1,1,1-Tris(aminomethyl)phenylmethane: 10% Pd/C (0.500 g) was added to a solution of 1,1,1-tris(azidomethyl)phenylmethane (1.28 g, 5 mmol) in anhydrous ethanol (25 mL) under argon. The solution was stirred under H_2 for 6 hours and then filtered through Celite, which was then washed with more ethanol. The solvent was removed under vacuum to yield 0.075g (99%) of a transparent oil. − $C_{10}H_{17}N_3$ (179.26): calcd. C 66.66, H 9.86, N 23.25; C 67.00, H 9.56, N 23.44. − ^1H NMR ($CDCl_3$): δ = 3.05 (s, 6 H, CH_2), 7.19−7.42 (m, 5 H, aromatics CH). − ^{13}C NMR ($CDCl_3$): δ = 45.4 (CH_2), 48.1 (C_6H_5-C), 125.2, 127.1 and 128.4 (aromatics CH), 141.7 (aromatic C).

1,1,1-Tris[di(*tert*-butylcarboxymethyl)aminomethyl]phenylmethane: 1,1,1-Tris(aminomethyl)phenylmethane (0.803 g, 4.72 mmol) was dissolved in acetonitrile (25 mL) by warming slightly. Potassium carbonate (7.834 g, 12 equiv.) and *tert*-butyl bromoacetate (11.056g, 12 equiv.) were then added and the solution stirred for one week at 60 °C. After cooling to room temperature the organic products were extracted with ethyl acetate. The organic layer was washed with saturated NaCl solution and dried with anhydrous sodium sulfate. After filtration the solvent was removed under vacuum to yield a crude oil, which was purified by column chromatography with silica gel and a cyclohexane/ethyl acetate gradient from 10:0 to 8:2. The product was obtained as an oil (0.590 g, 14.5%). MS (D/IC, NH_3 + isobutane): *m*/*z* = 864 $[M + 1]^+$. − ^1H NMR ($CDCl_3$): δ = 1.42 (s, 54 H, CH_3), 3.23 (s, 12 H, CH_2), 3.27 (s, 6 H, CH_2), 7.14−7.40 (m, 5 H, aromatics CH). − ^{13}C NMR ($CDCl_3$): δ = 28.18 (CH_3), 48.49 (C_6H_5-*C*), 56.44 (N*C*H_2CO_2tBu), 59.29 (C*C*H_2N), 80.40 [*C*(CH_3)$_3$], 125.82, 126.61 and 128.55 (aromatics CH), 144.69 (aromatic C), 171.19 (*C*O_2tBu).

1,1,1-Tris[di(carboxymethyl)aminomethyl]phenylmethane: 1,1,1-Tris[di(*tert*-butyl)aminomethyl]phenylmethane (0.200g, 0.232 mmol) in formic acid (5 mL, 97%) was stirred for three hours at 60 °C. The solvent was removed under vacuum and the residual product was dried overnight under vacuum to yield 0.120 g (98%) of product. − $C_{22}H_{29}N_3O_{12}\cdot 3H_2O$ (581.55): calcd. C 45.14, H 5.97,

N 8.70, O 36.63; C 45.43, H 6.02, N 7.23, O 41.30. Potentiometric analysis was consistent with this molecular weight. – ^{1}H NMR (D_2O, pD = 1.0): δ = 3.45 (s, 12 H, NCH_2CO$_2$H), 3.54 (s, 6 H, CCH_2N), 7.17–7.42 (m, 5 H, aromatics CH). – ^{13}C NMR (D_2O, pD = 1.0): δ = 48.00 (C_6H_5-*C*), 58.59 (N*C*H$_2$CO$_2$H), 63.30 (C*C*H$_2$N), 128.90, 130.79 and 132.06 (aromatics CH), 140.44 (aromatic C), 175.04 (CO$_2$ H). MS (FAB): *m*/*z* = 528 [M + 1]$^+$.

Potentiometric Titrations: All the measurements were made at 25 °C and the solutions were prepared with deionized and doubly distilled water. The ionic strength was fixed at I = 0.1 M with tetramethylammonium chloride (PROLABO puriss). The potentiometric titrations were performed using an automatic titrator system, DMS 716 Titrino (Metrohm), equipped with a combined glass electrode (Metrohm, filled with NaCl saturated solution) and connected to an IBM Aptiva microcomputer. The electrodes were calibrated to read pH according to the classical method.[13] The ligand and its metal(III) complex of ca. 0.001 M were titrated with standardized 0.025 M tetramethylammonium hydroxide. Argon was bubbled through the solutions to exclude CO_2 and O_2. Tetramethylammonium hydroxide solution was standardized against potassium hydrogenphthalate. Carbonate content was checked by Gran's method. The titration data were refined by the non-linear least-squares refinement program SUPERQUAD[6] to determine the deprotonation and/or stability constants (σ_{fit} in the range 1–5). Typically, about 150 data points were collected over the pH range 2.5–10.5 for the ligand solution and 100 points over the pH range 2.5–7 for the metal-ligand solution since precipitation occurred at a pH of about 7.5. The pK_{an} values were calculated from the cumulative constants determined by the program. The values of the stability constants are the mean values calculated from two or three titrations.

NMR Measurements: ^{17}O spectra (natural abundance) were recorded at 54.24 MHz on a Bruker AM 300 using 5 mm samples tubes. The ^{17}O shifts were referenced to the external $D_2{}^{17}O$ signal. The dysprosium-induced shifts (DIS) were obtained from the observed shift by making a correction for the bulk magnetic susceptibility of the solution. The solutions of the dysprosium complexes at a Dy^{III}/ligand molar ratio of 1 were prepared in doubly distilled water containing 20% D_2O. Concentrations ranged from 0.025 to 0.1 M. The pH was adjusted with tetramethylammonium hydroxide or HCl solution and measured by a pH meter employing a combined microelectrode and calibrated with standard buffers at pH 4.01, 6.86 and 10.01 from Polylabo.

Catalytic Activity Enhancement of a Cyclodextrin/Water-Soluble-Rhodium Complex System Due to its Gradual Supramolecular Organization in the Interphase

Michel Dessoudeix,[a] Martine Urrutigoïty,[a] and Philippe Kalck*[a]

Keywords: Biphasic catalysis / Cyclodextrins / Hydroformylation / Rhodium

Heavy terminal alkenes can be hydroformylated at a significant rate by using the water-soluble catalyst precursor $[Rh_2(\mu\text{-}S\textit{t}Bu)_2(CO)_2(TPPTS)_2]$ and β-cyclodextrin or its dimethylated form as phase-transfer agent. A study of the recycling has shown that the aqueous phase can be directly reintroduced into catalysis and also that each new run presents a slightly higher level of activity. Careful examination of the parameters of this catalysis leads us to propose that a gradual supramolecular organization in the interphase occurs for the rhodium complex, its solvation sphere and cyclodextrin which should involve at least two molecules in a head-to-tail or head-to-head arrangement.

Introduction

Homogeneous catalysts continue to play a prominent role as efficient tools to produce fine chemicals in enantioselective catalysis.[1,2] However, the separation of the catalyst from the reaction products is still one of the main concerns of chemists.[3] Among the various methods described in the literature,[3] the use of water soluble complexes with hydrophobic organic products, needing only a decantation step for the separation and the recycling of the catalyst, is increasingly popular. Nevertheless, for heavy substrates, the contact with the catalyst in the aqueous phase becomes the rate limiting step so that the use of cyclodextrins (CD's) as inverse phase-transfer agents appears to be an elegant way which preserves some economical viability.[4] Since the first report of the use of α-cyclodextrin in the hydroformylation reaction,[5] several studies have appeared to show that the transfer phenomenon is significantly enhanced between the organic phase and the aqueous phase where the catalyst is maintained.[6] In fact, it has been shown that CD — which is soluble in water but has poor solubility in polar solvents — forms inclusion complexes with both the substrate and the products transferring them into the aqueous phase. More recently, the efficiency of this process has been attributed to the greater complexation coefficient of the CD with the substrate than with the product.[7]

We have investigated the role of β-cyclodextrin and dimethyl-β-cyclodextrin in the biphasic low-pressure hydroformylation reaction of heavy alkenes catalyzed by the water-soluble complex $[Rh_2(\mu\text{-}S\textit{t}Bu)_2(CO)_2(TPPTS)_2]$. Various alkenes have been used as representative elements of heavy molecules and they range from C_8 to C_{18}. All the parameters of this reaction have been considered and their influence on the conversion rate and the regioselectivity analyzed. Moreover, the recycling of the aqueous phase containing both the catalyst and the cyclodextrin has been studied.

Results and Discussion

The general procedure adopted in the present experiments is 5 bar for the total pressure of a 1:1 H_2/CO mixture, a temperature of 80 °C and a stirring rate, for the mechanical stirrer of the autoclave, of 1870 rpm, i.e. in a chemical regime where the conversion rate does not depend on the stirring. Thus, the mass transfer of the substrate from the organic phase to the aqueous phase in which catalysis occurs remains constant. The stirring rate was adjusted to the same value from one experiment to another so that this parameter is not involved in the following discussion and does not affect the parameters which are analyzed.

We can recall[8] that, in the absence of cyclodextrin, oct-1-ene, whose solubility in water is only 2.07×10^{-3} g/L, is slowly transformed into the corresponding C_9 aldehydes since the yield is 11% in 20 h; the selectivity of *n*-nonanal vs. 2-methyloctanal is as high as 98% and is characteristic of a catalysis in pure water. After the addition of cyclodextrin in a oct-1-ene/cyclodextrin molar ratio of 28 and a β-CD/rhodium molar ratio of 18.4, the conversion rate reaches 26%, as shown in Table 1, and the linearity decreases to 88.5%. Such a lowering of the regioselectivity indicates that the medium where the catalytic activity of the system occurs is no longer completely aqueous and is, in fact, intermediate between aqueous and purely organic, since in a pure toluene phase previous experiments have shown a 75% selectivity. In Table 1 we have examined the effects of the chain length on the conversion. For dec-1-ene, the yield decreases to 6.2%, whereas the selectivity for the linearity is 90.2%. However, for higher alkenes, the reactivity is very modest and lies between 1 and 2% for C_{18} to C_{12} alkenes.

In order to improve significantly the mass transfer, we have used dimethylated-β-cyclodextrin (DM-β-CD) which

Table 1. Evolution of the yield and the linearity as a function of the number of carbon atoms of the alkene; reaction conditions: P_T = 5 bar, T = 80 °C, time = 18 h, catalyst = 0.25 mmol, P/Rh = 10, H_2O = 40 mL, alkene = 64 mmol, β-CD = 2.3 mmol, DM-β-CD = 2.6 mmol

Number of carbon atoms	β-CD		DM-β-CD	
	Yield (%)	Linear aldehyde (%)	Yield (%)	Linear aldehyde (%)
8	26.2	88.5	59.1	88.7
10	6.2	90.2	50.7	90.2
12	2.1	n. d.	30.1	93.2
14	1.6	n. d.	8.3	85.5
16	1.4	n. d.	5.3	79.1

is much more soluble in water than β-CD itself (590 and 18.5 g/L, respectively). These results are displayed in Table 1. For oct-1-ene the conversion is greatly improved since it reaches 59.1%, instead of 26% for β-CD, the linearity being unchanged. In addition dec-1-ene and dodec-1-ene are readily transformed whereas the C_{14} and C_{16} alkenes are still converted but at a lower rate. In fact, the distinct behavior between β-CD and its dimethylated form stems mainly from the differences which exist in the hydrogen-bond network and in their steric hindrance, β-CD being rigid and DM-β-CD showing a significant flexibility. In fact, it seems that the height of the CD's and the size of the cavity play a dramatic effect along the chain length for its inclusion inside the cavity to a greater or lesser extent by minimizing the hydrophobic effect. Such a fitting allows the aliphatic chain to be coiled up with mainly the carbon−carbon double bond emerging from the torus. These results show that DM-β-CD rapidly transforms various heavy alkenes as opposed to β-CD which cannot convert an alkene heavier than oct-1-ene. We have checked that, in an equimolar mixture of C_8, C_{10} and C_{12} alkenes, β-CD discriminates in favor of oct-1-ene since 70% is converted.

The influence of the quantities of the two cyclodextrins introduced has been investigated in a wide range. Table 2 displays the yields, the selectivities in linear aldehyde and the turnover frequencies when β-CD is progressively added. β-CD begins to precipitate at 2.3 mmol. Of course, beyond this value the yields remain constant.

Table 2. Influence of the quantity of β-cyclodextrin on the yield and the linearity during the hydroformylation of oct-1-ene; reaction conditions: P_T = 5 bar, T = 80 °C, time =18 h, catalyst = 0.25 mmol, P/Rh = 10, H_2O = 40 ml, oct-1-ene = 64 mmol

β-CD (mmol)	Yield (%)	Linearity (%)	TOF (h^{-1})	TOF/β-CD ($h^{-1} \times mmol^{-1}$)
0	2	98	0.6	–
0.44	6	98	1.8	4.1
0.88	10.2	97	3.0	3.4
1.32	14.1	95	4.2	3.2
1.76	19.2	93	5.7	3.3
2.20	26.2	88.5	7.8	3.5
4.41	30.1	87.2	9.0	2.0

As shown in Figure 1, variation of the yield with the amounts of added cyclodextrin occurs almost linearly until a plateau is reached beyond 2.3 mmol. Similarly, the linearity decreases slowly from 98% (in the absence of β-CD) to 88% near to the 2.3 mmol point. It occurred to us to investigate the turnover frequencies calculated per mol of CD versus the quantities of β-CD, thus expressed in h^{-1} per mol (last column in Table 2). Instead of the expected straight line, we observed that the curve decreases until it reaches a minimum near 1.5 mmol (Figure 2), then increases to a local optimum value of 2.3 mmol.

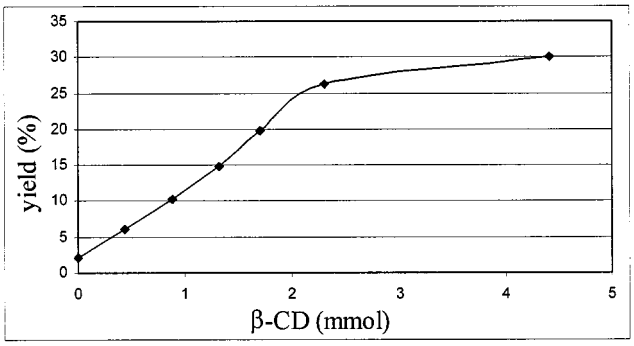

Figure 1. Variation of the yield versus quantity of β-CD

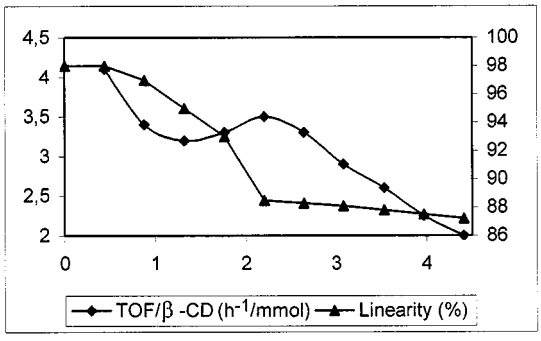

Figure 2. Curves of the TOF/β-CD and the linearity as a function of the quantity of β-CD

This phenomenon seems to be directly connected to the concentration of β-CD in the medium. An organization of the solvation sphere of the cyclodextrin should give a regular effect. We suggest that the observed effect could result from a particular arrangement of several cyclodextrin units. First, a decrease of the curve is consistent with an inhibiting effect which could be due to two CD's encapsulating one guest in a head-to-head manner.[9,10] The optimum value

Table 3. Evolution of the yield, the linearity and the TOF during recycling; reaction conditions: P_T = 5 bar,; T = 80 °C, time = 18 h, catalyst = 0.25 mmol, P/Rh = 10, H_2O = 40 mL, alkene = 64 mmol, DM-β-CD = 3.05 mmol

Recycling	Oct-1-ene			Dec-1-ene		
Yield (%)	Nonanal (%)	TOF (h^{-1})	Yield (%)	Undecanal (%)	TOF (h^{-1})	
0	65.9	85.0	19.7	65.5	89.7	19.6
1	80.0	88.6	23.9	69.1	89.3	20.6
2	87.5	86.8	26.1	73.0	88.8	21.8
3	91.1	85.7	27.2	84.7	87.6	25.3

should correspond to a peculiar arrangement of two or three β-CD's giving rise to a kind of tunnel, as already mentioned in the literature for the head-to-tail encapsulation of very large molecules.[11,12] The further decrease in the curve is due to the precipitation of β-CD (in the calculations the full quantity of β-CD has been introduced).

When the regioselectivity is considered, it is clear that the selectivity in linear aldehyde decreases dramatically for increasing amounts of β-CD. This unexpected decrease of the selectivity curve shows the role of the steric hindrance of the β-CD on the C=C double bond: in our opinion it is more and more included in the CD cavity thus providing preferential access of the terminal carbon to the hydride ligand in the step where the rhodium-alkyl species is formed (Figure 3). If the aim is to obtain the better yields of linear aldehydes, an examination of Figure 2 shows that a good compromise between the yield and the linearity lies in the range 1.76−2.20 mmol of β-cyclodextrin.

DM-β-CD shows similar trends, but for oct-1-ene, due to its too short chain length, only the inhibiting effect is observed, whereas for dec-1-ene and dodec-1-ene, the TOF/DM-β-CD versus the quantity of DM-β-CD remains constant, although a slight increase can be noted in the latter case. Here, the chain length is more adapted to the depth imposed by the arrangement of the two CD's. Except for oct-1-ene, which becomes more included inside the organophilic cavity and for which the linearity decreases as expected for an organic environment,[13] the linearity of the aldehydes formed from dec-1-ene and dodec-1-ene remains almost invariant showing once again the mutual adaptation of the two DM-β-CD's framework and these two alkenes.

Whereas recycling a catalyst produces generally either no variation in the yield or a decrease in the catalytic activity, we observed, on four successive runs, an important enhancement of the yield, with the linearity being almost the same (Table 3 and Figure 2).

Such an increase in the catalytic activity along the recycling means that the system keeps a sort of a local organization which improves the contact between the reactants. Indeed, from one run to the next, after decantation, the aqueous phase is directly recycled with no further work up. Thus, as this phase contains the cyclodextrin and the water-soluble rhodium complex, such a direct reintroduction does not disrupt the arrangement gained by the catalyst/cyclodextrin/substrate/solvent system during the previous run. The association of two cyclodextrin units, head-to-head or head-to-tail, is consistent with this hypothesis. We need also to consider how the organic/aqueous volume around the DM-β-CD/ $[Rh_2(\mu\text{-}S\textit{t}Bu)_2(CO)_2(TPPTS)_2]$ couple is organized. Indeed, the internal secondary alcohol groups inside the DM-β-CD torus are considered as hydrophobic whereas the external primary alcohol functions are compatible with the approach of water molecules. However, near the entrance of the cavity a mixed volume should be present containing toluene and water, especially at 80 °C, a temperature for which we are near the heteroazeotropic composition; the relative concentration of both solvents should vary, of course, inside this volume. The arrangement should associate the rhodium complex and the external part of the cyclodextrin(s) in the water-rich area and the alkene in the organic-rich part of this volume. Thus, such an organization could improve the transfer phenomenon from one run to the next. This system could possibly migrate more rapidly near the interface giving rise to a more efficient transfer of the alkene from the organic phase to the so-called aqueous phase. Such a view is not inconsistent with the association of two cyclodextrin units.

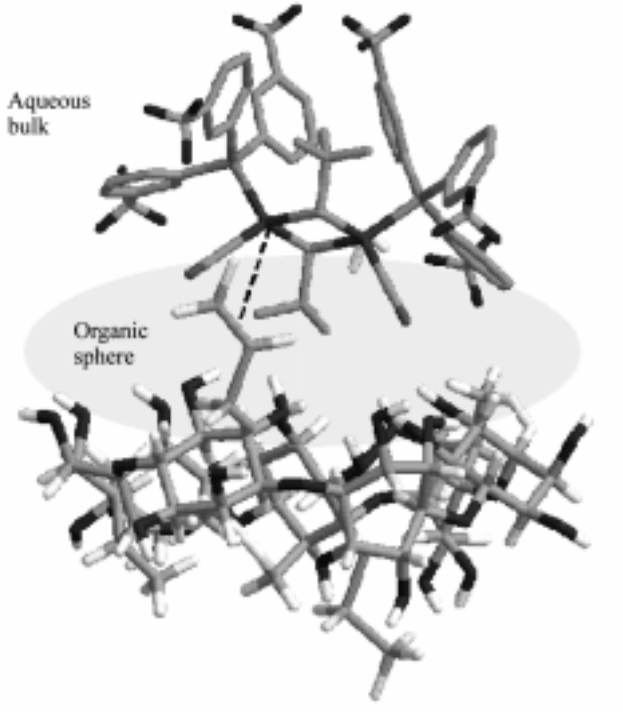

Figure 3. Scheme of the hydroformylation of oct-1-ene, using cyclodextrin, in the organic sphere

Conclusion

We can conclude that a solvation sphere is gradually organized in the volume where the cyclodextrin improves the contact between the carbon-carbon double bond and the rhodium center of the catalyst (Figure 3). This specific volume can be viewed as a supramolecular microreactor.

Experimental Section

Starting Materials: All reagents were purchased from Aldrich and used without further purification. Cyclodextrins are a generous gift from Wacker Chimie S.A. and tris(*m*-sodiumsulfonatophenyl)phosphane (TPPTS) a gift from Hoechst (Ruhrchemie). Rhodium trichloride trihydrate is a generous loan from Engelhardt-Comptoir-Lyon-Alemand-Louyot. The complex $[Rh_2(\mu\text{-}StBu)_2(CO)_2(TPPTS)_2]$ was prepared as previously described.[14]

Biphasic Catalysis: In a typical run, $[Rh_2(\mu\text{-}StBu)_2(CO)_2(TPPTS)_2]$ (0.25 mmol, 0.42 g) and TPPTS (4.5 mmol, 2.8 g) were dissolved in 40 mL of deaerated water in a Schlenk tube, and then 64 mmol of alkene was added. The reactor was evacuated and the solution introduced by suction. The reactor was then heated to 80 °C (preheated oil bath) under mechanical stirring (1870 rpm). When the temperature of 80 °C was reached, the autoclave was pressured with 5 bar of an equimolar CO/H_2 mixture. During the catalytic test, the pressure was kept constant and equal to 10 bar inside the reactor. After 18 h, the gas mixture feed was stopped and the reactor cooled to room temperature. The gas present inside the reactor was then slowly evacuated. After opening the reactor the biphasic solution was transferred by suction into a round-bottom flask and placed under nitrogen.

GPC: After catalysis the organic phases were analyzed by gas phase chromatography on a Carlo Erba HRGC 5160 apparatus equipped with a flame ionization detector and a capillary column Alltech Econocap FFAP (30m; 0.53 mm; 1.2μm), T_{det} = 200 °C, P_{H_2} = 0.5 bar.

Infrared Spectroscopy: Infrared spectra were recorded on a Perkin−Elmer 1710 FTIR apparatus.

Unique Evidence for a Rh^{III} to Rh^{I} Reduction by Deoxygenation of a Carbonate Moiety to CO_2 by an Out-of-Sphere Phosphane

Michele Aresta,[a] Angela Dibenedetto,[a] and Immacolata Tommasi*[a][‡]

Keywords: Carbon dioxide / Deoxygenation / Redox chemistry / Rhodium / Phosphanes

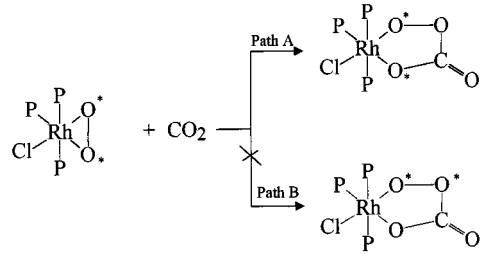
Rh^{III} carbonate generated from either a peroxocarbonate complex $[RhCl(CO_4)(PR_3)_3]$ or $[RhCl_3(PR_3)_3]$ and Na_2CO_3, is reduced to Rh^{I} by deoxygenation of the carbonate moiety to CO_2 by an out-of-sphere phosphane. The reaction takes place in mild conditions and is implied in the catalytic activity shown by Rh^{I} in the oxidation of styrene with O_2/CO_2 mixtures.

Introduction

Transition metal peroxo-carbonates have been known for some time.[1,2] They are usually prepared by reaction of metal dioxygen complexes with CO_2. Accordingly, Rh^{III} peroxocarbonates are easily obtained according to Equation (1). Alternatively, transition metal carbon dioxide complexes can react with dioxygen[3,4] to afford peroxocarbonates.

$$P_3RhCl + O_2 \longrightarrow P_3RhCl(O_2) \xrightarrow{CO_2} P_3RhCl(CO_4) \qquad (1)$$

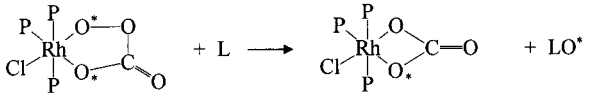
By using labelled species, we have recently shown that CO_2 reacts with $Rh(\eta^2\text{-}O_2)$ complexes by insertion into the O−O bond (Scheme 1, path A), rather than by insertion into the M−O bond (Scheme 1, path B).[5] The reaction pathway has been demonstrated through coupling an IR theoretical study (calculation of the vibrational frequencies of selected bonds of the peroxocarbonate complexes) with experimental vibrational frequencies. The latter match the values calculated for the species obtained assuming CO_2 insertion into the O−O bond (± 2 cm^{-1})[5] better than those of products originating from CO_2 insertion into the M−O bond. This reaction has also been modelled using the Impulse Oscillation Model, IOM,[6−8] which assumes that the vibrations of the metal-dioxygen complex and CO_2 must be synchronised in order for the insertion reaction to occur. IOM unequivocally shows that path A is preferred (up to 92% selectivity) over path B.[9,10]



Scheme 1. Alternative pathways for CO_2 reaction with a Rh dioxygen complex

Very interestingly, the reaction of carbon dioxide metal complexes with dioxygen to afford peroxocarbonates proceeds through the substitution of coordinated CO_2 by dioxygen and subsequent insertion of CO_2 into the O−O bond of the newly formed dioxygen complex.[11]

We have also shown that peroxocarbonates may act as selective one-oxygen transfer agents to an oxophile (Scheme 2).[12−15] By using asymmetrically labelled species, we have demonstrated that the oxygen bonded to the metal is the atom of the peroxo group transferred to the oxophile.[5] The Rh peroxocarbonate is thus converted into a Rh^{III} carbonate complex.



2 **3**

Scheme 2. One-oxygen transfer from the peroxocarbonate moiety to an oxophile

It should be noted that when the peroxocarbonate $[RhCl(CO_4)(PEt_2Ph)_3]$ acts as a one-oxygen transfer agent, the starting Rh^{I} complex $[RhCl(PEt_2Ph)_3]$ is found along with other compounds that undoubtedly originate from the peroxocarbonate. In principle, the Rh^{I} complex could be produced from the peroxocarbonate if the reaction in Equation (1) is reversible.

In an attempt to demonstrate if such a hypothesis holds or not, we have carefully investigated the reaction and have unequivocally shown that $[RhCl(PEt_2Ph)_3]$ originates from Rh^{III} carbonate $[RhCl(CO_3)(PEt_2Ph)_3]$, through an unprecedented carbonate deoxygenation to carbon dioxide promoted by an external phosphane. We describe in this paper some properties of Rh peroxocarbonate **2** and the reduction

of carbonate **3** to $[RhCl(PEt_2Ph)_3]$. The latter reaction has also been performed using an external carbonate source (Na_2CO_3, Ag_2CO_3) and a Rh^{III} chloride complex.

Results and Discussion

Rh^{III} peroxocarbonate was prepared by reaction of $[RhCl(PEt_2Ph)_3(O_2)]$ with CO_2 at 240 K in toluene[4,5] according to Equation (1). The pure compound is quite stable at low temperature (below 240 K) in the solid state for several days or for several minutes at a temperature as high as 340 K (see Experimental Section). Conversely, in solution above 250 K, or in the solid state at 323 K in the presence of an external phosphane, or any other species that may interact with the Rh centre, it readily reacts and transfers one oxygen atom to an oxophile to afford the carbonate complex **3** (Scheme 2). It is worth recalling that olefins and tetrahydrofuran can be oxidised in this way under mild conditions by Rh peroxocarbonates.[13]

When pure **2** is dissolved in CH_2Cl_2 at 250 K, the ^{31}P NMR spectrum unequivocally shows the conversion of the peroxocarbonate (Figure 1, spectrum A) into a number of other species (Figure 1, spectrum B). These have all been identified by comparison with the spectra of authentic samples. Resonances a−g have been assigned as follows: (a) assigned to the $O{=}PEt_2Ph$ species; (b) and (e) assigned to the *mer*-$RhCl(CO_3)(PEt_2Ph)_3$ species; (c) and (f) assigned to the *mer*-$RhCl(CO_4)(PEt_2Ph)_3$ species; (d and g) assigned to the *mer*-$RhCl_3(PEt_2Ph)_3$ species (see Experimental Section).

It is evident from these data that **2** behaves differently whether it is pure or is in the presence of external ligands or a solvent. Moreover, the fact that a coordinated phosphane is not oxidised (we recall that pure **2** is stable up to 345 K), demonstrates that the O-transfer process is intermolecular, not intramolecular.

The reactivity in the solid state and in solution find a common basis of interpretation. However, in solution the oxygen transfer is promoted by the solvent, which causes the phosphane dissociation (Scheme 3, path a).

The out-of-sphere phosphane formed in solution attacks the peroxo group affording carbonate and phosphane oxide (Scheme 3, path a). The latter may be found free in solution or coordinated to Rh, according to the nature of solvent.

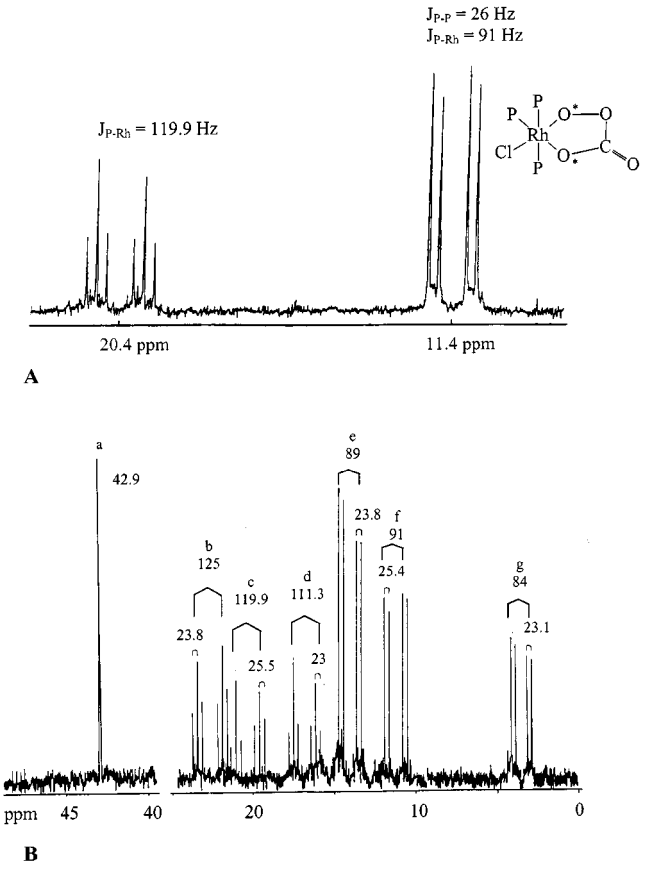

Figure 1. Spectrum A: ^{31}P NMR spectrum (213 K, CD_2Cl_2) of $[RhCl(CO_4)(PEt_2Ph)_3]$; spectrum B: ^{31}P NMR (CD_2Cl_2) spectrum of the solution from A warmed to 250 K

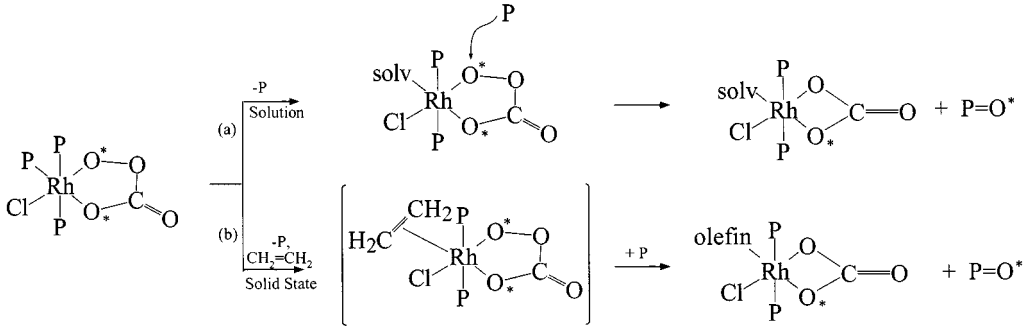
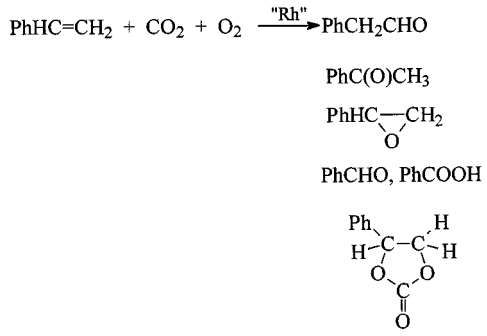
However, when solid Rh peroxocarbonate is warmed to 340 K with an equimolar amount of ethylene, phosphane is slowly released and then rapidly oxidised by the peroxocarbonate to Et_2PhPO (Scheme 3, path b). The selectivity of phosphane oxidation with respect to ethylene is 100%, as demonstrated by the gas-phase analysis which does not show the presence of ethylene oxidation products. The role of ethylene is therefore that of favouring the phosphane release from the Rh coordination sphere. Conversely, if more reactive olefins like styrene are used, in excess with respect to the stoichiometric ratio and under CO_2/O_2 atmosphere, they can be oxidised in solution by Rh peroxocarbonates (Scheme 4).



Scheme 3. Reactivity of $[RhCl(CO_4)(PR_3)_3]$ in solution (path a) and in the solid state in the presence of ethylene (path b)

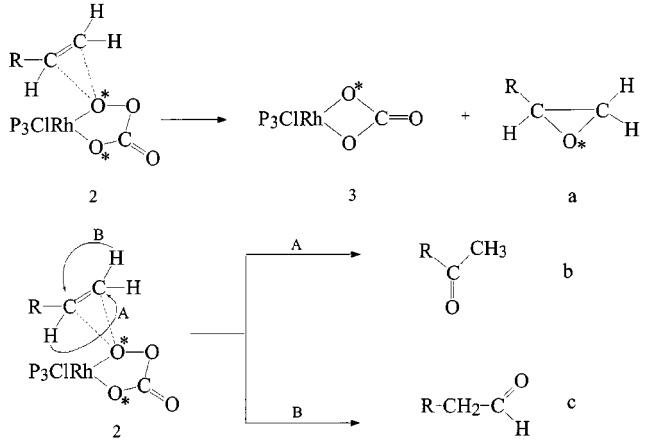


Scheme 4. Reaction of styrene with a CO_2/O_2 mixture promoted by Rh^{I}

Styrene is converted into a mixture of phenylacetaldehyde, phenylmethylketone and styrene epoxide, as major products, along with benzaldehyde which is produced by the cleavage of the styrene C−C double bond by O_2. It is worth noting that Rh peroxocarbonates and Rh dioxygen complexes show a different behaviour towards styrene oxidation.[5,13−18] While the dioxygen complex causes the cleavage of the double bond [Equation (2)], the peroxo-carbonate promotes a one-oxygen transfer to the olefin, mimicking mono-oxygenase enzymes (Scheme 4).

$$RHC{=}CH_2 + O_2 \longrightarrow RHCO + H_2CO \qquad (2)$$

The formation of the ketone and phenylacetaldehyde can be explained assuming a hydrogen shift promoted by the metal centre (Scheme 5).



Scheme 5. Formation of ketone and terminal aldehyde by H-migration promoted by Rh^{I}

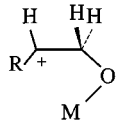
In such an oxidation reaction, if Rh complexes stabilised by monodentate P ligands are used, the catalyst has a lifetime of less than one hour. In fact, the reaction with the olefin releases the phosphane, which is easily oxidised according to Equation (3):

$$\underset{\mathbf{2}}{(PEt_2Ph)_3RhCl(CO_4)} + \text{olefin} \longrightarrow (\text{olefin})(PEt_2Ph)_2RhCl(CO_3) + P{=}O \qquad (3)$$

The phosphane oxidation can go on in the presence of an excess of olefin until complex **2** is totally converted into other species that are not active catalysts. The use of bidentate phosphanes or chelating nitrogen ligands, like dipyridyl or phenanthroline, stabilises the catalyst for up to two to three hours,[14,16] after which it has been converted into inactive species. The mechanism of deactivation of the catalyst when monodentate or bidentate ligands are used is quite different. In the case of monodentate ligands, as we have reported above, the oxidation of the dissociated phosphane causes the destruction of the catalyst [Equation (3)], whereas in the case of bidentate ligands, ligand scrambling causes the destruction of the active catalytic species as shown in Equation (4). In fact, the square-planar moiety "$Rh(L\text{-}L)_2$" (where L-L is a bidentate phosphane) is not active in catalysis as it does not promote the formation of the peroxocarbonate because two *cis*-positions are not available. Similarly, the olefin complex does not coordinate either dioxygen or CO_2.

$$2\,Rh(L\text{-}L)Cl + n\,(\text{olefin}) \longrightarrow \underset{\mathbf{5}}{Rh(L\text{-}L)_2Cl} + \underset{\mathbf{6}}{Rh(\text{olefin})_nCl} \qquad (4)$$

Compound **5** has been isolated from the reaction solution and its nature confirmed by comparison with an authentic sample. As reported above, the oxygen transfer reaction assumes a particular importance when olefins or ethers are used,[13] affording useful products. Peroxocarbonates can therefore be used to promote the transfer of a single oxygen atom of the original dioxygen molecule to an oxophile. The reaction path and products are reported in Scheme 5. In the case of an olefin, carbocation **6** could be the intermediate[13] that generates epoxides, aldehydes and ketones. The oxygen transfer reaction has been also modelled using IOM.[17,18] Very interestingly, if styrene is used (Scheme 4), the calculated distribution of products is very close to the experimental one.



7

Scheme 6. Formula of compound **6**

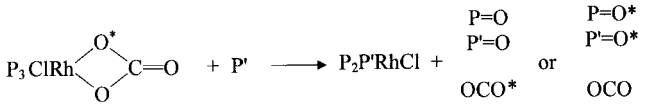
When peroxocarbonates react as oxidant towards an external phosphane or, in general when they act as one-oxygen transfer agents, as reported above, the carbonate is formed, as demonstrated by spectroscopic techniques (IR, NMR). The ^{31}P NMR spectrum shows a doublet of doublets (dd) at $\delta = 14.2$ ($J_{P\text{-}P} = 23.8$ Hz, $J_{P\text{-}Rh} = 89$ Hz) and a doublets of triplets (dt) at $\delta = 22.7$ ($J_{P\text{-}Rh} = 125$ Hz). These signals are also found in the ^{31}P spectrum when a solution of **2** in CD_2Cl_2, prepared at 240 K, is heated to room temperature. Interestingly, when the oxygen transfer occurs from the peroxocarbonate to the external phosphane, the

final reaction mixture shows the presence of a ^{31}P signal that can be attributed to $[RhCl(PEt_2Ph)_3]$.[19]

The formation of this species might be explained in terms of a reversible dissociation of CO_2 from the peroxocarbonate to afford the dioxygen complex that may give back $[RhCl(PEt_2Ph)_3]$ [Equation (1)]. We have tried to prove this hypothesis by GC-MS analysis and found that dioxygen is not detected. Conversely, CO_2 is released and, if labelled O_2 is used in the synthesis of the peroxocarbonate, a semi-labelled ^{18}O species is formed. Moreover, if a phosphane is added to the Rh carbonate formed from the peroxocarbonate after oxygen-transfer to the external oxophile, phosphane oxide is formed together with $[RhCl(PEt_2Ph)_3]$ [Equation (5)].

$$\underset{\mathbf{3}}{P_3ClRh(CO_3)} + P \longrightarrow \underset{\mathbf{4}}{P_3RhCl} + P{=}O + CO_2 \qquad (5)$$

This behaviour suggests that CO_2 could originate from a mechanism in which the carbonate is implicated in the phosphane oxidation. As a matter of fact we have performed a number of reactions which have clearly demonstrated that the "Rh^{III} carbonate ion" system can transfer one oxygen atom to the phosphane with formation of phosphane oxide and CO_2. The amount of CO_2 has been evaluated by a GC of the gas phase. The GC-MS spectrum of the gas phase also shows that if the carbonate has one ^{18}O oxygen atom that is used for binding the CO_3^{2-} moiety to the metal, the resulting CO_2 has ca. 50% of ^{18}O, as does the phosphane oxide (Scheme 7).



Scheme 7. Carbonate deoxygenation by an external phosphane ligand

The conversion of the carbonate to CO_2 with oxygen transfer to a substrate is reminiscent of the reaction of inorganic carbonates which form CO_2 and the metal oxide when heated at high temperature [Equation (6)].

$$MCO_3 \xrightarrow{1000\text{-}1200\ K} MO + CO_2 \qquad (6)$$
$$M = Ca, Mg$$

The release of CO_2 from coordinated carbonate complexes is not a trivial process. To the best of our knowledge, it has not been documented in the literature with phosphane as the reducing agent. It is known that hydrogen at high temperature and pressure is able to deoxygenate carbonates into carbon dioxide. In fact, $CoCO_3$ has been used for the synthesis of $Co_2(CO)_8$ with H_2 at 673 K.[20] Therefore, we decided to investigate if an external carbonate ion could itself undergo the deoxygenation reaction under mild conditions. We have thus reacted $[RhCl_3(PEt_2Ph)_3]$ with Na_2CO_3 or Ag_2CO_3 in the presence of a free phosphane. Interestingly, the reaction occurs at 353 K according to Equation (7) and (8), respectively.

$$(PEt_2Ph)_3RhCl_3 + Na_2CO_3 + P' \rightarrow (PEt_2Ph)_3RhCl + 2\,NaCl + P'{=}O + CO_2$$
$$P' = PCy_3 \qquad (7)$$

$$(PEt_2Ph)_3RhCl_3 + Ag_2CO_3 + 2\,P' \rightarrow 1/2\,[(PEt_2Ph)_2RhCl]_2 + 2\,(PEt_2Ph)AgCl + P'AgCl + P'{=}O + CO_2$$
$$P' = PEt_2Ph,\ PCy_3 \qquad (8)$$

In Equation (7), NaCl was isolated by extraction with water, and the Rh^I complex was isolated by recrystallisation from pentane. The latter has been characterised by elemental analysis, and its spectroscopic properties compared with those of an authentic sample. If PCy_3 is added as external phosphane, $O{=}PCy_3$ is the most abundant phosphane oxide, with minor amounts of $O{=}PEt_2Ph$. A limited degree of phosphane scrambling is observed (ca. 10%). Equation (7) represents a quite unique and interesting reaction, if one considers that the release of CO_2 from Na_2CO_3 requires high temperatures (>1000 K).[21] Ag_2CO_3 behaves in the same way. However, coordination to Rh lowers the decomposition temperature of the carbonate by more than 600 K. This finding rationalizes the behaviour of peroxocarbonate **2** and elucidates the reaction pathway relevant to Rh catalysis in styrene oxidation-carbonation,[12–15] allowing us to propose the cycle represented in Figure 2 for the Rh^I–Rh^{III} cyclic conversion.

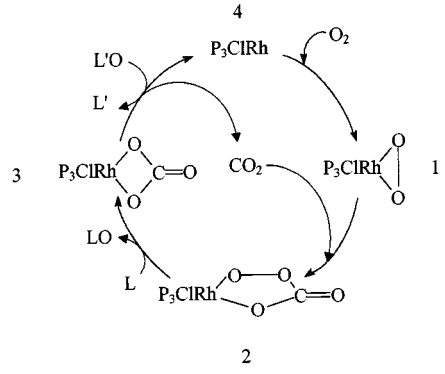


Figure 2. Double one-oxygen transfer to two different substrates from an O_2 molecule mediated by a Rh^I–Rh^{III}–Rh^I shuttle with the intermediacy of peroxocarbonate moiety; a ligand (P, L) scrambling is also observed

At the same time, the reduction of Rh^{III} to Rh^I explains the catalytic role of the metal. In fact, without reduction to Rh^I, only a stoichiometric reaction is observed in the O-transfer to the olefin from the peroxocarbonate complex. The observed turnover number. which is higher than one, can be interpreted only on the basis of a $Rh^{III} \rightarrow Rh^I$ reduction and reactivation of the catalyst.

Conclusions

The unprecedented deoxygenation of a carbonate ion to CO_2 in the presence of Rh^{III} has been observed. This finding represents an interesting new piece of chemistry demon-

strating that coordination of the carbonate anion allows the lowering of its decomposition temperature by more than 600 °C. However, this finding allows us to rationalise the catalytic role of Rh^{I} in the oxidation of styrene to styrene epoxide and other one-oxygen transfer products in an O_2/CO_2 atmosphere, with the intermediacy of peroxocarbonate−carbonate−carbon dioxide complexes.

Experimental Section

General: Unless otherwise stated, all reactions and manipulations were conducted under a dinitrogen or CO_2 atmosphere by using vacuum line techniques. All solvents were dried as described in the literature[22] and stored under dinitrogen. CO_2 (≥99.95%) and O_2 (≥99.98%) were purchased from Air Liquide Spa. The $RhCl(PR_3)_3$ complexes were prepared from $[RhCl(C_2H_4)]_2$ (Aldrich) and the corresponding phosphanes (Aldrich) according to previously reported experimental procedures.[4] The synthesis of $RhCl[^{18}O^{16}OC(^{16}O)^{18}O](PEt_2Ph)_3$ has been described previously.[5]

^{31}P NMR spectra were obtained at 81 MHz with a Varian XL-200 instrument. ^{31}P chemical shifts are referred to 85% H_3PO_4 using the high-frequency-positive convention. FTIR spectra were recorded using a Bruker 113V Fourier transform interferometer. Frequencies are accurate to ±1 cm^{-1}. Solid samples were studied as Nujol mulls (Nujol was previously dried over sodium wire and deoxygenated with argon). GC analyses were performed with a HP 5890 Series II gas chromatograph equipped with an Alltech-Heliflex AT-1000 capillary column (30 m × 0.00025 m, 0.2 μm thickness). GC-MS analysis was carried out with a gas chromatograph SHIMADZU 17 A-1000 (capillary column: 30 m × 0.00025 m, 0.25 μm thickness) detector linked to a SHIMADZU GCMS-QP 5050 mass spectrometer. GC analysis of gaseous phases was carried out with a gas chromatograph DANI equipped with a Carbowax column 3 m × 2.1 mm (ID) and TCD detector.

Study on the Thermal Stability of $(PEt_2Ph)_3RhCl(CO_4)$: a) Solid $[RhCl(CO_4)(PEt_2Ph)_3]$ (0.050 g, 0.07 mmol) was heated at 338 K for 10 min. under a dinitrogen atmosphere into Cell (a) (Figure 3) that was then connected to a GC and the gas phase analysed with a TCD. The GC analysis showed the absence of CO_2. The IR analysis of the solid showed that no reaction had occurred.
b) Analogous results were obtained when C_2H_4 was admitted into the cell and the system heated for 1−2 min. at 340 K. A longer reaction time produced a conversion of the Rh complex (see below).

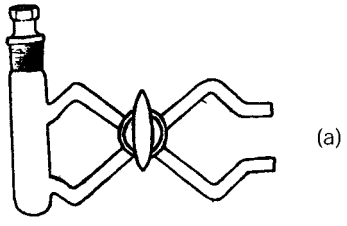

Figure 3. Apparatus used for the analysis of the gas phase in equilibrium with a solid

Conversion of $[RhCl(CO_4)(PEt_2Ph)_3]$ in CD_2Cl_2: A solution of **2** in CD_2Cl_2 was prepared at 213 K and the NMR spectrum recorded (Figure 1, spectrum A). The solution was heated to 250 K for 20 min. and the ^{31}P NMR spectrum recorded at this temperature (Figure 1, spectrum B). Heating produced the oxygen transfer to the phosphane. The following compounds were identified: *trans*-$RhCl(CO)(PEt_2Ph)_2$: δ = 26.0 (d, $J_{P\text{-}Rh}$ = 128.7 Hz); *mer*-$RhCl_3(PEt_2Ph)_3$: δ = 3.7 (dd, $J_{P\text{-}Rh}$ = 84 Hz, $J_{P\text{-}P}$ = 23.1 Hz), 16.9 (dt, $J_{P\text{-}Rh}$ = 111.3 Hz); *mer*-$RhCl(CO_3)(PEt_2Ph)_3$: δ = 14.2 (dd, $J_{P\text{-}Rh}$ = 89 Hz, $J_{P\text{-}P}$ = 23.8 Hz), 22.7 (dt, $J_{P\text{-}Rh}$ = 125 Hz); O=PEt_2Ph: δ = 42.9.

Reaction of $[RhCl(CO_4)(PEt_2Ph)_3]$ with PEt_2Ph: a) Solid **2** was heated with an equimolar amount of PEt_2Ph at 320 K under dinitrogen. The IR spectrum of the mixture showed the appearance of phosphane oxide (1150 cm^{-1}) within 4 hours and the formation of Rh^{III} carbonate (IR band at 1660 cm^{-1}), which was isolated from the mother mixture.

b) Compound **2** in CH_2Cl_2 solution was treated with an equimolar amount of PEt_2Ph at room temperature under dinitrogen. The solution was monitored at intervals of time by GC and GC/MS. The formation of phosphane oxide was clearly demonstrated to be a product of the oxidation process.

Reaction of Solid $[RhCl(CO_4)(PEt_2Ph)_3]$ with C_2H_4: Solid $[RhCl(CO_4)(PEt_2Ph)_3]$ (0.05 g, 0.07 mmol) was stirred at room temperature under a C_2H_4 atmosphere. The reaction was monitored by GC analysis of the equilibrium gas. No ethylene oxidation products were detected in the gas or solid phase, while in the solid phase phosphane oxide [^{31}P NMR: δ = 42.9 (s)] appeared after a couple of days. After a week the solid completely changed its appearance and the reaction was stopped and the solid analyzed by ^{31}P NMR spectroscopy. The residual solid was a mixture of compounds which had a ^{31}P spectrum close to that shown in Figure 1B. If an inert gas was used instead of ethylene, the complex lasted for a much longer time under the same experimental conditions.

Reaction of $(PEt_2Ph)_3RhCl(CO_4)$ with Styrene: Styrene (0.1 mL) in THF (2 mL) was added to **2** (0.100 g, 0.16 mmol) under a CO_2/O_2 atmosphere (10:1 v/v) and the solution stirred at room temperature. At intervals of 30 min., a sample was withdrawn and analysed by GC/MS. The presence of the following products was ascertained: benzaldehyde, phenylacetaldehyde, phenyl methyl ketone and styrene epoxide in a molar ratio 1:3:3:5. Benzoic acid and styrene carbonate were also present.

Reaction of $[RhCl_3(PEt_2Ph)_3]$ with Na_2CO_3: $[RhCl_3(PEt_2Ph)_3]$ (0.200 g, 0.3 mmol) was dissolved in toluene (5 mL) and a stoichiometric amount of Na_2CO_3 (0.031 g, 0.3 mmol) and free phosphane (0.050 g, 0.3 mmol) added. The reaction mixture was heated to 353 K. After 1 hour the GC analysis of the gas phase revealed the presence of CO_2 while in solution the free phosphane and phosphane oxide were detected. After 24 h, the amount of CO_2 in the gas phase increased to almost reach a CO_2/Rh ratio of 0.5. CO_2 was also present in solution. The total amount of released CO_2 allowed us to estimate when the reaction had reached completion. NaCl separated from the solution and was isolated by filtration. Its mass was 95% of the expected stoichiometric amount. From the mother solution 0.150 g of crude $[RhCl(PEt_2Ph)_3]$ was isolated, which was then crystallised from pentane. − $C_{30}H_{45}ClP_3Rh$ (636.97): calcd. C 56.57, H 7.12, Cl 5.57, P 14.59; found C 56.03, H 7.01, Cl 5.61, P 15.03.

Reaction of $(PEt_2Ph)_3RhCl_3$ with Ag_2CO_3: $[RhCl_3(PEt_2Ph)_3]$ (0.140 g, 0.2 mmol) was dissolved in CH_3CN (3 mL) and a stoichiometric amount of Ag_2CO_3 (0.050 g, 0.2 mmol) and PEt_2Ph (0.030 g, 0.2 mmol) were added. The reaction mixture was heated to 353 K. After 1 hour the GC analysis of the gas phase revealed

the presence of CO_2. After 24 h the gas phase showed an increased amount of CO_2 and from the solution a whitish-yellow solid separated, which was filtered, washed with pentane and dried in vacuo. It was analyzed as $AgCl(PEt_2Ph)$. From the solution $[RhCl(PEt_2Ph)_2]_2$ was isolated together with $O{=}PEt_2Ph$. The dimer was characterized by elemental analysis and its spectroscopic properties were compared to an authentic sample. – $C_{18}H_{33}AgClP$ (423.75): calcd. C 51.01, H 7.85, P 7.30, Cl 8.36; found C 50.85, H 7.54, P 7.10, Cl 8.16. – $C_{40}H_{60}Cl_2P_4Rh_2$ (941.54): calcd. C 51.03, H 6.42, Cl 7.53, P 13.16; found C 50.90, H 7.70, Cl 8.01, P 7.03.

In one run we used PCy_3 as the external phosphane. This was essentially totally converted into $O{=}PCy_3$. The isolated Rh complexes showed that some phosphane scrambling also took place and mixed phosphane species were obtained. The exchange did not exceed 10–15%, as demonstrated by ^{31}P NMR spectroscopy.

Keywords: Carboxylate ligands / Bridging ligands / Tripodal ligands / Manganese / SOD mimics

The crystal structure of a dimeric bis(μ-carboxylato)$Mn^{II}Mn^{II}$ complex (**2**) with a tetradentate *N*-centered tripodal ligand, *N*,*N*-bis[(1-methylimidazol-2-yl)methyl]glycinate, is presented. The carboxylates are bridging monodentate. This complex shows some striking differences to the previously published parent compound **1** obtained with the closely related ligand *N*-[(1-methylimidazol-2-yl)methyl]-*N*-(2-pyridylmethyl)glycinate. The carboxylato bridges in both structures are shown to be disrupted in solution. The reactivities in solution of compounds **1** and **2** toward superoxide were studied. In anhydrous DMSO solutions, a pathway involving a bis(μ-oxo)$Mn^{III}Mn^{IV}$ complex was identified. In water solutions, IC_{50} values were measured by the Fridovich test (1.7 ± 0.2 μM for **2** and 2.0 ± 0.2 μM for **1**), which showed these complexes to be good superoxide scavengers. Association constants for the complexes were estimated by means of a method based on IC_{50} measurements of the complexes under several conditions (alone and in the presence of excess ligand). They were found to be consistent with literature data.

Introduction

Superoxide ($O_2^{\cdot-}$) is the product of single-electron reduction of dioxygen. It is the first species in the dioxygen reduction cascade en route to hydrogen peroxide (H_2O_2) and the hydroxyl radical ($HO^{\cdot}$), and is known to be involved in oxidative stress.[1−5] Superoxide dismutases (SODs)[6] are metalloenzymes that actively protect cells against oxidative stress. They catalyze the dismutation of superoxide anion $O_2^{\cdot-}$ to hydrogen peroxide and oxygen. These enzymes can be classified into two major structural families, namely copper−zinc SODs and manganese or iron SODs.[1,5,7−9] SODs based on nickel have also been described,[10,11] but these have been much less well studied. Many complexes have been isolated and studied as superoxide scavengers. Such complexes contain either copper,[12−16] iron,[17−25] or manganese.[23,26−45] In our laboratory, two families of ligands have been developed with a view to obtaining iron or manganese complexes that might possibly react with superoxide. One family has been based on heptadentate polyamine hindered ligands,[19,38] while the other has been designed so as to reproduce the chemical environment of the active site in Mn and Fe SODs. In these enzymes, the first coordination sphere is a common feature, with an N_3O_1 set of ligand donors made up of three histidines and one monodentate carboxylate group, one histidine being more distant than the other ligands.[46−50] Nitrogen-centered tripodal tetradentate ligands have been synthesized with three appended moieties [two aromatic amines (pyridine or *N*-methylimidazole) and one carboxylate group], chosen in order to mimic the three closer ligands. Iron complexes have already been reported.[21,22] Manganese complexes are now being studied. Compound **1**, involving manganese(II) and *N*-[(1-methylimidazol-2-yl)methyl]-*N*-(2-pyridylmethyl)glycinate, hereafter referred to as IPG [acronym for (imidazolyl)(pyridyl)glycinate], has been described previously. It was shown to crystallize from MeOH with an infinite helical polymeric structure.[51] We describe herein the crystal structure of compound **2**, obtained from the closely related ligand *N*,*N*-bis[(1-methylimidazol-2-yl)methyl]glycinate [BIG; acronym for bis(imidazolyl)glycinate] and manganese(II). It crystallizes from water as a dinuclear bis(μ-carboxylato)-$Mn^{II}Mn^{II}$ complex. The reactivities in solution (anhydrous DMSO and aqueous buffer) of compounds **1** and **2** toward superoxide have been investigated and the results are reported herein.

Results

Synthesis of the Ligands

A given *N*-centered dissymmetric tripod can be synthesized by several pathways, depending on the order in which the different moieties are introduced. The yield-limiting step is usually the tertiarization of the amine. When this step is performed by reductive amination, improved yields over other synthetic methods are achieved, as previously reported in the case of *N*-[(1-methylimidazol-2-yl)methyl]-*N*-

(2-pyridylmethyl)glycinate (IPG).[51] We report here a high-yielding, one-step synthesis of the ligand *N*,*N*-bis[(1-methylimidazol-2-yl)methyl]glycinate (BIG). A three-step synthesis of BIG has been published previously, which involved the preparation of *N*,*N*-bis[(1-methylimidazol-2-yl)-methyl]amine from *N*-methyl-2-carboxyimidazole and further *N*-alkylation by treatment of the secondary amine with ethyl bromoacetate.[21] The overall yield for the aldehyde to ester conversion by this new pathway was improved from 10% to 75% using a one-step reductive amination with $NaBH_3CN$ (see Scheme 1).

Preparation of the Complexes

Mn^{II} complexes were obtained from these two ligands with PF_6^- as the counteranion, either in anhydrous methanol or in water. With BIG, crystals were successfully grown from aqueous solution providing the dimeric compound **2**. Experimental details are given in the Exp. Sect. (see also Table 1). With IPG, as previously described, crystals suitable for X-ray analysis were slowly grown from anhydrous methanolic solution (compound **1**), providing a polymeric inorganic helix.[51]

Solid-State Characterization of Complex 2 − Comparison with Complex 1

The X-ray structure of compound **1** has been described previously. It was shown to form infinite polymeric helices in the solid state, linked through carboxylato bridges in a rather unusual *syn-anti* geometry (see Figure 1). The Mn^{II} ion is hexacoordinated. Although the two tetradentate ligands IPG and BIG are very similar (see Scheme 1), the structure of compound **2** shows drastic differences from that of compound **1**. The structure of complex **2** revealed the formation of a dinuclear complex, in which the two Mn^{II} centers are linked by two oxygen atoms of the double carboxylate monodentate bridge (μ-η^1-carboxylato) through a diamond-shaped core. In the crystal structure, the charge of the $[(BIG)Mn^{II}(\mu\text{-}OCO)_2Mn^{II}(BIG)]^{2+}$ cation is balanced by the presence of two PF_6^- anions. Selected distances and angles are presented in Table 2 and a perspective view of the structure is shown in Figure 2.

A notable structural feature of the dinuclear Mn^{II} complex is the heptacoordination of the manganese atom. The coordination environment of the metal ion consists of the three nitrogen donors N1A, N1B, N provided by the two imidazole rings and the tripodal N atom, and the oxygen atoms (O1, O2) of the carboxylate groups grafted onto the tripodal N ligand, which bridge the two metal centers. The sixth and seventh coordination sites of each metal ion are occupied by two water molecules (Figure 2). In the IR spectrum, the presence of coordinated water was confirmed by

the appearance of two narrow lines at 3656 and 3580 cm^{-1}.[52] These lines were absent in the IR spectrum of compound **1**, in which the Mn^{II} ions do not bear coordinated water molecules. Moreover, when compound **2** was recrystallized from D_2O, these two lines were shifted to give one composite band at 3650 cm^{-1}. This further confirms the assignment to coordinated water. The $M-N_{tripodal}$ distance is of the same order as has previously been found for similar compounds consisting of tripodal amines and Mn^{II}.[38,51,53,54] This distance is shorter than the sum of the van der Waals radii (2.82 Å), indicating that the manganese ion is linked to the $N_{tripodal}$ atom.

The bis[Mn(μ-OCO)] core is characterized by Mn−O−Mn angles of 108.4(2)° and 106.4(4)° and an Mn−Mn distance of 3.672(2) Å. This distance is of the same order of magnitude as those reported for the $Mn^{II}(\mu\text{-}OCO)_2Mn^{II}$ core with a double monodentate bridging carboxylate group [3.712(2) and 3.726(4) Å].[54] A relevant feature is the planarity of the diamond-shaped core, the four atoms Mn, O1, O2, Mn′ being rigorously coplanar (mean displacement 0.001 Å from the least-squares mean plane). A striking finding of the crystal structure determination of the dinuclear complex is a complex intra- and intermolecular hydrogen-bond network that connects the various hydrogen-bond acceptors (COO^-) and the donors/acceptors (water molecules included in the cell).

The free oxygen atoms of the carboxylate groups, O9C and O9C′, and the water molecules W1′, W2 coordinated to the metal centers Mn and Mn′ are linked by strong intramolecular hydrogen bonds (from 2.66 Å to 2.74 Å). Another strong intramolecular hydrogen bond is evident between one water molecule W1 coordinated to the Mn ion and the other water molecule W2′ linked to the second metal center Mn′. Small differences are observed for the bis(μ-OCO) bridges. Oxygen atom O9C, which is not coordinated to the metal ion, is involved in only one intramolecular hydrogen bond, while the free oxygen atom O9C′ of the second carboxylate bridge is intra- and intermolecularly hydrogen-bonded in a twofold network.

Two- or threefold connected arrangements of the four water molecules coordinated to the metal centers and the water molecule W, cocrystallized, are seen in the crystal structure. The main features of the three-dimensional hydrogen-bond scheme are reported in Table 3.

Studies in Solution: Reactivity of the Complexes Toward Superoxide

Reactivity was studied in both anhydrous media and aqueous buffer. The studies in anhydrous media were motivated by the fact that the two complexes **1** and **2** display different levels of hydration. Direct reaction of the complexes with superoxide could be monitored in anhydrous media. DMSO was chosen as it solubilizes KO_2 up to a relatively high concentration in comparison to other solvents (see Exp. Sect. for details).[55,56] In aqueous buffer, an indirect test (namely the Fridovich test) was used. In order to investigate the reactions of O_2^- with complexes **1** and **2**

in solution, their molecular properties in solution first needed to be characterized.

Anhydrous DMSO Solutions

Both complexes are soluble in DMSO. Mononuclear species are present in solution, as shown by EPR spectroscopy and mass spectrometry. The EPR spectra of **1** and **2** in DMSO (10^{-4} to 5×10^{-3} mol·dm^{-3} based on Mn^{II} content) each show the sharp, six-line signal typical of mononuclear Mn^{II} with an average separation of 102 Gauss (some smaller lines can be seen in between, which are known to be due to $\Delta m_I = \pm 1$ forbidden transitions)[57−59] (see Figure 3A). Electrospray ionization mass spectrometry (ES) showed a peak at $m/z = 392$ for **1** and at $m/z = 395$ for **2**. These peaks correspond to [(L)Mn + DMSO] (L being either IPG or BIG). For the sake of simplicity, the soluble species are referred to hereafter as MnIPG for **1** and as MnBIG for **2** and concentrations are given in terms of the Mn^{II} content.

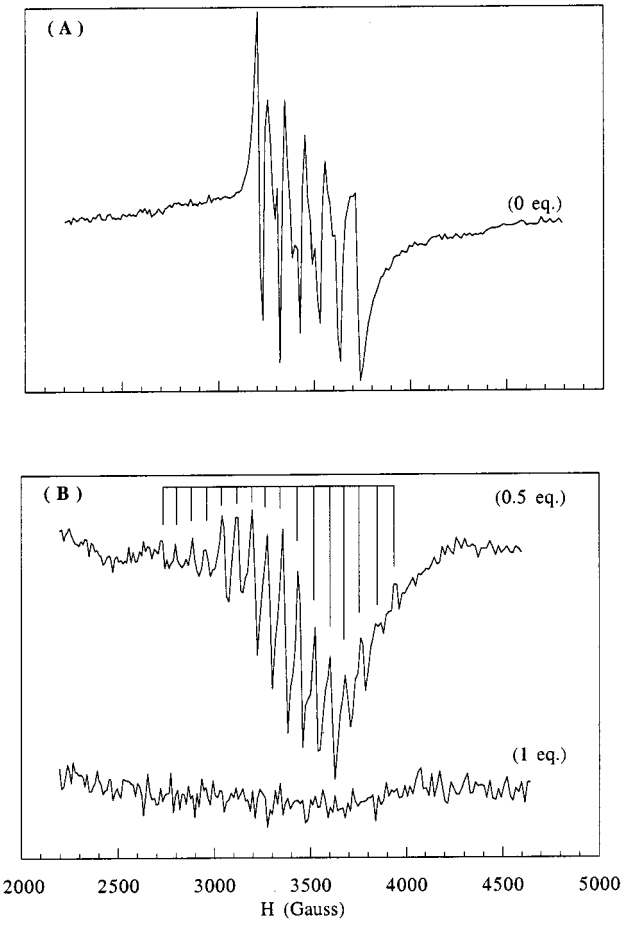

Figure 3. EPR spectra for the reaction of MnIPG (6.5×10^{-4} M based on Mn^{II} content) with potassium superoxide: A: 0 equiv. of O_2^-; B: 0.5 equiv. and 1 equiv. of O_2^- [$T = 8$ K, attenuation 44 dB (A) or 15 dB (B), modulation 5 G, gain 3.2×10^5, $t_c = 100$ ms, sweep time 200 s]

The cyclic voltammograms of both MnIPG and MnBIG in deoxygenated DMSO showed no reversible wave in the electroinactivity window of the solvent (−2.25 to 0.95 V vs. SCE), neither on platinum nor on glassy carbon working electrodes. Similarly, in acetonitrile, no wave was recorded in the range −1.8 to 1.8 V vs. SCE. Such behavior is not uncommon for Mn^{II} complexes.[38,60]

When the cyclic voltammogram of MnIPG or MnBIG in DMSO was recorded without deoxygenation, an irreversible cathodic wave was observed, corresponding to the reduction of dioxygen to superoxide. It is known that, in anhydrous DMSO, the redox couple O_2/O_2^- displays a revers-

ible wave at $E_{1/2} = -0.73$ V vs. SCE.[18,24,55,60,61] We verified that under our experimental conditions, in the absence of any complex, this reversible wave was indeed observed. Its reversibility confirmed the anhydrous nature of the solvent under the experimental conditions. The fact that the O_2/O_2^- wave became irreversible in the presence of the complexes gave a first indication that the complexes do indeed react with superoxide.

When the DMSO solution was saturated with oxygen, another reduction peak appeared at a more positive potential (+400 mV) than the O_2/O_2^- cathodic peak. Some similar pre-peaks have previously been reported for Mn^{II} complexes,[38,60] which were attributed to the reduction of dioxygen weakly bound to the metal center.[60]

Reactivity of MnIPG and MnBIG Towards Superoxide in Anhydrous DMSO

Incremental amounts of superoxide were added to an anhydrous DMSO solution containing either MnIPG or MnBIG (10^{-4} to 5×10^{-3} mol·dm^{-3} based on Mn^{II} content) and the course of the reaction at room temperature was monitored by UV/Vis spectrophotometry (room temp.), EPR (X-band) spectroscopy (100 K or 8 K), and cyclic voltammetry (room temp.). In all these experiments, special care was taken to maintain the anhydrous character of the DMSO solutions. Saturated solutions of KO_2 in DMSO were obtained as described in the Exp. Sect. Equivalents of superoxide added are given per manganese ion.

(a) Treatment of MnIPG with superoxide produced, after the addition of 1 equiv., a light-brown solution giving a typical UV/Vis spectrum as shown in Figure 4, featuring bands at 300, 360, and 510 nm. EPR spectra were recorded at 100 K and 8 K. The Mn^{II} signal intensity decreased on going from 0 to 0.5 equiv. of O_2^-. At 0.5 equiv., a small multi-line signal was observed, which appeared more clearly at 8 K (Figure 3B). On going from 0.5 to 1 equiv., this multi-line signal decreased and was no longer observed beyond 1 equiv. Above 1.5 equiv., a signal due to superoxide was recovered. The superoxide content was estimated to be approximately 0.5 equiv. and 0.9 equiv. when 1.5 equiv. and 2 equiv., respectively, of superoxide had been added (see Exp. Sect.).

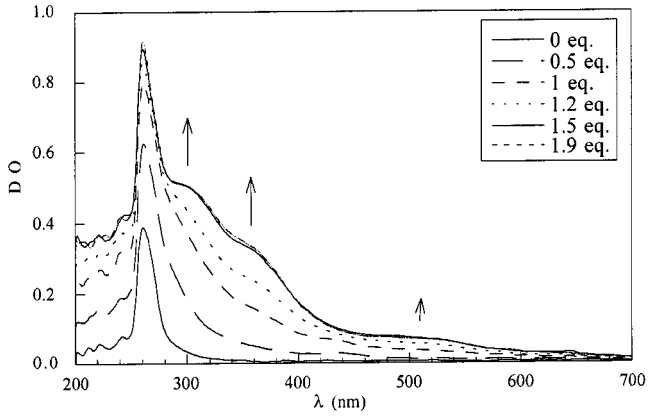

Figure 4. UV/Vis spectra for the reaction of MnIPG (10^{-4} M based on Mn^{II} content) with potassium superoxide

The reactivity of MnIPG toward superoxide was also investigated by cyclic voltammetry. This was performed by studying the evolution of the O_2/O_2^- wave.

In anhydrous DMSO, the redox couple O_2/O_2^- shows a reversible wave at $E_{1/2} = -0.73$ V vs. SCE.[18,24,55,60,61] The same reversible wave was observed from a deoxygenated 0.1 M Bu_4NPF_6/DMSO solution (15 min argon bubbling) to which a solution of KO_2 in the same electrolyte had been added (Figure 5). This wave remained stable upon further deoxygenation, indicating that it was due to superoxide and not to dioxygen that might have resulted from superoxide disproportionation. To ensure that superoxide was stable under the experimental conditions, successive amounts of superoxide in 0.1 M Bu_4NPF_6/DMSO (see Exp. Sect.) were added to a 0.1 M Bu_4NPF_6/DMSO solution in the electrochemical cell in the absence of any complex. The intensity of the anodic wave was seen to remain stable over 5−10 min and to vary linearly with the superoxide concentration.

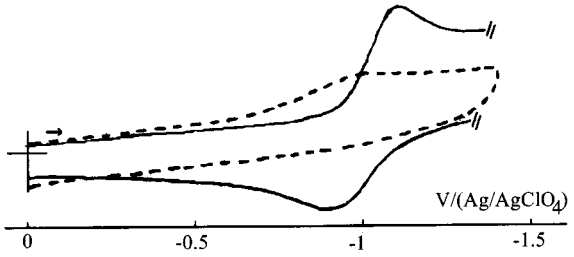

Figure 5. Cyclic voltammograms of a solution containing O_2/O_2^-; solid line: 5×10^{-4} M O_2^-; dashed line: 5×10^{-4} M MnIPG (based on Mn^{II} content) + 5×10^{-4} M O_2^-; potentials are reported vs. Ag/$AgClO_4$ in DMSO (+0.252 V vs. SCE)

When the cyclic voltammogram of MnIPG was recorded without deoxygenation of the solution, the O_2/O_2^- reduction wave became irreversible, showing no re-oxidation of superoxide at the electrode, not even at 200 mV.s^{-1}. Moreover, the O_2/O_2^- cathodic peak was slightly shifted to a more positive potential (see Figure 5), indicating an EC process. This shows that compound MnIPG reacts with superoxide produced at the electrode. When superoxide was added to the deoxygenated solution of MnIPG, no O_2/O_2^- wave was observed on going from 0.1 to 1 equiv. The superoxide wave appeared clearly after 2.5−3 equiv. of superoxide had been added.

(b) MnBIG was found to display a similar behavior upon superoxide addition, but with a different stoichiometry. The brown color and the UV band at 300 nm appeared after addition of 2 equiv. of superoxide. The multi-line EPR signal appeared after the addition of 1.5 equiv. and an EPR-silent species was obtained after the addition of a further 0.5 equiv.

In cyclic voltammetry, the O_2/O_2^- wave was absent when superoxide was added to a deoxygenated solution of **2**. After addition of 2 equiv. of superoxide, an irreversible cathodic wave appeared at 1.2 V vs. SCE, which intensified on adding further incremental amounts of superoxide. It was verified that the ligand BIG displays the same wave.

Reactivity of MnIPG and MnBIG Towards Superoxide in Aqueous Buffer

The reactivity of our complexes towards superoxide was investigated in aqueous phosphate buffer (pH = 7.8) by means of the xanthine/xanthine oxidase assay (hereafter referred to as the X/XO assay). This test, developed by Fridovich et al., is based on kinetic competition for superoxide reduction between the putative superoxide scavenger and ferricytochrome *c*.[7] The reduction of ferricytochrome *c* was monitored spectrophotometrically at 550 nm. This test requires several preliminary checks in order to improve its reliability (see Exp. Sect.).[5,35,38,62]

Compounds **1** (MnIPG) and **2** (MnBIG) in potassium phosphate buffer at pH = 7.8 were found to inhibit the reduction of ferricytochrome *c*, as shown in Figure 6. Inhibition percentages were measured for several complex concentrations and IC_{50} values were then deduced by two graphical methods (see Figure 7 and the Exp. Sect. for details).[7,35,63] The effects of chelators such as bovine serum albumin (BSA) and ethylenediaminetetraacetate (EDTA) were investigated in order to gain some insight into the stabilities of the complexes. BSA has been reported to be a powerful biological chelating agent capable of suppressing the SOD-like activity of copper complexes.[5,14] We have used it previously to test the activity of an (tris{2-[*N*-(2-pyridylmethyl)amino]ethyl}amine)Mn^{II} bis(hexafluorophosphate) (MnTPAA) in the X/XO assay. It was found that BSA (5 mg/mL) had no effect on the MnTPAA activity.[38] Similarly, BSA (5 mg/mL) showed no effect on the MnIPG activity. A small effect was observed for MnBIG in that its IC_{50} value was increased by a factor of 1.5 in the presence of BSA (5 mg/mL). The results suggest, at least for MnIPG, that as previously concluded for MnTPAA,[38] activity might be retained in vivo.

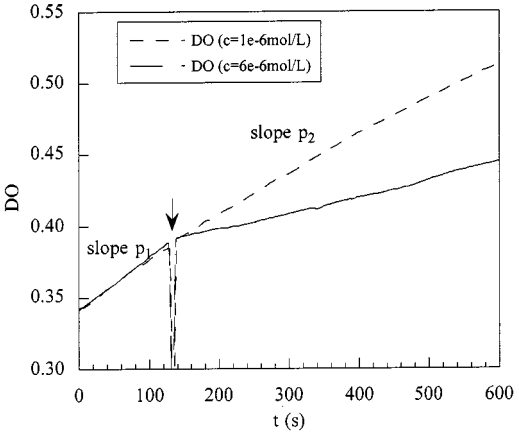

Figure 6. X/XO assay; 0−120 s: xanthine (200 μM), ferricytochrome *c* (22 μM), xanthine oxidase; after 120 s: xanthine (200 μM), ferricytochrome *c* (22 μM), xanthine oxidase, and compound MnBIG (concentration *c*, based on Mn^{II} content); the arrow indicates the addition of compound MnBIG

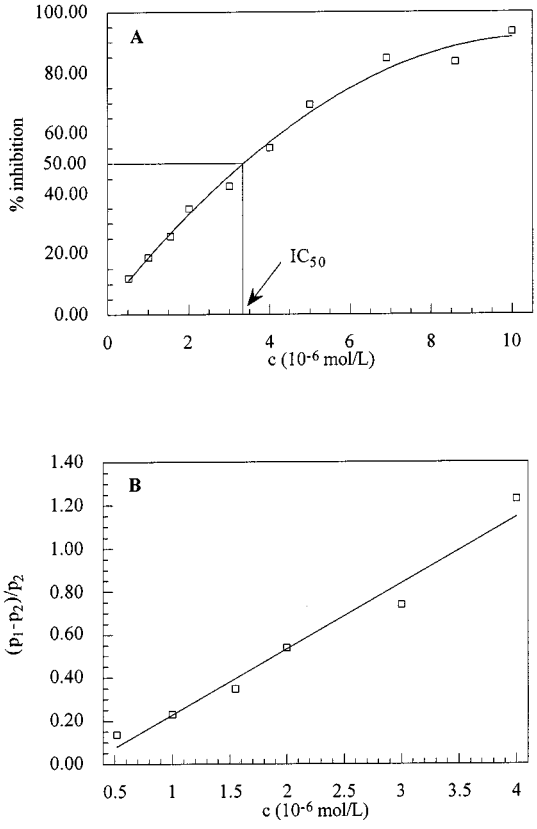

Figure 7. IC_{50} determination in the case of compound MnIPG; A: % inhibition versus concentration; B: $(p_1 - p_2)/p_2$ versus concentration

To further investigate the stabilities of the complexes, activity was measured in the presence of an excess of EDTA (3 mM, i.e. 1000 equiv.). The IC_{50} values of MnIPG and MnBIG were found to be increased by factors of 20 and 25, respectively (see Table 4), indicating low stabilities towards EDTA. Such contrasting behavior towards EDTA and BSA has previously been reported for (salen)Mn^{III} complexes. It was interpreted in terms of EDTA binding Mn from the complex rather than merely reacting with free Mn released by the complex.[5]

These experiments indicate that some decoordination might occur at concentrations in the range of the IC_{50}. Ligands IPG and BIG were tested and were found to show no activity in the X/XO assay. IC_{50} values reported so far in this article are apparent IC_{50} values (IC_{50app}) due to both

Table 4. Effect of chelators on the IC_{50} value [μM]

Compound	IC_{50app}	IC_{50} with EDTA (3 *m*M)	IC_{50} with BSA	IC_{50spe} (IC_{50} measured with excess ligand)

[a] IC_{50spe} values were measured in the presence of excess ligand (15 equiv.). – [b] This value was measured for a sample of $Mn^{II}(ClO_4)_2$ in the presence of excess EDTA (3 mM). – [c] TPAA: tris{2-[*N*-(2-pyridylmethyl)amino]ethyl}amine; DFB: desferrioxamine B; PA: picolinato; $HB(3,5\text{-}iPr_2pzH)_3$ hydrotris(3,5-diisopropyl-1-pyrazolyl)borate. – [d] IC_{50} values are reported in terms of Mn concentration. – [e] This value is an average for three replicates performed for each of the two determination procedures. – [f] This value is an average for two replicates performed for each of the two determination procedures.

the complexes and free Mn^{II}. The IC_{50} value for $Mn(ClO_4)_2$ (4.5 μM) was found to be higher than those for the complexes under the same experimental conditions. Thus, IC_{50app} values represent an overestimation of the real IC_{50} values (specific IC_{50}) that would have been measured without decoordination. To suppress this possible free Mn^{II} contribution to the inhibition, IC_{50} values were measured in the presence of an excess of the ligand (15 equiv.), thereby providing specific IC_{50} values (IC_{50spe}). These specific IC_{50} values are reported in Table 4 and are compared with literature data in Table 5.

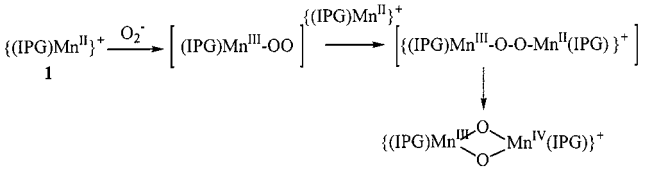
Discussion

The ligands IPG and BIG form two structurally distinct compounds with manganese(II). These two compounds reflect the rich structural diversity of (carboxylato)manganese complexes, as has been stressed by Iikura et al.[54] The coordination sphere about the manganese(II) ions adopts various geometries (see Table 2, Figure 1 and 2) and has various coordination numbers (6 or 7 for these two examples). This structural variety stems from the carboxylato moiety, which is μ-η^2-carboxylato-*syn-anti* in the polymeric helix adopted by **1** and μ-η^1-carboxylato in the dimeric structure of **2** in the solid state.

Reactivity in Anhydrous DMSO

Complexes **1** and **2** have different levels of hydration. In the reaction with superoxide, this hydration level is of critical importance as two protons are necessary for the superoxide reduction step producing H_2O_2. The ping-pong mechanism proposed for the enzyme suggests an inner-sphere electron-transfer, the first step being the binding of superoxide to the metal center.[49] Two concomitant pathways (inner- and outer-sphere electron transfer) have also been proposed for macrocyclic Mn^{II} derivatives.[34,37,39,44] With compound **1**, which does not have any coordinated water molecules, it is possible to test the reactivity in anhydrous media and thus, in the case of an inner-sphere mechanism, we may expect to characterize an Mn–superoxide adduct or a derivative thereof. This can be compared with the reactivity of complex **2**, as the presence of water should lead to some effective reaction with superoxide.

MnIPG reacts with 1 equiv. of superoxide, producing an EPR-silent species. After addition of 0.5 equiv., a $g = 2$, 16-line signal is observed in the EPR spectrum (see Figure 3). This indicates that a dimeric Mn–Mn $S = 1/2$ ground-state compound is obtained. This signal displays a width of 1200 G and an average spacing of 75 G. Such a spectrum is typical of bis(μ-oxo)$Mn^{III}Mn^{IV}$ complexes.[61,64–75] The conversion of Mn^{II} to bis(μ-oxo)$Mn^{III}Mn^{IV}$ species has been estimated to be 70% based on a comparison with the spectrum of a fully characterized $Mn^{III}Mn^{IV}$ compound.[76] The $Mn^{III}Mn^{IV}$ species further reacts with 0.5 equiv. of superoxide leading to an EPR-silent species, which could be either an $Mn^{III}Mn^{III}$ or an $Mn^{IV}Mn^{IV}$ species. This is consistent with the UV/Vis spectrum, as a possible assignment for the 300 and 360 nm bands is an $O \rightarrow Mn^{IV}$ LMCT.[74,77,78] Scheme 2 provides a rationalization of these experimental observations.



Scheme 2. Possible mechanism for bis(μ-oxo)$Mn^{III}Mn^{IV}$ dimer formation (after reaction of potassium superoxide with MnIPG)

The fact that the superoxide signal is recovered upon addition of 1.5 equiv. of superoxide shows that the silent EPR species formed at 1 equiv. of superoxide do not react with superoxide, at least in anhydrous media. A similar mechanism has previously been proposed for manganese–

porphyrins.[61] A (μ-peroxo)$Mn^{II}Mn^{III}$ species could also produce a $g = 2$, multi-line signal if the ground state had $S = 1/2$. However, as has been pointed out in the literature, a much larger spectrum would be expected.[65] Moreover, such a (μ-peroxo)$Mn^{II}Mn^{III}$ species would be expected to be unstable, whereas we found the multi-line signal to persist after the EPR tube had been left at room temperature for 5 min.

MnBIG exhibited the same pattern of spectroscopic and voltammetric characteristics, but only after 1 equiv. of superoxide per manganese ion had already been consumed. This observation has to be related to its level of hydration. The presence of water allows the production of hydrogen peroxide, either by direct reaction with superoxide or by reaction with an Mn−superoxide adduct. When the amount of superoxide was increased, an irreversible cathodic wave appeared at 1.2 V vs. SCE, which was shown to be due to the ligand BIG. This probably indicates destruction of the complex with release of the ligand.

Reactivity in Aqueous Buffer

The use of the X/XO assay to determine catalytic SOD-like activity is controversial. It has been shown, first by others, using stopped-flow techniques,[5][62] and then by us, using pulsed radiolysis,[38] that such an indirect test can give positive results both in the case of a catalytic scavenger and in the case of a stoichiometric superoxide scavenger. As a matter of fact, a small amount of superoxide is produced in the X/XO assay. For compounds displaying high IC_{50} values (in excess of 1 μM), the conditions required to probe catalytic behavior may not be fulfilled as $n_{complex} >> n_{superoxide}$ in the experiment. However, this test remains relevant for several reasons. The X/XO system provides a stationary state of superoxide of low concentration, which is closer to what is usually encountered in vivo.[14] Moreover, it provides a simple means of investigating the reactivities of complexes towards superoxide in aqueous buffers and of assessing the effect of additional compounds (e.g., chelators).[14,15,23,42,43]

The X/XO assay has proven that complexes **1** and **2** react with superoxide in aqueous solution. Experiments performed in the presence of excess chelators (BSA, EDTA) have shown that the complexes are partially decoordinated in the IC_{50} concentration range. Specific IC_{50} (IC_{50spe}) values were thus measured using an excess of the ligand. MnBIG and MnIPG show very close specific IC_{50} values, which is consistent with the two ligands being closely related. Their IC_{50spe} values fall at the low end of the range of those reported in the literature for Mn^{II} complexes (see Table 4). Much lower IC_{50} values have been reported for

Table 6. Association constants with Mn^{II} estimated for BIG and IPG and comparison with literature data; constants are given for the equilibrium Mn^{II}/L (1:1)

Mn−porphyrin compounds (see Table 4), but in these cases the manganese ion is in an Mn^{III} oxidation state. The IC_{50} value measured for MnBIG is more sensitive to the presence of chelators (EDTA, BSA, or BIG) (see Table 4). Qualitatively, this indicates that MnBIG has a smaller association constant K_{BIG} than MnIPG (K_{IPG}). Association constants could be roughly estimated from the apparent and specific IC_{50} values. Apparent IC_{50} values depend on the proportion of complex and Mn^{II} in the solution, and hence on the association constant. The apparent IC_{50} values could be approximated as the weighted average of the specific IC_{50} values for both compounds and Mn^{II}: $IC_{50app}(n) = IC_{50spe}(n)\cdot(1 - \alpha) + IC_{50spe}(Mn^{II})\cdot\alpha$ (n = MnIPG or MnBIG), α being the dissociation coefficient. This led to $K_{IPG} = 10^{6.0}$ and $K_{BIG} = 10^{5.3}$, respectively. Literature data on association constants of Mn^{II} complexes involving ligands of various denticity are reported in Table 5, together with our results from the present work.[79−81] The K_{ass} values estimated here for BIG and IPG are of the expected order of magnitude for tetradentate ligands and Mn^{II}.

As already mentioned, this X/XO assay is unable to distinguish between a catalytic and a stoichiometric scavenger for compounds showing IC_{50} values greater than 1 μM. Direct measurements of SOD activity using an excess of superoxide are necessary.[5] Pulsed-radiolysis kinetic analysis is now underway.

Conclusion

The preparation of compound **2** from Mn^{II} and *N*,*N*-bis[(1-methylimidazol-2-yl)methyl]glycinate (BIG) and its solid-state structure have been described. This compound has been shown to crystallize as an $Mn^{II}Mn^{II}$ dimer with a double carboxylato monodentate bridge (μ-η^1-carboxylato). Its geometry differs from that of compound **1**, an Mn^{II} compound prepared with the closely related ligand *N*-[(1-methylimidazol-2-yl)methyl]-*N*-(2-pyridylmethyl)-glycinate, IPG, which was previously shown to crystallize as a helical polymer.[51] Both these bridged structures are disrupted in DMSO, leading to monomeric species. In solution, compounds **1** and **2** have been shown to react with superoxide, both in anhydrous media and in aqueous buffer. They have been shown to form bis(μ-oxo) dimers in anhydrous media, such dimers being unreactive toward superoxide. IC_{50} values obtained in solution for these two compounds are among the best reported for Mn^{II} complexes, showing that the metal environment is appropriate for reaction with superoxide. However, the dimer formation, as seen under anhydrous conditions, might represent a pathway for inhibition of the activity toward superoxide in aqueous solution. We are currently working on modification of the ligand in order to prevent this possible dimerization and to enhance the stability of the complexes.

Experimental Section

General: IR spectra (KBr) were recorded with a Bruker IFS 66 FT-IR spectrometer. − ^{1}H NMR spectra were recorded with Bruker AM 200 and AM 250 spectrometers. − X-band electron paramagnetic resonance (EPR) spectra were recorded with a Bruker ER 200E spectrometer. − Cyclic voltammetry experiments were performed with an EG&G Princeton Applied Research Model 362 potentiostat connected to an Ifelec IF 2502 xy recorder. − Electronic absorption spectra were recorded with a Safas 190 DES double-mode spectrophotometer. − Chemical reagents were purchased from either Aldrich or Acros and were used without further purification. Extra-dry DMSO was purchased from Acros.[82] Xanthine oxidase and ferricytochrome *c* were purchased from Sigma.

Syntheses and Characterization

[(Ethoxycarbonyl)methyl]bis[(1-methylimidazol-2-yl)methyl]amine: Under argon at 0 °C, sodium cyanoborohydride (5 mmol, 0.32 g) was added to a deoxygenated solution of 1-methylimidazol-2-carboxaldehyde[83] (4.7 mmol, 0.52 g) and glycine ethyl ester hydrochloride ($ClNH_3CH_2COOEt$) (4.7 mmol, 0.65 g) in anhydrous MeOH (10 mL). After 2 h at 0 °C, the mixture was stirred for 12 h at room temperature. The solution was then cooled to 0 °C and acidified to pH = 5.5 with CF_3COOH, whereupon 1-methylimidazol-2-carboxaldehyde (7 mmol, 0.775 g) (in anhydrous MeOH, 2 mL) and sodium cyanoborohydride (9 mmol, 0.48 g) were added. After 2 h at 0 °C, the solution was stirred for 12 h at room temperature. It was then filtered, the methanol was evaporated, and the residual oil was extracted from the aqueous phase (pH = 8) with CH_2Cl_2. The combined organic phases were dried with Na_2SO_4 and concentrated. A yellow oil was obtained, which was purified by column chromatography (SiO_2; MeOH/CH_2Cl_2, 1:9). Yield (1.1 g, 75%). − ^{1}H NMR ($CDCl_3$): δ = 1.17 (t, 3 H, J = 7.25 Hz, CH_3CH_2COO), 3.34 (s, 2 H, NCH_2COOEt), 3.52 (s, 6 H, CH_3N_{im}), 3.80 (s, 4 H, Im-CH_2N), 4.04 (q, 2 H, J = 7.25 Hz, CH_3CH_2COO), 6.80 (d, 2 H, J = 2.25 Hz, H_{im}), 6.84 (d, 2 H, J = 2.25 Hz, H_{im}).

Potassium *N*,*N*-Bis[(1-methylimidazol-2-yl)methyl]glycinate (BIG): A solution of *N*,*N*-bis[(1-methylimidazol-2-yl)methyl]glycine ethyl ester (0.5 g) in ethanol (12 mL) was added to a solution of potassium carbonate (0.52 g) in water (35 mL). The resulting solution was stirred for 2 d at room temperature. The ethanol was then evaporated and the aqueous phase was washed with CH_2Cl_2 (2 × 10 mL). After concentration to dryness, residual K_2CO_3 was removed by extracting the carboxylate with anhydrous MeOH. Yield: 95%. − ^{1}H NMR (D_2O): δ = 3.10 (s, 2 H, NCH_2COOK), 3.45 (s, 6 H, CH_3N_{im}), 3.80 (s, 4 H, Im-CH_2N), 6.86 (d, 2 H, J = 2.25 Hz, H_{im}), 6.89 (d, 2 H, J = 2.25 Hz, H_{im}).

$[Mn(BIG)(H_2O)_2]_2\cdot 2PF_6$ (2): The pH value of a 2×10^{-3} M solution of BIG in water was adjusted to 8−8.5 by the addition of HCl. After evaporation of the water, the solid was dried overnight under reduced pressure in the presence of P_2O_5, and then KCl was removed by extraction of the ligand with anhydrous methanol. Typically, dimer crystals were obtained as follows: $MnBr_2$ (0.52 mmol, 112 mg) in deoxygenated doubly distilled water (15 mL) was added to a solution of the ligand (160 mg) in deoxygenated doubly distilled water (10 mL). The resulting mixture was allowed to stand for 2 h at 40 °C. Then, after cooling, a deoxygenated solution of NH_4PF_6 (3 equiv., 260 mg) in doubly distilled water (10 mL) was added dropwise. The resulting solution was left to stand for 3 weeks, allowing crystals to grow (see crystal data below). For further characterization and experiments, these crystals were ground and dried in vacuo over P_2O_5 for 48 h. Yield: 260 mg (55%). − $[C_{12}H_{16}N_5O_2Mn(H_2O)]_2\cdot 2PF_6$: calcd. C 30.01, H 3.78, N 14.58, F 23.74, P 6.45, Mn 11.44; found C 30.43, H 3.66, N 14.61, F 23.38, P 6.88, Mn 11.46. − IR (KBr): $\tilde{\nu}$ = 3656 and 3682 ($\nu_{linked\ water}$), 1590 (ν_{asCO}), 1382 (ν_{sCO}), 838 (PF_6), 738 ($\nu_{imid.\ deform.}$), 553 cm^{-1} (PF_6) (strong bands only).

Crystal Data for 2: $Mn_2C_{24}H_{40}N_{10}O_8{\cdot}2PF_6{\cdot}H_2O$,[84] M_r = 1014.47, monoclinic, space group $P2_1/c$, a = 9.240(4), b = 28.978(11), c = 15.586(6) Å, β = 95.49(4)°, V = 4154.1 Å^3, Z = 4, $D_{calcd.}$ = 1.622 g.cm^{-3}, λ = 0.71073 Å, T = 293(2) K, μ(Mo-K_α) = 0.796 mm^{-1}, F(000) = 2064. A prismatic crystal of dimensions 0.28 × 0.15 × 0.10 mm was mounted on an Enraf−Nonius Kappa-CCD diffractometer. A full sphere of data was collected by φ axis rotation with an increment of 1.5° over 360° and 170 s exposure per degree. "Dezingering" was accomplished by measuring each frame twice. The θ range for data collection was 1.41 to 29.07°. Data were analyzed using Kappa-CCD software.[85] Cell dimensions were refined with HKL Scalepack.[86] Data reduction was performed with Denzo.[86] Of a total of 13461 collected reflections, 7525 were independent (R_{int} = 0.046) and 4729 unique reflections had $I \geq 2\sigma(I)$. The structure was solved by direct methods (program SHELXS-86[87]) and was refined on F^2 for all reflections by least-squares methods using SHELXL-93.[88] Hydrogen atoms were included in calculated positions by using a riding model and were assigned isotropic thermal parameters 1.2 times that of the atoms to which they were bound. The asymmetric unit consists of one dimeric Mn^{II} complex, two PF_6 counteranions, and a water solvent molecule. The counteranions are subject to disorder. Two sites could be located on the difference Fourier map for each PF_6 anion. Several models for this disorder were tested. The best convergence was obtained with occupancies of 0.8 and 0.2. Refinement was pursued with restraints. The final conventional R_1 factor was found to be 0.075 for 4729 data, 84 restraints, and 585 parameters, and 0.13 for all data, wR_2 = 0.26 (all data); the largest peak and hole in the final difference map were within +0.5 and −0.3 eÅ^{-3}. A selection of bond lengths and angles is presented in Table 2. A perspective view of the Mn dimeric complex is shown in Figure 2. The hydrogen-bond network includes both intra- and intermolecular hydrogen bonds in the crystal structure, involving both the water molecules coordinated to the metal center (first coordination sphere), the noncoordinated oxygen atoms of the bis(μ-carboxylato) bridges of the dimeric complex, and the water solvent molecule included in the crystal structure. Structural data have been deposited with the Cambridge Crystallographic Data Centre (CCDC) under the depository number CCDC-150159. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat) + 44-1223/336-033; E-mail:deposit@ccdc.cam.ac.uk].

Reactivity in Anhydrous DMSO: Glassware was dried for at least one night at 125 °C and then cooled under a stream of argon. Solutions were manipulated in a Schlenk apparatus under a flow of argon and were kept under argon pressure. It was checked that superoxide disproportionation was negligible under the experimental conditions used (see below). DMSO solutions were prepared immediately prior to use. Saturated solutions of KO_2 in DMSO were obtained by stirring finely ground KO_2 in anhydrous DMSO for 1 h. The slurry was centrifuged for 10 min at 13000 g and the supernatant, which was slightly yellow, was titrated spectrophotometrically at 250 nm (ε = 2686 M^{-1}cm^{-1}).[89] Concentrations from 5 mM up to 6.5 mM were reproducibly obtained. We checked that this concentration was stable by recording UV/Vis spectra over a period of 10 min, in the course of which a decrease of less than 10% was usually recorded. This centrifugation procedure was compared with filtration and was found to provide solutions with slightly higher concentrations and improved stabilities (less decrease over 10 min). For cyclic voltammetry experiments, saturated solutions of KO_2 were prepared in 0.1 M Bu_4NPF_6 in DMSO. The same superoxide concentration was obtained.

EPR Experiments: Several concentrations of the complexes were tested (2×10^{-4} mol·dm^{-3}, 6.5×10^{-4} mol·dm^{-3}, and 1×10^{-3} mol·dm^{-3}). For each concentration, the experiment was performed in duplicate. Several Eppendorf vials were prepared containing the complex and 0−5 equiv. of superoxide with a final volume of 1 mL. Similar Eppendorf vials were prepared with superoxide alone (with quantities corresponding to 0.5−2 equiv.). These tubes were used to check that the superoxide EPR signal was observed under the experimental conditions. The intensity of the g = 2.00 signal was shown to vary linearly with superoxide concentration and could thus be used to give a rough estimate of the concentration in each experiment. After superoxide had been added, the Eppendorf vial was stirred manually. An aliquot of 100 μL was transferred to an EPR tube, immediately frozen in an EtOH/liq. N_2 bath, and kept in liq. N_2. EPR spectra were then recorded, either at 100 K or at 8 K. To estimate the conversion of Mn^{II} to $Mn^{III}Mn^{IV}$, a calibration curve was constructed. The spectra of a fully characterized bis(μ-oxo)$Mn^{III}Mn^{IV}$ compound, namely $[Mn_2O_2bispic(Me)_2en]^{3+}$,[76] at concentrations of 0.25×10^{-4} mol·dm^{-3}, 0.5×10^{-4} mol·dm^{-3}, 1×10^{-4} mol·dm^{-3}, and 1.5×10^{-4} mol·dm^{-3} in DMSO were recorded. The relative intensity of the six main peaks was plotted against concentration.

UV/Vis Experiments: Several concentrations were tested (1×10^{-4} mol·dm^{-3}, 2×10^{-4} mol·dm^{-3}, 6.5×10^{-4} mol·dm^{-3}). Successive equivalents of superoxide were directly added to the cuvette under magnetic stirring. EPR spectra of the solution from the cuvette were also recorded.

Cyclic Voltammetry Experiments: Cyclic voltammetry experiments were performed at room temperature under a stream of argon either in extra-dry DMSO containing 0.1 M Bu_4NPF_6 or in acetonitrile containing 0.1 M Bu_4NPF_6. An $Ag/AgClO_4$ electrode ($AgClO_4$ 10^{-2} M, Bu_4NPF_6 0.1 M) in DMSO was used as a reference for DMSO solutions and was separated from the solution by a glass frit. Its potential was measured as +0.252 V vs. SCE. Potentials are reported in the text vs. SCE. The working electrode was a platinum disc (2 mm diameter). Concentrations were 5×10^{-4} M and 1×10^{-3} M based on Mn^{II} content. When dioxygen-saturated electrolyte was required, dioxygen was bubbled through 0.1 M Bu_4NPF_6 in DMSO for half an hour.[55,60,90]

Xanthine/Xanthine Oxidase−Cytochrome *c* Assay: Superoxide anion was supplied to the system from the xanthine/xanthine oxidase reaction.

Reliability of the X/XO Test: To check that the tested compounds do not inhibit the production of superoxide by xanthine oxidase, the rate of conversion of xanthine to urate was determined by measuring the increase in absorbance at 290 nm over a period of 2 min in the absence and in the presence of the tested compounds. At concentrations higher than the IC_{50} values (which are of the order of 2−5 μM, see below), neither MnIPG nor MnBIG was found to inhibit this conversion. We also verified that ferricytochrome *c* was stable in the presence of both MnIPG and MnBIG. Moreover, it was important to ascertain whether the tested compounds react with H_2O_2 under the experimental conditions, as such a pathway could have led to side reactions.[62] Catalase can be added to the cuvette during the X/XO assay,[38][62] but this introduces another potential source of cross-reaction and interpretative errors.[5] Instead, we probed the H_2O_2 reaction with the complexes at a concentration in the range of the IC_{50} under the experimental conditions of the X/XO assay. The H_2O_2 concentration was found to be stable over a period of 20 min (see below).

Xanthine to Urate Assay: To measure the rate of conversion of xanthine to urate, xanthine oxidase (XO) (30 μL of 0.77 U·mL^{-1} XO)

was added to a potassium phosphate buffer solution (50 *m*M, pH = 7.8) containing 150 μM of xanthine at 25 °C to give a final volume of 1.0 mL. Urate production was monitored at 290 nm. No difference in the slope was observed in the presence or absence of the putative SOD mimics.

Reduction of Ferricytochrome *c*: The activities were measured on the basis of the ferricytochrome *c* reduction.[7,35][62] Assays were performed at 25 °C in 3 mL of reaction buffer (50 *m*M potassium phosphate buffer, pH = 7.8) containing 22 μM ferricytochrome *c*, 200 μM xanthine, and an amount of xanthine oxidase such as to give a rate of $\Delta DO_{550\ nm} = 0.025\ min^{-1}$ (about 0.01 $U{\cdot}mL^{-1}$) in the absence of any putative SOD mimic. The reduction of ferricytochrome *c* was monitored at 550 nm. After 2 min, various amounts of the relevant putative SOD mimic were added. Rates were linear for at least 8 min. The rates both in the absence and in the presence of the complex were determined for each concentration of complex added. The IC_{50} value represents the concentration of the putative SOD mimic that induces 50% inhibition of the reduction of cytochrome *c*. Values were determined as exemplified in Figure 7, where p_1 is the slope before addition of the putative SOD mimic and p_2 is the slope after its addition. The percentage inhibition is given by $\%I = (p_1 - p_2)/p_1{\cdot}100$. For each IC_{50} determination, $\%I$ was measured for several concentrations in the region of the IC_{50}. The IC_{50} value was obtained for $\%I = 50\%$. Additionally, $(p_1 - p_2)/p_2$ was also plotted against the complex concentration and the IC_{50} value was obtained for $(p_1 - p_2)/p_2 = 1$.[63] For tests with EDTA, this chelator was added to provide a final concentration of 3 *m*M in the cuvette. For tests with BSA, 30 μL of BSA (50 $mg{\cdot}mL^{-1}$) was added 4 min after the addition of xanthine oxidase and 2 min after the addition of the putative SOD mimic.

Reaction of Complexes with H_2O_2 under the X/XO Assay Conditions: H_2O_2 (10 equiv.) was added to a solution of the complex (2×10^{-6} M) in potassium phosphate (50 *m*M, pH = 7.8). The H_2O_2 concentration was determined at intervals of 5 min over half an hour by oxidation of iodide using the Ghormley method (colorimetric titration).[91]

Acknowledgments

We thank Dr. Philippe Maillard and Dr. Elodie Anxolabéhère-Mallart both for technical assistance and for discussions concerning electrochemistry, Prof. H. Toftlund for helpful suggestions, and Dr. J. P. Renault for useful discussions and comments. We also acknowledge Dr. Aurore Gref for lending us a platinum electrode. We would like to thank one of the referees for the suggestion to estimate the conversion of Mn^{II} species to the $Mn^{III}Mn^{IV}$ compound. We are grateful to Prof. J. J. Girerd's group for kindly providing us with the $Mn^{III}Mn^{IV}$ compound used as a concentration standard, in particular we would like to thank C. Hureau, Dr. G. Blondin, and Dr. P. Dorlet. We acknowledge the European Community for financial support (TMR contract FMRX-CT980174).

Olefin Epoxidation with Transition Metal η^2-Peroxo Complexes: The Control of Reactivity

Dirk V. Deubel,*[a,b] Jörg Sundermeyer,[a] and Gernot Frenking*[a]

Keywords: Density functional calculations / Epoxidations / Peroxo complexes / Transition states

The activation energies for olefin epoxidation with Mimoun-type η^2-peroxo complexes have been calculated using density functional methods. Six degrees of freedom of the complex [MOL$(O_2)$$(OER_3)$] and the olefin CH_2CHR' have been systematically modified. The calculations were based on the assumptions that the reaction follows a concerted oxygen-transfer mechanism suggested by Sharpless and that a peroxo oxygen atom *trans* to the phosphane oxide ligand is transferred. This was recently proved for the epoxidation of ethylene with the parent complex [$MoO(O_2)_2${$OP(CH_3)_3$}]. It has been found that the diperoxotungsten complexes (M = W; L = O_2) are more reactive than the diperoxomolybdenum complexes (M = Mo; L = O_2). The activation barriers for the monoperoxomolybdenum complexes (M = Mo; L = O) are significantly higher than the barriers for the corresponding diperoxo complexes (M = Mo; L = O_2), whereas equal activation energies have been predicted for both tungsten compounds (M = W; L = O_2 and O). The influence of the pnicogen oxide OER_3 on epoxidation activity is comparably small, while electron-releasing substituents R′ at the C=C bond reduce the activation barrier. The transition states for the epoxidation of alkenes with conjugated double bonds show a large extent of asymmetry, with the C–O bond at the terminal carbon atom being formed first. Additional ligands L′ coordinating to the metal center inhibit oxygen transfer. The results are in agreement with an electrophilic attack of the oxidant on the C=C double bond.

Introduction

Tremendous research efforts have focused on the epoxidation of olefins mediated by transition metal complexes,[1−7] in order to replace the chlorohydrin process which is still utilized on a million-ton-per-year scale despite its inefficiency and environmental impact.[8] Beside Herrmann-type diperoxorhenium compounds,[6] Mimoun-type diperoxo complexes of group 6 metals have been utilized as oxidants for olefins. As a promising method based on the *stoichiometric* epoxidation with Mimoun-type diperoxomolybdenum complexes [$MoO(O_2)_2(OPR_3)$] (R = NMe_2),[9] a *biphasic catalytic* system (R = *n*-dodecyl) has recently been developed[10] and patented by BASF.[11] Furthermore, *catalytic* methods in *one homogeneous phase* involving oxo- and diperoxomolybdenum compounds with the hmpa ligand (R = NMe_2)[12] and the 3-pyrazolylpyridine-*N*,*N*′ ligand[13] were reported.

In the last decade, modern computational chemistry has become an important tool in clarifying mechanisms of metal-complex-mediated epoxidations.[14−21] The long-standing controversy[22] about the mechanism of olefin epoxidation with Mimoun-type η^2-diperoxomolybdenum complexes [$MoO(O_2)_2(OPR_3)$] (**I**) has recently been settled with the help of density functional methods (Scheme 1).[16] The reaction does not follow a step-wise pathway[23] involving olefin coordination at the metal center (**II**), subsequent cycloinsertion yielding a 2,3-metalladioxolane (**III**), and cycloextrusion of the oxirane (**IV**) from the metallacycle. Although olefins coordinate with the d^0 metal center of the diperoxomolybdenum complexes (**I→II**),[24] subsequent formation of the metalladioxolane (**II→III**) does not occur; nor is a direct reaction pathway (**I→III**) from the reactants to the metallacycle energetically feasible.[16] Even if the metallacycle was formed, its decomposition would yield the carbonyl compound (**VI**) via hydrogen-migration-supported cycloreversion, rather than the epoxide (**IV**) via cycloextrusion (Scheme 2).[16] As suggested by Sharpless,[25] the oxygen atom is directly transferred from the metal peroxide to the olefin (**TS V**). Preferentially, the peroxo oxygen atom *trans*[26] to the phosphane oxide ligand is transferred and it has a *spiro* configuration in the **TS** geometry.[16] The transition state shows an anomeric effect, i.e. the O−P bond of the phosphane oxide is synperiplanar to the metal−oxygen bond being cleaved.[16,24] The concerted mechanism was also proved for olefin epoxidation with the methyloxodiperoxorhenium(VII) compound.[14] The electronic character of the oxygen transfer was clarified by Charge Decomposition Analysis (CDA)[27] of **TS V**.[20] The analysis identified donation *d* from the ethylene HOMO into the σ* orbital of the O−O bond as the predominant interaction (Figure 1). Backdonation *b*, from the oxygen lone pairs into the ethylene LUMO is significantly less important. This indicates an electrophilic attack of the metal peroxide on the olefin.[20]

Since the activation energy for the epoxidation of ethylene with [$MoO(O_2)_2${$OP(CH_3)_3$}] was calculated to be comparably high (18 kcal/mol),[16] the objective of this DFT study was to investigate the control of reactivity. A general-

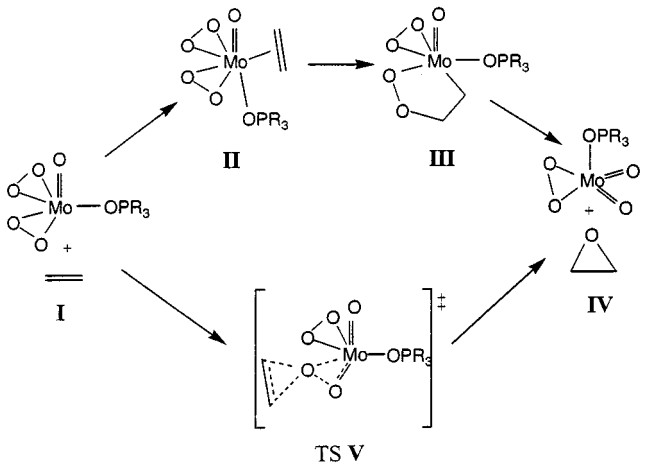
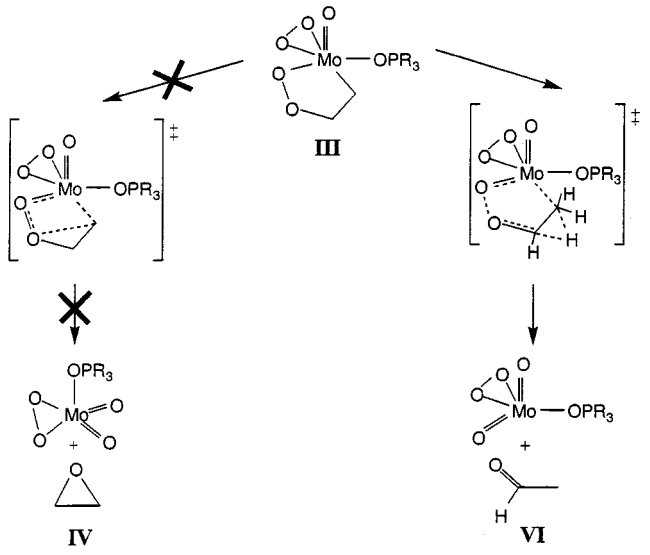


Scheme 1. The long-standing controversy about the mechanism of olefin epoxidation with Mimoun-type diperoxo complexes; the reaction follows a concerted pathway via **TS V**



Scheme 2. Fragmentation of the metallacycle; hydrogen-migration-supported cycloreversion (**III→VI**) is favored over the cycloextrusion of oxirane (**III→IV**)

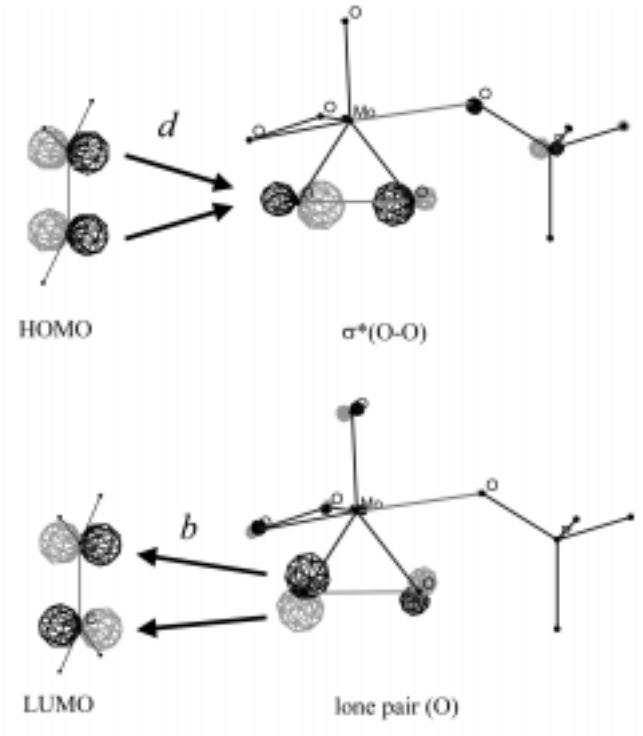


Figure 1. Predominant orbital interactions in the transition state for the epoxidation of ethylene with $[MoO(O_2)_2(OPH_3)]$; donation *d* is significantly more important than backdonation *b*

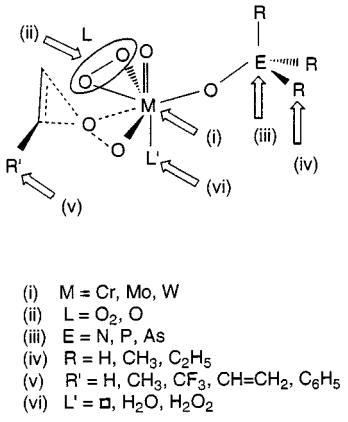

Scheme 3. Concepts for the control of reactivity of olefin oxidation with Mimoun-type peroxo complexes

ized model consisting of the metal complex $[MOL(O)_2(OER_3)L']$ and a terminal olefin CH_2CHR', contains six reactivity-determining degrees of freedom (Scheme 3) which are systematically modified in this study: (i) the metal center M, (ii) the oxo or peroxo ligand L, (iii) pnicogen E, (iv) the substituents R at the pnicogen atom, (v) the substituent R′ at the olefin, and (vi) additional ligands L′ at the metal center. The calculations were based on the assumption that the reaction follows the same concerted pathway as ethylene epoxidation with the parent complex $[MoO(O_2)_2\{OP(CH_3)_3\}]$.[16] Note that, in the catalytic systems, the coordination of the oxidant such as hydrogen peroxide, silyl peroxides, or *tert*-butyl hydroperoxide to the metal center and subsequent proton transfer can yield different species which are potentially more reactive than the parent η^2-peroxo complex.[10,13,17,21] Unless otherwise stated, transfer of the peroxo oxygen atom, which is located *trans* to the phosphane oxide, has been considered.[26]

Methods

The geometries of the molecules and transition states (**TS**) were optimized using the 3-parameter fit of the exchange potentials introduced by Becke (B3LYP).[28] Relativistic small-core ECPs[29] with a valence basis set splitting (441/2111/N1) were used for Cr (N = 4), Mo (N = 3), and W (N = 2), while 6−31G(d) all-electron basis sets were employed for the other atoms.[30] This is our standard basis set

II.[31] Vibrational frequencies and zero-point energy contributions (ZPE) were also calculated at B3LYP/II. All structures reported here are either minima (NIMAG = 0) or transition states (NIMAG = 1, **TS**) on the potential energy surface. The ZPE corrections are unscaled. Improved total energies were calculated at the B3LYP level using the same ECP and valence basis set for the metal atom, but totally uncontracted and augmented with one set of f-type polarization functions,[32] together with 6−31+G(d) basis sets for the other atoms.[33] This basis set combination is denoted III+.[34] Unless otherwise stated, the energies reported refer to the B3LYP/III+//B3LYP/II level of theory. For selected molecules, NPA atomic partial charges were calculated.[35] The computations were carried out with the program package Gaussian 98.[36]

Donor−acceptor interactions in selected transition states were examined using Charge Decomposition Analysis (CDA),[27] which is a quantitative interpretation of the Dewar−Chatt−Duncanson model.[37] The Kohn−Sham orbitals of the **TS** are expressed as a linear combination of the orbitals of the olefin and the remaining metal fragment [M] in the **TS** geometry. The orbital contributions are divided into the mixing of the occupied MOs of the olefin and the vacant orbitals of [M] (donation *d* $C_2H_3R'\rightarrow$[M]), the mixing of the vacant MOs of the olefin and the occupied orbitals of [M] (backdonation *b* $C_2H_3R'\leftarrow$[M]), and the mixing of the occupied MOs of the olefin and the occupied orbitals of [M] (repulsive polarization *r* $C_2H_3R'\rightleftarrows$[M]). A fourth term denoted as the rest term Δ gives the mixing of the unoccupied MOs of the olefin and the unoccupied MOs of [M]. The Δ term will be approximately zero if a discussion of the **TS** in terms of donor−acceptor interactions is permissible. The CDA calculations were performed using the program CDA 2.1.[38]

Results and Discussion

Tables 1−7 list the calculated activation energies for 21 systematically selected combinations (i−vi). In the tables and figures, reactants are denoted **R** and transition states are denoted **TS**. For the coordination of additional ligands L′ at the metal center (vi), stabilization energies were also calculated. The stabilized complexes are denoted **C**. The activation energies given in Table 7 refer to the stabilized complexes **C**.

(i) Influence of the Metal M

Since the patents of BASF[11] include the Mimoun-type diperoxotungsten complexes in addition to the molybdenum compounds, we are extending our study to all the group 6 metals. The reactivity of the diperoxo complexes $[MO(O_2)_2(OPR_3)]$, with M = Cr, Mo, W, with respect to ethylene epoxidation can easily be predicted. Since the oxidant attacks the olefin in an electrophilic manner,[16] the partial charges at the peroxy oxygen atoms of the free oxidants should be a measure of epoxidation activity. NPA partial charges of the three metal diperoxides are shown in Figure 2.[35] At the metal center, the charges increase from chromium to tungsten. Negative charges at the peroxo oxygen atoms of $[MO(O_2)_2(OPR_3)]$ increase in the same order; the highly negatively charged oxygen atoms of the tungsten complex are less electrophilic, and this complex should therefore be less reactive. This conclusion is supported by the reaction energies; according to the Bell−Evans−Polanyi principle,[39] a lower barrier for the chromium complex is expected due to the more exothermic reaction (Table 1). These results suggest that the activation energies increase in the order Cr < Mo < W.

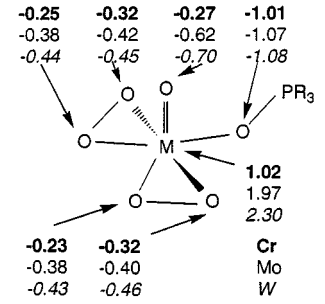

Figure 2. Calculated NPA partial charges of $[MO(O_2)_2\{OP(CH_3)_3\}]$; M = Cr (**R 1**, **bold**), Mo (**R 2**, plain), W (**R 3**, *italics*)

Table 1. O−O distances [Å] in diperoxo complexes $[MO(O_2)_2\{OP(CH_3)_3\}]$; M = Cr (**1**), Mo (**2**), W (**3**), *d*/*b* ratio in CDA of the transition states of ethylene epoxidation, reaction energies E_r [kcal/mol] and activation energies E_a [kcal/mol]; energies at the B3LYP/III+//B3LYP/II level; ZPE-corrected (B3LYP/II) values in parentheses

No.[a]	M	O−O	*d*/*b*	E_r	E_a
1	Cr	1.404	1.63[b]	−42.5 (−40.1)	21.8 (23.1)
2	Mo	1.452	1.76[c]	−37.2 (−35.4)	16.9 (17.9)
3	W	1.478	1.86[d]	−36.9 (−35.0)	14.5 (15.4)

[a] For geometry optimizations and frequency calculations, basis set STO-3G was used at the methyl groups. − [b] $d = 0.237$, $b = 0.145$, $r = -0.318$, $\Delta = -0.005$. − [c] $d = 0.237$, $b = 0.135$, $r = -0.312$, $\Delta = -0.004$. − [d] $d = 0.233$, $b = 0.125$, $r = -0.301$, $\Delta = -0.005$.

However, the calculated activation barriers show the opposite trend. Activation energies for ethylene epoxidation with $[MO(O_2)_2\{OP(CH_3)_3\}]$ decrease from chromium (23.1 kcal/mol), molybdenum (17.9 kcal/mol) to tungsten (15.4 kcal/mol, Table 1). Rösch and co-workers[19] have recently studied the epoxidation of ethylene with simpler model complexes $[MO(O_2)_2(NH_3)]$ using DFT methods. They found a similar trend for the activation energies with M = Cr, Mo, W.[40] A correlation between the σ*-orbital energy level and the activation barrier was given as an explanation.[18] This is plausible because donation from the olefin HOMO into the σ* orbital of the O−O bond being cleaved is the dominant interaction in the **TS**.[20] Furthermore, Rösch and co-workers[19] pointed out a stronger involvement of the metal d orbitals in the π* orbital of the O−O bond in the chromium compound, which increases the strength of the O−O bond and lowers the epoxidation ac-

tivity. This is also reflected by the O−O distances in the free oxidants (Table 1).

Originally, a three-membered ring transition state shown in Figure 3a was suggested.[25] If this had been true, the partial charges of the metal complexes would have led to the correct prediction of the epoxidation activity. We want to point out that the transition state is coarctate,[41] i.e. the metalladioxirane moiety is significantly involved, as schematically shown in Figure 3b. Therefore, the sum of partial charges $q(M) + q(O) + q(O)$ at the metalladioxirane moiety (Figure 2) predicts the trend of the activation barriers in relation to an electrophilic attack. A fragment-based population analysis, such as Charge Decomposition Analysis (CDA),[27] should also reflect the trend; the CDA results of the transition states are given in Table 1. The ratio donation/backdonation (d/b) is a measure of the electronic character of the oxidants. The analysis reveals that the d/b values, and therefore the electrophilicity of the oxidants increase in the order Cr < Mo < W. Since the oxidant attacks the olefin in an electrophilic manner, the reactivity of comparable oxygen-transfer agents correlates with their electrophilicity.

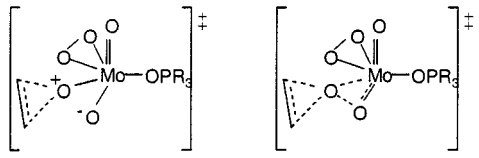

Figure 3. The nature of the transition state for olefin epoxidation with transition metal peroxo complexes: a) **TS** involving only the olefin and the oxygen atom that is transferred, b) coarctate **TS**

(ii) Reactivity of Monoperoxo Complexes

Olefin epoxidation with a diperoxo complex yields the oxirane2 and the monoperoxo complex, which might then oxidize an olefin. To highlight the reactivity of the monoperoxomolybdenum compounds, we calculated the activation energies for the epoxidation of ethylene with $[MoO(O_2)L(OPR_3)]$ (L = O_2, O; Table 2). CDA results are also given in Table 2. In contrast to the transition states presented in the other sections, both isomers of the **TS**s, i.e. for an olefin attack at the peroxo oxygen atom *cis* and *trans* to the phosphane oxide, have been considered since the preferential attack has not yet been clarified for the monoperoxo complexes. The **TS**s for a *cis* attack are denoted **c**. Figure 4 shows the optimized structures for the transition states of ethylene epoxidation with the molybdenum diperoxides $[MoO(O_2)_2(OPH_3)]$ (**TS 10** and **TS 10c**, respectively) and monoperoxides $[MoO_2(O_2)(OPH_3)]$ (**TS 12** and **TS 12c**, respectively). CDA of the diperoxo compounds indicates that the transfer of the *cis* oxygen atom is less electrophilic (**TS 10c**: $d/b = 1.60$), and therefore less reactive (E_a = 24.7 kcal/mol) than the transfer of the *trans* oxygen atom (**TS 10**: $d/b = 1.92$, E_a = 15.2 kcal/mol). The corresponding results for the monoperoxo complexes are surprising. Although the peroxo oxygen atom situated *trans* is also more electrophilic ($d/b = 2.00$ for **TS 12** versus 1.68 for **TS 12c**), the activation barriers are almost equal (17.8 and 18.0 kcal/mol, respectively). Does our simple model fail to explain the reactivity of the monoperoxo complexes? Note the optimized structures of the reactants given in Figure 5. While $[MoO(O_2)_2(OPR_3)]$ (**R 10**) has Mo−O(peroxo) bonds of equal length, the Mo−O(peroxo) bonds situated *cis* to the phosphane oxide in $[MoO_2(O_2)(OPR_3)]$ (**R 12**) are elongated. The cleavage of these bonds is already reflected by the reactant geometry, which is the reason for a moderate barrier despite its lower electrophilicity. CDA apparently describes the nature of the O−O bond rather than the metal−O(peroxo) bond. Bach and co-workers[42] pointed out for other oxidants that a prediction of activation energies based only on parameters of the O−O bond being cleaved is not always successful. In metal peroxides, the strength of the M−O bonds, reflected by their length, also has to be taken into account.

Table 2. Calculated (B3LYP/III+//B3LYP/II) activation energies E_a [kcal/mol] and CDA results of transition states of ethylene epoxidation with the diperoxo and monoperoxo complex $[MoOL(O_2)(OPH_3)]$; L = O_2 (**R 10**), O (**R 12**)

TS[a]	d $C_2H_4\rightarrow$[M]	b $C_2H_4\leftarrow$[M]	d/b	r $C_2H_4\leftrightarrow$[M]	Δ	E_a
TS 10	0.223	0.116	1.92	−0.275	−0.005	14.2 (15.2)
TS 10c	0.230	0.144	1.60	−0.332	−0.005	23.8 (24.7)
TS 12	0.230	0.115	2.00	−0.288	−0.004	17.0 (17.8)
TS 12c	0.208	0.124	1.68	−0.283	−0.005	17.0 (18.0)

[a] **TS** for an olefin attack on the peroxo oxygen atom *cis* to the phosphane oxide ligand are denoted **c**. Otherwise, the *trans* peroxo atom is attacked.

Olefin epoxidation with several (monoperoxo)Mo^{VI} complexes of the type $[X_2MoO(O_2)(H_2O)(NH_3)]$ was recently studied by Rösch and co-workers using density functional methods.[18] These monoperoxo complexes exhibit higher barriers for direct oxygen transfer to ethylene than those for the reference diperoxo complex $[MoO(O_2)_2(H_2O)(NH_3)]$.[18] The most electronegative ligands X induce the lowest barriers, which is in agreement with the concept of an electrophilic attack of the molybdenum peroxide on the olefin.

Our calculations reveal that the monoperoxomolybdenum complexes (**R 12**: E_a = 17.8 kcal/mol) are less reactive than the diperoxo complexes (**R 10**: E_a = 15.2 kcal/mol). The small reactivity of monoperoxomolybdenum compounds was supported by experiments[10,43] and a recent theoretical[18] study. However, the data provided in Table 3 reveal that the reactivities of the tungsten compounds are different. The calculated activation barriers for ethylene epoxidation with the monoperoxo- (**R 13**: E_a = 13.5 kcal/mol) and diperoxotungsten compounds (**R 11**: E_a = 12.7 kcal/mol) are almost equal, indicating that both tungsten species are active oxidants.

(iii) Influence of the Pnicogen E

Besides amphiphilic phosphane oxide ligands, the corresponding amine and arsane oxides are used in the metal-catalyzed epoxidation under biphasic conditions.[10,11] Thus, we have investigated the reactivity of the diperoxo complexes $[MO(O_2)_2\{OE(CH_3)_3\}]$ with M = Cr, Mo, W and with E = N, P, As. The results given in Table 4 are similar for the three metals; we focus on the molybdenum compounds for which the largest differences in the activation barriers are found. The calculations show that the complexes with the phosphane oxide ligands tend to be slightly more reactive than the amine and arsane oxide complexes. Phosphane oxides are weaker donors than their N and As analogues. Therefore, the OPR_3 complexes are more electrophilic at the metalladioxirane moieties and more reactive. This is in agreement with the experimental results for stoichiometric olefin epoxidation.[10] Surprisingly, the opposite trend is found for the reaction performed under biphasic conditions. In this system, the phosphane oxide complexes are less efficient.[10] Note that the turnover frequencies depend both on the intrinsic reactivity of the oxidants and on their Nernst distribution in the two phases. Amine and arsane oxides are comparably strong donors and they can extract the catalyst more efficiently into the organic phase, where epoxidation occurs. Despite higher activation barriers, the E = N, As systems are better oxidants under biphasic conditions due to their better extracting abilities,

which leads to a larger concentration of catalyst in the organic phase.[10] Although one should not over-interpret the small calculated differences in activation energies, the theoretically predicted activation barriers reflect the experimental trends.

Table 3. Calculated (B3LYP/III+//B3LYP/II) activation energies E_a [kcal/mol] for ethylene epoxidation with mono- and diperoxo complexes [$MOL(O_2)\{OE(CH_3)_3\}$]; M = Mo, W; L = O_2, O; ZPE-corrected (B3LYP/II) values are given in parentheses

[a] For geometry optimizations and frequency calculations, basis set STO-3G was used at the methyl groups. – [b] □ = free coordination site.

(iv) Influence of Substituents R at the Pnicogen Oxide

Amphiphilic pnicogen oxides with long alkyl chains *n*-C_kH_{2k+1} are used as ligands in the biphasic system. The turnover frequencies strongly depend on the chain length *k*; after increasing with increasing *k*, they remain constant from about $k = 8$.[32] The crucial question is whether the chain length has an influence on the reactivity of the complex, or only on its Nernst distribution equilibrium. Thus, we calculated activation energies for the epoxidation of ethylene by [$MoO(O_2)_2(OPR_3)$] with R = H, CH_3, C_2H_5 (Table 5). The decreasing reactivity from the phosphane oxide complexes (R = H, E_a = 15.2 kcal/mol) to the trimethylphosphane oxide complexes (R = CH_3, E_a = 17.5 kcal/mol) arises from a larger electron density at the metal center and at the peroxo oxygen atoms in the latter compound. The important result for the complex with R = C_2H_5 should be noted. The activation barrier increases by only 0.4 kcal/mol compared with that for the complex with R = CH_3. Alkyl chains longer than $k = 1$ influence the concentration of the catalyst [$MoO(O_2)_2\{OP(n\text{-}C_kH_{2k+1})_3\}$] in the organic phase rather than the reactivity. Therefore, trimethylphosphane oxide is an excellent model for the amphiphilic ligand in computational studies on the control of reactivity.[45]

Table 5. Calculated (B3LYP/III+//B3LYP/II) activation energies E_a [kcal/mol] for ethylene epoxidation with [$MoO(O_2)_2(OPR_3)$]; R = H, CH_3, C_2H_5; ZPE-corrected (B3LYP/II) values are given in parentheses

No.	(i) M	(ii) L	(iii) E	(iv) R	(v) R′	(vi) L′	E_a

2	Mo	O_2	P	CH_3 [a]	H	□	16.9 (17.9)
14	Mo	O_2	P	CH_3	H	□	16.6 (17.5)
15	Mo	O_2	P	C_2H_5	H	□	17.1 (17.9)

[a] For geometry optimizations and frequency calculations, basis set STO-3G was used at the methyl groups.

(v) Influence of Substituents R′ at the Olefin

In our quantum-chemical calculations, ethylene has been used as a model for the olefin, although the homogeneously catalytic activation of hydrogen peroxide is probably unnecessary for the industrial production of ethylene oxide. Heterogeneously catalytic epoxidation on silver surfaces with O_2 as the oxidant works perfectly for ethylene, but fails for alkyl-substituted olefins due to a chemoselectivity problem. Allylic C–H bonds of the latter substrates are preferentially oxidized.[46] Thus, we are expanding our study of epoxidation with [$MoO(O_2)_2(OPH_3)$] to olefins of the type C_2H_3R', with a variety of substituents R′ = H, CH_3, CF_3, $CH{=}CH_2$, C_6H_5. Since attempts to induce an enantioface selectivity of olefin epoxidation by the employment of chiral phosphane oxide ligands failed,[44] only one of four diastereomeric transition states was arbitrarily selected for the attack at the peroxo oxygen atom *trans* to the OPR_3 ligand, and was optimized with all substituents R′ (Scheme 3). Electron-donating substituents might lower the barrier and vice versa, because donation from the olefin HOMO into the σ*(O–O) orbital is the predominant interaction in the transition state. The data given in Table 6 confirm this hypothesis. The calculated barrier for 3,3,3-trifluoropropene (17.2 kcal/mol) is higher than for ethylene (15.2 kcal/mol), whereas propylene is oxidized faster (E_a = 12.9 kcal/mol). Additional alkyl substituents at the olefin should further accelerate the reaction.[23] π-Conjugation in *transoid*-butadiene and styrene also leads to slightly smaller activation barriers. While the orbital coefficients at the carbon atoms in the olefin HOMO decrease, the energy of this orbital increases due to conjugation.[47] The geometry of **TS 18** for *transoid*-butadiene given in Figure 6 reveals a strongly asynchronous but still concerted epoxidation of conjugated double bonds. The C–O bond at the terminal carbon atom

Table 6. Calculated (B3LYP/III+//B3LYP/II) activation energies E_a [kcal/mol] for epoxidation of olefins CH_2=CHR, R′ = H, CF_3, CH_3, CH=CH_2, C_6H_5 with [$MoO(O_2)_2(OPH_3)$]; ZPE-corrected (B3LYP/II) values are given in parentheses

No.	(i) M	(ii) L	(iii) E	(iv) R	(v) R′	(vi) L′	E_a
10	Mo	O_2	P	H	H	□	14.2 (15.2)

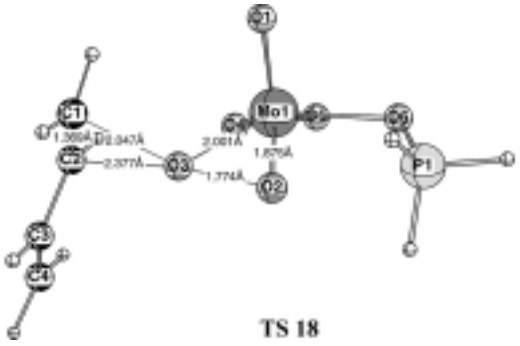

Figure 6. Optimized geometry of **TS 18** (B3LYP/II)

C1 is formed first because of the larger coefficient at C1 in the olefin HOMO.[47]

(vi) Influence of Additional Ligands L′ at the Metal Center

Due to the solubility of hydrogen peroxide in the organic phase ($CHCl_3$), epoxidation can occur in a different manner than that has been discussed for homogeneous *t*BuOOH activation:[13] Hydrogen peroxide can coordinate at the metal center, and catalytically active species might be formed in subsequent reactions.[13] In this section, we investigate the influence of an additional ligand L′ = H_2O, H_2O_2 on the stability and reactivity of diperoxo complexes [$MoO(O_2)_2(OPR_3)L'$]. The results are collected in Table 7. The coordination of an aqua and hydrogen peroxide ligand to [$MoO(O_2)_2\{OP(CH_3)_3\}$] is exothermic by −8.6 and −12.6 kcal/mol, respectively.[48,49] However, in agreement with the electrophilicity concept, the additional ligand increases the electron density at the reactive site and should therefore lower the reactivity. For the complex **C 21** with an additional H_2O_2 ligand, a corresponding transition state **TS 21** has not been optimized, because olefin attack at O3 leads to the dissociation of the hydrogen peroxide ligand. For the aqua complex **C 20**, the calculated activation energy for epoxidation increases to the comparably high value of 24.2 kcal/mol.

The coordination of a strong donor ligand inhibits the molybdenum-catalyzed epoxidation of olefins. This was already reported by Mimoun et al.[23] However, the reason for the inhibition is a lower electrophilicity of the complex rather than the blocking of a free coordination site for the olefin by the strong donor ligands at the metal center. It is interesting to note the slight influence that coordination of an aqua ligand to methyloxodiperoxorhenium(VII) compounds has on the reactivity of olefin epoxidation. Moreover, Kühn, Rösch, and co-workers[50] have recently found that Re-catalyzed olefin epoxidation is accelerated in the presence of N ligands. From the results of this section, an important conclusion for Mo-catalyzed epoxidations can be drawn. Due to the coordination of the oxidant, such as H_2O_2 or *t*BuOOH, to the metal center and due to the high activation barriers for the stabilized complexes, these catalytic processes must involve different species formed in subsequent reaction steps. Thiel and co-workers recently gave experimental[13] and theoretical[17] evidence for a potential proton transfer from an alkyl hydroperoxide ligand ROOH that is coordinated to the metal center, to an η^2-peroxo group of [$MoO(\eta^2\text{-}O_2)_2(NH_3)(ROOH)$]. During intramolecular proton transfer, the metalladioxirane moiety $M(O_2)$ is opened and species of the type [$MoO(\eta^2\text{-}O_2)(\eta^1\text{-}OOH)(NH_3)(\eta^1\text{-}OOR)$] are formed. The proton-transfer step also seems to be possible from hydroperoxide coordinating to the metal center.[21] Hence, in the presence of hydrogen peroxide, additional reaction mechanisms have to be taken into account, as suggested by Sheldon,[1,51] Sharpless[52] and Thiel,[13] for metal-complex-catalyzed epoxidations with alkyl hydroperoxides.

Conclusions

The reactivity of Mimoun-type peroxo complexes used for the epoxidation of olefins depends on six degrees of freedom of our extended model system [$MOL(O_2)(OER_3)L'$] and CH_2CHR' in the following way (see Scheme 3):

Table 7. Calculated (B3LYP/III+//B3LYP/II) stabilization energies E_s [kcal/mol] for the addition of L′ = {□, H_2O, H_2O_2} to [$MoO(O_2)(O_2)(OPR_3)$] and activation energies E_a [kcal/mol] for ethylene epoxidation with [$MoO(O_2)(O_2)(OPR_3)L'$]; ZPE-corrected (B3LYP/II) values are given in parentheses

No.	(i) M	(ii) L	(iii) E	(iv) R	(v) R′	(vi) L′	E_s	E_a
2	Mo	O_2	P	CH_3 [a]	H	□	–	16.9 (17.9)
20	Mo	O_2	P	CH_3 [a]	H	H_2O	−11.6 (−8.6)	23.8 (24.2)
21	Mo	O_2	P	CH_3 [a]	H	H_2O_2	−15.0 (−12.6)	–[b]

[a] For geometry optimizations and frequency calculations, basis set STO-3G was used at the methyl groups. – [b] The H_2O_2 ligand is removed from the metal center during olefin attack.

(i) Metal M = Cr, Mo, W: In the complexes $[MO(O_2)_2(OER_3)]$, we find the trend in the epoxidation activity to be W > Mo > Cr. While atomic partial charges and thermodynamic considerations fail to predict activation energies, Charge Decomposition Analysis (CDA) of the transition states was employed as a powerful tool to reveal the relationship between reactivity and the electrophilicity at the metalladioxirane moieties.

(ii) Diperoxo versus monoperoxo compounds; L = O_2, O: Activity O_2 > O. The monoperoxotungsten complex apparently is an active oxidant, whereas the corresponding monoperoxomolybdenum species seems to be inactive.

(iii) Pnicogen E = N, P, As: Activity P > N, As. In agreement with experimental data, complexes with the weaker donor phosphane oxide are more electrophilic and, thus more active under homogeneous conditions than their N and As counterparts. However, the better extracting ability of the latter compounds makes them superior in a biphasic protocol.

(iv) Substituents at the pnicogen R = H, CH_3, C_2H_5: Activity H > CH_3, C_2H_5. Long alkyl chains at the pnicogen oxides used as ligands in the biphasic catalytic system (BASF) have no influence on reactivity, but adjust the Nernst equilibrium, thereby favoring quantitative extraction of the catalyst.

(v) Substituents at the olefin R′ = H, CH_3, CF_3, CH=CH_2, C_6H_5: Reactivity CH_3, CH=CH_2, C_6H_5 > H > CF_3. Due to the electrophilic nature of oxygen transfer, more nucleophilic olefins react faster. The epoxidation of π-conjugated olefins is highly asynchronous; the C−O bond at the terminal carbon atom is formed first.

(vi) Additional ligands at the metal center L′ = □ (free coordination site), H_2O: Activity □ > H_2O. The reason why donor ligands, such as H_2O, inhibit oxygen transfer from the molybdenum compounds is the lower electrophilicity at the peroxo functionalities, rather than blocking the free coordination site for the activation of the olefin. Complexes of the type $[MoO(O_2)_2(OPR_3)L']$, with proton-containing ligands L′, such as H_2O and H_2O_2, can be expected to form compounds with η^1-OOH ligands via proton transfer. These species are probably more reactive than η^2-peroxo complexes.

[48] Note that experimental free-enthalpy values might differ from the calculated energies. For instance, the coordination of an additional ligand L′ to the metal center is an isokinetic reaction, i.e. the entropic contribution to the free enthalpy partially compensates the enthalpic stabilization. Solvation effects were not explicitly taken into account in our study because the molecules are too large. Furthermore, there is a basis-set-superposition error (BSSE), which is, however, expected to be very small since diffuse basis functions have been employed for energy calculations.
[49] In a previous study (ref.[24]), two isomers of the complex $[MoO(O_2)_2(OPH_3)(H_2O)]$ were found on the potential-energy surface. The OPH_3 and H_2O ligands occupy one equatorial and one axial coordination site of a pentagonal bipyramid. The isomer with the stronger phoshane oxide ligand in the equatorial position is favored by 5.3 kcal/mol over the isomer with the aqua ligand in the equatorial position. Due to electronic and steric reasons, we expected an even larger preference of the former isomer when the improved model $OPMe_3$ is utilized and omitted the investigation of the latter isomer using the improved model.

The EPR Pattern of [CrO(*cis*-1,2-cyclopentanediolato)$_2$]$^-$ and [CrO(*trans*-1,2-cyclopentanediolato)$_2$]$^-$

Sandra Signorella,*[a] Verónica Daier,[a] Mabel Santoro,[a] Silvia García,[a] Claudia Palopoli,[a] Juan Carlos González,[a] Lazlo Korecz,[b] Antal Rockenbauer,[b] and Luis F. Sala*[a]

Keywords: Chromates / Chromium / Redox chemistry / EPR spectroscopy

The addition of a large excess of 1,2-cyclopentanediol to a 1:1 mixture of glutathione and Cr^{VI} at pH 7.5 stabilises the intermediate Cr^V species formed by the one-electron reduction of Cr^{VI} by glutathione. The isotropic EPR parameters (g_{iso} and A_{iso}) of the Cr^V species formed with both *cis*- and *trans*-1,2-cyclopentanediol correspond to those calculated for five-coordinate oxo-Cr^V complexes with four alcoholato donors [Cr(O)(1,2-cyclopentanediolato)$_2$]$^-$. The five-coordinate oxo-Cr^V species formed with both 1,2-cyclopentanediol isomers show very similar EPR superhyperfine patterns, but differ in their stability and the conditions required for their formation due to the different chelation ability of the *cis*- vs. *trans*-1,2-diolato moiety.

Introduction

Cr^V intermediates are generated in the oxidation of a number of organic substrates by Cr^{VI} and are possibly linked to the formation of Cr-induced cancers.[1−2] The biological reduction of Cr^{VI} to lower states has been observed with a wide variety of naturally occurring cellular reductants.[3−7] Ligands that possess two oxygen atoms able to form five-membered rings about the metal ion are effective as nonenzymatic reductants and complexation agents towards hypervalent chromium and can stabilise the labile oxidation states of chromium.[8−14] Thus, it is becoming more apparent that diol ligands may play an important role in the stabilisation of Cr^V species formed during the reaction of Cr^{VI} with intracellular reductants. In particular, Cr^V-sugar species are very stable at physiological pH values and remain in solution for between several days and several months after the initiation of the reaction.[15−24]

The most common means of characterising Cr^V complexes in solution is EPR spectroscopy, where strong isotropic signals are observed at room temperature in the X-band spectra. An empirical relationship between the nature and the number of donor groups and the EPR spectral parameters of Cr^V complexes has been established.[25] Five-coordinate Cr^V species show higher g_{iso} and lower ^{53}Cr A_{iso} values than the corresponding six-coordinate species.[25−27] Thus, the assignment of the structures of new oxo-Cr^V species in solution may be made according to the isotropic EPR parameters (g_{iso} and A_{iso} values) and the superhyperfine (shf) pattern of the signal.

It has been found that the multiplicity of the EPR signal of Cr^V-diolato complexes is dependent upon whether the ligand is cyclically strained or not. It was observed that in Cr^V-diolato complexes formed with linear diols all the protons are equivalent in the isotropic EPR spectra,[28] but the strain of a six-membered ring imparts inequivalence to the magnetic environment of the protons in the second coordination sphere.[29] Thus, the signals in the EPR spectra of [CrO(*cis*-1,2-cyclohexanediolato)$_2$]$^-$ and [CrO(*trans*-1,2-cyclohexanediolato)$_2$]$^-$ exhibit a triplet and a singlet, respectively, and the difference was explained by arguing that only when the protons lie in the Cr^V-ligand plane is there a maximal overlap between the proton orbital and the Cr^V orbital containing the unpaired electron density.[29]

In the present work we study the Cr^V-diolato complexes formed by reduction of Cr^{VI} by glutathione (GSH) in the presence of *cis*- or *trans*-1,2-cyclopentanediol in order to extend the analysis of the EPR shf pattern to Cr^V-diolato species formed between Cr^V and five-membered ring 1,2-diols. Our results show that [CrO(*cis*-1,2-cyclopentanediolato)$_2$]$^-$ and [CrO(*trans*-1,2-cyclopentanediolato)$_2$]$^-$ yield EPR signals of the same multiplicity, with similar shf coupling constants — an EPR pattern markedly different from that observed for Cr^V complexes formed from *cis*- and *trans*-1,2-cyclohexanediol. Thus, the present results should be useful for the interpretation of the EPR spectra of the Cr^V species formed in the reduction of Cr^{VI} by biologically relevant substrates containing a five-membered 1,2-diolate ring.

Results

The reaction of Cr^{VI} with GSH (4.5 mM; 1:1 ratio) at pH = 7.5 affords three intermediate Cr^V species with EPR signals at g_{iso} = 1.9859, 1.9771 and 1.9719 [Figure 1(a)] and

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0707−1829 $ 17.50+.50/0

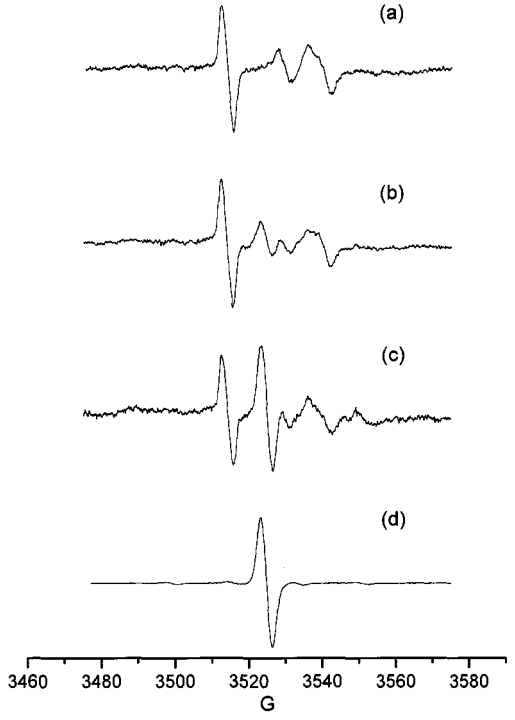

Figure 1. X-band EPR spectra of mixtures of: (a) GSH/Cr^{VI} = 1:1, [Cr^{VI}] = 4.5 mM; (b) GSH/Cr^{VI}/*trans*-diol= 1:1:100, [Cr^{VI}] = 4.5 mM; (c) GSH/Cr^{VI}/*trans*-diol = 1:1:500, [Cr^{VI}] = 1.0 mM; (d) GSH/Cr^{VI}/*trans*-diol = 1:1:5000, [Cr^{VI}] = 1.0 mM; T = 25 °C, pH = 7.5, t = 10 min., frequency = 9.7667 GHz. mod. ampl. = 4 G

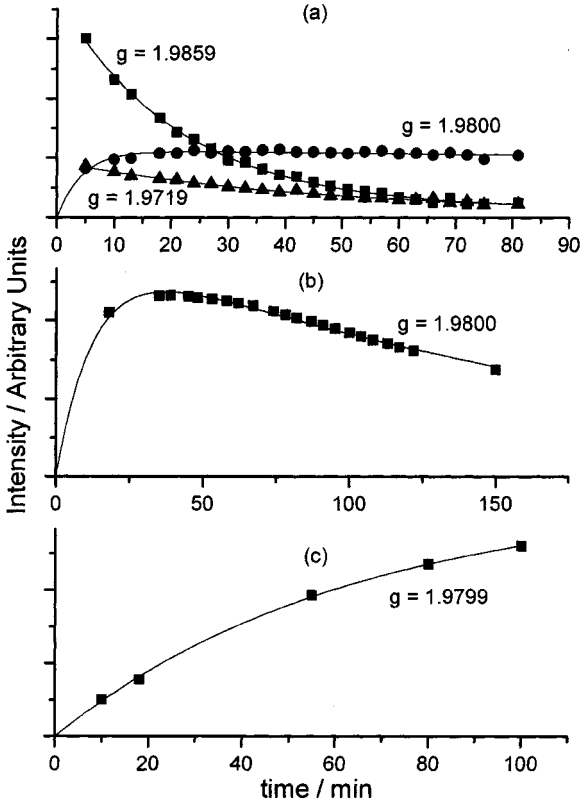

Figure 2. Time dependence of the EPR signal intensities; conditions: (a) GSH/Cr^{VI}/*trans*-diol = 1:1:100, [Cr^{VI}] = 4.5 mM; (b) GSH/Cr^{VI}/*trans*-diol = 1:1:5000, [Cr^{VI}] = 1.0 mM; (c) GSH/Cr^{VI}/*cis*-diol = 1:1:10000, [Cr^{VI}] = 0.5 mM. T = 25 °C, pH = 7.5

relative intensity 2.7:0.68:1, five minutes after the initiation of the reaction. The first signal decays twice as fast as the other two and they are no longer observed after 80 min. The same kinetic behaviour is observed for equimolar Cr^{VI}/GSH mixtures down to 0.5 mM.

When the same reaction is performed in the presence of a 100-fold excess of 1,2-*trans*-cyclopentanediol, the three signals attributed to the Cr^{V}-GSH intermediate species again decay with time and disappear 80 min. after mixing, while a fourth signal appears at g_{iso} = 1.9800 [Figure 1(b)]. This new signal reaches its maximum intensity 30 min. after mixing and decays slowly. The time-dependent variation of the intensity of this signal together with those corresponding to the decay of the Cr^{V}-GSH species at g_{iso} = 1.9859 and 1.9719 are shown in Figure 2(a).

In the presence of a 500-fold excess of *trans*-1,2-cyclopentanediol over the GSH/Cr^{VI} mixture, the EPR spectra are immediately dominated by the Cr^{V} signal at g_{iso} = 1.9800 [Figure 1(c)]. Under these conditions, this signal partially resolves into its components when the modulation amplitude is reduced to 0.4 G.

When the reaction is followed using a much larger *trans*-1,2-cyclopentanediol/Cr^{VI} ratio (5000:1), only the signal at g_{iso} = 1.9800 is observed [Figure 1(d)]. Under these conditions, this signal reaches its maximum intensity 40 min. after mixing and then decays slowly; the time-dependent trace shown in Figure 2(b). In this case, when the modulation amplitude is lowered to 0.4 G, the shf splitting of the signal resolves.

In the presence of excess *cis*-1,2-cyclopentanediol, a 100:1:1 diol/Cr^{VI}/GSH ratio is enough to afford a Cr^{V} signal at g_{iso} = 1.9799 as the only EPR feature in the spectrum. In this case a 500-fold excess of *cis*-1.2-cyclopentanediol is not enough to resolve the EPR signal [Figure 3(a)], but when a much larger excess (5000−10000:1:1 diol/Cr^{VI}/GSH) is used the multiplet resolves well [Figure 3(b)]. Under the last conditions, the rate of decay of the Cr^{V} signal is extremely slow and the signal intensity increases continuously for several hours [Figure 2(c)].

Discussion

It is well known that five-membered Cr^{V} chelates are the most stable and that the CrO^{3+} ion shows a marked preference for binding to *cis*- rather than *trans*-diol groups of cyclic diols.[15,21−24,30−32] Several observations confirm the expected higher ability of the *cis* vs. the *trans* isomer of 1,2-cyclopentanediol for binding Cr^{V}: the receiver gain required to observe the Cr^{V}-diolato signal is 1000 times higher for the *trans* than for the *cis* isomer; the excess of diol needed for the complete replacement of GSH in the Cr^{V} coordination sphere is much larger for the *trans* (5000:1) than for the *cis* (100:1) isomer; under the same experimental conditions, the rate of decay of the Cr^{V} signal is much faster for the *trans* than for the *cis* isomer of 1,2-cyclopentanediol.

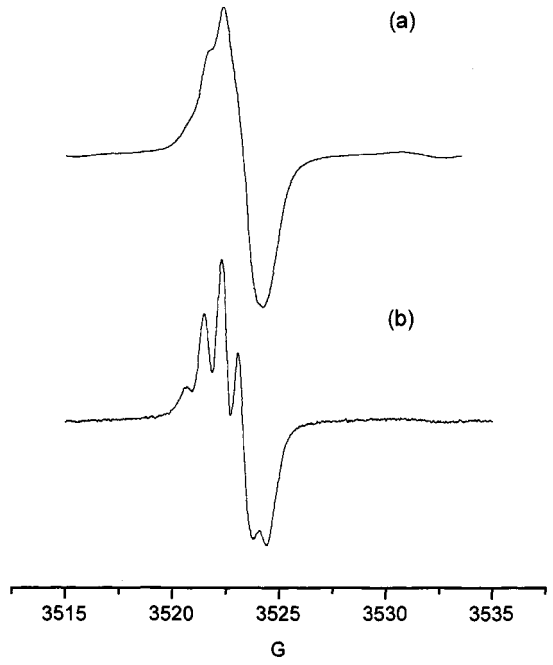

Figure 3. X-band EPR spectra of mixtures of: (a) GSH/Cr^{VI}/*cis*-diol = 1:1:500, [Cr^{VI}] = 1.0 mM; (b) GSH/Cr^{VI}/*cis*-diol = 1:1:10000, [Cr^{VI}] = 0.5 mM; T = 25 °C, pH = 7.5, t = 15 min., frequency = 9.7634 GHz. mod. ampl. = 0.04 G

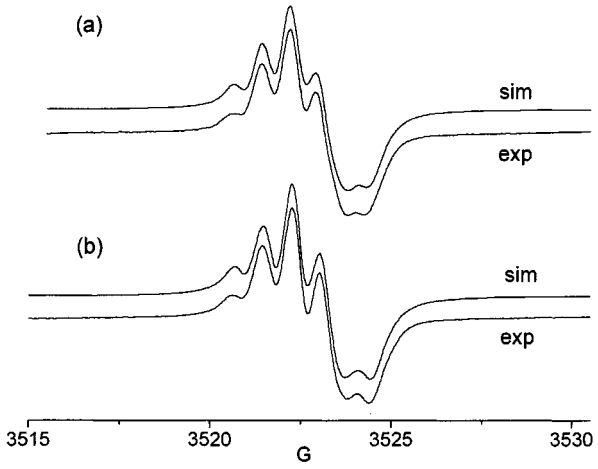

Figure 4. Experimental and simulated X-band EPR spectra of mixtures of: (a) GSH/Cr^{VI}/*trans*-diol = 1:1:5000, [Cr^{VI}] = 1.0 mM, frequency = 9.7620 GHz., mod. ampl. = 0.4 G; (b) GSH/Cr^{VI}/*cis*-diol = 1:1:5000, [Cr^{VI}] = 0.5 mM, frequency = 9.7634 GHz., mod. ampl. = 0.4 G

We used the isotropic EPR parameters g_{iso} and A_{iso} to estimate the coordination number and the nature of the donor groups of the Cr^V species formed in the reaction of Cr^{VI} with GSH in the presence of either excess *cis* or *trans* 1,2-cyclopentanediol, according to a described empirical method.[25−27] The EPR spectra were found to be composed of two Cr^V species (the signals were deconvoluted by fitting the spectra by Lorentzian derivatives). The best fit of the whole set of EPR spectra of Cr^V species formed with either the *cis* or *trans* isomer and different diol-to-Cr^{VI} ratios affords the spectral parameters listed in Table 1; the goodness-of-fit is shown in Figure 4. The spectral parameters for each Cr^V species listed in Table 1 are consistent within all simulation, with maximum deviations in the g_{iso} and ^{1}H a_{iso} values being ±0.0001 units and ±0.02 × 10^{-4} cm^{-1}, respectively. When setting all equivalent protons or pairs of equivalent protons to fit spectra, the spectral parameters were not consistent for all the simulated spectra even when some individual spectra showed a good correlation.

The g_{iso} and A_{iso} values of the Cr^V species formed with the two isomers correspond to those calculated for five-coordinate oxo-Cr^V complexes with four alcoholato donors.[25] In the presence of a large excess of either *cis*- or *trans*-1,2-cyclopentanediol, the EPR signal is a composite of two oxo-Cr^V-(diolato)$_2$ species with four (two from each chelate ring) and three carbinolic protons coupled to the Cr^V electronic spin, respectively (Table 1). In our simulations, we included values for ^{1}H a_{iso} only where the ^{1}H a_{iso} value is greater than the line width (LW) of the Cr^V species, since the signal is not significantly affected when the ^{1}H a_{iso} value is ≤ LW. Thus, the fourth carbinolic proton of the second component should be very weakly coupled to the Cr^V electronic spin resulting in a ^{1}H a_{iso} < LW. The values of ^{1}H a_{iso} of 0.41 × 10^{-4} and 0.47 × 10^{-4} cm^{-1} found for the second component of the EPR signals are just inside the lower simulation limit.

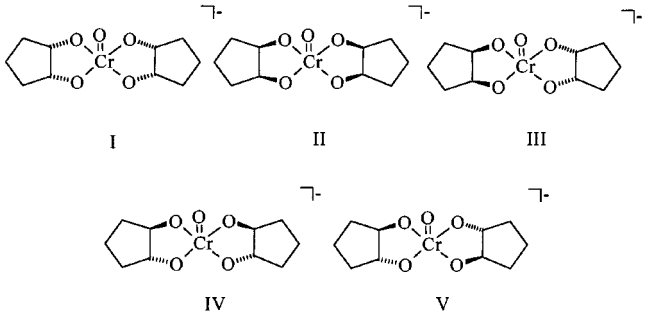
For the two protons lying in the Cr^V-ligand plane in [CrO(*cis*-1,2-cyclohexanediolato)$_2$]$^-$, the observed ^{1}H$_{eq}$ a_{iso} is approximately 0.9 × 10^{-4} cm^{-1}.[29] Measurements of isotropic and anisotropic ^{1}H ENDOR spectra of a series of oxo-Cr^V-diolato$_2$ complexes formed with linear diols showed that the shf coupling constants ^{1}H$_{eq}$ a_{iso} and ^{1}H$_{ax}$ a_{iso} are equal to 0.81 and 0.37 × 10^{-4} cm^{-1}, respectively.[33] This gives us an idea of the values of ^{1}H a_{iso} corresponding

Table 1. EPR spectral parameters

Cr^V species	g_{iso}	^{53}Cr A_{iso}/10^4 cm^{-1}	a_H/10^{4}cm^{-1}
[Cr(O)(*cis*-1,2-cyclopentanediolato)$_2$]$^-$	1.9803	15.9	0.84, 0.81,0.74, 0.64
	1.9798		0.76, 0.65, 0.41
[Cr(O)(*trans*-1,2-cyclopentanediolato)$_2$]$^-$	1.9804	15.9	0.84, 0.76, 0.72, 0.62
	1.9799		0.75, 0.64, 0.47

to the maximal and minimal overlap between the proton orbital and the Cr^V orbital containing the unpaired electron density in oxo-Cr^V-diolato$_2$ systems. Accordingly, in the present case, for the Cr^V species at g_{iso} = 1.9798/9 it is possible to differentiate two carbinolic protons with shf coupling constants intermediate between those corresponding to "pseudo-axial" and "pseudo-equatorial" protons, and two carbinolic protons close to the "pseudo-axial" orientation. While for the Cr^V species at g_{iso} = 1.9803/4, two carbinolic protons lie near the Cr^V-ligand plane and the two others form larger angles with the Cr^V-ligand plane.

The two components can be attributed to two geometric isomers of the $[Cr^V(O)(diolato)_2]^-$ moiety (Scheme 1).[29] Three different geometric isomers (I−III) are possible for $[Cr^V(O)(cis\text{-}1,2\text{-cyclopentanediolato})_2]^-$, whereas only two (IV−V) can exist for $[Cr^V(O)(trans\text{-}1,2\text{-cyclopentanediolato})_2]^-$. However, in both cases only two species are required to simulate the EPR signal. It seems reasonable to assume that the angles between the carbinolic protons and the Cr^V-ligand plane in two of the geometric isomers of $[Cr^V(O)(cis\text{-}1,2\text{-cyclopentanediolato})_2]^-$ are very similar, so we cannot distinguish between them (this should be the case for isomers I and II).



Scheme 1

For the largest diol/Cr^{VI} ratio used in this work the g_{quint}/g_{quart} ratios are 1:1.5 and 1:2.3 for Cr^V species formed with the *cis* and *trans* isomers, respectively, and are independent of the reaction time.

The shf EPR pattern observed for the $[Cr^V(O)(diolato)_2]^-$ species formed with *cis*- and *trans*-1,2-cyclopentanediol is clearly different from that reported for oxo-Cr^V-(diolato)$_2$ species formed with *cis*- and *trans*-1,2-cyclohexanediol. In the case of 1,2-cyclohexanediol, the *trans* isomer affords a singlet, while the *cis* isomer affords two triplets corresponding to two geometric isomers of $[Cr^V(O)(cis\text{-}1,2\text{-cyclohexanediolato})_2]^-$, each with two equivalent H_{eq} coupled to the Cr^V electronic spin. It seems evident that the $[Cr^V(O)(1,2\text{-cyclohexanediolato})_2]^-$ system differentiates the axially and equatorially disposed carbinolic protons, and, consequently, the resulting shf coupling corresponds to the maximal and minimal values expected for the ^1H coupled to the Cr^V electronic spin.

The situation is different for the oxo-Cr^V-(diolato)$_2$ species formed with *cis*- and *trans*-1,2-cyclopentanediol. The EPR spectra of $[Cr^V(O)(1,2\text{-cyclopentanediolato})_2]^-$ formed with both the *cis* and *trans* isomers show the same EPR spectral pattern corresponding to two Cr^V components split by nonequivalent carbinolic protons coupled to the Cr^V electronic spin: one Cr^V component with two "pseudo-equatorial" protons [^1H a_{iso} = 0.84, 0.81 × 10^{-4} cm^{-1} (*cis*-diolate) and 0.84, 0.76 × 10^{-4} cm^{-1} (*trans*-diolate)] and two protons disposed at angles in between the "pseudo-axial/equatorial" orientations, and a second Cr^V species with two "pseudo-axial" protons [^1H a_{iso} = 0.41, < LW (*cis*-diolate) and 0.47, < LW (*trans*-diolate)], and two protons protruding at intermediate angles. Thus, the strained bi-cycle arising from the two fused five-membered rings in $[Cr^V(O)(1,2\text{-cyclopentanediolato})_2]^-$ yields isotropic EPR spectra corresponding to the average conformations of two geometric isomers in which all the carbinolic protons are inequivalent.

Conclusions

Our results show that, as expected, *cis*-1,2-cyclopentanediol possesses a higher ability for binding Cr^V than *trans*-1,2-cyclopentanediol, and that the EPR spectra of Cr^V-(diolato)$_2$ species formed with either the *trans* or *cis* isomer of 1,2-cyclopentanediol exhibit a very similar EPR pattern. For both the *cis* and *trans* isomers, the EPR signal is a composite of two oxo-Cr^V-(diolato)$_2$ species split by four and three (the fourth ^1H a_{iso} is less than the line width) carbinolic protons coupled to the electronic spin, respectively. This new information on the spectral pattern of the EPR signal of Cr^V chelates formed with the *cis* and *trans* isomers of five-membered ring 1,2-diols should be useful in the interpretation of the EPR spectra of the Cr^V species formed in the reduction of Cr^{VI} by NAD(P)H[4] and nucleotides[34] by Cr^V binding to the *cis*-1,2-diolato moiety of the ribose ring and confirm the previous interpretation of the EPR spectra of Cr^V-furanosic sugar species.[21]

Experimental Section

Materials: *cis*-1,2-Cyclopentanediol (Aldrich grade), *trans*-1,2-cyclopentanediol (Aldrich grade), sodium dichromate (Mallinckrodt) and GSH (Sigma grade) were used without further purification. Water was purified by deionisation, followed by double distillation from a potassium permanganate solution. The pH of the solutions was adjusted by addition of 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES).

Warning: Chromic acids are toxic and carcinogenic.

Methods: EPR Measurements: The EPR spectra were performed on a Bruker ESP 300 E spectrometer. The microwave frequency was generated with a Bruker 04 ER (9−10 GHz) and measured with a Racal−Dana frequency meter. The magnetic field was measured with a Bruker NMR probe gaussmeter. All of the EPR experiments were carried out at room temperature. In a typical experiment, 10μL of an aqueous solution of Cr^{VI} (0.1 M) was added to a mixture of 10μL GSH (0.1 M), 0.5030 g diol and 1 mL HEPES (0.1 M) and immediately transferred to a flat quartz cell. The EPR spectra were simulated with a program for the automatic computer simulation of EPR spectra,[35] using 100% Lorentzian lineshapes.

Solvothermal Synthesis, Crystal Structure, and Thermoanalytical Investigations of the New Layered Thioantimonate(III) $[Fe(C_4H_{13}N_3)_2]Sb_6S_{10} \cdot 0.5\ H_2O$

Ralph Stähler,[a] Christian Näther,[a] and Wolfgang Bensch*[a]

Dedicated to Prof. Dr. Hk. Müller-Buschbaum on the occasion of his 70th birthday

Keywords: Thioantimonates / Solvothermal synthesis / Crystal structure / Thermoanalytical measurements

The novel thioantimonate(III) $[Fe(C_4H_{13}N_3)_2]Sb_6S_{10} \cdot 0.5\ H_2O$ was synthesised under mild hydrothermal conditions by allowing elemental Fe, Sb, and S to react in a 50% diethylenetriamine (dien) solution. The compound crystallises in the monoclinic space group $C2/c$ with a = 33.789(3), b = 8.5697(4), c = 24.620(2) Å, β = 118.411(8)°, and V = 6270.3(7) Å^3. In the crystal structure, five SbS_3 trigonal pyramids and one SbS_4 unit are interconnected by sharing common S atoms, forming Sb_2S_2, Sb_4S_4, and Sb_5S_5 heterocycles. The layered $[Sb_6S_{10}]^{2-}$ anion is formed by condensation of the rings in the order Sb_4S_4–Sb_5S_5–Sb_2S_2–Sb_5S_5–Sb_4S_4. The interconnection of the different Sb_xS_x heterocycles leads to the formation of a large $Sb_{16}S_{16}$ ring. The special geometries of the SbS_x units and their interconnection results in a new and unprecedented architecture of the four-atoms thick thioantimonate layer. The calculated bond valence sums (BVS) for the Sb atoms range from 3.07 to 3.16 v. u., indicating that the Sb atoms are formally trivalent. The $[Fe(dien)_2]^{2+}$ cations and the water molecule are located between neighbouring layers. The thermal behaviour of the compound was investigated using DTA-TG measurements. Upon heating decomposition starts at about 200 °C, which is accompanied by the removal of the organic ligands and the incorporated water molecules. In the X-ray powder pattern of the decomposition product, the three compounds Sb_2S_3, $FeSb_2S_4$, and FeS could be identified.

Introduction

In several articles published in the last few years the technologically useful properties of microporous solids have been reviewed in detail.[1−5] The syntheses of such microporous solids are typically carried out under solvothermal conditions in the presence of an organic molecule that should exert a directing effect on the crystallisation process, resulting in the formation of an open-framework inorganic material. The organic species is retained within the cavities or channels of the products. The vast majority of research work is focused on oxidic materials. But chalcogenidometallates with open frameworks have attracted considerable interest because several new compounds are semiconductors and show photoconductivity.[6,7] The syntheses and the structural features of chalcogenidometallates have been recently reviewed.[8,9] A large number of thioantimonates(III) exhibiting different degrees of condensation of the Sb_xS_y anionic fragments were reported.[10−23] In these compounds the linking of the complex anions leads to very different structures. Compounds with one-, two-, and three-dimensional structures were isolated and characterised. Despite the great differences between the thioantimonate(III) structures several structural relationships have been recognised.[9,24] For an insight into the general structural chemistry of the thioantimonates(III) new compounds must be synthesised and characterised. Here we report on the novel compound $[Fe(dien)_2]Sb_6S_{10} \cdot 0.5H_2O$, which adopts a new structure type.

Results and Discussion

The compound $[Fe(dien)_2]Sb_6S_{10} \cdot 0.5\ H_2O$ crystallises in the monoclinic space group $C2/c$ with eight formula units in the unit cell. There are two crystallographically independent Fe^{2+} cations in the asymmetric unit placed in a distorted octahedral environment of two chelating dien ligands (Figure 1: A and B). Hexacoordinated diethylenetriamine complexes of transition group elements have been known for a long time,[25,26] and the geometric isomers of the cations were intensively studied.[25,27−32] The ligand and the cation form fused five-membered rings with conformations that are expected to be different for both isomers. The two independent $[Fe(dien)_2]^{2+}$ cations in $[Fe(dien)_2]Sb_6S_{10} \cdot 0.5\ H_2O$ are meridional [Fe(1)] and *s*-facial [Fe(2)]. We note that $[Fe(dien)_2]^{2+}$ cations have not been reported until now. The Fe−N distances are between 2.185(3) and 2.257(3) Å (Table 1) and comparable with those reported in the literature.[33] The angles N−Fe−N vary between 78.1(2) and 156.2(2)°. As noted before the conformations of the two cations are significantly different and an attempt to fit the two cations onto each other results in a mean root deviation of about 1.5 Å.

Formal valence considerations suggest that all Sb atoms are trivalent. With the exception of Sb(6) each of the crystallographically unique Sb atoms is coordinated by three sulfur atoms with distances Sb−S ranging from 2.3920(8)

to 2.5209(8) Å (Table 1). The SbS_3 units have an approximately trigonal-pyramidal geometry with angles between 81.83(3) and 106.50(3)° (Table 1). For Sb(6) only two short bonds to S atoms of 2.4131(8) and 2.4824(8) Å are observed, and two longer distances of 2.7111(9) and 2.7522(8) Å (Table 1). The latter distances are longer than expected for single bonds that vary between about 2.4 and 2.6 Å, but they are significantly shorter than the typical so-called secondary bonds with Sb−S distances above around 2.9 Å. Hence, for the further discussion the two S atoms are included in the first coordination sphere of the Sb(6) atom. We note that SbS_4 units with distances between 2.4 and 2.85 Å were reported for $Cs_2Sb_8S_{13}$,[32] $(CH_3NH_3)_2Sb_8S_{13}$,[34] or $Cs_5Sb_8S_{18}(HCO_3)$.[20] All antimony atoms complete their coordination environments with sulfur neighbours at distances between 3.0567(8) and 3.7462(9) (Table 2), which is less than the sum of the van der Waals radii (S_{vdw} + Sb_{vdw} = 3.80 Å).[35] It is noted that the presence of short and long Sb−S distances is often observed in antimony sulfides. The longer Sb−S separations link the primary building blocks yielding higher structural units.

A way to describe the structure of the anion is based on the condensation of different Sb_xS_y heterocycles formed by the interconnection of the SbS_3 and SbS_4 units. The vertex linkage of SbS_3 pyramids involving Sb(1) to Sb(4) leads to

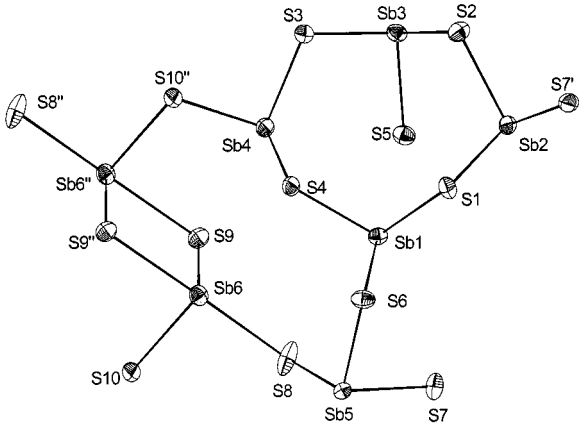

Figure 2. Condensation of the Sb_4S_4 heterocycle and the Sb_3S_8 unit generating an Sb_5S_5 ring; note: atoms denoted with superscripts are generated by symmetry operations

the formation of a puckered Sb_4S_4 ring (Figure 2). A second building-block with composition Sb_3S_8 is composed of two edge-sharing SbS_4 units [Sb(6) and Sb(6a)] being vertex-linked to the Sb(5)S_3 pyramid. The two Sb(6)S_4 units are related by a centre of symmetry forming an Sb_2S_2 ring (Figure 2).

The Sb_3S_8 unit is condensed to the Sb_4S_4 ring via two S atoms [S(6) and S(10a)], resulting in the formation of an

Sb_5S_5 ring [involving Sb(1), Sb(4), Sb(5), Sb(6), and Sb(6a)] (Figure 2). Due to the inversion centre located between the two $Sb(6)S_4$ units, a system of condensed heterocycles with the order $Sb_4S_4-Sb_5S_5-Sb_2S_2-Sb_5S_5-Sb_4S_4$ is generated (Figure 3). The assembly into the final layered anion is achieved by vertex linking of the condensed ring system via the terminal S(7) atoms. Consequently, another large heterocycle with composition $Sb_{16}S_{16}$ is present (shaded area in Figure 3). We note that the layers are four atoms thick, whereas for the overwhelming number of thioantimonates(III) two-atom thick layers are observed.

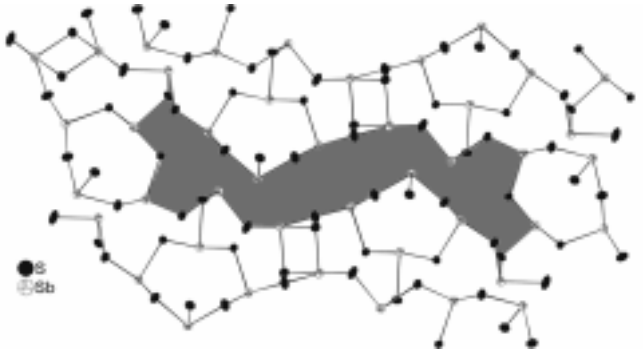

Figure 3. The layered anion with the large $Sb_{16}S_{16}$ ring (shaded area) with displacement ellipsoids drawn at the 50% probability level

The description becomes more complex when the secondary Sb−S bonds are considered. The Sb atoms in the Sb_4S_4 ring have longer Sb−S contacts [Sb(1)−S(5), Sb(1)−S(7), Sb(1)−S(8), Sb(2)−S(5), Sb(2)−S(6A), Sb(2)−S(6B), Sb(3)−S(6B), Sb(4)−S(5), Sb(4)−S(9), Sb(5)−S(1C), Sb(5)−S5(D), Sb(6)−S(4A), Sb(6)−S(5D)] ranging from 3.0567(8) to 3.7462(9) Å (Table 2), enhancing the coordination number from three to six. The atoms Sb(1) and Sb(6) have six neighbours and are in a distorted octahedral environment (Figure 4, B, F). When the s^2 lone pair is treated as a coordination site the polyhedron about Sb(3) may be described as distorted ψ-SbS_4 trigonal-bipyramid. The Sb(4) and Sb(5) atoms have two S neighbours, giving a distorted ψ-SbS_5 octahedron (Figure 4, C, D). With the enhanced coordination environments, different secondary building units can be identified (Figure 4). An Sb_3S_4 semicube (Figure 4, E) involving the two symmetry-related Sb(6) atoms and Sb(4) is formed, which is common in thioantimonates(III).[10,36−39]

The two symmetry-related $Sb(6)S_6$ octahedra share a common edge yielding an Sb_2S_{10} double-octahedron (Figure 4, F). Such a secondary building unit was found in $Cs_2Sb_8S_{13}$[36] and $(CH_3NH_3)_2Sb_8S_{13}$.[37] The three atoms Sb(1), Sb(2), and Sb(4) have secondary bonds to the S(5) atom that is located on top of the crown-like Sb_4S_5 heterocycle (Figure 4, A) thus joining the polyhedra of these Sb atoms of the ring.

The layered anions are within the (−101) plane, and are stacked onto each other parallel to the [110] plane. The cations as well as the water molecule are located between the layers (Figure 5). Six short intermolecular N−H···S distances (Table 3) with H···S distances ranging from 2.460 to 2.959 Å and N−H···S angles between 149.17° and 175.46° are observed, indicative of hydrogen bonding (Table 3).

The crystal structures of many thioantimonates(III) can be described on the basis of the condensation of different Sb_xS_y heterocycles. In the compound $[(CH_3NH_3)_{1.03}K_{2.97}]Sb_{12}S_{20}\cdot 1.34\,H_2O$,[40] in which the anionic part has the same composition when divided by two, the layered $[Sb_{12}S_{20}]^{4-}$ anion is formed by two complex rings having the same composition − $Sb_{12}S_{20}$ − and a very similar shape. Including the S atoms of the different rings (note: in the original contribution only the Sb atoms were counted) an Sb_8S_8 ring and four Sb_3S_3 rings are condensed giving the $Sb_{12}S_{20}$ complex ring system. The complex rings are interconnected into two-atom thick layers by so-called secondary bonds that are between 3.0567(8) and 3.5850(8)

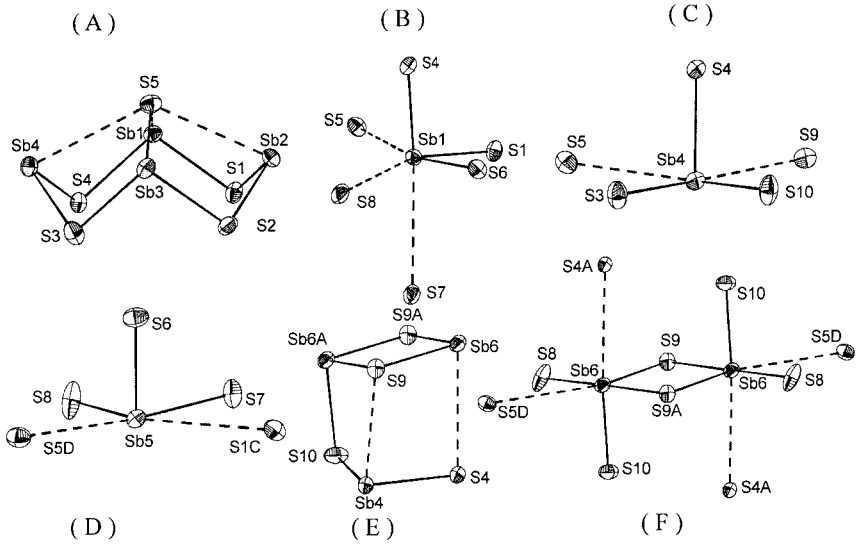

Figure 4. The environments of the Sb atoms with related long secondary bonds (dotted lines); the letters denote symmetry-related atoms (symmetry codes are given in Table 3); the probability ellipsoids are drawn at the 50% level

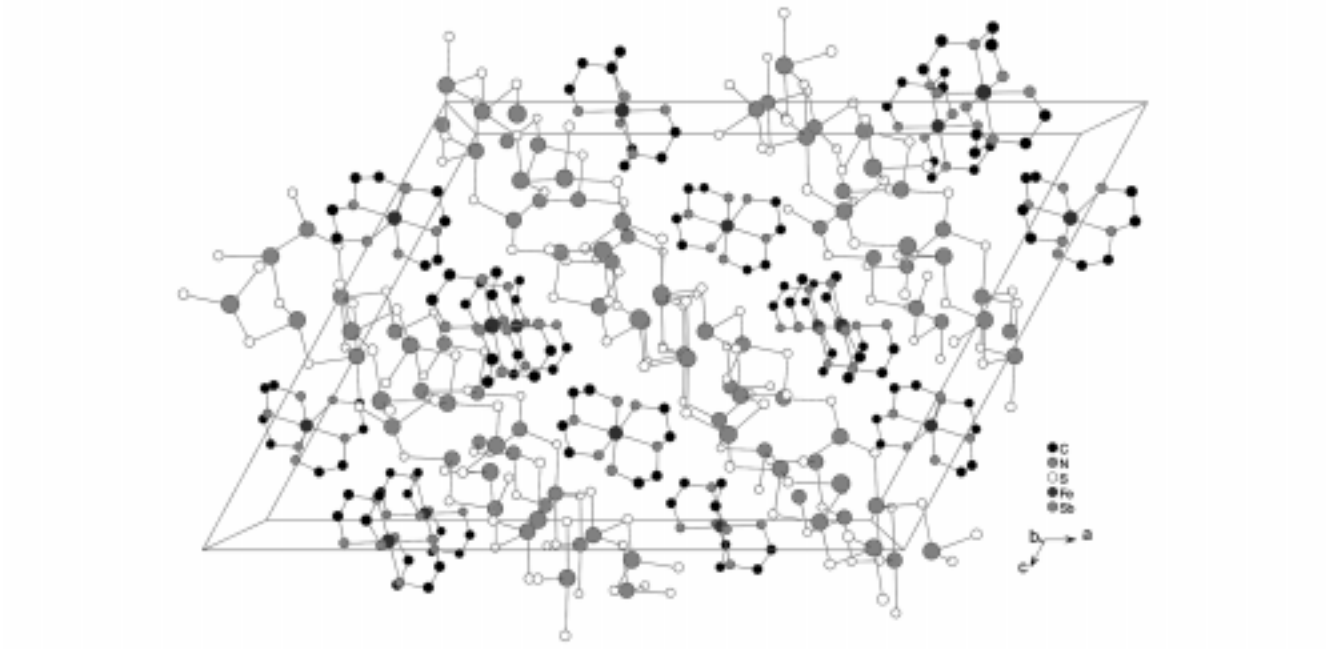

Figure 5. Arrangement of the $[Sb_6S_{10}]^{2-}$ anions and $[Fe(dien)_2]^{2+}$ cations in the crystal structure of $[Fe(C_4H_{13}N_3)_2]Sb_6S_{10} \cdot 0.5\ H_2O$ (water molecules and hydrogen atoms are omitted for clarity)

Å. The compound $[Ph_4P]_2Sb_6S_{10}$[41] contains also an $[Sb_6S_{10}]^{2-}$ anion, but it forms an infinite one-dimensional anionic $(Sb_6S_{10}^{2-})_n$ chain by vertex linkage of SbS_3 pyramids. The interconnection of the pyramids leads to the formation of condensed 10-membered Sb_5S_5 rings with alternating Sb and S atoms. The anionic part of this structure is similar to that reported for $Sb_3S_5{\cdot}N(C_3H_7)_4$.[23] It can be assumed that the size, shape, and charge of the cations determine the dimensionality and the condensation density of the thioantimonate(III) anion.

The Sb_3S_3 rings as well as Sb_4S_4 rings are also found in $[(CH_3CH_2CH_2CH_2NH_2CH_2)_2]_{0.5}Sb_7S_{11}$.[39] In the thioantimonates(III) $[H_3N(CH_2)_3NH_3]Sb_{10}S_{16}$,[42] $(CH_3NH_3)_2Sb_8S_{13}$,[34] $(enH_2)Sb_8S_{13}$ [43], and $(NH_4)_2Sb_4S_7$ [10], the Sb_3S_3 rings are present, and the former two compounds may be viewed as 3-dimensional framework structures when the longer Sb−S contacts are considered.

The bond valence sums (BVS) for the Sb atoms were calculated using the parameters from Brese and O'Keeffe[44] (minimum valence = 0.01). The BVS range from 3.07 to 3.16 v. u. indicating that the Sb atoms formally trivalent. Strong deviations of the calculated BVS from integer numbers are correlated to the stereoactivity of the lone electron pairs (LEP).[45,46] Applying the procedure reported in ref.[47] the BVS of the SbS_x polyhedra are plotted against a parameter $|\Phi|$, which is the length of the vector $\Phi = -\Sigma\Phi_{ij}$ with Φ_{ij} being a vector pointing from Sb_i to the coordinating atom S_j at the distance D_{ij}. The length of Φ_{ij} is given by $\exp(-D_{ij}/0.2)$. The summation is performed over all coordinating S atoms of a polyhedron. For a strong deviation of the spatial distribution of the LEP from spherical symmetry, large $|\Phi|$ values are expected. We observe higher $|\Phi|$ values for Sb(1), Sb(3), and Sb(5), indicating stronger sp^3 character of their LEP.[45] One can assume that the LEP of these Sb^{III} cations are on the opposite side of the three shortest Sb−S bonds of each SbS_3 pyramid.

Thermal Investigations

The thermal behaviour of the title compound was investigated using simultaneous difference thermal analysis and thermogravimetry experiments (Figure 6). Heating selected single crystals of $[Fe(dien)_2]Sb_6S_{10} \cdot 0.5\ H_2O$ under argon a mass loss of 16.5% is observed at T_{onset} = 240.7 °C in the TG curve, which can be attributed to the complete removal

of the dien ligands and the incorporated water molecules $\{-\Delta m_{theor.}[(dien)_2 + 0.5\ H_2O = 16.2\%]\}$. The removal of the ligands is accompanied by two endothermic events at T_P = 261.1 °C and T_P = 277.5 °C. These two peaks were always observed, irrespective of whether large single crystals or powdered samples were used. Such a splitting of the DTA peak during the loss of this organic ligand was also observed for other compounds in which metal cations are surrounded by two dien ligands.[30,47,48] For the present thermal reaction the splitting of the DTA peak is presumably due to a stepwise loss of the ligands, because both cations are in a different environment. In the X-ray powder pattern of the product, the compounds Sb_2S_3, $FeSb_2S_4$, and FeS could be identified. Spectroscopic investigations prove the loss of the organic ligands during the thermal decomposition and elemental analysis shows that only a small amount of carbon and nitrogen is present in the residue (C: 1.11%; N: 0.6%).

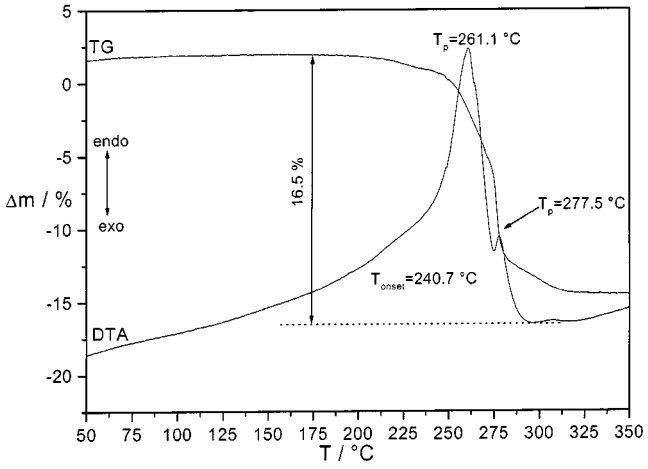

Figure 6. DTA-TG curve for $[Fe(dien)_2]Sb_6S_{10}\cdot 0.5\ H_2O$ (under argon, weight 108.5 mg, powdered crystals, T_p = peak temperature)

Experimental Section

Synthesis: $[Fe(dien)_2]Sb_6S_{10}\cdot 0.5\ H_2O$ (dien = diethylenetriamine) was prepared by treating elemental Fe, Sb, and S in an aqueous solution of dien under solvothermal conditions. In a typical synthesis, 1 mmol of Fe (0.055847 g), 1 mmol of Sb (0.121757 g), and 3 mmol of S (0.032066 g) were added to 10 mL of 50% dien solution. The mixture was heated in a Teflon-lined autoclave at 150 °C for 6 d. The reaction mixture was filtered, washed with water and acetone, and cleaned in an ultrasonic bath. The product consisted of two phases: dark-red needle-like crystals of the title compound as the major phase (yield: 90% based on Sb) and a grey microcrystalline powder as the minor phase, which was amorphous against X-ray powder diffraction. In the by-product the elements iron, sulfur, and antimony were identified with an EDAX analysis.

Structure Determination: Intensities were collected with a STOE Imaging Plate Diffraction System (IPDS) using monochromated Mo-K_α radiation (λ = 0.71073 Å). The intensities were corrected for Lorentz, polarisation, and absorption effects. Structure solution was performed using SHELXS-97.[49] Refinement was done against F^2 using SHELXL-97.[50] All heavy atoms were refined anisotropically. The hydrogen atoms were positioned with idealised geometry and refined with fixed isotropic displacement parameters using a riding model. Technical details of data acquisition and refinement results are summarised in Table 4.

Synthesis and Structures of Boron- and Aluminum-Containing Spirocycles with P-P Units

Wolfgang Köstler[a] and Gerald Linti*[a]

Keywords: Boron / Phosphorus / Aluminum / Heterocycles / Density functional calculations

The reaction of aluminum trichloride with $(t\text{BuP})_2K_2$ affords the potassium salt of the candy-like tricylic compound $[(t\text{BuP})_8Al_2]^{2-}$ **3**.With boron trifluoride–dimethyl etherate the bicyclic spiropentane derivative $(t\text{BuP})_3(t\text{BuPMe})B$ **1** is formed. Obviously, cleavage of the dimethyl ether has occurred. The formation of **1** is accompanied by a boron-phosphorus macrocyclic compound resulting from THF cleavage. All structures have been confirmed by single crystal X-ray crystallography. BP_4R_4 compounds were investigated by DFT methods.

Introduction

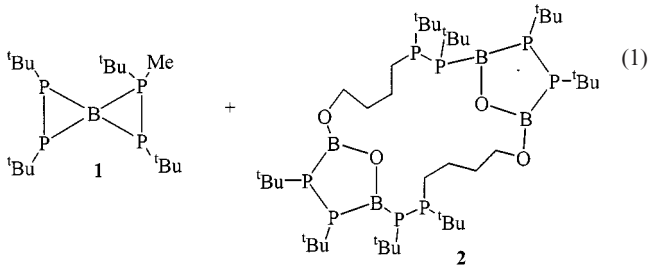
The chemistry of heterocyclic compounds of phosphorus with elements of group 13 has been investigated extensively in the past decades. This is especially true for the chemistry of boron.[1] In the case of aluminum four-membered ring compounds of type $(R_2AlPR'_2)_2$ are the most common;[2] they are considered as dimeric phosphanylalanes. In recent years the monomeric phosphanylalanes[3] have attracted interest in the investigation of possible p-p(π) interactions between atoms of group 13 and 15. With $(MesAlPPh)_3$ [4] the first AlP heterocycle with three coordinated aluminum and phosphorus atoms was synthesized. Comparatively little work has been done on heterocycles of these elements with P-P groups. Only diphospaboriranes $(t\text{BuP})_2BNEt_2$ [5] and the bicyclobutane derivative $tmpBP_2Btmp$[6] (tmp = 2,2,6,6-tetramethylpiperidino) and 1,2,3,4-diphosphadiboretanes such as $(t\text{BuP})_2(BNMe_2)_2$ [7] have been structurally characterized.

On the other hand, butadiene analogues $R_2B-(PR')_2-BR_2$ have been used in the discussion on the correlation of hybridization and bond length.[8] Recently, we reported the gallium analogue $tmp_2Ga(Pt\text{Bu})_2Gatmp_2$.[9] Here we present the results of reactions of the dipotassium salt of the diphosphandiide $(t\text{BuPP}t\text{Bu})^{2-}$ [10] with halides of boron and aluminum.

Results and Discussion

Reactions

If boron trifluoride-dimethyl etherate is reacted with $(t\text{BuP})_2K_2\cdot 0.5THF$ [Equation (1)] the expected product of simple substitution of the fluoride groups at the boron center is not observed. Compound **1** is isolated instead in good yields.



(1)

This compound is the product of the cleavage of dimethyl ether by a proposed intermediate such as $[(t\text{BuP})_4B]^-$. Neither an expected by-product of the type X_2BOMe nor the product of cleavage of Me_2O by a Lewis acidic boron compound could be observed in the reaction mixture by means of ^{11}B NMR spectroscopy. The macrocycle **2** is a minor by-product of this reaction. It is formed by cleavage of THF instead of dimethyl ether at the Lewis acidic boron centers and nucleophilic phosphorus atoms.

With aluminum trichloride and $(t\text{BuP})_2K_2$ the dianionic spirocycle **3** is obtained [Equation (2)]. No products of ether cleavage could be identified. In contrast to the BP_4

derivative **1** the tricyclic Al_2P_8 compound **3** contains a six-membered AlP ring in addition to three-membered rings. Thus, **3** might be viewed as a dimer of the hypothetical AlP_4 compound **4**.

Crystal Structure Analyses

Compound **1** crystallizes in the orthorhombic crystal system, space group $P2_12_12_1$ (Table 1). The boron atom in the spirocyclic molecule (Figure 1) is coordinated in a distorted tetrahedral fashion. There is a three-membered ring formed by a $(t\text{BuP})_2$ unit and a boron atom. A second three-membered ring is made up by the boron center and a tBuP−P(Me)tBu unit. Thus, at first glance **1** may be viewed as a phosphane adduct of a trisphosphanyl borane. Both of the three-membered rings are orthogonal to one another, as is expected for a spiropentane analogue.

The boron-phosphorus bond lengths to the three-coordinate phosphorus atoms are between 194 and 198 pm. This distance is as expected for boron phosphorus bonds between tetracoordinate boron and λ^3 phosphorus atoms, for example in $(Et_2P)_2B(\mu\text{-}PEt_2)_2B(PEt_2)$.[1] The B(1)−P(4) bond (i.e. the λ^4-B−λ^4-P bond) is only 189 pm long. This is remarkable, because at the first glance this bond is expected to be the longest one. Actually, a short bond length like this is typical for bonds between three-coordinate boron and phosphorus atoms. Other examples of three-membered rings are $(t\text{BuP})_2BNEt_2$ [$d_{BP'}$ = 189 pm][5] and $(tmpB)_2P_2$ [d_{BP} = 190.5 (av.)].[6] In **1** two different P−P bond lengths are observed; the P(1)−P(2) bond [d_{PP} = 219.4(2) pm] is 4 pm longer than the P(3)−P(4) bond [d_{PP} = 215.6(2) pm]. Again, the bond involving the λ^4 phosphorus atom is the shorter one. A possible explanation may be found by inspecting the formal charges in **1**. If these are taken as real charges, the P(4)−B(1) bond is shortened by electrostatic attraction. This is discussed more precisely in the following subsection. In comparison to other compounds with P−P bonds, the P-P units in **1** show quite short bonds. For example, in $Et_2NB(Pt\text{Bu}_2)_2$ the P−P bond is longer [d_{PP} = 223 pm]. In contrast with this, even shorter P−P bonds [d_{PP} = 210 pm] are observed in open chain diboryldiphosphanes.[8]

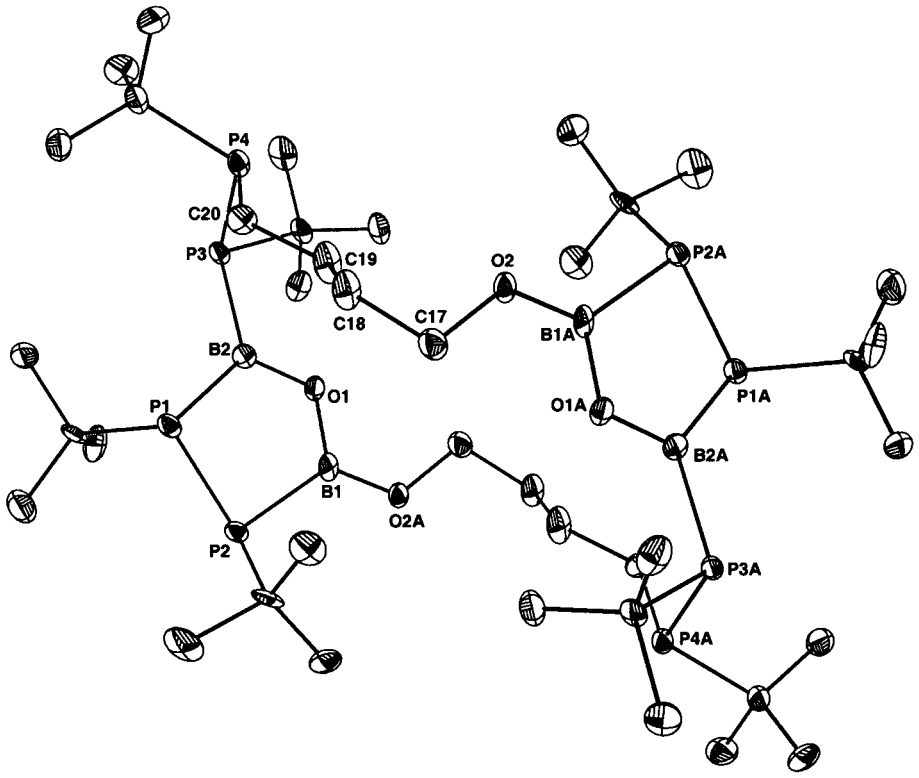

Figure 2. ORTEP view of a molecule of **2**

Compound **2** crystallizes triclinically in the space group $P\bar{1}$.[11] The molecule (Figure 2) consists of a central large 20-membered ring, consisting of four boron, four phosphorus, four oxygen and eight carbon atoms. The boron and oxygen atoms are also part of fused five-membered B_2OP_2 rings. Due to the low quality of the X-ray structure determination no bonding parameters will be discussed.

Compound **3** crystallizes in the monoclinic space group $P2_1/n$. The centrosymmetric molecule (Figure 3) consists of two three-membered and one six-membered aluminum phosphorus ring in a chair conformation. In this spirocycle, the three-membered P_2Al rings and the AlP_2 units of the six-membered ring show an interplanar angle of only 70°. The aluminum atoms reside in a distorted tetrahedral array of four phosphorus atoms. The P(3)−Al−P(4) angle within the three-membered ring is very acute [54.72(4)°]; the corresponding one, P(1)−Al−P(2)A, in which the phosphorus atoms involved are part of the six-membered ring, is near the tetrahedral angle [107.26(5)°]. Consequently, the P−Al−P angles out of the rings are wider than 109°. The central Al_2P_4 ring adopts a chair conformation. P(2) and P(3) are coordinated in a trigonal pyramidal fashion by aluminum, carbon and phosphorus centers, the sum of angles being 337.2° at P(2) and 295.0° at P(3). P(1) and P(4) have contacts to a potassium cation [d_{KP} = 322 and 323 pm]. Consequently, P(1) and P(4) have longer Al−P bonds than P(2) and P(3). The distance K−P(2) is longer by 55 pm [$d_{K-P(2)}$ = 376.7 pm]. Thus, it is longer than the sum of the van der Waals radius of a phosphorus atom (190 pm) and

Figure 3. P(3)−P(4)	220.1 (215.6)	223.1	−	227.8	−	−	227.6	217.1

the effective ionic radius of a potassium cation (150 pm). The potassium centers can be considered to be coordinated distorted tetrahedrally by two phosphorus atoms and two diethyl ether molecules. The P−P bonds in the three- and six-membered rings do not differ very much and are similar to those in **1**. The Al−P distances are between 236.9 and 239.2 pm long. This is shorter than in oligomeric phosphanylalanes $(R_2AlPR'_2)_n$ (range 243.3−247.5 pm).

Results of DFT Calculations

The most striking feature in the unusual spiropentane derivative **1** is the short λ P−B bond. Therefore, **1** and related compounds have been investigated by Density Functional methods. All calculations were done with the Turbomole program package[12] (**5a, b**) with RI approximation, the BP86 functional and SV(P) bases for all atoms.

For both, **1** and **5** a good agreement was found between the experimentally determined and the calculated structures (see Figure 4 and Table 2).

In **1** and in the all-hydrogen substituted spiropentane derivative **5** the λ^4 P−B bond is the shortest one and the other B−P bond, which is part of the same three-membered ring, is the longest one in the molecule. Obviously, steric arguments do not apply when explaining this observation. In the anionic compounds **6** and **8** four identical B−P bonds are expected and this is verified by the calculations. These B−P distances are similar to those in the $(RP)_2B$ rings in **1** and **5**.

By inspecting the atomic charges obtained from an Ahlrich−Heinzmann population analysis, a negative charge is found on the tetracoordinated boron atoms of **1** (−0.74), **5** (−0.75), **6** (−0.73) and **8** (−0.73) and a nearly equal positive charge on the tetracoordinated phosphorus atoms in **1** (+0.65) and **5** (+0.41). This is in line with the formal charges on these atoms and explains the short bond lengths. All other phosphorus atoms have very small charges (<+0.14). According to the shared electron numbers (SEN) obtained from this population analysis all B−P bonds are to be regarded as single bonds (SEN = 1.25−1.35). In particular, the short λ^4 PB bond has an SEN similar to the other B−P bonds; the longest B−P bonds in **1** and **5** have the smallest SEN, as expected. This is in line with the electrostatic interpretation of the bond shortening. The P(3)−P(4) bond in **1** and **5** is shorter than the λ^3[P(1)−P(2)] bond by 4 pm. A possible explanation may be found by inspecting the results of a natural bond orbital analysis. According to this, the P1−P2 bond acts as an electron donor into the σ*(B1P3) and σ*(B1P4) orbitals. Hereby a stabilization of 58 kJ·mol^{-1} is achieved. The P3−P4 bond is a weaker donor. By donation of electrons into the σ*(B1P1) and σ*(B1P2) orbitals a stabilization of only 36 kJ·mol^{-1} results.

The possible dimerization of **6** to afford **7** is endothermic (ΔH_{Dim} = 140 kJ·mol^{-1}). The B−P bonds in the dimer are longer than those in **6** by 4 pm. The P−P bonds are almost unaffected.

For the aluminum homologue **9**, the dimerization to **10** is also endothermic, but only by 64 kJ·mol^{-1}. Taking into account that **3** is not a free dianion as assumed for **10**, with the larger aluminum atom as spiro-center the dimeric structure is preferred over the monomer.

The Al−P bonds in **10** are similar to those in **3**, but longer than in **9**. Very striking are the long P−P bonds in **9**, which are in contrast to those in **3**. Here, the influence of substituents and the missing counterions is evident (compare P−P bond lengths in **1** and **5**−**8**). In a similar manner to **3**, the P−Al−P angles in **10** within the three-membered ring are 57.8°; within the six-membered rings they are 109.8° and 115.9°. Quantum chemical calculations are also helpful in assigning the NMR signals in **1**. For the calculated structure of **1** NMR shielding parameters can be calculated using the GIAO method[13] implemented in the Gaussian98 program. As reference points the shielding parameters for BF_3 and PH_3 were also calculated on the same level. The results, which are in good agreement with the experimentally observed data, and the assignment are summarized in Table 3. The ^{11}B NMR shift is in the typical range for tetracoordinated boron compounds. In the ^{31}P NMR spectrum a line-rich ABCX spin system is observed. The three chemically different P*t*Bu units are observed in a small range of 20 ppm as the tetracoordinated phosphorus atom is better shielded.

Table 3. ^{11}B and ^{31}P NMR shifts for **1** from GIAO calculations (BP86/6−31G*) and experimental values

	1 (DFT)	**1** (exp.)
δ^{11}B	−23.4	−25.9
δ^{31}P	−66 P(4)	−59.5
	−125 P(1)	−136.2
	−133 P(2)	−145.3
	−141 P(3)	−158.1

Conclusion

The group 13-phosphorus spirocycles **1** and **3** are new classes of heterocyclic small ring compounds. The larger covalent radius of aluminum compared to boron causes the different ring sizes in **1** and **3**.

Experimental Section

General Remarks: All experiments were performed under purified nitrogen or in vacuo with Schlenk techniques. All yields are referenced to $K_2P_2tBu_2$. Elemental analyses were performed in the microanalytical laboratory of the University of Karlsruhe. NMR: Bruker ACP200 and 250; Mass spectra: Varian MAT711; X-ray crystallography: Suitable crystals were mounted with a perfluorinated polyether oil on the tip of a glass fiber and cooled immediately on the goniometer head. Data collections were performed with Mo-K_α radiation (graphite monochromator) on a STOE STADI4 diffractometer (**2**, **3**) in a ω-scan mode or on a Siemens Bruker P4 diffractometer with CCD detector (**1**). Structures were solved and refined with the Bruker AXS Shelxtl 5.1 program package. Refinement in full-matrix against F^2. All non-hydrogen atoms were included as a riding-model with fixed isotropic U values in the final refinement. For further data see Table 1.

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-152829 (**1**) and -152830 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Quantum chemical calculations: The program packages TURBOMOL[12] and Gaussian98W[13] were used for the RI-DFT calculations[14] (BP86 functional,[15] SV(P)base), the NBO and GIAO calculations

(*t*BuP)$_2$B(P*t*Bu)P(*t*Bu)Me (1) and (2): $tBu_2P_2K_2$·0.5THF (0.48 g, 1.65 mmol) was suspended in 15 mL of diethyl ether and a solution of BF_3·OMe_2 (0.50 g; 4.40 mmol) in 25 mL diethyl ether was added dropwise at ambient temperature. After stirring for 12 h all volatiles were removed in vacuo. The residue was then taken up in 30 mL of pentane. KBF_4 (0.43 g) was separated by filtration. The solution was concentrated to a volume of 5 mL. At −30 °C colorless plates of **1** crystallized; yield: 0.14 g (45%), m.p. 72−74 °C. From the reduced mother liquor (2 mL) some colorless crystals of **2** were isolated, 0.02 g (5%).

1: ^{1}H NMR (C_6D_6): δ = 1.05 (d, $^2J_{PH}$ = 18 Hz, PMe), 1.28 (d, $^3J_{PH}$ = 12 Hz, *t*Bu), 1.40 (m, 3*t*Bu). − ^{31}P NMR(C_6D_6): δ = −158.1 (m, N = 253 Hz, P*t*Bu), −145.3 (m, N = 665.8 Hz, *t*Bu), −136.2 (m, N = 170 Hz, P*t*Bu), −59.5 (m, N = 407 Hz, PM*e*tBu). − ^{11}B NMR: δ = −25.9 ("d", $^1J_{BP}$ = 40 Hz). − MS (70 eV, EI): *m*/*z* (%) = 378 (38) [M$^+$], 321 (28) [M − *t*Bu]$^+$, 265 (30) [M − *t*Bu − C_4H_8]$^+$, 207 (100) [MeBP$_4$*t*Bu]$^+$. − $C_{17}H_{39}BP_4$ (378.2): calcd. C 53.99, H 10.39; found C 52.09, H 10.18.

Al$_2$(P*t*Bu)$_8$K$_2$·(OEt$_2$)$_4$ (3): A solution of $AlCl_3$ (0.11 g, 0.83 mmol) in 10 mL diethyl ether was added dropwise at ambient temperature to a suspension of $tBu_2P_2K_2$·0.5THF (0.36 g, 1.24 mmol) in 25 mL diethyl ether. After stirring for 1 day the mixture was filtered and the colorless solution was reduced in volume to 20 mL. On standing at ambient temperature colorless plates of **3** crystallized; yield: 0.24 g (68%, ref to $tBu_2P_2K_2$), m.p. (dec.) >90 °C. Compound **3** is extremely pyrophoric and does not redissolve in common NMR solvents. Thus, analytical data given are incomplete (a ^{31}P NMR spectrum recorded from the reaction mixture exhibited several groups of signals between δ = −220 and −10 which could not be assigned unequivocally). − MS (70 eV, EI): *m*/*z* (%) = 499 (0.1) [Al(P*t*Bu)$_5$PH]$^+$, 494 (0.1) [Al$_2$(P*t*Bu)$_5$]$^+$, 352 (5) [(P*t*Bu)$_4$]$^{+\cdot}$, 264 (7) [P*t*Bu)$_3$]$^{+\cdot}$, 57 (100) [*t*Bu]$^+$.

Some New Dicationic Dihydrogen Complexes of Ruthenium

Kanak K. Majumdar,[a] H. V. Nanishankar,[a] and Balaji R. Jagirdar*[a]

Keywords: Hydrogen / Hydride ligands / NMR spectroscopy / Acidity / Ruthenium

A series of new dicationic dihydrogen complexes of ruthenium of the type *trans*-[(dppe)$_2$Ru(η^2-H$_2$)(RCN)][BF$_4$]$_2$ [dppe = Ph$_2$PCH$_2$CH$_2$PPh$_2$; R = CH$_3$, CH$_3$CH$_2$, CH$_3$CH$_2$CH$_2$, CH$_2$=CH, *p*-CH$_3$–C$_6$H$_4$–CH$_2$, C$_6$H$_5$, and (CH$_3$)$_2$N] have been prepared by the protonation reaction of the precursor hydrides, *trans*-[(dppe)$_2$Ru(H)(RCN)][BF$_4$] using HBF$_4$·OEt$_2$. The variable temperature spin-lattice relaxation times (T_1, ms) and the H, D coupling constants of the η^2-HD isotopomers indicate the intact nature of the H–H bond in these complexes. It was found that the spectroscopic and chemical properties of these derivatives are not very sensitive to the change in the *trans* nitrile ligand. The pK_a values of the dihydrogen complexes have been determined using the equilibrium: *trans*-[(dppe)$_2$Ru(H)(RCN)][BF$_4$] + HBF$_4$·OEt$_2$ ⇄ *trans*-[(dppe)$_2$Ru(η^2-H$_2$)(RCN)][BF$_4$]$_2$ + Et$_2$O by ^{1}H NMR spectroscopy.

Introduction

The dihydrogen molecule can be activated toward heterolytic cleavage when coordinated to a cationic metal center. This was first realized by Crabtree and Lavin in the deprotonation reaction of the H$_2$ ligand in [(PPh$_3$)$_2$(bq)Ir(η^2-H$_2$)H]$^+$ (bq = 7,8-benzoquinolato) in the presence of alkyllithium reagents in preference to the loss of hydride ligand.[1] The heterolysis of dihydrogen has been observed for a variety of complexes and has been shown to depend on the nature of the metal center as well as the ancillary ligand environment.[2] Lau and co-workers[2l] recently prepared and characterized various dihydrogen complexes of ruthenium with triazacyclononane, trimethyltriazacyclononane, and hydrotris(pyrazolyl)borate as ancillary ligands. They found their dicationic complexes to be more acidic than their monocationic hydrotris(pyrazolyl)borate and cyclopentadienyl counterparts. Morris et al.[2p] reported a highly acidic dicationic dihydrogen complex, *trans*-[(dppe)$_2$Ru(η^2-H$_2$)(CNH)][OTf]$_2$ that was found to be stable with respect to loss of protons or H$_2$ in the presence of strong acids like HOTf. However, it should not be implied that the dicationic dihydrogen complexes would be stronger acids than the monocationic derivatives. Harman and Taube[3] found the dicationic osmium complex, [Os(H$_2$)(NH$_3$)$_5$]$^{2+}$ to be a weak acid that is stable toward moderately strong bases such as NaOMe.

The dicationic dihydrogen complexes of transition metals reported to date are very few in number. Therefore, we sought to synthesize and characterize a series of isostructural dicationic dihydrogen complexes of ruthenium bearing bis(1,2-diphenylphosphanyl)ethane (dppe) and nitrile ligands. In addition, we also wanted to study the variation in some of the properties of dihydrogen complexes, for example, the H−H distances and the acidities with a change in the steric and the electronic properties of the nitrile ligand that is *trans* to the dihydrogen moiety.

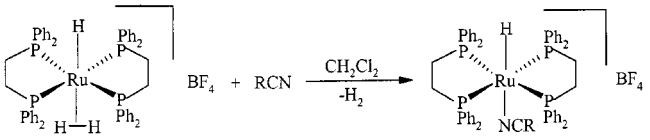
Results and Discussion

Synthesis and Characterization of the New Ruthenium Hydride Complexes

The complexes *trans*-[(dppe)$_2$Ru(H)(RCN)][BF$_4$] [R = CH$_3$ (**1**), CH$_3$CH$_2$ (**2**), CH$_3$CH$_2$CH$_2$ (**3**), CH$_2$=CH (**4**), *p*-CH$_3$−C$_6$H$_4$−CH$_2$ (**5**), C$_6$H$_5$ (**6**), (CH$_3$)$_2$N (**7**)] were prepared from *trans*-[(dppe)$_2$Ru(η^2-H$_2$)(H)][BF$_4$] by the substitution of the dihydrogen ligand by the nitrile, analogous to the preparation of *trans*-[(dppe)$_2$Os(H)(CH$_3$CN)][BF$_4$] reported by Schlaf et al.[2i] [Equation (1)].



R = CH$_3$- (**1**), CH$_3$CH$_2$- (**2**), CH$_3$CH$_2$CH$_2$- (**3**), CH$_2$=CH- (**4**), *p*-CH$_3$-C$_6$H$_4$-CH$_2$- (**5**), C$_6$H$_5$- (**6**), (CH$_3$)$_2$N- (**7**)

(1)

The products were obtained in fairly good yields as summarized in Table 1. They are all colorless to off-white solids. Purification of the complexes was achieved by crystallization by slow diffusion of Et$_2$O into a CH$_2$Cl$_2$ solution containing the hydride complex and a slight excess of the appropriate nitrile. In the absence of the excess nitrile in the crystallization solution, we observed that loss of the nitrile ligand bound to ruthenium takes place due to its lability. This results in the decomposition of the hydride complex into intractable products.

The ^1H NMR spectra of the complexes show quintets for the hydride ligand confirming the coupling of the hydride with the four *cis*-phosphorus (dppe) ligands. The value of *J*(H,P) is remarkably similar in all these derivatives (20 Hz) indicating that the variation of the *trans*-nitrile ligand has no effect on the coupling constant. The $^{31}P\{^1H\}$ NMR spectra consist of only one singlet for the dppe phosphorus nuclei. This suggests that all the four phosphorus atoms are equivalent in solution. The ^1H and $^{31}P\{^1H\}$ NMR spectroscopic data for these complexes are summarized in Table 2.

In order to obtain some insight with regard to the cavity formed by the sterically encumbered $[(dppe)_2Ru(H)]^+$ fragment, we examined the X-ray crystal structure of *trans*-$[(dppe)_2Ru(H)(p\text{-}CH_3-C_6H_4-CH_2CN)][BF_4]$ (**5**). Unfortunately, the structure solution could not be achieved satisfactorily because the *p*-$CH_3-C_6H_4-CH_2CN$ group was severely disordered (the structure details can be found in the Supporting Information). Nevertheless, it is instructive to note that the nitrile should be almost *rod-shaped* in order to be accommodated *trans* to the hydride. Attempts to prepare hydride complexes with more bulky *trans* nitrile ligands failed and the starting hydride-dihydrogen complex *trans*-$[(dppe)_2Ru(\eta^2\text{-}H_2)(H)][BF_4]$ was recovered.

Preparation and Properties of the Dihydrogen Complexes

The protonation of the starting hydride complexes *trans*-$[(dppe)_2Ru(H)(RCN)][BF_4]$ with excess 54% $HBF_4{\cdot}OEt_2$ yielded the corresponding dihydrogen complexes, *trans*-$[(dppe)_2Ru(\eta^2\text{-}H_2)(RCN)][BF_4]_2$ [R = CH_3 (**1a**), CH_3CH_2 (**2a**), $CH_3CH_2CH_2$ (**3a**), CH_2=CH (**4a**), *p*-$CH_3-C_6H_4-CH_2$ (**5a**), C_6H_5 (**6a**), $(CH_3)_2N$ (**7a**)]. These reactions were carried out in CD_2Cl_2 under 1 atm. of either dihydrogen or argon. The dihydrogen complexes were characterized by NMR spectroscopy. All of these derivatives were found to be stable in solution at room temperature for periods as long as two days before undergoing decomposition into the starting hydride complex and a proton equivalent (exists as $HOEt_2^+BF_4^-$).

Table 3. ^1H and $^{31}P\{^1H\}$ NMR spectroscopic data (δ) of *trans*-$[(dppe)_2Ru(\eta^2\text{-}H_2)(RCN)][BF_4]_2$ complexes in CD_2Cl_2

The ^1H NMR spectrum of the dihydrogen complexes shows a broad singlet in the hydride region whose line widths ($\Delta\nu_{1/2}$) are in the range 36 to 43 Hz. This signal is shifted downfield with respect to the starting hydride complex. The $^{31}P\{^1H\}$ NMR spectrum also shows a singlet for the dppe phosphorus atoms that is also shifted downfield in relation to the precursor hydride complex. The ^1H and $^{31}P\{^1H\}$ NMR spectroscopic data are summarized in Table 3.

The classification of **1a**−**7a** as dihydrogen complexes is based on variable temperature ^1H spin-lattice relaxation time (T_1, ms) measurements and the observation of H, D coupling constants of the η²-HD isotopomers **1b**−**7b**. The measured and the calculated T_1 minima data[4] as a function of temperature are given in Table 4. All of these derivatives exhibit short T_1 minima (18−21 ms) demonstrating that there is an intact H−H bond in these complexes. These values have been obtained directly from the experiments and also by fitting the equations that describe the dominant dipolar relaxation mechanism to the variable temperature T_1 data as described earlier by Morris and co-workers.[5] From the T_1 minima, the H−H distances can be calculated after appropriate corrections[6] have been made for the relaxation contributions from other nuclei in the vicinity. The analysis of T_1 data leads to three possible values for the H−H distance depending upon the relative rate at which the H_2 ligand undergoes rotation (slow, fast, and intermediate).[5,7] Table 4 also lists the H−H distances (for slow and fast rotation regimes of H_2) as determined from the T_1 minima for the complexes **1a**−**7a**. The H−H distances thus obtained fall in the range 1.12 to 0.87 Å for the slow and the fast spinning regimes, respectively.

Table 4. Observed and calculated spin-lattice relaxation times (T_1 minima; 400 MHz) and the H−H distances of the dihydrogen ligand in the complexes *trans*-$[(dppe)_2Ru(\eta^2\text{-}H_2)(RCN)][BF_4]_2$ **1a**−**7a** in CD_2Cl_2

R	T_1(obs), ms (T, K)	T_1(calc), ms	r_{HH} (Å)[a]

[a] For fast rotation/static regimes of the H_2 ligand.

