated from $[Pd(dba)_2] + 2PPh_3$ and performed in the presence of chloride ions in DMF is a reversible reaction which affords a (σ-allyl)palladium chloride complex [Equation (13)] and not a cationic (π-allyl)palladium(II) complex $[(\eta^3\text{-}C_3H_5)PdL_2]^+X^-$ (X = Cl or AcO).[19]

$$Pd^0(dba)(PPh_3)_2 + CH_2{=}CH\text{-}CH_2\text{-}OAc + Cl^- \rightleftharpoons (\eta^1\text{-}C_3H_5)PdCl(PPh_3)_2 + AcO^- + dba \quad (13)$$

Formation of $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ in THF

The reaction of the dimeric (π-allyl)palladium(II) chloride **1** with four equivalents of PPh_3 in [D$_8$]THF afforded the (σ-allyl)palladium chloride complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ **(2)** (Table 1, Scheme 1, route a) characterized by its two signals, a quintet (1 H, $J = 10$ Hz) and a doublet (4 H, $J = 10$ Hz) (Table 1) as observed in DMF (vide supra). The ^{31}P NMR spectrum performed in THF exhibited a single, broad major signal ($\Delta\nu = 135$ Hz, Table 1) whose shift strongly depended on the solvent. Indeed, when DMF was added (THF:DMF = 1:1), the ^{31}P NMR signal shifted from $\delta = 11.85$ to 15.35. The phosphonium cation **3** was not observed in pure THF, even at longer times (over 1 h). It is only after addition of two equivalents of dba that the phosphonium cations **3** and **6** could be detected on the ^{31}P NMR spectrum, together with $[Pd^0(dba)(PPh_3)_2]$ ($\delta = 27.34$ and 25.57). This shows that the equilibrium shown in Equation (3) is still operating in THF but is considerably less shifted towards its right-hand side than in DMF, probably because THF is a weaker ligand than DMF for $[Pd^0PPh_3)Cl^-]$ and a weaker solvent for the phosphonium cations **3** and **6**.

Reaction of $[(\eta^3\text{-}C_3H_5)PdCl(PPh_3)]$ **(7)** with one equivalent of PPh_3 or $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^-$ **(8)** with one equivalent of nBu$_4$NCl in THF afforded the (σ-allyl)palladium chloride complex **2** (Scheme 1, route b and c, respectively). As in DMF, no cationic (π-allyl)palladium is formed in THF from **1**, **7**, and **8**, in the presence of chloride ions delivered either by the precursors (**1** or **7**) or deliberately added (to **8**). The three precursors provide the same (σ-allyl)palladium chloride complex **2** (Scheme 1a,b,c).

When 72 equivalents of $CH_2{=}CH{-}CH_2{-}OAc$ were added to a solution of $[Pd^0(dba)_2] + 2PPh_3$ in THF, the absorbance of $[Pd^0(dba)(PPh_3)_2]$ at 394 nm decreased and reached a limiting value corresponding to the thermodynamic concentration of $[Pd^0(dba)(PPh_3)_2]$ imposed in the equilibrium shown in Equation (14) (Figure 1b, $t < 300$ s).[17] This equilibrium is similar to that observed in DMF [Equation (9)] except for the ionic species' ion-pairing.

$$Pd^0(dba)(PPh_3)_2 + CH_2{=}CH{-}CH_2{-}OAc \rightleftharpoons (\eta^3\text{-}C_3H_5)Pd(PPh_3)_2{}^+AcO^- + dba \quad (14)$$

When one equivalent of nBu$_4$NCl was added, the absorbance decreased to almost zero (Figure 1b). This shows that the reaction of one chloride ion with $[(\eta^3\text{-}C_3H_5)PdL_2]^+(AcO)^-$ **(10)** formed in the oxidative addition [Equation (14)] was more efficient than in DMF, shifting this equilibrium to give the total disappearance of $[Pd^0(dba)(PPh_3)_2]$ as soon as one equivalent of Cl^- were added (compare Figure 1a and 1b). This establishes that the reversible overall reaction in Equation (13) is shifted more towards its right-hand side in THF than in DMF.

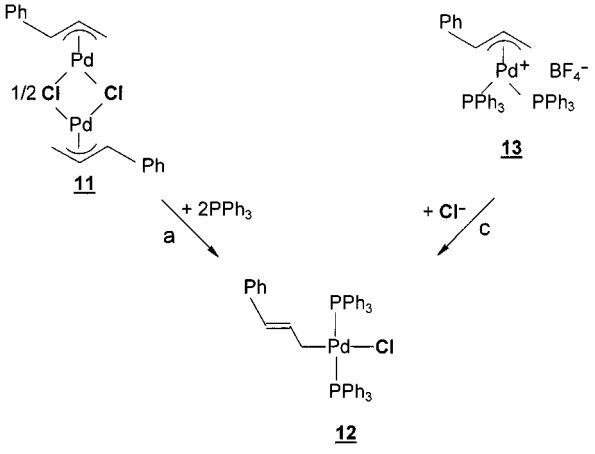
Formation of $[(\eta^1\text{-Ph}-CH{=}CH-CH_2)PdCl(PPh_3)_2]$

When four equivalents of PPh_3 were added to a solution of the dimeric (π-cinnamyl)palladium(II) chloride $[Pd(\eta^3\text{-}Ph-C_3H_4)(\mu\text{-}Cl)]_2$ **(11)** in $CDCl_3$, the four nonaromatic ^{1}H NMR signals characteristic of complex **11** (Table 2) totally disappeared and three new ^{1}H NMR signals were observed and assigned to the (σ-cinnamyl)palladium(II) chloride complex **12** $[(\eta^1\text{-Ph}-CH{=}CH-CH_2)PdCl(PPh_3)_2]$ (Scheme 2, route a).

Table 2. Characterization of cinnamyl−Pd^{II} complexes (Scheme 2)

	^{1}H NMR (ppm)[a]
11[b]	2.97 (d, J = 12 Hz, 1 H) 3.90 (d, J = 6.7 Hz, 1 H) 4.55 (d, J = 11.5 Hz, 1 H) 5.73 (ddd, J = 12, 11.5 and 6.7 Hz, 1 H)
12[c][d]	3.22 (d, J = 10 Hz, 2 H) 5.45 (d, J = 13 Hz, 1 H) 6.10 (dt, J = 10 and 13 Hz, 1 H)
13[b]	3.68 (t, J = 6.5 Hz, 1 H) 3.80 (pseudo t, J = 10 Hz, 1 H) 5.45 (pseudo t, J = 12 Hz, 1 H) 6.41 (m, 1 H)

[a] 250 MHz; shifts are referred to TMS. Solvent: $CDCl_3$. For simplification, aromatic protons are voluntarily omitted. − [b] Authentic sample. − [c] Formed in reaction of **11** with 4 equiv. PPh_3. − [d] Formed in reaction of **13** with 1 equiv. nBu$_4$NCl.



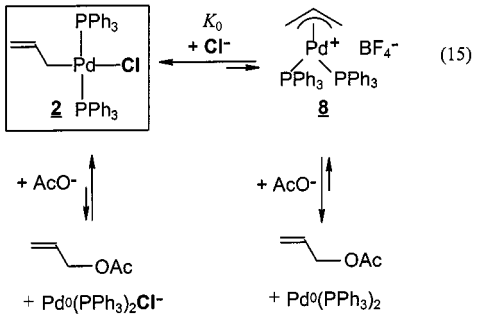
Scheme 2. Formation of a (σ-cinnamyl)palladium chloride complex

This reaction also gives the phosphonium cation $Ph-CH{=}CH-CH_2-PPh_3^+$ (24%) as in the allyl series (see above, Scheme 1). In contrast to the (σ-allyl)palladium(II) chloride complex **2**, which was found to be involved in a fast equilibrium between two σ-forms [Equation (2)], the (σ-cinnamyl)palladium(II) chloride complex **12** is not involved in such an equilibrium (or the equilibrium is very slow) because of the phenyl substituent. Indeed, the ^{1}H NMR spectrum (three different types of non aromatic ^{1}H with an integration of 1:1:2, Table 2) is clearly consistent with a complex of structure $Ph-CH{=}CH-CH_2-PdClL_2$ and not with the isomerized form $Ph-CH(PdClL_2)-CH{=}CH_2$ whose ^{1}H NMR spectrum should exhibit four different non aromatic signals with the same integration.

Complex **12** was also formed when one equivalent of nBu$_4$NCl was added to a solution of the cationic (π-cinnamyl)palladium complex **13** in $CDCl_3$ (Scheme 2, route b) whose four ^{1}H NMR signals were no longer detected (Table 2).

About the Permanence of the Cl^- Effect in the Presence of Increasing Amounts of AcO^- Produced During a Catalytic Reaction

In the case where a catalytic reaction is initiated by the precursor mixture $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2$ **(1)** + 4PPh_3, the chloride ion concentration is low compared to that of the acetate ions, which are progressively released from the allylic acetate when the catalytic reaction proceeds. One may think that our present results might be affected as a function of the conversion. However, this is not the case. Indeed, it is important to stress that the relative concentration of the (σ-allyl)palladium(II) chloride complex **2** versus the (π-allyl)palladium(II) complex **8** is not affected by the acetate concentration but only depends on the chloride concentration [Scheme 3, reaction (15)].



Scheme 3

The (σ-allyl)palladium(II) chloride complex **2** is quantitatively formed from {**1** + 4PPh_3}, and as well as when one equivalent of Cl^- is added to the cationic complex **8** (see above) so that the equilibrium between **2** and **8** [Scheme 3, Equation (15)] lies considerably in favor of **2** with $K_0\times[Cl^-] >> 100$. The nucleophile may then react with either **2** and **8**, or with both complexes in parallel. In the presence of AcO^-, two competitive reversible reactions occur, which lead to the formation of the allylic acetate (Scheme 3). But provided that reaction (15) in Scheme 3 remains at equilibrium, these reactions do not affect the relative concentration of **2** and **8**, since it only depends on Cl^- concentration

and not on $[Cl^-]/[AcO^-]$. One therefore has: $[\mathbf{2}]/[\mathbf{8}] = K_0 \times [Cl^-] >> 100$, whatever the AcO^- concentration. The effect of AcO^- concentration is only to decrease the absolute concentrations of **2** and **8** but not their ratio, so that the nature of the reactive species, which reacts with the nucleophile, will not be affected by the acetate concentration but will only depend on the intrinsic reactivity of the nucleophile with **2** or **8** and on K_0 and the Cl^- concentration, which determine the respective concentrations of **2** and **8**. When reaction (15) is displaced from its equilibrium by the combined actions of OAc^- and the nucleophile, the kinetic situation becomes much more intricate. The comparative reactivity of a nucleophile with cationic $[(\eta^3\text{-allyl})PdL_2]^+(BF_4)^-$ [20] complexes or with the related complexes $[(\eta^1\text{-allyl})PdClL_2$ is under investigation.

Conclusion

In DMF or THF, the cationic (π-allyl)palladium complex $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+Cl^-$ is not formed from $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2 + 4PPh_3$, $[(\eta^3\text{-}C_3H_5)PdCl(PPh_3)] + 1PPh_3$ or $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^- + 1Cl^-$. Instead, these three precursors lead to the formation of the same (σ-allyl)palladium chloride complex $[(\eta^1\text{-}CH_2{=}CH{-}CH_2)PdCl(PPh_3)_2]$ (Scheme 1a,b,c). Moreover, the latter complex is also formed instead of $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(AcO)^-$ when the oxidative addition of palladium(0) complexes to the allylic acetate is performed in the presence of chloride ions, either already ligated to the palladium(0) complex (when $[PdCl_2(PPh_3)_2]$ is the Pd^0 precursor) or deliberately added to a chloride-free palladium(0) complex (when $[Pd(dba)_2] + 2PPh_3$ is the Pd^0 precursor) (Scheme 1f,g,d,e).

This emphasizes the crucial role of presumably "innocent", ligands such as chloride ions, which do not behave as simpler counter-anions of cationic (π-allyl)palladium(II) complexes[2][7b] but modify the chemical structure of reactive intermediates by formation of neutral (σ-allyl)palladium(II) chloride complexes. This also shows that the catalytic precursors of Tsuji–Trost reactions, i.e., $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2 + 4PPh_3$ or $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^-$ are not equivalent since the former system does not lead to the latter complex due to the presence of chloride in its structure. They become equivalent only when chloride ions are added to $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2]^+(BF_4)^-$ but then both provide a neutral (σ-allyl)palladium(II) chloride.

Therefore, among the four catalytic precursors **A**: $[Pd^0L_4]$, **B**: $[Pd^0(dba)_2] + nL$, **C**: $[(\eta^3\text{-}C_3H_5)PdL_2]^+(BF_4)^-$, and **D**: $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2 + 4PPh_3$, the precursor **D** behaves quite differently. Indeed, the intermediate prone to react with the nucleophile is not a cationic (π-allyl)palladium(II) complex, as usually assumed, but a neutral (σ-allyl)palladium(II) chloride. Consequently, this may affect the regioselectivity of the reaction as well as its enantioselectivity in the case of substituted allylic acetates and chiral ligands. The formation of a neutral (σ-allyl)palladium(II) chloride should then be taken into consideration when chloride anions are purposely added to any Pd-catalyzed nucleophilic allylic substitution.

Experimental Section

General Remarks: ^{31}P NMR spectra were recorded on a Bruker spectrometer (101 MHz) using H_3PO_4 as an external reference. – ^1H NMR spectra were recorded on a Bruker spectrometer (250 MHz) using TMS as an internal reference. – UV spectra were recorded on a DU 7400 Beckman spectrophotometer. – Cyclic voltammetry was performed with a home made potentiostat and a wave form generator Tacussel GSTP4. The cyclic voltammograms were recorded on a Nicolet 301 oscilloscope. – Conductivity was measured on a Tacussel CDM210 conductivity meter (cell constant = 1 cm^{-1}).

Chemicals: DMF was distilled from calcium hydride under vacuum and THF from sodium/benzophenone. Commercial allylic acetate $CH_2{=}CH{-}CH_2{-}OAc$ (Acros) was used after filtration through alumina. Commercial (π-allyl)palladium(II)chloride dimer complex, $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2$ (Acros) was used without any purification. $[(\eta^3\text{-}C_3H_5)PdCl(PPh_3)]$,[9] $[(\eta^3\text{-}C_3H_5)Pd(PPh_3)_2][BF_4]$,[17] $[Pd(\eta^3\text{-Ph}{-}C_3H_4)(\mu\text{-}Cl)]_2$ [21] $[Pd(\eta^3\text{-Ph}{-}C_3H_4)(PPh_3)]_2$ [20] and $[Pd(dba)_2]$[22] were prepared according to published procedures.