The partial incorporation of deuterium into the H_2 ligand could, in general, be accomplished by exposing the dihydrogen complex to D_2 gas or the use of deuterated acid (in the current work, $DBF_4{\cdot}OEt_2$ has been used) to deuterate the starting hydride complex. It was proposed that a combination of the lability and the acidity of the H_2 ligand is responsible for the formation of the HD isotopomers.[8] The HD isotopomers, *trans*-$[(dppe)_2Ru(\eta^2\text{-}HD)(RCN)][BF_4]_2$ [R = CH_3, CH_3CH_2, $CH_3CH_2CH_2$, CH_2=CH, *p*-$CH_3-C_6H_4-CH_2$, C_6H_5, $(CH_3)_2N$] were obtained from the starting hydride complexes by the addition of excess DBF_4 [prepared from HBF_4 and D_2O in the ratio 3:1 (v/v)] in CD_2Cl_2. The ^1H NMR spectra at room temperature exhibit a sharp triplet of quintets after nullifying the signal due to η²-H_2 from the known spin-lattice relaxation times (T_1, ms). The intensity ratio of the triplet resonance is approximately 1:1:1 with J(H,D) values in the range 26−28 Hz. Further splitting of each of the triplet signals into quintets, although not fully resolved, is due to coupling with the four dppe phosphorus atoms with a corresponding $J(H,P_{cis})$ of ca. 5 Hz. There does not seem to be a consistent trend for the J(H,D) values, which are relatively insensitive to the nature of the nitrile *trans* to the H_2. This is typical of complexes that have η²-HD bound *trans* to a strong-field π-acid ligand.[9] Figure 1 shows the hydride region of the ^1H NMR spectrum of *trans*-$[(dppe)_2Ru(\eta^2\text{-}HD)(p\text{-}CH_3-C_6H_4-CH_2-CN)][BF_4]_2$. The HD resonances of all the complexes suffer from upfield shifts from the H_2 signals (Δδ from 34 to 43 ppb) which is typical for the dihydrogen complexes reported thus far.[10] The shift that is observed in the case of H_2/HD gas is on the order of +36 ppb.[11]

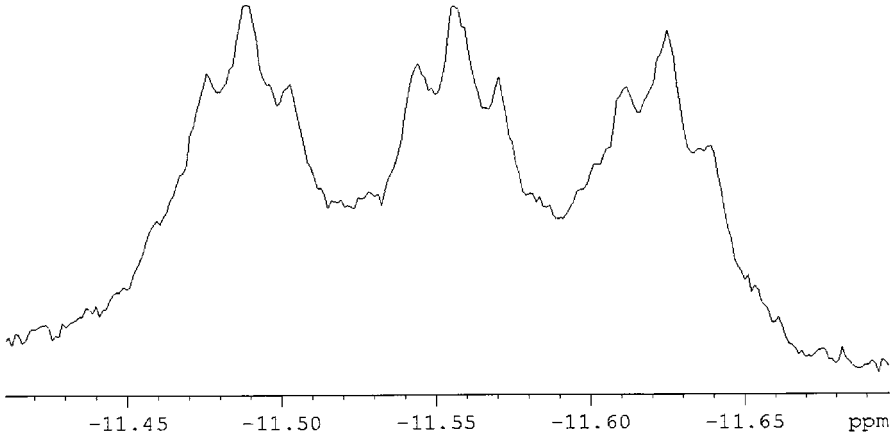

Figure 1. ^{1}H NMR spectrum (hydride region) of *trans*-[(dppe)$_2$Ru(η^2-HD)(*p*-CH$_3$−C$_6$H$_4$−CH$_2$CN)][BF$_4$]$_2$ (400 MHz, 298 K) in CD_2Cl_2; resonance due to η^2-H$_2$ ligand has been nullified

The H-H distances (r_{HH}) could be calculated from the inverse relationship between r_{HH} and J(H,D) of the HD isotopomer.[12] Thus, distances on the order of 0.96−0.97 Å have been obtained for our complexes. Gusev et al.[13] analyzed the T_1 minima and J(H,D) values of certain reported dihydrogen complexes that have $J(H,D) \geq 25$ Hz. According to this analysis, in complexes of the type *trans*-[(P-P)$_2$M(H)(η^2-H$_2$)]$^+$ (M = Fe, Ru; P-P = chelating phosphane), it is necessary to invoke the fast rotation approximation in order to obtain a reasonable H−H distance for the H$_2$ ligand. However, Morris and Wittebort[7] have shown that the rotation around M−H$_2$ in a majority of complexes is either in the fast motion regime or is a librational motion. Table 5 lists the H−H distances for the complexes **1a**−**7a** calculated from the J(H,D) values. The H−H distances obtained from the H−D coupling constants lie between the distances (slow and fast) obtained from T_1 values, suggesting that the relaxation of the dihydrogen ligand in this series of complexes is significantly dominated by libration and torsional motions as described earlier by Morris and Wittebort.[7] Many examples have been reported in the literature where such a situation has been observed.[7] The relatively long H−H distances found for these derivatives is consistent with the tight binding of H$_2$ to the ruthenium center.

Table 5. H−H Distances of *trans*-[(dppe)$_2$Ru(η^2-H$_2$)(RCN)][BF$_4$]$_2$ complexes **1a**−**7a** obtained from J(H,D)

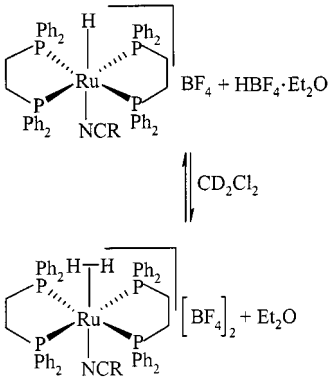
(CH$_3$)$_2$N (**7a**)	27	0.96

Acidities of the Dihydrogen Complexes

The acidities of the dihydrogen complexes have been measured on the pseudo aqueous pK_a scale.[2c][2i][2k][2l][12b,14] The equilibrium constants for the protonation of the hydride complex using an acid whose aqueous pK_a is known are determined in a nonaqueous medium. Then, the pseudo aqueous pK_a of the dihydrogen complex is calculated with respect to the aqueous pK_a of the protonating agent. The pK_a values of the dihydrogen complexes **1a**−**7a** have been estimated by studying the equilibrium shown in Equation (2) using ^{1}H NMR spectroscopy at −30 °C.



(2)

R = CH_3-, CH_3CH_2-, $CH_3CH_2CH_2$-, CH_2=CH-, *p*-CH_3-C_6H_4-CH_2-, C_6H_5-, $(CH_3)_2N$-

The relative molar concentrations of the hydrides, HBF_4·OEt_2, the dihydrogen complexes, and Et_2O were estimated from the ^{1}H NMR spectral integrations of the respective signals. As suggested earlier by Kristjánsdóttir and Norton,[15] the pK_a values of the dihydrogen complexes have been estimated from the equilibrium constants K_{eq} of Equation (2) and the pK_a of the protonating agent, here HBF_4·OEt_2 (−2.4)[16] using Equation (3).

$$pK_a[RuH_2]^{2+} = pK_a[HBF_4 \cdot Et_2O] + \log K_{eq} \quad (3)$$

$[RuH_2]^{2+}$ = *trans*-[(dppe)$_2$Ru(η^2-H$_2$)(RCN)][BF$_4$]$_2$

The pK_a values of the dicationic dihydrogen complexes **1a**−**7a** are summarized in Table 6. The magnitude of these pK_a values are very approximate and accurate values could only be obtained when the actual non-ion-paired pK_a of $HOEt_2^+BF_4^-$ in CH_2Cl_2 is determined and corrections are made for ion pairing for all of the species in solution.[17] All of these derivatives exhibit low pK_a values indicating that they are quite acidic species. At this juncture, it is quite appropriate to compare the acidity of *trans*-[(dppe)$_2$Ru(η^2-H_2)(CNH)][OTf]$_2$ reported by Morris et al.[2p] with those of ours. *trans*-[(dppe)$_2$Ru(η^2-H_2)(CNH)][OTf]$_2$ is the first member of this class of compounds. This complex was found to be highly acidic since it was only completely formed in an excess of HOTf in CH_2Cl_2. Furthermore, it was proposed that the pK_a of this complex was very near to that of HOTf in CH_2Cl_2 (the aqueous pK_a of HOTf has been estimated to be −4.9).[2k] The complexes reported in this work are less acidic in comparison to that of Morris' (compare with the pK_a of the protonating agent used, HBF_4·OEt_2 = −2.4). In general, the acidity of isostructural dihydrogen complexes decreases as ligands become more electron donating. The trend in the pK_a values of our complexes does seem to corroborate this: the greater the electrophilicity of the metal center, the greater is the activation of the dihydrogen towards heterolysis. In addition to this series of dicationic dihydrogen complexes that are quite acidic and at the same time stable at room temperature with respect to loss of H_2, several other derivatives have also been reported earlier by other groups.[2k,10d,18]

Table 6. Estimation of the acidities of *trans*-[(dppe)$_2$Ru(η^2-H_2)(RCN)][BF_4]$_2$ complexes in CD_2Cl_2

R	K_{eq} [a]	pK_a[b]

Conclusions

The complexes *trans*-[(dppe)$_2$Ru(H_2)(RCN)][BF_4]$_2$ [R = CH_3 (**1a**), CH_3CH_2 (**2a**), $CH_3CH_2CH_2$ (**3a**), CH_2=CH (**4a**), *p*-CH_3−C_6H_4−CH_2 (**5a**), C_6H_5 (**6a**), $(CH_3)_2N$ (**7a**)] are formulated as dihydrogen complexes based on their short T_1 values and the observation of H, D coupling in the corresponding HD isotopomers. All of these derivatives are stable at room temperature. The long H−H distances and the relatively nonlabile nature of the H_2 ligand shows strong M−H_2 interactions in these complexes. The pK_a values of these complexes indicate that they are quite acidic.

Experimental Section

General: All reactions except those involving the dihydrogen complexes were carried out under dry and purified nitrogen atmosphere at room temperature using standard Schlenk[19] and inert atmosphere techniques, unless otherwise specified. The manipulations involving solutions of dihydrogen complexes were carried out under an atmosphere of dihydrogen or argon gas. 1,2-Bis(diphenylphosphanyl)ethane (dppe)[20] and the complex *trans*-[(dppe)$_2$Ru(η^2-H_2)(H)][BF_4][21] were prepared according to published procedures.

The ^{1}H and ^{31}P NMR spectra were obtained on a AMX Bruker 400 MHz instrument. The shift of the residual protons of the deuterated solvent was used as an internal reference. All ^{31}P NMR spectra were proton decoupled. ^{31}P NMR chemical shifts have been measured relative to 85% H_3PO_4 in CD_2Cl_2. Variable temperature proton T_1 measurements were carried out at 400 MHz using the inversion recovery method (180°-τ-90° pulse sequence at each temperature).[22] Microanalyses were performed at the Institut für Anorganische Chemie, der Universität Göttingen, Germany and National Chemical Laboratory, Pune, India.

Preparation of *trans*-[(dppe)$_2$Ru(H)(CH_3CN)][BF_4] (1): A method similar to the preparation of the osmium analogue of (**1**) reported[2i] earlier was employed for this preparation. *trans*-[(dppe)$_2$Ru(η^2-H_2)(H)][BF_4] (60 mg, 0.06 mmol) was dissolved in 3 mL of CH_2Cl_2 under 1 atm. of dihydrogen. Acetonitrile (50 mg, 1.22 mmol) was then added with a syringe and the mixture was allowed to stir at room temperature for 12 h. Addition of 20 mL of Et_2O caused complete precipitation of the pale yellow product. Et_2O was removed with a cannula and the precipitate was dried by passing a slow stream of H_2. Yield: 47 mg (75%). The product was crystallized from a CH_2Cl_2 solution containing the hydride complex and a few drops of the nitrile by the diffusion of Et_2O at room temperature. The ^{1}H and ^{31}P{^{1}H} NMR spectroscopic data are summarized in Table 2.

The complexes, *trans*-[(dppe)$_2$Ru(H)(RCN)][BF_4] [R = CH_3CH_2 (**2**), $CH_3CH_2CH_2$ (**3**), CH_2=CH (**4**), *p*-CH_3−C_6H_4−CH_2 (**5**), C_6H_5 (**6**), $(CH_3)_2N$ (**7**)] were similarly prepared from *trans*-[(dppe)$_2$Ru(η^2-H_2)(H)][BF_4] and the corresponding nitrile as summarized in Table 1. All of these products were purified by crystallization from a solution containing the respective hydride complex and a few drops of the corresponding nitrile in CH_2Cl_2 by the diffusion of Et_2O. The ^{1}H and ^{31}P NMR spectroscopic data are summarized in Table 2.

Preparation of *trans*-[(dppe)$_2$Ru(η^2-H_2)(CH_3CN)][BF_4]$_2$ (1a): In a typical experiment, a sample (15 mg) of *trans*-[(dppe)$_2$Ru(H)(CH_3CN)][BF_4] (**1**) was placed in a 5 mm NMR tube provided with a septum. The tube was carefully evacuated and then filled with dihydrogen in three cycles. The hydride complex was then dissolved in CD_2Cl_2 (0.7 mL) and 10 μL of 54% HBF_4·OEt_2 was added. The reaction was found to be almost instantaneous and the protonation was complete within a few seconds. The solution was then analyzed by NMR spectroscopy. The ^{1}H and ^{31}P{^{1}H} NMR spectroscopic data are summarized in Table 3.

The corresponding dihydrogen complexes, *trans*-[(dppe)$_2$Ru(η^2-H_2)(RCN)][BF_4]$_2$ [R = CH_3CH_2 (**2a**), $CH_3CH_2CH_2$ (**3a**), CH_2=CH (**4a**), *p*-CH_3−C_6H_4−CH_2 (**5a**), C_6H_5 (**6a**), $(CH_3)_2N$ (**7a**) were similarly prepared and characterized. The ^{1}H and ^{31}P{^{1}H} NMR spectroscopic data of these derivatives are given in Table 3.

Decomposition Reaction of *trans*-[(dppe)$_2$Ru(η^2-H_2)(CH_3CN)][BF_4]$_2$ (1a): An NMR tube provided with a septum, loaded with *trans*-

$[(dppe)_2Ru(\eta^2\text{-}H_2)(CH_3CN)][BF_4]_2$ **(1a)** (10 mg) in CD_2Cl_2 (0.7 mL) under a hydrogen atmosphere was allowed to stand at room temperature for several days. ^1H NMR spectra were recorded periodically to monitor the stability of the dihydrogen complex. It was found that after ca. 36−72 h, the hydride complex *trans*-$[(dppe)_2Ru(H)(CH_3CN)][BF_4]$ (**1**) started to appear. This suggests that the dihydrogen complex is unstable for an extended period of time and that it undergoes decomposition to the hydride complex and a proton.

Preparation of the H−D Isotopomers of *trans*-$[(dppe)_2Ru(\eta^2\text{-}H_2)(RCN)][BF_4]_2$ [R = CH_3, CH_3CH_2, $CH_3CH_2CH_2$, CH_2=CH, *p*-$CH_3-C_6H_4-CH_2$, C_6H_5, $(CH_3)_2N$]: These derivatives were prepared in the following manner: Each of the hydride complexes (15 mg) was dissolved in 0.7 mL CD_2Cl_2 in a 5 mm NMR tube under an atmosphere of Ar followed by the addition of DBF_4 (prepared from $HBF_4{\cdot}OEt_2$ and D_2O in a 3:1 ratio). The η^2-HD signals were observed in the ^1H NMR spectrum by nullifying the signal due to η^2-H_2 by the inversion recovery method using the relationship $T_1 = \tau_{null}/\ln 2$ and the known T_1 values of the dihydrogen complexes at room temperature.[8,23,24] The J(H,D) values together with the H−H distances for these complexes are summarized in Table 5.

Acidity Measurements: In a typical experiment, a 5 mm NMR tube was charged with 20 mg of the hydride complex. It was dissolved in 0.6 mL of CD_2Cl_2 and the solution was cooled to 243 K. The ^1H and $^{31}P\{^1H\}$ NMR spectra were then recorded with the probe at 243 K. One equivalent of 54% $HBF_4{\cdot}Et_2O$ was added to the tube, shaken for some time and transferred back to the probe at 243 K. The relative concentrations of all the species [as in Equation (2)] were calculated from the integrations of the respective peaks in the ^1H NMR spectra. The pK_a values were calculated from the equilibrium depicted in Equation (2) and are summarized in Table 6.

Supporting Information Available: Observed and calculated spin-lattice relaxation time (T_1, ms; 400 MHz) data as a function of temperature of the dihydrogen ligand in the complexes *trans*-$[(dppe)_2Ru(\eta^2\text{-}H_2)(RCN)][BF_4]_2$ [R = CH_3 (**1a**), CH_3CH_2 (**2a**), $CH_3CH_2CH_2$ (**3a**), CH_2=CH (**4a**), *p*-$CH_3-C_6H_4-CH_2$ (**5a**), C_6H_5 (**6a**), and $(CH_3)_2N$ (**7a**)] and tables of crystal data, structure solution and refinement, atomic coordinates, bond lengths and angles, anisotropic thermal parameters, hydrogen atom coordinates, and an ORTEP diagram for **5**. Crystallographic data (excluding structure factors) for the structure(s) reported in the Supporting Information of this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-159782. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support from the Council of Scientific and Industrial Research of India is gratefully acknowledged. We thank the Sophisticated Instruments Facility, Indian Institute of Science for the NMR spectroscopic data and Institut für Anorganische Chemie, der Universität Göttingen, Germany and Dr. Amitabha Sarkar, National Chemical Laboratory, Pune, India, for elemental analysis data. We also thank the National Single Crystal Diffractometer Facility at the University of Hyderabad funded by the Department of Science and Technology for crystal structure data and Ms. Nisha Mathew for help with the data analysis.

Construction and Characterization of Organic-Inorganic Hybridized Molecules with Infinite 2D Grid Network and 1D Zigzag Chain Structures

Wei-Yin Sun,*[a] Bao-Li Fei,[a] Taka-aki Okamura,[b] Wen-Xia Tang,[a] and Norikazu Ueyama[b]

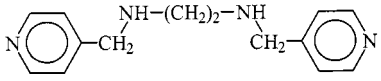
Keywords: Organic-inorganic hybrid composites / Structure elucidation / Supramolecular chemistry / Copper / N ligands

Two coordination polymers with a 2D grid network structure of $[Cu(L1)]NO_3 \cdot H_2O$ (**1**) and $[Cu(L1\text{-}2H)](AcOH)_2 \cdot (C_2H_5)_2O \cdot 4H_2O$ (**2**) were obtained by reaction of the flexible tetradentate ligand 1,2-bis(4′-pyridylmethylamino)ethane (L1) with one mol of $[Cu(CH_3CN)_4]NO_3$ or $Cu(OAc)_2 \cdot H_2O$. The syntheses of a new bridging ligand 1,2-bis(4′-pyridylmethyleneamino)ethane (L2) and its copper(I) complexes are described. When L2 reacts with $[Cu(CH_3CN)_4] \cdot ClO_4$ or $[Cu(CH_3CN)_4] \cdot NO_3$, two interesting complexes with an infinite zigzag chain-like structure $[Cu(L2)(CH_3CN)]NO_3$ (**3**) and $[Cu(L2)(CH_3CN)]ClO_4$ (**4**), involving the coordination of an acetonitrile molecule, were obtained. These coordination complexes were characterized by X-ray crystallography. The results showed that the rigidity of the ligand and the different chemical valence of the transition metal ions have a large effect on the construction of supramolecular frameworks.

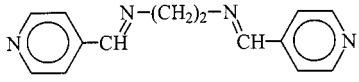
Introduction

The metal-ion-directed generation of molecular entities currently provides a very efficient method for the construction of coordination frameworks. Recently, many efforts have been devoted to the investigation of the crystal engineering of one (1D), two (2D) and three-dimensional (3D) coordination polymers.[1,2] However, flexible bridging ligands have not often been employed to construct coordination polymers with transition metal ions, perhaps due to the difficulties in predicting the resulting network structures.[3,4] Previous work has demonstrated that the flexible tetradentate ligand 1,2-bis(4′-pyridylmethylamino)ethane (L1) gives 1D or 2D frameworks depending on the counter anions.[5] In the silver(I) complexes, the structure of $[Ag(L1)]NO_3$ is an infinite 1D hinged cationic chain, while in the case of the complex with a perchlorate anion, $[Ag(L1)]ClO_4 \cdot CH_3CN$ is an infinite 2D cationic network. It is clear that the counter anions play an important role in the construction of these supramolecular complexes.[5] We describe here the reaction of the flexible tetradentate ligand L1 with $[Cu(CH_3CN)_4]NO_3$ and $Cu(OAc)_2 \cdot H_2O$ with the aim of obtaining different network structures by changing the chemical valence of the metal ions.

The generation of supramolecular frameworks is influenced by factors such as the solvent system, templates, counterions, ligand geometry and sometimes the ratio between the metal salt and the ligand.[6–13] In order to add rigidity to L1, we synthesized a new tetradentate ligand 1,2-bis(4′-pyridylmethyleneamino)ethane (L2) (Scheme 1) to detect the influence of the rigidity of the ligand on the supramolecular construction progress.



L1



L2

Scheme 1

We report here the assembly of an infinite 2D cationic grid $[CuL1]^+$, an infinite neutral grid network $[Cu(L1\text{-}2H)](AcOH) \cdot (C_2H_5)_2O \cdot 4H_2O$ and two polymeric copper(I) complexes with infinite zigzag chain-like structures $[Cu(L2)(CH_3CN)]NO_3$ and $[Cu(L2)(CH_3CN)]ClO_4$.

Results and Discussion

Synthesis and Reactivity

In principle, supramolecular networks can be obtained by the concurrent action of both extended coordination and hydrogen bonds. We chose to react the flexible tetradentate ligand 1,2-bis(4′-pyridylmethylamino)ethane (L1) with Cu^I and Cu^{II} salts to construct networks by the formation of coordination bonds. The ligand 1,2-bis(4′-pyridylmethyleneamino)ethane (L2) is a di-Schiff base and an analogue of L1. The difference between the L1 and L2 ligands is that L2 is more rigid.

The polymeric complexes $[Cu(L1)]NO_3·H_2O$ (**1**), $[Cu(L1\text{-}2H)](AcOH)_2·(C_2H_5)_2O·4H_2O$ (**2**), $[Cu(L2)(CH_3CN)]NO_3$ (**3**) and $[Cu(L2)(CH_3CN)]ClO_4$ (**4**) were readily obtained by the reaction of Cu^I or Cu^{II} salts with the ligands L1 and L2 in a molar ratio of 1:1 under mild conditions (see Exp. Section). The elemental C, H and N analysis and X-ray crystal structure analysis confirmed the chemical formulation of these complexes. The complexes **1**, **3** and **4** are stable in the solid state, but not very stable in solution. Crystals of **2** rapidly lose solvent molecules when they are isolated from the reaction mixture.

Crystal Structure Description

The structures of complexes **1**, **2**, **3** and **4** were determined by X-ray crystallography. The crystal and data collection parameters are summarized in Table 1 and selected bond lengths and angles are listed in Table 2.

As shown in Figure 1a, each copper(I) atom in the complex **1** is coordinated by two N atoms of an ethylenediamine unit of one L1, and two N atoms of a pyridyl unit from two other L1 ligands. The coordination geometry of the copper(I) atom is distorted tetrahedral with coordination angles (N−Cu−N) ranging between 85.4(2) to 124.0(3)° and an average Cu−N bond length of 2.082(6) Å (Table 2).

Figure 1. (a) Crystal structure of $[Cu(L1)]NO_3$ **1** with the ellipsoids drawn at the 50% probability level; (b) infinite grid structure of $[Cu^{I}(L1)]NO_3$ **1**

Complex **1** forms an infinite 2D grid network connected by Cu−N coordination bonds (Figure 1b) in which each L1 ligand has an almost linear conformation with a dihedral angle of 82.5° between the two terminal pyridyl rings of the L1 ligand.1

Complex **1** has one water molecule in the crystal in addition to the nitrate anion, as confirmed by thermogravimetric analysis: the TGA data of complex **1** showed an initial weight loss of 4.9% (calcd. 4.7%) centered at 80 °C, representing the loss of uncoordinated water molecule. The nitrate anions and water molecules are located at the vacancy between the two adjacent cationic layers through two N−H···O and three C−H···O hydrogen bonds as tabulated in Table 3. In the previously reported analog $[Cu(L1)]ClO_4$, there is only one C−H···O hydrogen bond between the ClO_4^- and pyridyl ring of the adjacent ligand.[5] In addition to these hydrogen bonds, there are T-type edge-to-face π-π interactions between pyridine rings which are similar to those of the perchlorate analog, as discussed previously.[5,14]

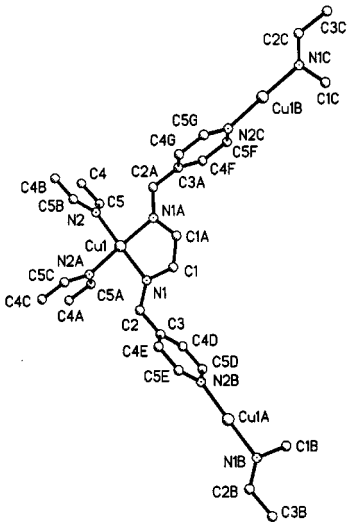
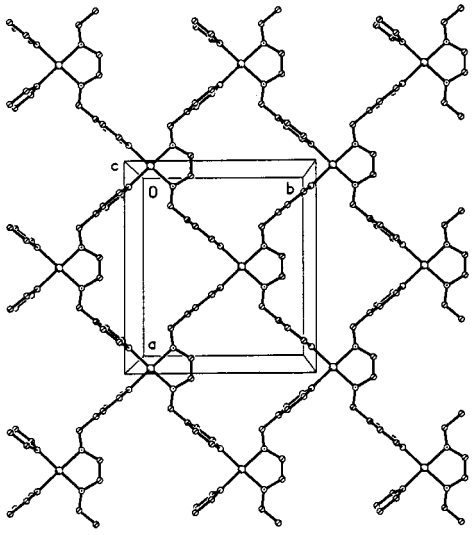
In contrast to the tetrahedral geometry of Cu^{I}, four-coordinate Cu^{II} complexes are usually square planar. After several attempts at reactions between the L1 and Cu^{II} salts with various anions, we finally succeeded in obtaining single crystals of a complex of $Cu(OAc)_2$ with L1, i.e. $[Cu(L1\text{-}2H)](AcOH)_2·(C_2H_5)_2O·4H_2O$ (**2**). The structure around the Cu^{II} atom is shown in Figure 2a, along with the atom numbering scheme. The atoms Cu(1), N(1), N(2), C(1), C(2) and C(3) are all at special positions in the crystallographic mirror plane. The ethylenediamine moiety is deprotonated since all its' atoms are completely coplanar. The existence of acetic acid rather than an acetate anion was confirmed by IR spectroscopy. Each Cu^{II} atom is coordinated by four N atoms from three L1 ligands with a square-planar coordination geometry. The bond lengths of Cu(1)−N(1) and Cu(1)−N(2) are 2.032(4) and 2.008(4) Å, respectively. Each L1 ligand coordinates to three Cu^{II} atoms. Such a coordination mode means that complex **2** forms an infinite 2D network (Figure 2b). It is obvious that the 2D sheet of **2** is different from that of complex **1**, even though they are both grids. First, the sheet of **2** is completely planar and each grid is a square (see Figure 1b and Figure S1 in the Supporting Information) while that of **1** has a corrugated and wavy network structure. In addition, the ligand forms a "V" shape to match the coordination geometry of **2**, while in the case of **1** L1 has an almost linear



(a)



(b)

Figure 2. (a) Crystal structure of the cationic moiety of [Cu(L1-2H)]$(AcOH)_2$·$(C_2H_5)_2O$·$4H_2O$ **2** with atom numbering scheme; (b) infinite 2D grid network of [Cu(L1-2H)]$(AcOH)_2$·$(C_2H_5)_2O$·$4H_2O$ **2**

conformation. The Cu−Cu separation in the square of **2** is 9.12 Å. There are open channels in **2** since the two adjacent sheets are parallel to each other (see Figure S2 in the Supporting Information). The channels are occupied by distorted acetic acid, diethyl ether and water molecules (see Figures S1 and S2 in the Supporting Information). The Cu−Cu distance between two adjacent sheets is 9.40 Å. There are two C(5)−H···O(1) and C(32)−H···O(4) hydrogen bonds (Table 3). Complex **2** rapidly loses diethyl ether in the air; however, the presence of water and acetic acid can be confirmed by thermogravimetric analysis. The TGA data of **2** showed a loss of water and acetic acid centered at 110 and 180 °C, respectively.

We obtained two unexpected infinite zigzag chains **3** and **4** by using a readily prepared ligand L2. The very similar cell parameters of complexes **3** and **4** indicate that they are isomorphous and isostructural. Therefore, only the structure of **3** is described here. The repeat unit of the crystal structure of **3** is illustrated in Figure 3a. Each Cu^I atom is coordinated by two N atoms of the ethylenediimine unit of one L2, a pyridine group of the other L2 and one acetonitrile molecule. The coordination environment of the copper(I) atom is a distorted tetrahedron. The average Cu−N distance of 2.035(3) Å is similar to those (2.02−2.07 Å) of four-coordinate copper(I) complexes,[15] and is shorter than that of complex **1** [2.082(6) Å]. The Cu(1)−N(31) (MeCN) distance of 1.936(3) Å is in the range of reported four-coordinate copper(I) complexes with acetonitrile ligands [1.86−2.26 Å].[16−18] The Cu−Cu separation of 7.54 Å is much longer than that in Cu metal (2.56 Å), and implies no Cu^I−Cu^I interactions in the crystal. The dihedral angle between the two terminal pyridine units of the L2 ligand is 8.6° which is different from that of **1** (82.5°). It has been reported that a di-Schiff base ligand obtained from pyridine-2-carbaldehyde and ethane-1,2-diamine, when reacted with silver(I) complexes, forms a dinuclear double-stranded helical complex.[19]

It is interesting to note that one pyridine unit of the L2 ligand remains uncoordinated, with one acetonitrile molecule coordinating to the Cu^I atom instead. This phenomenon is unusual in tetradentate bridging ligands since the coordination ability of acetonitrile is weaker than that of the pyridine unit. Such a coordination mode gives an extended polynuclear Cu^I cation with a zigzag chain-like structure as illustrated in Figure 3 (b and c). It is noteworthy that each Cu^I atom in **3** is coordinated by three N atoms from two L2 ligands and, in turn, each L2 ligand connects two Cu^I atoms, while in the case of **1**, **2** and other complexes with the L1 ligand, each metal ion is coordinated by four N atoms from three L1 ligand and each L1 ligand connects three metal ions. The nitrate counter ions are located between the two chains by formation of two C−H···O hydrogen bonds between the oxygen atom and pyridyl C−H group (Table 3).

From the present and previous studies it was found that both metal ions and organic ligands have a great influence on the construction of supramolecular frameworks. The reactions between the flexible ligand L1 and Ag^I, Cu^I, Cu^{II} salts with different anions are summarized schematically in Figure 4. It has been reported that different 2D networks can be prepared by reactions of 2,1,3-benzothiadiazoles with copper(I) perchlorate and nitrate due to the different coordination ability of perchlorate and nitrate ions.[20] However, in the case of our copper(I) complexes, the same frameworks were obtained from L1 and $Cu(CH_3CN)_4ClO_4$ and $Cu(CH_3CN)_4NO_3$. This implies that there is no obvious influence of the anions on the formation of networks

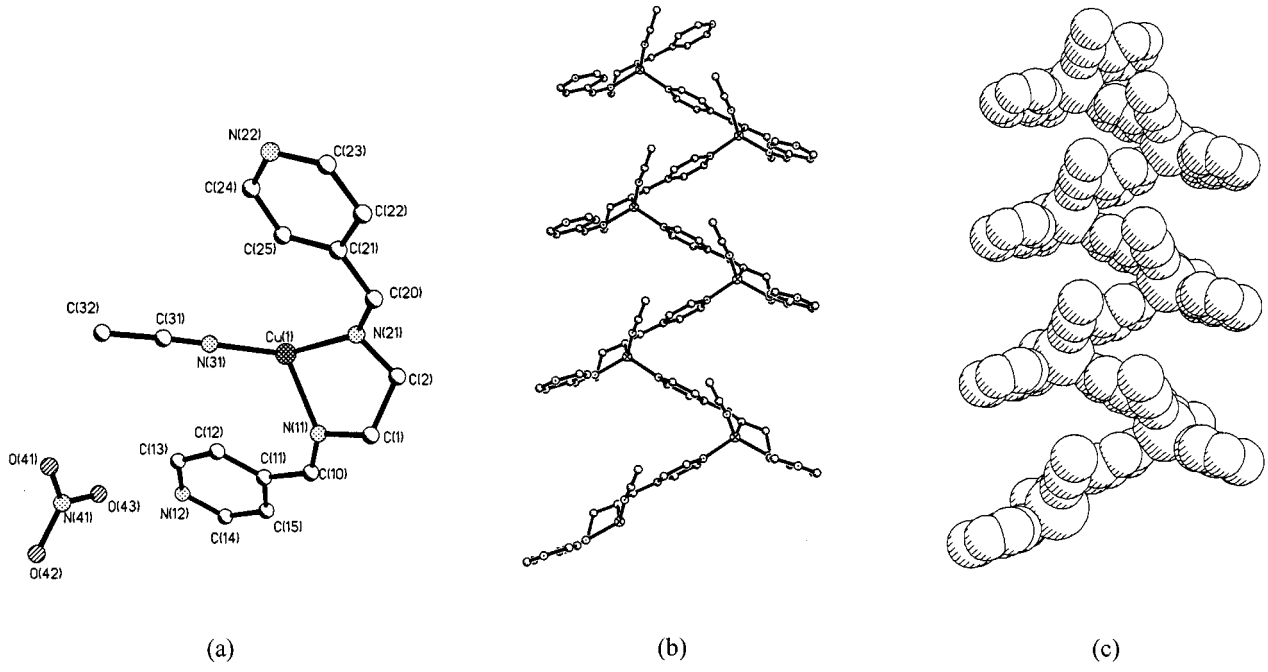


Figure 3. (a) Crystal structure of $[Cu(L2)(CH_3CN)]NO_3$ **3** with atom numbering scheme; (b) part of the single helical structure of **3**; (c) space-filling representation of **3**

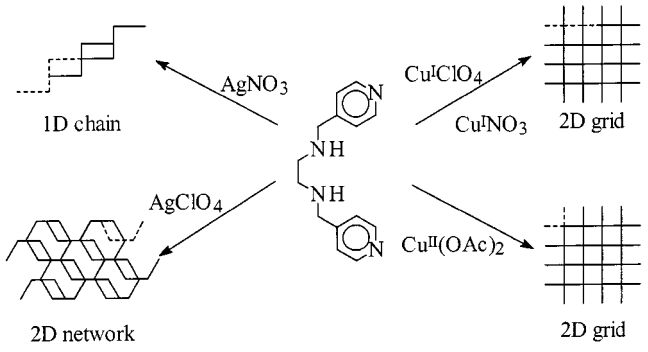

Figure 4. Schematic drawing for reactions between the L1 and Ag^I, Cu^I and Cu^{II} salts; the dashed line refers to one of the L1 ligands

in the Cu^I–L1 system; in the case of silver(I) complexes with the same L1 ligand, 1D and 2D arrays were formed by self-assembly of L1 with silver(I) nitrate and perchlorate, respectively.[5] These results imply that the assembly process is also influenced by the nature of the metal ions. The different structures of complexes **1** and **2** were considered to be caused by the different geometric needs of Cu^I and Cu^{II} ions.

Properties

Powdered samples of the Cu^{II} complex of L1 (**2**) showed photoluminescence with an emission maximum at 430 nm upon excitation at 310 nm. However, no photoluminescence was observed for the Cu^I complex **1**. Powdered **3**, with the di-Schiff base ligand, also showed photoluminescence, with an emission maximum at 391 nm upon excitation at 291 nm. These results indicate that the luminescent properties of the synthesized complexes depend on the nature of the organic ligand and the oxidation state of the metal ions.

The magnetic properties of complex **2** were studied by susceptibility measurements. The effective moment of complex **2** is 1.98 μ_B ($\mu_B \approx 9.27 \times 10^{-24}$ J T^{-1}) at 300 K and 1.73 μ_B at 75 K, which is the same as the spin-only value of 1.73 μ_B expected for isolated Cu^{II} ($S = 1/2$). The slight smooth decrease of μ_{eff} with T shows that a very weak antiferromagnetic exchange is operative due to the large intermetallic distance, as revealed by the X-ray crystal structure.

Conclusion

We have shown that the ligand L1 reacts with $[Cu(CH_3CN)_4]NO_3$ and $Cu(OAc)_2{\cdot}H_2O$ to afford two coordination networks. The two grids of complexes **1** and **2** are slightly different, the ligand in the structure of **1** is linear, whilst in **2** it is in a "V" shape. This is due to the different coordination requirement of the metal ions, which in turn is due to the different ionic radii. These results indicate that even if the same ligand is used, the assembly process may be different due to the different valence of te metal ions. To the best of our knowledge, examples of this are very rare.

The ligand L2 is similar to L1 except for the rigidity: when they react with $[Cu(CH_3CN)_4]NO_3$, the resulting sup-

ramolecular frameworks are very different. One product is an infinite chain structure and the other is a 2D grid network. In addition, complexes of **1** and **2** are stabilized by T-type edge-to-face π-π interactions, whereas no such interactions were observed in the structure of **3**. This suggests that the rigidity of a ligand may have a significant effect on the construction of complexes.

These results imply that the coordination geometry of the ligand and the coordination requirement of the transition metal ion are the primary factors in the construction of supramolecular structures.

Experimental Section

General Methods: All commercially available chemicals were of reagent grade and used as received without further purification. Acetonitrile and ethanol were dried and purified by distillation before use. L1 and $[Cu(CH_3CN)_4]NO_3$ were prepared according to literature methods.[5,21] Samples for C, H and N analyses were dried in vacuum and the analyses were made on a Perkin−Elmer 240C elemental analyzer at the analysis center of Nanjing University. ^1H NMR spectroscopy was performed on a Bruker AM-500 NMR spectrometer, using TMS ($SiMe_4$) as an internal reference at room temperature. Thermogravimetric and differential analyses were taken on a simultaneous SDT 2960 thermal analyzer under N_2 with a heating rate of 10 °C/min. Luminescence spectra were recorded on an Hitachi 850 fluorescence spectrophotometer at room temperature (25 °C). Magnetic measurements on powdered samples were carried out using a CHAN-2000 Faraday magnetometer in the 75 ≈ 300 K temperature range. The apparatus was calibrated with $[Ni(en)_3]S_2O_3$ (en = ethylenediamine). Diamagnetic corrections were made using Pascal's constants.

Synthesis of 1,2-Bis(4′-pyridylmethyleneamino)ethane (L2): 1,2-Ethanediamine (0.53 mL, 7.9 mmol) was dissolved in 30 mL of refluxing absolute methanol and pyridine-4-carbaldehyde (1.41 mL, 15.0 mmol) in 30 mL of absolute methanol was added slowly to give a clear yellowish solution. The mixture was refluxed for 3 h and stirred overnight at ambient temperature. The solvents were removed by evaporation, then 30 mL deionized water was added, and the products were extracted with chloroform (4 × 25 ml). The chloroform solution was evaporated to a syrupy residue under reduced pressure. A powder was obtained by recrystallization of the residue from chloroform and diethyl ether. Washing with diethyl ether and drying in vacuum gave L2 (1.64 g, 92%). − ES-MS: *m/z* = 239.1 $[L2 + H]^+$. − $C_{14}H_{14}N_4$ (238.29): calcd. C 70.56, H 5.92, N 23.51; found C 70.49, H 5.64, N 23.53.

Synthesis of $[Cu(L1)]NO_3·H_2O$ (1): All the procedures for synthesis and spectral measurements were carried out under an argon atmosphere. An acetonitrile solution of $Cu(CH_3CN)_4NO_3$ (0.1 mmol) was added dropwise to a solution of L1 (24.2 mg, 0.1 mmol) in acetonitrile (10 mL) at room temperature to give a clear solution. Orange single crystals (22.1 mg, 40%) suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into the clear filtrate for several days. − ^1H NMR (CD_3CN, 25 °C): δ = 2.81 (s, 4 H), 3.79 (s, 4 H), 7.36 (br, 4 H), 8.60 (br, 4 H). − $C_{14}H_{18}CuN_5O_3$ (367.87): calcd. C 45.71, H 4.93, N 19.04; found C 45.77, H 5.17, N 19.18.

Synthesis of $[Cu(L1-2H)](AcOH)_2·(C_2H_5)_2O·4H_2O$ (2): A deionized aqueous solution (1 mL) of $Cu(OAc)_2·H_2O$ (19.9 mg, 0.1 mmol) was added dropwise to an ethanol solution (10 mL) of L1 (24.2 mg, 0.1 mmol) at 50 °C and stirred for 20 min. Blue single crystals (45.2 mg, 70%) suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into the clear filtrate for several days. − $C_{18}H_{28}CuN_4O_6$ (459.99): calcd. C 47.00, H 6.14, N 12.18; found C 47.38, H 6.01, N 11.93. (The diethyl ether and part of water molecules might be lost during the drying process)

Synthesis of $[Cu(L2)(CH_3CN)]NO_3$ (3): The complex was prepared in the same way as complex **1** except that L1 was replaced by L2. Orange single crystals suitable for X-ray diffraction were obtained (25.8 mg, 64%). − $C_{16}H_{17}CuN_6O_3$ (404.89): calcd. C 47.46, H 4.23, N 20.75; found C 47.24, H 4.32, N 20.89.

Synthesis of $[Cu(L2)(CH_3CN)]ClO_4$ (4): The procedure was similar to that of complex **3** except $[Cu(CH_3CN)_4]NO_3$ was changed to $[Cu(CH_3CN)_4]ClO_4$. Orange single crystals were obtained (26.5 mg, 60%). − $C_{16}H_{17}ClCuN_5O_4$ (442.34): calcd. C 43.44, H 3.87, N 15.83; found C 43.65, H 4.19, N 15.76.

X-ray Crystal Structure Analysis for Complexes 1, 2 and 3: The intensity data were collected at −50 °C for **1** and **3** on a Rigaku RAXIS-RAPID Imaging Plate diffractometer. The data collection for **2** was performed on a Rigaku AFC7S automatic four-circle diffractometer at room temperature, using graphite-monochromated Mo-K_α radiation (λ = 0.7107 Å). The structures were solved by direct methods with SIR92,[22] and expanded using Fourier techniques.[23] All data were refined anisotropically by the full-matrix least-squares method for non-hydrogen atoms. The hydrogen atoms were generated geometrically. All calculations were carried out on SGI workstation using the teXsan crystallographic software package of Molecular Structure Corporation.[24]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-154337 (**1**), CCDC-154338 (**2**) and CCDC-154339 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Control of the Microarchitecture of a Double Helix – Electrochemical Synthesis and Characterisation of a Novel Dinickel(II) Helicate with Different Groove Sizes

Miguel Vázquez,[a] Manuel R. Bermejo,*[a] Matilde Fondo,[a] Ana M. González,[a] José Mahía,[b] Lorenzo Sorace,[c] and Dante Gatteschi[c]

Dedicated to Professor Rafael Usón on the occasion of his 75th birthday

Keywords: Supramolecular chemistry / Helicates / Nickel / Schiff bases / Electrochemical synthesis

Self-assembly of nickel ions and the N_4 Schiff base **H_2PTs** [**H_2PTs**: *N,N′*-bis(2-tosylaminobenzylidene)-1,3-diaminopropane] in an electrochemical cell leads to the novel neutral double-stranded dinuclear helicate $[NiPTs]_2 \cdot CH_3CN$ (**1**). Complex **1** was fully characterised by elemental analysis, IR and EPR spectroscopy, FAB mass spectrometry, and magnetic measurements. The single X-ray crystal structure of **1** shows that both ligands are asymmetrically positioned around the Ni–Ni axis, leading to a double-helical complex that presents a major and a minor groove.

Introduction

Helicate architectures have received a great deal of attention in recent years mainly due to DNA showing double-helical arrays.[1–8] However, the similarities between the structure of nucleic acids and that of synthetic metallo-helicates are very limited, principally because in most helicates the metal binding units are usually positioned symmetrically and on opposite sides of the helix, leading to two equivalent grooves. Hence, an important challenge of supramolecular chemistry is to design ligand strands that can associate on one side of the helical axis. This should lead to the isolation of asymmetrical helicates, which could be models of DNA structure.

Furthermore, it is highly desirable that these ligands are inexpensive, readily prepared, and easily modified donors, in order to enable wider access to this field. Schiff bases seem to be suitable ligands for this proposal.

By merging these two assumptions, one should try to find direct ways of preparing helical asymmetrical compounds with different groove sizes. However, very little work involving this concept has been published. In 1984 Van Koten et al.[9] described a binuclear $[Ag_2(N_4)_2]^{2+}$ dication with helical structure, where the N_4 donors are not symmetry re lated. More recently, Fabrizzi et al.[10] prepared a bis-iminoquinoline Cu^I helical cation with a certain degree of asymmetry, due to the reciprocal positioning of the ligand strands. It was not until 1999, however, that Hannon et al.[11] emphasised the significance of such asymmetry, and reported a Schiff base silver(I) double helical complex containing a major and a minor groove.

Our studies of the first-row transition metal complexes with imine-based ligands lead us to isolate mono-, di-, or trinuclear helical species.[12–15] As a continuation of this research, and considering that π-stacking interactions between benzylidene groups may provide a suitable tool for controlling the spatial orientation of ligand strands in a double-helical structure,[11] we have designed a new symmetric N_4 Schiff base ligand (see Scheme 1). This ligand contains four acyclic N donor atoms, an acyclic flexible spacer, and terminal bulky groups that should prevent the formation of undesired mononuclear species.[16–18] Furthermore, the Schiff base presents two benzylidene rings fused to the acyclic nitrogen atoms that could give rise to π-stacking interactions, as we have previously observed.[19] This could dictate a non-equivalent wrapping of the ligands around the M···M axis. The reaction of this potential bis-bidentate and dianionic ligand with nickel under electrochemical conditions was studied, and the results achieved are reported herein.

Results and Discussion

Design and Synthesis of the Ligand

The Schiff base **H_2PTs** [IUPAC name: *N,N′*-bis(2-tosylaminobenzylidene)-1,3-diaminopropane] has been prepared following a three-step procedure (Scheme 1) with a overall yield of 60%. The first step involves the oxidation of the

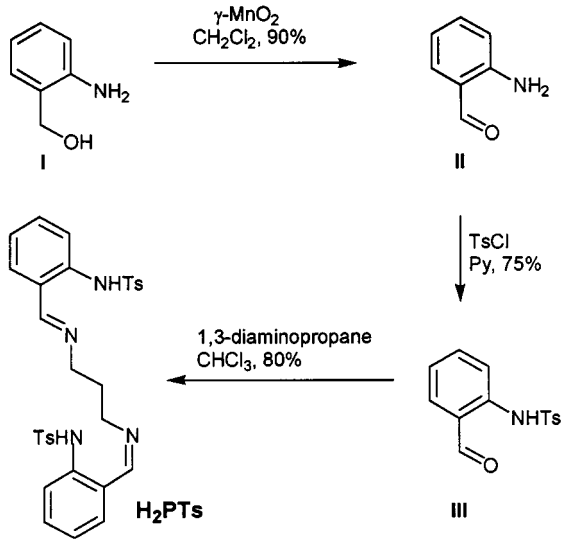


Scheme 1. Synthesis of the ligand $\mathbf{H_2PTs}$

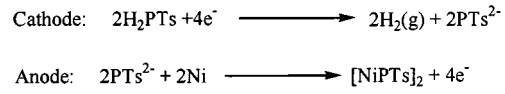
OH group of **I** to give aldehyde **II**. Subsequently, *N*-tosylation of 2-aminobenzaldehyde **II** with tosyl chloride afforded aldehyde **III**.[20] Finally, treatment of **III** with 1,3-diaminopropane in chloroform under reflux conditions gave the N_4 Schiff base ligand $\mathbf{H_2PTs}$.

The yellow powdery solid formed was satisfactorily characterised by elemental analysis, IR, ^{1}H NMR spectroscopy, and FAB mass spectrometry. Besides, the structure of the ligand was known by X-ray diffraction studies.[21] This structure shows that the bulky terminal tosyl groups are *trans* to each other, in order to minimise the steric hindrance. Thus, it seems that the ligand should preferably act as bis-bidentate, spanning two metal centres, and preventing the formation of mononuclear species, in order to avoid the tosyl groups getting closer. In addition, the benzylidene moieties, fused to the N-atoms of different ligands, give rise to π-stacking interactions when the ligand is free. These interactions could be also present in the corresponding complexes, as has been previously observed for similar systems,[19] and could predispose the ligands to associate asymmetrically around the helical axis, leading to helicates with different groove sizes.

Electrochemical Synthesis of the Nickel Complex

Complex **1** was obtained by electrochemical oxidation of a nickel anode in an acetonitrile solution of the ligand $\mathbf{H_2PTs}$, in the presence of a small quantity of tetraethylammonium perchlorate as supporting electrolyte. The cell can be summarised as Pt(−)|H_2PTs + MeCN|Ni(+). This synthetic procedure yields the neutral $[NiPTs]_2$ complex with high purity and in high yield.[12−15,22]

The electrochemical efficiency of the cell E_f was close to 0.5 mol·F^{-1}, which is compatible with the reactions shown in Scheme 2.



Scheme 2

The green powder nickel complex formed by this synthetic route is insoluble in water and apolar organic solvents, and soluble in common polar organic solvents. It appears to be stable both in the solid state and in solution.

Crystal Structure

Green plate single crystals of $[NiPTs]_2.CH_3CN$ (**1**), suitable for X-ray diffraction studies, were grown by vapour diffusion of diethyl ether into an acetonitrile solution of the powder $[NiPTs]_2$. An Ortep view of the structure is shown in Figure 1. Experimental details are presented in Table 3

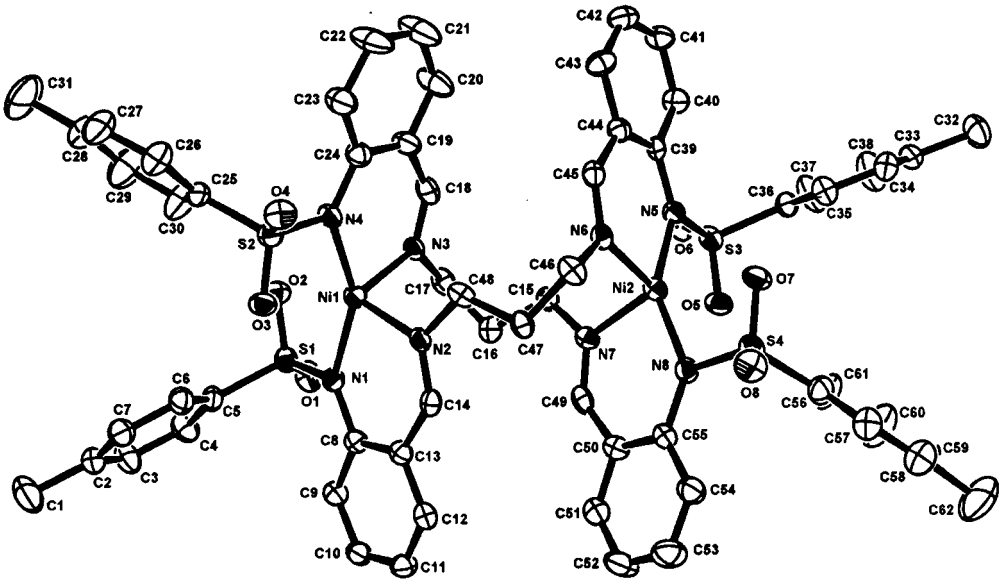


Figure 1. ORTEP view of complex **1** (thermal ellipsoids are drawn at 30% of probability level and hydrogen atoms and solvent molecules have been omitted for clarity)

and selected bond lengths and angles in Table 1 and Table 2.

The asymmetric unit contains a $[NiPTs]_2$ molecule with two acetonitrile solvates at 0.5 occupancy. The compound is a binuclear nickel complex, with the ligands spanning both metal centres, and intertwined to give a double helix. Both enantiomers (left- and right-handed) are observed in the unit cell.

Each ligand uses both nitrogen atoms of one binding moiety [N(1), N(2); N(3), N(4)] to coordinate one metal centre [Ni(1)]. The remaining imine nitrogen [N(6), N(7)] and amide nitrogen [N(5), N(8)] atoms of the second binding units of both $[PTs]^{2-}$ coordinate the second nickel atom [Ni(2)]. Thus, the environment of the metal centres can be described as distorted tetrahedral, with both ligands acting as bisbidentate N_4 donors. This distortion is shown by the angles between nitrogen and nickel atoms, which range from 91.7(2)° to 151.7(2)° for Ni(1) and from 149.8(2) to 91.7(2) for Ni(2). The longer angles [151.7(2)° and 149.8(2)°] are those between nickel and the amide nitrogen atoms, and this seems to be the result of the attempt to minimise the steric hindrance between the tosyl groups.

This tetrahedral geometry is quite unusual for dinickel helical complexes, where the nickel atom is usually six-coordinated.[13−14,23−25] Thus, in nickel complexes with imine-based ligands of the hydrazone type, composed by two bidentate arms and a spacer with a donor atom, two different possibilities of reaching the coordination number 6 have been described.[13−14,23] The most general one is the linking of two bidentate arms and two central donor atoms, which act as bridges, to the same metal atom.[13−14,23] When this type of complex is recrystallised in a donor solvent, the central bridges break and the donor atoms of the spacers are now linked to only one metal centre, acting as terminal donors. This would lead to a coordination number of six for one metal atom and to a coordination number of four for the other one. The two free coordination positions of the second nickel atom are now filled by donor solvent molecules, giving rise to a [6 + 4 + (2)] helix.[13−14]

However, when the ligand does not contain a donor atom in the spacer group, the octahedral environment with bis-bidentate Schiff bases is normally achieved by simultaneous coordination of three strands to two metal centres. Thus, the most common nickel helical complexes with Schiff bases described in literature are the dinuclear triple helical ones.[24−25] In this case study, two factors can prevent the coordination of a third [H_2PTS] ligand or solvent molecules in order to achieve a coordination number six: 1) the steric hindrance of the bulky tosyl groups; 2) the closeness of some of the tosyl oxygen atoms to Ni(1) [O(2) and O(3)] and Ni(2) [O(5) and O(7)]. These distances of ca. 2.5 Å seem to indicate that one oxygen atom of each tosyl group is weakly interacting with one metal atom. Thus, the aforementioned distances could be taken as secondary intramolecular bonds, since they are too long to be considered true coordinated bonds. This fact could have a profound influence on the adopted tetrahedral geometry, as maybe these oxygen atoms are too close to the nickel centres to allow any other ligand to complete their environment requirements.

Each ligand forms two six-membered chelate rings, one around each metal atom, which are nearly planar, with angles between the chelate rings of 85.75° and 80.18° around Ni(1) and Ni(2), respectively. The Ni−N(imine) bond lengths [Ni(1)−N(2) = 1.999(6) Å, Ni(1)−N(3) = 2.017(5) Å, Ni(2)−N(6) = 2.018(6) Å, and Ni(2)−N(7) = 2.018(6) Å] are shorter than those found for octahedral triple dinickel helicates with Schiff bases.[25] This could be a reflection of the lower coordination number in the latter complexes. The same occurs with the Ni−N(amide) bonds [Ni(1)−N(1) = 1.991(5) Å, Ni(1)−N(4) = 1.985(5) Å, Ni(2)−N(5) = 1.977(6) Å, and Ni(2)−N(8) = 1.971(6) Å], which are shorter than the Ni−Ni(amide) distances found for hexa-coordinated nickel Schiff base complexes containing the NTos radical.[26] The Ni(1)···N(2) distance of 6.207 Å is shorter than the ones reported for nickel triple helical complexes[24−25] (about 11 Å), but longer than the ones for double helical nickel complexes with hydrazone ligands,[13−14,23] as was expected.

All these distances and angles also show the non-equivalence of the environment of the nickel atoms and of both Schiff bases, giving rise to a certain degree of asymmetry. This asymmetry leads to the formation of two grooves of different size. The two distinct grooves (major and minor) seem to be exacerbated by aromatic π-stacking interactions between the benzylidene rings of the binding moieties. Two interactions of different strength can be observed between aromatic rings of different ligand strands, as is shown in Figure 2. From now we will call A and B the two benzylidene rings of the dark strand, and C and D those of the light strand. Interaction between A and D (Figure 2, left) gives

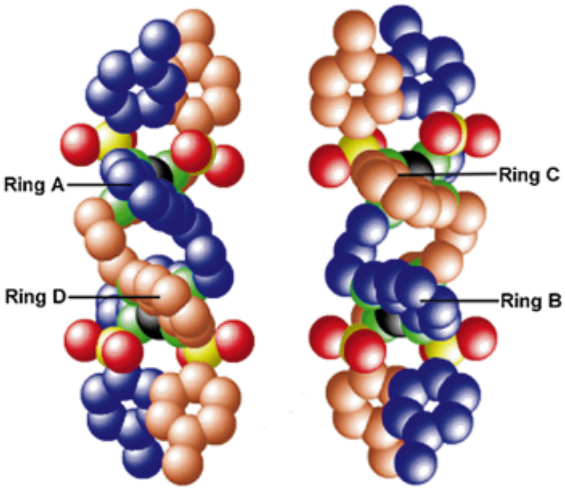

Figure 2. Space-filling representation of complex **1**, showing the minor (left) and major (right) grooves. Both representations correspond to the same enantiomer, turned 180°

rise to distances of 2.455−3.179 Å between the atoms of A and mean plane of D, with an angle between their least-square planes of 16.0°. Similarly, C overlaps with B (Figure 2, right) leading to a longer distance (2.682−3.755 Å) and to a bigger acute angle (25.2°). Thus, to the best of our knowledge, this is the first example where π-stacking interactions between aromatic rings of the binding moieties (not of the spacer group) control the micro-architecture of the helix, and lead to an asymmetrical double-stranded helicate with a major and a minor groove.

However, no specific π-stacking interactions (face-face or face-edge π-π) are identifiable between the terminal tosyl aromatic rings, which probably appear separated to minimize the steric repulsion.

Finally, the helical turn, defined as the angle subtended by the centroids of the inner benzylidene rings of the ligand along the Ni−Ni axis (helical axis), are 174.8° and 179.6° for each strand.

IR Spectroscopy and FAB Mass Spectrometry

The IR spectra of **1** shows a strong band at ca. 1625 cm^{-1} due to the imine ν(C=N) mode, which exhibit a shift of 10 cm^{-1} to lower energy from the free ligand value, indicative of coordination of the ligand to nickel. In addition, the band due to ν(C−N) mode undergoes a negative shift (1303 vs. 1340 cm^{-1} in the free ligand). This behaviour is compatible with the participation of both imine an amide nitrogen atoms in the coordination to nickel centres.[27−28]

The FAB mass spectrum of **1** presents a peak at m/z = 646 due to the fragment $[NiPTs]^+$, that confirms the coordination of the ligand to the metal centre. Besides a prominent peak at m/z = 1292 is assigned to the fragment $[NiPTs]_2^+$, which seems to indicate a dinuclear nature of complex **1**, as the X-ray structure shows.

Magnetic and EPR Characterisation

Nickel(II) tetrahedral complexes usually exhibit a large magnetic moment, due to the largely unquenched orbital momentum; this is usually observed together with a large dependence of the magnetic moment on temperature. However, distortion from ideal tetrahedral symmetry may remove the orbital degeneration of the ground state, thus reducing both the temperature dependence and the absolute value of the magnetic moment.[29−31]

The high temperature value of the magnetic moment of **1** (1.36 emu K per mol of Ni^{2+}at 280 K) is quite low for a tetrahedral nickel(II), thus indicating that, as expected from the structural data, large distortions from tetrahedral symmetry are active in reducing the orbital contribution to the magnetic moment. The temperature dependence of the product (shown in Figure 3) is quite small. In agreement with this interpretation, on lowering the temperature, χT slowly decreases to 1.20 emu K per mol of Ni^{2+} centre at 22 K. Only below this temperature does it drop until it reaches 0.32 emu K mol^{-1} at 2 K. As the two tetrahedral units of Ni^{2+} are quite far from each other (6.207 Å), and there are no bridging ligands capable of transmitting the exchange coupling interaction between them, it seems reasonable to attribute this behaviour to a large Zero Field Splitting of the $S = 1$ ground state, which is a well-known characteristic of nickel(II) complexes.

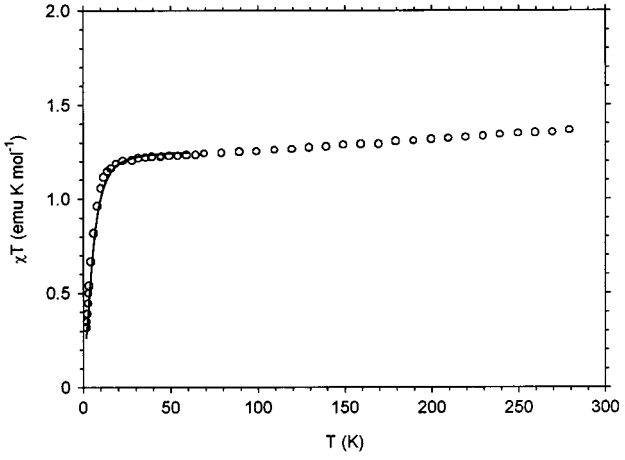

Figure 3. Plot of χT versus T for **1**, in the range 2−280 K

This hypothesis was confirmed both by the absence of any X-Band EPR signal at 4.2 K, and by the behaviour of the M vs. H curve, measured at 3 K. As shown in Figure 4, the magnetisation is slowly increasing with the field and it

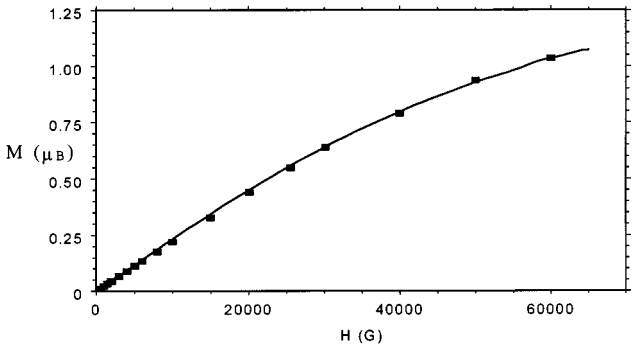

Figure 4. Magnetisation plot (M) versus H for **1**

is still far from saturation at 6.0 T (1.04 μ_B per Ni^{2+}). The magnetisation curve was fairly well reproduced (Figure 4, continuous line) assuming a D value of 13.0±0.2 cm^{-1} and a g value of 2.20±0.03, in agreement with what was expected for Ni^{2+}. Assuming the same parameters, we were then able to reproduce (Figure 3, continuous line) the low temperature part of the χT curve. The large D value may be due to the presence of low-lying excited states admixed through spin-orbit coupling. As far as the slight difference in the two tetrahedral units is concerned, it should be stressed that these parameters represent an average between the values of each single centre.

Conclusion

This work shows that careful selection and design of Schiff base ligands can yield helical nickel complexes. The presence of bulky terminal groups in the N_4 donor **H_2PTs** described herein constrains the ligand to act as binucleating. Besides, the presence of benzylidene moieties in the ligand strands seems to play a fundamental role in the asymmetrical structure of the helix. Thus, a neutral double-stranded dinickel helical complex, so scarce in literature, can be isolated by means of the electrochemical synthesis. In addition, internal π-stacking interactions between ligand binding domains control the micro-architecture of the double helix, leading to a helicate with different size grooves, reminiscent of DNA structure.

Variation of the length and rigidity of the spacer, as well as studies of further factors that can affect the spatial orientation of ligand strands in metallo-supramolecular compounds, are in progress in our laboratory.

Experimental Section

Elemental analysis was performed on a Carlo Erba EA 1108 analyser. − The NMR spectra were recorded on a Bruker WM-250 spectrometer using $CDCl_3$ as solvent. − Infrared spectra were recorded as KBr pellets on a Bio-Rad FTS 135 spectrophotometer in the range of 4000−600 cm^{-1}. − Mass spectrometry (FAB) was performed on a Micromass Autospec mass spectrometer, employing *m*-nitrobenzyl alcohol as a matrix. − The EPR spectrum of **1** was recorded using a Varian ESR9 spectrometer equipped with a ^{4}He continuous flow cryostat. − Magnetic measurements between 2 and 280 K were performed using a Cryogenics Squid magnetometer with field up to 6.5 T. The data were corrected for sample holder contribution and diamagnetism of the sample using Pascal constants.

Syntheses: All the starting materials were purchase from Aldrich and used without further purification. 2-tosylaminobenzaldehyde **III** was prepared according to a method previously reported in literature,[20] as shown in Scheme 1.

***N,N′*-Bis(2-tosylaminobenzylidene)-1,3-diaminopropane (H_2PTs):** To a solution of 2-tosylaminobenzaldehyde **III** (5.0 g, 18.2 mmol) in chloroform (150 mL) 1,3-diaminopropane (0.8 mL, 9.1 mmol) was added and the mixture was heated under reflux. The volume of the solution was reduced over a 4 h period to ca. 50 mL, using a Dean−Stark trap, and was then allowed to cool. The resultant yellow solution was concentrated to ca. 10 mL. The solid, which precipitated, was collected by filtration, washed with diethyl ether (3 mL) and dried in vacuo. Yield 4.3 g (80%). m.p.: 145 °C. − $C_{31}H_{32}N_4O_4S_2$ (588.8): calcd. C 63.24, H 5.48, N 9.52, S 10.89; found C 63.0, H 5.3, N 9.4, S 10.5. FAB-MS: m/z = 589.2 [M^+]. − ^{1}H NMR (250 MHz, $CDCl_3$, ppm): δ = 13.0 (s, 2 H), 8.4 (s, 2 H), 7.7 (d, 4 H), 7.6 (d, 2 H), 7.2 (m, 6 H), 7.1 (d, 2 H), 7.0(dt, 2 H), 3.8 (t, 4 H), 2.3 (s, 6 H), 2.2 (q, 2 H). − IR (KBr, cm^{-1}): ν(C=N) 1635 s, ν(C−N) 1340 s, $\nu_{as}(SO_2)$ 1287 s, $\nu_s(SO_2)$ 1163 s.

[NiPTs]$_2$: A solution of H_2PTs (0.2 g, 0.3 mmol) in acetonitrile (80 mL), containing 10 mg of tetramethylammonium perchlorate as supporting electrolyte, was electrolysed for 3.6 h using a current of 5 mA and 7.2 V. Concentration of the resultant solution to a third of its initial volume yielded a green solid that was washed with diethyl ether and dried in vacuo. Yield: 0.2 g (86%). − $C_{62}H_{60}N_8Ni_2O_8S_4{\cdot}CH_3CN$ (1333.9): calcd. C 57.7, H 4.7, N 9.5, S 9.6; found C 58.0, H 4.6, N 9.5, S 9.8. FAB-MS, m/z (%) = 646 (54, NiPTs), 1292 (42, Ni_2PTs_2). − IR (KBr, cm^{-1}): ν(C=N) 1625 s, ν(C−N) 1303 s, $\nu_{as}(SO_2)$ 1260 s, $\nu_s(SO_2)$ 1129 s.

Recrystallisation of the green powder in acetonitrile yields crystals of [NiPTs]$_2{\cdot}CH_3CN$ **1** suitable for X-ray diffraction studies.

CAUTION: Perchlorate salts are potentially explosive and should therefore be handled with the appropriate care.

X-ray Crystallography: Crystals of **1** suitable for X-ray diffraction studies were grown as previously detailed. X-ray data were collected on a Siemens SMART CCD area-detector diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) operating at room temperature, using ω scans (Table 3). The structure was solved by direct methods[32] and refined by full-matrix least-squares on F^2. Absorption and incident beam corrections were applied (SADABS). All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were included in the model at geometrically calculated positions and refined using a riding model.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-142926. Copies of the data can be obtained free of charge

Keywords: Cage amines / Functionalization / Polymers / Electrochemistry

Structural studies have confirmed that it is possible to exploit the relatively low nucleophilicity of the "external" amino substituents on the Co^{III} complex of 1,8-diaminosarcophagine ("sarcophagine" = sar = 3,6,10,13,16,19-hexaazabicyclo[6.6.6]-icosane) in acylation and alkylation reactions leading to a variety of functionalized cage amine complexes. With the appropriate choice of solvent, all these reactions can be conducted with high efficiency, and the new complexes display properties foreshadowing the application of cage systems in, for example, electroactive polymers.

Introduction

The presence of external functional groups on the metal complexes of the very readily obtained cage amine "diaminosarcophagine" {1,8-diamino-3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane = $(NH_2)_2$sar},[1] has led to the exploration of reactions of these groups to generate derivatives offering a variety of possible applications.[2] Our interests in this area include the incorporation of $[M\{(NH_2)_2sar\}]^{n+}$ (M = metal) units into amide polymers and the use of cage complexes as electrocatalysts, and so we have been particularly interested in acylation reactions of $[M\{(NH_2)_2sar\}]^{n+}$, as well as in processes whereby potentially electroactive groups can be introduced into such complexes. A known difficulty with reactions of amino groups attached to a cationic complex ion centre is that the nucleophilicity of these groups may be strongly reduced by the proximity of the positive site.[1−6] Carboxymethylation reactions of $[Cu\{(NH_2)_2sar\}]^{2+}$, for example, proceed considerably more rapidly than those of $[Co\{(NH_2)_2sar\}]^{3+}$, although such reaction studies have also demonstrated the utility of metal ion coordination in controlling the extent and position of substitution.[6] In the present work, we explore the use of cobalt(III) complexes of cage amines in reactions that may provide models for polymer formation processes or produce materials that may be converted into polymers by electrochemical means. Thus, we have examined reactions at the external amino groups leading to the formation of amide and imide derivatives or to the attachment of groups with electropolymerizable substituents (or with substituents readily functionalized for the purpose of subsequent polymerization).

Results and Discussion

Structural studies based on X-ray crystallography were an essential component of the present work, not only for the purpose of defining the nature of the species isolated but also to characterize the mutual influences of the core cage complex and the peripheral substituents upon one another. Certain aspects of the solid-state structures are nonetheless familiar from earlier extensive studies of simpler cage amine complexes,[1−8] so that in general we comment only briefly on the cage stereochemistry and on the interactions of counteranions with coordinated NH atoms. For convenience, the Co(sarcophagine) units in all the structures determined (Figure 1) are shown in the Δ configuration, though in fact all syntheses were conducted with racemic reactants and all crystals proved to be racemic compounds. In cases where the cage substituents were acidic or basic in nature, the localization of protons was sometimes problematic and the models presented as "best" must be regarded as tentative. It is possible, of course, that the species considered to be immobilized within the solids are not those dominant in solution, though the forms of association seen in the solids, while predictable, are nonetheless useful in considering modes that may influence solution behaviour.

The rapid electron-transfer reactions and kinetic inertness in more than one oxidation state of many cage amine complexes makes the incorporation of these entities into insoluble polymers of possible interest, for example, in constructing novel rechargeable battery systems.[9] Polyamide formation from $[M\{(NH_2)_2sar\}]^{n+}$ units would seem an

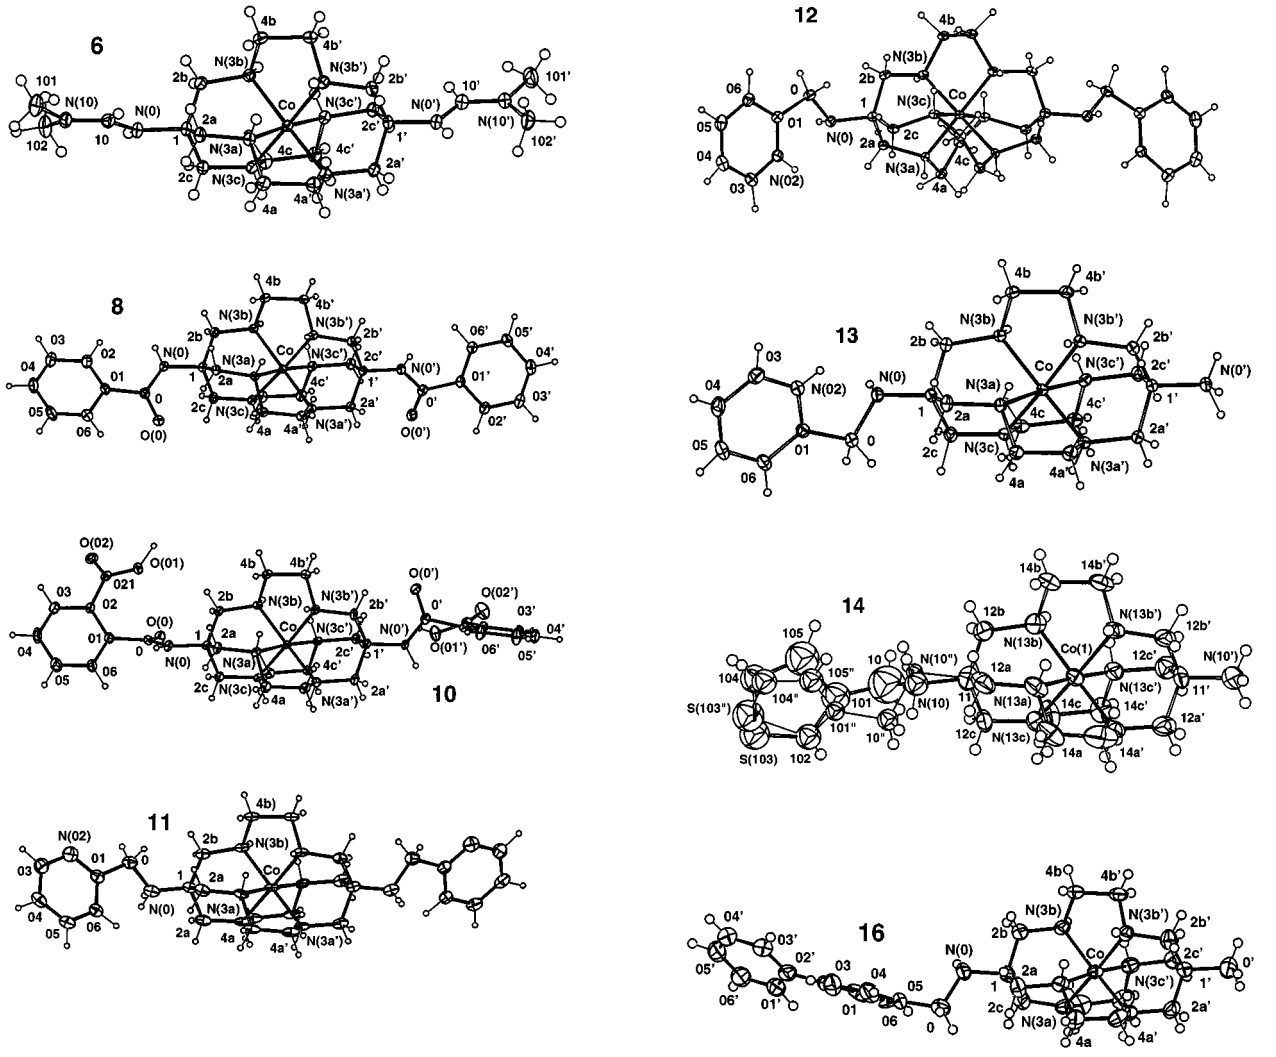

Figure 1. Projections of the cations of **6**, **8**, **10**, **11**, **12**, **13**, **14**, and **16** (cations 1 for **10**, **14**, **16**) in common orientation

obvious path to such polymers, but there is considerable flexibility in the way in which such a synthesis might be conducted. The Schotten−Baumann reaction[10] is one of the longest-known and simplest reactions for the formation of aromatic carboxamides from water-soluble amines, hence, given the fact that $[M\{(NH_2)_2sar\}]^{n+}$ complexes are typically highly water-soluble (as their chlorides, for example), this reaction was explored to see whether acceptable efficiency could be obtained even with an amine of low nucleophilicity. In the event, this was not the case, but a structure determination of the benzoylation product was of interest with regard to the possibility that the poor yields and relatively facile acid-catalysed hydrolysis might be consequences of unusual distortions of the amide resulting from its incorporation into the cage complex. The structure of hydrated $[Co\{sar(NHCOC_6H_5)_2\}]Cl_3$ (**8**, Figure 1), shows the cage Co(sar) unit to be very similar to that in the parent compound and many derivatives thereof,[1−8] with its *lel*$_3$ conformation seemingly once again stemming from the chelation of chloride counteranions by coordinated NH groups [Cl(1)···H(3a′,c) 2.49(2), 2.25(2); Cl(2)···H(3b′,a) 2.38(3), 2.29(2); Cl(3)···H(3c′,b) 2.27(3), 2.47(3) Å]. The structure is well-defined, with all hydrogens being locatable other than those in the vicinity of the partially occupied water molecule site, and both the amide NH [H(0′)···O(01) 2.22(3) Å] and O [H(01a)···O(0′) ($2 - x$, $y + 1/2$, $1\,^1/_2 - z$) 2.07(4) Å] atoms are involved in H-bonding. The amide geometry is comparable with that of benzamide itself;[11−14] benzoylation of the cage complex causes no substantial electronic distortions of the product components, though presumably the charge of the complex may facilitate attack of a polar nucleophile at the amide carbon.

A useful discovery made during efforts to use nonaqueous solvents for the acylation of $[Co\{(NH_2)_2sar\}]^{3+}$ was that the 1,8-amino groups were found to be acylated very rapidly with activated acylating agents. Thus, formation of the formamidino derivative of the cage complex appears to be complete within the time of mixing at room temperature in a benzoyl chloride/dimethylformamide medium. The presumed mechanism for this process is shown in Figure 2.

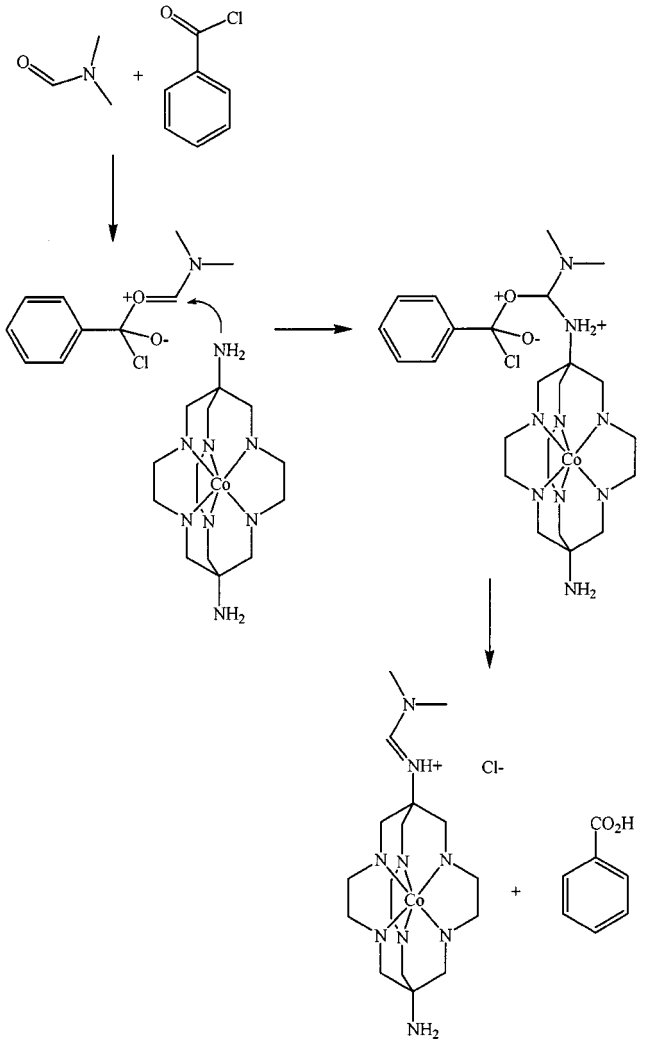

Figure 2. A possible pathway for amidine formation from dimethylformamide and $[Co\{(NH_2)_2sar\}]^{3+}$

The structure determination for $[Co\{sar[NHCHN(CH_3)_2]\}]Cl_5{\cdot}3H_2O$, **6** (Figure 1), was again sufficiently precise for hydrogen atom refinement, exemplifying yet another case of the *lel*$_3$ conformation arising from NH-bond chelation of chloride counteranions [Cl(1)···H(3c′,b) 2.34(2), 2.30(2); Cl(2)···H(3b′,a) 2.30(2), 2.29(2); Cl(3)···H(3a′,c) 2.30(2), 2.29(2) Å]. The structure confirms amidine formation, presumably as a result of the activation of DMF by acylation; both amidine groups remain sufficiently basic to be protonated in dilute HCl. Extensive H-bonding interactions are seen between the nitrogen atoms of the pendant groups and the anions and lattice water [Cl(5)···H(1) 2.31(2); O(03)···H(1′) 1.94(2) Å], and there are also direct interactions between the latter entities [Cl(3)···H(02a) 2.28(4); Cl(4)···H(02b), H(03b) ($1-x$, $-y$, $1-z$) 2.18(3), 2.33(3); Cl(5)···H(01a) (x, $y-1$, z) 2.35(3); O(2)···H(03a) (x, $y-1$, z) 1.93(3) Å]. The particular properties of dimethylformamide may be important in favouring amidine formation, as was also observed in early efforts to conduct phthaloylation reactions (see below) in this solvent; such behaviour was no longer prominent when dimethylacetamide was used as solvent. In turn, it was these observations that ultimately led to the use of dimethylacetamide in an efficient synthesis of the dibenzoylated cage complex.

As a model for reactions possibly involving the formation of a polyimide based on a cage amine and, for example, perylene dicarboximide units,[15] the formation of phthalimide derivatives of $[Co\{(NH_2)_2sar\}]^{3+}$ was examined. While the use of acetic acid as the reaction solvent appeared to result in formation of the bis(phthalimide) complex, under the conditions necessary for chromatographic purification of the reaction products ring opening to give the bis(phthalamic acid) was essentially complete. Such reactivity of the imide unit is perhaps unsurprising, given its incorporation into a highly charged cation. The use of dimethylacetamide (DMA) as a solvent for phthaloylation reactions is known[15] to favour phthalamic acid formation and, indeed, the reaction of $[Co\{(NH_2)_2sar\}]^{3+}$ with a moderate excess of phthalic anhydride in DMA led to essentially quantitative and direct formation of the "open" bis(phthalamic acid), **10**, which was structurally characterized as its chloride salt. As with the bis(benzoyl) derivative, the product did not display any anomalous structural features. The cage unit is again *lel*$_3$, once more arising from chloride anion chelation, and both the amide NH and carboxylic acid groups are involved in extended H-bonding arrays involving both water and the chloride anions. The mean bond lengths in the amide units (C−O 1.22 Å; C−N 1.35 Å) suggest some contraction of the C−O bond and elongation of the C−N bond relative to those in a simple phthalamide such as 2-phenylcarbamoylbenzoic acid,[16] although in the context of a less precise complex ion structure these differences cannot be seen as significant.

Like simpler amic acids,[15] the bis(phthalamic acid) complex could be converted into an imide form by heating in the solid state, but even under rather extreme conditions (180 °C, 5 Torr pressure, 5 h) this conversion was only ca. 20% complete. Hence, there appears to be a genuine resistance to the formation of imides, at least from $[Co\{(NH_2)_2sar\}]^{3+}$, and the hydrolytic stability seen for the bis(phthalamic acid) and, to a lesser extent, the simpler bis(benzamide) described above led us to the conclusion that the formation of polyamides should be a favourable method for the inclusion of cage units in polymers. Obviously, dimethylacetamide must currently be regarded as the solvent of choice for such reactions.

Reductive alkylations involving intermediate formation of imines between a carbonyl compound and cage amino substituents have been successfully used in the generation of a number of $[Co\{(NH_2)_2sar\}]^{3+}$ derivatives[3,5] and the work reported herein has served to extend the variety of these syntheses. We have found that the generation of imine species in reactions between aromatic aldehydes and $[Co\{(NH_2)_2sar\}]^{3+}$ in dimethyl sulfoxide can be readily monitored by ^{1}H NMR spectroscopy (most readily, through the appearance of an imine group CH resonance near $\delta = 8.5$), although in the presence of only a moderate excess of the aldehyde, conversion is slow and incomplete and, after

reduction, the product mixtures are invariably found to contain both mono- and dialkylated species. In the case of $[Co\{(CH_3)(NH_2)sar\}]^{3+}$, however, fully (mono)alkylated species are obtained more readily. In both systems, however, exhaustive chromatography of the reaction products has provided evidence of minor amounts of other (as yet, unidentified) products and the chemistry of these reactions cannot be said to be fully characterized, even though the desired products can be obtained with acceptable efficiency. Significant features of the ^1H NMR spectra of the isolated products containing groups other than 2-pyridylmethyl are summarized in Table 1. No anomalies are apparent, although it is unclear as to why the diastereotopicity of the methylene linker-group protons should be evident in some spectra (which show an AB quadruplet) and not in others.

To establish the structural influences of various cage alkylations, single-crystal structure determinations have been performed on $[Co\{(2\text{-}pyCH_2NH)_2sar\}]^{3+}$ as its monoprotonated tetranitrate **11** and its diprotonated bis(dithionate) chloride **12**, on $[Co\{(NH_2)(2\text{-}pyCH_2NH)sar\}]^{3+}$ as its diprotonated bis(dithionate) chloride **13**, and on $[Co\{(CH_3)(C_6H_5C_6H_4CH_2NH)sar\}]^{3+}$ as its mixed nitrate chloride **16** (see also the discussion of structure **14** below). The dialkylated cage structures (Figure 1) provide further examples of different conformers of a given cage complex being found in different salts;[5,6] thus, the 5+ cation of the dithionate chloride is found to be in the ob_3 form, while the 4+ cation in the tetranitrate is in the lel_3 form. This may be the only significant consequence of alkylation on the structure of the inner cage species. While there is some evidence that the preferred conformation of cages of the sarcophagine complex type may depend on the size of the 1,8-substituents,[3,5] the hydrogen atoms of the secondary N-donor atoms in the Co^{III} complexes are always involved in markedly different interactions with the counteranions and lattice solvent in the different conformers, and the availability of an H-bond acceptor capable of bridging between two NH units of different caps appears to be a significant factor favouring the lel_3 form.[3,6] Although the simple form of tris-chelation of anions as in structures **6**, **8**, and **10** does not apply for **11**, an equally elegant relative does apply (Figure 3). One of the two crystallographically independent anions is disposed with its axis (and those of its symmetry related images) approximately parallel to that of the cation, so that its three oxygen atoms interact with different cations, each O chelating two NH bonds. Thus, the relevant distances are N(3a)···O(12,13) (1/2 + x, 1/2 + y, z) 3.343(7), 3.244(6); N(3a′)···O(11,12) (1 − x, y, 1/2 − z) 3.223(6), 3.221(7); N(3b)···O(11,13) (x − 1/2, 1/2 + y, z) 3.178(7), 3.137(7) Å; from the opposite viewpoint, O(11)···N(3a′) (1 − x, y, 1/2 − z), N(3b) (1/2 + x, y − 1/2, z) 3.223(6), 3.178(7); O(12)···N(3a) (x − 1/2, y − 1/2, z), N(3a′) (1 − x, y, 1/2 − z) 3.343(7), 3.221(7); O(13)···N(3a) (x − 1/2, y − 1/2, z) 3.244(6), N(3b) (x + 1/2, y − 1/2, z) 3.137(7) Å (Figure 3).

The well-defined pendant amine hydrogen interacts with the water oxygen [H(0NA)···O(01) 2.0 (est.)], and the hydrogen of the latter is in turn coordinated by the pyridine nitrogen [N(02)···O(01) (1 − x, 1 − y, 1 − z) 2.67(1) Å]; beyond this the remainder of the structure (the other nitrate group) is disordered, with the assignment of the final hydrogen atom, as well as those of the water molecule, being dubious. The latter have four potential hydrogen-bonding interactions, two of which are presumably donor interactions [to N(02) (pyridine) (1 − x, 1 − y, 1 − z) and nitrate O(23) (disordered)], one an acceptor interaction [N(0)], and one ambiguous.

While the single proton associated with **11** appears to be bound to an amino rather than a pyridine nitrogen, in the diprotonated species **12** both protons are localized on pyridine *N* centres. Given that the acidity-enhancing effect of the adjacent Co^{III} cation should vary with distance from the metal centre,[17] it is perhaps not surprising to find a similar affinity for the two sites. In any case, protonation of the pendant groups strongly influences the nature of the H-bonding array in the solid, which in this case includes coordination of the NH units to separate H-bond acceptors [Cl···H(3b) 2.46(3), O(13)···H(3c) 2.04(4), O(22)···H(3a′) ($1\,^1/_2$ + x, y − 1/2, 1/2 − z) 2.32(4) Å] and, as in other examples of this form of H-bonding,[6] also involves the ob_3 conformation of the cage ligand. Other H-bonding interactions involve the pyridine and adjacent external amino groups [O(11)···H(0N) (x, 1 − y, z − 1/2) 2.16(5), H(02) ($1\,^1/_2$ − x, y − 1/2, −z − 1/2) 2.09(4) Å], water molecules (assumed on the basis of O···O separations, since associated protons were not located) [O(01)···O(01) (2 − x, y, 1/2 − z) 2.745(8), O(02) ($1\,^1/_2$ − x, 1/2 + y, 1/2 − z) 2.761(6); O(02)···O(03) 2.682(6); O(03)···O(03) (11/2 − x, 1/2 − y, 1 − z) 2.608(6) Å], and the dithionate anion [O(01)···O(21) 2.816(5); O(03)···O(12) (x, 1 − y, 1/2 − z) 2.744(6) Å]. The chloride environment is sparse, there being two contacts at 2.46(3) Å as above and two more to H(4cA) (x, 1 − y, 1/2 + z) (etc.) with distances of 2.74(3) Å.

That the particular choice of anions and degree of protonation are not the sole determinants of the solid-state conformation of the cage is shown by the fact that $[Co\{sar(NH_3)[NHCH_2(C_5H_4NH)]\}](S_2O_6)_2Cl\cdot 3H_2O$ (**13**), in which protonation of the pyridine nitrogen again seems preferred to that of the alkylated aliphatic nitrogen, is found in the lel_3 conformation. This is associated with a return to prominence of the tris(chelate) role of the core amine hydrogens in this compound, although with a diversity of interaction types: Cl···H(3b′,a) 2.17(4), 2.36(4) Å is conventional; H(3c′)···O(13) (x, y − 1, z), H(3b)···O(12) (x, y − 1, z) 2.31(3), 2.09(4) Å indicate a spanning of the pair of NH groups by O−S−O of one end of a dithionate anion, and in H(3a′,c)···O(03) 1.91(4), 1.95(4) Å, a water molecule oxygen is sequestered. The chloride shows a close contact to a water molecule, Cl···H(02A) 2.2 Å (est.). The terminal protonated NH_3^+ group shows contacts with a water molecule [H(0′A)···O(02) (x, y − 1, z) 1.69(7) Å] and with anionic oxygen atoms [H(0′B)···O(11) (− x, 1 − y, 1 − z) 1.88(4), H(0′c)···O(33) (x, 1/2 − y, z − 1/2) 2.09(5) Å], while at the other end the strongest interaction is found between the pyridinium hydrogen and an anionic oxygen [H(02)···O(21) 2.17(4) Å]. A limited number of the remaining anionic oxy-

gens are strongly hydrogen-bonded with water: O(31)···H(01A) (1 − *x*, *y* − 1/2, 1 $^1/_2$ − *z*) 1.8 (est.), O(41)···H(02B) (1 − *x*, 1/2 + *y*, 1/2 − *z*) 2.3 (est.), O(42)···H(01B), H(03B) (1 − *x*, *y* + 1/2, 1 $^1/_2$ − *z*) 2.2, 1.9 Å (est.). A strong water···water interaction [H(03A)···O(01) 1.7 (est.)] is found. In **13**, as in **12**, there is no evidence of stacking interactions of the pyridine rings, despite the fact that in **12** parallel arrays of pyridine rings from separate complex ion units may be discerned in the lattice. In **11**, however, arrays of parallel pyridine rings may be indicative of some stacking, as suggested by C···C contacts of ca. 3.7 Å.

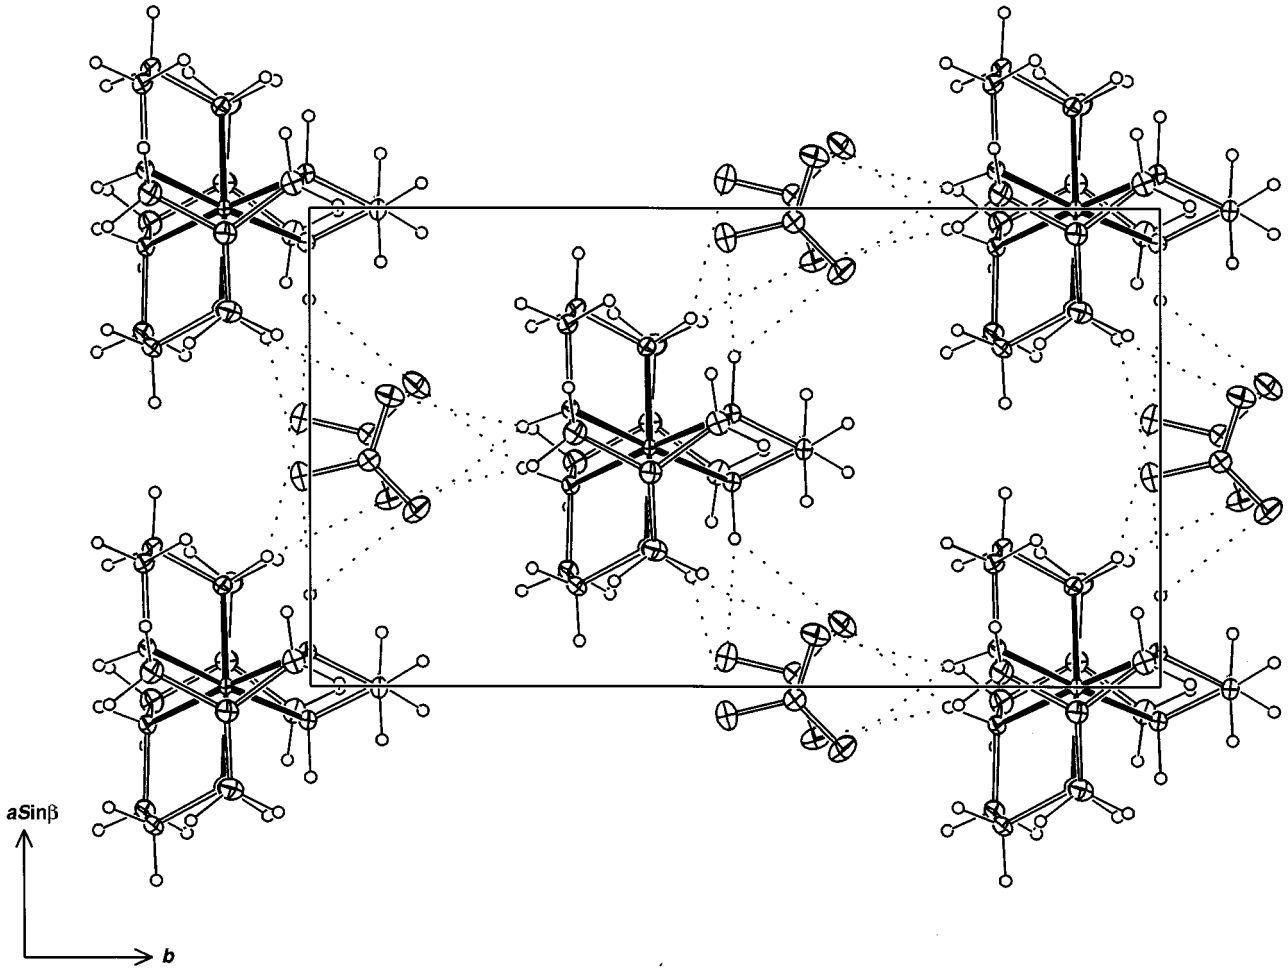

Figure 3. Section of the structure of **11**, projected down *a*, showing the cations centred at $z = 1/4$, on twofold axes, with the cage pendants being omitted so as to display the linking of cations centred on that plane by associated hydrogen-bonded nitrate ions

When a neutral aromatic unit is introduced as a substituent, as is the case with the biphenylmethyl unit in **16**, diminished charge repulsions appear to allow more significant stacking interactions, as indicated by the "herringbone" array of the biphenyl groups evident in this solid (in the projection down *a*). The cage unit adopts an lel_3 conformation, once again attributable to NH chelation of the anions, though the interactions are somewhat complicated to describe in this mixed anion species. Those of cation 1 involve the halide and a pair of nitrate groups: Cl···H(13b′,a) 2.5, 2.1; O(21)···H(13b,c′) 1.9, 2.2; O(13)···H(13a′,c) (x, 2 − y, z + 1/2) 2.2, 2.2 (est.) [also involving O(12)···H(13a′) (x, 2 − y, z + 1/2) 2.2 Å]. For cation 2, one chelate involves a water oxygen, O(06)···H(23b′,a) (x, y + 1, z) 2.3, 2.0, while the other two involve nitrate oxygens, O(41)···H(23c′,b) (x, 1 − y, z + 1/2) 2.1, 2.0; O(52,52′)···H(23c′,a) (x, y + 1, z) 2.2, 2.1; 2.30, −; O(53,53′)···H(23a′) (x, y + 1, z) 2.2, 2.3 Å (est.). Other H-bonds are formed to the pendant amino group nitrogen atom: H(10N)···O(12) 1.9, H(20N)···O(53) (x, 2 − y, z − 1/2) 2.0 Å (est.).

The introduction of aromatic substituents on cage amine complexes through the present and other means[18] is facile and is of interest in that the stability of these complexes in strongly acidic media allows functionalization of the aromatic units under simple, conventional conditions for electrophilic substitution. Such further functionalization could endow the complexes with new properties, for example, the introduction of vinyl substituents may possibly offer another route to polymer-immobilized cage complexes. As in the acylation and alkylation reactions of amino groups attached to the cages, some retardation of electrophilic attack, in this case on a pendant aromatic unit, was to be expected as a result of the cationic charge on the complex. At least in the case of $[Co\{(C_6H_5CH_2NH_2)_2sar\}]^{5+}$, however, this did not appear to be an important effect. Reaction of the complex in H_2SO_4/HNO_3 at room temperature for 5 min resulted in predominant symmetrical disubstitution at the 3-positions of the ring, with a small amount of mono-3-substituted material also being present. Reductions of these nitro compounds and reactions of the resulting aromatic amine derivatives are currently under investigation.[19]

A more direct pathway to the formation of polymers incorporating cage complex substituents is offered by complex derivatives containing electropolymerizable groups

such as furan, pyrrole, and thiophene.[20] Although reductive alkylation of $[Co\{(NH_2)_2sar\}]^{3+}$ with 2-pyrrolecarbaldehyde appeared to be successful, the product underwent acid-catalysed conversion into a "pyrrole black",[21] which was irreversibly absorbed on Dowex 50 cation-exchange resin; as yet we have not succeeded in obtaining the simple pyrrolylmethyl cage derivatives in a pure form. The furan and thiophene analogues, however, are readily obtained. As derivatives of 2-substituted heterocycles, these are not expected[20,21] to readily undergo oxidative polymerization, but they can at least be taken as putative models for the behaviour at the metal centre in a polymerized derivative. Encouragingly, electrochemical measurements have shown that the substituted Co^{III} cage complexes exhibit a quasi-reversible Co^{III}/Co^{II} couple at potentials essentially identical to those of their unsubstituted analogues. For both the thiophene and furan derivatives, a highly irreversible oxidation wave near +1.4 V may be consistent with an oxidation process at the ring, but no real evidence has been obtained for any resulting polymerization (for example, ion-exchange chromatography after extensive electrolysis or vigorous chemical oxidation only showed the presence of materials with similar elution characteristics to those of the reactants). The heterocycle oxidation wave alone has been taken as evidence for the occurrence of polymerization processes in closely related systems,[22] but in the present case measurements were made in aqueous solution and water is known to strongly inhibit oxidative polymer formation.[20]

More interesting redox properties were expected of the 3-substituted thiophene derivative, and to characterize fully the nature of the 3-thiophenyl substituent attached to a cage, the structure of $[Co\{[3\text{-}(C_4H_3S)CH_2NH_2](NH_3)sar\}]Cl_5\cdot 3H_2O$ (**14**) was determined by single-crystal X-ray crystallography. This confirmed the anticipated nature of the complex, with the cation adopting the familiar lel_3 conformation and the substituent lying in an extended position such that the cobalt cage unit clearly does not congest regions near the 2- (and 4-) positions of the thiophene ring. The cage again chelates chloride anions [(cation 1) Cl(1,1′)···H(13c′) 2.4, 2.7; Cl(1,1′)···H(13b) 2.2, 2.0; Cl(7)···H(13a′,c) (x, 1 − y, z − 1/2) 2.2, 2.1; Cl(8)···H(13b′,a) (x, 1 − y, z − 1/2) 2.3 (×2); (cation 2) Cl(6)···H(23c′,b) (1/2 + x, 1/2 + y, z) 2.3, 2.2; Cl(5)···H(23b′,a) (1 + x, y, z) 2.3, 2.1; Cl(3)···H(23a′,c) (1 + x, y, z) 2.1, 2.3 Å (all est.)], albeit with some disorder, and while the thiophene rings can be seen to form a herringbone array, there are no close inter-ring contacts. Cyclic voltammetry of the complex (in aqueous media) showed characteristics similar to those of the 2-thiophenyl analogue in that an irreversible oxidation wave near +1.4 V was apparent, but vigorous chemical oxidation in concentrated nitric acid gave contrasting results in that the product did show some properties of a large molecule. Thus, the product was of very low solubility in water and the bulk of it was irreversibly retained on both Sephadex and Dowex cation-exchange resins (it appeared possible to elute some material initially, but, on standing, even this small fraction became impossible to elute). Furthermore, the solid was a bright-yellow colour and in aqueous solution showed an absorption spectrum with an intense maximum near 420 nm, quite atypical of Co^{III} cage amine complexes, but typical of polythienyls.[20] All "solutions" were in fact perceptibly cloudy to the eye, again consistent with the solid containing high molecular weight species. The most prominent feature of the cyclic voltammogram of the solution was a strong oxidation wave near 1.4 V, with evidence for interconversion of a Co^{III}/Co^{II} couple near −0.3 V being retained. This material is currently being subjected to a more detailed investigation, one of the possible complications arising from its method of synthesis being that of nitrosation,[1,6,7] although it may be noted that simple dissolution of the dialkylated reactant complex in concentrated HNO_3 alone gives only species having the characteristics of mononuclear Co^{III} cage amine complexes.

A more conventional approach to oxidative polymerization of thiophene derivatives is to use electrochemical methods in nonaqueous solvents. Although the choice of solvent is restricted by the nature of the cage amine complex, it is possible to examine the triflate salt of the mono(3-thiophenyl) derivative in acetonitrile. Representative cyclic voltammograms for a series of measurements using a Pt working electrode and sodium triflate as the electrolyte are shown in Figure 4.

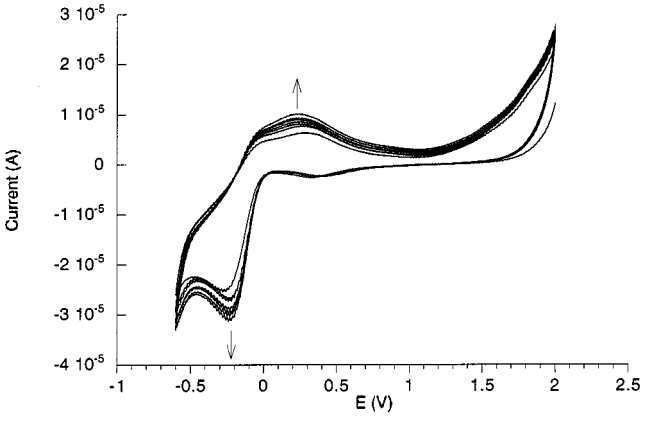

Figure 4. Electropolymerization of Co-cage thiophene conjugate

Although simple chemical experiments show the Co^{III}/Co^{II} interconversion to be reversible, it is apparently not electrochemically reversible, seemingly because of adsorption of the Co^{II} species in the present case.[23] Nevertheless, repeated scanning shows the current to increase with each consecutive scan, consistent with the deposition of a conductive material on the electrode surface. After such a series of measurements, the electrode was removed, washed well with water to remove any adhering monomeric complex, dried, and then placed in a simple acetonitrile solution of sodium triflate. Cyclic voltammograms subsequently obtained are shown in Figure 5.

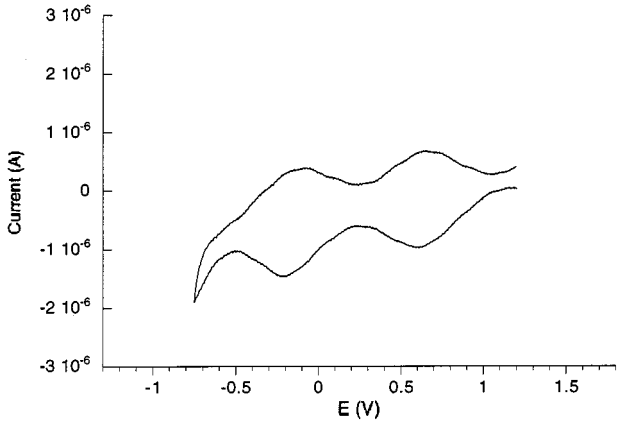

Figure 5. Cyclic voltammogram of modified electrode

Clearly, a conductive and electroactive material had been deposited on the electrode surface, and we tentatively ascribe the two waves with very small anodic/cathodic peak separations to polymer-pendant Co^{III}/Co^{II} (near −0.2 V) and polythiophene (near +0.6 V) centred processes. Obviously, there are interesting prospects here with regard to use of chiral Co^{III} monomers as sources of possible asymmetric electrocatalysts[24] and with regard to varying the electrochemical properties of the polymer by substituting the Co by other transition metals.

Conclusion

From the present and related works,[2,3,5,6] a substantial array of usefully 1,8-functionalized derivatives of the cage complex $[Co(sar)]^{3+}$ is now available. It would appear to be generally true that substitution at the 1,8-positions of this complex does not significantly modify the properties of the central unit. Correspondingly, the properties of the pendant groups do not appear to be critically modified by the presence of the nearby cationic centre. The Co^{III} should be replaceable by numerous other metals,[2,6] so that there may be many pathways to truly practical applications of cage amine complexes, such as in radiopharmaceutical agents based on Cu^{II}, for example.[25]

Experimental Section

General Remarks: NMR spectra were acquired from samples in D_2O solution on Varian Gemini 200 (^1H at 200 MHz and ^{13}C at 50.3 MHz) or Bruker ARX 500 (^1H at 500.13 MHz and ^{13}C at 125.8 MHz) spectrometers. Chemical shifts are expressed in ppm relative to an internal standard of acetone ($\delta = 2.04$ for ^1H NMR spectra and $\delta = 29.4$ for ^{13}C NMR, relative to TMS). − Ion-exchange chromatography was performed under gravity flow using Dowex 50W × 2 (H^+ form, 200−400 mesh) or SP Sephadex C25 (Na^+ form, 200−400 mesh) cation-exchange resins. All evaporations were performed at reduced pressure (ca. 20 Torr) using a Büchi rotary evaporator and a water aspirator. The Schlenk technique using high purity argon or high purity nitrogen was employed wherever it was necessary to exclude oxygen from preparative mixtures. − UV/Vis absorption spectra (200−800 nm) were recorded on a Hewlett−Packard 8452A diode-array spectrophotometer. − Cyclic voltammograms were recorded with a MacLab$\curlyvee$ potentiostat controlled by a Macintosh SE computer employing AD Instruments Echem software, using a platinum working electrode, a platinum counterelectrode, and a silver/silver chloride reference electrode. All solutions had a composition of 1−5 mM analyte in 0.1 M $NaClO_4$ solution. Water was purified using a Milli-Q ultra-pure water system. All solutions were purged with argon and were analysed at ambient temperatures. − Microanalyses for carbon, hydrogen, and nitrogen were carried out by the Australian National University Microanalytical Service. All samples were thoroughly dried in vacuo (0.1 Torr) at 50 °C for 4 h prior to their analysis.

$[Co\{(NH_3)_2sar\}]Cl_5\cdot H_2O$ was prepared as described previously.[7] Solvents from Fluka (pyridine, acetonitrile, dimethyl sulfoxide, dimethylformamide) and Eastman (dimethylacetamide) were used as received, as were reagents (phthalic anhydride, triethylamine) from Aldrich. Benzoyl chloride (Aldrich) was distilled prior to use. Aldehydes (2-pyridinecarbaldehyde, 4-pyridinecarbaldehyde, benzaldehyde, 3- and 4-methylbenzaldehyde, 2-phenylpropanal (hydratropaldehyde), biphenyl-4-carboxaldehyde, furancarbaldehyde, 2-thiophenecarbaldehyde, and 3-thiophenecarbaldehyde) from Aldrich were used as received. Various solids containing the $[Co\{(NH_2)_2sar\}]^{3+}$ cation were used as sources of this unprotonated cage complex (although equivalent results were often obtained simply by adding a base such as triethylamine to a solution of a protonated complex salt). $[Co\{(NH_2)_2sar\}]Cl_3\cdot nH_2O$ was prepared by heating (80 °C) a mixture of $[Co\{(NH_3)_2sar\}]Cl_5\cdot H_2O$ (5.7 g) and Li_2CO_3 (0.74 g) in water (5 mL) until effervescence had ceased. The deep brown-yellow solution was filtered, cooled, and gradually diluted with ethanol (50 mL) to precipitate a yellow, crystalline solid (4.5 g, 92%). − **$[Co\{(NH_2)_2sar\}]Cl_3\cdot 1.5H_2O$ (1):** calcd. C 33.18, H 7.36, N 22.11; found C 33.4, H 7.4, N 22.2. The analogous acetate salt was obtained by passing a solution of $[Co\{(NH_3)_2sar\}]Cl_5\cdot H_2O$ (5.70 g) in water (5 mL) through a column containing a tenfold excess of acetate-form Dowex 1 × 8 anion-exchange resin. The complex was washed from the column with water, the eluate was concentrated to a viscous, orange oil under reduced pressure, the residue was almost dried by twofold co-evaporation of ethanol, and finally it was crystallized from ethanol by the addition of diethyl ether. (Note that without the repeated evaporations, the solid retained some excess acetic acid.) Yield: 3.50 g, 52%. − **$[Co\{(NH_2)_2sar\}](CH_3CO_2)_3\cdot 6.5H_2O$ (2):** calcd. C 35.98, H 8.45, N 16.78; found C 35.9, H 8.5, N 16.8. To obtain the triperchlorate, perchloric acid (70%, 1 mL; CAUTION!) was added to a solution of the acetate (0.99 g) in ethanol (10 mL) to give initially a yellow, crystalline precipitate (1.13 g, 81%) of the pentaperchlorate. This was collected by filtration and washed first with ethanol/diethyl ether and then with diethyl ether. The solid rapidly underwent a colour change to red-orange on exposure to air, presumably as a result of hydration, although it did not deliquesce. − **$[Co\{(NH_3)_2sar\}](ClO_4)_5\cdot 4H_2O$ (3):** calcd. C 17.80, H 4.69, N 11.86; found C 17.9, H 5.1, N 11.9. (Note that as a possibly safer procedure, the pentaperchlorate may also be isolated from water as orange needles, although the yield is poor due to the high solubility of the compound.) The pentaperchlorate (1.40 g) and NaOH (0.11 g; one pellet) were dissolved in water (1 mL). The resulting solution took on a dark-yellow colour before copious precipitation of yellow-brown crystals commenced. Ethanol (10 mL) was then added and the mixture was cooled in ice to maximize precipitation of the solid (0.92 g, 88%), which was collected and washed with ethanol and

diethyl ether. − **[Co{$(NH_2)_2$sar}]$(ClO_4)_3$·2H_2O (4):** calcd. C 23.76, H 5.41, N 15.83; found C 23.9, H 5.7, N 15.8. Despite the apparently low solubility in water of the triperchlorate, attempts to isolate it directly from the more convenient starting material [Co{$(NH_3)_2$sar}]$Cl(ClO_4)_4$·2H_2O[6] invariably resulted in the chloride-perchlorate. Thus, [Co{$(NH_3)_2$sar}]$Cl(ClO_4)_4$·2H_2O (2.3 g) and NaOH (0.25 g) were dissolved in water (2.5 mL) to give a dark-brown solution; $NaClO_4$·H_2O (2.00 g) was added and the solution was diluted with ethanol (50 mL) to give a yellow precipitate, which was then recrystallized from hot water (5 mL) containing concentrated aqueous ammonia (2 drops) by the addition of ethanol (50 mL). Yield: 1.65 g, 100%. − **[Co{$(NH_2)_2$sar}]$Cl_2(ClO_4)$·H_2O (5):** calcd. C 29.93, H 6.46, N 19.95; found C 30.3, H 6.7, N 19.9.

Reactions of [Co{$(NH_2)_2$sar}]$^{3+}$ under Benzoylation Conditions: Attempts to react aqueous solutions of [Co{$(NH_3)_2$sar}]Cl_5·H_2O (containing sufficient base to both deprotonate the complex and neutralize the acid produced in acylation) with benzoyl chloride resulted in very low yields of (mono- and di-) benzoylated complexes, even when highly concentrated solutions (ca. 1−5 M) of the very soluble complex were used. For example, from the reaction of [Co{$(NH_3)_2$sar}]Cl_5H_2O (5.70 g, 10 mmol) in water (10 mL) with a fourfold excess of benzoyl chloride (5.60 g) in the presence of triethylamine (6.10 g), cation-exchange chromatography (SP Sephadex, 0.5 M NaCl/0.5 M $NaClO_4$ as eluent) enabled the isolation of ca. 200 mg of the monobenzoylated and ca. 20 mg of the dibenzoylated complexes. Absorption on Dowex 50W × 2 cation-exchange resin and re-elution with HCl to recover the complexes from the Sephadex column eluates led to partial hydrolysis of the benzoyl compounds, so these yields are lower estimates but not dramatically so. Attempts to use other solvents (acetonitrile, dimethyl sulfoxide, pyridine) as the reaction medium were even less successful, except in the cases of dimethylformamide and dimethylacetamide. In dimethylformamide, benzoylated products could be observed in moderate yields along with formamidino derivatives of the cage, and by varying the reaction conditions both products could be obtained quite readily.

[Co{[$(CH_3)_2$NCHNH]$_2$sar}]Cl_5·3H_2O (6): Triethylamine (0.5 mL) was added to a solution of [Co{$(NH_3)_2$sar}]$Cl(ClO_4)_4$·H_2O (0.50 g) in dimethylformamide (5 mL), which led to an appreciable darkening of the yellow solution. Under vigorous stirring, benzoyl chloride (0.70 g) was rapidly added, resulting in a lightening of the colour of the solution, followed, almost immediately, by the deposition of a yellow precipitate. After 5 min, the mixture was poured into water (50 mL) containing concentrated HCl (2 mL) and the precipitated benzoic acid was extracted into dichloromethane. The aqueous phase was passed through a column of H^+ form Dowex 50W × 2 cation-exchange resin to absorb the complex cation(s). The column was washed with water, then eluted with 1 M HCl to remove $[HN(C_2H_5)_3]^+$, and finally the yellow complex band was eluted with 3 M HCl. Although no separation was observed, ^{1}H NMR spectra of the residues obtained upon evaporation of the solvent from sequential eluate fractions indicated that at least two materials were present; resonances near δ = 7.5 and 7.9 showed a significant variation in their relative intensities through the sequence. The combined eluates were concentrated to dryness under reduced pressure and the yellow residue was redissolved in water (2 mL). Addition of ethanol (50 mL) led to precipitation of a yellow solid, which was recrystallized in a similar manner to furnish a material (0.20 g, 44%) showing only the lower field of the aforementioned two resonances in its ^{1}H NMR spectrum. A further recrystallization from water by vapour diffusion of ethanol provided clear yellow tablets suitable for X-ray crystallography. − ^{1}H NMR: δ = 2.62−2.85 (m, cage amine CH_2, 12 H), 2.92, 3.18 (two s, formamidino methyl groups, 12 H), 3.30−3.40 (m, cage amine CH_2, 12 H), 7.85 (br. s, formyl H, 2 H). − ^{13}C NMR: δ = 39.1, 46.6 (formamidino methyl), 55.5, 57.6 (cage methylene), 62.5 (cage quaternary), 156.3 (formyl). − For elemental analysis, the complex was recrystallized from 1 M HCl by the addition of ethanol; the results indicated that the complex formed as a "hydrochloride" under these conditions. − $[CoC_{20}H_{46}N_{10}]Cl_5HCl$·4$H_2O$ = $C_{20}H_{55}Cl_6CoN_{10}O_4$: calcd. C 31.14, H 7.19, N 18.16; found C 31.1, H 6.4, N 17.7.

[Co{$(C_6H_5CONH)(NH_3)$sar}]$(NO_3)_4HNO_3$·2H_2O (7): Triethylamine (0.41 g) was added to a solution of [Co{$(NH_2)_2$sar}]$(ClO_4)_3$·2H_2O (0.68 g) in dimethylformamide (1 mL), which led to a colour change from yellow-orange to dark brown. The resulting solution was cooled in ice, and then benzoyl chloride (0.56 g) was added under vigorous stirring. A yellow precipitate formed immediately and, after 5 min, precipitation was completed by the addition of ethanol (20 mL) and diethyl ether (10 mL). The solid was collected by filtration and redissolved in water (2 mL). Addition of ethanol (50 mL) precipitated a yellow powder (largely composed of the formamidino compound described above), which was filtered off, and then the filtrate was concentrated to dryness under reduced pressure. The deliquescent residue was redissolved in water (2 mL) and the yellow solution was cooled in ice. Dilute nitric acid (4 M, 2 mL) was added and the mixture was kept in the ice-bath as a crystalline precipitate formed. After 5 min, this was collected, washed with methanol and diethyl ether, and dried, giving 0.35 g (44%) of the complex. Analysis for $[CoC_{21}H_{39}N_8O](NO_3)_4$·$HNO_3$·2$H_2O$ ≡ $C_{21}H_{44}CoN_{13}O_{18}$: calcd. C 30.55, H 5.37, N 22.06; found C 30.8, H 5.3, N 22.3. − ^{1}H NMR: δ = 2.80−3.05 (m, cage amine CH_2, 12 H), 3.33−3.51 (m, cage amine CH_2, 12 H), 7.35 (m, ArH, 2 H), 7.46 (m, ArH, 1 H), 7.53 (m, ArH, 2 H). Additional very weak signals in this spectrum were possibly indicative of the presence of some mixed formamidino-benzoyl cage complex. The most efficient preparation of the dibenzoyl complex was that conducted in dimethylacetamide, after which chromatography indicated no more than trace amounts of any other product. Thus, triethylamine (0.41 g) was added to a solution of [Co{$(NH_2)_2$sar}]$(ClO_4)_3$ (0.68 g) in dimethylacetamide (1 mL), which led to a colour change from yellow-orange to dark brown. The resulting solution was cooled in ice, and then benzoyl chloride (0.56 g) was added under vigorous stirring. The colour of the solution rapidly became lighter and a yellow precipitate began to form within 10 s. After 5 min, ethanol (5 mL) was added to ensure hydrolysis of any remaining benzoyl chloride, and then diethyl ether (50 mL) was added to complete precipitation of the yellow solid. This was collected and redissolved in water (10 mL); the yellow solution was filtered and the filtrate was treated with conc. HCl (1 mL). Some precipitate formed but redissolved upon addition of ethanol (50 mL). Diethyl ether (ca. 400 mL) was then added to the point of permanent turbidity and the mixture was left to stand for 30 min to allow precipitation of fine, yellow crystals (0.37 g, 41%). Despite the intent to obtain the complex as its chloride, this procedure seemed to result in retention of the original perchlorate anion. − [Co{$(C_6H_5CONH)_2$sar}]$(ClO_4)_3$·4H_2O (**8**) ≡ $C_{28}H_{50}Cl_3CoN_8O_{18}$: calcd. C 35.32, H 5.29, N 11.77; found C 35.0, H 5.0, N 11.7. To ensure conversion into the chloride, **9**, this solid was shaken with an aqueous slurry of chloride-form Dowex 1 × 8 anion-exchange resin and the solution obtained was concentrated to dryness under reduced pressure. Crystals suitable for X-ray diffraction analysis were grown by redissolving the residual solid in hot (80 °C) water and allowing the solution to cool slowly to room temperature. − ^{1}H NMR: δ = 2.93−2.99 (br. d, cage amine CH_2,

6 H), 3.18, 3.24 (d, cage amine CH_2, 6 H), 3.57−3.67 (m, cage amine CH_2, 12 H), 7.55 (m, ArH, 2 H), 7.66 (m, ArH, 1 H), 7.73 (d, ArH, 2 H). − ^{13}C NMR: δ = 54.2, 55.5 (cage methylene), 60.6 (cage quaternary C), 129.8, 131.2, 135.1, 135.7 (ArC), 173.9 (carbonyl C).

Phthaloylation of $[Co\{(NH_2)_2sar\}]^{3+}$. − Method 1: A mixture of $[Co\{(NH_2)_2sar\}]Cl_3\cdot 2H_2O$ (1.00 g, 1.94 mmol) and phthalic anhydride (1.44 g, 9.73 mmol) in glacial acetic acid (80 mL) was heated under reflux for 2 h, in the course of which the initially orange solution darkened appreciably. The solvent was then removed under reduced pressure, the residue was extracted with water (50 mL), and the insoluble (white) material was filtered off. The filtrate was concentrated to leave an orange residue (1.10 g), which was redissolved in water (200 mL) and applied to a column (30 cm × 4 cm) of Na^+-form SP Sephadex C25 cation-exchange resin. The column was eluted with 0.5 M NaCl solution to separate four components, from which the complexes present were individually isolated by absorbing the eluate fractions on H^+-form Dowex 50W × 2 cation-exchange resin, washing the resin with water (100 mL) and 1 M HCl (100 mL), eluting the orange material with 3 M HCl, and concentrating the eluate to dryness under reduced pressure. Fraction 1 (ca. 0.20 g, 12%): ^{1}H NMR: δ = 2.50−3.95 (m, cage amine CH_2, 24 H), 7.41−8.06 (m, ArH, 8 H). − ^{13}C NMR: δ = 52.8, 55.0, 59.6, 128.7, 129.4, 131.7, 131.9, 134.3, 137.7, 171.0, 174.4. This was identified as the bis(phthalamic acid) derivative. Fraction 2 (ca. 0.60 g, 36%), as isolated, gave identical spectra to Fraction 1 except for the presence of a sharp singlet at δ = 7.84 in the ^{1}H spectrum, consistent with the presence of ca. 5% of an imide species. Fractions 3 and 4 were not well-separated and provided residues with identical spectroscopic properties, consistent with those of a mono(phthalamic acid): ^{1}H NMR: δ = 2.76−3.74 (m, cage amine CH_2, 24 H), 7.40−8.04 (m, ArH, 4 H). − ^{13}C NMR: δ = 52.6, 55.5 (cage methylene), 60.0 (cage quaternary C), 128.6, 128.8, 131.7, 131.9, 134.4, 137.8 (ArC), 170.5, 174.2 (carbonyl C).

Method 2: A mixture of $[Co\{(NH_2)_2sar\}]Cl_3\cdot 2H_2O$ (1.00 g, 1.94 mmol) and phthalic anhydride (1.44 g, 9.73 mmol) in dimethylacetamide (DMA; 70 mL) was heated at 90 °C for 17 h. After cooling the orange solution, it was diluted with diethyl ether (400 mL) and placed in a refrigerator (4 °C), whereupon orange needles slowly precipitated. The crystals were collected, washed with diethyl ether, and then redissolved in water (500 mL) to allow absorption of the complex(es) on a column (30 cm × 4 cm) of Na^+-form SP Sephadex C25 cation-exchange resin. Elution with 0.5 M NaCl produced a single band, from which the complex (1.30 g, 77%) was recovered as described above. The ^{1}H and ^{13}C NMR spectra of the residue were identical to those summarized above for the bis(phthalamic acid). The complex was recrystallized from hot water by cooling in ice to furnish orange needles. − $[CoC_{30}H_{42}N_8O_6]Cl_3\cdot 5H_2O$ (**10**) = $C_{30}H_{52}Cl_3CoN_8O_{11}$: calcd. C 41.60, H 6.05, N 12.94; found C 41.6, H 5.1, N 12.9.

Reductive Alkylation of $[Co\{(NH_2)_2sar\}]^{3+}$ and $[Co\{(CH_3)(NH_2)sar\}]^{3+}$

The following procedures, described for reactions involving 2-pyridinecarbaldehyde, were also carried out using 4-pyridinecarbaldehyde, benzaldehyde, 4-methylbenzaldehyde (*p*-tolualdehyde), 3-methylbenzaldehyde, 2-phenylpropanal (hydratropaldehyde), 4-biphenyl-4-carboxaldehyde (the product from reaction with $[Co\{(CH_3)(NH_2)sar\}]^{3+}$ ultimately being characterized by a crystal structure determination as the nitrate-chloride, **16**), furancarbaldehyde and 2-thiophenecarbaldehyde. In most cases, the relevant products were obtained in acceptable yields, though the syntheses were not optimized in each individual case and as a result some reactions of $[Co\{(NH_2)_2sar\}]^{3+}$ provided only the monoalkylation product. An efficient alternative synthesis of the product of the reaction of $[Co\{(CH_3)(NH_2)sar\}]^{3+}$ with 4-pyridinecarbaldehyde has been described in the literature.[3]

$[Co\{(2\text{-}pyCH_2NH)_2sar\}]^{3+}$ and $[Co\{(2\text{-}pyCH_2NH)(NH_2)sar\}]^{3+}$: $[Co\{(NH_3)_2sar\}]Cl_5\cdot H_2O$ (1.8 g, 3 mmol) was converted into its acetate salt by dissolution in water, passage through a column of acetate-form Dowex 1 × 8 anion-exchange resin, concentration of the eluate to a viscous oil, and crystallization of the latter by precipitation from methanol by the addition of diethyl ether. Although conversion was quantitative, the acetate prepared in this way invariably appeared to have a composition intermediate between those of $[Co\{(NH_3)(NH_2)sar\}](O_2CCH_3)_4$ and $[Co\{(NH_2)_2sar\}](O_2CCH_3)_3$, hence a base was added in the following step of the synthesis. Thus, the acetate was dissolved in dimethyl sulfoxide (30 mL) containing triethylamine (1 mL). 2-Pyridinecarbaldehyde (0.96 g, 9 mmol) was added and the resulting mixture was heated at 90 °C for 12 h under a nitrogen atmosphere. After cooling the solution to room temperature, sodium borohydride (0.50 g) was added and the mixture was stirred vigorously for 1 h. The excess borohydride was then destroyed by the slow addition of 3 M HCl (20 mL), and the solution was diluted with water (1 L) containing hydrogen peroxide (30%, 1 mL) to ensure complete conversion of Co^{II} back to Co^{III}. The orange solution thus obtained was absorbed on a column (4 × 50 cm) of H^+-form Dowex 50W × 2 cation-exchange resin and, after washing the column with water (2 L) and 0.5 M HCl (1 L), the remaining orange complexes were eluted with 3 M HCl. Three components were observed; the individual eluates were concentrated under reduced pressure and then the complexes were precipitated by the addition of ethanol. The first band contained unchanged starting material, the second (F2) contained the monosubstituted complex, and the third (F3) contained the disubstituted complex. Yield from F2: 1.13 g, 56%. − $C_{20}H_{41}Cl_5CoN_9\cdot 1.5H_2O$: calcd. C 35.81, H 6.61, N 18.79; found C 35.8, H 6.6, N 19.0. − UV/Vis (0.1 M HCl): λ_{max} = 472 nm, ε_{max} = 115 M^{-1} cm^{-1}. − ^{1}H NMR: δ = 2.76−3.60 (complex multiplet, 24 H, cage methylene), 4.41 (s, 2 H, CH_2py), 8.00, 8.02, 8.04, 8.06, 8.54, 8.58, 8.59, 8.74, 8.77 (m, 4 H, ArH). − Yield from F3: 1.18 g 53%. − $C_{26}H_{45}Cl_4CoN_{10}\cdot 2H_2O$: calcd. C 42.52, H 6.72, N 19.07; found C 42.5, H 6.3, N 19.1. − UV/Vis (0.1 M HCl): λ_{max} = 470 nm, ε_{max} = 95.4 M^{-1} cm^{-1}. − ^{1}H NMR: δ = 2.61, 2.67, 2.69 and 3.16, 3.22, 3.26 (ill-resolved multiplets, 24 H, cage methylene), 4.23 (s, 4 H, CH_2py), 7.1 (br. s, 6 H, NH), 7.73, 7.76, 7.80, 7.86, 8.30, 8.35, 8.38, 8.50, 8.54 (m, 8 H, ArH). − In seeking to obtain crystals from F3 suitable for X-ray crystallography, aqueous solutions of the chloride were treated with dilute HNO_3 and $Li_2S_2O_6$, giving, on slow evaporation of the solvent from the product solutions at room temperature, materials that were established by subsequent structure determinations (see below) to be the differently protonated species $[Co\{(2\text{-}pyCH_2NH)(2\text{-}pyCH_2NH_2)sar\}](NO_3)_4\cdot 2H_2O$ (**11**) and $[Co\{(2\text{-}pyCH_2NH_2)_2sar\}](S_2O_6)_2Cl\cdot 6H_2O$ (**12**), respectively. F2 was subsequently also crystallized by the use of dithionate to give the diprotonated dithionate-chloride $[Co\{sar(NH_3)[NHCH_2(C_5H_4NH)]\}](S_2O_6)_2Cl\cdot 3H_2O$ (**13**).

$[Co\{(2\text{-}pyCH_2NH)(CH_3)sar\}]^{3+}$: $[Co\{(CH_3)(NH_3)sar\}]Cl_4\cdot 0.5H_2O$ (1.05 g, 2 mmol) was converted into the acetate following the procedure described above. This was dissolved in dimethyl sulfoxide (30 mL) containing triethylamine (0.20 g), after which 2-pyridinecarbaldehyde (0.32 g, 3 mmol) was added and the mixture was heated at 90 °C for 10 h. Reduction with borohydride, re-oxidation of the metal, and chromatographic workup of the product mixture

were conducted as described above. In this case, only two bands were observed, the first corresponding to the reactant and the second being the desired product. Yield (F2): 1.10 g, 88%. − $C_{21}H_{41}Cl_4CoN_8{\cdot}H_2O$: calcd. C 40.40, H 6.94, N 17.95; found C 40.4, H 6.9, N 18.0. − UV/Vis (0.1 M HCl): λ_{max} = 472 nm, ε_{max} = 129 M^{-1} cm^{-1}. − ^{1}H NMR: δ = 0.98 (s, 3 H, CH_3), 2.45, 2.52, 2.71, 2.78. 2.82, 2.86, 3.06, 3.10, 3.13, 3.35, 3.39 (m, 24 H, cage methylene), 4.31 (s, 2 H, CH_2py), 7.00, 7.15 (br. s, 6 H, NH), 7.98, 8.01, 8.03, 8.05, 8.54, 8.58, 8.62, 8.75, 8.79 (m, 4 H, ArH).

Apparent Polymerization Processes

When the procedure described above for the reactions of $[Co\{(NH_3)_2sar\}]Cl_5{\cdot}H_2O$ was followed using 2-pyrrolecarbaldehyde as the substrate, all proceeded as expected until attempts were made to elute the crude reaction product from H^+-form Dowex 50W × 2 resin using 3 M HCl. The orange eluate rapidly began to darken and within a few hours appeared black. Dilution and reabsorption of the solution on the resin gave a black deposit, which could not be removed even by the use of concentrated HCl as eluent.

In the case of the product obtained from the reaction with 3-thiophenecarbaldehyde, isolation of the alkylated cage complexes was straightforward, but under strongly oxidative conditions some evidence of polymerization was obtained. Thus, 3-thiophenecarbaldehyde (0.35 g) was added to a solution of $[Co\{(NH_2)_2sar\}](ClO_4)_3$ (1.00 g) in dimethylacetamide (2 mL) and the mixture was heated on a steam bath for 20 min. Excess $NaBH_4$ (0.10 g) was added to the cooled orange solution, which led to an immediate colour change to an intense violet (presumably due to the *N*-deprotonated cage complex[7]). After 5 min, this solution was poured into 1 M HCl (50 mL) and, when the effervescence due to decomposition of the excess $[BH_4]^-$ had subsided, the orange solution was left to stand at room temperature for 12 h, in the course of which the bulk of the dialkylated product complex precipitated as fine, yellow needles. This solid (0.30 g, 26%) was filtered off, washed with ethanol, and the combined filtrate and washings were passed through a column of H^+-form Dowex 50W × 2 resin to absorb the residual soluble complexes as an orange band. The column was washed with 1 M HCl to remove Na^+, then eluted with a gradient of 3 M → 7 M HCl to reveal three orange components. The first proved to be a trace of reactant, the second consisted of the monoalkylated complex (0.26 g, 26%), and the third consisted of additional dialkylated complex (0.17 g, 14%). Note that in a similar experiment using only 0.18 g of 3-thiophenecarbaldehyde in the hope of obtaining largely the monoalkylated complex, a mixture of the same three species was obtained, although the monoalkylated complex (0.36 g, 37%) did predominate over the dialkylated (0.18 g, 15%). Analysis for the monoalkylated complex $C_{19}H_{40}Cl_5CoN_8S{\cdot}3H_2O$: calcd. C 32.47, H 6.60, N 15.94, S 4.56; found C 33.0, H 7.3, N 15.4, S 4.3; for the dialkylated complex $C_{24}H_{44}Cl_5CoN_8S_2{\cdot}5H_2O$: calcd. C 34.52, H 6.52, N 13.42, S 7.68; found C 34.8, H 6.8, N 13.5, S 7.4. − UV/Vis: monoalkylated complex (0.1 M HCl): λ_{max} = 472 nm, ε_{max} = 108 M^{-1} cm^{-1}; dialkylated complex (water): λ_{max} = 471 nm, ε_{max} = 152 M^{-1} cm^{-1}. Monoalkylated complex: ^{1}H NMR: δ = 2.80 (m), 3.42 (m, ethylene bridge AA′BB′ system), 2.91 (d), 3.32 (d, cap methylene AB systems), 4.16 (s, substituent methylene), 7.02 (d), 7.35 (q), 7.44 (d, thiophene CH). − ^{13}C NMR: δ = 40.1, 49.1, 50.3, 53.17, 53.21 (CH_2), 55.0, 60.0 (quaternary C), 126.9, 127.0, 127.1 (thiophene ArCH), 129.7 (thiophene ArC); dialkylated complex: ^{1}H NMR: δ = 2.40 (d), 3.02 (d, cap methylene AB system), 2.56 (m), 3.10 (m, ethylene bridge AA′BB′ system), 3.58 (q, substituent methylene), 6.88 (d), 7.10 (d), 7.24 (q, thiophene CH). − ^{13}C NMR: δ = 40.2, 48.1, 52.4 (CH_2), 59.7 (quaternary C), 127.0, 127.2, 127.5 (thiophene ArCH), 128.6 (thiophene ArC). Note that, as for all cage complexes with basic external substituents, chemical shift values and the overall appearance of the spectra are generally very dependent on both the concentration and pH of the solutions.[7] Crystals of the monoalkylated complex (as its pentachloride, **14**) suitable for X-ray diffraction analysis were obtained by adding ethanol to a solution of the complex in water to the point of turbidity and then allowing the mixture to stand at room temperature for 24 h. Of various attempts made to achieve chemically oxidative oligomerization of the thiophene-substituted complexes, only the following provided some evidence of success. The dialkylated complex (chloride, **15**; 100 mg) was dissolved in concentrated HNO_3 (2 mL) and this orange solution was mixed with a slurry of $[NH_4]_2[Ce(NO_3)_6]$ (80 mg) in concentrated HNO_3 (1 mL). Agitation of the mixture resulted in the rapid dissolution of all solids and a colour change of the solution to deep yellow-orange. After 5 min, water (10 mL) was added, which led to the deposition of a yellow-orange solid. The mixture was cooled in ice for 5 min and then the precipitate was collected, washed with water (2 mL), ethanol, and diethyl ether, and dried in air (74 mg). The cloudy filtrate and washings were pale-yellow in colour.

Structure Determinations

Diffraction data were acquired in a number of modes, at the specified temperature, using monochromatic Mo-K_α radiation, λ = 0.71073 Å, on all instruments. Using a single counter instrument in 2θ/θ scan mode, *N* unique reflections were measured within the specified $2\theta_{max}$ limit, N_o with $I > 3\sigma(I)$ being considered "observed", gaussian absorption corrections being applied. Data were also measured using a Bruker AXS CCD instrument ($2\theta_{max}$ = 58°), the total number of reflections, N_t, within a full sphere being merged to *N* unique, R_{int} as specified after "empirical"/multiscan absorption correction within the proprietary/preprocessing software; the "observed" criterion applied was $F > 4\sigma(F)$. Anisotropic thermal parameter forms were refined in a full-matrix context for non-hydrogen atoms, $(x, y, z, U_{iso})_H$ being constrained at estimated values. Conventional residuals *R*, R_w (statistical weights) on |*F*| are quoted at convergence. Neutral atom complex scattering factors were employed within the Xtal 3.4 program system.[24] Pertinent results are given in the Figures and below; individual variations in procedure/difficulties/idiosyncrasies are cited as "*variata*". Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-151305−151312. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge, CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk]. Cation projections are shown in Figure 1; common *ad hoc* crystallographic numbering is shown, carbon atoms being denoted by number only. Non-hydrogen atoms are shown with 20% (room temperature) or 50% (low temperature) probability displacement ellipsoids. Bond lengths and angles are generally as expected throughout the array and are not addressed further, the interest lying in the isomeric and conformational variations discussed in the text above and shown in the Figures.

Crystal/Refinement Data

6. $[Co\{sar[NHCHN(CH_3)_2]\}]Cl_5{\cdot}3H_2O$ ≡ $C_{20}H_{52}Cl_5CoN_{10}O_3$, $M \approx 716.9$. CCD-instrument, $T \approx 153$ K. Triclinic, space group $P\bar{1}$ (C_i^1, No.2), a = 8.902(1), b = 12.105(2), c = 16.378(2) Å, α = 70.584(2), β = 76.662(2), γ = 82.194(2)°, V = 1616.1 Å^3. $D_{calcd.}$ (Z = 2) = 1.473 g cm^{-3}. μ_{Mo} = 9.9 cm^{-1}; specimen: 0.35 × 0.20 × 0.08 mm; $T'_{min.,max}$ = 0.68, 0.89. N_t = 18312, N = 7724 (R_{int} =

0.022), $N_o = 6978$; $R = 0.027$, $R_w = 0.038$. $|\Delta\rho_{max}| = 0.51(2)$ e Å^{-3}.

Variata: $(x, y, z, U_{iso})_{HHH}$ were refined throughout.

8. [Co{sar(NHCOC$_6$H$_5$)$_2$}]Cl$_3$·1.63H$_2$O ≡ $C_{28}H_{45.26}Cl_3CoN_8O_{3.63}$, $M \approx 717.4$. Single-counter instrument, $T \approx 295$ K. Monoclinic, space group $P2_1/c$ (C_{2h}^5, No.14), $a = 16.242(8)$, $b = 13.810(4)$, $c = 16.714(16)$ Å, $\beta = 115.93(5)°$, $V = 3372$ Å^3. $D_{calcd.}$ ($Z = 4$) = 1.426 g cm^{-3}. $\mu_{Mo} = 7.9$ cm^{-1}; specimen: 0.22 × 0.65 × 0.60 mm; $T_{min.,max} = 0.62, 0.93$. $2\theta_{max} = 60°$; $N = 7728$, $N_o = 5795$; $R = 0.035$, $R_w = 0.039$. $|\Delta\rho_{max}| = 0.44$ e Å^{-3}.

Variata: Site occupancy of O(2) refined to 0.630(6); no associated hydrogen atoms were located. For all other hydrogen atoms, (x, y, z, U_{iso}) were refined.

10. [Co{sar[NHCO(*o*-C$_6$H$_4$CO$_2$H)]$_2$}]Cl$_3$·6^3/$_4$H$_2$O ≡ $C_{30}H_{55.5}Cl_3CoN_8O_{12.75}$, $M \approx 897.6$. CCD instrument, $T \approx 300$ K. Triclinic, space group $P\bar{1}$, $a = 13.433(1)$, $b = 17.434(2)$, $c = 18.997(2)$ Å, $\alpha = 97.181(2)$, $\beta = 99.057(2)$, $\gamma = 108.238(2)°$, $V = 4100$ Å^3. $D_{calcd.}$ ($Z = 4$) = 1.454 g cm^{-3}. $\mu_{Mo} = 6.8$ cm^{-1}; specimen: 0.45 × 0.35 × 0.15 mm; $'T'_{min.,max} = 0.74, 0.87$. $N_t = 47686$; $N = 19991$ ($R_{int} = 0.032$), $N_o = 7593$; $R = 0.055$, $R_w = 0.058$. $|\Delta\rho_{max}| = 0.84$ e Å^{-3}.

Variata: High "thermal motion" was evident in relation to a number of residues modelled as water molecule oxygen atoms; refinement of site occupancies suggested only that of O(14) to be seriously deviant from unity, disposed over a pair of sites 1.79(2) Å apart, its occupancies refining to ca. 0.5 and being constrained thus. Hydrogen atoms were located in difference maps as being associated with O(1)−O(7).

11. [Co{sar(NH$_2$CH$_2$C$_5$H$_4$N)(NHCH$_2$C$_5$H$_4$N)}](NO$_3$)$_4$·2H$_2$O ≡ $C_{26}H_{49}CoN_{14}O_{14}$, $M = 840.7$. Single-counter instrument, $T \approx 295$ K. Monoclinic, space group $C2/c$ (C_{2h}^6, No. 15), $a = 8.416(2)$, $b = 14.877(3)$, $c = 27.405(4)$ Å, $\beta = 95.39(1)°$, $V = 3461$ Å^3. $D_{calcd.}$ ($Z = 4$) = 1.634 g cm^{-3}. $\mu_{Mo} = 5.9$ cm^{-1}; specimen: 0.40 × 0.25 × 0.30 mm; $T_{min.,max} = 0.84, 0.96$. $2\theta_{max} = 50°$; N_t (hemisphere to 50°; sphere to 40°) = 8648, $N = 3009$ ($R_{int} = 0.079$), $N_o = 1947$; $R = 0.060$, $R_w = 0.062$. $|\Delta\rho_{max}| = 1.00$ e Å^{-3}.

Variata: Protonation as indicated is incompatible with $Z = 4$ in the centrosymmetric space group; difference map considerations suggested protonation of the "diamsar" nitrogen atoms and the proton was located thus, occupancy 0.5; other disorder, notably among one of the nitrate groups, also modelled as disposed over two sets of sites, occupancies 0.5, may be concerted with that of the protonation. Attempted refinement in a lower symmetry was (inherently) unfruitful (it has not escaped our notice that in later determinations in the series, the pyridine moiety is definitively described as protonated, rather than the NH group).

12. [Co{sar[NHCH$_2$(C$_5$H$_4$NH)]$_2$}](S$_2$O$_6$)$_2$Cl·6H$_2$O ≡ $C_{26}H_{58}ClCoN_{10}O_{18}S_4$, $M = 1021.5$. Single-counter instrument, $T \approx 295$ K. Monoclinic, space group $C2/c$, $a = 16.353(3)$, $b = 14.783(3)$, $c = 17.510(3)$ Å, $\beta = 98.38(2)°$, $V = 4188$ Å^3. $D_{calcd.}$ ($Z = 4$) = 1.620 g cm^{-3}. $\mu_{Mo} = 7.6$ cm^{-1}; specimen: 0.55 × 0.50 × 0.26 mm; $T_{min.,max} = 0.72, 0.83$. $2\theta_{max} = 55°$; N_t (hemisphere) = 7753, $N = 4813$ ($R_{int} = 0.029$), $N_o = 3694$; $R = 0.050$, $R_w = 0.066$. $|\Delta\rho_{max}| = 0.91$ e Å^{-3}.

Variata: Hydrogen atoms were not located as being associated with "water molecule oxygen atoms" O(2,3), these having apparent occupancies of unity based on refinement behaviour; (x, y, z, U_{iso}) (all other H) were refined.

13. [Co{sar(NH$_3$)[NHCH$_2$(C$_5$H$_4$NH)]}](S$_2$O$_6$)$_2$Cl·3H$_2$O ≡ $C_{20}H_{47}ClCoN_9O_{15}S_4$, $M = 876.3$. CCD instrument, $T \approx 300$ K. Monoclinic, space group $P2_1/c$ (C_{2h}^5, No. 14), $a = 14.457(1)$, $b = 9.8567(8)$, $c = 24.562(2)$ Å, $\beta = 96.990(2)°$, $V = 3474$ Å^3. $D_{calcd.}$ ($Z = 4$) = 1.675 g cm^{-3}. $\mu_{Mo} = 8.9$ cm^{-1}; specimen: 0.24 × 0.16 × 0.10 mm; $'T'_{min.,max} = 0.66, 0.93$. $N_t = 38653$, $N = 8676$ ($R_{int} = 0.038$), $N_o = 5464$; $R = 0.045$, $R_w = 0.052$. $|\Delta\rho_{max}| = 0.78$ e Å^{-3}.

Variata: (x, y, z, U_{iso}) were refined for all hydrogen atoms except those associated with the water molecules, which were located from difference maps.

14. [Co{sar(NH$_3$)(NH$_2$CH$_2$C$_4$H$_3$S)}]Cl$_5$·3H$_2$O ≡ $C_{19}H_{46}Cl_5CoN_8O_3S$, $M = 702.9$. CCD instrument, $T \approx 153$ K. Monoclinic, space group Cc (C_s^4, No. 9), $a = 19.321(3)$, $b = 19.624(3)$, $c = 16.989(2)$ Å, $\beta = 91.255(2)°$, $V = 6440$ Å^3. $D_{calcd.}$ ($Z = 8$) = 1.450 g cm^{-3}. $\mu_{Mo} = 10.5$ cm^{-1}; specimen: 0.65 × 0.17 × 0.15 mm; $'T'_{min.,max} = 0.54, 0.88$. $N_t = 17751$, $N = 4560$ ($R_{int} = 0.050$), $N_o = 4167$ ("Friedel pairs" preserved distinct); $R = 0.060$, $R_w = 0.073$; $x_{abs} = 0.06(4)$. $|\Delta\rho_{max}| = 0.70(3)$ e Å^{-3}.

Variata: The pendant residue on molecule 1 of the two independent molecules in the asymmetric unit was modelled as being disordered over two sets of sites; occupancies were set at 0.5 each after trial refinement and coalesced with a more extensive mass of disordered fragments modelled as water molecule oxygen atoms; site occupancies 0.5. Cl(1,2) were also modelled as being disordered over pairs of sites, with separations of 0.80(3), 1.49(4) Å, and occupancies refining to 0.74(2), 0.72(2); under unit totality constraint after trial refinement, these complemented the smaller fragments of the Cl; those of the other disordered non-hydrogen atoms were refined with isotropic thermal parameter forms.

16. [Co{sar(CH$_3$)(NHCH$_2$C$_6$H$_4$C$_6$H$_5$)}](NO$_3$)$_{2.5}$Cl$_{0.5}$ca. 4^1/$_8$H$_2$O ≡ $C_{28}H_{53.25}Cl_{0.5}CoN_{9.5}O_{11.625}$, $M \approx 785.7$. CCD instrument, $T \approx 153$ K. Monoclinic, space group $C2/c$, $a = 60.926(5)$, $b = 15.353(1)$, $c = 15.365(1)$ Å, $\beta = 92.410(2)°$, $V = 14360$ Å^3. $D_{calcd.}$ ($Z = 16$) = 1.454 g cm^{-3}. $\mu_{Mo} = 5.9$ cm^{-1}; specimen: 0.80 × 0.35 × 0.10 mm; $'T'_{min.,max} = 0.52, 0.86$. $N_t = 79381$, $N = 12608$ ($R_{int} = 0.10$), $N_o = 7314$; $R = 0.099$, $R_w = 0.12$. $|\Delta\rho_{max}| = 3.71(4)$ e Å^{-3}.

Variata: The anion complement was modelled in terms of a total charge of three, made up of one-half of a chloride ion and two-and-a-half nitrate ions, one of the latter being modelled as being disordered over two sets of sites, oxygen occupancies set at 0.5 after trial refinement. The molecules pack as double layers disposed on either side of the plane(s) $x = 0.125$ (etc.), interleaved by layers comprising residues modelled in terms of some anions and water molecule oxygen atoms, about the plane(s) $x = 0$ (etc.). These encompass considerable disorder with a number of site occupancies modelled being set at 0.5 after trial refinement.

Intercalates of Vanadyl Phosphate with Branched Alcohols

Ludvík Beneš,*[a] Vítězslav Zima,[a] and Klára Melánová[a]

Keywords: Vanadium / Phosphate / Alcohols / Intercalations

Intercalates of $VOPO_4$ with several branched alcohols (2-propanol, 2-methyl-1-propanol, 3-methyl-1-butanol, 4-methyl-1-pentanol, 2-methyl-2-propanol, 2,2-dimethyl-1-propanol, 3,3-dimethylbutanol, 3-methyl-1-pentanol, 2-methyl-1-pentanol, 2-hexanol, 2-ethyl-1-butanol, 2-propyl-1-pentanol) were prepared and characterized by powder X-ray diffractometry and thermogravimetry. Only 2-propanol, 2-methyl-1-propanol and 3-methyl-1-butanol were directly intercalated into vanadyl phosphate dihydrate. The other intercalates were prepared by the displacement of 2-propanol. Gas chromatography of the solid intercalates showed that no mixed intercalates still containing the starting alcohol are formed, except the 4-methyl-1-pentanol intercalate. The arrangement of the guest molecules in the interlayer space of the host is discussed. The alcohols are anchored to the host layers by donor-acceptor bonds between their oxygen atoms and the vanadium atoms of the host structure, and by hydrogen bonding.

Introduction

A number of papers have reported attempts to find the principles governing the structure arrangements of unbranched aliphatic molecules with terminal functional groups during their intercalation into various host structures.[1,2] With this aim the intercalations of, for example, aliphatic alcohols, diols and amines into some natural silicates,[3,4] vanadyl phosphate and sulfate,[5−8] α- and γ-$Zr(HPO_4)_2{\cdot}H_2O$,[9,10] and other similar hosts were investigated.

The reaction of solid $VOPO_4{\cdot}2H_2O$ with liquid or molten 1-alkanols in a microwave field leads to intercalation compounds with the general formula $VOPO_4{\cdot}2C_nH_{2n+1}OH$ ($n = 2-18$).[8] The structure of these polycrystalline layered complexes retains the original layers of $(VOPO_4)_\infty$. The molecules of the alcohols are placed between the host layers in a bimolecular arrangement, and are anchored by donor-acceptor bonds between the oxygen atom of the OH group and the vanadium atom, as well as by hydrogen bonds. The aliphatic chains of the intercalated alcohol molecules possess an *all-trans* configuration and their axes are perpendicular to the host layers.

Little attention has been paid to the intercalation of molecules with branched alkyl chains. The intercalation of 2-butylamine, isobutylamine and neopentylamine into mixed niobyl-vanadyl phosphate was studied.[11] Smaller amounts of 2-butylamine than isobutylamine are intercalated, because of the larger cross-section area. An increase in the molecular volume (neopentylamine) also decreases the amine content. The basal spacing of these amine intercalates is close to that of 1-propylamine and their molecules are arranged in a bimolecular way with their main axis tilted at an angle of 58° with respect to the layer. 2-Propanol, 2-methyl-1-propanol and 3-methyl-1-butanol were intercalated into anhydrous vanadyl sulfate.[6] The basal spacing of these intercalates is very similar to that of the unbranched alcohol with the same length of the main alkyl chain. The content of isoalcohols in the intercalates is lower than that for 1-alkanols.

In this paper the structure of the $VOPO_4$ intercalates with several branched alcohols is discussed.

Results and Discussion

Preparation and Characterization of Intercalates

Only 2-propanol, 2-methyl-1-propanol and 3-methyl-1-butanol were directly intercalated into vanadyl phosphate dihydrate. The intercalates of vanadyl phosphate with other branched alcohols were prepared by displacement of 2-propanol. To exclude the possible formation of a mixed intercalate of 2-propanol with the branched alcohol, an analogous reaction was carried out starting from the 1-propanol intercalate as a precursor. All intercalates are yellow, indicating that vanadium(V) is not significantly reduced. The intercalates of the branched alcohols are distinctly less stable than the intercalates of 1-alkanols,[8] and rapidly decompose in air (relative humidity of 50%) and hydrate to $VOPO_4{\cdot}2H_2O$.

The intercalates prepared are crystalline solids. The diffractograms show a series of sharp (00*l*) reflections (typical diffractograms are shown in Figure 1). The *a* parameter of the tetragonal lattice was determined from the (200) and (201) diffraction lines (Table 1). The same lattice parameter *c* was obtained for the intercalates prepared by displacement of 1-propanol. Gas chromatography of the solid intercalates showed that no mixed intercalates containing starting alcohol were formed, with just one exception (see below). The stoichiometric quotient x_{exp} obtained by the thermogravimetric analysis and several checking analyses of

carbon and hydrogen contents are given in Table 1, together with the values of x_{calc} calculated as a ratio of the volume of alcohol intercalated and the molar volume of alcohol calculated from its density. The volume of the alcohol intercalated was calculated as a difference between the unit cell volume of the intercalate and anhydrous $VOPO_4$.

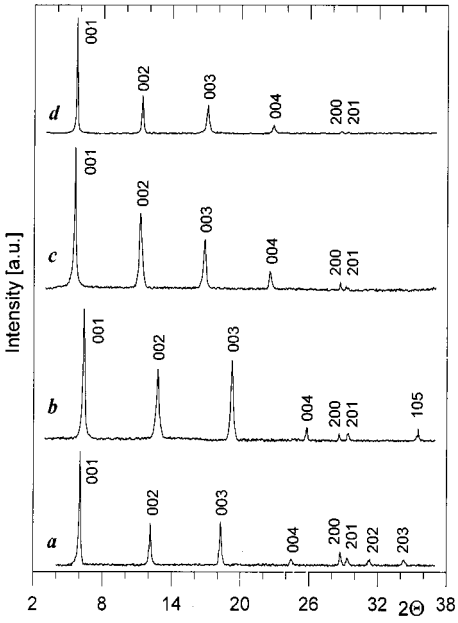

Figure 1. Diffractograms of the $VOPO_4$ intercalates with: (a) 2-methyl-1-propanol, B; (b) 2,2-dimethyl-1-propanol, K; (c) 3,3-dimethyl-1-butanol, J; (d) 2-ethyl-1-butanol, I

Table 1. Lattice parameters and composition of intercalates (mol alcohol/mol $VOPO_4$)

Alcohol	Denotation	a [Å]	c [Å]	x_{exp}	x_{calc}
2-Propanol	A	6.21	13.26	1.45	1.39

2-Methyl-2-propanol	L	6.21	12.80	1.00	1.07

The IR spectra of the $VOPO_4$ intercalates shows a ν(V=O) band in the region 1000−1007 cm^{-1}, overlapping the intense bands of the PO_4 tetrahedron. This indicates the presence of a donor-acceptor bond between the oxygen atom of the alcohol and the vanadium atom similar to the bond between the water or 1-alkanol molecules and the host layers.[12,13] Several broad bands in the region from 3600 to 3100 cm^{-1} were found, which could be assigned to a valence vibration of the OH group affected by the interaction of the alcohol with the host lattice.

Suggested Arrangements of Guest Molecules

A set of 12 alcohols with branched aliphatic chains was chosen so as to provide maximum information about the influence of the chain branching on the composition, basal spacing, and stability of the intercalates formed. The structures of the chains are shown in Figure 2. In the following text, the properties of these intercalates are compared with the intercalates of $VOPO_4$ with the 1-alkanols and 2-alkanols studied earlier.[8,15] The influence of the number of the carbon atoms in the main chain on properties of the intercalates is examined. A chain with increasing number of the carbon atoms in a series is considered as the main chain.

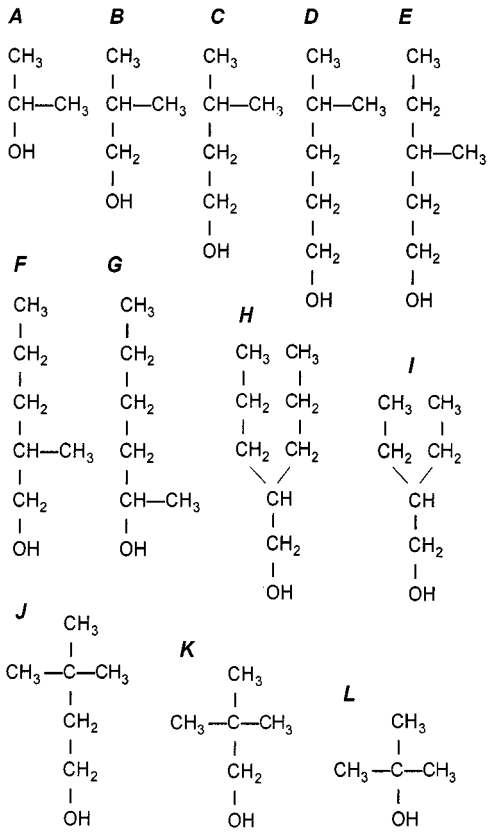

Figure 2. Structure of the guest molecules; see also Table 1

Intercalates with Isoalcohols

With increasing length of the main chain the basal spacing of the intercalates of the first three isoalcohols (A−C) changes linearly, increasing by one carbon atom (1.51 Å) at a time. This increase is equal to 1.28 Å for an unbranched alkyl *all-trans* chain placed perpendicularly to the host layers.[14] It is obvious that the molecules of these three isoalcohols form a bilayer system between the $(VOPO_4)_\infty$ sheets, and their main chains are tilted at an angle $\alpha = 36°$ to the host layers.

The experimental stoichiometric coefficient (TGA) and that calculated from the changes of the volume is ≈1.3 for these intercalates (Table 1). For 3-methyl-1-butanol, x_{exp} =

1.4 and $x_{calc} = 1.3$. The free interlayer volume available to 3-methyl-1-butanol in the intercalate is given by

$$V_i = (d - d_H) \times a^2 = 466.24 \text{ Å}^3$$

where d is the basal spacing of the intercalate, d_H is the thickness of the host layer (which is equal to the basal spacing of anhydrous $VOPO_4$), and a is the parameter of the tetragonal layer. The molecular volume of 3-methyl-1-butanol is $V_g = 180.8$ Å^3 (calculated by the ChemSketch program). The theoretical number of the guest molecules which can be placed at one vanadium site is therefore

$$x_{theor} = V_i/(V_g \times Z) = 1.29$$

where $Z = 2$ (number of formula units per cell as found for $VOPO_4 \cdot 2H_2O$).[16] To complement the coordination sphere of every vanadium atom in the host layer to an octahedron, one alcohol molecule should be bonded by a donor-acceptor bond to every vanadium atom. The rest of the alcohol molecules should be bonded by hydrogen bonds only and placed in the cavities among the donor-acceptor-bonded molecules. A similar principle of the guest arrangement was proposed for the intercalate of vanadyl phosphate with propargyl alcohol.[17]

The intercalate with 4-methyl-1-pentanol has a distinctly higher basal spacing than the other three alcohols from this group (see Table 1). Only this intercalate decomposes to a multiphase during drying carried out either by vacuum distillation at 25 °C in an evacuated ampoule or by washing with ether and subsequent blowing with dry nitrogen. The basal spacing is practically the same as that for the 1-pentanol intercalate (19.71 Å),[8] indicating that the guest molecules are roughly perpendicular to the host layers. We can assume that the intercalate prepared is in fact a cointercalate containing 2-propanol or 1-propanol (according to the precursor used) in the cavities among the methyl groups of the 4-methyl-1-pentanol molecules. The presence of 2-propanol or 1-propanol was confirmed by gas chromatography of the hydrolyzate of the wet samples after washing with 4-methyl-1-pentanol; propanol was not found in the hydrolyzate of the dry multiphase product. The decomposition of the sample during drying is connected to the release of the propanol molecules from the intercalate structure.

Intercalates with Alcohols Having Three Methyl Groups at the Terminal Carbon Atom of the Main Chain

Three alcohols were intercalated into $VOPO_4$: 2-methyl-2-propanol (*tert*-butyl alcohol, see structure L in Figure 2), 2,2-dimethyl-1-propanol (K), and 3,3-dimethylbutanol (J). As for the isoalcohols, alcohols with three terminal methyl groups change the basal spacing linearly with increasing chain length in increments of 1.50 Å per carbon atom. This implies that these alcohols are also present in the space in two layers and their main chain is tilted to the host layer at an angle of 36°. The amount of alcohol intercalated was distinctly lower than that for the isoalcohol intercalates and the stoichiometric coefficient is ≈1. This value and the value of the basal spacing allow us to propose a relatively simple arrangement of the alcohol molecules in the interlayer space as depicted in Figure 3.

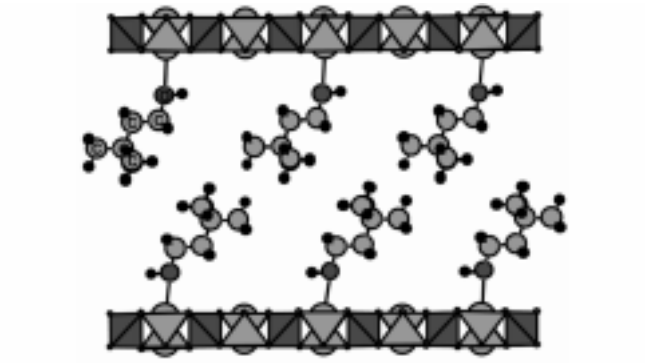

Figure 3. Proposed arrangement of 3,3-dimethyl-1-butanol between the $VOPO_4$ layers viewed in the direction of the *xy* diagonal

From a comparison of the isoalcohol intercalates with this group of intercalates we deduced that the amount of intercalated alcohol was lower for more-branched alcohols; nevertheless the basal spacing and, consequently, the orientation of the main chain with respect to the host layers remained the same.

The Effect of the Position of the Methyl Group in the Main Chain

This effect on the composition and structure was followed in the series 4-methyl-1-pentanol (see structure D in Figure 2), 3-methyl-1-pentanol (E), 2-methyl-1-pentanol (F), and 2-hexanol (which can be considered as "1-methyl-1-pentanol" in the given series, G). As mentioned above, 4-methyl-1-pentanol forms a very unstable cointercalate containing propanol and having a distinctly higher basal spacing. The other three alcohols form intercalates with roughly the same basal spacing and their stoichiometric coefficient x is equal to 1 (see Table 1). A two-layer arrangement of the guest molecules was proposed for the 2-alkanol intercalates, with the guest chain tilted with respect to the host layers at $\alpha = 25.6°$; this also applies to the 2-hexanol intercalate (see Figure 4).[15] With regard to the similar

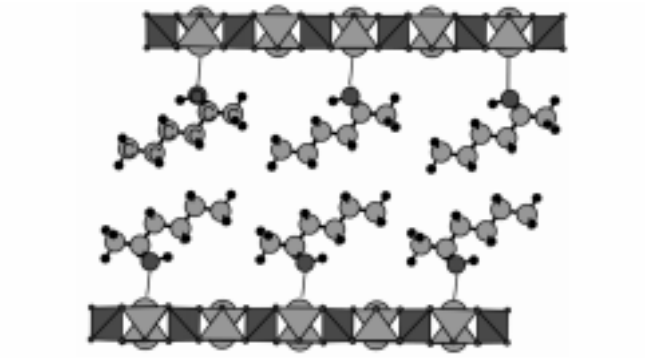

Figure 4. Proposed arrangement of the 2-hexanol molecules between the $VOPO_4$ layers viewed in the direction of the *xy* diagonal

basal spacing, it is very probable that the 2-methyl-1-pentanol and 3-methyl-1-pentanol molecules are found in the interlayer space in a similar arrangement. This means that the position of the methyl group probably does not influence the arrangement of these alcohols in the intercalates. In contrast to 1-pentanol ($x = 2$), which forms a bilayer arrangement with the chains perpendicular to the host layers, there is a significant decrease of the amount of intercalated alcohol ($x = 1$), which is connected to a distinct inclination of the carbon chain. Only a methyl group placed at the end of the long chain allows a perpendicular arrangement as inferred from the higher value of the basal spacing for the 4-methyl-1-pentanol intercalate.

Influence of the Size of Two Identical Alkyl Groups in 2,2-Dialkyl-1-ethanol

Intercalates with 2-methyl-1-propanol (B), 2-ethyl-1-butanol (H), and 2-propyl-1-pentanol (I) were prepared in this series. In contrast to the ethanol intercalate there is a distinct decrease of the stoichiometric coefficient, which is equal to one for the longer alcohols. An arrangement of the 2-propyl-1-pentanol molecules in the interlayer space is proposed in Figure 5. For this alcohol we can consider the heptane chain as a main alkyl chain in the *all-trans* configuration with a -CH_2CH_2OH group (a hydroxyethyl group) bonded to its fourth carbon atom. The hydroxyethyl group is anchored to the host layers by a donor-acceptor bond between the guest oxygen atom and the vanadium atom of $VOPO_4$. The heptane chain is oriented in the direction of the diagonal of the host sheet and is inclined to this sheet at an angle of less than 90°.

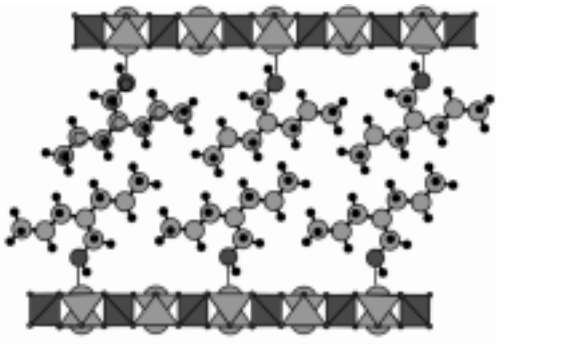

Figure 5. Proposed arrangement of the 2-propyl-1-pentanol molecules between the $VOPO_4$ layers viewed in the direction of the *xy* diagonal

Comparison of Ethanol, 2-Propanol, and *tert*-Butyl Alcohol Intercalates

Whereas the basal spacing of the intercalates of all three alcohols discussed is roughly the same, the stoichiometric coefficient decreases in the series $VOPO_4$·ethanol > $VOPO_4$·(2-propanol) > $VOPO_4$·(*tert*-butyl alcohol), with a value of $x = 1$ for the *tert*-butyl alcohol intercalate. It can be presumed that the molecules of all three alcohols are arranged in two layers in the interlayer space. The decrease of the stoichiometric coefficient with increasing branching is due to steric effects. The molecules of 2-propanol and *tert*-butyl alcohol, anchored by their oxygen atoms to the vanadium atoms of the layers, do not allow other molecules bonded only by the H bonds to fill the space between coordinated molecules as they have larger cross-sections than ethanol.

Experimental Section

Preparation: Intercalates of the isoalcohols were prepared by suspending $VOPO_4·2H_2O$ (0.3 g) in dry alcohol (7 mL) and subsequent short exposure (0.5−2 min.) to a microwave field. Intercalates of other branched alcohols were obtained by a displacement reaction. The solid 2-propanol intercalated host was prepared in advance and used as a starting material for the reactions with other alcohols. After cooling, the solid product formed was filtered off. All samples used for X-ray diffraction analyses contained small amounts of the free alcohol. The samples for TG-DTA and elemental analyses were washed with dry ether and dried in nitrogen at room temperature.

Analyses: The TGAs of the intercalates were performed with a Derivatograph MOM (Hungary), the measurements being carried out in the temperature interval of 30−600 °C in air at a heating rate of 5 °C/min. The weight of the samples was 100 mg. In some cases the composition was determined by elemental analysis (C, H).

Gas chromatography was used to check whether the intercalates contained starting alcohol (2-propanol or 1-propanol) or not. The sample was washed with an excess of the alcohol intercalated to remove 2-propanol or 1-propanol released by the intercalation. The intercalate was then hydrolyzed in a small amount of water and the hydrolysate was analyzed by GC with a Chrom4 chromatograph (Czech Republic).

X-ray Diffraction Measurements: The powder data of the intercalates with a small excess of the guest alcohol were obtained with an X-ray diffractometer (HZG-4, Germany) using Cu-$K_{\alpha 1}$ radiation ($\lambda = 1.54051$ Å) with removal of the Cu-K_β radiation by a nickel filter. The Cu-$K_{\alpha 2}$ intensities were removed from the original data. Silicon ($a = 5.43055$ Å) was used as the internal standard. Diffraction angles were measured from 1.5° to 37° (2Θ).

IR Spectroscopy: Infrared spectra of the solid intercalates were measured in Nujol suspensions in the region of 4000−400 cm^{-1} using a Perkin−Elmer 684 spectrometer.

1-Oxa-3-aza-2,4-disilacyclobutanes − Synthesis, X-ray Structures, and Reactivity

Uwe Klingebiel,*[a] M. Noltemeyer[a]

Keywords: Silicon / Structure elucidation / Silanes / Small ring systems

Lithium aminodi(*tert*-butyl)silanolate reacts with F_3SiR to give the aminosiloxane $(Me_3C)_2SiNH_2–O–SiF_2R$ [**1**; R = 2,4,6-$(tBu)_3C_6H_2$]. In the reaction of **1** with BuLi a four-membered (Si–O–Si–NH) ring system **2** is formed [–$(Me_3C)_2$Si–O–SiFR–NH–]. The amino-1,3-disiloxane $RSiF_2–NH–Si(CMe_3)_2–O–SiF_2R$ (**3**) is obtained from dilithiated amino(di-*tert*-butyl)silanol and F_3SiR. Compound **1** reacts with BuLi with formation of a dimeric lithium derivative through the Li–N bond (**4**). In **4** the transannular Si···Si distance was found to be 237.2 pm, which is the shortest distance so far found between two silicon atoms contained in four-membered rings. Compound **4** reacts with $Me_3SiOSO_2CF_3$ with substitution of the lithium by the Me_3Si group to give **5**.

Introduction

In silicon chemistry it is possible to stabilize compounds with two or three OH or NH_2 groups bonded to one silicon atom, in contrast to carbon chemistry. The first silanediols and -diamines were described by Sommer and Tyler in the fifties.[1] Silanetriols and -triamines followed about thirty years later.[2−4] We succeeded in preparing stable halosilanols,[5] (e.g. chlorosilanols) from the reaction of silanediols with PCl_5, accompanied by formation of HCl and $POCl_3$. The reaction of di-*tert*-butyl-dichlorosilane with ammonia proceeds with complete cleavage of hydrogen chloride to afford the amino-di-*tert*-butylsilanol, the only aminosilanol known so far,[2,6] which is stable towards self-reaction [Equation (1)].

$$R_2Si(OH)_2 \xrightarrow[-HCl,\ -POCl_3]{+PCl_5} R_2Si(OH)Cl \xrightarrow[-NH_4Cl]{+2\ NH_3} R_2Si(OH)NH_2 \quad (1)$$

The kinetic stabilization of the aminosilanol led to the stepwise synthesis of numerous acyclic and cyclic organosilicon compounds.[7] After lithiation of the aminosilanol,[6] treatment with a halosilane always results in attachment of the new organosilicon group to the oxygen atom; aminosiloxanes are formed [Equation (2)]. Lithiation of these aminosiloxanes normally leads again to the bonding of lithium to the oxygen atom. In this case aminosilanolates of type I are formed. This means that in the lithiation reaction the silyl substituent on the oxygen atom is displaced by the Lewis acidic lithium, so that an O → N silyl group migration is observed.[8] This rearrangement can be prevented by bulky groups [Equation (2)]. Siloxaneamides of type II are then formed. Therefore the success of the substitution of the silyl groups determines which isomer is obtained.[8] In reactions with other halosilanes silylamino-1,3-disiloxanes are obtained.

In attempting to obtain cyclic products by salt elimination from isomeric lithium compounds we isolated eight-membered (Si−O−Si−N) rings [Equation (2)].[9,10] Lithium derivatives of type I are found to be very stable; they can be distilled without decomposition.[11] However, they are direct precursors of four-membered (Si−O−Si−N) rings when catalytic amounts (1−5%) of fluorosilanes are added to a solution of the lithium compounds.[8,12]

In this paper we describe the preparation of 1-[amino-1,1-di(*tert*-butyl)]-3-[2,4,6-tri(*tert*-butyl)phenyl]-3,3-difluoro-1,3-disiloxane, its cyclisation to the first (Si−NH−Si−O) four-membered ring system, and the formation of its lithium derivative.

Results and Discussions

In preparative ring chemistry bulky groups lead to the formation of small ring compounds. In order to prepare a fluoro-functionalized Si(F)−O−Si−N(H) four-membered ring system we used the bulky $Si(CMe_3)_2$ and $F_2SiC_6H_2(CMe_3)_3$ units. The lithiated aminodi(*tert*-butyl)silanol[6] reacts with 2,4,6-tri(*tert*-butyl)phenyltrifluorosilane to yield the aminosiloxane **1** [Equation (3)], which is stable against HF or NH_3 condensation.

Our attempts to isolate the lithium derivative of **1** in the reaction of **1** and BuLi were unsuccessful, LiF elimination occurred and the 1-aza-3-oxa-2,4-disilacyclobutane **2** was obtained [Equation (4)].

Crystal Structure of 2

Colorless crystals of **2** with space group $P\bar{1}$ were obtained from a saturated solution of *n*-hexane. The atoms N(1), Si(1), O(1) and Si(2) of the molecule form a planar four-membered ring, but there are some irregularities as follows. At the oxygen and the nitrogen atoms there is a slight open-

(4)

ing of the Si(1)−O(1)−Si(2) angle (93.42°) and the Si(1)−N(1)−Si(2) angle (94.03°), which is accompanied by a contraction of the angles at the other ring atoms [N(1)−Si(1)−O(1) = 87.15°; N(1)−Si(2)−O(1) = 85.4°]. The Si(1)−O(1) (167.2 pm), and the Si(2)−O(1) (170.2 pm) bond lengths are lengthened. The Si(1)−N(1) (166.6 pm) and Si(2)−N(1) (169.1 pm) bonds are short, even shorter than the Si−O bonds. In order to see if there is any O/NH split occupancy of O(1) re-refinements of O/NH occupancies were carried out on both sites. However, strong correlation with ADPS leads to unstable refinement. Also, no hydrogen atoms could be located in the difference maps and riding models had to be used throughout. The Si···Si nonbonding distance in the ring is 245.6 pm, the corresponding N···O distance is 230.1 pm. These short distances illustrate that the ring atoms in a four-membered ring as strained as this one are forced to approach each other to an extraordinary extent. The C(1) atom of the aryl group is found to have no planar environment: the sum of the angles at C(1) amounts to 355.7°. Figure 1 shows the structure of compound **2**.

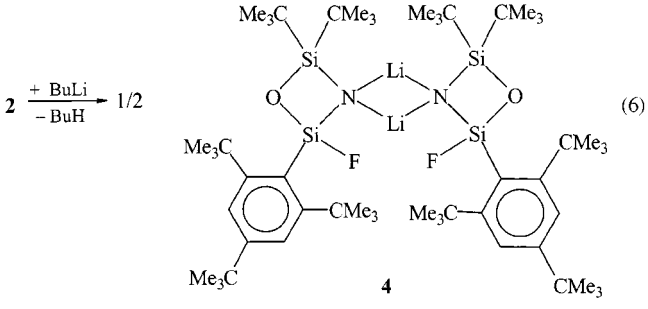
Disilylation of the aminosilanol is possible by starting from the dilithium derivative according to Equation (5):

Crystal Structure of 4

The lithium compound **4** is obtained in high yields [Equation (6)] from the reaction of **2** with BuLi, thus confirming the structure of **4**.



(6)

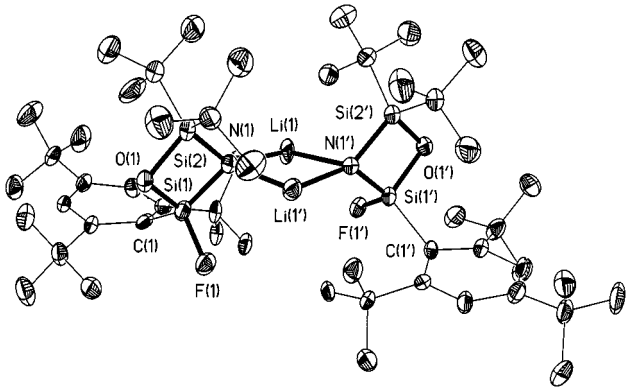


Figure 2. Structure of **4**; selected bond lengths [pm] and angles [°]: Si(1)−F(1) 161.8(4), Si(1)−O(1) 166.7(5), Si(1)−N(1) 172.1(6), Si(1)−C(1) 187.6(7), Si(1)−Si(2) 237.2(3), Si(2)−O(1) 169.6(5), Si(2)−N(1) 174.3(6), Si(2)−C(8) 190.1(8), Li(1)−N(1) 195.1(12), Li(1)−N(1′) 203.5(13), Li(1)−Li(1′) 232(2), N(1)−Li(1′) 201.5(13), Si(1′)−F(1′) 160.5(5), Si(1′)−O(1′) 166.7(5), Si(1′)−N(1′) 172.9(6), Si(1′)−Si(2′) 237.3(3), Si(2′)−O(1′) 169.8(5), Si(2′)−N(1′) 173.5(6), Li(1′)−N(1′) 195.4(12); F(1)−Si(1)−O(1) 110.8(2), F(1)−Si(1)−N(1) 109.1(2), O(1)−Si(1)−N(1) 92.6(3), O(1)−Si(1)−Li(1′) 102.1(3), N(1)−Si(1)−Li(1′) 37.9(3), O(1)−Si(2)−N(1) 90.9(3), N(1)−Li(1)−N(1′) 107.7(6), N(1)−Li(1)−Li(1′) 55.5(4), Si(1)−N(1)−Si(2) 86.4(3), Li(1)−N(1)−Li(1′) 71.5(5), Si(1)−O(1)−Si(2) 89.7(2), O(1′)−Si(2′)−N(1′) 91.1(3), N(1′)−Li(1′)−N(1) 108.4(6), Si(1′)−N(1′)−Si(2′) 86.5(3), Li(1′)−N(1′)−Li(1) 71.0(5), Si(1′)−O(1′)−Si(2′) 89.7(2)

Compound **4** crystallizes from *n*-hexane as a dimer in the space group *C*2/*c* (Figure 2) Again the crystal structure shows some irregularities. The dimer of **4** is formed from a four-membered $(Li-N)_2$ ring system, which is not entirely planar but folded by 10.7° across the Li···Li line. The Si−O−Si−N rings have an angle of 86° to the central $(LiN)_2$ ring and of 5.8° to each other. The *tert*-butyl groups and therefore the aryl group and the fluorine atom are in *cis* positions. The sum of the angles around C(1) amounts to 355.1°. In contrast to compound **2**, the Si−O distances here are shorter than the Si−N distances. Now the ring angles at Si(1) (92.6°) and Si(2) (90.9°) are above 90° and the angles at O(1) (89.7°) and N(1) (86.4°) are smaller than 90°. This brings the Si(1) and Si(2) atoms into a close approximation. The Si···Si nonbonding distance in the ring is only 237.2 pm, which as far as we are aware is the shortest nonbonding Si···Si contact found so far. The transannular O···N distance is found to be 245.1 pm. The bonding properties of such small four-membered rings containing two opposite silicon atoms have been investigated by various theoretical methods[5,13−16]. Table 1 shows examples of known rings. The presence of a transannular σ bond has been excluded, in agreement with the very small Si···Si coupling constant.[17] Grev and Schäfer have explained the short Si···Si contacts in terms of an "unsupported π bond", which lies in the plane of the ring.[15]

The bulky groups at this lithiated fluorine-containing ring system motivated us to test the possibility of a LiF elimination. In the eighties and nineties we were successful in the preparation of iminosilanes in the following reaction [Equation (7)]:

Table 1. Geometric parameters of $[R_2Si-X]_2$ four-membered rings; X = CR_2', NR′ and O

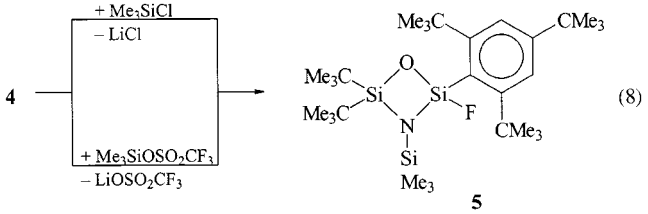
In the analogous reaction of **4** with Me_3SiCl, however, we isolated the silyl-substituted compound **5**, which was also obtained from the reaction of **4** and $Me_3Si-O-SO_2-CF_3$ [Equation (8)].



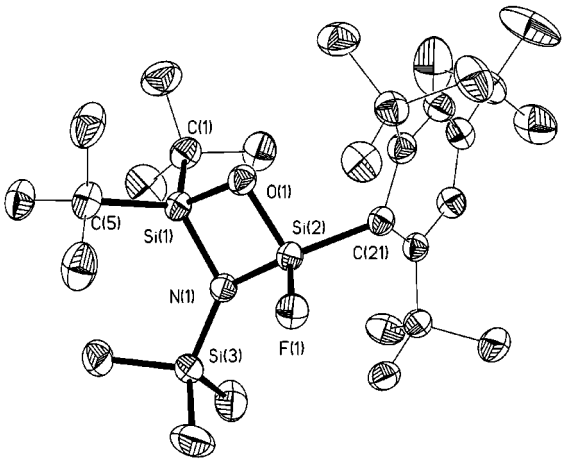


Figure 3. Structure of **5**; selected bond lengths [pm] and angles [°]: Si(1)−O(1) 167.56(12), Si(1)−N(1) 177.41(14), Si(1)−C(1) 189.9(2), Si(1)−C(5) 190.4(2), Si(1)−Si(2) 244.53(7), Si(2)−F(1) 159.38(10), Si(2)−O(1) 165.32(12), Si(2)−N(1) 175.26(14), Si(3)−N(1) 174.80(14); O(1)−Si(1)−N(1) 88.07(6), F(1)−Si(2)−O(1) 113.60(6), F(1)−Si(2)−N(1) 107.73(6), O(1)−Si(2)−N(1) 89.51(6), Si(3)−N(1)−Si(2) 137.28(8), Si(3)−N(1)−Si(1) 128.32(8), Si(2)−N(1)−Si(1) 87.79(6), Si(2)−O(1)−Si(1) 94.54(6)

Crystal Structure of 5

Crystals of **5** were obtained from a THF solution. It crystallizes in the space group *Pbcn* (Figure 3). The ring system of **5** resembles the ring system of **2**. The ring angles at the Si atoms are smaller than 90° and the angles at the N and O atoms are larger, although in **5** the Si−N bonds are much longer than in **2** and than the Si−O bonds. The transannular Si···Si distance is 244.5 pm. Compound **5** has a planar (O−Si−N−Si) four-membered ring. The sum of the angles around the N atom is 353.39°, indicating a slightly trigonal environment. The C(21) atom deviates slightly from the plane, as well [ΣC(21) = 356.26°]. The angle between the four-membered ring and Si(3) amounts 21.3°.

Experimental Section

All experiments were performed in oven-dried glassware using standard inert atmosphere and vacuum-line techniques. The NMR spectra were recorded in $CDCl_3$ (**1**, **3**) or C_6D_6 (**2**, **4**, **5**) with $SiMe_4$ and C_6F_6 (^1H, ^{13}C, ^{19}F, ^{29}Si) as internal and $MeNO_2$ (^{15}N) as external references. The progress of the reactions was monitored by ^{19}F NMR spectroscopy. The compounds were isolated analytically pure.

1-[Aminodi(*tert*-butyl)]-3-{[2,4,6-tri(*tert*-butyl)phenyl]difluoro}1,3-disiloxane (1): To a solution of $(Me_3C)_2Si(NH_2)OLi$ (5.4 g, 0.03 mol) in 50 mL THF was slowly added at room temperature 2,4,6-$(CMe_3)_3C_6H_2SiF_3$ (9.9 g, 0.03 mol) in 20 mL THF. The reaction mixture was refluxed for 1 h and cooled to room temperature. Compound **1** was separated from LiF by condensing into a cooled trap in vacuo and then distilled to give a pure sample, which crystallized. − Yield 88%, b.p. 155 °C/0.03 mbar, m.p. 88 °C. − ^1H NMR: δ = 1.00 ($SiCMe_3$), 1.35 (4-C_6CMe_3), 1.54 (2,6-C_6CMe_3), 7.44 (C_6H_2). − ^{13}C NMR: δ = 20.05 (SiC), 27.95 ($SiCC_3$), 31.36 (4-C_6CC_3) 33.45 (t, $^5J_{CF}$ = 2.7 Hz, 2,6-C_6CC_3), 34.96 (4-C_6C), 39.01 (2,6-C_6C), 117.53 (t, $^2J_{CF}$ = 23.7 Hz, F_2SiC), 123.07 (3,5-C_6), 152.05 (4-C_6), 160.81 (t, $^3J_{CF}$ = 1.3 Hz, 2,6-C_6). − ^{19}F NMR: δ = 46.7. − ^{29}Si NMR: δ = −73.50 (t, J_{SiF} = 248.9 Hz, SiF_2), −7.66 ($SiNH_2$). − MS (EI): *m*/*z* (%) = 470 (1) $[M - CH_3]^+$, 428 (28) $[M - C(CH_3)_3]^+$. − $C_{26}H_{49}F_2NOSi_2$ (485.85): calcd. Synthesis, Structures and Ethylene Polymerisation Behaviour of Low Valent β-Diketiminato Chromium Complexes

Vernon C. Gibson,*[a] Claire Newton,[a] Carl Redshaw,[a] Gregory A. Solan,[a] Andrew J. P. White,[a] and David J. Williams[a]

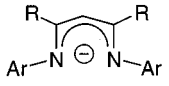
Keywords: Chromium / N ligands / Ethylene / Polymerisation

The preparation, reaction chemistry and ethylene polymerisation behaviour of low valent β-diketiminato chromium complexes are described. $[(DDP)CrCl(\mu\text{-}Cl)]_2$ (**1**) [DDPH = 2-{(2,6-diisopropylphenyl)amino}-4-{(2,6-diisopropylphenyl)imino}-pent-2-ene] is formed by treatment of $CrCl_3(THF)_3$ with LiDDP. Alkylation of **1** with $AlMe_3$ results in the formation of the binuclear dimethyl complex $[(DDP)CrMe(\mu\text{-}Cl)]_2$ (**2**). In contrast, the attempted alkylation of **1** with benzylmagnesium chloride results in reduction to form the dichromium(II) complex $[(DDP)Cr(\mu\text{-}Cl)]_2$ (**3**). Depending on the conditions of crystallisation, **3** can be obtained as the THF adduct [**3(THF)$_2$·THF**] or co-crystallised with a molecule of dibenzyl [**3·Bz-Bz**]. Cleavage of the dimeric unit in **1** can be achieved by the addition of carboxylates or β-diketonates to give $[(DDP)CrCl(O_2CR)(THF)]$ (R = Me **4a**, Ph **4b**) and $[(DDP)CrCl(\{O(R)C\}_2CH)]$ (R = Me **5a**, Ph **5b**), respectively. Single crystal X-ray diffraction studies have been performed on **1**, **2**, **3(THF)$_2$·THF**, **3·Bz-Bz**, **4a**, and **5b**. Complexes **1**, **2** and **3(THF)$_2$·THF** are dimeric and have molecular C_{2h} symmetry. Complex **3·Bz Bz** is also dimeric but has its potential C_{2h} symmetry removed by a significant tetrahedral distortion of the chromium coordination geometry. Compound **4a** has an octahedral chromium centre coordinated to a single bidentate diketiminate ligand, a bidentate acetate, a chloride and a THF molecule. Complex **5b** has a square pyramidal chromium with apical chloride and basal η^2 diketiminate and diketonate ligands. The complex contains strong intramolecular C–H···π stabilising interactions. All the complexes are active in ethylene polymerisation on treatment with suitable aluminium activators, affording high molecular weight polyethylene.

Introduction

Supported chromium catalysts play a key role in the worldwide production of polyethylene, and much effort has been directed towards developing an understanding of these systems from a surface science/heterogeneous catalysis point of view.[1,2] A complementary approach is to develop homogeneous model systems, not only to gain understanding of the chromium-centred chemistry of the supported systems, but also to advance chromium olefin polymerisation catalysis into an era of well-defined, single-site catalysts. To date, the majority of reports of homogeneous chromium catalysts for olefin polymerisation have been on half-sandwich chromium systems.[3−4] However, more recently there has been growing interest in non-cyclopentadienyl chromium catalysts.[5,6]

In this paper we are concerned with chemistry of low-valent chromium compounds containing the monoanionic *N,N*-chelate β-diketiminato ligand, $[ArNC(Me)CHC(Me)NAr]^-$ (Ar = 2,6-*i*$Pr_2C_6H_3$, DDP). This ligand (DDP) and members of the general family, $[ArNC(R)CHC(R)NAr]^-$, have been the subject of intense interest in recent years and complexes incorporating early[7] and late[8] transition metals, main group metals[9] and lanthanides have been reported.[10] Their ease of preparation, facility for aryl (Ar) and R group variation and variability in bonding mode,[7c] are particularly attractive features.



DDP (Ar = 2,6-^{i}Pr$_2$C$_6$H$_3$, R = Me)

In independent studies, Theopold and this group have communicated chromium(III) (d^3) complexes supported by β-diketiminato ligands, albeit with different aryl groups, as olefin polymerisation catalysts.[6h,6i] Herein we report, as part of a general study of the olefin polymerisation capability of non-cyclopentadienyl-containing chromium complexes,[6b−6h] our findings on a range of DDP-supported chromium(II) and -(III) systems (Scheme 1).

Results and Discussion

The protonated β-diketiminato ligand, 2-[(2,6-diisopropylphenyl)amino]-4-[(2,6-diisopropylphenyl)imino]pent-2-ene (DDPH) was prepared using a method similar to that reported for related ligands[11] and more recently by Feldman for DDPH itself.[8b] The lithium salt of DDPH was prepared by addition of one equivalent of *n*BuLi to a THF solution of DDPH at −78 °C and used without isolation.

Addition of one equivalent of $CrCl_3(THF)_3$ to LiDDP in THF gave $[(DDP)CrCl(\mu\text{-}Cl)]_2$ (**1**) as a green solid in good yield upon workup (Scheme 1). Crystals of **1** suitable for an X-ray structure determination were grown from a concentrated pentane solution at −20 °C. The structure is dimeric

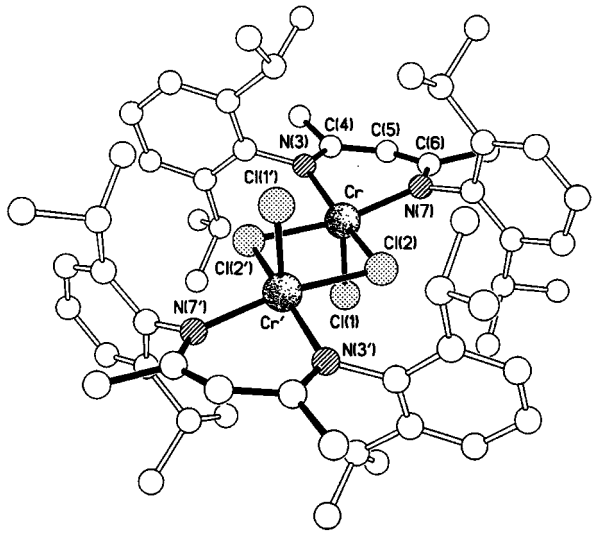

Figure 1. The molecular structure of **1**

(Figure 1) and has non-crystallographic C_{2h} symmetry about an axis passing through the two bridging chlorine atoms (the crystallographic symmetry is C_i). The geometry at chromium is distorted square pyramidal with the chromium atom being displaced by 0.35 Å out of the basal plane in the direction of Cl(1). Although the bridging Cr−Cl distances are identical within the errors of the structure determination, there is a marked asymmetry in the apical/basal Cr−Cl distances, with the apical bond being ca. 0.17 Å shorter than its basal counterparts (Table 1). The Cr−N distances are unexceptional. The nonbonded Cr···Cr separation (3.69 Å) is long, and extends outside the range found in a number of other chloride-bridged chromium(III) complexes.[12−15] This distance may in part be due to the steric repulsion between the bulky aryl ligands. The six-membered chelate ring has a boat conformation with the chromium and C(5) atoms lying 0.60 and 0.13 Å, respectively, out of the N(3)−C(4)−C(6)−N(7) plane (which is coplanar to within 0.01 Å). There is a pronounced pattern of delocalisation in the bond lengths of the N(3) to N(7) linkages. All four 2,6-diisopropylphenyl rings are oriented essentially orthogonally (84 and 87°) to their respective chelate C−N−Cr planes, a geometry that is stabilised by pairs of C−H···N(p_π) interactions[16] between N(3) and N(7) and their proximal isopropyl methine hydrogen atoms; the H···N distances are in the range 2.42 to 2.54 Å with associated C···N distances of between 2.89 and 3.00 Å. There are no intermolecular packing interactions of note.

It is noteworthy that substitution of the 2,6-diisopropylphenyl groups in DDP for phenyl groups results in a mononuclear six-coordinate chromium(III) dichloride complex in which the coordination sphere is completed by THF molecules.[6i] The preference of complexes coordinated by β-diketiminato ligands, with bulky groups on the 2,6-positions of the aryl substituents, to exhibit low coordination

[a] The two sets of values refer to the two crystallographically independent molecules.

numbers has also recently been observed by Budzelaar and co-workers.[8a]

The *N,N*-β-diketiminato chromium derivatives **2**−**5** have been prepared by in situ formation of **1** followed by treatment with the reagents shown in Scheme 1. The reaction with $AlMe_3$ affords a dark oily residue. Extraction of this residue into pentane and cooling to −20 °C gives crimson needles of [(DDP)CrMe(μ-Cl)]$_2$ (**2**) in good yield. A crystal prepared in this manner was used for a single crystal X-ray diffraction study. Complex **2** crystallises with two independent molecules in the asymmetric unit. Both have crystallographic C_{2h} symmetry and essentially identical conforma-

tions — the maximum deviation of the best fit of the two molecules (excluding the isopropyl methyl groups) is 0.08 Å. Replacement of the apical chloride in **1** by a methyl group to give **2** has virtually no effect on the geometry of **2**, the central core (including the two chelate rings) fitting to within 0.1 Å of that in **1**, though the Cr−N distances are noticeably increased by ca. 0.04 Å (Table 1). The Cr−Me distances in the two independent molecules are 2.037(7) and 2.042(8) Å. The displacement of the chromium atom out of the basal plane in the direction of the apical methyl group (ca. 0.25 Å) is noticeably less than that towards the chloride in **1**. The nonbonded Cr···Cr separation is slightly reduced (ca. 3.66 Å). Within the chelate ring Cr and C(2) lie 0.52 and 0.14 Å out of the N(3)−C(4)−C(6)−N(7) plane (see Figure 1) in one independent molecule and 0.55 and 0.15 Å, respectively, in the other. Each of the 2,6-diisopropylphenyl rings are rotated by ca. 85° out of their respective chelate C−N−Cr planes, a conformation again stabilised by pairs of C−H···N(p_π) interactions; the C···N distances are in the range 2.87 to 3.00 Å with associated H···N distances of between 2.40 and 2.52 Å. As with **1**, there are no noteworthy intermolecular packing interactions.

Attempted alkylation of **1** with benzyl Grignard reagent, however, results in the reduction of **1** to give [(DDP)Cr(μ-Cl)]$_2$ (**3**) as a green solid in high yield. Recrystallisation of this solid from THF gives **3(THF)$_2$·THF** while from pentane **3·Bz-Bz** is obtained. Single crystals of both forms of **3** were obtained by cooling the corresponding solutions to −20 °C overnight. The X-ray analysis showed **3(THF)$_2$·THF** to be structurally related to **2**, having crystallographic C_{2h} symmetry (Figure 2) but with the apical methyl ligand replaced by a weakly bound THF molecule [Cr−O(20) = 2.442(3) Å, Table 2] which is disordered about the mirror plane which passes through Cr, Cr′, O(20) and O(20′). The geometry at chromium is still square pyramidal with the chromium atom lying 0.13 Å out of the basal plane. The Cr−N distance [2.071(2) Å] is increased relative to that in **2** [av. 2.030 Å], although it still lies within the range observed for Cr−N bonds in the literature. The chelate rings retain a boat conformation with Cr and C(2) lying 0.43 and 0.12 Å, respectively, out of the N−C(1)−N′−C(1′) plane. The non-bonded Cr···Cr separation is 3.67 Å and lies at the top end of the range reported for chloride-bridged dichromium(II) complexes.[17,18] The 2,6-diisopropylphenyl rings are rotated by ca. 85° out of their respective chelate C−N−Cr planes, a conformation again stabilised by pairs of C−H···N(p_π) interactions; the C···N distances are in the range 2.91 to 2.94 Å with associated H···N distances of between 2.41 and 2.50 Å. There are no significant intermolecular close contacts between the complexes or the included THF solvent molecule.

In the structure of **3·Bz-Bz**, where there is an absence of apical substituents on the chromium centres, the geometry at chromium is square planar (Figure 3), although with a marked tetrahedral distortion, the N−N−Cr and Cr−Cl−Cl planes being inclined by 18°. The complex has crystallographic C_i symmetry and symmetric Cr−Cl bridges (Table 3). The Cr−N bond lengths are the same as

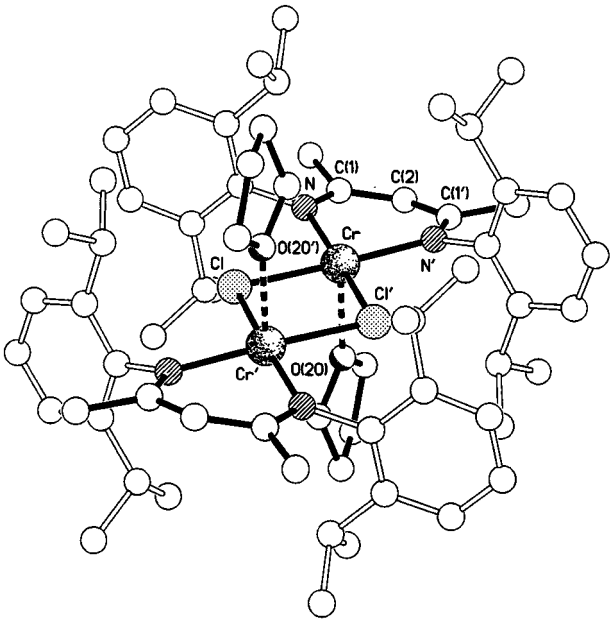

Figure 2. The molecular structure of the metal complex in **3(THF)$_2$·THF**

Table 2. Selected bond lengths (Å) and angles (°) for **3(THF)$_2$·THF**

Cr−Cl′	2.4182(6)	Cr−Cl	2.4182(6)

Cr−Cl−Cr′	98.79(3)		

in **2**. The non-bonded Cr···Cr separation here is 3.60 Å, noticeably shorter than in **1**, **2** and **3(THF)$_2$·THF**. The chelate ring, whilst still having a boat conformation, is distinctly flattened in comparison to **1**, **2** and **3(THF)$_2$·THF**, with Cr and C(3) lying 0.30 and 0.09 Å, respectively, out of the N(1)−C(2)−C(4)−N(5) plane. The 2,6-diisopropylphenyl rings are rotated by 85 and 88° out of their respective chelate C−N−Cr planes, with associated C−H···N(p_π) interactions (C···N distances in the range 2.87 to 2.92 Å, H···N distances between 2.39 and 2.50 Å). There are no notable intermolecular packing interactions involving either the complex or the co-crystallised dibenzyl molecules.

It is noteworthy that complex **3(THF)$_2$·THF** can also be prepared more directly by treating $CrCl_2$·THF with one equivalent of LiDDP in THF.

The pathway by which **3** is formed from **1** is uncertain. However, it would seem possible that benzylation of the apical *trans* sites in **1** occurs initially to give the benzyl analogue of **2** in a manner similar to the benzylation of [Cp*CrCl(μ-Cl)]$_2$,[13e] followed by isomerisation to the *cis* isomer and reductive coupling of benzyl groups to give **3** and di-

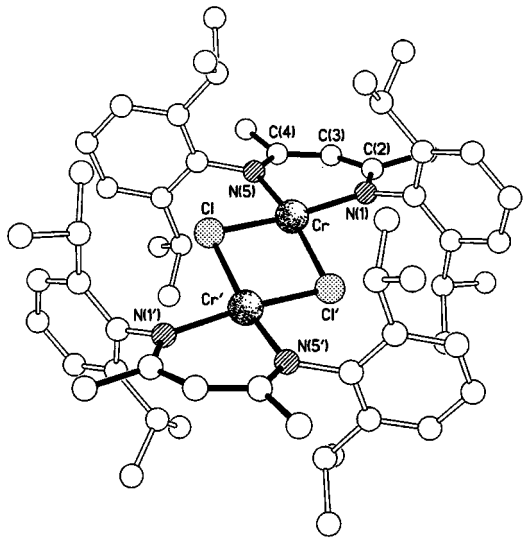

Figure 3. The molecular structure of the chromium-containing species in **3·Bz-Bz**

benzyl (Scheme 2). It is noteworthy that Theopold has recently postulated a related *trans-cis* isomerisation of the related complex $[Cp^*CrMe(\mu\text{-}Cl)]_2$.[13a] However, we cannot rule out Wurtz coupling occurring independently of the transition metal centre in a way that is often observed during the preparation of benzylic Grignard reagents.[19,20]

Whilst reaction of **1** with either $AlMe_3$ or BzMgCl results in preservation of the dimeric core, interaction with carboxylates or β-diketonates results in cleavage of the dimer to give discrete mononuclear chromium(III) complexes. For example, treatment of **1** with NaO_2CR (R = Me, Ph) at −78 °C gives the complexes [(DDP)CrCl(O_2CR)(THF)] (R = Me **4a**, Ph **4b**) in high yield. Both **4a** and **4b** can be recrystallised from a concentrated pentane solution at −20 °C. A single crystal of **4a** was subjected to an X-ray diffraction study. The structure of **4a** consists of an octahedral chromium centre with the oxygen atom of the THF ligand and one of the oxygen atoms of the acetate ligand in the same plane as the nitrogen atoms of the bidentate ligand; the remaining oxygen atom of the η^2-chelating acetate group occupies a site *trans* to the chloride ligand (Figure 4). The structure of **4a** thus resembles that of the less sterically demanding diphenyl β-diketiminato complex [{PhNC(Me)CHC(Me)NPh}$CrCl_2$-$(THF)_2$],[6i] with a THF and a chloride ligand effectively replaced by an acetate group. In **4a** the geometry at chromium is distorted with *cis* angles in the range 63.7(1) to 101.9(1)°, the acute angle being associated with the bite of the acetate ligand. The Cr−N distances (Table 4) are the same as in **2** and **3·BzBz**, and the Cr−Cl distance [2.295(1) Å] is similar to that to the terminal chloride in **1**. The Cr−O(THF) distance [2.119(3) Å] is consistent with the presence of a formal σ-bond, similar to that to the loosely associated apical ligand in **3(THF)$_2$·THF** [2.442(3) Å]. The six-membered chelate ring has a distinctive boat conformation with the chromium and C(3) lying 0.60 and 0.11 Å, respectively, out of the N(1)−C(2)−C(4)−N(5) plane. There are characteristic orthogonal orientations (83 and 87°) of the 2,6-diisopropylphenyl ring systems to the chelate ring. Stabilisation of this conformation is again by weak C−H···N(p_π) interactions (C···N distances in the range 2.89 to 2.98 Å, H···N distances between 2.41 and 2.50 Å). The packing is normal van der Waals.

Compound **4b** is presumed to possess a similar structure to **4a**. Unlike the reactions of **1** with carboxylates, treatment of **1** with the more sterically demanding β-diketonates, {CH[C(R)O]$_2$}$^-$ [R = Me (acac), Ph (dbm)], results in the five-coordinate complexes [(DDP)CrCl({O(R)C}$_2$CH)] (R = Me **5a**, Ph **5b**). Both **5a** and **5b** can be recrystallised from pentane at −20° C. Compound **5b** has been the subject of a single crystal X-ray diffraction study. This study shows **5b** to have a square pyramidal coordination geometry at chromium (Figure 5), with the basal sites occupied

O(36)−Cr−Cl	88.65(9)		

by the two η^2 ligands and the apical site by a chloride ligand. The metal atom lies 0.32 Å out of the basal plane (which is planar to within 0.002 Å) in the direction of the chloride ligand [Cr−Cl 2.229(1) Å]. The Cr−N distances (Table 5) are the same as in **2**, **3·Bz-Bz** and **4a**. The diketiminate chelate ring has, as in all the other complexes, a boat conformation with the chromium and C(3) lying 0.43 and 0.11 Å, respectively, out of the N(1)−C(2)−C(4)−N(5) plane. The Cr(dbm) chelate ring is much flatter, with the chromium and C(8) lying 0.23 and 0.02 Å, respectively, out of the O(6)−C(7)−C(9)−O(10) plane. The 2,6-diisopropylphenyl ring systems are, as usual, oriented orthogonally (83 and 86°) to the chelate ring, with C−H···N(p_π) stabilisation (C···N distances in the range 2.90 to 2.98 Å, H···N distances between 2.38 and 2.49 Å). In contrast, the planes of the two phenyl rings of the dbm ligand lie close to that of their chelate ring (twists of ca. 10 and 20°) and as a consequence direct one of their *ortho* C−H hydrogen atoms into the faces of their proximal 2,6-diisopropylphenyl rings of the diketiminate ligand; the H···π distances are short at 2.40 and 2.53 Å and have associated C−H···π angles of 168 and 160°, respectively. Accompanying this interaction is a noticeable contraction of both the O(6)−C(7)−C(42) and O(10)−C(9)−C(48) angles [115.8(3) and 116.2(3)°, respectively], and to a lesser extent also those for C(7)−C(42)−C(37) and C(9)−C(48)−C(47) [117.3(2) and 118.0(2)°, respectively], from normal trigonal values. These interactions are directly analogous to those present between the *ortho* hydrogen atoms of a dbm ligand coordinated to iridium and the phenyl rings of a pair of triphenylphosphane ligands coordinated to the same metal centre.[21] There are no packing interactions of note.

Examples of mononuclear five-coordinate Cr^{III} complexes are rare, due to the significant ligand-field stabilisation of the d^3 configuration in an octahedral geometry.[20] **5a** is presumed to possess a similar structure to **5b**.

All the complexes are paramagnetic, affording broad uninformative ^{1}H NMR spectra. The mononuclear complexes **4** and **5** exhibit magnetic moments between 3.8 and 4.1 BM (Evans Balance at ambient temperature) consistent with three unpaired electrons (d^3) while the dimeric chromium(III) complexes **1** and **2** display magnetic moments of 3.5 and 3.6 BM characteristic of antiferromagnetically coupled $S = 3/2$ chromium(III) centres.[7f,23] In addition, the X-band EPR spectra of all the Cr^{III} complexes in toluene at ambient temperature all support the complexes being assigned Cr^{III} with sharp signals corresponding to g values of ca. 1.98 with no observable hyperfine coupling.[24]

The FAB mass spectra of the mononuclear complexes **4** and **5** give molecular ion peaks and/or peaks corresponding

to fragmentation peaks. For the dimeric complexes **1**−**3** fragmentation of the dinuclear unit must readily occur in the instrument as only peaks attributable to mononuclear fragments are observed. This observation is consistent with the ready cleavage of the dimeric assembly in the presence of carboxylates or β-diketonates (see complexes **4** and **5**) leading to the prospect that **1**−**3** can be regarded as loosely associated monomers.

The results of Schlenk-scale ethylene polymerisation screening tests at 1 bar/25 °C using dual-component catalyst systems (**1**−**5** + cocatalyst) are collected in Table 6. Three types of aluminium co-catalyst have been employed to activate pre-catalysts **1**−**5**, namely methylaluminoxane (MAO), diethylaluminium chloride (DEAC) and dimethylaluminium chloride (DMAC) (see Table 6; runs 1−19). The results reported in Table 6 were reproduced several times, though not optimised beyond the conditions reported.

Table 6. Results of ethylene polymerisation runs using precatalysts **1**−**5**[a]

Run	Precatalyst (mmol)	Activator[b] (mmol/ equiv.)	Yield PE (g)[c]	Activity (g/mmol·h·bar)

[a] *General conditions*: 1 bar ethylene Schlenk test carried out in toluene (40 mL) at 25 °C, over 60 min., reaction quenched with dil HCl and the solid washed with methanol (50 cm^3) and dried in a vacuum oven at 40 °C. – [b] MAO = methylaluminoxane. – [c] Solid polyethylene. – [d] Activity reported per chromium centre. – [e] As a representative example, GPC analysis of the polyethylene afforded M_w = 925000, M_n = 110000, M_w/M_n = 8.4. Care should be taken in the interpretation of these values, however, since, in general, the polymers derived from these polymerizations are not fully soluble in the 1,2,4-trichlorobenzene GPC solvent, even upon heating at 160 °C for several hours.

On analysis of Table 6 several points emerge. Firstly, all DDP-supported chromium complexes are active in the presence of alkylaluminum activator, converting ethylene to high molecular weight polyethylene. In no case has polyethylene been obtained using **1**−**5** in the absence of an aluminium activator, nor has there been any evidence for low molecular weight oligomers (by GCMS). Secondly, the most active systems (runs 9 and 13) comprise a combination of one equivalent of chromium complex to thirty equivalents of alkylaluminium chloride activator. We have found that activities start to fall with a greater or lower concentration of activator. Notably, MAO (400 equiv.) results in lower activities (runs 1, 3, 5, 8, 11, 14, 17). Thirdly, the similar activities [*cf.* 75 (run 2), 72 g/mmol·h·bar (run 6)] observed employing the DDP-supported Cr^{III}- and Cr^{II}-chloride complexes **1** and **3**, and the purple colour of the active catalyst (in both cases), suggest a common active species.

The mechanism by which these dual component systems operate is uncertain. The fact that the most active systems combine an alkylaluminium chloride rather than MAO rather suggests that alkyl abstraction to form a cationic species is not occurring here. This may account for the generally lower activities observed by comparison with the Cp-amine systems reported by Jolly where a cationic active centre is believed to operate. The identity of the active oxidation state is uncertain but the similarity in productivities and reactivity involving the Cr^{II} and Cr^{III} complexes **1** and **3**, coupled with the ready reduction of **1** on benzylation, lends some support for a Cr^{II} species.

Conclusions

The chemistry of the sterically demanding β-diketiminato ligand DDP on low valent chromium has been explored. Complexation of DDP with $CrCl_3(THF)_3$ leads to a readily derivatisable coordinatively unsaturated dimeric species **1**. Preservation of the dimeric core occurs on alkylation or reduction of **1**, while addition of chelating carboxylate or β-diketonate ligands to **1** causes fragmentation to give discrete mononuclear complexes. Notably, only in the case of **4** is the more common octahedral geometry of Cr^{III} achieved. All the complexes polymerise ethylene on addition of aluminium activators to give high molecular weight polyethylene.

Experimental Section

General: All manipulations were carried out under an atmosphere of nitrogen using standard Schlenk and cannula techniques or in a conventional nitrogen-filled glove-box. Solvents were refluxed over an appropriate drying agent, and distilled and degassed prior to use. Elemental analyses were performed by the microanalytical services of the Department of Chemistry at Imperial College and Medac Ltd. NMR spectra were recorded on a Bruker spectrometer at 250 MHz (^1H) and 62.9 MHz (^{13}C) at room temperature; chemical shifts are referenced to the residual protonated impurity of the deuterated solvent. IR spectra (nujol mulls, KBr/CsI windows) were recorded on Perkin−Elmer 577 and 457 grating spectrophotometers. Mass spectra were obtained using fast atom bombardment (FAB). Gel permeation chromatographs (GPC) were obtained using a Waters 150CV [columns are supplied by Shodex (807, 806 & 804) BP Chemicals Ltd.]. Magnetic Susceptibility studies were performed using an Evans Balance at room temperature. Diamagnetic corrections for the samples were determined from Pascal's constants and literature values.[25]

$CrCl_3(THF)_3$ [26] and DDPH[8b] were prepared according to the established procedures. The reagents $AlMe_3$ (2.0 M solution in toluene), Et_2AlCl (1.8 M solution in toluene), Me_2AlCl (1.0 M solution in hexane), MAO (10% solution in toluene) and BzMgCl (2.0 M solution in THF) were purchased from Aldrich Chemical Co. All other chemicals were obtained commercially and used as received unless stated otherwise.

Preparation of [(DDP)CrCl(μ-Cl)]$_2$ (1): $CrCl_3(THF)_3$ (1.00 g, 2.67 mmol) was loaded into a Schlenk flask containing one equivalent of the lithium salt of DDPH (1.13 g, 2.67 mol) in THF (40 mL) at −78 °C. The solution was stirred overnight at room temperature giving an olive green solution. The volatiles were removed under reduced pressure and pentane (50 mL) added. Filtration of the lithium salts gave the crude product which was recrystallised by standing at −20 °C overnight to give **1** (1.08 g, 75%). FAB-MS: m/z = 504 [$M^+/2$]. − $C_{58}H_{82}Cl_4Cr_2N_4$ (1081.1): calcd. C 64.44, H 7.59, N 5.19; found C 64.65, H 7.81, N 5.41. − μ_{eff} = 3.60 BM.

Preparation of [(DDP)CrMe(μ-Cl)]$_2$ (2): A THF (40 mL) solution of **1** was formed as above by stirring $CrCl_3(THF)_3$ (1.00 g, 2.67 mmol) and LiDDP (1.13 g, 2.67 mol) together overnight. $AlMe_3$ (2.5 mL, 5.0 mmol) was introduced to the green solution with a syringe at room temperature. After stirring overnight the solution was taken to dryness to give a dark oily residue. Extraction with pentane (60 mL) followed by filtration gave a dark purple solution. Concentration of the solution to half volume and standing at −20 °C gave **2** as crimson needles (0.94 g, 68%). FAB-MS: m/z = 469 [$M^+/2$ − Me − Cl]. − $C_{60}H_{88}Cl_2Cr_2N_4$ (1040.3): calcd. C 69.30, H 8.47, N 5.39; found C 69.41, H 8.81, N 5.82. − μ_{eff} = 3.50 BM.

Preparation of [(DDP)Cr(μ-Cl)]$_2$ (3): A THF (40 mL) solution of **1** was formed as above by stirring $CrCl_3(THF)_3$ (1.00 g, 2.67 mmol) and LiDDP (1.13 g, 2.67 mol) together overnight. Benzylmagnesium chloride (2.67 mL, 5.34 mmol) was added to the green solution at −78 °C with a syringe and the solution allowed to warm to room temperature to give an apple green solution. Dioxane (2 mL) was added to the solution after 12 h, stirred for a further 2 h and filtered to give an apple green solution. The complex **3(THF)$_2$·THF** (1.09 g, 71%) could be isolated as lime green crystals by cooling the apple green THF/dioxane solution to −20 °C. Alternatively, **3·Bz-Bz** (1.03 g, 65%) could be isolated as green crystals by stripping the volatiles from the reaction mixture and extracting the residue with pentane and cooling the solution to −20 °C.

3(THF)$_2$·THF: $C_{66}H_{98}Cl_2Cr_2N_4O_2$ (1154.4): calcd. C 68.69, H 8.50, N 4.86; found C 68.81, H 8.70, N 4.69. − FAB-MS: m/z = 469 [$M^+/2$ − Cl − THF].

3·Bz-Bz: $C_{72}H_{96}Cl_2Cr_2N_4$ (1192.5): calcd. C 72.54, H 8.06, N 4.70; found C 72.71, H 8.34, N 4.69. − FAB-MS: m/z = 469 [$M^+/2$ − Cl − $C_6H_5CH_2$].

Preparation of [(DDP)CrCl(O$_2$CR)(THF)] (R = Me 4a, Ph 4b): To a THF (40 mL) solution of the lithium salt of DDPH (1.13 g, 2.67 mmol) at −78 °C was added $CrCl_3(THF)_3$ (1.00 g, 2.67 mmol). The solution was allowed to warm to room temperature and stirred for 3 h before the addition of sodium acetate (0.22 g, 2.67 mmol) or sodium benzoate (0.38 g, 2.67 mmol) at −78 °C. The solutions were allowed to warm to room temperature and stirred for a further 12 h. After removal of the solvent under reduced pressure, pentane (60 mL) was introduced and the lithium salts filtered. Concentration of the filtrates to half volume and cooling to −20 °C overnight gave **4a** (0.68 g, 45%) and **4b** (0.85 g, 49%) as green crystals.

4a: FAB-MS: m/z = 563 [M^+ − THF], 528 [M^+ − Cl − THF], 467 [M^+ − Cl − THF − O_2CMe]. − $C_{35}H_{52}ClN_2O_2$ (568.26): calcd. C 66.09, H 8.18, N 4.41; found C 66.12, H 8.41, N 4.29. − μ_{eff} = 3.80 BM.

4b: FAB-MS: m/z = 696 [M^+], 590 [M^+ − Cl − THF], 467 [M^+ − Cl − THF − O_2CPh]. − $C_{40}H_{54}ClCrN_2$ (650.33): calcd. C 68.82, H 7.74, N 4.01; found C 68.91, H 7.89, N 3.98. − μ_{eff} = 3.74 BM.

Preparation of [(DDP)CrCl({O(R)C}$_2$CH)] (R = Me 5a, Ph 5b): To a THF (40 mL) solution of the lithium salt of DDPH (1.13 g, 2.67 mmol) at −78 °C was added $CrCl_3(THF)_3$ (1.00 g, 2.67 mmol). The solution was allowed to warm to room temperature and stirred for 3 h before the addition of the lithium salts of either 2,4-pentanedione (0.28 g, 2.67 mmol) or dibenzoylmethane (0.61 g, 2.67 mmol) at −78 °C. The solutions were allowed to warm to room temperature and stirred for a further 12 h. After removal of the solvent under reduced pressure pentane (60 mL) was introduced and the lithium salts filtered. Concentration of the filtrates to half volume and cooling to −20 °C overnight gave **5a** (0.72 g, 45%) and **5b** (0.99 g, 51%) as red crystals.

5a: FAB-MS: m/z = 568 [M^+ − Cl], 419 [M^+ − Cl − {O(Me)C}$_2$CH − Cr]. − $C_{34}H_{48}ClCrN_2O_2$ (604.21): calcd. C 67.61, H 7.95, N 4.64; found C 67.30, H 8.01, N 4.44. − μ_{eff} = 4.06 BM.

5b: FAB-MS: m/z = 692 [M^+ − Cl], 419 [M^+ − Cl − {O(Ph)C}$_2$CH − Cr]. − $C_{44}H_{52}ClCrN_2O_2$ (728.36): calcd. C 72.58, H 7.15, N 3.85; found C 73.71, H 6.99, N 3.78. − μ_{eff} = 3.80 BM.

Polymerisation Procedure: Results of Schlenk-line tests (1 bar) are listed in Table 6; the polymerisation procedure is as follows: The precatalyst (0.01−0.015 mmol of **1**−**5**) was dissolved in toluene (40 mL) and the co-catalyst (MAO, DEAC or DMAC) added. The Schlenk tube was purged with ethylene and the contents magnetically stirred and maintained under ethylene (1 bar) for the duration of the polymerisation. After 1 h the polymerisation was terminated by the addition of dil. HCl/MeOH. The solid polyethylene was recovered by filtration, washed with methanol (50 mL) and dried (vacuum oven at 50 °C).

X-ray Crystal Structure Determinations of 1, 2, 3(THF)$_2$.THF, 3·Bz-Bz, 4a, and 5b: Table 7 provides a summary of the crystal data, data collection, and refinement parameters for compounds **1**, **2**, **3(THF)$_2$·THF**, **3·Bz-Bz**, **4a** and **5b**.

The structures were solved by direct methods, and the major occupancy non-hydrogen atoms were refined anisotropically using full-matrix, least-squares based on F^2. In **1**, **2**, **3(THF)$_2$·THF** and **4a** disorder was found in the solvent molecules; in each case two partial occupancy orientations were identified with, in **1**, **3(THF)$_2$·THF** and **4a**, the major occupancy non-hydrogen atoms refined anisotropically and the minor occupancy non-hydrogen atoms refined isotropically, and in **2** all the disordered non-hydrogen atoms refined anisotropically. Throughout all six structures the C−H hydrogen atoms of methyl groups bound to sp^2 centres were located from ΔF maps, idealised, assigned isotropic thermal parameters [U(H) = 1.5U_{eq}(C)] and allowed to ride on their parent atoms. The remaining hydrogen atoms were placed in calculated positions, assigned isotropic thermal parameters [U(H) = 1.2U_{eq}(C); U(H) = 1.5U_{eq}(C-Me)], and allowed to ride on their parent atoms. All computations were carried out using the SHELXTL PC program system.[27]

Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no's: CCDC-150447−150452 for structures **1**−**5b**, respectively (Table 7). Copies of the data can be obtained free of charge on application to CCCD, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-1223/336-033: E-mail: deposit@ccdc.cam.ac.uk].

Palladacycles − An Old Organometallic Family Revisited: New, Simple, and Efficient Catalyst Precursors for Homogeneous Catalysis

Jairton Dupont,[a] Michel Pfeffer,*[b] and John Spencer[c]

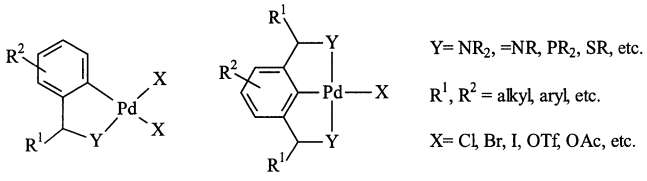
Dedicated to the memory of Professor John Osborn

Keywords: Metallacycles / Palladium / Homogeneous catalysis / C−C coupling / Hydrogenations

Nitrogen-, phosphorus-, and sulfur-containing palladacycles, typically containing four- or six-electron donor anionic metallated ligands, are emerging as a new family of organometallic catalyst precursors. These thermally and air-stable complexes are easy to handle and their synthesis is often straightforward. Palladacycles are now being successfully exploited in catalytic reactions ranging from classical hydrogenations to enantioselective aldol-type condensations. The main recent achievements pertaining to their use in homogeneous organometallic catalysis are outlined herein.

Introduction

Palladacycles are a popular and thoroughly investigated class of organopalladium compounds. The vast majority of these complexes possess anionic four-electron (bidentate) or six-electron (tridentate) donor ligands, with five-membered nitrogen-containing rings being the most common (Scheme 1).[1] Such systems have been known since the 1960s.[2]



Scheme 1. Examples of palladacycles

Their synthesis is facile and it is possible to modulate their electronic and steric properties simply by changing (i) the size of the metallacyclic ring (3−10 membered), (ii) the

Jairton Dupont was born in 1958 in Farroupilha (Brazil). He studied chemistry at the PUCRS (Brazil) and received his Ph.D. in 1988 under the guidance of Dr. M. Pfeffer at the Université Louis Pasteur in Strasbourg. After a postdoctoral position (1988−1990) with Prof. S. G. Davies at the Dyson Perrins Laboratory, University of Oxford (U.K.), he began to work as a visiting scientist (1990−1992) at the Institute of Chemistry, UFRGS (Brazil). In 1992, he became a Professor of Organic Chemistry at the same Institute. His research interests are centered around synthetic organometallic chemistry with a special emphasis on homogeneous catalysis in biphasic media. He is the author of around 60 scientific publications and 7 patents.

Michel Pfeffer was educated at the University of Strasbourg, where he obtained his Ph.D. in 1975 in the Laboratoire de Chimie de Coordination with Prof. Jean Dehand. He then spent one year with Prof. F. G. A. Stone at the University of Bristol as a postdoctoral student. Since 1973, he has held a position in the CNRS at the UniversitéLouis Pasteur in Strasbourg, where he became Directeur de recherche in 1985. His current research interests lie at the interface of inorganic, organometallic, and organic chemistry, with an emphasis on metal-mediated functionalization of C−H bonds through reactions aimed at producing new carbon−carbon or carbon−heteroatom bonds.

John Spencer obtained a B.Sc. (1st class, Hon.) at Sussex University in Chemistry with European Studies in 1990 before studying for a Ph.D. under the supervision of Michel Pfeffer, Strasbourg (1990−1994). After a postdoctoral stay with Antonio Togni at the ETH, Zurich, he returned to England where he first worked in the pharmaceutical industry (Xenova, Cerebrus). He then took up his current position at the Thrombosis Research Institute (London), where he is now a Senior Research Scientist. He is a co-author of over a dozen papers and patents and his research interests include organopalladium and organoboron chemistry, as well as asymmetric catalysis.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

nature of the metallated carbon atom (aliphatic, aromatic, vinylic, etc.), (iii) the type of donor group (N-, P-, S-, O-containing group, etc.) and its substituents (alkyl, aryl, etc.), or (iv) the nature of the X ligands (halide, triflate, or solvent, e.g. THF, H_2O). These factors determine whether the complex is dimeric, monomeric, neutral, or cationic. This flexibility confers a plethora of potential applications upon this class of compounds.

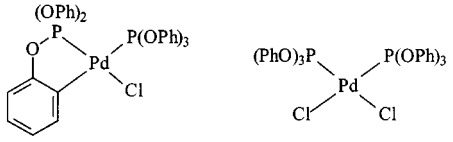
In the following applications, palladacycles can be further subdivided into two classes of compounds: one in which the Pd−C bond remains intact, i.e. the cyclopalladated unit is used as an ancillary ligand, and a second class where the palladated carbon atom is functionalized (mainly for organic synthesis). Indeed, these complexes have been used as intermediates for organic synthesis,[3] as new materials[4] (in liquid crystals, nonlinear optics, etc.), in bioorganometallic chemistry,[5] and, much more recently, they have undergone a renaissance as a result of their increasingly impressive applications in organometallic homogeneous catalysis.

The catalytic properties of cyclopalladated complexes were investigated more than a decade ago,[6] although previous reviews have tended to focus on the synthesis of palladacycles and their applications in mainly stoichiometric processes with scant progress being achieved in the area of catalytic applications. It is only recently that the true potential of palladacycles in organometallic catalysis has been recognized. There are two intriguing aspects regarding this last point: (i) the Pd−C bond in the majority of palladacycles is reactive towards a wide range of nucleophilic and electrophilic reagents exploited in catalysis, and (ii) the palladacycle can often be recovered unchanged following catalysis and can sometimes even be recycled. Mechanistic studies aimed at ascertaining the actual role of the palladium atom in these catalytic systems are a matter of intense current discussion since, besides the classical Pd^0/Pd^{II} catalytic cycles, several studies are now pointing to the involvement of Pd^{II}/Pd^{IV} cycles. However, no definitive argument in favour of one or other of these hypotheses has yet been presented.

Palladacycles are now emerging as a new family of catalyst precursors for a host of reactions. These derivatives easily fall into the current paradigm for homogeneous catalysis; they are often easily prepared in high yields through a C−H activation process, are often air- and moisture-stable, and, once catalytically active (usually above 100 °C), can attain high turnover numbers (TONs). Their applications in mainly Heck-type reactions were recently reviewed by Herrmann and co-workers;[7] this review covered complexes derived from the palladation of tris(*o*-tolylphosphane) developed in their laboratory. However, as already mentioned, palladacycles offer a much wider variety of catalytic applications and several new and efficient complexes based on different ligand backbones have since been reported. This brief overview will concentrate on recent examples involving the use of genuine, well-characterized palladacycles as catalyst precursors, in particular for catalytic C−C bond-forming reactions.

Hydrogenations

The use of palladacycles as catalyst precursors for hydrogenations represents one of the first applications of this class of compounds in catalysis. It was demonstrated that cyclopalladated triphenyl phosphite was effective in promoting the hydrogenation of C=C bonds, whereas its non-*ortho*-palladated analogue decomposed under the catalytic conditions and did not promote the reduction reaction (Scheme 2).[6]



Scheme 2. Palladated and nonpalladated triphenyl phosphite ligands

The presence of a Pd−C bond in hydrogenation catalyst precursors, derived from the *ortho*-palladation of azobenzenes, hydrazobenzenes, or *N*,*N*-dimethylbenzylamine, was also found to be essential to effectively promote the selective reduction of nitroaromatic compounds, nitroalkenes, nitriles, alkynes, alkenes, and aromatic carbonyl compounds.[8] Surprisingly, however, despite the report of these very promising results, the use of palladacycles in reduction processes has not been further explored.

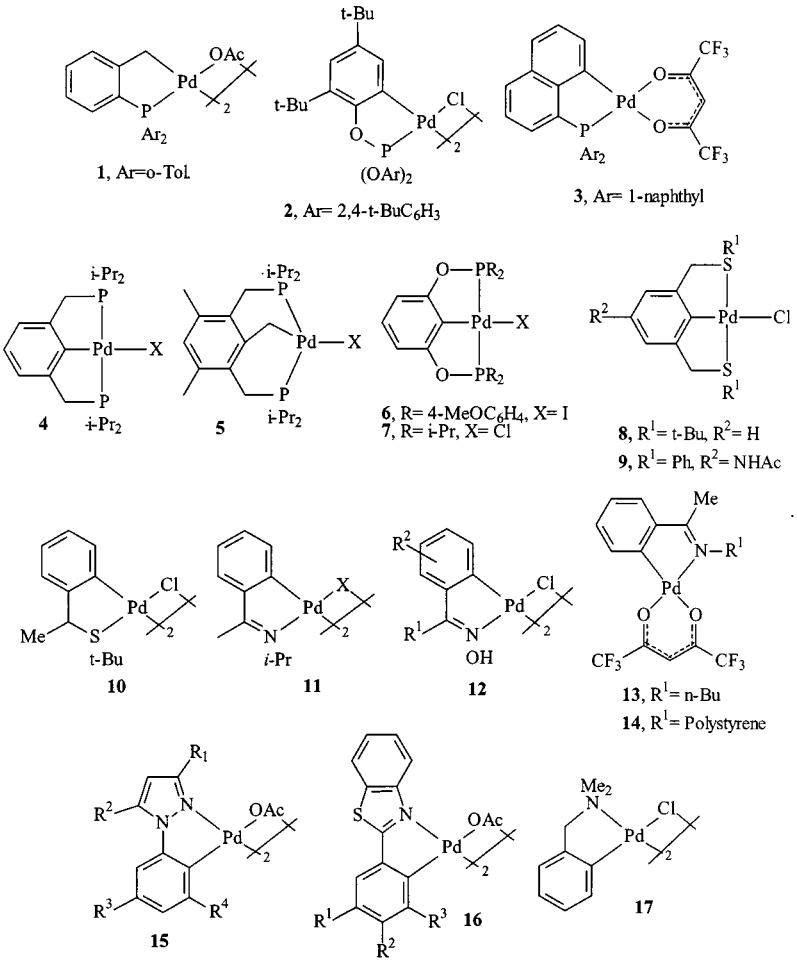
Heck Coupling Reactions

The arylation of C=C double bonds (Heck reaction)[9] is mediated by a variety of Pd^{II} and Pd^0 catalyst precursors (Scheme 3).

Scheme 3. Heck coupling reaction

In this context, phosphorus-,[7,10−21] nitrogen-,[22−27] and sulfur-containing[28−30] palladacycles are among the most active catalyst precursors for the promotion of such reactions reported to date (Scheme 4).

All of the palladacycles shown in Scheme 4 promote the Heck reaction of aryl iodides with acrylic esters (Table 1). In this reaction, the highest catalytic activity observed to date was achieved with the palladacycle **6** (Table 1, Entry 9). It is interesting to note that this palladacycle only promotes the Heck reaction between aryl iodides and acrylic esters. However, it should be pointed out that almost any Pd^{II} or Pd^0 derivative, irrespective of whether it is associated with stabilizing ligands, is capable of promoting Heck reactions involving aryl iodides or aryl bromides substituted with electron-withdrawing groups. In contrast, only a few palladacycles are active catalyst precursors for electron-rich aryl bromides (Table 1). Moreover, in the case of aryl chlorides, complexes **1**, **7**, **8**, and **11** were found to be the only active palladacycles (Entries 23−30, Table 1). In particular, **7** promotes the Heck reaction of electron-rich aryl chlorides, such as 4-chloroanisole (Entry 29, Table 1).[21]



Scheme 4. Palladacyclic catalyst precursors for the Heck reaction

It was recently demonstrated that cationic derivatives of binuclear conjugated palladacycles (Scheme 5) are also highly active catalyst precursors for the Heck reaction of iodobenzene with styrene or methyl acrylate.[31]

Palladacycles can also be involved in recyclable catalytic systems, e.g. by running the reaction of phosphapalladacycle **1**[32,33] in ionic liquids,[34] or by employing the polyethylene glycol bound sulfur-containing palladacycle **9**[28] or the polystyrene-bound imine-containing palladacycle (see later).[26] Moreover, trifluoroacetate-bridged derivatives of **1** have been shown to catalyse Heck reactions in supercritical carbon dioxide.[35,36]

Palladacycle **1** has also been successfully used as a catalyst precursor for an intramolecular Heck-type reaction generating six-membered ring D analogues of the pentacyclic alkaloid cephalotaxine in high yields (Scheme 6).[37]

Benzothiazole palladacycles such as **16** have been used as catalysts in a three-component cascade process (Scheme 7) yielding 1-substituted styrenes in high yields (82−92%) under relatively mild reaction conditions (80 °C, 10 h).[27]

Optically active sulfur-containing palladacycle **10** promotes the arylation of 3,4-dihydro-2*H*-pyran under mild reaction conditions, albeit without any asymmetric induction (Scheme 8). This suggests that the palladacyclic moiety is probably not present in the catalytically active species.[38]

It is often assumed that the mechanism[39] of the Heck reaction involves the in situ generation of a Pd^0 species, which undergoes oxidative addition of the aryl halide yielding a Pd^{II}−aryl intermediate. Coordination of the olefin and its migratory insertion into the Pd−aryl bond leads to a Pd^{II}−alkyl complex. β-Hydrogen elimination affords the arylated olefin and a Pd−H species, which, through reductive elimination, regenerates the Pd^0 catalytically active species.[9]

The cyclopalladated moiety could sometimes be isolated unchanged after catalysis and in certain cases it was recycled.[22,28] It has also been observed that the Pd−C bond of these palladacycles is usually unreactive towards C=C units. Hence, no reduction of Pd^{II} to Pd^0 should occur through, for instance, a reductive elimination of HX following the β-elimination process of the cyclopalladated ligand coupled with the olefin. Moreover, since in most of these cases no formation of metallic palladium was noted, an alternative mechanism involving Pd^{II}/Pd^{IV} has recently been proposed by Shaw[19] and has been adapted for phosphorus-containing palladacycles such as **7**.[21] The key step in this mechanism is a reversible nucleophilic attack on the Pd^{II}−olefin complex by acetate or halide anions generating an electron-rich Pd^{II} species, which then undergoes oxidative addition of the aryl halide. Loss of the nucleophile fol-

lowed by migratory insertion of the thus generated C=C bond into the Pd^{IV}–aryl bond, β-hydrogen elimination, and reductive elimination of HX then produces the arylated olefin and regenerates the Pd^{II} catalyst. However, one important feature disfavouring this suggestion is the lack of precedence for observing the oxidative addition of aryl halides to Pd^{II} as compared to the now well-known oxidative addition of alkyl halides to organopalladium(II) species.[40] Nevertheless, it would seem that a Pd^{IV} intermediate has recently been isolated in the arylation of norbornene (see later).[41] In the case of palladacycles of type **1**, Herrmann et al. have suggested that they constitute a reservoir of highly active Pd^0 species, which are generated by heterolytic cleavage of the Pd–C bond with subsequent reduction to Pd^0.[7] Very recently, in the case of cyclopalladated imine complexes such as **13** and **14** (Scheme 4), the involvement of Pd^0 nanoparticles originating from the immobilized palladacycles has been proposed.[26] It is unclear as to which mechanism is the most likely to be operative. Further studies to strengthen one or other of the proposals are still required.

Suzuki and Stille Cross-Coupling Reactions

The cross-coupling of aryl halides with organoboron compounds (Suzuki cross-coupling reaction)[42] or or-

ganotin compounds (Stille cross-coupling reaction)[43] is mediated by a variety of palladium catalyst precursors, the latter usually bearing phosphane ligands.

Suzuki and Stille cross-couplings have only been investigated with a few palladacycles (Table 2).

Table 2. Suzuki and Stille cross-couplings catalysed by palladacycles (ArX + PhM → ArPh + MX)

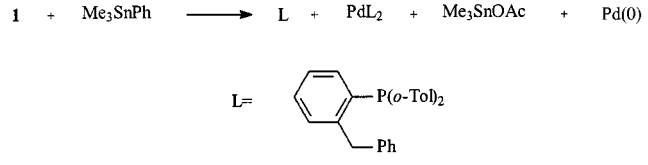
Phospha- and nitrogen-palladacycles effectively promote the Suzuki cross-coupling of aryl bromides, albeit only at elevated temperatures (100−130 °C). It is important to note that $Pd(OAc)_2$ has also been shown to catalyse the Suzuki cross-coupling reaction of aryl bromides with high turnovers, and consequently these substrates (in particular 4-bromoacetophenone) are not useful benchmarks for testing new catalysts in Suzuki couplings.[46] Palladacycle **12** was only tested in the coupling of 4-bromoacetophenone with phenylboronic acid at 110 °C.[24] However, sulfur-containing palladacycles catalyse these couplings at room temperature (see Table 2, Entries 10 and 12) and, moreover, they also promote the reaction of less reactive aryl chlorides, although higher reaction temperatures are required in the latter cases. This system represents the most effective phosphane-free catalyst system for the room temperature Suzuki cross-coupling reported to date.[47]

Mechanistic insights into the Stille coupling have been obtained by monitoring the reaction of palladacycle **1** with Me_3SnPh by NMR spectroscopy. The investigators observed the formation of free and palladium-ligated arylated phosphane and P(*o*Tol)$_3$ ligands (Scheme 9).[37]

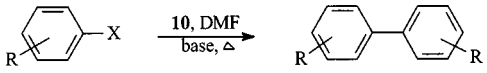


Scheme 9. The formation of Pd^0 catalytically active species

These observations suggested that the catalytically active species in the Stille and Suzuki couplings possess either P(*o*-Tol)$_3$ or modified PAr(*o*Tol)$_2$ ligands, or a combination of the two, associated with Pd^0. In these cases, the palladacycle may act as a reservoir of catalytically active Pd^0 species.

Phosphapalladacycle **1** has also been shown to catalyse the coupling of functionalized bromoarenes to a polystyrene-bound aryl tributylstannane. This reaction provides a convenient method for the synthesis of several biaryl compounds on resins.[48]

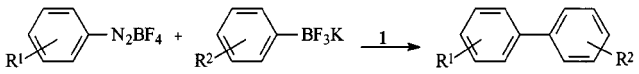
The phosphapalladacycle **1** is also an effective catalyst precursor for other coupling reactions, such as Grignard and Negishi-type protocols.[7] Very recently, it was reported that cyclopalladated oximes such as **12** also promote the Ullmann homo-coupling reaction of 4-iodo- and 4-bromoacetophenone with modest TONs (up to 50).[24] In contrast, sulfur-containing palladacycles such as **10** (Scheme 4) efficiently catalyse the homo-coupling of various aryl iodides and bromides in high yields (> 90%, Scheme 10).[49]



R= H, Me, COMe, OMe, NO_2, etc.; X= Br, I.

Scheme 10. Ullmann homo-coupling promoted by palladacycle **10**

Palladacycle **1** has been shown to be one of the most efficient of the classical Pd catalysts for a Suzuki-like reaction between Ar−N_2BF_4 and Ar′−BF_3K affording the expected biphenyl Ar−Ar′ as a result of a cross-coupling (Scheme 11).[50]

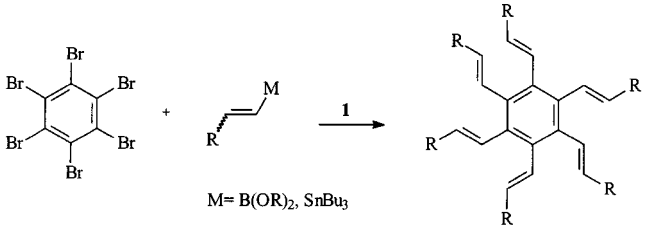


Scheme 11. Cross-coupling of organotrifluoroborates

The catalyst is usually active at low concentrations (0.1%) and the reactions proved successful with substrates bearing either electron-withdrawing or electron-donating substituents. The same catalyst was also effectively used in the formation of styrene and stilbene derivatives by the reac-

tions of $Ar-N_2BF_4$ with vinyl and styryl trifluoroborates, respectively.

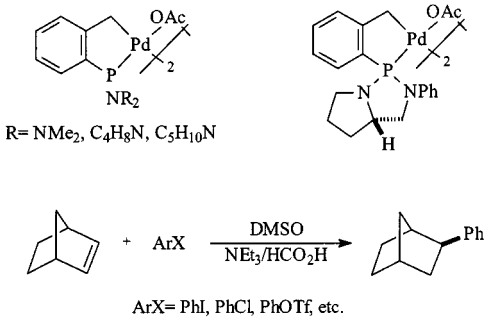
Palladacycle **1** was also used in the sixfold alkenylation of hexabromobenzene through Suzuki and Stille couplings (Scheme 12), generating hexakis(3,3-dimethyl-1-butenyl)-benzene in good yields.[51]



Scheme 12. Sixfold coupling of hexabromobenzene catalysed by palladacycle **1**

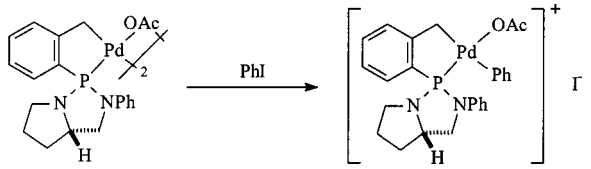
Hydroarylation of Olefins

Cyclopalladated aminophosphane-based ligand systems (Scheme 13) are highly efficient catalysts for the hydroarylation of norbornene, giving rise to exceptionally high TONs. Indeed, the latter can reach an incredible and unprecedented 10^{10}, corresponding to a catalyst loading of as little as 5×10^{-9} mol-%.[41,52]



Scheme 13. Hydroarylation of norbornene catalysed by a phosphapalladacycle

An enantioselective variant has been developed, giving modest *ee* values (up to 25%) in the hydroarylation of norbornene with phenyl triflate.[41] By treating the phosphapalladacycle with iodobenzene, the authors isolated a rather strange organopalladium species (Scheme 14).

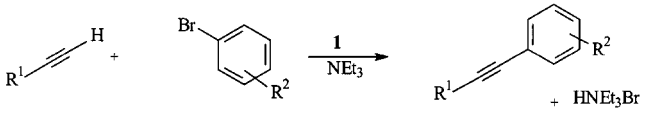


Scheme 14. The formation of a Pd^{IV} intermediate

Its crystal structure suggested the presence of a cationic tetracoordinate Pd^{IV} species having an iodide as a counterion. Although no details have been given concerning the behaviour of this product, confirmation of this preliminary result would provide a strong argument for the existence of a $Pd^{II}-Pd^{IV}$ pathway in, for example, the Heck reaction.

Sonogashira Reaction

The palladium-catalysed coupling of aryl iodides and bromides with terminal alkynes is a well-established method for the preparation of disubstituted alkynes (Scheme 15).[53] A wide variety of palladium catalyst precursors efficiently promote this reaction, usually in the presence of CuI as a co-catalyst. Not surprisingly, phosphorus-,[54] nitrogen-,[23] and sulfur-containing [55] palladacycles mediate this coupling reaction. However, in the case of palladacycle **1**, the reaction is catalysed in the absence of a co-catalyst and using a very low catalyst loading. Turnover numbers up to 8000 have been reported in the coupling of 4-bromoacetophenone with phenylacetylene.[54]

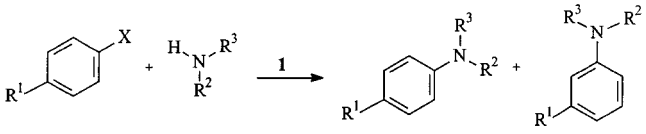


Scheme 15. The Sonogashira coupling reaction

Here also, a mechanism involving Pd^{IV} species has been postulated as being operative in the case of palladacycle **1**.

Amination of Aryl Halides[56,57]

Phosphapalladacycles were among the first palladium catalyst precursors to be used to promote the amination of aryl halides leading to substituted anilines (Scheme 16).[37,58] The reactions of secondary amines with bromoarenes and activated chloroarenes are efficiently catalysed by palladacycle **1** using NaO*t*Bu or KO*t*Bu as a base at temperatures in the range 100−130 °C.[58]

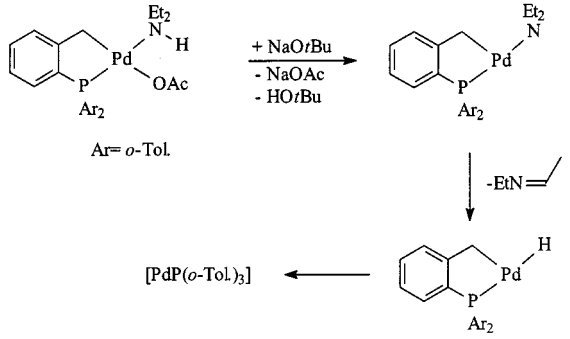


X= Br, R^1= COMe, CN, F, Me, H, OMe; amine= piperidine, $HNBu_2$, $HNPh_2$, $HNiPr_2$

X= Cl, R^1= CF_3, COPh; amine= piperidine, $HNBu_2$, $HNPh_2$, $HNiPr_2$, etc.

Scheme 16. Amination of aryl halides promoted by palladacycle **1**

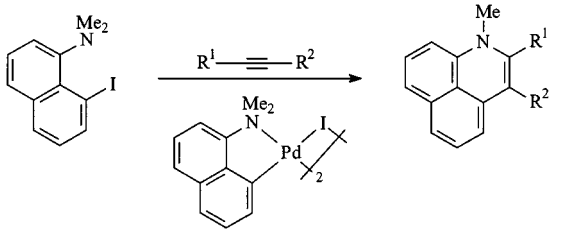
It is interesting to note that the *meta* isomer was also obtained, and that a side mechanism involving aryne intermediates was shown to be operative by running the reaction in the absence of a catalyst. Elegant studies showed that in these cases the palladacycle **1** again serves as a reservoir of catalytically active Pd^0−phosphane species. The latter are probably formed through a β-hydrogen elimination followed by a reductive elimination process from a palladium amide complex (Scheme 17).



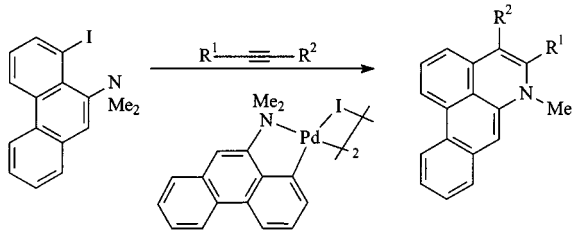
Scheme 17. Postulated mechanism for the generation of Pd^0 species from palladacycle **1** in the presence of $HNEt_2$

Hetero- and Carbo-Annulation Reactions

Palladacycles are also effective catalyst precursors for the preparation of *N*-methylbenzo[*d*,*e*]quinolines,[59] *N*-methyldibenzo[*d*,*e*,*g*]quinolines,[60] and 2,3-diphenylindenone.[7] Cyclopalladated (dimethylamino)naphthalene (Scheme 18) and -phenanthrene complexes (Scheme 19) were shown to mediate the reaction of internal alkynes with (dimethylamino)iodonaphthalene and -phenanthrene derivatives, respectively, leading to quinolines in reasonable to good yields (Schemes 18 and 19).

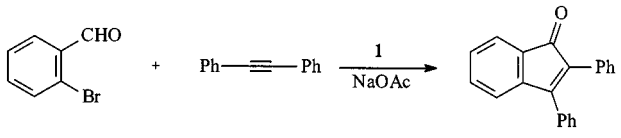


Scheme 18. Nitrogen palladacycle catalysed quinoline synthesis



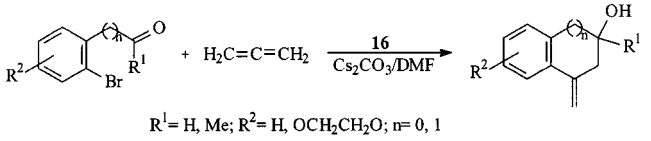
Scheme 19. Pd-catalysed construction of the B-fragment of the Aporphine skeleton

It has recently been shown that 2,3-diphenylindenone can be prepared by the reaction of 2-bromobenzaldehyde with diphenylacetylene in the presence of 0.1 mol-% of palladacycle **1** (Scheme 20).[7]



Scheme 20. Synthesis of a substituted indenone catalysed by **1**

Palladacycles of type **16** (Scheme 4) have been used to generate catalytically active Pd^0 species for the intramolecular nucleophilic addition of allylic intermediates, generated from allene, to 2-bromoaryl aldehydes or ketones (Scheme 21).[61]

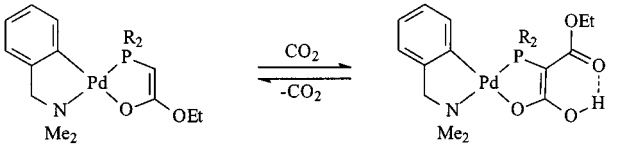


Scheme 21. Carbopalladation of allenes

Despite the high potential of this method for the synthesis of carbo- and heterocycles, which starts from easily accessible substrates, few examples of these types of reactions have appeared. Nevertheless, many related processes are mediated by catalytic systems based on palladium acetate.[62]

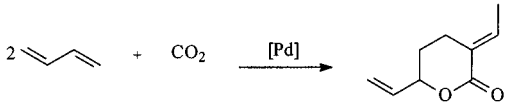
Telomerization of Dienes

Cyclopalladated phosphane enolates bearing *N*,*N*-dimethylbenzylamine ligands (Scheme 22) have been shown to be reversible CO_2 carriers at room temperature.[63]



Scheme 22. Phosphane enolate palladacycles as reversible CO_2 carriers (R = Ph, Cy)

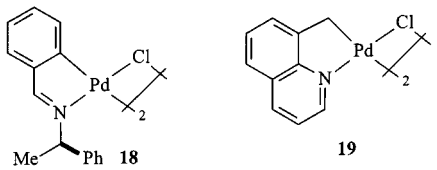
These complexes catalyse the telomerization of butadiene with CO_2 under relatively mild reaction conditions (20 bar CO_2, 90 °C) to furnish the lactone 2-ethylidene-6-hepten-5-olide with good selectivity (up to 93%) (Scheme 23).[64]



Scheme 23. Telomerization of butadiene with CO_2

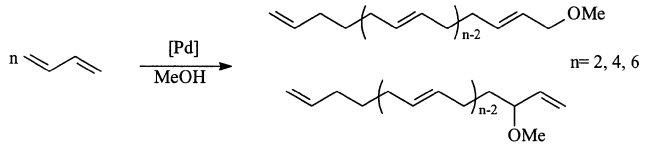
These complexes were the first examples of CO_2 carriers showing catalytic activity towards CO_2. It is also interesting to note that the cyclopalladated unit was isolated intact after catalysis, demonstrating its ancillary behaviour.

Not surprisingly, nitrogen-containing palladacycles, such as those derived from amines, imines, and quinolines (Scheme 24), promote the selective telomerization of 1,3-dienes with alcohols.[65,66]



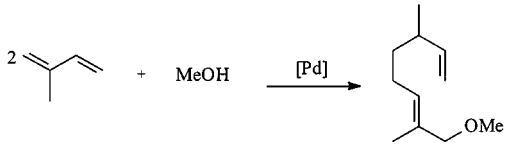
Scheme 24. Palladacycle catalyst precursors for the telomerization of 1,3-dienes

The cationic palladacycles derived from **17**−**19** mediate the telomerization of butadiene with methanol giving telomers containing 2−6 diene units (Scheme 25).



Scheme 25. Palladacycle-catalysed telomerization of butadiene with methanol

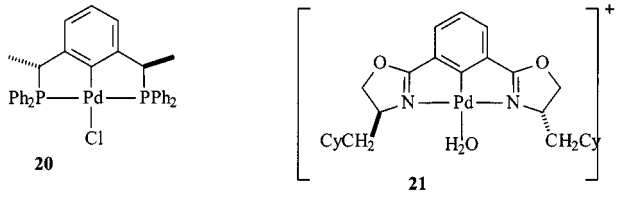
The selectivity was found to be strongly influenced by the nature of the palladacycle catalyst precursor, suggesting that the ligands it bears are present in the catalytically active species. Selectivities of up to 61% in high telomers (4 and 6 monomeric units) could be achieved using palladacycle **17**.[66] This selectivity is superior to that obtained with other palladium catalysts such as π-allyl complexes.[67] Palladacycle **16** was also shown to be effective in the generation of catalytic species for the telomerization of isoprene with methanol, yielding 1-methoxy-2,6-dimethyl-2,7-octadiene with selectivities of up to 67% (Scheme 26).[65]



Scheme 26. Telomerization of isoprene with methanol

Aldol-Type Reactions[68−70]

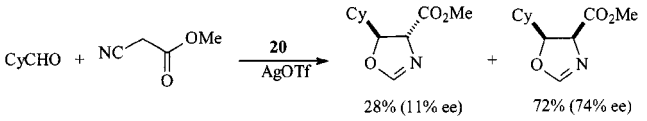
Cyclopalladated complexes containing PCP and NCN ligands have recently been utilized in asymmetric aldol-type reactions (Scheme 27).



Scheme 27. Palladacycles used as catalyst precursors for aldol-type reactions

The rationale behind the deployment of such complexes stemmed from the observation that classical ligands, including BINAP and DIOP, led to poor selectivities in these reactions, which was attributed to the fact that the key enantioselective step occurred too far away from the chiral pocket. PCP and NCN ligand-based systems offer a deeper chiral pocket, leading to some enantio-discrimination without the need for pendant groups designed for secondary interactions.[71]

To carry out the aforementioned reaction using methyl isocyanoacetate and various aldehydes (Scheme 28), it was found that the cyclopalladated complex had to be activated by halide abstraction with a silver salt.



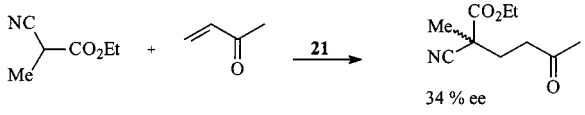
Scheme 28. Asymmetric aldol reaction catalysed by a cyclopalladated PCP complex

Some pertinent observations were made regarding this system:

(i) Palladium complexes are more effective than their platinum congeners. Moreover, *cis* selectivity is higher than that with similar related platinum complexes.[72]

(ii) THF is the solvent of choice; other variations, such as the order of addition of the reactants or the nature of the base used, have little effect on the reaction outcome.

Cyclopalladated NCN ligands were found to be ineffective in the above reaction and also in Diels−Alder reactions. However, they were found to be effective in the formation of a quaternary centre through chiral Michael addition (Scheme 29).

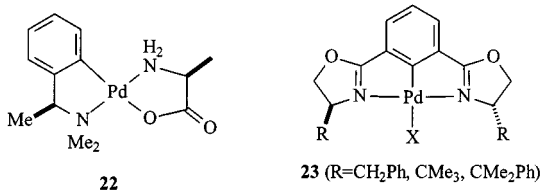


Scheme 29. Asymmetric Michael addition mediated by an NCN palladacycle

For these reactions, selectivities were found to be higher in toluene and increased when bulky substituents were present on the oxazoline ligands, although reaction times were often longer. The reaction is presumed to proceed through a Pd^{II} intermediate acting as a Lewis acid. An immobilized catalyst system is envisaged as offering an improvement in the near future.

Cyclopropanation

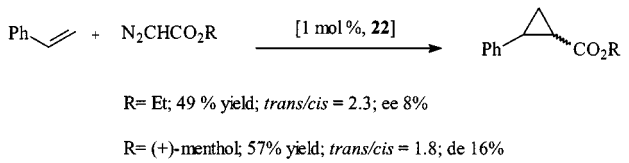
Recent reports have shown that neutral acetylacetonato and amino acid chelated cyclopalladated complexes (Scheme 30) are capable of catalysing cyclopropanation reactions.[73]



Scheme 30. Chiral palladacyclic catalyst precursors used in cyclopropanation reactions

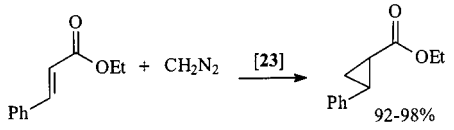
The enantioselectivities achieved with these palladacycles are poor, with the highest *ee* values being less than 10%. Diastereoselectivities reached 20% when a menthol-con-

taining diazoacetate derivative was used as a chiral starting material (Scheme 31).



Scheme 31. Cyclopropanation catalysed by a nonracemic benzylamine amino acid palladacycle

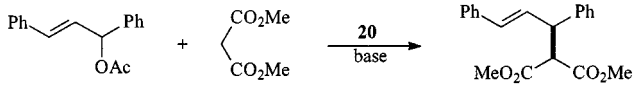
Non-racemic aryloxazoline palladacycles such as **21** have been shown to efficiently promote the diazomethane-based cylopropanation reaction (Scheme 32), but all the obtained products were racemic.[74]



Scheme 32. Cyclopropanation catalysed by aryloxazoline palladacycles

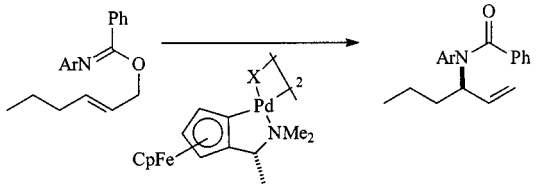
Allylic Substitution and Rearrangement[75]

Archetypal allylic substitutions of 1,3-diphenylprop-2-enyl acetate were investigated with PCP ligands such as that used in palladacycle **18** and modest enantioselectivities were achieved (Scheme 33).[76] Here though, when associated with π-allylpalladium complexes, the ligands are likely to adopt a bidentate PP-type coordination mode, taking them beyond the scope of this review.



Scheme 33. Allylic substitution reaction

Functionalized allylic alcohols can be converted into chiral allylic amine derivatives by a palladium-catalysed 3,3-sigmatropic rearrangement.[77] The achiral version of this reaction is effected by $PdCl_2(PhCN)_2$ and the authors chose palladium complexes containing an anionic ligand as a "chiral mimic" of the aforementioned complex.[78] Planar chiral ferrocene derivatives (Scheme 34) proved to be the most effective catalysts, affording excellent enantioselectivities with good reaction rates and yields, whilst avoiding side products due to 1,3-rearrangements (e.g. hexadienes).



Scheme 34. Chiral planar ferrocenyl palladacycle mediated allylic rearrangements

Conclusions and Perspectives

It is quite fitting that the majority of the work cited herein has been published during the last five years as our goal has been to demonstrate that the chemistry of cyclopalladated complexes, which is still in its infancy in terms of catalytic applications, will undoubtedly have a lot more to offer in the near future.

It is clear from the state of the art that further detailed mechanistic studies will have to be performed in order to unambiguously determine whether or not the cyclopalladated ligand is indeed attached to the catalytically active Pd species or whether these compounds are merely powerful sources of ligand-stabilized Pd^0 in which the Pd−C bond has been cleaved. This will aid the rational design of ligands and complexes, thereby leading to even more efficient palladium-containing catalysts. With TONs reaching 10^5 and even 10^{10} in some cases, more applied synthetic (e.g. natural products) and industrial applications can soon be anticipated. Palladacycles such as **1** are now commercially available and general procedures for their preparation are part of classical organometallic procedures.[79]

The Crystal Structure of a Phosphite Ozonide, $C_2H_5C(CH_2O)_3PO_3$

Anton Dimitrov[a] and Konrad Seppelt*[a]

Keywords: Ozone / Phosphorus / Ozonolysis

The crystal structure of $C_2H_5C(CH_2O)_3PO_3$ shows that this ozonide contains a symmetric, almost planar, four-membered PO_3 ring with two crystallographically different, but otherwise essentially equal, molecules in the asymmetric unit cell.

Generally, ozonides are salts containing the O_3^- anion[1] or the reaction products of ozone with unsaturated organic materials. In the latter case it is common to distinguish between primary ozonides having a 1,2,3-trioxacyclopentane ring and secondary ozonides with a 1,2,4-trioxacyclopentane ring. The organic ozonides are thought to be formed by a sequence of [2 + 3] addition and reversion reactions ("Criegee mechanism"), and there is abundant evidence for this mechanism.[2]

Ozone also adds across the 9,10 position of a substituted anthracene, and this "primary" ozonide is the first one that is stable enough to be characterized by a single-crystal structure determination.[3] From this it is evident, in spite of some disorder in the structure, that the O_3 molecule has simply added across the central carbon atoms of the anthracene molecule, a reaction that, at least formally, can be described as a [3 + 4] addition reaction.

There is yet another class of ozonides, the phosphite ozonides, which could be classified as inorganic covalent ozonides. They were first observed in 1961.[4] They are formed in the reaction between organic phosphites and ozone at low temperatures. There is abundant work on triphenylphosphite ozonide.[4−15] The thermal stability of some phosphite ozonides reach almost room temperature, especially if cyclic and polycyclic phosphite ozonides are considered.[16−26]

Phosphite ozonides are very convenient precursors of singlet oxygen, since they all tend to evolve singlet oxygen with simultaneous formation of the stable phosphates. These ozonides are assumed to have a four-membered, λ^5-PO_3 ring. In this context a high resolution ^{17}O NMR spectrum could be informative; however, the results are not conclusive (see below).

Of particular interest would be the detailed structure of such a phosphite ozonide. This could finally answer the questions as to whether these ozonides definitely contain a four-membered PO_3 ring, whether this ring is C_{2v} symmetric (planar and with equal bond lengths), and what is the general coordination around the five-coordinate phosphorous atom.

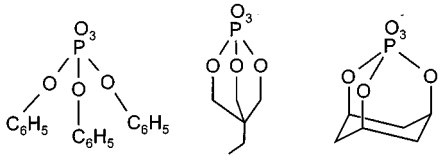
E-mail: seppelt@chemie.fu-berlin.de

In the following sections we will describe the crystal structure of a well-selected phosphite ozonide to address these questions. At this point the remarkable formation of a PO_2 three-membered ring (dioxaphosphirane) from a three-valent phosphorus precursor and molecular oxygen should be noted.[27]

Results

At the beginning of this survey we had to select one of the more stable phosphite ozonides. The candidates were triphenylphosphite ozonide (**1**), 4-ethyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane ozonide (**2**),[16,23] or 1-phospha-2,8,9-trioxaadamantane ozonide (**3**).[18,23] We have chosen **2** as a compromise between stability of **3** and ease of preparation of **1**. After all, the triol starting material for the preparation of **2** is commercially available and **2** is said to be stable below −15 °C. Such temperatures can easily be maintained for preparation, crystal growth, and single-crystal structure determination.



1 **2** **3**

The preparation of **2** followed the published procedures. Crystal growth was monitored by ^{31}P NMR spectroscopy, which readily helps to analyze the amounts of starting material phosphite, product phosphite ozonide, and phosphate as the major decomposition product. Obtaining suitable single crystals was, however, not trivial. Compound **2** of about 90% purity did not recrystallize from various solvents at all, or it formed microcrystalline powders. Single crystals were, however, obtained from CH_2Cl_2 solution.

In the first and reproducibly monoclinic crystalline modification the organic part of the molecule is at least twofold, possibly even threefold, disordered, whereas the environment around the phosphorous is reasonably well resolved. The four-membered PO_3 ring looks very much the same as in the crystallographic determination of modification 3. Therefore, and also because the criteria for a good crystal

structure are only modestly met, we include in Table 1 only the lattice constants of this modification. In a second modification, which has been obtained only once, there was no disorder, but the crystallographic criteria are even worse than in the first modification, due to an imperfect crystal.

Acceptable results were obtained by recrystallization from $CHFCl_2$ solution. These crystals also contain solvent molecules. The crystal structure data are also summarized in Table 1 and detailed bond distances and bond lengths are collected in Table 2. The asymmetric unit of the cell contains two molecules of **2** along with three molecules of $CHFCl_2$. The two crystallographic different molecules of **2** differ significantly only in the orientation of the terminal ethyl group with respect to the PO_3 ring plane.

The coordination polyhedron around the phosphorous atoms is clearly a tetragonal pyramid (Figure 1). The O3 and O23 atoms are considered as apexes and have bond angles of 102−105° to the other four oxygen atoms bonded to phosphorous. The apical P−O bond is, as expected, the shortest of the P−O bonds. The PO_2 angles within the basal part are strongly influenced by the four-membered PO_3 ring, since the PO_2 inner-ring angle is only 78°. All other inner ring angles are slightly above 90° so that an inner-ring-angle sum of 360° is obtained, indicating near planarity of the ring. The dihedral angles of the four-membered rings are about 7°.

The distances within the four-membered ring are pairwise about equal. The O−O bond lengths of 146 pm indicate the single-bond character of these bonds, in contrast to the bond lengths of 127 pm in free ozone. The O−O bond lengths compare nicely with those in $F_3-O-O-O-CF_3$ [143.7(2) crystal, 145.2(5) gas],[28] but not so well with 9-*tert*-butyl-10-methylanthracene 9,10-ozonide [136.1(6) and 142.8(6) pm]. In the latter, however, the central oxygen atom is disordered over two symmetrically equivalent positions, and, strictly speaking, all the other atoms as well, so that the estimated standard deviations may be much larger than given. This also holds for the O−O−O bond angle of 113.3(4)°. This is found to be 106.4(1)° in $CF_3-O-O-O-CF_3$,[28] but only 92° in **2**.

The NMR spectra are inconclusive for the structure of **2**. While the ^{31}P resonance shows the expected septets due to ^{1}H-^{31}P coupling, the ^{17}O resonance of **2** made from ^{17}O enriched ozone exhibits a broad line at δ = 411.7 with a shoulder at δ = 470.6, which can be assigned to the phosphorous-bonded oxygen atoms of the O_3 unit and the cent-

ral oxygen atom. In $CF_3-O-O-O-CF_3$ the chemical shift values for the corresponding oxygen atoms are δ = 321 and 479.[29] In ozone, extremely high shifts of δ = 1590 and 1020 are observed.[30]

Experimental Section

General: All chemicals and solvents were dried prior to use and handled in a glove box and/or glass vacuum line. NMR spectra: JEOL multinuclear instrument at 400 MHz for ^1H. Spectra are recorded relative to $H_3{}^{31}PO_4$, ^{13}C-TMS, and $H_2{}^{17}O$ as external standards. Raman spectra: Bruker RPS 100 S instrument with Nd: YAG laser excitation, λ = 1064 nm. Samples were kept in glass tubes, and Raman scattering of the tubes was subtracted digitally. Crystal structures: A suitable crystal was fixed on the tip of a glass needle with the help of a special cooling device[31] and mounted on the Bruker SMART CCD 1000 TU diffractometer equipped with Mo-K_α irradiation, a graphite monochromator. The data set was measured in steps of 0.3° in ω, and 3 times 600 scans in ψ = 0°, 90°, and 240°, with exposure times of 10 sec/frame and a detector to crystal distance of 4.0 cm. A full shell of data up to 2θ = 53° was measured. Data were reduced to intensities and corrected for background (SAINT). The structures were solved[32] and refined[33] with the SHELTL program suite.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-155612. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of 4-Ethyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane: This compound was prepared according to the literature procedure from $CH_3CH_2C(CH_2OH)_3$ and PCl_3,[34] and recrystallized from n-pentane. M.p. 55.7 °C, ^{31}P NMR ($CDCl_3$): δ = 93.1 ($^3J_{P,H}$ = 1.9 Hz). − ^1H NMR ($CDCl_3$): δ = 0.75 (^3J = 7.8 Hz, CH_3), 1.11 (CH_3-CH_2), 3.92 ($^3J_{H,P}$ = 1.9 Hz, CH_2O). − ^{13}C NMR ($CDCl_3$): δ = 6.79 (CH_3), 24.40 ($^4J_{C,P}$ = 5.4 Hz, CH_3-CH_2), 34.39 ($^3J_{C,P}$ = 22.1 Hz, C), 70.49 (CH_2O).

Preparation of 4-Ethyl-1-phospha-2,6,7-trioxabicyclo [2.2.2]octane Ozonide(2):[16,17] The phosphite (100 mg) was dissolved in 4 mL of CH_2Cl_2 or $CHFCl_2$ in a 10 mm-diameter glass tube. This was connected via a septum and two 1.5 mm-diameter inlet and outlet tubes of PFA (perfluoroether-tetrafluoroethylene copolymer) with an ozone generator. At −78 °C an O_3/O_2 stream was bubbled through the solution until it turned blue due to dissolved ozone at the end of the reaction. The excess of ozone and about half of the solvent were pumped out at −78 °C on the vacuum line. In the case of $CHFCl_2$ as a solvent the tube was sealed. In case of CH_2Cl_2 as a solvent, about 1 mL of $CFCl_3$ was added to the concentrated solution of the ozonide before sealing the tube. Suitable single crystals for X−ray diffraction were grown at −85 °C.

For experimental details of the crystal structures see Table 1; for numerical values of the structure see Table 2.

The purity of the samples was monitored by recording ^{31}P NMR spectra: ^{31}P NMR: δ = −43.1. ($^3J_{H,P}$ = 8.9 Hz; ref.[17] −43.6). At −78 °C only the signal of the ozonide and at room temperature only those of the phosphate were present: Raman spectrum (solid), bands below 1500 cm^{-1}: $\tilde{\nu}$ = 1474(30), 1446(10), 1345(3), 1286(9), 1256(11), 1156(15), 1088(10), 1047(15), 981(4), 964(6), 905(8)*, 887(50)*, 867(25)*, 853(35), 838(4), 820(3), 792(70), 776(2), 762(8), 727(7), 671(100), 629(3), 598(3), 516(9), 488(12), 471(6), 458(25), 443(2), 409(20), 388(25), 367(4), 325(30), 307(4), 280(6), 217(4), 193(1), 160(4), 116(10) cm^{-1}. The bands marked with an asterisk are not present in the phosphite starting material or the phosphate decomposition product and are therefore assigned to the PO_3 ring vibrations.

For ^{17}O NMR measurements, the ozonide was synthesized using ozone prepared by the discharge method in a closed system[35] with oxygen enriched to 35% ^{17}O. CD_2Cl_2 (3 mL) in a 10 mm-diameter glass tube was saturated at −78 °C with the labeled ozone. An aliquot of a 0.2 M solution of the phosphite in CD_2Cl_2 was added slowly from a precooled syringe connected to a 1.5 mm-diameter

inlet tube of FEP into the O_3 solution until only a pale blue color of dissolved ozone remained (typically 1−2 mL of the solution were needed). After the addition was complete, the excess ozone and part of the solvent were pumped out at −78 °C. The remaining solution was transferred into an NMR tube and the tube sealed. According to the ^{31}P NMR spectra some phosphate was always formed.

^{17}O NMR spectra were recorded at −70, −40, −20, 0 °C and at room temperature. At −70 °C two broad signals at δ = 470.6 (the smaller one probably belonging to the central oxygen of the trioxaphosphetane ring of the ozonide) and at δ = 411.6 (main signal, probably due to the two terminal oxygens of the trioxaphosphetane ring) were observed. Upon raising the temperature the signals broadened. At −20 °C the low-field signal was no longer observable, and the remaining signal at δ = 412 had a Δν1/2 value of 928 Hz.

At room temperature these signals disappeared and the signal of the labeled P=^{17}O part of the phosphate increased: ^{17}O NMR (CD_2Cl_2): δ = 65.75 (d, $^1J_{P,O}$ = 153 Hz).

Rearrangement of a Titanium Alkoxide Cluster upon Substitution of the Alkoxide Groups by Carboxylate Ligands − Synthesis of $[Ti_6O_4(OEt)_{14}(OOCPh)_2]$ from $[Ti_7O_4(OEt)_{20}]$

Ivan Mijatovic,[a] Guido Kickelbick,[a] and Ulrich Schubert*[a]

Keywords: Titanium / Cluster compounds / X-ray diffraction / Polyoxometalates / Carboxylate ligands

Reaction of $[Ti_7O_4(OEt)_{20}]$ with benzoic acid results in the formation of the new cluster $[Ti_6O_4(OEt)_{14}(OOCPh)_2]$ with concomitant rearrangement of the cluster structure. The molecular structure of the new cluster was determined by single-crystal X-ray diffraction and can be represented by the extended formula $[Ti_6(\mu_4\text{-}O)_2(\mu_2\text{-}O)_2(\mu_2\text{-}OEt)_6(\mu_2\text{-}benzoate)_2(\mu_1\text{-}OEt)_8]$.

Introduction

Metal oxide clusters capped by reactive organic groups are interesting building blocks for the synthesis of inorganic-organic hybrid materials due to their well-defined shape and their size in the lower nanometer range.[1] A key issue for the preparation of organically modified transition metal oxide clusters (OMTOCs) is the attachment of suitable organic groups to the metal atoms at the cluster surface. The introduction of organic groups can often be achieved with bi- (or multi)dentate (chelating or bridging) groups, such as carboxylates, sulfonates, phosphonates, β-diketonates, etc. These groups may also carry organic functionalities, such as polymerizable double bonds.

OMTOCs can be prepared by two strategies. The multidentate groups can either be grafted to a pre-formed cluster ("surface modification" method) or introduced during the cluster synthesis ("in situ" method). The latter method has been used successfully for the preparation of carboxylate- or β-diketonate-substituted metal oxide clusters by reaction of metal alkoxides with carboxylic acids or β-diketones,[1,2] where concomitant ester formation results in the formation of oxo and hydroxo ligands. There are also well-established routes for the preparation of a variety of neutral or (mostly) charged metal oxide clusters. The subsequent modification of their surface by organic groups requires: (i) reactive groups, such as OH, Cl or OR, bonded to the surface metal atoms, and (ii) the simultaneous balancing of charges and coordination numbers upon substitution of these groups. The latter is only possible without major difficulties if both the number of the occupied coordination sites and the charges of the entering ligands are the same as those of the leaving groups. For example, when $[Ti_{16}O_{16}(OEt)_{32}]$ was reacted with small amounts of carboxylic acids, a few of the bridging OEt groups were replaced by bridging carboxylate groups (for higher carboxylate:Ti proportions, the cluster core was cleaved).[3]

Getreidemarkt 9, 1060 Wien, Austria

The substitution of mono-anionic, *mono*dentate groups (OR, OH, Cl etc.) by mono-anionic, *bi*dentate ligands (carboxylates, β-diketonates, etc.) requires either rearrangement of the cluster or a change of the coordination modes of the bridging groups (e.g., bridging OR or OH to terminal, or μ_3 oxygens to μ_2 oxygens) to make additional coordination sites available. Reaction of the clusters with bidentate ligands may even lead to the complete degradation to monomeric compounds; for example, $[Zr(acac)_2(OMc)_2]$ (OMc = methacrylate, acac = acetylacetonate) was obtained from the reaction of $[Zr_4O_2(OMc)_{12}]$ with acetylacetone.[4]

Results and Discussion

In this paper we describe the rearrangement of a titanium oxoalkoxide cluster upon partial substitution of alkoxide groups by carboxylate groups. Among the many structurally characterised titanium polyoxoalkoxides with compositions ranging from $[Ti_3O(OR)_{10}]$ to $[Ti_{18}O_{27}(OR)_{18}]$[5] we have selected $[Ti_7O_4(OEt)_{20}]$ (**1**) as a model compound.[6,7] When **1** was reacted with a 1.5-molar excess of benzoic acid in benzene solution at ambient temperature [Equation (1); monitored by ^{13}C NMR spectroscopy], both starting compounds were completely consumed (more than 1.5 equivalents of benzoic acid results in the formation of increasing amounts of a poorly soluble precipitate). The NMR spectra of the reaction solution indicated the presence of a single cluster. When the volatile compounds were removed and the resulting residue was dissolved in heptane, the ^{13}C NMR spectrum was still that of the initially formed cluster. From this solution, crystals of $[Ti_6O_4(OEt)_{14}(OOCPh)_2]$ (**2**) precipitated at −20 °C. The ^{13}C NMR spectra of the initially formed cluster (the composition and structure of which is still unknown) and **2** are very similar, but can be clearly distinguished. The main difference is that **2** shows more signals in the CH_2 and CH_3 region than the initially formed cluster. The formation of **2** from the initial cluster is reversible, i.e. if the crystals are redissolved in the mother

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/0808−1933 $ 17.50+.50/0

liquid, the spectrum of the initial cluster is again observed. This indicates that **2** is in equilibrium with the initial cluster. Once **2** was isolated analytically pure and dissolved in heptane, it did not reconvert into the initial cluster. We can exclude that the formation of both the initial cluster and **2** is due to the presence of water — which might be produced by ester formation between benzoic acid and the cleaved ethanol — because both the initial cluster and **2** (precipitating from its solution) were observed when **1** was reacted with acetic benzoic anhydride instead of benzoic acid. In the latter reaction, ethyl acetate was formed as a by-product.

$$[Ti_7O_4(OEt)_{20}]\ (\mathbf{1}) + 1.5\ PhCOOH \rightarrow [Ti_6O_4(OEt)_{14}(OOCPh)_2]\ (\mathbf{2}) + ... \quad (1)$$

The structure of **2** was determined by a single crystal X-ray structure analysis (Figure 1). The composition of **2** formally differs from that of **1** by a $Ti(OEt)_4$ unit and the substitution of two of the remaining ethoxide ligands by benzoate ligands. An inspection of the molecular structures shows, however, that this is accompanied by an extensive structural rearrangement. The titanium atoms are octahedrally coordinated in both clusters. The total 42 coordination sites in **1** (general formula $Ti_7O_4X_{20}$, X = mono-anionic ligand) are occupied by two μ_4-O, two μ_3-O, eight bridging OEt and twelve terminal OEt {i.e., $[Ti_7(\mu_4\text{-}O)_2(\mu_3\text{-}O)_2(\mu_2\text{-}OEt)_8(\mu_1\text{-}OEt)_{12}]$}.[7,8] In the resulting Ti_6 cluster **2**, only 36 coordination sites are available for the ligands. Thus, when two bridging OEt ligands are formally replaced by two bridging benzoate ligands, other ligands must change their coordination mode in order to adjust for the smaller number of available coordination sites. As a matter of fact, two of the bridging oxygen atoms in **2** are μ_2 coordinated, rather than μ_3 in **1**, i.e. the extended formula of **2** is $[Ti_6(\mu_4\text{-}O)_2(\mu_2\text{-}O)_2(\mu_2\text{-}OEt)_6(\mu_2\text{-benzoate})_2(\mu_1\text{-}OEt)_8]$. The changing of the two oxygen atoms from a μ_3 coordination mode to μ_2 necessarily implies that the titanium octahedra in **1** and **2** are connected in a different way (Figure 2).

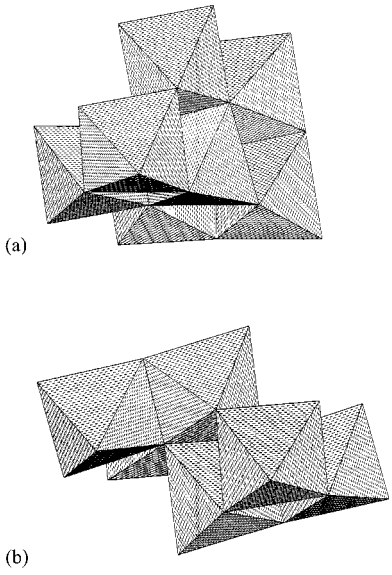

Figure 2. Arrangement of the Ti octahedra in **1** (a)[6,7] and **2** (b)

Several types of carboxylate-substituted titanium polyoxoalkoxides have been obtained by reaction of $Ti(OR)_4$ with carboxylic acids,[9−11] with the degree of substitution by carboxylate groups (r = carboxylate/Ti ratio) ranging from 1.78 in $[Ti_9O_8(OR)_4(OOCR')_{16}]$ to 0.5 in $[Ti_4O_2(OR)_{10}(OOCR')_2]$. Compared with the known clusters, **2** is exceptional in two respects: (i) it is the only cluster prepared by substitution of a pre-formed polyoxoalkoxide (with concomitant rearrangement of the cluster core), and (ii) it has the lowest degree of substitution (r = 0.33). Interestingly, only the two clusters with the lowest degree of substitution, $[Ti_4O_2(OR)_{10}(OOCH)_2]$[10] and **2**, contain μ_4-oxygens, while the other clusters are less condensed with only μ_2- and μ_3-oxygens. For example, in the other known cluster with the general composition $Ti_6O_4X_{16}$, $[Ti_6O_4(O\textit{i}Pr)_{12}(OOCMe)_4]$,[11] the two additional carboxylate groups (compared to **2**) do not replace two μ_2-OR groups; instead, the coordination mode of both the μ_4-oxygens in **2** is changed to μ_3 in order to accommodate the two bridging ligands {i.e., the extended formula is $[Ti_6(\mu_3\text{-}O)_2(\mu_2\text{-}O)_2(\mu_2\text{-}O\textit{i}Pr)_6(\mu_2\text{-acetate})_4(\mu_1\text{-}O\textit{i}Pr)_6]$}.

Experimental Section

All operations were carried out in Schlenk tubes under an argon atmosphere.

$Ti_6O_4(OEt)_{14}(OOCPh)_2$ (2): A solution of benzoic acid (64 mg, 0.52 mmol) in 5 mL of benzene was added dropwise at room temperature to a solution of $Ti_7O_4(OEt)_{20}$ [**1**: ^{13}C NMR δ = 18.5, 18.8, 19.0, 19.2, 19.6, 19.67, 19.74 (CH_3), 66.0, 70.4, 70.8, 70.9, 71.4, 71.5, 71.6, 71.8 (CH_2)] (450 mg, 0.35 mmol) in 5 mL of benzene. The solution was stirred for 12 h at 25 °C. After removal of all volatiles and addition of heptane (5 mL) the following ^{13}C NMR spectrum was observed: δ = 18.4, 18.9, 19.3 (CH_3), 69.1, 71.0, 71.5, 72.6, 72.8 (CH_2), 128.2, 130.2, 131.9, 135.0 (Ph), 172.2 (COO). From this solution, cluster **2** crystallized at −20 °C during 12 h. Yield 304 mg (0.25 mmol; yield: 61% relative to Ti, 93% relative to benzoic acid). Selected spectroscopic and analytic data of **2**: $C_{42}H_{80}O_{22}Ti_6$ calcd. C 41.2, H 6.6, Ti 23.5; found C 41.0, H 6.2, Ti 23.6. − ^{13}C NMR δ = 17.8, 17.9, 18.2, 18.4, 18.9, 19.3, 19.4 (CH_3), 69.1, 69.6, 71.1, 71.6, 73.0, 73.3, 74.3 (CH_2), 128.3, 130.4, 132.0, 135.2 (Ph), 172.3 (COO). − IR (KBr): $\tilde{\nu}$ = 841 (w), 890 (s), 924 (s), 1069 (vs), 1124 (vs), 1352 (s), 1375 (s), 1401 (s, COO sym), 1447 (vs), 1469 (m), 1493 (m), 1552 (s), 1595 (s, COO asym), 1821 (w), 1934 (w), 2697 (w), 2858 (vs), 2924 (vs), 2968 (vs), 3065 (w).

X-ray Structure Analysis of 2. A selected crystal (0.54 × 0.32 × 0.22 mm) was mounted on a Siemens SMART diffractometer with a CCD area detector. Graphite-monochromated Mo-K_α radiation (71.073 pm) was used for all measurements. The crystal-to-detector distance was 4.40 cm. A hemisphere of data was collected by a combination of three sets of exposures at 294 K. Each set had a different φ angle for the crystal, and each exposure took 20 s and covered 0.3° in ω. 12010 reflections were collected. The data were corrected for polarization and Lorentz effects, and an empirical absorption correction (SADABS) was applied. The cell dimensions were refined with all unique reflections. Crystal data: M = 1224.29, monoclinic, Z = 2, a = 1245.8(2), b = 1780.9(3), c = 1417.7(3) pm, β = 108.351(4), U = 2985.4(9)·10^6 pm^3, space group $P2_1/n$, D_{calc} = 1.362 gcm^{-3}, μ(Mo-K_α) = 8.31 cm^{-1} The structure was solved by direct methods (SHELXS-86). Refinement was carried out with the full-matrix least-squares method based on F^2 (SHELXL-93) with anisotropic thermal parameters for all non-hydrogen atoms using 3631 unique reflections. Hydrogen atoms were inserted in calculated positions and refined riding with the corresponding atom. R_1 = 0.042 [$I > 2\sigma(I)$], R_2 = 0.121, GOF = 1.013. Crystallographic data (excluding structure factors) for the structure of **2** have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 157 873. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Complexes of Manganese, Iron, Zinc, and Molybdenum with a Superbasic Tris(guanidine) Derivative of Tris(2-ethylamino)amine (Tren) as a Tripod Ligand

Harald Wittmann,[a] Volker Raab,[a] Andrea Schorm,[a] Jörn Plackmeyer,[a] and Jörg Sundermeyer*[a]

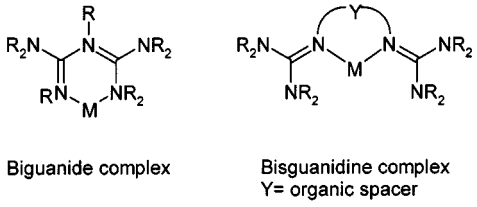
Dedicated to Professor Herbert Roesky on the occasion of his 65th birthday

Keywords: Ligand design / N ligands / Tripodal ligands / Coordination chemistry / Manganese / Iron / Zinc / Molybdenum

The synthesis of the novel tripod ligand $N[CH_2CH_2N{=}C(NMe_2)_2]_3$, based on the tris(2-ethylamino)amine (tren) backbone and having a set of three superbasic tetramethylguanidine (TMG) donor atoms instead of the primary amine functionalities, is described. This ligand has been prepared by treating tren with the Vilsmeyer salt $[(Me_2N)_2CCl]Cl$ in the presence of triethylamine as an auxiliary base and NaOH. Complexes of manganese(II), iron(II), and zinc(II) as biologically relevant transition metal ions as well as of molybdenum(0) have been synthesized and spectroscopically and structurally characterized. The electrochemical properties of selected complexes have been studied.

Introduction

Peralkylguanidines belong to the strongest neutral organic bases known.[1] They are several orders of magnitude more basic than tertiary amines due to the excellent stabilization of the positive charge over their resonance-stabilized cations.[2] This trend is illustrated by the pK_{BH^+} values (MeCN) of the 1,2,2,6,6-pentamethylpiperidinium cation (18.62), the parent guanidinium cation (23.00), and the pentamethylguanidinium cation (25.00).[2c] Therefore, in aqueous media, guanidines exist almost exclusively in the protonated form.[3] Guanidines are currently attracting attention as anion receptors,[4] both in enzymes and in model systems. Due to their hydrophilic nature, they also play an important role in the mediation of solubility of natural products[5] and in the stabilization of protein conformations through hydrogen bonding.[5–7] However, surprisingly little is known about the coordination chemistry of guanidines. There is some indication that the guanidine functionality of arginine may play a role as a neutral donor towards various metal cations in the hydrophobic domains of cytochrome *c* enzymes and other such systems.[2,5,6,8] There have been a few reports on coordination compounds of monoguanidines $HN{=}C(NRR')_2$.[5,6,8,9] The first complexes of chelating bis(guanidine)s have recently been reported by Kuhn[10] and ourselves.[11a] We became interested in the coordination chemistry of bis-, tris-, and oligoguanidines because of the marked tendency of biguanides to stabilize unusually high oxidation states of metals, e.g. in Ag^{III} [12] and Ni^{III} [13] complexes (Scheme 1).



Scheme 1. Guanidine-based complexes

The focus of this investigation is the evaluation of the donor capabilities of tetradentate pentaalkylguanidine derivatives. The basicities of these neutral ligands are intermediate between those of tertiary amines and amido ligands, but the question remains as to how well they interact with Lewis acids. Indeed, the question arises as to whether, in addition to their strong σ-donor interaction sp^2-N→M, guanidines may also be π-acidic like Schiff bases or π-basic like amido ligands. Various aspects of guanidine coordination chemistry remain unexplored, such as the fine tuning of the basicity, donor strength, steric demand, and control of the solubility by variation of the substituents at the guanidine function. Following our study on guanidine derivatives of the tmeda and tame backbones,[11a] we wish to report our first results on the synthesis and coordination chemistry of guanidine derivatives of the tren ligand family (Scheme 2). The target molecule 1,1,1-tris{2-[N^2-(1,1,3,3-tetramethylguanidino)]ethyl}amine (**1**) (TMG_3tren) is structurally related to known Schiff bases,[14] tris(pyridylmethyl)amine (tmpa),[15] and other tripodal ligands[16] based on the well-known tren backbone (Scheme 2).

Results and Discussion

Ligand Synthesis

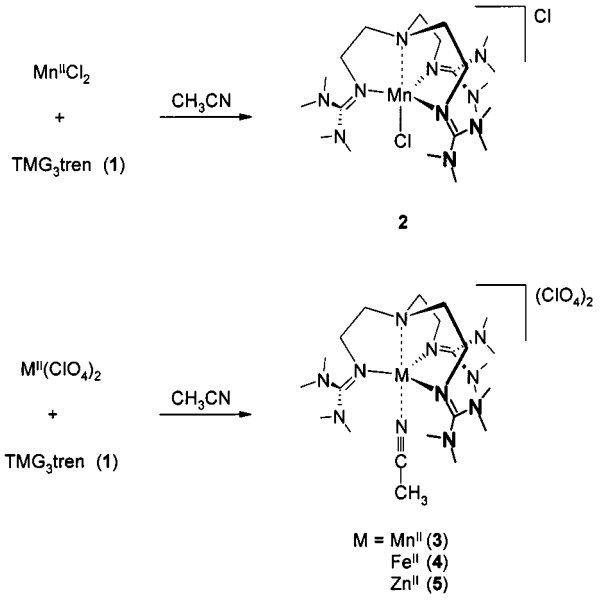
The synthesis of the target ligand **1** was accomplished following our general procedure that allows the transformation of primary bis-, tris-, or polyamines into the corresponding tetramethylguanidino derivatives.[11] The main problem associated with this synthesis is that polyguanidines as well as their hydrochlorides are extremely hygroscopic. Typically, they cannot be distilled/sublimed without decomposition and may not be purified by column chromatography on polar phases (SiO_2, Al_2O_3). Because of these purification difficulties, it was imperative that the synthesis involved selective reactions. A nearly quantitative transformation of a primary amine functionality into the guanidine may be accomplished by reaction with the Vilsmeyer salt $[(Me_2N)_2CCl]Cl$, a method first described by Eilingsfeld and Seefelder[17] and later improved by Kantlehner et al.[18] for *mono*guanidines. The Vilsmeyer salt is obtained by reaction of tetramethylurea with phosgene[19] or oxalyl chloride in toluene.[20] Reaction of the latter with tren in the presence of triethylamine as an auxiliary base leads to the corresponding hydrochloride **1A** (Scheme 3). Separation from the by-product Et_3NHCl is accomplished by adding 1 equiv. of NaOH per guanidine functionality and removing the resulting Et_3N and NaCl by crystallization from acetonitrile/diethyl ether. In the present case, the free base **1** was obtained in an overall yield of up to 86% by deprotonation of the tris(hydrochloride) using a two-phase system of MeCN/50% aqueous KOH.

The spectroscopic features of the protonated ligand **1A** are very similar to those of the free guanidine base **1**. A difference can be seen in the IR spectra, where TMG_3tren shows a single absorption at $\nu(C{=}N) = 1620\ cm^{-1}$ while the corresponding absorption of the tris(hydrochloride) is split into two separate bands at 1627 and 1584 cm^{-1}. This splitting is a typical feature due the decreased molecular symmetry in guanidinium cations. It is also observed for the hexamethylguanidinium cation.[21] In order to avoid steric interactions, the Me_2N substituents adopt a mutually twisted propeller-like conformation[21,22] rather than a coplanar one. The UV/Vis spectrum of **1** in MeCN shows an absorption at 216 nm with a molar extinction coefficient ε of approximately $1{\cdot}10^4$ for each guanidinium unit, attributable to the $\pi{\rightarrow}\pi^*$ transition of the C=N bond.[23] The ^1H NMR spectrum of **1** features only one signal due to the methyl groups, while the ^{13}C NMR spectrum reveals the presence of two chemically non-equivalent methyl groups. It is known from the literature that the barrier to rotation about the C=N double bond of pentaalkylguanidines (Scheme 4) leading to a *syn-anti* isomerization[2b,24] is markedly lowered by protonation or by increased steric demand of the alkyl groups. The bulkiness of the tren backbone leads to a lower barrier, which is manifested in the equivalence seen in the ^1H NMR spectrum.

Scheme 4. The *syn-anti* isomerization of pentasubstituted guanidines

Synthesis of the Metal Complexes

The free guanidine base **1** is moderately stable in D_2O. Due to slow hydrolysis, tetramethylurea is formed over a period of several days by decomposition of the guanidinium hydroxide. In contrast, the hydrochloride **1A** is perfectly stable in D_2O. In order to avoid side reactions due to hydrolysis of the ligand and of the metal salts, the latter were dehydrated by the orthoester method[25] prior to complexation. The complexes were synthesized in good yields by combining the dehydrated metal salts with 1.05 equiv. of TMG_3tren (**1**) in dry acetonitrile and stirring for 30 min (Scheme 5). The resulting ionic complexes **2**–**5** proved to be soluble in polar aprotic media such as MeCN, CH_2Cl_2, or acetone, but insoluble in diethyl ether and hydrocarbons.

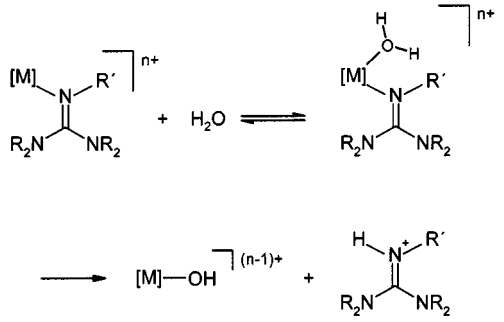


Scheme 5. Complexation of M^{2+} salts with TMG_3tren

The spectroscopic properties of the complexes resemble those of the protonated ligand (**1A**). For example, two IR absorptions are seen in the 1600 cm^{-1} region due to ν(C=N). The UV/Vis maxima are shifted 5–10 nm to lower wavelengths. While the zinc(II) complex (**5**) is diamagnetic, the manganese(II) (**2**, **3**) and iron(II) (**4**) complexes are paramagnetic with spin-only values of the order expected for d^5 and d^6 high-spin complexes[26] comparable to those of known complexes: μ_{eff}[Mn(Me_6tren)Br]Br: 6.01 B.M.; μ_{eff}[Fe(Me_6tren)Br]Br: 5.34 B.M.;[27] μ_{eff}[Mn(ntb)Cl]Cl [ntb = tris(2-benzimidazolylmethyl)amine]: 5.83 B.M.[28] Their magnetic susceptibilities, μ_{eff}(**2**): 5.9 B.M.; μ_{eff}(**3**): 5.8 B.M.; μ_{eff}(**4**): 5.4 B.M., all with an uncertainty of ±0.1, were determined by the Evans method.[29]

Attempts to prepare well-defined complexes of **1** with Fe^{III} and Mn^{III} salts have hitherto proved unsuccessful. It seems that, due to steric repulsion, the bite of the ligand is better matched with larger ions than with smaller, highly charged ions. This interpretation is in accordance with the electrochemical results discussed below, which reveal the rapid decomposition of the oxidized iron species.

The stabilities of compounds **2**–**5** towards hydrolysis were examined. All the complexes were found to be sensitive to air and moisture, despite the extreme steric shielding provided by the ligand. In general, it was observed that metal hydroxides along with the protonated ligand were formed when **2**–**5** were exposed to aqueous solvent mixtures. These findings may be explained by the extremely high proton affinity of guanidines. Deprotonation of an aqua ligand irreversibly induces the hydrolytic cleavage of the metal–nitrogen bond, a pattern that is also typical for amido complexes (Scheme 6).



Scheme 6. Hydrolytic cleavage of the metal–nitrogen bond

Structural Characterization

Single crystals of all the ionic complexes suitable for X-ray crystallography were grown by slow diffusion of diethyl ether into acetonitrile solutions. The results of the structure analyses are presented in Figures 1–6, while selected bond lengths and angles are collected in Table 1 and parameters relating to the data collection and refinement are listed in Tables 7 and 8. Complexes **2** (Figures 1 and 2), **3** (Figure 3), **4** (Figure 4), and **5** (Figure 5) each possess a nearly C_3-symmetrical trigonal-bipyramidal molecular geometry, with the amine nitrogen atom located in one of the axial positions, and *N*-coordinated acetonitrile (**3**, **4**, **5**) or chloride ion (**2**) occupying the other.

The imino nitrogen atoms of the guanidine groups define the equatorial plane. The metal atom is slightly axially distorted from the equatorial plane towards the acetonitrile molecule. As is evident from Table 2, this deviation is accompanied by a change in the ionic radius of the metal center. It also has an effect on the bond lengths between the amine and guanidine nitrogen atoms and the metal ion, whereas the distance to the acetonitrile nitrogen atom remains essentially the same. Other compounds containing Mn, Fe, and Zn in similar tren ligand coordination spheres are included in the table in order to correlate our results.

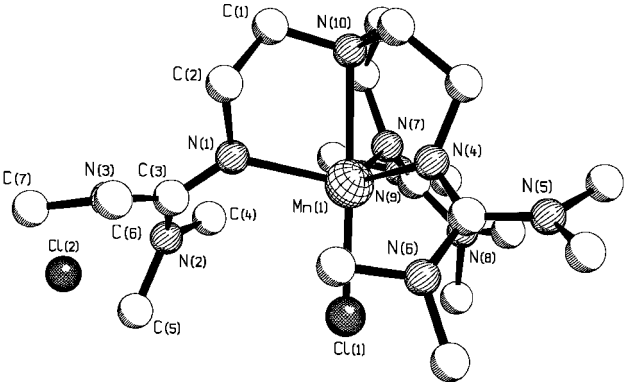

Figure 1. Molecular structure of **2**[44]

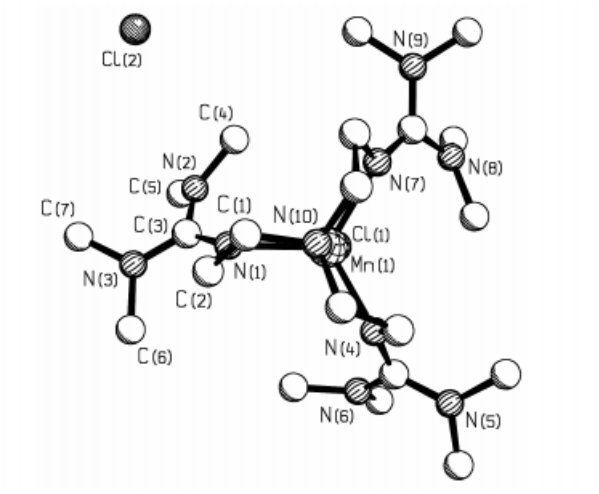

Figure 2. Molecular structure of $[Mn^{II}(TMG_3tren)Cl]Cl$ (**2**); SCHAKAL plot of a projection along the local C_3 axis[44]

However, an absolute comparison remains difficult because the ligand properties differ significantly, e.g. in terms of steric hindrance or considering the different neutral and anionic coligands, which lead to different effective charges at the metal atoms and hence to different bond lengths to the equatorial nitrogen atoms.[30]

Comparing complex **2**, which bears an anionic chloro ligand, with dicationic **3**, which has a neutral acetonitrile ligand instead, the increased contraction of the TMG_3tren ligand can be directly attributed to the higher effective charge at the metal center. As expected, the axial distortion decreases with decreasing ion radius of the central atom.

A comparison of **2** with $[Mn^{II}(Me_6tren)Br]Br$ [48] (**A**) as regards the relative donor abilities of the amine and guanidine ligands is made difficult by the different steric requirements of the two ligand regimes. In the case of **1**, steric repulsion is greatest at the periphery. Since donor ability incorporates both basicity and steric hindrance, the TMG_3tren ligand can be estimated to be superior to Me_6tren in its donor ability. The guanidine sp^2-nitrogen atom is much more basic than the amine sp^3-nitrogen atom of Me_6tren and is also sterically less hindered. The net result is that the average bond length between the equatorial guanidine nitrogen atoms and the metal center is much smaller (218 pm) than the corresponding amine−metal distance in $[Mn^{II}Br(Me_6tren)]Br$ (**A**) (227 pm). A stronger donor component of the equatorial guanidines is also consistent with the longer distance to the axial amine in **2** (238 pm) compared to that in the corresponding Me_6tren

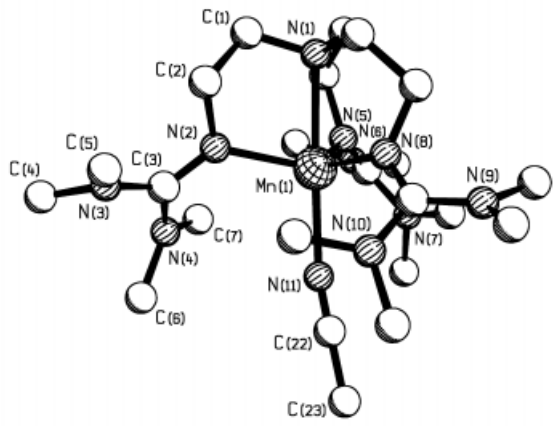

Figure 3. Molecular structure of **3**[44]

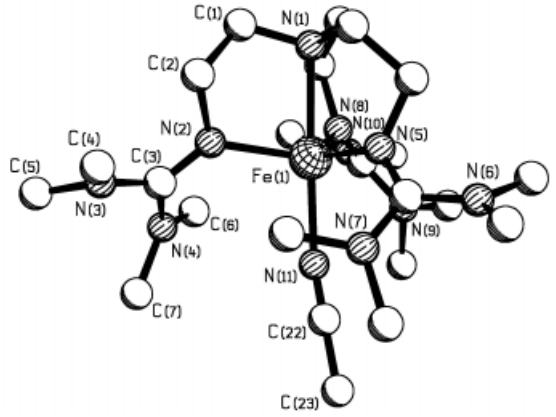

Figure 4. Molecular structure of **4**[44]

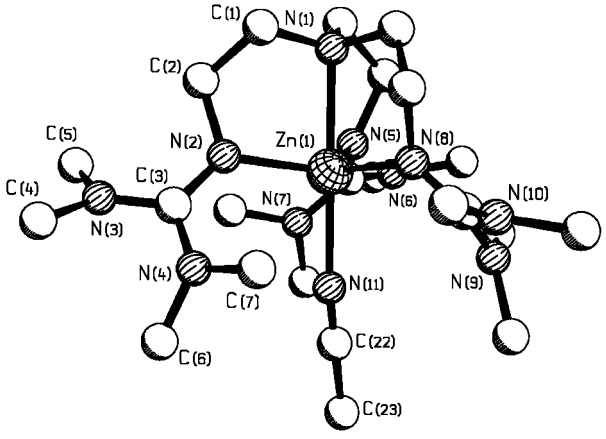

Figure 5. Molecular structure of **5**[44]

complex **A** (219 pm). In the latter donor−acceptor complex, the axial amine has to provide more electron density towards the overall charge compensation. As a consequence, the displacement of the manganese cation out of the equatorial plane is significantly greater in **2** (51 pm) compared to that in $[Mn^{II}(Me_6tren)Br]Br$ (**A**) (36 pm).

A characteristic structural feature of all the complexes **2**−**5** is shown in Figure 2. In order to reduce steric repulsion, the guanidine dimethylamino units are twisted by approximately 40° into a propeller-like conformation. The dimethylamino groups are not coplanar within the planar guanidine CN_3 unit but show out-of-plane torsion angles of 20−45° (Table 3). A similar distortion has been found for the hexamethylguanidinium cation in its ground state.[31]

In spite of these steric limitations to perfect π-conjugation in the outer ligand sphere, the superbasic tripod **1** efficiently stabilizes dicationic complexes by delocalizing the charge over the three perfectly planar guanidinium cations (sum of angles in representative **2**: see Table 5).

According to a CCDC search,[32] no structurally characterized complexes of iron and manganese with pentacoordination by five neutral N donor ligands have hitherto been reported. On the other hand, for d^{10} Zn^{2+},[33] Cd^{2+},[34] Ag^{+},[35] and d^9 Cu^{2+},[36] this coordination mode is more common. Just a few representatives involving the tren ligand or its *N*-methyl derivatives and an anionic ligand have been reported, for example the halide complexes of Di Vaira et al.[48] and Templeton et al.,[50] and the pseudohalide (OCN^- and SCN^-) complexes investigated by Laskowski and co-workers.[37]

The Question of π-Bonding Contributions of Guanidine Ligands

Because the C=N valence vibrations of coordinated guanidines do not seem to give a reliable measure of the donor and acceptor qualities of TMG_3tren, we set out to synthesize a complex containing CO as an indicator ligand for electronic interactions of the coligands. The tris(acetonitrile) complex $[Mo(CH_3CN)_3(CO)_3]$ was found to react cleanly with **1** to give compound **6** in 79% yield (Scheme 7). The IR spectrum of **6** features more than two ν(C=N) absorptions in the region 1515−1580 cm^{-1}, while in the ^{13}C NMR spectrum two resonances due to guanidine CN_3 moieties are observed. Complex **6** proved to be stable under atmospheric conditions for a short period of time, but ultimately turned from yellow to brown. It showed a similar sensitivity to oxidation in solution. While the TMG_3tren ligand is able to displace even an anionic chloro ligand from **2**, it is incapable of displacing more than three carbon monoxide ligands from $[Mo(CO)_6]$ or derivatives thereof. It bonds in a facial manner, leaving one guanidine functionality as a dangling arm. This may be taken as an indication that **1** is not a good π-acceptor, and furthermore that it is a ligand of constrained geometry, not being able to stabilize geometries other than trigonal-bipyramidal in its tripodal coordination mode. Figure 6 shows the results of an X-ray analysis of single crystals of **6** obtained from acetonitrile/diethyl ether.

The molecule of **6** exhibits local C_s symmetry in the crystalline state with a mirror plane defined by Mo, N(1), C(23), and C(24). The molybdenum atom is coordinated in a distorted octahedral manner. The inner ligand core is defined by three facial carbonyl ligands, one amine, and two guanidine ligands. One dangling guanidine arm points away from the inner core. The amine is bonded with a slightly longer Mo−N(1) distance [235.4(2) pm] than the two guanidines Mo−N(2) [233.6(2) pm] and Mo(1)−N(5) [231.9(2) pm]. However, this difference in bonding is not reflected in specific bonding differences of the *trans*-CO ligands. On the

other hand, a comparison of the structural parameters of the closely related complexes **6** and $[Mo(CO)_3(dien)]$,[38] in which *cis*-diethylenetriamine (dien) acts as a pure σ-donor, indicates slightly stronger donation by the guanidine ligand. Back-donation in **6** is slightly stronger; the Mo−C bonds tend to be shorter and the C−O bonds tend to be slightly longer as compared to those in the amine complex $[Mo(CO)_3(dien)]$ (Table 4).

Table 4. Comparison of bond lengths in **6** and $[Mo(CO)_3(dien)]$; dien = *cis*-diethylenetriamine

	6	$[Mo(CO)_3(dien)]$[38]
av.(Mo−N_{amine}) [pm]	235.4	232.3
av.(Mo−N_{imine}) [pm]	232.7	−
av.(Mo−C) [pm]	192.6	194.3
av.(C−O) [pm]	117.8	115.3
av.(C−Mo−C) [°]	84.8	85.3

Carbonyl stretching frequencies are often used as an additional criterion for evaluating the donor/acceptor qualities of coligands. There is no clear trend when guanidine **6** (1883 cm^{-1}) is compared to complexes of amines that act as pure σ-donors such as $[Mo(CO)_3(tacn)]$ (1850 cm^{-1})[39] or $[Mo(CO)_3(dien)]$ (1887 cm^{-1}).[38] On the basis of structural and IR spectroscopic evidence, it appears that there is no π-interaction between the metal center and ligand **1**.

Finally, the comparison of C−N bond lengths in guanidines, guanidinium hydrochlorides, and guanidine complexes (Lewis acid adducts) allows us to estimate the extent of electron density donation to a proton or a Lewis acid, respectively. The greater the donation, the more the imino nitrogen−carbon bond length should become equivalent to the peripheral C−NMe_2 bond lengths. In the dangling guanidine group of **6**, a short C−$N_{guanidine}$ bond [127.6(4) pm] and two long bonds to the peripheral C−NMe_2 groups [139.6(4) and 137.8(4) pm] are observed. The differences between these three guanidine C−N bond lengths become much smaller when the guanidine is coordinated to a Lewis acid (e.g. **2**), and become negligible upon protonation as a result of complete charge delocalization (Table 5).

Cyclic Voltammetric Measurements

In order to gain additional information about the synthesized compounds, cyclic voltammetry experiments were carried out. A reversible $Mn^{+3/+2}$ couple could be observed for **2** ($E_{1/2}$ = +0.47 V, $\Delta E_{1/2}$ = 0.11 V, i_a/i_c = 1), along with

Table 5. Bond angle sums [°] and selected guanidine C−N distances [pm] in the non-coordinated guanidine of **6**, the coordinated guanidine in **2**, and the protonated guanidine in bis(tetramethylguanidino)ethane hydrochloride

an additional wave ($E_{1/2}$ = +0.92 V, $\Delta E_{1/2}$ = 0.22 V, i_a/i_c = 4) for the couple $Mn^{+4/+3}$. The latter was irreversible, pointing to rapid decomposition of the oxidized species (Figure 7).

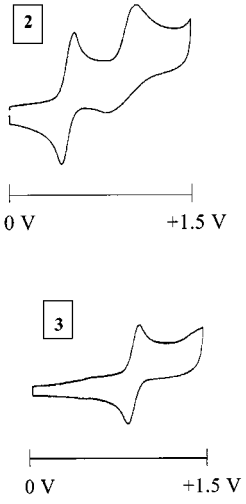

Figure 7. Cyclic voltammograms of **2** and **3** (CH_3CN/TBAP, 2 mm glassy carbon/SCE/Pt, v = 100 mV s^{-1}, 20 °C)

Complex **3** shows only a single wave in the anodic region at $E_{1/2}$ = +0.88 V ($\Delta E_{1/2}$ = 0.09 V, i_a/i_c = 1), corresponding to the reversible couple $Mn^{+3/+2}$. The $Mn^{II} \rightarrow Mn^{III}$ transition for compound **2** was found to occur at a lower oxidation potential than the corresponding step for **3** owing to the presence of the anionic chloro ligand, which facilitates the oxidation of **2**. The oxidation potential of $Mn^{III} \rightarrow Mn^{IV}$ does not lie within the window of 0 to 1.5 V.

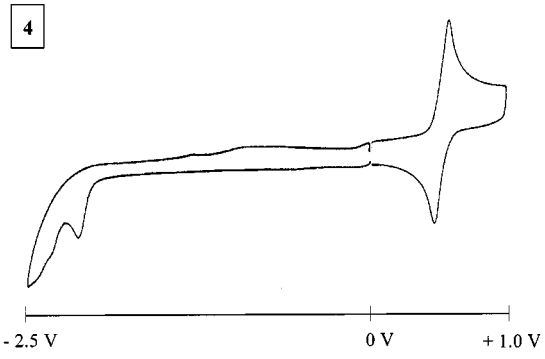

Figure 8. Cyclic voltammogram of **4** (CH_3CN/TBAP, 2 mm glassy carbon/SCE/Pt, v = 100 mV s^{-1}, 20 °C)

Complex **4** displays a potential of $E_{1/2}$ = +0.52 V ($\Delta E_{1/2}$ = 0.11 V) for the $Fe^{II} \rightarrow Fe^{III}$ electron transfer, i_a/i_c = 1 (Figure 8). The irreversible wave in the cathodic region (− 2.09 V) can only cautiously be assigned to an $Fe^{II} \rightarrow Fe^{I}$ reduction because of its low intensity and position near the border of the electrochemical window.

The values of the normal potentials can only be compared indirectly due to the different recording conditions (solvent, temperature) but can still be used to draw qualitative conclusions. All the complexes display lower oxidation potentials compared to the redox potentials of the aqua complexes Mn (II → III): +1.54 V; Fe (II → III): +0.77 V[40] as a result of the electron-donating TMG$_3$tren ligand. As expected, the monocationic complex **2** is more easily oxidized than the dicationic compound **3** (Table 6).

Table 6. Selected redox potentials

Metal complex	$E_{1/2}$[40] [V]
$[Mn(H_2O)_6]^{2+}$ (+3/+2)[a]	+1.54
[(**1**)Mn(NCMe)]$^{2+}$ (+3/+2)[b]	+0.88
[(**1**)Mn−Cl]$^{+}$ (+3/+2)[b]	+0.47
$[Fe(H_2O)_6]^{2+}$ (+3/+2)[a]	+0.77
[(**1**)Fe(NCMe)]$^{2+}$ (+3/+2)[b]	+0.52

[a] Recorded in H_2O. − [b] Recorded in MeCN.

Besides the inherent donor abilities of a given ligand, steric factors cannot be neglected with regard to the resulting oxidation potential and stability of the oxidized species.[41] This statement is related to the investigations of Ray[42] and Schrock,[43] who commented on the oxidation potentials of various transition metal complexes with tren-like amido ligands possessing varying degrees of steric strain. We believe that the instability of our oxidized complexes is due to the steric strain of the ligand periphery imposed by the reduced radius of the cation in its oxidized form.

Conclusions

Peralkyloligoguanidines are an unexplored class of multidentate nitrogen ligands within the large family of chelating N-donors typically containing amines, imines (Schiff bases), and azaaromatic building blocks. The novel tripod ligand TMG_3tren (**1**), a derivative of tren with three superbasic pentaalkylguanidine donor functions and a geometry constrained to coordinate metal ions preferably in a trigonal-bipyramidal mode, has been introduced. Due to its ability to delocalize positive charge over the three guanidinium moieties, **1** stabilizes cationic and even dicationic complexes, which are not so common for the corresponding parent compounds with tren ligands. However, increasing steric strain on the ligand periphery as a consequence of the decreased ionic radii of highly oxidized metal cations seems to limit the stability of such high-valent species. Initial evidence that larger cations are coordinated more favourably than smaller ones was provided by the bite angle and steric constraints of the tripodal ligand sphere of **1**. Our current interest is focused on the Lewis acid activation of small molecules other than acetonitrile and their transformations in the molecular pocket imposed by the guanidine ligand environment. Furthermore, we are extending our investigation of this class of ligands to other metals and other guanidine building blocks.

Experimental Section

Materials and Methods: All experiments were carried out in glassware that was assembled while hot and cooled under vacuum. Inert gas argon 4.8 was dried with granulated P_4O_{10}. Solvents were purified according to literature procedures and were also kept under an inert gas. Tris(2-aminoethyl)amine and the metal salts were used as purchased from Fluka. Triethylamine was freshly distilled and stored under argon prior to use. Substances sensitive to air and moisture were kept in a nitrogen-flushed glove-box (Braun, Type MB 150 BG-1). − Spectra were recorded with the following spectrometers: NMR: Bruker AM 400 (^{13}C: gated-decoupled). − IR: Bruker IFS 88 FT. − MS (EI, 70 eV): Varian MAT CH-7a. − Elemental analysis: Heraeus CHN-Rapid. − Melting points: Büchi MP B-540 apparatus (uncorrected values). − X-ray crystallography: Enraf−Nonius CAD4 and Siemens P4. − Magnetic susceptibility: Momentum apparatus, using the Evans method.[29]

Electrochemical Measurements: Cyclic voltammetry (CV) was performed with electrochemical equipment from AMEL (Milano) consisting of a Model 552 potentiostat, a Model 563 multipurpose unit, a Nicolet Model 3091 storage oscilloscope, and a Kipp & Zonen Model BD 90 x/y recorder. The electrochemical cell was operated under argon, with glassy carbon, platinum rod, and saturated calomel (SCE) serving as working, counter, and reference electrodes, respectively. For temperature control, the cell was immersed in a thermostatted cooling bath. CV curves were obtained at a scan rate of 100 mV s^{-1} working at 20 °C in MeCN/0.1 M nBu$_4$NClO$_4$.

Caution! Phosgene is a severe toxic agent that can cause pulmonary embolism and in cases of heavy exposure may be lethal. It should only be used in a well-ventilated fume hood. Perchlorate salts are potentially explosive and should be handled with care.

Chlorotetramethylformamidinium Chloride:[19] In a flask fitted with a reflux condenser cryostatted at −30 °C, phosgene was passed through a solution of tetramethylurea (50.00 g, 430 mmol) in toluene (200 mL) kept at 0 °C for 2 h. The phosgene inlet was then closed and the solution was allowed to warm to room temperature under stirring for a period of 24 h, with the reflux condenser being maintained at −30 °C. The precipitate formed was collected by filtration, washed three times with dry diethyl ether, and dried in vacuo. Yield ca. 95%.

1,1,1-Tris{2-[*N*^{2}-(1,1,3,3-tetramethylguanidino)]ethyl}amine (1): To a solution of tris(2-aminoethyl)amine (14.62 g, 100 mmol) and triethylamine (30.36 g, 41.6 mL, 300 mmol) in acetonitrile (50 mL), a solution of $[(Me_2N)_2CCl]Cl$ (51.32 g, 300 mmol) in acetonitrile (150 mL) was slowly added under cooling in an ice bath. After the exothermic reaction had occurred, the mixture was refluxed for 3 h, in the course of which a clear solution was produced. NaOH (12.00 g, 300 mmol) in water (30 mL) was subsequently added under vigorous stirring in order to deprotonate the Et_3NHCl. After evaporation of the solvents and excess NEt_3, TMG_3tren (**1**) was obtained by deprotonation of **1A** [tris(hydrochloride)] with 50% KOH (50 mL) and extracting the aqueous phase with MeCN (3 × 50 mL). The combined extracts were concentrated to dryness and the residue was taken up in warm hexane. The resulting solution was dried with $MgSO_4$, stirred with activated charcoal while still warm to eliminate impurities, and then filtered through Celite. Finally, removal of the solvent and drying of the residue in vacuo gave TMG_3tren (**1**) as a pale-yellow slowly crystallizing oil in 86% yield (38.03 g, 86 mmol). − M.p. 59−60 °C. − ^{1}H NMR (200.1 MHz, $CDCl_3$, 25 °C, $CDCl_3$): δ = 3.23 (m, 6 H, CH_2), 2.84−2.59 (m, 42 H, CH_2 + CH_3). − ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C, $CDCl_3$): δ = 160.4 (CN_3), 58.2, 48.3 (CH_2), 39.6, 38.8 (CH_3). − IR (film): $\tilde{\nu}$ = 2880 s, 2839 sh, 1620 s [ν(C=N)], 1495 m, 1453 w, 1364 s, 1236 w, 1130 m, 1062 w, 989 w cm^{-1}. − UV/Vis (MeCN): λ_{max} (ε) = 216 nm (24000 mol^{-1} dm^3 cm^{-1}). − MS (70 eV, EI): *m/z* (%) = 439.0 (1) $[M - H]^+$, 312.0 (100) $[C_{15}H_{34}N_7]^+$, 210.0 (73) $[C_{11}H_{22}N_4]^+$, 142.0 (43) $[C_7H_{16}N_3]^+$, 128.0 (54) $[C_6H_{14}N_3]^+$, 85.0 (82) $[C_4H_9N_2]^+$, 72.0 (26) $[C_3H_8N_2]^+$, 58.0 (80) $[C_2H_6N_2]^+$. − $C_{21}H_{48}N_{10}$ (440.7): calcd. 1,1,1-Tris{2-[*N*^{2}-(1,1,3,3-tetramethylguanidinium)]ethyl}amine Trichloride (1A; 1·3HCl): The hydrochloride salt could be obtained by treating the free oligoguanidine base (0.57 g, 1.13 mmol) dissolved in EtOH (10 mL) with the requisite amount of 1 M HCl (3.5 mL). Recrystallization from EtOH/Et_2O gave strongly hygroscopic, colorless crystals that analyzed as the trihydrate. Yield 0.51 g (0.84 mmol, 74%). Following our synthesis of **1**, the TMG_3tren tris(hydrochloride) **1A** could also be obtained without isolation of the free base. After deprotonation of Et_3NHCl with an equimolar amount of NaOH dissolved in the minimum volume of water and removing all volatiles in vacuo, the crude tris(hydrochloride) was redissolved in warm MeCN. The resulting solution was dried with $MgSO_4$, treated with activated charcoal, passed through Celite, and the solvent was evaporated. The residue was washed with dry diethyl ether and dried in vacuo to yield the tris(hydrochloride) **1A** as a colorless, strongly hygroscopic solid that analyzed as the trihydrate. − M.p. 153 °C (dec.). − ^{1}H NMR (200.1 MHz, CD_3CN, 25 °C, CD_3CN): δ = 8.91 (br. s, 3 H, NH), 3.76 (br., 12 H, CH_2), 2.92 (s, 36 H, CH_3), 2.55 (br., 6 H, H_2O). − ^{13}C NMR (50.3 MHz, CD_3CN, 25 °C, CD_3CN): δ = 161.3 (CN_3), 51.7 (CH_2), 39.5 (CH_3), 39.3 (CH_2). − IR (KBr): $\tilde{\nu}$ = 3431 s, 1627 s, 1584 s [ν(C=N)], 1457 m, 1406 s, 1311 w, 1233 w, 1176 w, 1136 w, 1067 w, 900 m, 668 br cm^{-1}. − UV/Vis (H_2O): λ_{max} (ε) = 213 nm (34000 mol^{-1} dm^3

General Procedure for the Synthesis of the TMG_3tren Complexes: The metal salts were first dehydrated by the orthoester method.[25] Thus, the hydrated salts were stirred in dry EtOH containing twice the molar amount, with respect to the water present in the salt, of triethyl orthoformate at 60 °C for 1 h. Equimolar amounts of the dehydrated metal salt and **1** were separately dissolved in 5-mL portions of dry MeCN under argon. These solutions were then combined and the resulting mixture was stirred for 30 min. at 40−50 °C, filtered through Celite, and concentrated to a volume of ca. 3 mL. The complex was then precipitated by the addition of dry diethyl ether (10 mL), washed with absolute diethyl ether, and dried in vacuo. Single crystals suitable for X-ray analysis could be grown by slow diffusion of diethyl ether into the respective acetonitrile solutions.

Chloro{1,1,1-tris[N^2-(1,1,3,3-tetramethylguanidino)ethyl]amine}manganese(II) Chloride (2): The general procedure was followed using $MnCl_2$ (0.15 g, 1.12 mmol) and **1** (0.66 g, 1.15 mmol). Yield 0.59 g (1.04 mmol, 93%) as colorless crystals. − M.p. 230 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 2947 m, 2881 m, 1618 s, 1573 s [ν(C=N)], 1553 vs, 1427 m, 1395 m, 1342 w, 1164 sh, 1151 s, 1075 m, 891 m, 764 m cm^{-1}. − UV/Vis (MeCN): λ_{max} (ε) = 226 nm (49000 mol^{-1} dm^3 cm^{-1}). − MS (70 eV, EI): *m/z* = 312.0 (60) $[C_{15}H_{34}N_7]^+$, 210.0 (33) $[C_{11}H_{22}N_4]^+$, 142.0 (32) $[C_7H_{16}N_3]^+$, 128.0 (43) $[C_6H_{14}N_3]^+$, 85.0 (100) $[C_4H_9N_2]^+$, 71.0 (31) $[C_3H_7N_2]^+$, 58.0 (74) $[C_2H_6N_2]^+$, 28.0 (80) $[CH_2N]^+$. − μ_{eff} (Evans method, 5% [D6]benzene in CD_3CN, 25 °C): μ_B/mol = 5.9±0.1. − CV (MeCN/TBAP, 2 mm GC/SCE/Pt, *v* = 100 mV s^{-1}, 20 °C): $E_{1/2}(+3/+2)$ = 0.47 V, $\Delta E_{1/2}(+3/+2)$ = 0.11 V, $I_{pa/pc}$ = 1; $E_{1/2}(+4/+3)$ = 0.92 V, $\Delta E_{1/2}(+4/+3)$ = 0.22 V, $I_{pa/pc}$ = 4. − $C_{21}H_{48}Cl_2MnN_{10}$ (566.5): calcd. Acetonitrile(1,1,1-tris{2-[N^2-(1,1,3,3-tetramethylguanidino)]ethyl}amine)iron(II) Diperchlorate (4): The general procedure was followed using $Fe(ClO_4)_2$ (0.32 g, 1.26 mmol) and **1** (0.57 g, 1.30 mmol). Yield 0.83 g (1.13 mmol, 89%) as light-yellow crystals. − IR (KBr): $\tilde{\nu}$ = 2893 m, 2270 w [ν(C≡N)], 1614 sh, 1558 vs, 1533 sh [ν(C=N)], 1463 m, 1427 m, 1399 s, 1346 m, 1257 w, 1166 m, 1090 vs [ν(Cl=O)], 908 w, 894 m, 772 m, 623 s cm^{-1}. − μ_{eff} (Evans method, 5% [D_6]benzene in CD_3CN, 25 °C): μ_B/mol = 5.4±0.1. − CV (MeCN/TBAP, 2 mm GC/SCE/Pt, v = 100 mV s^{-1}, 20 °C): $E_{1/2}(+3/+2)$ = 0.52 V, $\Delta E_{1/2}(+3/+2)$ = 0.11 V, $I_{pa/pc}$ = 1, $E_{1/2}(+2/+1)$ = −2.09 V. − $C_{23}H_{51}Cl_2FeN_{11}O_8$ (736.5): calcd. C 37.51, H 6.98, N 20.92; found C 36.90, H 7.03, N 20.52.

Acetonitrile(1,1,1-tris{2-[N^2-(1,1,3,3-tetramethylguanidino)]ethyl}amine)zinc(II) Diperchlorate (5): The general procedure was followed using $Zn(ClO_4)_2$ (0.41 g, 1.54 mmol) and **1** (0.71 g, 1.60 mmol). Yield 0.96 g (1.29 mmol, 84%) as colorless crystals. − ^{1}H NMR (200.1 MHz, $CDCl_3$, 25 °C, $CDCl_3$): δ = 3.02−2.77 (br. m, 48 H, CH_3 + CH_2), 2.04 (s, 3 H, $NCCH_3$). − ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C, $CDCl_3$): δ = 165.9 (CN_3), 53.8 (CH_2), 46.6 (CH_2), 39.3 (CH_3). − IR (KBr): $\tilde{\nu}$ = 2948 w, 2894 w, 2251 w [ν(C≡N)], 1620 sh, 1571 s, 1555 s [ν(C=N)], 1463 w, 1427 m, 1398 s, 1348 w, 1250 w, 1165 m, 1146 m, 1096 vs [ν(Cl=O)], 894 w, 766 w, 625 m cm^{-1}. − MS (70 eV, EI): m/z (%) = 85.0 (100) $[C_4H_9N_2]^+$, 71.0 (33) $[C_3H_7N_2]^+$, 44.0 (60) $[C_2H_6N]^+$. − $C_{23}H_{51}Cl_2N_{11}O_8Zn$ (746.0): calcd. C 37.03, H 6.89, N 20.65; found C 36.88, H 7.09, N 20.53.

Tricarbonyl(*fac*-tris{2-[N^2-(1,1,3,3-tetramethylguanidino)]ethyl}amine)molybdenum(0) (6): The general procedure was followed using $[Mo(CH_3CN)_3(CO)_3]$ (0.42 g, 1.40 mmol) and **1** (0.88 g, 2.00 mmol). Yield 0.69 g (1.11 mmol, 79%) as a yellow powder. − ^{1}H NMR (300.1 MHz, CD_3CN, 25 °C, CD_3CN): δ = 3.50 (m, 2 H, CH_2), 3.16 (m, 6 H, CH_2), 2.70 (m, 40 H, CH_3 + CH_2). − ^{13}C NMR (75.5 MHz, CD_3CN, 25 °C, CD_3CN): δ = 232.7, 230.1 (CO), 166.5 (CN_3, coordinated TMG), 160.8 (CN_3, free TMG), 66.1, 57.2, 50.7, 46.2 (CH_2), 39.8, 39.3 (CH_3). − IR (KBr): $\tilde{\nu}$ = 2889 s, 1883 s, 1740 vs, 1730 sh [ν(C=O)], 1619 s, 1577 s, 1553 sh, 1515 s [ν(C=N)], 1455 m, 1424 w, 1390 s, 1236 m, 1142 m, 1060 w, 1026 w, 976 w, 895 w, 763 w cm^{-1}. − MS (70 eV, EI): m/z (%) = 621.0 (1) $[M]^+$, 594.0 (2) $[M - CO]^+$, 312.0 (98) $[C_{15}H_{34}N_7]^+$, 255.0 (17) $[C_{11}H_{25}N_7]^+$, 210.0 (52) $[C_{11}H_{22}N_4]^+$, 142.0 (60) $[C_7H_{16}N_3]^+$, 128.0 (64) $[C_6H_{14}N_3]^+$, 101.0 (40) $[C_5H_{13}N_2]^+$, 85.0 (96) $[C_4H_9N_2]^+$, 72.0 (53) $[C_3H_8N_2]^+$, 58.0 (100) $[C_2H_6N_2]^+$, 44.0 (37) $[C_2H_6N]^+$, 28.0 (72) $[CH_2N]^+$. − $C_{21}H_{48}MoN_{10}O_3$ (620.7): calcd. C 46.45, H 7.80, N 22.57; found C 45.89, H 8.07, N 22.29.

X-ray Structure Analysis: Crystal data and experimental conditions are listed in Tables 7 and 8. The molecular structures are illustrated as SCHAKAL[44] plots in Figures 1−6. Selected bond lengths and angles with standard deviations in parentheses are presented in Table 1. Intensity data were collected with graphite-monochromated Mo-K_α radiation (λ = 71.069 pm). The collected reflections were corrected for Lorentz and polarization effects. The structures

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

of **2**, **5**, and **6** were solved by direct methods and refined by full-matrix least-squares methods on F^2, while those of **3** and **4** were solved using SIR-92.[45] Hydrogen atom positions were calculated and isotropically refined except for those of H23A, B, C of **3** and **4**, which were found and then isotropically refined. An empirical absorption correction based on the ψ-scans of 9 reflections (T_{min} = 0.4508, T_{max} = 0.5098) was performed for **4**.[46]

Acknowledgments

Financial support from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, BASF AG Ludwigshafen, Dr. A. Hettche, and Dr. A. Oftring is gratefully acknowledged. We thank Prof. Ch. Elschenbroich for his kind support and for discussions with regard to the CV measurements.

Reductions of 1,3,5-Triboracyclohexanes and Related 1,3,5-Triboraalkanes with Alkali Metals to Trishomoaromatic Aggregates — Tetrameric Lithium and Sodium, and Polymeric Sodium and Potassium Trishomoaromatic Cyclotriborate Compounds

Wolfgang Lößlein,[a] Hans Pritzkow,[a] Paul von Ragué Schleyer,*[b] Lawrence R. Schmitz,[c] and Walter Siebert*[a]

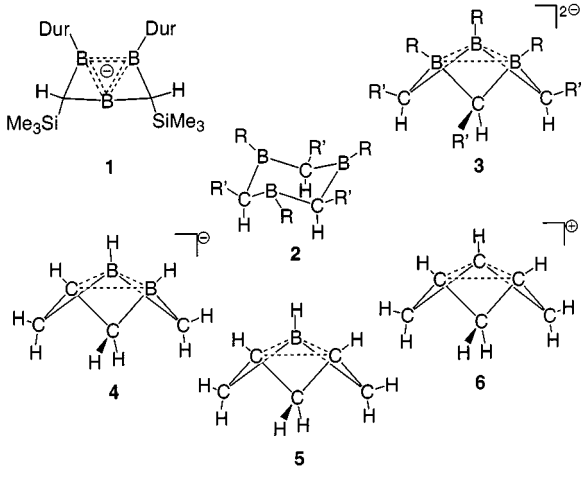
Dedicated to Prof. Kurt Dehnicke on the occasion of his 70th birthday

Keywords: Boron / Aromaticity / NMR spectroscopy / Alkali metals

Hexamethyl-1,3,5-triboracyclohexane can be reduced by alkali metals in donor solvents. Two electrons are added to the combination of p-orbitals at the boron centers forming trishomoaromatic dianions. X-ray structure analyses show a variety of arrangements, depending on the alkali metal: Tetrameric aggregates with lithium, a polymeric, meander-like chain or a complex tetramer with sodium, and a zigzag-chain polymer with potassium. The set of dianions show characteristic NMR chemical shifts in the high-field region, but do not obey a monotonous order with the counterions Li^+ to Cs^+. Lithium is out of line because of its exceptionally low electronegativity. IGLO chemical shift calculations agree very well with the experimentally observed data. The computed Nucleus-Independent Chemical Shift (NICS) values prove the strong homoaromatic character of the reduced triboraheterocycles. Compared with isoelectronic analogues the reduced triboraheterocycle shows a remarkable stabilization energy towards the corresponding, non-aromatic species.

Introduction

Reduction of unsaturated boron heterocycles in donor solvents by alkali metals leads to the formation of aromatic anions.[1] Remarkable results such as the synthesis of the doubly-aromatic anion **1** with σ and π 3c,2e bonding have been reported by Berndt et al.[2,3] Recently we obtained the new, trishomoaromatic system **3** by reducing 1,3,5-triboracyclohexanes **2** with lithium.[4,5] The empty p-orbitals of **2** are able to accept two electrons to form the dianion **3**, which is isoelectronic with the trishomocyclopropenylium cation **6**.[6] We now describe the reactions of the hexamethyl derivative **2** with various alkali metals and the influence of these metals on the structures and on the NMR chemical shifts of the trishomoaromatic dianions **3**. Our investigations are supported by computational studies on the stabilization and on the Nucleus-Independent Chemical Shifts (NICS)[7] of the isoelectronic, parent trishomoaromatic set **4**, **5**, and **6**.



Results and Discussion

Formation and X-ray Structure Analyses of Trishomoaromatic Dianions

Hexamethyl-1,3,5-triboracyclohexane (**2**) reacted with Li powder at 0 °C in both Et_2O and THF (Scheme 1) to give yellow-orange solutions after filtration. Removal of the solvent gave only amorphous products $\{\mathbf{3}[(Li^+)_2(OEt_2)_{2n}]\}_m$ and $\{\mathbf{3}[(Li^+)_2(thf)_{2n}]\}_m$ of unknown structure.

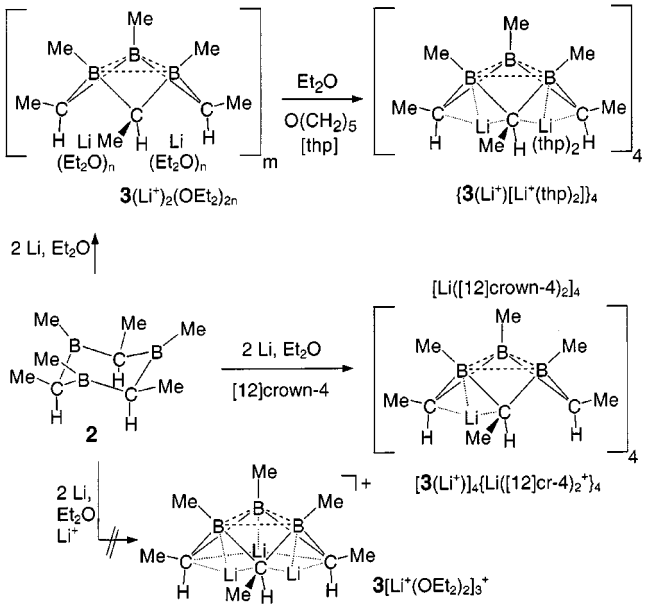
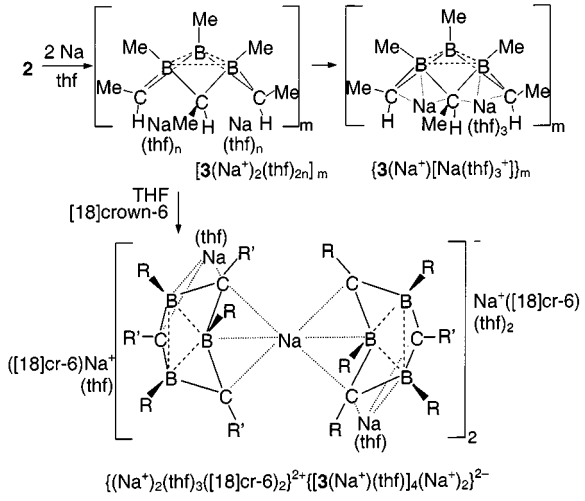


Scheme 1

Very air- and moisture-sensitive crystals were obtained by adding tetrahydropyran (thp) or [12]crown-4 to THF solutions of reduced **2**. Surprisingly, the X-ray structures (see below) revealed tetrameric aggregates for $\{\mathbf{3}(Li^+)[Li(thp)_2^+]\}_4$ and for $[\mathbf{3}(Li^+)]_4\{Li([12]cr\text{-}4)_2^+\}_4$. The low solubility of both these compounds precluded spectroscopic characterization. An attempt to obtain $\mathbf{3}[Li(OEt_2)_2]_3^+$ by reducing **2** with lithium in Et_2O in the presence of LiCl failed to give any monomeric product.

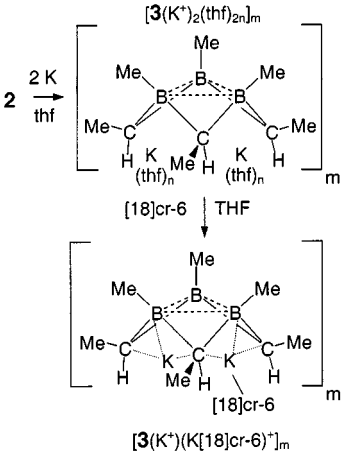
To study the reaction with the other alkali metals **2** was treated with sodium, potassium, rubidium, or cesium as described above (Scheme 2−4). The initially formed amorphous reduction products were soluble in $[D]_8THF$.



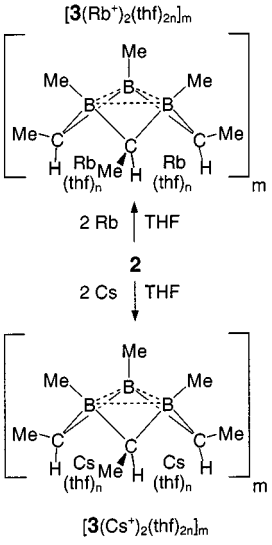
$\{(Na^+)_2(thf)_3([18]cr\text{-}6)_2\}^{2+}\{[\mathbf{3}(Na^+)(thf)]_4(Na^+)_2\}^{2-}$

Scheme 2. Reduction of **3** with sodium; in the formula of $\{(Na^+)_2(thf)_3([18]cr\text{-}6)_2\}^{2+}\{[\mathbf{3}(Na^+)(thf)]_4(Na^+)_2\}^{2-}$ the hydrogen atoms are omitted

The reduction of **2** with sodium or potassium gave crystals in addition to the amorphous products. X-ray structure analyses revealed a polymeric aggregation of $\mathbf{3}(Na^+)_2(THF)_3$ and, in the presence of [18]crown-6, an interesting tetramer. In contrast the potassium structure forms only a zigzag polymer (see below). The X-ray structures of all the reduced **2** products reveal that they adopt *nido* arrangements with axial methine hydrogens and equatorial CH_3 groups.



Scheme 3



Scheme 4

For $[\mathbf{3}(Li^+)Li(thp)_2]_4$ only a very limited data set ($2\theta_{max} = 30°$) was obtained. However, the structure could be solved and showed severe disorder of the thp ligands; a gross description of the structure (Figure 1) can therefore be given. The structure of $[\mathbf{3}(Li^+)]_4\{Li([12]cr\text{-}4)_2^+\}_4$ with [12]crown-4 as ligand refined well (Figure 2). In both structures four $(MeCH)_3(MeB)_3$ units in the cyclic tetramer are connected by Li cations. While the second Li of each dianion in $\{\mathbf{3}(Li^+)[Li(thp)_2^+]\}_4$ complexed by two thp is capping the third C_2B plane, in $[\mathbf{3}(Li^+)]_4\{Li([12]cr\text{-}4)_2^+\}_4$ the second Li is completely separated from the dianion **3** by two crown ether ligands leaving the third C_2B plane uncoordinated. The boron−boron distances in the B_3 ring are larger than 2c,2e B−B bonds and differ somewhat [1.825(5) Å when both B atoms coordinate to Li's, vs. 1.851(5) and

1.848(5) Å, when only one B coordinates to Li]. The Li···B contacts are long [2.239(6) and 2.251(6) Å] and the B−C bond lengths are normal for a single bond [between 1.603(5) and 1.632(4) Å]. In $[\mathbf{3}(Li^+)]_4\{Li([12]cr\text{-}4)_2{}^+\}_4$ the axial hydrogen substituents could be located.

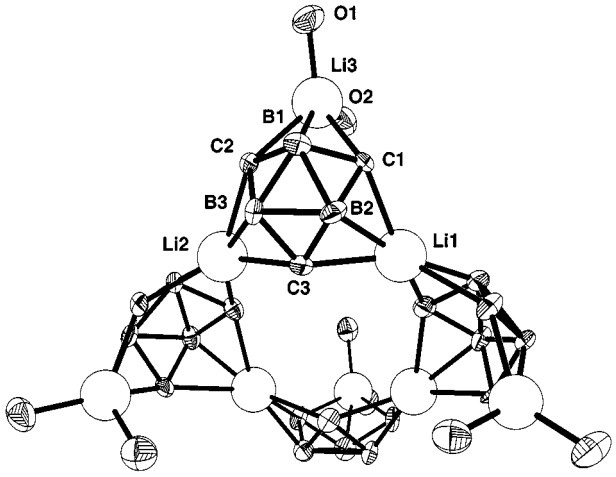


Figure 1. Structure of $\{\mathbf{3}(Li^+)[Li(thp)_2{}^+]\}_4$ in the crystal [the $(CH_2)_4$ chain of the thp ligands and the methyl groups are omitted for clarity]

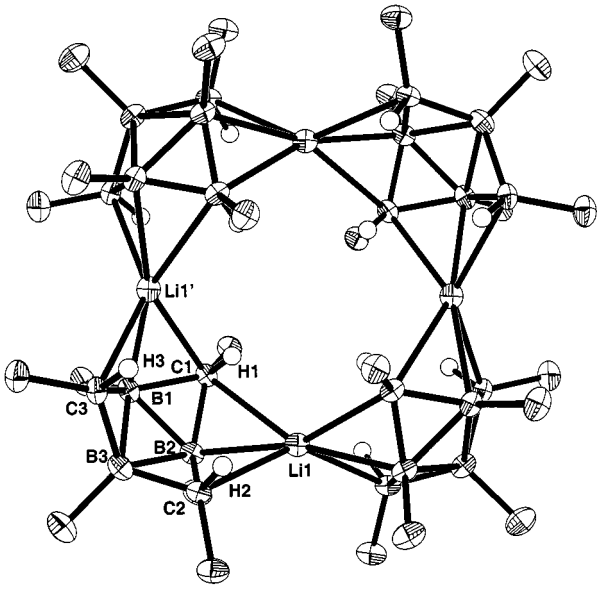

Figure 2. Molecular structure of the tetrameric anion in $\{\mathbf{3}(Li^+)[(Li[12]cr\text{-}4)_2{}^+]\}_4$ in the crystal; selected distances [Å] and angles [°]: B1−B2 1.825(5), B1−B3 1.851(5), B2−B3 1.848(5), Li1−C1 2.456(6), Li1′−C1 2.354(6), Li1′−C3 2.285(6), Li1−C2 2.247(6), Li1′−B1 2.239(6), Li1−B2 2.251(6); B2−B1−B3 60.4(2), B1−B2−B3 60.5(2), B1−B3−B2 59.1(2), B1−C1−B2 68.6(2), B2−C2−B3 70.0(2), B1−C3−B3 69.8(3) (symmetry operation for ′: y, 3/2 − x, 1/2 − z)

Air- and moisture-sensitive crystals of $\{\mathbf{3}[(Na^+)_2(thf)_3]\}_m$ were obtained after partial removal of the THF solvent. Surprisingly, the X-ray structure analysis (Figure 3a,b) revealed a polymeric arrangement of $\{\mathbf{3}(Na^+)[Na(thf)_3{}^+]\}_m$, consisting of a two-dimensional, meander-like chain pattern. There is no contact between individual chains. Half of the sodium centers bridge the **3** units through C_2B interactions and are solvent free; the other sodium centers in the terminal positions are coordinated by three THF ligands.

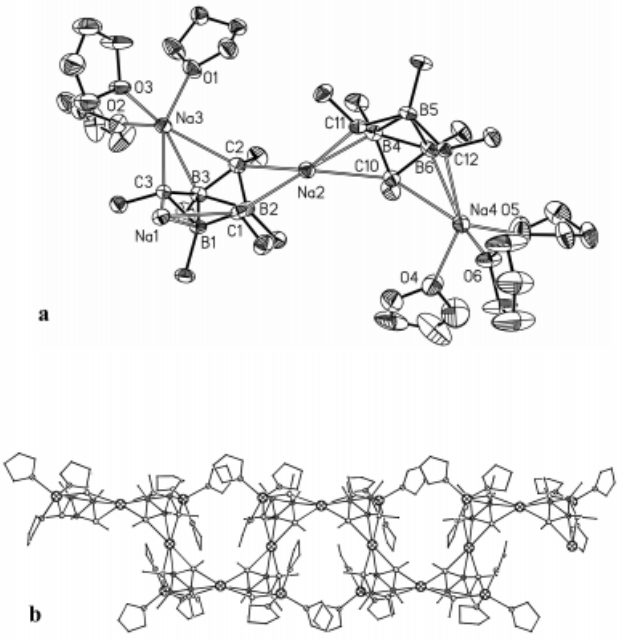

Figure 3. (a) Structure of two units of $\{\mathbf{3}(Na^+)[Na(thf)_3{}^+]\}_m$ in the crystal; selected distances [A] and angles [°]: B−B 1.827−1.846(6), Na1(2)−B 2.447−2.471(5), Na1(2)−C 2.621−2.764(5), Na3−B3 2.595(5), Na4−B6 2.601(6), Na3−C 2.673(4), 2.827(5), Na4−C 2.689(4), 2.768(5), Na3(4)−O 2.316−2.360(4); B−B−B 59.6−60.7(3), B−C−B 68.2−69.5(3); (b) structure of the meander-like chain of $\{\mathbf{3}(Na^+)[Na(thf)_3{}^+]\}_m$ in the crystal

A few crystals could be obtained when an excess of [18]crown-6 was added to the solution of the Na-reduced ring. An X-ray structure analysis showed tetrahedral aggregation of four units of **3** around an octahedron of six sodium ions, each connecting two C_2B faces of adjacent dianions of **3**. Four of the six sodium ions are complexed by a THF ligand, while the remaining two *trans*-oriented Na^+ ions have no other contacts than to the two adjacent C_2B units in **3**. In the crystal these two Na ions are shielded by a $\{(thf)_2Na([18]cr\text{-}6)\}^+$ unit and a $\{(thf)Na([18]cr\text{-}6)\}^+$ unit, which balance the charge of the tetrameric dianion (Figure 4 and 5).

Unfortunately, no NMR spectroscopic data could be obtained. The "vacant" coordination site of $\{(thf)Na^+([18]cr\text{-}6)\}^+$ is involved in an agostic interaction with a methyl group of **3** (dashed line in Figure 5). Disorder decreases the quality of the X-ray structure analysis.

The addition of [18]crown-6 after reduction of **2** with potassium yielded crystals. One of the K^+ ions bridges the C_2B faces of two adjacent units **3** resulting in a zigzag chain (Figure 6 and 7). The other K^+ ion occupies the third face of **3** and is coordinated by [18]cr-6.

In the structures the bond lengths and angles within **3** are almost identical. Due to the growing ionic radii from Li^+ to K^+ the distances of the cations to the C_2B faces

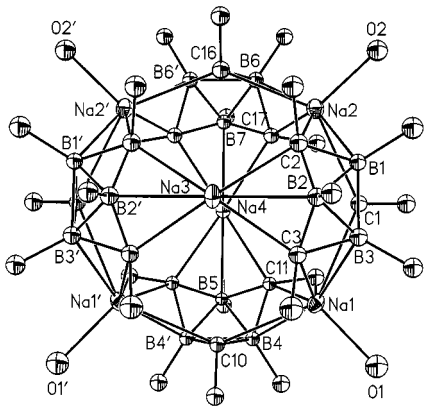

Figure 4. Structure of the dianion of compound $\{(thf)_2Na([18]cr-6)\}^+\{[\mathbf{3}(Na^+)(thf)]_4(Na^+)_2\}^{2-}\{(thf)Na([18]cr-6)\}^+$ in the crystal (symmetry operation for ′: $x, y, -z$)

increase. For a comparison with the structures of other organoalkali metal compounds see ref.[8]

NMR spectroscopic Characterization

Two broad ^1H NMR signals at $\delta = -3.2$ and -3.4 are assigned to the methine protons of the initial reduction product $\{\mathbf{3}[(Li^+)_2(thf)_{2n}]\}_m$ in $[D]_8THF$ solution. Since the reduction yielded a mixture of diastereomers with different axial/equatorial C−Me orientations, three B−Me and two C−Me signals were found. This had already been observed by NMR spectroscopy and by X-ray crystal analysis for $(MeCH)_3(ClB)_3$, the precursor of **2**.[5] The ^{11}B NMR signal of reduced **2** at $\delta = -29.2$ is at extremely high-field (neutral **2**: $\delta = 84.3$), and indicates the increased connectivity of the boron atoms.

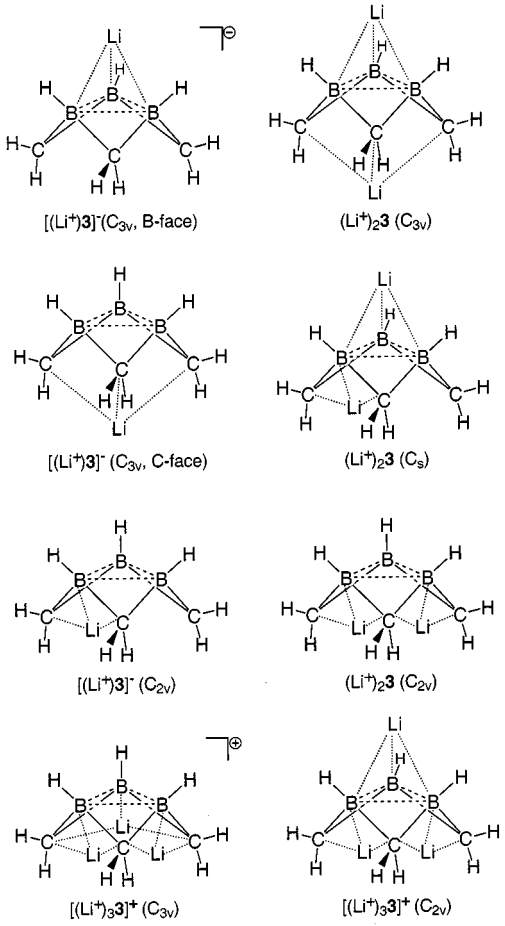
The NMR signals could be assigned to a mixture of two diastereomers — one form with all the methine protons in axial configurations and the other with one equatorial and two axial methine protons. The ratio of diastereomers varies, but the all-axial form always dominates.

The reduction products show a pronounced high-field shift in their ^{11}B NMR spectra (Table 1), although there are quantitative differences showing two trends of opposite direction. The ^{11}B NMR chemical shifts decrease monotonously in absolute value within the alkali metal group, but only from Na to Cs, from $\delta = -35.3$ for $\{\mathbf{3}[(Na^+)_2(thf)_{2n}]\}_m$ to $\delta = -29.8$ for $\{\mathbf{3}[(Cs^+)_2(thf)_{2n}]\}_m$; the Li-reduced product $\{\mathbf{3}[(Li^+)_2(thf)_{2n}]\}_m$ ($\delta = -29.2$) does not seem to fit this trend. The same ordering occurs in the ^{13}C NMR spectra for the C−Me groups and the methine carbon atoms, again with $\{\mathbf{3}[(Li^+)_2(thf)_{2n}]\}_m$ as the exception. In contrast the ^1H NMR spectra show a trend to higher-field methine proton chemical shifts.

The special behavior of the Li-reduced species can be attributed to the decreased electronegativity (EN) of lithium.[9,10] This is due to the smaller effective charge of the Li nucleus. From sodium to cesium the EN decreases monotonously and the C−H and C−Me proton shifts appear at increasingly higher fields (see Table 1).

Computational Results

IGLO ^{11}B NMR shift calculations[7,11] of the C_{3v} model of $[(CH_2)_3(BH)_3Li_3]^+$ $\{[(Li^+)_3\mathbf{3}]^+\}$ gave $\delta^{11}{}_B = -31.8$, in very good agreement with the experimental value. The NICS values,[7] $\delta = -28.5$ at the center of all the C and B atoms and $\delta = -42.3$ at the center of the three boron atoms, also indicate pronounced homoaromatic character (see below). Comprehensive computations on the various possible monomeric minima $[(CH_2)_3(BH)_3Li_3]^+$ $\{[(Li^+)_3\mathbf{3}]^+\}$, $(CH_2)_3(BH)_3Li_2$ $[(Li^+)_2\mathbf{3}]$ and $[(CH_2)_3(BH)_3Li]^-$ $\{[(Li^+)\mathbf{3}^-]\}$, reveal that Li attachment at the B_3 face is preferred over a C_2B unit in all cases $\{[(Li^+)\mathbf{3}^-]$: C_{3v} (B-face); $[(Li^+)_2\mathbf{3}]$: C_s; $[(Li^+)_3\mathbf{3}]^+$: $C_{2v}\}$. The lithium bonding is predominantly electrostatic, but small covalent contributions to the interactions between the Li^+ centers and nearby H, B and C atoms are present. The C_2B-face coordination observed experimentally for $\{\mathbf{3}(Li^+)[Li(thp)_2^+]\}_4$ and $\{\mathbf{3}(Li^+)[(Li[12]cr\text{-}4)_2^+]\}_4$ may be attributed to the combined effects of the steric influences of the methyl groups at the B_3 face and to the electrostatic advantages of the tetrameric association.



Most surprising is the remarkable homoaromatic stabilization energy[3] of the $[(CH_2)_3(BH)_3]^{2-}$ dianion (**3**, R =

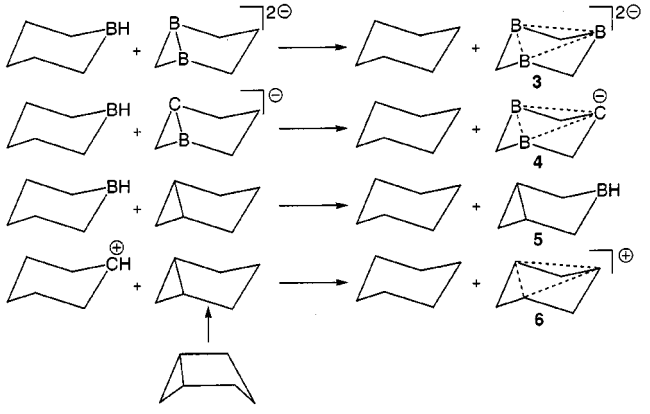
[a] The isodesmic equations (Scheme 5) involve cyclohexane and **3**−**6** as product pairs. The reactants are cyclohexyl cation (for **6**) and boracyclohexane (for **3**−**5**), as well as bicyclo[3.1.0]hexane (for **5** and **6**) and its 1-(B^-) (for **4**) and 1,5-(B^-)$_2$ (for **3**) counterparts. − [b] Energy differences between **3**−**6** and their boat-form conformers which lack 3c,2e bonding (see ref.[7f] for a prior use of this method). − [c] Computed at the mass unweighted centers of the 6-rings. − [d] The ring current contributions (localized by the IGLO method) computed at the centers of the three C/B atom triangles involved in 3c,2e bonding.

R′ = H), which is larger than all three of the isoelectronic counterparts **4**−**6** (Table 2), even when evaluated by two different methods.[12] These stabilization energies are based on the isodesmic reactions in Scheme 5 and the chair (delocalized)−boat (localized) energy differences. This is caused by the reduced coulombic interaction between the two negative charges when they are delocalized over the B_3 triangle. In contrast, the electron repulsion in the classic reference species is high because of two adjacent B^- units. The positive stabilization energies of the neutral analog **5** reflect the ring strain required to achieve the chair conformation (which is greater than the stabilization to be gained). This situation is discussed in ref.[12] The NICS(0) values, based on total NMR shieldings in the six-membered ring centers, and the NICS(rc) values in the 3c,2e ring centers (also given in Table 2) measure the current contributions. Malkin's implementation[7b] of Kutzelnigg's IGLO program[11] provides a detailed breakdown of the total shieldings in terms of all the localized orbital contributions.



Scheme 5

Of greatest interest are the diatropic effects due to the cyclic electron delocalization [i.e., the magnetic evaluation of the 3c,2e "aromatic" bonding given by NICS(rc)]. These values are augmented by the local diatropic shielding contributions of nearby C−C, C−H and B−H bonds. Hence, the NICS(0) values are displaced further upfield. (The local induced circulations of the sigma C−C bonds in benzene, in contrast, are paratropic and reduce the NICS(0) value to ca −10.) The benzene NICS(rc, i.e. π) of about −22 at the ring center is quite similar to the 3c,2e data above.

Conclusion

The reaction of **2** with lithium gave tetrameric aggregates of the trishomoaromatic compounds $\{\mathbf{3}(Li^+)[Li(thp)_2^+]\}_4$ and $[\mathbf{3}(Li^+)]_4\{Li([12]cr\text{-}4)_2^+\}_4$ in the solid state. The expected monomeric dianion **3** (R = R′ = Me) and the cation $\mathbf{3}[(Li^+)(thf)_2]_3^+$ as electronic analogues to the trishomocyclopropenylium cation **6**[6] could not be isolated. Alternatively, the monomeric unit $\mathbf{3}[(Li^+)(thf)_2]_3^+$, with two donor molecules at each of the three Li centers, may be described as a hypho cluster with 26 skeleton electrons.[13]

The reduction product of **2** with sodium crystallizes as a polymeric, meander-like chain, in which the trishomoaromatic units are bridged at C_2B faces by half of the sodium ions, with the other half connected in terminal positions to one C_2B face and three THF ligands. A tetramer of **3** with an unusual structure was obtained in the presence of [18]crown-6. The linear polymer $[\mathbf{3}(K^+)(K[18]cr\text{-}6)^+]_m$ is formed with potassium as the electron donor. NMR spectroscopic data show that reduction with rubidium and with cesium also led to the doubly reduced ring systems.

The NMR spectra of all the Li-reduced compound $\{\mathbf{3}[(M^+)_2(thf)_{2n}]\}_m$ show regular trends of chemical shifts from Na to Cs, but the Li values are often out of line due to the exceptional electronegativity of lithium. The trishomoaromatic delocalized three center, two electron bonding in the reduced 1,3,5-triboracyclohexanes (**3**), as well as in the isoelectronic series **3**−**5**, is demonstrated by the highly negative NICS values computed inside the rings. These indicate the presence of large induced diatropic ring currents in all these systems. In addition, the stabilization energies due to the 3c,2e delocalization are quite large.

Experimental Section

General: All reactions were carried out under dry argon or nitrogen using standard Schlenk techniques. Solvents were dried, distilled,

and saturated with nitrogen. Glassware was dried with a heat-gun under high vacuum. The alkali metals were washed with *n*-hexane and THF, heated in THF for 2 h under reflux and filtered. Lithium was used as a powder, and sodium, potassium, rubidium and cesium as blocks. – ^{1}H, ^{13}C and ^{11}B NMR: Bruker DRX 200 spectrometer, NMR references are $(CH_3)_4Si$ and $Et_2O{\cdot}BF_3$.

General Procedure for the Reduction of the Triboraheterocycles: A suspension of excess alkali metal in THF or Et_2O was cooled to 0 °C. The boron heterocycle was added and stirred overnight while warming to room temperature. Separation of the unreacted alkali metal by filtration through a glass filter of G III porosity led to clear yellow-orange solutions. Removal of the solvent gave amorphous residues of $[\mathbf{3}(M^+)_2(thf_2)_{2n}]_m$ and $[\mathbf{3}(M^+)_2(OEt_2)_{2n}]_m$, which are soluble in [D$_8$]THF.

Reduction of 2 with Lithium: Amounts: diethyl ether (20 mL), **2** (200 mg, 1.23 mmol). For crystallization the solution was concentrated to 1−2 mL by vacuum evaporation and THP or [12]crown-4 (0.2 mL) was added to yield $[\mathbf{3}(Li^+)]_4[Li(thp)_2{}^+]_4$ (28 mg, 7%) or $[\mathbf{3}(Li^+)]_4\{Li([12]cr\text{-}4)_2{}^+\}_4$ (12 mg, 3%). NMR spectroscopic data of the initial reduction product $[\mathbf{3}(Li^+)_2(OEt_2)_{2n}]_m$: ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −3.42 [q, ^3J(H,H) = 3 Hz, 3 H, CH_{ax}], −3.2 (br. m, 2 H, CH_{ax}), −1.7 (br. m, 1 H, CH_{eq}], −0.6 (br. s, 9 H, BCH_3), −0.5 (br. s, 6 H, BCH_3), −0.5 (br. s, 3 H, BCH_3), 0.81 [d, ^3J(H,H) = 3 Hz, 3 H, $C(CH_3)_{ax}$], 1.23 [d, ^3J(H,H) = 3 Hz, 6 H, $C(CH_3)_{eq}$], 1.35 [d, ^3J(H,H) = 3 Hz, 9 H, $C(CH_3)_{eq}$]. – ^{13}C NMR (50 MHz, [D$_8$]THF): δ = −4.0 (CH), 15.4 (CCH_3), 15.6 (BCH_3). – ^{11}B NMR (64 MHz, [D$_8$]THF): δ = −29.2.

Reduction of 2 with Sodium: Amounts: THF (40 mL), **2** (150 mg, 0.93 mmol). Crystallization from the filtered solution after solvent removal to ca. 1 mL gave $\{\mathbf{3}(Na^+)[Na(thf)_3{}^+]\}_m$ (95 mg, 0.22 mmol, 24%). After addition of [18]crown-6 (420 mg) to the filtered solution, crystallization occurred after solvent evaporation to 1 mL to give $\{(thf)_2Na([18]cr\text{-}6)\}^+\{[\mathbf{3}(Na^+)\text{-}(thf)]_4(Na^+)_2\}^{2-}\{(thf)Na([18]cr\text{-}6)\}^+$ (43 mg, 0.02 mmol, 9%). NMR spectroscopic data of the initial reduction product $[\mathbf{3}(Na^+)_2(thf)_{2n}]_m$ (ratio of diastereomers $(CH_{ax})_3/(CH_{ax})_2(CH_{eq})$ = 3:1): ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −3.34 [q, ^3J(H,H) = 3 Hz, 3 H, CH_{ax}], −3.03 [q, ^3J(H,H) = 3 Hz, 2 H, CH_{ax}], −1.57 [q, ^3J(H,H) = 3 Hz, 1 H, CH_{eq}], −0.6 (br. s, 9 H, BCH_3), 0.82 [d, ^3J(H,H) = 3 Hz, 3 H, $C(CH_3)_{ax}$], 1.05 [d, ^3J(H,H) = 3 Hz, 6 H, $C(CH_3)_{eq}$], 1.16 [d, ^3J(H,H) = 3 Hz, 9 H, $C(CH_3)_{eq}$]. – ^{13}C NMR (50 MHz, [D$_8$]THF): δ = −3.9 (CH), 15.2 (CCH_3), 15.4 (BCH_3). – ^{11}B NMR (64 MHz, [D$_8$]THF): δ = −35.3 and −37.1.

Reduction of 2 with Potassium: Amounts: THF (40 mL), **2** (140 mg, 0.86 mmol). After reaction and filtration, [18]crown-6 (350 mg) was added to the solution. The solvent was partially removed in vacuum and $[\mathbf{3}(K^+)(K[18]cr\text{-}6)^+]_m$ (56 mg, 0.11 mmol, 12%) crystallized. NMR spectroscopic data of the initial reduction product $[\mathbf{3}(K^+)_2(thf)_{2n}]_m$ (ratio of diastereomers $(CH_{ax})_3/(CH_{ax})_2(CH_{eq})$ = 6:1): ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −3.64 [q, ^3J(H,H) = 3 Hz, 3 H, CH_{ax}], −3.34 [q, ^3J(H,H) = 3 Hz, 2 H, CH_{ax}], −1.80 [q, ^3J(H,H) = 3 Hz, 1 H, CH_{eq}], −0.7 (br. s, 9 H, BCH_3), −0.6 (br. s, 6 H, BCH_3), 0.82 [m, 3 H, $C(CH_3)_{ax}$], 1.03 [d, ^3J(H,H) = 3 Hz, 6 H, $C(CH_3)_{eq}$], 1.09 [d, ^3J(H,H) = 3 Hz, 9 H, $C(CH_3)_{eq}$]. – ^{13}C NMR (50 MHz, [D$_8$]THF): δ = −2.1 (CH), 15.5 (CCH_3), 16.0 (BCH_3). – ^{11}B NMR (64 MHz, [D$_8$]THF): δ = −32.4.

Reduction of 2 with Rubidium: Amounts: THF (50mL), **2** (200 mg, 1.23 mmol). NMR spectroscopic data of the amorphous reduction

product $[\mathbf{3}(Rb^+)_2(THF)_{2n}]_m$ (ratio of diastereomers $(CH_{ax})_3/(CH_{ax})_2(CH_{eq}) = 9:1$): ^1H NMR (200 MHz, [D$_8$]THF): δ = −3.78 [q, $^3J(H,H)$ = 3 Hz, 3 H, CH_{ax}], −3.46 [q, $^3J(H,H)$ = 3 Hz, 2 H, CH_{ax}], −1.84 [q, $^3J(H,H)$ = 3 Hz, 1 H, CH_{eq}], −0.7 (br. s, 9 H, BCH_3), −0.6 (br. s, 6 H, BCH_3), 0.84 [m, 3 H, $C(CH_3)_{ax}$], 0.93 [d, $^3J(H,H)$ = 3 Hz, 6 H, $C(CH_3)_{eq}$], 1.05 [d, $^3J(H,H)$ = 3 Hz, 12 H, $C(CH_3)_{eq}$]. − ^{13}C NMR (50 MHz, [D$_8$]THF): δ = −1.3 (CH), 16.1 (CCH_3), 17.8 (BCH_3). − ^{11}B NMR (64 MHz, [D$_8$]THF): δ = −31.5.

Reduction of 2 with Cesium: Amounts: THF (50mL), **2** (190 mg, 1.17 mmol). NMR spectroscopic data of the amorphous reduction product $[\mathbf{3}(Cs^+)_2(THF)_{2n}]_m$ (ratio of diastereomers $(CH_{ax})_3/(CH_{ax})_2(CH_{eq}) = 12:1$): ^1H NMR (200 MHz, [D$_8$]THF): δ = −3.89 [q, $^3J(H,H)$ = 3 Hz, 3 H, CH_{ax}], −3.64 [q, $^3J(H,H)$ = 3 Hz, 2 H, CH_{ax}], −1.89 [q, $^3J(H,H)$ = 3 Hz, 1 H, CH_{eq}], −0.8 (br. s, 9 H, BCH_3), −0.7 (br. s, 6 H, BCH_3), 0.82 [d, $^3J(H,H)$ = 3 Hz, 3 H, $C(CH_3)_{ax}$], 0.91 [d, $^3J(H,H)$ = 3 Hz, 6 H, $C(CH_3)_{eq}$], 1.01 [d, $^3J(H,H)$ = 3 Hz, 9 H, $C(CH_3)_{eq}$]. − ^{13}C NMR (50 MHz, [D$_8$]THF): δ = −1.3 (CH), 16.1 (CCH_3), 17.8 (BCH_3). − ^{11}B NMR (64 MHz, [D$_8$]THF): δ = −29.8.

X-ray Structure Determinations of $\{3(Li^+)[Li(thp)_2^+]\}_4$, $[3(Li^+)]_4\{Li([12]cr\text{-}4)_2^+\}_4$, $\{3(Na^+)[Na(thf)_3^+]\}_m$, $\{(thf)_2Na([18]cr\text{-}6)\}^+\{[3(Na^+)(thf)]_4(Na^+)_2\}^{2-}\{(thf)Na([18]cr\text{-}6)\}^+$ and $[3(K^+)(K[18]cr\text{-}6)^+]_m$: Crystal data and details of the structure determinations are listed in Table 3. Intensity data for $\{3(Li^+)[Li(thp)_2^+]\}_4$ and $[3(Li^+)]_4\{Li([12]cr\text{-}4)_2^+\}_4$ were collected at 210 K with a Siemens Stoe AED2 diffractometer, and for $\{3(Na^+)[Na(thf)_3^+]\}_m$, $\{(thf)_2Na([18]cr\text{-}6)\}^+\{[3(Na^+)(thf)]_4(Na^+)_2\}^{2-}\{(thf)Na([18]cr\text{-}6)\}^+$ and $[3(K^+)(K[18]cr\text{-}6)^+]_m$ at 173 K with a Bruker AXS Smart 1000 (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, ω-scan). The structures were solved by direct methods and refined by least-squares methods based on F^2 with all measured reflections (SHELXL-97).[14] Non-hydrogen atoms were refined anisotropically (in $\{(thf)_2Na([18]cr\text{-}6)\}^+\{[3(Na^+)(thf)]_4(Na^+)_2\}^{2-}\{(thf)Na([18]cr\text{-}6)\}^+$ only the Na atoms). Most of the hydrogen atoms were inserted in their calculated positions. The THF and crown ligands are in some cases severely disordered. The crystal structure of $\{(thf)_2Na([18]cr\text{-}6)\}^+\{[3(Na^+)(thf)]_4(Na^+)_2\}^{2-}\{(thf)Na([18]cr\text{-}6)\}^+$ is not very precise, due to the very limited data set.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication nos. CCDC-133326 ($[\mathbf{3}(Li^+)_2([12]cr\text{-}4)_2]_4$), -156933 ($\{\mathbf{3}(Na^+)[Na(thf)_3^+]\}_m$), -156934 ($\{(thf)_2Na([18]cr\text{-}6)\}^+\{[3(Na^+)(thf)]_4(Na^+)_2\}^{2-}\{(thf)Na([18]cr\text{-}6)\}^+$) and -156935 ($[\mathbf{3}(K^+)(K[18]cr\text{-}6)^+]_m$). Copies of the data can be obtained free of charge upon application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Vinylidene, Vinyl, and Carbene Ruthenium Complexes with Chelating Diphosphanes as Ligands

Helmut Werner,*[a] Stefan Jung,[a] Pablo González-Herrero,[a] Kerstin Ilg,[a] and Justin Wolf[a]

Dedicated to Professor Wolfgang Kiefer on the occasion of his 60th birthday

Keywords: Ruthenium / Carbene ligands / Vinylidene ligands / Chelates / Phosphanes

The ruthenium vinylidenes $[RuCl_2(=C=CHR)(PR'_3)_2]$ (**1**, **2**) react with 1,2-$C_2H_4(PCy_2)_2$ (**3**) to give the chelate complexes $[RuCl_2(=C=CHR)(\kappa^2\text{-}\mathbf{3})]$ (**4**, **5**) by displacement of the two monodentate phosphane ligands. In contrast, the reaction of the hydrido compound $[RuHCl(=C=CH_2)(PCy_3)_2]$ (**6**) with excess **3** proceeds by migration of the hydride to the Cα carbon atom of the vinylidene unit and affords the six-coordinate vinyl complex *trans*-$[RuCl(CH=CH_2)(\kappa^2\text{-}\mathbf{3})_2]$ (**7**). Protonation of **7**, followed by addition of NH_4PF_6, yields the cationic ruthenium carbene *trans*-$[RuCl(=CHCH_3)(\kappa^2\text{-}\mathbf{3})_2]PF_6$ (**8**), together with small quantities of the hydrido compound $[RuH(\kappa^2\text{-}\mathbf{3})_2]PF_6$ (**9**). The Grubbs catalyst $[RuCl_2(=CHPh)(PCy_3)_2]$ (**10**) reacts with both **3** and $[Fe(\eta^5\text{-}C_5H_4PPh_2)_2]$ (**11**), also by ligand substitution, to give the corresponding chelate complexes $[RuCl_2(=CHPh)(\kappa^2\text{-}\mathbf{3})]$ (**12**) and $[RuCl_2(=CHPh)(\kappa^2\text{-}\mathbf{11})]$ (**13**); the latter has been characterized by X-ray crystal structure analysis.

Introduction

Recently, we reported that the reaction of the hydrido compound $[RuHCl(=C=CH_2)(PCy_3)_2]$ with acids HA, having a non-coordinating anion A^- such as BF_4^- or $B(Ar_f)_4^-$ [Ar_f = 3,5-$C_6H_3(CF_3)_2$], affords, in the presence of a donor solvent S, the six-coordinate carbyne(hydrido) complexes $[RuHCl(\equiv CCH_3)(PCy_3)_2(S)]A$ instead of the anticipated five-coordinate vinylideneruthenium derivatives $[RuCl(=C=CH_2)(PCy_3)_2(S)]A$.[1] Although the carbyne(hydrido) cations are highly efficient catalysts for the ring-opening metathesis polymerization (ROMP) of cyclooctene as well as for the cross-olefin metathesis of cyclopentene with methylacrylate, their lifetime is rather limited and significantly shorter than that of the corresponding ruthenium carbene $[RuCl_2(=CHCH_3)(PCy_3)_2]$.[2,3] This unfavorable aspect prompted us to prepare five-coordinate vinylideneruthenium complexes with chelating diphosphanes as ligands, which, we hoped, would be more suitable starting materials for the synthesis of stable cationic ruthenium carbynes. In this context it has to be mentioned that during the progress of this work, Hofmann et al. described the preparation and structural characterization of the carbeneruthenium compounds $[RuCl_2(=CHR)\{\kappa^2\text{-}tBu_2P(CH_2)_nPtBu_2\}]$ (n = 1 and 2) which, in the presence of trimethylsilyl triflate, catalyze the ring-opening metathesis polymerization (ROMP) of strained cycloolefins such as cyclooctene or norbornene.[4,5]

Results and Discussion

The reaction of the dichlororuthenium compound **1**[6] with an excess of the sterically demanding diphosphane **3** in ether results in the displacement of the two monodentate phosphane ligands and the formation of the chelate complex **4**, which precipitated as a yellow solid and was isolated in 94% yield (Scheme 1). The synthesis of the related complex **5** could only be achieved using **2** as the starting material since the bis(tricyclohexylphosphane)ruthenium counterpart $[RuCl_2(=C=CHPh)(PCy_3)_2]$[6,7] does not react with **3** by substitution of the PCy_3 units. The yield of **5** is relatively low (31%) due to the formation of an insoluble (probably polymeric) by-product. Both **4** and **5** are quite stable in the solid state but slowly decompose in solution. The ^1H NMR spectra of **4** and **5** display a triplet at δ = 3.26 (**4**) and 4.62 (**5**), which is assigned to the =C*H*R proton of the vinylidene ligand. The ^{13}C NMR spectra show the resonance for the Cα carbon atom of the Ru=C=CHR unit at δ = 353.0 (**4**) and 355.4 (**5**), the low-field chemical shift

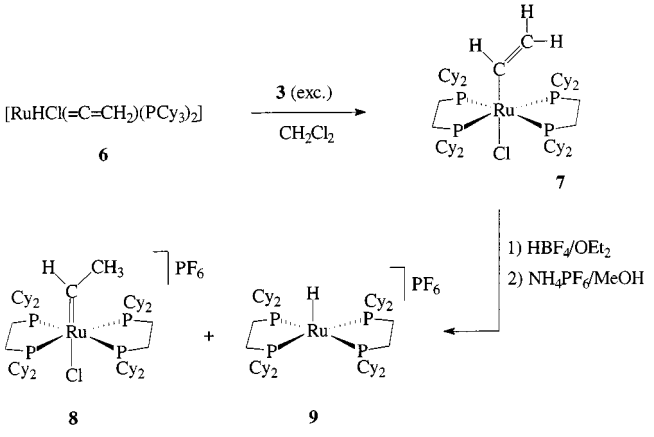
being in good agreement with the data observed for other mononuclear ruthenium vinylidenes.[6–8]

The most important feature of the NMR spectroscopic data of **4** and **5**, however, is the appearance of *two* signals at δ = 74.9, 73.5 (**4**) and 76.9, 74.5 (**5**) in the ^{31}P NMR spectra that are part of an AB system. The conclusion is that the chelating five-coordinate vinylidene complexes do not possess any plane of symmetry and, as found in the crystal structure of **1**,[6] the C–R bond lies parallel to one of the Ru–Cl bonds. Moreover, the rotation around the Ru=C=C axis must be significantly hindered, possibly due to the steric requirements of the four cyclohexyl groups.

Both **4** and **5** can be protonated with $HBF_4{\cdot}OEt_2$. While the protonation of **4** requires only one equivalent of the acid, the corresponding reaction of **5** requires an excess. In both cases a mixture of two products is formed of which one, according to the ^1H and ^{31}P NMR spectroscopic data, is the expected cationic ruthenium carbyne. Unfortunately, all attempts to separate the two compounds by fractional crystallization failed. The protonation is reversible and thus, upon addition of ether to a solution of the products in CH_2Cl_2, the ruthenium vinylidenes **4** and **5** are regenerated.

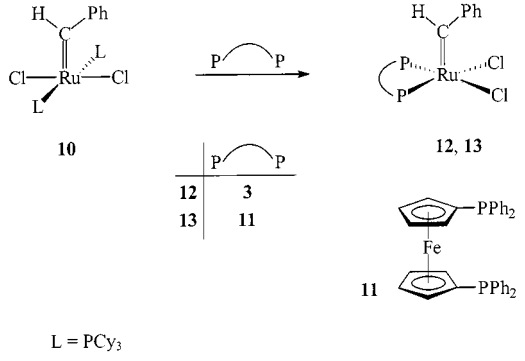
In contrast to **1**, which upon treatment with **3** affords the vinylidene compound **4**, the reaction of the chloro(hydrido) derivative **6** with a sixfold excess of **3** gives the vinylruthenium(II) complex **7** in 75% isolated yield (Scheme 2). A similar conversion of a RuH(=C=CHR) to a Ru(CH=CHR) moiety was recently reported by Caulton et al. who prepared the cationic vinyl compound [Ru(CH=CHSiMe$_3$)(CNMe)$_3$(P*t*Bu$_2$Me)$_2$]I from [RuHI(=C=CHSiMe$_3$)(P*t*Bu$_2$Me)$_2$] and methyl isocyanide.[9] With regard to the structure of **7**, we assume that the two chelating diphosphane ligands are *trans* disposed which is consistent with the single resonance in the ^{31}P NMR spectrum at δ = 53.2.

In analogy to the five-coordinate vinyl complex [Ru(CH=CH$_2$)(CH$_3$CN)$_2$(PCy$_3$)$_2$]BF$_4$, which reacts with HBF_4 in ether to generate the dicationic ruthenium carbene [Ru(=CHCH$_3$)(CH$_3$CN)$_2$(PCy$_3$)$_2$](BF$_4$)$_2$,[10] treatment of **7** with ethereal HBF_4, followed by addition of NH_4PF_6, gives the monocationic, six-coordinate carbene compound **8** in moderate yield. The hydrido complex **9** is formed (yield 10%) as a by-product; it was previously obtained by Winter and Hornung from [RuCl$_2$(DMSO)$_4$], **3** and NH*i*Pr$_2$ in the presence of NH_4PF_6.[11] Typical spectroscopic features of **8** are the signal for the RuC*H* proton at δ = 16.48 in the ^1H NMR spectrum and the multiplet for the carbene carbon atom at δ = 342.9 in the ^{13}C NMR spectrum; the latter appears as a singlet after $^{13}C\{^{31}P\}$ decoupling. Similarly to **4** and **5**, the ^{31}P NMR spectrum of **8** displays two resonances at δ = 80.3 and 78.9, corresponding to an AB system, which illustrates that the PCy$_2$ units are pairwise inequivalent.



Scheme 2

In order to compare the reactivity of the five-coordinate ruthenium vinylidenes **1** and **2** with that of related ruthenium carbenes, the Grubbs catalyst **10** was also treated with **3** as well as with 1,1′-bis(diphenylphosphanyl)ferrocene (**11**). In both cases the monodentate PCy$_3$ ligands are readily displaced and the chelate compounds **12** and **13** (Scheme 3) are isolated in nearly quantitative yield. Both **12** and **13** can be stored under argon for weeks without decomposition, and they are also significantly more stable in solution than their vinylidene counterparts **4** and **5**. The ^1H NMR spectra of **12** and **13** show the expected triplet resonance for the Ru=C*H*Ph proton at δ = 14.68 (**12**) and 17.18 (**13**), while the signal for the carbene carbon atom is observed in the ^{13}C NMR spectra at δ = 282.6 (**12**) and 364.3 (**13**). Consistent with the results obtained by Hofmann and co-workers,[4,5] the ruthenium carbenes **12** and **13** are inactive in the ROMP of cyclooctene, but become good catalysts for olefin metathesis upon addition of trimethylsilyl triflate.



Scheme 3

The molecular structure of **13** is shown in Figure 1. In contrast to the ruthenium vinylidene [RuCl$_2$(=C=CHPh)(PCy$_3$)$_2$][7] and the related ruthenium carbenes [RuCl$_2$(=CHCH=CMe$_2$)(κ^2-*t*Bu$_2$PCH$_2$P*t*Bu$_2$)][4] and [RuCl(=CHPh)(κ^2-*t*Bu$_2$PCH$_2$CH$_2$-P*t*Bu$_2$)],[5] the geometry around the metal center is not square-pyramidal but distorted trigonal-bipyramidal. The P1–Ru–Cl2 axis, connecting the ligand atoms in the apical positions, is somewhat bent [167.23(5)°] which could be due to the steric hindrance between the two phenyl rings containing the carbon atoms C30–C35 and C2–C7. While the angle C1–Ru–P2 is near to 90°, the two other bond angles in the basal plane of the molecule are considerably larger [123.93(14)° and 146.96(5)°, respectively]. Owing to the che-

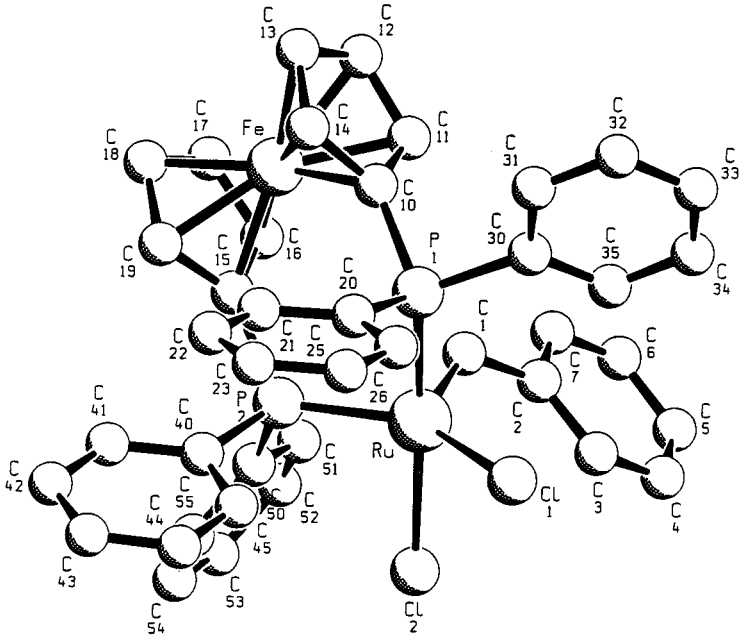


Figure 1. Molecular structure (SCHAKAL plot) of **13**; four of the five phenyl rings are reduced in size and the hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Ru−C1 1.860(5), Ru−P1 2.3151(14), Ru−P2 2.2718(12), Ru−Cl1 2.3949(13), Ru−Cl2 2.4115(14), C1−C2 1.470(7); P1−Ru−P2 95.32 (5), P1−Ru−C1 90.46(16), P1−Ru−Cl1 84.07(5), P1−Ru−Cl2 167.23(5), P2−Ru−C1 89.07(14), P2−Ru−Cl1 146.96(5), P2−Ru−Cl2 87.13(5), Cl1−Ru−Cl2 86.93(5), C1−Ru−Cl1 123.93(14), C1−Ru−Cl2 102.09(16), Ru−C1−C3 125.3(4)

lating coordination of **11**, the cyclopentadienyl rings are not parallel to each other, the two planes C10−C11−C12−C13−C14 and C15−C16−C17−C18−C19 forming a dihedral angle of 37.7(3)°. The Ru−C1 bond length [1.860(5) Å] is almost identical to that of the Hofmann compounds [$RuCl_2(=CHCH=CMe_2)(\kappa^2$-$t Bu_2PCH_2Pt Bu_2)$] [1.858(2) Å][4] and [$RuCl_2(=CHPh)(\kappa^2$-$t Bu_2PCH_2CH_2Pt Bu_2)$] [1.836(3) Å][5] and differs only slightly from that of the bis(tricyclohexylphosphane) complexes [$RuCl_2(=CH$-p-$C_6H_4Cl)(PCy_3)_2$] [1.839(3) Å][2] and [$RuCl(CN)(=CHCH_3)(PCy_3)_2$] [1.810(6) Å].[12] The Ru−P distances of **13** are in the expected range and that is also true for the Ru−Cl bond lengths.

Experimental Section

All operations were carried out under argon using Schlenk techniques. The starting materials **1**,[6] **2**,[7] **3**,[13] **6**,[3] and **10**[2] were prepared as described in the literature. Compound **11** was a product from Aldrich. − NMR: Bruker AC 200 and AMX 400 [dvt = doublet of virtual triplets; $N = {}^3J(PH) + {}^5J(PH)$ or ${}^2J(PC) + {}^4J(PC)$]. − MS: Finnigan 90 MAT. − Melting points determined by DTA.

Preparation of [$RuCl_2(=C=CHt Bu)(\kappa^2$-3)] (4): A solution of **1** (1.13 g, 1.39 mmol) in 60 mL of ether was treated with **3** (878 mg, 2.08 mmol) and stirred for 7.5 h at room temperature. A yellow solid precipitated, which was separated from the mother liquor, washed with ether (2 × 10 mL) and recrystallized from CH_2Cl_2/pentane (1:10) (−20 °C); yield 884 mg (94%); m.p. 174 °C (dec.). − IR (KBr): ν(C=C) = 1648 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 3.26 [t, J(PH) = 3.8 Hz, 1 H, =C*H*R], 2.59−1.26 (br. m, 48 H, CH_2 and C_6H_{11}), 1.20 (s, 9 H, CCH_3). − $^{13}C\{^1H,^{31}P\}$ NMR (100.6 MHz, $CDCl_3$): δ = 353.0 (Ru=C), 118.9 (=*C*HR), 40.2, 39.9, 39.3, 38.3 (CH of C_6H_{11}), 33.1 (CCH_3), 32.1 (CCH_3), 30.4, 30.0, 29.9, 29.6, 28.8, 28.7, 28.2, 27.7, 27.5, 27.4, 26.9, 26.1, 26.0 (CH_2 of C_6H_{11}), 21.5, 20.1 (CH_2 of **3**). − $^{31}P\{^1H\}$ NMR (162.0 MHz, $CDCl_3$): δ = 74.9, 73.5 (AB system, J = 13.5 Hz). − $C_{32}H_{58}Cl_2P_2Ru$ (676.7): calcd. C 56.97, H 8.64; found C 56.60, H 8.22.

Preparation of [$RuCl_2(=C=CHPh)(\kappa^2$-3)] (5): A solution of **2** (347 mg, 0.58 mmol) in 20 mL of ether was treated with **3** (438 mg, 1.04 mmol) and stirred for 2.5 h at room temperature. A pink solid slowly precipitated which was separated from the mother liquor, washed with ether (2 × 10 mL) and suspended in 8 mL of CH_2Cl_2. A color change from pink to yellow occurred upon stirring this suspension for 4.5 h at room temperature. The suspension was filtered to remove the insoluble by-product, the filtrate was concentrated to ca. 3 mL in vacuo and 20 mL of ether was added. A greenish-yellow precipitate was formed which was recrystallized from CH_2Cl_2/ether (1:10) (−20 °C): yield 127 mg (31%); m.p. 128 °C (dec.). − IR (KBr): ν(C=C) = 1626 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 7.20, 7.02 (both m, 5 H, C_6H_5), 4.62 [t, J(PH) = 3.5 Hz, 1 H, =C*H*Ph], 2.69−0.90 (br. m, 48 H, CH_2 and C_6H_{11}). − $^{13}C\{^1H,^{31}P\}$ NMR (100.6 MHz, $CDCl_3$): δ =355.4 (Ru=C), 128.5, 127.9, 126.8, 125.9 (all C_6H_5), 112.3 (=*C*HPh), 40.9, 40.0, 39.5, 38.0 (CH of C_6H_{11}), 30.2, 30.0, 29.3, 28.9, 28.6, 28.4, 27.5, 27.2, 27.1, 27.0, 26.9, 26.6, 26.0, 25.9, 25.5, 25.4 (CH_2 of C_6H_{11}), 22.3, 20.4 (CH_2 of **3**). − $^{31}P\{^1H\}$ NMR (162.0 MHz, $CDCl_3$): δ = 76.9, 74.5 (AB system, J = 15.3 Hz). − $C_{34}H_{54}Cl_2P_2Ru$ (696.8): calcd. C 58.61, H 7.81; found C 58.25, H 7.44.

Preparation of *trans*-[$RuCl(CH=CH_2)(\kappa^2$-3)$_2$] (7): A solution of **6** (350 mg, 0.48 mmol) in 25 mL of CH_2Cl_2 was treated with a solution of **3** (1.21 g, 2.85 mmol) in 15 mL of CH_2Cl_2 and stirred for 1 h at room temperature. The solvent was evaporated in vacuo, and the off-white solid was washed with pentane (2 × 10 mL) and dried: yield 365 mg (75%); m.p. 54 °C (dec.). − IR (KBr): ν(C=C) = 1528 cm^{-1}. − ^1H NMR (300 MHz, CD_2Cl_2): δ = 6.74 (m,

1 H, RuCH), 4.67 [d, *J*(HH) = 7.2 Hz, 1 H, one H of CH_2 *cis* to =CH], 3.91 [d, *J*(HH) = 15.3 Hz, 1 H, one H of CH_2 *trans* to =CH], 2.43−1.14 (br. m, 96 H, CH_2 of **3** and C_6H_{11}). − $^{13}C\{^1H\}$ NMR (75.5 MHz, CD_2Cl_2): δ = 146.8 (m, RuCH), 120.1 (m, $=CH_2$), 39.3, 35.5 (both m, CH of C_6H_{11}), 30.5, 29.9, 29.6, 29.1, 28.0, 27.7, 27.4, 27.3, 26.1, 26.0 (all s, CH_2 of C_6H_{11}), 18.0 (m, CH_2 of **3**). − $^{31}P\{^1H\}$ NMR (162.0 MHz, CD_2Cl_2): δ = 53.2 (s). − $C_{54}H_{99}ClP_4Ru$ (1008.8): calcd. C 64.29, H 9.89; found C 64.13, H 9.88.

Preparation of *trans*-[RuCl(=CHCH$_3$)(κ^2-3)$_2$]PF$_6$ (8): A solution of **7** (309 mg, 0.31 mmol) in 20 mL of CH_2Cl_2 was treated at −78 °C with 0.4 mL of a 1.6 M solution of HBF_4 (0.64 mmol) in ether. After stirring the solution 30 min. at −78 °C, the solvent was evaporated in vacuo and the residue washed with ether (2 × 10 mL). The brownish yellow solid, which according to the ^1H NMR spectrum consists of a mixture of the BF_4^- salts of the cations $[RuCl(=CHCH_3)(\kappa^2\text{-}\mathbf{3})_2]^+$ and $[RuH(\kappa^2\text{-}\mathbf{3})_2]^+$, was suspended in 15 mL of methanol and the suspension was treated dropwise with a solution of NH_4PF_6 (340 mg, 2.09 mmol) in 10 mL of methanol. Stirring the reaction mixture for 25 min. at room temperature led to the formation of a pink precipitate of **8**, which was separated from the mother liquor, washed with methanol (2 × 15 mL) and dried: yield 111 mg (39%). From the mother liquor and the combined washings a yellow solid slowly precipitated which was identified as $[RuH(\kappa^2\text{-}\mathbf{3})_2]PF_6$ (**9**) by comparison with reference data.[11]

8: m.p. 92 ° C (dec.). − Λ(CH_3NO_2) = 53.4 cm$^2\Omega^{-1}$ mol^{-1}. − ^1H NMR (400 MHz, CD_2Cl_2): δ = 16.48 [m; in $^1H\{^{31}P\}$: q, *J*(HH) = 6.0 Hz, 1 H, =CH], 2.94 [d, *J*(HH) = 6.0 Hz, 3 H, CH_3], 2.81, 2.66, 2.44−0.90 (all m, 96 H, CH_2 and C_6H_{11}). − $^{13}C\{^1H\}$ NMR (100.6 MHz, CD_2Cl_2): δ = 342.9 [quin, *J*(PC) = 14.5 Hz, Ru=C], 49.5 (s, CH_3), 39.9 [d, *J*(PC) = 21.6 Hz, CH of C_6H_{11}], 38.0 [d, *J*(PC) = 24.2 Hz, CH of C_6H_{11}], 37.6 [d, *J*(PC) = 22.9 Hz, CH of C_6H_{11}], 37.5 [d, *J*(PC) = 25.4 Hz, CH of C_6H_{11}], 29.9, 29.4, 29.3 (all s, CH_2 of C_6H_{11}), 28.9 [d, *J*(PC) = 2.6 Hz, CH_2 of C_6H_{11}], 28.6 [d, *J*(PC) = 6.4 Hz, CH_2 of C_6H_{11}], 28.5 [d, *J*(PC) = 5.1 Hz, CH_2 of C_6H_{11}], 27.8−27.1 (m, CH_2 of C_6H_{11}), 26.7 [d, *J*(PC) = 11.4 Hz, CH_2 of C_6H_{11}], 26.4, 26.2, 26.1 (all s, CH_2 of C_6H_{11}), 20.0, 19.4 [both dd, *J*(PC) = 29.2 and 8.9 Hz, CH_2 of **3**]. − $^{31}P\{^1H\}$ NMR (162.0 MHz, CD_2Cl_2): δ = 80.3, 78.9 (AB system, *J* = 21.8 Hz), −144.4 [sept, *J*(PF) = 710.7 Hz, PF_6^-]. − $C_{54}H_{100}ClF_6P_5Ru$ (1154.8): calcd. C 56.17, H 8.73; found C 55.88, H 8.27.

Preparation of *trans*-[RuCl$_2$(=CHPh)(κ^2-3)] (12): A solution of **10** (202 mg, 0.25 mmol) in 8 mL of CH_2Cl_2 was treated with a solution of **3** (129 mg, 0.31 mmol) in 5 mL of CH_2Cl_2 and stirred for 3.5 h at room temperature. The solvent was evaporated in vacuo, the remaining greenish solid was washed with pentane (3 × 10 mL) and ether (2 × 8 mL) and then dried: yield 160 mg (92%); m.p. 76 °C (dec.). − ^1H NMR (400 MHz, CD_2Cl_2): δ = 14.68 [t, *J*(PH) = 16.1 Hz, 1 H, =C*H*Ph], 8.41, 7.70−7.34 (both m, 5 H, C_6H_5), 2.30−0.86 (m, 48 H, CH_2 and C_6H_{11}). − $^{13}C\{^1H\}$ NMR (100.6 MHz, CD_2Cl_2): δ = 292.6 [t, *J*(PC) = 16.5 Hz, Ru=C], 148.7 (s, *ipso*-C of C_6H_5), 131.5, 130.5, 128.8 (all s, C_6H_5), 38.1, 36.3 (both m, CH of C_6H_{11}), 30.1, 28.8, 28.4, 28.2 (all s, CH_2 of C_6H_{11}), 27.5−26.5 (m, CH_2 of C_6H_{11}), 26.4, 26.0 (both s, CH_2 of C_6H_{11}), 20.1 [dd, *J*(PC) = 20.4 and 16.5 Hz, CH_2 of **3**]. − $^{31}P\{^1H\}$ NMR (162.0 MHz, CD_2Cl_2): δ = 81.7 (s). − $C_{33}H_{54}Cl_2P_2Ru$ (684.7): calcd. C 57.89, H 7.95; found C 57.65, H 7.57.

Preparation of *trans*-[RuCl$_2$(=CHPh)(κ^2-11)] (13): A solution of **10** (492 mg, 0.60 mmol) in 15 mL of CH_2Cl_2 was treated with a solution of **11** (398 mg, 0.72 mmol) in 10 mL of CH_2Cl_2 and stirred for 7 h at room temperature. The solvent was evaporated in vacuo, the remaining olive-green solid was washed with acetone (2 × 5 mL) and pentane (2 × 6 mL) and then dried: yield 430 mg (88%); m.p. 176 °C (dec.). − ^1H NMR (200 MHz, CD_2Cl_2): δ = 17.18 [t, *J*(PH) = 18.2 Hz, 1 H, =C*H*Ph], 7.88−7.02 (br. m, 25 H, C_6H_5), 4.78, 4.59, 4.47, 4.36 (all s, 8 H, C_5H_4). − $^{13}C\{^1H\}$ NMR (100.6 MHz, CD_2Cl_2): δ = 364.3 [t, *J*(PC) = 21.0 Hz, Ru=C], 150.5 (s, *ipso*-C of C_6H_5), 135.7, 133.5 [both t, *J*(PC) = 5.1 Hz, C_6H_5], 132.7, 131.0, 130.7, 129.6, 129.5 (all s, C_6H_5), 127.9, 127.2 [both t, *J*(PC) = 5.1 Hz, C_6H_5], 74.6 [t, *J*(PC) = 5.1 Hz, C_5H_4], 74.5 (s, C_5H_4), 72.5 [t, *J*(PC) = 5.1 Hz, C_5H_4], 69.3 (s, C_5H_4). − $^{31}P\{^1H\}$ NMR (162.0 MHz, CD_2Cl_2): δ = 50.9 (s). − MS (FAB): *m*/*z* = 816 [M$^+$]. − $C_{41}H_{34}Cl_2FeP_2Ru$ (816.5): calcd. C 60.31, H 4.20, Ru 12.38; found C 59.95, H 4.64, Ru 11.77.

Determination of the X-ray Crystal Structure of 13: Single crystals were grown upon cooling of a saturated solution of **13** in CH_2Cl_2 from 25 °C to −20 °C. Crystal data (from 5000 reflections, 2.34° < Θ < 25.00°): triclinic; space group $P2_1/c$ (No. 14); *a* = 13.998(2), *b* = 14.7459(16), *c* = 20.125(3) Å, β = 98.417(18)°; *V* = 4109.3(10) Å^3, *Z* = 4; $d_{calcd.}$ = 1.593 g·cm^{-3}; μ(Mo-K_α) = 1.220 mm^{-1}; crystal size 0.18 × 0.18 × 0.12 mm; IPDS (STOE), Mo-K_α radiation (0.71073 Å), graphite monochromator; *T* = 173(2) K; -scans, max. 2θ = 50.00°; 32351 reflections measured, 7226 independent ($R_{int.}$ = 0.0530), 4891 with $I > 2\sigma(I)$. Intensity data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (SHELXS-97).[14] Atomic coordinates and the anisotropic thermal parameters of non-hydrogen atoms were refined by full-matrix least-squares on F^2 (SHELXL-97).[15] The positions of all hydrogen atoms were calculated according to ideal geometry and refined by using the riding method. The asymmetric unit includes two molecules of CH_2Cl_2 which were refined anisotropically with restraints. One of them was found to be disordered and two positions were refined with occupancy factors of 0.85 and 0.15, respectively. Conventional *R* = 0.0403 [for 4891 reflections with $I > 2\sigma(I)$], and weighted wR_2 = 0.1041 for all 7226 located reflections; reflection/parameter ratio 14.5; residual electron density +0.121/−0.067 eÅ^{-3}.

Crystallographic data (excluding structure factors) for **13** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-159684. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347), the BASF AG, and the Fonds der Chemischen Industrie. We are grateful to the latter in particular for a Ph. D. grant (to K. I.) and also thank the European Commission under the Training and Mobility of Researchers program for a Marie Curie Fellowship (to P. G.-H.). Moreover, we thank Dr. W. Buchner and Mrs. M.-L. Schäfer for NMR measurements, Mrs. R. Schedl and Mr. C. P. Kneis for elemental analyses and DTA measurements, and Dr. G. Lange and Mr. F. Dadrich for mass spectra.

Diastereoselectivity of Octahedral Cobalt(II) Pybox Complexes

Christophe Provent,[a] Gérald Bernardinelli,[b] Alan F. Williams,*[a] and Nathalie Vulliermet[c]

Keywords: Cobalt / Chirality / N ligands / Coordination chemistry

The cobalt(II) complexes prepared with a series of enantiopure ligands (**1**–**3**) containing the bis(oxazolinyl)pyridine unit have been studied. The ligands form high spin octahedral complexes as shown by the X-ray crystal structure of the homochiral complex $[Co(R,R\text{-}\mathbf{1})_2](ClO_4)_2(CH_3CN)_3$. The diastereoselectivity of complex formation has been studied: equimolar mixtures of *RR* and *SS* ligands show mixtures of homochiral and heterochiral complexes for **2** and **3**, but the phenyl-substituted ligand **1** shows exclusive formation of the heterochiral species. This selectivity is correlated with structural and electronic properties of the complexes.

Introduction

The use of chiral ligands in coordination chemistry is becoming increasingly important.[1] When two or more chiral ligands are bound to the same ligand, diastereomers may be formed, and the selectivity for one or other diastereomer may be studied.[2–7] The bis(oxazolinyl)pyridine (pybox) family of ligands (Scheme 1) were first developed by Nishiyama and co-workers for enantioselective homogeneous catalysis,[8,9] and have also been used to generate chiral Lewis acid catalysts.[10] We have recently used these ligands for the enantioselective synthesis of helical complexes.[11] During this work it was observed that the phenyl derivative **1** showed significantly different behavior from the other ligands **2** and **3**, forming a cyclic trinuclear helicate rather than a linear dinuclear helicate. This difference could be attributed to intramolecular attractions between the phenyl substituents and the pyridine moiety.[12] It therefore seemed of interest to study the chemistry of simple, mononuclear octahedral complexes of the type $[ML_2]$ to see if these substituent effects were also observed in these simple systems. In this paper we report on the remarkable difference in diastereoselectivity observed with the three different ligands with cobalt(II).

Synthesis of Complexes

The cobalt(II) complexes were prepared by adding two equivalents of ligand in acetonitrile to a solution of one equivalent of cobalt(II) perchlorate in acetonitrile at 20 °C (the heterochiral complex synthesis was carried out by mixing one equivalent of *R*,*R* ligand, one equivalent of *S*,*S* ligand and one equivalent of cobalt salt). The solutions were stirred for 30 minutes and then concentrated, before crystallization by diffusion of diethyl ether or *tert*-butyl methyl ether. The crystals prepared with $[Co(R,R\text{-}\mathbf{1})_2]^{2+}$ were of suitable quality for an X-ray structure determination. The complexes were characterized in solution by electrospray mass spectrometry (ESMS) and ^{1}H NMR spectroscopy. ESMS showed the exclusive formation of $[CoL_2]^{2+}$ with the base peak due to $[CoL_2]^{2+}$ and a weaker peak due to $\{[CoL_2](ClO_4)\}^+$. The ^{1}H NMR spectra are discussed below.

Crystal Structure of $[Co(R,R\text{-}\mathbf{1})_2](ClO_4)_2(CH_3CN)_3$

The X-ray crystal structure analysis of the orange crystals of $[Co(RR\text{-}\mathbf{1})_2](ClO_4)_2(CH_3CN)_3$ shows the expected octahedral ML_2 structure with the ligand acting as a meridional tridentate ligand (Figure 1). The cobalt(II) cation is coordinated by two pyridine-N atoms and four oxazoline-N atoms [av. Co-N(oxazoline) distance: 2.15 Å; av. Co-N(pyridine) distance: 2.06 Å]. The chelate bite angles are similar and close to 76°. The small bite angle results in considerable deviation of the angles at the cobalt atom from 90°, but the two pyridine rings are inclined at 93.2(8)°, close to the ideal value.

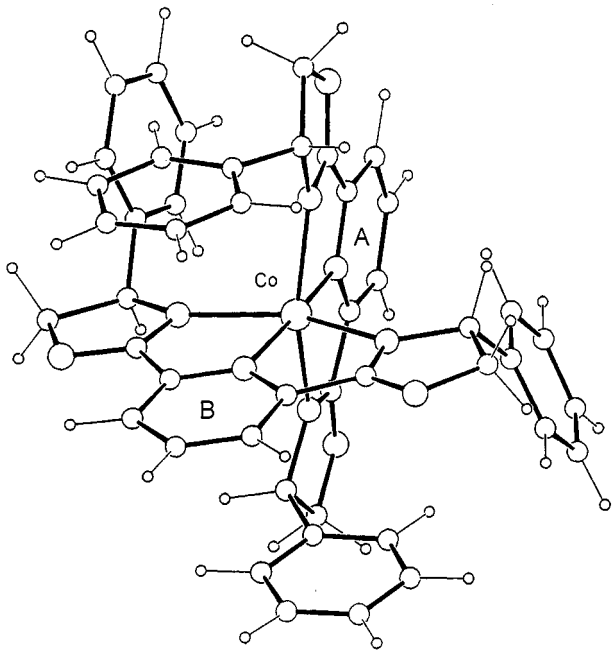

Figure 1. Structure of the cation $[Co(R,R\text{-}\mathbf{1})_2]^{2+}$; the stacking interaction is observed between the pyridine of ligand B and the phenyls of ligand A

The two ligands differ in the conformation of the phenyl substituents. Ligand A has the two phenyl rings oriented at roughly 90° to the oxazoline plane, in such a way as to lie almost parallel to the pyridine of ligand B [interplane angles: 3.7(7) and 3.0(7)°; interplane distances: 3.55(7) and 3.66(6) Å] indicating a stacking interaction similar to that observed in the circular trinuclear helicate.[11] The phenyl groups of ligand A are offset with respect to the coordinated pyridine of ligand B, as expected according to the model of Hunter and Sanders.[13] This orientation of ligand A, however, brings the phenyl rings close to those of ligand B. The geometry of this phenyl−phenyl interaction cannot be regarded as an edge-to-face interaction[14] since the hydrogen atoms are not directed toward the phenyl carbons. It may therefore be considered as a repulsion that prevents the phenyls of B from stacking with the pyridine of A. The phenyls of B are inclined at 17.9(9) and 31.1(1)° with respect to the pyridine of A, the interplane distances are longer, and the overlap is poor. The steric repulsion between the phenyls is shown by a CPK representation of the cation and by the slight deviations of the bis(oxazoline)pyridine units from planarity. The presence of the stacking interaction in one direction but not in the other reduces the molecular symmetry from D_2 to C_2.

Properties in Solution

Table 1 summarizes the electronic and CD transitions associated with the d-d bands in acetonitrile solution. The values are typical of high spin octahedral cobalt(II) with spin-allowed bands around 1100 nm and 470 nm. The ligand field as estimated by the d-d band positions decreases in the series **1** > **2** > **3**. The CD spectrum shows negative bands associated with the spin-allowed d-d bands for the *R*,*R* enantiomer of the ligand, although only the higher energy band falls completely within the range of the instrument. Two other weak CD bands are observed around 520 and 620 nm and are assumed to be associated with spin-forbidden or two-electron excitations. MLCT bands are observed around 340 nm as shoulders on ligand-based absorptions, at slightly higher energy than a strong CD signal (negative for the *R*,*R* isomer). The CD spectra of complexes of the *S*,*S* enantiomers of the ligands are the inverse of those of the *R*,*R* enantiomers.

The fast electronic relaxation times of high spin cobalt(II) allow the ^{1}H NMR spectra to be recorded at 20 °C in acetonitrile (Figure 2). The proton α to the nitrogen of the oxazoline lies closest to the metal center and has an NMR shift of δ = 86.3. The other peaks lie between δ = 0 and 40. The spectra show the two ligands to be equivalent and symmetric. The ^{1}H NMR spectra allow the investigation of the diastereoselectivity of complex formation. If an enantiopure ligand is used, only the homochiral complex is obtained, but if a racemic mixture of *R*,*R* and *S*,*S* ligands is used then the heterochiral *meso*-complex $[Co(R,R\text{-}\mathbf{L})(S,S\text{-}\mathbf{L})]^{2+}$ may also be formed. The two enantiomers of the homochiral complexes have identical spectra, but the heterochiral complex shows a different spectrum. Reaction of cobalt(II) with an equimolar amount of *R*,*R* and *S*,*S* ligands may thus be used to study the diastereoselectivity. The three ligands show very different behavior. Ligand **1** shows exclusive formation of the heterochiral complex $[Co(R,R\text{-}\mathbf{1})(S,S\text{-}\mathbf{1})]^{2+}$ with a spectrum totally different from $[Co(R,R\text{-}\mathbf{1})_2]^{2+}$ and no trace of the homochiral complex. Ligands **2** and **3**, on the other hand, show the presence of

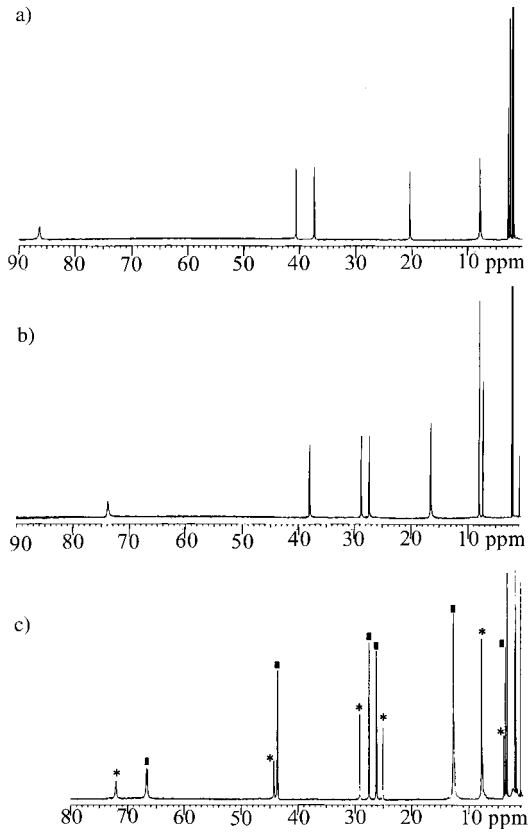

Figure 2. ^{1}H NMR spectra in [D$_3$]acetonitrile of (a) [Co(*R*,*R*-**1**)$_2$]$^{2+}$, (b) [Co(*R*,*R*-**1**) (*S*,*S*-**1**)]$^{2+}$, and (c) an equimolar mixture of cobalt(II), *R*,*R*-**2**, and *S*,*S*-**2**; the peaks due to the homochiral complex are marked with an asterisk, those of the heterochiral complex with a block

Cyclic voltammetry of [Co(*R*,*R*-**1**)$_2$]$^{2+}$ in acetonitrile showed three redox waves, two assigned to ligand reduction at −1.30 and −0.45 V, and a peak at +1.15V assigned to the Co^{III}/Co^{II} couple. This latter value is quite high, but may be understood in terms of the low donor strength of the oxazoline ligands, the π-acceptor properties of the ligand, and possible steric hindrance which prevents the shortening of the Co−N bond lengths associated with oxidation of Co^{II}.[15] The voltammogram for [Co(*R*,*R*-**2**)$_2$]$^{2+}$ is essentially identical, although for [Co(*R*,*R*-**3**)$_2$]$^{2+}$ no oxidation of Co^{II} was observed. For the heterochiral complex [Co(*R*,*R*-**1**)(*S*,*S*-**1**)]$^{2+}$ the ligand reduction potentials were unchanged but the Co^{III}/Co^{II} potential was significantly lower (+1.01 V) than for the homochiral complex.

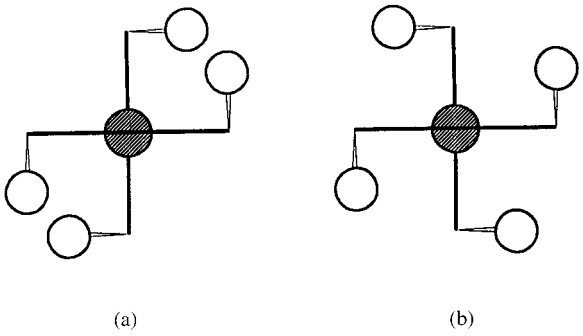
Discussion

The three ligands studied here all form octahedral complexes of the type ML$_2$ with cobalt(II), but show significant differences in their physical and chemical properties arising from the different substituents on the oxazoline ring. We assume that these effects are due to the size and shape of these substituents rather than from inductive electronic effects. The results suggest that the benzyl group of ligand **3** provides the greatest hindrance, resulting in the lowest ligand field strength and the absence of oxidation of Co^{II}. Logically one would expect the phenyl group to exert a steric effect similar to the benzyl, but it is in fact ligand **2** with a methyl substituent that is closer to the benzyl group in ligand field strength, although in this case oxidation to Co^{III} may be observed. The phenyl-substituted ligand **1** shows the strongest ligand field of the homochiral complexes. Furthermore, ligand **1** is unique in its diastereoselectivity, forming the heterochiral complex exclusively whereas **2** and **3** give mixtures, that for ligand **3** being essentially statistical.

Two features render the phenyl substituent unique: firstly, all atoms of the phenyl group lie in the same plane, and it is therefore possible to orient the substituent so that it lies parallel to the bisoxazolinyl plane of the second ligand in the complex of [Co(*R*,*R*-**1**)$_2$]$^{2+}$, as shown in Figure 1. Attempts to grow crystals of the other complexes were unfortunately unsuccessful, but modeling studies show that in the benzyl and methyl complexes the methylene hydrogens of the substituent must be directed towards the second ligand: this is not the case for the phenyl substituent. Secondly, the phenyl groups can actually give an attractive interaction with the pyridine of the second ligand. This was clearly established in the trinuclear silver complex,[11] and, on the basis of the crystal structure, appears to be the case here. The lesser interligand repulsion of **1** compared to **2** and **3** can therefore explain the higher ligand field. Intramolecular stacking interactions have previously been reported as enhancing the stability of 2:1 complexes.[16]

The diastereoselectivity may also be understood from an examination of the crystal structure of [Co(*R*,*R*-**1**)$_2$](ClO$_4$)$_2$. If we look along the pyridine−cobalt−pyridine axis, the ligand planes form a cross, with the substituents at right angles to the arms of the cross. In the homochiral complex, the substituents are directed into two diagonally opposed quadrants of the cross, and consequently may repel each other. In the heterochiral complex each substituent is directed into a different quadrant, and repulsion is avoided. It is now possible to obtain four π-stacking interactions between the pyridine and the phenyl groups. In consequence, the ligand field increases, and the cobalt(II) oxidation potential is lowered. Indeed, the first d-d band of the heterochiral complex moves to higher energy relative to the homochiral complex. This diastereoselectivity will be most marked for the phenyl-substituted ligand **1**, since it projects far enough out of the ligand plane for the substituents to repel each other in the homochiral complex (Scheme 2). For the smaller methyl-substituted ligand the extension is not sufficient, and the benzyl group is sufficiently flexible to be able to bend away from the other ligand.

This effect has been observed previously by Evans[10] for complexes of **1** with copper(II): the crystal structures of [Cu(*S*,*S*-**1**)$_2$]$^{2+}$ and [Cu(*R*,*R*-**1**)(*S*,*S*-**1**)]$^{2+}$, although they are affected by a Jahn−Teller distortion, show the repulsion of the phenyls in the homochiral complex that is absent in the



Scheme 2. Intraligand repulsion between substituents in the homochiral complex (a) and the heterochiral complex (b)

heterochiral complex. The greater stability of the heterochiral complex was shown by the nonlinear response of the enantioselectivity of reactions catalyzed by $[Cu(\mathbf{1})]^{2+}$ to the enantiomeric purity of ligand **1**: the selective formation and precipitation of $[Cu(R,R\text{-}\mathbf{1})(S,S\text{-}\mathbf{1})]^{2+}$ resulted in an enrichment of one enantiomer of the catalytically active species $[Cu(\mathbf{1})]^{2+}$ in solution. A similar nonlinear effect has been observed in other reactions catalyzed by oxazoline ligands.[17,18]

The remarkable difference in diastereoselectivity may thus be explained in terms of the properties of the substituent. The phenyl group which stood apart from the others in helicate chemistry[11] also shows different behavior in simple octahedral complexes. It is reasonable to suppose that this effect might influence the enantioselectivity of catalytic reactions using these ligands, and, indeed, Evans and coworkers[10] did observe that the enantioselectivity was highest for the phenyl-substituted ligand when compared with benzyl, isopropyl and *tert*-butyl substituents.

Experimental Section

General: The ligands were prepared according to the literature.[8,11,12] Diethyl ether was purified according to standard procedures. Other solvents (Fluka p.a.) were used without further purification. Hexaaquacobalt(II) perchlorate (Fluka) was used without purification. ^{1}H NMR spectra were recorded on a Varian Gemini-300 (at 300 MHz); shifts are given with reference to TMS. NMR solvents ([D$_3$]acetonitrile): Dr. Glaser AG Basel, isotopic purity > 99.80 atom%D. UV/visible spectra were recorded on a Cary/Varian spectrometer; 0.1 or 1 cm cell; 22 °C. CD spectra were recorded on a Jasco J-715 spectropolarimeter; 1 cm cell; 22 °C.

Cyclic Voltammetry: Electrochemical measurements were performed with a three-electrode system consisting of a platinum working electrode, a platinum counter-electrode and an Ag/AgCl reference electrode. All measurements were carried out under N_2 in degassed, freshly distilled solvent (acetonitrile), using 0.1 M nBu$_4$NPF$_6$ as supporting electrolyte. Before measurement, the system was standardized with the Ru(bipy)$_3$(ClO$_4$)$_2$ complex and potentials are given with respect to the normal hydrogen electrode. A Bioanalytical System Model CV-50 W was used to record and process the data.

General Procedure for Complex Synthesis: An acetonitrile/dichloromethane solution (4:1) of enantiopure ligand (4.08×10^{-4} mol) was added dropwise to a solution of 2.04×10^{-4} mol of metal salt [Co(ClO$_4$)$_2$·6H$_2$O] in acetonitrile. The solution was stirred for 30 minutes at room temperature and then concentrated to 1−2 mL. The complex was crystallized from the acetonitrile solution by diffusion of diethyl ether or *tert*-butyl methyl ether. Yields were typically 75%. For the synthesis of heterochiral species, the acetonitrile/dichloromethane solution contained 2.04×10^{-4} mol of the *R*,*R* enantiomer and 2.04×10^{-4} mol of the *S*,*S* enantiomer.

[Co(*R*,*R*-1)$_2$(ClO$_4$)$_2$]: Yield 76%. $C_{46}H_{38}Cl_2CoN_6O_{10}.1/2H_2O$: calcd. C 54.94, H 3.91, N 8.36; found C 54.95, H 3.97, N 8.34. − ^{1}H NMR (300 MHz, [D$_3$]acetonitrile, TMS): δ = 0.10 (2 H), 2.54 (8 H), 2.90 (4 H), 7.82 (8 H), 20.29 (4 H), 37.29 (4 H), 40.53 (4 H), 86.32 (4 H). − ES-MS (acetonitrile): *m*/*z* (%) = 399.0 (100) $[Co(\mathbf{1})_2]^{2+}$, 896.0 (15) $[Co(\mathbf{1})_2ClO_4]^+$. Very small peaks corresponding to the ligand and to the (complex + acetonitrile) were also observed. These last peaks are attributable to fragmentation in the spectrometer. Cyclic voltammetry: +1.14 V (Δ*E* = 105 mV), −0.43 V (Δ*E* = 75 mV), −1.30 V (Δ*E* = 80 mV).

[Co(*S*,*S*-2)$_2$](ClO$_4$)$_2$: Yield 72%. $C_{26}H_{30}Cl_2CoN_6O_{10}$ (716.39): calcd. C 41.73, H 4.04, N 11.23; found C 41.36, H 3.97, N 11.14. − ^{1}H NMR spectrum and electrochemical data identical to [Co(*R*,*R*-2)$_2$](ClO$_4$)$_2$.

Equimolar mixture of Co(ClO$_4$)$_2$·6H$_2$O, *R*,*R*-2 and *S*,*S*-2: ^{1}H NMR (300 MHz, [D$_3$]acetonitrile, TMS): two species. 33% of homochiral complex: δ = 3.96 (2 H), 7.80 (12 H), 25.08 (4 H), 29.20 (4 H), 44.18 (4 H), 72.20 (4 H). 66% of heterochiral complex: δ = 3.73 (2 H), 12.69 (12 H), 26.18 (4 H), 27.48 (4 H), 43.66 (4 H), 66.70 (4 H).

[Co(*R*,*R*-3)$_2$](ClO$_4$)$_2$ and [Co(*S*,*S*-3)$_2$](ClO$_4$)$_2$: Yield 80%. ^{1}H NMR (300 MHz, [D$_3$]acetonitrile, TMS): δ = 0.24 (8 H), 3.96 (12 H), 5.64 (4 H), 16.52 (2 H), 17.40 (4 H), 22.89 (4 H), 30.10 (4 H, broad), 49.69 (4 H, broad), 66.00 (4 H). − Cyclic voltammetry: −0.43 V (Δ*E* = 73 mV), −1.24 V (Δ*E* = 74 mV). − ES-MS (acetonitrile): *m*/*z* (%) = 426.7 (100) $[Co(\mathbf{3})_2]^{2+}$, 952.0 (16) $[Co(\mathbf{3})_2ClO_4]^+$.

Equimolar Mixture of Co(ClO$_4$)$_2$·6H$_2$O, *R*,*R*-3 and *S*,*S*-3: ^{1}H NMR (300 MHz, [D$_3$]acetonitrile, TMS): two species. ≈50% of homochiral complex: δ = 0.49 (8 H), 3.94 (12 H), 6.13 (4 H), 16.48 (2 H), 17.63 (4 H), 22.96 (4 H), 29.68 (4 H, broad), 50.58 (4 H, broad), 65.75 (4 H). ≈50% of heterochiral complex: δ = 5.66 (12 H), 6.79 (8 H), 6.89 (2 H), 17.13 (4 H), 20.91 (4 H, broad), 24.92 (4 H), 26.07 (4 H), 50.18 (4 H), 63.29 (4 H, broad).

Crystal Structure of $[Co(R,R\text{-}1)_2](ClO_4)_2\cdot 3MeCN$, $Co(C_{22}H_{19}N_3O_2)_2(ClO_4)_2(CH_3CN)_3$: Molecular mass = 1119.8, orange crystal 0.22 × 0.22 × 0.23 mm, monoclinic, $P2_1$, a = 10.907(1) Å, b = 21.717(3) Å, c = 11.879(1) Å, β = 112.768(8)°, V = 2594.5(5) (Å)^3, Z = 2, D_x = 1.43 g·cm^{-3}. Data collection, Stoe STADI4, Cu-K_α, graphite monochromator, T = 200 K, ω-2θ scan, 3° < 2θ < 110°, −11 < h < 11; 0 < k < 22; 0 < l < 12 and all antireflections of these. 6557 reflections measured, 6344 unique, 5159 observed ($|F_o| > 4\sigma(F_0)$], μ = 4.147 mm^{-1}, spherical absorption correction A* min., max = 1.862, 1.954. Structure solved by direct methods,[19] and refined by full-matrix least-squares with hydrogens in calculated positions using 687 parameters for 5159 reflections.[20] Final R value 0.057, R_w = 0.048, Flack absolute structure parameter = 0.00(1).[21,22]

Crystallographic data (excluding structure factors) for the structure included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149396. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Molecular Modeling: Calculations were carried out using the Universal force field 1.02[23] with charge equilibration.[24] A reasonable agreement between calculated structure and that observed for $[Co(RR\text{-}1)_2]^{2+}$ was obtained as judged by superposition of the structures, although the optimized Co−N bond lengths were too short (1.811 Å compared with the experimental average of 2.1190 Å).

σ-Donor versus η⁶-π-Arene Interactions in Monomeric Europium(II) and Ytterbium(II) Thiolates − An Experimental and Computational Study

Mark Niemeyer[a]

Dedicated to Professor Glen B. Deacon on the occasion of his 65th birthday

Keywords: Ab initio calculations / Lanthanides / π interactions / S ligands / Ytterbium

The base-free, hydrocarbon-soluble complexes $M(SAr^*)_2$ (**4a**: M = Eu, orange; **4b**: M = Yb, purple; Ar^* = 2,6-$Trip_2C_6H_3$; Trip = 2,4,6-$i Pr_3C_6H_2$) have been prepared by a protolysis reaction of the Grignard-analogous compound RLnI (R = 2-$F_3CC_6H_4$) with $HSAr^*$. Compound **4b** has been characterized by melting point, elemental analysis, ^1H, ^{13}C, and ^{171}Yb NMR, IR spectroscopy, UV/Vis spectrophotometry, mass spectrometry, and X-ray crystallography. Additionally, the purple Yb^{III} complex $YbI_2(SAr^*)(THF)_3$ (**3**) and the yellow DME adduct $Yb(SAr^*)_2(dme)_2$ (**5**) have been synthesized and characterized by X-ray crystallography. The solid-state structures of **4a** and **4b** (as THF or benzene hemisolvates) show monomeric units with the metal atom bonded to two terminal thiolate ligands [av. M–S: 281.7 pm (**4a**)/269.1 pm (**4b**)]. Additional η⁶-π-arene interactions are observed to two C_6H_2 rings of the Trip substituents [av. M···C: 306.5 pm (**4a**)/297.3 pm (**4b**)]. The binding energy for these interactions has been determined by variable-temperature ^1H NMR spectroscopy to be 54.3 kJ mol^{-1} (in methylcyclohexane) and 57.1 kJ mol^{-1} (in toluene). The nature and strength of the η⁶-π-arene bonding has been studied by ab initio calculations on the model systems $[M(arene)]^{2+}$ (arene = C_6H_6, C_6F_6, 1,3,5-$Me_3C_6H_3$, 1,3,5-$i Pr_3C_6H_3$) and $Yb(SH)_2(C_6H_6)_n$ (n = 1, 2). The results are compared with the binding energies in the σ-donor adducts $[M(THF)]^{2+}$, $[M(dme)]^{2+}$, and $[M(imidazol\text{-}2\text{-}ylidene)]^{2+}$.

Introduction

The use of charged π-donor ligands and the principle of steric saturation by associated neutral σ-donors or the addition of anionic ligands have dominated organolanthanoid[1] chemistry over the past decades. More recently, however, there has been a growing interest in low-coordinate σ-bonded lanthanoid complexes with bulky substituted organyls,[2,3] Group 14, Group 15, or Group 16 heteroelements.[4] Moreover, the avoidance of coordinating solvents often leads to novel structures and unusual lanthanoid−ligand interactions. Examples of the latter include agostic-type interactions[5] with alkyl-substituted ligands[6−11] or metal−π-arene interactions[12−15] in aryl-substituted ligand systems. In this paper, the synthesis and characterization of the *m*-terphenyl-based[16] metal thiolates $YbI_2(SAr^*)(THF)_3$ (**3**) (Ar^* = 2,6-$Trip_2C_6H_3$; Trip = 2,4,6-$i Pr_3C_6H_2$), $M(SAr^*)_2$ [M = Eu (**4a**), Yb (**4b**)], and $Yb(SAr^*)_2(dme)_2$ (**5**) are described. The σ-donor-free compounds **4a** and **4b** show two metal−η⁶-π-arene interactions in the solid state. According to NMR-spectroscopic results, these interactions persist in solution. The nature and strength of these interactions has been studied by ab initio calculations on simple model systems.

Results and Discussion

Syntheses

The syntheses of compounds **1**−**5** are summarized in Scheme 1. Initially, the ytterbium(II) thiolate **4b** was obtained from the reaction of $Yb[N(SiMe_3)_2]_2$ with $HSAr^*$. Mixing the two compounds in *n*-pentane resulted in a color change from orange to purple. Removal of the solvent followed by recrystallization of the residue from a mixture of *n*-heptane and benzene gave **4b** as an extremely air-sensitive crystalline material. However, a much easier route to **4b**, which circumvents the somewhat cumbersome preparation[17] of donor-free $Yb[N(SiMe_3)_2]_2$, is a direct synthesis starting from ytterbium metal and 2-iodobenzotrifluoride. The reaction of lanthanide metals with organyl iodides to give Grignard-analogous compounds RLnI (Ln = Sm, Eu, Yb) has been known for some time.[18] The isolation and structural characterization of such compounds has, however, only recently been achieved.[15,19−21] The initially formed arylytterbium(II) iodide **1b** is instantly protolysed by the thiol $HSAr^*$ to give the mixed (thiolato)ytterbium(II) iodide **2b**. Replacing THF by *n*-pentane as the solvent causes the precipitation of $YbI_2(THF)_4$.[22] After removal of the solvent and recrystallization of the residue from an *n*-heptane/toluene mixture, purple **4b** is obtained in 66% yield. The preparation of the donor-free europium(II) thiolate $Eu(SAr^*)_2$ **4a** was accomplished in a similar manner. Attempts to isolate the intermediate mixed (thiolato)-lanthanide(II) iodides **2a** and **2b** did not prove to be successful. Thus, in the case of the ytterbium derivative, crystalliza-

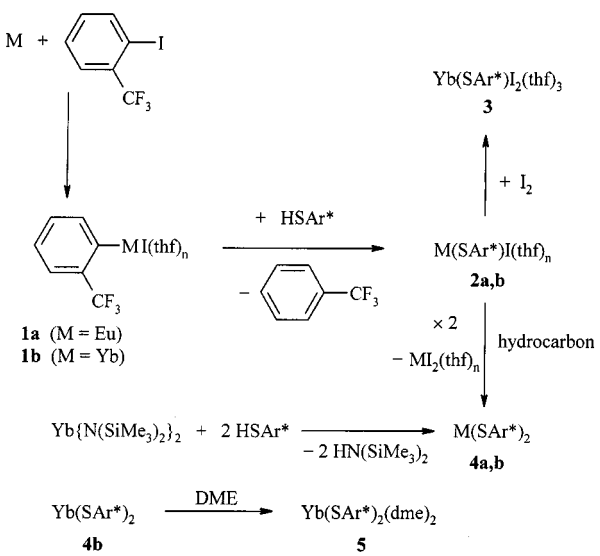
tion at −15 °C only afforded $YbI_2(THF)_4$. Nevertheless, the formation of **2b** was confirmed by its ^{171}Yb NMR signal. Moreover, it was possible to synthesize the diiodo(thiolato)ytterbium(III) complex **3** in good yield by oxidation of **2b** with iodine. A remarkable feature of the preparation of **4a** and **4b** is the ease with which the coordinated tetrahydrofuran can be removed. Although in the case of **4b** coordination of THF is observed at low temperatures (vide infra), it can be completely removed by pumping at 10^{-3} mbar at ambient temperature. In the case of the europium compound, it is even possible to crystallize donor-free **4a** from an *n*-heptane/THF mixture to give the packing complex **4a**·$(THF)_{0.5}$, in which no Eu−O(THF) interactions are observed. This unusual behavior is in contrast to the preparation of other unsolvated lanthanide(II) compounds, e.g. $LnCp^*_2$ or $Ln(OAr)_2$, from solvated complexes, which normally requires repeated sublimation at elevated temperatures.[23] Using dimethoxyethane as a more strongly chelating ligand, it is possible to synthesize the more stable yellow complex $Yb(SAr^*)_2(dme)_2$ (**5**). Even in this case, complete removal of the coordinated solvent can be achieved by pumping overnight at 20 °C/10^{-3} mbar.



Scheme 1. Syntheses of compounds **1**−**5**

The protolysis of the aryllanthanide(II) iodides **1a** and **1b** seems to be of general interest for the preparation of other lanthanide(II) complexes. In contrast, the usual metathesis reactions often lead to alkali metal halide contaminated products or to the formation of unwanted ate complexes, while the related one-pot transmetallation/protolysis route of Deacon et al.[17] relies on poisonous Ph_2Hg. Using our method, we were able to synthesize the known compounds[23] $Yb[N(SiMe_3)_2]_2(THF)_2$, $Yb(OAr')_2(THF)_2$ (Ar′ = 2,6-*t*Bu_2-4-MeC_6H_2), and $YbCp^*_2(THF)_2$ in pure form and good yields.[24] Although the 2-iodobenzotrifluoride used here can be replaced by other aryl iodides, we have found it to be superior, giving shorter reaction times and improved purity of the products.[24]

X-ray Crystal Structures

Compounds **3**, **4a**, **4b**, and **5** were examined by X-ray crystallography. Their molecular structures are shown in Figures 1, 2, 3 and 4, while salient structural parameters are given in Tables 1, 2 and 3. The solid-state structure of purple $YbI_2(SAr^*)(THF)_3$ (**3**) consists of monomeric units (Figure 1). The central Yb atom shows a distorted octahedral coordination with two iodo ligands in apical positions [I(1)−Yb−I(2) = 176.74(3)°]. Despite the presence of the sterically crowded SAr* ligand, the Yb−S bond length of 258.1(2) pm seems to be the shortest ytterbium−sulfur distance yet reported for a molecular ytterbium compound.[4] It may be compared with the average Yb−S bond lengths in the six-coordinate complexes $Yb(STrip)_3(py)_3$ and *mer*-$Yb(SPh)_3(py)_3$, which were determined as 264.8 pm and 264.7 pm, respectively (Table 4). The shortest Yb−S distance of 260.9(4) pm is found *trans* to one pyridine ligand in the latter. In **3**, the Yb−I bond lengths of 291.0(1) pm [Yb−I(1)] and 298.4(1) pm [Yb−I(2)] are close to the values seen in the previously reported dimeric complex $[(\mu\text{-}OMe)YbI_2(dme)]_2$ (av. 293.2 pm)[25] and the formally eight-coordinate compound $Yb(Cp)_2I(THF)$ (293.2 pm).[26] The different Yb−I bond lengths in **3** can be attributed to the significant deviation of the Yb atom from the S−O(41)−O(51)−O(61) plane by 10.6 pm (Table 1). A notable feature of the structure of **3** is that the Yb−O distances to the coordinated THF ligands are rather different. With a value of 239.0(6) pm, the Yb−O(41) bond *trans* to the SAr* group is unusually long, whereas the others (av. Yb−O = 227.3 pm) are in the normal range for Yb^{III} complexes with six-coordinate metal centers.[27] The long Yb−O(41) bond may be compared with the average Yb−O distance of 239.5 pm *trans* to the C_6H_5 groups in *fac*-$YbPh_3(THF)_3$.[28] The *trans* influence of THF ligands in lanthanoid(III) chemistry has been noted previously.[29]

Because of their very similar features, the solid-state structures of the compounds $Eu(SAr^*)_2$ [**4a**·$(THF)_{0.5}$] and $Yb(SAr^*)_2$ [**4b**·$(C_6H_6)_{0.5}$] will be discussed together. Both complexes crystallize as monomers. Their molecular struc-

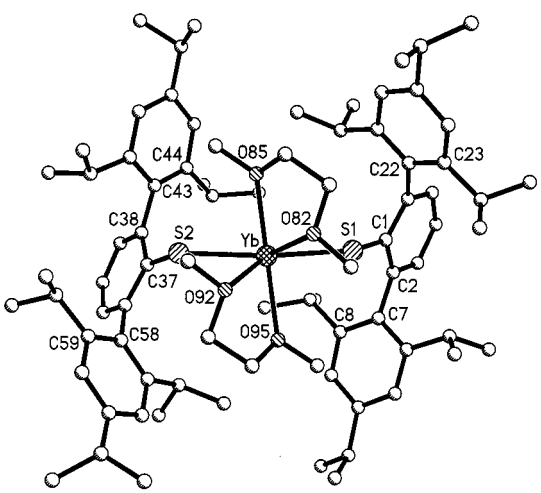

Figure 4. Molecular structure of **5**, showing the atom numbering scheme; hydrogen atoms and the minor parts of the disordered isopropyl groups have been omitted for clarity

tures are illustrated in Figure 2 (**4a**) and Figure 3 (**4b**), while salient bond parameters are listed in Table 2. Despite the difference in the ionic radii of europium(II) and ytterbium(II), both complexes crystallize in isomorphous cells. They differ in the type of solvent that is packed in the cavities of the structure. There are, however, no significant interactions between the metal centers and the co-crystallized tetrahydrofuran or benzene molecules. Each metal atom is coordinated to the sulfur atoms of the thiolate ligands with S−M−S angles of 141.89(4)° (**4a**) and 142.73(8)° (**4b**), respectively. The most striking structural features of **4a** and **4b** are the additional η⁶-π-interactions to two *ortho*-2,4,6-triisopropylphenyl rings of the terphenyl groups (Figure 3). Although the occurrence of two η⁶-π-bonded arene rings is unprecedented for structurally authenticated di- or trivalent lanthanide species,[12] such interactions are well-known in some bis(arene)lanthanide(0) derivatives. Structurally characterized examples include the compounds M(η⁶-1,3,5-tBu$_3$C$_6$H$_3$)$_2$ (M = Y, Gd, Ho).[30] It should be noted that the cyclometallated scandium(II) complex ScH(η⁶-tBu$_3$C$_6$H$_3$)[η⁶,η¹-(CH$_2$CMe$_2$)tBu$_2$C$_6$H$_3$], which was formed by C−H insertion from Sc(η⁶-1,3,5-tBu$_3$C$_6$H$_3$)$_2$, may also possess two metal−π-arene interactions, although this was based purely on ESR evidence.[31]

The two terphenylthiolate ligands in **4a** and **4b** are orientated in such a way that the most favorable η⁶-π-arene bonding is maximized. In effect, the interplanar angles between the M−S−C planes and the central 2,6-substituted phenyl rings, i.e. A/D and E/H (Table 2), are in the range 0.3° to 6.7°. Together with the perpendicular arrangement of the *ortho*-Trip groups (A/B, A/C, E/F, E/G = 82.0−89.5°), an almost parallel orientation of the C(7)−C(12) and C(43)−C(48) rings to the central S(1)−M−S(2) plane is achieved (B/I, F/I = 6.3−13.6°). Despite the formal coordination number of eight, the observed europium−sulfur and ytterbium−sulfur distances are surprisingly short. In fact, they are ca. 8−13 pm (**4a**) and 7−19 pm (**4b**) pm shorter than the metal−sulfur distances reported for other europium(II) and ytterbium(II) thiolates (Table 4). In **4a**, the europium ion interacts essentially equally with both Trip rings with Eu−C distances in the relatively narrow range of 298.8(3)−315.0(3) pm for C(7)−C(12) and 296.7(3)−316.1(3) pm for C(43)−C(48), with average values of 307.0 pm and 305.9 pm, respectively. In **4b**, the Yb−C interactions to the C(7)−C(12) ring were found to have distances between 287.0(8) and 305.2(8) pm (av. 296.3 pm), with a somewhat greater variation of 282.4(8)−313.9(8) pm (av. 298.3) for the bonding to the second C(43)−C(48) arene ring. The average metal−centroid distances are 272.8 pm (**4a**) and 263.7 pm (**4b**), whereas the X(1)−M−X(2) angles, where X(1) and X(2) define the centroids of the coordinated arene rings, are 166.9° and 164.5° respectively. Salient structural parameters in known compounds with europium− and ytterbium−η⁶-π-arene coordination are summarized in Table 5. The Yb−C interactions in **4b** are comparable to the reported average Yb^{II}−C distances, which fall in the range 296−304 pm. In accordance with the smaller radius of Yb^{III}, the complex Yb(C$_6$Me$_6$)(AlCl$_4$)$_3$ shows shorter Yb−C distances of 286 pm (av.). The nine-coordinate Eu center in the tetrameric compound [Eu(C$_6$Me$_6$)(AlCl$_4$)$_2$]$_4$ exhibits an average Eu−C interaction of 300 pm. The shortening by 6−7 pm compared to **4a** may be explained in terms of a stronger polar attraction between the Eu ion and the arene ring caused by the more electronegative AlCl$_4^-$ ligands.

The molecular structure of the yellow complex Yb(SAr*)$_2$(dme)$_2$ (**5**) is shown in Figure 4. The Yb atom has a distorted octahedral coordination, in which the thiolate groups and each DME ligand occupy a *cis* position. The

[a] Atoms marked with an asterisk define the least-square plane. − [b] Least-square planes defined by the following atoms: A: C(1) to C(6); B: C(7) to C(12); C: C(22) to C(27); D: C(1), S, Yb.

rather different S(1)−Yb−S(2), O(82)−Yb−O(85), and O(92)−Yb−O(95) angles of 141.3(1)°, 64.8(2)°, and 65.1(2)°, respectively, reveal a severe distortion from the ideal octahedral environment. The Yb−S bond length of 273.9 pm and the average Yb−O distances of 248.0 pm may be compared with the corresponding values of 275.6(8) pm and 253.5 pm in the related complex $Yb(SMes^*)_2(dme)_2$.[32] Apparently, the slightly shorter distances in **5** are compensated by the more acute S−Yb−S angle of 124.4(2)° in the latter.

Although the Ar* and Mes* substituents are of similar size, they often induce different oligomerization and solvent complexation behavior, as has been noted previously.[16] In contrast to the structures of **4a** and **4b**, the interplanar angles between the M−S−C planes and the central C_6H_3 arene rings, i.e. A/D and E/H (Table 3), are close to 90°, which is a consequence of repulsive forces between the DME ligands and the *ortho*-Trip groups.

It is interesting to compare the molecular structures of **3**, **4a**, **4b**, and **5** in terms of the different degrees of steric crowding. Thus, the average M−S−C angle increases from 115° and 116° in **4b** and **4a**, through 125° in **3**, up to 146° in **5**. Furthermore, the average displacement of the *ipso*-Trip carbon atoms [i.e. C(7), C(22), C(43), and C(58)] from the central C_6H_3 plane increases in the order **4a** (8.2 pm), **4b** (9.6 pm), **3** (13.3 pm), and **5** (22.9 pm). Apparently, the maximum steric congestion is observed for compound **5**.