UV Experiments: These were performed in a thermostated 1 mm path length cell on solutions of $[Pd(dba)_2]$ (11 mg, 0.02 mmol, 1 mmol dm^{-3}) and 2 equivalents of PPh_3 (10 mg, 0.04 mmol) in 20 mL of DMF or THF with the appropriate amount of $CH_2{=}CH{-}CH_2{-}OAc$ and nBu_4NCl (see text and Figure 1).

Electrochemical Set-up and Procedure for Voltammetry: Experiments were carried out in a three-electrode cell connected to a Schlenk line. The counter electrode was a platinum wire of ca. 1 cm^2 apparent surface area; the reference was a saturated calomel electrode (Tacussel) separated from the solution by a bridge filled with 3 mL of DMF containing nBu_4NBF_4 (0.3 g, 0.3 mol dm^{-3}). Cyclic voltammetry was performed at a steady gold disk electrode (diameter 0.5 mm) with a scan rate of 0.2 V s^{-1} from a solution of $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2$ (9 mg, 0.024 mmol) and 4 equivalents of PPh_3 (25 mg, 0.096 mmol) in 12 mL of DMF containing nBu_4NBF_4 (1.2 g, 0.3 mol dm^{-3}).

[13] For commercial **3**·Cl: $\delta(CH_2{-}P^+) = 4.95$ in $CDCl_3$. Since ion pairs were formed in $CDCl_3$, the ^{1}H NMR shift of **3**·Cl is very sensitive to the ionic strength and varies from $\delta = 4.95$ to 4.67 and 4.33 after addition of nBu$_4$NBF$_4$ (0.5 and 2.7 equiv. respectively). The signal position is also sensitive to the counteranion as observed for authentic samples of **3**·Br in $CDCl_3$: $\delta(CH_2{-}P^+) = 4.60$.

Heterocyclopentadienyl Complexes of Group-3 Metals

François Nief[a]

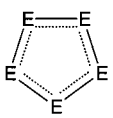
Keywords: Lanthanides / Actinides / Coordination modes / Heteroelements / Cyclopentadienes

Heterocyclopentadienyl complexes of group-3 metals (scandium, yttrium, lanthanum and the lanthanides, and uranium) are compounds in which one or more –CH units of a cyclopentadienyl-like ligand have been replaced by a heteroelement (nitrogen, phosphorus, arsenic, or antimony). These ligands can have very diverse substitution patterns, notably with bridged and cavitand-like structures. In addition to the classical η^5-coordination behaviour, the heterocyclopentadienyl ligand can adopt a very large array of coordination patterns. Some complexes have a very promising chemistry since they have been found to activate small molecules such as nitrogen and ethylene.

I. Introduction

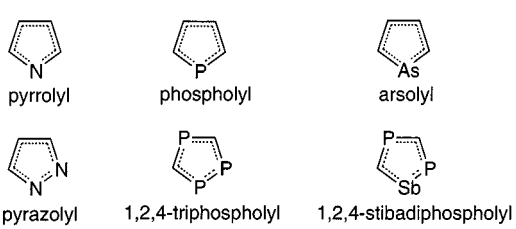
Cyclopentadienyl π-complexes of group-3 metals (including scandium, yttrium, lanthanum and the lanthanides, and the actinides) have received a tremendous amount of attention in the past few years.[1] These metals can achieve very high coordination numbers (c.n.) (up to 12), but it is possible to obtain stable complexes with lower coordination numbers by increasing the steric bulk on the cyclopentadienyl ligand. For instance, introduction of the η^5-pentamethylcyclopentadienyl (Cp*) ligand, which has become ubiquitous in this chemistry, has allowed for the isolation of stable complexes such as $Cp^*_2LnX_2^-$ (X = halogen, c.n. = 8), Cp^*_2LnR (R = alkyl, c.n. = 7), or even the divalent lanthanide complexes Cp^*_2Ln (Ln = Sm, Eu, c.n. = 6). In addition, some of these complexes are highly efficient homogeneous catalysts.[2]

Another possibility for modifying a cyclopentadienyl ligand is the replacement of one or several carbon atoms of this ring by a group-15 heteroelement; an isoelectronic heterocyclopentadienyl ligand is thus obtained.



E = CH, N, P, As, Sb, Bi

Several such heterocyclopentadienyl ligands have been used in group-3 metal chemistry. They include the pyrrolyl, phospholyl, and arsolyl ring systems with one heteroelement in the ring, the pyrazolyl ligand with two heteroelements and the 1,2,4-triphospholyl and 1,2,4-stibadiphospholyl ligands with three heteroelements. Like the cyclopentadienyl anion, all these ligands, in the anionic form, formally derive from the corresponding pyrrole, phosphole, arsole, pyrazole, 1,2,4-triphosphole and 1,2,4-stibadiphosphole ring systems, respectively, by deprotonation.



Of course many types of substituents have been introduced on these rings, notably by benzoannelation such as in

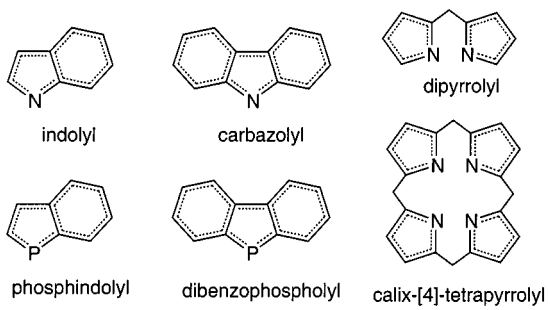
François Nief was born, raised, and educated in Paris. He graduated as Docteur ès Sciences from the University of Paris in 1981. After a one-year post-doctoral stay in 1982 at the University of Wisconsin, Madison, with Professor C. P. Casey, he joined the research group of Professor F. Mathey where he currently holds joint appointments at CNRS as chargé de recherche (senior researcher) and at Ecole Polytechnique as maître de conférences (associate professor). His main research interests include the applications of phosphorus ligands in the organometallic chemistry of the early transition metals, especially the lanthanides.

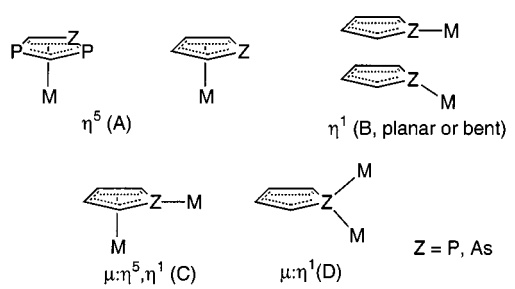
MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434–1948/01/0404–0891 $ 17.50+.50/0

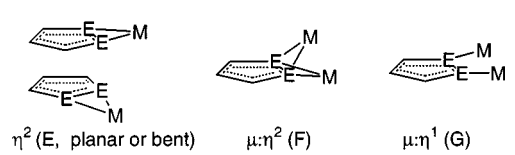
indolyl, phosphindolyl, carbazolyl, and dibenzophospholyl ligands. Bridged ligands have also been used: Complexes with chelating or cavitand-like pyrrolyl ligands such as bipyrrolyl or calix[4]tetrapyrrolyl (porphynogen) have recently been prepared (it is worth noting that a cavitand structure based on cyclopentadienyl has not been made yet).



All these 5-membered ring systems, except for pyrazolyl, have been shown to behave as "true" heterocyclopentadienyl ligands in the sense that complexes displaying the η^5-coordination mode (A), which is typical of the cyclopentadienyl group, have been isolated. Since the heteroatom in the ring still possesses a lone pair of electrons, other coordination patterns are possible, namely the η^1-mode (B, planar or bent), in which there is a σ bond with the group-3 metal, the $\mu{:}\eta^5,\eta^1$-mode (C), in which both the ring and the lone pair are coordinated, and the $\mu{:}\eta^1$-bridging mode (D).



The proximity of two heteroatoms in the pyrazolyl, 1,2,4-triphospholyl, and 1,2,4-stibadiphospholyl ligands can give rise to other coordination modes: η^2-(E, planar or bent), $\mu{:}\eta^2$-(F) and $\mu{:}\eta^1$-(G).



Heterocyclopentadienyl complexes of group-3 metals have been studied less than the cyclopentadienyl complexes. However, many references have appeared in the past few years and so this field is rapidly expanding.

Interest in the structure and reactivity of these complexes stems from:

a) coordination mode A and comparison with analogous cyclopentadienyl complexes,

b) the additional possibilities offered by coordination modes C and E for mononuclear complexes,

c) coordination modes D, F, and G which give rise to polynuclear complexes,

d) heterocyclopentadienyl complexes based on pyrrolyl ligands with bridging or cavitand structures, and

e) synthetic pathways possibly different from those of cyclopentadienyl complexes.

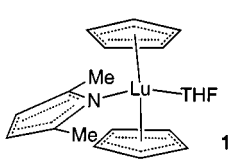
This review will tentatively cover the complexes of group-3 metals (scandium, yttrium, lanthanum and the lanthanides, and uranium) with heterocyclopentadienyl ligands as described above. Group-3 metal complexes with ligands that have extended delocalised structures, such as porphyrin, or with pyrazolylborates, in which the formal negative charge does not reside on the heterocyclic ring, will not be considered in this survey.

II. Complexes with Nonbridged Ligands

A. Monocyclic Pyrrolyl, Phospholyl and Arsolyl Complexes

1. Pyrrolyl Complexes

In contrast to the cyclopentadienyl ligand, there is a dissymmetry in the ligand ring electron density of the heterocyclopentadienyl ligand, owing to the fact that the heteroatom bears a larger part of the overall electronic density than the carbon atoms. This effect is more important for the pyrrolyl ligand because of the higher electronegativity of the nitrogen atom. Considering the strong electrophilicity of group-3 metals, one would thus expect mostly the η^1-bonding mode between the pyrrolyl ligand and these elements. As an illustration, Schumann et al. have prepared a series of complexes containing both the Cp or Cp* ligand and the pyrrolyl (pyr) or the 2,5-dimethylpyrrolyl (Dmpyr) ligand:[3] $[(\eta^5\text{-Cp})_2(\eta^1\text{-L})\text{Lu(THF)}]$ (L = pyr, Dmpyr) and $[(\eta^5\text{-Cp*})_2(\eta^1\text{-pyr})\text{Y(THF)}]$. X-ray data on $[(\eta^5\text{-Cp})_2(\eta^1\text{-Dmpyr})\text{Lu(THF)}]$ (**1**) and NMR evidence show that in these complexes, the pyrrolyl ligand is indeed σ-bonded to the group-3 metal.

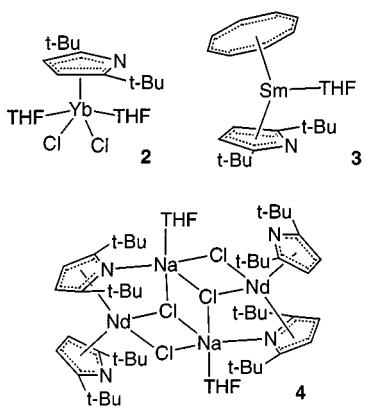


1

However, π-coordination of the pyrrolyl ligand can be also achieved. In a seminal paper, Marks[4] prepared $[\text{U(Dmpyr)}_4]$ by reaction of KDmpyr with UCl_4. Although no structural data are available for this compound, a VT NMR study suggests that the low-temperature structure of this fluxional complex is that of $[\text{U}(\eta^1\text{-Dmpyr})_3(\eta^5\text{-Dmpyr})]$. Presumably, $[\text{U(Dmpyr)}_4]$ with all the Dmpyr ligands σ-bonded would be sterically too unsaturated (c.n. =

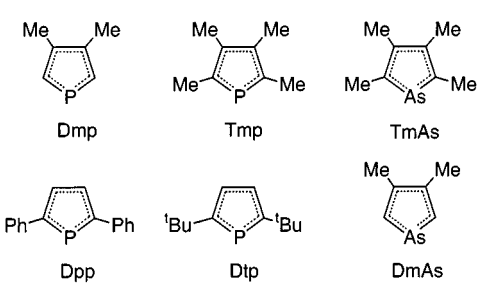
4) and so one of the ligands is π-bonded in order to decrease this unsaturation.

Schumann et al. then introduced the 2,5-di-*tert*-butylpyrrolyl ligand (Dtpyr) in group-3 metal chemistry. It was expected that for steric reasons, the two *tert*-butyl groups would inhibit coordination with the nitrogen lone pair and indeed mostly η^5-coordinated complexes have been obtained with this ligand, such as the bis(pyrrolyl)Ln^{II} complexes $[(\eta^5\text{-Dtpyr})_2Ln(THF)]$ (Ln = Sm, Yb),[5] the (pyrrolyl)Yb^{III} compound $[(\eta^5\text{-Dtpyr})YbCl_2(THF)_2]$[6] (**2**), and the mixed (cyclooctatetraenyl/pyrrolyl)Ln^{III} complexes $[(\eta^8\text{-COT})(\eta^5\text{-Dtpyr})Sm(THF)]$ (**3**) and $[(\eta^8\text{-COT})(\eta^5\text{-Dtpyr})Ln]$ (Ln = Tm, Lu).[7] However, σ,π complexation of the Dtpyr ligand is also possible since the nitrogen lone pair of this ligand is coordinated with sodium in the neodymate(III) dimer $[\{(\eta^5\text{-Dtpyr})(\mu{:}\eta^5,\eta^1\text{-Dtpyr})(\mu^2\text{-Cl})(\mu^3\text{-Cl})Na(THF)\}_2]$[5] (**4**).