Spectroscopic Characterization

The diamagnetic complexes **4b** and **5** have been characterized by ^1H and ^{13}C NMR spectroscopy. In addition, compounds **2b**, **4b**, and **5** have been examined by ^{171}Yb NMR spectroscopy (Table 6). The ^{171}Yb NMR spectrum of an in situ prepared solution of **2b** in $[D_8]THF$ shows a main signal at $\delta = 351$. Smaller resonances of equal height at $\delta = 281$ and $\delta = 457$ can be assigned to the dithiolato species $Yb(SAr^*)_2(THF)_x$ (**6**) and solvated ytterbium(II) iodide $YbI_2(THF)_4$ (**4b**).[33] In the ^{171}Yb NMR spectrum of **4b** in $[D_8]$toluene or $[D_6]$benzene, a sharp resonance is observed at $\delta = 768$. A different chemical shift is found if the aromatic solvent is replaced by an alkane. Thus, a ^{171}Yb NMR signal at $\delta = 837$ is observed in $[D_{14}]$methylcyclohexane at 233 K, whereas no ^{171}Yb resonance is detectable at ambient temperature. The reaction of purple **4b** with more strongly coordinating solvents such as THF or DME results in a color change to yellow. In the ^{171}Yb NMR spectrum, a shift to higher field is observed with resonances at $\delta = 204$ (at 233 K) and $\delta = 281$ for the solvated complexes $Yb(SAr^*)_2(dme)_2$ **5** and $Yb(SAr^*)_2(THF)_x$ **6**, respectively. These values may be compared with the ^{171}Yb NMR chemical shifts of the ytterbium(II) thiolate $Yb(SMes^*)_2(dme)_2$ and related selenolates and tellurolates, which are found at lower field, specifically at $\delta = 485$[32] and $\delta = 430-526$,[34] respectively. It is notable that no ^{171}Yb NMR signal can be detected for **5** at ambient temperature. Apparently, dynamic processes such as solvent exchange, intermolecular arene coordination, or equilibria due to hindered rotation complicate the interpretation of solution NMR-spectroscopic data for compounds **4b** and **5**. In order to gain more insight into these different processes, variable-temperature ^1H NMR experiments were performed. At room temperature, the ^1H NMR spectrum of **4b** in $[D_8]$toluene shows only one type of thiolate ligand environment with equivalent Trip

substituents, although the signals are very broad. If the temperature is gradually increased, the linewidth decreases and sharp signals are observed at 358 K. At lower temperatures, two coalescence points were detected at 284 K and 227 K, corresponding to energy barriers of 57.1 kJ mol^{-1} and 46.5 kJ mol^{-1}, respectively. A full interpretation of the low-temperature ^{1}H NMR spectra has not yet been possible due to their complex nature and overlapping signals. It is clear, however, that below 284 K two different Trip substituent environments exist, as is evident from the appearance of two different resonances for the *m*-Trip protons. This observation can be interpreted in terms of hindered rotation about the S(1)−C(1) or S(2)−C(37) bonds and hence the persistence of the metal−π-arene interactions in solution. In order to exclude additional interactions with the aromatic solvent toluene, further low-temperature ^{1}H NMR experiments were performed in [D$_{14}$]methylcyclohexane. In this solvent, a single energy barrier of 54.3 kJ mol^{-1} is found and two signals due to the aromatic protons of the Trip substituents are observed below 263 K. In contrast, the ^{1}H NMR spectrum of **5** shows only one set of signals due to the Trip substituents and the coordinated DME molecules in the temperature range 223−300 K.

The weak tendency of **4b** to coordinate THF was examined by additional ^{171}Yb NMR experiments. As mentioned above, a yellow solution of **4b** in neat [D$_8$]THF shows a

^{171}Yb NMR resonance of δ = 281. In contrast, there is no detectable signal in the ^{171}Yb NMR spectrum at ambient temperature if a 4:1 mixture of toluene and THF is used as solvent. However, if this purple solution is cooled to 253 K, a color change to yellow is observed and a broad resonance appears at δ = 316 ($w_{1/2}$ = 700 Hz). At 233 K, the signal is shifted to δ = 336 and the linewidth is reduced to 180 Hz. Apparently, if the concentration of THF is too low, the solvated complex $Yb(SAr^*)_2(THF)_x$ (**6**) is only stable at low temperatures. The temperature dependence of the chemical shift for **6** (−0.85 ppm K^{-1}) may be compared with other reported values, which typically vary between +2 and −0.5 ppm K^{-1}.[34]

In the mass spectra of **4a** and **4b**, intense signals due to the molecular ions were found (base peak for **4b**; rel. intensity of 48% for **4a**). In addition, solutions of **4b** in *n*-pentane (purple) and THF (yellow) were studied by UV/Vis spectro-

photometry. Absorption maxima were observed at 475/546 nm and 369/417 nm, respectively.

It is know from studies on dimeric lanthanide and actinide aryl oxide complexes $M_2(OAr)_6$ (Ar = 2,6-*i*$Pr_2C_6H_3$; M = La, Nd, Sm, Er, U) that infrared spectroscopy is a valuable tool for the identification of η⁶-arene-bridged dimeric structures.[35−37] IR spectroscopy shows distinct differences in the aromatic C=C vibrational modes for the π-bound and *O*-bridged phenoxide ligands in these compounds. Table 7 shows the IR vibrational frequencies for the aromatic stretching modes in compounds **3**, **4a**, **4b**, **5** and the thiol Ar*SH, recorded as Nujol mulls. Two bands in the regions 1604−1606 cm^{-1} and 1565−1569 cm^{-1} are common to all the spectra. Additional stretching modes at 1591/1545 cm^{-1} (**4a**) and 1592/1544 cm^{-1} (**4b**) are observed only in the IR spectra of the donor-free compounds. The latter clearly indicate a weakening of the aromatic C=C bonds, consistent with the presence of π-arene interactions, as observed by X-ray crystallography.

Ar*SH	1605		1567	

Ab initio Calculations

Previous theoretical studies of lanthanide bonding to arenes have been mainly limited to complexes of the zero-valent metals.[38,39] To gain more insight into the Eu^{2+}− or Yb^{2+}−arene interactions present in **4a** and **4b**, ab initio calculations on suitable model systems were performed. Quasi-relativistic pseudo-potentials of the Stuttgart/Bonn group were employed for atoms heavier than sulfur.

(a) [Ln(donor)]$^{2+}$ Species

In order to test the influence of different substituents and to gain a qualitative impression of the magnitude of the Ln^{2+}−η⁶-arene interaction, the simple complexes $[Ln(arene)]^{2+}$ (Ln = Eu, Yb; arene = C_6H_6, C_6F_6, 1,3,5-$Me_3C_6H_3$, 1,3,5-*i*$Pr_3C_6H_3$) were first examined. For comparison, the coordination of Eu^{2+} and Yb^{2+} to the strong σ-donors tetrahydrofuran, dimethoxyethane, and the Arduengo-type carbene imidazol-2-ylidene was also investigated. Table 8 summarizes the results of these calculations,

Table 8. B3LYP/6−31G*-optimized bond lengths [pm] and binding energies [kJ mol^{-1}] for [Ln(arene)]$^{2+}$, [Ln(THF)]$^{2+}$, [Ln(dme)]$^{2+}$, and [Ln(imidazol-2-ylidene)]$^{2+}$ species (Ln = Eu, Yb)

[a] For the isolated arenes, the following C−C distances were obtained at the B3LYP/6−31G* level of theory: 139.7 (C_6H_6), 139.4 (C_6F_6), {139.9} (1,3,5-$Me_3C_6H_3$) {140.0} (1,3,5-$iPr_3C_6H_3$). − [b] {Av. values}.

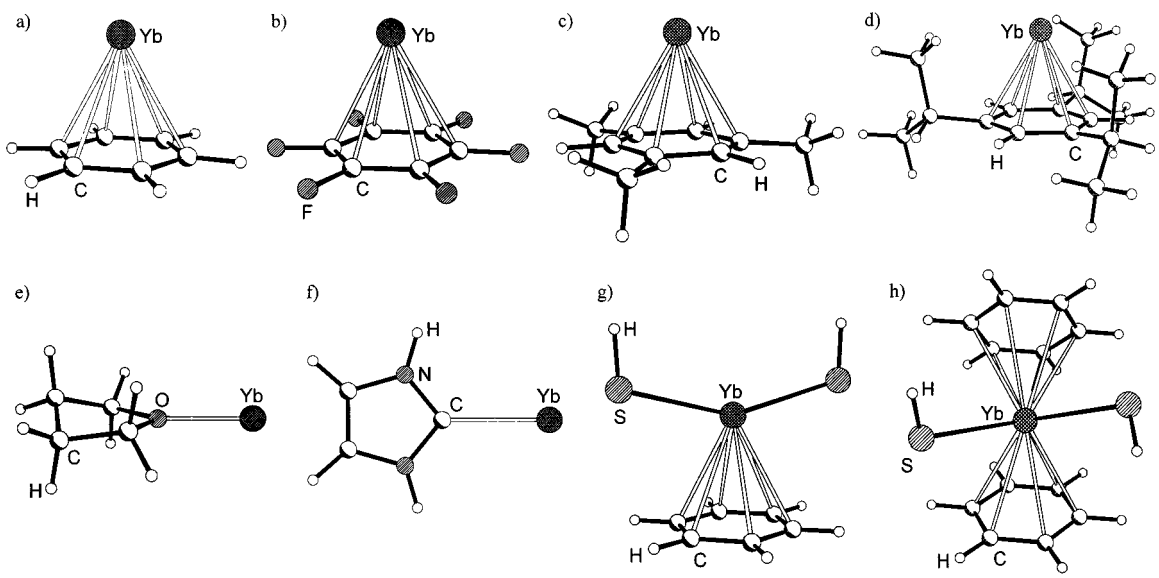

Figure 5. Optimized structures for the model compounds (a) $[Yb(C_6H_6)]^{2+}$, (b) $[Yb(C_6F_6)]^{2+}$, (c) $[Yb(1,3,5\text{-}Me_3C_6H_3)]^{2+}$, (d) $[Yb(1,3,5\text{-}iPr_3C_6H_3)]^{2+}$, (e) $[Yb(THF)]^{2+}$, (f) [Yb(imidazol-2-ylidene)]$^{2+}$, (g) $[Yb(SH)_2(C_6H_6)]$, and (h) $[Yb(SH)_2(C_6H_6)_2]$; calculations were either performed at the B3LYP/6−31G* [(a)−(f)] or the MP2/6−31G* [(g), (h)] level of theory

which were performed at the B3LYP/6−31G* level of theory. The optimized structures of the Yb^{2+} adducts are shown in Figure 5 (a)−(f). Obviously, the binding energy largely depends on the electron-withdrawing or -donating ability of the substituents on the arene rings, as would be expected for a cation−arene interaction dominated by electrostatics. Therefore, as a result of the strong $-I$ effect of the fluorine atoms, the smallest binding energy (ΔH_0) of −113.5 kJ mol^{-1} is calculated for the compound $[Eu(C_6F_6)]^{2+}$, whereas a value of −273.3 kJ mol^{-1} is calculated for the benzene complex $[Eu(C_6H_6)]^{2+}$. The introduction of electron-donating alkyl groups leads to a substantial increase in ΔH_0 from −330.6 kJ mol^{-1} for $[Eu(1,3,5\text{-}Me_3C_6H_3)]^{2+}$ to −383.3 kJ mol^{-1} for $[Eu(1,3,5\text{-}iPr_3C_6H_3)]^{2+}$. With a value of 297 kJ mol^{-1}, the dissociation energy of the adduct $[Eu(THF)]^{2+}$ is intermediate between the values for $[Eu(C_6H_6)]^{2+}$ and $[Eu(1,3,5\text{-}Me_3C_6H_3)]^{2+}$. This is in accordance with the experimental observation that intramolecular arene binding in **4a** and **4b** is favored over the coordination of THF. It is notable that the binding energy for the interaction of Eu^{2+} with the Arduengo-type carbene imidazol-2-ylidene is substantially larger than that for the coordination of THF and comparable to that for coordination of the arene 1,3,5-$iPr_3C_6H_3$. Therefore, it should be possible to obtain adducts of **4a** or **4b** with substituted carbenes of the imidazol-2-ylidene type. As one might expect, the greatest dissociation energy of 423 kJ mol^{-1} is found for the compound $[Eu(dme)]^{2+}$. This is in agreement with the isolation of the bis(DME) adduct **5**. Compared to the corresponding Eu^{2+} compounds, the binding energies of the Yb^{2+} complexes are increased by 9−14%, which is attributable to the smaller ionic radius of

the latter. In accordance with the electronic properties of the various arene ligands, the metal···C(arene) distances also vary considerably by 16−17 pm, being shortest in $[M(1,3,5\text{-}iPr_3C_6H_3)]^{2+}$ and longest in $[M(C_6F_6)]^{2+}$. A notable feature of the calculated $[M(1,3,5\text{-}iPr_3C_6H_3)]^{2+}$ structures is the presence of three agostic-type M···H interactions to C−H bonds of the isopropyl groups (Eu···H: 296.2 pm; Yb···H: 285.5 pm). The shortest experimentally determined M···H distances in **4a** and **4b** are 303 pm and 301 pm, respectively.

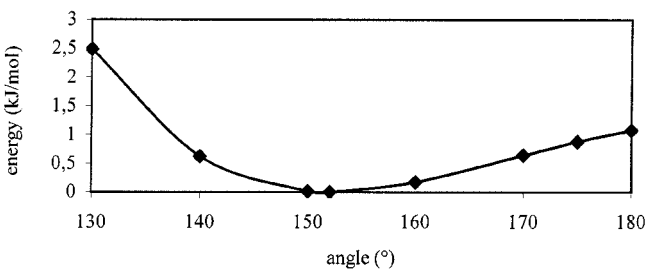

Figure 6. Bending potential curve for *syn*/*syn* $Yb(SH)_2$ at the MP2/6−31+G** level of theory

(b) $Yb(SH)_2$

DFT calculations with two different basis sets revealed at least two stable conformers (Table 9). The U-shaped *syn*,*syn* species with C_2 symmetry is energetically favored by ca. 6 kJ mol^{-1} over the W-shaped *anti*,*anti* conformer (C_{2v}). According to MP2 results, only the former is a minimum on the potential-energy surface. The bending angle at the Yb center and the Yb−S distance were computed at MP2/6−31+G** level to be 152.1° and 271.3 pm, respectively. The DFT calculations showed slightly shorter Yb−S bonds and a more acute S−Yb−S angle of ca. 130° for both conformers. The occurrence of bent equilibrium geometries for some lanthanide MX_2 species[40,41] and related compounds of the heavier alkaline earth elements[42,43] is now well established. This bending can be explained by the presence of small σ-bonding contributions (involving metal d orbitals) and/or the polarization of the metal cation by the ligands. According to Kaupp et al., the MX_2 compounds can be divided into molecules with genuinely bent structures [for example, EuF_2, $Ba(CH_3)_2$] and molecules with quasi-linear equilibrium geometries (for example, $SmCp_2$, CaF_2). The latter show almost no energy change (< 1−2 kJ mol^{-1}) when the equilibrium angle is increased to 180°, whereas the former exhibit considerable linearization energies of up to 33 kJ mol^{-1}.

Figure 6 shows the rather shallow bending potential curve for *syn*/*syn* $Yb(SH)_2$ calculated at the MP2/6-31+G** level of theory. With a linearization energy of 1.1 kJ mol^{-1}, it can be classified as a quasi-linear molecule.

(c) $Yb(SH)_2(C_6H_6)_n$ Complexes (n = 1, 2)

Calculated bond parameters and binding energies for $Yb(SH)_2(C_6H_6)$ and $Yb(SH)_2(C_6H_6)_2$ species, both of which were computed at the B3LYP and MP2 levels of theory using the 6−31G* basis set, are summarized in Table 10. The MP2-optimized structures are shown in Figure 5 (g) and (h). Compared to the experimentally determined distances in complex **4b**, the calculated Yb−S bond lengths for the model compound $Yb(SH)_2(C_6H_6)_2$ are overestimated by 5.1 pm (MP2) and 7.1 pm (B3LYP), respectively. The difference between the DFT-computed and observed Yb···C distances is quite substantial, amounting to +22.3 pm. A much better description is provided by the MP2 calculation, which overestimates the distance of the Yb···arene interaction by only 5.6 pm. Replacing the coordinated benzene in $Yb(SH)_2(C_6H_6)_2$ by the substituted arene 1,3,5-$iPr_3C_6H_3$ can be expected to result in a further reduction in the Yb···C distances, which might, however, be partly compensated by repulsion between the isopropyl groups. The dissociation enthalpy corresponding to the reaction

Table 10. Calculated bond lengths [pm], bond angles [°], torsion angles [°], and binding energies [kJ mol^{-1}] for $Yb(SH)_2(C_6H_6)$ and $Yb(SH)_2(C_6H_6)_2$ species at different levels of theory

Compound[a]	Symm.	Yb−C[b]	Yb−S	S−Yb−S	H−S−Yb−S	ΔE_e	ΔE_{ZPE}	ΔH_0 [c]
	B3LYP/6−31G*							
$Yb(SH)_2(C_6H_6)$	C_2	{310.5}	272.9	139.1	0.4	−70.8	+4.4	−66.4
$Yb(SH)_2(C_6H_6)_2$	C_2	{319.6}	276.2	124.5	44.0	−105.2	+7.3	−97.9
	MP2/6−31G*							
$Yb(SH)_2(C_6H_6)$	C_2	{298.1}	271.8	149.9	0.02	−108.3	+4.6[d]	−103.7
$Yb(SH)_2(C_6H_6)_2$	C_2	{302.9}	274.2	126.6	52.4	−185.4	+7.8[d]	−177.6

[a] *syn*/*syn* isomers only. − [b] {Av. values}. − [c] According to the reaction $Yb(SH)_2 + n\ C_6H_6 \rightarrow Yb(SH)_2(C_6H_6)_n$. − [d] E_{ZPE} was taken from the DFT calculation above.

$Yb(SH)_2(C_6H_6)_2 \rightarrow Yb(SH)_2(C_6H_6) + C_6H_6$ was estimated to be 31.5 kJ mol^{-1} (B3LYP) and 73.9 kJ mol^{-1} (MP2). These values may be compared with the NMR-spectroscopically determined energy barriers of 57.1 kJ mol^{-1} and 54.3 kJ mol^{-1} found for solutions of **4b** in [D_8]toluene or [D_{14}]methylcyclohexane.

Conclusion

The use of the very bulky *m*-terphenyl-substituted Ar*S ligand has permitted the synthesis of the first monomeric σ-donor-free lanthanide(II) thiolates. In the solid state, steric saturation of the europium and ytterbium centers is achieved by two η^6-π-arene interactions, as has been demonstrated by X-ray structural analysis and IR spectroscopy. Evidence that these interactions also persist in solution has been provided by variable-temperature NMR experiments, which show an energy barrier of 54.3 kJ mol^{-1} for **4b** in methylcyclohexane solution. In contrast, the ^{1}H NMR spectrum of the bis(DME) adduct **5** shows no dynamic character in the temperature range 223−300 K, despite the more crowded environment of the Yb center. From ab initio calculations on the model system $Yb(SH)_2(C_6H_6)_2$, it has been estimated that the dissociation of one molecule of benzene requires between 31.5 and 73.9 kJ mol^{-1} depending on the method used.

Experimental Section

General: All manipulations were performed using standard Schlenk techniques under purified argon. Solvents were freshly distilled under argon from Na wire or $LiAlH_4$. The compounds $Yb[N(SiMe_3)_2]_2$ [17] and Ar*SH[44] were synthesized according to known literature procedures. − NMR spectra were recorded with Bruker AM 200, AC250, and AM 400 instruments and were referenced to solvent resonances (^{1}H, ^{13}C) or $YbCp^*_2(THF)_2$ [34] (^{171}Yb). − UV spectra were recorded with a Bruins Omega 10 spectrophotometer. − IR spectra were recorded in the range 4000−200 cm^{-1} with a Perkin−Elmer Paragon 1000 PC spectrometer. − Mass spectra were measured with a Varian MAT711 instrument. − Melting points were determined under Ar in sealed glass tubes.

$Yb(SAr^*)I_2(THF)_3$ (3): A solution of **2b** was prepared from Ar*SH (1.76 g, 3.41 mmol), Yb chips (0.59 g, 3.41 mmol), and 2-iodobenzotrifluoride (0.48 mL, 3.41 mmol) as described below for the synthesis of **4b**. With stirring, a solution of iodine (0.42 g, 3.31 mmol) in THF was added dropwise at 0 °C. The mixture was allowed to warm to ambient temperature and ca. 30 mL of *n*-heptane was added. After filtration through a glass filter frit, the resulting purple solution was concentrated until crystallization commenced and then stored in a freezer at ca. −25 °C for 2 d to give **3** as purple crystals (2.25 g, 57%); m.p. 120−240 °C (dec., compound gradually decolorizes). − IR (CsBr, Nujol): $\tilde{\nu}$ = 1605 ms, 1565 m, 1358 s, 1345 sh, 1315 ms, 1299 s, 1247 m, 1166 ms, 1154 mw, 1130 mw, 1115 m, 1098 m, 1068 ms, 1037 s, 1000 vs, 954 w, 940 m, 916 m, 878 s, 851 sh, 835 vs, 800 s, 774 s, 745 s, 732 s, 674 m, 663 mw, 650 ms, 608 w, 590 w, 526 m, 508 w, 427 mw, 410 cm^{-1} w. − $C_{48}H_{73}I_2O_3SYb$ (1157.0): calcd. C 49.83, H 6.36; found C 49.50, H 6.38.

$Eu(SAr^*)_2$ (4a): At 0 °C, an Eu ingot (3.9 g, 25.7 mmol) was added to a stirred solution of Ar*SH (1.08 g, 2.10 mmol) and 2-iodobenzotrifluoride (0.48 mL, 3.41 mmol) in THF (60 mL). Stirring was continued for 1 h at 0 °C and for a further 1 h at 20 °C, whereupon the resulting light-orange solution was carefully decanted from the excess Eu metal. The volume of the solution was reduced to ca. 5 mL and *n*-heptane (ca. 20 mL) was added. After separation from the precipitated $EuI_2(THF)_5$, the remaining solution was concentrated in vacuo until crystallization commenced. Storage in a freezer at 5 °C overnight afforded **4a**·$(THF)_{0.5}$ as orange crystals (0.89 g, 70%); m.p. 289−292 °C (compound softens > 216 °C). − IR (CsBr, Nujol): $\tilde{\nu}$ = 1606 m, 1591 m, 1569 ms, 1545 m, 1411 m, 1363 s, 1336 m, 1314 ms, 1249 ms, 1167 ms, 1150 m, 1110 ms, 1081 m, 1069 ms, 1049 vs, 1003 m, 939 ms, 922 m, 886 vs, 870 s, 850 w, 791 s, 775 m, 756 m, 738 vs, 733 vs, 649 ms, 612 w, 587 m, 562 w, 519 ms, 426 w, 360 cm^{-1} m. − EI-MS (70 eV): *m*/*z* (%) = 1179.7 (48) [$Eu(SAr^*)_2^+$], 666.3 (100) [$EuSAr^{*+}$], 514.4 (77) [SAr^{*+}]. − $C_{74}H_{102}EuO_{0.5}S_2$ (1215.7): calcd. C 73.11, H 8.46; found C 72.91, H 8.72.

$Yb(SAr^*)_2$ (4b). − Method A: Ar*SH (0.26 g, 0.50 mmol) was added through a solid-addition tube to a stirred solution of $Yb[N(SiMe_3)_2]_2$ (0.12 g, 0.24 mmol) in *n*-pentane (ca. 15 mL). The reaction mixture was stirred for a further 30 min and then the solvent was removed under reduced pressure. The intensely colored residue was redissolved in a mixture of *n*-heptane and a small amount of benzene. Cooling in a freezer at 5 °C afforded **4b**·$(C_6H_6)_{0.5}$ as purple crystals (0.19 g, 64%), which were suitable for X-ray crystallographic studies. The solvate-free compound **1** was obtained by pumping at 10^{-3} mbar for 2 h. − **Method B:** Ar*SH (2.06 g, 4.00 mmol) and Yb chips (1.1 g, 6.36 mmol) were suspended in THF (60 mL) at 0 °C. With stirring, 2-iodobenzotrifluoride (0.56 mL, 4.00 mmol) was added dropwise and after a short induction period a color change to orange was observed. Stirring was con-

tinued for 2 h, whereupon the resulting maroon solution was carefully decanted from the unchanged excess Yb metal. Most of the solvent was removed under reduced pressure and the concentrate was treated with *n*-pentane (50 mL). The solution was separated from the precipitated greenish-yellow $YbI_2(THF)_4$ and all volatile materials were distilled off in vacuo. Recrystallization of the purple-brown residue from *n*-heptane/toluene (20:1) followed by pumping at 10^{-3} mbar for 2 h gave pure **4b** as a purple powder (1.58 g, 66%); m.p. 263−265 °C (compound softens > 220 °C). − ^{1}H NMR (250.1 MHz, [D$_8$]toluene, 85 °C): δ = 1.06 [d, $^3J_{HH}$ = 6.9 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 1.24 [d, $^3J_{HH}$ = 6.9 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 1.31 [d, $^3J_{HH}$ = 6.9 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 2.89 [sept, $^3J_{HH}$ = 6.9 Hz, 8 H, *o*-CH(CH$_3$)$_2$], 3.07 [sept, $^3J_{HH}$ = 6.9 Hz, 4 H, *p*-CH(CH$_3$)$_2$], 6.86 (m, 6 H, *m*/*p*-C$_6$H$_3$), 7.17 (s, 8 H, *m*-Trip). − ^{13}C NMR (62.9 MHz, [D$_8$]toluene, 85 °C): δ = 23.8, 24.3, 24.8 [*o*/*p*-CH(*C*H$_3$)$_2$], 31.2 [*o*-*C*H(CH$_3$)$_2$], 34.0 [*p*-*C*H(CH$_3$)$_2$], 120.6 (*p*-C$_6$H$_3$), 122.0 (*m*-Trip), 129.0 (*m*-C$_6$H$_3$), 141.6, 142.7 (*i*-Trip, *o*-C$_6$H$_3$), 148.3 (*o*-Trip), 149.3 (*p*-Trip), 152.5 (*i*-C$_6$H$_3$). − ^{171}Yb NMR (70.1 MHz, [D$_6$]benzene, 25 °C): δ = 768 ($w_{1/2}$ = 8 Hz) − IR (CsBr, Nujol): $\tilde{\nu}$ = 1606 m, 1592 m, 1568 m, 1544 m, 1314 ms, 1249 ms, 1168 ms, 1150 m, 1110 ms, 1082 m, 1069 m, 1049 s, 1004 w, 939 s, 920 m, 886 vs, 869 vs, 849 w, 791 vs, 774 m, 755 ms, 740 vs, 733 vs, 650 s, 611 w, 587 m, 519 s, 425 w, 363 m, 306 cm^{-1} w. − EI-MS (70 eV): *m*/*z* (%) = 1200.7 (100) [Yb(SAr*)$_2^+$], 687.3 (32) [YbSAr*$^+$], 514.4 (19) [SAr*$^+$]. − $C_{72}H_{98}S_2Yb$ (1200.74): calcd. C 72.02, H 8.23; found C 71.41, H 8.36. − UV/Vis (*n*-pentane): λ_{max} (ε) = 475 nm (110 M^{-1} cm^{-1}), 546 (90). − UV/Vis (THF): λ_{max} (ε) = 369 nm (480 M^{-1} cm^{-1}), 417 (250).

Yb(SAr*)$_2$(THF)$_x$ (6): ^{1}H NMR (200.13 MHz, [D$_8$]THF, 25 °C): δ = 0.95 [d, $^3J_{HH}$ = 6.8 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 1.16 [d, $^3J_{HH}$ = 6.8 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 1.26 [d, $^3J_{HH}$ = 6.8 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 2.86 [sept, $^3J_{HH}$ = 6.8 Hz, 4 H, *p*-CH(CH$_3$)$_2$], 2.95 [sept, $^3J_{HH}$ = 6.8 Hz, 8 H, *o*-CH(CH$_3$)$_2$], 6.67 (m, 6 H, *m*/*p*-C$_6$H$_3$), 6.93 (s, 8 H, *m*-Trip). − ^{13}C NMR (50.33 MHz, [D$_8$]THF, 25 °C): δ = 24.5, 24.5, 25.8 [*o*/*p*-CH(*C*H$_3$)$_2$], 31.2 [*o*-*C*H(CH$_3$)$_2$], 34.9 [*p*-*C*H(CH$_3$)$_2$], 119.3 (*p*-C$_6$H$_3$), 121.1 (*m*-Trip), 129.9 (*m*-C$_6$H$_3$), 142.9, 144.4 (*i*-Trip, *o*-C$_6$H$_3$), 146.3 (*p*-Trip), 147.3 (*o*-Trip), 152.5 (*i*-C$_6$H$_3$). − ^{171}Yb NMR (70.1 MHz, [D$_8$]THF, 25 °C): δ = 281 ($w_{1/2}$ = 50 Hz). − ^{171}Yb NMR {70.1 MHz, [D$_8$]toluene (ca. 80%) + [D$_8$]THF (ca. 20%), −40 °C}: δ = 336 ($w_{1/2}$ = 180 Hz).

Yb(SAr*)$_2$(dme)$_2$ (5): In a Schlenk tube, purple **4b** (0.35 g, 0.29 mmol) was treated with two drops of DME, which immediately gave **5** as a yellow, microcrystalline material in quantitative yield. The excess DME was carefully removed in vacuo at 0 °C. Prolonged pumping at 10^{-3} mbar overnight gave **4b** once more. Crystals of **5** suitable for X-ray crystallographic studies were obtained from an *n*-pentane/DME mixture (5:1) at −25 °C; m.p.: compound darkens > ca. 110 °C and melts to a purple-brown liquid between 265 and 270 °C. After cooling to ambient temperature and standing for 1 h, the upper crust of the solid turns yellow again. − ^{1}H NMR (250.1 MHz, [D$_{10}$]DME, 25 °C): δ = 0.97 [d, $^3J_{HH}$ = 6.8 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 1.18 [d, $^3J_{HH}$ = 6.8 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 1.25 [d, $^3J_{HH}$ = 6.8 Hz, 24 H, *o*/*p*-CH(CH_3)$_2$], 2.87 [m, 12 H, *o*- + *p*-CH(CH$_3$)$_2$], 3.27 (s, 12 H, OCH$_3$), 3.43 (s, 8 H, OCH$_2$) [these two signals correspond to the coordinated non-deuterated DME; another set of signals is observed for the perdeuterated solvent], 6.67 (m, 6 H, *m*- + *p*-C$_6$H$_3$), 6.88 (s, 8 H, *m*-Trip). − ^{171}Yb NMR (70.1 MHz, [D$_{10}$]DME, −40 °C): δ = 204 ($w_{1/2}$ = 75 Hz). − IR (CsBr, Nujol): $\tilde{\nu}$ = 1604 m, 1566 ms, 1358 s, 1315 ms, 1276 w, 1243 ms, 1209 w, 1190 m, 1168

X-ray Crystallography: X-ray-quality crystals were obtained as described above. Crystals were removed from Schlenk tubes and immediately covered with a layer of viscous hydrocarbon oil (Paratone N, Exxon). A suitable crystal was selected, attached to a glass fibre, and instantly placed in a low-temperature N_2 stream.[45] All data were collected at 173 K using either a Syntex $P2_1$ (**3**, **5**) or a Siemens P4 (**4a**, **4b**) diffractometer. Crystal data are given in Table 11. Calculations were carried out with the SHELXTL PC 5.03[46] and SHELXL-97[47] program systems installed on a local PC. The structures were solved by direct methods and refined against F_o^2 by full-matrix least-squares techniques. An absorption correction was applied by using semiempirical ψ-scans (**5**) or the program XABS2[48] (**3**, **4b**). For **4a**, no absorption correction was used. Anisotropic thermal parameters were included for all non-hydrogen atoms with the exception of the co-crystallized THF molecule, which was refined with a common isotropic U value. The methyl carbon atoms of two (**5**) or four (**4a**, **4b**) disordered isopropyl groups were refined with split positions. The geometries of the disordered isopropyl groups and the co-crystallized benzene molecule (**4b**) were restrained with SADI and DFIX commands. H atoms were placed in geometrical positions and were refined using a riding model that included free rotation of the methyl groups. Their isotropic thermal parameters were either allowed to refine or were constrained to 1.2 (aryl H) or 1.5 (methyl groups) times U_{eq} of the carbon atom to which they were bound. Final R values are listed in Table 11. Salient bond lengths and angles are given in Tables 1−3. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-150909 (**3**), -150907 (**4a**), -150908 (**4b**), and -150910 (**5**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: The Gaussian 98[49] package was used for all energy and frequency calculations. The geometries of the molecules were optimized using either density functional theory (DFT) with the functional B3LYP or second-order Møller−Plesset perturbation theory (MP2). Quasi-relativistic 11- or 10-valence-electron pseudo-potentials of the Stuttgart/Bonn group were employed for the heavy atoms Sc,[50] Eu, and Yb.[51,52] The corresponding (8s7p6d1f)/[6s5p3d1f] valence basis set for Sc was taken from the literature, whereas the (7s6p5d)/[5s4p3d] valence basis sets for Eu and Yb were augmented by one set of f-functions. The basis sets for C, H, F, and S were either 6−31G* or 6−31+G** [$Yb(SH)_2$ species only]. Frequency calculations were carried out to verify that the geometries were true minima on the potential-energy surface and to obtain the zero-point energy (E_{ZPE}). The sum of the electronic energy (E_e) and the zero-point energy was used to calculate differences interpreted as reaction enthalpies (ΔH_0) at 0 K. For calibration purposes, test calculations were performed to compute the cation−ring binding energy of $[Sc(C_6H_6)]^+$, which was determined experimentally as -222 ± 21 kJ mol^{-1}.[53,54] The results of B3LYP and MP2 calculations with the 6−31+G** basis set fall within the experimental error bars. The binding energy was found to be overestimated by 9−16% using the 6−31G* or 6−311+G** basis sets.

Synthesis and Structural Studies of Pyridine-2-selenolates − Reactions with Electrophilic Phosphorus(III) Compounds and Related Complex Chemistry

Jörg Laube,[a] Stefan Jäger,[a] and Carsten Thöne*[a]

Dedicated to Professor Henning Hopf on the occasion of his 60th birthday

Keywords: Selenium / P ligands / Molybdenum / Metallacycles / Coinage-metal complexes

The reaction intermediates in the synthesis of 2,2′-bis(pyridyl) diselenide (2,2′-Py_2Se_2) have been determined. The reaction of Na_2Se_2 with 2-BrC_5H_4N (2-BrPy) leads to a tautomeric mixture of pyridine-2-selenol (2-PySeH) and pyridine-2(1*H*)-selone (2-PyHSe), which have been investigated by spectroscopic means. Additionally, the crystal structure of the latter has been determined. Reductive cleavage of the Se–Se bond in 2,2′-Py_2Se_2 with K*B*s*Bu*$_3$H leads to K-2-SePy, which was trapped, either as [(18-crown-6)K]$^+$[2-PySe]$^-$, whose structure contains polymeric cation–anion chains, or as [Et_4N]$^+$[2-PySe]$^-$. Reactions of K-2-SePy or [Et_4N]$^+$[2-PySe]$^-$ with Ph_2PCl, *t*Bu_2PCl, or *t*$BuPBr_2$ lead to the corresponding, extremely air-sensitive (pyridyl)selenophosphanes Ph_2P-2-SePy, *t*Bu_2P-2-SePy, and *t*BuP(2-SePy)$_2$. The latter was trapped as *t*BuP(O)(2-SePy)$_2$, whose crystal structure has been determined. Metal complexes of these (pyridyl)selenophosphanes have been prepared starting from the phosphane and CuBr, AgBr, (tht)AuCl (tht = tetrahydrothiophene), or [(η^6-C_7H_8)Mo(CO)$_3$], in one-pot syntheses. All crystal structures of the resulting metallacycles [({(C$_5$H$_4$N-2-Se)*t*Bu_2P}-*N,P*)Cu(μ-Br)]$_2$, [({(C$_5$H$_4$N-2-Se)*t*Bu_2P}-*N,P*)Ag(μ-Br)]$_2$, [({(C$_5$H$_4$N-2-Se)*t*Bu_2P}-*P*)AuCl], and [({(C$_5$H$_4$N-2-Se)$_2$*t*BuP}-*N,N′,P*)Mo(CO)$_3$], were determined. Additionally, comprehensive spectroscopic investigations are presented.

Introduction

Recent research in our laboratory has shown that 2,2′-bis(pyridyl) diselenide (Py_2Se_2) is a useful starting material for the preparation of (pyridyl-2-selenolato)metal complexes.[1] The most common reaction mechanisms comprise oxidative addition of Py_2Se_2 to unsaturated metal centres and reductive cleavage of the Se−Se bond with organoboron hydrides, and subsequent reactions of the formed $PySe^-$ anion with halometal complexes. Additionally, oxidative addition of Py_2Se_2 to finely divided elemental metals could be employed, as shown for In.[2]

Apart from homoleptic (pyridineselenolato)metal complexes, which can serve as volatile starting materials for the preparation of thin metal selenide layers,[3] the coordination chemistry of ligands that contain the soft/hard Se/N donor set is surprisingly unexplored,[4] although Py_2Se_2 was first synthesized in 1962,[5] and its use in organic syntheses[6] and biochemistry[7] is well documented. The mechanism of Py_2Se_2 formation from Na_2Se_2 and 2-BrPy under acidic conditions is also not well understood. Py_2Se_2 is usually synthesized by oxidation of Py-2-SeH with various oxidising agents, but the reported syntheses of Py-2-SeH are often unreliable for different reasons.[3a,5][7c,8] In the first part of this paper, we report on the synthesis and characterization of Py-2-SeH and its tautomeric form pyridine-2(1*H*)-selone PyH-2-Se, together with the synthesis of the useful starting material in pyridineselenolate chemistry, [Et_4N][2-PySe]. We also report the crystal structure of PyH-2-Se and [(18-crown-6)K][2-PySe].

(Organoseleno)phosphanes are relatively rare in the literature, and apart from $P(SePh)_3$, no crystal structure has been published.[9] Heteroatom-substituted phosphanes were shown to be useful ligands that display enhanced catalytic activities,[10] as described for the reaction of ketones with propane-2-ol to form corresponding alcohols with [$RuCl_2(PPh_3)_3$] or [$RuCl_2(PPh_3)$(N,P,N)] [N,P,N = bis(2-oxazoline-2-yl-methyl)(phenyl)phosphane] as catalyst.[11] One possibility for controlling the reaction pathways and the selectivity of phosphane-containing catalysts is the modification of the surrounding phosphane by varying the donor atom sets, which are usually C, N, and P. The introduction of selenium offers different coordination modes with hard and soft metal centres. In the second part of the paper, we therefore describe the syntheses of (pyridylseleno)-phosphanes and related metal complexes, together with the crystal structures of *t*BuP(O)(2-SePy)$_2$, [({(C$_5$H$_4$N-2-Se)*t*Bu_2P}-*N,P*)Cu(μ-Br)]$_2$, [({(C$_5$H$_4$N-2-Se)*t*Bu_2P}-*N,P*)Ag-(μ-Br)]$_2$, [({(C$_5$H$_4$N-2-Se)*t*Bu_2P}-*P*)AuCl], and [({(C$_5$H$_4$N-2-Se)$_2$*t*BuP}-*N,N′,P*)Mo(CO)$_3$].

Results and Discussion

Pyridine-2-selenol (1), Pyridine-2(1*H*)-selone (2), and Related Selenolates

Our previously described synthesis of Py-2-SeH is strongly dependent on the reaction conditions.[1a] All attempts to repeat the synthesis at slightly different temper-

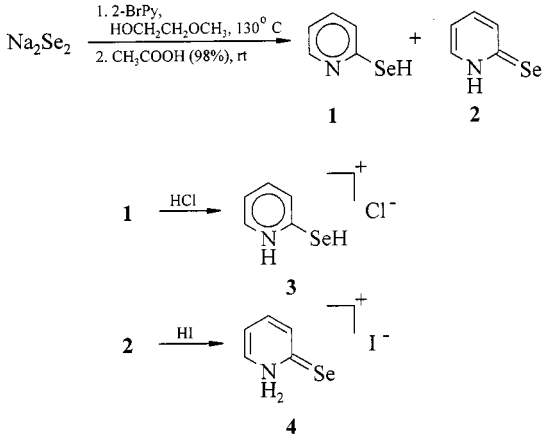
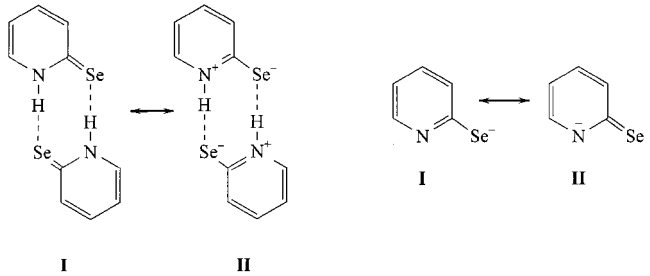
atures or pH values have been unsuccessful. This prompted us to examine this reaction in more detail. The results are shown in Scheme 1.



Scheme 1. Synthesis of 2-pyridineselenol (**1**) and pyridine-2(1*H*)-selone (**2**) and their reactions with HCl and HI

The acidification of the reaction mixture Na_2Se_2/2-BrPy, after refluxing it for 24 h in glycol monomethyl ether, with glacial acetic acid, leads to a mixture of Py-2-SeH (**1**) and PyH-2-Se (**2**) (ratio 1:6). These could be easily separated, since **1** and **2** have different physical properties: **1** is a light-yellow air-sensitive powder, soluble in polar solvents (alcohols, H_2O), but only sparingly soluble in CH_2Cl_2; **2** is a dark-yellow to orange air-stable and crystalline solid, soluble in polar solvents, but only sparingly soluble in H_2O. Once separated, **2** does not equilibrate to **1** in polar solvents. However, the mixture of **1** and **2** does not have to be separated for the synthesis of Py_2Se_2. The tautomerism of **1** and **2** was examined by spectroscopic means. It was shown that the UV/Vis spectrum of **2** is similar to the corresponding spectrum of 1-methylpyridine-2(1*H*)-selone, which gives a first hint of the selone structure.[5,12] Additional measurements of the dipole moment suggest the selone to be dimeric and resonance-stabilized (Scheme 2).



Scheme 2. Resonance forms of the dimeric pyridine-2(1*H*)-selone (**2**) and the 2-$PySe^-$ anion

The zwitterionic form **II** contributes markedly, since the dipole moment is relatively high and strongly solvent-dependent. ^{1}H NMR spectroscopic data show that the SeH signal of **1** (δ = 8.53) is shifted to low field in comparison with other organic selenols [PhSeH: δ = 1.36 (m); 2,4,6-$(CF_3)_3C_6H_2$SeH: δ = 2.36].[13] The tautomeric forms **1** and **2** are therefore easily distinguishable, since **2** displays a corresponding ^{1}H NMR resonance at a lower field (δ = 12−14; depending on the solvent and concentration). Further experiments showed that **1** and **2** react with acids to produce, e.g., the corresponding pyridinium hydrochloride and hydroiodide **3** and **4**. Protonation occurs exclusively at the nitrogen atom, and again the ^{1}H NMR spectroscopic data allow a clear distinction. Thus, the resonance for SeH of **3** appears at δ = 4.96, with an H−Se coupling constant of 14 Hz, derived from ^{77}Se satellites. The corresponding resonance of the amine proton is shifted to lower field (δ = 11.93). The ^{1}H NMR spectrum of **4** displays a resonance for the equivalent amine protons at δ = 8.88 (av. value of three measurements).

To confirm the NMR results, an X-ray structure analysis of **2** was performed (Figure 1). Alternative positions of the pyridine N atom and the *o*-carbon atom C2 were refined to establish the exact connectivity (see Exp. Sect.).

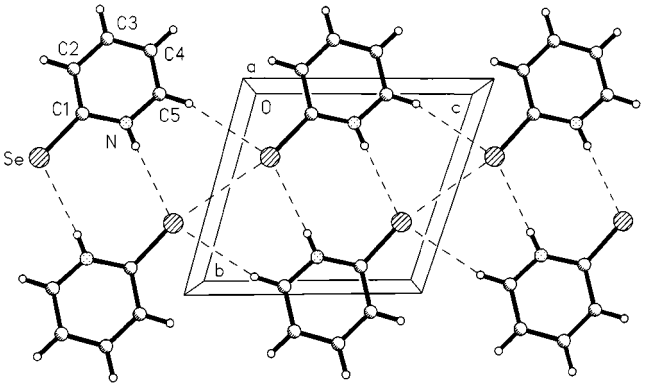


Figure 1. Molecular structure of PyH-2-Se (**2**) displaying intermolecular hydrogen bonding and weak Se−Se interactions (ellipsoids drawn at 50% probability level); selected bond lengths [pm] and angles [°]: Se−C1 184.6(8), N−C1 135.4(10), N−C5 133.8(10), N···Se^{i} 336.2(6), C5···Se^{ii} 386.0(8), Se···Se^{iii} 353.9(2); Se−C1−N 120.5(5), Se−C1−C2 124.8(6), C1−N−C5 125.5(7), N−C1−C2 114.7(7), N−H1···Se^{i} 164(8), C5−H5···Se^{ii} 163.7, C1−Se···Se^{iii} 167.7(2); *i*: x, y + 1, z; *ii*: x, y + 1, z + 1; *iii*: x, y + 1, z − 1

The crystal structure consists of dimeric pyridine-2(1*H*)-selones with planar monomeric units (max. dev. 8 pm for the N−H proton H1), connected via N−H···Se hydrogen bonds. The C=Se bond length of 184.6(8) pm is attributable to a resonance-stabilized C−Se double bond (Scheme 2). In selones not stabilized by resonance, the C=Se bonds are significantly shorter {1,5-dimethyl-3,7-dithiabicyclo[3.3.1]nonane-9-selone 177.4(6) pm; 4,4′-dimethoxyselenobenzophenone 179.0(4) pm; calculated value for selenoformaldehyde 173.9 pm}.[14] All other bond lengths are similar to those in pyridine.[15] Figure 2 shows the packing of **2**. The dimeric units are linked by weak Se···Se contacts of 353.9(2) pm and non-classical C−H···Se hydrogen bonds of C···Se 386.0(8) pm and H···Se 294 pm to form planar tapes, parallel to the *c* axis.

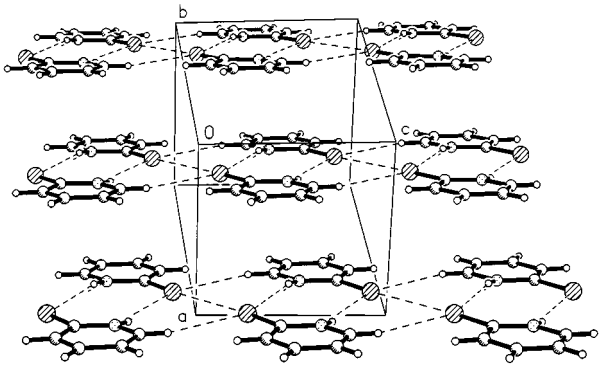

Figure 2. Packing diagram of (**2**) displaying the planar ribbons parallel to the *c* axis; radii are arbitrary; dashed lines correspond to N−H···Se hydrogen bonds, Se···Se contacts, and C−H···Se hydrogen bonds

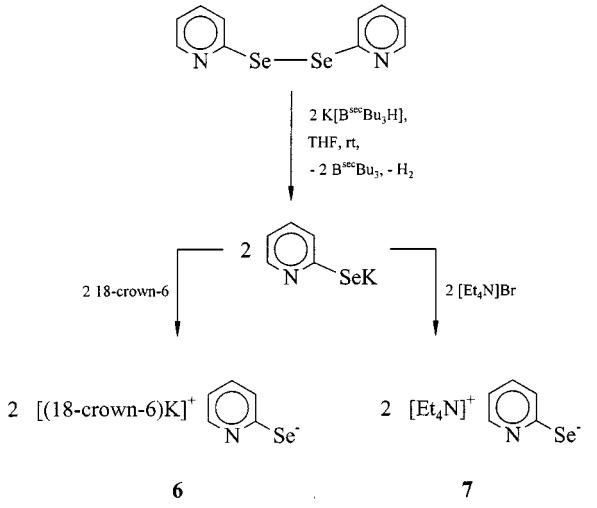
To exploit the synthetic potential of the strongly nucleophilic 2-$PySe^-$ anion, it was necessary to introduce a new starting material with suitable properties, since many known syntheses of $PySe^-$ often suffer from a lack of reliability. One possible starting material is the pale-yellow compound $[Et_4N][2\text{-SePy}]$ (**7**), which can be easily prepared as described in Scheme 3.



Scheme 3. Synthesis of the stable pyridine-2-selenolates [(18-crown-6)K][2-SePy] (**6**) and $[Et_4N][2\text{-SePy}]$ (**7**)

The synthesis strongly depends on the reducing agent for 2,2′-Py_2Se_2 (**5**). Usually, reactions with 2-$PySe^-$ are performed in situ with Na, NaH, or MBR_3H (M = Li, Na) as reducing agents for **5**. The disadvantages of such procedures are as follows: (i) an excess of Na or NaH is difficult to remove from the reaction mixture, and can lead to undesired side-reactions if the reactants are redox-sensitive; (ii) the concentration of commercially available MBR_3H solutions is neither stable nor easy to monitor. In the case of **7**, these problems do not occur, since K*B*s*Bu*$_3$H solutions can be used in excess, and $[Et_4N]Br$ is not redox-sensitive. Additional advantages are the low solubility of $[Et_4N]Hal$ (Hal = Cl^-, Br^-) in many organic solvents, which can be regarded as the driving force in reactions of **7** with halogen derivatives, and the easy handling of the less air-sensitive **7**, which can be weighed in air.

A second possibility for stabilizing the 2-$PySe^-$ anion is the reaction of K-2-SePy with 18-crown-6 ether. The colourless oily product [(18-crown-6)K][2-SePy] (**6**) could be crystallised from ethanol/diethyl ether in moderate yield. The resonances in the ^{77}Se NMR spectra appear at low field [**2**: δ = 314.0 ($CDCl_3$), δ = 214.9 (H_2O); **6**: δ = 441.8 (CD_3OD); **7**: δ = 359.6 (CD_3OD)]. The values for **6** and **7** indicate a strong contribution of the ionic and the amide mesomeric form, as depicted in Scheme 2. This is in agreement with the shift of the resonance of **2** to higher field, when changing the solvent to H_2O, in which the ionic mesomeric form is more favoured. In systems where mesomeric forms display markedly different contributions, the resonances of the selenolates are usually shifted to higher field, compared with the corresponding selenols.[16] Unfortunately, appropriate data for **1** are not available.

The crystal structure of **6** is shown in Figure 3. It consists of cation−anion pairs with the potassium ion 82.8(3) pm outside the ideal plane through the oxygen atoms, linked by short K···N and K···Se contacts of 276.5(6) and 348.5(2) pm, respectively. Comparable, slightly smaller values for K···Se contacts were observed in $\{K[Ph_2P(Se)NSiMe_3]\cdot THF\}_2$ [336.6(5) and 338.9(4) pm] and 2-$MeOC_6H_4COSeK$ [330.9(1) pm].[17] In all such compounds, the negative charge at the selenium atom is delocalized; crystal structures with the negative charge centred at the selenium atom are unknown. Weak non-classical C−H···O hydrogen bonds of 264.4 and 255.5 pm (H···O) link the cation−anion pairs to infinite chains along the *a* axis. The Se−C bond, at 186.6(6) pm, is only slightly longer than the corresponding one in **2**, and can therefore also be described as a resonance-stabilized C−Se double bond (Scheme 3). Similar

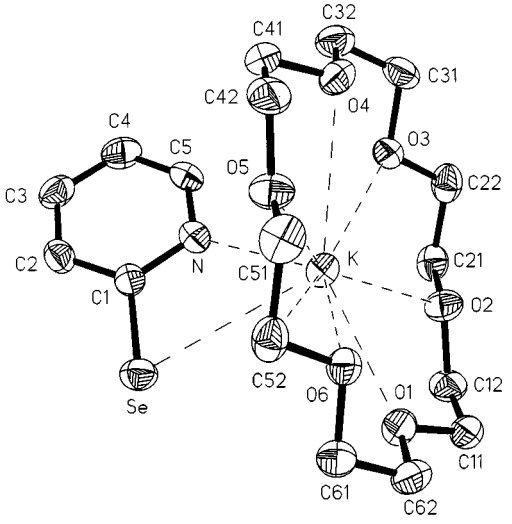


Figure 3. Molecular structure of $[(18\text{-crown-6})K]^+[2\text{-PySe}]^-$ (**6**) (ellipsoids drawn at 50% probability level): H atoms omitted for clarity; selected bond lengths [pm] and angles [°]: Se−C1 186.6(6), N−C1 136.1(8), N−C5 133.6(8), K−O 280.3(4) to 314.1(4), K···Se 348.5(2), K···N 276.5(6); C1−N−C5 117.5(6), N−C1−C2 120.0(6), N−C5−C4 125.3(6), N−C1−Se 118.3(5)

bonding patterns were detected in the corresponding thiolate [(18-crown-6)K][2-SPy] with a K···N contact of 285.4(3) and a K···S contact of 325.58(1) pm.[18]

(2-Pyridylseleno)phosphanes and Related Complexes

K-2-SePy and [Et_4N][2-SePy] (**7**) are useful starting materials for introducing 2-$PySe^-$ into phosphanes (Scheme 4).

The nature of the products in such reactions is strongly dependent on the nucleophilicity of the starting material used, as shown for the reaction of Ph_2PCl with NaSePh, which leads quantitatively to Ph_3PSe even at low temperatures.[19] Apart from *t*Bu_2P(2-SePy) (**9**), which can be crystallised as an analytically pure yellow compound at low temperatures, the resulting yellow (2-pyridylseleno)phosphanes Ph_2P(2-SePy) (**8**) and *t*BuP(2-SePy)$_2$ (**10**) are extremely air-sensitive and oily compounds. Therefore, reactions with **8** and **10** should be performed in situ. The synthesis of **10** cannot be performed with **7** as starting material, since the nucleophilicity is not sufficient at room temperature. Performing the reaction at higher temperatures leads to an inseparable mixture of phosphorus-containing compounds. During the synthesis of **10** with K-2-SePy at room temperature, KCl forms an emulsion, which leads to difficulties in the workup procedure. Attempts to remove KCl resulted in complete oxidation of **10** to the corresponding phosphane oxide *t*BuP(O)(2-SePy)$_2$ **11**, whose crystal structure was determined (vide infra).

Compounds **9** and **11** have been fully characterized, whereas **8** and **10** have only been characterized by ^{31}P NMR spectroscopy. All (2-pyridylseleno)phosphanes and the phosphane oxide derivative display singlets in the ^{31}P NMR spectra in the range $\delta = +20$ to $+110$. The ^{31}P-^{77}Se coupling constants derived from ^{77}Se satellites (219−236 Hz for **8**, **9**, and **10**; 413 Hz for **11**) are typical values for P−Se single bonds, and the greater magnitude of the value for **11** shows the typical influence of the oxidation state change from P^{III} to P^{V}, accompanied by the introduction of an electron-withdrawing substituent.[16] Similar values of the chemical shift and the ^{31}P-^{77}Se coupling constant were found in Me_2PSeMe ($\delta = 0.8$, 218 Hz), $(CF_3)_2$PSeMe ($\delta = 27.9$, 294 Hz), and [Ph_2PSePPh_2Cr(CO)$_5$] [$\delta = 25.7$ with 244 Hz (λ^3-P), $\delta = 78.6$ with 312 Hz (λ^4-P)].[20] The corresponding resonance signals in the ^{77}Se NMR spectra appear at $\delta = +271$ for **9** and $\delta = +437.8$ for **11**, as doublets with coupling constants of the same magnitude.

The crystal structure of **11** is shown in Figure 4. It consists of loose dimers, linked by non-classical C−H···O hydrogen bonds with H···O = 259 pm. Additionally, intramolecular C−H···O hydrogen bonds with H···O = 245 pm are observed. The angles at the selenium atom differ considerably with values of 95.28(12)° and 104.92(12)°, probably associated with the intramolecular hydrogen bond. The observed P−Se bond lengths of 224.68(11) and 225.62(12) pm are attributable to P−Se single bonds and similar to the central P−Se bonds in [*t*BuP(Se)(μ-Se)]$_2$ with 226.9(2) pm.[21]

The (pyridylseleno)phosphanes **9** and **10** were treated with unsaturated metal complexes in order to examine which binding site of the potentially three- or five-atom donor set could be used for complexation reactions (Scheme 5, Scheme 6, and Scheme 7).

In the case of Cu^I and Ag^I, the doubly bromo-bridged dinuclear complexes [({(C_5H_4N-2-Se)*t*Bu_2P}-*N*,*P*)Cu(μ-Br)]$_2$ (**12**) and [({(C_5H_4N-2-Se)*t*Bu_2P}-*N*,*P*)Ag(μ-Br)]$_2$ (**13**) were formed in almost quantitative yield as air-stable pale-yellow to colourless solids. The reaction of **9** with (tht)AuCl

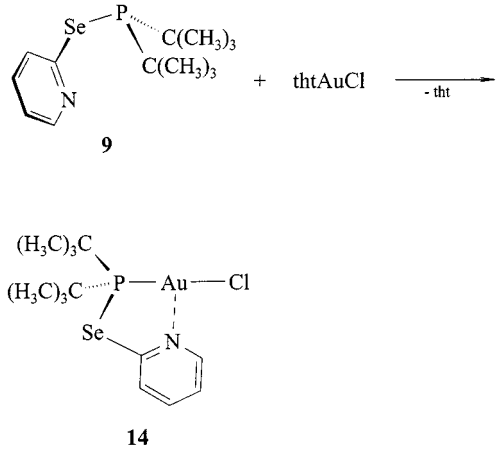
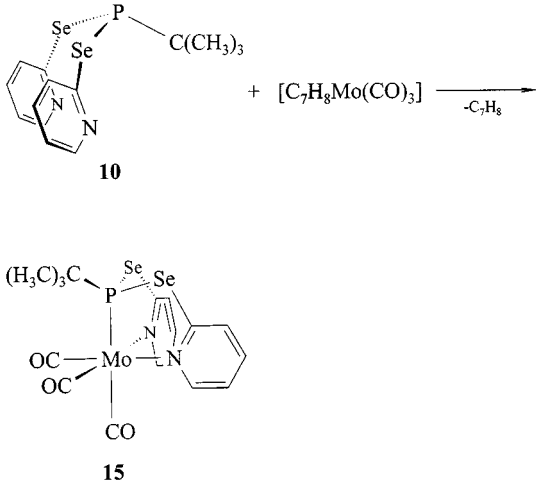


Scheme 6. Synthesis of the Au^{I} complex **14**

(tht = tetrahydrothiophene) leads in contrast to the mononuclear complex [({(C$_5$H$_4$N-2-Se)*t*Bu$_2$P}-*P*)AuCl] (**14**). Finally, the reaction of the bis(pyridylseleno)phosphane **10** with [(η^6-C$_7$H$_8$)Mo(CO)$_3$] leads to the deep-red mononuclear complex [({(C$_5$H$_4$N-2-Se)$_2$*t*BuP}-



Scheme 7. Synthesis of the Mo^{0} complex **15**

N,*N*′,*P*)Mo(CO)$_3$] (**15**) in moderate yield. All complexes were fully characterized, including crystal structure analyses.

The resonances in the ^{31}P NMR spectra show a shift to lower field, going from the Cu^{I} complex **12** to the Au^{I} complex **14**, with values of δ = 72.4 (**12**), δ = 84.7 (**13**), and δ = 117.3 (**14**) (chemical shift for **9**: δ = 90.3). By contrast, generally the opposite tendency is observed, caused by an increasing electron density from Cu to Au. This observation could be explained in terms of metal−nitrogen bonds of different strengths. The strongest metal−nitrogen bond in this row can be apparently found in **12**, leading to an increased electron density at Cu^{I}, whereas the Au^{I}−N bond in **14** must be considered as weak. This results in a stronger metal−phosphorus back donation, which explains the shift of the ^{31}P NMR resonances of **12** and **13** to higher field, compared with the uncomplexed phosphane. The explanation of the corresponding resonances in the ^{77}Se NMR spectra with values of δ = +520 (**12**), δ = +470 (**13**), and δ = +501 (**14**) (chemical shift for **9**: δ = +271) seems to be more complicated, since a clear tendency cannot be observed. Even the ^{77}Se-^{31}P coupling constants (240 to 322 Hz) are similar to that of the uncomplexed phosphane (235 Hz), so that the interpretation of the electron densities in the examined nuclei, as derived from ^{77}Se NMR spectroscopic data, is not reasonable. In the case of the Mo^{0} complex **15**, the ^{31}P NMR resonance with δ = 155.9 is strongly shifted to lower field, compared with the corresponding value for **10** (δ = 101). Additionally, the equivalent Se atoms display a chemical shift in the ^{77}Se NMR spectrum at extremely low field (δ = +761.1). Unfortunately, the corresponding data for **10** are not available, since its instability does not permit ^{77}Se NMR experiments. Since **12** and **13** are isostructural, their crystal structures are discussed together (Figure 5).

The common feature in both structures is that two monomeric units are doubly bridged by bromide to form dinuclear complexes. The resulting central four-membered M$_2$Br$_2$ rings are folded across the M···M vector, with corresponding interplanar angles of 20.25(5)° for **12** and 24.62(3)° for

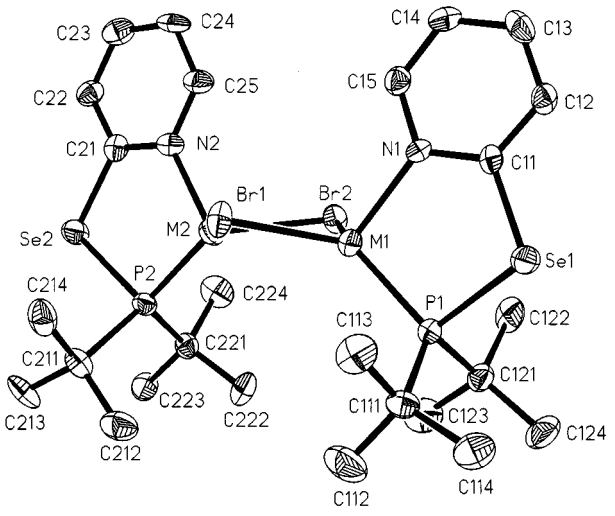


Figure 5. Molecular structures of [({$(C_5H_4N$-2-Se)tBu$_2$P}-*N*,*P*)M(μ-Br)]$_2$ [M = Cu (**12**), Ag (**13**)] (ellipsoids drawn at 50% probability level); H atoms omitted for clarity; selected bond lengths [pm] and angles [°] (the second value corresponds to the silver complex **13**): M1−N1 210.9(4)/245.6(3), M2−N2 210.4(5)/248.8(3), M1−P1 220.15(17)/241.16(11), M2−P2 220.09(17)/241.76(11), M1−Br1 245.96(10)/263.12(6), M1−Br2 249.77(10)/270.17(6), M2−Br1 248.43(10)/265.32(7), M2−Br2 247.73(10)/267.84(6), P1−Se1 226.41(17)/225.45(12), P2−Se2 226.92(17)/225.37(12), Se1−C11 191.8(6)/194.5(4), Se2−C21 192.7(6)/194.3(4), M1···M2 314.30(11)/313.33(6), Br1···Br2 377.66(10)/421.53(8); N1−M1−P1 95.11(14)/85.14(8), M1−P1−Se1 101.07(7)/105.33(5), P1−Se1−C11 99.31(17)/100.98(12), Se1−C11−N1 119.7(4)/119.2(3), C11−N1−M1 121.8(4)/122.9(3), N2−M2−P2 94.74(14), M2−P2−Se2101.52(7)/106.76(5), P2−Se2−C21 99.6(2)/101.66(13), Se2−C21−N2 120.1(4)/120.5(3), C21−N2−M2 123.2(4)/124.5(3)

13, which leads to relatively short metal−metal contacts of 314.30(11) and 313.33(6) pm, respectively. These values and corresponding bonding parameters are often found in Cu_2Br_2 and Ag_2Br_2 rings.[22] The (2-pyridylseleno)phosphane ligands act as chelates and are bound through the phosphorus and nitrogen atoms. The P−Se bond lengths in both complexes are 226.41(17) and 226.92(17) pm for **12**, and 225.45(12) and 225.37(12) pm for **13**, which correspond to P−Se single bonds. The strength of the metal−nitrogen bond may be assumed to be greater in **12** [210.9(4), 210.4(5) pm] than in **13** [245.6(3), 248.8(3) pm], consistent with the greater hardness of Cu^I centres compared with Ag^I centres. The molecular structure of the Au^I complex **14** is shown in Figure 6.

In contrast to the dimeric complexes **12** and **13**, complex **14** forms a simple monomer with a semi-chelating (2-pyridylseleno)phosphane ligand and essentially linear bonding at Au. An additional Au···N contact of 282.8(7) pm, which is too long for a bonding interaction is also formed. Normal Au−N single bonds in Au^I−amine complexes are much shorter (ca. 200 pm).[23] The P−Se bond length of 225.3(2) pm is again assignable to a P−Se single bond. In the molecular structure of the Mo^0 complex **15**, the bis(2-pyridylseleno)phosphane **10** acts as a tridentate chelating ligand (Figure 7).

Complex **15** crystallized with one disordered CH_2Cl_2 molecule per asymmetric unit, which was refined in two alternative positions. The coordination sphere of the molybdenum centre is slightly distorted octahedral, with angles ranging from 82.91(8) to 96.77(13)° and 175.26(13) to 177.08(13)°. The ligand is exclusively bound through both nitrogen and phosphorus atoms in a *fac* arrangement, and shows a strong *trans* influence with Mo−C bond lengths of 194.2(4) pm (av. value, carbonyl groups *cis* to the P atom) and 200.9(4) pm (carbonyl group *trans* to the P atom). The P−Se bond lengths of 226.59(10) and 227.12(10) pm match the observed values in **12**, **13**, and **14**, and therefore again correspond to P−Se single bonds. All other bonding para-

meters in the complexes **12** to **15** are consistent with the usually observed values.

Experimental Section

General Techniques: All reactions were performed under dry dinitrogen using conventional Schlenk techniques. Solvents were dried and degassed using standard procedures prior to use. − NMR spectra were recorded with a Bruker AC 200 at room temperature [^{1}H: 200.1 MHz; ^{13}C: 50.32 MHz; ^{31}P: 81.0 MHz; ^{77}Se: 38.2 MHz; standards Me_4Si (^{1}H, ^{13}C); 85% H_3PO_4 (^{31}P); 100% Me_2Se (^{77}Se)]. − IR spectra were recorded in KBr with a Biorad FTS 165 spectrometer. − UV/Vis spectra were recorded with a Perkin−Elmer Lambda 15 spectrometer using quartz cuvettes with a diameter of 1 cm. − MS: Finnigan MAT 8430 at 70 eV. − Elemental analyses of the isolated products were performed by the analytical laboratory of this Institute. − (2,2′-Bispyridyl) diselenide was prepared according to a literature procedure.[1a] All other commercial-grade chemicals were used without further purification.

Py-2-SeH (1) and PyH-2-Se (2): Na_2Se_2 was prepared according to the procedure of Klayman et al. starting from grey selenium (30 g, 0.38 mol) and $NaBH_4$ (10 g, 0.27 mol) in 500 mL of ethanol.[24] After the reaction was complete, the solvent was removed in vacuo at 50 °C. Ethylene glycol monomethyl ether (500 mL) was added to the grey-violet solid, affording a dark-red solution. To this solution was added 2-BrPy (20.1 g, 0.127 mol), and the reaction mixture was allowed to reflux for 24 h. The resulting yellow-brown solution was filtered and concentrated, and H_2O (320 mL, degassed) was added. After addition of glacial acetic acid (80 mL) with stirring, red selenium precipitated, which was removed by filtration after 1 h of stirring at ambient temperature. The yellow filtrate was concentrated at 80 °C and the resulting yellow solid was extracted with CH_2Cl_2 (500 mL) using a Soxhlet apparatus. Concentration of the yellow extract afforded pale-yellow **1** (1.7 g, 9%). Subsequent evaporation of the solvent and storage at −30 °C afforded dark-yellow **2** (12 g, 60%) as a crystalline product. Suitable crystals of **2** for an X-ray structure analysis were obtained from liquid-liquid diffusion of hexanes into a CH_2Cl_2 solution. **1:** ^{1}H NMR ([D$_6$]DMSO): δ = 6.96 (m, 1 H, *p* to CSeH), 7.43 (m, 1 H, *p* to N), 7.61 (m, 1 H, *o* to N), 7.80 (m, 1 H *o* to CSeH), 8.53 (s, br, 1 H, SeH); ref.[1a] ($CDCl_3$): δ = 6.98, 7.38, 7.71, 7.86, 8.41. − **2:** M.p.: 137 °C. − C_5H_5NSe (158.06): calcd. C 37.99, H 3.19, N 8.86; found C 38.05, H 3.16, N 8.86. − IR (CH_2Cl_2, $\tilde{\nu}$ [cm^{-1}]): 1607 (m, br), 1572 (st), 1561 (st), 1420 (st, br), 1271 (st), 1244 (st), 1107 (m), 1078 (m), 1044 (w), 893 (vs), 774 (vs, br), 685 (vs, br). − ^{1}H NMR ($CDCl_3$): δ = 6.96 (m, 1 H, *p* to C=Se), 7.38 (m, 1 H, *p* to NH), 7.73 (m, 1 H, *o* to NH), 7.85 (m, 1 H, *o* to C=Se), 13.44 (s, br, 1 H, NH, av. value of six measurements with values of δ = 12.03 to 14.07). − ^{13}C NMR ($CDCl_3$): δ = 118.6 (s, *p* to C=Se), 131.3 (s, *o* to C=Se), 137.8 (s, *p* to NH), 143.4(s, *o* to NH), 162.0 (s, *C*=Se). − ^{77}Se NMR ($CDCl_3$): δ = 314.0 s; (H_2O with C_6D_6 capillary): δ = 214.9 s. − UV/Vis (10^{-3} M in H_2O, λ_{max} [nm]): 228, 283, 357; ref.[5] (H_2O, pH = 5.7): 227, 285, 358.

[HPy-2-SeH]$^+$Cl$^-$ (3): A suspension of **1** (500 mg, 3.16 mmol) in 40 mL of THF was treated with Ph_2PCl (698 mg, 3.16 mmol) at room temperature. A clear yellow solution was formed immediately. After 3 h of stirring, a pale yellow precipitate had formed, which was filtered off and dried in vacuo (370 mg, 60%). − ^{1}H NMR ([D$_6$]DMSO): δ = 4.96 [s, 1 H, Se*H*, ^{77}Se satellites, *J*(H,Se) = 14.2 Hz], 7.39 (m, 1 H, *p* to CSeH), 7.82 (m, 2 H, *o* and *p* to NH), 8.57 (m, 1 H, *o* to CSeH), 11.93 (s, br, 1 H, N*H*).

[H$_2$Py-2-Se]$^+$I$^-$ (4): A 57% HI solution in H_2O (3 mL) was added to a suspension of **2** (500 mg, 3.16 mmol) in 20 mL of H_2O. A clear yellow solution formed immediately. Removal of H_2O in vacuo gave **4** as a pale yellow solid in quantitative yield. Compound **4** decomposes in neutral H_2O, and is sparingly soluble in $CHCl_3$ and acetone. Solutions of **4** in methanol or DMSO are dark-yellow. − C_5H_6INSe (285.97): calcd. C 21.00, H 2.11, N 4.90; found C 20.81, H 2.11, N 4.72. − ^{1}H NMR ([D$_6$]DMSO): δ = 7.30 (m, 1 H, *p* to C=Se), 7.79 (m, 2 H, *o* and *p* to NH_2), 8.43 (m, 1 H, *o* to C=Se), 8.88 (s, br, 2 H, NH_2, av. value of two measurements with values of δ = 8.64 and 9.12).

[(18-crown-6)K]$^+$[2-PySe]$^-$ (6): A solution of KB*s*Bu$_3$H (6.33 mL of a 1 M solution in THF, 6.33 mmol) was added to a solution of 2,2′-Py_2Se_2 (**5**; 1 g, 3.16 mmol) in 40 mL of THF. Gas evolution occurred and a pale yellow solid precipitated, leaving a colourless supernatant solution. After 1 h of stirring at ambient temperature, the solvent was removed in vacuo and 20 mL of ethanol and solid 18-crown-6 ether (1.67 g, 6.33 mmol) was added. After 30 min, the product was crystallized with diethyl ether at −30 °C (450 mg, 15%). − M.p.: 152 °C. − $C_{17}H_{28}KNO_6Se$ (460.47): calcd. C 44.34, H 6.13, N 3.04; found C 44.72, 3.03, 6.19. − ^{1}H NMR (CD_3OD): δ = 3.66 (s, 24 H, CH_2), 6.92 (m, 1 H, *p* to CSe), 7.26 (m, 1 H, *p* to N), 7.71 (m, 1 H, *o* to N), 8.10 (m, 1 H, *o* to CSe). − ^{13}C NMR (CD_3OD): δ = 71.3 (s, *C*H$_2$), 118.6 (s, *p* to CSe), 132.7 (s, *o* to CSe), 135.8 (s, *p* to N), 148.9 (s, *o* to N), 164.5 (s, *C*Se). − ^{77}Se NMR (CD_3OD): δ = 441.8 s. − MS (FAB): *m*/*z* (%) = 303 (100) [(18-crown-6)K]$^+$, 158 (100) [2-PySe]$^-$.

[Et$_4$N]$^+$[2-PySe]$^-$ (7): K-2-SePy was prepared in the same manner as described for **6**, starting from 25.3 mL of a 1 M KB*s*Bu$_3$H solution in THF (25.3 mmol) and **5** (4 g, 12.65 mmol) in 100 mL of THF. The pale yellow solid was dissolved in 100 mL of ethanol and Et_4NBr (5.32 g, 25.31 mmol) was added. After 15 min of stirring at ambient temperature, the solvent was removed in vacuo and the remaining solid was suspended in 200 mL of acetone. The workup procedure comprised filtration and washing of the solid for several times with 20 mL of acetone until the filtrate became colourless. The combined acetone extracts were concentrated, washed with diethyl ether and dried in vacuo, leaving a pale yellow solid of **7** (5.98 g, 82%), soluble in polar organic solvents such as CH_3CN, DMSO or alcohols. − M.p.: 108 °C. − $C_{13}H_{24}N_2Se$ (287.31): calcd. C 54.35, H 8.42, N 9.75; found C 53.28, H 8.37, N 9.52. − ^{1}H NMR ([D$_6$]DMSO): δ = 1.15 [t, 12 H, CH_3, ^{3}*J*(H,H) = 7.2 Hz], 3.21 [q, 8 H, CH_2, ^{3}*J*(H,H) = 7.2 Hz], 6.49 (m, 1 H, *p* to CSe), 6.78 (m, 1 H, *p* to N), 7.26 (m, 1 H, *o* to N), 7.84 (m, *o* to CSe). − ^{13}C NMR ([D$_6$]DMSO): δ = 7.1 (s, *C*H$_3$), 51.4 (s, *C*H$_2$), 113.7 (s, *p* to CSe), 131.8 (s, *o* to CSe), 132.6 (s, *p* to N), 147.7 (s, *o* to N), 172.7 (s, *C*Se). − ^{77}Se NMR (CD_3OD): δ = 359.6 s. − UV/Vis (10^{-3} M in H_2O, λ_{max} [nm]): 233, 277, 352.

Ph$_2$P-2-SePy (8). − Route A: To a solution of K-2-SePy, prepared from a solution of **5** (1 g, 3.16 mmol) in 40 mL of diethyl ether and 6.33 mL of a 1 M KB*s*Bu$_3$H solution in THF at −70 °C, was added Ph_2PCl (1.41 g, 6.37 mmol) dropwise via a syringe. The reaction mixture was allowed to warm to room temperature within 1 h, and was stirred for additional 2 h at 25 °C and then filtered, leaving a dark-yellow filtrate. − **Route B:** Ph_2PCl (195 mg, 0.88 mmol) was added dropwise via a syringe to a solution of **7** (254 mg, 0.88 mmol) in 20 mL of CH_3CN at 0 °C. After 2 h of additional stirring, the mixture was filtered, leaving a dark-yellow filtrate (quantitative yield, monitored by ^{31}P NMR means). **8** was completely oxidized during the workup, leading to various unidentified products, but it is stable in solution under N_2. − ^{31}P NMR (THF

solution, C_6D_6 capillary): δ = 22.40 [s, ^{77}Se satellites, J(P,Se) = 219 Hz].

***t*Bu$_2$P-2-SePy (9):** A solution of *t*Bu$_2$PBr (1.21 g, 5.35 mmol) in 60 mL of CH_3CN was added dropwise to a solution of **7** (1.54 g, 5.35 mmol in 60 mL of CH_3CN). The reaction mixture was stirred for 3 h at room temperature, to leave a colourless solution. The workup procedure comprised removal of the solvent in vacuo, addition of 10 mL of diethyl ether, filtration of Et_4NBr and removal of the diethyl ether, leaving a pale yellow oil that crystallized upon standing at −30 °C in nearly quantitative yield. Compound **9** is soluble in nearly all common organic solvents. − M.p.: 28 °C. − $C_{13}H_{22}NPSe$ (302.26): calcd. C 51.66, H 7.34, N 4.63; found C 51.74, H 7.35, N 4.44. − ^{1}H NMR ([D$_6$]acetone): δ = 1.34 [d, 18 H, CH_3, ^3J(H,P) = 12 Hz], 7.13 (m, 1 H, *p* to CSe), 7.59 (m, 1 H, *p* to N), 7.91 (m, 1 H, *o* to N), 8.36 (m, 1 H, *o* to CSe). − ^{13}C NMR ($CDCl_3$): δ = 30.3 [d, *C*H$_3$, ^2J(C,P) = 15 Hz], 34.8 [d, *C*(CH$_3$)$_3$, J(C,P) = 32.9 Hz], 120.5 (s, *p* to CSe), 126.5 [d, *o* to CSe, ^3J(C,P) = 12.9 Hz], 136.3 (s, *p* to N), 149.6 [d, *o* to N, ^4J(C,P) = 2.4 Hz], 156.8 [d, *C*Se, ^2J(C,P) = 17.5 Hz]. − ^{31}P NMR ($CDCl_3$): δ = 90.33 [s, ^{77}Se satellites, J(P,Se) = 235.5 Hz]. − ^{77}Se NMR ($CDCl_3$): δ = 271 [d, J(Se,P) = 235.1 Hz]. − MS (EI): *m*/*z* (%): 303 (2) [M]$^+$, 246 (100) [M − *t*Bu]$^+$.

***t*BuP(2-SePy)$_2$ (10) and *t*BuP(O)(2-SePy)$_2$ (11):** K-2-SePy was prepared from **5** (1.74 g, 5.51 mmol) in 40 mL of THF and 11.01 mL of a 1 M K*B*s*Bu*$_3$H solution (11.01 mmol) in THF. A solution of *t*BuPCl$_2$ (876 mg, 5.51 mmol) in 20 mL of THF was added over 30 min. The yellow reaction mixture was stirred for additional 2 h, and contained **10** and KCl as an emulsion. − ^{31}P NMR (THF, C_6D_6 capillary): δ = 101.0 [s, ^{77}Se satellites, J(P,Se) = 228.4 Hz]. − Removal of the solvent in vacuo led to an oily solid mixture, which was then suspended in 50 mL of CH_2Cl_2 and filtered through silica. The dark-yellow filtrate was reduced to 10 mL and crystallized by addition of hexanes and storage at −30 °C (1.43 g, 62%, yellow prisms). − M.p.: 85 °C. − $C_{14}H_{17}N_2OPSe_2$ (418.20): calcd. C 40.21, H 4.10, N 6.70; found C 39.83, H 4.12, N 6.59. − ^{1}H NMR ([D$_6$]acetone): δ = 1.30 [d, 9 H, CH_3, ^3J(H,P) = 21.7 Hz], 7.36 (m, 2 H, *p* to CSe), 7.73 (m, 2 H, *p* to N), 7.94 (m, 2 H, *o* to N), 8.48 (m, 2 H, *o* to CSe). − ^{13}C NMR ($CDCl_3$): δ = 25.0 [d, *C*H$_3$, ^2J(C,P) = 1.4 Hz], 46.0 [d, *C*(CH$_3$)$_3$, J(C,P) = 49 Hz], 123.2 (s, *p* to CSe), 131.6 [d, *o* to CSe, ^3J(C,P) = 1.7 Hz], 137.0 (s, *p* to N), 150.3 (s, *o* to N), 151.2 [d, *C*Se, ^2J(C,P) = 5.7 Hz]. − ^{31}P NMR ([D$_6$]acetone): δ = 72.1 [s, ^{77}Se satellites, J(P,Se) = 412.5 Hz]. − ^{77}Se NMR ($CDCl_3$): δ = 437.8 [d, J(Se,P) = 417.8 Hz]. − MS (CI): *m*/*z* (%): 376 (100) [M − *t*Bu]$^+$, 262 (2) [M − SePy]$^+$.

[({(C$_5$H$_4$N-2-Se)*t*Bu$_2$P}-*N*,*P*)Cu(μ-Br)]$_2$ (12), [({(C$_5$H$_4$N-2-Se)*t*Bu$_2$P}-*N*,*P*)Ag(μ-Br)]$_2$ (13), and [({(C$_5$H$_4$N-2-Se)*t*Bu$_2$P}-*P*)AuCl] (14): Complex **12** was prepared from CuBr (176 mg, 1.23 mmol) and **9** (371 mg, 1.23 mmol), complex **13** from AgBr (391 mg, 2.08 mmol) and **9** (629 mg, 2.08 mmol), and complex **14** from thtAuCl (774 mg, 2.41 mmol) (tht = tetrahydrothiophene) and **9** (730 mg, 2.41 mmol), by addition of a solution of the metal halide to a solution of **9** (in the case of **12**), or addition of a solution of **9** to a solution of the metal halide (in the case of **13**, **14**) in CH_3CN (60 mL), and stirring for 3 h at room temperature under exclusion of light. The solvent was removed in vacuo, and crystallisation from a CH_2Cl_2 solution by layering with hexanes afforded colourless (**13**) to pale-yellow (**12**, **14**) solids. Single crystals suitable for an X-ray analysis were obtained directly from the reaction mixture in all cases.

12: Nearly quantitative yield, M.p.: 233 °C. − $C_{26}H_{44}Br_2Cu_2N_2P_2Se_2$ (891.42): calcd. C 35.03, H 4.98, N 3.03; found C 35.09, H 4.98, N 3.03. − ^{1}H NMR ($CDCl_3$): δ = 1.45 [d, 36 H, CH_3, ^3J(H,P) = 15.4 Hz], 7.20 (m, 2 H, *p* to CSe), 7.52 (m, 4 H, *o* and *p* to N), 8.87 (m, 2 H, *o* to CSe). − ^{13}C NMR (CD_2Cl_2): δ = 30.4 [d, *C*H$_3$, ^2J(C,P) = 9.8 Hz], 37.0 [d, *C*(CH$_3$)$_3$, J(C,P) = 4.5 Hz], 122.3 [d, *p* to CSe, ^5J(C,P) = 1.9 Hz], 126.2 (s, *o* to CSe), 137.6 [d, *p* to N, ^4J(C,P) = 1.5 Hz], 151.1 [d, *o* to N, ^4J(C,P) = 2.5 Hz], 155.4 [d, *C*Se, ^2J(C,P) = 6.5 Hz]. − ^{31}P NMR ($CDCl_3$): δ = 72.4 (s, br). − ^{77}Se NMR (CD_2Cl_2): δ = 520.4 [d, J(Se,P) = 240 Hz]. − MS (EI): *m*/*z* (%) {monomer = [M]$^+$}: 445 (31) [M]$^+$, 246 (100) [2-SePyP*t*Bu]$^+$.

13: 882 mg, 87%, M.p.: 189 °C. − $C_{26}H_{44}Ag_2Br_2N_2P_2Se_2$ (980.07): calcd. C 31.86, H 4.53, N 2.86; found C 31.87, H 4.52, N 2.84. − ^{1}H NMR ($CDCl_3$): δ = 1.43 [d, 36 H, CH_3, ^3J(H,P) = 15.8 Hz], 7.16 (m, 2 H, *p* to CSe), 7.47 (m, 4 H, *o* and *p* to N), 8.77 (m, 2 H, *o* to CSe). − ^{13}C NMR (CD_2Cl_2): δ = 30.4 [d, *C*H$_3$, ^2J(C,P) = 11 Hz], 37.2 [d, *C*(CH$_3$)$_3$, J(C,P) = 8.8 Hz], 122.4 [d, *p* to CSe, ^5J(C,P) = 1.5 Hz], 127.1 (s, *o* to CSe), 137.6 [d, *p* to N, ^4J(C,P) = 1.4 Hz], 151.7 (s, *o* to N), 152.0 [d, *C*Se, ^2J(C,P) = 2.6 Hz]. − ^{31}P NMR ($CDCl_3$): δ = 84.7 (s, br). − ^{77}Se NMR (CD_2Cl_2): δ = 470.2 [d, J(Se,P) = 273.8 Hz]. − MS (EI): *m*/*z* (%): 246 (100) [2-SePyP*t*Bu]$^+$.

14: 1.16 g, 90%, M.p.: > 126 °C (dec.). − $C_{13}H_{22}AuClNPSe$ (534.68): calcd. C 29.20, H 4.15, N 2.62; found C 29.00, H 4.19, N 2.48. − ^{1}H NMR (CD_2Cl_2): δ = 1.49 (d, 18 H, CH_3, ^3J(H,P) = 17.2 Hz), 7.30 (m, 1 H, *p* to CSe), 7.60 (m, 1 H, *p* to N), 7.75 (m, 1 H, *o* to N), 8.50 (m, 1 H, *o* to CSe). − ^{13}C NMR (CD_2Cl_2): δ = 30.0 [d, *C*H$_3$, ^2J(C,P) = 6.5 Hz], 40.1 [d, *C*(CH$_3$)$_3$, J(C,P) = 14 Hz], 123.8 (s, *o* to N), 131.4 [d, *o* to CSe, ^3J(C,P) = 2.2 Hz], 137.8 (s, *p* to N), 151.0 (s, *o* to N), 151.8 (s, CSe). − ^{31}P NMR (CD_2Cl_2): δ = 117.3 [s, ^{77}Se satellites, J(P,Se) = 319.8 Hz]. − ^{77}Se NMR (CD_2Cl_2): δ = 501.0 [d, J(Se,P) = 322.3 Hz]. − MS (EI): *m*/*z* (%): 535 (31) [M]$^+$, 246 (100) [2-SePyP*t*Bu]$^+$.

[({(C$_5$H$_4$N-2-Se)$_2$*t*BuP}-*N*,*N*′,*P*)Mo(CO)$_3$] (15): The yellow reaction mixture of **10** (5.1 mmol) was concentrated to dryness, and the remaining solid was suspended in 40 mL of toluene. A solution of [(η^6-C$_7$H$_8$)Mo(CO)$_3$] (1.38 g, 5.1 mmol) in 50 mL of toluene was added dropwise at room temperature under exclusion of light to the reaction mixture. After 12 h of stirring at room temperature, the solvent was removed in vacuo. The workup procedure comprised addition of 60 mL of CH_2Cl_2, filtration through silica, and column chromatography on silica (40 × 3 cm; eluent: CH_2Cl_2/hexanes, 75:25). After four fractions (yellow, orange, brown, red) that contained traces of unidentified by-products, the deep-red main fraction of **15** eluted. Crystals of the CH_2Cl_2 hemisolvate were obtained by layering a CH_2Cl_2 solution (20 mL) with hexanes (150 mL) at room temperature. − Yield: 1.15 g, 34%, M.p.: > 125 °C (dec.). − $C_{17.5}H_{18}ClMoN_2O_3PSe_2$ (624.63): calcd. C 33.65, H 2.90, N 4.48; found C 33.56, H 2.89, 4.39. − IR (CH_2Cl_2, ṽ [cm^{-1}]): 1931 vs, 1838 st, br, 1815 st, br (Mo−*CO*). − ^{1}H NMR ([D$_6$]acetone): δ = 1.67 [d, 9 H, CH_3, ^3J(H,P) = 17.7 Hz], 5.62 (s, 1 H, CH_2Cl_2), 7.18 (m, 2 H, *p* to CSe), 7.61 (m, 2 H, *p* to N), 7.75 (m, 2 H, *o* to N), 9.49 (m, 2 H, *o* to CSe). − ^{13}C NMR ([D$_6$]acetone): δ = 28.6 [d, *C*H$_3$, ^3J(C,P) = 6.2 Hz], 41.5 [d, *C*(CH$_3$)$_3$, J(C,P) = 10.9 Hz], 54.9 (s, *C*H$_2$Cl$_2$), 122.8 (s, *p* to CSe), 127.6 [d, *o* to CSe, ^3J(C,P) = 2.7 Hz], 138.0 (s, *p* to N), 154.4 [d, *o* to N, ^4J(C,P) = 5.6 Hz], 163.3 [d, *C*Se, ^2J(C,P) = 10.8 Hz], 222.8, 227.2, 227.3 (s, Mo*C*O). − ^{31}P NMR ([D$_6$]acetone): δ = 155.9 [s, ^{77}Se satellites, J(P,Se) = 257.1 Hz]. − ^{77}Se NMR ([D$_6$]acetone): δ = 761.1 [d, J(Se,P) = 258.8 Hz]. − MS (EI): *m*/*z* (%): 582 (1) [M]$^+$, 246 (32) [PySeP*t*Bu]$^+$, 57 (100) [*t*Bu]$^+$.

Crystal Structure Analyses: The crystal structures for **2**, **6**, **11**, **12**, **13**, **14**, and **15** were performed with a Siemens P4 diffractometer

(graphite-monochromated Mo-K_α radiation, λ = 71.073 pm) at −100 °C in the ω-scan mode (Table 1 and Table 2). Cell parameters were refined from setting angles at 2Θ = 20−24°. Absorption corrections based on Ψ-scans were applied. The structures were solved by direct methods using SHELXS-86/97,[25] and subjected to full-matrix least-squares refinement on F^2 using SHELXL-93/97,[26] with anisotropic displacement parameters for non-H atoms. Correct positions for nitrogen and carbon atoms in the crystal structure of **2** were established from the refinement of alternative positions and subsequent comparison of the R values and the final electron density ($wR2$: 0.1585 vs. 0.1703, ρ_{max} 1.28·10^{-6} e pm^{-3}). Methyl groups were treated as rigid groups and N-bonded hydrogen atoms were refined freely. All other hydrogen atoms were included using a riding model. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-150945 (**2**), -150946 (**6**), -150947 (**11**), -150948 (**12**), -150949 (**13**), -150950 (**14**), and -150951 (**15**). Copies

of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the Fonds der Chemischen Industrie and the Braunschweigischer Hochschulbund for financial support and Prof. Peter G. Jones for helpful discussions. Diffractometer maintenance by Andreas Weinkauf is gratefully acknowledged.

Bi-Layer Complexes Incorporating Large Organic Cations and Anionic Tetra-*p*-Sulfonated Calix[4]arene Capsules

Timothy Ness,[b] Peter J. Nichols,[b] and Colin L. Raston*[a]

Keywords: Supramolecular chemistry / Calixarenes / Crown compounds / Macrocycles

H_4TMTAA^{2+}/18-crown-6, H_4TMTAA^{2+}/2-hydroxybenzimidazole and $cyclamH_4^{4+}$ self-assemble with sodium tetra-*p*-sulfonated calix[4]arene to form capsules within overall bilayer structures. $[H_4TMTAA^{2+}]_2$[*trans*-{$Na^+\subset$(18-crown-6)$(H_2O)_2$}$\subset$ {(*p*-O_3S-calix[4]arene)$_2$} + $3H^+$]·$17H_2O$ crystallises in the triclinic space group $P\bar{1}$ and contains the "Russian Doll" assembled superanion capsule, {$Na^+\subset$(18-crown-6)$(OH_2)_2$}$\subset${(*p*-O_3S-calix[4]arene)$_2$}$^{7-}$. $[H_4TMTAA^{2+}]_2[(C_7N_2OH_7^+)_2\subset$ {(*p*-O_3S-calix[4]arene)$_2$} + $2H^+$]·$17H_2O$ also crystallises in the triclinic space group $P\bar{1}$ and also contains a superanion capsule with two 2-hydroxybenzimidazolium cations as the capsule core. [$cyclamH_4^{4+}$][{$cyclamH_4^{4+}\subset$ {(*p*-O_3S-calix[4]-arene)$_2$}]·$18H_2O$ crystallises in the space group $P2_1/n$ and is an example of a slipped capsule, with the slight "mismatch" allowing stronger internal capsule H-bonding. The cations influence the spacing between the bilayers and can span the calixarene layers.

Introduction

Capsules based on two *p*-sulfonatocalix[n]arenes shrouding other molecules including 18-crown-6[1−4] and protonated cylam[5] (n = 4) and H_2SO_4 (n = 5),[6] have recently been established. In the solid state these capsules (n = 4) have host-guest hydrophobic complementarity and hydrogen bonding mediated by a variety of inorganic cationic species including lanthanide cations,[7] aluminium(III)/Keggin ions,[3] chromium(III)[1,4] and rhodium(III)[3] polynuclear oxo/hydroxo cations. Some of these complexes take on a bi-layer structure with an adjacent calix[4]arene from different capsules, with alternating H-bonding and π-stacking in opposite directions, as shown in cartoon form for *trans*-{$Na^+\subset$(18-crown-6)$(H_2O)_2$} in Figure 1.[1,8a−8g] Other examples of the bilayer structures represent "slipped" capsules (a misalignment of the calixarenes), which in some cases allows one sulfonate group to be in or over the cavity of the other calixarene, and vice versa, through to a complete mismatch of the calixarenes in opposing layers. Generally the inorganic ions stabilise the capsule by H-bonding and reside in the hydrophilic layers in the complexes. The 18-crown-6-containing capsules held together by the dimeric and trimeric oxo-chromium cations are located in a considerably distorted bilayer arrangement.[2] The Keggin ion complexes completely disrupt the bilayer structure with the presence of two types of calixarenes.[4] The large cation, La^{3+}, also completely disrupts the bi-layer structure.[7] Herein we report the use of large organic cations, H_4TMTAA^{2+} (TMTAAH$_2$ = 5,7,12,14-tetramethyldibenzo[*b,i*][1,4,8,11]tetraazacyclotetradecane) and $cyclamH_4^{4+}$, tetra-protonated 1,4,8,11-tetraazacyclotetradecane, to assembly a variety of capsules based on the assembly of two tetra-*p*-sulfonatocalix[4]arenes.

Results and Discussion

The synthesis of the new capsule-type complexes (Figure 2) is summarised in Scheme 1. For compounds $[H_4TMTAA^{2+}]_2[trans\text{-}\{Na^+\subset(18\text{-crown-}6)(H_2O)_2\}\subset\{(p\text{-}O_3S\text{-calix[4]arene})_2\} + 3H^+]\cdot 17H_2O$ (**1**) and $[H_4TMTAA^{2+}]_2[(C_7N_2OH_7^+)_2\subset\{(p\text{-}O_3S\text{-calix[4]arene})_2\} + 2H^+]\cdot 17H_2O$ (**2**), the products are also contaminated with 2,4-dimethyl-1,5-benzodiazepinium chloride due to acid decomposition of H_4TMTAA^{2+}. Compound **1** crystallises in the triclinic space group $P\bar{1}$ and contains the "Russian Doll"-assembled superanion capsule $\{Na^+\subset(18\text{-crown-}6)(OH_2)_2\}\subset\{(p\text{-}O_3S\text{-calix[4]arene})_2\}^{7-}$. The capsule has internal H-bonding (axially bound water molecules; sulfonate to water O···O distance: 2.78 Å) and external H-bonding through H_4TMTAA^{2+} interactions (sulfonate to imine O···N distance: 2.77 Å) as well as H-bonding through waters of crystallisation (O···O distance: 2.82 Å).

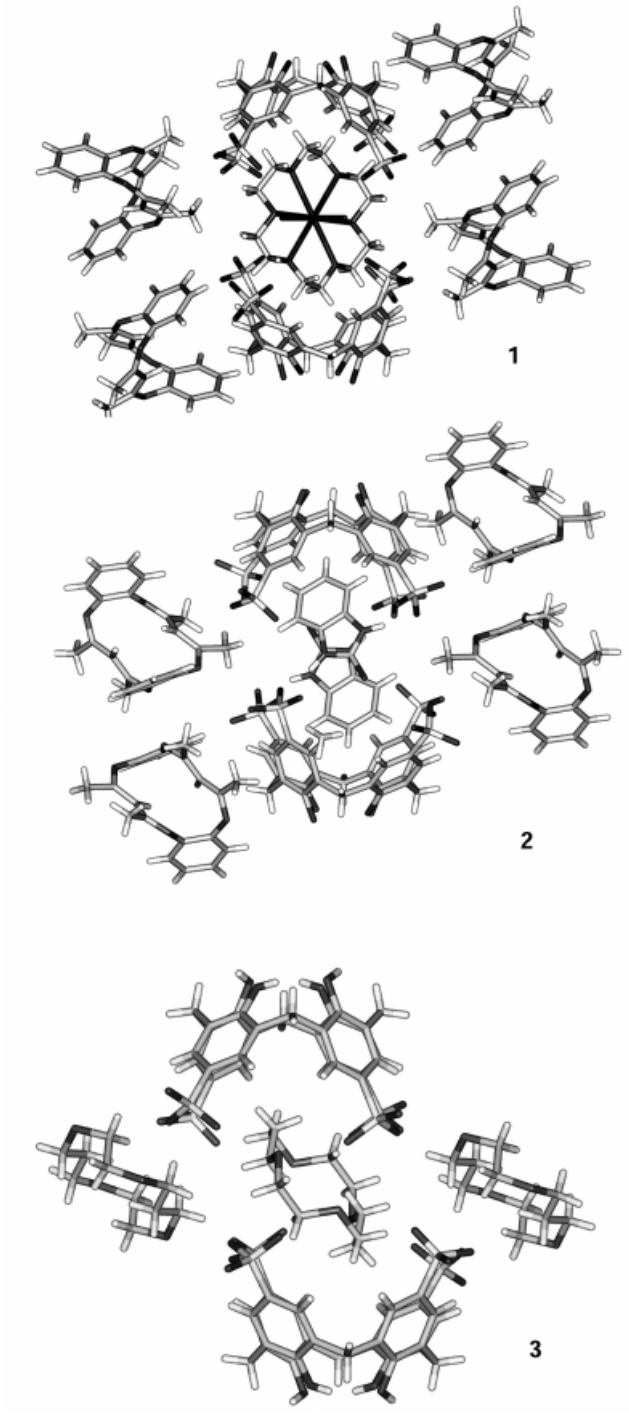

Figure 2. Comparison of the structures of compounds **1**–**3**

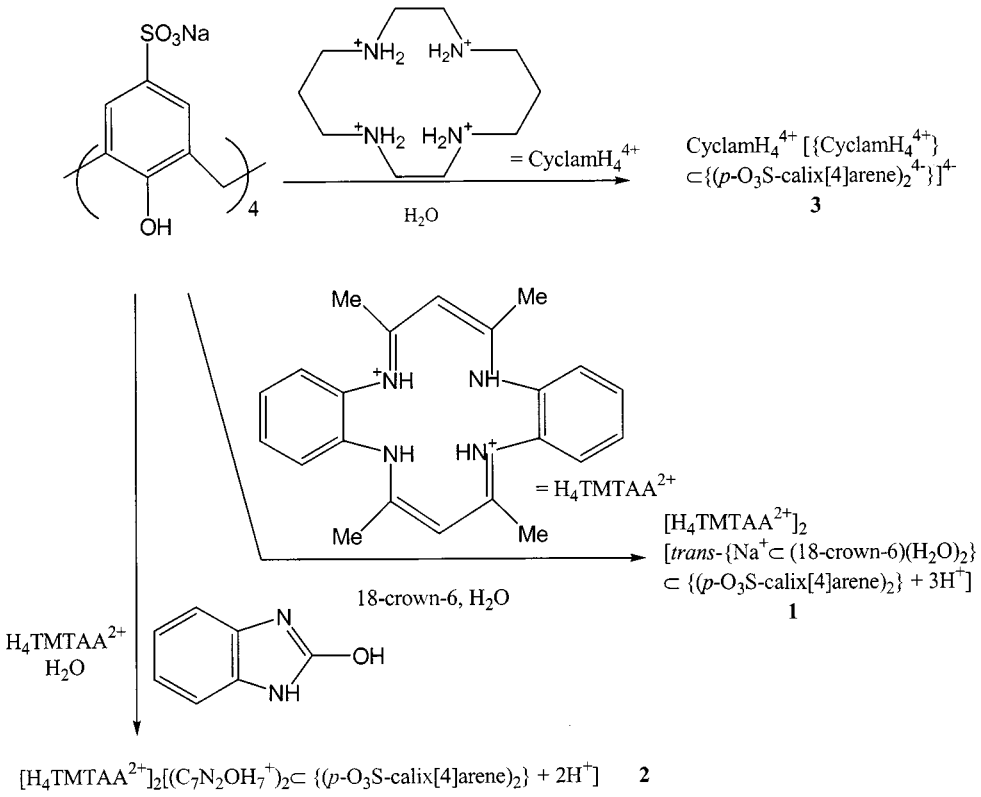
Remarkably a bilayer structure is formed in the presence of the large organic cation H_4TMTAA^{2+}, which has similar dimensions to p-O_3S-calix[4]arene and essentially substitutes alternate calix[4]arenes in the usual bilayer found in p-O_3S-calix[4]arene^{4-} complexes that consist of columns of "up"/"down" calix[4]arenes.[8a–8g] Within each column an "up" calix[4]arene is in close proximity to two other "down" calix[4]arenes with each interacting through aromatic ring π-stacking and two sulfonate-to-hydroxy H-bonds associated with the stacked rings. Four other calix[4]arene molecules in the two adjacent columns are then associated through sulfonate-to-sulfonate H-bonds possibly mediated by water. In the present structure, H_4TMTAA^{2+} cations are interspersed between columns of "up"/"down" calix[4]arenes. Within each calix[4]arene column an "up" calix[4]arene is in close proximity to two other "down" calix[4]arenes with each interacting through aromatic ring π-stacking (offset, coplanar with shortest C···C contacts of 3.40 Å) and two sulfonate-to-hydroxy H bonds (O···O distance: 3.02 Å) associated with the stacked rings. The H_4TMTAA^{2+} cations interact with calix[4]arenes through a non-classical H bond (a methyl hydrogen pointing to the centre of the calix[4]arene aromatic ring; methyl carbon to ring carbons: C···C distances = 3.54–3.62 Å, with a C···ring centroid distance of 3.31 Å) and the imine hydrogen to sulfonate H bond described above. Two other H_4TMTAA^{2+} cations pack close to each calix[4]arene with no obvious interactions: the phenyl- or methyl-lined concave surfaces are seemingly two steep to accommodate the concave-convex supramolecular interaction seen in many Ni(TMTAA) complexes.[9a–9e] Water also permeates the H_4TMTAA^{2+} and calix[4]arene layer, with H-bonding to both calix[4]arenes and H_4TMTAA^{2+} cations.

The hydrophilic layer consists of the di-aqua sodium/18-crown-6 complex and water of crystallisation, with the 18-crown-6 complex within the capsule thus spanning the layers. H_4TMTAA^{2+} cations form "up"/"down" columns perpendicular to the calix[4]arene columns and interacting across the layers through aromatic ring π-stacking. Within the calix[4]arene layer there are offset, coplanar aromatic rings with shortest C···C distances of 3.42 Å. Within the hydrophilic layer there are offset, coplanar aromatic rings with shortest C···C distances of 3.31 Å. The calix[4]arene separation across the capsules (or layers) is characterised by pairs of sulfonate groups with a shortest O···O distance of 4.27 Å.

Compound **2** also crystallises in the triclinic space group $P\bar{1}$ and also contains a superanion, $\{(C_7N_2OH_7^+)_2\subset\{(p\text{-}O_3S\text{-calix[4]arene})_2\}^{6-}$. The capsule also has internal H-bonding (2-hydroxybenzimidazol-N and -O to sulfonate



Scheme 1

oxygen interactions: N···O = 2.75, 2.81 Å; O···O = 3.36, 3.44 Å) and external H-bonding through waters of crystallisation (distances 2.61 Å). H-bonding for H_4TMTAA^{2+} to calix[4]arene in this complex is weaker than in compound **1** (sulfonate to imine: O···N distance = 3.10 Å). The guest molecules form an aromatic ring π-stacked dimer (coplanar; closest contacts: O···C = 3.42 Å; C···N = 3.41 Å; C···C = 3.37 Å) with the monomers *anti* to each other.

The calix[4]arene layer again consists of H_4TMTAA^{2+} interspersed between columns of calix[4]arenes. The "up"/"down" calix[4]arene columns exhibiting the usual sulfonated phenol π-stacking/H-bonding interactions (coplanar rings: C···C distances = 3.61−3.64 Å; sulfonate oxygen to phenolic oxygen distance: 3.22 Å). Across the columns the calix[4]arenes interact with H_4TMTAA^{2+} through "non-classical" H-bonding interactions (C···ring centroid = 3.46 Å). Columns of H_4TMTAA^{2+} cations, perpendicular to the calix[4]arene columns, again transverse the calix[4]arene layer. The H_4TMTAA^{2+} columns therefore span the bilayer by aromatic ring π-stacking (well aligned; coplanar aromatic rings with C···C distances of 3.40−3.58 Å and 3.55−3.62 Å for the stacking in and out of the hydrophilic layer, respectively). The calix[4]arene separation across the capsules (or layers) is characterised by sulfur-to-sulfur distances of 5.42 and 6.70 Å (closest O···O contact: 4.00 Å).

$[cyclamH_4^{4+}][\{cyclamH_4^{4+}\}\subset\{(p\text{-}O_3S\text{-calix[4]arene})_2\}]\cdot 18H_2O$ (**3**) crystallises in the space group $P2_1/n$ and is an example of a slipped capsule, with the slight "mismatch" allowing stronger internal H-bonding interactions. A similar capsule has been observed in $[Cr_2(OH)_2(H_2O)_8][\{cyclamH_4^{4+}\}\subset\{(p\text{-}O_3S\text{-calix[4]arene})_2\}]$.[4] The capsule in compound **3** is characterised by internal H bond interactions (N···O distances: 2.73, 2.78 and 2.90 Å) with the shortest O···O calix[4]arene separations at 5.21 Å. The capsule also features external H-bonding through the *exo*-$cyclamH_4^{4+}$ interactions (N···O distance: 2.79 Å) as well as H-bonding through waters of crystallisation (shortest O···O distance: 2.58 Å).

The overall structure is characterised by the bilayer arrangement with the cyclam cations located in the hydrophilic layer. Each calix[4]arene molecule is in close proximity to two other calix[4]arenes through sulfonated phenol π-stacking/H-bonding interactions (coplanar rings; C···C distances: 3.67−3.79 Å; sulfonate oxygen to phenolic oxygen distance: 3.16 Å). Four other calix[4]arene molecules in the two adjacent columns are associated through sulfonate-to-sulfonate O···H bonds, some mediated by water. The cyclam cations are well separated (shortest C···C distance: 4.03Å) but are H-bonded to water molecules in the hydrophilic layer.

Conclusion

The sulfonated phenol π-stacking/H-bonding interaction in tetra-*p*-sulfonatocalix[4]arene complexes leading to columns of alternating "up"/"down" calix[4]arenes dominates in the overall assembly of calix[4]arene complexes. As seen

in the results presented in this study, the presence of charge-balancing cations *exo* and *endo* to the calix[4]arenes can influence the overall structures in two major ways: they can determine the calix[4]arene layer separation and they can act to separate columns of calix[4]arenes within the calix[4]arene layer. The alignment of calix[4]arene columns to allow capsule formation and the subsequent efficient internal and external H-bonding leads to more tightly bound structures. The encapsulation of guest molecules within the superanions offers the possibility of arranging molecules to permit subsequent stereospecific reaction, and, in view of the dimer observed in the 2-hydroxybenzimidazole capsule, offers the possibility to study π-stacking in amino acid pairs. The H_4TMTAA^{2+} complexes contain columns of the cations running transverse to the columns of the calix[4]-arene anions and thus spanning the calix[4]arene layers, which is of current interest with respect to understanding transport across bilayer structures.[8b]

Experimental Section

Synthesis of $[H_4TMTAA^{2+}]_2[$*trans*-{$Na^+\subset$(18-crown-6)-$(H_2O)_2$}$\subset${(*p*-O_3S-calix[4]arene)$_2$} $+3H^+]\cdot 17H_2O$ (1): Equimolar amounts of $TMTAAH_2$, 18-crown-6 and tetrasodium tetra-*p*-sulfonatocalix[4]arene (0.038 mmol) were mixed in a 50/50 mix of water and ethanol (overall 20 mL) to which 4 mL of 1 M HCl had been added. The solution soon changed from colourless to orange. On slow evaporation crystalline material deposited, the bulk of which (ca. 48 mg; 90%) consisted of clear, colourless crystals of $[H_4TMTAA^{2+}]_2[$*trans*-{$Na^+\subset$(18-crown-6)$(H_2O)_2$}$\subset${(*p*-O_3S-calix[4]arene)$_2$} + $3H^+]\cdot 17H_2O$ (**1**). Purple/yellow dichroic crystals of 2,4-dimethyl-1,5-benzodiazepinium chloride were also present. The colour change on mixing and subsequent isolation of the 2,4-dimethyl-1,5-benzodiazepinium chloride are a result of the aqueous-acid instability of $TMTAAH_2$. The presence of multiple products in these reactions as well as the general rapid loss of water from the complex hydrates meant that good microanalyses could not be obtained.

Synthesis of $[H_4TMTAA^{2+}]_2[(C_7N_2OH_7^+)_2\subset${(*p*-$O_3$S-calix-[4]arene)$_2$} + $2H^+]\cdot 17H_2O$ (2): Reaction of equimolar amounts of $TMTAAH_2$, tetrasodium tetra-*p*-sulfonatocalix[4]arene and 2-hydroxybenzimidazole (0.038 mmol) in acidic aqueous acid solution resulted in a coloured solution which, on evaporation of the solvents, gave $[H_4TMTAA^{2+}]_2[(C_7N_2OH_7^+)_2\subset${(*p*-$O_3$S-calix[4]arene)$_2$} + $2H^+]\cdot 17H_2O$ (**2**; ca. 38 mg; 72%) and 2,4-dimethyl-1,5-benzodiazepinium chloride. The presence of multiple products in these reactions as well as the rapid loss of water from the complex hydrates meant that good microanalyses could not be obtained.

Synthesis of $[cyclamH_4^{4+}][\{cyclamH_4^{4+}\}\subset\{$(*p*-$O_3$S-calix-[4]arene)$_2\}]\cdot 18H_2O$ (3): Reaction of cyclam (6.3 mg, 0.031 mmol), tetrasodium tetra-*p*-O_3S-calix[4]arene (6.3 mg, 0.076 mmol) and $Fe(NO_3)_3\cdot 9H_2O$ (7.0 mg, 0.17 mmol) in aqueous solution, with the pH adjusted to 0.99 using $HClO_4$, followed by slow evaporation of the yellow solution gave pale yellow crystals of $[cyclamH_4^{4+}][\{cyclamH_4^{4+}\}\subset\{$(*p*-$O_3$S-calix[4]arene)$_2\}]\cdot 18H_2O$, (ca. 20 mg; 60%). Due to loss of solvent from the crystals, satisfactory results from microanalysis were unobtainable.

X-ray Crystallographic Study: Crystals were mounted onto glass capillaries under oil. X-ray data were collected at 123(1) K on an Enraf−Nonius KappaCCD single crystal diffractometer with Mo-K_α radiation (λ = 0.71073 Å). Data was corrected for Lorentzian and polarisation effects, but not absorption. The non-hydrogen atoms (except oxygen atoms in waters of crystallisation) were refined anisotropically and hydrogen atoms were included at geometrically estimated positions but not refined.

1: Colourless, prismatic crystal of dimensions 0.20 × 0.20 × 0.15 mm. The structure was solved using direct methods (teXsan[10]) and refined by full-matrix least-squares on F (teXsan[10]): $C_{112}H_{157}N_8Na_1O_{57}S_8$, M_r = 2806.96 g mol^{-1}, triclinic, $P\bar{1}$ (no. 2), a = 14.3711(5), b = 17.3467(6), c = 17.5191(4) Å, α = 115.261(1)°, β = 95.759(2)°, γ = 112.623(1)°, V = 3498.0(0.2) Å^3, ρ_{calc} = 1.36 gdm^{-3}, μ = 2.24 cm^{-1} (no correction), Z = 1, 50839 reflections (17557 unique), $2\theta_{max}$ = 60.2° [9102 observed, $I > 2\sigma(I)$, R = 0.148, Rw = 0.155].

2: Clear, orange, prismatic crystal of dimensions 0.25 × 0.20 × 0.15 mm. The structure was solved using direct methods (teXsan[10]) and refined by full-matrix least-squares on F (teXsan[10]): $C_{57}H_{78}N_6O_{25.5}S_4$, M_r = 1383.51 g mol^{-1}, triclinic, $P\bar{1}$ (no. 2), a = 14.6516(5), b = 15.8265(6), c = 16.3448(4) Å, α = 108.430(2)°, β = 105.402(2)°, γ = 108.984(1)°, V = 2929.9(0.1) Å^3, ρ_{calc} = 1.475 gdm^{-3}, μ = 2.44 cm^{-1} (no correction), Z = 2, 45397 reflections (15658 unique), $2\theta_{max}$ = 60.0° [8516 observed, $I > 2\sigma(I)$, R = 0.090, Rw = 0.070].

3: Prismatic crystal of dimensions 0.5 × 0.3 × 0.2 mm. The structure was solved using direct methods (XSEED/SHELXL-97[10]) and refined by full-matrix least-squares on F^2 (XSEED/SHELXL-97[10]): $C_{76}H_{80}N_8O_{50}S_8$, M_r = 2161.96 g mol^{-1}, monoclinic, $P2_1/n$ (No. 14), a = 10.841(2), b = 28.092(6), c = 15.740(3) Å, β = 96.29(3)°, V = 4764.6(1.6) Å^3, ρ_{calc} = 1.507 gdm^{-3}, μ = 2.92 cm^{-1} (no correction), Z = 2, 29563 reflections (11988 unique), $2\theta_{max}$ = 52° [8088 observed, $I > 2\sigma(I)$, R = 0.060, Rw = 0.127].

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149551 (**1**), CCDC-149552 (**2**), and CCDC-149553 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

(*E,E,E*)-1,6,11-Tris(arenesulfonyl)-1,6,11-triazacyclopentadeca-3,8,13-trienes (**1**) form very stable complexes with Pd^0 and Pt^0, and moderately stable complexes with Ag^I. The three olefins in the macrocycle are responsible for the complexation. The X-ray structures of two complexes of Pd^0 and Pt^0 are presented; both complexes are planar trigonal.

Introduction

Nitrogen-containing 15-membered macrocycles are commonplace.[1,2] However, nitrogen-containing 15-membered macrocycles featuring internal olefinic double bonds are exceptional. The few known examples contain only one double bond, and metathesis is the key step for their preparation.[3] In 1998 we described the serendipitous formation of (*E,E,E*)-1,6,11-tris(arenesulfonyl)-1,6,11-triazacyclopentadeca-3,8,13-trienes (**1**) and the complex **2b-Pd^0** (Scheme 1) by nonselective palladium(0)-catalyzed Tsuji−Trost allylation of arenesulfonamides with *cis*-2-butene-1,4-diol dicarbonate.[4] The macrocycle **1b** affords the complex **2b-Pd^0** by treatment with sources of Pd^0. This complex is very stable, catalyses certain Suzuki-type cross-coupling reactions, and is easily recovered after catalysis.[5] Later we published the optimized preparations of macrocycles **1** featuring a vast array of substituents at the arenesulfonyl moieties.[6]

The complexes $Pd_2(dba)_3$-solvent and $Pd_2(dba)_4$ [7] are very well-known and their catalytic effect has been recognized. Many other complexes of olefins with palladium(0) and platinum(0) have been described.[8−10] However, only a few complexes of transition metals with triolefinic macrocycles are known. Thus, the diverse configurational isomers of the 12-membered carbocycle cyclododeca-1,5,9-triene have a rich coordination chemistry, and their Ni^0 complexes have played a fundamental role in catalysis and in organonickel chemistry.[11] X-ray diffraction data of the (*E,E,*E) isomer show that the complex is planar trigonal.[11b] Other metals form complexes with cyclododecatrienes: Cu^I,[12] Pd^{II},[13] Ag^I,[14] Rh^{III},[15] and Ru^{II}.[16] Related 12-membered carbocycles also form nickel(0) complexes.[17] At the upper limit of ring size, 13-membered (*Z,E,Z*)-cyclotrideca-1,5,9-triene forms a complex with Ag^I.[18] A special case is the complexation of Ag^I by [2.2.2]paracyclophanes, which occurs in an η^2 manner at each of the three benzene rings.[19] The related [2_6](1,2,4,5)cyclophane (deltaphane) presents the same behavior.[19b] In contrast, (*Z,Z,Z*)-tribenz[12]annulene, the triunsaturated analogue of [2.2.2]orthocyclophane coordinates Ag^I through the three olefins.[20] Metal complexes of macrocyclic triolefins higher than 13-membered are unknown.

Spurred on by these findings we decided to study the complexing ability of macrocycles **1** towards transition metals.

Results and Discussion

Complexes **2** were very easily prepared by the reaction of macrocycles **1** with familiar sources of the corresponding metals. Both tetrakis(triphenylphosphane)palladium(0) and $Pd(dba)_2$ gave excellent results as Pd sources, whereas only tetrakis(triphenylphosphane)platinum(0) was tested for platinum (Scheme 1). Silver tetrafluoroborate was used for the formation of the silver complexes. These complexes are much less stable than those of Pd^0 and Pt^0. Strong evidence for the structures was secured by X-ray diffraction for **2a-Pd^0** (Figure 1 and 2) and **2a-Pt^0** (Figure 3 and 4) and in all cases by MALDI-TOF mass spectrometry.

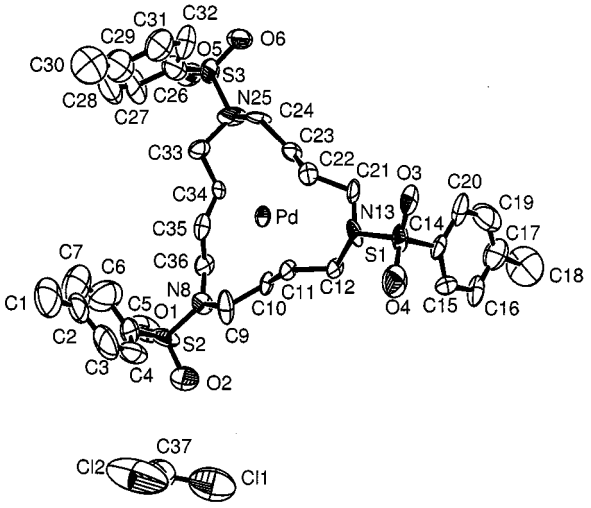

Figure 1. Perspective view of the **2a-Pd^0** molecule with the crystallographic atom numbering; atoms are represented as their thermal vibration ellipsoids (50% probability)

Complexes **2a-Pd^0** and **2a-Pt^0** are planar trigonal, with the distances from the metal atoms to the plane defined by the central points of the three olefin bonds being 0.018 and 0.015 Å, respectively. The complexes crystallize with one molecule of dichloromethane. They are not symmetrical, and in particular they lack a C_3 axis of symmetry. Two C=C bonds are longer than in the corresponding free ligand **1a**[6] (see Table 1). However, the third C=C bond is shorter than the other two in both complexes, and is close to the distance in the free ligand. These facts suggest that complexation by one olefin is weaker than complexation by the other two, a feature that is also evident in solution from NMR spectroscopic data.

The ^{13}C NMR spectrum of **2a-Pd^0** shows three signals of about the same intensity for three different types of CH_2 groups at δ = 45.1, 48.2, and 49.5 (Table 2). Also, three different signals appear, again of similar intensities, for three different types of olefinic CH groups, at δ = 78.5, 78.7, and 82.8. Moreover, the signals of the aromatic pro-

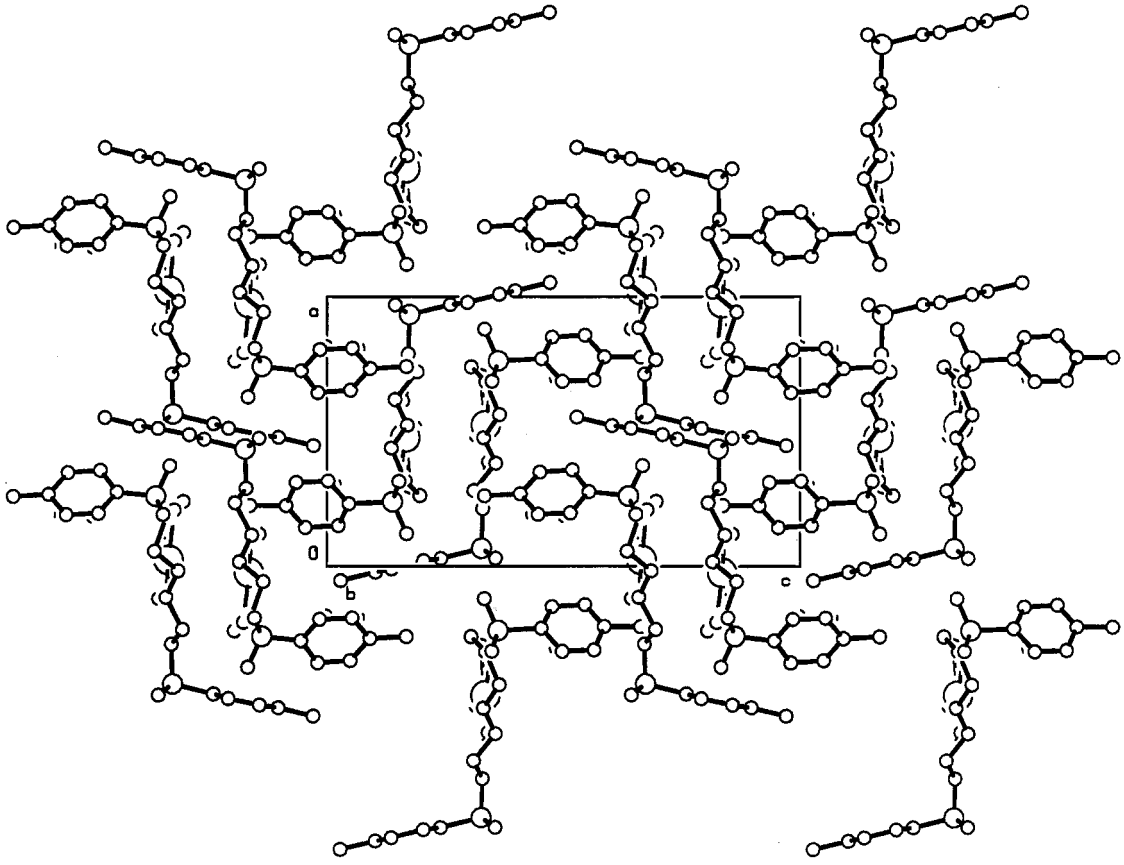

Figure 2. Perspective view of the unit cell of **2a-Pd^0**

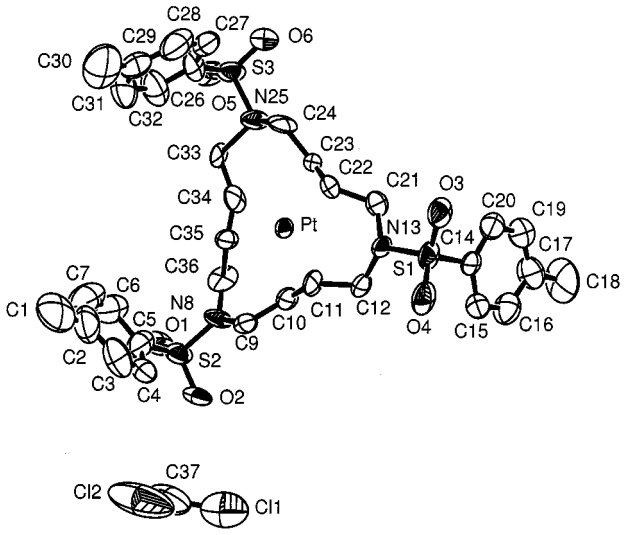

Figure 3. Perspective view of the **2a-Pt^0** molecule with the crystallographic atom numbering; atoms are represented as their thermal vibration ellipsoids (50% probability)

tons appear in two sets, one set of signals being about twice the intensity of the other, confirming that two olefins behave the same both in the ^{1}H NMR and ^{13}C NMR spectra and the third behaves differently. This is a general behavior for complexes **2-Pd^0** and **2-Pt^0**, and can only be compatible with an averaged plane of symmetry rather than with a C_3 symmetry axis. The ^{1}H NMR spectra were further complicated by the fact that the protons pertaining to the same methylene group are not averaged, due to conformational rigidity. These methylenic protons are in different environments and therefore they give signals at very different chemical shifts. Selective 1D TOCSY experiments performed on complexes **2a-Pd^0**, **2a-Pt^0**, and **2b-Pd^0** permitted the determination of the chemical shifts and coupling constants indicated in Table 2. Thus, the pairs of positions C2−C15, C3−C14, C4−C13, and C5−C12 are connected by an averaged plane of symmetry, as are the pairs C7−C10 and C8−C9 (see Scheme 2 for numbering). A simplified representation of the equilibrium causing this averaged response is shown in Scheme 2. As a consequence, the olefinic carbon atoms (and their corresponding hydrogen atoms) in positions C3 and C14 give the same signals, which are different from the signals due to the other bound carbons (positions C4 and C13). Moreover, the third double bond at positions C8 and C9 is different from the others, and positions C8 and C9 give the same signal. In other words the NMR spectroscopic data show that, in solution, two olefins complex the metal with the same strength, and the third one complexes differently, as already shown in the solid phase by X-ray diffraction studies.

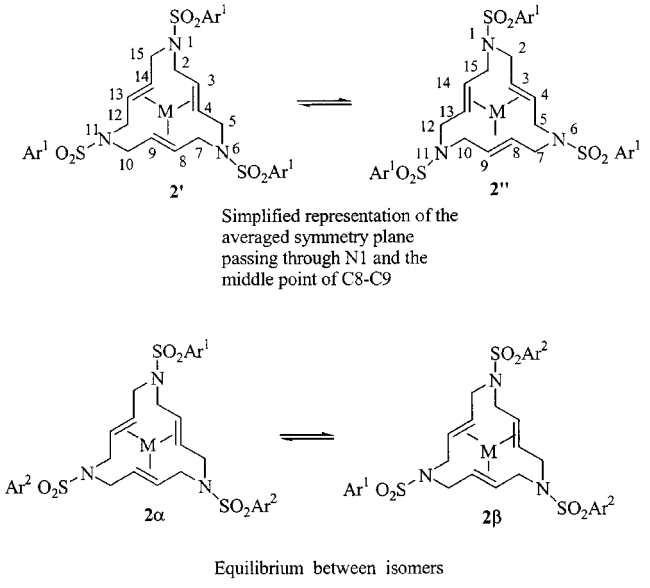
[a] ^{1}H and ^{13}C NMR spectra for **2a-Pd^0** and **2a-Pt^0** were recorded in $CDCl_3$. − [b] ^{1}H and ^{13}C NMR spectra for **2b-Pd^0** were recorded in [D_8]toluene.



Scheme 2. Averaged plane of symmetry and equilibrium between isomers in complexes **2**

In the case of different N-substituents, as for **2c-Pd^0**, two different isomers are expected depending on which substituent occupies the position opposite to the singular olefin. Although no attempts have been performed to separate these possible isomers, the ^{13}C NMR spectrum for **2c-Pd^0** confirms this situation in solution. Thus, the **2α** isomer (Scheme 2) has the unique (2,4,6-triisopropyl)phenylsulfonyl group opposite the singular olefin, and therefore it has an averaged plane of symmetry and three different signals are predicted for the olefinic protons and for the ring methylene protons, whereas the **2β** isomer has no symmetry whatsoever, and therefore six different signals are predicted for the olefinic protons and for the methylenic protons. The experimental result is that **2c-Pd^0** has nine signals in the olefinic region between δ = 77.6 and 88.4 and eight signals in the CH_2 region between δ = 43.7 and 49.5. Efforts are presently being made to prepare crystals of different N-substituted macrocycles.

The silver complexes were not stable and could not be studied in depth.

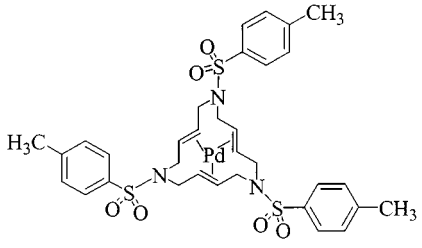
Conclusion

Preparations of the first Pd^0, Pt^0, and Ag^I complexes of 15-membered macrocyclic triolefins are described. X-ray analysis and NMR spectroscopic data indicate that the complexes have an averaged plane of symmetry rather than a C_3 axis.

Experimental Section

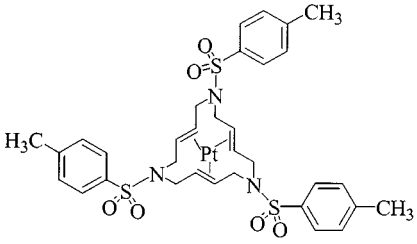
General: Macrocycles **1** were prepared as described previously.[5,6] Melting points were determined with a Kofler apparatus and are uncorrected. − IR spectra were recorded with a Nicolet FT-IR 510 ZDX. − NMR spectra were recorded with a Bruker-Analytik AC250. ^{1}H NMR (250 MHz) chemical shifts are reported relative to $CHCl_3$ at δ = 7.26 or tetramethylsilane at δ = 0.00. Coupling constants are reported in Hz. ^{13}C NMR (62.5 MHz) chemical shifts are expressed relative to $CDCl_3$ at δ = 77.00 or tetramethylsilane at δ = 0.00. Mass spectra (EIMS) were obtained with a Hewlett−Packard 5989A spectrometer and determined at an ionizing voltage of 70 eV. MALDI-TOF spectra were recorded on a BIFLEX spectrometer (Bruker−Franzen Analytik) equipped with a pulsed nitrogen laser (337 nm), operating in positive-ion reflector mode, and using 19 kV acceleration voltage. Matrices (α-cyanocinnamic acid) were prepared at 5 mg/mL in THF. Analytes were dissolved at concentrations between 0.1 and 5 mg/mL in THF or chloroform. − Elemental analyses were determined at the Servei d′Anàlisi Química de la Universitat Autònoma de Barcelona.

(*E,E,E*)-1,6,11-Tris[(4-methylphenyl)sulfonyl]-1,6,11-triazacyclopentadeca-3,8,13-trienepalladium(0) (2a-Pd^0): A solution of macrocycle **1a** (0.150 g, 0.125 mmol) and tetrakis(triphenylphosphane)palladium(0) (0.100 g, 0.150 mmol) in tetrahydrofuran (4 mL) was refluxed for 24 h. More tetrakis(triphenylphosphane)palladium(0) (0.50 g, 0.75 mol) was then added and the reflux continued for a further 24 h. The solvent was then evaporated and the residue was passed through a silica gel column with hexane/ethyl acetate/dichloromethane (2:1:1) as eluent to afford **2a-Pd^0** (0.164 g, 95%) as a solid, m.p. 237−240 °C (dec). − IR (KBr): $\tilde{\nu}$ = 1340, 1162, 1094, 904, 657 cm^{-1}. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.60 (m, 2 H), 1.63 (dd, *J* = 14.3 and 10.7 Hz, 2 H), 2.39 (s, 9 H), 2.79 (t, *J* = 11.7 Hz, 2 H), 3.07 (dd, *J* = 14.2 and 11.3 Hz, 2 H), 3.75 (d, *J* = 8.9 Hz, 2 H), 3.93−4.03 (m, 2 H), 4.62 (d, *J* = 14.0 Hz, 2 H), 4.64 (d, *J* = 14.3 Hz, 2 H), 4.78 (d, *J* = 14.3 Hz, 2 H), 7.28 (d, *J* = 8.2, 6 H), 7.64 (d, *J* = 8.2 Hz, 4 H), 7.71 (d, *J* = 8.2 Hz, 2 H). − ^{13}C NMR (62.5 MHz, $CDCl_3$): δ = 21.5, 45.1, 48.2, 49.5, 78.5, 78.7, 82.8, 127.0, 127.2, 129.8, 135.2, 136.1, 143.4, 143.6. − MALDI-TOF MS: *m/z* (%) = 774.9 [M]$^+$, 798.1 [M + Na]$^+$, 813.9 [M + K]$^+$. − $C_{33}H_{39}N_3O_6PdS_3{\cdot}CH_2Cl_2$ (861.2): calcd. C 47.42, H 4.80, N 4.88, S 11.15; found C 47.47 and 47.46, H 4.82 and 4.80, N 4.71 and 4.67, S 10.76 and 10.89.



2a-Pd(0)

(*E,E,E*)-1,6,11-Tris[(4-methylphenyl)sulfonyl]-1,6,11-triazacyclopentadeca-3,8,13-trieneplatinum(0) (2a-Pt^0): A solution of macrocycle **1a** (0.186 g, 0.149 mmol) and tetrakis(triphenylphosphane)platinum(0) (0.186 g, 0.149 mmol) in tetrahydrofuran (6 mL) was refluxed for 144 h. The solvent was then evaporated and the residue was passed through a silica gel column with hexane/ethyl acetate/dichloromethane (2:1:1) as eluent to afford **2a-Pt^0** (0.078 g, 60%) as a solid, m.p. 260−263 °C (dec., change of crystalline structure at 168−172 °C). − IR (KBr): $\tilde{\nu}$ = 1340, 1162, 1092, 909, 661 cm^{-1}. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.34−1.46 (m, 4 H), 2.07 (td, *J* = 13.3 and 2.3 Hz, 2 H), 2.40 (s, 9 H), 2.98 (dd, *J* = 13.6 and 11.5 Hz, 2 H), 3.22−3.25 (m, 2 H), 3.41 (td, *J* = 11.6 and 3.8 Hz, 2 H), 4.58 (dd, *J* = 13.6 and 3.8 Hz, 2 H), 4.62 (d, *J* = 12.0 Hz, 2 H), 5.02 (d, *J* = 12.7 Hz, 2 H), 7.26 (d, *J* = 8.2 Hz, 6 H), 7.62 (d, *J* = 8.2 Hz, 4 H), 7.65 (d, *J* = 8.2 Hz, 2 H). − ^{13}C NMR (62.5 MHz, $CDCl_3$): δ = 21.5, 44.3, 47.2, 48.5, 62.7, 63.2, 69.0, 127.0, 127.2, 129.8, 135.0, 136.0, 143.4, 143.6. − MALDI-TOF MS: *m/z* (%) = 864.9 [M]$^+$, 887.9 [M + Na]$^+$, 903.9 [M + K]$^+$. − $C_{33}H_{39}N_3O_6PtS_3{\cdot}CH_2Cl_2$ (949.9): calcd. C 43.00, H 4.35, N 4.42, S 10.11; found C 43.57, H 4.07, N 4.15, S 9.73.



2a-Pt(0)

(*E,E,E*)-1,6,11-Tris[(4-methylphenyl)sulfonyl]-1,6,11-triazacyclopentadeca-3,8,13-trienesilver(I) Tetrafluoroborate (2a-Ag^{I}BF$_4$): A solution of macrocycle **1a** (0.300 g, 0.45 mmol) and silver tetrafluoroborate (0.216 g, 0.90 mmol) in acetone (12 mL) was stirred for 5 min. at room temperature and the mixture was then left for 20 h. The formed precipitate was filtered off to afford **2a-Ag^{I}BF$_4$** as a white solid (0.200 g, 54%), m.p. 206−208 °C (dec). − IR (KBr): $\tilde{\nu}$ = 1700, 1392, 1349, 1165, 1092, 1058, 1009, 939, 904, 815, 754, 659 cm^{-1}. − ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.44 (s, 9 H), 3.75 (s, 12 H), 5.74 (s, 6 H), 7.33 (d, *J* = 7.9 Hz, 6 H), 7.66 (d, *J* = 7.9 Hz, 6 H). − MALDI-TOF MS: *m/z* (%) = 776.1 [M of cation]$^+$, 692.2 [M − Ag + Na]$^+$. − $C_{33}H_{39}AgBF_4N_3O_6S_3{\cdot}CH_3COCH_3$ (922.6): calcd. 2d-Pd(0)

X-ray Analysis of 2a-Pd^0 and 2a-Pt^0. Data Collection and Processing: Crystal data and experimental conditions for the two complexes are listed in Table 3. The collected reflections were corrected for Lorentz, polarization and absorption effects [empirical Difabs, max. and min. transmission were 0.8669−0.3950 for **2a-Pd^0**, and 0.5907−0.3170 for **2a-Pt^0**]. The lattice constants were determined by least-squares fitting of the setting angles of 25 reflections. Data were recorded using the ω-2θ scan mode up to a 2θ of 49.98 for **2a-Pd^0** and 50.02 for **2a-Pt^0**.

The structure was solved by direct methods using SHELXS-97 and refined by full-matrix least-squares methods on F^2 over the complete set of data using SHELXL-97. Anisotropic thermal parameters were refined for the non-hydrogen atoms and the hydrogen atoms were introduced in calculated positions.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic data center as supplementary publications nos. CCDC-150655 and -150656 for **2a-Pd^0** and **2a-Pt^0**, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support from MEC of Spain (projects PB93−0896 and PB98−0902), and from CIRIT-Generalitat de Catalunya (projects 98SGR0056 and 2000SGR0062, and predoctoral scholarships to J. C., S. C., and J. T.) is gratefully acknowledged.

Synthesis and Properties of 1,2-Dichlorodisilane and 1,1,2-Trichlorodisilane

Andreas Gupper[a] and Karl Hassler*[a]

Keywords: Silanes / NMR spectroscopy / IR spectroscopy / Raman spectroscopy / Isomers

The previously unknown disilanes 1,1,2-trichlorotri(1-naphthyl)disilane and 1,2-dichlorotetra(1-naphthyl)disilane were prepared by the reaction of 1-lithionaphthalenide with hexachlorodisilane. Reduction with $LiAlH_4$ afforded 1,1,2-tri(1-naphthyl)disilane. Treatment of 1,2-di(1-naphthyl)disilane and 1,1,2-tri(1-naphthyl)disilane with liquid hydrogen chloride gave ClH_2SiSiH_2Cl and $ClH_2SiSiHCl_2$ in quantitative yields, along with naphthalene. The chlorodisilanes were easily separated and purified by fractional condensation. Both disilanes are stable for weeks at room temperature, but undergo rapid H/Cl exchange reactions and SiSi cleavage upon the addition of traces of catalysts such as $AlCl_3$. The ^{29}Si chemical shifts and $J(^{29}Si,^{1}H)$ coupling constants, including those of ClH_2SiSiH_3 and $Cl_2HSiSiH_3$, are reported. The infrared and Raman vibrational spectra clearly prove that both chlorodisilanes comprise mixtures of *gauche* and *anti* rotamers in the liquid state.

Introduction

The chemical properties of hydridohalodisilanes $Si_2H_nX_{6-n}$ (X = F, Cl, Br and I) differ considerably from those of their carbon analogues $C_2H_nX_{6-n}$. First, the polarities of the SiH and CH bonds are opposite ($Si^{\delta+}H^{\delta-}$ vs. $C^{\delta-}H^{\delta+}$), and second the silicon atom easily forms transition states with coordination numbers >4 because of its larger size. Therefore, hydridohalosilanes easily react with water forming Si−O−Si linkages and hydrogen halides HX. In contrast to the halogenated ethanes, the activation energy for the reaction of halosilanes with oxygen is very low, making them spontaneously inflammable on contact with air. In addition, they are very prone to undergo halogen/hydrogen exchange reactions, which is not the case for the haloethanes.

The combination of these properties makes the synthesis and the handling of the compounds a difficult task. Earlier attempts focused on the reaction of disilane Si_2H_6 with various halogenating agents. For chlorodisilanes, HCl,[1−3] Cl_2,[4] BCl_3,[5−8] AgCl[3] or $SnCl_4$ [9] were used. Not unexpectedly, mixtures of chlorodisilanes were obtained that were difficult or even impossible to separate. Methods which avoided Si_2H_6 as a starting material comprised the reaction of monoiododisilane with AgCl,[10] the reaction of $SiCl_2H_2$ in an electrical discharge[11,12] or the electrophilic cleavage of the Si-phenyl bonds of tetraphenyldisilane (and other phenyldisilanes) with HCl/$AlCl_3$.[13] By these procedures, only Si_2H_5Cl could be obtained in pure form and in preparative quantities. The reaction of tetraphenyldisilane with HCl/$AlCl_3$ [13] had the disadvantage that the benzene which formed simultaneously could not be separated from the tetrachlorodisilane. In 1979, the isolation of pentachlorodisilane from a mixture of chlorosilanes obtained as a by-product of the thermal decomposition of $HSiCl_3$ for the generation of ultrapure semiconductor-grade silicon was reported.[14]

HBr and HI,[15,2,16] Br_2 [4] and I_2,[17,18] as well as BBr_3 and BI_3,[8,19] have all been used for the bromination or iodination of disilane. Monobromodisilane and monoiododisilane could be successfully prepared and purified, but not disilanes with a number of halogen atoms exceeding one.

Synthetic strategies for the preparation of fluorodisilanes comprised reactions of difluorosilylene SiF_2 with H_2S,[20] B_2H_6,[21] HBr[22] or PH_3,[23] as well as the selective reduction of bromofluorodisilanes such as $F_3SiSiHBr_2$ with Me_3SnH[24] or halogen exchange with SbF_3 [8] or ZnF_2.[25] So far, FSi_2H_5,[26] F_3SiSiH_3,[21,24] F_5Si_2H[22] and $F_2HSiSiHF_2$ [25] have been synthesised by these procedures.

In our group we have focused on the electrophilic cleavage of silicon-aryl bonds by HCl, HBr or HI:

$$\text{Si-Aryl} + HX \rightarrow Si{-}X + \text{ArylH} \quad (1)$$

Under appropriate conditions, SiH functionalities are not attacked and the method can be used for the synthesis of a variety of bromo- and iododisilanes $X_nSi_2H_{6-n}$,[27] as well as bromo- and iodotrisilanes $X_nSi_3H_{8-n}$.[28] If the boiling points of the disilanes and trisilanes differ considerably from that of benzene, hydridophenyldisilanes and -trisilanes can be used as starting materials as their synthesis poses the least problems.[29] In all other cases, the introduction of larger aryl groups such as mesityl or naphthyl seems indispensable. For instance, 1,1,2,2-tetrachlorodisilane can be prepared from 1,1,2,2-tetramesityldisilane,[25] and 1,2-dibromodisilane from 1,2-di(1-naphthyl)disilane.[30] The disilanes can then be purified simply by distillation or fractional condensation. The disadvantage with this approach is that for the preparation of naphthyldisilanes and naphthyltrisilanes the coupling reaction of chloronaphthylmonosilanes with alkali metals is not an appropriate method due to side

reactions at the aryl group. Similar problems are encountered with mesityl groups due to their increased bulkiness.

In a previous paper we reported on the synthesis of pentachloro(1-naphthyl)disilane and tetrachloro-1,2-di(1-naphthyl)disilane from hexachlorodisilane and naphthyllithium.[31] This method can be expanded for the preparation of tri- and tetranaphthyldisilanes as well, which in turn can be used for the preparation of the title hydridochlorodisilanes.

Results and Discussion

(1-Naphthyl)disilanes

The two most convenient methods for the preparation of arylated disilanes are the reductive coupling of the appropriate arylhalomonosilanes with Li, Na, K and Mg and the reaction of silyllithium, -sodium or -potassium compounds with arylhalosilanes. Unfortunately, neither method can be used for the synthesis of naphthyldisilanes as the naphthyl group easily reacts with alkali metals leading to a large number of badly defined products.

These difficulties can be circumvented by the use of naphthyllithium which, under appropriate conditions, reacts with hexachlorodisilane (although not without appreciable Si−Si bond cleavage) to form naphthylpentachlorodisilane and 1,2-dinaphthyltetrachlorodisilane:[31]

$$Si_2Cl_6 + LiC_{10}H_7 \rightarrow (C_{10}H_7)Cl_2SiSiCl_3 \quad (2)$$

$$Si_2Cl_6 + 2\,LiC_{10}H_7 \rightarrow (C_{10}H_7)Cl_2SiSiCl_2(C_{10}H_7) \quad (3)$$

Increasing the stoichiometric ratio of $LiC_{10}H_7$ vs. Si_2Cl_6 allows the preparation of 1,1,2-trichlorotrinaphthyldisilane and 1,2-dichlorotetranaphthyldisilane in moderate yields. Appreciable quantities of trichloronaphthylsilane are formed as a by-product due to increased Si−Si bond cleavage by $LiC_{10}H_7$. Both disilanes can be separated from the reaction mixture by distillation and can be purified by fractional crystallization. They are easily reduced with lithium aluminum hydride to give the corresponding naphthylhydridosilanes in nearly quantitative yields.

Chlorodisilanes

The arylated disilanes $Ar_nSi_2H_{6-n}$ are the most suitable precursors for the preparation of the halodisilanes $X_nSi_2H_{6-n}$ as the aryl groups are easily replaced by halogen atoms X (X = Cl, Br and I) upon reaction with either the liquefied hydrogen halides HX or solutions of HX in benzene. The latter method has the disadvantage that small quantities of $AlCl_3$ have to be used as a catalyst and this cannot usually be removed completely from the halodisilane. Furthemore, traces of $AlCl_3$ also catalyse halogen/hydrogen exchange reactions and Si−Si bond cleavage, thereby leading to a rapid decomposition of the disilanes. With iodine and bromine these reactions are quite slow and the disilanes can be stored at −70 °C for several weeks without any appreciable decomposition. For chlorodisilanes, disproportionation occurs quickly. Therefore, the chlorodisilanes described herein were prepared by the reaction of the naphthyldisilanes with liquefied HCl in a sealed tube. For instance, ClH_2SiSiH_2Cl prepared this way can be stored for weeks at room temperature without any decomposition.

^{29}Si NMR spectra

Table 1 and 2 summarize the ^{29}Si chemical shifts (ppm against tetramethylsilane) and $J(^{29}Si,^{1}H)$ coupling constants (Hz) for the naphthyldisilanes and chlorodisilanes, respectively. The data for 1,1,1,3-tetrachlorodinaphthyldisilane and 1,1-dichlorodisilane have been included as these molecules were also identified in the reaction mixtures. Chlorodisilane ClH_2SiSiH_3 was also prepared for NMR spectroscopic purposes; the chemical shifts and coupling constants for related disilanes described elsewhere have been included, too.

Table 1. ^{29}Si NMR chemical shifts (δ_{Si} vs. TMS) and $J(^{29}Si,^{1}H)$ coupling constants (Hz) of (1-naphthyl)chlorodisilanes and (1-naphthyl)disilanes

Figure 1 displays the proton coupled ^{29}Si NMR spectra of chlorodisilane and 1,2-dichlorodisilane exemplifying the quality of the spectra that have been obtained. The inter-

pretation of the spectra is straightforward as all couplings are first order.

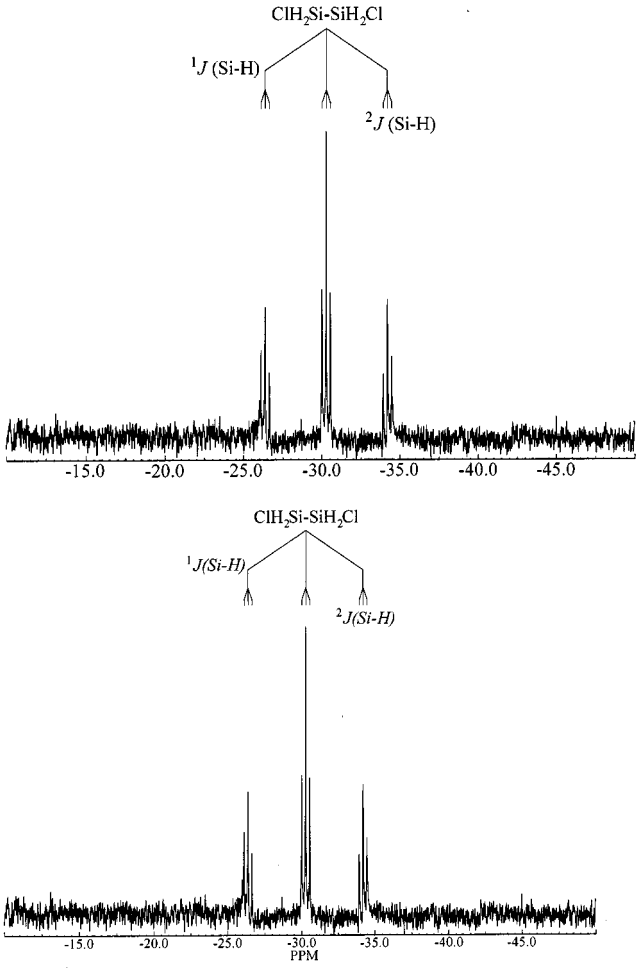

Figure 1. Proton coupled ^{29}Si NMR spectra of 1,2-dichlorodisilane (top) and chlorodisilane (bottom)

Figure 2 presents the spectrum of 1,1,2-trichlorodisilane in the range $\delta = +10$ to -40 after equilibration upon addition of $AlCl_3$. Interestingly, no 1,2-dichlorodisilane is formed. 1,1-Dichlorodisilane and 1,1,2,2-tetrachlorodisilane are readily detected, along with monosilanes such as H_3SiCl, H_2SiCl_2 and $HSiCl_3$.

From mixtures of chlorodisilanes, Söllradl and Hengge[13] deduced NMR parameters for all possible chlorodisilanes. The data presented here agree quite well with theirs.

Infrared and Raman Vibrational Spectra

Infrared and Raman vibrational spectra were recorded for 1,2-dichlorodisilane and 1,1,2-trichlorodisilane. The spectra at ambient temperatures possess more lines than predicted by the selection rules based on symmetry arguments, a clear indication for rotational isomerism. The raman spectra at low temperatures confirm this prediction, as the intensity ratio of a number of pairs of bands changes with temperature. Table 3 summarizes the data that have been obtained for the gases (IR) and the liquids (Raman).

Figure 3 illustrates the effect of temperature on the Raman spectrum of 1,1,2-trichlorodisilane. For instance, the relative intensities within the line triple at 396/407/424 cm^{-1}, and of the line pairs at 209/216, 517/525 and 550/571

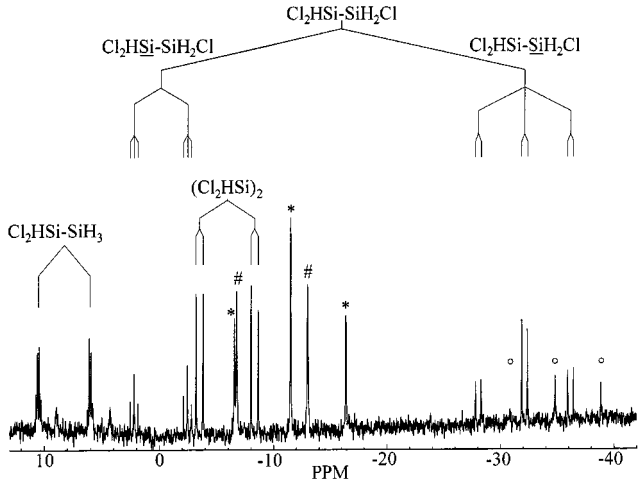

Figure 2. Proton coupled ^{29}Si NMR spectrum of 1,1,2-trichlorodisilane in the range from $\delta = +10$ to -40 after equilibration with $AlCl_3$; lines marked with ○, * and # are due to H_3SiCl, H_2SiCl_2 and $HSiCl_3$, respectively

Table 3. Absorption frequencies and assignments in the infrared spectra (gas, 2200−280 cm^{-1}) and Raman spectra (liquid, 2200−150 cm^{-1}) of 1,2-dichlorodisilane and 1,1,2-trichlorodisilane

cm^{-1} are clearly temperature dependent. Similar effects are observed for 1,2-dichlorodisilane. As it is impossible to accurately assign the spectra of the conformers without the help of ab initio calculations of harmonic frequencies, only approximate descriptions of the modes are given in Table 3 without any reference to individual rotamers.

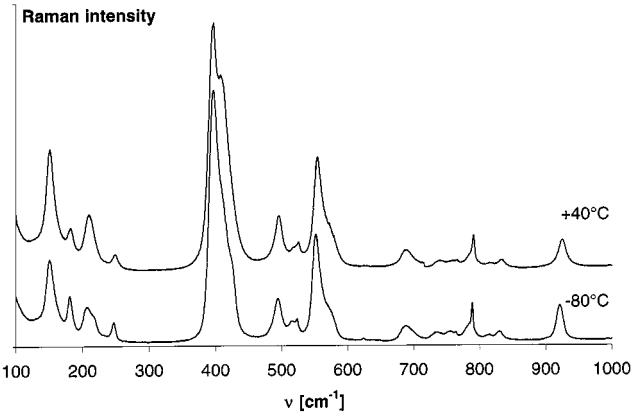

Figure 3. Raman spectra in the range $\tilde{\nu} = 100-1000\ cm^{-1}$ of 1,1,2-trichlorodisilane at two different temperatures

So far, the rotational isomerism of 1,1,2,2-tetrachlorodisilane has been examined by electron diffraction[33] and variable temperature Raman spectroscopy[34] with the result that the *gauche* conformer is found to be more stable in both the gas and the liquid phase. Ab initio calculations at various levels of theory predict the *anti* rotamer as the low energy conformer. We will report on detailed investigations of the rotational isomerism of the title molecules, including spectra of the deuterated isotopomers as well as electron diffraction experiments, in a forthcoming publication.

Experimental Section

General: Most chlorinated organosilanes are sensitive towards moisture with the formation of Si−O−Si bonds and hydrogen chloride. Furthermore, hydridochlorosilanes are also sensitive towards oxygen, many of them igniting spontaneously on contact with air. All manipulations were therefore carried out under an atmosphere of dry, oxygen-free nitrogen. All solvents were dried by distillation from potassium prior to use.

Raman spectra were recorded with a T64000 spectrometer from Jobin-Yvon, equipped with a triple monochromator. The spectra were excited with the green line (514 nm) of an Ar laser. The chlorodisilanes were condensed into 1 mm capillary glass tubes which were sealed under an inert N_2 atmosphere.

The gas-phase infrared spectra of the hydridochlorodisilanes were recorded with a Perkin−Elmer 883 spectrometer using a Perkin−Elmer gas cell with a path length of 10 cm.

NMR spectra were recorded with a Bruker MSL 300 spectrometer as solutions in mesitylene (hydridochlorodisilanes) or toluene (naphthlydisilanes) using a capillary with D_2O as an external standard. Standard pulse sequences such as INEPT were employed.

Synthesis of 1,1,2-trichlorotrinaphthyldisilane: A solution of hexachlorodisilane (45.0 g, 167.4 mmol) in 100 mL of toluene was added dropwise to a suspension of naphthyllithium in toluene [594.0 mmol; prepared from 1-bromonaphthalene (123.0 g, 594.0 mmol) and *n*-butyllithithum]. A temperature of −20 °C was maintained throughout the procedure. Upon completion, the reaction mixture was refluxed for three hours. The salts were then separated by filtration and the solvent removed by evaporation in vacuo. The liquid residue was fractionated in vacuo. All volatile products up to a temperature of 120 °C (0.01 Torr) were collected. They comprised a mixture of naphthyltrichlorosilane, pentachloronaphthyldisilane and tetrachlorodinaphthyldisilane. The residue that solidified at room temperature was found to be a mixture of 1,1,2-trichlorotrinaphthyldisilane and 1,2-dichlorotetranaphthyldisilane. Crystallization from toluene/petroleum ether (1:5) afforded 34.8 g (38%) of pure trichlorotrinaphthyldisilane. − $C_{30}H_{21}Cl_3Si_2$ (544.0): calcd. C 66.23, H 3.89; found C 66.45, H 3.86.

Synthesis of 1,1,2-Trinaphthyldisilane: The hydridodisilane was obtained in quantitative yields by standard reduction of the trichlorotrinaphthyldisilane with $LiAlH_4$ in diethyl ether. After addition of a solution of lithium aluminum hydride to the solution of the chlorodisilane at 0 °C, the reaction mixture was refluxed for several hours. Subsequently, it was added dropwise to 2 N H_2SO_4 at a temperature of 0 °C. The organic layer was then separated and the diethyl ether removed in vacuo. The residue was recrystallized from petroleum ether giving the desired product as colorless crystals. − $C_{30}H_{24}Si_2$ (440.7): calcd. C 81.76, H 5.49; found C 81.75, H 5.59.

Synthesis of 1,2-Dichlorodisilane: 1,2-Dinaphthyldisilane[31] (5.0 g) or the equivalent amount of 1,2-dimesityldisilane[35] was placed in a thick-walled glass tube. A large excess of hydrogen chloride was then condensed into the tube, which was sealed carefully. The reaction mixture was cooled to −70 °C for five hours. The glass tube was then transferred to a vacuum line and the unreacted hydrogen chloride removed very carefully. 1,2-Dichlorodisilane was then separated from naphthalene (or mesitylene) by fractional condensation, as a colorless liquid. The yield was quantitative.

Synthesis of 1,1,2-Trichlorodisilane: In a procedure completely analogous to the synthesis of 1,2-dichlorodisilane, 1,1,2-trichlorodisilane was obtained in quantitative yields from 1,1,2-trinaphthyldisilane and liquid HCl. It was purified by fractional condensation.

Keywords: Gold / Rhodium / Iridium / S ligands / Hydrogenation

The use of dinuclear gold derivatives $[Au_2(\mu\text{-}S\text{-}S)(PR_3)_2]$ (S-S = benzenedithiolate, toluenedithiolate; PR_3 = PPh_3, PPh_2Me) as S-donor ligands, with rhodium and iridium complexes $[M(cod)_2]BF_4$ (M = Rh, Ir; cod = cyclooctadiene) affords new heteronuclear compounds containing the $\{Au_2M\}$ core, with the general formulation $[Au_2M(\mu\text{-}S\text{-}S)(cod)(PR_3)_2]BF_4$. One of these decomposes upon heating to give $[AuIr(\mu\text{-}S_2C_6H_4CH_3)(cod)(PPh_3)]$. The crystal structure of the former and $[Au_2Ir(\mu\text{-}S_2C_6H_4)(cod)(PPh_3)_2]BF_4$ have been established by X-ray diffraction. The sulfur atoms from the dithiolene ligands bridge two different metal centres.

Introduction

Until recently, gold and its compounds were thought to be catalytically inactive.[1] In recent years, however, gold complexes have been used as homogeneous catalysts, mainly in the addition of water and alcohols to alkynes,[2] and in the use of luminescent compounds as photocatalysts.[3]

Heteropolynuclear complexes are particularly attractive because of their interesting structural and reactive features and their potential applications in catalysis.[4] In these complexes, two or more different metal atoms or ions are present in the same molecule and may cooperate in some reactions that could not be handled by a single metal centre. This leads to new types of reactions and affords new opportunities for catalytic processes.[5] Thus, heteropolynuclear complexes containing gold and other metal centres more commonly used in homogeneous catalysis, such as rhodium and iridium, can enhance the catalytic properties of the monometallic complexes.

Different approaches can be taken to the preparation of heterometallic derivatives. The tendency of thiolate ligands to act as bridges is a good starting point for the synthesis of polynuclear compounds, and several dinuclear thiolate complexes of rhodium and iridium are active in homogeneous catalytic hydrogenation reactions.[6] Some complexes containing gold and rhodium or iridium with thiolate ligands acting as a bridge between the metal centres have been reported, such as $[Cp^*M(\mu\text{-}SR)_2AuCl_2]Cl$ (M = Rh, Ir), but their crystal structures are at present unknown.[7]

In this paper we present the synthesis of heterometallic complexes containing iridium or rhodium with dithiolene-gold compounds as ligands. The new derivatives have the general formula $[Au_2M(\mu\text{-}S\text{-}S)(cod)(PR_3)_2]BF_4$ (M = Rh, Ir; S-S = benzenedithiolate, toluenedithiolate; cod = cyclooctadiene; PR_3 = PPh_3, PPh_2Me) and $[AuIr(\mu\text{-}S_2C_6H_4CH_3)(cod)(PPh_3)]$. The crystal structures of two gold-iridium complexes have been determined by X-ray diffraction and show short iridium−gold contacts ranging

from 2.8544(4) to 2.9120(8) Å. Their reactivity with H_2 and CO has been investigated.

Results and Discussion

Synthesis of Polynuclear Compounds $[Au_2M(\mu\text{-S-S})(cod)(PR_3)_2]BF_4$

The polynuclear compounds **1**−**8** were prepared by the reaction of $[Au_2(\mu\text{-S-S})(PR_3)_2]$ (S-S = benzenedithiolate or toluenedithiolate; PR_3 = PPh_3, PPh_2Me) with the corresponding $[M(cod)_2]BF_4$ (M = Rh, Ir) derivative (Scheme 1).

The compounds $[Au_2(\mu\text{-S-S})(PR_3)_2]$ have a dithiolate ligand bridging the two gold centres in a μ_2 fashion. The crystal structures of several of these complexes, with different dithiolenes and different phosphane ligands, have been determined by X-ray diffraction.[8,9] In these structures, in addition to the typical gold−gold interactions, there is also one weak interaction between S and Au. This interaction points to the possibility of further coordination to another metal centre through the sulfur atoms. We therefore tested the reactivity of these dinuclear gold compounds towards the incorporation of another gold atom giving rise to $[Au_3(\mu\text{-S-S})(PR_3)_3]ClO_4$.[8] This positive result and the recent reports regarding the activity of gold complexes as catalysts,[2] have encouraged us to synthesise complexes with these digold ligands and rhodium or iridium fragments. These two metals are well known in the homogeneous catalyst area, and, in particular, some dinuclear thiolate complexes of these metals have been shown to be active in catalytic hydrogenation reactions.[6]

$[M(cod)_2]^+$ (M = Rh, Ir) derivatives are used as starting materials, with the expectation that our gold-containing compounds could substitute one of the cyclooctadiene ligands, giving the corresponding heteronuclear products. The reactions were carried out in dichloromethane. Unknown yellow solids precipitated in this solvent and were filtered off. Little information about the yellow solids has at present been obtained, due to their insolubility in all the common solvents. Their elemental analyses indicate a low percentage of carbon, which would correspond to polynuclear species with high metallic content. From the remaining dichloromethane solutions, the new products **1**−**8** were obtained, together with $[Au(PR_3)_2]BF_4$, after addition of diethyl ether. Different solvents were tried to separate the complexes **1**−**8** from the bis(phosphane)gold(I) salts, with the best results being obtained by recrystallization from $CHCl_3$/diethyl ether. The final yields were quite poor (around 20%) due to the similar solubility of both compounds.

The IR spectra show an absorption corresponding to tetrahedral BF_4^-. From the two active vibration modes only the asymmetric tension vibration (ν_a) at ≈1050 cm^{-1} can be assigned. The asymmetric deformation vibration (∂_a) at ≈ 530 cm^{-1} is coincident with the phosphane vibration zone and it cannot be differentiated.

The $^{31}P\{^1H\}$ NMR spectra show a singlet due to the phosphanes for all the compounds (Table 1). In the new complexes **1**−**8**, after the metal coordination, the sulfur atoms become asymmetric centres. Therefore, the Au−PR_3 group can adopt an *anti* or a *syn* configuration. In both cases, only one singlet should appear in the ^{31}P NMR spectrum. NMR experiments at low temperature (193 K) still show the presence of only one singlet. This indicates that either there is only one diastereoisomer in solution or there is a very rapid interchange between the *anti* and the *syn* configuration. The singlets corresponding to the Rh complexes **1**−**4** appear at lower fields than those in the gold starting materials, whilst the singlets of the Ir complexes **5**−**8** are displaced to higher field, although in both cases the magnitude is about $\Delta\delta = 1$. It is worth noting that complexes with toluendithiolate (**2**, **4**, **6** and **8**) do not show the predicted two resonances for the phosphorous due to the asymmetric nature of the ligand: only one singlet is present in their spectra, even at low temperature, as in the gold starting materials $[Au_2(\mu\text{-}S_2C_6H_3CH_3)(PR_3)_2]$.[8] A fast interchange of $AuPPh_3$ fragments should be present in solution.

Crystal Structure of $[Au_2Ir(S_2C_6H_4)(cod)(PPh_3)_2]BF_4$ (5)

The molecular structure of the complex $[Au_2Ir(S_2C_6H_4)(cod)(PPh_3)_2]BF_4$ (**5**) has been established by X-ray diffraction and the cation is shown in Figure 1. General information is given in Table 2 and selected bond lengths and angles in Table 3. The cation of **5** consists of a benzenedithiolate ligand bridging two $AuPPh_3^+$ and one $Ir(cod)^+$ fragments, in a similar arrangement to $[Au_3(S_2C_6H_3CH_3)(PPh_3)_3]ClO_4$.[8] The dithiolene and cod ligands are chelated to the iridium centre. The average Ir−S distance is 2.32 Å and the average Ir−C distance 2.15 Å. These bond lengths are similar to the ones found in the Ir^I dimers $[Ir(\mu\text{-SR})(cod)]_2$.[10]

The iridium−gold distances are Ir−Au(1) = 2.9208(9) and Ir−Au(2) = 2.9120(8) Å. These distances are longer than the corresponding single Ir−Au bond, which are in the range 2.59−2.81 Å[11] and are similar to the reported metal−metal interactions in other iridium-gold complexes.[12] There is probably a considerable similarity be-

tween the Au−Ir interaction in **5** and the numerous examples of short Au−Au contacts shown in Au^I complexes,[13] or in the case of $[Au_3(S_2C_6H_3CH_3)(PPh_3)_3]ClO_4$ [8] [2.9624(12) and 3.1966(14) Å]. The two $AuPPh_3$ units are in an up/down configuration either side of the Ir(S-S)(cod) square planar fragment. Therefore, taking into account these two gold−iridium interactions, the coordination around the iridium can be regarded as a heavily distorted octahedron.

Despite the presence of gold−iridium interactions, the gold atoms are almost linearly coordinated considering the P−Au−S arrangement, the most frequent type of configuration for gold(I) complexes, with angles P(1)−Au(1)−S(1) = 176.07(13)° and P(2)−Au(2)−S(2) = 161.33(12)°. These gold centres lie out of the plane formed by P−S−Ir by 0.079 Å for Au(1) and 0.042 Å for Au(2). The gold−sulfur bond lengths are Au(1)−S(1) = 2.372(3) and Au(2)−S(2) = 2.392(3) Å, and are a little longer than in the previously reported complex $[Au_3(S_2C_6H_3CH_3)(PPh_3)_3]ClO_4$ [8] [2.315(5) and 2.332(4) Å for the external gold atoms]. The gold−phosphorus distances are Au(1)−P(1) = 2.257(3) and Au(2)−P(2) = 2.248(3), and are similar to the values found in other Ir−Au phosphane complexes (2.199−2.292 Å).[14]

The coordination plane for the Ir centre forms a dihedral angle of 176° with the dithiolene plane. The Au−PPh_3 groups are in an *anti* configuration, giving an *R*-configuration for both sulfur atoms.

Reactivity and Catalytic studies

We have studied the reactivity of the complexes [$Au_2M(\mu$-$S_2C_6H_4)(cod)(PPh_3)_2]BF_4$ (M = Rh **1**, Ir **5**). Dichloromethane solutions of both products were treated with H_2 and CO at room temperature and pressure. While we did not observe any reaction with H_2, both compounds react with CO. The dichloromethane solutions change from yellow to green and two new absorptions are observed in the IR spectra at 1993 and 2019 cm^{-1}, corresponding to terminal ν_{CO} vibrations due to the coordination of two CO molecules to the metal centres, replacing the cod ligand.[15] Evaporation of the solvent gives green solids that do not contain absorptions in the CO region, showing that the proposed dicarbonyl complex is not stable under these conditions.

Studies testing the catalytic activity of these complexes in the hydroformylation and hydrogenation of styrene were performed. The hydroformylation test was performed at 353 K and P_{CO/H_2} (1:1) = 5 atm., in dichloroethane, using complex **1** as the catalyst precursor. The catalytic test for the hydrogenation was performed at 298 K and P_{CO/H_2} = 5 atm., in dichloromethane. The catalyst precursor for the hydrogenation run was complex **5**. Both reactions were followed by gas chromatography, but neither hydroformylation nor hydrogenation were observed. The final reaction mixtures were green solutions with black solids in suspension. The black solids may correspond to the formation of reduced metals due to the presence of hydrogen pressure and/or higher temperatures.

Preparation and Crystal Structure of [AuIr(μ-$S_2C_6H_3CH_3$)(cod)(PPh_3)]

Since complex **1** decomposed in the hydroformylation and hydrogenation reactions, we studied the behaviour of complexes **1**−**8** at the temperature of refluxing acetone in order to test their thermal stability. All the complexes give insoluble black solids and [$Au(PR_3)_2]BF_4$, as confirmed by ^{31}P NMR spectroscopy. Only in the case of [$Au_2Ir(\mu$-$S_2C_6H_3CH_3)(cod)(PPh_3)_2]BF_4$ (**7**) was one diethyl ether soluble complex isolated in quite good yield and characterized as [AuIr(μ-$S_2C_6H_3CH_3$)(cod)(PPh_3)] (**9**). It shows a similar ^{31}P NMR spectrum to that of **7** with only one signal at δ = 35.1, although with toluenedithiolate several isomers should be present. The ^1H NMR spectrum shows different resonances for the cod protons, pointing to the presence of a nonsymmetrical coordination for the diolefinic ligand. In addition, the integration of the phenyl protons suggests that only one $AuPPh_3$ group is present for each cod ligand. The elemental analysis and the IR spectrum, with the lack of absorptions corresponding to a BF_4 anion, confirm the proposed stoichiometry for **9**.

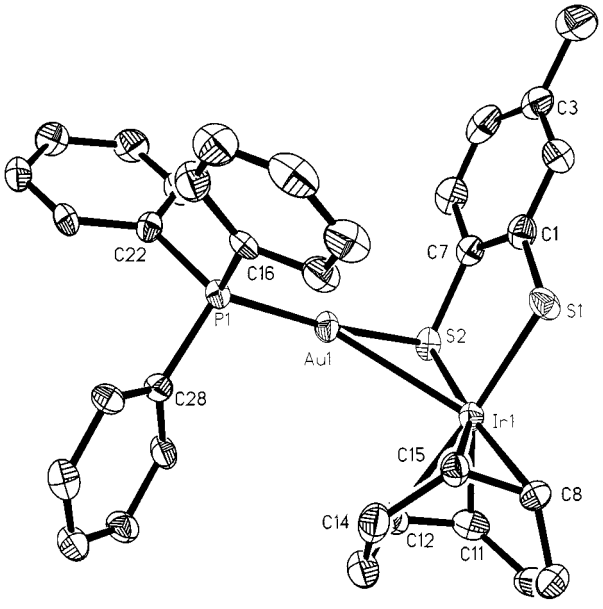

Figure 2. Molecular structure of **9**; thermal ellipsoids are drawn at the 50% probability level and H atoms have been omitted for clarity

The dinuclear structure of **9** was confirmed by X-ray analysis (Figure 2). General information is given in Table 2 and selected bond lengths and angles in Table 4. The molecule can be described as a toluenedithiolate ligand bridging one $AuPPh_3^+$ and one $Ir(cod)^+$ fragment, in a similar arrangement to that present in $[Au_2Ir(S_2C_6H_4)(cod)(PPh_3)_2]BF_4$ (**5**). In fact, the structure of **9** is very similar to **5** with the addition of a methyl group, the lack of the BF_4 anion and the presence of only one $AuPPh_3$ fragment. Complex **9** retains the planarity of the Ir(S-S)(cod) fragment and the pseudo linearity of $SAu(PPh_3)$ skeleton. The Ir−S, Au−S, Ir−C and Au−P distances are nearly identical in **5** and **9**. Only the Ir(1)−S(1) distance with the nonbridging sulfur is slightly shorter than either the Ir(1)−S(2) in complex **9** or any of the Ir−S distances in complex **5**. In addition only one iridium−gold distance in **9** [2.8544(4) Å] is shorter than the two Ir−Au contacts in **5**, showing that the interaction between the two metals is now stronger than in the trinuclear complex, although this value it is not short enough to be considered a real metal−metal bond.[11,12]

In summary, we have prepared new polynuclear complexes with Au_2Rh, Au_2Ir, and AuIr cores using dithiolate ligands to bridge the metal centres. The crystal structures of $[Au_2Ir(\mu\text{-}S_2C_6H_4)(cod)(PPh_3)_2]BF_4$ (**5**) and $[AuIr(\mu\text{-}S_2C_6H_3CH_3)(cod)(PPh_3)]$ (**9**) show that there are gold−iridium interactions ranging from 2.9208(9) in the former to 2.8544(4) Å in the latter. The new complexes are not active precursors for either the hydroformylation or hydrogenation of styrene. This inactivity may be due to the instability of the complexes either at high P_{CO/H_2} or at high temperature.

Experimental Section

General: IR spectra were recorded on a Perkin−Elmer 883 spectrophotometer, over the range 4000−200 cm^{-1}, as Nujol mulls between polyethylene sheets. ^1H and ^{31}P NMR spectra were recorded on a Varian GEMINI 300 in $CDCl_3$ solution; chemical shifts are quoted relative to $SiMe_4$ (^1H) or H_3PO_4 (external ^{31}P). The C,H,N and S analyses were performed with a Perkin−Elmer 2400 microanalyser. Mass spectra were recorded on a VG Autospec, by liquid secondary ion mass spectrometry (LSIMS +) using nitrobenzyl alcohol as matrix and a caesium gun. Gas chromatography was performed on a Hewlett−Packard 5840A chromatograph with a flame ionisation detector using an Ultra-2 (5% diphenylsilicone/95% dimethylsilicone) capillary column (25 m × 0.2 mm Ø).

Materials: The starting materials $[Au_2(\mu\text{-}S_2C_6H_4)(PPh_3)_2]$,[8] $[Au_2(\mu\text{-}S_2C_6H_4)(PPh_2Me)_2]$,[8] $[Au_2(\mu\text{-}S_2C_6H_3Me)(PPh_3)_2]$,[8] $[Au_2(\mu\text{-}S_2C_6H_3Me)(PPh_2Me)_2]$,[8] $[Rh(cod)_2]BF_4$ [16] and $[Ir(cod)_2]BF_4$ [16] were prepared as previously described. All other reagents were commercially available, and all the reactions were carried out under an argon atmosphere. All the synthesised complexes were isolated as air-stable solids.

Preparation of Complexes 1−8: To a solution of $[Au_2(\mu\text{-}S\text{-}S)(PR_3)_2]$ [S-S = $S_2C_6H_4$, PR_3 = PPh_3 (0.106 g, 0.1 mmol), PPh_2Me (0.093 g, 0.1 mmol); S-S = $S_2C_6H_3Me$, PR_3 = PPh_3 (0.107 g, 0.1 mmol), PPh_2Me (0.095 g, 0.1 mmol)] in CH_2Cl_2 was added $[M(cod)_2]BF_4$ [M = Rh (0.041 g, 0.1 mmol), Ir (0.050 g, 0.1 mmol)]. After stirring for 1 h a yellow solid was filtered off. The solutions were concentrated in vacuum; addition of cold diethyl ether, resulted in the precipitation of yellow solids, which were filtered off, washed with cold diethyl ether and vacuum dried. These solids contained complexes **1−8** with $[Au(PR_3)_2]BF_4$. Recrystallization from chloroform/diethyl ether afforded the new compounds as yellow solids. Only the initial batch of crystals were collected as later fractions were found to be contaminated with bis(phosphane)gold(I) tetrafluoroborate.

[AuIr(μ-$S_2C_6H_3$Me)(cod)(PPh_3)$_2$] (9): A solution of **7** (0.073 g, 0.05 mmol) in acetone (20 mL) was refluxed for 3 h. After removal of the solvent to ca. 5 mL and addition of diethyl ether (20 mL) a white solid was formed, which was characterized as [Au(PPh_3)$_2$]BF_4. Partial evaporation of the solution and addition of hexane gave a yellow solid. Yield: 26 mg (57%). − $C_{33}H_{33}AuIrPS_2$: calcd. C 43.4, H 3.6, S 7.0; found C 43.8, H 3.7, S 6.6. − ^{1}H NMR: δ = 1.6 (m, 4 H, -CH_2-$_{endo}$, cod), 1.8 (m, 4 H, -CH_2-$_{exo}$, cod), 2.4 (s, 3 H, C_6H_3*Me*), 4.0 (m, 2 H, -CH=CH-, cod), 4.1 (m, 2 H, -CH=CH-, cod), 6.7 (d, 1 H, C_6H_3Me), 7.3−7.1 (m, 15 H, Ph), 7.4 (s, 1 H, C_6H_3Me), 7.5 (d, $^3J_{H-H}$ = 9.0 Hz, 1 H, C_6H_3Me) − ^{31}P{^{1}H} NMR: δ = 35.1 (s, PPh_3). − MS: *m*/*z* (%) = 913 (20) [M]$^+$.

Crystallography: Single crystals were grown by diffusing hexane into dichloromethane solutions of [Au_2Ir(μ-$S_2C_6H_4$)-(cod)(PPh_3)$_2$]BF_4 (**5**) and [AuIr(μ-$S_2C_6H_3$Me)(cod)(PPh_3)] (**9**). They were mounted at low temperature in inert oil. Crystal data and data collection parameters are summarised in Table 4. Data were collected on a Delft Instruments FAST TV area detector diffractometer positioned at the window of a rotating-anode generator with graphite monochromated Mo-K_α radiation (λ = 0.71069 Å), following procedures described elsewhere.[17]

Structure Solution and Refinement: The structures were solved using SHELXS-86 and SHELXS-97,[18] and refined by full-matrix least-squares on F_o^2, using the programs SHELXL-93 and SHELXL-97.[19] In the case of **5** the data were corrected with the program DIFABS,[20] and for **9** with the program SORTAV.[21] The non-hydrogen atoms were refined with anisotropic thermal parameters. All hydrogen atoms were included in idealized positions.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-157923 (**5** and **9**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Hydrogenation Procedure: The reaction was carried out in a small home-made autoclave. The styrene (0.92 cm^3, 8 mmol) and catalyst precursor **5** (57.8 mg, 0.04 mmol) were dissolved in dichloromethane (6 cm^3) and shaken under 5 atm. of H_2 at 298 K for 24 h. The conversion was measured by gas chromatography.

Hydroformylation Procedure: The catalyst precursor **1** (68.1 mg, 0.05 mmol) and styrene (1.15 cm^3, 10 mmol) were dissolved in 7.5 cm^3 of dichloromethane. This solution was transferred to the evacuated autoclave, which was then pressurised with *syn*-gas to about 80% of the reaction pressure (5 atm.). The preheated water circuit was connected to the autoclave jacket, and when thermal equilibrium was reached (5−10 minutes) more gas mixture was introduced until the required pressure was achieved. At the end of the reaction the autoclave was cooled to room temperature and depressurised. The sample was analysed by gas chromatography.

Acknowledgments

The Spanish authors thank the Dirección General de Enseñanza Superior (PB98- 0542 and PB97−0407-C05−01) for financial support, the Ministerio de Educación y Cultura for a grant (to R.T.), and the Generalitat de Catalunya (CIRIT) for a grant (to I del R.). Reactions of *t*Bu-Calix[6]arene with Lanthanide Triflates: Synthesis and Crystal Structure Determination of Novel Bimetallic Calixarene Complexes of La, Sm and Yb

Pascal C. Leverd,*[a] David Rinaldo,[a] and Martine Nierlich[a]

Keywords: O ligands / Calixarenes / Lanthanides / N ligands

The reactions of *t*Bu-calix[6]arene (H_6L) with $Ln(O_3SCF_3)_3$ (Ln = La, Sm, Yb) were used to isolate $[\{La(O_3SCF_3)(pyridine)_7\}_2H_2L]$ (**1**), $[\{Sm(O_3SCF_3)(pyridine)_4\}_2H_2L]$ (**2**) and $[\{Yb(O_3SCF_3)(terpyridine)(pyridine)\}_2H_2L]$ (**3**), three novel bimetallic calixarene complexes of the lanthanides. The solid state structures of **2** and **3** were determined by X-ray crystallography revealing compounds where the two metal cations are anchored on both sides of the macrocycle in the 1,2,3-alternate conformation. Compounds **1**–**3** are the first bis-alkoxy triflate species $\{M(OR)_2(O_3SCF_3)\}$ to be characterized in lanthanide coordination chemistry.

Introduction

Calixarenes consist of phenolic units linked by methylene bridges into a macrocyclic arrangement. These molecules, and their various substituted derivatives, make up one of the most important families of supramolecular chemistry.[1] From a coordination chemistry point of view, the parent unsubstituted calixarenes can be considered as large, flexible polyalkoxide ligands whose size and flexibility vary with the number of their phenolic units.[2] The interest and fascinating potential of this class of molecules for the design of new metal complexes is well illustrated by calix[6]arene, which has already been used for the synthesis of compounds containing one,[3] two,[4] three,[5] and even five[6] metal cations. Moreover, like all calix[$n > 5$]arenes, it has a tendency to act as a "cluster keeper"[2c,7] and has been used to stabilise polymetallic species of uranium,[2c] titanium[8] and potassium.[9]

Although the donor properties of the calixarenes have long prompted the interest of coordination chemists in their search for new ligands well-suited for the large and hard cations of the f-elements,[2d] it seems that the coordination chemistry of calix[6]arene as a ligand for the lanthanide family has not yet been investigated in detail. In fact the europium complex $[Eu(H_4L)(OH)(dmf)_6]$ (H_6L = *t*Bu-calix[6]arene) is the only 4f-metal complex of a calix[6]arene derivative whose crystal structure has been solved.[3a] This is all the more surprising, as the supposed most usual 1,2,3-alternate conformation of this macrocycle suggests that it should be an ideal platform for the complexation of two trivalent cations on both sides of the inverted cone (Figure 1). The only example of a calix[6]arene derivative complexing two metal cations is the dimeric $[UO_2(H_2L)]_2$,[4] where the uranyl units (UO_2^{2+}) are sandwiched between the two organic macrocycles in a distorted pinched-cone conformation.

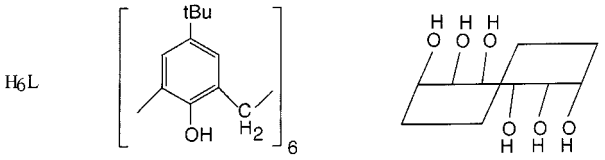

Figure 1. Schematic representation of the 1,2,3-alternate conformation of H_6L

In order to improve the knowledge of the use of H_6L as a ligand towards the lanthanides and to test the possibility of complexing two metal cations on both its coordination sites, we set out to study the reactions of H_6L with lanthanide triflates. We report herein the synthesis of $[\{La(O_3SCF_3)(pyridine)_7\}_2H_2L]$ (**1**), $[\{Sm(O_3SCF_3)(pyridine)_4\}_2H_2L]$ (**2**) and $[\{Yb(O_3SCF_3)(terpyridine)(pyridine)\}_2H_2L]$ (**3**). The solid state structures of **2** and **3** have been determined by X-ray crystallography. Compounds **1**–**3** are the first bis-alkoxy triflate species $\{M(OR)_2(O_3SCF_3)\}$ to be characterized in lanthanide coordination chemistry.

Results and Discussion

Treatment of $Ln(O_3SCF_3)_3$ with H_6L in pyridine led to the formation of a pale-yellow solution of $[\{Ln(O_3SCF_3)(pyridine)_n\}_2H_2L]$ [Scheme 1; Ln = La (**1**), Sm (**2**)]. In the case of ytterbium, an insoluble yellow powder, probably closely related to **1** and **2**, was instantly formed by the reaction. This precipitate was insoluble in hot pyridine and had a tendency to decompose in the other organic solvents.[10] However, it could be successfully dissolved in a mixture of terpyridine and pyridine to afford a bright orange solution of the complex $[\{Yb(O_3SCF_3)(terpyridine)(pyridine)\}_2H_2L]$ (**3**). The synthesis of **3** can

easily be achieved from the addition of stoichiometric amounts of the three reagents in pyridine.

$$2\,Ln(O_3SCF_3)_3 + H_6L \xrightarrow{\text{pyridine}}$$

$$[\{Ln(O_3SCF_3)(pyridine)_x\}_2H_2L] + 4\,[HNC_5H_5][O_3SCF_3]$$

(Ln = **L**a, Sm, x = 7, 4)

$$2\,Yb(O_3SCF_3)_3 + H_6L + terpyridine \xrightarrow{\text{pyridine}}$$

$$[\{Yb(O_3SCF_3)(pyridine)(terpyridine)\}_2H_2L] + 4\,[HNC_5H_5][O_3SCF_3]$$

Scheme 1

One difficulty we had to circumvent in order to fully characterise complexes **1**–**3** was their rapid decomposition when isolated as solids. Although the solutions of the complexes in pyridine can be kept long enough to proceed with crystallisation experiments and analyses, in the form of microcrystalline powders they invariably turned to dark green after a few hours under argon or N_2,[11] even when the samples were kept in the dark to prevent light-induced reactions. No further complexes could be isolated from this stage. This transformation, which has not yet been understood, affects **2** and **3** completely within a few hours, but is slower for **1**. This somewhat puzzling behaviour (air-sensitive complexes are usually less sensitive in the solid state than in solution) could be due to the displacement of coordinated pyridine molecules under vacuum, leading to an increased reactivity with even traces of water or air, or to a redox process leading to the degradation of the calixarene, possibly into its quinone form. As a result, all elemental analysis had to be performed on freshly isolated samples. Compared to its Sm and Yb counterparts, **1** is highly soluble in pyridine thus we did not manage to grow single crystals suitable for an X-ray analysis.[12] The exact stoichiometry of complex **1** had to be determined by mass spectrometry. The solubility of **1** in pyridine, combined with its decomposition in the other usual organic solvents, was a hindrance to its complete purification.[10] In the end, we did not manage to synthesize **1** in its elementally pure form, but only as a triflic acid containing mixture. Solutions of **2** and **3** were allowed to stand and, after a few days, crystals suitable for X-ray crystallography could be recovered. The crystal structures were solved and revealed that in both **2** and **3**, *t*Bu-calix[6]arene acts as a double-bidentate ligand that is able to bind a metal cation on its two symmetry-related coordination sites (Figure 2 and 3).

The molecular structures of **2** and **3** present similarities in the way the trivalent cations are bound to the macrocycle. The metal centres are coordinated by seven donor atoms, the coordination geometry being a distorted, capped trigonal prism.[13] Two σ-bonds are made with phenolate groups of the calixarene. The mean M–O distances are equal to 2.179(5) Å in **2** and 2.07(2) Å in **3**, in good agreement with similar bond lengths found in the literature.[14] The crystal structures of samarium and ytterbium complexes of calixarene derivatives containing an aryloxide bond have only been reported on two occasions but never yet for the parent calixarenes.[15] One unchanged triflate group makes the last σ-bond to the metal. The M–O(triflate) bonds are significantly longer than the alkoxide one and equal to 2.449(4) Å in **2** and to 2.30(1) Å in **3**. Although only a few triflate complexes of Sm and Yb have been characterized crystallographically,[16] bond lengths of that order of magnitude are to be expected from this fairly labile ligand. The rest of the coordination sphere is occupied by nitrogen ligands coming from four pyridine molecule in **2** and from one pyridine molecule and one ter-

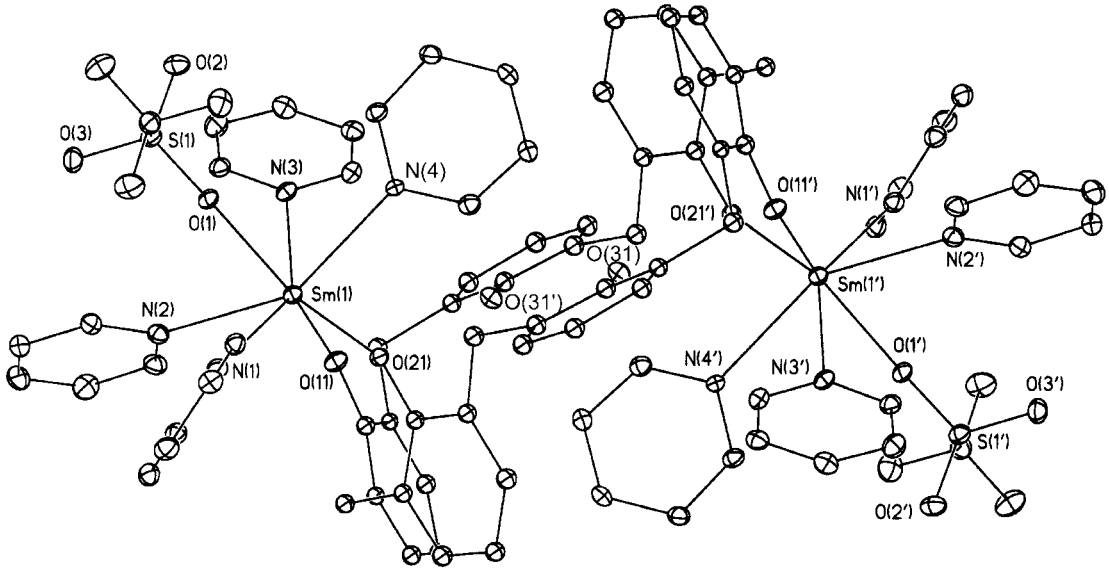

Figure 2. X-ray structure of complex **2** showing partial atom labelling; all *t*Bu groups and hydrogen atoms have been omitted for clarity; selected bond lengths [Å] and angles [°]: Sm(1)–O(1) 2.449(4), Sm(1)–O(11) 2.184(5), Sm(1)–O(21) 2.174(4), Sm(1)–N(1) 2.610(5), Sm(1)–N(2) 2.629(6), Sm(1)–N(3) 2.672(5), Sm(1)–N(4) 2.604(5)

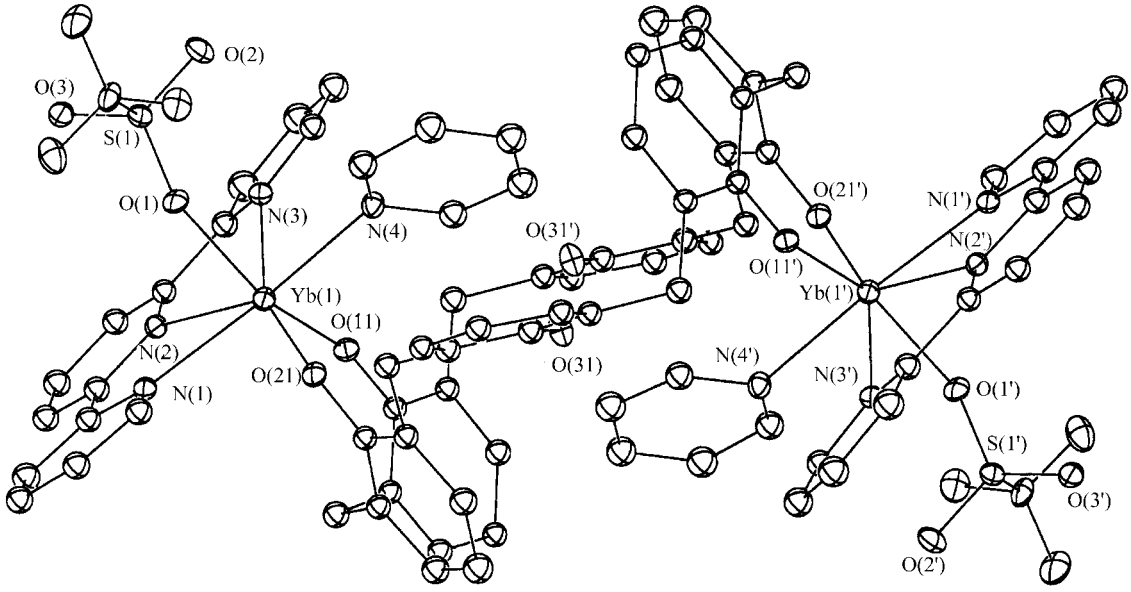

Figure 3. X-ray structure of complex **3** showing partial atom labelling; all *t*Bu groups and hydrogen atoms have been omitted for clarity; selected mean bond lengths [Å] and angles [°]: Yb(1)−O(1) 2.301(4), Yb(1)−O(11) 2.071(6), Yb(1)−O(21) 2.081(9), Yb(1)−N(1) 2.48(2), Yb(1)−N(2) 2.49(2), Yb(1)−N(3) 2.508(5), Yb(1)−N(4) 2.472(4)

pyridine ligand in **3**. The mean M−N bond lengths for the pyridine ligand are 2.63(3) Å in **2** and 2.472(4) Å in **3**, and 2.49(2) Å for the terpyridine ligand in **3**. All M−N distances are unremarkable when compared to literature data.[17] Along the series **1−3**, the number and type of N donor ligands adapt to the decreasing size of the lanthanide cation: whereas seven pyridine molecules are bound to the large La cation in **1**, only four remain on the Sm complex **2** and one in the Yb complex **3,** where the coordination sphere of the cation is completed by a terpyridine molecule. Interestingly, the replacement of three pyridine ligands in **2** by a terpyridine molecule in **3** does not lead to major differences in the coordination geometry of the two complexes, probably because the smaller bite angle imposed by the chelating ligand is balanced by the ionic radius of the smaller cation [N(1)−M−N(3) angles are equal to 147.0(1)° and 126.3(4)° in **2** and **3**, respectively]. The main crystallographic difference between **2** and **3** is the presence of two independent molecules in the asymmetric unit of **3**, both sitting on an inversion centre, thus resulting in a larger cell volume.

The organic macrocycles in **2** and **3** are deprotonated four times and both adopt the same distorted 1,2,3-alternate conformation. The presence of a hydrogen bond between O(31) and O(11′) in **2**, which is absent in **3** [O(31)−O(11′) bond lengths equal to 2.976(5) Å and 3.85(2) Å in **2** and **3**, respectively], could be one reason for the differences that can be observed in the torsion angles φ and χ[1a] of the two complexes.[18] Interestingly, the pyridine ligand bearing N(4) is located within the macrocycle in a niche that is delimited by the aromatic faces bearing O(11′) and O(21′), their methylene bridge and *t*Bu groups.[19] In this respect, the calixarene is both a first- and a second-sphere ligand of the lanthanide cation.[20]

As far as we are aware, such bis-alkoxy triflate species {$M(OR)_2$(triflate)} as **1−3** have not yet been encountered in the coordination chemistry of terminal lanthanide alkoxides. This new combination of ligands, where a metal is anchored by two strong alkoxide bonds to an organic platform but retains a reactive site, could be of interest especially in the field of catalysis in which f-metal alkoxides have long been renowned for their activity.[21] In this respect, calix[4]arene complexes were successfully used as models of d-metal oxide surfaces.[22] The synthesis of **1−3** further reinforces the ideas that large polyalkoxide ligands, such as calixarenes, are appropriate for the design of new metal-complex architectures, and that a rich chemistry can be built at the boundary between macrocyclic, supramolecular and coordination chemistries.

Experimental Section

General: All NMR spectra were performed on a Bruker DPX-200. ^{19}F NMR spectra were referenced internally by addition of $CFCl_3$. Elemental analyses were performed at Service de Microanalyse, I.C.S.N., C.N.R.S., 91198 Gif sur Yvette, France. All reactions were performed in a glove box under a dry N_2 atmosphere. All chemicals were purchased by Aldrich and used without further purification. H_6L was dried under vacuum for 12 hours at 323 K. Pyridine was dried on Na (CAUTION!) and distilled prior use. The mass spectrum of **1** was recorded on a ZAB HF VG-analytical F.A.B. mass spectrometer.

Synthesis of 1: [$La(O_3SCF_3)_3$] (0.150 g, 0.256 mmol) was treated with H_6L[6] (0.125 g, 0.128 mmol) in pyridine (20 mL) at 293 K for 2 hours. The colourless solution obtained was filtered, concentrated under vacuum to 5 mL and toluene was then added (5 mL). After 45 days at 253 K, the yellow powder that had deposited was separated by filtration, washed with toluene and dried under vacuum

to afford $[\{La(NC_5H_5)_2(O_3SCF_3)\}_2(H_2L)]\cdot 2.7(HO_3SCF_3)$ (0.172 g, 0.076 mmol, 30%). – ^{1}H NMR: δ = 0.74 (s, 18 H, *t*Bu), 1.29 (s, 36 H, *t*Bu), 2.82 (d, *J* = 11 Hz, 2 H, Ar–CH_2–Ar), 4.27 (d, *J* = 13 Hz, 4 H, Ar–CH_2–Ar), 4.28 (d, *J* = 13 Hz, 4 H, Ar–CH_2–Ar), 4.36 (d, *J* = 11 Hz, 2 H, Ar–CH_2–Ar), 7.12 (s, 12 H, ArH), 15.35 (br., 2 H, OH). – ^{19}F NMR: δ = –6.56 ($CFCl_3$) – $C_{90.7}H_{102.7}F_{14.1}La_2N_4O_{20.1}S_{4.7}$ (2267.02): calcd. C 48.05, H 4.57, 2.47; found C 48.09, H 4.76, N 2.49.[23] During the course of the reaction an aliquot of the pyridine solution was taken and sent to the mass analysis: *m*/*z* = 2653.94 ($[\{La(O_3SCF_3)(pyridine)_7\}_2H_2L]$).

Synthesis of 2: $[Sm(O_3SCF_3)_3]$ (0.150 g, 0.251 mmol) was treated with H_6L[6] (0.122 g, 0.125 mmol) in pyridine (20 mL) at 293 K for 2 hours. The pale-yellow solution obtained was filtered and concentrated under vacuum to 10 mL. It was then left standing for two days to afford a colourless microcrystalline powder that was filtered off, washed with cold pyridine and dried in vacuo to afford $[\{Sm(NC_5H_5)_6(O_3SCF_3)\}_2(H_2L)]\cdot 0.5(HO_3SCF_3)$ (0.204 g, 0.096 mmol, 77%). – $C_{98.5}H_{110.5}F_{7.5}N_6O_{13.5}S_{2.5}Sm_2$ (2117.87): calcd. C 55.86, H 5.26, N 3.97; found C 55.78, H 4.83, N 3.95. Several recrystallizations from pyridine enabled us to separate $[\{Sm(NC_5H_5)_3(O_3SCF_3)\}_2(H_2L)]$ from residual triflic acid (0.062 g, 0.030 mmol, 24%) – $C_{98}H_{110}F_6N_6O_{12}S_2Sm_2$ (2042.83): calcd. C 57.62, H 5.43, N 4.11; found C 58.17, H 5.62, N 3.88.[23]

Synthesis of 3: $[Yb(O_3SCF_3)_3]$ (0.150 g, 0.242 mmol) was treated with H_6L[6] (0.118 g, 0.121 mmol) and terpyridine (0.057 g, 0.244 mmol) in pyridine (20 mL) at 293 K for 2 hours. The orange microcrystalline powder that formed was filtered off, washed with pyridine and dried in vacuo to afford $[\{Yb(N_3C_{15}H_{11})(O_3SCF_3)\}_2(H_2L)]\cdot(NC_5H_5)$ (0.171 g, 0.079 mmol, 65%). – $C_{103}H_{107}F_6N_7O_{12}S_2Yb_2$ (2159.23): calcd. C 57.30, H 5.00, N 4.54; found C 56.98, H 5.01, N 4.68.[23]

X-ray Crystallographic Studies: Crystal data collection was performed on a Nonius Kappa-CCD diffractometer equipped with a fibre glass collimator.

Crystal Data of 2·4(NC_5H_5): $C_{128}H_{140}F_6N_{12}O_{12}S_2Sm_2$ (2517.34), 0.14 × 0.12 × 0.10 mm^3, triclinic, $P\bar{1}$, *Z* = 1, *a* = 14.852(3), *b* = 15.160(3), *c* = 15.364(4) Å, α = 91.17(3)°, β = 118.85(3), γ = 92.55(3)°, *V* = 3023(2) Å^3, $\rho_{calcd.}$ = 1.382 g·cm^{-3}, *F*(000) = 1298, $2\theta_{max}$ = 51.42°, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), μM_o = 1.070 cm^{-1}, *T* = 100 K. The structure was solved by direct methods[24] and refined on F^2.[25] Of the 20805 reflections measured, 10577 were found to be independent (R_{int} = 0.113), 6735 of which were considered as observed [$I > 2\sigma(I)$]. All reflections were used in the refinement of the 611 parameters, leading to a final R_1 of 0.0625 and an R_{all} of 0.1205. wR_{obs} and wR_2 were equal to 0.1134 and 0.1343, respectively. All atoms were considered anisotropic with the exception of the carbon atoms of the calixarene core, which were kept isotropic in order to keep a reasonable data/parameter ratio. Hydrogen atoms were introduced in the calculation as riding on their parent atom. The goodness-of-fit parameter *S* was 0.983 and the maximum residual density 0.620 eÅ^{-3}. Two other cells corresponding to different solvates were found for the monocrystals of **1** recrystallised from pyridine: **1**·3(NC_5H_5): *a* = 14.84(1), *b* = 15.15(1), *c* = 15.34(1) Å, α = 86.45(3)°, β = 61.15(3), γ = 87.53(3)°, *V* = 3014(7) Å^3; **1**: *a* = 14.929(3), *b* = 13.799(3), *c* = 28.128(5) Å, β = 94.62(3), *V* = 5776(4) Å^3.

Crystal Data of 3·4.5(NC_5H_5): $C_{130.5}H_{134.5}F_6N_{12.5}O_{12}S_2Yb_2$ (2594.21), 0.14 × 0.12 × 0.12 mm^3, triclinic, $P\bar{1}$, *Z* = 2, *a* = 15.679(3), *b* = 15.917(3), *c* = 26.833(4) Å, α = 102.52(3)°, β = 93.12(3), γ = 107.18(3)°, *V* = 6195(2) Å^3, $\rho_{calcd.}$ = 1.391 g.cm^{-3}, *F*(000) = 2654, $2\theta_{max}$ = 51.56°, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), μM_o = 1.607 cm^{-1}, *T* = 100 K. The structure was solved by direct methods[24] and refined on F^2.[25] Of the 32794 reflections measured, 19393 were found to be independent (R_{int} = 0.124), 8349 of which were considered as observed [$I > 2\sigma(I)$]. All reflections were used in the refinement of the 864 parameters, leading to a final R_1 of 0.0884 and an R_{all} of 0.2199. wR_{obs} and wR_2 were equal to 0.1830 and 0.2444, respectively. Solvent pyridine molecules were constrained to regular hexagons. All non-carbon atoms were considered anisotropic, with the exception of the nitrogen atoms of the solvated pyridine molecules. Hydrogen atoms were introduced in the calculation as riding on their parent atoms. The goodness-of-fit parameter *S* was 0.970 and the maximum residual density 0.943 eÅ^{-3}.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-150779 [**2·4(NC_5H_5)**] and -150780 [**3·4.5(NC_5H_5)**]. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Acknowledgments

We would like to thank Dr. Jacques Vicens for helpful discussions throughout the work.

[10] With the exception of pyridine and for **1** of the 1:1 mixture of toluene/pyridine, compounds **1–3** decompose in more or less all the solvents or mixtures of solvents we tried to dissolve them in. They were too reactive to survive in solution containing anhydrous pentane, diethyl ether, tetrahydrofuran or toluene for a long time.

[11] The change of colour from pale-yellow or orange to a dark green was observed for the microcrystalline powders of **1**−**3** even when kept in closed tubes in N_2 or argon atmosphere glove boxes ($O_2 < 1$ ppm). In the end, the complexes had to be kept in glass tubes sealed under vacuum to prevent decomposition.

[12] Concentrated solutions of **1** (0.5 g, 2−5 mL) in pyridine and in mixtures of pyridine and toluene were left standing at room temperature and in the fridge (253 K) for several months but never grew any single crystal suitable for an X-ray analysis.

[13] The geometry around the metal centre is a distorted, capped trigonal prism in both **2** and **3**. O(11)−O(21)−N(1) and N(4)−N(3)−O(1) define the faces of the prism and N(2) caps the O(11)−N(3)−O(1)−N(1) face.

Dinuclear Cobalt(II) Complexes of an Acyclic Phenol-Based Dinucleating Ligand with Four Methoxyethyl Chelating Arms − First Magnetic Analyses in an Axially Distorted Octahedral Field

Hiroshi Sakiyama,*[a] Rie Ito,[a] Hitoshi Kumagai,[b] Katsuya Inoue,[b] Masatomi Sakamoto,[a] Yuzo Nishida,[a] and Mikio Yamasaki[c]

Keywords: Dinuclear cobalt(II) complex / Dinucleating ligand / Crystal structure / Magnetic properties

An end-off type acyclic ligand with four methoxyethyl chelating arms, 2,6-bis[bis(2-methoxyethyl)aminomethyl]-4-methylphenol [H(bomp)], formed dinuclear cobalt(II) complexes $[Co_2(bomp)(MeCO_2)_2]BPh_4$ (**1**) and $[Co_2(bomp)(PhCO_2)_2]BPh_4$ (**2**). X-ray analysis revealed that complex **1**·$CHCl_3$ contains two cobalt ions bridged by a phenolic oxygen and two acetate groups, forming a μ-phenoxo-bis(μ-acetato)dicobalt(II) core. Magnetic susceptibility was measured for **1** and **2** over the temperature range 1.8–300 K. The data were successfully analyzed using a new theoretical method assuming an axially distorted octahedral field (Δ = 753 and 775 cm^{-1}, respectively) for each cobalt(II) ion to reveal weak antiferromagnetic interactions (J = −0.96 and −1.74 cm^{-1}, respectively).

Introduction

Dinuclear cobalt complexes have attracted our interest since the active site structure of methionine aminopeptidase (MAP, EC 3.4.11.18) was revealed to contain a bis(μ-carboxylato)dicobalt(II,II) core.[1] From the point of view of coordination chemistry, it is interesting and invaluable to study the relationship between dinuclear structures and their properties and functions. In order to synthesize the dinuclear metal complexes systematically, the development of multinucleating ligands is of importance. We have developed an acyclic dinucleating ligand 2,6-bis[bis(2-methoxyethyl)aminomethyl]-4-methylphenol [H(bomp)].[2] The dinuclear zinc(II) complexes[2] and dinuclear manganese(II) complexes[3] of this ligand have been reported. The ligand consists of a phenolate head unit, two aminomethyl shoulders, and four methoxyethyl arms, providing two NO_3 coordination sites. The dizinc(II) complexes have been shown to possess an aminopeptidase function in removing *N*-terminal amino acids from substrates, and the dimanganese(II) complexes have been demonstrated to have a catalytic catalase function in the disproportionation of hydrogen peroxide into water and molecular oxygen.

We are also interested in the magnetism of dinuclear cobalt(II,II) complexes. The lowest orbital state of the free cobalt(II) ion is $^4F_1$, and the second lowest $^4P_1$ is more than 10^4 cm^{-1} higher. In the week field of O_h symmetry,[4] the $^4F_1$ term sprits into $^4T_{1g}$, $^4T_{2g}$, and $^4A_{2g}$ terms, in that order, whereas the $^4P_1$ term is not split and remains in the $^4T_{1g}$ state. As the ground state of the high-spin cobalt(II) is $^4T_{1g}$,

under pure O_h symmetry, the contribution of the orbital momentum cannot be ignored, and it is the most significant one among 3d transition elements.[5] The orbital momentum complicates the magnetic equations, a difficulty that has prevented many coordination chemists from analyzing the magnetic data of the cobalt(II) complexes.

As long ago as 1963, Lines introduced a calculation method for $^4T_{1g}$-ground-state magnetism[6] in an axially distorted octahedral field, considering the axial field splitting and the spin-orbit coupling. In the 1960s, Figgis also introduced a method considering the axial field for $^2T_{1g}$,[7] $^3T_{1g}$,[8] $^5T_{1g}$,[9] and $^4T_{1g}$,[10] showing that the axial field treatment is useful for analyzing cryomagnetic data of mononuclear cobalt(II) complexes. This successful study corresponded to a mononuclear case, but, in 1971, Lines reported a theory for the analysis of the magnetic coupling between two high-spin cobalt(II) ions of pure O_h symmetry using temperature-dependent Hamiltonian.[11] This remarkable theory enabled the analysis of the magnetic data of some dinuclear cobalt(II) complexes,[12] but it was limited to only highly symmetrical cases.

In this study, we have synthesized new dicobalt(II) complexes using the dinucleating ligand bomp$^-$, and their cryomagnetic data have been analyzed using a newly obtained set of magnetic equations for dinuclear cobalt(II) complexes in lower symmetry. In this method, the axial splitting parameter Δ is adopted according to Figgis and Lines, avoiding overparameterization, to describe the axial distortion. The axial splitting parameter Δ is defined as the splitting of the orbital degeneracy of the $^4T_{1g}$ term by the asymmetric ligand component, in the absence of any spin-orbit coupling, and is taken to be positive when the orbital singlet is lowest. This enables us to analyze the data using only four variables, the axial splitting parameter Δ, the spin-orbit coupling λ, the orbital reduction factor κ, and the coupling constant J. The axial zero-field splitting parameter D and the anisotropic g-factors, g_z and g_x, can be calculated using the four variables. To the best of our knowledge, this is the first standard analytic method for the magnetism of dinuclear high-spin cobalt(II) complexes in lower symmetry, except for the specific low-temperature study,[13] and these complexes are the first examples whose cryomagnetic data are analyzed in the whole temperature range using the method in lower symmetry.

Results and Discussion

X-ray Crystal Structure of Complex 1·CHCl$_3$

The crystal structure consists of $[Co_2(bomp)(MeCO_2)_2]^+$ complex cations, tetraphenylborate anions, and chloroform molecules in a 1:1:1 molar ratio. The structure of the complex cation is depicted in Figure 1. Selected distances and angles with their estimated standard deviations are listed in Tables 1 and 2. The complex cation consists of one dinucleating ligand bomp$^-$, two cobalt(II) ions, and two acetate groups. The two cobalt ions are bridged by the one phenolic oxygen of bomp$^-$ and the two acetate ions, forming a μ-phenoxo-bis(μ-acetato)dicobalt(II) core structure. The Co(1)···Co(2) separation is 3.3360(3) Å.

Co(1) has a distorted octahedral geometry with O(1), O(2), O(3), and N(1) of bomp$^-$ and O(6) and O(8) of the two acetate groups. Coordination geometry around Co(2) is also distorted octahedral with O(1), O(4), O(5), and N(2) of bomp$^-$ and O(7) and O(9) of the two acetate groups. The geometries around Co(1) and Co(2) are very similar to each other, and the complex cation has a pseudo C_2 axis along C(14), C(4), C(1), and O(1). The least-squares plane of the aromatic ring of bomp$^-$ and the plane defined by Co(1), Co(2), and O(1) are twisted with a dihedral angle of 46.0°. The bond lengths between the cobalt atoms and axial ether oxygen atoms [2.200(1)−2.229(1) Å] are longer than those between cobalt atoms and equatorial ether oxygen atoms [2.156(1)−2.160(1) Å] (Figure 2). This tendency has also been observed in the related dizinc(II) complexes with acetate bridges.[2] However, in the dimanganese(II) complexes with benzoate bridges, all the manganese-oxygen(ether) bonds have almost the same length.[3] This may be explained by the steric repulsion between the two bridging benzoate ions and methoxy groups of the dinucleating ligand bomp$^-$. Thus, the symmetry around the metal ions in the benzoate-bridged complex cations is higher than that of the acetate complexes.

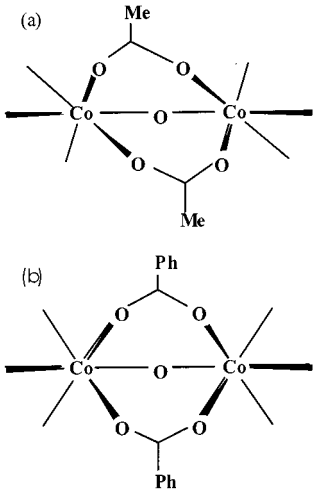

Figure 2. Schematic drawing of dinuclear cobalt(II) cores for (a) complex **1** and (b) complex **2**

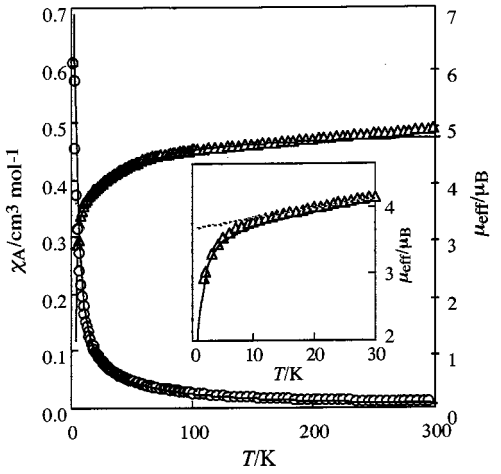

Figure 3. Temperature dependence of χ_A (O) and μ_{eff} (Δ) of the complex **1**. Dashed curves are based on equations (2a) in the text, using $\kappa = 0.96$, $\lambda = -140$ cm^{-1}, and $\Delta = 753$ cm^{-1}. Solid curves are based on a set of equations in the supplementary material section, using $\kappa = 0.96$, $\lambda = -140$ cm^{-1}, $\Delta = 753$ cm^{-1}, and $J = -0.96$ cm^{-1}

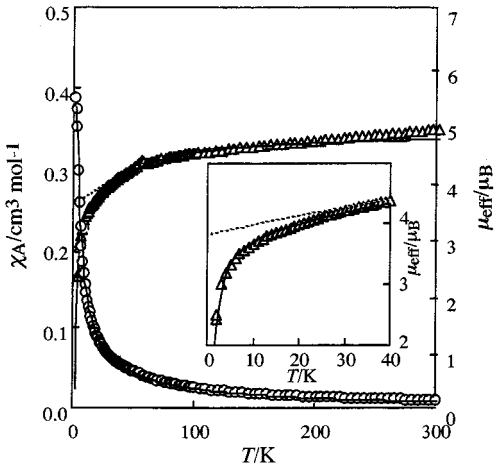

Figure 4. Temperature dependence of χ_A (O) and μ_{eff} (Δ) of the complex **2**. Dashed curves are based on equations (2a) in the text, using $\kappa = 0.92$, $\lambda = -156$ cm^{-1}, and $\Delta = 775$ cm^{-1}. Solid curves are based on a set of equations in the supplementary material section, using $\kappa = 0.92$, $\lambda = -156$ cm^{-1}, $\Delta = 775$ cm^{-1}, and $J = -1.74$ cm^{-1}

Magnetic Susceptibility of Complexes 1 and 2

Magnetic susceptibility measurements for cobalt complexes **1** and **2** were made on polycrystalline samples in the temperature range 1.8−300 K. The temperature dependence of χ_A and μ_{eff} per Co for **1** and **2** is shown in Figures 3 and 4. The μ_{eff} values per Co^{II} of the complexes at room temperature are 4.93 and 4.90 μ_B, respectively. These values are larger than the spin-only value of high-spin cobalt(II) (3.87 μ_B; $\mu_{SO} = [4S(S + 1)]^{1/2}$; $S = 3/2$), but close to the value expected when the spin momentum and the orbital momentum exist independently [5.20 μ_B; $\mu_{LS} = [L(L + 1) + 4S(S + 1)]^{1/2}$; $L = 3$, $S = 3/2$]. This indicates a contribution of the orbital momentum typical for the $^4T_{1g}$ ground state. The magnetic moments decrease with decreasing temperature, and three factors are considered to elucidate this phenomenon; (1) the contribution of the orbital momentum, (2) an intramolecular antiferromagnetic coupling between two Co^{II} centers, and (3) an intermolecular antiferromagnetic coupling. However, we neglect the intermolecular coupling in this study since the X-ray analysis shows the dinuclear cobalt(II) centers to be well separated from each other. In order to evaluate the two remaining effects, we first tried to analyze the experimental cryomagnetic data using the isotropic one-ion approximation with the spin-orbit coupling in pure O_h symmetry, $\boldsymbol{H} = -(3/2)\kappa\,\lambda\,\boldsymbol{L}\cdot\boldsymbol{S} + \beta[-(3/2)\kappa\,\boldsymbol{L} + g_e\boldsymbol{S}]\cdot H$. A magnetic susceptibility equation was obtained as follows;[5,10]

$$\chi_A = \frac{N\beta^2}{kT}\frac{F_1}{F_2} \quad (1a)$$

$$F_1 = \frac{63}{20}(-2+\kappa)^2 x + \frac{2(4+3\kappa)^2}{25\kappa} + [\frac{2}{45}(11-3\kappa)^2 x + \frac{88(4+3\kappa)^2}{2025\kappa}]\exp(-\frac{15\kappa}{4}x) + [\frac{1}{36}(10+3\kappa)^2 x - \frac{10(4+3\kappa)^2}{81\kappa}]\exp(-6\kappa x) \quad (1b)$$

$$F_2 = x[3 + 2\exp(-\frac{15\kappa}{4}x) + \exp(-6\kappa x)] \quad (1c)$$

where $x = \lambda/(k\ T)$, λ is the spin-orbit coupling, κ is the orbital reduction factor, and other symbols have their usual meanings. The cryomagnetic data could not be explained by this equation. The magnetic interaction between intramolecular two cobalt(II) ions has also been taken into consideration using Lines' isotropic theory,[11] but the simulation was not successful. This is probably due to the trigonal distortion around the cobalt(II) centers.

Secondly, we considered the distortion around the cobalt(II) ions for the magnetic data analysis introducing the axial splitting parameter Δ. It has been shown that the axial parameter Δ can be used in both the trigonal and the tetragonal field.[7,8] In the higher temperature range ($k\ T >> |J|$), one-ion approximation is available, and a magnetic susceptibility equation for a mononuclear model was obtained[5,6,10] using the van Vleck formula[15] as follows;

$$\chi_A = \frac{\chi_z + 2\chi_x}{3} \quad (2a)$$

$$\chi_{z(x)} = N\frac{\sum_n (\frac{E^{(1)}_{z(x),n}}{kT})^2 - 2E^{(2)}_{z(x),n})\exp[\frac{-E^{(0)}_n}{kT}]}{\sum_n \exp[\frac{-E^{(0)}_n}{kT}]} \quad (2b)$$

Energies $E^{(0)}_n$, $E^{(1)}_{n,z(x)}$, and $E^{(2)}_{n,z(x)}$ ($n = \pm1-\pm6$) were calculated by solving the 12×12 secular matrix,[5,6] and the resulting energy equations are shown in the supplementary material section. An important feature of this method is that only three parameters, namely, κ, λ, and Δ, are required for analyzing the cryomagnetic data in an axially distorted octahedral field. The data were well simulated in the temperature range 50−300 K for each complex, and calculated curves are also shown in Figure 3 and 4. Fitting parameters were $\kappa = 0.96$, $\lambda = -140$ cm^{-1}, and $\Delta = 753$ cm^{-1} for complex **1**, and $\kappa = 0.92$, $\lambda = -156$ cm^{-1}, and $\Delta = 775$ cm^{-1} for **2**. The g values were calculated as $g_z = 2.18$ and $g_x = 4.97$ for **1** and $g_z = 2.20$ and $g_x = 4.93$ for **2**. Agreement factors defined as $R = \Sigma(\chi_A^{calcd.} - \chi_A^{obs})^2/\Sigma(\chi_A^{obs})^2$ were 1.4×10^{-4} and 3.6×10^{-4}, respectively.

The spin-orbit coupling λ for cobalt(II) ion is theoretically expected to be -172 cm^{-1}. The λ value for the complex **2** is slightly smaller than this, and the value for complex **1** is much smaller. The orbital reduction factor κ means the reduction of the orbital momentum caused by the delocalization of the unpaired electrons, but it also contains the admixture of the upper $^4T_{1g}(^4P_1)$ state into the $^4T_{1g}(^4F_1)$ ground state. In the free cobalt(II) ion, $\kappa_{free\ ion}$ is known to be ≈0.93,[11,16] but smaller values such as ≈0.75 are also obtained when the physical distortion is large.[11] Known values of the axial splitting Δ are in the range ≈200−≈800 cm^{-1}.[10] The three parameters obtained for complex **2** are normal, while the parameters for **1** deviate slightly from the normal values. This can be explained by the fact that the symmetry of complex **1** is lower than that of **2**. Thus, the axial approximation is adequate for **2**, but not so much for **1**. In any case, in the low-temperature range, the observed data for both complexes were smaller than the calculated values in one-ion approximation, indicating antiferromagnetic interaction between two cobalt(II) ions in the complex cation.

Finally, the interaction between two cobalt(II) ions is introduced to the axial mononuclear model as a perturbation; $\boldsymbol{H} = -(3/2)\kappa\ \lambda\ \boldsymbol{L}\cdot\boldsymbol{S} + \beta[-(3/2)\kappa\ \boldsymbol{L} + g_e\boldsymbol{S}]\cdot H - J\ \boldsymbol{S}_1\cdot\boldsymbol{S}_2$. When Δ values are in the range 700−800 cm^{-1}, the energy separation between the lowest and the second lowest Kramers doublets, which corresponds to the axial zero-field splitting D, is estimated to be 120−200 cm^{-1}. The magnitude of the coupling constant J is expected to be smaller than 2 cm^{-1} ($|J| < 2$ cm^{-1}) since the susceptibility maximum was not observed[5] in either complex. In these cases ($|J| << |D|$), the perturbation of the magnetic coupling is effective only in the lowest doublet. In other words, upper states can be ignored when the magnetic interaction is observed in the lower-temperature range ($|J| \approx k\ T << |D|$), while the magnetic interaction can be neglected when the second lowest state is thermally populated in the higher-temperature range ($|J| << |D| \approx k\ T$). The same one-ion energy equations can be used, but the susceptibility equations were slightly modified (see supplementary material section). The data were well simulated in the whole temperature range using four parameters, namely, κ, λ, Δ, and J. The best-fitting parameters were $\kappa = 0.96$, $\lambda = -140$ cm^{-1}, $\Delta = 753$ cm^{-1}, $J = -0.96$ cm^{-1}, $g_z = 2.18$, and $g_x = 4.97$, and $R = 5.3 \times 10^{-4}$ for complex **1**. The corresponding parameters for complex **2** were $\kappa = 0.92$, $\lambda = -156$ cm^{-1}, $\Delta = 775$ cm^{-1}, $J = -1.74$ cm^{-1}, $g_z = 2.20$, $g_x = 4.93$, and $R = 3.6 \times 10^{-4}$ (Table 3). In order to ascertain the resulting parameters, the low-temperature data ($T < 30$) were also analyzed by the method considering only the ground Kramers doublet,[13] using the g-factors obtained above. The results were $J = -0.85$ cm^{-1}, $g_z = 2.18$, $g_x = 4.97$, $N\alpha = 0.35$ cm^{3}mol^{-1}, $R = 7.5 \times 10^{-5}$ for **1** and $J = -1.54$ cm^{-1}, $g_z = 2.20$, $g_x = 4.93$, $N\alpha = 0.24$ cm^{3}mol^{-1}, $R = 3.9 \times 10^{-4}$ for **2**. The J value obtained previously for each complex is in good agreement with the corresponding value obtained from the low-temperature data.

Table 3. Magnetic data for complexes **1** and **2**

Complex	κ	λ/cm^{-1}	Δ/cm^{-1}	J/cm^{-1}	g_z	g_x	D/cm^{-1}	$R/10^{-4}$
1	0.96	-140	753	-0.96	2.18	4.97	125	5.3
2	0.92	-156	775	-1.74	2.20	4.93	138	3.6

Limitations of Our New Theoretical Method

In this study, we have developed a new equation set for analyzing the magnetism of dinuclear high-spin cobalt(II) complexes in lower symmetry. Axial symmetry has been assumed for each cobalt(II) ion; thus, the theory is available for a trigonally-distorted octahedral field and a tetragonally-distorted one. When the symmetry around the cobalt(II) ions is rhombic and cannot be approximated by the axial field, this method is no longer useful. When the magnetic coupling between any cobalt(II) ions is negligible ($J = 0$), the magnetic equation set is completely the same as that of the axially distorted mononuclear model of Figgis and Lines. In the present theory, magnetic coupling was considered only for the lowest doublet. This approximation is valid when the coupling constant J is much smaller than the axial zero-field splitting D ($|J| << |D|$). It has been reported that the axial splitting Δ of the cobalt(II) ions in normal mononuclear cobalt(II) complexes is in the range 200−800 cm^{-1},[10] and the axial zero-field splitting is in the range 120−330 cm^{-1}. Usually, the magnitude of the coupling constant J is smaller than 10 cm^{-1} ($|J| < 10$ cm^{-1}); thus, the approximation we used in this study is expected to be useful for most dinuclear high-spin cobalt(II) complexes. However, it should be emphasized again that there is a limit in the symmetry around the cobalt(II) ion. (1) If the symmetry is isotropic ($\Delta \approx 0$), Lines' theory[11] would be preferable for the estimation of the J value. (2) If the symmetry is axial, the method we have shown in this study may be more useful than Lines' theory. (3) If the symmetry is rhombic, no method is useful at this moment, to the best of our knowledge.

Conclusion

In this study, two dinuclear cobalt(II) complexes (**1** and **2**) were made using the dinucleating ligand, $bomp^-$, and the crystal structure of complex **1** was determined. For the purpose of analyzing the cryomagnetic data, a new theoretical method was developed assuming an axially distorted octahedral field, and the experimental data were analyzed. This is the first successful magnetic analysis for dinuclear high-spin cobalt(II) complexes in an axially distorted octahedral field.

Experimental Section

Measurements: Elemental analyses were obtained at the Elemental Analysis Service Centre of Kyushu University. − Infrared (IR) spectra were recorded on a Hitachi 270−50 spectrophotometer. − Fast atom bombardment (FAB) mass spectra were measured on a Fisons ZabSpec Q mass spectrometer in *N*,*N*-dimethylformamide (DMF) with a glycerol matrix. − Molar conductances were measured on a DKK AOL-10 conductivity meter at room temperature. − Electronic spectra were recorded on a Shimadzu UV-240 spectrophotometer. − Magnetic susceptibility was measured between 1.8 and 300 K by using a Quantum Design SQUID magnetometer MPMS-5S in fields up to 5 T. All the magnetic calculations were made using the MagSaki[17] magnetic software program of our laboratory.

Materials: All chemicals were commercial products, and were used as supplied. The ligand Na(bomp) was prepared by the method reported previously.[2]

Synthesis of $[Co_2(bomp)(MeCO_2)_2]BPh_4$ (1): To a methanolic solution (15 mL) of Na(bomp) (1.0 mmol, 0.42 g) was added cobalt(II) acetate dihydrate (2.0 mmol, 0.50 g), and the resulting solution was heated under reflux for 1 h to give a pink solution. The addition of sodium tetraphenylborate (1.0 mmol, 0.34 g) resulted in the precipitation of pink microcrystals. The compound was recrystallized from a mixture of acetonitrile and 2-propanol. Yield: 0.23 g (24%). − $C_{49}H_{63}BCo_2N_2O_9$: calcd. C 61.75, H 6.65, N 2.95, Co 12.4; found C 61.60, H 6.65, N 2.90, Co 12.4. − Selected IR data (KBr): $\tilde{\nu}$ = 3050−2900, 1600, 1410, 1090, 730, 700 cm^{-1}. − FAB mass spectrum: m/z = 633 $[Co_2(bomp)(MeCO_2)_2]^+$. − Molar conductance [in DMF] = 46 Λ_M/Scm^2mol^{-1}. − UV/Vis: λ_{max} (ε/$dm^3cm^{-1}mol^{-1}$, in DMF) = 485 (30), 512 (35) nm.

Synthesis of $[Co_2(bomp)(PhCO_2)_2]BPh_4$ (2): This was prepared as pink microcrystals by a method similar to that of **1**, using cobalt(II) benzoate instead of cobalt (II) acetate tetrahydrate. Yield: 0.24 g (23%). − $C_{59}H_{67}BCo_2N_2O_9$: calcd. C 65.80, H 6.25, N 2.60, Co 11.0; found C 65.80, H 6.25, N 2.60, Co 10.9. − Selected IR data (KBr): $\tilde{\nu}$ = 3050−2900, 1610, 1400, 1085, 730, 700 cm^{-1}. − FAB mass spectrum: m/z = 757 $[Co_2(bomp)(PhCO_2)_2]^+$. − Molar conductance (in DMF) = 43 Λ_M/Scm^2mol^{-1}. − UV/Vis λ_{max} (ε/$dm^3cm^{-1}mol^{-1}$, in DMF) = 480 (40), 510 (45) nm.

Single Crystal X-ray Analysis of Complex 1·$CHCl_3$: Crystal data: $C_{50}H_{64}BCo_2Cl_3N_2O_9$, M = 1072.10, a = 13.2229(6), b = 14.5043(9), c = 16.0204(8) Å, α = 68.8982(6), β = 82.022(1), γ = 64.279(2)°, V = 2581.9(2) $Å^3$, Z = 2, $d_{calcd.}$ = 1.379 g cm^{-3}, triclinic, space group $P\bar{1}$ (no. 2), $F(000)$ = 1120.00. − Data collection: A purple prismatic crystal of **1**·$CHCl_3$ having approximate dimensions of 0.40 × 0.40 × 0.30 mm was mounted in a loop. All measurements were made on Rigaku/MSC Mercury CCD diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71069 Å). The ω scan was made to a maximum 2θ value of 54.6° at −170 ± 1 °C. Of the 29279 reflections, 11541 were unique (R_{int} = 0.019), and $I > 2.0\,\sigma(I)$ data were used. The linear absorption coefficient μ(Mo-K_α) was 8.53 cm^{-1}. A symmetry-related absorption correction was applied, which resulted in transmission factors ranging from 0.62 to 0.77. The data were corrected for Lorentz and polarization effects. − Structural analysis and refinement: The structure was solved by direct methods,[18] and expanded using Fourier techniques.[19] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined isotropically. The final cycle of full-matrix least-squares refinement was based on 11541 observed reflections. The final values of R and R_w were 0.065 and 0.147, respectively ($R = \Sigma||Fo| - |Fc||/\Sigma\,|Fo|$, $R_w = \{\Sigma w(|Fo| - |Fc|)^2/\Sigma\ wFo^2\}^{1/2}$). All calculations were performed using the teXsan[20] crystallographic software package of Molecular Structure Corporation.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-151304. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Conformational Preferences of Racemic Ethylene-Bridged Bis(indenyl)-Type Zirconocenes: An ab initio Hartree−Fock Study

Mikko Linnolahti,*[a] Tapani A. Pakkanen,*[a] Reko Leino,[b] Hendrik J. G. Luttikhedde,[b][‡] Carl-Eric Wilén,[b] and Jan H. Näsman[b][†]

Keywords: Ab initio calculations / Conformational analysis / Metallocenes / Polymerization catalysts / Zirconium

The ab initio Hartree–Fock method has been utilized to rationalize the conformational preferences of racemic ethylene-bridged bis(indenyl)-type zirconocenes in dichloride and cationic methyl forms. This group of catalysts is characterized by conformational isomerism due to fluxionality of the ethylene bridge resulting in two distinct orientations of the indenyl ligands, indenyl-forward (Π) and indenyl-backward (Y). A systematic investigation of the influence of methyl and trialkylsiloxy substitution on the relative stabilities of Π and Y conformations was performed. For the dichloride catalyst precursors the stabilities and orientations of the equilibrium structures are determined on the basis of repulsive interactions within the ligand framework. In the cationic methyl intermediates of the olefin polymerization catalytic cycle, the electron-rich indenyl ligand appears to reduce the electron deficiency of the cation by tilting towards the metal.

Introduction

Homogeneous olefin polymerization catalysis currently represents the most significant application of metallocenes.[1] The field has been extensively studied by experimental techniques[2−4] and, during the last decade, also by theoretical approaches.[5−120] Undoubtedly, the most influential breakthroughs have been the discoveries of isospecific polymerization of propylene by C_2-symmetric racemic *ansa*-metallocenes,[121] together with the activation of metallocene catalyst precursors with methylaluminoxane (MAO) co-catalyst.[122]

A distinct characteristic of two-atom bridged metallocenes is the conformational freedom of their five-membered metallacycles. The combination of an ethylene bridge with bis(indenyl)- or bis(tetrahydroindenyl)-based ancillary ligands results in two limiting conformations, indenyl-forward (Π) and indenyl-backward (Y) (Figure 1). If the barrier for transformation is small, the interconversion between the conformers may be rapid. In such case both conformations exist in solution and the crystal structure solely is inadequate to describe the structure of the catalyst precursor. Furthermore, notwithstanding the maintenance of C_2 symmetry, the polymerization properties, especially the stereoregulating ability of the catalytically active species formed from these two catalyst precursors have been proposed to be different.[123]

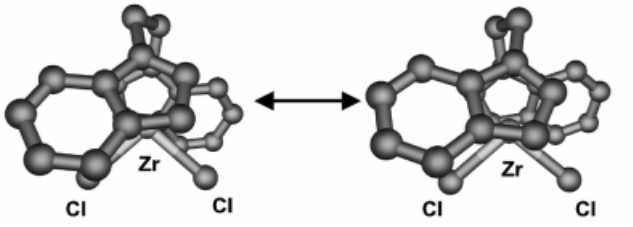

Figure 1. Top view of indenyl-forward (Π) and indenyl-backward (Y) conformations of bis(indenyl)zirconocene dichlorides

In most cases, racemic ethylene-bridged bis(indenyl)-type metallocenes crystallize in the Π conformation,[123−127] apparently due to larger nonbonding interactions within the ligand in the Y conformation.[128] The less favorable Y conformation has been observed for at least some group-IV bis(indenyl) and bis(tetrahydroindenyl) adducts and amido complexes,[129−132] but also for 2,4,7-Me_3-substituted ethylenebis(indenyl)zirconium dichloride[133] as well as for the majority of trialkylsiloxy-substituted metallocenes.[134−138] Hence, the role of ligand substituents in determination of the preferred conformation seems apparent. The aim of the present study is to clarify the relationship between the degree of ligand substitution and the preferred conformation for both dichloride precursors and cationic intermediates of olefin polymerization process.

Computational Details

Calculations were carried out with a Gaussian 94 program package,[139] using the restricted Hartree−Fock method with a standard double-zeta basis set, 3-21G*. Earlier work based on a data set of 62 bridged zirconocene dichlorides demonstrated that the HF/3-21G* method pro-

vides reliable structures for zirconocenes, the accuracy being comparable to the more expensive BLYP,[140,141] B3LYP,[141,142] and MP2 calculations with larger basis sets.[118] The good performance of the HF/3-21G* method is apparently due to small near-degeneracy and relativistic effects in several complexes of zirconium,[143,144] including zirconocenes. Furthermore, the Hartree−Fock method should be reasonable for conformational energetics[145] regardless of the lack of electron correlation, since its influence on rotational barriers is insignificant.[146]

The interconversion barrier between the Π and Y conformations was studied by systematic modification of the torsion angle of the ethylene bridge. The torsion angle was specified to a certain value while the rest of the molecule was fully optimized. The specified torsion angle was changed with intervals of 10°, after which the new constrained structure was optimized. In order to obtain the structures and energies for the local minima, the bridge constraints of the nearest intermediate structures were relieved and a full geometry optimization without symmetry constraints was performed. In order to confirm the local minima and to obtain zero-point corrections to the total energy, frequency calculations were carried out.[147] The influences of zero-point corrections on relative stabilities of the conformers are very small, on average 0.4 kJ/mol and at maximum 0.9 kJ/mol, and are therefore omitted in the interpretation of the calculations.

As a result of the procedure, the structures of the limiting Π and Y conformations and the relative stabilities of the Π−Y transformations were obtained as a function of the ethylene bridge torsion. It should be noted that the relative stability alone does not determine the preferred conformation. Crystal packing effects may be a contributory cause, since the molecules must be accommodated in the crystal lattice.

Results and Discussion

Π−Y Transformation in Dichloride Precursors

Schematic structures of the studied racemic zirconocenes are presented in Figure 2. In addition to unsubstituted bis(indenyl) (**1**) and bis(tetrahydroindenyl) (**2**) complexes, various methyl- (**3**) and siloxy-substituted (**4**) complexes were investigated. A detailed interpretation of the results follows.

Unsubstituted Ligands

The energetics for the Π−Y transformation of **1** and **2** are shown in Figure 3. The barriers for rotation are low, as verified experimentally for **1** by NMR at room temperature,[123] suggesting a feasible interconversion between the conformers. The orientation of the ethylene bridge in the Π and Y conformations corresponds to the *gauche* conformation of butane. The rotation barriers of approximately 20 kJ/mol are close to the butane *gauche-cis* energy difference of 22 kJ/mol at the HF/3-21G* level. The limit conformations are somewhat distorted from the optimal *gauche* conformation of 67° due to strain of the metallacycle and nonbonding repulsions between the indenyl ring and the ethylene bridge (Figure 4). In the Π conformation the orientation determining repulsion occurs between the bridge and H(2), whereas the orientation of the Y conformation is limited by H(7)−ethylene bridge interaction.

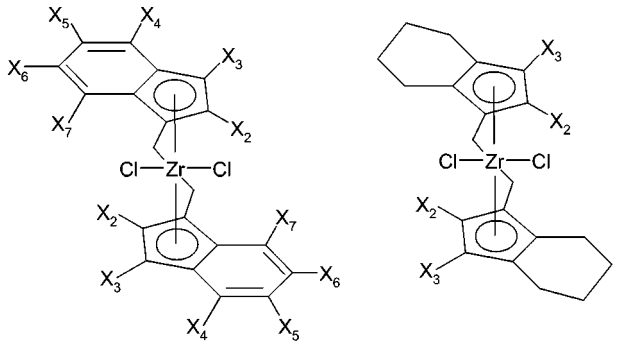

Figure 2. Schematic structures of the studied zirconocene dichlorides; X = H, unless otherwise mentioned

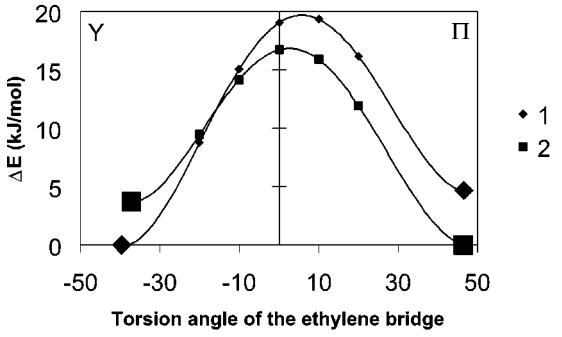

Figure 3. The Π−Y rotation energetics for bis(indenyl)- (**1**) and bis(tetrahydroindenyl)zirconocene dichlorides (**2**); the limiting Π and Y conformations are indicated by larger labels

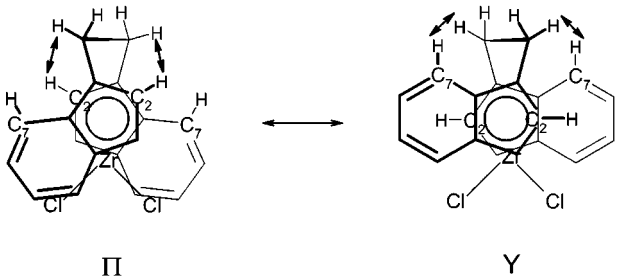

Figure 4. Orientation-determining intramolecular interactions

Both complexes crystallize in the Π conformation,[123,148] apparently due to stronger H(7)−bridge interactions[128] rather than the balancing H(2)−bridge repulsion. The calculations suggest almost identical stabilities for the conformers, in accordance with the earlier molecular mechanics calculations on complex **1**.[133] The small energy differences of approximately 4 kJ/mol are apparently beyond the quantitative accuracy of the method.

Methyl Substituents

The Π−Y transformation energies of monomethyl-substituted bis(indenyl)zirconocene dichlorides are presented in Figure 5. Due to the absence of additional substituent−bridge interactions, the energetics of **3b**−**3e** are nearly identical, also being very similar to the unsubstituted complex **1**. Supposing that the qualitative trends are correct and crystal packing effects are insignificant, **3b**−**3e** should crystallize in the Π conformation similar to **1**, which is true for **3b**, at least.[125] The energetics for **3a** and **3f** are quite different because of a small distance between the substituent and the bridge. The repulsion between the C(2) and the ethylene bridge is the orientation-determining interaction in the Π conformation of **3a**, whereas the Y conformation of **3f** is limited by the C(7)−bridge repulsion.

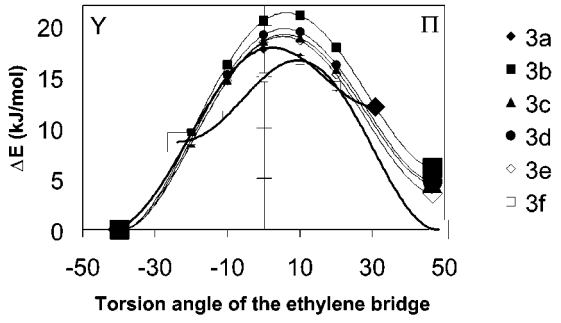

Figure 5. The Π−Y rotation energetics for monomethyl-substituted bis(indenyl)zirconocene dichlorides

Relative stabilities of **3a**−**3f** are given in Table 1. The substituent−bridge repulsion destabilizes the Π conformation of **3a**, while both limit conformations of **3f** become strongly destabilized. This suggests stronger interactions for the latter, hence supporting the earlier proposals.[123,128] Intuitively, it could be assumed that whenever several substituents are simultaneously present, the role of 7-substituent (prefers Π) is the most important, followed by 2-substituent (prefers Y), and that the role of 3-, 4-, 5- and 6-substituents is insignificant.

Table 1. Relative stabilities [kJ/mol] of ethylene-bridged methyl-substituted bis(indenyl)zirconocene dichlorides

	Π	Y
3a	22	10
3b	13	7
3c	5	0
3d	15	11
3e	14	11
3f	39	48

The Π−Y transformation energies are presented in Figure 6 for 2,4-Me_2- (**3g**), 2,7-Me_2- (**3h**), 4,7-Me_2- (**3i**), and 2,4,7-Me_3-substituted (**3j**) complexes. Due to the orientation of 4-methyl groups away from the bridge, the energetics of **3g** and **3i** are identical with the corresponding monomethyl-substituted **3a** and **3b**, respectively. The crystal structure of **3i** is Π,[126] which, as suggested by the calculations, is the more stable conformer due to C(7)−bridge repulsion. This is in accordance with the earlier proposals by Resconi et al.[126]

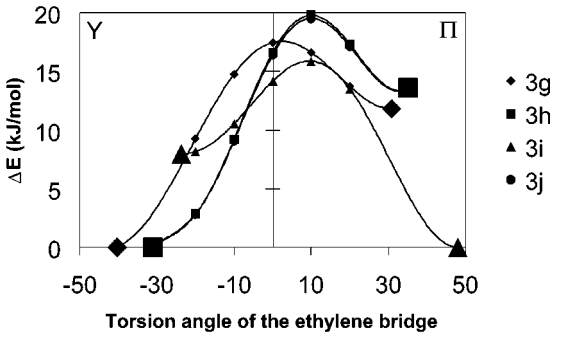

Figure 6. Π−Y rotation energetics for the studied di- and trimethyl-substituted bis(indenyl)zirconocene dichlorides

The presence of both 2- and 7-substituents (**3h** and **3j**) restricts the fluxionality of the ethylene bridge to a narrower area due to methyl−bridge interactions in both conformations. The significant stabilization of the Y conformation despite of generally stronger influence of 7-substituent is not apparent. The explanation is, in fact, further destabilization of the Π conformation, rather than stabilization of the Y conformation. The 2-methyl substituent is forced to interact with the opposite 7-methyl group, and the interaction is much stronger in the Π conformation [see Figure 4 and consider changing the hydrogen atoms of C(2) and C(7) to methyl groups]. Overall, the Y conformation is destabilized due to close contact between 7-Me and the bridge, but the Π conformation is destabilized even more because of the presence of both 2-Me−bridge interactions and the repulsion of the opposite 2-Me and 7-Me substituents. The 4-methyl substituent of **3j** has no relevance. Therefore, as suggested by the calculations, **3j** crystallizes in the Y conformation.[133] This was observed by molecular mechanics calculations as well, even though the local minimum of the unstable Π conformation was not detected.[133]

Siloxy Substituents

Siloxy-substituted zirconocenes represent a uniform group of heteroatom-functionalized group-IV metallocene complexes, showing high activities at reduced co-catalyst concentrations. In the present context, siloxy-substituted zirconocene dichlorides are particularly interesting for two reasons. First, a number of crystal structures are available, making comparisons between stabilities of the limit conformations and identities of the crystal structures possible.

Secondly, most of the crystallographically characterized siloxy-substituted metallocenes favor the generally less common Y conformation. Therefore, the role of the siloxy substituent in determining the preferred conformation deserves a detailed computational investigation.

Five crystallographically characterized siloxy-substituted zirconocenes (**4a**−**4e**) were selected for the study. Depending on the size and position of the substituents, the following classifications can be made. The attached groups are either *tert*-butyldimethylsiloxy groups (**4a**−**4c**) or triisopropylsiloxy groups (**4d**−**4e**), referred to as TBDMS and TIPS, respectively. Depending on the position of the siloxy group, the molecules are denoted 2-siloxy (**4a**, **4b**, **4d**, **4e**) or 1-siloxy (**4c**). The Π−Y transformation energies are presented in Figure 7.

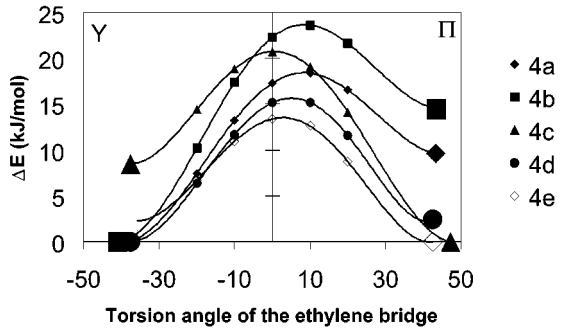

Figure 7. Π−Y rotation energetics for siloxy-substituted zirconocene dichlorides

The 2-TBDMS-substituted complexes (**4a** and **4b**) favor the Y conformation because of repulsions due to the siloxy groups. Each siloxy substituent participates in three close repulsive interactions, namely with one chlorine ligand and with both bridge carbon atoms (Figure 8). However, since the distance between the siloxy substituent and C(1) is constant in both limit conformations, only the repulsions with the oxygen atom and C(2) are orientation-determining. The Cl−O distance of 3.7 Å for the Y conformations and 4.0 Å for the Π conformations indicate smaller repulsions for the latter. On the other hand, the C(2)−O distance is 1.0 Å shorter in the Π conformation. Apparently, the repulsions at the bridge side are more significant than the balancing siloxy−chlorine repulsions. The calculations are in good agreement with experimental observations, since both **4a**[134] and **4b**[135] crystallize in the energetically favored Y conformation.

Increasing the size of the 2-siloxy substituent (TBDMS → TIPS) results in substantial repulsive interactions between the chlorine atom and the carbon atoms of the siloxy group. The Π conformation has more space to accommodate the bulky substituent, as suggested by longer Cl−C(3) distances (Figure 8). Consequently, both limit conformations become destabilized: Π due to the presence of the 2-substituent and Y because of its bulkiness. The destabilization of both conformers leads to lower rotation barriers and to almost equal stabilities. Consequently, **4d**[136] crystallizes

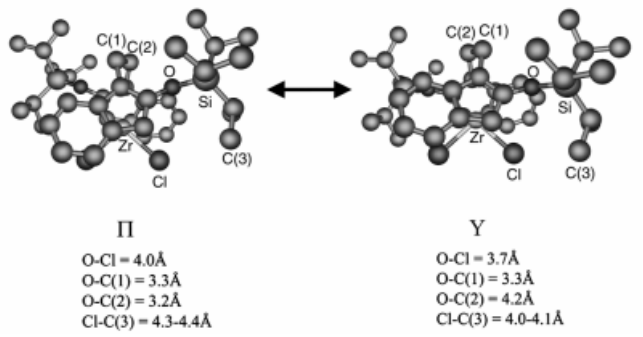

Figure 8. Orientation-determining repulsions in 2-siloxy-substituted zirconocene dichlorides

in the Π conformation while **4e**[136] crystallizes in the Y conformation.

Due to the absence of substituent−bridge interactions, these interpretations are not valid for the 1-siloxy-substituted complex **4c**, in which the siloxy group is directed towards the chlorine atoms. Repulsions with the chlorine atoms are relevant, but constant. Hence, the 1-siloxy substituent has a marginal effect on the preferred limit conformation, and Π is preferred because of its general preference over the Y conformation. This is in agreement with the experimentally determined crystal structure of **4c** (Π).[138]

Cationic Methyl Intermediates

Cationic methyl complexes represent the simplest approximations of the active species. Since the catalytic system is influenced by a number of other components, such as co-catalyst, an accurate consideration of all effects present is not quantitatively feasible. Whenever quantitative accuracy is unattainable, qualitative observations are generally useful. After all, many of the molecular properties are not influenced by the counter ion. In large co-catalyst molecules the negative charge is evenly distributed to a large space. The resulting complex is not a tight ion pair, but can be regarded as a positive complex surrounded by a uniform cloud of negative charge. The structure of such a cation is primarily determined by the internal bonding, which could be qualitatively modeled by the cation itself. It was thus decided to start from the simplest approximation, i.e., the cationic monomethyl metallocene.

Schematic structures of the studied cationic methyl intermediates are presented in Figure 9. The barriers for Π−Y transformation (Figure 10) are slightly lower than for the corresponding dichloride forms. The Π conformation is generally favored, even by the 2-substituted compounds **7** and **8**, despite of substituent−bridge repulsions.

The equilibrium structures of **5** and **6** are presented in Figure 11. In **5Π** the electron deficiency is reduced by electron donation from the indenyl ring to the metal center, resulting in "bending" of the indenyl ring. A similar type of stabilizing interaction has been recently observed in benzyl-substituted zirconocenes.[149,150] The indenyl−metal interaction is less significant in the Y conformation due to closeness of the opposite cyclopentadienyl ring, and espe-

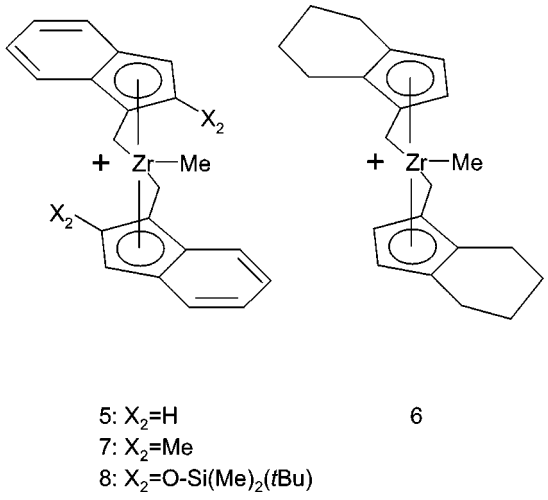

Figure 9. Schematic structures of the studied cationic zirconocenes

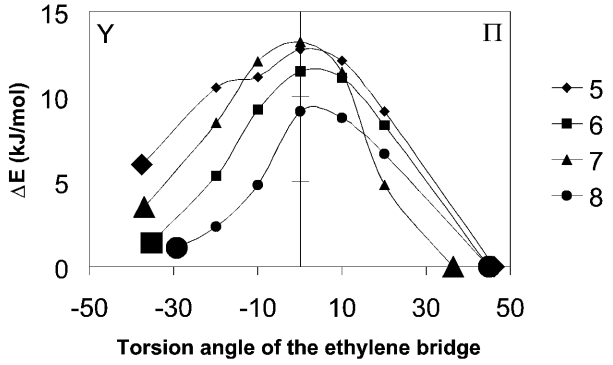

Figure 10. The Π−Y transformation energies for cationic methyl complexes

cially the carbon atom in position 2. The electron donation to the metal ion is absent in **6** as well, due to the saturated tetrahydroindenyl ligand.

By bending towards the metal ion, the quaternary carbon atoms connecting the five- and six-membered rings must distort from the optimal sp^2 hybridization. A number of crystal structures for strained metallocenes showing such distortion are available.[151−157] A direct consequence of the distortion is destabilization of the structure, which in the case of cationic **5Π** is cancelled by greater stabilization due to carbon−metal interaction. In order to verify the relevance of the phenomenon, the energy required for bending of the ring was calculated for the anionic indenyl fragment. The degree of bending, 26°, that was observed for **5Π** leads to destabilization of the structure by 34 kJ/mol. Considering the energy of approximately 80 kJ/mol gained by coordination of C=C double bond of the monomer to the metal center, the tilting of the aromatic ligand seems relevant. Apparently, the degree of bending in **5Π** represents an optimal compromise between destabilization due to distortion from the sp^2 hybridization and stabilization due to electron donation from indenyl to the electron-deficient metal ion.

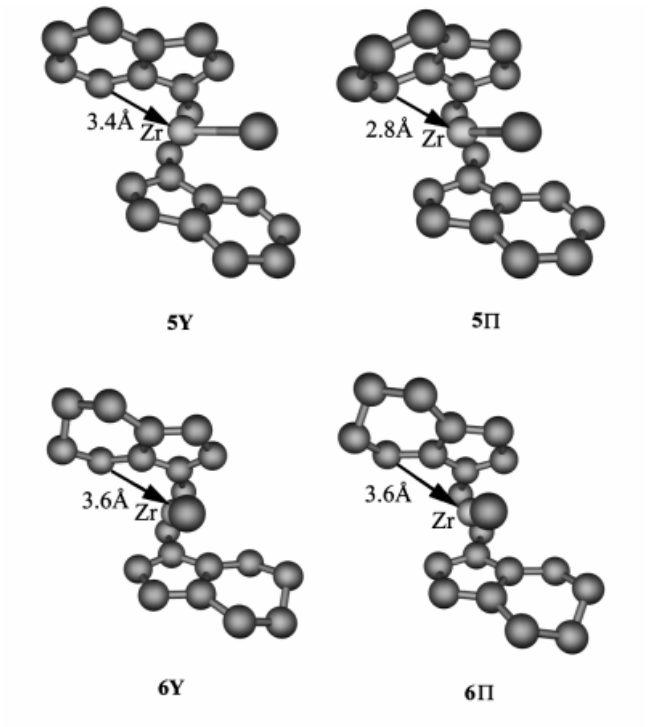

Figure 11. Optimized equilibrium structures of **5** and **6**

The influences of the selected 2-substituents on capability for indenyl bending were studied as well (Figure 12). The stabilization due to ligand−metal interaction is the least significant for unsubstituted **5**, followed by methyl-substituted **7**. The coordination energies for **5** and **7** are very small, less than 5 kJ/mol, and therefore hardly affect the coordination of the incoming monomer. Instead, the coordination energies for siloxy-substituted **8** are much larger, more than 10 kJ/mol for the Π conformation. The presence of indenyl−metal interaction in a real catalytic system would affect the polymerization process in many ways. In addition to minor blocking of the metal center, such interaction would stabilize the cation resulting in higher concentration of cationic metal centers available for the incoming monomer. Possibly, the ligand−metal interaction in combination with the electron-donating siloxy substituent[119] results in an unusually stable active species,[117] as indicated by high catalytic activities at low MAO concentrations.[135,137,158] A third possible consequence could be the increase in the number of different active species with potentially different stereoregulating abilities, possibly resulting in broadening of the molecular weight distributions of the produced polymers.[159]

Conclusion

The indenyl-forward (Π) and indenyl-backward (Y) conformations are relatively similar in energy. Furthermore, the interconversion between the conformers is rapid as also verified experimentally by Resconi et al.[123] Consequently, both conformations can be readily available in the solution,

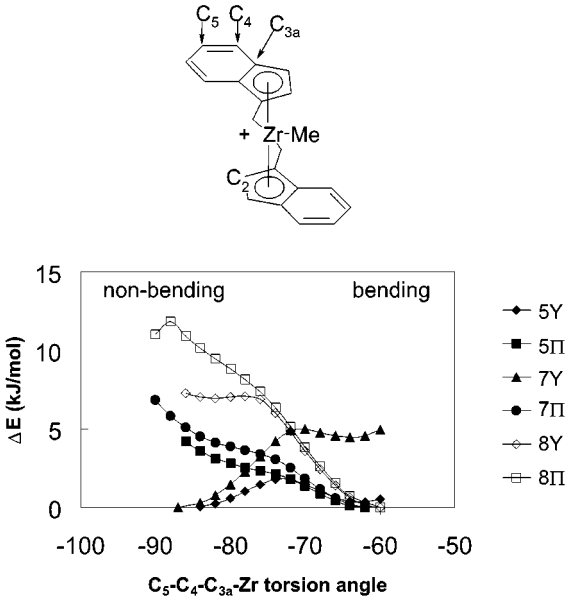

Figure 12. Energetics for the indenyl ring bending

making the crystal structure of the complex alone an inadequate representation for the structure of the precatalyst.

Conformational freedom of dichloride precursors is limited mainly by repulsions within the ligand. In the Π conformation, the most significant repulsion occurs between the bridge and the 2-substituent of the indenyl ring. In the Y conformation, the strongest repulsion can be observed between the bridge and the 7-substituent. These particular repulsions determine the orientations of the ethylene bridge in the limit conformations.

The identities and relative stabilities of the Π and Y conformations are notably changed when the corresponding cationic methyl intermediates of the olefin polymerization catalyst cycle are considered. The electron-rich indenyl ligand donates electrons to the electron-deficient metal ion by tilting towards it. The coordination is less significant for the Y conformation, resulting in general preference of the Π conformation for cations. The strength of the interaction can be controlled by substituents attached to 2-position of the indenyl ligand. The coordination energies are low with hydrogen and methyl substituents, but increase significantly by the introduction of a siloxy group.

[147] In a few cases, a very small imaginary frequency of around 0−10 cm^{-1} was obtained, suggesting a slight distortion form the local minimum conformation. A test calculation using tighter convergence criteria at the cost of increased resource usage resulted in disappearance of the imaginary frequency. However, neither the structure of the molecule nor its energy was affected.

Tetranuclear Complexes Containing Bimetallic Tetracarboxylates and Ferrocene − Models for Subunits of One-Dimensional Organometallic Polymers

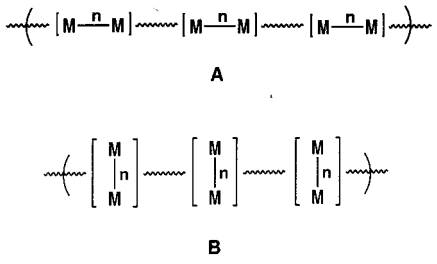
Wen-Mei Xue[a] and Fritz E. Kühn*[a]

Keywords: Metal-metal interactions / Molybdenum / Polymers / Rhodium / Ferrocene

The tetranuclear compounds $M_2(O_2C\text{-}R)_4L_2$ [M = Rh, R = nC_7H_{15}, L = ferrocenyl-4-pyridylacetylene (FPA) (**1a**); M = Rh, R = CH_3, L = FPA (**1b**); M = Mo, R = CF_3, L = FPA (**2b**); M = Rh, R = nC_7H_{15}, L = 4-ferrocenylpyridine (FP) (**3a**); M = Rh, R = CH_3, L = FP (**3b**); M = Mo, R = nC_7H_{15}, L = FP (**4a**); M = Mo, R = CF_3, L = FP (**4b**)] have been synthesized by the reaction of bimetallic tetracarboxylates with L in a 1:2 ratio, in a noncoordinating solvent. The reaction of $Mo_2(O_2C\text{-}nC_7H_{15})_4$ with FPA in a 1:2 molar ratio leads to a trinuclear compound $Mo_2(O_2C\text{-}nC_7H_{15})_4$(FPA) (**2a**). A soluble oligomer $[Rh_2(O_2C\text{-}nC_7H_{15})_4(BPEF)]_n$ [**5**, BPEF = 1,1′-bis(4-pyridylethynyl)ferrocene] is obtained by the reaction of $Rh_2(O_2C\text{-}nC_7H_{15})_4$ with BPEF in a 1:1 ratio in CH_2Cl_2 or $CHCl_3$, whereas the reaction of $Mo_2(O_2C\text{-}nC_7H_{15})_4$ with BPEF leads to a pentanuclear compound $[Mo_2(O_2C\text{-}nC_7H_{15})_4]_2$(BPEF) (**6**), even when BPEF is in excess. ^{1}H NMR, Raman, UV/Vis absorption spectroscopy and cyclic voltammetry indicate that the metal-metal bonds are weakened by the metal-axial ligand interaction and the donor-acceptor interactions occurring between the building blocks of the multinuclear compounds and oligomers. The interaction between the bimetallic centers and the ferrocene moiety is enhanced by shortening the distances between them. This shortening is achieved by modification of the axial ligand from FPA to FP. A significant electronic communication between the ferrocene units is not observed.

Introduction

Since Cotton's recognition of metal-metal bonds in 1964, the field of multiple bonds between metal atoms has been an active area of research in modern coordination chemistry. Oligomers and polymers containing metal-metal bonds in the backbone may display novel optical and magnetic properties.[1] Two general types of one-dimensional polymers can be envisaged, and these are shown in Scheme 1.[2a]



Scheme 1

In **A**, the M−M axis associated with the M−M bond is parallel to the propagating axis, whereas in **B** the M−M axis is perpendicular. Examples of the latter type are oligomers composed of $Mo_2(O_2C\text{-}tBu)_2$ and $^-OOC-R-COO^-$ units, which have been reported by Chisholm et al.[2] Polymers of type **A** can be constructed by axial coordination of the linking ligands to the bimetallic complexes. A number of bimetallic tetracarboxylates have been linked by bidentate organic axial ligands, resulting in polymeric species.[3] These types of polymers have the advantage of being readily accessible. A wide diversity of bimetallic centers, equatorial ligands and axial linkages can be used. As a result the polymer properties, such as solubility, strength of metal-axial ligand interaction, electronic and electrochemical behaviors, can be easily tuned. However, to the best of our knowledge, examples of these types of oligomers and polymers with organometallic spacing groups are very rare.[4] Nevertheless, organometallic linkers are interesting alternatives to organic linkers. Several of these organometallic complexes can be quite easily obtained and can be modified to a significant degree by well-established synthetic strategies. A much broader variety of potential product molecules are available than with simple organic molecules.

We attempted to incorporate bimetallic units into one-dimensional organometallic polymers of type **A**.[4] As this area of chemistry is relatively new, we chose to work with dimolybdenum(II) and dirhodium(II) tetracarboxylates since their molecular and electronic structures have been extensively studied.[1] Conjugated ligands containing a ferrocene moiety were selected as bridging ligands, due to the favorable electrochemical properties of ferrocene, and the comparatively easy accessibility and high synthetic yields of these complexes.

We recently reported oligomers with backbones containing 1,1′-bis(4-pyridylethynyl)ferrocene (BPEF) and bimetallic tetracarboxylates. However, it was found that these oligomers are insoluble in noncoordinating solvents, and the use of strongly coordinating solvents, such as CH_3CN

and THF, resulted in the destruction of the polymer chain due to replacement of the comparatively weakly coordinating BPEF ligands by solvent molecules.[4a] The poor solubility hinders complete characterization and detailed examination of their properties. An important step forward is to make the oligomers and polymers soluble in both coordinating and noncoordinating solvents. In this work we report on how this can be achieved. Furthermore, the axial ligands for the model compounds are modified from ferrocenyl-4-pyridylacetylene (FPA) to 4-ferrocenylpyridine (FP), in order to investigate the effect on the electronic coupling between the two ferrocene units resulting from the decreased distance between them.

Results and Discussion

Preparation and Characterization

The reactions of the bimetallic tetracarboxylates with the monodentate ligands FPA or FP, in a 1:2 molar ratio, led to the formation of the tetranuclear complexes **1a**, **1b**, **2b**, **3a, 3b**, **4a** and **4b** (Scheme 2). Compound **2a** has only one axial ligand due to the relatively weak metal-axial ligand interaction between $Mo_2(O_2C\text{-}nC_7H_{15})_4$ and FPA. Similarly, the reaction of $Mo_2(O_2C\text{-}nC_7H_{15})_4$ with a bidentate ligand BPEF in a 1:1 molar ratio gave a pentanuclear complex **6**, whereas BPEF with $Rh_2(O_2C\text{-}nC_7H_{15})_4$ formed the oligomeric compound **5**.

While the dirhodium complexes **1a**, **1b**, **3a**, **3b**, and **5** are air-stable, the dimolybdenum complexes **2a**, **2b**, **4a**, **4b**, and **6** decomposed when exposed to air for a few hours in the solid state, and within a couple of minutes in solution. The bimetallic compounds containing long-chain carboxylates are very soluble. The oligomer **5** is soluble in some noncoordinating solvents such as CH_2Cl_2 and $CHCl_3$, in contrast to the previously reported oligomers $[Rh_2(O_2CCH_3)_4(BPEF)]_n$, $[Rh_2(O_2CCF_3)_4(BPEF)]_n$, and $[Mo_2(O_2CCF_3)_4(BPEF)]_n$ which are insoluble in any noncoordinating solvent and decompose in coordinating solvents.[4]

The complexes were characterized by elemental analysis, NMR, solid state IR and Raman spectroscopies. Selected spectroscopic data are listed in Table 1.

The resonance signals for the pyridyl protons of the dirhodium complexes **1a**, **1b**, **3a**, **3b** and **5** appear at a lower field than those of the respective free ligands FPA, FP and BPEF. In contrast, upfield shifts of the pyridyl protons are observed in the dimolybdenum complexes. The coordination of the pyridyl ligands used here to form complexes with $Rh_2(O_2CCH_3)_4$ and $Rh_2(O_2C\text{-}nC_7H_{15})_4$, leads to a comparable downfield shift of the α-pyridyl protons ($\Delta^1H \approx 0.6-0.8$ ppm), reflecting the tendency of dirhodium(II) centers to bind axial ligands. The chemical shifts of the α-pyridyl protons of **2b** ($\delta = 8.03$) and **4b** ($\delta = 7.90$) differ significantly from those of the respective free ligands FPA ($\delta = 8.53$) and FP ($\delta = 8.45$), as a result of the relatively strong Lewis acidity of $Mo_2(O_2CCF_3)_4$. However, those of **2a** ($\delta = 8.30$) and **4a** ($\delta = 8.21$) differ from the free ligands by only

ca. δ = 0.23, reflecting a rather weak metal-axial ligand interaction in the $Mo_2(O_2C$-$nC_7H_{15})_4$ derivatives. The ^{1}H NMR signal of the CH_3CO_2 group is shifted downfield from δ = 1.76 in the axial-ligand free $Rh_2(O_2CCH_3)_4$, to δ = 1.88 in the FPA-coordinated complex **1b** and to δ = 1.93 in the FP ligated complex **3b**. This demonstrates that electron density must be donated back to the axial ligands. In the cases of the tetraoctanoate bimetallic derivatives, the chemical shifts of only the CH_2(2) and CH_2(3) protons are affected by the coordination of axial ligands. The resonances of the CH_2(2) moiety are shifted upfield from δ = 2.34 in the axial-ligand free $Rh_2(O_2C$-$nC_7H_{15})_4$ to ca. δ = 2.11 in the complexes **1a**, **3a** and **5**. The signals of CH_2(3) are shifted from δ = 1.54 to ca. δ = 1.43. The resonances of CH_2(2) and CH_2(3) in the cases of the dimolybdenum complexes **2a**, **4a** and **6**, are shifted downfield from δ = 2.82 [$Mo_2(O_2C$-$nC_7H_{15})_4$] to δ = 2.90−2.96 [CH_2(2)] and from δ = 1.80 to δ = 1.83−1.87 [CH_2(3)]. The ferrocene proton resonances in the FPA-coordinated complexes do not show a significant difference relative to those of the free ligand (Table 1). However, the ferrocene protons of the FP derivatives, especially the dirhodium complexes, differ notably in their chemical shifts from the free ligand as a result of the shortened distance between the ferrocene moiety and the M_2 center, thus enhancing their electronic interaction. It is also interesting to note that the ferrocene proton resonances of oligomer **5** [$\delta(H_\alpha)$ = 4.71, $\delta(H_\beta)$ = 4.50] are shifted downfield from those of the free ligand BPEF [$\delta(H_\alpha)$ = 4.57, $\delta(H_\beta)$ = 4.37], whereas the signals of its tetranuclear model complex **1a** [$\delta(H_\alpha)$ = 4.60, $\delta(H_\beta)$ = 4.33] are quite similar to the free ligand FPA [$\delta(H_\alpha)$ = 4.54, $\delta(H_\beta)$ = 4.31]. This might indicate a better electronic delocalization in the oligomer than in the tetranuclear model compound.

As demonstrated previously, Raman spectroscopy is more informative than single-crystal X-ray analysis with regard to metal-metal interactions.[5] The strong Raman band centered at 324 cm^{-1} for complex **3a** is unambiguously assigned to the stretching frequency of the Rh−Rh bond, which is shifted 20 cm^{-1} lower in energy relative to the axial-ligand free complex $Rh_2(O_2C$-$nC_7H_{15})_4$ [ν(Rh−Rh) = 344 cm^{-1}]. This observation is probably due to the fact that coupling between the Rh−Rh stretching mode and the Rh-axial ligand stretching mode leads to a weakening of the Rh−Rh interaction. However, the coupling between the dirhodium center and the axial ligands in the cases of the FPA and BPEF derivatives is weaker than in the FP-coordinated compound **3a**, as indicated by the fact that the Rh−Rh vibration frequencies of compounds **1a** (339 cm^{-1}) and **5** (342 cm^{-1}) are very similar to that of the parent precursor. The same behavior has also been observed in the cases of the $Rh_2(O_2CCH_3)_4$ derivatives. The compound $Rh_2(O_2CCH_3)_4(FP)_2$ shows a Rh−Rh vibration at 320 cm^{-1}, which is 31 cm^{-1} lower in energy than the parent compound $Rh_2(O_2CCH_3)_4$ (ν(Rh−Rh) = 351 cm^{-1}). However, compounds **1b** and $[Rh_2(O_2CCH_3)_4(BPEF)]_n$ display their Rh−Rh vibrations at 341 and 343 cm^{-1}, respectively, with a deviation of about 10 cm^{-1} from the vibration of the parent precursor. These observations also demonstrate that $Rh_2(O_2CCH_3)_4$ and $Rh_2(O_2C$-$nC_7H_{15})_4$ have a similar tendency to bind axial ligands, the weakening of the metal-metal bond is mainly dependent on the donor strength of the axial ligands. Since $Mo_2(O_2C$-$nC_7H_{15})_4$ is only weakly bonded to the axial ligands, the Mo-Mo vibrations of complexes **2a**, **4a** and **6** display their bands at 397, 400 and 397 cm^{-1}, respectively, with a deviation within the measurement error range from that of the free precursor (401 cm^{-1}). Due to the relatively strong metal-axial ligand interaction in the cases of the $Mo_2(O_2CCF_3)_4$ derivatives, the Mo−Mo vibration is shifted to lower energies (ca. 27−33 cm^{-1} relative to the precursor).

In order to demonstrate an oligomer chain growth in solution, ^{1}H NMR investigations were performed on a mixture of $Rh_2(O_2C$-$nC_7H_{15})_4$ and BPEF, in different molar ratios in $CDCl_3$. The concentrations of the compounds in solution were in the range of 2×10^{-3} to 4×10^{-3} M. The measurements were performed after the solution was stirred at room temperature for 1 h. The results of this ^{1}H NMR study are summarized in Table 2, the data for oligomer **5**

[a] A_mB_n represents the molar ratio of BPEF to $Rh_2(O_2C\text{-}nC_7H_{15})_4$ which is *m*:*n*; the concentration of subunit is in the range of 2×10^{-3} to 4×10^{-3} M. − [b] I = integration, the calculated data are in parenthesis.

and the precursors $Rh_2(O_2C\text{-}nC_7H_{15})_4$ and BPEF are also included for comparative purposes. It is interesting to note that the species present in solution depends on the molar ratio of the two precursor complexes. The oligomer chain grows as the molar ratio of BPEF:$Rh_2(O_2C\text{-}nC_7H_{15})_4$ (A:B) increases. The spectrum of the solution containing BPEF and $Rh_2(O_2C\text{-}nC_7H_{15})_4$ in a 5:6 ratio is quite similar to that of the isolated oligomer **5**. This observation suggests that the repeating unit of oligmer **5** is at least 5, and its molecular weight is not lower than 5832 amu.

Electronic Absorption Spectra

The electronic absorption spectroscopic data of the complexes and their precursors are given in Table 3. Figure 1 presents a comparison of the UV/Vis spectra of oligomer **5** and its precursors. The characteristic absorptions of the product complexes are similar to those of the ferrocenyl pyridine precursors. In general, a peak at ca. 330−370 nm and a broad band centered at ca. 420−480 nm are assigned to d−d transitions in the ferrocene unit.[4,6] The fairly intense bands at λ = 320 nm are assigned to a π→π* pyridyl transition. A comparison of the lowest energy d−d transition band between compounds **1a**, **1b**, **2a**, **2b** and their axial ligand FPA, reveals that the coordination of FPA does not noticeably disturb the d−d transition energy in the ferrocene unit. This is probably due to the relatively weak metal-axial ligand interaction, weak donor ability of FPA and the long distance between the ferrocene moiety and the

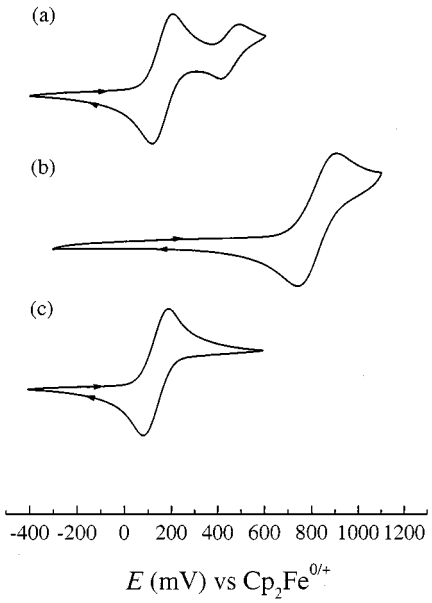

Figure 2. Cyclic voltammograms of (a) $Rh_2(O_2C\text{-}nC_7H_{15})_4(FP)_2$ (**3a**), (b) $Rh_2(O_2C\text{-}nC_7H_{15})_4$ and (c) FP at the same scan rate of 50 mV/s in CH_2Cl_2 with 0.1 M TBAH at room temperature

dimetallic centers. The ^1H NMR spectroscopic data described above are also in good agreement with this observation. However, in the cases of the FP derivatives, the lowest energy d−d transition band is shifted from 454 nm in FP to 456 nm in **3a**, 458 nm in **3b**, 463 nm in **4b** and 476 nm in **4a**. This again demonstrates that the shortening of the distance between the ferrocene unit and the bimetallic centers increases the electronic interaction between the building blocks. Even though the bathochromic shifts of the respective UV/Vis transitions are not quite pronounced, the stronger extinction coefficients of the products vs. their precursors probably indicate a better electronic delocalization. However, a metal-to-metal (ferrocene to dimetallic center) charge transfer (MM′CT) band is not found in the electronic absorption spectra (200−1100 nm).

Electrochemical Properties

As depicted in Figure 2, the cyclic voltammogram of complex **3a** in CH_2Cl_2 exhibits two subsequently reversible anodic couples. The first oxidation with $E_{1/2} = 0.15$ V is assigned to the oxidation of the two ferrocene units, whereas the second with $E_{1/2} = 0.44$ V is due to the oxidation process of the $[Rh_2]^{5+/4+}$ couple. The coordination of dirhodium(II) by FP results in a pronounced cathodic shift of the $[Rh_2]^{5+/4+}$ couple from the parent $Rh_2(O_2C\text{-}nC_7H_{15})_4$ (0.81 V), but a weak anodic shift of the $Fe^{3+/2+}$ couple from the free ligand FP (0.13 V). The same results were obtained when comparing the electrochemical behavior of the product molecules **1a**, **1b** and **3b** with their respective precursors (Table 3). The fact that the oxidation potentials of the $Fe^{3+/2+}$ couple for the above mentioned complexes are close to ones of the free ligands testifies the low electronic perturbation of the ferrocene unit caused by the linkage to the dirhodium centers. However, the $[Rh_2]^{5+/4+}$ oxidation potential is significantly shifted by the electron-donor effect of the pyridyl ligands.

The electrochemical experiments performed with the oligomer **5** were not very successful, only one reversible oxidation couple with $E_{1/2} = 0.33$ V is observed. We are not able to assign this to the oxidation process of the $[Rh_2]^{5+/4+}$ or $Fe^{3+/2+}$ couple without any doubt. Nonetheless, all the tetranuclear model complexes show a single oxidation process for the ferrocene units. We believe that the absence of electronic communication in the tetranuclear model complexes excludes the possibility of electronic communication in the corresponding polymers.

Conclusions

One-dimensional organometallic oligomers with a backbone consisting of bimetallic tetracarboxylates and π-conjugated ferrocene derivatives are generated by mixing the precursor compounds in noncoordinating solvents at room temperature. The solubility of the oligomers in noncoordinating solvents is enhanced by using octanoates as equatorial ligands. These complexes are soluble in both noncoordinating and coordinating solvents, thus enabling a complete characterization and a more detailed examination of their properties than was possible for related complexes previously examined. The electronic and electrochemical investigations of the tetranuclear model compounds indicate that the ferrocene units are electronically noncommunicating, despite the fact that the axial ligands are modified from FPA to FP which remarkably shortens the distance between the two ferrocene units. However, especially in the case of complexes consisting of Rh−Rh units and FP as the axial ligands, the Rh−Rh interaction is significantly influenced (weakened) by the coordinating ligands.

Experimental Section

General: The preparations and manipulations were carried out under an oxygen- and water-free argon atmosphere using the standard

Schlenk techniques. Solvents were dried by standard procedures, distilled, and kept under argon over molecular sieves. The syntheses of the ligands ferrocenyl-4-pyridylacetylene (FPA), 1,1′-bis(4-pyridylethynyl)ferrocene (BPEF), and the tetranuclear complexes $Rh_2(O_2CCH_3)_4(FPA)_2$ (**1b**), $Mo_2(O_2CCF_3)_4(FPA)_2$ (**2b**) have been described previously.[4] 4-Ferrocenylpyridine (FP) was prepared by a literature method.[7]

Elemental analyses were performed in the Mikroanalytisches Labor of the TU München in Garching. − ^1H, ^{13}C and ^{19}F NMR spectra were obtained with Joel JNM GX-400 spectrometers. − IR spectra were recorded on a Perkin−Elmer FT-IR spectrometer using KBr pellets as the IR matrix. − Raman spectra of the solid samples were measured on a Bio-Rad FTS 575C spectrometer using a 1064 μm excitation of the Nd:YAG laser. − Electronic absorption spectra were obtained by using a Perkin−Elmer Lambda 2 UV/Vis spectrometer. − Cyclic voltammograms were recorded with a computer-controlled Model 173 Potentiostat/galvanostat (EG&G Princeton Applied Research) in argon-saturated dried solutions, with tetrabutylammonium hexafluorophosphate (TBAH, 0.1 M) as the supporting electrolyte. The working electrode was platinum and the reference electrode was silver. Potentials are quoted vs. the ferrocene-ferrocenium couple as an internal standard.

$Rh_2(O_2C$-*n*$C_7H_{15})_4$: Prepared by ligand exchange reaction between $Rh_2(O_2CCH_3)_4$ and $CH_3(CH_2)_6COOH$ according to a literature method.[8] − $C_{32}H_{60}O_8Rh_2$ (778.24): calcd. C 49.34, H 7.77; found C 48.74, H 7.80. − IR (KBr): $\tilde{\nu}$ = 2954 s, 2922 s, 2851 s, 1568 vs, 1522 m, 1467 m, 1433 s, 1412 s, 1312 m, 740 m, 679 m cm^{-1}. − ^1H NMR ($CDCl_3$, room temp.): δ = 0.82 (t, 12 H, CH_3), 1.18 [m, 32 H, $CH_2(4-7)$], 1.54 [m, 8 H, $CH_2(3)$], 2.34 [t, 8 H, $CH_2(2)$]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 14.0 (CH_3), 22.6, 26.2, 29.1, 31.8, 37.5 (CH_2), 194.5 (CO_2).

$Mo_2(O_2C$-*n*$C_7H_{15})_4$: Prepared by a literature method.[9] − $C_{32}H_{60}Mo_2O_8$ (764.70): calcd. C 50.26, H 7.91; found C 50.77, H 8.10. − IR (KBr): $\tilde{\nu}$ = 2956 vs, 2929 vs, 2852 vs, 1506 vs, 1468 s, 1430 vs, 1412 vs, 1306 m, 1177 m, 1110 m, 802 m, 718 m, 657 m, 466 m cm^{-1}. − ^1H NMR ($CDCl_3$, room temp.): δ = 0.88 (t, 12 H, CH_3), 1.30 [m, 32 H, $CH_2(4-7)$], 1.80 [m, 8 H, $CH_2(3)$], 2.82 [t, 8 H, $CH_2(2)$]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 14.1 (CH_3), 22.7, 26.7, 29.1, 29.2, 31.9, 37.0 (CH_2), 185.7 (CO_2).

$Rh_2(O_2C$-*n*$C_7H_{15})_4(FPA)_2$ (1a): $Rh_2(O_2C$-*n*$C_7H_{15})_4$ (60 mg, 0.077 mmol) dissolved in 15 mL of CH_2Cl_2, was added to a 10 mL CH_2Cl_2 solution of FPA (49 mg, 0.17 mmol). After stirring at room temperature for 2 h, the solution was evaporated to dryness under vacuum and the residue was washed with *n*-hexane. The crude product obtained was purified by recrystallization from diethyl ether to give an orange powder. Yield: 90 mg, 86%. − $C_{66}H_{86}Fe_2N_2O_8Rh_2$ (1352.32): calcd. C 58.57, H 6.41, N 2.07; found C 58.22, H 6.80, N 2.03. − IR (KBr): $\tilde{\nu}$ = 2954 s, 2924 s, 2854 s, 2207 s, 1600 vs, 1587 vs, 1500 m, 1456 m, 1413 vs, 1314 m, 1214 m, 1170 m, 1107 m, 1011 m, 924 m, 826 m, 725 m, 677 m, 600 m, 540 m, 500 m, 486 m, 446 m cm^{-1}. − ^1H NMR ($CDCl_3$, room temp.): δ = 0.86 (t, 12 H, CH_3), 1.19 [m, 32 H, $CH_2(4-7)$], 1.42 [m, 8 H, $CH_2(3)$], 2.10 [t, 8 H, $CH_2(2)$], 4.29 (s, 10 H, C_5H_5), 4.33 [s, 4 H, $C_5H_4(\beta)$], 4.60 [s, 4 H, $C_5H_4(\alpha)$], 7.69 [s, br., 4 H, $C_5H_4N(\beta)$], 9.24 [s, br., 4 H, $C_5H_4N(\alpha)$]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 14.1 (CH_3), 22.6, 25.9, 28.9, 29.0, 31.7, 37.3 (CH_2), 63.5, 69.6, 70.2, 71.9 (C_5H_4 & C_5H_5), 83.8 [C≡*C*C_5H_4), 95.5 (NC_5H_4C≡C), 126.5 [$C_5H_4N(\beta)$], 133.1 [$C_5H_4N(\gamma)$], 150.8 [$C_5H_4N(\alpha)$], 194.2 (CO_2).

$Mo_2(O_2C$-*n*$C_7H_{15})_4$(FPA) (2a): A 20 mL diethyl ether solution containing $Mo_2(O_2C$-*n*$C_7H_{15})_4$ (122 mg,0.16 mmol) was added to a 20 mL diethyl ether solution of FPA (100 mg, 0.35 mmol). After stirring at room temperature for 2 h, the solution was evaporated to dryness under vacuum and the residue was washed with small portions of *n*-hexane. The orange product was obtained in a 65% yield (110 mg). − $C_{49}H_{73}FeMo_2NO_8Rh_2$ (1050.84): calcd. C 55.96, H 6.95, N 1.33; found C 55.32, H 7.10, N 1.28. − IR (KBr): $\tilde{\nu}$ = 2955 s, 2924 vs, 2853 s, 2202 s, 1601 s, 1507 vs, 1458 m, 1423 s, 1376 m, 1316 m, 1261 w, 1218 m, 1171 m, 1107 m, 1000 m, 928 m, 828 m, 801 m, 724 w, 645 w, 595 w, 542 w, 500 m, 446 w cm^{-1}. − ^1H NMR ($CDCl_3$, room temp.): δ = 0.88 (t, 12 H, CH_3), 1.29 [m, 32 H, $CH_2(4-7)$], 1.85 [m, 8 H, $CH_2(3)$], 2.92 [t, 8 H, $CH_2(2)$], 4.22 (s, 5 H, C_5H_5), 4.28 [s, 2 H, $C_5H_4(\beta)$], 4.50 [s, 2 H, $C_5H_4(\alpha)$], 7.22 [s, br., 2 H, $C_5H_4N(\beta)$], 8.30 [s, br., 2 H, $C_5H_4N(\alpha)$]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 14.1 (CH_3), 22.7, 26.7, 29.1, 29.2, 29.7, 31.8, 37.0 (CH_2), 63.4, 69.5, 70.1, 71.8 (C_5H_4 & C_5H_5), 83.3 (C≡*C*C_5H_4), 95.1 (NC_5H_4C≡C), 125.3 [$C_5H_4N(\beta)$], 132.9 [$C_5H_4N(\gamma)$], 149.4 [$C_5H_4N(\alpha)$], 185.4 (CO_2).

$Rh_2(O_2C$-*n*$C_7H_{15})_4(FP)_2$ (3a): $Rh_2(O_2C$-*n*$C_7H_{15})_4$ (100 mg, 0.13 mmol) and FP (74 mg, 0.28 mmol) were dissolved in 15 mL CH_2Cl_2. The solution was stirred at room temperature for 2 h, and evaporated to dryness under vacuum. The residue was washed with *n*-hexane and recrystallized in CH_2Cl_2/*n*-hexane. The orange product was obtained in a 71% yield (120 mg). − $C_{62}H_{86}Fe_2N_2O_8Rh_2$ (1304.88): calcd. C 57.07, H 6.64, N 2.15; found C 56.83, H 6.68, N 2.06. − IR (KBr): $\tilde{\nu}$ = 2954 m, 2924 s, 2854 m, 1605 s, 1585 vs, 1516 s, 1412 s, 1216 m, 1107 m,1034 w, 1017 m, 828 m, 687 m, 530 w, 498 m cm^{-1}. − ^1H NMR ($CDCl_3$, room temp.): δ = 0.86 (t, 12 H, CH_3), 1.20 [m, 32 H, $CH_2(4-7)$], 1.45 [m, 8 H, $CH_2(3)$], 2.12 [t, 8 H, $CH_2(2)$], 4.14 (s, 10 H, C_5H_5), 4.50 [t, 4 H, $C_5H_4(\beta)$], 4.86 [t, 4 H, $C_5H_4(\alpha)$], 7.67 [d, 4 H, $C_5H_4N(\beta)$], 9.93 [d, 4 H, $C_5H_4N(\alpha)$]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 14.1 (CH_3), 22.7, 25.9, 29.0, 29.1, 31.8, 37.3 (CH_2), 67.1, 70.1, 70.4, 81.0 (C_5H_4 & C_5H_5), 121.6, 149.8, 150.7 (C_5H_4N), 194.2 (CO_2).

$Rh_2(O_2CCH_3)_4(FP)_2$ (3b): A THF solution (20 mL) containing $Rh_2(O_2CCH_3)_4$ (57 mg, 0.13 mmol) and FP (75 mg, 0.28 mmol) was stirred at room temperature for 2 h, which led to an orange precipitate. The solvent was reduced to ca. 5 mL in vacuum, to which 20 mL of diethyl ether was added. The precipitate was collected and washed with 3 × 20 mL of diethyl ether. The orange product was purified by recrystallization in CH_2Cl_2/Et_2O. Yield: 110 mg (87%). − $C_{38}H_{38}Fe_2N_2O_8Rh_2$ (968.23): calcd. C 47.17, H 3.96, N 2.89; found C 47.63, H 4.17, N 2.63. − IR (KBr): $\tilde{\nu}$ = 3093 w, 2931 w, 1605 vs, 1590 vs, 1518 m, 1429 vs, 1343 m, 1290 w, 1223 m, 1108 m, 1016 m, 890 w, 836 m, 820 m, 694 m, 644 w, 627 w, 529 m, 518 m, 500 m, 434 w cm^{-1}. − ^1H NMR ($CDCl_3$, room temp.): δ = 1.93 (s, 12 H, CH_3), 4.14 (s, 10 H, C_5H_5), 4.51 [t, 4 H, $C_5H_4(\beta)$], 4.87 [t, 4 H, $C_5H_4(\alpha)$], 7.70 [d, 4 H, $C_5H_4N(\beta)$], 9.21 [d, 4 H, $C_5H_4N(\alpha)$]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 23.9 (CH_3), 67.2, 70.1, 70.5, 80.7 (C_5H_4 & C_5H_5), 121.7, 150.2, 150.6 (C_5H_4N), 191.9 (CO_2).

$Mo_2(O_2C$-*n*$C_7H_{15})_4(FP)_2$ (4a): $Mo_2(O_2C$-*n*$C_7H_{15})_4$ (100 mg, 0.13 mmol) and FP (69 mg, 0.26 mmol) were dissolved in 15 mL of CH_2Cl_2. The solution was stirred at room temperature for 2 h, and evaporated to dryness under vacuum. The residue was washed with *n*-hexane and recrystallized in CH_2Cl_2/*n*-hexane. The orange product was produced in a 53% yield (90 mg). − $C_{62}H_{86}Fe_2N_2O_8Mo_2$ (1304.88): calcd. C 57.07, H 6.64, N 2.15; found C 56.83, H 6.68, N 2.06. − IR (KBr): $\tilde{\nu}$ = 2955 s, 2919 s, 2852 s, 1506 vs, 1468 m, 1431 s, 1412 vs, 1315 w, 1109 m, 1031 w, 828 m, 718 m, 658 m, 466 m cm^{-1}. − ^1H NMR ($CDCl_3$, room temp.): δ = 0.88 (t, 12 H, CH_3), 1.30−1.41 [m, 32 H, $CH_2(4-7)$], 1.87 [m, 8 H, $CH_2(3)$], 2.96 [t, 8 H, $CH_2(2)$], 4.00 (s, 10 H, C_5H_5), 4.40 [t, 4 H, $C_5H_4(\beta)$], 4.66

[t, 4 H, C_5H_4(α)], 7.21 [d, 4 H, C_5H_4N(β)], 8.21 [d, 4 H, C_5H_4N(α)]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 14.1 (CH_3), 22.7, 26.7, 29.0, 29.1, 29.2, 31.8, 37.1 (CH_2), 66.9, 70.0, 70.3, 80.6 (C_5H_4 & C_5H_5), 120.5, 149.6 (C_5H_4N), 185.4 (CO_2).

$Mo_2(O_2CCF_3)_4(FP)_2$ (4b): $Mo_2(O_2CCF_3)_4$ (102 mg, 0.16 mmol) and FP (91 mg, 0.35 mmol) were dissolved in 15 mL of CH_2Cl_2. The solution was stirred at room temperature for 2 h, and evaporated to dryness under vacuum. The residue was washed with *n*-hexane and recrystallized in CH_2Cl_2/*n*-hexane. The orange product was obtained in a 96% yield (180 mg). − $C_{38}H_{26}F_{12}Fe_2Mo_2N_2O_8$ (1170.19): calcd. C 39.00, H 2.24, N 2.39; found C 39.20, H 2.52, N 2.51. − IR (KBr): $\tilde{\nu}$ = 1684 m, 1631m, 1603 vs, 1520 m, 1428 m, 1194 vs, 1160 s, 1108 w, 1031 w, 1014 m, 1003 m, 856 m, 822 m, 778 w, 730 s, 684 m, 527 m, 496 m cm^{-1}. − ^{1}H NMR ($CDCl_3$, room temp.): δ = 3.99 (s, 10 H, C_5H_5), 4.42 [t, 4 H, C_5H_4(β)], 4.64 [t, 4 H, C_5H_4(α)], 7.19 [d, 4 H, C_5H_4N(β)], 7.90 [d, 4 H, C_5H_4N(α)]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 67.0, 70.1, 70.7, 79.8 (C_5H_4 & C_5H_5), 114.9 (CF_3), 124.2, 148.7, 151.1 (C_5H_4N), 166.1 (CO_2). − ^{19}F NMR ($CDCl_3$, room temp.): δ = −9.29.

$[Rh_2(O_2C\text{-}nC_7H_{15})_4(BPEF)]_n$ (5): A mixture of $Rh_2(O_2C\text{-}nC_7H_{15})_4$ (117 mg, 0.15 mmol) and BPEF (58 mg, 0.15 mmol) was dissolved in 25 mL of dichloromethane. The solution was stirred at room temperature overnight, and then filtered to remove traces of the precipitate. The filtrate was then evaporated to dryness under vacuum. The crude product was washed with diethyl ether and recrystallized by diffusion of diethyl ether into its dichloromethane solution. The deep orange product was obtained in a 86% yield (150 mg). − $[C_{56}H_{76}FeN_2O_8Rh_2]_n$ ($n \times$ 1166.31): calcd. C 57.62, H 6.57, N 2.40; found C 57.38, H 6.30, N 2.43. − IR (KBr): $\tilde{\nu}$ = 2955 s, 2925 s, 2853 s, 2211 s, 1600 s, 1588 vs, 1500 m, 1458 m, 1413 s, 1314 m, 1215 m, 1172 w, 1010 m, 925 w, 826 m, 730 w, 669 w, 601 w, 550 w, 496 m cm^{-1}. − ^{1}H NMR ($CDCl_3$, room temp.): δ = 0.85 (t, 12 H, CH_3), 1.19 [m, 32 H, CH_2(4−7)], 1.43 [m, 8 H, CH_2(3)], 2.11 [t, 8 H, CH_2(2)], 4.50 [s, 4 H, C_5H_4(β)], 4.71 [s, 4 H, C_5H_4(α)], 7.72 [d, 4 H, C_5H_4N(β)], 9.26 [d, 4 H, C_5H_4N(α)]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 14.1 (CH_3), 22.6, 25.9, 29.0, 31.7, 37.3 (CH_2), 65.1, 72.5, 73.5 (C_5H_4), 84.5 (C≡*C*C_5H_4), 94.3 (NC_5H_4*C*≡C), 126.5 [C_5H_4N(β)], 132.8 [C_5H_4N(γ)], 150.9 [C_5H_4N(α)], 194.2 (CO_2).

$[Mo_2(O_2C\text{-}nC_7H_{15})_4]_2(BPEF)$ (6): A mixture of $Mo_2(O_2C\text{-}nC_7H_{15})_4$ (128 mg, 0.17 mmol) and BPEF (65 mg, 0.17 mmol) was dissolved in 20 mL of dichloromethane. The solution was stirred at room temperature overnight, and the solvent was then evaporated to dryness under vacuum. The residue was washed with one portion of 5 mL of diethyl ether and several portions of *n*-hexane. The pale-orange powder was recrystallized from CH_2Cl_2/*n*-hexane. Yield: 80 mg, 49% yield based on $Mo_2(O_2C\text{-}nC_7H_{15})_4$. − $C_{88}H_{136}FeMo_4N_2O_{16}$ (1917.66): calcd. C 55.12, H 7.15, N 1.46; found C 54.78, H 6.80, N 1.60. − IR (KBr): $\tilde{\nu}$ = 2956 vs, 2920 vs, 2852 vs, 2207 m, 1596 m, 1506 vs, 1458 m, 1430 s, 1412 vs, 1315 m, 1257 w, 1213 w, 1177 m, 1110 m, 1026 w, 928 w, 874 w, 816 m, 718 m, 657 m, 541 w, 489 m, 466 m, 444 m cm^{-1}. − ^{1}H NMR ($CDCl_3$, room temp.): δ = 0.88 (t, 24 H, CH_3), 1.29 [m, 64 H, CH_2(4−7)], 1.83 [m, 16 H, CH_2(3)], 2.90 [t, 16 H, CH_2(2)], 4.35 [t, 4 H, C_5H_4(β)], 4.54 [t, 4 H, C_5H_4(α)], 7.15 [d, 4 H, C_5H_4N(β)], 8.31 [d, 4 H, C_5H_4N(α)]. − ^{13}C NMR ($CDCl_3$, room temp.): δ = 14.1 (CH_3), 22.7, 26.7, 29.1, 29.2, 31.8, 37.0 (CH_2), 65.4, 71.8, 73.4 (C_5H_4), 84.2 (C≡*C*C_5H_4), 125.2 [C_5H_4N(β)], 132.6 [C_5H_4N(γ)], 149.4 [C_5H_4N(α)], 185.6 (CO_2).

Acknowledgments

W. M. X. thanks the Bayerische Forschungsstiftung for a postdoctoral research associate fellowship. Professor W. A. Herrmann is acknowledged for the continuous support of our work. The authors are also grateful to the Fonds der Chemischen Industrie for financial support. Dr. É. S. Bencze is acknowledged for recording the vibrational spectra.

Di-, Tri-, and Tetranuclear Complexes of Ni, Pd, and Zn with Oxalamidinato Bridges: Syntheses, Structures and Catalytic Reactions

Dirk Walther,*[a] Thomas Döhler,[a] Nils Theyssen,[a] and Helmar Görls[a]

Keywords: Nickel / N ligands / Oligomerizations / Palladium / Polymerizations

The reaction of oxalic amidines $R^1N{=}C(NHR^2){-}C(NHR^2){=}NR^1$ ($oxamH_2$) with 2 equiv. $(allyl)_2M$ or $(acac)_2M$ (M: Ni, Pd) results in the formation of dinuclear complexes [(**T**)M(oxam)M(**T**)] containing dianionic bridging oxalamidinate and η^3-allyl or acac as terminal ligands **T**. The complexes were characterized by elemental analyses, mass spectrometry, and ^1H and ^{13}C NMR spectroscopy. In addition, the solid-state structures of **1** (M: Ni; **T**: η^3-allyl; R^1 = *p*-tolyl; R^2 = mesityl), **2** (M: Ni; **T**: η^3-allyl; $R^1 = R^2$ = mesityl), **9** (M: Pd; **T**: acac; R^1 = phenyl; R^2 = *p*-tolyl), and **10** (M: Pd; **T**: acac; $R^1 = R^2$ = *p*-tolyl) were determined by X-ray single-crystal diffraction analyses. All complexes contain the metal ions in a square-planar environment. Furthermore, in the η^3-allyl complexes two isomers are found in which the two allyl groups are oriented in *syn* and *anti* positions. Trinuclear complexes of the composition [(**T**)M(oxam)M^1(oxam)M(**T**)] (M^1: Zn; M: Ni or Pd) are obtained by treating Et_2Zn with 2 equiv. of an oxalic amidine in toluene, followed by addition of 2 equiv. $M(acac)_2$ or $Pd(allyl)_2$. The synthesis and solid-state X-ray analysis of the tetranuclear complex [(**T**)M(oxam)M^1(oxam)M^1(oxam)M(**T**)] (**16**: M = M^1: Zn; oxam: R^1 = *p*-tolyl; R^2 = mesityl) is also described. A number of Ni^{II} complexes oligomerize or polymerize ethylene upon activation with MAO or Et_3Al. The catalyses can be adjusted by the bulkiness of the nitrogen substituents, the nature of the cocatalyst, and the nuclearity of the complexes. The most active and selective polymerization catalyst is the heterotrinuclear NiZnNi complex **12** which contains two tetramesityloxalamidinato bridges and acac as terminal ligands **T**. Complex **12** can be activated by using only 2 equiv. Et_3Al per Ni. Initial efforts show that the palladium complexes are catalysts for the Heck coupling.

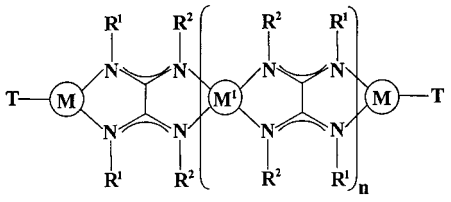
Introduction

Transition metal complexes with oxalic acid amidinato bridging ligands (“oxam“) have, surprisingly, attracted little attention. Complexes of this type should be interesting candidates for a number of attractive applications, such as the construction of well-defined linear oligonuclear complexes or the synthesis of coordination polymers starting from dinuclear complexes which contain labile terminal ligands **T**. Moreover, linear oligometal complexes with tuneable catalytic properties at peripheral positions, adjusted by inner metal ions, should offer new possibilities for catalytic reactions.

Since oxalamidinato complexes have the tendency to form ill-defined polymeric amorphous complexes[1,2] only a few structurally characterized complexes are known. The first dinuclear complex $Cp_2Ti(oxam)TiCp_2$ has been synthesized by Floriani in the 1970s.[3] Döring and Beckert prepared a number of mono- and dinuclear complexes containing for example $M(CO)_4-$ and/or the Cp_2Ti- fragments and investigated the organic chemistry of these complexes.[4−7]

We have found that mono- and dinuclear ruthenium complexes containing bpy derivatives as additional supporting ligands form stable compounds which are non-luminescent.[8] Furthermore, we have prepared the first example of dinuclear magnesium oxalamidinates. These compounds reacted with carbon dioxide to form trimeric carbamato complexes which can be considered as structural models for rubisco.[9]

In a preliminary paper we have recently communicated that dinuclear nickel complexes of the type [(acac)Ni(oxam)-Ni(acac)] can readily be synthesized by treating free oxalic amidines with $Ni(acac)_2$. Additionally, the first linear tri- and tetranuclear complexes could be isolated.[10] Some of the complexes were found to be catalytically active in ethylene oligomerization or polymerization upon activation with MAO. Apart from our preliminary communication there exists no report of oxalamidinato complexes having been used in catalytic C−C linkage reactions. From a general point of view we can consider oxalic amidinato complexes as members of a general range of the following composition in which each oxam ligand bridges two metal fragments.



In this paper we describe the construction of well-defined di- or oligometal Ni, Pd, and Zn complexes of the above range, and investigate their catalytic behaviour in the oligomerization/polymerization of ethylene. Furthermore, initial

investigations of the use of some of the complexes in the Heck coupling are communicated.

Results and Discussion

Dinuclear Complexes Containing Ni, Pd, or Zn

Table 1 shows the dinuclear complexes **1**−**11** containing η^3-allyl or acetylacetonato ligands as terminal groups which were used in both the catalytic ethylene conversion and as catalysts in the Heck reaction. Complexes **6**−**8** were already described in a preliminary paper.[10]

Table 1. Di- and trinuclear oxalamidinato complexes (according to Schemes 1 and 3)

Compd.	M	Terminal ligand **T**	R^1	R^2
Dinuclear complexes of the type (**T**)M(oxam)M(**T**)

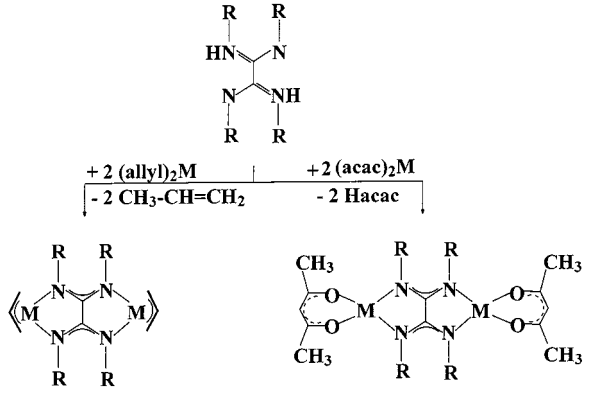
[a] (*E*) arrangement of R^1 and R^2 (Scheme 2, **A** and **B**). − [b] (*Z*) arrangement of R^1 and R^2 (Scheme 2, **C** with acac instead of allyl). − [c] (*E*) arrangement of R^1 and R^2 (Scheme 2, **A** with acac instead of allyl).

A variety of dinuclear η^3-allyl complexes of Ni^{II} and Pd^{II} could be prepared by the reaction of the corresponding bis(η^3-allyl)metal complexes with the oxalic amidine (molar ratio 2:1, Scheme 1). In these reactions propene was eliminated resulting in neutral complexes of the type [(allyl)M-(oxam)M(allyl)] which are the first members of the above-mentioned homologous range (with $n = 0$).



Scheme 1. Syntheses of dinuclear complexes **1**−**10**

Analogous dinuclear oxalamidinato complexes **6**−**10** containing acetylacetonato groups as terminal ligands were obtained in good yields starting from the corresponding bis(acetylacetonato)metal(II) complexes and oxalamidines (molar ratio 2:1). After workup, complexes of the type [(acac)M(oxam)M(acac)] (**6**−**10**) were isolated as crystalline compounds. The formation of coordination polymers was not observed in this reaction, due to the stable bonding of the terminal acetylacetonates in **6**−**10**. On the other hand, the complexes can easily react with organoaluminium compounds to form dinuclear Ziegler−Natta catalysts.

The synthesis of the heterodinuclear compound **11** required another preparative route: Reaction of $ZnEt_2$ with acetylacetone (molar ratio 1:1) in toluene resulted in the dimeric complex $[(acac)Zn(Et)]_2$ (**17**) which was used as starting product for **11**. Colorless crystals of compound **17** were obtained from toluene. Due to the insufficient quality of the crystals, only the structure motif could be determined by an X-ray diffraction analysis (Figure 1).

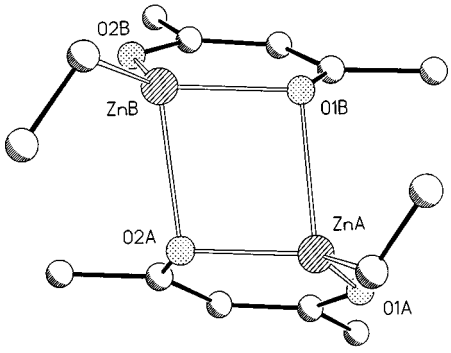


Figure 1. Structure motif of complex **17**

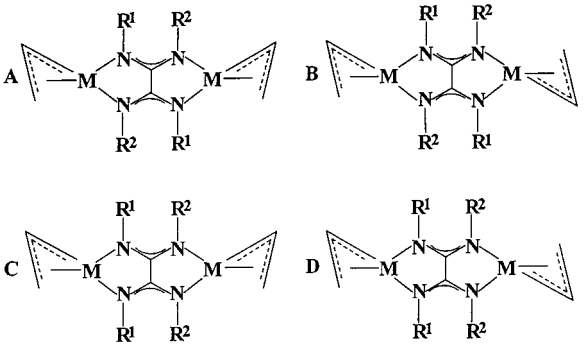
Complex **17** is a dimer in which the two Zn^{II} ions are held together by two bridging oxygen atoms of the acetylacetonate ligands yielding a four-membered Zn_2O_2 ring. Each Zn^{II} centre is tetrahedrally surrounded by three oxygen atoms of the acetylacetonato ligands and one ethyl group. Reaction of **17** with the oxalic amidine in THF (1:1 molar ratio) followed by treatment of the reaction mixture with 1 equiv. $Ni(acac)_2$ resulted in the formation of **11**. Upon recrystallization from toluene, **11** was isolated in 95% purity.

Structures of Dinuclear Complexes

The dinuclear complexes **1**−**11** were characterized by elemental analyses, mass spectrometry, and ^1H and ^{13}C NMR spectroscopy. In addition, the solid-state structures of **1**, **2**, **9**, and **10** were elucidated by X-ray single-crystal diffraction analyses. In principle, dinuclear η^3-allyl complexes containing oxalamidinates with different nitrogen substituents R^1, R^2 can exist in four isomers (Scheme 2), since the oxalamidinato bridge can bind either as the (*E*) isomer or as the

(*Z*) isomer; furthermore, the two η^3-allyl groups can assume *anti* or *syn* positions to each other (Scheme 2, **A**–**D**).



Scheme 2. Possible isomeric allylmetal complexes with bridging oxalamidinato ligands

The mass spectra of the Ni complexes **1** and **2** are typical for dinuclear oxalamidinato allylmetal complexes exhibiting the molecular ion peaks at $m/z = 698$, and 734, respectively, and peaks of smaller fragment ions due to successive loss of the allyl group giving the basic peak, and the (allyl)Ni fragment etc.

Single crystals of complex **1**, grown from *n*-hexane were used to determine its solid-state structure by an X-ray diffraction analysis. The molecular structure of **1** containing an oxalamidinato ligand with two different nitrogen substituents shows that **1** consists of a dimetallic centrosymmetric unit in which the oxalamidinato ligand acts in a bis(chelating) fashion bridging two nickel(II) ions (Figure 2).

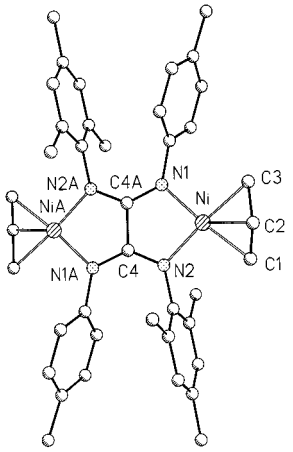


Figure 2. Molecular structure of complex **1**; for clarity the disordered allyl group is omitted; selected bond lengths [Å] and bond angles [°]: Ni–N1 1.912(2), Ni–N2 1.907(2), Ni–C1 1.988(3), Ni–C2 1.970(7), Ni–C3 1.992(3), N1–C4A 1.321(3), N2–C4 1.322(3), C4–C4A 1.522(5); N1–Ni–N2 84.49(9), N1–Ni–C1 174.8(1), N2–Ni–C3 174.0(1), N2–Ni–C1 100.6(1), C1–Ni–C3 73.8(1), Ni–N1–C4A 113.9(2), N1–C4A–C4 113.4(3), C4A–C4–N2 113.2(3), C4–N2–Ni 114.2(2); symmetry transformations used to generated equivalent atoms: A $-x + 1$, $-y + 1$, $-z + 1$

Each metal ion is in a planar environment created by two N atoms from the bridging ligand and the η^3-allyl ligand. The double chelate ring containing the CN_2 units is essentially planar. All C–N bonds are equivalent with a high double-bond character indicating a complete electron delocalization over the two CN_2 units. The C1–C1A bond length between the CN_2 units is that of a single bond [1.522(5) Å]. Other selected bond lengths and angles are listed in Figure 2. The C3, C3A atoms of the allyl groups are disordered and distributed in two positions with equal occupancy factors. Furthermore, the oxalamidinate bridging ligand is coordinated in the (*E*) form. In other words, both isomeric forms **A** and **B** (Scheme 2) are present in the solid state. The Ni–C distances in the allylnickel fragment are identical within the experimental error; furthermore, the aromatic substituents are orientated to the plane of the oxalamidinato bridge at an angle of 82.3 and 78.8°, respectively.

The solid-state structure of complex **2** is very similar to that of **1** (Figure 3). The η^3-allyl groups are also disordered, according to the presence of the *syn* and the *anti* isomer (**A** and **B**, Scheme 2) in the solid state. Bond lengths and angles are very close to those of **1** and need no further discussion.

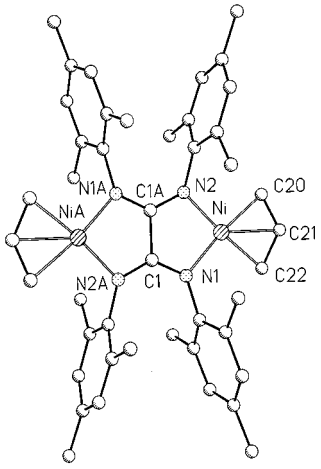

Figure 3. Molecular structure of complex **2**; for clarity the disordered allyl group is omitted; selected bond lengths [Å] and bond angles [°]: Ni–N1 1.919(2), Ni–N2 1.918(2), Ni–C20 2.005(3), Ni–C21 1.986(5), Ni–C22 2.005(3), N1–C1 1.327(3), N2–C1A 1.336(3), C1–C1A 1.525(4); N1–Ni–C20 173.4(1), N1–Ni–N2 85.18(7), N1–Ni–C22 100.5(1), N2–Ni–C20 101.3(1), N2–Ni–C22 174.3(1), C20–Ni–C22 73.1(1), Ni–N1–C1 113.5(1), N1–C1–C1A 114.2(2), C1–C1A–N2 113.3(2), C1A–N2–Ni 113.7(1); symmetry transformations used to generate equivalent atoms: A $-x + 2$, $-y$, $-z + 1$

The NMR-spectroscopic data confirm the presence of both the *syn*- and *anti*-allyl isomers in solution (see Exp. Sect.). The NMR spectra of **2** are relatively complicated. In the ^{1}H NMR spectrum, in [D_8]toluene at room temperature, two doublets of doublets for the CH_2 protons of the terminal allylic group are observed whilst the *meso*-CH protons give a multiplet at $\delta = 5.07$–5.17. These data are in agreement with the existence of two isomers in solution (Scheme 2, **A** and **B**) in which the sterically demanding mesityl groups are unsymmetrically bound giving rise to four different signals for the *o*-mesityl groups as well as for the *p*-methyl groups.

The relatively simple NMR spectra of complex **4** allow a deeper insight into the structure of the complex in $CDCl_3$ solution. In the ^1H NMR spectrum at room temperature only one signal for the protons of the methyl groups of the four *p*-tolyl substituents is observed at δ = 2.06 (relative intensity: 12). The aromatic protons of the CH groups resonate at δ = 6.50 and 6.56. Furthermore, two doublets for the 1-H/1′-H and 2-H/2′-H protons of the allyl groups of C-1 and C-1′, which each integrated for 4 H, are observed.

The most characteristic signals are the resonances of the *meso*-allylic protons, observed at δ = 5.28 and δ = 5.30, both as triplets of triplets integrated for 2 H. This clearly indicates the presence of two isomers in solution, which can be attributed to be the *syn* and the *anti* isomers **A** and **B** (with $R^1 = R^2$, Scheme 2). The molar ratio **A/B** is about 1:1. Consequently, in the ^{13}C NMR spectrum of **4** two resonances for the CH_2 carbon atoms of the allyl groups (at δ = 60.0, and 59.9) are observed. Furthermore, the carbon atoms of the aromatic ring show a double signal set. Additionally, the carbon atoms of the oxalamidinato bridge give rise to two signals at δ = 165.7 and 165.7. This also strongly supports the existence of both **A** and **B** in solution.

The palladium complex **5** contains two different nitrogen substituents and can therefore form four isomers **A**−**D** (Scheme 2). The exact orientation of the nitrogen substituents in the solid state as well as in solution is, however, still unknown.

The solid-state structures of the dinuclear (acetylacetonato)palladium(II) complexes **9** and **10** have also been fully characterized by X-ray diffraction. Figure 4 shows a view of the structure of **9** with the atom-numbering scheme and selected bond lengths and angles.

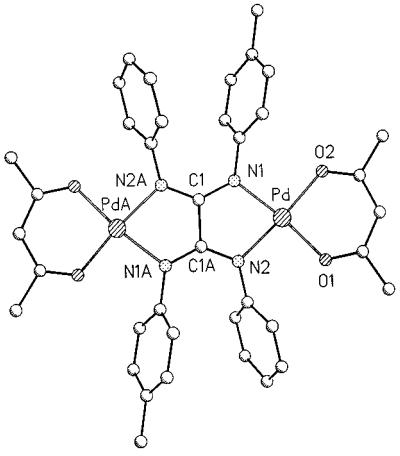

Figure 4. Molecular structure of complex **9**; selected bond lengths [Å] and bond angles [°]: Pd−O1 2.007(2), Pd−O2 2.015(2), Pd−N1 2.015(3), Pd−N2 2.024(3), N1−C1 1.332(4), N2−C1A 1.332(4), C1−C1A 1.522(6); N1−Pd−N2 80.9(1), N1−Pd−O1 173.9(1), N1−Pd−O2 94.3(1), N2−Pd−O1 93.0(1), N2−Pd−O2 174.7(1), O1−Pd−O2 91.79(9), Pd−N1−C1 115.4(2), N1−C1−C1A 114.2(3), C1−C1A−N2 114.5(3), C1A−N2−Pd 115.0(2); symmetry transformations used to generate equivalent atoms: A $-x + 2, -y + 1, -z + 2$

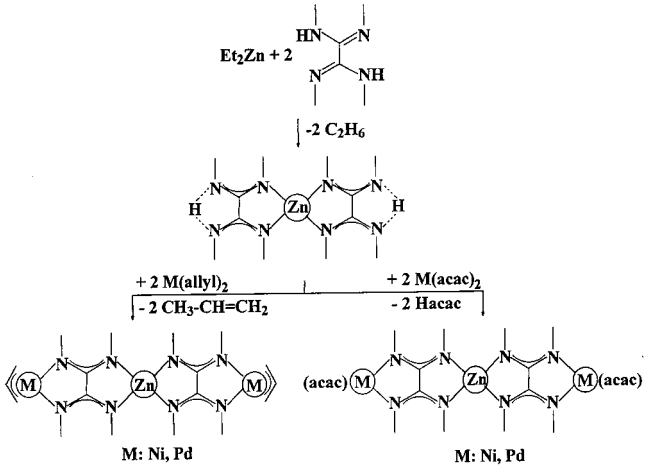
As expected, the coordination around the palladium centre is square-planar. The bond lengths and angles are quite normal and comparable with those of the other dinuclear oxalamidinato complexes. The substituents R^1 and R^2 at the oxalamidinate ligand assume the (*E*) form. In the ^1H NMR spectrum, in $CDCl_3$, complex **9** shows the expected number of resonances for the protons in the aromatic region and for the CH_3 and the CH protons of the acac ligand having the expected intensities.

Complex **10** containing four *p*-tolyl substituents has the same molecular structure in the solid state as **9** (not depicted). Furthermore, the bond lengths and angles are very close to those found in complex **9**. Consequently, the ^1H NMR spectrum of **10** in $[D_8]THF$ at room temperature shows the expected simple pattern for a symmetrical structure: The number of signals of the oxalamidinato and acetylacatonato ligands (δ = 1.43 for the methyl protons of the acac ligand; δ = 2.05 for the *p*-methyl groups; δ = 5.04 for the *meso* proton of acac; δ = 6.52 and 6.59 for the aromatic protons) and their integration confirm the equivalence of the two halves of the complex, as already observed in the solid state. As expected for a symmetrical structure, nine signals were found in the ^{13}C NMR spectrum of **10**.

Tri- and Tetranuclear Complexes Containing Zinc(II) in the Inner Part

The synthesis of oligometal complexes with Zn^{II} as the inner metal ion ("structural" metal) was carried out as follows: According to Scheme 3, 1 equiv. $ZnEt_2$ was very slowly treated with a solution of 2 equiv. of the free oxalamidine. Once the formation of ethane was finished, the in situ formed bis(oxalamidinato)Zn^{II} complex, containing two monoanionic oxalamidinates, was treated with $M(acac)_2$ or with $(allyl)_2Pd$ resulting in the elimination of acetylacetone or propene. Upon workup, the crystalline heterotrinuclear complexes **12**−**14** were isolated (Scheme 3).



Scheme 3. Formation reaction of the heterotrinuclear complexes **12**−**14** [**12**: Ni(acac), tetramesityloxalic amidinate as bridge; **13**: Pd(acac), tetrakis(*p*-tolyl)oxalic amidinate as bridge; **14**: (allyl)Pd, tetrakis(*p*-tolyl)oxalic amidinate as bridge]

The NMR spectra of **12** and **13** are very similar. Since the Pd complex **13** contains two different types of nitrogen-

bound *p*-tolyl substituents (coordinating either at Pd or at Zn), the ^{1}H NMR spectrum ([D$_8$]THF) displays two resonances at δ = 2.02 and 2.09 for the methyl protons of the *p*-tolyl groups, a singlet for the methyl protons of the acac ligands at δ = 1.54, a singlet for the *meso*-CH group of acac at δ = 5.10, and a multiplet for the aromatic protons between δ = 6.49 and 6.55. The relative intensities of these proton signals (12:12:12:2:32) are in agreement with the trinuclear structure of **13**.

Two different resonances for the methyl protons were also found in the trinuclear η^3-allyl−Pd−Zn−Pd complex **14**. Furthermore, in the region of the CH$_2$ protons of the η^3-allyl groups four signals between δ = 2.66 and 2.44 are observed indicating the presence of two stereoisomers in solution. The ^{13}C NMR spectrum of **14** in CDCl$_3$ at room temperature confirms this. Two signals are indicated for both the carbon atoms of the CH$_2$ group (at δ = 20.52 and 20.58) and the CH group (at δ = 59.9 and 60.5) of the allyl ligands.

The tetranuclear complexes **15** and **16** were formed as follows: In the first step the inner Zn^{II} part was built up in situ by treating 2 equiv. of ZnEt$_2$ with 3 equiv. of the oxalamidine to form a reactive intermediate "[(H-oxam)Zn(oxam)Zn(oxam-H)]", which was able to act as a "metalloligand" using two N−H functions at the periphery for the reaction with 2 equiv. Ni(acac)$_2$. Upon elimination of acetylacetone, **15** crystallized at 0 °C. Alternatively, the above Zn$_2$ intermediate can undergo a reaction with ZnEt$_2$ or [(Et)Zn(acac)]$_2$ (**17**) resulting in the formation of the Zn$_4$ complex **16**.

Both complexes **15** and **16** contain two inner metal ions (Zn) and two peripheral metal ions (Ni or Zn). The single-crystal study of **16** reveals a tetrameric molecule that possesses two acetylacetonate ligands bound to each peripheral Zn ion. The four Zn ions adopt distorted tetrahedral coordination geometries with two ZnN$_4$ donor sets in the middle and two ZnN$_2$O$_2$ donor sets at the periphery. The structure of **16** is depicted in Figure 5. This molecule has no imposed symmetry. The relevant bond lengths and angles are collected in the figure captions. The Zn−N distances of the four Zn-containing tetrahedrons are statistically indistinguishable. Each of the acetylacetonate ligands is bound to Zn in a symmetrical bidentate manner. The Zn(acac) moieties are associated with average Zn−O distances of 1.952(5) Å.

The most interesting finding is, that the bis(mesityl)bis(*p*-tolyl)oxalamidinate ligands coordinate in different forms. The two peripheral oxam ligands assume the (*Z*) configuration with the two mesityl groups situated in peripheral positions. This may be due to the bulkiness of the mesityl groups. In the oxalamidinato bridge in the middle, however, the nitrogen substituents assume the (*E*) configuration. Consequently, the two inner Zn ions are surrounded by three *N*-tolyl groups and one *N*-mesityl group.

The only remarkable difference to the molecular structure of the Ni$_2$Zn$_2$ complex **15** is, that in **15** the peripheral Ni^{II} centres are in a square-planar environment,[10] whereas the inner part adopts the same coordination of the Zn

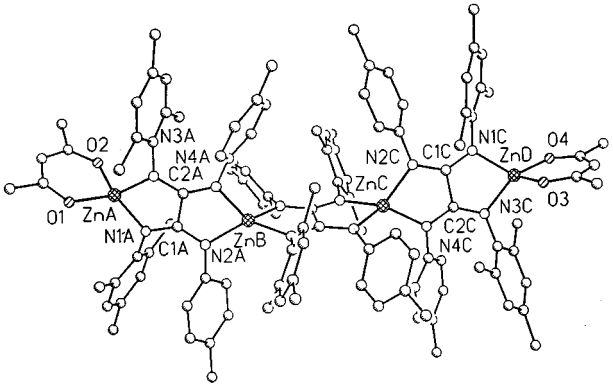


Figure 5. Molecular structure of complex **16**; selected bond lengths [Å] and bond angles [°]: ZnA−O1 1.949(4), ZnA−O2 1.963(5), ZnA−N1A 1.970(5), Zn−N3A 1.990(5), N1A−C1A 1.340(7), N2A−C1A 1.331(7), N3A−C2A 1.338(7), N4A−C2A 1.331(7), C1A−C2A 1.553(9), ZnB−N2A 1.996(5), ZnB−N4A 2.002(5), ZnB−N1B 1.995(5), ZnB−N3B 1.995(5), N1B−C1B 1.324(7), N2B−C1B 1.341(7), N3B−C2B 1.311(7), N4B−C2B 1.347(7), C1B−C2B 1.573(7), ZnC−N2B 1.992(5), ZnC−N4B 1.992(5), ZnC−N2C 2.006(5), ZnC−N4C 1.994(5), N1C−C1C 1.322(8), N2C−C1C 1.341(8), N3C−C2C 1.333(7), N4C−C2C 1.332(8), C1C−C2C 1.571(8), ZnD−N1C 1.978(5), ZnD−N3C 1.986(5), ZnD−O3 1.955(5), ZnD−O4 1.940(5); O1−ZnA−O2 95.3(2), O1−ZnA−N1A 126.1(2), O1−ZnA−N3A 119.7(2), O2−ZnA−N1A 120.6(2), O2−ZnA−N3A 112.7(2), N1A−ZnA−N3A 84.2(2), N2A−ZnB−N4A 83.1(2), N2A−ZnB−N1B 132.0(2), N2A−ZnB−N3B 120.6(2), N4A−ZnB−N1B 121.4(2), N4A−ZnB−N3B 122.6(2), N2B−ZnC−N4B 83.5(2), N2B−ZnC−N2C 120.4(2), N2B−ZnC−N4C 119.4(2), N4B−ZnC−N2C 120.4(2), N4B−ZnC−N4C 133.0(2), N2C−ZnC−N4C 83.1(2), O3−ZnD−O4 95.9(2), O3−ZnD−N1C 115.9(2), O3−ZnD−N3C 117.2(2), O4−ZnD−N1C 123.5(2), O4−ZnD−N3C 122.1(2), N1C−ZnD−N3C 84.4(2)

atoms as in **16**. The relevant bond lengths and angles in **16** are also very close to those in **15**. Since complex **16** has limited solubility in common solvents, its ^{13}C NMR spectrum could not be recorded. The ^{1}H NMR spectrum of **16** consists of six signals for the different methyl groups, one resonance for the CH proton of acac, and the signals for the aryl protons.

Catalytic Reactions

Catalytic Oligomerization/Polymerization of Ethene

Although the catalytic polymerization/oligomerization of ethylene is a well-known reaction[11−13] selective catalysts for the polymerization based on Ni^{II} or other late transition metals are very rare. Recently, Brookhart and co-workers described cationic diimine−Ni and −Pd catalysts as highly active for ethylene polymerization.[14−18] Independently, Brookhart,[19] and Gibson[20] developed cationic Fe^{II} catalysts with tridentate pyridiniminato ligands as efficient catalysts. Very recently, Grubbs and co-workers demonstrated that salicylaldiminatophenyl−Ni^{II} complexes are highly active single-site catalysts for the polymerization of 1-olefins.[21,22] Our initial investigations have shown that some dinuclear (oxalamidinato)Ni^{II} complexes are able to

act as catalysts for the oligomerization or for the polymerization of ethylene.[10]

Here we describe a study of the catalytic behaviour of di- and oligonuclear oxalamidinato complexes towards ethylene with the aim to rationalize the influence of the following three factors: bulkiness of the ligands, nature of the cocatalyst, and effect of the inner metal ion (Zn) on the catalytic activity and selectivity of the peripheral Ni^{II} ions.

The results of ethylene oligomerization/polymerization experiments are listed in Tables 2 and 3, respectively. Several features are noteworthy. In general, the catalysts are moderately active. When the catalytic reactions were carried out under an initial pressure of 10 atm in a sealed autoclave (containing 4000 mol of ethylene per mol catalyst) at 25 °C, the reactions could be used to determine the activities of the catalysts dependent on the above mentioned parameters.

The activities of the catalysts for the oligomerization were calculated from the GC traces, using extrapolated values for C_4-C_8; The catalytic activities for the polymerization were calculated from the amount of the isolated and dried polymer (see Exp. Sect.). Typically, the molecular weights of the polymers formed were around $1.2-6.7 \times 10^5$ g/mol (M_W) with $M_w/M_n = 1.4-2.0$ (Table 2).

Clearly, steric protection of the active sites is a crucial factor in controlling the selectivity and activity (Entries 4−6, Table 2). Upon activation with MAO or Et_3Al complex **8**, containing four sterically demanding mesityl substituents, is a polymerization catalyst. The reduced bulkiness of the four *p*-tolyl substituents on the nitrogen donor atoms in **6** leads to an oligomerization catalyst. In this case only C_4-C_8 olefins, and traces of C_{10} compounds are formed. Complex **7**, possessing both two *p*-tolyl groups and two mesityl groups in a (*Z*) arrangement in the oxam bridge,[10] catalyzes the oligomerization (to form C_4-C_8 olefins) as well as the polymerization reaction (Entry 6, Table 2). From this finding we can conclude that in complex **7** *both* Ni centres are catalytically active: One Ni^{II} centre, surrounded by the bulky mesityl group catalyzes the polymerization of ethylene. The other Ni^{II} centre on the opposite side, coordinating two sterically less demanding nitrogen-bound *p*-tolyl donor groups catalyzes the oligomerization of ethylene to yield C_4-C_8 oligomers.

This conclusion is supported by comparing the catalytic activity of the heterodinuclear Zn−Ni complex **11** with that of the homodinuclear Ni complex **8**. Both **8** and **11** contain

[a] Solvent: toluene (20 mL); catalysts: 0.031 mmol; ethylene: 0.123 mol in the sealed reactor = ca. 4000 mol ethylene/mol catalyst (ethylene pressure: 10 atm); reaction temperature 25 °C. − [b] TON: turnover number = mol of ethylene consumed/mol of Ni catalyst.

four bulky mesityl substituents and therefore act as polymerization catalysts in the presence of MAO. However, **8** contains *two* catalytically active Ni^{II} centres which produce the twofold amount of polyethylene as **11**, in which only *one* Ni^{II} is present while the opposite side of the oxalamidinato bridge is coordinated by Zn^{II} which is inactive (Entries 7 and 8, Table 2).

To examine the role of the cocatalyst in the polymerization we carried out several tests in which the cocatalysts as well as the ratio cocatalyst/Ni were varied. Table 3 lists the results. Upon activation with MAO, **8** is a polymerization catalyst, however a large excess of the cocatalyst is necessary for high turnover numbers (Entry 4, Table 2; Entry 3, Table 3). In contrast, Et_3Al activates the precatalyst **8** which is already at low ratios [Al]/[Ni]: Only 3 equiv. of this cocatalyst per Ni produce an active and selective polymerization catalyst (Entry 9, Table 3) while a large excess does not significantly increase the activity. These results are in agreement with the assumption that in the case of the oxalamidinato complexes bearing dianionic oxalamidinato bridges cationic species are responsible for the catalytic activity. Furthermore, Et_3Al only activates the "polymerization site" of complex **7**, since no oligomerization products were obtained.

To test the influence of the inner metal ion Zn on the catalytic activity we compared the catalytic behavior of the dinuclear complex **8** with that of the trinuclear $ZnNi_2$ complex **12**. Both complexes contain only bulky mesityl substituents and are therefore polymerization catalysts. Table 3 clearly demonstrates that a high excess of MAO ([Al]/[Ni] = 150:1) activates the polymerization of ethylene; however, the Zn-containing complex **12** is significantly more active (Entries 1−4, Table 3). On the other hand, Et_3Al is also a powerful cocatalyst for both complexes; in this case much lower concentrations are required (Entries 5−12, Table 3). The most important finding is, however, that **12** is much more active than **8** when Et_3Al is used. Remarkably, only 2 equiv. Et_3Al per Ni are necessary to establish a highly active system (Entry 8, Table 3). In conclusion, all results of Table 3 clearly demonstrate that the inner Zn ion significantly increases the catalytic activity.

The tetranuclear complex **15** is an oligomerization catalyst, although the two peripheral Ni atoms are surrounded by two bulky *N*-mesityl groups similar to both the catalysts **8** and **12**, which are active in polymerization. The reason for this difference may be seen in the additional influence of the inner coordination polyhedra on the peripheral active Ni^{II} centres. In **8** and **12**, all nitrogen donor groups bear bulky mesityl substituents, while the inner part in **15** contains less bulky *p*-tolyl groups. This difference might be responsible for switching the polymerization activity found for both **8** and **12** to oligomerization activity observed for **15** (Entries 3 and 4, Table 3 versus Entry 18, Table 2). As expected, the Zn_4 complex **16** is catalytically inactive. Furthermore, both the η^3-allyl complexes, and the Pd complexes are inactive.

In order to test the productivity of a typical polymerization catalyst at higher pressure we carried out the catalytic reaction with the system **8**/MAO (1:300) using an initial pressure of 50 bar ethylene at 60 °C. Under these conditions a waxy polymer was formed in a selective polymerization reaction with a turnover frequency of approximately 10^5 mol ethylene consumed/(Ni × h × bar ethylene). This polymer contained about 140 methyl groups per 1000 CH_2 groups, determined by ^1H NMR spectroscopy.

In conclusion, the catalytic activity and selectivity of oligonuclear (oxalamidinato)nickel(II) complexes can be tuned by the bulkiness of the nitrogen substituents (sterically demanding substituents increase the polymerization activity), the nature of the cocatalyst (Et_3Al in low molar ratios is the best cocatalyst), and the nuclearity of the complexes (the inner Zn ion in complexes with bulky nitrogen substituents increases significantly the polymerization activity).

Catalytic Heck Reaction

The Heck coupling is a very useful method for the formation of substituted arylated olefins starting with Ar−X and the substituted olefins, which is catalyzed by a variety of palladium complexes with different controlling ligands.[23,24] Among the most active catalysts are palladacycles with C,P coordination [25−27] and (carbene)palladium complexes.[28−32]

To test the ability for catalyzing the Heck coupling we used, in initial catalytic experiments, some di- and trinuclear palladium complexes as homogeneous catalysts for the coupling of bromoacetophenone with *n*-butyl acrylate. Table 4 shows that most of the coupling reactions were fast and selective, when the catalytic reactions were carried out at 120 °C in dimethylacetamide as solvent using sodium acetate as base. The main product is *n*-butyl (*E*)-4-acetylcinnamate. A deposit of palladium was not observed when the reactions were carried out below 125 °C.

The experimental data clearly show that the influence of different nitrogen substituents is low (Entries 1−4, Table 4). On the other hand, the inner metal ion (Zn) increases the selectivity of the catalytic reaction (Entries 5−8, Table 4). With the heterotrinuclear Pd_2Zn complex **14** turnover numbers of 285000 (after 5 h) and 435000 can be achieved (Entry 8 after 27 h). This corresponds with an average turnover frequency (TOF) of about 57000 mol converted substrate/mol catalyst per hour in the first 5 h and a TOF of about 16100 over the next 27 h. These results clearly demonstrate the catalytic potential of the (oxalamidinato)palladium complexes and give evidence for the activating effects of the inner "structural metal ion" (Zn) on the catalytic behavior of the peripheral "functional" metal ions.

Experimental Section

General: The oxalic amidine ligands were prepared according to literature procedures. CH_3MgBr and CH_3MgCl (3 M in diethyl ether), purchased from Aldrich were used without additional purification. All reactions were carried out under argon and the solvents used were dried by means of standard Schlenk techniques. −

Table 4. Catalytic Heck coupling between bromoacetophenone and *n*-butyl acrylate with di- and trinuclear palladium-based catalysts

[a] Conditions: 6.25 mmol *p*-bromoacetophenone, 6.75 mmol *n*-butylacrylate, solvent *N*,*N*-dimethylacetamide (8 mL), 7 mmol CH_3COONa as base, molar ratio substrate/catalyst Entries 1−6: 5000:1; Entry 7: 50000:1; Entry 8: 500000:1; reaction temperature: 120 °C. − [b] *n*-Butyl (*E*)-4-acetylcinnamate.

^1H and ^{13}C NMR spectra were recorded at ambient temperature, unless otherwise stated, with a Bruker AC 200-MHz spectrometer. Numbering for the η^3-allyl groups in the ^1H NMR spectra: CH_2-allyl: 1-H, and 2-H; *meso*-CH-allyl: 3-H. All spectra were referenced to TMS or deuterated solvent as an internal standard. − FAB mass spectra were obtained with a Finnigan MAT SSQ 710 spectrometer (2,4-dimethoxybenzyl alcohol as matrix). − IR measurements were carried out with a Perkin−Elmer System 2000 FT-IR. − Elemental analyses (C, H, and N) were carried out at the Microanalytical Laboratory of the Friedrich-Schiller-Universität Jena. For the determination of the metals, the organic material of the complexes were oxidized using hot concentrated perchloric acid (***CAUTION: Explosions are possible!***) followed by distillation of most of the acid, and slow addition of water to the cold solutions. Metals were determined by complexometric titrations. − The syntheses of the oxalamidinato complexes **6−8**, **11**, and **15** were recently described in a preliminary communication.[10] Oxalic amidines,[33] $(\eta^3\text{-allyl})_2Ni$,[34] and $[\eta^3\text{-allylPdCl}]_2$,[35] were prepared as described. − $(\eta^3\text{-allyl})_2Pd$ was prepared by the following modified method:[36] Bis[(η^3-allyl)chloropalladium(II)] (0.5 g, 1.37 mmol), dissolved in 40 mL of THF, was cooled to −60 °C. To the clear yellow solution allylmagnesium chloride (2.74 mmol of a 2 M solution in THF) was added dropwise under stirring. Then the reaction mixture was allowed to warm very slowly to −30 °C, followed by evaporation of the solvent from the brown solution at −25 °C in vacuo. The solid reaction product was washed twice with 10 mL of *n*-pentane at 18 °C (decomposition at 20 °C), the yellow *n*-pentane solution was cooled to −50 °C. At this temperature the solvent was removed in vacuo.The last step was the sublimation of the reaction product in vacuo at −25 °C to form the very pure complex. Yield 180 mg (70%).

Complex 1: Bis[η^3-allyl(chloro)nickel(II)] (0.263 g, 0.97 mmol) was dissolved in 60 mL of THF. At −78 °C allylmagnesium chloride (1.945 mmol of a 2 M solution in THF) was added very slowly to the stirred solution. Then the yellow reaction mixture was allowed to warm to −20 °C. Slow addition of bis(mesityl)bis(*p*-tolyl)oxalamidine (0.490 g, 0.97 mmol), dissolved in 20 mL of THF, to the stirred solution resulted in a deep yellow solution. After 12 h of stirring at −5 °C, the reaction mixture was warmed to room temperature. After 2 h, the solvent was removed in vacuo. The residue was extracted with *n*-pentane and the solution filtered. At 5 °C yellow crystals of complex **1** formed. Single crystals of **1** were obtained by recrystallization from *n*-pentane or *n*-hexane. Yield 560 mg (82%). − $C_{40}H_{46}N_4Ni_2$ (700.2): calcd. Complex 5: The crude material was extracted with diethyl ether at room temperature. Colorless crystals were isolated at 4 °C. Yield 716 mg (90%). − $C_{40}H_{46}N_4Pd_2$ (795.6): calcd. C 60.38, H 5.83, N 7.04; found C 59.68, H 5.51, N 6.84. − ^{1}H NMR ($CDCl_3$, 298 K, 400 MHz): δ = 1.96, 2.01, 2.04, 2.17, 2.19, 2.22, 2.24, 2.25, 2.27, 2.29 (m, CH_3, 24 H), 2.31, 2.33, 2.36, 2.38, 2.44 (m CH_2-allyl, 8 H), 5.22 (m, CH-allyl), 6.32 (broad, CH-aromat, 4 H), 6.48, 6.62 (AA′BB′, $^3J_{AB}$ = 8.1 Hz, CH aromat, 4 H + 4 H). − ^{13}C NMR ([D_8]THF, 298 K, 50.3 MHz): δ = 19.4, 20.6 (CH_3), 57.5, 59.0 (CH_2-allyl), 114.4, 114.5, 114.6 (CH-allyl), 123.5, 123.6, 127.7, 128.2, 128.3 (CH aromat), 129.9, 130.3, 130.4, 131.7, 132.0 (C aromat), 148.8, 150.7 (*ipso*-C of *p*-tolyl, mesityl), 164.4 (C of the oxam bridge). − IR (nujol): $\tilde{\nu}$ = 1539, 155 8, 1609 cm^{-1} (C=C_{aromat}, CN). − MS (EI): *m*/*z* (%) = 794 (31) [M^+], 647 [$M^+ - C_3H_5Pd$].

Complex 9: Bis(phenyl)bis(*p*-tolyl)oxalamidine (418 mg, 1 mmol) and bis(acetylacetonato)palladium(II) 710 mg, 2 mmol), suspended in 20 mL of toluene, were refluxed for 3 h to give a clear solution. Upon distillation of 15 mL of the solvent at normal pressure the solid was filtered from the warm solution and washed first with toluene at room temperature, and then three times with diethyl ether. Recrystallization from hot benzene gave red crystals, suitable for an X-ray analysis. Compound **9** is sparingly soluble in $CHCl_3$, THF, and toluene, and practically insoluble in *n*-pentane. Yield 745 mg (90%). − $C_{38}H_{38}N_4O_4Pd_2$ (827.6): calcd. C 55.15, H 4.63, N 6.77; found C 55.62, H 4.60, N 6.31. − ^{1}H NMR ($CDCl_3$, 298 K, 400 MHz): δ = 1.41, 1.43 (2 × s, CH_3-acac, 12 H), 2.01 (s, CH_3-*p*-tolyl, 6 H), 5.04 (s, CH-acac, 2 H), 6.54−6.60, 6.70 (2 × m, CH-aromat, 16 H). − ^{13}C NMR ([D_8]THF, 298 K, 50.3 MHz): δ = 20.8 (CH_3-*p*-tolyl), 25.2 (CH_3-acac), 100.4 (CH-acac), 123.8, 127.3, 127.4, 128.0, 128.3, 133.4, 142.4, 145.2 (CH-aromat), 169.7 (C, oxam bridge). − IR (nujol): $\tilde{\nu}$ = 1506, 1539, 1578 cm^{-1} (C=C_{aromat}, CN, C=O). − MS (EI): *m*/*z* (%) = 828 (10) [M^+], 728 (4) [M^+ − acac], 621 (1) [M^+ − acacPd], 415 (4) [M+ − $acac_2Pd_2$].

Complex 10: The reaction was carried out as described for **9** using tetrakis(*p*-tolyl)oxalic amidine (440 mg, 0.98 mmol). Yield 755 mg (90%). − $C_{40}H_{42}N_4O_4Pd_2$ (855.6): calcd. C 56.15, H 4.95, N 6.55; found C 55.71, H 4.68, N 6.30. − ^{1}H NMR ($CDCl_3$, 298 K, 400 MHz): δ = 1.43 (s, CH_3-acac, 12 H), 2.05 (s, CH_3-*p*-tolyl, 12 H), 5.04 (s, CH-acac, 2 H), 6.52, 6.59 (AA′BB′, $^3J_{AB}$ = 8.5 Hz, CH-aromat, 12 H). − ^{13}C NMR ($CDCl_3$, 298 K, 50.3 MHz): δ = 20.8 (CH_3-*p*-tolyl), 25.4 (CH_3-acac), 100.3 (CH-acac), 127.1, 127.3, 132.9, 141.4 (CH-aromat), 169.4 (C, oxam bridge), 185.8 (CH-acac). − IR (nujol): $\tilde{\nu}$ = 1506, 1522, 1540, 15744 cm^{-1} (C=C_{aromat}, CN, C=O). − MS (EI): *m*/*z* (%) = 856 (3) [M^+], 756 (4) [M^+ − acac], 657 (4) [M^+ − 2 acac], 649 (3) [M^+ − acacPd], 550 (4) [M^+ − $acac_2Pd$], 443 (7) [M^+ − $acac_2Pd_2$].

Complex 12: Tetramesityloxalic amidine (2 mmol, 1.12 g) was dissolved in 50 mL of THF, and dropwise treated with $ZnEt_2$ (1.1 M solution in toluene, 0.91 mL) at room temperature. After stirring and heating for about 30 min, a solution of bis(acetylacetonato)-nickel(II) (0.51 g, 2 mmol in 10 mL of THF) was added. The color turned red within a few minutes. After stirring overnight, a red microcrystalline substance precipitated. The precipitate was filtered and washed with 10 mL of diethyl ether. Yield about 0.90 g (30%). − $C_{86}H_{102}N_8Ni_2O_4Zn$ (1494.6): calcd. C 69.11, H 6.88, N 7.50, Ni 7.85, Zn 4.38; found C 69.42, H 6.51, N 7.20, Ni 7.24, Zn 4.23. − ^{1}H NMR ([D_8]THF, 298 K, 200 MHz): δ = 1.05, 1.13 (m, CH_3-acac, 12 H), 1.69 (s, CH_3-mesityl, 12 H), 1.93, 1.95 (s, CH_3-mesityl, 12 H), 2.14 (s, CH_3-mesityl, 12 H), 2.50, 2.53, (s, CH_3-mesityl, 36 H), 4.98, 5.05 (s, CH-acac, 2 H), 6.25−6.34 (m, CH-aromat, 16 H). − ^{13}C NMR ([D_8]THF, 298 K, 50.3 MHz): δ = 19.7, 20.5, 20.6, 21.0 (CH_3-aromat), 24.9 (CH_3-acac), 100.3, 100.7 (CH-acac), 127.7, 127.9, 128.4, 131.9, 132.3, 132.9, 133.1, 134.55, 134.63, 140.64, 141.3, 143.1 (C-aromat), 162.6, 166.4 (C_{tert}-bridge), 186.8, 194.6 (CO-acac).

Complex 13: To a stirred solution of tetrakis(*p*-tolyl)oxalic amidine (440 mg, 0.98 mmol) in 30 mL of toluene, $ZnEt_2$ (0.49 mmol), dissolved in 20 mL of toluene, was slowly added dropwise, followed by 15 min of stirring. At room temperature a suspension of bis(acetylacetonato)palladium(II) (300 mg, 0.98 mmol) in 20 mL of toluene was added and the mixture was refluxed for 1 h. The solvent was then removed in vacuo, and the orange residue was washed four times with 10-mL portions of *n*-pentane. The residue was dissolved in 50 mL of diethyl ether under 15 min of stirring and filtered. The solvent was very slowly removed. In a first fraction Pd(acac)$_2$ crystallized from the solution, while **15** crystallized later. Upon dissolution of impure **15** in diethyl ether this procedure was repeated. Orange crystals of **15** were isolated, which are soluble in THF, toluene, and diethyl ether, and practically insoluble in *n*-pentane. Yield 602 mg (45%). − $C_{70}H_{70}N_8O_4Pd_2Zn$ (1365.6): calcd. C 61.57, H 5.17, N 8.21; found C 61.3, H 5.22, N 7.66. − ^{1}H NMR ($CDCl_3$, 298 K, 400 MHz): δ = 1.54 (s, CH_3-acac, 12 H), 2.09, 2.20 (2 × s, CH_3-*p*-tolyl, 24 H), 5.10 (s, CH-acac, 2 H), 6.25−6.55 (m CH-aromat, 32 H). − ^{13}C NMR ($CDCl_3$, 298 K, 50.3 MHz): δ = 20.7, 20.8 (CH_3-*p*-tolyl), 24.6 (CH_3-acac), 100.4 (CH-acac), (CH-aromat), 162.1 (C, oxam bridge), 186.4 (CH-acac). − IR (nujol): $\tilde{\nu}$ = 1507, 1540, 1572, 110 cm^{-1} (C=C_{aromat}, CN, C=O). − MS (ESI, THF/CH_3OH/$CHCl_3$ as solvent mixture): *m*/*z* (%) = 1159 (1) [M^+ − acacPd], 475 (100) [M^+ − $acac_2Pd_2$], 444 [M^+ − $acac_2Pd_2$ − Zn].

Complex 14: The reaction was carried out as described for **13** using bis([η^3-allyl)palladium(II)] at 0 °C. Upon distillation of the solvent in vacuo the residue was washed four times with *n*-pentane. Recrystallization from diethyl ether yielded yellow crystals soluble in THF, toluene, and diethyl ether. Compound **14** contains 1 equiv. diethyl ether/mol complex (GC). Yield 480 mg (36%). − $C_{70}H_{76}N_8OPd_2Zn$ (1323.6): calcd. C 63.35, H 5.74, N 8.47, Zn 4.94; found C 63.73, H 5.60, N 8.21, Zn 4.70. − ^{1}H NMR ($CDCl_3$, 298 K, 200 MHz): δ = 2.03, 2.06 (s, CH_3-*p*-tolyl, 24 H), 2.44, 2.47, 2.54 (3 × d, CH_2-allyl, $^3J_{3,2}$ = 3.4 Hz, 3 H), 2.66 (m, CH_2-allyl, 5 H), 5.31 (m, CH-allyl, 2 H), 6.16−6.51 (m, CH-aromat, 32 H). − ^{13}C NMR ($CDCl_3$, 298 K, 50.3 MHz): δ = 20.52, 20.58 (CH_3-*p*-tolyl), 59.9, 60.5 (CH_2-allyl) 114.1, 114.3 (CH-allyl), 123.97, 123.01, 124.2, 124.6, 127.47, 127.51, 127.66, 127.71, 130.48, 130.51, 130.99, 131.02 (CH-aromat), 143.77, 143.82, 150.0, 150.3 (C-aromat), 160.7, 160.8 (C oxam bridge). − IR (nujol): $\tilde{\nu}$ = 1506, 1609 cm^{-1} (C=C_{aromat}, CN). − MS (EI): *m*/*z* (%) = 1248 (< 1) [M^+], 740 (5) [M^+ − oxamZn], 591 (2) [M^+ − allylPd − oxamZn].

Complex 16: Bis(mesityl)bis(*p*-tolyl)oxalic amidine (1 mmol, 0.50 g) was dissolved in 38 mL of THF, and treated dropwise with 2 mmol

of $ZnEt_2$ (1.1 M solution in toluene, 1.8 mL) at room temperature. After 5 min of heating, the solution was stirred for 20 min and then treated with bis(mesityl)bis(*p*-tolyl)oxalic amidine (2 mmol, 1.0 g, dissolved in 12 mL of THF). This solution was refluxed for 3 min, cooled and treated with bis(acetylacetonato)(ethyl)zink(II) complex **19** (2 mmol, 0.387 g, dissolved in 10 mL of THF). Standing at room temperature for 2 d resulted in the crystallization of pure, colorless crystals of **16**, crystallizing with 2.5 equiv. THF, suitable for an X-ray analysis. Yield 290 mg (45%). − $C_{112}H_{122}N_{12}O_4Zn_4 \times 2.5$ C_4H_8O (2142.1): calcd. C 68.41, H 6.68, N 7.85; found C 67.0 H, 6.55, N 7.42. − ^{1}H NMR ($CDCl_3$, 298 K, 400 MHz): δ = 1.49, 1.64, 1.77, 1.91, 2.01, 2.08 (s, CH_3-acac, CH_3-*p*-tolyl, CH_3-mesityl, 84 H), 5.01 (s, CH-acac, 2 H), 6.1−6.54 (CH-aromat, 36 H). − MS (ESI in CH_3OH/THF): *m*/*z* (%) = 1067 (4) [$Zn(oxam)_2$].

Complex 17: Acetylacetone (10 mmol, 1.001 g), dissolved in 10 mL of toluene, was slowly treated with $ZnEt_2$ (10 mmol, 1.1 M toluene solution) at room temperature. After all the ethane was released, the solution was kept at −18 °C and colorless crystals were isolated. Yield 2.11 g (55%). − $C_{14}H_{24}O_4Zn_2$ (387.1): calcd. C 43.43, H 6.25; found C 43.64, H 6.11. − ^{1}H NMR ([D_8]toluene, 298 K, 200 MHz): δ = 0.52 (q, CH_2-ethyl, 2 H), 1.44 (t, CH_3-ethyl, 3 H), 1.75 (s, CH_3-acac, 6 H), 5.01 (s CH-acac 1 H). − ^{13}C NMR ([D_8]toluene, 298 K, 50.3 MHz): δ = − 0.03 (CH_2-ethyl), 12.8 (CH_3-methyl), 28.1 (CH_3-acac), 101.8 (CH-acac). − MS (EI): *m*/*z* (%) = 262 (61) [$Zn(acac)_2$], 192 (6) [M^+/2], 163 (68) [M^+/2 − 2 Et].

Catalytic Polymerization/Oligomerization: A 200-mL stainless steel autoclave was heated in vacuo for 2 h at approximately 100 °C and subsequently cooled to 25 °C. A solution of 0.031 mol of the catalyst precursor, dissolved in toluene, was treated either with MAO (5 M solution in toluene) or with Et_3Al (1.9 M solution in toluene). The total volume of the added solutions was 20 mL. After the autoclave was charged with this solution, catalytic reactions were carried out at 25 °C in the sealed autoclave whilst stirring (initial pressure of ethylene: 10 atm = 0.123 mol ethylene). No further ethylene was added during the reaction. After the desired reaction time (Tables 2 and 3) the reaction mixture was cooled to 0 °C. The ethylene pressure was then released, and the cooled reaction mixture was treated with a small amount of dilute hydrochloric acid at 0 °C to inactivate the catalyst, followed by addition of 1.18 mL (0.87 g) of *n*-decane as standard for GC measurements.

Analysis of the Ethylene Oligomers: An aliquot (1 mL) of the reaction mixture was very slowly treated with dilute hydrochloric acid at 0 °C, followed by separation of the organic layer. After drying the organic phase with solid Na_2CO_3, the oligomers were analyzed by GC/MS using a methylsilicon column (CPSIL 5 CB), injector temperature 40 °C, with the following temperature program: 20 °C/min up to 300 °C (15 min). The individual products were identified by MS and integrated, using *n*-decane as the internal standard (comparison with GC calibration experiments). The turnover numbers (TON) were calculated as follows:

mol ethylene consumed = g oligomers/mol weight of ethylene = g oligomers/28 $gmol^{-1}$

TON = mol of ethylene consumed/mol catalyst = mol of ethylene consumed/$0.031 \cdot 10^{-3}$ mol catalyst.

In a typical example the following C_6 olefins from the catalysis with the oligomerization catalyst **6** (Entry 5, Table 2) were characterized by GC/IR (comparison with authentic samples): overall amount of C_6 olefins = 0.33 g (100%); 4-methylpentene: 2.1%; 2,3-dimethylbutene 3.2%; 1-hexene: 53%; *trans*-3-hexene: 21%; *trans*-2-hexene: 3.2%. Retention times under the analytical conditions used were as follows: butenes: 1.238 min; 4-methylpentene: 1.478 min; 2,3-dimethylbutene: 1.584 min; 1-hexene: 1.644 min; *trans*-3-hexene: 1.69 min; *trans*-2-hexene: 1.72 min. − In most of the catalytic reactions (Tables 2 and 3) only C_4 and C_6 olefins were found. Small amounts of C_8 olefins were found in a few of the catalytic reactions (Entries 5, 6, and 10, Table 2). C_{10} oligomers were detected only in traces (Entry 5, Table 2).

Analysis of the Polymer: An aliquot of the above solution was treated with a mixture of 500 mL of methanol and 20 mL of hydrochloric acid while stirring to precipitate the polymer. After the methanol/hydrochloric acid mixture was decanted, the polymer was washed with methanol (3 × 50 mL), and dried at 70 °C in vacuo. Yields and molecular weights can be found in Tables 2 and 3. The TONs for the polymerization were determined analogously with the above calculation (see Tables 2 and 3). The polymers were analyzed by GPC using THF as a solvent and polystyrene standards. Columns were packed with styrene−divinylbenzene copolymer; column temperature: 30 °C; flow rate: 1.00 mL/min; detector 1: UV 975 (Fa. Jasco); detector 2: RI 930 (Fa. Jasco). − Typically, M_w was around $1.57 \cdot 10^5$ to $6.73 \cdot 10^5$ with polydispersity indices between 1.46 and 2.66 (Table 2).

Polymerization at Higher Pressure: A typical experiment proceeded as follows: 0.031 mmol of complex **8** and $0.93 \cdot 10^{-2}$ mol of MAO ([Ni]/[Al] = 1:150) were dissolved in 20 mL of toluene. The catalysis was carried out at 55 bar ethylene pressure at 60 °C and stirring of the reaction mixture for 10 min. The isolation of the polymer followed the above procedure. Yield 9.1 g; turnover frequency (TOF): approximately 55 g/mmol cat × bar × h. In this case a waxy polymer was obtained. According to the integration of the CH, CH_2, and CH_3 protons in the ^{1}H NMR spectrum ([D_8]toluene, 298 K, 200 MHz) approximately 140 branches/1000 ethylene units were present.

Heck Coupling: In a typical run, a 25-mL Schlenk tube was charged with an aryl halide (6.25 mmol), anhydrous sodium acetate (7 mmol) and put under argon followed by addition of *N*,*N*-dimethylacetamide (8 mL) and *n*-butyl acrylate (6.75 mmol) The solution was heated to 120 °C before the catalyst, dissolved in toluene, was added. After the reaction time, the reaction mixture was cooled and analyzed by gas chromatography.

Crystal Structure Determination: The intensity data for the compounds were collected with a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarization effects, but not for absorption.[37,38] The structures were solved by direct methods (SHELXS[39]) and refined by full-matrix least-squares techniques against F_o^2 (SHELXL-97[40]). Since the quality of the data of compound **17** is too bad, only the conformation of the molecule and the crystallographic data are communicated. Furthermore, this data will not be published in the Cambridge Crystallographic Data Centre. The allyl groups of **1** and **2** are disordered. The disorder could be solved. The hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[41] XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

Crystal Data for 1:[41] $C_{40}H_{46}N_4Ni_2$, M_r = 700.23 g·mol^{-1}, gold-yellow prism, size 0.20 × 0.20 × 0.10 mm, triclinic, space group $P\bar{1}$, *a* = 8.8877(4), *b* = 9.2005(5), *c* = 11.8562(5) Å, α = 107.550(3), β = 95.843(3), γ = 98.779(3)°, *V* = 902.23(7) Å^3, *T* = −90 °C, *Z* = 1, $\rho_{calcd.}$ = 1.289 gcm^{-3}, μ(Mo-K_α) = 10.76 cm^{-1}, *F*(000) = 370, 6624 reflections in *h*(−11/11), *k*(−11/11), *l*(−15/14), measured in the range 3.19° ≤ Θ ≤ 27.53°, completeness Θ_{max} = 98.7%, 4104 independent reflections, R_{int} = 0.028, 3353 reflections with $F_o > 4\sigma(F_o)$, 218 parameters, 0 restraints, $R1_{obs}$ = 0.053, wR^2_{obs} = 0.101,

A Novel Salt Formed by Mixed-Valence Vanadium(IV, V) $[(VO)_2O(bpy)_2(C_2O_4)_2]$ Anions and Ferromagnetic $[Cu_2(bpy)_4(C_2O_4)]$ Cations: Structure, Spectroscopic Characterization and Magnetic Properties

Otilia Costisor,*[a] Maria Brezeanu,[a] Yves Journaux,[b] Kurt Mereiter,[c] Peter Weinberger,[d] and Wolfgang Linert[d]

Keywords: Vanadium / Copper / Oxalate ligands / Magnetic properties

The new heterometallic, mixed-valence compound $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$ has been synthesized, its crystal structure determined and its spectroscopic characterization accomplished by means of solid-state vibrational (far and mid FTIR) spectroscopy. The title compound crystallises in the triclinic system, space group $P\bar{1}$ (No. 2) [a = 13.488(5) Å, b = 14.160(6) Å, c = 15.829(9) Å, α = 87.22(2)°, β = 66.33(2)°, γ = 64.49(2)°, V = 2471(2) Å^3, Z = 1]. The compound consists of the cationic binuclear copper(II) complex $[Cu_2(bpy)_4(C_2O_4)]^{2+}$, two anionic binuclear mixed valence vanadium(IV)–vanadium(V) complexes $[(VO)_2O(bpy)_2(C_2O_4)_2]^-$, and ten uncoordinated water molecules. The copper atom exhibits a Jahn–Teller-distorted octahedral coordination. The vanadium atoms adopt a strongly distorted octahedral coordination and form a characteristic O=V–O–V=O moiety with a significantly bent V–O–V link. The temperature dependence of the magnetic susceptibilities has been investigated in the temperature range 2–300 K and explained in terms of the ferromagnetic interaction between Cu^{II} ions giving J = 22.7 yJ (1.14 cm^{-1}) and g = 2.014.

Introduction

Homo- and heterometallic systems involving oxalate ions (ox) as bridging ligands have been intensively studied since these ligands are very effective in transmitting exchange interactions.[1−3] Homopolynuclear copper(II) complexes consisting of both dinuclear and chain structures[4−6] have been studied, and in order to tune the dimension of spin coupling, complexes with terminal ligands such as tetramethyl-1,2-ethanediamine,[7] 1,2-ethanediamine,[8] 1,10-phenanthroline[9] or 2,2′-bipyridine[10] (bpy) have been synthesized so far. Complexes of VO^{3+} or VO^{2+} containing the oxalate ion as a bidentate ligand are also known, but they have not been studied that extensively.[11−13] Heterodimetallic copper(II)−oxovanadium(IV) oxalates, $[(terpy)Cu(ox)VO(ox)(H_2O)]\cdot H_2O$ and $[(terpy)_2Cu_2(ox)_2VO(H_2O)](ClO_4)_2\cdot H_2O$ (terpy = 2,2′:6′,2′′-terpyridine), have been the subject of recent studies[14] with the aim of elucidating the mechanism of spin coupling between paramagnetic ions through the bridging oxalate ligand. Bimetallic oxalate complexes in the copper(II)−oxovanadium(IV) system have been synthesized[15] and their ability to act as catalysts for the autoxidation of aliphatic aldehydes has been proved. As part of our continuing work in this field[16] this paper presents the structural and spectroscopic characterisation of a new heterometallic, mixed-valence compound obtained in the system vanadium/copper/oxalate which turned out to be $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2\cdot 10H_2O$.

Results and Discussion

Synthesis

The synthesis of the title compound was performed in a basic aqueous solution of Na_2S. Some experimental parameters, including the Cu:V molar ratio, were varied, but the resulting products remained the same. Finally, a copper/vanadium ratio of 1:2 was used. Although the crystals formed from an aqueous solution, their solubility in pure water was low. The crystals are insoluble in common organic solvents (i.e. DMSO, DMF, C_1-C_5 alcohols, acetone, acetonitrile, and chloroform).

Crystal Structure

$[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2\cdot 10H_2O$ crystallises in the triclinic system, space group $P\bar{1}$, with a unit cell content of one formula unit. It consists of a cationic, dinuclear copper(II) complex (Figure 1), an anionic, dinuclear mixed-valence vanadium(IV)−vanadium(V) complex (Figure 2), and water molecules filling large voids of the structure (Figure 3). The $[Cu_2(bpy)_4(C_2O_4)]^{2+}$ complex is centrosymmetric with the centre of inversion halfway between the carbon atoms C(1) and C(1A) of the bridging

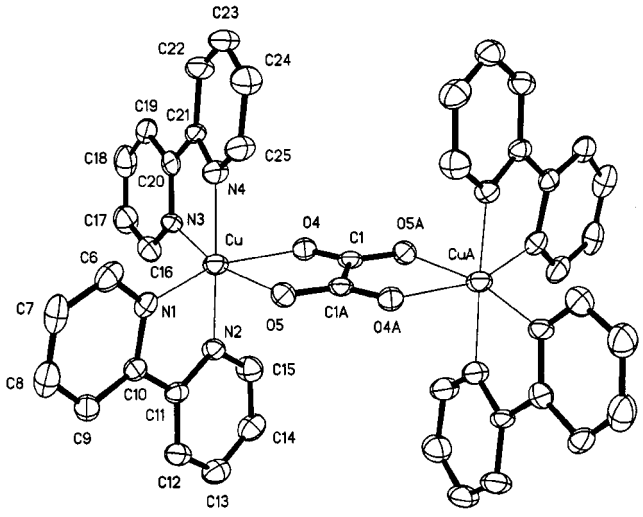

Figure 1. Thermal ellipsoid plot (20% ellipsoids) of the cationic dinuclear copper(II) complex $[Cu_2(bpy)_4(C_2O_4)]^{2+}$

bis-bidentate oxalate anion (Figure 1). The complex, including the bpy moieties, approaches quite well a noncrystallographic 2/*m* symmetry with the twofold axis passing through the two Cu atoms.

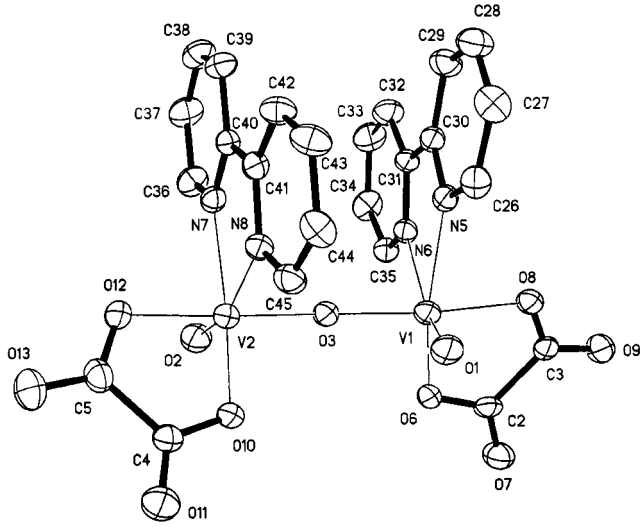

Figure 2. Thermal ellipsoid plot (20% ellipsoids) of the anionic mixed valence vanadium(IV, V) complex $[(VO)_2O(bpy)_2(C_2O_4)_2]^-$

Copper exhibits a moderately distorted octahedral coordination to two O atoms and four N atoms. A relatively weak Jahn–Teller distortion of the CuO_2N_4 polyhedron towards an elongated octahedron with four short equatorial bonds to N(1), N(2), N(4), and O(4) (Cu–N: 1.981– 2.059 Å; Cu–O: 2.141 Å) and two slightly longer axial bonds to N(3) and O(5) (Cu–N: 2.125Å; Cu–O: 2.237 Å) can be noted. The bond angles in the CuO_2N_4 octahedron are clearly controlled by the chelating bidentate ligands oxalate and 2,2′-bipyridine (O–Cu–O: 75.4 °; chelating N–Cu–N

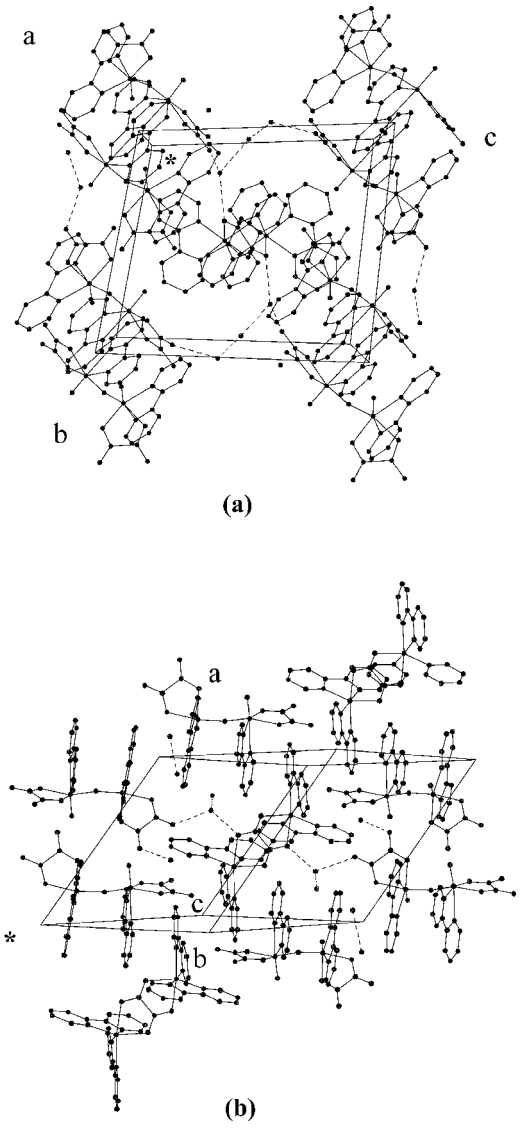

Figure 3. Packing diagram of $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$ (a) viewed down the *a* axis; and (b) view approximately perpendicular to $(0\bar{1}1)$ showing the π-stacking most clearly (see text)

angles: 78.8–80.2°) whereas the remaining angles vary in the ranges 83.7–108.0° and 157.4–175.7°. Similar weak Jahn–Teller distortions were found for CuO_2N_4 octahedra in related complexes.[17,18] While the title compound represents the first example of a binuclear oxalato-bridged Cu complex with Cu:bpy = 1:2, such complexes with Cu:bpy in a 1:1 ratio have been observed before in several cases. However, they differ from the title compound by having either a square planar or a square pyramidal coordination for Cu, for example in $[Cu_2(bpy)_2(ox)(H_2O)_2][Cu(bpy)(ox)](BF_4)_2$.[19]

The dinuclear mixed-valence vanadium(IV)–vanadium(V) complex $[(VO)_2O(bpy)_2(C_2O_4)_2]^-$ is built up from two crystallographically independent vanadium atoms in distorted octahedral coordinations, each with four O and two N atoms. Each of the two vanadium atoms forms a typ-

ical vanadyl group (V=O) with a terminal oxo oxygen strongly bonded [V(1)−O(1) = 1.588 Å and V(2)−O(2) = 1.586 Å]. The second shortest V−O bonds are towards the bridging oxo oxygen O(3), with V(1)−O(3) = 1.814 Å, V(2)−O(3) = 1.796 Å and V(1)−O(3)−V(2) = 164.8°. This oxygen O(3), the V-bonded oxygen atoms of the chelating oxalate groups and the nitrogen atoms N(5) and N(7) define, with intermediate bond lengths, the slightly pyramidal equatorial coordination environments around the V(1)−O(1) and V(2)−O(2) groups. The significantly longest bonds are those to the nitrogen atoms N(6) and N(8) *trans* to O(1) and O(2). The mean V−O,N bond lengths of the two VO_4N_2 octahedra are 1.975 Å for V(1) and 1.969 Å for V(2). This, and the similarity in V−O(3) bond lengths, suggests that tetra- and pentavalent vanadium is approximately equally distributed over the two crystallographic metal sites. A further support for this view is that the complex exhibits a clear-cut noncrystallographic twofold pseudosymmetry with the twofold pseudoaxis passing approximately parallel to the V-bonded bpy's and through the bridging O(3) (Figure 2). The dimensions of the V coordination polyhedra in the title compound are in good agreement with many other oxo-bridged vanadium(IV,V) compounds. Of particular interest is the geometry of the O(1)=V(1)−O(3)−V(2)=O(2) fragment with respect to V−O−V bond angle, as well as to the O=V···V=O torsion angle. Whereas in many compounds[20−22] these quantities are exactly, or close to, 180°, in the title compound they are 164.8(3)° and 141.6(2)° and thus are close to the values for the compound of Chakravarty et al.[23] (142.0 and 160.8°) which has vanadium(V) in a square-pyramidal coordination.

The spatial arrangement of the Cu and V complexes in the title compound is shown in a view down the *a*-axis (Figure 3, a). Layer-like arrangements of the Cu and V complexes parallel to the $(0\bar{1}1)$ plane can be clearly seen in this view. Between the layers there are large open channels extending parallel to *a* which are occupied by the 10 water molecules per formula unit (5 independent molecules per asymmetric unit). These molecules are anchored in the structure mainly through hydrogen bonds to oxalate oxygen atoms with five independent O(w)···O(ox) distances to four different O(w) below 3.0 Å. Further hydrogen bonds appear to exist between the water molecules themselves, as indicated by the eight independent O(w)···O(w) distances below 3.0 Å. Among them O(3w) stands out in having only three contacts to O(w) but none to oxalate oxygen atoms. Figure 3 (b) shows another view of the structure approximately perpendicular to $(0\bar{1}1)$. This view is interesting because it indicates that the crystal structure owes much of its stability to π-stacking of the bpy molecules, in particular the molecules 2 (Cu-bonded), and 3 and 4 (V-bonded), which have their main planes all aligned approximately in the view direction and exhibit mean plane-separations of about 3.5−3.7 Å. These interactions may be considered to stabilize a structure that suffers from a destabilizing effect due to the large number of noncoordinated water molecules.

The question may arise as to whether the title compound might be a stoichiometrically H^+-bearing vanadium(IV) dimer rather than a mixed valence vanadium(IV, V) compound without additional H^+ as described above. This hypothesis was rejected for the following reasons:

(1) Bond valence calculations according to Brese and O'Keefe[24] show that the assignments of O(1), O(2) and O(3) to oxide oxygen atoms is beyond doubt (bond valence sums between 1.7 and 2.0 indicating that no OH group is present).

(2) H^+ atoms in the hydrate structure or at terminal oxalate oxygen atoms have to be accompanied by outstandingly short hydrogen bond O···O distances (2.4−2.6 Å). Since all O···O distances outside the cation coordination polyhedra are longer than 2.73 Å this possibility can be ruled out as well.

Vibrational Spectroscopy

The solid-state far- and mid-FTIR spectra are given in Figure 4 and 5. The spectra were checked with respect to reproducibility and several measurements of different samples yielded identical results.

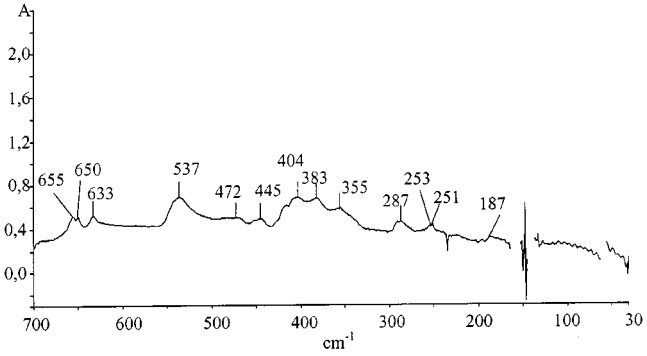

Figure 4. Solid-state far-IR spectrum of $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2{\cdot}10H_2O$

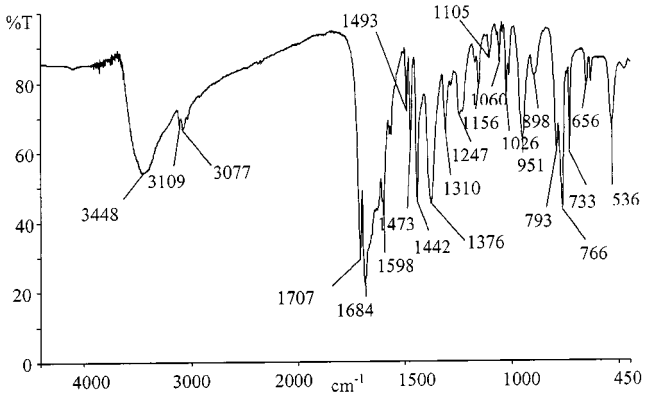

Figure 5. Solid-state mid-IR spectrum of $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2{\cdot}10H_2O$

In the far IR the prominent absorption at 537 cm^{-1} is attributable to combinations of V−O(oxalate) with oxalate C−C stretching vibrations.[25] The equal prominent peak at 383 cm^{-1} is assigned to the V−N(bpy) stretching vibrations.[26] The weaker peak at 355 cm^{-1} is considered as being due to combinations of V−O(oxalate) stretching vibra-

tions with V-oxalate chelate ring deformation vibrations.[27] The rather weak absorption at 287 cm^{-1} is due to the symmetric stretching mode ν_{Cu-N} of the Cu−N(bpy) moieties.[28]

The sharp and strong absorption at 1707 cm^{-1} can be assigned to the asymmetric in-phase stretching vibration $\nu_{C=O}$ of the four terminal carbonyl groups C2−O7, C3−O9 and C4−O11, C5−O13 of the two vanadium-bonded oxalate groups. In accordance with literature data the broad and strong absorption at 1685 cm^{-1} is considered as a superposition of two asymmetric out-of-phase stretching vibrations of the carbonyl groups of the same oxalates. The strong absorption at 1376 cm^{-1} is attributed to a mode coupling of the symmetric stretching vibrations of the bridging carbonyls C2−O6, C3−O8 and C4−O10, C5−O12 with the C−C stretching vibrations of the C2−C3 and the C4−C5 bonds, respectively. The slightly weaker peak at 1247 cm^{-1} is due to a combination of the symmetric stretching vibration of the binding carbonyls C2−O6, C3−O8 and C4−O10, C5−O12, with the out-of-plane bending vibrations $\delta_{O-C=O}$ of the oxalates bound to the vanadium atoms. The very prominent absorption at 952 cm^{-1} is characteristic for the vanadyl stretching mode $\nu_{V=O}$ of the V1−O1 and V2−O2 bonds.[29] The fact that only one sharp peak is observed supports the explanation that the two vanadyl groups are indistinguishable, and is consistent with the almost identical V−O bond lengths (see Table 1). The V=O(vanadyl) stretching vibration in mixed-valence vanadium(IV, V) is detected within the range of 947 cm^{-1} (see Nishizawa et al.[30]), 980 cm^{-1} (see Pessoa et al.[31]) and 995 cm^{-1} (see Chakravarty et al.[23]), whereas the V=O(vanadyl) stretching vibration of vanadium(IV) compounds is observed at 975 cm^{-1} and at 890−920 cm^{-1} for vanadium(V) compounds (see Nishizawa et al.[30]). The strong peak at 794 cm^{-1} represents the combination mode consisting of the bending vibration $\delta_{O-C=O}$ and the stretching vibration ν_{V-O}. The rather weak absorption at 898 cm^{-1} could be the stretching vibration of V−O−V. Thus, according to the classification of Robin and Day,[32] the mixed valence vanadium(IV, V) complex of the title compound should belong to type II, where the two metal ions are in inequivalent positions with the unpaired electron shared equally between them.

Magnetochemical Investigations

The magnetic properties of $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$ (SQUID, 2−100 K) are depicted in Figure 6. At 100 K, $\chi_M T$ is equal to 19.2 10^{-6} m^3 mol^{-1} K (1.53 cm^3 mol^{-1} K). This value is equal to that expected for two vanadyl ions and two noninteracting copper centres. The expected behaviour for the two mixed-valence vanadium dimers is a Curie law for two uncoupled $S = 1/2$. Therefore, all the variation of the $\chi_M T$ value with temperature is due to the $[Cu_2(bpy)_4(C_2O_4)]$ entity. Upon cooling, $\chi_M T$ increases smoothly showing that the dominant interaction between the Cu^{II} ions is ferromagnetic. The best fit is obtained using the following parameters $J = 22.7$ yJ (1.14 cm^{-1}) and an average g value for the copper and vanadyl ions of $g = 2.014$. The individual g factor for the copper and the vanadium cannot be determined from the magnetic data nor from EPR spectrum. The agreement factor R is then equal to $3.4 \cdot 10^{-6}$. Many binuclear Cu^{II} complexes with an oxalato bridging ligand have been structurally and magnetically characterized. Most of them are antiferromagnetically coupled, but the coupling constants depend strongly on the coordination sphere around the copper ions. The experimental coupling constants are in the −7950 to 22.8 yJ (−400 to +1.2 cm^{-1}). The largest interaction is observed for the so-called coplanar arrangement **1a**,[33] intermediate interactions are measured in the case of the perpendicular geometry **1b**,[34] and finally rare cases of ferromagnetic interactions are observed for the parallel geometry **1c**.[34,35] All these behaviours have recently been rationalized by theoretical DFT calculations.[36]

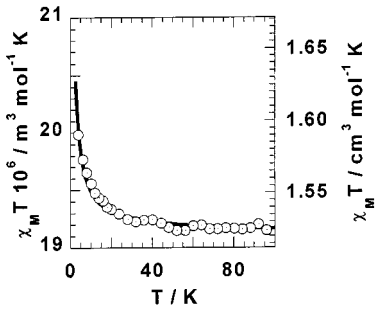

Figure 6. Plot of $\chi_M T$ vs. T for $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$

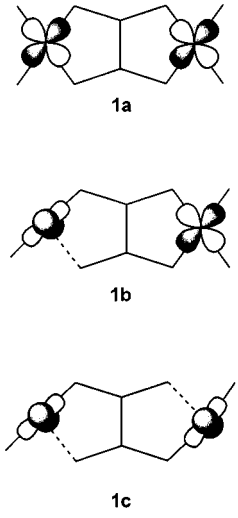
The binuclear copper unit in $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$ belongs to the **1c** family (see Scheme 1) with the equatorial planes of elongated octahedra perpendicular to the oxalato bridge. It is therefore not surprising to find a ferromagnetic interaction. Furthermore, the magnitude of the coupling observed for $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$ is in the same range as the previous examples.



Scheme 1

Conclusion

The heterodimetallic compound $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$ was synthesized and the structure was determined by crystallographic analysis. The anions consist of binuclear mixed-valence vanadium(IV)−vanadium(V) complexes in which: (*i*) the metal centres lie at almost equal distance to the bridging oxo oxygen, (*ii*) the unpaired electron is equally shared, and (*iii*) no magnetic interactions occur between the paramagnetic centres. Ferromagnetic interactions occur at low temperature between the copper(II) centres as a result of the orthogonality of the neighbouring magnetic orbitals on the oxalato bridge.

Experimental Section

General: All reagents were purchased from commercial sources (Fluka).

$[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$: $Cu(CH_3COO)_2 \cdot H_2O$ (0.5 g, 2.5 mmol) was mixed with 2,2′-bipyridine (0.78 g, 5 mmol) in 20 cm^3 water and the blue solution thus obtained was poured into 60 cm^3 of a solution containing 5 mmol $VO(C_2O_4)$ (stock solution) with vigorous stirring. The suspension formed was treated after a few minutes with a solution of Na_2S (0.08 g, 2.5 mmol) in 5 mL water. The obtained mixture was heated to 80 °C for one hour. After cooling to room temperature the solution was filtered. While keeping the clear solution in darkness at 5 °C (refrigerator) for a period of 2−3 weeks green crystals of the novel compound formed as a by-product, as our intention was to obtain copper-vanadium compounds with sulfide as ligand. − $C_{90}H_{84}Cu_2N_{16}O_{36}V_4$ (2296.6): calcd. C 47.07, H 3.69, N 9.76, Cu 5.53, V 8.87; found C 46.98, H 3.72, N 9.68, Cu 5.58, V 8.94.

Vibrational Spectroscopy: The dark-green powdered sample was characterised by far and mid-range FTIR spectroscopy. The solid state far-IR measurements were performed on a Perkin−Elmer System 2000 FT spectrometer with polyethylene as the matrix. To accomplish a good signal-to-noise ratio 1000 cycles, each cycle consisting of one reference scan (pure polyethylene), four sample scans and again one reference scan, were summed. During the measurement the spectrometer (optical bench including the sample chamber and the detector) was purged with nitrogen gas of purity >99.99%. The mid-range FTIR was recorded on a Perkin−Elmer 16 PC spectrometer. For good signal-to-noise ratio 64 scans in KBr as matrix were summed. During the measurement the spectrometer was also purged with nitrogen gas (>99.99%).

Magnetochemical Investigations: Magnetic measurements were performed on a Quantum Design SQUID MPMS5 magnetometer. The data were collected in the range 2−300 K for powered microcrystalline samples of $[Cu_2(bpy)_4(C_2O_4)][(VO)_2O(bpy)_2(C_2O_4)_2]_2 \cdot 10H_2O$ at 0.5 T. Diamagnetic corrections were applied based on Pascal's constant. This paper uses the SI units. The molar magnetic susceptibility χM is expressed in $m^3 \cdot mol^{-1}$. The conversion factor to the irrational emu quantity χM(ir) is $106/4\pi$. The energies are expressed in 10^{-24} Joule. The submultiple prefix for 10^{-24} is yocto, its symbol is y. Therefore 1 yJ means 10^{-24} Joule. The conversion factor to cm^{-1} is $5.034 \cdot 10^{-2}$ (1 $cm^{-1} \approx 20$ yJ).

X-ray Crystallographic Study

Crystal Data: formula $C_{90}H_{84}Cu_2N_{16}O_{36}V_4$, molecular mass 2296.58 amu, triclinic, $P\bar{1}$ (No. 2), a = 13.488(5), b = 14.160(6), c = 15.829(9) Å, α = 87.22(2)°, β = 66.33(2)°, γ = 64.49(2)°, V = 2471(2) $Å^3$, Z = 1, d = 1.544 $g \cdot cm^{-3}$, μ = 0.88 mm^{-1}, T = 301 K.

Data Collection: All available crystals were of relatively small size, poor quality and gave only low X-ray intensities. Data collection was therefore restricted to θ_{max} = 23°. X-ray data were harvested with a Siemens/Bruker SMART 3-circle diffractometer with a CCD area detector (sealed X-ray tube, Mo-K_α radiation, graphite monochromator) using ω-scan frames with Δω = 0.3° and 20 seconds per frame to cover a complete sphere of the reciprocal space by 4 × 606 frames. Absorption and crystal decay were corrected semi-empirically by equivalents.[37] Measured reflections 27550, unique reflections 6859, completeness of data 99.6%.

Structure Analysis and Refinement: The structure was solved by direct methods.[38] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the bpy moieties were introduced in calculated positions and refined using a riding model. The hydro-

gen atoms of the water molecules could not be located with acceptable reliability and were therefore left out. The structure was refined against F^2 with the program SHELXL-97.[39] Final agreement indices were $R1 = 0.058$ [4094 $F_o > 4\sigma(F_o)$] and 0.106 for all 6859 data, $wR2 = 0.172$, $GOF = 0.98$, 667 parameters.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-154154. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Reactions of (1,1′-Bi-1*H*-phosphirene)iron Complexes − Crystal Structure of a Bridged (1-Phosphaallyl-1*H*-phosphirene)diiron(*Fe*−*Fe*) Complex[‡]

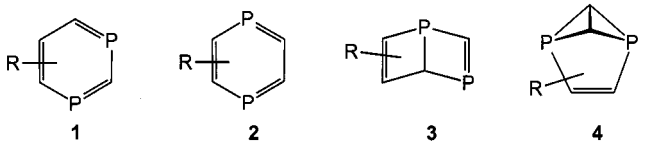
Jürgen Simon,[a] Guido J. Reiß,[a] Uwe Bergsträßer,[a] Heinrich Heydt,*[a] and Manfred Regitz*[a]

Keywords: Iron / Phosphorus heterocycles / P ligands / Valence isomerization / Twinning

The reactions of 1-chloro-1*H*-phosphirenes **5** with disodium tetracarbonlyferrate lead to the selective formation of the mono complexed bi-1*H*-phosphirenes **7**, which are converted into the doubly complexed species **9** upon treatment with diiron nonacarbonyl. Photochemical opening of one of the two three-membered ring systems in **9** furnishes the bridged complexes **10** containing phosphirene and phosphaallyl units together with an iron-iron σ-bond.

Introduction

Since the 1960's investigations on the synthesis and reactivity of phosphinines and their valence isomers have played a significant role in the development of the chemistry of low-coordinated phosphorus compounds.[2−5] In contrast, the only known representatives of diphosphinines are the 1,3[6] and 1,4 derivatives[7] **1** and **2** (Scheme 1). Recently, an access to valence isomers of the 1,3-diphospha-Dewarbenzene **3** and diphosphabenzvalene **4** types was established using specific trapping reactions of a short-lived 1,3-diphosphacyclobutadiene with suitably substituted alkynes.[8] 1,3-Diphosphinines **1** are also able to undergo a valence isomerization to the Dewar isomers on prolonged heating.[6c]



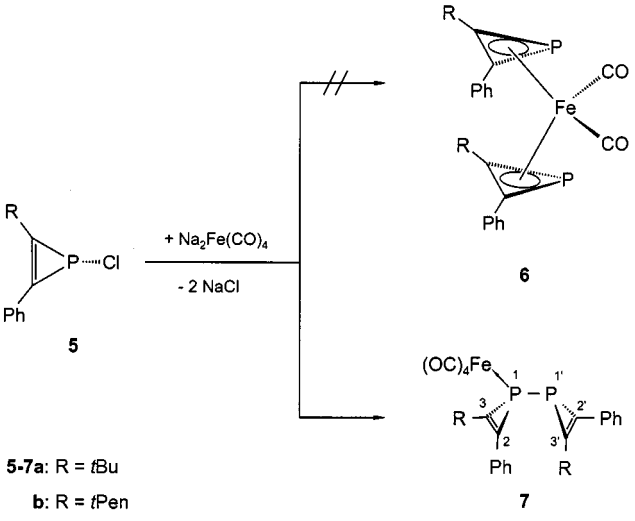
Scheme 1

In the present report, we described the synthesis of the iron complexed 1,1′-bi-1*H*-phosphirenes **7** and **9** as a further, previously unknown class of valence isomers of the diphosphinines.[9] Very recently, the corresponding 1,1′-bisilacyclopropenes, the valence isomers of 1,4-disilabenzenes, have also been synthesized.[10]

Results and Discussion

Synthesis of the (1,1′-Bi-1*H*-phosphirene)iron Complexes 7a and 7b

In the reactions of the 1-chloro-1*H*-phosphirenes **5** with disodium tetracarbonylferrate, the mono η^1 complexed 1,1′-bi-1*H*-phosphirenes **7a** and **7b** (58 and 60%) are formed highly selectively (Scheme 2), instead of the expected $\eta^{3:3}$-(bisphosphirenylium)dicarbonyliron complexes **6**.



Scheme 2

Elemental analysis and mass spectroscopic data unequivocally demonstrate that the complexes **7a** and **7b** are 2:1 adducts of the 1-chloro-1*H*-phosphirenes **5a** and **5b** with Collman's reagent, formed under concomitant loss of two molecules of sodium chloride.

Mixtures of two diastereomers that cannot be separated by column chromatography are obtained. One diastere-

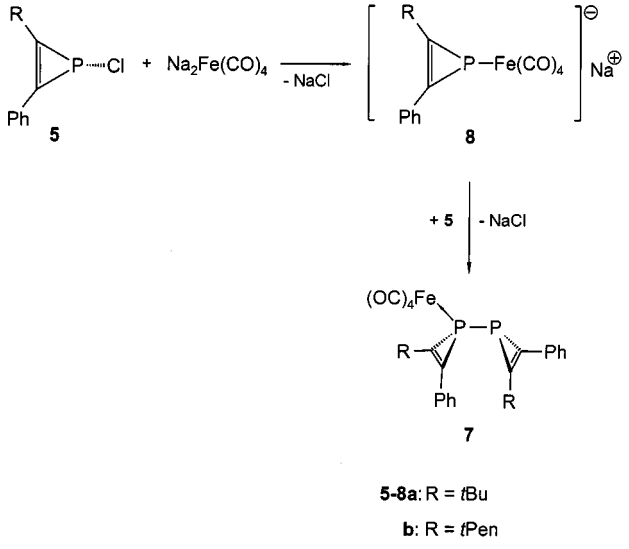
omer, however, can be enriched up to a ratio of 8:1 (**7a**) or 4:1 (**7b**) (as determined by ^{1}H NMR spectroscopy) by crystallization. The NMR spectroscopic data provide diagnostic information for the structure elucidation, as discussed below for the example of **7a** (major diastereomer; R = *t*Bu).

The formation of this product is demonstrated by its ^{31}P NMR spectrum, which reveals a significant, large $^1J_{P,P}$ coupling constant of 427.3 Hz. The signal at δ = −88.1 is assigned to the iron complexed phosphorus atom P-1 by comparison with the published values for iron complexed 1*H*-phosphirenes[11], while the signal at higher field (δ = −134.2) originates from the non-complexed phosphirene unit.

A conspicuous feature of the ^{13}C NMR spectrum of **7a** is a drastic reduction of the intracyclic carbon/phosphorus coupling constants in the complexed three-membered ring ($^1J_{C,P}$ = 22.0 and 27.1 Hz) in comparison with those of the non-complexed three-membered ring ($^1J_{C,P}$ = 50.8 and 57.7 Hz). This is a generally observed phenomenon on going from three- to four-coordinated 1*H*-phosphirenes.[12] The chemical shifts of the alkyl- and aryl-substituted ring carbon atoms are also in agreement with literature data.[13] The resonance signals at lower field (δ = 140.5 and 138.5) are attributed to the alkyl-substituted carbon atoms C-3 and C-3′ while the phenyl-substituted C atoms C-2 and C-2′ give rise to the signals at markedly higher field (δ = 124.8 and 120.3).

The formation of **7a** and **7b** must proceed through a multi-step sequence, although ^{31}P NMR monitoring of the reaction mixture did not provide any indications for the existence of intermediates (Scheme 3).

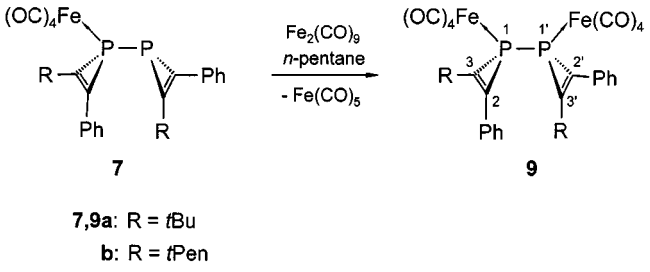


Scheme 3

A plausible mechanism involves the substitution of the chlorine atom in **5** by an anionic tetracarbonyliron fragment to afford the anionic 1*H*-phosphirene complex **8**. This complex then undergoes an immediate nucleophilic substitution with a further molecule of **5** to afford the mono complexed 1,1′-bi-1*H*-phosphirenes **7**.

Further Complexation of (1,1′-Bi-1*H*-phosphirene)iron Complexes 7a and 7b with Diironnonacarbonyl To Afford (1,1′-Bi-1*H*-phosphirene)diiron Complexes 9a and 9b

The additional complexation of the free phosphorus atom provides a possibility to improve the crystallization properties of the novel diphosphinine valence isomers **7**. Reactions of **7** with a slight excess of diiron nonacarbonyl proceed selectively to afford the (1,1′-bi-1*H*-phosphirene)-diiron complexes **9** carrying two tetracarbonyliron fragments (Scheme 4). After workup by column chromatography and subsequent recrystallization from *n*-pentane the binuclear complexes **9a** and **9b** are obtained in good yields (63% and 54%, respectively) in the form of yellow-orange crystals.



Scheme 4

Elemental analysis and mass spectroscopic data unequivocally confirm the presence of two $Fe(CO)_4$ fragments in **9a** and **9b**. The NMR spectroscopic data of these complexes are highly simplified, and discussed for the example of the main diastereomer **9a**.

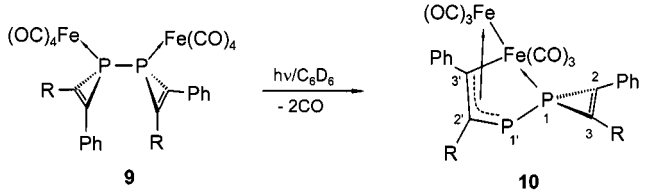
The magnetically equivalent phosphorus atoms P-1 and P-1′ in **9a** give rise to a singlet signal in the ^{31}P NMR spectrum at δ = −69.3. In comparison to the spectrum of **7a** the additional complexation results in a pronounced deshielding by 64.9 ppm of the ^{31}P NMR signals of the formerly non-coordinated phosphorus.

The ^{13}C NMR spectrum of **9a** reflects the double complexation by the appearance of pseudo-triplet signals for the carbonyl and ring carbon atoms. Furthermore, the intracyclic phosphorus-carbon coupling constants of the 1*H*-phosphirene unit that was not complexed in **7a** are, as expected, drastically reduced as a result of the complexation with the second tetracarbonyliron fragment. In analogy with compound **7**, the signals for the ring carbon atoms seen at lower field are assigned to the alkyl-substituted carbon atoms C-3 and C-3′ (δ = 142.2). Similar to the ^{31}P NMR spectroscopic data of **9a** and **9b**, the ^{13}C NMR signals of the ring carbon atoms also experience a clear shift to lower field as a result of the additional complexation.

Final confirmation of the structure of the iron complexed 1,1′-bi-1*H*-phosphirene **9a** was obtained by X-ray crystallography.[9]

Photolyses of the (1,1′-Bi-1*H*-phosphirene)diiron Complexes 9a and 9b To Give the (1-Phosphaallyl-1*H*-phosphirene)-diiron(*Fe*−*Fe*) Complexes 10a and 10b

Previously, only a single example of a photochemically induced rig opening reaction of a complexed 1*H*-phosphirene was known.[14] When a solution of the doubly complexed 1,1′-bi-1*H*-phosphirenes **9a** or **9b** in C_6D_6 is irradiated in an NMR tube using a 125 W high-pressure mercury lamp, ^{31}P NMR monitoring of the mixture reveals a relatively unselective reaction sequence (Scheme 5). After workup by column chromatography and subsequent recrystallization from *n*-pentane/diethyl ether, the pure compounds **10a** or **10b** are isolated only in low yields (5 and 6%, respectively).



9 **10**

9,10a: R = *t*Bu
b: R = *t*Pen

Scheme 5

Elemental analysis and mass spectroscopic data unambiguously demonstrate the cleavage of two carbonyl groups from **9a** and **9b**. The NMR spectroscopic data also provide diagnostic information on the constitutions of compounds **10a** and **10b**.

The ^{31}P NMR spectra, discussed here for the example of **10a**, contains two doublets at δ = −1.6 and −70.4. Of these, the signal at higher field is only shifted slightly in comparison to that of the starting compound **9a**, thus confirming the retention of one of the two 1*H*-phosphirene units. On the other hand, the low-field shift of the other doublet indicates that the second three-membered ring unit has been opened. This signal can be assigned to a (1-phosphaallyl)iron complex by comparison with published values for structural increments of this type.[15]

The $^{13}C\{^1H\}$ NMR spectrum of **10a** is in agreement with the proposed structure, and contains 8 different signals in addition to those of the aryl and alkyl substituents. Although only one doublet at δ = 212.4 with a coupling constant of 6.8 Hz is observed for one of the two $Fe(CO)_3$ groups, a doublet signal with an appreciably larger carbon-phosphorus coupling constant of 27.1−28.8 Hz is found for each CO ligand of the second transition metal fragment. The occurrence of different signals for the carbonyl ligands of this $Fe(CO)_3$ group confirms a hindered exchange between the axial and equatorial positions of the carbonyl ligands. Since the η^3-coordination of the 1-phosphaallyl fragment creates high steric demands, these signals may safely be assigned to the tricarbonyliron fragment of this structural increment.

The carbon atoms C-2′ and C-3′of the 1-phosphaallyl element give rise to signals at δ = 191.2 and 153.9. Since the signal at lower field is split into a double doublet it is assigned to the C-2′ atom directly bonded to phosphorus. The extremely low-field position of this signal is also characteristic for a P=C double bond system. The bridging carbon atom C-3′ of **10a**, on the other hand, gives a signal at appreciably higher field. A comparison of the chemical shift of this carbon atom (C-3′; δ = 153.9) with the published values for bridged allyl complexes[16] provides further support for this structure. The signals of the ring carbon atoms C-2 and C-3 are found at δ = 150.6 (C-3) and δ = 124.6 (C-2) in the region typical for 1*H*-phosphirenes with this substitution pattern. The chemical shifts have been assigned analogously to those for compounds **7** and **9**. Although the $^{13}C\{^1H\}$ NMR signals of the phenyl substituents cannot be assigned individually, this is possible for the alkyl substituents. As expected, two sets of signals are observed for the two *tert*-butyl groups, with one of the signal sets being markedly shifted to lower field. By comparison with the values for other allyl complexes,[15] the signals at lower field are attributed to the alkyl substituents at C-2′.

This low-field signal shift of the substituents of the phosphaallyl unit is also observed in the ^1H NMR spectrum of **10a**. Thus, the *tert*-butyl group at C-2′ gives rise to a signal at δ = 1.42, while the alkyl substituent of the phosphirene ring produces a signal at δ = 1.16. The signals of the protons of the phenyl groups overlap, resulting in the observation of only a multiplet in the typical aromatic proton region.

The structure of **10a** was finally and irrevocably confirmed by X-ray crystallography (Figure 1).

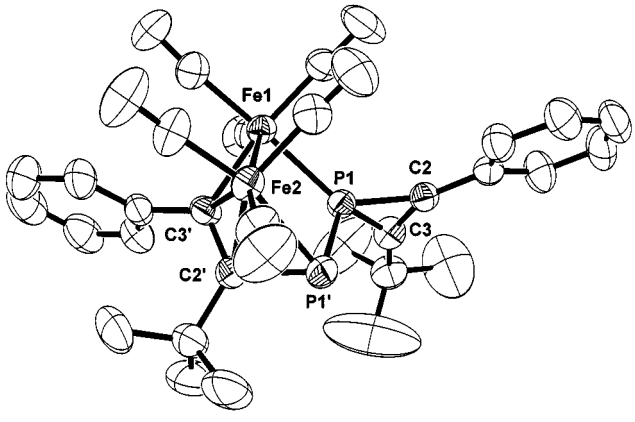


Figure 1. Molecular structure of **10a**. Selected bond lengths [Å] and angles [°]: Fe(1)−C(3′) 2.037(3), Fe(1)−P(1) 2.2078(9), Fe(1)−Fe(2) 2.6493(6), Fe(2)−C(3′) 2.102(3), Fe(2)−C(2′) 2.135(3), Fe(2)−P(1′) 2.3684(12), P(1)−C(2) 1.773(3), P(1)−C(3) 1.795(3), P(1)−P(1′) 2.1597(11), P(1′)−C(2′) 1.811(3), C(2)−C(3) 1.341(4), C(2′)−C(3′) 1.445(4); C(3′)−Fe(1)−P(1) 83.08(10), C(3′)−Fe(2)−C(2′) 39.87(12), C(3′)−Fe(2)−P(1′) 76.14(10), C(2′)−Fe(2)−P(1′) 47.07(8), C(2)−P(1)−C(3) 44.16(14), C(2)−P(1)−P(1′) 115.28(10), C(3)−P(1)−P(1′) 118.56(11), C(2′)−P(1′)−P(1) 92.56(10), C(3)−C(2)−P(1) 68.82(18), C(2)−C(3)−P(1) 67.0(2), C(3′)−C(2′)−P(1′) 115.8(2), C(2′)−C(3′)−Fe(1) 125.2(2)

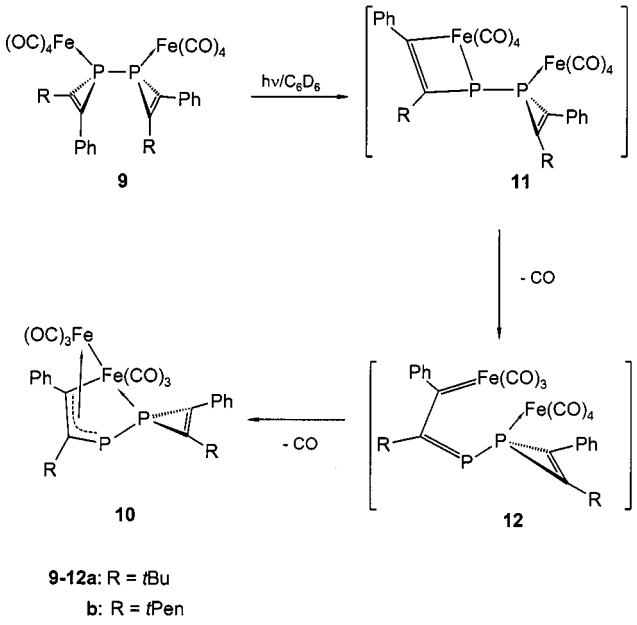
The resultant ORTEP plot clearly reveals the opening of one of the two phosphirene rings with formation of an η^3 complexed 1-phosphaallyl system. The crystal structure analysis also confirms the formation of an iron-iron single bond (see below), as well as the retention of the second phosphirene ring. The Fe1−P1 bond length of 2.208(9) Å is in the typical range for an iron complexed phosphane,[17] and is comparable with the iron-phosphorus bond length in **9a**. On the other hand, the Fe−P1′ bond length in the 1-phosphaallyl unit of 2.368(1) Å is appreciably stretched in comparison with those of other η^3-phosphaallyl-iron complexes.[15] This is readily explained by the steric requirements of the substituents that force the $Fe(CO)_3$ fragment away from the 1-phosphaallyl unit. The iron-carbon separations in this structural increment are almost identical to those in a comparable compound formed by the reaction the μ_3-RP bridged cluster $(\mu_3\text{-RP})Fe_3(CO)_{10}$ with terminal alkynes.[15] The bond lengths in the phosphaallyl unit of 1.811(3) Å (P1′−C2′) and 1.445(4) Å (C2′−C3′) are clearly lengthened, and are of magnitudes typical for single bonds. This is probably due to the enormous spatial requirements of the substituents. The iron−iron bond length of 2.6493(6) Å in **10a** is also of a typical magnitude for this type of single bond.[15] The P1−P1′-bond length of 2.159(1) Å is considerably shortened in comparison with those of uncomplexed phosphanes or that of **9a**.[18] This observation can be rationalized by the ring-bracketing effect of the Fe−C-3′ bond. The intracyclic bonding parameters of the intact phosphirene ring of **10a** are in the typical ranges for a transition-metal complexed 1*H*-phosphirene.[12]

On the basis of $^{31}P\{^1H\}$ NMR monitoring of the photolysis reaction of **9a** a multi-step sequence can be assumed. By comparison of the resonance signals of the various intermediates with those of known compounds, the following mechanism can be proposed:

The initial step in the formation of **10** could be the insertion of one of the two $Fe(CO)_4$ fragments into a P−C bond of the coordinatively attached three-membered ring systems. This results in the intermediate **11**, in which a metallaphosphacyclobutene system is linked to a complexed phosphirene system (Scheme 6). The signal for the phosphorus atom in the three-membered ring of **11a** appears in the $^{31}P\{^1H\}$ NMR spectrum of the reaction solution as a doublet at $\delta = -99.5$ ($^1J_{P,P} = 322.4$ Hz). A further doublet with the same coupling constant is seen at $\delta = 56.0$. This chemical shift value is typical for a compound with a metallaphosphacyclobutene skeleton as revealed by a comparison with an analogous rhodium complex.[19] The subsequent cleavage of a carbonyl ligand from the $Fe(CO)_4$ fragment of the four-membered ring then initiates the conversion of the η^2-coordinated complex **11** with ring opening to the 16-valence electron carbene complex **12**. The P=C double bond of the phosphaalkene system in **12a** gives rise to a $^{31}P\{^1H\}$ NMR signal at $\delta = 282.1$. This value is in the typical range for a phosphaalkene. Since the 16-VE fragment in **12** is coordinatively unsaturated and thus possesses only a low stability, subsequent rearrangement occurs with cleavage of a CO ligand and formation of an Fe−C σ-bond and the Fe−Fe single bond.



Scheme 6

Experimental Section

General Remarks: The reactions were carried out under an atmosphere of argon (purity > 99.998%) in a previously baked-out and evacuated apparatus (Schlenk techniques). The solvents were dried by standard procedures (*n*-pentane and diethyl ether: Na/K alloy), distilled and stored under argon. − Melting points: Mettler FP 61 (heating rate: 3 °C/min). − FT-IR spectra: Perkin−Elmer infrared-spectrometer 16PC. − Mass spectra: Finnigan MAT 90 spectrometer. − NMR spectra: Bruker AMX 400 (^{1}H: 400 MHz, ^{13}C: 101 MHz) and Bruker AC 200 (^{1}H: 200 MHz, ^{13}C: 50 MHz, ^{31}P: 81 MHz) spectrometers, solvent as internal standard (^{1}H and ^{13}C); the chemical shifts for ^{31}P are relative to external 85% orthophosphoric acid. − Compounds **5a** and **5b** were prepared by published methods.[13] Disodium tetracarbonylferrate was purchased from Aldrich and used without further purification.

Column chromatography was formed in water-cooled glass tubes with a positive pressure of argon on the column. Silica gel and neutral aluminum oxide were heated for 5 h under vacuum and then deactivated with 4% water.

Synthesis of the (1,1′-Bi-1*H*-phosphirene)iron Complexes 7a and 7b. − General Procedure: To a suspension of disodium tetracarbonylferrate in diethyl ether (30 mL) was added dropwise with stirring at −78 °C a solution of two equivalents of the corresponding 1-chloro-1*H*-phosphirene **5** in diethyl ether (20 mL). The reaction mixture was allowed to warm up to room temp. with stirring. The mixture was then evaporated under vacuum and the residue purified by column chromatography on silica gel with *n*-pentane/diethyl ether [40:1 (**7a**), 100:1 (**7b**)] as eluent. The yellow eluate was evaporated to dryness and the resulting red solid was recrystallized from *n*-pentane at −28 °C to yield pure **7** as orange-yellow crystals.

[3,3′-Bis(1,1-dimethylethyl)-2,2′-diphenyl-1,1′-bi-1*H*-phosphirene-κ*P*^{1}]tetracarbonyliron (7a): Starting materials: 791 mg (3.52 mmol)

1-chloro-3-(1,1-dimethylethyl)-2-phenyl-1*H*-phosphirene (**5a**), 609 mg (1.76 mmol) disodium tetracarbonylferrate. − Yield 560 mg (58%), orange-yellow crystals, mixture of two diastereomers (ratio 8:1). − m.p.: 97 − 99 °C. − IR (CCl_4, cm^{-1}): $\tilde{\nu}$ = 2966 (w), 2042 (s, CO), 1971 (m, CO), 1939 (vs, CO), 1474 (w), 1072 (m), 1008 (m), 620 (s). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): *major diastereomer*: δ = −88.1 (d, $^1J_{P,P}$ = 427.3 Hz, P-1), −134.2 (d, $^1J_{P,P}$ = 427.3 Hz, P-1′); *minor diastereomer*: δ = −86.8 (d, $^1J_{P,P}$ = 427.1 Hz, P-1), −132.6 (d, $^1J_{P,P}$ = 427.1 Hz, P-1′). − ^1H NMR ($CDCl_3$): *major diastereomer*: δ = 1.44 [s, broad, 18 H, $C(CH_3)_3$]; *minor diastereomer*: δ = 1.50 [s, broad, 18 H, $C(CH_3)_3$]. − $^{13}C\{^1H\}$ NMR ($CDCl_3$): not all signals could be assigned because of overlapping effects: *major diastereomer:* δ = 29.2 [d, $^3J_{C,P}$ = 1.7 Hz, $C(CH_3)_3$], 29.5 [s, $C(CH_3)_3$], 33.9 [dd, $^2J_{C,P}$ = 6.4 Hz, $^3J_{C,P}$ = 3.0 Hz, $C(CH_3)_3$], 34.2 [d, $^2J_{C,P}$ = 6.8 Hz, $C(CH_3)_3$], 120.3 (d, $^1J_{C,P}$ = 50.8 Hz, C-2′), 124.8 (dd, $^1J_{C,P}$ = 22.0 Hz, $^2J_{C,P}$ = 4.2 Hz, C-2), 127.3 (d, $J_{C,P}$ = 7.6 Hz, Ph), 128.6 (s, Ph), 128.9 (s, Ph), 129.7 (d, $J_{C,P}$ = 5.1 Hz, Ph), 130.4 (d, $J_{C,P}$ = 4.2 Hz, Ph), 131.3 (s, Ph), 138.5 (d, $^1J_{C,P}$ = 57.7 Hz, C-3′), 140.5 (dd, $^1J_{C,P}$ = 27.1 Hz, $^2J_{C,P}$ = 5.1 Hz, C-3), 213.9 (d, $^2J_{C,P}$ = 19.5 Hz, CO); *minor diastereomer*: δ = 29.2 [s, $C(CH_3)_3$], 29.4 [d, $^3J_{C,P}$ = 2.5 Hz, $C(CH_3)_3$], 34.3 [d, $^2J_{C,P}$ = 5.9 Hz, $C(CH_3)_3$], 121.3 (dd, $^1J_{C,P}$ = 48.9 Hz, $^2J_{C,P}$ = 2.6 Hz, C-2′), 125.0 (dd, $^1J_{C,P}$ = 33.7 Hz, $^2J_{C,P}$ = 3.4 Hz, C-2), 127.2 (d, $J_{C,P}$ = 11.0 Hz, Ph), 128.6 (s, Ph), 129.7 (d, $J_{C,P}$ = 5.1 Hz, Ph), 130.3 (d, $J_{C,P}$ = 4.2 Hz, Ph), 131.2 (s, Ph), 135.6 (d, $^1J_{C,P}$ = 56.2 Hz, C-3′), 141.8 (dd, $^1J_{C,P}$ = 26.3 Hz, $^2J_{C,P}$ = 4.2 Hz, C-3), 214.2 (d, $^2J_{C,P}$ = 18.7 Hz, CO). − MS (EI, 70 eV): *m/z* (%) = 546 (8) [M^+], 434 (41) [M^+ − 4CO], 276 (100) [M^+ − 4CO − $C_{12}H_{14}$], 98 (43) [$C_2P_2Fe(CO)_2^+$], 189 (68) [$C_{12}H_{14}P^+$], 143 (26) [$C_{11}H_{11}^+$]. − $C_{28}H_{28}FeP_2O_4$ (546.32 g/mol): calcd. [3,3′-Bis(1,1-dimethylpropyl)-2,2′-diphenyl-1*H*-phosphirene-κ*P*^{1}]-tetracarbonyliron (7b): Starting materials: 649 mg (2.72 mmol) 1-chloro-3-(1,1-dimethylpropyl)-2-phenyl-1*H*-phosphirene (**5b**), 471 mg (1.36 mmol) disodium tetracarbonylferrate. − Yield 470 mg (60%), orange-yellow solid, mixture of two diastereomers (ratio 4:1). − IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2967 (s), 2934 (w), 2039 (vs, CO), 1963 (s, CO), 1938 (vs, CO), 1636 (m), 1464 (m), 1074 (s), 620 (s). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): *major diastereomer*: δ = −90.6 (d, $^1J_{P,P}$ = 427.6 Hz, P-1), −132.2 (d, $^1J_{P,P}$ = 427.6 Hz, P-1′); *minor diastereomer*: δ = −88.3 (d, $^1J_{P,P}$ = 426.6 Hz, P-1), −132.3 (d, $^1J_{P,P}$ = 426.6 Hz, P-1′). − ^1H NMR ($CDCl_3$): *major diastereomer:* δ = 0.96 (t, 3 H, $^3J_{H,H}$ = 7.6 Hz, CH_2-CH_3), 1.12 (t, 3 H, $^3J_{H,H}$ = 7.0 Hz, CH_2-CH_3), 1.42, 1.43, 1.46, 1.47 [each s, 12 H, $C(CH_3)_2CH_2$], 1.63 − 1.92 (m, 4 H, CH_2-CH_3; *minor diastereomer:* the signals could not be assigned because of overlapping effects. − $^{13}C\{^1H\}$ NMR ($CDCl_3$): not all signals could be assigned because of overlapping effects: *major diastereomer:* δ = 8.7 (d, $^4J_{C,P}$ = 6.3 Hz, CH_2-CH_3), 9.1 (d, $^4J_{C,P}$ = 4.5 Hz, CH_2-CH_3), 25.7 [s, $C(CH_3)_2$], 26.2 [d, $^3J_{C,P}$ = 5.4 Hz, $C(CH_3)_2$], 26.5 [s, $C(CH_3)_2$], 26.9 [s, $C(CH_3)_2$], 34.4 (d, $^3J_{C,P}$ = 5.4 Hz, CH_2-CH_3), 34.4 (s, CH_2-CH_3), 37.0 [s, $C(CH_3)_2Et$], 37.7 [d, $^2J_{C,P}$ = 5.4 Hz, $C(CH_3)_2Et$], 120.9 (d, $^1J_{C,P}$ = 51.2 Hz, C-2′), 125.1 (d, $^1J_{C,P}$ = 22.4 Hz, C-2), 127.0 (d, $^3J_{C,P}$ = 8.3 Hz, *o*-Ph), 127.2 (d, $^3J_{C,P}$ = 7.2 Hz, *o*-Ph), 128.3 (s, Ph), 128.6 (s, Ph), 129.4 (d, $^2J_{C,P}$ = 16.2 Hz, *i*-Ph), 129.5 (d, $^2J_{C,P}$ = 14.4 Hz, *i*-Ph), 130.1 (s, Ph), 131.2 (s, Ph), 138.3 (d, $^1J_{C,P}$ = 57.5 Hz, C-3′), 141.4 (dd, $^1J_{C,P}$ = 28.3 Hz, $^2J_{C,P}$ = 4.0 Hz, C-3), 213.7 (d, $^2J_{C,P}$ = 18.0 Hz, CO); *minor diastereomer*: δ = 34.2 (s, CH_2-CH_3), 35.8 [s, $C(CH_3)_2Et$], 125.0 (d, $^1J_{C,P}$ = 21.5 Hz, C-2), 128.3 (s, Ph), 128.6 (s, Ph), 130.0 (s, Ph), 130.9 (s, Ph), 134.8 (d, $^1J_{C,P}$ = 59.2 Hz, C-3′), 139.9 (d, $^1J_{C,P}$ = 27.8 Hz, C-3), 214.1 (d, $^2J_{C,P}$ = 18.0 Hz, CO). − MS (EI, 70 eV): *m/z* (%) = 574 (1) [M^+], 462 (7) [M^+ − 4CO], 172 (28) [$C_{13}H_{16}^+$], 157 (14) [$C_{12}H_{13}^+$], 143 (100) [$C_{11}H_{11}^+$], 128 (23) [$C_{10}H_8^+$]. − HR-MS (EI, 70 eV); [M^+]: calcd. 574.1135; found 574.1130.

Synthesis of the (1,1′-Bi-1*H*-phosphirene)diiron Complexes 9a, b. − General Procedure: A mixture of the diastereomers of the corresponding mono complexed 1,1′-bi-1*H*-phosphirenes **7** was dissolved in *n*-pentane and treated with an excess of nonacarbonyldiiron. The suspension was stirred at room temp. for 24 h. The resulting dark red reaction solvents were evaporated to dryness. The brown residue was purified by column chromatography on neutral aluminum oxide with *n*-pentane as eluent. Recrystallization from *n*-pentane gave products **9a** and **9b** as yellow crystals.

Crystallographic Data for 10a: Crystallization of **10a** from different solvents and inspection of the crystals by preliminary X-ray crystallographic studies, showed that all investigated specimens were twinned. The twinning element was in all cases a twofold axis along [100]. According to the metrical peculiarity of the monoclinic lattice constants [*a* = 14.045(1), *b* = 11.127(1), *c* = 20.109(2) Å, β = 99.077(10)°, *V* = 3103.3(5) Å³, *Z* = 4] all reflections *hkl* with *h* = 0, 9, 11, −9, −11 overlap nearly exactly, while the reflections of all other layers, depending on the resolution of the diffractometer setting, are more or less separated (twinning by reticular meohedry). The twin matrix evaluated from the orientation matrices of both twin components was calculated to (1 0 0, 0 −1 0, −0.4526 0 −1). Data collection on an IPDS-diffractometer has been performed using a light yellow crystal with the dimensions 0.30 × 0.25 × 0.20 mm³.

The standard integration and data reduction methods[20] results in data sets, that only contain non-overlapped reflections. Structure solution by direct methods and completion of the structure model by difference Fourier synthesis using only these non-overlapping reflections succeeded in the space group $P2_1/n$. For a twin refinement in SHELXL-97[21] by the method of Pratt, Coyle, and Ibers[22] for the overlapped reflections the sum of F_c^2 values of the individual twin components, each multiplied by its fraction contribution, was fitted to the F_o^2 value and its fraction contribution. Hence, the diffractometer output has to be reformatted according to the abovementioned twin law, and all reflections that neither overlap exactly nor can be resolved properly have been discarded. A simultaneous refinement of both twin components converged to a twin ratio of 0.3957/0.6043(5). All hydrogen atoms were included in the last stages of refinement in geometrically calculated positions, and their U_{iso} values were set to 1.2 and 1.5 times the U_{eq} value of the corresponding aromatic and methyl carbon atoms, respectively. Refinement of 410 parameters based on 9292 reflections converged to $wR2(F^2)$ = 0.0781, R1(*F*) = 0.0353 [for 6237 reflections with $F_o^2 > 2\sigma(F_o^2)$], GoF = 1.029, $\Delta\rho_{min}/\Delta\rho_{max}$ = −0.198/0.231 e/Å³, $(\Delta/\sigma)_{max}$ = 0.045.

Crystallographic data (excluding structure factors) for the structure included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-157268. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the Landesregierung of Rheinland-Pfalz for a graduate grant (to J. S.) and the Fonds der Chemischen Industrie for generous financial support.

Pyrazolylcyclohexanol Complexes of Vanadium − A Temperature- and Solvent-Dependent Monomer−Dimer Equilibrium

Holger Glas,[a] Klaus Köhler,[a] Eberhardt Herdtweck,[a] Peter Maas,[a] Michael Spiegler,[a] and Werner R. Thiel*[b]

Keywords: Catalysis / Oxidation / Chelates / Vanadium

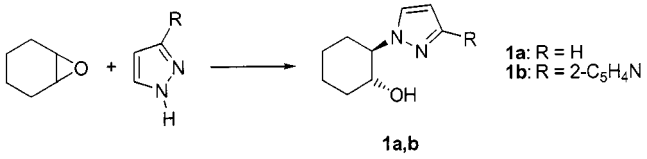
The reaction of $VOCl_3$ with tridentate *rac-trans*-[1-pyrazolyl-3-(2-pyridyl)]cyclohexanol in the presence of K_2CO_3 generates a mononuclear six-coordinate V^V complex. With the bidentate ligand *rac-trans*-2-(pyrazol-1-yl)cyclohexan-1-ol, reduction of V^V to V^{IV} takes place to give a dinuclear complex with bridging alkoxo units; this compound is also accessible starting directly from the V^{IV} precursor $VOSO_4$ and LiCl. Both complexes were characterized spectroscopically and by X-ray diffraction. The dimeric V^{IV} complex is in equilibrium with its monomeric counterpart; this temperature- and solvent-dependent equilibrium was followed by EPR spectroscopy.

Introduction

Vanadium compounds are widely used in catalytic oxidation reactions.[1−3] However, the molecular structures of the actual catalytically active species are often unknown.[4] In a project on vanadium-catalyzed olefin epoxidation, our group has investigated structurally well-defined vanadium(V) complexes bearing bidentate pyrazolylpyridine ligands equipped with alkyl and ester side chains.[5] Owing to this feature, these ligands increase the solubility of the derived metal complexes in nonpolar organic solvents and therefore should allow detailed mechanistic investigations on the oxygen-transfer processes. They are active catalysts for the epoxidation of olefins as well as for the oxidation of aromatic alcohols, giving the corresponding aldehydes in high yield. However, when unfunctionalized olefins are used instead of allylic alcohols, complete conversion of the substrate has never been reached owing to catalyst deactivation, which might be due to ligand dissociation. In the present paper, the synthesis of a V^V complex bearing a tridentate pyrazolylpyridine cyclohexanolato ligand is described. Additionally, the reaction of bidentate pyrazolylcyclohexanol with $VOCl_3$ in the presence of a base was investigated, leading to a new dinuclear V^{IV} complex, which is also accessible by reacting $VOSO_4{\cdot}(H_2O)_3$ with pyrazolylcyclohexanol and LiCl in CH_3CN.

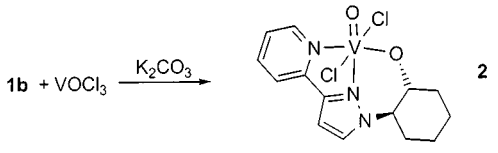
Results and Discussion

Our group has been interested in 1,3-amino alcohols bearing aromatic pyrazolyl N-donor fragments, where both donor sites are attached to a rigid cycloalkane backbone, for some time.[6−9] Such ligands can be obtained by nucleophilic attack of a pyrazole derivative on an epoxycycloalkane, giving the corresponding 1,2-*trans* configured cycloalkanols. Following this procedure, the ligands **1a,b** have been synthesized (Scheme 1, only one of the two stereoisomers is presented, as is the case in the following schemes).[8]



Scheme 1

The V^V oxoalkoxo complex **2** is accessible by reacting racemic *trans*-[1-pyrazolyl-3-(2-pyridyl)]cyclohexanol (**1b**) with $VOCl_3$ in the presence of K_2CO_3 (Scheme 2, only one of the two stereoisomers is shown). Owing to the tridentate ligand, the position of the oxo ligand is fixed *trans* to pyrazole, which is confirmed by a single ^{51}V NMR resonance and one set of resonances in the ^1H NMR spectrum. This is in contrast to the behavior of oxoalkoxo V^V complexes of bidentate pyrazolylpyridines,[5] which exist as mixtures of two isomers differing in the orientation of the oxo and alkoxo ligands relative to the *N*,*N*′-donor.



Scheme 2

As expected, the tridentate ligand enhances the stability of the V^V complex relative to the V^V complexes of bidentate pyrazolylpyridines. Unfunctionalized olefins like cyclooctene are thus efficiently converted into the corresponding epoxides (yield: 80−95%; reaction conditions: **2**/olefin/

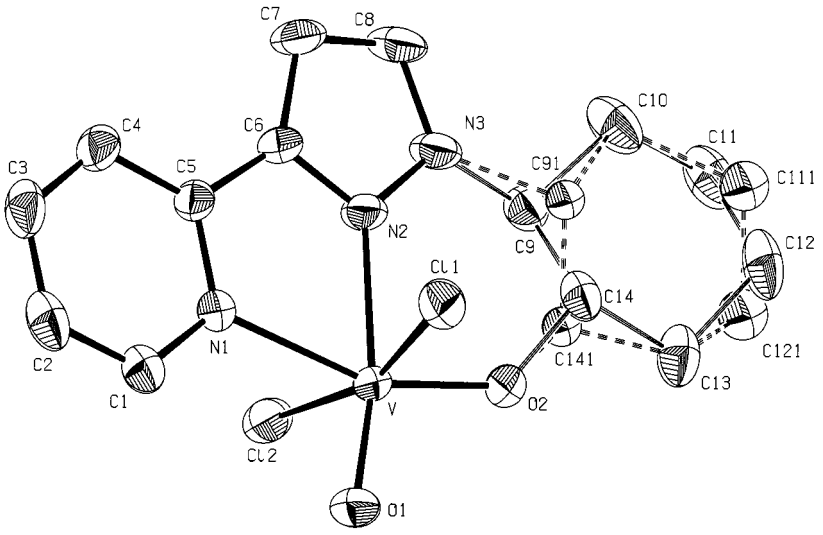

Figure 1. ORTEP[10] drawing of the molecular structure of **2** in the solid state; thermal ellipsoids are at the 50% probability level and hydrogen atoms are omitted for clarity

*t*BuOOH = 0.01:1:1, 24 h at 55 °C, solvent: $CHCl_3$). However, the vanadium complex bearing an enantiomerically pure (1*S*,2*S*)-*trans*-[1-pyrazolyl-3-(2-pyridyl)]cyclohexanol ligand[8] does not induce any enantioselectivity in the epoxidation of prochiral olefins such as 1,2-dihydronaphthalene or allylic and homoallylic alcohols.

Compound **2** crystallizes from acetone in the centrosymmetric monoclinic space group $P2_1/n$ with 0.5 equiv. of the solvent. Figure 1 shows the molecular structure of **2** in the solid state, and a selection of characteristic bond lengths and angles is given in Table 1.

Table 1. Selected bond distances (Å) and angles (°) for **2**

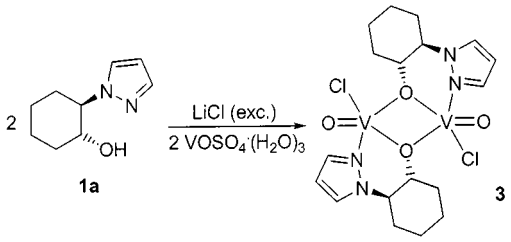
Cl2−V−N2	83.18(6)		

The three ring systems (pyridine, pyrazole, cyclohexane) of the N,N,O ligand and the V=O unit are found in an almost coplanar orientation, while the chloro ligands complete the distorted octahedral coordination geometry at vanadium. Despite the crystallographic disordering in the individual crystal that was used for the structure determination, a satisfactory solution of the structure could be performed. While the V=O [1.597(2) Å] and V−O distances [1.762(2) Å] in **2** are only a few pm longer than the distances found in the isostructural oxoalkoxo vanadium(V) complexes bearing bidentate pyrazolylpyridine ligands [V=O = 1.575(3) and 1.579(2) Å; V−O = 1.740(2) and 1.735(2) Å],[5] the V−N distances in **2** are drastically shortened due to the tridentate ligand system. Usually, the M−N bonds (N = *N*-donor ligand) in the *trans* position to strong σ-donor ligands (e.g. oxo) are found to be about 10−15 pm longer than those in the *trans* position to alkoxo ligands. This is no longer true for **2**: here V−N2 [2.145(2) Å] is slightly shorter than V−N1 [2.167(2) Å], which means that the V−N bond *trans* to the oxo ligand is about 17 pm shorter when a tridentate ligand is coordinated instead of a bidentate ligand [V−N2 = 2.310(3) and 2.338(2) Å] with analogous donor properties.

Since there was no chiral induction in the epoxidation of prochiral olefins with (1*S*,2*S*)-**2**, the reaction of the bidentate ligand *trans*-2-pyrazol-1-ylcyclohexanol (**1a**) with $VOCl_3$ was investigated in order to open up an additional coordination site at the vanadium center for interaction with the substrates. Performing this reaction as for the synthesis described for **2** gives a deep orange-brown solution. However, the primary product is not stable even at −20 °C and decomposes in solution and in the solid state, leading to a black and oily precipitate, which was not investigated further, and a small amount of deep blue crystals. X-ray analysis of these crystals proved that reduction of V^V had taken place, and a dinuclear V^{IV} complex **3**, bearing one chelate, one oxo and one chloro ligand per vanadium center was formed. With this information in mind, a high yield synthesis of **3** starting from *trans*-2-pyrazol-1-ylcyclohexanol (**1a**), $VOSO_4 \cdot (H_2O)_3$ and LiCl was established (Scheme 3). Among a series of solvents (THF, CH_2Cl_2, $CHCl_3$, MeOH) which were examined for this reaction, acetonitrile proved to be the best.



Scheme 3

Catalytic tests with compound **3** showed that the blue color of the complex vanishes after the addition of *t*BuOOH to give an orange-colored solution, indicating the oxidation of V^{IV} to V^{V}. However, it has not been possible up to now to characterize the V^{V} compound(s) formed here due to rapid decomposition. The catalytic activity of these solutions is about 20% of the activity of compound **2**.

Compound **3** crystallizes from $CHCl_3/Et_2O$ in the centrosymmetric monoclinic space group $P2_1/n$. Figure 2 shows the molecular structure of **3** in the solid state, and a selection of characteristic bond lengths and angles is given in Table 2.

In the solid state structure of **3**, the two V^{IV} centers V1 and V2, which are not equivalent in terms of crystal symmetry, are bridged by the alcoholato moieties of the chelate ligands leading to the formation of a planar V_2O_2 ring with V−O distances of about 2.0 Å. The distance V1···V2 is 3.125(1) Å, which excludes a V−V single bond. The oxo ligands O1 and O3 are found in a *cis* orientation, which has been observed in only a few V^{IV} complexes before.[11−15] Two homochiral chelate ligands are coordinated at the vanadium centers, which leads to a dimeric structure with nearly C_2 symmetry. The square-pyramidal coordination of the V^{IV} centers is completed by the chloro ligands. Complex **3** can be best compared with $[VO(THFfo)Cl]_2$ (THFfo = tetrahydrofurfuryl alcoholate), obtained from $VOCl_2$ and Na(THFfo), wherein the alcoholato moieties are also bridging the two V^{IV} centers.[13] Owing to the five-membered chelate rings formed by the THFfo ligands, the V−O distances in the V_2O_2 ring are shortened, which causes the V−V distance in $[VO(THFfo)Cl]_2$ [3.070(1) Å] to shrink slightly, compared to **3**.

Compound **3** shows an interesting dynamic behavior in solution. When a deep-blue solution of **3** in $CHCl_3$ is treated with MeOH or EtOH, the color turns to green within a few hours at room temp. Decreasing the temperature of the mixture to 0 °C brings back the original blue color. This procedure can be repeated several times, which

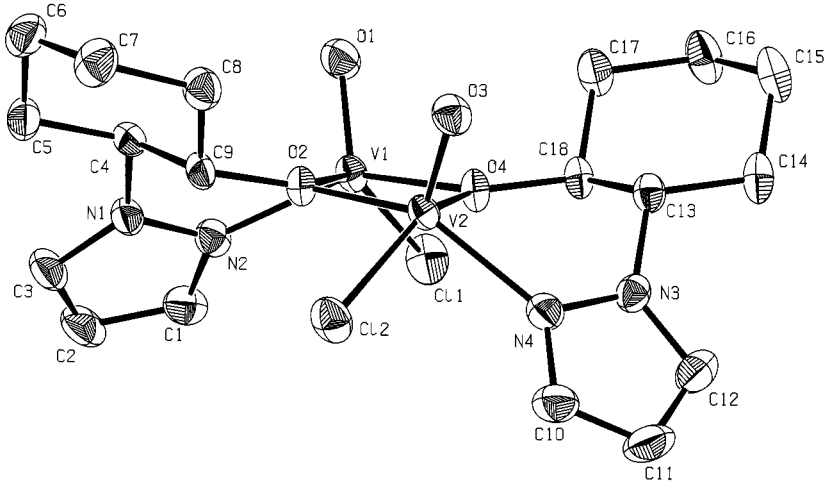

Figure 2. ORTEP[10] drawing of the molecular structure of **3** in the solid state; thermal ellipsoids are at the 50% probability level and hydrogen atoms are omitted for clarity

indicates a reversible reaction, for example a monomer ⇄ dimer equilibrium. When pyridine or THF are added to a solution of **3** in $CHCl_3$, an intense green color is observed, which persists even at low temperatures. However, when the solvents are removed in vacuum, blue microcrystalline **3** is recovered. For a deeper insight into these processes, EPR experiments were carried out.

The monomer ⇄ dimer equilibrium is illustrated in Figure 3 by the EPR spectra of complex **3** in $CHCl_3$ solution with and without addition of pyridine as donor.

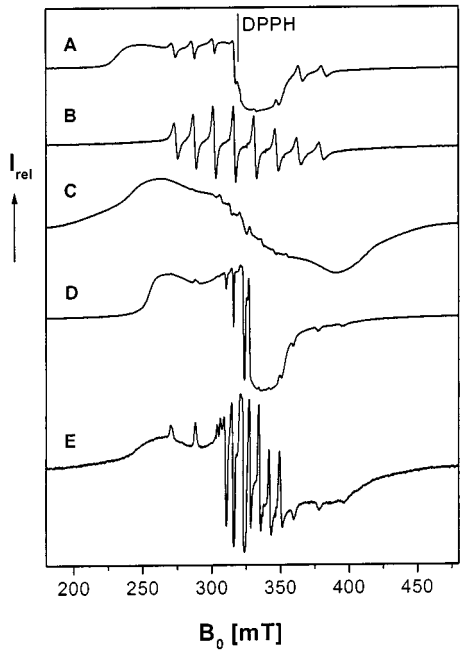

Figure 3. Liquid (A, B; T = 293 K) and frozen (C-E; T = 130 K) solution EPR spectra of the vanadium complex **3** in $CHCl_3$ ($5\cdot10^{-3}$ M) before (A and C) and after addition of pyridine (B and E: excess pyridine, D: few drops of pyridine)

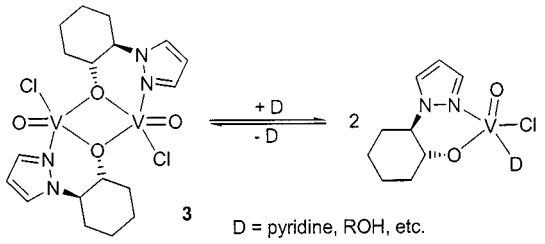
The broad sigmoid EPR resonance line at $g \approx 1.97$ (line width $\Delta B_{pp} \approx 130$ mT; Figure 3 A, C−E) results from a weak magnetic interaction of the two unpaired spins in the dimeric vanadium complex (no resonance was observed at ''half-field'', i.e. no $\Delta M_S = 2$ transition). Similar EPR spectra (partially with better resolution) have been reported in the literature for dinuclear vanadium(IV) complexes.[13,16,17] The vanadium centers of **3** are weakly coupled both at room temperature in solution (Figure 3 A) and in a frozen glass (T = 30 K, Figure 3 C, D). In all cases at least a residual amount of a monomeric vanadium(IV) species is present depending on the temperature. This is reflected by the superposition of a well-resolved line octet which results from the hyperfine interaction of the unpaired electron with the nuclear spin of ^{51}V ($I = 7/2$).

The addition of pyridine at room temperature changed the color of the solution to green. An excess of pyridine provides an EPR spectrum of the monomer only at room temperature [Figure 3 B; $g_0 = 1.974$ (±0.001); $a_0 = 15.1$ (±0.03) mT]. Figure 3 C−E illustrate the effect of the stepwise addition of pyridine. Figure 3 E shows a well-resolved frozen solution EPR spectrum of the monomer superimposed on the residual dimeric species. The parameters of the former are typical for a single $S = 1/2$ VO^{2+} complex with a square-pyramidal coordination sphere of mixed donor atoms (N, O, Cl)[13] $g_{\|} = 1.952$; $g_{\perp} = 1.983$ (±0.001); $A_{\|}(^{51}V) = 18$ mT; $A_{\perp}(^{51}V) = 6.45$ mT (±0.05 mT); $B_{pp} = 1.5(_{\perp}) - 2.0(_{\|})$ mT. According to the EPR results, a monomer ⇄ dimer equilibrium can be postulated, which is influenced by the addition of donor molecules (D) (as shown in Scheme 4) and also by the variation of the temperature.



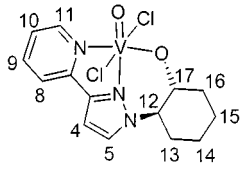
Scheme 4

Conclusion

It could be shown that using a monoanionic tridentate ligand instead of a neutral bidentate ligand enhances the catalytic performance of the V^V catalyst in the olefin epoxidation and in the oxidation of benzylic alcohol due to a reduced tendency for catalyst decomposition. However, this strategy prevents enantioselective epoxidation. Cleaving one of the neutral N-donor sites destabilizes the V^V complex and leads to a formally five-coordinate V^{IV} system, which undergoes dimerization through the alcoholato ligands. This dimerization is a reversible process as shown by EPR spectroscopy.

Experimental Section

All syntheses were performed under an atmosphere of nitrogen; solvents were dried, distilled and degassed before use. The ^1H NMR spectrum of **2** is assigned according to Scheme 5.[18]



Scheme 5

Dichlorooxo{*rac-trans*-[1-pyrazolyl-3-(2-pyridyl)]cyclohexyloxy}-vanadium(V) (2): K_2CO_3 (0.50 g, 3.62 mmol) was dried for 10 min. at 300 °C in a 100 mL flask under vacuum. After cooling to room temperature, a solution of *rac-trans*-[1-pyrazolyl-3-(2-pyridyl)]cyclohexanol[8] (**1b**; 0.30 g, 1.24 mmol) in CH_2Cl_2 (40 mL) was added and the mixture was cooled to 0 °C. A solution of $VOCl_3$ (0.12 mL, 1.24 mmol) in CH_2Cl_2 (10 mL) was added dropwise and the mixture was stirred for 1 h at 0 °C and for 2 h at room temp. The

precipitate was removed by filtration, the solvent was removed in vacuum and the orange-red colored residue was dissolved in acetone (20 mL). After 7 days at −18 °C, **2** (0.16 g, 33%) was obtained as dark red crystals, containing 0.5 equiv. of acetone. Concentration of the mother liquor gave rise to further crystallization (0.113 g, 24%). − $(C_{14}H_{16}Cl_2N_3O_2V)_2{\cdot}C_3H_6O$ (818.35): calcd. C 45.50, H 4.68, N 10.27; found C 45.20, H 4.78, N 10.13. − IR (KBr): $\tilde{\nu}$ = 1018 vs ($\nu_{V=O}$) cm^{-1}. − ^1H NMR (400 MHz, 25 °C, $CDCl_3$): δ = 9.51 (d, $^3J_{10,11}$ = 5.5 Hz, 1 H, 11-H), 8.01 (t, $^3J_{9,10}$ = 6.5 Hz, 1 H, 9-H), 7.80 (d, $^3J_{8,9}$ = 7.5 Hz, 1 H, 8-H), 7.73 (d, $^3J_{4,5}$ = 2.5 Hz, 1 H, 5-H), 7.52 (dd, 1 H, 10-H), 6.83 (d, 1 H, 4-H), 4.34 (ddd, $^3J_{12,17}$ = 13.0 Hz, $^3J_{16,17}$ = 4.5 Hz, $^3J_{16',17}$ = 9.0 Hz, 1 H, 17-H), 2.69 (m, 1 H, 12-H), 2.27 (m, 2 H, CH_2), 1.97−1.24 (m, 6 H, CH_2). − ^{51}V NMR (105.2 MHz, 25 °C, $CDCl_3$): δ = −394.9.

Bis[chlorooxo(*rac-trans*-2-pyrazol-1-ylcyclohexyloxy)vanadium(IV)] (3): $VOSO_4{\cdot}(H_2O)_3$ (0.22 g, 1.00 mmol), *rac-trans*-2-(pyrazol-1-yl)-cyclohexan-1-ol[9] (**1a**; 0.17 g, 1.00 mmol) and LiCl (0.06 g, 1.50 mmol) were dissolved in acetonitrile (40 mL) and heated to 60 °C for 4 h. The resulting blue mixture was filtered and the solvent was removed in vacuum. The blue residue was dissolved in $CHCl_3$ (10 mL) and diethyl ether was condensed slowly into the solution. After a few days, deep blue crystals of **3** (0.36 g, 67%) were obtained. − $C_{18}H_{26}Cl_2N_4O_4V_2$ (535.21): calcd. C 40.39, H 4.90; N 10.47; found C 40.18, H 4.88, N 10.40. − IR (KBr): $\tilde{\nu}$ = 1014 s, 1003 vs ($\nu_{V=O}$) cm^{-1}. − EPR: see text.