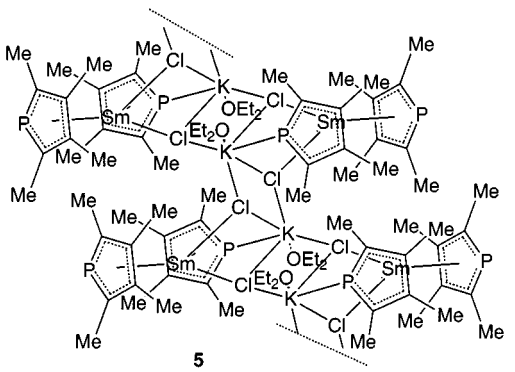


2. Phospholyl and Arsolyl Complexes

In contrast to pyrrolyl, one would expect mostly η^5- or $\mu{:}\eta^5,\eta^1$-bonding modes of the phospholyl (or arsolyl) ligand owing to the close electronegativities of the =CH− and =P− (or =As−) entities (the so-called diagonal analogy).[8] We will see that this is not always so. The following phospholyl and arsolyl ligands have been used.

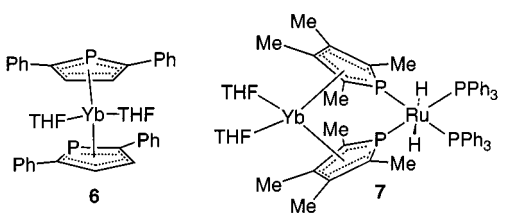


With the Tmp and TmAs ligands, one can usually obtain the same types of η^5-complexes as those described with the Cp* ligand. For instance, classical Ln^{III} ate complexes such as $[(\eta^5\text{-Tmp})_2LnCl_2Li(solv)_2]$[9] [Ln = Y, Lu, solv = Et_2O, dimethoxyethane (DME)] or $[(\eta^5\text{-Tmp})_2LnCl_2K]$ (Ln = Nd, Sm)[10] have been prepared by the reaction of the appropriate alkali metal phospholide with $LnCl_3$. In the case of $[(\eta^5\text{-Tmp})_2YCl_2Li(Et_2O)_2]$, it has been possible to observe the coupling of ^{31}P with ^{89}Y by NMR. From the small value of this coupling and from the triplet pattern in the ^{89}Y spectrum, it has been suggested that this complex retains the η^5-structure in solution. The polymeric crystal structure of $[\{(\eta^5\text{-Tmp})(\mu{:}\eta^5,\eta^1\text{-Tmp})Ln(\mu_3\text{-Cl})_2K(Et_2O)\}_n]$ (**5**), while similar to that of $[\{(\eta^5\text{-Cp*})_2Ce(\mu_3\text{-Cl})_2K(THF)\}_n]$,[11] shows additional coordination of the lone pair of one Tmp ligand to potassium. As was the case with their Cp* analogues, $[(\eta^5\text{-Tmp})_2LnCl_2K]$ could be transformed into the neutral alkyl complexes $[(\eta^5\text{-Tmp})_2LnCH(SiMe_3)_2]$ (Ln = Nd, Sm) by reaction with $LiCH(SiMe_3)_2$.



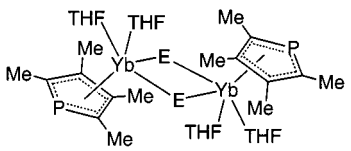
Divalent lanthanide chemistry with phospholyl ligands is also similar to that observed with the Cp* ligand. Thus, $[(\eta^5\text{-L})_2Ln(THF)_2]$ (Ln = Yb, Sm, L = Tmp, TmAs, Dpp)[12] could be obtained by the classical metathesis reaction of the potassium phospholides with $LnI_2(THF)_2$. More interestingly, these molecules could also be prepared by insertion of metallic ytterbium or samarium (in the form of the commercial powders) into the P−P bond of a 1,1′-biphospholyl or -biarsolyl.[13] Once again, investigation of the ytterbium complexes by multinuclear (^{31}P, ^{171}Yb) NMR suggests π-complexation of the phospholyl ligand with Yb. The structure of $[(\eta^5\text{-Dpp})_2Yb(THF)_2]$ (**6**) has been determined by X-ray crystallography.

In $[(\eta^5\text{-L})_2Ln(THF)_2]$ (L = Tmp, TmAs, Ln = Sm, Yb), THF is very easily lost under vacuum, with the formation of decomposition products L_2Ln, which are insoluble in nonpolar solvents.[13] In contrast, it is known that $[(\eta^5\text{-Cp*})_2Sm(THF)_2]$ sublimes by heating under high vacuum, to give unsolvated toluene-soluble $[(\eta^5\text{-Cp*})_2Sm]$.[14] Although the structures of L_2Ln are still unknown, it is suspected that these materials are polymers, with Ln−P or Ln−As σ-bonds. However, L_2Ln compounds are reactive in nonpolar solvents: $[Tmp_2Yb]$ reacts in toluene with a stable nucleophilic carbene such as *N*,*N*-diisopropyl-2,3-dimethylimida-



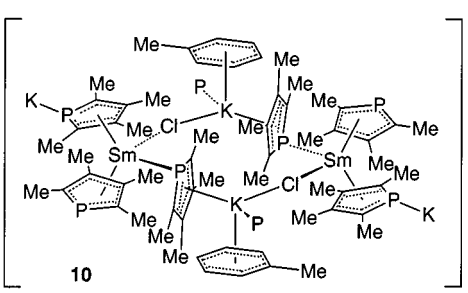
zolylidene (carb) to give the adduct $[(\eta^5\text{-Tmp})_2\text{Yb(carb)}]$.[15] Since the Tmp_2Yb moiety still possesses two lone pairs at the phosphorus atoms, it can act as a chelating ligand in the heterobimetallic Yb/Ru complexes, $[(L)_2\text{Yb}(\mu{:}\eta^5,\eta^1\text{-Tmp})_2\text{RuH}_2(\text{PPh}_3)_2]$ [L = THF (**7**), Carb].[15,16]

The use of zerovalent Yb as a precursor to phospholyl complexes could be extended to the synthesis of monophospholyl Yb complexes. Insertion of Yb metal into the P−Cl bond of 1-chloro-2,3,4,5-tetramethylphosphole or the P−S bond of 1-phenylthio-2,3,4,5-tetramethylphosphole afforded the corresponding Yb^{II} dimers $[\{(\eta^5\text{-Tmp})\text{Yb}(\mu\text{-E})(\text{THF})_2\}_2]$ [E = Cl (**8**), SPh (**9**)].[17]

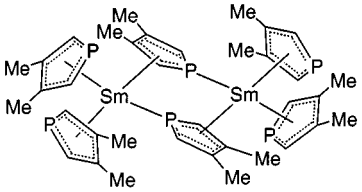


E = Cl (**8**), SPh (**9**)

The following examples illustrate how the substitution pattern on the heterocyclopentadienyl ring can influence its coordination chemistry. Compounds such as $[(\eta^5\text{-Cp*})_3\text{M}]$ (M = Nd, Sm, U)[18] exist but they cannot be synthesised by the metathesis reaction of MX_3 (X = halogen) with the appropriate alkali metal salts, because these reactions often require donor solvents such as THF which can react with the sterically overcrowded $Cp*_3M$ intermediates. However, removal of just one methyl group on the Cp* ring allows for the easy synthesis of $[(\eta^5\text{-}C_5Me_4H)_3\text{Ln}]$ (Ln = La, Sm, Tb) by the metathesis route.[19] In a way, the Tmp ligand may be regarded as looking more like C_5Me_4H than Cp*: The lone pair on the phosphorus atom in the Tmp ligand is sterically more similar to a C−H bond in Cp than to a $C-CH_3$ bond in Cp*. However, reaction of three equivalents of KTmp with $SmCl_3$ in toluene did not give $[(\eta^5\text{-Tmp})_3\text{Sm}]$. An ate complex of polymeric two-dimensional structure, which retains KCl, was obtained instead. Its X-ray structure has been determined and is that of $[\{(\eta^5\text{-Tmp})\text{Sm}(\mu{:}\eta^5,\eta^1\text{-Tmp})_2(\mu\text{-Cl})\text{K}(\eta^6\text{-toluene})\}_n]$[20] (**10**).



This complex looks like a reaction intermediate towards a hypothetical $[(\eta^5\text{-Tmp})_3\text{Sm}]$ since the Sm atom in **10** is complexed with three Tmp ligands, but KCl has not been eliminated. Under the same conditions with the Dmp ligand, a neutral tris(Dmp) dimer, $[\{(\eta^5\text{-Dmp})_2(\mu{:}\eta^5,\eta^1\text{-Dmp})\text{Sm}\}_2]$ (**11**), was obtained[20]. In this case, since the Dmp ligand is smaller, the Sm atom can achieve a c.n. of 10.

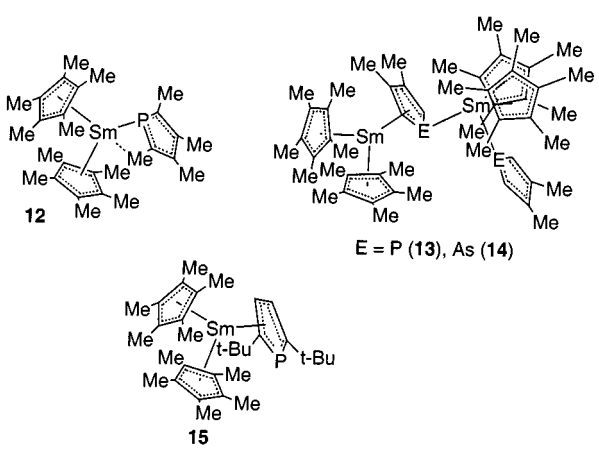


11

It thus seemed interesting to study the coordination of the phospholyl ligand around Sm in complexes of composition $Cp*_2\text{Sm(L)}$ (L = phospholyl, arsolyl), that is, when the Sm atom is in a very crowded environment imposed by two Cp* ligands. $Cp*_2\text{Sm(L)}$ (L = Tmp, Dmp, Dmas, Dtp) was prepared by reductive cleavage of the P−P or As−As bonds of the corresponding 1,1′-biphospholyls or -biarsolyls by $Cp*_2Sm$.[21] Three types of structures were obtained.

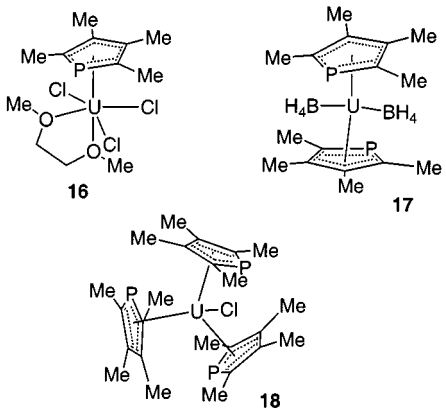
With Tmp as ligand, the structure is that of $[(\eta^5\text{-Cp*})_2(\eta^1\text{-Tmp})]$ (**12**). The Tmp ligand is only σ-bonded to Sm, but since this atom is still coordinatively unsaturated (c.n. = 7), it will look for additional electronic density through an interaction with one of the α-methyl groups of the σ-Tmp ligand, which thus becomes unsymmetrically bonded to Sm.

With Dmp or Dmas as ligands, the structure is that of an unsymmetrical dimer, $[(\eta^5\text{-Cp*})_4\text{Sm}_2(\eta^1\text{-L})(\mu{:}\eta^5,\eta^1\text{-L})]$ [L = Dmp (**13**), Dmas (**14**)]. Apparently, there is enough room around the Sm atom to achieve π-coordination with the less bulky Dmp or Dmas. However, the lone pair on this π-ligand is still available for complexation with another $Cp*_2Sm$ unit, which then only needs σ-coordination with another Dmp or Dmas ligand to achieve the optimum c.n. of 8. With Dtp as ligand, the lone pair is sterically hindered, so only π-coordination is possible and the structure is that of $[(\eta^5\text{-Cp*})_2(\eta^5\text{-Dtp})]$ (**15**).

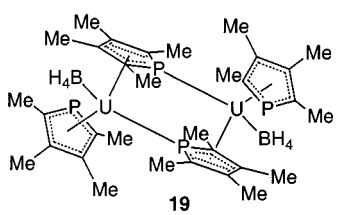


The Tmp ligand has been extensively used in actinide chemistry, in which most of its chemistry parallels that observed with the Cp* ligand. Mono- or bis(phospholyl)U^{IV} complexes such as $[(\eta^5\text{-Tmp})\text{UCl}_3(\text{DME})]$[22] (**16**), $[(\eta^5\text{-Tmp})_2\text{UCl}_2]$,[22] $[(\eta^5\text{-Tmp})_2\text{U}(\text{BH}_4)_2]$[23] (**17**), and $[(\eta^5\text{-}$

Tmp)U(BH$_4$)$_3$][24] could be prepared by reaction of UCl$_4$ or U(BH$_4$)$_4$ with KTmp. A mixed Tmp/Cp* complex, [(η^5-Tmp)(η^5-Cp*)U(BH$_4$)$_2$],[22,25] could also be obtained from KTmp and [(η^5-Cp*)U(BH$_4$)$_3$]. These Tmp complexes could, in turn, be converted into [(η^5-Tmp)UX$_3$(DME)], [(η^5-Tmp)(η^5-Cp*)UX$_2$], and [(η^5-Tmp)$_2$UX$_2$] (X = alkyl, alkoxy) by reaction with the appropriate nucleophiles.[22] However, contrary to the case with the Cp* ligand, tris(phospholyl)U^{IV} complexes can be obtained: [(η^5-Tmp)$_3$UCl] (**18**) was prepared from KTmp and UCl$_4$ and this compound was transformed into [(η^5-Tmp)$_3$UMe] and [(η^5-Tmp)$_3$UH].[26] Here, the Tmp ligand behaves similarly to the C$_5$Me$_4$H ligand since [(η^5-C$_5$Me$_4$H)$_3$UCl][27] has been prepared and its structure determined by X-ray.