X-ray Crystal Structure Determination: The complexes were crystallized from acetone (**2**) or by slow diffusion of diethyl ether into a chloroform solution (**3**). The intensity data were obtained with graphite monochromated Mo-K_α radiation on an imaging plate diffraction system (IPDS; STOE & CIE GmbH) equipped with a rotating anode (NONIUS FR591; 50 kV; 60/80 mA; 3.0/4.0 kW). Both structures were solved by a combination of direct methods and difference-Fourier syntheses. Full-matrix least-squares refinements on 307/375 parameters were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with SHELXL-97 weighting scheme and stopped at shift/err < 0.001/0.003. Neutral-atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for X-ray Crystallography.[19] All calculations were performed on a DEC 3000 AXP workstation and an Intel Pentium II PC with the STRUX-V system,[20] including the programs PLATON,[10] SIR92,[21] and SHELXL-97.[22] Additional crystal data, intensity collection data and refinement parameters are presented in Table 3.

Data Collection, Structure Solution and Refinement for Complex 2: Data collection was performed within the Θ range of 2.84°< Θ < 24.65° with an exposure time of 600 seconds per image (oscillation scan modus from Θ = 0° to 270° with ΔΘ = 1.0°). A total number of 16128 reflections were collected. 273 Systematic absent reflections were rejected from the original data set. Data were corrected for Lorentz, polarization, decay and absorption effects with the DECAY algorithm.[23] Two different modes of disordering had to be included in the refinement process. At first, the positions of the chiral vanadium complex were occupied by the two stereoisomers in a 79:21 ratio. This resulted in a disordering model for the cyclohexan-1,2-diyl units wherein the positions of the carbon atoms 10 and 13 were identical for both six-membered rings. All non-hydrogen atoms of the vanadium complex were refined anisotropically with the exception of the disordered cyclohexandiyl carbon atoms of the minor species. Half an equivalent of acetone is disordered at an inversion center of the crystal system. All acetone non-hydrogen atoms were refined anisotropically. All hydrogen atoms of the major stereoisomer were found in the difference-Fourier map and refined with isotropic thermal displacement parameters. All hydrogen atoms of the minor stereoisomer and of the acetone were calculated in ideal positions (riding model; U_H = 1.2·U_C).

Data Collection, Structure Solution and Refinement for Complex 3: Data collection was performed within the Θ range of 3.15°< Θ < 25.65° with an exposure time of 180 seconds per image (oscillation scan modus from Θ = 0° to 135° with ΔΘ = 1.0°). A total number of 11436 reflections were collected. 460 Systematic absent reflections were rejected from the original data set. Data were corrected for Lorentz, polarization, decay and absorption effects, with the DECAY algorithm.[23] All non-hydrogen atoms of the vana-

Kinetic and Equilibrium Study on the Axial-Ligand Substitution Reaction of the Head-to-Tail α-Pyridonate-Bridged *cis*-Diammineplatinum(III) Dinuclear Complex: *trans* Effect of the Axial Ligand through the Pt−Pt Bond to the Opposite Axial Ligand

Nami Saeki,[a] Yuji Hirano,[a] Yasunari Sasamoto,[a] Ichiro Sato,[a] Tsuyoshi Toshida,[a] Sousei Ito,[a] Noriko Nakamura,[a] Koji Ishihara,*[a] and Kazuko Matsumoto*[a]

Keywords: Platinum / Pt^{III} dimer / Kinetics / Reaction mechanisms / α-Pyridone

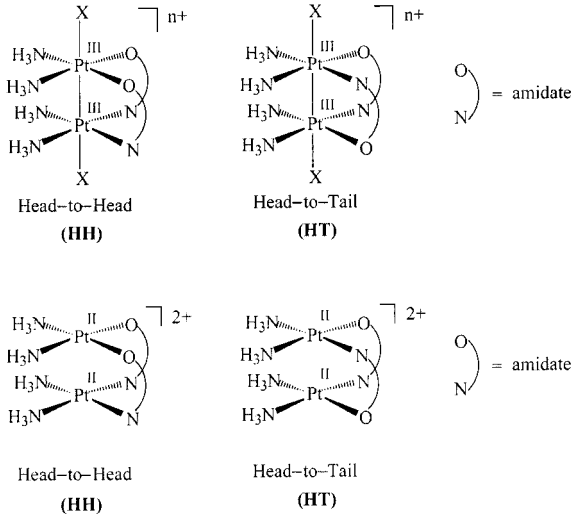
Acid dissociation constant of the axial aqua ligand in the Head-to-Tail (HT) α-pyridonate-bridged *cis*-diammineplatinum(III) dimer complex $\{[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(H_2O)]^{4+}\}$ was determined spectrophotometrically to be $-\log(K_{h1}/M) = 1.98\pm0.01$ at 25 °C and $I = 2.00$ M. Successive substitution reaction of the HT dimer with halide ions X^- (X^- = Cl^- and Br^-) at the two axial sites to give monohalo and dihalo complexes was studied kinetically:

$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(H_2O)]^{4+} + X^- \rightleftarrows$
$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(X)]^{3+} + H_2O$ (k_{obs1})
$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(X)]^{3+} + X^- \rightleftarrows$
$[(X)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(X)]^{2+} + H_2O$ (k_{obs2})

Formation constants of the monohalo and dihalo complexes were determined spectrophotometrically to be $\log(K_1^{Cl}/M^{-1}) = 5.27\pm0.02$ and $\log(K_2^{Cl}/M^{-1}) = 3.83\pm0.01$ for the reaction with Cl^-, and $\log(K_1^{Br}/M^{-1}) = 5.33\pm0.03$ and $\log(K_2^{Br}/M^{-1}) = 4.44\pm0.02$ for the reaction with Br^-. In the HT dimer having two equivalent platinum atoms, the deprotonation occurs to the water molecule on one of the two Pt atoms, whereas the first nucleophilic substitution with X^- occurs to the other Pt atom. Substitution of the second water ligand with Cl^- proceeds by a simple substitution path, whereas the second substitution with Br^- proceeds by two parallel paths: one includes the dissociation of the axially coordinated water molecule followed by the Br^- coordination, and the other is the simple one-step substitution path. The difference of the reaction paths is reasonably explained by the different *trans* effect of the halide ions exerted through the Pt–Pt bond to the other terminal Pt atom in the monohalo complexes.

Introduction

There are a substantial number of diplatinum(III) complexes that involve metal−metal bonding between two d^7 platinum atoms.[1−10] They are classified into two groups: the first group involves symmetrical bridging ligands with identical coordinating atoms at both ends of the bridge, such as pyrophosphate-*P,P*, sulfate-*O,O*, and hydrogen phosphate-*O,O* ligands, and the complexes have the "lantern" structure with four symmetrically bridging ligands. The second group, which we will deal with in this report, involves complexes having asymmetrical bridging ligands with different coordinating atoms, such as α-pyrrolidonate-*N,O*, α-pyridonate-*N,O*, and acetamidate-*N,O*. These bridging ligands also appear in a class of multinuclear mixed-valent complexes called "platinum blues".[11−20] The complexes in the second group, Head-to-Head (HH) dinuclear Pt^{III} complexes $[Pt_2(NH_3)_4(N^{\cap}O)_2(X)_2]^{n+}$ ($N^{\cap}O$ = amidate, X = NO_3^-, NO_2^-, H_2O, or Cl^-, n = 2 or 4) are formed by the oxidation of "platinum blues". The two platinum atoms in the HH form are not equivalent, as shown by Scheme 1. The other isomer, head-to-tail (HT) is also known for this class of compounds, however isomerization between HH and HT of the Pt^{III} dimers does not occur in aqueous solution. The HH to HT or vice versa isomerization takes place only for the Pt^{II} dimer complexes.



Scheme 1

As an exception, an isomerization reaction has been reported for the Pt^{III} dimer complex HH-$[Pt_2^{III}(CH_3)_4$(2-hy-

droxy-6-fluoropyridonato)$_2$Py], which isomerizes to the head-to-tail (HT) isomer, HT-[$Pt_2^{III}(CH_3)_4$(2-hydroxy-6-fluoropyridonato)$_2$(Py)$_2$], when the former reacts with pyridine in chloroform.[21] Such HH to HT isomerization has been reported for several Pt^{II} dimer complexes with similar bridging amidate ligands,[22] but for Pt^{III} dimer complexes, the above-mentioned reaction represents the only example of this isomerization reported so far. Unlike their reduced forms, i.e., the Pt^{II} dimers $[Pt_2(NH_3)_4(N^{\cap}O)_2]^{2+}$, the Pt^{III} dimer complexes have axial ligands at both ends of the Pt−Pt axis, and these axial ligands play an important role in determining the chemical properties of the complex in solution. In spite of this fact, there are few kinetic studies on the axial ligand substitution reactions for the Pt^{III} dimer complexes; only a few kinetic studies have been reported for Pt^{III} dimers of the first group,[23,24] and even the reports on the simplest yet fundamentally important equilibrium parameters such as the acidity constant of the axially coordinated water are limited.[8,25]

In this paper we report the kinetic and equilibrium study on the axial aqua ligand substitution by halide ligands on the HT α-pyridonate-bridged Pt^{III} dinuclear complex, HT-$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(H_2O)]^{4+}$. Halide ions were selected as ligands rather than NO_2^-, SO_4^{2-}, etc., in order to avoid the problem of so-called "proton ambiguity" in kinetics,[26] since the dinuclear Pt^{III} complexes are found to be hydrolyzed even in highly acidic aqueous solution.

Results and Discussion

Preliminary ^{1}H NMR measurements were done, as is shown in Figure 1. When a small amount of Cl^- was added to the HT dimer solution, new peaks appeared at δ = 8.15 and 8.63 (Figure 1, b and c). Another peak was enhanced at δ = 8.7 with a decrease of the peaks at δ = 8.15 and 8.63, as [Cl^-] was increased. The peaks at δ = 8.15 and 8.63, and δ = 8.7 are assigned to the monochloro and dichloro complexes, respectively, and show that only one monochloro complex is formed and is converted to the dichloro complex.

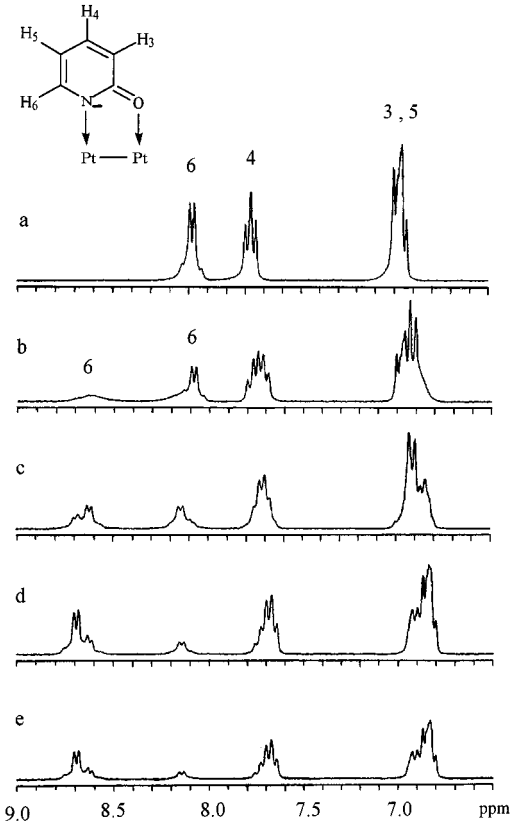

Figure 1. The ^{1}H NMR spectra of the HT dimer in acidic D_2O solution with different C_{Cl^-} at room temperature; [$DClO_4$] = 1.3 M, [HT] = 1.9×10^{-2} M, [Cl^-]/[HT] = 0 (a), 0.5 (b), 1.0 (c), 1.5 (d), 2.0 (e); solid began to precipitate at (d)

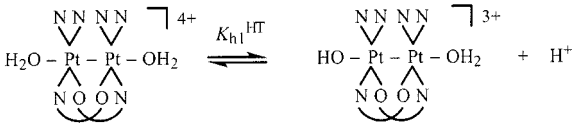
Acid Dissociation Constant of the HT Dimer

The X-ray crystallography study shows[4] that two nitrate ions cap axial positions of the HT-[$Pt_2^{III}(NH_3)_4$(α-pyridonato)$_2$(NO_3)$_2$]$^{2+}$ in solid state. Both axial nitrate ions are completely replaced by H_2O or OH^- on dissolution, since no spectral change was observed when sodium nitrate was added up to 0.020 M (mol dm^{-3}) to the aqueous solutions of the HT dimer (5.0×10^{-5} M). When the acidity of the solution was varied, an isosbestic point was observed at 244 nm (Figure SI-1, see Supporting Information). The HT dimer is stable in strongly acidic aqueous solution, and no decomposition was observed by acidification at least for several hours. The spectral change (Figure SI-1, see Supporting Information) is pH-dependent and the change can be reversed by pH adjustment. The spectral change corresponds to deprotonation of the coordinated axial water molecule as expressed in Equation (1). The deprotonation occurs to either one of the two equivalent water molecules in the HT isomer.



(1)

$[H_2O{-}Pt(N_3O){-}Pt(N_3O){-}OH_2]^{4+}[HO{-}Pt(N_3O){-}Pt(N_3O){-}OH_2]^{3+}$

The apparent molar absorption coefficient ε is expressed as $\varepsilon = (\varepsilon_1 + \varepsilon_2 K_{h1}[H^+]^{-1})(1 + K_{h1}[H^+]^{-1})^{-1}$, where ε_1 and ε_2 are the molar absorption coefficients of the undissociated dimer $H_2O{-}Pt(N_3O){-}Pt(N_3O){-}OH_2$ and the deprotonated dimer $H_2O{-}Pt(N_3O){-}Pt(N_3O){-}OH$, respectively, and K_{h1} is the first acid dissociation constant of the diaqua complex. The ε values at 250, 255, 260, 270, and 280 nm were analyzed simultaneously as a function of [H^+] by using a nonlinear least-squares fitting method. The K_{h1} values obtained at I = 2.00 M are as follows: $-\log(K_{h1}/M)$ = 1.98±0.01 (25.0 °C), 1.68±0.02 (35.0 °C). The value of K_{h1} for the present HT dimer is more than 1 order of magnitude larger than that of the related Pt^{III} dimer complex with dif-

ferent bridging ligands: $-\log(K_{h1}/M) = 3.49$ for the 1-methyluracilate-bridged HT dimer.[8] This difference can be explained by the less-donating α-pyridonate coordination, as compared to methyluracilate. Because of the weaker donation, the Pt^{III} atom in the α-pyridonate complex would be more electron withdrawing.

Formation Constants of the Monohalo and Dihalo Complexes

The absorption spectra were measured at $I = 2.00$ M, $[H^+] = 1.27$ M, and 25 °C, under various C_X^-/C_{HT} for a fixed C_{HT}. The results are shown in Figure 2 for both reactions with Cl^- and Br^-, in which two distinct isosbestic points are observed at 251 and 273 nm, and at 256 and 295.5 nm, respectively.

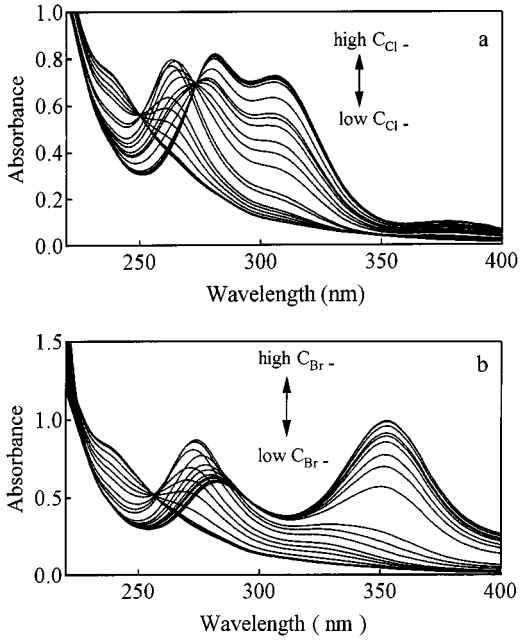


Figure 2. The UV/Vis spectra of the HT dimer in acidic aqueous solution with different C_{Cl}^- (a) and C_{Br}^- (b) at 25 °C and $I = 2.00$ M. $[H^+] = 1.27$ M; $C_{Cl}^- = (0-1.35) \times 10^{-2}$ M (a); $C_{Br}^- = (0-1.20) \times 10^{-2}$ M (b); $C_{HT} = 2.5\times10^{-5}$ M (a), 2.8×10^{-5} M (b)

Plots of the absorbance at the isosbestic point of the longer wavelength (273 nm, 295.5 nm) against C_X^-/C_{HT} showed a clear inflection point at $C_X^-/C_{HT} = 1$, however, another inflection point corresponding to $C_X^-/C_{HT} = 2$ was obscured, probably because of the smaller formation constant of the dihalo complex. The formation of the dichloro complex has also been confirmed by X-ray crystallography for the dichloro HH α-pyrrolidonate-bridged dimer,[26] in addition to the ^1H NMR results mentioned above. Therefore, the observed spectral change in Figure 2 corresponds to the following reactions.

$$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(H_2O)]^{4+} + X \xrightleftharpoons{K_1^X} [(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(X)]^{3+} + H_2O \quad (2)$$

$$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(X)]^{3+} + X \xrightleftharpoons{K_2^X} [(X)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(X)]^{2+} + H_2O \quad (3)$$

The K_1^X and K_2^X values were obtained at $I = 2.00$ and 25 °C, by simultaneously analyzing the absorbance at twelve different wavelengths between 235 nm and 305 nm, and are given in Table 1 together with K_{h1} values. The K_1^{Cl} and K_2^{Cl} values are comparable to those reported for the HH α-pyrrolidonate-bridged cis-diammineplatinum(III) dimer with Cl^-.[25]

Table 1. Equilibrium constants for the reaction of the HT α-pyridonate-bridged *cis*-diammineplatinum(III) dimer with halides determined at $I = 2.00$ M ($[H^+] = 1.27$ M) and 25 °C spectrophotometrically

[a] For HT 1-methyluracilate-bridged *cis*-diammineplatinum(III) dimer.[8]

Kinetics for the Formation of the Monohalo Complexes

Under the conditions of $C_{HT} >> C_X^-$ and $[H^+] = 0.10-0.82$ M, reactions of the HT dimer with X^- were first order and monophasic, i.e., only reaction (2) was observed. The formation rate of the monohalo complex (Pt_2X) is given by Equation (4), where $[X^-]$ is the concentration of the free halide ion. The conditional first-order rate constant, k_{obs1} was found to involve the dimer concentration and $[H^+]$.

$$d[Pt_2X]/dt = k_{obs1}[X^-] \quad (4)$$

Since k_{obs1} was linearly dependent on C_{HT} at a given $[H^+]$ as shown in Figure 3 (a), k_{obs1} is expressed as Equation (5), where k_{f1} is the second order rate constant.

$$k_{obs1} = k_{f1}C_{HT} \quad (5)$$

The two Pt atoms in the HT dimer are equivalent, and deprotonation occurs to either one of the two axial water molecules. Since the deprotonated water molecule in the octahedral aquahydroxo complexes is generally not easily replaced by other ligands, the halide substitution would take place at the other water molecule on the opposite Pt atom, $Pt(N_3O)$. That is, the deprotonation [Equation (1)] and the first substitution reaction with halide [Equation (2)] would occur to the opposite axial sites of the Pt^{III} dimer.

Therefore, two reaction pathways shown in Scheme 2 should be considered under the present condition for the

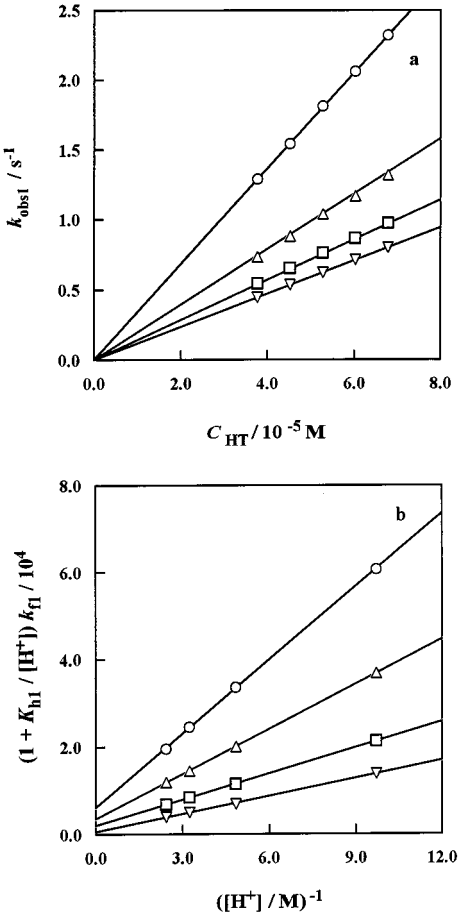

Figure 3. (a) The dependence of k_{obs1} on C_{Pt2} for the reaction of the HT dimer with bromide ion in acidic aqueous solution at 20 °C and I = 2.00 M. [H$^+$] = 0.103 (O); 0.206 (Δ); 0.309 (□); 0.412 (▽) M. $C_{Br^-} = 8.75\times10^{-7}$ M. (b) Plot of $(1 + K_{h1}/[H^+])k_{f1}$ against 1/[H$^+$] for the reaction of the HT dimer with bromide ion at 20 °C and I = 2.00 M; T = 25.0 (O); 20.0 (Δ); 15.0 (□); 10.6 (▽) °C

monohalo complex formation. For the reaction pathways in Scheme 2, the rate constant k_{obs1} is given by Equation (6).

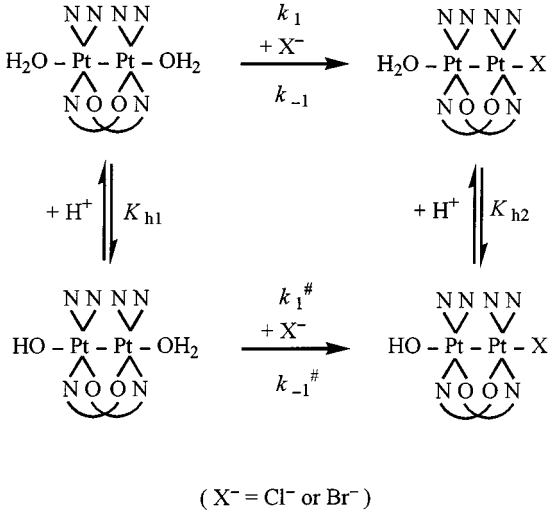
$$k_{obs1} = \frac{k_1 + \frac{k_1^{\#}K_{h1}}{[H^+]}}{1 + \frac{K_{h1}}{[H^+]}} C_{HT} \quad (6)$$

Comparison of Equation (5) with Equation (6) gives Equation (7).

$$\left(1 + \frac{K_{h1}}{[H^+]}\right) k_{f1} = k_1 + \frac{k_1^{\#}K_{h1}}{[H^+]} \quad (7)$$

The plots of the left-hand side of Equation (7) against $[H^+]^{-1}$ were linear as shown in Figure 3 (b).

The values of k_1 and $k_1^{\#}$ were obtained by applying a nonlinear least-squares fitting to Equation (7), and are listed in Table 2. The K_{h1} values at each temperature are given as Supporting Information and were used for the calculation of k_1 and $k_1^{\#}$.



Scheme 2

Table 2. The rate constants (25 °C) and activation parameters for the first steps of the reactions of the HT dimer with halides

ligand	path	k [M^{-1}s^{-1}]	$\Delta H^{\#}$ [kJ mol^{-1}]	$\Delta S^{\#}$ [J mol^{-1}K^{-1}]
Cl$^-$	k_1	2.4×10^3 1.2×10^3 [a]	87.8±21.0	114±72
	$k_1^{\#}$	6.6×10^5 3.3×10^5 [a]	11.9±1.5	−93.7±5.3
Br$^-$	k_1	6.5×10^3 3.3×10^3 [a]	79.7±1.0	95.3±3.0
	$k_1^{\#}$	5.3×10^5 2.7×10^5 [a]	23.1±0.7	−57.9±2.0

[a] Statistical factor was taken into account (see text).

In the following discussion, half of k_1 was considered, since X$^-$ can replace both aqua ligands with an equal probability. Interestingly, the k_1 value for the reaction with Br$^-$ is larger than that with Cl$^-$; this relation is the same as that for the reactions of mononuclear Pt^{II} complexes, where the heavier halides with higher polarizability react faster. On the contrary, the $k_1^{\#}$ value is larger for Cl$^-$ than Br$^-$, which may reflect the decreased polarizability of the Pt(N$_3$O) in the HT dimer due to the deprotonation of the water molecule on the opposite axial site. We concluded that the ligand substitution rates on the axial sites of the HT dimer are sensitive to the nature of the ligands on the opposite axial site.

It is noteworthy that the rate constants k_1 and $k_1^{\#}$ in Table 2 are much larger than those for the direct substitution paths of the square planar Pt^{II} Werner-type complexes, which are of the order of 10^{-3} M^{-1}s^{-1}. A linear relationship was observed between $\Delta H^{\#}$ and $\Delta S^{\#}$ as shown in Figure SI-2 (Supporting Information, see footnote on the first page of this article), which suggests that both k_1 and $k_1^{\#}$ paths are via the same mechanism.[27,28]

For many octahedrally coordinated metal ions $[M(H_2O)_6^{n+}]$, substitution rate constants on the hexaaqua metal ions are smaller by 2−3 orders of magnitude than those of the corresponding pentaaquahydroxo metal ions $[M(H_2O)_5(OH)^{(n-1)+}]$.[29] The k_1 and $k_1^{\#}$ values in Table 2 show that the same tendency holds even through the present complexes having metal−metal bonds.

The values of k_1 and $k_1^{\#}$ in Table 2 are much larger than the rate constants of the axial ligand substitution (k_1 = 0.9 and 0.3 $M^{-1}s^{-1}$, k_2 = 0.8 and 0.4 $M^{-1}s^{-1}$ for X = Cl^- and Br^-, respectively) for the following $Pt^{III}-Pt^{III}$ system.[1]

$$Pt_2(\mu\text{-}PO_4H)_4(H_2O)_2^{2-} \underset{}{\overset{k_1}{\underset{+X^-}{\rightleftharpoons}}} Pt_2(\mu\text{-}PO_4H)_4X(H_2O)^{3-} \overset{k_2}{\underset{+X^-}{\rightleftharpoons}} Pt_2(\mu\text{-}PO_4H)_4X_2^{4-} \quad (8)$$

The large difference in the k_1 values would come from the difference of the bridging ligand, as well as the affinity difference of the halide ions for the positively charged amidate-bridged complex and for the negatively charged complex in Equation (8).

The effect of ion pairing was not observed for both reactions (2) and (3), in spite of the highly positive charge of the complexes (4+ or 3+). This is probably because the rate constants were measured at high ionic strength (2 M), where an ion-paring effect is attenuated, and the formal charge would be delocalized over the dinuclear complexes. The rate constant for reaction (2), k_{obs1}, was measured at low C_{HT} (10^{-4} M > C_{HT} >> C_X-).

Kinetics for the Formation of the Dihalo Complexes

Under the conditions of C_{HT} << C_X^- and $[H^+]$ = 0.11−1.3 M, the reaction of the HT dimer was biphasic as shown in Figure 4. The rate constant was calculated only for the slower reaction by assuming two consecutive first-order reactions.

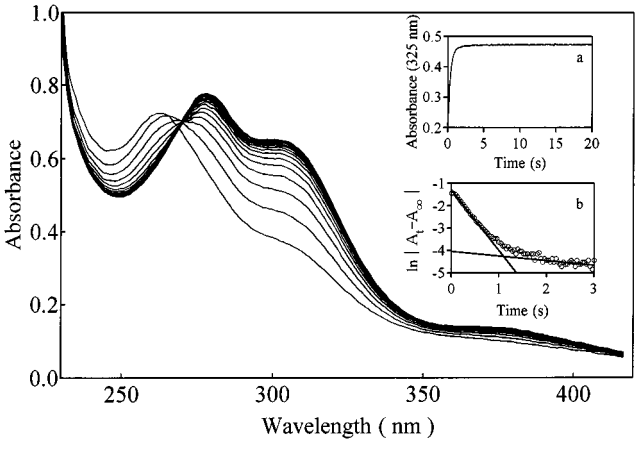


Figure 4. The UV/Vis spectra for the reaction of the HT dimer with chloride ion in acidic aqueous solution at 25 °C and I = 2.00 M. Measurement every 80 ms, C_{Cl^-} = 8.0×10^{-4} M, C_{HT} = 2.0×10^{-5} M, $[H^+]$ = 0.102 M. The inserted figure (a) shows the time dependence of the absorbance at 325 nm, and the semi-log plot (b) of the data in (a) shows clearly that the reaction is biphasic

The formation rate of the dihalo complex (Pt_2X_2) is expressed as Equation (9), where [HT−X] is the concentration of the monohalo-HT dimer.

$$d[Pt_2X_2] / dt = k_{obs2}[HT\text{-}X] \quad (9)$$

For the reaction with Cl^-, k_{obs2} was linear with respect to C_{Cl^-} at a given $[H^+]$ as shown in Figure 5 (a). The straight lines correspond to Equation (10), where k_{f2} and k_{d2} are the slope and the intercept in Figure 5 (a), respectively.

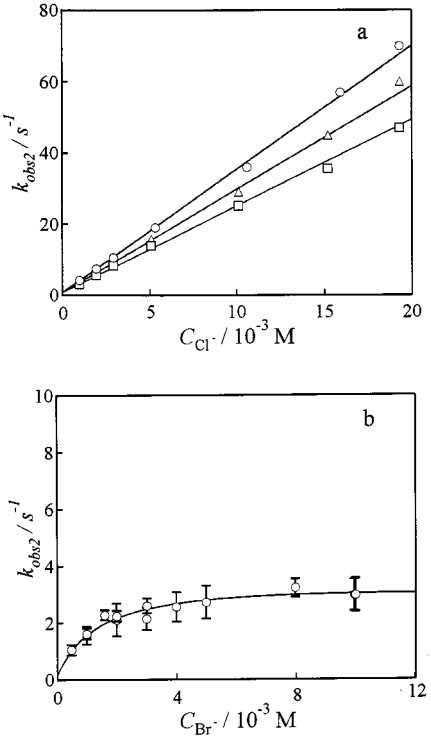

Figure 5. The dependence of k_{obs2} on C_X^- in acidic aqueous solution at 25 °C and I = 2.00 M. (a) for the reaction of the HT dimer with chloride ion, C_{HT} = 2.0×10^{-5} M, $[H^+]$ = 1.27 (□), 0.424 (Δ), 0.106 (O) M; (b) for the reaction of the HT dimer with bromide ion, C_{HT} = 2.0×10^{-5} or 4.0×10^{-5} M, $[H^+]$ = 0.4−1.6 M. The solid lines were drawn by applying a linear or non-linear least-squares fitting

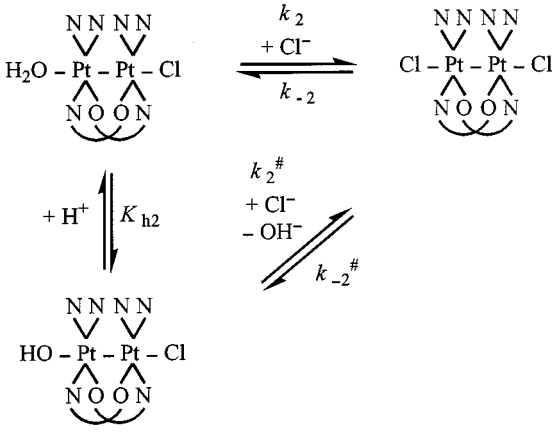
$$k_{obs2} = k_{f2} C_{Cl^-} + k_{d2} \quad (10)$$

It is obvious from Figure 5a that k_{obs2} varies with $[H^+]$ in the same way as in Figure 3 (a), that is, k_{f2} in Equation (10) decreases with increasing $[H^+]$, whereas k_{d2} does not depend on $[H^+]$. For the second Cl^- substitution reaction, the reaction path in Scheme 3 was postulated, for which Equation (11) was derived.



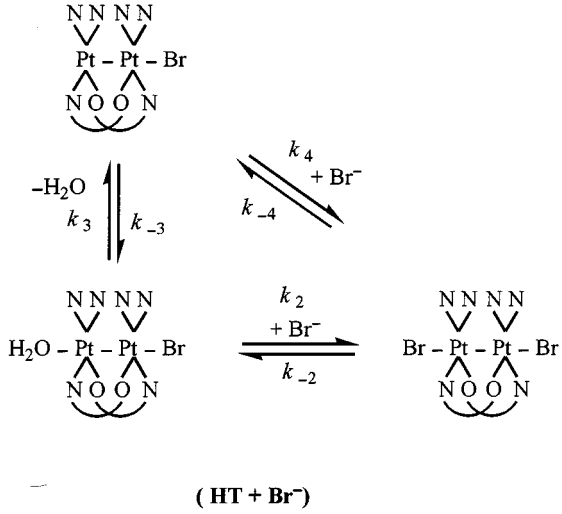
Scheme 3

$$k_{obs\,2} = \frac{k_2 + \frac{k_2^{\#} K_{h2}}{[H^+]}}{1 + \frac{K_{h2}}{[H^+]}} C_{Cl^-} + k_{-2} + \frac{k_{-2}^{\#} K_w}{[H^+]} \qquad (11)$$

The observed dependence of k_{f2} on $[H^+]$ corresponds to the coefficient of C_{Cl^-} in Equation (11). In Scheme 3, it was assumed that the coordinated OH^- is replaced by X^-. If the OH^- in the hydrolyzed species (the chlorohydroxo dimer in Scheme 3) is unreactive towards Cl^-, then $k_{obs2} = k_2[H^+][Cl^-]/([H^+] + K_{h2}) + k_{-2}$ is obtained. This equation does not correspond with the experimental observation that k_{obs2} decreases with increasing $[H^+]$. Thus, the $k_2^{\#}$ path, in which OH^- in the [HO−Pt−Pt−X] is replaced by X^-, must be involved in the HT + Cl^- system. This is unusual, considering the usual inertness of OH^- in $M(H_2O)_5(OH)^{(n-1)+}$. In HH α-pyridonate-dibridged complexes, HH-[Cl−Pt(N_2O_2)−Pt(N_4)−X], when X^- is changed from less donating NO_3^- to more donating Cl^-, the opposite (N_2O_2)Pt−Cl distance (236.0 pm → 245.5 pm) as well as the Pt−Pt length (262.4 pm → 263.7 pm) are elongated.[30] Such significant trans influence of Cl^- on the opposite axial ligand suggests that the Pt−OH distance in the HT-[HO−Pt−Pt−Cl] can be longer than usual, and OH^- in the HT-[HO−Pt−Pt−Cl] may be replaced by Cl^-. The third term in Equation (11) is negligible under the present conditions ($[H^+]$ = 0.11−1.3 M), that is, k_{d2} is virtually equal to k_{-2}.

The conditional formation constant (k_{f2}/k_{d2}) for the dichloro complex of the HT dimer can be calculated from the slope (k_{f2}) and the intercept (k_{d2}) at a given $[H^+]$. The obtained $\log(k_{f2}/k_{d2})$ value (3.64) at $[H^+]$ = 1.27 M agrees with $\log K_2^{Cl}$ listed in Table 1, within the experimental error.

On the other hand, for the reaction with Br^-, k_{obs2} increases linearly with $[Br^-]$ at lower $[Br^-]$, and at higher $[Br^-]$ it also increases linearly, but with a different slope as shown in Figure 5 (b). In both non-Werner Pt^{II} complexes and octahedral Pt^{IV} complexes, e.g., $Pt^{II}R_2S_2$ (R = Me, Ph; S = Me_2S, Me_2SO) or $Pt^{IV}Me_4(Me_2S)_2$, a dissociative mechanism has been proposed for the solvolysis reactions, and this is because of the strong *trans* labilizing effect of Me and Ph groups.[31−34] The trans effect is also observed through the Pt−Pt bond for the present HT dimer as mentioned above. It is reported that there is virtually no axial ligand on the Pt(N_4) in the HH pivalamidate-bridged Pt^{III} dimer with the alkyl ligand (R) on the Pt(N_2O_2), i.e., [Pt^{II}(N_4)−Pt^{IV}(N_2O_2)−R].[24] On the basis of these findings, it seems that reaction (3) proceeds also through a dissociative path via a coordinatively unsaturated complex as depicted in Scheme 4. It is also notable that k_{obs2} is almost independent of $[H^+]$. If the steady-state approximation is applied to the monohalo dimer without an axial ligand at the opposite site in Scheme 4, Equation (12a) involving the three terms is obtained. The first and second terms in Equation (12a) are related to the k_2 path, and the third is to the k_3 path. The $k_2^{\#}$ path in Scheme 3 is irrelevant in Scheme 4, since k_{obs2} does not vary with $[H^+]$ for the (HT + Br^-) system.



Scheme 4

$$k_{obs2} = k_2[Br^-] + k_{-2} + \frac{k_3 k_4 [Br^-] + k_{-3} k_{-4}}{k_{-3} + k_4 [Br^-]} \qquad (12a)$$

The following values were estimated from the data in Figure 5 (a, b) by applying a non-linear least-squares fitting to Equation (11) or Equation (12b) derived from Equation (12a), assuming that $k_{-2}^{\#} K_W/[H^+] = 0$ in Equation (11), and $k_{-2} = 0$ and $k_{-3}k_{-4}/k_4 = 0$ in Equation (12b): k_2 = 2490±40 $M^{-1}s^{-1}$, $k_2^{\#}K_{h2}$ = 115±5 s^{-1}, and k_{-2} = 0.59±0.38 s^{-1} for Figure 5 (a); k_2 = −25±29 $M^{-1}s^{-1}$, k_3 = 3.7±0.4 s^{-1}, and k_{-3}/k_4 = (1.4±0.2) ×10^{-3} M for Figure 5 (b) (k_2 could not be determined accurately because of the large error in k_{obs2}).

$$k_{obs2} = k_2[Br^-] + k_{-2} + \frac{k_{-3}[Br^-] + k_{-3}k_{-4}/k_4}{k_{-3}/k_4 + [Br^-]} \quad (12b)$$

The data in Figure 5 (b) were also analyzed by assuming a mechanism that involves ion pair formation. However, the fit was very poor, and the ratio of the resulting rate constants, k_2/k_{-2}, did not agree at all with K_2 obtained from the spectrophotometry, and so the ion pair formation is negligible under the present conditions.

The *trans* influence and/or the *trans* effect through the Pt−Pt bond seems to determine the reaction paths (see Schemes 3 and 4). In the aquachloro HT dimer, [H_2O−Pt−Pt−Cl], the axial aqua ligand is more acidic than that in the corresponding monobromo HT complex because of the weaker trans influence of chloride, but yet the trans effect of the axial chloride ligand is strong enough to replace the OH^- with Cl^- in the chlorohydroxo HT dimer, as is the case in Scheme 3. On the other hand, the increased *trans* influence and *trans* effect of the bromide lengthen and labilize the H_2O−Pt bond in the aquabromo HT complex, which promotes the dissociation of H_2O to produce the monohalo dimers without an axial ligand at the opposite site. This is the case in Scheme 4.

The mechanistic difference between the HT-[H_2O−Pt−Pt−Cl] and HT-[H_2O−Pt−Pt−Br] systems would reflect the relative extent of the electron donor ability of Cl^- and Br^-, that is, softer Br^- donates more electrons to the H_2O−Pt atom through the Pt−Pt bond, which enhances more the electron delocalization in the dimer (such as [H_2O−Pt^{II}−Pt^{IV}−Br]).

Conclusion

The first deprotonation occurs on one of the water molecules on the two equivalent Pt atoms and the first nucleophilic substitution with X^- occurs to the other Pt atom in the HT dimer. The formation of the HT dichloro complex from the aquachloro complex proceeds through two pathways: by a direct substitution of the aqua ligand and by a path involving OH^- substitution in the chlorohydroxo complex. The formation of the dibromo complex from the aquabromo complex, on the other hand, proceeds through a dissociative path by a coordinatively unsaturated complex as well as through a direct substitution path. The ligand substitution rates on the axial sites of the HT dimer are very sensitive to the nature of the ligands on the opposite axial sites. The mechanistic difference of the ligand substitution on the aquahalo complexes is reasonably explained by the different electron donor ability of Cl^- and Br^-.

Experimental Section

Reagents: The *cis*-[$PtCl_2(NH_3)_2$] (N.E. Chemcat) was purchased and was used without purification. Reagent grade α-pyridone (Kanto Chemical Co. Inc., Tokyo) was recrystallized once from benzene. Sodium chloride (99.99%, Kanto), sodium bromide (99.99%, Aldrich), and perchloric acid (60% UGR for trace analysis, Kanto) were used as received. Sodium perchlorate was prepared and purified according to the literature.[35] Head-to-tail [$(NO_3)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(NO_3)](NO_3)_2\cdot 0.5H_2O$ (HT isomer) were prepared according to the literature method.[4]

Measurements: Ionic strength was maintained at 2.00 M with perchloric acid and sodium perchlorate. All the sample solutions were prepared by using water twice distilled just before measurement. Spectrophotometric measurements were performed with a rapid-scan/stopped-flow spectrophotometer USP-500 (Unisoku Scientific Instruments, Osaka) and spectrophotometers UV-160A (Shimadzu, Kyoto), UV-2200 (Shimadzu), and UV-2400 (Shimadzu). The NMR spectra were recorded on a JEOL Lambda 270 spectrometer, operating at 270 MHz for ^1H. Chemical Shifts are reported relative to TMS (tetramethylammonium perchlorate, 3.190 ppm to TMS). Under the present experimental conditions with the concentration of sodium halide (C_{X^-}, X^- = Cl^- or Br^-) in large excess over that of the HT dimer (C_{HT}), the reaction was biphasic as shown in Figure 4, and is expressed by the equation: $A_t = A_e + \alpha\exp(-k_{obs1}t) + \beta\exp(-k_{obs2}t)$, where A_t and A_e are the absorbances at time t and ∞, respectively, and α and β are composite parameters.[28] Though it is possible to estimate k_{obs1} and k_{obs2} simultaneously under the condition $C_{HT} << C_{X^-}$, k_{obs1} was determined independently under the conditions $C_{HT} >> C_{X^-}$ in order to obtain more accurate values. Rate constants were measured by monitoring the absorbance change at 265 nm for the reaction of the HT dimer with Cl^-, and at 270 nm with Br^- for k_{obs1}, at 250 nm for the reaction of the HT dimer with Cl^-, and at 265 or 350 nm for the reaction of the HT dimer with Br^- for k_{obs2}, as a function of time after mixing the solutions of the dimer and sodium halide. For the reaction with Br^-, the dependence of k_{obs2} on C_{Br^-} was not straightforward (see Results). The acid dissociation constant (K_{h1}) of the HT dimer and the formation constants (K_1^X and K_2^X) of the monohalo and the dihalo complexes were determined spectrophotometrically under the following conditions: C_{HT} = (5−6) $\times 10^{-5}$ M, $[H^+] = 1.00\times 10^{-3}$ to 0.501 M for K_{h1}; $C_{HT} = 2.48\times 10^{-5}$ M, $[H^+]$ = 1.27 M, $C_{Cl^-} = 0-1.3\times 10^{-2}$ M for K_1^{Cl} and K_2^{Cl}; $C_{HT} = 2\times 10^{-5}$ M, $[H^+]$ = 1.27 M, $C_{Br^-} = (0-4)\times 10^{-2}$ M for K_1^{Br} and K_2^{Br}. The values of K_2^{Br} was determined by using the spectroscopic data obtained only for $C_{Br^-} < 1.2\times 10^{-2}$ M, since the spectra changed differently with a different isosbestic point at higher C_{Br^-}, probably due to the reduction of the Pt^{III} dimers by water.[19]

Tripodal Iminophenolate Ligand Complexes of Gallium(III), Indium(III), and Thallium(III)

Mélanie Figuet,[a] Marie Thérèse Averbuch-Pouchot,[a] Amaury du Moulinet d'Hardemare,[a] and Olivier Jarjayes*[a]

Keywords: Coordination chemistry / Gallium / Tripodal ligands / Schiff bases / Isotope effects

The polydentate tripodal Schiff base ligand **H_3L** has been prepared by treating a methanolic solution of tris(aminoethyl)-amine and 5-bromosalicylaldehyde. This ligand, and its complexes with group-13 metal ions (Ga^{III}, In^{III}, and Tl^{III}) have been characterized by elemental analysis, NMR spectroscopy, FAB$^+$-MS, and X-ray diffraction analysis. The ligand, not preorganized in the solid state, acts as a hexadentate N_3O_3 ligand in all cases to form octahedral structures, the apical nitrogen not being involved in the chelation even for the [Tl(**L**)] complex. NMR studies reveal that the intact and rigid structures of the complexes are maintained in solution. For the [Tl(**L**)] complex, long-range thallium isotope effect on the chemical shift (δ_H and δ_C) and on the coupling constants ($J_{Tl\text{-}H}$ and $J_{Tl\text{-}C}$) has been observed, confirming a strong and stable bond between Tl^{III} and **H_3L**.

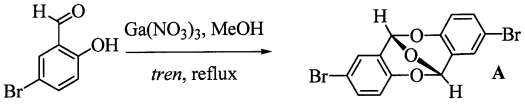
Introduction

Single photon emission computed tomography (SPECT) imaging with ^{99m}Tc radionuclide is the most widely used method for routine diagnostic in nuclear medicine. If technetium-99m holds the foremost rank, this is due to its favorable nuclear characteristics (half-life 6.02 h, γ 140 keV), availability, and low cost. But when the pharmacokinetics of the radiopharmaceuticals are not well matched with the physical half-life of ^{99m}Tc, the preferred radionuclides for imaging are ^{111}In (half-life 67.4 h) or ^{67}Ga (half-life 78.1 h). Despite the great potential of the group-13 metal radionuclides in diagnostics, there are still few ligands devoted to the complexation of such radioactive ions. The most popular one, especially for In^{III} is diethylenetriaminetetraacetic acid (DTPA)[1] and its derivatives, in which one carboxylate group is often engaged to link the chelate moiety and the receptor-binding motif. However, the decreased denticity of such DTPA derivatives lower the stability of the formed complexes.[2] Thus, studying other chelation systems for the group-13 metal ions constitutes an important strategy for enhanced labelling efficiency of molecules of biological interest like peptides and monoclonal antibodies. Our laboratory is involved in the search and the synthesis of new radiopharmaceuticals for diagnostic or therapeutic applications. This led us to investigate the coordination chemistry of Ga, In, and to a lesser extent Tl (which have fewer biomedical applications). It might be worthwhile considering that, like [DTPA−In], numerous indium- or gallium-based radiopharmaceuticals are not fully chemically characterized. It is, however, of prime interest to determine the actual structure that is essential for obtaining a satisfactory comprehension of the properties of the complexes. Since group-13 (M^{III}) metal ions are usually hexacoordinated, we have investigated the chelating pattern of the tripodal imine ligand **H_3L**, derived from triethylenetriamine (*tren*) and 5-bromosalicyladehyde. Complexes of lanthanides and imine ligands derived from *tren* and salicylaldehyde[3,4] or aromatic ketones have already been described by Orvig et al.[5,6] These complexes where very unstable to moisture, and this property was attributed to the imine function, presumably hydrolyzed in water with the assistance of the acidic Ln^{III} ion. This observation led the author to study the complexation of lanthanides[7] and some group-13 metal ions (Al, Ga, and In)[8] with the saturated **H_3L**, where the imine double −N=CH− bond has been reduced to the much more stable amine −NH−CH_2− bond. The capability of the imine **H_3L** ligand to chelate Ga, In, or Tl has not been previously reported. This situation could be due to the reluctance of chemists to work with the so-called acid-sensitive imine-derived ligands. We report here the synthesis and the spectroscopic and structural characterizations of the whole post-transition group-13 metal complexes with **H_3L**.

Results and Discussion

Preparation

The one-pot complexation of M^{III} ions is not an effective method. Indeed, mixing a methanolic solution of *tren* and 5-bromosalicylaldehyde followed by the appropriate metal salt, results in the formation of a crystalline product, which was identified as the bicyclic acetal **A** shown in Scheme 1.



Scheme 1. Self-acetalization of 5-bromosalicylaldehyde

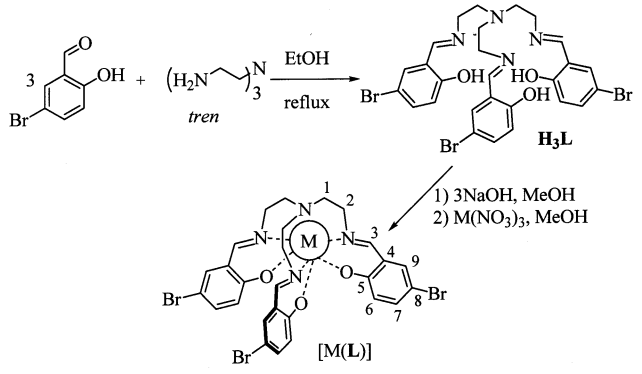
The recovery of this product is very likely due to the high Lewis acidity of the tricationic oxidation state of the group-13 metal ions, which are able to catalyze the self condensation of the bromosalicyladehyde. The strong acidic character of M^{III} is also confirmed by the formation of the nitrate salt of *tren*, also recovered under these conditions. Curiously, the more expected dimethoxyacetal, resulting from the reaction of the solvent (MeOH) and the aldehyde, is not isolated. This fact could be explained by a competition between the two reactions of acetalization that are chemically in equilibrium; but since **A** is less soluble in methanol than the dimethoxyacetal, the precipitation of the former shifts the equilibrium to its formation.

We can infer these observations to the lack of stability of the imine functions of the ligand in strongly acidic solutions. In other respects it is preferable to purify the ligand **H_3L** before complexation, otherwise poorer purity of the chelates results. Thus, a two-step synthesis was preferred. As depicted in Scheme 2, the tripodal **H_3L** ligand was synthesized according to Liu et al.[7] and purified by recrystallization in ethanol. It is of prime necessity to neutralize the acidic phenol functions of the ligand with a methanolic solution of NaOH (3 equiv.) prior to the introduction of a methanolic solution of the selected M^{III} salts in order to isolate the desired complexes. By this way, the result is a high recovery of the chelates (the yields ranging from 75 to 95%).



Scheme 2. Preparation scheme of **H_3L** ligand and [M(**L**)] complexes where M = Ga^{III}, In^{III} or Tl^{III}

The complexes are air-stable under neutral conditions both in the solid state and in solution in MeOH, $CHCl_3$, or DMSO, allowing their NMR characterization {exception [In(**L**)], scarcely soluble}. These results point out that once isolated, the imine complexes are not subject to hydrolysis as was written by Orvig et al.[7] Thus, the experimental preparation process is the key point for hydrolysis to occur. It happens only at low pH values if the acidity released during the complexation is not neutralized with a base. Our results are in accordance with those of Costes et al.,[9] and Kocian et al.[10] In this latter case, triethylamine proves to be too weak to allow the recovering of imine-phenole Gd^{III} complexes, only a strong base like hydroxide or methoxide ion permits the preparation of the desired chelates.

All our complexes gave satisfactory elemental analyses. The FAB^+ mass spectra obtained in a 3-nitrobenzyl alcohol matrix show the molecular ion peaks at $[M + H]^+$ (100% intensity) and the IR data show a characteristic strong band near 1625 cm^{-1} that confirms the presence of the imine function. Furthermore, no band was detected in the range 3500−3000 cm^{-1}, indicating the complete deprotonation of the phenol groups by NaOH and the absence of the N−H bond. This later remark also strongly supports the stability of the imine function in the complexes. Indeed, as a possible event, hydrolysis of the imine should result in the formation of such an N−H bond. All these data are consistent with the proposed formulation $[M(\mathbf{L})]^0$. Slow concentration of diluted methanolic solution gave crystalline material suitable for X-ray crystallographic study.

Crystallographic Studies

An ORTEP drawing of **H_3L** is illustrated in Figure 1 and details of the structure determination are collected in Table 1.

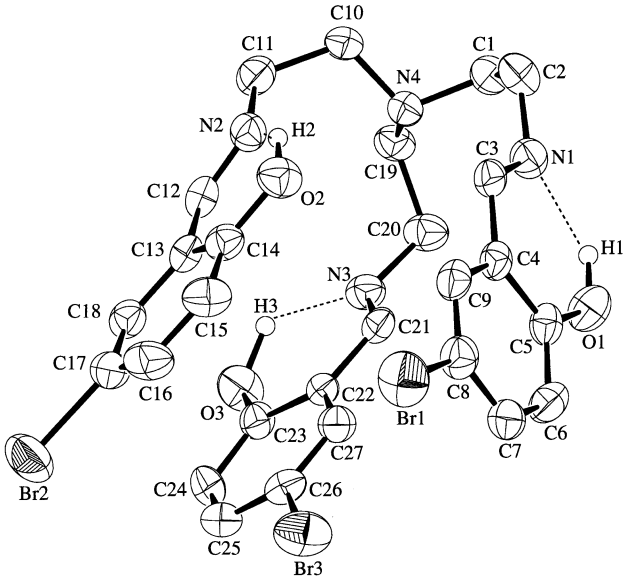


Figure 1. Structural representation of **H_3L**; hydrogen atoms are omitted for clarity

There are two **H_3L** molecules in each triclinic unit cell. All the interatomic distances and bond angles for the organic part are in the range of those given by Allen et al.[15] There is a strong hydrogen bond connecting the hydroxy hydrogen atoms and the imine nitrogen atoms (O1−H1···N1 1.89 Å, O2−H2···N2 1.67 Å, O3−H3···N3 1.79 Å) thus forming an almost planar six-membered ring. No interstrand bonds are detected, and contrary to what it is observed for other tripodal ligands,[16,17] there is no preorganization of **H_3L** in the solid state. The formation of a three-dimensional cavity with a specific spatial arrangement of the donor atoms is only achieved in the presence of the metal ions.

An ORTEP drawing of [Ga(**L**)] is illustrated in Figure 2. All the complexes are neutral with a triply deprotonated N_3O_3 imine phenol ligand completely encapsulating the M^{III} ions. The In^{III} and Tl^{III} compounds are isostructural.

In the three complexes, the cations have an octahedral environment where the ligand occupies all six coordination sites around the metal ion by bonding through the lone pairs of the three imino nitrogen atoms and the three deprotonated phenolic oxygen atoms, leading to a three-fold axis passing through the metal ion and the tertiary amine function.

Despite the larger size of In^{III} and Tl^{III}, the coordination of all seven donor atoms is not observed. Indeed, the apical nitrogen atom of the *tren* part, being in all cases at much longer distances from the metal center [Tl: 2.759(3) Å; In: 2.828(3) Å; and Ga: 3.342(3) Å] does not participate in the chelation of group-13 metal ions. Each N_3 and O_3 donor set coordinates to the M^{III} ions in a facial way to form a distorted octahedral geometry as shown in Table 2.

The TlO_3N_3 and InO_3N_3 octahedra are more distorted than the GaO_3N_3 one. For [Tl(**L**)], the distortion of the coordination sphere is most evident in the compression of O−Tl−O (average 85.76°) and expansion in the N−Tl−O angles (average 106.77°) from 90°. As a result, the three

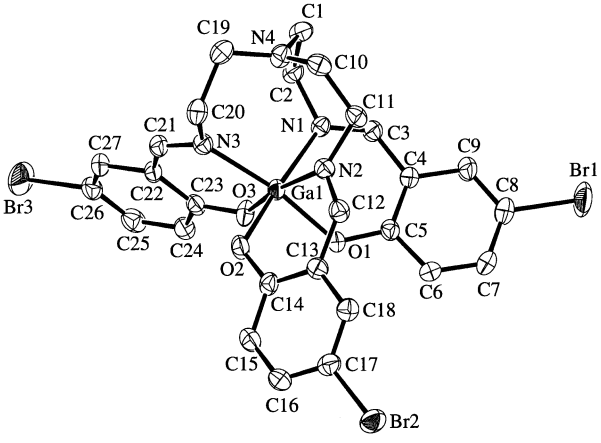

Figure 2. Structural representation of [Ga(**L**)]; hydrogen atoms are omitted for clarity

trans-O−Tl−N angles have an average value of 163.08°. If one considers the angles, those of the GaO_3N_3 octahedron are closer to regular values.

Table 2. Main bond angles [°] in the GaO_3N_3, InO_3N_3 and TlO_3N_3 entities; standard deviations are given in parentheses

The coordination behavior of **H_3L** is not dependent on the size of the coordinated metal ion. This ligand presents a roughly invariable coordination cavity. Indeed, the three metal ions (Ga^{III}, In^{III}, and Tl^{III}) are bonded in a similar way by an N_3O_3 donor set, which leads us to consider that **H_3L** is well tailored for six-coordinated neutral group-13 and lanthanide metal ion complexes. This cavity seems to fit to these three metal ions, with no significant strain on the coordinated ligand framework, contrary to the tripodal N_4O_3 amine phenol ligand where the coordination mode is metal-dependent: for large lanthanide ions, homodinuclear dimers are formed, while cationic mononuclear complexes are obtained with Al^{III} and Ga^{III}.[7,18] Selected bond lengths and angles are listed in Table 3 for the three complexes.

Table 3. Main interatomic distances [Å] for [Ga(**L**)], [In(**L**)], and [Tl(**L**)]

[Ga(**L**)]		[In(**L**)]		[Tl(**L**)]	
Ga1−O1	1.932(2)	In1−O1	2.125(2)	Tl1−O1	2.235(2)
Ga1−O2	1.922(2)	In1−O2	2.131(2)	Tl1−O2	2.243(2)
Ga1−O3	1.931(2)	In1−O3	2.148(2)	Tl1−O3	2.252(2)
Ga1−N1	2.077(3)	In1−N1	2.245(3)	Tl1−N1	2.295(3)
Ga1−N2	2.190(3)	In1−N2	2.271(3)	Tl1−N2	2.343(3)
Ga1−N3	2.090(3)	In1−N3	2.280(3)	Tl1−N3	2.328(3)

Comparison of the bond lengths shows that M^{III}−N and M^{III}−O increase on going from Ga^{III} to Tl^{III}. This trend is consistent with the larger ionic radius of the Tl^{III} ion in an octahedral environment. Ga−O and Ga−N, In−O and In−N distances are very similar to those found in other tripodal amine phenol N_4O_3 and N_3O_3 complexes[18,19] and imine phenol N_3O_3 complexes.[20]

It has been postulated that complex stability is closely related to the size of the chelate rings, and to the size of metal ion.[21] As chelate ring size increases from five to six, stability of metal complexes generally decreases. The larger the coordinated metal ion, the greater the destabilization in the metal complex as the chelate ring size increases from five to six. However, despite this general trend, we have been able to synthesize and characterize the three [M(**L**)] complexes.

NMR Studies

^{1}H NMR spectra of the ligand **H_3L** and the three complexes are shown in Figure 3. The ^{1}H NMR spectrum of the ligand in $CDCl_3$ at 400 MHz is relatively simple, with three aromatic proton signals at δ = 6.49, δ = 6.83, and δ = 7.32. The imine proton resonates at δ = 7.80 and the two methylene groups giving an AA′XX′ splitting pattern at δ = 2.83 and δ = 3.55. The proton signals were assigned using homonuclear 2D techniques (COSY) and are consistent with literature results.[7,17]

^{1}H and ^{13}C NMR spectra of the Ga^{III} and In^{III} complexes were recorded in $CDCl_3$ while the Tl^{III} complex was recorded in [D_6]DMSO. However, they both show similar features. Only one set of ^{1}H NMR resonance signals proved that the three chelating arms of the ligand remained chemically equivalent upon coordination. This is in contrast with amine phenol Al, Ga, and In complexes described by Orvig et al.,[8] in which the Ga atom is coordinated by an N_4O_2 donor set from the N_4O_3 amine phenol ligand, with one of the three phenolate oxygen atoms remaining noncoordinating and protonated.

For the [Ga(**L**)] complex, the ethylenic hydrogen atoms form an AA′BB′ spin system consisting of a distinct resonance corresponding to each of the four hydrogen atoms. This is a pattern already described for similar systems[22,23] and small heterocyclic ring structures,[24] whereby the ethylenic hydrogen atoms are locked in an axial/equatorial-type conformation.

From the crystallographic data, the angles and dihedral angles between the four different protons are available. The schematic Newman representation depicted in Figure 3 is drawn from these values. The angles between H_A and $H_{A'}$, H_A and H_B, and H_B and $H_{B'}$ are 70°, −61°, and 169°, respectively. According to the literature,[25] the coupling constants $J_{BB'} = J_{trans}$ lie in the range of 10 to 13 Hz, while the geminal coupling constants J_{AB} and $J_{A'B'}$ or J_{gem} have aver-

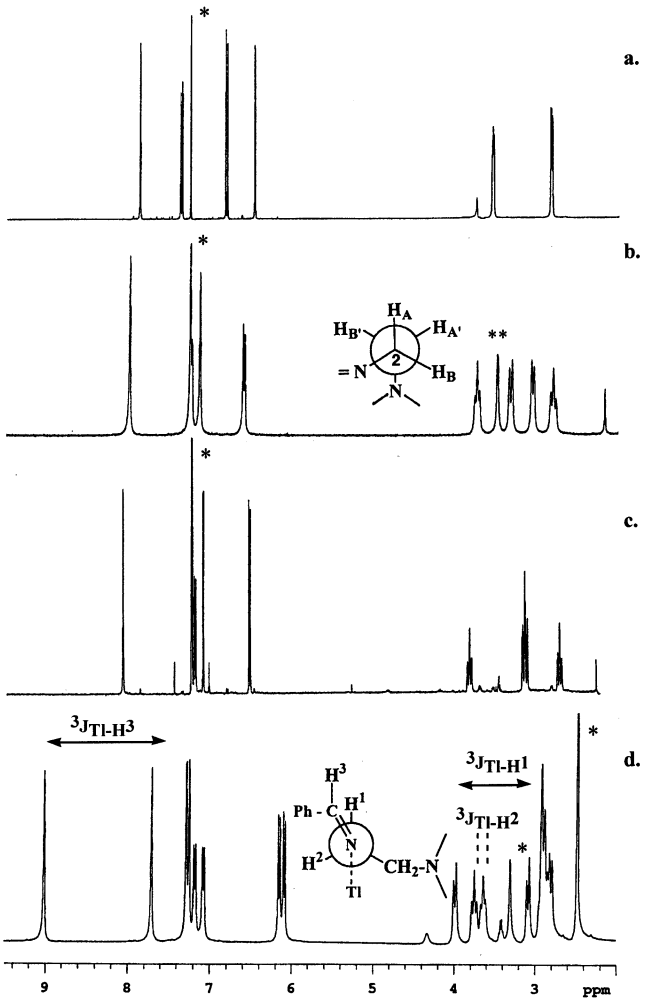

Figure 3. ^{1}H NMR spectra of a: $\mathbf{H_3L}$, b: [Ga(**L**)], c: [In(**L**)], in $CDCl_3$ and d: [Tl(**L**)] in DMSO; the asterisks (*) represent residual solvent peaks and methanol (**)

age values of −10 to −16 Hz. Moreover, if we take into account the model of Karplus, the $J_{AA'}$ and $J_{BA'}$ values must be very small or equal to zero. Finally, considering all of these data, the AA′BB′ part of the spectrum can be simulated and compared to the experimental spectrum. Using an iteration method, one can obtain a simulated spectrum for the [Ga(**L**)] complex superimposed on the experimental one, for the values of $J_{BB'}$, J_{AB}, and $J_{A'B'}$ equal to 13.3 Hz, −11.3 Hz, and −13.2 Hz, respectively. Similarly, the $J_{A'B}$, $J_{AB'}$ and $J_{AA'}$ values are 0.2 Hz, 0.1 Hz, and 0.2 Hz, respectively. In this case, the two protons H_A and $H_{A'}$ appear as two doublets at δ = 3.05 and δ = 3.32, respectively, while the two protons H_B and $H_{B'}$ appear as two pseudo triplets at δ = 3.73 and δ = 2.80, respectively. The same analysis has been ruled out for the [In(**L**)] complex, and the experimental spectrum could be simulated. The only difference to note with [Ga(**L**)] is the overlap of the two doublets of protons A and A′ giving rise to another pseudo triplet with an intensity of two. These observations clearly demonstrate that the rigid structures of the complexes are consistent with the determined structures by X-ray diffraction.

The $^{13}C\{^1H\}$ NMR spectrum consist for the [Ga(**L**)] complex of nine resonances. The complete assignment was made with the aid of 2D homonuclear (COSY) and heteronuclear (HMQC and HMBC) experiments. The aromatic carbon signals all appear in the range of δ = 105−168. The ethylenic carbon signals appear at δ = 57−61, while the imine carbon signal lies at δ = 170. The analysis of this spectrum also supports the structure of the complex shown in Figure 2 in which the metal ion is bound to the N_3O_3 core in a facial arrangement. The solubility of the [In(**L**)] complex was so poor in most of the common NMR solvents that recording the ^{13}C spectrum was excluded.

The [Tl(**L**)] complex has also been studied in solution in [D_6]DMSO. The ^{1}H NMR spectrum characterizing the complex is reported in Figure 3, and is very similar to the two previous complexes [Ga(**L**)] and [In(**L**)]. All three arms are equivalent as a result of the symmetric binding of the ligand to the metal center. Indeed, the observation of the relative simplicity of the ^{1}H and ^{13}C spectra implies that a C_3 symmetry axis is present for [M(**L**)] in solution. $^{205,203}Tl-^1H$ couplings are noticeable for most of the protons of the complex. The largest coupling constant ($^3J_{Tl-H3}$ = 523 Hz) is observed for the imine proton. A value of 709 Hz has also recently been given for a macrobicyclic complex of Tl^{III}.[26] Aromatic protons also show small coupling constants with Tl^{III} ranging from 13 to 41 Hz for ^4J and ^5J. The ethylenic protons H^1 and H^2 of the complex also form a part of an AA′BB′ spin system, but are split by the presence of the Tl^{III} ion. Assuming that a Karplus-like relationship[27,28] is also valid for this kind of vicinal coupling between Tl and the protons, the larger value of $^3J_{Tl-H}$ is indicative of a *trans* position between H^1 and Tl, while the smaller one ($^3J_{Tl-H2}$ = 45 Hz) is interpreted as resulting from a torsional angle smaller than 90°, where a minimum in the Karplus function is expected. These considerations are supported by the crystallographic data. Indeed, in the solid state, the dihedral angle values between Tl and H^1, and Tl and H^2 are −171° and 62°, respectively. Moreover, the dihedral angle value between the imine proton (H^3) and Tl is −167°, which explains the large value of this coupling. The $^3J_{Tl-H}$ can thus be seen as a stereochemically sensitive parameter, as described for [Tl−EDTA] complexes.[29] Once formed, the neutral complex is stable, and even in DMSO, a good coordinating solvent, the spectroscopic behavior of [Tl(**L**)] is in complete agreement with the solid-state data. The stability in DMSO of such complexes has also been noted for tripodal Ln complexes derived from 3-methoxysalicylaldehyde, only if deprotonation of the ligands is made with a strong base prior to the addition of Ln^{III} ions.[30]

In order to examine the fluxionality of the complexes in organic solvents ($CDCl_3$ and [D_6]DMSO), the variable-temperature (298−355 K) ^{1}H NMR spectra were recorded for [Ga(**L**)] and [Tl(**L**)], since all the complexes have very similar structures, the behavior of the In species must be very similar. No significant changes in the spectral parameters were noticed, except for minor shifts probably caused by

the thermal vibrations of the coordinated ligand framework. This clearly shows that all the complexes remain unchanged in solution in this temperature range. Therefore, the intact and rigid structure of these complexes in solution is demonstrated.

Finally, a specificity interesting to notice is that natural thallium consists of two spin 1/2 isotopes, ^{203}Tl and ^{205}Tl present in the relative abundance of 0.295 and 0.705, respectively. Spin-spin coupling constants between Tl and ^{1}H, and Tl and ^{13}C are thus observable. Moreover, one can observe a $^{205/203}$Tl isotope effect on ^{1}H and ^{13}C in the NMR spectra as shown in Figure 4.

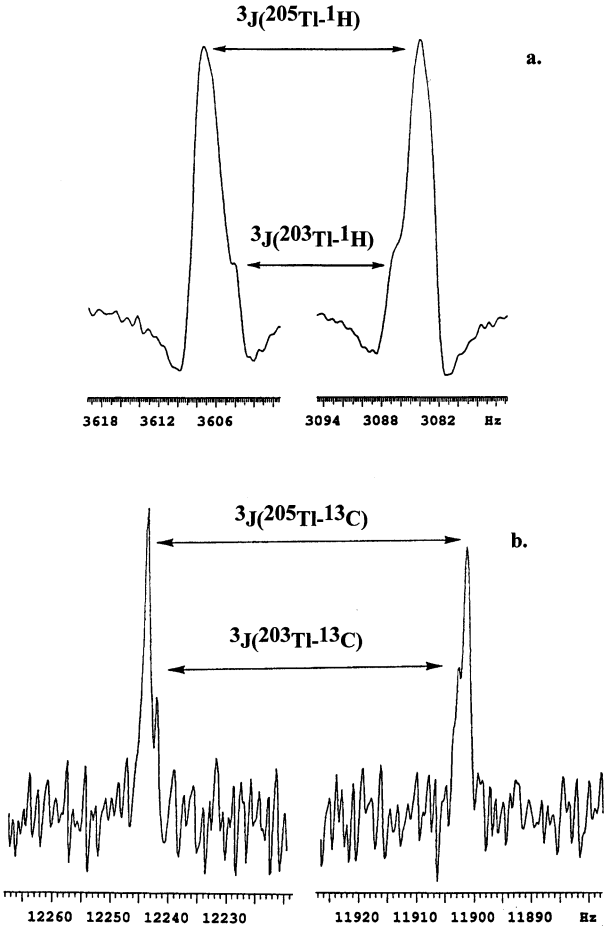

Figure 4. NMR spectra of [Tl(**L**)] in DMSO showing the isotope effect in a. on H^3 and in b. on C^4

The presence of the two thallium isotopes induces a secondary isotope effect on ^{1}H and ^{13}C in the NMR spectra, which is also called isotope shift. This secondary isotope effect on nuclear shielding is defined as the difference (Δ) in the chemical shift (δ) of a nucleus N in the isotopomer with the heavier isotope ^{k}X relative to the isotopomer with the lighter isotope ^{l}X at a site *n* bonds away and expressed by[31]

$$^{n}\Delta\delta N(^{k/l}X) = \delta N(^{k}X) - \delta N(^{l}X)$$

The superscript *n* is the number of bonds between nuclei N and X. In most cases,[32] the chemical shift for the higher isotope is at a lower frequency, thus $^{n}\Delta\delta N(^{k/l}X)$ is negative. This means that the heavier isotope causes increased shielding. In this study, the contrary is observed. Positive values of 0.625 ppb and 2.780 ppb are obtained for $^{3}\Delta\delta H(^{205/203}Tl)$ and $^{3}\Delta\delta C(^{205/203}Tl)$, respectively. It is very difficult to comment on these data because to the best of our knowledge no such $^{3}\Delta\delta H$ and $^{3}\Delta\delta C$ are available in the literature for coordination compounds. However, similar values lying in the range -1.76 to -0.88 ppb are observed for $^{3}\Delta\delta F$ in chlorofluorocarbons.[33]

For spin-spin coupling constants, the magnitude of the interaction *J*(YZ), expressed in Hz, also depends on the magnetogyric ratio of the Y and Z nuclei, and when a nucleus ^{m}Y is replaced by an isotopic species ^{n}Y, the ratio $J(^{m}YZ)/J(^{n}YZ)$ is equal to $\gamma(^{m}Y)/\gamma(^{n}Y)$. According to Figure 4, the ratios $^{3}J(^{203}Tl-^{1}H)/^{3}J(^{205}Tl-^{1}H)$ and $^{3}J(^{203}Tl-^{13}C)/^{3}J(^{205}Tl-^{13}C)$ are equal to 0.9886 and 0.9915, respectively, while $\gamma(^{203}Tl)/\gamma(^{205}Tl) = 0.9902$ confirming thus an isotope effect on coupling constants. If the isotopically substituted nucleus Y (^{m}Y/^{n}Y substitution) is involved in spin-spin interaction, one can measure a primary isotope effect on the coupling constant[32] defined as

$$^{p,q}\Delta J_X = \frac{\gamma(^{m}Y)}{\gamma(^{n}Y)} J(^{r}X^{n}Y) - J(^{r}X^{m}Y) \qquad \text{with } n > m$$

where *p* and *q* denote the number of bonds separating the site of isotopic substitution and each of the two nuclei involved in spin-spin coupling. From ^{1}H and ^{13}C NMR spectra, $^{0,3}\Delta J_H$ and $^{0,3}\Delta J_C$ values of 0.86 Hz and -0.43 Hz, respectively, are obtained only from the imine proton H^3, and the carbon atom C^4, these two atoms having the largest coupling constant with Tl^{III}. These rather low $^{0,3}\Delta J_H$ and $^{0,3}\Delta J_C$ values, which do not exceed 0.2% of the coupling constants, represent an effect through three bonds. Data on isotope effects for the coupling constants between heavy isotopes other than protons are more documented for organic compounds,[32,34] but nonexistent in coordination chemistry. However, the largest $^{1}J(^{13}C-Tl)$ values have been measured for mono- and dicyano complexes of Tl^{III}, with $^{0,1}\Delta J$ visualized in the spectra,[35] but not investigated. Any discussion of these isotope effect values would require theoretical developments.[34] Yet, what can be said is that the observation of an isotope effect implies a strong Tl−ligand coordination bond.

Conclusion

We have shown that tripodal Schiff base phenol complexes derived from salicylaldehyde, *tren* and the acidic Ga^{III}, In^{III}, and Tl^{III} metal ions could be easily prepared without noticeable imine hydrolysis. The accurate structure of all the complexes show a constant coordinating pattern

of the tripodal ligand that acts as a hexadentate ligand, giving isostructural species from Ga^{III} to Tl^{III}. Further, NMR-spectroscopic data strongly support that the rigid structure in the solid state is maintained in DMSO or $CDCl_3$ solutions. Consequently, these facts involve a strong coordination of the metal ions. This characteristic is very favorable for biomedical applications. Investigations concerning this topic are currently underway and the results will be described elsewhere.

Experimental Section

General Remarks: Tris(aminoethyl)amine (*tren*) and hydrated metal salts [$Ga(NO_3)_3$, $In(NO_3)_3$ and $Tl(NO_3)_3$] were obtained from Acros. 5-Bromosalicylaldehyde was obtained from Lancaster. All chemicals were used without further purification. Thallium is highly poisonous and should be handled with caution.[36] – NMR spectra were recorded with a Varian U400 spectrometer (operating at 100.58 MHz for ^{13}C). Each spectrum was referenced to the solvent used at room temperature. – Mass spectrometry (FAB^+ mode) experiments were run in a 3-nitrobenzyl alcohol matrix with a Nermag R10 spectrometer. – Infrared spectra were recorded as KBr disks in the range 400−4000 cm^{-1} with a Nicolet Impact 400 spectrometer. – Elemental analysis for C, H and N were performed by the Service Central d'Analyses (CNRS) at Vernaison (France).

Synthesis of Tris[(5-bromosalicylidene)aminoethyl]amine (H_3L): The ligand tris[(5-bromosalicylidene)aminoethyl]amine (**H_3L**) was prepared according to the method reported in the literature.[7] To a warm solution of 5-bromosalicyladehyde (6.03 g, 30 mmol) in absolute ethanol (100 mL) was added a solution of tris(aminoethyl)amine (1.46 g, 10 mmol) in EtOH (40 mL). After the addition was complete, the resulting bright yellow suspension was heated at reflux for 20 min and then stirred at room temperature for 0.5 h. The mixture was cooled in an ice bath for 15 min, and the yellow microcrystals were collected by filtration, washed with cold EtOH (40 mL) and Et_2O. The solid was dried under vacuum. Yield 5.36 g (77%). M.p. 145−146 °C (ref.[7] 144−145 °C). Slow evaporation of the solvent from the filtrate yielded suitable crystals for X-ray diffraction studies.

Synthesis of the Complexes, General Procedure: [M(**L**)] complexes were prepared as follows. To a suspension of the ligand **H_3L** (1 mmol) in methanol (25 mL), was added NaOH (0.12 g, 3 mmol in 10 mL of MeOH). To this homogeneous solution was added the metal nitrate in methanol (1 mmol in 25 mL). A precipitate formed immediately. The mixture was stirred at reflux for 15 min and then cooled to room temperature. The solid was filtered off; washed with methanol (2 × 20 mL) and diethyl ether (2 × 10 mL), and then dried in vacuum. Slow concentration of the filtrate over a period of two weeks yielded suitable crystals for X-ray diffraction studies.

[Ga(L)] (1): Yield: 0.720 g, 94%. – $C_{27}H_{24}Br_3GaN_4O_3$: calcd. C 42.56, H 3.17, N 7.35; found C 42.55, H 3.51, N 7.08. – ^{13}C NMR ($CDCl_3$, room temp.): δ = 57.2 (C^1), 61.7 (C^2), 105.1 (C^8), 118.4 (C^4), 125.2 (C^6) 135.8 (C^9), 137.5 (C^7), 167.9 (C^5), 169.6 (C^3). – IR (KBr): $\tilde{\nu}$ = 3047 (weak, C−H phenyl), 2877, 2840 (s, C−H aliphatic), 1622 (very strong, C=N imine), 1182 (s, C−O) cm^{-1}. – MS (FAB^+): *m/z* (%) = 763 (100) $[M + H]^+$.

[In(L)] (2): Yield: 0.605 g, 75%. – $C_{27}H_{24}Br_3InN_4O_3$: calcd. C 40.18, H 3.00, N 6.94; Br, 29.70; found C 39.71, H 2.94, N 6.77; Br, 29.36. – IR (KBr): $\tilde{\nu}$: = 3048 (weak, C−H phenyl), 2908, 2846 (s, C−H aliphatic), 1627 (very strong, C=N imine), 1169 (s, C−O) cm^{-1}. – MS (FAB^+): *m/z* (%) = 807 (100) $[M + H]^+$.

[Tl(L)] (3): Yield: 0.848 g, 95%. – $C_{27}H_{24}Br_3TlN_4O_3$: calcd. C 36.17, H 2.70, N 6.25; Br, 26.74; found C 35.76, H 2.77, N 6.18; Br, 26.53. – ^{13}C NMR ([D_6]DMSO, room temp.): δ = 55.2 (C^1), 55.7 (C^2, ^2J = 193.03 Hz), 102.1 (C^8, ^5J = 32.59 Hz), 120.0 (C^4, ^3J = 342.05 Hz), 125.2 (C^6, ^3J = 160.10 Hz), 135.1 (C^9, ^4J = 10.44 Hz), 136.5 (C^7, ^4J = 40.19 Hz), 170.2 (C^3, ^2J = 93.96 Hz), 172.1 (C^5, ^2J = 195.85 Hz). – IR (KBr): $\tilde{\nu}$ = 3047 (weak, C−H phenyl), 2877, 2840 (s, C−H aliphatic), 1622 (very strong, C=N imine), 1182 (s, C−O) cm^{-1}. – MS (FAB): *m/z* (%) = 897 (100) $[M + H]^+$.

X-ray Crystallographic Study: The main crystallographic features, the strategy used for the crystal structure determination, and its results are gathered in Table 1. Data collections were carried out at room temperature. The U_{iso} values of the H atoms have been fixed to 1.2 × $U_{equiv.}$ of the C atoms they are attached to. The structures were solved by direct methods (SIR92).[37] Crystallographic data (excluding structure factors), for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-152917, -152918, -152919, -152920 for [Tl(**L**)], [In(**L**)], [Ga(**L**)] and **H_3L**, respectively. Copies of the data can be obtained free of charge on applicaton to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

Conformational Features of Group-4 *ansa*-Metallocenes with Long $-(CH_2)_n-$ Chains Connecting Their Cyclopentadienyl Ligands

Tim Jödicke,[a][‡] Frederik Menges,[a] Gerald Kehr,[a] Gerhard Erker,*[a] Udo Höweler,[a][‡] and Roland Fröhlich[a][‡‡]

Keywords: Metallocenes / Zirconium / Conformation analysis / Density functional calculations / Polymerization

Treatment of 1,9-bis(lithiocyclopentadienyl)nonane (**8b**) with $ZrCl_4(THF)_2$, in dilute solution, gave the crystalline mononuclear "large" *ansa*-metallocene **3b** (7% isolated). The X-ray crystal structure analysis of **3b** revealed a metallocene conformation where the nonamethylene bridge is oriented toward the lateral sector of the bent metallocene wedge. An analogous structure of **3b** is probable in solution, as shown by dynamic ^1H NMR spectroscopy. The activation barrier for the metallocene conformational equilibration process of **3b** was determined as $\Delta G^{\ddagger}_{rot}$ (203 K) = 8.8 ± 0.3 kcal/mol in [D_8]toluene. A combination of force-field and DFT calculations revealed similar conformational minima for **3b** and a series of related "large" *ansa*-metallocene complexes in the gas phase. The corresponding complex $[(CH_2)_{12}(C_5H_4)_2]ZrCl_2$ (**3d**) was also prepared. When activated by treatment with methylalumoxane, both complexes **3b** and **3d** give very active metallocene Ziegler–Natta catalysts for the polymerization of ethene and the oligomerization of propene.

Introduction

A specific section of the many possible group-4 *ansa*-metallocenes has become of great importance in homogeneous catalysis. These systems usually exhibit small bridges (i.e. R_2Si, R_2C or $-CH_2-CH_2-$) between a pair of Cp, indenyl, or related ligands. They have formed the basis for the generation of homogenous Ziegler−Natta-type catalysts, which often show extraordinary reactivity/selectivity features.[1] Such systems are conformationally rigid with the "*ansa* bridge" strictly located at the narrow back side of the bent metallocene wedge. This seems to be a key factor for their controlling abilities in the actual catalytic process.[2,3] Open, non-bridged group-4 metallocenes have also been shown to lead to active Ziegler−Natta catalysts. Here, control of the stereoselectivity of polyolefin formation is sometimes achieved, based on the specific dynamic conformational properties of the alkyl- or aryl-substituted bent metallocene system.[4,5]

"Large" *ansa*-metallocenes, which have their cyclopentadienyl or indenyl ligands connected by long $-(CH_2)_n-$ chains ($n \geq$ ca. 8), comprise an interesting class of compounds. It is possible that some members of this group form stable global (or kinetically protected local) conformational minima that have the oligomethylene chain located at specific sectors of the bent metallocene wedge, where they may actively shield the active sites at the central metal center, or may get involved in reactions taking place at the activated group-4 metal inside this arrangement.[6] A long bridging $-(CH_2)_n-$ chain in a "large" *ansa*-metallocene could, for instance, be located symmetrically at the front of the bent metallocene wedge and spatially separate the space in front of the activated metal center. This may potentially alter the catalytic action in such a system relative to a less-restricted non-bridged metallocene or a conventional "small" *ansa*-metallocene system.

To the best of our knowledge, only two examples of such "large" *ansa*-metallocenes have been characterized by X-ray diffraction so far, and these show very different conformational features. Mach et al. have described the structure of $[(CH_2)_8Cp^*_2]TiCl_2$ (**1**, see Figure 1) which has the bridging octamethylene chain located at the narrow back side, almost like a "small" *ansa*-metallocene.[7] In contrast, in *rac*-$[(CH_2)_{12}(1\text{-indenyl})_2]ZrCl_2$ (*rac*-**2c**), the other previously described example, the bridging hydrocarbyl chain is C_2-symmetrically located at the front of the bent metallocene wedge.[8] This bisects the Cl−Zr−Cl angle as shown in the bottom projection in Figure 1.

From the static solid-state structures it is not clear whether these two forms represent the respective global conformers of these bent metallocenes, or if they are just local conformational minima that have been stabilized by specific solid-state features under these experimental conditions. Thus, we have characterized several representative "large" *ansa*-metallocenes, i.e. $(CH_2)_n$-bridged bis(cyclopentadienyl) or bis(indenyl) complexes of zirconium (and in one case titanium) with the number of bridging methylene units ranging from eight to twelve, by computational chemistry using force-field and DFT methods. We have found a remarkable dependence of the thermodynamically favored metallocene conformations on the length of the oligomethylene bridge. These results were complemented experimentally by the synthesis of two representative "large" *ansa*-zirconocene dichlorides, the investigation of their respective

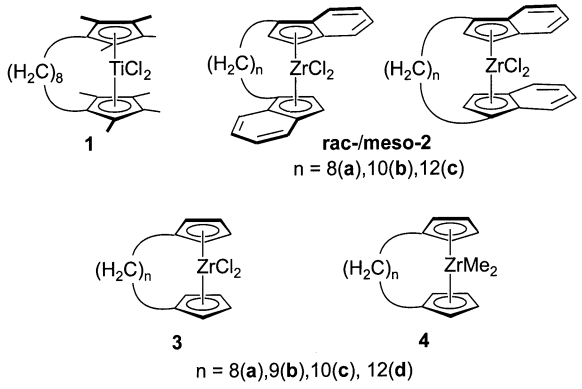
dynamic conformational interconversion in solution, and the structural characterization of one example by X-ray diffraction. This has provided us with a much more detailed picture of the conformational properties of the interesting group-4 "large" *ansa*-metallocene complexes, relative to the selected views derived from previous descriptions based only on a limited number of experimental observations.

Results and Discussion

Computational Studies

The various local conformational minima of a series of $[(CH_2)_n(C_5H_4)_2]ZrCl_2$ complexes **3a**−**d** (n = 8, 9, 10, and 12) were determined and optimized using a metallocene-adapted force-field method that we had described and applied previously (see Scheme 1).[9] Relative energies of the located conformers were determined. These geometries were then used in the DFT calculation to give the respective single-point energies on the B3LYP level[10] for comparative purposes. We made sure that the conformational characteristics were predominately determined by the bent metallocene framework itself and not by the σ-substituents attached at the zirconium atom. This was done by investigating several corresponding $[(CH_2)_n(C_5H_4)_2]Zr(CH_3)_2$ complexes **4a**−**d** with the same number of bridging methylene groups. The Zr−C(sp^3) parameterization of the organometallic molecular modeling/force-field program was carried out in the course of this study (see Exp. Sect.). In addition, a similar series of *rac*- and *meso*-$[(CH_2)_n(1\text{-indenyl})_2]ZrCl_2$ complexes (*rac*-/*meso*-**2a**−**c**, n = 8, 10, and 12) was investigated by this combination of force-field/DFT calculations, and the Ti-based system **1** recently described by K. Mach et al. (see above),[7] was included in the study for comparison.



Scheme 1. "Large" *ansa*-metallocene complexes calculated by force-field and DFT methods in this study

For clarity and simplicity we want to characterize the metallocene conformations using a grid (see Figure 2) that is superimposed on a projection of the bent metallocene from the top. In this projection, the bent metallocene opens towards the right, with its σ-substituents directed toward the "east" position. In the center of that position we will place the origin of the conformational designation (i.e. 0°), we will then proceed clockwise through the "south" (90°), "west" (180°), and "north" (−90°) positions back to the origin. In the designation of a specific metallocene conformation (denoted by *mc*), we will first note the position of the Cp−CH_2− vector of the upper substituted cyclopentadienyl (or indenyl) ligand, followed by that of the lower C(Cp)−CH_2− position in degrees in this reticule, which has its center (idealized) position superimposed with the Cp(centroid)−Cp(centroid) vector. The structurally characterized examples **1** and *rac*-**2c** (see Figure 1) are thus characterized by the metallocene conformational descriptors *mc* 159/−159 (M = Ti, n = 8) and *mc* 16/−18 (M = Zr, n = 12).

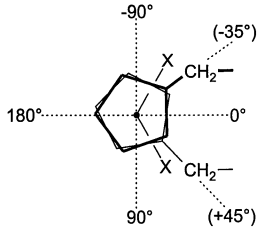


Figure 2. Reticule used for the characterization of the bent metallocene conformers; the specific example depicted would be termed as the *mc* −35/45 conformation

The molecular mechanics calculation has revealed that *rac*-**2c** is characterized by a very shallow conformational hypersurface. A variety of metallocene conformations with very similar energies were found that represent local minima on the conformational surface. The local minima of *rac*-**2c** with the lowest energies, exhibiting the oligomethylene chain predominantly in the "front", "lateral" or "back" sector of the bent metallocene wedge are listed in Table 1. The force-field calculations locate the global minimum conformation (*mc* 9/−9) with an orientation that is very close to the experimental X-ray structure of *rac*-**2c** (see Figure 1), with a structurally even closer conformation (*mc* 16/−16) close by. However, it must be noted that several other structurally different conformational minima of *rac*-**2c**, with only slightly higher energies, were found in this calculation (see Table 1). The overall picture is supported by the result of the DFT calculation. An optimized global minimum structure (*mc* 19/−19) is calculated (see Table 1), that is structurally marginally different from the observed experimental structure of *rac*-**2c**.

The situation changes systematically when the oligomethylene chain is shortened. The decamethylene-bridged system *rac*-**2b** exhibits a set of preferred "lateral" conformations as the global minimum (e.g. *mc* 74/137), whereas the orientation of the $-(CH_2)_{10}-$ bridge at the "front" side is markedly disfavored for the hypothetical system *rac*-**2b** according to this force-field calculation. This situation becomes consistently more pronounced on further shortening of the oligomethylene chain. In *rac*-**2a**, the $-(CH_2)_8-$ chain is preferentially located laterally (global minimum *mc* 85/

[a] Energy relative to the most stable "lateral" conformation, metallocene force field [kcal mol^{-1}]. – [b] B3LYP-optimized [kcal mol^{-1}]. – [c] No minimum found. – [d] B3LYP single point energies [kcal mol^{-1}] of the calculated force-field structure. – [e] From ref.[8]

123 by the B3LYP-DFT calculation, *mc* 97/128 by our metallocene force-field method), and the "front" orientation is strongly disfavored (see Table 1). A similar picture is found in the force-field and DFT calculations of the corresponding *meso*-[−$(CH_2)_n$−(1-indenyl)$_2$]$ZrCl_2$ systems, *meso*-**2a**−**c** (n = 8, 10, 12, see Table 1).

These results showed that the DFT calculations are very good at predicting the preferred conformations of "large" *ansa*-metallocenes. Furthermore, the much simpler metallocene force-field investigation gave quite acceptable results. Therefore, we used both methods for a priori characterization of the preferred metallocene conformations of the parent [$(CH_2)_n(\eta^5$-$C_5H_4)_2$]$ZrCl_2$ "large" *ansa*-zirconocene dichloride complexes **3a**−**d** (n = 8, 9, 10, and 12). A similar trend as in the *rac*-/*meso*-**2** series of complexes is observed here. The smaller members of the series [**3a** (n = 8), **3b** (n = 9), **3c** (n = 10)] all favor metallocene conformations that exhibit a "lateral" orientation of the oligomethylene bridge. However, the difference in energy between the preferred "lateral" conformation and the less favored "back" and "front" arrangements decreases progressively from **3a** to **3c**. Eventually, the cross-over point is reached with complex **3d** (n = 12), where the energy difference between the "front" and "lateral" arrangements becomes marginal (actually, the "front" orientation of the −$(CH_2)_{12}$− chain is slightly favored by the DFT calculation, see Table 2).

The complex **3b** (n = 9) has been synthesized and its molecular structure in the crystal has been determined (see below). The experimentally observed "lateral" orientation of the bridging nonamethylene chain is characterized by the metallocene conformational descriptor *mc* 83/83 (see Figure 2). The force-field-calculated global-minimum structure has an *mc* of 78/81, the DFT (B3LYP) global minimum has an *mc* of 77/83. This is a remarkably accurate structural coincidence in such a flexible conformational system. This result highlights the high predictive potential of both computational chemistry methods used in this investigation.[11]

We have also characterized the preferred metallocene conformations of the members of the corresponding series of [$(CH_2)_n(\eta^5$-$C_5H_4)_2$]$Zr(CH_3)_2$ complexes **4a**−**d** (n = 8, 9, 10, and 12), using our newly parameterized metallocene force-field program. The structural preferences were very similar to the [$(CH_2)_n(\eta^5$-$C_5H_4)_2$]$ZrCl_2$ series (see above). We therefore refer to the Supporting Information for the details of this study.

Finally, we have analyzed the titanium system **1**. It can be seen from Table 3 that in this case the force-field method does not reproduce the observed metallocene conformation.

Furthermore, the DFT calculation is not decisive, it reveals that the highly methyl-substituted "large" *ansa*-titanocene complex **1** is probably characterized by a very shallow conformational hypersurface. It is likely that the observed structure of **1** does not represent the global conformational minimum of the system, but rather one of the many metallocene conformations that are similar in energy, which has been stabilized by crystal packing forces in the solid state.

Experimental Studies

Previously, we and others had tried to prepare "large" *ansa*-metallocenes by coupling reactions, by means of intramolecular metallacyclopentane formation[12] using pendant alkenyl groups attached at the Cp ligands.[6,7] The metallacyclopentane formation is not problematic, but the necessary subsequent cleavage by e.g. HCl, appears to lead to the expected "large" *ansa*-metallocene product only in a limited number of cases. Mach's peralkylated *ansa*-titanocene complex **1** was actually synthesized in that way.[7] Even in the titanium systems, competing pathways leading to ring-opened acyclic products were observed. This completely dominated the protolytic cleavage in the case of the corresponding zirconocene examples, as we had recently shown.[6]

Therefore, we have chosen to synthesize the "large" *ansa*-metallocene examples used in this study using a different pathway. Starting materials were 1,9-dihydroxynonane (**5b**) or 1,12-dihydroxydodecane (**5d**), respectively. These compounds were converted into their respective dimesylates **6b** and **6d** by treatment with methanesulfonyl chloride in pyridine. Subsequent treatment with an excess of lithium cyclopentadienide resulted in clean, twofold substitution reactions, with carbon−carbon bond formation in each case, yielding 1,9- and 1,12-bis(cyclopentadienyl)nonane (**7b**, ca. 60% isolated) and -dodecane (**7d**, 86%), respectively (see Scheme 2). These two products were then deprotonated twice by treatment with *n*-butyllithium in ether. The corresponding α,ω-bis(lithiocyclopentadienyl)alkanes **8b** and **8d** were obtained almost quantitatively, as extremely insoluble solids. These dianion equivalents were only characterized by elemental analysis and by hydrolysis and deuteriolysis experiments, and then directly employed as reagents for the metathetical reaction with zirconium tetrachloride.

(*) mixture of double bond isomers

Scheme 2. Syntheses of the *ansa*-metallocene complexes **3**

The reaction involving the poorly soluble $[Cp-(CH_2)_9-Cp]^{2-}(Li^+)_2$ (**8b**) was carried out with $ZrCl_4(THF)_2$ suspended in toluene. Under these circumstances, similar conditions to those used in typical high-dilution techniques[13] were obtained. The resulting product mixture nevertheless apparently contained oligomeric metallocene materials, which were highly insoluble, as the major components. Soxhlet extraction with pentane over 60 h eventually gave a soluble fraction of 1,1′-nonamethylenebis(cyclopentadienyl)zirconium dichloride (**3b**), which was obtained pure after subsequent recrystallization from toluene at −30 °C, in a 7% yield. 1,1′-Dodecamethylenebis-(cyclopentadienyl)zirconium dichloride (**3d**) was prepared analogously by treatment of the reagent **8d** with $ZrCl_4(THF)_2$, and isolated with a yield of 18%.

Crystals of complex **3b**, that were suitable for X-ray crystal structure analysis, were obtained from a benzene solution over a period of several weeks. In the solid state the nonamethylene-bridged system **3b** exhibits an eclipsed metallocene conformation that has the large *ansa* bridge oriented almost perfectly toward one lateral sector. The specific metallocene conformation can be described by the experimental metallocene conformational descriptor *mc* 83/83 (see Figure 2 and Figure 3). The chlorine atom Cl1 is disordered over two positions, therefore bonding parameters involving this atom will not be discussed in detail. The Cp(centroid)−Zr−Cp(centroid) angle in **3b** is equal to 130.6° and the averaged Cp(centroid)−Zr distance is 2.194 Å; both values are in a very typical zirconocene range {for comparison: Cp_2ZrCl_2 (129.3°/2.203 Å),[14] $[(CH_2)_3(C_5H_4)_2]ZrCl_2$ (129.5°/2.193 Å),[15] Cp_2TiCl_2 (131.0°/2.059 Å)}.[16] Only large substituents at the Cp rings result in noticeable distortions toward larger "bite angles" (and consequently smaller Cp(centroid)−Zr−Cp(centroid) angles $[(Me_3SiC_5H_4)_2ZrCl_2$ (125.4°/2.197 Å),[17] $(Me_3CC_5H_4)_2ZrCl_2$ (116.6°/2.192 Å)].[18] The opposite effect is observed for the pair of "large" *ansa*-metallocenes *rac*-**2c** [Cp(centroid)−Zr−Cp(centroid) angle 133.8°, Cp(centroid)−Zr distance 2.242 Å[8]] and **1** (137.9°/2.140 Å,[7] see Figure 1).

Thus, it appears that the $[(CH_2)_9(C_5H_4)_2]ZrCl_2$ system **3b** represents an unstrained system within the family of the "large" *ansa*-metallocenes, that can attain a normal bent metallocene core with almost no structural distortion, sim-

ilar to ordinary non-bridged $(RCp)_2MX_2$-type group-4 bent metallocene complexes. The $-(CH_2)_9-$ chain in **3b** adopts a crown-shaped cycloalkane conformation, similar to that found in many medium- and large-ring cycloalkanes (Figure 3).[19] The experimentally observed conformer of **3b** obtained in the solid state by X-ray diffraction (*mc* 83/83) is not completely identical but very similar to the probable global-minimum gas-phase structure as calculated by the force-field method (*mc* 78/81) and the DFT calculation (*mc* 77/83, see Table 2).

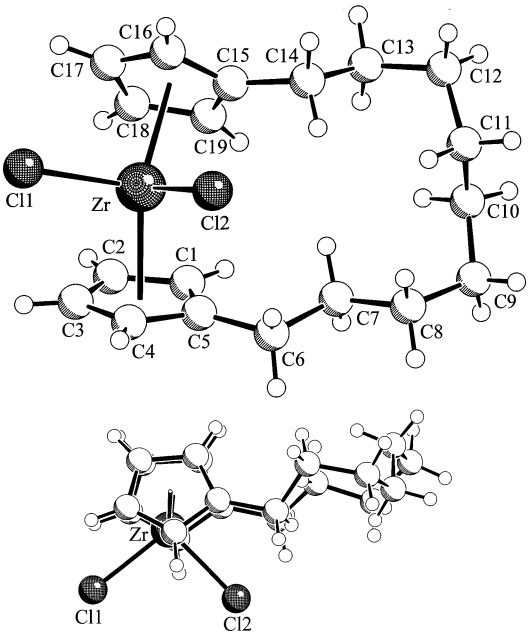

Figure 3. Two views of the molecular structure of the "large" *ansa*-metallocene **3b** in the crystal; selected bond lengths [Å], angles [°] and dihedral angles [°]: Zr−Cl1 2.424(1), Zr−Cl2 2.431(1), C1−C2 1.412(6), C1−C5 1.399(7), C2−C3 1.385(8), C3−C4 1.394(8), C4−C5 1.408(8), C5−C6 1.503(7), C6−C7 1.508(7), C7−C8 1.518(6), C8−C9 1.523(7), C9−C10 1.525(6), C10−C11 1.495(7), C11−C12 1.516(6), C12−C13 1.533(7), C13−C14 1.501(8), C14−C15 1.506(7), C15−C16 1.400(7), C15−C19 1.396(7), C16−C17 1.389(8), C17−C18 1.382(8), C18−C19 1.412(7); Cl1−Zr−Cl2 95.60(5), C5−C6−C7 113.4(4), C6−C7−C8 113.9(4), C7−C8−C9 113.2(4), C8−C9−C10 114.7(4), C9−C10−C11 114.7(4), C10−C11−C12 114.1(5), C11−C12−C13 113.9(4), C12−C13−C14 113.3(5), C13−C14−C15 114.2(5); C5−C6−C7−C8 168.3(5), C6−C7−C8−C9 173.6(4), C7−C8−C9−C10 53.9(6), C8−C9−C10−C11 65.2(6), C9−C10−C11−C12 −169.1(4), C10−C11−C12−C13 64.4(7), C11−C12−C13−C14 63.4(7), C12−C13−C14−C15 −175.0(4)

The conformational behavior of $[(CH_2)_9(C_5H_4)_2]ZrCl_2$ in solution was characterized by dynamic NMR spectroscopy. In a $[D_8]$toluene solution, complex **3b** reveals spectroscopic data of apparent C_{2v} symmetry at ambient temperature, which is caused by a rapid conformational equilibrium on the NMR-spectroscopic time scale. At ambient temperature this leads to five $-CH_2-$ ^{13}C NMR resonances assigned to the *ansa* bridge at δ = 28.6, 26.6, 25.6, 24.6 and 23.7. The intensity of the latter signal is half that of the other signals. Under these conditions there are three Cp resonances at δ = 137.9 (*ipso*-C), δ = 111.7 and 115.7. The ^1H NMR spectrum (600 MHz) at "high" temperature (298 K) is similar, exhibiting methylene signals at δ = 2.40 (α-CH_2), 1.24 (8 H), 1.18 (2 H), and 1.13 (4 H) in addition to Cp methine signals at δ = 5.65 and 5.93. Lowering of the temperature eventually results in a freezing of the dynamic conformational equilibration process on the ^1H-NMR-spectroscopic time scale. Below 203 K (at 600 MHz), the well-separated ^1H NMR resonance of the methylene group in the α-position to the Cp ring system, begins to split into two signals of equal intensity that eventually appear at δ = 2.74 and 2.07 at 183 K. Under these static conditions the hydrogen atoms at the α-CH_2 group have thus become diastereotopic. Their nonequivalence indicates the presence of a single metallocene conformational minimum that is non-C_{2v}-symmetric. The remaining apparent C_s symmetry of the spectroscopically observed system may be real, or may be caused by a remaining very rapid local conformational symmetrization effect being operative in the medium-sized annelated nonamethylene ring system. In principle, a bis(lateral) conformation of **3b** in solution, similar to that observed in the crystal seems likely. Consequently, the pair of Cp ^1H NMR resonances broadens with decreasing temperature (Figure 4). Decoalescence is observed at ca. 203 K which results in the formation of two pairs of α,α′- and β,β′-C_5H_4 ^1H NMR resonances of equal intensity, at δ = 6.47/6.09 (3-H, 4-H) and δ = 5.09/4.92 (2-H/5-H). From these values a Gibbs activation energy of $\Delta G^{\ddagger}_{rot}(203\ K) = 8.8 \pm 0.3$ kcal/mol was obtained[20] for the conformational equilibration process of the "large" *ansa*-metallocene complex **3b** in $[D_8]$toluene. The conformational barrier is apparently not solvent-dependent. In the more polar solvent $CDFCl_2/CDF_2Cl$ (1:1),[21] a similar dynamic behavior was observed and an activation barrier of $\Delta G^{\ddagger}_{rot}(184\ K) = 8.5 \pm 0.3$ kcal/mol was obtained for the conformational equilibration process.

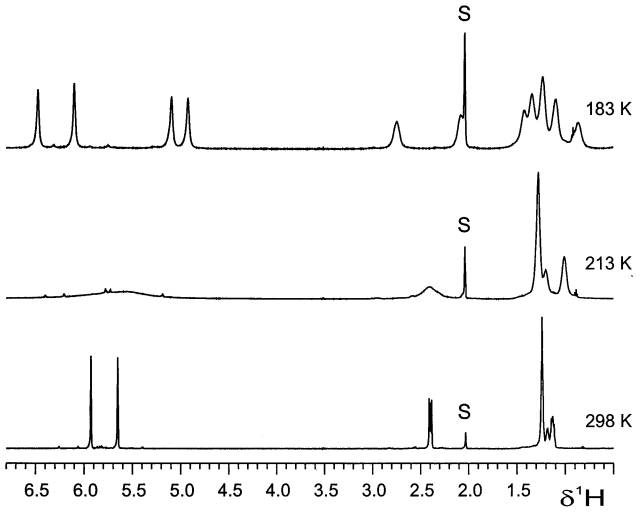

Figure 4. Dynamic ^1H NMR spectra (600 MHz) of **3b** in $[D_8]$toluene

From the dynamic NMR spectra it cannot be determined whether the C_9-oligomethylene chain moves through the front or back sector of the bent metallocene wedge during this conformational automerization process. From the computational energies of the $[(CH_2)_9(C_5H_4)_2]ZrCl_2$ system **3b**

that are compiled in Table 2, it appears that the nonamethylene chain may be accommodated slightly better at the back of the metallocene during such a migration process, although the respective ground-state energy differences are not prohibitively large and the transition-state energies were not calculated.

It can be assumed that steric interactions decrease for the dodecamethylene-bridged system $[(CH_2)_{12}(C_5H_4)_2]ZrCl_2$ (**3d**). Indeed, a similar 600-MHz ^{1}H NMR spectrum of **3d** was obtained at ambient temperature. In this case the conformational equilibration process of the "large" *ansa*-metallocene framework could not be frozen on the 600-MHz ^{1}H-NMR-spectroscopic time scale, even when the lowest temperature, 133 K, was reached (for spectroscopic details see the Exp. Sect.). It appears that the "large" *ansa*-metallocene complex **3d** exhibits dynamic properties similar to those of simple open, non-bridged alkyl-substituted group-4 bent metallocene complexes $[(prim.\text{-}alkyl)C_5H_4]_2ZrCl_2$ that are characterized by very low activation barriers for the conformational equilibration process.[22]

Olefin Polymerization Reactions

The combined conformational studies have shown that the complexes $[(CH_2)_9(C_5H_4)_2]ZrCl_2$ (**3b**) and $[(CH_2)_{12}(C_5H_4)_2]ZrCl_2$ (**3d**) attain favored conformations that have their long bridging oligomethylene chains oriented toward a lateral sector of the bent metallocene wedge, or that they are conformationally labile and may very easily turn away from the front sector. In any case, an active Ziegler−Natta catalytic system could be derived from such a singly bridged "large" *ansa*-metallocene that will allow for the unrestricted approach of reagents at the front sector of the bent metallocene wedge. This is essential for the catalyst's action, and we thus would expect that the systems **3b** and **3d** might lead to very active olefin polymerization catalysts on activation. This is indeed observed.

Activation of $[(CH_2)_9(C_5H_4)_2]ZrCl_2$ (**3b**) with methylalumoxane (MAO)[23] in toluene (Al/Zr ratio ca. 1800) at room temperature gave a very active homogeneous Ziegler−Natta catalyst for ethene polymerization. Polyethylene (m.p. 127 °C) was formed with an activity of $a \approx 2500$ kg polymer/mol [Zr]·h·bar (at 40 °C and 2 bar ethene pressure). The catalyst derived from complex $[(CH_2)_{12}(C_5H_4)_2]ZrCl_2$ (**3d**) was equally active in ethene polymerization under similar conditions ($a \approx 2400$). Both catalysts are also active in propene polymerization. Activation of **3b** was again achieved by treatment with a large excess of MAO (Al/Zr ≈ 1450). Polymerization at 40 °C (2 bar propene pressure) yielded ca. 21 g of an oily polypropylene with an activity of $a \approx$ 450 kg polypropylene/mol [Zr]·h·bar. The ^{1}H-NMR-spectroscopic analysis revealed that a low molecular weight oligomer was formed under these conditions. End-group analysis by ^{1}H NMR spectroscopy showed that an average 14-mer was obtained. The catalyst derived from the C_{12}-bridged "large" *ansa*-metallocene produced a similar propene oligomer (oligomerization degree of ca. 10 according to the NMR $H_2C{=}C(CH_3)-$ end group analysis)[24] with a catalyst activity of $a = 330$. The ^{13}C NMR pentade analysis showed that both polymers were atactic. The polypropylene formed at the **3b**/MAO-derived catalyst shows an mmmm ^{13}C NMR methyl pentade intensity of 6.7%, the material obtained at the **3d**/MAO catalyst 5.5% mmmm.

We conclude that the singly bridged "large" *ansa*-metallocenes studied in this work exhibit favored specific metallocene conformations if the bridging oligomethylene chains are small enough. Most often these chains are then found oriented toward lateral positions. Complexes with chain lengths of C_{12} or longer seem to be similar to non-bridged complexes.[25] The metal center in such monobridged systems is rather open and can easily be approached by external reagents. This results in rather active but stereochemically unselective Ziegler−Natta catalysts on activation with, for example, methylalumoxane. Bridge-specific effects will probably require a covalent fixation of a given metallocene conformation by the introduction of a second bridge.[6] It will be interesting to see how fixing a large $-(CH_2)_n-$ bridge in front of the bent metallocene alters the zirconocene behavior in an activated system. Such investigations and syntheses are actively being pursued in our laboratory.

Experimental Section

Computational Study: The force-field calculations were carried out with the program MAXIMOBY[26] using parameters based on the AMBER force field.[27] The parameters for the description of zirconium and its ligands in the $[Zr]Cl_2$ complexes were used as previously described by us.[9] A new set of parameters was deduced for the Zr−(sp^3-C) bond (carbon atom type MC) using 12 representative metallocene structures from the Cambridge Structural Database (details are provided with the Supporting Information). The following force-field data for the "new" carbon atom type MC were used (force constant in kcal mol^{-1}, reference values in Å or °): ZR−MC (110/2.275), HC−MC (330/1.09), MC−ZR−MC (80/95.5), MP−ZR−MC (80/104.2), XC−MC−ZR (5/109.5), HC−MC−ZR (40/109.5), −ZR−MC− (0/180.0, threefold) [MP denotes the artificial Cp(centroid) atom used in the metallocene force-field calculation and XC is the sp^2-carbon atom that is common to both the five- and six-membered ring of the indenyl ligand]. The starting geometries for the optimization were prepared using the visualization tool MOBY.[28] New conformations were generated within the MAXIMOBY program by breaking the central (sp^3-C)−(sp^3-C) bond of the oligomethylene chain, followed by changing the torsional angles successively by a 120° increment. Every new conformation was then optimized under the constraint that the ends of the resulting carbon chains formed initially after changing the torsion angles were not more than 6 Å apart to speed up the calculations. In addition the orientation of the ligands was changed systematically to provide different starting points for the force-field optimization procedures. The obtained results are listed in Tables 1−3. For additional information see the Supporting Information. − The validity of the force-field calculation was checked by a correlation with respective ab initio energies and ab initio conformational minimum structures. This was achieved by single-point calculations of all local minima of the obtained force-field structures by the DFT method B3LYP,[10] using the LAN L2DZ basis set. It contains a double-ζ valence basis set (8s6p4d)/[3s3p2d] with Hay and Wadt "effective core potentials" that substitute the Zr

electrons up to the 3d level,[29] and the Huzinaga−Dunning "double-ζ valence" basis set for the remaining atoms.[30] Resulting single-point energies and structures are provided in the Supporting Information. Results from the DFT optimizations are contained in Tables 1−3, and additional information (energies) are included in the Supporting Information. For details about the ZR-MC force-field parameterization, the force field and the DFT calculations see Supporting Information.

Synthetic Work. − General Information: Reactions with organometallic compounds were carried out under argon using Schlenk-type glassware or in a glove-box. Solvents (including deuterated solvents used for spectroscopic measurements) were dried and distilled prior to use. For additional general information, including a list of spectrometers used, see ref.[6] $ZrCl_4(THF)_2$,[31] 1,9-nonanediylbis(methanesulfonate) (**6b**),[32] and 1,12-dodecanediylbis(methanesulfonate) (**6d**)[33] were synthesized according to literature preparations. 1,9-Bis(cyclopentadienyl)nonane (**7b**) and 1,12-bis(cyclopentadienyl)dodecane (**7d**) were both obtained by procedures analogous to the literature preparations[34] of these compounds.

Preparation of 1,9-Bis(cyclopentadienyl)nonane (7b): Cyclopentadiene (4.10 mL, 49.4 mmol) was dissolved in 100 mL of THF at −15 °C. *n*-Butyllithium (28.5 mL of a 1.6 M solution in *n*-hexane, 45.6 mmol) was added dropwise, while stirring, over 1 h. The mixture was stirred for 3 h at 0 °C. A solution of 1,9-nonanediylbis(methanesulfonate) (**6b**) (6.00 g, 19.0 mmol) in 100 mL of THF was added dropwise at 0 °C (ice bath). The mixture was allowed to slowly warm to room temperature with stirring over a period of 12 h. Diethyl ether (75 mL) and a saturated aqueous sodium chloride solution (75 mL) was added, the organic phase separated and washed with water. The aqueous phase was extracted with ether (3×). The combined organic solutions were dried with anhydrous magnesium sulfate, filtered and concentrated in vacuo. Purification of the product was achieved by precipitation from acetone at −25 °C and gave **7b** as a pale yellow oil, as a mixture of isomers that exhibit the side chains at the 2- and 3-positions of the cyclopentadienyl rings. Yield of **7b**: 2.84 g (59%). − ^{1}H NMR (200.1 MHz, [D$_6$]benzene, 300 K): δ = 6.45 (m, 2 H, =CH), 6.34 (m, 1 H, =CH), 6.18 (m, 2 H, =CH), 5.92 (m, 1 H, =CH), 2.78, 2.68 (m, each 2 H, CH_2 of C_5H_5 of the two isomers), 2.38−2.26 (m, 4 H, 1-H, 9-H of the chain), 1.54−1.10 (m, 16 H, 2-H to 8-H of the chain). − ^{13}C NMR (50.3 MHz, [D$_6$]benzene, 300 K): δ = 149.7, 147.6 (C-1/C-2 of C_5H_5, two isomers), 135.1, 133.7, 132.8, 130.4, 126.8, 126.0 (=CH of C_5H_5, two isomers), 43.4, 41.4 (CH_2 of C_5H_5), 31.1, 30.3, 29.9 (double intensity), 29.3 (C1−C9).

1,12-Bis(cyclopentadienyl)dodecane (7d): The synthesis was carried out analogously as described above by treatment of cyclopentadiene (9.6 mL, 116.0 mmol) in 300 mL of THF with *n*-butyllithium (68.8 mL of a 1.6 M solution in *n*-hexane, 110.0 mmol) at −15 °C, followed by addition of a solution of 1,12-dodecanediylbis(methane sulfonate) (**6d**) (16.0 g, 53.6 mmol) in 200 mL of THF to give a ca. 1:1 mixture of two isomers of **7d** as an oil. Yield: 13.7 g (86%). − ^{1}H NMR (200.1 MHz, [D$_6$]benzene, 300 K): δ = 6.46 (m, 2H =CH), 6.33 (m, 1 H, =CH), 6.19 (m, 2 H, =CH), 5.97 (m, 1 H, =CH), 2.79, 2.70 (m, each 2 H, CH_2 of C_5H_5, two isomers), 2.39−2.27 (m, 4 H, 1-H, 12-H of the chain), 1.60−1.15 (m, 20 H, 2-H to 11-H of the chain). − ^{13}C NMR (50.3 MHz, [D$_6$]benzene, 300 K): δ = 149.2, 147.6 (C-1/C-2 of C_5H_5, two isomers), 135.1, 133.7, 132.6, 130.4, 126.8, 125.9 (=CH of C_5H_5, two isomers), 43.4, 41.1 (CH_2 of C_5H_5), 31.1, 30.3, 30.1, 30.0, 29.9, 29.4 (C-1−C-12).

1,9-Bis(lithiocyclopentadienyl)nonane (8b): *n*-Butyllithium (11.9 mL of a 1.6 M solution in *n*-hexane, 19.2 mmol) was added dropwise to a solution of 1,9-bis(cyclopentadienyl)nonane (**7b**) (2.08 g, 8.09 mmol) in 50 mL of diethyl ether at 0 °C. The mixture was stirred for 4 h at ambient temperature. The resulting white precipitate was collected by filtration, washed with ether (2 × 20 mL) and dried in vacuo to yield 2.02 g (93%) of **8b**, m.p. 176 °C (decomp.). − IR (KBr): $\tilde{\nu}$ = 3077 (w), 2926 (vs), 2853 (vs), 1463 (m), 1443 (m), 1077 (w), 1060 (m), 1041 (m), 1026 (m), 818 (s), 755 (vs) cm^{-1}. − $C_{19}H_{24}Li_2{\cdot}C_4H_{10}O$ (340.4): calcd. C 80.68, H 10.60; found C 80.98, H 9.90. − The product **8b** is insoluble in the usual solvents, even in the presence of 12-crown-4 crown ether. For further characterization it was therefore hydrolyzed with H_2O (a) or D_2O (b) and the resulting respective hydrocarbon products analyzed. − MS (70 eV): *m*/*z* (a) = 256 [M$^+$]; *m*/*z* (b) = 258 [M$^+$].

1,12-Bis(lithiocyclopentadienyl)dodecane (8d): The preparation was carried out analogously as described above by treatment of 1,12-bis(cyclopentadienyl)dodecane (**7d**), (9.18 g, 30.8 mmol) in 150 mL of diethyl ether with a solution of *n*-butyllithium (38.0 mL of a 1.6 M solution in *n*-hexane, 61.6 mmol), to yield 9.01 g (94%) of **8d**, m.p. 189 °C (decomp.) as an insoluble material. − IR (KBr): $\tilde{\nu}$ = 3079 (w), 2924 (vs), 2853 (vs), 1464 (m), 1367 (w), 1261 (w), 1089 (m), 1060 (m), 1041 (m), 1026 (m), 818 (s), 755(vs) cm^{-1}. − $C_{22}H_{30}Li_2{\cdot}2(C_4H_{10}O)$ (456.6): calcd. C 78.57, H 11.43; found C 78.75, H 11.13. − Hydrolysis with H_2O (a) or D_2O (b) was carried out analogously as described above to yield the respective hydrolysis products. − MS (70 eV): *m*/*z* (a) = 298 [M$^+$]; *m*/*z* (b) = 300 [M$^+$].

[1,9-Nonanediylbis(η^5-cyclopentadienyl)]zirconium Dichloride (3b): A suspension of $ZrCl_4(THF)_2$ (6.32 g, 16.8 mmol) in 100 mL of toluene was cooled to −78 °C and then slowly added to a cold (−78 °C) suspension of 1,9-bis(lithiocyclopentadienyl)nonane (**8b**) (4.50 g, 16.8 mmol) in 300 mL of THF. The mixture was allowed to warm to room temperature overnight, with stirring. The solvent was removed in vacuo. The orange colored residue was Soxhlet-extracted with pentane for 60 h to give **3b** as a grayish powder. Recrystallization from toluene at −30 °C gave **3b** as white crystals, yield 457 mg (7%), m.p. 198 °C. − $C_{19}H_{26}Cl_2Zr$ (416.5): calcd. C 54.79, H 6.29; found C 54.15, H 6.65. − IR (KBr): $\tilde{\nu}$ = 3100 (m), 2931 (vs), 2852 (s), 1487 (m), 1458 (m), 1439 (w), 1261 (m), 1096 (m), 1071 (m), 1053 (m), 1039 (m), 1029 (m), 875 (w), 853 (w), 818 (s), 732 (w) cm^{-1}. − The NMR assignments were supported by a series of 2D experiments (GHSQC, GHMBC, GCOSY);[35] the dynamic behavior of complex **3b** was examined by ^{1}H/^{13}C 1D and 2D NMR spectroscopy[20] in [D$_8$]toluene in a temperature range between 298 K and 183 K and by ^{1}H NMR in $CDFCl_2/CDF_2Cl$ (1:1)[21] between 253 K and 133 K. − ^{1}H NMR (599.9 MHz, [D$_8$]toluene, 298 K): δ = 5.93 (pseudo-t, 4 H, 3-H, 4-H of C_5H_4), 5.65 (pseudo-t, 4 H, 2-H, 5-H of C_5H_4), 2.40 (m, 4 H, 1-/9-H), 1.24 (m, 8 H, 2-/8-H and 4-/6-H), 1.18 (m, 2 H, 5-H), 1.13 (m, 4 H, 3-/7-H). − ^{13}C NMR (150.8 MHz, [D$_8$]toluene, 298 K): δ = 137.9 (C-1 of C_5H_4), 115.7 (C-3/C-4 of C_5H_4), 111.7 (C-2/C-5 of C_5H_4), 28.6 (C-1/C-9), 26.6 (C-2/C-8), 25.6 (C-3/C-7), 24.6 (C-4/C-6), 23.7 (C-5). − ^{1}H NMR (599.9 MHz, [D$_8$]toluene, 183 K): δ = 6.47 and δ = 5.09 (br., each 2 H, 3-H and 4-H of C_5H_4), 6.09 and 4.92 (br., each 2 H, 2-H and 5-H of C_5H_4), 2.74 and 2.07 (br., each 2 H, 1-H,H′ and 9-H,H′), 1.65−0.85 (m, 14 H, 2-H to 8-H). − Coalescence of 1-H,H′/9-H,H′ of the nonamethylene chain at ca. 203 K: Δν (183 K) = 399 Hz, $\Delta G^{\ddagger}_{rot}$ (203 K) = 9.0 ± 0.3 kcal mol^{-1}. Coalescence of the two groups of C_5H_4 proton resonances at ca. 203 K: Δν (183 K) = 701 Hz, $\Delta G^{\ddagger}_{rot}$ (203 K) = 8.8 ± 0.3 kcal mol^{-1}; Δν (183 K) = 828 Hz, $\Delta G^{\ddagger}_{rot}$ (203 K) = 8.7 ± 0.3 kcal mol^{-1}; averaged value in [D$_8$]toluene: $\Delta G^{\ddagger}_{rot}$ (203 K) = 8.8 ± 0.3 kcal mol^{-1}. − GHSQC NMR (599.9 MHz, [D$_8$]toluene, 183 K): δ (^{1}H)/(^{13}C) = 6.47/125.6, 6.09/115.6, 5.09/106.2, 4.92/106.5 (C_5H_4), 2.74/28.2,

Table 4. Ethene and propene polymerization reactions at the **3b**/MAO and **3d**/MAO catalysts

Precursor	Monomer[a]	mg (μmol) [Zr]	g (mmol) [Al]	Al/Zr ratio	Reaction time [min]	PE/PP[b] [g]	Activity[c]	m.p. (PE) n[d] (PP)
3b	E	8.0 (19.2)	2.1 (34.5)	1800	5	8.1	2540	127
3d	E	9.7 (21.2)	2.1 (34.5)	1630	5	8.6	2420	127
3b	P	9.8 (21.5)	2.1 (34.5)	1470	60	21.5	456	14
3d	P	10.1 (22.0)	2.1 (34.5)	1570	60	14.6	332	10

[a] All reactions were carried out at 2 bar monomer pressure at 40 °C. − [b] E = ethene, P = propene, PE = polyethylene, PP = polypropylene. − [c] Polymerization activity in kg (polymer)/mol [Zr]·h·bar. − [d] Oligomerization degree, determined by ^{1}H NMR end group analysis.

2.07/28.2, 1.45/23.5, 1.36/25.7, 1.36/22.3, 1.25/25.8, 1.24/23.5, 1.13/25.4, 1.10/22.3, 0.88/25.3 (CH_2). − ^{1}H NMR (599.9 MHz, $CDFCl_2/CDF_2Cl$, 253 K): δ = 6.45 (pseudo-t, 4 H, 3-H, 4-H of C_5H_4), 6.26 (pseudo-t, 4 H, 2-H, 5-H of C_5H_4), 2.67 (m, 4 H, 1-H, 9-H), 1.55−1.25 (m, 14 H, 2-8-H). − ^{1}H NMR (599.9 MHz, $CDFCl_2/CDF_2Cl$), 133 K): δ = 6.63 (br., 2 H), 6.36 (br., 4 H) and 6.30 (br., 2 H, C_5H_4), 2.68 and 2.46 (br., each 2 H, 1-H,H′, 9-H,H′), 1.38 (m, 14 H, 2-8-H). − 1-H,H′/9-H,H′ coalescence at ca. 183 K: Δν (133 K) = 132 Hz, $\Delta G^{\ddagger}_{rot}$ (183 K) = 8.5 ± 0.3 kcal mol^{-1}; coalescence of one group of C_5H_4 resonances at ca. 188 K: Δν (133 K) = 200 Hz, $\Delta G^{\ddagger}_{rot}$ (188 K) = 8.6 ± 0.3 kcal mol^{-1}. Averaged value in $CDFCl_2/CDF_2Cl$: $\Delta G^{\ddagger}_{rot}$(188 K) = 8.5 ± 0.3 kcal mol^{-1}.

X-ray Crystal Structure Analysis of 3b: Single crystals of complex **3b** were obtained by slow evaporation of solvent from a solution in benzene. Empirical formula $C_{19}H_{26}Cl_2Zr\cdot 1/2\ C_6H_6$, M = 455.57, colorless crystal 0.30 × 0.20 × 0.10 mm, a = 39.555(2), b = 6.512(1), c = 16.689(1) Å, β = 102.57(1)°, V = 4195.8(7) Å^3, $\rho_{calcd.}$ = 1.442 g cm^{-3}, μ = 7.81 cm^{-1}, empirical absorption correction via SORTAV (0.799 ≤ T ≤ 0.926), Z = 8, monoclinic, space group $C2/c$ (No. 15), λ = 0.71073 Å, T = 198 K, ω and φ scans, 19815 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.65 Å^{-1}, 4795 independent (R_{int} = 0.054) and 3448 observed reflections [I ≥ 2 σ(I)], 226 refined parameters, R = 0.054, wR^2 = 0.117, max. residual electron density 1.54 (−1.58) e Å^{-3} close to Cl1, Cl1 disordered over two positions, no disorder model used in the final refinement, hydrogen positions calculated and refined as riding atoms. Data set was collected with a Nonius KappaCCD diffractometer, equipped with a rotating anode generator Nonius FR591. Programs used: data collection COLLECT (Nonius B. V., **1998**), data reduction Denzo-SMN (Z. Otwinowski, W. Minor, *Methods Enzymol.* **1997**, *276*, 307−326), absorption correction SORTAV (R. H. Blessing, *Acta Crystallogr.* **1995**, *A51*, 33−37; R. H. Blessing, *J. Appl. Crystallogr.* **1997**, *30*, 421−426), structure solution SHELXS-97 (G. M. Sheldrick, *Acta Crystallogr.* **1990**, *A46*, 467−473), structure refinement SHELXL-97 (G. M. Sheldrick, Universität Göttingen, **1997**), graphics SCHAKAL (E. Keller, Universität Freiburg, **1997**). − Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication CCDC-156106. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, CambridgeCB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

[1,12-Dodecanediylbis(η^5-cyclopentadienyl)]zirconocene Dichloride (3d): A cold (−78 °C) suspension of $ZrCl_4(THF)_2$ (9.64 g, 25.6 mmol) in 250 mL of toluene was added to a suspension of the reagent **8d** (8.00 g, 25.8 mmol) in 600 mL of THF at −78 °C. The mixture was allowed to warm to room temperature overnight and then kept for 4 h at 60 °C. The solvent was removed in vacuo and the residue extracted (Soxhlet) with pentane for 60 h to give 2.06 g (18%) of **3d**, m.p. 144 °C. − $C_{22}H_{32}Cl_2Zr$ (458.6): caldc. C 57.62, H 7.03; found C 57.48, H 7.22. − IR (KBr): $\tilde{\nu}$ = 3102 (m), 2927 (vs), 2855 (s), 1488 (m), 1458 (m), 1439 (w), 1261 (w), 1094 (w), 1074 (w), 1052 (w), 1034 (m), 852 (m), 847 (m), 817 (s) cm^{-1}. − NMR assignments in [D_8]toluene were supported by GHSQC and GHMBC 2D NMR experiments[35] at 298 K. − ^{1}H NMR (599.9 MHz, [D_8]toluene, 298 K): δ = 5.85 (pseudo-t, 4 H, 3-H, 4-H of C_5H_4), 5.71 (pseudo-t, 4 H, 2-H, 5-H of C_5H_4), 2.42 (m, 4 H, 1-H/12-H of the chain), 1.35−1.23 (m, 20 H, 2-H to 11-H of the chain). − ^{13}C NMR (150.8 MHz, [D_8]toluene, 298 K): δ = 137.0 (C-1 of C_5H_4), 114.2 (C-3/C-4 of C_5H_4), 113.1 (C-2/C-5 of C_5H_4), 29.5 (C-1/C-12), 28.1, 27.7, 27.6, 27.4, 26.9 (C-2 to C-11). − The dynamic features of **3d** were examined by ^{1}H NMR spectroscopy in $CDFCl_2/CDF_2Cl$ in a temperature range between 253 K and 133 K; the 1-H,H′/12-H,H′ resonance shows the start of decoalescence at the lowest temperature reached (133 K). Since the temperature could not be lowered further in this solvent, the separated signals were not observed. − ^{1}H NMR (599.9 MHz, $CDFCl_2/CDF_2Cl$, 253 K): δ = 6.39 (pseudo-t, 4 H, 3-H, 4-H of C_5H_4), 6.19 (pseudo-t, 4 H, 2-H, 5-H of C_5H_4), 2.62 (m, 4 H, 1-H, 12-H), 1.63−1.27 (m, 20 H, 2-H to 11-H of the chain).

Olefin Polymerization Reactions: These were carried out in a toluene solution using a Büchi glass autoclave. Activation of the zirconocene dichlorides was carried out by treatment with a 10.5 w-% MAO solution in toluene, and the polymers worked up as previously described by us.[36] The ^{1}H NMR end group analysis of the polypropylene samples were carried out in 1,2,4-trichlorobenzene ([D_8]benzene lock) at 353 K. The stereochemical characterization was performed by ^{13}C NMR methyl pentade analysis.[24] Details of the polymerization experiments are compiled in Table 4.

Acknowledgments

Financial support from the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft is gratefully acknowledged. We thank Dr. Christian Mück-Lichtenfeld for his help with the computational studies.

The 2D and 3D Compounds $[M_2bpm(dca)_4]\cdot nH_2O$ (M = Ni, Zn; bpm = bipyrimidine; dca = dicyanamide; n = 0, 1) − Structural Analysis and Magnetic Properties

Susana Martín,[a] M. Gotzone Barandika,[a] Roberto Cortés,*[a] J. I. Ruiz de Larramendi,[a] M. Karmele Urtiaga,[b] Luis Lezama,[c] M. Isabel Arriortua,[b] and Teófilo Rojo*[c]

Keywords: Magnetic properties / Structure elucidation / N ligands / Nickel / Zinc

The combined use of bpm (2,2′-bipyrimidine) and dca (dicyanamide) has led to the preparation of two compounds of general formula $[M_2bpm(dca)_4]\cdot nH_2O$. Compound **1** (M = Ni, n = 1) exhibits a 2D layered structure based on ladder-like moieties. These units, whose steps are bpm groups, extend through single dca bridges, the connection between distinct ladder-like units taking place through double dca bridges. Compound **2** (M = Zn, n = 0) consists of a 3D structure based on the same type of ladder-like moieties that are connected to another four on the plane perpendicular to the extension of the ladders.

Introduction

The design of multidimensional networks has been an important area of research in coordination chemistry. Thus, the preparation of crystalline materials exhibiting some desired structural and topological features becomes a fascinating challenge as it implies the control of the related physical and chemical properties. In this sense, the synthetic strategy has been widely confirmed to be a major factor.

Among the variety of extended frameworks reported during the last few years, there are plenty of examples that illustrate the relevance of the synthetic strategy. Since the azide pseudohalide has been one of the most used ligands, a couple of azide systems can be mentioned in this context (Scheme 1). For instance, the compound $[Mn(N_3)_2bpy]_n$ (bpy = 2,2′-bipyridine) consists of Mn chains where the Mn^{II} ions are alternatively bridged by double *end-on* (EO) and double *end-to-end* (EE) azide bridges.[1] The substitution of bpy by the tetradentate bpm (2,2′-bipyrimidine) in an M:bpm molar ratio of 2:1 induces the connection of the Mn chains resulting in the compound $[Mn_2(N_3)_4bpm]_n$. This is a 2D honeycomb-like structure where the sheets exhibit an infinite hexagonal array of Mn^{II} ions bridged by bis-chelating bpm and double EO azide-bridges.[2]

A further step in the synthetic strategy could consist of the substitution of the azide group to generate new M-bpm-L compounds (L being the new ligand). With this aim, we have selected dicyanamide (dca), as previously done by other researchers.[3] This ligand, similarly to the azide li-

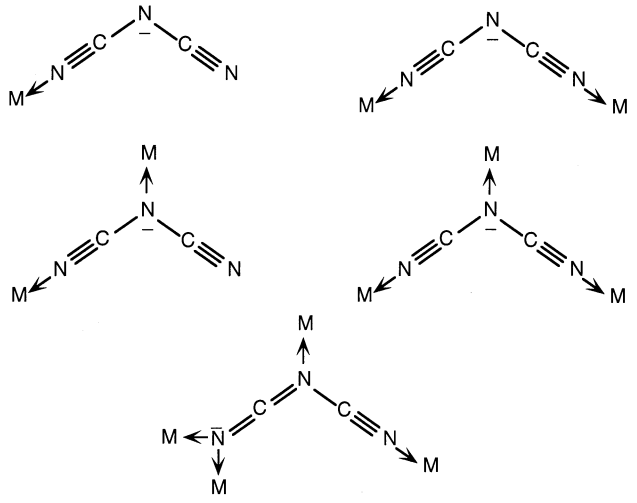
gand, exhibits several coordination modes. Thus, besides the monodentate terminal coordination,[4] bidentate,[5] tridentate[6] and even tetradentate[7] modes have been reported for dca (Scheme 2). The potential of dca for the preparation of extended frameworks is illustrated by the great deal of recent attention focussed on coordination polymers containing this ligand.[8]



Scheme 2

Taking into account the above-mentioned aspects, two compounds of general formula $[M_2bpm(dca)_4]\cdot nH_2O$ (M = Ni, $n = 1$ for compound **1**; M = Zn, $n = 0$ for compound **2**) have been synthesised and magnetostructurally characterised. For both of them, a ladder-like moiety can be proposed as a basic structural unit whose repetition leads to a 2D array for **1** and to a 3D network for **2**.

Results and Discussion

Structural Analysis

The structural characterisation of compound **1** has been carried out by means of X-ray powder-diffraction pattern analysis on the basis of the structure of $[Co_2bpm(dca)_4]\cdot H_2O$ (**3**). This compound has been structurally characterised at 100 K by Marshall et al.[3] and at 273 K by us. Therefore, since the X-ray powder-diffraction data collection for **1** was carried out at 273 K, we have used our structural data for **3** as initial parameters for the refinement of **1**. The observed, calculated and difference X-ray diffraction pattern for **1** are displayed in Figure 1. As can readily be seen, there is a good agreement between the theoretical and experimental data. Thus, the fact that **1** and **3** exhibit the same stoichiometry and space group (*Pnma*) and similar structural parameters [a = 16.111(3) Å, b = 12.755(2) Å, c = 10.455(2) Å for **1** and a = 16.212(2) Å, b = 12.972(2) Å, c = 10.502(2) Å for **3**] clearly indicates that compounds **1** and **3** are isomorphous. This isomorphous relationship is also confirmed by the rest of the analytical techniques discussed in this work for **1**.

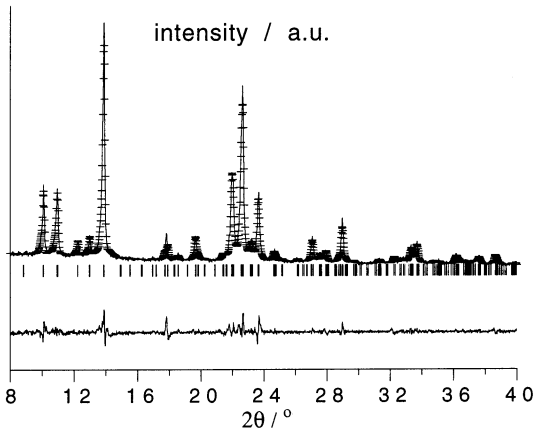


Figure 1. Observed, calculated and difference X-ray diffraction patterns for **1**

Figure 2 shows a view of the structures of **1** and **3**. As observed, they consist of layers of octahedrally coordinated metallic cations. The 2D network can be described on the basis of ladder-like moieties extending along the x direction through single dca bridges, the steps being the bpm groups. These ladders are connected through double dca bridges along the y direction. The intermetallic distance through bpm is the shortest one (5.770 Å for **3**) while the distance through the single dca bridges is the longest one (8.299 Å for **3**), with the one through double dca links being intermediate (7.202 Å for **3**). The layers are waved and are closely packed along the z direction. Additionally, there are molecules of water of crystallisation located between these layers.

Compound **2** consists of a 3D network where each Zn^{II} cation is octahedrally bonded to one bpm (through N1 and N2 atoms) and four dca ligands (two N3−C5−N4−C6−N5 groups and two N6−C7−N7−C8−N8 groups). As seen in Figure 3, the two N_{bpm} atoms occupy two of the equatorial positions. Since the bpm ligands are N,N',N'',N'''-tetradentate they allow the connection between two metallic cations. On the other hand, the four dca groups act as 1,5-bridges with the N3 and N6 atoms at the remaining equatorial positions and the N5 and N8 atoms at the axial positions. As a result each Zn^{II} cation is linked to five metallic centres: one through bpm (Zn···Zn distance is 5.895 Å) and four by dca ligands [Zn···Zn distances through the N3,N5- and N6,N8-bonded dca groups are 7.446 and 7.656 Å, respectively].

The 3D structure of **2** can also be described on the basis of covalently interconnected ladder-like moieties. Thus, as observed in Figure 4, the ladder-like moieties also consist of bpm steps. These units extend along the x direction through N3−C5−N4−C6−N5 dca groups. Each ladder unit is connected to another four through N6−C7−N7−C8−N8 dca groups along the [011] and [$\bar{0}$1] directions.

Table 1 displays the selected bond lengths and angles for **2**. As can be seen, the coordination sphere is quite distorted in relation to both distances and angles. The presence of the rigid bpm ligand accounts for the bond angles being far from the ideal values. The Zn−N8 distance deserves special

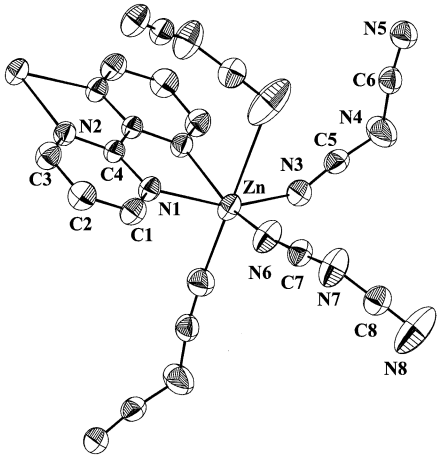

Figure 3. ORTEP view (50% probability) of the coordination environment for **2**

attention as the value of 2.8 Å clearly implies that the covalent connection between distinct ladder-like units is weak. Nevertheless, similar values have been accepted in the literature as bond lengths.[9]

[a] Symmetry transformations used to generate equivalent atoms: i = $-x$, $-y$, $-z$; ii = $x-1$, y, z; iii = $x+1$, y, z.

The main difference between the structures for **1** and **2** lies in the connection between ladder-like units. Thus, while each ladder is connected to another two through double dca bridges along the *y* direction for **1**, each ladder is linked to another four through single dca bridges for **2**. This is a

consequence of the orientation of the coordination octahedra in relation to the extension of the ladder-like moiety. Thus, for **1** the axial direction of the octahedra fully coincides with the extension direction, while for **2** it does not. Obviously, this different disposition is responsible for the occurrence of a 2D array for **1** and a 3D structure for **2**.

IR and ESR spectroscopy

A summary of the most important IR bands corresponding to compounds **1** and **2**, together with their tentative assignment,[10] is displayed in Table 2. As observed, both compounds exhibit strong absorptions in the region 2315−2190 cm^{-1} that correspond to $\nu_{C\equiv N}$ modes. There are also strong bands at about 1580 cm^{-1} for both of them (with a shoulder at lower wavenumbers for **2**) that have been attributed[11] to the asymmetric doublet characteristic of ring stretching for bis-chelating bpm. The absorptions due to molecules of water of crystallisation were detected for **1** at about 3400 cm^{-1}.

Table 2. IR bands (cm^{-1}) and assignments for compounds **1** and **2**

	1	**2**
dca, ν_{sym} + ν_{asym} (C≡N)	2312i	2352i,2292i
dca, ν_{asym} (C≡N)	2257i	2265i
dca, ν_{sym} (C≡N)	2190i	2225i, 2165i
dca, ν (C−N)	1413m, 1360m	1415i, 1360i
bpm, (C=C, C=N), bis-chelating	1585m	1580i, 1565i
H_2O, crystallisation (O−H)	3410m	−

An X-band ESR spectrum at room temp. was recorded on a powdered sample of **2** doped with 1 mol % Cu (Figure 5). As observed, the signal is characteristic of an axial *g* tensor exhibiting hyperfine splitting on the parallel component which corresponds to the electronic spin−nuclear spin (^{67}Cu, $I = 3/2$) coupling. Values of $g_{\|} = 2.315$, $g_{\perp} = 2.075$ and $A_{\|} = 143 \times 10-4\,cm^{-1}$ have been determined. The sequence $g_{\|} > g_{\perp} > 2.04$ indicates a $d_{x^2-y^2}$ ground state in good agreement with the elongated octahedral topology of the $[CuN_6]$ chromophores.[12]

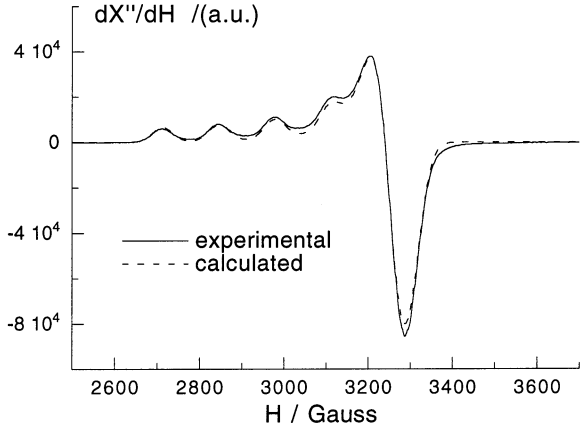

Figure 5. Experimental and calculated ESR powder spectra for $[(Zn_{0.99}Cu_{0.01})_2bpm(dca)_4]$

Magnetic Properties

The magnetic characterisation of compound **1** was carried out by measurement of the thermal variation of the magnetic susceptibility, χ_m. The experimental data, plotted as the thermal variation of the reciprocal susceptibility (χ_m^{-1}) and the product $\chi_m T$ are shown in Figure 6.

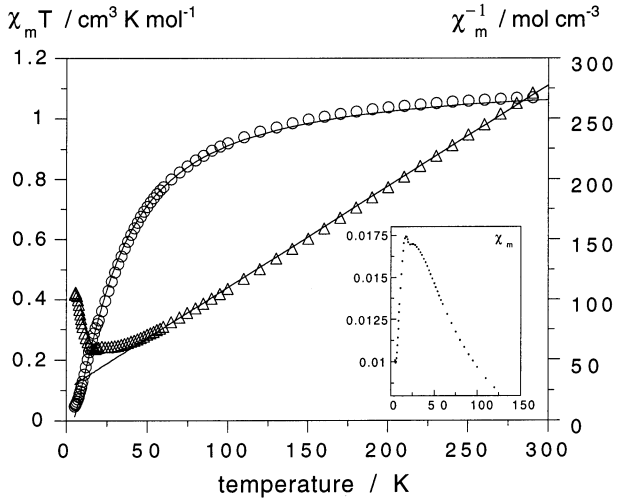

Figure 6. Thermal evolution of χ_m^{-1} and $\chi_m T$ for **1** and their corresponding theoretical curves (fit 2 for $\chi_m T$)

The χ_m values for **1** increase from 3.53×10^{-3} cm^3 mol^{-1} at room temp. up to a maximum, and afterwards decrease, tending to zero. The peak in χ_m shows two maxima (16.54×10^{-3} cm^3 mol^{-1} at 24 K and 16.95×10^{-3} cm^3 mol^{-1} at 17 K). This small anomaly, shown in the inset in Figure 6, will be discussed below. The Curie−Weiss law is followed down to 50 K with values of $C_m = 1.19$ cm^3 K mol^{-1} and $\theta = -30.75$ K. The $\chi_m T$ curve decreases continuously upon cooling from 1.07 cm^3 K mol^{-1} (per Ni atom) at room temp., tending to zero.

The magnetic results for **1** are clearly indicative of the occurrence of antiferromagnetic coupling between metallic centres. Since the dca ligand is a poor magnetic mediator,[13] these interactions should be attributed mainly to the exchange through the bpm ligand.[3,14]

In order to evaluate the antiferromagnetic interactions for **1**, Equation (1) was used first. This expression, based on the isotropic spin Hamiltonian $H = -JS_A \cdot S_B$, accounts for the molar magnetic susceptibility corresponding to a Ni^{II} dimer ($S_A = S_B = 1$).

$$\chi_m = \frac{2N\beta^2 g^2}{kT}\left[\frac{\exp(J/kT) + 5\exp(3J/kT)}{1 + 3\exp(J/kT) + 5\exp(3J/kT)}\right] \quad (1)$$

where *N* and *k* are the Avogadro and Boltzmann constants, respectively, and β is the Bohr magneton.

This model reproduces the experimental data quite accurately with values of $J = -18.3$ cm^{-1} and $g = 2.12$ (fit 1). However, as mentioned above, there is a small anomaly on the χ_m vs. *T* curve for **1** that has not been explained. This anomaly could be attributed to the occurrence of weak ex-

change through the dca bridges at low temperatures that could provoke a slight lack of compensation of the antiparallel spins. If we now consider this exchange as an interdimer molecular field,[3] the magnetic data for **1** can be interpreted by Equation (2). The best theoretical curve generated (fit 2) is displayed in Figure 6 ($J = -16.5$ cm^{-1}, $g = 2.14$ and $zJ' = -3.1$ cm^{-1}). It is worth mentioning that no significant improvement has been found compared to fit 1.

$$\chi = \frac{\chi_m}{\left(1 - \frac{2k}{Ng^2\beta^2} zJ' \chi_m\right)} \quad (2)$$

The sign and magnitude of the exchange constants J calculated for the interaction through bpm is comparable to others found in the literature. Thus, values between -14 and -11 cm^{-1} have been reported for Ni-bpm-Ni bridges.[15] The moderate efficiency of bis-chelating bpm as a magnetic coupler is explained by the strong overlap between $d_{x^2-y^2}$ magnetic orbitals (the x and y axes being the ones corresponding to the $Ni-N_{bpm}$ bonds) through the symmetry-adapted HOMO of the bpm bridge.[16] The fact that the Ni-bpm-Ni fragment is practically planar favours the overlap increasing the magnitude of the coupling.

The isomorphous Co^{II} compound (**3**) has been characterised magnetically by Marshall et al.[3] Compound **3** exhibits antiferromagnetic interactions that are mainly attributed by the authors to the dimeric exchange through bpm (as found for **1**). Unfortunately, since the attempts by Marshall et al. to model the magnetic behaviour of **3** do not lead to any J values, there is no possible comparison between the exchange constants for **1** and **3**.

Conclusion

The combined use of dca and bpm has led to the preparation of extended frameworks with two Ni^{II} and Zn^{II} atoms. The antiferromagnetic Ni^{II} compound exhibits a 2D array where ladder-like units are connected through double dca bridges. The bpm ligands are the steps in the ladder-like moieties, their extension taking place through single dca bridges. Molecules of water of crystallisation can be found between the resulting waved planes. The Zn^{II} compound is anhydrous and exhibits the same kind of ladder-like units. In this case, however, each unit is connected to another four through single dca bridges resulting in a 3D array.

Experimental Section

Synthesis: The synthesis of compound **1** was carried out by mixing an aqueous solution of $Ni(NO_3)_2\cdot 6H_20$ (0.50 mmol) and a methanolic solution of bpm (0.25 mmol). Afterwards, an aqueous solution of dca (1 mmol) was added and left to stand at room temperature. After several days, poor-quality blue crystals were obtained (45% yield, 62.57 mg). Unfortunately, further attempts to recrystallise this product did not lead to better quality crystals. The synthesis of compound **2** was performed in a similar manner with $ZnCl_2$. In this case, prismatic, yellow, X-ray quality single crystals (34% yield, 62.22 mg) were obtained.

Elemental analysis and atomic absorption results were in good agreement with the $C_8H_3N_8NiO_{0.5}$ stoichiometry for **1**, and the $C_8H_3N_8Zn$ stoichiometry for **2**.
1: calcd. C 34.4, H 1.4, N 40.2, Ni 21.0; found C 33.0, H 1.7, N 38.3, Ni 21.2.
2: calcd. C 34.7, H 1.1, N 40.5, Zn 23.6; found C 34.5, H 1.0, N 39.3, Zn 23.1.

Physical Measurements: Microanalyses were performed with a LECO CHNS-932 analyser. Analytical measurements were carried out in an ARL 3410 + ICP with a Minitorch equipment. IR spectroscopy was performed on a Nicolet 520 FTIR spectrophotometer in the 400−4000 cm^{-1} region. ESR spectroscopy was performed on powdered samples at the X-band frequency, with a Bruker ESR 300 spectrometer equipped with a standard OXFORD low-temperature device, which was calibrated by the NMR probe for the magnetic field. The frequency was measured with a Hewlett−Packard 5352B microwave frequency computer. Magnetic susceptibilities and the magnetisation of powdered samples were carried out in the temperature range 1.8−300 K at values of the magnetic field up to 10000 G, using a Quantum Design Squid magnetometer, equipped with a helium continuous-flow cryostat. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal tables).

Crystal Structure Determination: X-ray powder diffraction data for compound **1** were collected on a PHILIPS X′PERT powder diffractometer with Cu-K_α radiation in steps of 0.02° (2θ) over the 5−60° (2θ) angular range and a fixed-time counting of 4 seconds at 25 °C. The powder diffraction patterns were indexed with the FULLPROF[16] program based on the Rietveld method[17−18]using the *Profile Matching* option. Crystallographic data and processing parameters for compound **1** are given in Table 3.

X-ray measurements for **2** were carried out at room temperature on an Enraf−Nonius CAD-4 diffractometer operating in the ω/2θ scanning mode. Accurate lattice parameters were determined from a least-squares refinement of 25 well-centred reflections. Intensity data were collected in the θ range 1−30°. During data collection, two standard reflections observed periodically showed no signific-

ant variation. Corrections for Lorentz and polarisation factors were applied to the intensity values. The structure for **2** was solved by heavy-atoms Patterson methods using the program SHELXS-97[19] and refined by a full-matrix least-squares procedure on F^2 using SHELXL-97.[20] Non-hydrogen atomic scattering factors were taken from International Tables of X-ray Crystallography.[21] Crystallographic data and processing parameters for **2** are shown in Table 4.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-150936 (**2**) and -150937 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Syntheses, Structures and Nonlinear Optical Properties of Ferrocenyl Complexes with Arylethenyl Substituents

José A. Mata,[a] Eduardo Peris,*[a] Rosa Llusar,[b] Santiago Uriel,[b] Marie P. Cifuentes,[c] Mark G. Humphrey,*[c] Marek Samoc,[d] and Barry Luther-Davies[d]

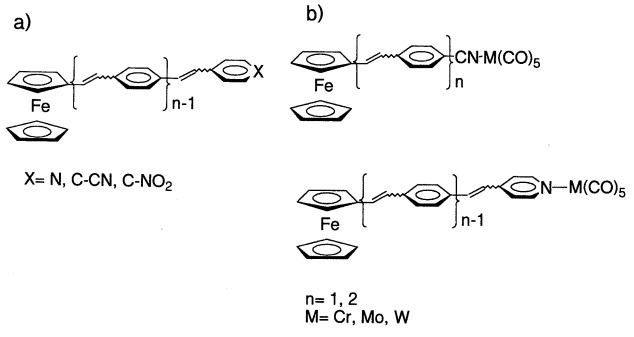
Keywords: Ferrocene / NLO / Bimetallic compounds / Crystal structure

The complexes (*E*)- and (*Z*)-Fe(η^5-C_5H_4CHO)(η^5-C_5H_4CH=CH–C_6H_4-4-NO_2) [**2**-(*E*) and **2**-(*Z*), respectively], (*E*)- and (*Z*)-Fe(η^5-C_5H_4CHO)(η^5-C_5H_4CH=CH–C_6H_4-4-CN) [**3**-(*E*) and **3**-(*Z*), respectively], (*E*,*E*)-, (*E*,*Z*)-, and (*Z*,*Z*)-Fe(η^5-C_5H_4CH=CHC_6H_4-4-NO_2)$_2$ [**4**-(*E*,*E*), **4**-(*E*,*Z*), and **4**-(*Z*,*Z*), respectively], (*E*,*E*)-, (*E*,*Z*)-, and (*Z*,*Z*)-Fe(η^5-C_5H_4CH=CHC_6H_4-4-CN)$_2$ [**5**-(*E*,*E*), **5**-(*E*,*Z*), and **5**-(*Z*,*Z*), respectively], and Fe(η^5-C_5H_5)(η^5-C_5H_4–(*E*)-CH=CH–4-{(η^6-C_6H_4)$Cr(CO)_3$}–(*E*)-CH=CH–η^5-C_5H_4)Fe(η^5-C_5H_5) (**7**) have been synthesized. Structural studies on **2**-(*E*), **4**-(*E*,*Z*), **5**-(*E*,*E*), Fe(η^5-C_5H_5){η^5-C_5H_4–(*E*)-CH=CH–4-C_6H_4–(*E*)-CH=CH–η^5-C_5H_4}Fe(η^5-C_5H_5) (**6**) and **7** have been performed. Electrochemical studies of **2**–**5** reveal trends in the oxidation potentials which are consistent with the more effective conjugation of the (*E*) isomers, and the better electron-accepting character of NO_2 than CN and of CHO than H. Powder SHG measurements by the Kurtz technique using fs pulses at the telecommunications wavelength of 1.3 μm reveal low responses for **4**-(*E*,*E*), **5**-(*E*,*E*), and **7**. Third-order NLO measurements by Z-scan using fs pulses at 800 nm suggest an increase in |γ| on increasing the electron-acceptor strength [when proceeding from **5**-(*E*,*Z*) to **4**-(*E*,*Z*), CN is replaced by NO_2], and on introduction of the $Cr(CO)_3$ unit, when proceeding from **6** to **7**.

Introduction

Ferrocene is a versatile building block. Its excellent thermal and photochemical stability, and combination of useful redox properties and chemical versatility, provides access to materials with potentially useful physical and chemical properties.[1–3] With the importance of ferrocene in the field of material science, there is currently great interest in the chemistry of ferrocenyl-based oligomers and ferrocenyl-containing conjugated compounds. The former contain the ferrocene building block in the repeat unit, and the latter couple ferrocene to a potentially π-delocalizable system. These complexes are of interest because of, amongst other things, their nonlinear optical (NLO) properties; the significant electron-donating strength of the ferrocenyl group has made it a good candidate for the design of chromophores with high NLO responses.

We previously reported on the syntheses, characterization, and molecular quadratic NLO behavior of ferrocene-containing conjugated compounds with pyridine, nitro, and nitrile pendant groups. This allowed us to obtain heterobimetallic complexes containing a series of electron-accepting moieties derived from $M(CO)_6$ (M = Cr, Mo, W) [Scheme 1 (a) and (b)].[4–6] Electrochemical studies together with the planar conformation of the molecular structures suggested effective electron delocalization along the conjugated chains. In a continuation of these studies, we have now synthesized a series of ferrocenyl 1,1′-bis-substituted complexes with nitro and nitrile pendant groups, whose electronic and solid-state structural properties have been studied. The results from these studies are reported herein. Similar 1,1′-bis-substituted ferrocenyl complexes with pendant pyridine groups have been reported by Lee et al., and show very interesting structural features.[7]



Scheme 1

We have also investigated arylethenyl-linked biferrocenes, with and without the presence of bridge arene-ligated $Cr(CO)_3$ units, the syntheses of which were reported by Müller et al.[8] while the current studies were underway. We

report herein a modified synthesis of the $Cr(CO)_3$-ligated complex, together with X-ray structural studies of both complexes.

Although the number of studies reporting second-order NLO responses of ferrocenyl complexes is very high, comparatively fewer studies exist in which third-order NLO responses are reported.[9] Since the effective delocalization in the molecular structures of our complexes fulfill a basic requirement for third-order NLO-active materials, we have measured and report herein on their cubic hyperpolarizabilities at 800 nm by Z-scan. While the bulk second-order susceptibilities of many ferrocenyl complexes have been reported,[10] much extant data has been obtained at wavelengths close to those of material resonances, resulting in significant resonance enhancement of the response. We therefore also report the bulk susceptibilities for these complexes by the Kurtz powder method at wavelengths remote from electronic absorption bands, thus enabling an assessment of off-resonance nonlinearity to be obtained.

Results and Discussion

Syntheses of 2−5

Based on our previous experience[4−6] we have synthesized compounds **2**−**5** by conventional Wittig and Horner−Emmons−Wadsworth methods (Scheme 2). The first step of the two-step reaction procedure afforded the bis-substituted complexes **2** and **3** with (*Z*) and (*E*) stereochemistry, together with small amounts of the bis-olefinated complexes (**4** and **5** in all their isomeric forms). Compounds **2** and **3** may be of interest in the design of new materials, since the presence of the carboxaldehyde group may provide access to a variety of functional groups. Complexes **2** and **3** undergo further olefination in the second step to yield **4** and **5** in all their isomeric forms [**4** and **5** exist as three isomers by combination of the (*E*) and (*Z*) dispositions of the vinylic group, i.e. (*E,E*), (*E,Z*) and (*Z,Z*)]. All three isomers were fully characterized for both the nitro and nitrile derivatives. Higher yields of the bis-substituted compounds **4** and **5** were obtained when performing the one-step (direct reaction) procedure. In all cases, separation of the (*E*) and (*Z*) isomers was easily achieved by column chromatography. Reaction of any of the complexes in refluxing toluene in the presence of iodine leads to the all-*E*-isomers in almost quantitative yields (see Experimental section).

Synthesis of 7

The synthesis of **6** was again based on Horner−Emmons−Wadsworth (HEW) olefinations using the corresponding phosphonate reagent. A synthesis of **7** was reported while the present studies were underway,[8] and involved olefination by HEW reaction of an η^6-coordinated carbonylchromium phenylene-bisphosphonate with ferrocenecarboxaldehyde. In the present study, η^6-coordination of the tri(carbonyl)chromium moiety to the phenylene bridging group of **6** was performed by heating compound **6** with $Cr(CO)_6$ in refluxing butyl ether (Scheme 3).

X-ray Structural Studies of 2-(*E*), 4-(*E,Z*), 5-(*E,E*), 6, and 7

The identities of **2**-(*E*) (ORTEP plots in Figures 1 and 2), **4**-(*E,Z*) (Figure 3), **5**-(*E,E*) (Figures 4 and 5), **6** (Figure 6), and **7** (Figure 7) were confirmed by single-crystal X-ray studies; crystallographic data are summarized in Table 5, and selected bond angles and distances are listed in Tables 1 and 2.

The structural studies reveal a number of interesting features. Complexes **2**-(*E*), **4**-(*E,Z*), and **5**-(*E,E*) provide the opportunity to assess the impact of π-system chain lengthening, stereochemistry, and acceptor modification on metrical parameters and crystal packing preference. In

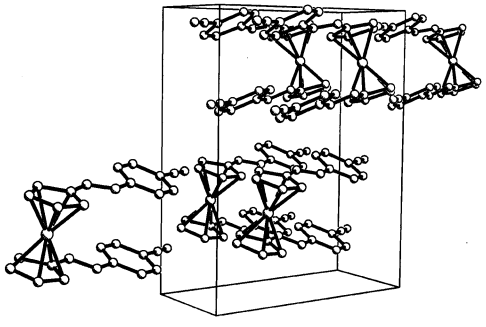

Figure 5. Cell packing diagram for **5**-(*E,E*), Fe{η^5-C_5H_4−(*E*)-CH=CHC_6H_4-4-CN}$_2$

ferrocenyl complexes, it has been reported that two molecular motions relieve steric strain:[1] (i) the rotation from an eclipsed to a staggered disposition of the two Cp rings and (ii) their tilting from a parallel disposition. For these three complexes, little tilting is observed; the two cyclopentadienyl rings are slightly tilted (dihedral angles 2.7−4.3°) with respect to each other. Compounds **2**-(*E*), **4**-(*E,Z*), and **5**-(*E,E*) show *syn* conformations with respect to the two ancillary ligands, with a perfect eclipsed disposition of the Cp rings of the ferrocene unit in **2**-(*E*) and **5**-(*E,E*).

The distances from iron to the cyclopentadienyl rings and the C−C distances within the rings in these three structures, lie in the expected range. As seen in Figures 1, 2, 3, and 4, all the molecules with (*E*) stereochemistry have an almost idealized coplanar arrangement between the ferrocenyl donor and the vinylene-phenylene functionalized fragment. The two ancillary ligands in compound **5**-(*E,E*) show intra-

molecular π-stacking, as can be clearly seen in Figure 4; the two ligands smoothly increase their separation from 3.44 [C(20)−C(11)] to 3.92 Å [N(1)−N(2)]. In the crystal lattice of compound **2**-(*E*), centrosymmetric dimer pairs are connected by hydrogen-bonding through the oxygen and hydrogen atoms of the aldehyde group (Figure 2). This hydrogen-bond of the type C−H···O is pervasive in crystalline organometallic transition metal complexes, especially when the C−H is of the sp^2 type.[11] In our case, the oxygen atom of the aldehyde polarizes the C−H bond enhancing its H-donor capabilities. Compound **5**-(*E,E*) crystallizes in the noncentrosymmetric space group $P2_1$. The crystal arrangement of **5**-(*E,E*) (Figure 5), despite being noncentrosymmetric, reveals an anti-parallel alignment of the molecular dipoles, therefore low second-harmonic generation (SHG) is expected for the bulk material. This canceling of the molecular dipoles has also been observed for other noncentrosymmetric ferrocenyl compounds.[12]

Compounds **6** and **7** both crystallize in the centrosymmetric space group $P2_1/c$, the inversion center for compound **6** is located in the middle of the phenyl ring. The crystallographic inversion center lies very close to the chromium atom, generating another molecule with a face to face disposition when compared with the previous one, thus resulting in disorder. The bond lengths and angles in **6** lie in the expected range,[13] with the ferrocenyl units adopting the sterically less hindered *anti* conformation. The cyclopentadienyl and phenyl rings in **6** are roughly coplanar (maximum dihedral angle 3.37°). The bond lengths and angles in **7** lie in the expected range, except the Cr−C−O angles which are significantly distorted from linearity (ca. 167°). The most significant structural feature of **7** is the *syn*/*syn* conformation adopted by the two ferrocenyl and the tri(carbonyl)chromium units. The two substituted-cyclopentadienyl rings and the phenyl group are more distorted from coplanarity (maximum dihedral angle 5.03°) than the similar rings in compound **6**.

The Fe−Cr distances in **7** are 6.1 Å (through space) and 8.2 Å (through bonds), so a direct bonding effect must be discounted. In the absence of conclusive theoretical calculations, we believe that the more sterically hindered disposition of the ligated metal units may be due to packing effects. In fact, this kind of disposition has also been observed in other related compounds.[14]

Cyclic Voltammetry

The electrochemical data obtained for complexes **2**−**5** are summarized in Table 3. In all cases, we observed the chemically reversible ferrocene/ferrocenium couple with $i_{pa}/i_{pc} = 1$. Although the peak to peak separations in all the compounds are greater than the ideal value for a fully reversible one-electron process, this difference ($E_{pc} - E_{pa}$) is similar to that measured for ferrocene under the conditions of the experiment. When compared with the previously reported ferrocenyl derivatives with one 4-nitrophenylethenyl or 4-cyanophenylethenyl substituent,[4−6] the bis-substituted complexes show a more anodic half-wave potential (ca. 100 mV), suggesting that the extra electron-accepting substituent has an important electronic effect on the ferrocenyl fragment. When comparing complexes with analogous stereochemical features, the nitro compounds **4** have a higher oxidation potential than the homologous nitrile derivatives **5**, thus confirming the better electron-accepting nature of the nitro group. The complexes with a higher degree of (*E*) stereochemistry (i.e. *E,E* > *E,Z* > *Z,Z*) possess a lower half-wave potential than those with a higher degree of (*Z*) stereochemistry (half-wave potential **4**-(*E,E*) < **4**-(*E,Z*) < **4**-(*Z,Z*) and **5**-(*E,E*) < **5**-(*E,Z*) < **5**-(*Z,Z*)]. This is in good agreement with the greater stabilization of the positive charge corresponding to the more effective conjugation of the (*E*) isomers, and indicates a higher degree of charge transfer from the metal center to the polyene backbone.[5,6,15] The aldehydes **2** and **3** possess a much higher half-wave potential than the ferrocenyl complexes with one 4-nitrophenylethenyl or 4-cyanophenylethenyl substituent,[4−6] perhaps due to the electron-accepting nature of the aldehyde group. The substitution of the aldehyde group by the corresponding conjugated ligand to give **4** and **5**, results in a shift to more cathodic potentials, probably as a consequence of the enhanced stabilization of the positive charge of the resultant ferrocenium species at the two conjugated ancillary ligands.

Literature electrochemical data suggest that biferrocene complexes similar to **6** and **7** do not show effective electronic communication between the two ferrocene moieties.[8,13] For such complexes, and homologues with pentamethylcyclopentadienyl ligands, only one peak is observed for the oxidation of the iron atoms. However, the potential for this two-electron oxidation is sensitive to modification of the bridging unit; electrochemical data for compound **7** shows that the oxidation of the iron atom is clearly influenced by the carbonyl fragment. A shift from 455 mV in compound **6** to 351 mV in **7** is consistent with oxidation of the ferrocene centers which is facilitated by incorporation of the chromium carbonyl unit.[8] In fact, one would expect that the electron-accepting nature of chromium tricarbonyl should increase the oxidation potential of the compound in contrast to what we observed. The same effect has been described by Müller for compound **7** and other related ferrocenyl-chromium tricarbonyl complexes[8] and, in fact, may be justified by the amphoteric character of $Cr(CO)_3$ proposed by the same author and his co-workers.[16]

Electronic Spectra

Table 3 contains the electronic spectroscopic data for the bis-substituted complexes **2**−**5**. In a typical electronic spectrum of substituted ferrocenyl complexes, two prominent bands are often observed in the range of 500 to 300 nm. The more energetic band (300−360 nm) is assigned to a π−π* intra-ligand transition, and the less energetic band (400−500 nm) is assigned to a metal to ligand charge-transfer band (MLCT). A weak band at higher wavelengths (about 500 nm), assigned to a *d-d* transition, is only discernible in some cases as a shoulder on the MLCT band, and is not shown in Table 3. This assignment is in accordance to the theoretical results reported by Barlow et al. (model III in ref.[17]) and to other experimental results,[5,6,12,18−23] although we are aware that some controversy about this assignment has been reported.[24] The MLCT band is influenced by the nature of the ancillary ligand, showing a hypsochromic shift on increasing the (*E*) character of the complex. The more intense π-π* band shows a similar dependence on the nature of the ligand; this is because the (*E*) stereochemistry promotes a more effective conjugation than the (*Z*) stereochemistry, thus lowering the energy of the π* orbital. Solvatochromism affords an idea of the dipole moments in the ground and in the excited states. These are related to hyperpolarizability, and therefore solvatochromism is a useful indicator for the potential for second-order NLO behavior. The bis-substituted ferrocenyl complexes show moderate solvatochromic behavior across the solvents surveyed.

Kurtz Powder Studies

Kurtz powder measurements were performed on **4**-(*E,Z*), **4**-(*Z,Z*), **4**-(*E,E*), **5**-(*E,Z*), **5**-(*E,E*), **6**, and **7**. Initial studies using ns pulses at 1.064 μm suggested the doubling of the frequency for a number of samples (green flashes were observed when the samples were irradiated), but absorption associated with the MLCT bands in these complexes rendered these results qualitative at best. A second qualitative test at the important telecommunications wavelength of 1.3 μm using fs pulses again suggested the doubling of the frequency (red flashes were observed for most complexes). A third qualitative test at 1.4 μm confirmed this result. Importantly, all complexes are transparent at both the fundamental and second-harmonic frequencies corresponding to the wavelength of 1.3 μm, so the SHG merit of these complexes was quantified against an urea standard, the results for which are summarized in Table 4.

Complexes **4**-(*E,Z*), **4**-(*Z,Z*), and **5**-(*E,Z*) showed a relatively strong emission with a significant blue component; this may be due to other NLO processes, and it masks any SHG which may be present, rendering further discussion of these complexes unwarranted. The ferrocene-containing conjugated compounds **4**-(*E,E*) and **5**-(*E,E*) both gave significant responses. Noncentrosymmetric crystal packing is a requirement for observable SHG, therefore it is worthy to note that the structural study of **5**-(*E,E*) reveals a lack of a center of symmetry in the crystal lattice. Complex **6** shows no observable SHG at 1.3 μm, in contrast to the $Cr(CO)_3$-ligated complex **7**. Both complexes crystallize in the centrosymmetric space group $P2_1/c$. The observed SHG for the centrosymmetric **7** is not unique; similar observations for $[Ru(C{=}CPhN{=}N{-}4\text{-}C_6H_4OMe)(PPh_3)_2(\eta^5\text{-}C_5H_5)]BF_4$[25] and $[(\eta^5\text{-}C_5H_5)(CO)_2Fe(\mu\text{-}CO)\{\mu\text{-}(E)\text{-}CH{=}CH{-}4\text{-}C_6H_4\text{-}NMe_2\}Fe(CO)_2(\eta\text{-}C_5H_5)]BF_4$,[26] both of which pack in centrosymmetric space groups, were assigned to effects originating in the noncentrosymmetric crystal surface, small contributions from a noncentrosymmetric phase, or minor deviations from centrosymmetry. Electron diffraction studies to resolve this ambiguity were similarly inconclusive.

The results of the present series of samples emphasize the challenges inherent in translating significant molecular nonlinearities to useful bulk susceptibilities. Thus, while $Fe(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4{-}(Z)\text{-}CH{=}CH{-}4\text{-}C_6H_4NO_2)$ is reported to give SHG with an efficiency 62 times that of urea,[19,26–28] incorporation of a further 4-nitrophenylethenyl group in proceeding to **4**-(*E,Z*) or **4**-(*Z,Z*), results in complexes for which observable SHG could not be determined unambiguously.

Third-Order NLO Studies

Third-order nonlinearities of **4**-(*Z,Z*), **5**-(*E,E*), **6**, and **7** were evaluated by the Z-scan technique at 800 nm;[29] the results of these measurements are given in Table 4. Complex **4**-(*E,E*) was insufficiently soluble, in both dichloromethane and THF, to afford useful data.

Early studies of ferrocenyl complexes by optical power limiting afforded very high nonlinearities (10^{-32} to 10^{-31} esu),[30–32] but this technique is carried out on a ns time scale, and contributions from thermal effects may exist. For structure-activity studies, it is more useful to use Z-scan with fs pulses, as in the present study. The cubic nonlinearities $|\gamma|$ of these new ferrocenyl complexes are of the same magnitude as those of related conjugated ferrocenyl complexes examined by degenerate four-wave mixing (DFWM).[33]

One advantage of Z-scan relative to DFWM is that one can readily determine the real and imaginary components of the cubic hyperpolarizabilities, (these are also listed in Table 4). We have previously used Z-scan to study the cubic hyperpolarizabilities of acetylide complexes,[34–40] for which most real components are large and negative, and imaginary components are large, indicative of significant two-photon dispersion effects. The real components of the nonlinearities γ_r for the present series of complexes are large and positive and, with the exception of **4**-(*E,Z*), the imaginary components γ_i are small; two-photon effects are therefore likely to be minor, permitting cautious comment on the effect of structural variation on cubic NLO merit. Replace-

[a] All solution measurements (linear optical spectra, third-order NLO studies) in THF as solvent. All complexes are optically transparent at 1.3 μm and 800 nm. – [b] Bulk second-order responses by the Kurtz powder method at 1.3 μm. – [c] Third-order NLO measurements by Z-scan at 800 nm, referenced to the nonlinear refractive index of silica $n_2 = 3{\cdot}10^{-16}$ cm$^2{\cdot}$W^{-1}. – [d] Not determined unambiguously. – [e]Insufficiently soluble.

ment of CN by NO_2 in proceeding from **5**-(*E,Z*) to **4**-(*E,Z*), leads to a significant increase in both γ_r and $|\gamma|$; increase in acceptor-strength leads to increased quadratic nonlinearity in dipolar organometallic complexes,[10] and a similar increase in cubic nonlinearity for the present complexes on increasing acceptor-strength is not unexpected. Errors do not permit comment on the effect of bridge stereochemistry modification on γ_r and $|\gamma|$. The linked complex **6** has substantial γ_r and $|\gamma|$ values despite the absence of a molecular dipole; a large cubic nonlinearity ($\gamma = 504 \pm 52 \times 10^{-36}$ esu, as measured by DFWM at 0.60 μm) was reported for a complex with this composition in earlier work, although the bridge stereochemistry was not specified.[33] Interestingly, incorporation of the bridge-ligated $Cr(CO)_3$ unit in proceeding from **6** to **7**, results in an increase in both γ_r and $|\gamma|$. Recent studies concluded that the $Cr(CO)_3$ unit behaves as an electronically amphoteric auxochrome in chromium carbonyl arene complexes with conjugated side-chains,[16] resulting in significant quadratic nonlinearities for complexes with donor- or acceptor- substituents on the side-chain. In the present system, complex **6** has a donor-bridge-donor composition, whereas our electrochemistry studies suggest that **7** has a donor-donor-donor composition; the increase in the ease of oxidation in proceeding from **6** to **7** probably correlates with an increase in the ease of polarization of electron density, and may be responsible for the increased cubic nonlinearity.

Experimental Section

General Remarks: All reactions were carried out under a nitrogen atmosphere using standard Schlenk techniques. Solvents for synthesis and electrochemical measurements were dried and deoxygenated by standard methods before use. Chromatographic work was performed on silica gel 60 Å or neutral alumina columns.

NMR spectra were recorded on Varian Innova 300 MHz and 500 MHz spectrometers, using $CDCl_3$ as solvent unless otherwise stated. − IR spectra were recorded on a Perkin−Elmer System 2000 FT-IR using NaCl pellets. − Electronic absorption spectra were obtained on a UV-1603 Shimadzu spectrophotometer. − Elemental analyses were performed on a EA 1108 CHNS-O Carlo Erba instrument. − Cyclic voltammetry experiments were performed with a Echochemie pgstat 20 electrochemical analyzer. All measurements were carried out at room temperature with a conventional three-electrode configuration consisting of platinum working and auxiliary electrodes and a Ag/AgCl reference electrode containing aqueous 3 M KCl. The solvent used in all experiments was CH_2Cl_2, which was obtained in HPLC grade and used as received. The supporting electrolyte was 0.1 M tetra-*n*-butylammonium hexafluorophosphate, synthesized by reaction of tetra-*n*-butylammonium bromide and HPF_6, recrystallized from ethanol and dried under vacuum. $E_{1/2}$ values were determined as $(E_{p,a} + E_{p,c})/2$, where $E_{p,a}$ and $E_{p,c}$ are the anodic and cathodic peak potentials, respectively. All reported potentials are not corrected for the junction potential. − Electrospray mass spectra were recorded using a Micromass Quattro LC instrument, using CH_3CN and/or CH_3OH as the mobile phase solvent. The samples were added to give a mobile phase with an approximate concentration of 0.1 mM. This solution was injected into the spectrometer via a Rheodyne injector fitted with a 10 μL sample loop, and nitrogen was employed as a drying and nebulizing gas. − $Fe(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4\text{-}(E)\text{-}CH{=}CH\text{-}4\text{-}C_6H_4\text{-}(E)\text{-}CH{=}CH\text{-}\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_5)$ (**6**) was synthesized by literature procedures.[41,42]

1. Preparation of (*E*)- and (*Z*)-Fe(η⁵-C₅H₄CHO)(η⁵-C₅H₄CH=CH−C₆H₄-4-NO₂) (2) and (*E*)-and (*Z*)-Fe(η⁵-C₅H₄CHO)(η⁵-C₅H₄CH=CH−C₆H₄-4-CN) (3): Potassium *tert*-butoxide (258 mg, 2.3 mmol) was added to a solution of 4-nitrobenzyltriphenylphosphonium bromide (988 mg, 2.1 mmol), or 4-cyanobenzyltriphenylphosphonium bromide (963 mg, 2.1 mmol) in THF (100 mL) at 0 °C, and the resulting suspension was allowed to warm to room temperature. After 30 min, the yellow-orange suspension indicated that the ylide was completely formed. 1,1′-Ferrocenebis(carboxaldehyde), **1** (500 mg, 2.1 mmol), was then added at 0 °C and the solution was stirred for ca. 15 h at room temperature. After removing the solvent under reduced pressure, the product was separated with a $CH_2Cl_2/H_2O/NaHCO_3$ mixture and the dichloromethane extract dried with $MgSO_4$. Purification by column chromatography on silica gel using hexane/CH_2Cl_2 (3:7) as the eluent afforded pure **2**-(*E*), **2**-(*Z*), **3**-(*E*), and **3**-(*Z*), although **3**-(*Z*) was obtained in such a low yield that only spectroscopic characterization could be achieved.

Compound 2-(*E*), Fe(η⁵-C₅H₄CHO){η⁵-C₅H₄−(*E*)-CH=CH−C₆H₄-4-NO₂}: Yield 35%. − ^{1}H NMR (500 MHz, $CDCl_3$): δ = 9.90 (s, 1 H, CHO); 8.20 (d, 2 H, $^3J_{H\text{-}H}$ = 8.4 Hz, C_6H_4); 7.56 (d, 2 H, $^3J_{H\text{-}H}$ = 8.1 Hz, C_6H_4); 6.96 (d, 1 H, $^3J_{H\text{-}H}$ = 16.2 Hz, CH=CH); 6.76 (d, 1 H, $^3J_{H\text{-}H}$ = 15.9 Hz, CH=CH); 4.78 (s, 2 H, C_5H_4); 4.62 (s, 2 H, C_5H_4); 4.58 (s, 2 H, C_5H_4); 4.46 (s, 2 H, C_5H_4). − ^{13}C NMR (500 MHz, $CDCl_3$): δ = 69.4, 71.5, 71.9, 75.0 (8 C, C_5H_4); 80.6, 84.3 (2 Cq, C_5H_4); 124.8, 126.2, 126.9, 131.2 (6 C, CH=CH and C_6H_4); 144.3, 146.9 (2 Cq, C_6H_4); 194.1 (1 C, CHO). − $C_{19}H_{15}FeNO_3$ (361.18): calcd. C 63.20, H 4.19, N 3.88; found C 63.53, H 4.27, N 3.80.

Compound 2-(*Z*), Fe(η⁵-C₅H₄CHO){η⁵-C₅H₄−(*Z*)-CH=CH−C₆H₄-4-NO₂}: Yield 17%. − ^{1}H NMR (500 MHz, $CDCl_3$): δ = 9.87 (s, 1 H, CHO); 8.14 (d, 2 H, $^3J_{H\text{-}H}$ = 8.5 Hz, C_6H_4); 7.43 (d, 2 H, $^3J_{H\text{-}H}$ = 8.0 Hz, C_6H_4); 6.55 (d, 1 H, $^3J_{H\text{-}H}$ = 12.0 Hz, CH=CH); 6.39 (d, 1 H, $^3J_{H\text{-}H}$ = 12.0 Hz, CH=CH); 4.74 (s, 2 H, C_5H_4); 4.54 (s, 2 H, C_5H_4); 4.31 (s, 2 H, C_5H_4); 4.23 (s, 2 H, C_5H_4). − ^{13}C NMR (500 MHz, $CDCl_3$): δ = 71.3, 71.4, 71.5, 75.0 (8 C, C_5H_4); 81.1, 83.0 (2 Cq, C_5H_4); 124.2, 127.4, 130.1, 130.4 (6 C, CH=CH and C_6H_4); 145.2, 147.2 (2 Cq, C_6H_4); 193.8 (1 C, CHO). − $C_{19}H_{15}FeNO_3$ (361.18): calcd. C 63.20, H 4.19, N 3.88; found C 63.01, H 4.07, N 3.79.

Compound 3-(*E*), Fe(η⁵-C₅H₄CHO){η⁵-C₅H₄−(*E*)-CH=CH−C₆H₄-4-CN}: Yield 40%. − ^{1}H NMR (500 MHz, $CDCl_3$): δ = 9.90 (s, 1 H, CHO); 7.62 (d, 2 H, $^3J_{H\text{-}H}$ = 7.5 Hz, C_6H_4); 7.52 (d, 2 H, $^3J_{H\text{-}H}$ = 8.0 Hz, C_6H_4); 6.89 (d, 1 H, $^3J_{H\text{-}H}$ = 16.0 Hz, CH=CH); 6.72 (d, 1 H, $^3J_{H\text{-}H}$ = 16.0 Hz, CH=CH); 4.79 (s, 2 H, C_5H_4); 4.60 (s, 2 H, C_5H_4); 4.58 (s, 2 H, C_5H_4); 4.44 (s, 2 H, C_5H_4). − ^{13}C NMR (500 MHz, $CDCl_3$): δ = 69.3, 71.5, 71.7, 74.9 (8 C, C_5H_4); 80.7, 84.6 (2 Cq, C_5H_4); 110.9 (1 C, CN); 126.8, 127.1, 130.1, 133.3 (6 C, CH=CH and C_6H_4); 119.8, 142.4 (2 Cq, C_6H_4); 194.2 (1 C, CHO). − $C_{20}H_{15}FeNO$ (341.19): calcd. C 70.43, H 4.43, N 4.11; found C 70.12, H 4.17, N 4.25. − Electrospray MS. Cone 60 V. *m/z* (fragment): 364 [M^+ + Na].

Compound 3-(*Z*), Fe(η⁵-C₅H₄CHO){η⁵-C₅H₄−(*Z*)-CH=CH−C₆H₄-4-CN}: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 9.86 (s, 1 H, CHO); 7.56 (d, 2 H, $^3J_{H\text{-}H}$ = 8.1 Hz, C_6H_4); 7.38 (d, 2 H, $^3J_{H\text{-}H}$ = 8.4 Hz, C_6H_4); 6.50 (d, 1 H, $^3J_{H\text{-}H}$ = 12.0 Hz, CH=CH); 6.33 (d, 1 H, $^3J_{H\text{-}H}$ = 12.0 Hz, CH=CH); 4.73 (t, 2 H, $^3J_{H\text{-}H}$ = 1.8 Hz, C_5H_4);

4.54 (t, 2 H, $^3J_{H-H}$ = 1.8 Hz, C_5H_4); 4.30 (t, 2 H, $^3J_{H-H}$ = 1.8 Hz, C_5H_4); 4.22 (t, 2 H, $^3J_{H-H}$ = 1.8 Hz, C_5H_4).

2. Preparation of (*E,E*)-, (*E,Z*)-, and (*Z,Z*)-Fe{η^5-C_5H_4CH=CHC_6H_4-4-NO_2)$_2$ (4) and (*E,E*)-, (*E,Z*)-, and (*Z,Z*)-Fe{η^5-C_5H_4CH=CHC_6H_4-4-CN}$_2$ (5): These compounds were prepared by two different procedures.

(i) Potassium *tert*-butoxide (202 mg, 1.8 mmol) was added to a solution of 4-nitrobenzyltriphenylphosphonium bromide (706 mg, 1.5 mmol), or 4-cyanobenzyltriphenylphosphonium bromide (688 mg, 1.5 mmol) in THF (100 mL) at 0 °C, and the resulting suspension was allowed to warm to room temperature. After 30 min, the yellow-orange suspension indicated that the ylide was completely formed. Compound **2** or **3** (1.0 mmol) was then added at 0 °C and the solution was stirred for ca. 15 h at room temperature. After removing the solvent under reduced pressure, the product was separated with a CH_2Cl_2/H_2O/$NaHCO_3$ mixture, and the CH_2Cl_2 extract dried with $MgSO_4$. Purification by column chromatography on silica gel using hexane/CH_2Cl_2 (6:4) as the eluent afforded pure compounds **4**-(*E,Z*), **4**-(*Z,Z*), **4**-(*E,E*), **5**-(*E,Z*), **5**-(*Z,Z*), and **5**-(*E,E*).

(ii) Following the same general method described for compounds **2** and **3**, but using a threefold (3.0 mmol) excess of the phosphonium salt with 1.0 mmol Fe(η^5-$C_5H_4CHO)_2$ (**1**), afforded the complexes in higher yields.

Compound 4-(*E,Z*), Fe{η^5-C_5H_4−(*Z*)-CH=CHC_6H_4-4-NO_2}{η^5-C_5H_4−(*E*)-CH=CHC_6H_4-4-NO_2}: Yield 25%. − ^{1}H NMR (500 MHz, $CDCl_3$): δ = 8.21 (d, 2 H, $^3J_{H-H}$ = 8.5 Hz, C_6H_4); 8.07 (d, 2 H, $^3J_{H-H}$ = 8.5 Hz, C_6H_4); 7.53 (d, 2 H, $^3J_{H-H}$ = 8.5 Hz, C_6H_4); 7.38 (d, 2 H, $^3J_{H-H}$ = 8.0 Hz, C_6H_4); 6.98 (d, 1 H, $^3J_{H-H}$ = 16.0 Hz, CH=CH); 6.70 (d, 1 H, $^3J_{H-H}$ = 16.0 Hz, CH=CH); 6.40 (d, 1 H, $^3J_{H-H}$ = 11.5 Hz, CH=CH); 6.37 (d, 1 H, $^3J_{H-H}$ = 12.5 Hz, CH=CH); 4.48 (s, 2 H, C_5H_4); 4.34 (s, 2 H, C_5H_4); 4.24 (s, 2 H, C_5H_4); 4.18 (s, 2 H, C_5H_4). − ^{13}C NMR (500 MHz, $CDCl_3$): δ = 69.5, 71.4, 71.5, 72.0 (8 C, C_5H_4); 82.0, 83.5 (2 Cq, C_5H_4); 124.2, 124.9, 126.3, 126.6, 129.9, 132.0, 132.7 (12 C, CH=CH and C_6H_4); 144.8, 145.5, 146.9 (4 Cq, C_6H_4). − $C_{26}H_{20}FeN_2O_4$ (480.30): calcd. C 65.00, H 4.20, N 5.83; found C 65.12, H 4.07, N 5.89. − Electrospray MS. Cone 25 V. *m/z* (fragment): 503 [M^+ + Na].

Compound 4-(*Z,Z*), Fe{η^5-C_5H_4−(*Z*)-CH=CHC_6H_4-4-NO_2}$_2$: Yield 10%. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.13 (d, 4 H, $^3J_{H-H}$ = 8.7 Hz, C_6H_4); 7.46 (d, 4 H, $^3J_{H-H}$ = 8.4 Hz, C_6H_4); 6.47 (d, 2 H, $^3J_{H-H}$ = 12.0 Hz, CH=CH); 6.39 (d, 2 H, $^3J_{H-H}$ = 11.5 Hz, CH=CH); 4.20 (s, 4 H, C_5H_4); 4.10 (s, 4 H, C_5H_4). − ^{13}C NMR (300 MHz, $CDCl_3$): δ = 71.4, 71.5 (8 C, C_5H_4); 81.9 (2 Cq, C_5H_4); 124.1, 125.8, 130.0, 131.8 (12 C, CH=CH and C_6H_4); 145.5, 146.8 (4 Cq, C_6H_4). − $C_{26}H_{20}FeN_2O_4$ (480.30): calcd. C 65.00, H 4.20, N 5.83; found C 65.23, H 4.37, N 5.92. − Electrospray MS. Cone 40 V. *m/z* (fragment): 503 [M^+ + Na].

Compound 4-(*E,E*), Fe{η^5-C_5H_4−(*E*)-CH=CHC_6H_4-4-NO_2}$_2$: Yield 34%. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.20 (d, 4 H, $^3J_{H-H}$ = 8.7 Hz, C_6H_4); 7.56 (d, 4 H, $^3J_{H-H}$ = 8.4 Hz, C_6H_4); 7.11 (d, 2 H, $^3J_{H-H}$ = 16.2 Hz, CH=CH); 6.79 (d, 2 H, $^3J_{H-H}$ = 16.2 Hz, CH=CH); 4.62 (s, 4 H, C_5H_4); 4.49 (s, 4 H, C_5H_4). − ^{13}C NMR (300 MHz, $CDCl_3$): δ = 71.6, 72.0 (8 C, C_5H_4); 82.3 (2 Cq, C_5H_4); 124.5, 124.9, 127.0, 128.2 (12 C, CH=CH and C_6H_4); 143.5, 144.7 (4 Cq, C_6H_4). Yield 34%. − $C_{26}H_{20}FeN_2O_4$ (480.30): calcd. C 65.00, H 4.20, N 5.83; found C 64.92, H 4.32, N 5.75. − Electrospray MS. Cone 40 V. *m/z* (fragment): 503 [M^+ + Na].

Compound 5-(*E,Z*), Fe{η^5-C_5H_4−(*Z*)-CH=CHC_6H_4-4-CN}{η^5-C_5H_4−(*E*)-CH=CHC_6H_4-4-CN}: Yield 27%. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.62 (d, 2 H, $^3J_{H-H}$ = 8.1 Hz, C_6H_4); 7.48 (m, 4 H, C_6H_4); 7.32 (d, 2 H, $^3J_{H-H}$ = 8.4 Hz, C_6H_4); 6.91 (d, 1 H, $^3J_{H-H}$ = 15.9 Hz, CH=CH); 6.61 (d, 1 H, $^3J_{H-H}$ = 16.2 Hz, CH=CH); 6.31 (s, 2 H, CH=CH); 4.48 (s, 2 H, C_5H_4); 4.34 (s, 2 H, C_5H_4); 4.24 (s, 2 H, C_5H_4); 4.17 (s, 2 H, C_5H_4). − ^{13}C NMR (500 MHz, $CDCl_3$): δ = 69.5, 71.4, 71.7, 72.1 (8 C, C_5H_4); 82.6, 84.3 (2 Cq, C_5H_4); 110.6, 110.8 (2 C, CN); 125.5, 126.8, 129.9, 131.3, 131.5, 132.6, 133.2 (12 C, CH=CH and C_6H_4); 119.7, 119.8, 142.8, 143.4 (4 Cq, C_6H_4). − $C_{28}H_{20}FeN_2$ (440.33): calcd. C 76.42, H 4.58, N 6.36; found C 76.02, H 4.75, N 6.39. − Electrospray MS. Cone 45 V. *m/z* (fragment): 463 [M^+ + Na].

Compound 5-(*Z,Z*), Fe{η^5-C_5H_4−(*Z*)-CH=CHC_6H_4-4-CN}$_2$: Yield 10%. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.54 (d, 4 H, $^3J_{H-H}$ = 7.8 Hz, C_6H_4); 7.39 (d, 4 H, $^3J_{H-H}$ = 7.5 Hz, C_6H_4); 6.42 (d, 2 H, $^3J_{H-H}$ = 11.7 Hz, CH=CH); 6.32 (d, 2 H, $^3J_{H-H}$ = 11.7 Hz, CH=CH); 4.17 (s, 4 H, C_5H_4); 4.06 (s, 4 H, C_5H_4). − ^{13}C NMR (300 MHz, $CDCl_3$): δ = 71.3, 71.5 (8 C, C_5H_4); 82.1 (2 Cq, C_5H_4); 110.7 (2 C, CN); 126.2, 129.9, 131.1, 132.5 (12 C, CH=CH and C_6H_4); 119.7, 143.4 (4 Cq, C_6H_4). − $C_{28}H_{20}FeN_2$ (440.33): calcd. C 76.42, H 4.58, N 6.36; found C 76.55, H 4.26, N 6.20. − Electrospray MS. Cone 45 V. *m/z* (fragment): 463 [M^+ + Na].

Compound 5-(*E,E*), Fe{η^5-C_5H_4−(*E*)-CH=CHC_6H_4-4-CN}$_2$: Yield 36%. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.48 (d, 4 H, $^3J_{H-H}$ = 7.5 Hz, C_6H_4); 7.28 (d, 4 H, $^3J_{H-H}$ = 8.1 Hz, C_6H_4); 6.83 (d, 2 H, $^3J_{H-H}$ = 15.9 Hz, CH=CH); 6.53 (d, 2 H, $^3J_{H-H}$ = 15.9 Hz, CH=CH); 4.48 (s, 4 H, C_5H_4); 4.36 (s, 4 H, C_5H_4). − ^{13}C NMR (300 MHz, $CDCl_3$): δ = 69.2, 71.7 (8 C, C_5H_4); 83.8 (2 Cq, C_5H_4); 110.4 (2 C, CN); 125.4, 126.6, 130.9, 133.1 (12 C, CH=CH and C_6H_4); 119.7, 142.6 (4 Cq, C_6H_4). − $C_{28}H_{20}FeN_2$ (440.33): calcd. C 76.42, H 4.58, N 6.36; found C 76.36, H 4.63, N 6.27. − Electrospray MS. Cone 45 V. *m/z* (fragment): 463 [M^+ + Na].

3. Isomerization Reactions: Compounds **4**-(*E,Z*), **4**-(*Z,Z*), **5**-(*E,Z*), or **5**-(*Z,Z*) could be isomerized to the all-(*E*) complexes by the following method. **4**-(*E,Z*) (300 mg) (or any of the other complexes), was dissolved in 10 mL of toluene with I_2 (10 mg). The mixture was refluxed for 20 minutes, after which the solvent was eliminated by reduced pressure. The crude product was flash-chromatographed, yielding pure **4**-(*E,E*) compound. Yield 85%. Yields for **4**-(*Z,Z*), **5**-(*E,Z*), or **5**-(*Z,Z*) in the range 80−90%.

4. Preparation of Fe(η^5-C_5H_5)(η^5-C_5H_4−(*E*)-CH=CH−4-{(η^6-C_6H_4)Cr$(CO)_3$}-(*E*)-CH=CH−η^5-C_5H_4)Fe(η^5-C_5H_5) (7): $Cr(CO)_6$ (660.2 mg, 3.0 mmol) was added to a solution of compound **6** (300 mg, 0.6 mmol) in butyl ether (40 mL), and the resulting solution stirred for 15 h at 150 °C. After cooling the mixture to room temperature, the solution was filtered and the solvent removed under reduced pressure. Purification by column chromatography on alumina with CH_2Cl_2/hexane (1:1) as the eluent afforded pure **7**, yield 65%.

X-ray Diffraction Studies: Single crystals were grown by slow diffusion of hexane into concentrated CH_2Cl_2 solutions and mounted on a glass fiber in a random orientation. Data collection was performed at room temperature on a Siemens Smart CCD diffractometer using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) with a nominal crystal to detector distance of 4.0 cm. A hemisphere of data was collected based on three ω-scan runs (starting ω = −28°) at values φ = 0°, 90°, and 180° with the detector at 2θ = 28°. At each of these runs, frames (606, 435, and 230, respectively) were collected at 0.3° intervals and 20 s per frame for compound **2**-(*E*), 40 s per frame for compound **4**-(*E,Z*), 45 s per frame for compound **5**-(*E,E*), 10 s per frame for **6** and 80 s per frame for **7**. The diffraction frames were integrated using the

SAINT package and corrected for absorption with SADABS.[43,44] Space group assignments are based on systematic absences, E statistics, and successful refinement of the structures. Structures were solved by direct methods with the aid of successive difference Fourier maps and were refined using the SHELXTL 5.1 software package. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were assigned to ideal positions and refined using a riding model. Data collection parameters are given in Table 5.

Kurtz Powder Studies: Samples were ungraded powders placed in the circular cavity (10 mm diameter × 0.5 mm depth) of a microscope slide with a cover slip. Powder SHG efficiencies were measured using the Kurtz technique.[45] Studies utilizing the fundamental output of a Q-switched Quanta-Ray GC-130 Nd:YAG laser (1.06 μm) were inconclusive due to material resonances at the second-harmonic frequency. The powder measurements were therefore performed at 1.3 and 1.4 μm using a Light Conversion Topas optical parametric generator pumped with a Clark MXR regenerative amplifier. This afforded approximately 150 fs pulses at a 1 kHz repetition rate which were directed onto the sample as an unfocussed beam (spot size about 5 mm; energy per pulse: up to 20 mJ). The intensity of the generated powder SHG was determined using a Coolsnap Photometric CCD camera. Measurements thus made were compared with those of a urea powder sample.

Z-scan Measurements: Z-scan measurements were performed at 800 nm using 100 fs pulses from a system consisting of a Coherent Mira Ti-sapphire laser pumped with a Coherent Innova or Coherent Verdi cw pump and a Ti-sapphire regenerative amplifier pumped with a frequency-doubled Q-switched pulsed YAG laser (Spectra Physics GCR) at 30 Hz and employing chirped pulse amplification. Tetrahydrofuran solutions were examined in a glass cell with a 0.1 cm path length. The Z-scans were recorded at three concentrations for each compound [two concentrations for **4**-(*E,E*), **4**-(*Z,Z*), and **5**-(*E,E*)] and the real and imaginary part of the nonlinear phase change determined by numerical fitting.[29] The real and imaginary part of the hyperpolarizability of the solute was then calculated assuming linear concentration dependencies of the nonlinear phase shifts. The nonlinearities and light intensities were calibrated using measurements of a 1 mm thick silica plate for which the nonlinear refractive index $n_2 = 3 \cdot 10^{-16}$ cm^2·W^{-1} was assumed.

Supplementary Data: Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-152432 for compound **2**-(*E*), CCDC-152433 for compound **4**-(*E,Z*), CCDC-152434 for compound **5**-(*E,E*), CCDC-152435 for compound **6**, and CCDC-152436 for compound **7**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK. [Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Reactions of Arylthiazylamides with Internal and External Fluoro Electrophiles − Formation of Products with Unusual Structures

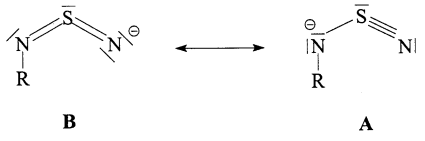
Enno Lork,[a] Rüdiger Mews,*[a] Makhmut M. Shakirov,[b] Paul G. Watson,[a] and Andrey V. Zibarev*[b]

Keywords: Amides / Fluorine / Electrophiles / Reaction mechanisms / Pi interactions / Structure elucidation

The heteroatom reactivity of the title anions [as $(Me_2N)_3S^+$ and Cs^+ salts] toward both internal and external fluoro electrophiles has been investigated. The intramolecular nucleophilic cyclization of $[ArNSN]^-$ (as the cesium salts) bearing at least one *ortho* fluorine afforded 2,1,3-benzothiadiazoles (e.g. **2a**,**b**), whereas intermolecular condensation with polyfluorinated pyridine and naphthalene afforded Ar–N=S=N–R with R = 4-Py_F (**4**) and R = 2-Np_F (**8**). Further interaction of $[ArNSN]^-$ with **4** or **8** proceeded with the transfer of NSN units resulting in $(ArN=)_2S$ (**5**) and $[RNSN]^-$, followed by decomposition (R = 4-Py_F) to 4-Py_FNH_2 (**6**) or intramolecular cyclization (R = 2-Np_F) to the polyfluorinated thiadiazole **9**. The compounds of types **4**, **5**, **8**, and **9** have been characterized by single-crystal X-ray diffraction as having both *Z,E* and *Z,Z* configurations [**8** and **9** as molecular complexes with $C_{10}F_8$ and $(Ph–N=)_2S$ (**5e**), respectively, featuring π-stacking interactions of the arene–polyfluoroarene type]. Besides normal aryl–polyfluoroaryl interactions, the **8**·$C_{10}F_8$ complex also displays unusual polyfluoroaryl–polyfluoroaryl π-stacking.

Introduction

We recently reported the preparation, isolation, and X-ray structural characterization of $(Me_2N)_3S^+$ (TAS^+) salts of $[RNSN]^-$ anions (R = Me_3C, Me_3Si,[1] various aryl substituents[2,3]). It emerged from the X-ray data that due to the unexpectedly short terminal SN bond, these anions should be regarded as thiazylamide (**A**) rather than as sulfurdiimide (**B**) anions (Scheme 1),[1−3] in accordance with calculations at the MP2/6−31G* and B3LYP/6−311+G* levels of theory. Thus, the $[RNSN]^-$ anions belong to the rare class of compounds featuring sulfur−nitrogen triple bonds and therefore they deserve more detailed investigation.



B **A**

Scheme 1

Previously, some $[RNSN]^-$ anions (R = Ar_F−X−; X = −, S) generated in situ in the form of Cs^+ salts have been shown to be involved in intramolecular nucleophilic *ortho* cyclizations, which resulted in the previously unknown and otherwise inaccessible polyfluorinated 2,1,3-benzothiadiazoles (X = −, Ar_F = 4-RC_6F_4),[4] naphtho[1,2-*c*]- and naphtho[2,3-*c*][1,2,5]thiadiazoles (X = −; Ar_F = 2-$C_{10}F_7$),[5] or 1,3,2,4-benzodithiadiazines (X = S; Ar_F = C_6F_5), depending on Ar_F and X.[6] With Ar_F = 4-Py_F and X = −; S (4-Py_F = 2,3,5,6-tetrafluoro-4-pyridinyl), however, no heterocycles could be prepared, and polyfluorinated 4-aminopyridine was the major product instead.[7] It follows from the available data[4−7] that the reactivity of these intermediate anions toward internal electrophiles (*ortho* cyclization), as well as their stability,[1−3] depends strongly on the substituents at the NSN^- moiety {whilst TAS^+ $[RNSN]^-$ salts (R = Me_3C, Me_3Si) are moderately stable at room temperature,[1] their R = Ar analogues decompose rapidly at temperatures above −20 °C[2,3]}.

The present paper provides detailed experimental information on the reactivity of $[RNSN]^-$ anions (as the TAS^+ and Cs^+ salts; R = Ar) towards both internal and external fluoro electrophiles, as well as a description of nontrivial structural features of the synthesized compounds.

Results and Discussion

Reactivity of Arylthiazylamides $[ArNSN]^-$ Towards Internal Fluoro Electrophiles

The starting point for our considerations was the isolation of salts with fluorinated anions $[Ar_FNSN]^-$,[2,3] which are probable intermediates in the CsF-induced intramolecular *ortho* cyclization of polyfluorinated sulfurdiimides $Ar_FNSNSiMe_3$ to give polyfluorinated benzo- and naphthothiadiazoles.[4,5] This approach might be extended to low-fluorinated derivatives (e.g. **1a**,**b**). When treated with CsF in boiling CH_3CN, cyclization to the well-known 2,1,3-benzothiadiazole **2a**[8] and its previously unreported 4-fluoro derivative **2b** was observed (the 5-F isomer of **2b** was prepared some time ago[9]). Our approach represents a use-

ful extension of the established methods for the preparation of carbocyclic-substituted derivatives of **2a**.[8]

Comparison of the ^{15}N NMR spectra of **2a** [$\delta^{15}N$ = 329.9 (t, J = 0.5 Hz)] and **2b** [$\delta^{15}N$ = 330.1 (s), 325.1 (d, J = 2.9 Hz)] allows assignment of the low-field signal of **2b** to N^1 and the high-field signal to N^3. This assignment is also consistent with the known tendency[10] for enhanced shielding of those nitrogen nuclei that are *ortho* to F in fluorinated (hetero)aromatics.

The method seems to be restricted to fluoride as a leaving group; no heterocyclic products could be obtained under the same conditions from the corresponding *ortho*-Cl- or *ortho*-O_2N-containing precursors $ArNSNSiMe_3$ **1c**,**d** [Ar = 2,6-$Cl_2C_6H_3$ (**1c**), 2-$O_2N-C_6H_4$ (**1d**)]. Only the corresponding amines $ArNH_2$ were isolated. This cyclization (Scheme 2) would require a conversion of CsF into CsCl and $CsNO_2$, respectively, which is thermodynamically unattractive and thus responsible for the lack of cyclization.

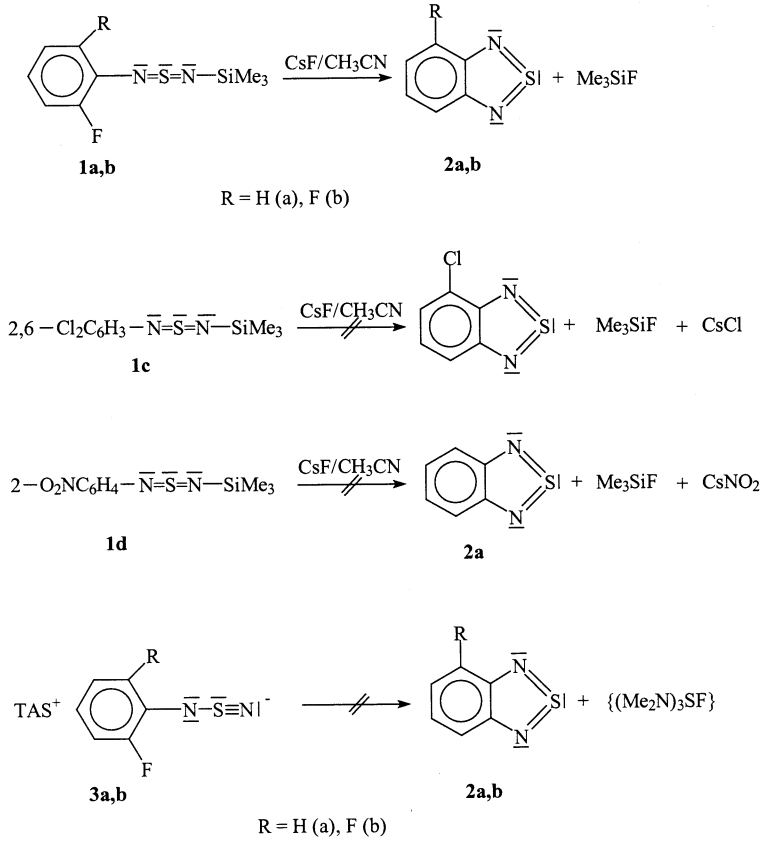
Although attempts to isolate polyfluorinated $[Ar_FNSN]^-$ anions have proved unsuccessful,[2,3] [2-$FC_6H_4NSN]^-$ (**3a**) and [2,6-$F_2C_6H_3NSN]^-$ (**3b**), the likely intermediates en route to benzothiadiazole formation (Scheme 2), have been isolated and structurally characterized in the form of TAS^+ salts.[2] Thermal decomposition of salts **3a**,**b** (Scheme 2) gave only tarry products and none of the expected thiadiazoles **2a**,**b**. This failure to isolate the expected cyclization products from the thermal decomposition of **3a**,**b** is not at variance with the formation of arylthiazylamide anions as intermediates. In the decomposition reactions of the TAS^+ salts, fluoride is an unfavorable leaving group, thus the activation barrier for this intramolecular fluoride exchange seems to exceed the stability[2,3] of the arylthiazylamide anions.

Trapping of Arylthiazylamides $[ArNSN]^-$ by External Fluoro Electrophiles

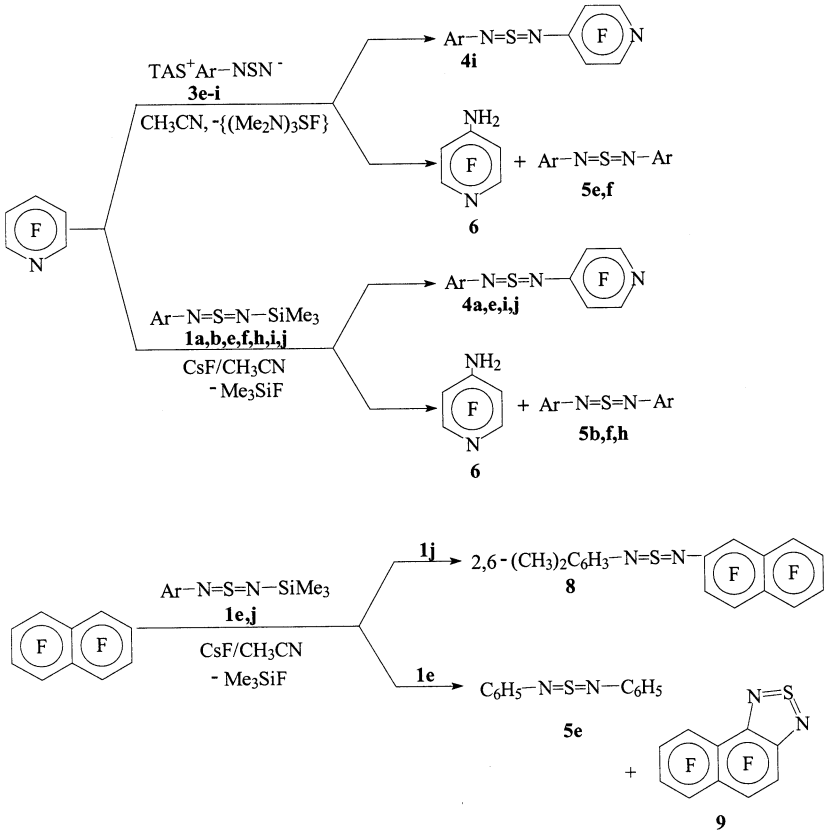
In view of the unsuccessful attempts to obtain benzothiadiazoles by intramolecular fluoride elimination from TAS^+ $[Ar_FNSN]^-$, it was expected that trapping and stabilization of the $ArNSN^-$ moiety should only be possible, if at all, with highly reactive fluoro electrophiles. Highly reactive electrophiles of this type are pentafluoropyridine and octafluoronaphthalene.[11]

It has been found that reactions of arylthiazylamide anions as their TAS^+ and Cs^+ salts with these external electrophiles afford two types of products. In the case of pentafluoropyridine, the products are the expected *N*-aryl-*N*′-(2,3,5,6-tetrafluoro-4-pyridinyl)sulfurdiimides (**4**) and the rather unexpected symmetric *N*,*N*′-bis(aryl)sulfurdiimides (**5**), as well as 4-amino-2,3,5,6-tetrafluoropyridine (**6**), depending on the Ar group and the cation (Scheme 3).

With TAS^+ salts in CH_3CN at −40 °C, it was found that the expected trapping product **4i** could only be obtained with an anion bearing a strongly electron-releasing *para*-substituent (e.g. CH_3O) on the aromatic ring. In all other such experiments, only **6** and the symmetric compounds **5**



Scheme 2



Scheme 3

were produced, except in the case of anions bearing strongly electron-withdrawing *para*-substituents (e.g. CF_3), where no products could be identified in the resulting dark tar (Scheme 3).

With Cs^+ salts in CH_3CN, the expected trapping products **4a**,**e**,**i**,**j** were obtained from the parent anion $[PhNSN]^-$ and its 2-fluoro-, 4-methoxy-, and 2,6-dimethyl-substituted derivatives, whereas amine **6** and symmetric sulfurdiimides **5b**,**f**,**h** were isolated from the reaction mixtures in all other cases (Scheme 3). With starting material **1h** (Ar = 4-$CF_3C_6H_4$), bearing a strong acceptor substituent, the latter were obtained in only trace amounts.

In the reaction of $C_{10}F_8$ with Cs^+ $[2,6\text{-}XyNSN]^-$ (2,6-Xy = 2,6-dimethylphenyl), typical octafluoronaphthalene β-substitution[11] proceeded to afford the expected *N*-(2,6-Xy)-*N*′-(2-Np_F) sulfurdiimide **8** (2-Np_F = 1,3,4,5,6,7,8-heptafluoronaphth-2-yl) (Scheme 3), which was isolated from the reaction mixture as a molecular complex **8**·$C_{10}F_8$. Complexes of this type have not been reported previously. In contrast, reaction of $C_{10}F_8$ with Cs^+ $[PhNSN]^-$ unexpectedly yielded the polyfluorinated naphtho[1,2-*c*][1,2,5]thiadiazole (**9**) and the symmetric sulfurdiimide $(PhN{=})_2S$ (**5e**) (Scheme 3), which was again isolated from the reaction mixture as a molecular complex **5e**·**9** and was of a previously unknown type.

The dichotomous reactivity of $[ArNSN]^-$ anions toward external fluoro electrophiles cannot be attributed solely to the influence of the aryl substituents since the alkylthiazylamides $[AlkNSN]^-$ [Alk = *t*Bu, adamant-1-yl (1-Ad)] show similar behaviour. Thus, the expected nonsymmetric sulfurdiimide 1-Ad−N=S=N−Py_F-4 was obtained from Cs^+ [1-AdNSN]$^-$ and pentafluoropyridine, whereas reaction of Cs^+ $[AlkNSN]^-$ (Alk = *t*Bu,1-Ad) with octafluoronaphthalene resulted in the heterocycle **9**.[12]

Thus, although the described anions have the thiazylamide structure,[2,3] they rearrange to a sulfurdiimide form in the final reaction products. In this context, it is interesting to note that the carbon analogues of the title anions, $[RNCN]^-$ (R = Me_3Si), have similar $R{-}\underline{\bar{N}}{-}C{\equiv}\bar{N}$ structures[13a] according to X-ray crystallographic data. They form $R'_2C{=}\bar{N}{-}C{\equiv}\bar{N}$ derivatives upon reaction with $R'_2C{=}O$.[14] By analogy, the initial products of the reactions of the title anions with fluoro electrophiles R_FF can be envisaged as $R_F(Ar)\bar{N}{-}\bar{S}{\equiv}\bar{N}$ undergoing intramolecular rearrangement to the more stable $R_F\bar{N}{=}\bar{S}{=}\bar{N}{-}Ar$ compounds due to the known general instability of these $R\bar{S}{\equiv}\bar{N}$ derivatives.[3] When such a rearrangement of the initial reaction products is not possible, as in the case of $R'_2C{=}\bar{N}{-}\bar{S}{\equiv}\bar{N}$ obtained from the reaction of $Cs^+Me_3Si\text{-}\underline{\bar{N}}\text{-}\underline{\bar{N}}\text{-}CR'_2$ with $R'_2C{=}O$, they are stabilized in a different manner, namely as $R'_2C{=}\bar{N}{-}\bar{N}{=}CR'_2$ compounds (R′ = various aryls).[13b]

It is quite likely that the expected trapping products **4** are formed in all cases, but that in some cases this reaction is very slow, and in the presence of an effective excess of the starting salt further interaction of the trapping product and

the salt is possible to give the symmetric $(ArN=)_2S$ (**5**) and the $[4\text{-}Py_FNSN]^-$ anion **7**. It is known that **7** does not undergo nucleophilic ring-closure even in boiling CH_3CN; it only decomposes to give the corresponding amine **6**[7] (Scheme 4). The identification of traces of $(4\text{-}Py_F)_2NH$ (**10**) in some experiments implies the participation of $[4\text{-}Py_FN\cdot^-]$ intermediates.

In the case of octafluoronaphthalene, further interaction of type **11** trapping products with the starting salt leads to the $[2\text{-}Np_FNSN]^-$ anion (Scheme 4), which, in contrast to **7**, is known to undergo highly regioselective intramolecular cyclization resulting in **9** as the major product.[5]

To the best of our knowledge, transfer of the NSN^- moiety from aromatics to polyfluoroaromatics, as depicted in Scheme 4, has not previously been observed. The driving force behind this substituent exchange is probably the well-known high electron affinity of polyfluoroaromatics.

The structures of the expected **4i,j** and **8·$C_{10}F_8$** and the unexpected **5f** and **5e·9** trapping products were confirmed by X-ray crystallographic analysis (see below). The structure of **5b**[15] had been determined previously.

Some of the synthesized compounds were also characterized by $^{14/15}N$ NMR spectroscopy. Three signals in the ^{15}N NMR spectrum of **4i** ($\delta^{15}N$ = 292.5, 278.7, and 217.8) could be assigned to Ar−N=, 4-Py_F−N=, and 4-Py_F, respectively, by comparison with the spectra of **5e** ($\delta^{14}N$ = 294),[16] **5b** (see below), other $(Ar-N=)_2S$ compounds,[17] and **6** [$\delta^{15}N$ = 212.1 (t, J = 50.0 Hz), 50.2 (t, J = 91.3 Hz)]. This assignment is also consistent with the known tendency[10] for enhanced shielding of those nitrogens that are *ortho* to F in fluorinated functional aromatics [*cf.* also **5e**[16] and **5b** ($\delta^{15}N$ = 272.1)]. The ^{15}N NMR spectrum of **8·$C_{10}F_8$** features two resonances ($\delta^{15}N$ = 312.8, 266.4), which could be assigned on the basis of similar arguments as above to 2,6-Xy−N= and 2-Np_F−N=, respectively. The ^{14}N NMR spectrum of **5e·9** shows a broad resonance ($\Delta\nu_{1/2} \approx$ 2000 Hz) with two well-defined maxima [$\delta^{14}N$ = 332 (**9**) and 301 (**5e**)], which are in very good

Structures of the Synthesized Sulfurdiimides RNSNR′

The trapping products of types **4** and **8** might be particularly interesting as ligands for coordination compounds as they possess two very different electron lone-pairs on the NSN fragments, along with a lone-pair from the tetrafluoropyridyl moiety in the case of **4**. According to X-ray crystallographic data (Figures 1 and 2, Tables 1 and 2), they adopt *Z*,*E* and *Z*,*Z* configurations in the solid state, typical of bis(aryl)sulfurdiimides.[3,15,18−23] Thus, in the crystal, compound **4i** exists as the perfectly planar *Z*,*E* isomer, whereas **4j** and **8** (in the complex with $C_{10}F_8$) exist as *Z*,*Z* isomers with the rings being essentially parallel to one another and perpendicular to the NSN plane. The bis(aryl)-sulfurdiimide parent compound **5e** (liquid in the pure state)[24] adopts the nonplanar *Z*,*E* configuration in the complex with **9**, whereas compound **5f** has an almost planar *Z*,*E* configuration. Compound **5b** (*Z*,*Z* isomer in the crystal)[15] has been structurally characterized previously.

Table 3 lists the data obtained in this work along with selected representative conformational data for previously reported bis(aryl)sulfurdiimides.[3,15,18−23] Sterically unhindered bis(aryl)sulfurdiimides adopt the *Z*,*E* configuration with the less electron-withdrawing substituent in the *Z*-position. Steric strain in this position is released by adopting a wide CNS angle (≈130°), which is 10−15° wider than that for the *E*-substituents. A further reason for the small angle in the *E*-position is the rotation of the aryl ring out of the NSN plane by 30−40°. For strongly electron-withdrawing groups (C_6F_5, C_5F_4N), this torsion angle is very small (7°), leading to an appreciable opening of the CNS angle (124−125°).

In *Z*,*E*-(2,4,6-$Br_3C_6H_2N$=)$_2$S, steric strain is released through the adoption of an almost perpendicular orientation of the aryl groups relative to the NSN plane. As pointed out previously, substitution of H by F, Br, or Me in the *o*,*o*-positions, although sterically less favoured, leads to the *Z*,*Z*-configuration.[21,22] Steric strain in these cases is released by a parallel rotation of both groups out of the NSN plane by 55−70°. In spite of this, the NSN angle in the *Z*,*Z*-configuration is 10° larger than that in the *Z*,*E* derivatives.

Notably, with planar molecular geometry in the *Z*,*E* configuration (*cf.* **4i**), the synthesized compounds satisfy the primary requirements for materials with nonlinear optical properties in that they contain donor (Ar) and acceptor (4-Py_F) fragments connected by an −N=S=N− bridge capable of π-conjugation.[25]

[a] At the PM3 level of theory.[21,22]

Even more interesting than the stereochemistry of the bis(aryl)sulfurdiimides is the interaction of one of the phenyl rings of $(C_6H_5N=)_2S$ (**5e**) with the heteropolyfluoroaromatic system **9** in the solid state, as well as the interaction of 2,6-$Me_2C_6H_3N=S=NC_{10}F_7$ (**8**) with 1/2$C_{10}F_8$ (Figures 3 and 4).