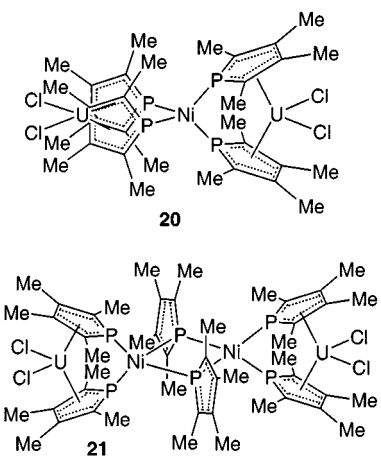


Low-valent (phospholyl)U^{III} complexes could also be obtained either by reduction of the corresponding U^{IV} complexes with sodium amalgam or by reaction of TmpK with the U^{III} precursor [(η^6-mesitylene)U(BH$_4$)$_3$].[23] When these reactions were performed in THF, U^{III} ate complexes such as [{(η^5-Tmp)$_2$U(BH$_4$)$_2$}(M)] and [{(η^5-Tmp)U(BH$_4$)$_3$}(M)] (M = Na, K) were obtained. However, reduction of [(η^5-Tmp)$_2$U(BH$_4$)$_2$] or [(η^5-Tmp)(η^5-Cp*)U(BH$_4$)$_2$] in toluene led to the precipitation of NaBH$_4$ and to the isolation of neutral U^{III} dimers [{(η^5-Tmp)(μ:η^5,η^1-Tmp)U(BH$_4$)}$_2$] (**19**) and [{(η^5-Cp*)(μ:η^5,η^1-Tmp)U(BH$_4$)}$_2$], respectively. In these compounds, the ^{31}P NMR signal of the bridging Tmp ligand was detected very far downfield (δ ≈ 3500−3900). The structure of **19** has been determined by an X-ray crystal structure analysis.[25]



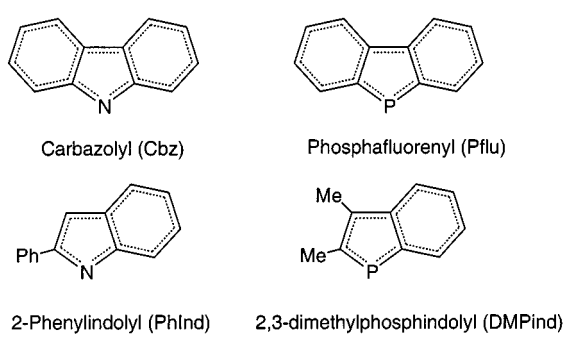
A comparison of the electronic properties of the Tmp and Cp* ligand has been made by electrochemical measurements. The following one-electron reversible potentials (vs. ferrocene/ferricinium) were found for [(η^5-Tmp)$_2$U(BH$_4$)$_2$] (−1.49 V), [(η^5-Tmp)(η^5-Cp*)U(BH$_4$)$_2$] (−1.66 V), and [(η^5-Cp*)$_2$U(BH$_4$)$_2$] (−1.83 V). These results clearly show that the Tmp ligand is less electron-rich than the Cp* ligand. An additional piece of evidence for this is the fact that only [(η^5-Tmp)$_2$U(BH$_4$)$_2$] was reduced when an equimolar mixture of [(η^5-Tmp)$_2$U(BH$_4$)$_2$] and [(η^5-Cp*)$_2$U(BH$_4$)$_2$] was treated with 0.5 equivalents of sodium amalgam. The chemistry of (phospholyl)uranium complexes is therefore not only influenced by steric but also by electronic factors.[22]

Finally, further evidence for the accessibility of the phosphorus lone pairs was found by the X-ray characterisation of two U−Ni heterobimetallic compounds: [Cl$_2$U(μ:η^5,η^1-Tmp)$_2$Ni] (**20**) and [{Cl$_2$U(μ:η^5,η^1-Tmp)$_2$(μ-Tmp)Ni}$_2$][28] (**21**).



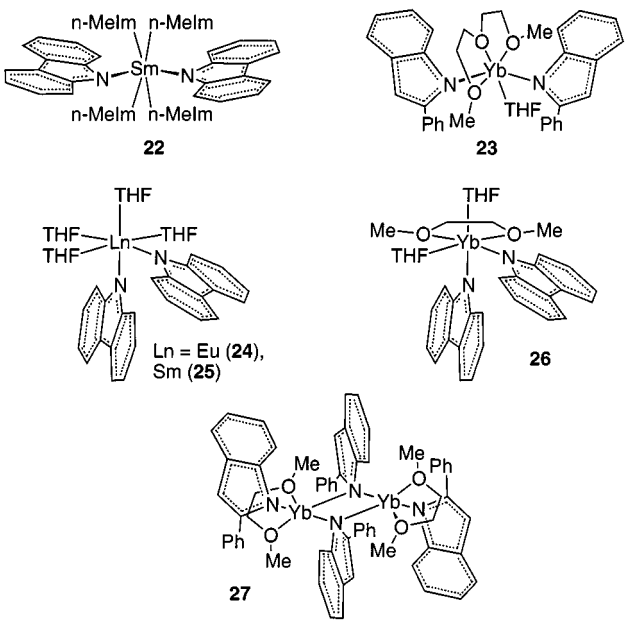
B. Ring-Fused Pyrrolyl and Phospholyl Complexes

Another opportunity for comparing the phospholyl and pyrrolyl ligands is the study of the effect of benzoannelation on the coordinating properties of these ligands. The following ligands have been used, mostly in Ln^{II} chemistry.

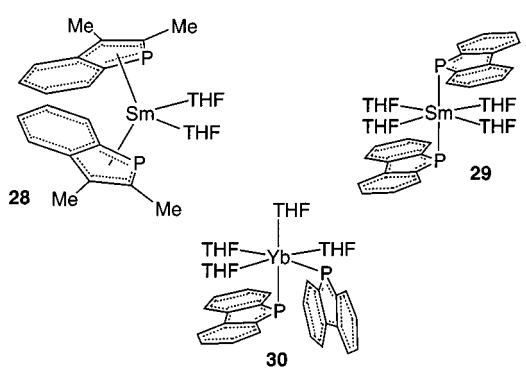


In general, the Ln^{II} complexes are 6-coordinate octahedral or distorted octahedral complexes of general formula [(η^1-L)$_2$Ln(D)$_4$] (L = PhInd, Cbz; Ln = Sm, Eu, Yb; D = donor). Planarity or near-planarity at the nitrogen atom is achieved and thus coordination of type B (planar) is present. The ligands L can be either axial, e.g. in [(η^1-Cbz)$_2$Sm(*N*-MeIm)$_4$][29] (**21**, *N*-MeIm = *N*-Methylimidazole) and [(η^1-PhInd)$_2$Yb(THF)(diglyme)][30] (**23**) or equat-

orial, e.g. in $[(\eta^1\text{-Cbz})_2Ln(THF)_4]$ [Ln = Eu[31] (**24**), Sm[29] (**25**)] and $[(\eta^1\text{-Cbz})_2Yb(THF)_2(DME)]$[32] (**26**). The steric bulk of the PhInd ligand probably causes the lability of the THF ligand in $[(PhInd)_2Yb(THF)_4]$. Heating this compound in toluene in the presence of DME produced a five-coordinate dimer, $[\{(\eta^1\text{-PhInd})(\mu{:}\eta^1\text{-PhInd})Yb(DME)\}_2]$ (**27**), in which there is an unprecedented coordination of type E for one of the PhInd ligands.[30] A single Sm^{III} complex, $[(PhInd)_3Sm(THF)]$, has been mentioned but its structure is unknown.[31]



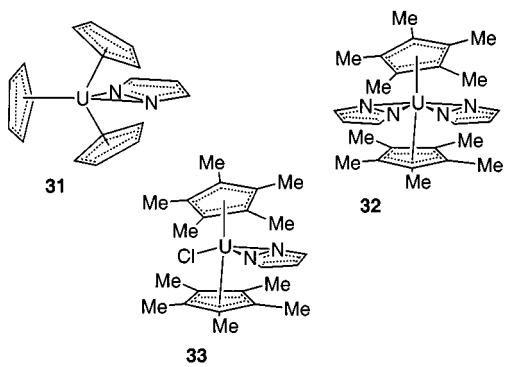
The phosphorus analogues of the indolyl and carbazolyl ligands have a completely different behaviour. The DMPind (2,3-dimethylphosphindolyl) ligand is still π-complexed with the Sm atom in $[(\eta^5\text{-DMPind})_2Sm(THF)_2]$[33] (**28**) while this is no longer the case in the octahedral phosphafluorenyl complexes, $[(\eta^1\text{-Pflu})_2Ln(THF)_4]$ [Ln = Sm[33] (**29**), Yb[34] (**30**)], which display type B (bent) coordination. Remarkably, the Pflu ligands in **29** are axial while in **30** they are equatorial, which points to a probable small energy difference between the two forms.



The difference in coordination behaviour between the phosphindolyl and phosphafluorenyl ligands is due to the weaker electron density of the 5-membered ring in the phosphafluorenyl ligand (because of the double benzoannelation), that prevents π-coordination by this ring, so only σ-coordination of the phosphafluorenyl ligand is possible. However, unlike the carbazolyl ligand, the phosphafluorenyl ligand is bent at the phosphorus atom because of the greater tendency of phosphorus to form pyramidal compounds. However, indenyl and fluorenyl complexes of Sm^{II} are both η^5-coordinated.[35]

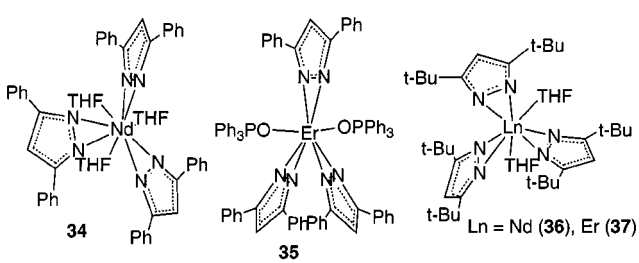
C. Pyrazolyl, Triphospholyl and Stibadiphospholyl Complexes

Raymond and Eigenbrodt, Jr. were the first to demonstrate the planar η^2-coordination mode of the pyrazolyl ligand (mode E) in uranium chemistry. The metathesis reactions of $[Cp_3UCl]$ and $[Cp^*_2UCl_2]$ with potassium pyrazolate afforded $[Cp_3U(pz)]$[36] (**31**, pz = pyrazolate) and $[Cp^*_2U(pz)_2]$[37] (**32**) or $[Cp^*_2U(Cl)(pz)]$[37] (**33**), respectively (depending on the stoichiometry).



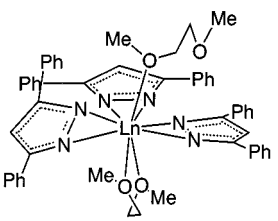
Early experiments involved the reaction of lanthanide halides with sodium pyrazolate or 3,5-dimethylpyrazolate (Dmpz). Polynuclear sodium pyrazolyllanthanoidates such as $[Ln_3(\mu\text{-Dmpz})_6(\eta^2\text{-Dmpz})_2(\mu^3\text{-O})Na_2(THF)_2]$ (Ln = Y, Ho, Yb, Lu) were obtained, in which the interstitial oxygen atom most likely originated from water present as an impurity in the solvents. Here, the Dmpz ligand can be found in coordination modes E and G.[38]

In almost all other group-3 pyrazolate metal complexes, coordination mode E is present for at least one of the pyrazolyl ligands. In $[LnL_3(D)_n]$ (L = substituted pyrazolyl; D = donor ligand), the coordination mode of the remaining pyrazolyl ligands depends on the substitution pattern of the pyrazolyl ring. With ligands possessing a group with relatively low steric bulk, such as Dmpz, both coor-

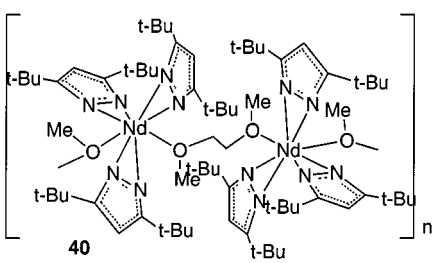


dination modes E and G can be found, e.g. in [{(η^2-Dmpz)$_2$(μ:η^1-Dmpz)Nd(μ-THF)}$_2$].[39] With bulkier pyrazoyls such as 3,5-diphenylpyrazolyl (Dppz) or 3,5-di-*tert*-butylpyrazolyl (Dtpz), only type E is encountered in [(η^2-Dppz)$_3$Nd(THF)$_3$] (**34**), [(η^2-Dppz)$_3$Ln(OPPh$_3$)$_2$] [Ln = La, Nd, Er (**35**)],[40] and [(η^2-Dtpz)$_3$Ln(THF)$_2$] [Ln = Y, La, Nd (**36**), Sm, Gd, Dy, Er (**37**), Yb, Lu].[41]

It should be noted that because Dppz is sterically less bulky than Dtpz, the coordination number for the Nd atom in **34** (c.n. = 9) is greater than in **36** (c.n. = 8). Likewise, there are two DME ligands (one chelating and one η^1) in 9-coordinate [(η^2-Dppz)$_3$Ln(η^2-DME)(η^1-DME)] [Ln = Er[42] (**38**), Nd[43] (**39**)] while the structure of 8-coordinate [{(η^2-Dtpz)$_3$Nd(μ-DME)}$_n$] is polymeric, with one bridging DME ligand[42] (**40**).