It should be noted that noncovalent interactions between aromatic and polyfluoroaromatic groups[26−28] (a special

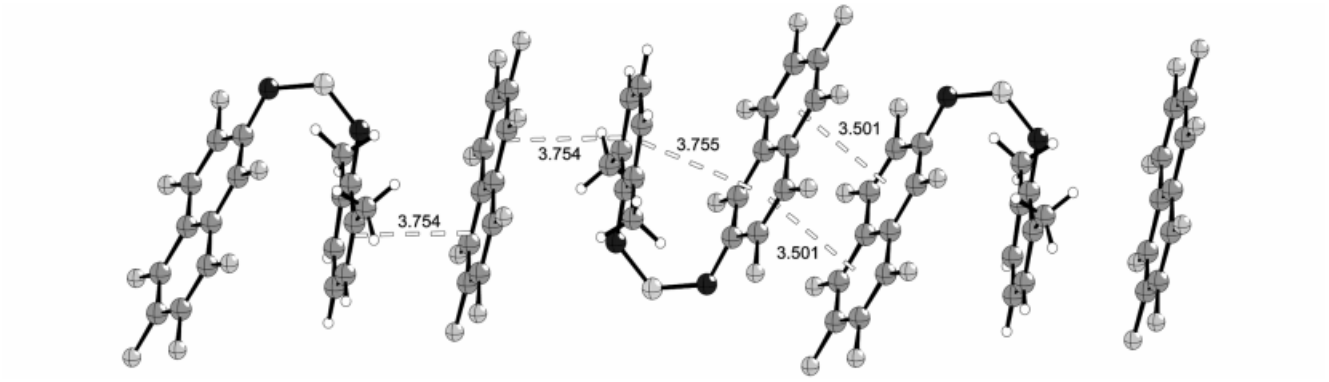

Figure 3. π-Stacking of the arene−polyfluoroarene and polyfluoroaryl−polyfluoroaryl types in the crystal of **8**·$C_{10}F_8$

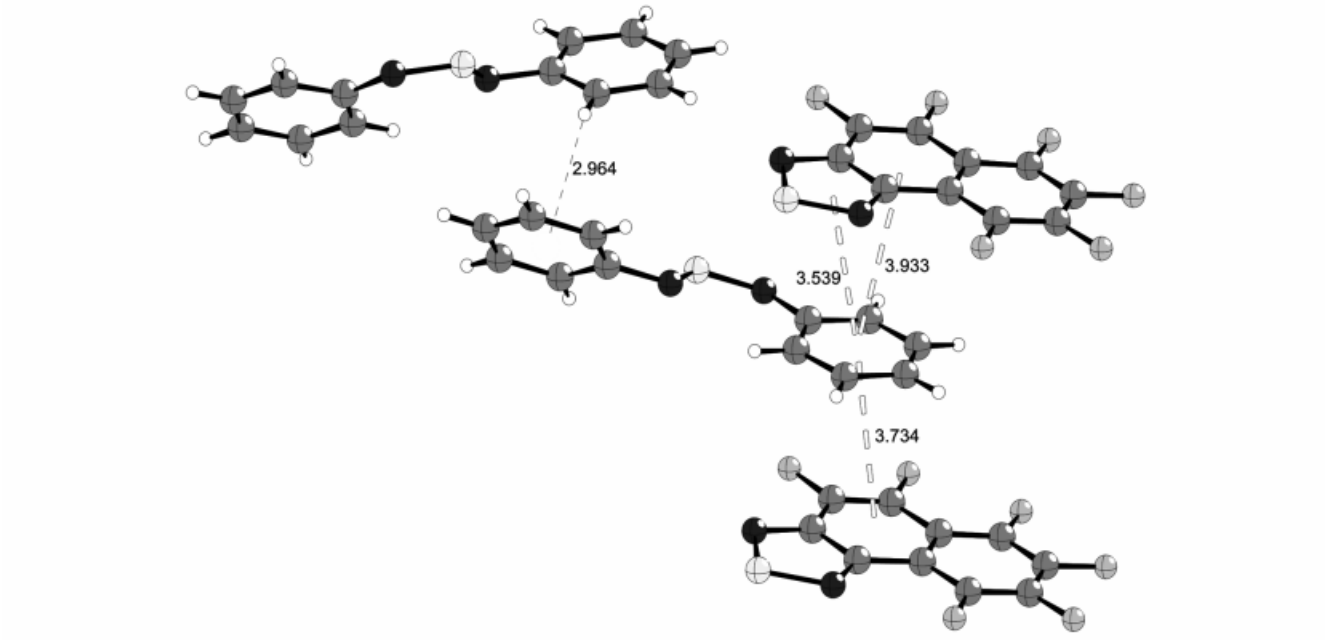

Figure 4. π-Stacking of the arene−polyfluoroarene type in the crystal of **5e**·**9**

case of noncovalent interactions between aromatic units that is known to play a significant role in determining the structures and properties of molecular assemblies in biology, supramolecular chemistry, and materials science)[29,30] have been extensively studied in recent years, leading to important new possibilities in crystal engineering for the design of advanced functional materials.[31−36] Co-crystals of benzene/hexafluorobenzene,[37,38] their (poly)substituted derivatives,[31,32,34,37,39] biphenyl/decafluorobiphenyl,[40] naphthalene/octafluoronaphthalene[41] and larger aromatic hydrocarbon/fluorocarbon,[42,43] and of decamethylferrocene/perfluorophenanthrene[44] have been produced and have been found to involve alternating 1:1 π-stacking. This face-to-face stacking arrangement is thought to be dominated by electrostatic forces,[45] in particular by large but opposite-in-sign quadrupole moments of the C_6H_6 and C_6F_6 components.[27] The electrostatic potential map of benzene reveals concentrations of negative potential above and below the molecular plane, and a ring of positive potential in the plane centred on the hydrogens; hexafluorobenzene possesses the opposite charge distribution[46] (see also ref.[31]).

Significantly, neither heterocycles (**5e**·**9**) nor markedly bent (tweezer-like) molecules (**8**·$C_{10}F_8$) have previously been found to be involved in noncovalent arene−polyfluoroarene interactions, with one probable exception in the latter case being a complex of 1,4-diiodotetrafluorobenzene with a cone-shaped 1,3-bis(pyridylmethyl)calix[4]arene.[47]

Both complexes **5e**·**9** and **8**·$C_{10}F_8$ feature face-to-face π-stacking of the arene−polyfluorene type.[26−28] Additionally, **8**·$C_{10}F_8$ shows another structural motif, namely an unprecedented π-stacking of the heptafluoronaphth-2-yl moieties with an interplanar separation of 350.1 pm (Figure 3), thus representing a new type of arene−polyfluoroarene complex. (It is noteworthy that the crystal packing of octafluoronaphthalene does not, of course, reveal any π-stacking interactions, but rather a face-to-edge orientation of neighbouring molecules[48]). The peculiarity mentioned

above is in sharp contrast to the purely electrostatic interpretation of the interactions under consideration and clearly requires further investigation, both experimentally and especially theoretically. It seems that the dispersion forces[27] (responsible, for example, for the solid-state structure of octafluoronaphthalene[48]) should also be taken into account.

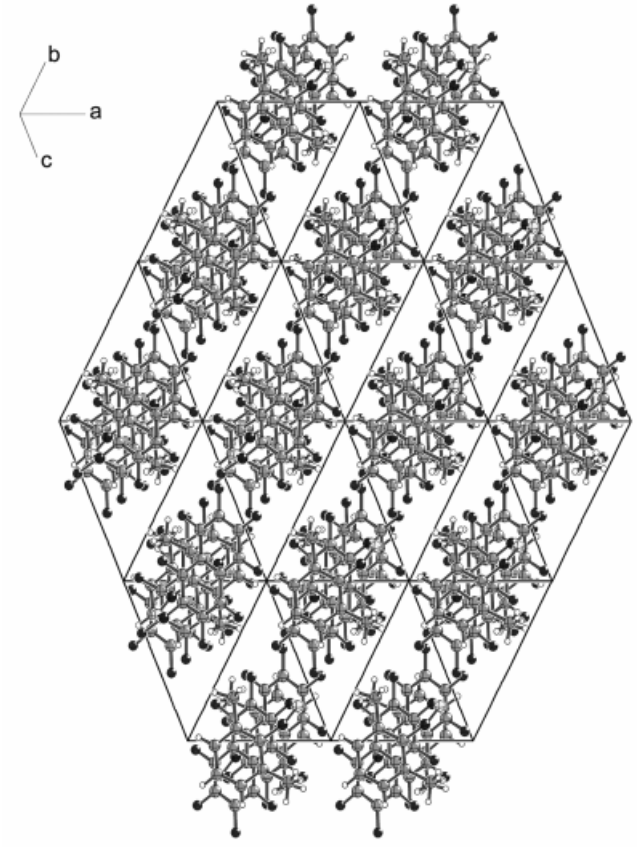

Figure 5. Crystal packing of **8**·$C_{10}F_8$

On the other hand, a 2,6-dimethylphenyl−2,6-dimethylphenyl interaction is not seen.

Within the stacks, the arene−polyfluoroarene separation is 353.9−393.3 pm for **5e·9** and 350.1−375.5 pm for **8**·$C_{10}F_8$, as compared to 377 pm for the lowest-temperature phase of the benzene/hexafluorobenzene co-crystals[38] and 368.6−377.1 pm for the naphthalene/octafluoronaphthalene co-crystals.[41]

The crystal packing of **8**·$C_{10}F_8$ and **5e·9** is depicted in Figures 5 and 6.

The alternating stacked aryl−polyfluoroaryl arrangement is concluded to be a general supramolecular motif of significant importance with regard to new developments in crystal engineering.[32] In view of the fact that **5e·9** and **8**·$C_{10}F_8$ combine π-stacked structures with the potential ability to coordinate transition metals through NSN bridges, the findings of this work can be envisaged as offering new prospects in this field.

Conclusions

The intramolecular nucleophilic cyclization of arylthiazylamides bearing at least one *ortho* fluorine offers a novel synthetic approach to 2,1,3-benzothiadiazoles. Despite some complications, the interaction of arylthiazylamides with fluoro electrophiles such as pentafluoropyridine and octafluoronaphthalene makes it possible to synthesize *N*-aryl-*N′*-(tetrafluoro-4-pyridinyl)sulfurdiimides (**4**) and *N*-aryl-*N′*-(heptafluoronaphth-2-yl)sulfurdiimides (**8**), which are not readily accessible by other means. Thus, the intramolecular nucleophilic cyclization of arylthiazylamide anions has now been expanded to intermolecular condensation. Compounds **4** and **8** represent promising ligands for coordination chemistry. With planar molecular geometries in the *Z,E* configuration (*cf.* **4i**), these compounds also satisfy

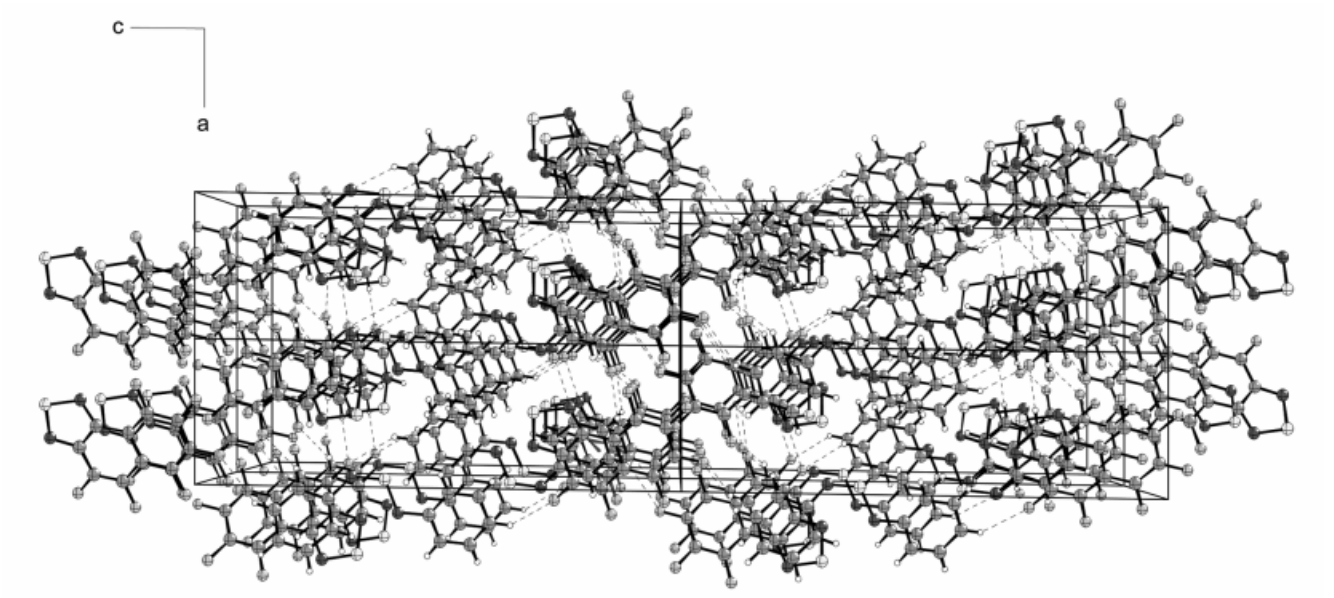

Figure 6. Crystal packing of **5e·9**

the primary requirements for materials with nonlinear optical properties as they contain donor (Ar) and acceptor (4-Py_F) fragments connected by an −N=S=N− bridge capable of π-conjugation. Complexes **5e·9** and **8**·$C_{10}F_8$ are the first examples of a heterocycle (**9**) and an essentially nonplanar tweezer-like molecule (*Z,Z*-**8**) to feature arene−polyfluoroarene π-stacking interactions. Besides typical aryl−polyfluoroaryl stacking, the crystal packing of **8**·$C_{10}F_8$ also reveals an unprecedented supramolecular motif, namely polyfluoroaryl−polyfluoroaryl π-stacking, thus making this a new type of arene−polyfluoroarene complex.

Experimental Section

General Remarks: ^{1}H and ^{19}F NMR spectra were recorded on a Bruker DPX-200 spectrometer, and ^{13}C NMR spectra on a Bruker DRX-500 spectrometer, at frequencies of 200.13, 188.28, and 125.76 MHz, respectively, with samples in $CDCl_3$ solution; chemical shifts are given with respect to TMS (^{1}H, ^{13}C) or $CFCl_3$ (^{19}F) Nitrogen NMR spectra were measured on a Bruker DRX-500 spectrometer at frequencies of 67.80 MHz (^{15}N) and 36.14 MHz (^{14}N) with samples in $CDCl_3$ solution; chemical shifts are given relative to NH_3 (liq.). − High-resolution mass spectra (EI, 70 eV) were measured with a Finnigan MAT MS 8200 mass spectrometer. − UV/Vis spectra were recorded on a Specord UV/Vis instrument with samples in heptane solution.

Crystallographic Analysis: The single-crystal X-ray structure determinations (Tables 1 and 2) were carried out on a Siemens P4 diffractometer using graphite-monochromated Mo-K_α (0.71073 Å) radiation. Refinement based on F^2; $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. Programs used: SHELX-97[49] and DIAMOND.[50]

The transparent crystals were mounted on a thin glass fibre using KEL-F oil. The structures were solved by direct methods (SHELXS[49]). Subsequent least-squares refinements (SHELXL-97−2[49]) located the positions of the remaining atoms in the electron density maps. All non H-atoms were refined anisotropically.[51]

Syntheses: TASF was prepared by established methods;[52] 1-aryl-3-(trimethylsilyl)sulfurdiimides Ar−N=S=N−$SiMe_3$ (**1a**,**b**,**e**−**j**) were obtained by known procedures.[3] Tris(dimethylamino)sulfonium arylthiazylamides TAS^+ $[ArNSN]^-$ were synthesized as described previously.[2,3] Cesium fluoride was calcinated immediately prior to use. The syntheses described below were performed in dry solvents with stirring under an argon atmosphere. The reagents were added dropwise and the solvents were distilled off under reduced pressure. The compounds **2a**,[8] **6**,[53] and **5b**,**f**[54] have been reported previously. Table 4 lists the physical and analytical data for the synthesized compounds.

1-Aryl-3-(trimethylsilyl)sulfurdiimides (1c,**d):** A solution of the appropriate ArNSO[55] (60 mmol) in hexane (25 mL) was added to a suspension of $LiN(SiMe_3)_2$ (10.0 g, 60 mmol) in hexane (50 mL) at −30 °C. The temperature was raised to 20 °C over a period of 2 h, and then a solution of Me_3SiCl (6.6 g, 60 mmol) in hexane (10 mL) was added. The precipitate formed was filtered off, the solvent was distilled, and the residue was distilled in vacuo. Compounds **1c**,**d** were obtained as orange oils.

2,1,3-Benzothiadiazole (2a) and 4-Fluoro-2,1,3-benzothiadiazole (2b): A solution of the appropriate Ar−N=S=N−$SiMe_3$ (**1a**,**b**) (20 mmol) in CH_3CN (25 mL) was added to a boiling suspension of CsF (3.04 g, 20 mmol) in CH_3CN (75 mL) over a period of 30 min. After a further 30 min, the reaction mixture was allowed

[a] From the Cs^+ salt. − [b] From the TAS^+ salt.

to cool to 20 °C, filtered, and the solvent was distilled off. The residue (a mixture of the target heterocycle and the corresponding $ArNH_2$, according to ^1H NMR and MS data) was redissolved in Et_2O (50 mL) and treated with 6 N hydrochloric acid (20 mL). The organic layer was separated, dried with $CaCl_2$, and the solvent was distilled off. The residue was sublimed in vacuo and then recrystallized from hexane. Compounds **2a** and **2b** were obtained as long colorless needles.

2b: ^{13}C NMR: δ = 156.0 (C^{7a}), 152.4 (C^4), 145.2 (C^{3a}), 128.7 (C^6), 116.8 (C^7), 112.0 (C^5). − UV/Vis: λ_{max} (log ε) = 307 nm (3.83) [*cf.* **2a:** 311 nm (4.15)].[56]

Under the same conditions, only the parent $ArNH_2$ compounds were obtained from **1c**,**d** (yields 50% and 65%, respectively).

Interaction of $[TAS]^+$ $[ArNSN]^-$ Salts (3e−i) with Pentafluoropyridine: *N*-(4-Methoxyphenyl)-*N*′-(2,3,5,6-tetrafluoro-4-pyridinyl)sulfurdiimide (4i), *N*,*N*′-Bis(aryl)sulfurdiimides (5e−f), and 4-Amino-2,3,5,6-tetrafluoropyridine (6): C_5F_5N (0.85 g, 5 mmol) was condensed onto a solution of $[TAS]^+$ $[ArNSN]^-$ (**3e−i**; 5 mmol) in CH_3CN (20 mL) at −196 °C by means of a vacuum line. After 16 h at −40 °C, the solvent was distilled off at the same temperature, and the residue was sublimed in vacuo and recrystallized from hexane. Compound **4i** was obtained as ruby-red crystals (single crystals suitable for X-ray structure analysis were obtained by a further recrystallization from $CHCl_3$). Compounds **5** and **6** were separated by fractional sublimation in vacuo followed by recrystallization from hexane. In the case of **3e**, compound **5e** was identified in the reaction mixture spectroscopically (^1H NMR and MS). In the case of **3g**,**h**, no products were identified.

CsF-Induced Interaction of Ar−N=S=N−SiMe$_3$ (1a,b,e,f,h−j) with Pentafluoropyridine: *N*-Aryl-*N*′-(2,3,5,6-tetrafluoro-4-pyridinyl)-sulfurdiimides (4a,e,i,j), *N*,*N*′-Bis(aryl)sulfurdiimides (5b,f,h), 4-Amino-2,3,5,6-tetrafluoropyridine (6), and Bis(2,3,5,6-tetrafluoro-4-pyridinyl)amine (10): Solutions of the appropriate Ar−N=S=N−$SiMe_3$ (**1a**,**b**,**e**,**f**,**h−j**; 5 mmol) and C_5F_5N (0.85 g, 5 mmol) in CH_3CN (5 mL aliquots) were added to a suspension of CsF in CH_3CN (25 mL) at 20 °C. After 1 h, the reaction mixture was filtered, the solvent was distilled off, and the residue was sublimed in vacuo and then recrystallized from hexane. Compounds **4a**,**e**,**i**,**j** were obtained as orange-red crystalline solids. Compounds **5b**,**f** and **6** were separated by fractional sublimation followed by recrystallization (**5b**,**f**: orange crystals; **6**: long colorless needles). In the case of **1h**, traces of **5h** and **6** were identified in the reaction residue by spectroscopic means (^1H and ^{19}F NMR, MS).

4e: UV/Vis: λ_{max} (log ε) = 412 nm (3.93) [*cf.* $(Ar-N=)_2S$].[54]

In some experiments, small amounts of compound **10** were identified alongside **6**; this could be isolated at a trace level by vacuum sublimation followed by recrystallization from hexane. **10**: Colorless crystals; m.p. 152−153 °C; ^1H NMR: δ = 8.30. − ^{19}F NMR: δ = −92.0, −153.6; these correspond to the published data.[57]

CsF-Induced Interaction of Ar−N=S=N−SiMe$_3$ (1e,j) with Octafluoronaphthalene: 4,5,6,7,8,9-Hexafluoronaphtho[1,2-*c*][1,2,5]thiadiazole (9; complex with 5e) and *N*-(2,6-Dimethylphenyl)-*N*′-(1,3,4,5,6,7,8-heptafluoronaphth-2-yl)sulfurdiimide (8; complex with $C_{10}F_8$): A solution of the appropriate Ar−N=S=N−$SiMe_3$ (**1e**,**j**) (5 mmol) and $C_{10}F_8$ (1.36 g, 5 mmol) in CH_3CN (25 mL) was added to a boiling suspension of CsF (0.76 g, 5 mmol) in MeCN (50 mL) over a period of 30 min. After a further 30 min, the reaction mixture was allowed to cool to 20 °C, the solvent was distilled off, and the residue was sublimed in vacuo and recrystallized from hexane. Compound **9** (as a complex with **5e**) was obtained as shiny orange crystals, while compound **8** (as a complex with $C_{10}F_8$) was obtained as transparent orange-red scales. Single crystals of **8**·$C_{10}F_8$ suitable for X-ray structure analysis (red prisms) were obtained by a further crystallization from $CHCl_3$.

8·$C_{10}F_8$: ^{13}C NMR: δ (2,6-Xy) = 144.2, 127.1, 125.4, 119.4, 18.2.
9·5e: ^{13}C NMR: δ (**5e**) = 145.3, 128.7, 126.7, 123.1.

Acknowledgments

The authors are grateful to Mr. Peter Brackmann for technical assistance, and to the Deutsche Forschungsgemeinschaft (Germany) and the Russian Foundation for Basic Research (Russia) for joint financial support of this work (DFG: 436 RUS 113/486/0; RFBR: 98−03−04107). A. Z. is also grateful to the Royal Society of Chemistry (U.K.) for an RSC Journals Grant for International Authors.

Platinum(II) and Palladium(II) Compounds Containing Chiral Thioimines

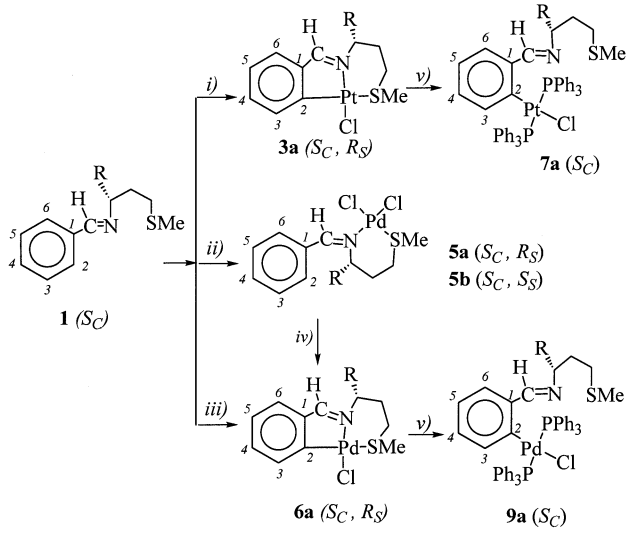
Xavier Riera,[a] Concepción López,*[a] Amparo Caubet,*[a] Virtudes Moreno,[a] Xavier Solans,[b] and Mercè Font-Bardia[b]

Keywords: Palladium / Platinum / Metallacycles / Chiral metallacycles / Cyclometallation

A comparative study of the reactivity of the optically pure thioimine: (S_C)-(−)-C_6H_5–CH=N–CH(CO_2Me)–CH_2–CH_2–SMe (**1**) versus platinum(II) and palladium(II) salts is reported. The reaction of **1** with *cis*-[$PtCl_2$(dmso)$_2$] leads to the cycloplatinated derivative (S_C,R_S)-(+)-[Pt{C_6H_4–CH=N–CH(CO_2Me)–CH_2–CH_2–SMe}Cl] (**3a**). The absolute configuration of **3a** has been established unambiguously by X-ray diffraction: orthorhombic, with a = 8.979 (4), b = 9.605(9), c = 18.205(6) Å, α = β = γ = 90.0°, space group $P2_12_12_1$. Compound **3a** contains a [6.5.6] tricyclic system generated by the fusion of a phenyl ring, a five-membered platinacycle and a six-membered chelate ring formed by the coordination of the nitrogen and sulfur to the platinum. When **1** was treated with $Na_2[PdCl_4]$ in methanol at room temperature a (7.9:1) mixture of the two diastereomers {(S_C,R_S)-**5a** and (S_C,S_S)-**5b**} of *cis*-[Pd{C_6H_5–CH=N–CH(CO_2Me)–CH_2–CH_2–SMe}Cl_2] (**5**) was formed. However, when the reaction was performed in the presence of sodium acetate, the activation of the σ($C_{sp^2,phenyl}$–H) bond took place giving the cyclopalladated complex: (S_C,R_S)-(+)-[Pd{C_6H_4–CH=N–CH(CO_2Me)–CH_2–CH_2–SMe}}Cl] (**6a**). In **6a**, the ligand acts as a monoanionic (C,N,S)$^-$ terdentate group. The study of the reactivity of **3a** and **6a** with PPh_3 is also reported.

Introduction

An important area of organometallic chemistry is that of cyclopalladated and cycloplatinated compounds.[1] Interest in such compounds has increased exponentially due to their applications in several areas.[2−12]Among the cyclometallated complexes described, those derived from optically pure N-donor ligands have attracted additional interest, since they can be used for the resolution of mono- or bidentate ligands[10−11] as well as in chiral discrimination processes.[12] As a part of a project directed towards the design of new optically pure cyclometallated complexes derived from Schiff bases of general formula: C_6H_5−CH=N−CH(R)R′ or [(η^5-C_5H_5)Fe{(η^5-C_5H_4)−CH=N−CH(R)R′}] {R = alkyl, R′ = phenyl, benzyl, or naphthyl groups}[11c,12−14] we attempted to elucidate whether the replacement of the R′ group by a pendant arm containing a prochiral atom with good donor abilities (i.e. N, O, S, or P) could determine, not only the diastereoselectivity of the coordination of the ligand to the palladium(II) or platinum(II), but also the nature of the final product formed in the cyclometallation process. The incorporation of a sulfur atom, which according to Pearsons' concept[15] is a softer base, in the backbone of the ligand may strengthen the binding to the palladium or platinum. In addition, the activation of the *ortho* σ(C−H) bond of the ligand may produce metallacycles with a (C,N,S)$^-$ terdentate group, which are uncommon in the literature.[16−17] Furthermore, optically pure platina- or palladacycles containing this sort of environment are very scarce.[18] With these aims we prepared the Schiff base: (S_C)-(−)-C_6H_5−CH=N−CH(CO_2Me)−CH_2−CH_2−SMe (**1**) (Scheme 1) and studied its reactivity towards platinum and palladium(II) salts.



Scheme 1. R = CO_2Me. *i) cis*-[$PtCl_2$(dmso)$_2$] in refluxing methanol. *ii)* $Na_2[PdCl_4]$ in methanol at room temperature. *iii)* $Na_2[PdCl_4]$ and NaAcO in refluxing methanol. *iv)* NaAcO in refluxing methanol. *v)* PPh_3 in $CDCl_3$ at room temperature

Results and Discussion

Ligand **1** was prepared according to the general procedure described for most arylaldimines.[19] The ^{1}H and

$^{13}C\{^1H\}$ NMR spectra of **1** (Exp. Section) suggested that only one isomer (*E*-form) was present in solution. When **1** was treated with $K_2[PtCl_4]$ at room temperature, the reaction produced a yellow solid. Its ^1H NMR spectrum was complex and three signals assigned to the imine proton were detected at $\delta \approx 9.15$, 9.26, and 8.30. The ^{195}Pt NMR spectrum showed three singlets at ca. $\delta = -3029$, -3059, and -3832 {of relative intensities: 2:0.3:3}. This indicated that the crude material contained at least three platinum(II) compounds. The position of signals at $\delta = -3029$ and -3059 was similar to those reported for: $[Pt(C_6H_5-CH=N-CH_2-CH_2-SEt)Cl_2]$,[17] $[Pt(H_2N-CH_2-CH_2-SEt)Cl_2]$,[20] and for related compounds containing a "$Pt(N,S)Cl_2$" core.[21] This result suggested that two isomers of *cis*-$[Pt\{C_6H_5-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}Cl_2]$ may be present in solution. The chemical shift of the third signal was similar to that of $[Pt\{C_6H_4-CH=N-CH_2-CH_2-SMe\}Cl]$ (**2**),[17] $[Pt\{(\eta^5\text{-}C_5H_5)Fe[(\eta^5\text{-}C_5H_3)-CH(R)-NMe_2]\}Cl(dmso)]$,[22] and related compounds.[21,23] Unfortunately, attempts to separate the major components of the mixture by either column chromatography or fractional crystallization failed due to the formation of metallic platinum during these experiments. More satisfactory results were obtained when the reaction was carried out using *cis*-$[PtCl_2(dmso)_2]$[24] as starting material under refluxing conditions for 12 h. The slow evaporation of the solvent yielded single crystals suitable for X-ray diffraction. Elemental analyses of this material agreed with those expected for $[Pt\{C_6H_4-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}Cl]$ (**3**). The two-dimensional heteronuclear $\{^1H\text{-}^{13}C\}$ NMR spectrum suggested that the activation of the $\sigma(C_{sp^2,phenyl}-H)$ bond had taken place. The position of the signal detected in the ^{195}Pt NMR spectrum was similar to that reported for **2**[17] and for related platinum(II) compounds with a "Pt(C,N,S,Cl)" core.[21]

Recent studies have shown that for optically pure organic imines or amines, such as: $R^1-CH=N-CH(Me)-R^2$ {R^1 = phenyl or ferrocenyl groups and R^2= phenyl or naphthyl groups} or $C_{10}H_7-CH(R^1)-NR^2R^3$ {R^1, R^2, R^3 = alkyl groups} the formation of the metallacycle through the activation of the $\sigma(C_{sp^2,aryl}-H)$ bond does not modify the absolute configuration of the stereogenic centre of the ligand.[11a,11c,25] Consequently, since **1** contains a stereogenic carbon and a prochiral sulfur atom, **3** may consist of a mixture of two diastereomers: {(S_C,R_S) or (S_C,S_S) hereinafter referred to as **3a** and **3b**}. The use of molecular models and the SPARTAN 4.0 computer program[26] indicated that in **3a**, where the $-CO_2Me$ and the Me group bound to the sulfur are on opposite sides of the coordination plane, the steric hindrance is clearly smaller than in the (S_C,S_S) isomer (**3b**). Thus, the formation of **3a** is expected to be strongly preferred to that of **3b**. ^1H and ^{13}C NMR spectra indicated that only one of the diastereomers of **3** was present in solution and its absolute configuration was determined by X-ray diffraction. An ORTEP diagram of **3a** is shown in Figure 1.

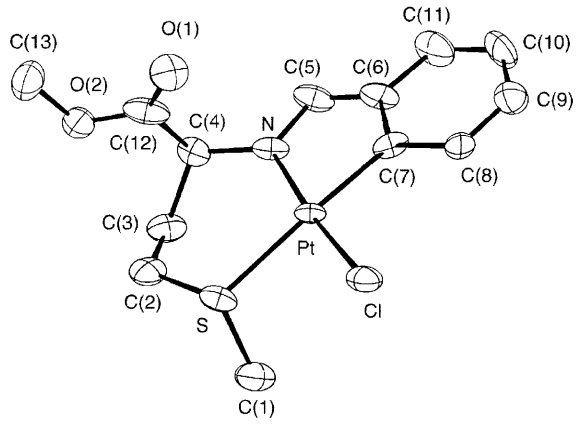

Figure 1. ORTEP diagram of the crystal structure of (S_C,R_S)−(+)−$[Pt\{C_6H_4-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}Cl]$ (**3a**). Selected bond lengths [in Å]: Pt−N, 1.984(11); Pt−S, 2.349(3); Pt−Cl, 2.308(4); Pt−C(7), 1.954(14); N−C(5), 1.954(14). Selected bond angles [in deg.]: C(7)−Pt−Cl, 94.0(4); N−Pt−S, 99.2(3); Cl−Pt−S, 85.84(13); N−Pt−Cl, 174.8(3); Pt−N−C(5), 114.9(11); N−C(5)−C(6) 119.6(16)

The structure consists of discrete molecules of $[Pt\{C_6H_4-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}]$ separated by van der Waals interactions. The platinum atom is bound to the chloride, the sulfur, the imine nitrogen and the *ortho*-carbon {C(7)} of the phenyl ring in a slightly distorted square-planar environment. The molecule contains a [6.5.6] tricyclic system derived from the fusion of the six-membered chelate ring, formed by the coordination of the sulfur and the nitrogen to the platinum(II), a five-membered platinacycle and the phenyl ring.

The metallacycle, which is formed by the atoms: Pt, N, C(5), C(6), and C(7), is practically planar and contains the >C=N− functional group. The >C=N− bond length is in the range described for related five-membered platinacycles derived from imines.[27] The ligand adopts the *anti*-conformation [(*E*)-form] and the phenyl ring forms an angle of 6.27° with the plane of the platinacycle.

The six-membered chelate ring formed by the platinum and the "$N-CH(CO_2Me)-CH_2-CH_2-S-$" moiety exhibits a chair-conformation in which the atoms C(3) and Pt deviate from the mean plane −0.6148 and +0.0928 Å, respectively.

The comparison of the bond lengths and angles involving the platinum(II) atom in **3a** and in **2**,[17] which contains a [6.5.5] tricyclic system, shows that in **3a** the Pt−C(7) bond length [1.954(14) Å] is clearly shorter than in **2** [2.012(8) Å]. However, this variation does not significantly affect the length of the Pt−S bond in a *trans* position [2.349(3) Å in **3a** and 2.334(10) Å in **2**]. In contrast, an increase in the size of the chelate ring [a five-membered ring in **2** and a six-membered ring in **3a**] introduces significant differences in the angles involving the pair of atoms Pt and Cl. For instance, in **2**, the angles: C−Pt−Cl and Cl−Pt−S are bigger than in **3a**. This finding, together with the higher value of

the Pt−Cl bond length in **3a** compared with **2**, suggests that the environment of the chlorine is more crowded in **3a**.

The absolute configuration of the molecule is determined by the chirality of the carbon atom (S_C) and the relative arrangement of the Me bound to the sulfur towards the $-CO_2Me$ group. In **3a**, these groups face opposite sides of the coordination plane of the palladium [the torsion angle C(1)−S−C(4)−C(12) is 166.81°]. As mentioned above, if these substituents were on the same side a strong steric hindrance would arise. This arrangement of groups on the stereogenic centres of **3a** is formally identical to that found in $[Pd_2\{(C_4H_3S)-CH=N-C(CO_2Me)-CH_2-CH_2-SMe\}_2Cl_2]$ (**4**).[18]

The comparison of the results obtained in the reaction of *cis*-$[PtCl_2(dmso)_2]$ with **1** or $C_6H_5-CH=N-CH_2-CH_2-SEt$[17] shows that cycloplatination of **1** occurs easily, leading to one of the two diastereomers. These differences may be attributed to the presence of a bulky group[28] in the proximity of the imine nitrogen.

When **1** was treated with $Na_2[PdCl_4]$ in methanol at ca. 20 °C *cis*-$[Pd\{C_6H_5-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}Cl_2]$ (**5**) was obtained. The ^1H NMR spectrum of **5** showed two superimposed sets of signals of relative intensities 7.9:1.0, which suggested the presence of two species in solution. $^{13}C\{^1H\}$ NMR spectroscopic studies also confirmed these results. Complex **5** could also consist of different isomers which may differ in *a)* the conformation of the ligand (*E*- or *Z*-forms) and/or *b)* the chirality of the sulfur atom in the complex (R_S or S_S). Previous NMR spectroscopic studies of palladium(II) and platinum(II) compounds containing imines have shown that the chemical shift of the methinic proton indicates the conformation of the ligand.[13,17,29,30] The ^1H NMR spectrum of **5** showed two singlets assigned to the imine protons at lower fields (δ = 8.41 and 8.38) than in **1**, thus suggesting that in the two species the imine had the (*Z*) form. Consequently, the two isomers may have a different origin, which might be related to the presence of the prochiral sulfur atom in **1**. The formation of the six-membered chelate ring by coordination of the N and S atoms to the palladium(II) may produce two diastereomers [(S_C,R_S) and (S_C,S_S)]. On this basis we assumed that the complexity of the ^1H and ^{13}C NMR spectra of **5** could be due to the presence of the two diastereomers [(S_C,R_S), **5a** and (S_C,S_S), **5b**]. Attempts to separate them by crystallization or SiO_2-column chromatography failed due to the low solubility of **5**.

The use of molecular models and the SPARTAN 4.0 computer program[26] also suggested that the less hindered isomer corresponds to the (S_C,R_S) diastereomer (**5a**). Thus, we assume that the absolute configuration of the main component is (S_C,R_S).

In order to examine whether the activation of the $\sigma(C_{sp^2,phenyl}-H)$ bond of **1** could be promoted by palladium(II) salts, more drastic reaction conditions were used (i.e. refluxing methanol and reaction periods of up to 7 days). However, no evidence of the formation of any palladacycle was detected by NMR spectroscopy. Better results were obtained when the reaction was carried out under reflux in the presence of NaAcO, which yielded a bright yellow solid. Its elemental analyses agreed with those expected for the complex $[Pd\{C_6H_4-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}Cl]$ (**6**). Its ^1H, $^{13}C\{^1H\}$, and the two dimensional heteronuclear $\{^1H$-$^{13}C\}$ NMR spectra suggested the formation of a palladacycle with a $\sigma(Pd-C_{sp^2,phenyl}-H)$ bond and the presence of only one of the two diastereomers of **6** in solution. In the view of the results obtained from the SPARTAN 4.0 program[26] and from the X-ray crystal structure of the platinum(II) analogue (see above) we assume that the absolute configuration of the isolated material is (S_C,R_S).

Compound **6a** could also be isolated by treatment of **5** with the stoichiometric amount of NaOAc in refluxing methanol. The transformation of **5** to **6a** requires the isomerization (*Z*) → (*E*) of the ligand and the formation of the $\sigma(Pd-C_{sp^2,aryl})$ bond.

Potentially terdentate chelating ligands $[N,C,X]^-$ {where X = N, P, O, or S} may adopt different binding modes and hapticities which is relevant to catalytic processes. As a first approach to explore whether the mode of binding or the hapticity of **1** could be modified under mild experimental conditions, the reactions of **3a** and **6a** with PPh_3 were studied in solution. When PPh_3 was added to a solution of **3a** {Pt:PPh_3 molar ratio equals to 1:2} in $CDCl_3$ at 20 °C, a pale yellow solution was obtained. Its ^1H and $^{13}C\{^1H\}$ NMR spectra suggested the formation of $[Pt\{C_6H_4-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}Cl(PPh_3)_2]$ (**7a**). Its ^{195}Pt NMR spectroscopic data is consistent with the values reported for platinum(II) compounds having a *trans*-"Pt(C,Cl,P_2)" core.[31]

This result is in sharp contrast with that reported for **2**, for which the addition of large excesses of PPh_3 did not produce the cleavage of the Pt−N bond[17] and suggests a higher lability of the Pt−N bond in complex **3a**. The use of the SPARTAN 4.0 computer program[26] for the diastereomer (S_C)-$[Pt\{C_6H_4-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}Cl(PPh_3)]$ (**8a**) reveals that the environment around the metal is very crowded and at least one of the phenyl rings of the PPh_3 ligand is very close to the atoms of the $-CO_2Me$ group. This would increase the steric hindrance and reduce the stability of the molecule which may be related to the higher proclivity of **3a** {compared with **2**} to undergo a ring-opening process. The cleavage of the Pt−N bond would permit the free rotation around the N−C* bond, leading to a larger separation between the aryl rings and the "CO_2Me" fragment.

When the reaction was performed in identical experimental conditions, but using **6a** and PPh_3, $[Pd\{C_6H_4-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}Cl(PPh_3)_2]$ (**9a**) was formed in solution and its ^{31}P NMR spectrum suggested a *trans*- arrangement of the PPh_3 ligands.

Since the formation of **7a** and **9a** involves the cleavage of the M−S bond (in **3a** and **6a**, respectively), the absolute configuration of these derivatives is expected to be S_C.

To sum up, the results reported in this work show the importance of the presence of a bulky and electron-withdrawing group on the stereogenic carbon atom of **1** in the

diastereoselectivity of the reactions under study. The preferential formation of **5a** versus **5b** (*d.e.* = 77.5%) may be attributed to steric effects. In **5a**, where the $-CO_2Me$ group and the Me bound to the sulfur are pointing towards opposite sides of the coordination plane of the metal, the steric hindrance is clearly smaller than in **5b**. A similar argument can be used to explain the formation of the metallacycles **3a** and **6a**. These findings suggest that the absolute configuration of the stereogenic carbon in **1** induces a high degree of diastereoselectivity in the coordination of the prochiral sulfur.

Several authors have postulated that the presence of an electron-withdrawing group favours the metallation of aliphatic carbon atoms.[1,18,32] On this basis, for **1**, which contains an electron-withdrawing group[28] at the stereogenic carbon, the activation of a ($C_{sp^2,phenyl}-H$) or a ($C^*_{sp^3}-H$) bond, in principal, could be expected. However, for **1**, the metallation of the phenyl ring is strongly preferred and no evidence of the presence of the metallacycles with a $\sigma(M-C^*_{sp^3})$ bond was detected by NMR spectroscopy. These findings are in sharp contrast with those obtained in the cyclopalladation of $[(C_4H_3S)-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe\}]$[18] which produced: $[Pd_2\{(C_4H_3S)-CH=N-C(CO_2Me)-CH_2-CH_2-SMe\}_2Cl_2]$ (**4**) through activation of the $\sigma(C^*_{sp^3}-H)$ bond.[18] Consequently, the results presented here reveal the importance of the group bound to the imine carbon in determining the type of the $\sigma(M-C)$ bond to be formed [$\sigma(M-C_{sp^2,aryl})$ or $\sigma(M-C^*_{sp^3})$] in the cyclometallation process. Besides that, compounds **3a** and **6a** have an additional interest since they may be potentially useful in a wide variety of processes, i.e. as chiral recognition compounds or discriminators, or as precursors for the asymmetrical synthesis of novel organic or organometallic derivatives.

Experimental Section

Materials and Synthesis: Benzaldehyde was obtained from standard sources and purified by vacuum distillation before use. (S_C)-Methionine methyl ester hydrochloride was obtained from Janssen Chimica and transformed into the free amine before use. *cis*-$[PtCl_2(dmso)_2]$ was prepared as previously described.[24] All the solvents used in this study were HPLC grade.

Elemental analyses (C, H, N, and S) were carried out at the Serveis Científico Tècnics de la Universitat de Barcelona and at the Serveis de Recursos Científics (Universitat Rovira i Virgili, Tarragona). − Infrared spectra were obtained with a Nicolet Impact 400 instrument using NaCl discs for **1** and KBr pellets for the solid samples. − ^1H and the two dimensional $\{^1H$-$^{13}C\}$ heteronuclear NMR experiments were run using a Varian VXR-500 or a Bruker Avance 500DMX instrument. The solvents and references used are specified in the characterization section of each compound. $^{13}C\{^1H\}$- and ^{195}Pt NMR spectra were recorded with a Bruker-250DXR instrument. The ^{195}Pt chemical shifts are referred to a $Na_2[PtCl_6]$ solution in D_2O as external reference. $^{31}P\{^1H\}$ NMR spectra were obtained with a Bruker-250DXR instrument using $CDCl_3$ as solvent and $P(OMe)_3$ as reference $\{\delta^{31}P[P(OMe)_3] = 140.17\}$. The chemical shifts (δ) are given in ppm and the coupling constants (*J*) in Hz. − The optical rotations were determined in CH_2Cl_2 using a Perkin−Elmer 241MC-polarimeter. − FAB^+ mass spectra were obtained with a VG-Quatro Fisions instrument using 3-nitrobenzyl alcohol as matrix.

Preparation of (S_C)-(−)-$C_6H_5-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe$ (1): Benzaldehyde (304 mg, $2.86\cdot10^{-3}$ mol) was added to a solution of $H_2N-CH(CO_2Me)-CH_2-CH_2-SMe$ (467 mg, $2.86\cdot10^{-3}$ mol) in 15 mL of methanol. The mixture was refluxed for 3 h. Then, the solution was concentrated to dryness giving a whitish oil. (Yield 601 mg, 82%). − IR: ν(−CO): 1736 and ν(>C=N−): 1644 cm^{-1}. − ^1H NMR (in $CDCl_3$):[33] δ = 2.09 (s, 3 H, −SMe), 2.18−2.35 (m, 2 H, $-CH_2-$), 2.46−2.60 (m, 2 H, $-SCH_2-$), 3.75 (s, 3 H, −OMe), 4.22 (m, 1 H, >CH−), 7.43 (m, 1 H, H^4), 7.45 (m, 2 H, H^3 and H^5), 7.80 (d, 2 H, H^2 and H^6), 8.33 (s, 1 H, −CH=N−). − $^{13}C\{^1H\}$ NMR (in $CDCl_3$):[33] δ = 16.2 (−SMe), 30.2 ($-SCH_2-$), 31.9 ($-CH_2-$), 52.3 (−OMe), 71.2 (>CH−), 135.4 (C^1), 128.5 (C^2 and C^6), 128.5 (C^3 and C^5), 131.2 (C^4), 164.3 (−CH=N−), 172.1 ($>CO_2$). $[\alpha]_{24\ °C}$ (c = 0.05 g/100 mL) = −24.12.

Preparation of (S_C,R_S)-(+)-[Pt{$C_6H_4-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe$}Cl] (3a): To a hot solution formed by *cis*-$[PtCl_2(dmso)_2]$ (100 mg, $2.36\cdot10^{-4}$ mol) and 20 mL of methanol, **1** (59 mg, $2.35\cdot10^{-4}$ mol) was added. The suspension was refluxed for 12 h and filtered out. Then, the filtrate was concentrated to ca. 5 mL on a rotary evaporator. The slow evaporation of the solvent at ca. 20 °C produced golden crystals, which were collected and air-dried. (Yield 92 mg, 81.0%). − $C_{13}H_{16}ClNO_2SPt$: calcd. (found) C 32.5 (32.5), H 3.3 (3.3), N 2.9 (3.0), S 6.7 (6.7). − IR: ν(−CO): 1739 cm^{-1} and ν(>C=N−): 1594 cm^{-1}. − ^1H NMR (in $CDCl_3$):[33] δ = 2.55 [s, 3 H, −SMe, ^3J(Pt−H) = 20], 2.62 and 2.79 (m, 2 H, $-SCH_2-$), 2.30 and 2.60 (m, 2 H, $-CH_2-$), 3.74 (s, 3 H, −OMe), 4.52 [m, 2 H, >CH−, ^3J(Pt−H) = 52], 7.31 (d, 1 H, H^3), 7.09 (t, 1 H, H^4), 7.28 (t, 1 H, H^5), 7.95 [d, 1 H, H^6, ^4J(Pt−H) = 39], 8.27 [s, 1 H, −CH=N−, ^3J(Pt−H) = 133]. − $^{13}C\{^1H\}$ NMR (in $CDCl_3$):[33] δ = 21.2 (Me), 27.7 ($-SCH_2$), 31.4 ($-CH_2-$), 53.3 (−OMe), 66.3 (>CH−), 143.0 (C^1), 152.1 (C^2), 128.2 (C^3), 124.3 (C^4), 133.4 (C^5), 132.2 (C^6), 181.9 (−CH=N−), 170.0 ($-CO_2$). − ^{195}Pt NMR (in $CDCl_3$): −3832. $[\alpha]_{24\ °C}$ (c = 0.1 g/100 mL) = +73.9. FAB^+(selected data): 481 $[M + H]^+$, 445 $[M - Cl]^+$.

Preparation of *cis*-[Pd{$C_6H_5-CH=N-CH(CO_2Me)-CH_2-CH_2-SMe$}$Cl_2$] (5): Ligand **1** (157 mg, $6.25\cdot10^{-4}$ mol) was dissolved in 15 mL of methanol. A solution formed by $Na_2[PdCl_4]$ (184 mg, $6.25\cdot10^{-4}$ mol) and 10 mL of methanol was then added. The mixture was stirred at ca. 20 ° C for 3 h. The solid formed was collected, washed with methanol (3·2 mL) and air-dried. (Yield 143 mg, 53.3%). − $C_{13}H_{17}Cl_2NO_2SPd$: calcd. (found) C 36.5 (36.3), H 4.0 (4.0), N 3.3 (3.1), S 7.5 (7.45). − IR: ν(−CO): 1740 cm^{-1} and ν(>C=N−) = 1624 cm^{-1}. − ^1H NMR spectroscopic data (in $CDCl_3$):[33] *Major isomer,* **5a** $\{(S_C,R_S)\}$: δ = 2.63 (s, 3 H, −SMe), 2.50 and 2.55 (m, 2 H, $-SCH_2-$), 3.40 and 3.90 (m, 2 H, $-CH_2-$), 3.88 (s, 3 H, −OMe), 4.22 (m, 1 H, >CH−), 7.69−7.82 (m, 3 H, H^3, H^4 and H^5), 8.38 (s, 1 H, −CH=N−) and 9.23 (d, 2 H, H^2 and H^6). *Minor isomer,* **5b** $\{(S_C,S_S)\}$: δ = 2.52 (s, 3 H, SMe), 2.60 and 2.45 (m, 2 H, $-SCH_2-$), 3.40 and 3.90 (m, 2 H, $-CH_2-$), 3.81 (s, 3 H, −OMe), 4.02 (m, 1 H, >CH−), 7.69 (m, 3 H, H^3, H^4 and H^5), 8.41 (s, 1 H, −CH=N−), 9.05 (d, 2 H, H^2 and H^6). − ^1H NMR spectroscopic data (in $[D_6]$DMSO):[33] *Major isomer,* **5a** $\{(S_C,R_S)\}$: δ = 2.88 (s, 3 H, −SMe), 2.96−3.11 (m, 2 H,$-SCH_2-$), 3.40−3.90 (m, 2 H, $-CH_2-$), 4.07 (s, 3 H, −OMe), 4.96 (m, 1 H, >CH−), 7.69−7.82 (m, 3 H, H^3, H^4, and H^5), 8.38 (s, 1 H, −CH=N−), 9.23 (d, 2 H, H^2 and H^6). − $^{13}C\{^1H\}$ NMR spectroscopic

data (in [D$_6$]DMSO):[33] *Major isomer,* **5a** {(S_C,R_S)}: δ = 21.1 (−SMe), 29.3 (−SCH_2−), 30.7 (−CH_2−), 53.2 (OMe), 70.5 (>CH−), 132.0 (C^1), 132.3 (C^2 and C^4), 129.2 (C^3 and C^5), 134.7 (C^4), 168.4 (−CO_2), 178.3 (−CH=N−).

Preparation of (S_C,R_S)-(+)-[Pd{C_6H_4−CH=N−CH(CO_2Me)−CH_2−CH_2−SMe}Cl] (6a): This complex was isolated by two different procedures using either compounds **1** or **5** [methods *(a)* and *(b)*, respectively] as starting materials.

Method A: A 100 mg amount ($3.98\cdot10^{-4}$ mol) of **1** was dissolved in 10 mL of methanol. $Na_2[PdCl_4]$ (117 mg, $3.98\cdot10^{-4}$ mol) and NaOAc (33 mg, $4.0\cdot10^{-4}$ mol) were then added and the mixture was refluxed for 2 h. The solid formed was removed by filtration and discarded. Slow evaporation of the filtrate produced the precipitation of a yellow solid, which was filtered out and air-dried. (Yield 87 mg, 56).

Method B: Compound **5** (98 mg, $2.28\cdot10^{-4}$ mol) was suspended in methanol (15 mL), and a solution of NaOAc (19 mg, $2.31\cdot10^{-4}$ mol) and 10 mL of methanol was added. The mixture was refluxed for 2 h and filtered out. The filtrate was allowed to evaporate at ca. 20 °C and the solid formed was collected by filtration and air-dried. (Yield 58 mg, 68%). $C_{13}H_{16}ClNO_2PdS$: calcd. (found) C 39.8 (39.8), H 4.1 (4.2), N 3.6 (3.6), S 8.2 (8.3). − IR: ν(−CO): 1736 cm^{-1} and ν(>C=N−): 1601 cm^{-1}. − ^{1}H NMR spectroscopic data (in $CDCl_3$):[33] δ = 2.51 (s, 3 H, −SMe), 2.22−2.70 (m, 2 H, −SCH_2−), 2.58−2.72 (m, 2 H, CH_2−), 3.80 (s, 3 H, −OMe), 4.42 (m, 1 H, >CH−), 8.06 (s, 1 H, −CH=N−), 7.33 (d, 1 H, H^3), 7.09 (t, 1 H, H^4), 7.21 (t, 1 H, H^5), 7.94 (t, 1 H, H^6). − ^{13}C{^{1}H} NMR spectroscopic data (in $CDCl_3$):[33] δ = 19.9 (−SMe), 27.6 (−SCH_2−), 30.4 (−CH_2−), 53.1 (−OMe), 66.6 (>CH−), 179.8 (−CH=N−), 169.2 (−CO_2), 144.0 (C^1), 160.1 (C^2), 128.2 (C^3), 124.9 (C^4), 131.6 (C^5), 134.7 (C^6). − $[\alpha]_{24\ °C}$ (c = 0.05 g/100 mL) = −51.6. − FAB$^+$(selected data): 391 $[M + H]^+$, 357 $[M - Cl]^+$.

Table 1. Crystal data and details of the refinement of the crystal structure of **3a**

Empirical formula	$C_{13}H_{16}ClNO_2PtS$
Mr	480.88
Crystal size [mm × mm × mm]	0.1 × 0.1 × 0.2
a [Å]	8.797(4)
b [Å]	9.605(9)
c [Å]	18.205(6)
α, β, γ [deg.]	90.0
V [Å^3]	1538.2(17)
Crystal System	Orthorhombic
Space group	$P2_12_12_1$
Z	4
λ [Å]	0.71069
T [K]	293(2)
$D_{calcd.}$ [Mg·m^3]	2.081
Absorption coefficient [mm^{-1}]	9.891
F(000)	912
Θ range for data collection [deg.]	from 2.57 to 29.94
Refinement method	Full-matrix least-squares on F^2
Number of collected reflections	2571
Number of independent reflections	2552 [R(int) = 0.0107]
Number of data	2526
Number of parameters	173
Goodness of fit on F^2	0.994
Final R indices [$I \geq 2\sigma(I)$]	R_1 = 0.0484, wR_2 = 0.1124
R indices (all data)	R_1 = 0.0709, wR_2 = 0.1205
Absolute structure parameter	0.00(2)
Largest difference peak and hole [eÅ^{-3}]	0.835 and −0.894

Preparation of (S_C)-[Pt{C_6H_4−CH=N−CH(CO_2Me)−CH_2−CH_2−SMe}Cl(PPh_3)$_2$] (7a): This complex was prepared on an NMR spectroscopic scale. A 10 mg ($2.05\cdot10^{-5}$ mol) amount of **3a** was dissolved in 0.7 mL of $CDCl_3$, then PPh_3 (11 mg, $4.16\cdot10^{-5}$ mol) was added. The mixture was stirred vigorously for 5 min. at ca. 20 ° C and the pale solution was characterized by NMR spectroscopies. − ^{1}H NMR spectroscopic data (in $CDCl_3$):[33] δ = 2.59 (s, 3 H, −SMe), 2.54 and 2.72 (m, 2 H, −SCH_2−), 2.61 and 2.75 (m, 2 H, −CH_2−), 3.75 (s, 3 H, −OMe), 5.72 [br., 1 H, >CH-], 6.45 [d, 1 H, H^3], 6.90 [t, 1 H, H^4], 6.58 (t, 1 H, H^5), 8.68 (s, 1 H, −CH=N−) and 7.10−7.80 (m, 31 H, H^6 and protons of PPh_3). − ^{13}C{^{1}H} NMR spectroscopic data (in $CDCl_3$):[33−35] δ = 16.6 (−SMe), 29.9 (−SCH_2−), 30.0 (−CH_2−), 57.7 (−OMe), 68.3 (>CH−), 171.4 (−CO_2), 168.6 (−CH=N−), 131.8 (C^3), 123.4 (C^4), 132.6 (C^5), 138.1 (C^6). − ^{195}Pt NMR (in $CDCl_3$): δ = −4439, ^1J(^{195}Pt-^{31}P)= 3637. − ^{31}P NMR spectroscopic data (in $CDCl_3$): δ = 13.69, ^1J(^{31}P-^{195}Pt)= 3635.

Preparation of (S_C)-[Pd{C_6H_4−CH=N−CH(CO_2Me)−CH_2−CH_2−SMe}Cl(PPh_3)$_2$] (9a): This complex was prepared according to the procedure described for **7a** but using **6a** (40 mg, $5.1\cdot10^{-5}$ mol) and PPh_3 (54 mg, $2.06\cdot10^{-5}$ mol). − ^{1}H NMR spectroscopic data (in $CDCl_3$):[33] δ = 2.09 (s, 3 H, −SMe), 2.38 and 2.48 (m, 2 H, −SCH_2−), 2.60 and 2.65 (m, 2 H, −CH_2−), 3.74 (s, 3 H, −OMe), 5.46 (m, 1 H, >CH−), 6.39 (d, 1 H, H^3), 6.90 (t, 1 H, H^4), 6.56 (t, 1 H, H^5), 8.42 (s, 1 H, −CH=N−), 7.30−8.60 (m, 31 H, H^6 and *protons* of PPh_3). − ^{13}C{^{1}H} NMR spectroscopic data (in $CDCl_3$):[33−34] δ = 15.3 (−SMe), 30.5 (−SCH_2−), 31.8 (−CH_2−), 52.4 (−OMe), 65.0 (>CH−), 171.7 (−CO_2), 177.3 (−CH=N−), 158.8 (C^1), 147.90 (C^2), 130.8 (C^3), 124.0 (C^4), 128.9 (C^5), 138.1 (C^6). − ^{31}P NMR spectroscopic data (in $CDCl_3$): δ = 28.86.

Crystallography: A prismatic crystal of **3a** was selected and mounted on an Enraf CAD4 four-circle diffractometer. Unit cell parameters were determined from automatic centering of 25 reflections in the range $12° < \Theta < 21°$ and refined by least-squares method. Intensities were collected with graphite monochromated Mo-K_α radiation, using ω/2Θ scan technique. Three reflections were measured every 2 h as orientation and intensity control, and no significant intensity decay was observed. Lorentz-polarization and absorption corrections were made. The structure was solved by Direct methods using the SHELXS97 computer program[36] and refined by full-matrix least-squares method with the SHELXL97 computer program[37] using 2526 reflections (very negative intensities were not assumed). The function minimized was $\Sigma||F_o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.0795\ P)^2]^{-1}$ and $P = (|F_o|^2 + 2\ |F_c|^2)/3$. f, f', and f'' were obtained from the literature.[38] The chirality of the structure was defined from the Flack coefficient.[39] All the hydrogen atoms were computed and refined with an overall isotropic temperature factor using a riding model. The final R(on F) factor was 0.048 and wR(on F) = 0.112. Further details concerning the resolution and refinement of the crystal structure of **3a** are presented in Table 1. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-152831. Copies of the data can be ob-

tained free of charge on applications to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Intramolecular Metal Ligand Aromatic Cation−π Interactions in Crystal Structures of Transition Metal Complexes

Miloš Milčić[a] and Snežana D. Zarić*[a]

Dedicated to Prof. M. B. Ćelap on the occasion of his 80th birthday

Keywords: Cation−π interactions / Density functional calculations / Metal complexes / Crystal structures

Cation–π interactions between ligands coordinated to a metal cation and aromatic groups have been predicted by theoretical calculations, and have been found in crystal structures of metalloproteins from the Protein Data Bank (PDB). We proposed metal ligand aromatic cation–π (MLACπ) interaction as intramolecular interactions in transition metal complexes. Searching crystal structures of transition metal complexes from the Cambridge Structural Database (CSD) reveals that there are quite a number of metal complexes, where an aromatic ring interacts with a hydrogen atom from a ligand in the same complex. The hydrogen atom is separated from the metal center by a few bonds and gains positive charge from the metal atom. In the complexes there are various metal atoms and various ligands. In the most of the complexes, the aromatic ring is separated from the metal center by two or four bonds, and interacts with the hydrogen atom of another ligand. In complexes where the aromatic ring is separated from the metal center by four or five bonds, there are examples of aromatic groups interacting with the hydrogen atom in the same ligand. By quantum chemical computations it was evaluated for the model systems of cationic cobalt(III) complexes with a charge of +1, that the energy of this intramolecular MLACπ interaction is about 4 kcal/mol.

Introduction

The cation−π interaction is considered an important non-covalent bonding force in a wide range of molecular systems.[1,2] Gas-phase studies of ion-molecule complexes established that cations bind strongly to molecules with π bonds.[2] High-level theoretical studies of ion−molecule systems have shown excellent agreement between calculated and experimental bonding energies, and have shown the geometries of the ion−molecule complexes.[3−15] The experimental and theoretical studies provide an understanding of the nature of the cation−π interaction.[1,16−18]

Cation−π interactions are important for molecular recognition in many biological systems.[1,2] Investigations on cation−π interactions in proteins show that cation−π interaction pairs contribute at least as much to protein stability and the structural motifs of a native protein as more conventional interactions. Hence, it was proposed that cation−π interactions should be considered the same way as hydrogen bonds, salt bridges, and hydrophobic effects in analyses of the stability of the native protein structure.[16,19,20]

Recently, the interaction of metal complexes as cations with π systems were investigated.[21−23] It is possible to predict cation−π interactions by quantum chemical calculations, since in theoretical work it was shown that calculated interaction energies for cation−π systems are in agreement with experimental data.[3−15] In our previous work, the interactions of π systems with the cationic metal complex $[Co(NH_3)_6]^{3+}$ were predicted by quantum chemical calculations. The bonding energies obtained with the B3LYP method for benzene, acetylene, and ethylene π complexes are 31.34 kcal/mol,[21] 18.30 kcal/mol, and 17.02 kcal/mol,[22] respectively. Since these calculations showed strong cation−π interactions, we proposed[21,22] that the cation−π interaction may exist when ligands coordinated to a metal ion can get in contact with π systems. This can be the case in metalloproteins, in metal complexes, in supramolecular structures, and when DNA and RNA interact with metal cations.

Cation−π interactions with a cationic metal complex were observed by analyzing crystal structures of DNA and RNA. It was noticed that cation−π interactions of divalent cations with the π systems of bases are important in stabilizing unstacked conformations of DNA and RNA.[24,25] Metal ligand aromatic cation−π (MLACπ) interactions in metalloproteins were discovered by searching crystal structures of metalloproteins from the Protein Data Bank (PDB).[23] These data reveal that there are quite a number of metalloproteins, where aromatic rings from phenylalanine, tyrosine, and tryptophan are close to a metal center, interacting with coordinated ligands. Among these ligands are amino acids like asparagine, aspartate, glutamate, histidine, and threonine, but also substrates like water and ethanol. These interactions play a role in stability and conformation of metalloproteins, and in some cases may also be directly involved in the mechanism of enzymatic reactions which occur at the metal center. For the enzyme superoxide dismutase, we evaluated by quantum chemical

computations that Trp163 has an interaction energy of 10.09 kcal/mol with the ligands coordinated to the iron center.

We propose that intraligand MLACπ interactions, where ligands coordinated to a metal center interact with aromatic groups, exist in transition metal complexes. Intermolecular interactions between hydrogen atoms and π systems have been noticed in organometallic crystals.[24] In this work, we screened crystal structures of metal complexes in the Cambridge Structural Database (CSD) in order to find such intramolecular interactions. The structures with these interactions are described and the energy of the interactions was evaluated by quantum chemical calculations on model systems.

Results and Discussion

We have found that intramolecular MLACπ interactions, between a coordinated ligand and the aromatic ring in the

same complex, can be observed in a number of crystal structures of transition metal complexes. Data about these interactions in different crystal structures are compiled in Table 1 and Table 2. The data show that there are numerous metal complexes where there is close contact between an aromatic ring and a hydrogen atom from a ligand, and that different metal ions and ligands can be involved.

In all of the observed cases where this interaction occurs, the ligand interacting with an aromatic group possesses a hydrogen atom pointing towards the aromatic ring. A partial positive charge of the ligand, induced by the metal charge, is situated on the hydrogen atom interacting with the aromatic ring. In most of the crystal structures the positions of hydrogen atoms were given, and in Table 1 and Table 2 the distances from the interacting hydrogen atom to the center of the aromatic ring and to the closest carbon atom of the aromatic ring are given. We also list the distances from the heavy atom (oxygen or nitrogen) to which the hydrogen atom is bound.

Based on the type of the ligand containing with the aromatic group, we can separate the metal complexes with MLACπ interactions into two groups. In the first group are

complexes where the aromatic group is bound to the atom that is coordinated to the metal ion. In this way there are only two bonds between the metal center and the aromatic group (Figure 1, a and b). In the second group are complexes where the aromatic group is separated from the metal center by several bonds (Figure 1, c, d, and e).

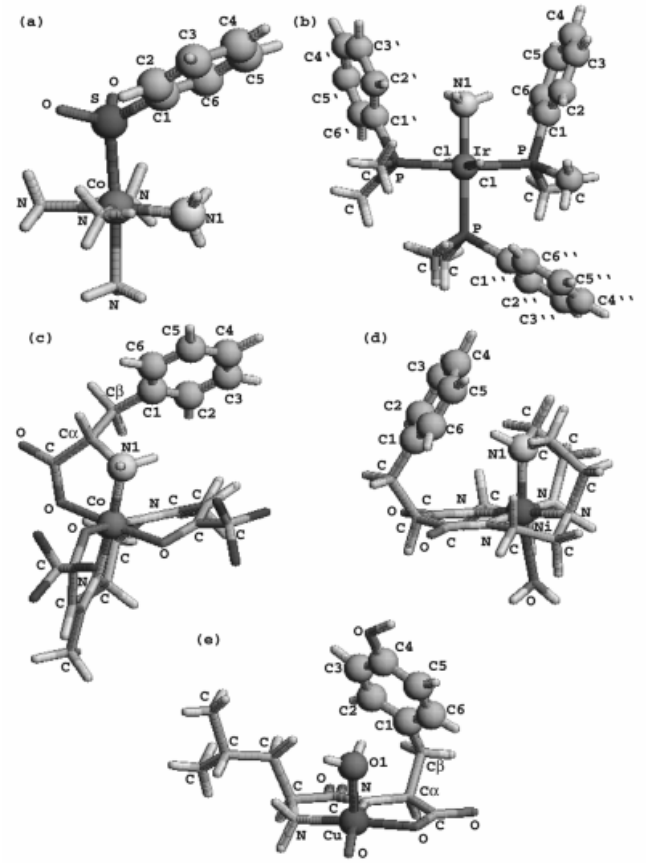

Figure 1. Structures of complexes with intramolecular MLACπ interaction; (a) BZSACS, (b) PEDXAX, (c) VAFSIE, (d) DUSJIK, (e) LETYCU10

Complexes with Two Bonds between the Aromatic Ring and the Metal Center

In these complexes, organic ligands with aromatic groups can make MLACπ interactions only if the ligand is coordinated in a *cis* position, and there is no possibility for such an interaction within the same ligand. In the structures given in Table 1 the aromatic ring is bonded to the atoms N, P, S, Si, Sb (last column in Table 1), while at the same time these atoms are coordinated to the metal ion. The carbon atom of the aromatic ring that is the closest to the interacting hydrogen atom is the one that is bonded to the heteroatom, and is the closest to the metal center (C1 in Figure 1, a). An example for this type of complex, structure BZSACS, is shown in Figure 1, a. In this complex, a cobalt ion is octahedrally coordinated by five NH_3 groups and the sulfur atom of a benzenesulfinato ligand. The phenyl ring of the benzenesulfinato ligand interacts with the hydrogen atoms of the NH_3 ligand in *cis* position. In the crystal structure there are two hydrogen atoms oriented towards the aromatic ring, with the distances to the closest carbon atom of 3.16 and 2.83 Å. The torsion angle C1−S−Co−N1 is 15.8° which is very favorable for a MLACπ interaction.

In other complexes (structures CUBXAY, TSACOP, PIRKAC, PEDXAX) there are also two hydrogen atoms of the same ligand interacting with the same aromatic ring (Table 1). In some complexes there are two MLACπ interactions in the same complex. In the structures AQTPRU, DIKMUF, PEDXAX, and WAXGIL there are two aromatic groups of two ligands interacting with the hydrogen atoms of the same ligand (Table 1). The structure of the *trans,mer*-$[IrCl_2(NH_3)(PMe_2Ph)_3]^+$ complex (PEDXAX) is shown in the Figure 1, b. Two PMe_2Ph ligands, which are in *cis* positions relative to the NH_3, have phenyl groups oriented towards NH_3. The torsion angles C1−P−Ir−N1 and C1′−P−Ir−N1 are 7.5 and 26.9°, and the N1−C1 and N1−C1′ distances are 3.01 and 3.09 Å, respectively (Table 1, column 7). In this structure there is one more MLACπ interaction, that is not listed in the Table 1, since we searched and listed only interactions where there are two bonds between the hydrogen atom and the metal center. The third interaction in this complex is the interaction of a third phenyl group with the hydrogen atom of the CH_3 group (Figure 1, b); the C1′′−H distance is 2.43 Å.

It can be expected that when the interacting hydrogen atom is separated from the metal center by more bonds it could gain less positive charge from the metal ion, resulting in a diminished interaction. However, here we are considering intramolecular interactions, and there are many steric constrains. Hence, it is not possible to observe a regular correlation between the interaction distances and the amount of positive charge on the hydrogen atom, as is possible with metalloproteins where MLACπ interactions are not as constrained by steric influences.[23] It is interesting to point out that from spectra of the *trans,mer*-$[IrCl_2(NH_3)(PMe_2Ph)_3]^+$ complex in solution, it is evident that there is rapid rotation about the Ir−P bonds,[45] which means that there are no MLACπ interactions in solution.

The structures TOJCIE, KAJROC, and CIRNUM are structures of binuclear complexes. In these three complexes the aromatic rings interact with the hydrogen atoms of the ligands in the bridge.

In the complexes listed in the Table 1 there is not much freedom for the ligands to adjust their mutual orientation. Due to steric constraints, the mutual orientation of the aromatic ring and the interacting hydrogen atom of the ligand in a *cis* position is such that the hydrogen atom and the heavy atom are close to the C1 atom of the aromatic ring, but rather far from its center (Figure 1, a). This can also be noticed by comparing the interaction distances in these complexes (Table 1) with the distances in other complexes listed in Table 2.

Complexes with Several Bonds between the Aromatic Ring and the Metal Center

The data for these complexes are shown in Table 2. In most of the structures there are four bonds between the

metal center and the aromatic ring, but there are a few exceptions. In the structures DEMHAE, NOVBAB, ZURREJ, and NOLQIO, there are three bonds between the metal center and the aromatic ring, and in structure DUSJIK there are five bonds.

In the structures with several bonds between the metal center and the aromatic ring there is a possibility for MLACπ interactions with the hydrogen atom of another ligand, but also with the hydrogen atom of the same ligand (structures 1−8 in Table 2). In the phenylalaninato complex (structure VAFSIE, Figure 1, c) there is an intraligand MLACπ interaction, where the phenyl ring interacts with the hydrogen atom bonded to the coordinated nitrogen atom. The value of the torsion angle C1−Cβ−Cα−N1 is −52.8°. Due to steric constraints, as in all other structures with intraligand MLACπ interactions, the closest carbon atom to the interacting hydrogen atom is C1 (Figure 1, c). The C1−H distance is 2.33 Å, one of the shortest C−H distances among complexes listed in Table 2. In the structure NEGREV there is a binuclear complex, and the ligand with intraligand MLACπ interaction is in the bridge, coordinated to both metal ions.

For complexes with an intraligand MLACπ interaction, the range of the interaction distances (Table 2, structures 1−8) is small compared to other complexes with such interactions (Table 1 and Table 2). For example, the C−H distances range from 2.66 to 2.23 Å, which is smaller than in other complexes in Table 1 and Table 2 (structures 10−22). The C−H and C−N distances are the shortest (Table 1 and Table 2), but distances to the center of the aromatic ring are longer than for other complexes in Table 2. The reason for the small range of distances is that in all these complexes the interactions are very similar, and in all cases there are very strong steric constraints as the aromatic group and the interacting hydrogen atom are on the same ligand. At the same time the steric constrains do not allow the hydrogen atom to be directed to the center of the ring, but it remains close to only one or two carbon atoms in the ring.

Among all structures in Table 1 and Table 2, DUSJIK is the structure with the shortest distance between the hydrogen atom and the center of the ring. It is a very special structure, where Ni^{III} is coordinated by one pentadentate ligand and a water molecule. A pentadentate ligand is coordinated with five nitrogen atoms and has a benzyl group (Figure 1, d). There are a large number of bonds between the aromatic ring and the interacting hydrogen atom, and there is a possibility for the phenyl ring to orient itself in a way that the interacting hydrogen atom is directed to the center of the aromatic ring. The distance from the hydrogen atom to the center of the ring is 2.21 Å. The authors[56] noticed an unusual orientation of the benzyl group and a very short distance between the hydrogen atom and the aromatic ring, and attributed this to π-electron donor−acceptor interactions.

Among the structures where the aromatic group is separated from the metal center by several bonds (Table 2) there are a number of structures where the aromatic ring interacts with the hydrogen atom of another ligand (structures 10−22). In the structure LETYCU10 there is a five-coordinate complex of Cu^{II} (Figure 1, e). The dipeptide L-leucyl-L-tyrosine is coordinated as a tridentate chelate; the fourth coordination site is occupied by water. The fifth ligand is the carboxyl oxygen atom of a dipeptide, coordinated to another metal atom. In this way there are chains in the crystal structure. The aromatic ring interacts with the hydrogen atom of coordinated water. In this structure the interacting hydrogen atom is closer to the center of the ring (2.58 Å) than to the carbon atom (2.66 Å) (Table 2).

The ligand with the interacting hydrogen atom is very often coordinated water (all examples in Table 2, where the heavy atom is oxygen). In other cases the interacting hydrogen atom is part of some coordinated amine. In structures NALPIZ and ZURREJ there is a simple NH_3 ligand.

In many of the structures there are two MLACπ interactions in the same complex. In some complexes there are two pairs of identical ligands making almost identical interactions, as in the structures DEMHAE, DIXHAT, and NOVBAB (Table 2). In case of NALPIZ, two phenyl groups interact with the same NH_3 ligand, and it is the only structure in this group with this type of interaction. In the structure NUTKES, the complex is binuclear. In this case, in one of the MLACπ interactions the aromatic group is of the ligand forming the bridge, in the other interaction an aromatic group of one metal ion interacts with the H_2O molecule ligated to the other metal ion. These two interactions are rather different (Table 2).

In the complexes with the aromatic ring separated from the metal center by several bonds and interacting with hydrogen atoms of another ligand (Table 2, structures 11−22) there are less steric constraints preventing the interaction of the whole aromatic ring. Here the interaction distances to the center of the ring are shorter, and at the same time the distances to the closest carbon atom are longer compared with other complexes (Table 1 and Table 2, structures 1−8).

Calculated Intramolecular MLACπ Interactions

Since the complexes in which intramolecular MLACπ interactions exist are rather large, for DFT calculations model systems with smaller ligands were used. The geometries and energies for structures with various conformations of the aromatic ring in the model systems were calculated. Based on the difference in energy for conformers with and without MLACπ interactions, the energy of the interactions was evaluated. It can be expected that the partial positive charge on interacting hydrogen atoms depends on the charge of the whole complex. By quantum chemical calculations it was shown that the MLACπ interaction is stronger if the complex is more positively charged.[68] The evaluated energy in these calculations is for the model systems of cationic complexes of Co^{III} with charge of +1.

Calculations on Complexes with Two Bonds between the Aromatic Ring and the Metal Center

A suitable model system for calculations on this type of interactions was the cobalt(III) complex $[CoCl_2(NH_3)_3$-

Table 3. Some geometrical data of optimized conformers of model systems

Structure[a]	Type of interaction	Torsion angle [°][b]	N···center of ring [Å]	H···center of ring [Å]	N···C [Å]	H···C [Å]
$[CoCl_2(NH_3)_3(C_6H_5NH_2)]^+$	ligand in *cis* position	2.6	3.638	2.721	2.965	2.269
$[CoCl(NH_3)_3Phe]^+$						
	intraligand	49.8	3.875	3.091	2.973	2.425, 2.497
	ligand in *cis* position	49.8	3.674	2.654	3.584	2.579
	intraligand	−50.8	3.859	3.112	2.964	2.439, 2.683

[a] Structures are shown in Figure 2. – [b] In case of $[CoCl_2(NH_3)_3(C_6H_5NH_2)]^+$, the torsion angle is C1−N1−Co−N2, in case of $[CoCl(NH_3)_3Phe]^+$ the torsion angle is C1−Cβ−Cα−N1.

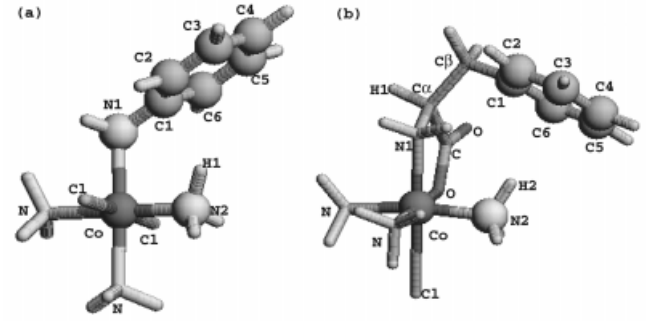

Figure 2. Geometries of model systems used for calculations of intramolecular MLACπ interactions: (a) $[CoCl_2(NH_3)_3(C_6H_5NH_2)]^+$, (b) $[CoCl(NH_3)_3Phe]^+$

$(C_6H_5NH_2)]^+$ (Figure 2, a). The coordinated aniline molecule has two NH_3 and two Cl^- ligands in *cis* positions. Optimizing the geometry for this complex always gives a structure where the aromatic ring is situated above the NH_3 group. In this structure the torsion angle C1−N1−Co−N2 (Figure 2, a) is 2.6°. One hydrogen atom of the NH_3 ligand is oriented towards the aromatic ring. The interaction distances C1···H1 and C1···N2 are 2.269 and 2.965 Å, respectively (Table 3). These distances are a little shorter than distances found in the crystal structures (Table 1). In order to find the energy of the geometry where the aromatic ring is above Cl we fixed the torsion angle C1−N1−Co−Cl to 2.6°, a value that we obtained for the torsion angle C1−N1−Co−N2 of the optimized structure. The difference in energy for structures where the aromatic ring is above the NH_3 and Cl^- ligands is 7.28 kcal/mol. In the first structure the aromatic ring has attractive interactions with the partially positively charged hydrogen atom (+0.36), in the second one it has repulsive interactions with the partially negatively charged chloro ligand (−0.22). Hence, the difference in energy is not only caused by attractive MLACπ interactions, but also by repulsive interactions. We evaluate that the energy of MLACπ interaction is about half of this difference, so it is between 3.5 and 4.0 kcal/mol.

Calculations on Complexes with Several Bonds between the Aromatic Ring and the Metal Center

In these complexes there is the possibility for the aromatic ring to interact with a hydrogen atom in the same ligand, or with the hydrogen atom in another ligand. To study both of these interactions we used the $[CoCl(NH_3)_3Phe]^+$ complex as model system (Figure 2, b). In the coordinated phenylalaninato ligand there are three possible conformations of the phenyl ring, which can be defined by the torsion angle C1−Cβ−Cα−N1 (Figure 2, b). The ideal values for this torsion angle are 60°, −60°, and 180°. Using these ideal torsion angles as a starting point for the optimization, gave optimized structures with angles of 49.8, −50.8, and −143.6°, respectively (Table 3). In the first conformer (with a torsion angle of 49.8°) there is an intraligand MLACπ interaction and a MLACπ interaction with the *cis*-NH_3 ligand. In the conformer with a torsion angle of −50.8° there is only an intraligand interaction, and in the conformer with the torsion angle of −143.6° there is no interaction. The calculated distances for intraligand MLACπ interactions (Table 3) are in the range of distances that are observed in crystal structures (Table 2, structures 1−8). In the case of the interaction of the phenyl ring with the NH_3 ligand in *cis* position, the calculated C−H distance (Table 3) is shorter than most of the C−H distances in crystal structures, while the calculated C−N distance is longer than most C−N distances in crystal structures (Table 2, structures 11−22).

The conformer with only one intraligand MLACπ interaction is more stable then the conformer without MLACπ interaction by 3.63 kcal/mol. The conformer with two MLACπ interactions is more stable by 7.61 kcal/mol. Since the distances of intraligand interactions are very similar in both conformers (Table 3), one can conclude that the energies are also similar. It means that in the conformer with the two MLACπ interactions, about 3.5 kcal/mol is stabilization for the intraligand interaction and the rest of about 4 kcal/mol is stabilization of interaction with the ligand in the *cis* position.

Conclusion

MLACπ interactions are proposed as intramolecular interactions in metal complexes. By coordination to a metal cation, ligands get positive charge, and can interact with an aromatic ring in the same complex. The Cambridge Structural Database was systematically searched to find intramolecular interactions between ligands coordinated to a metal center and aromatic rings. It turned out that this type of

interaction is ubiquitous in metal complexes. Examples were found for various metal ions and ligands. In most of the complexes there are two or four bonds between the metal center and the aromatic ring. The aromatic ring of an organic ligand can interact with a hydrogen atom of another ligand, or, in complexes where there are four or five bonds between the metal center and the aromatic ring also with hydrogen atoms of the same ligand. In this latter case, the aromatic ring can also interact with hydrogen atoms of the same ligand. The steric constraints in the complexes have an important influence on the geometry and probably the strength of intramolecular MLACπ interactions.

DFT calculations on model systems of Co^{III} complexes with a total charge of +1 have been done in order to evaluate the energy of intramolecular MLACπ interactions. Geometries and energies have been calculated for conformers with different orientations of the phenyl ring. Calculated geometric parameters of the interactions were very similar to those found in the crystal structures of complexes. By comparing the energies of conformers both with and without MLACπ interactions, we determined that the energy of interactions in these model systems is about 4 kcal/mol.

Experimental Section

Data Screening and Computational Methods: Crystal structures of metal complexes containing a phenyl ring and transition metal ions with coordinated nitrogen or oxygen atoms were extracted from the CSD. The structures of these metal complexes were screened for intramolecular cation−π interactions between ligands coordinated to the metal ion and aromatic groups using geometric criteria. We used the same criterion for distance as proposed by McFail-Isom et al.[25] for screening crystal structures of DNA for cation−π interactions between a metal ion and an aromatic base of DNA, for searching for MLACπ interactions in metalloproteins.[23] However, we did not use any restrictive criteria for the angle of the normal of the aromatic ring plane with the distance vector between the center of the aromatic ring and the metal center. Since in this case we were investigating intramolecular interactions, the aromatic ring is part of a ligand and therefore the orientation of the aromatic ring can be different. This is not the case where the aromatic group was not part of a coordinated ligand. We searched for structures, where the distance between the metal ion and the center of the aromatic ring is less than d_0 = 5.5 Å. Screening the CSD with the described criterion provided a large number of structures, where an aromatic ring is close to a metal center. We considered only structures with R factors < 0.06, and chose a number of structures where it was clear that an intramolecular MLACπ interaction between coordinated ligand and aromatic ring exists. Since it was shown that the interaction is stronger if the hydrogen atom that is interacting with the aromatic group is closer to the metal center,[23] we considered only structures where there are only two bonds between the hydrogen atom and the metal ion. − The optimized geometries and energies for the model system of the complexes with the cation−π interaction were obtained using the density functional theory (DFT) with the Becke (B3) three-parameter exchange function,[69] and the Lee−Yang−Parr (LYP) correlation functional.[70] These B3LYP calculations were carried out with the Gaussian98 program.[71] For all atoms the LANL2DZ basis sets were chosen. Recently, reliable results with DFT methods were obtained for other cation−π systems.[17][72−75] On the other hand, DFT methods also give good results for all transition metal complexes including transition metal complexes of the first row,[76−88] hence in this work the DFT method was used. − The geometries of all conformers of the model systems were fully optimized. Only in one case where the conformer was not a stationary point did we constrain the torsion angle of the aromatic ring in order to keep it in a certain position.

Acknowledgments

We would like to thank Prof. E. W. Knapp and Z. Tomić for useful discussions. M. M. was supported by a DAAD fellowship. The calculations were carried out at the computer center of the Free University of Berlin.

Stereoselective Interactions and Photo-Electron Transfers between Mononucleotides or DNA and the Stereoisomers of a HAT-Bridged Dinuclear Ru^{II} Complex (HAT = 1,4,5,8,9,12-hexaazatriphenylene)

André Brodkorb,[a] Andrée Kirsch-De Mesmaeker,*[a] Todd J. Rutherford,[b] and F. Richard Keene[b]

Keywords: Electron transfer / Ruthenium / DNA recognition / Molecular recognition / Stereoselectivity

The dinuclear complex $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ (phen = 1,10-phenanthroline, HAT = 1,4,5,8,9,12-hexaazatriphenylene), can exist in three different stereoisomeric forms: the *meso* ($\Delta\Lambda$) and *rac* diastereoisomers, the latter of which has two enantiomeric forms, namely $\Delta\Delta$ and $\Lambda\Lambda$. Each of the stereoisomers was studied in the presence of the mononucleotides guanosine 5′-monophosphate (GMP) and adenosine 5′-monophosphate (AMP), and deoxyguanosine (dG) at pH = 7 and 9. Absorption studies revealed the formation of ion pairs or aggregates between the complexes and the mononucleotides (GMP and AMP) and dG. The equilibrium constants for the formation of these species were higher for the *meso* form than for the $\Delta\Delta$ and $\Lambda\Lambda$ enantiomers. Laser flash photolysis indicated the existence of a stereoselective photo-induced electron-transfer between the guanine of GMP and the stereoisomers. Luminescence data with the purine mononucleotides also indicated the existence of an equilibrium between the free excited complex and a luminescent ion pair or an emitting aggregate between the complex and the mononucleotide. The luminescence of these species depended on the pH and on the identity of the stereoisomer. The investigated spectroscopic behaviour of the complex stereoisomers in the presence of denatured CT-DNA was also isomer-dependent, in agreement with the conclusions drawn from the data with the mononucleotides. The results of this work clearly indicate stereoselectivity of the interaction with the purine mononucleotides and denatured CT-DNA in the ground and excited state of the complex, in favour of the *meso* form in both cases.

Introduction

Ruthenium complexes involving polypyridyl ligands have been studied in numerous research contexts,[1−3] more recently as photo-probes and photo-reagents of DNA.[4−6] It was shown that the mononuclear Ru^{II} complexes with oxidising polyazaaromatic ligands are able to photo-oxidise the guanines by a direct electron transfer with formation of a reduced complex.[7,8] This charge transfer process was demonstrated by laser flash photolysis and was compared with the photo-induced electron transfer observed with guanosine 5′-monophosphate (GMP). The associated luminescence quenching by GMP could be analysed easily.

The dinuclear complex $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ (Figure 1) is also rather oxidising due to the bridging hexaazatriphenylene ligand HAT (the redox potential in the excited state is significantly positive, +1.04 V/SCE).[9] Therefore, like the mononuclear complexes with oxidising polyazaaromatic ligands, this species under illumination is also able to abstract an electron from a guanine molecule. However, in contrast to the situation with the mononuclear species, the first experiments with the dinuclear complex revealed the presence of aggregates with GMP, which made the quenching behaviour by GMP difficult to interpret.[10] These experiments with GMP had been performed with the nonseparated stereoisomers present after synthesis of the dinuclear complex. As the stereoisomeric mixture could be the cause of the complicated behaviour, in this work, we have carefully examined the effects of GMP and the other mononucleotides on the photophysical behaviour of each stereoisomer (viz. the $\Delta\Delta$ and $\Lambda\Lambda$ enantiomers and the *meso* form $\Delta\Lambda$, Figure 1) obtained after chromatographic separation.[11] The goal is not only to clarify the quenching behaviour, but also to investigate the possible existence of stereospecific formation of aggregates and stereospecific electron transfer process.

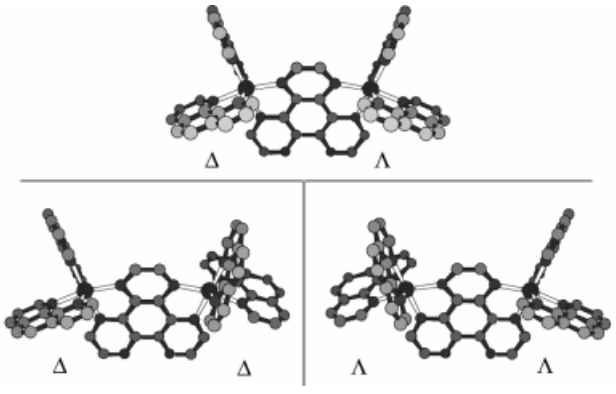

Figure 1. Chem 3D structure of the three stereoisomers $\Delta\Delta$, $\Lambda\Lambda$, and $\Delta\Lambda$ (*meso*) of the dinuclear complex $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$

Although with the mononuclear Ru^{II} compounds, understanding of the behaviour with the mononucleotides constituted a valuable help in rationalising the effect of DNA, with the dinuclear complex $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ the situation is again more complicated. It was indeed shown that this species does not interact with a polynucleotidic double helix (normal calf thymus DNA or synthetic polynucleotides), but interacts with denatured calf thymus DNA.[12] This behaviour was attributed to the fact that the large dinuclear complex cannot penetrate inside the DNA grooves of a normal double-stranded DNA, but can be hosted inside pockets formed by the two strands of denatured DNA separated along a certain number of bases. These deformation sites (bulges, hairpins etc.) contain more AT than GC base pairs.[13] Therefore, a correlation between a luminescence quenching of the complex by GMP and by denatured DNA, as observed previously with mononuclear complexes, is not expected. Moreover, the interaction of the complex is probably controlled by the recognition of certain uncharacterised deformation sites present in denatured DNA. This is in contrast to the situation with mononuclear species that interact inside the regular grooves of a normal DNA double helix. In spite of these limitations for the comparison of the effects of mononucleotides and DNA, we have also examined in this work, the behaviour of each stereoisomer of $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ with denatured DNA. The goal is to test whether there would be some stereospecific recognition in the interaction sites of this DNA and whether it would be the same as that with the mononucleotides.

Results

1. Absorption Spectroscopy in the Presence of Mononucleotides and dG

In water, the absorption spectra of the three stereoisomers of $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ are similar (Figure 2a, b, c). Organic solvents were avoided in this study because it was previously observed[9] that slow (photo) degradation of the complex occurred in nonaqueous environments.

As shown in Figure 2a, the addition of GMP to the *meso* form of $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ in aqueous solution at pH = 7 induced an important blue shift on the 570-nm absorption component of the MLCT band. AMP had a much less pronounced effect, and shifted this band slightly to the red region. CMP and TMP had no effect at all. On the other hand, as shown by the comparison of Figure 2a with b and c, the *meso* form displayed the most significant change on the addition of GMP compared with the ΛΛ and ΔΔ enantiomers (the *meso* form was also the most affected by AMP). Only the GMP and dG effects were analysed quantitatively, because the influence of AMP was too weak (even with the *meso* form) to allow a quantitative treatment.

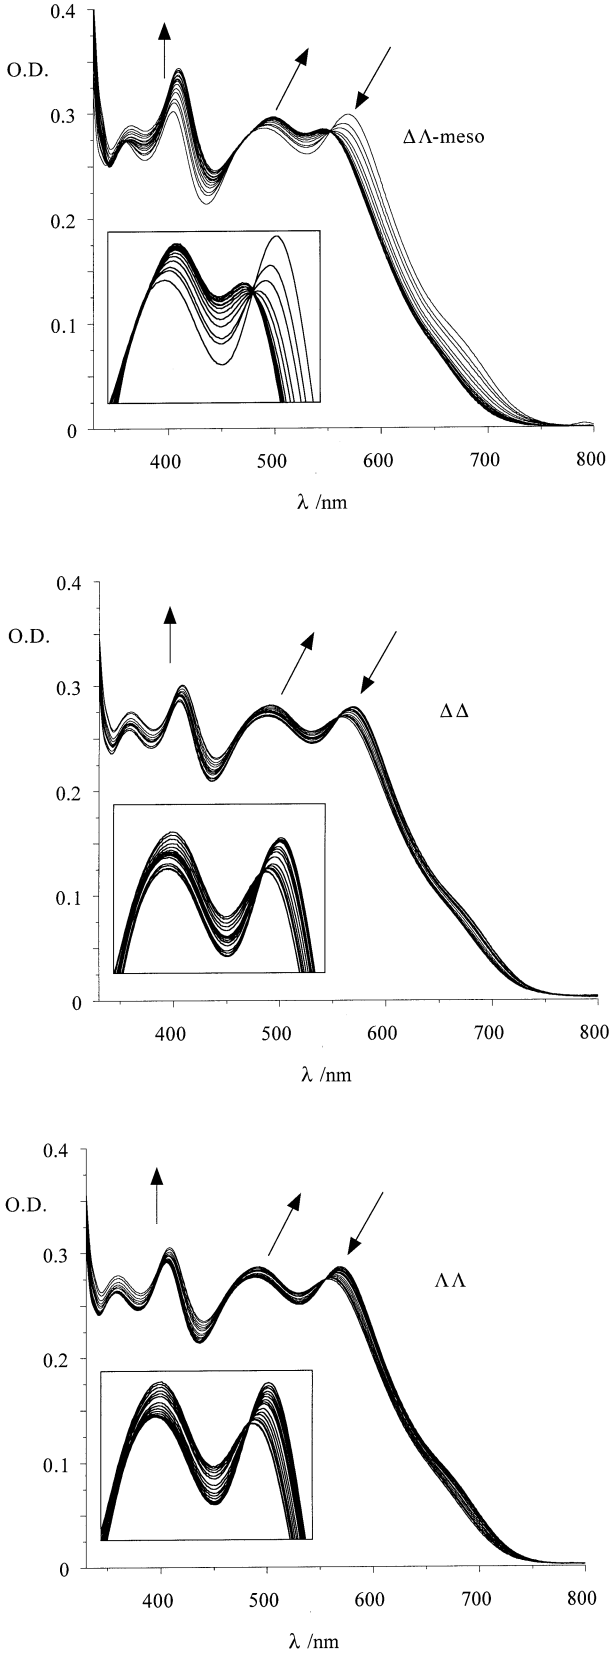

Figure 2. Absorption spectra of (a, top) *meso*-, (b, center) ΔΔ-, and (c, bottom) ΛΛ-$[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ (5×10^{-5} M) in the presence of increasing GMP concentrations until 80 mM GMP at pH = 7 (100 mM phosphate buffer); inset: expansion of the MLCT band

Analysis of the GMP Effect at pH = 7

Examination of the spectra (Figure 2a, b, c) shows that isosbestic points were observed. This suggests that a 1:1

ground state association exists between the Ru complex and the mononucleotide, but only at lower GMP concentrations (< 80 mM). For higher GMP concentrations, the isosbestic points became diffuse and associations of higher order or different geometry probably took place.

$$[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+} + GMP \overset{K_{gs}}{\rightleftharpoons} \{[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}\cdots GMP\}$$

The ground state association constant K_{gs} can be calculated using the Hildebrand−Benesi Equation (1)[14], where ΔA represents the difference in absorption in the absence and in the presence of mononucleotide ($\Delta A = A_0 - A_{GMP}$) at a given wavelength, and $\Delta\varepsilon$ is the difference of the molar extinction coefficients of the free and associated complex ($\Delta\varepsilon = \varepsilon_F - \varepsilon_A$).

$$\frac{1}{\Delta A} = \frac{1}{\Delta\varepsilon[Ru]} + \frac{1}{\Delta\varepsilon[Ru]K_{gs}[GMP]} \quad (1)$$

The changes of concentration of free GMP due to this equilibrium were negligible compared with the amount of added GMP (i.e. $[GMP]_0$). This was not true for the free Ru complex concentration that varied with the addition of GMP because the initial concentration (i.e. $[Ru]_0 = 5 \times 10^{-5}$ M for each stereoisomer) was much lower. When $1/\Delta A$ was plotted as a function of $1/[GMP]_0$, K_{gs} was obtained from the intercept/slope ratio (Figure 3). The corresponding values for the association constants for each stereoisomer were tentatively determined in this way. Only the value of the association constant for the *meso* form is given in Table 1, because there is no dependence with the wavelength in this case, and the variation of absorption is well measurable.

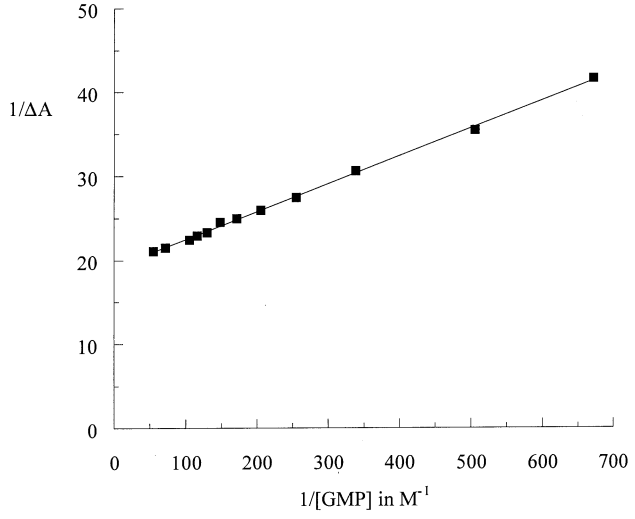

Figure 3. Hildebrand−Benesi plots for *meso*-[{Ru(phen)$_2$}$_2$(μ-HAT)]$^{4+}$ in the presence of GMP at pH = 7 (100 mM phosphate buffer) at 570 nm

Table 1. Association constants K_{gs} for the *meso* form in the presence of GMP and dG at pH = 7 and 9; estimated experimental error ca. 10%

	pH	K_{gs} [M^{-1}]
GMP	7	585
GMP	9	445
dG	7	335
dG	9	270

As shown in Figure 2b and c, the absorbance changes for the two enantiomers ΔΔ and ΛΛ were weak (the errors associated with K_{gs} thus become larger), and in addition the estimated values for the association constants varied with the wavelength of the measurement. For the ΛΛ enantiomer, the value varied from 65 M^{-1} at 570 nm to 7 M^{-1} at 405 nm. For the ΔΔ enantiomer, K_{gs} = 17 M^{-1} at 570 nm and could not be determined at 405 nm because the Hildebrand−Benesi plot was not linear in the concentration range studied. These problems reveal the presence of more than one type of aggregate complex-GMP, so that the Hildebrand−Benesi model of a 1:1 association is no longer valid for the two enantiomers.

Analysis of the GMP Effect at pH = 9

As some luminescence experiments were carried out at pH = 9 (see below), the effect of GMP on the absorption spectra of the complexes was also examined at pH = 9. The charge of GMP became more negative at pH = 9 due to further deprotonation of the phosphate group and to partial deprotonation of the guanine base.[13] The addition of GMP to a buffered solution (pH = 9) of *meso*-[{Ru(phen)$_2$}$_2$(μ-HAT)]$^{4+}$ again revealed a significant change in the absorption spectra (not shown), which was very similar to the one observed at pH = 7. The resulting calculated association constant (Table 1) is of the same order of magnitude as observed at pH = 7, at least for GMP concentrations below 25 mM. For higher GMP concentrations, deviations in the linear Hildebrand−Benesi plot appear. Again, the ΔΔ and ΛΛ enantiomers behaved differently. The K_{gs} values varied with the wavelength of measurement; for the ΛΛ enantiomer it varied from 140 M^{-1} at 570 nm to 7 M^{-1} at 405 nm, and for the ΔΔ enantiomer from 200 M^{-1} at 570 nm to a nonmeasurable value at 405 nm. This wavelength dependence again reflects the presence of more than one type of aggregate, where the Hildebrand−Benesi model is no longer valid.

Analysis of the dG Effect at pH = 7 and 9

The effect of dG on the absorption of the complexes was examined. A difference in the complex behaviour by the addition of GMP or dG is indeed possible due to the absence of the negatively charged phosphate group in dG, while the base and the chirality of the sugar component remained unchanged. The deoxyguanosine was selected instead of guanosine because of its better solubility in water,

although still limited. The titration with dG could thus be carried out only up to a concentration of 7 mM in dG.

The absorption spectrum of the *meso* form at pH = 7 was significantly changed by the presence of dG (not shown). There was a blue shift in the 570 nm band, similar to that observed with GMP at pH = 7. The association constant was smaller compared with the case for GMP at pH = 7 (Table 1). In contrast to this, the variation of absorption of the two enantiomers ΔΔ and ΛΛ with the addition of dG did not produce isosbestic points, and determination of the association constants was not possible because the Hildebrand−Benesi plots were not linear.

At pH = 9, only the *meso* form exhibited a significant change of the absorption in the presence of dG, with the appearance of an isosbestic point. The corresponding value of K_{gs} was smaller than at pH = 7 (Table 1). The treatment of the results for the enantiomers ΔΔ and ΛΛ at pH = 9 led to the same problems observed at pH = 7.

2. Steady State Emission Spectroscopy in the Presence of Mononucleotides and dG

Emission occurs from the triplet MLCT state, which corresponds to the lowest excited state of the dinuclear species (i.e. an Ru → μ-HAT ^{3}MLCT state).[9] In the absence of nucleotide no difference in the luminescence maximum was found between the *meso* compound and the two enantiomers. However, a difference of quantum yield of emission was observed with $\varphi_{meso} < \varphi_{racemic}$.[11]

Change of Emission with GMP

The addition of GMP at pH = 7 and 9 produced a significant blue shift of the emission, which followed the order *meso* (ca. 30 nm) > ΔΔ (ca. 5 nm) > ΛΛ (no shift). Because the emission maximum appeared in the region of 800 nm, where the sensitivity of the red-sensitive photomultiplier tube drastically decreases, all the spectra had to be corrected. As this correction becomes very important around 800 nm, it is difficult to give accurate values for the spectral shifts. The same problem of sensitivity has previously prevented us from determining the emission quantum yield of each stereoisomer.[11]

Emission Intensity at pH = 7

For the *meso* form, the emission intensity increased slightly with the addition of GMP at pH = 7 (30% emission increase with 80 mM GMP). Figure 4 shows the plot of I_0/I versus the GMP concentration, where I_0 represents the luminescence intensity in the absence of GMP and I in the presence of GMP. As the emission intensity I was enhanced with GMP, I_0/I decreased for the *meso* form and reached a plateau at approximately 20 mM in GMP. In contrast, the I_0/I values versus the GMP concentration for the two enantiomers at pH = 7 appear to lead to normal Stern−Volmer plots, indicating a quenching by GMP (for ΛΛ 24% and for ΔΔ 12% quenching at 80 mM GMP). However, these plots exhibit a downward curvature for increasing GMP concentrations.

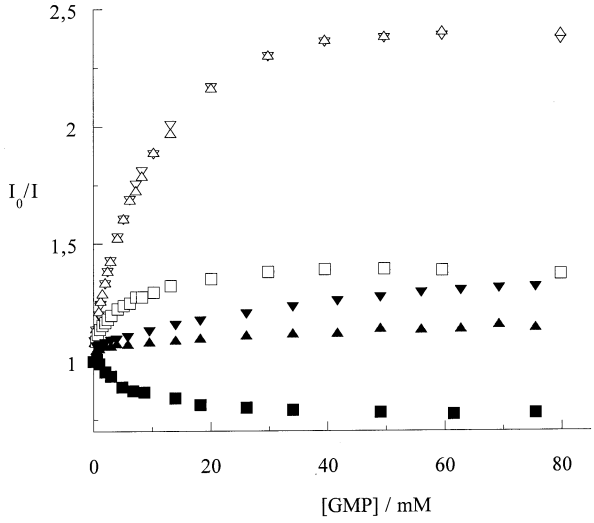

Figure 4. I_0/I vs. GMP concentration (I_0 is the emission intensity in the absence of GMP and I is the emission intensity in the presence of GMP) for the stereoisomers of $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ (100 mM phosphate buffer); full markers for pH = 7, open markers for pH = 9; ■ = *meso*, ▲ = ΔΔ, ▼ = ΛΛ

Emission Intensity at pH = 9

The guanine base is partially deprotonated at pH = 9. Therefore, the redox potential associated with the oxidation of the guanine of GMP is less anodic at pH = 9 than at pH = 7 (60 mV/pH unit). In agreement with this increased reducing power of the guanine at pH = 9, the excited state of $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ was reductively quenched more efficiently by the nucleotide base at pH = 9 than at pH = 7, following the order ΛΛ ≈ ΔΔ (58% quenching at 80 mM GMP) > *meso* (27% quenching at 80 mM GMP). Thus the emission of the *meso* form, although enhanced by GMP at pH = 7, was quenched at pH = 9 (Figure 4). The corresponding I_0/I plots versus [GMP] for the three stereoisomers at pH = 9 deviate significantly from a linear Stern−Volmer plot, and reveal a downward curvature, reaching a plateau for GMP concentrations larger than 20 mM for the *meso* form and 40 mM for the enantiomers. It is interesting to note that for the *meso* form, the I_0/I plots at pH = 9 (luminescence quenching) and at pH = 7 (luminescence enhancement) appear to be quasi-mirror images around the x axis.

Effect of dG at pH = 7

It is difficult to measure the change of luminescence of the three stereoisomers upon addition of dG at pH = 7. This is mainly due to the low concentration of dG that can be used for the titration (not higher than 7 mM). However, the slight change in the emission intensities followed the same tendency as for the titration with GMP at pH = 7. Thus, the emission of the *meso* form increased slightly,

whereas the emission of the ΔΔ and ΛΛ enantiomers decreased slightly with the addition of dG.

Effect of dG at pH = 9

As expected, the change in pH again had a significant effect on the emission. As observed with GMP, the emission of the three stereoisomers was quenched when dG was added at pH = 9, following the order ΛΛ ≈ ΔΔ (45% quenching at 7 mM dG) > *meso* (35% quenching at 7 mM dG). The Stern−Volmer plots are curved slightly downward and are very similar to the titrations with GMP at pH = 9 in the same concentration range of quencher (< 7 mM).

Effect of the other Mononucleotides at pH = 7

The presence of AMP did not significantly change either the intensity or the λ_{max} value of emission at pH = 7. Thus, no change was observed for the ΛΛ form, and a very slight intensity increase was detected for the ΔΔ and the *meso* forms. As no quenching was detected with AMP at pH = 7, no further experiments were performed at pH = 9 for a comparison of quenching efficiency. No effect of CMP and TMP was detected on the emission

3. Laser Flash Photolysis in the Presence of Mononucleotides

The existence of a photo-induced electron transfer from GMP (pH = 7) to the excited $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ with samples containing the three nonseparated stereoisomers has been demonstrated previously by laser flash photolysis experiments.[10] However, since each stereoisomer exhibited a different absorption and luminescence behaviour in the presence of GMP at pH = 7, laser flash photolysis experiments were carried out again in the present work with each stereoisomer separately. In each case, the differential transient absorption recorded 1 μs after the laser pulse, in the presence of 70 mM GMP, indicated the existence of a long-lived mono-reduced complex (even with the *meso* compound). The absorption transients decayed during a few hundred μs and did not reach the baseline after this decay time (Figure 5).

This absorption that remained, was attributed to the formation of a photo-product.[10] The intensity of the transient absorption (Figure 5) was too weak to perform a kinetic analysis. However, the differential transient absorption was slightly higher for the ΛΛ enantiomer than for the ΔΔ form, and the signal of the latter was somewhat higher than that of the ΔΛ (*meso*) form. Although this difference in intensity was not much larger than the error limit, it is interesting to note that it followed the same trend as observed for the luminescence quenching, i.e. ΛΛ > ΔΔ, and no quenching for the *meso* form. Although no flash photolysis experiments were performed at pH = 9, nor with dG, the existence of a photo-electron transfer can nevertheless be assumed at pH = 9 as a luminescence quenching was clearly observed at this pH for the three stereoisomers, and it was more pronounced than at pH = 7. No mono-reduced species was detected in the presence of AMP, CMP, or TMP

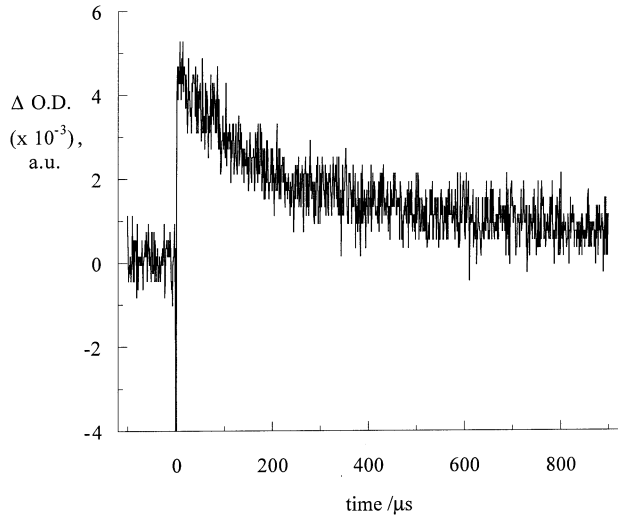

Figure 5. Laser flash photolysis; transient absorption decay for ΔΔ-$[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ under pulsed excitation in the presence of 70 mM GMP at pH = 7 (100 mM phosphate buffer)

at pH = 7, which means that there is no electron transfer between these mononucleotides and the excited complex $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ under these conditions.

4. Time-Resolved Emission Spectroscopy in the Presence of Mononucleotides and dG

In the absence of mononucleotides, the excited state lifetimes in air-equilibrated buffered solutions at pH = 7 were the same (as expected) for both enantiomers ΔΔ and ΛΛ, τ_0 = 295 ± 5 ns, but it was shorter for the diastereoisomer ΔΛ-(*meso*), τ_0 = 221 ± 4 ns (Table 2). No differences in lifetimes were detected between pH = 7 and 9. Moreover, no clear measurable differences were observed in the presence of CMP or TMP.

In contrast, the luminescence decays of each stereoisomer in the presence of GMP, dG (at both pH = 7 and pH 9), and AMP (at pH = 7) were not strictly single-exponential decays (Table 2). They could be analysed according to bi-exponential decays, where the short component had a very low percentage contribution and the longer component always contributed more than 80% (normalised pre-exponential factor, see Table 2). Since laser flash photolysis experiments clearly showed that there was no electron transfer from AMP to the excited complex at pH = 7, the shorter lifetime components with AMP (Table 2) cannot be associated with a quenching process by the mononucleotide. Therefore, in this case the short component probably arises from dynamic processes, such as those associated with the equilibrium in the excited state between the free complex and the complex in aggregation with the mononucleotide. Such biphasic decays can indeed be expected when an equilibrium takes place in the same time domain as the deactivation processes to the ground state.[15] Under such conditions the lifetimes correspond to apparent lifetimes.

With GMP or dG, the short components could have the same origin because GMP and dG also form ion pairs or aggregates with the complex, as discussed above. Both long

[a] $\tau_{av} = (\Sigma B_i\tau_i)/\Sigma B_i$ for the bi-exponential decays; $I(t) = A + B_1 \exp(-t/\tau_1) + B_2 \exp(-t/\tau_2)$ in the presence of mononucleotides, τ_1 and τ_2 are the corresponding two lifetimes components with their normalised contribution; $\alpha_j = 100\% \times B_j/\Sigma B_i$. The mononucleotide concentrations correspond to the approximate plateau value of I_0/I (Figure 4), i.e. [GMP] = 100 mM at pH = 7, [GMP] = 20 mM at pH = 9, [dG] = 7 mM (maximum concentration which can be reached) at pH = 7 and 9, [AMP] = 20 mM at pH = 7. (a): Measurements performed with the mode-locked argon pumped dye laser (see Exp. Sect.). (b): Measurements performed with the Edinburgh Instruments SPC (see Exp. Sect.). The number of counts at the decay maximum is lower for these measurements (5000 counts). The decays are therefore of poor quality so that they do not always allow the detection of a low contribution of a second decay component. (c): Weighted average lifetimes for the multi-exponential decays; 10 mM phosphate buffer pH = 7, [Nu]/[Ru] = 30 (Nu = concentration of equivalent nucleobases in denatured CT-DNA).

and short decay components varied with the GMP or dG concentration. Because of the difficulties related to the experimental measurements at 800 nm, and the resultant poor quality of the signal, and the complexity of the kinetic treatment (see Discussion), only the results for the decays corresponding to the higher nucleotide concentration (where a plateau was reached for the I_0/I plots, Figure 4) are collected in Table 2. For the sake of comparison, the weighted average lifetimes are given in Table 2 as the values of each component probably correspond to apparent lifetimes.

Effect of GMP

The weighted average lifetimes were slightly affected by the presence of 100 mM GMP at pH = 7 (Table 2). The ΔΔ and ΛΛ forms appeared to be quenched, whereas for the *meso* form the average emission lifetime increased in the presence of GMP. At pH = 9, the lifetimes of the three stereoisomers were clearly shortened by GMP in the order ΔΔ > ΛΛ > *meso*. It is interesting to note that at both pH values, the luminescence quenching was more pronounced for the enantiomers than for the *meso* form. These results are in agreement with the steady-state emission results. In order to detect a possible short-lived species in the subnanosecond time range, an additional experiment was carried out with the *meso* form in the presence of 100 mM GMP at pH = 7 in a much shorter time range. No luminescent short-lived component with a lifetime shorter than a few hundred ps could be detected under those conditions. This experiment was performed with the *meso* form because the laser flash photolysis experiments indicated the formation of a small amount of monoreduced complex, although no obvious decrease of emission intensity or of the average luminescence lifetime could be detected.

Effect of dG

As the concentration of dG did not exceed 7 mM, an effect on the lifetimes was difficult to detect. A shortening of the τ_{av} value was only clearly observed at pH = 9, and it followed the same trend as in the equivalent experiment with GMP at pH = 9.

Effect of AMP

The addition of AMP at pH = 7 significantly increased the weighted average luminescence lifetime of the excited *meso* form. There was no major effect on the average emission lifetimes of the enantiomers.

6. Absorption and Emission Spectroscopy with Denatured DNA

Absorption and emission measurements for different ratios of denatured DNA/complex at a constant complex concentration were taken, starting from a high ratio and diluting the sample step by step with a buffered stock solution of the complex (10 mM phosphate buffer). No NaCl was added in order to induce a higher binding of the complex to the DNA. In this part of the work, as explained in the introduction, only the effect of denatured CT-DNA was examined because normal double-stranded DNA had no effect,[10] even when the experiment was performed with each stereoisomer.

In the presence of denatured CT-DNA at pH = 7, the absorption spectra changed in a similar manner as observed in the presence of GMP (i.e. a hypsochromic shift), with the same trends from one isomer to the other. Thus the *meso* diastereoisomer showed the largest hypsochromic absorption shift, followed by the ΔΔ and ΛΛ forms. However, the hypsochromic shift of the 570-nm absorption band with denatured CT-DNA was not as pronounced as with GMP.

The emission intensity of the three stereoisomers increased in the presence of denatured CT-DNA (Figure 6). The *meso* form exhibited the highest increase of emission and the ΛΛ form showed the weakest enhancement (*meso* > ΔΔ > ΛΛ).

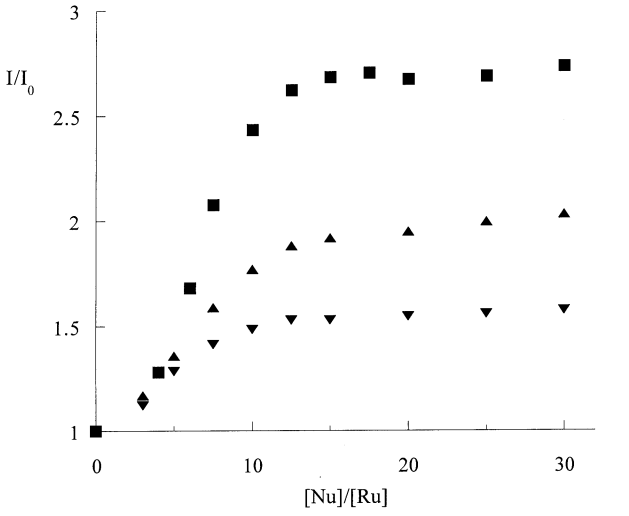

Figure 6. Steady-state emission with denatured CT-DNA (10 mM phosphate buffer pH = 7); I/I_0 vs. [Nu]/[Ru] ratio for the three stereoisomers of $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$; I_0 is the emission intensity in the absence of denatured DNA; I is the emission intensity in the presence of denatured DNA; [Nu] is the equivalent concentration of nucleotide in the DNA; [Ru] is the concentration of Ru complex; ■ = *meso*, ▲ = ΔΔ, ▼ = ΛΛ

7. Time-Resolved Emission Measurements in the Presence of Denatured DNA

The emission decays in the presence of denatured CT-DNA at pH = 7 had to be analysed according to multi-exponential decays (Table 2). A distribution of different luminescence lifetimes can indeed be expected. In addition to different binding sites in single-stranded parts of the denatured DNA, the fact that these sites contain guanine or adenine residues also differently affects the luminescence lifetimes since a quenching or an enhancement of emission can take place. Hence, the emission lifetimes given in Table 2 are expressed as weighted average lifetimes. In the distribution of lifetimes, it is interesting to note that only the ΔΔ and ΛΛ forms displayed some short-lifetime components of 238 ± 10 ns (32%) and 209 ± 9 ns (28%), respectively. These were shorter than the luminescence lifetime of the corresponding excited free complex in solution (295 ± 5 ns). The presence of denatured DNA increased the weighted average luminescence lifetime of the three stereoisomers (Table 2). The lifetime enhancement followed the same tendency as that in the steady-state experiments, *meso* > ΔΔ > ΛΛ.

Discussion

1. Interaction with the Mononucleotides

Formation of Ion Pairs or Aggregates

Absorption spectra show that ion pairs (1 complex/1 mononucleotide) or aggregates (1 complex/> 1 mononucleotide) are formed between each stereoisomer and the purine mononucleotides (GMP and AMP). As the complex has a 4+ charge and the mononucleotides are negatively charged, this interaction could be regarded as purely electrostatic. However, this is not the case because the association constants (K_{gs}, Table 1) related to the formation of these species are not significantly different when the phosphate group of GMP is absent, such as in dG. Formation of these ion pairs or aggregates could thus be driven by a π-stacking interaction between a part of the π-aromatic system of the HAT ligand and the π system of the purine base. It is also clear in this work that the *meso* form of the dinuclear complex is more disposed than the two enantiomers ΔΔ or ΛΛ to form an ion pair at pH = 7 and 9 (K_{gs} for *meso* > ΔΔ or ΛΛ). Moreover, for the ΔΔ and ΛΛ forms, the data from the absorption change do not correspond to a 1:1 ground state association, but to aggregates. From the absorption data, it is thus concluded that stereoselectivity plays some role when the complex interacts with the purine mononucleotides.

Different Behaviour between AMP and GMP

Although both purine mononucleotides interact with the complex, AMP does not form the same types of ion pairs or aggregates as GMP. This is shown by the different change exhibited by the MLCT absorption of the complex in response to the addition of GMP or AMP (hypsochromic effect with GMP and bathochromic shift with AMP). This may be due to different conformations adopted by AMP and GMP in solution (*anti* for AMP and *syn* for GMP).[13,16] Moreover, with AMP, no photo-electron transfer from the base to the excited complex was observed by laser flash photolysis experiments. This absence of photoredox processes can be attributed to the poorer reducing power of adenine as compared with guanine (0.1 V difference). In contrast, the guanine of GMP is capable, according to the laser flash photolysis data, of producing a mono-reduced complex under visible illumination of the system "complex + GMP" at pH = 7 or 9.

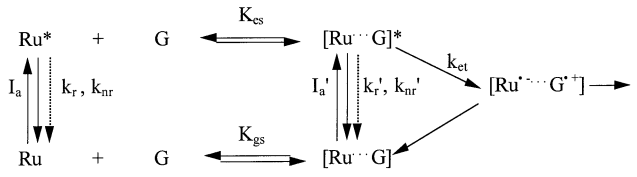
Model To Explain the Different Luminescence Behaviours in the Presence of GMP

At pH = 7, although the laser flash photolysis of the complex in the presence of GMP indicated the presence of

a monoreduced complex with each of the three stereoisomers, the steady-state luminescence data showed a slight luminescence quenching by GMP only with the ΔΔ or ΛΛ enantiomers. In contrast, a slight increase of luminescence was observed for the *meso* form with increasing GMP concentrations.

The *meso* Form at pH = 7

The increasing emission of the *meso* isomer reached a plateau value at approximately 20 mM in GMP. According to the affinity constant of the *meso* form in the ground state for GMP at pH = 7 (585 M^{-1}), more than 92% of the *meso* complex would be in the form of an ion pair in the presence of 20 mM GMP. Therefore, the luminescence data could be explained by the reactions shown in Scheme 1.



Scheme 1. Photophysical scheme; K_{gs} and K_{es} are the equilibrium constants in the ground and excited state, I_a and I'_a are the excitation rates, k_{et} is the rate of electron transfer, $k_r^{(\prime)}$ and $k_{nr}^{(\prime)}$ are the radiative and nonradiative decay rates, respectively

In this Scheme, we assume that the ion pair pumped in the excited state by irradiation corresponds to a new luminescent species. This explains the appearance of constant luminescence intensity once the equilibrium is completely shifted towards the excited ion pair. According to the data, the latter has a λ_{max} value of emission different from the free excited complex, a higher quantum yield of emission (leading under steady-state illumination to a ratio of emission intensity $I_0/I < 1$), and a longer excited-state lifetime. This lifetime, measured under pulsed illumination, is of the order of τ_{av} = 258 ns (longer than that of the free excited complex, 221 ns). Moreover, in competition with the deactivation of the excited ion pair to the ground state, this species has to lead to an electron transfer process (k_{et}) with formation of monoreduced complex as observed by laser flash photolysis.

The I_0/I curves have been simulated for the *meso* form for different values of the parameters associated with Scheme 1; i.e. the excited-state lifetime of the ion pair, keeping the value of the equilibrium constant in the excited state the same as in the ground state (i.e. 585 M^{-1}). It is concluded that this simulation does not fit with the experimental data points of Figure 4 for the *meso* form at pH = 7, although this Scheme takes into account a decrease of I_0/I with increasing GMP concentration up to a plateau value. This discrepancy can be attributed to the fact that the equilibrium constant in the excited state is not the same as in the ground state.[17,18] This is in agreement with the observation that luminescence decays were not purely mono-exponential in the presence of mononucleotides under pulsed illumination (even for the higher mononucleotide concentrations). As discussed above, this can be attributed to the dynamics of the equilibrium in the excited state, so that the excited-state lifetimes most probably correspond to apparent lifetimes.

Due to the poor experimental conditions for these measurements (long emission wavelength, low emission intensity), good accurate data for the luminescence decays cannot be obtained for all the nucleotide concentrations, and therefore we have no experimental access to the different rate constants associated with Scheme 1.

The *meso* Form at pH = 9

The data at pH = 9 for the *meso* form can also be rationalised using the same Scheme; i.e. with formation of a luminescent ion pair. The difference, compared to pH = 7, is that k_{et} from the luminescent ion pair has to be higher than at pH = 7, so that the resulting excited-state lifetime of the ion pair becomes shorter than that of the free excited complex. Consequently, the plateau value I_0/I is > 1, when the equilibrium is displaced to the right. As explained previously, a higher k_{et} can be attributed[10] to an increased driving force of the electron transfer process due to partial deprotonation of the guanine at pH = 9 (the base form of the guanine has a higher reducing power).

In conclusion, the appearance of plateau values in the I_0/I curves versus the GMP concentration at pH = 9 and 7 with the *meso* complex can be explained by formation of luminescent excited ion pairs between the *meso* form and GMP. The curves at pH = 7 and 9 appear quasi-symmetric along the abscissa for the *meso* form because the equilibrium constant values associated to Scheme 1 are indeed rather similar at both pH values.

The Enantiomers at pH = 7 and 9

The data for these forms are also in agreement with Scheme 1. The I_0/I plateau values for the two enantiomers are reached at higher GMP concentrations (> 40 mM; the plateau cannot be clearly observed at pH = 7). This is in agreement with a lower tendency of the enantiomers to form aggregates with GMP (at least in the ground state). Moreover, the I_0/I plateau values are larger than 1 (at pH = 7 and 9), and the excited-state lifetimes of the luminescent aggregates are shorter than the free excited enantiomers (for [GMP] > 40 mM, τ_{av} = 141 ns and 155 ns for each enantiomer at pH = 9, thus shorter than 295 ns observed for the free excited enantiomers). This behaviour indicates an electron transfer (k_{et}), which is faster for the ΔΔ and ΛΛ luminescent aggregates than for the emitting *meso* ion pair (pH = 7 or 9). Moreover, this electron transfer process for the enantiomer aggregates is faster at pH = 9 than at pH = 7 due to a difference in the driving force of the process, as concluded for the *meso* form.

2. Interaction with Denatured DNA

As explained in the introduction, the comparison of the effects of mononucleotides and denatured DNA is rather difficult because many other factors play a role in denatured DNA. For example the hydrophobic micro-environment of

the deformed sites in denatured DNA, where the complex interacts, increases the luminescence intensity and lifetime of the complex and influences its absorption. These factors are of course absent with the mononucleotides.

A striking similarity emerges, however, from the comparison. The most important effects in absorption and luminescence are indeed observed with the *meso* form in the presence of mononucleotides and for denatured DNA. The stereoselectivity is thus the same for these two systems. There are other qualitative similarities with the effects of the purine mononucleotides (pyrimidine mononucleotides have no effect):

1. In absorption, denatured DNA has a slight hypsochromic shift effect, similar, but less pronounced than that of GMP. This would be in agreement with resulting effects of AMP and GMP. Indeed, although AMP gives a bathochromic effect, it is less important than the hypsochromic shift with GMP.

2. In luminescence, the interaction of the two enantiomers with the guanine residues of denatured DNA should produce a lower luminescence than in solution if the behaviour was similar to that with GMP. In agreement with this, one component of the luminescence lifetimes of the enantiomers with denatured DNA is indeed shorter than that in solution. The fact that the data show a significant overall increase in both the emission intensity and weighted average lifetime, is due to the hydrophobic environment present in denatured DNA as mentioned above.

3. In addition to this hydrophobic environment, it is probable that the effect of the adenine and guanine nucleobases at pH = 7 also play a role in the emission intensity increase of the *meso* form, due to some contribution to the global emission of the luminescent ion pair, detected with the mononucleotides.

3. Conclusion

This study has shown the presence of new interesting processes in the systems "dinuclear complex plus mononucleotides" i.e. a stereoselectivity in the ion pairing and in the photo-induced electron transfer. To the best of our knowledge, this is the first time that such stereoselective processes have been evidenced. This work has also clarified the complicated behaviour observed previously with the nonresolved mixture of stereoisomers.[10]

We have shown that the formation of aggregates or ion pairs in the ground state with purine mononucleotides is stereospecific. The aggregation originated from some π-stacking interaction. The order of selectivity is: *meso* > ΔΔ, ΛΛ. This study also demonstrates from the emission data, the existence of luminescent ion pairs or aggregates with the purine mononucleotides. These species have longer or shorter excited-state lifetimes than those of the corresponding free excited isomers, depending on the stereoisomer, on GMP or AMP, and on the pH of the solution. In competition with the deactivation process to the ground state, these luminescent aggregates with GMP can lead to an electron transfer process that is faster at a same pH for the enantiomer aggregates than with the *meso* form ion pairs.

For the reasons developed in the introduction, a comparison between the systems "complex plus mononucleotides" and "complex plus denatured DNA" is not obvious. However, this study shows also a stereoselectivity in the interaction of the complex with denatured DNA, which is the same as with the purine mononucleotides, i.e. the *meso* form interacts better than the enantiomers. The origin of this same stereoselectivity could be due to the fact that the dinuclear complex hosted in sites where the DNA strands are separated, exhibits a stereoselectivity governed mainly by the nucleotidic chain and of course not by the DNA helicity which is absent in these interaction sites.

Experimental Section

Materials: The pure stereoisomers [ΔΔ, ΛΛ, (*meso*-)ΔΛ] of $[\{Ru(phen)_2\}_2(\mu\text{-HAT})]^{4+}$ were prepared by T. Rutherford et al.[11] The phosphate buffers were adjusted by mixing Na_2HPO_4 and NaH_2PO_4 (Aldrich, A.C.S. reagent) in Milli Q water. Deoxyguanosine, guanosine- and adenosine-5′-monophosphate (dG, GMP and AMP; Sigma Chemicals) were used without further purification as sodium salt. Denatured CT-DNA was prepared as described previously.[10]

Absorption and Emission Spectroscopy: All measurements were carried out at room temperature (25 °C). A 100 mM phosphate buffer at pH = 7 or 9 was used for the titrations with the mononucleotides and dG, and a 10 mM phosphate buffer at pH = 7 for the titrations with denatured DNA. − Absorption spectra were recorded with a double-beam UV/Vis spectrophotometer Perkin−Elmer Lambda 40 or an HP 8452 UV/Vis diode array. − Emission spectra were obtained using a Shimadzu RF-5001 PC spectrofluorimeter equipped with a Hamamatsu R928 red-sensitive photomultiplier tube. The samples were excited at 550 nm and corrected for a same percentage of absorbed light. Because the complexes emit in the near infrared (λ_{max} = 820 nm), which is on the edge of the response curve of the PM tube, corrections were needed. The data were therefore treated externally with a correction file, which was elaborated using a calibrated tungsten source from Edinburgh Analytical Instruments. The emission spectra were integrated to obtain the I_0/I ratios. − Emission lifetimes were determined using a mode-locked argon pumped dye laser [λ_{exc} = 550 nm, ν_0 = 400 kHz, fwhm (full width half maximum) = 80 ps] in the laboratory of Prof. De Schryver (KU Leuven, Belgium). Emission was detected by a micro-channel plate Hamamatsu R2909 Single Photon Counting unit at 800 nm. Deconvolution was achieved using home-made software with a porphyrin as a reference (τ = 15 ns). Other SPC measurements were performed with an Edinburgh Instruments FL-900 spectrofluorimeter equipped with a nitrogen-filled discharge lamp and a Peltier-cooled Hamamatsu R-928 photomultiplier tube. The emission decays were analysed with the Edinburgh Instruments software (version 3.0), based on nonlinear least-square regressions using Marquardt algorithms. − Laser flash photolysis experiments were performed in a cross beam setup using a xenon lamp as the monitoring source and the second harmonic of a pulsed Nd/YAG laser (Continuum NY 61−10, λ = 532 nm, 20 mJ per pulse). The transient signal was detected by a modified Applied Photophysics laser kinetic spectrometer equipped with a red-sensitive Hamamatsu R-928 photomultiplier tube connected to an oscilloscope HP

5248. The transient absorption signals were transferred to a PC and treated externally.

Synthesis, Structure, Electrochemistry, and Magnetism of [$Mn^{III}Mn^{III}$], [$Mn^{III}Fe^{III}$] and [$Fe^{III}Fe^{III}$] Cores: Generation of Phenoxyl Radical Containing [$Fe^{III}Fe^{III}$] Species

Cláudio Nazari Verani,[a] Eberhard Bothe,[a] Dirk Burdinski,[a] Thomas Weyhermüller,[a] Ulrich Flörke,[b] and Phalguni Chaudhuri*[a]

Dedicated to Prof. H.-J. Haupt on the occasion of his 65th birthday

Keywords: N,O ligands / Electrochemistry / Manganese / Iron / Radicals / Magnetic properties

Neutral homo- and heterobinuclear complexes with the general formula [(tmtacn)M_A(salox)$_3M_B$] where M_A (Mn^{III} or Fe^{III}) is facially coordinated to the cyclic amine 1,4,7-trimethyl-1,4,7-triazacyclononane (tmtacn) and M_B (Mn^{III} or Fe^{III}) is coordinated to the azomethine nitrogens and phenolate oxygens of the bridging ligand, salicylaldoxime, thus yielding $M_AN_3O_3$ and $M_BN_3O_3$ cores. The compounds were characterized by IR, UV/Vis, mass spectrometry, Mössbauer spectroscopy, electrochemistry, and variable-temperature (2–295 K) magnetic susceptibility measurements. The molecular structures of the compounds [(tmtacn)Fe^{III}(salox)$_3$-Fe^{III}] (**3**) and [(tmtacn)Fe^{III}(*t*BuSalox)$_3Fe^{III}$] (**4**) were established by X-ray diffraction. Three oximate groups –HC=N–O bridge the metal centers with Fe···Fe separations of 3.571(1) and 3.486(1) Å for (**3**) and (**4**), respectively. Analysis of the susceptibility data yields antiferromagnetic interactions between the metal centers for the complexes $Fe^{III}Fe^{III}$ and Mn^{III}-Fe^{III}, but a ferromagnetic interaction for $Mn^{III}Mn^{III}$. The electrochemistry of all complexes was investigated in detail. For the complexes $Fe^{III}Fe^{III}$ (**3**) and (**4**) a series of reversible one-electron transfer waves leads to the formation of the cations $[Fe_2]^{1+/2+/3+}$ that are attributed to the generation of salox-based phenoxyl radicals.

Introduction

Current interest in the coordination chemistry of phenol containing ligands[1−4] is mainly due to the discovery of the widespread occurrence of tyrosinase radicals in metalloproteins, involved in oxygen-dependent enzymatic radical catalysis.[5−8] Amongst the catalytically essential redox-active amino acids, glycyl, cysteinyl, tryptophan, tyrosyl, and modified tyrosyl are the most prevalent, and tyrosine-based radical enzymes are the best characterized.

As part of an effort directed toward the development of biologically inspired homogeneous catalysis[9−11] for the aerial oxidation of organic substrates like alcohols and amines, we are investigating the synthesis and reactivity of phenolate complexes of the transition metals, together with their one-electron oxidized phenoxyl radical complexes. Such phenoxyl radical complexes, stable in the solid state, are rather rare. This scarcity is partly due to the fact that the metal−phenolate bond to a late transition metal ion should be relatively weak. For the early transition metal ions, the metal−phenolate bonding is strengthened by π-donation from the lone pair of electrons on oxygen into an empty d-orbital on the metal, but for the late transition metal ions such empty low-lying orbitals are not always available.

In another field of modern coordination chemistry there is a continuous interest in polynuclear exchange-coupled systems that are relevant to the area of both magnetic materials[12−15] and biomodeling.[5,16−18] Of special interest in this context is the rational synthesis of polynuclear complexes with desired nuclearity by reaction of mono or dinuclear complexes with different metal complexes[19] of the same or different nature, i.e. the use of metal complexes as ligands.

In this regard we have reported several series of linear complexes comprising [M_A-M_B], [$M_A-M_B-M_A$], [$M_A-M_B-M_C$], and [$M_A-M_B-M_B-M_A$] cores,[20−23] involving the end-capping amine tmtacn and several bridging oximes together with nonlinear tetranuclear [$(M_A)_2(\mu$-$O)_2(M_B)_2$] complexes containing salicylaldoxime, *salox*.[24]

Although salicylaldoxime was used as a complexing agent as early as 1930,[25] comparatively few reports on its ligating properties towards the trivalent transition metal ions have been published.[24,26−30] During the course of the preparative work involving M^{III}(saloxH)$_3$, where M = Fe^{III}, Mn^{III}, saloxH = the monoanion of salicylaldoxime H_2salox, we envisaged the possibility of preparing a series of neutral dinuclear complexes with the general formula [(tmtacn)M_A(salox)$_3M_B$], where M_A = Mn^{III} or Fe^{III}, and is facially coordinated to the cyclic amine 1,4,7-trimethyl-1,4,7-triazacyclononane, *tmtacn*, and M_B = Mn^{III} or Fe^{III} and is coordinated to the three salox units.

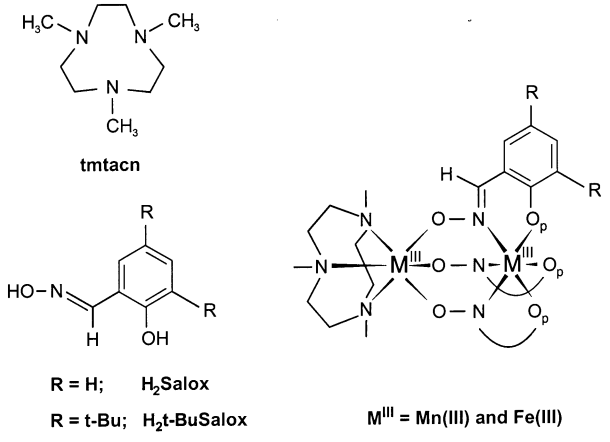

Scheme 1. Ligands and general frame of the [(*tmtacn*) M_A (*salox*)$_3$ M_B] complexes

It has been recently established by Wieghardt et al.[31] that *tert*-butyl substituents at the *ortho* and *para* positions of the phenolates facilitate one-electron oxidation to the corresponding phenoxyl radicals, because these substituents decrease the oxidation potential of the phenolates and provide enough steric bulk to suppress bimolecular decay reactions. Accordingly, we have synthesized salicylaldoxime with *tert*-butyl substituents at the *ortho* and *para* positions i.e., 4,6-di-*tert*-butyl salicylaldoxime, abbreviated *tBu-salox*, and investigated the electrochemical behavior amongst other studies, to generate the phenoxyl radical species from the parent dinuclear Fe^{III} complex. Thus, the compounds [(tmtacn)Mn^{III}(salox)$_3$$Mn^{III}$] (**1**), [(tmtacn)$Mn^{III}$(salox)$_3$$Fe^{III}$] (**2**), [(tmtacn)$Fe^{III}$(salox)$_3$$Fe^{III}$] (**3**), and [(tmtacn)$Fe^{III}$(*t*Bu-salox)$_3$$Fe^{III}$] (**4**), were synthesized and characterized by means of various spectroscopic methods. The single crystal X-ray structure determinations of (**3**) and (**4**) were also performed.

Results and Discussion

The complexes [(tmtacn)M_A(salox)$_3$$M_B$] were obtained by reaction of an appropriate metal salt with the ligand H_2salox in oxygen-free methanol, in the presence of triethylamine, followed either by the solid [Fe(tmtacn)Cl_3] or [(tmtacn)$_2$$Mn^{III}_2$(μ-O)(μ-OAc)$_2$]$^{2+}$, produced in situ, in stoichiometric equivalents. Dark microcrystalline products were collected with yields varying between 40 to 70%. Satisfactory analyses (C, H, N, Fe, Mn) were obtained. Our attempts to characterize the species produced by the reaction of salicylaldoxime with either $FeCl_3$ or "Mn^{III} acetate" are yet to be successful. However, these species are able to yield the dinuclear complexes **1**, **2**, **3**, and **4**, in the presence of a base (Et_3N) and the [M(tmtacn)]$^{3+}$ unit [M = Fe^{III} or Mn^{III}]. The function of the added base is to provide a medium needed for deprotonation of the −HC=N−OH groups present.

Since the IR spectra of complexes **1**, **2**, **3**, and **4** are quite similar, the discussion is confined to the most important vibrations of the 4000−400 cm^{-1} region in relation to the structure. The free ligands, H_2salox and 4,6-*t*Bu-H_2salox, have intense sharp absorptions at 3411 and 3438 cm^{-1}, attributed to the ν(OH) vibrations of the phenolic and enolic groups, respectively. This absorption is missing in the spectra of the dinuclear complexes, indicating that the phenolic and enolic protons are lost on chelation. The very intense band at 1619 cm^{-1} for H_2salox and a medium intense at 1609 cm^{-1} for 4,6-*t*Bu-H_2salox are assigned to the $\nu_{(C=N)}$ vibration mode. These bands shift to ca. 1592 cm^{-1} for **1**−**4**. The medium strong band at ca. 1150−1170 cm^{-1} for the free oxime ligands shifts slightly (ca. 5 cm^{-1}) to higher frequency for all dinuclear complexes and has been assigned to the $\nu_{(N=O)}$ vibration of the oxime groups. Finally, a set of intense and medium-intensity peaks between 3007 and 2864 cm^{-1} is present in both ligand 4,6-*t*Bu-H_2salox and complex **4** and reveals the presence of the *tert*-butyl groups.

Mass spectrometry in the ESI positive mode has been proved to be a very useful analytical tool for characterization of complexes **1**−**4**. Homometal complexes **1**, **3**, and **4** provide the respective molecular ion peaks with the expected isotope ratios in the ESI positive mode as the base peaks (100%), but the heterometal complex, **2** fails to provide the molecule peak as the base peak; the latter is observed at *m*/*z* = 710, and can be assigned to the ion [M + Na]$^+$.

The optical spectra of **1**, **2**, and **3** in MeCN have been measured in the 350−1200 nm wavelength range. Only one maximum is observed for each complex: for **1** at 571 nm (ε = 2820 L mol^{-1} cm^{-1}), for **2** at 501 nm (ε = 5880 L mol^{-1} cm^{-1}), and for **3** at 486 nm (ε = 7844 L mol^{-1} cm^{-1}). As these transitions are unusually intense for a high-spin Mn^{III} or Fe^{III} d-d transition, they are assigned to a phenolate-to-M^{III} [M^{III} = Fe or Mn] transition. Thus these bands can be assigned to a transition from pπ orbitals on the phenolate oxygen atoms to the dπ* orbitals on M^{III}.[32−35] The expected ligand field transitions, $^6A_1 \rightarrow {}^4T_2$ (^4G) for Fe^{III} and $^5E_g \rightarrow {}^5T_{2g}$ for Mn^{III}, which are likely to

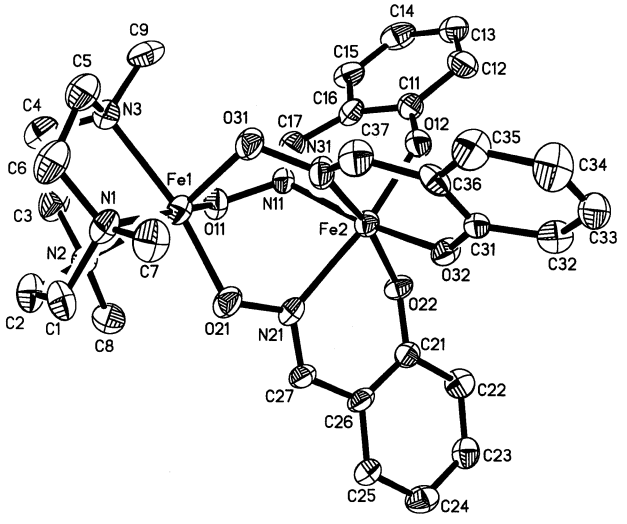

Figure 1. Molecular structure of the dinuclear $Fe^{III}Fe^{III}$ core in **3**, showing the atom-numbering scheme

occur in the 500−700 nm region, are obscured by the more intense charge transfer phenolate-to-metal (III) transition.

Molecular Structure of [(tmtacn)Fe^{III}(salox)$_3Fe^{III}$]·MeOH (3) and of [(tmtacn)Fe^{III}(*t*Bu-salox)$_3Fe^{III}$]·3.5 $CHCl_3$ (4)

The structures of the neutral complexes in crystals of **3** and **4** were determined, and as expected they are identical with respect to the coordination geometry of the Fe^{III} centers. Hence we are refraining from describing both structures in detail, and accordingly the ORTEP for **3** is shown in Figure 1. Table 1 lists selected bond lengths and angles for both **3** and **4**.

The coordination geometry of Fe(1) is distorted octahedral with three nitrogen atoms, N(1), N(2), and N(3), from the facially coordinated tridentate macrocyclic amine, and three oxygen atoms O(11), O(21), and O(31) from the bridging oximate groups. The Fe(1)−N (average 2.22 Å) and Fe(1)−O (average 1.94 Å) correspond to those of the known values[36,37] for Fe^{III} complexes with this macrocyclic amine, and are in agreement with a d^5 high-spin electron configuration of the Fe^{III}-center. A deviation from the idealized orthogonal geometry is found for the ligand tmtacn, the N−Fe(1)−N angles ranging between 78.6° and 79.3°, whereas O−Fe(1)−O angles fall between 96.1° and 99.6°. The Fe(1) is displaced by 0.10 Å from the mean basal plane comprising N(1)N(3)O(11)O(21) atoms, toward the apical oxygen atom O(31) of the oximate group. The ligand tmtacn exhibits no unexpected features.

The Fe(2) center is also six-fold coordinated. Coordination occurs facially through three phenolate oxygen atoms, O(12), O(22), and O(32), and three azomethine nitrogen atoms, N(11), N(21), and N(31), from the salox ligands. The average Fe(2)−N and Fe(2)−O bond lengths, 2.16 Å and 1.94 Å, respectively, fall within the ranges that are consid-

ered as normal covalent bonds for Fe^{III} centers with a d^5 high-spin electronic configuration.[29,30] The largest deviation from idealized 90° inter-bond angles is 6.3°, which occurs within the six-membered N−Fe(2)−O−C−C−C chelate rings, the N−Fe(2)−N angles ranging between 88.4° and 83.4°, whereas the O−Fe(2)−O angles fall between 90.4° and 95.8°. The Fe(2) lies practically on the best basal plane comprising N(11)N(21)O(12)O(32) atoms, and is displaced only 0.08 Å above the plane toward the apical atom O(22) of a phenolate group. Thus, the metrical parameters of the Fe(2) center in **3** are very similar in magnitude to the Fe(1) center and to those reported earlier for the FeN_3O_3 core.[37]

The binuclear skeleton is not coplanar, but is bent with a Fe(1)···Fe(2) separation of 3.570(1) Å. The dihedral angle between the planes Fe(1)N(1)N(3)O(11)O(21) and Fe(2)N(11)N(21)O(12)O(32) is 109.8°.

The deviation from octahedral symmetry for the Fe(1) and Fe(2) centers has been evaluated from the twist angle (60° for an ideal octahedral and 0° for a trigonal prismatic arrangement). The $Fe(2)N_3O_3$ core is more trigonally distorted than the $Fe(1)N_3O_3$ core. The N_3O_3 donor atoms are arranged around the Fe(2) center with a twist angle of 49.2°, whereas for the Fe(1) center the twist angle is 51.1°. In other words, the coordination polyhedron around Fe(2) is 10.8° away from the octahedral symmetry.

The N−O (average 1.38 Å) and C=N (average 1.28 Å) bond lengths and C−N−O bond angle (average 113.4°) of the bridging salicylaldoxime ligand are found to be very similar to those of other comparable structures.[38−39]

The structure determinations for **3** and **4** unambiguously show that, in both structures, the oxidation level of all iron centers is +3 with d^5 high-spin electron configuration.

Table 1 compares the important bond lengths in both salox complexes. It can be easily observed that in **3** these distances are slightly longer than those in complex **4**. This general trend can be explained by considering that the *tert*-butyl groups act in both inductive (+I) and mesomeric (+M) fashion as electron-donors. It implies that the substituted salox complex **4** provides a more electron-rich coordination environment and consequently the interaction between donor atoms (O, N) and iron is stronger, producing a small but significant shortening of the bond lengths.

Mössbauer Spectroscopy and Magnetic Susceptibility Measurements

The 3+ oxidation state and the high spin electronic configuration of the iron centers in complexes **2** and **3** were confirmed by Mössbauer spectroscopy.[40] The spectra were measured at 80 K and zero-field. They consist of asymmetrical quadrupole doublets with isomer-shifts (δ) of 0.530 mms^{-1} for **2**, 0.566 mms^{-1} and 0.451 mms^{-1} for **3**, and quadrupole splitting (ΔE_Q) of 0.350 for **2**, 0.261 and 0.175 mms^{-1} for **3**.

The Mössbauer spectra have provided us with another piece of important information. Examination of the literature values[41] for the isomer-shifts (ΔE_Q) of the Fe^{III}-center that is capped by the tmtacn ligand shows that the ΔE_Q values lie within the range 0.44 to 0.47 mms^{-1}. Thus the isomer shifts of 0.530 for **2** and 0.566 mms^{-1} for **3** are attributed to the Fe^{III} centers coordinated to the phenolate oxygen and azomethine nitrogen atoms of the salicylaldoxime ligand. This establishes that the Mn^{III} center in **2** is coordinated to the macrocyclic tmtacn ligand. In other words, the fact that the metal ions have remained associated with their different ligands originating from their respective starting materials and practically no scrambling of the ligands has occurred, are evidenced by the Mössbauer experiments.

Magnetic susceptibility data for polycrystalline samples of **1**, **2**, **3**, and **4** were collected in the temperature range 2 to 290 K and the magnetic parameters are listed in Table 2. The spin Hamiltonian $\mathbf{H} = -2\boldsymbol{J}\cdot\boldsymbol{S_1}\cdot\boldsymbol{S_2}$ with $S_1 = S_2 = 2$ for **1**, $S_1 = 2$, $S_2 = {}^5/_2$ for **2**, and $S_1 = S_2 = {}^5/_2$ for **3** and **4** is used throughout.

Table 2. Magnetochemical data for complexes **1** to **4**

Compound	J [cm^{-1}]	$g_1 = g_2$	θ [K]	PI
[(tmtacn)$\mathbf{Mn^{III}}$(salox)$_3$$\mathbf{Mn^{III}}$] (**1**)	+6.5	2.07	−0.43	–
[(tmtacn)$\mathbf{Mn^{III}}$(salox)$_3$$\mathbf{Fe^{III}}$] (**2**)	−4.8	2.03	–	0.06
[(tmtacn)$\mathbf{Fe^{III}}$ (salox)$_3$$\mathbf{Fe^{III}}$] (**3**)	−11.8	2.00	–	–
[(tmtacn)$\mathbf{Fe^{III}}$(*t*Bu-salox)$_3$$\mathbf{Fe^{III}}$] (**4**)	−12.2	2.07	–	–

The effective magnetic moment for **1** increases monotonically with decreasing temperature until a plateau is reached at 20−15 K with an μ_{eff} value of 9.11 μ_B (Figure 2). Below 15 K μ_{eff} starts to decrease reaching a value of 8.4 μ_B at 2 K. The temperature behavior of μ_{eff} for **1**, Mn^{III} Mn^{III}, is characteristic of a ferromagnetic exchange coupling between two high-spin d^4 Mn^{III} ions. The data could be fitted using the Heisenberg−Dirac−van Vleck (HDvV) model and the least-squares fitting computer program Julius-F[42] with a full-matrix diagonalization approach. The best fit was obtained with $J = +6.5$ cm^{-1}, $g = 2.07$ and $\theta = -0.43$ K and is shown in Figure 2.

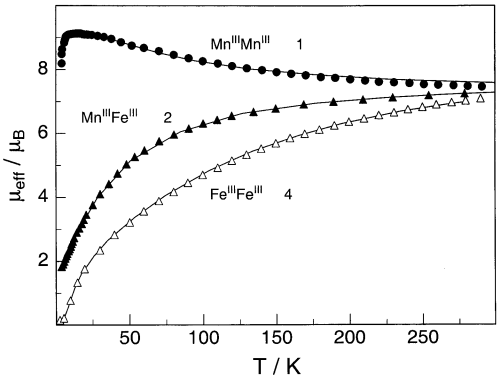

Figure 2. Plots of μ_{eff} vs. temperature for **1**, **2**, and **4**. Temperature-dependence of μ_{eff} of **3** is nearly identical to that of **4**. The solid lines represent the best fits to the spin Hamiltonian $H = -2J\cdot S_1\cdot S_2$ (see text)

For complex **2** the temperature dependence of the effective magnetic moment shows a monotonic decrease from 7.25 μ_B at 275 K to 1.85 μ_B at 4 K. This is typical of an

Table 3. Electrochemical data for complexes **1** to **4**; all potentials in Volts referred to Fc^+/Fc in CH_3CN ($E_{1/2}$ = 0.081 V)

Compound	$E_{1/2}$ (ox3)	$E_{1/2}$ (ox2)	$E_{1/2}$ (ox1)	$E_{1/2}$ (red1)	$E_{1/2}$ (red2)
[(tmtacn)**Mn^{III}**$(salox)_3$ **Mn^{III}**] (**1**)	–	0.30	−0.28	−0.86	−1.30
[(tmtacn)**Mn^{III}**$(salox)_3$ **Fe^{III}**] (**2**)	–	–	−0.19	−0.89	−1.81
[(tmtacn)**Fe^{III}** $(salox)_3$ **Fe^{III}**] (**3**)	0.97	0.77	0.41	−1.32	−1.86

antiferromagnetically coupled two-spin system with total spin ground state $S_t = {}^1/_2$ arising from $S_{Mn} = 2$ and $S_{Fe} = {}^5/_2$. Temperature independent paramagnetism (TIP) of $400 \cdot 10^{-6}$ cm^3 mol^{-1} and a monomeric impurity (6%, $S = 2$) were considered to account for the excess magnetic moment of the sample at 4 K. Fitting for the isotropic exchange yielded $J = -4.8$ cm^{-1} and $g = 2.03$ (Figure 2).

The magnetic behaviors of complexes **3** and **4** are, as expected, nearly identical, and hence they will be treated together. On lowering the temperature, the effective magnetic moments decrease monotonically for both complexes. Representative μ_{eff} values for complexes **3** and **4** (given in brackets) are 6.86 μ_B (7.09 μ_B) at 290 K, 4.68 μ_B (4.70 μ_B) at 100 K, 0.24 μ_B (0.21 μ_B) at 5 K, and 0.16 μ_B (0.15 μ_B) at 2 K, indicating a diamagnetic ground state $S_t = 0$ for both **3** and **4**. This arises from antiparallel spin coupling between two Fe^{III} centers with $S = {}^5/_2$. Simulation of the data yielded $J = -11.8$ cm^{-1}, $g_1 = g_2 = 2.00$ for **3** and $J = -12.2$ cm^{-1}, $g_1 = g_2 = 2.07$ for **4**. It was not necessary to consider terms for TIP or paramagnetic impurity in the simulation procedure. The experimental data together with the simulation for complex **4** are shown in Figure 2.

Electro- and Spectroelectrochemistry

Complexes **1**−**4** were submitted to electrochemical studies in order to characterize the nature of its redox processes. Table 3 summarizes the results, and Figure 3 and Figure 4 show representative examples of the electrochemical measurements.

The cyclic voltammogram of [(tmtacn)$Mn^{III}$$(salox)_3Mn^{III}$] (**1**) shows four consecutive reversible one-electron-transfer waves (Figure 3), which are detected with scan rates varying from 20 to 500 mVs^{-1} at +0.30 V, −0.28 V, −0.86 V, and −1.30 V versus Fc^+/Fc. The oxidation processes at +0.30 V and −0.28 V are assigned to the following equilibria shown in Equation (1).

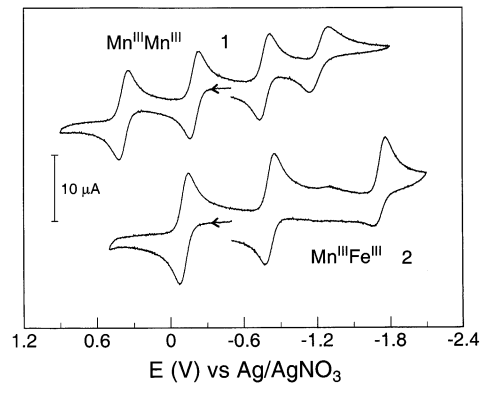

Figure 3. Cyclic voltammograms of **1** (top) and **2** (bottom) in CH_3CN (0.10 M $[(nBu_4)N]PF_6$ at a glassy carbon electrode; scan rate: 200 mV/s; complex ≈ 10^{-3} M; 298 K)

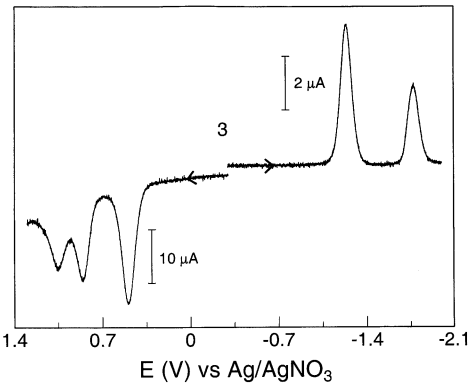

Figure 4. Square wave voltammograms for oxidation and reduction of **3** in MeCN, 0.1 M $[TBA]PF_6$. Oxidation: 0.25 mm Pt working electrode (WE), scan frequency 3000 Hz. Reduction: 2 mm GC WE, 5 Hz

$$\begin{array}{l} [(tmtacn)Mn^{III}(salox)_3Mn^{III}]^0 \\ \quad\quad \mathbf{1} \\ E_{1/2}(ox1) \quad -1e^- \downarrow\uparrow +1e^- \\ [(tmtacn)Mn^{IV}(salox)_3Mn^{III}]^+ \\ E_{1/2}(ox2) \quad -1e^- \downarrow\uparrow +1e^- \\ [(tmtacn)Mn^{IV}(salox)_3Mn^{IV}]^{2+} \end{array} \quad (1)$$

Electrochemically-reversible one-electron-transfer steps preclude any significant structural rearrangement during these oxidation processes, i.e., no change in the actual framework of the structures for all three species has occurred. The electrochemical behavior of complex **1** in the more negative potential range (−0.4 to −2.0 V vs. Ag/$AgNO_3$) can be assigned to the following redox scheme shown in Equation (2), on the basis of earlier reports.[21]

$$\begin{array}{l} [(tmtacn)Mn^{II}(salox)_3Mn^{II}]^{2-} \\ E_{1/2}(red2) \quad -1e^- \downarrow\uparrow +1e^- \\ [(tmtacn)Mn^{II}(salox)_3Mn^{III}]^- \\ E_{1/2}(red1) \quad -1e^- \downarrow\uparrow +1e^- \\ [(tmtacn)Mn^{III}(salox)_3Mn^{III}]^0 \\ \quad\quad \mathbf{1} \end{array} \quad (2)$$

The CV of **2** (Figure 3) exhibits two reversible one-electron waves at −0.19 V and −0.89 V versus Fc^+/Fc, and one quasi-reversible cathodic wave at more negative potentials that may be attributed to the reduction of iron center coordinated with phenolate and azomethine nitrogen atoms of the salicylaldoxime. Controlled-potential coulometry established a one-electron transfer process for the reversible cases. The following equilibria are thus involved during the manganese-centered electron-transfer processes (Equation 3).

$$
\begin{array}{l}
[(tmtacn)Mn^{III}(salox)_3Fe^{III}]^0 \\
\mathbf{2} \\
E_{1/2}(ox1) \quad -1e^- \downarrow\uparrow +1e^- \\
[(tmtacn)Mn^{IV}(salox)_3Fe^{III}]^+ \\
[(tmtacn)Mn^{III}(salox)_3Fe^{III}]^0 \\
\mathbf{2} \\
E_{1/2}(red1) \quad -1e^- \uparrow\downarrow +1e^- \\
[(tmtacn)Mn^{II}(salox)_3Fe^{III}]^- \\
E_{1/2}(red2) \quad -1e^- \uparrow\downarrow +1e^- \\
[(tmtacn)Mn^{II}(salox)_3Fe^{II}]^{2-}
\end{array}
\qquad (3)
$$

Complex **3** in MeCN exhibits five redox processes. The voltammetric waves of two of them, at +0.41 V and at −1.32 V versus Fc^+/Fc show reversible appearance under "standard" conditions (2 mm working electrode and scan rates of 0.05−0.5 V/s in CV and about 60 Hz in square wave voltammetry, SQW). Controlled potential coulometry at the appropriate potentials reveals that these waves originate from a one-electron oxidation and a one-electron reduction, respectively. The oxidation must be ligand-centered, and the reduction is assigned to an Fe^{III}/Fe^{II} couple. Two further (ligand-centered) oxidations at +0.77 and +0.97V and one more reduction at −1.86 V (assigned to reduction of the second iron) are detectable by SQW. The second reduction is best seen at relatively slow scan frequencies (< 10 Hz) most probably due to its slow heterogeneous electron transfer step. The two additional oxidations are detectable only at much higher frequencies (> 1000 Hz) because of rapid homogeneous following-up reactions. The results for the oxidations and reductions are displayed in Figure 4.

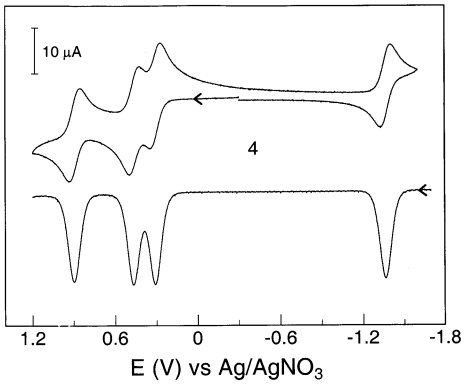

Figure 5. Square wave voltammogram (at 20 Hz) and CV (at 0.2 V/s) of **4** in MeCN, 0.1 M [TBA]PF_6

For complex **4** in MeCN, four reversible one electron waves were observed at the following potentials: +0.89, +0.47, +0.31, and −1.37 V, versus Fc^+/Fc. Additionally, an irreversible wave at $E_p^{ox} = -2.08$ V versus Fc^+/Fc is also found (Figure 5). The two reductive waves at −1.37 V and −2.08 V versus Fc^+/Fc are attributed to processes centered on the metal centers as described in Equation (4a), whereas the three oxidation waves are attributed to successive ligand-centered phenoxyl-radical formation [Equation (4b)]. The overall redox processes are given below where ($salox^\bullet$) represents a salox-based phenoxyl-radical.

reductive processes

$$
\begin{array}{l}

E_{1/2}(red1) \quad -1e^- \downarrow\uparrow +1e^- \\
[(tmtacn)Fe^{III}(t\text{Bu-salox})_3Fe^{III}]^0 \\
\mathbf{4}
\end{array}
\qquad (4a)
$$

oxidative processes

$$
\begin{array}{l}
[(tmtacn)Fe^{III}(t\text{Bu-salox})_3Fe^{III}]^0 \\
\mathbf{4} \\
E_{1/2}(ox1) \quad -1e^- \downarrow\uparrow +1e^- \\
[(tmtacn)Fe^{III}(t\text{Bu-salox})_2(t\text{Bu-salox}^\bullet)Fe^{III}]^+ \\
E_{1/2}(ox2) \quad -1e^- \downarrow\uparrow +1e^- \\
[(tmtacn)Fe^{III}(t\text{Bu-salox})(t\text{Bu-salox}^\bullet)_2Fe^{III}]^{2+} \\
E_{1/2}(ox3) \quad -1e^- \downarrow\uparrow +1e^- \\
[(tmtacn)Fe^{III}(t\text{Bu-salox}^\bullet)_3Fe^{III}]^{3+}
\end{array}
\qquad (4b)
$$

Each of these waves involves a $1e^-$-transfer, as detected by coulometry at fixed potentials. Both complexes **3** and **4** contain two high spin Fe^{III} ions in an octahedral *fac*-N_3O_3 donor set, but complex **4** in MeCN exhibits two additional ligand-centered reversible oxidation processes absent in **3**, as shown in Figure 5.

Spectroelectrochemical experiments were performed intending to isolate and characterize (by EPR spectroscopy) the resulting oxidized complexes. As the electron transfer processes during coulometric measurements at appropriately fixed potentials at ambient temperature has been found to be too slow (>> $^1/_2$ h), characterization of the radical complexes by UV/Vis and EPR spectroscopy has not been possible. Lowering the temperature of the experiments was also not effective, and the measurements resulted

in ill-defined isosbestic points. Nevertheless, the growth of peaks around 420−450 nm (ε ≈ 10580 $M^{-1}cm^{-1}$) serves as a strong indication for the radical nature of the generated complexes.

Concluding Remarks

The results summarized here for **3** and **4** suggest the generation of three ligand-centered oxidation processes, attributable to phenoxyl-radicals, rather than the formation of unusually high oxidation states at the central iron centres. On the contrary, in case of manganese, facile oxidation of metal centres rather than the ligands occurs. In contrast to the general notion that azomethine N-donor sets stabilize the 2+ oxidation state of iron centers, salicylaldoxime as a ligand with coordinated phenolato and azomethine groups enormously stabilizes 3+ oxidation state in such metal centers. This is a general feature of the phenolato iron complexes.

Experimental Section

Solvents and reagents were obtained from commercial sources and used without further purification. The synthon [Fe(tmtacn)]Cl_3[37] and the cyclic amine 1,4,7-trimethyl-1,4,7-triazacyclononane, tmtacn[43] were prepared according to previous published methods. − Infrared spectra were measured from 4000 to 400 cm^{-1} as KBr pellets at room temperature on a Perkin−Elmer FT-IR-Spectrophotometer 2000. − C, H, N, and metal content of the compounds were determined by the Microanalytical Laboratory of the Ruhr-Universität Bochum. − UV/Visible spectra of $5.0 \cdot 10^{-4}$ M solution in MeCN were recorded on a Perkin−Elmer UV/Vis Spectrophotometer Lambda 19 in the range 200−1200 nm. − Cyclic voltammetry and square wave voltammetry experiments were performed using an EG&G Potentiostat/Galvanostat 273A. A standard three-electrode-cell was employed with a glassy-carbon working electrode, a platinum-wire auxiliary electrode, and a $Ag/AgNO_3$ reference electrode. Measurements were made under an inert atmosphere at room temperature. All the potentials are referenced to Fc^+/Fc as the internal standard. − The magnetochemical measurements of the powdered samples were performed in a Quantum Design SQUID-Magnetometer MPMS in a field of 1 T. The samples were put in gelatine-capsules, and the response function was measured four times for each 32 measured temperature points. Diamagnetic contributions were estimated for each compound by making use of Pascal's constants. − Mössbauer data were recorded on alternating constant-acceleration spectrometers. The minimal experimental linewidth was 0.24 mms^{-1} full width at half maximum. The sample temperature was kept constant at 80 K either in an Oxford Variox or an Oxford Mössbauer-Spectromag cryostat. $^{57}Co/Rh$ was used as the radiation source. The measurements were carried out with solid samples containing the isotope ^{57}Fe and the isomer shifts are given relative to α-Fe at room temperature.

X-ray Crystallography: The crystallographic data of [LFe(salox)$_3$Fe] (**3**) and [LFe(*t*Bu-salox)$_3$Fe] (**4**) are summarized in Table 4.

Graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) was used throughout. Intensity data were corrected for Lorentz-Polarization and absorption effects using the program SADABS.[44] The structures were solved by direct methods using SHELXTL plus.[45] The function minimized during full-matrix least-squares refinement was $\Sigma w(|F_o| - |F_c|)^2$. Hydrogen atoms attached to carbon were placed at calculated positions and refined as riding atoms with isotropic thermal parameters. All non-hydrogen atoms were refined with anisotropic thermal parameters. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication number CCDC-151864. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.uk].

Preparation of the Compounds

Salicylaldoxime (H_2salox): was prepared by heating a solution of salicylaldehyde and free hydroxylamine in EtOH for 0.5 h under reflux. The yellowish white solid obtained on cooling was recrystallized from EtOH. Purity of the sample was checked by comparing its spectroscopic properties with those of the material salicylaldoxime available on the market.

4,6-Di-*tert*-butylsalicylaldoxime (4,6-*t*Bu-H_2salox): In a round bottom flask hydroxylamine−hydrochloride (5.6 g: 80 mmol) was dissolved in 10 mL of distilled water. Simultaneously, 4,6-di-*tert*-butylsalicylaldehyde (5.0 g: 20 mmol) was dissolved in 40 mL of warm MeOH. Both solutions were mixed and heated gently for 1 h under reflux. On cooling, a white product was isolated and washed with distilled water. M.p. 130−134 °C; yield 5.10 g (96%).− $C_{15}H_{23}NO_2$ (249.4): calcd. C 72.25, H 9.30, N 5.62; found C 72.5, H 9.4, N 5.4. − ^{1}H NMR [250 MHz, $CDCl_3$, 300 K] δ/ppm = 1.28; 1.42 [2 × s, 2 × 9 H (*t*Bu)], 6.98 [s, 1 H (H−ON)], 7.09; 7.35 [2 × s, 2 × 1 H (H-Ar)], 8.22 [s, 1 H (H−O−Ar)], 10.02 [s, 1H (H−C-Ar)]. − EI-MS: m/z = 249 $[M]^+$ and 234 $[M - CH_3]^+$ (100%).

[(*tmtacn*)Mn^{III}(*salox*)$_3Mn^{III}$] (1): A solution of the cyclic amine (0.17 g; 1 mmol) in 40 mL of MeOH was treated with a sample of manganese(III) acetate (0.52 g; 2 mmol) under vigorous stirring in an atmosphere of argon. After 0.5 h the resulting red-brown solution was charged with a sample of salicylaldoxime (0.41 g; 3 mmol) and 1 mL of triethylamine. The very dark solution was heated under reflux for 1 h, followed by a filtration to get rid of some green solid, presumably, Mn(Hsalox)$_3$. The solution kept at room temperature provided deep brown (almost black) crystals. The crystals were collected by filtration and air-dried. Yield 350 mg (≈50%). − $C_{30}H_{36}Mn_2N_6O_6$ (686.5): calcd. C 52.26, H 5.26, N 12.19, Mn 15.94; found C 52.0, H 5.3, N 12.3, Mn 16.0. − MS (ESI-positive in CH_3CN): m/z = 686 $[M]^+$ (100%).

[(tmtacn)Mn^{III}(salox)$_3Fe^{III}$] (2): A solution of the cyclic amine (0.17 g; 1 mmol) in 40 mL of MeOH was treated with a sample of manganese(III) acetate (0.52 g; 2 mmol) under vigorous stirring in an atmosphere of argon. After 0.5 h the resulting red-brown solution was charged with a suspension of $FeCl_3$ (0.16 g; 1 mmol) and salicylaldoxime (0.41 g; 3 mmol) in MeOH (30 mL) containing 1 mL of triethylamine. The very dark solution was heated under reflux for 2 h and then filtered to remove any solid particles. The solution kept at room temperature provided a deep brown solid. Deep brown crystals were obtained by diffusion of n-pentane into a MeCN solution of the solid. The crystals were collected by filtration and air-dried. Yield 270 mg (≈40%). − $C_{30}H_{36}FeMnN_6O_6$ (687.4): calcd. C 52.19, H 5.28, N 12.20, Mn 7.99, Fe 8.12; found C 52.3, H 5.2, N 12.1, Mn 7.8, Fe 8.1. − MS (ESI-positive in CH_3CN): m/z = 688 $[M + H]^+$ (75%), 710 $[M + Na]^+$ (100%).

[(tmtacn)Fe^{III}(salox)$_3Fe^{III}$]·MeOH (3): $FeCl_3$ (0.16 g; 1 mmol) was added to a degassed solution of salicylaldoxime (0.41 g; 3 mmol) in dry MeOH (50 mL) containing 1 mL of triethylamine under vigorous stirring. The resulting suspension was stirred at room temperature for 1 h and then charged with a solid sample of [Fe(tmtacn)Cl_3][37] (0.33 g; 1.0 mmol) and gently heated under reflux for 1 h. The resulting dark brown solid was collected by filtration and air-dried. X-ray quality crystals as dark red needles were obtained by diffusion of MeOH into a MeCN solution of **3**. Yield 450 mg (≈62%). − $C_{31}H_{40}N_6O_7Fe_2$ (720.4): calcd. C 51.69, H 5.60, N 11.67, Fe = 15.53; found C 52.0, H 5.5, N 11.6, Fe 15.3. − MS (ESI-positive in CH_3CN): m/z = 689 (100%) $[M + H]^+$.

[(tmtacn)Fe^{III}(*t*Busalox)$_3Fe^{III}$]·3.5 $CHCl_3$ (4): [Fe(tmtacn)Cl_3] (0.33 g; 1.0 mL) was added to a degassed solution of 4,6-di-*tert*-butylsalicylaldoxime (0.75 g; 3 mmol) in MeOH (50 mL) containing 0.84 mL of triethylamine under vigorous stirring. A solid sample of $FeCl_3$ (0.16 g; 1 mmol) was added and the resulting dark-red solution was stirred for further 0.5 h under gentle reflux. The solution kept at room temperature provided a dark-red microcrystalline solid, which was collected by filtration and air-dried. Yield 710 mg (≈70%). − $C_{54}H_{84}Fe_2N_6O_6$ (1025.0): calcd. C 63.28, H 8.26, N 8.20, Fe 10.9; C 62.9, H 8.2, N 8.2, Fe 10.8. − MS (ESI-positive in CH_3CN): a single peak at m/z = 1025 (100%) $[M + H]^+$. Recrystallization from $CHCl_3$ yielded X-ray quality crystals.

syn−*anti* Conversion in Octahedral Bis(β-diketonato)diorganotin(IV) Derivatives Containing Fluorinated 4-Acyl-5-pyrazolonato Donors

Claudio Pettinari,*[a] Fabio Marchetti,[a] Augusto Cingolani,[a] Asta Gindulyte,[b,c] Lou Massa,[b,c] Miriam Rossi,[d] and Francesco Caruso*[e]

Keywords: Ab initio calculations / Configuration determination / Diazo compounds / Ligand effects

Six-coordinate organotin derivatives L_2SnR_2 [L = 3-methyl-1-(4-trifluoromethylphenyl)-4-R^3-C=O-5-pyrazolonato (R^3 = CH_3, L = L^1; R^3 = C_6H_5, L = L^2; R^3 = CF_3, L = L^3; R = CH_3, *n*-C_4H_9, C_6H_5)] have been synthesized and characterized by analytical and spectroscopic (^1H, ^{13}C, ^{119}Sn, and ^{19}F NMR, IR) techniques. Partial dissociation of one ligand in chlorohydrocarbon solvents gives rise to cationic five-coordinate L-(solvent)-diorganotin(IV) complexes. The X-ray crystal structure of bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]diphenyltin (**6**) shows the metal in a distorted octahedron (skewed trapezoidal bipyramidal) with the two β-diketonato donors in *syn* positions, a C–Sn–C bond angle of 165.2(2)° and two sets of tin–oxygen bonds [2.141(5) and 2.139(3) Å for Sn–O(pyrazolonato) and 2.250(4) and 2.272(5) Å for Sn–O(acyl)]. Surprisingly, the recently reported dimethyltin derivative has the *anti* configuration, in contrast to expectations based on all previous experience. Large scale Hartree–Fock (HF) and Density Functional Theory (DFT) calculated structures for the *anti* configuration of bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin show good agreement with the experimental structure obtained from X-ray methods. The hypothetical *syn* configuration of bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin was also studied theoretically and both methods also predict characteristic structural features, such as: (from HF) a C–Sn–C bond angle of 150.0°, Sn–O(pyrazolonato) bond lengths of 2.088 and 2.084 Å and Sn–O(acyl) bond lengths of 2.385 and 2.401 Å. Results from the *syn* calculated structures suggest that intramolecular repulsive F···F interactions contribute to the *syn*–*anti* conversion.

Introduction

Organotin compounds have varied applications, including their use as boat paint additives to prevent attack by microorganisms,[1] and as insecticides and fungicides.[2−3] They are also effective antitumor agents.[4−8] We are particularly interested in organotin derivatives of 4-acyl-5-pyrazolones because these ligands possess several sites for substitution, allowing for a systematic analysis of their effects on the subsequent biological activity. So far, only the variation at R^3 has been fully explored (Figure 1).[9−20]

Recently, we have modified the R^1 position and synthesized some organotin derivatives, with R^1 = methyl[21] (usually it is a phenyl group), that possess an increased solubility in water and alcohols, an important feature for biological applications. Since halogen-substituted anions induce stronger biological activity in their organotin derivatives, both as antitumor agents[5−8] and as insecticides,[22] and, in particular, fluorine substituents have been reported to strongly influence the antitumor activity,[23−26] we then synthesized a ligand with R^1 = *p*-CF_3-Ph (Figure 2). This chemical modification results in a ligand with a lower donating ability of the O(pyrazolonato) atom and a greater ring-electron delocalization in the crystalline compound bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin. However, its structure rather unexpectedly has an *anti* configuration,[27] the first to be observed.

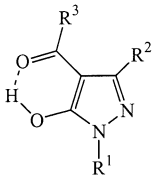

Figure 1. Proligands

Since the *anti* configuration was obtained after a seemingly subtle change in a peripheral area (substitution of a CF_3 group for a H atom in the *para* position of R^1 phenyl), we discuss the *syn*−*anti* variation after analyzing the theoretically calculated *syn* molecular structure and supporting experimental data. Large-scale ab initio calculations were performed on these metal complexes as a large number of atoms is involved.

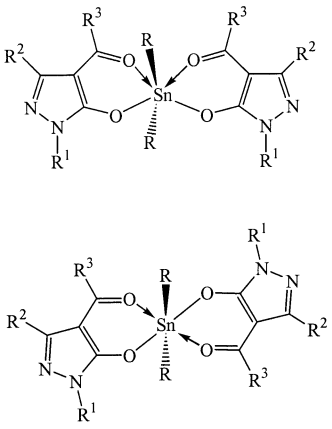

Figure 2. (top) *syn* configuration (normally observed in bis(4-acyl-5-pyrazolonato)diorganotin complexes; (bottom) *anti* configuration

A related *cis*−*trans* conversion has been reported by Gielen[28,29] and us,[11−13,17−19,21] for analogous monoorganotin(IV) β-diketonates in solution. However, in the case of diorganotin(IV) acylpyrazolonates, the *syn*−*anti* variation seems also to be feasible in the solid state, as previously demonstrated by multinuclear NMR spectroscopy and Mössbauer studies.[11,17]

Results and Discussion

We analyzed other diorganotin derivatives containing related ligands and the same R^1 (*p*-CF_3-Ph) substituent in an attempt to explain why the unexpected *anti* configuration of bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin is the form experimentally observed (described in Exp. Sect.). Since a previous diphenyltin derivative of a related 4-acyl-5-pyrazolonato showed less octahedral deformation than usual,[17] we selected bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]diphenyltin **6** from the compounds synthesized, and determined its molecular structure by X-ray diffraction methods.

Diffraction Study of $(L^2)_2SnPh_2$, 6

The crystal structure is formed from well-separated discrete molecules with no imposed crystallographic symmetry (Figure 3). The six-coordinate metal is surrounded by four O atoms from the two anionic chelating pyrazolonato ligands, and two C atoms from the phenyl groups, in a distorted octahedral arrangement so that the ligands have their equivalent arms facing one another (*syn* configuration), a geometry normally observed for bis(4-acyl-5-pyrazolonato)-diorganotin complexes. The relatively small octahedral distortion, described later in Table 1, is similar (although a bit larger) to that of another diphenyltin derivative, namely bis[4-(*p*-bromobenzoyl)-3-methyl-1-phenylpyrazolon-5-ato]-diphenyltin,[17] [C−Sn−C′ bond angle of 173.0(7)°, Sn−O1 bond length of 2.143(7) Å, Sn−O1′ bond length of 2.12(1) Å, Sn−O2 bond length of 2.223(8) Å, Sn−O2′ bond length

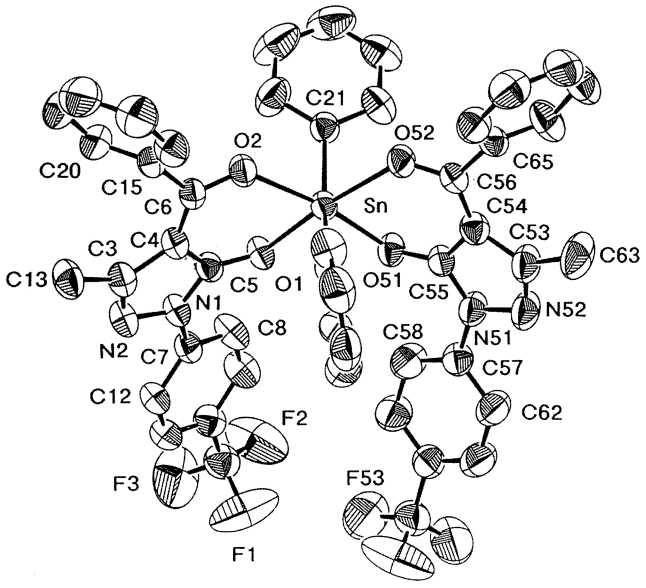

Figure 3. X-ray ORTEP drawing of bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]diphenyltin **6**

of 2.26(1) Å, O1−Sn−O2 bite angle of 84.5° and O1′−Sn−O2′ bite angle of 85.1(3)°].

The dihedral angles between the pyrazole ring and its attached *p*-CF_3-Ph ring are 16.6(7)° in one ligand, and −13.6(7)° in the other ligand, whereas in the above-mentioned bis(4-*p*-bromobenzoyl-3-methyl-1-phenyl)diphenyltin structure[17] the values are 13.9° and −11.7°, respectively. This quasi co-planarity between the rings is associated with the intramolecular distances O1···H1 [2.294(7) Å] and O51···H13 [2.265(8) Å], which are shorter than the van der Waals value of 2.60 Å[30] (H1 and H13 are bound to C8 and C58, respectively); this feature is also characteristic of these compounds. A specific feature of this structure is that the sum of the equatorial bond angles is equal to 360°: all other previously reported *syn* bis(4-acyl-5-pyrazolonato)-diorganotin complexes[10−14,17−21] show the tin somewhat shifted out of the equatorial plane, which makes this value smaller than 360°.

Theoretical Calculations

The molecular structures of bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin in both the *anti* and *syn* configurations were studied by theoretical methods. The starting coordinates for the *anti* compound were those obtained by X-ray diffraction[27] and were optimized by energy minimization with the Hartree−Fock (HF) and Density Functional Theory (DFT) methods (see Figures 4 and 5). Table 1 shows some geometrical features. There is excellent agreement with X-ray[27] data for the Sn polyhedron although HF calculates slightly shorter Sn−O bonds and slightly smaller bite angles, and, generally, DFT agrees better with the X-ray data than HF. A marked difference between HF and DFT is seen in the dihedral angle between the planar pyrazole and its attached phenyl. These values are 3.8 and −3.9° (DFT) and 24.2 and −24.3° (HF),

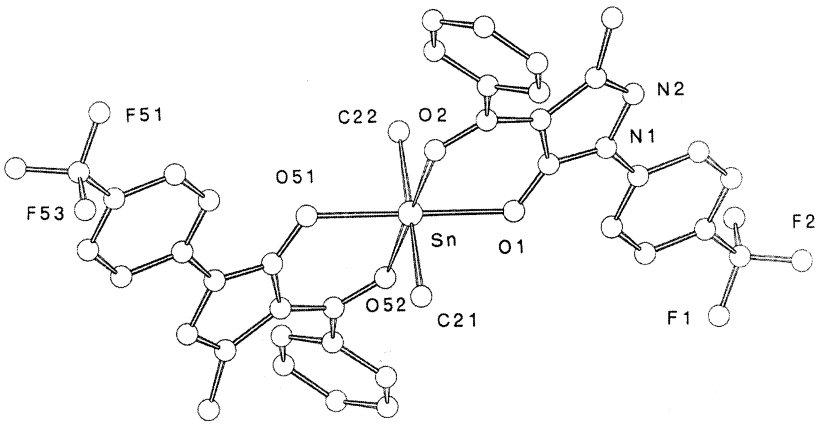

Figure 4. Bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin (*anti* configuration) obtained by the DFT method

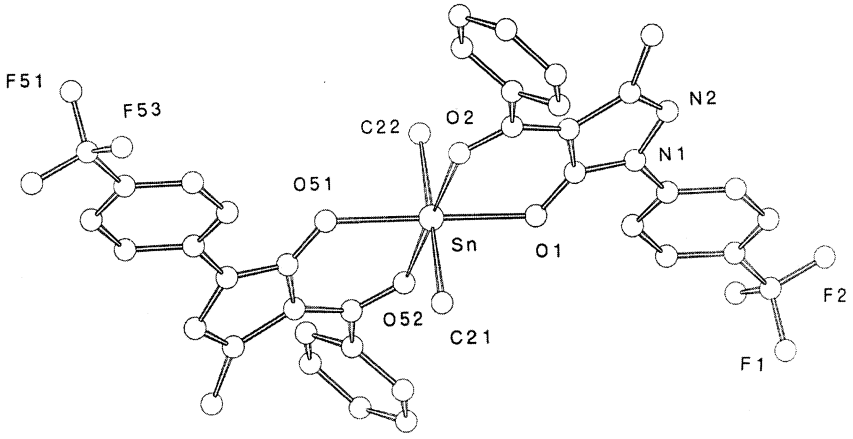

Figure 5. Bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin (*anti* configuration) obtained by the HF method

whereas the X-ray values are 16.6 and −16.6°. In the *syn* compounds there is a tendency for these two planes to be co-planar,[19] although this dihedral angle shows a large range of values, which suggests that the energy changes as a function of dihedral angle are small, and therefore can be affected by packing and/or intramolecular forces. Moreover, this angle can differ greatly even within the same molecule: for instance, in bis[4-(*p*-bromobenzoyl)-3-methyl-1-phenylpyrazolon-5-ato]dimethyltin it is 13.7° in one ligand and −39.8° in the second ligand.[13]

Since the theoretical results agree closely with the experimental values, we then proceeded to calculate the molecular structure of the *syn* configuration with the coordinates of bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)-pyrazolon-5-ato]diphenyltin **6** described above. The phenyl groups bound to tin were replaced by methyl groups and the structure was optimized as above. Selected structural parameters are also given in Table 1 and the calculated structures are shown in Figures 6 and 7.

The *syn* structures in Table 1 confirm that when methyl groups are replaced by phenyl groups a smaller octahedral distortion is induced. This was previously observed in bis(4-acylpyrazolon-5-ato)diorganotin complexes studied using X-ray diffraction methods.[17] The driving force is the electron-withdrawing effect of the Ph that attracts electron density from the tin atom and induces further ligand donation, which is provided by O2.[17] Consequently, in diphenyltin derivatives the Sn−O2 bond length is shorter than in dialkyltin derivatives. As a result, diphenyltin derivatives have similar Sn−O1 and Sn−O2 bond lengths and show less octahedral deformation, that is, the C−Sn−C′ bond angle is closer to 180°.

Table 1 shows that the polyhedron deformation in the *syn* structures (for the three methods, XR, HF, and DFT) is characterized by having Sn and its four linked O atoms in a plane [the sum of the four angles, O1−Sn−O2 (ligand 1 bite), O1′−Sn−O2′ (ligand 2 bite), O1−Sn−O1′ and O2−Sn−O2′, equals 360°]. As mentioned above, this is the first time that this feature (seen in compound **6**) has been observed for *syn*-bis(4-acyl-5-pyrazolonato)diorganotin complexes, and is confirmed theoretically.

All bis(4-acylpyrazolon-5-ato)diorganotin *syn* structures solved so far by X-ray diffraction display approximate mirror symmetry, with the mirror plane containing Sn and its two bonded C atoms. The calculated molecules are single and isolated (intermolecular forces do not exist) and, if mirror symmetry exists, should show equivalence in both bite angles, as well as the bond lengths Sn−O1 and Sn−O1′, Sn−O2 and Sn−O2′, and the angles O1−Sn−O2′ and O1′−Sn−O2. However, Table 1 shows that this is not the

Table 1. Selected geometrical parameters in bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]-di-R-tin compounds obtained with different structural methods (XR = X-ray diffraction, HF = Hartree−Fock, DFT = Density Functional Theory)

[a] Hypothetical compound. Labels in Figure 3 are related so that O51 is O1′, O52 is O2′, N51 is N1′, etc. Distances [Å], angles [°]. Energy values for calculated structures (a.u.): HF, −2573.72811 (*anti*), −2573.73406 (*syn*); DFT, −2587.11444 (*anti*), −2587.11749 (*syn*).

case. A peripheral structural feature confirms this: the dihedral angle between the pyrazole and its attached phenyl differs in each ligand (24.4° and 8.2° for DFT and 30.6° and 25.8° for HF). These results are in contrast with the *anti* species described above where both dihedral angles obtained from DFT, HF, and X-ray methods are equal.

Further analysis of the calculated *syn* structures for bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin in Table 1 shows good agreement with a characteristic feature observed by X-ray diffraction:[10−21] the Sn−O(pyrazolonato) bond lengths are shorter than the Sn−O(acyl) bond lengths. The variation between these sets of bond lengths using the DFT method is less than when using the HF method. This geometry was described as skewed trapezoidal bipyramidal (STB) by Kepert in a theoretical treatment.[31] The short side of the trapezoid links the two O(pyrazolonato) atoms that form the short Sn−O bonds, whereas the long side links the two O(acyl) atoms that form the long Sn−O bonds (see Figure 8).

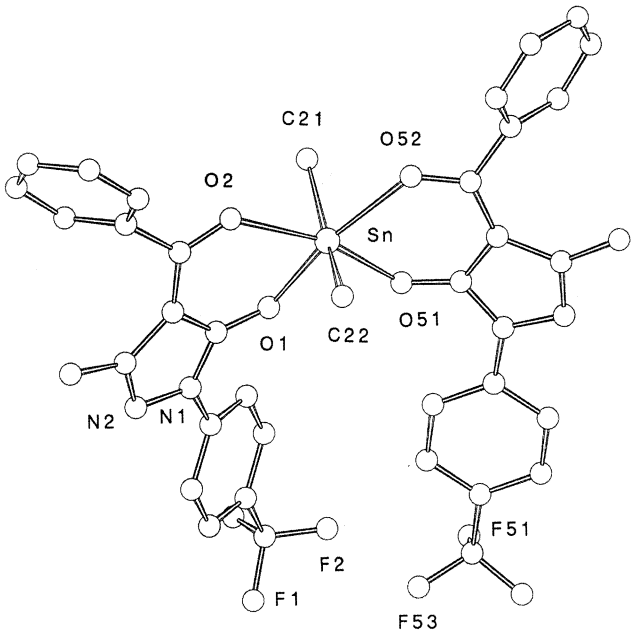

Figure 6. Bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin (*syn* configuration) obtained by the DFT method

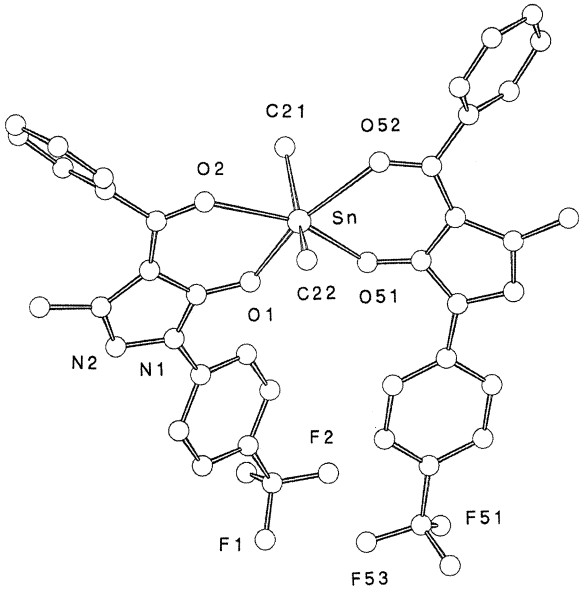

Figure 7. Bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin (*syn* configuration) obtained by the HF method

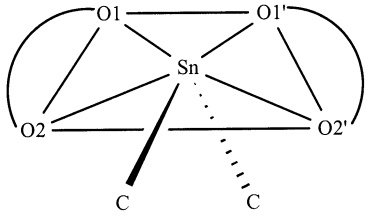

Figure 8. Skewed trapezoidal bipyramidal configuration

In the experimental *syn*-bis(4-acyl-5-pyrazolonato)-di-R-tin complexes studied so far, it is the R = alkyl substituents that induce the strongest octahedral deformation[10−14,17−21] on the geometry of these complexes. This is described by:[19]

(a) a small *trans* C−Sn−C′ angle
(b) a small O1−Sn−O1′ angle
(c) a large O2−Sn−O2′ angle.

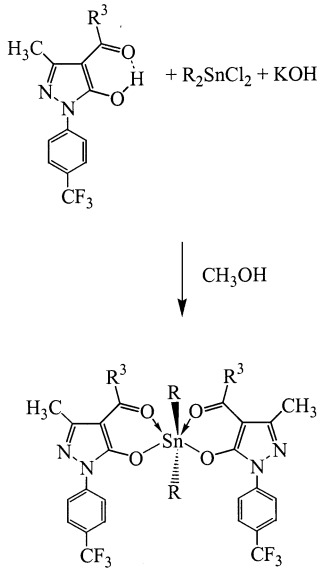
Experimentally, when R^1 = Ph, R^2 = methyl, R^3 = Ph and R = methyl, a *syn* species is obtained,[12] whereas when R^1 = *p*-CF_3-Ph, an unexpected *anti* species results.[27] Therefore, the CF_3 group causes a "perturbation". DFT and HF methods react differently to the CF_3 "perturbation": DFT predicts a large C−Sn−C′ angle while, in contrast, HF calculates a smaller C−Sn−C′ angle. Table 1 shows markedly different (a) and (c) values for HF and DFT calculations on the hypothetical *syn*-bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin. However, the value of O1−Sn−O1′ is similar for both DFT (83.0°) and HF (82.4°); in general, the value of O1−Sn−O1′ in bis(4-acyl-5-pyrazolonato)dialkyltin complexes (containing R^1 = Ph) is smaller. The O1−Sn−O1′ angle for both DFT and HF theoretical methods corresponds to the closest approach of the F atoms (the shortest separations are F1···F53 = 3.09 Å and F2···F53 = 3.05 Å, for HF, and F2···F53 = 2.88 Å and F2···F51 = 3.00 Å, for DFT; these distances are close to the F···F van der Waals value of 2.94 Å).[30] We see that the limiting *syn* octahedral deformation predicted by theory corresponds to an O1−Sn−O1′ angle that differs from those previously observed[19] (as mentioned above, X-ray values are smaller). We conclude that the CF_3 "perturbation" is associated with greater intramolecular R^1···R^1 steric hindrance; it is therefore not surprising that an *anti* species (that avoids such strain) is obtained. It is worthwhile to note that diorganotin STB deformation can be greatly enhanced; for instance, in the less crowded bis(*N*-benzoyl-*N*-phenylhydroxylamino)di-*n*-butyltin complex, the C−Sn−C′ bond angle is 133(9)°.[32] This also suggests that repulsion factors are responsible for the extent of deformation in the STB configuration. Moreover, Kepert's theoretical treatment is based on repulsion features[31] (in other words increasing deformation may imply stronger repulsion on the short side of the trapezoid).

The strength of repulsive F···F interactions is demonstrated by the existence of WF_6 as a gas at room temperature. The large polarization of F−W bonds makes the F atoms highly negatively charged; the WF_6 octahedrons therefore repel each other inducing an unusual gaseous state. In our case, the alternative to the sterically hindered R^1···R^1 *syn* structure is the *anti* structure. We have calculated the energy for bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin to be slightly lower for the *syn* structure than for the *anti* structure (3.7 kcal/mol, for HF, and 1.9 kcal/mol for DFT); this feature will be addressed later.

Solution Study

Since the crystals of *anti*-bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin **4** were obtained directly from the alcoholic reaction mixture,[27] while all the previous bis(4-acylpyrazolon-5-ato)diorganotin derivatives precipitated in such a medium (they were later recrystallized from other solvents to obtain crystals suitable for diffraction),[11−13,16−21] we decided to study the behavior of **4** and related complexes containing ligands with the same R^1 substituent, in solution.

The proligands 4-acetyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazol-5-one (L^1H), 4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazol-5-one (L^2H), and 3-methyl-4-(trifluoroacetyl)-1-(4-trifluoromethylphenyl)pyrazol-5-one (L^3H) react with dichlorodiorganotin(IV) acceptors in basic methanol solution by substitution of the two chlorine atoms and yield the six-coordinate tin(IV) derivatives L_2SnR_2 **1−9** (see Scheme 1).

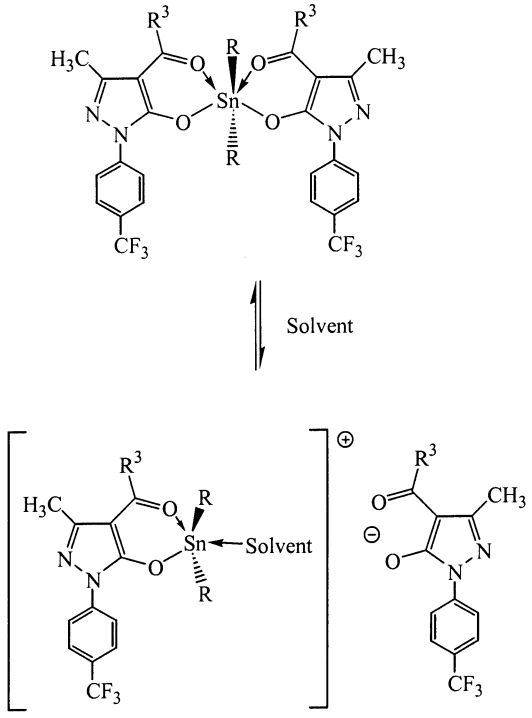


Compound	L	R^3	R
1	L^1	CH_3	CH_3
2	L^1	CH_3	Bu^n
3	L^1	CH_3	Ph
4	L^2	Ph	CH_3
5	L^2	Ph	Bu^n
6	L^2	Ph	Ph
7	L^3	CF_3	CH_3
8	L^3	CF_3	Bu^n
9	L^3	CF_3	Ph

Note: R^1 = *p*-CF_3-Ph and R^2 = CH_3 in all compounds.

Scheme 1

They are air- and moisture-stable solids, very soluble in aromatic and chlorohydrocarbons, acetone and dimethylsulfoxide (DMSO). They are partially dissociated in all these solvents with the exception of the aromatic hydrocarbons: In fact, vapor pressure osmometric molecular mass determinations of derivatives **1** and **3−5** in chloroform indicate a partial dissociation, the ratio *r* (molecular mass/formula mass) being generally in the range 0.60−0.90. Conductivity data carried out in dichloromethane seem to indicate the presence of non-ionic species. This could be due to ion-pairing effects, which result in a much lower conductivity value than that observed in DMSO. The molecular mass study on derivative $(L^2)_2SnMe_2$ **4**, shown in Figure S1 (Supporting Information, see also footnote on the first page of this article), indicates that dissociation increases with dilution. In fact, the experimental molecular mass values increase with concentration of the solution, approaching the theoretical formula mass when the concentration is higher than 0.02 m (m = mol of solute/kg of solvent). This behavior in solution is unexpected since previous studies[11−13,16−21] show an absence of conductivity for bis(4-acyl-5-pyrazolonato)diorganotin complexes, and the experimental molecular mass values in solution are typical of mononuclear non-ionic species. These results demonstrate that the CF_3 substituent in the *para* position of R^1 phenyl can influence the stability of the L_2SnR_2 species in solution.



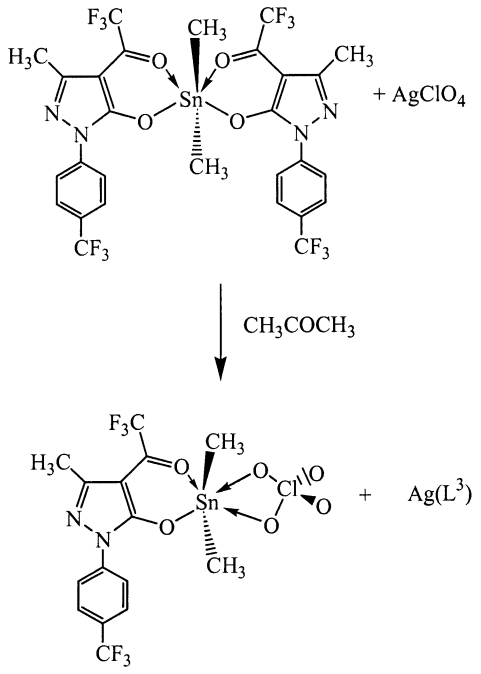
Scheme 2

Dissociation is confirmed by multinuclear NMR spectroscopic experiments. Broad resonances (compounds **1** and **2**) or three sets of signals (compounds **4** and **5**) for the ligand moiety in the ^1H NMR spectra, and two sets of signals for the $(alkyl)_2Sn$ moiety in the ^1H and ^{119}Sn NMR spectra are observed. This is in agreement with Scheme 2. We observed the same multiplicity in the ^{13}C NMR spectra. The assignments of the ^{13}C resonances of the groups bonded to tin are straightforward from the $^nJ(^{13}C\text{-}^{119/117}Sn)$ coupling constants, whereas the L carbon resonance assignments are based on the $^{13}C\text{-}^{19}F$ coupling constants. Holecek[33] and Lockhart[34] reported that $^1J(^{13}C\text{-}^{119}Sn)$ can be used to indicate the tin coordination number in diorganotin(IV) compounds. Six-coordinate dialkyl- and diaryltin(IV) complexes exhibit couplings in the range 800−1000 Hz, whereas five-coordinate complexes are in the range 500−700 Hz.[33−35] Most of the diorganotin(β-diketonates) in this work exhibit at least one signal with characteristic coupling satellites. The $^1J(^{13}C\text{-}^{119}Sn)$ coupling constants vary in the range 700−900 Hz, in accordance with a coordination number halfway between 5 and 6. These values can also be related to the size of the C−Sn−C angle, according to the equations derived by Holecek[33] and Lockhart.[34] The θ values of the studied compounds range from 145 to 157°. They are greater for L^1 and L^2 than for L^3 diorganotin(IV) derivatives. This suggests that the solid state six-coordinate structure is lost in solution in the case of L^3 complexes to generate a five-coordinate species, as also indicated by the values of the $^2J(^1H\text{-}^{119}Sn)$ coupling constants in the spectra of the dimethyl- and diphenyltin derivatives **7** and **9**, which correspond to typical five-coordinate diorganotin(IV) complexes.[33−35] However, it should be noted that the coupling constants values are determined by the metal coordination number as well as by electronic and steric factors, and we cannot exclude the occurrence of strong deformations from the octahedral structure in solution.

^{119}Sn NMR spectroscopic data further confirm the presence of different species in solution for dimethyl, di-*n*-butyl and diphenyltin(IV) derivatives of L^1 and L^2 as at least two resonances are found. The more intense is in the typical range for six-coordinate species [δ = −300 to −500 from $Sn(CH_3)_4$],[17] whereas the other is in the typical range for five-coordinate species δ = −80 to −250 from $Sn(CH_3)_4$].[33,35] The existence of species such as $[L(solvent)_xSn(CH_3)_2]^+$ (deduced from the equilibrium in Scheme 2) was confirmed by treating an acetone solution of $(L^3)_2Sn(CH_3)_2$ **7** with $AgClO_4$, yielding $[(L^3)Sn(CH_3)_2ClO_4]$ (**10**) according to Scheme 3 (see Exp. Sect.). Upon addition of a large excess of HL^1 and NEt_3 (1:1 relative molar ratio) to a $CDCl_3$ solution of **1**, the signal at δ = −100.6 disappeared, whereas that at δ = −323.9 remained unchanged.

The ^{19}F NMR spectra of the L^1 derivatives **1** and **3** have one resonance at room temperature that splits into four or five resonances at −50 °C (Figure S2), whereas the ^{19}F NMR spectra of derivatives **4−9** recorded at room temperature show several signals, in accordance with dissociation (Scheme 2).

Therefore, dissociation of a pyrazolonato anion in Scheme 2 generates ionic species, increasing the solubility in the moist alcoholic reaction mixture and allowing slow crystallization of the *anti* species **4**.



Scheme 3

Conclusion

Theoretical methods (HF and DFT) give calculated energies for the *syn* and *anti* configurations of bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin that are almost equivalent: the energy needed for the existence of the *anti* species could easily be provided by crystallization. In addition, such an arrangement for bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin, experimentally obtained in the solid state after crystallization from the reaction mixture, is favored by partial complex dissociation with the formation of the ionic species $[(solvent)(L)Sn(CH_3)_2]^+$ and the pyrazolonato anion (in contrast to ligands containing R^1 = Ph or methyl). Furthermore, the calculated O1−Sn−O1′ angle of the hypothetical *syn*-bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin is wider than those of other bis(4-acyl-5-pyrazolonato)dialkyltin complexes and this is due to repulsive F···F interactions. Therefore, the *anti* species arises from the synergistic action of: a) increased solubility in the reaction mixture due to ionic separation; b) repulsion between CF_3 groups for the *syn* configuration that is avoided in the *anti* species; and c) the small energy difference between the *syn* and *anti* configurations, which can be accounted for by the crystallization process.

The *syn* configuration [clearly preferred in bis(4-acyl-5-pyrazolonato)diorganotin complexes] is observed experimentally for bis[4-benzoyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]diphenyltin (**6**) The intramolecular repulsion between $R^1\cdots R^1$ groups in this less-distorted octahedral species is avoided because of the wider O1−Sn−O1′ angle than that of the calculated dimethyltin analogue.

Experimental Section

General: The organotin(IV) halides were purchased from Alfa (Karlsruhe) and Aldrich (Milwaukee) and used as received. − The samples for microanalysis were dried in vacuum to constant mass (20 °C, about 0.1 Torr). − Elemental analyses (C,H,N) were performed in house with Fisons Instruments 1108 CHNS-O Elemental Analyzer. − Molecular mass determinations (molecular mass) were performed at 40 °C with a Knauer KNA0280 vapor pressure osmometer calibrated with benzil. The solvent was Baker Analyzed Spectrophotometric grade chloroform. The results were reproducible to ±2%. − IR spectra were recorded from 4000 to 100 cm^{-1} with a Perkin−Elmer System 2000 FT-IR instrument. − ^1H, ^{19}F, ^{13}C, and ^{119}Sn NMR spectra were recorded on a VXR-300 Varian spectrometer operating at room temperature (300 MHz for ^1H, 75 MHz for ^{13}C, 282.2 MHz for ^{19}F, and 111.9 MHz for ^{119}Sn), referred to TMS (^1H and ^{13}C), $CFCl_3$ (^{19}F), and $(CH_3)_4Sn$ (^{119}Sn). The ^{119}Sn NMR experiments were carried out with a spectral width of 900 ppm. − Melting points were taken on an IA 8100 Electrothermal Instrument. − The electrical conductances (reported as Ω^{-1} cm^2 mol^{-1}) of dichloromethane, DMSO, and acetone solutions (M = mol/L) were measured with a Crison CDTM 522 conductimeter at room temperature.

Synthesis of the Donors: The donors L^1H, L^2H, and L^3H were synthesized by previously reported methods.[36]

Synthesis of the Metal Derivatives

Bis[4-acetyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]-dimethyltin(IV) $(L_1)_2SnMe_2$ (1): KOH (2 mmol) and Me_2SnCl_2 (1 mmol) were added to a methanol solution (30 mL) of L^1H (2 mmol). A precipitate formed immediately. The mixture was stirred overnight and the precipitate was then filtered, washed with methanol (ca. 10 mL) and dried under reduced pressure at room temperature. The product was then recrystallized from chloroform/*n*-hexane. Yield: 86%. M.p. 230−231 °C. − $C_{26}H_{26}F_6N_4O_4Sn$: calcd. C 47.02, H 3.66, N 7.83; found C 47.34, H 3.76, N 8.02; formula mass 715; molecular mass 486 ($0.9\cdot10^{-2}$ m; r = 0.68), 529 ($1.4\cdot10^{-2}$ m; r = 0.74). − Molar conductance: Λ_M ($0.8\cdot10^{-3}$ M in CH_2Cl_2) = 0.3; Λ_M [$0.9\cdot10^{-3}$ M in $(CH_3)_2SO$] = 17.7. − IR (nujol): $\tilde{\nu}$ = 1618 s ν(C=O), 593 s ν(Sn−C), 442 s, 401 s ν(Sn−O). − ^1H NMR ($CDCl_3$): δ = 0.86 [s, $^2J(^1H\text{-}Sn)$ = 103.6, 99.6 Hz, 3 H, Sn−CH_3], 1.12 [s, $^2J(^1H\text{-}Sn)$ = 79.3 Hz, 3 H, Sn−CH_3], 2.44, 2.46 (2 br. s, 12 H, CH_3C=O and C3−CH_3), 7.55, 7.70, 8.10, 8.16 (4 d, 8 H, AA′BB′ pattern for the four protons in C_6H_4-4-CF_3). − ^{13}C NMR ($CDCl_3$, 20 °C): δ = 9.18 (s, Sn−CH_3), 9.75 (s, Sn−CH_3), 16.14 (s, 3-CH_3), 17.89 (s, 3-CH_3), 26.10 (s, CH_3CO), 28.51 (s, CH_3CO), 105.20 (s, C3), 120.4 (s, CH_{arom}), 120.9 (s, CH_{arom}), 124.4 [q, CF_3, ^1J(C−F): 271.5 Hz], 126.4 (s, CH_{arom}), 127.1 (s, CH_{arom}), 141.4 (s, C4), 141.62 (s, C4), 150.22 (s, C−N), 150.35 ($C-CF_3$), 162.92 (C5), 193.7 (C=O). − ^{19}F NMR ($CDCl_3$, 20 °C): δ = −62.9; ($CDCl_3$, −50 °C): δ = −62.1, −62.2, −62.3, −62.6. − ^{119}Sn NMR ($CDCl_3$): δ = −100.6 [1], −323.9 [2]; ^{119}Sn NMR ([D_6]benzene): δ = −324.1. − Derivatives **2−3**, **5−6**, **9**, were synthesized in a similar way.

Bis[4-acetyl-3-methyl-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]di-*n*-butyltin(IV) $(L^1)_2Sn$*n*Bu_2 (2): Yield: 73%. M.p. 173−175 °C. − $C_{34}H_{38}F_6N_4O_4Sn$: calcd. Bis[3-methyl-4-(trifluoroacetyl)-1-(4-trifluoromethylphenyl)-pyrazolon-5-ato]diphenyltin(IV) (L^3)$_2$SnPh$_2$ (9): Yield: 72%. M.p. 254−256 °C. − $C_{38}H_{24}F_{12}N_4O_4Sn$: calcd. C 48.18, H 2.55, N 5.91; found C 47.95, H 2.70, N 5.68; formula mass 947.3. Molar conductance: Λ_M ($1.0\cdot10^{-3}$ M in CH_2Cl_2) = 0.3; Λ_M [$1.1\cdot10^{-3}$ M in $(CH_3)_2SO$] = 4.5. − IR (nujol): $\tilde{\nu}$ = 1628 s ν(C=O), 266 s, 223 vs ν(Sn−C), 449 vs, 424 s ν(Sn−O). − ^{1}H NMR ($CDCl_3$, 20 °C): δ = 2.19, 2.21, 2.30, 2.38 (4 q, 6 H, C3−CH_3), 7.12−7.62, 7.78−7.94 (2 br. m, 18 H, AA′BB′ pattern for the four protons in C_6H_4-4-CF_3 and Sn−Ph). − ^{13}C NMR ($CDCl_3$, 20 °C): δ = 15.65 (br., 3-*C*H_3), 15.93 (s, 3-*C*H_3), 17.05 (s, 3-*C*H_3), 102.0 (br., *C*3), 118.1 (s, *C*H_{arom}), 120.5 (br., *C*H_{arom} + *C*F_3), 125.86, 126.02, 126.08, 126.1 (m, *C*H_{arom} + *C*F_3 + Sn−Ph), 127.5, 128.0, 128.3, 128.5, 128.7, 128.9, 129.1 (m, *C*H_{arom} + *C*F_3 + Sn−Ph), 130.0 [s, Sn−Ph, ^4J(^{13}C-Sn) = 16 Hz], 134.6 (s, *C*H_{arom}), 135.4 (br., *C*H_{arom} + *C*F_3 + Sn−Ph), 136.2 (s, *C*H_{arom}) 140.0 (br., *C*4), 149.0 (br., *C*H_{arom}) 157.2, (br., C−N), 164.0 (m, C5). − ^{19}F ($CDCl_3$, 20 °C) NMR: δ = −63.3, −63.6, −69.3, −71.6, −76.7, −82.1. − ^{119}Sn NMR ($CDCl_3$, 20 °C): δ = −278.7 [2], −301.4 [1], −319.2 [1], −320.2 [1].

[3-Methyl-4-(trifluoroacetyl)-1-(4-trifluoromethylphenyl)pyrazolon-5-ato]dimethyltin(IV) Perchlorate [(L^3)SnMe$_2$(ClO_4)] (10): Silver perchlorate (0.104 g, 0.5 mmol) was added to a stirred acetone solution (30 mL) of [(L^3)$_2$SnMe$_2$] (0.358 g, 0.5 mmol). A colorless precipitate formed within 6 hours which was filtered and identified as Ag(L^3) by elemental analysis and IR data. Yield: 40%. M.p. <300 °C. − $C_{13}H_{10}AgF_3N_2O_2$ (391.1): calcd. C 39.92, H 2.58, N 7.16; found C 40.12, H 2.70, N 7.34. − IR (nujol): $\tilde{\nu}$ = 1646 vs ν(C=O). The clear solution was then evaporated and the pale yellow residue was washed with diethyl ether/*n*-hexane (20 mL) and shown to be compound **10**. It was recrystallized from acetone/diethyl ether. Yield: 40%, M.p. 150 °C. − $C_{15}H_{16}ClF_3O_6N_2Sn$ (531.4): calcd. C 33.90, H 3.03, N 5.27; found C 34.03, H 3.16, N 5.45. − IR (nujol): $\tilde{\nu}$ = 1621 vs ν(C=O), 1099 vs. br., 1076 vs. br., 618 s ν(ClO_4), 586 m ν(Sn−C), 440 s, 422 m ν(Sn−O). − ^{1}H NMR ($CDCl_3$, 20 °C): δ = 1.26 [^2J(^{1}H-^{119}Sn) = 105 Hz; ^2J(^{1}H-^{117}Sn) = 100 Hz, 6 H, Sn−CH_3], 2.48 (s, 3 H, C_3−CH_3), 2.63 (s, 3 H, CH_3C=O), 7.40, 7.73 (2 d, 4 H, N−$C_6H_4$$CF_3$).

X-ray Crystallographic Study: A preliminary study was performed with a Weissenberg Camera to determine cell parameters and the triclinic space group. A $P2_1$ Syntex diffractometer was used for the measurements of the cell constants and for the data collection; a set of 25 reflections (with high theta angle) was used to obtain refined cell parameters. Decay correction was applied since monitoring of three reflections (taken every 100 reflections) indicated decay, average 14.8%. Slight absorption anisotropy was found after a psi-scan (transmission factor range 0.93−1.00), and so data were corrected for absorption, as well as for Lorentz and polarization effects.[37] The molecular structure was solved using the Patterson−Fourier method using CAOS.[38]

Subsequent calculations were performed as follows: refinement based on the minimization of the function $w(|F_o| - |F_c|)^2$ with the weighting scheme $w = 1/(a + F_o + cF_o^2)$, where a and c are of the order of $2F_o$(min) and $2/F_o$(max), respectively;[39] anisotropic displacement parameters were refined for non-H atoms. After refinement convergence, H atoms were introduced at fixed positions with a C−H distance of 0.96 Å, and H isotropic displacement parameters were kept fixed until final refinement convergence was reached. Atomic scattering factors and anomalous dispersion terms were taken from the literature.[40] Chemical formula, $C_{48}H_{34}F_6N_4O_4Sn$; M_w = 963.50; crystal habitat, block; crystal size [mm], 0.40 × 0.25 × 0.15; crystal system, triclinic; space group, $P\bar{1}$ (no. 2); crystal color, colorless; a = 9.299(4), b = 16.004(7), c = 15.557(6) Å; α = 96.03(2)°, β = 95.69(2)°, γ = 112.80(2)°; V = 2098(3) Å^3; Z = 2; T = 298 K; $D_{calcd.}$ = 1.526 g/cm^3; $2\theta_{max}$ = 60°; μ = 0.698 mm^{-1} graphite monochromated wavelength, Mo-K_α; scan speed = 4 °/min; scan range = 1.3°; index range, *h*: 0/12, *k*: −22/20, *l*: −21/21; measured reflections, 12904; unique reflections, 12863; refined reflections [$F>6\sigma(F)$] = 8261; refined parameters, 568; R, R_w = 0.052, 0.068; S = 1.29; $R(F) = \Sigma||F_o| - |F_c||/\Sigma F_o$; $S = [\Sigma\{w(F_o^2 - F_c^2)^2\}/(n - p)]^{0.5}$, n = no. of data and p = no. of refined parameters.

Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-149841. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax 44 123/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Study: All computations were carried out with the MULLIKEN program[41] package on an IBM/SP2 supercomputer. Hartree−Fock and MB3LYPDFT (Density Functional Theory)[42] methods were used. The basis set used with both methods was 6-31G*. For the tin atom an ECP approximation[43−51] was applied, as implemented within MULLIKEN, using a double zeta basis. The MULLIKEN default convergence criteria were used in computations of energies and geometries.

Applications of the Laddering Principle — A Two-Stage Approach to Describe Lithium Heterocarboxylates

Andrew Downard[a] and Tristram Chivers*[a]

Dedicated to the memory of the late Dr. Ron Snaith[+]

Keywords: Lithium / Carboxylate ligands / Electrostatic interactions / Cluster compounds / Ladder polymers

Since the development of the laddering principle in the mid-1980s, it has become a useful concept for describing structural features in a wide variety of organoalkali metal (particularly organolithium) and other main-group element oligomers. Here a brief account of the laddering principle is given, and a two-stage approach to understanding structural diversity is described for several lithium heterocarboxylates. "Primary laddering" describes the initial aggregation of monomeric units, whereas "secondary laddering" deals with the assembly of these primary laddered units into larger structures. Both homo- and heteromolecular clusters can be formed by these processes. In this context, several examples are discussed, with particular emphasis on the effects of solvation and heteroatoms.

1. Introduction

Our group has been concerned for some time with novel cluster structures involving alkali metal cations and polyimido anions with a central p-block element.[1] The structures of these polycyclic systems can usually be rationalized after they are known, but the goal of accurately predicting cluster geometry remains elusive. Here we outline a two-stage approach to application of the laddering principle that has proven useful for describing a range of lithium heterocarboxylates with diverse architectures. The ideas of "primary" and "secondary" laddering are explored, and several recent examples are rationalized using this binary version of the principle as a guide. While the goal of developing a complete principle with predictive validity far exceeds the scope of this Microreview, we hope that some progress towards a better comprehension of laddered structures will be possible at its conclusion.

[+] Pioneer of the concept of laddering in organoalkali metal chemistry

1.1. The Laddering Principle

The concept of laddering first appeared in the mid-1980s in seminal papers by Snaith and co-workers describing the formation of imidolithium hexamers.[2] These prototypical

Tristram Chivers was born in Bath, England in 1940. He received his B. Sc. in chemistry from the University of Durham (U.K.) in 1961 and his Ph. D. from the same university in 1964 working with R. D. Chambers on pentafluorophenylboron chemistry. He carried out postdoctoral studies in organometallic electrochemistry with R. E. Dessy at the University of Cincinnati (1964−65) and on inorganic ring systems with N. L. Paddock at the University of British Columbia (1967−69). From 1965 to 1967 he was a Tutorial Fellow at the University of Sussex. He joined the University of Calgary in 1969 and was promoted to Professor in 1978. The focus of his research is the chemistry of the main group elements. He is a Fellow of the Royal society of Canada (1991). Recent awards include the Alcan (1987) and E. W. R. Steacie (2001) Awards of the Canadian Society for Chemistry and the Main Group Element Chemistry award of the Royal Society of Chemistry (1993).

Andrew Downard was born in Calgary, Canada in 1974. He graduated with first class honours in Chemistry (with a minor in Philosophy) from the University of Calgary, Canada, in 1996. He obtained his Ph. D. from the same university in 2000 under the supervision of Professor T. Chivers in the area of main group element chemistry. Dr. Downard is currently an NSERC (Canada) postdoctoral fellow at the Queen's University Ionic Liquids Laboratories, Belfast, N. Ireland in the group of Professor K. Seddon.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

compounds contained Li_6N_6 cores and were described as "stacked pairs of cyclic trimers" joined by Li−N bonds.[2a] The original laddering principle has been expanded and elucidated in the intervening years by the groups of Snaith and Mulvey, among many others. It is now known that laddering can give rise to many different cluster architectures depending on the steric and electronic environment of the centres involved, and on the presence/absence of coordinating solvent.

Laddering has been reviewed extensively,[3,4] and laddered aggregates are now well-known throughout main-group element chemistry. This is particularly true among organoalkali metal compounds, where a wide variety of clusters ranging from dimers to polymers has been found.[3] While the reasons for the occurrence of laddering as a structural motif are generally well understood, the method by which the principle of laddering should be applied, particularly in advance of structural characterization, is still a topic of ongoing investigation.