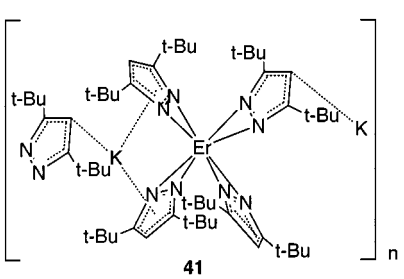


Ln = Er (**38**), Nd (**39**)

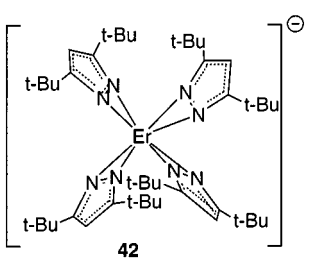


40

In the absence of donor solvents, the reaction of erbium chloride with KDtpz in toluene gave polymeric [{K(μ-Dtpz)$_3$Er}$_n$] (**41**) displaying an unprecedented η^3-interaction of the Dtpz ligand with the potassium atom. Adding 18-C-6 and DME to this polymer resulted in the isolation of a homoleptic 8-coordinate erbate complex, [{K(18-C-6)(DME)(Toluene)}$^+$ · {(η^2-Dtpz)$_4$Er}$^-$] (**42**).[44]

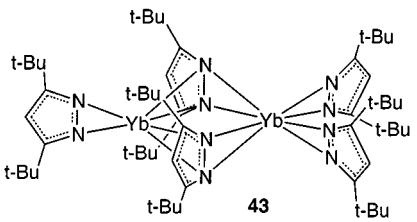


41



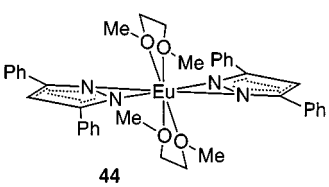
42

Neutral homoleptic complexes could be obtained under harsher conditions: Reaction of neat neutral HDtpz with the lanthanide metal in the presence of Hg metal at 220 °C had a different outcome, depending on the metal. The following compounds were obtained: complexes of Nd^{III} and Sm^{III}, [Ln(Dtpz)$_3$] (Ln = Sm, Nd), an Eu^{II} complex, [Eu(Dtpz)$_2$], and an interesting mixed valence Yb^{II,III} complex, [(η^2-Dtpz)$_3$(μ:η^2-Dtpz)$_2$Yb$_2$] (**43**) with coordination modes E and F. Coordination mode F is also present in [(η^2-Dtpz)$_4$(μ:η^2-Dtpz)$_2$Nd$_2$][45]

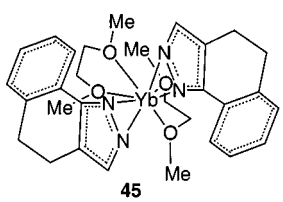


43

Ln^{II} complexes could be prepared by several routes, notably by redox-transmetallation reactions involving lanthanide powders and mild oxidants such as thallium or mercury pyrazolates or even diphenylmercury in the presence of pyrazoles. With DME as donor ligand, all complexes have the structure of 8-coordinate [(η^2-L)$_2$Ln(DME)$_2$] {Ln = Sm, Eu (**44**), Yb, L = Dtpz, Dppz, and 4,5-dihydro-2*H*-benz[*g*]indazolyl (**45**)}. The pyrazolyl ligands generally have the *cis* configuration, except in [(η^2-Dppz)$_2$Eu(DME)$_2$] in which they are *trans*.[46]

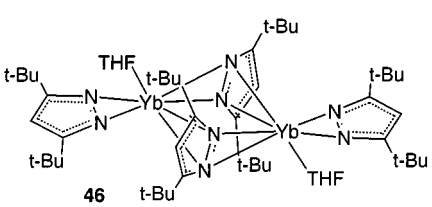


44



45

In the case of Yb and with THF as donor ligand, there is only one coordinated THF, and both coordination types E and F are present in [(η^2-Dtpz)$_2$(μ:η^2-Dtpz)$_2$Yb$_2$(THF)$_2$][47] (**46**).



46

Organolanthanide complexes containing the pyrazolyl ligand have also been prepared. The reaction of [(η^5-MeC$_5$H$_4$)$_3$Ln] with Dmpz gave [(MeC$_5$H$_4$)Ln(Dmpz)$_2$] (Ln = Nd, Gd, Dy, Yb). These compounds reacted with silicone grease, and insertion of a dimethylsilanone unit into an Ln−N bond took place, thus affording dimeric [{(η^5-MeC$_5$H$_4$)(η^2-Dmpz)(μ:η^1,η^2-OSiMe$_2$-Dmpz)Ln}$_2$] [Ln = Yb[48a] (**47**), Dy[48b]]. In this oxygen-bridged dimer, both

Dmpz moieties display the type F (planar) coordination mode.[48]

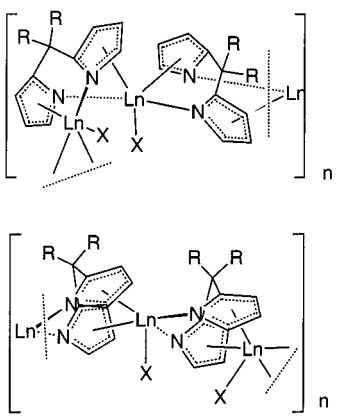
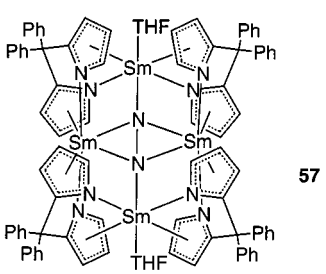
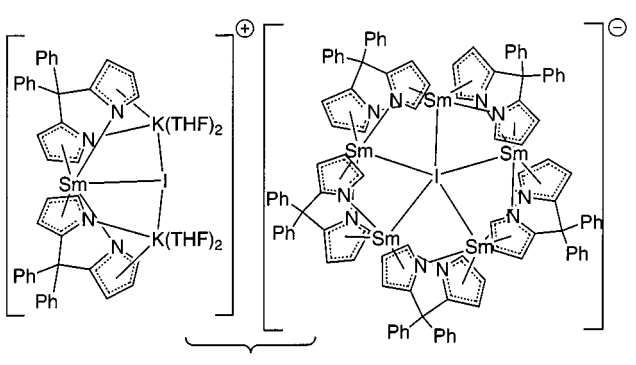
Almost all compounds described so far with this type of ligand display σ,π-complexation of both pyrrolyl rings to a lanthanide metal centre, and thus polynuclear complexes are obtained, frequently in cyclic structures. Generally, the two π-complexing rings belong to two different bridged ligands, but there is one example in which the lanthanide metal centre is π-complexed to two rings belonging to the same ligand.



The proximity of the metal centres in these polynuclear complexes allow for the cooperative behaviour of the metallic centres: Reaction of K_2Dpdp with $SmI_2(THF)_2$ in the presence of nitrogen irreversibly gave a tetranuclear Sm^{III}−nitrogen (formally N_2^{4-}) complex, [{(μ:η^5,η^1-Dpdp)Sm}$_4$(μ:η^1,η^1,η^2,η^2-N_2)] (**57**). In the absence of nitrogen, a compound of global composition [{(Dpdp)Sm}$_7$ · SmI_2] was obtained; it is in fact a zwitterionic Sm^{II} species, [{(μ:η^5,η^1-Dpdp)Sm}$_5$(μ$_5$-I)$^-$ · {(μ:η^5,η^1-Dpdp)}$_2$Sm$_3$(THF)$_3$(μ$_3$-I)$^+$] (**58**). Reduction of this zwitterion with KH in the presence of N_2 yielded the nitrogen compound **57**.[53]

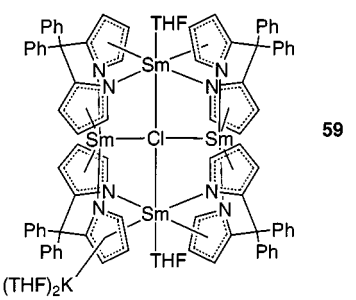


57

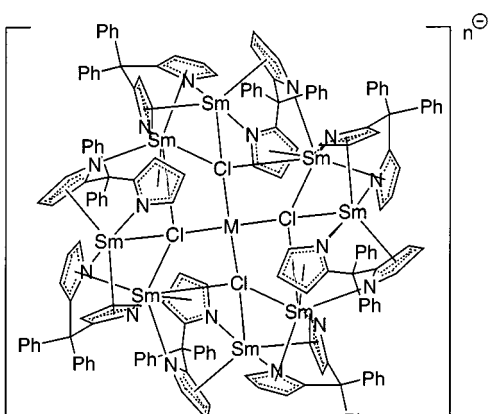


58

The reaction of K_2Dpdp with $SmCl_3(THF)_3$ gave a yellow compound (presumably [DpdpSmCl]) which was further reduced with alkali metals under argon; surprisingly, the outcome of this reduction was different, depending on the alkali metals used. With potassium, a tetrameric samarium(II) compound, [{(μ:η^5,η^1-Dpdp)Sm}$_4$(μ$_4$-Cl)K(THF)$_2$] (**59**), was obtained, which displays η^5-coordination of potassium with one pyrrolyl ring. With lithium and sodium, the reduction was not complete and mixed-valent $Sm^{II,III}$ octameric anionic complexes **60**, [{(μ:η^5,η^1-Dpdp)Sm}$_8$(μ$_4$-Cl)$_4$Li}$^{2-}$ · {$Li_2Cl(THF)_4$}$^+$ · {$Li(THF)_4$}$^+$], and **61**, [{(μ:η^5,η^1-Dpdp)Sm}$_8$(μ$_4$-Cl)$_4$Na}$^-$ · {$Na(THF)_5$}$^+$], respectively, were obtained. While the overall structures of **60** and **61** are similar, the reduction surprisingly occurred to a greater extent with lithium than with sodium since **60** displays one Sm^{III} and seven Sm^{II} atoms whereas in **61** there are two Sm^{III} and six Sm^{II} atoms. The reaction of **60** and **61** with KH in the presence of N_2 gave the above-mentioned tetranuclear Sm nitrogen complex **57**.[54]

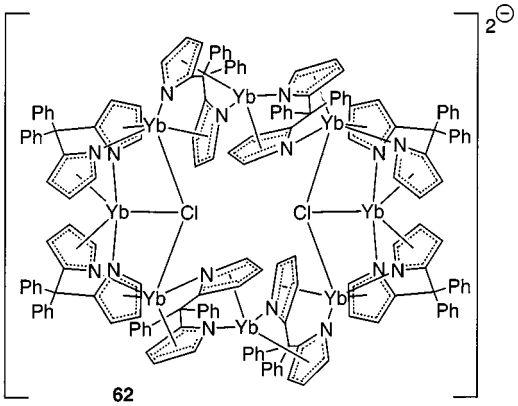


59

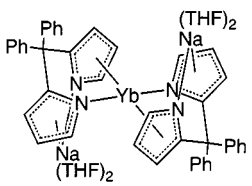


M = Li, n = 2 (**60**)
M = Na, n = 1 (**61**)

The reaction of Li_2Dpdp with $YbCl_3(THF)_3$ gave a yellow-orange compound (presumably [DpdpYbCl]) that was further reduced to Yb^{II} complexes with alkali metals. With lithium an octameric ytterbium(II) dianionic species, [{(μ:η^5,η^1-Dpdp)Yb}$_8$(μ$_3$-Cl)$_2$Li}$^{2-}$ · {[$Li(THF)_4$]$^+$}$_2$] (**62**) was obtained, whereas with sodium a monomeric ytterbate(II) complex, [(μ:η^5,η^1-Dpdp)$YbNa_2(THF)_4$] (**63**), was isolated displaying μ:η^5,η^1-type coordination both to ytterbium and to sodium.[55]

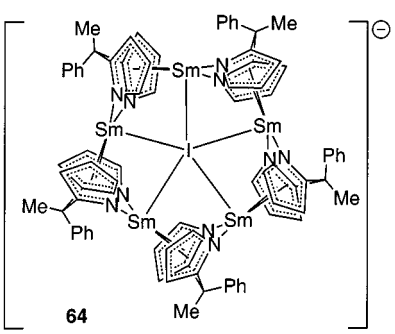


62

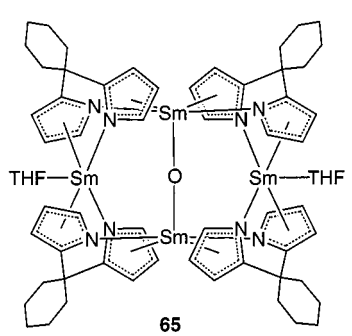


63

Structural variations of the dipyrrolyl ligand included the use of the Dpch and Dpet ligands in samarium chemistry. The reaction of K_2Dpet with $SmI_2(THF)_2$ gave a pentanuclear μ-iodo anionic complex, $[\{(\mu{:}\eta^5,\eta^1\text{-Dpet})Sm\}_5(\mu_5\text{-}I)^- \cdot K(THF)_6^+]$ (**64**), similar to that observed with the Dpdp ligand. Each metal centre is now π-bonded to pyrrolyl rings belonging to the same ligand. The results obtained with the Dpch ligands are different since reaction of K_2Dpch with $SmI_2(THF)_2$ or of Na_2Dpch with $SmCl_3(THF)_3$ followed by reduction with sodium metal afforded a mixed-valence complex, $[\{(\mu{:}\eta^5,\eta^1\text{-Dpch})Sm\}_4(\mu_2\text{-}O)(THF)_2]$ (**65**). Presumably, the oxygen atom comes from a THF molecule. It thus seems that the modifications on the ligand greatly affect the redox potential of the coordinated metal centres.[56]



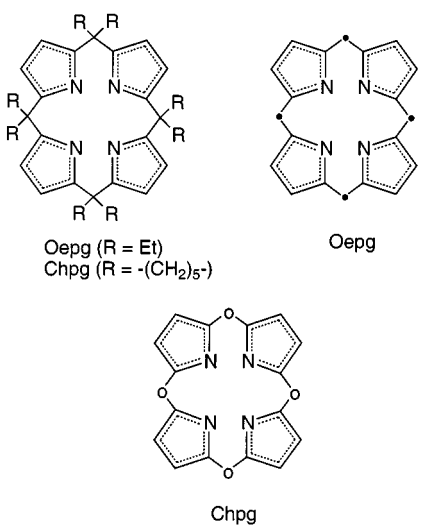
64



65

B. Macrocyclic Tetrapyrrolyl Complexes

Cyclic calix[4]tetrapyrrolyl (also called porphynogen) macrocyclic ligands have been used in lanthanide chemistry. These ligands provide a rather rigid environment in which the lanthanide metal centre can use most of its coordination sites, often in an $\eta^5,\eta^1,\eta^5,\eta^1$-coordination mode with the pyrrolyl rings, one or two coordination sites on the metal centre then being left for chemical transformations. In addition, the very electron-rich environment (up to four negative charges on the tetrapyrrolide anion) enhances the reactivity of the metal centre towards the activation of small molecules, as reported hereafter. Two ligands have been used, mainly octaethylporphynogen (Oepg) as well as cyclohexylporphynogen (Chpg) (Scheme 1).



Oepg (R = Et)
Chpg (R = -(CH$_2$)$_5$-)

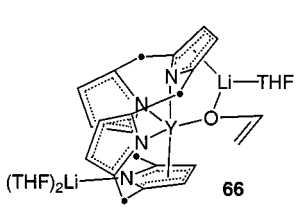
Oepg

Chpg

Scheme 1. For clarity, the following abbreviations are used in the subsequent schemes: • = C(Et)$_2$, o = C [−(CH$_2$)$_5$−]

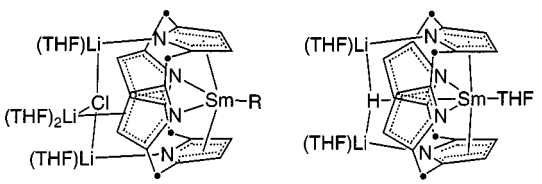
The outcome of the reaction of $LnCl_3$ with porphynogen anions depends very much on the nature of the counterion; the reactions of the lithium salts are described first.