Here we will define laddering in the simplest case as the lateral association of E−M (E = group 15−17, M = group 1−2) units to form E_2M_2 rings. Such interactions are typically electrostatic in origin, occurring as a result of polarity within the E−M moiety, and can be considered as essentially ionic.[4] In addition to "open" ladders of various lengths, a variety of "closed" ladder clusters can also be constructed from the basic E_2M_2 dimeric unit (Figure 1). For many of these aggregates multiple descriptions apply; for example, an E_6M_6 hexamer might be called a closed six-rung ladder or a pair of stacked E_3M_3 rings. We will generally focus on the former view in order to stress the utility and consistency of the approach discussed here, although in some cases other descriptions may be more appropriate.

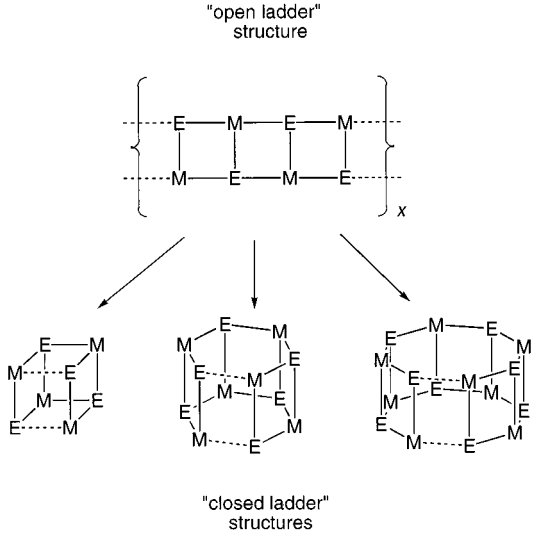

Figure 1. Open and closed E_xM_x ladder frameworks; the substituents on E have been omitted for clarity

1.2. Cisoid and Transoid Geometries

Laddered structures generally exhibit curvature, twisting, or other deviations from planarity in order to accommodate the steric demands of the substituents. The terminology to describe this effect in primary and secondary lithium amides was first introduced by Mulvey,[5] and focused on the relative orientation of substituents about the Li_2N_2 rings. We have adopted a natural extension of these terms, using *cisoid* and *transoid* to describe arrays of any three contiguous four-membered rings as well (Figure 2).[6]

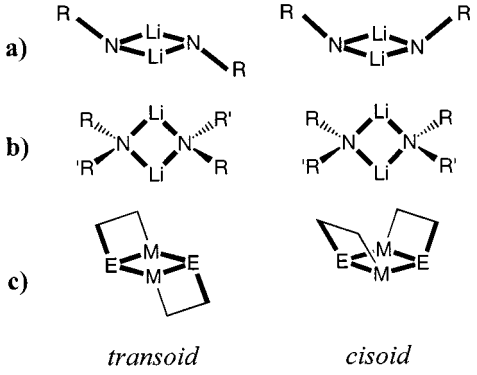

Figure 2. *Cisoid* and *transoid* orientations in: a) primary lithium amides; b) asymmetric, secondary lithium amides; c) arrays of three contiguous four-membered rings

Where laddering is limited to dimerization by bulky substituents and/or solvation, a *transoid* geometry is most often observed,[7] as would be expected on steric grounds. However, in ladders with three or more rungs there is often a preference for regions of *cisoid* geometry, either exclusively or intermixed with *transoid* regions.[5,6,8] Presumably this is because a *cisoid* geometry sometimes provides a greater separation of substituents that are two or more rungs apart than would the corresponding *transoid* arrangement. This distribution of ring conformations influences the overall topology of laddered aggregates as curving occurs to minimize van der Waals repulsions between the substituents. For example, in four-rung ladder segments, an exclusive *transoid* geometry produces a sterically crowded, repeating stair-shape, whereas an exclusive *cisoid* geometry produces a curvilinear shape (Figure 3). Since the ring conformation has a pronounced effect on the eventual outcome of laddering, any general principle describing such aggregation must take it into account.

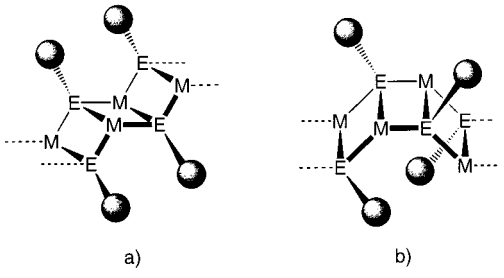

Figure 3. Alternative conformations in E_xM_x ladders with bulky substituents on E (represented by filled spheres): a) *transoid* region; b) *cisoid* region

1.3. Solvation Effects

Donor solvent molecules generally limit the oligomerization of laddered compounds in two ways: 1) by the forma-

tion of E−M bonds that are too sterically encumbered to undergo lateral association; 2) by maximizing the coordination number of the cations through solvent contacts. Solvents which are effective at limiting ladder length typically have one or more Lewis basic centres capable of forming dative bonds with cations such as lithium, sodium, magnesium, etc. Common examples include *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA), pentamethyldiethylenetriamine (PMDETA), and tetrahydrofuran (THF).

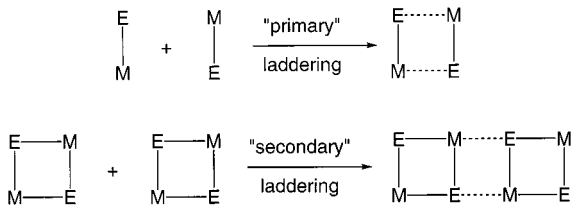
2. A Two-Stage Approach to Laddering

Snaith's original description of an imidolithium hexamer as two stacked trimers[2a] implied that the laddering principle should be somewhat hierarchical in nature. While it is true that any aggregate can be described as a collection of monomeric units, it is often more fruitful for laddered compounds to be described as being formed from slightly larger units that then associate in various ways to produce oligomers. For example, while an E_6M_6 hexamer can be thought of as six EM monomers, a more useful description might make reference to two E_3M_3 trimers associated by ring stacking, or three E_2M_2 dimers associated by laddering. In this way multiple distinct, but related, aggregation pathways may be invoked to explain the architecture of any given structure.

The purpose of this Microreview is to outline our method of describing lithium heterocarboxylates by using a two-stage approach to the laddering principle, and to show how this can be applied to other, similar, systems within the rubric of organolithium chemistry. Our methodology for rationalizing structures focuses on the use of small building blocks to construct large aggregates. As such, we have found it useful to formally separate the process of laddering into "primary" and "secondary" components as follows (Scheme 1):

Primary laddering describes the lateral association of monomeric EM fragments to produce a primary laddering unit (PLU). Such units are often homomolecular dimers, but other types of oligomers are also possible.

Secondary laddering describes the association of PLUs to form clusters. When secondary laddering does occur, the structure of the compound as a whole can often be rationalized by understanding the behaviour of PLUs as they aggregate.



Scheme 1. Homomolecular primary and secondary laddering of E_xM_x; the substituents on E have been omitted for clarity

The hierarchical nomenclature of these principles is intentional; primary laddering processes must occur before secondary, and secondary laddering cannot occur in the absence of primary. Thus, when examining a laddered system the pertinent questions to ask are:

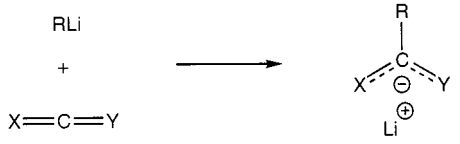
1) Will primary laddering occur?
2) If so, what is the resultant PLU?
3) Will secondary laddering of PLUs occur?
4) If so, what is the resultant structure?

We have found that by answering the four questions above a good conceptual understanding of laddered lithium heterocarboxylate structures can be gained, and we believe that this approach may be applicable to a wider variety of systems. In the cases discussed here the most common PLU is a dimer, as illustrated in Scheme 1. We note, however, that this need not be the case — primary laddering can, in theory, generate trimers, tetramers, etc., as well as dimers, and secondary laddering can occur with any combination of these PLUs. Thus, while the dimer will be given special attention in this account, it is not true that the dimers are the only PLUs of interest.

The idea of primary and secondary units of aggregation is well-established in other areas, most prominently supramolecular chemistry.[9] Indeed, although they are not typically discussed as such, many laddered compounds can be considered as supramolecules.[3a,10] In addition, Snaith's description of a hexamer as two stacked trimers[2a] is one of many examples where a two-stage approach to laddering is used without invoking the terminology suggested here. Thus, the novelty and value of this approach lies not in the concepts of primary and secondary aggregation themselves, but rather in developing an understanding of how this two-stage framework can be *systematically* and *consistently* applied in the specific context of laddering.

3. Two-Stage Laddering in Lithium Heterocarboxylates

Carboxylate anions $[RCO_2]^-$ are ubiquitous ligands, as are a number of other related "heterocarboxylates" $[RCXY]^-$ (X, Y = main group centre, e.g. xanthates $[(RO)CS_2]^-$, thiocarbamates $[(R_2N)COS]^-$, dithiocarboxylates $[RCS_2]^-$, etc.). Such systems can be understood as monomeric units in which a single unit of negative charge is delocalized throughout an XCY unit. While lithium heterocarboxylates are well-known as sources of anionic ligands in metathetical syntheses, we have investigated several lithium amidinates, oxoamidates, and thioamidates as probes to explore a two-stage approach to the laddering principle. Convenient access to these compounds is provided by the reaction between nucleophiles and heteroallenes [X=C=Y] (1). Use of this route to synthesize carboxylic acids from CO_2 is well-known.[11]



(1)

X = Y = O, carbon dioxide → carboxylate
X = Y = NR', carbodiimide → amidinate
X = NR', Y = O, isocyanate → oxoamidate
X = NR', Y = S, isothiocyanate → thioamidate

3.1. Secondary Laddering of Dimeric Primary Laddered Units

The lithium oxoamidate and thioamidate hexamers $[Li\{(nBu)CE(NtBu)\}]_6$ (**1**: E = O; **2**: E = S)[12,13] provide illustrative examples of secondary laddering employing dimeric PLUs. However, even though both structures clearly involve laddering, comparing the hexameric cores of **1** and **2** (Figure 4) highlights an interesting contrast: the two Li_6E_6 hubs are quite similar even though the ligand orientations are strikingly different.

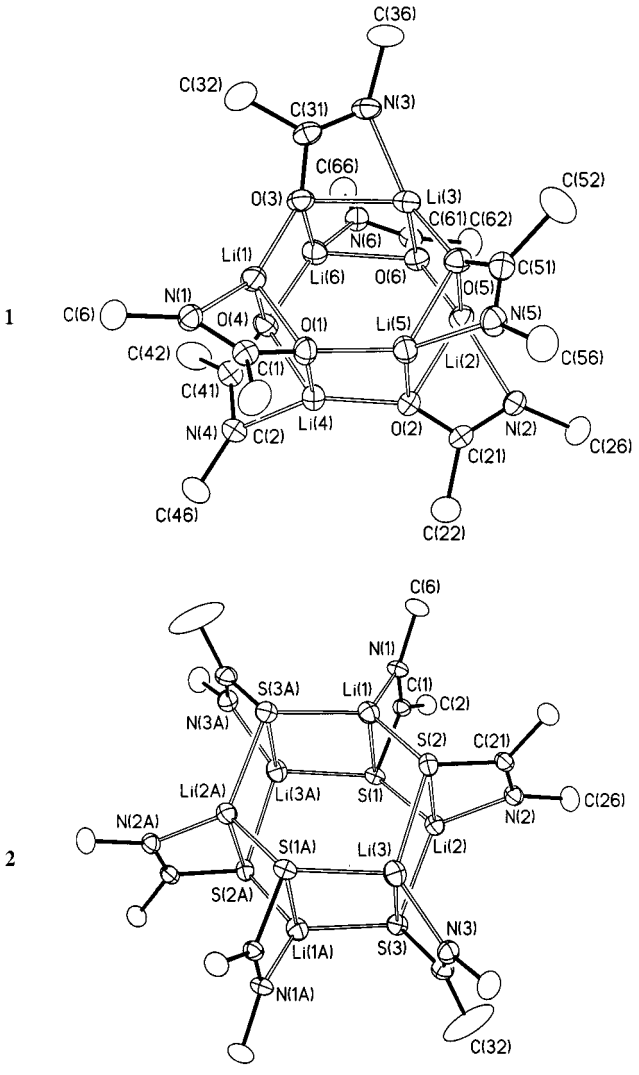


Figure 4. The cores of $[Li\{(nBu)CE(NtBu)\}]_6$ (**1**: E = O; **2**: E = S)

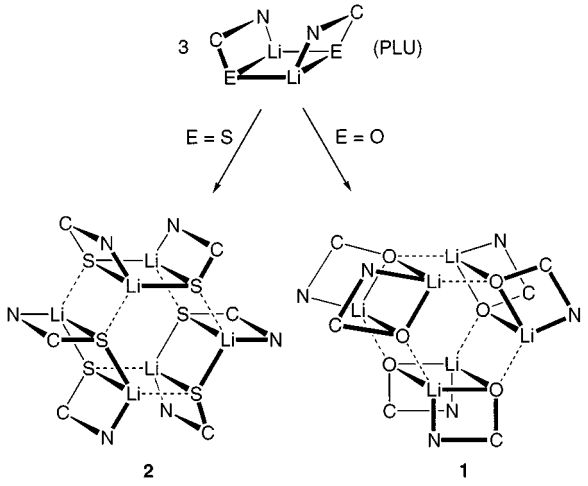
This phenomenon can be explained by using a two-stage approach to the laddering principle. The formation of both hexamers can be visualized as a secondary laddering (trimerization) of *cisoid*, dimeric PLUs (Scheme 2). In the case of **1**, secondary laddering occurs such that the transannular bonds of the PLU form the Li_3O_3 rings in the hexamer. In **2**, however, the transannular bonds of the PLU become the links between the two Li_3S_3 hexagonal rings of the hexameric unit. Thus, whereas **1** adopts a D_3-symmetric, trilobate conformation in the solid-state, **2** is observed to assume a D_{3d}-symmetric, paddle-wheel like shape.



Scheme 2. Secondary laddering (trimerization) of dimeric, *cisoid* PLUs producing **1** and **2**; the dashed lines indicate bonds being formed

We attribute the difference in conformations for **1** and **2** to a heteroatom-related secondary laddering effect. The shorter Li−O (compared to Li−S) distances result in steric constraints that prevent **1** from adopting the paddle-wheel conformation, which otherwise would be preferred.[12] Some credence is lent to the notion of secondary laddering of dimeric PLUs as a mechanism of assembly for **1** and **2** by the fact that **1** adopts a conformation in which the lobes of the Li_3O_3 rings are eclipsed rather than staggered. While a staggered conformation (Figure 5) would certainly be less sterically hindered, this is not the conformation actually adopted by the hexamer. We speculate that this is because it is not accessible as an aggregate of dimers, and hence cannot be generated by the primary and secondary laddering of such dimers.

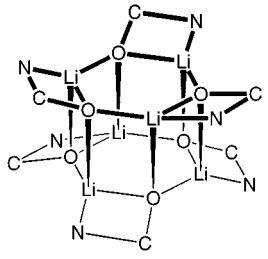


Figure 5. A possible, but unobserved, conformation for the core of $[Li\{(nBu)CO(NtBu)\}]_6$ (**1**)

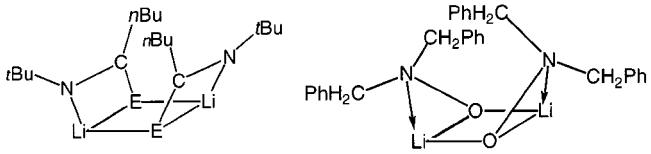
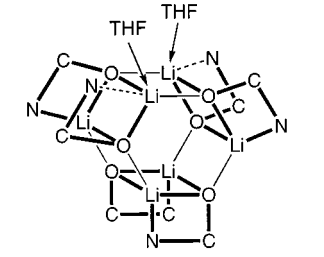
A different scenario is encountered in the case of the hexameric lithiated hydroxylamine $[Li\{ON(CHPh)_2\}]_6$.[14] The situation here is somewhat similar to the ones discussed above: each lithium cation is chelated by both oxygen and nitrogen, yielding three membered [NOLi] rings. However, in the case of oxoamidates and thioamidates, the geometry at nitrogen is three-coordinate and planar (**A**), while in the lithiated hydroxylamine it is four-coordinate and pyramidal (**B**). This prevents the formation of the *cisoid* dimer **B** on steric grounds.

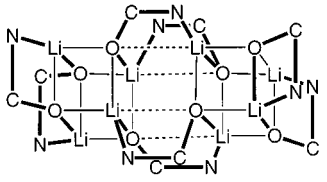


A **B**

Interestingly, the architecture adopted by $[Li\{ON(CHPh)_2\}]_6$ is a Li_6O_6 hexagonal prism with staggered $N(CHPh)_2$ lobes. This arrangement probably arises due to the stacking of trimeric rings, thus it is unsurprising that the less sterically demanding staggered conformation is preferred[14] over the eclipsed conformation of **2**. We note that this observation lends support to our hypothesis that **2** forms by the secondary laddering of dimers, since ring stacking should evidently prefer the conformation depicted in Figure 5. We note also that both the solvated and unsolvated forms of the lithium oxoamidate $[Li\{(C_6H_5)CO(NiPr)\}]_x{\cdot}n$THF (**3a**: $x = 6$, $n = 2$; **3b**: $x = 8$, $n = 0$)[15] can be generated from *cisoid*, dimeric PLUs in a manner similar to that described for **1** and **2** (Figure 6).



3a

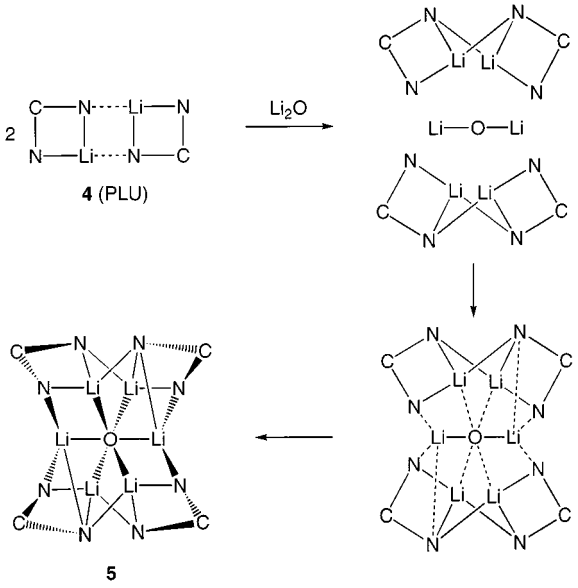


3b

Figure 6. The cores of $[Li\{(C_6H_5)CO(NiPr)\}]_x{\cdot}n$THF (**3a**: $x = 6$, $n = 2$; **3b**: $x = 8$, $n = 0$) viewed as secondary laddered aggregates of dimeric PLUs

3.2. Heteromolecular Primary and Secondary Laddering

In cases where steric constraints are preclusive, dimeric homomolecular PLUs like those discussed above may be unable to associate further. Thus, while lithium oxo- and thioamidates will readily form dimeric PLUs which then undergo secondary laddering, the same is not true of the lithium amidinate $Li[(nBu)C(NtBu)_2]$ (**4**). In this case, other, less hindered laddering units must be employed to promote secondary laddering. For example, the aggregation of **4** with Li_2O in a non-coordinating solvent yields the cluster $[Li\{(nBu)C(NtBu)_2\}]_4{\cdot}Li_2O$ (**5**).[16] In **5**, two $Li[(nBu)C(NtBu)_2]$ monomers associate laterally to give a homomolecular, dimeric PLU. Unlike **1** and **2**, the secondary laddering of these PLUs cannot occur due to steric hindrance. However, in the presence of an unhindered, incipient Li_2O fragment, heteromolecular secondary laddering involving three fragments takes place to give the aggregate **5** (Scheme 3).



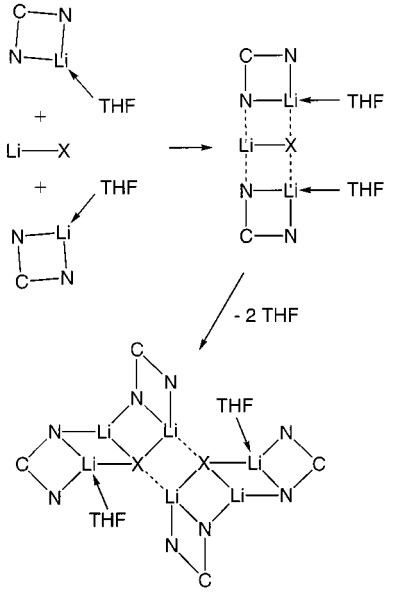
4 (PLU)

5

Scheme 3. Formation of $[Li\{(nBu)C(NtBu)_2\}]_4{\cdot}Li_2O$ (**5**) by primary and heteromolecular secondary laddering; the dashed lines indicate bonds being formed

The addition of a coordinating solvent to **4** effectively appends a substituent at lithium and causes even greater steric congestion around the monomeric unit. This apparently prevents homomolecular primary laddering. However, the presence of an unhindered fragment suitable for the promotion of primary laddering can alleviate this circumstance. Thus, the addition of LiX (X = OH, Cl, Br) to a solution of **4** in THF generates the laddered complexes $[(Li\{(nBu)C(NtBu)_2\})_2{\cdot}LiX{\cdot}THF]_2$ (**6a**, X = OH; **6b**, X = Cl; **6c**, X = Br),[6] which arise *via* heteromolecular laddering (Scheme 4). Here two $Li[(nBu)C(NtBu)_2]{\cdot}THF$ monomers and one LiX fragment associate to produce a heteromolecular PLU, which then undergoes secondary laddering (dimerization) with concomitant loss of solvent.

The topologies of **6a**−**c** are clearly a consequence of the conformation adopted by the PLUs involved. Each three-rung ladder is composed of contiguous *cisoid* and *transoid* units, an arrangement which minimizes the steric congestion and imparts a gentle undulation to the structure as a



Scheme 4. Formation of $[(Li\{(nBu)C(NtBu)_2\})_2{\cdot}LiX{\cdot}THF]_2$ (**6a**, X = OH; **6b**, X = Cl; **6c**, X = Br) by heteromolecular primary and secondary laddering; the dashed lines indicate bonds being formed

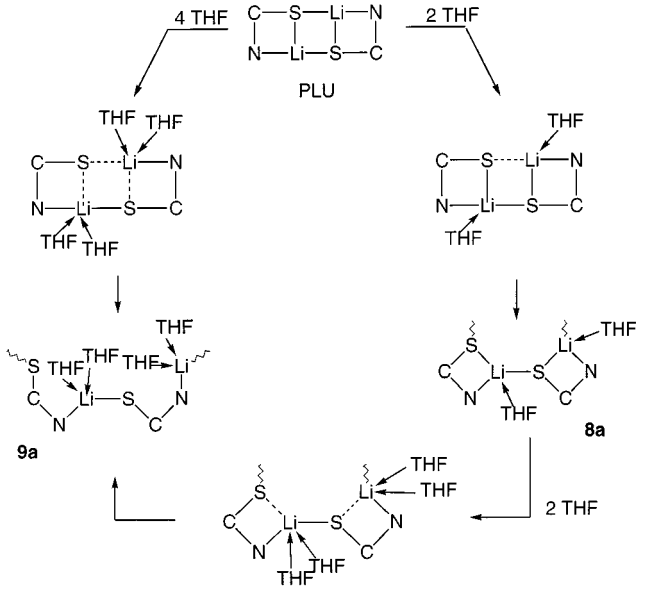
whole. Secondary laddering occurs through a *transoid* $[LiX]_2$ ring. We note that this secondary laddering process does not occur when the added fragment is LiI; in that case the heteromolecular PLU $[(Li\{(nBu)C(NtBu)_2\})_2{\cdot}LiI{\cdot}2THF]$ (**7**) forms and does not associate further, probably due to the relative weakness of Li−I bonds compared to the other lithium halides.[6] Thus, solvation is preferable as a mechanism to disperse charge in this case, and no secondary laddering occurs. We note also that **7** has the same basic topology as the PLUs proposed for **6a**−**c**.

3.3. Unladdered Structures from Primary Laddered Units

The previous examples demonstrated that various PLUs can associate through secondary laddering to produce a range of molecular architectures. However, other aggregation pathways are also possible, some of which lead to unladdered, extended arrays. While it is not immediately clear that such structures should fall in the same category as their laddered counterparts, it would certainly be useful if the laddering principle could explain not only situations where laddering *does* occur, but also situations where laddering could reasonably be expected to occur but *does not*.

For lithium thioamidates at least, this is the case: use of a two-stage approach to laddering is sufficient to explain the formation of unladdered, solvated polymers in addition to the laddered structures discussed above. Originally we reasoned that replacing the bulky butyl groups in **2** by methyl groups might afford alternative secondary laddering routes resulting in higher laddered oligomers. Accordingly, the lithium thioamidates Li[MeCS(NR)] (**8**: R = *t*Bu; **9**: R = Me) were prepared. However, the crystallographic characterization of these species revealed the unladdered, solvated polymers $[Li\{MeCS(NtBu)\}{\cdot}THF]_\infty$ (**8a**) and $[Li\{MeCS(NMe)\}{\cdot}2THF]_\infty$ (**9a**).[13]

Although the connection between structures **8a** and **9a** and the laddering principle is not obvious, both polymeric forms can in fact be derived from a common dimeric PLU, which is then broken down upon solvation by THF (Scheme 5). Significantly, the putative PLUs for **8a** and **9a** are analogous to the one which undergoes secondary laddering (trimerization) to form **2**. The degradation of laddered structures upon solvation is a well-documented phenomenon in the literature, although it is usually used to explain the disassembly of higher states of oligomerization to lower oligomers.[17] Here the opposite occurs, with solvation producing polymers by opening the Li_2S_2 and LiNCS rings of laddered dimers.



Scheme 5. Generation of $[Li\{MeCS(NR)\}{\cdot}xTHF]_\infty$ (**8a**: R = *t*Bu, *x* = 1; **9a**: R = Me, *x* = 2) from a common dimeric PLU; the dashed lines indicate bonds being broken

The polymer **8a** is produced by the solvation of both lithium centres in the dimeric PLU, leading to the rupture of one Li−S bond. The orientation adopted by **9a** is generated either from further solvation, leading to disruption of the exocyclic Li−S bonds, or directly from the dimeric PLU upon solvation of each lithium ion by two THF molecules; thus the three disparate structures **2**, **8a**, and **9a** all stem from the same primary unit. While other descriptions are certainly possible for each structure viewed independently, the use of a two-stage approach to the laddering principle affords a consistent rationale for all three structures despite their substantial differences.

The fact that **2** remains unsolvated in the solid state, even when recrystallized from THF, is of significance. We suggest that this occurs because the steric bulk of the substituents in **2** prevents solvent molecules from entering the coordination sphere of the PLU. This allows an unsolvated, oligomeric structure to form through secondary laddering. In **8a** and **9a**, smaller substituents allow solvation of the PLU; solva-

tion effectively competes with secondary laddering as a mechanism to disperse electronic charge and solvated, unladdered polymers result.

3.4. Other Examples

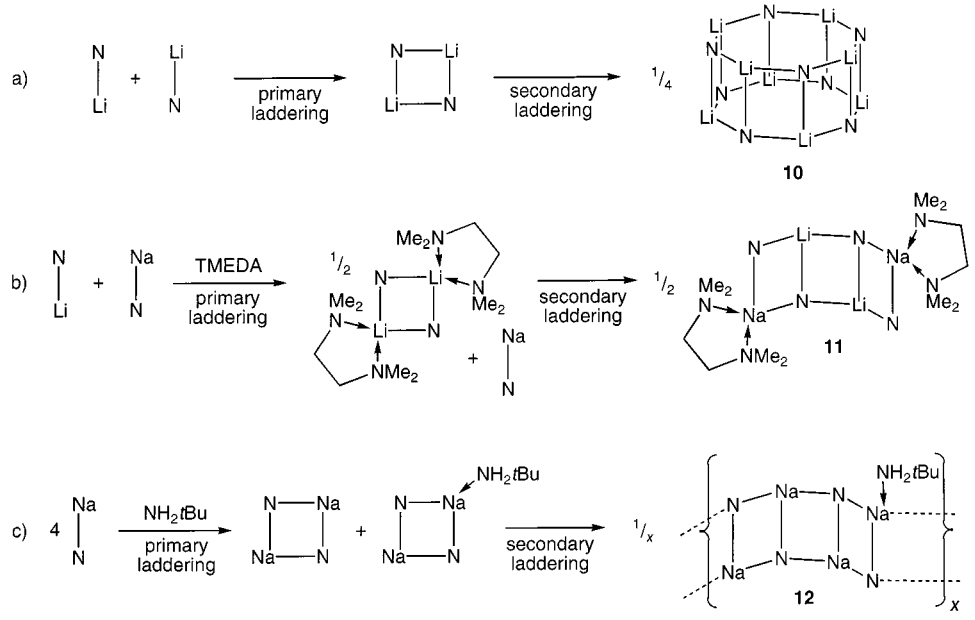
A two-step approach to laddering is also useful for understanding systems other than lithium heterocarboxylates. For example, the lithium arenethiolate $[\{Li[SC_6H_4\{(R)\text{-}CH(Me)NMe_2\}\text{-}2]\}]_6$ forms a hexamer[18] composed of three dimeric PLUs assembled in much the same manner as **2**. Likewise the laddered polymer $[PhCH_2SLi{\cdot}NC_6H_5]_\infty$ can be viewed as resulting from the secondary association of monosolvated dimers.[19]

An illustrative series of examples from alkali metal amide chemistry is provided by the lithium,[20] sodium,[5] and heterobimetallic lithium/sodium[5] derivatives of *tert*-butyl amide,[3e] all of which can be rationalized through primary and secondary laddering processes (Scheme 6). The unsolvated octamer $[Li(HNtBu)]_8$ (**10**) can be viewed as a secondary aggregate of dimeric, *cisoid*, homomolecular PLUs forming a closed ladder. Primary laddering in the mixed system $[LiNa(HNtBu)_2{\cdot}TMEDA]_2$ (**11**) probably forms a solvated, dimeric $[Li_2N_2]$ PLU initially, which then loses solvent upon secondary laddering with Na−N units. The final aggregate is thus centred around a *cisoid* $[Li_2N_2]$ ring, and further laddering is prevented by solvation of the outer Na−N rungs. In contrast, the solvated polymer $[\{Na(HNtBu)\}_3{\cdot}NH_2tBu]_\infty$ (**12**) arises from the unhindered secondary laddering of solvated and unsolvated dimeric PLUs. As in **10** the PLUs are all *cisoid*, but secondary laddering in **12** involving the solvated Na−N unit produces a *transoid* $[NaN]_2$ ring, probably due to the "steric intrusion"[5] of the solvent molecule.

Clearly, alternative descriptions are possible for each of the systems discussed here. For example, **10** could be viewed as an arrangement of eight monomers or two stacked tetramers rather than four laddered dimers. However, as was the case for the lithium heterocarboxylate structures discussed earlier, a two-stage approach to the laddering principle allows a diverse range of architectures to be understood using a single conceptual framework. While we feel that this is an important point in favour of using the two-stage approach consistently, we note that is not sufficient for every case, such as, for example, structures arising from the stacking of M_nE_n ($n > 2$) rings[14] as well as odd-numbered and/or asymmetric oligomers.[17g] Such cases are in the minority, however, and can generally be handled by using a similar two-stage approach wherein building blocks may be unladdered and further aggregation steps (tertiary, etc.) may need to be invoked. We have seen this in our own work, for example the lithium diazasulfite hexamers $[Li_2\{SO(NtBu)(NR)\}]_6$ (R = *t*Bu, $SiMe_3$), derived from the aggregation of three hexagonal prisms through Li_2O_2 faces (R = *t*Bu), or the dimerization of eighteen-atom cages through Li_3O_3 faces (R = $SiMe_3$).[21]

4. Polymeric Laddered Compounds

It has been accepted for some time that organolithium species that precipitate as insoluble, amorphous solids (i.e. do not crystallize easily) are probably laddered polymers. While confirmation of this hypothesis has long been anticipated for lithium amides in particular, few "unsolvated," polymeric ladder structures have been characterized to date, and in each of these cases some form of internal solvation is present. For example, 2,3,4,5-tetramethyl-1-sodiopyrrole[22]



Scheme 6. Primary and secondary laddering processes leading to: a) $[Li\{HNtBu\}]_8$ (**10**); b) $[LiNa(HNtBu)_2{\cdot}TMEDA]_2$ (**11**); c) $[\{Na(HNtBu)\}_3{\cdot}NH_2tBu]_\infty$ (**12**)

and phenyllithium[23] both form ladder polymers wherein the lithium cations are coordinated by the aromatic substituents on neighbouring rungs. Likewise, monolithiated ethylenediamine $[Li\{HN(CH_2)_2NH_2\}]_\infty$ [8] consists of an infinite ladder wherein each lithium cation is chelated by both the amide and amine ends of the molecule. In fact, although a few truly unsolvated, laddered lithium amides are now known,[17b,20] none have proven to be polymeric. Conversely, although some alkali metal amide polymers have been characterized (notably $[LiN(i\text{Pr})_2]_\infty$ [24]), none have been found that are both laddered and unsolvated.

A recent survey[10] tallied only two examples of unsolvated organolithium polymers involving any laddered portions, $[LiOPh]_\infty$ [25] and $[LiC(OEt)=CH_2)]_\infty$,[26] among several solvated examples and several unsolvated, finite ladders. This demonstrates two important points: 1) that solvation does not preclude polymerization, and may even encourage it in some cases (e.g. **8a** and **9a**); and 2) that unsolvated laddered compounds, whether polymeric or not, can indeed be crystallized (i.e. they are not necessarily amorphous solids). With these observations in mind, we note that the two-stage framework presented here leaves room, and provides rationale, for a number of alternative architectures; it does not point exclusively to laddered polymers for any particular class of compounds. Given the wide diversity of laddered structures now known, we feel that this is a point in favour of this approach.

5. Conclusions and Outlook

We have tried to show briefly how a two-stage approach to the laddering principle provides a useful framework for describing and understanding laddered structures, particularly among lithium heterocarboxylates. We note also an initially unanticipated feature of this approach: it can explain unladdered systems topologically related to laddered ones. Thus, as with the lithium thioamidates **2**, **8**, and **9**, widely disparate structures can be understood in terms of a single conceptual process. Furthermore, we have shown that the nature of secondary laddered structures is strongly dependent on the behaviour of PLUs with regard to steric effects, solvation, etc. This is true for both homo- and heteromolecular aggregation. While these influences on laddering processes have been noted previously,[3] the two-stage approach discussed here affords a consistent and systematic method of gauging their effect on structure.

Finally, we anticipate that the continued development of the laddering principle may have implications outside the realm of main-group element chemistry. Recently we have seen that a process much like primary and secondary laddering (involving dimeric PLUs) can be used to explain the formation of copper(I) thioamidate oligomers.[27] Although not strictly within the rubric of laddering as defined here, the behaviour of these derivatives can evidently be understood in a similar manner. A complete investigation of this phenomenon is currently underway, and may prove germane to developing a more generally applicable laddering principle.

Cobalt(III) Complexes with Carboxamido-*N* and Sulfenato-*S* or Sulfinato-*S* Ligands Suggest that a Coordinated Sulfenate-*S* is Essential for the Catalytic Activity of Nitrile Hydratases

Laurent Heinrich,[a] Aude Mary-Verla,[a] Yun Li,[a] Jacqueline Vaissermann,[b] and Jean-Claude Chottard*[a]

Keywords: Cobalt / Nitrile hydratase / Enzyme mimics / S ligands / Catalysis

A bis(sulfenato-*S*)Co^{III} complex and its corresponding bis(sulfinato-*S*) complex were prepared. Their catalytic nitrile hydration activity was tested. Whereas the former catalyzes the hydration of CH_3CN under mild acidic conditions, the latter is inactive. A mechanism for this reaction is proposed, in relation with nitrile hydratase activity.

Introduction

Nitrile hydratases (NHases) are non-heme iron or non-corrinoid cobalt-containing enzymes that catalyze the hydration of nitriles to amides.[1] NHases are used for the industrial production of acrylamide[2] and for the removal of nitriles from waste streams.[3] Both active and inactive forms of the iron NHases have recently been characterized by X-ray diffraction and ENDOR (Electron Nuclear Double Resonance) spectroscopy. The coordination sphere of the metal centre is very unusual. For the active form of the NHase from *Rhodococcus* sp.R312, the structure at 2.65 Å resolution showed that iron is bound to three cysteinthiolates, two amido nitrogen atoms from peptide bonds of the protein main chain,[4] and an axial hydroxide or water molecule as the sixth ligand.[5] For the inactive form of the NHase from *Rhodococcus* sp.N-771, the structure at 1.7 Å resolution revealed that two of the coordinated sulfur atoms belong to sulfenic (Cys-SOH) and sulfinic (Cys-SO_2H) moieties, and one nitric oxide ligand occupies the sixth position.[6] The cysteine-sulfinate and cysteine-sulfenate ligands are assigned to the post-translational modification of former cysteines. The iron and cobalt NHases have similar metal sites, according to EXAFS data.[7] A very recent study of a Co-substituted Fe-NHase showed that the catalytic activity is correlated to the post-translational oxidation of a cysteine.[8] This oxidation of one cysteine into cysteine-sulfinate has been established by mass spectrometry, but this does not exclude the existence of a former relatively unstable cysteine-sulfenate at the enzyme active site.

All these data did not suggest a role for the sulfenato-*S* and/or sulfinato-*S* ligands in NHase catalysis. The study of relevant mimetic complexes, however, should yield clues to this question. Several mimetic Fe^{III} and Co^{III} model compounds of NHases have recently been synthesized.[9–12] Some of them have been oxidized by H_2O_2 to give the sulfinato-*S* species[10a][11a][11d] and one gave an inert η^2-sulfenato, sulfinato-*S* derivative.[12b] Only one cobalt mimetic complex has been reported to have nitrile hydratase activity.[11b] The structure of this presumably hydroxo complex $[Co(PyPS)(OH)]^{2-}$ is not known (although it is assumed to contain one pyridine, two carboxamido-*N* and one thiolato ligands in a plane, and the second thiolate in an axial position). It allowed conversion of acetonitrile into acetamide at 50 °C and pH = 9.5 (18 turnovers). This reaction probably involves the nucleophilic property of the hydroxide ligand.

We have reported the first example of the oxidation of a carboxamido-*N*, thiolato-Fe^{III} complex $[FeN_2S_3]^{2-}$ by dioxygen to give a sulfinato-*O* species $[FeN_2S_2OSO]^{2-}$ raising the question of *S*- vs. *O*-coordination to the metal.[9c] To investigate which factors could control the eventual oxidation of the bound in-plane thiolates in Co-NHases, we have synthesized a tetradentate eleven-atom ligand $H_4N_2S_2$, containing two aliphatic thiols and two aliphatic amides **1** (H_4L).[13] The derived square-planar complex $[Co^{III}L]^-$ (**2**) was characterized by X-ray diffraction.[9b] Cyanides and isocyanides were the only ligands found able to give hexacoordinated complexes upon bis-axial coordination, as shown by spectroscopic data together with an EXAFS study.[9b] Such a coordination allows oxygenation of the in-plane thiolates to take place by air or hydrogen peroxide. We have thus reported the preparation of the disulfenato compound $Na[Co(L\text{-}N_2SOSO)(t\text{BuNC})_2]$ (**3**).[9a] We now report the preparation of the corresponding disulfinato derivative $(Me_4N)[Co(L\text{-}N_2SO_2SO_2)(t\text{BuNC})_2]$ (**4**). Whereas **3** exhibits nitrile hydration catalytic activity, **4** is inactive.

Results and Discussion

The addition of 50% aq. H_2O_2 to a solution of the square-planar complex $[Co^{III}L]^-$ (**2**)[9b] in EtOH, in the

presence of excess *t*BuNC and one equivalent of Me_4NCl, gave the yellow disulfinato complex $(Me_4N)[Co(L\text{-}N_2SO_2\text{-}SO_2)(t\text{BuNC})_2]$ (**4**) (Scheme 1). Single crystals of **4** suitable for X-ray analysis were formed by slow diffusion of Et_2O into an EtOH solution in the presence of a small amount of H_2O. The X-ray structure of **4** is shown in Figure 1.

CAMERON representation (ellipsoid at 30% probability level) of **4**; H atoms are omitted for clarity; selected bond lengths (Å) and angles (°): Co(1)−S(1) 2.2114(9), Co(1)−S(2) 2.2255(9), Co(1)−N(1) 1.962(3), Co(1)−N(2) 1.954(3), Co(1)−C(14) 1.877(3), Co(1)−C(19) 1.867(3), C(14)−N(4) 1.149(4), C(19)−N(4) 1.143(4), S(1)−O(11) 1.449(3), S(1)−O(12) 1.470(3), S(2)−O(21) 1.452(3), S(2)−O(22) 1.472(3); S(1)−Co(1)−S(2) 95.56(4), S(1)−Co(1)−N(1) 86.87(8), N(1)−Co(1)−N(2) 90.9(1), S(1)−Co(1)−N(1) 86.87(8), S(2)−Co(1)−N(2) 86.65(8), C(14)−Co(1)−C(19) 174.7(1), Co(1)−C(19)−N(4) 175.0(3), Co(1)−C(14)−N(3) 176.5(3), C(14)−N(3)−C(15) 166.5(3), C(19)−N(4)−C(20) 173.6(3)

Compound **4** is a distorted octahedral Co^{III} complex with an N_2S_2 equatorial plane containing carboxamido-*N* and sulfinato-*S* ligands and two axial isocyanido ligands. Water molecules help to stabilize the crystal lattice through hydrogen bonding to the oxygen atoms of the sulfinato-*S* and carboxamido-*N* ligands. The presence of one Me_4N^+ cation per cobalt in the unit cell of **4** confirms the oxidation state as cobalt(III). The Co−N bond lengths are similar to those reported for carboxamido-*N* ligands in hexacoordinated Co^{III} complexes,[11] but are 0.08 Å longer than those found in the parent square-planar complex **2**.[9b] The Co−S bond lengths (2.22 Å) are similar to those reported for structurally characterized Co^{III}-sulfinato complexes.[10a,11a,11d] The Co−*C*-isocyanido bonds are 0.04 Å longer than the only reported values (1.83−1.79 Å) for Co^{III}−*C*-isocyanido cyclopentadienyl compounds.[14] The isocyanides are almost linearly coordinated to the metal, with a Co−C−N angle of 176°, a C−N−C angle of 173° and a C−N bond length of 1.14 Å, which confirms a C≡N triple bond. The IR spectrum (KBr pellet) of **4** shows the characteristic coordinated carboxamido-*N* ν_{CO} frequency at 1565 cm^{-1} and strong absorptions at 1195, 1065 cm^{-1} corresponding to the ν_{SO} stretching vibrations of coordinated *S*-sulfinates.[9b] The strong asymmetric ν_{CN} stretching frequencies of the isocyanides are increased from 2140 cm^{-1} to 2215 cm^{-1} upon coordination, indicating a higher bond order in **4** than in the free ligand, fitting the C≡N triple bond description and a prevailing σ-donor character of the isocyanide ligands rather than a potential π-acceptor contribution.

It is noteworthy that the overall geometries of $[Co(L\text{-}N_2SOSO)(t\text{BuNC})_2]^-$ (**3**) and $[Co(L\text{-}N_2SO_2SO_2)(t\text{BuNC})_2]^-$ (**4**) are very similar. The two complexes have comparable Co−N and Co−S bond lengths, but the Co−C bonds are longer in **4** than in **3** suggesting that the sulfinato (SO_2) group is a stronger-field ligand than the sulfenato (SO) group.

Yellow solutions of **4** in polar solvents (alcohols, DMSO, DMF, H_2O) are stable in air and the complex behaves as a hexacoordinated species with a diamagnetic low spin Co^{III} (Evans method). The electrospray mass spectrum exhibits a peak at m/z = 591 ($[Co(L\text{-}N_2SO_2SO_2)(t\text{BuNC})_2]^-$). The structural and spectral characteristics of **4** are similar to those of a Co^{III}-sulfinato complex reported very recently.[10a]

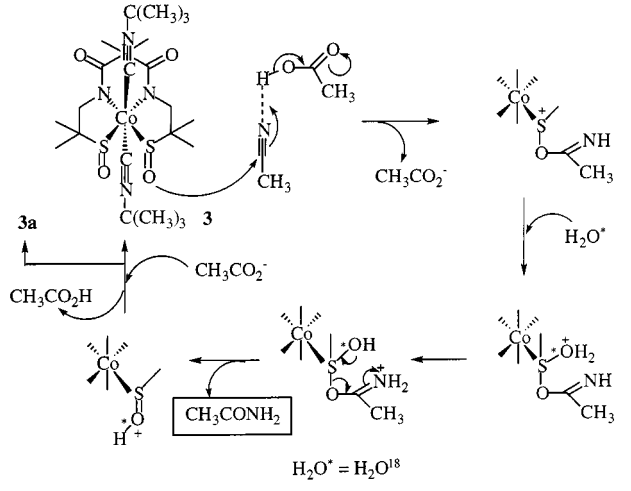
The testing of the hydration catalytic activity of compounds **3** and **4** was conducted in a mixture of CH_3CN/H_2O under various conditions of temperature and pH. The reaction is slow and could be followed by ^1H NMR spectroscopy using 1,3,5-trimethoxybenzene as internal reference for turnover number determination. Only **3** led to the formation of acetamide; no trace could be detected with **4**. Under alkaline conditions (aq. $NaHCO_3$, pH = 9), no conversion of CH_3CN was observed. At pH = 7 and 20 °C, acetamide was formed (2 turnovers) and **3** remained unchanged (^1H NMR spectroscopy) after 24 h. Varying the temperature did not improve the turnover number. Acidic pH = 4.8 (1 M HOAc/NaOAc buffer) at 4 °C gave the best

result (50 turnovers). Other acidic conditions (0.5 M HOAc/NaOAc buffer, pH = 4.8; 0.4 M HOAc; 0.03 M HCl; or 0.5 M H_3PO_4/KH_2PO_4 buffer, pH = 2.1) gave a less efficient reaction.

Although **3** gives a slow reaction under the conditions studied, the hydration mechanism deserves interest. At variance with the known[11b] complex $[Co(PyPS)(OH)]^{2-}$, which promotes the conversion of acetonitrile into acetamide (18 turnovers) only at 50 °C and pH = 9.5 (Tris buffer), probably through a Co^{III}-bound hydroxide ligand, **3** does not catalyze nitrile hydration in basic conditions (pH = 9). The reaction works better in mildly acidic conditions, although **3** undergoes a slow decomposition under these conditions, probably due to the protonation of the carboxamido-*N* ligands. Compound **3** has no free coordination site to allow either water or acetonitrile binding to Co^{III} and our results suggest that a general acid catalysis could be required for nitrile hydration catalyzed by **3**. The absence of catalytic activity of **4** points to a possible role of the nucleophilicity of the coordinated *S*-sulfenates in **3**. The oxygen atom of S-bound sulfenates has been shown to exhibit nucleophilic properties.[15]

When 30% $H_2{}^{18}O/H_2{}^{16}O$ was used for the hydration of acetonitrile in a 1 M HOAc/NaOAc buffer (pH = 4.8) at 4 °C for 17 h, complex **3** gave the complexes $[Co(L\text{-}N_2S^{18}OS^{16}O)(t\text{BuNC})_2]^-$ (**3a**) and $[Co(L\text{-}N_2S^{18}OS^{18}O)(t\text{BuNC})_2]^-$ (**3b**) characterized by electrospray mass spectrometry (*m*/*z* = 561, 563 respectively). This indicates that an exchange of oxygen atom occurs at the coordinated sulfenates during the hydration catalysis. That this exchange occurs during the actual hydration catalysis is demonstrated by the absence of any ^{18}O incorporation into **3** when acetonitrile is absent in exactly the same conditions.

Our observations, together with the known nucleophilic properties of coordinated *S*-sulfenates,[15] lead us to propose a tentative mechanism for the formation of complexes **3a** and **3b** during the hydration of CH_3CN catalyzed by **3** (Scheme 2). Complex **3** displays nucleophilic catalysis, assisted by general acid catalysis by the HOAc/NaOAc buffer.



Scheme 2. Tentative mechanism for the hydration of CH_3CN catalyzed by **3**

Conclusion

This study has shown the importance of coordinated sulfenates (SO) for nitrile hydration catalysis by a carboxamido-*N* Co^{III} complex. The corresponding sulfinato (SO_2) derivative is inactive under the same conditions. Our results suggest that in the case of Fe or Co NHases, the post-translational oxidation of metal-bound cysteines into sulfenic moieties, is a crucial step for nitrile hydration. Although the hydration reaction catalyzed by **3** appears to be of low efficiency due to its intermolecular character, this situation could be overcome by a proximity reaction within the enzyme active site. The conjunction of nucleophilic and general acid catalyses might explain the enzyme uncommon route for nitrile hydration.

Experimental Section

Complex 3: This compound was prepared according to our previously reported procedure[9a] with some slight modifications. *t*BuNC (51 mg, 0.6 mmol) was added to a deep green solution of Na[CoL]·DMF (**2**)[9b] (46 mg, 0.1 mmol) in DMF (0.5 mL) and acetone (1 mL) cooled to −10 °C. The resulting pink solution was stirred for 10 min. and then solid H_2O_2·urea (56 mg, 0.6 mmol) was added. After 1 h at −10 °C, acetone (1 mL) was added and the orange precipitate was filtered, rinsed with acetone, and dried under vacuum to afford $Na[Co^{III}(L\text{-}N_2SOSO)(t\text{BuNC})_2]$·urea (**3**) (55 mg, 85%). − ^1H NMR (250 MHz, [D$_6$]DMSO): δ = 5.44 (s, 4 H, urea), 3.60 (d, *J* = 13.3 Hz, 2 H, NCH_AH_B), 3.09 (d, 2 H, NCH_AH_B), 1.39 (s, 18 H, *t*BuNC), 1.28 (s, 6 H, CH_3), 1.17 (s, 6 H, CH_3), 1.12 (s, 6 H, CH_3).

Complex 4: Me_4NCl (16 mg, 0.15 mmol) and *t*BuNC (60 mg, 0.72 mmol) were added successively to a deep green solution of Na[CoL]·DMF (**2**)[9b] (54 mg, 0.12 mmol) in degassed EtOH (1 mL) cooled to −10 °C. The resulting pink solution was stirred under Ar for 10 min. and an aq. 50% solution of H_2O_2 (310 mg, 5.44 mmol) was then added dropwise. The orange solution was stirred at −10 °C for 3 h and kept in a refrigerator overnight. The precipitate (NaCl) was filtered off and rinsed with EtOH (95%, 1 mL). Et_2O (≈ 20 mL) was added to the combined yellow solution and kept at 4 °C overnight. The resulting yellow crystals were filtered and dried under vacuum to afford $(Me_4N)[Co^{III}(L\text{-}N_2SO_2SO_2)(t\text{BuNC})_2]\cdot H_2O$ (**4**) (70 mg, 96%). − $C_{27}H_{54}CoN_5O_7S_2$ (683.81): calcd. C 47.42, H 7.96, N 10.24, S 9.38; found C 47.17, H 7.54, N 10.11, S 9.26. − UV/Vis (MeOH) [λ_{max}, nm (ε, $m^{-1}\,cm^{-1}$)]: 400 (sh), 312 (20000), 208 (13000). − IR (KBr): $\tilde{\nu}$ = 2215 (s, ν_{CN}), 1565 (s, ν_{CO}), 1195 and 1065 (s, ν_{SO}) cm^{-1}. − ^1H NMR (250 MHz, [D$_6$]DMSO): δ = 7.75 (br. s, 2 H, D_2O exchangeable, H_2O), 3.18 (s, 4 H, NCH_2), 1.39 (s, 18 H, *t*BuNC), 1.31 [s, 12 H, $(CH_3)_4N^+$], 1.27 (s, 6 H, CH_3), 1.18 (s, 12 H, CH_3). − Electrospray MS (MeOH): *m*/*z* (%) = 591 [M − Me_4N^+]$^-$.

Crystal Data for 4·H_2O: $C_{27}H_{54}CoN_5O_7S_2$, *M* = 683.81, yellow crystals, monoclinic, space group $P2_1/n$, *a* = 11.621(7), *b* = 16.845(6), *c* = 18.468(4) Å, *Z* = 4, β = 79.64(3)° *V* = 3556(3) Å^3, D_c = 1.28 g·cm^{-3}, *T* = 295 K, Mo-K_α radiation (λ = 0.71069 Å),

7606 reflections were measured, 4631 of which were used in all calculations (R_{int} = 0.02). The structure was solved by SHELXS-86[16] and refined by least-squares analysis using anisotropic thermal parameters, H atoms were introduced in calculated positions, with $F_o > 3\sigma(F_o)$, the programs CRYSTALS[17] and CAMERON[18] were used, R = 0.0479, R_W = 0.0574.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-161812. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Typical Procedure for the Catalytic Hydration of CH_3CN: A mixture of Na[Co^{III}(L-N_2SOSO)(tBuNC)$_2$]·urea (**3**) (5 mg, 0.008 mmol) and 1,3,5-trimethoxybenzene (7 mg, 0.042 mmol) in CH_3CN (0.5 mL) and a HOAc/NaOAc buffer (1 M, pH = 4.8, 0.5 mL) was stirred at 4 °C for 17 h. After lyophilization, [D_6]Me_2SO was added to the mixture and the presence of 0.144 mmol of acetamide was determined (18 turnovers) by ^{1}H NMR spectroscopy. The turnover number increases with the reaction time. 42 Turnovers and 50 turnovers were found after 3 and 6 days, respectively.

Acknowledgments

[μ_2-(*O*-Acylhydroxycarbene)]dicobalt Hexacarbonyls by Carbon-to-Oxygen Acyl−Acyl Coupling

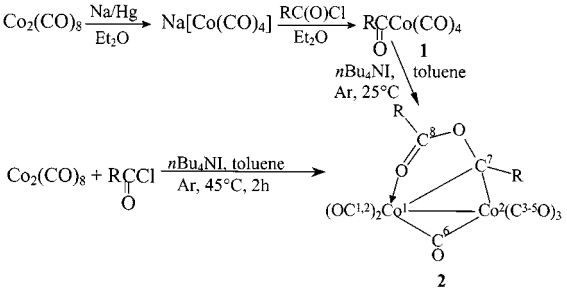
Claudia Zucchi,[a] Erika Soós,[b] Vilmos Galamb,[b] Gyula Váradi,[c] László Párkányi,[d] and Gyula Pályi*[a]

Keywords: Cobalt / Carbonyl ligands / Tishchenko reaction / Acylations

The acylcobalt tetracarbonyls [RC(O)Co(CO)$_4$] (**1**) undergo self-acylation in the presence of *n*Bu$_4$NI, in toluene at room temp., to yield the dinuclear μ_2-acylhydroxycarbene-type complexes [{RC(O)}$_2$Co$_2$(CO)$_6$] (**2**). Complex **2**, with R = *t*Bu, was also characterised by X-ray diffraction.

Introduction

The acylcobalt tetracarbonyls[1] (**1**) have been identified as intermediates of industrially important C−C bond-forming reactions.[2] Since the discovery of the favourable influence of tertiary phosphanes in hydroformylation[3] several reactions of complexes **1** with nucleophiles (Lewis bases) have been studied,[1] although reactions with electrophiles have not been studied so often.[1,4] Here we report on the electrophilic reaction of the acyl oxygen of compounds **1**.



Scheme 1

Results and Discussion

We observed (Scheme 1) that the acylcobalt tetracarbonyls[1] [RC(O)Co(CO)$_4$] (**1**) undergo self-acylation (a kind of Tishchenko reaction[5]) in toluene solution in the presence of *n*Bu$_4$NI, under mild conditions, yielding the dinuclear complexes [{RC(O)}$_2$Co$_2$(CO)$_6$] (**2**). A one-pot synthesis starting from [Co$_2$(CO)$_8$], RC(O)Cl and *n*Bu$_4$NI under similar conditions was also found to give **2** as the only cobalt carbonyl. Complexes **2** were characterised by elemental analysis, IR, ^{1}H and ^{13}C NMR spectroscopy and single crystal X-ray diffraction of one representative compound (**2c**) (Figure 1).

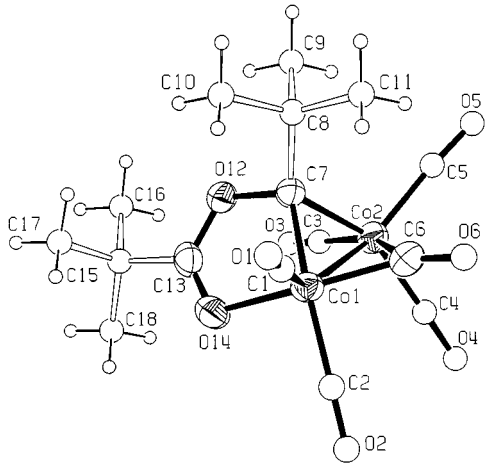


Figure 1. ORTEP drawing of the molecular structure of **2c**; selected bond lengths (pm) and angles (deg.): Co−Co 241.5(1), Co−C(O)$_t$ (av.) 180.9, Co−C(O)$_{br}$ (av.) 191.7, Co−C(7) (av.) 198.7, Co(1)−O(14) 202.6(4), Co(1)−C(13) 273.4(4), C(13)−O(14) 123.0(6), C(13)−O(12) 131.4(6), C(7)−O(12) 146.9(6); Co(1)−C(7)−Co(2) 74.8(3), Co(1)−C(6)−Co(2) 78.0(4), C(7)−O(12)−C(13) 116.6(6), C(8)−C(7)−O(12) 103.6(6)

The spectra show close analogies with other [(μ_2-L′)(μ_2-L′′)Co(CO)$_5$L′′′] complexes.[4,6] The X-ray crystal structure shows a Co$_2$(CO)$_6$ skeleton with the acylhydroxy carbene and a carbonyl ligand in bridging positions and an O-to-

Co coordination of the oxygen in the "acylating" acyl group. The overall structure of complexes **2** is a new type of cobalt carbonyl, showing some analogy to that of the "lactone" complexes [(μ_2-butenolide)(μ_2-CO)$Co_2(CO)_6$].[7] Such an O-to-Co coordination is a very rare phenomenon[8] with low-valent cobalt carbonyls. The relative orientation of the bridging carbonyl and the ester groups indicates a quantitative stereoselectivity of the formation of complexes **2**.[9] The preparative and structural results can be rationalized by supposing I^- coordination to (a part of) the acylcobalt carbonyls, which could increase the charge separation and thus facilitate the formation of the acyl electrophile, followed by the organization of the dinuclear structure of **2** (Scheme 2). This picture could give an insight into the mechanism of action of ionic additives in Co-catalysed CO chemistry.[10] I^- coordination to low-valent cobalt carbonyls has been documented previously.[11] The μ_2-hydroxycarbene ligand in complexes **2** might bear some relevance to the as-yet not fully explored question of the mechanism of the Fischer−Tropsch reaction.[12]

$$RC(O)Co(CO)_4 + (nBu_4N)I \rightleftharpoons (nBu_4N)[RC(O)Co(CO)_3(I)] + CO$$

$$RC(O)Co(CO)_4 + [RC(O)Co(CO)_3(I)]^- \longrightarrow \{\mu_2,O\text{-}\eta^1\text{-}[RC(O)]_2\}(\mu_2\text{-}CO)Co_2(CO)_5 + CO + I^-$$

Experimental Section

All experiments were performed using standard Schlenk techniques, with carefully deoxygenated, dry gases and solvents.

Preparation of Complex 2c: Dicobalt octacarbonyl (684 mg, 2 mmol) and *n*-tetrabutylammonium iodide(960 mg, 2.6 mmol) were placed into a thermostated reaction vessel under Ar. Toluene (15 mL) was then added and the mixture was stirred for 10 min. at 25 °C. After this period *t*BuC(O)Cl (640 mg, 5.3 mmol) was added. The temperature was then raised to 45 °C and the solution was stirred for an additional 2 h. After this period the solution was left to cool to room temp., filtered, the filtrate was dried at reduced pressure (room temp.) and an oily product (1551 mg, 82%) was obtained which contained **2c** as the only cobalt carbonyl (IR). This crude product was dissolved in 3 mL *n*-hexane and the solution cooled to −78 °C to give brownish yellow [m.p. 73.5 °C (dec.)] crystals (278 mg, 15%). Occasionally the recrystallization was repeated using 0.5−1.5 mL of *n*-hexane. The product is very soluble in all solvents which did not react with **2c**, hence the low yields of crystalline product.

2c could also be prepared from 1 mmol of **1c** {obtained from $Na[Co(CO)_4]$ (195 mg, 1 mmol) and pivaloyl chloride (121 mg, 1 mmol) in 15 mL Et_2O} and pivaloyl chloride (60 mg, 0.5 mmol) in toluene (15 mL), at room temp., under Ar atmosphere after 2 h stirring. Yield: 60−70% (IR). − $C_{16}H_{18}Co_2O_8$ (456.18): calcd. C 42.13, H 3.98, Co 25.84; found C 42.3, H 4.1, Co 25.7. MW calcd. 456.18; found (m.s.) 456.

Macrocyclic Siloxanes with Two Exocyclic *trans*-Silanol and Two Exocyclic *trans*-Amino Functions − Stereoselective Syntheses and Structures

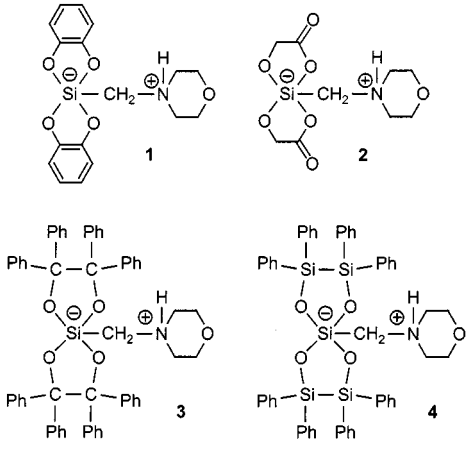
Reinhold Tacke,*[a] Christian Burschka,[a] Joachim Heermann,[a] Ingo Richter,[a] Brigitte Wagner,[a] and Reiner Willeke[a]

Keywords: Silicon / Macrocycles / Siloxanes / Silanols / Pentacoordination

A simple preparative method for the stereoselective synthesis of ten- and twelve-membered cyclosiloxanes with two exocyclic *trans*-silanol and two exocyclic *trans*-amino functions has been developed. Thus, treatment of trimethoxy(morpholinomethyl)silane (**5**) with two molar equivalents of $HOPh_2Si–SiPh_2OH$ and $HOPh_2Si–O–SiPh_2OH$, respectively, yielded *trans*-1,6-bis(2-hydroxy-1,1,2,2-tetraphenyldisilan-1-yloxy)-1,6-bis(morpholinomethyl)-3,3,4,4,8,8,9,9-octaphenyl-2,5,7,10-tetraoxa-1,3,4,6,8,9-hexasilacyclodecane (**6**, 10-membered ring) and *trans*-2,8-bis(3-hydroxy-1,1,3,3-tetraphenyldisiloxan-1-yloxy)-2,8-bis(morpholinomethyl)-4,4,6,6,10,10,12,12-octaphenylcyclohexasiloxane (**7**, 12-membered ring). In contrast, treatment of **5** with two molar equivalents of $HOPh_2C–CPh_2OH$ afforded (morpholiniomethyl)bis[tetraphenylethane-1,2-diolato(2−)]silicate (**3**), a zwitterionic spirocyclic λ^5*Si*-silicate. Compounds **3**, **6**·EtOAc, and **7**·PhMe were characterized by elemental analyses (C, H N), solid-state ^{29}Si VACP/MAS NMR studies, solution NMR experiments (^{1}H, ^{13}C, ^{29}Si; $CDCl_3$), and crystal structure analyses.

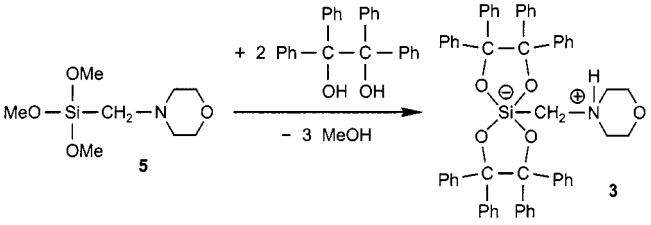
Introduction

Various organic *vic*-diols (e.g. 1,2-dihydroxybenzene and glycolic acid derivatives) have been used to prepare zwitterionic spirocyclic λ^5*Si*-silicates with two bidentate diolato(2−) ligands,[1] such as compounds **1** and **2**. Following the strategy applied to the syntheses of **1** and **2**, we attempted to prepare the related zwitterionic λ^5*Si*-silicates **3** and **4**.



Results and Discussion

To synthesize compounds **3** and **4**, trimethoxy(morpholinomethyl)silane[2] (**5**) was treated with two molar equivalents of the respective *vic*-diol, tetraphenylethane-1,2-diol or tetraphenyldisilane-1,2-diol[3] (Scheme 1 and 2). Both reactions were performed in acetonitrile at room temperature, and compound **3** was obtained in 93% yield as a colorless crystalline solid. However, to our great surprise treatment of **5** with $HOPh_2Si−SiPh_2OH$ under the same conditions as applied to the synthesis of **3** did not yield the expected product **4**, we instead obtained the ten-membered cyclosiloxane **6**. This compound was isolated, after recrystallization from ethyl acetate, as the solvate **6**·EtOAc (yield 70%).



Scheme 1. Synthesis of the zwitterionic λ^5*Si*-silicate **3**

From a formal point of view, the formation of **6** could be rationalized in terms of a dimerization of **4**; however, there is no experimental evidence for this assumption. The reaction mechanism is still under investigation and it is an open question as to whether the zwitterion **4** is an intermediate in this reaction or not. Nevertheless, it appears that we have discovered an efficient stereoselective synthetic method for the preparation of macrocyclic siloxanes with two exocyclic *trans*-silanol groups and two exocyclic *trans*-amino functions. As a further example of this method, we have succeeded in synthesizing the twelve-membered cyclosiloxane **7**. This compound was obtained analogously to the synthesis of **6** by treatment of **5** with two molar equivalents of tetraphenyldisiloxane-1,3-diol[4] in acetonitrile at room

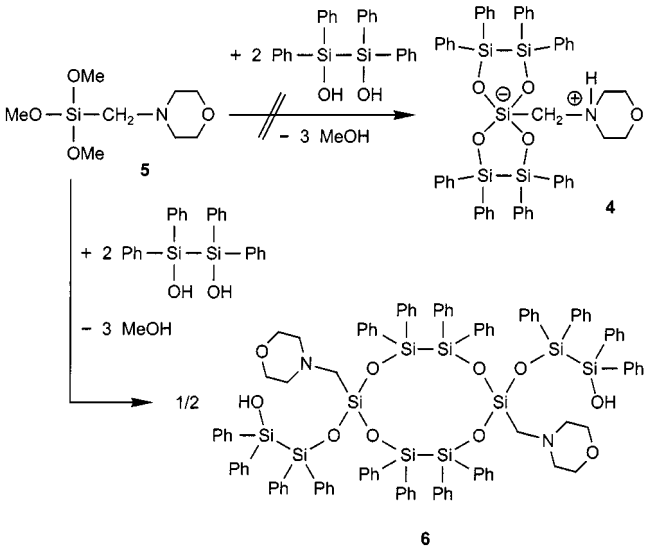
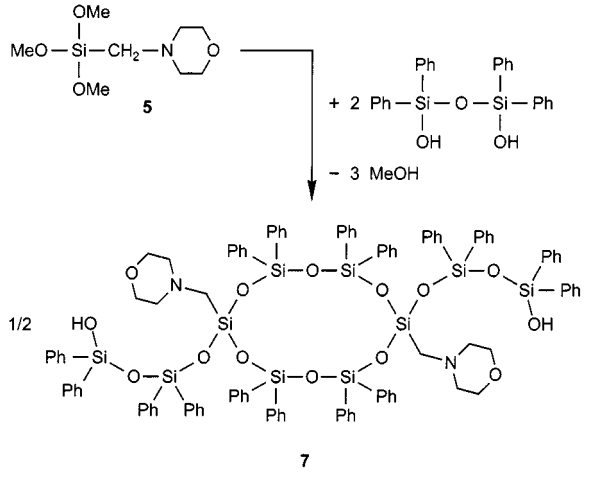


Scheme 2. Synthesis of the ten-membered cyclosiloxane **6**

temperature (Scheme 3). The product was isolated, after recrystallization from toluene/petroleum ether, as the solvate **7**·PhMe (yield 72%).



Scheme 3. Synthesis of the twelve-membered cyclosiloxane **7**

Compounds **3**, **6**·EtOAc, and **7**·PhMe were characterized by elemental analyses (C, H N), solid-state ^{29}Si VACP/MAS NMR studies, solution NMR experiments (^{1}H, ^{13}C, ^{29}Si; $CDCl_3$),[5] and crystal structure analyses.

The Si coordination polyhedron of **3** is a strongly distorted trigonal bipyramid (Berry distortion 42.3%),[6] each bidentate tetraphenylethane-1,2-diolato(2−) ligand spanning one axial and one equatorial site (Figure 1). The zwitterion forms an intramolecular N−H···O1 hydrogen bond in the crystal [N−H 0.85(3), H···O1 2.31(2), N···O1 2.746(2) Å, N−H···O1 112(2)°].[7]

Compounds **6**·EtOAc and **7**·PhMe show some common structural features (Figure 2 and 3). With respect to the positions of their silicon atoms, the ten- and twelve-membered rings adopt a chair conformation, both ring systems being characterized by a center of symmetry. The two morpholinomethyl substituents occupy axial positions, whereas the

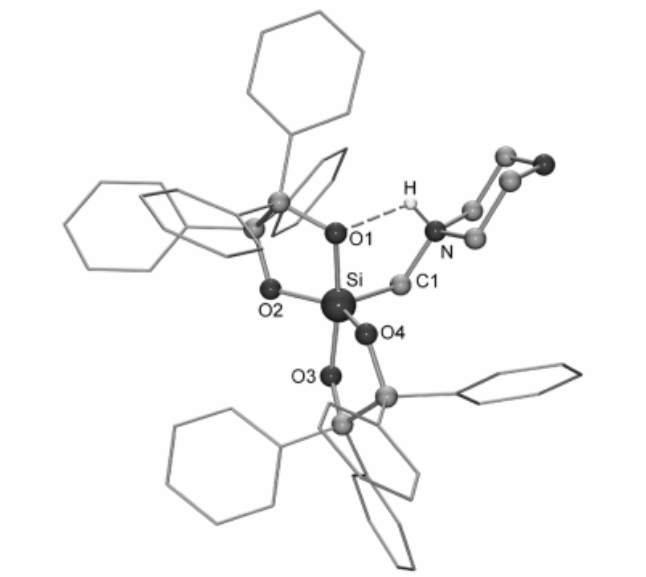


Figure 1. Molecular structure of **3** in the crystal (hydrogen atoms, except for N*H*, are omitted for clarity); selected distances [Å] and angles [°] (standard deviations in parentheses): Si−O1 1.7728(15), Si−O2 1.6992(15), Si−O3 1.7303(15), Si−O4 1.6987(15), Si−C1 1.909(2); O1−Si−O2 86.67(7), O1−Si−O3 170.44(7), O1−Si−O4 89.05(7), O1−Si−C1 94.32(8), O2−Si−O3 88.95(7), O2−Si−O4 136.82(7), O2−Si−C1 111.01(9), O3−Si−O4 88.33(7), O3−Si−C1 95.18(9), O4−Si−C1 112.15(9)

two $OPh_2Si-SiPh_2OH$ (**6**·EtOAc) or $OPh_2Si-O-SiPh_2OH$ (**7**·PhMe) groups occupy equatorial sites. Thus, each of the two pairs of identical exocyclic functional groups (two silanol and two amino moieties) are in *trans*-position to each other. The conformations present in the crystal allow the formation of intramolecular O−H···N hydrogen bonds [**6**·EtOAc: O4−H 0.8198, H···N 1.9325, O4···N 2.737(3) Å, O4−H···N 166.75°; **7**·PhMe: O4−H 0.78(7), H···N 2.02(7), O4···N 2.787(5) Å, O4−H···N 172(8)°].[7] The three Si1−O distances of **6**·EtOAc [1.6034(17)−1.6092(16) Å] and **7**·PhMe [1.603(3)−1.605(3) Å] are somewhat shorter than the other Si−O distances [**6**·EtOAc: 1.6369(16)−1.6482(18) Å; **7**·PhMe: 1.620(3)−1.635(3) Å]. The Si−O−Si angles of the ring systems amount to 157.13(11) and 164.18(12)° (**6**·EtOAc) and to 152.1(2)−153.9(2)° (**7**·PhMe). The Si−C distances are in the range 1.866(2)−1.882(2) Å (**6**·EtOAc) and 1.843(5)−1.859(5) Å (**7**·PhMe), and the Si−Si distances (**6**·EtOAc) amount to 2.3610(11) and 2.3907(11) Å.

In conclusion, contrary to the reaction of silane **5** with two molar equivalents of $HOPh_2C-CPh_2OH$ (which gives formation of the zwitterionic λ^5*Si*-silicate **3**), treatment of **5** with two molar equivalents of $HOPh_2Si-SiPh_2OH$ or $HOPh_2Si-O-SiPh_2OH$ leads to the formation of macrocyclic siloxanes. With the syntheses of compounds **6** and **7** we have discovered an efficient stereoselective synthesis of ten- and twelve-membered macrocyclic siloxanes with two exocyclic silanol and two exocyclic amino functionalities in mutual *trans*-positions. To the best of our knowledge, functionalized cyclic siloxanes of this particular formula type have not been described in the literature.[8] Due to these exocyclic functionalities, in addition to the characteristic chemical reactivity of the Si−O−Si and

Si−Si bonds in the ring skeletons, such compounds represent promising starting materials for the preparation of novel polymeric SiO-based materials.[9] Future studies will elucidate the synthetic potential of the title compounds.

Experimental Section

General: All syntheses were carried out under dry nitrogen. The organic solvents used were dried and purified according to standard procedures and stored under nitrogen. Melting points were determined with a DuPont Instruments differential scanning calorimeter, type Thermal-Analyzer 910. The ^{1}H, ^{13}C, and ^{29}Si solution NMR spectra were recorded at 22 °C on a Bruker DRX-300 NMR spectrometer (^{1}H: 300.1 MHz; ^{13}C: 75.5 MHz; ^{29}Si: 59.6 MHz). $CDCl_3$ was used as solvent. Chemical shifts (ppm) were determined relative to internal $CHCl_3$ (^{1}H: δ = 7.24), $CDCl_3$ (^{13}C: δ = 77.0), or external TMS (^{29}Si: δ = 0). Assignment of the ^{13}C NMR data was supported by DEPT 135 experiments. Solid-state ^{29}Si VACP/MAS NMR spectra were recorded at 22 °C on a Bruker DSX-400 NMR spectrometer with bottom layer rotors of ZrO_2 (diameter 7 mm) containing ca. 300 mg of sample [79.5 MHz; TMS as external standard (δ = 0); spinning rate: 5 kHz (**3**, **6**·EtOAc) or 7 kHz (**7**·PhMe); contact time: 5 ms; 90° ^{1}H transmitter pulse length: 3.6 μs; repetition time: 4 s].

Synthesis of (Morpholiniomethyl)bis[tetraphenylethane-1,2-diolato(2−)]silicate (3): Compound **5** (1.04 g, 4.70 mmol) was added at 20 °C to a stirred solution of tetraphenylethane-1,2-diol (3.44 g, 9.39 mmol) in acetonitrile (250 mL) and the mixture then kept un-

disturbed for 4 days at the same temperature. The resulting precipitate was isolated by filtration, washed with acetonitrile (2 × 10 mL), and dried in vacuo (0.01 Torr, 1 h) to give 3.83 g (4.46 mmol) of colorless crystals (yield 95%). M.p. 260 °C (dec.). – Due to the poor solubility of **3**, solution NMR experiments failed. – ^{29}Si VACP/MAS NMR: δ = −98.9. – $C_{57}H_{51}NO_5Si$ (858.1): calcd. C 79.78, H 5.99, N 1.63; found C 79.8, H 5.9, N 1.8.

Synthesis of *trans*-1,6-Bis(2-hydroxy-1,1,2,2-tetraphenyldisilan-1-yloxy)-1,6-bis(morpholinomethyl)-3,3,4,4,8,8,9,9-octaphenyl-2,5,7,10-tetraoxa-1,3,4,6,8,9-hexasilacyclodecane−Ethyl Acetate (6·EtOAc): Compound **5** (27.8 mg, 126 μmol) was added at 20 °C to a stirred solution of tetraphenyldisilane-1,2-diol (100 mg, 251 μmol) in acetonitrile (5 mL). Stirring was continued for 1 h and the mixture then kept undisturbed for 2 days at the same temperature. The resulting precipitate was isolated by filtration, washed with acetonitrile (2 × 1 mL), recrystallized from ethyl acetate, and dried in vacuo (0.01 Torr, 1 h) to give 85.3 mg (44.1 μmol) of colorless crystals (yield 70%). M.p. 212 °C (loss of ethyl acetate at ca. 127 °C). – ^{1}H NMR: δ = 1.25 (t, 3 H, OCH_2CH_3), 1.40 (s, 4 H, $SiCH_2N$), 1.83−2.05 (m, 8 H, CCH_2N), 2.03 [s, 3 H, $C(O)CH_3$, overlapping with the multiplet for CCH_2N], 3.29−3.42 (m, 8 H, CCH_2O), 4.10 (q, 2 H, OCH_2CH_3), 6.77−6.86, 6.87−7.01, and 7.06−7.36 (m, 80 H, SiC_6H_5), 8.3 (br. s, 2 H, SiOH). – ^{13}C NMR: δ = 14.2 (OCH_2CH_3), 21.1 [$C(O)CH_3$], 48.0 ($SiCH_2N$), 56.9 (CCH_2N), 60.4 (OCH_2CH_3), 65.6 (CCH_2O), 127.5, 127.6, 127.7, and 127.9 (C-2/C-6 or C-3/C-5, SiPh), 129.1, 129.3, 129.65, and 129.71 (C-4, SiPh), 134.6 (two non-equivalent sites, not resolved), 135.1, and 135.2 (C-2/C-6 or C-3/C-5, SiPh), 135.8, 136.2, 136.6, and 138.0 (C-1, SiPh), $CO)CH_3$ resonance not found. – ^{29}Si NMR: δ = −73.7 (SiO_3C), −17.1, −16.1, and −15.3 ($SiSiOC_2$). – ^{29}Si VACP/MAS NMR: δ = −75.6 (SiO_3C), −17.4, −15.2, −14.1, and −10.7 ($SiSiOC_2$). – $C_{110}H_{110}N_2O_{12}Si_{10}$ (1932.9): calcd. C 68.35, H 5.74, N 1.45; found C 68.6, H 5.8, N 1.5.

Synthesis of *trans*-2,8-Bis(3-hydroxy-1,1,3,3-tetraphenyldisiloxan-1-yloxy)-2,8-bis(morpholinomethyl)-4,4,6,6,10,10,12,12-octaphenylcyclohexasiloxane−Toluene (7·PhMe): Compound **5** (133 mg, 601 μmol) was added at 20 °C to a stirred solution of tetraphenyldisiloxane-1,3-diol (500 mg, 1.21 mmol) in acetonitrile (4 mL). Stirring was continued at the same temperature for 1 day, and the resulting precipitate was isolated by filtration, washed with acetonitrile (2 × 1 mL), crystallized from toluene/petroleum ether [1:1 (v/v); addition of petroleum ether (b.p. 40−60 °C) to a solution of **7** in toluene at 20 °C], and dried in vacuo (0.01 Torr, 1 h) to give 434 mg (217 μmol) of colorless crystals (yield 72%). M.p. (dec.) 169−170 °C (loss of toluene at ca. 90 °C). – ^{1}H NMR: δ = 1.38 (s, 4 H, $SiCH_2N$), 1.65−1.80 (m, 8 H, CCH_2N), 2.32 (s, 3 H, CCH_3), 3.02−3.16 (m, 8 H, CCH_2O), 6.98−7.44 (m, 85 H, SiC_6H_5, $C_6H_5CH_3$), 8.9 (br. s, 2 H, SiOH). – ^{13}C NMR: δ = 21.8 ($PhCH_3$), 47.5 ($SiCH_2N$), 57.1 (CCH_2N), 66.1 (CCH_2O), 125.3 (C-4, PhMe), 127.5, 127.6 (two non-equivalent sites, not resolved), and 127.8 (C-2/C-6 or C-3/C-5, SiPh), 128.2 and 129.0 (C-2/C-6 or C-3/C-5, PhMe), 129.6, 130.0 (two non-equivalent sites, not resolved), and 130.2 (C-4, SiPh), 133.8 and 134.1 (C-1, SiPh), 134.3 (two non-equivalent sites, not resolved), 134.5, and 134.6 (C-2/C-6 or C-3/C-5, SiPh), 134.9 (C-1, PhMe), 136.0 (C-1, SiPh), one resonance signal (C-1, SiPh) not found. – ^{29}Si NMR: δ = −77.3 (SiO_3C), −47.0, −44.4, and −37.2 ($SiSiOC_2$). – ^{29}Si VACP/MAS NMR: δ = −77.6 (SiO_3C), −48.8, −47.7, −42.9, and −35.3 ($SiSiOC_2$). – $C_{113}H_{110}N_2O_{14}Si_{10}$ (2000.9): calcd. C 67.83, H 5.54, N 1.40; found C 67.9, H 5.9, N 1.3.

Crystal Structure Analyses of 3, 6·EtOAc, and 7·PhMe: Suitable single crystals were mounted in inert oil (perfluoroalkyl ether, ABCR) on a glass fiber and then transferred to the cold nitrogen-gas stream of the diffractometer (Stoe IPDS; graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å). The structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-squares on F^2 with all unique reflections (SHELXL-97).[10] For the hydrogen atoms, a riding model was employed, except for the N*H* atom of **3** and O*H* atom of **7**·PhMe, which were refined freely.

Selected Data for 3: Single crystal (0.4 × 0.3 × 0.3 mm) obtained from the reaction mixture, $C_{57}H_{51}NO_5Si$, M_r = 858.08, analysis at 173(2) K, monoclinic, space group $P2_1/n$, a = 14.930(3), b = 16.257(3), c = 18.462(4) Å, β = 99.54(3)°, V = 4419.2(15) Å^3, Z = 4, $\rho_{calcd.}$ = 1.290 g cm^{-3}, μ = 0.107 mm^{-1}, $F(000)$ = 1816, $2\theta_{max}$ = 49.62°, 36433 collected reflections, 7550 unique reflections (R_{int} = 0.0682), 581 parameters, R_1 = 0.0433 [$I > 2\sigma(I)$], wR_2 (all data) = 0.1117, S = 0.889, largest difference peak and hole +0.285 and −0.447 e Å^{-3}.

Selected Data for 6·EtOAc: Single crystal (0.4 × 0.4 × 0.2 mm) obtained from ethyl acetate at 20 °C, $C_{106}H_{102}N_2O_{10}Si_{10}$·EtOAc, M_r = 1932.90, analysis at 253(2) K, triclinic, space group $P\bar{1}$, a = 14.274(2), b = 14.363(3), c = 14.459(2) Å, α = 61.057(19), β = 87.579(19), γ = 82.08(2)°, V = 2568.4(7) Å^3, Z = 1, $\rho_{calcd.}$ = 1.250 g cm^{-3}, μ = 0.189 mm^{-1}, $F(000)$ = 1020, $2\theta_{max}$ = 53.84°, 29307 collected reflections, 10267 unique reflections (R_{int} = 0.0757), 599 parameters, R_1 = 0.0457 [$I > 2\sigma(I)$], wR_2 (all data) = 0.1267, S = 0.906, largest difference peak and hole +0.692 and −0.510 e Å^{-3}. The crystal contains ethyl acetate molecules located on a center of inversion.

Selected Data for 7·PhMe: Single crystal (0.4 × 0.3 × 0.1 mm) obtained from toluene/petroleum ether at 20 °C, $C_{106}H_{102}N_2O_{14}Si_{10}$·PhMe, M_r = 2000.93, analysis at 173(2) K, triclinic, space group $P\bar{1}$, a = 13.832(2), b = 14.207(2), c = 16.989(2) Å, α = 74.54(2), β = 71.44(2), γ = 64.97(2)°, V = 2833.6(7) Å^3, Z = 1, $\rho_{calcd.}$ = 1.173 g cm^{-3}, μ = 0.175 mm^{-1}, $F(000)$ = 1054, $2\theta_{max}$ = 46.62°, 20277 collected reflections, 7726 unique reflections (R_{int} = 0.0738), 683 parameters, 581 restraints, R_1 = 0.0545 [$I > 2\sigma(I)$], wR_2 (all data) = 0.1525, S = 0.861, largest difference peak and hole +0.551 and −0.374 e Å^{-3}. The crystal contains tubes along [1 0 0] which are occupied by the toluene molecules.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-158876 (**3**), CCDC-158877 (**6**·EtOAc), and CCDC-158878 (**7**·PhMe). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of a [{Mono-*N*-(4-vinylbenzyl)-1,4,7-triazacyclononane}$_2$Hg](OTf)$_2$ Sandwich Complex, Polymerization of this Monomer with Divinylbenzene, and Hg^{2+} Ion Selectivity Studies with the Demetallated Resin[‡]

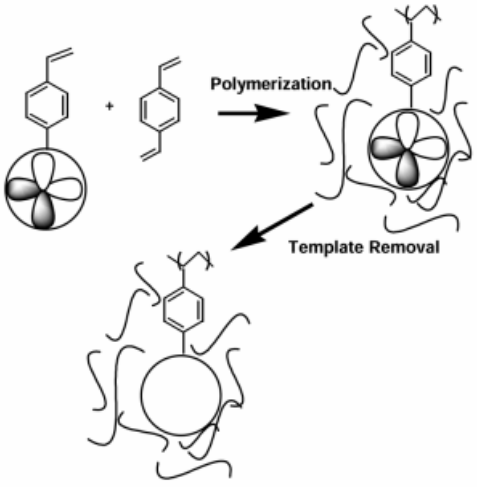
H. Christine Lo,[a,b] Hong Chen,[a,c] and Richard H. Fish*[a]

Keywords: Template synthesis / Mercury / Cations / Sandwich complexes / Polymers

We have synthesized a novel, 1,4,7-triazacyclononane (TACN)-Hg^{2+} sandwich monomer, [{mono-*N*-(4-vinylbenzyl)-1,4,7-TACN}$_2$Hg](OTf)$_2$, which was co-polymerized with the cross-linking agent divinylbenzene to form a Hg^{2+}-ion templated polymer that was demetallated (>96%) with 6 N HCl, and subsequently found to be highly selective to reintroduced Hg^{2+} ions in competition with Cd^{2+}, Ag^{+}, Pb^{2+}, Cu^{2+}, and Fe^{3+} ions at pH 2, the ionic radius and the thermodynamic parameter being more critical than imprinting.

Introduction

The elegant concept of templated polymers was introduced by Wulff and Mosbach, and further developed by Shea, among others,[1] and initially involves formation of a vinyl monomer host and a bound guest acting as a template. This vinyl monomer host-guest template complex is then polymerized with a cross-linking agent, which provides spatially regulated sites in the polymer matrix and, if possible, the continual recognition of the removable guest template in subsequent reintroduction steps (Scheme 1).



Scheme 1. The templated polymer concept

More importantly, the area of metal-ion templated polymers has received much less attention than the corresponding organic compound templated polymers.[2] Recently, we extended the metal-ion templated polymer field to a novel system that utilized the mono-*N*-(4-vinylbenzyl)TACN ligand (**1**) and found that the monomeric Zn^{2+} sandwich complex of **1**, [{mono-*N*-(4-vinylbenzyl)TACN}$_2$Zn](OTf)$_2$, could be polymerized to provide the same spatial sandwich arrangement in the polymer matrix (2:1 ratio of TACN:Zn).[3,4] Subsequent demetallation of the Zn^{2+}-templated polymer with 6 N HCl, followed by reintroduction of the Zn^{2+} ions in competition with Ni^{2+}, Co^{2+}, and Mn^{2+} at pH 4.5, maintained the ≈2:1 TACN:Zn ratio, and there-

fore *allowed us to speculate that the demetallated polymer also had a sandwich arrangement of TACN ligands, polymer* **2**, *with the distance between the polymeric TACN ligands possibly a consequence of the ionic radius of Zn (0.69 Å).*

Results and Discussion

To further determine whether this interesting result was a consequence of the ionic radius of the template metal-ion used in the original polymerization reaction, which would possibly allow selective metal-ion removal from aqueous acidic solution, we prepared the Hg^{2+} (with a larger ionic radius of 1.10 Å) templated sandwich monomer of ligand **1**, [{mono-*N*-(4-vinylbenzyl)-1,4,7-TACN}$_2$Hg](OTf)$_2$ (**3**),[3,4] [Equation (1)] in 70% yield, and polymerized it with the cross-linking agent 80% divinylbenzene (DVB) using AIBN in methanol at 75 °C (overnight in a Schlenk tube covered with aluminum foil) to provide the Hg^{2+}-templated polymer **4** [Equation (2)].

2:1 TACN: Hg ratio

After the total removal of the template Hg^{2+} ion from **4** with 6 N HCl, a demetallated bulk polymer resulted (0.35% Hg, > 96% removed), which had very high selectivity for reintroduced Hg^{2+} ions in competition with a mixture of Cd^{2+} (0.97 Å; 518:1), Pb^{2+} (1.21 Å; 259:1), Ag^{+} (1.26 Å; 1111:1), Cu^{2+} (0.72 Å; 165:1), and Fe^{3+} ions (0.53 Å; 24:1), at pH 2.0, with very high equilibrium selectivity coefficients, $K_{Hg^{2+}/M^{n+}}$, in favor of the Hg^{2+} ion (Table).[5]

Initial observations indicate that the template Hg^{2+} ion is able to compete extremely effectively with metal ions of similar or larger ionic radii, as well as with those that are smaller. However, to our total surprise, we found that the reintroduced Hg^{2+}-ion content in the bulk demetallated polymer was now *15.6% Hg*, and this provided a ratio of TACN:Hg of ~1:1, dramatically different from the Zn^{2+} demetallated polymer, which gave a ~2:1 TACN:Zn/Cu ratio upon reintroduction of Zn^{2+} or Cu^{2+} ions.[3] More importantly, we had previously verified, in a control experiment,[3] that we were *not able* to synthesize a polymer of the vinyl monomer **1** *without the metal ion template*, in order to show that this non-templated polymer lacked selectivity, in comparison to the templated polymer, for the metal ions studied. We observed soluble oligomers by FAB-MS analysis, but no insoluble polymer. We therefore concluded that the metal ions are critical for the dramatic increase in polymerization rates for the templated metal-ion complexes of vinyl monomer **1**, presumably due to an electronic effect.

Clearly, it appears that as you go to metal ions with higher ionic radii, such as Hg^{2+}, the larger distances between the TACN ligands may cause them to operate independently, as suggested in the demetallated Hg^{2+}-selective polymer formed from **4** (Table 1). It is also important to note that in the *absence* of the competing Hg^{2+} ion very small amounts of the other competitor metal ions were removed from solution with demetallated **4**. This is especially dramatic for Cu^{2+} ions (0.83%; ionic radius, 0.72 Å), which were found to be highly selective when reintroduced into the *sandwich arrangement* of polymer **2** (initially Zn templated), where it was observed that ~2% Cu^{2+} ions were removed from acidic solution (pH 2, Cu:Fe = 240:1 vs. 4:1 in Table 1; 5−8% at pH 4.5).[3] This latter result may add some

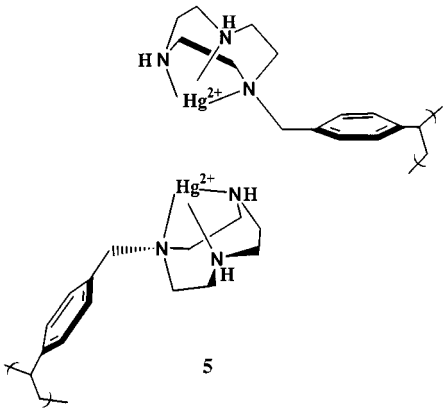
Table 1. Competitive metal-ion selectivity studies with the demetallated Hg^{2+} polymer

Metal ion[c]	In the presence of Hg^{2+} ions [$K_{Hg^{2+}/M^{n+}}$]	In the absence of Hg^{2+} ions
Hg^{2+}	15.6% (777.7 μmol/g)	–
Cd^{2+}	0.017% (1.5 μmol/g) [2.2×10^8]	not determined
Ag^{+}	0.008% (0.7 μmol/g) [9.8×10^9]	0.26% (24.1 μmol/g)
Pb^{2+}	0.063% (3.0 μmol/g) [1.6×10^8]	0.018% (0.87 μmol/g)
Cu^{2+}	0.030% (4.7 μmol/g) [6.7×10^8]	0.83% (130.6 μmol/g)
Fe^{3+}	0.18% (32.2 μmol/g) [1.9×10^7]	0.23% (41.2 μmol/g)

[a] Demetallated Hg^{2+} polymer (6 mg) and a mixture of metal ions (0.04 M each) were suspended in a stirring H_2O solution (10 mL) at room temperature for 18 h (pH = 2). The resulting polymer was washed thoroughly with H_2O and MeOH, and then dried in vacuo over P_2O_5 for 24 h. Inductive Coupled Plasma (ICP) was used for all the metal analyses. – [b] The reported numbers represent % metal ion by weight, and μmol/g of polymer (in parentheses) indicates the mol of each metal ion on the final collected polymer (per gram). – [c] The counter ion used for the selectivity studies was NO_3^-; therefore, Hg analysis for the sandwich Hg^{2+} polymer from polymerization of **3** (prior to demetallation) was back-calculated to be 8.3% instead of 7.66%, where the counter ion was OTf.

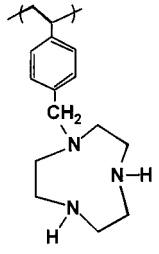
credence to the concept that the ionic radius of the template metal-ion has an effect on both the selectivity of reintroduced metal ions and on the ability of the polymeric TACN ligands to either maintain the sandwich arrangement (Zn^{2+}, Cu^{2+}) or to operate independently (Hg^{2+}).

Thus, our results suggest that the high selectivity for reintroduced Hg^{2+} ions might be better predicated on the basis of the thermodynamic stability of the complex between Hg^{2+} and the proposed polymeric arrangement of the demetallated TACN ligands, as shown in polymer **5**, as well as, to some extent, on the larger ionic radius.



5

More importantly, as discussed, we were never able to synthesize a non-templated polymer of vinyl monomer **1** to compare to the templated polymer **2**. However, in order to overcome this dilemma, we found that simply anchoring a TACN ligand on a 6% crosslinked chloromethylated **PS-DVB** bead gave **PS-TACN** (0.7 mmol/g) with a statistical distribution of TACN ligands rather than a sandwich arrangement, which demonstrated a dramatically lower selectivity for Cu^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, and Mn^{2+} ions, as well as a greatly diminished capacity (a ratio of 0.014!; ratio of Cu/Zn = 41:1 vs. 240:1 in polymer **2**).[4]



PS-TACN

In contrast, similar preliminary studies with **PS-TACN** and Hg^{2+} ions show high selectivity, as do all the polymer pendant ligands we have studied with Hg^{2+}.[5] Accordingly, the **PS-TACN** results further strengthen the concept of the spatial sandwich arrangement of TACN ligands in a templated polymer matrix being a novel method for the selectivity of metal ions of smaller ionic radius, as well as for the removal of higher capacities of those metal ions from aqueous solution, while also implicating the ionic radius in the apparent loss of the sandwich arrangement for a higher-than-expected Hg^{2+}-ion capacity. Additionally, other parameters could include the softness of the Hg^{2+} ion and its affinity for the relatively soft nitrogen atom (a thermodynamic effect with an equilibrium selectivity coefficient of $K > 10^7$), as well as the preorganized geometry of the TACN ligands in the surrounding coordination sphere.

It is interesting to note that the $[(TACN)_2Cd]^{2+}$ sandwich complex has been characterized by X-ray analysis[6] and shows Cd−N bond lengths of ~2.3 Å and a distance between the two TACN ligands of ~3.3 Å. This type of X-ray data may, in the future, provide more definitive information on the relationship between the ionic radius of the template metal-ion and the TACN:metal ratio of the reintroduced metal ions. Moreover, tying the two *N*-(4-vinylbenzyl)TACN ligands together with an appropriate sized tether might prevent the TACN ligands from operating independently with larger sized metal ions. Finally, the application of these TACN-templated polymers in environmental remediation studies, especially for highly selective Hg^{2+} ion removal from acidic waste streams containing benign metal ions such as Fe^{3+}, as well as for Hg^{2+}-ion sensor applications, will be pursued in the future.[7]

Experimental Section

***N*-(4-vinylbenzyl)-1,4,7-triazacyclononane, 1:**[8] A 50-mL 2-necked Schlenk flask equipped with a J-coiled condenser was charged with TACN (500.0 mg, 3.87 mmol), followed by the addition of EtOH (12 mL, deoxygenated), and the second neck was capped with a septum. LiOH·H_2O (35.8 mg, 0.85 mmol) in 5 mL of deoxygenated H_2O was then added in one portion to this stirring mixture through the septum. The resulting solution was slightly cloudy and was allowed to stir at 50 °C in an oil bath for 2 h, after which time the septum was replaced with an addition funnel, and 4-vinylbenzyl chloride (115.0 mg, 0.75 mmol) in 5 mL of EtOH was added dropwise to the reaction flask through this funnel under N_2. The reaction mixture was refluxed under N_2 and the course of the reaction was followed by TLC (EtOAc/MeOH = 2:3 with a drop of Et_3N). After 3 h, the reaction mixture was concentrated on a rotary evaporator to ~5 mL. About 15 mL of H_2O was added to the residue and CH_2Cl_2 (25 mL × 3) was used to extract the product. The combined CH_2Cl_2 extracts were then washed with brine (20 mL) and dried with Na_2SO_4, filtered, and the collected filtrate was concentrated on a rotary evaporator to ~10 mL. The impurity was removed by adding a small amount of pentane to the resulting CH_2Cl_2 solution until a cloudy suspension was observed. The mixture was then allowed to sit at room temperature for 15 min., and any precipitate or suspension was filtered off. The process was repeated three times until no appreciable cloudiness was observed upon the addition of pentane. The solution was then concentrated to ~ 1 mL and pentane was used to solidify the desired compound upon removing the solvent on a high vacuum line. The obtained solid was further dried in vacuo over P_2O_5 to give the title compound as a pale-yellow, foamy solid (144.2 mg, 78%). If the product did not solidify after the removal of solvent, more pentane was added to the resulting residue along with a small amount of CH_2Cl_2 and the solvent was removed on a high vacuum line. Another alternative to solidify the product was by using Et_2O instead

of pentane. The title compound (mp 58−60 °C) was hygroscopic and was kept in the freezer, and in the dark.

[{*N*-(4-vinylbenzyl)-1,4,7-triazacyclononane}$_2$Hg](OTf)$_2$, 3: Compound **1** (169.6 mg, 691.2 × 10^{-3} mmol) was placed in a 100-mL round flask, followed by the addition of MeOH (25 mL, deoxygenated). An addition funnel was then connected to the top of the flask and Hg(OTf)$_2$ (172.0 mg, 344.8 × 10^{-3} mmol) in 10 mL of MeOH (deoxygenated) was added dropwise to the reaction flask through the addition funnel over 30 min. in the dark. The flask was then covered with aluminum foil. Upon the addition of Hg(OTf)$_2$ solution, some cloudiness was observed. The reaction was allowed to stir at room temperature for 48 h, and any insoluble species were filtered off. The solvent was removed from the filtrate on a high vacuum line to give a foamy, pale-yellow solid. This solid was transferred into a N_2-filled glove box, and ~3 mL of MeOH was added to make a solution. The resulting solution was slightly cloudy, and some insoluble species were observable. A small amount of Et_2O was then added until the solution turned cloudy. The resulting mixture was allowed to sit at room temperature for 2 min., and precipitate was filtered off over a Celite bed. This process was repeated three times, and the solvent of the final filtrate was removed on a high vacuum line to yield an off-white foamy solid, which was further dried in vacuo over P_2O_5 to give the title complex in 70% (238.1 mg) yield. The title complex was found to be light sensitive, and demercuriation occured upon exposing a solution of the title complex to light and air for a long time.

A Novel and Perfectly Aligned Crystal of a Ferrocenyl Chromophore Displaying High Quadratic Nonlinear Optical Bulk Efficiency

Jérome Chiffre,[a] Frédéric Averseng,[a] Gilbert G. A. Balavoine,[a] Jean-Claude Daran,[a] Gabriel Iftime,[a] Pascal G. Lacroix,[a] Eric Manoury,*[a] and Keitaro Nakatani[b]

Keywords: Iron / Chromophores / Nonlinear optics / Crystal engineering

The highest nonlinear optical bulk efficiency for a 2-(4-nitrophenyl)ethenylferrocene (140 times that of urea) has been achieved for ***E*-4** owing to a favourable noncentrosymmetrical packing in which all molecules are perfectly aligned (*P*1 space group).

Introduction

Molecular nonlinear optical materials has been recognised for many years as a promising field because of their potential applications in emerging photonic technologies.[1] Most efforts have been devoted to organic molecules in which electron donor/acceptors are linked through conjugated backbones. More recently organometallic molecules have attracted attention because metal complexes are capable of strong electron acceptor/donor effects depending upon the nature of the metal, its oxidation states and coordination spheres. These new characteristics may allow a subtle tuning of the NLO properties and make organometallic species very attractive.[2] In any case, two prerequisites are needed for quadratic NLO activity: first, the constituting chromophores have to possess a molecular hyperpolarizability (β) as large as possible, and secondly they must be arranged in a noncentrosymmetrical fashion. A dramatic illustration of such requirements can be found in organometallic chemistry.[3] The (*Z*)-2-(4-nitrophenyl)ethenylferrocene isomer **Z-1** has a β value of 13×10^{-30} esu, and the *E* isomer ***E*-1** possesses a larger hyperpolarizability at the molecular level ($\beta = 31 \times 10^{-30}$ esu; see Table 1). However, whereas the *Z* isomer exhibits a large second harmonic generation (SHG) efficiency in the solid state (62 times that of urea), the *E* isomer is completely inactive in the solid state due to its centrosymmetrical crystal packing.[4] We have been able to overcome this tendency for centrosymmetric crystallisation of ***E*-1** by using chiral enantiomerically pure analogues of this molecule that furnished noncentrosymmetrical crystals, sometimes with high bulk efficiencies (up to 100 times that of urea).[5] More recently, we became interested in analogues of ***E*-1** bearing substituents on the second cyclopentadienyl ring (see Scheme 1) in order to modulate crystal packing or to incorporate chromophores into polymers. In the next section we will disclose our first results with a particular emphasis on ***E*-4**, which possesses a high NLO efficiency because of a very unusual crystal packing.

Results and Discussion

To obtain our target molecules, we developed a new procedure to prepare 1,1′-disubstituted ferrocenes involving the monoacetal **2** (see Scheme 1). The free aldehyde function was used to build the first substituent. Hydrolysis of the acetal function could then furnish a new formyl group in order to build up the second substituent. During our studies, we were able to isolate compound ***E*-4** and to obtain single crystals suitable for X-ray diffraction analysis. ***E*-4** crystallises in the *P*1 space group. Each unit cell contains one single molecule (Figure 1). The crystal has no symmetry elements so all the molecules of ***E*-4** are strictly identical and absolutely parallel to each other (see Figure 2). This packing is unique and very favourable for the NLO efficiency because each chromophore will add its contribution to the overall property. The *P*1 space group is very rare for NLO active chromophores. Only few examples of such crystal packings have been disclosed, usually for merocyanine- or 4-nitrophenol-based materials.[6] However, to the best of our knowledge, only one such crystal where the NLO chromophore is alone and perfectly aligned, has already been described.[6a]

The NLO properties of these materials has been measured by a Kurtz−Perry powder test.[7] An SHG efficiency of 140 times that of urea has been recorded at 1.906 μ. This efficiency is the highest value recorded so far in this series of 2-(4-nitrophenyl)ethenylferrocenes and one of the highest for organometallic compounds in general.[2,8] The optical properties of ***E*-4** are very close to those of the related compound ***E*-1**.[9] Furthermore, the molecular hyperpolarizability β of ***E*-4** has been calculated by ZINDO (see Table1).[10] The calculated β value is only slightly higher for ***E*-4** than for ***E*-1**, so the high NLO bulk efficiency of ***E*-4**

crystals is probably due to the very favourable crystal packing.

The nonlinear optical properties of 2-(4-nitrophenyl)ethenylferrocenes have been extensively studied,[2] but only a few types of crystal packing for such compounds have been reported. These compounds have a clear tendency for head-to-tail crystallisation.[4,5,11] Why, then, does ***E*-4** crystallise with such a completely different packing? The still common opinion about a tendency of molecules with a large dipole moment for head-to-tail crystallisation has been ruled out by a thorough study.[12] It therefore seems clear to us that the noncentrosymmetrical crystallisation of ***E*-4** is not due to a lower dipole moment compared to ***E*-1**.[13] The crystal structure of ***E*-4** arises from infinite ribbons of molecules with short nitro−dioxane distances. A close study of the distances within the crystal reveals six relatively short H−O contacts that cannot be explained by geometrical constraints within the molecule (see Table 2 and Figure 3). These contacts may be described as C−H···O hydrogen bonds, as defined in the literature, between slightly acidic protons and oxygen acceptors.[14] Indeed, all C−O distances and all C−H···O angles fall into the expected range for such bonds (3−4 Å and 90−180°, respectively).[14b] The six short H−O contacts correspond to two unsymmetrically bifurcated interactions between one hydrogen atom and the two oxygen atoms of the nitro group, and two interactions between one hydrogen atom and only one oxygen atom of the nitro group (see Figure 3).[14d] In the absence of stronger intermolecular forces, such as OH···O hydrogen bonds, π-π stacking or donor−acceptor interactions, we believe that these C−H···O interactions are responsible for the unique crystal packing of ***E*-4**. Furthermore, this proposal is

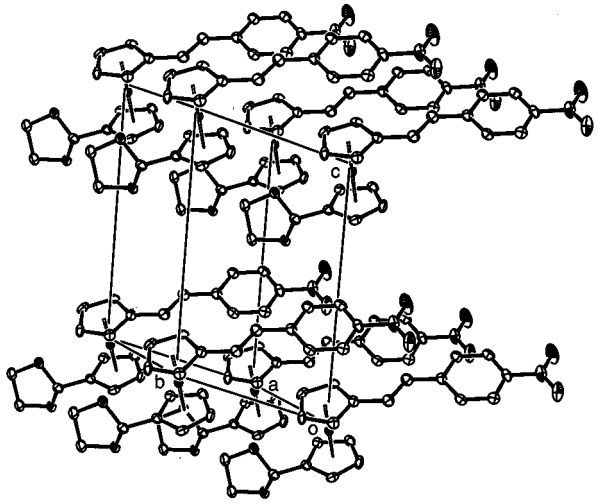

Figure 2. View of the packing in ***E*-4** showing the perfect alignment of the chromophores

Table 2. Distances and angles for C−H···O contacts

Contact[a]	O−C distance (Å)	O−H distance (Å)	O−H−C angle (°)

[a] The symmetry transformations used to generate the dioxane fragment [C(62), C(63), H···] are $x - 1$, $y - 2$, $z + 1$.

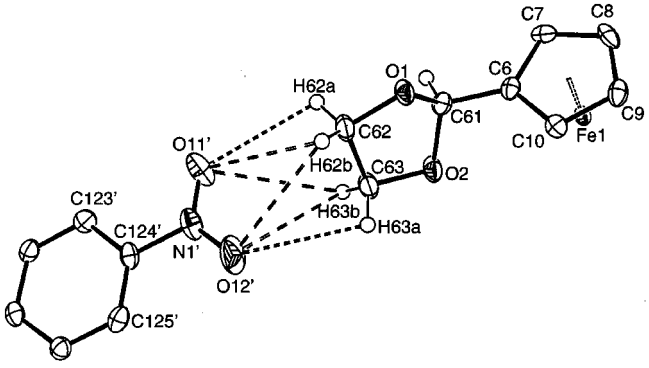

Figure 3. View showing the hydrogen interactions C−H···O between the hydrogen atoms of the dioxane moiety and the O atoms of the nitro group in ***E*-4**

strengthened by the study of a closely related molecule ***E*-7**, obtained by formally replacing the acceptor nitro group of ***E*-4** by a methoxy group. ***E*-7** lacks a good acceptor, such as a nitro group, able to form C−H···O hydrogen bonds and crystallises in the centrosymmetric space group $P2_1/c$.[15]

We also decided to study a close analogue of ***E*-4** where the five-membered dioxane ring has been replaced by the six-membered dioxolane ring, namely compound ***E*-6**. Single crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of hexane into a dichloromethane solution of ***E*-6** (Figure 4). In this case, we observed a centrosymmetrical packing and, of course, no NLO bulk

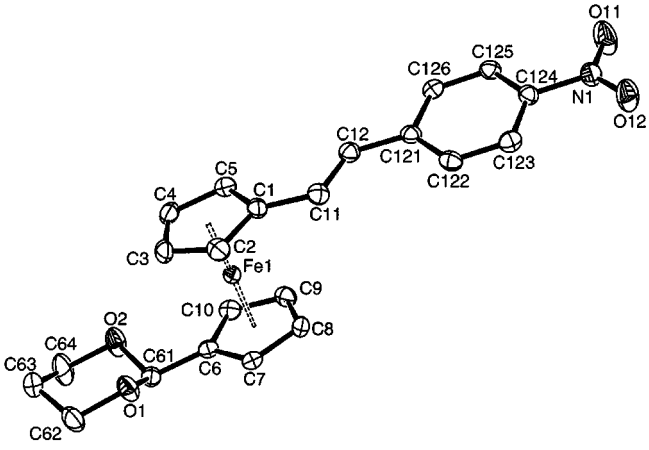

Figure 4. Molecular view of ***E*-6** with atom labelling scheme; ellipsoids represent 30% probability

efficiency. If the nitrostyryl fragments of ***E*-4** and ***E*-6** are identical within experimental errors as shown in Table 2, the relative geometry of the dioxane or dioxolane with respect to the Cp ring to which they are attached is different. The dioxane ring is twisted with respect to the Cp by a dihedral angle of 73.9°, whereas the dioxolane moiety is nearly parallel to the Cp with a dihedral angle of 13.5°. The twist observed for the dioxane in ***E*-4** allows the four hydrogens of the two CH_2 groups to form hydrogen bonds with the nitro fragment of the symmetry related molecule, as shown in Figure 3. In ***E*-6**, however, the presence of a third CH_2 group prevents the interaction of the four acidic hydrogens close to the oxygen atoms with the nitro group, the tendency for centrosymmetrical packing cannot therefore be overcome, and it packs in a more common centrosymmetrical way. However, the intermolecular packing is still stabilised by C−H···O interactions between the oxygen of the nitro group and two hydrogens H(8′) and H(9′) of the unsubstituted Cp ring of the symmetry related molecule. Such C−H···O interactions between a Cp ring of a ferrocene moiety and the O atoms of a nitro group seems to be rather common and many examples can be found in the literature.[16] These interactions lead to the head-to-tail packing of two molecules arranged around the inversion centre shown in Figure 5.

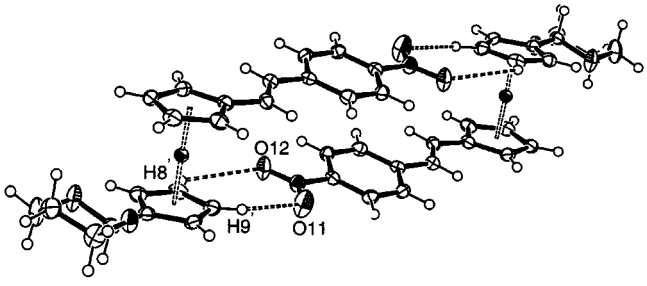

Figure 5. View showing the hydrogen interactions between the oxygen of the nitro group and some hydrogen atoms of the Cp ring in ***E*-6** [O(11)···C(9′) 3.627(3), O(11)···H(9′) 2.99 Å and O(11)···H(9′)−C(9′) 124.7(2)°; O(12)···C(8′) 3.744(3), O(12)···H(8′) 2.44 Å and O(12)···H(8′)−C(8′) 156.3(2)°]

In conclusion, we have reported a rare example of a highly efficient NLO materials (SHG efficiency 140 times the value for urea!) where the crystal contains only perfectly aligned chromophores. Furthermore, we have discovered specific interactions between a dioxane ring and a nitro group which, if they can be generalised in other systems,

might be a new and useful example of a supramolecular building block for crystal engineering.[17]

Experimental Section

All reactions were carried out in the absence of air using standard Schlenk techniques and vacuum line manipulations. Thin layer chromatography was carried out on Merck 60F254 precoated silica gel plates. Preparative flash chromatography was performed on Merck Kieselgel. Instrumentation: Bruker AM250 (^1H, ^{13}C NMR), Hewlett−Packard HP MSD 7590 (GC-MS), Stoe IPDS (X-ray). Elemental analyses were performed by the Service d'Analyse du Laboratoire de Chimie de Coordination, Toulouse (France).

1,1′-Ferrocenedicarboxaldehyde was synthesised according to ref.[18] 4-(Nitrobenzyl)triphenylphosphonium bromide was synthesised by a similar procedure to that described in ref.[19] for the synthesis of 4-(nitrobenzyl)triphenylphosphonium chloride.

2-(1′-Formylferrocenyl)-1,3-dioxolane (3): 1,1′-Ferrocenedicarboxaldehyde (5 g, 20.6 mmol) was added to a round-bottomed flask equipped with a Dean−Stark apparatus. The system was purged with argon and the red solid was dissolved in 80 mL of dry toluene. Ethylene glycol (1.15 mL, 20.6 mmol) and *p*-toluenesulfonic acid (300 mg, 1.58 mmol) were then added successively to the reaction mixture. After heating for 2 h at 170 °C, the reaction mixture was cooled back to room temp. and diluted with 100 mL of dichloromethane. Anhydrous potassium carbonate was then added and the mixture was stirred for 1 h. After filtration through celite and evaporation of the solvents, the crude materials was purified by flash chromatography on silica gel with a pentane/ether mixture (1:2, v/v) as eluent to yield 3.54 g of **3** as a brown solid (yield = 60%). − ^1H NMR ($CDCl_3$): δ = 9.90 (s, 1 H, CHO), 5.55 (s, 1 H, O−CH−O), 4.76 (t, *J* = 1.9 Hz, 2 H, Cp), 4.57 (t, *J* = 1.9 Hz, 2 H, Cp), 4.36 (t, *J* = 1.9 Hz, 2 H, Cp), 4.21 (t, *J* = 1.9 Hz, 2 H, Cp), 3.93 (m, 4 H, CH_2-CH_2). − ^{13}C NMR ($CDCl_3$): δ = 193.9 (CHO), 101.8 (O−CH−O), 86.2 (quat. Cp), 80.1 (quat. Cp), 80.0 (Cp), 73.9 (Cp), 70.4 (Cp), 69.9 (Cp), 65.4 (CH_2-CH_2). − MS (DCI, NH_3): *m*/*z* (%) = 287 (32) [M + 1]. − $C_{14}H_{14}FeO_3$ (286.11): calcd. C 58.77, H 4.93; found C 58.73, H 4.75.

(*E*)-2-[1′-(4-Nitrostyryl)ferrocenyl]-1,3-dioxolane (*E*-4): *t*BuOK (2.10 g, 18.7 mmol, 3.1 equiv.) and 50 mL of dry toluene were added to a distillation apparatus. The system was purged with argon. 4-(Nitrobenzyl)triphenylphosphonium bromide (7.20 g, 15.1 mmol, 2.5 equiv.) was then added and the mixture was warmed up to reflux. After one hour, 30 mL of toluene was removed by distillation and the solution was kept at reflux for another two hours. After cooling back to room temp., a solution of **3** (1.70 g, 5.94 mmol) dissolved in 40 mL of dry toluene was added and the solution was warmed again to reflux. 20 mL of toluene was removed by distillation over a period of one hour and the solution was kept at reflux for another two hours. After cooling to room temperature, the organic phase was extracted with dichloromethane, washed with brine, dried over sodium sulfate and the solvents evaporated under reduced pressure. The crude material was purified by flash chromatography with a pentane/ether mixture (3:1, v/v) on silica gel to yield 2.38 g of **4** (yield 99%) as a mixture of Z and *E* isomers (*Z*/*E* = 1:3).

A mixture of **4** (***Z***+***E***) (1.45 g, 3.58 mmol) and I_2 (90 mg, 0.1 equiv.) dissolved in 40 mL of dry toluene was added to a one-necked round bottomed flask equipped with a condenser. The system was purged with argon and the mixture was then refluxed for 15 minutes. After cooling back to room temperature, the mixture was extracted with dichloromethane, washed with a sodium thiosulfate solution (2 M) then with brine, dried over sodium sulfate and the solvents were evaporated. After flash chromatography on silica gel, 1.40 g (97%) of pure ***E*-4** was isolated. − ^1H NMR ($CDCl_3$): δ = 8.21 (d, *J* = 8.8 Hz, 2 H, Ph), 7.75 (d, *J* = 8.8 Hz, 2 H, Ph), 7.34 (d, AB, *J* = 16.2 Hz, 1 H, vinyl), 6.95 (d, AB, *J* = 16.2 Hz, 1 H, vinyl), 5.66 (s, 1 H, O−CH−O), 4.66 (t, *J* = 1.8 Hz, 2 H, Cp), 4.44 (t, *J* = 1.8 Hz, 2 H, Cp), 4.31 (t, *J* = 1.9 Hz, 2 H, Cp), 4.19 (t, *J* = 1.9 Hz, 2 H, Cp), 3.84−4.01 (m, 4 H, CH_2-CH_2). − ^{13}C NMR ($CDCl_3$): δ = 146.3 (quat. Ph), 145.4 (quat. Ph), 133.4 (vinyl), 126.2 (Ph), 124.4 (Ph), 124.0 (vinyl), 102.4 (O−CH−O), 86.5 (quat. Cp), 83.1 (quat. Cp), 71.0 (Cp), 69.8 (Cp), 68.7 (Cp), 68.6 (Cp), 65.3 (CH_2-CH_2). − MS (DCI, NH_3): *m*/*z* (%) = 406 (100) [M + 1]. − $C_{21}H_{19}FeNO_4$ (405.23): calcd. C 62.24, H 4.73, N 3.46; found C 61.97, H 4.34, N 3.68.

(*E*)-1′-(4-Nitrostyryl)ferrocenecarboxaldehyde (*E*-5): A solution of ***E*-4** (1.40 g) in 30 mL of dichloromethane was added to 15 mL of a solution containing 150 mg of *p*-toluenesulfonic acid monohydrate in deoxygenated water in a Schlenk tube. The mixture was stirred for 3 h at 60 °C. After cooling, the solution was diluted with diethyl ether, washed with water, dried with sodium sulfate, evaporated and purified by flash chromatography with a pentane/ether mixture (1:2, v/v) on silica gel to yield 1.10 g of pure ***E*-5** (yield 88%). − ^1H NMR ($CDCl_3$): δ = 9.88 (s, 1 H, CHO), 8.19 (d, *J* = 8.9 Hz, 2 H, Ph), 7.55 (d, *J* = 8.9 Hz, 2 H, Ph), 6.94 (d, AB, *J* = 16.3 Hz, 1 H, vinyl), 6.75 (d, AB, *J* = 16.3 Hz, 1 H, vinyl), 4.78 (t, *J* = 2.0 Hz, 2 H, Cp), 4.60 (t, *J* = 1.9 Hz, 2 H, Cp), 4.58 (t, *J* = 2.0 Hz, 2 H, Cp), 4.44 (t, *J* = 1.9 Hz, 2 H, Cp). − ^{13}C NMR ($CDCl_3$): δ = 193.5 (CHO), 146.4 (quat. Ph), 143.7 (quat. Ph), 130.6 (vinyl), 126.3 (Ph), 125.6 (Ph), 124.2 (vinyl), 83.7 (quat. Cp), 80.1 (quat. Cp), 74.3 (Cp), 71.2 (Cp), 70.8 (Cp), 68.7 (Cp). − MS (DCI, NH3): *m*/*z* (%) = 379 (100) [M + 18], 362 (32) [M + 1]. − $C_{19}H_{15}FeNO_3$ (361.18): calcd. C 63.20, H 4.20, N 3.88; found C 63.01, H 4.47, N 3.64.

(*E*)-2-[1′-(4-nitrostyryl)ferrocenyl]-1,3-dioxane (*E*-6): ***E*-5** (1.0 g, 2.64 mmol) dissolved in 30 mL of dry toluene was added to a round-bottomed flask equipped with a Dean−Stark apparatus. The system was purged with argon and 1,3-propanediol (0.265 mL, 3.66 mmol) and *p*-toluenesulfonic acid (53 mg, 0.27 mmol) were added successively to the reaction mixture. After 2 h heating at 110 °C, the reaction mixture was cooled back to room temp. and diluted with 100 mL of dichloromethane. Anhydrous potassium carbonate was then added and the mixture was stirred for 1 h. After filtration through celite and evaporation of the solvents, the crude material was purified by flash chromatography on silica gel with a pentane/ether mixture (3:1, v/v) as eluent to yield 0.85 g of ***E*-6** as a red solid (yield 79%). − ^1H NMR ($CDCl_3$): δ = 8.18 (d, *J* = 8.8 Hz, 2 H, Ph), 7.52 (d, *J* = 8.8 Hz, 2 H, Ph), 7.08 (d, AB, *J* = 16.1 Hz, 1 H, vinyl), 6.70 (d, AB, *J* = 16.1 Hz, 1 H, vinyl), 5.25 (s, 1 H, O−CH−O), 4.51 (t, *J* = 1.8 Hz, 2 H, Cp), 4.39 (t, *J* = 1.8 Hz, 2 H, Cp), 4.29 (t, *J* = 1.8 Hz, 2 H, Cp), 4.14 (m, 2 H, OCH_2), 4.11 (t, *J* = 1.8 Hz, 2 H, Cp), 3.79 (td, *J* = 12.3 Hz and 2.3 Hz, 2 H, OCH_2), 2.2−1.9 (m, 1 H, $CH_2CH_2CH_2$), 1.34 (br. d, *J* = 13 Hz, 1 H, $CH_2CH_2CH_2$). − ^{13}C NMR ($CDCl_3$): δ = 145.8 (quat. Ph), 144.4 (quat. Ph), 132.7 (vinyl), 125.8 (Ph), 124.2 (Ph), 123.4 (vinyl), 99.6 (O−CH−O), 87.1 (quat. Cp), 82.2 (quat. Cp), 70.8 (Cp), 69.2 (Cp), 68.3 (Cp), 67.7 (Cp), 67.1 (OCH_2), 25.7 ($CH_2CH_2CH_2$). − MS (DCI, NH3): *m*/*z* (%) = 420 (100) [M + 1]. − $C_{22}H_{21}FeNO_4$ (419.26): calcd. C 62.21, H 4.73, N 3.46; found C 63.24, H 4.94, N 3.10.

NLO Measurements: The measurements of second harmonic generation (SHG) intensity were carried out by the Kurtz−Perry powder technique[7] with a nanosecond Nd-YAG-pulsed (10 Hz) laser operating at λ = 1.064 μm. The outcoming Stokes-shifted radiation at 1.907 μm, generated by Raman effects in a hydrogen cell, was used as the fundamental beam for second harmonic generation. The SHG signal was detected by a photomultiplier and read on an ultrafast Tektronic 7834 oscilloscope. Samples were calibrated as microcrystalline powders obtained by grinding in the range 50−80 μm and put between two glass plates. The recorded efficiencies were expressed versus that of powdered (50−80 μm) urea.

X-ray Crystallographic Study: Data for ***E*-4** and ***E*-6** were collected on a Stoe IPDS diffractometer. The final unit cell parameters were obtained by the least-squares refinement of 8000 reflections. Only statistical fluctuations were observed in the intensities monitored over the course of the data collections.

Both structures were solved by direct methods (SIR97[20]) and refined by least-squares procedures on *F*. All H atoms were introduced in the calculation in idealised positions [d(CH) = 0.96 Å] and treated as riding models with isotropic thermal parameters related to the carbon to which they are attached. Least-squares refinements were carried out by minimising the function $\Sigma w(|F_o| - |F_c|)^2$, where F_o and F_c are the observed and calculated structure factors. The absolute configuration for ***E*-4** was determined by refining the Flack enantiopole parameter.[21] The weighting scheme used in the last refinement cycles was $w = w'[1 - \{\Delta F/6\sigma(F_o)\}^2]^2$, where $w' = 1/\Sigma_1^n A_r T_r(x)$ with three coefficients A_r for the Chebyshev polynomial $A_r T_r(x)$ where x is $F_c/F_c(\max)$.[22] The models reached convergence with $R = \Sigma(||F_o| - |F_c||)/\Sigma(|F_o|)$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2]^{1/2}$, with the values listed in Table 3.

The calculations were carried out with the CRYSTALS package programs.[22] Molecular views were produced with the help of ORTEP32.[23]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-160780 (***E*-4**) and -160781 (***E*-6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mononuclear Thiomolybdenyl Complexes − Synthesis and Structural and Spectroscopic Characterization

Charles G. Young,*[a] Robert W. Gable,[a] Jason P. Hill,[a] and Graham N. George[b]

Keywords: Molybdenum / Sulfur / Thiomolybdenyl complexes / EPR spectroscopy / X-ray absorption spectroscopy

The first series of mononuclear thiomolybdenyl complexes, $Tp^*Mo^VSX_2$ [Tp^* = hydrotris(3,5-dimethylpyrazol-1-yl)borate, X/X_2 = anion/dianion], has been prepared. The complexes, which have been characterized by analytical, mass spectrometric, spectroscopic and X-ray crystallographic studies, provide insights into the electronic nature and chemistry of the catalytically and biologically important thiomolybdenyl unit.

Introduction

The thiomolybdenyl unit, $\{Mo^V{=}S\}^{3+}$, has been implicated in the turnover of industrial catalysts[1,2] and mononuclear, pterin-containing molybdenum enzymes such as xanthine oxidase and aldehyde oxidase.[3−6] However, mononuclear thiomolybdenyl complexes are extremely rare due to their susceptibility to redox, polynucleation, and hydrolysis reactions.[3−6] Consequently, our understanding of their chemical, structural, and spectroscopic characteristics is very limited. This stands in stark contrast to well advanced studies of molybdenyl, $\{Mo^V{=}O\}^{3+}$, complexes.[7−17] Indeed, only two mononuclear thiomolybdenyl complexes have ever been isolated and completely characterized. The first of these, $Tp^*Mo^VSCl_2$ [Tp^* = hydrotris(3,5-dimethylpyrazol-1-yl)borate], was reported by Young et al. in 1987.[18] This complex was prepared by treating Tp^*MoOCl_2 with boron sulfide and has been characterized by infrared, UV-visible, electron paramagnetic resonance (EPR), Raman, and X-ray absorption (XAS) and extended X-ray absorption fine structure (EXAFS) spectroscopy.[18−21] Crystallographic characterization of the compound has not been attempted due to the high probability of disorder of the thio and chloro ligands.[22] A number of related complexes, viz., $[Tp^*MoS(S_2PR_2)]^+$ and $[Tp'MoS(S_2PR_2)]^+$ [Tp' = hydrobis(3-isopropylpyrazol-1-yl)(5-isopropylpyrazol-1-yl)borate] have been generated in solution.[23,24] Recently, a second mononuclear thiomolybdenyl complex, $Mo^VS(N[R]Ar)_3$ {N[R]Ar = $N[C(CD_3)_2CH_3](3,5\text{-}Me_2C_6H_3)$}, was reported by Johnson et al.[25] This complex, a member of the series MoE(N[R]Ar)$_3$ (E = O, S, Se, Te), was prepared by oxidizing Mo(N[R]Ar)$_3$ with S_8 or ethylene sulfide. The MoE(N[R]Ar)$_3$ complexes exhibit rhombic EPR spectra with A_{Mo} values decreasing in the order Mo=O > Mo=S > Mo=Se > Mo=Te, consistent with increasing covalency in complexes of the heavier chalcogenides. The crystal structure of MoS(N[R]Ar)$_3$ revealed a distorted tetrahedral complex possessing a terminal thio ligand with an Mo=S distance of 2.1677(12) Å.

Synthetic access to a series of related thiomolybdenyl complexes would permit systematic spectroscopic and structural studies leading to a detailed electronic description of the $\{Mo^V{=}S\}^{3+}$ unit and insights into its vital roles in industrial and biological catalysis. We report here the synthesis and characterization of the complexes $Tp^*Mo^VSX_2$ [X = OPh, 2-(ethylthio)phenolate (etp), 2-(*n*-propyl)phenolate (pp); X_2 = benzene-1,2-diolate (cat), 4-methylbenzene-1,2-dithiolate (tdt), benzene-1,2-dithiolate (bdt)] and the crystal structures of $Tp^*MoS(etp)_2$ and $Tp^*MoS(bdt)$; the latter, features a pseudo-dithiolene co-ligand and is of direct relevance to molybdoenzyme intermediates such as the Very Rapid centre of xanthine oxidase, proposed to contain an $[Mo^VOS(dithiolene)]^-$ moiety.[3−6]

Results and Discussion

We have employed two general methods in the generation of Tp^*MoSX_2 complexes. The first, the reaction of Tp^*MoOX_2[9] with boron sulfide, is useful for the generation of species in situ (as demonstrated by EPR spectroscopy) but does not lend itself to isolation of the compounds. The second method, metathesis of Tp^*MoSCl_2[18] with salts of X^- or X_2^{2-}, permits the isolation of pure Tp^*MoSX_2 (e.g., X = OPh, etp, pp; X_2 = cat, bdt, tdt) following workup. The reactions are conveniently monitored by EPR spectroscopy, which reveals the clean replacement of Tp^*MoSCl_2 by product in reaction times of 2 to 16 h. Rapid anaerobic work-up, including volume reduction and passage through a short bed of silica, is essential to the isolation of pure products. As solids the compounds are moderately air-stable but recrystallizations and solution studies must be performed under strictly anaerobic conditions. The stability of the thiomolybdenyl complexes appears to be enhanced by the presence of very bulky *O*-donor co-ligands, such as

etp and pp, or chelate ligands. The complexes have been characterized by microanalytical, mass spectrometric and spectroscopic methods. Clean electron-impact mass spectra with strong parent ions are observed for the more stable (etp, pp, cat, tdt, bdt) derivatives. The IR spectra of the complexes exhibit a single, strong ν(Mo=S) band in the range 505−490 cm^{-1}, as well as bands characteristic of Tp* and the *O*- or *S*-donor co-ligands.

The structures of Tp*MoS(etp)$_2$ and Tp*MoS(bdt) have been determined by X-ray crystallography and ORTEP diagrams are given in Figure 1 and Figure 2, respectively. The distorted octahedral complexes contain a terminal thio ligand, two monodentate *O*-donor ligands (etp) or a bidentate, dithiolenic, *S*-donor ligand (bdt), and a facial, tridentate Tp* ligand. The Mo−S(1) distances of 2.1279(10) Å and 2.1231(11) Å, respectively, are typical of Mo=S units observed in MoS(N[R]Ar)$_3$[25] and polynuclear complexes.[26] For Tp*MoS(etp)$_2$, the Mo−O(4) and Mo−O(5) distances are 1.953(2) Å and 1.951(2) Å and the associated Mo−O−C angles are 140.9(2)° and 134.4(2)°, respectively. The Mo atom lies 0.264(1) Å out of the plane of the O(4), O(5), N(21) and N(31) atoms toward the thio ligand and the S(1)−Mo−O angles are consequently opened to ca. 103°. The Mo−N(*n*1) distances are dictated by the relative *trans* influences of the co-ligands, the Mo−N(11) distance being lengthened by 0.104(6) Å relative to the other Mo−N bonds. A very similar *trans* influence of 0.105(5) Å is observed for Tp*MoO(etp)$_2$.[27] For Tp*MoS(bdt), the Mo−S(4) and Mo−S(5) distances are 2.3704(12) Å and 2.3668(12) Å, respectively, and the associated Mo−S−C angles are ca. 104.2°. The Mo atom lies 0.296(1) Å out of the plane of the S(4), S(5), N(21), and N(31) atoms and 0.592(7) Å out of the plane of the bdt ligand, toward the thio ligand. The Mo−N(11) distance is lengthened by ca. 0.2 Å relative to the other two Mo−N bonds. A comparatively large *trans* influence has also been observed for Tp*MoO(catCl$_4$) (catCl$_4$ = 1,2,3,4-tetrachlorobenzene-5,6-diolate)[12] and Tp*MoO(bdt);[13] steric interaction between bidentate ligands and the nearby 3-methyl group [C(11) in Figure 2] accounts for this lengthening as well as the discernable bend in the MoX$_2$ fragment about the E···E vector (E = O, S) (such that the benzene ring moves away from said methyl group). In the thiomolybdenyl complexes, there are no interactions between the terminal thio ligand and co-ligand sulfur atoms, the S···S distances (> 4.5 Å) being considerably larger than the van der Waals contact distance.

Related structures for the other members of the series have been established by molybdenum and sulfur K-edge XAS and EXAFS studies. MoK-edge EXAFS spectra exhibit a strong backscattering component consistent with the presence of a thiomolybdenyl unit, with Mo=S distances in the range 2.1−2.2 Å. Intense pre-edge features are seen in the S K-edge X-ray absorption spectra of the compounds (Figure 3). The most intense feature, at ca. 2466 eV, is characteristic of terminal thio ligation and is assigned to S(1s)→Mo=S π* transitions.[19] In each case, the pre-edge feature is broader than expected based on the experimental resolution and deconvolution of the band provides evidence

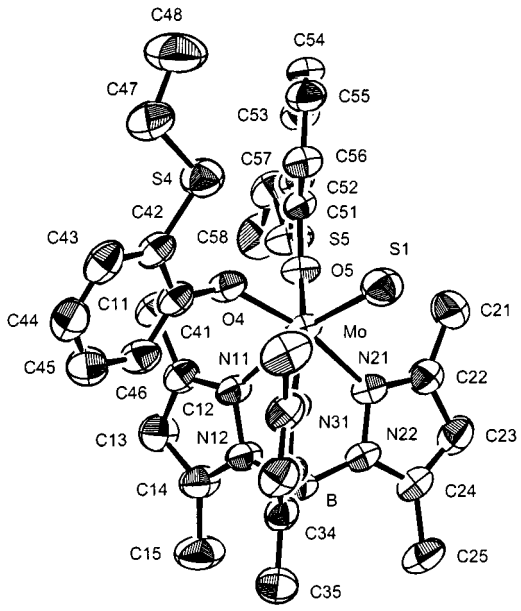

Figure 1. Molecular structure of Tp*MoS(etp)$_2$. Additional bond lengths [Å] and angles [deg]: Mo−N(11) 2.279(3), Mo−N(21) 2.174(3), Mo−N(31) 2.175(3); S(1)−Mo−O(4) 104.20(8), S(1)−Mo−O(5) 101.11(7), S(1)−Mo−N(11) 168.28(7), S(1)−Mo−N(21) 91.01(8), S(1)−Mo−N(31) 92.81(8), O(4)−Mo−O(5) 89.96(9)

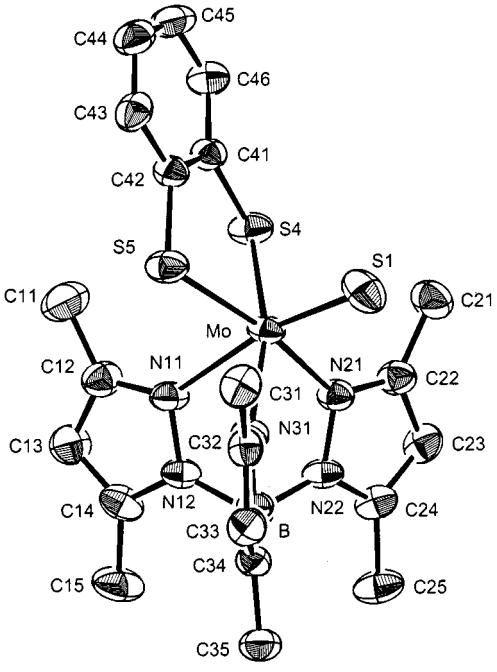

Figure 2. Molecular structure of Tp*MoS(bdt). Additional bond lengths [Å] and angles [deg]: Mo−N(11) 2.393(3), Mo−N(21) 2.201(3), Mo−N(31) 2.189(3); S(1)−Mo−S(4) 101.24(5), S(1)−Mo−S(5) 100.99(5), S(1)−Mo−N(11) 168.93(8), S(1)−Mo−N(21) 92.88(9), S(1)−Mo−N(31) 95.09(9), S(4)−Mo−S(5) 83.84(8)

for several transitions, probably to nearly degenerate Mo=S π* orbitals with S p and Mo d_{xz} and d_{yz} orbital character (*z* along Mo=S). For example, deconvolution of the spectrum of Tp*MoS(pp)$_2$ (Figure 3, a) reveals transitions at

2466.3 and 2467.0 eV. The precise origin of these and related transitions is currently under further experimental and theoretical interrogation. Similar pre-edge features are observed in the S K XAS spectra of Tp*WOSCl[28,29] and Tp^{Pr}MoOS(OPh) [Tp^{Pr} = hydrotris(3-isopropylpyrazol-1-yl)borate].[29] These complexes exhibit three distinct S K pre-edge features at energies different to those of the thiomolybdenyl complexes (around 2466.1, 2467.7 and 2469.6 eV compared to 2466 and 2469 eV for the thiomolybdenyl complexes). The feature at 2469 eV is tentatively assigned to a sulfur 1s→σ* transition associated with the Mo=S unit.

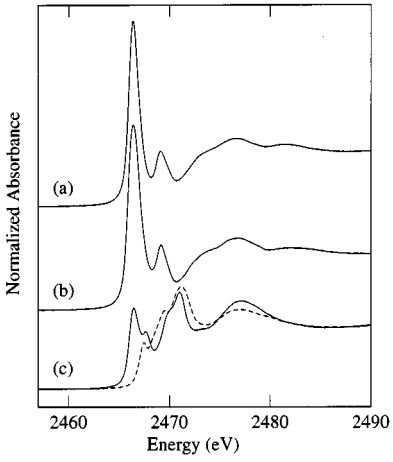

Figure 3. Selected sulfur K-edge X-ray absorption spectra of solids at 293 K. (a) Tp*MoS(pp)$_2$, (b) Tp*MoS(cat), (c) Tp*MoS(bdt), overlaid with the (dashed) spectrum of Tp*MoO(bdt)

The thiomolybdenyl complexes are EPR-active and generally exhibit highly anisotropic monoclinic frozen-glass EPR spectra (Table 1), with g_{iso} values substantially lower than their oxo analogues.[9] This results from a lowering of all the ***g*** tensor components, particularly g_3, rather than any change in the sense of the anisotropy. Very similar EPR parameters, with an unusually low g_3 and consequently high ***g*** anisotropy, characterize the three available Tp*MoS(OR)$_2$ complexes. These complexes exhibit relatively large A_{iso} values around 46×10^{-4} cm^{-1}. As a group, they also exhibit similar electronic spectra with intense LMCT absorptions in the regions 465−509 nm and 354−400 nm, and a d−d band at ca. 1300 nm (ε ca. 100 м$^{-1}$·cm^{-1}, cf. d−d band at 800 nm in oxo analogues[9,18]). Expressions for the principal ***g*** tensor components for compounds of this type have been presented;[18] the decrease in the tensor components is ascribed to a decrease in the energies of the ground to excited-state d−d transitions, most importantly $(d_{x^2-y^2})^1 \rightarrow (d_{xz})^1$ and $(d_{x^2-y^2})^1 \rightarrow (d_{yz})^1$, as a consequence of the weaker ligand field of the thio ligand. The similar A_{Mo} values for the Tp*MoSX$_2$ (X = Cl, OR) complexes implies an essentially similar ground state electronic configuration [viz., $(d_{x^2-y^2})^1$] with a similar degree of Mo−X covalency. The EPR spectrum of Tp*MoS(cat), which contains a pseudo ene-1,2-diolate moiety, differs dramatically from those of the Tp*MoS(OR)$_2$ complexes; for Tp*MoS(cat), g_1 and g_2 are very similar and g_{iso} is consequently increased compared to Tp*MoS(OR)$_2$. Similar "chelate effects" have been observed for analogous oxo complexes and may be ascribed to an increase in the energy of ground to excited-state transitions as a consequence of pπ−dπ interactions.[10] Higher g_{iso} and lower A_{iso} parameters characterize the thiolate complexes Tp*MoS(SPh)$_2$, Tp*MoS(bdt), and Tp*MoS(tdt), with the chelate complexes again exhibiting a higher g_{iso} than the non-chelated complex. The electronic spectra of Tp*MoS(cat), Tp*MoS(SPh)$_2$, and Tp*MoS(tdt) exhibit intense charge transfer bands only in accessible spectral regions; a near-IR absorption around 1300 nm is not observed. A multi-frequency EPR study of the compounds is currently underway.

Table 1. Selected EPR parameters (A values $\times 10^{-4}$ cm^{-1})

Compound	g_1	g_2	g_3	g_{iso}	Δg_i	A_{iso}
Tp*MoSCl$_2$[18]	1.941	1.921	1.919	1.928	0.022	46.8
Tp*MoS(etp)$_2$	1.961	1.914	1.864	1.909	0.097	46.6

[a] Generated in situ, not isolated.

Success in derivatizing Tp*MoSCl$_2$ has provided synthetic access to a variety of thiomolybdenyl complexes of the type Tp*MoSX$_2$. These are currently the focus of systematic structural and spectroscopic, especially EPR, MCD, XAS, and EXAFS, studies aimed at elucidating the electronic structure of thiomolybdenyl and related units and understanding their roles in industrial and biological catalysis.

Experimental Section

General: All syntheses and solution studies were carried out under an atmosphere of dinitrogen using dried, deoxygenated, and distilled solvents. The method of Young et al.[18] was employed in the synthesis of Tp*MoSCl$_2$. The course of metathesis reactions were monitored using EPR spectroscopy and work-up was initiated upon complete conversion of Tp*MoSCl$_2$ to product. − Chromatographic separations and purifications were performed under dinitrogen using dried, deoxygenated solvents and Merck Art 7734 Kieselgel 60. Spectroscopic studies were carried out under strictly anaerobic conditions. − Mass spectra were obtained on a JOEL JMS-AX505H mass spectrometer. − Infrared spectra were recorded on a BIO-RAD FTS-165 FTIR spectrophotometer as pressed KBr discs. − EPR spectra were run on a Bruker ECS 106 ESR spectrometer, equipped with a flow through low temperature device, allowing frozen spectra to be recorded at approximately 120 K. The spectral parameters in Table 1 were obtained by inspection. − Electronic spectra were obtained on a Hitachi 150-20 spectrophotometer. − Microanalyses were performed by Atlantic Microlabs, Norcross, GA, USA.

Tp*MoS(etp)$_2$: 2-Ethylthiophenol (0.18 cm^3, 1.01 mmol) and triethylamine (0.15 cm^3, 1.01 mmol) were added to a stirred solution

of Tp*MoSCl$_2$ (250 mg, 0.5 mmol) in dichloromethane (30 cm^3). The solution rapidly turned a purple color, then became brown. After 4 h the volume of the solution was reduced by half and it was filtered through a bed (4−5 cm) of silica gel. The bed of silica was washed with dichloromethane (30 cm^3), then the combined filtrate and washings were reduced to a minimum volume and treated (dropwise) with methanol to precipitate the red crystalline product. Yield 150 mg (41%).

$C_{31}H_{40}BMoN_6O_2S_3$ (731.6): calcd. C 50.89, H 5.51, N 11.49, S 13.15; found C 51.06, H 5.27, N 11.69, S 13.30. − IR (KBr): $\tilde{\nu}$ = 2525, m, ν(BH); 1570, m; 1541, s, ν(CN); 1459, s; 1364, s; 1261, s; 1201, s; 1068, s; 857, s; 748, s; 693, s; 615, s; 500, s, ν(Mo=S). − Mass Spec: *m*/*z* [M − H]$^+$ 732.

Tp*MoS(bdt): 1,2-Benzenedithiol (0.1 cm^3, 0.90 mmol) and triethylamine (0.29 cm^3, 1.90 mmol) were added to a stirred solution of Tp*MoSCl$_2$ (450 mg, 0.90 mmol) in dichloromethane (30 cm^3). The solution rapidly turned a red color and after 2 h the volume of the solution was reduced to a minimum, filtered through a short bed of silica and recrystallized as described above for Tp*MoS(etp)$_2$. The yield of red crystals was 220 mg (43%). The analytical sample was purified by anaerobic column chromatography on silica gel using 3:2 dichloromethane/hexane as eluent, then recrystallized from dichloromethane/methanol.

$C_{21}H_{26}BMoN_6S_3{\cdot}0.5CH_3OH$ (581.4): calcd. C 44.41, H 4.85, N 14.45, S 16.54; found: C 44.02, H 4.77, N 14.40, S 16.49. − IR (KBr): $\tilde{\nu}$ = 2557, m, ν(BH); 1540, s, ν(CN); 1447, s; 1435, s; 1412, s; 1357, s; 1262, m; 1202, s; 1093, m; 1074, s; 1036, s; 854, m; 814, m; 790, s; 745, s; 692, m; 666, w; 647, w; 499, s, ν(Mo=S) cm^{-1}. − Mass Spec: *m*/*z* [M + H]$^+$ 568.

The other members of the series were prepared by essentially similar methods.

Crystal Structure Determination for Tp*MoS(etp)$_2$: Crystallographic data: $C_{31}H_{40}BMoN_6O_2S_3$, M = 731.65, triclinic, $P\bar{1}$, a = 10.825(2), b = 11.584(2), c = 14.428(2) Å, α = 86.735(11), β = 88.669(12), γ = 71.998(13)°, V = 1717.8(5) Å^3, d_c = 1.414 g·cm^{-3}, Z = 2. A total of 6039 unique data with 4871 reflections having $I > 2\sigma(I)$ were collected. The structure was solved by Patterson and direct methods (SHELXS-86)[30] and was refined on F^2 by a full-matrix least-squares procedure (SHELXL-97)[31] using all data. All hydrogens were included at geometrical estimates. R_1 [$I > 2\sigma(I)$] = 0.0390 and wR_2 (all data) = 0.0998. Figure 1 and Figure 2 were prepared using the program ORTEP.[32]

Crystal Structure Determination for Tp*MoS(bdt): Crystallographic data: $C_{21}H_{26}BMoN_6S_3$, M = 565.43, monoclinic, $P2_1/n$, a = 10.0296(13), b = 14.729(2), c = 16.846(2) Å, β = 95.456(10)°, V = 2477.3(6) Å^3, d_c = 1.516 g·cm^{-3}, Z = 4. A total of 4346 unique data with 2922 reflections having $I > 2\sigma(I)$ were collected and the structure was solved as described above. R_1 [$I > 2\sigma(I)$] = 0.0346 and wR_2 (all data) = 0.0967.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-157193 and CCDC-157194. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

X-ray Absorption Spectroscopy: X-ray absorption spectroscopy was carried out at the Stanford Synchrotron Radiation Laboratory with the SPEAR storage ring containing 60−100 mA at 3.0 GeV. Molybdenum K-edge spectra were collected on beamline 7−3 using a Si(220) double crystal monochromator with an upstream vertical aperture of 1 mm and a wiggler field of 1.8 T. Harmonic rejection was accomplished by detuning one monochromator crystal to approximately 60% off-peak. X-ray absorption was measured in transmittance using nitrogen-filled ionization chambers. The spectrum of molybdenum foil was collected simultaneously with that of the sample and data were calibrated with reference to the lowest energy inflection point of the standard (assumed to be 20003.9 eV). Samples were prepared in a boron nitride matrix and during data collection were maintained at a temperature of approximately 10 K using an Oxford Instruments liquid helium flow cryostat.

Sulfur K edge experiments were performed on beamline 6−2 using an Si(111) double crystal monochromator and wiggler field of 1.0 T. Harmonic rejection was accomplished by using a flat nickel coated mirror downstream of the monochromator adjusted so as to have a cutoff energy of about 4500 eV. Incident intensity was monitored using an ion chamber contained in a (flowing) helium-filled flight path. X-ray absorption was monitored by recording total electron yield and the energy scale was calibrated with reference to the lowest energy peak of the sodium thiosulfate standard ($Na_2S_2O_3{\cdot}5H_2O$) which was assumed to be 2469.2 eV. Samples were examined at ambient temperature. Peak positions in near-edge spectra were estimated by curve-fitting to a sum of pseudo-Voigt peaks using the program EDG FIT (pseudo-Voigt deconvolution).[33]

Dinucleating Hybrid Ligands Providing a "Soft" P∩N and an Adjacent N-Rich Coordination Pocket − Controlled Synthesis of Unsymmetric Homodinuclear and Heterodinuclear Complexes

Matthias Konrad,[a] Susanne Wuthe,[a] Franc Meyer,*[a] and Elisabeth Kaifer[a]

Dedicated to Prof. Dr. Ernst-G. Jäger on the occasion of his 65th birthday

Keywords: Bridging ligands / Nickel / P,N ligands / Palladium / Bimetallic complexes

New unsymmetric dinucleating pyrazolate ligands with different chelating side arms in the 3- and 5-positions of the heterocycle have been prepared. These ligands provide a "soft" P∩N site and either an adjacent "N_3" (HL^a) or "N_2S_2" (HL^b) coordination pocket, and they have been employed to build homo- and heterobimetallic complexes featuring various types of asymmetry. Both L^a and L^b form the mixed-spin dinickel(II) chloride systems **4** and **5**, respectively, which in the former case dimerizes via Cl bridges to give a tetranuclear compound. In the heterobimetallic complex **6** the Pd^{II} is specifically housed within the P∩N compartment. All new complexes have been characterized by X-ray crystallography, and conformational and electronic coupling between the two metal ions of the dinuclear scaffolds have been analyzed.

Introduction

At present, research on di- and oligonuclear transition metal complexes is a flourishing field with major interests focused on the modeling of metallobiosites and on cooperative phenomena in catalysis and magnetism.[1−4] Among the diverse ligand frameworks designed and employed to hold two metal centers in close proximity and to induce the sought-after cooperativity, pyrazole derivatives appear particularly suited due to their well-known ability to span adjacent metal ions at a favorable distance.[5] Further control of the metal−metal separation, as well as of the steric and electronic properties of the individual metal ions can be achieved by appropriate chelating side arms attached to the 3- and 5-positions of the heterocycle. Most of these multidentate pyrazolate systems known to date are of the symmetric type,[6−11] although the individual metal ions are often assumed to play quite distinct roles in bimetallic catalysis, both in nature and in synthetic systems. The development of unsymmetrical dinucleating ligands that would give unsymmetric homobimetallic complexes, or might allow the controlled synthesis of heterobimetallic complexes is thus highly desirable.[2] However, a major obstacle to a more widespread use of such systems is their limited accessibility since, in general, the synthesis of unsymmetrical dinucleating ligands is much more arduous than the synthesis of the symmetrical analogues. Recently, we developed a versatile synthetic route which provides access to asymmetric pyrazole-based ligand matrices, providing two different coordination compartments.[11] These ligands enabled a predictable preparation of bimetallic complexes that exhibit various kinds of asymmetry. Initial emphasis was laid on the design and study of dinucleating systems that provide chemically distinct N- and S-rich donor atom sets for the two metal ions. Following the same synthetic strategy, we now report on the preparation and coordination chemistry of new compartmental type **A** ligands (Scheme 1) that comprise a bidentate P∩N binding site and an adjacent N-rich coordination pocket. Chelating P∩N ligands have been extensively used in organometallic chemistry, in particular in palladium-catalyzed reactions.[12] It is our intention in this context to tune the activity or selectivity of substrate transformations occurring at such organometallic centers by the cooperative effect of a second Lewis acidic metal ion positioned in close proximity of the active site. The present contribution lays a foundation for this goal by providing appropriate ligand frameworks that might help to preorganize the two metal ions, and by demonstrating the suitability of these new ligands for the building of heterobimetallic Pd−M complexes.

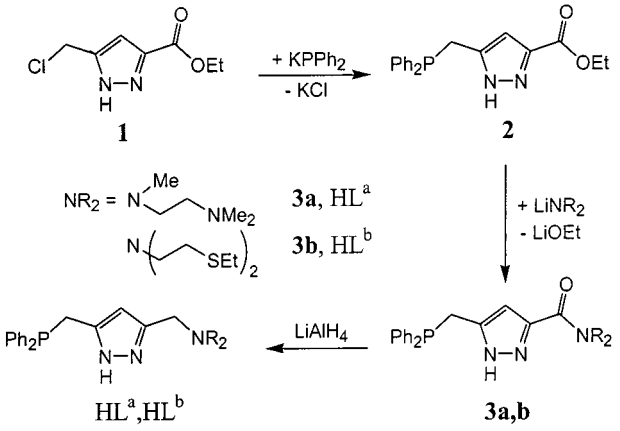
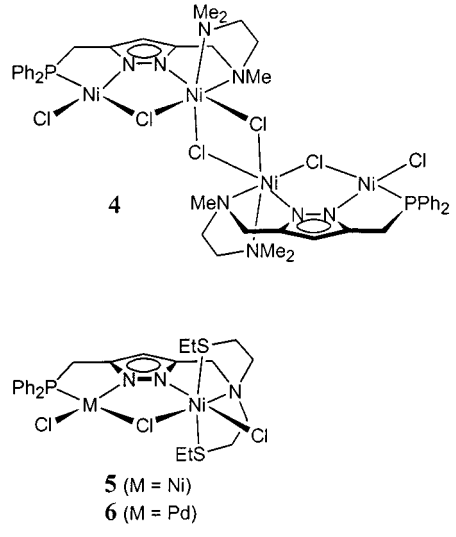
obtained by cycloaddition of ethyl diazoacetate and propynol,[13] and subsequent treatment with thionyl chloride.[11] Of the two different side arms, the diphenylphosphanyl moiety is introduced first by treating **1** with $KPPh_2$ to establish the P∩N site. The ester group in **2** is then converted into an amide function by treatment with different lithiated amines. Reduction of the resulting amide in **3a**,**b** completes the assembly of the second coordination compartment, which provides an "N_3" donor set in HL^a or an "N_2S_2" donor set in HL^b. The complexation potential of such individual P∩N,[6] "N_3"[10] and "N_2S_2"[11] sites has previously been explored to some extent in coordination compounds of related symmetric pyrazolate ligand systems.



Scheme 2

Synthesis and Structural Characterization of Complexes

Homobimetallic dinickel(II) complexes of HL^a and HL^b were studied in order to provide some insight into the specific coordination behavior of the different donor sites.



Scheme 3

Complexes $[L^aNi_2Cl_3]_2$ (**4**) and $L^bNi_2Cl_3$ (**5**) (Scheme3) were prepared by deprotonation of the pyrazole ligand with KO*t*Bu and subsequent treatment with 2 equiv. of $NiCl_2{\cdot}6H_2O$. Crystalline red material was obtained by diffusion of petroleum ether into solutions of the products in CH_2Cl_2 (**5**) or $CH_2Cl_2/CHCl_3$ (**4**), respectively. Complex **4** crystallizes in the space group *Pbcn*, while **5** crystallizes in the space group *Pc* with two independent molecules in the unit cell. The molecular structures of the complexes as determined by X-ray crystallography are depicted in Figures 1 and 2 together with selected atom distances and bond angles.

In both cases, the nickel ions are nested within their respective coordination compartments. The P∩N donor set exerts a stronger ligand field and brings about a low-spin configuration with an approximate square-planar coordination environment around its bound nickel ion [sum of the four angles around Ni1 in **4** 360.3(7)° and around Ni2 in **5** 359.9(6)°; magnetic measurements confirm the presence of only one high-spin nickel(II) ion per bimetallic entity in both **4** and **5**]. In contrast, the nickel ions in the "N_3" and "N_2S_2" sites are six-coordinate, which in the former case results from dimerization of two pyrazolate-based bimetallic moieties through a double Cl bridge to form the tetranuclear compound $[L^aNi_2Cl_3]_2$ (**4**). Similar structural motifs have also been observed for nickel chloride complexes of related symmetric pyrazolate ligand systems providing either two "N_3" or two "N_2S_2" compartments.[10,11] According to a common classification,[2a,14] **4** and **5** exhibit various kinds of asymmetry, e.g. donor atom asymmetry and coordination number asymmetry. As expected, bond lengths are generally shorter for the low-spin nickel(II) ions, which is most obvious for the asymmetrically bridging Cl2 atom within each pyrazolate-based dinuclear array: d(Ni1−Cl2) = 2.240(9) Å versus d(Ni2−Cl2) = 2.512(1) Å in **4** and d(Ni2−Cl2) = 2.255(2)/2.275(1) Å versus d(Ni1−Cl2) = 2.436(4)/2.432(8) Å in **5**. The double Cl bridges in **4** are asymmetric as well: d(Ni2−Cl3) = 2.394(5) versus d(Ni2−Cl3 A) = 2.456(7) Å. In all cases the distance between the low-spin Ni^{II} and the Cl atom *trans* to P is significantly larger than those between the low-spin Ni^{II} and the terminal Cl, because of the greater *trans* influence of the P ligand and the bridging position of the former Cl atom. A number of rather short interactions (< 3.0 Å) with C−H groups are present for all Cl ligands, which may be considered as weak hydrogen-bond interactions.[15]

Owing to the very different characteristics of their adjacent donor compartments, HL^a and HL^b appear to be well preorganized for the controlled synthesis of bimetallic complexes containing two different metal ions in distinct environments. When HL^b was first deprotonated and subsequently treated with 1 equiv. each of $PdCl_2$ and $NiCl_2{\cdot}6H_2O$ in a sequential fashion, the heterobimetallic green complex $L^bNiPdCl_3$ (**6**) was obtained in excellent yield. FAB mass spectrometry did confirm the heterodinuclear nature of the complex and did not reveal any indication of the presence of its homobimetallic analogues, i.e. of **5** or $L^bPd_2Cl_3$, thus suggesting that the complexation reaction is highly selective and that each of the different metal ions binds specifically to one of the distinct ligand compartments.

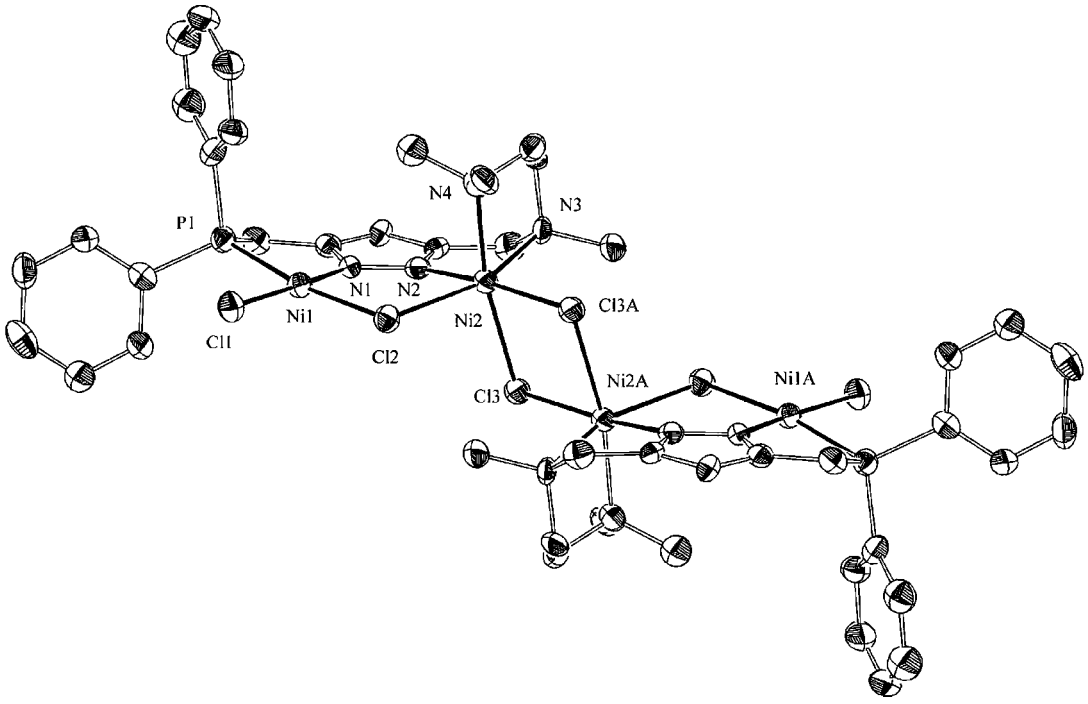


Figure 1. View of the molecular structure of **4**; in the interests of clarity all hydrogen atoms have been omitted; selected interatomic distances [Å] and bond angles [°]: Ni1−N1 1.869(2), Ni1−P1 2.155(8), Ni1−Cl1 2.171(6), Ni1−Cl2 2.240(9), Ni2−N2 1.997(2), Ni2−N3 2.200(3), Ni2−N4 2.151(2), Ni2−Cl2 2.512(3), Ni2−Cl3 2.394(5), Ni2−Cl3A 2.456(7), Ni1···Ni2 3.780(6), Ni2···Ni2A 3.705(1); Ni1−Cl2−Ni2 105.24(3), Ni2−Cl3−Ni2A 99.58(3), N1−Ni1−P1 83.06(7), P1−Ni1−Cl1 91.75(3), Cl1−Ni1−Cl2 92.76(3), Cl2−Ni1−N1 92.80(7)

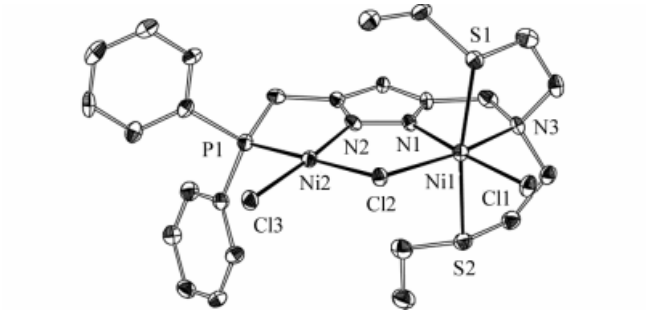

Figure 2. View of the structure of one of the two independent molecules of **5**; in the interests of clarity all hydrogen atoms have been omitted; selected interatomic distances [Å] and bond angles [°] [values for the second independent molecule in brackets]: Ni1−N1 1.958(5) [1.989(5)], Ni1−N3 2.151(5) [2.168(5)], Ni1−Cl1 2.357(2) [2.384(1)], Ni1−Cl2 2.436(4) [2.432(8)], Ni1−S1 2.473(2) [2.428(1)], Ni1−S2 2.435(1) [2.439(1)], Ni2−N2 1.857(5) [1.855(5)], Ni2−P1 2.137(2) [2.141(2)], Ni2−Cl2 2.255(2) [2.275(1)], Ni2−Cl3 2.168(1) [2.158(2)], Ni1···Ni2 3.697(5) [3.707(2)]; Ni1−Cl2−Ni2 103.9(5) [103.8(4)], N2−Ni2−P1 84.4(5) [83.6(8)], P1−Ni2−Cl3 88.6(4) [88.5(1)], Cl3−Ni2−Cl2 93.4(1) [94.4(1)], Cl2−Ni2−N2 93.4(8) [93.3(2)]

Two different types of single crystals suitable for a crystallographic analysis were obtained by layering solutions of complex **6** in CH_2Cl_2 with light petroleum ether. In one form (**6′**), the compound crystallizes in the space group *Pn* with two independent molecules in the unit cell. In the second form (**6′′**), the compound crystallizes in the space group $P2_1/n$ with two CH_2Cl_2 solvent molecules included in the crystal lattice. The overall constitution of **6** is the same in both crystal forms, but details of its molecular features are distinct, as described below. The structures of **6′′** and of one of the two independent (but similar) molecules of **6′** are depicted in Figures 3a and b together with selected atom distances and bond angles.

The bimetallic framework of **6** is closely related to the structure of its homobimetallic dinickel(II) analogue **5**. As anticipated, the palladium atom is found in an approximate square-planar environment within the P∩N pocket, while the nickel ion is located in the "N_2S_2" compartment. Geometric parameters of the Pd fragment are as expected [sum of the four angles around the Pd atom equal to 359.9(6)/360.0(6)/359.9(2)° for **6′** and **6′′**, respectively] and are comparable with the findings for a related $PdCl_2$ complex of a mononucleating pyrazolate-based P∩N ligand.[16] Geometric characteristics of the nickel ions housed in the "N_2S_2" compartments are basically identical for all cases. In particular, the Ni1("N_2S_2")−N1(pyrazole) bond lengths are found in the same range [1.965(5) − 1.991(5) Å] for **5**, **6** and for the symmetric ("N_2S_2")$_2$ complex reported previously.[11] This suggests that the choice of the second metal ion (high-spin Ni^{II} or low-spin Ni^{II}, or Pd^{II}) may only have a slight influence on the electronic properties of the six-coordinate nickel ion within the "N_2S_2" binding pocket. This is further analyzed by means of electrochemical experiments as described below.

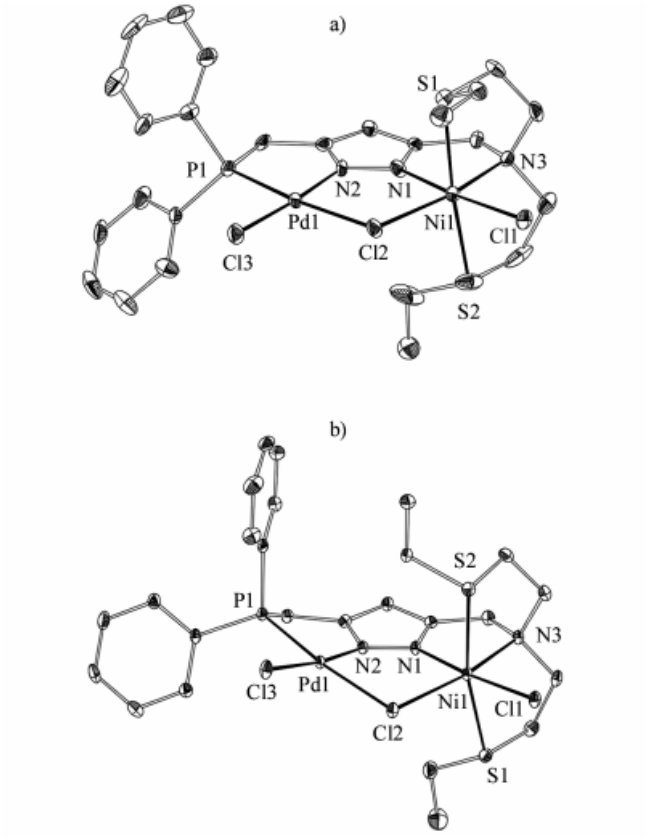

Figure 3. View of the structures of **6′** (a) (one of the two independent molecules) and **6′′** (b); in the interests of clarity all hydrogen atoms have been omitted; selected interatomic distances [Å] and bond angles [°]: **6′** [values for the second independent molecule in brackets]: Pd1−N2 1.989(7) [2.010(7)], Pd1−P1 2.219(2) [2.214(3)], Pd1−Cl2 2.395(2) [2.394(2)], Pd1−Cl3 2.299(2) [2.296(2)], Ni1−N1 1.981(6) [1.986(8)], Ni1−N3 2.166(7) [2.171(7)], Ni1−S1 2.455(2) [2.454(3)], Ni1−S2 2.397(3) [2.464(3)], Ni1−Cl1 2.366(2) [2.325(3)], Ni1−Cl2 2.452(2) [2.420(2)], Pd1···Ni1 3.808(2) [3.779(2)]; Pd1−Cl2−Ni1 103.57(8) [103.44(9)], N2−Pd1−P1 81.6(2) [81.7(2)], P1−Pd1−Cl3 94.11(8) [93.50(9)], Cl3−Pd1−Cl2 91.98(8) [93.21(9)], Cl2−Pd1−N2 92.3(2) [91.5(2)]; **6′′**: Pd1−N2 1.993(2), Pd1−P1 2.221(1), Pd1−Cl2 2.425(5), Pd1−Cl3 2.313(7), Ni1−N1 1.984(2), Ni1−N3 2.173(2), Ni1−S1 2.408(5), Ni1−S2 2.427(1), Ni1−Cl1 2.369(3), Ni1−Cl2 2.479(2), Pd1···Ni1 3.806(4); Pd1−Cl2−Ni1 101.79(3), N2−Pd1−P1 81.84(7), P1−Pd1−Cl3 92.54(3), Cl3−Pd1−Cl2 96.00(3), Cl2−Pd1−N2 89.49(7)

The most noticeable difference between the various crystalline forms of **6** is the conformation adopted by the five-membered chelate ring of the bidentate P∩N site and the resulting displacement of the P and Pd atoms out of the plane defined by the pyrazolate heterocycle. This is best visualized from a superposition of the P∩N subunits of the individual solid-state molecular structures of **6** shown in Figure 4 (one of the two independent molecules of **5** has been included as well, although the metal−ligand bond lengths are slightly shorter for Ni than for Pd). These various structures reflect individual geometric points on the pathway of interconversion between the λ and the δ conformers of the five-membered chelate ring. A trajectory of such fluxional motion has to pass through a flattened planar ring structure, which is represented by one of the two independent molecules of **6′** (see also Figure 3a). The observation of different static geometries for the P∩N chelate ring located between the limiting λ and δ conformers − which at the same time exhibit very similar geometric arrangements of the Ni("N_2S_2") coordination site − confirms that the two subunits of the bimetallic pyrazolate framework are conformationally largely decoupled. Conformational interconversion of the P∩N coordination unit is evidently facile, and each particular situation observed in the solid state should thus be mainly determined by intermolecular crystal-packing interactions.

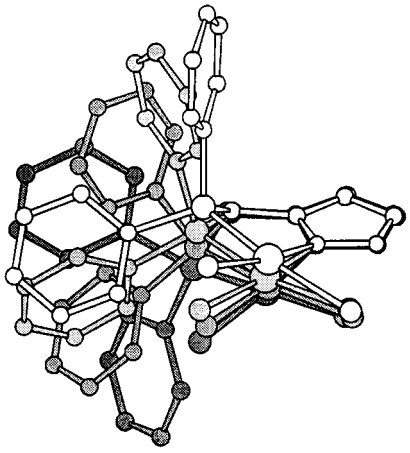

Figure 4. Overlay of the P∩N fragments of the solid-state structures of **5** (one of the two independent molecules), **6′** (both independent molecules), and **6′′**

Spectroscopy and Electrochemistry

While any comprehensive NMR-spectroscopical characterization of the complexes is hampered by their paramagnetic nature, broad low-field shifted ^{31}P NMR signals of the diamagnetic subunits are still found at δ = +241 and +257 for CD_2Cl_2 solutions of **4** and **5**, respectively. In the case of **6**, poor solubility precludes the detection of its ^{31}P NMR resonance.

The electronic absorption spectrum of **6** in CH_2Cl_2/MeCN (5:1) shows two weak bands at λ = 1100 (ν_1; ε = 26 $M^{-1}\cdot cm^{-1}$) and 620 nm (ν_2; ε = 12 $M^{-1}\cdot cm^{-1}$) that are assigned to spin-allowed transitions from $^3A_{2g}$ to $^3T_{2g}$ and $^3T_{1g}(F)$ for the six-coordinate Ni^{II}. The ν_3 band [$^3A_{2g}$ to $^3T_{1g}(P)$] expected for a near-octahedral d^8 ion[17] seems to be masked by strong high-energy absorptions extending as low as λ = 450 nm [peaks at λ = 336 nm (ε = 1710 $M^{-1}\cdot cm^{-1}$) and 301 nm (ε = 2620 $M^{-1}\cdot cm^{-1}$)]. These bands presumably correspond to intraligand and LMCT excitations. From the ν_1 band a ligand-field value of Δ_{oct} = 9090 cm^{-1} can be deduced for the nickel(II) ion in **6**. Complex **5** likewise features a low-intensity ν_1 band (λ = 1095 cm^{-1}; ε = 35 $M^{-1}\cdot cm^{-1}$), indicating Δ_{oct} = 9130 cm^{-1}. The almost identical ligand-field splitting observed for the high-spin Ni^{II} in both **5** and **6** confirms the conclusion already derived from the structural data, i.e. the choice of the second metal ion (either Pd^{II} in **6** or low-spin Ni^{II} in **5**) does not significantly alter the electronic situation at the high-spin ("N_2S_2")Ni^{II} site. Δ_{oct} for a related symmetrical dinickel(II)

complex that is composed of two identical "N_2S_2" compartments was found to be 8730 cm^{-1}.[11] An additional strong absorption for **5** at $\lambda = 498$ nm ($\varepsilon = 690$ $M^{-1}\cdot cm^{-1}$) is assigned to the square-planar low-spin Ni^{II}, presumably masking the much weaker ν_2 band. Intraligand and LMCT excitations dominate the spectrum of **5** below 350 nm, but a further d-d absorption is discernible as a shoulder at $\lambda =$ 379 nm ($\varepsilon \approx 645$ $M^{-1}\cdot cm^{-1}$).

Complexes **5** and **6** have been studied by cyclic voltammetry in CH_2Cl_2 solution (Figure 5). The dinickel(II) complex **5** undergoes a quasi-reversible oxidation at +1.00 V ($\Delta E = 162$ mV) versus the saturated calomel electrode (SCE), closely followed by further anodic processes at higher potential. The first oxidation wave at +1.00 V can be assigned to the six-coordinate nickel ion within the "N_2S_2" compartment, by comparison with the electrochemical properties of the PdNi compound **6** as well as the symmetric ("N_2S_2")$_2$dinickel(II) complex studied previously.[11] Complex **6** features a reversible oxidation at $E_{1/2} = +1.04$ V [i_{pa}/i_{pc} close to 1; $i_{pc}/v^1/_2 \approx$ const.; $\Delta E_p = 115$ mV with $\Delta E_p(Cp_2Fe/Cp_2Fe^+) = 120$ mV under the same experimental conditions] that is assigned to the formation of the $Pd^{II}Ni^{III}$ species. In this case, further oxidation processes are only observed at much higher potentials above +1.5 V. Obviously, oxidation of the nickel ion in the "N_2S_2" binding pocket is not significantly influenced by the choice of either a low-spin Ni^{II} or a Pd^{II} ion in the nearby P∩N site. This is in accordance with the above interpretation of the electronic spectra and structural features of **5** and **6**. The symmetric ("N_2S_2")$_2$dinickel(II) complex was shown to undergo a reversible first oxidation at $E_{1/2} = +0.87$ V, followed by a further oxidation process at $E_p^{ox} = +1.26$ V, indicating that Ni^{III} within the "N_2S_2" compartment is somewhat more efficiently stabilized by a second high-spin Ni^{II} ion than by an adjacent low-spin Ni^{II} (or Pd^{II}) as in **5** and **6**. Cathodic processes are irreversible for both **5** and **6**, with $E_p^{red} = -1.22$ V for the NiNi compound, and an ill-defined cyclic voltammetric response with a peak around −1.6 V for the PdNi species (all values at scan rate 200 mVs^{-1}).

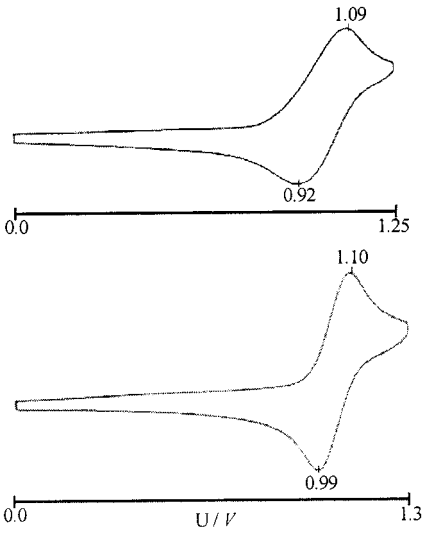

Figure 5. Cyclic voltammograms of complex **5** (top) and **6** (bottom) in CH_2Cl_2 containing 0.1 M $nBu_4N^+PF_6^-$ at a scan rate of 200 mVs^{-1}

Conclusions

New dinucleating ligands have been synthesized that feature two distinct binding pockets: a "soft" P∩N site, and either an adjacent "N_3" (HL^a) or "N_2S_2" (HL^b) compartment. These systems proved suitable for the preparation of unsymmetric bimetallic complexes in a controlled and predetermined fashion. In homobimetallic $(Ni^{II})_2$ compounds, a mixed-spin configuration is enforced by the strongly different ligand fields of the two binding pockets, while in a heterobimetallic $Ni^{II}Pd^{II}$ complex the different metal ions are selectively incorporated into their respective binding pockets, i.e. the Pd^{II} is exclusively nested in the P∩N site. Structural, spectroscopic and electrochemical features of the bimetallic systems indicate that the two coordination subunits are only moderately coupled with regard to conformational and electronic aspects. It is now hoped that these ligands will provide tailored scaffolds for the synthesis of novel bimetallic systems combining an organometallic and a Werner-type fragment in close proximity, which might enable unusual cooperative effects in metal-mediated substrate transformations.

Experimental Section

General Procedures and Methods: All manipulations were carried out under dry nitrogen by employing standard Schlenk techniques. Compound **1** was prepared as reported.[11] Solvents were dried according to established procedures, all other chemicals were used as purchased. Microanalyses: Mikroanalytische Laboratorien des Organisch-Chemischen Instituts der Universität Heidelberg. − NMR spectra: Bruker AC 200 at 200.13 (^{1}H) and 50.32 (^{13}C) MHz; solvent signal as chemical shift reference ($CDCl_3$: $\delta_H = 7.27$; $\delta_C = 77.0$). − Cyclic voltammetry: PAR equipment (potentiostat/galvanostat 273), in 0.1 M Bu_4NPF_6/CH_2Cl_2. Potentials in V on glassy carbon electrode, referenced to SCE at ambient temperature. − IR spectra: Perkin−Elmer 983G; recorded as KBr pellets. − FAB-MS spectra: Finnigan MAT 8230. − UV/Vis spectra: Perkin−Elmer Lambda 19; recorded in CH_2Cl_2 (**5**) or CH_2Cl_2/MeCN 5:1 (**6**). − Magnetic measurement: Bruker Magnet B-E 15 C8, field-controller B-H 15, Sartorius microbalance M 25 D-S. Experimental susceptibility data were corrected for the underlying diamagnetism.

Ethyl 5-[(Diphenylphosphanyl)methyl]-1*H*-pyrazole-3-carboxylate (2): A solution of diphenylphosphane (4.1 g, 22.0 mmol) in THF (100 mL) was treated with 1 equiv. of KO*t*Bu (2.5 g, 22.0 mmol). The red solution was stirred for 1 h, cooled to −70 °C and a solution of ethyl 5-(chloromethyl)pyrazole-3-carboxylate[11] (1.9 g, 10.0 mmol) in THF (50 mL) was slowly added. After warming to room temperature, the solution was left stirring overnight, then quenched with saturated NH_4Cl solution. The organic phase was dried with $MgSO_4$ and filtered. The solvent was evaporated in vacuum and the residue was redissolved in a small amount of Et_2O. The product was precipitated as a white powder by addition of light petroleum ether, filtered and dried in vacuum to yield 2.9 g

(8.5 mmol, 85%) of **2**. – ^{1}H NMR: δ = 1.33 (t, J_{HH} = 7.1 Hz, 3 H, CH_3), 3.51 (s, 2 H, PCH_2), 4.31 (q, J_{HH} = 7.1 Hz, 2 H, OCH_2), 6.51 (s, 1 H, CH^{pz}), 7.30–7.45 (m, 10 H, CH^{ar}). – ^{13}C NMR: δ = 14.0 (CH_3), 25.8 (d, $^1J_{CP}$ = 15.9 Hz, PCH_2), 60.6 (OCH_2), 107.3 (d, $^3J_{CP}$ = 5.3 Hz, $C^{pz,4}$), 128.3–132.6 (C^{ar}), 137.2 (d, $^2J_{CP}$ = 14.6 Hz, $C^{q,ar}$), 140.8 ($C^{pz,3}$), 143.4 (d, $^1J_{CP}$ = 10.9 Hz, $C^{pz,5}$), 161.5 (CO). – ^{31}P NMR: δ = –16.4. – MS (FAB*): m/z* (%) = 338 (100) [M^+], 309 (10) [M^+ – Et], 292 (12) [M^+ – OEt], 261 (9) [M^+ – Ph], 185 (100) [PPh_2^+], 183 (95) [dibenzophosphole$^+$]. – $C_{19}H_{19}N_2O_2P$ (338.35): calcd. C 67.45, H 5.66, N 8.28; found C 66.71, H 5.70, N 8.15.

***N*-[2-(Dimethylamino)ethyl]-5-[(diphenylphosphanyl)methyl]-*N*-methyl-1*H*-pyrazole-3-carboxamide (3a):** A solution of BuLi (3.4 mL, 2.5 M) in hexane was added to a solution of trimethylethylenediamine (1.8 g, 17.2 mmol) in THF (75 mL) at –70 °C. This mixture was slowly added to a solution of **2** (2.9 g, 8.6 mmol) in THF (150 mL) at –70 °C. After warming to room temperature, the solution was left stirring overnight, then quenched with saturated NH_4Cl solution and the aqueous phase extracted several times with Et_2O. The combined organic phases were dried with $MgSO_4$ and filtered. After evaporation of the solvent in vacuum, the product **3a** (2.7 g, 81%) remained as a yellow oil. – ^{1}H NMR: δ = 2.30 (s, 6 H, NMe_2), 2.57 (m, 2 H, CH_2), 3.01/3.15 (br, 3 H, NMe, *Z*/*E*), 3.44 (s, 2 H, PCH_2), 3.57 (br, 2 H, CH_2), 6.15/6.33 (br, 1 H, CH^{pz}), 7.29–7.44 (m, 10 H, CH^{ar}). – ^{13}C NMR: δ = 27.2 (br, PCH_2), 33.8/37.1 (NMe, *Z*/*E*), 46.2 (NMe_2), 45.5/49.5 (CH_2, *Z*/*E*), 56.4/57.1 (CH_2, *Z*/*E*), 106.8/107.5 ($C^{pz,4}$), 128.4–132.8 (C^{ar}), 138.0 (d, $^1J_{CP}$ = 10.7 Hz, $C^{q,ar}$), $C^{pz,3}$/$C^{pz,5}$ not observed, 162.4 (CO). – ^{31}P NMR: δ = –16.5. – MS (EI): *m/z* (%) = 395 (16) [M^+], 58 (100) [$CH_2NMe_2^+$]. – $C_{22}H_{27}N_4OP$ (394.45): calcd. C 66.99, H 6.89, N 14.20, P 7.85; found C 66.98, H 7.05, N 13.80, P 8.24.

5-[(Diphenylphosphanyl)methyl]-*N*,*N*-bis[2-(ethylsulfanyl)ethyl]-1*H*-pyrazole-3-carboxamide (3b): Compound **3b** was synthesized as described for **3a** using bis[2-(ethylsulfanyl)ethyl]amine[11] (3.3 g, 17.2 mmol). Yield (3.8 g, 91%). – ^{1}H NMR: δ = 1.25 (m, 6 H, CH_3), 2.48–2.78 (m, 8 H, SCH_2), 3.46 (s, 2 H, PCH_2), 3.64 (m, br, 2 H, NCH_2), 3.79 (m, br, 2 H, NCH_2), 6.34 (s, 1 H, C^{pz}), 7.33–7.51 (m, 10 H, CH^{ar}). – ^{13}C NMR: δ = 14.7 (CH_3), 25.8/26.2 (PCH_2/SCH_2) 28.6/30.0 (SCH_2, *Z*/*E*), 47.6/49.4 (NCH_2, *Z*/*E*), 106.8 ($C^{pz,4}$), 128.3–132.6 (C^{ar}), 137.1 (d, $^1J_{CP}$ = 14.0 Hz, $C^{q,ar}$), $C^{pz,3}$/$C^{pz,5}$ not observed, 162.4 (CO). – ^{31}P NMR: δ= –17.0. – MS (EI): *m/z* (%) = 486 (8) [M^+], 457 (87) [M^+ – Et], 397 (54) [M^+ – CH_2CH_2SEt], 293 (68) [M^+ – $N(CH_2CH_2SEt)_2$], 185 (64) [PPh_2^+], 183 (76) [dibenzophosphole$^+$], 89 (100) [$CH_2CH_2SEt^+$]. – $C_{25}H_{32}N_3OPS_2$ (485.65): calcd. ***N*²-{5-[(Diphenylphosphanyl)methyl]-1*H*-pyrazol-3-yl}-*N*¹,*N*¹,*N*²-trimethylethane-1,2-diamine (HL^a):** A solution of **3a** (2.7 g, 6.8 mmol) in THF (100 mL) was slowly added to a suspension of $LiAlH_4$ (0.24 g, 6.8 mmol) in THF (50 mL). After stirring overnight, the mixture was refluxed for 30 min, then cooled to 0 °C and hydrolyzed by dropwise addition of H_2O (0.5 mL), NaOH (0.5 mL, 15%) and H_2O (1.5 mL). The solids were filtered off and washed several times with Et_2O. The combined organic phases were dried with $MgSO_4$ and filtered. After evaporation of the solvent in vacuum, the product HL^a (2.1 g, 81%) remained as a colorless oil. – ^{1}H NMR: δ = 2.15 (s, 6 H, NMe_2), 2.18 (s, 3 H, NMe), 2.35 (m, 4 H, CH_2), 3.42 (s, 2 H, PCH_2), 3.48 (s, 2 H, NCH_2), 5.79 (s, 1 H, CH^{pz}), 7.25–7.43 (m, 10 H, CH^{ar}). – ^{13}C NMR: δ = 27.5 (br, PCH_2), 42.7 (NMe), 45.5 (NMe_2), 53.1 (br, CH_2), 54.2 (CH_2), 57.3 (CH_2), 103.9 (d, $^3J_{CP}$ = 5.1 Hz, $C^{pz,4}$), 127.8–132.9 (C^{ar}), 138.3 (d, $^1J_{CP}$ = 14.5 Hz, $C^{ar,q}$), $C^{pz,3}$/$C^{pz,5}$ not observed. – ^{31}P NMR: δ = –16.6. – MS (EI): *m/z* (%) = 380 (7) [M^+], 322 (44) [M^+ – CH_2NMe_2], 279 (40) [M^+ – $MeNCH_2CH_2NMe_2$], 185 (45) [PPh_2^+], 183 (80) [dibenzophosphole$^+$]. – $C_{22}H_{29}N_4P$ (380.47): calcd. C 69.45, H 7.68, N 14.73; found C 68.72, H 7.78, N 12.88.

***N*-{5-[(Diphenylphosphanyl)methyl]-1*H*-pyrazol-3-yl}-*N*,*N*-bis[(2-ethylsulfanyl)ethyl]amine (HL^b):** A solution of **3b** (3.8 g, 7.8 mmol) in THF (50 mL) was slowly added to a suspension of $LiAlH_4$ (0.27 g, 7.8 mmol) in Et_2O (100 mL). After stirring overnight, the mixture was refluxed for 30 min, then cooled to 0 °C and hydrolyzed by dropwise addition of H_2O (0.6 mL), NaOH (0.6 mL, 15%) and H_2O (1.8 mL). The solids were filtered and washed several times with Et_2O. The combined organic phases were dried with $MgSO_4$ and filtered. After evaporation of the solvent in vacuum, the product HL^b (2.2 g, 59%) remained as a colorless oil. – ^{1}H NMR: δ = 1.23 (t, J_{HH} = 7.3 Hz, 6 H, CH_3), 2.44–2.74 (m, 12 H, CH_2), 3.43 (s, 2 H, PCH_2), 3.64 (s, 2 H, NCH_2), 5.85 (s, 1 H, CH^{pz}), 7.33–7.49 (m, 10 H, CH^{ar}). – ^{13}C NMR: δ = 14.6 (CH_3), 25.9 (SCH_2), 27.3 (d, $^1J_{CP}$ = 14.8 Hz, PCH_2), 29.4 (SCH_2), 49.8 (NCH_2), 53.5 (NCH_2), 103.5 (d, $^3J_{CP}$ = 5.5 Hz, $C^{pz,4}$), 128.1–132.7 (C^{ar}), 138.0 (d, $^1J_{CP}$ = 14.3 Hz, $C^{ar,q}$), 143.7 (br, $C^{pz,3/5}$). – ^{31}P NMR: δ = –16.8. – IR (film): $\tilde{\nu}$ = 3180–2863 (vs), 1950/1870/1806 (w), 1565/1476 (s), 1446/1428 (vs), 1369/1302/1262/1182 (s), 1096 (vs), 1065/1024/997/803 (s), 741/695 cm^{-1} (vs). – MS (EI): *m/z* (%) = 471 (5) [M^+], 396 (100) [M^+ – CH_2SEt], 279 (78) [M^+ – $N(CH_2CH_2SEt)_2$], 185 (13) [PPh_2^+], 183 (16) [dibenzophosphole$^+$], 89 (61) [$CH_2CH_2SEt^+$]. – $C_{25}H_{34}N_3PS_2$ (471.67): calcd. C 63.66, H 7.27, N 8.91; found C 63.43, H 7.17, N 8.44.

($L^aNi_2Cl_3$)$_2$ (4): Solutions of KO*t*Bu (0.06 g, 0.5 mmol) in EtOH (30 mL) and $NiCl_2·6H_2O$ (0.37 g, 1.0 mmol) in EtOH (15 mL) were added stepwise to a solution of HL^a (0.19 g, 0.5 mmol) in THF (50 mL) at 0 °C. After stirring for 3 h, the solvent was evaporated in vacuum. Layering a solution of the product in CH_2Cl_2/$CHCl_3$ (1:1) with light petroleum ether afforded red crystals of **4** (0.24 g, 80%). – ^{31}P NMR: δ = 241 (br). – MS (EI): *m/z* (%) = 567 (100) [$L^aNi_2Cl_2^+$], 532 (31) [$L^aNi_2Cl^+$]. – $C_{44}H_{56}Cl_6N_8Ni_4P_2$ (1206.42): calcd. C 43.81, H 4.68, N 9.29; found C 44.32, H 5.38, N 8.62.

$L^bNi_2Cl_3$ (5): KO*t*Bu (0.06 g, 0.5 mmol) and a solution of $NiCl_2·6H_2O$ (0.37 g, 1.0 mmol) in EtOH (15 mL) were added stepwise to a solution of HL^b (0.24 g, 0.5 mmol) in CH_2Cl_2 (50 mL). The red reaction mixture was stirred for 3 h. After evaporation of the solvent, the remaining solid was washed with EtOH and Et_2O. Layering a solution of the product in CH_2Cl_2 with Et_2O afforded red crystals of **5** (0.28 g, 80%). – ^{31}P NMR (CD_2Cl_2): δ = 257 (br). – IR (KBr): $\tilde{\nu}$ = 2957–2861 (vs), 1461/1447 (w), 1430 (s), 1312/1255 (w), 1102 (s), 1062/1039/736/688/536 cm^{-1} (w). – MS (FAB): *m/z* (%) = 658 (70) [M^+ – Cl], 609 (100). – UV/Vis: λ (ε [$M^{-1}·cm^{-1}$]) = 379 (645, sh), 498 (690), 1095 nm (35). – M.p. > 240 °C. – $C_{25}H_{33}Cl_3N_3Ni_2PS_2$ (694.39): calcd. C 43.24, H 4.80, N 6.05; found C 42.75, H 4.70, N 5.93.

$L^bNiPdCl_3$ (6): KO*t*Bu (0.06 g, 0.5 mmol), $NiCl_2·6H_2O$ (0.12 g, 0.5 mmol) and $PdCl_2$ (0.09 g, 0.5 mmol) were added stepwise to a solution of HL^b (0.24 g, 0.5 mmol) in CH_2Cl_2 (50 mL). The product was isolated as described for **5** to yield green crystals of **6** (0.26 g, 69%). – IR (KBr): $\tilde{\nu}$ = 3084–2835 (vs), 1445 (w), 1429 (s), 1311/1256 (w), 1100 (s), 1065/1036/690/534 cm^{-1} (w). – MS (FAB): *m/z* (%) = 706 (100) [M^+ – Cl]. – UV/Vis: λ (ε [$M^{-1}·cm^{-1}$]) = 301 (2620), 336 (1710), 620 (12), 1100 nm (26). – $C_{25}H_{33}Cl_3N_3NiPPdS_2$ (741.12): calcd. C 40.52, H 4.49, N 5.67; found C 39.73, H 4.52, N 5.57.

X-ray Crystallography: The measurements were carried out with a Nonius–Kappa CCD diffractometer using graphite-monochrom-

ated Mo-K_α radiation. All calculations were performed using the SHELXT PLUS software package. Structures were solved by direct methods with the SHELXS-97 and refined with the SHELXL-97 program.[18] Atomic coordinates and thermal parameters of the non-hydrogen atoms were refined in anisotropic models by full-matrix least-squares calculation based on F^2. In general the hydrogen atoms were placed at calculated positions and allowed to ride on the atoms they are attached to. Table 1 compiles the data for the structure determinations. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-159461 (**6′**), -159462 (**5**), -159463 (**6′′**) and -159464 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to Prof. Dr. G. Huttner for his generosity and his continuous interest in our work. The Deutsche Forschungsgemeinschaft is sincerely thanked for a Heisenberg-fellowship (to F. M.) and the Fonds der Chemischen Industrie for financial support. A donation of $PdCl_2$ by Degussa AG (Hanau) is gratefully acknowledged.

$K_2In_{12}Se_{19}$, a Complex New Structure Type Based on Icosahedral Units of Se^{2-}

Marc Schlosser,[a] Christof Reiner,[a] Hans-Jörg Deiseroth,*[a] and Lorenz Kienle[b]

Dedicated to Prof. Dr. W. Jeitschko on the occasion of his 65th birthday

Keywords: Potassium selenoindate / Crystal structure / Icosahedron / Order-disorder transition

$K_2In_{12}Se_{19}$ is a new ternary chalcogenide in the system K_2Se–In_2Se_3 (m.p. 997 K; colour: dark red) with the two components in a molar ratio of 1:6. This unusual solid shows a temperature-dependent order-disorder transition originating mainly from a dynamical disorder of In^{3+} at elevated temperatures. The average structure of the dynamically disordered phase at 673 K was analysed by means of high-temperature single-crystal X-ray data [a = 1393.18(5) pm, c = 1772.26(9) pm, Z = 3, $R\bar{3}$, hexagonal setting]. The most prominent feature of the complex solid is a partial structure of slightly distorted icosahedra formed by Se1 (central atom), Se3, and Se4. The topological arrangement of the icosahedra corresponds to a cubic close packing. A further independent partial structure enveloping the icosahedra is build up by Se2. The latter form large distorted polyhedra intermediate between icosahedra and cuboctahedra. In1, In2, and In3 occupy tetrahedral holes inside (In2) and outside the icosahedra (In1 and In3), whereas K is located in distorted octahedral holes. In2 and In3 are located in neighboured face-sharing tetrahedra showing an approximate 50% occupancy. They are alternatively occupied in the sense of a dynamical disorder ("average structure"). In1 and K are not affected directly by the disorder. Structural relations between $K_2In_{12}Se_{19}$ and an earlier published unusual quaternary indium chalcogenide are discussed.

Introduction

Close packing of tetrahedra based on three-dimensional interpenetrating icosahedra as structural units is common with intermetallic compounds,[1–4] but not with semiconducting or isolating solids, such as the one represented by the title compound.

We recently, however, published structural and NMR results[5,6] that surprisingly showed clear evidence for the importance of tetrahedral close packing also in the field of non-metallic solids. Typical examples are found among the group of filled β-manganese phases like $M_2Ga_6Te_{10}$ (M: Li, Na) or α-$RbAg_4I_5$,[7,8] both representing well-defined solids with interpenetrating icosahedral arrangements of the β-Mn type formed by the anions Te^{2-} and I^{1-}, respectively. A low percentage of tetrahedral holes (ca. 15%) is filled by the cations Ga^{3+} and Ag^+. Furthermore, Li^+, Na^+, or Rb^+ occupy a few additional non-tetrahedral holes ("metaprisms"). Another classical example for the importance of tetrahedral close packing with non-metals is represented by the family of filled Laves phases ("argyrodites"), in which the arrangement of anions (Se^{2-}, Te^{2-}, ...) is topologically identical to the arrangement of the Mg and Cu atoms in the cubic Laves phase $MgCu_2$.[9] Again, a low percentage (ca. 30%) of the tetrahedral holes is filled by cations.

The physical properties of filled Laves phases as well as of filled β-Mn phases are characterized by a high mobility of cations, primarily moving between face-sharing tetrahedra. Special aspects of the dynamical disorder of Ag^+ in γ-Ag_9AlSe_6 were recently analysed by means of an anharmonic structure refinement based on X-ray data.[10]

$K_2In_{12}Se_{19}$, the title compound of this paper, is a new crystalline solid that in contrast to the conventional oxidation numbers of its constituents (K^+, In^{3+}, Se^{2-}) is based on unconventional icosahedral subunits of Se^{2-}. It is evident that the structure is neither of the filled β-Mn nor of the filled Laves phase types. Furthermore, the structural characterization of the new solid is unexpectedly complicated by a temperature-dependent order-disorder transformation caused by a dynamical disorder of indium atoms and accompanied by the formation of a superstructure. The latter one is indicated by diffuse X-ray reflections and the occurrence of anti-phase domains at low temperatures. Combined X-ray and TEM (transmission electron microscopy) investigations, in particular concerning the complex microstructure of the anti-phase domains and the superstructure are currently in progress.[11] This paper is therefore mainly restricted to single-crystal X-ray results obtained for the dynamically disordered high-temperature structure (*average structure*) of $K_2In_{12}Se_{19}$ at 673 K. The ordering process at lower temperatures does not influence the general

topology of the structure, but only specific aspects of the crystal chemical behaviour of selected In positions.

Results and Discussion

General

The title compound adds one further example to the small group of known normal and mixed valence alkali metal selenoindates that are summarized in Table 1.

Table 1. Summary of known alkali metal selenoindates

Formula	Structure type	Ref.
$LiInSe_2$	β-$NaFeO_2$	[16]
$NaInSe_2$	α-$NaFeO_2$	[17]
$KInSe_2$	$TlGaSe_2$	[18]
$RbInSe_2$	$TlGaSe_2$	[19]
$RbIn_7Se_9$	$CsIn_7S_9$	[19]
$CsIn_7Se_9$	$CsIn_7S_9$	[19]
$Rb_4In_2Se_5$	$Rb_4In_2S_5$	[18]
$Na_7In_3Se_8$	$Na_7In_3Se_8$	[20]
$Na_2In_6Se_{10}$	$Na_2In_6Se_{10}$	[21]

In most of these compounds (except the mixed valence ones) In^{3+} is exclusively tetrahedrally coordinated by Se^{2-} whereas the alkali metal atoms show larger coordination numbers with different coordination polyhedra. It turned out that the unsatisfactorily characterized mixed-valent indium chalcogenide $In_{\approx 2.01}X_3$ (X = S, Se, Te)[12] is structurally related to the title compound. A short discussion at the end of this chapter will refer to this relationship.

Selected X-ray data, positional and thermal parameters, as well as interatomic distances for the average structure of $K_2In_{12}Se_{19}$ at $T = 673$ K are summarized in Tables 2, 3, 4 and 5.

At a first glance, the overall structure looks rather complicated in that it shows up as a complex three-dimensional arrangement of corner-, edge-, and face-sharing $InSe_4$ tetrahedra with K atoms distributed in "isolated" distorted octahedra (Figure 1).

A typical feature of the average structure is the observed disorder for two (In2, In3) of the three crystallographically independent indium positions. Due to the extreme weakness of superstructure reflections for $T > 400$ K, but a continuously increasing occurrence of diffuse X-ray scattering upon cooling exclusively in layers *hkl*, with $l = 2n + 1$ (referring to the superstructure with a double *c* axis) (Figure 2) we assume a dynamical disorder at high temperatures. This disorder shows up in an approximate 50% occupancy of the respective positions (In2, In3, see Table 3). All other atomic positions (K, In1, Se) are fully occupied and do not show any irregularities.

The just mentioned diffuse scattering in the vicinity of Bragg positions in layers *hkl* with $l = 2n + 1$ indicates a successive ordering with respect to the atomic positions In2 and In3. The crystallographic aspects are seriously complicated by the ordering process and result in a *c* axis doubling and the associated formation of anti-phase domains.

It should be noted, however, that the ordering process does *not* remarkably change the overall structure of $K_2In_{12}Se_{19}$, which is the focus of this paper. There are, however, some important changes in detail that are closely related to the shape of the diffuse reflections, to crystal chemical aspects of the local coordination of selected atoms and the *c* axis doubling.

In order to gain some systematic understanding for the complex structure, the discussion of its main structural aspects is divided into three parts:

– *Primary structure:* individual coordination polyhedra

– *Secondary structure:* complex icosahedral and distorted cuboctahedral units of Se^{2-} and their decoration by In^{3+} and K^+

– *Tertiary structure:* three-dimensional connection of primary and secondary structural elements

Primary Structure

Relevant aspects of the local tetrahedral coordination of In^{3+} and the distorted octahedral ("metaprismatic") coordination of K^+ in the average structure are shown in Figure 3 (a, b). Whereas In2 and In3, located in neighbouring face-sharing tetrahedra, show an approximate 50% occupancy, the In1 position is fully occupied.

A simple distance calculation immediately demonstrates that the atomic positions In2 and In3 *cannot* be occupied *simultaneously* due to an unreasonable short interatomic distance d(In2−In3) = 103 pm. This contradiction is resolved at high temperatures by assuming a dynamic exchange process between both positions, resulting in a successive ordering at lower temperatures, a picture that is

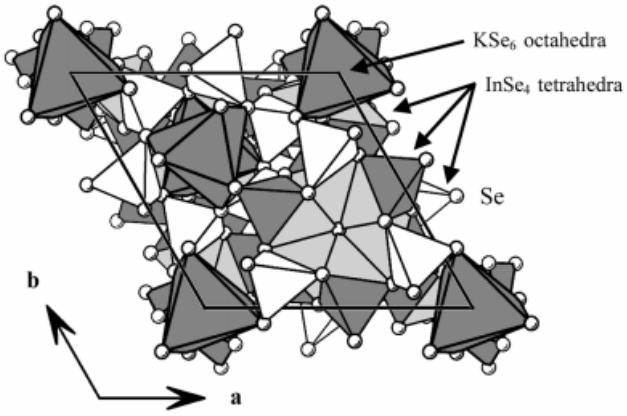

Figure 1. Projection of the average structure of $K_2In_{12}Se_{19}$ along [001] emphasising the complex arrangement of InS_4 tetrahedra and distorted KSe_6 octahedra (because of the closed polyhedra representation the In atoms inside the tetrahedra and the K atoms inside the octahedra are "invisible")

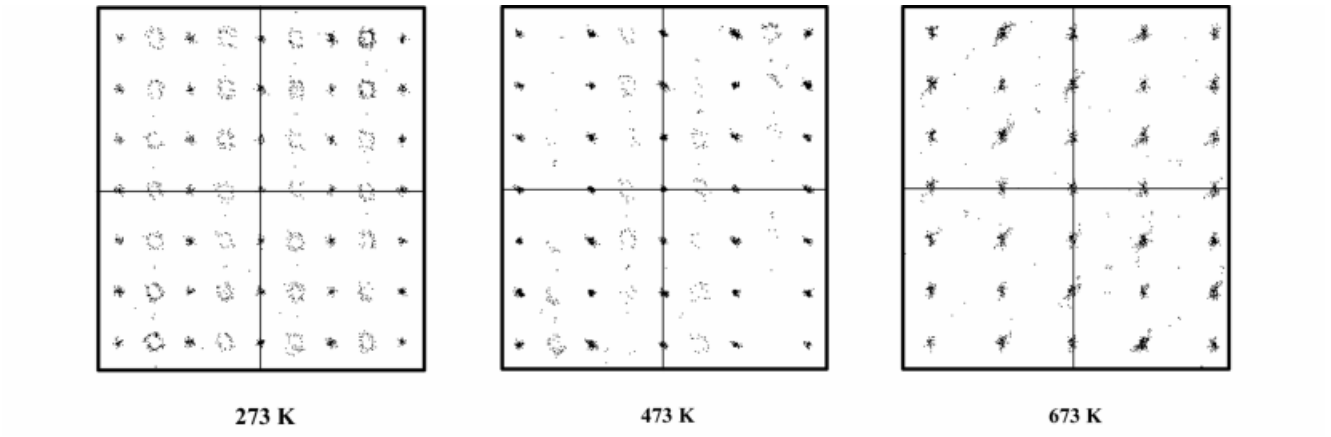

Figure 2. A temperature-dependent sequence of similar reciprocal lattice sections showing the gradual appearance of diffuse disk-shaped reflections in layers *hkl* ($l = 2n + 1$, referring to the superstructure with a double *c* axis) with decreasing temperature

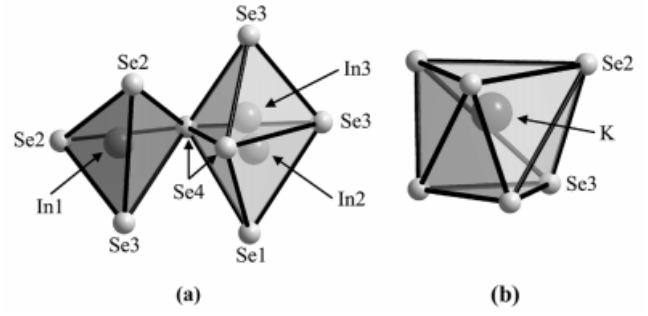

Figure 3. A comparison of the first coordination sphere polyhedra for In1, In2, In3 (a), and K (b) in the average structure of $K_2In_{12}Se_{19}$; note that In2 and In3 are not simultaneously present [$d = 103.3(2)$ pm] but represent two positions with a 50% occupancy corresponding to *one* In atom that is dynamically disordered

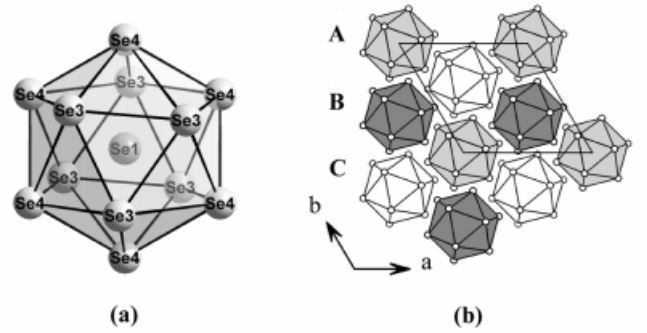

Figure 4. One icosahedral unit around Se1 formed by Se3 and Se4 (a) and a section of the three-dimensional arrangement of these units (b) representing the pattern of a cubic close packing

strongly supported by single-crystal X-ray studies at different temperatures and additional TEM investigations.

A special situation occurs for Se^{2-} for which a coordination number (CN) of 4 or 3 ($3 \times In + 1 \times K$ or $2 \times In + 1 \times K$ etc.) is usually found in similar compounds. This, however, seems to be true only in the case of Se2 and Se3 (Table 5). The seemingly unreasonable coordination numbers > 4 for Se1 and Se4 are due to the fact that both atom types are direct neighbours of the dynamically disordered In2 and In3. Obviously the type of static disorder emerging at lower temperatures is among others closely related to the attempt of the structure to reach a reasonable coordination for all Se^{2-} (CN = 3−4). Indeed, the determination of the ordered structure at low temperatures ($c_{LT} = 2 \times c_{HT}$) results in normal values for the coordination number of all Se^{2-}.[11]

Secondary Structure

Fascinating aspects of the secondary structure of $K_2In_{12}Se_{19}$ emerge upon analysing the partial structure of Se^{2-} omitting at first the In and K atoms. Figure 4 (a) shows Se1 together with Se3 and Se4 forming icosahedra of symmetry $\bar{3}$ centred by Se1. The icosahedra are made up by two types of triangles: equilateral ones formed by Se3 and non-equilateral ones formed by Se3 and Se4.

Typical interatomic distances between the central Se1 and the peripheral Se3 and Se4 are in the range of 402−420 pm. Distances between peripheral Se3 and Se4 differ somewhat more, between 418 and 459 pm (Table 5). Figure 5 (a) shows how the dynamically disordered atomic positions In2 and In3 decorate the icosahedra around Se1. As can be seen from Figure 5 (a, b), Se1 forms one apex of a tetrahedron around In2 (i.e. the central atom of the given icosahedron), whereas one apex of a tetrahedron around In3 is Se3 of a *neighbouring* icosahedron. The six In3 positions belonging to one icosahedron connect to three icosahedra *above* and to three *below* the central one, thus forming a cubic close packing of icosahedra [Figure 4 (b), Figure 5 (b)].

Figure 6 (a) shows that Se2, which does not participate in the icosahedra, forms large, strongly distorted polyhedra that encapsulate the icosahedra around Se1. They can be described as intermediate between icosahedra and cuboctahedra. The difficulties of classifying these polyhedra result from the fact that their description as cuboctahedra neglects the slight folding of the quadrilateral planes (dihedral angle: 21.5°) defined by four Se2. If one assumes the

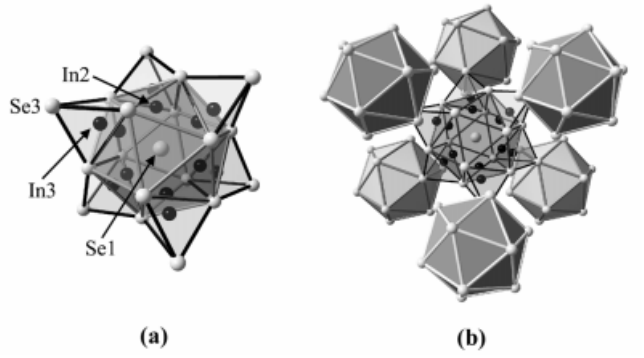

Figure 5. The decoration of the icosahedral units around Se1 by the dynamically disordered positions In2/In3 (a) and their connection to neighboured icosahedra (b)

folding line to be an additional edge, the polyhedron would better be described as an icosahedron formed by 20 strongly distorted triangular faces. Due to the just mentioned encapsulation, an endohedral unit of the type $(Se1)_1@(Se3/Se4)_{icos.}@(Se2)_{cuboct./icos.}$ can be formulated.

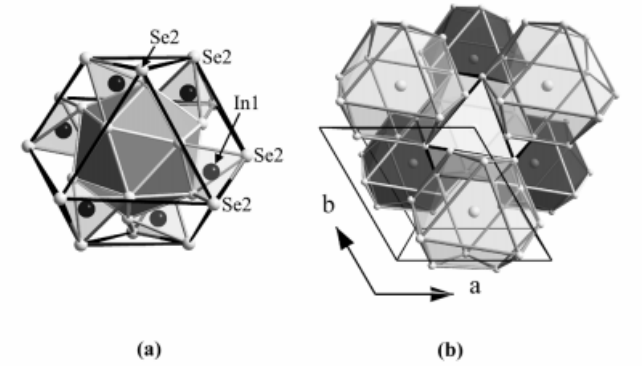

Figure 6. The large distorted cuboctahedral/icosahedral unit (see text) formed by Se2 which encapsulates the icosahedra around Se1: $Se1@(Se3,4)_{icos.}@(Se2)_{cuboct./icos.}$ and the positions of the tetrahedrally coordinated In1 in a shell between the surface of the icosahedron and the cuboctahedron/icosahedron (a); three-dimensional arrangement of the large cuboctahedra/icosahedra (b)

As Figure 6 (a) shows, atoms of the type In1 are located in tetrahedra (2 × Se2, 1 × Se3, 1 × Se4) within a shell between the surface of an icosahedron and the large surrounding cuboctahedron. The first coordination sphere of K^+ is formed by three Se3 atoms belonging to an icosahedron around Se1 and three Se2 each belonging to two *neighbouring* distorted cuboctahedra (the latter ones are not shown in Figure 7).

Tertiary Structure

As mentioned above [Figure 4 (b)], the three-dimensional arrangement of the icosahedra around Se1 corresponds to the pattern of a cubic close packing with a stacking vector parallel to [001]. Moreover, one can see from Figure 7 that the polyhedra around K are connected to somewhat smaller polyhedra along [001] that are, however, empty in $K_2In_{12}Se_{19}$. Filled and empty polyhedra form three-membered columns that connect neighbouring icosahedra along [001]. In the $In_{\approx 2.01}X_3$ phase (see below) In^{3+} is located in half of these empty polyhedra. A further consequence of the complex atomic arrangement is the fact that In2/In3 together with the icosahedra around Se1 form a three-dimensional independent substructure, which interpenetrates the arrangement of distorted cuboctahedra made up by Se2. Because Se1 atoms act as common centres also for the cuboctahedra, the topology of these endohedral units, which are connected by common edges, again corresponds to cubic-close packing [Figure 6 (b)]. Both K and In1 are cations that act as connecting links between the two partial structures.

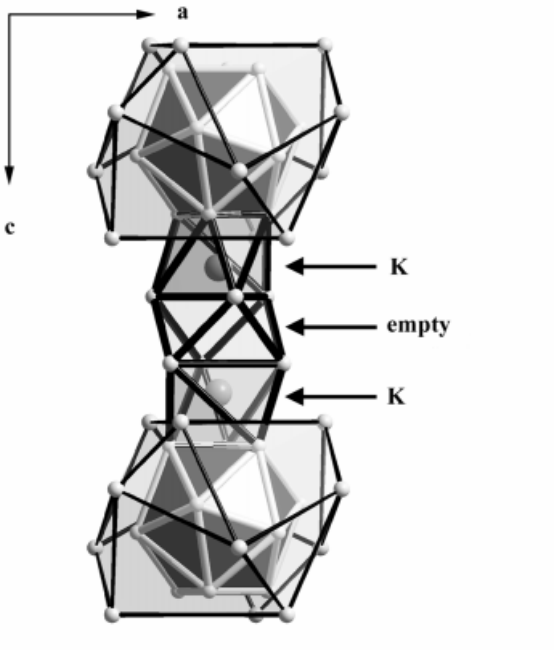

Figure 7. Section of the structure that emphasises the alternating arrangement of filled (K) and empty metaprismatic polyhedra along [001], and their connecting function between neighboured symmetrically equivalent icosahedra/distorted cuboctahedra along the same direction

Order-Disorder Transition (General Aspects)

The ordering process for In2/In3 positions at lower temperatures, which is visualised by the gradual appearance of ring shaped diffuse reflections around Bragg positions in layers *hkl* with $l = 2n + 1$ (Figure 2), and an associated doubling of the *c* axis, does not influence the above described atomic arrangement in principle (except small adjustments of the interatomic distances and angles). Face sharing between tetrahedra occupied by In atoms, however, is avoided in the ordered structure.

An important crystal chemical aspect of the ordering process is that the coordination of In2 and 3 by Se and vice versa is optimised with respect to reasonable coordination numbers for both species (see above) and with respect to interatomic distances *d*(In−In). Due to the experimentally observed doubling of the *c* axis, the ordering patterns that

do not require a *c* axis doubling can be excluded from the set of possible ordering patterns. Among the rest, there are several patterns with a non-balanced variety of short and long distances d(In−In) that can also be excluded. The remaining solution, however, leads to a structure model that inevitably produces anti-phase domains of variable size. The latter are responsible for the appearance of diffuse reflections, and reflect a complex structural frustration problem along the boundaries between adjacent anti-phase domains. Further crystallographic details of the ordered low-temperature structure, in particular with respect to results of TEM investigations, focussing on the formation of anti-phase domains are discussed in detail elsewhere.[11]

Comparison between $K_2In_{12}Se_{19}$ and the Mixed Crystal $In_{\approx 2.01}X_3$ (X = S, Se, Te)

$In_{\approx 2.01}X_3$ (X = S, Se, Te)[12] is a quaternary mixed crystal indium chalcogenide with crystallographic data closely related to those of the ordered low-temperature phase of $K_2In_{12}Se_{19}$ ($In_{\approx 2.01}X_3$: a = 1400.3 pm, c = 3522.8 pm, space group $R\bar{3}$). A closer inspection of the results published,[12] however, shows several anomalies and contradictions in particular with respect to split positions, disorder, and interatomic distances. In general, the anionic partial structure (S/Se/Te) of $In_{\approx 2.01}X_3$ and $K_2In_{12}Se_{19}$ are topologically more or less identical, although the complex secondary and tertiary structural features as described in this paper were not recognized for $In_{\approx 2.01}X_3$. In addition, there are discrepancies with respect to the positions of various cations, e.g. the positions for K atoms in $K_2In_{12}Se_{19}$ are claimed to be empty sites in $In_{\approx 2.01}X_3$. A more detailed comparison of both structures is given in ref.[13]

Conclusion

The high-temperature structure (“average structure”) of $K_2In_{12}Se_{19}$ represents a new structure type for ternary selenides, which is characterized by two interpenetrating Se substructures. One is formed by Se1, Se3, and Se4, and corresponds to a cubic close packed arrangement of centred Se_{13} icosahedra. The other one consists of a three-dimensional arrangement of large distorted polyhedra (intermediate between cuboctahedra and icosahedra), and is formed by Se2 exclusively. Both polyhedra form endohedral units of the type $(Se1)_1@(Se3/Se4)_{icos.}@(Se2)_{cuboct./icos.}$ with common centre atoms (Se1). This means that the polyhedral system formed by Se2 envelopes the icosahedra. The dynamically disordered In2/In3 positions (50% occupancy) are located inside (In2) and outside (In3) the icosahedra with the tetrahedra around In3 connecting neighbouring icosahedra. The position In1 is fully occupied, and located in tetrahedra between the outer surface of the icosahedra (Se1,Se3,Se4) and the inner surface of the distorted cuboctahedra (Se2). The K atoms occupy metaprismatic holes each connecting one neighboured icosahedron and six neighboured distorted cuboctahedra.

Experimental Section

Single crystals and homogeneous powder samples of $K_2In_{12}Se_{19}$ were prepared by heating stoichiometric mixtures of the elements in evacuated dry quartz glass ampoules. The elements were heated to 1270 K for 3 h and finally quenched in ice-cold water. After homogenisation under argon, the raw product was annealed at 950 K for 14 d, resulting in a completely homogeneous product. X-ray powder diffraction data at room temp. for the lattice refinement were determined from an X-ray powder diffraction pattern (Cu-$K_{\alpha 1}$ radiation) using a Siemens D5000 X-ray powder diffractometer. For the refinement of the lattice parameters the program package WinXPow[14] was used. All lines can be indexed with a trigonal *R*-centred cell with the hexagonal constants a = 1384.69(6) pm, c = 1758.32(9) pm. Figure 8 shows a good agreement between the measured (293 K) and calculated X-ray powder data for $K_2In_{12}Se_{19}$ (atomic parameters based on the average structure). Superstructure reflections could not be observed because of their diffuse character and weakness.

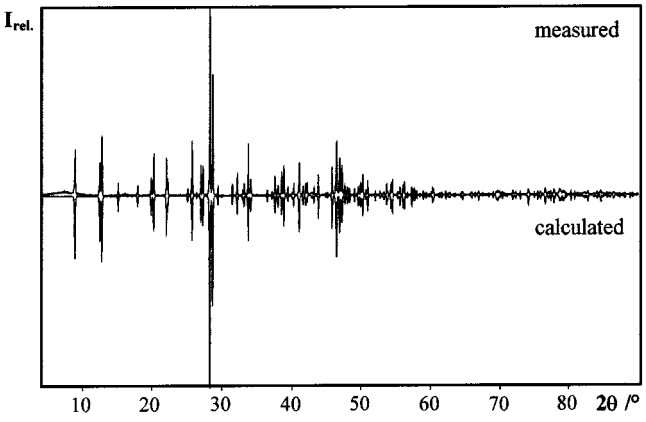

Figure 8. Comparison of experimental and calculated powder diagrams (Cu-$K_{\alpha 1}$) for $K_2In_{12}Se_{19}$ (calculation based on atomic positions for the average structure)

Well-shaped single crystals of mm size were found, both on top of the bulk product and, due to a gas-phase transport of unknown mechanism, in the colder section of the ampoule too. Powdered samples of $K_2In_{12}Se_{19}$ are reddish-brown, crystals − dependent on their thickness − dark red to black. $K_2In_{12}Se_{19}$ is not markedly air-sensitive and decomposes at 997 K. All experimental details concerning the single crystal measurement of $K_2In_{12}Se_{19}$ at 673 K are given in Table 2. The chemical composition of $K_2In_{12}Se_{19}$, especially the occurrence of K with respect to the compound $In_{\approx 2.01}X_3$, was independently proven from the X-ray results, by wavelength-dispersive analytical scanning microscopy with a CamScan microprobe CS44, equipped with a MICROSPEC WDX spectrometer. Graphics were obtained with DIAMOND 2.1.[15] Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-411816.