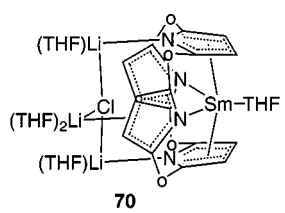
The reaction of $OepgLi_4$ with $YCl_3(THF)_{3.5}$ gave an enolate complex, $[Li(THF)_2(Oepg)Y(\mu\text{-}OCH{=}CH_2)Li(THF)]$ (**66**), in which the yttrium atom is $\eta^5,\eta^1,\eta^1,\eta^1$-bonded to the Oepg ligand. The enolate moiety probably arises from THF cleavage. Attempted substitution of this enolate with an alkyl or hydride group was unsuccessful and instead a lithium salt of the Oepg ligand, $[\{(Oepg)[Li(THF)]_4\}\{(THF)Li(OCH{=}CH_2)\}_2]$, was isolated[57].



66

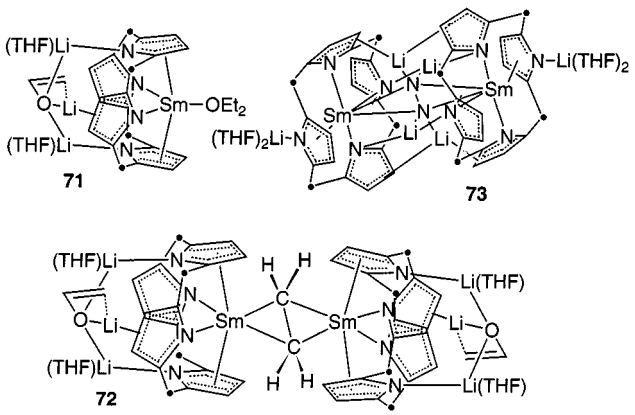
The reaction of $SmCl_3(THF)_3$ with $OepgLi_4$ or $ChpgLi_4$ gave $[(Oepg)ClSm(\mu_3\text{-}Cl)Li_3(THF)_4]$ (**67**) and $[(Chpg)ClSm(\mu_3\text{-}Cl)Li_3(THF)_4]$, respectively. In this case, the Sm atom displays $\eta^5,\eta^1,\eta^5,\eta^1$-coordination with the pyrrolyl ligands, and the lithium atoms are also bonded to the pyrrolyl groups. These compounds have a very rich chemistry: The reaction of $[(Oepg)ClSm(\mu_3\text{-}Cl)Li_3(THF)_4]$ with RLi gave the σ-bonded $[(Oepg)RSm(\mu_3\text{-}Cl)Li_3(THF)_4]$ [R = Me, vinyl (**68**)]. Treatment of $[(Oepg)RSm(\mu_3\text{-}Me)Li_3(THF)_4]$ with H_2 or phenylsilane afforded an Sm^{III} hydride, $[(Oepg)(THF)Sm(\mu_3\text{-}H)Li_2(THF)_2]$ (**69**), which could also be conveniently obtained from $[(Oepg)RSm(\mu_3\text{-}Cl)Li_3(THF)_4]$ by reaction with $LiAlH_4$. Compound **68** was thermally unstable and decomposed into an Sm^{II} complex, $[(Oepg)(THF)Sm(\mu_3\text{-}Cl)Li_3(THF)_4]$.[58]

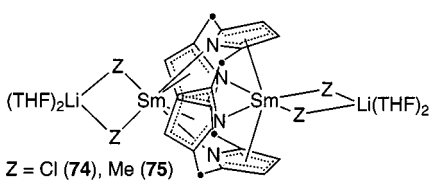


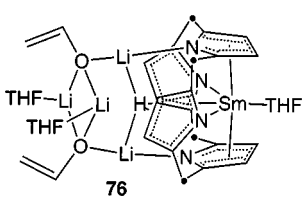


Similar μ_3-chloro−Sm^{II} complexes are also available by lithium reduction of the appropriate chloro−Sm^{III} complexes: Reaction of lithium with $[(Chpg)ClSm(\mu_3\text{-}Cl)Li_3(THF)_4]$ under argon gave $[(Chpg)(THF)Sm(\mu_3\text{-}Cl)Li_3(THF)_4]$ (**70**) while reduction of $[(Oepg)ClSm(\mu_3\text{-}Cl)Li_3(THF)_4]$ resulted in an μ_3-enolato−Sm^{II} complex, $[(Oepg)(Et_2O)Sm(\mu_3\text{-}OCH{=}CH_2)Li_3(THF)_2]$ (**71**), in which the enolate moiety is again likely to arise from THF cleavage. This complex **71** reversibly added ethylene to give an Sm^{III} dimer, $[\{(Oepg)Sm(\mu_3\text{-}OCH{=}CH_2)Li_3(THF)_2\}_2(\mu\text{-}CH_2CH_2)]$ (**72**), in which the ethylene has been formally reduced to its dianion as suggested by the long C−C bond (1.49 Å).[59] The reaction of lithium with $[(Oepg)ClSm(\mu_3\text{-}Cl)Li_3(THF)_4]$ [formed in situ by reaction of $SmCl_3(THF)_3$ and $OepgLi_4$] under nitrogen resulted in nitrogen reduction and the formation of an Sm^{III} complex containing a tetralithium hydrazide, $[\{(Oepg)SmLi\ (THF)_2\}_2(N_2Li_4)]$ (**73**), presumably through a transient Sm^{II} species which is reoxidized to Sm^{III} by means of an electron transfer to N_2.[60]

A different series of complexes was obtained when the reaction stoichiometry of Sm and Oepg is 2:1. The reaction of 2 equivalents of $SmCl_3(THF)_3$ with one equivalent of $OepgLi_4$ gave the dinuclear $[(Oepg)\{Sm(\mu\text{-}Cl)_2Li(THF)_2\}_2]$ (**74**) in which both Sm atoms are $\eta^5,\eta^1,\eta^5,\eta^1$-coordinated to the Oepg ligand. Permethylation of this complex with MeLi afforded $[(Oepg)\{Sm(\mu\text{-}Me)_2Li(THF)_2\}_2]$ (**75**). Hydrogenolysis of **75** did not give the expected result (replacement of the two μ-Me ligands by two μ-H ligands) but instead yielded the above-mentioned monosamarium hydride complex **69**. This complex **69** was also obtained by reduction of **74** with phenylsilane, but in this case a bis(μ-enolate) intermediate, $[(Oepg)(THF)Sm(\mu_3\text{-}H)Li_2(\mu_3\text{-}OCH{=}CH_2)_2Li_2(THF)_2]$ (**76**), was isolated.[61]

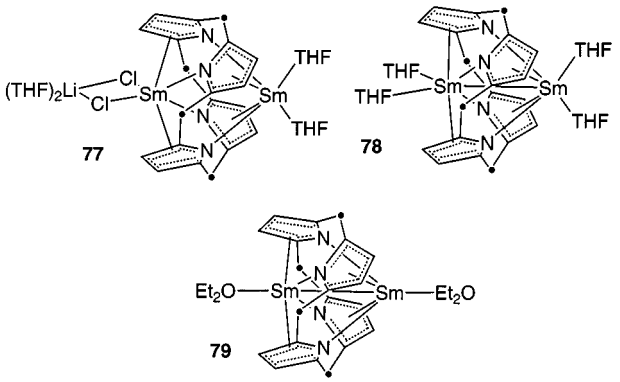




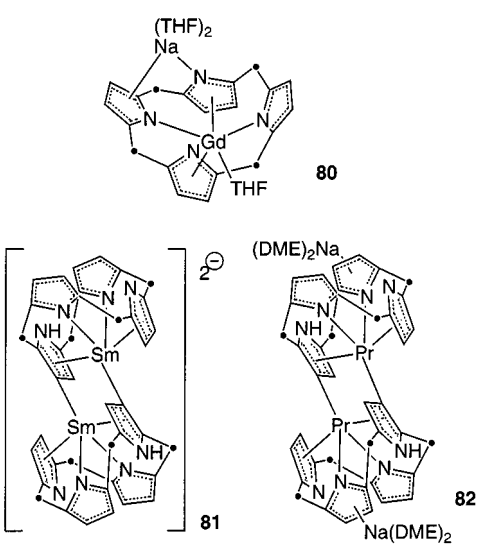


The reaction of **74** with $LiAlH_4$ did not give the expected dihydride either but instead reduction to Sm^{II} occurred. This reduction could be performed stepwise. Depending on the reaction conditions, a mixed-valent $Sm^{II,III}$ complex, $[(THF)_2Sm(Oepg)Sm(\mu\text{-}Cl)_2Li(THF)_2]$ (**77**), or a fully reduced Sm^{II} complex, $[(Oepg)Sm_2(THF)_4]$ (**78**), was obtained. This latter complex could also be made by lithium reduction of **74** or by the metathesis reaction of $OepgLi_4$ with $SmI_2(THF)_2$. The closely related $[(Oepg)Sm_2(Et_2O)_2]$ (**79**) could be prepared by the acid−base reaction of the Sm^{II} precursor, $[\{(TMS)_2N\}_2Sm(Tmeda)]$, with $OepgH_4$.[60b] All bimetallic Oepg−Sm complexes described above display a remarkably short Sm−Sm distance (3.30−3.40 Å), with the consequence that the magnetic moments of **78** and **79** (1.98 and 1.95 μ_B, respectively) are much lower than expected, presumably because of a magnetic interaction between the two Sm atoms.[61]

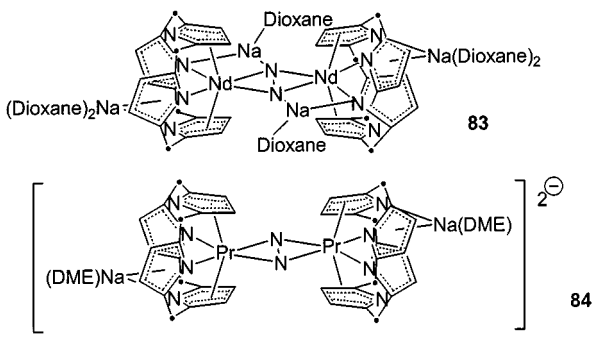
The reaction of the sodium salt of Oepg ($OepgNa_4$) with lanthanide halides provides an entry into yet another class of compounds. Here, the structure of the isolated products



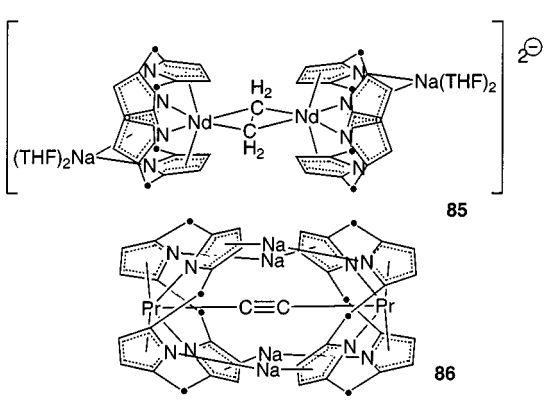
is very much dependent on the reaction conditions and in particular on the solvent used in the reaction and/or for recrystallisation. In all cases there are no anionic ligands other than the Oepg macrocycle bonded to the Ln metal centre (such as chloride or enolate as described above when $OepgLi_4$ was used as the precursor). In THF, the reaction of $OepgNa_4$ with $LnCl_3(THF)_n$ gave [(Oepg)Ln(THF)Na(THF)$_2$] [Ln = Pr, Nd, Sm, Eu, Gd (**80**), Yb], in which the ligand is $\eta^5,\eta^1,\eta^5,\eta^1$-coordinated to the lanthanide metal centre and the sodium is η^3-ligated to one of the pyrrolyl rings and η^1-bonded to a nitrogen atom on another. By recrystallisation from DME, striking structural changes occur and $[\{(Oepg)_2Ln_2\}^{2-} \cdot 2\ \{Na(DME)_3\}^+]$ [Ln = Pr, Nd, Sm (**81**) Eu, Gd] were obtained. In these compounds, the macrocyclic ring bonded to the lanthanide centre has dimerised, with the formation of an Ln−C(pyrrole) σ-bond owing to C−H activation by the Ln metal centre. Further recrystallisation of these complexes in THF, THF/DME, or THF/dioxane mixtures only affects the coordination mode of the sodium atom and the $(Oepg)_2Ln_2$ dimeric structure in $[\{(Oepg)_2Ln_2\}\{Na(S)_2\}_2]$ (Ln = Pr, Nd, Sm, Gd; S = DME or THF) (**82**: Ln = Pr, S = DME) and in the polymeric $[(\{(Oepg)_2Ln_2\}\{Na(THF)\}_2\{\mu\text{-Dioxane}\})_n]$ (Ln = Nd, Gd) is left intact. Thus, it appears that the Oepg dimerisation by C−H activation is essentially irreversible.[62]



The reaction of [(Oepg)Ln(THF)Na(THF)$_2$] with sodium naphthalenide in the presence of N_2 resulted in the reduction and formation of a diazenide dianion (N_2^{2-}) complexed to two OepgLn entities, $[\{[Na(THF)_2]_2(Oepg)Ln\}_2(\mu{:}\eta^2,\eta^2\text{-}N_2)]$ (Ln = Pr, Nd). Again, recrystallisation from donor solvents resulted in structural variations concerning the bonding properties of the sodium cation: In dioxane two sodium atoms are also bonded to the diazenide ligand in $[\{[Na(Dioxane)_2(Oepg)Nd(Dioxane)Na]_2(\mu{:}\eta^1\mathit{Na},\eta^2\mathit{Nd},\eta^1\mathit{Na}',\eta^2\mathit{Nd}'\text{-}N_2)]$ (**83**), while in DME only one sodium atom is bonded to the Oepg moiety in the anionic complex $[\{[Na(THF)_2(Oepg)Pr]_2(\mu{:}\eta^2,\eta^2\text{-}N_2)\}^{2-} \cdot 2\ \{Na(DME)_3\}^+]$ (**84**). Evidence for a diazenide is provided by the N=N bond length (1.24 Å).[63]



Similarly, reduction of [(Oepg)Ln(THF)Na(THF)$_2$] (Ln = Pr, Nd) with sodium naphthalenide in the presence of ethylene yielded $[\{[Na(THF)_2(Oepg)Ln]_2(\mu{:}\eta^2,\eta^2\text{-}CH_2CH_2)\}^{2-} \cdot \{Na_2(THF)(18\text{-}C\text{-}6)_2(\mu\text{-Dioxane})\}^{2+}]$ [Ln = Pr, Nd (**85**)] in which the ethylene has been reduced to ($CH_2CH_2^{2-}$) as indicated by the C−C single-bond length of 1.49 Å. Interestingly, these compounds could also be obtained from the above-mentioned diazenide complexes **83** and **84** simply by reaction with ethylene in the presence of [18-C-6]. The behaviour of [(Oepg)Ln(THF)Na(THF)$_2$] in the presence of sodium naphthalenide has been attributed to a reduction of these complexes to transient Pr^{II} and Nd^{II} species which are then able to activate small molecules such as N_2 or C_2H_4 by electron transfer.



When the [(Oepg)Ln(THF)Na(THF)$_2$] (Ln = Pr, Nd)/sodium naphthalenide methodology was applied to acetylene,

deprotonation occurred (not reduction) and the resulting acetylide led to the formation of $[\{(Oepg)LnNa_2\}_2(\mu\text{-}C{\equiv}C)]$ (**86**) in which four unsolvated sodium atoms and the C≡C unit are inserted as "spacers" between the two OepgLn units.[64]

Conclusion

The use of heterocyclopentadienyl ligands in group-3 metal chemistry has led to the formation of compounds with several coordination modes. Some of them exhibit remarkable reactivity, for instance, in the activation of small molecules (N_2 and ethylene) and in achieving transient uncommon low-valent oxidation states [Pr^{II}, Nd^{II}]. From here, there are some obvious challenges that for some of them will, undoubtedly, be met in the future.

The relatively electron-poor π-phospholyl ligand might be used to stabilise uncommon lanthanide(II) oxidation states such as Tm^{II}. There is also a clear synthetic challenge to include the phospholyl or other phosphorus-based ligands in the bridged or cavitand-like structures such as those used with the pyrrolyl ligand.

As far as nitrogen-based ligands are concerned, there still remains the objective of preparing a complex with an η^5-coordinated pyrazolyl ligand. The reactivity of the bridged or cavitand-like pyrrolyl complexes with other small molecules such as CO and CO_2 will certainly be investigated.

The actinide chemistry is relatively underrepresented, especially in the domain of the nitrogen-based ligands.

Finally, several reported complexes have great potential in catalytic applications.[65]

Stability of the Metal Configuration in Chiral-at-Metal Half-Sandwich Compounds

Henri Brunner[a]

Keywords: Chirality / Half-sandwich complexes / Metal configuration / Configuration determination / Fluxionality

Half-sandwich compounds with a three-legged piano-stool geometry are prominent examples of optically active chiral-at-metal complexes. In these compounds, the configuration at the metal atom may be stable or labile in solution. Configurationally stable compounds can be used for the elucidation of the stereochemical course of substitution reactions and for organic synthesis in ligand transformation reactions. With configurationally labile compounds, the rate of change of the metal configuration can be measured, which sets an upper limit with regard to the handling of the compounds in solution. Surprisingly, in a number of recent papers the lability of the metal configuration has been overlooked resulting in misinterpretations and wrong conclusions.

Introduction

Organometallic compounds of the transition elements with chiral metal atoms can be resolved with respect to the metal configuration for many different ligand combinations and geometries.[1−21] As discussed in a recent review,[1] pseudo-tetrahedral half-sandwich complexes with a three-legged piano stool geometry, as in $\boldsymbol{R}_{\mathrm{Mn}}$-**1** and $\boldsymbol{S}_{\mathrm{Mn}}$-**1**,[22,23] are prominent examples. For the specification of the metal configuration, see refs.[24,25]

In a classical resolution procedure, a racemic mixture is converted into a pair of diastereomers by introducing an enantiomerically pure auxiliary. The auxiliary is then removed from the separated diastereomers to give the resolved enantiomers. The ultimate goal of such a resolution is to obtain both enantiomers in pure form. Enantiomers have mirror image chiroptical properties but give identical NMR spectra; their NMR differentiation is only possible with the help of chiral shift-reagents.

Diastereomers differ in their physical properties, such as solubility, and usually also in their ^{1}H NMR spectra. Therefore, the progress of the diastereomer separation can be monitored by NMR spectroscopy and the diastereomer ratio can be determined by the integration of suitably resolved signals. Thus, the NMR spectrum of a given diastereomer shows whether the "other" diastereomer is present or absent, without the need for the addition of a chiral shift-reagent. As far as NMR differentiation is concerned, diastereomers thus contain more information than enantiomers.

In most of the organometallic compounds described herein, the optically active auxiliary is part of one of the ligands. Usually, it is not easy to remove the chiral auxiliary after diastereomer separation. Therefore, resolution proced-

Henri Brunner was born in 1935 and studied chemistry at the University of Munich. He obtained his Ph. D. (1963) under the supervision of E. O. Fischer. After a postdoctoral year at the University of California, Los Angeles, with Prof. H. D. Kaesz, he completed his "habilitation" at the TU Munich in 1969. In 1970, he became Chair of Inorganic Chemistry at the University of Regensburg, a position which he still occupies. His research fields concern the stereochemistry of organometallic compounds and reactions, enantioselective catalysis, and the use of platinum complexes in the chemotherapy of cancer. He has received several awards, most recently the German−French Alexander von Humboldt Award (1993), the Max Planck Award for International Cooperation (1997), and the Horst Pracejus Award of the German Chemical Society (1999).

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ures frequently stop after separation of the diastereomers, which differ only in the configuration at the metal atom.

In solution, the chiral-at-metal compounds behave differently. Some of them prove to be configurationally stable; their metal configuration does not change even at higher temperatures. Others are labile with respect to the metal configuration; the isomers interconvert at various rates. The solution behavior is in contrast to the behavior in the solid state. All of the organometallic compounds discussed herein are configurationally stable at the metal atom in the solid state, even those which are configurationally labile in solution. This fact was already emphasized in the very first study.[22] It is the configurational stability at the metal center in organometallic compounds in solution which is the key aspect of this Microreview. The configurational stability sets an upper limit with regard to the handling of a given compound in solution and to the conditions for its reactions in which the stereochemical course with respect to the metal center is to be elucidated. It also determines the accessible temperature range for measuring the kinetics of the change of the metal configuration. Another reason for taking up the issue of the stability of the metal configuration in this Microreview is its misinterpretation in a number of recent papers, which has led to wrong conclusions (see later).

Measurement of the Change of Configuration at the Metal Atom

The configurational change at the metal atom can be monitored by polarimetric measurements. In such measurements, enantiomeric complexes that contain only chiral metal atoms approach the 1:1 racemization equilibrium. Figure 1 shows the decrease in the optical activity and the approach to the racemization equilibrium $\boldsymbol{R}_{Mn}$-**2** $\leftrightharpoons$ $\boldsymbol{S}_{Mn}$-**2**.[26]

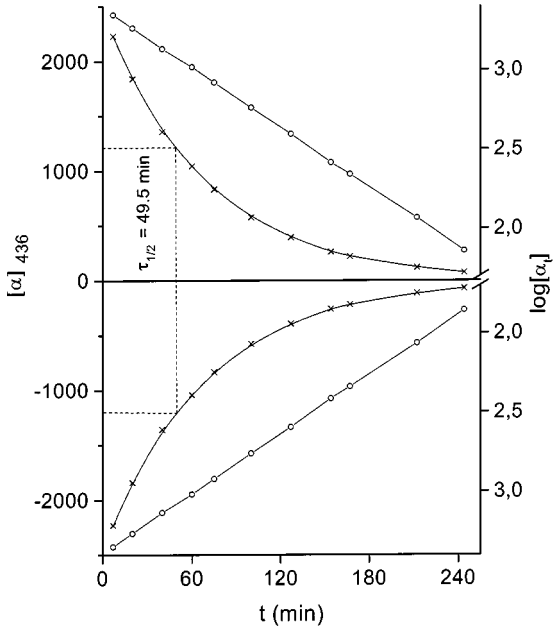

Figure 1. Racemization of $\boldsymbol{R}_{Mn}$-**2** and $\boldsymbol{S}_{Mn}$-**2** in toluene solution at 20 °C

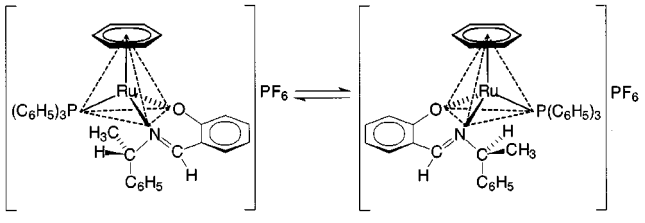
$\boldsymbol{R}_{Mn}$-**2** $\boldsymbol{S}_{Mn}$-**2**

If the diastereomers which are used in such polarimetric studies contain, besides the configurationally labile metal atom, configurationally stable asymmetric carbon atoms, the epimerization at the metal atom results in equilibria with nonzero optical rotations and equilibrium ratios displaced from 1:1. Under these circumstances, the equilibrium ratio of two diastereomers that differ only in the metal configuration gives a measure of the chiral induction of the enantiomerically pure ligand on the metal configuration under thermodynamic control.[15]

Because organometallic complexes of the transition elements are generally colored and absorb strongly in the visible region, the transparency in the polarimetric measurements is usually limited. Therefore, only dilute solutions can be studied, the air-sensitivity of which represents a possible source of error in such measurements.

Diastereomers such as $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**3** and $\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**3** differ in their ^{1}H NMR spectra.[27,28] Thus, the kinetics of the configurational change at the metal atom can be followed by time-dependent integration of suitable signals. In this technique, the quantities to be used are larger, the possibilities for the exclusion of air are better and, therefore, the results are more reliable than those obtained from polarimetry. Figure 2 shows the change in the concentration of the complexes $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**3** and $\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**3** as a function of time, as measured by ^{1}H NMR spectroscopy, during approach of the epimerization equilibrium $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**3**/$\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**3** = 95.8:4.2 in $CDCl_3$ solution, and its interpretation according to first-order kinetics.[27,28]



$\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**3** $\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**3**

In most cases, the configurational change at the metal atom is a first-order process. Therefore, a convenient measure of the configurational stability is given by the half-life $\tau_{1/2}$. The half-life for the approach to the racemization equilibrium of complexes $\boldsymbol{R}_{Mn}$-**2** and $\boldsymbol{S}_{Mn}$-**2** in toluene at 20 °C is 49.5 min,[26] while the half-life for the approach to the epimerization equilibrium of complexes $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**3** and $\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**3** (Figure 2) in $CDCl_3$ at 12 °C is 25 min.[27] Thus, a

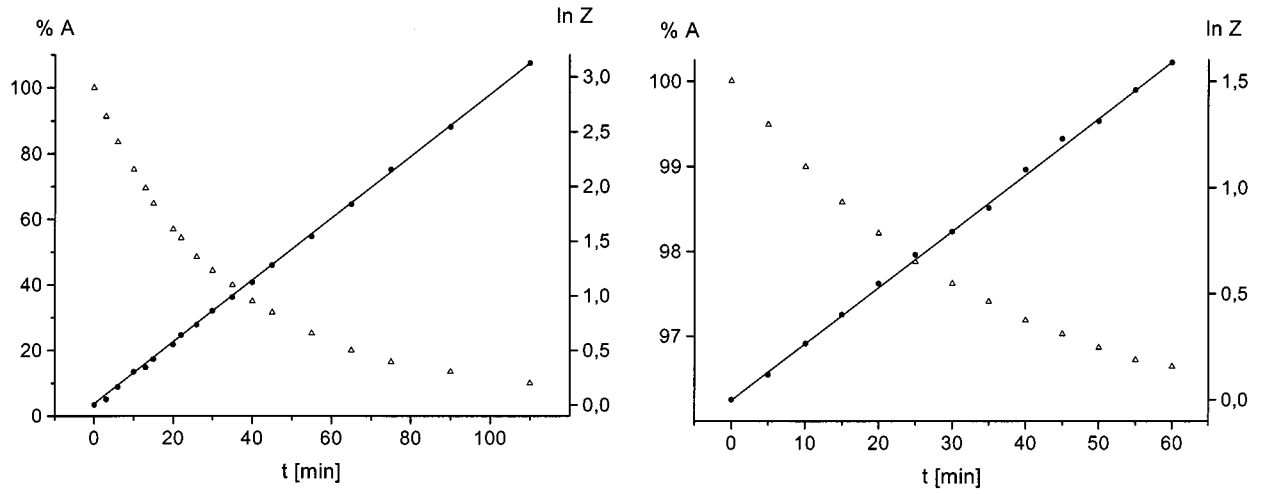


Figure 2. Epimerization of $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**3** (left side) and $\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**3** (right side) in $CDCl_3$ solution at 12 °C; left ordinates: $[A_t]$ by ^1H NMR integration; right ordinates: ln$Z$, where $Z = ([A_o] - [A_\infty])/([A_t] - [A_\infty])$

change in the configuration at the metal atom takes place in solution in both cases, although this is much faster for $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**3** and $\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**3** than for $\boldsymbol{R}_{Mn}$-**2** and $\boldsymbol{S}_{Mn}$-**2**.

As first-order reactions are not concentration dependent, the study of the racemization or epimerization kinetics is not restricted to pure enantiomers or diastereomers. Even samples only partly resolved, or those already partly racemized or epimerized, can be used to measure the change of a labile metal configuration, provided that the composition is sufficiently displaced from the equilibrium composition. The rate constant k, and from it the half-life $\tau_{1/2}$, are obtained from the function $\ln[(A_o - A_\infty)/(A_t - A_\infty)] = kt$, where A_o = starting concentration, A_t = concentration at time t, and A_∞ = equilibrium concentration after ten half-lives. By virtue of proportionality, instead of the concentrations A, the measured optical rotations of the sample or the integrals of suitable NMR signals can be used directly. For enantiomers, $A_\infty = 0$ and for diastereomers, $A_\infty \neq 0$. In order to dissect the first-order rate constant k for approach to equilibrium for diastereomers into k_1 and k_{-1} for the forward and backward reactions, respectively, and to determine the equilibrium constant K from the equilibrium optical rotation, the optical rotations of the pure diastereomers must be known. If the diastereomers differ in their ^1H or ^{31}P NMR spectra, these quantities can be directly determined by integration of the spectrum of an equilibrated sample. Thus, information concerning the change of the metal configuration can be obtained through studies of both the racemization of enantiomers and the epimerization of diastereomers.

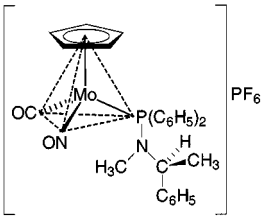
Half-Sandwich Complexes with Stable and Labile Metal Configurations

The first resolved organometallic compounds $\boldsymbol{R}_{Mn}$-**1**/$\boldsymbol{S}_{Mn}$-**1** are configurationally stable at the metal atom and do not undergo racemization in solution. They can be kept in CH_2Cl_2 for weeks without any decrease in the optical rotation.[23] On the other hand, the benzoyl compounds $\boldsymbol{R}_{Mn}$-**2**/$\boldsymbol{S}_{Mn}$-**2**, which are formed in the reaction of $\boldsymbol{R}_{Mn}$-**1**/$\boldsymbol{S}_{Mn}$-**1** with phenyllithium, are configurationally labile at the Mn atom (Figure 1).[26] Thus, compounds $\boldsymbol{R}_{Mn}$-**1**/$\boldsymbol{S}_{Mn}$-**1** and $\boldsymbol{R}_{Mn}$-**2**/$\boldsymbol{S}_{Mn}$-**2**, which were involved in the early studies of optically active organotransition metal compounds, are representative examples of the two alternatives, having stable and labile metal configurations, respectively. This makes it even more surprising that so many ambiguities have recently arisen regarding the stability of the metal configuration in similar compounds (see later).

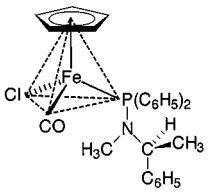
The configurational stability of the benzoyl complexes $\boldsymbol{R}_{Mn}$-**2** and $\boldsymbol{S}_{Mn}$-**2** can be tuned by *para*-substitution of the phenyl ring of the benzoyl ligand[26] and by *para*-substitution of the phenyl rings of the triphenylphosphane ligand.[29] An NMe_2 substituent on the benzoyl ligand reduces the half-life at 20 °C in toluene to 3.6 min, whereas a CF_3 substituent increases it to 418 min.[26] The same *para*-substituents have the opposite effect if they are attached to the phenyl rings of the triphenylphosphane ligand. As the benzoyl and triphenylphosphane ligands are on different sides of the critical bond, this indicates that it is the Mn−P bond that undergoes dissociation in the rate-determining step. CF_3 substituents in the *para*-position of the phenyl rings of the phosphane ligand give a half-life of 5.9 min, while OCH_3 substituents extend it to 337 min.[29] Hammett plots have been constructed for both series of compounds. Thus, a combination of an NMe_2 substituent on the benzoyl ligand and a CF_3 substituent on the triphenylphosphane ligand would give an extremely labile metal configuration, whilst the opposite combination should give the most stable compound in this series.[18] Obviously, knowledge of the half-life for the change of the metal configuration is important with regard to the handling of solutions of optically active compounds without appreciable loss of enantiomeric purity.

The aminophosphanes (*S*)-$Ph_2P-NH-CH(Me)(Ph)$ and (*S*)-$Ph_2P-N(Me)-CH(Me)(Ph)$ have proved to be versatile chiral phosphane ligands[30] akin to triphenylphosphane.[31]

The complex $\boldsymbol{R}_{Mo}\boldsymbol{S}_{C}$-**4**, containing (*S*)-$Ph_2P-N(Me)-CH(Me)(Ph)$ as the optically active auxiliary, is configurationally stable in solution even at higher temperatures.[32,33] In contrast, the chloro complex $\boldsymbol{R}_{Fe}\boldsymbol{S}_{C}$-**5**, a derivative of the same optically active aminophosphane ligand, is configurationally labile at the Fe atom. $\boldsymbol{R}_{Fe}\boldsymbol{S}_{C}$-**5** has a half-life of 181 min. at 20 °C in benzene solution, while the corresponding bromo compound epimerizes in the same solvent with a half-life of 185 min. at 45 °C.[34] With a half-life of 51 min. at 70 °C, the corresponding iodo compound has the highest configurational stability of the compounds CpFe(CO)Hal(aminophosphane).[35] The analogous compound CpFe(CO)Me(aminophosphane) epimerizes with respect to the iron configuration in benzene solution with a half-life of 70 min. at 70 °C.[36] However, the thermal epimerization of CpFe(CO)Me(aminophosphane) has to be distinguished from the epimerization induced by electron transfer (reaction with $[Cp_2Fe]PF_6$), which, at room temperature, is complete within five minutes.[36]

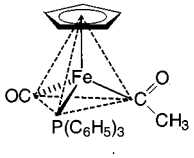


$R_{Mo}S_{C}$-**4**

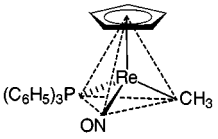


$R_{Fe}S_{C}$-**5**

The enantiomeric acetyl complexes $\boldsymbol{R}_{Fe}$-**6** and $\boldsymbol{S}_{Fe}$-**6**, which are configurationally stable at room temperature, have been developed as optically active auxiliaries for enantioselective organic synthesis.[7–11,37–40] These highly selective stoichiometric reagents are commercially available and allow the synthesis of a variety of compounds by virtue of the enolate chemistry of the acetyl substituent. Most of the $[CpRe(PPh_3)(NO)X]$ compounds[2,4,5] described by Gladysz, for example $\boldsymbol{S}_{Re}$-**7**,[41] are configurationally stable at the metal atom, even at higher temperatures. However, it cannot be ruled out that one or other of the compounds, reported to be configurationally stable, will start to racemize or epimerize at higher temperatures before decomposition occurs.



R_{Fe}-**6**

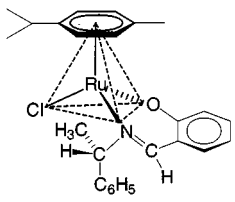


S_{Re}-**7**

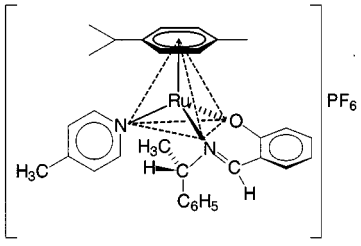
Whereas half-sandwich complexes of the three-legged piano-stool type racemize or epimerize through ligand dissociation, half-sandwich complexes of the four-legged piano-stool type, which are notoriously labile at the metal center, do so by intramolecular rearrangements without ligand dissociation.[1,3,14,17–19] These isomerizations at the metal atom can sometimes be investigated by ^1H NMR spectroscopy with the help of diastereotopic probes, a resolution with respect to the metal configuration being unnecessary. Such coalescence measurements are, however, restricted to relatively rapid reactions, in contrast to those that can be followed by time-dependent integration of suitable diastereomer signals. Half-sandwich complexes of the four-legged piano-stool type will not be considered further in this review.

Half-Sandwich (η^6-Arene)ruthenium Complexes

Recently, half-sandwich (η^6-arene)ruthenium(II) complexes have attracted much interest as catalyst precursors for organic transformations.[42] In 1991, Mandal and Chakravarty synthesized chiral-at-metal half-sandwich ruthenium compounds of the type $[(\eta^6\text{-cymene})Ru(LL^*)L']ClO_4$ and $[(\eta^6\text{-cymene})Ru(LL^*)Hal]$, with cymene = 1-isopropyl-4-methylbenzene and LL* = the anion of (*S*)-(1-phenylethyl)salicylaldimine. L′ was a unidentate ligand, such as triphenylphosphane or 4-methylpyridine, and Hal a halide ligand.[43] The complexes $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**8** and $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**9** are representative examples.

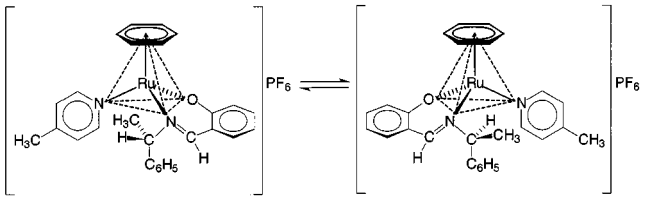


$R_{Ru}S_{C}$-**8**



$R_{Ru}S_{C}$-**9**

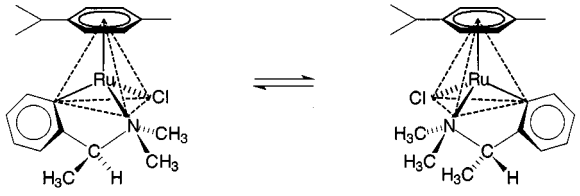
In subsequent studies, the stereochemistry of the substitution of the chloro ligand in $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**8** by other ligands was investigated,[44,45] for example, by 4-methylpyridine in the reaction $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**8** → $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**9**. Through not taking into account the configurational instability of their compounds, Mandal and Chakravarty made serious misassignments. What they referred to as "retention or inversion stereochemistry of substitution reactions" had actually nothing to do with the substitution reactions themselves. It only reflected the different stabilities of the diastereomers in the diastereomer equilibria, which were rapidly established before and after the slow substitution reactions. The terms "retention" and "inversion" imply that the reactions under consideration are kinetically controlled and that there is no prior or subsequent epimerization. However, compounds of the type $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**8** and $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**9** are configurationally labile at the metal center. Thus, the diastereomers $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**10** and $\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**10** of the benzene derivative $[(\eta^6\text{-}C_6H_6)Ru(LL^*)4\text{-Mepy}]PF_6$ interconvert through a change in the Ru configuration. The approach to the equilibrium $\boldsymbol{R}_{Ru}\boldsymbol{S}_{C}$-**10** ⇆ $\boldsymbol{S}_{Ru}\boldsymbol{S}_{C}$-**10** at −35 °C in acetone solution has a half-life of $\tau_{1/2}$ = 82 min.[46]



$R_{Ru}S_C$-10 $S_{Ru}S_C$-10

A similar equilibration is observed for [(η^6-cymene)Ru(LL*)4-Mepy]PF_6, the $\boldsymbol{R_{Ru}S_C}$-**9**/$\boldsymbol{S_{Ru}S_C}$-**9** equilibrium distribution at room temperature being 76:24 in [D_6]-acetone and 82:18 in $CDCl_3$.[47] These values do not prove predominant retention of configuration in the substitution of the chloro ligand by the 4-methylpyridine ligand in the reaction $\boldsymbol{R_{Ru}S_C}$-**8** → $\boldsymbol{R_{Ru}S_C}$-**9** as claimed by Mandal and Chakravarty. They give instead a measure of the different stabilities of the diastereomers in diastereomer equilibria such as $\boldsymbol{R_{Ru}S_C}$-**10** ⇆ $\boldsymbol{S_{Ru}S_C}$-**10**. After having uncovered these mistakes, the author's group published a corrigendum[47] including an appeal for the proper use of stereochemical terminology. Note that on going from $\boldsymbol{R_{Ru}S_C}$-**8** to $\boldsymbol{R_{Ru}S_C}$-**9** there is a change in the relative Ru configuration and simultaneously a change in the priority sequence of the ligands from cymene > Cl > O > N in $\boldsymbol{R_{Ru}S_C}$-**8** to cymene > O > N(imine) > N(4-methylpyridine) in $\boldsymbol{R_{Ru}S_C}$-**9**.

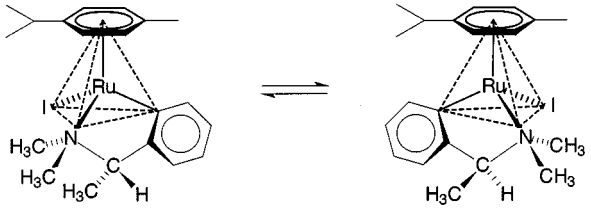
In 1995, Nelson and co-workers synthesized the compounds [(η^6-arene)Ru(LL*)Cl], with η^6-arene = benzene, toluene, cymene, and LL* = *ortho*-metalated (*S*)-*N*,*N*-dimethyl-1-phenylethylamine.[48] The parent compounds, from which all the other cymene complexes were derived, were the chloro complexes $\boldsymbol{R_{Ru}S_C}$-**11**/$\boldsymbol{S_{Ru}S_C}$-**11**.



$R_{Ru}S_C$-11 $S_{Ru}S_C$-11

The chloro complexes were obtained in a diastereomer ratio $\boldsymbol{R_{Ru}S_C}$-**11**/$\boldsymbol{S_{Ru}S_C}$-**11** = 87:13. Erroneously, the diastereomers $\boldsymbol{R_{Ru}S_C}$-**11** and $\boldsymbol{S_{Ru}S_C}$-**11** were described as being configurationally stable at the ruthenium center:[48] "the ^{1}H NMR spectra obtained in $CDCl_3$, [D_6]acetone, and CD_3NO_2 solutions.....are independent of time (days) and temperature (−20 to 50 °C), indicating their configurational stability". The authors must have used equilibrated samples for their NMR experiments at −20 °C, otherwise they would have noticed that it is in this temperature range that the Ru configuration starts to change. The author's group demonstrated that the half-life for approach to the equilibrium $\boldsymbol{R_{Ru}S_C}$-**11** ⇆ $\boldsymbol{S_{Ru}S_C}$-**11** at 4 °C in CD_2Cl_2 is 108 min. The half-life was found to be 9 min. at 11 °C, showing that solutions of the complexes cannot be handled at room temperature without rapid change of the metal configuration.[49]

The wrong assumption of configurational stability was repeated by Nelson's group in a paper published in 1996[50] and in three papers published in 1999.[51−53] Fatally, it was used as a basis for stereochemical assignments in substitution reactions, which were inevitably wrong. The authors cited our warning in ref.[47] but did not take it into account. For example, on addition of NaI to complexes $\boldsymbol{R_{Ru}S_C}$-**11**/$\boldsymbol{S_{Ru}S_C}$-**11** the iodo complexes $\boldsymbol{R_{Ru}S_C}$-**12**/$\boldsymbol{S_{Ru}S_C}$-**12** are formed in a reaction for which "predominant retention of configuration at ruthenium", was claimed.[50] This is true only in a strictly formal sense. However, as the authors presented associative, dissociative, and ring-slippage mechanisms at length, they definitely addressed the substitution reaction itself, which was as unjustified as it was in the case of Mandal and Chakravarty's work.



$R_{Ru}S_C$-12 $S_{Ru}S_C$-12
